Oregon Green azide (**13**) was used as a model compound to assess the efficiency and kinetics of the metal-free azide click immobilization on ADIBO-coated slides. To ensure that a fluorescent dye is immobilized on the slides only by the click reaction and not due to physical absorption or other chemical reactions, we spotted the epoxy-coated plate with ADIBO-amine (**6**). After overnight incubation and washing, these plates were immersed in a PBS solution of Oregon green azide (**13**, 0.01 mM) for 100 min and washed with acetone, then sonicated for 15 min in methanol, rinsed with acetone, and dried under a stream of nitrogen. The fluorescence image of the resulting slide demonstrates that dye **13** specifically binds to the ADIBO-derivatized surface and not to the rest of the slide (Figure 1, insert A). While the value of relative fluorescence intensity (spot versus background) depends on the starting epoxy plate (we have also tested VWR Microarray Epoxy 2 Slides and Corning Epoxide Slides), Oregon green spots always showed bright fluorescence with 2000−6000 contrast ratio. In the following fluorescent dye patterning experiments, 2 μL drops of 0.1 mM or 0.01 mM PBS solutions of azide−dye conjugate were applied onto ADIBO-derivatized slides. Thus, 0.1 mM solution of Lissamine rhodamine B azide (**14**) was spotted on the ADIBO-

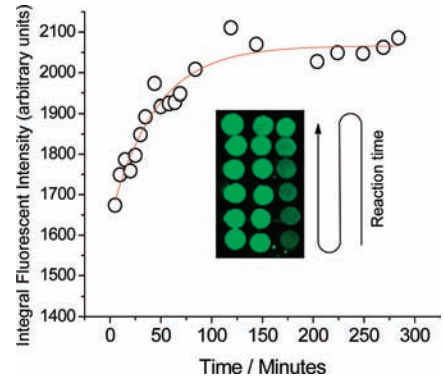

Figure 2. Integral fluorescent intensity of Oregon green azide (**13**) spots on ADIBO-derivatized slide versus reaction time.

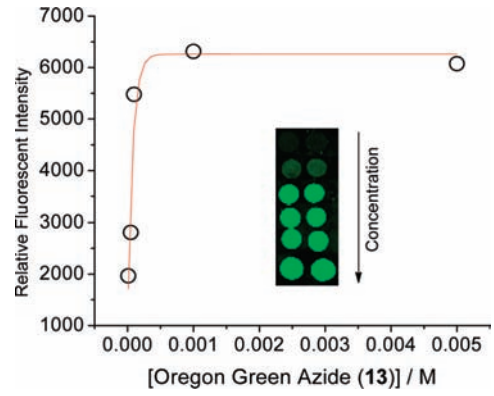

Figure 3. Integral fluorescent intensity of Oregon green azide (**13**) spots on ADIBO-derivatized slide versus concentration (10 μM, 50 μM, 0.1 mM, 1 mM, and 5 mM).

slide, incubated for 1 h, and thoroughly washed. The fluorescence image also has a good contrast ratio (Figure 1, insert B).

Kinetics of Metal-Free Click Immobilization. To evaluate the kinetics of the ADIBO−azide reaction on the surface, we spotted 2 μL drops of a 0.1 mM Oregon green azide (**13**) PBS solution onto ADIBO-derivatized slides. The first spot was allowed to react for 284 min; subsequent drops were applied at different times, with the last drop applied just 5 min before washing. The slides were stored in a humidity chamber during this procedure. The immobilization reaction shows excellent kinetics. Within 5 min, the relative fluorescent intensity reaches

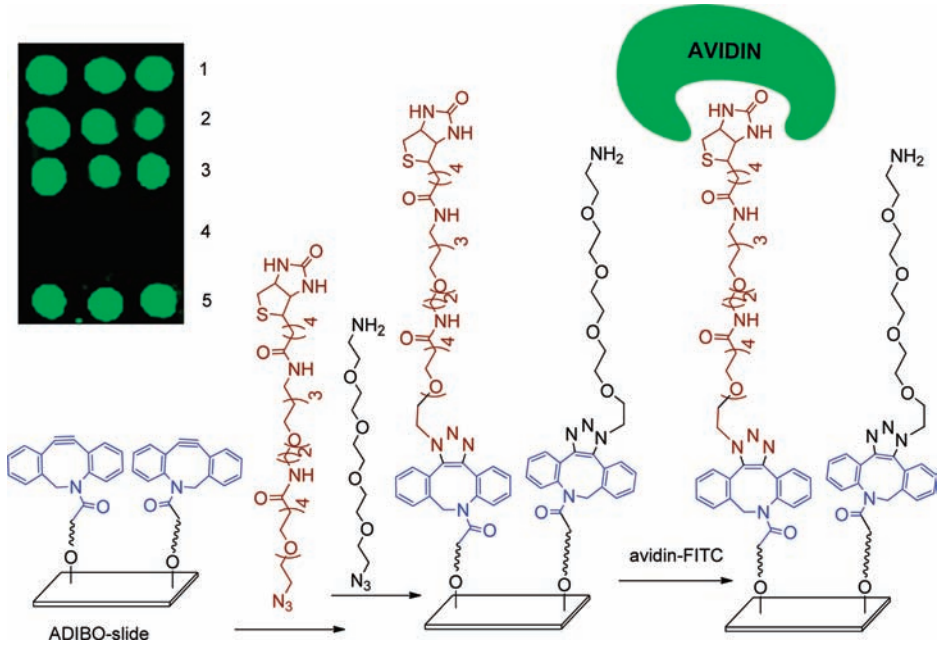

Figure 4. Schematic representation of patterned biotinylation of ADIBO-coated slide followed by selective immobilization of avidin-FITC. The insert shows the fluorescent image of ADIBO-slide spotted with 1 μL of the following solutions: lanes 1−3, 10 mM, 1 mM, and 0.1 mM PBS solutions of Biotin-dPEG3 + 4-azide; lane 4, 1 mM biotin-PEG$_4$-C≡CH; lane 5, 0.1 mM of Oregon green azide (**13**). The slide was then treated with aminoPEG$_4$azide and developed with avidin−FITC solution.

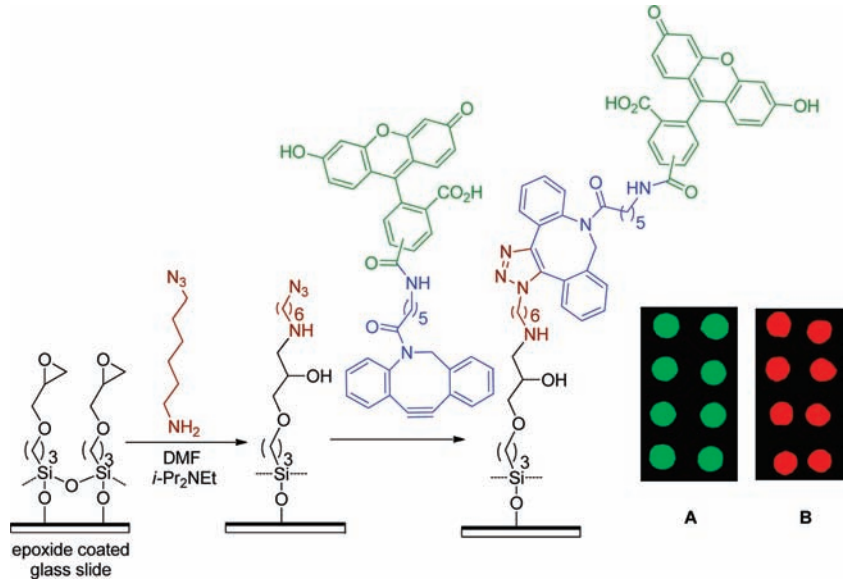

Figure 5. Schematic representation of azide derivatization of an epoxy-coated slide followed by copper-free click immobilization of ADIBO-fluor (*10*). Inserts show fluorescent images of azide slides patterned with (A) ADIBO-fluor (*10*) and (B) ADIBO-Rhodamine (*12*).

44−80% of the maximum value, and saturation of fluorescence is achieved at ca. 100 min at 0.1 mM of azide (Figure 2). As a result, incubation with the coupling reagent for 100 min was selected as a standard procedure for subsequent experiments.

To optimize the concentration of the substrate for the metal-free click immobilization, we spotted an ADIBO slide with PBS solutions of various concentration of Oregon green azide (**13**): 10 μM, 50 μM, 0.1 mM, 1 mM, and 5 mM. After incubation for 100 min and washing, the image of the slide was recorded and the integral fluorescent intensity analyzed (Figure 3). The saturation of Oregon green fluorescence is achieved at approximately 0.1 mM concentration of the azide **13**.

Biotinylation of ADIBO-Slides and Immobilization of Avidin. The exceptional selectivity and high binding constant between avidin and biotin (dissociation constant = 10^{-15} M) (*47*) is widely used in bioconjugation and surface immobilization applications (*1*−*5*, *10*, *48*−*53*). Therefore, we decided to test the efficiency of surface biotinylation using a copper-free azide click reaction. As shown in Figure 4, 1 μL drops of three different concentrations (10 mM, 1 mM, and 0.1 mM) of biotin-dPEG3+4-azide solutions in PBS were applied onto an ADIBO-functionalized glass slide. For a comparison, 1 μL drops of a 0.1 mM PBS solution of Oregon green azide (**13**) were also spotted on the slide. To test for the possibility of nonspecific absorption of biotin conjugates on the ADIBO slides, a 1 mM PBS solution of biotin-PEG$_4$-C≡CH was also spotted on the slide. After an hour-long incubation and washing, slides were immersed in a 1% DMF solution of aminoPEG$_4$azide and incubated overnight. Our initial experiment showed that dibenzocyclooctynes have significant affinity toward proteins. Ex-

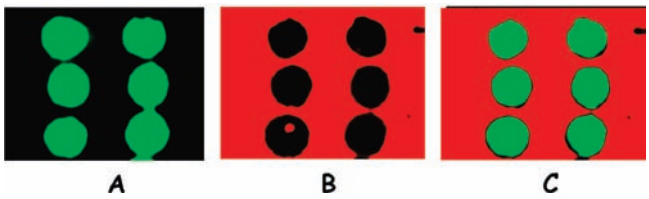

Figure 6. Two-color derivatization of azide slides. The slide was spotted with ADIBO-fluor (**10**), washed, and immersed in a solution of ADIBO-Rhodamine (*12*). (A) Fluorescent image recorded using 495/520 nm filter; (B) image recorded using 532/580 nm filter; (C) images A and B merged.

posure to the aminoPEG$_4$azide solution converts unreacted aza-dibenzocyclooctyne fragments into triazole−PEG conjugates. Patterned biotinylated slides were developed with an avidin-FITC PBS solution for 15 min at 2 °C and washed thoroughly. The fluorescent image of this slide shows selective immobilization of the protein in the biotinylated areas, while nonspecific binding of avidin was not observed (Figure 4). Incubation of the avidin-FITC-patterned slides in a PBS solution containing BSA does not reduce the fluorescence, confirming the immobilization of avidin via specific biotin−avidin interactions.

Patterning of Fluorescent Dyes on Azide-Coated Slides. To assess the efficiency of a reverse copper-free click surface derivatization, we prepared azide-coated glass slides (vide supra). Such a surface provides a convenient platform for immobilization using both conventional (i.e., copper-catalyzed) and catalyst-free azide click reactions. One microliter drops of a 1 mM PBS solutions of aza-dibenzocyclooctyne **6** conjugates with fluorescein (ADIBO-fluor, **10**) or with Lissamine rhodamine B (ADIBO-Rhodamine, **12**) were allowed to react for 12 h, then washed thoroughly. Fluorescent images of the resulting slides with fluorescein (Figure 5, insert A) and Lissamine rhodamine B (Figure 5, insert B) illustrate the efficiency of substrate immobilization on the azide-derivatized surface using metal-free click chemistry.

After immobilization, slides are often subjected to vigorous washing procedures, including the use of detergents and sonication in aqueous solutions and organic solvents. To test the stability of the azide surface to the washing procedures and to explore the feasibility of multisubstrate surface derivatization using copper-free click chemistry, we studied the sequential immobilization of two fluorescent dyes. The azide-coated glass slide was initially spotted with 1 μL drops of a 1 mM PBS solution of ADIBO-fluor (**10**) and incubated in a humidity chamber for 12 h at rt. The slide was rinsed with acetone, sonicated in DMF for 30 min, and rinsed with distilled water, then immersed in a 0.1 mM solution of ADIBO-Rhodamine (**12**) for another 12 h, then thoroughly washed. The fluorescent image recorded with a green (495−520 nm) filter clearly shows a pattern of fluorescein-immobilized spots (Figure 6A). The bright background of Lissamine rhodamine B fluorescence and dark spots, where azide groups were consumed in the first step, are visible on the image recorded with a red (532−580 nm) filter (Figure 6B). Figure 6C shows merged images A and B, which demonstrates that reactivity of an azide-derivatized surface is not significantly affected by washing procedures.

Patterned Biotinylation of Azide-Slides and Selective Immobilization of Avidin. To further demonstrate the versatility of the copper-free click reaction for protein immobilization, we have conducted patterned biotinylation of azide-derivatized slides, followed by the immobilization of avidin. Azide-functionalized glass slides were spotted with 1 μL drops of four different concentrations (10 mM, 1 mM, 0.1 mM, and 0.01 mM) of a PBS solution of ADIBO−biotin (*8*). Slides were incubated in a humidity chamber for 30 min, 2.5 h, and 3.5 h and washed with copious amounts of acetone, then water, and sonicated in DMF. To reduce nonspecific binding of the protein, slides were immersed in a blocking solution containing 0.1% ADIBO-PEG$_4$-amine (**9**) in DMF and kept overnight. The slides were then washed, incubated

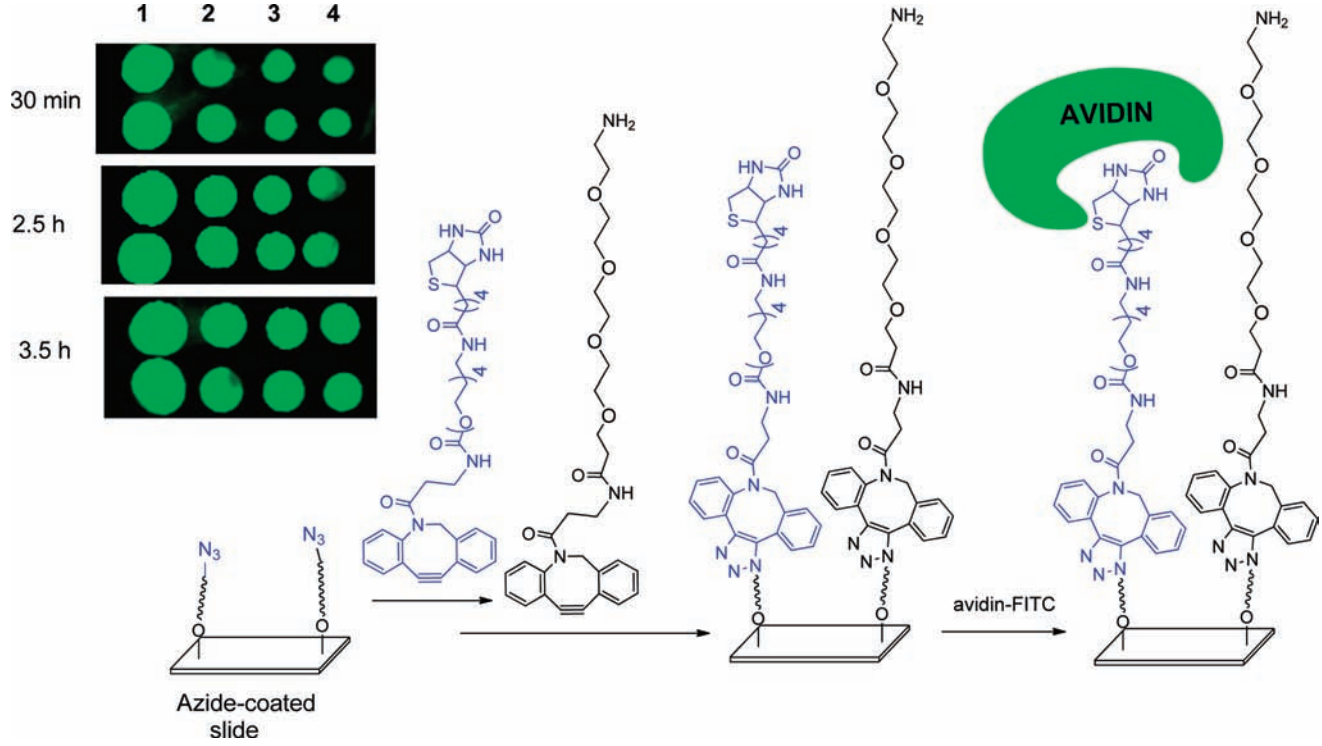

Figure 7. Schematic representation of patterned biotinylation of azide-coated slides followed by selective immobilization of avidin-FITC. The insert shows the fluorescent image of azide-derivatized slide spotted with 1 μL of ADIBO-biotin (**8**) solutions of the following concentrations: (1) 10 mM; (2) 1 mM; (3) 0.1 mM; (4) 0.01 mM. The first slide was incubated for 30 min, the second for 2.5 h, and the third for 3.5 h. Slides were then immersed in a solution of ADIBO-PEG$_4$-amine and developed with a solution of avidin-FITC.

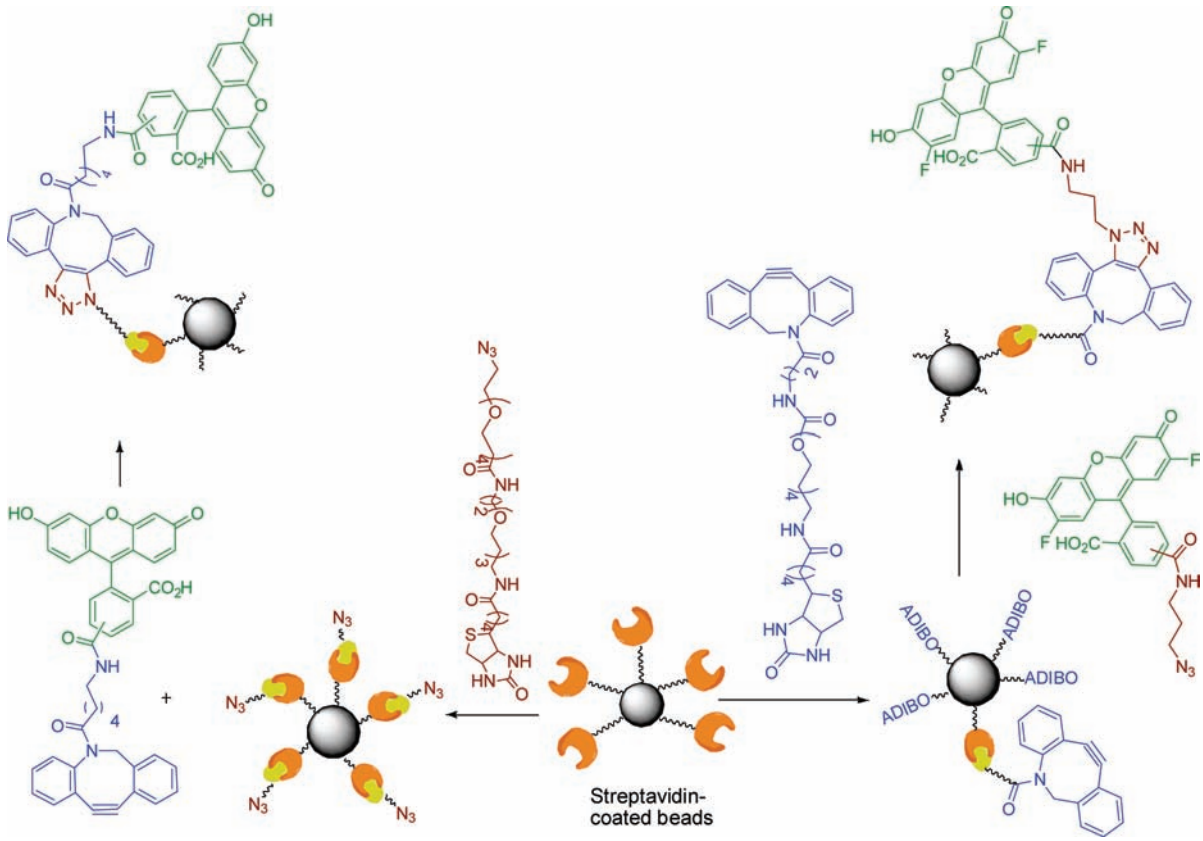

Figure 8. Schematic representation of derivatization of streptavidin-coated magnetic beads with azide and aza-dibenzocyclooctyne moieties, followed by the metal-free azide click coupling to fluorescent dyes.

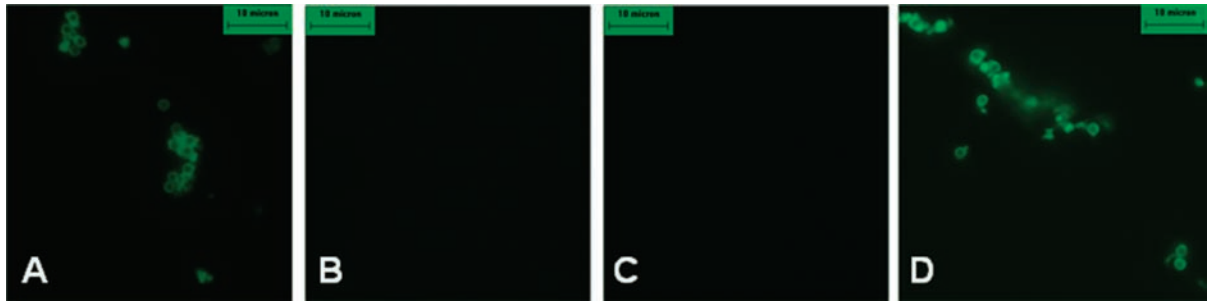

Figure 9. Fluorescent confocal microscope images of PBS suspensions of streptavidin-coated magnetic beads: (A) treated with ADIBO−biotin (**8**) followed by reaction with Oregon green azide (**13**); (B) treated with biotin-PEG_4-C≡CH and then with Oregon green azide (*13*); (C) incubated with ADIBO-fluor only (**10**); (D) treated with biotin-dPEG3 + 4-azide and then with incubated ADIBO-fluor (*10*).

in a solution of avidin-FITC at 2 °C for 15 min, and washed again. As in the case of patterned biotinylation of ADIBO slides, fluorescent images show selective immobilization of the fluorescently labeled protein in biotinylated areas. No significant nonspecific binding of avidin to the slides was observed (Figure 7). Fluorescent intensity of the spots produced at various concentrations of ADIBO-biotin and incubation time illustrate the efficiency of the reaction. Even at 10 μM concentration of ADIBO-biotin (**8**), a 30 min incubation produces a brightly fluorescent spot after avidin-FTIC development.

Catalyst-Free Derivatization of Microbeads. To demonstrate the utility of the copper-free azide click reaction for the modification of microparticle surfaces, we have explored the application of this reaction to the fluorescent labeling of streptavidin-coated magnetic beads. The surface of the beads was derivatized with azide groups by treating a suspension of the beads with biotin-dPEG3+4-azide (Figure 8). The aza-dibenzocyclooctyne functionalization of streptavidin beads was achieved by reacting the former with ADIBO-biotin (**8**, Figure 8).

The ADIBO-functionalized streptavidin beads were suspended in a PBS solution of Oregon green azide (**13**) and incubated for 3 h at rt. Beads were washed and resuspended in PBS for imaging via fluorescent confocal microscopy. Figure 9A shows the bright fluorescence of these Oregon green-labeled beads. The starting (unmodified) streptavidin magnetic beads treated with **13** under the same conditions show no detectable emission. As an additional control experiment, we have derivatized the beads with terminal acetylene groups by treating streptavidin beads with biotin-PEG_4-C≡CH. Incubation of the resulting particles in an Oregon green azide (**13**) solution, followed by thorough washing, did not induce detectable fluorescence in the beads (Figure 9B). Azide-derivatized microbeads were labeled with fluorescein by reacting them with an ADIBO−fluorescein

conjugate (**10**, Figure 9C). Magnetic streptavidin beads directly treated with ADIBO-fluor (**10**) showed no fluorescence (Figure 9D).

CONCLUSIONS

We have described an efficient synthesis of aza-dibenzocyclooctynes (ADIBO) starting from inexpensive precursors. This method allows for preparation of ADIBO derivatives on a large scale. The utility and excellent kinetics of catalyst-free ADIBO-azide cycloaddition for the patterned derivatization of glass slides and streptavidin beads has been demonstrated. The same metal-free click reaction was employed for the PEGylation of unfunctionalized areas of the surface. Such treatment allowed for dramatic reduction or complete elimination of nonspecific binding of proteins to the surface. The strategy described in this report provides a convenient tool for the site-specific covalent immobilization of various biomolecules. These procedures can be especially useful in cases where the presence of copper ions has to be avoided.

ACKNOWLEDGMENT

Authors thank Ms. Sara Orski and Dr. Jason Locklin for the useful discsussions and assistance in surface characterization; Georgia Cancer Coalition for the support of this project.

Self-Assembled Terplexes for Targeted Gene Delivery with Improved Transfection

Qiao Zhang, Si Chen, Ren-Xi Zhuo, Xian-Zheng Zhang, and Si-Xue Cheng*

Key Laboratory of Biomedical Polymers of Ministry of Education, Department of Chemistry, Wuhan University, Wuhan 430072, People's Republic of China. Received July 7, 2010; Revised Manuscript Received September 20, 2010

To improve transfection efficiency and to incorporate target ligands to the gene delivery systems, heparin and heparin−biotin were introduced to complexes of polyamidoamine dendrimer and DNA (PAMAM/DNA) via electrostatic interactions to form self-assembled PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes, respectively. The self-assembled terplexes were characterized by agarose gel electrophoresis and particle size analysis. The MTT assay indicated that, after incorporation of heparin and heparin−biotin, the terplexes exhibited decreased cytotoxicity. In addition, as compared with PAMAM/DNA and PAMAM/DNA/heparin complexes, the PAMAM/DNA/heparin−biotin complexes exhibited much higher cellular uptake into HeLa cells due to the specific interactions between biotin and biotin receptors on HeLa cells, which led to the enhanced transfection activity. The PAMAM/DNA/heparin−biotin complexes would be a promising targeting gene delivery system.

INTRODUCTION

Gene therapy is a promising approach for the treatment of incurable diseases and genetic disorders such as cancers (*1, 2*). The efficient and safe gene transfer vectors are of critical importance for the applications of gene therapy. Nonviral vectors such as cationic liposomes and polycations have attracted much attention because of their low immune response and safety. However, the low transfection efficiency greatly limits their clinical applications (*3*).

To improve the performance of nonviral vectors and to overcome the barriers in gene delivery, many modification strategies have been developed. Among them, incorporation of various ligands to the polycation vectors could effectively enhance the cellular uptake and achieve improved transfection efficiency for the targeted cells (*4*). The frequently reported targeting ligands include monoclonal antibodies, peptides (*5*), carbohydrates such as galactose for hepatocyte targeting (*6*), and vitamins such as folate (*7*). Most commonly, the targeting ligands are incorporated to the polymer vectors through covalent bonds.

Molecular self-assembly is a rapid and powerful method for fabricating nanosized materials with various supramolecular architectures. In comparison with the chemical reactions, the self-assembly is more convenient, flexible, and favorable for keeping the bioactivity of the ligands. As far as we know, the studies on incorporation of target ligands to gene delivery systems through self-assembly are very limited. In this study, we developed a new strategy to introduce ligands to gene delivery systems through electrostatic interactions; i.e., heparin−biotin was introduced to the complexes of PAMAM/DNA via electrostatic interactions to from PAMAM/DNA/heparin−biotin terplexes. For comparison, PAMAM/DNA/heparin terplexes without the targeting ligand were also prepared through self-assembly. Biotin (vitamin H) is an essential vitamin for the division of all cells, especially for the rapid proliferations of tumor cells. The cancer cells often overexpress biotin receptors on the cell surface. There are many reports on the incorporation of biotin as cell targeting ligands for targeted drug delivery (*8–11*). The reported biotin targeted tumor cell lines include L1210FR, Ov2008, M109, 4T1 (*8*), HeLa (*9*), JC, MCF-7 (*10*), and HepG2 (*11*). Heparin as one of the most potent anticoagulants has been widely used to enhance the blood compatibility of biomaterials (*12*). The conjugation of heparin to polyethylenimine (PEI) can inhibit the adsorption of serum proteins to the PEI surface and improve the in vivo gene transfection efficiency (*13*). In addition, the negatively charged heparin can form complexes with polycations such as PEI and PAMAM (*14–16*). In the current study, heparin was used to improve the biocompatibility and partially shield the positive charge of PMAMA/DNA complexes to reduce the cytotoxicity. Biotin was used as a cell targeting ligand to enhance the cellular uptake for particular cancer cells. The existence of heparin or heparin−biotin lowered the cytotoxicity and enhanced the transfection efficiencies of the terplexes. In addition, the transfection activity of PAMAM/DNA/heparin−biotin terplexes in particular tumor cells could be further improved due to the increased biotin receptor mediated cell uptake. The terplexes have promising applications in targeting gene delivery to cancer cells.

EXPERIMENTAL PROCEDURES

Materials. Poly(amidoamine) (PAMAM) dendrimer (generation 5 with 128 surface amino groups) was purchased from Aldrich. Heparin sodium and heparin−biotin sodium (molecular weight 15 000 Da) were obtained from Sigma. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) was from Amresco. Dimethylsulfoxide (DMSO) was from Sigma.

The reporter plasmids, pGL3-Luc and pEGFP-C1, were purchased from Promega and Invitrogen, respectively. Plasmids were amplified in *Escherichia coli* and extracted and purified by E.Z.N.A. Fastfilter Endo-free Plasmid Maxi Kit (Omega). Plasmids were suspended in deionized water and stored at −20 °C.

HeLa, HEK293T, and COS-7 cells were obtained from China Center for Typical Culture Collection (Wuhan, China) and cultured in Dulbecco's Modified Eagle's Medium (DMEM) (Gibco), supplemented with 10% fetal bovine serum (FBS), 2

mg/mL $NaHCO_3$, and 100 unit/mL penicillin/streptomycin. Cells were incubated at 37 °C in humidified air/5% CO_2.

Formation of PAMAM/DNA/Heparin and PAMAM/DNA/Heparin−Biotin Terplexes. PAMAM was diluted to an appropriate concentration in deionized water and stored at 4 °C until use. PAMAM/DNA complexes were made up by adding the aqueous solution of PAMAM to an equal volume of plasmid DNA in deionized water at a particular N/P ratio, followed by incubation at 37 °C for 30 min. The N/P ratio was based on the calculation of the number of terminal -NH_2 groups on the dendrimer versus the number of phosphate groups of the DNA.

PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes were prepared by mixing the PAMAM/DNA complexes containing aqueous solution with an aqueous solution of heparin or heparin−biotin of equal volume and then incubating at 37 °C for 30 min.

Agarose Gel Electrophoresis. Terplexes with different compositions were evaluated by agarose gel retardation assay. Five microliters of complexes containing solution with 0.1 μg DNA was electrophoresed on the 0.7% (w/v) agarose gel containing GelRed with Tris-acetate-EDTA (TAE) running buffer at 80 V for 80 min. DNA was visualized on a Vilber Lourmat UV-transilluminator.

Size and Zeta Potential Measurements. The size and zeta potential of complexes were measured using a Nano-ZS ZEN3600 (Malvern Instruments). The complexes contained solution containing 4 μg pGL3-Luc were diluted by deionized water to 0.8 mL for the size and zeta potential measurements. The data are given as mean ± standard deviation (SD) based on three independent measurements.

Cytotoxicity. The cytotoxicities of PAMAM/DNA complexes, PAMAM/DNA/heparin, and PAMAM/DNA/heparin−biotin complexes with the heparin/DNA or heparin−biotin/DNA weight ratio of 2 at various N/P ratios were examined by MTT assay. The HeLa cells were seeded in the 96-well plates at a density of 6×10^3 cells/well in 200 μL of DMEM containing 10% FBS. After incubation for 24 h, the medium was replaced by 200 μL of serum-free DMEM. Then, the complexes containing solution (20 μL containing 0.2 μg DNA) was added into the well. After coincubation at 37 °C for 48 h, the medium was removed and 20 μL of MTT (5 mg/mL) solution was added to each well and further incubated for 4 h. Thereafter, the medium was removed carefully, and 150 μL DMSO was added to each well to dissolve the formazan crystals. The absorbance was measured at 570 nm by a microplate reader (Biorad 550). The cells without coincubation with the complexes were used as the control. The data are given as mean ± standard deviation (SD) based on five measurements.

In Vitro Transfections. The transfection activities of various complexes in HeLa, COS-7, and 293T cells were examined. Unless otherwise mentioned, the transfections were carried out in serum-free media. The detailed transfection procedure is as follows. The cells were seeded at a density 5×10^4 cells per well in a 24-well plate with 1 mL of DMEM containing 10% FBS and incubated at 37 °C. After incubation for 24 h, the medium was replaced by 1 mL of serum-free DMEM. Then, the complexes containing solution (100 μL containing 1 μg DNA) was added into the well and incubated at 37 °C for 4 h. After that, the serum-free DMEM was replaced with fresh DMEM containing 10% FBS, and the cells were further incubated for 44 h. (For the transfections carried out in serum containing media, the cells and the complexes were coincubated in DMEM containing 10% FBS for 4 h. Other conditions were the same as that for the transfections carried out in serum-free media.)

To assay the expression of pGL3-Luc, the medium was removed and the cells were rinsed gently by phosphate buffered saline (PBS, 0.1 M, pH 7.4). After thorough lysis of the cells with reporter lysis buffer (Promega) (200 μL/well), the luciferase activity was determined by detecting the light emission from an aliquot of cell lysate incubated with 100 μL of luciferin substrate (Promega) in a luminometer (Lumat LB9507, Berthold). The protein content of the cell lysate was determined by BCA protein assay kit (Pierce). The optical density (OD) value was determined at 570 nm using a microplate reader (Biorad 550). The data are given as mean ± standard deviation (SD) based on three independent measurements.

To assay the expression of pEGFP-C1, the cells expressing green fluorescent proteins were directly observed by an inverted microscope (IX 70, Olympus) with a digital color camera (Roper CoolSnap Color). The micrographs were obtained at the magnification of 100× and recorded using *Image-Pro Plus* software.

Cellular Uptake Study. The uptake of complexes into HeLa cells was studied by confocal microscopy. YOYO-1 was used as molecular probe to label pGL3-Luc. One microgram of pGL3-Luc plasmid was mixed with 2.5 μL YOYO-1 solution (10 μM) and incubated for 15 min at 37 °C. The cells were seeded at a density of 5×10^4 cells per well in a 24-well plate with 1 mL of complete growth medium containing 10% FBS and incubated at 37 °C. After incubation for 24 h, the medium was replaced by 1 mL serum-free DMEM. Then, the complexes (100 μL containing 1 μg DNA) were added into the well and incubated at 37 °C for 4 h. After that, the medium was removed, the cells were washed twice with PBS, and then 200 μL DMEM containing 10% FBS and 20 μL Hoechst 33258 solution (10 mg/mL) were added and incubated at 37 °C for 20 min to stain nuclei of the cells. Finally, the solution was removed, cells were washed with PBS twice, and 1 mL of fresh DMEM containing 10% FBS was added. The cells were observed under excitation at 488 nm using a confocal laser scanning microscope (Nikon C1-si TE2000). The micrographs were obtained at the magnification of 800× and recorded using Nikon EZ-C1 *FreeViewer* software.

RESULTS AND DISCUSSION

Formation and Characterization of PAMAM/DNA/Heparin and PAMAM/DNA/Heparin−Biotin Terplexes. PAMAM dendrimers are a class of spherical, nanoscopic, highly ordered polymers with primary amino groups on the surface, which have lower cytotoxicity compared with PEI and have been extensively investigated as gene vectors (*17*). Heparin is a highly sulfated anionic polysaccharide. It was reported that PAMAM and heparin can form complexes through electrostatic interactions (*15, 16*). As we know, in order to condense DNA effectively, the complexes of polycation/DNA for gene delivery usually have a positive charge on the surface. In the current study, after mixing the positively charged PAMAM/DNA complexes with the negatively charged heparin and heparin−biotin, PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes were formed, respectively.

It was reported that heparin could replace DNA in the polycation/DNA complexes by vigorously mixing. In this study, the stability of different complexes was assessed by the agarose gel retardation assay and the results are shown in Figure 1. For PAMAM/DNA/heparin terplexes with a heparin/DNA weight ratio of 2 (Figure 1a), when the PAMAM/DNA N/P ratios were in the range 5−60, the complexes were able to completely bind DNA. Similarly, for PAMAM/DNA/heparin−biotin terplexes with a heparin−biotin/DNA weight ratio of 2 (Figure 1b), they could efficiently bind DNA at the PAMAM/DNA N/P ratio from 5 to 60. However, for PAMAM/DNA/heparin−biotin terplexes with a PAMAM/DNA N/P ratio of 20 (Figure 1c), PAMAM/DNA/heparin−biotin could not completely prevent DNA from

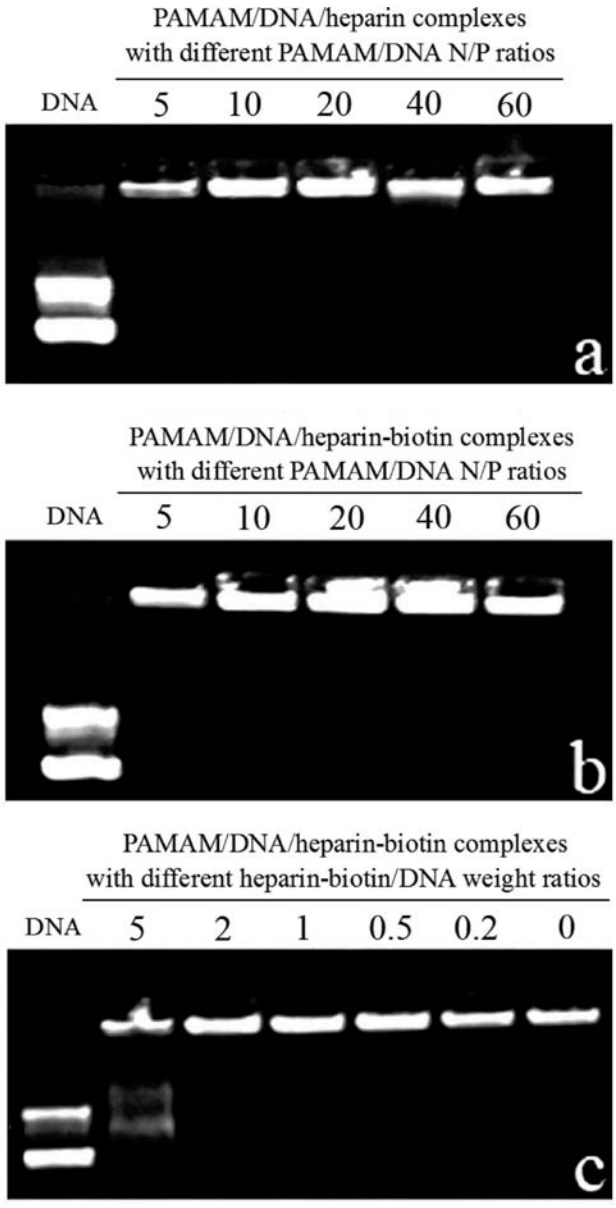

Figure 1. Agarose gel retardation assay of different complexes: (a) PAMAM/DNA/heparin complexes with a heparin/DNA weight ratio of 2 and different PAMAM/DNA N/P ratios, (b) PAMAM/DNA/heparin−biotin complexes with a heparin−biotin/DNA weight ratio of 2 and different PAMAM/DNA N/P ratios, and (c) PAMAM/DNA/heparin−biotin complexes with a PAMAM/DNA N/P ratio of 20 and different heparin−biotin/DNA weight ratios.

migrating into the gel when the weight ratio of heparin−biotin/DNA was 5, indicating that, in order to bind DNA completely, the weight ratio of heparin−biotin/DNA should be less than 5.

The particle sizes of different complexes were measured as shown in Figure 2. All sizes of PAMAM/DNA complexes at different N/P ratios were less than 200 nm, which indicated DNA could be effectively condensed by PAMAM at the N/P ratio higher than 5. As compared with the sizes of PAMAM/DNA complexes, the sizes of PAMAM/DNA/heparin slightly increased. This is due to the fact that the negatively charged heparin was attached to the surface of PAMAM/DNA complexes, leading to the increased sizes. Compared with PAMAM/DNA complexes, the size of PAMAM/DNA/heparin−biotin also increased. Compared with PAMAM/DNA/heparin terplexes, most commonly the sizes of PAMAM/DNA/heparin−biotin terplexes were smaller. The possible reason for this phenomenon is the hydrophobic nature of biotin moiety, which resulted in a

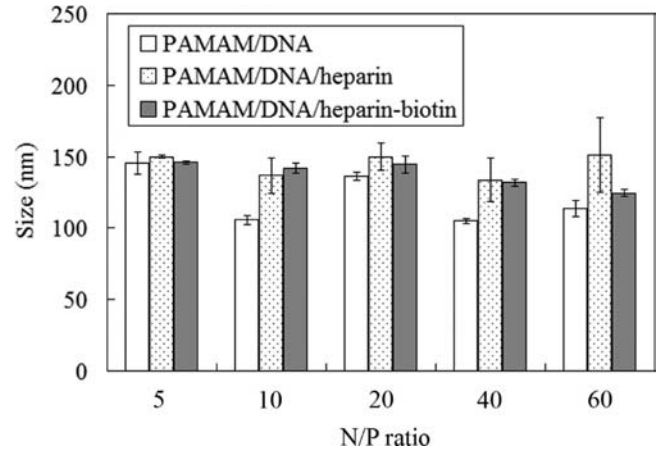

Figure 2. Particle sizes of different complexes with different PAMAM/DNA N/P ratios. The weight ratio of heparin/DNA and heparin−biotin/DNA is 2.

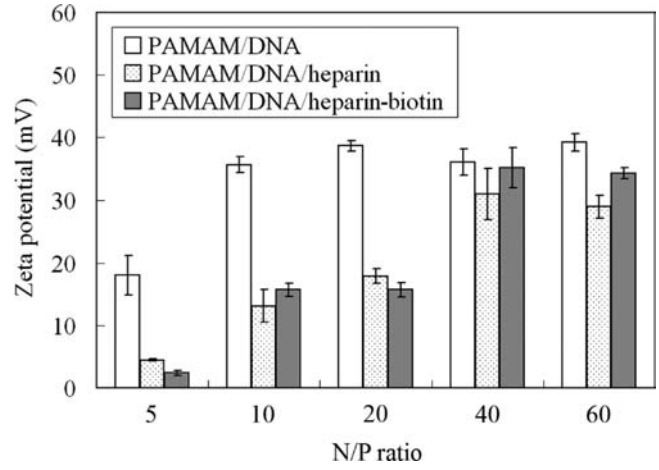

Figure 3. Zeta potentials of different complexes with different PAMAM/DNA N/P ratios. The weight ratio of heparin/DNA and heparin−biotin/DNA is 2.

less extended configuration of heparin−biotin chains on the surface of the terplexes. Nevertheless, the size differences between different complexes were not large, and all complexes had the mean sizes less than 200 nm.

The zeta potentials of different complexes are shown in Figure 3. The zeta potentials of all complexes were positive. Because of the positive surface charge caused by the excess PAMAM and the strong electrostatic interactions between PAMAM/DNA complexes and heparin or heparin−biotin, the heparin and heparin−biotin in the systems could form terplexes and the free heparin and heparin−biotin could be ignored. The zeta potentials of the complexes increased with increasing PAMAM/DNA N/P ratio when the N/P ratio was less than 20. Compared with PAMAM/DNA, the zeta potential of PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin decreased significantly, especially at the relatively low N/P ratios, because the negatively charged heparin or heparin−biotin was attached to the surface of PAMAM/DNA complexes. As a result, the positive surface charges of the PAMAM/DNA complexes were partially neutralized. The positive zeta potential values of all complexes were in good agreement with the result of agarose gel retardation assay, which also indicated that PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes with different N/P ratios were stable when the weight ratio of heparin/DNA and heparin−biotin/DNA was 2.

In Vitro Cytotoxicity. The cytotoxicity of different complexes in HeLa cells was evaluated by MTT assay. As presented

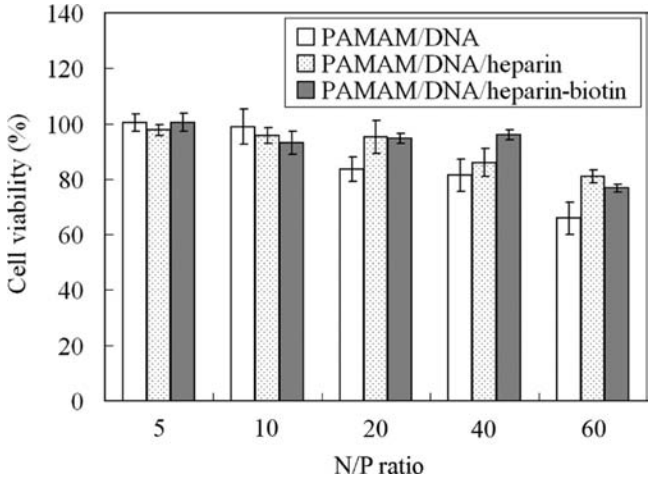

Figure 4. Cell viability of HeLa cells after coincubation with different complexes with different PAMAM/DNA N/P ratios. The weight ratio of heparin/DNA and heparin−biotin/DNA is 2.

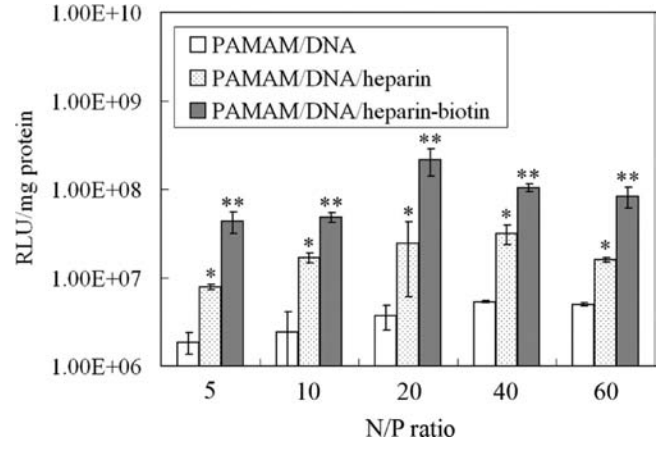

Figure 5. Luciferase expression in HeLa cells transfected with different complexes with different PAMAM/DNA N/P ratios. The weight ratio of heparin/DNA and heparin−biotin/DNA is 2. (* $p < 0.05$ as compared with the data of PAMAM/DNA complexes at the same N/P ratio, and ** $p < 0.05$ as compared with the data of PAMAM/DNA/heparin complexes at the same N/P ratio.)

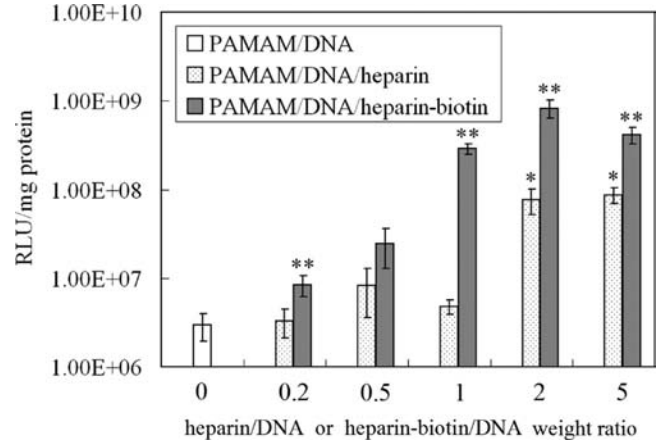

Figure 6. Luciferase expression in HeLa cells transfected with different complexes with different heparin/DNA or heparin−biotin/DNA weight ratios. The PAMAM/DNA N/P ratio is 20. (* $p < 0.05$ as compared with the data of PAMAM/DNA complexes, ** $p < 0.05$ as compared with the data of PAMAM/DNA/heparin complexes at the same heparin/DNA or heparin−biotin/DNA weight ratio.)

in Figure 4, for PAMAM/DNA complexes, with an increase in N/P ratio, the cell viability decreased. As expected, generally the cytotoxicities of PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes were lower than that of the PAMAM/DNA complexes, especially at the high N/P ratios. As we know, during the gene transfection, the positive charge on the surface of complexes is essential for binding the negatively charged cell membranes and thus being taken up via an endocytic mechanism. However, the higher positive surface charge means higher cytotoxicity of the complexes, and the high cytotoxicity of the polycations limits their clinical applications as gene vectors. One of the strategies to reduce the cytotoxicity is to neutralize or partially shield the positive charge on the polycation/DNA complexes. For example, the PEG chains grafted to polycations could shield the positive surface charge and thus reduce the cytotoxicity while maintaining the efficient transfection ability of the polycations (*18–20*). In this study, heparin and heparin−biotin were used to partially neutralize the positive charge of PAMAM/DNA complexes. The resultant terplexes showed relatively lower zeta potential as compared with PAMAM/DNA, which resulted in their lowered cytotoxicity.

In Vitro Transfection. The luciferase expressions in HeLa cells transfected with different complexes with the heparin/DNA or heparin−biotin/DNA weight ratio of 2 and different PAMAM/DNA N/P ratios are shown in Figure 5. For all N/P ratios, as compared with PAMAM/DNA complexes, PAMAM/DNA/heparin terplexes exhibited a much higher gene transfection activity. In addition, the gene expression levels mediated by PAMAM/DNA/heparin−biotin terplexes could obviously be further improved. Both comparisons between the data of PAMAM/DNA and PAMAM/DNA/heparin and the data of PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin showed $p < 0.05$, indicating that the differences were statistically significant. As we know, heparin is one of the most potent anticoagulants and has been widely used to enhance the blood compatibility of biomaterials. According to previous studies of other researchers, the conjugation of heparin to PEI or physical modification of PEI with heparin via electrostatic interactions can improve the cytocompatibility and transfection efficiency (*13, 14*). Our results are in accordance with the previous studies.

Biotin is an essential vitamin for the division of all cells, especially for the rapid proliferations of tumor cells. The cancer cells often overexpress biotin receptors on the cell surface. The improvement of gene expression mediated by PAMAM/DNA/heparin−biotin suggested that the presence of biotin moiety facilitated the uptake of terplexes in tumor cells due to the specific interactions between biotin and its receptors on HeLa cells (*9*) and led to the improved transfection efficiency. Our results are in agreement with the previous literature. As reported, the biotin conjugated PAMAM (G5) exhibited enhanced cellular uptake of HeLa cells, i.e., about 2 times higher than that without incorporation of biotin as determined by the mean fluorescence (*9*). In our study, the luciferase expressions in HeLa cells transfected with PAMAM/DNA/heparin−biotin were about 2 to 6 times higher than that transfected with PAMAM/DNA/heparin when the N/P ratios were in the range 5−60 (Figure 5).

From Figure 5, the gene expressions increased with increasing N/P ratio at the N/P ratio ranging from 5 to 20. A further increase in N/P ratio did not result in an obvious improvement in the transfection. This is because the complexes with a low N/P ratio could not efficiently mediated gene expressions, while the N/P ratio of more than 20 was too high, which caused the low cell viability after transfection. Thus, we fixed the N/P ratio at 20 for further study.

As shown in Figure 6, when fixing the PAMAM/DNA N/P ratio at 20, the gene expressions mediated by PAMAM/DNA/

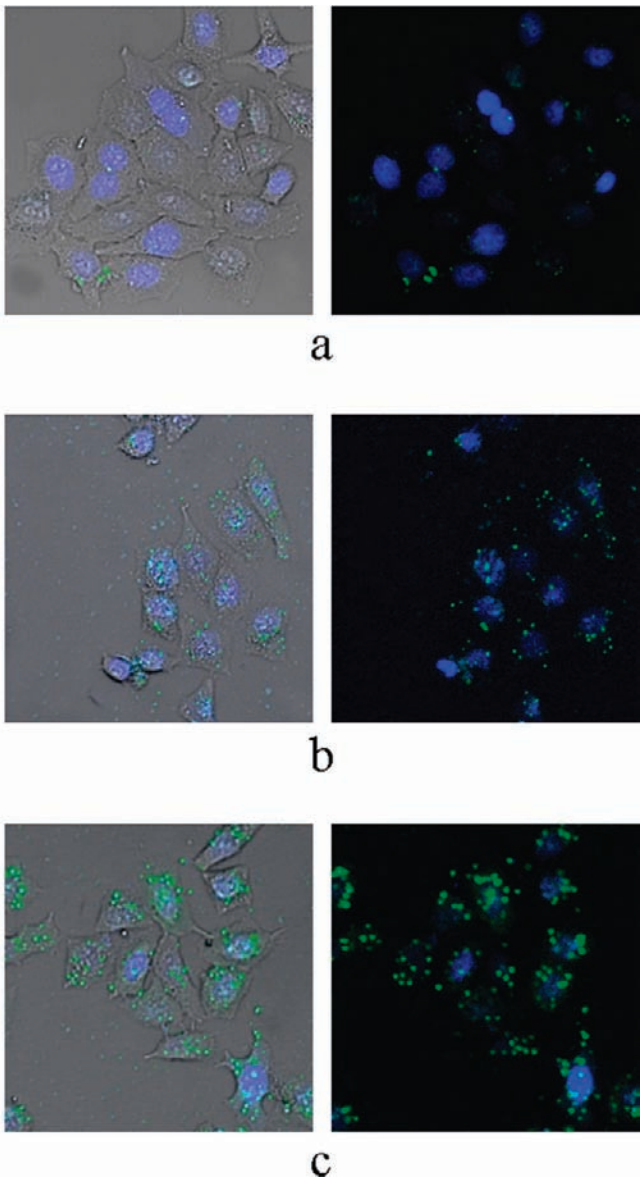

Figure 7. Confocal images of HeLa cells after incubation with (a) PAMAM/DNA, (b) PAMAM/DNA/heparin, and (c) PAMAM/DNA/heparin−biotin complexes. The PAMAM/DNA N/P ratio is 20, and the weight ratio of heparin/DNA and heparin−biotin/DNA is 2.

heparin and PAMAM/DNA/heparin−biotin terplexes increased with increasing weight ratio of heparin/DNA or heparin−biotin/DNA, reached maximum values at the heparin/DNA or heparin−biotin/DNA weight ratio of 2, implying that the heparin/DNA or heparin−biotin/DNA weight ratio at 2 was high enough to improve the transfection activity of the terplexes. For the different complexes at each particular heparin/DNA or heparin−biotin/DNA weight ratio, the same trend could be found, i.e., the transfection level increased significantly by binding heparin or heparin−biotin on the surface of PAMAM/DNA complexes, and the PAMAM/DAN/heparin−biotin complexes exhibited the highest transfection efficiency.

To further confirm the mechanism of the improvement of transfection in the presence of biotin moiety, we used confocal microscopy to visualize the cell uptake of different complexes. As shown in Figure 7, after coincubation with PAMAM/DNA complexes for 4 h, only a few green fluorescence dots could be observed in HeLa cells (Figure 7a), while more green fluorescence dots could be observed for the cells treated with PAMAM/DNA/heparin terplexes (Figure 7b), suggesting that adding

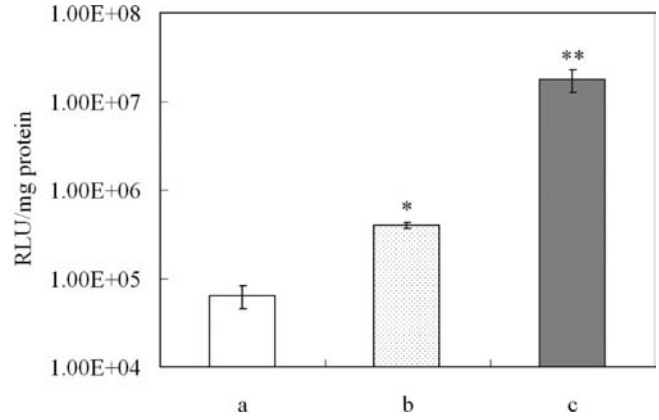

Figure 8. Luciferase expression in HeLa cells transfected with (a) PAMAM/DNA, (b) PAMAM/DNA/heparin, and (c) PAMAM/DNA/heparin−biotin complexes in DMEM containing 10% FBS. The PAMAM/DNA N/P ratio is 20, and the weight ratio of heparin/DNA and heparin−biotin/DNA is 2. (* $p < 0.05$ as compared with the data of PAMAM/DNA complexes, ** $p < 0.05$ as compared with the data of PAMAM/DNA/heparin complexes.)

appropriate heparin increased the cellular uptake. According to the earlier reports, anionic dendrimer could result in a markedly improved cellular uptake of oligonucleotide, and the positive surface charge is not the sole factor determining the cell uptake (*21*). Our result was consistent with the literature. The intensity of fluorescence was highest for the cells treated with PAMAM/DNA/heparin−biotin terplexes (Figure 7c), indicating that the existence of the biotin moiety played an important role in the cell uptake and the PAMAM/DNA/heparin−biotin terplexes could enter the cells through specific interactions between biotin and its receptors. The confocal microscopic observation clearly indicated that the level of cellular uptake in HeLa cells markedly increased by the presence of heparin and especially heparin−biotin. These results were in good agreement with the results of the in vitro transfection.

As it is well know that the presence of serum could reduce the transfection efficiency of polycations, the excess positive charge on the surface of the polycation/DNA complexes results in nonspecific adsorption of plasma proteins in serum. Heparin could inhibit the adsorption of serum proteins to the surfaces of liposomes and PEI (*13*, *22*). In this study, the transfection mediated by different complexes in the serum-contained media was investigated. As shown in Figure 8, the gene expression level increased significantly with the presence of heparin or heparin−biotin in the complexes. However, the expression levels decreased greatly in the serum-containing media (Figure 8) as compared with that in the serum-free media (Figure 5c). This is probably because all the terplexes were still positively charged, and their transfection efficacy was also affected by the presence of serum.

To further assess the transfection activities of terplexes in HeLa cells, another plasmid pEGFP-C1 was used to form PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes. Being consistent with gene transfection results using plasmid pGL3-Luc, the images in Figure 9 also showed that the PAMAM/DNA/heparin terplexes exhibited enhanced transfection activity and the PAMAM/DNA/heparin−biotin terplexes had the highest transfection activity, because the weakest fluorescence emission was observed for the HeLa cells transfected by PAMAM/DNA, whereas the highest fluorescent density was observed for the cells transfected with PAMAM/DNA/heparin−biotin.

In order to evaluate the transfection activity of the terplexes, the in vitro transfections were carried out in both 293T cells

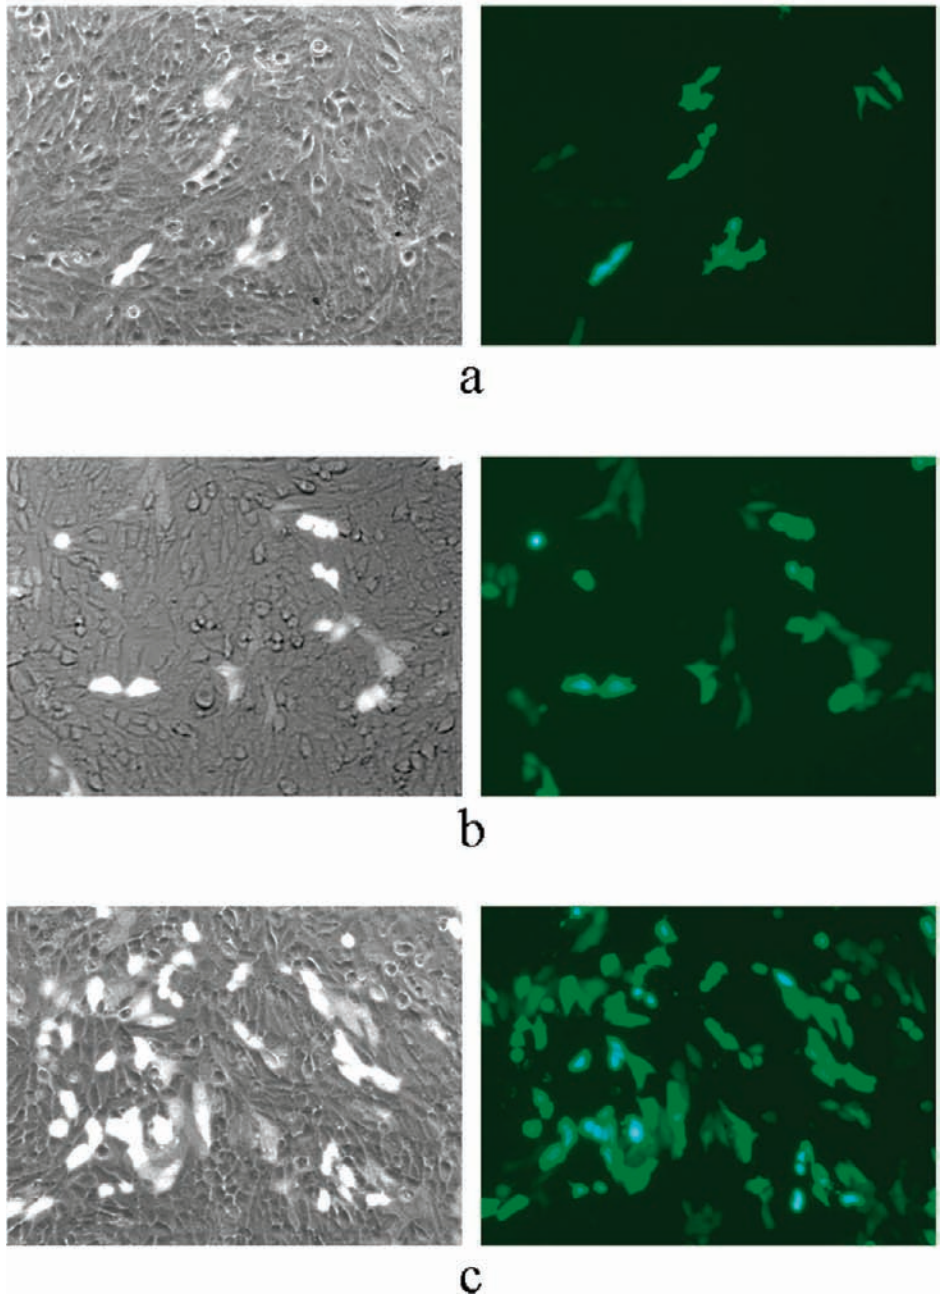

Figure 9. Enhanced green fluorescent protein expression in HeLa cells transfected with (a) PAMAM/DNA, (b) PAMAM/DNA/heparin, and (c) PAMAM/DNA/heparin−biotin complexes. The PAMAM/DNA N/P ratio is 20, and the weight ratio of heparin/DNA and heparin−biotin/DNA is 2.

(Figure 10) and COS-7 cells (Figure 11). The transfection activities of PAMAM/DNA/heparin terplexes and PAMAM/DNA/heparin−biotin terplexes were also statistically significantly higher than that of PAMAM/DNA complexes ($P < 0.05$). These results suggested that the presence of heparin or heparin−biotin was favorable for the transfection in these cells. According to the literature (*8–11*), most tumor cell types overexpress receptors involved in vitamin uptake such as biotin, although some tumor cell types do not overexpress biotin receptors, and normal cells do not overexpress biotin receptors. In our study, the transfection activity of PAMAM/DNA/heparin−biotin terplexes was almost the same as that of PAMAM/DNA/heparin terplexes in 293T and COS-7 cells. The presence of biotin on the surface of the complexes could not further enhance the transfection, implying that biotin receptors were not overexpressed in 293T and COS-7 cells, which were nontumor cells.

CONCLUSIONS

In this study, heparin and heparin−biotin were introduced to the complexes of PAMAM/DNA via electrostatic interactions. The presence of appropriate amounts of heparin and heparin−biotin did not affect the DNA condense ability of PAMAM and could lead to lowered cytotoxicities and improved gene transfection activities for the self-assembled PAMAM/DNA/heparin and PAMAM/DNA/heparin−biotin terplexes. The PAMAM/DNA/heparin−biotin terplexes exhibited an enhanced cellular uptake into HeLa cells due to the specific interactions between biotin and biotin receptors on HeLa cells, and thus led to further improvement in the gene transfection in HeLa cells as compared with PAMAM/DNA/heparin. These results indicated that PAM-

Received July 18, 2010; Revised Manuscript Received September 11, 2010

A series of novel long-chain hyperbranched poly(ethylene glycol)s (LHPEGs) with biodegradable connections were designed and synthesized in one pot through proton-transfer polymerization using PEG and commercial glycidyl methacrylate as monomers and potassium hydride as catalyst. The LHPEGs were hydrolyzed at neutral pH resulting in the decrease of molecular weights. In vitro evaluation demonstrated that LHPEGs were biocompatible and displayed negligible hemolytic activity. The efficient cellular uptake of LHPEGs was confirmed by flow cytometry and confocal laser scanning microscopy. Moreover, conjugation of a model hydrophobic anticancer drug methotrexate to LHPEGs inhibited the proliferation of a human cervical carcinoma Hela cell line. MTT assay indicated that the conjugated methotrexate dose required for 50% cellular growth inhibition against Hela cells was 20 μg/mL. By combining the advantages of long-chain hyperbranched structure and PEG, LHPEG provides a promising drug carrier for therapeutic fields.

INTRODUCTION

Poly(ethylene glycol) (PEG) has attracted great attention in biomedical fields due to its good hydrophilicity, biocompatibility, nonimmunogenicity, ion-transporting ability, and chemical stability under basic or neutral conditions (*1*−*13*). The conjugation of PEG has been used to various investigational and clinical compounds, such as peptides, proteins, oligodeoxynucleotides, antibodies, polymers, liposomes, and inorganic/organic nanoparticles (*14*−*22*). It is worth noting that PEG is often the first choice in the biopharmaceutical industry for the improvement of pharmacological properties (*23, 24*). PEG−drug conjugates can change the physical and chemical properties of the linked drugs, including the conformation, electrostatic binding, and hydrophilic−hydrophobic balance. More significantly, PEG can increase the stability and retention time in the blood of the conjugated drug, as well as reduce the proteolysis, renal excretion, and immunogenicity (*25*). However, a major problem for PEG as a drug carrier lies in the fact that linear PEG possesses a limited attachment capacity, with only one or two end groups depending on the inherent structure of polymer chain (*25, 26*). Therefore, PEG with many functional groups is highly attractive for drug delivery applications.

In contrast to linear polymers, dendritic polymers including dendrimers and hyperbranched polymers are highly branched macromolecules with low viscosity, good solubility, and plenty of terminal functional groups (*27*−*33*). Recently, dendritic polymers have been widely used for drug conjugates, because they can carry multiple copies of drug and/or targeting/imaging ligands (*34*). In the past few years, hyperbranched polyglycerols and PEG-methacrylate polymers with cross-linkers have been produced as PEG-mimic hyperbranched polymers (*26, 35*−*39*). Due to their structural similarity to PEG and highly branched nature, these mimics exhibit a broad range of potential applications in medicine and pharmacology. On the other hand, long-chain hyperbranched polymers are particularly interesting and have received growing attention because of their unique long-chain and hyperbranched structures (*40*−*49*). For example, Hutchings and co-workers developed the "macromonomer" approach to prepare long-chain hyperbranched polymers (*49*). By employing a Williamson coupling reaction of α,ω,ω'-trifunctional AB_2 macromonomers, a series of long-chain hyperbranched polymers have been obtained. However, to the best of our knowledge, a drug carrier based on PEG with a long-chain hyperbranched structure has not yet been reported. Herein, through the molecular design, a novel long-chain hyperbranched PEG which integrates the advantages of long-chain hyperbranched structure and PEG has been prepared in one pot via proton-transfer polymerization of PEG and commercial glycidyl methacrylate with the help of potassium hydride. The transformation of PEG from the conventional linear structure to the unique long-chain hyperbranched architecture with biodegradable connection provides a promising material for drug carriers.

MATERIALS AND METHODS

Materials. Potassium hydride (KH, 30 wt % dispersion in mineral oil, Acros), acridine orange (AO, Aldrich), ethidium bromide (EB, Aldrich), polyethylenimine (PEI, M_w = 25 kDa, Aldrich), *N*-hydroxysuccinamide (NHS, Acros), *N*,*N*-dicyclohexylcarbodiimide (DCC, Aldrich), 4-dimethylamino-pyridine (DMAP, Aldrich), and 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT, Aldrich) were used as received. PEG (M_n = 600, Acros) was dried by azeotropical distillation from anhydrous toluene. Glycidyl methacrylate (GMA, Acros) and dimethyl sulfoxide (DMSO) were dried over calcium hydride (CaH_2) and distilled under reduced pressure. Tetrahydrofuran (THF) was dried by refluxing over fresh sodium benzophenone complex (a deep purple color indicating an oxygen- and moisture-free solvent) and distilled just before polymerization. Methotrexate (MTX) was purchased from

Sangon Biotech (Shanghai) Co., Ltd. Clear polystyrene tissue culture treated 12-well and 96-well plates were obtained from Corning Costar. All other reagents and solvents were purchased from the domestic suppliers and used as received.

Synthesis of Long-Chain Hyperbranched PEG (LHPEG). A suspension of KH in mineral oil (30% in weight) was introduced in a dry, preweighed 100 mL Schlenk flask under argon (Ar). The mineral oil was removed by three extractions with THF, and the remaining THF was removed by vacuum. When KH was completely dried, the flask was weighted again to determine the amount of KH (0.542 g, 13.5 mmol). Then, 30 mL DMSO and PEG600 (16.2 g, 27.0 mmol) were introduced into the flask (Caution: hydrogen gas was generated). The solution was stirred for 2 h to form the potassium alcoholate. Subsequently, GMA (3.84 g, 27.0 mmol) was added by syringe and the polymerization was conducted at 80 °C for 48 h. Upon completion of the polymerization, the mixture was precipitated into 1000 mL acetone/diethyl ether (v/v = 1/4). The product was redissolved in methanol and neutralized by filtration over cation-exchange resin. The obtained polymer was precipitated twice from methanol solution into cold diethyl ether. The residues were dissolved in distilled water. Exhaustive dialysis against exchanged distilled water was carried out for 7 days, followed by lyophilization to give the LHPEG (yield: 12.9 g, 64.5%).

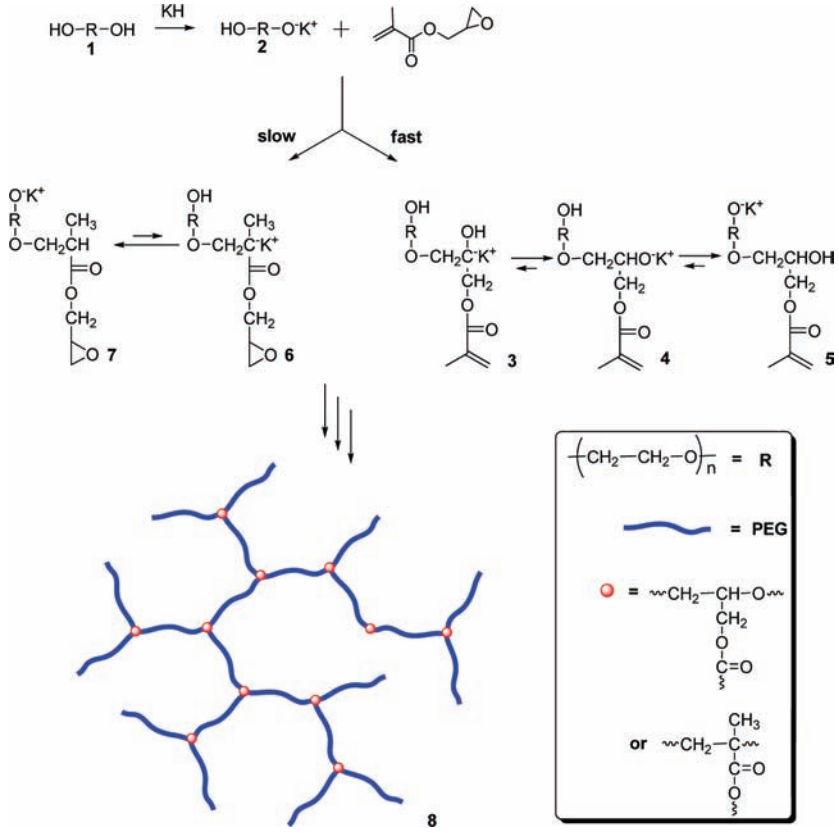
Rhodamine B Labeled LHPEG (LHPEG-RB). A typical rhodamine B (RB) conjugation reaction is described as follows: NHS (130.0 mg, 1.132 mmol) and RB (542 mg, 1.132 mmol) were dissolved in 20 mL of DMF, and then DCC (256.6 mg, 1.246 mmol) and DMAP (276.3 mg, 2.265 mmol) were added to the solution. The mixture was stirred at 50 °C overnight. LHPEG (830 mg, 0.126 mmol) in 10 mL DMF was added to the reaction solution. The reaction was conducted at room temperature for another 48 h. Then, the insoluble substance was filtered and DMF was removed by rotary evaporation. The residues were dissolved in distilled water. Exhaustive dialysis against exchanged distilled water was carried out for 7 days, followed by lyophilization to give the LHPEG-RB.

MTX Conjugated LHPEG (LHPEG-MTX). In a typical experiment, MTX (665.2 mg, 1.46 mmol), LHPEG (878.2 mg, 0.133 mmol), DCC (316.6 mg, 1.54 mmol), and DMAP (178.6 mg, 1.46 mmol) were mixed in a 100 mL flask with 20 mL DMF. The solution was stirred for 48 h at room temperature under a nitrogen atmosphere. Then, the insoluble dicyclohexylurea was filtered and DMF was removed by rotary evaporation. The crude product was purified by repeatedly dissolved in methanol and then precipitated in diethyl ether. The residues were dissolved in distilled water. Exhaustive dialysis against exchanged distilled water was carried out for 7 days, followed by lyophilization to give LHPEG-MTX.

Characterization of Polymers. ^{1}H and ^{13}C NMR spectra of the polymers were recorded using Bruker Avance III 400 spectrometer with dimethyl sulfoxide-d_6 (DMSO-d_6) as a solvent. Quantitative ^{13}C NMR spectra were measured by the method of inverse gated ^{1}H decoupling. In DEPT experiments, the ^{1}H tip angle θ was set to 135° to determine carbon multiplicities with CH, CH_3 up, and CH_2 down. ^{1}H, ^{1}H-COSY and ^{13}C, ^{1}H-HSQC spectra were recorded using the standard pulse sequence provided by Bruker. Fourier transformed infrared (FTIR) spectrum measurements were performed on a Bruker Equinox-55 FTIR spectrometer with a disk of KBr. The molecular weights and polydispersity indexes (PDIs) were determined by gel permeation chromatography (GPC). GPC was performed on a Perkin-Elmer series 200 system (10 μm PL gel 300 × 7.5 mm mixed-B and mixed-C column, PEG calibration) equipped with a refractive index (RI) detector. DMF contained 0.01 mol/L lithium bromide was used as the mobile phase at a flow rate of 1 mL/min at 70 °C. The glass transition temperature (T_g) and melting behavior of polymers were measured with a TA Instruments Q2000 differential scanning calorimeter (DSC) under nitrogen (N_2) atmosphere. All samples were heated from −80 to 100 °C at a heating rate of 20 °C/min. The midpoint of the slope change of the heat capacity plot of the second heating scan was taken as T_g. UV−vis measurements were performed on a Perkin-Elmer Lambda 20 UV−vis spectrometer in the range 300−500 nm.

Degradation of LHPEG. Degradation behavior of LHPEG was estimated by the measurement of molecular weights. In brief, 0.2 g LHPEG was dissolved in 10 mL PBS and incubated at 37 °C with shaking. A series of 1 mL solutions were extracted and lyophilized after appropriate time intervals. The molecular weights of the lyophilized samples were measured by GPC analysis.

Cell Cultures. NIH 3T3 cells (a mouse embryonic fibroblast cell line) and Hela cells (a human cervical carcinoma cell line) were cultured in DMEM (Dulbecco's modified Eagle's medium) supplied with 10% FBS (fetal bovine serum) and antibiotics (50 units/mL penicillin and 50 units/mL streptomycin) at 37 °C in a humidified atmosphere containing 5% CO_2.



Cytotoxicity of LHPEG. NIH 3T3 cells were seeded into 96-well plates at an initial seeding density of 8.0×10^3 cells/well in 200 μL medium. After 24 h incubation, the culture medium was removed and replaced with 200 μL medium containing serial dilutions of LHPEG. The cells were grown for another 24 h. Then, 20 μL of 5 mg/mL MTT assays stock solution in phosphate buffered saline (PBS) was added to each well. After incubating the cells for 4 h, the medium containing unreacted dye was removed carefully. The obtained blue formazan crystals were dissolved in 200 μL per well DMSO, and the absorbance was measured in a BioTek Elx800 at a wavelength of 490 nm.

AO/EB Double Staining. NIH 3T3 cells were seeded in 6-well plates at 5×10^5 cells per well in 1 mL complete DMEM and cultured for 24 h, followed by removing culture medium and adding 1 mL LHPEG solutions (in DMEM medium) with the concentration of 1 mg/mL. After 24 h incubation, cells were rinsed by PBS twice and incubated in PBS containing AO (5 μg/mL) and EB (5 μg/mL) at 37 °C in 5% CO_2 for 10 min. Then, the cells were rinsed by PBS twice and directly imaged by an Olympus BX61 fluorescence microscope.

Hemolysis Assay. The blood was drawn from the ear vein of a male New Zealand white rabbit (2.5 kg body weight). A 2% (w/v) suspension of red blood cells (RBCs) was isolated through the following procedure. First, the blood was centrifuged at 2000 rpm for 5 min at 4 °C, and the plasma and top of the pellet were discarded. The pellet was resuspended in PBS (pH = 7.4) that had been prechilled to 4 °C. The suspension was subjected to another repeating centrifugation step as described. Finally, the pellet was resuspended in a volume appropriate to 2% (w/v) suspension using PBS (pH = 7.4). Samples were dissolved at concentrations of 2 mg/mL in PBS and added to an equal volume of 2% (w/v) RBC suspension in PBS. Dextran and PEI were used as reference controls, and Triton X-100 (1% v/v) was used to give a 100% hemolysis value. Hemoglobin release was determined by a Perkin-Elmer Lambda 20 UV−vis spectrometer at 545 nm and expressed as a percentage of hemoglobin release relative to the Triton X-100 control.

Cell Internalization. Cell internalization was characterized by flow cytometry and confocal laser scanning microscopy (CLSM). Flow cytometry was used to provide statistics on the uptake of LHPEG into Hela cells. Hela cells (5.0×10^5 cells per well) were seeded in a 6-well tissue culture plate. After 24 h culture, the RB labeled P1 dissolved in DMEM culture

Scheme 1. Detailed Proton-Transfer Polymerization Mechanism of LHPEG

medium with a concentration of 1 mg/mL was added to different wells and the cells were incubated at 37 °C for predetermined time intervals. After the incubation, samples were prepared for flow cytometry analysis by removing the cell growth media, rinsing with PBS buffer, and treating with trypsin. Data for 1.0 $\times$ 10^4 gated events were collected, and analysis was performed by means of a BD FACSCalibur flow cytometer and *CELLQuest* software.

For CLSM, Hela cells (2.0 $\times$ 10^5 cells per well) were seeded on coverslips in a 6-well tissue culture plate. After 24 h culture, the LHPEG-RB dissolved in DMEM culture medium with a concentration of 1 mg/mL was added to different wells and the cells were incubated at 37 °C for predetermined time intervals. After being washed with PBS, the cells were fixed with 4% formaldehyde for 30 min at room temperature, and the slides were rinsed with PBS three times. Finally, the cells were stained with 2-(4-amidinophenyl)-6-indolecarbamidine dihydrochloride (DAPI) for 10 min, and the slides were rinsed with PBS three times. The slides were mounted and observed by a LSM 510META.

Activity Analyses. The inhibition of LHPEG-MTX against Hela cells was evaluated in vitro by MTT assay, using free MTX with the same concentrations as the control. Hela cells were seeded into 96-well plates at an initial seeding density of 5.0×10^3 cells/well in 200 μL medium. After 24 h incubation, the culture medium was removed and replaced with 200 μL medium containing serial concentrations of free MTX or conjugated MTX. The cells were grown for another 72 h. The culture

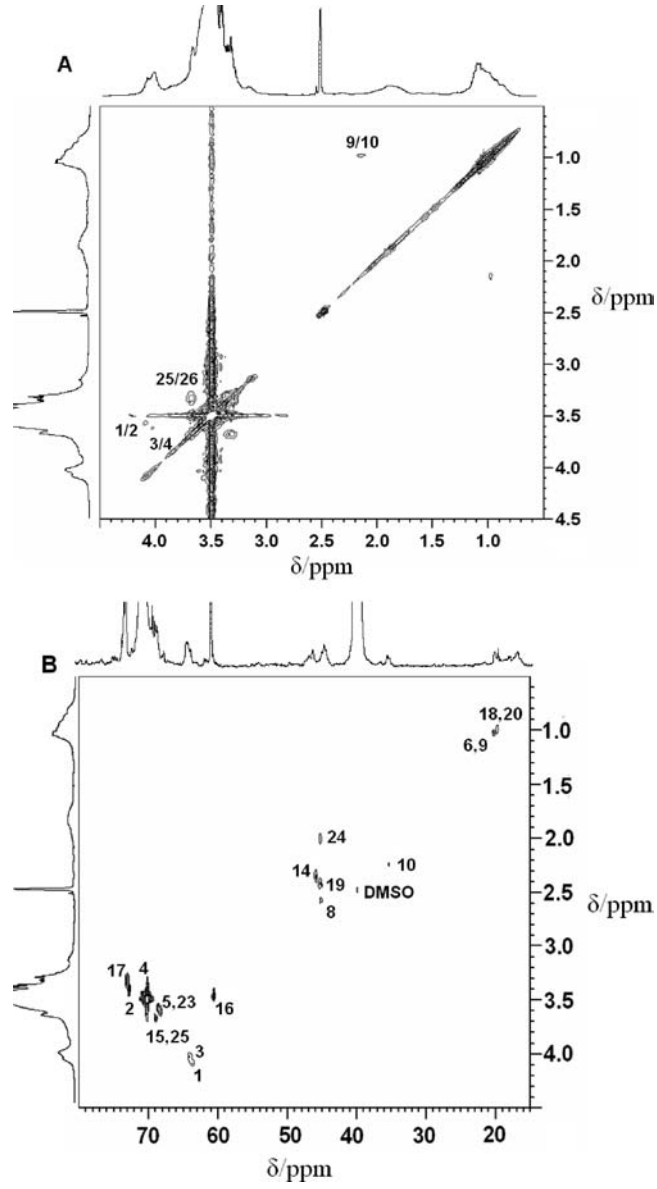

Figure 3. 2D NMR spectra of P1: (A) ^1H, ^1H-COSY spectrum, (B) ^{13}C, ^1H-HSQC spectrum.

medium was replenished with fresh DMEM after 48 h incubation. Then, 20 μL of 5 mg/mL MTT assay stock solution in PBS was added to each well. After incubating the cells for 4 h, the medium containing unreacted MTT was removed carefully. The obtained blue formazan crystals were dissolved in 200 μL per well DMSO, and the absorbance was measured in a VarioskanFlash at a wavelength of 570 nm.

RESULTS AND DISCUSSION

Synthesis and Characterization of LHPEG. On the basis of the molecular design, LHPEGs were synthesized through proton-transfer polymerization by oxyanionic initiation. GMA is a typical monomer for proton-transfer polymerization, because of the existence of two different reactive groups, namely, a vinyl group and an epoxy group. Both the epoxy group and the double bond of GMA could be polymerized through oxyanionic initiation (*50*). Correspondingly, the ester bond introduced in the backbone can make the polymer degradable in biological milieu. PEG was used as an oxyanionic active center to initiate the proton-transfer polymerization of GMA with the help of KH catalyst.

The detailed proton-transfer polymerization mechanism of LHPEG from PEG and GMA through oxyanionic initiation is shown in Scheme 1. The hydroxyl groups of PEG **1** are easily initiated by KH, producing the initiator **2** with the release of hydrogen gas (H_2). Because GMA has a vinyl group and an epoxy group, there are two possibilities for the reaction of **2** with GMA. **2** initiates the epoxy group of GMA leading to **3**, while **2** reacts with the vinyl group of GMA producing **6**. It has been extensively reported that the active anion center of the secondary alkoxide or carbonanion can transfter immediately to the more stable primary alkoxide through proton transfer (*51*−*53*). Thus, the intermidiate compounds **4**, **5**, and **7** are expected. Further polymerization of **3**, **4**, **5**, **6**, and **7** gives the LHPEG **8**. Highly viscous product was obtained after the polymerization was carried out in DMSO at 80 °C for 48 h. The reaction proceeded homogeneously, and no gelation took place throughout the polymerization. Table 1 summarizes the experimental conditions and corresponding characterization data.

Figure 1 displays the structural units of LHPEG synthesized from PEG and GMA. To confirm the existence of these structures, both ^{1}H and ^{13}C NMR experiments were performed. ^{1}H NMR spectra were used to investigate the conversion of GMA into the polymer (Figure 2A). The peaks at 6.05 and 5.70 ppm corresponding to the vinyl group of GMA and peaks at 3.23, 2.78, and 2.65 ppm corresponding to the epoxide group of GMA disappear completely in the ^{1}H NMR spectrum of LHPEG. As expected, a new signal around 1.04 ppm assigning to the methyl group of GMA units appears and the resonances around 2.50 and 1.84 ppm assigned to the methylene of GMA units are strengthened in the spectrum of LHPEG. These data indicate that the GMA monomer has been successfully converted to LHPEG polymer. Figure 2B,C gives a DEPT-135 spectrum to distinguish methylene and methane or methine carbons. The peaks 6, 9, 18, and 20 are assigned to the methyl groups from GMA units. To further verify the branched topology of the polymerized product, the two-dimensional NMR (2D-NMR) technique was used (*54*). Figure 3A,B gives the ^{1}H, ^{1}H-COSY and ^{13}C, ^{1}H-HSQC spectra, respectively. It can be found that 1-H/2-H, 3-H/4-H, 9-H/10-H, and 25-H/26-H are in different spin systems. On the basis of the information from the ^{1}H, ^{1}H-COSY and ^{13}C, ^{1}H-HSQC spectra, the detailed assignment is shown in Figure 3. According to the following equation proposed by Fréchet (*55*), the degree of branching (DB) for LHPEG can be determined

$$\mathrm{DB} = (D + T)/(D + T + L)$$

where D, T, and L represent the fractions of the dendritic, terminal, and linear units, respectively. Table 1 shows the DBs of the polymerized samples. The DBs of these polymers are at 0.57−0.65, suggesting the formation of long-chain hyperbranched products.

FTIR results provide the additional chemical structure information of LHPEG (Figure 4A). The strong absorption peak at 1092 cm^{-1} is attributed to the C−O−C stretching vibrations. The band at 1466 cm^{-1} results from the asymmetric deformation vibration of the $-CH_2-$ groups. The band around 2868 cm^{-1} corresponds to the $-CH_2-$ vibrations of PEG, while the broad O−H stretching vibration around 3494 cm^{-1} indicates the appearance of many hydroxyl groups. In contrast to PEG, an apparent strong ester carbonyl band at 1727 cm^{-1} emerges, confirming the presence of ester bonds in LHPEG. Furthermore, DSC analyses verify the hyperbranched structures of LHPEGs. As shown in Figure 4B, the DSC curve of PEG600 shows one melting endotherm at 20.9 °C. For LHPEGs, the introduction of branched GMA units weakens the regular stacking ability of PEG chains. Therefore, the melting endotherm decreases to 17.0, 15.0, and 13.3 °C for P3, P2, and P1, respectively. In the meantime, both the glass transition temperatures (T_g) at about −49 °C and the cold crystallization peak around −10 °C can be observed for all LHPEG samples. In addition, the molecular weights and PDI values of these polymers were measured by GPC, and the data are summarized in Table 1. In detail, the molecular weights of P1, P2, and P3 are 6600, 6200, and 5600 g/mol, with the PDI values of 3.02, 2.96, and 2.81, respectively. The real molecular weights of LHPEGs may be even larger than the values estimated by GPC analysis using linear PEG as the calibration, because dendritic polymers generally have smaller sizes than linear polymers with the same molecular weight and can hardly be expanded in solution (*56*). These results further testify to the successful preparation of LHPEGs.

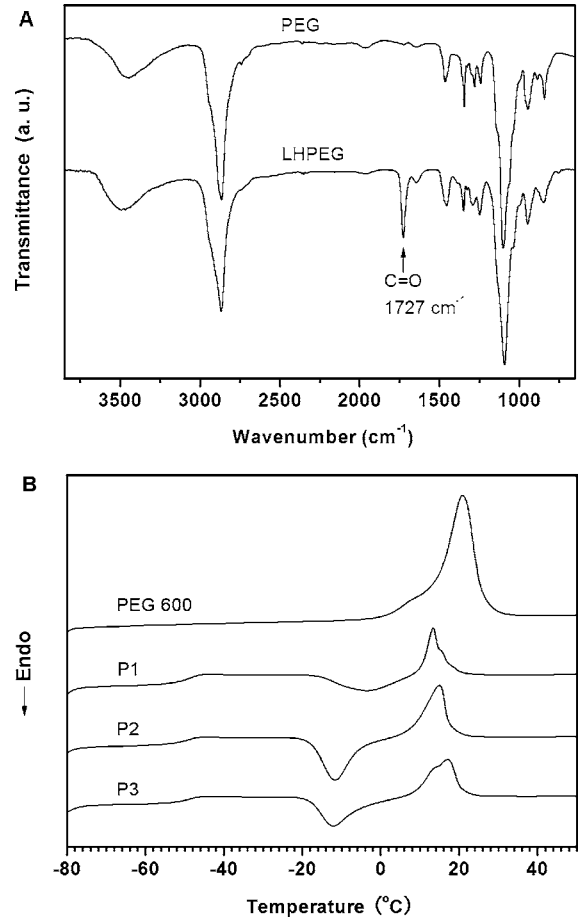

Figure 4. FTIR spectra of PEG and P1 (A); DSC curves of LHPEGs and PEG600 (B).

Degradation and Cytotoxicity. The biodegradability of polymeric materials is of great importance for biomedical applications. As is well-known, the degradation of polymers decreases the cytotoxicity and makes them easy to eliminate through the excretion pathway in vivo (*57*, *58*). Here, the degradation abilities of LHPEGs were determined by incubation at 37 °C in PBS to simulate the in vivo environment. Samples of the degradation products were extracted at appropriate time intervals and analyzed by the GPC technique. The GPC results of degraded polymers at different time points suggest that the ester bonds in the backbone of LHPEG are susceptible to hydrolysis at physiological conditions to form low molecular weight products (Figure S1 in Supporting Information).

The relative cytotoxicity of LHPEG was estimated by MTT assay and AO/EB double staining methods. NIH 3T3 cells were cultured for 24 h to permit cell attachment. After this time, the culture medium was removed and replaced with culture medium containing serial dilutions of LHPEG. The cells were grown

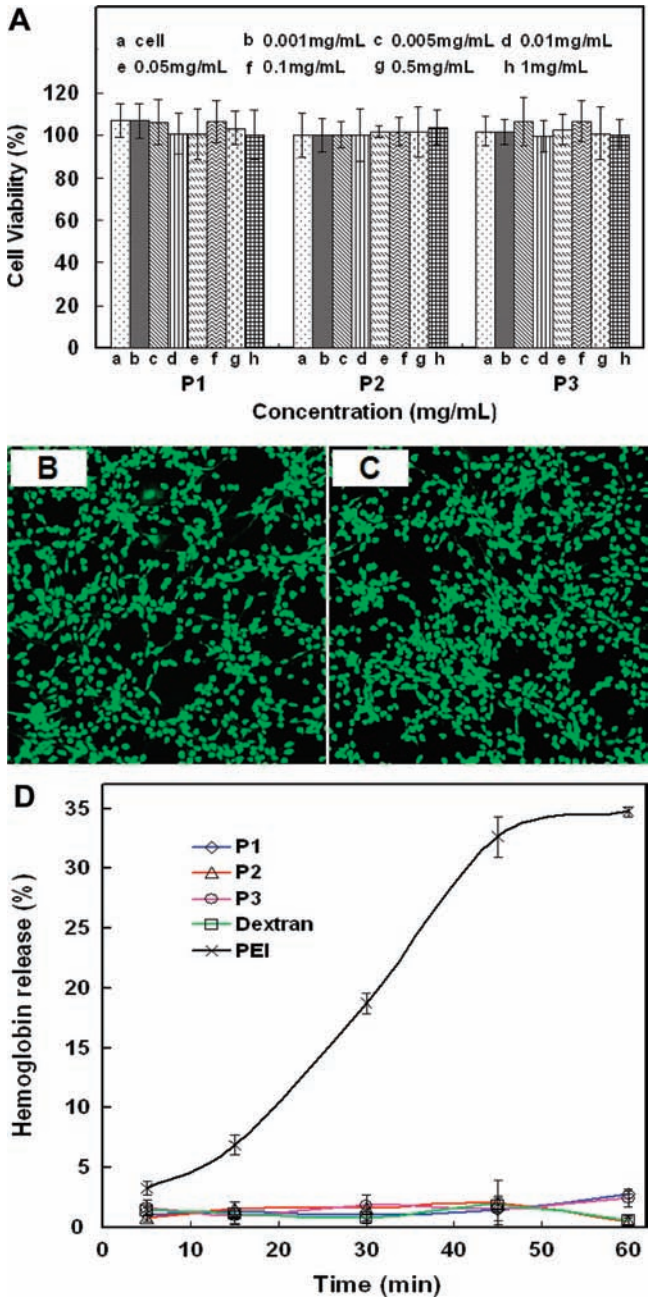

Figure 5. Cytotoxicity of LHPEGs determined by MTT assay against NIH 3T3 cells (A), fluorescence images of NIH 3T3 cells after incubation without (B) or with (C) 1 mg/mL LHPEG for 24 h (cells were stained by AO and EB), (D) hemolysis assay of 1 mg/mL LHPEG at different time intervals compared to PEI and dextran (Triton X-100 was used as a 100% hemolysis value).

for another 24 h. Figure 5A shows the cell viability after 24 h incubation with LHPEG at different concentrations from 0.001 to 1 mg/mL. The results demonstrate that NIH 3T3 cells cultured with LHPEG remain near 100% viability when the polymer concentration is up to 1 mg/mL. That is to say, the obtained LHPEG exhibits nontoxicity to NIH 3T3 cells. Furthermore, AO/EB double-staining results demonstrate the cell compatibility of LHPEG directly. Healthy cells have green nuclei and uniform chromatin with intact cell membrane. On the contrary, the cells undergoing apoptosis have orange nuclei and condensed chromatin with nuclear shrinkage. Moreover, the cells in necrosis or in the late stage of apoptosis have red nuclei with damaged cell membranes (*59*). As an example, the NIH 3T3 cells after incubation with the LHPEG of 1 mg/mL for 24 h are all healthy

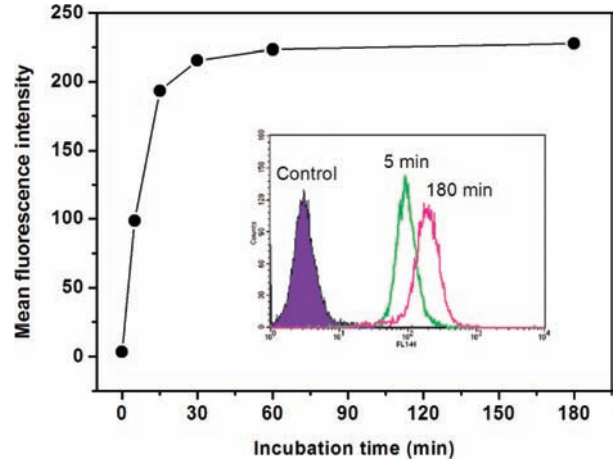

Figure 6. Cellular uptake of LHPEG-RB by Hela cells versus the incubation time by flow cytometry analysis. Insert is the representative flow cytometry histogram profiles of Hela cells cultured with LHPEG-RB for 5 and 180 min, respectively.

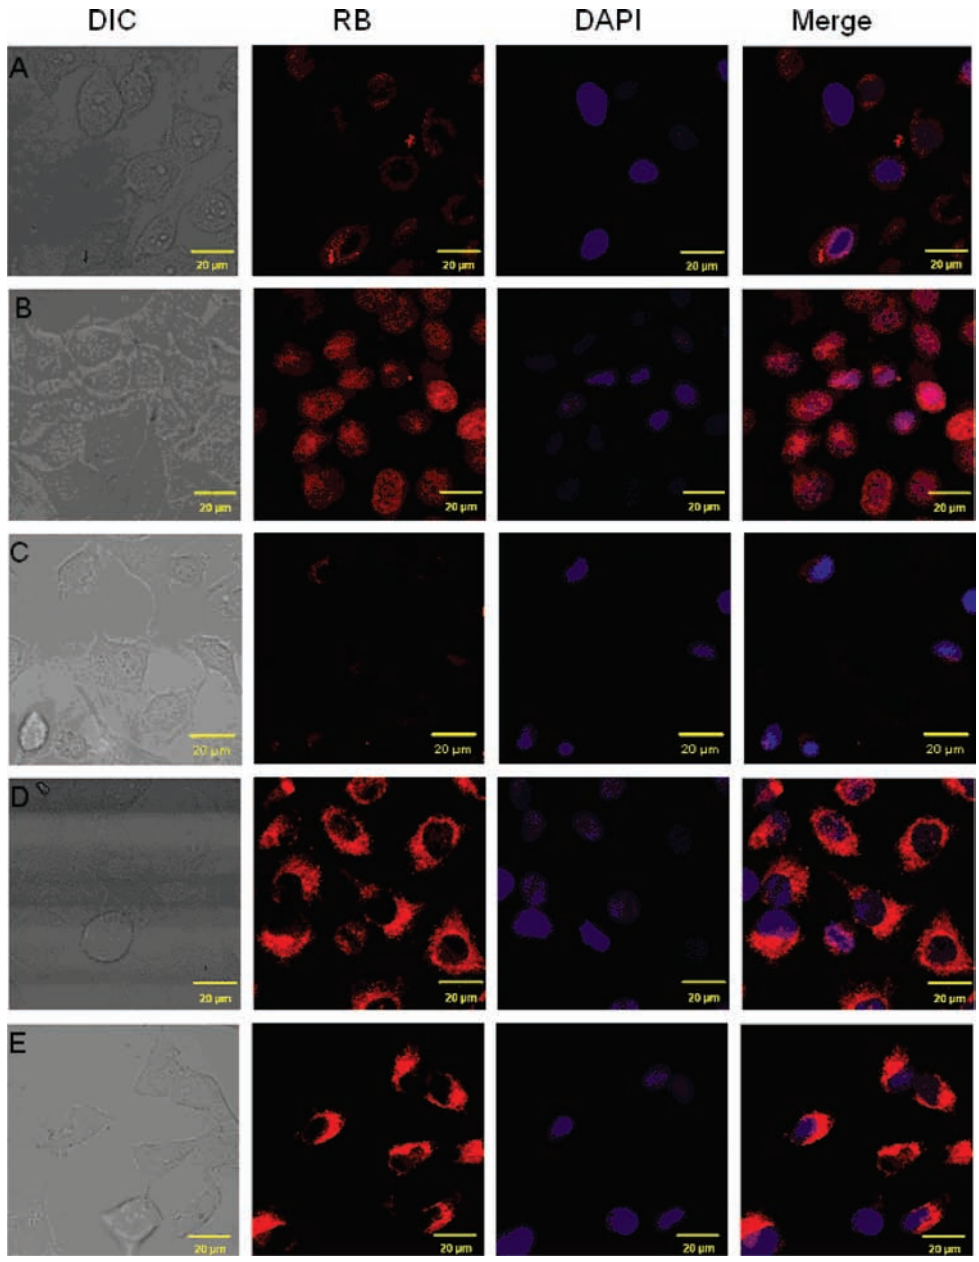
with green nuclei in comparison to the untreated cells, which indicates the good viability of cells (Figure 5B,C).

It is well-known that PEG can provide a long circulation time in blood, which makes it a good candidate for drug conjugates. The stability of LHPEG in physiological conditions was evaluated through red blood hemolysis assay, which also served as a model to assess cell membrane toxicity of LHPEG (*60, 61*). The P1, P2, and P3 were dissolved at a concentration of 2 mg/mL in PBS and added to an equal volume of 2% (w/v) red blood cell (RBCs) suspension in PBS. Dextran and PEI were used as reference controls, and Triton X-100 (1% v/v) was used as a 100% hemolysis value. All samples were stored at 37 °C for predetermined time intervals. Hemolysis was evaluated by measuring the amount of hemoglobin released in the supernatant at 545 nm. Under these conditions, LHPEGs show comparable hemoglobin release to dextran, which is significantly lower than the corresponding incubation time of PEI (Figure 5D). PEI causes a serious hemoglobin release, indicating that it damages the erythrocytes (*60*). When incubated for 1 h, PEI causes 80 times higher hemoglobin release than that of LHPEGs. The hemolysis assays demonstrate negligible hemolytic activity of LHPEG compared to those of blank values.

Cell Internalization Studies. To study the cellular transport of LHPEG, RB was used as a fluorescence probe and conjugated to the polymers. The cellular uptake of LHPEG was determined by measuring the intracellular fluorescence intensity using flow cytometry. Cells without any treatment were used as a blank control. It is obvious that the fluorescence is found within 5 min and the fluorescence intensity increases rapidly over a period of 15 min (Figure 6). After incubation for 15 min, the relative geometrical mean fluorescence intensity (GMFI) of polymer pretreated cells is about 55-fold that of nonpretreated cells. The fast enhancement of fluorescence signals indicates high cellular uptake of LHPEGs by Hela cells. With the incubation time increasing to 180 min, the GMFI of Hela cells increases from 3 to 228. Rejman examined the internalization rate of the fluorescent latex beads by murine melanoma cells, and found that smaller objects were taken up more rapidly (*62*). Thus, we speculate that the efficient intracellular uptake of LHPEGs can be attributed to the global molecular structure as well as the small hydrodynamic volume (*63*).

Moreover, the cellular uptake of LHPEGs by Hela cells was also evaluated by CLSM. Both the red fluorescence from RB and the blue fluorescence from DAPI were used to study the localization of LHPEG within the cells. First, Hela cells were incubated with RB-labeled LHPEGs for different time intervals.



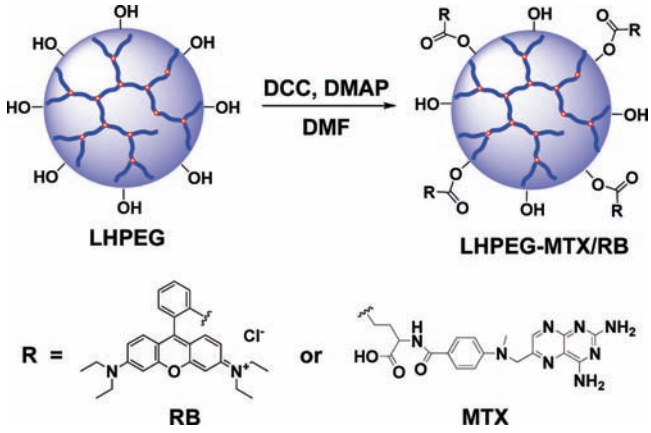


Figure 7. CLSM photos of Hela cells incubated with free RB or LHPEG-RB for different intervals. The pictures from left to right are differential interference contrast (DIC), RB fluorescence, DAPI fluorescence, and the merged image, respectively. (Cell nucleuses were stained with DAPI). (A) RB treated cells for 5 min, (B) RB treated cells for 60 min, (C) LHPEG-RB treated cells for 5 min, (D) LHPEG-RB treated cells for 60 min, (E) LHPEG-RB treated cells for 180 min.

Meanwhile, free RB was used as a control. Subsequently, the cell nucleus was stained by DAPI, and then the treated cells were fixed with formaldehyde. As shown in Figure 7A, red fluorescence was predominantly localized in the cytosol compared with blue nucleus after the cells incubated with free RB for 5 min. When prolonging the incubation time to 1 h, the localization of RB fluorescence in cells was changed and accumulated mainly in the nucleus (Figure 7B). On the other hand, the detectable red RB fluorescence of the cells incubated with LHPEG-RB for 5 min were similarly located in the perinuclear region instead of the nucleus (Figure 7C). However, with the incubation time increasing to 180 min, the red fluorescence of LHPEG-RB in cells still emerged at the cytosol rather than the nucleus. This result may be attributed to the endocytosis mechanism of the cellular internalization of LHPEG (*64*, *65*). Hence, the LHPEG can be efficiently transported by living cells.

Drug Conjugate and Tumor Cell Proliferation Inhibition. The good biocompatibility and efficient living cell transportation of LHPEGs encouraged us to further evaluate their potential as a polymeric drug carrier. Methotrexate (MTX), a folic acid antagonist, is a widely used agent for the treatment of certain human cancers (*66*). As displayed in Scheme 2, the LHPEG-MTX was prepared by coupling the end hydroxyl groups of LHPEG with the γ-carboxyl groups of MTX in the present of DCC and DMAP in dry DMF. The resulting conjugate was purified by repeatedly dissolving in methanol and precipitating in diethyl ether, and then exhaustive dialysis against water. NMR analysis was performed to evaluate the drug content of the final obtained conjugate (Figure 8). Calculating from the ^{1}H NMR spectrum of LHPEG-MTX, the MTX content was determined to be 20.5 wt % by calculating the relative intensity of the peak at 7.71 or 6.81 ppm (protons from the phenyl group in MTX) and the peak around 4.03 ppm (methylene groups in

Scheme 2. Synthetic Route of LHPEG-MTX/RB Conjugates

the end of the PEG chain). That is to say, one LHPEG carrier conjugates three MTX molecules. The drug content was also confirmed by GPC chromatography. As shown in Figure S2 in the Supporting Information, the molecular weight is increased by 1500 after the conjugation of MTX with LHPEG. The GPC analysis indicates that one LHPEG-MTX possesses about three MTX molecules. In addition, the drug content of the LHPEG-MTX was further measured by UV−vis spectra at 400 nm (Figure S3 in Supporting Information). According to the calibration curve of MTX in DMF, the drug content is determined to be about 20 wt % in LHPEG-MTX, which is consistent with the results of NMR and GPC techniques.

To demonstrate the therapeutic potential of LHPEG-MTX, in vitro evaluation was performed by MTT assay against Hela cells. It is worth pointing out that LHPEG shows nontoxicity against Hela cells with the concentration up to 1 mg/mL (Figure S4 in Supporting Information). To compare the cytotoxic activity of LHPEG-MTX with that of the free drug, MTX in the free form was used as a control. The Hela cell proliferation results are shown in Figure 9. It is found that the conjugated MTX dose required for 50% cellular growth inhibition (IC_{50}) is 20 μg/mL. This result indicates that LHPEG-MTX is able to enter the cell and produce the desired pharmacological action. On the other hand, the IC_{50} of free MTX is 5 μg/mL, which exhibits higher inhibition compared with conjugated MTX. It has been well-documented that the free drug is more potent than the conjugated drug (*67*). The antiproliferation effect of LHPEG-MTX might be attributed to the drug release from the conjugate in the course of incubation. Once the conjugate enters the cell, it

is conceivable that the acidic pH and the enzymes in the endosomes would eventually hydrolyze the ester bond and slowly release MTX, which provides the therapeutic effect (*68, 69*).

CONCLUSIONS

A series of novel long-chain hyperbranched poly(ethylene glycol)s were prepared in one pot through proton-transfer polymerization by oxyanionic initiation using PEG and GMA as monomer with the help of KH catalyst. The polymer structure and properties were analyzed by NMR, FTIR, GPC, and DSC techniques. The DBs of these polymers were at 0.57−0.65, and their molecular weights were around 6000 g/mol with PDI about 3.0. GPC measurements revealed that these polymers were hydrolyzed. DSC curves showed that LHPEGs had a T_g of about −49 °C and a T_m of ∼15 °C. Moreover, in vitro MTT and AO/EB double-staining assays demonstrated that HPEGs were nontoxic against NIH 3T3 cells even at a high dose of 1 mg/mL. Hemolysis assay confirmed that these polymers possessed negligible hemolytic activity comparable to those of blank values. That is to say, these HPEGs had no cell membrane toxicity. Furthermore, flow cytometry and CLSM analysis suggested that LHPEGs could be easily internalized by Hela cells and preferentially accumulated in the cytoplasm instead of the nucleus. In addition, conjugation of MTX to LHPEGs inhibited the proliferation of Hela cells. MTT assay indicated that the conjugated MTX dose required for 50% cellular growth inhibition against Hela cells was 20 μg/mL. As it combines the advantages of long-chain hyperbranched structure and PEG together, LHPEG provides a promising material for a drug carrier.

Calculation of the degree of branching (DB) of LHPEG

It can be seen from Figure 1 that there exist ten structural units in LHPEG: four dendritic unit (D_1, D_2, D_3, and D_4), five linear units (L_1, L_2, L_3, L_4, and L_5) and one terminal unit. The DB can be determined by the following equation:

$$DB = (D + T) / (D + T + L)$$

where,

$$D = D_1 + D_2 + D_3 + D_4 = S_{C18} + S_{C20} + S_{C21} + S_{C24}$$

$$L = L_1 + L_2 + L_3 + L_4 + L_5 = S_{C3} + S_{C6} + S_{C9} + S_{C11} + S_{C16}$$

$$T = S_{C1}$$

therefore, the DBs of LHPEGs can be calculated in details by the following equation:

$$DB = (S_{C18} + S_{C20} + S_{C21} + S_{C24} + S_{C1}) / (S_{C18} + S_{C20} + S_{C21} + S_{C24} + S_{C1} + S_{C3} + S_{C6} + S_{C9} + S_{C11} + S_{C16})$$

where,

S_{CX} are the integrated areas of the carbon peaks (x = 1, 2…) as labeled in the Figure 1.

The calculated DB values of LHPEGs can be found in Table 1.

Synthesis of water-soluble 5-mer peptide nucleic acids (PNAs) functionalized at their 5′- and 3′-ends with two original precursors of pentamethine cyanine dye synthesis is reported. The successful use of these PNA probes for sensing DNA hairpin structures in vitro was also demonstrated where specific hairpin formation was associated with the appearance of a characteristic fluorescence signal at 660 nm. A comparative study between three different strategies where PNAs were targeting either the stem or the loop of the hairpin was carried out. Best sensitivity was obtained using PNA sequences complementary to the loop sequence and directing both functional moieties toward the base of loop. Unprecedented proof-of-concept for the simultaneous sensing of hairpin and quadruplex DNAs with a nonoverlapping two-color system (C3 and C5) is also demonstrated.

INTRODUCTION

Although the most abundant form of DNA in vivo is the double-stranded helical conformation reported for the first time in 1953 by Watson and Crick (*1*), it has been known for more than 50 years that nucleic acids can also adopt alternative (i.e., non B-DNA) secondary structures under physiological conditions. Such structures can be either single-stranded (e.g., hairpins, intramolecular G-quadruplexes, pseudoknots) or double-stranded (e.g., cruciforms, bimolecular G-quadruplexes) and have received increasing attention because of the role they were proposed to play in transcription regulatory mechanisms (*2*). For instance, it has been known for several decades that DNA sequences containing a high density of clustered guanines were able to adopt four-stranded secondary structures named guanine (G)-quadruplexes or tetraplexes in the presence of physiological cations, notably K^+ and Na^+ (Figure 1) (*3*−*7*). More recently, in silico studies have revealed the high prevalence of such G-rich DNA sequences throughout the human genome, particularly in gene promoter regions (*8*−*10*). Hairpin formation has also been demonstrated both in vitro and in vivo (*11*). Stem-loop hairpin structures are obtained by folding of a partially self-complementary or palindromic DNA sequence (Figure 1). Their presence in gene promoters (*12*) or near gene replication origins (*13*), for instance, strongly suggests that DNA hairpins could play a functional role in naturally occurring regulatory mechanisms of gene expression. For this reason, non-Watson−Crick DNA secondary structures represent attractive therapeutic targets to regulate the expression of specific genes via chemical or biochemical intervention. Successful examples of gene regulation with small molecules that bind to and stabilize hairpin or quadruplex DNA (or RNA) have been recently reported in the literature (*14*−*18*). Although these studies represent converging evidence that such structures do form in the context of the cell, there is still an urgent need for chemical probes capable of sensing the formation of nucleic acid structures both in vitro and in vivo.

There is currently a growing interest in the development of new fluorescent chemosensors based on supramolecular systems which have the ability to recognize and bind to a specific metabolite with high affinity. As a result of this interaction, the system re-equilibrates, thus leading to a change of the physical properties (i.e., changes in fluorescence intensity and/or fluorescence emission wavelength) of the medium. Since the 1960s, engineered DNA molecules have been used extensively as highly specific fluorescent probes in order to explore various biological processes (e.g., DNA transcription, DNA recombination) and more recently for genotyping applications. Among them, molecular beacons (MBs) have received particular attention because of their broad applications in modern bioresearch (*19*). Typically, MBs are DNA hairpin structures functionalized at their 5′- and 3′-ends with a fluorescence donor and a fluorescence acceptor. Binding of the MB to a DNA or RNA target, through sequence-specific hybridization, results in the opening of the MB, thus separating the fluorescence donor from its neighboring fluorescence acceptor. Other examples include the use of modified (e.g., fluorescently labeled) oligonucleotides or oligonucleotide mimics in oligonucleotide-templated reactions. In such systems, a specific reaction of dye formation occurs only upon hybridization of the probes to a complementary nucleic acid target. A characteristic fluorescent signal will then be emitted which can be directly linked to the detection of the

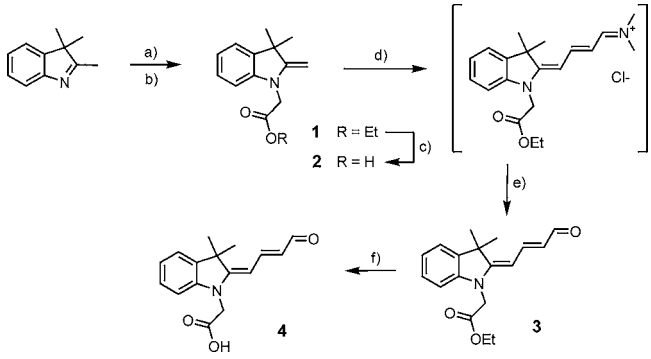
targeted sequence and/or structure (*20*). Most recent reports of DNA-templated reactions applied to oligonucleotide sensing are based on the Staudinger reaction (*21*−*25*), aldol-type (*26*, *27*), organomercury-activated (*28*), or S_NAr (*29*) reactions.

Because peptide nucleic acids (*30*, *31*) offer the advantage of a higher stability, they have been recently used as an alternative to DNA for the design of highly specific nucleic acid probes (*32*−*36*). We recently reported the use of fluorogenic PNA probes for sensing G-quadruplex formation. Upon binding of both probes to the single-stranded flanking arms of a quadruplex, formation of a trimethine cyanine dye from two nonfluorescent precursors was templated (*27*). Herein, we describe the synthesis of a novel fluorescent Fisher's base aldehyde probe-head, its incorporation in a PNA strand, and the applications of the resulting fluorescently labeled probe for sensing hairpin DNA secondary structures. Reaction between this fluorescent Fisher's base aldehyde and a nonfluorescent indolenine molecule leads to the formation of a pentamethine cyanine dye (Cy5) absorbing and emitting at a significantly longer wavelength than its precursor. The system has been designed such that the Cy5 product forms solely upon simultaneous hybridization of both probes to either the loop or the stem of a unique hairpin DNA target. Therefore, hairpin formation will be directly linked to the appearance of a fluorescent signal at long wavelength ($\lambda_{em} > 650$ nm), well above the residual fluorescence of biological media, and above the fluorescence emission wavelength of most fluorescent products formed in oligonucleotide-templated reactions (*21*−*29*), including that previously reported by us (*27*). Simultaneous sensing of various DNA structures via a two-color (Cy3-Cy5) system will also be presented.

EXPERIMENTAL PROCEDURES

Ethyl 2-(3,3-Dimethyl-2-methyleneindolin-1-yl)-acetate (1). A mixture of 2,3,3-trimethyl-3*H*-indole (1.00 g, 6.28 mmol) and ethyl iodoacetate (1.61 g, 7.53 mmol) was heated at 80 °C for 5 h. After cooling the reaction mixture to room temperature, the red solid obtained was triturated with ether, filtered, and dried under vacuum. To the solid, 1 N NaOH (25 mL) was added and stirred for 1 h at RT. The reaction mixture was then extracted with CH_2Cl_2 (3 × 30 mL), and the combined organic layers were dried over Na_2SO_4, filtered, and concentrated in vacuo. The residue was purified by column chromatography on SiO_2 (PE/ether, 3:1; Rf = 0.48) to give the title compound (1.28 g, 83%) as a yellow oil. ^{1}H NMR (400 MHz, DMSO): δ = 7.16 (dd, J = 7.3, 0.9 Hz, 1H), 7.06 (td, J = 7.7, 1.2 Hz, 1H), 6.74 (td, J = 7.5, 0.6 Hz, 1H), 6.67 (d, J = 7.9 Hz, 1H), 4.39 (s, 2H), 4.10 (q, J = 7.2 Hz, 2H), 3.87 (d, J = 2.2 Hz, 1H), 3.81 (d, J = 2.0 Hz, 1H), 1.29 (s, 6H), 1.17 (t, J = 7.2 Hz, 3H) ppm. ^{13}C NMR (100 MHz, DMSO): δ = 168.6, 161.0, 145.4, 136.7, 127.3, 121.8, 118.8, 105.7, 74.8, 60.4, 43.6, 43.5, 29.6 (× 2) 14.1 ppm. HRMS (ESI) *m*/*z*: calcd for $C_{15}H_{19}NO_2$ $[M+H]^+$ 246.149; found 246.150.

2-(3,3-Dimethyl-2-methyleneindolin-1-yl)acetic Acid (2). To a solution of ethyl 2-(3,3-dimethyl-2-methyleneindolin-1-yl)acetate (1.30 g, 5.30 mmol) in ethanol (40 mL) was added 1 N NaOH solution (30 mL) at RT, and the mixture was stirred at the same temperature overnight. Later, the solvent was removed in vacuo, and the residue was dissolved in a minimum amount of water (15 mL) and then acidified to pH = 3 with 1 N HCl solution. The solution was concentrated, and the residue was dissolved in ethanol. The suspension was filtered, and this process was repeated at least two times. Finally, the filtrate was concentrated, and the residue was purified by column chromatography on SiO_2 (CH_2Cl_2/MeOH 8:2; Rf = 0.20) to give the title compound (860 mg, 75%) as a thick brown oil. ^{1}H NMR (400 MHz, DMSO): δ = 7.15 (dd, J = 7.3, 0.7 Hz, 1H), 7.06 (td, J = 7.7, 1.2 Hz, 1H), 6.73 (t, J = 7.2 Hz, 1H), 6.65 (d, J = 7.9 Hz, 1H), 4.26 (s, 2H), 3.85 (d, J = 2.0 Hz, 1H), 3.81 (d, J = 2.0 Hz, 1H), 1.28 (s, 6H) ppm, CO_2H signal not visible. ^{13}C NMR (100 MHz, DMSO): δ = 170.1, 160.8, 145.5, 136.7, 127.3, 121.7, 118.6, 105.6, 74.4, 43.6, 43.5, 29.7 (× 2) ppm. HRMS (ESI) *m*/*z*: calcd for $C_{13}H_{15}NO_2$ $[M+H]^+$ 218.116; found 218.119.



Ethyl 2-((2*E*)-2-((*E*)-3-Formylallylidene)-3,3-dimethylindolin-1-yl)acetate (3). Acetic anhydride (12.5 mL) was added dropwise to dimethylaminoacrolein (1.76 g, 1.78 mL, 17.8 mmol) and the mixture was stirred at RT for 15 min. Then, a solution of ethyl 2-(3,3-dimethyl-2-methyleneindolin-1-yl)acetate (1.25 g, 5.09 mmol) in CH_2Cl_2 (5 mL) was added dropwise. After stirring the reaction mixture for 2 d at RT, the solvent was removed in vacuo. The residue was dissolved in THF (30 mL), and a saturated solution of K_2CO_3 (60 mL) was added carefully. After stirring the mixture for 30 min at RT, the layers were separated and the aqueous layer was extracted with EtOAc (3 × 20 mL). The combined organic layers were dried over Na_2SO_4, filtered, and concentrated in vacuo. The residue was purified by column chromatography on SiO_2 (CH_2Cl_2/EtOAc 9.5:0.5; Rf = 0.20) to give the title compound (1.32 g, 86%) as a yellow oil. ^{1}H NMR (400 MHz, DMSO): δ = 9.46 (d, J = 8.3 Hz, 1H), 7.88−7.82 (m, 1H), 7.37 (d, J = 7.3 Hz, 1H), 7.19 (td, J = 7.8, 1.1 Hz, 1H), 6.98−6.93 (m, 2H), 5.81 (dd, J = 14.2, 8.3 Hz, 1H), 5.62 (d, J = 12.6 Hz, 1H), 4.70 (s, 2H), 4.14 (q, J = 7.3 Hz, 2H), 1.59 (s, 6H), 1.19 (t, J = 7.3 Hz, 3H) ppm. ^{13}C NMR (100 MHz, DMSO): δ = 192.4, 167.8, 164.6, 150.2, 143.4, 138.5, 127.8, 123.6, 121.9, 121.4, 107.8, 95.3, 61.0, 46.3, 43.7, 27.9 (× 2), 14.0 ppm. HRMS (ESI, positive mode) *m*/*z*: calcd for $C_{18}H_{21}NO_3$ $[M+H]^+$ 300.159; found 300.160.

2-((2*E*)-2-((*E*)-3-Formylallylidene)-3,3-dimethylindolin-1-yl)acetic Acid (4). To a solution of ethyl 2-((2*E*)-2-((*E*)-3-formylallylidene)-3,3-dimethylindolin-1-yl)acetate (300 mg, 1.00 mmol) in EtOH (2 mL) was added 1 N NaOH (1.5 mL) at RT and the mixture was stirred at the same temperature for 1.5 h. Later, the solvent was removed in vacuo, and the residue was dissolved in a minimum amount of water (3 mL) and then acidified to pH = 3 with 1 N HCl solution. The aqueous layer was extracted with EtOAc (4 × 10 mL). The combined organic layers were dried over Na_2SO_4, filtered, and concentrated in vacuo to give the title compound (260 mg, 96%) as a blue−green solid. The crude product was directly used for PNA coupling without further purification. ^{1}H NMR (400 MHz, DMSO): δ = 13.1 (br. s, 1H), 9.45 (d, J = 8.3 Hz, 1H), 7.88−7.81 (m, 1H), 7.36 (d, J = 7.0 Hz, 1H), 7.19 (td, J = 7.8, 1.1 Hz, 1H), 6.98−6.93 (m, 2H), 5.81 (dd, J = 14.2, 8.3 Hz, 1H), 5.62 (d, J = 12.6 Hz, 1H), 4.58 (s, 2H), 1.59 (s, 6H) ppm. ^{13}C NMR (100 MHz, DMSO): δ = 192.3, 169.1, 164.8, 150.4, 143.6, 138.6, 127.8, 123.3, 121.8, 121.3, 107.9, 95.1, 46.4, 43.7, 27.9 (× 2) ppm. HRMS (ESI, negative mode) *m*/*z*: calcd for $C_{16}H_{17}NO_3$ $[M-H]^-$ 270.112; found 270.110.

PNA Synthesis. PNAs were synthesized on a solid support using Fmoc chemistry. The PNA strand was cleaved from the resin with trifluoroacetic acid/triisopropylsilane/H_2O (95:2.5:2.5) solution and purified by HPLC. The final compounds were characterized by MALDI-TOF. **Pna1** *m*/*z*: $[M+H]^+$ calcd for $C_{87}H_{116}N_{38}O_{19}^+$ 1997.928, found 1997.718. **Pna2** *m*/*z*: $[M+H]^+$ calcd for $C_{88}H_{124}N_{39}O_{19}^+$ 2030.993, found 2030.923. **Pna3** *m*/*z*: $[M+H]^+$ calcd for $C_{84}H_{115}N_{36}O_{19}^+$ 1931.913, found 1932.082.

DNA Folding. Hairpin and quadruplex DNA folding was carried out by heating a DNA solution (5 μM) in potassium phosphate buffer (10 mM, pH 7.4 also containing 100 mM KCl) at 95 °C for 10 min and then letting it slowly cool down to room temperature over 6 h.

Scheme 1. Synthesis of 2-Methylene-Indolenin Derivative and Fischer's Base Aldehyde[a]

[a] Reagents and conditions: (a) ethyl iodoacetate, 80 °C, 5 h; (b) 1 N NaOH, EtOH, 25 °C, 1 h (83% over two steps); (c) 1 N NaOH, EtOH, 25 °C, 16 h (75%); (d) dimethylaminoacrolein, AcOH, CH_2Cl_2, 48 h; (e) sat. aq. K_2CO_3, THF, 25 °C, 1 h, (86% over two steps); (f) 1 N NaOH, EtOH, 25 °C, 1.5 h (96%).

Fluorescence Studies. Fluorescence emission spectra were recorded in quartz cells (500 μL with a 5 mm path length) at 20 °C on a Jobin Yvon Fluorolog 3.22 instrument. The excitation and emission bandwidths were fixed to 5 and 5 nm, respectively.

Ligation/Sensing Experiments. In a typical experiment, 500 μL of a mixture of **Pna1** (500 nM), **Pna2** (500 nM), and prefolded hairpin DNA (500 nM) in a potassium phosphate buffer (10 mM, pH 7.4 also containing 100 mM KCl) was prepared freshly in a fluorescence Quartz cuvette (5 mm path length) and kept sealed at 20 °C for the duration of experiment. Formation of the pentamethine cyanine dye product was then monitored by fluorescence spectroscopy (at t_0 and then every hour over 10 h).

Dual Sensing Experiments. After a screening of various concentrations of both DNA and PNA sequences, the following ratio 1:4:4:2:4 **Pna1**/**Pna2**/**Pna3**/**Hairp1a**/**Quad1** was found to give the optimal sensitivity and selectivity. Working with stoichiometric amounts of all PNA and DNA strands resulted in good sensitivity but lower selectivity (data not shown). Ligation experiments in the presence of both quadruplex and hairpin DNA were carried out in 500 μL quartz cuvettes by incubating a freshly prepared mixture of three PNA probes (**Pna1**−**3**) and two DNA targets (**Hairp1a** and **Quad1**) in potassium phosphate buffer.

RESULTS AND DISCUSSION

Design and Synthesis of the PNA Probes. Two 5-mer PNAs (**Pna1** and **Pna2**) were synthesized on solid support, which also contained two *ε*-*N*,*N*-dimethyl lysine residues to ensure solubility of both PNAs in water at near-physiological pH. These PNA probes were functionalized at their C- or N-terminus with two precursors for the synthesis of pentamethine cyanine dyes: *N*-alkyl-2,3,3-trimethylindolenine **2** and aldehyde **4**, respectively. Both precursors were synthesized from commercially available 2,3,3-trimethylindoline (Scheme 1).

Reaction of 2,3,3-trimethyl-3*H*-indole with ethyl iodoacetate gave the corresponding quarternized salt which was subsequently isomerized to 2-methylene-indolenin **1** via treatment with 1 N NaOH solution. Condensation of **1** with dimethylaminoacrolein in the presence of acetic anhydride provided the activated hemicyanine intermediate, which was then hydrolyzed into aldehyde **3** with a saturated K_2CO_3 solution. Final hydrolysis of the ethyl ester of compounds **1** and **3** using 1 N NaOH afforded both C5 precursors **2** and **4**, respectively. While indolenine **2** is nonfluorescent, aldehyde **4** emits maximally at 476 nm when excited at 410 nm. Reaction between compounds **2** and **4** leads to the formation of a symmetrical pentamethine cyanine dye (C5) characterized by its unique fluorescent properties (λ_{exc} = 625 nm, λ_{em} = 660 nm), very different from those of its two precursors.

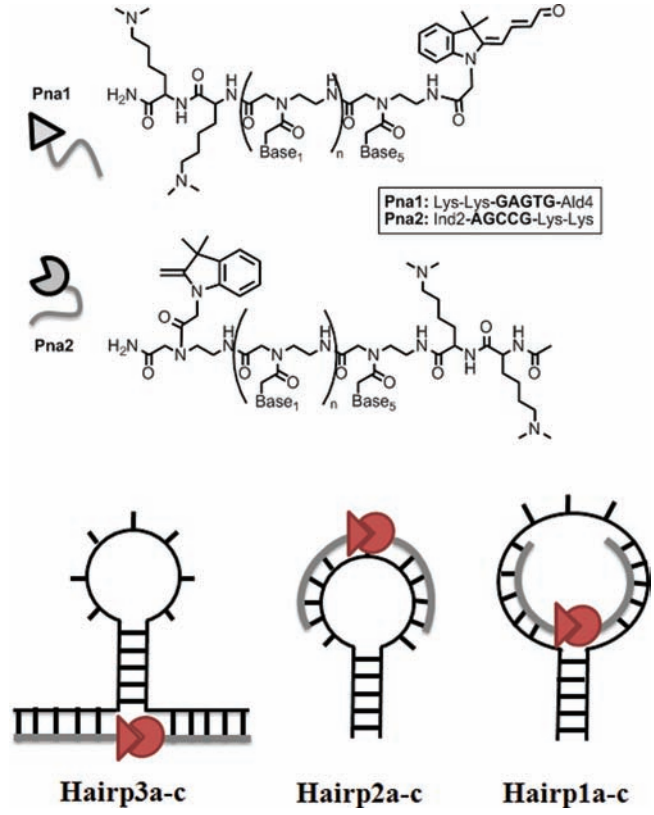


Figure 2. Structures of PNA probes **Pna1** and **Pna2** (top). Schematic representation of the hairpin DNA-templated synthesis of the pentamethine cyanine dye upon simultaneous hybridization of both PNA probes to either the hairpin flanking regions (**Hairp3a-c**) or the hairpin loop (**Hairp2a-c** and **Hairp1a-c**) (bottom).

[a] DNA sequences are given from the 5′- to 3′-end. [b] PNA sequences are given from the C-terminal to N-terminal end.

Although highly unfavorable in water, this aldolization−elimination reaction can be templated when carried out in a favorable chemical environment. **Pna1** and **Pna2** (see Figure 2 and Table 1 for structures and sequences) were synthesized on rink amide MBHA resin (Merck Biosciences, loading 0.56 mmol/g) using standard solid-phase Fmoc chemistry. They were subsequently purified by reversed-phase HPLC and characterized by MALDI.

5-mers PNA was chosen as the minimal length necessary for a full and sequence-specific PNA−DNA hybridization under near-physiological conditions. On the basis of the abundant literature on PNAs (*37*), it is anticipated that our short PNA/

DNA duplexes will have melting temperatures above 40 °C, indicating that almost all the PNA probes will be hybridized to the DNA target in the conditions of our experiments. It is also noteworthy that the presence of two Lysine residues is likely to increase even further the stability of the heteroduplex formed. In the case of unusually unstable (AT-rich) sequences, however, stability of the PNA−DNA heteroduplex would need to be increased. For instance, this could be achieved by increasing the length of the PNA strands, without interfering with the reaction of cyanine dye formation which occurs at the other end of the PNA.

Hairpin DNA Sensing. Reaction between stoichiometric amounts of **Pna1** and **Pna2** (500 nM each) was investigated in a 10 mM potassium phosphate solution (pH = 7.4) also containing 100 mM potassium chloride, in the presence and in the absence of various nucleic acid templates. In each case, reaction efficiency was determined by monitoring the formation of the pentamethine cyanine (product of the reaction between indolenine **2** and aldehyde **4**) by fluorescence spectroscopy over a ten hour period. In the absence of any template, and at a 500 nM concentration of both PNAs, only traces of the fluorescent cyanine dye product were ever detectable. We then investigated the possibility to use our PNA probes for sensing hairpin DNA structures. Three different strategies were developed that consisted of targeting either the hairpin single-stranded flanking arms or the hairpin loop (Figure 2). In the former approach, a hairpin structure was designed which contained two single-stranded flanking arms at its 3′- and 5′-ends, the sequences of which were complementary to those of **Pna1** and **Pna2**. This system (sequences **Hairp3a-c**, table1) was designed so that (i) **Pna1** and **Pna2** could hybridize in a sequence-specific manner to these two single-stranded arms and (ii) the reactive functionalities of both PNAs would be brought in close enough proximity to react with each other only when the hairpin was formed, while remaining separated in the absence of any DNA folding.

In the latter approach, a hairpin DNA structure was chosen that also contained a large central loop, the sequence of which included both **Pna1** and **Pna2** complementary sequences (Figure 2). Once again, only upon simultaneous hybridization of both PNA probes to their cDNA sequences located in the loop region, will the aldehyde be able to react with the 2-methylene-indolenine. Two systems were designed in which the cyanine dye was expected to form either at the center of the loop (sequences **Hairp2a-c**, Table 1) or at the intercept between the loop and the stem (sequences **Hairp1a-d**, Table 1). It is noteworthy that (i) all DNA sequences **Hairp1**−**3** were shown to form stable hairpin structures under the conditions of our experiment and in the absence of PNA probes, and (ii) DNA hairpins **Hairp1** and **Hairp2** were designed which contained larger loops than **Hairp3** in order to allow complete hybridization of both 5-mer PNAs to the hairpin loop.

The potential of **Hairp3a-c**, **Hairp2a-c**, and **Hairp1a-c** to serve as a DNA template for the reaction of cyanine dye formation was determined. Briefly, a stoichiometric mixture of **Pna1**, **Pna2**, and one hairpin DNA was reacted in potassium phosphate buffer at physiological pH, and the appearance of the cyanine dye product was monitored by fluorescence spectroscopy (λ_{exc} = 625 nm). As a control experiment, a reaction was carried out under the same conditions but lacking the DNA template. Interestingly, every hairpin DNA tested proved capable of significantly increasing the reaction efficiency, although at different levels depending on whether the PNA probes were targeting the loop or the stem of the hairpin (Figure 3). Moreover, as previously observed by us with other fluorogenic systems ((*27*) and unpublished data) and although no detectable fluorescence is observed in the absence of template (F_0 < 350),

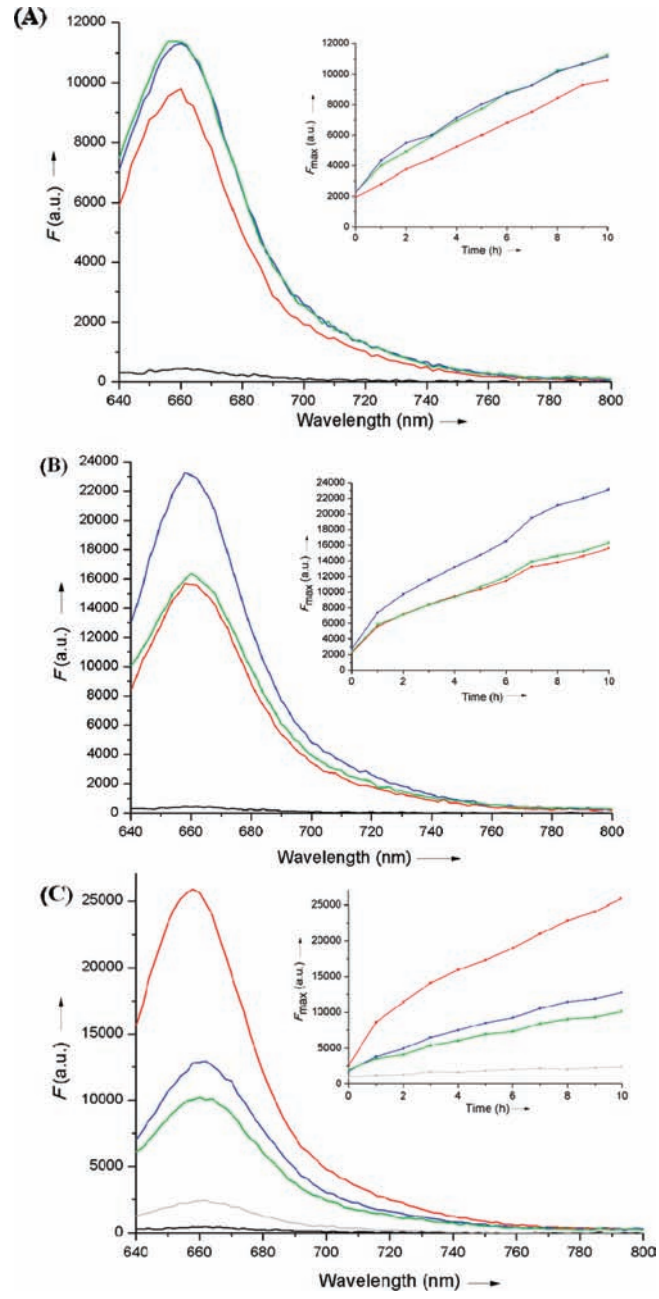

Figure 3. Fluorescence emission spectra of a stoichiometric mixture of **Pna1** and **Pna2** (500 nM each) measured after 10 h (λ_{exc} = 625 nm) in the absence (black) or in the presence of various DNA templates: (A) **Hairp3a** (red), **Hairp3b** (blue), and **Hairp3c** (green); (B) **Hairp2a** (red), **Hairp2b** (blue), **Hairp2c** (green); (C) **Hairp1a** (red), **Hairp1b** (blue), **Hairp1c** (green), **Hairp1d** (gray). Reaction time courses (maximum fluorescence intensity vs time) are also given as insets for each DNA templated reaction.

DNA-catalyzed reactions are all characterized by a fast and almost instantaneous appearance of fluorescence (F_0 > 6000) followed by a slower increase over 10−12 h. The kinetics of cyanine dye formation proved generally slow, the fluorescence intensity still rising even after 10 h, even in the presence of a template (Figure 3). However, the facts that (i) only residual amounts of fluorescent product form in the absence of DNA template (i.e., very low background signal) and (ii) a very fast initial phase of cyanine dye formation is observed in the presence of template make this chemistry suitable for the detection of DNA secondary structures. Indeed, a signal-to-noise ratio of ≥17 was obtained for all hairpin DNA-templated reactions after less than 10 min reaction.

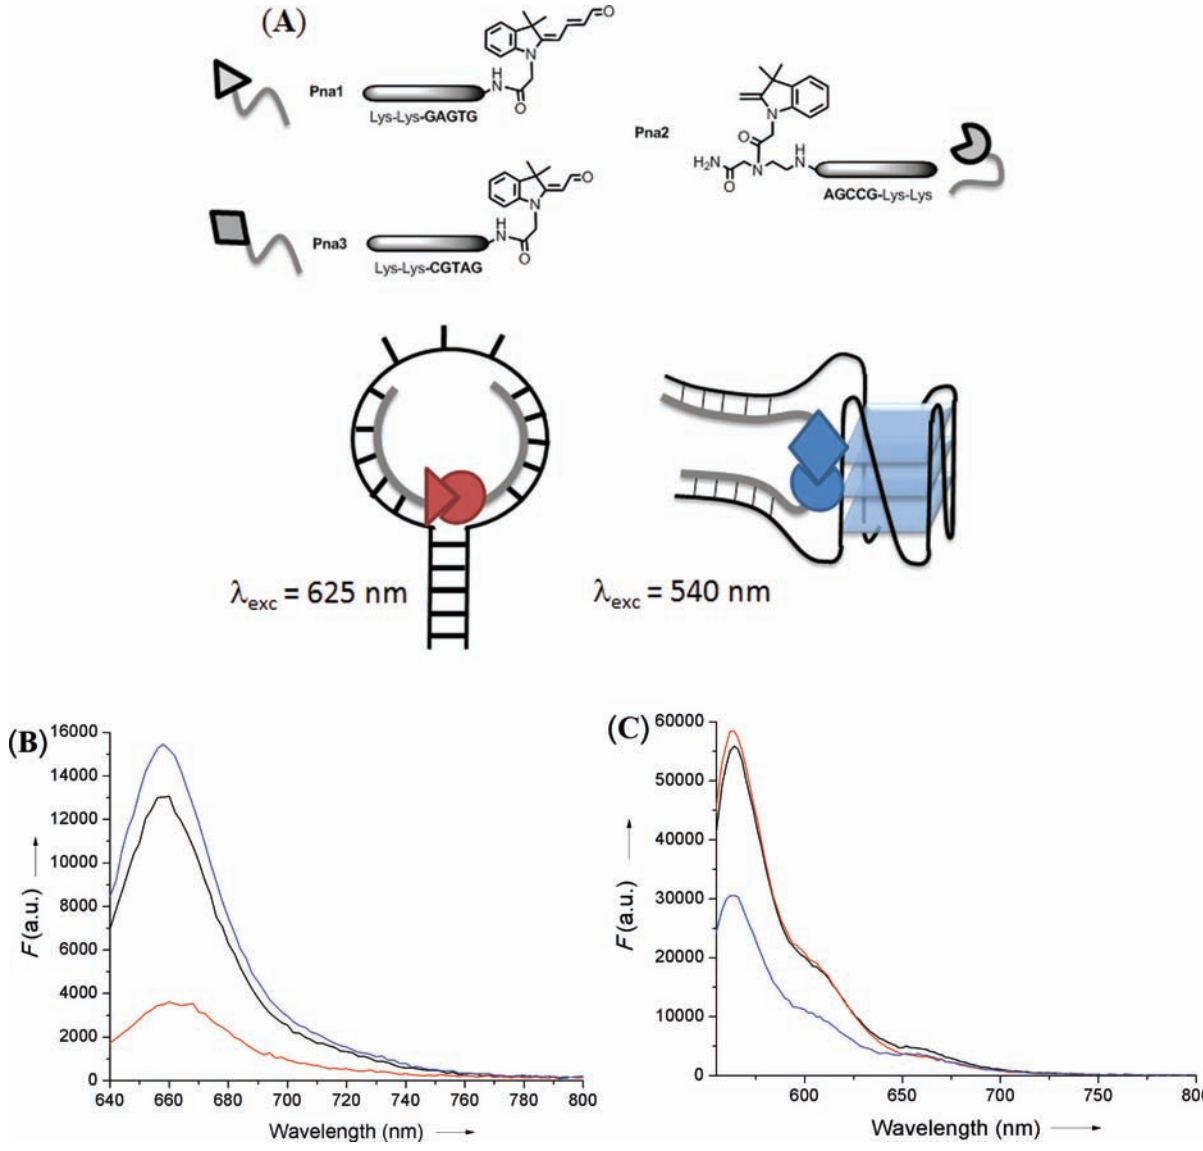

Figure 4. Schematic representation of the general system for sensing simultaneously hairpin and quadruplex DNA, based on a dual-color detection system (A). Fluorescence emission spectra (λ_{exc} = 540 nm) of a mixture of **Pna1** (250 nM), **Pna2** (1 μM), and **Pna3** (1 μM) in potassium phosphate buffer (10 mM, pH = 7.4 also containing 100 mM KCl) in the presence of 500 nM **Hairp1a** (blue), 1 μM **Quad1** (red), or a mixture of 500 nM **Hairp1a** and 1 μM **Quad1** (black). Excitation wavelengths were either λ_{exc} = 625 nm (B) or λ_{exc} = 540 nm (C). Emission spectra were recorded after 12 h incubation at room temperature.

The least effective templating effect was obtained when targeting the 3′ and 5′ single-stranded flanking ends of the hairpin (**Hairp3a**−**c**). This effect also proved almost independent of the number of nucleotides located between the PNA complementary sequences and the first nucleotide involved in the stem formation. Indeed, comparable fluorescence intensities were obtained from **Hairp3a**, **Hairp3b**, and **Hairp3c**, which contain a one-, two-, and three-nucleotide gap between the PNA/DNA duplex regions and the hairpin stem, respectively (Figure 3a).

Sensing hairpin formation proved, however, more efficient when both PNAs were directed against the hairpin loop, the amount of cyanine dye formed after 10 h of reaction being, for instance, twice as high with **Hairp1a** as with **Hairp3a**. Two slightly different approaches were considered for targeting hairpin loops, the reaction of cyanine dye formation taking place either at the center of the loop or at its base, in the vicinity of the stem. Both approaches proved equally effective (same fluorescence intensity at the maximum emission wavelength obtained after 10 h with **Hairp1a** and **Hairp2b**) although being highly dependent on the overall design. While a four-nucleotide gap between the functional ends of **Pna1** and **Pna2** led to the optimal reaction efficiency within the **Hairp2** series (**Hairp2b**, Figure 3b), hybridization of both PNAs starting from the first nucleotides constituting of the loop was found twice as effective as systems where **Pna1** and **Pna2** were separated further (**Hairp1a** versus **Hairp1b**,**c**, Figure 3c).

While **Hairp1a** and **Hairp2b** proved to be equally good templates for the aldolization−elimination reaction, they are based on two different strategies that can find distinct applications in modern bioresearch, in particular, for sensing hairpin DNA formation in vitro and maybe also in vivo. In order to demonstrate the strong link between hairpin formation and pentamethine cyanine dye formation, an analogue of **Hairp1a** was designed which was missing six nucleotides at its 3′-end in order to prevent hairpin formation. The ability of this new single-stranded DNA (so-called **Hairp1d**) to act as a template was investigated by fluorescence spectroscopy (gray curve, Figure 3c). Not surprisingly, the fluorescence intensity obtained with **Hairp1d** was ca. 10 times lower than that obtained with **Hairp1a**, thus demonstrating that the templating effect observed with the latter was indeed structure-specific.

Whether the hairpin remains "hairpin-like" or opens up upon hybridization of both PNAs to the DNA template remains to be demonstrated. **Hairp2** is likely to open after PNA ligation, as is commonly observed with MBs (thus forming a highly stable 10-mer PNA/DNA heteroduplex with single-stranded DNA flanking arms). In the case of **Hairp1** and **Hairp3**, however, the complex formed between the ligation product and the DNA template can be defined as a PNA/DNA hybrid three-way junction and could therefore be significantly more stable than the "open" structure. Additional structural studies will be required to further address this question.

Dual Hairpin + Quadruplex DNA Sensing Using a Dual-Color System. We recently demonstrated that two fluorogenic PNA probes (**Pna2** and **Pna3**, Figure 4a) could be used for sensing the formation of G-quadruplex DNA in vitro. The system was designed so that simultaneous and sequence-specific hybridization of both PNAs to a unique G-quadruplex-containing oligonucleotide were the only conditions inducing the formation of a fluorescent trimethine cyanine dye (λ_{em} = 563 nm) (*27*). Since the fluorescent properties of this trimethine cyanine dye were significantly different compared to those of **Pna1** aldehyde (λ_{em} = 476 nm) and to those of the pentamethine analogue formed when reacting **Pna1** with **Pna2** (λ_{em} = 660 nm), we reasoned that it should be possible to simultaneously detect the formation of both hairpin and quadruplex DNAs using a non-overlapping, two-color "Cy3-Cy5" system. The system was designed so that a unique nucleophilic PNA, **Pna2**, could potentially react with two electrophilic PNA aldehydes, **Pna1** and **Pna3**, to form a pentamethine (λ_{em} = 660 nm) and a trimethine (λ_{em} = 563 nm) cyanine dye, respectively. While **Pna1** and **Pna2** are directed against hairpin DNA **Hairp1a**, **Pna2** and **Pna3** are directed against quadruplex DNA **Quad1**. Hence, it was our expectation to be able to specifically correlate quadruplex and hairpin DNA formation with the appearance of characteristic fluorescence signals at λ_{em} = 563 nm and λ_{em} = 660 nm, respectively. In order to demonstrate the concept, a mixture of **Pna1** (250 nM), **Pna2** (1 μM), and **Pna3** (1 μM) was incubated under near-physiological conditions and in the presence of various DNA templates: (i) **Hairp1a** (500 nM), (ii) **Quad1** (1 μM), and (iii) a mixture of **Hairp1a** and **Quad1** (500 nM and 1 μM, respectively). In each case, the formation of the trimethine and pentamethine cyanine dyes were monitored by fluorescence spectroscopy (λ_{exc} = 540 and 625 nm, respectively) (Figure 4a). Under our experimental conditions, detection of hairpin DNA proved highly specific, even in the presence of an alternative DNA secondary structure. Indeed, comparable fluorescence intensities were obtained when using as a template either **Hairp1a** alone or a mixture of **Hair1a** and **Quad1**, while only residual fluorescence was detectable when using the quadruplex **Quad1** alone (Figure 4b).

Detection of quadruplex DNA in the presence of hairpin DNA also proved possible, the amount of trimethine cyanine dye formed decreasing by only <5% upon addition of competitor hairpin DNA (Figure 4c). However, significant background fluorescence (ca. 50%) was also obtained under our conditions, which could be interpreted as the result of a nonspecific formation of trimethine cyanine dye templated by hairpin DNA. So far, attempts to combine on a single oligonucleotide the quadruplex and hairpin forming sequences (both structures being separated by a polyT linker) in order to simultaneously detect both structures were unsuccessful due to high background signal, which is likely due to the formation of complex tertiary structures resulting in nonspecific reaction of dye (C3 and C5) formation.

CONCLUSION

Detection of nucleic acid secondary structures remains a key challenge for chemists due to their large abundance and structural diversity within the genome. Of particular interest are structures located in regions essential for DNA replication or transcription (e.g., in gene promoters) which could serve as therapeutic targets for regulating gene expression. Whether a DNA strand can potentially form into a hairpin or a quadruplex conformation based on the DNA primary sequence can now be easily predicted, and with reasonably good accuracy. However, whether these structures actually form (or not) depending on the context (in vitro or in vivo) or the experimental conditions remains much more challenging. Therefore, fluorescent probes capable of detecting the folding of specific nucleic acid sequences would represent an important way to validate the existence of such structures in vivo and also maybe to identify new targets. Herein, we reported three different strategies for sensing hairpin DNA formation by targeting either the loop or the stem with short PNAs functionalized at their 3′- or 5′-end with two precursors of a pentamethine cyanine dye. When working at low PNA concentrations (500 nM each), the aldolization−elimination reaction is highly unfavorable, thus resulting in no significant appearance of fluorescence. However, a significant increase (>50-fold) in fluorescence intensity can be obtained upon sequence-specific hybridization of both PNAs to either the loop or the stem of the hairpin target. Therefore, this PNA-based approach represents an original strategy for sensing hairpin DNA formation in vitro, the best sensitivity being obtained when targeting the hairpin loop with the cyanine dye forming in the vicinity of the hairpin stem (**Hairp1a**). Compared to other DNA-templated reactions described in the literature that also involve the formation of a fluorescent product, our system offers the significant advantages of (i) absorbing and emitting in the far-red part of the spectrum (λ_{em} = 660 nm), thus making it suitable for in vivo applications, and (ii) requiring no catalysis, thus making it biocompatible. It is also noteworthy that this unprecedented DNA-templated C5 synthesis can be orthogonal to the DNA-templated C3 synthesis recently reported by us (*27*), thus allowing simultaneous detection of at least two different structures within a two-color (C3−C5) system. Although such approach still requires optimization, we demonstrated that it was possible to use a combination of three PNA probes for sensing, within a mixture of hairpin and quadruplex DNA, either or both secondary structures. The development of PNA probes of increased specificity (e.g., longer PNAs) and higher sensitivity for in vivo applications is currently underway in our group.

New Unsymmetrical Bolaamphiphiles: Synthesis, Assembly with DNA, and Application for Gene Delivery

Namrata Jain, Youri Arntz, Valérie Goldschmidt, Guy Duportail, Yves Mély, and Andrey S. Klymchenko*

Laboratoire de Biophotonique et Pharmacologie, UMR 7213 CNRS, Université de Strasbourg, Faculté de Pharmacie, 74, Route du Rhin, 67401 ILLKIRCH Cedex, France. Received July 23, 2010; Revised Manuscript Received September 20, 2010

The success in gene therapy relies strongly on new efficient gene delivery vectors. Nonviral vectors based on lipids and polymers constitute an important alternative to the viral vectors. However, the key problem with these vectors is the poor structural control of their DNA complexes. In the present work, following new design we synthesized unsymmetrical bolaamphiphiles, molecules bearing neutral sugar (gluconic acid) and dicationic ornithine head groups connected by different long hydrophobic spacers. Within this design, a positively charged headgroup is expected to bind DNA, the hydrophobic spacer is to drive the formation of a monolayer membrane shell around DNA, while the neutral group is to be exposed outside of the complex. Our fluorescence and gel electrophoresis data showed that self-assembly of bolas and their interaction with DNA depend strongly on the bola structure. The size of bola/DNA complexes (bolaplexes) estimated from dynamic light scattering data was ~100 nm at low N/P (cationic nitrogen/DNA phosphate molar ratio), while at higher N/Ps it was significantly larger due to neutralization of their surface charge. Atomic force microscopy studies revealed nanostructural rod-shaped or spherical morphology of the bolaplexes. Transfection efficiency of the bolaplexes in vitro was significant when either DOPE or chloroquine were used as helping agents, suggesting that the key barrier for their internalization is the endosomal escape. Finally, all bolas showed low cytotoxicity (cell viability >80%). The present results show that bolas are prospective candidates for construction of nonviral gene delivery vectors. We believe that further optimization of polar head groups and a hydrophobic spacer in the bolas will lead to vectors with controlled small size and high transfection efficiency.

INTRODUCTION

The vast majority of natural and synthetic lipids studied so far are "monopolar" amphiphiles, that is, molecules presenting one polar headgroup and generally two hydrophobic chains. However, bipolar amphiphiles, which are analogues of lipids presenting polar groups at the two opposite sides of the hydrophobic chain(s), so-called bolaamphiphiles (bolas), became the matter of intensive research only in the recent years (*1*). A remarkable feature of bolas is that in contrast to bilayer membranes formed by lipids they can form monolayer membranes (Figure 1), having bolas with membrane-spanning hydrophobic chains, which are believed to be responsible for enhanced physical stability of bola membranes (*1, 2*). In nature, they are mainly present in archaebacteria and ensure the integrity of the bacterial membrane at high temperature (90 °C) and low pH (1−1.5) (*3, 4*). Membranes made from synthetic bolas, forming either nanotubes or vesicles, can also show an exceptional stability, some of them being stable even in the dry phase (*5, 6*) or in some organic solvents (*7*). Unsymmetrical bolas, bearing two different polar head groups, assembled in a parallel fashion can form asymmetric membranes, so that the two opposite sides of the monolayer membrane present different functional groups (Figure 1) (*5, 6*). One of the attractive applications of bolas, which is still in its infancy stage, is gene delivery, a domain for which "monopolar" cationic lipids and other cationic agents are currently maintaining a dominant position.

Gene delivery, which is a main concern in gene therapy, relies heavily on development of new delivery vectors. Nonviral vectors based on lipids are highly attractive, since they can deliver large quantities of genetic information and are weakly immunogenic (*8*). A variety of cationic lipids for gene delivery has been developed in recent decades (*8*−*19*). Their complexes with DNA (lipoplexes) show high transfection efficiency in vitro, though their application for gene therapy in vivo remains a challenge. One of the key problems of cationic lipids is the poor structural control of their lipoplexes (*10, 20*). Indeed, symmetric lipid bilayers made of cationic lipids interact with DNA by forming infinite sandwich-like structures of high polydispersity (Figure 1) (*10*).

In this respect, unsymmetrical bolas bearing positively charged and neutral head groups could be an attractive alternative to the cationic lipids. These molecules could generate asymmetric membranes (in form of vesicles or nanotubes) having positively charged inner and neutral outer surfaces. In such a case, the inner membrane surface can be used to wrap the DNA molecule (Figure 1), while the outer neutral membrane surface, being inert to DNA, would prevent further oligomerization of the complex and could be utilized for efficient exposure of the biological signal for specific targeting. The examples of successful application of bolas for gene delivery, which has been shown only in the recent years, include synthetic unsymmetrical bolas (*21*−*25*) and archaebacteria-derived lipids (*26, 27*). Among unsymmetrical bolas, the most promising were those bearing a sugar (gluconic or lactonic acid) residue on one side and mono- or oligo-cationic ammonium-based group on the other (*21, 23*). Moreover, the galactose-bearing bolas showed some specificity to HepG2 cell line, expressing a galactose receptor of endocytosis (*21, 22*).

In the present work, three new bolaamphiphiles were synthesized, bearing neutral sugar and dicationic ornithine head groups, connected by different hydrophobic spacers. We showed

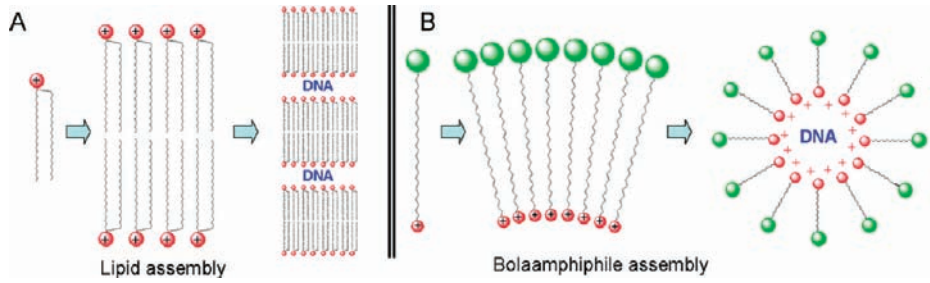

Figure 1. Lipids and bolaamphiphiles assembly with DNA. (A) Schematic presentation of bilayers formed from cationic lipids and further formation of DNA complexes, so-called lipoplexes. (B) Assembly of bolaamphiphiles into asymmetric membranes and formation of DNA complexes, so-called bolaplexes.

that the nature of spacer defines the bola self-assembly, the interaction with DNA and the morphology of the obtained complexes. Moreover, some bolas can transfect efficiently COS-7 cells in the presence of either a helper lipid (DOPE) or an endosomolytic reagent (chloroquine) (*28*). The latter indicates that the key barrier for gene delivery with the present bolas resides in the endosomal escape. This work presents new bolaamphiphile-based nonviral vectors and provides insights for further improvements of their efficiency.

MATERIALS AND METHODS

All chemicals and solvents for synthesis were purchased from Sigma-Aldrich. Mass spectra were measured using Mass Spectrometer Mariner System 5155. LC-MASS was performed on Agilent, 1956 B/MSD. ^{1}H NMR spectra were recorded on Bruker 300 MHz spectrometer.

***N*-Boc-4-aminophenol (1).** 4-Aminophenol (4 g, 36.7 mmol) and Boc_2O (8 g, 36.7 mmol) were dissolved in 30 mL of THF and left stirring overnight. Then 100 mL of water was added and the product was extracted with ethyl acetate (3 × 50 mL) and further dried with sodium sulfate. After solvent evaporation in vacuo, the crude product **1** was used without further purification.

16-(4-tert-Butoxycarbonylaminophenoxy)-hexadecanoic Acid Methyl Ester (2). Boc-protected 4-aminophenol (**1**) (1.8 g, 8.6 mmol) and 16-bromohexadecanoic acid methyl ester (3 g, 8.6 mmol, prepared by methylation of the acid in methanol and thionyl chloride) were dissolved in 10 mL of DMF and supplemented with 1.8 g (13 mmol) of potassium carbonate. After 12 h of stirring at room temperature (RT), the solution was poured in water (50 mL) and the product was extracted with dichloromethane (3 × 30 mL) and dried with sodium sulfate. Then the solvent was removed and the product **2** (1.6 g, 40%) was crystallized from ethanol. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 7.24 (d, 2H), 6.82 (d, 2H), 6.4 (s, 1H), 3.91 (t, 2H), 3.67 (s, 3H), 2.31 (t, 2H), 1.82−1.58 (m, 4H), 1.55−1.48 (m, 9H), 1.46−1.2 (m, 24H). LC-MS (*m*/*z*): found $[M + 1]^+$ = 378.2; calcd for $C_{28}H_{47}NO_5^+$-$C_5H_9O_2$ (Boc) = 378.3.

16-[4-(2,5-Bis-tert-butoxycaronylamino-pentanoylamino)-phenoxy]-hexadecanoic Acid Methyl Ester (3). Boc was removed from **2** (3.14 mmol, 1.5 g) by treating with 5 mL TFA and 3% H_2O for 1 h at RT. The solvent was evaporated and 1.54 g (3.1 mmol) of the obtained deprotected amine was coupled with 2,5-bis-tert-butoxycarbonyl amino-pentanoic acid (3.57 mmol, 1.15 g) using BOP (3.44 mmol, 1.52 g), HOBt (4.3 mmol, 0.58 g), and DIEA (12.6 mmol, 2.2 mL) in DMF (15 mL) and dichloromethane (30 mL). The mixture was stirred overnight at RT. Then, solvent was evaporated and product was crystallized from acetonitrile. The precipitate was filtered off and dried to give compound **3** (1.6 g, 76%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.41 (s, 1H), 7.41 (d, 2H), 6.81 (d, 2H), 5.25 (s, 1H), 4.73 (s, 1H), 4.39 (s, 1H), 3.9 (t, 2H), 3.65 (s, 3H), 3.4 (s, 1H), 3.09 (s, 1H), 2.28 (t, 2H), 1.83−1.69 (m, 4H), 1.67−1.53 (m, 4H), 1.47−1.38 (m, 18H), 1.37−1.16 (m, 22H). LC-MS (*m*/*z*): found $[M + 1]^+$ = 491.2; calcd for $C_{38}H_{65}N_3O_8^+$-$C_{10}H_{18}O_4$ (2Boc) = 491.2.

(1-{4-[15-(2-Amino-ethylcarbamoyl)-pentadecyloxy]-phenylcarbamoyl}-4-tert-butoxycabonylamino-butyl)-carbamic Acid tert-Butyl Ester (4). Methyl ester of **3** (0.7 mmol, 0.5 g) was substituted with ethylenediamine (150 mmol, 10 mL) for 72 h at 70 °C. Then the excess of ethylenediamine was evaporated, 50 mL of water was added and the product **4** was filtered (0.45 g, 87%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 8.45 (s, 1H), 7.42 (d, 2H), 6.82 (d, 2H), 6.05 (s, 1H), 5.30 (s, 1H), 4.75 (s, 1H), 4.37 (s, 1H), 3.91 (t, 2H), 3.42−3.25 (m, 3H), 3.16−3.02 (m, 1H), 2.84 (t, 2H), 2.17 (t, 2H), 2.06−1.92 (m, 4H), 1.79−1.7 (m, 2H), 1.67−1.54 (m, 4H), 1.48−1.37 (m, 18H), 1.37−1.20 (m, 20H). LC-MS (*m*/*z*): found $[M + 1]^+$ = 720.4; calcd for $C_{39}H_{69}N_5O_7^+$ = 720.4.

[4-tert-Butoxylamino-4-(4-{15-[2-(2,3,4,5,6-pentahydroxy-hexanoylamino)-ethylcabamoyl]-pentadecyloxy}-phenylcarbamoyl)-butyl]-carbamic Acid tert-Butyl Ester (5). D-gluconic acid δ-lactone (0.23 mmol, 0.04 g) was added to solution of **4** (0.11 mmol, 0.1 g) in 15 mL of methanol. Then, DIEA (1.4 mmol, 0.24 mL) was added and the reaction mixture was stirred at 70 °C for about 24 h. Solvents were evaporated in vacuo. Compound **5** (0.09 g, 90%) was crystallized from methanol. ^{1}H NMR (CD_3OD, 300 MHz): δ 7.42 (d, 2H), 6.87 (d, 2H), 4.21 (s, 1H), 4.18−4.06 (m, 2H), 3.96 (t, 2H), 3.83−3.6 (m, 5H), 3.09 (t, 2H), 2.19 (t, 2H), 1.86−1.54 (m, 10H), 1.48−1.41 (m, 18H), 1.39−1.26 (m, 22H). LC-MS (*m*/*z*): found $[M + 1]^+$ = 898.57; calcd for $C_{45}H_{79}N_5O_{13}^+$ = 898.57.

16-[4-(2,5-Diamino-pentanoylamino)-phenoxy]-hexadecanoica-cid[2-(2,3,4,5,6-pentahydroxy-hexanoylamino)-ethyl]-amide (Orn-C16-G). Boc was removed from 50 mg of **5** using 0.5 mL TFA and 3% H_2O (1 h) to get the final product Orn-C16-G (27 mg, 90%). LC-MS (Bruker, HTCultra) (*m*/*z*): found $[M + 1]^+$ = 698.4; calcd for $C_{35}H_{64}N_5O_9^+$ = 698.4.

Fluorescence Measurements. Absorption spectra were recorded on a Cary 400 spectrophotometer (Varian) and fluorescence spectra either on FluoroMax 3.0 or Fluorolog (Jobin Yvon, Horiba) spectrofluorimeters. All the emission spectra were corrected from the background signal of the corresponding blank (corresponding solution without the fluorescent dye). For measurements with 1,8-ANS, 50 nM of the dye dissolved in 20 mM MES buffer (pH 7.4 or 6.0) solution was titrated with increasing quantities of the corresponding bola, added from stock solutions. All spectra were recorded 2 min after each addition. In the ethidium bromide (EtBr) exclusion assay, an aliquot of CT-DNA (final concentration 20 μM) was added to the solution of EtBr (0.4 μM). After 2 min, increasing quantities of the corresponding bola were added from stock solutions (in DMF with 10% of water). Fluorescence intensity recorded at 600 nm (excitation at 550 nm) was recorded 2 min after each addition of bola aliquot.

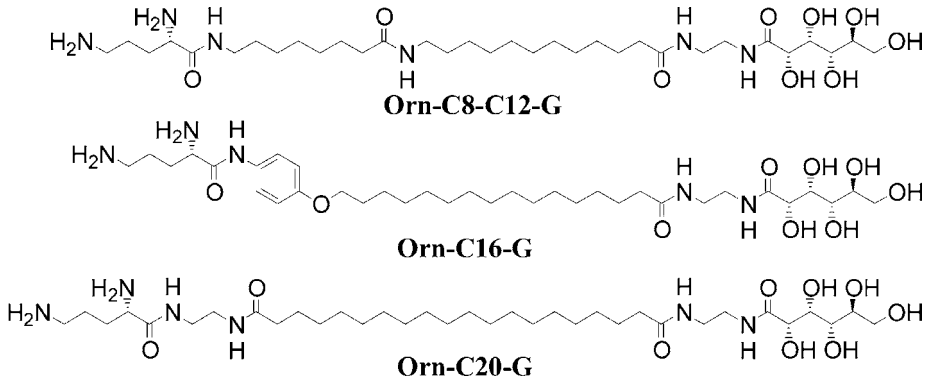

Figure 2. Chemical structures of bolaamphiphiles.

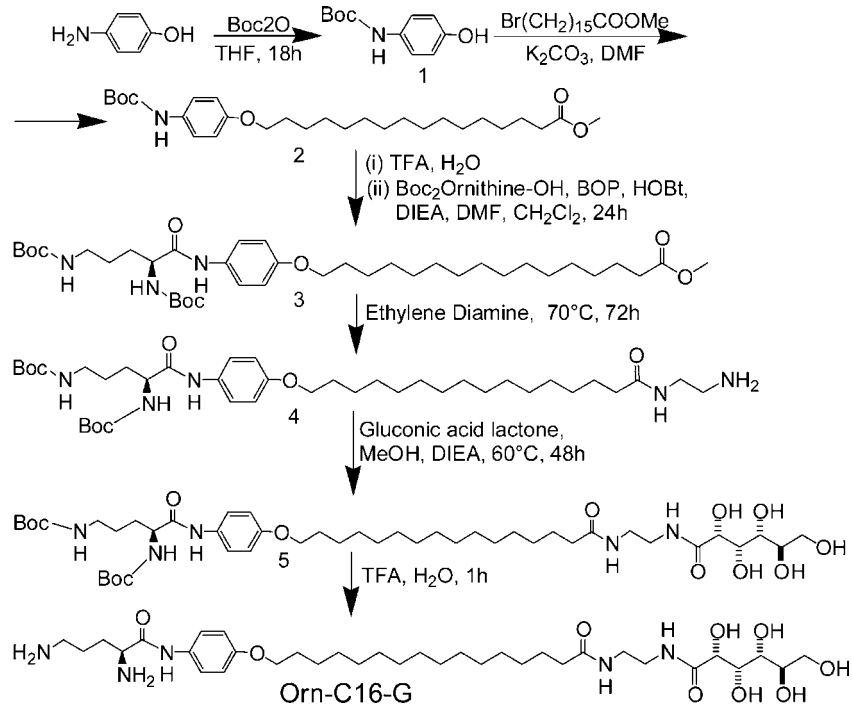
Dynamic Light Scattering (DLS) and ζ-Potential Measurements. The bolaplexes were prepared in 20 mM MES at pH 7.4 by mixing equal volumes of the solutions of calf thymus DNA (CT-DNA) or pCMV-Luc plasmid (pDNA) and the corresponding bolas. The bola solutions were prepared by adding aliquots of their stock solutions (in DMF with 10% of water) to the buffer. The final DNA concentration (expressed in phosphate) was 20 μM, while the bolas concentration was adjusted according to a desired N/P ratio. The N/P ratio between bolas and pDNA was expressed as the molar ratio between all the protonable amino groups of the bolas and the phosphate groups of the DNA. The DLS measurements were performed after 30 min of incubation at room temperature. The average size of the complexes was determined with a Zetasizer Nano ZS (Malvern Instruments) with the following specifications: sampling time, 30 s; medium viscosity, 0.8872 cP; refractive index (RI) medium, 1.33; RI particle, 1.590; scattering angle, 90°; temperature, 25 °C. For particle analysis, the statistics based on particle volume and particle number were presented. For ζ-potential measurements, the same sample preparation was done using CT-DNA at 30 μM concentration. The instrumental specifications were the same, accounting for a solvent dielectric constant of 78.5.

Gel Electrophoresis. The bolaplexes were prepared at different N/P ratios using 60 μM pCMV-Luc plasmid (final phosphate concentration), followed by 30 min incubation at room temperature. Four microliters of loading dye (Lonza, 6×) was added to 20 μL of the prepared complexes and then 12 μL of this mixture was loaded on 0.9% agarose gel prepared with 0.5X TAE (tris-acetate-ethylenediaminetetraacetic acid) buffer. In parallel, a 10 kbp DNA ladder (Lonza) was loaded on the gel. Electrophoresis was carried out with 0.5X TAE buffer at a constant voltage of 100 mV. DNA bands were visualized by UV trans-illuminator (GeneGenius, Syngene) after coloration with EtBr (0.5 μg/mL) for 15 min.



AFM Measurements. AFM measurements were performed using the Solver Pro-M (NT-MDT) instrument. The measurements were performed in liquid phase (MES buffer pH 7.4) by using the tapping mode. The cantilevers used were NSG03 type (NT-MDT) with a typical spring constant of 1.7 N/m, a resonance frequency of 32 kHz in liquid, and a tip curvature radius of 10 nm. Images were acquired with a resolution of 512 × 512 and a scan rate of 2 Hz. The samples were prepared as for DLS measurements, then 100 μL of the solution was deposited on the freshly cleaved mica followed by the addition of 10 μL of a $MgCl_2$ stock solution to obtain a final concentration of 10 mM. The measurements were performed 10 min after sample preparation.

Transfection and Cytotoxicity. COS-7 cells (African Green Monkey kidney fibroblast cell line) were grown in Dulbecco's modified Eagle's medium (Gibco-Intvitogen), supplemented with 10% fetal bovine serum (FBS, Lonza) and 100 U/ml of penicillin and streptomycin (Gibco-Intvitogen) at 37 °C in a humidified atmosphere containing 5% CO_2. Cells were seeded at a density of 1×10^5 cells in a 24-well plate, 24 h before transfection.

Transfection was done by using bola/pDNA (pCMV-Luc plasmid, 1 μg/well) complexes at different N/P ratios in serum-free Opti-MEM (Gibco-Invitrogen) or complete culture medium (DMEM containing 10% of FBS). For this purpose, bolaplexes were prepared in MES buffer (pH 7.4) as for DLS measurements and then added to the cells in Opti-MEM. Chloroquine (100 μM) or DOPE (1:1 molar ratio with respect to bola) was used to enhance transfection efficiency in some formulations. In formulations with DOPE, a mixture of DOPE and a corresponding bola in ethanol was evaporated in a round-bottom flask to obtain a film. Then, MES buffer (pH 7.4) was added and the samples were hydrated overnight at RT. Then, the samples were vortexed vigorously for 1 min and further sonicated in an ultrasonic bath for 15 min. The obtained suspensions were mixed with an equal volume of pDNA in the buffer to obtain a desired N/P ratio. All formulations were incubated at RT for 30 min before addition to the cells. After 3 h of incubation of cells with bolaplexes at 37 °C, 10% of FBS was added to serum-free samples, while for all the samples with chloroquine the transfection medium was replaced with fresh complete culture medium and then cells were cultured for another 45 h. Total incubation time for all samples was 48 h. Luciferase gene expression of lysed cells was quantified using a commercial kit (Invitrogen) and a luminometer (CentroXS^3 LB 960, BERTHOLD Technologies). Results were expressed as relative light units integrated over 10 s per mg of total cell protein lysate (RLU/mg of total protein). The experiments were repeated six times for serum-free samples and three times for samples with serum. The total protein was determined by BC assay (Protein Quantitation Kit, Interchim) using Cary 4000 spectrophotometer. As a positive control in the transfection measurements, commercially available agent jetPEI (Polyplus) was used following protocols provided in the kit.

Cytotoxicity of bolas was evaluated using 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyltetrazolium bromide (MTT, Sigma-Aldrich) assay (*29*). COS-7 cells were seeded in a 24-well plate at 1×10^5 cells per well and after 24 h of incubation at 37 °C supplemented with bolas at different concentrations or jetPEI (150 μM, expressed as concentration of nitrogen residues) in serum-free Opti-MEM. After incubation for 3 h at 37 °C, 10% of FBS was added and cells were cultured for another 45 h. Cells were washed with phosphate buffer saline (PBS) and incubated with serum free medium containing 0.5 mg/mL MTT for 3 h at 37 °C. Media was discarded and formazan crystals were resuspended in 0.5 mL MTT solvent (Sigma-Aldrich). Absorbance of formazan solution was measured at 570 nm with

Scheme 1. Synthesis of Bola Orn-C16-G

respect to the background at 690 nm using Cary 4000 spectrophotometer. Cell viability was expressed as relative absorbance (%) of the sample versus control cells.

RESULTS AND DISCUSSION

Design and Synthesis. The basic design of bolas relies on one neutral group and one dicationic group connected by a hydrophobic spacer. As neutral group we selected a sugar residue, which is biocompatible and relatively inert. The dicationic headgroup responsible for DNA binding was the ornithine residue (Orn), featuring two amino groups separated by a 4-carbon atom distance. This distance ensures protonation of both amino groups at neutral pH and thereby efficient interaction with negatively charged DNA. On the basis of this design, three new bolaamphiphiles were synthesized, presenting different hydrophobic spacers: (a) a dipeptide composed of end-substituted amino acids of 8- and 12-carbon atoms, Orn-C8-C12-G; (b) a hydrophobic linker composed of an alkyl chain of C16-carbon atoms and an aromatic unit, Orn-C16-G; and (c) a long (20-carbon atoms) alkyl chain, Orn-C20-G (Figure 2). This variation of the hydrophobic spacer could tune the hydrophobic, H-bonding and π-stacking interactions between bolas. An example of synthesis of Orn-C16-G is presented in Scheme 1. Initially, the amino group of 4-aminophenol was protected with Boc-group (**1**) and its hydroxyl was further reacted with methyl 16-bromohexadecanoate. Then, the amino group in the obtained conjugate **2** was further deprotected and substituted with Boc-protected ornithine. The obtained conjugate **3** was further reacted with ethylene diamine giving **4**. The latter was then substituted with D-gluconic acid δ-lactone followed by Boc-removal, affording final bola Orn-C16-G. The yields of the individual steps were systematically >50% and the obtained final bolas in 100−200 mg quantities were sufficiently pure according to NMR, LC-MS and HPLC techniques (see also Supporting Information).

Self-Assembly. 1,8-ANS dye is poorly fluorescent in water, while on binding to lipid membranes it becomes strongly fluorescent (*30*). In the present work, we used this probe to study the concentration-dependent bolas assembly. Solutions at pH 7.4 and 6.0 were tested, which could alter the protonation of the amino groups of bolas in the self-assembled state. It can be seen from Figure 3 that for Orn-C16-G at pH 7.4, fluorescence intensity grows rapidly with bola concentration showing beginning of saturation at higher concentrations. In contrast, at pH 6.0, a moderate increase in fluorescence intensity is followed by rapid increase at concentrations >20 μM. These data suggest that the critical aggregation concentration (CAC) at pH 7.4 is too low to be detected with this method, while at pH 6.0 it is clearly much larger being close to 20 μM. We could speculate that the self-assembly could be accompanied by a partial deprotonation of bola amino groups, so that lower pH may favor disassembly (i.e., higher CAC). In contrast, for bola Orn-C20-G rapid increase of 1,8-ANS fluorescence intensity was observed both at pH 7.4 (see Figure S1 in Supporting Information) and 6.0 (Figure 3). This indicates that CAC of Orn-C20-G is much

	bola/DOPE/pDNA N/P 5 (50 μM bola)	1440	100	1350

lower than that of Orn-C16-G, probably because of its hydrophobic spacer, which is longer and does not contain bulky aromatic group, thus ensuring tight bola packing. Finally, Orn-C8-C12-G showed relatively weak increase in the fluorescence of 1,8-ANS with increasing concentration suggesting that it does not assemble at the studied concentration range. The latter result is probably connected to the presence of an amide group within the bola hydrophobic spacer, which may strongly diminish its hydrophobic interactions and thus increase its CAC.

The information about molecular order of bolas assemblies can be provided from fluorescence anisotropy of a rod-shaped molecule TMA-DPH (*31*). The observed values of fluorescence anisotropy for Orn-C16-G and Orn-C20-G assemblies at 100 μM are relatively high (0.30−0.32) at 20 °C and correspond to a rigid and highly ordered environment similar to lipid membranes in solid gel phase (0.32) for DPPC at 20 °C (data not shown) (*32*). These high values of fluorescence anisotropy suggest that bolas are probably organized in monolayers with a transmembrane spanning orientation, thus excluding possible bolas bilayer structure presenting a U-shaped conformation, as reported for some other bolas (*33*).

According to DLS data, Orn-C16-G and Orn-C20-G at 100 μM concentration form a significant fraction of small structures (around 100 nm, Table 1) in line with fluorescence data suggesting self-assembly of bolas at these conditions. These structures were stable for 1−2 h, while after longer incubation some precipitation of the bolas was observed.

Interactions with DNA. To study interactions of bolas with DNA, gel electrophoresis was first used. It can be seen from Figure 4A that Orn-C8-C12-G forms complexes with firefly luciferase plasmid DNA (pDNA) only at high N/P ratios (ratio between cationic groups of bola and phosphate groups of DNA). Indeed, only at N/P > 10 the pDNA band disappears. This indicates a relatively weak affinity of this bola to DNA. In contrast, Orn-C16-G (Figure 4B) and Orn-C20-G (Figure 4C) form complexes with pDNA at N/P values close to 1.0−1.2. It can be noted that Orn-C20-G shows a slightly stronger interaction since the DNA band disappears at lower N/P ratio (1.2) as compared to Orn-C16-G (1.6). By taking into account that all bola molecules are bearing the same dicationic ornithine residue, the stronger interaction of Orn-C16-G and Orn-C20-G with DNA is probably connected with a higher hydrophobicity of their spacers, which in turn favors their self-assembly and their cooperative interaction with DNA. Thus, we can assert that the interaction of the present bolas with DNA is controlled in part by their ability to self-assemble. Finally, a mixture of Orn-C16-G with a helper lipid DOPE (1:1 molar ratio with respect to bola), which was important in our transfection experiments (see below), showed complex formation at slightly higher N/P ratio, being completed at N/P 3 (see Figure S2 in Supporting Information).

The DNA condensation within the bolaplexes can be followed by the ethidium bromide (EtBr) exclusion assay (*34*). This dye when intercalated into DNA is highly fluorescent, while after DNA condensation it is expelled from its intercalation site, thus resulting in a strong decrease of its fluorescence intensity (up to 90%). For these studies, a linear DNA from calf thymus was used as the model. According to our data, Orn-C8-C12-G showed a relatively weak and rather linear decrease of EtBr fluorescence intensity as a function of N/P ratio (Figure 5), which is in line with the gel electrophoresis data showing its

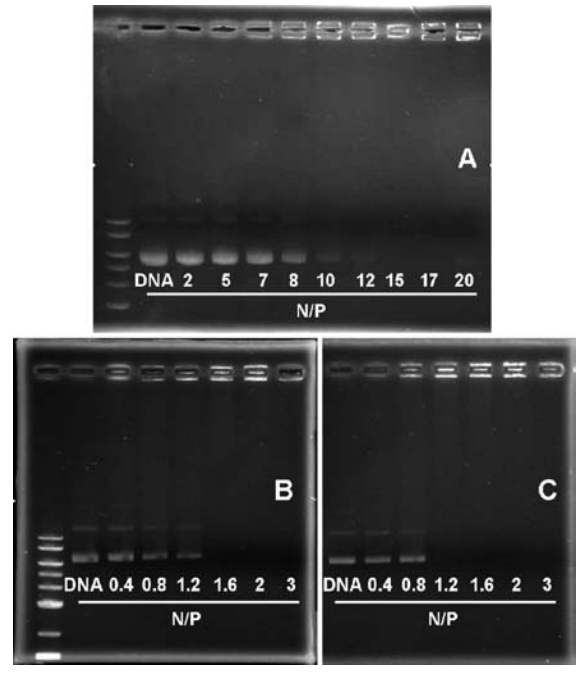

Figure 4. Agarose gel electrophoresis (0.9%) of Orn-C8-C12-G (A), Orn-C16-G (B), and Orn-C20-G (C) complexed with pDNA at different N/P ratios. Bands at the left of gels (A) and (B) correspond to 10 kbp DNA ladder.

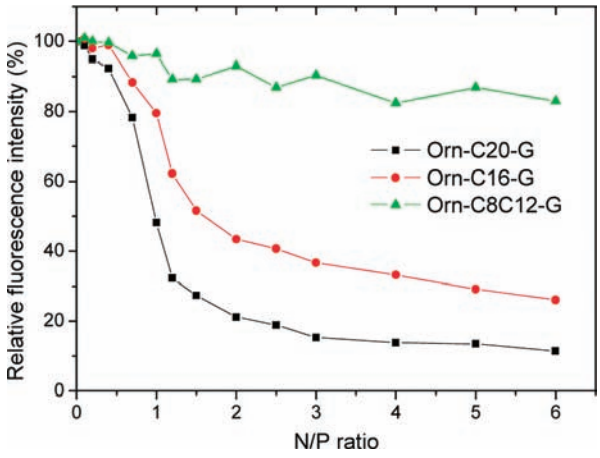

Figure 5. Exclusion of EtBr from CT-DNA complexes with bolas at different N/P ratios. The fluorescence intensity was normalized to 100% of the initial intensity.

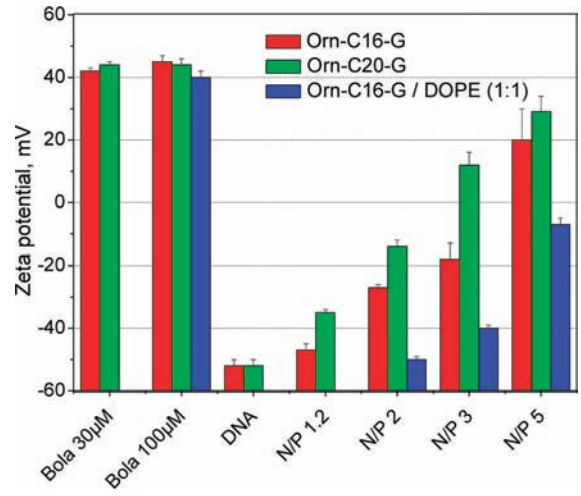

Figure 6. ζ-potential of nanostructures formed by bolas alone and by their formulations with DOPE and CT-DNA in MES buffer (pH 7.4) at different N/P ratios.

weak interaction with DNA. In contrast, both Orn-C16-G and Orn-C20-G showed a sharp decrease of EtBr fluorescence at N/P around 1. Thus, in accordance with the gel electrophoresis data it is confirmed that these bolas bind strongly to DNA by showing a significant level of DNA condensation. It can be also noticed that, similarly to the gel electrophoresis data, Orn-C20-G shows an EtBr fluorescence decrease at lower N/P ratio as compared to Orn-C16-G. Moreover, the fluorescence decrease is stronger for the former bola (ca. 85% for Orn-C20-G as compared to ca. 70% for Orn-C16-G). Thus, we can conclude that Orn-C20-G presents a stronger affinity to DNA and condense it more significantly as compared to Orn-C16-G. This conclusion corroborates with the observed stronger ability of Orn-C20-G to self-assemble without DNA evidenced by 1,8-ANS data. Since Orn-C8-C12-G shows a poor affinity to DNA and almost a negligible DNA condensation ability, we excluded this compound from further characterization, focusing only on Orn-C16-G and Orn-C20-G bolas.

Structural Characterization of Bolaplexes. To estimate the size of the obtained bolaplexes, DLS technique was used. Initially, the bolaplexes at different N/P ratios were prepared by direct addition of increasing quantities of Orn-C16-G from stock to pDNA solution. It was observed that at low N/P ratios, the particle size was relatively small (around 100 nm), while above N/P 1.2, their size increased rapidly reaching a maximum at N/P 2 (700 nm) and then further decreases until N/P 5 (see Supporting Information). In a second approach, the bolaplexes were prepared by mixing equal volumes of bolas and DNA aqueous solutions, followed by 30 min incubation at RT. This method gave similar DLS results for low N/P ratios (1.2 and 2): relatively small particles at N/P = 1.2 and much larger at N/P = 2 (Table 1). It is important to note that for Orn-C16-G at lower concentration the bolaplexes at N/P 2 (30 min incubation) showed much smaller sizes (150 nm). In contrast, after 5 min of incubation, Orn-C16-G/pDNA complexes presented similar small sizes (ca. 150 nm) for both low and high bola concentrations. Thus, the higher bola concentration probably favors aggregation of bolaplexes into larger particles. At N/P 5, this preparation method (with 30 min incubation) also gave relatively large particles as for N/P 2. The observed discrepancy between the two methods of preparation for N/P 5 is probably related to the incubation time, since in the first approach the measurements were done 5 min after each addition. The DLS data obtained with Orn-C20-G were similar to those with Orn-C16-G (Table 1), so that bolaplexes were small at N/P ratio 1.2, while their size increased significantly at higher N/P ratios. Moreover, for Orn-C16-G/DOPE mixture (1:1), a similar increase in the size of the bolaplexes was observed at higher N/P ratios (Table 1). The observation of larger complexes at higher N/Ps differs clearly from behavior of polyplexes and lipoplexes. Indeed, the latter at N/Ps close to 1 show relatively large complexes because of neutral charge of the complex, while at higher N/Ps they are much smaller because of their strong positive charge (*35*−*37*). Interestingly, our observations are in line with recent reports on other bolas featuring cationic group on one end and a neutral sugar residue on the other (*23*, *24*). Therefore, we can suggest that the increase in size of bolaplexes at higher N/Ps could be a special feature of this type of bolas, which is probably because their bolaplexes do not become positively charged at higher N/Ps. This hypothesis was verified by measuring the zeta potential of bolaplexes (Figure 6). The bolas alone showed strongly positive ζ-potentials, while the bolaplexes at low N/P ratios were negatively charged and reached neutrality at N/P ratios around 3. At N/P 5, the observed ζ-potential was positive, however, we suspect that it could be due to excess of bola molecules that do not complex with DNA, thus contributing to apparent positive potential values. For Orn-C16-G/DOPE mixture (1:1), the ζ-potentials were systematically more negative, though a clear neutralization of the complexes was observed at N/P 5 (Figure 6). We expect that, as shown in Figure 1B, the positively charged part of bola interacts with DNA, while the neutral sugar residue is exposed at the bolaplex surface. This structure may favor neutrality of the bolaplex at higher N/Ps. Presence of DOPE does not change this tendency, but only shifts the complex neutralization to higher N/P ratios.

To access the nanoscopic architecture of bolaplexes, we performed atomic force microscopy (AFM) measurements in liquid (buffer) phase on a mica surface. An efficient absorption of the bolaplexes (N/P 2 or 1.2) at the mica surface was achieved only in the presence of magnesium cations. This indicates that the bolaplexes at the studied N/P ratios are negatively charged, so that Mg^{2+} ions act as a link between bolaplexes and the negatively charged mica surface. Orn-C16-G bolaplexes with pDNA formed relatively small and spherical structures (Figure 7A). The average height and width of the particles were 12 and 120 nm, respectively, which correspond to an average particle volume of about 1.7×10^5 nm^3 and an equivalent spherical particle diameter of 70 nm. This size is smaller than the one observed by DLS for N/P 2 (12 μM bola). Several reasons may explain this discrepancy. At first, the smaller size particles observed by AFM is based on a particle by particle data analysis, while DLS measures an average size with higher sensitivity to larger particles. Indeed, the DLS data based on particle number

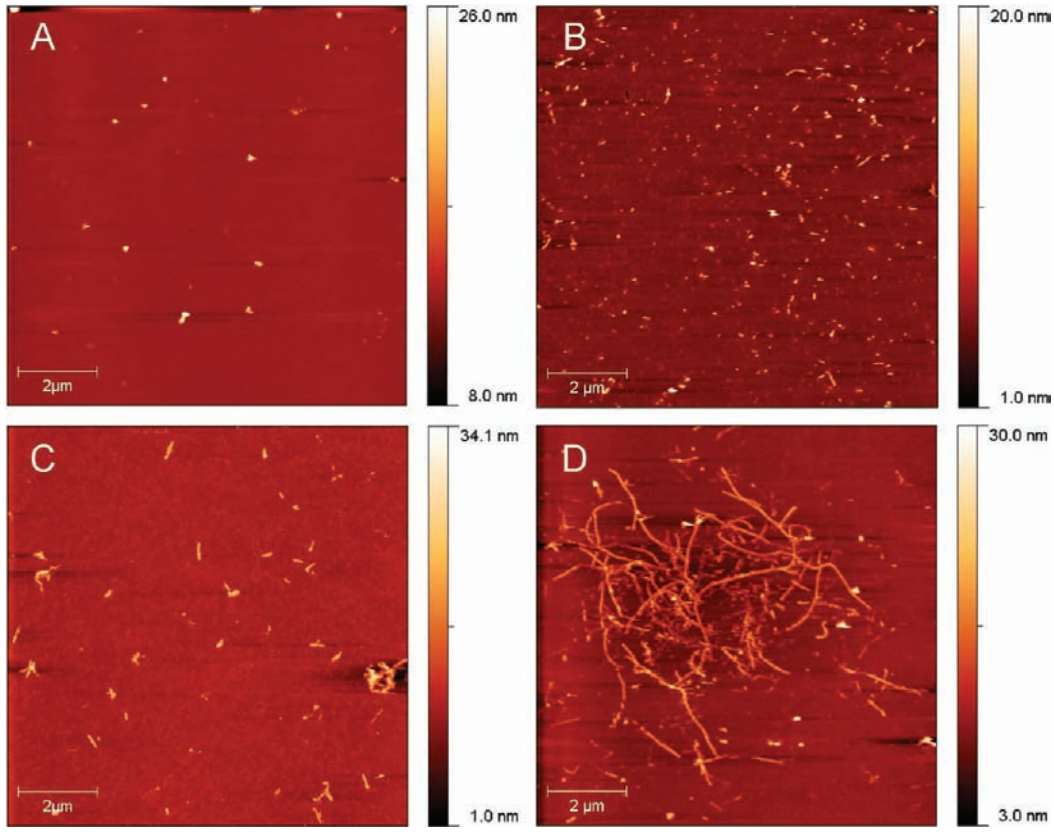

Figure 7. AFM images of Orn-C16-G (A and B, N/P 2) and Orn-C20-G (C and D, N/P 1.2) bolaplexes with pDNA (A and C) and CT-DNA (B and D). Images were obtained by tapping mode.

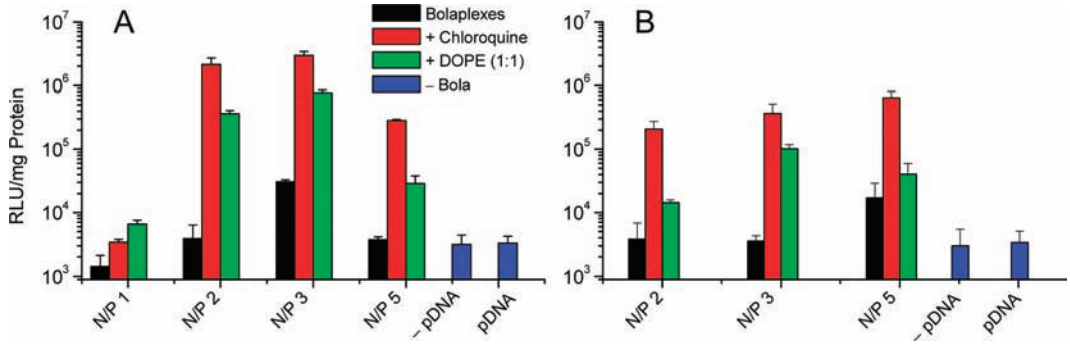

Figure 8. Transfection efficiency of the Orn-C16-G bolaplexes at different N/P ratios in COS-7 cells without (A) and with serum (B). Cells were incubated in serum-free Opti-MEM (A) or complete culture medium, DMEM containing 10% of FBS (B) with a bolaplex composed of plasmid DNA (1 μg per well), Orn-C16-G, and DOPE (when indicated). For some samples, the medium contained 100 μM chloroquine. After 3 h, 10% of FBS was added to the serum-free samples, while for all the samples with chloroquine the transfection medium was replaced with fresh complete culture medium. The luciferase activity quantification was performed after 48 h of incubation. Transfection efficiency determined from the luciferase assay was expressed as RLU/mg of protein. The negative controls were nontreated cells (-pDNA) and those transfected with naked pDNA (pDNA). The experiments were repeated six times for serum-free samples (A) and three times for samples with serum (B).

statistics is much closer to AFM data than those based on volume analysis (Table 1). Moreover, DLS data provides a hydrodynamic size of the particles, which is larger than the real size. Finally, in AFM measurements, the particles are stabilized by adsorption at the surface, while in DLS they are free in solution and can further aggregate to form larger particles. Bolaplexes of Orn-C16-G with CT-DNA showed high polydispersity and formed both spherical and short rodlike structures (Figure 7B). The presence of short rods of 8−10 nm height, 40−60 nm width, and 300−600 nm length could be explained by the linear structure of CT-DNA that favored the formation of elongated structures. In contrast, Orn-C20-G/DNA bolaplexes at N/P 2 were very large and polydisperse, in line with DLS data, which prompted us to study the bolaplexes at N/P 1.2. Remarkably, the complexes at N/P 1.2 showed predominantly rodlike structures for both pDNA and CT-DNA (Figure 7C and D). However, in the case of pDNA, the observed rods were relatively short, having height and width around 10 and 120 nm, respectively, while in the case of CT-DNA, they correspond to very long fibers of 16 nm height and 80 nm width. The formation of these "spaghetti-like" structures was previously reported for cationic lipids (*38*). It was proposed that in this kind of structure, the DNA molecule is located in the core, being surrounded by the lipid membrane. Probably, Orn-C20-G/CT-DNA bolaplexes present a similar structure, where single or multiple DNA strands are surrounded by a monolayer of bola molecules, similarly to the idealistic model in Figure 1B.

Transfection Efficiency and Cytotoxicity. The transfection efficiency of bolaplexes was in serum-free and serum-containing media for the different formulations by using the luciferase expression assay (Figure 8). For serum-free samples (Figure 8A), considerable transfection efficiency was observed for Orn-C16-G bolaplexes at N/P 2, 3, and 5 only in the presence of helper lipid DOPE or the endosomolytic reagent chloroquine (*28*). The better efficiency observed in the presence of DOPE is in line with previously reported data concerning other bolaamphiphiles (*21, 23*). DOPE probably improves the fusion of bolaplexes with cellular and endosomal membranes (*39, 40*). However, the strong effect of chloroquine on bolaplexes delivery is reported for the first time. This result clearly shows that the key barrier for internalization of bolaplexes is related to the endosomal escape. In the presence of serum, the transfection efficiency decreased significantly for all samples with DOPE (Figure 8B), which is in line with previous reports showing that DOPE-containing lipoplexes are highly sensitive to serum (*41*). In the presence of chloroquine, the effect of serum was less important, and the transfection efficiency increased systematically at higher N/P ratio. At N/P = 5, the sample with serum showed even slightly higher transfection efficiency than that without serum (Figure 8). Similar results were reported for lipoplexes, where higher N/Ps increased their resistance to serum (*42*).

On the other hand, bolaplexes of Orn-C20-G displayed relatively poor transfection efficiency for most of the formulations, which can be related to their larger size and spaghetti-like architecture (Figure 7). It should be noted that the observed values of transfection efficiency for Orn-C16-G were significantly lower than that for highly efficient commercial agent jetPEI (3×10^8 RLU/mg protein in the present study), while they were comparable with those recently reported for some other bolaamphiphiles (*21, 22*). Taking into account that the area of bolaamphiphiles as nonviral vectors is still poorly explored, we believe that there is a lot of room for improvement of their transfection efficiency. It will require optimization of bola chemical structure to achieve better control on the size and stability of the bolaplexes as well as on their ability to escape from endosomes. This work is currently in progress and will be reported in due course.

MTT-based assay suggested that new bolas do not show any considerable cytotoxicity. In the concentration range 30−200 μM of bolas with 48 h incubation, the observed cell viability was >80%, while for jetPEI (150 μM, expressed for nitrogen residues) it was only about 60% (see Supporting Information). The MTT results correlated well with the observed relatively high total protein (>80% vs. control) after 48 h of transfection with bolaplexes. This low cytotoxicity of the new bolas is an important advantage compared to polyplexes and lipoplexes. Thus, the obtained results showed the potentials of the new bolas molecules, especially Orn-C16-G, for the elaboration of highly efficient nonviral vectors.

CONCLUSIONS

We have synthesized three new bolaamphiphiles, bearing cationic and neutral groups at opposite sides of a hydrophobic spacer. The two bolaamphiphiles with more hydrophobic spacers exhibit low critical aggregation concentration and stronger affinities to DNA. At low N/P ratio (1.2), these bolas form bolaplexes of relatively small size, showing spherical and rodlike structures, while at higher N/P ratio their size increases due to neutralization of the complexes. Bolaplexes showed considerable transfection efficiency only in presence of the helper lipid DOPE or the endosomolytic agent chloroquine, indicating that the endosomal escape constitutes the main barrier to the internalization of these complexes. The present work provides strong basis for a further development of new efficient gene delivery vectors based on this original class of compounds.

ACKNOWLEDGMENT

This work was supported by Fondation pour la Recherche Médicale (FRM). We thank the groups of J.-S. Remy and B. Frisch for help with luminometry and DLS measurements. We also thank G. Zuber for fruitful discussions.

Supporting Information Available: Procedures for synthesis of Orn-C20-G and Orn-C8-C12-G. Some DLS data. Total protein and MTT-based cytotoxicity assays. This material is available free of charge via the Internet at http://pubs.acs.org.

New unsymmetrical bolaamphiphiles: synthesis, assembly with DNA and application for gene delivery

Namrata Jain, Youri Arntz, Valerie Goldschmidt, Guy Duportail, Yves Mely, Andrey S. Klymchenko

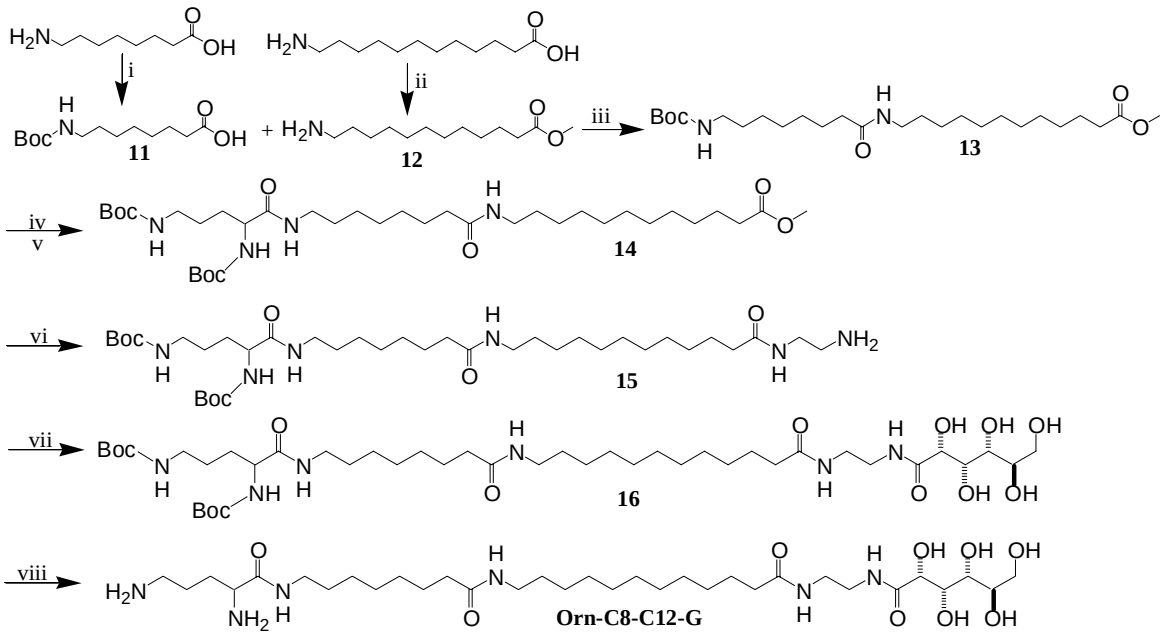
1. Synthesis of Orn-C12-G and Orn-C8-C12-G bolas.

Reagents: (i) MeOH, H_2SO_4, $C_2H_4Cl_2$, 85°C, 24h (25%) ; (ii) BOP, HOBt, DIEA, DMF, CH_2Cl_2, 24h (72%) ; (iii) TFA, H_2O, 1h; (iv) BOP, HOBt, DIEA, DMF, CH_2Cl_2, 40°C, 24h (70%) ; (v) Ethylene Diamine, 70°C, 72h (93%) ; (vi) Gluconic acid lactone, MeOH, DIEA ; (vii) TFA, H_2O, 1h (90%).

Scheme S1. Synthesis of **Orn-C20-G.**

Eicosanedioic acid monomethyl ester (6). The procedure was adapted from Ref. (1). Eicosanedioic acid (14.6 mmol, 5 g) was dissolved in 300 ml of ethylene chloride at 85°C. Methanol (7.4 mmol, 0.59 ml) was added to the clear solution, then H_2SO_4 (1.4 ml) was cautiously added, and the reaction was left for reflux overnight at 85°C. The solvent was concentrated and water was added. Three phases were obtained: aqueous, organic and slurry. To the organic phase, which contained mainly di- and mono-esters, carbon tetrachloride was added and placed in a separate funnel. The organic layer was washed with water, then dried over $MgSO_4$ and evaporated. Product was subjected to column chromatography, where di-ester was eluded with dichloromethane and the monoester **6** with ethyl acetate (25 % yield). ^{1}H NMR ($CDCl_3$, 300 MHz): 3.65 (s, 3H), 2.36-2.26 (m, 4H), 1.65-1.56 (m, 4H), 1.39-1.19 (m, 28H).

19-(2-tert-Butoxycarbonylamino-ethylcarbamoyl)-nonadecanoic acid methyl ester (7). *N*-Boc-ethylenediamine (1 mmol, 0.162 g) was coupled with mono-methyl ester **6** (0.84 mmol, 0.3 g) using BOP (0.93 mmol, 0.41 g), HOBt (1.2 mmol, 0.16 g) and DIEA (3.4 mmol, 0.6 ml) in DMF (5 ml) and dichloromethane (20 ml). The mixture was stirred overnight at room temperature. Then the solvent was evaporated and the product was crystallized from acetonitrile to give product **7** (0.3 g,



72 %). ^{1}H NMR (DMSO, 300 MHz): 7.62 (s, 1H), 6.61 (s, 1H), 3.58 (s, 3H), 3.05 (t, 2H), 2.97 (t, 2H), 2.27 (t, 2H), 2.03 (t, 2H), 1.57-1.42 (m, 4H), 1.4-1.33 (m, 9H), 1.32-1.17 (m, 28H). LC-MS: (m/z) Found $[M+1]^+$ = 399.2 (calcd for $C_{28}H_{54}N_2O_5^+$ - $C_5H_9O_2$ (Boc) = 399.3).

19-[2-(2,5-Bis-tert-butoxycarbonylamino-pentanoylamino)-ethylcarbamoyl]-nonadecanoic acid methyl ester (8). Boc-group was removed from **7** (0.54 mmol, 0.27 g) by treating with 1 ml TFA and 3% H_2O, for 1 h at RT. The solvent was evaporated and obtained de-protected amine was coupled with 2,5-Bis-tert-butoxycarbonyl-aminopentanoic acid (0.62 mmol, 0.207 g) using BOP (0.93 mmol), HOBt (1.2 mmol) and DIEA (3.4 mmol, 0.6 ml) in DMF (10 ml) and dichloromethane (10 ml). The mixture was stirred overnight at 40 °C. Then the solvent was evaporated and the product was crystallized from ethyl acetate. The precipitate was filtered off and dried to give solid crystals of compound **8** (0.34 g, 70 %). ^{1}H NMR ($CDCl_3$, 300 MHz): 6.95 (s, 1H), 6.39 (s, 1H), 5.18 (s, 1H), 4.76 (s, 1H), 4.17 (s, 1H), 3.65 (t, 3H), 3.4-3.2 (m, 5H), 3.11-2.99 (m, 1H), 2.28 (t, 2H), 2.15 (t, 2H), 1.87-1.7 (m, 2H), 1.67-1.5 (m, 8H), 1.46-1.38 (m, 18H), 1.34-1.17 (m, 30H). LC-MS: (m/z) Found $[M+1]^+$ = 613.4 (calcd for $C_{38}H_{72}N_4O_5^+$ - $C_5H_9O_2$ (Boc) = 613.4).

(1-{2-[19-[2-(2-Amino-ethylcarbamoyl)-nonadecanoylamino]-ethylcarbamoyl}-4-tert-butoxycarbonylamino-butyl)-carbamic acid tert-butyl ester (9). Methyl ester **8** (0.4 mmol, 0.3 g) was reacted with ethylenediamine (150 mmol 10 ml) for 72 h at 70°C. Then the excess of ethylenediamine was evaporated and water was poured into the reaction flask. Formed precipitate was filtered off to give compound **9** (0.29 g, 93 %). ^{1}H NMR (CD_3OD, 300 MHz): 3.96 (s, 1H), 3.05 (t, 2H), 2.73 (t, 2H), 2.23-2.16 (m, 4H), 1.67-1.5 (m, 8H), 1.46-1.44 (m, 18H), 1.39-1.23 (m, 30H). LC-MS: (m/z) Found $[M+1]^+$ = 741.4 (calcd for $C_{39}H_{76}N_6O_7^+$ = 741.5).

[4-tert-Butoxycabonylamino-4-(2-{19-[2-(2,3,4,5,6-pentahydroxy-hexanoylamino)-ethylcarbamoyl]-nonadecanoylamino}-ethylcabamoyl)-butyl]-carbamic acid tert-butyl ester (10). δ-Gulonic-γ-Lactone (0.23 mmol, 0.04 g) was added to solution of **9** (0.13 mmol, 0.1 g) in 10 ml of methanol. Then, DIEA (1.4 mmol, 0.24 ml) was added and reaction mixture was stirred at 70°C for about 24 h. Solvents were evaporated in vacuo. The obtained compound was crystallized from methanol to give product **10** (0.095 g, 95 %). ^{1}H NMR (CD_3OD, 300 MHz): 4.21 (s,1H), 4.1 (s, 1H), 3.98 (s, 1H), 3.84-3.59 (m, 5H), 3.07 (t, 2H), 2.25-2.12 (m, 4H), 1.68-1.49 (m, 8H), 1.49-1.4 (m, 18H), 1.4-1.21 (m, 30H). LC-MS: (m/z) Found $[M+1]^+$ = 919.6 (calcd for $C_{45}H_{86}N_6O_{13}^+$ = 919.6).

Eicosanedioic acid [2-(2,5-diamino-pentnoylamino)-ethyl]-amide[2-(2,3,4,5,6-pentahydroxy-hexanoylamino)-ethyl]-amide (Orn-C20-G). 40 mg of the Boc-protected product **10** was treated with 0.4 ml TFA and 3 % H2O for clean removal of Boc group to get final compound **Orn-C20-G** (27 mg, 90 %). LC-MS: (m/z) Found $[M+1]^+$ = 719.5 (calcd for $C_{35}H_{71}N_6O_9^+$ = 719.5).

Reagents: (i) Boc_2O, DMF, CH_2Cl_2, 20h (92%); (ii) $SOCl_2$, MeOH, 20h (94%); (iii) BOP, HOBt, DIEA, DMF, CH_2Cl_2, 24h (81%); (iv) TFA, CH_2Cl_2, 1h; (v) BOP, HOBt, DIEA, DMF, CH_2Cl_2, 24h (92%); (vi) $C_2H_8N_2$, 70°C, 72h (96%); (vii) MeOH, DIEA, 70°C, 24h; (viii) TFA, H_2O, 1h (92%).

Scheme S2. Synthesis of **Orn-C8-C12-G.**

8-tert-Butoxycabonylamino-octanoic acid (11). Amino group of 8-Aminooctanoic acid (31.4 mmol, 5 g) was protected by Boc using Di-tert-butyl dicarbonate (34.6 mmol, 7.54 g) in solution of DMF (30 ml) and dichloromethane (40 ml).Then, DIEA (94.2 mmol, 16.38 ml) was added and the reaction mixture was stirred for 20 h at RT. The solvent was evaporated and product was crystallized from dichloromethane. The precipitate was filtered off and dried to give compound **11** (7.5 g, 92 %). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 4.55 (s, 1H), 3.07 (t, 2H), 2.3 (t, 2H), 1.67-1.5 (t, 4H), 1.56-1.37 (t, 9H), 1.37-1.21 (m, 6H).

12-Amino-dodecanoic acid methyl ester (12). Thionyl chloride (103.4 mmol, 7.5 ml) was added drop-wise to 100 ml of methanol at 0 °C and the mixture was stirred for another 20 min. Then, 10 g of 12-aminododecanoic acid (46.5 mmol) was added and reaction mixture was stirred for 20 h at RT. The solvent was evaporated and product was crystallized from heptane to give compound **12** (10 g, 94 %). ^{1}H NMR (DMSO, 300 MHz): δ 7.89 (s, 2H), 3.68 (s, 3H), 2.75 (t, 2H), 2.28 (t, 2H), 1.58-1.15 (m, 18H).

12-(8-tert-Butoxycarbonylamino-octanoylamino)-dodecanoic acid methyl ester (13). Compound **12** (6.5 mmol, 1.5 g) was coupled with **11** (7.2 mmol, 1.87 g) using BOP (7.2 mmol, 3.18 g), HOBt (8.9 mmol, 1.2 g) and DIEA (25.9 mmol, 4.5 ml) in DMF (15 ml) and dichloromethane (30 ml). The reaction mixture was stirred 24 h at RT. Then the solvents were evaporated and product was crystallized from ethyl acetate : heptane (8:2). The precipitate was filtered off and dried to give compound **13** (2.5 g, 81 %). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 5.41 (s, 1H), 4.48 (s, 1H), 3.65 (s, 3H), 3.21 (t, 2H), 3.08 (t, 2H), 2.29 (t, 2H), 2.13 (t, 2H), 1.69-1.15 (m, 39H). LC-MS: (m/z) Found $[M+1]^+$ = 371.2 (calcd for $C_{26}H_{50}N_2O_5^+$ - $C_{10}H_{18}O_4$ (2Boc) = 371.2).

12-[8-(2,5-Bis-tert-butoxycarbonylamino-pentanoylamino)-octanoylamino]-dodecanoic acid methyl ester (14). Boc group of **13** (2.13 mmol, 1 g) was removed in dichloromethane (3 ml) in the presence of 2 ml of TFA for 1 h at RT. The solvent was evaporated and 1 g (2.1 mmol) of the obtained deprotected amine was coupled with 2,5-Bis-tert-butoxycarbonyl amino-pentanoic acid (2.2 mmol, 0.72 g) using BOP (2.4 mmol, 1.04 g), HOBt (2.96 mmol, 0.4 g) and DIEA (8.63 mmol, 1.5 ml) in DMF (5 ml) and dichloromethane (15 ml). The mixture was stirred overnight at RT. Then solvent was evaporated and product **14** (1.3 g, 92 %) was crystallized from acetonitrile. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 6.46 (s, 1H), 5.56 (s, 1H), 5.2 (s, 1H), 4.73 (s, 1H), 4.17 (s, 1H), 3.65 (s, 3H), 3.28-3.04 (m, 6H), 2.28 (t, 2H), 2.13 (t, 2H), 1.66-1.19 (m, 50H). LC-MS: (m/z) Found $[M+1]^+$ = 585.4 (calcd for $C_{36}H_{68}N_4O_8^+$ - $C_{10}H_{18}O_4$ (2Boc) = 585.4).

(1-{7-[11-(2-Amino-ethylcarbamoyl)-undecylcarbamoyl]-heptylcarbamoyl}-4-tert-butoxycarbonylamino-butyl)-carbamic acid tert-butyl ester (15). The methyl ester of **14** (1.75 mmol, 1.2 g) was reacted with ethylenediamine (150 mmol, 10 ml) for 72 h at 70°C. Then the excess of ethylenediamine was evaporated, the water was added and the product **15** was filtered (1.2 g, 96 %). ^{1}H NMR (CD_3OD, 300 MHz): δ 3.99 (s, 1H), 3.28-3.13 (m, 6H), 3.06 (t, 2H), 2.73 (t, 2H), 2.24-2.15 (m, 4H), 1.67-1.28 (m, 50H). LC-MS: (m/z) Found $[M+1]^+$ = 713.4 (calcd for $C_{37}H_{72}N_6O_7^+$ = 713.4).

[4-tert-Butoxycabonylamino-4-(7-{11-[2-(2,3,4,5,6-pentahydroxy-hexanoylamino)-ethylcarbamoyl]-undecylcarbamoyl}-heptylcabamoyl)-butyl]-carbamic acid tert-butyl ester (16). δ-Gulonic-γ-Lactone (0.95 mmol, 0.17 g) was added to solution of **15** (0.56 mmol, 0.4 g) in 30 ml of methanol. Then, DIEA (5.64 mmol, 0.98 ml) was added and the reaction mixture was stirred at 70°C for about 24 h. Solvents were evaporated in vacuo. The obtained compound was crystallized from methanol to get product **16** (0.15 g, 88 %). ^{1}H NMR (DMSO, 300 MHz): δ 7.83-7.61 (m, 4H), 6.8-6.64 (m, 2H), 5.35 (d, 1H), 4.57-4.26 (m, 5H), 4.0-3.75 (m, 3H), 3.61-3.38 (m, 6H), 3.22-2.81 (m, 11H), 2.06-1.95 (m, 4H), 1.54-1.37 (m, 10H), 1.36-1.32 (m, 18H), 1.31-1.11 (m, 24H). LC-MS: (m/z) Found $[M+1]^+$ = 891.6 (calcd for $C_{43}H_{82}N_6O_{13}^+$ = 891.6).

12-[8-(2,5-Diamino-pentanoylamino)-octanoylamino]-dodecanoic acid[2-(2,3,4,5,6-pentahydroxy-hexanoylamino)-ethyl]-amide (Orn-C8-C12-G). Boc group of **16** was removed from 0.1 g (0.11 mmol) of the compound using 1 ml TFA and 3% of H2O to afford the final product **Orn-C8-C12-G** (0.095 g, 92 %). MS: (m/z) Found $[M+1]^+$ = 691.5 (calcd for $C_{33}H_{67}N_6O_9^+$ = 691.5). MS: (m/z) Found $[M+1]^+$ = 691.5 (calcd for $C_{33}H_{67}N_6O_9^+$ = 691.5).

2. 1,8-ANS fluorescence data.

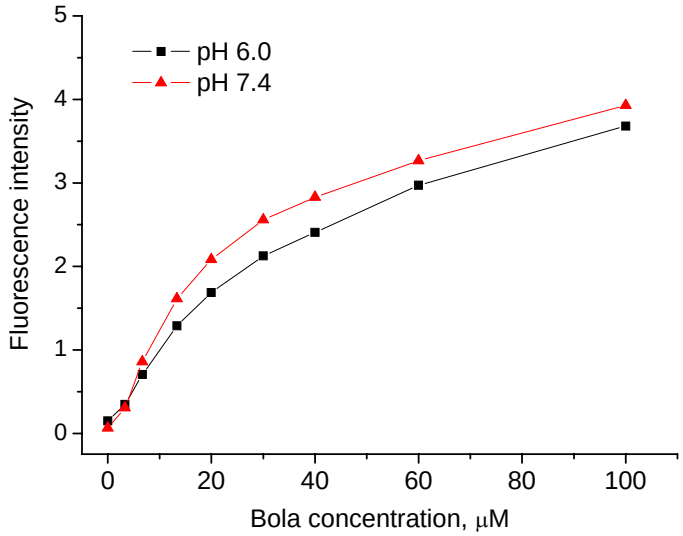


Fig. S1. Fluorescence intensity of 1,8-ANS (50 nM) as a function of Orn-C20-G bola concentration at two different pH.

3. Gel electrophoresis data.

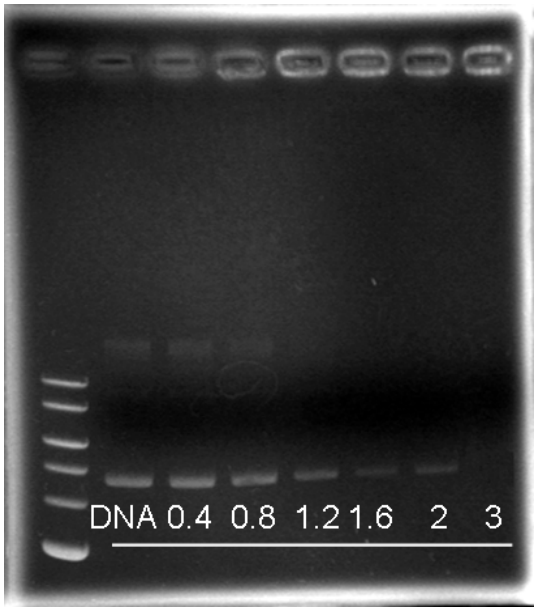

Fig. S2. Agarose gel electrophoresis (0.9%) of Orn-C16-G/DOPE (1:1) mixture complexed with pDNA at different N/P ratios. Bands at the left of the gel correspond to 10 kbp DNA ladder.

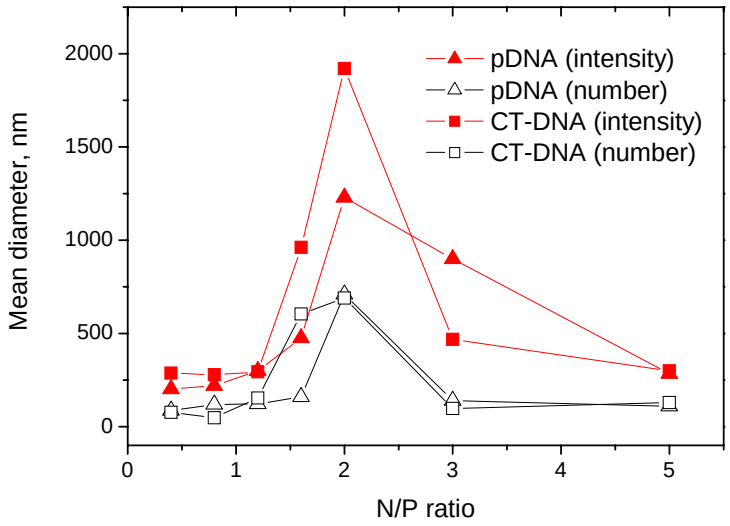
4. DLS data



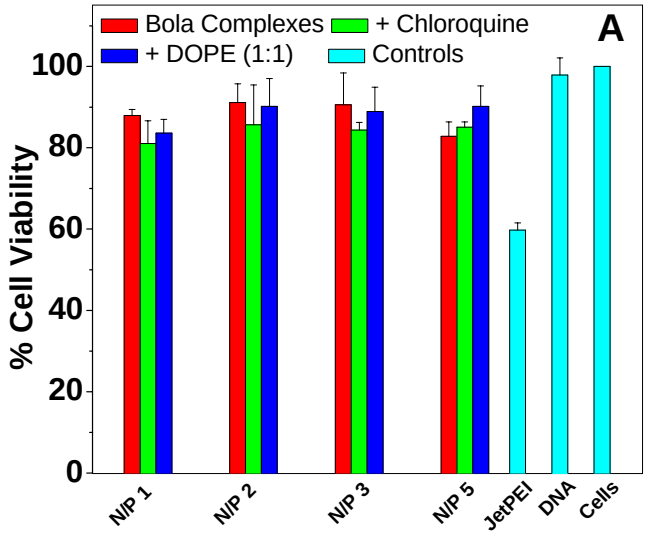


Fig. S3. Mean diameters as measured by DLS of Orn-C16-G complexes with pDNA (triangle) and CT-DNA (square) at different N/P ratios. The experiments were performed in MES buffer (pH 7.4) by addition of increasing quantities of bola stock solution (in DMF/water) to pDNA solution. Each measurement was proceeded 5 min after each addition of bola aliquot. Mean diameters are presented based on statistics of scattered intensity (filled symbols) and particle number (open symbols).

5. Cytotoxicity and total protein assays.

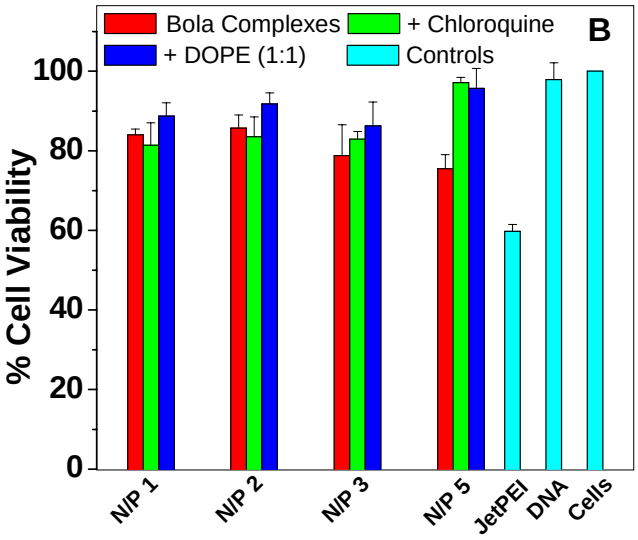

Fig. S4. Total protein concentration from the transfection experiments in COS-7 cells for **Orn-C16-G** (A) and **Orn-C20-G** (B) bolas. The data are normalized to 100% for the control non-treated cells. Cells were incubated in serum-free Opti-MEM with a bolaplex composed of plasmid DNA (1 μg per well), bola and DOPE (when indicated) at pH 7.4. Different N/P ratios were tested. After 3 h, the transfection medium was replaced with fresh complete culture medium, and cells were cultured for an additional 45 h. When indicated the medium contained 100 μM chloroquine. Then cells were lysed and the total protein was estimated using BC assay.

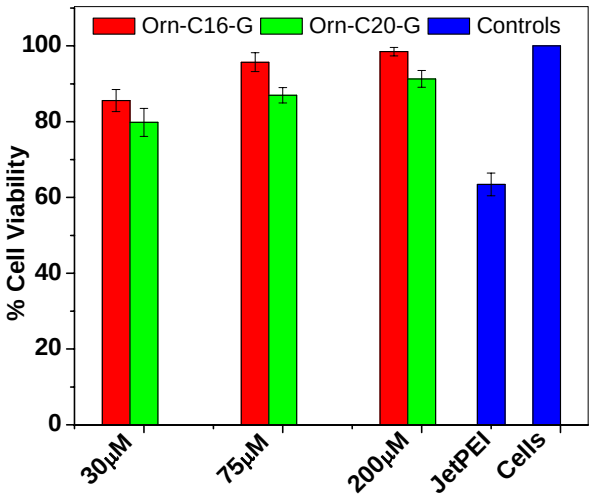

Fig. S5. Cytotoxicity of bolas based on MTT assay. COS-7 cells were incubated for 48 h with the bolas (as described in Fig. S1) at the mentioned concentrations or with JetPEI (150 μM, expressed as concentration of nitrogen residues).

Received July 28, 2010; Revised Manuscript Received September 20, 2010

Previously, we successfully conjugated galactosylated poly(ethylene glycol) (Gal-PEG) to oligonucleotides (ODNs) via an acid labile ester linker (Zhu et al., *Bioconjugate Chem.* **2008**, *19*, 290−8). In this study, sense strands of siRNA were conjugated to Gal-PEG and mannose 6-phosphate poly(ethylene glycol) (M6P-PEG) for targeted delivery of siRNAs to hepatocytes and hepatic stellate cells (HSCs), respectively. These siRNA conjugates were purified by ion exchange chromatography and verified by gel retardation assay. To evaluate their RNAi functions, the validated siRNA duplexes targeting firefly luciferase and transforming growth factor beta 1 (TGF-β1) mRNA were conjugated to Gal-PEG and M6P-PEG, and their gene silencing efficiencies were determined after transfection into HepG2 and HSC-T6 cells. The disulfide bond between PEG and siRNA was cleaved by dithiothreitol, leading to the release of intact siRNA. Both Gal-PEG-siRNA and M6P-PEG-siRNA conjugates could silence luciferase gene expression by about 40% without any transfection reagents, while the gene silencing effects reached more than 98% with the help of cationic liposomes at the same dose. Conjugation of TGF-β1 siRNA with Gal-PEG and M6P-PEG could silence endogenous TGF-β1 gene expression as well. In conclusion, these siRNA conjugates have the potential for targeted delivery of siRNAs to hepatocytes and hepatic stellate cells for efficient gene silencing in vivo.

INTRODUCTION

Significant progress has been made in enhancing the potency and specificity of RNA interference (RNAi) molecules, which include double-stranded RNA (dsRNA), small interfering RNA (siRNA) (19−23 base pairs), short hairpin RNA (shRNA), and micro RNA (miRNA). Although they are structurally different, all of these molecules induce sequence-specific gene silencing by either degrading or inhibiting the target mRNA via perfect or mismatched binding in the presence of RNA-induced silencing complex (RISC) (*1, 2*). The simplest and most effective strategy of gene silencing is to synthesize siRNAs based on the target mRNA sequence. siRNA has been shown to have the potential to treat numerous diseases, including cancer, fibrosis, genetic disorders, and viral infection (*3*−*5*). However, siRNAs have not been successfully used as clinical therapeutics due to several obstacles, including the poor enzymatic stability, short circulation time in the bloodstream, nonspecific tissue or cell targeting, and insufficient intracellular transport (*6*).

Various cationic lipids and polymers are being used as transfection reagents for siRNA delivery. siRNAs could be condensed by these carriers via electrostatic interaction into nanosized particles which are easy for cells to take up via endocytosis, membrane fusion, or both. After complex formation, siRNAs are protected from enzymatic digestion (*7*). However, cationic carriers are not suitable for in vivo delivery of siRNAs since they may bind to negatively charged serum proteins and undergo aggregation resulting in undesired distribution, and induction of inflammatory cytokines release and activation of the complement system (*8, 9*).

PEGylation is known to increase the in vitro and in vivo stability of drug molecules, as well as improve their pharmacokinetic profiles. We previously reported that the conjugation of galactose (*10*)−poly(ethylene glycol) (PEG) to oligonucleotide (ODN) using an acid-labile ester linker successfully stabilized ODN, prolonged its circulation time, and specifically delivered ODN to hepatocytes after systemic administration (*11*). The linkage between ODN and PEG could be cleaved at pH 5.5 (endosomal pH), and free ODN could be released. In a separate study, we have also demonstrated that mannose-6-phosphate (M6P) as a ligand could significantly increase the accumulation of ODN in hepatic stellate cells (HSCs) in rats.

Here, we used a similar strategy to Gal-PEG-ODN conjugate to design two siRNA conjugates, Gal-PEG-siRNA and M6P-PEG-siRNA, for targeted delivery of siRNAs to hepatocytes via asialoglycoprotein receptor-mediated endocytosis and HSCs via M6P/insulin-like growth factor-II receptor (M6P/IGF2R) mediated endocytosis, respectively. In this study, the heterobifunctional PEG, (*ortho*-pyridyl) disulfide−poly(ethylene glycol)−*N*-hydroxysuccinimidyl ester (OPSS-PEG-NHS), was used as a backbone followed by modification with either Gal or M6P at its NHS end and with the 3′-sense strand of siRNA at its OPSS end via disulfide bond. To make sure there is no loss in gene silencing due to bioconjugation, Luciferase siRNA and TGF-β1 siRNA were used as model siRNA sequences.

MATERIALS AND METHODS

Materials. OPSS-PEG-NHS (MW: 3400 Da) was purchased from Creative PEGWorks (Winston Salem, NC). Palladium (10 wt % on activated carbon), thiophosgene, dithiothreitol (DTT), L-glutathione (GSH) reduced, *p*-aminophenyl β-D-galactopyranoside, ethidium bromide (EtBr), *p*-nitrophenyl-α-D-mannopyranoside, dimethylformamide (DMF), and deuterium oxide (D_2O) were purchased from Sigma-Aldrich Chemicals (St. Louis, MO). Sodium chloride, acetic acid, and HPLC-grade water were purchased from Fisher Scientific (Fair Lawn, NJ). Luciferase assay kit, TE buffer, 6× gel loading buffer, and Tris-hydrochloride were purchased from Promega (Madison, WI).

Human/mouse TGF-β1 ELISA kit was purchased from eBioscience (San Diego, CA). Dialysis tubing (MWCO 1000 Da) was purchased from Spectrum Laboratories, Inc. (Houston, TX). Zeba Spin Desalting Columns (MWCO: 7000 Da) was purchased from Thermo Scientific (Rockford, IL). Dulbecco's modified Eagle's medium (DMEM), penicillin streptomycin solution (100×), phosphate buffered saline (PBS), trypsin-EDTA, agarose, and Lipofectamine 2000 were purchased from Invitrogen Corporation (Carlsbad, CA). Bovine serum albumin (BSA) (fraction V, purity >98%) was purchased from Atlanta Biologicals (Lawrenceville, GA). Pyridinium cationic liposomes containing pyridinium lipid (C16:1, amide linker, trans)/DOPE (1:1 mol/mol) cationic liposomes were prepared by Zhu et al. (*12*).

Small Interfering RNAs (siRNAs). Luciferase siRNA (sense strand: CUUACGCUGAGUACUUCGA[dT][dT], antisense strand: UCGAAGUACUCAGCGUAAG[dT][dT]) was purchased from Invitrogen Corporation. TGF-β1 siRNA (*13*) (sense strand: GCUGUACAUUGACUUUAGG[dT][dT], antisense strand: CCUAAAGUCAAUGUACAGC[dT][dT]) (Accession no.: NM_021578) and the scramble siRNA were purchased from Invitrogen Corporation (Carlsbad, CA). For conjugation purposes, the sense strand of the siRNA was modified with a thiol group (-$(CH_2)_3$-S-S-$(CH_2)_3$-OH-3′) at its 3′ end by Invitrogen Corporation.

Methods. *Synthesis of p-Aminophenyl β-D-Galactopyranoside and p-Aminophenyl-6-phospho-α-D-mannopyranoside. p*-Aminophenyl β-D-galactopyranoside was synthesized according to our previous study (*11*). Briefly, p-nitrophenyl β-D-galactopyranoside was reduced with 10% palladium on activated carbon under hydrogen (1 atm) in a 1:1 (v/v) ethanol−water mixture for 2 h. The product, *p*-aminophenyl β-D-galactopyranoside, was concentrated by solvent evaporation and characterized by ^{1}H NMR and mass spectrometry after dissolving in D_2O.

p-Aminophenyl-6-phospho-α-D-mannopyranoside was synthesized according to our previous study (*14*) by dissolving *p*-nitrophenyl-α-D-mannopyranoside (pnpM) (0.3 g, 1 mmol) in the mixture of acetonitrile, pyridine, and water (1/0.4/0.04, v/v/v). Phosphorus oxide chloride (0.4 mL, 4.4 mmol) was added and stirred for 1 h on an ice−water bath. The reaction mixture was poured onto 20 g of ice. After the ice melted, pH was adjusted to 7.0 by slowly adding 2.5 M NaOH, and the solution was evaporated to dryness. The solid material was dissolved in water and crystallized at 4 °C overnight. The crystals were filtered and washed with 5 mL of absolute ethanol. The compound was recrystallized in a mixture of 1 mL of water and 10 mL of ethanol, redissolved in water, and lyophilized to give *p*-nitrophenyl-6-phospho-α-D-mannopyranoside (pnpM6P). PnpM6P was reduced with 100 mg of 10% palladium on activated carbon under H_2 (1 atm) in a 4:1 (v/v) methanol−water mixture for 2 h. After filtration, the residue was redissolved in water and lyophilized to give *p*-aminophenyl-6-phospho-α-D-mannopyranoside (papM6P). The product was characterized using ^{1}H NMR and mass spectrometry.

Synthesis of Gal-PEG-OPSS and M6P-PEG-OPSS. OPSS-PEG-NHS (50 mg) and *p*-aminophenyl β-D-galactopyranoside (50 mg) were dissolved separately in 0.4 mL of dimethylformamide (DMF), mixed together, and stirred for 6 h at room temperature under N_2 protection in the dark. The reaction mixture was dialyzed against distilled water for 48 h with MWCO 1000 to remove the unreacted *p*-aminophenyl β-D-galactopyranoside. The product Gal-PEG-OPSS was freeze−dried and characterized by ^{1}H NMR after dissolving it in D_2O.

OPSS-PEG-NHS (50 mg) were dissolved in 0.4 mL of DMF, and papM6P (50 mg) was dissolved in 0.4 mL of distilled water. Then, they were mixed and stirred for 6 h at room temperature under N_2 protection in the dark. The reaction mixture was dialyzed against distilled water for 48 h with MWCO 1000 to remove the unreacted papM6P. The product M6P-PEG-OPSS was freeze−dried and characterized by ^{1}H NMR after dissolving it in D_2O.

Synthesis of Gal-PEG-siRNA and M6P-PEG-siRNA. The lyophilized 3′ thiol-siRNA was reconstituted in TE buffer of pH 8.3−8.5 at a concentration of approximately 100 A260 units/mL. siRNA solution was then treated with 0.1 M dithiothreitol (DTT) aqueous solution at room temperature for 30 min. The excess DTT was removed by gel filtration and 3′-sulfhydryl siRNA was stored under N_2 to avoid oxidative dimerization to the disulfide before conjugation. 3′-Sulfhydryl siRNA and Gal-PEG-OPSS (or M6P-PEG-OPSS) were dissolved in 0.5 mL PBS (pH7.5) at a molar ratio of 1:100, and stirred under nitrogen at room temperature for 6 h. The reaction mixture was analyzed and purified by ion exchange high-performance liquid chromatography, which was carried on a Resource Q ion exchange column (GE Healthcare Life Sciences, Piscataway, NJ) by an HPLC system (Waters, Milford, MA) with detection at 260 nm using a gradient starting from 0% B to 80% B (A, 20 mM Tris-HCl buffer; B, 20 mM Tris-HCl buffer containing 0.1 M sodium chloride) at a flow rate of 1 mL/min at 25 °C. The purified Gal-PEG-siRNA and M6P-PEG-siRNA were desalted using Zeba Spin Desalting Column by centrifugation at the speed of 2000 *g* and freeze−dried.

Characterization of Gal-PEG-siRNA and M6P-PEG-siRNA. The concentrations of siRNA and siRNA conjugate solutions were quantitated by a UV spectrophotometer. To determine the cleavage of the disulfide bond and siRNA dissociation from Gal-PEG-siRNA and M6P-PEG-siRNA, 2 μg siRNA and the conjugates containing 2 μg siRNA were incubated in 50 mM DTT aqueous buffer for 40 min at room temperature. The DTT-treated samples and controls (nontreated siRNA and siRNA conjugate) were mixed with 6× gel loading buffer and applied on the 1% agarose gel and run at 10 V/cm for 60 min at room temperature followed by ethidium bromide (EtBr) staining and visualization under UV light.

Cell Cultures and Transfections. HepG2 cells were maintained in a complete growth medium containing DMEM medium supplemented with 10% FBS, 100 IU/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a 5% CO_2 humidified atmosphere. HSC-T6 cells, kindly provided by Dr. Scott Friedman (Mount Sinai School of Medicine, New York), were maintained in the same condition as HepG2 cells. Before transfection, the cells were seeded in 24-well plates and maintained in 0.5 mL of complete growth medium at 37 °C for 24 h. The cell number was about 4×10^4 cells per well.

Luciferase expression plasmid (pDNA3-Luc) was first transfected with cells by pyridinium cationic liposomes (*12*). Briefly, 0.2 μg/well luciferase plasmid and pyridinium cationic liposomes were diluted to 25 μL by Opti-MEM I medium, respectively, and incubated for 5 min at room temperature. Lipoplexes were prepared by mixing plasmid and liposomes in equal volume and incubated for 20 min at room temperature to allow complex formation. Immediately before transfection, the medium was removed, and cells were washed gently with sterile phosphate buffered saline. Lipoplexes were added to each well and diluted to 0.5 mL by Opti-MEM I medium, and the plate was incubated under 5% CO_2 at 37 °C for 6 h. Following transfection, the culture medium was replaced with complete growth medium and maintained overnight before further treatment.

To transfect luciferase siRNA and its conjugate, two methods were used. In the first method, siRNA and its conjugates were added directly into cell cultures without the assistance of cationic liposomes. In the second method, siRNA and its conjugates were mixed with cationic liposomes to form the lipoplexes before

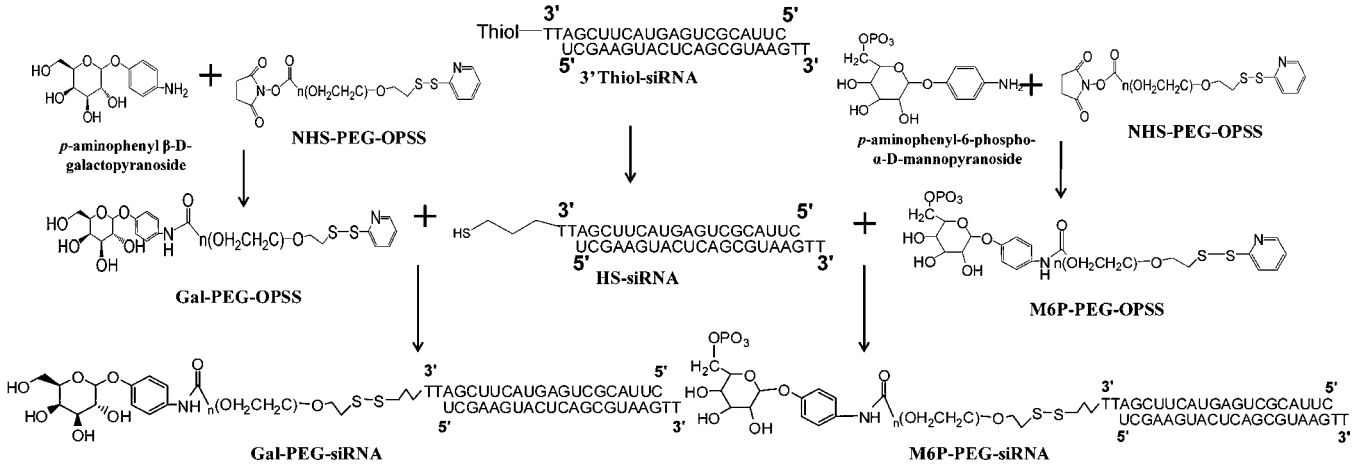

Figure 1. Synthesis scheme of Gal-PEG-siRNA and M6P-PEG-siRNA.

adding into cell cultures. After 6 h of transfection, the medium was replaced with the complete growth medium and incubated for an additional 42 h.

To determine luciferase gene expression, the cells were collected and lysed. The cell lysate was measured for luciferase gene expression by Luciferase Assay Kit (Promega, Madison, WI). The total protein concentration was measured by bicinchoninic acid (BCA) protein assay reagent (Pierce, Rockford, IL). Luciferase activity was normalized by the total protein content and expressed as relative light unit (RLU) per microgram of protein (RLU/μg protein).

To determine their gene silencing effects, TGF-β1 siRNA and its conjugates were mixed with the media and added into HepG2 cells and HSC cells. After 6 h of transfection, the medium was replaced with the complete growth medium and incubated for additional 42 h. To determine TGF-β1 gene expresstion, the supernatant was collected and measured by Human/Mouse TGF-β1 ELISA kit.

RESULTS

Synthesis of Gal-PEG-siRNA and M6P-PEG-siRNA. The synthesis scheme of Gal-PEG-siRNA and M6P-PEG-siRNA was shown in Figure 1. Before conjugation, *p*-nitrophenyl β-D-galactopyranoside was reduced to *p*-aminophenyl β-D-galactopyranoside. ESI-MS and ^{1}H NMR spectra of this intermediate product were not shown but could be found in our previous paper (*11*). *p*-Nitrophenyl-α-D-mannopyranoside (pnpM) was phosphorylated to *p*-nitrophenyl-6-phospho-α-D-mannopyranoside (pnpM6P) and pnpM6P was reduced to *p*-aminophenyl-6-phospho-α-D-mannopyranoside (papM6P). ESI-MS and ^{1}H NMR results of this intermediate product are shown in Figure 2.

Gal-PEG-OPSS and M6P-PEG-OPSS were synthesized from heterofunctional PEG derivative, NHS-PEG-OPSS and identified by ^{1}H NMR. After reaction with Gal or M6P, the two peaks (a and b positions) of the benzene ring were found in the NMR spectra. The data indicated that Gal and M6P reacted with NHS group and linked with PEG (Figure 3). Gal-PEG-OPSS and M6P-PEG-OPSS were then conjugated to 3′-sulfhydryl siRNA by disulfide exchange reaction between sulfhydryl and OPSS groups. Ion exchange HPLC was used to monitor the conjugation reaction and purify the final products. The ion exchange HPLC chromatograms of siRNA, M6P-PEG-OPSS, and M6P-PEG-siRNA were shown in Figure 4. M6P-PEG-OPSS eluted first, since they have no charge and cannot bind to anion exchange resin; free siRNA is a negatively charged molecule and bound to anion exchange resin and eluted last. After conjugation, the charge of siRNA was partially blocked by the flexible long chain of PEG and eluted between PEG and siRNA. The chromatograms of Gal-PEG-OPSS and Gal-PEG-siRNA were not shown, since they are similar to those of M6P-PEG-OPSS and M6P-PEG-siRNA. Gal-PEG-siRNA and M6P-PEG-siRNA conjugates were also identified by 1% agarose gel electrophoresis and visualized under UV light (Figure 5).

Dissociation of siRNAs from Gal-PEG-siRNA and M6P-PEG-siRNA Conjugates. To determine whether the disulfide bond between Gal-PEG or M6P-PEG and siRNA is cleavable and free siRNA can be released, siRNA and its conjugates were treated with DTT aqueous buffer for 40 min and analyzed by gel retardation assay. Gal-PEG-siRNA and M6P-PEG-siRNA conjugates migrated more slowly than free siRNA. However, after treatment with DTT for 40 min, the disulfide bond was completely cleaved and free siRNA was released and migrated at the same speed as the siRNA control (Figure 5).

Gene Silencing Study. Firefly luciferase expression plasmid was transfected into both HepG2 and HSC-T6 cells using previously optimized pyridinium cationic liposomes at the charge ratio of 3:1 (N/P) (*12*). Gene silencing efficiencies of siRNA conjugates were determined after transfection of luciferase expression plasmid. In the absence of cationic liposomes, Gal-PEG-siRNA conjugate showed luciferase gene silencing up to about 45% at the dose of 400 nM compared to the naked siRNA group and the control group (plasmid group) without siRNA treatment (Figure 6A). Addition of an excessive amount of Gal-PEG-OPSS into HepG2 cells before transfection of siRNA conjugate abolished the gene silencing ability of Gal-PEG-siRNA conjugate. Similarly, pretreatment of HSC-T6 cells with an excess amount of M6P-PEG-OPSS before the transfection of M6P-PEG-siRNA conjugate abolished the gene silencing ability of this conjugate. Target cells were pretreated with an excess amount of Gal-PEG-OPSS or M6P-PEG-OPSS to saturate the surface receptors and inhibit the receptor-mediated cellular uptake of siRNA conjugates. Since the molecular weights of galactose or mannose 6-phosphate are too small and may not be effective in saturating the target receptors, the conjugates containing the ligands are commonly used (*11*). To keep data comparable, we used 400 nM siRNA conjugates in Gal-PEG+ conjugate and M6P-PEG+conjugate groups.

Figure 6B showed the luciferase gene silencing efficiency of siRNA and Gal-PEG-siRNA. After complex formation with pyridinium cationic liposomes, the gene silencing of Gal-PEG-siRNA significantly increased and reached up to 90% even at the dose of 100 nM, while the gene silencing effect of luciferase siRNA was just about 60% at the same dose. Figure 6C showed the gene silencing ability of M6P-PEG-siRNA in HSC-T6 cells without pyridinium cationic liposomes. M6P-PEG-siRNA could

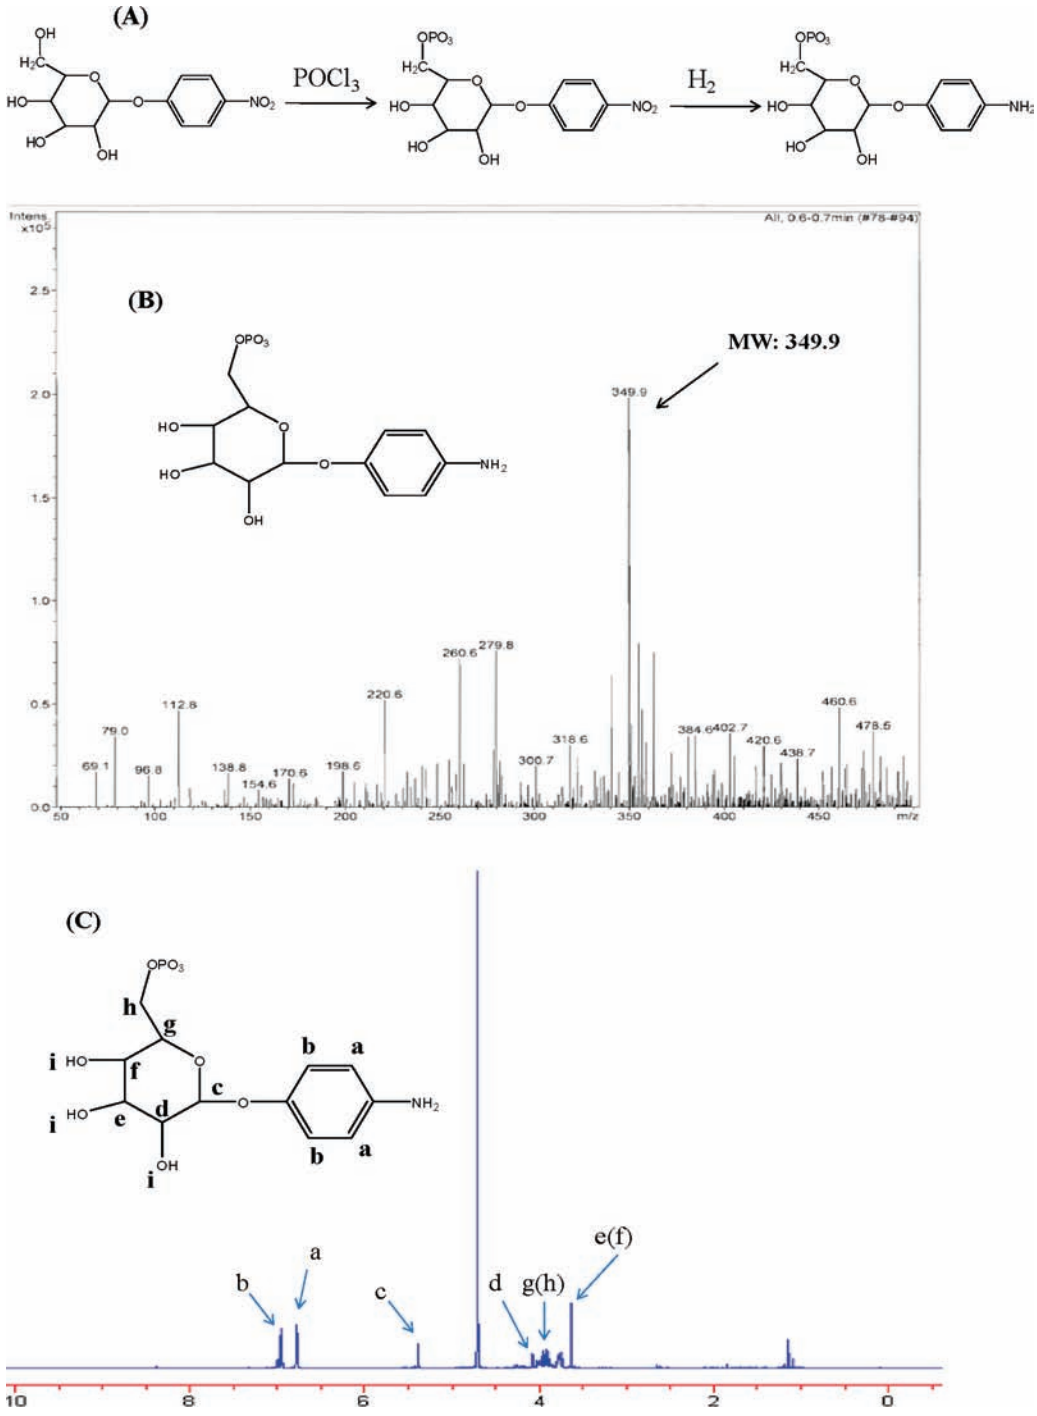

Figure 2. Synthesis and characterization of *p*-aminophenyl-6-phospho-α-D-mannopyranoside with ESI-MS and ^{1}H NMR. (A) Synthesis scheme of *p*-aminophenyl-6-phospho-α-D-mannopyranoside. (B) Electron spray ionization mass spectra were obtained after dissolving the product in a 4:1 (v/v) methanol−water mixture on an ESQUIRE-LC ion trap LC/MS sy stem in negative mode. (C) For ^{1}H NMR, samples were dissolved in D_2O, and the spectra were recorded on a Bruker ARX-500 MHz NMR spectrometer at 25 °C.

silence luciferase gene expression at a similar level to Gal-PEG-siRNA. Luciferase gene silencing was dependent on Gal-PEG-siRNA and M6P-PEG-siRNA dose in both the absence and presence of pyridinium cationic liposomes.

To determine the effect of bioconjugation on TGF-β1 gene silencing in HepG2 and HSC-T6 cells, the sense strand of a potent TGF-β1 siRNA duplex was conjugated with either Gal-PEG-OPSS or M6P-PEG-OPSS to form TGF-β1 siRNA conjugates. After transfection, the level of TGF-β1 protein in the cell medium was measured by ELISA kit. The gene silencing effects of siRNA conjugates were shown in Figure 7. Without transfection reagents, conjugation of TGF-β1 siRNA with Gal-PEG-OPSS or M6P-PEG-OPSS significantly enhanced TGF-β1 gene silencing effects up to 40% of the nontreatment group compared to TGF-β1 siRNA.

DISCUSSION

Effective delivery of siRNA to specific cell types in vivo is critical for the successful therapeutic use of siRNA. The current studies of siRNA delivery systems are focused on the electrostatic interaction with cationic liposomes and polymers, since negatively charged siRNAs are poorly taken up by the cells. Although the use of these cationic carriers is effective in vitro, an ideal siRNA carrier should not bear any positive charge, since

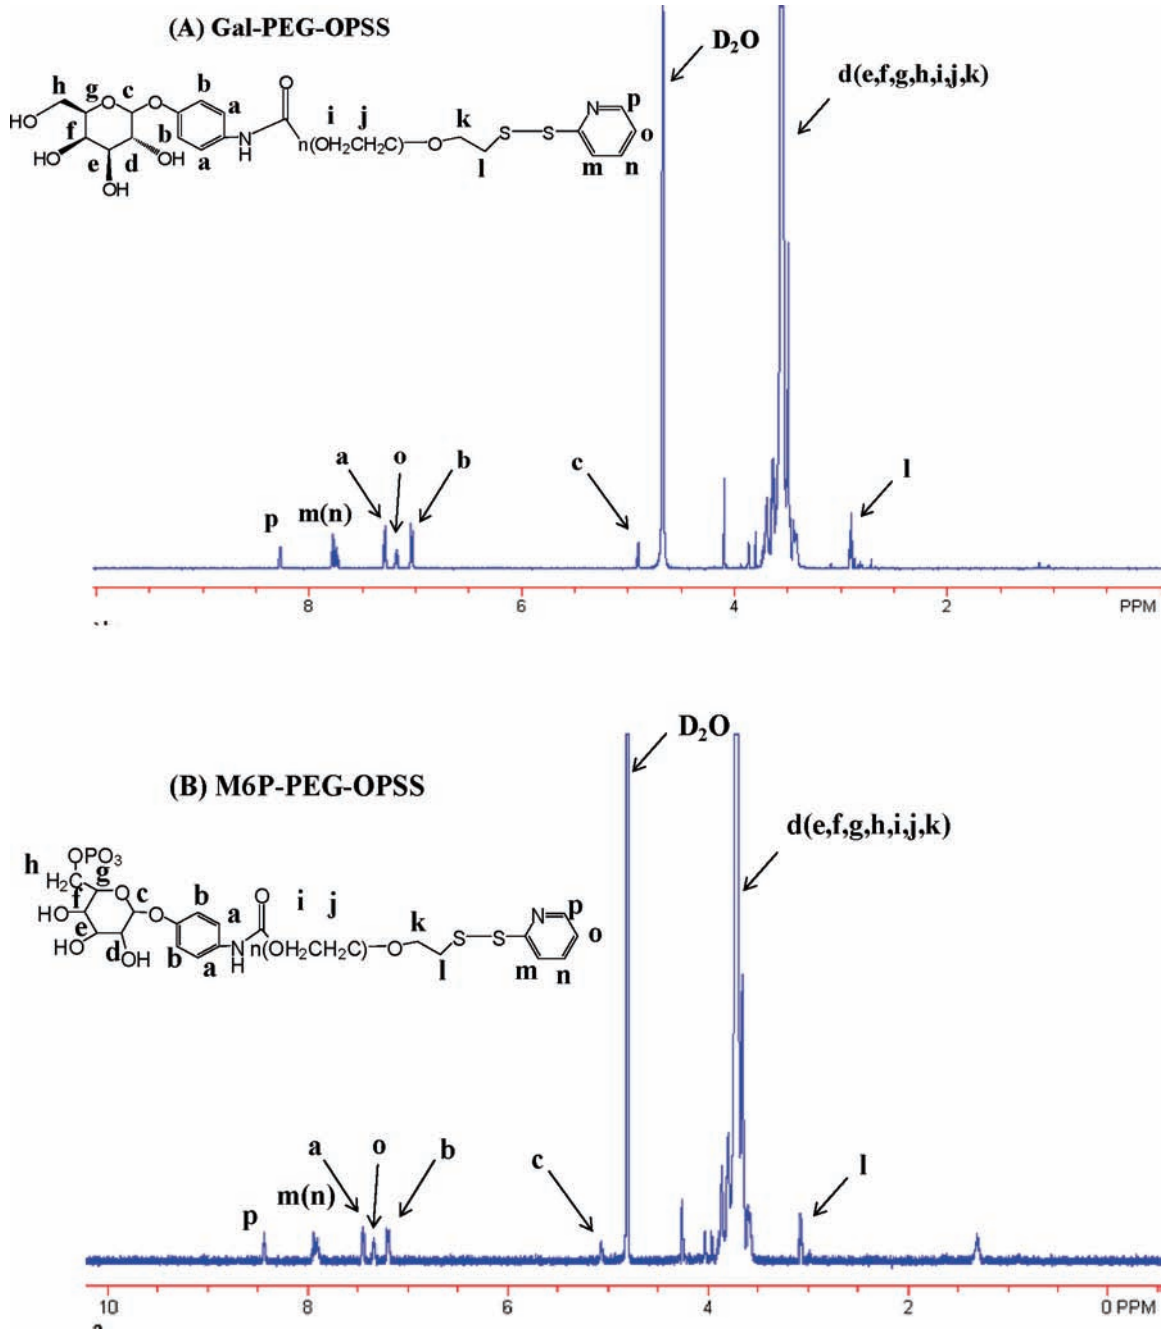

Figure 3. Characterization of Gal-PEG-OPSS (A) and M6P-PEG-OPSS (B) with ^{1}H NMR. The samples were dissolved in D_2O, and the spectra were recorded on a Bruker ARX-500 MHz NMR spectrometer at 25 °C.

it may cause an immune response and unexpected distribution due to nonspecific ionic interaction with plasma proteins. To avoid the use of polycations, Rajue et al. directly conjugated asialoglycoprotein to ODNs via disulfide bonds to target hepatocytes (*15*). Nakagawa et al. directly conjugated the small-molecule ligand, anisamide, to ODNs, to target the σ receptor on the surface of human lung cancer cells (*16*). The lipophilic molecule, α-tocopherol, was also covalently conjugated to the antisense strand of siRNA to target the liver (*17*). Although direct conjugation of ligands to ODN or siRNA increased their targeting efficiencies, it might not significantly improve the stability or dissociation of loaded ODN and siRNA. PEGylation is known to significantly enhance the stability of ODNs and siRNAagainst exonucleases and reduce renal clearance compared to unmodified ones (*18*−*20*), which improves their bioactivity by increasing plasma residence time and decreasing nuclease degradation. The flexible PEG chains also shield the inherent negative charge of these ODNs and siRNA, thereby possibly facilitating cellular uptake of the conjugated ODNs and siRNA (*21*).

Oligonucleotides and siRNA are cleared rapidly from the blood circulation and accumulated in the peripheral tissues, especially in the liver and kidney (*22*−*24*). Their in vivo activity depends on their pharmacokinetic profiles, especially the rate of excretion and degradation. In a previous study, we successfully conjugated ODN to Gal-PEG via an acid-labile linkage and demonstrated that systemic administration of Gal-PEG-ODN significantly increased accumulation in hepatocytes via galactose/asialoglycoprotein receptor-mediated endocytosis (*11*). In a separate study, we synthesized M6P-BSA and conjugated this to ODN. Systemic administration of M6P-BSA-ODN conjugate increased the accumulation of ODNs in HSCs via M6P/IGF2R mediated endocytosis compared to other types of liver cells in rats (*14*).

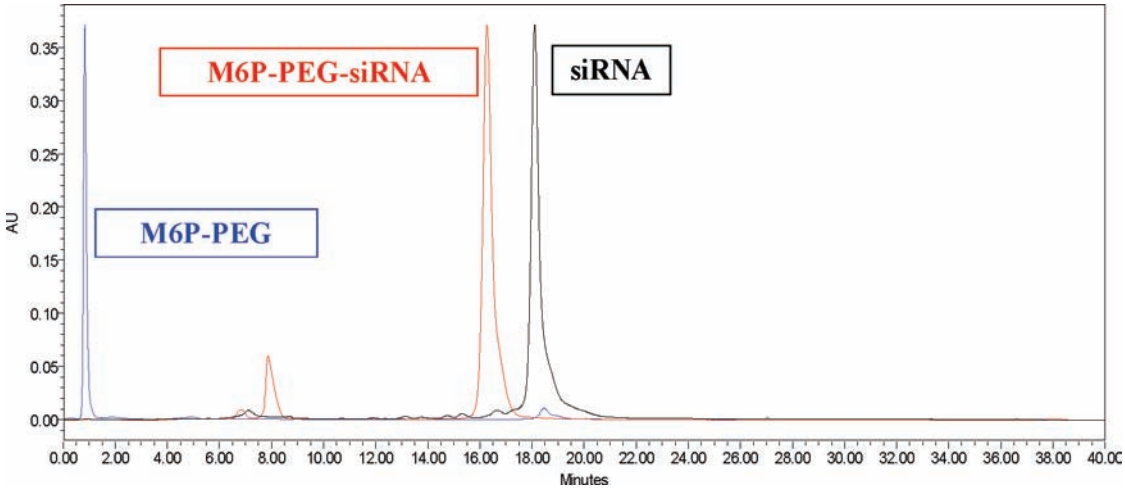

Figure 4. Purification of M6P-PEG-siRNA conjugate by ion-exchange chromatography. The reaction mixture was carried on a Resource Q ion exchange column (GE Healthcare Life Sciences, Piscataway, NJ) by an HPLC system (Waters, Milford, MA) with detection at 260 nm using a gradient starting from 0% B to 80% B (A, 20 mM Tris-HCl buffer; B, 20 mM Tris-HCl buffer containing 0.1 M sodium chloride) at a flow rate of 1 mL/min at 25 °C.

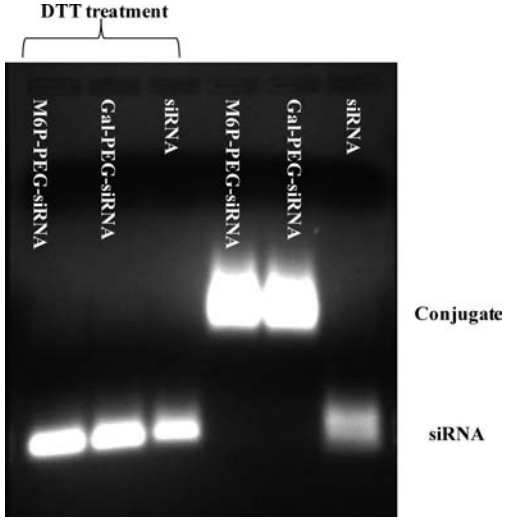

Figure 5. Identification of siRNA conjugates by gel retardation assay. Two microgram aliquots of siRNAs, Gal-PEG-siRNA, and M6P-PEG-siRNA were incubated with 50 mM DTT at room temperature for 40 min. The treated samples and nontreated controls were applied on 1% agarose gel and run at 10 V/cm for 60 min followed by EtBr staining, then visualized under UV light.

siRNAs can be covalently linked with functional molecules via either noncleavable or cleavable linkages, such as acid-labile ester (*11, 25*) and reducible disulfide bond (*19, 26*). For single-stranded ODNs, both 3′- and 5′-termini of these molecules are reported to be used as functional sites for the conjugation reaction (*11, 27*). For the siRNA duplex, however, the antisense strand of siRNA plays a key role and works as the template in RISC to perform RNAi. Improper modification of antisense strands may cause the loss of RNAi function (*28*). It was further shown that the 5′-terminus of the antisense strand was more important than the 3′-terminus and determined RNAi activity (*29*−*31*). In comparison to the antisense strand, manipulation of the sense strand of siRNA is relatively safe and effective. Both 3′- and 5′-ends of the sense strand can be used for conjugation (*32*).

In the present study, we investigated the application of a PEG-based macromolecular delivery system using two different ligands for siRNA delivery. Since the disulfide bond has been proven to be cleaved by reducing agents in the cytoplasm and was extensively used in drug delivery systems (*19, 33*−*35*), we used cleavable disulfide bonds as the linkage between siRNA and PEG to ensure the release of intact siRNA molecules from the conjugates in the reducing environment in the cytoplasm where RNAi takes action after endocytosis. This is expected to be better than the use of PEGylated cationic liposomes and PEI, where the PEG chain may influence the endosomal escape, as the PEG chain often cannot be released from the carriers.

Chronic liver injury and inflammation of hepatocytes or other hepatic cells cause liver fibrosis, resulting in excessive accumulation of extracellular matrix (ECM) proteins and activation and transformation of HSCs to proliferative myofibroblast-like cells. Many inflammatory cytokines were up-regulated during liver fibrosis. Among them, TGF-β1, which is mainly expressed by HSCs, plays a key role in initiation and maintenance of liver fibrosis (*36*). TGF-β1 gene silencing has been shown to inhibit the ECM production as well as accelerate its degradation resulting in resolution of fibrogenesis (*37*). In our previous study, we demonstrated siRNA sequence and dose-dependent TGF-β1 gene silencing and consequent inhibition of collagen synthesis (*13*). Therefore, hepatocytes and HSCs are often chosen as targets to deliver the therapeutics to treat liver fibrosis. Excessive ECM causes the loss of sinusoidal fenestrae (*38*), suggesting that liposomal and other particulate delivery systems may not be suitable for siRNA delivery to hepatic cells. In comparison to particulate delivery systems, the water-soluble delivery systems, Gal-PEG-siRNA and M6P-PEG-siRNA, are much more attractive for siRNA delivery to hepatocytes and HSCs in fibrotic liver. In this study, the 3′-thiol modifier was first reduced to a 3′-sulfhydryl group, which was active and could form a disulfide bond with an (*ortho*-pyridyl)-disulfide (OPSS) group by disulfide exchange reaction in PBS. The disulfide bond was cleaved, and free siRNAs were released after treatment with a reducing agent DTT. The gel retardation assay confirmed that, after conjugation with PEG, the migration rate of siRNA conjugates was significantly slower than that of free siRNA, but after DTT treatment, the linker between siRNA and PEG was cleaved, and the released siRNA showed a similar migration rate to unconjugated siRNA (Figure 5). We did not use mass spectrophotometry to identify the siRNA conjugates, because siRNA may get degraded during the MALDI-TOF MS test, and it requires a large amount of siRNA to get the signal (*39, 40*).

Luciferase gene silencing of siRNA conjugates indicated that siRNAs did not lose their RNAi function during conjugation and after dissociation from siRNA conjugates (Figure 6). siRNA

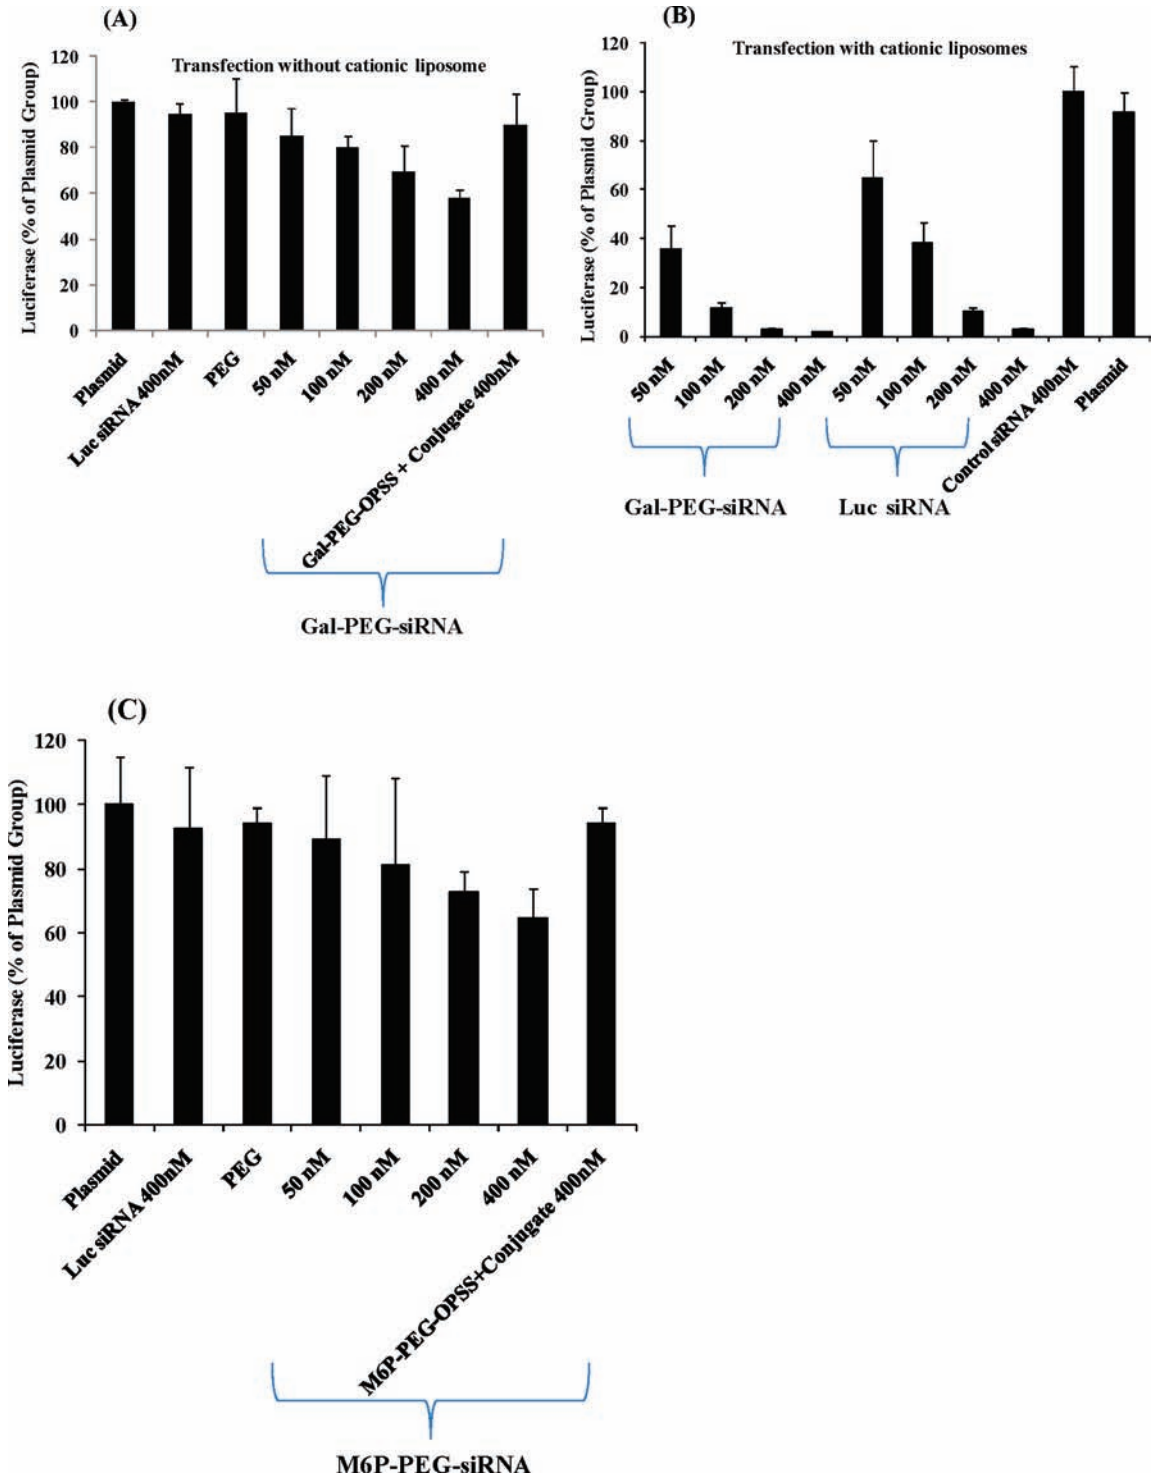

Figure 6. Luciferase gene silencing effects of Gal-PEG-siRNA and M6P-PEG-siRNA. Before the gene silencing study, luciferase plasmid was transfected into both HepG2 and HSC-T6 cells using lipoplexes formed between luciferase plasmid and pyridinium cationic liposomes at the charge ratio of 3/1 (±). The dose of plasmid was 0.2 μg per well in a 24-well plate. To study the gene silencing ability of Gal-PEG-siRNA, luciferase siRNA and its Gal-PEG-siRNA conjugate were added into HepG2 cells without (A) and with (B) the formation of siRNA/liposome complexes using pyridinium cationic liposomes. For M6P-PEG-siRNA, luciferas siRNA and its M6P-PEG-siRNA conjugate were added directly into HSC-T6 cells without cationic liposomes (C). After 6 h of transfection, the medium was replaced with the complete growth medium and incubated for additional 42 h. The cell number was about 4×10^4 cells per well in a 24-well plate.

conjugates had about 40% down-regulation of luciferase gene at the dose of 400 nM in both HepG2 and HSC-T6 cells in the absence of cationic liposomes (Figure 6A,C), while the luciferase gene was almost completely silenced in the presence of cationic liposomes at the same condition (Figure 6B). Without condensation with cationic liposomes, the flexible hydrophilic PEG chain surrounds and shields siRNA or the ligand on it from accessing the cell membrane, thereby decreasing both specific and nonspecific endocytosis. After complex formation with cationic liposomes, the lipoplexes were slightly positively charged and easy for cells to take up (nonspecific) and had high gene silencing effects. Furthermore, the combination of ligand−receptor-mediated specific endocytosis, siRNA conjugates showed higher gene silencing effect compared to naked

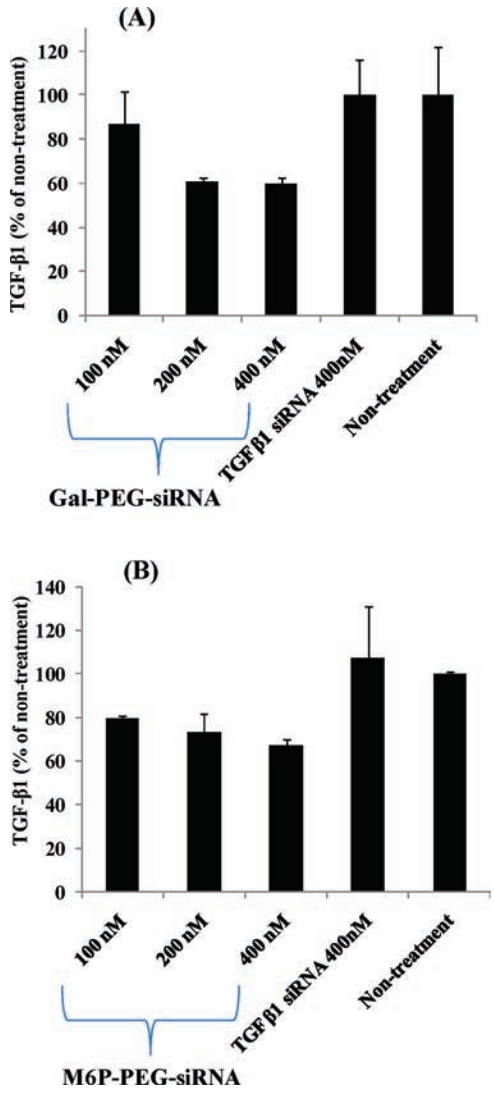

Figure 7. TGF-β1 gene silencing effects of Gal-PEG-siRNA and M6P-PEG-siRNA. (A) TGF-β1 siRNA and Gal-PEG-siRNA were added directly into HepG2 cells without cationic liposomes. (B) TGF-β1 siRNA and M6P-PEG-siRNA were added directly into HSC-T6 cells without cationic liposomes. After 6 h of transfection, the medium was replaced with the complete growth medium and incubated for an additional 42 h. There were about 4×10^4 cells per well in a 24-well plate.

siRNAs (Figure 6B). However, in the in vivo situation, PEGylated siRNAs will be retained in blood circulation and cleared very slowly compared to naked siRNAs. Our previous studies showed that pegylated ODN could significantly prolong the elimination half-life ($t_{1/2\beta}$) of ODN up to 118.61 $\pm$ 22.06 min (*11*) compared to only 34.60 $\pm$ 4.32 min of naked ODN after i.v. injection in rats (*14*). The longer residence will provide sufficient time for siRNA conjugates to access their target cells and initiate ligand−receptor-mediated endocytosis. In Figure 6A,C, preaddition of an excessive amount of Gal-PEG or M6P-PEG significantly inhibited the gene silencing effects of corresponding siRNA conjugates, which indicated that the cellular uptake of siRNA conjugates was ligand−receptor-mediated endocytosis, not nonspecific endocytosis.

To verify the function of PEG-based siRNA conjugate, we used TGF-β1 siRNA as the model sequence. The similar gene silencing effects were observed when TGF-β1 siRNA was conjugated to Gal-PEG-OPSS and M6P-PEG-OPSS (Figure 7A,B). On the basis of these results, we can predict that cation-free Gal-PEG-siRNA and M6P-PEG-siRNA conjugates will be specifically accumulated in hepatocytes or HSCs and minimize the nonspecific distribution and immunostimulatory effect in vivo.

In conclusion, we successfully conjugated siRNA to Gal-PEG-OPSS and M6P-PEG-OPSS via a disulfide bond. The gene silencing effects of these siRNA conjugates were observed in HepG2 and HSC-T6 cells. These siRNA conjugates have the potential to be used for targeted delivery of siRNAs to hepatocytes and hepatic stellate cells in vivo.

Received August 2, 2010; Revised Manuscript Received September 29, 2010

Imaging and targeted delivery to macrophages are promising new approaches to study and treat a variety of inflammatory diseases such as atherosclerosis. In this manuscript, we have designed and synthesized iron oxide based magnetic nanoparticles bearing hyaluronic acid (HA) on the surface to target activated macrophages. The HA-coated nanoparticles were prepared through a co-precipitation procedure followed by postsynthetic functionalization with HA and fluorescein. The nanoparticles were characterized by transmission electron microscopy, thermogravimetric analysis, elemental analysis, dynamic light scattering, and high-resolution magic angle spinning NMR and were biocompatible with cells and colloidally stable in the presence of serum. The HA immobilized on the nanoparticles retained their specific biological recognition with the HA receptor CD44, which is present on activated macrophages in high-affinity forms. Cell uptake studies demonstrated significant uptake of HA nanoparticles by activated macrophage cell line THP-1, which enabled magnetic resonance imaging of THP-1 cells. The uptake of nanoparticles was found to be both HA and CD44 dependent. Interestingly, Prussian blue staining showed that the magnetite cores of the HA-coated nanoparticles were only transiently present inside the cells, thus reducing the potential concerns of nanotoxicity. Furthermore, fluorescein on the nanoparticle was found to be delivered to the cell nucleus. Therefore, with further development, these HA functionalized magnetic nanoparticles can potentially become a useful carrier system for molecular imaging and targeted drug delivery to activated macrophages.

INTRODUCTION

Macrophages play central roles in mediating a wide range of infectious and inflammatory diseases, such as tuberculosis, atherosclerosis, rheumatoid arthritis, multiple sclerosis, and graft rejection (*1, 2*). They are critical in the initiation and maintenance of inflammation, which can lead to tissue destruction. For example, in atherosclerotic plaque development, a large number of macrophages are recruited to the cholesterol-rich site of injured aorta, which damages the fibrous tissue capping the plaques (*3, 4*). The weakened plaques can rupture, resulting in heart attack and stroke. The presence of a large number of active macrophages in plaques can be viewed as a biomarker for plaque instability (*5*). Therefore, effective technologies for monitoring macrophages as well as delivery of drugs to modulate macrophage activities can have great diagnostic and therapeutic potentials (*1, 6*).

Recently, the use of nanoparticle systems for biological imaging and drug delivery has attracted increasing attention (*1*). With their nanometer dimensions and large surface area, nanoparticles present a powerful platform for the attachment of multiple copies of diverse ligands. Furthermore, nanoparticles can have unique magnetic, optic, or fluorescent properties, rendering them suitable for biological imaging (*7*−*9*). Although nanoparticles can be nonspecifically taken up by macrophages, the development of nanoparticles bearing specific ligands that are capable of actively targeting macrophages can potentially enhance the efficiency and selectivity of delivery.

An attractive targeting ligand is hyaluronic acid (HA[1]), a member of the glycosaminoglycan family (*10*). HA is composed of tandem disaccharide repeats of β-1,4-D-glucuronic acid-β-1,3-D-N-acetylglucosamine. As an important component of the extracellular matrix, HA has been shown to be involved in multiple cellular processes, including cell adhesion, cell migration, innate immunity, and wound healing (*10, 11*). In addition, HA is highly biocompatible and readily available. These attributes render it uniquely suited for imaging and drug delivery applications (*12*) which has been studied in cancer (*13*), cartilage (*14*), liver cirrhosis (*15*), and arthritis (*16*). However, HA has not been utilized for macrophage targeting.

Macrophages are known to express HA receptors such as CD44, the major HA receptor in human bodies (*17, 18*). The interactions between HA and CD44 are crucial for the recruitment of leukocytes and macrophages in atherosclerotic plaque development (*19*−*21*). As part of our ongoing program to study atherosclerosis, we have begun to investigate whether the HA immobilized nanoparticles can be used to actively target and

image macrophages. Herein, we report our results on the uptake and intracellular distribution of HA-coated magnetic nanoparticles in macrophages.

EXPERIMENTAL PROCEDURES

Material. All chemicals were reagent grade and were used as received from the manufacturer. Dextran (MW 9−11 kDa), iron(II) chloride, ammonium hydroxide, sodium hydroxide, epichlorohydrin, bovine serum albumin, goat serum, and LPS from *E. coli* strain 0111:B4 were purchased from Sigma-Aldrich (St. Louis, MO) and used as is. Iron(III) chloride was purchased from Honeywell Riedel de Haen. Hyaluronic acid (MW 30 kDa) was purchased from Lifecore Biomedical. Fluorescein isothiocyanate (FITC), mouse antihuman CD44 monoclonal antibody (clone MEM85), and Alexa Fluor 594 goat antimouse IgG_{2b} secondary antibody were purchased from Invitrogen (Carlsbad, CA). Water used during synthesis was cell culture grade Millipore filtered water.

Cell Culture. THP-1 (human monocytic cell line), EA.hy926 (human vascular endothelial cell line), and LNCaP (human prostate cancer cell line) were purchased from American Type Culture Collection (Manassas, VA). THP-1 and LNCaP were maintained in RPMI 1640 supplemented with fetal bovine serum (10%, Sigma-Aldrich, endotoxin free), Penicillin−streptomycin−glutamine (1%), HEPES buffer (1%), and sodium pyruvate (1%). EA.hy926 cells were kept in M199 supplemented with fetal bovine serum (10%), penicillin−streptomycin−glutamine (1%), HEPES buffer (1%), and sodium pyruvate (1%). The cells were kept in an 37 °C incubator equipped with 5% CO_2. All cell culture related supplies were purchased from GIBCO (Invitrogen, Carlsbad, CA). MTS was purchased from Promega (Madison, WI) and TNF-α ELISA kit was purchased from R&D systems (Minneapolis, MN).

Synthesis of HA-DESPIONs and FITC-HA-DESPIONs. Dextran (4.5 g, MW 9−11 kDa) and iron(III) chloride (0.32 g, 1.2 mmol) were dissolved in water (10 mL), and filtered through a 0.22 μm membrane (Millipore). The mixture was cooled to 0 °C and 0.22 μm membrane filtered solution of iron(II) chloride (0.13 g, 0.63 mmol) in water (0.45 mL) was added dropwise. The reaction mixture was then neutralized by addition of ice-cold ammonium hydroxide solution (0.45 mL). This greenish suspension was heated between 75 and 85 °C for 1.5 h with continuous stirring under a nitrogen atmosphere. Upon completion, reaction was cooled to room temperature, and the excess dextran and ammonium hydroxide were removed using ultrafiltration (Millipore). The reaction mixture was further concentrated to 20 mL total volume using ultrafiltration and filtered through 0.22 μm membrane, followed by washing with water (4 mL) leading to dextran-coated superparamagnetic iron oxide nanoparticles (DESPIONs). To this nanoparticle suspension, an aqueous solution of 5 M NaOH (10 mL) was added followed by dropwise addition of epichlorohydrin (4 mL). The reaction mixture was stirred vigorously for 24 h, after which it was purified using dialysis against DI water with 5 exchanges over 24 h. The reaction was then concentrated to final volume of 30 mL using ultrafiltration. Ammonium hydroxide (8 mL) solution was then added and the reaction was heated at 37 °C for 36 h. The reaction mixture was then purified using dialysis against DI water with 10 water exchanges over 2 days producing NH_2-DESPIONs. HA was then conjugated to NH_2-DESPIONs. HA (100 mg, MW 30 kDa) was dissolved in water and mixed with Amberlite H^+ resin until pH ∼3 and stirred for 4 h to convert HA into its carboxylic acid form. Upon completion, the resin was filtered off and water was evaporated to dryness. The protonated HA was then dissolved in a mixture of 4 mL water and 2.5 mL acetonitrile, under nitrogen. To this mixture, *N*-methyl morpholine (50 μL) was added, followed by addition of 2-chloro-4,6-dimethoxy-1,3,5-triazine (CDMT, 30 mg). The reaction was stirred at RT for 1 h, after which NH_2-DESPIONs (26 mg in 10 mL water) was added. The reaction was stirred at RT for 20 h, followed by neutralization with Dowex H^+ resin. The resin was filtered off and the product was dialyzed using a 14 kDa cutoff membrane for 2 days with 10 water changes.

FITC labeling of HA-nanoparticles (HA-DESPION) was carried out by adding a solution of FITC (5 mg) in DMSO (1 mL) to an aqueous solution of HA-DESPION (30 mg, 6 mL water). As FITC has low aqueous solubility, DMSO (5 mL) was added to the reaction until a homogeneous solution was achieved. The reaction was stirred in the dark for 3 days and purified using ultrafiltration with 100 kDa cutoff membrane.

High-Resolution Magic Angle Spinning (HRMAS) NMR. HRMAS NMR experiments were carried out on a Varian Inova-500 NMR spectrometer equipped with a 4 mm gHX Nanoprobe (Variannmr Inc., Palo Alto, CA) available at the University of Tennessee Health Science Center (Memphis, TN). The HR-MAS probe with internal lock is capable of performing either direct or indirect (inverse) detection experiments. MAS experiments were performed at spinning rates of up to 2.5 kHz using a 40 μL glass rotor. The HA-DESPIONs were dissolved in D_2O solvent and were further diluted at different concentrations with D_2O to find out the concentration limit to the NMR signal broadening. HRMAS ^1H NMR spectra were obtained using 100−600 scans for each experiment. The sample temperature was regulated with an accuracy of ±0.1 °C.

Competitive Enzyme Linked Immunosorbent Assay (ELISA). In a 96 well-plate, 100 μL of goat antihuman IgG F_C γ (3 μg/well, Millipore, cat no. AP113) in PBS buffer was added to each well. The plate was covered with aluminum foil and incubated at 4 °C overnight. The wells were then washed 3 times with 200 μL PBST buffer (0.5% Tween 20) as follows: the plate was emptied by inversion over a sink, tapped against some layers of soft paper tissue to remove residual liquid, and then washed with buffer repeatedly (insufficient washings may lead to undesired high background). Blocking was completed by adding 5% BSA in PBS (200 μL) to each well followed by incubation at 37 °C for 2 h. The plate was then washed as described above. 100 μL of CD44-F_C γ chimera (0.2 μg/well, R&D systems, cat no. 3660-CD) in PBS buffer was then added to each well and incubated at 37 °C for 45 min. The plate was washed 3 times with 200 μL PBST buffer (0.05% Tween 20) as before. 100 μL of b-HA (0.5 μg/well), b-HA + HA 16 KDa (2.5 μg/well), or b-HA + HA-NPs (7.32, 3.66, 2.75, 1.5, 0.88, 0.55, 0.15, 0.088, 0.055 μg HA/well) solutions were then added to each well and incubated at room temperature for 2 h. The plate was then washed 3 times with 200 μL PBST buffer (0.05% Tween 20) and twice with PBS buffer. 100 μL Avidin-HRP in 0.2% BSA−PBS solution was then added to each well and incubated at room temperature for 1 h. The plate was then washed 3 times with 200 μL PBST buffer (0.05% Tween 20) and twice with PBS buffer. 100 μL of chromogenic TMB solution was added to each well, homogenized, and incubated for 15 min, or until a blue color appeared. The plate should be protected against light during this incubation. The reaction was then quenched by adding 0.5 M H_2SO_4 (50 μL) to each well with positive wells becoming yellow. For quantitative measurements, it was important that each well was incubated for exactly the same length of time. Optical absorbance was directly assessed through the bottom of the microwell plate using an automated ELISA plate reader (Biorad) at 450 nm.

Colloidal Stability Studies. The nanoparticles (HA-DESPIONs or FITC-HA-DESPION) were suspended in PBS or RPMI 1640 containing 10% FBS at a concentration of 1 mg/mL. The change in size was monitored by over a period of six

days using a Zetasizer Nano zs instrument. The samples were stored at RT and the FITC-HA-DESPIONs were stored in the dark at RT.

MTS Cell Viability Assay. THP-1 cells were inoculated in a 96 well plate at cell density of 4×10^5 cells/mL, 200 μL/well. They were differentiated using phorbol 12-myristate 13-acetate (PMA, 10 ng/mL) to induce adhesion. After 16 h, the supernatant was replaced by the desired incubation media (either media alone or serum free media containing 50 μg/mL HA-DESPION). The incubation was carried out for varying periods of times (see data). The supernatant was removed, cells were washed using serum containing RPMI 1640 twice, and then incubated with serum containing media for 48 h. After 48 h, 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS, 20 μL) reagent was added to each well and the plate was further incubated for 3 h. The intensity of brown color was measured using absorbance plate reader at 490 nm (Molecular Devices SpectraMax M5[e]). All the experiments were performed in triplicates.

HA-DESPION Adherence Assay with THP-1 Cells. THP-1 cells were serially diluted from a concentration of 2 million to 8600 cells/mL and plated in a 96 well plate at 200 μL/well, followed by the addition of 20 μL of MTS reagent. The cells were incubated at 37 °C for 3 h and the resulting brown color was read at 490 nm using a plate reader (Molecular Devices SpectraMax M5[e]). The readings were used to generate a standard curve of absorbance vs number of viable cells. To perform the adherence assay, a 96 well nunc plate was coated with human umbilical cord HA (5 mg/mL) overnight at 4 °C. The plate was washed 3 times with PBS to remove unattached coating. The THP-1 cells were treated with LPS (1 μg/mL) for 2 h, washed with media, counted using Trypan blue. The activated THP-1 cells were added to half the plate with unactivated THP-1 cells on the other half as a control. The plate was then incubated for1.5 h at 37 °C. Upon completion, the plate was washed with cell culture media 6 times to remove unbound cells, followed by resuspension in 200 μL of media in each well. At this time, the MTS reagent (20 μL) was added to each well and the plate was incubated for 3 h and read using a plate reader at 490 nm. The absorbance was correlated to the cell density using the previously generated standard curve. Each set was done in triplicate.

Determination of Cellular Uptake by Flow Cytometry. The cells were inoculated in a 6 well plate at a density of 5×10^5 cell/mL, treated with LPS (1 μg/mL) for 2 h at 37 °C, centrifuged to remove the supernatant media, and resuspended in serum free media containing FITC-HA-DESPION or FITC-DESPION (2.5 μg of FITC/mL of media) for 2 h at either 37 or 4 °C. Upon completion, the cells were centrifuged, washed with serum containing media twice, resuspended in 300 μL of the media, and analyzed using BD Vantage SE flow cytometer. Viability was assessed using propidium iodide. For the EA.hy926, the same procedure was used except the LPS treatment. After incubation with nanoparticles, the cells were detached using trypsin−EDTA (0.5%) and processed using the above procedure.

Cellular Uptake Monitoring by Confocal Microscopy. The cells were suspended in chambered cover glass (Nunc, FisherSci) at a density of 5×10^5 cells/mL. The THP-1 cells were treated with PMA (10 ng/mL) overnight to induce adhesion followed by LPS (1 μg/mL) treatment for 2 h at 37 °C. After one hour, the cells were treated with LysoTracker-594 DND (Invitrogen) at the final concentration of 1 μM, and the samples were incubated at 37 °C for another hour. Upon completion, the supernatants were removed and the cells were washed using PBS, fixed with 10% neutral buffered formalin for 20 min, and treated with 4′,6-diamidino-2-phenylindole (DAPI) at 300 nM concentration to stain the nuclei fluorescent blue. The samples were washed with PBS and water. Images were gathered using the Olympus FluoView 1000 LSM confocal microscope.

Prussian Blue Staining. The cells were suspended in chambered cover glass (Nunc, FisherSci) at a density of 5×10^5 cells/mL. The THP-1 cells were treated with PMA (10 ng/mL) overnight to induce adhesion followed by LPS (1 μg/mL) treatment for 2 h at 37 °C. The cells were washed to remove LPS and serum free media containing HA-DESPION or DESPION was added. The cells were incubated with the nanoparticles for half an hour, 1 h, 4 h, and 24 h, respectively, and were then washed repeatedly to remove the unbound particles. The cells were then fixed using 10% neutral buffered formalin for 20 min, washed with PBS buffer, and treated with 1:1 mixture of 4% potassium ferrocyanide and 4% HCl for 25 min at RT. Upon completion, the slides were rinsed with PBS and treated with 0.1 mL of nuclear fast red solution (Sigma) as a counterstain for 5 min, followed by rinsing with PBS. The resulting slides were observed under 40× magnification of an optical microscope.

MRI of Cells. THP-1 cells were plated at a density of 5×10^5 cells/mL in a 6 well plate, differentiated using PMA (10 ng/mL) for 16 h followed by treatment with LPS at 1 μg/mL for 2 h at 37 °C. After 2 h, the supernatant was removed and HA-DESPION (100 μg/mL, 10 μg/mL Fe) was added in serum free media to separate wells, and incubated for 2, 4, and 24 h, respectively, at 37 °C. After completion, the supernatant was removed; cells were washed with PBS to remove unbound particles, resuspended in 0.5 mL PBS, and assessed using MRI. MRI measurements were carried out on a GE 3T Signa HDx MR scanner (GE Healthcare, Waukesha, WI) with a wrist coil. Fast, spoiled gradient recalled echo 3D T_2*-weighted images were acquired with the following parameters: flip angle = 15°; echo times (TEs) = 5.9 ms, 14.5 ms, 23.0 ms, 31.6 ms, 40.2 ms, 48.7 ms, 57.3 ms, and 65.9 ms; time of repetition (TR) = 72.5 ms; receiver bandwidth (rBW) = ±15.6 kHz; field of view (FOV) = 6 cm; slice thickness = 1.5 mm; number of slices = 16; acquisition matrix = 256 × 256; number of excitation (NEX) = 1; and scan time = 1 min 39 s.

Antibody Blocking of THP-1 Cell Uptake of HA-DESPIONs. The THP-1 cells were differentiated using PMA (10 ng/mL) for 16 h at 37 °C, followed by treatment with LPS 1 μg/mL for 2 h at 37 °C. Various concentrations of mouse antihuman CD44 antibody (MEM-85 clone) were added to cells, and the cells continued to be incubated at 37 °C for 1 h. The supernatant was removed and FITC-HA-DESPION (100 μg/mL) was added in serum free media. The cells were incubated at 37 °C for one hour and then washed multiple times to remove unbound particles. Upon completion, the cells were lysed using 1% SDS and the fluorescence of the supernatant was measured using a plate reader. The experiment was performed in 5 sets for each time point.

RESULTS AND DISCUSSION

Synthesis and Characterization of HA-DESPIONs. The preparation of HA coated nanoparticles started from formation of the water-soluble nanoparticles by co-precipitating Fe^{3+} and Fe^{2+} salts in the presence of dextran (9−11 kDa) (*22*). The resulting nanoparticles (DESPIONs) were cross-linked by epichlorohydrin to improve the stability of the coating, which was followed by ammonium hydroxide treatment leading to NH_2-DESPIONs (*22*). HA (30 kDa) was then immobilized onto the nanoparticles through amide linkages promoted by CDMT (*23*) leading to magnetic nanoparticle HA-DESPIONs (Figure 1a). Dynamic light scattering data showed that the DESPION prepared has a hydrodynamic radius of 155 nm with a zeta potential of +43.4 mV. In comparison, HA-DESPION has a hydrodynamic radius of 205 nm with a zeta potential of −33.7

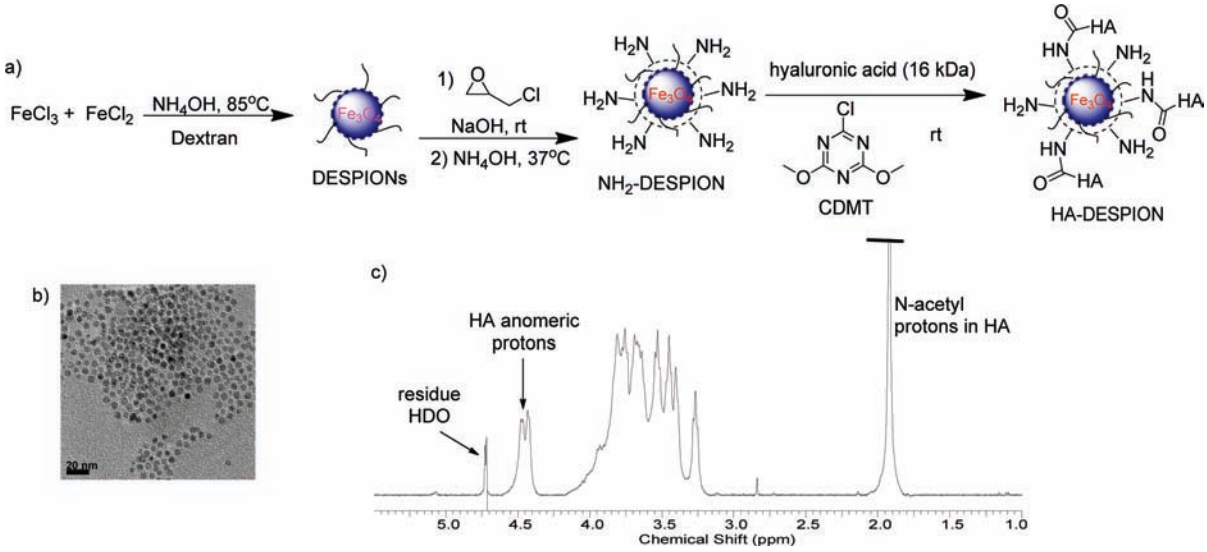

Figure 1. (a) Synthesis, (b) TEM image, and (c) ^{1}H-HRMAS NMR spectrum of HA-DESPION.

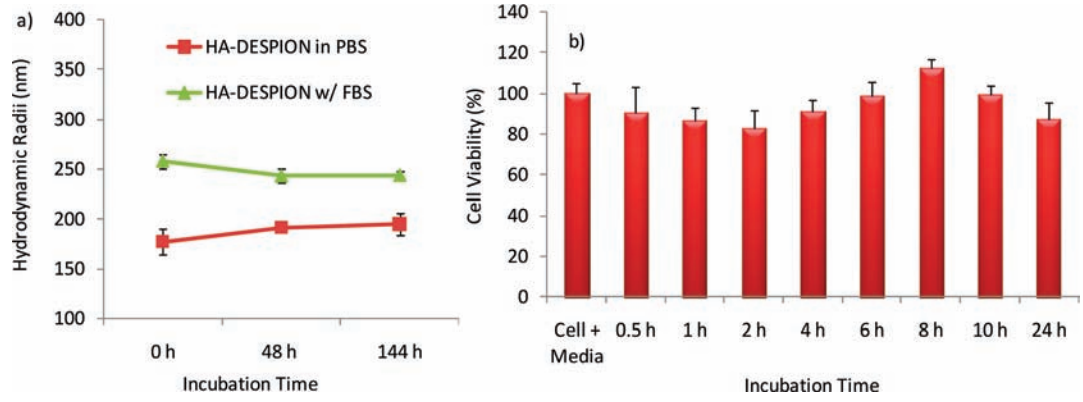

Figure 2. (a) Hydrodynamic radii (nm) of HA-DESPIONs in PBS or in 10% FBS containing media. (b) Percent of viable THP-1 cells upon incubation with HA-DESPIONs (100 μg/mL) as determined by MTS cell viability assays.

mV. The large change of zeta potential is attributed to the negatively charged nature of HA on the external surface of HA-DESPIONs. TEM revealed that the nanoparticle cores of HA-DESPIONs are quite homogeneous with an average diameter of 6 nm (Figure 1b). Under dry vacuum conditions encountered in TEM studies, the surface polysaccharides could collapse to form a tight coating, thus explaining the short interparticle distances observed in TEM images. TGA analysis showed that, upon HA incorporation, the percentage of the weight loss due to thermolysis of organics on HA-DESPIONs increased from 78% to 90% (Supporting Information Figure S1) and elemental analysis confirmed the increase of nitrogen upon HA functionalization (Supporting Information Table S1). The presence of HA on HA-DESPIONs was further ascertained by the HRMAS-NMR technique, which is a powerful method to overcome the field inhomogeneity caused by the superparamagnetic nature of the nanoparticles (*24*, *25*). ^{1}H-HRMAS NMR spectrum of the HA-DESPIONs showed resonances characteristic of HA with the anomeric protons appearing at 4.48 ppm and 4.43 ppm together with a singlet at 1.92 ppm due to the N-acetyl group (Figure 1c). On the basis of ^{1}H NMR integration as well as TGA data, the molar ratio of HA to dextran is determined to be 3:1.

In order to test whether HA immobilized on the nanoparticles can be recognized by receptors, we established a competitive ELISA procedure. CD44 was anchored onto microtiter plates in an IgG chimera form. The binding between a biotinylated HA polymer (0.5 μg/mL) and immobilized CD44 was then tested in the presence of various concentrations of HA-DESPIONs. HA-DESPIONs effectively inhibited the binding between the HA polymer and CD44 with an IC_{50} value of 0.5 μg/mL, while the DESPION without HA did not have any effect on HA-CD44 interaction even at a concentration of 50 μg/mL. This proves that HA immobilized on HA-DESPION retains its biological recognition.

Colloidal stability of nanoparticles under physiological conditions is an important factor for biological applications. The particle stability in biological media was evaluated by monitoring their hydrodynamic radii by DLS. The HA-DESPIONs maintained their sizes in both PBS buffer and culture media containing 10% fetal bovine serum (FBS) over one week, thus demonstrating that serum proteins do not induce nanoparticle aggregations (Figure 2a). HA-DESPIONs are also biocompatible, which had no effects on cell viabilities as determined through MTS cell viability assays (Figure 2b).

In order to facilitate fluorescence monitoring of cellular interactions, fluorescein was attached onto HA-DESPIONs through the reaction with FITC. The resulting FITC-HA-DESPIONs were characterized in a same manner as HA-DESPIONs and were found to have similar properties. Fluorescein can also serve as a model drug to evaluate drug delivery. Control reaction of FITC and HA alone under identical conditions gave FITC-HA conjugate with 10% of fluorescence intensity compared with that from FITC-HA-DESPION. This suggests FITC is attached to both HA and the aminated dextran on the nanoparticle surface.

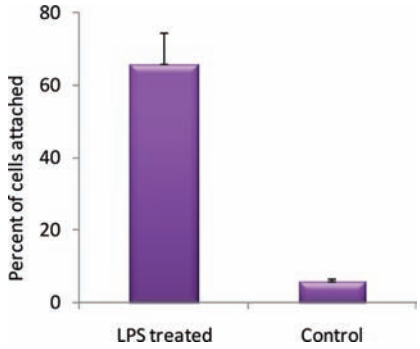

Figure 3. Percentage of differentiated THP-1 cells adhered on HA coated plates with and without LPS treatment. LPS treatment significantly enhanced THP-1 affinity with HA.

THP-1 Nanoparticle Uptake Kinetics. With the HA coated nanoparticles in hand, we examined their interactions with a human monocytic cell line THP-1. THP-1 cells can be differentiated into adherent and macrophage-like cells by exposure to PMA, which has been used quite extensively as a model for human macrophages (*26, 27*). The presence of CD44 on THP-1 cells was established by immunohistostaining. Incubation of THP-1 cells with antihuman CD44 IgG mAb followed by Alexafluor 594 labeled anti-IgG secondary antibody gave intense cell surface staining (Supporting Information Figure S2a). Western blot analysis further confirmed the presence of CD44 in THP-1 cells (Supporting Information Figure S2d).

It is known that the interactions between HA and CD44 are subject to tight regulations such that the receptor is normally maintained in a quiescent state showing little appreciable HA binding (*28*). For example, although freshly isolated peripheral blood monocytes and lymphocytes express CD44, they do not bind HA (*29*). During inflammation, however, the pro-inflammatory cytokine tumor necrosis factor α (TNF-α) induces sulfation and subsequent conformational changes of CD44, which transforms it into a form with much greater HA affinity (*21, 28, 30, 31*). To establish the THP-1 activation condition, we treated the PMA differentiated THP-1 cells with *E. coli* LPS, which led to the excretion of a large amount of TNF- α (2500 pg/mL) to the media (Supporting Information Table S2). In comparison, a very low TNF-α level (37.5 pg/mL) was detected from THP-1 culture without the addition of LPS. The high TNF- α level following LPS should turn CD44 into its high-affinity HA binding form, which was tested in a plate adhesion assay (Figure 3). Upon incubation of cells on HA coated cell culture plates, 66% of the LPS activated THP-1 cells adhered to these plates as compared to 6% of cells not treated with LPS, thus confirming the enhanced affinity of activated THP-1 cells with HA (*32*).

Next, we examined the interactions of HA-DESPIONs with THP-1 cells. LPS activated THP-1 cells were incubated with FITC-HA-DESPIONs for varying periods of time (0.5 h, 1 h, 2 h, 4 h, and 24 h), which was followed by extensive washing to remove unbound particles. The amount of fluorescence retained by the cells was then quantified. Significant amounts of the nanoparticles were rapidly uptaken by THP-1 cells, which did not change much after two hours (Figure 4a). The presence of HA on the nanoparticles was crucial for uptake, as the mean fluorescence intensity of cells incubated with FITC-DESPION without HA coating was only 20% of that with HA coated nanoparticles (Figure 4b). In addition, although other cells such as endothelial cell EA.hy926 also express CD44 (Supporting Information Figure S3), the THP-1 cells have 6-fold higher uptake capacities than EA.hy926 (Figure 4c). This suggests that the HA-DESPIONs can be used as a carrier to enhance delivery selectively to activated macrophages.

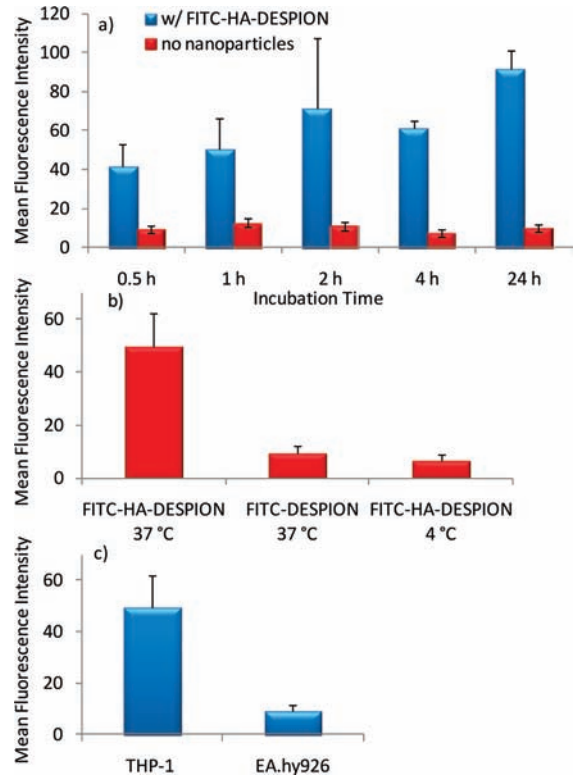

Figure 4. (a) Time-dependent uptake of FITC-HA-DESPION (100 μg/mL) by LPS activated THP-1 cell as measured by the mean fluorescence intensity of the cells. (b) Uptake comparison between FITC-HA-DESPION and FITC-DESPION as well as FITC-HA-DESPION at 37 °C vs 4 °C by activated THP-1 cells. (c) FITC-HA-DESPION uptake by THP-1 cells compared with that by CD44 expressing endothelial cell EA.hy926.

It is known that extracellular HA is typically endocytosed into lysosomes (*33*). For effective drug delivery using the HA-DESPION platform, it is important that the cargo can escape the lysosomes after internalization inside the cells. To monitor the intracellular distribution, we analyzed THP-1 cells by confocal microscopy following incubation with FITC-HA-DESPION (Figure 5). Interestingly, the green fluorescence was found concentrated in the nuclei (cyan color in Figure 5d) with some in the lysosomes. This points to the potential of using HA-DESPIONs for nuclear drug delivery such as gene therapy (*34*).

To further analyze nanoparticle uptake, we stained the THP-1 cells with Prussian blue stain, which reacts with iron ions present in the magnetite core yielding a characteristic blue color. The cells were incubated with nanoparticles for specific periods of time (0.5 h, 1 h, 4 h, and 24 h) and the unbound particles were washed off. With half-hour HA-DESPION incubation, most Prussian blue stains were found on THP-1 cell exterior surface as evident from the diffuse appearance of the blue color at cell surface (Figure 6a). With one hour incubation, the blue color appeared inside the cells indicating intracellular nanoparticle uptake (Figure 6b). Interestingly, as time went by, the blue color disappeared from inside the cells, suggesting efflux of the core of the nanoparticles from the cellular interior (Figure 6c,d). At 24 h, most of the staining was observed on the exterior cell surface. In contrast, with DESPIONs devoid of HA, the nanoparticles were retained inside the cells even after 24 h (Figure 6e), which was consistent with literature reports (*35, 36*).

An important application of magnetic nanoparticles is in MR imaging, as the magnetite nanoparticles are effective MRI contrast agents (*8, 37*). The uptake of the HA-DESPIONs by activated THP-1 cells was monitored by MRI upon incubation

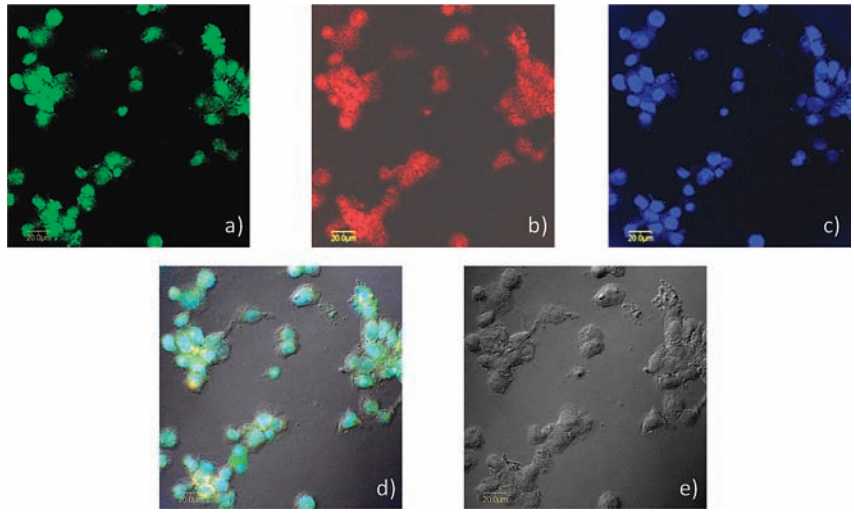

Figure 5. Confocal microscopy images of LPS activated THP-1 cells 1 h after incubation with FITC-HA-DESPION. (a) Fluorescein channel; (b) Lysotracker channel showing location of lysosomes; (c) DAPI channel showing location of nucleus; (d) overlay of a−c; (e) laser image of the cells. The image overlay indicated that the fluorescein was concentrated in the cell nuclei.

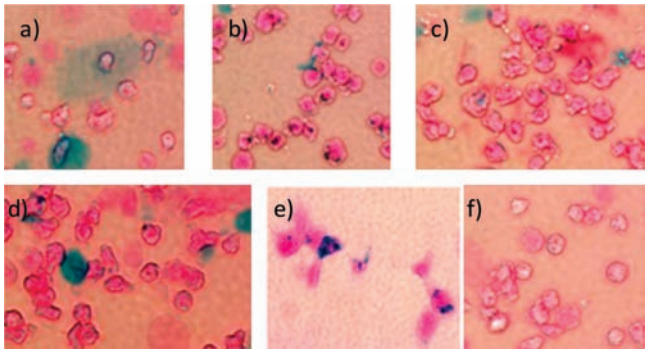

Figure 6. Prussian blue staining images of activated THP-1 cells incubated with HA-DESPIONs after (a) 0.5 h (the dispersed blue staining patterns suggested that nanoparticles were bound to the outer cell membrane); (b) 1 h; (c) 4 h; (d) 24 h followed by washing off unbound particles. The magnetite cores were found to be exocytosed out of the cells. (e) Activated THP-1 cells after 24 h incubation with DESPIONS. The intracellular staining suggested the retention of the magnetite core inside the cells. (f) Activated THP-1 cells without nanoparticle incubations.

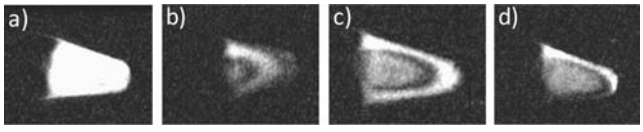

Figure 7. T2* weighted MR images of activated THP-1 cells (TE = 40.2 ms). (a) Before incubation with HA-DESPIONs, (b) 2 h, (c) 4 h, and (d) 24 h after incubation with HA-DESPIONs (100 μg/mL) followed by washing off unbound particles. The significant T2* contrast changes upon nanoparticle incubation suggested HA-DESPIONs can be used to monitor macrophages by MRI.

of HA-DESPIONs with cells for set time periods and washing off unbound particles. Significant changes in T2 weighted MR images of THP-1 cells were observed (Figure 7). Despite the fact that most HA-DESPIONs were exocytosed out of the interior of the cells with 24 h incubation (Figure 6d), sufficient amounts of HA-DESPIONs remained bound on the cell surface leading to large contrast change in MRI (Figure 7d). This suggested the potential applicability of these nanoparticles for noninvasive in vivo monitoring of macrophages. Various iron oxide nanoparticles including DESPIONs have been used previously for MR imaging (*8*, *37*). Although, in general, these nanoparticles are found to be biocompatible (*38*, *39*), side effects

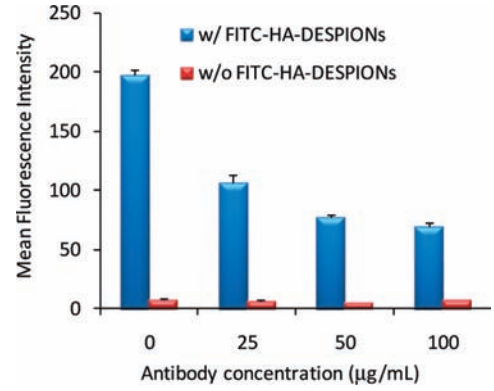

Figure 8. Mean fluorescence intensities of activated THP-1 cells incubated with various concentrations of blocking antibody MEM-85, followed by 1 h incubation with FITC-HA- DESPION (100 μg/mL) and washing off unbound particles. MEM-85 significantly reduced cell fluorescence intensities suggesting CD44 was involved in HA-DESPION uptake.

due to iron toxicities and nanotoxicities have been observed both in vitro and in vivo (*40*−*42*). For example, internalization of iron oxide nanoparticles resulted in a dose dependent reduction of the viability of growing neuron cells (*41*). Our observations that the magnetic cores of HA-DESPIONs are only transiently present inside the cells suggest the side effects from administrations of these particles will likely be small.

Mechanistic Studies of Nanoparticle Uptake. To better understand HA-DESPION uptake, we examined its temperature dependence. While significant uptake was observed at 37 °C, incubation of HA-DESPION at 4 °C reduced the uptake to the background level (Figure 4b). In addition, the phagocytosis inhibitor cytochalasin D (*43*) did not significantly affect the uptake (data not shown), which suggested that the uptake was most likely due to an energy-dependent receptor-mediated endocytosis process. In order to test the role of CD44, LPS activated THP-1 cells were incubated with anti-CD44 mAb MEM-85, which has been shown to block the binding of HA by CD44 (*44*), prior to the introduction with HA-DESPIONs. In the presence of MEM-85, the uptake was significantly decreased highlighting the important role CD44 played (Figure 8). However, other mechanisms should be operating, as there was still 30% residual uptake following MEM-85 blocking.

Fluorescein nuclear localization and exocytosis of the magnetite core can be explained by the involvement of CD44. HA-

DESPIONs bound with cell surface CD44 and were endocytosed into endosomes and lysosomes. It is known that HA can be digested inside the cells, presumably by acid-active lysosomal hyaluronidases (*45*). Thus, the HA on HA-DESPIONs can be partially cleaved, which would release HA fragments labeled with fluorescein and allow their trafficking to the nucleus. This is supported by the observation from Wight and co-workers that exogenous HA added to permeabilized fibroblast cells could be found in cell nucleus (*46*). With the large amount of HA on the exterior surface, HA-DESPIONs could remain bound to CD44 in the endosomes, recycle to the cell surface, and be released from the cells accounting for the disappearance of magnetite cores from the intracellular space.

CONCLUSIONS

We have synthesized iron oxide magnetic nanoparticles coated with HA, which have excellent colloidal stability and biocompatibility. The HA-DESPIONs retained the native biological recognition of HA by HA receptor CD44. HA-DESPIONs could be efficiently uptaken by activated macrophages, which enabled their imaging by MRI and paved the way for future in vivo studies. Furthermore, the dual labels (fluorescein and magnetite core) on the NPs enabled us to track the magnetite core and the cargo individually. This led to the unique observation that the magnetite core was only present transiently inside the cells. The cargo fluorescein was found to be delivered to the cell nucleus, unveiling the potential of using the HA-DESPION platform for nuclear drug delivery.

ACKNOWLEDGMENT

This work was supported by an NSF CAREER award (X.H.), and an American Heart Association Postdoctoral Fellowship (M.N.K.) and Predoctoral Fellowship (K.E.). We would like to thank Prof. Jetze Tepe, Michigan State University, for access to the cell culture facility and the Department of Radiology, Michigan State University, for the usage of the MRI scanner. We would like to thank Melinda Frame for her help with confocal microscopy and Dr. Louis King for FACS studies.

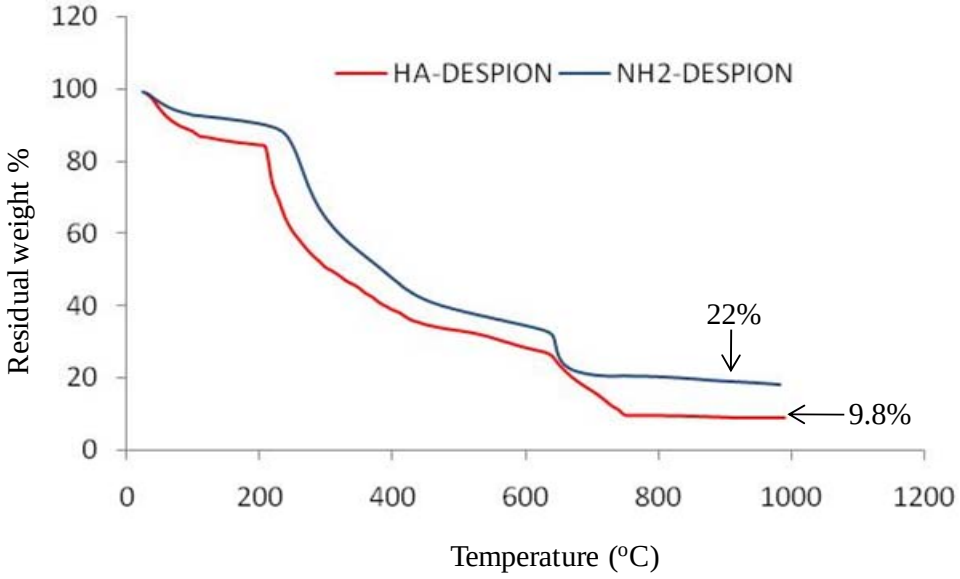
Table S2	S7

Figure S1. Thermogravimetric analysis of NH_2-DESPION and HA-DESPION. The additional weight loss upon heating of HA-DESPION compared to NH_2-DESPION was attributed to HA immobilized on the NPs.



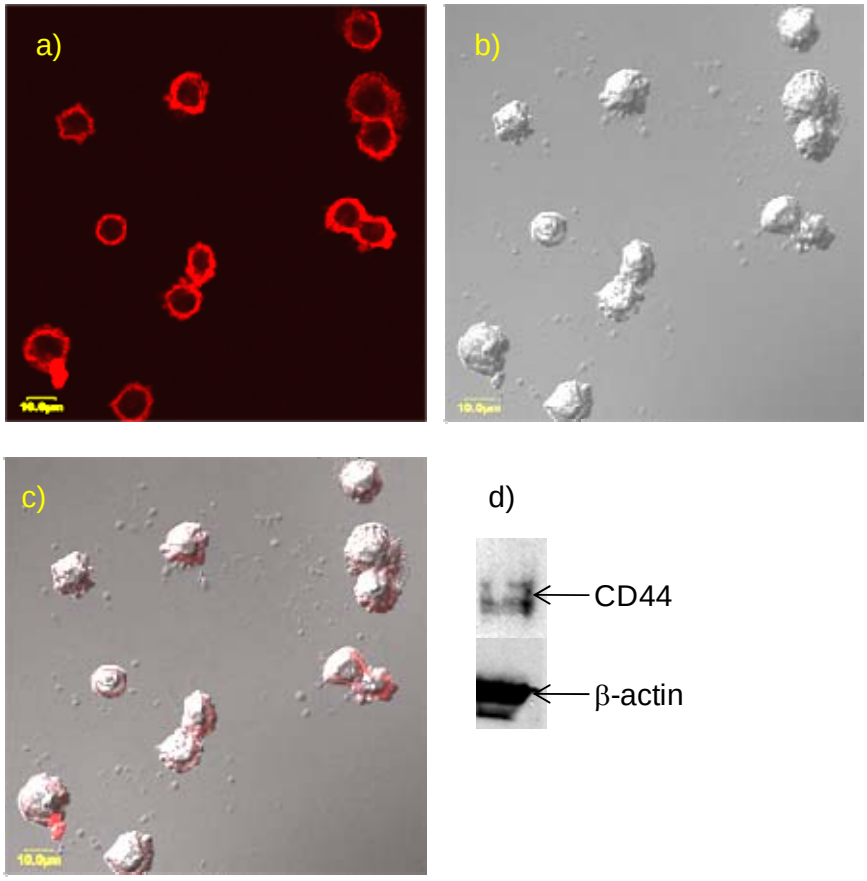


Figure S2. a) Confocal fluorescent microscopy image of THP-1 cells upon incubation with anti-human CD44 mAb followed by Alexafluor 594 labeled anti-IgG secondary antibody; b) Laser image of the cells; and c) Overlay of the fluorescent and laser images. The intense red color in a) suggested the presence of CD44 in THP-1 cells. This was confirmed by d) Western blot of THP-1 cells.

Immunohistostaining for CD44: The cells were inoculated in 4 chambered cover glass (LabTek, Fisher Science) at a cell density of $4x10^5$cells/mL. THP-1 cells were differentiated with PMA(10 μg/mL) to allow adhesion overnight. Next morning the cells were fixed using 10% neutral buffered formalin for 15min, washed with PBS containing 0.05% tween20 (Sigma) (wash buffer) twice for 10 min each. The cells were blocked using PBS containing 10% goat serum and 1% BSA for 2 h at RT. After 2 h, the blocking solution was drained and 300μL of 50μg/mL mouse anti human CD44 mAb (MEM 85, Invitrogen) diluted in PBS containing 1% BSA was added. The samples were then incubated in a moisture chamber at 4^oC for 48 h. For control, the blocking solution was used. Upon completion of incubation period, the supernatants were drained and washed with wash buffer twice for 10 min each. Chambers were dried by decanting and then were treated with 300 μL of 10 μg/mL goat antimouse IgG_{2b} secondary antibody labeled with Alexa Fluor 594 for 1 h, in dark. After an hour, the chambers were

washed buffer twice with 10 min each followed by water, in dark. Samples were imaged using confocal microscopy on Olympus Fluoview 1000 LSM.

Western Blot analysis to determine CD44 expression: The medium was removed from cell culture either by centrifugation or aspiration. The cells were washed with cold PBS twice and then lysed using a mixture of RIPA buffer, protease inhibitor phenyl methyl sulphonyl fluoride (PMSF), and phosphatase inhibitor cocktail. The lysate was centrifuged to remove cell debris. The total protein concentration was determined using Bradford assay (Bio-Rad). The samples together with high-molecular weight prestained standards were electrophoresed on non reducing 10% SDS gel, and then transferred to a PVDF membrane. The membrane was blocked using 4% non-fat milk in TBS-tween (TBST) buffer for 1 h and then treated with mouse anti-human CD44 antibody (156-3C11, Cell signaling) diluted to 1:1000 in 4% non-fat milk in TBST at 4°C overnight followed by goat anti-mouse HRP antibody (Bio-Rad) for 1 h. The blot was sprayed with chemiluminescent HRP detection reagent (Denville Scientific) and developed using autoradiography. β-actin was used as a positive control and was detected using mouse anti-human β-actin peroxidase antibody AC-15 (Sigma-Aldrich,) diluted at 1:40,000 in 4%Milk-TBSTfor 1 h at RT. The blot was developed using aforementioned protocol.

Figure S3. a) Confocal fluorescent microscopy image of EA.hy926 cells upon incubation with anti-human CD44 mAb followed by Alexafluor 594 labeled anti-IgG secondary antibody; b) Laser image of the cells; and c) Overlay of the fluorescent and laser images. The intense red color in a) suggested the presence of CD44 in EA.hy926 cells. This was confirmed by d) Western blot of EA.hy926 cells.

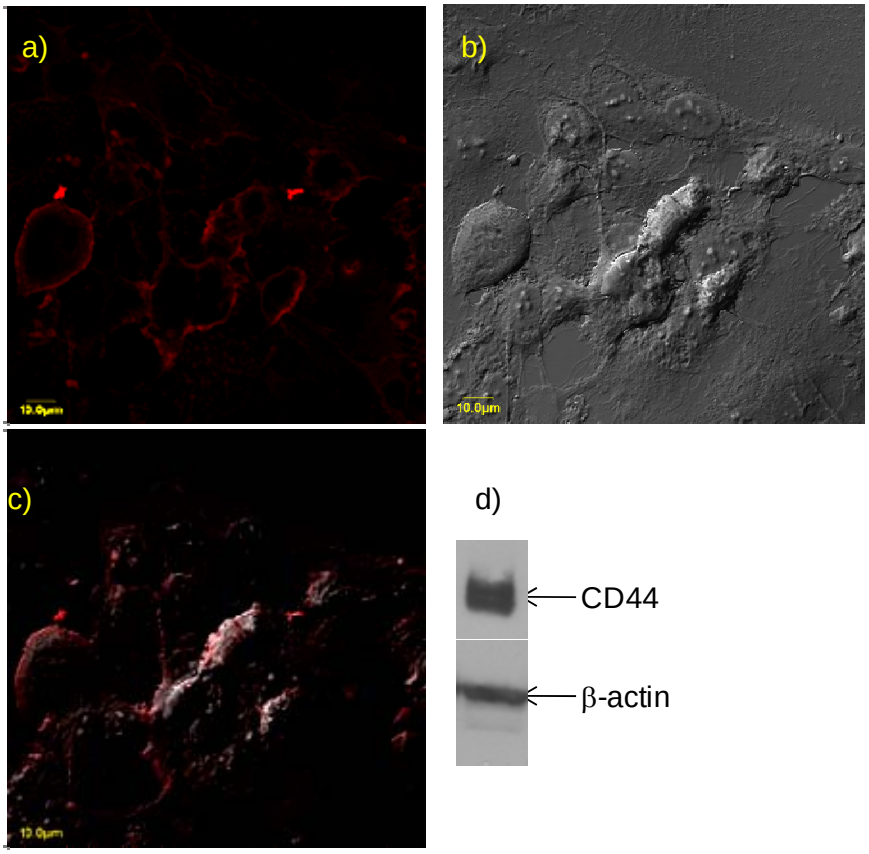

Table S1. Elemental analysis of nanoparticles. The significant increase of % of nitrogen in HA-DESPION confirmed the immobilization of HA on NPs.

Nanoparticles	C (%)	H (%)	N (%)
DESPION	45.09	6.28	0.09
NH_2-DESPION	42.42	6.09	1.02
HA-DESPION	40.09	5.81	3.03

Table S2. Concentration of TNF-α released from THP-1 cells under various conditions as determined from an anti-TNF-α ELISA.

	Treatment method	Amount of TNF-α (pg/mL)
1	Control	0
2	Media only	0
3	PMA (10 ng/mL)	37.5
4	Cholesterol (10 ng/mL)	40.5
5	PMA + LPS (10 ng/mL)	2500

Anti-TNF-α ELISA: The THP-1 cells were treated with endotoxin free media, PMA containing media (10 ng/mL, 16 h), and LPS containing media (10 ng/mL, 2 h), at a density of $5x10^5$ cells/mL. After completion of the treatment, the supernatant was collected, centrifuged to remove cellular debris, and subjected to ELISA. The ELISA was performed according to the manufacturer's instructions (R&D systems) to determine the cytokine concentration.

Synthesis and Photophysical Properties of Thioglycosylated Chlorins, Isobacteriochlorins, and Bacteriochlorins for Bioimaging and Diagnostics

Received August 4, 2010; Revised Manuscript Received September 23, 2010

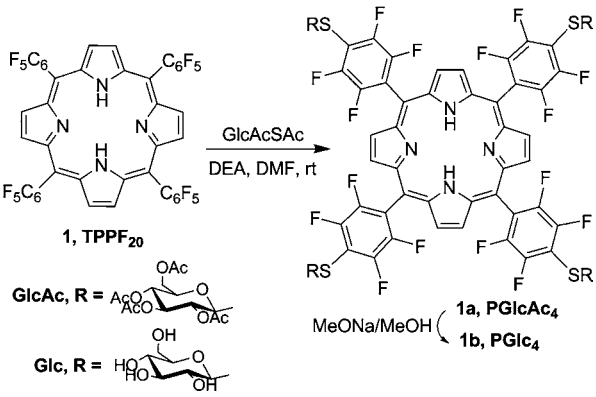
The facile synthesis and photophysical properties of three nonhydrolyzable thioglycosylated porphyrinoids are reported. Starting from *meso*-perfluorophenylporphyrin, the nonhydrolyzable thioglycosylated porphyrin ($PGlc_4$), chlorin ($CGlc_4$), isobacteriochlorin ($IGlc_4$), and bacteriochlorin ($BGlc_4$) can be made in 2−3 steps. The ability to append a wide range of targeting agents onto the perfluorophenyl moieties, the chemical stability, and the ability to fine-tune the photophysical properties of the chromophores make this a suitable platform for development of biochemical tags, diagnostics, or as photodynamic therapeutic agents. Compared to the porphyrin in phosphate buffered saline, $CGlc_4$ has a markedly greater absorbance of red light near 650 nm and a 6-fold increase in fluorescence quantum yield, whereas $IGlc_4$ has broad Q-bands and a 12-fold increase in fluorescence quantum yield. $BGlc_4$ has a similar fluorescence quantum yield to $PGlc_4$ (<10%), but the lowest-energy absorption/emission peaks of $BGlc_4$ are considerably red-shifted to near 730 nm with a nearly 50-fold greater absorbance, which may allow this conjugate to be an effective PDT agent. The uptake of $CGlc_4$, $IGlc_4$, and $BGlc_4$ derivatives into cells such as human breast cancer cells MDA-MB-231 and K:Molv NIH 3T3 mouse fibroblast cells can be observed at nanomolar concentrations. Photobleaching under these conditions is minimal.

INTRODUCTION

Chlorins are porphyrinoids with one pyrrole double bond missing. Isobacteriochlorins and bacteriochlorins are porphyrinoids with two pyrrole double bonds missing on adjacent or opposite pyrroles, respectively. Oxidative or reductive transformations of porphyrins can yield these chromophores. Porphyrins, chlorins, bacteriochlorins, and isobacteriochlorins each have unique photophysical properties that are exploited by nature and can be used for diverse applications (*1, 2*). Compared to the parent tetraarylporphyrin, the intensity of the lowest-energy UV−visible absorption band near 650 nm can increase by ∼20-fold for chlorins and by ∼5-fold for the isobacteriochlorins. For bacteriochlorins, the absorption band near 650 nm is similar to porphyrins, but an additional high-intensity absorption band appears near 730 nm. The excited-state lifetimes, singlet and triplet quantum yields, and distortion upon metal ion binding are significantly different for these three types of macrocycles (*3, 4*).

For diagnostic and photodynamic therapeutic (PDT) applications, the enhanced intensity of the low-energy absorption bands allows more efficient use of wavelengths of light that penetrate further into tissues (*5*−*8*). An example of a chlorin PDT photosensitizer is *meso*-tetrakis(3′-hydroxyphenyl)chlorin (m-THPC) and its derivatives (*9*). Other water-soluble chlorins are reported (*10*−*12*). For therapeutic uses of PDT agents, high triplet quantum yields are desirable to photosensitize the formation of singlet oxygen and other reactive oxygen species, which then cause damage to diverse cellular components. For diagnostics, the dyes appended with appropriate targeting motifs need to have greater fluorescence quantum yields for use as fluorescent tags or trackers (*13*). Fluorescent dyes with targeting motifs can be used in fluorescence guided surgery (*14*).

Porphyrins, chlorins, isobacteriochlorins, bacteriochlorins, and phthalocyanines with 1−8 appended sugar moieties can have cytotoxic activity, because the sugars can direct the chromophore to some cancer cells (*15*−*27*). However, most reported compounds have O-glyco linkages where hydrolysis may diminish in vivo effectiveness compared to corresponding nonhydrolyzable derivatives. The number, type, and position of the sugar moieties have long been known to effect cell uptake and photochemical properties (*16, 21, 28*). The synthesis of a polyglycerol dendrimer with a porphyrin core is reported (*29*), click reactions have been used to glycosylate chlorin e_6 (*30*), and polysaccharides have been appended to porphyrins (*31*).



Previously, we reported the synthesis of nonhydrolyzable thioglycosylated tetraarylporphyrins and showed that the tetraglucose derivative ($PGlc_4$, Scheme 1, **1b**) is a selective and effective PDT agent in vitro using several cell lines, such as MDA-MB-231 human breast cancer cells, whereas the galactose derivative is much less effective (*32*). Also, the glycosylated compounds were taken up by transformed mouse $3Y1^{vSrc}$ cells but not taken up by normal mouse fibroblast cells (*32, 33*). We first reported the synthesis and ground-state electronic properties of a glycosylated chlorin formed using a dipolar addition to $TPPF_{20}$ to append a fused *N*-methyl-pyrrolidine moiety and the same chemistry to append the sugars (Scheme 2) (*34*).

One advantage of using the tetraperfluorophenylporphyrin ($TPPF_{20}$) is that it can serve as a core platform for a host of materials (*35, 36*) and biochemical applications because the para fluoro group can be routinely substituted with a variety of

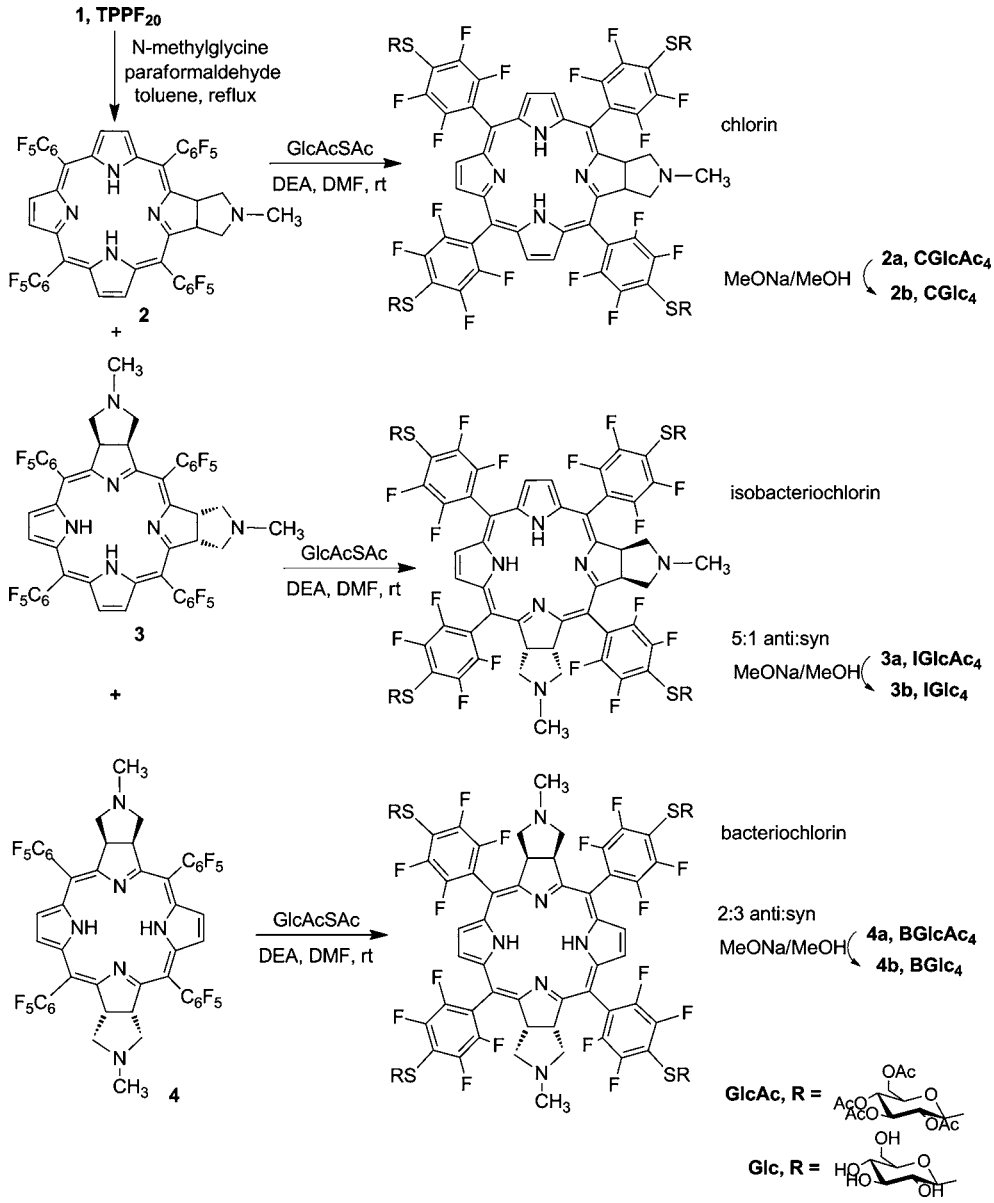
Scheme 1. Synthesis of $PGlc_4$ from Tetrakis(pentafluorophenyl)porphyrin ($TPPF_{20}$)

nucleophiles to form bioconjugates, biocompatible compounds, and combinatorial libraries (*33, 37*−*41*). For example, we have appended ethylene glycols, polyamines, lysines, alkanes, fluorous alkanes, sugars, and nucleotides using both primary amines and thiols. Subsequently, glycols with an oxygen linkage were also reported (*42*). The PDT activity of many of these derivatives has been studied with a variety of cell lines, and the glycosylated compounds affect apoptosis in several cases (*22, 42*−*44*). Also, the 16 fluoro groups make this compound amenable for in vivo ^{19}F NMR studies of localization (*45*).

Given the diversity of the targeting moieties on the core platform, it is desirable to be able to tune the photophysical properties of the chromophore for these assorted applications, and an obvious means to accomplish this is to adjust the number of double bonds in the macrocycle as is done in nature (*46*). There are many strategies to make porphyrins lacking one or two double bonds using oxidative and reductive strategies (*5, 47*). The formation of the perfluorophenylchlorin (CF_{20}), perfluorophenylisobacteriochlorin (IF_{20}), and perfluorophenylbacteriochlorin (BF_{20}) by 1,3-dipolar additions was reported by the Cavaleiro group (*48*−*52*). The advantage of this route is that it does not use toxic reagents and the products are reasonably stable chemically and to photobleaching. Vicente and co-workers exploited the thio coupling chemistry on CF_{20} to append carboranyl groups (*53*), and Hirohara has appended sugars to free base and Pt derivatives (*54, 55*) for potential therapeutic applications. We now report the synthesis, photophysical properties, and relative cell uptake of the glycosylated chlorin **2b** ($CGlc_4$), isobacteriochlorin **3b** ($IGlc_4$), and bacteriochlorin **4b** ($BGlc_4$) analogues (Scheme 2).

EXPERIMENTAL PROCEDURE



Materials and Methods. *General.* ^1H and ^{13}C NMR spectra were recorded in a Brüker Avance 500 MHz spectrometer and the ^{19}F spectra in a JEOL 400 MHz spectrometer. Electrospray ionization mass spectrometric analyses were performed at the CUNY Mass Spectrometry Facility at Hunter College using an Agilent Technologies HP-1100 LC/MSD instrument. The electrospray ionization was run in methanol, with 0.1% formic acid. UV-visible spectra were recorded on a Varian Bio3 spectrophotometer. Steady-state fluorescence (emission) spectra were measured with a Fluorolog τ3, Jobin-SPEX Instruments S.A., Inc. All reagents were obtained from commercial sources and used without further purification. $TPPF_{20}$ porphyrin was obtained from Frontier Scientific. Dulbecco's Modified Eagle Medium (DMEM), trypsin-EDTA, and antimycotic for cell culture were obtained from GibcoBRL. Hanks' balanced salt solution was obtained from Cellgro (Mediatech). Bovine calf serum was obtained from HyClone. Phosphate buffered saline (PBS) was purchased from Invitrogen. Flash column chromatography was performed using silica gel-60, and the analytical TLC was carried out on precoated sheets with silica gel (0.2 mm thick), both from Sorbent Technologies. The octanol/water partition coefficients were determined by saturating 1:1 (v/v) mixtures of the solvents with the porphyrinoid, waiting 8−10 h, and measuring the Soret and first Q-band intensities. This data were confirmed by saturating each solvent separately before mixing equal volumes.

Synthesis. *Improved Synthesis $PGlcAc_4$ (**1a**).* To a solution of $TPPF_{20}$, **1** (50 mg, 51 μmol), and 2,3,4,6-tetra-*O*-acetyl-glucosylthioacetate (90 mg, 233 μmol, 4.6 equiv) in DMF (5 mL), diethyl amine (1 mL) was added. The reaction mixture was stirred at room temperature for 1.5 h. Then, the product was precipitated with methanol/water and the solid filtered through a short column of Celite and washed with water. The crude mixture was recovered in dichloromethane and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/hexanes (3:1) as eluent. The glycoporphyrin **1a** (110 mg, 92%) was obtained after crystallization in dichloromethane/hexane, as a red powder.

*Synthesis of Porphyrin $PGlc_4$ (**1b**).* Porphyrin **1a** (50 mg, 21 μmol) was dissolved in methanol/dichloromethane (3:1, 8 mL) and treated with sodium methoxide (0.5 M solution in methanol, 1 mL). The reaction mixture was stirred at room temperature for 1.5 h and then neutralized by an aqueous citric acid solution. The mixture was filtered through a Waters Sep-Pak C_{18} 35 cm^3 reverse-phase prep column and washed with water. The deprotected glycoporphyrin **1b** was then purified on flash chromatography (silica gel) eluted using a mixture of ethyl acetate/methanol (3:1) and crystallized in methanol/CH_2Cl_2 (33.5 mg, 96%). mp > 250 °C. ^{19}F NMR (DMSO-d_6): δ −133.82 to −132.57 (m, 8F, Ar-*m*-F), −139.75 to −139.50 (m, 8F, Ar-*o*-F). ^1H NMR (DMSO-d_6): δ 9.33 (bs, 8H, pyrrolic β-H), 5.78 (bs, 4H, Glc-H), 5.10−5.29 (m, 13H, Glc-H), 4.72 (bs, 4H, Glc-H), 3.82−3.84 (m, 5H, Glc-H), 3.52−3.55 (m, 6H, Glc-H), 3.18−3.23(m, 12H, Glc-H), −3.17 (s, 2H, NH).

*Synthesis of Protected Thioglycosylated Chlorin, $CGlcAc_4$ (**2a**).* Chlorin **2** was prepared as previously reported method (*48, 49*). To a solution of chlorin **2** (25 mg, 24 μmol) and 2,3,4,6-tetra-*O*-acetyl-glucosylthioacetate (42 mg, 109 μmol, 4.5 equiv) in DMF (2.5 mL) diethyl amine (0.5 mL) was added. The reaction mixture was stirred at room temperature for 1 h. Then, the reaction mixture was precipitated with methanol/water, and the solid was filtered through a short column of Celite and washed with water. The crude mixture was recovered in CH_2Cl_2 and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/hexanes (3:2) as eluent. Chlorin **2a** (48 mg, 82%) was obtained after crystallization in CH_2Cl_2 /hexanes, as a green powder. Because the *N*-methyl-pyrrolidine points to one face of the chlorin and the stereo centers on the sugars, **2a** is made as a mixture of diastereomers at the β-pyrrole positions bearing the *N*-methyl-pyrrolidine moieties. These are seen in some of the resonances in the ^1H NMR and especially the complexity of the phenyl region of the ^{13}C NMR, which show the coupling to ^{19}F and the diastereomers. The peaks in the ^{19}F NMR spectrum are somewhat broader than the achiral starting material. mp > 250 °C. ^{19}F NMR (DMSO-d_6): δ −130.09 to −129.81, −130.56 to −130.25 (2m, 4F, Ar-*m*-F), −131.69 to −131.54 (m, 4F, Ar-*m*-F), −137.10 to −136.78 (m, 2F, Ar-*o*-F), −138.98 to −138.82 (m, 6F, Ar-*o*-F). ^1H NMR ($CDCl_3$): δ 8.82−8.84, 8.55−8.57, 8.48−8.50 (3m, 6H, pyrrolic β-H), 5.11−5.40 (3m, 18H, 2H β-H [C (sp^3)] and 16H, Glc-H), 4.26−4.35 (m, 8H, Glc-H), 3.88−3.91 (m, 4H, Glc-H), 2.58 and 3.16 (2t, 4H, pyrrolidine-H), 2.22 (s, 3H, NCH_3), 2.07−2.10 (m, 48H, acetyl-H), −1.74 (s, 2H, NH). ^{13}C NMR ($CDCl_3$): δ 20.6 and 20.7 (CH_3CO_2), 41.2 (NCH_3), 53.1 and 53.2 (C2 and C3), 61.7 and 61.9 (Glc), 63.0 (CH_2), 68.0, 68.1, 70.7, 73.9, 84.5 and 84.6

Scheme 2. Synthesis of $CGlc_4$, $IGlc_4$, and $BGlc_4$

(Glc), 97.5, 106.7, 106.8, 111.6, 111.8, 122.1, 122.4, 124.0, 124.3, 128.2, 128.3, 132.5, 134.9, 135.0, 140.0, 141.1, 144−149 (C_6F_4), 152.3, 168.6, 168.8, 169.4 (CH_3CO_2), 170.2 and 170.7 (CH_3CO_2). HRMS calcd for $C_{103}H_{95}F_{16}N_5O_{36}S_4$ $(M+2H)^+$ 2409.4384, found 2409.4318.

*Synthesis of Thioglycosylated Chlorin, $CGlc_4$ (**2b**).* This details what we previously reported (*34*) and was later modified by Hirohara et al (*54*). Glycochlorin **2a** (30 mg, 12.4 μmol) was dissolved in methanol/CH_2Cl_2 (3:1, 4 mL) and treated with sodium methoxide (0.5 M solution in methanol, 1 mL). The reaction mixture was stirred at room temperature for 1 h and then neutralized by an aqueous citric acid solution. The mixture is filtered through Waters Sep-Pak C_{18} 35 cm^3 reverse-phase prep column and washed with water. The deprotected glycochlorin **2b** was then eluted with methanol and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/methanol (3:2) as eluent. Chlorin **2b** (20 mg, 93%) was obtained after crystallization in methanol/CH_2Cl_2, as a green powder. **2b** is also a mixture of diastereomers. These are not well-resolved in the ^{1}H NMR but are observed, especially the complexity of the phenyl region of the ^{13}C NMR, which shows the coupling to ^{19}F and the diastereomers. mp > 250 °C. ^{19}F NMR (DMSO-d_6): δ −132.67 to −132.28 (m, 4F, Ar-*m*-F), −133.79 to −133.64 (m, 4F, Ar-*m*-F), −137.90 to −137.53 (m, 2F, Ar-*o*-F), −139.93 to −139.82 (m, 6F, Ar-*o*-F). ^{1}H NMR (DMSO-d_6): δ 9.14, 8.81 and 8.74 (3bs, 6H, pyrrolic β-H), 5.02−5.10, 5.28 and 5.75 (1m and 2bs, 18H, 2H β-H [C (sp^3)] and 16H, Glc-H), 4.55−4.68 (m, 4H, Glc-H), 4.10 (m, 2H, Glc-H), 3.73−3.78, 3.51, 3.18 and 3.04 (1m and 3bs, 26H, 4H pyrrolidine-H and 22H Glc-H), 2.05 (s, 3H, NCH_3), −1.97 (s, 2H, NH). ^{13}C NMR (DMSO-d_6): δ 41.0 (NCH_3), 49.1 and 53.1 (C2 and C3), 61.7, 61.71, and 61.9 (Glc), 62.9 (CH_2), 70.57, 70.60, 70.68, 70.78, 70.8, 75.1, 75.2, 78.51, 78.54, 78.6, 79.6, 82.2, 82.3, 84.9, 85.0 and 85.2 (Glc), 97.8, 106.8, 113.8, 113.9, 114.1, 114.2, 119.5, 119.6, 119.8, 120.0, 120.2, 126.6, 129.8, 133.5, 135.1, 140.3, 143−149 (C_6F_4), 152.4, 170.2. HRMS calcd. for $C_{71}H_{62}F_{16}N_5O_{20}S_4$ $(M+H)^+$ 1736.2615, found 1736.2603.

*Synthesis of Isobacteriochlorin (**3**) and Bacteriochlorin (**4**).* These compounds are made using modifications of the previously reported procedure (*49*) and scaled up. A toluene (20 mL) solution of $TPPF_{20}$ (100 mg, 0.1 mmol), *N*-methylglycine (30 mg, 1 mmol), and paraformaldehyde (20 mg, 0.22 mmol) was heated at reflux for ca. 12 h under a nitrogen atmosphere. Further portions of *N*-methylglycine (30 mg) and

paraformaldehyde (20 mg) were again added, and the resulting mixture was refluxed for a total of 24 h (2 × 12 h). The compounds were separated by flash chromatography (silica gel) using hexane/CH_2Cl_2 (50:50 v/v) to elute the negligible amount of unreacted porphyrin **1**, followed by CH_2Cl_2 to get the chlorin **2** (45 mg, 42%) and then CH_2Cl_2/acetone (95:5) to get the isobacteriochlorin **3** (40 mg, 34%). However, we found that a small amount (ca. 10−15%) of the bacteriochlorin consistently elutes with the isobacteriochlorin under these conditions. Thus, compounds **2**, **3**, and **4** were separated using a petroleum ether/ethyl acetate gradient on a flash silica gel column. From 100 mg $TPPF_{20}$ (102.6 μmol) is obtained 70 mg of the chlorin compound **2** (67.89 μmol, 66% yield), 15 mg of the anti isobacteriochlorin compound **3** (13.77 μmol, 13% yield), and 5 mg of both the syn and anti bacteriochlorin compound **4** (4.6 μmol, 5% yield). The diastereomeric anti form of compound **3** is preferentially formed; conversely, the syn form of compound **4** is the major product (3:2 syn/anti), and the NMR, HRMS, and UV−visible spectra for **3** and **4** were consistent with the previous report (*49*).

*Synthesis of Protected Thioglycosylated Isobacteriochlorin, IGlcAc$_4$ (**3a**).* To a solution of isobacteriochlorin **3** (25 mg, 23 μmol) and 2,3,4,6-tetra-*O*-acetyl-glucosylthioacetate (40 mg, 103 μmol, 4.5 equiv) in DMF (2.5 mL), diethyl amine (0.5 mL) was added. The reaction mixture was stirred at room temperature for 4 h. The reaction mixture was precipitated with methanol/H_2O and the solid filtered through a short column of Celite and washed with water. The crude mixture was recovered in CH_2Cl_2 and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/hexanes (3:1) as eluent. Isobacteriochlorin **3a** (49 mg, 86%) was obtained after crystallization in CH_2Cl_2/hexanes, as a pink powder. Because the *N*-methyl-pyrrolidine points to opposite faces of the isobacteriochlorin and of the stereo centers on the sugars, **3a** is made as a mixture of two sets of diastereomers on the four β-pyrrole positions bearing the *N*-methyl-pyrrolidine moieties. These are seen in some of the resonances in the ^{1}H NMR and especially the complexity of the phenyl region of the ^{13}C NMR, which shows the coupling to ^{19}F and the multiplicity due to the adjacent pair of diastereomers. mp > 250 °C. ^{19}F NMR (DMSO-d_6): δ −128.46 to −128.35, −128.81 to −128.70 (2m, 2F, Ar-*m*-F), −130.11 to −129.88, −130.45 to −130.35, −130.91 to −130.81 and −131.62 to −131.41 (4m, 6F, Ar-*m*-F), −136.79 to −136.64, −137.35 to −137.17, −139.42 to −139.23 and −140.04 to −139.94 (4m, 8F, Ar-*o*-F). ^{1}H NMR ($CDCl_3$): δ 7.64, 7.63, 7.22, 7.17 (4d, j = 5 Hz, 4H, pyrrolic β-H), 5.03−5.32 (m, 16H, Glc-H), 4.45−4.50 and 4.16−4.25 (2m, 14H, 4H β-H [C (sp^3)], 2H NH and 8H Glc-H), 3.83(d, j = 5 Hz, 4H, Glc-H), 2.70 and 2.88 (2t, j = 8.2 Hz, 4H, pyrrolidine-H), 2.06−2.31 (m, 58H, 4H pyrrolidine-H, 6H NCH_3, 48H, acetyl-H). ^{13}C NMR ($CDCl_3$): δ 20.6 ($\underline{C}H_3CO_2$), 41.0 (NCH_3), 47.8 and 51.7 (C2, C3, C7, and C8), 61.4, 61.8, 62.5 (CH_2 and Glc), 68.0, 70.2, 70.5, 73.81, 73.83, 76.3, 84.5 and 84.6 (Glc), 92.2, 98.2, 111.0, 111.1, 111.3, 113.6, 121.4, 121.5, 121.6, 128.5, 128.6, 144.4−148.7 (C_6F_4), 169.37, 169.38, 169.41, 170.16 and 170.62 ($CH_3\underline{C}O_2$). HRMS calcd. for $C_{106}H_{100}F_{16}N_6O_{36}S_4$ $(M)^{+\bullet}$ 2464.4806, found 2464.4700.

*Synthesis of Thioglycosylated Isobacteriochlorin, IGlc$_4$ (**3b**).* Isobacteriochlorin **3a** (30 mg, 12.1 μmol) was dissolved in methanol/CH_2Cl_2 (3:1, 4 mL) and treated with sodium methoxide (0.5 M solution in methanol, 1 mL). The reaction mixture was stirred at room temperature for 1 h and then neutralized by an aqueous citric acid solution. The mixture was filtered through Waters Sep-Pak C_{18} 35 cm^3 reverse-phase prep column and washed with water. The deprotected isobacteriochlorin **3b** was eluted with methanol and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/methanol (3:2) as eluent. Isobacteriochlorin **3b** (19 mg, 88%) was obtained after crystallization in methanol/CH_2Cl_2 as a pink powder. **3b** is likewise a mixture of two sets of diastereomers. These are not resolved in the ^{1}H NMR, but are observed especially in the complexity of the phenyl region of the ^{13}C NMR, which shows the coupling to ^{19}F and the multiplicity due to the adjacent pair of diastereomers. mp > 250 °C. ^{19}F NMR (DMSO-d_6): δ −131.31 to −131.01, −132.98 to −132.25 and −133.68 to −133.43 (3m, 8F, Ar-*m*-F), −138.2 to −137.59, −140.13 to −140.04, −140.37 to −140.31 and −140.89 to −140.79 (4m, 8F, Ar-*o*-F). ^{1}H NMR (DMSO-d_6): δ 7.78 and 7.30 (2s, 4H, pyrrolic β-H), 5.67 (m, 4H, Glc-H), 5.21−5.24, 5.02−5.06 and 4.91−4.95 (3m, 12H, Glc-H), 4.40−4.44 and 4.05−4.13 (2m, 12H, 4H β-H [C (sp^3)], 2H NH, 8H Glc-H), 3.16−3.26 (m, 20H), Glc-H), 2.70, 2.57, 2.19 and 2.18 (4bs, 8H, pyrrolidine-H), 2.01 (s, 6H, NCH_3). ^{13}C NMR (DMSO-d_6/methanol-d_4): δ 40.6 (NCH_3), 47.7, 49.06 (C2, C3, C7, and C8), 61.5, 61.6, 61.7, 62.5, 70.48, 70.52, 75.0, 75.1, 78.44, 78.46, 78.48, 84.8, 85.0 (CH_2 and Glc), 92.2, 97.8 113.2, 113.3, 113.36, 113.38, 113.61, 119.0, 119.2, 146.0−148.6 (C_6F_4). HRMS calcd. for $C_{74}H_{69}F_{16}N_6O_{20}S_4$ $(M+H)^+$ 1793.3194, found 1793.3197.

*Synthesis of Protected Thioglycosylated Bacteriochlorin, BGlcAc$_4$ (**4a**).* To a solution of bacteriochlorin **4** (7 mg, 6.4 μmol) and 2,3,4,6-tetra-*O*-acetyl-glucosylthioacetate (12 mg, 29 μmol, 4.5 equiv) in DMF (0.5 mL), diethyl amine (0.1 mL) was added. The reaction mixture was stirred at room temperature for 4 h. Then, the reaction mixture was precipitated with methanol/H_2O, and the solid was filtered through a short column of Celite and washed with water. The crude mixture was recovered in CH_2Cl_2 and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/hexanes (3:1) as eluent. Bacteriochlorin **4a** (13 mg, 86%) was obtained after crystallization in CH_2Cl_2/hexanes, as a green powder. Because of the stereo centers on the sugars, **4a** is made as a mixture of two sets of diastereomers. mp > 250 °C. ^{19}F NMR ($CDCl_3$): δ −129.05 to −128.15 (4m, 8F, Ar-*m*-F), −132.80 to −132.40 (m, 4F, Ar-*o*-F), −134.95 to −134.45 (m, 4F, Ar-*o*-F). ^{1}H NMR ($CDCl_3$): δ 8.30 (m, 4H, pyrrolic β-H), 5.12−5.23 (m, 20H, 16H Glc-H, 4H, β-H [C (sp^3)]), 4.15−4.30 (m, 8H Glc-H), 3.88 (m, 4H, Glc-H), 3.05−3.10 (m, 4H, pyrrolidine-H), 2.45−2.46 (m, 4H pyrrolidine-H), 2.06−2.31 (m, 54H, 6H NCH_3, 48H, 48H, acetyl-H), −1.75 (s, 2H, NH). ^{13}C NMR ($CDCl_3$): δ 20.6 (CH_3CO_2), 41.2 (NCH_3), 52.4 and 52.5 (C2, C3, C7, and C8), 61.7, 61.8 (CH_2 and Glc), 68.0, 70.6, 73.88, 76.70, 77.0, 77.3, 84.6 and 84.7 (Glc), 92.2, 99.7, 107.7, 111.4, 111.5, 115.5, 115.6, 122.6, 122.7, 136.0, 136.1, 144.4−148.7 (C_6F_4), 164.0, 169.38, 169.40, 170.19, and 170.64 (CH_3CO_2). HRMS calcd. for $C_{106}H_{100}F_{16}N_6O_{36}S_4$ $(M)^{+\bullet}$ 2464.4806, found 2464.4813.

*Synthesis of Thioglycosylated Bacteriochlorin, BGlc$_4$ (**4b**).* Bacteriochlorin **4a** (10 mg, 4.0 μmol) was dissolved in methanol/CH_2Cl_2 (3:1, 1.5 mL) and treated with sodium methoxide (0.5 M solution in methanol, 0.2 mL). The reaction mixture was stirred at room temperature for 1 h and then neutralized by an aqueous citric acid solution. The mixture is filtered through Waters Sep-Pak C_{18} 35 cm^3 reverse-phase prep column and washed with water. Though **4** has a plane of symmetry, because of the chiral centers on the sugars on **4a** and **4b**, these are prepared as a set of two diastereomers. The deprotected bacteriochlorin **4b** was eluted with methanol and purified by flash chromatography (silica gel) using a mixture of ethyl acetate/methanol (3:2) as eluent. Bacteriochlorin **4b** (6.5 mg, 88%) was obtained after crystallization in methanol/CH_2Cl_2, as a green powder. mp > 250 °C. ^{19}F NMR (MeOD): δ −134.0 to −132.5 (4m, 8F, Ar-*m*-F), −137.2 to −136.0 (m, 4F, Ar-*o*-F), −140.0 to −139.0 (m, 4F, Ar-*o*-F). ^{1}H NMR (MeOD): δ 8.42 (bs, 4H, pyrrolic β-H), 5.30−5.45 (m, 4H, Glc-H), 5.05−5.14 (m, 4H, β-H [C (sp^3)]), 3.73−3.74 and 3.63−3.65 (2m, 8H,

Glc-H), 3.49−3.54 and 3.41−3.43 (2m, 16H, 8H, and 8H Glc-H), 3.15−3.18 (m, 4H, pyrrolidine-H), 2.79−2.82 (m, 4H, pyrrolidine-H), 2.28 (s, 6H, NCH_3). ^{13}C NMR (MeOD): δ 39.8 (NCH_3), 51.8, 51.9 (C2, C3, C7, and C8), 61.6, 70.5, 74.57, 74.59, 78.3, 81.36, 81.37, 84.9, 85.12 (CH_2 and Glc), 99.91, 99.94, 100.0, 103.9, 113.32, 113.34, 113.45, 113.50, 120.86, 121.0, 136.2, 136.3, 136.4, 146.0−148.6 (C_6F_4). HRMS calcd. for $C_{74}H_{69}F_{16}N_6O_{20}S_4$ $(M+H)^+$ 1793.3194, found 1793.3179.

UV−visible, Fluorescence Spectroscopy, and Quantum Yield Calculations. UV−visible and fluorescence measurements were performed on dilute solutions, typically ~2 μM, of compounds in ethanol, phosphate buffered saline (PBS), and ethyl acetate. The UV−visible spectra were obtained from 330 to 800 nm using 1 cm quartz cuvettes. For steady-state fluorescence spectroscopy, samples were excited at 509 nm for ethyl acetate and 512 nm for PBS and ethanol where absorbencies are ≤0.1. For emission spectra, both the excitation and detection monochromators had a band-pass of 1 nm. The corrected emission (for instrument response) and absorption spectra were used to calculate the quantum yield. Fluorescence quantum yields were determined for chlorin, isobacteriochlorin, and bacteriochlorin solutions relative to TPP in toluene, which has a fluorescence quantum yield of 0.11 (*57, 58*). The quantum yields were measured indirectly using TPP; thus, these values may have some systematic error. All experiments were carried out on the same day, using identical concentrations to minimize any experimental errors. These three glycosylated conjugates are quite stable toward photobleaching. When ethanolic solution of $IGlc_4$ is exposed to sunlight with a power of ca. 40−80 W/m^2 for ca 2 h, we found only 10.5% of the compound decomposed (Supporting Information).

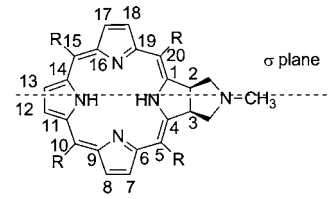
Quantum Yield of Singlet Oxygen Production (Φ_Δ). Φ_Δ values were determined on a relative basis by using *meso*-tetrakis(4-sulfonatophenyl)porphine dihydrochloride (TSPP) as a reference sensitizer ($\Phi_{\Delta,TSPP} = 0.7$ in methanol) (*56*). A time-resolved Nd:YAG laser (Polaris II, Electro Scientific Industries, Inc.) equipped with low-temperature cooled Ge detector (Applied Detector Corporation) was employed as an excitation source at 532 nm. All of the experiments were carried out in deuterium methanol-d_1. The absorbances from samples and TSPP at 532 nm were controlled between 0.1 and 0.5. $^1O_2$ luminescence was monitored as a function of sensitizer absorbance. Slopes were analyzed from a plot of $^1O_2$ intensity via absorbance. Φ_Δ can be calculated according to following equation:

$$\Phi_{\Delta,\text{sample}}/\Phi_{\Delta,\text{reference}} = \text{slope}_{\text{sample}}/\text{slope}_{\text{reference}}$$

Cell Culture. 3T3 K:MOLV NIH cells maintained in DMEM, 10% BCS, 1% antimycotic at 37 °C and in 5% CO_2 atmosphere were plated onto coverslips in cell culture dishes. $PGlc_4$, $CGlc_4$, and $IGlc_4$ dissolved in methanol were added to the cell cultures to a final concentration of 1 or 2.5 μM such that there was never more than 0.5% methanol in the solution. After 20 h incubation, cells were washed with PBS 3−5 times and fixed in 4% paraformaldehyde solution for 10 min at room temperature. The cells were then washed with PBS 3 times. The cells were visualized using a Nikon Optiphot 2 fluorescence microscope. Images were captured as JPEG files at 10× magnification, with a 505−565 nm excitation band-pass filter and a 565−685 nm emission band-pass filter. For each set of experiments, cells were cultured and the fluorescence images were taken under identical culture and microscopic conditions. For quantitative studies, the image intensities of the cells in the fluorescence micrographs were calculated by FLim program available at http://nathan.instras.com/projects/FLim/index.html.

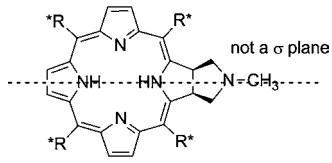
Confocal Microscopy. Cells were plated onto coverslips in cell culture dishes. $BGlc_4$ dissolved in DMSO was added to the cultures to a final concentration of 10 μM (DMSO concentrations were <0.2%). After incubation for 24 h, the cells were rinsed three times with PBS and incubated with a 4% paraformaldehyde solution for 15 min at 37 °C under cell growth conditions. Cells were then washed three times with PBS, mounted in Dako fluorescence mounting medium, and visualized using a Zeiss LSM510 laser scanning confocal microscope where images were captured with excitation at 514 nm, emission used a 710−750 nm band-pass filter.

RESULTS AND DISCUSSION



The reduction of $TPPF_{20}$ is carried out by modifications of a reported 1,3-dipolar cycloaddition reaction of an azomethine ylide with $TPPF_{20}$, **1**, to produce chlorin **2**, isobacteriochlorin **3**, and bacteriochlorin **4** (Scheme 2) (*48, 49, 51*). The reaction is scaled up by 5-fold, and the chlorin, bacteriochlorin, and isobacteriochlorin products were separated by column chromatography using a petroleum ether/ethyl acetate gradient as eluent. When compound **3** is the target, the products are formed in yields of ca. 66% for **2**, 13% yield of the anti isomer of **3**, and 5% yields for the syn and anti isomers of the bacteriochlorin **4**. These yields are somewhat different from those reported, and reflect the yield of the isobacteriochlorin to the bacteriochlorin as ca. 5:1 rather than a few percent of the latter.

The mechanism of these dipolar additions has been discussed (*51*). Interestingly, chiral HPLC assays and CD spectra indicate a trace quantity of what is likely the product of a nonconcerted addition reaction in the crude reaction mixture in the synthesis of the chlorin. This may arise because of the stability of an intermediate conferred by the macrocycle (*59, 60*), but we did not pursue this. Statistically, the second dipolar addition reaction should prefer the adjacent pyrrole 2:1 over the opposite pyrrole, but IF_{20} is formed at 3:1. As with previous reports, for IF_{20} the anti structure (Scheme 2) forms predominantly by ca. 7-fold (*48, 49*), and our preliminary dynamics calculations indicate steric crowding between the *N*-methyl-pyrrolidine methylenes, and adjacent fluorophenyls result in distortion of the macrocycle and partial blocking of the syn face. In the case of the BF_{20}, the syn isomer is the major product. The dipolar addition mechanism in terms of MO calculations was discussed (*51*).



The principal goal was to obtain the four compounds in one step and in sufficient quantity for the next reactions. NMR and mass spectrometry are consistent with the previous report and attest to the purity of these porphyrinoid-F_{20} intermediates. The nucleophilic substitution of the thioglucose at the para position of the perfluorophenyl substituents of these porphyrinoids is a modification of that previously reported (*33*). Specifically, 4.5 equiv of 1-thioacetate-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranose, a greater quantity of diethylamine (DEA), in 1 h reactions yields $PGlcAc_4$ **1a**. Thus, **2a** ($CGlcAc_4$), **3a** ($IGlcAc_4$), and **4a** ($BGlcAc_4$) are obtained from **2**, **3**, and **4**, respectively (Scheme 2). More than four thiosugars can be added with greater equivalents and longer reaction times. Flash chromatography yields the protected glycosylated derivatives as the mixture of diastereomers in ca. 85% yields. The carbohydrate protection groups were removed by treating **1a**, **2a**, **3a**, and **4a** with sodium methoxide in dry methanol to obtain the glycoporphyrinoids **1b**, **2b**, **3b**, and **4b** in ca. 95−98% yield (Scheme 2) (Supporting Information).

Since the *N*-methyl-pyrrolidine points toward one face of the macrocycle, addition of moieties with chiral centers such as the sugars to chlorin **2** results in diastereomers at the *N*-methylpyrrolidine β-carbons for **2a** and **2b**, even though **2** has a plane of symmetry. Thus, **2a** and **2b** are 2R,3S diastereomers, which was not previously recognized. As pointed out in the synthesis (*51*), there is a set of enantiomers at the β-carbons for the anti conformer of **3**; thus, the addition of the sugars further

Scheme 3. $CGlc_4$ Diastereomers (see Supporting Information)

(2*R*,3*S*) - meso when R is achiral

(2*R*,3*S*) - optically active diastereomer when R* is chiral

differentiates these in **3a** and **3b** into diastereomers 2R,3S,7S,8R and 2S,3R,7R,8S. Both the syn and anti forms of bacteriochlorin **4** have a plane of symmetry, but addition of the sugars results in a set of diastereomers, 2R,3S,12S,13R and 2S,3R,12R,13S (Scheme 3).

The structures of all porphyrinoids were confirmed by NMR, UV−visible, and mass spectrometry and HRMS analysis. The ^{1}H NMR spectra of **2a**, **3a**, and **4a** show the porphyrinoid core pyrrole β protons near 8.9 ppm and the pyrrole NH protons near −2 ppm. The ^{1}H NMR spectra of all three compounds show resonance at 2.1 and 2.3 ppm, due to the acetyl protons, and the resonances of the other protons of the carbohydrate unit appear between 4 and 6 ppm. The resonances of the anomeric protons appear as doublets at 5.03 ppm to 5.40 ppm. The N-methyl groups are observed in the 2.22 ppm for **2a** and are obscured by the acetyl groups in **3a** and **4a**. While the diastereomers are observed for some resonances for the protected derivatives, they are not well-resolved for **2b**, **3b,** and **4b**.

The ^{19}F NMR spectra confirm the substitution of the para-fluorine atom by the sugar unit, showing the disappearance of the resonances due to the para-fluorine atoms in **2**, **3**, and **4** at −150 ppm. An important diagnostic is the signal due to the meta-fluorine atom shift from −160 ppm in **2**, **3**, and **4** to −130 ppm for **2a**, **3a**, and **4a**. The ortho-fluorine atom resonances remain near −140 ppm. The ^{19}F NMR spectra do not exhibit marked differences between **2a** and **2b**, **3a** and **3b**, or **4a** and **4b**, though these peaks are broadened due to the diastereomeric centers. The ^{13}C NMR clearly indicates the multiple resonances arising from the diastereomers, especially for the phenyl carbons, which remain coupled to the F-atoms, and are closest to the chiral centers of **2a**, **2b**, **3a**, **3b**, **4a**, and **4b**.

Considering the large dependence of the photophysical properties of polar chromophores on the solvent matrix and on other experimental parameters, it is important to develop a self-consistent set of data for accurate comparison of these properties and assessment of potential applications. Since the dye can partition into lipophilic, hydrophilic, or amphipathic cellular structures, we have assayed the photophysical properties in three different solvents. Thus, PBS at pH = 7.4, ethanol, and ethyl acetate solvents were used to probe the photophysical properties (the partition coefficients and photophysical properties are summarized in Tables 1 and 2). While the initial association with the cell is mediated by glucose receptors and the four glycosyl groups on the chromophore, some nonspecific partition into the membrane is also indicated. Because of the size of the molecules, uptake is unlikely to proceed by active or passive transport, but the high local concentration around the cell increases diffusion. Thus, uptake is also dependent on the relative hydrophobicity of the compounds (*61*). The octanol/water partition coefficient and R_f for the glycosylated compounds are listed in Table 1.

Table 1. Partition Coefficients

compound	octanol/water	R_f[a]
$PGlc_4$	43.9 (4.8)	0.6 (5.5)
$CGlc_4$	28.5 (3.13)	0.37 (3.4)
$IGlc_4$	9.1 (1)	0.11 (1)
$BGlc_4$	12.7 (1.4)	0.13 (1.2)

[a] Normalized values in parentheses; see Experimental Section.

The electronic spectra of **2**, **3**, and **4** and the glycosylated derivatives are significantly different from the $TPPF_{20}$. The lowest-energy Q-band of chlorin, $CGlc_4$, in PBS buffer at 649 nm has about 25-fold greater intensity than corresponding Q-band of porphyrin $PGlc_4$ at 646 nm. For isobacteriochlorin, $IGlc_4$ in the same buffer, the lowest-energy Q-band at 645 nm is 5-fold more intense than the porphyrin at the same wavelength. For $BGlc_4$, the strong lowest-energy peak is located at 730 nm improving the absorption in the red region of the spectrum. The fluorescence emission spectra for the four glycosylated porphyrinoids are correspondingly different and have a strong solvent dependence (Table 2).

There are negligible Stokes shifts for $PGlc_4$, $CGlc_4$, and $BGlc_4$ in the three solvents, indicating minimal specific solvent−solute interactions with the macrocycle effecting vibrational processes (*62*). Notably, for the $IGlc_4$ in PBS, the strongest fluorescence band λ_{max} is at 606 nm with a weaker emission centered at 650 nm, while for $BGlc_4$, the peak is presented at 725 nm. Excitation spectra all indicate the presence of only the given compounds. The 0.17 and 0.36 fluorescence quantum yields for $CGlc_4$ and for $IGlc_4$ in PBS are 6 times and 12 times, respectively, that of the porphyrin analogue $PGlc_4$, while for $BGlc_4$ it is 0.03, similar to the $PGlc_4$. There is a small decrease in fluorescence quantum yield upon replacement of the para F atom by the thiocarbohydrate group due to both electronic and heavy atom effects. The greater fluorescence quantum yield of **2b** than m-THPC (*13*) or a water-soluble dimeso substituted chlorin (*10*) likely arises from the presence of the 16 F groups and relative energies of the molecular orbitals, and is consistent with the quantum yield of singlet oxygen generation by **2** (*63*). However, tetraarylporphyrins with a tripeptide (*64*) and other meso aryl chlorins (*65*) have similar photophysical properties to what we find. The sugars have little direct effect on the photophysics but modulate the amphipathicity and enable the observed solvent dependence.

The quantum yields of singlet oxygen formation for three of the compounds in methanol-d_1 are listed in Table 2. Since the porphyrin ring is the reactive site for $^1O_2$ production, the frequency of collisions that result in the formation of $^1O_2$ is related to the probability that an $^3O_2$ molecule makes physical contact with the chromophore in the excited, triplet state. The additional steric effect of the pyrrolidine-fused rings on $CGlc_4$ and $IGlc_4$ could result in reduced collision frequencies and a lower Φ_Δ compared to $PGlc_4$. It is reasonable to expect that internal conversion is somewhat consistent between the compounds, so the increased fluorescence quantum yield means a decrease in the amount of triplet formed. The Φ_Δ data dovetail with the observe fluorescence yields, but the Φ_Δ for $IGlc_4$ in methanol is more consistent with the PBS buffer data.

Because our previous studies with thioglycosylated porphyrin $PGlc_4$ indicated good uptake and photodynamic effects on several cancer cell lines, K:Molv NIH 3T3 mouse fibroblasts (Figure 2) and the MDA-MB-231 breast cancer cell line were used to evaluate the cellular uptake of the glycosylated

Table 2. Photophysical Properties of Glycosylated Porphyrinoid Derivatives

compound	solvent	UV−visible[a]	emission λ_{max}	Φ_F[b]	$^1O_2$ Φ_Δ

derivatives. Our initial hypothesis was that the *N*-methylpyrrolidine moieties used to make and stabilize the chlorin, bacteriochlorin, and isobacteriochlorin (as well as the stereo centers at the β positions) would have minimal effect on cell uptake, because these are sandwiched between the glycosylated tetrafluorophenyl groups. K:Molv NIH 3T3 cells were incubated identically with 2.5 μM concentrations of $PGlc_4$, $CGlc_4$, and $IGlc_4$, rinsed with buffer, and the relative uptake was quantified by comparison of images taken by fluorescence microscopy under identical settings (*38*). Confocal microscopy using 10 μM $BGlc_4$ was used because the red absorption and emission are outside the range of our fluorescence microscope (Figure 3). The electronic spectra, fluorescence, and fluorescence microscopy studies all show that these compounds are robust to photobleaching. The remaining 16 F groups impart oxidative stability and further enhance the photonic properties.

At 2.5 μM, the relative integrated intensities for $PGlc_4$, $CGlc_4$, and $IGlc_4$ in the fluorescence micrographs of the K:Molv NIH 3T3 are 1:2:7, respectively (Figure 2). Taking into consideration both the partition coefficients and the fluorescence quantum yields, one would expect that the relative uptake of these compounds into the cells measured by fluorescence to be ca. 1:4:2 for the $PGlc_4$/$CGlc_4$/$IGlc_4$, respectively. The disparity may arise from differences in cell specificity or the degree of aggregation of the compounds in the PBS buffer and/or aggregation as the local concentration of the dyes around the cell increases (*17*). The propensity of aggregation inside the cell may also vary. Also, some diastereomers may be taken up preferentially over others. The mechanism of uptake and photodynamic effects in this and other cell lines will be reported elsewhere.

Though there may be differences in uptake among these compounds, we have shown that the $PGlc_4$ compound localizes in the endoplasmic reticulum because of the metabolic needs of this organelle (*43*). The significantly greater fluorescence quantum yield of the $IGlc_4$ system means that ca. 25 nM concentrations can be used to follow receptors and/or glycolysis processes in the cell (Figure 4). Thus, $IGlc_4$ is better suited for tagging and sensor applications. For PDT applications, sensitizers with strong red absorptions are generally considered better because these wavelengths penetrate deeper into tissue (*6, 7*). The optical cross section of $CGlc_4$ in the red region is significantly larger than the porphyrin or isobacteriochlorin analogues. Thus, if red light is used to activate the second-generation dye $CGlc_4$, the increased light absorptivity more than compensates the reduced triplet quantum yield. Given the very strong 730 nm absorption, the low fluorescence quantum yield, and the greater triplet quantum yield of $BGlc_4$, this may be the best photosensitizer for PDT of the compounds described herein. However, a more efficient synthesis and purification of the isomers and diastereomers needs to be developed for the bacteriochlorin compounds to be used. The detailed photophysics of these compounds, including in biological systems, will be the subject of future studies.

Though the fluorescence of $CGlc_4$ and $IGlc_4$ is greater than that of the parent porphyrin, there is still sufficient triplet formation to effect cell death via necrosis and/or apoptosis. This indicates that these compounds can be used as dual function

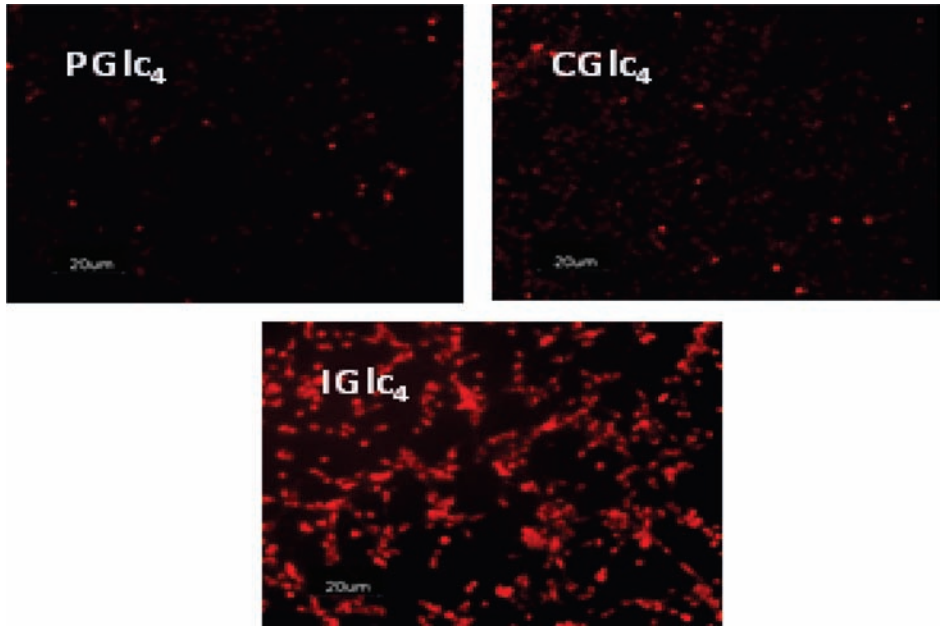

Figure 2. Fluorescence microscopy of K:Molv NIH 3T3 cells treated with 2.5 μM $PGlc_4$ (**1b**), $CGlc_4$ (**2b**), and $IGlc_4$ (**3b**). K:Molv NIH 3T3 cells were incubated for 20 h with porphyrinoids, followed by removal of unbound dye from the cell culture by repeated rinsing with PBS, and the cells were imaged under identical microscope settings and not enhanced; magnification 10×.

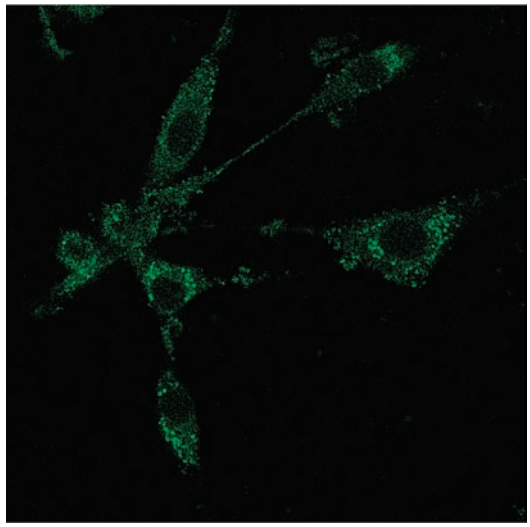

Figure 3. K:Molv NIH 3T3 cells were incubated with 10 μM $BGlc_4$ for 24 h, rinsed three times with PBS buffer, and fixed with 4% paraformaldehyde solution. Confocal microscope excitation at 514 nm, emission monitored with a 710−750 band-pass filter. No images are observed using a 610−650 nm emission band-pass filter, so fluorescence does not arise from the one of the other dye systems. The image is not enhanced; magnification is 60×.

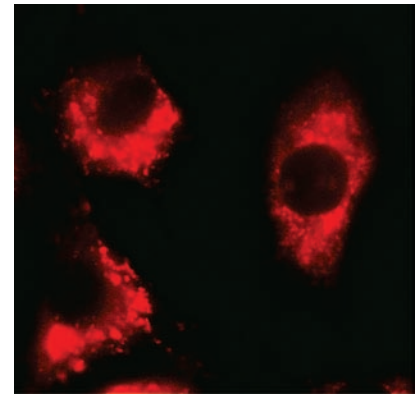

Figure 4. Fluorescence image of a MDA-MB-231 breast cancer cell treated with 25 nM $IGlc_4$ and rinsed three times with PBS buffer to remove unbound dye (see Supporting Information for comparisons to the other porphyrinoids).

agents that both locate and treat cancerous cells. To demonstrate PDT activity, $CGlc_4$ and $IGlc_4$ were tested under the same conditions as $PGlc_4$ (10 μM concentration and 10 min irradiation with white light from a 13 W fluorescent bulb). $CGlc_4$ and $IGlc_4$ induce cell death only after twice the light power is used (data not shown).

We have also made the chlorin via a gemdiol on one pyrrole unit of $TPPF_{20}$ and the corresponding tetraglycosylated derivative (*47, 66*), but the yield and stability are not as good as the those of the compounds described herein (Supporting Information). Similar to the parent $TPPF_{20}$, preliminary studies indicate the same high-yield substitution chemistry can yield an array of conjugates on these core platforms to target various tissues (*2, 34, 38*), cell types, and cellular structures (*67*).

In conclusion, these core platforms will enable rapid development of new multifunctional imaging, sensing, and therapeutic agents (*68*) for specific targets, and the ability to assess the effectiveness appended motifs in targeting. These platforms will also facilitate the development of effective probes for fundamental biochemical/biophysical studies (*44, 69*). Both $CGlc_4$ and $IGlc_4$ have significantly enhanced fluorescence quantum yields compared to $PGlc_4$, while the $BGlc_4$ derivative has a fluorescence quantum yield that is similar to the parent porphyrin. Thus, $IGlc_4$ has greatest potential use as fluorescent tags, diagnostics, or imaging agents. The intermediate fluorescence of the $CGlc_4$ system may well serve as a dual purpose agent for targeting, detecting, and treating diseased tissues. The $BGlc_4$ system has near-optimal properties as the PDT agent, but new synthetic strategies are needed to make these compounds.

$PGlc_4$ $CGlc_4$ $IGlc_4$

Figure S35. Cell uptake of the three $PGlc_4$, $CGlc_4$, and $IGlc_4$ by MDA-MB-231 breast cancer cells. a-c: fluorescence images after uptake from 0.05 μM solutions; d-f: cellular fluorescence after uptake from 0.5 μM solutions. 60x magnification.

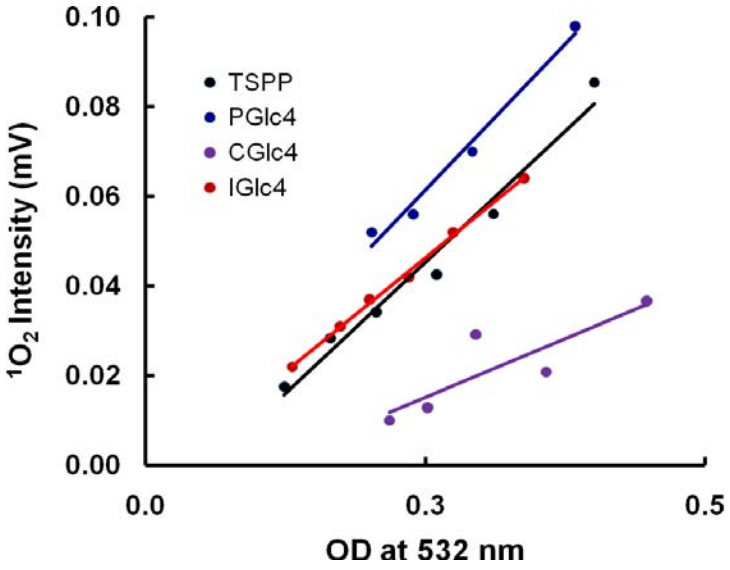

Figure S36. Changes in $^1O_2$ intensity as a function of OD at 532 nm. The lower Φ_Δ from $CGlc_4$ may partially due to the inefficient light absorption at 532 nm compared to $IGlc_4$.

Ideally, all of the lines in Figure S36 should go through zero. However, in many cases the background signals from laser pulse and detector can result in a positive intercept. This is largely accounted for since the Φ_Δ were calculated by comparing the slopes to a standard (TSPP).

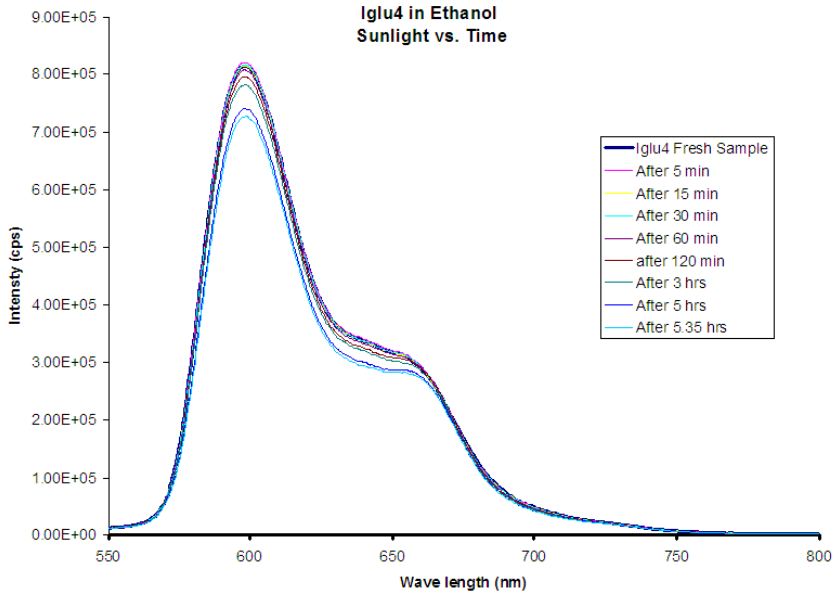

Figure S37. Emission spectra of $IGlc_4$ in ethanol in air in a closed vial shows only a small degree of photobleaching of $IGlc_4$ in sun light with time.

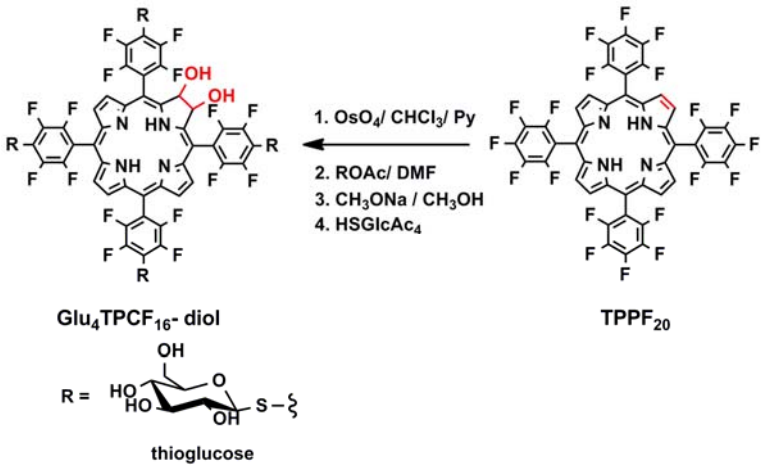

Figure S38. The para F substitution chemistry works on the diols formed using the procedures outlined in: Lara, K. K., Rinaldo, C. R., and Brückner, C. (2005) meso-Tetraaryl-7,8-diol-21,23-dithiachlorins and their pyrrole-modified derivatives: a spectroscopic comparison to their aza-analogues. *Tetrahedron 61*, 2529-2539.

Convenient Synthesis of a Propargylated Cyclic (3′-5′) Diguanylic Acid and Its "Click" Conjugation to a Biotinylated Azide

Andrzej Grajkowski,*[,‡] Jacek Cieślak,[‡] Alexei Gapeev,[§] Christian Schindler,[†] and Serge L. Beaucage[‡]

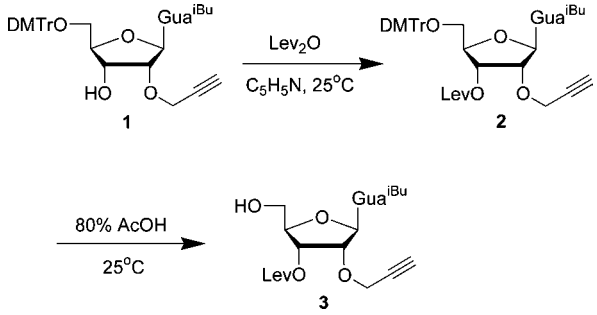
Division of Therapeutic Proteins, Center for Drug Evaluation and Research, Food and Drug Administration, 8800 Rockville Pike, Bethesda, Maryland 20892, United States, Department of Microbiology & Immunology, Columbia University, 701 West 168th Street, New York, New York 10032, United States, and Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, 1000 Hilltop Circle, Baltimore, Maryland 21250, United States.
Received August 26, 2010; Revised Manuscript Received September 16, 2010

The ribonucleoside building block, N^2-isobutyryl-2′-*O*-propargyl-3′-*O*-levulinyl guanosine, was prepared from commercial N^2-isobutyryl-5′-*O*-(4,4′-dimethoxytrityl)-2′-*O*-propargyl guanosine in a yield of 91%. The propargylated guanylyl(3′-5′)guanosine phosphotriester was synthesized from the reaction of N^2-isobutyryl-2′-*O*-propargyl-3′-*O*-levulinyl guanosine with N^2-isobutyryl-5′-*O*-(4,4′-dimethoxytrityl)-2′-*O*-*tert*-butyldimethylsilyl-3′-*O*-[(2-cyanoethyl)-*N*,*N*-diisopropylaminophosphinyl] guanosine and isolated in a yield of 88% after *P*(III) oxidation, 3′-/5′-deprotection, and purification. The propargylated guanylyl(3′-5′)guanosine phosphotriester was phosphitylated using 2-cyanoethyl tetraisopropylphosphordiamidite and 1*H*-tetrazole and was followed by an in situ intramolecular cyclization to give a propargylated c-di-GMP triester, which was isolated in a yield of 40% after *P*(III) oxidation and purification. Complete *N*-deacylation of the guanine bases and removal of the 2-cyanoethyl phosphate protecting groups from the propargylated c-di-GMP triester were performed by treatment with aqueous ammonia at ambient temperature. The final 2′-desilylation reaction was effected by exposure to triethylammonium trihydrofluoride affording the desired propargylated c-di-GMP diester, the purity of which exceeded 95%. Biotinylation of the propargylated c-di-GMP diester was easily accomplished through its cycloaddition reaction with a biotinylated azide derivative under click conditions to produce the biotinylated c-di-GMP conjugate of interest in an isolated yield of 62%.

INTRODUCTION

Cyclic (3′-5′)diguanylate (c-di-GMP) was first identified in *Acetobacter xylinum* as a factor that allosterically regulates membrane cellulose synthesis (*1*−*3*). More recently, enzymes controlling the intracellular levels of c-di-GMP, particularly those including the GGDEF (Gly-Gly-Asp-Glu-Phe) and EAL (Glu-Ala-Leu) domains, which possess diguanylate cyclase and phosphodiesterase activities, respectively, have been identified in the majority of bacterial genomes (*2*). Consistent with these findings, functional studies have determined that c-di-GMP levels regulate important bacterial programs, such as those associated with a switch from planktonic to biofilm growth and those associated with virulence (*2*). Moreover, c-di-GMP has been identified as a potent adjuvant, owing to its ability to induce the expression of a number of inflammatory cytokines and chemokines (e.g., TNF-α, IL-1, IFN-*β*, IP-10, and Rantes) (*4*, *5*). More recent studies have provided evidence for a cytosolic sensor that detects c-di-GMP and initiates this inflammatory response (*5*). However, the sensor responsible for eliciting this inflammatory response, as well as many components in bacterial c-di-GMP signaling cascades, remains unidentified. The development of a biotinylated c-di-GMP conjugate provides an important tool for the identification and characterization of the proteins binding this ligand and their respective signaling pathways, both in prokaryotes and in eukaryotes. Moreover, these tools may also prove valuable in characterizing the responses associated with c-di-AMP (*6*).

Various synthetic strategies have been implemented for the synthesis of c-di-GMP and its analogues. Indeed, in addition to the hydroxybenzotriazole phosphotriester method (*7*,*8*), combinations of phosphoramidite and phosphotriester (*9*−*12*), phosphoramidite and *H*-phosphonate (*13*), or phosphotriester and *H*-phosphonate (*14*, *15*) methods have also been reported for this purpose. Interestingly, an enzymatic approach and a solid-phase approach to the synthesis of c-di-GMP have recently been described in the literature (*16*, *17*). We now report a straightforward solution-phase synthesis of the propargylated c-di-GMP **10** using exclusively, for the first time, phosphoramidite chemistry. The synthetic strategy consists of exploiting commercially available starting materials (**1** and **4**) and clustering synthetic operations in order to minimize the number of purification steps (Schemes 1−3). As outlined in Scheme 4, synthesis of the biotinylated azide **13** from commercial aminoalkylated biotin amide **12** and conversion of **13** to the biotinylated c-di-GMP **14** via a copper(I)-catalyzed [3 + 2] azide−alkyne cycloaddition reaction (CuAAC or click chemistry) (*18*, *19*) are described in detail in this report.



EXPERIMENTAL PROCEDURES

***N*^{2}-Isobutyryl-3′-*O*-levulinyl-2′-*O*-propargyl Guanosine (3).** To a solution of N^2-isobutyryl-5′-*O*-(4,4′-dimethoxytrityl)-2′-*O*-propargyl guanosine (**1**, 1.73 g, 2.50 mmol) in dry pyridine (10 mL) was added levulinic anhydride (*20*, *21*) (2.50 g, 10.0 mmol); the solution was stirred at ∼25 °C for 16 h and was then evaporated to a gummy material under reduced pressure. The residue was dissolved in $CHCl_3$ (30 mL) and was vigorously

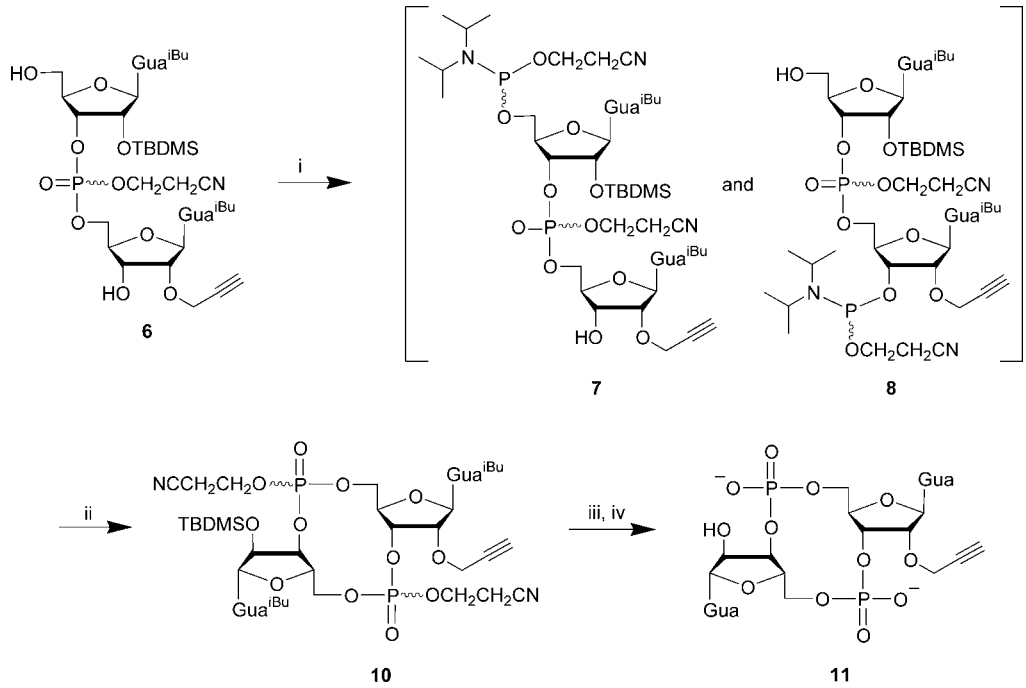
mixed with water (15 mL). The organic layer was collected and evaporated under low pressure. The crude ribonucleoside **2** was dissolved in 80% AcOH (10 mL) in order to remove the 5′-protecting group; progress of the reaction was monitored by TLC, which revealed complete cleavage of the 4,4′-dimethoxytrityl (DMTr) ether after a reaction time of 3 h. The reaction mixture was concentrated under vacuum to an oil, which was dissolved in $CHCl_3$ (3 mL) and purified by chromatography on silica gel (∼40 g) using a gradient of MeOH (0 → 3%) in $CHCl_3$. Fractions containing the ribonucleoside **3** were collected and evaporated under reduced pressure to give a white solid (1.12 mg, 2.28 mmol) in a yield of 91% based on the molar amount of ribonucleoside **1** that was used as the starting material. ^{1}H NMR (300 MHz, DMSO-d_6): δ 12.1 (bs, 1H), 11.7 (bs, 1H), 8.29 (s, 1H), 5.90 (d, 1H, J = 7.7 Hz), 5.38 (m, 2H), 4.83 (dd, 1H, J = 7.7, 7.7 Hz), 4.14 (m, 3H), 3.63 (m, 2H), 3.41 (t, 1H, J = 2.4 Hz), 2.77 (m, 2H), 2.76 (sept, 1H, J = 6.7 Hz), 2.56 (m, 2H), 2.13 (s, 3H), 1.12 (d, 6H, J = 6.7 Hz). ^{13}C NMR (75 MHz, DMSO-d_6): δ 206.7, 180.1, 171.7, 154.6, 148.9, 148.4, 137.1, 119.8, 84.1, 83.9, 79.1, 78.7, 77.9, 71.4, 61.0, 57.6, 37.3, 34.7, 29.5, 27.5, 18.7. +ESI-HRMS: Calcd for $C_{22}H_{27}N_5O_8$ $[M + H]^+$, 490.1932, found 490.1935.



Propargylated Guanylyl(3′-5′)guanosine Phosphotriester 6. To a stirred solution of pre-dried ribonucleoside **3** (970 mg, 2.00 mmol) and phosphoramidite **4** (1.94 g, 2.00 mmol) in anhydrous MeCN (20 mL) was added solid 1*H*-tetrazole (210 mg, 3.00 mmol). ^{31}P NMR analysis of the reaction mixture showed, within 4 h at ∼25 °C, the appearance of two singlets

(δ_P = 140.7 and 139.5 ppm) corresponding to the expected diastereomeric diribonucleoside phosphite triesters **5**. Addition of 5.5 M *tert*-butyl hydroperoxide in decane (730 μL) to the reaction mixture resulted in the conversion of the phosphite triesters to their diastereomeric phosphate triester derivatives within 30 min. The solution was evaporated under vacuum to an oily residue, which was treated with a solution (40 mL) of 0.5 M hydrazine hydrate in pyridine/AcOH (3:2 v/v) for 15 min; 2,4-pentanedione (2 mL) was then added to the solution in order to quench unreacted hydrazine hydrate. The volatiles were removed under reduced pressure, and the reaction product was partitioned between $CHCl_3$ (40 mL) and H_2O (20 mL). The organic phase was collected and evaporated to dryness under vacuum; the remaining material was dissolved in $CHCl_3$ (5 mL) and purified by chromatography on silica gel (~40 g) using a gradient of MeOH (0 → 5%) in $CHCl_3$. Fractions containing the 3′-deprotected dinucleoside phosphate triester were collected and evaporated under low pressure to give a yellowish powder, which was dissolved in of 80% AcOH (15 mL) and left stirring for 3 h at ~25 °C. Hexanes (25 mL) was added to the vigorously stirred reaction mixture in order to extract the 4,4′-dimethoxytrityl alcohol side product. After phase separation, the lower layer was collected and evaporated to dryness under vacuum. The thoroughly dried material was dissolved in CH_2Cl_2 (5 mL), and the solution was added dropwise to stirred hexanes (100 mL). The precipitate was filtered to give the diribonucleoside phosphate triester **6** (2.25 g, 1.76 mmol) as a white solid in a yield of 88% relative to the molar amount of ribonucleoside **3** that was used as starting material. ^{31}P NMR (121 MHz, DMSO-d_6): δ −1.96, −2.38. +ESI-HRMS: Calcd for $C_{40}H_{56}N_{11}O_{14}PSi$ $[M + H]^+$ 974.3588, found 974.3594.

Propargylated c-di-GMP 11. Vacuum-dried propargylated diribonucleoside phosphotriester **6** (973 mg, 1.00 mmol) and 2-cyanoethyl tetraisopropylphosphordiamidite (301 mg, 1.00 mmol) were dissolved in dry MeCN (20 mL) to which was added solid 1*H*-tetrazole (70 mg, 1.0 mmol) in four portions over a period of 1 h under an inert gas atmosphere. The solution was stirred for an additional 2 h at ~25 °C, and 1*H*-tetrazole (140 mg, 2.00 mmol) was then added to the reaction mixture, which was left stirring for 16 h. Without any workup, *tert*-butyl hydroperoxide (5.5 M in decane, 550 μL) was added to the stirred solution. After 30 min, the reaction mixture was concentrated under vacuum to an oil, which was dissolved in $CHCl_3$ (5 mL) and purified by chromatography on silica gel (~30 g). The product eluted from the silica gel column when employing a gradient of MeOH (0 → 8%) in $CHCl_3$. Fractions containing the propargylated c-di-GMP triester **10** were checked by TLC [R_f ($CHCl_3$/MeOH 9:1 v/v) = 0.33], collected, and evaporated under reduced pressure to give a white solid (435 mg, 400 μmol) in a yield of 40%. The purified c-di-GMP triester **10** (109 mg, 100 μmol) was treated with concentrated aqueous ammonia (3 mL) in a sealed glass vial for 30 h at ~25 °C; excess aqueous ammonia was then evaporated to dryness under reduced pressure. The material left was dissolved in neat triethylamine trihydrofluoride (4.00 mL, 24.5 mmol), and the solution was allowed to stir for 20 h at ~25 °C. The fully deprotected product was purified by RP-HPLC using a 5 μm Supelcosil LC-18S column (25 cm × 10 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 2.5% MeCN/min is pumped at a flow rate of 3 mL/min for 40 min. Fractions containing the product were collected and evaporated using a stream of air to give the propargylated c-di-GMP **11** in a near-quantitative yield. ^{1}H NMR (300 MHz, DMSO-d_6): δ 10.78 (bs, 1H), 9.76 (bs, 1H), 8.00 (s, 1H), 7.95 (s, 1H), 6.59 (bs, 4H), 5.85 (d, 1H, J = 4.3 Hz), 5.73 (d, 1H, J = 5.3 Hz), 4.88 (m, 1H), 4.73 (m 1H), 4.58 (t, 1H, J = 4.0 Hz), 4.53 (t, 1H, J = 5.2 Hz), 4.46 (dd, 1H, ^2J = 15.2 Hz, ^4J = 2.3 Hz), 4.38 (dd, 1H, ^2J = 15.2 Hz, ^4J = 2.3 Hz), 4.23−4.06 (m, 4H), 3.91 (m, 2H), 3.43 (t, 1H, ^4J = 2.3 Hz). ^{13}C NMR (75 MHz, DMSO-d_6): δ 156.5, 153.9, 151.1, 150.7, 135.0, 134.7, 116.24, 116.16, 86.5, 85.1, 80.4 (d, J_{C-P} = 9.2 Hz), 80.2 (d, J_{C-P} = 5.7 Hz), 79.7, 78.4, 77.6, 72.6 (d, J_{C-P} = 5.7 Hz), 72.0, 71.0, 62.8 (d, J_{C-P} = 5.7 Hz), 62.5 (d, J_{C-P} = 5.7 Hz), 57.7, 45.4, 8.44. ^{31}P NMR (121 MHz, DMSO-

d_6): δ −0.29, −1.25. +ESI-HRMS: Calcd for $C_{23}H_{26}N_{10}O_{14}P_2$ $[M + H]^+$ 729.1178 found 729.1184.

Biotinylated Azide 13. To a solution of commercial *N*-D-(+)-biotinyl-4,7,10,13,16-pentaoxa-1,19-diaminononadecane (**12**, 50 mg, 94 μmol) in 1 mL of MeCN/C_5H_5N (9:1 v/v) was added azidoacetic anhydride (35 mg, 0.19 mmol). The solution was stirred at ~25 °C for 1 h and was then concentrated to an oil using a stream of argon. The crude product was purified by chromatography on silica gel (2 g) using a gradient of MeOH (0−10%) in $CHCl_3$. Fractions containing the product were collected and evaporated under vacuum to give **13** as a solid (35 mg, 57 μmol, 61%). +ESI-HRMS: Calcd for $C_{26}H_{47}N_7O_8S$ $[M + H]^+$ 618.3280, found 618.3283.

Biotinylated c-di-GMP 14. To the propargylated c-di-GMP **11** (150 OD_{260}) was added a solution of 10 mM biotinylated azide **13** (800 μL), 100 mM $CuSO_4$ (120 μL), and 100 mM *tris*-(benzyltriazolylmethyl)amine (TBTA, 240 μL), each in DMSO/*tert*-BuOH (3:1 v/v). A solution of 400 mM sodium ascorbate in H_2O (175 μL) was then added to the reaction mixture, which was left stirring at ~25 °C for 16 h. The crude reaction product was purified by RP-HPLC under conditions identical to those described for the purification of the propargylated c-di-GMP **11**. Fractions containing the product were collected and evaporated under a stream of air to give the biotinylated c-di-GMP **14** (93 OD_{260}) in an isolated yield of 62%. ^{31}P NMR (121 MHz, D_2O): δ −1.73, −2.06. +ESI-HRMS: Calcd for $C_{49}H_{73}N_{17}O_{22}P_2S$ $[M + H]^+$ 1346.4385, found 1346.4429; $[M + 2H]^{2+}$ 673.7229, found 673.7229.

RESULTS AND DISCUSSION

Our solution-phase approach to the synthesis of the biotinylated c-di-GMP conjugate **14** began with the preparation of the ribonucleoside building block **3** (Scheme 1) from the commercially available propargylated ribonucleoside **1**, which was 3′-*O*-acylated by treatment with levulinic anhydride (*20*, *21*) in dry pyridine. After extractive workup, the fully protected ribonucleoside **2** was treated with 80% AcOH in order to remove the 5′-DMTr group. The 5′-deprotected ribonucleoside was purified by chromatography on silica gel to give pure **3** in a yield of 91%. The ribonucleoside was characterized by ^{1}H and ^{13}C NMR spectroscopies and by high-resolution mass spectrometry (HRMS).

The commercial availability of the 2′-*O*-*tert*-butyldimethylsilyl (TBDMS) ribonucleoside phosphoramidite **4** (Scheme 2) and the pervasive use of the click chemistry for labeling nucleosides and oligonucleotides with fluorophores, carbohydrates, and other functional groups (*22*, *23*) have been motivational in the development of our synthetic approach to the synthesis of **14**. Indeed, the reaction of **4** with the 5′-hydroxyl function of ribonucleoside **3** in the presence of 1.5 molar equiv of 1*H*-tetrazole in anhydrous MeCN produced the dinucleoside phosphate triester **5** (Scheme 2). After *P*(III) oxidation by *tert*-butyl hydroperoxide and upon concentration of the reaction mixture to an oil, a solution of hydrazine hydrate in pyridine and acetic acid was added in order to remove the levulinyl group from the terminal 3′-hydroxyl of the diribonucleoside phosphate triester. The hydrazinolysis reaction was stopped by the addition of 2,4-pentanedione, and following an extractive workup, the reaction product was purified by silica gel chromatography. The 5′-DMTr group of the purified material was then cleaved under acidic conditions (80% AcOH) to give, after workup and precipitation from hexanes, the propargylated diribonucleoside phosphate triester **6** in a yield of 88% relative to the molar amount of ribonucleoside building block **3** that was used as the starting material. This yield is excellent given that out of four synthetic operations only one purification step was performed. The dinucleoside phosphotriester **6** was characterized, as a mixture of two

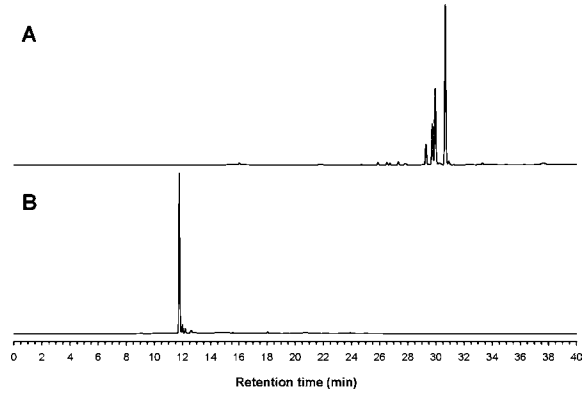

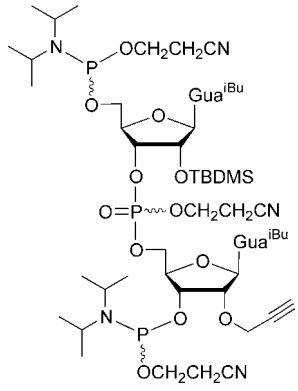

Figure 2. RP-HPLC analysis of the conversion of the propargylated c-di-GMP triester **10** to the propargylated c-di-GMP **11**. (A) Chromatogram of the silica gel-purified propargylated c-di-GMP triester **10**. (B) Chromatogram of the propargylated c-di-GMP **11** that was obtained from silica gel-purified **10** after complete deprotection, which was effected by treatment with (i) concentrated aqueous ammonia for 30 h at 25 °C and (ii) triethylamine trihydrofluoride for 20 h at 25 °C. Analytical chromatographic conditions are described in the Supporting Information under Materials and Methods. Peak heights were normalized to the highest peak, which was set to 1 arbitrary unit.

P-diastereomers, by ^{31}P NMR spectroscopy and HRMS (see Experimental Procedures section). The purity of **6** was assessed by RP-HPLC (Figure 1) and was determined to be 95%.

The preparation of the propargylated and fully protected c-di-GMP derivative **10** (Scheme 3) was carried out in MeCN by the phosphitylation of **6** with strictly 1 mol equiv of 2-cyanoethyl tetraisopropylphosphordiamidite and solid 1*H*-tetrazole, which was added at the rate of 0.25 mol equiv per 15 min under rigorously anhydrous conditions. Such a stoichiometry presumably favored the formation of the 5′-phosphoramidite **7** relative to that of the 3′-phosphoramidite **8** and 3′,5′-bis-phosphoramidite **9**, the formation of which cannot conclusively be ruled out. The intramolecular cyclization of **7** and **8** was then performed by adding two molar equivalents of solid 1*H*-tetrazole to the initial phosphitylation reaction mixture. The concentration of the reagents, with the exception of 1*H*-tetrazole, was sufficiently low (~50 mM) to favor intramolecular cyclization rather than intermolecular polymerization. The intramolecular cyclization reaction was allowed to proceed overnight (16 h) and was followed by the addition of a solution of *tert*-butyl hydroperoxide in decane in order to convert the newly formed phosphite triester function to its tetracoordinated phosphate triester state and complete the synthesis of **10**. The crude product was purified by chromatography on silica gel to give an amorphous white

solid in a yield of 40% based on the starting propargylated dinucleoside phosphate triester **6**.

The modest yield of intramolecular cyclization may be attributed to a number of factors. The use of only 1 mol equiv of 2-cyanoethyl tetraisopropylphosphordiamidite is necessary to minimize if not prevent the formation of **9**, which otherwise would result in a commensurate loss of cyclic product in addition to residual unphosphitylated **6**. Perhaps the most important factor contributing to a lower yield of **10** may be related to the presence of adventitious water in a relatively large volume of MeCN, which would lead to hydrolysis of the 1*H*-tetrazole-activated phosphoramidite functions of **7** and **8** and prevent intramolecular cyclization. However, these limitations, which are inherent to our approach to the synthesis of **10**, are clearly outweighed by the simplicity and convenience of the method.

9

RP-HPLC analysis of **10** revealed the expected presence of four diastereomers, two for each chiral phosphate function (Figure 2A). The asymmetry of **10** in addition to the chirality of its two tetracoordinated phosphate esters contributed to the complexity of its ^{1}H, ^{13}C, and ^{31}P NMR spectra. Indeed, the proton-decoupled ^{31}P NMR analysis of **10**, which revealed six out of theoretically eight signals, underscores the challenging characterization of **10** by spectroscopic techniques. In order to mitigate this difficulty, the strategy of converting **10** to the c-di-GMP **11** was adopted. Complete deprotection of **10** consisted of removing the N^2-isobutyryl and 2-cyanoethyl phosphate protecting groups first by treatment with concentrated aqueous ammonia in a sealed glass vial over a period of 30 h at ambient temperature. Lastly, the cleavage of the 2′-*O*-TBDMS group was effected by reaction with triethylamine trihydrofluoride to give, nearly quantitatively, the propargylated c-di-GMP **11**, as judged by RP-HPLC analysis of the deprotection reaction (Figure 2B). This analysis also revealed the purity of **11**, which was determined to be 95%. The propargylated c-di-GMP **11** was adequately characterized by ^{1}H, ^{13}C, and ^{31}P NMR spectroscopies and HRMS (see Experimental Procedures section).

The preparation of the biotinylated azide **13** was required for the biotinylation of **11** (Scheme 4). Acylation of the commercial aminoalkylated biotin derivative **12** with azidoacetic anhydride in a solution of 10% pyridine in MeCN over a period of 1 h at ambient temperature afforded **13** in moderate yield after purification. Azidoacetic anhydride was generated in situ from azidoacetic acid and *N*,*N*′-dicyclohexylcarbodiimide in THF under conditions similar to those employed for the preparation of levulinic anhydride (*20*, *21*). Azidoacetic acid was prepared from the reaction of bromoacetic acid and sodium azide, as described in the literature (*24*). Given the inherent complexity of the ^{1}H and ^{13}C NMR spectra of biotinylated azide **13**, its characterization by HRMS was found to be the most informative.

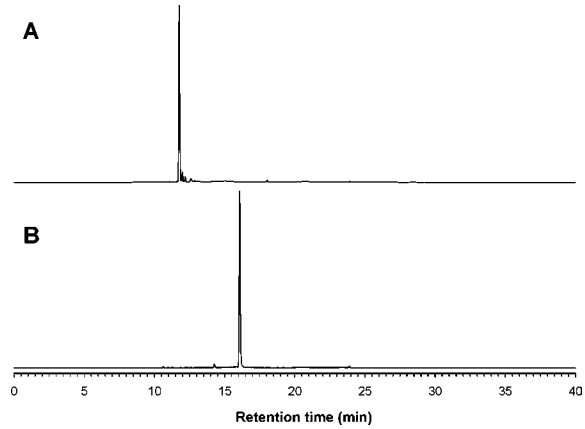

Figure 3. RP-HPLC analysis of the "click" conjugation of the propargylated c-di-GMP **11** with the biotinylated azide **13**. (A) Chromatogram of the propargylated c-di-GMP **11**. (B) Chromatogram of the purified biotinylated c-di-GMP **14** obtained from "click" conjugation of **11** with **13** under the conditions described in the Experimental Procedures section. Analytical chromatographic conditions are described in the Supporting Information under Materials and Methods. Peak heights were normalized to the highest peak, which was set to 1 arbitrary unit.

The copper(I)-catalyzed [3 + 2] cycloaddition of **13** with the propargylated c-di-GMP **11** was performed essentially as reported by Berndl et al. (*25*). The biotinylated c-di-GMP **14** was purified by RP-HPLC and was isolated in a yield of 62%, which is based on the molar amount of **11** used as the starting material. Figure 3 illustrates the "click" conjugation of the biotinylated azide **13** with the propargylated c-di-GMP **11.**

CONCLUSION

The synthetic strategy for the synthesis of the propargylated c-di-GMP **10** reported herein is based on the use of commercial starting materials including the propargylated ribonucleoside **1** and the 2′-*O*-TBDMS ribonucleoside phosphoramidite **4**. The absence of a vicinal hydroxyl function in **4** precluded the notorious migration of the TBDMS group (*26*) and formation of any isomeric side product when using this reagent. Phosphitylation of the propargylated diribonucleoside phosphate triester **6** when employing only 1 mol equiv of commercial 2-cyanoethyl tetraisopropylphosphordiamidite led to the formation of **10**, for the first time through exclusively phosphoramidite chemistry. The yield of **10** is perhaps lower than those reported using other cyclization procedures, but the convenience and simplicity of our synthetic strategy prevail over other preparative synthetic approaches in terms of the availability of starting materials, minimization of potential side reactions, and number of necessary purification steps. As mentioned above, the biological implications of the biotinylated c-di-GMP **14**, in regard to identification and characterization of the proteins recognizing and binding to c-di-GMP, are currently being investigated and may provide valuable insight into their signaling pathways and bioactivity in prokaryotes and eukaryotes. The results of these studies are beyond the scope of this report and will be communicated elsewhere. In this context, our straightforward approach to the synthesis of the propargylated c-di-GMP **11** is being exploited in the preparation of structural analogues of **11** having either one or two (2′-5′)phosphodiester linkages instead of the native (3′-5′)phosphodiester functions in order to assess whether their biotinylated conjugates may permit the identification of proteins that may or may not be similar to those associated with the recognition and binding of **11**. This work is again based on the commercial availability of both the 3′-*O*-propargylated and 3′-*O*-TBDMS isomers of ribonucleoside **1**

and ribonucleoside phosphoramidite **4**, respectively. The results of these studies will be reported in due course.

Materials and Methods. Common chemicals and solvents in addition to bromoacetic acid, DMSO, *tert*-butanol, tripropargyl amine, benzyl azide, sodium azide, levulinic acid, hydrazine hydrate, 2,4-pentanedione, 1,3-dicyclohexycarbodiimide, pyridine, triethylamine trihydrofluoride, 2-cyanoethyl tetraisopropylphosphordiamidite, 1*H*-tetrazole, 5.5 M *tert*-butyl hydroperoxide in decane, tetrakis(acetonitrile)copper(I) hexafluorophosphate, copper(II) sulfate pentahydrate, sodium ascorbate, and concentrated aqueous ammonia were all purchased from commercial sources and used without further purification. Azidoacetic acid was prepared from the reaction of bromoacetic acid and sodium azide as described by Dyke, J. M. et al. (*J. Am. Chem. Soc.* **1997**, *119*, 6883-6887). *Tris*(benzyltriazolylmethyl)amine was prepared as reported by Chan, T. R. et al. (*Org. Lett*. **2004**, *6*, 2853-2855). N^2-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-2'-*O*-propargyl guanosine, N^2-isobutyryl-5'-*O*-(4,4'-dimethoxytrityl)-2'-*O*-*tert*-butyldimethylsilyl-3'-*O*-[(2-cyanoethoxy)-*N*,*N*-diisopropylamino]phosphinyl guanosine, *N*-D(+)-biotinyl-4,7,10,13,16-pentaoxa-1,19-diaminononadecane, anhydrous solvents (MeCN, CH_2Cl_2, C_6H_6, pyridine, THF) and deuterated solvents (C_6D_6, D_2O, DMSO-d_6) were obtained from reputable sources and used as received.

Flash chromatography purifications were performed on glass columns (0.6 and 2.5 cm I.D.) packed with silica gel 60 (230-400 mesh), whereas analytical thin-layer chromatography (TLC) analyses were conducted on 2.5 cm × 7.5 cm glass plates coated with a 0.25 mm thick layer of silica gel 60 F_{254}.

Analytical RP-HPLC analyses were performed using a 5 μm Supelcosil LC-18S column (25 cm × 4.6 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 2.5% MeCN/min is pumped at a flow rate of 1 mL/min for 40 min. Preparative RP-HPLC purifications were performed using a 5 μm Supelcosil LC-18S column (25 cm × 10 mm) according to the following conditions: starting from 0.1 M triethylammonium acetate pH 7.0, a linear gradient of 2.5% MeCN/min is pumped at a flow rate of 3 mL/min for 40 min. 2 M Triethylammonium acetate buffer was purchased from Applied Biosystem and diluted to 0.1 M with HPLC grade water prior to use.

All NMR experiments were performed using a spectrometer at the field of 300.13, 75.47 and 121.5 MHz for one-dimensional ^{1}H, ^{1}H-decoupled ^{13}C and ^{1}H-decoupled ^{31}P, respectively. Samples were maintained at a temperature of 298 ºK. All spectra were recorded in deuterated solvents or as indicated and chemical shifts δ were reported in parts per million (ppm) relative to appropriate internal references.

High resolution mass spectra used to confirm the elemental composition of compounds **3**, **6**, **11**, **13** and **14** were obtained on a Bruker Daltonics ApexQ FT-ICR mass spectrometer equipped with a 12 T magnet. Electrospray ionization in positive ion mode was used to generate $[M+H]^+$ and $[M+Na]^+$ ions out of test samples (0.01 mg dissolved in 1 mL of 10 mM ammonium acetate in MeCN:H_2O (1:1 v/v)). Spectra were externally calibrated using 0.5 mg/mL solution of CsI in water, which yielded a series of peaks in the mass range used for analysis (200-2000 m/z).

Preparation of levulinic anhydride. To a solution of levulinic acid (3.5 g, 30 mmol) in anhydrous THF (100 mL) was added 1,3-dicyclohexylcarbodiimide (32 g, 15 mmol). The reaction mixture was stirred for 5 h at ~25 ºC and was then filtered in order to remove the solid 1,3-dicyclohexylurea side product. The filtrate was evaporated under reduced pressure. The material left was isolated in near quantitative yield and was used without further purification in the acylation of **1**.

Preparation of azidoacetic anhydride. To a solution of azidoacetic acid acid (202 mg, 2.00 mmol) in anhydrous THF (3 mL) was added 1,3-dicyclohexylcarbodiimide (206 mg, 1.00 mmol). The reaction mixture was stirred for 5 h at ~25 ºC and was then processed as described above for the preparation of levulinic anhydride. Azidoacetic anhydride was isolated in near quantitative yield and was used without further purification in the acylation of **12**.

Effects of Charge on Antibody Tissue Distribution and Pharmacokinetics

C. Andrew Boswell,[†] Devin B. Tesar,[‡] Kiran Mukhyala,[§] Frank-Peter Theil,[†] Paul J. Fielder,[†] and Leslie A. Khawli*[,†]

Department of Pharmacokinetic and Pharmacodynamic Sciences, Department of Antibody Engineering, and Department of Bioinformatics, Genentech Research and Early Development, South San Francisco, California 94080, United States. Received June 8, 2010; Revised Manuscript Received October 3, 2010

Antibody pharmacokinetics and pharmacodynamics are often governed by biological processes such as binding to antigens and other cognate receptors. Emphasis must also be placed, however, on fundamental physicochemical properties that define antibodies as complex macromolecules, including shape, size, hydrophobicity, and charge. Electrostatic interactions between anionic cell membranes and the predominantly positive surface charge of most antibodies can influence blood concentration and tissue disposition kinetics in a manner that is independent of antigen recognition. In this context, the deliberate modification of antibodies by chemical means has been exploited as a valuable preclinical research tool to investigate the relationship between net molecular charge and biological disposition. Findings from these exploratory investigations may be summarized as follows: (I) shifts in isoelectric point of approximately one pI unit or more can produce measurable changes in tissue distribution and kinetics, (II) increases in net positive charge generally result in increased tissue retention and increased blood clearance, and (III) decreases in net positive charge generally result in decreased tissue retention and increased whole body clearance. Understanding electrostatic interactions between antibodies and biological matrices holds relevance in biotechnology, especially with regard to the development of immunoconjugates. The guiding principles and knowledge gained from preclinical evaluation of chemically modified antibodies will be discussed and placed in the context of therapeutic antibodies that are currently marketed or under development, with a particular emphasis on pharmacokinetic and disposition properties.

INTRODUCTION

Antibody therapy is an increasingly important therapeutic modality based on identification and pharmacological exploitation of molecular targets associated with inflammatory, oncologic, and autoimmune diseases. Advances in hybridoma technology and molecular biology have enabled the development of murine, chimeric, humanized, and fully human monoclonal antibodies (mAb). As a result, in recent decades several novel therapeutic antibodies have been approved for the treatment of a variety of diseases and have been mass-produced as highly specific and relatively homogeneous reagents (*1, 2*). One major goal in biotechnology is to improve the clinical utility of these reagents with respect to antigen targeting and potency to encourage effective disease therapy. Achieving this goal depends not only upon a thorough understanding of molecular properties underlying antibody behavior and function, but also upon the development of techniques to manipulate these properties in such a way that specifically enhances properties desired for a particular application without exacerbating undesirable ones. For instance, pharmacodynamic (PD) response is often directly proportional to tissue exposure and, thus, plasma half-life (*3*). As such, a typical goal in biotherapeutic development is to identify a candidate molecule having desirable pharmacokinetic (PK) properties or, alternatively, to manipulate a molecule's properties to improve PK properties while preserving antigen recognition.

Pharmacokinetic and pharmacodynamic (PKPD) properties of antibodies are governed by both molecule-dependent and species-dependent parameters (*4*). Biological processes are important determinants in antibody PK; examples include binding to antigens (*5*) and other cognate receptors (*6*). Furthermore, an antibody's valency, shape, size, isoelectric point (pI), dosage, and injection method may also influence its disposition kinetics and clearance (*3, 7*). Molecular charge is only one of the many parameters that collectively influence antibody PK (*4, 8*), and its long-established importance (*9*) will be emphasized in this review. Following a brief overview of antibody structure and function, the results of preclinical studies involving charge-modified antibodies will be summarized. Finally, the physiological implications of electrostatic properties of antibodies will be considered at cellular and tissue levels.

ANTIBODY STRUCTURE AND FUNCTION

Immunoglobulins (Igs or antibodies) are the fundamental protein players of both innate and acquired immunity. Immunoglobulins are tetramers consisting of two light chains (LCs, ~25 kDa each) and two heavy chains (HCs, ~55 kDa each) arranged in a shape that resembles the letter "Y" (Figure 1a,b). The LCs contain an N-terminal variable domain and a C-terminal constant domain, while the HCs consist of a variable N-terminal domain and three to four C-terminal constant domains. The Fab domain (antigen binding fragment) is composed of the LC and the first two N-terminal domains of the HC. The association of the LC and HC variable domains creates an N-terminal "hypervariable region" which confers the specificity of the antibody by virtue of the interaction of amino acids within the hypervariable region with molecular components (often amino acids) of an antigen. The Fc region (crystallizing fragment) is a dimer of the two or more C-terminal domains of the HC that are not part of the Fab. Whereas the

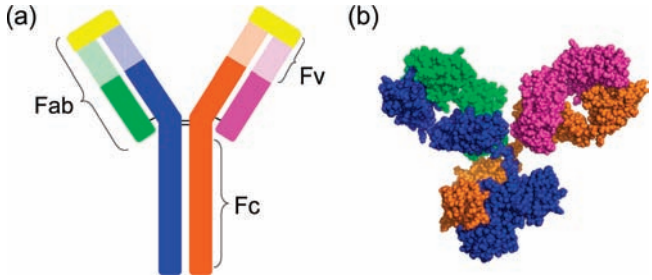

Figure 1. The four-chain structure of an immunoglobulin. The cartoon representation in (a) highlights the overall structural features of a human IgG, with CDRs depicted in yellow, and the Fab, Fv, and Fc regions indicated using brackets. The image of IgG1 (PDB code 1igy) in (b) was generated using the PyMOL molecular visualization system (*106*). In both (a) and (b), the two heavy chains are depicted in blue and orange and the two light chains in green and magenta.

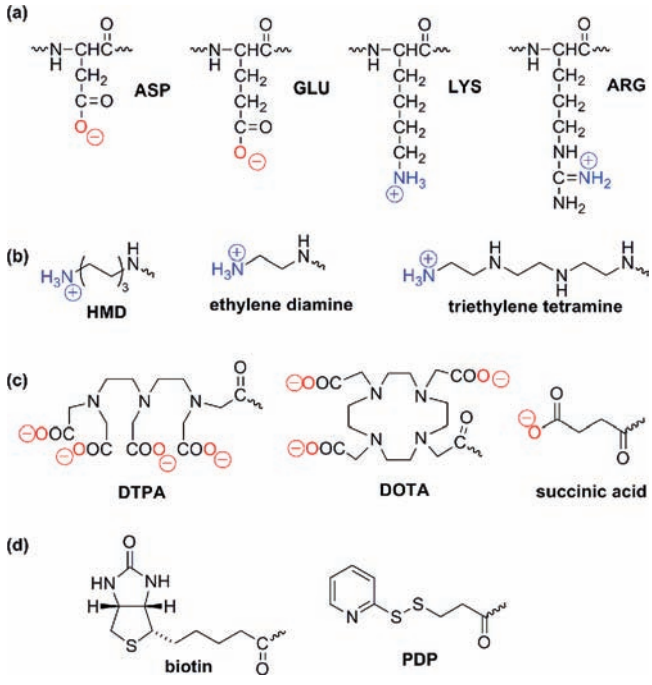

Figure 2. Natural/artificial groups contributing to antibody charge. Chemical structures of naturally occurring amino acids that are usually charged at physiological pH values (a) are shown. Also presented are structures of (b) cationic groups, (c) anionic groups, and (d) neutral groups for charge modification with wavy bonds indicating the potential site of protein conjugation. Abbreviations: HMD, hexamethylenediamine; DTPA, diethylene triamine pentaacetic acid; DOTA, 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid; PDP, pyridyl disulfide propionate.

Fab is responsible for antigen recognition and binding, the Fc regulates the biological functions of the antibody by binding to Fc receptors and eliciting immune effector functions. Binding to Fc receptors can also mediate transport of antibodies within cells or protect them from proteolytic degradation. Of particular importance for therapeutic Abs, the Fc portion of IgG binds pH-dependently to the neonatal Fc receptor (FcRn) (*10*) which protects antibodies from degradation and partially accounts for their long serum half-lives (*6, 11*).

In mammals, IgG is the most abundant Ig in serum (~80% of total serum Ig) and is the principle Ig that participates in the adaptive immune response. There are four human IgG subclasses (IgG_1, IgG_2, IgG_3, and IgG_4), which are distinguished from one another by differences in the constant region of the HC sequence. These sequence differences affect the length of the hinge region as well as the position and number of disulfide bonds between the two HCs of the IgG molecule. Additionally,

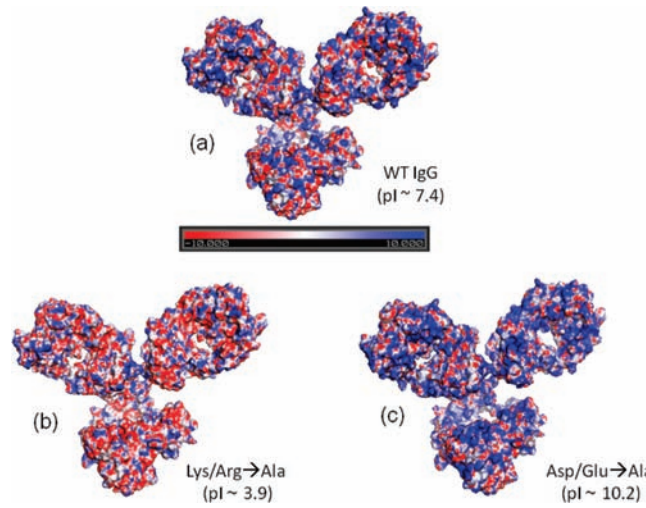

Figure 3. Graphical illustration of antibody charge modification. Electrostatic surface images of native IgG1 (PDB code 1igy) (a) and two simulated charge-modified variants (b,c) are displayed using the PyMOL molecular visualization system (*106*) to illustrate regions of neutral (white), positive (blue), and negative (red) charge. Note that, despite the extreme degree of protein modification in these simulated charge variants, the estimated pI values are roughly within the range of values shown for experimental test molecules listed in Table 2. The variant structures were created from the native protein by manual point mutation, using *DeepView* v 4.0.1 Swiss PdbViewer (http://www.expasy.org/spdbv/) (*107*), of all 86 Lys and 38 Arg residues (b) or all 60 Asp and 64 Glu residues (c) to Ala. Electrostatic potential maps were computed with default settings using the PBEQ Solver within CHARMM-GUI running from The University of Kansas Department of Molecular Biosciences Center for Bioinformatics Lab (http://www.charmm-gui.org/) (*108*). Estimated pI values were calculated from the corresponding sequences using *Scripps Protein Calculator* v 3.3 (http://www.scripps.edu/~cdputnam/protcalc.html).

different IgG subclasses bind to different Fc receptors with varying affinities. Thus, IgGs of one subclass may be more or less efficient at eliciting certain effector functions than IgGs of another subclass. For example, IgG_3 is the most effective subclass at activating the complement, followed by IgG_1 and IgG_2, whereas IgG_4 cannot activate the complement. Circulating IgG participates in adaptive immunity by binding to antigens in the circulation. Antigens are cleared through subsequent activation of complement and/or other effector functions such as opsonization (phagocytosis of antigen/pathogen by macrophages and neutrophils) and antibody-dependent cell-mediated cytotoxicity (ADCC).

ANTIBODY CHARGE: NATURAL HETEROGENEITY AND METHODS FOR MODIFICATION

Heterogeneity in the physicochemical properties of antibodies is a ubiquitous phenomenon resulting from the very complex, macromolecular nature of immunoglobulins. For instance, the influence of charged amino acids (Figure 2a) within a complex three-dimensional structure explains the presence of charged surfaces that often encourage protein−protein interactions under physiological conditions (*12*). Illustrated in Figure 3a is a typical variable charge distribution pattern that exists intramolecularly, across different surface regions of a single antibody. Note that, in some antibodies, a sizable degree of polarity may result from the presence of oppositely charged regions within different areas of the macromolecule. Furthermore, significant intermolecular heterogeneity (i.e., polydispersity) exists among different antibody molecules comprising any given preparation. A fundamental property of antibodies and other proteins is the isoelectric point (pI), which is defined as the pH at which the macromolecule carries no net electrical charge. While the approximate

[a] Theoretical pI values were computed by inputting the heavy chain (HC), light chain (LC), or full protein sequence of each antibody (http://www.drugbank.ca) (*97*) into the ProtParam tool within the ExPASy Proteomics Server of the Swiss Institute of Bioinformatics (http://www.expasy.ch/tools/protparam.html) (*98*). [b] Charges imparted by the conjugated chelator, tiuxetan, were not factored into the theoretical pI calculations.

surface charge distribution (Figure 3a) and overall pI (Table 1) of an antibody can be predicted from its sequence and structure, charge variation (often in the form of covalent modification of amino acid residues or glycan moieties) is known to spontaneously arise during production and manufacturing. Such alterations vary between different production methods and is of particular relevance in the biotechnology industry (reviewed in *refs* 13−15).

Despite an inherent charge polydispersity that arises spontaneously in production, efforts to isolate charge variants and evaluate them on an individual basis suggest that differences of less than approximately one pI unit are inconsequential for PK (*16*). As such, methods have been developed for deliberately modifying the net charge of antibodies, often yielding more drastic changes in pI values (Figure 3b,c). The rationale for these efforts is twofold: (I) to permit exploratory preclinical study of the relationships between the net molecular charge and in vivo disposition kinetics and (II) to potentially improve the PK properties of antibodies for the diagnosis or treatment of disease. One promising approach to this endeavor is antibody engineering technology, which can produce changes in pI and biological clearance through substitutions involving charged amino acids (Figure 2a) (*17*). An alternative approach is the deliberate modification of antibody charge through direct chemical modification of amino acid side chains with positive (Figure 2b), negative (Figure 2c), or neutral (Figure 2d) chemical groups. Chemical modification of antibodies is commonly used to deliver payloads such as radionuclides (*18*) or toxins (*19*), but can also allow alteration of net molecular charge. As a point of reference, the amino acid modifications in Figure 3b,c would be equivalent to conjugation of 25 diethylene triamine pentaacetic acid (DTPA) molecules (Figure 2c) through Lys residues (assuming a maximum net −5 charge reduction (*20*)) or 62 hexamethylenediamine (HMD) molecules (Figure 2b) through Asp/Glu residues (assuming a maximum net +2 charge increase (*21*)), respectively. Such modifications can also produce significant changes in pI and, in turn, noticeable changes in plasma and tissue PK as demonstrated by numerous examples in the proceeding section.

PK AND TISSUE DISPOSITION OF CHARGE-MODIFIED ANTIBODIES

Deliberate chemical modifications of antibodies with a variety of acidic, basic, or neutral chemical entities have been exploited to change the net molecular charge of antibodies (Figure 2b−d) (*22*). Apart from the chemical nature of the appended functional group, the site of modification (e.g., tyrosines, lysines, cysteines, oligosaccharides) has also been shown to affect tissue distribution and elimination of modified antibodies (*23*).

Cationization. Progress in molecular biology has yielded novel therapeutic strategies including gene therapy and cellular protein delivery, which rely on the entry of charged macromolecules into intracellular compartments. Cationization of antibodies is a drug delivery strategy wherein the pI is raised, often by conversion of surface carboxyl groups to primary amines or other positively charged groups. A number of cationic groups can be utilized, including HMD, ethylene diamine, and triethylene tetramine (Figure 2b). The resulting modified proteins have demonstrated altered biological properties, with a general trend toward increased plasma clearance and volume of distribution and increased disposition in both target (e.g., tumor) and normal tissues (Table 2) (*24*−*29*). Increased volume of distribution due to cationization can be demonstrated visually by whole body radiographic imaging, such as for an indium-111 (^{111}In)-labeled murine antibody against the human epidermal growth factor receptor (EGFR) (Figure 4) (*30*).

A common goal for therapeutic antibodies is to extend plasma half-life as a means to increase exposure, often expressed in terms of the area under the plasma concentration−time curve (*6*). In contrast, cationization tends to shorten plasma half-life due to an enhancement in both the rate and the magnitude of tissue distribution. However, cationization might prove to be a useful strategy in specific applications in which prolonged antibody exposure may be sacrificed for the sake of rapid, enhanced tissue uptake (e.g., targeting antibodies to efficiently cross the blood-brain barrier (*25*)). Cationization of antibodies has also been explored as a means to encourage extravasation, antigen binding, and receptor-mediated endocytosis (*31*) of antibodies into target cells. In contrast to native Abs, which are generally excluded from cell membranes in the absence of receptor-mediated endocytosis, cationized Abs are better able to reach the intracellular space via absorptive-mediated endocytosis (*32*, *33*). Electrostatic interactions between positively charged proteins and negatively charged cell membranes (*34*) could permit cell entry via nonspecific membrane flow and have been implicated in the mechanism by which cationized antibodies are rapidly endocytosed by cells in vitro (*35*). A similar phenomenon is suggested to induce absorptive-mediated transcytosis across microvascular endothelial barriers in vivo (*36*).

Although cationization has been shown to improve endocytosis and target tissue retention, several undesirable effects have also been reported. In general, retention in nontarget tissues is also significantly increased for cationized antibodies relative to

Table 2. Summary of Reported Preclinical Studies Involving Charge-Modified Antibodies

test molecules/target (species)	modifying group/Δ pI	effect on tissue disposition	effect on blood, plasma, or whole body clearance (CL)†	ref
		Cationized Antibodies		
^{125}I-goat colchicine-specific polyclonal IgG (rat)	HMD 5.85−9.0 to 8.65−10.3	↑ (74-fold) in V_D	↑ (114-fold) in systemic CL	*24*
^{125}I-AMY33/anti-β-amyloid (BALB/c mice)	HMD 7 to 9	↑ in %ID/g (2 h) for liver, kidney, lung, heart, brain	↑ (28-fold) in plasma CL	*25*
^{111}In-AMY33/anti-β-amyloid (BALB/c mice)	HMD (but also DTPA) 7 to (n/a)	↑ in %ID/g (2 h) for liver, kidney; not in lung, heart, brain	↑ (3.2-fold) in plasma CL	*25*
^{111}In-murine anti-EGFR (SCID mice)	HMD (but also DTPA) 8.1−8.3 to 8.7	↑ in %ID/g (1 h) for liver, lung	↑ in blood CL (i.e., decrease in AUC^{SS})	*30*
^{125}I-anti-HIV immune globulin (SCID mice)	HMD 6.3−7.3 to 8.1− >9.5	↑ in V_D (2 h) for liver, kidney, lung, brain	↑ (1600-fold) in blood CL	*26*
^{125}I-murine mAb D146/ anti-*Ras* peptide (BALB/c mice)	HMD 8.5 to >9.5	↑ in V_D (2 h) for liver, kidney, lung, heart, brain	↑ (58-fold) in plasma CL	*27*
^{125}I-humanized 4D5/anti-HER2 (rat)	HMD 8.6 to >9.3	↑ in V_D (2 h) for brain, heart, lung, liver, kidney	↑ (23-fold) in plasma CL_{SS}	*28*
mouse monoclonal IgG, MOPC21 (SCID mice)	HMD 6.0 to 8.6 − 9.3	↑ in tumor microvascular permeability; P_v (10^{-7} cm s^{-1}): 4.25−5.27 vs 1.47−4.07	↑ in plasma CL (i.e., decrease in k, time constant of concentration decay in the plasma: 500−1500 vs 3400−8200 s)	*29*
		Anionized Antibodies		
mouse monoclonal IgG, MOPC21 (SCID mice)	succinate 6.0 to 3.0−3.9	↓ in tumor microvascular permeability; P_v (10^{-7} cm s^{-1}): 1.11−2.53 vs 1.47−4.07	↑ in plasma CL based on decrease in k, time constant of concentration decay in the plasma	*29*
^{111}In-rabbit IgG/antihuman serum albumin (BALB/c mice)	DTPA 9.43−4.65 to 7.9−4.27	↓ in %ID/g (4 h) for intestine, colon ↑ in %ID/g (4, 24 h) for liver	n/a	*51*
human, nonspecific, polyclonal IgG (rat)	DTPA 6.6−9.3 to 6.0−8.3	↓ in %ID/g (up to 24 h) for most tissues	No Δ in plasma CL based on terminal half-life ($t^2_{1/2}$ (h) = 20.5 ± 1.9 vs 20.7 ± 1.6)	*52*
^{111}In-bovine IgG (ddY mice)	succinate (as well as DTPA) pI values n/a	↑ in %ID (1 h) for liver Suc_{50}-IgG > Suc_{22}-IgG > IgG	↑ in total CL: CL_{total} (mL/h) at 20 mg/kg dose: 0.46 (Suc_{22}-IgG) vs 2.86 (Suc_{50}-IgG) vs 0.4 (IgG)	*53*
		Neutralized Antibodies		
^{125}I-chTNT-3/B/antihistone HI and DNA [BALB/c mice (PK); athymic nude mice (distribution)]	biotin >9.6 to 8.0−9.6	↓ in %ID/g (72 h) for most tissues	↑ in whole body CL based on whole body $t_{1/2}$: 90.0 ± 8.1 vs 134.2 ± 4.0 h	*59*
$^{125/131}$I-B72.3/murine anti-TAG72 IgG1 (BALB/c mice (PK); athymic nude mice (distribution))	SPDP 4.8−5.0 to 4.5−4.7	↓ in %ID/g (72 h) for most tissues (except tumor)	↑ in whole body CL based on whole body $t_{1/2}$: 20 vs 120 h	*60*
$^{125/131}$I-Lym-1/murine IgG2a anti-HLA-Dr (BALB/c mice (PK); athymic nude mice (distribution))	SPDP 7.2−7.8 to 5.1−6.0	↓ in %ID/g (7 d) for most tissues (except tumor)	↑ in whole body CL based on whole body $t_{1/2}$: 60 vs 144 h	*60*
$^{125/131}$I-TNT-1/antihistone HI and DNA (BALB/c mice (PK); athymic nude mice (distribution))	SPDP 5.8−6.0 to 4.8−5.1	↓ in %ID/g (72 h) for most tissues	↑ in whole body CL based on whole body $t_{1/2}$	*60*
^{125}I-TNT-1/antihistone HI and DNA (BALB/c mice (PK); athymic nude mice (distribution))	biotin >9.6 to 7.2	↓ in %ID/g (72 h) for most tissues	↓ in whole body CL based on whole body $t_{1/2}$: 17.4 ± 2.4 vs 30.4 ± 1.8 h	*58*
^{125}I-TNT-2/antihistone HI and DNA (BALB/c mice (PK); athymic nude mice (distribution))	biotin >9.6 to 8.2	↓ in %ID/g (5 d) for most tissues	No Δ in whole body CL based on whole body $t_{1/2}$ 175.1 ± 3.0 vs 178.7 ± 7.2 h	*58*
^{125}I-TNT-3/antihistone HI and DNA (BALB/c mice (PK); athymic nude mice (distribution))	biotin >9.6 to 7.2	↓ in %ID/g (72 h) for most tissues	↑ in whole body CL based on whole body $t_{1/2}$: 90.1 ± 3.8 vs 134.2 ± 4.0 h	*58*

control antibodies (Figure 4). In addition, cationized human IgGs have been shown to form soluble immune complexes that induce activation of human platelets at much lower concentrations than native, noncationized human IgGs (*37*).

Anionization. Attempts have also been made to produce anionized Abs by chemically converting neutral or positively charged groups into negatively charged groups; this modification typically increases plasma clearance while decreasing tissue uptake and retention. While it may seem counterintuitive that both cationization and anionization increase plasma clearance, different underlying mechanisms are involved: tissue sequestration in the former case, and more rapid whole body clearance in the latter. Various anionic groups may be exploited for this type of modification, including DTPA (*38*), 1,4,8,11-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) (*39*, *40*), and succinic acid (*41*) (Figure 2c). Similar induction of negative charge is imparted by protein conjugation to 1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (TETA) (*39*, *42*) and other polyaminopolycarboxylate chelates that are routinely used in radiopharmaceutical applications (*18*, *43*). Considering that so few macrocyclic chelates are occupied by metal cations in high-specific-activity radiotracer preparations, alteration of antibody pI occurs irrespective of the presence or absence of cationic metal radionuclides.

The majority of antibodies possess a more basic isoelectric point (pI > 6) than most serum proteins (pI < 5.5) (*44*); this is

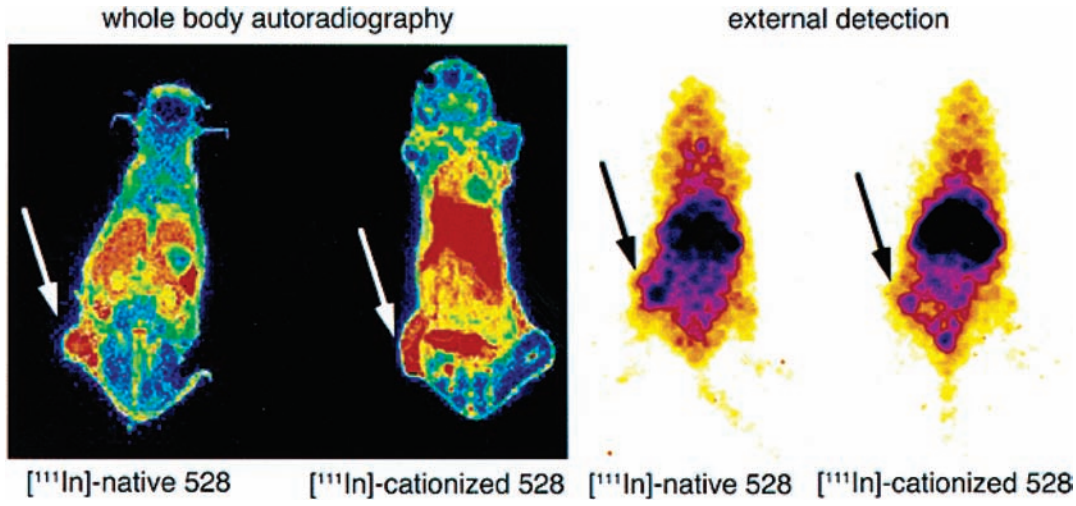

Figure 4. Effects of antibody cationization on tissue distribution. Figure reproduced with permission from Lee and Pardridge, 2003 (*30*). Whole body autoradiography (left) or gamma counter external detection (right) of female SCID mice implanted with U87 subcutaneous tumors in the right flank (arrows). Mice were injected with 50 μCi of either [^{111}In]-native 528 mAb or [^{111}In]-cationized 528 mAb. At 24 h after injection, the animals were anesthetized for external detection and then sacrificed for whole body autoradiography. The tumors were imaged 15 days after implantation.

particularly true for human IgGs (Table 1) and is a property that is in fact commonly exploited in their purification (*45*). This also makes them susceptible to ionic interactions with negatively charged glycan chains on cell surfaces (*46*) and heparin sulfate proteoglycans within the extracellular matrix (ECM) (*47*−*50*), collectively promoting higher tissue disposition and retention. Anionization partially abrogates these attractive forces, thereby reducing such non-antigen-dependent tissue uptake.

Anodal shifts in antibody pI generally induce faster blood clearance and lower tissue accumulation, with the exception of liver (Table 2) (*29, 51*−*53*). It is important to note that the increased hepatic retention of radioactivity may be due in part to transchelation of ^{111}In from the DTPA chelate to transferrin, with subsequent localization in the liver and other organs of the reticuloendothelial system (*23*). This behavior might be avoided by choosing a different radiometal/chelate pair such as ^{111}In/DOTA, taking advantage of the higher kinetic stability of the metal complex formed by this macrocyclic chelate.

It is evident that cautious interpretation is necessary when comparing uptake data obtained using both residualizing (e.g., radiometal chelate-based) and nonresidualizing (radiohalogenated tyrosine-based) probes. Specifically, it is advisible to only compare data obtained using a single labeling method when studying charge-dependent trends in tissue uptake. For instance, when antibodies conjugated to radiometal-chelate probes undergo endocytosis upon binding in antigen-expressing tissues, a greater cumulative tissue uptake of radioactivity is observed due to probe residualization following lysosomal catabolism (*54*). This effect is not related to molecular charge of the intact antibody; rather, it is driven by the inability of the resulting highly polar, charged radiometal-chelate-amino acid metabolites to cross the cell membrane, in contrast to the diffusible degradation products of antibodies that are directly radioiodinated through tyrosine residues. Radiometal-chelate probes are often preferred for tumor-targeting diagnostic and therapeutic applications for this reason. For instance, an ^{111}In-DTPA-labeled IgG against the carcinoembryonic antigen (CEA) resulted in 41% of the injected dose per gram being localized within human colorectal xenografts at 24 h compared to 9% for a nonbinding ^{111}In-DTPA-labeled control IgG and 19% for the analogous radioiodinated anti-CEA antibody (*55*). Such trends induced by probe residualization are most profound in antigen-expressing tumors or in antigen-expressing normal tissues. In contrast, non-antigen-expressing tissues have demonstrated little or no differences in levels of radioactivity between residualizing (^{111}In) and nonresidualizing (^{125}I) labeling methods (*54*).

Neutralization. Improvements in the biodistribution of antibodies have been sought using another approach in which an uncharged group is appended to a charged amino acid residue (e.g., lysine). A variety of neutral, uncharged groups may be utilized, including biotin and the heterobifunctional linker, pyridyl disulfide propionate (PDP) (Figure 2d). Additionally, PEGylation (PEG = poly(ethylene glycol)) is a broad modification strategy for therapeutics (reviewed in *refs* 56, 57). Such modifications will not be further considered here, however, as the large size (1−25 kDa) of PEG groups routinely used in antibody PEGylation often induces simultaneous changes in multiple molecular properties, including conformation, electrostatic binding, and hydrophobicity. Neutralization of positive charge (i.e., net reduction of charge) is much more common than neutralization of negative charge due to facile chemical methodologies which can be used to cap the nucleophilic amino groups of lysines.

In some cases, antigen binding may be preserved in charge-modified antibodies while still reducing nonspecific organ uptake. For instance, favorable results were obtained for a series of biotin-modified TNT mAbs, which yielded preparations having 65−69% immunoreactivity in a cell binding assay, more rapid whole body clearance, and higher tumor-to-background ratios due to lower uptake in normal tissues (Figure 5) (*58*). The masking of positive charges in proteins often produces changes in biological behavior similar to those induced by anionization (Figure 5) (Table 2) (*58*−*60*). Once again, such generalizations must be approached with caution, as the nature of the capping group can heavily influence the impact of the modification on antibody disposition.

pI/PK Relationships. By analyzing the directional changes indicated by arrows in Table 2, certain overall trends from preclinical evaluation of charge-modified antibodies should become apparent to the reader. In general, antibodies that were chemically modified to achieve higher, more basic pI values (Table 2, Cationized Antibodies) are associated with increased tissue uptake and increased blood clearance. In contrast, modified antibodies having more acidic pI values (Table 2, Anionized/Neutralized Antibodies) displayed decreased tissue uptake and increased whole-body (including blood) clearance. Nevertheless, cautious interpretation of data must be exercised

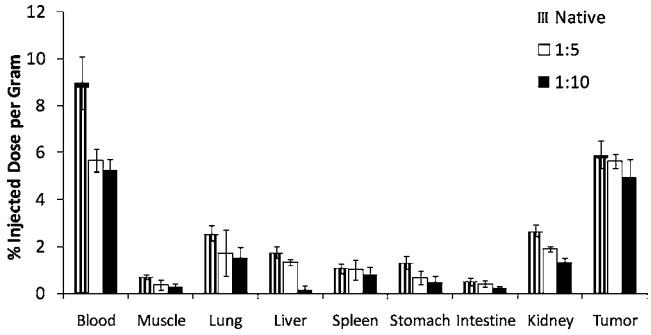

Figure 5. Effects of neutralization of positive charge in antibodies on tissue distribution. Data adapted with permission from Khawli et al. 2002 (*58*). Five-day tissue biodistribution and tumor uptake of ^{125}I-labeled parental (striped) and biotinylated (mAb/biotin ratio = 1:5, white; 1:10, black) chTNT-2 mAbs in Madison 109 murine lung adenocarcinoma-bearing BALB/c mice.

due to additional consequences of charge modification beyond electrostatic interactions, such as conformational changes in overall antibody structure and steric effects (*41*). It is also plausible that chemical modification of antibodies may, in some cases, deleteriously impact an antibody's binding affinity to FcRn (*10*) which, in turn, could trigger a reduction in serum half-life (*61*−*64*). Furthermore, the degree to which these putative changes would arise is highly dependent on the number, bulkiness, and physicochemical properties of small molecule charge modifiers attached to the protein. Another potential unwanted effect associated with antibody modification is increased immunogenicity due to creation of new antigenic determinants (*65*, *66*). Such responses might compromise antibody efficacy by direct neutralization, acceleration of clearance, prevention of further dosing, and induction of serum sickness (*67*). However, accumulating experimental data shows that incidence rates of clinical immunogenicity for some chemically modified antibodies are quite acceptable. For instance, 4% for a yttrium-90-labeled anionic chelate-modified murine anti-CD20 IgG (ibritumomab tiuxetan, i.e., Zevalin) (*68*), <2% for a somewhat hydrophobic calicheamicin-modified humanized IgG_4 (gemtuzumab ozogamicin, i.e., Mylotarg) (*68*), and 9% for a biotin-modified iodine-131-labeled chimeric tumor necrosis therapy antibody (^{131}I-TNT) (*69*).

Antibody Engineering Approches. As depicted in Figure 3, charged groups tend to be distributed randomly across the entire surface on a chemically modified antibody variant; this is governed by location of available amino acids that can undergo chemical reaction with modifying groups. In contrast, the use of modern protein engineering technologies can allow charge modification via site-directed mutagenesis. For instance, charge-modified antibodies were produced through selective point mutations of amino acids located exclusively in the variable (Fv) region (see Figure 1) and evaluated in normal and in β2-microglobulin knockout mice (*17*); these studies demonstrated a relationship between the plasma PK and pI values of antibodies that was independent of the FcRn salvage pathway (*17*). Consistent with the data in Table 2, increasing the pI value produced increases in plasma clearance; however, antibody variants with decreased pI values conversely showed enhanced plasma half-lives. The discrepancy between these observations and the data presented in Table 2 could result from charge localization within the variable region, which would affect the dipole moments (*70*) of engineered antibodies more drastically than for chemically modified variants. Alternatively, as suggested by Igawa et al., chemical modification may deleteriously affect FcRn binding and, hence, antibody PK (*17*). However, nearly a 4-fold reduction in β-phase half-life of an IgG was achieved by a single amino acid substitution in the Fc region, demonstrating that dramatic changes in PK, possibly modulated by FcRn affinity, can occur even in the absence of chemical modification (*71*). These and other plausible arguments warrant further plasma and tissue PK studies of antibody charge variants produced by both chemical and genetic means, but with full characterization of FcRn binding affinity.

pI/PK Relationships beyond IgG. Although this review is primarily focused on full-length IgG, similar charge modification strategies have been applied to a variety of antibody fragments and other macromolecules. In most cases, similar trends in blood PK and/or tissue distribution are observed. In fact, the same pI/p*K* trend observed for cationized IgG (Table 2) has also been reported for other classes of macromolecules including dextrose derivatives, for which cationization shortened the half-life in mice while anionization prolonged it (*72*). However, comparisons should be made only within a given class of molecules due to the additional influence of molecular size (*53*, *73*).

The same trend of increased plasma clearance for cationized proteins relative to native proteins has been observed for both an IgG and its corresponding Fab (*24*). It should be noted, however, that an antibody fragment is much more susceptible to electrostatic interactions within the kidneys than a full-length IgG because the fragment's size is below the glomerular filtration threshold (*18*, *74*). For instance, one study involving a series of anionized (glycolated) Fabs demonstrated that renal accumulation via reabsorption into renal proximal tubules decreased as the pI decreased (*75*); similar trends were observed for a series of glycolated disulfide-bonded variable region fragments (dsFv) (*76*). Co-administration of lysine was shown to block the renal uptake of radiolabeled dsFv, offering a strategy in lessening nephrotoxicity during radioimmunotherapy (*77*). In a somewhat related strategy, co-administration of a $sc(Fv)_2$ with a highly cationic peptide, penetratin (pI = 12.3), was able to increase tumor uptake of the protein despite the lack of a covalent bond between the two molecules, implicating electrostatic $sc(Fv)_2$−penetratin interaction as a plausible mechanism (*78*). Studies involving scFv−calmodulin fusion proteins demonstrated that derivatives having pI values between 5.0 and 9.0 had better tumor targeting ability than those with extreme pI values (*79*).

CHARGE-DEPENDENT PHYSIOLOGICAL INTERACTIONS

Positive charge on the surface of an antibody may lead to aberrant interactions with the cell membrane due to the presence of negatively charged groups that decorate the lipid bilayer surface of most mammalian cells (*22*). As such, the complex nature of biological matrices must be appreciated in order to provide a framework for interpreting charge effects in antibody PK, PD, and metabolic outcome. For instance, video microscopy has demonstrated that masking of the negative charge on the surface of red blood cells (RBCs) with a cationic polymer significantly increased RBC flow velocity through capillaries, presumably due to reduced electrostatic repulsive forces between the RBCs and negatively charged macromolecules on the surface of capillary endothelial cells (*80*). Circulating antibodies are susceptible to similar repulsive electrostatic forces but, due to their ability to permeate through openings in capillary walls, experience such forces at both the luminal and serosal surfaces of the vascular endothelial wall. In this section, the physicochemical attributes of selected physiological compartments, including the extracellular matrix, healthy tissues, and solid tumors, will be further considered.

Overview of Interstitial Space/Extracellular Matrix. Both body fluid balance and maintenance of interstitial hydration are regulated by the distribution volume of macromolecules (e.g., albumin, IgG) (*81*). In turn, the distribution volumes of

macromolecules are influenced by anionic glycosaminoglycans in the ECM (*81*). Following extravasation, antibodies experience various electrostatic forces within the interstitial fluid space due to the presence of negatively charged heparin sulfate and other anionic proteoglycans on the surface of cells within the interstitium (*47, 48, 82*). Proteoglycans are produced by most mammalian cells as components of the ECM. Diversity in the number of chains, chain lengths, and sulfation patterns allow these macromolecules to make significant contributions to ECM structure and function (*48, 82*). Electrostatic attraction between cationized molecules and anionic heparan sulfate (*82*) proteoglycans have been implicated in cellular internalization of viruses, basic peptides, and polycation-nucleic-acid complexes for gene transfer and protein delivery to mammalian cells (*47*).

Interstitial fluid volumes (V_i) measured using the extracellular space marker chromium-51-ethylenediaminetetraacetic acid (^{51}Cr-EDTA) can be combined with radiolabeled macromolecule data to derive the relative available (V_a/V_i) and excluded (V_e/V_i) interstitial volume fractions. Values of V_e/V_i for positively (pI = 8.7) and negatively (pI = 6.6) charged radioiodinated IgG were measured in rat skin (0.37 and 0.65, respectively) and in muscle (0.24 and 0.51, respectively) (*83*). Higher V_e/V_i values for anionic IgG in both tissues suggested that fixed negative charges, most likely glycosaminoglycans, discouraged interstitial antibody localization via charge repulsion, thereby regulating interstitial fluid balance (*83*).

Further insight into electrostatic interactions between antibodies and the negatively charged mammalian interstitium may be gained by considering analogous data for albumin. A higher V_e/V_i value was obtained for native (pI = 4.9) HSA than for cationized (pI = 7.6) HSA in rat skeletal muscle (0.26 and 0.16, respectively) and in rat skin (0.40 and 0.30, respectively) (*84, 85*). The magnitude of difference in V_e/V_i between the same two charged macromolecules decreased in rat dermis with increasing dehydration, likely due to a reduced hydration domain surrounding tissue and probe macromolecules in conditions of increased electrostatic interactions (*81*). Negatively charged hyaluronic acid associated with collagen was implicated as a contributing factor in the intrafibrillar volume of collagen, possibly influencing V_e/V_i (*81*).

Organ-Specific Interactions. Charge-selective renal filtration is considered to be largely facilitated by heparan sulfate in the glomerular basement membrane (GBM) (*49, 86*). Minimization of albumin loss from plasma is regulated by several mechanisms, including renal handling, charge repulsion with the capillary wall, and the FcRn-mediated salvage pathway (*87*). In addition to maintaining normal physiology, charge of antibodies can also play an important role in several disease states. For instance, the high positive charge of sugar chains on anti-DNA antibodies are involved in the pathology of renal disorders in lupus patients (*88*). Furthermore, in preclinical studies addressing the etiology of anti-GBM nephritis, glomerular deposition of cationic anti-GBM antibodies was 4-fold higher than that of anionic antibodies (*89*). Likewise, analysis of urine from patients with proximal renal tubular disease revealed that urinary IgG was reabsorbed in a cationic-preferential manner (*90*). Moreover, in an effort to avoid nephrotoxicity due to high renal accumulation of radiolabeled or toxin-conjugated small immunoproteins used for cancer therapy, positive charge can be decreased to discourage electrostatic attraction to the polyanionic brush border of the renal proximal tubules (*75, 76*).

The localization and clearance of antibodies in the liver may be affected by both hydrophobic and electrostatic interactions. The increased tendency for hydrophobic antibodies to undergo hepatobiliary excretion is widely accepted (*91, 92*); however, molecular charge may also influence the degree of hepatic uptake (*53, 93*). In lungs, the presence of negative charges on pulmonary endothelial cells, basement membranes, and interstitial matrices may attract positively charged (i.e., basic) proteins, effectively retarding their plasma-lymph transport while enhancing their extravascular distribution volume and initial clearance (*94*). Cationization of antibodies has been explored as a means to enhance transport of antibodies across the blood-brain barrier (BBB) (*25*).

Solid Tumor Interactions. To improve exposure of biologics in solid tumors, both chemical and protein engineering (*7*) strategies have been employed to manipulate the molecular size, charge, valency, and binding affinity of antibodies and other biotherapeutics. Similarly to the situation in normal tissues, electrostatic repulsion between anionic macromolecules and the negatively charged tumor ECM can limit their extravasation and/or extravascular dispersion, effectively causing them to be partially excluded from the interstitial compartment. For example, a lower V_e/V_i was observed for trastuzumab (pI = 9.2) relative to control IgG (pI = 7.6) in tumors established in rats (0.29 and 0.36, respectively) (*95*). Similarly, cationized albumin (pI = 7.6) possessed a lower V_e/V_i relative to native albumin (pI = 5.0) (0.21 and 0.38, respectively) (*95*).

An alternative interpretation of these data could be that cationized macromolecules having lower V_e/V_i values display higher vascular permeabilities. Similar conclusions were reached in a separate study, where the vascular permeabilities of HMD-cationized bovine serum albumin (BSA, pI 8.6−9.1) and IgG (pI 8.6−9.3) in human colon adenocarcinoma (LS174T) tumors were more than 2-fold higher than that of the succinylate-anionized BSA (pI ≈ 2.0) and IgG (pI 3.0−3.9) (Table 2) (*29*). Although cationized molecules extravasated more rapidly in solid tumors than similarly sized neutral or anionic derivatives, they also displayed a nearly 2-fold faster plasma clearance than succinylated molecules, as well as enhanced drug delivery to normal organs (*29*).

CONCLUDING REMARKS

The technologies driving advances in the production of therapeutic antibodies have markedly influenced the evolution of the biotechnology industry. Extensive examinations of the molecular biology, toxicology, metabolism, PK, and PD of antibodies have been conducted, yet these biological parameters are seldom related to the physicochemical properties of the macromolecules themselves. Charge-dependent interactions between antibodies and biological matrices hold relevance in biotechnology, especially with regard to the development of immunoconjugates. While antigen binding specificity and kinetics are important considerations in antibody therapy, the charge (pI) of antibodies also bears an important influence on their PK and tissue distribution.

Heterogeneity in molecular charge distribution occurs spontaneously in the routine production of antibodies, can be deliberately induced through chemical or genetic means, and can be characterized using a combination of analytical and chromatographic techniques. In particular, the deliberate modification of antibodies by chemical means has been exploited as a valuable preclinical research tool to investigate the relationship between net molecular charge and biological disposition. Findings from these exploratory investigations may be summarized as follows: (I) shifts in isoelectric point of approximately one pI unit or more can produce measurable changes in tissue distribution and kinetics, (II) increases in net positive charge generally result in increased tissue retention and increased blood clearance, and (III) decreases in net positive charge generally result in decreased tissue retention and increased whole body clearance.

The last fifteen years has produced a variety of strategies to optimize the use of antibodies in humans. The generation of

engineered forms (chimeric, humanized, human) of antibodies and the exploration of novel modifications to improve PK represent exciting areas of biotechnological research. As biotherapeutics become increasingly important in disease treatment, a more extensive investigation of the biological consequences of variations in charge and other physicochemical properties will likely be required. Insight into the underlying mechanisms behind unexpected or undesirable PK properties of antibody therapeutics may be gained by including electrostatic parameters in clinically predictive physiologically based models of disposition kinetics (*96*). Finally, charge modification of antibodies as a means of "fine tuning" plasma PK parameters and target accumulation is an exciting and potentially useful approach to the development of new biotherapeutics.

ACKNOWLEDGMENT

The authors would like to thank Allison Bruce for assistance with graphics and Wendy Putnam, Daniela Bumbaca, and Scott Northrup for helpful discussions. The authors express appreciation to their many colleagues and peers who have contributed over the years to the development of antibodies and immunoconjugates. Apologies are extended to those whose important and relevant work was omitted due to lack of space. Disclosure Statement: All authors are employees of Genentech, a member of the Roche Group, and hold financial interest in Roche.

Generation of Endosomolytic Reagents by Branching of Cell-Penetrating Peptides: Tools for the Delivery of Bioactive Compounds to Live Cells in Cis or Trans

Alfredo M. Angeles-Boza,[†] Alfredo Erazo-Oliveras,[†] Ya-Jung Lee, and Jean-Philippe Pellois*

Department of Biochemistry and Biophysics, 300 Olsen Boulevard, Texas A&M University, College Station, Texas 77843-2128, United States. Received March 9, 2010; Revised Manuscript Received October 19, 2010

We describe the synthesis and cellular delivery properties of multivalent and branched delivery systems consisting of cell-penetrating peptides assembled onto a peptide scaffold using native chemical ligation. A trimeric delivery system presenting three copies of the prototypical cell-penetrating peptide TAT shows an endosomolytic activity much higher than its monomeric and dimeric counterparts. This novel reagent promotes the endosomal release of macromolecules internalized into cells by endocytosis, and as a result, it can be used to achieve cytosolic delivery of bioactive but cell-impermeable macromolecules in either cis (covalent conjugation) or trans (simple coincubation).

Cell-penetrating peptides (CPPs) can be conjugated to cell-impermeable macromolecules and carry their cargo into mammalian cells (*1*−*3*). A prototypical CPP is the cationic TAT peptide (GRKKRRQRRR). TAT−macromolecule conjugates interact with cell-surface proteoglycans and are internalized into cells by TAT-induced macropinocytosis and other endocytosis mechanisms. TAT and its cargo then enter the cytosolic space of the cell by escaping from endosomes (*4*). This endosomolytic activity is however only modest, and a large fraction of macromolecules remain trapped inside endocytic organelles and unable to reach their intracellular targets (*4*, *5*). In order to increase delivery of cargo to the cytoplasm, the challenge is to enhance the endosomolytic activity of TAT. This is particularly difficult given that the exact mechanisms involved in this critical step of the delivery process are unclear. A potential solution to this problem, however, is to create multivalent delivery agents displaying multiples copies of the peptide (*6*). This is based on the principle that multivalency results in an increase of the local concentration of the CPP at the sites where the peptide interacts with cellular components. It has been clearly established that such an approach can increase the endocytic uptake of cationic peptides and that branched molecules can function and multitask in ways their linear homologues cannot (*7*−*9*). Whether multivalency enhances the endosomolytic activity of CPPs remains, however, uncertain. In this report, we hypothesize that branched TAT derivatives would also have an increased endosomolytic activity as compared to TAT and that these reagents could induce the release of macromolecules trapped inside endocytic organelles into the cytosolic space of cells. To test this hypothesis, we report a simple and modular synthetic route to generate branched multivalent CPPs carrier agents. We show that dimerization of TAT does not improved its delivery properties, while species with more than 3 branches lead to unproductive membrane binding. In contrast, a trimeric TAT translocates into live cells with much higher efficiency than its monomeric counterpart. Importantly, the endosomolytic activity of the trimeric peptide is sufficiently increased so that it is able to deliver a bioactive peptide in trans. Together, these results should be important for the future design of multivalent delivery agents and establish branched CPP species as noncytotoxic endosomolytic agents that could complement numerous delivery methodologies.

Our synthetic approach consists of assembling multiple CPPs onto scaffold peptides using native chemical ligation (NCL) (*10*). The scaffold peptides contain several lysines that have been modified at the ε NH_2 with a cysteine residue (Figure 1) (*11*). Each cysteine is available to react with TAT containing a C-terminal thioester to generate branched species. The scaffold peptides were synthesized by SPPS using standard Fmoc protocols. Two to six lysine residues bearing Mtt protecting groups at the ε NH_2 were incorporated on Rink amide resin and separated by glycine residues to reduce steric hindrance during synthesis and NCL. The lysine side chains were deprotected orthogonally with 2% TFA, and Boc-Cys(S^tBu)-OH was coupled onto the exposed ε NH_2. This was followed by N-terminal Fmoc deprotection and subsequent coupling of 5(6)-carboxyfluorescein (Fl). TFA cleavage and HPLC purification afforded the scaffold peptides containing 2 to 6 sites for NCL. TAT thioester was obtained by SPPS on a sulfamylbutyryl resin using reported protocols (*12*). The multivalent TAT compounds were obtained by reacting the scaffold peptides containing *n* cysteines with 3*n* equiv of TAT-thioester at room temperature in aqueous buffer at pH 7.5. Formation of the products, Fl-TAT*n*, was detected by HPLC as early as 1 h, and the reactions were complete in less than 12 h.

The cellular import of the multivalent compounds was first investigated by live-cell fluorescence microscopy. The fluorescein molecule installed at the N-terminus of the peptides was used as both a fluorescent label and a model of a small molecule cargo. A fluorescein labeled TAT (Fl-TAT) was evaluated as a "nonbranched" control. Fl-TAT, Fl-TAT2, and Fl-TAT3 were incubated with HeLa cells for 30 min at 1 or 5 μM. These concentrations were chosen because Fl-TAT is known to penetrate cells poorly under a concentration threshold of 5−10 μM (*13*). We therefore considered that it would be possible to observe any enhancement of activity by Fl-TAT2 and Fl-TAT3 as compared to Fl-TAT under conditions where the monomeric peptide shows low activity. After washing the cells with fresh media, cells were imaged by fluorescence confocal microscopy (Figure 1b). In the case of Fl-TAT and Fl-TAT2, a punctate distribution consistent with accumulation of the compounds inside endocytic organelles was observed at both concentrations. No accumulation of the peptides in the cytosol was detected.

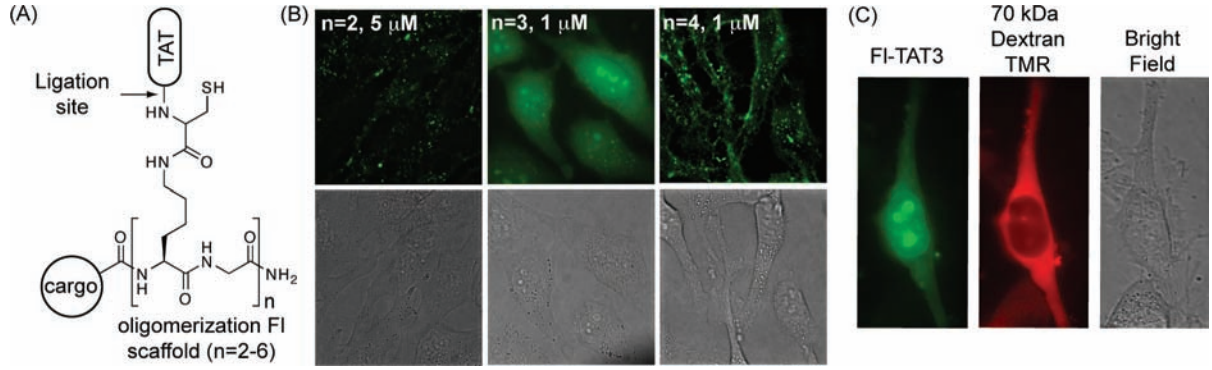

Figure 1. (A) Structure of the multivalent delivery agents Fl-TAT*n*. Multiple copies of the TAT peptide are ligated to a cysteine-containing oligomerization scaffold by NCL while a cell-impermeable cargo, fluorescein (Fl), is incorporated during SPPS. (B) Fluorescence and bright field images of live HeLa cells treated with Fl-TAT2 ($n = 2$), Fl-TAT3 ($n = 3$), and Fl-TAT4 ($n = 4$). The fluorescent cargo is trapped inside endocytic organelles with Fl-TAT2 (punctate distribution, 5 μM; same results were obtained for Fl-TAT at 5 μM) but released into the cytosol with Fl-TAT3 (diffuse distribution in cytosol and nucleus) at only 1 μM. Fl-TAT4 is bound to the plasma membrane. (C) Fluorescence images of live HeLa cells treated with Fl-TAT3 (1 μM) and 70 kDa Dextran-TMR (10 μM), a marker of pinocytosis. The cells represented in B or C were not stained by SYTOX Blue. This indicates that the membrane of these cells was not compromised.

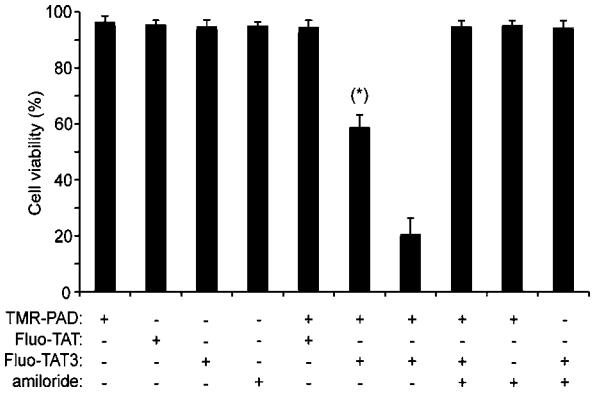

Figure 2. Delivery of TMR-PAD into HeLa cells mediated by Fl-TAT (10 μM) and Fl-TAT3 (1 μM where highlighted with * or 3 μM otherwise) as measured by a reduction in cell viability. SYTOX Blue staining was used to detect dead or dying cells 240 min after incubation with the peptides. Amiloride was used to inhibit macropinocytosis. Cell viability is expressed in % in comparison to an untreated sample. These results represent the average cell viability and corresponding standard deviation from three experiments.

In contrast, Fl-TAT3 exhibited a clear, diffuse, and cytosolic distribution at 1 or 5 μM indicative of an increase in the translocation efficiency as compared to the monomeric and dimeric compounds. Importantly, this was not accompanied by an increase in cytotoxicity of Fl-TAT3 (see next paragraph and Figure 2). The transport of Fl-TAT3 into the cytosol was inhibited by amiloride, an inhibitor of macropinocytosis. These results indicate that Fl-TAT3 is predominantly internalized by macropinocytosis and that it reaches the cytosol of cells by escaping from the endocytic pathway. Fl-TAT*n* with $n = 4$, 5, and 6 were also tested but could not be washed from the cell surface to a satisfactory level after incubation, and analysis of their transport properties was therefore difficult. These results are consistent with the work of Futaki and co-workers who have reported the synthesis of peptides with four branched chains of the type $(R_n)_4$ ($n = 1-6$) (*14*). $(R_2)_4$ was shown to internalized into cells with an efficiency similar to that of its linear homologue R_8, while $(R_6)_4$ was found to only accumulate at the plasma membrane without being able to enter cells (*15*). Likewise, Fl-TAT*n* with $n = 4$, 5, and 6 might bind to cell-surface components to such an extent that, in this case, it leads to a membrane-bound state that is not productive. Accordingly, these reagents were not considered further in our experiments.

To characterize the delivery activity of Fl-TAT3, we tested whether Fl-TAT3 might be capable of inducing the release of macromolecules from endosomes. This idea is based on the principle that, if Fl-TAT3 and a macromolecule are coincubated and accumulate together within endocytic vesicles, Fl-TAT3 might cause leakage of the endosomal membrane and release of the macromolecule into the cell (*16*). This was first suggested by the observation that 70 kDa Dextran-TMR, a marker of pinocytosis that typically accumulates inside endocytic vesicles when coincubated with cells, was present in the cytosol of cells when coincubated with Fl-TAT3 (Figure 1C). To test this hypothesis further and evaluate the delivery of a bioactive macromolecule, the pro-apoptotic peptide KLAKLAKKLAK-LAK-NH_2 (PAD) was used. PAD is cell-impermeable and has a negligible cytotoxicity toward mammalian cells (*17*). However, if delivered into the cytosol of cells, PAD permeabilizes the mitochondrial membrane and induces apoptosis (*18*, *19*). Cell death was therefore used as an indicator of the efficiency with which Fl-TAT3 might deliver PAD into cells. PAD labeled with carboxytetramethylrhodamine (TMR-PAD, 10 μM) was coincubated with Fl-TAT (1 to 10 μM) or Fl-TAT3 (1 to 3 μM) for 30 min. The import of TMR-PAD, Fl-TAT, and Fl-TAT3 into cells was monitored by confocal microscopy, and cell viability was assessed by SYTOX Blue staining. SYTOX Blue stains the nucleus of apoptotic or necrotic cells with a compromised plasma membrane without staining live cells. When TMR-PAD was coincubated with Fl-TAT, TMR-PAD was present inside endocytic organelles but did not appear to enter the cytosol of cells (as monitored by TMR fluorescence; not shown) regardless of the concentration of Fl-TAT used. In addition, the cell viability was not affected by treatment with these peptides (Figure 2). These results are consistent with a model where Fl-TAT cannot promote endosomal release of TMR-PAD, and as a result, TMR-PAD is unable to induce cell death. In contrast, cells incubated with Fl-TAT3 and TMR-PAD showed a diffuse and cytosolic distribution for both TMR-PAD and Fl-TAT3 (Figure 3). These cells were not stained by SYTOX Blue 60 min post-incubation. However, 40% and 80% of the cells became SYTOX Blue positive 240 min post-incubation when 1 or 3 μM Fl-TAT3 were used, respectively. Progression to classic morphological changes such as membrane blebbing and nuclear fragmentation further confirmed that cells were undergoing apoptosis. Treatment with amiloride inhibited delivery of Fl-TAT3 and TMR-PAD into cells as well as cell death (Figures 2 and 3). These results therefore indicate that the cytotoxicity observed when Fluo-TAT3 and TMR-PAD are coincubated arises from the delivery of TMR-PAD by Fl-TAT3

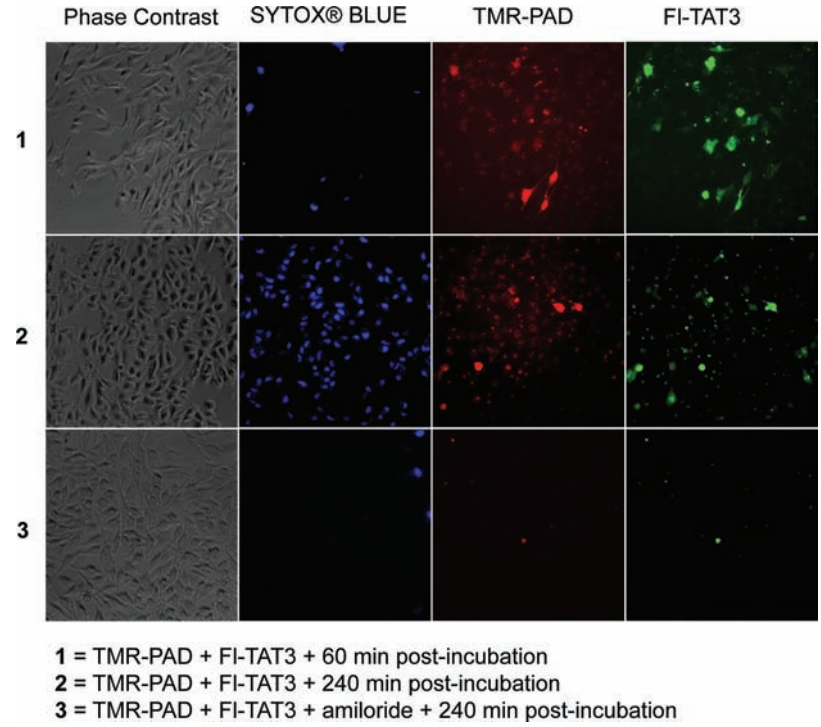

Figure 3. Images of cells incubated with TMR-PAD (10 μM), Fl-TAT3 (3 μM), and with or without the macropinocytosis inhibitor amiloride. Cells were incubated with the peptides for 30 min and washed with fresh media, and SYTOX Blue was added to detect dead cells. Images were acquired 60 or 240 min after addition of SYTOX Blue. Blue nuclei in the SYTOX Blue images represent dead or dying cells. Cells containing a cytosolic distribution of both TMR-PAD and Fl-TAT3 can be observed at 60 min.

as opposed to cytotoxic effects that might arise when the peptides are combined and not related to the transport of TMR-PAD. Together, these results support a model where Fl-TAT3 and TMR-PAD are first internalized into cells by endocytic mechanisms and where Fl-TAT3 then releases TMR-PAD into the cytosol of cells.

The NCL synthesis scheme used in this report generates Fl-TAT*n* compounds that contain *n* free thiols. On one hand, these thiols could be used to attach molecular cargos to the multivalent delivery reagents. On the other hand, the thiols, when left unmodified, could promote the aggregation of Fl-TAT*n* through the formation of intermolecular disulfide bridges. Such aggregates could participate in the cellular activities observed. The presence of aggregates could not be detected when the Fl-TAT*n* compounds dissolved in PBS were oxidized by bubbling oxygen in the media (HPLC and mass spectrometry analysis), suggesting that intramolecular disulfide bonds might form preferentially over intermolecular bonds (Supporting Information). Nonetheless, in vitro assays might not reproduce what happens inside cells, and it is possible that aggregates form in the lumen of endosomes. To address this issue, the thiols of Fl-TAT3 were blocked with iodoacetamide to form an acetamidated analogue of Fl-TAT3 (synthesis and characterization in Supporting Information). This product, Fl-TAT3-(S-CH_2-CO-NH_2)$_3$, cannot form disulfide bonds because the thiols are replaced by thioethers. To compare the delivery activity of Fl-TAT3-(S-CH_2-CO-NH_2)$_3$ with that of Fl-TAT3, Fl-TAT3-(S-CH_2-CO-NH_2)$_3$ (3 μM) and TMR-PAD (10 μM) were coincubated for 30 min with HeLa cells, and cell viability was assessed by microscopy. While incubation with Fl-TAT3-(S-CH_2-CO-NH_2)$_3$ alone resulted in a cell viability of 90%, coincubation with TMR-PAD resulted in a cell-viability of 25% 240 min post-incubation (Supporting Information). These results are similar to those obtained with Fl-TAT3. This suggests that the delivery activity of Fl-TAT3 is not a result of aggregation of the compound and that the presence of the thiols is not necessary to achieve delivery.

Overall, the trimeric TAT reported appears to have an endosomolytic activity much greater than its monomeric and dimeric counterparts without displaying the unproductive membrane binding observed for constructs containing more branches. As a result, it can deliver the small molecule cargo fluorescein in cis at concentrations much lower than that required for Fl-TAT. In addition, it can also be used to achieve delivery of a bioactive but cell-impermeable peptide in trans. This is important because this demonstrates that a macromolecule does not need to be labeled with an extraneous delivery peptide to be delivered, thereby greatly simplifying delivery protocols for in vitro applications. We are now testing the applicability of this delivery method to other macromolecules and exploring the effect of the structure and spatial orientation of the scaffold peptide on the delivery activity of the TAT trimer.

SUPPORTING INFORMATION

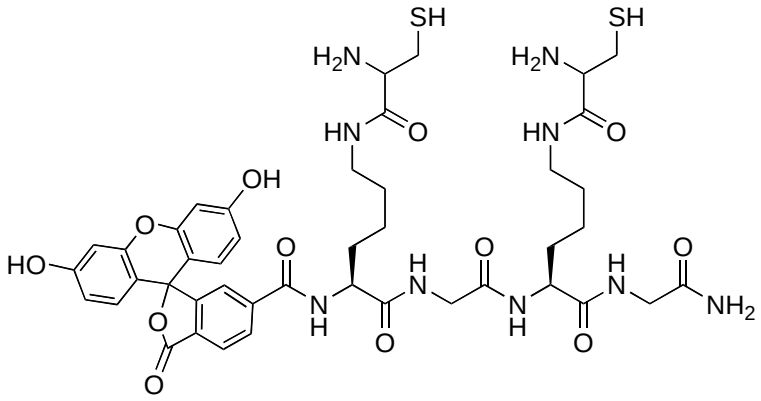
Live-cell Imaging Experiments:

HeLa cells were seeded on 8-well chamber glass slide (Lab-Tek^{TM} Cat. No. 177402, 0.8 cm^2/well, Nunc International, Naperville, IL) at 3.0 x 10^4 cells/well in Dulbecco's modified Eagle's medium supplemented with 10% FBS and incubated for 24 h at 37°C in a humidified atmosphere containing 5% CO_2. For live-cell imaging, cells were washed and incubated with Leibovitz's L-15 Medium and placed under an inverted epifluorescence microscope (Model IX81, Olympus, Center Valley, PA) equipped with a heating stage maintained at 37°C. The microscope is configured with a spinning disk unit (DSU, Olympus) to perform both confocal and wide-field fluorescence microscopy. Images were collected using a Rolera-MGI Plus back-illuminated EMCCD camera (Qimaging, Surrey, BC, Canada) mounted on the microscope with UPlanFl 100× / 1.3 NA oil, or LCPlan 20× / 0.4 NA objectives. Images were acquired using phase contrast and three standard fluorescence filter sets: CFP (Ex = 436±20 nm / Em= 480±40 nm), Texas Red (Ex = 560±40 nm / Em= 630±75 nm), and FITC (Ex = 482±35 nm / Em= 536±40 nm). (Semrock, Rochester, NY). Cells were treated with the different peptides in L-15 medium. The concentrations of the peptides were determined by measuring the absorbance of the

fluorescein moiety at 492 nm (ε = 56000 M^{-1} cm^{-1} at pH 7.4). For macropinocytosis inhibition, cells were first pretreated with 50 μM of amiloride (Sigma, MO*)* for 30 minutes, and then with the peptides while keeping amiloride present. After incubation at 37°C for 30 minutes, the cells were washed with PBS 5 times and the medium was replaced with fresh L-15. The integrity of the plasma membrane of the cells was determined by addition of the cell-impermeable DNA stain SYTOX® Blue (5 μM, dead cells are stained in less than 5 min at this concentration). Cells were then placed on the microscope and images were acquired in the CFP fluorescence channel for detection of SYTOX® Blue. TMR was detected with the Texas Red filter set and Fl with the FITC filter set. Images were processed using the SlideBook 4.2 software (Olympus, Center Valley, PA).

For the delivery of TMR-PAD to live cells reported in Figure 2 and 3, cells were imaged with a 20 X objective by phase contrast and fluorescence imaging for up to 4 hours. Ten to twenty images were acquired for each experiment. The total number of cells in a given image was determined from the phase contrast image while the number of dead cells was determined by identifying cells containing a blue fluorescent nucleus stained by SYTOX® Blue. Cell viability was determined by first establishing a ratio of dead cells/total number of cells for each sample (1000 cells were counted in each experiments and each experiments were repeated 3 times).

Peptide Synthesis and Purification



All amino acids were obtained from Novabiochem (San Diego, CA and used as received. Peptides were synthesized in-house by SPPS using standard Fmoc protocols. Fmoc-Lys(Boc)-OH, Fmoc-Lys(Mtt)-OH, Fmoc-Gly-OH, Fmoc-Arg(Pbf)-OH, Fmoc-Gln(Trt)-OH, Fmoc-Leu-OH, Fmoc-Ala-OH, and Boc-Cys(StBu) were used to assemble the peptides. Reactions were carried out in SPPS vessels at room temperature using a stream of dry N_2 to provide agitation. Fmoc deprotection was performed by addition of piperidine in DMF (20%, 5 mL) to the Fmoc-peptide resin (0.72 mmol). Deprotection was carried out for 1×3 min and 1×10 min. Coupling reactions were carried out for 2 h with a mixture of Fmoc-amino acid (2.88 mmol), HBTU (1.06 g, 2.80 mmol), and DIEA (1.25 mL, 7.2 mmol) in DMF. Upon completion of the reaction, the resin was washed with DMF. The peptides were analyzed and purified by reverse phase HPLC. HPLC analysis was performed on a Hewlett-Packard 1200 series instrument and a Vydac C18 column (5 micron, 4 x 150 mm). Flow rate was 1 mL/min and detection was at 214 nm and 450 nm. Semi-preparative HPLC was performed on a Vydac C18 10 × 250 mm column. Flow rate was 4 mL/min and detection was at 214 nm and 450 nm. All runs used linear gradients of 0.1% aqueous TFA (solvent A) and 90% acetonitrile, 9.9% water and 0.1% TFA (solvent B). The correct identity of the peptides was confirmed by time-of-flight mass spectrometry performed with a Shimadzu/Kratos instrument (AXIMA-CFR, Shimadzu, Kyoto).

Synthesis of Fl-(Kε(C)-G)$_n$-NH$_2$

The Fl-(Kε(C)-G)$_n$-NH$_2$, n=2-6, peptides were assembled using a standard Fmoc solid phase peptide synthesis strategy. Fmoc-Gly-OH was first coupled to the Rink amide resin (0.72 mmol scale). Fmoc-Lys(Mtt)-OH and Fmoc-Gly-OH were the alternatively coupled to generate the peptides Fmoc-(Kε(Mtt)-G)$_n$-Rink amide. The Mtt protecting groups were cleaved by treating the resin with 2% TFA in DCM for 30 min and Boc-Cys(S^{t}Bu)-OH (3 x n equivalents) was coupled onto the exposed ε amino groups in DMF containing DIEA and HBTU (3 x n eq.). This was followed by *N*-terminal Fmoc deprotection and subsequent overnight coupling of 5(6)-carboxyfluorescein (Fl, 1.1 eq) in DMF containing HBTU (1.1 eq.). The S-StBu

groups on the Cys side chains were cleaved on the solid phase using 100 eq of PBu_3 and 400 eq of H_2O in DMF:DCM for 4h. The peptides were cleaved from the resin with 92.5% TFA, 2.5% TIS, 2.5% EDT, and 2.5% H_2O. The crude products were precipitated and washed with cold diethyl ether and then lyophilized to yield crude peptide solids that were purified by preparative scale reverse phase HPLC using a water/acetonitrile gradient in the presence of 0.1% TFA.

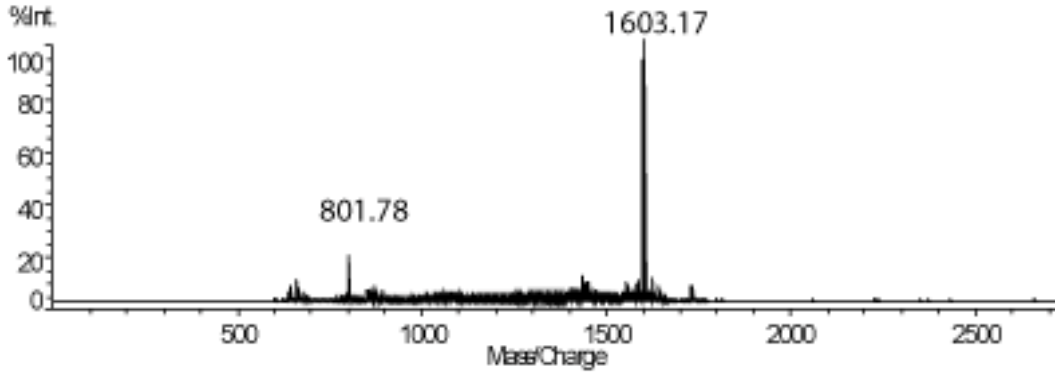
Synthesis of TAT-thioester

The TAT peptide thioester (GRKKRRQRRRG-thioester) was readily prepared by SPPS on the 4-sulfamylbutyryl-AM resin using reported protocols.[1] The resin was pre-swollen in 10 volumes of dry methylene chloride for 1 h. During this period, Fmoc-Gly-OH (4 equiv) along with 1-methylimidazole (4 equiv) was dissolved in a 4:1 mixture of dry methylene chloride (DCM) and dimethylformamide (DMF) under a blanket of inert gas. *N*,*N*′-diisopropylcarbodiimide (DIC) was added and the solution was mixed for 5 min at room temperature. This acylation mixture was added to the drained resin. The resin was agitated with a stream of N2 for 18 h at room temperature and then drained. The resin was washed with DCM and DMF. The desired peptide is then formed via standard manual peptide synthesis. Boc-Gly-OH was used in the last coupling. The resin was washed with DMF and DCM. For activation of the resin prior to cleavage, a solution of iodoacetonitrile (25 equiv) and diisopropylethyl amine (10 equiv) in 3 mL of DMF and 1 mL of hexamethylphosphoric triamide was added to the drained resin. The resin was agitated with a stream of N2 for 18 h at room temperature. The solution was drained, and the resin was washed with DMF and DCM prior to immediate cleavage. The peptide was then cleaved from the activated resin with mercaptophenylacetic acid. First, mercaptophenylacetic acid (2.0 mmol for 0.1 mmol resin) was suspended in DCM (10 mL) in a round-bottom flask flushed with argon. The mixture was cooled to 0 °C and DIEA (1.0 mmol) was added dropwise over 5 min. The resin pre-swollen in DCM was drained and treated with the thiol solution. The resin bed was stirred for 18 h at room temperature. The resin was drained and the filtrate collected. The resin was washed with three additional portions of DCM, these being pooled with the original filtrate. The filtrate was concentrated in vacuo to provide a crude product. The residue was treated with 10 mL of a 95:2.5:2.5 TFA/water/triisopropylsilane (TIS) mixture to remove the side-chain protecting groups. The product was filtered to remove excess insoluble thiol, concentrated in vacuo, and precipitated and washed with cold diethyl ether. The peptide was purified by reversed-phase HPLC and analyzed by mass spectrometry. Expected mass: 1603.9 Da, observed mass: 1603.2 Da.

Characterization of TAT-thioester

Chemical Formula: C65H118N32O14S
Molecular Weight: 1603.90

Figure S5. Structure and expected molecular weight of TAT-MPAA thioester (GRKKRRQRRRK-MPAA).



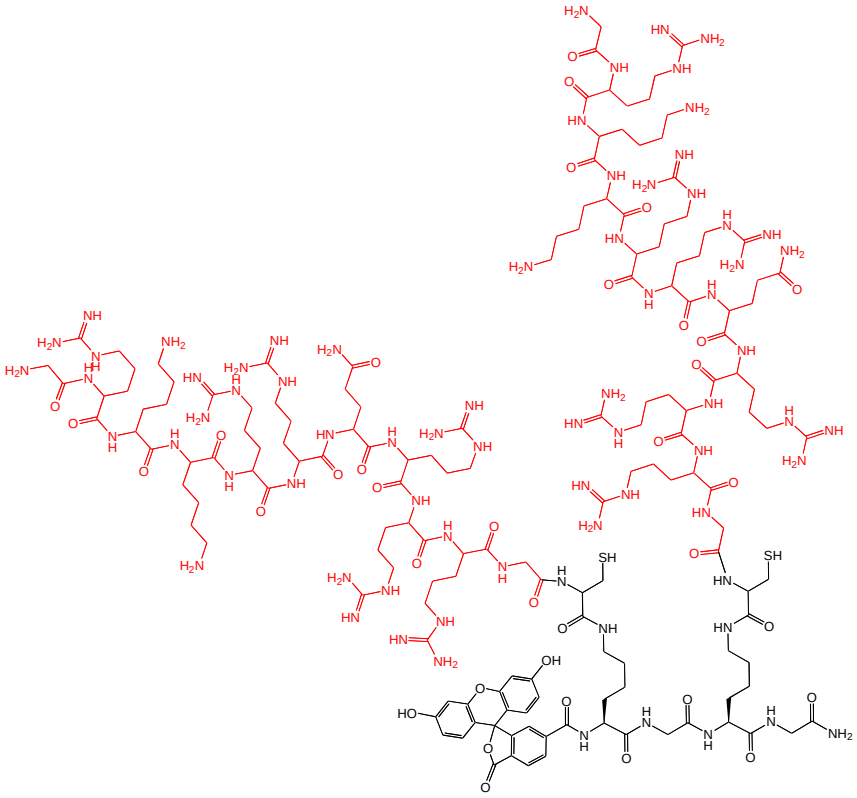


Figure S6. MALDI-MS spectrum of TAT-MPAA thioester. The peak at 801.78 corresponds to the doubly-charged product.

Synthesis of Fl-TATn

Fl-TATn was formed by addition of TAT-MPAA thioester (3 x n equivalents) to Fl-(Kε(C)-G)$_n$-NH_2 (1 mM) in 25 mM HEPES, 100 mM MESNa, and 10 mM TCEP at pH 7.5 (TAT-MPAA thioester exchanges to TAT-mercaptoethanesulfonate thioester under these conditions). After 16 hours of reaction at room temperature, the crude product was purified by preparative scale reverse phase HPLC using a water/acetonitrile gradient in the presence of 0.1% TFA.

Characterization of Fl-TAT2

Chemical Formula: $C_{157}H_{273}N_{73}O_{36}S_2$
Molecular Weight: 3823.45

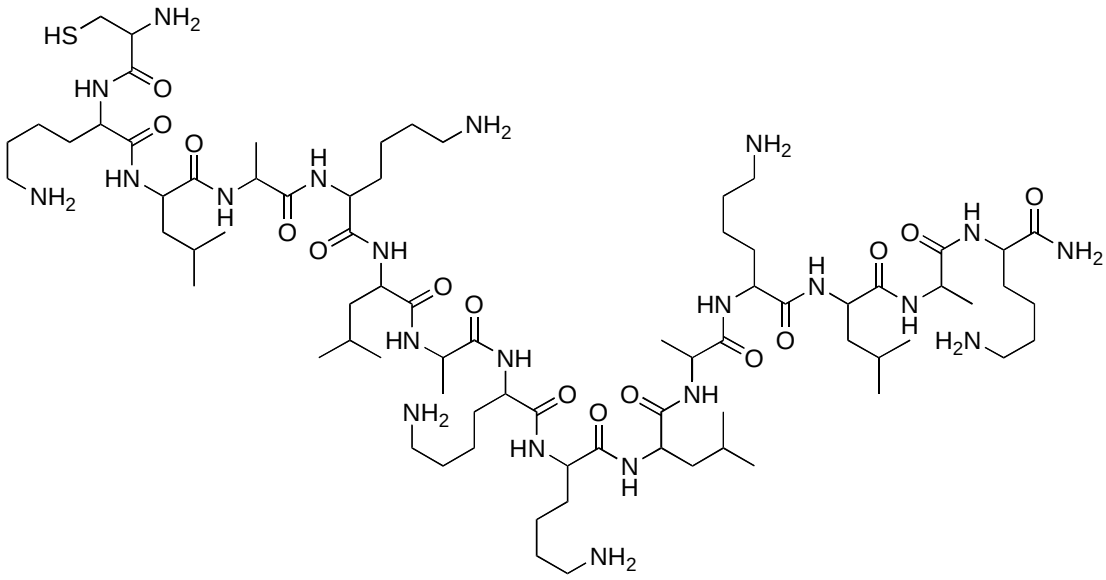
Synthesis of Fl-TAT

Fl-TAT (GRKKRRQRRRK(Fl)G-NH_2) was prepared by SPPS on the Rink amide resin. Fmoc-G-R(Pbf)-K(Boc)-K(Boc)-R(Pbf)-R(Pbf)-Q(Trt)-R(Pbf)-R(Pbf)-R(Pbf)-K(Mtt)-G was first assembled on the resin. The Mtt protecting group was cleaved by treating the resin with 2% TFA in DCM for 30 min and 5(6)-carboxyfluorescein (Fl, 1.1 eq.) was coupled onto the exposed ε amino groups in DMF containing DIEA and HBTU (1.1 eq.). This was followed by *N*-terminal Fmoc deprotection with 20% piperidine in DMF. The peptide was cleaved from the resin with 92.5% TFA, 2.5% TIS, 2.5% EDT, and 2.5% H_2O. The crude product was precipitated and washed with cold diethyl ether and then lyophilized to yield crude solid that was purified by preparative scale reverse phase HPLC using a water/acetonitrile gradient in the presence of 0.1% TFA. . Expected mass: 1939.2 Da, observed mass: 1937.2 Da.

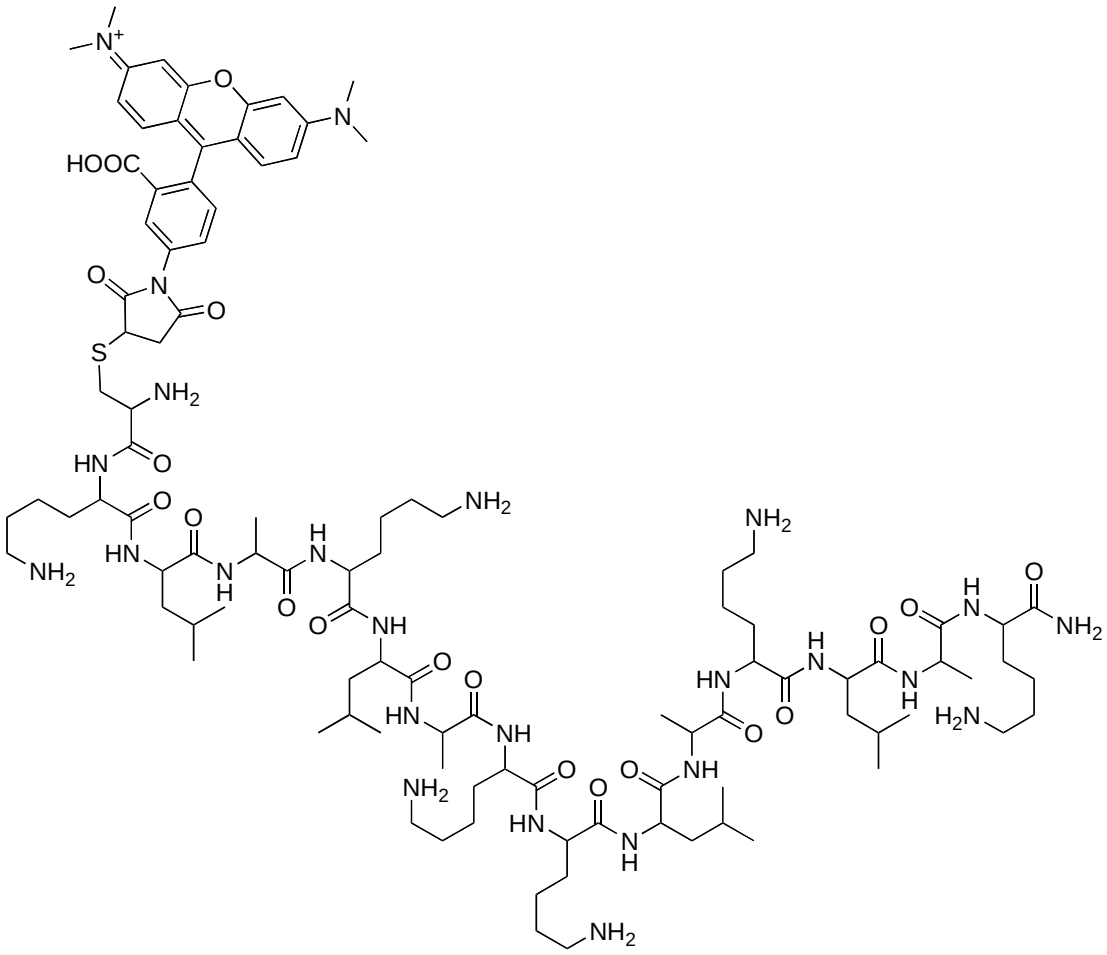


Chemical Formula: $C_{84}H_{135}N_{35}O_{19}$
Molecular Weight: 1939.19

Figure S14. Structure and expected molecular weight of Fl-TAT (GRKKRRQRRRK(Fl)G-NH_2)

Synthesis of Cys-PAD (CKLAKLAKKLAKLAK-NH_2)

The Cys-PAD (CKLAKLAKKLAKLAK) peptide was assembled using a standard Fmoc solid phase peptide synthesis strategy on a rink amide resin. The protected peptide was cleaved from the resin with 92.5% TFA, 2.5% TIS, 2.5% EDT, and 2.5% H_2O. The crude product was precipitated and washed with cold diethyl ether. The precipitated peptide was then lyophilized, dissolved in HPLC buffer and purified by preparative scale reverse phase HPLC using a water/acetonitrile gradient in the presence of 0.1% TFA. Expected mass: 1626.1 Da, observed mass: 1626.6 Da.



Chemical Formula: $C_{75}H_{144}N_{22}O_{15}S$
Molecular Weight: 1626.15

Figure S15. Structure and expected molecular weight of C-PAD (CKLAKLAKKLAKLAK-NH_2)

Synthesis of TMR-PAD (TMR-CKLAKLAKKLAKLAK-NH_2)

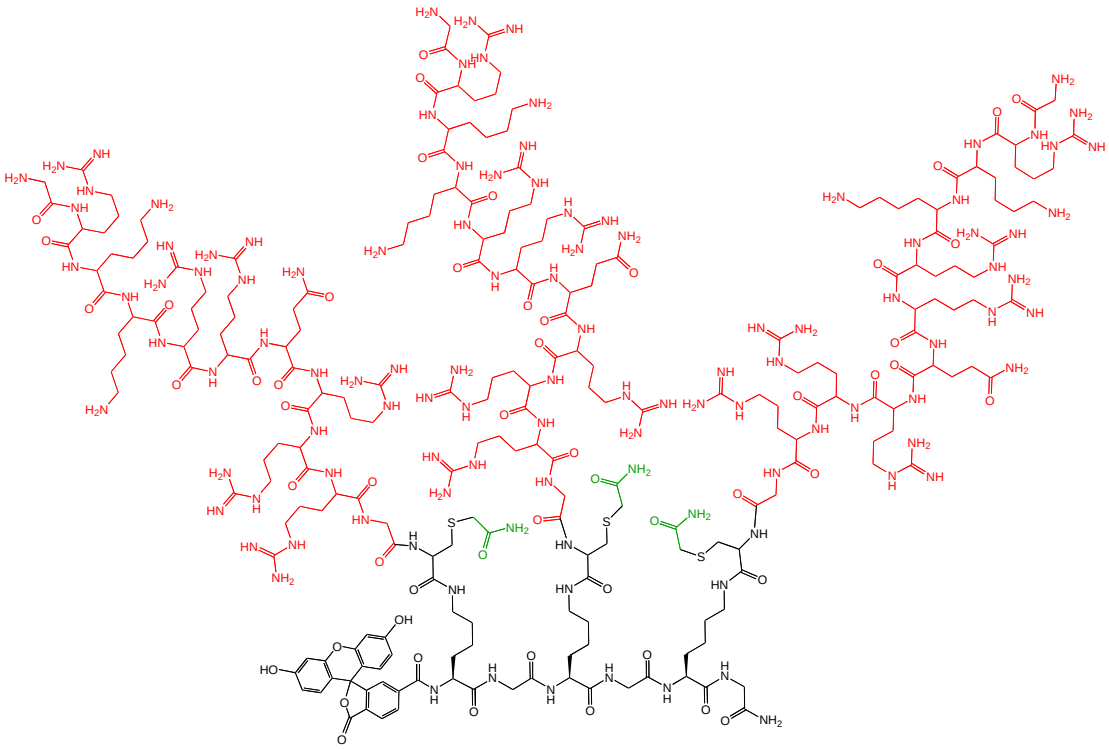
TMR-PAD (TMR-CKLAKLAKKLAKLAK-NH2) was obtained by reaction between the Cys-PAD peptide and the fluorophore tetramethylrhodamine-5(6)-maleimide. Cys-PAD (0.38 μmol) was dissolved in 25 mM Hepes at pH 7.5, 100 mM MESNa, and 20 mM TCEP (0.38 mM mM final concentration). To this was added the fluorophore tetramethylrhodamine-5(6)-maleimide (0.38 μmol). After 36 hours at 4 °C, the reaction was complete and the crude product was purified by preparative scale reverse phase HPLC using a water/acetonitrile gradient in the presence of 0.1% TFA. Expected mass, 2108.66, observed mass: 2109.40 Da.

Chemical Formula: $C_{103}H_{168}N_{25}O_{20}S^+$
Molecular Weight: 2108.66

Figure S16. Structure and expected molecular weight of TMR-PAD (TMR-CKLAKLAKKLAKLAK-NH_2)

Oxidation of Fl-TATn

To test whether the thiols present in the Fl-TATn compounds could lead to aggregate formation through the formation of intermolecular disulfide bridges, the compounds (10 μM in PBS, this concentration reflects the highest concentration used in the cell-based assays) were oxidized by bubbling O2 in the media for 1 hour. Formation of aggregates of higher molecular weights was monitored by HPLC analysis and mass spectrometry. The HPLC profiles and MS spectra of the oxidized Fl-TATn compounds were similar to those presented above and to the samples treated with the reducing agent TCEP (10 mM), indicating that no intermolecular disulfide bridges formed between the Fl-TATn molecules. Instead, intramolecular disulfide bridges might have formed. Given the close proximity of the cysteine residues in the Fl-TATn compounds, these intramolecular disulfide bonds would have a greater probability of formation than intermolecular disulfide bridges. These intramolecular disulfide bridges might however not lead to a shift in HPLC retention time. The mass spectrometry analysis was also not accurate enough to unequivocally confirm the loss of 2 H that would accompany the formation of each disulfide bridge.



In the case of Fl-TAT2 and Fl-TAT4, oxidation of the cysteines was confirmed by monitoring the reducing activity of the compounds. Fl-TAT2 and Fl-TAT4 were first reduced with immobilized TCEP in PBS. The TCEP beads were filtered and the solution was immediately added to a solution of Aldrithiol-2 (2,2'-dithiopyridine, 100 μM). Aldrithiol forms a thiopyridone salt upon reduction and this is accompanied by an increase in absorbance at 350 nm. As expected, the reduced Fl-TAT2 and Fl-TAT4 caused an increase in the absorbance of the solution at 350 nm. In a parallel assay, the freshly reduced Fl-TAT2 and Fl-TAT4 were bubbled with O2 as described in the previous paragraph. In this case, addition of Aldrithiol did not cause an increase in the absorbance 350 nm (the absorbance of fluorescein at 490 nm was measured to confirm that the reduced and oxidized Fl-TATn compounds were used at the same concentration). These results therefore confirm that the reducing activity of Fl-TAT2 and Fl-TAT4 was abolished after the oxidation step, further confirming that intracellular disulfide bonds are formed.

In the case of Fl-TAT3, one can presume that one intramolecular disulfide bridge might form, leaving one cysteine that could potentially form an intermolecular

disulfide bond. The fact that we did not detect aggregates of high molecular weight might reflect that fact that intermolecular disulfide bond formation is sterically unfavorable. Indeed, Fl-TAT3 had the ability to reduce Aldrithiol-2 even after the oxidation step, confirming that a free thiol might remain even after bubbling oxygen (aldrithiol is a small molecule that presumably might have access to this free thiol). However, to unequivocally confirm that aggregates of the Fl-TAT3 compound were not involved in the unique delivery properties of this compound, the free thiol groups present in the molecule were capped with iodoacetamide. These results are described in the next section.

Synthesis and Characterization of Fl-TAT3-(S-CH2-CO-NH2)3 (Fl-TAT3 acetamidated with iodoacetamide to block the thiols and prevent disulfide bond formation)

Fl-TAT3-(S-CH2-CO-NH2)3 was formed after addition of iodoacetamide (50 mM) to Fl-TAT3 (1.4 mM) in 6 M GnHCl, 25 mM HEPES, and 50 mM TCEP at pH 8.5. The solution was placed on a shaker at room temperature. The reaction was monitored by analytical reversed-phase HPLC and MALDI-TOF. After 24 h, the elution peak corresponding to Fl-TAT3 had completely disappeared to lead to the formation of a single peak corresponding to the product. The product was purified by reverse-phase HPLC. The Aldrithiol test described in the previous section was used to confirm that the compound formed had no reducing activity and therefore no free thiol (Fl-TAT3 was used as a positive control). Yield: 69.3 %. Expected mass: 5718.66 Da, Observed mass: 5722.25 Da.

Chemical Formula: $C_{231}H_{412}N_{112}O_{54}S_3$
Molecular Weight: 5718.66

Figure S17. Structure and expected molecular weight of Fl-TAT3-(S-CH2-CO-NH2)3**.**

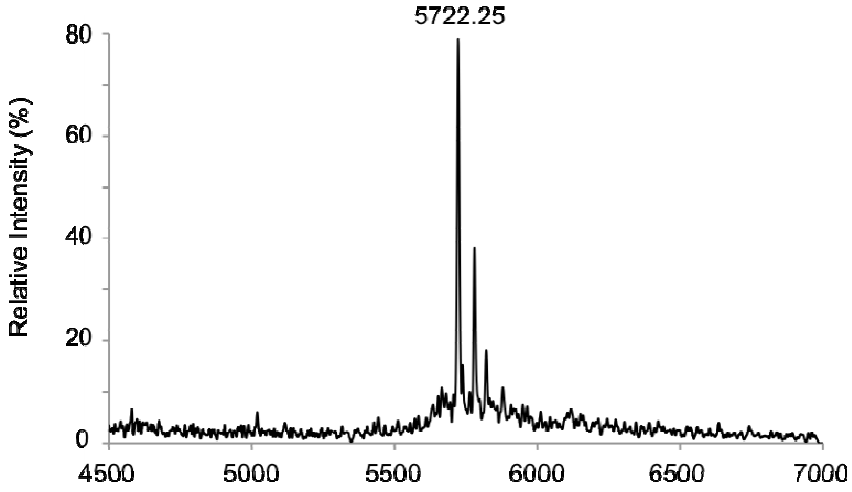


Figure S18. MALDI-TOF MS spectrum of Fl-TAT3-(S-CH2-CO-NH2)3.

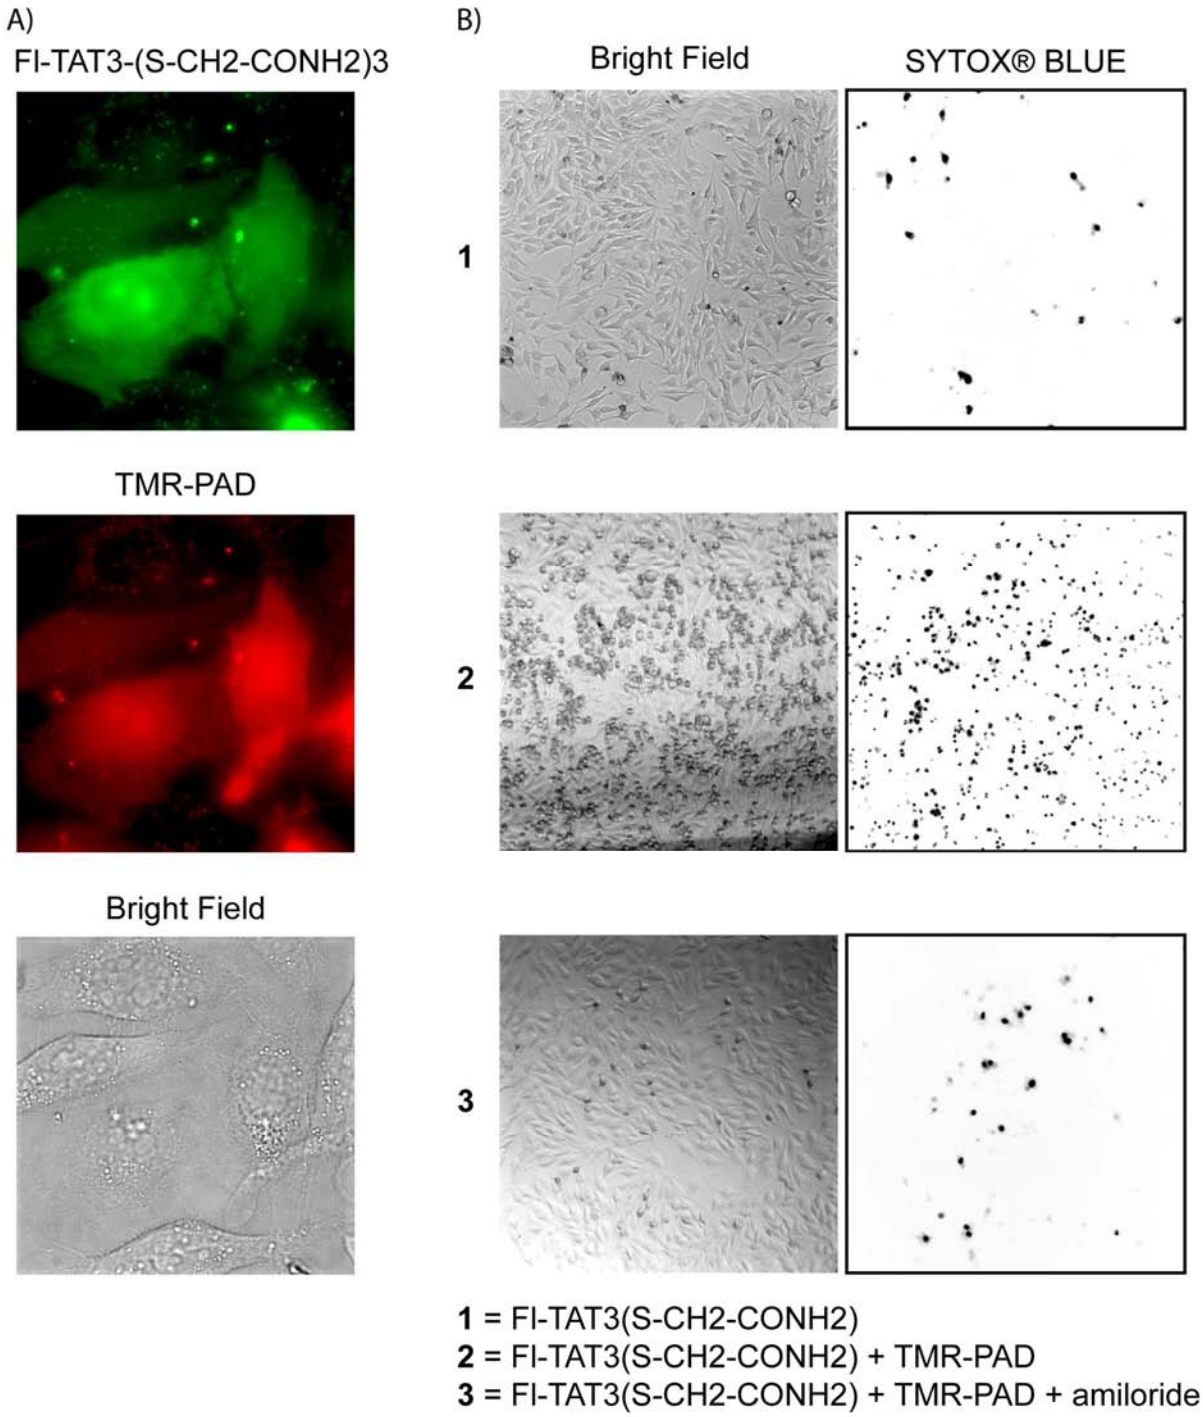

Figure S19. A) C) Fluorescence images of live HeLa cells treated with Fl-TAT3-(S-CH2-CO-NH2)3 (3 μM) and TMR-PAD (10 μM) after a 30 min co-incubation at 37°C (the objective used was 100X). The cells represented were not stained by SYTOX® Blue at this early time point. This indicates that the membrane of these cells was not compromised. B) Images of cells incubated with TMR-PAD (10 μM), Fl-TAT3-(S-CH2-CO-NH2)3 (3 μM), and with or without the macropinocytosis inhibitor amiloride. Cells were incubated with the peptides for 30 min, washed with fresh media, and SYTOX Blue was added to detect dead cells. Images were acquired 240 min after addition of SYTOX® Blue. Black nuclei in the SYTOX® Blue images represent dead or dying cells (images are represented as inverted monochrome).

As shown in Figure S19, Fl-TAT3-(S-CH2-CO-NH2)3 alone does not cause extensive cell-death (>90% viability). In contrast, co-incubation of TMR-PAD and Fl-TAT3-(S-CH2-CO-NH2)3 causes cell-death in a time-dependent manner. Figure S19 A illustrates that cells are viable immediately after incubation while Figure S19 B shows that cell viability was reduced to less than 25% after 240 min (cell viability was determined as describe in page 2 of this document). The control showing that TMR-PAD alone is not toxic to cells is shown in Figure 2. Finally, addition of amiloride to the incubation media blocks macropinocytosis and the delivery of TMR-PAD into live cells by Fl-TAT3-(S-CH2-CO-NH2)3.

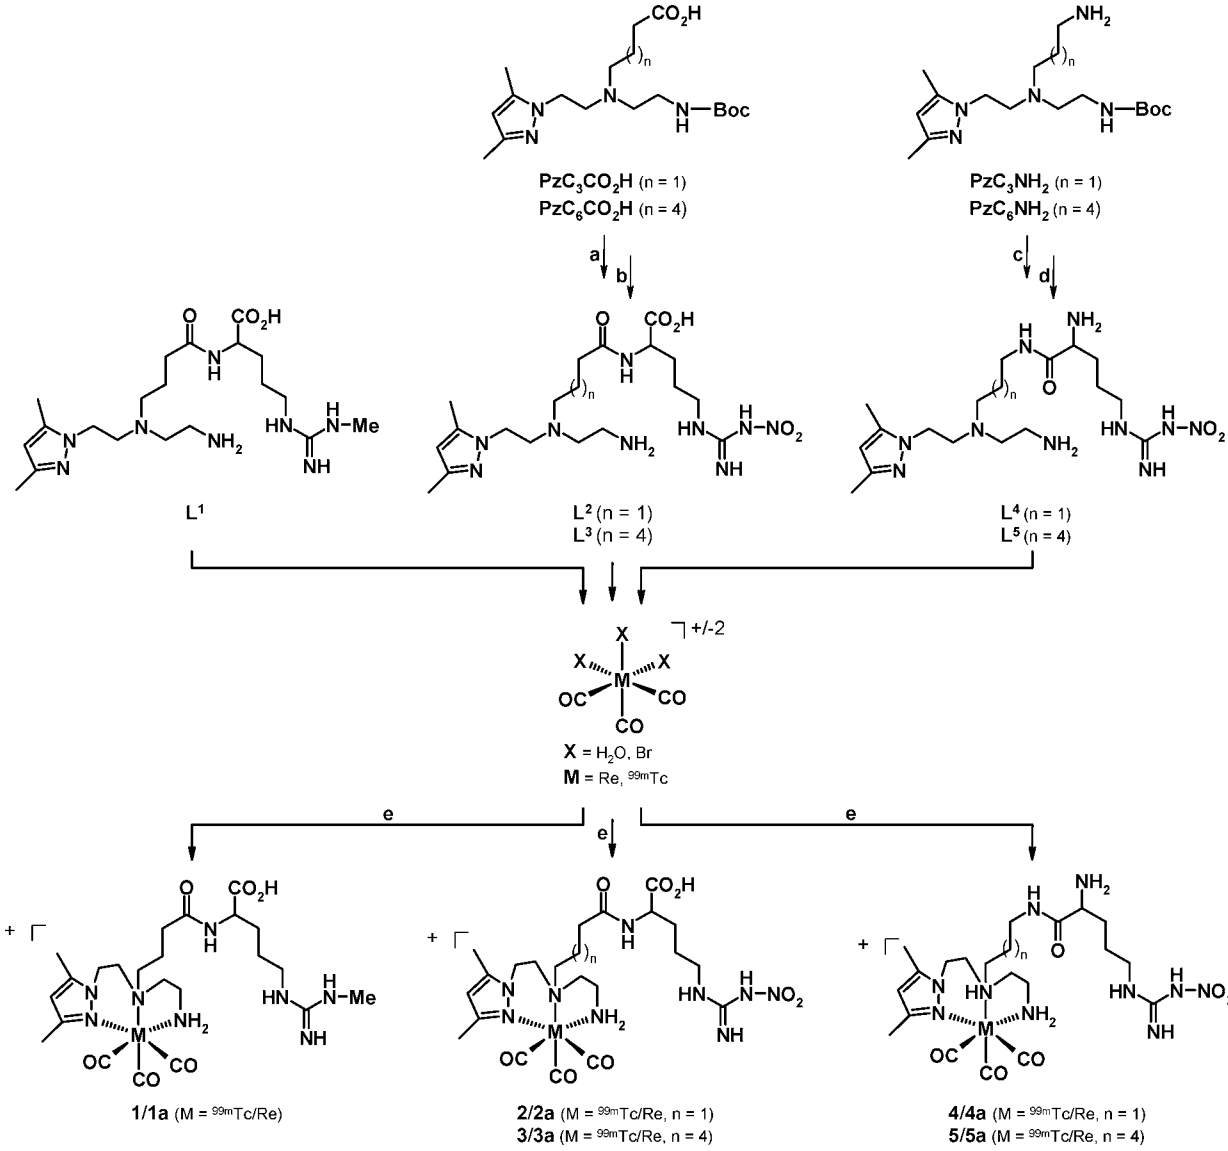
Received June 28, 2010; Revised Manuscript Received October 12, 2010



The in vivo molecular imaging of nitric oxide synthase (NOS), the enzyme responsible for the catalytic oxidation of L-arginine to citrulline and nitric oxide (NO), by noninvasive modalities could provide valuable insights into NO/NOS-related diseases. Aiming at the design of innovative ^{99m}Tc(I) complexes for targeting inducible NOS (iNOS) in vivo by SPECT imaging, herein we describe a set of novel ^{99m}Tc(CO)$_3$ complexes (**2**−**5**) and the corresponding rhenium surrogates (**2a**−**5a**) containing the NOS inhibitor N^{ω}-nitro-L-arginine. The latter is linked through its α-NH_2 or α-COOH group and an alkyl spacer of variable length to the metal center. The complexes **2a** (propyl spacer) and **3a** (hexyl spacer), in which the α-NH_2 group of the inhibitor is involved in the conjugation to the metal center, presented remarkable affinity for purified iNOS, being similar to that of the free nonconjugated inhibitor (K_i = 3−8 μM) in the case of **3a** (K_i = 6 μM). **2a** and **3a** are the first examples of organometallic complexes that permeate through RAW 264.7 macrophage cell membranes, interacting specifically with the target enzyme, as confirmed by the suppression of NO biosynthesis in LPS-treated macrophages (**2a**, ca. 30% inhibition; **3a**, ca. 50% inhibition). The ^{99m}Tc(I)-complexes **2** and **3**, stable both in vitro and in vivo, also presented the ability to cross cell membranes, as demonstrated by internalization studies in the same cell model. The biodistribution studies in LPS-pretreated mature female C57BL6 mice have shown that **2** presented an overall higher uptake in most tissues of the LPS-treated mice compared to the control group (30 min postinjection). This increase is significant in lung (3.98 ± 0.63 vs to 0.99 ± 0.13%ID/g), which is known to be the organ with the highest iNOS expression after LPS treatment. These results suggest that the higher uptake in that organ may be related to iNOS upregulation.

The in vivo molecular imaging of nitric oxide synthase (NOS), the enzyme responsible for the catalytic oxidation of L-arginine to citrulline and nitric oxide (NO), by noninvasive modalities could provide valuable insights into NO/NOS-related diseases such as cancer, neurological disorders, or vascular malfunctions, among others (*1*−*10*). So far, the main modalities explored for NOS imaging include positron emission tomography (PET) and optical imaging (OI) (*9*−*15*). The nuclear imaging modalities PET or single photon emission computed tomography (SPECT), due to their favorable features, and broad range of available probes offer high clinical potential (*16*−*18*). Technetium-99m (^{99m}Tc) is the radionuclide of choice for SPECT imaging due to its almost ideal nuclear properties ($t_{1/2}$ = 6.02 h, $E_{\gamma_{max}}$ = 140 keV) and rich chemistry, which allows modulation of the biological properties of the radioactive complexes. Taking into consideration our interest in the design of innovative ^{99m}Tc(I)-complexes for targeting molecular processes in vivo (*19*−*21*), we have recently proposed a set of novel ^{99m}Tc(CO)$_3$ complexes containing pendant L-arginine or NOS inhibitors for targeting NOS expression by SPECT imaging (*22*, *23*). Enzymatic assays of purified inducible NOS (iNOS) activity in the presence of the analogue Re(CO)$_3$-complexes, prepared as "nonradioactive" surrogates, have shown that the Re complexes **1a** (K_i = 36 μM) and **2a** (K_i = 84 μM) stabilized by bioconjugates bearing N^{ω}-monomethyl- (**L**^{1}) or N^{ω}-nitro-L-arginine pendant moieties (**L**^{2}), respectively, still presented inhibitory action (Scheme 1). Indeed, **1a** and **2a** are the first examples of organometallic complexes able to inhibit the iNOS (*22*). Interestingly, **2a** presented higher inhibitory potency than the corresponding metal-free bioconjugate **L**^{2} (K_i = 178 μM). These encouraging results prompted us to introduce structural changes in **2a** aimed at increasing the affinity of the metal complex for the enzyme. Such modifications involved, on one hand, introduction of a longer alkyl chain between the N^{ω}-nitro-L-arginine pendant arm and the chelating unit and, on the other hand, conjugation of the amino acid derivative to the metal complex trough its α-COOH group. Toward this goal, we synthesized the new bioconjugates **L**^{3}−**L**^{5} in a two-step procedure by direct conjugation of the Boc-protected precursors **PzC$_6$CO$_2$H**, **PzC$_3$NH$_2$**, and **PzC$_6$NH$_2$** to the corresponding N^{ω}-nitro-L-arginine derivative using standard coupling reagents, followed by hydrolysis of the protecting groups under acidic conditions (Scheme 1). All amino acid-containing bioconjugates were obtained as air-stable colorless oils after purification by semipreparative reversed-phase high-performance liquid chromatography (RP-HPLC) with ≥98% purity (see Supporting Information). All bioconjugates were characterized by elemental analysis, ^{1}H/^{13}C NMR (including 2D-NMR experiments such as ^{1}H-^{1}H-^{1}H COSY and ^{1}H-^{13}C HSQC) and IR spectroscopy, and electrospray ionization mass spectrometry (see Supporting Information). Reaction of **L**^{1}−**L**^{5} with the organometallic

Scheme 1. Synthesis of Bioconjugates L^2−L^5 and Organometallic Complexes 1/1a−5/5a[a]

[a] Reagents and conditions: (a) N^{ω}-nitro-L-arginine methyl ester, HBTU, Et_3N, DMF/ACN, r.t.; (b) HCl 3 N, r.t.; (c) N^{α}-Boc-N^{ω}-nitro-L-arginine, DCC, HOBt, DMF/DCM, r.t.; (d) TFA/DCM, r.t..; (e) H_2O, 100 °C. ACN = acetonitrile; Boc = *t*-butoxycarbonyl; DCC = *N*,*N*′-Dicyclohexylcarbodiimide; DCM = dichloromethane; DMF = dimethylformamide; HBTU = *O*-Benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyl-uronium-hexafluoro-phosphate; HOBt = *N*-Hydroxybenzo-triazole; r.t. = room temperature; TFA = trifluoroacetic acid.

precursor *fac*-$[^{99m}Tc(CO)_3(H_2O)_3]^+$, obtained using an IsoLink kit, afforded in high radiochemical yield (>95%) cationic complexes of the type *fac*-$[^{99m}Tc(CO)_3(k^3\text{-L})]^+$ (**L** = $\mathbf{L}^1$, **1**; $\mathbf{L}^2$, **2**; $\mathbf{L}^3$, **3**; $\mathbf{L}^4$, **4**; $\mathbf{L}^5$, **5**) (Scheme 1).

The hydro(lipo)philic nature of all ^{99m}Tc(I)-complexes was evaluated by determining the partition coefficient in physiological conditions (Supporting Information), and the results were expressed as log $P_{o/w}$. The radiocomplexes with a propyl spacer (log $P_{o/w}$ **1** = −2.19, log $P_{o/w}$ **2** = −1.41, and log $P_{o/w}$ **4** = −1.29) presented higher hydrophilic character than the ones with a hexyl spacer (log $P_{o/w}$ **3** = −0.29, and log $P_{o/w}$ **5** = −1.01).

The in vitro stability studies performed (incubation with solutions of amino acids with high affinity for Tc(I) such as histidine and cysteine, in phosphate-buffered saline pH 7.4, and human plasma at 37 °C for 24 h) have shown that all ^{99m}Tc(I)-complexes are stable, since no decomposition or reoxidation products were observed by RP-HPLC analysis (purity ≥95%).

The chemical identity of the ^{99m}Tc(I) complexes has been established by comparing their RP-HPLC analytical radioactive traces (γ-detection) with the UV/vis traces of the rhenium complex surrogates **1a**−**5a**, which have been prepared by reacting $\mathbf{L}^1$−$\mathbf{L}^5$ with the precursor $(NEt_4)_2[ReBr_3(CO)_3]$ in refluxing water, in the 1:1 molar ratio (Scheme 1). The complexes were obtained as air-stable colorless viscous oils in moderate yields (40−94%), after evaporation of the reaction solvent and washing of the residue obtained with $CHCl_3$ for NEt_4Br removal and further purification by preparative RP-HPLC (purity ≥95%). The novel complexes **3a**−**5a** were fully characterized (Supporting Information) by RP-HPLC, elemental analysis, ESI-MS, and NMR spectroscopy ($^1H/^{13}C$ NMR, ^1H-^1H COSY, and ^1H-^{13}C HSQC).

To assess the influence of the structural modifications introduced in **2a** in the enzymatic activity of NOS, the new bioconjugates $\mathbf{L}^3$−$\mathbf{L}^5$ and corresponding rhenium complexes **3a**−**5a** were tested as competitive inhibitors of purified mouse recombinant iNOS, and their activity compared to that of the previously described analogues (*22*). The iNOS activity was determined spectrophotometrically by monitoring the NO-mediated conversion of oxyhemoglobin to methemoglobin at two wavelengths (401 and 421 nm). The inhibition constants

[a] Results are given as a mean of three or more independent experiments. Standard deviations of ±5−10% were observed.

(K_i), determined by the method of Eisenthal and Cornish-Bowden, are summarized in Table 1.

All bioconjugates showed decreased inhibitory potencies to iNOS (L^2−L^5) when compared with free, nonconjugated, N^{ω}-nitro-L-arginine. When the latter is coupled through its α-NH_2 group to the bifunctional chelator, a longer spacer length led to an increased affinity to the enzyme as can be concluded by comparing the K_i values of L^3 (36 μM) and L^2 (178 μM). An opposite effect has been observed when the α-CO_2H group of N^{ω}-nitro-L-arginine is involved in the attachment to the chelator. In this case, the longer spacer length led to a lower affinity for the enzyme (L^4, K_i = 35 μM; L^5, K_i = 137 μM). Unlike L^4, reaction of the analogue bioconjugates L^2 (K_i = 178 μM), L^3 (K_i = 36 μM), and L^5 (K_i = 137 μM) with the organometallic moiety *fac*-$[Re(CO)_3]^+$ gave complexes with increased inhibitory potencies (**2a**, K_i = 84 μM; **3a**, K_i = 6 μM; **5a**, K_i = 118 μM).

The increased inhibitory potency after metalation occurs independently of the functional group of the amino acid involved in the chemical bonding to the chelating unit (e.g., **3a** vs **5a**) and spacer length (e.g., **2a** vs **3a**). Such an effect has already been observed with other metal complexes that presented higher inhibitory potency than the corresponding metal-free inhibitors (*25*). Remarkably, in the case of **3a**, the inhibitory potency (K_i = 6 μM) is comparable to that of the free nonconjugated inhibitor N^{ω}-nitro-L-arginine (K_i = 3 μM).

These unprecedented results motivated us to evaluate the ability of the compounds to cross cellular membranes, a key feature for improving tracer uptake in vivo, and to interact intracellularly with their target (iNOS enzyme).

Both the ^{99m}Tc(I) complexes and their Re(I) surrogates were tested in RAW 264.7 macrophages, which present increased NO biosynthesis due to iNOS overexpression after treatment with endotoxins such as lipopolysaccharide (LPS) (*26*). LPS-induced iNOS overexpression was confirmed by Western blot analysis of protein extracts using an anti-iNOS antibody (Figure 1).

We began by evaluating the ability of bioconjugates L^2−L^5 and rhenium complexes **1a**−**5a** to inhibit intracellular iNOS by measuring nitrite accumulation using the Griess method (Figure 2). In order to assess the intrinsic cytotoxicity of the compounds at the concentration used in the NO assay (500 μM) and, consequently, its influence in nitrite accumulation, we have also performed a cell viability assay in parallel (MTT assay). The

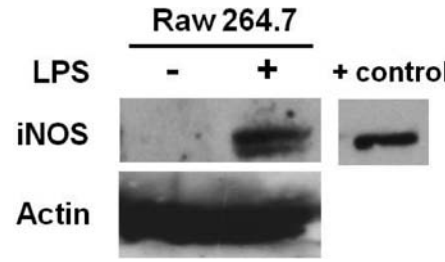

Figure 1. iNOS expression in RAW 264.7 macrophages after treatment with LPS for 24 h. Recombinant iNOS (6 μg) was used as a positive control and actin as an internal loading control.

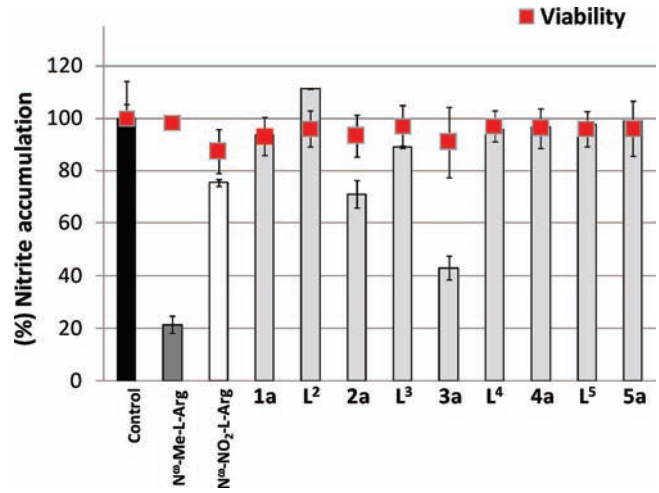

Figure 2. Effect of compounds L^2−L^5 and **1a**−**5a** in nitrite accumulation and cell viability in LPS-induced RAW 264.7 macrophages (mean ± S.D., n = 8). Cells were LPS-treated and cultured in the presence of the compounds. Final concentration of all compounds was 500 μM. NO production and viability in LPS-induced cells in the absence of any compound (control) was considered 100%. This experiment was repeated three times with comparable results.

assay has shown that all compounds tested are nontoxic for the cells under the described experimental conditions (Figure 2).

The rhenium complexes **2a** (ca. 30% inhibition) and **3a** (ca. 50% inhibition) appeared as the most potent inhibitors of NO production by LPS-activated macrophages. Remarkably, **3a** inhibited NO biosynthesis more effectively than the free inhibitor N^{ω}-nitro-L-arginine (N^{ω}-NO_2-L-Arg - ca. 25%). These results are in line with the in vitro enzymatic assays performed with purified iNOS, where complexes **2a** and **3a** also exhibited the highest inhibitory potency toward iNOS (**2a**, K_i = 84 μM; **3a**, K_i = 6 μM; Table 1). Since the inhibition of NO biosynthesis is being influenced not only by the intrinsic inhibitory capacity of the complexes as desired, but also by their ability to cross the cell membrane, we have performed internalization studies in the same cellular model with the radioactive ^{99m}Tc(I) analogues **2** and **3**, and compared their internalization levels with that of **1** (Figure 3).

These studies allowed us to conclude that the affinity of compound **3a** for the enzyme is strong enough to surpass the lower ability for crossing the cell membrane presented by the corresponding radioactive complex **3**, as demonstrated by its lower internalization level, when compared with compound **2** (0.43 ± 0.06% vs 0.83 ± 0.06% internalization/mg protein, respectively).

Despite presenting comparable ability for crossing cell membranes, as demonstrated by the similar internalization levels shown by **1** and **2** (0.76 ± 0.10% and 0.83 ± 0.06% internalization/mg protein, respectively), the surrogate compound **1a**, which presented a higher affinity for purified iNOS than

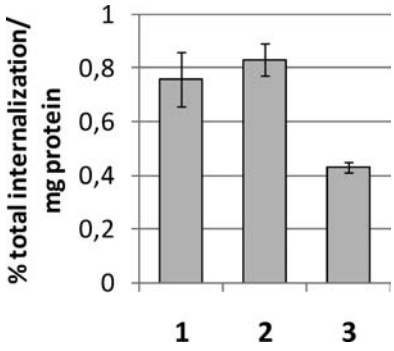

Figure 3. Internalization of the radioactive complexes **1**−**3** in LPS-induced RAW 264.7 macrophages (mean ± S.D., $n = 4$; 37 °C, 4 h post-incubation). The internalization level is expressed as a percentage of applied radioactivity per milligram of total protein.

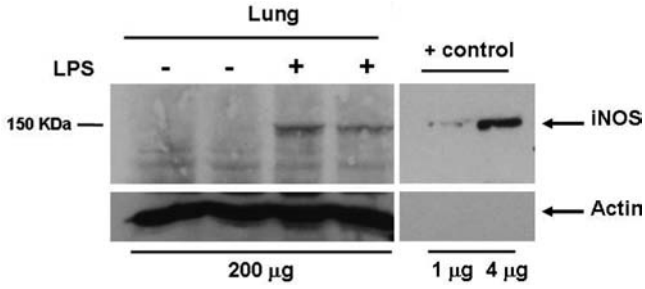

Figure 4. iNOS expression in the lungs of LPS-treated mice (10 mg/kg of LPS, 6 h). Recombinant iNOS (4 μg) was used as a positive control and actin as internal loading control.

compound **2a**, is not able to inhibit intracellular iNOS in the macrophages assay as is the case of **2a**.

As far as we are aware, the matched pairs **2/2a** and **3/3a** are rare examples of organometallic complexes able to cross cell membranes and interact specifically with a cytosolic enzyme. Encouraged by both the ability of **2a** and **3a** to interact with intracellular iNOS, inhibiting biosynthesis of NO in LPS-activated RAW 264.7 macrophages, and the moderate ability of **2** and **3** to cross cell membranes, the biodistribution of these ^{99m}Tc(I) complexes has been evaluated in LPS-pretreated mature female C57BL6 mice. Mice were treated with bacterial LPS (10 mg/kg, iv) to induce iNOS expression 6 h before the radioactive compounds were injected. The control group was injected with PBS. It has been demonstrated that iNOS mRNA and protein expression after LPS stimulation are increased in many organs, with the highest iNOS expression in the lungs (*27*). We have also confirmed increased levels of iNOS expression in lungs of LPS-treated mice by Western blot analysis of total protein (Figure 4).

The complexes **2** and **3** are stable in vivo as demonstrated by RP-HPLC analysis of urine and serum samples collected at sacrifice time. In fact, more than 98% of the radioactivity could be assigned to the complexes.

Compound **3** did not present any significant increase of radioactivity in the lungs of pretreated animals compared to the control group at 15 and 60 min postinjection. This result is in agreement with the cellular internalization data obtained for this compound and confirms the importance of crossing cell membranes for in vivo intracellular targeting and retention.

Compound **2** presented an overall higher uptake in most tissues of LPS-treated mice compared to the control group at 30 min postinjection (Figure 5). Unlike compound **3**, this increase is particularly relevant in lung (3.98 ± 0.76 vs 0.99 ± 0.13%ID/g), which is known to be the organ with the highest iNOS expression (*27*). This result suggests a direct correlation

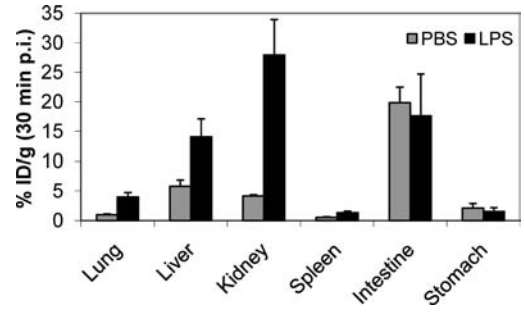

Figure 5. Biodistribution of **2** in LPS-treated mature female C57BL/6 mice (LPS) and control group (PBS) 30 min after intravenous injection (mean ± standard deviation, $n = 4$−5). ID: injected dose.

between lung uptake and iNOS upregulation. In contrast to intestine and stomach, the increased uptake in the excretory organs kidney and liver, as well as in the spleen, may also be partially related to iNOS overexpression in these tissues (*27*).

In conclusion, we have shown that complexes **2a** and **3a**, "inactive" surrogates of the ^{99m}Tc(I)-complexes **2** and **3**, presented remarkable affinity for purified iNOS, being similar to that of the free nonconjugated inhibitor in the case **3a**. Both complexes permeate through macrophage cell membranes and interact specifically with the cytosolic target enzyme, as confirmed by the inhibition of NO biosynthesis in LPS-treated macrophages. The ^{99m}Tc(I) complexes **2** and **3** are stable in vitro and present the ability to cross cell membranes. The biodistribution studies demonstrated that these complexes are stable in vivo and suggested that **2** is able to recognize iNOS in vivo. Therefore, the latter complex **2** presents a set of adequate features for potential targeting/imaging of NOS expression in vivo. These encouraging results brought together proved that metal complexes in general, and ^{99m}Tc(I)/Re(I) complexes in particular, can be "structurally tuned" to target intracellular low-capacity systems such as enzymes, paving the way to the design of innovative, more specific diagnostic or therapeutic agents.

ACKNOWLEDGMENT

This work has been partially supported by the Fundação para a Ciência e Tecnologia (FCT), Portugal (POCI/SAU-FCF/58855/2004). B. L. Oliveira thanks FCT for a PhD grant (SFRH/BD/38753/2007). Dr. J. Marçalo is acknowledged for performing the ESI-MS analyses. The QITMS instrument was acquired with the support of Contract REDE/1503/REM/2005 - ITN of FCT and is part of RNEM.

Bioconjugate Chemistry – Communication

General procedures and materials: All chemicals and solvents were of reagent grade and were used without purification unless stated otherwise. The precursor *tert*-butyl (2-{[2-(3,5-dimethyl-1*H*-pyrazol-1-yl)ethyl]amino}ethyl)carbamate (**PzBoc**), **L[1]**, **L[2]**, **1**/**1a**, **2**/**2a** and $(Et_4N)_2[Re(CO)_3Br_3]$ were prepared according to published methods (*1-3*). All other chemicals not specified above were purchased from Aldrich. $Na[^{99m}TcO_4]$ was eluted from a $^{99}Mo/^{99m}Tc$ generator using 0.9% saline. The radioactive precursor *fac*-$[^{99m}Tc(CO)_3(H_2O)_3]^+$ was prepared using a IsoLink® kit (Malinckrodt, Inc.). ^1H and ^{11}C NMR spectra were recorded at room temperature on a Varian Unity 300 MHz spectrometer. ^1H and ^{11}C chemical shifts were referenced with the residual solvent resonances relatively to tetramethylsilane. The spectra were assigned with the help of 2D experiments (^1H–^1H correlation spectroscopy, COSY and ^1H–^{13}C heteronuclear single quantum coherence, HSQC). Assignments of the ^1H and ^{13}C NMR resonances are given in accordance with the identification system shown in **Scheme S1**. Infrared spectra were recorded as KBr pellets on a Bruker Tensor 27 spectrometer. All compounds were characterized by electrospray ionization mass spectrometry (ESI-MS) using a Bruker model Esquire 3000 plus. Aliquots of ~ 5 mg of pure compounds (≥ 98 % ascertained by RP-HPLC) were lyophilized in eppendorf tubes and used for radioactive labelling and *in vitro* studies. HPLC analyses were performed on a Perkin Elmer LC pump 200 coupled to a Shimadzu SPD 10AV UV/Vis and to a Berthold-LB 509 radiometric detector, using an analytic Macherey-Nagel C18 reversed-phase column (Nucleosil 100-5, 250 x 3 mm) with a flow rate of 0.5 mL/min. Purification of the inactive compounds were achieved on a semi-preparative Macherey-Nagel C18 reversed-phase column (Nucleosil 100-7, 250 x 8 mm) or on a preparative Waters μ Bondapak C18 (150 x 19 mm) with a flow rate of 2.0 mL/min and 5.5 mL/min, respectively. UV detection: 220 or 254 nm. Eluents: aqueous 0.1% CF_3COOH/MeOH. Gradient: t = 0-5 min: 10%

MeOH; 5-30 min: 10→100% MeOH; 30-34 min: 100% MeOH; 34-35 min: 100→10% MeOH; 35-40 min: 10% MeOH.

NOS assays were recorded on an Agilent Technologies 8453 UV-Vis diode array spectrophotometer with a thermostated multicuvette holder with stirring. The iNOS (mouse recombinant enzyme), bovine hemoglobin, NADPH, BH_4 (Tetrahydrobiopterin), HEPES and DTT were purchased from Sigma Chemical Co.

Scheme S1. Synthesis of the precursor compounds **PzC_6CO_2H**, **PzC_3CNH_2** and **PzC_6NH_2** i) ethyl 7-bromoheptanoate or ethyl 4-bromobutanoate, K_2CO_3, KI, CH_3CN, reflux, ON; ii) NaOH, H_2O, THF, reflux, ON; iii) TFA, CH_2Cl_2, r.t.; iv) *N*-(3-bromopropyl)phthalimide or *N*-(6-bromohexyl)phthalimide, K_2CO_3, dioxane, reflux, overnight; v) MeOH, $NH_2NH_2 \cdot H_2O$, reflux;

vi) TFA, CH_2Cl_2, r.t. (*identification system for NMR assignments is displayed for PzC_6CO_2H as an example).*

- Synthesis of 7-{(2-aminoethyl)[2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl]amino}heptanoic acid (PzC_6CO_2H)

*Synthesis of ethyl 7-((2-(tert-butoxycarbonylamino)ethyl)(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)amino)heptanoate (**I**)*: The precursor **PzBoc** (0.40 g, 1.40 mmol) was dissolved in CH_3CN (60 mL) and ethyl 7-bromoheptanoate (0.67 g, 2.83 mmol), an excess of K_2CO_3 (0.39, 2.83 mmol), and a catalytic amount of KI were added. After refluxing for 18h, the solution was filtered, vacuum dried, and the residue was purified by column chromatography (hexane/EtOAc (50-100%). The intermediate compound **I** was obtained as a pale yellow oil upon removal of the solvents from the collected fractions. Yield: 79 % (0.50 g, 1.13 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 5.72 (s, CH^b, 1H), 5.05 (br s, NHBoc, 1H), 4.08 (q, OCH_2CH_3, 2H), 3.93 (t, CH_2^d, 2H), 3.02 (br m, 2H), 2.73 (t, 2H), 2.46 (t, 2H), 2.36 (t, 2H), 2.23 (t, 2H), 2.21 (s, CH_3pz, 3H), 2.17 (s, CH_3pz, 3H), 1.55 (m, 2H), 1.32 (s, CH_3, 9H), 1.27 (m, 2H), 1.21 (m, OCH_2CH_3 + CH_2, 5H), 1.16 (m, 2H). HPLC (R_t): 21.0 min (λ = 220 nm).

*Synthesis of 7-((2-(tert-butoxycarbonylamino)ethyl)(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)-amino)heptanoic acid (**II**)*: A solution of **I** (0.50 g, 1.13 mmol) and excess NaOH (0.45 g, 11.31 mmol) in H_2O/THF (3 mL/30mL) was refluxed overnight. The solution was carefully neutralized with HCl 1M at 0 ^oC and extracted with CH_2Cl_2. The organic phases were collected, dried over $MgSO_4$, filtered and the solvent evaporated. The crude product was purified by column chromatography ($CHCl_3$/MeOH (5-100%)) giving a yellow pale oil corresponding to **II**. Yield: 86 % (0.40 g, 0.97 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 5.70 (s, CH^b, 1H), 5.16 (br s, NHBoc, 1H),

3.91 (t, 2H), 2.97 (m, 2H), 2.72 (t, 2H), 2.43 (t, 2H), 2.35 (t, 2H), 2.16 (s, CH_3pz, 3H), 2.12 (s, CH_3pz, 3H), 1.45 – 1.20 (m, 10H), 1.37 (s, CH_3, 9H). HPLC (R_t): 20.0 min (λ = 220 nm).

*Synthesis of 7-((2-aminoethyl)(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)amino)heptanoic acid (**PzC_6CO_2H**)*: **PzC_6CO_2H** was obtained directly by dissolving **II** (0.17 g, 0.41 mmol) in a mixture of CH_2Cl_2/TFA (1 mL/3 mL) and allowed to react for 3 h at room temperature with stirring. The residue obtained after evaporation of the solvent was dissolved in H_2O, filtered through a 0.45 µm Millipore® filter, and purified by preparative RP-HPLC. The fractions containing $\mathbf{L^3}$ were collected and the solvent removed to provide a clear viscous colorless oil. Yield: 92 % (0.16 g, 0.38 mmol, calcd. for $C_{16}H_{30}N_4O_2$.TFA). IR (KBr, cm^{-1}): 3524m, 1694s, 1559m, 1442m and 1210m ^{1}H-NMR (D_2O): δ(ppm) 5.94 (s, CH^b, 1H), 4.35 (t, CH_2^d, 2H), 3.59 (t, CH_2^e, 2H), 3.44 (m, CH_2^f, 2H), 3.33 (m, CH_2^g, 2H), 3.09 (m, CH_2^m, 2H), 2.23 (m, CH_2^h, 2H), 2.20 (s, CH_3pz, 3H), 2.12 (s, CH_3pz, 3H), 1.52 (m, CH_2^l, 2H), 1.45 (m, CH_2^i, 2H), 1.18 (m, CH_2^j, CH_2^k, 4H). ^{13}C-NMR (D_2O): δ(ppm) 176.5 (CO), 165.3 (q, CF_3COO^-), 149.3 (pz), 145.4 (pz), 118.3 (q, CF_3COO^-), 106.4 (pz), 54.3 (CH_2), 53.4 (CH_2), 49.8 (CH_2), 42.2 (CH_2), 33.8 (CH_2), 33.5 (CH_2), 27.7 (CH_2), 25.3 (CH_2), 24.4 (CH_2), 22.9 (CH_2), 12.5 (CH_3pz), 9.8 (CH_3pz). HPLC (R_t): 18.6 min (λ = 220 nm). ESI-MS (+) (m/z): 311.1 $[M+H]^+$, calcd. for $C_{16}H_{30}N_4O_2$ = 310.2.

- *Synthesis of N^1-(2-aminoethyl)-N^1-(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)propane-1,3-diamine (PzC_3NH_2)*

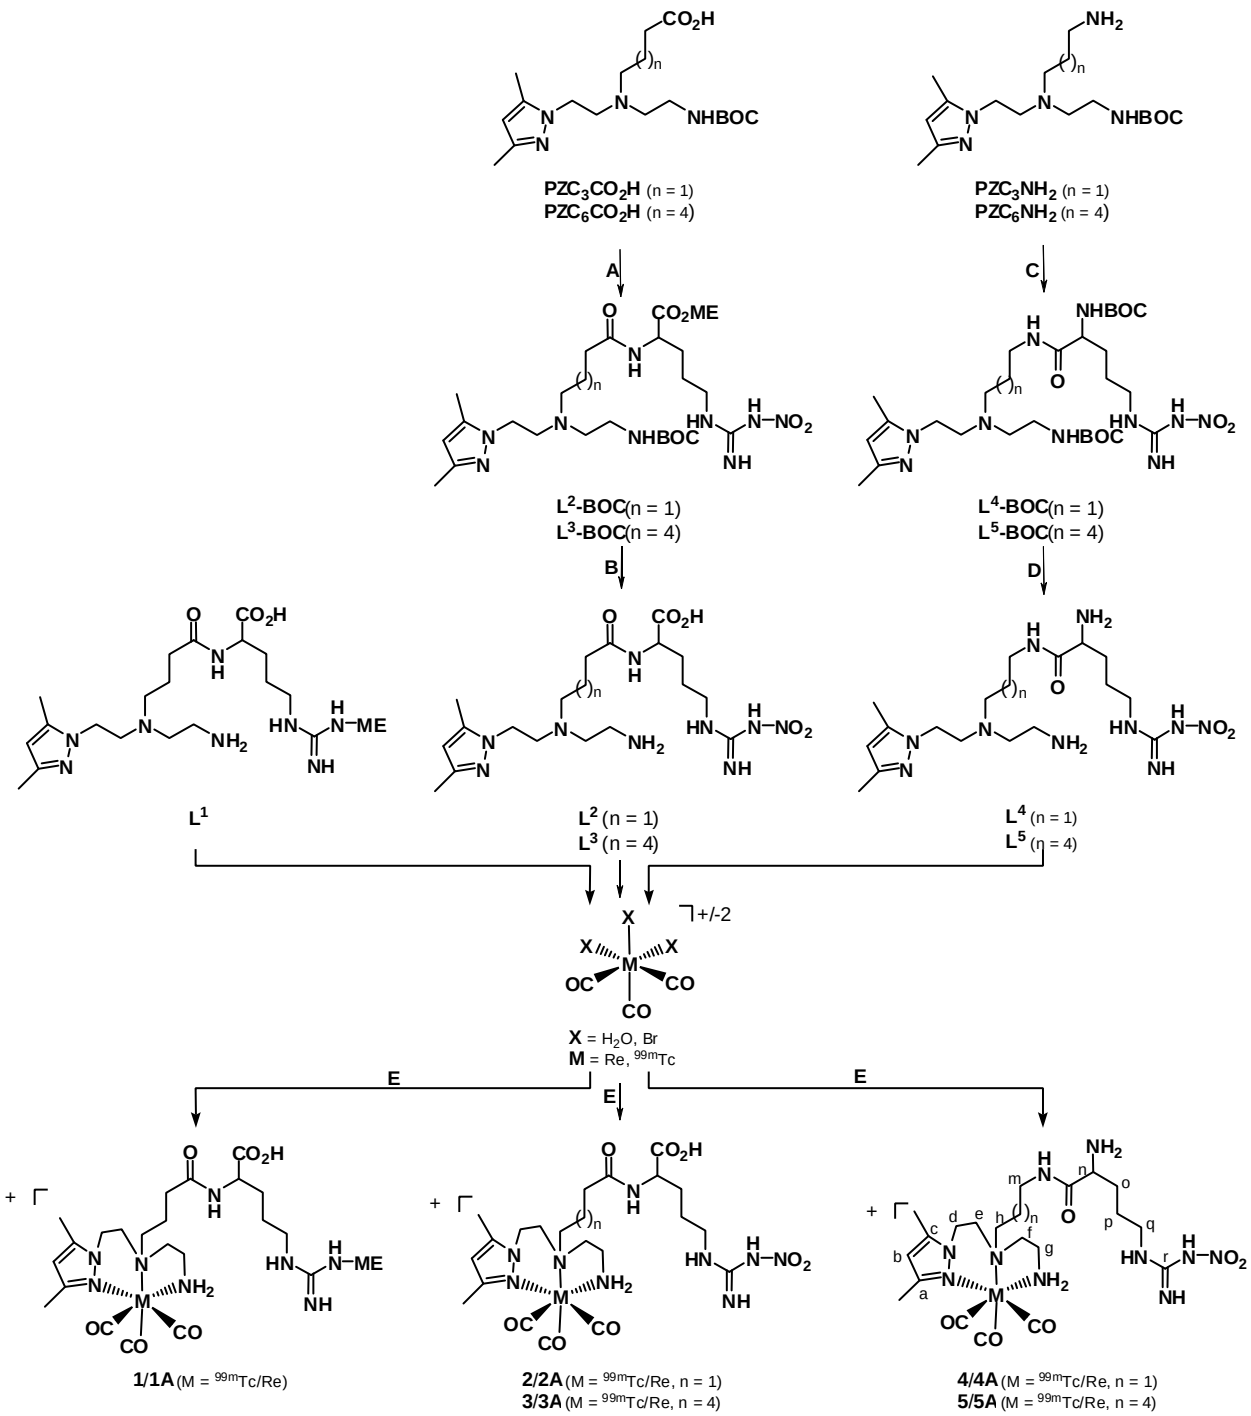
*Synthesis of tert-butyl 2-((2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)(3-(1,3-dioxo-2,3-dihydro-1H-inden-2-yl)propyl)amino)ethylcarbamate (**III**)*: A solution of **PzBoc** (1.11 g, 3.94 mmol), N-(3-bromopropyl)phthalimide (2.14 g, 8.05 mmol), and K_2CO_3 (1.10 g, 8.02 mmol) in dioxane (35 mL) was refluxed overnight. After reaction, the solution was filtered and the solvents evaporated

to give an oily residue which was purified by column chromatography (n-hexane to EtOAc). The fractions containing **III** were collected and the compound was obtained as an yellow oil after evaporation of the elution solvents. Yield: 78 % (1.45 g, 3.07 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 7.85 (m, phthalimide, 2H), 7.72 (m, phthalimide, 2H) 5.74 (s, CH^b, 1H), 5.15 (br s, NHBoc, 1H), 3.96 (t, CH_2^d, 2H), 3.61 (t, CH_2^e, 2H), 3.05 (m, CH_2^f, 2H), 2.78 (t, CH_2^h, 2H), 2.46 (m, CH_2^g/CH_2^j, 4H), 2.20 (s, CH_3pz, 3H), 2.15 (s, CH_3pz, 3H), 1.76-1.66 (m, CH_2^i, 2H), 1.39 (s, CH_3, 9H).

*Synthesis tert-butyl 2-((3-aminopropyl)(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)amino)-ethylcarbamate (**IV**)*: To a solution of **III** (1.45 g, 3.07 mmol) in MeOH (10 mL) was added hydrazine hydrate (3.01 mL, 63.20 mmol). After refluxing for 6 h, the solution was carefully acidified with HCl 1 M to pH 4 and a white precipitate was formed, which was removed by filtration. The obtained clear solution was neutralized with NaOH 1 M and extracted with $CHCl_3$. The organic layer was dried over $MgSO_4$. Removal of the solvent yielded an oily residue, which was purified by column chromatography ($CHCl_3$ to MeOH). After evaporation of the solvents, **IV** was obtained as a yellow oil. Yield: 86 % (0.90 g, 2.65 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 5.75 (s, CH^b, 1H), 5.28 (br s, NH_2, 2H), 5.10 (br s, NHBoc, 1H), 3.96 (t, CH_2^d, 2H), 3.07 (m, CH_2^e, 2H), 2.76 (t, CH_2^f, 2H), 2.60 (t, CH_2^g, 2H), 2.48 (m, CH_2^h/CH_2^j, 4H), 2.21 (s, CH_3pz, 3H), 2.19 (s, CH_3pz, 3H), 1.50-1.45 (m, CH_2^i, 2H), 1.42 (s, CH_3, 9H).

*Synthesis of N^1-(2-aminoethyl)-N^1-[2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl]propane-1,3-diamine (**PzC_3NH_2**):* **PzC_3NH_2** was obtained directly by dissolving **IV** (0.06 g, 0.17 mmol) in a mixture of CH_2Cl_2/TFA (1 mL/3 mL) and allowed to react for 3 h at room temperature with stirring. The residue obtained after evaporation of the solvent was dissolved in H_2O, filtered through a 0.45 µm Millipore® filter, and purified by preparative RP-HPLC. The fractions containing **PzC_3NH_2**

were collected and the solvent removed to provide a clear viscous colorless oil. Yield: 50 % (0.04 g, 0.086 mmol, calcd. for $C_{12}H_{25}N_5$.2TFA). IR (KBr, cm^{-1}): 1675s, 1190s and 1100m. ^{1}H-NMR (D_2O): δ(ppm) 5.83 (s, CH^b, 1H), 3.96 (t, CH_2^d, 2H), 2.85 (t, CH_2^e, 2H), 2.76 (m, CH_2^f/CH_2^g, 4H), 2.66 (m, CH_2^h, 2H), 2.51 (t, CH_2^j, 2H), 2.11 (s, CH_3pz, 3H), 2.01 (s, CH_3pz, 3H), 1.61 (m, CH_2^i, 2H). ^{13}C-NMR (D_2O): δ(ppm) 165.4 (q, CF_3COO^-), 151.2 (C^c), 144.1 (C^a), 118.7 (q, CF_3COO^-), 107.9 (C^b), 54.5 (C^e), 52.8 (C^f), 52.5 (C^d), 47.9 (C^h), 39.9 (C^j), 39.28 (C^g), 26.2 (C^i), 14.4 (CH_3pz), 12.5 (CH_3pz). HPLC (R_t): 16.8 min (λ = 220 nm). ESI-MS (+) (m/z): 240.2 $[M+H]^+$, calcd. for $C_{12}H_{25}N_5$ = 239.2.



- Synthesis of *N*^{1}-(2-aminoethyl)-*N*^{1}-(2-(3,5-dimethyl-1*H*-pyrazol-1-yl)ethyl)hexane-1,6-diamine (PzC_6NH_2)

*Synthesis of tert-butyl 2-((2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)(6-(1,3-dioxo-2,3-dihydro-1H-inden-2-yl)hexyl)amino)*ethylcarbamate (***V***): **V** was prepared as described for **III**. Starting with 0.49 g (1.74 mmol) of **PzBoc**, and 1.85 g (5.96 mmol) of N-(6-bromohexyl)phthalimide, a yellowish oil formulated as **V** was obtained after purification by column chromatography (n-hexane to EtOAc). Yield: 50 % (0.45 g, 0.87 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 7.81 (m, phthalimide, 2H), 7.68 (m, phthalimide, 2H), 5.73 (s, CH^b, 1H), 5.04 (br s, NHBoc, 1H), 3.93 (t, CH_2^d, 2H), 3.64 (t, CH_2^e, 2H), 3.03 (m, CH_2^f, 2H), 2.75 (t, CH_2^g, 2H) 2.46 (t, CH_2^h, 2H), 2.38 (t, CH_2^m, 2H), 2.20 (s, CH_3pz, 3H), 2.17 (s, CH_3pz, 3H), 1.67-1.57 (m, CH_2^i, CH_2^l, 4H), 1.30 (s, CH_3, 9H), 1.30-1.20 (m, CH_2^j, CH_2^k, 4H).

*Synthesis of tert-butyl 2-((6-aminohexyl)(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)amino)-ethylcarbamate (**VI**):* **VI** was prepared as described for **IV**. Starting with 0.46 g (0.89 mmol) of **V** and 0.86 mL (17.12 mmol) of hydrazine hydrate, a yellowish oil formulated as **VI** was

obtained after purification by column chromatography ($CHCl_3$ to MeOH). Yield: 90 % (0.33 g, 0.83 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 5.70 (s, CH^b, 1H), 5.02 (br s, NHBoc, 1H), 3.91 (t, CH_2^d, 2H), 3.00 (m, CH_2^e, 2H), 2.72 (t, CH_2^f, 2H), 2.62 (t, CH_2^g, 2H), 2.44 (t, CH_2^h, 2H), 2.35 (t, CH_2^m, 2H), 2.17 (s, CH_3pz, 3H), 2.15 (s, CH_3pz, 3H), 1.55 (m, CH_2^i, 2H), 1.32 (s, CH_3, 9H), 1.23 (m, CH_2^j + CH_2^k + CH_2^l, 6H).

Synthesis of N^1-(2-aminoethyl)-N^1-(2-(3,5-dimethyl-1H-pyrazol-1-yl)ethyl)hexane-1,6-diamine ***(PzC_6NH_2)***: Boc-deprotection of **VI** (0.080 g, 0,20 mmol) with CH_2Cl_2/TFA (1 mL/3 mL), as previously described, gave a colorless oil corresponding to **PzC_6NH_2** after purification by preparative RP-HPLC. Yield: 49 % (0.050 g, 0.098 mmol, calcd. for $C_{15}H_{31}N_5$.2TFA). IR (KBr, cm^{-1}): 1680s, 1200s and 1100m. ^{1}H-NMR (D_2O): δ(ppm) 6.03 (s, CH^b, 1H), 4.42 (t, CH_2^d, 2H), 3.59 (t, CH_2^e, 2H), 3.49 (m, CH_2^f, 2H), 3.34 (m, CH_2^g, 2H), 2.85 (t, CH_2^m, 2H), 2.15 (m, CH_2^h, 2H), 2.20 (s, CH_3pz, 3H), 2.12 (s, CH_3pz, 3H), 1.52 (m, CH_2^i, CH_2^l, 4H), 1.23 (m, CH_2^j, CH_2^k, 4H). ^{13}C-NMR (D_2O): δ(ppm) 165.4 (q, CF_3COO^-), 150.3 (C^c), 144.2 (C^a), 118.6 (q, CF_3COO^-), 107.1 (C^b), 54.0 (C^e), 51.9 (C^f), 49.8 (C^d), 42.2 (C^m), 39.3 (C^h), 33.8 (C^g), 26.7 (C^l), 25.4 (C^i), 25.3 (C^k), 22.9 (C^J), 11.8 (CH_3pz), 10.2 (CH_3pz). HPLC (R_t): 18.2 min (λ = 220nm). ESI-MS (+) (m/z): 282.2 $[M+H]^+$, calcd. for $C_{15}H_{31}N_5$ = 281.2.

Scheme S2. Synthesis of the intermediate bioconjugates $\mathbf{L^2}$ – $\mathbf{L^5}$ and organometallic complexes **1**/**1a** – **5**/**5a**. Numbering scheme for NMR assignment is presented for compound **4a**/**5a**.

- Synthesis of L^3

To a solution of **PzC_6CO_2H** (0.050 g, 0.12 mmol) in DMF were added triethylamine (0.036 g, 0.365 mmol) and *O*-benzotriazol-1-yl-*N*,*N*,*N*´,*N*´-tetramethyluronium hexafluorophosphate (HBTU, 0.054 g, 0.145 mmol). After 10 minutes N^{ω}-nitro-L-arginine methyl ester (0.039 g, 0.145 mmol) was added, and the reaction mixture stirred at room temperature under a nitrogen atmosphere for 2 h. The solvent was then removed under vacuum, and the residue purified by column chromatography ($CHCl_3$ to MeOH). The intermediate **L^3-Boc** was obtained as a yellowish oil. Yield: 66 % (0.050 g, 0.080 mmol). ^{1}H-NMR ($CDCl_3$): δ(ppm) 7.69 (br s, NH, 2H), 6.48 (br s, NH, 1H), 5.70 (s, CH^b, 1H), 5.10 (br s, NH, 1H), 4.57 (br s, NH, 1H), 3.91 (t, CH_2^d, 2H), 3.69 (s, OCH_3, 3H), 3.64 (br m, CH^n, 1H), 2.98 (m, CH_2, 2H), 2.72 (t, CH_2, 2H), 2.44 (t, CH_2, 2H), 2.36 (t, CH_2, 2H), 2.22 (m, CH_2, 2H) 2.19 (s, CH_3pz, 3H), 2.16 (s, CH_3pz, 3H), 1.89 (m, CH_2, 1H), 1.70 – 1.52 (m, CH_2, 7H), 1.40 (s, CH_3, 9H), 1.39 – 1.15 (m, CH_2, 6H). ^{13}C-NMR ($CDCl_3$): δ(ppm) 174.3 (CO), 172.6 (CO), 159.4 (C^r), 159.4 (CO), 147.3 (pz), 138.9 (pz), 104.9 (pz), 78.9 ($C(CH_3)_3$), 54.1, 53.7, 53.3, 52.7, 50.6, 47.0, 40.3, 38.4, 36.2, 30.8, 28.8, 28.4, 26.7, 25.4, 24.6, 13.4 (CH_3pz), 11.0 (CH_3pz).

L^3 was obtained directly by hydrolysis of the methyl ester group and Boc-deprotection of the intermediate **L^3-Boc** (0.090 g, 0.144 mmol) with a 3 N HCl solution (5 mL) at room temperature, for 72 h. After neutralization of the reaction mixture with a 1 M NaOH solution, the water was evaporated and the obtained residue extracted with MeOH. The solvent was evaporated, the residue dissolved in water and purified by RP-HPLC to give a colorless oil. Yield: 33 % (0.030 g, 0.048 mmol, calcd. for $C_{22}H_{41}N_9O_5$·TFA). IR (KBr, cm^{-1}): ~ 1650s, 1390m, 1265m (NO_2), 1200m and 1130m. ^{1}H-NMR (D_2O): δ(ppm) 5.76 (s, CH^b, 1H), 4.34 (br m, CH^n, 1H) 3.98 (t, CH_2^d, 2H), 3.87 (t, CH_2, 2H), 2.65 (m, CH_2, 4H), 2.31 (t, CH_2, 2H), 2.16 (s, CH_3pz, 3H), 2.14

(m, CH_2, 2H), 2.06 (s, CH_3pz, 3H), 1.79 (m, CH_2, 1H), 1.70 – 1.40 (m, CH_2, 7H), 1.39 – 1.00 (m, CH_2, 6H). ^{13}C-NMR ($CDCl_3$): δ(ppm) 175.3 (CO), 172.7 (CO), 162.2 (q, CF_3COO^-), 160.0 (C^r), 147.0 (pz), 139.7 (pz), 116.4 (q, CF_3COO^-), 105.1 (pz), 54.3, 53.1, 52.1, 51.1, 46.5, 40.5, 38.0, 35.4, 33.5, 28.9, 26.8, 26.6, 25.6, 24.7, 12.1 (CH_3pz), 9.7 (CH_3pz). ESI-MS (+) (*m/z*): 564.1 $[M+K]^+$; calcd for $C_{23}H_{43}N_9O_5$ = 525.3. Retention time (analytic RP-HPLC, 220 nm): 14.6 min. Elemental analysis calcd. for $C_{22}H_{41}N_9O_5$·TFA: C, 46.06; H, 6.76; N, 20.15. Found: C, 45.40; H, 6.20; N, 19.60 %.

- Synthesis of L^4

N^{α}-Boc-N^{ω}-nitro-L-arginine (0.11 g, 0.36 mmol), *N*,*N'*-Dicyclohexylcarbodiimide (DCC, 0.075 g, 0.36 mmol), and *N*-Hydroxybenzotriazole (HOBt, 0.050 g, 0.36 mmol) were dissolved in DMF (ca 5 mL) at room temperature under stirring. After 1 h, the reaction was cooled down with an ice bath, and *N*,*N*-Diisopropylethylamine (DIPEA, 125.4 µL, 0.72 mmol) and a solution of **PzC_3NH_2** (0.12 g, 0.36 mmol) in dichloromethane was added under stirring. After 18 h at room temperature the reaction was treated with water and the white precipitate corresponding to urea was removed by filtration. The aqueous phase was extracted with ethyl acetate, the organic phases were collected and dried over magnesium sulfate. Evaporation of the solvent afforded a yellowish oil which was chromatographed on an appropriate column of silica gel with methanol/dichloromethane/ammonia (10:89:1) to afford a colorless oil corresponding to **L^4-Boc**. This oil was dissolved in a dichloromethane/TFA solution (1 mL:3 mL) and stirred at room temperature for 3 h. The solvent was removed under vacuum, the residue dissolved in water and purified by semi-preparative RP-HPLC. Evaporation of the solvent from the collected fractions yielded compound **L^4·2TFA** as a colorless oil. Yield: 20 % (0.057 g, 0.073 mmol, calcd. for

$C_{18}H_{36}N_{10}O_3$·2TFA). IR (KBr, cm^{-1}): 3405m, ~1680s, 1427m, 1203m and 1134m. ^{1}H-NMR (D_2O): δ(ppm) 6.15 (s, H^b(4)pz, 1H), 4.53 (t, CH^d_2, 2H), 3.84 (t, CH^n, 1H), 3.57 (t, CH^e_2, 2H), 3.48 (m, CH^f_2, 2H) 3.34 (m, CH^g_2, 2H), 3.24 - 3.15 (t, CH^q_2/CH^h_2/CH^j_2) 2.22 (s, CH_3pz, 3H), 2.16 (s, CH_3pz, 3H), 1.77 (m, CH^o_2/CH^i_2, 4H), 1.52 (m, CH^p_2, 2H). ^{13}C-NMR (D_2O): δ(ppm) 169.9 (C=O), 162.3 (q, CF_3COO^-), 158.9 (C^r), 148.2 (C^c(3)pz), 146.7 (C^a(5)pz), 116.4 (q, CF_3COO^-), 108.2 (C^b(4)pz), 52.9 (C^n), 51.7 (C^h), 51.1 (C^e), 49.8 (C^f), 42.0 (C^d), 40.3 (C^q), 36.5 (C^j), 33.7 (C^g), 28.1 (C^i), 23.2 (C^p), 23.1 (C^o), 11.5 (CH_3pz), 10.1 (CH_3pz). ESI-MS (+) (*m/z*): 441.2 $[M+H]^+$; calcd for $C_{18}H_{36}N_{10}O_3$ = 440.3. Elemental analysis calcd. for $C_{18}H_{36}N_{10}O_3$·2TFA: C, 36.81; H, 5.02; N, 17.90. Found: C, 36.53; H, 5.32; N, 17.82 %. Retention time (analytic RP-HPLC, 220 nm): 21.1 min.

- Synthesis of L^5

N^{α}-Boc-N^{ω}-nitro-L-arginine (0.084 g, 0.262 mmol), *N*,*N'*-Dicyclohexylcarbodiimide (DCC, 0.064 g, 0.314 mmol), and *N*-Hydroxybenzotriazole (HOBt, 0.042 g, 0.314 mmol) were dissolved in DMF (ca 5 mL) at room temperature under stirring. After 1 h, the reaction was cooled down with an ice bath, and *N*,*N*-Diisopropylethylamine (DIPEA, 0.067 g, 0.524 mmol) and a solution of PzC_6NH_2 (0.100 g, 0.262 mmol) in DMF was added under stirring. After 18 h at room temperature the solvent was removed and the residue treated with water/ethyl acetate. The organic layer was dried over $MgSO_4$. Removal of the solvent yielded an oily residue, which was purified by column chromatography ($CHCl_3$ to MeOH). Yield: 70 % (0.125 g, 0.183 mmol). ^{1}H-NMR (CDCl3): δ(ppm) 7.69 (br s, NH, 2H), 6.92 (br s, NH, 1H), 5.79 (s, CH^b, 1H), 5.59 (br s, NH, 1H), 5.20 (br s, NH, 1H), 4.22 (br m, NH, 1H), 4.01 (t, CH_2^d, 2H), 3.71 (br m, CH^n, 1H), 3.50 – 3.20 (m, CH_2, 4H), 3.03 (m, CH_2, 2H), 2.76 (t, CH_2, 2H), 2.49 (t, CH_2, 2H), 2.42 (t, CH_2,

2H), 2.24 (s, CH_3pz, 3H), 2.20 (s, CH_3pz, 3H), 1.93 (m, CH_2, 3H), 1.70 (m, CH_2, 5H), 1.44 (s, CH_3, 9H), 1.43 (s, CH_3, 9H), 1.35 (m, CH_2, 2H), 1.25 (m, CH_2, 2H).

The Boc-deprotection of the intermediate **L^5-Boc** with CH_2Cl_2/TFA (1 mL/3 mL), as described above for **L^4**, gave a colorless oil after purification by preparative RP-HPLC corresponding to **L^5**. Yield: 92 % (0.120 g, 0.169 mmol, calcd. for $C_{21}H_{42}N_{10}O_3$·2TFA). IR (KBr, cm^{-1}): 3255m, ~1654s, 1396m, 1275m and 1203m. ^{1}H-NMR (D_2O): δ(ppm) 6.16 (s, H^b(4)pz, 1H), 4.55 (t , CH^d_2, 2H), 3.81 (t, CH^n, 1H), 3.59 (t, CH^e_2, 2H), 3.53 (m, CH^f_2, 2H) 3.35 (m, CH^g_2, 2H), 3.21-3.13 (m, CH^q_2/CH^h_2/CH^j_2) 2.24 (s, CH_3pz, 3H), 2.18 (s, CH_3pz, 3H), 1.75 (m, CH^o_2/ ´´, 2H), 1.54-1.50 (m, CH^p_2, CH^i_2, 4H) 1.34 (m, CH^l_2, 2H), 1.17 (m, CH^j_2/CH^k_2, 4H). ^{13}C-NMR (D_2O): δ(ppm) 169.2 (C=O), 158.7 (C^r), 147.9 (C^c(3/5)pz), 146.8 (C^a (3/5)pz), 108.4 (C^b), 53.9 (C^q), 53.0 (C^n), 50.8 (C^e), 49.7 (C^f), 42.0 (C^d), 40.3 (C^m), 39.5 (C^h), 33.7 (C^g), 28.1 (C^o), 28.0 (C^l), 25.8 (C^p), 25.3 (C^i), 23.3 (C^k), 22.8 (C^J), 10.6 (CH_3pz), 10.2 (CH_3pz). ESI-MS (+) (*m/z*): 242.0 $[M+H]^{2+}$; calcd for $C_{21}H_{42}N_{10}O_3$ = 482.3. Elemental analysis calcd. for $C_{21}H_{42}N_{10}O_3$·2TFA: C, 42.23; H, 6.24; N, 19.71. Found: C, 43.00; H, 6.50; N, 19.90 %. Retention time (analytic RP-HPLC, 220 nm): 23.1 min.

General procedure for the preparation of the Re complexes *fac*-[Re(CO)$_3$(k^3-L)] (3a, L = L^3; 4a, L = L^4; 5a, L = L^5)

$(NEt_4)_2[ReBr_3(CO)_3]$ was reacted with equimolar amounts of the compounds **L^3 – L^5** in refluxing water for 18h. After this time, the solvent was removed under vacuum, and the resulting residue washed with $CHCl_3$ to remove excess $[NEt_4]Br$. The resulting residue was dissolved in water, the precipitate formed eliminated by centrifugation and the supernatant purified by preparative RP-HPLC.

***Synthesis of fac-[Re(CO)$_3$(k^3-L^3)]$^+$* (3a)**

Starting from 0.035 g (0.055 mmol) of **L^3·TFA**, a colorless oil formulated as **3a** was obtained (0.020 g, 40 %, calcd. for $C_{25}H_{41}N_9O_8Re$·TFA). IR (KBr, cm^{-1}): 2024s and 1910s (C≡O), 1675s, 1290m, 1230m and 1135m. ^{1}H-NMR (CD3OD): δ(ppm) 6.20 (s, CH^b(4)pz, 1H), 5.50 (br s, NH, 1H), 4.55 – 4.49 (dd, CH_2, 1H), 4.45 (m, CH, 1H), 4.26 – 4.17 (dd, CH_2, 1H), 4.08 (m, NH, 1H), 3.66 (m, CH_2, 1H), 3.37 - 3.15 (m, overlapped with CD3OD, 7H), 2.82 (m, CH_2, 2H), 2.71 - 2.62 (m, CH_2, 1H), 2.57 - 2.43 (m, CH_2, 1H), 2.44 (s, CH_3pz, 3H), 2.36 (s, CH_3pz, 3H), 2.29 (t, CH_2, 2H), 1.93 (m, CH_2, 1H), 1.80 - 1.60 (m, CH_2, 5H), 1.42 (m, CH_2, 4H). ^{13}C-NMR (CD_3OD): δ(ppm) 197.0 (C≡O), 176.2 (C=O), 175.0 (C=O), 166.6 (C^r), 155.9 (C^c(3)pz), 145.6 (C^a(5)pz), 109.2 (C^b(4)pz), 68.7, 62.9, 53.4, 51.5, ~ 48.7 (2 signals overlapped with solvent CD_3OD), 43.7, 41.7, 37.8, 31.3, 31.0, 27.7, 26.5, 25.4, 16.0 (CH_3pz), 11.4 (CH_3pz). ESI-MS (+) (*m/z*): 782.0 [M]$^+$; calcd for $C_{25}H_{41}N_9O_8Re$ = 782.2. Elemental analysis calcd. for $C_{25}H_{41}N_9O_8Re$·TFA: C, 36.15; H, 4.72; N, 14.06. Found: C, 37.00; H, 4.90; N, 14.65 %. Retention time (analytic RP-HPLC, 220 nm): 24.0 min.

***Synthesis of fac-[Re(CO)$_3$(k^3-L^4)]$^+$* (4a)**

Starting from 0.040 g (0.060 mmol) of **L^4·2TFA**, a colorless oil formulated as **4a** was obtained (0.053 g, 94 %, calcd. for $C_{21}H_{36}N_{10}O_6Re$·2TFA). IR (KBr, cm^{-1}): 3410s, 2227s and 1903s (C≡O), 1674s, 1318m, 1201m and 1125m. ^{1}H-NMR (D_2O): δ(ppm) 6.05 (s, CH^b(4)pz, 1H), 5.05 (br s, NH, 1H), 4.31 (dd, CH$^{d'}$, 1H), 4.04 (m, CH$^{d''}$, H), 3.88 (t, CH^n, 1H), 3.66 (m, NH, 2H), 3.52 (m, CH$^{h'}$, 1H), 3.45-3.28 (m, CH$^{h''}$/CH$^{e'}$/CH$^j{}_2$, 4H), 3.20-3.06 (m, CH$^{g'}$/CH$^q{}_2$, 3H), 2.72 (m, CH$^f{}_2$, 2H), 2.55 (m, CH$^{e''}$, 1H), 2.39 (m, CH$^{g''}$, 1H), 2.27 (s, CH_3pz, 3H), 2.17 (s, CH_3pz, 3H), 2.10 (m, CH$^{i'}$, 1H), 1.81 (m, CH$^{i'}$/CH$^o{}_2$, 3H), 1.59 (m, CH$^p{}_2$, 2H). ^{13}C-NMR (D_2O):

δ(ppm) 197.2, 196.6, 195.2 (C≡O), 172.1 (C=O), 161.4 (C^{r}), 156.1 (C^{c}(3)pz), 146.7 (C^{a}(5)pz), 110.3 (C^{b}(4)pz), 67.1 (C^{h}), 64.2 (C^{f}), 55.5 (C^{n}), 55.4 (C^{e}), 49.5 (C^{d}), 44.6 (C^{g}), 39.8 (C^{j}), 39.7 (C^{q}), 30.7 (C^{o}), 26.7 (C^{i}), 26.5 (C^{p}), 17.7 (CH_3pz), 13.3 (CH_3pz). ESI-MS (+) (*m/z*): 711.1 $[M]^+$; calcd for $C_{21}H_{36}N_{10}O_6Re$ = 711.2. Elemental analysis calcd. for $C_{21}H_{36}N_{10}O_6Re$·2TFA: C, 31.94; H, 4.07; N, 14.90. Found: C, 31.50; H, 4.50; N, 14.70 %. Retention time (analytic RP-HPLC, 220 nm): 26.7 min.

***Synthesis of fac-[Re(CO)$_3$(k^3-L^5)]$^+$* (5a)**

Starting from 0.040 g (0.056 mmol) of **L^5·2TFA**, a colorless oil formulated as **5a** was obtained (0.041 g, 73 %, calcd. for $C_{24}H_{42}N_{10}O_6Re$·2TFA). IR (KBr, cm^{-1}): 3418m, 2026s and 1900s (C≡O), 1670s, 1289m, 1234m and 1135m. ^{1}H-NMR (D_2O): δ(ppm) 6.08 (s, CH^{b}(4)pz, 1H), 5.06 (br s, NH, 1H), 4.35 (dd, $CH^{d'}$, 1H), 4.12 (dd, $CH^{d''}$, 1H), 3.87 (t, CH^{n}, 1H), 3.66 (m, NH, 2H), 3.47 (m, $CH^{h'}$, 1H), 3.37-3.19 (m, $CH^{h''}$/CH^{m}_2, 3H), 3.01 (m, $CH^{e'}$/$CH^{g'}$/CH^{q}_2, 3H), 2.75 (m, CH^{f}_2, 2H), 2.66-2.55 (m, $CH^{e''}$, 1H), 2.47 - 2.38 (m, $CH^{g''}$, 1H), 2.31 (s, CH_3pz, 3H), 2.20 (s, CH_3pz, 3H), 1.87-1.79 (m, CH^{o}_2/$CH^{i'}$, 3H), 1.60 (m, $H^{i''}$, 1H), 1.45 (m, CH^{p}_2/ CH^{l}_2, 4H), 1.29 (m, CH^{j}_2/CH^{k}_2, 2H). ^{13}C-NMR (D_2O): δ(ppm) 194.7, 194.4, 193.0 (C≡O), 169.2 (C=O), 156.9 (C^{r}), 153.7 (C^{c}(3)pz), 144.2 (C^{a}(5)pz), 107.9 (C^{b}(4)pz), 67.6 (C^{h}), 61.9 (C^{f}) 53.3 (C^{e}), 53.3 (C^{n}), 47.0 (C^{d}), 42.2 (C^{g}), 40.5 (C^{m}), 39.6 (C^{q}), 28.2 (C^{l}), 28.2 (C^{o}), 25.9 (C^{j}/C^{K}), 24.4 (C^{l}), 24.4 (C^{i}), 23.8 (C^{p}), 15.3 (CH_3pz), 10.9 (CH_3pz). ESI-MS (+) (*m/z*): 753.1 $[M]^+$; calcd for $C_{24}H_{42}N_{10}O_6Re$ = 753.2. Elemental analysis calcd. for $C_{24}H_{41}N_{10}O_6Re$·2TFA: C, 34.24; H, 4.51; N, 14.27. Found: C, 34.18; H, 5.00; N, 14.60 %. Retention time (analytic RP-HPLC, 220 nm): 27.4 min.

Synthesis of the ^{99m}Tc(I) Complexes (1 - 5)

General Method. In a nitrogen-purged glass vial, 100 μL of a 10^{-3} or 10^{-4} M aqueous solution of the corresponding bioconjugate compounds (**L^2 – L^4**) were added to 900 μL of a solution of the organometallic precursor *fac*-[^{99m}Tc$(H_2O)_3(CO)_3]^+$ (1 - 2 mCi) in saline. The reaction mixture was then heated to 100 ºC for 30 - 60 min, cooled on an ice bath and the final solution analyzed by RP-HPLC. Retention times: 24.4 min (**3**), 27.4 min (**4**) and 28.1 min (**5**).

Plasma Stability *In Vitro*.

100 μl of **3**, **4** and **5** were added to 500 μl of human plasma and incubated at 37 ºC. After incubation (24h), aliquots (100 μl) were taken and the plasmatic proteins precipitated with ethanol (200 μl). The plasma was centrifuged at 3000 rpm for 15 min at 4ºC and the supernatant (protein free plasma) filtered trough a Millipore filter (0.22 μm), and analyzed by RP-HPLC.

Cysteine and Histidine Challenge

Aliquots of 100 μL of the ^{99m}TcI-complexes were added to 400 μL of 5 x 10^{-3} M cysteine or histidine solutions in PBS (pH 7.4). The solutions were incubated at 37 °C for 24 h and analyzed by analytical RP-HPLC.

Partition Coefficient

Was evaluated by the "shakeflask" method (*4*). The radioconjugate was added to a mixture of octanol (1 mL) and 0.1 M PBS pH = 7.4 (1 mL), previously saturated in each other by stirring the mixture. This mixture was vortexed and centrifuged (3000 rpm, 10 min, room temperature) to allow phase separation. Aliquots of both octanol and PBS were counted in a gamma counter.

The partition coefficient ($P_{o/w}$) was calculated by dividing the counts in the octanol phase by those in the buffer, and the results expressed as Log $P_{o/w}$.

Enzyme kinetic assays

The iNOS activity assay was based on the method of hemoglobin assay previously described by Hevel and Marletta with slight modifications (*5*,*6*). The kinetic parameters for iNOS were determined using initial rate analysis. Initial rate data were fitted to irreversible single substrate Michaelis-Menten models. The kinetic parameters were determined using the direct linear plot of Eisenthal and Cornish-Bowden and the Hyper software (J.S. Easterby, University of Liverpool, UK; http://www.liv.ac.uk/~jse/software.html) (*7*,*8*). The K_m and K_i values represent a mean of triplicate measurements. Standard deviations of ± 5 to 10 % were observed.

Hemoglobin capture assay

Preparation of Oxyhemoglobin

Oxyhemoglobin was prepared using a previously described protocol with some modifications (*9*). Briefly, bovine hemoglobin in 50 mM HEPES pH 7.4 was reduced to oxyhemoglobin with 10-fold molar excess of sodium dithionite. The sodium dithionite was later removed by dialysis against 50 volumes of HEPES buffer for 18 hours at 4°C. The buffer was replaced 3 times. The concentration of oxyhemoglobin was determined spectrophotometrically using $\varepsilon_{415\ nm}$ = 131 $mM^{-1}cm^{-1}$. Oxyhemoglobin was stored at -80°C before use.

Determination of kinetic parameters

Determination of K_m values

All initial velocity measurements were recorded at 37 ºC. Total reaction volumes were 1500 μL and contained 50 mM HEPES pH 7.4, 6 μM oxyhemoglobin, 200 μM NADPH, 10 μM BH_4, 100 μM DTT and at least three concentrations of the L-arginine (20 – 500 μM). Magnetic stirring in the spectrophotometer cuvette was essential to maintain isotropic conditions. Reactions were initiated by the addition of iNOS enzyme (~ 1 U) to the prewarmed cuvette (~ 5 min). The NO-mediated conversion of oxyhemoglobin to methemoglobin was followed by monitoring the increase in absorbance at dual wavelength (401 and 421 nm) for 10 min (*10*). Controls were performed in the some conditions without iNOS enzyme.

Determination of K_i Values.

The K_i values were obtained by measuring inhibition with at least three concentrations of L-arginine (20 – 150 μM) in the presence of 150 μM of the inhibitor, in the same conditions previously described. The formula used to calculate the K_i is: $K_i = [I]/((K_m^{app} / K_m) - 1)$ where [I] is the inhibitor concentration, K_m is the Michaelis-Menten constant of the substrate L-arginine and K_m^{app} is the apparent value of K_m for a substrate in the presence of the inhibitor (*7*). K_m value for L-arginine was determined as 6 μM.

Cell Culture

RAW 264.7 macrophages were grown in Dulbecco's Modified Eagle Medium (DMEM) with GlutaMax I supplemented with 10 % heat-inactivated foetal bovine serum and 1 % penicillin/streptomycin antibiotic solution (all from Gibco, Alfagene, Lisbon). Cells were

cultured in a humidified atmosphere of 95 % air and 5 % CO_2 at 37 ºC, with the medium changed every other day. The cells were adherent in monolayers and, when confluent, were harvested from the cell culture flasks, using a scrapper, and seeded farther apart.

Evaluation of the inhibitory effect of compounds L^1 - L^4 and 1a - 5a in NO biosynthesis in LPS-activated RAW 264.7 macrophages

Macrophages (in DMEM without phenol red and 10 % FBS) were plated at a density of 9 x 10^4 cells per well in 96-well plates. Cells were immediately induced with 10 μL of LPS (2 μg/mL in PBS) for 4 h, and then incubated for 24 h in the presence of various concentrations of compounds. At the end of the incubation period, the culture medium was collected and assayed for nitrite production using the commercially available Griess reagent method (Sigma-Aldrich) (*11*,*12*). Owing to solubility problems, compound **3** was dissolved in a 5 % MeOH/H_2O solution (10 mM solution) and further diluted with water, untill a final concentration of 1 mM was reached. Final MeOH concentrations were ≤ 0.25%, and were shown to not interfere neither with the nitrite assay nor with cell viability.

Western blot methodology

Western blot experiments were performed to demonstrate the overexpression of iNOS in LPS-induced RAW 264.7 macrophages and in the lungs of LPS-treated mice.

RAW 264.7 macrophages were treated with LPS (2 μg/mL) for 24 h and lysed in Cell Lytic-MT Extraction reagent (Sigma) supplemented with Complete protease inhibitor cocktail tablets (Roche Applied Science). After 15 miuntes on ice, lysates were centrifuged at 14000g for 10 min at 4 °C to pellet the cellular debris and the supernatants removed for further use.

Mature female C57BL/6 mice were induced with 10 mg/kg of LPS (or PBS) for 6h. Lungs from non-treated and LPS-treated mice were harvested and homogenized on a pre-chilled manual Poter-Elvehjem homogenizer. Homogenates were centrifuged at 14000g for 10 min at 4 °C and the supernatants removed for further use.

The total protein content was determined by using the DC Protein Assay Kit (Biorad) and aliquots of protein (200 micrograms) from each sample were analyzed using standard western blot procedures. Briefly, protein extracts were subjected to electrophoresis on a 7% SDS-polyacrylamide gel and transferred electrophoretically onto nitrocellulose membranes. The blots were blocked with PBS-T containing 5% nonfat dry milk for 1 h. Then, the blotting membranes were incubated with primary antibodies against iNOS (1:1000, Sigma) and actin (1:8000, Sigma) separately overnight. Membranes were washed with PBS-T and incubated for 1 h with secondary antibody (goat anti-mouse IgG-HRP, Biorad) diluted 1:3000. Finally, membranes were developed using the SuperSignal WetsPico Substrate kit (Pierce, Rockford, IL) according to the manufacturer's instructions.

Cellular Internalization of Radiocomplexes

Internalization assays of the radiocomplexes **1 - 3** were performed in RAW 264.7 macrophages seeded at a density of 0.3 million/well, in complete culture medium containing LPS 1 μg/mL, in a 24-well tissue culture plates and allowed to attach and to induce the expression of iNOS for 24 h at 37ºC. Then, the culture medium was removed and the cells were incubated with about 200000 cpm of the radiocomplexes **1** – **3** in 0.5 mL of assay medium (Modified Eagle's Medium with 25 mM HEPES and 0.2% BSA) for a period of 5 min to 4 h at 37 °C. Incubation was terminated by washing the cells with ice-cold assay medium. Cell-surface bound radioligand was

removed by two steps of acid wash (50 mM glycine.HCl/100 mM NaCl, pH 2.8) at room temperature for 5 min. The pH was neutralized with cold PBS with 0.2% BSA, and subsequently the cells were lysed by 10 min incubation with 0.5 N NaOH at 37ºC to determine internalized radioligand. Total macrophage protein has been determined using a commercially available BioRad® *DC* Protein Kit assay.

Biodistribution in LPS-treated mice

All animal experiments were performed in compliance with Portuguese regulations for animal treatment. The animals were housed in a temperature- and humidity-controlled room with a 12 h light/12 h dark schedule.

The biodistribution studies were performed in mature female C57BL/6 mice (10 – 14 weeks old) treated with bacterial lipopolysaccharide (LPS) (10 mg/kg, iv), to induce iNOS expression, 6h before the radioactive compounds were injected. The control group was injected with PBS instead of LPS. Animals were then intravenously injected into the retro-orbital sinus with the radiocomplexes 2 or 3 (60-90 μCi) diluted in 100 μL of PBS pH 7.2. Mice were killed by cervical dislocation at 15 and 30 min (complex 2), and at 60 min (complex 3) after injection. The dose administered and the radioactivity in the killed animals were measured using a dose calibrator (Curiemeter IGC-3, Aloka, Tokyo, Japan or Carpintec CRC-15W, Ramsey, USA). The difference between the radioactivity in the injected and that in the killed animals was assumed to be due to excretion. The tissues of interest were dissected, rinsed to remove excess blood, weighed, and their radioactivity was measured using a c-counter (LB2111, Berthold, Germany). Lungs from control and LPS-treated animals were harvested and analysed latter by Western Blot to demonstrate that 6h LPS-treatment was adequate to strongly increase iNOS expression in that

organ. Blood and urine were also collected and pooled together at the time the animals were killed to evaluate the stability *in vivo* of radiocomplexes. The uptake in the tissues of interest was calculated and expressed as a percentage of the injected radioactivity dose per gram of tissue. For blood, bone, muscle, and skin, total activity was estimated assuming that these organs constitute 6, 10, 40, and 15% of the total body weight, respectively.

Received July 12, 2010; Revised Manuscript Received October 19, 2010

Herein, we developed matrix metalloprotease (MMP) sensitive gold nanorods (MMP-AuNR) for cancer imaging and therapy. It was feasible to absorb NIR laser and convert into heat as well as visualize MMP activity. We showed the possibility of gold nanorods as a hyperthermal therapeutic agent and MMP sensitive imaging agent both in vitro and in vivo condition. The results suggested potential application of MMP-AuNR for simultaneous cancer diagnosis and therapy.

Simultaneous diagnosis and therapy contain in vivo real-time imaging of the diseased site and provide opportunities for rationally modulated clinical activities (*1*). It can be achieved by a combination of biotechnology, nanotechnology, and information technology. Especially, molecular bioimaging and nanomedicine allow not only noninvasive characterization of disease at the molecular level, but also optimized treatment with minimum toxicity (*2, 3*). In addition, they provide a synergistic method to visualize biodistibution of drug, determine the optimal therapeutic dosage or administration frequency, and monitor the process or cure of the disease. This strategy can assist in the discovery of various fundamentals in basic biological research or development of clinical applications for personalized medicine (*4*).

For many years, gold nanorods (AuNR) have been receiving much attention in applications of both imaging and therapy. AuNR have surface plasmon resonance (SPR), which is a common characteristic of gold materials and therefore has been applied as an imaging agent with various techniques like two-photon luminescence, optical coherence tomography, dark-field microscopy, photoacoustic tomography, Raman scattering, and computed tomography (CT) (*5*−*7*). In addition to its applications in imaging, AuNR have been used as a heat source for hyperthermia because AuNR are able to absorb laser irradiation strongly and convert it into heat efficiently (*8*−*11*). High temperatures over 43 °C are effective for selective destruction of cancer cells because of their lower heat tolerance caused by poor blood supply; therefore, hyperthermia is attractive for cancer therapy (*12, 13*). Especially, the wavelength of peak absorbance can be adjusted into the near-infrared (NIR) region by changing the aspect ratio of AuNR (*14*−*16*). For these properties, AuNR have great potential in both imaging and therapy. Therefore, in this report, we developed novel multifunctional agents for simultaneous diagnosis and therapy with AuNR.

Matrix metalloprotease (MMP) is a family of zinc-dependent proteins and the production of MMPs are distinctly involved in cancer metabolism (*17*). Therefore, in vivo imaging of MMPs could provide valuable information in cancer diagnosis, and various imaging modalities were developed for this purpose (*18, 19*). To develop a fluorescent probe for MMP with AuNR (MMP-AuNR), NIR fluorescent dye, Cy5.5, was conjugated to a peptide sequence (Gly-Pro-Leu-Gly-Val-Arg-Gly-Cys) known to be degraded by MMP (*20*), and the surfaces of AuNR were modified with the Cy5.5-conjugated MMP substrate. A schematic representation of the production of MMP-AuNR is shown in Scheme 1. For the quenching effect of AuNR, NIR fluorescence was quenched until the substrate was degraded by MMP enzymes which were secreted by cancer cells (*21*). By the recovery of quenched fluorescence, we could determine the expression of MMP and cancer progress as well as perform cancer therapy simultaneously based on photothermal effects of AuNR.

The morphology of AuNR was examined with TEM images after conjugation with MMP substrates and Cy5.5 NIR fluorescent dye (Figure 1A). It showed that the aspect ratio of MMP-AuNR was approximately 2 (length/width) and uniformly dispersed. The optical properties of MMP-AuNR were also confirmed with UV−vis absorption, in which two unique surface plasmon resonance (SPR) peaks were shown (Figure 1B). Between the two SPR peaks originating from the longitudinal and transverse oscillation of electrons on the AuNR surface, strong absorption was adjusted to the NIR (650−670 nm) region to minimize absorption by tissue and maximize AuNR absorption of laser (671 nm) irradiation by tuning their aspect ratio. The wavelength of SPR peaks was not changed after conjugation. On the basis of these data, it was proven that conjugated substrate did not affect the optical property and stability of AuNR. The optical changes after addition of 1,4-dithiothreitol (DTT) or MMP-2 were measured with a fluorescence spectrometer and also confirmed in NIR fluorescent images (Figure 1C,D). The fluorescence of Cy5.5 was quenched near the surface of AuNR due to surface energy transfer properties (*22*).

Scheme 1. Schematic Representation of Synthesis of MMP-AuNR for Simultaneous Imaging and Photothermal Therapy

However, the incubation of MMP-AuNR with activated MMP-2 (6.75 nM, 37 °C, 60 min) resulted in significant augmentation of the NIRF signal (7.8-fold) because the distance between AuNR and the fluorescence dye, Cy5.5, increased and the quenching effect was reduced by cleavage of the MMP substrate.

The NIRF recovery of Cy5.5 from the quenched state in MMP-AuNR was induced not from the nonspecific detachment of MMP substrate but from the specific decomposition, because recovery of the fluorescence was strongly disrupted in the presence of the MMP-2 inhibitor (2.6-fold). Also, the addition of DTT led to an enhanced NIRF-signal recovery because DTT caused a displacement of the MMP peptide from the AuNR surface (*18*). However, the aggregation of AuNR occurred 10 min after addition of DTT, because the displacement of substrate on the surface induced instability of AuNR. On the other hand, the decomposition of MMP substrate did not cause the aggregation of AuNR in the TCNB buffer. The unique color of AuNR was preserved throughout coating of MMP peptide and incubation with MMP-2.

As shown in Figure 1D, the peak intensity of DTT was 33% higher than that of MMP-2 because MMP peptide-Cy5.5 bound to AuNR was fully removed, maybe due to the smaller steric hindrance of DTT than that of the large MMP enzyme (*23*). This strong reducing property of DTT was employed to determine the amount of MMP substrates bound to AuNR. UV absorbance titration of Cy5.5 (675 nm) was performed by addition of DTT (10 mM) in MMP-AuNR colloid. The UV−vis absorption of detached free Cy-MMP substrate was calibrated with the standard curve of Cy5.5, and we estimated the amount of 1.34×10^2 molecules of Cy-MMP per AuNR. In addition, photothermal properties of MMP-AuNR were compared with those of cetyltrimethylammonium bromide (CTAB)-stabilized AuNR (Figure 1E). Laser was irradiated to AuNR and MMP-AuNR, respectively, and their temperature was measured with the needle probe of a T-type thermocouple. It was increased over 4 min up to 50 °C at which cancer cells could be selectively damaged (*14*). IR thermographic images of MMP-AuNR also demonstrated this result, and they showed that the temperature increment was not localized in the focal point of the laser (Figure 1F). Therefore, it was confirmed that Cy5.5-conjugated MMP substrate did not affect the photothermal properties or stability of MMP-AuNR.

The enzyme selectivity of MMP-AuNR was evaluated by incubation with various other MMP enzymes (MMP-3, -7, -9, -13), and their NIRF signals were measured by a fluorescence spectrometer (Figure 2A,B). After incubation with the respective enzymes and the inhibitor at 37 °C for 120 min, MMP-AuNR recovered its NIRF signal against various MMP enzymes (approximately 6.6-, 8.2-, and 6.6-fold for MMP-3, -9, and -13, respectively). However, when it comes to MMP-7, the NIRF signal was not recovered significantly (3.7-fold). It showed that MMP-AuNR has specificity against certain MMP enzymes. Furthermore, samples were moved to a 96-well plate and visualized with

a Kodak image station 4000MM equipped with filter systems for Cy5.5. The same results were able to be simply visualized through NIRF images, which could be applied for quantitative and visual analysis of the MMP enzyme activity.

In many areas of research, wide application of AuNR has been limited due to the existence of cytotoxic CTAB coated on its surface (*24*). We expected that the large portion of CTABs were exchanged with MMP peptide-Cy5.5, and this could reduce the cytotoxicity of our AuNR. To determine this, the cell viability test of AuNR and MMP-AuNR was performed without irradiation, before the photothermal therapeutic effect was investigated. MTT assay revealed that biocompatibility of MMP-AuNR was significantly improved because CTAB bilayers, which are noncovalently adsorbed onto the AuNR surface, were replaced by the MMP substrate (Figure 2C). To examine the feasibility of MMP-AuNR as an imaging and photothermal therapeutic agent, optical NIRF imaging of MMP enzymes in the cell culture media was performed. HeLa cells were cultured in a 96-well plate according to different numbers of cells (10^3, 10^4, 10^5 cell/well, respectively) using DMEM cell culture media (without FBS). After 24 h of incubation, cell culture media were extracted and mixed with the same volume of MMP-AuNR (8 mg/mL) at 37 °C for 90 min. The mixed culture media were centrifuged, and NIRF images of the supernatant were obtained. The activated MMP enzymes existing in the cell culture media were successfully visualized with MMP-AuNR by the NIR imaging technique (Figure 2D). Also, the calculated integrities from the NIRF images coincided with other previous results. Cellular uptake of MMP-AuNR was observed through a dark-field microscope (Figure 2E). It was confirmed that a large amount of MMP-AuNR was taken up within 1 h by HeLa cells, and no sign of cell damage was observed. A photothermal therapeutic effect of MMP-AuNR was also examined. After incubation of HeLa cells with MMP-AuNR (final conc.: 400 μg/mL) for 2 h and washing

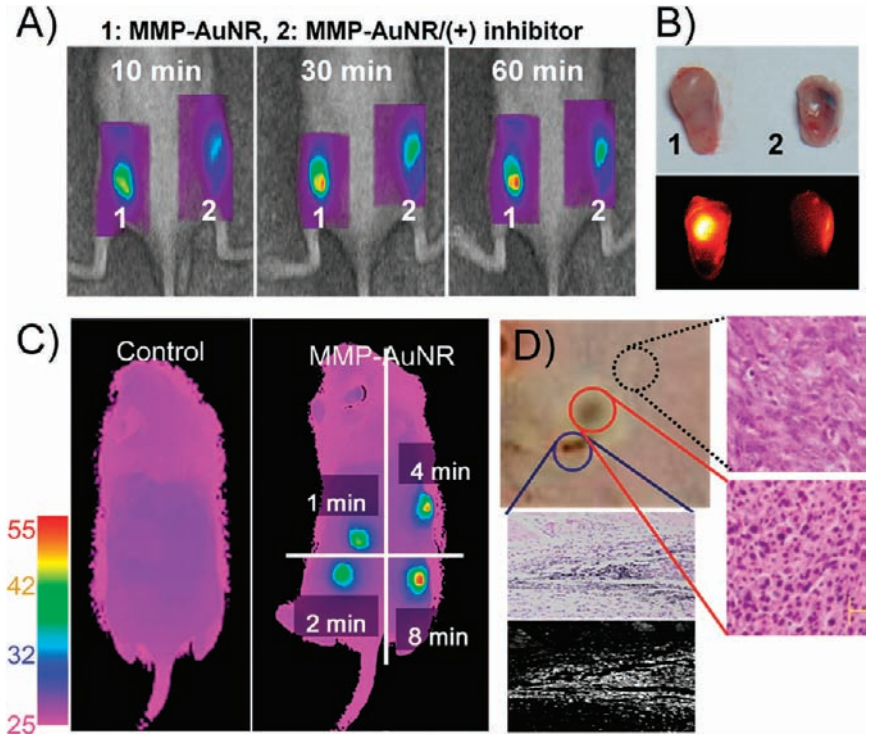

Figure 3. (A) NIRF tomographic images of SCC-7 tumor-bearing mice after intratumoral injection of the MMP-AuNR probe without (1) and with (2) inhibitor. (B) Optical and NIRF images of excised tumor after injection of MMP-AuNR without and with MMP-2 inhibitor. (C) Infrared thermal images of tumor-bearing mice according to different laser irradiation times. AuNR was injected intratumorally prior to laser irradiation. (D) Optical images of exterior of SCC-7 tumor irradiated by laser. Histology (right) and dark field image (lower) of tumor after treatment are also presented.

with DMEM, culture dishes were exposed to CW laser (671 nm, 200 W) for 10 min. After incubation for another 1 h, cells were stained with 0.4% trypan blue for 10 min to obtain distinct images of cell viability through a microscope. Dead cells were observed when the cells took up MMP-AuNR and were irradiated by a laser (Figure 2F, upper). However, cell viability was not affected when cells were exposed only to MMP-AuNR or laser. The same results were obtained when the samples were observed using annexin V-FITC assay through a microscope (Figure 2F, lower). The damaged cells were stained with FITC, which indicated apoptotic HeLa cells caused by photothermal therapy.

Finally, MMP-AuNR was tested for in vivo NIR imaging and photothermal therapy. In the back of an athymic nude mouse, two SCC-7 tumors were xenografted, and one of them was treated with MMP-2 inhibitor prior to 30 min of intratumoral injection of MMP-AuNR to both sites. As seen in the Figure 3A, enhanced NIR fluorescence was observed when the tumor was not treated with MMP inhibitor compared with that treated with inhibitor. Maximum NIRF intensity was observed 60 min after injection. These results were further confirmed with ex vivo NIR fluorescence imaging of tumors. They were excised after 4 h of MMP-AuNR injection, and their NIR fluorescence image was taken in the Kodak Image Station 4000MM. Intensive recovery of quenched fluorescence of Cy5.5 was revealed when the tumor was not treated with inhibitor (Figure 3B). In addition to optical imaging, hyperthermal therapy was facilitated with MMP-AuNR, which was able to absorb NIR laser and convert into heat. Four SCC-7 tumors were xenografted in the back of a nude mouse and MMP-AuNR was injected. The increased temperature after laser irradiation at different times was measured with a hypodermic thermocouple and visualized with an infrared thermal imaging device according to the irradiation time (Figure 3C). It was confirmed that the temperature was increased over 45 °C after about 4 min of irradiation, which was coincident with previous in vitro results. The hyperthermal treatment was assessed with histology stained with hematoxylin-eosin. The SCC-7 tumor tissue with MMP-AuNR showed internal damage when laser irradiation was given (Figure 3D). However, the sole irradiation did not cause any cell damage. The tissue damage was able to be verified with the naked eye because burning of the external skin of the SCC-7 tumor was observed. Also, the existence of MMP-AuNR in the tissue was further examined with dark-field microscopy, and the signal of MMP-AuNR was found in the damaged tissue.

In summary, MMP-AuNR was applied as an optical molecular imaging agent for visualization of MMP enzyme activity using its quenching property. Also, as a photothermal therapeutic agent, it was able to absorb NIR laser and convert into heat. We visualized enzymatic activity of MMP with optical NIRF imaging in vivo and successfully induced damage to cancer tissue by hyperthermia. The outstanding properties of MMP-AuNR suggested its potential application for simultaneous diagnosis and therapy.

Preparation of Cy5.5-MMP substrate conjugated gold nanorod (MMP-AuNR): Cy5.5 was conjugated to MMP substrate by same method in previous report.[18] AuNR was functionalized with Cy5.5-MMP by simple mixing method. First, cetyltrimethylammonium bromide (CTAB) stabilized AuNR was centrifuged (9000 rpm, 12 min) and washed twice to remove with TCNB buffer containing 100 mM of Tris, 5 mM of calcium chloride, 200 mM of NaCl, and 0.1% of Brij. Cy5.5-MMP (0.1 ml, 100 μg/ml) solution was added in AuNR colloid and it was kept in the absence of light at 25°C under stirring for 24 h. The solution was purified by repeated centrifugation (9000 rpm, 12 min) and washing 2 times in the presence of 20 % (v/v) of DMSO.

In vitro fluorescence recovery test: UV absorbance titration of Cy5.5 (675 nm) was performed to determine the amount of Cy5.5-MMP bound to the AuNR surface. The Cy5.5-MMP bound to AuNR was detached by addition of dithiothreitol (DTT, 10 mM) and its UV-

vis absorption was detected with UV-vis spectroscopy. The concentration of free Cy5.5-MMP was calibrated with a standard UV absorbance curve of Cy5.5 in aqueous solution and the amount of Cy5.5-MMP was calculated from known concentrations of DTT-treated AuNR. The NIRF recovery of MMP-AuNR was examined in terms of MMP enzyme specificity. MMP enzymes (MMP-2, 3, 7, 9 or 13) were activated by incubation at 37 ^{o}C for 1 h with 2.5 nM of 4-Aminophenylmercuric Acetate (APMA) in the TCNB buffer. Inhibitor of MMP-2 was co-incubated with MMP-2 enzyme before reaction with MMP-AuNR. The same amount of MMP-AuNR colloid was added to MMP enzyme solution and incubated additionally at 37 ^{o}C for 1 h. After incubation, samples were centrifuged and the fluorescence intensity of supernatant was monitored with F-7000 fluorescence spectrometer (Hitachi, Tokyo, Japan). The excitation wavelength was fixed at 675 nm and emission spectra were recorded from 680 to 800 nm using a 1 ml cuvette. In addition, NIRF images of MMP-AuNR was obtained from a 12-bit CCD (charge coupled device) camera (Kodak Image Station 4000MM, New Haven, CT, USA) equipped with the special C-mount lens and the Cy5.5 bandpass emission filter (680 nm to 720 nm; Omega Optical Inc., Brattlebore, VT, USA).

In vitro imaging and photothermal therapy: HeLa cells were cultured in DMEM medium at 37 °C in a humidified atmosphere of 5 % CO_2. Cells were seeded in 96-well flatbottomed plates at a density of 0, 10^2, 10^3, 10^4 and 10^5 cells/well respectively and allowed to adhere for 24 h. The cell media was extracted from 96-well plate and mixed with MMP-AuNR colloid (final concentration : 2 mg/ml) in Eppendorf tubes at 37 °C for 1 h. The mixture was moved to a 96-well plate and visualized with a Kodak image station 4000MM. For NIR photothermal therapy, NIR Diode Pumped Solid State (DPSS) laser (671 nm, 200 mW) was used. HeLa cells in 12-well plate (10 x 10^4 cell/ml) was exposed to 0.8 mg/ml of MMP-AuNR for 1 h and then washed with DPBS buffer and then exposed to the red laser light for

10 min. After treatment, cells were stained with 0.4% trypan blue (Gibco Invitrogen, Paisley, UK) for 10 min and observed through microscope and imaged under X10 in bright field.

Annexin V assay : annexin V-FITC fluorescence microscopy kit (BD Bioscience, San Jose, CA, USA) was used according to the protocol provided by manufacturer. Briefly, after the treatment of HeLa cells with laser, they were washed once with Annexin V Binding Buffer after fixation. Then, the cells were stained with annexin V-FITC solution for 10 min. The annexin V-FITC solution was removed and washed with Binding Buffer once for the observation under the microscopy. The cells were visualized using IX81 fluorescence microscope (Olympus, Tokyo, Japan) with excitation at 488 nm and emission at 530 nm.

In vivo imaging and photothermal therapy: Squamous cell carcinoma (SCC) - 7 cells cell line (1 X 10^6 cells/mouse) was cultured in RPMI 1640 medium containing 10% fetal bovine serum and xenografted subcutaneously into the backs of athymic nude mice (Crlj-nu, 5-6 weeks, male). When the size of tumors became 5 mm in diameter, 50 μl of MMP-AuNR (2 mg/ml) probe was injected intratumorally. For MMP inhibition experiment, MMP inhibitor was intratumorally administered into the other SCC-7 tumor, 30 min prior to injection of the MMP-AuNR. After injection of MMP-AuNR, the fluorescence recovery profiles of SCC-7 tumor-bearing mice were imaged using eXplore Optix system (ART advanced Research Technologies Inc., Montreal, Canada). A 670 nm pulsed laser diode was used and the laser power and count time settings were optimized to 15 μW and 0.3 per point, respectively. NIRF tomographic images were obtained by collecting NIR fluorescence emission at 700 nm with a fast photomultiplier tube (Hamamatsu, Japan) and time-correlated single photon counting system (Becker and Hickl GmbH, Berlin, Germany). After 4 hours of post-injection, tumors were dissected and ex vivo NIR fluorescence images were taken using Kodak Image Station 4000MM. For therapy, tumor-bearing mice were exposed to NIR laser after injection of MMP-AuNR under same condition and their infrared thermal images were obtained

according to irradiation time (1, 2, 4, 8 min, respectively). The exact temperature was measured with a 33 gauge T-type hypodermic thermocouple (Omega Engineering, Inc., Stamford, CT, USA). After irradiation, tumors were dissected, fixed and stained with hematoxylin-eosin for microscopic observation.

Facile Synthesis of Raman Active Phospholipid Gold Nanoparticles

Gold nanoparticle-based surface-enhanced Raman scattering (SERS) probes have shown promise for disease detection and diagnosis. To improve their structural and functional stability for in vivo applications, we synthesized a colloidal SERS gold nanoparticle that encapsulates Raman molecules adsorbed on 60 nm gold with a nonthiol phospholipid coating. Transmission electron microscopy and Raman and UV spectroscopy validated its reproducibility and stability. This novel lipid-based SERS probe provides a viable alternative to the PEGylation and silica coating strategies.

INTRODUCTION

Gold nanoparticles (AuNPs) have been extensively investigated for biological applications due to their inherent unique optical, chemical, and electrical properties. In particular, AuNPs exhibit surface-enhanced Raman scattering (SERS), which augment Raman scattering up to $10^{14}-10^{15}$ orders of magnitude upon illumination (*1, 2*). SERS AuNPs are ultrasensitive and photostable, and can be used for multiplexing due to the unique Raman scattering spectra of different molecules (*1, 3*). The inertness and low toxicity (*4, 5*) of AuNPs are attractive; however, AuNPs can be unstable especially in biological systems. Hence, to implement SERS AuNPs for in vitro and in vivo applications, increasing stability and biocompatibility are critical.

Currently, there are two classes of SERS colloidal AuNPs used in vivo (*2, 3*). They both utilize 60 nm AuNPs as their core and differ only by the surface coating where one has poly(ethylene glycol) (PEG) to confer biocompatibility, to prevent biofouling, and to prolong in vivo circulation times (*6*); the other SERS AuNP is covered with silica for long-term stability. Phospholipids are an appealing alternative, as they truly mimic cell membranes for maximum biocompatibility and have also been shown to stabilize AuNPs. In fact, a range of phospholipid-coated colloidal gold nanoparticles have been made, including gold-lipoprotein mimics using 6 nm AuNPs (*7,8*). Furthermore, phospholipid AuNPs from 1 to 70 nm (*9*−*11*) and gold nanorods (*12, 13*) have been found to stabilize and increase biocompatibility; however, none of these have included a Raman dye for SERS capability. To our knowledge, both PEG and phospholipid-stabilized gold nanoparticles have depended on either direct thiol PEG/lipid or templating agent such as dodecanethiol, which we found to have a detrimental effect on the stability of the Raman tag on the AuNP surface (Supporting Information Figure S1).

In the present study, we successfully designed and encapsulated Raman dye coated AuNPs with nonthiol containing phospholipid (Scheme 1) suitable for in vivo applications. The resulting Raman-active phospholipid AuNPs (RAP AuNPs) are rendered biocompatible by the lipid coating, while the presence of the Raman dye allows for SERS detection. Here, we used 60 nm colloidal gold particles to augment the Raman scattering signals, as this is the optimal size for maximum SERS enhancement in the biologically relevant red/near-infrared wavelength range (∼600−800 nm) (*2*).

RESULTS AND DISCUSSION

To synthesize RAP AuNPs, a 10 μM aqueous solution of Raman dye—in this instance, we used crystal violet—was first adsorbed onto the citrate-stabilized 60 nm AuNP also in aqueous solution. Since Raman dyes can easily aggregate AuNPs, the Raman tag was added gradually, while the Raman signals were monitored in real time from the stirring solution.

A 1:1 mix of double-chain and single-chain phospholipids (1,2-dimyristoyl-*sn*-glycero-3-phosphocholine, DMPC ($C_{36}H_{72}NO_8P$); 1-myristoyl-2-hydroxy-*sn*-glycero-3-phosphocholine, MHPC ($C_{22}H_{46}NO_7P$), respectively) was prepared in 19:1 chloroform/methanol as solvent. The Raman-coated AuNPs were stirred and gradually heated to 65 °C, while the phospholipid solution was added dropwise. Immediate evaporation of the organic solvents formed liposome-like structures that encapsulate the Raman-coated AuNPs. Since the phospholipid-encapsulated AuNPs were of much higher density than any free liposomes or free lipids in solution, purification was achieved through multiple rounds of centrifugation. The final product was redispersed in aqueous solution for further characterization. It is important to note that the presence of the single fatty acid chain phospholipid MHPC was imperative for the stable encapsulation of the AuNPs with a lipid bilayer. This is likely due to the tighter curvature that is possible with a mix of single- and double-chain phospholipids (*14, 15*), resulting in closer positively charged choline headgroup interaction with negatively charged citrate remaining on the Raman-coated gold surface (*16*). Negative phosphates on the lipid headgroup may also interact with AuNP surface by replacing any remaining citrate on AuNP surface, since Rhim et al. (2008) noted that the phosphate backbone of plasmid DNA has a stronger Au interaction than carboxylates (citrates). Nevertheless, dynamic light scattering (DLS) analyses demonstrated an increase in the hydrodynamic diameter throughout the synthesis steps. The

Scheme 1. Synthesis of Raman-Active Phospholipid Gold Nanoparticles

starting citrate-stabilized AuNPs measured 54.4 ± 1.8 nm, while no increase in size was found after coating it with Raman dyes on the AuNP surface (53.8 ± 2.8 nm). After the final phospholipid addition, the hydrodynamic diameter of RAP AuNPs increased to 69.0 ± 1.4 nm.

The absorbance and Raman spectra of the starting, intermediate, and final AuNPs are shown in Figure 1a,b, respectively. Citrate-stabilized 60 nm AuNPs have λ_{max} of 538 nm, and no change was observed after addition of the Raman dye, confirming that the amount of crystal violet added maximized the SERS signal without causing aggregation. As expected from the hydrodynamic size increase, a small red shift of 4 nm was observed (λ_{max} = 542 nm) after addition of phospholipid to make RAP AuNPs. The Raman spectra of AuNPs measured during synthesis showed that the Raman dye is unperturbed on the AuNP surface. Further evidence of stable phospholipid coating is provided by transmission electron microscopy (TEM) analysis. TEM images of RAP AuNPs clearly show the presence of a encompassing lipid layer around the AuNPs (Figure 1c (4)) as opposed to the starting citrate AuNPs (Figure 1c (1)) and intermediate Raman coated AuNPs (Figure 1c (2)). This is especially obvious when particles are closely dried during sample preparation, where a fusion of lipid layers is observed (Supporting Information Figure S2).

The discrepancy between the size of RAP AuNPs between DLS and the TEM images is expected, as a thin layer of H_2O is known to exist at the zwitterionic phosphocholine headgroup in aqueous solutions of DMPC bilayers on metallic surfaces (*17*). Although there was an approximate 14 nm increase in diameter by DLS, the TEM images showed an approximate 6 nm increase (Supporting Information Figure S3). For the hydrodynamic size measurement, the 7 nm radius increase correlates well with an expected increase of 6−7 nm for DMPC bilayers in aqueous environment (*18*). Analysis of TEM images shows a 3-nm-thick phospholipid bilayer surrounding the AuNP, which is slightly lower than the expected 3.7−4.3 nm bilayer length of interdigitated DMPC leaflets (*19*−*22*). However, a gradual decrease in the thickness of the encapsulating bilayer

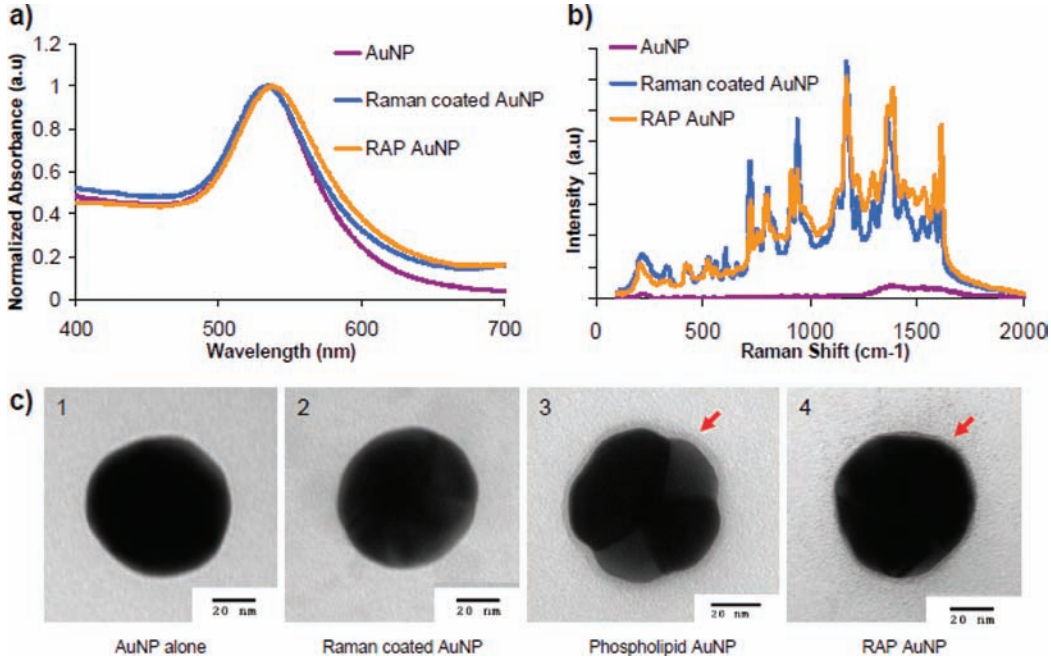

Figure 1. UV−vis spectroscopy (a) and Raman spectroscopy (b) of starting, intermediate, and final materials in RAP AuNP synthesis. (c) TEM images of AuNPs at each stage; red arrows indicate the phospholipid coating.

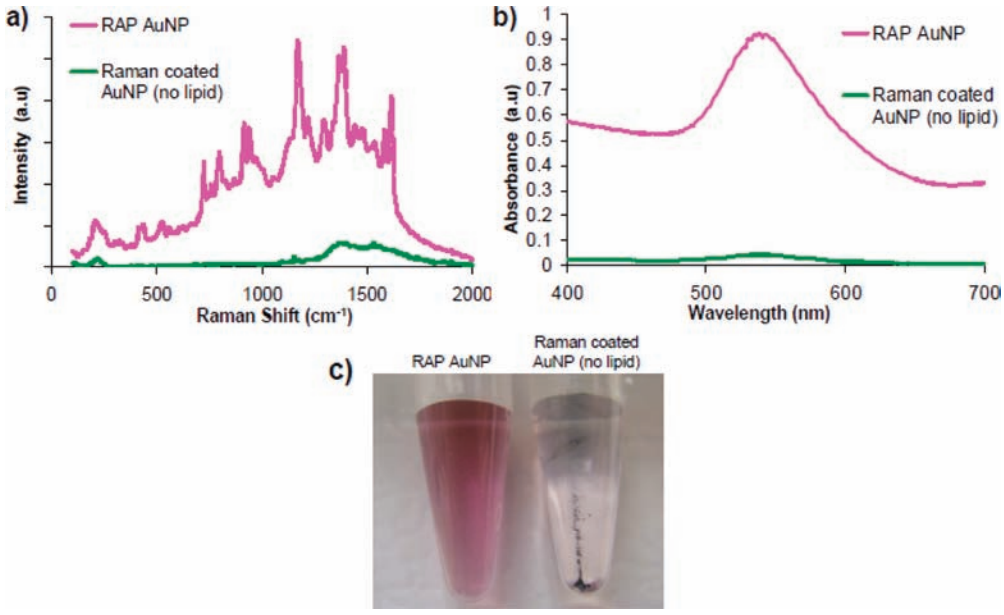

Figure 2. Raman (a) and UV−vis (b) spectra of Raman-coated AuNPs with (RAP AuNP) and without a phospholipid layer (only added organic solvents) after centrifugation. Photo of the RAP AuNP in aqueous solution compared with flocculated AuNPs without phospholipid protection (c).

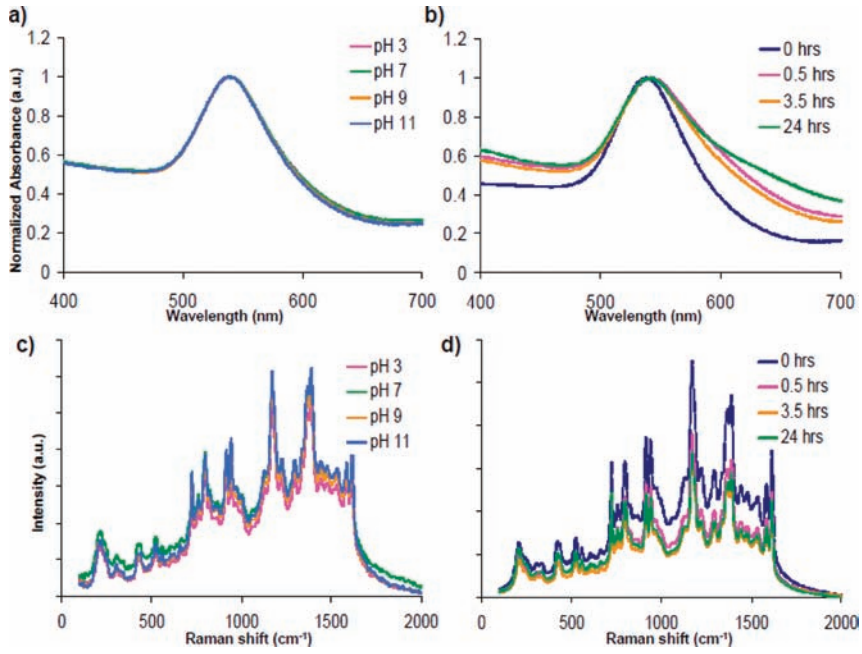

Figure 3. UV−vis spectra (a,b) and Raman spectra (c,d) to assess the RAP AuNP stability in various pHs (a,c) and in 10% serum in PBS at 37 °C for various time points (b,d).

was observed over time during TEM image acquisition. It is believed that the power of the electron beam caused a thinning of the bilayer surrounding the AuNPs, thereby accounting for a thinner coating than expected.

Raman spectra from RAP AuNPs and unprotected Raman dye-coated AuNPs reveal that the phospholipid layer not only retains and protects the Raman tag at the gold surface, but also stabilizes the entire nanoparticle. In Figure 2a, the presence of phospholipid on the surface preserved the Raman tag and thus the SERS enhancement on the metal nanoparticle surface even after purification through multiple rounds of centrifugation and resuspension. However, in the absence of the phospholipid encapsulation, the Raman signals are lost by centrifugation (Figure 2a). This is likely a result of the weakness of the Raman dye adsorption on the gold surface and lack of stabilizing interactions (*23*). Furthermore, the encompassing phospholipid coating also protects the AuNP in aqueous solution from aggregation (Figure 2c). Black precipitates (Figure 2c-right) show that there was flocculation of the Raman-coated AuNPs after two centrifugation steps following a mock lipid addition (containing only the organic solvent mixture). In contrast, RAP AuNPs easily redisperse into aqueous solutions after the same two centrifugations (Figure 2c left). This clearly indicates that this stabilization and retention of the Raman signals were not due to any procedures but only by the presence of phospholipids.

We further analyzed the stabilizing effect of the phospholipid layer in various pHs and in physiological buffer in order to test the biocompatibility of RAP AuNPs. Figure 3a,c shows the UV and Raman spectra of RAP AuNPs in a wide range of pH (3−11) after incubation for at least 30 min in phosphate buffer. Absence of any changes in the absorption maxima or Raman intensities indicated that RAP AuNPs did not aggregate and

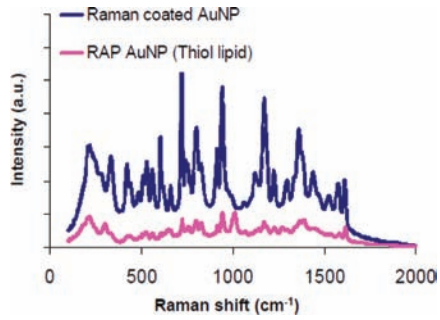

Figure 4. Raman spectra of RAP AuNPs made by thiol-containing phospholipid.

did not lose the phospholipid or the adsorbed Raman tag. For biocompatibility (Figure 3b,d), RAP AuNPs were subjected to 10% fetal bovine serum in phosphate buffered saline. There was a small 3 nm shift in the absorption maxima and a broadening of the absorption curve after 30 min incubation of RAP gold in 10% fetal bovine serum made up in phosphate buffer saline. This is likely due to protein adhesion on the particles, as there was an increase in absorption at 280 nm (Supporting Information Figure S4). However, this small absorption maxima shift did not increase with increasing incubation time in serum and thus is not indicative of induced aggregation. Further evidence of monomeric particles in solution is the lack of increasing Raman intensities. With aggregation of AuNPs, we expect a significant increase in the SERS signal due to the increased electromagnetic field by the close proximity of the oscillating plasmons on the metallic surface (*1, 24*). However, because our Raman measurements showed slightly lowered intensities, we ruled out any aggregation of RAP gold under physiological conditions. In fact, there was no time-dependent change in the SERS signal up to 24 h in serum. Moreover, the long-term stability of the RAP AuNPs was monitored, with no change in Raman intensities observed after 16 days at 4 °C storage in H_2O (Supporting Information Figure S5). This is likely attributed to the lack of competing interactions of the Raman tag and surrounding phospholipid on the AuNP surface. In fact, synthesis of RAP AuNPs with thiol-containing phospholipid (1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol) resulted in a significant loss of Raman signals (Supporting Information Figure 4). This result showed that the strong interaction of thiol-containing molecules to AuNPs (*25*) can compete for sites on the AuNP surface and displace the adsorbed Raman tag—especially one without any thiol moieties such as crystal violet.

In summary, we have demonstrated the robust synthesis of Raman-active phospholipid gold nanoparticles with stable Raman signals. These lipid-coated nanoparticles are highly stable and are suitable for biological applications. By encapsulating AuNPs with a phospholipid coating after the adsorption of Raman dye, SERS signals are retained, while the nanoparticles become more water-soluble. The stable phospholipid coating renders the nanoparticle biologically compatible and highly versatile. This provides a nanoparticle platform from which targeted probes can be developed, since straightforward modifications to the coating, such as conjugating targeting ligands or incorporating targeting lipid/lipopeptide moieties, will allow for the construction of a range of targeting probes.

Materials.

60 nm gold nanoparticles were purchased from Ted Pella, Inc. Crystal violet was purchased from Sigma Aldrich. 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC), 1-myristoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (MHPC), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphothioethanol were purchased from Avanti Polar Lipids and used as received.

Methods.

Synthesis: A 10μM aqueous solution of crystal violet was prepared and kept stirring for at least 1 h for complete solubilization. 1.1 mL of 60 nm citrate stabilized AuNPs in aqueous solution were then stirred in a cuvette while being continuously monitored on a compact Raman system using 785nm excitation (Advantage Raman Series, Delta Nu). Fractions of crystal violet (11 μL) were added intermittently until a stable Raman intensity was reached on the highest scattering peak at 1173cm^{-1}. The Raman coated AuNPs were then transferred to 20 mL scintillation vials, diluted 1:3 with distilled de-ionized H_20 and heated to 65°C with stirring. Upon reaching 55°C, the phospholipid solution (DMPC (5mg) and MHPC (5mg)) in 500μL 19:1 chloroform to methanol was added dropwise slowly. The organic solvents were allowed to evaporate and the bubbles formed by evaporating organic solvents were allowed to settle between each addition. After the final addition, the vial was left to cool to room temperature and then aliquoted into microcentrifuge tubes. The resulting nanoparticles were purified by

two rounds of centrifugation for 15 min at 500xg. The supernatant was removed after each centrifugation step and re-dispersed in distilled de-ionized H_20

Characterization: RAP AuNPs were characterized by dynamic light scattering (Zetasizer Nano ZS90, Malvern Instruments), transmission electron microscopy (Hitachi H-7000 TEM) and UV-Vis Spectroscopy (Cary 50 UV-Vis Spectrophotometer, Varian).

In the efforts to explore an aptamer-based approach for target sensing and detection with higher sensitivity and specificity, instead of directly labeling aptamer with fluorophores, we proposed a new strategy by attaching a polymerase chain reaction (PCR) template to an oligonucleotide aptamer selected by systematic evolution of ligands by exponential enrichment (SELEX), so that after aptamer target binding, the template moiety serves as the PCR template in real-time quantitative PCR (RT-PCR), and therefore, the binding event can be reported by the following RT-PCR signals. Using the subtractive SELEX method, the oligonucleotide aptamers specific for the Fc fragment of mouse IgG were selected and subjected to coupling with the PCR dsDNA template by using overlap and the asymmetric extension PCR method. The target binding affinity of the PCR template tethered aptamer has been proven by electrophoretic mobility shift assay (EMSA), and further template tethered aptamer mediated real-time quantitative PCR (A-PCR) was conducted to validate the application for such a template tethered aptamer to be a sensitive probe for IgG detection. The results show that the protocols of A-PCR can detect 10-fold serial dilutions of the target, demonstrating a new mechanism to convert aptamer target binding events to amplified RT-PCR signal, and the feasibility of the PCR template tethered aptamer as a facile, specific, and sensitive target probing and detection is established. This new approach also has potential applications in multiple parallel target detection and analysis in a wide range of research fields.

INTRODUCTION

In order to develop powerful biological probes which can provide insightful information on biological processes and mechanisms, highly sensitive, specific, and facile analytical machinery has been extensively exploited. Out of a variety of approaches, aptamers demonstrate high binding affinity and specificity to their non-nucleic acid target molecules, such as peptides, proteins, drugs, and organic and inorganic molecules, and are capable of distinguishing among homologous proteins (*1*−*3*) or nearly identical low molecular weight compounds (*4*−*11*). Their unique characteristics offer ideal recognition elements for use in analytical devices and techniques. Since the introduction of SELEX (systematic evolution of ligands by exponential enrichment) in 1990 (*12, 13*), design, screening, in vitro selection, and evolution of specific oligonucleotide aptamers has become routinely achievable. Moreover, advances in SELEX also make it possible for nucleic acid aptamers specific for almost every target to now be obtained (*14*−*21*). This opens up the door for aptamers to be feasible for a wide range of applications in multiple target detection and sensing (*22*−*24*). The key issue in the development of aptamer-based analytical methods and sensors is how to convert target recognition and binding into a measurable signal.

In aptamer-based electrochemical detection devices, aptamers are designed to be immobilized on the electrode allowing that the conformational transition of the aptamers upon binding to targets leads to the electron transfer switch "on or off" between the electrode and the electro-active molecules either labeled on or noncovalently trapped in aptamers (*24*−*26*). Quantum dots are also used to signal the aptamer−target binding because of its electronic and fluorescence properties. Aptamer-capped near-infrared PbS QD was constructed to detect target protein binding which can result in fluorescence quenching due to charge transfer from protein amino group to the QD (*27*). In another study, aptamer-functionalized QD 605 is capable of sensing the presence of small molecule targets through FRET signal switches (*28*).

More formats of signaling aptamer strategies based on mono- or dual- fluorophore labeling and measurement techniques have been abundantly demonstrated. In these approaches, target aptamer binding is transformed into changes of fluorescent signals (*22, 23, 29, 30*). The molecular beacon aptamer (MBA) approach is one of them and was proposed by combining the high binding specificity of the aptamer to its target with the sensitive signal transduction mechanism of the molecular beacon (*30, 31*), so that the aptamer target interaction event can be successfully reported by monitoring the changes in fluorescence intensity before and after aptamer−target binding. In a typical MBA assay, the aptamer is labeled with a fluorophore and a quencher. If the positions of the two labels are properly designed, upon binding to its target, the conformational change of the aptamer leads to the change in the distance between the fluorophore and the quencher; consequently, the significant change in fluorescence intensity before and after aptamer target binding can be measured. So far, beacon

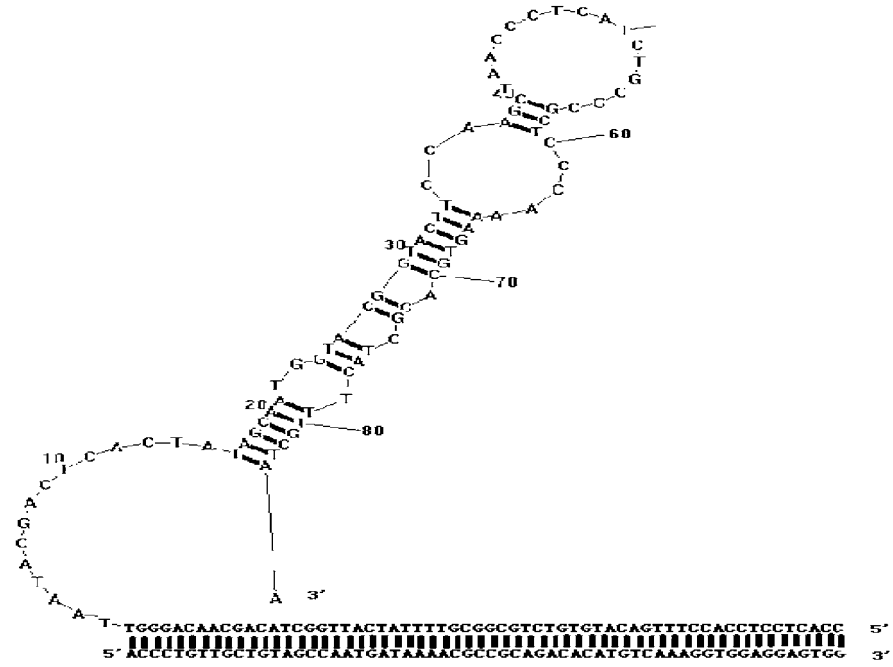

Figure 1. Secondary structure of constructed real-time quantitative-PCR template tethered aptamer targeting against IgG. The double-strand fragment (lower part) serves as PCR template and the loop-stem fragment functions as aptamer moiety.

aptamers for protein binding assay have been demonstrated well, such as that for detection of thrombin and Tat protein of HIV-1 (*32*−*35*). On the other hand, since the conformational change of aptamer has a negative effect on aptamer−target recognition and binding, in order to obtain a better beacon aptamer, usually more selection rounds are needed in the process of beacon aptamer construction. We also noticed that, in the existing aptamer-based assay methods, either the needs for electrode surface immobilization of aptamers or the needs for mono- or dual labeling of aptamers may increase the complexity and costs in real-world application. To overcome these remaining limitations, we are interested in searching more general strategies to couple the aptamer with an appropriate moiety or detection system, which could be used to signal the aptamer target binding with higher sensitivity and less complexity.

RT-PCR provides a precise and sensitive method for determination of specific DNA and RNA sequences in samples within a broad dynamic range (at least 5 orders of magnitude). The principle of RT-PCR is based on detecting the fluorescent signal produced proportionally during PCR amplification with the aid of computer analysis. The assays are easy to perform, capable of high throughput, and can combine high sensitivity with reliable specificity (*36*−*38*). So far, fluorescence-based RT-PCR is widely used for the quantification of steady-state DNA (and RNA) levels, and is becoming a standard tool box for biomedical researches (*39*). We further conceived that a dsDNA fragment which is linked at the terminal of the aptamer will be able to act as an amplification template in RT-PCR. The signal generated from RT-PCR therefore can be used as an indicator for aptamer−target binding after the bound aptamer is separated from the unbound one. In addition, the PCR signal can also be used to identify and quantitate target (such as protein) level in homogeneous solution. On the other hand, if properly designed, the dsDNA template would not interfere with aptamer target binding and vice versa due to high binding specificity of aptamers.

In this paper, we describe the design and construction of a new type of aptamer-based probe through which a target binding event can be reported by amplified RT-PCR signals. In such an aptamer (Figure 1), a ds DNA is coupled to the normal oligonucleotide aptamer selected by SELEX so that this attached dsDNA sequence can be used as a template in RT-PCR; upon target aptamer binding, the binding event could be easily monitored by conducting RT-PCR, and thus, the amplified PCR signal serves as an indicator of the target aptamer binding with high sensitivity (Figure 2). Using HBV antibodies as detection targets and dsDNA template tethered aptamer as probe, a proof-of-concept of the aptamer-mediated real-time quantitative PCR (A-PCR) assay for aptamer target binding is presented.

EXPERIMENTAL PROCEDURES

SELEX Selection. The polystyrene microtiter plate (Maxisorp96-wells, Nunc) was coated with mouse IgG (50 μL, 5 mg/mL) in 0.05 M carbonate buffer (pH 9.6) overnight at 4 °C. The negative control well was treated with carbonate buffer without IgG under the same conditions as above. Afterward, the wells were blocked with Tris-buffered saline (TBS) containing 5% (w/v) fat-free powdered milk (TBSM). A random library (5′-TAA TAC GAC TCA CTA TAG CAA TGG TAC GGT ACT TCC (N25) CA AAA GTG CAC GCT ACT TTG-3′; (N = A,C,T,G,)) was constructed as previously described (*12*) and was denatured by heating at 95 °C, maintained at that temperature for 5 min, and then cooled immediately to 0 °C in selection buffer (5 mM $MgCl_2$ in PBS). In order to reduce background interference, 1 mg/mL of yeast tRNA (Sigma) was added. Subtractive selection was performed by washing three times to elute IgG-aptamers with buffer (7 M urea, 0.5 M NH_4Ac, 1 mM EDTA, and 0.2% SDS) and extracting with phenol−chloroform. ssDNA was precipitated by 10 mM $MgCl_2$ and 0.3 M NaAc and a 2.5-fold volume of ethanol. Selected ssDNA was dissolved in PCR mixture containing 10 μL of 10 × PCR buffer, 8 μL of dNTP (10 mM each, Takara), 6 μL of 25 mM $MgCl_2$, 1 μL of 25 mM P7 long primer (5′-TAA TAC GAC TCA CTA TAG CAA TGG TAC GGT ACT TCC-3′), 1 μL of 25 mM P11 primer (5′-TTA GCA AAG TAG CGT GCA CTT TTG-3′), 73.5 μL of water, and 0.5 μL (2.5 U) of Taq DNA polymerase (Takara). The mixture was thermally cycled five times at 94 °C for 1 min, at 37 °C for 2 min, and at 72 °C for 2 min. The purified PCR products were used as templates to prepare ssDNA for the next round of SELEX.

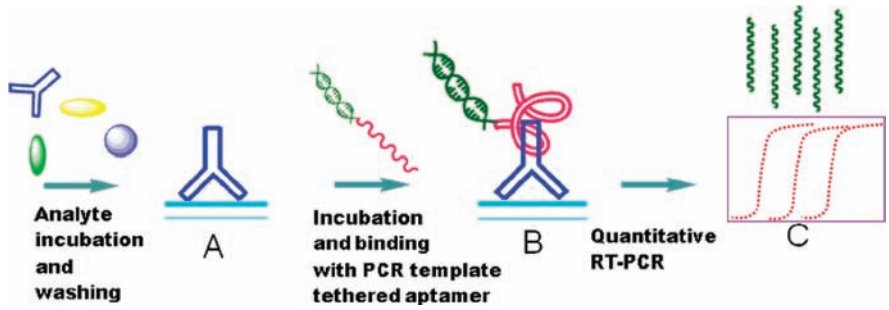

Figure 2. Aptamer-based sensitive detection of target molecules via real-time quantitative-PCR signal amplification. The target (mouse IgG) molecules are first captured on a surface (A); the following incubation with dsDNA PCR template-tethered aptamer specific to the target results in target aptamer binding and immobilization (B). Further real-time quantitative-PCR using attached DNA template generates amplified PCR signals that quantitate the target molecules (C).

Preparation of ssDNA Aptamer and Radioactive Labeling. The PCR mixture consisting of 5 μL of 1 pM dsDNA templates purified as described above, 2 μL of 25 mM P7 primer (5′-TAA TAC GAC TCA CTA TAG CAA TGG TAC GGT ACT TCC-3′), 0.2 μL of 25 mM P11 primer (3′-TTA GCA AAG TAG CGT GCA CTT TTG-5′), 8 μL of dNTP (10 mM each Takara), 6 μL of 25 mM $MgCI_2$, 10 μL of 10 × PCR buffer, 68.3 μL of water, and 0.5 μL (2.5 U) Taq DNA polymerase (Takara) was thermally cycled (94 °C for 30 s; 55 °C for 30 s; 72 °C for 30 s, 35 cycles). The PCR product was purified using 10% denatured polyacrylamide (0.5% bisacrylamide) gels containing 7 M urea. Radiolabeled ssDNA was prepared the same way as described above, except that ^{32}P-dATP was added to the PCR mixture instead of dATP.

Probing the Dot Blot with Radioactive Aptamer and Autoradiography. Radiolabeled ssDNA aptamers were denatured by heating to 95 °C and cooling immediately to 4 °C in selection buffer (5 mM $MgCl_2$ in PBS). 5 μL of serial dilutions of mouse IgG (0.5−25 μg) were dot-blotted on nitrocellulose membranes and blocked at 37 °C for 30 min in TBS containing 5% (w/v) of fat-free powdered milk (TBSM). A negative control membrane was treated with carbonate buffer without IgG. The membranes were then incubated with equal amounts of a mixture of radiolabeled ssDNA aptamers in 200 μL of selection buffer at 37 °C for 30 min. After washing three times with 3 mL of selection buffer, these nitrocellulose membranes were air-dried and autoradiographed.

Preparation of dsDNA Attached Aptamers. First, double-stranded DNA aptamers were prepared by overlap extension PCR. Typically, a PCR mixture containing 1 μL of a 25 μM negative strand of selected aptamer ssDNA(5′-TTA GCA AAG TAG CGT GCA CTT TTG GGA GCG CGC AGA TGA GGG TTA GCT TGG AAG TAC CGT ACC ATT GCT ATA GTG AGT CGT ATT A-3′) and 1 μL of 25 μM synthetic ssDNA (5′-CCA CTC CTC CAC CTT TGA CAT GTG TCT GCG GCG TTT TAT CAT TGG CTA CAG CAA CAG GGT TAA TAC GAC TCA CTA TAG CAA TGG TAC GGT ACT TCC-3′) as templates, 8 μL of dNTP (10 mM each, Takara), 6 μL of 25 mM $MgCl_2$, 10 μL of 10× PCR buffer, 0.5 μL (2.5 U) Taq DNA polymerase (Takara), and distilled H_2O in a final volume of 100 μL was thermally cycled (94 °C for 30 s; 55 °C for 30 s; 72 °C for 30 s, 5 cycles). Then, the single-stranded DNA attached aptamers were prepared by an asymmetric PCR method. A PCR mixture containing 10 μL overlap extension PCR product as templates, 2.2 μL of 25 μM P201 primer (5′-CCA CTC CTC CAC CTT TGA C-3′), 0.2 μL of 25 μM P11 primer (5′- TTA GCA AAG TAG CGT GCA CTT TTG-3′), 8 μL of dNTP (or ^{32}P-dATP was added into the PCR mixture instead of dATP for preparation of the radiolabeled one) (10 mM each, Takara), 6 μL of 25 mM $MgCl_2$, 10 μL of 10× PCR buffer, and 0.5 μL (2.5 U) Taq DNA polymerase (Takara), and distilled H_2O in a final volume of 100 μL was thermally cycled (94 °C for 30 s; 55 °C for 30 s; 72 °C for 30 s, 35 cycles). Meanwhile, the negative ssDNA was prepared by an asymmetric PCR method. A PCR mixture containing 10 μL overlap extension PCR product as template, 0.2 μL of 25 μM P201 primer (5′-CCA CTC CTC CAC CTT TGA C-3′), 2.2 μL of 25 μM P214 primer (5′-ACCCTGTTGCTGTAGCCA-3′), 8 μL of dNTP (or ^{32}P-dATP was added into the PCR mixture instead of dATP for preparation of the radiolabeled one) (10 mM each, Takara), 6 μL of 25 mM $MgCl_2$, 10 μL of 10× PCR buffer, and 0.5 μL (2.5 U) Taq DNA polymerase (Takara), and distilled H_2O in a final volume of 100 μL was thermally cycled (94 °C for 30 s; 55 °C for 30 s; 72 °C for 30 s, 35 cycles). Finally, the two asymmetric PCR products were combined and thermally cycled (95 °C for 5 min; 4 °C for 60 s) to afford the ssDNA aptamers attached with a dsDNA sequence. Further PAGE gel electrophoresis analysis (10% denatured PAGE gel at 100 V for 60 min) was conducted to characterize and separate the expected product.

Electrophoretic Mobility Shift Assay (EMSA). After the IgG-specific aptamers (5′-CCA CTC CTC CAC CTT TGA CAT GTG TCT GCG GCG TTT TAT CAT TGG CTA CAG CAA CAG GGT TAA TAC GAC TCA CTA TAG CAA TGG TAC GGT ACT TCC AAG CTA ACC CTC ATC TGC GCG CTC CCA AAA GTG CAC GCT ACT TTG CTA A-3′) were labeled by [α-^{32}P] ATP as described above, 100 pM ^{32}P-labeled DNA aptamers were incubated with serial dilutions of IgG (from 5 to 20 μg) in 20 μL binding buffer [10 mM HEPES (pH 7.6), 1 mM EDTA, 2 mM dithiothreitol, 50 mM KCl, 0.05% Triton X-100, and 5% glycerol] at 37 °C for 60 min. Bound and unbound DNA species were separated on 0.5% native agarose gel in 0.5× Tris-borate-EDTA (TBE) electrophoretic buffer at 80 V for 2 h. The gel was fixed with 10% acetic acid 50% methanol for 2 h, dried, and subjected to autoradiography. After autoradiography, the same gels were stained again with Coomassie brilliant blue, eluted, and photographed.

Real-Time Quantitative A-PCR. All RT-PCRs were carried out with a TaqMan probe on the Rotor-gene 3000 (Australian). The immuno-PCR microwells (Nunc TopYield) were coated with 20 μL of 10-fold serial dilutions of mouse anti-HBsAg IgG at 37 °C for 2 h 37 °C for 2 h or 4 °C overnight in 0.05 M carbonate buffer (pH 9.6). After blocking with TBSM (TBS buffer containing 5% (w/v) fat-free powdered milk), the microwells were washed with TBSET (TBS buffer containing 5 mM EDTA and 0.5% Tween-20) three times. Similarly, other specific or nonspecific IgG and protein samples were immobilized in microwells as described above. Then, 1 pg/mL dsDNA template tethered aptamers were added to the microwells and incubated in 20 μL binding buffer [10 mM HEPES (pH 7.6), 1 mM EDTA, 2 mM dithiothreitol, 50 mM KCl, 0.05% Triton X-100, and 5% glycerol] at 37 °C for 1 h, and then

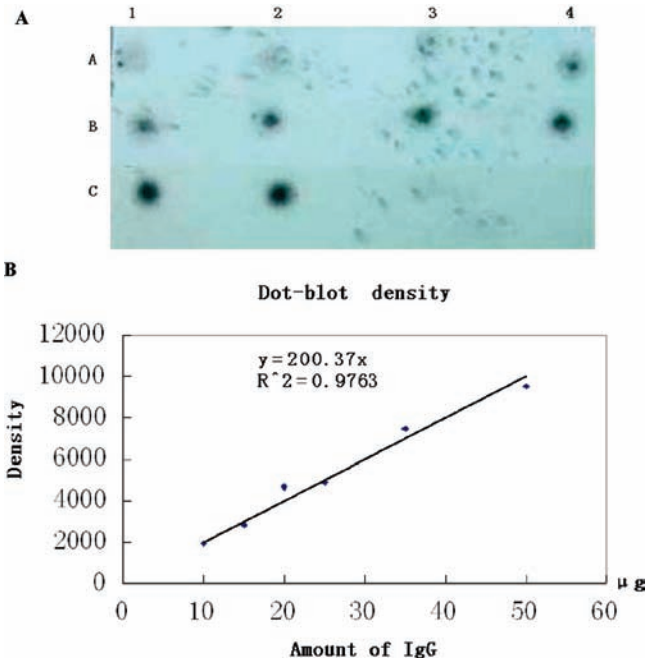

Figure 3. Dot-blot autoradiography assay for the binding of selected aptamer with IgG on nitrocellulose membranes. (A) Quantities of the target (IgG) dotted on the nitrocellulose membrane were as follows: A1, 0.25 μg; A2, 1 μg; A3, 2.5 μg; A4, 5 μg; B1, 10 μg; B2, 15 μg; B3, 20 μg; B4, 25 μg; C1, 35 μg; C2, 50 μg; C3, 0 μg. Images were taken after the nitrocellulose membrane was coincubated with ^{32}P-labeled aptamer. (B) The linear regression of dot-blot autoradiography was assayed by Melanie 3 - the 2-D Gel Image Analysis software package.

washed three times with binding buffer containing 0.5% Tween-20. The PCR mixture containing 1× PCR buffer (Takara), 4.5 mM $MgCl_2$, 0.25 mM of each primer, 0.8 mM of TaqMan probe, 0.25 mM of dNTP, 2.5 U Taq DNA polymerase (Takara), and distilled H_2O in a final volume of 20 μL was thermally cycled (94 °C for 5 min, followed by 40 cycles of 95 °C for 45 s, 55 °C for 60 s) by real-time PCR. Negative controls containing no template DNA were included in each batch of PCR tests. The threshold cycle (Cts) values were set as the cycle at which the measured fluorescence intersected the cycle threshold line.

RESULTS

Specific Binding Assay of the Selected Aptamers by Dot-Blot. Forty aptamers against the mouse IgG Fc fragment were selected after 16 rounds of SELEX. The selected aptamer with highest affinity was used for subsequent binding assay by dot-blot (Figure 3A). The blots were further analyzed by using the 2-D Gel Image Analysis software package (Melanie 3). The dot-blot autoradiography showed that the intensity of the dots had a linear relation with the IgG concentration (Figure 3B). The dot-blot binding assay of the aptamers with albumin, egg white protein, fat-free powdered milk, mouse IgG1, mouse IgG2a, and mouse anti-HBV IgG were conducted in parallel. The results showed that the selected aptamers specifically bind with mouse IgG1, mouse IgG2a, and mouse anti-HBV IgG, but not with albumin, egg white protein, or fat-free powdered milk. These results indicate the successful selection of oligonucleotide aptamers that can bind to the Fc fragment of mouse IgG with high affinity and specificity.

Construction and Electrophoresis Analysis of dsDNA Template Tethered Aptamer. The combination of overlap extension strategy and asymmetric PCR was carried out to generate expected dsDNA template tethered aptamer. Following denaturing, polyacrylamide gel electrophoresis (PAGE) (10% denatured PAGE gel at 200 V for 60 min) was carried out to analyze the dsDNA template−aptamer adduct (Figure 4). After consecutive PCRs and annealing process, lanes 1 and 2 show disappearance of both ssDNA template strand (band E) and ssPCR template DNA−aptamer adduct (band B) and appearance of ds DNA template tethered aptamer (band A). The band for dsDNA tethered aptamer is easily distinguishable from other oligo components in the PCR mixture showing a decent yield in preparation of the expected DNA tethered aptamer (Figure 4, band A).

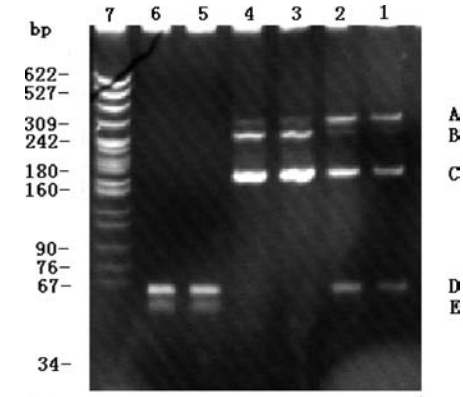

Figure 4. 10% denatured PAGE gel electrophoresis analysis of PCR template DNA attached aptamers. Lanes 1 and 2: A, dsDNA template tethered aptamer (positive strand only); C, dsDNA template tethered dsDNA aptamer; D, dsDNA template. Lanes 3 and 4: B, ssDNA template (positive strand) tethered aptamer (positive strand only); C, dsDNA template tethered dsDNA aptamer. Lanes 5 and 6: D, dsDNA template; E, ssDNA template (negative strand). Lane 7: M-pBR322DNA/MspI markers.

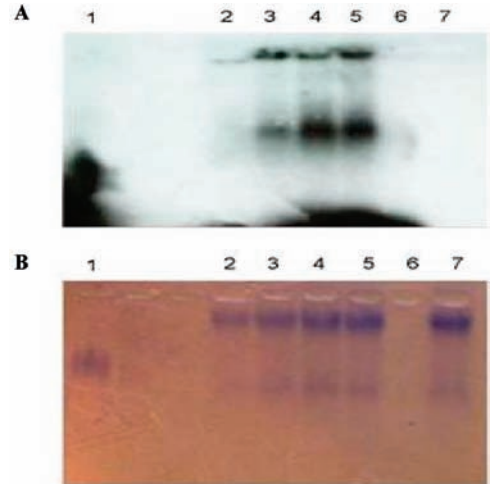

Figure 5. EMSA assay for specific binding of template tethered aptamers and target IgG. (A) EMSA autoradiography image of the binding complex of aptamer and IgG. Lane 1: mixture of boiled IgG (20 μg) and ^{32}P-template tethered aptamer (70 ng). Lanes 2−5: mixture of IgG (5 μg, 10 μg, 15 μg, 20 μg) and ^{32}P-template tethered aptamer (70 ng). Lane 6: ^{32}P-template tethered aptamer (70 ng) without IgG. Lane 7: IgG (20 μg) without ^{32}P-template tethered aptamer. (B) EMSA autoradiography gel stained with Coomassie brilliant blue.

EMSA Assay of the Binding Specificity of the PCR Template Tethered Aptamers. EMSA analyses were used to evaluate the binding affinity of the PCR template tethered aptamers with IgG (Figure 5A,B). The EMSA gels were subjected to autoradiography (Figure 5A), then were stained by Coomassie brilliant blue to quantify the bound IgG with DNA template tethered aptamer (Figure 5B). The color density of the electrophoretic bands corresponding to the aptamer-bound IgG increases with increasing concentration of IgG (Figure 5). On

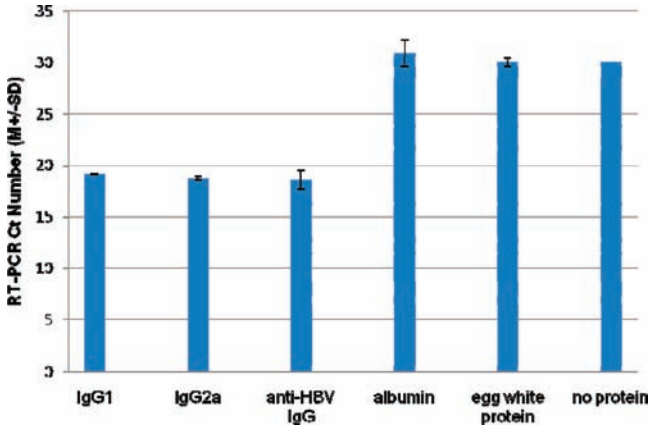

Figure 6. Ct values of the real-time quantitative A-PCR assay using specific and nonspecific protein as aptamer targets. RT-PCRs were carried out after sequential incubation of targets and PCR dsDNA template tethered aptamer in anti-HBV IgG, IgG1, IgG2a, albumin, egg white protein, and no protein precoated microwells. The Ct value results show very significant differences between specific and nonspecific targets ($p < 0.001$).

the contrary, the aptamer lost binding affinity to denatured IgG (Figure 5B) indicating that the PCR template tethered aptamers retain binding specificity and affinity to natural mouse IgG. The binding affinity of all three synthesized PCR tethered aptamers with IgG is shown to be the same, implying that the different template DNA-attached aptamers could bind with homologous Fc fragments of different mouse IgG subtypes.

Real-Time Quantitative A-PCR Assay for Target Detection. The capability of DNA template tethered aptamers as a novel probe to detect target molecules was further demonstrated using mouse IgG as the target and postbinding real-time quantitative-PCR as the signaling source. In the microwells coated with different target molecules including both specific and nonspecific proteins such as anti-HBsAg IgG, mouse IgG1, mouse IgG2a, albumin, egg white protein, and fat-free powdered milk and blocked with TBSM, further incubation with DNA template tethered aptamers leads to specific binding with immobilized mouse IgG in the microwells. After washing with TBSET to remove unbound ones, the following real-time quantitative A-PCR was carried out and Ct values of RT-PCR signals after aptamer incubation were recorded and summarized (Figure 6). A distinctive difference (40%) in RT-PCR Ct values is observed between RT-PCR runs after specific IgG target incubation and nonspecific protein incubation. The Ct values for nonspecific protein controls and for the "no protein" group were the same (as high as ~30) (Figure 6). This Ct level represents a background signal due to nonspecific immobilization of the dsDNA aptamer adduct. Further titration of the RT-PCR signal was conducted by using 10-fold serially diluted specific IgG ranging from 0.001 to 0.000 001 ng as a detection target. Within this range, the results show a linear relation with decreased Ct value versus increased IgG concentration (Figure 7).

DISCUSSION

The high affinity and specificity of aptamer make it an ideal probe in a variety of applications. The way to signal the aptamer target binding directly influences the feasibility of aptamer-based analysis and dominates the detection sensitivity. In this regard, the electron transfer switch, quantum dots, and FRET have been coupled with aptamer target binding as signaling methods (*22, 23*). Due to aptamer's nucleic acid nature, PCR amplification had been used to detect proteins with the aid of templates generated by postbinding ligation (*41, 42*). More recently, RT-PCR was

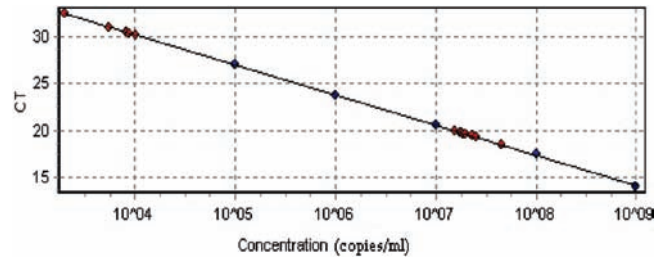

Figure 7. Real-time quantitative A-PCR shows a linear relation between decreased Ct values and increased specific target (IgG) concentration.

applied to aptamer-based protein detection using aptamer sequence as a template (*43*). In our earlier efforts to make use of aptamer fragments as PCR amplification template, we found, in a continuous workflow, that postbinding PCR could often be impaired, possibly due to existing target molecules which may compromise both polymerase template binding and hybridization between template and primer. More efficient and universal strategies are highly desirable.

In this study, we proposed a dsDNA template attached aptamer as a novel approach for sensing and detection of a specific target instead of using an aptamer fragment as PCR template. The dsDNA−aptamer adducts are composed of normal oligonucleotide aptamers selected by SELEX and dsDNA sequences which can be used as PCR template. Such a structure not only retains an aptamer's characteristic of specific binding to the target, but also endows the capacity to generate amplified PCR signal to report aptamer target binding. One advantage over beacon aptamer and electrochemical aptamer is that dsDNA attached aptamer probes do not need intrinsic fluorophore or electro-active molecular labels to produce observable signals. which may be more costly and may cause more complexity in aptamer design and selection. On the contrary, the dsDNA template attached aptamer is label-free, and the widely equipped RT-PCR tool box is used to transduce target aptamer binding into observable signal, providing PCR template tethered aptamer based assay, a more general and accessible method in wide range of applications. Moreover, the amplified signal produced by RT-PCR allows sensitive detection of target molecules at a similar low level at which a DNA sample could be detectable using RT-PCR. In comparison with other PCR-aided aptamer probing mechanisms mentioned above, attaching a DNA template to aptamer also allows more simple and straightforward detection. Thus, in a typical target detection, DNA template tethered aptamer mediated real-time quantitative PCR (A-PCR) can be fulfilled with a continuous workflow in a microwell: immobilize target molecules on surface, incubate with template tethered aptamers leading to formation of aptamer target binding complex, and wash to ensure that only the specific template tethered aptamer−target complex is retained on the surface. The following real-time quantitative PCR with on-aptamer dsDNA as template will generate an amplified signal to quantitate the existence of the target (Figure 2). These features enable dsDNA attached aptamer sensors to be more feasible for real-world analytical and biomedical research at low cost and ease.

Three DNA template tethered aptamer sensors were designed in this research, which are specific for IgG, all having the same primer but with different complementary sequences of TaqMan probes, respectively. The secondary structures of the template tethered aptamer sensors were analyzed using RNA structure 3.7 software. The ssDNA fragment contains a target binding sequence, and the dsDNA fragment serves as PCR template, including various Taqman probe complementary sequences flanked by defined primer binding sites (Figure 1). The conformations of the target binding fragment (aptamer moiety) and the PCR template fragment are very distinguishable (Figure

1). It is predictable that the recognition and binding of aptamer moiety and target molecule would not be interfered with, and neither would the following PCR be impaired by the target molecule. In construction of such a template tethered aptamer, the combined use of overlap extension strategy and asymmetric PCR supplied the expected conjugate containing both binding and signaling moieties in a simple and straightforward way. Parallel multiple target probing and detection of biological molecules will provide dynamic and insightful information on biomedical research and therefore are highly desirable. The simplicity and versatility of preparation of DNA template tethered aptamers has been shown. This method is adaptable, allowing us to attach DNA template onto different aptamers targeting a variety of analytes such as protein, peptide, nucleic acid, toxin, and ions. In combination with the routinely used RT-PCR tool box, this new approach may greatly expand its applications to target sensing and detection in a wide range of fields, and its extensive application would make multiplex target detection and sensing an achievable goal.

In this work, the proof-of-principle of A-PCR has been established using IgG as the target molecule. The sensitive detection of IgG within the range from 0.001 to 0.000 001 ng was realized. The higher quality of RT-PCR is dependent on the larger copy number of the dsDNA template attached with IgG bound aptamer and closely relevant to the lower cycle threshold (Ct) value in the RT-PCR amplification. When the other two different DNA template tethered aptamers were used, the same real-time quantitative A-PCR results in terms of Ct values were observed. As we expected, the results demonstrate that the aptamer retains its target binding specificity after an extra fragment of DNA template is attached. On the other hand, the extra DNA fragment does not interfere with the target-aptamer binding; this ensures an unambiguous detection of target using real-time quantitative A-PCR. In conclusion, a new mechanism to transduce the aptamer target binding event into a RT-PCR signal is fully validated by using the DNA template tethered aptamer as probe. Such an aptamer-based, RT-PCR-aided probing system shows potential as a universal tool to address the problem of parallel and multiple target detection and sensing and will greatly facilitate the systematic studies of biological processes and diagnosis. More efforts are underway by us focusing on multiplex detection of targets using A-PCR.

An Approach to Multiplexing an Immunosorbent Assay with Antibody−Oligonucleotide Conjugates

Ki-Cheol Han, Dae-Ro Ahn,* and Eun Gyeong Yang*

Life Sciences Research Division, Korea Institute of Science and Technology, P.O. Box 131, Cheongryang, Seoul 130-650, Republic of Korea. Received March 23, 2010; Revised Manuscript Received October 20, 2010

Early detection of cancer biomarkers provides clinically valuable information. While the conventional enzyme-linked immunosorbent assay (ELISA) has been routinely used for individual cancer markers, methods for simultaneous determination of multiple markers within a single sample are still in demand. Here, we present a novel oligonucleotide-linked immunosorbent assay (OLISA) with a multiplexing capability on the same microwell plate-based system as in ELISA. Employing a DNA oligonucleotide that is covalently conjugated to the detection antibody and a complementary RNA oligonucleotide which is appended with a fluorophore and a quencher, degradation of the RNA in the DNA-RNA duplex by RNase H is exploited for fluorescent signal generation. Iterative cycles of DNA-RNA duplexation and subsequent degradation of the RNA in the duplex by RNase H further lead to amplification of the detection signal in OLISA. Moreover, the use of antibody−oligonucleotide conjugates enables multiplexing of OLISA, which is successfully demonstrated by tethering DNA molecules to detection antibodies and by performing assays for three common cancer markers including α-fetoprotein, prostate-specific antigen, and carcinoembryonic antigen. With the simple procedure and reliable detection performance, the developed multiplex OLISA has a wide potential for use in analysis of a panel of biomarkers in clinical diagnostics.

INTRODUCTION

Enzyme-linked immunosorbent assay (ELISA) is the most widely used analytical technology to detect biologically informative molecules for disease diagnosis, as well as for biomedical research. The sandwich ELISA, in particular, permits accurate and sensitive detection of an antigen of interest, thereby providing highly quantitative and reproducible results in clinical laboratories. However, the traditional sandwich ELISA is unsuitable for simultaneous determination of multiple targets in a single assay.

In efforts made to remedy such drawbacks, a variety of platforms have been devised to meet the increased needs of multiplex immunoassays especially from the clinical area. Sticking to the principle of the sandwich ELISA, Q-Plex multiplex ELISA from Quansys Biosciences detects chemiluminescence signals from 96-well microplates in which each well contains multiple spots coated with specific capture antibodies (cAbs). On the other hand, flow cytometric multiplex assays such as the cytometric bead array (CBA) system from BD Biosciences and the multianalyte profiling (xMAP) technology from Luminex have been introduced by use of a proprietary set of beads, which are immobilized with fluorescent detection antibodies (dAbs), and thus readily analyzed by flow cytometry (*1*,*2*). Such multiplex bead assays have been successfully applied for the simultaneous quantitation of multianalytes including cytokines (*3*−*5*) and antibodies (*6*, *7*). In addition, more sophisticated technology developed by Meso Scale Discovery (MSD) has been incorporated into multiplex array kits, which comprise a microplate with electrodes integrated into its bottom and each electric wire coated with specific cAbs. Since the dAbs are conjugated to electrochemiluminescent labels, the assay detects emitted light by stimulation of the labels on the electrodes located in the bottom of microplates. In contrast, nucleic acids have been utilized for multiplex assays as in immuno-PCR coupled with gel electrophoresis (*8*). Multiple DNA-encoded antibody barcode arrays have also been patterned within the channels on a chip for in situ protein measurements (*9*). In improving performance of immunoassays, such exploitation of DNA−antibody conjugates has particularly been gaining more attention since the nucleic acid part presents various signal amplification strategies (*10, 11*). Although some methods require sophisticated instruments or delicately prebuilt array systems, the use of nucleic acids in general permits highly sensitive detection of different proteins across broad dynamic ranges and high-throughput analysis (*10, 11*).

In this study, we have attempted to develop a facile multiplex immunoassay compatible with the conventional sandwich assay in well plate format. Our novel oligonucleotide-linked immunosorbent assay (OLISA) is designed based on a dAb tethered with a DNA by incorporating the concept of RNase H-mediated signal amplification reported previously for an aptamer-based biosensor (*12*). Further, the use of DNA renders multiplexing ability of the assay, and thus, multi-RNA probes that are complementary to DNA sequences conjugated to dAbs and that contain different fluorophore/quencher pairs are utilized to recognize multitarget proteins. Proteins in a sample can be quantified by simply measuring fluorescence intensity at the relevant emission wavelengths of fluorophores, which is demonstrated by performing multiplex OLISA for simultaneous analysis of three cancer biomarkers.

EXPERIMENTAL PROCEDURES

Reagents. Biotinamidohexanoic acid *N*-hydroxysuccinimide ester and human serum were purchased from Sigma-Aldrich (St. Louis, MO, USA) and Streptavidin-HRP was from abcam (UK). *N*-[α-Maleimidoacetoxy]succinimide ester (AMAS), *N*-[ε-

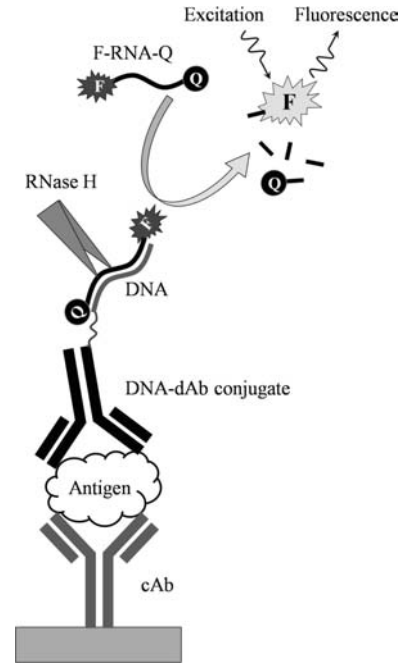
F-RNA3-Q	Cy5−5′-CUACAACGCU-3′-BHQ2	

maleimidocaproyloxy]succinimide ester (EMCS), succinimidyl-6-[(β-maleimidopropionamido)hexanoate] (SMPH), and succinimidyl-4-[*N*-maleimidomethyl]cyclohexane-1-carboxy-[6-amidocaproate] (LC-SMCC) were obtained from Pierce (Rockford, IL, USA). Anti-α-fetoprotein (AFP) and anti-prostate-specific antigen (PSA) antibodies were from Fitzgerald (Acton, MA, USA), and anti-carcinoembryonic antigen (CEA) antibodies from Biodesign (Saco, Maine, USA). TMB substrate solution and stop solution were purchased from GenDepot (Barker, TX, USA), Protector RNase Inhibitor (PRI) was from Roche (Mannheim, Germany), and RNase H was from Takara (Japan). All other reagents were of highest grade commercially available.



Preparation of Biotinylated dAbs for ELISA. One microliter of 20 mM biotinamidohexanoic acid *N*-hydroxysuccinimide ester was mixed with 50 μL of 2.5 mg/mL dAb and incubated for 30 min at room temperature. The biotinylated antibody was then purified using Amicon Ultra-15 centrifugal filter units (MWCO = 50 000, Millipore, Billerica, MA, USA).

ELISA Procedure. Each well of a transparent 96-well plate (Greiner bio-one, Germany) was coated with 100 μL of cAbs (2 μg/mL) by incubation overnight at 4 °C, followed by washes with PBS (3 × 300 μL). The cAb-coated wells were blocked with 200 μL of Blocking Buffer (3% BSA in PBS), incubated for 1 h at room temperature, and rinsed with PBST (0.05% Tween-20 in PBS, 3 × 300 μL). Protein solutions of varying concentrations (0, 0.625, 1.25, 2.5, 5, and 10 ng/mL) in 100 μL of Assay Buffer (1% BSA in PBST) were added to the wells, followed by incubation for 1 h at room temperature. The plate was then washed with PBST (3 × 300 μL) before addition of the biotinylated dAbs (100 μL, 3 μg/mL in Assay Buffer) and incubation for 1 h at room temperature. After rinsing with PBST (3 × 300 μL), streptavidin-HRP (2 μg/mL) in Assay Buffer (100 μL) was added and incubated for 1 h at room temperature. The plate was further washed with PBST (3 × 300 μL), and each well was incubated in TMB substrate solution (100 μL) for 20 min at 25 °C. After addition of TMB stop solution (100 μL) to the each well, optical density at 450 nm was immediately measured by means of a 96-well microplate reader (SpectraMax Plus, Molecular Devices, Sunnyvale, CA, USA).

Design and Preparation of DNA Labels and RNA Probes. DNA1, **DNA2**, and **DNA3** for conjugation with dAbs were designed to exhibit specificity and 50% of G + C content with the aid of *Vector NTI* software (Invitrogen, Carlsbad, CA, USA), and modified with a thiol group at the 5′-end for conjugation to dAbs. RNA probes whose sequences are complementary to the corresponding DNA labels were designed to contain fluorophores and their matching quenchers. All DNA labels and RNA probes whose sequences are presented in Table 1 were synthesized by Integrated DNA Technologies (Coralville, IA, USA).

Preparation of DNA-dAb Conjugates. DNA-dAb conjugates were prepared as shown in Scheme 2. A dAb (2.5 mg/mL) was incubated with AMAS, EMCS, SMPH, or LC-SMCC (2 mM) in PBS (50 μL) for 30 min at room temperature. After removal of unreacted linker molecules by using Amicon Ultra-15 centrifugal filter units (MWCO = 50 000), the solution of linker-modified dAb was added to the thiol-modified DNA (500 μM) in PBS (50 μL) and incubated for 30 min at room temperature and purified by using Amicon Ultra-15 centrifugal filter units (MWCO = 50 000).

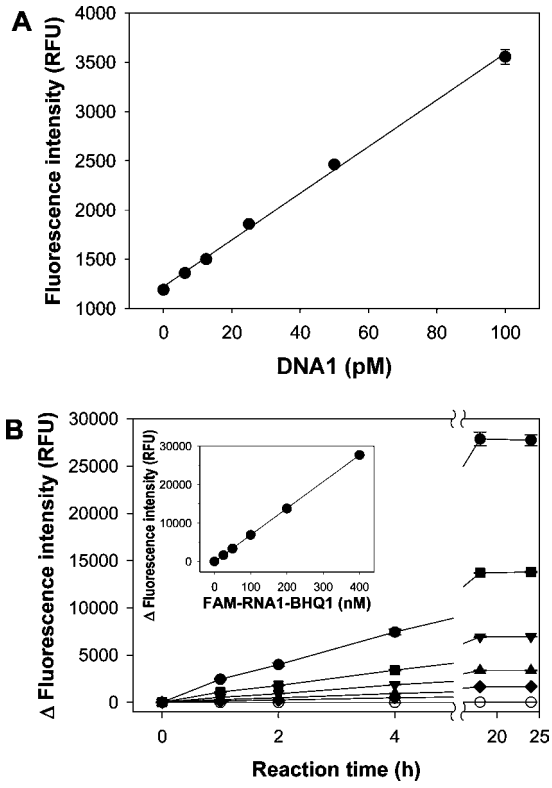
Scheme 1. Working Principle of OLISA

OLISA Procedure. Black 96-well microplates (Greiner bio-one, Germany) were coated with cAbs (2 μg/mL) in PBS (100 μL/well) by incubation overnight at 4 °C. Each well was then washed with PBS (3 × 300 μL), blocked with Blocking Buffer (200 μL), and incubated for 1 h at room temperature. After rinses with PBST (3 × 300 μL), protein solutions of varying concentrations (0, 0.625, 1.25, 2.5, 5, and 10 ng/mL) in 100 μL of Assay Buffer were added to the wells, followed by incubation for 1 h at room temperature. The plate was washed with PBST (3 × 300 μL) before addition of DNA-dAb conjugates (100 μL, 3 μg/mL in Assay Buffer) and incubated for 1 h at room temperature. After rinsing with PBST (3 × 300 μL), the RNase H reaction solution (100 μL) containing 200 nM F-RNA-Q probe, 0.4 U of PRI, and 20 U of RNase H in RNase H buffer (40 mM Tris-HCl, 4 mM $MgCl_2$, 1 mM DTT, 0.003% BSA, pH 7.7) was added and incubated for 3 h at 25 °C. The reaction was then stopped by adding 10 mM EDTA (200 μL) and fluorescence intensities were measured by Appliskan (Thermoscientific, Waltham, MA, USA) with excitation/emission filter sets of 485/535 nm, 544/589 nm, and 633/700 nm for FAM, ROX, and Cy5, respectively. All assays were performed in duplicate.

Multiplex OLISA Procedure. Black 96-well microplates were coated with a mixture of cAbs for AFP, PSA, and CEA (2 μg/mL) in PBS (100 μL). Assays were carried out using mixed solutions of three marker proteins (AFP, PSA, and CEA) of varying concentrations, a mixed solution of three DNA-dAb conjugates (**DNA1**-dAb_{AFP}, **DNA2**-dAb_{PSA}, and**DNA3**-dAb_{CEA}) specific to the markers, and a mixed solution of three RNA probes (**F-RNA1-Q**, **F-RNA2-Q**, and **F-RNA3-Q**) in the same manner as described in the OLISA for a single analyte.

RESULTS

Our OLISA is based on the sandwich immunoassay, which can be performed on a conventional 96-well plate format. In terms of working principle (Scheme 1), OLISA is distinguished from the conventional ELISA in three aspects: (1) DNA, instead of protein, is conjugated with the dAb; (2) RNase H, instead of horseradish peroxidase (HRP), performs the enzymatic reaction; and (3) fluorescence signal, instead of chemiluminescence signal, is amplified as a result of antigen detection. The antigen bound



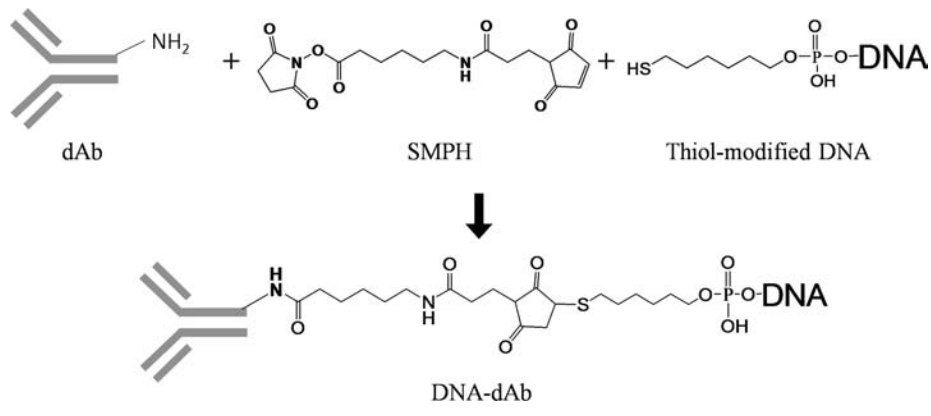


Figure 1. RNase H-mediated fluorescence signal amplification. (A) Mixtures containing **F-RNA1-Q** (200 nM) and RNase H (0.6 U) in RNase H buffer were incubated with varying concentrations of **DNA1** for 1 h at 25 °C, followed by fluorescence measurements. (B) Mixtures containing **DNA1** (300 pM) and RNase H (0.6 U) in RNase H buffer were incubated with varying concentrations of **F-RNA1-Q** (○, 0; ♦, 25; ▲, 50; ▼, 100; □, 200; ●, 400 nM) at 25 °C, followed by fluorescence measurements. The inset graph is a plot of the final fluorescence value as a function of the concentration of the RNA probe.

to the cAb on the plate is recognized by the dAb tethered with DNA, which then hybridizes with the complementary RNA probe, F-RNA-Q, which is appended with a fluorophore (F) at the 5′-end and a quencher (Q) at the 3′-end, respectively. The RNA in the RNA/DNA duplex, whose fluorescence is quenched by the quencher in proximity, is degraded with RNase H; this results in fluorescence recovery due to separation of the fluorophore from the quencher. Since F-RNA-Q degradation by RNase H leaves the DNA undamaged and thus available for duplex reformation with another F-RNA-Q molecule, the cycle of RNA/DNA duplexation followed by RNase H digestion leads to fluorescence signal amplification.

Since the signal amplification is directly dependent upon degradation of the RNA probe by RNase H, we first tested the level of fluorescence signal generation from **F-RNA1-Q** at a constant amount in the presence of increasing concentrations of **DNA1**. As shown in Figure 1A, the increased fluorescence intensity led by the reaction was linearly proportional to the concentration of **DNA1**. At a given reaction time, the limit of detection was as low as 5.4 pM. To confirm that the fluorescence signal is amplified by iterative cycles of RNA/DNA hybridization and subsequent degradation by RNase H, we measured fluorescence changes with varying concentrations **of F-RNA1-Q** in the presence of a small amount of **DNA1**. As predicted from the assay design, fluorescence signal increased with reaction time reached saturating values that were proportional to the concentration of the RNA probe (Figure 1B). We further reconfirmed signal amplification via iterative cycles of RNA/DNA duplexation by measuring the maximal fluorescence value upon degradation of the RNA probe by RNase, which was closely similar to the maximal signal obtained by OLISA (data not shown). To integrate such RNase H-mediated signal amplification into an immunoassay, we chose a well-known cancer marker AFP, and conjugated DNA to dAb_{AFP} (Scheme 2) using various cross-linker molecules including AMAS, EMCS, SMPH, and LC-SMCC, all of which contain an amine-reactive moiety at one end and a thiol-reactive moiety at the other end, respectively, but differ in their length. The conjugation reaction yielded products of approximately 0.9 **DNA1** per dAb of AFP (dAb_{AFP}) as determined based on the ratio of absorbance values at 260 and 280 nm. When these DNA-dAb conjugates mixed with **F-RNA1-Q** were subjected to RNase H treatment, similar increases in fluorescence intensity were observed irrespective of the linkers (data not shown). Therefore, the conjugate synthesized using SMPH was chosen to further evaluate the effects of the linker length. The linker length was varied by inserting thymidine-base linkers of T_{10}, T_{20}, and T_{30} between **DNA1** and SMPH, and fluorescence changes were monitored after incubation with **F-RNA1-Q** in the presence of RNase H. Interestingly, the longer the linker was inserted, the less fluorescence signal was generated by the RNase H reaction (Figure 2). Although the mechanism of such observations is not apparently clear, the linkers between DNA and antibody might hamper the formation of the duplex between DNA and the RNA probe.

On the basis of these results, the DNA-antibody conjugated directly with SMPH was utilized for setting up a sandwich immunoassay. The initial trial employed a conventional sandwich assay in well plate format for AFP on a 96-well plate precoated with cAb_{APF}, but establishment of a standard curve was unsuccessful due to unexpectedly high background. In attempts to resolve such background issue, we found that the

Scheme 2. Synthesis of DNA-dAb Conjugates: An Example with a Cross-Linker SMPH Is Shown

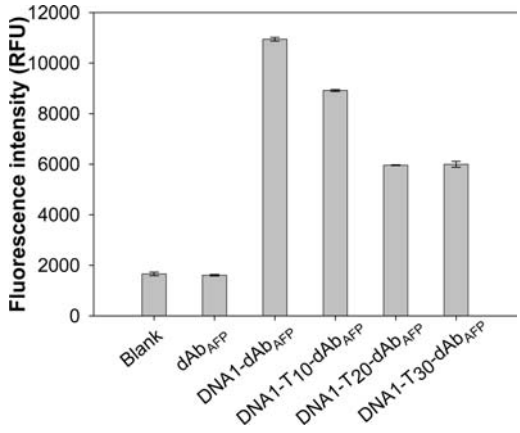

Figure 2. Effect of thymidine linkers between DNA and dAb on the RNase H reaction. Fluorescence intensities were measured for the mixtures containing **F-RNA1-Q** (200 nM) and RNase H (6.0 U) in RNase H buffer in the absence or presence of dAb$_{AFP}$, **DNA1**-dAb$_{AFP}$, **DNA1**-T$_{10}$-dAb$_{AFP}$, **DNA1**-T$_{20}$-dAb$_{AFP}$, or **DNA1**-T$_{30}$-dAb$_{AFP}$ (500 pM) after incubation for 1 h at 25 °C.

fluorescent signal increased considerably even in the absence of RNase H and **DNA1**-dAb$_{APF}$ when **F-RNA1-Q** alone was added to the well precoated with cAb$_{AFP}$. Since cAbs were purified from serum and thus its solution might still be contaminated with traces of ribonucleases, such a possibility was examined by inclusion of an RNase inhibitor PRI that is known to inhibit RNase A, RNase B, and RNase T2. When **F-RNA1-Q** was added to the cAb$_{AFP}$-coated wells in the presence of PRI, fluorescence signals generated by ribonuclease activity were diminished to the background level, and a small amount of PRI (0.125 U/well) was enough to inhibit the nonspecific degradation of the **F-RNA1-Q** probe (Figure 3A), confirming that the increased intensity was indeed due to ribonucleases remaining in antibody solutions. On the other hand, the RNase H reaction was not affected by PRI as demonstrated by fluorescence measurements of solutions containing **DNA1** and **F-RNA1-Q** (Figure 3B).

Using the assay buffer supplemented with PRI, we next performed sandwich immunoassays based on OLISA. As shown in Figure 4A (open circles), the fluorescence intensities at 535 nm generated as **F-RNA1-Q** was degraded in OLISA linearly increased with increasing concentrations of AFP. In addition, we analyzed two other cancer markers, PSA and CEA, using the same protocol. Microwell plates coated with cAb$_{PSA}$ or cAb$_{CEA}$ were prepared, and the corresponding detection antibodies, dAb$_{PSA}$ or dAb$_{CEA}$ conjugated with **DNA2** and **DNA3** (Table 1), were applied to detect PSA or CEA, respectively. As expected, fluorescence increases at 589 and 700 nm were found

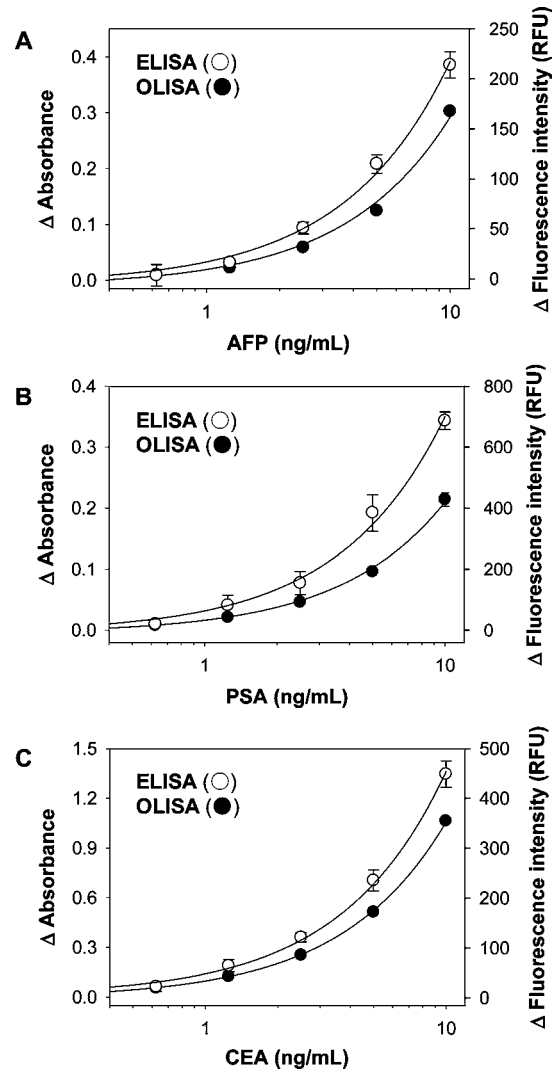

Figure 4. Comparison of OLISA with ELISA for (A) AFP, (B) PSA, and (C) CEA. ELISA results were obtained in changes of absorbance (○) while OLISA results were in changes of fluorescence intensity (●).

to be linearly proportional to the concentrations of PSA (Figure 4B, open circles) and CEA (Figure 4C, open circles), demonstrating general applicability of the developed assay to various analytes. To evaluate the performance of OLISA in comparison to ELISA, we also set up ELISA assays in parallel in which streptavidin-conjugated HRP was used to detect the bound biotinylated dAbs for the three markers. When absorbance changes in ELISA were compared with fluorescence changes

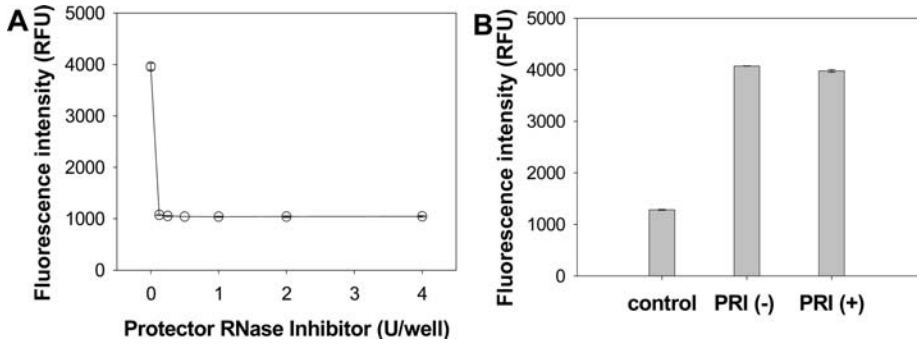

Figure 3. Blockade of nonspecific degradation of RNA probes by PRI treatment. (A) **F-RNA1-Q** (200 nM) in RNase H buffer was incubated with increasing concentrations of PRI on cAb$_{AFP}$-coated wells at 25 °C for 1 h, followed by fluorescence measurements. (B) Mixtures containing **DNA1** (500 pM) and **F-RNA1-Q** (200 nM) in RNase H buffer were incubated with or without PRI (2 U) in the presence of RNase H (6.0 U) for 1 h at 25 °C, followed by fluorescence measurements. A control sample was measured in the absence of RNase H.

Table 2. Detection Limits of ELISA and OLISA for Cancer Biomarkers

	limit of detection (ng/mL)		
biomarker	ELISA	single OLSIA	multiplex OLISA
AFP	1.05	1.07	0.74
PSA	0.60	0.99	0.43
CEA	0.48	1.03	1.29

in OLISA for these markers (Figure 4), the signal increases linearly depending on the concentration of the markers in OLISA appears as reliable as those in ELISA. To assess sensitivity of OLISA and ELISA, we also determined the limit of detection (LOD) for each marker by interpolating each concentration curve with the average value of the blank plus 3 times the standard deviation of the blank. The LOD values calculated for both ELISA and OLISA are summarized in Table 2. For all three cancer markers, OLISA showed sensitivity comparable to ELISA, and the LOD values in OLISA were estimated about 1 ng/mL for all three cancer markers. More specifically, AFP could be analyzed by OLISA with almost the same sensitivity as by ELISA, while ELISA assays for CEA and PSA were slightly more sensitive than OLISA assays.

After establishing single OLISA for the markers with successful performance, we finally attempted to quantitate all three markers in a single aliquot of sample by multiplex OLISA. Since all three markers need to be measured simultaneously, analytical specificity for each is imperative. Therefore, the possibility of cross duplexation between DNA labels and RNA probes was examined by performing RNase H reactions in solutions containing one of three DNA sequences in the presence of all three RNA probes. As shown in Figure 5, fluorescence signals were amplified only at the emission wavelength of the fluorophore attached to the complementary RNA probe, proving that each DNA binds to its complementary RNA but not to others. We also tested cross-reactivity of the detection antibodies. After addition of each biomarker onto the microwells plated with the cAb, followed by incubation with a mixture of three DNA-dAbs, a mixture of the RNA probes was added along with RNase H to generate fluorescence signal and found that the fluorescence signal increased in an antigen-concentration-dependent fashion only at the emission wavelength of the fluorophore corresponding to the biomarker present in the assay (Figure 6). As this result indicated that false positive signals would not be observed in a multiplex format, a mixture of cAb_{AFP}, cAb_{PSA}, and cAb_{CEA} was used to coat the microwell plate for multiplex OLISA. After a mixture of all three cancer markers was added to the wells of the plate, a mixture of three DNA-dAbs was allowed to bind to the corresponding proteins as illustrated in Scheme 3. When fluorescence measurements at 535, 589, and 700 nm were made to identify and quantitate cancer markers in the mixture, amplifications of fluorescence with increasing concentrations of AFP, PSA, and CEA exhibited linear curves at corresponding wavelengths (Figure 7). The LODs for AFP, PSA, and CEA in this multiplex OLISA were determined as 0.74, 1.06, and 1.29 ng/mL, respectively, which are comparable to the values obtained from the single assays (Table 2).

To further evaluate analytical performance of the multiplex OLISA, precision and accuracy were determined by preparing 35 serum samples spiked with a mixture of 3 cancer markers at 20, 40, and 80 ng/mL in human serum, followed by analyses via the developed multiplex OLISA and calculations of CV and recovery. As summarized in Table 3, analysis at low concentrations resulted in less precise data as presented by high %CV values, which were generally observed in other previous immunoassay formats (*13*). AFP was more precisely detected than the other two markers, showing the lowest %CV values at

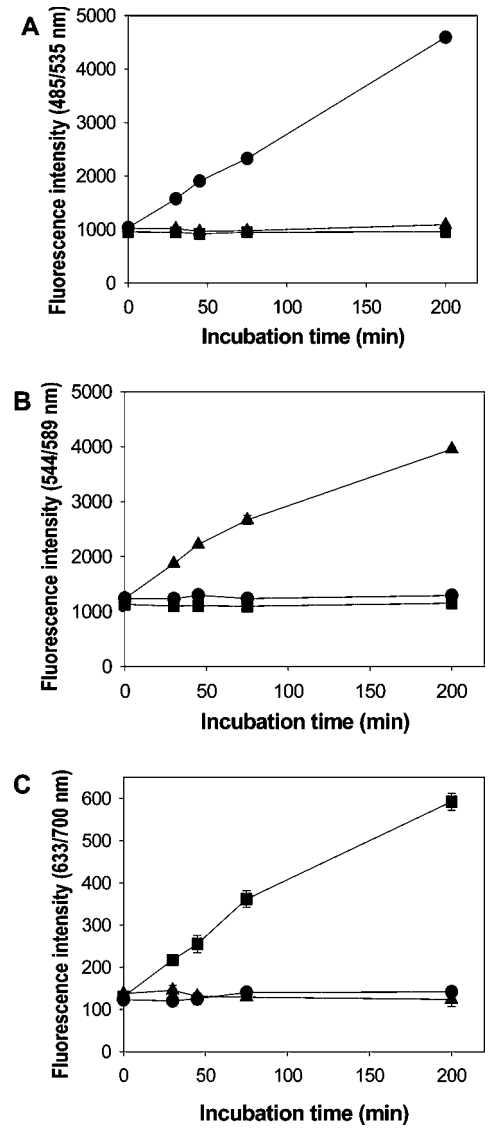

Figure 5. Specific degradation of RNA probes. RNA probe mixtures containing **F-RNA1-Q**, **F-RNA2-Q**, and **F-RNA3-Q** at 200 nM each in RNase H buffer were mixed with 500 pM of (A) **DNA1**, (B) **DNA2**, or (C) **DNA3** in the presence of RNase H (6 U), and incubated at 25 °C, followed by fluorescence measurements. Filled circles, triangles, and squares denote the fluorescence intensities obtained at 535, 589, and 700 nm upon excitation at 485, 544, and 633 nm, respectively.

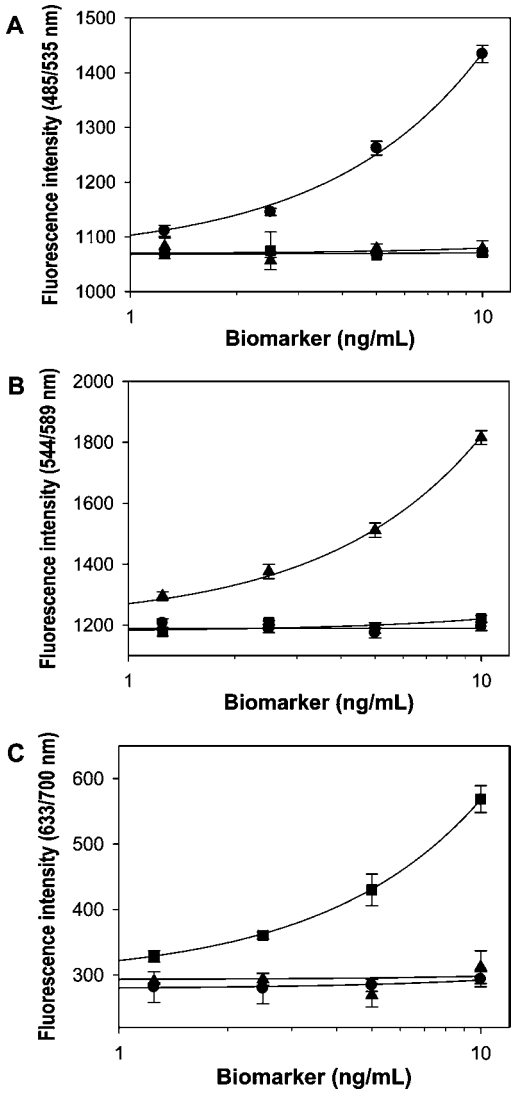
all concentrations. While the level of precision in multiplex OLISA did not reach that routinely obtained by ELISA (less than 10%), the precision obtained in a multiplex format could be regarded as acceptable for clinical applications. Accuracy values of multiplex OLISA as expressed in %Recovery ranged from 91% to 116%, which were also not inferior to those shown by previously developed multiplex immunoassays (*13*).

DISCUSSION

Recent advances in cancer proteomics and other related research have promoted identification of tumor biomarkers. Thus, there is an urgent need to utilize a panel of biomarkers for detecting the presence of cancer accurately and faithfully. Although ELISA is a highly quantitative and reproducible method, it is limited to measurement of one analyte per assay in general. To enable the present sandwich assay in well plate format to perform multiplexed assays, a novel detection strategy was devised in the present study for quantifying multiple protein biomarkers simultaneously. Our new assay named OLISA



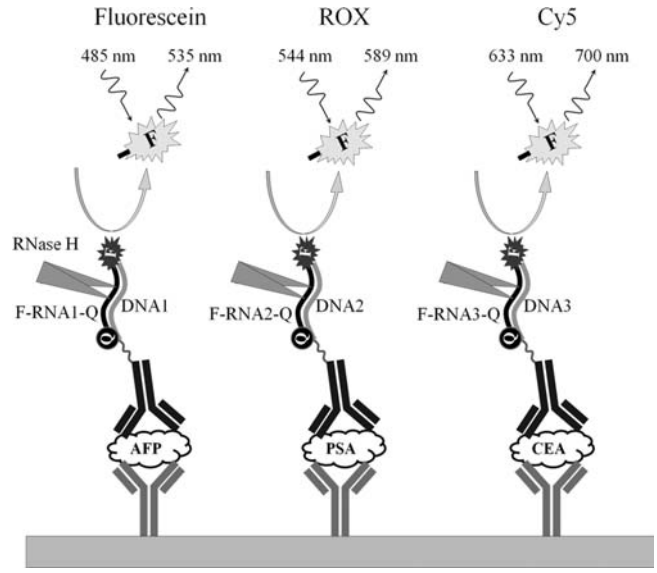


Figure 6. Specific fluorescence signal generation for biomarkers. Assays were performed as described in Experimental Procedures using a mixture of three DNA-dAb conjugates, followed by RNase H reaction in the presence of a mixture of **F-RNA1-Q**, **F-RNA2-Q**, and **F-RNA-3-Q** for (A) AFP, (B) PSA, or (C) CEA. Filled circles, triangles, and squares denote the fluorescence intensities obtained at 535, 589, and 700 nm upon excitation at 485, 544, and 633 nm, respectively.

employed DNA-conjugated dAbs, complementary RNA probes, and RNase H, which was optimized and validated using individual cancer biomarkers. In addition, simultaneous detection of three biomarkers was established to demonstrate the feasibility of the developed multiplex OLISA, which was facilitated by uniquely designed DNA labels that discriminate multiple analytes as intermediators of signal amplification.

Similarly to other multiplex immunoassays, multiplex OLISA is critically dependent on specificities of antibodies (*14*). Accordingly, a set of biomarkers including AFP, PSA, and CEA was chosen to demonstrate the feasibility of triplex OLISA since their monoclonal antibody pairs for the sandwich assays show no cross-reactivity to each other. As a result, successful performance of triplex OLISA has been attained, suggesting that OLISA could be applicable to reliable simultaneous detection of cancer biomarkers. The candidates include CA15-3 and CEA for breast cancer (*15*) or CA125, apolipoprotein, and α-chain of haptoglobin for ovarian cancer (*16, 17*) if appropriate antibodies are available. Because only a limited number of fluorophores can be selected to prevent spectral interference arising from excitation of a fluorophore by emission of another

Scheme 3. Design of Multiplex OLISA for Three Cancer Markers

fluorophore, less than 10 analytes can be practically assayed on multiplex OLISA. For the level of multiplexity, commercially available multiplex technologies such as Luminex xMAP technology and MSD system allow detection of up to 100 analytes in one sample. Despite its limited multiplexing capacity, our OLISA would be useful for clinical diagnosis based on a few biomarkers, since the cAb-coated microplates for multiplex OLISA can be readily prepared by simply mixing and incubating reagents similarly as for ELISA, and the operational procedures are analogous to those of ELISA.

Sensitivity, precision, accuracy, and linearity for OLISA have been characterized in a pre-study validation, which is mandatory before routine application of new analytical methods in order to ensure its fitness for purpose (*18*). AFP, PSA, and CEA are present in normal blood at less than 10, 4, and 5 ng/mL, respectively, whereas high levels of these markers are indicators

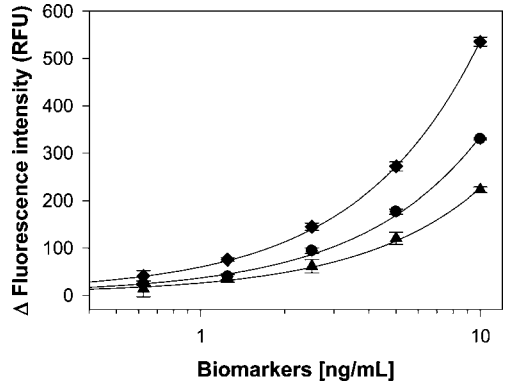

Figure 7. Multiplex OLISA for simultaneous detection of three cancer markers. Filled circles, triangles, and squares denote the data obtained for AFP, PSA, and CEA, respectively.

Table 3. Precision (%CV) and Accuracy (%Recovery) of Multiplex OLISA

	% CV/nominal concentration			% recovery/nominal concentration		
biomarker	20 ng/mL	40 ng/mL	80 ng/mL	20 ng/mL	40 ng/mL	80 ng/mL
AFP	7.9	3.1	3.3	91	98	96
PSA	8.7	12.8	7.0	113	105	99
CEA	20.8	16.8	11.6	116	96	102

of hepatocellular carcinoma, prostate cancer, and colorectal cancer, respectively, which are currently determined by ELISA as clinical tests. The LODs in multiplex OLISA as well as in OLISA for analysis of single markers are sensitive enough to cover the concentration ranges of the markers in clinical blood samples even after dilution. From the analyses of spiked serum samples, multiplex OLISA has been confirmed to satisfy the acceptance criteria of 20% for accuracy and precision to be adopted for immunoassay applications (*18*). Considering that other methods based on DNA−antibody conjugates including rolling circle amplification and immuno-PCR provide more sensitive immunoassays (*10, 11*), the sensitivity of OLISA needs to be improved by use of branched DNA or dendrimer molecules (*19, 20*) or by incorporating a rolling circle amplification reaction followed by RNase H reaction (*21*). Currently, we are working on modifying OLISA with a desire to create an ultrasensitive multiplex immunoassay.

In conclusion, we have devised an ELISA-based OLISA and demonstrated that OLISA is a convenient method to simultaneously detect multiple biomarkers in serum. OLISA exhibits comparable LODs to ELISA and reliable analytical performance. Moreover, OLISA could be multiplexed for simultaneous detection of three cancer markers in a sample solution with acceptable levels of precision and accuracy. Therefore, the developed multiplex OLISA would be well-suited for integrated analysis of individual ELISA-based methods for a few biomarkers.

Mixed Stimuli-Responsive Magnetic and Gold Nanoparticle System for Rapid Purification, Enrichment, and Detection of Biomarkers

Michael A. Nash, Paul Yager, Allan S. Hoffman, and Patrick S. Stayton*

Department of Bioengineering, University of Washington, Seattle, Washington 98195, United States. Received April 23, 2010; Revised Manuscript Received October 5, 2010

A new diagnostic system for the enrichment and detection of protein biomarkers from human plasma is presented. Gold nanoparticles (AuNPs) were surface-modified with a diblock copolymer synthesized using reversible addition−fragmentation chain transfer (RAFT) polymerization. The diblock copolymer contained a thermally responsive poly(*N*-isopropylacrylamide) (pNIPAAm) block, a cationic amine-containing block, and a semi-telechelic PEG_2-biotin end group. When a mixed suspension of 23 nm pNIPAAm-modified AuNPs was heated with pNIPAAm-coated 10 nm iron oxide magnetic nanoparticles (mNPs) in human plasma, the thermally responsive pNIPAAm directed the formation of mixed AuNP/mNP aggregates that could be separated efficiently with a magnet. Model studies showed that this mixed nanoparticle system could efficiently purify and strongly enrich the model biomarker protein streptavidin in spiked human plasma. A 10 ng/mL streptavidin sample was mixed with the biotinylated pNIPAAm-modified AuNPs and magnetically separated in the mixed nanoparticle system with pNIPAAm mNPs. The aggregates were concentrated into a 50-fold smaller fluid volume at room temperature where the gold nanoparticle reagent redissolved with the streptavidin target still bound. The concentrated gold-labeled streptavidin could be subsequently analyzed directly using lateral flow immunochromatography. This rapid capture and enrichment module thus utilizes the mixed stimuli-responsive nanoparticle system to achieve concentration of a gold-labeled biomarker that can be directly analyzed using lateral flow or other rapid diagnostic strategies.

INTRODUCTION

Diagnostic testing is expanding from centralized hospital laboratories to more distributed settings in both the developed and developing worlds. A current dominant point-of-care diagnostic test format is the lateral flow immunoassay (LFIA) (*1*), which relies on capillary wicking of fluids through porous nitrocellulose strips. Such tests typically rely on the specific binding between gold-labeled biomarkers with capture antibodies immobilized at the test line of the solid phase. Current devices possess many desirable features, such as being rapid, inexpensive, portable, and easy to use. However, they suffer from a limitation in sensitivity related to the small sample volume (*2*) that limits the biomarker repertoire to those at relatively higher blood and plasma concentrations (*3*). These limitations have created a need for rapid and simple sample processing strategies for purifying and enriching biomarkers in a form that could then be applied directly to the existing lateral flow tests or other types of newly developed rapid tests.

Magnetic separation and enrichment strategies represent one of the most common methods for biomarker purification and separation. We have recently described a stimuli-responsive magnetic nanoparticle system (*4*, *5*) that circumvents one of the primary limitations of magnetic separations. This nanoparticle system allowed the use of very small magnetic nanoparticles that optimize biomarker binding, while still allowing rapid magnetophoretic separation of thermally aggregated nanoparticle−biomarker complexes. This system was useful for purification and concentration, but additional steps of biomarker release and gold labeling for optimized visual detection would be required in lateral flow or flow-through tests. AuNPs have a long history as optical labels in immunoassay and biodetection (*6*−*13*) due to their large extinction coefficients (>10^9 M^{-1} cm^{-1}) in the visible range and enhanced electric near-fields at the particle surface. While one potential solution to simplifying this system would be to use a stimuli-responsive core−shell Au/mNP system (*14*−*19*), we present here the finding that mixed stimuli-responsive AuNPs and mNPs coaggregate efficiently.

This system thus achieves rapid magnetic separation of the Au-labeled biomarker in a simple mixture of separate stimuli-responsive nanoparticles where each can be optimized independently. Stimuli-responsive polymers such as poly(*N*-isopropylacrylamide) (pNIPAAm) with "smart" phase-transition properties have been shown to enhance the capture/separation capabilities of immunoassays (*20*). The work presented herein shows that the pNIPAAm-mNPs can capture the pNIPAAm-AuNPs through a coaggregation mechanism, so that the thermally triggered and high-efficiency enrichment of the Au-labeled biomarker to be used in lateral flow is achieved in one step. To our knowledge, this is the first time the general strategy of stimuli-responsive phase separations has been applied to synergistically direct coaggregation of nanoparticles with different compositions and functions, i.e., magnetic nanoparticles aggregated with a gold nanoparticle labeling reagent. The coaggregates are large enough to rapidly magnetophorese toward the applied magnet. This strategy for purification and enrichment might also circumvent the high-dose "hook" effect that can occur when excess sample antigen occupies all of the binding sites on the solid phase, preventing the gold-labeled antigen from binding (*21*). This confounds LFIAs, because it results in lower signal strength at high antigen concentrations. Magnetic separation eliminates the high-dose "hook" effect because only antigen molecules bound to a label are separated and applied to the flow strip. Magnetic separation/enrichment of the gold-labeled

biomarkers from larger plasma volumes could therefore not only increase the sensitivity of LFIA, but also eliminate sample-matrix-derived interferences.

EXPERIMENTAL PROCEDURES

Materials and Suppliers. *N*,*N*-Dimethylaminoethylacrylamide (DMAEAm; Monomer, Polymer, & Dajac Laboratories) was twice-distilled through a short path prior to use. NIPAAm (Sigma, 97%) was recrystallized from hexanes prior to use. 2,2-Azobis(2-methylpropionitrile) (AIBN; Aldrich, 98%) was recrystallized from methanol. The RAFT chain transfer agent 4-cyano-4-(dodecylsulfanylthiocarbonyl)sulfanyl pentanoic acid (DCT) was synthesized as described in the literature (*22*). 2-(Dodecylsulfanylthiocarbonylsulfanyl)-2-methylpropionic acid (DMP) was a gift from Noveon. Dioxane (EMD, 99%), dimethylformamide (DMF; EMD, 99.8%), dichloromethane (DCM; EMD, 99.8%), pentane (J. T. Baker, 99%), tetraglyme (Aldrich, 99%), methanol (MeOH; EMD, 99.9%), tetrahydrofuran (THF; Mallinckrodt, 99.8%), *N*,*N*′-dicycohexylcarbodiimide (DCC; Fluka, 99%), *N*-hydroxysuccinimide (NHS; Fluka, 97%), $HAuCl_4$ (Aldrich, 99.99%), $Fe(CO)_5$ (Aldrich, 99.9%), and D-biotin (Aldrich, 99%) were used as received. Cellulose ultrafiltration membranes for AuNP purification were from Millipore (regenerated cellulose, 44.5 mm diameter, NMWL 100 000, cat no. 14422AM), and PD-10 desalting columns were from GE Healthcare. NH_2-PEG_2-biotin, HABA biotin quantitation kit, and dialysis membranes (7 and 20 kDa MWCO) were purchased from Pierce. Streptavidin labeled with Alexafluor 750 (SA-750 streptavidin) was purchased from Invitrogen. Purified rabbit polyclonal anti-streptavidin IgG was purchased from Abcam (product no. Ab6676). 1× phosphate buffered saline packets (1× PBS; 10 mM phosphate, 138 mM NaCl, 2.7 mM KCl, pH 7.4 at 25 °C) were purchased from Sigma. Human plasma in disodium EDTA (Valley Biomedical Inc., product no. HP1051) was centrifuged at 1000 × *g* for 30 min, and filtered through GDX graded syringe filters (Whatman) prior to use. Magnets were NdFeB, 1.27 cm × 0.63 cm, Br max = 12.1 kGauss (Force Field Magnets.com). Nitrocellulose LFIA membranes were Millipore HiFlow Plus 180. Zymed nonspecific membrane blocking solution was purchased from Invitrogen.

Polymer Synthesis. RAFT polymerization was carried out using previously published procedures with slight modification (*4*). A homo-pNIPAAm polymer with a target molecular weight of 15 kDa was polymerized by dissolving in a round-bottom flask 2 g (17.7 mmol) of NIPAAm, 54 mg (0.134 mmol) of DCT, and 2.2 mg (13.4 μmol) of AIBN in 4 g *p*-dioxane. The flask was purged with N_2 for 30 min and heated at 60 °C for 12 h, followed by precipitation into pentane. The product was dried under vacuum, dialyzed against DI water at 4 °C, and freeze−dried. A 5 kDa homo-pNIPAAm for use in mNP synthesis was prepared by polymerization in a round-bottom flask containing 2 g (17.7 mmol) of NIPAAm, 143.3 mg (0.4 mmol) of DMP, 6.66 mg (40.5 μmol) of AIBN, and 4 g of *p*-dioxane. Precipitation and purification was carried out identically as for the 15 kDa homo-pNIPAAm.

Diblock extension was performed by dissolving in a round-bottom flask 1.32 g (83 μmol) of the ∼15 kDa homo-pNIPAAm mCTA, 0.2258 g (1.59 mmol) of DMAEAm, 0.18 g (1.59 mmol) of NIPAAm, 1.4 mg (8.3 μmol) of AIBN in 8 mL of MeOH. This resulted in a [DMAEAm]:[NIPAAm]:[mCTA]:[initiator] ratio of 18:18:1:0.1. The flask was purged with N_2 for 30 min, followed by heating at 60 °C for 18 h. The MeOH was removed by rotary evaporation, and the product was dissolved in 5 mL of THF and precipitated thrice into pentane. The precipitate was dried under vacuum, dissolved in DI water, purified by PD-10 desalting column, and freeze−dried.

Polymer Analysis. Polymers were characterized using GPC performed on an Agilent 1200 series liquid chromatography system, equipped with TSKgel alpha 3000 and TSKgel alpha 4000 columns (TOSOH biosciences). The mobile phase was LiBr (0.01 M) in HPLC-grade DMF at a flow rate of 1 mL/min. MALS data were obtained on a miniDAWN TREOS (Wyatt Technologies Corp.) with 658 nm laser source and three detectors at 45.8°, 90.0°, and 134.2°. The instrument calibration constant was 5.746×10^{-5} V^{-1} cm^{-1}. Refractive index was measured using an Optilab Rex detector (Wyatt Technologies Corp.). The d*n*/d*c* value for the homo-pNIPAAm macro-chain-transfer agent (mCTA) was determined under the assumption of 100% mass recovery. The d*n*/d*c* value for the diblock copolymer was determined by injecting polymer samples at known concentrations into the RI detector postcolumn. The d*n*/d*c* value was then calculated using linear regression with the *Astra 5.3.4.14* data analysis software package (Wyatt Technologies Corp.). ^1H NMR (300 MHz.) spectroscopy in $CDCl_3$ was performed on a Bruker AV300. Nanoparticle absorption was measured on a Hewlett-Packard 8453 diode array extinction spectrophotometer with quartz cuvette sample holder. TEM was performed on a Technai G2 F20 200 kV microscope. Absorbance and fluorescence measurements were made using a 96-well microplate reader (Tecan).

Biotinylation of Diblock Copolymer. NHS activation of the diblock copolymer was performed by dissolution of 1.29 g (73 μmol) of polymer, 76 mg (372 μmol) of DCC, and 42 mg (365 μmol) of NHS in 7 mL of DCM. The reaction proceeded for 24 h at 22 °C, at which time an additional 76 mg of DCC and 42 mg of NHS were added. The reaction was allowed to proceed for an additional 24 h. The mixture was precipitated into pentane and dried under vacuum. The NHS-activated polymer was then mixed with 100 mg (266 μmol) of NH_2-PEG_2-biotin in 3 mL of DMF. The conjugation proceeded for 48 h at 22 °C and was precipitated into diethyl ether. The product was dried under vacuum, dissolved in DI water, filtered through a 0.2 μm filter, and obtained through PD-10 column purification and freeze−drying. Biotinylation efficiency was estimated using a commercially available HABA biotin quantification kit carried out according to manufacturer's instructions.

Nanoparticle Synthesis and Characterization. Citrate-stabilized colloidal gold was prepared according to the literature (*23*). All glassware was cleaned with aqua regia, thoroughly rinsed with DI water, and dried in an oven before use. 150 mL of 0.1 mg/mL $HAuCl_4$ was brought to a boil in a round-bottom flask. 1.76 mL of 10 mg/mL sodium citrate in DI water was added. The reaction was boiled under reflux for 30 min and cooled to room temperature. The pH was raised to 8 by addition of 0.1 M NaOH. Next, 1.2 mL of a 10 mg/mL solution of 17.7 kDa biotinylated diblock copolymer in DI water was added. The flask was purged with N_2 for 45 min. The gold sol was then sealed and stirred at 22 °C for 24 h in darkness, after which 1 g of NaCl was added, followed by an additional 24 h of stirring. The particles were then concentrated under 35 psi of N_2 using a membrane ultrafiltration system with a cellulose membrane (MWCO = 100 000 kDa). The polymer-modified gold nanoparticles (AuNPs) were washed off of the membrane with 3 mL of PBS buffer. The AuNPs were stored in PBS at 4 °C under N_2 for up to 4 months and used for further streptavidin binding/enrichment studies.

Magnetic nanoparticles (mNPs) coated with 5 kDa homo-pNIPAAm (without biotin) were synthesized as previously described (*4*, *5*), with slight modification. Briefly, the 5 kDa homo-pNIPAAm was dissolved in tetraglyme (3.6 mM) at 100 °C. Iron pentacarbonyl ($Fe(CO)_5$) was filtered through a 0.45 μm syringe filter prior to use. Four microliters of $Fe(CO)_5$ per mL of tetraglyme was added. After 10 min of stirring, the temperature was raised to 180 °C for 5 h. The reaction was cooled, and the mNPs obtained by precipitation into pentane,

drying under vacuum, dialysis against DI water at 4 °C, and freeze−drying. The mNPs were then dissolved in DI water at 50 mg/mL and stored at 4 °C for up to 3 months. TEM samples were prepared by dissolving particles in DI water (1 nM for the AuNPs, and 3 mg/mL for the mNPs). Particle solutions were aerosolized onto carbon-stabilized Formvar-coated copper grids (Ted Pella) using a spray bottle.

Magnetic Enrichment of Alexafluor-750-Labeled Streptavidin. Pooled human plasma was diluted with an equal volume of 2× PBS (20 mM phosphate, 276 mM NaCl, 5.4 mM KCl, pH 8.0). Alexafluor-750-labeled streptavidin (AF-750 streptavidin) was spiked into the 50% human plasma at a concentration of 5 nM. Stock solutions of the nanoparticle reagents were added to achieve final concentrations of 3 nM and 2 mg/mL for the AuNPs and mNPs, respectively. 8 kDa homo-pNIPAAm free polymer was added to a final concentration of 2 mg/mL. As a negative control, 1 μM free biotin was included in the plasma dilution buffer. 100, 250, or 500 μL of the 5 nM AF-750 streptavidin in 50% human plasma was added to Eppendorf tubes. Samples were incubated for 15 min with orbital shaking (400 rpm) inside an aluminum tube-holder equilibrated in an incubator set to 45 °C. This was followed by incubation of the sample tubes in close contact with neodymium iron boron magnets for 15 min at 45 °C using an in-house fabricated magnet holder. Next, the supernatant was discarded with a pipet, and the precipitate that had been captured along the side of the tube was resuspended into 10 μL of 1× PBS pH 6.0 buffer at 4 °C. Fluorescence of the AF-750 streptavidin (λ_{ex} = 752 nm, λ_{em} = 776 nm), and absorbance of the AuNPs at 520 nm was measured using a fluorescence/absorbance microwell plate reader (Tecan).

LFIA Device Fabrication. Rabbit polyclonal antistreptavidin IgG was deposited at 3 mg/mL onto HiFlow 180 nitrocellulose assay membranes using an in-house fabricated protein striping system (*23*). The membrane was diced into rectangles measuring 16 × 3 mm^2 using a CO_2 laser system (Universal Laser Systems). The strips were submerged in goat protein nonspecific blocking solution (Zymed) for 30 min, followed by drying in a vacuum desiccator overnight. The strips were then applied to adhesive-coated Mylar substrates measuring 48 × 3 mm^2. An absorbent pad (35 × 3 mm) was placed at the distal end of the flow strip to drive capillary wicking of the fluids. The length of the overlap between the assay membrane and the absorbent pad was 3 mm. LFIA strips were stored in a desiccator at 23 °C and used within one week.

Effect of Streptavidin Dose on LFIA Signal. 200 μL samples of 50% human plasma containing variable amounts of nonfluorescent streptavidin, from 50 ng/mL to 0 ng/mL, were prepared. The AuNPs, mNPs, and 8 kDa homo-pNIPAAm were added to achieve final concentrations of 3 nM, 2 mg/mL, and 2 mg/mL, respectively. Heating, magnetic separation, and removal of the supernatant were performed as described in the fluorescent capture study (see above). The magnetically captured particle aggregates were resuspended into 10 μL of 1× PBS pH 6.0 at 4 °C. Ten microliter droplets of the captured protein/particle mixture were deposited into wells of a 96-well plate. LFIA strips were placed into the droplets, which completely wicked into the strips within 5−6 min. The membranes were then transferred to wells containing PBS pH 6.0 rinse buffer. The buffer rinse was allowed to proceed for 20 min, or until the absorbent pad was saturated. Imaging of the developed strips was performed using a digital camera (Canon SD400) on digital macro setting. Strips were illuminated from behind at an oblique angle using a white light source, and the transmission images were quantified by image analysis. All samples were run in triplicate on three separate LFIA strips and imaged under identical lighting conditions.

Image analysis was performed using *Image J* software. The background-corrected mean pixel intensity of the green channel in the RGB images was measured from a region of interest encompassing the leading edge of the antibody binding patch.

Effect of Increasing Sample Volume on LFIA Signal. 10 ng/mL of streptavidin in 50% human plasma was prepared. Stock solutions of the nanoparticle/polymer reagents were added to achieve final concentrations of 3 nM, 2 mg/mL, and 2 mg/mL for the AuNPs, mNPs, and 8 kDa homo-pNIPAAm free polymer, respectively. The stock protein/particle solution at a fixed streptavidin concentration (10 ng/mL) was divided into aliquots of 100, 200, 300, 400, or 500 μL. Each sample tube was processed as described above. The captured aggregates were resuspended into 10 μL of 1× PBS pH 6.0 buffer at 4 °C. 10 μL droplets of the concentrated particle mixture were run on the LFIA strips following the protocol described for the dose−response experiment (see above).

RESULTS

System Design. The bioseparation/enrichment system consists of a mixture of magnetic and gold nanoparticles, each with a "smart" polymer coating. Gold nanoparticles (∼25 nm diameter) were modified with a biotinylated amine-containing diblock copolymer, and magnetic nanoparticles (∼10 nm diameter) were synthesized directly with a homo-pNIPAAm polymer surface coating. When mixtures of these two particle types were heated above the polymer LCST, the particles coaggregated, driven by hydrophobic interactions between the collapsed polymers. 8 kDa homo-pNIPAAm (2 mg/mL) was added to the particle mixture to facilitate mNP and AuNP cross-aggregation. The aggregates contained both magnetic (iron oxide) and gold aggregates with a strongly enhanced magnetophoretic mobility that allowed them to be rapidly coseparated in an applied magnetic field gradient. The separation mechanism is depicted in Figure 1. By resuspending the magnetically captured particle aggregates into a smaller volume of fluid, the gold-labeled model target biomarker streptavidin could be concentrated many-fold. The enriched gold-labeled target protein was then analyzed and visualized with an antistreptavidin immunochromatographic flow strip.

Polymer Synthesis and Characterization. Polymer synthesis was carried out using two thermally initiated RAFT polymerizations. The target molecular weight of the first RAFT polymerization was 15 kDa. A [NIPAAm]:[CTA]:[Initiator] ratio of 132:1:0.1 was used in *p*-dioxane. The homo-pNIPAAm product (**(1)** in Figure 2) was purified and analyzed. GPC showed the polymer had M_n = 15.7 kDa, polydispersity index (PDI) = 1.01, and d*n*/d*c* of 0.074. ^{1}H NMR analysis confirmed the NIPAAm chemical shifts, with peaks at δ (ppm) 1.15 (s, R-CO-NH-CH-($C\underline{H}_3$)$_2$) and at 4.00 (s, R-CO-NH-C$\underline{H}$-(CH_3)$_2$). These two peaks had an integrated peak area ratio of ∼6:1, consistent with the proton ratio in the NIPAAm monomer.

Diblock extension was performed using the 15.7 kDa homo-pNIPAAm as a macrochain transfer agent (mCTA). The mCTA was chain extended with a short random copolymer block of NIPAAm-co-DMAEAm. [NIPAAm]:[DMAEAm]:[mCTA]:[Initiator] ratios of 18:18:1:0.1 were used in MeOH. MeOH was chosen because the mCTA was highly soluble in MeOH. The diblock copolymer (**(2)** in Figure 2) was found to have a M_n = 17.7 by MALS, PDI = 1.25, and d*n*/d*c* = 0.071. GPC traces of the mCTA and the diblock copolymer can be found in the Supporting Information (Figure S1). ^{1}H NMR of the diblock copolymer can be found in the Supporting Information (Figure S2). ^{1}H NMR results from diblock copolymer preparations showed that the chemical shift of the DMAEAm methyl group protons was dependent on the protonation state of the tertiary amine. Diblock copolymers treated with 10 equiv of NaOH to

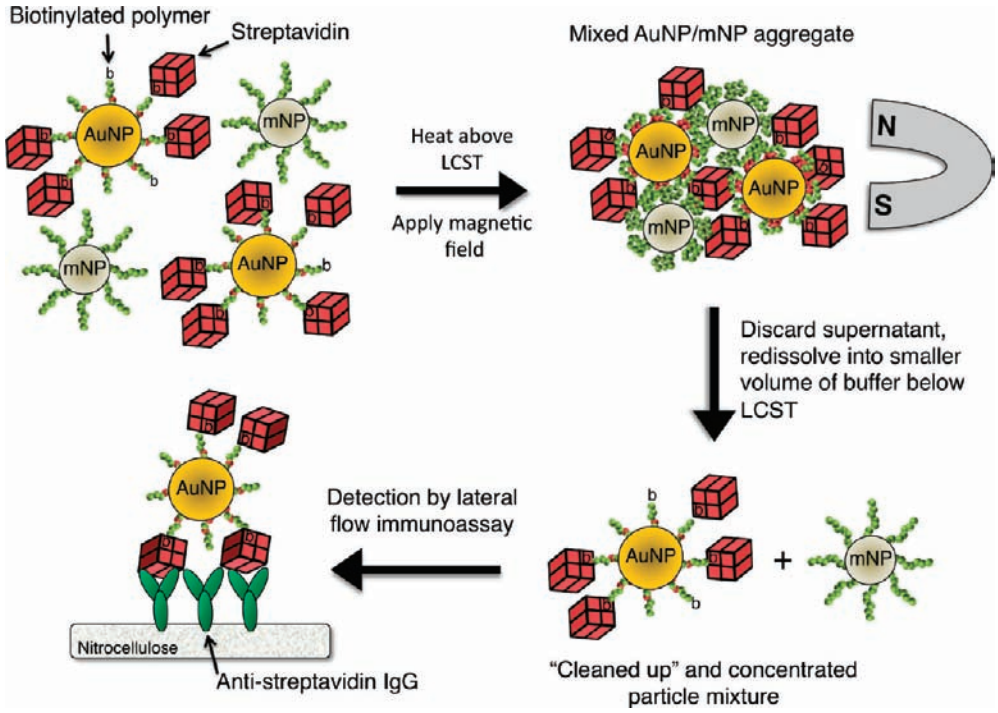

Figure 1. Dual nanoparticle magnetic separation scheme. AuNPs coated with biotinylated diblock copolymers bind to streptavidin spiked into 50% human plasma. mNPs coated with homo-pNIPAAm are added, and the temperature is raised above the polymer LCST. Mixed streptavidin−AuNP/mNP aggregates are separated by a magnet. The separated aggregates with gold-labeled target protein are resuspended into a smaller volume of buffer below the LCST and flowed through an LFIA strip with immobilized capture antibodies. Visualization of the target protein is achieved by AuNP light extinction at the capture line of the LFIA strip, while the non-biofunctional mNPs are rinsed away.

deprotonate the amines of DMAEAm were found to have DMAEAm methyl group shifts at δ (ppm) 2.26 (s, R-N(C$\underline{H}_3)_2$. Polymers treated with 10 equiv of HCl prior to NMR analysis, however, were found to have DMAEAm methyl group shifts at δ (ppm) = 3.1 (s, R-N(C$\underline{H}_3)_2$. Previous studies have reported the proton shift of the DMAEAm methyl group in monomeric form to be δ (ppm) 2.26 (*24*). In analyzing Supporting Information Figure S2, the four protons located between the amide and tertiary amine groups of DMAEAm were also assigned to the peak at δ (ppm) 3.1, which therefore represented 10 DMAEAm protons. The DPN of DMAEAm in the diblock was ∼15, based on the 1:1.15 integrated peak area ratio of the single NIPAAm hydrogen at δ (ppm) 4.0 to the 10 DMAEAm protons at δ (ppm) 3.1. The overall NIPAAm:DMAEAm ratio in the diblock copolymer was ∼9:1.

Biotinylation of Diblock Copolymer. The 17.7 kDa diblock copolymer was biotinylated via DCC/NHS ester activation and conjugation to NH_2-PEG_2-biotin. The dicyclohexylurea byproduct was removed using a 0.2 μm syringe filter. Biotinylation efficiency was measured by commercially available HABA dye-displacement assay (*25*). Known amounts of polymer were added to a solution of HABA-saturated avidin. The decrease in absorbance at 500 nm due to HABA dye displacement from the binding pocket was measured. A standard curve generated by addition of variable amounts of free biotin to the HABA-saturated avidin was used as a reference to quantify the number of available biotin moieties in the polymer preparations. The biotinylation efficiency was found to be 78% for the 17.7 kDa diblock copolymer. Results from the HABA dye displacement assay can be found in the Supporting Information (Figure S3).

Nanoparticle Synthesis and Characterization. Citrate-stabilized gold nanoparticles were synthesized using a protocol from the literature (*23*). Within 3 min of addition of sodium citrate to the boiling gold chloride solution, a rapid color change from yellow to deep red was observed. The positively charged diblock copolymer was allowed to interact with the negatively charged citrate-capped AuNPs overnight. In addition to electrostatics, chemisorption of the trithiocarbonate group from the RAFT CTA likely contributes to successful modification of the AuNPs (*26*). The polymer-modified AuNPs were then successfully transferred into 3 mL of 1× PBS buffer using membrane ultrafiltration. The AuNPs were washed off of the cellulose membrane and remained soluble for months stored in PBS buffer under N_2 at 4 °C. AuNPs were characterized by TEM imaging, particle sizing image analysis, and absorption spectrophotometry (Figure 3, top panel A−C). From TEM images, the AuNPs had pseudospherical morphology with diameter 23.5 ± 4.28 nm (mean ± standard deviation, no. of particles counted >200). The LSPR absorption peak (Figure 3, C) was observed at 530 nm. The extinction coefficient of the 23 nm AuNPs was estimated to be 2×10^9 M^{-1} cm^{-1} from sizing data and the literature (*27*). This molar extinction coefficient was used in further studies to estimate the concentration of the AuNPs.

Unlike citrate-stabilized AuNPs, the polymer-modified AuNPs were found to be colloidally stable in physiological buffers (e.g., PBS). The localized surface plasmon resonance (LSPR) wavelength did not red-shift after transfer of the particles into PBS buffer. The LSPR wavelength of the AuNPs was red-shifted upon raising the temperature above the LCST of the polymer (Figure 4C,D). Below the LCST, the gold colloid had an absorption peak at 530 nm, and transmitted white light appeared pink (Figure 4C). After raising the temperature above the LCST, the LSPR was red-shifted by ∼40 nm and the solution appeared purple (Figure 4D). The color change was due to dielectric coupling of LSPR oscillations between aggregated AuNPs in close proximity to each other (*28*). This behavior was similar to what has been previously reported on "smart" polymer−AuNP conjugates (*29*−*33*). Interestingly, the red shift of the LSPR was prevented upon addition of 0.2 mg/mL of homo-pNIPAAm free polymer. Addition of free polymer insulates the AuNPs from one another, preventing them from becoming sufficiently close in proximity to allow for coupling of the LSPR.

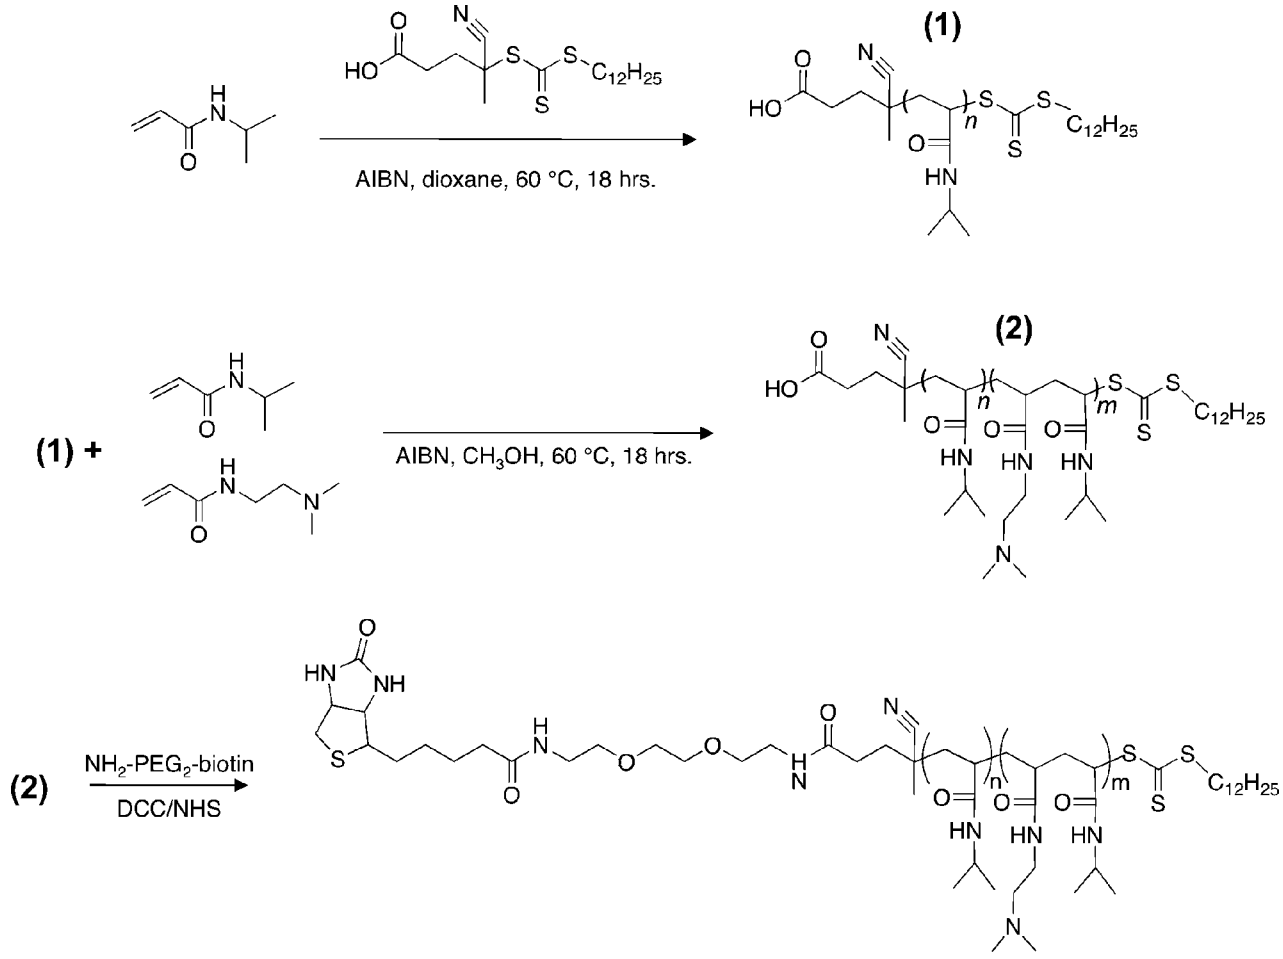

Figure 2. Diblock copolymerization scheme. The polymer contains a homo-pNIPAAm block ($n = 130$) for thermal responsiveness, a cationic DMAEAm-*co*-NIPAAm random copolymer block ($m = 15$) to drive adsorption onto anionic AuNPs, and a terminal biotin moiety.

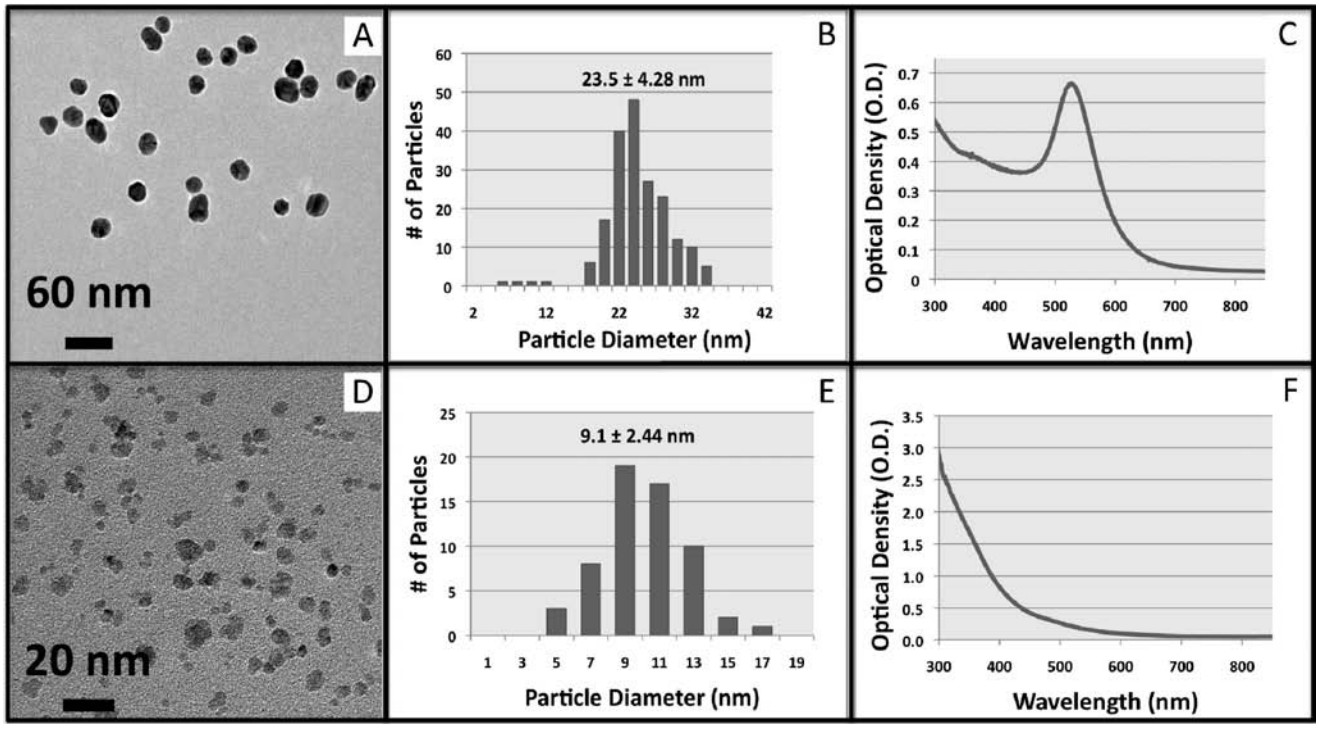

Figure 3. Characterization of magnetic and gold nanoparticles. TEM images, image analysis particle sizing histograms, and visible absorption spectra of AuNPs (top panel, A−C) and mNPs (bottom panel, D−F).

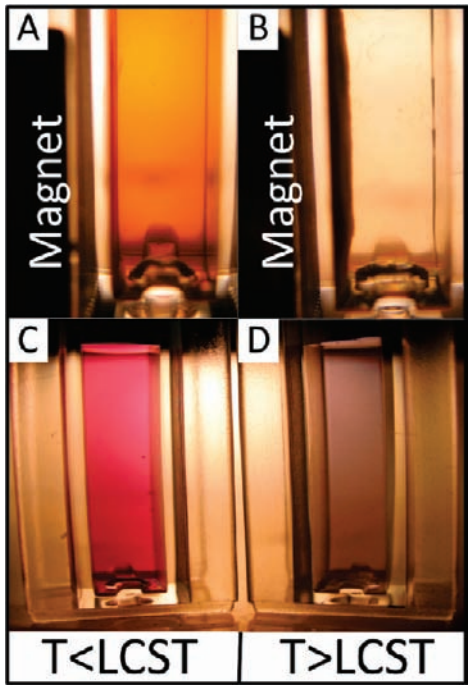

Figure 4. Photographs of white light transmittance through nanoparticle solutions. mNPs below the polymer LCST (A) do not respond to the magnet, but above the LCST (B) are aggregated and magnetically pulled against the cuvette wall. AuNPs below the LCST (C) appear pink, while above the LCST (D) appear purple due to aggregation and near-field plasmonic coupling.

The mNPs were synthesized using a 5 kDa homo-pNIPAAm, as previously described (*4*). This homo-pNIPAAm served as a stabilizer during mNP synthesis, resulting in pNIPAAm-coated mNPs. TEM and particle size analysis of the mNPs (Figure 3D,E) showed they have an average long-axis diameter of 9.1 ± 2.44 nm (mean ± standard deviation, no. of particles counted >60). The optical absorption spectrum of the mNPs showed a Rayleigh scattering profile, as seen in Figure 3F. The mNPs exhibited a thermally triggered increase in the magnetophoretic mobility, as has been previously described (*4, 5, 34, 35*). This behavior is demonstrated in Figure 4A,B. Below the LCST (Figure 4A), the mNPs did not rapidly respond to the magnet placed against the side of the cuvette, because they exist as <10 nm particles. When the temperature was raised above the polymer LCST (Figure 4B), the large aggregates had much larger magnetophoretic mobility and were rapidly separated against the cuvette side-wall by the magnet.

Both particle types (AuNPs and mNPs) therefore exhibit thermally triggered aggregation that modulates their magnetic and/or optical properties. It was found that mixtures of these two particle types possessed the magnetic separation behavior of the mNPs combined with the optical extinction properties of the AuNPs. AuNPs modified with the diblock copolymers could therefore be magnetically separated upon coaggregation with the pNIPAAm-coated mNPs and application of a magnetic field gradient. Video stills demonstrating magnetic separation of AuNPs can be found in the Supporting Information (Figure S4).

Magnetic Enrichment of Alexafluor-750-Labeled Streptavidin. As a validation of the bioseparation technique, we tested the ability of AuNPs to bind fluorescently labeled streptavidin, and concentrate the target protein via polymer-induced coaggregation and magnetic separation with mNPs. An advantage of this nanoparticle system is the ability to process large sample volumes as easily as microliter quantities. This capability was demonstrated by increasing the total processed sample volume at a fixed concentration of labeled streptavidin. AF-750 streptavidin (5 nM) spiked into 50% human plasma was used to mimic a clinical sample. Three nanomoles per liter of diblock-copolymer-modified AuNPs, 2 mg/mL mNPs, and 2 mg/mL of 8 kDa homo-pNPAAm were added sequentially. Each AuNP is expected to bind no more than 50 streptavidin molecules based on nanoparticle size and a theoretical streptavidin monolayer density of 2.8 ng/mm^2 (*36*).

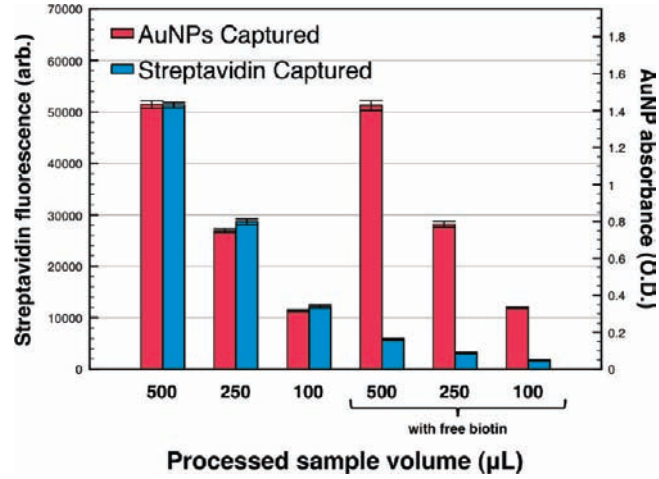

Figure 5. Magnetic enrichment of fluorescent streptavidin by AuNP/mNP mixtures. AF-750 labeled streptavidin fluorescence and AuNP absorbance were measured after processing variable volumes of 50% human plasma containing 5 nM fluorescent streptavidin. In all cases, the captured particles were redissolved into 10 μL of PBS 6.0 buffer, achieving a 50-fold, 25-fold, or 10-fold particle/protein enrichment factor for the 500, 250, and 100 μL samples, respectively. Samples spiked with 1 μM free biotin served as negative controls to block the streptavidin binding sites preventing fluorescence capture, while particle capture/absorbance remained high.

Samples of 100, 250, or 500 μL were heated to 45 °C causing polymer collapse and mixed AuNP/mNP aggregate self-assembly. A magnet was applied, and the aggregates were captured at the side of the carrying vessel. The supernatant was discarded, and the captured pellet was redissolved into a 10 μL volume of cool (<LCST) PBS 6.0 buffer. Figure 5 shows fluorescence and absorbance measurements taken on the redissolved aggregates below the LCST. Data bars in Figure 5 represent mean ± SD (n = 5) of labeled streptavidin fluorescent intensity at 776 nm or particle absorbance at 520 nm. Increasing the sample volume results in a corresponding linear increase in the AuNP absorbance and streptavidin fluorescence. In the presence of free biotin, the streptavidin binding sites are blocked and fluorescence capture is eliminated, demonstrating that capture is occurring via specific streptavidin−biotin binding. Only a small amount of fluorescence is captured due to nonspecific adsorption of the labeled streptavidin to the nanoparticle/polymer aggregates.

LFIA Device Fabrication. We further demonstrated the capabilities of the bioseparation/enrichment system by developing a quantitative lateral flow immunoassay of the model protein analyte streptavidin. LFIA strips were fabricated using an in-house protein striping system (*23*) capable of depositing the capture antibody (rabbit polyclonal antistreptavidin IgG) within the confines of a narrow line ~1.5 mm in width onto nitrocellulose substrates. The nitrocellulose strips and absorbent wicking pads were placed onto adhesive-coated Mylar. An image of the lateral flow strip can be seen in Figure 6, top.

Effect of Streptavidin Dose on LFIA Signal. Figure 6 shows the light extinction signal generated by processing varying amounts of streptavidin from 200 μL sample volumes and flowing the resuspended particle mixtures through the capture antibody line on the LFIA strips, followed by a rinse step. The curve is linear with a limit of detection of 6 ng/mL, determined

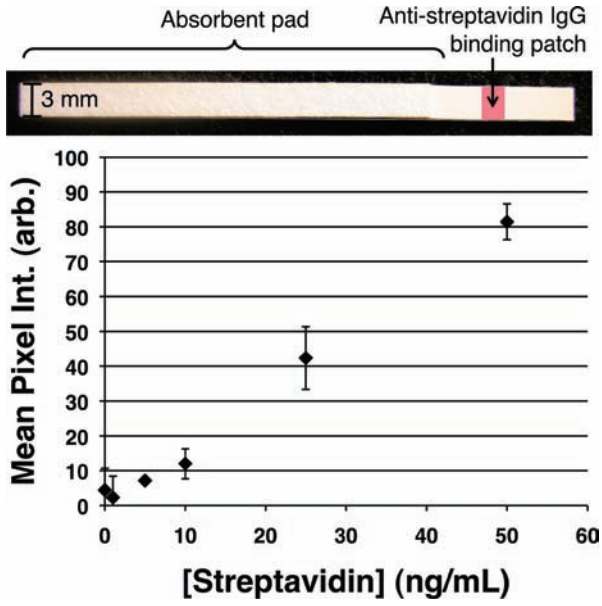

Figure 6. Lateral flow immunoassay standard curve. (Top) Image of the flow strip. (Bottom) Variable amounts of streptavidin spiked into 50% human plasma samples were captured at a fixed sample volume of 200 μL. The background-subtracted mean pixel intensity (mean $\pm$ SD, ($n = 3$)) at the leading edge of the antistreptavidin IgG binding patch on the nitrocellulose membrane was measured using *Image J*.

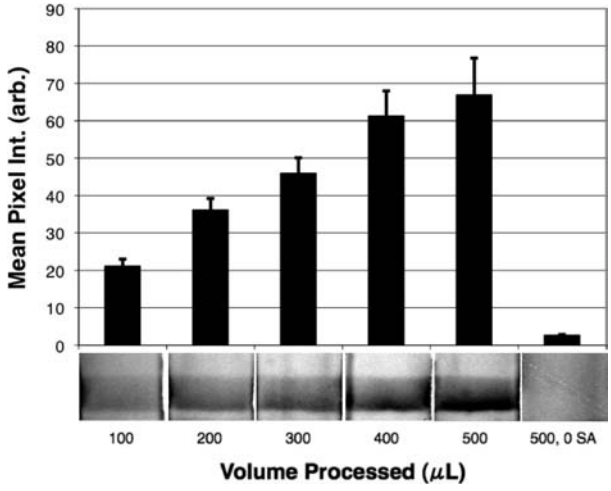

Figure 7. Effect of increasing sample volume on LFIA signal. Increasing sample volumes from 100 to 500 μL each with the same concentration of streptavidin (10 ng/mL) were processed using the AuNP/mNP bioseparaton method. 500 μL of 50% human plasma containing the nanoparticle reagents but no streptavidin (500, 0 SA) served as the negative control.

using 3 times the standard error of the zero antigen sample as the lower signal limit. The dual AuNP/mNP nanoparticle system is therefore able to generate specific signal proportional to the amount of diagnostic target in the sample, facilitating quantitative assays when combined with optical reader technologies.

Effect of Concentrating Model Biomarker from a Larger Sample Volume on LFIA Signal. By increasing the volume of the sample processed at a fixed concentration of streptavidin, we effectively capture more molecules of the target protein, which translates into increased light extinction at the test line of the LFIA strip. Figure 7 shows the increase in LFIA signal that was accomplished by increasing the sample volumes from 100 to 500 μL for a fixed 10 ng/mL of streptavidin. A 500 μL sample without streptavidin (500, 0 SA) served as the negative control. These results demonstrate that the smart nanoparticle system can increase the signal at a fixed analyte concentration by processing larger volumes of sample. Where larger samples can be obtained from the patient, this finding has implications for opening up new biomarkers to point-of-care testing that are currently too dilute to be detected by conventional nonconcentrating LFIA.

DISCUSSION

These results demonstrate the possibility of enhancing the performance of rapid tests using the dual AuNP/mNP system to achieve rapid and integrated biomarker labeling, purification, enrichment, and detection. Our key innovation was using stimuli-responsive coatings to direct coaggregation of two different types of nanoparticles, each with predesigned functionalities. The mNPs enable separation/enrichment of the diagnostic target bound to the AuNPs when the aggregate size is large enough to achieve rapid magnetophoretic separations, while the AuNPs provide a high-efficiency absorbing species by which the target molecule is visualized without the need for advanced optical instrumentation. A primary advantage of the mixed nanoparticle system compared to the core−shell nanoparticle approach is that it allows the direct purification of the gold-biomarker detection half-sandwich species. This half-sandwich is the active species that can be applied directly to lateral flow or flow-through diagnostic tests without the complications of having magnetic nanoparticles also bound to the biomarker. A second advantage of the dual particle system over a magnetic-core/gold-shell nanoparticle system is the ability to independently control the stoichiometric ratios of the magnetic and gold particles. This allows optimization of each particle type independent from one another and also facilitates tuning the magnetophoresis behavior. For example, when magnetophoresis is found to be slow, more magnetic particles can be added to improve the separation without changing the amount of detection gold nanoparticles in the mixture. This may allow more efficient optimization of signal to background noise in some assay systems. Future work will focus on transferring these proof-of-concept results to a real biomarker system by incorporating capture antibodies onto the AuNPs for disease-related and multiplexed antigen detection from clinical samples.

Supporting Figure S2. ^{1}H-NMR (300 MHz in $CDCl_3$) of the 17.7 kDa diblock copolymer before biotinylation (compound (2) in Figure 2).

Supporting Figure S3. Quantitation of biotinylation efficiency. HABA dye-displacement assay on the 17.7 kDa biotinylated diblock copolymer was performed with free biotin as a standard reference. The biotinylation efficiency was found to be ~78%.

Supporting Figure S4. Video stills of dual AuNP/mNP co-aggregation and magnetic separation. For the purposes of the video, the sample comprised 250 μL of the AuNP/mNP/homo-pNIPAAm mixture in PBS buffer. 250 μL of 5M NaCl was used to trigger the pNIPAAm phase transition seconds before image 1 was acquired. The magnet was then applied for a total of 20 minutes. Comparable magnetic separation behavior was observed for mixtures that were co-aggregated using a thermal stimulus. The AuNP particle capture efficiency was evaluated by measuring the absorbance at 530 nm before and after magnetic capture and resuspension into an equal volume of fluid below the LCST. Typical nanoparticle capture efficiencies from 50% human plasma were found to be 75-85%.

Intracellular Delivery of a Protein Antigen with an Endosomal-Releasing Polymer Enhances CD8 T-Cell Production and Prophylactic Vaccine Efficacy

Protein-based vaccines have significant potential as infectious disease and anticancer therapeutics, but clinical impact has been limited in some applications by their inability to generate a coordinated cellular immune response. Here, a pH-responsive carrier incorporating poly(propylacrylic acid) (PPAA) was evaluated to test whether improved cytosolic delivery of a protein antigen could enhance CD8+ cytotoxic lymphocyte generation and prophylactic tumor vaccine responses. PPAA was directly conjugated to the model ovalbumin antigen via reducible disulfide linkages and was also tested in a particulate formulation after condensation with cationic poly(dimethylaminoethyl methacrylate) (PDMAEMA). Intracellular trafficking studies revealed that both PPAA-containing formulations were stably internalized and evaded exocytotic pathways, leading to increased intracellular accumulation and potential access to the cytosolic MHC-1 antigen presentation pathway. In an EG.7-OVA mouse tumor protection model, both PPAA-containing carriers robustly inhibited tumor growth and led to an approximately 3.5-fold increase in the longevity of tumor-free survival relative to controls. Mechanistically, this response was attributed to the 8-fold increase in production of ovalbumin-specific CD8+ T-lymphocytes and an 11-fold increase in production of antiovalbumin IgG. Significantly, this is one of the first demonstrated examples of in vivo immunotherapeutic efficacy using soluble protein−polymer conjugates. These results suggest that carriers enhancing cytosolic delivery of protein antigens could lead to more robust CD8+ T-cell response and demonstrate the potential of pH-responsive PPAA-based carriers for therapeutic vaccine applications.

INTRODUCTION

There is continuing effort to develop more effective vaccines for infectious disease and as a therapeutic modality for cancer. For protein-based vaccines that represent an outside-in delivery paradigm, a considerable challenge is the intracellular delivery of antigens into the cytosol of antigen presenting cells (APCs) where the class I antigen presentation pathway may be more efficiently accessed. This pathway leads to generation of CD8+ cytotoxic T-lymphocytes (CTLs), which are capable of immunorecognition and direct apoptotic induction in cancer cells (*1, 2*). A diversity of approaches has been explored for delivering antigens to optimally stimulate CD8+ T-cell responses. Incorporation of MHC-1 adjuvants, such as CpG-DNA (*3*) or toll-like receptor (TLR) ligands (*4, 5*) into carrier formulations has been utilized to promote MHC-1 antigen presentation and induce production of antigen-specific CD8+ T-cells. Additionally, recombinant viral vectors have been employed as inside-out strategies for efficiently transfecting target cells (*6, 7*), and fusion with bacterial toxins (*8, 9*) has also been employed to enhance cytosolic delivery of vaccine antigens.

Synthetic carriers for protein antigen delivery have been intensively investigated to circumvent the safety concerns of viral vectors, but their efficiency is generally significantly lower. Liposomal systems (*10−13*), particles formed from poly(D,L-lactic-*co*-glycolic acid) (PLGA), and micelle carriers have been investigated for antigen delivery (*14−22*). There is substantial evidence from these studies that particle and micelle based systems yield a more efficient MHC-1 response relative to soluble conjugates due to uptake via phagocytotic pathways, as well as the possible adjuvancy of PLGA itself (*14, 15, 18, 23−25*).

The majority of synthetic vaccine delivery vehicles have been designed to explore or exploit the effects of particle size on immune response, but relatively little attention has been paid to other strategies for directing intracellular trafficking of antigens within APCs. Previous studies have employed pH-responsive degradable elements based on poly(L-glutamic acid)-poly(L-phenylalanine ethyl ester) (*26, 27*) and acid-labile particles and microgels that degrade at endosomal pH (*28−31*). However, pH-responsive polymeric carriers that actively alter vesicular trafficking pathways and promote endosomal escape of protein or peptide antigens have not been previously explored. This study aimed at testing whether an endosomal-releasing carrier would increase generation of antigen-specific CD8+ T-cells and provide a prophylactic effect in the ovalbumin vaccine model. Poly(propylacrylic acid) (PPAA)-based carriers have been investigated for intracellular delivery of biologic drugs including proteins, peptides, and siRNA (*32−40*). A PPAA carrier has previously been shown to enhance MHC-1 presentation and specific T-cell activation in an in vitro ovalbumin cell culture model (*41*). The present study further explored the mechanism of PPAA as a protein vaccine carrier and evaluated its efficacy in an in vivo mouse tumor protection model that allowed quantitation of the ovalbumin-specific CD8+ T-cell response. Both soluble conjugate and particulate PPAA-based formulations were tested, and importantly, both carriers were able to stimulate specific CD8+ T-cell development, antibody production, and significant tumor protection responses in vivo. These data show the potential of PPAA-based systems for

vaccine delivery and also suggest that modulating intracellular trafficking might enhance the effectiveness of induced immune responses.

EXPERIMENTAL PROCEDURES

Polymer Synthesis and Formulation with Ovalbumin. The synthesis and characterization of PPAA and poly(methacrylic acid) (PMAA) polymers and ovalbumin conjugates has been described previously (*41*). Briefly, PPAA was prepared by bulk free radical polymerization at 60 °C using the initiator azobisisobutyronitrile (AIBN). PMAA was prepared as a control polymer with similar structure to PPAA except that, due to its lower pK_a and decreased hydrophobicity, it does not enable effective endosomal escape (*41*). PMAA was prepared by reversible addition−fragmentation chain transfer (RAFT) polymerization at 40 °C using the chain transfer agent 4-cyanopentanoic acid dithiobenzoate (*41*) (CPAD) and the initiator 2,2′-azobis (2,4-dimethyl valeronitrile) (V65) in the absence of oxygen. A pyridyl disulfide functional acrylate monomer (PDSA) (*37*) was incorporated into these polymers at 3−5 mol % to provide protein conjugation sites. The polymers were purified by three rounds of precipitation from dimethyl formamide into diethyl ether. Characterization was performed by H^1 NMR and by spectrophotometric quantification of pyridine 2-thione release following reduction with dithiothreitol (DTT). Polymer molecular weight and polydispersity were determined by gel permeation chromatography (GPC) (Viscotek VE2001 sample module, VE3580 RI Detector, Waters Corp. Ultrahydrogel columns) in 0.1 M sodium phosphate buffer, pH 8, using poly(ethylene oxide) (PEO) standards (Polysciences, Inc., Warrington, PA).

Cationic poly(dimethylaminoethyl methacrylate) (PDMAEMA) was synthesized for nanoparticle formation driven by ionic complexation with anionic PPAA ovalbumin conjugates. DMAEMA monomer (Sigma-Aldrich) was distilled and polymerized using RAFT in the absence of oxygen at 33 wt % monomer in DMF at 30 °C for 16 h. 4-Cyano-4-(ethylsulfanylthiocarbonyl)sulfanyl pentanoic acid (ECT) served as the chain transfer agent (CTA) and 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) (V-70) was the radical initiator at an [ECT]/[V-70] molar ratio of 10. PDMAEMA was isolated by precipitation three times in 50% diethyl ether/50% pentane. Molecular weights were determined using GPC run with a DMF 0.1 wt % LiBr mobile phase at 60 °C and based on elution times of poly(methyl methacrylate) (PMMA) standards.

Ovalbumin (Ova) was conjugated to PPAA and PMAA via disulfide exchange reactions. Thiol groups were incorporated into ovalbumin using 2-iminothiolane (Traut's Reagent) as previously described (*41*). Thiolated proteins were subsequently reacted with the pendant pyridyl disulfide groups on the PPAA and PMAA polymers. Disulfide exchange reactions were carried out with a 2.5:1 molar ratio (polymer/ovalbumin) in 0.1 M phosphate buffer, pH 7.8, 0.15 M NaCl, 5 mM EDTA. Conjugation efficiency was quantified by measuring absorbance at 343 nm of the pyridine-2-thione, which is released upon disulfide exchange. PPAA−ovalbumin (PPAA-Ova) and PMAA−ovalbumin (PMAA-Ova) conjugates were purified using PD-10 desalting columns (GE Healthcare).

Particles containing PPAA-Ova soluble conjugates were formed by ionic complexation of cationic PDMAEMA with the anionic PPAA-Ova conjugate (PPAA-Ova/PDMAEMA). To form particles, PPAA-Ova conjugates were dissolved in PBS, pH 7.4, and PDMAEMA was added at ∓ charge ratios ranging from 1:1 to 60:1 The particle size and zeta potential were measured using a Brookhaven BI90Plus instrument, and particle sizes are reported as the number average. Particle size standard deviations were calculated from the reported polydispersity as previously described (*41*), and particle formation conditions were identified for subsequent testing based on production of nanoparticles in a desirable size range.

In Vitro Analyses of PPAA-Ova Conjugates and PPAA-Ova/PDMAEMA Particles. *Cytotoxicity of Polymer−Ovalbumin Conjugates and Particles.* The cytotoxicity of PPAA-Ova soluble conjugate and PPAA-Ova/PDMAEMA particulate delivery systems was tested in RAW macrophages using the Alamar Blue cytotoxicity assay. RAW macrophages were plated at 25 000 cells per well in 150 μL media (DMEM supplemented with 10% fetal bovine serum (FBS)) in a 96-well plate and incubated for 30 min at 37 °C. Alamar Blue reagent (20 μL) was added to each well, and PPAA-Ova conjugates or PPAA-Ova/PDMAEMA particles were added to the cells at polymer concentrations of 100 μg/mL, 200 μg/mL, 500 μg/mL, and 750 μg/mL. Samples were incubated for 24 h, and fluorescence was measured using a fluorescence plate reader. Percent viability compared to untreated cells was calculated for each sample.

Intracellular Uptake and Exocytotic Trafficking of PPAA-^{14}C-Ova and PPAA-^{14}C-Ova/PDMAEMA in Macrophages. Radiolabled conjugates were prepared for uptake and exocytosis studies as described previously (*41*). Briefly, Traut's reagent was reacted with ovalbumin at a 20-fold excess, followed by a 3-fold molar excess of ^{14}C-iodoacetamide (MP Biomedical). Polymer−Ova conjugation and particle formulation was subsequently completed as described above. To assess intracellular uptake, RAW macrophages were plated in a 48-well plate at 75 000 cells/well and allowed to grow overnight. Then, ^{14}C-Ova, PPAA-^{14}C-Ova, PMAA-^{14}C-Ova, or PPAA-^{14}C-Ova/PDMAEMA was added to the cells at a concentration of 50 μg/mL ovalbumin ($n \geq 3$ per treatment). Samples were incubated for 1 min and were then washed twice with PBS and lysed using 1% Triton X-100 in water. Radioactivity in the cell media, PBS wash, and cell lysate was measured using a liquid scintillation counter. Percent uptake of ^{14}C-ovalbumin was calculated based on the percent of the total radioactivity delivered that was present in the cell lysate.

Exocytosis studies were completed to gauge the ability of each of the Ova formulations to escape vesicular entrapment and endocytosis/exocytosis trafficking pathways in order to access the cytosolic MHC-1 presentation pathway. In these studies, ^{14}C-Ova, PMAA-^{14}C-Ova, PPAA-^{14}C-Ova, or PPAA-^{14}C-Ova/PDMAEMA was added to RAW cells at a concentration of 50 μg/mL ovalbumin ($n \geq 3$ per treatment). Samples were incubated for 15 min, media containing non-internalized ovalbumin was aspirated, and cells were washed twice with media. In a subset of samples, the percentage of the total ^{14}C-ovalbumin delivered that was internalized during the initial 15 min pulse was determined using cell lysates gathered in 1% Triton X. Parallel samples were then incubated with new media, which was then collected and replaced with fresh media at 5 min, 10 min, 20 min, 30 min, 1 h, 2 h, and 4 h. After 4 h, the cells were treated with 1% Triton X and the cell lysates were collected. ^{14}C-ovalbumin recycled into the extracellular media was quantified at each time point, and the quantity remaining in the cell lysates after 4 h was determined as a percentage of the quantity of ^{14}C-ovalbumin internalized during the initial 15 min pulse.

In Vivo Tumor Protection Against Ovalbumin Expressing Tumors. All animal studies were performed in compliance with the University of Washington Animal Care and Use Committee. Female C57Bl/6 mice 7−8 weeks old were purchased from Jackson Laboratories. E.G7-OVA thymoma cells stably transfected with the ovalbumin gene leading to cell surface expression of ovalbumin epitopes were obtained from ATCC and cultured per the supplier's instructions. Mice were anesthetized with isofluorane and injected subcutaneously on the dorsum with 150

μL of PBS, Ova, PMAA-Ova, PPAA-Ova, or PPAA-Ova/PDMAEMA, with an equivalent of 100 μg ovalbumin delivered to each mouse ($n \geq 4$ per group). Seven days after vaccination, mice were anesthetized and the hair on the left flank was removed using depilatory cream. The E.G7-OVA tumor cells (1×10^6 cells per mouse) were injected in a volume of 100 μL PBS subcutaneously on the left flank. Mice were monitored every 2−3 days, and tumor length and width were measured using digital calipers. Tumor volume was estimated using the commonly employed formula that is based on an ellipsoid geometry (*30, 42*).

Flow Cytometric Tetramer Detection of Ovalbumin-Specific CD8+ T-Cell Response in Vivo. In order to assess the ability of the PPAA carrier to induce CD8+ T-cell production, a flow cytometric assay using phycoerythrin (PE)-conjugated iTAg MHC-1 tetramers (Immunomics/Beckman Coulter) was used. MHC-1 tetramers have been employed to evaluate CD8+ responses in vaccine strategies using ovalbumin (*42*−*44*), as well as other antigens (*45, 46*). Here, the fluorescently labeled tetramers (PE-MHC-1/SIINFEKL) are complexes of MHC molecules and a specific ovalbumin epitope (SIINFEKL) that allows for the evaluation of the percentage of CD8+ T-cells from spleens of immunized mice that can recognize this specific ovalbumin fragment presented via an MHC-1 mechanism. For this experiment, 6−8-week-old female C57Bl/6 mice (4 per group) were immunized subcutaneously with 150 μL of PBS, Ova, PMAA-Ova, PPAA-Ova, or PPAA-Ova/PDMAEMA, with an equivalent of 100 μg ovalbumin delivered to each mouse. Seven days later, mice were euthanized and their spleens harvested. Spleens were forced through a 100 μm cell strainer into a Petri dish containing DMEM culture medium. Cells were counted and resuspended at 8×10^6 cells/mL. They were then stained according to the manufacturer's protocol, in addition to simultaneous staining with a FITC-labeled rat antimouse CD8a antibody to allow for identification of CD8+ T-cells within the heterogeneous cell population. The cells were analyzed using flow cytometry, and the percent of CD8 cells that stained positive for PE-MHC-1/SIINFEKL was determined.

ELISA Measurement of In Vivo Antibody Response. To evaluate the humoral immune response to the administered vaccines, the production of antiovalbumin IgG antibody was measured for the mice in the tumor study. Plasma was collected from blood harvested retro-orbitally and assayed for antiovalbumin IgG using a modification of the ELISA procedure described by Chung et al. (*47*). Nunc Maxisorp 96-well plates were coated overnight with 5 μg/mL ovalbumin at 4 °C and then blocked with 1% bovine serum albumin (BSA) solution in PBS for 1.5 h at room temperature. Plasma samples diluted 1:5000 in PBS and antiovalbumin standards (3−200 ng/mL clone OVA-14 IgG1, Sigma) were added in triplicate for 3 h at room temperature. The plate was washed 3 times with PBS−Tween and treated for 2 h with goat antimouse IgG conjugated to peroxidase (Sigma) at 1:3000 in 0.1% BSA PBS−Tween. The plate was washed 3 times with PBS−Tween, and SureBlue Reserve TMB peroxidase substrate (KPL Inc.) was used to quantify antiovalbumin antibody concentration in plasma samples relative to the standards by measuring absorbance at 450 nm.

Statistical Analysis. ANOVA was utilized to test for treatment effects, and Tukey's test was employed for posthoc comparisons. Significant differences were defined as $p < 0.05$.

RESULTS

Polymer Synthesis and Formulation with Ovalbumin. The PPAA copolymer had $M_n = 22$ kD and $M_w/M_n = 2.0$, with 3 mol % PDSA, and the PMAA copolymer had $M_n = 27$ kD and $M_w/M_n = 2.1$, with 2 mol % PDSA. The PDMAEMA used to form the PPAA-Ova/PDMAEMA ionic complexes had $M_n = 7.8$ kD and $M_w/M_n = 1.2$. The PPAA-Ova and PMAA-Ova conjugates used in this study were similar to those characterized in our previous in vitro experiments (*41*). Fifteen percent of the total available lysines in ovalbumin were thiolated, which equates to an average of three thiols per protein. The BCA assay revealed that both the PPAA-Ova and PMAA-Ova conjugates contained 38% ovalbumin by weight. GPC analysis revealed that $M_n = 43$ kD and $M_w/M_n = 2.9$ for the PPAA-Ova conjugate and $M_n = 54$ kD and $M_w/M_n = 2.4$ for the PMAA-Ova conjugate. The ^{14}C-labeled conjugates used for the cellular internalization studies were similar in size with $M_n = 40$ kD and $M_w/M_n = 3.5$ for the PPAA-^{14}C-Ova and $M_n = 50$ kD and $M_w/M_n = 2.4$ for the PMAA-^{14}C-Ova. The degree of thiolation of the ovalbumin used to form these radiolabeled conjugates was determined to be 30%, and the final conjugates were found to be 34% and 40% ovalbumin by weight for the PPAA-^{14}C-Ova and PMAA-^{14}C-Ova conjugates, respectively.

The particle formulation resulted in PPAA-Ova/PDMAEMA ionic particles that were characterized using dynamic light scattering (DLS) and zeta potential measurements (Supporting Information Table S1). For subsequent in vitro and in vivo experiments, the focus was the formulation with a ∓ charge ratio of 20:1 due to the formation of particles in a desirable size range using this composition. The 20:1 ∓ formulation had a hydrodynamic radius of 178 ± 45 nm (reported as number average), in PBS at pH 7.4, and the zeta potential was found to be −32 mV, which is consistent with the excess of negatively charged PPAA used in particle formation.

Mechanistic In Vitro Analyses of PPAA-Ova Conjugates and PPAA-Ova/PDMAEMA Particles. *Cytotoxicity of Polymer*−*Ovalbumin Conjugates and Particles.* After incubating RAW macrophages for 24 h with the polymer conjugates or PPAA-Ova/PDMAEMA particles, cell viability was evaluated using the Alamar Blue assay. Previous results (*41*) that found PPAA-Ova and PMAA-Ova conjugates to be nontoxic were corroborated, and it was confirmed that the particles also demonstrate cytocompatibility despite their larger size, different architecture, and inclusion of cationic PDMAEMA. For example, cells treated with PPAA-Ova/PDMAEMA particles maintained >98% viability at polymer concentrations up to 750 μg/mL, which is five times the concentration utilized for subsequent cellular uptake and exocytosis assays.

Intracellular Uptake, Cytosolic Accumulation, and Exocytotic Trafficking of PPAA-^{14}C-Ova and PPAA-^{14}C-Ova/2 > PDMAEMA in Macrophages. The uptake and intracellular accumulation was evaluated for ^{14}C-Ova, PMAA-^{14}C-Ova, PPAA-^{14}C-Ova, and PPAA-^{14}C-Ova/PDMAEMA in the RAW macrophages. The PMAA-^{14}C-Ova control is analogous in structure to PPAA-^{14}C-Ova, but PMAA has a shorter alkyl tail and its carboxylic acid has a lower pK_a relative to PPAA. PMAA serves as a control polymer with related chemistry to PPAA but with significantly reduced endosomolytic activity. Initial cellular uptake was found to be statistically equivalent for all groups at the 1 min time point (Figure 1A) indicating that significant early differences were not present among the different ^{14}C-Ova formulations. However, on longer time scales when intracellular quantities reflect a composite of uptake and exocytotic recycling, both the PPAA-^{14}C-Ova and PPAA-^{14}C-Ova/PDMAEMA formulations accumulated intracellularly to a significantly greater extent than the control ^{14}C-Ova and PMAA-^{14}C-Ova (Figure 1b, Supporting Information Figure S1). After normalizing to the quantity of ovalbumin initially internalized in a 15 min "pulse", exocytosis of PPAA-^{14}C-Ova and PPAA-^{14}C-Ova/PDMAEMA particles was significantly reduced compared to the protein and PMAA control conjugate (Figure 1B) as seen previously with the soluble conjugate (*41*). At the

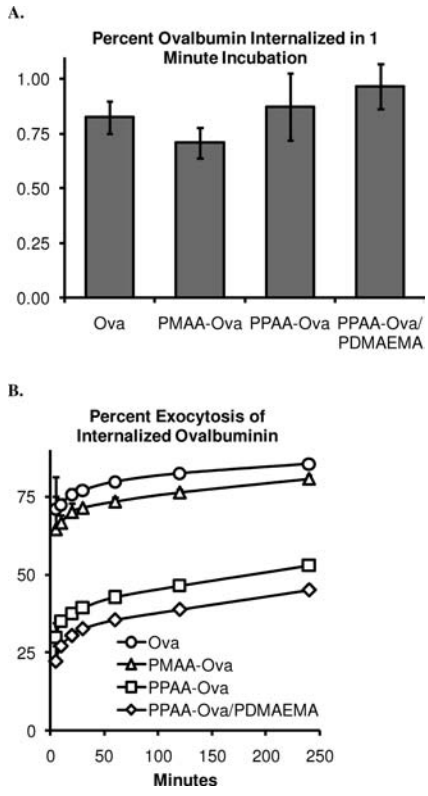

Figure 1. Enhanced ^{14}C-Ova intracellular accumulation and decreased exocytosis for PPAA-^{14}C-Ova conjugates and PPAA-Ova/PDMAEMA particles. (A) RAW macrophages incubated for 1 min with samples at a concentration of 50 μg/mL ^{14}C-ovalbumin showed that uptake of ^{14}C-ovalbumin was the same for all formulations during a time frame that precludes the effects of exocytosis (no significant differences between treatment groups). (B) Following a 15 min incubation with ^{14}C-ovalbumin formulations, the amount of ovalbumin exocytosed at each time point was determined. Significantly less exocytosis was seen with PPAA-containing carriers, indicating PPAA functionality in evading exocytotic fates. All experimental groups are statistically different in the exocytosis experiment.

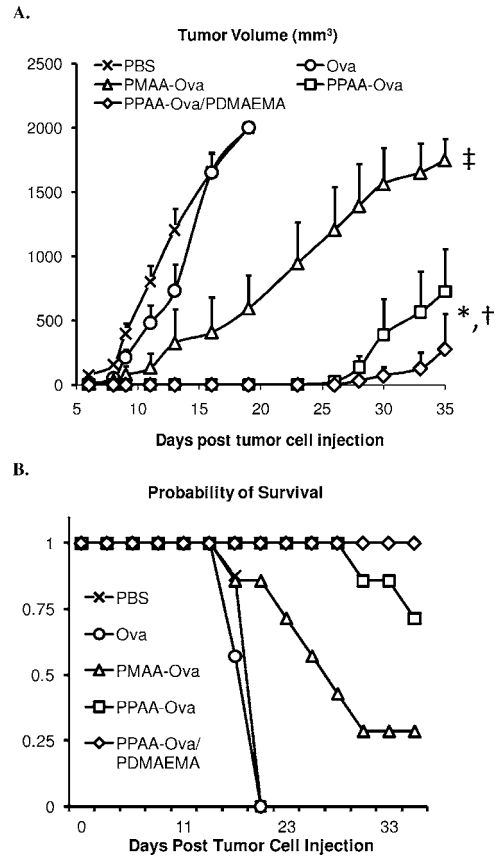

Figure 2. Enhanced tumor protection in mice immunized with PPAA-based vaccines. (A) C57Bl/6 mice were vaccinated with PBS, Ova, PMAA-Ova, PPAA−Ova, or PPAA-Ova/PDMAEMA at 100 μg ovalbumin per mouse. After 1 week, mice were injected with E.G7-OVA tumor cells, and tumor size was measured until it exceeded 2000 mm^3, at which point that animal was euthanized. The tumor size for euthanized mice was taken to be 2000 mm^3 for the calculation of mean tumor size at all subsequent time points until all mice in that treatment group were euthanized. PPAA-Ova and PPAA-Ova/PDMAEMA showed significant tumor protection relative to all other treatment groups, while PMAA-Ova had enhanced tumor protection relative to mice delivered the PBS control. Data are represented as mean ± standard error mean (SEM) and represent $n \geq 4$. *Significantly different from PBS and Ova. †Significantly different from PMAA-Ova. ‡Significantly different from PBS. (B) Kaplan−Meier survival plots for this study display the probability of survival as the fraction of mice whose tumors have not exceeded 2000 mm^3 on the indicated day. This plot illustrates the enhanced survival in mice vaccinated using PPAA-based carriers.

conclusion of the study at 4 h, less than 50% of the PPAA-containing formulations had been exocytosed. In contrast, ^{14}C-Ova and PMAA-^{14}C-Ova were rapidly exocytosed, with over 75% of the free Ova recycled back into the extracellular environment within 30 min. The rapid recycling rate observed for ^{14}C-Ova was in accordance with previous studies (*41*, *48*−*50*). The intracellular quantity of ^{14}C-labeled formulations was also evaluated and accurately complemented the exocytosis data, with the PPAA-containing formulations having significantly extended residence within the cells (Supporting Information Figure S1). Taken together, these data indicate that the pH-responsive, PPAA-containing formulations may be evading exocytosis pathways by aiding in endosomal escape and cytosolic delivery where protein cargo can potentially access the MHC-1 presentation pathway.

In Vivo Tumor Protection Against Ovalbumin Expressing Tumors. The in vivo efficacy of PPAA as a vaccine carrier was evaluated using a murine ovalbumin expressing tumor protection model. This model allows the characterization of prophylactic vaccine tumor protection, and additionally, it allows the quantitation of Ova-specific CD8+ induction to test whether the endosomal-releasing polymers enhance this presentation pathway. In this model, delivery of soluble PPAA-Ova and particulate PPAA-Ova/PDMAEMA vaccines dramatically prevented tumor growth compared to controls, as evidenced by the tumor growth curves (Figure 2A) and Kaplan−Meier survival plots (Figure 2B). Most PBS and Ova immunized control mice developed tumors within the 10 days of tumor cell injection and had to be euthanized by day 19 when tumors exceeded 2000 mm^3. PMAA-Ova delayed tumor growth to an extent compared to the saline controls, but statistical differences between tumor growth curves for free Ova and PMAA-Ova were not significant. Interestingly, PPAA-Ova conjugates and the PPAA-Ova/PDMAEMA particles both significantly delayed tumor growth, and there was no significant statistical difference between the soluble and particulate formulations in this study. As summarized in Table 1, PPAA-Ova and PPAA-Ova/PDMAEMA immunized mice averaged nearly 5 weeks before tumors developed following tumor cell inoculation. In terms of tumor-free survival following cell injection, PMAA-Ova immunized mice remained tumor-free significantly longer than the PBS and Ova controls but developed palpable tumors significantly earlier than mice immunized with PPAA-containing vaccines. The larger size of the PMAA-Ova conjugates compared to Ova alone and potential inflammatory stimulation could explain the small effects of this control formulation.

Table 1. Number of Days of Tumor Protection[a]

sample	avg. days tumor protection
PBS	9 ± 1
Ova	11 ± 3
PMAA-Ova	20 ± 7[b]
PPAA-Ova	33 ± 3[b,c]
PPAA-Ova/PDMAEMA	34 ± 3[b,c]

[a] Tumor protection is reported as the number of days post tumor challenge that each mouse developed a measurable tumor larger than 200 mm^3 For PPAA-Ova and PPAA-Ova/PDMAEMA groups, some mice were assigned a value of 35 days at the conclusion of the experiment even though they still did not present with tumors greater than 200 mm^3 at that time. [b] Significantly different from PBS and Ova. [c] Significantly different from PMAA-Ova.

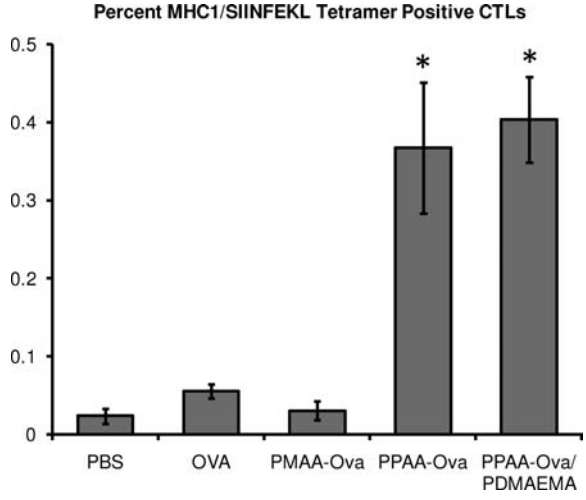

Figure 3. Enhanced CD8+ spleen-derived T-cell production in mice immunized with PPAA-based vaccines. C57Bl/6 mice were vaccinated with PBS, Ova, PMAA-ova, PPAA-Ova, and PPAA-Ova/PDMAEMA (100 μg ova per mouse). Seven days later, spleens were collected and splenocytes were stained with FITC-anti-CD8 and PE-MHC-1/SIINFEKL tetramers. Flow cytometric evaluation showed a significantly enhanced antiovalbumin MHC-1 driven CD8+ T-cell response induced by the PPAA-Ova soluble and PPAA-Ova/PDMAEMA particulate vaccines. Data are presented as mean $\pm$ SEM $n = 4$ per group, and * indicates significantly different from PBS, Ova, PMAA-Ova.

Flow Cytometric Tetramer Detection of Ovalbumin-Specific CD8+ T-Cell Response in Vivo. To investigate whether enhanced CTL generation played a role in the prophylactic immune response observed for the PPAA-Ova and PPAA-Ova/PDMAEMA groups, MHC-1/SIINFEKL tetramers were used to measure the number of Ova-reactive CD8+ T cells in the spleen using flow cytometry. In splenocytes harvested from mice 7 days postvaccination, delivery of free Ova or PMAA-Ova did not result in statistically significant CD8+ T-cell production compared to PBS. Vaccination with soluble PPAA-Ova and particulate PPAA-Ova/PDMAEMA resulted in enhanced CD8+ T-cell generation compared to all other treatment groups as evidenced by the increased number of CD8+/tetramer+ T-cells as depicted in Figure 3. Soluble and particulate PPAA-containing vehicles resulted in an approximately 8-fold increase in CD8+ T-cell development relative to delivery of free Ova. Surprisingly, the soluble PPAA-Ova conjugate was able to overcome any potential advantage of the PPAA-Ova/PDMAEMA particulate formulation in terms of increased uptake/presentation (*15, 18, 23*−*25*) and was found to lead to a similar level of ovalbumin SIINFEKL epitope recognition by CD8+ T-cells in vivo.

ELISA Measurement of In Vivo Antibody Response. To determine the role of the humoral component in the prophylactic immune response observed for PPAA-Ova and PPAA-Ova/PDMAEMA vaccinated mice, blood was drawn from all mice 20 days after vaccination and the antiovalbumin IgG titer was measured by ELISA. As show in Figure 4, no appreciable antibody production was observed for mice vaccinated with PBS, Ova, or PMAA-Ova. Conversely, a significant increase in antiovalbumin IgG was detected for PPAA-Ova and PPAA-Ova/PDMAEMA vaccinated mice, indicating that an antibody-mediated response also contributed to the tumor protection observed in these groups. No differences were detected, however, in PPAA-containing soluble conjugate and particulate forms.

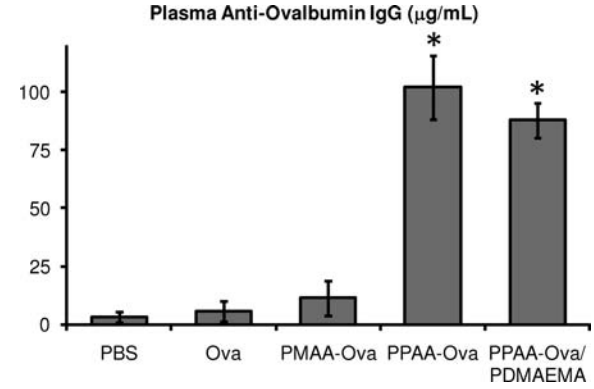

Figure 4. PPAA-based vaccine triggered antiovalbumin IgG antibody production. Mice were vaccinated with PBS, Ova, PMAA-Ova, PPAA-Ova, PPAA-Ova/PDMAEMA (100 μg ovalbumin per mouse). Twenty days after vaccine injection, blood was drawn and an ELISA was performed on plasma samples. The antiovalbumin antibody response induced by the PPAA soluble and particulate conjugates is significantly greater than that resulting from vaccination with Ova or PMAA-Ova. Data presented as mean $\pm$ SEM, and $n = 4$ per group. * indicates significantly different than PBS, Ova, PMAA-Ova.

DISCUSSION

In this study, PPAA-based protein vaccines effectively stimulated prophylactic immune responses with a single injection that led to a statistically significant delay in tumor development in the ovalbumin vaccine mouse model. Interestingly, both the soluble PPAA-Ova and particulate PPAA-Ova/PDMAEMA immunizations delayed tumor growth for nearly five weeks, while control mice injected with PBS and free ovalbumin developed tumors in less than 10 days. The robust antitumor response observed for both soluble and particulate PPAA-based carriers was mediated through an enhanced CD8+ T-cell response and a marked production of antiovalbumin antibodies. These data indicate that pH-responsive polymer protein conjugates may be able to access the MHC-1 pathway in the cytosol by triggering endosome escape, and this is, to our knowledge, the first reported account of soluble protein−polymer conjugates eliciting comparable antitumor activity to particulate platforms.

Mechanistically, both CD8+ T-cell generation and antibody production contributed to the robust antitumor response observed for the PPAA-based carriers. Enhanced CD8+ T-cell production of PPAA-based vaccines in vivo was in agreement with our previous in vitro observations that these carriers increase intracellular accumulation through pH-responsive endosomal escape and enhance MHC-1 presentation/T-cell activation (*41*). The antiovalbumin antibody production could be expected, and previous studies have found concomitant CD8+ T-cell generation and antibody response (*51*). Since the PPAA-based carriers increase accumulation in APCs, it is logical that these carriers would also enter the MHC-2 antigen presentation pathway, which can be accessed through specialized endosomal vesicles. This would lead to CD4+ T-helper cell activation and increased antibody production following treatment with the PPAA-containing vaccines.

Interestingly, the soluble and particulate PPAA-based carriers elicited comparable tumor protection and T-cell/antibody responses in vivo. As shown in Figure 1, both PPAA-Ova and PPAA-Ova/PDMAEMA had positive effects on protein evasion of exocytosis, but the particulate PPAA-Ova/PDMAEMA formulation resulted in slightly lower exocytosis in macrophages. The increase in stable internalization may be related to the presence of the cationic PDMAEMA component to neutralize a portion of the PPAA anionic charges and/or due to phagosomal uptake of particulate substances (*52*−*56*). It has not been clearly elucidated why the better in vitro performance of the PPAA-Ova/PDMAEMA particles relative to the PPAA-Ova conjugates was less evident in the in vivo studies. We hypothesize that diffusional limitations of the particles because of their larger size could hinder access to APCs and thus cell uptake in vivo. Unpackaging of the ionically complexed particles may also be a limiting step in antigen delivery to APCs for this formulation, and this step could lower this system's overall efficiency in vivo. Finally, it is possible that both the conjugate and the PPAA-Ova particles are saturating the in vivo response in this model, limiting our ability to discriminate differences due to the different formulations. It remains to be seen whether other types of particles incorporating PPAA may provide a better combination of particulate form and PPAA functionality.

It was also interesting to note that the PMAA-Ova conjugate provided an intermediate degree of tumor protection in vivo, although this formulation did not markedly decrease exocytotic fate in vitro or elicit measurable CD8+ T-cell or antibody production in vivo. This observation may be due to a CD4+ T-cell response, which is induced by MHC-2 presentation and does not require cytosolic entry of the antigen for activation. This pathway may have resulted in production of cytokines by CD4+ helper T-cells, leading to activation of cytotoxic macrophages and delayed tumor growth. Alternatively, there may have been a smaller or more transient effect from the PMAA-Ova treatment that was functionally significant for tumor protection although it was not detected at the specific time point analyzed in our CD8+ T-cell and antibody assays.

In the context of previous studies, the degree of tumor protection produced by the PPAA-based vaccines with a single dose and no adjuvant was substantial when compared to other vaccine formulations tested using the ovalbumin-based protein vaccine model. Discrepancies in the number of tumor cells injected, the number of rounds of immunization, and the inclusion of adjuvants hinder absolute comparison to previous studies, but some general comparisons demonstrate the effectiveness of the conjugate formulation. For example, the often-used PGA nanoparticle vaccine delivery strategy prevented tumor formation for approximately 16 days after tumor injection (*27*). Similarly, a particulate, acid-degradable carrier kept mice tumor-free for just over 2 weeks (*30*). Liposomes, another extensively tested vaccine delivery vehicle, have been shown to prevent tumor formation for 20−25 days when codelivered with the CpG-ODN adjuvant (*57*) and for 45 days when the carriers contain the cytokine IL-2 (*51*).

Relative to these previous studies, one can conclude that both soluble PPAA-Ova conjugates (33 ± 3 days tumor protection) and PPAA-Ova/PDAEMA particulate vaccine carriers (34 ± 3 days tumor protection) meet or exceed the precedent established in previous reports. Furthermore, the current results represent the first evidence of a soluble polymer−protein conjugate performing as well as a particulate carrier, which had been the previous standard. The promise of PPAA-based vaccines can be further expanded when one considers the potential improvements that may further enhance their efficacy such as multiple immunization protocols, codelivery with adjuvants, or inclusion of APC-specific targeting moieties. Examination of these avenues and evaluation of this technology against true therapeutic targets (human tumor xenografts, viral pathogens, etc.) are warranted for future investigation.

Received April 27, 2010; Revised Manuscript Received October 26, 2010

Potential boron neutron capture therapy (BNCT) agents have been designed on the basis of the evidence about translocator protein (TSPO) overexpression on the outer mitochondrial membrane of tumor cells. The structure of the first TSPO ligand bearing a carborane cage (compound **2d**) has been modified in order to find a suitable candidate for in vivo studies. The designed compounds were synthesized and evaluated for their potential interaction with TSPO and tumor cells. In vitro biological evaluation showed in the case of fluoromethyl derivative **4b** a nanomolar TSPO affinity very similar to that of **2d**, a significantly lower cytotoxicity, and a slightly superior performance as boron carrier toward breast cancer cells. Moreover, compound **4b** could be used as a ^{19}F magnetic resonance imaging (MRI) agent as well as labeled with ^{11}C or ^{18}F to obtain positron emission tomography (PET) radiotracers in order to apply the "see and treat" strategy in BNCT.

INTRODUCTION

BNCT (boron neutron capture therapy)[1] is a binary approach to cancer radiotherapy that establishes its potentialities on two distinct actions: enrichment of tumor cells with ^{10}B atoms and subsequent irradiation with a thermal neutron flux (*1*). The less abundant boron isotope ^{10}B (ca. 20% of total boron) has the interesting peculiarity of providing a large absorption cross section for thermal neutrons. The nuclear reaction of neutron capture produces high LET (linear energy transfer) particles such as ^{7}Li and α, which cause great damage in the range (less than 10 μm) of the cell diameter. The efficient energy transfer produces selective damage in the cells containing ^{10}B so that boron microdistribution plays a crucial role in BNCT selectivity. Provided that a ^{10}B concentration sufficient to produce cell death is reached in the tumor, and that a high concentration ratio between tumor and normal cells is obtained, uniform irradiation with thermal neutrons ensures the selective destruction of the tumor cells. With the neutron sources now available, in order to keep the irradiation times acceptable, the ^{10}B concentration in the tumor must be higher than 20−35 μg per gram of tissue.

BNCT has been used in the experimental treatment of a number of different tumors (e.g., glioblastoma (*2*−*4*), skin melanoma (*5*), head and neck cancer (*6*), mesothelioma (*7*), and diffuse liver metastases (*8*)) and could provide a useful option in the cases of tumors unaffected by conventional therapies or difficult to remove surgically (*9*). In fact, when metastases are spread through an entire organ, the use of a selective BNCT agent should allow the selective destruction of each single cell belonging to tumor nodules, without the necessity of their selective irradiation.

The selective ^{10}B incorporation inside cancer cells requires boron carrier molecules that show a particular tropism toward the target cells. A wide range of boron carriers have been designed, synthesized, and evaluated during the past decades (*10*), but only two compounds have been approved for clinical practice, namely, boronophenylalanine (BPA) (*11*) and sodium borocaptate (BSH) (*12*).

BPA is a derivative of the essential amino acid and is actively taken up by tumor cells. However, studies performed in animals and patients bearing liver metastases showed a maximum uptake ratio of about 6 between tumor and liver tissues (*2*, *13*). Research efforts are needed in order to develop new boron carriers capable of producing boron concentration ratios higher than those currently obtained with BPA and BSH. The use of boron clusters such as a carborane cage instead of single boron atoms allows to increase loading capability. Moreover, the carborane moiety is compatible with the biological environment (*14*, *15*) and carries 10 boron atoms per molecule.

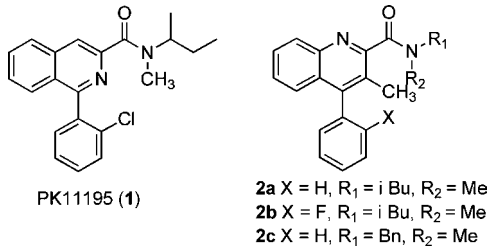

Figure 1. Structures of TSPO ligands **1** and **2a**−**c**.

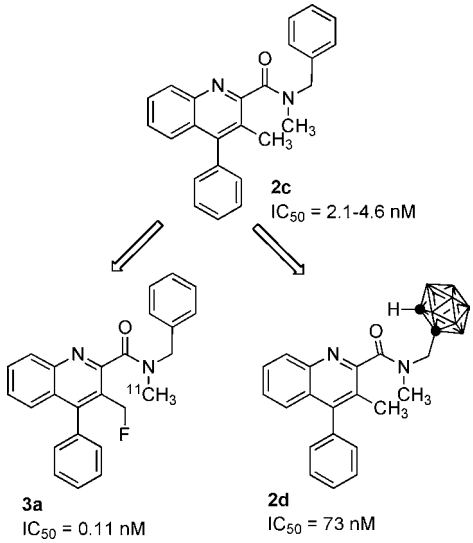

Figure 2. Development of PBR ligands **2d** and **3a**. In the icosahedral cage structure, closed circles represent carbon atoms and the vertices represent BH units.

The peripheral benzodiazepine receptor (PBR), recently renamed translocator protein (TSPO), is a 18 kDa protein showing five trans-membrane domains localized on the outer mitochondrial membrane (*16*−*18*). TSPO is linked to the voltage-dependent anion channel (VDAC) and to the adenine nucleotide translocase (ANT) and appears to be implicated in the regulation of the opening of the mitochondrial permeability transition pore (MPTP). Kidney, heart, testis, and adrenal gland are organs particularly rich in TSPO protein, while lower levels are found in the brain parenchyma, ependyma, choroid plexus, and olfactory neurons. Furthermore, high TSPO levels have been found in a variety of tumors (e.g., breast carcinoma, colorectal cancer, liver tumors, ovarian cancer, certain brain tumors, etc.), and its expression appears to be related to the degree of tumor malignancy (*19*−*26*). Isoquinolinecarboxamide derivative PK11195 (**1**, Figure 1) binds TSPO with nanomolar affinity and is largely used as a pharmacological tool for the study of the expression and the function of TSPO. Compound **1** was labeled with carbon-11 and used for the in vivo imaging of microglial/macrophage activation present in different brain disorders including tumors by means of positron emission tomography (PET) (*27*−*29*).

Our long-lasting interest in the synthesis of TSPO ligands has produced outstanding compounds in the class of PK11195 derivatives (*30*, *31*). For instance, potent quinoline carboxamide ligands **2a**−**c** were ^{11}C-labeled and the biodistribution studies indicated that these compounds are promising PET tracers for the in vivo imaging of PBR (*32*−*34*). Moreover, compound **2c** was used as a lead compound in the design of both the first PBR ligand bearing a carborane cage **2d** (Figure 2) (*35*) potentially useful in boron neutron capture therapy (BNCT) and fluoroderivative **3a**, which can be considered one of the most potent PET radiotracers for the in vivo imaging of the PBR so far described (*36*).

On the basis of the interesting results obtained, the program of the structural modification of compounds **2** was pursued in order to optimize the interaction of the 1,2-dicarba-*closo*-dodecaboranyl derivative **2d** with TSPO and with cancer cells, as well as to find a suitable candidate for the in vivo (e.g., biodistribution and efficacy) studies. Thus, this paper describes the results of a structure−activity relationship study focused on the selection of a candidate for in vivo studies endowed with nanomolar affinity for TSPO and low intrinsic cytotoxicity and capable of concentrating ^{10}B atoms into tumor cells.

EXPERIMENTAL PROCEDURES

Chemistry. All chemicals used were of reagent grade. Yields refer to purified products and are not optimized. Melting points were determined in open capillaries on a Gallenkamp apparatus and are uncorrected. Merck silica gel 60 (230−400 mesh) was used for column chromatography. Merck TLC plates with silica gel 60 F_{254} were used for TLC. ^{1}H NMR spectra were recorded by means of a Bruker AC 200 or a Bruker DRX 400 AVANCE spectrometer in the indicated solvents (TMS as internal standard); the values of the chemical shifts are expressed in parts per million, and the coupling constants (*J*) in hertz. Mass spectra were recorded on a ThermoFinnigan LCQ-Deca. The purity of compounds **4a**−**j** was assessed by RP-HPLC and was found to be higher than 95%. An Agilent 1100 Series system equipped with a Zorbax Eclipse XDB-C8 (4.6 × 150 mm) column was used in the HPLC analysis with acetonitrile−0.1% aqueous formic acid (95:5) as the mobile phase at a flow rate of 0.7 mL/min. UV detection was achieved at 220 nm.

***N*-[1,2-Dicarba-*closo*-dodecaboran(12)-1-ylmethyl]-3-methyl-4-phenylquinoline-2-carboxamide (4g).** A solution of carboxylic acid **5** (*30*) (0.13 g, 0.49 mmol) in $SOCl_2$ (3.0 mL) was refluxed for 2 h. Most of the $SOCl_2$ was distilled under reduced pressure, and the remainder was removed by azeotropic distillation with toluene. The residue was diluted with CH_2Cl_2 (6.0 mL), cooled at 0−5 °C, and treated in sequence with (aminomethyl)-*o*-carborane hydrochloride (*37*) (0.11 g, 0.52 mmol) and pyridine (0.10 mL, 1.2 mmol). The reaction mixture was stirred at room temperature for 30 min, washed with water, dried over sodium sulfate, and concentrated under reduced pressure. Purification of the residue by flash chromatography with $CHCl_3$ as the eluent gave **4g** as a white solid (0.14 g, yield 68%). An analytical sample was obtained by recrystallization from diethyl ether (mp 195−196 °C). HPLC: retention time = 3.8 min, purity = 96.3%.^{1}H NMR (200 MHz, $CDCl_3$): 0.75−3.75 (br m, 10BH), 2.54 (s, 3H), 4.06 (br s, 1H), 4.19 (d, J = 7.0, 2H), 7.21−7.55 (m, 7H), 7.70 (m, 1H), 8.10 (d, J = 8.4, 1H), 8.86 (t, J = 6.3, 1H). ^{1}H{^{11}B}-NMR (400 MHz, $CDCl_3$): 2.18 (br s, 5H), 2.29 (br s, 2H), 2.38 (br s, 1H), 2.47 (br s, 2H), 2.53 (s, 3H), 4.07 (br s, 1H), 4.19 (d, J = 6.9, 2H), 7.22 (m, 2H), 7.38 (m, 1H), 7.51 (m, 4H), 7.71 (m, 1H), 8.12 (d, J = 8.4, 1H), 8.89 (t, J = 6.8, 1H). MS (ESI): m/z 419 ($M + H^+$).

***N*-[1,2-Dicarba-*closo*-dodecaboran(12)-1-ylmethyl]-3-fluoromethyl-4-phenylquinoline-2-carboxamide (4h).** The title compound was synthesized starting from carboxylic acid **7** (*36*) (0.10 g, 0.35 mmol), (aminomethyl)-*o*-carborane hydrochloride (*37*) (73 mg, 0.35 mmol), and pyridine (0.10 mL, 1.2 mmol) following the same procedure used for compound **4g**. After purification by flash chromatography (dichloromethane as the eluent), compound **4h** (0.11 g, yield 72%) was recrystallized from diethyl ether to obtain colorless prisms melting at 173−174 °C. HPLC: retention time = 3.4 min, purity = 99.9%. ^{1}H NMR (200 MHz, $CDCl_3$): 0.75−3.75 (br m, 10BH), 4.08 (br s, 1H), 4.22 (d, J = 7.0, 2H), 5.77 (d, J = 46.6, 2H), 7.31 (m, 2H), 7.55 (m, 5H), 7.82 (m, 1H), 8.17 (d, J = 8.5, 1H), 8.76 (br t, 1H). MS (ESI): m/z 437 ($M + H^+$).

***N*-[1,2-Dicarba-*closo*-dodecaboran(12)-1-ylpropyl]-3-fluoromethyl-4-phenylquinoline-2-carboxamide (4i).** The title compound was synthesized starting from carboxylic acid **7** (*36*) (52 mg, 0.18 mmol), (aminopropyl)-*o*-carborane hydrochloride (*37*) (43 mg, 0.18 mmol), and pyridine (0.050 mL, 0.62 mmol) following the same procedure used for compound **4g**. Compound **4i** was purified by flash chromatography with dichloromethane as the eluent to obtain a white solid (60 mg, yield 72%) melting at 105−106 °C. HPLC: retention time = 3.2 min, purity = 95.2%. ^{1}H NMR (200 MHz, $CDCl_3$): 0.75−3.75 (br m, 10BH), 1.89 (m, 2H), 2.38 (m, 2H), 3.52 (q, J = 6.5, 2H), 3.67 (br s, 1H), 5.79 (d, J = 46.5, 2H), 7.31 (m, 2H), 7.52 (m, 5H), 7.77 (m, 1H), 8.11 (m, 2H). MS (ESI): *m*/*z* 465 ($M + H^+$).

***N*-[(1-Adamantyl)methyl]-3-methyl-4-phenylquinoline-2-carboxamide (4j).** The title compound was synthesized starting from carboxylic acid **5** (*30*) (0.50 g, 1.9 mmol), commercial 1-adamantanemethylamine (0.34 mL, 1.9 mmol), and TEA (1.0 mL) following the same procedure used for compound **4g**. Compound **4j** was purified by recrystallization from ethyl acetate−chloroform to obtain colorless needles melting at 169−170 °C (0.57 g, yield 73%). HPLC: retention time = 5.0 min, purity = 99.9%. ^{1}H NMR (200 MHz, $CDCl_3$): 1.56−1.77 (m, 12H), 2.01 (s, 3H), 2.54 (s, 3H), 3.22 (d, J = 6.7, 2H), 7.21−7.66 (m, 8H), 8.10 (m, 2H). MS(ESI): *m*/*z* 433 ($M + Na^+$).

***N*-[3,5-Bis(trifluoromethyl)benzyl]-*N*,3-dimethyl-4-phenylquinoline-2-carboxamide (4f).** The title compound was synthesized starting from carboxylic acid **5** (*30*) (0.13 g, 0.49 mmol), *N*-[3,5-bis(trifluoromethyl)benzyl]methylamine hydrochloride (0.15 g, 0.51 mmol), and pyridine (0.10 mL, 1.2 mmol) following the same procedure used for compound **4g**. Compound **4f** was purified by flash chromatography with dichloromethane-ethyl acetate (8:2) as the eluent to obtain a colorless glassy solid (0.13 g, yield 53%). HPLC: retention time = 3.2 min, purity = 99.0%. ^{1}H NMR (200 MHz, $CDCl_3$; the spectrum of this amide derivative shows the presence of two different rotamers in the ratio of about 55:45; for the sake of simplicity, the integral intensities have not been given): 2.22 (s), 2.23 (s), 2.92 (s), 3.14 (s), 4.56 (s), 4.97 (s), 7.21−7.27 (m), 7.35−7.71 (m), 7.83 (s), 7.93 (s), 7.99−8.13 (m). MS(ESI): *m*/*z* 503 ($M + H^+$).

***N*,3-Dimethyl-*N*-[2-methyl-1,2-dicarba-*closo*-dodecaboran(12)-1-ylmethyl]-4-phenylquinoline-2-carboxamide (4a).** *From Compound **4g**.* A solution of **4g** (50 mg, 0.12 mmol) in dry DMF (1.0 mL) was treated in sequence with methyl iodide (0.25 mL, 4 mmol) and NaH (3.0 mg, 0.13 mmol). After stirring at room temperature for 10 min, the reaction mixture was poured into ice−water, and the precipitate was extracted with dichloromethane. The organic layer was dried over sodium sulfate and concentrated under reduced pressure. The resulting residue was purified by flash chromatography with *n*-hexane−ethyl acetate (65:35) as eluent to obtain pure **4a** (20 mg, yield 37%) as a white solid melting at 146−147 °C. HPLC: retention time = 4.0 min, purity = 97.7%. ^{1}H NMR (200 MHz, $CDCl_3$; the spectrum of this amide derivative shows the presence of two different rotamers (*38*) in the ratio of about 9:1; for the sake of simplicity, the signals of the minor rotamer have been omitted): 0.75−3.75 (br m, 10BH), 2.26 (s, 3H), 2.34 (s, 3H), 3.07 (s, 3H), 4.37 (s, 2H), 7.27 (m, 2H), 7.42−7.71 (m, 6H), 8.09 (d, J = 8.5, 1H). MS(ESI) *m*/*z*: 447 ($M + H^+$).

*From Compound **2d**.* A solution of **2d** (60 mg, 0.14 mmol) in dry DMF (3.0 mL) was treated in sequence with methyl iodide (0.25 mL, 4 mmol) and NaH (4.0 mg, 0.17 mmol). After stirring at 45−50 °C for 1.5 h, the reaction mixture was poured into ice−water, and the precipitate was extracted with dichloromethane. The organic layer was dried over sodium sulfate and concentrated under reduced pressure. The resulting residue was purified by flash chromatography with *n*-hexane−ethyl acetate (65:35) as eluent to obtain 22 mg of unreacted **2d** and pure **4a** (13 mg, yield 21%) as a white solid.

***N*-[1,2-Dicarba-*closo*-dodecaboran(12)-1-ylmethyl]-3-fluoromethyl-*N*-methyl-4-phenylquinolin-2-carboxamide (4b).** A solution of **4h** (45 mg, 0.10 mmol) in dry DMF (1.0 mL) was treated in sequence with methyl iodide (0.32 mL, 5.1 mmol) and KOH (17 mg, 0.30 mmol). After stirring at room temperature for 30 min, the reaction mixture was poured into ice−water, and the precipitate was extracted with dichloromethane. The organic layer was dried over sodium sulfate and concentrated under reduced pressure. Purification of the resulting residue by flash chromatography with dichloromethane as eluent gave pure **4b** (11 mg, yield 24%) as a white solid melting at 189−190 °C. HPLC: retention time = 4.1 min, purity = 97.6%. ^{1}H NMR (200 MHz, $CDCl_3$; the spectrum of this amide derivative shows the presence of two different rotamers in the ratio of about 8:2 as in the case of **2d** (*38*); for the sake of simplicity, the integral intensities have not been given): 0.75−3.75 (br m), 3.11 (s), 3.26 (s), 3.99 (br s), 4.32 (br s), 5.37 (d, J = 47.4), 5.75 (br s), 7.32 (m), 7.54 (m), 7.79 (m), 7.99 (d, J = 8.1), 8.17 (d, J = 8.4). MS (ESI): *m*/*z* 451 ($M + H^+$).

3-Fluoromethyl-*N*-[2-methyl-1,2-dicarba-*closo*-dodecaboran(12)-1-ylmethyl]-*N*-methyl-4-phenylquinoline-2-carboxamide (4c). Compound **4c** was obtained as the more polar fraction of the flash chromatography purification of compound **4b** (32 mg, yield 69%, mp 181−182 °C). HPLC: retention time = 4.7 min, purity = 99.6%. The spectra of this amide derivative show the presence of two different rotamers (*38*) in the ratio of about 95:5; for the sake of simplicity, the signals of the minor rotamer have been omitted.^{1}H NMR (200 MHz, $CDCl_3$): 0.75−3.75 (br m, 10BH), 2.33 (s, 3H), 3.13 (s, 3H), 4.39 (s, 2H), 5.38 (d, J = 47.5, 2H), 7.32 (m, 2H), 7.54 (m, 5H), 7.79 (m, 1H), 8.18 (d, J = 8.5, 1H). ^{1}H{^{11}B}-NMR (400 MHz, $CDCl_3$): 2.20 (br s, 3H), 2.30 (br s, 2H), 2.33 (s, 3H), 2.37 (br s, 2H), 2.45 (br s, 3H), 3.13 (s, 3H), 4.40 (s, 2H), 5.38 (d, J = 47.6, 2H), 7.34 (m, 2H), 7.53 (m, 5H), 7.78 (m, 1H), 8.17 (d, J = 8.5, 1H). MS (ESI): *m*/*z* 465 ($M + H^+$).

3-Fluoromethyl-*N*-[2-methyl-1,2-dicarba-*closo*-dodecaboran(12)-1-ylpropyl]-*N*-methyl-4-phenylquinoline-2-carboxamide (4d). The title compound was synthesized starting from **4i** (43 mg, 0.093 mmol) following the same procedure used for compound **4b**. Compound **4d** was purified by flash chromatography with dichloromethane−ethyl acetate (9:1) as the eluent to obtain 20 mg of a pale yellow glassy solid (yield 44%). HPLC: retention time = 3.9 min, purity = 99.2%. ^{1}H NMR (200 MHz, $CDCl_3$; the spectrum of this amide derivative shows the presence of two different rotamers (*38*) in the ratio of about 6:4; for the sake of simplicity, the integral intensities have not been given): 0.75−3.75 (br m, 10BH), 2.04 (m), 2.41 (m), 2.95 (s), 3.19 (s), 3.31 (t, J = 6.8), 3.73 (t, J = 6.4), 5.39 (d, J = 47.6), 7.31 (m), 7.54 (m), 7.78 (m), 8.10 (m). MS (ESI): *m*/*z* 515 ($M + Na^+$).

***N*-[(1-Adamantyl)methyl]-*N*,3-dimetyl-4-phenylquinoline-2-carboxamide (4e).** The title compound was synthesized starting with **4j** (0.50 g, 1.2 mmol) following the same procedure used for the preparation of compound **4a.** Compound **4j** was purified by flash chromatography with chloroform−ethyl acetate (9:1) as the eluent to obtain 0.15 mg of white solid (yield 29%). An analytical sample was obtained by recrystallization from ethyl acetate−chloroform (mp 207−209 °C). HPLC: retention time = 4.2 min, purity = 97.9%. ^{1}H NMR (200 MHz, $CDCl_3$; the spectrum of this amide derivative shows the presence of two different rotamers in the ratio of about 8:2; for the sake of simplicity, the integral intensities have not been given):

1.38−2.01 (m), 2.21 (s), 2.25 (s), 2.96 (s), 3.21 (s), 3.26 (s), 3.34 (s), 7.21−7.68 (m), 8.09 (m). MS(ESI): *m*/*z* 447 ($M + Na^+$).

X-ray Crystallography. Single crystals of **4h** were submitted to X-ray data collection on an Oxford-Diffraction Xcalibur Sapphire 3 diffractometer with a graphite monochromated Mo−Kα radiation ($\lambda = 0.710\ 73$ Å) at 293 K. The structures were solved by direct methods implemented in *SHELXS-97* program (*39*). The refinements were carried out by full-matrix anisotropic least-squares on F2 for all reflections for non-H atoms by means of the *SHELXL-97* program (*40*). The structure shows a statistical disorder, and two different positions have been found for most of the atoms with site occupation factors refined to 0.51(1) and 0.49(1), respectively. Crystallographic data (excluding structure factors) for the structure in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 793508. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: + 44 (0) 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk).

In Vitro Binding Assays. Male Sprague−Dawley CD rats (Charles River Italia, Calco, CO, Italy) with body masses of 200−250 g were used. Rats were acclimatized to the new housing conditions for at least one week. They were housed six per cage under an artificial 12-h-light, 12-h-dark cycle at a constant temperature of 22 ± 2 °C and a relative humidity of 65%. They had free access to water and standard laboratory food at all times. Animal care and handling throughout the experimental procedures were in accordance with the European Communities Council Directive of 24 November 1986 (86/609/EEC).

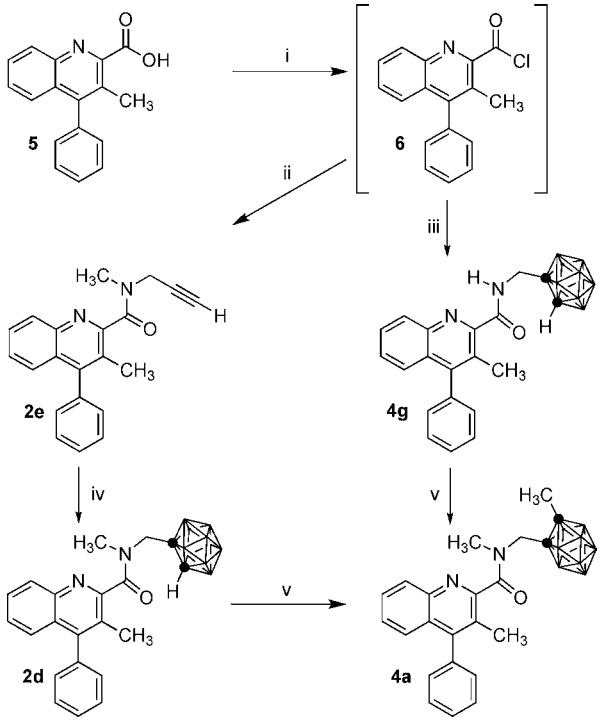
Rats were sacrificed by decapitation, and their brains were rapidly dissected into the various areas, which were stored at −80 °C until the day of the assay. The binding assays were performed as described in the literature (*41*). The cerebral cortex was subsequently thawed and then homogenized in 50 volumes of ice-cold Dulbecco's phosphate-buffered saline (PBS) pH 7.4 at 4 °C with a Polytron PT 10 disrupter (setting 5 for 20 s). The homogenate was centrifuged at 40 000*g* and 4 °C for 30 min, and the resulting pellet was resuspended in the same volume of fresh buffer and recentrifuged. The new pellet was resuspended in 10 volumes of the incubation buffer (PBS) and used for the binding assay.

[^{3}H]PK11195 binding was measured in a final volume of 500 μL, consisting of 50 μL of membrane suspension (0.15−0.20 mg of protein), 50 μL of [^{3}H]PK11195 (s.a. 85.5 Ci/mmol, New England Nuclear; final assay concentration of 1 nM), 5 μL of drug solution or solvent, and 395 μL of PBS. The binding reaction was performed at 25 °C for 90 min and began with the addition of membranes. The incubation was terminated by rapid filtration through glass-fiber filters (Whatman GF/B), which had been presoaked with 0.3% polyethyleneimine and placed in a cell harvester filtration manifold (Brandel). The filters were washed five times with 4 mL of ice-cold PBS, after which filter-bound radioactivity was quantified by liquid scintillation spectrometry. Nonspecific binding was defined as binding in the presence of 10 μM of unlabeled PK11195 (Sigma). Specific binding was determined by subtracting the nonspecific from the total binding and was about 80% of the total binding. The concentration of the test compounds that inhibited [^{3}H]ligand binding by 50% (IC_{50}) was determined by means of *Jandel Sigmaplot* (*42*) program with 6 to 10 concentrations of the displacers, each performed in triplicate.

MDAMB231 Cell Line. The highly invasive breast cancer cells MDAMB231 were grown in RPMI 1640 (Euroclone, Devon, UK) containing 10% fetal bovine serum (FBS, Euroclone), in the presence of L-glutamine (2 mM, Euroclone) and antibiotics (100 U/mL penicillin and 100 μg/mL streptomycin, Euroclone), at 37 °C, 95% humidity, in 5% CO_2. The cultures were free of mycoplasma.

DHD/K12/TRb Cell Line. DHD/K12/TRb (DHD) is an established cell line from colon adenocarcinoma, chemically induced in BD-IX rats by oral administration of 1,2-dimethylhydrazine (no. 90062901, ECACC, Salisbury, Wiltshire, U.K.) (*43, 44*). DHD cells were grown as a monolayer in a medium composed of a 1:1 (v/v) mixture of Ham's F10 and DMEM (Euroclone, Italy), with low glucose concentration (1 g/L), and containing 40 μg/mL gentamicin and 10% fetal bovine serum.

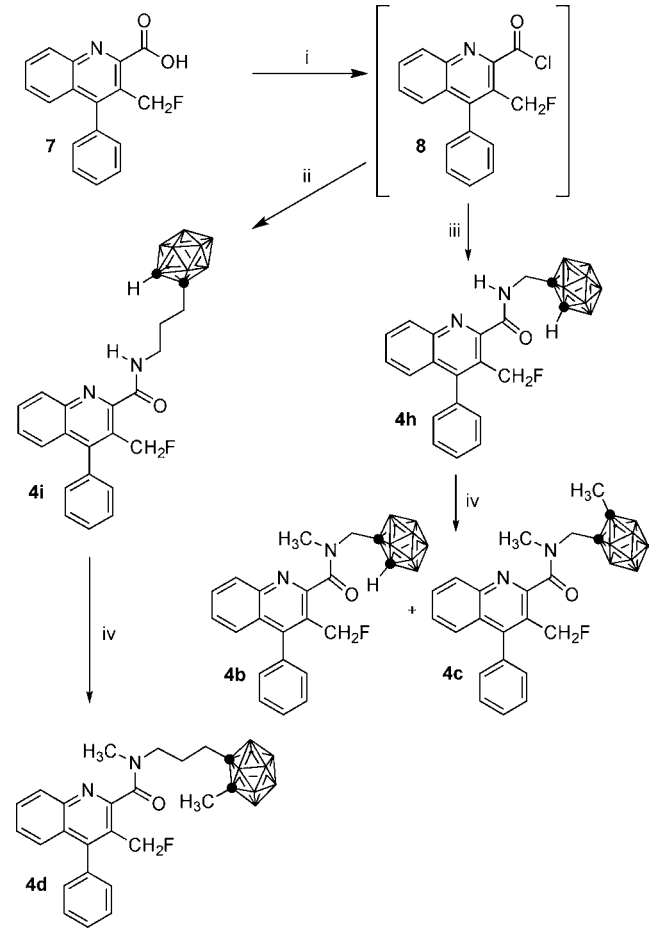
Cytotoxicity Evaluation. MDAMB231 cells were plated (5×10^4 cells/mL) in 100 μL RPMI 1640 with 10% FBS. After 4 h of incubation, the medium was changed to RPMI containing 0.5% FBS. After overnight incubation, the medium was changed to RPMI 1640 containing 10% FBS and the cells were treated with different concentrations (0−150 μM) of the studied compound for 72 h. The effect of the compounds was determined by ATP lite 1 step assay (Perkin-Elmer, Boston, MA). Briefly, cells were treated with 100 μL of luciferase and D-luciferin. The plates were placed in the dark for 10 min, and the luminescence was measured in a fluorescence microplate reader (FLUOstar Optima, BMG Labtech, Offenburg, Germany). Then, data analysis for IC_{50} calculations was performed with the LSW Data Analysis Package plug-in for *Excel* (Microsoft). The results are reported as mean ± SEM of three experiments, each performed in triplicate.



In DHD cells, the cytotoxicity of carborane derivative **2d** was evaluated by means of the plating efficiency test. Cells, after a 4 h incubation with **2d** (100 μM), were plated at three different dilutions (50, 100, 250 cells/plate) in five replicate Petri plates for each of them. They were allowed to grow at 37 °C for about 10 days. Colonies were fixed, stained, and counted. The ratio between the number of colonies with more than fifty cells and the number of seeded cells gives the value of the plating efficiency (PE). The cell survival is obtained by dividing the PE of the treated samples by the PE of the control sample.

Intracellular ^{10}B Uptake. MDAMB231 were seeded on a 6 well plate (Costar, Cambridge, MA) in RPMI 1640 containing 10% FBS at a concentration of 4.0×10^6 cells/well. After overnight starving, the medium was changed to RPMI 1640 containing 10% FBS, and the cells were treated with two different concentrations (50 μM and 100 μM) of the studied compound. From each well, 200 μL of supernatant was taken after 5 min, to allow diffusion. The compounds were incubated for 1 h at 37 °C. The cells were then washed and harvested with 200 μL of phosphate saline buffer (PBS). All the supernatant and cell suspensions were then added to Mylar disks.

For boron uptake measurements in DHD cells, these were cultured in a medium supplemented with carborane derivatives **2d** or BPA. After 4 h of treatment, the medium was removed and the cells were washed three times in PBS, trypsinized, and resuspended in boron-free medium. Control cells were processed in the same way as the boron-treated samples. Cells, enriched by centrifugation (10 min, 300 g), were finally layered on Mylar disks at a concentration of 4.0×10^6 cells/disk.



Boron Concentration Measurements. Boron concentration was measured by α spectroscopy, a method based on the ^{10}B(n, α)^{7}Li reaction induced by thermal neutrons (*45, 46*). Samples were prepared by depositing a known amount of cells on Mylar disks. The cells were left on the same support for the drying process. All samples were weighed before and after drying in order to determine the weighing factor necessary to correct for the concentration obtained in dry specimens. The Mylar supports covered by dry cells were positioned in a rotating holder, facing a thin silicon detector. The holder and the detector were placed

Scheme 1[a]

[a] Reagents: (i) $SOCl_2$, CH_2Cl_2; (ii) $CH_3-NH-CH_2C{\equiv}CH$, CH_2Cl_2, TEA; (iii) $NH_2-CH_2C(B_{10}H_{10})CH\cdot HCl$, CH_2Cl_2, pyridine; (iv) $B_{10}H_{14}$, CH_3CN, $CH_3C_6H_5$; (v) CH_3I, NaH, DMF.

Scheme 2[a]

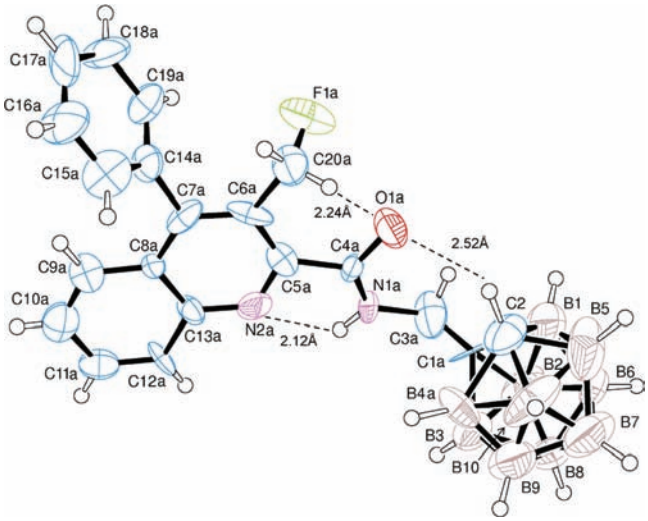
[a] Reagents: (i) $SOCl_2$, CH_2Cl_2; (ii) $NH_2-CH_2CH_2CH_2C(B_{10}H_{10})CH\cdot HCl$, CH_2Cl_2, pyridine; (iii) $NH_2-CH_2C(B_{10}H_{10})CH\cdot HCl$, CH_2Cl_2, pyridine; (iv) CH_3I, KOH, DMF.

inside a vacuum chamber, and the entire system was irradiated inside the thermal column of the TRIGA Mark II reactor at the University of Pavia, Italy. At the irradiation position, the thermal neutron flux was about 2×10^9 cm^{-2} s^{-1}. The rotating device allowed irradiation and analysis of 10 samples without shutting down the reactor and opening the column. A scheme of this home-built apparatus is shown in ref *47*. Each sample was irradiated for 10 min. The spectra of all the charged particles emitted by the sample (i.e., α particles and ^7Li ions from the reaction of boron, and protons from the reaction of nitrogen) were collected electronically. The portion of spectra due to the α component only was used to calculate the boron concentration in the dry cells. The concentration of the original sample was then obtained by means of the correction factor measured before. This technique is innovative compared to the standard methods used in BNCT and offers a number of advantages. In particular, for tissues taken from a tumor zone, it allows the separation of the contributions coming from the tumor, the normal tissue, the necrotic tissue, and all other kinds of tissues that may coexist in a biopsy. Separation is accomplished by correcting the result of the spectroscopy with neutronographic images of a subsequent cut of the sample and with the histology of a third cut of the same sample. By means of this method, it is possible to determine the concentration of ^{10}B in the tumor cells with a higher precision compared to the conventional methods that provide only an average estimation of the concentration in the entire sample.

RESULTS AND DISCUSSION

Chemistry. First, 1,2-dicarba-*closo*-dodecaboranyl derivative **2d** was prepared following a linear procedure based on the reaction of propargyl derivative **2e** with a bis(acetonitrile)decaborane complex (Scheme 1) (*35*). As decaborane is a highly toxic compound, which forms impact-sensitive mixtures with several materials, the convergent synthesis shown in Schemes 1 and 2 was studied. The preparation of the required carborane synthons (e.g., (aminomethyl)-*o*-carborane hydrochloride and (aminopropyl)-*o*-carborane hydrochloride) was performed as reported in the literature (*37*) in order to reduce the exposure to the hazardous decaborane reagent to a minimum. In the convergent procedure, acid **5** (*30*) was activated to the corresponding acid chloride **6** and made to react with (aminomethyl)-*o*-carborane hydrochloride (*37*) in the presence of pyridine as the base to obtain secondary amide **4g**. Methylation of **4g** with methyl iodide in the presence of sodium hydride at room temperature gave the double-methylated compound **4a**. On the other hand, methylation of tertiary amide **2d** in the same conditions required a gentle warming to give compound **4a** (see the Experimental Procedures). These results suggest that a bidentate anion of **4g** is formed as a consequence of its NH deprotonation.

Interestingly, a similar reaction sequence performed on fluoro derivative **7** (*36*) (Scheme 2) allowed the required tertiary amide **4b** to be obtained in acceptable overall yield when methylation of the secondary amide **4h** was performed in the presence of potassium hydroxide. This result demonstrates that the labeling of **4b** with $[^{11}C]CH_3I$ is actually feasible. On the other hand, the use of the same experimental conditions in the methylation of secondary amide **4i** (obtained with (aminopropyl)-*o*-carborane hydrochloride (*37*)) led to the double-methylated amide **4d**. Although these results are quite functional to our medicinal chemistry work, their rationalization (e.g., the role of intramolecular H-bonding in the methylation reaction) requires further research work.



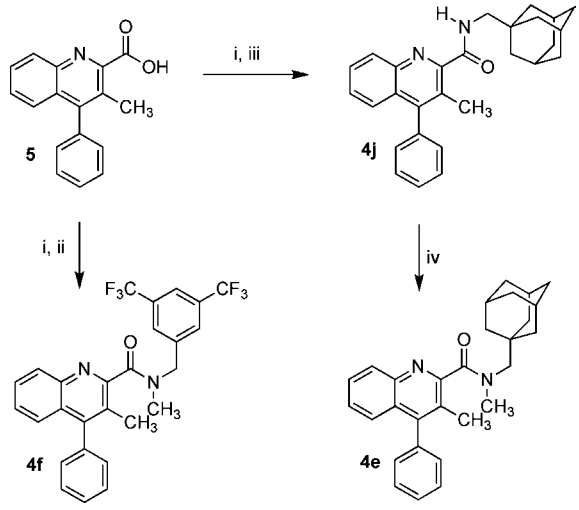


Figure 3. Crystal structure of a molecule (occupancy 0.51) of the secondary amide **4h**. Ellipsoids enclose 50% probability. Significant distances for hydrogen bonding interactions are also reported.

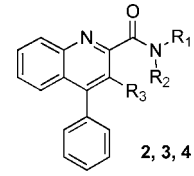
Scheme 3[a]



[a] Reagents: (i) $SOCl_2$, CH_2Cl_2; (ii) $(3,5\text{-}CF_3C_6H_3)CH_2NHCH_3$, TEA, CH_2Cl_2; (iii) 1-aminomethyladamantane, TEA, CH_2Cl_2; (iv) CH_3I, NaH, DMF.

Interestingly, the crystal structure of compound **4h** (Figure 3) shows the presence of an intramolecular hydrogen-bond network. The amide carbonyl oxygen atom behaves as an H-bond acceptor in two unconventional hydrogen bonding interactions with two polarized C−H groups: one belonging to the carborane cage (*38*) and the other belonging to the CH_2F group. Furthermore, the other potential H-bond acceptor present in the **4h** molecule, namely, the quinoline nitrogen atom, is involved in an H-bond interaction with amide N−H. Distances and angles of these interactions reflect the criteria for hydrogen bonds (*48*). They may play a key role in both conformational preferences and reactivity of compound **4h**.

Bulky tertiary amides **4e**,**f** were obtained by means of conventional amide chemistry from 2-quinolinecarboxylic acid **5** (*30*) (Scheme 3).

Binding Studies. Compounds **4a**−**h** were tested for their potential activity in inhibiting the specific binding of [^{3}H]**1** to TSPO in rat cortical membrane in comparison with reference compound **1**. The results of the binding studies are shown in Table 1, along with the previously published TSPO affinities of some selected 2-quinolinecarboxamide derivatives (**2c**,**d** and **3a**) that are included for comparison.

Table 1. TSPO Binding Affinities of Compounds 2c,d, 3a, and 4a−h

[a] Each value is the mean ± SEM of 3 determinations and represents the concentration giving half the maximum inhibition of [^{3}H]**1** (final concentration 1nM) specific binding to rat cortical membranes. [b] See ref *35*. [c] See ref *36*.

The structure−affinity relationship analysis of the compounds included in Table 1 confirm the previously observed difference in affinity between secondary and tertiary amides (*30*). In fact, *o*-carboranylmethyl secondary amides **4g**,**h** show significantly lower TSPO affinities when compared to their *N*-methylated counterparts **2d**, **4b**.

The replacement of the benzyl group of compound **2c** and **3a** with the 1,2-dicarba-*closo*-dodecaboran-1-ylmethyl moiety of **2d** and **4b** appears to be tolerated by TSPO, but the comparison between the couples **2c**/**3a** and **2d**/**4b** shows that the positive effect of the fluorine atom observed for compound **3a** is not paralleled in the couple **2d**/**4b**. This result suggests that the replacement of the phenyl with an *o*-carboranyl moiety produces a change in the binding modalities of these 2-quinolinecarboxamide derivatives.

The nanomolar affinity of carboranylmethyl derivative **4b** attains a particular importance in consideration of the presence of a fluorine atom in its structure; thus, compound **4b** may be considered a potential ^{19}F magnetic resonance imaging agent or can be labeled either with C-11 or with F-18 in order to apply the "see and treat" concept in BNCT.

Methylation of the carborane C−H of **2d** and **4b** produces an affinity decrease of about 1 order of magnitude (compare **2d** with **4a** and **4b** with **4c**). This result suggests that carborane C−H plays a significant role in the interaction with TSPO. Reynolds and co-workers proposed that the carborane substituent sterically approximates a rotating phenyl ring and reported that the hydrogen attached to C2 of the carborane cage shows a pronounced positive partial charge (*49*). Thus, carborane C−H can behave as an H-bonding donor as suggested by the structural studies performed on compounds **4h** and **2d** (*38*). Moreover, the comparison of methylated carborane derivatives **4a**,**c** (IC_{50} = 1750, 1060 nM, respectively) with adamantyl derivative **4e** (IC_{50} = 2100 nM) supports the role of carborane C−H in the interaction with TSPO binding site and suggests that the methylated carborane moiety is recognized by the receptor in a similar manner as an adamantyl moiety. From this viewpoint, it is noteworthy that the introduction of bulky CF_3 substituents in the phenyl group of **2c** amide benzyl is tolerated by TSPO binding site better than its conversion into adamantane moiety (compare **4f** with **4e**). This result suggests that the micromolar affinities shown by adamantyl derivative **4e** and methylated

Table 2. ^{10}B Uptake Obtained by Exposition of Two Different Tumor Cell Lines to Compounds 2d, 4b, and BPA

compd	cell line	[^{10}B][a] medium (ppm)	time (h)	[^{10}B][b] tumor cell (ppm)	uptake ratio	ratio with respect to BPA
BPA	colon cancer	40	4	7.8	0.2	1
2d	colon cancer	8	4	56.5	7.1	35
2d	breast cancer	2	1	9.8	4.9	24
2d	breast cancer	1	1	5.6	5.6	28
4b	breast cancer	2	1	8.2	4.1	20
4b	breast cancer	1	1	7.8	7.8	39

[a] The ^{10}B concentration in the medium was calculated on the basis of the concentration of the boronated compound and ^{10}B abundance. [b] The experimental error associated to the boron concentration measurement by alpha spectrometry is in the order of 10%.

carboranyl derivatives **4a**,**c** can be rationalized in terms of specific interaction failure rather than of steric problems.

Finally, the elongation of the spacer between the amide nitrogen and the carborane moiety from one methylene unit (compound **4c**) to three methylene unities (**4d**) leads to an affinity decrease of about 1 order of magnitude, so that this transformation is unsuitable for optimizing the ligand−receptor interaction.

Cytotoxicity Studies. The structure−affinity relationship study performed with the carborane-conjugated 2-quinolinecarboxamide ligands described in the present paper consolidates the outstanding position of the *o*-carboranylmethyl tertiary amides **2d** and **4b** as nanomolar affinity TSPO ligands carrying 10 boron atoms per molecule. Therefore, these 2-quinolinecarbxamide derivatives can behave as boron carriers targeted toward the mitochondrial outer membrane of cells overexpressing TSPO and potentially capable of producing the ratios of boron concentration between tumor and normal tissues required to lead to tumor destruction with minimal side effects on the normal tissues. In order to minimize the side effects, the most important prerequisite for a boron carrier is the absence of intrinsic toxicity. Thus, the potential cytotoxicity of *o*-carboranylmethyl derivative **2d** was evaluated in DHD cells by means of the plating efficiency test, and no relevant toxic effect (21 ± 5.1%) was observed for treatments at a concentration of 100 μM for 4 h. Moreover, the potential cytotoxicity of **2d** and **4b** was evaluated in MDAMB231 cells in comparison with the nonboronated congener **2c**, which was included in order to obtain information on the structure−toxicity relationships. The ATP-based cell viability studies showed for *o*-carboranylmethyl derivatives **2d** and **4b** IC_{50} values (116 ± 4.1 and 195 ± 49 μM, respectively) higher with respect to the one shown by benzyl congener **2c** (IC_{50} = 66 ± 1.5 μM). This result suggests a low cytotoxicity for the potential boron carrier molecules **2d** and **4b**, even lower than that of nonboronated congener **2c**.

Intracellular ^{10}B Uptake. In order to assess the potential ability of compounds **2d** and **4b** to cross cellular membrane and accumulate into the tumor cells, the boron uptake was determined by means of α spectroscopy. After exposition to compounds **2d** and **4b** and placing on mylar disks, the cells were irradiated in the thermal column of the TRIGA Mark II reactor of Pavia University. The ^{10}B concentration was measured by analyzing the spectra of charged particles emitted in neutron capture reaction and recorded on a thin silicon detector. The results are summarized in Table 2, which includes the values of the uptake ratio obtained by normalizing the value of ^{10}B concentrations in the tumor cells as determined by neutron irradiation with respect to those present in the incubation medium.

The results reported in Table 2 demonstrate that *o*-carboranylmethyl derivatives **2d** and **4b** behave as effective boron carriers in vitro, since they are capable of concentrating boron atoms inside tumor cells. Interestingly, all the uptake values obtained with carborane derivatives **2d** and **4b** are higher than the corresponding values measured with BPA. A previous study (*50*) suggested that BPA is effectively incorporated by DHD cells through an active transport mechanism. The BPA uptake is thought to depend on the concentration used for the treatment, being only slightly dependent on the incubation period and showing a mild increase with increasing contact time. In our procedure, the ^{10}B concentration in the medium was optimized in order to obtain reliable measurements of the ^{10}B concentration in the cells. It is worth noting that, in the case of compound **2d**, a boron concentration of 1 ppm in the medium was sufficient to produce reliable boron concentrations (1 order of magnitude higher than the experimental error estimated in 0.5 ppm) in the cells, while in the case of BPA, a boron concentration in the medium of 40 ppm is required to obtain comparable results.

CONCLUSIONS

In the development of new BNCT agents, targeting mitochondria by means of a mitochondrial receptor such as TSPO can be considered an attractive concept because of the importance of these subcellular structures in the control of cell death. The irradiation with thermal neutrons can be assumed to induce damages to the mitochondria bearing carborane derivatives bound to TSPO. This could produce cytochrome c release in the cytosol with the activation of caspase cascades up to apoptosis. Therefore, carborane derivatives showing high TSPO binding affinity can be considered interesting tools to explore an alternative mechanism in BNCT in which tumor destruction should be obtained at boron concentrations lower than the usual ones. Thus, further exploration of the TSPO binding site by means of 2-quinolinecarboxamide derivatives **4a**−**h** produced the *o*-carboranylmethyl tertiary amide **4b**, which shows nanomolar affinity for TSPO very similar to that shown by previously published **2d**. Therefore, both these two carborane derivatives can be considered potential boron carriers targeted toward the mitochondrial outer membrane of tumor cells overexpressing TSPO. On the basis of these results, their interaction with cancer cells was evaluated in vitro in MDAMB231 breast cancer and DHD/K12/TRb colon adenocarcinoma cells. The cell viability studies suggests a low intrinsic toxicity for **2d** and **4b** and the boron uptake studies demonstrate that these *o*-carboranylmethyl derivatives behave in vitro as effective boron carriers, in that they are capable of concentrating boron atoms into the tumor cells investigated. Although fluoromethyl derivative **4b** is slightly less potent than **2d** in the TSPO binding studies, its significantly lower cytotoxicity, the good results obtained in boron uptake, and its potentialities as a ^{19}F magnetic resonance imaging (MRI) agent induce one to select it as a promising candidate for in vivo studies. Moreover, compound **4b** can be labeled either with C-11 or F-18 in order to monitor its in vivo pharmacokinetics, tumor extraction, and regional distribution by positron emission tomography (PET) in order to apply the "see and treat" strategy in BNCT.

ACKNOWLEDGMENT

The authors are grateful to Prof. Stefania D'Agata D'Ottavi for the careful reading of the manuscript and to Dr. Francesco Berrettini (CIADS, Università di Siena) for the X-ray data collection. G. Giorgi gratefully thanks Dr. Mark E. Light, School of Chemistry University of Southampton, for useful support for

X-ray data refinement. This work was financially supported by Ministero dell'Università e della Ricerca - PRIN (Programmi di ricerca di Rilevante Interesse Nazionale) and by Istituto Nazionale di Fisica Nucleare (INFN).

Investigations on the Use of Fluorescence Dyes for Labeling Dendrimers: Cytotoxicity, Accumulation Kinetics, and Intracellular Distribution

A. M. Scutaru,[†] M. Krüger,[†] M. Wenzel,[†] J. Richter,[‡] and R. Gust*[,†,§]

Institute of Pharmacy, Freie Universität Berlin, Königin Luise Str. 2 + 4, 14195 Berlin, Germany, Charité Campus Benjamin Franklin, Institute of Clinical Physiology, Hindenburgdamm 30, 12203 Berlin, Germany, and Department of Pharmaceutical Chemistry, Institute of Pharmacy, University of Innsbruck, Innrain 52a, A-6020 Innsbruck, Austria. Received April 28, 2010

Fluorescent dyes (e.g., dansyl, fluoresceine isothiocyanate, or naphthalimide groups) are widely used as markers to study biological properties of drugs. In order to evaluate possible mediated cytotoxicity, we attached three molecules each to 1,3,5-tris(3-propylamino)benzene initially synthesized as core molecule for the design of dendrimers. Cytotoxic effects were only observed for the NO_2-substituted naphthalimide conjugate. The intracellular distribution was visualized via confocal fluorescence microscopy and pointed to an accumulation in the endosome or nucleus, dependent on the cell line used.

INTRODUCTION

Dendrimers have attracted considerable attention in the past two decades. The advantages of dendrimers, if compared with classical polymers, are their monodisperse geometry, the high terminal group density at their surface, as well as the possibility of a determined surface functionality.

The biological properties of dendrimers, including in vitro and in vivo toxicity and biodistribution, have gained more and more importance in the past few years. Their unique physical and chemical properties make them ideal candidates for drug delivery systems (*1*−*3*). Drugs can be covalently attached at the surface of the molecule, or in the case of larger dendrimers, they can be enclosed as guest molecules. Both concepts ensure targeted release (*4*−*11*).

For the use of macromolecular tumor therapy, it is important to control the accumulation of the carrier in the tumor tissue and the intercellular distribution. For this purpose, the carriers are miscellaneously labeled for detection through trace analysis. The most commonly used markers are radioactive elements such as ^{125}I (*12*−*16*), ^{51}Cr (*17*), and ^{111}In (*18*−*20*), which can easily be detected in vivo and in vitro, e.g., by methods in radioactive trace analysis. Alternatively, fluorescence analysis and high-resolution confocal fluorescence microscopy can be used to visualize the subcellular distribution if the molecule is labeled by fluorophors such as rhodamine (*21*), fluoresceine (*15, 22*−*24*), or Oregon Green (*25, 26*).

The use of dendrimers as drug delivery systems implies no cytotoxic properties of the macromolecule with and without labeling. In a previous study, we synthesized various dendrimers starting from the 1,3,5-tris(3-propylamino)benzene core molecule (**1**, Scheme 1) (*27*). This G0 molecule did not influence the growth of hormone-dependent MCF-7 or hormone-independent MDA-MB 231 cells. Therefore, we decided to use it to study the influence of macromolecular-bound fluoresceine isothiocyanate (FITC), naphthalimide, and nitronaphthalimide fluorophores on cytotoxicity, the accumulation kinetics, and the intracellular distribution in MCF-7 and MDA-MB-231 breast cancer cell lines.

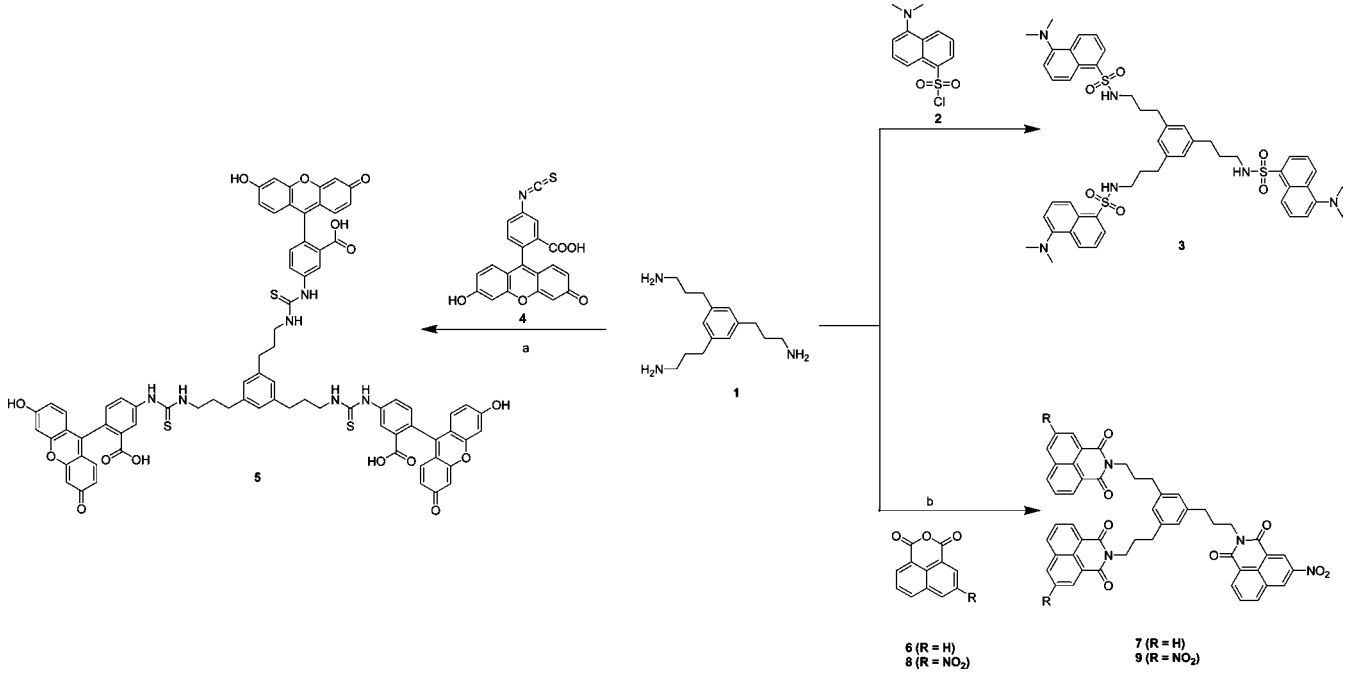
MATERIALS AND METHODS



Synthesis. Compounds **1** and **3** were prepared according to the literature procedure (*27*). The other starting materials were purchased from commercial sources and were used without purification. Solvents were dried under standard conditions. ^{1}H NMR spectra were taken on a Bruker Avance/DPX 400 MHz with TMS as internal standard. Melting points (uncorrected) were measured with a Büchi Melting Point B-545. All column chromatography purifications were done by using silica gel 60 (0.063−0.1 mm, Merck). TLC was performed on silica gel 60 GF_{254} plates (Merck). Elemental analysis was carried out on a Vario EL (Hanau). EI spectra were recorded on a Thermo-Fisions VG Auto Spec (70 eV). The FAB spectra were measured on a CH-5, Varian MAT, Bremen. The ESI-TOF spectra were measured on an Agilent 6210 ESI-TOF, Agilent Technologies, Santa Clara, CA, USA. Solvent flow rate was adjusted to 4 μL/min; spray voltage set to 4 kV. Drying gas flow rate was set to 15 psi (1 bar). All other parameters were adjusted for a maximum abundance of the relative $[M+H]^+$.

1,3,5-Tris[*N*-(5-fluorescenyl)thiourea-propane-3,1-diyl]benzene (5). 1 × 3HCl (34.54 mg, 0.096 mmol) was dissolved in DMSO and treated with 0.16 mL of triethylamine (1.152 mmol). FITC was added to the solution, and the mixture was stirred for 24 h at room temperature in the dark. The solution was then poured in water and the pH value was adjusted to 4 with 5% hydrochloric acid. The color of the mixture changed from orange to yellow−green, and a solid precipitated. The compound was filtered off, washed with water, and then dried to afford an orange solid (100 mg, 73.4%); mp > 400 °C. ^{1}H NMR (400 MHz, CD_3OD): 1.98 (quin, ^3J(H,H) = 7.16 Hz, 6H, CH_2), 2.68 (t, ^3J(H,H) = 7.18 Hz, 6H, CH_2Ar), 3.61 (m, 6H, CH_2NH), 6.55 (dd, ^3J(H,H) = 2.34 Hz, 8.64 Hz, 6H, FITC), 6.69 (d, ^3J(H,H) = 1.94 Hz, 9H, FITC), 6.71 (s, 3H, FITC), 6.99 (s, 3H, Ar), 7.11 (d, ^3J(H,H) = 8.22 Hz, 3H, FITC), 7.69 (d, ^3J(H,H) = 7.31 Hz, 3H, FITC), 8.12 (s, 3H NH). MS (ESI): calcd. for $C_{78}H_{60}N_6O_{15}S_3Na^+$, 1439.3171; found 1439.3118. Anal. ($C_{78}H_{60}N_6O_{15}S_3$) C, H, N.

1,3,5-Tris{3-[1*H*-benzo[de]isoquinoline-1,3(2*H*)-dione]propylamino}benzene (7). 1 × 3HCl (359 mg, 1 mmol) was dissolved in 20 mL of dry ethanol and treated with 1.7 mL of dry

triethylamine. 1,8-Naphtalic anhydride (654 mg, 3.3 mmol) was added and the mixture was refluxed for 3 h in the dark. The precipitated solid was vacuumed off, washed with ethanol, and dried over P_2O_5. Yield: 650 mg (82%) as a colorless solid; mp = 300 °C. ^{1}H NMR (400 MHz, $CDCl_3$): 1.97 (quin, ^3J(H,H) = 7.64 Hz, 6H, CH_2), 2.55 (t, ^3J(H,H) = 8.28 Hz, 6H, CH_2Ar), 4.20 (t, ^3J(H,H) = 7.38 Hz, 6H, CH_2N), 6.77 (s, 3H, Ar), 7.70 (t, ^3J(H,H) = 7.61 Hz, 6H, naphthalimide), 8.16 (d, ^3J(H,H) = 7.61 Hz, 6H, naphthalimide), 8.55 (d, ^3J(H,H) = 7.61 Hz, 6H, naphthalimide). MS (EI, 80 eV, 300 °C); *m*/*z* (%): 789.4 (1.74) [M^+], 398.9 (100.0) $C_{27}H_{28}NO_2$, 197.9 (49.95), $C_{12}H_7NO_2$. Anal. ($C_{51}H_{39}N_3O_6$) C, H, N.

1,3,5-Tris{3-[5-nitro-1*H*-benzo[de]isoquinoline-1,3(2*H*)-dione]propylamino}benzene (9). **1** × 3HCl (200 mg, 0.56 mmol) was dissolved in 10 mL of dry ethanol and treated with 940 μL of dry triethylamine. 3-Nitro-1,8-naphthalic anhydride (447.4 mg, 1.84 mmol) was added, and the mixture was refluxed for 3 h in the dark. The precipitated solid was vacuumed off, washed with ethanol, and dried over P_2O_5. Yield: 320 mg (61.8%) as a brown powder; mp = 272 °C. ^{1}H NMR (400 MHz, $CDCl_3$): 1.97 (quin, ^3J(H,H) = 7.41 Hz, 6H, CH_2), 2.53 (t, ^3J(H,H) = 7,93 Hz, 6H, CH_2Ar), 4.20 (t, ^3J(H,H) = 7.44 Hz, 6H, CH_2N), 6.74 (s, 3H, Ar), 7.92 (t, ^3J(H,H) = 7.67 Hz, 3H, naphthalimide), 8.40 (d, ^3J(H,H) = 8.14 Hz, 3H, naphthalimide), 8.75 (d, ^3J(H,H) = 6.46 Hz, 3H, naphthalimide), 9.10 (d, ^3J(H,H) = 2.10 Hz, 3H, naphthalimide), 9.24 (d, ^3J(H,H) = 2.13 Hz, 3H, naphthalimide). MS (FAB+, MNBA/DCM) *m*/*z* (%): 925.3 (30.23) [M+H]$^+$, 699.4 (65.70) [M-$C_{12}H_5N_2O_3$]$^+$. Anal. ($C_{51}H_{36}N_3O_6$) C, H, N.

Cell Culture. The human MCF-7 and MDA-MB 231 breast cancer cell lines were obtained from the American Type Culture Collection (ATCC). Cell line banking and quality control were performed according to the seed stock concept reviewed by Hay (*28*). The MCF-7 cells were maintained in Eagle's minimal essential medium (EMEM) containing L-glutamine supplemented with $NaHCO_3$ (2.2 g/L), sodium pyruvate (110 mg/L), gentamycin (50 mg/L), and 10% fetal calf serum (FCS, Gibco, Eggenheim, Germany) using culture flasks (75 cm^2, Nunc) in a water-saturated atmosphere (5% CO_2) at 37 °C. The MDA-MB-231 cells were maintained in McCoy's 5a Medium and 5% FCS. The cells were serially passaged weekly following trypsin treatment using a solution of trypsin (0.05%) and EDTA (0.02%).

In Vitro Chemosensitivity Assay. The in vitro testing of the compounds for cytotoxic activity was carried out on exponentially dividing cancer cells according to a previously published microtiter assay (*29*). Briefly, in 96-well microtiter assay plates (Nunc), 100 μL of a cell suspension was plated into each well and incubated at 37 °C for 3 days (MCF-7) and 2 days (MDA-MB-231) in a water-saturated atmosphere (5% CO_2). The desired test concentration was obtained by addition of an adequate volume of a stock solution of the respective compound to the medium. Sixteen wells were used for each test concentration and for the control, which contained the corresponding amount of solvent (0.1% v/v) respectively. After appropriate incubation periods, the medium was removed and the cells were fixed with a glutaraldehyde solution and stored at 4 °C. Cell biomass was determined by a crystal violet staining technique. The influence of the complexes on cell growth is expressed as the corrected *T*/*C* value according to the equation

$$\text{Cytostatic effect: } \%T/C_{\text{corr}} = [(T - C_0)/(C - C_0)] \times 100$$

in which *T* (test) and *C* (control) are the optical density values at 578 nm of the crystal violet extract of the cells in the wells (that is, the chromatin-bound crystal violet extracted with 70% ethanol), and C_0 is the density of the cell extract immediately before treatment. A microplate reader at 590 nm (Flashscan Analytik Jena AG) was used for the automatic estimation of the optical density of the crystal violet extract in the wells. The calculated %*T*/*C* values can be interpreted as follows:

$T/C > 80\%$: no antiproliferative effect
$80\% > T/C > 20\%$: antiproliferative effect
$20\% > T/C > 0\%$: cytostatic effect

Cellular Uptake Studies. The cells were seeded in 6-well plates (Nunc). When the cells reached 50−60% confluence (approximately after 5 days of incubation), the medium was exchanged for serum-free EMEM/Mc Coy's containing the compounds. The medium was removed after appropriate

Table 1. Excitation and Emission Wavelengths of the Fluorescence-Labeled Conjugates

compound	fluorophor	λ_{max}ex (nm)	λ_{max}em (nm)
3	dansyl	340	535
5	fluoresceine isothiocyanate	450	519
7	naphthalimide	333	387
9	nitronaphthalimide	361	440

incubation periods, and the cells were washed with ice-cold PBS. After trypsination, the cells were harvested, washed two times with ice-cold PBS, and centrifuged (2000 *g*, 4 °C, 5 min) for storage at −18 °C until analysis. The cell pellet was homogenized by sonification in a Triton X-100 solution (1% (w/w)) and was adequately diluted for protein determination (*30*). The cellular concentrations of the compounds in the cells were determined as previously published (*31*).

RESULTS AND DISCUSSION

Synthesis. The synthesis of the dansyl derivative **3** (formulas of the conjugates; see Scheme 1) was already described in a previous paper (*27*). For the synthesis of the FITC-derivative **5**, the core molecule **1** × 3HCl was dissolved in DMSO and treated with triethylamine to provide the free base. Subsequently, FITC was added and the mixture was stirred in the dark at room temperature. The pure product **5** was obtained with 73% yield. To obtain **7** and **9**, **1** and the respective naphthalic anhydride (**6**, respectively, **8**) were refluxed for 3 h in ethanol under protection from light. The final products were precipitated from the reaction mixture.

In Vitro Cytotoxicity. The antiproliferative activity of the conjugates was determined in tests on the human MCF-7 and MDA-MB-231 breast cancer cell lines. Cisplatin used as a reference influenced the cell growth in a concentration-dependent manner and caused almost 100% inhibition in both cell lines at the highest concentration (5 μM).

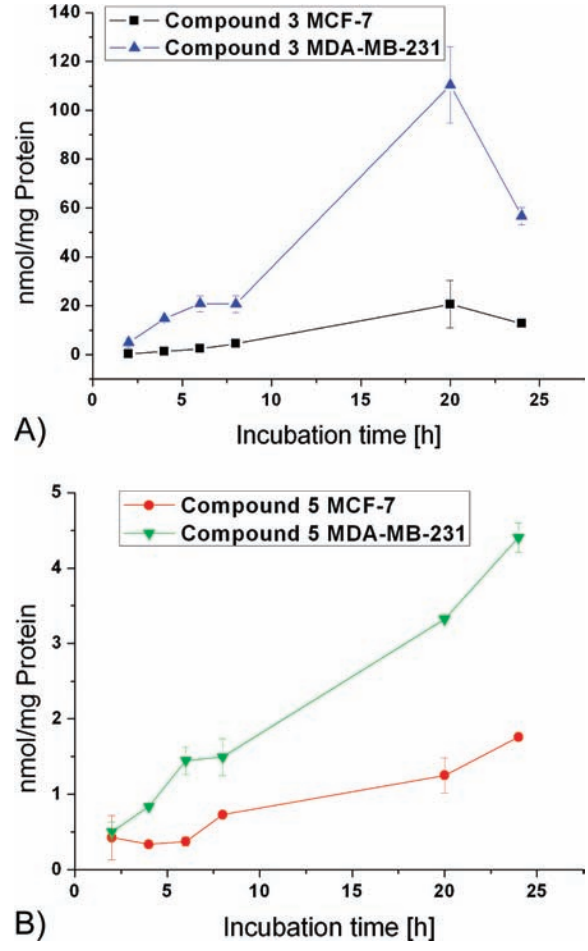

Figure 3. Accumulation kinetics of (A) dansyl conjugate **3** and (B) FITC conjugate **5**.

The antiproliferative effect (at concentrations of 1, 5, and 10 μM) expressed as T/C_{corr} values (T, treated group; C, control group) was correlated with the incubation time and documented for the free core molecule **1** (*27*) as well as the dansyl, fluoresceine isothiocyanate, and naphthalimide conjugates **3**, **5**, and **7**. No influence on the growth of MCF-7 and MDA-MB-231 cells could be observed (data not shown).

Interestingly, introduction of a nitro group to the naphthalimide in **7** strongly increased the cytotoxicity of the conjugate. As depicted in Figure 1, the effects of **9** were more pronounced

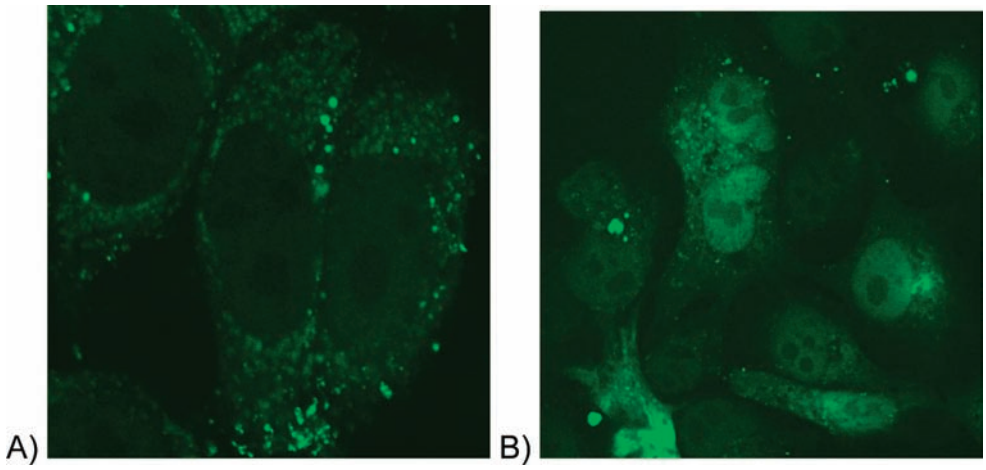

Figure 4. Fluorescence microscopy images of **5**: (A) MCF-7 cells; (B) MDA-MB-231 cells.

at the MDA-MB-231 cell line up to an incubation time of 72 h. The recuperation of the cells until the end of the test equals the effects at both cell lines. A possible explanation for these antitumor properties could be an involvement of the nitro group in intracellular redox reactions (*32*).

These findings documented the suitability of the dansyl, fluoresceine isothiocyanate, and the naphthalimide residue as fluorescence marker and require the determination of their spectroscopical properties after binding to **1**.

Fluorophor Characterization. The fluorescence of the synthesized conjugates was characterized by using a Hitachi F-4500 fluorescence spectrophotometer. All compounds showed only one excitation maximum. As an example, the 3D fluorescence spectrum of **5** is depicted in Figure 2.

The emission maximum of conjugates **3**, **5**, **7**, and **9** depended on the dye used (Table 1). Only **3** and **5** fulfill the requirement for accumulation studies (λ_{max} em > 500 nm) and can be used for accumulation studies.

Accumulation Kinetics. In order to quantify the cellular uptake, MCF-7 and MDA-MB-231 cells were incubated with 5 μM of the dye conjugates **3** and **5**, respectively, and the accumulation of the substance expressed as nmol/mg protein was fluorimetrically estimated. Possible inactivation reactions of the compounds due to protein binding were minimized by growing the cells in FCS-free EMEM. FCS is necessary for cell growth, but the short-term incubation did not change cell morphology and cell growth.

As depicted in Figure 3A, the dansylated conjugate **3** was accumulated to a higher degree in the tumor cells than **5** (Figure 3B). Furthermore, the kinetics differed significantly. In MDA-MB-231 cells, a fast accumulation of **3** occurred with saturation after 20 h. After 24 h, the intracellular content amounted to 56 nmol/mg protein. In the MCF-7 cells, the saturation was also reached after 20 h, but the intracellular amount of the dye was much lower (13 nmol/mg protein).

Exchange of the dansyl residue by fluoresceine isothiocyanate (**3** → **5**) reduced the accumulation kinetics. At both cell lines, no saturation was observed during the incubation time of 24 h. Furthermore, the intracellular amount of the conjugate **5** was considerably reduced.

Intracellular Localization. Conjugates **3**, **5**, **7** and **9** were incubated with either MCF-7 or MDA-MB-231 cells at a concentration of 10 μM for 24 h to visualize the intracellular distribution. Confocal fluorescence microscopy (Zeiss LSM 510) shots of the adnated cells clearly showed an accumulation of the fluorescence labeled conjugates in cell compartments. Surprisingly, the intracellular distribution differs depending on the cells used. The dye was mainly determined in the endosomes of MCF-7 cells, while the conjugates accumulated in MDA-MB-231 cells at the nucleus. Fluorescence microscopy images of **5** were depicted as examples in Figure 4.

CONCLUSION

Attachment of fluorescence dyes to the core molecule **1** did not increase the cytotoxicity but determined the intracellular distribution dependent on the cell type. Only the NO_2-bearing naphthalimide derivative **9** reduced the growth of MCF-7 and MDA-MB-231 cells, probably due to the interference in intracellular redox processes.

ACKNOWLEDGMENT

Department of Chemical Science and Engineering, Graduate School of Engineering, and Organization of Advanced Science and Technology, Kobe University, 1-1 Rokkodaicho, Nada, Kobe 657-8501, Japan. Received April 28, 2010; Revised Manuscript Received October 18, 2010

A ZZ domain (ZZ) and alkaline phosphatase (AP), luciferase (Luc), or glucose oxidase (GOD) were conjugated using Sortase A (SrtA) from *Staphylococcus aureus*. The specific peptidyl linker for SrtA was genetically fused to the C-terminus of ZZ, and the other linker was fused to the N-terminus of AP, Luc, or GOD, respectively. The resultant proteins were obtained separately by bacterial expression. The recombinant peptide-tagged ZZ and AP, Luc, or GOD were site-specifically conjugated by SrtA through the extra peptidyl linkers in vitro. The SrtA reaction had little influence on either the antibody-binding activity of the ZZ moiety or the enzymatic activity of AP, Luc, or GOD moieties of the conjugates. Additionally, antibody-ZZ-proteins were yielded easily by mixing antibody with ZZ-AP, ZZ-Luc, or ZZ-GOD, allowing their use in an enzyme-linked immunosorbent assay. These results suggest that the enzymatic approach with SrtA facilitates the construction of ZZ-proteins. Furthermore, mixing antibody and ZZ-proteins produces a wide variety of antibody-ZZ-proteins.

INTRODUCTION

Site-specific protein modification is a powerful strategy in biological research, because it enables protein manipulation without significant loss of function. Chemical modification is widely employed, although this strategy is not always "site-specific", but rather "residue-specific". If the target protein has a number of reactive residues, chemically modified products are often heterogeneous due to random modifications. Since cysteine (Cys) residues do not occur frequently in native proteins and a genetically introduced Cys may represent the only site to be modified, Cys-based protein modification with thiol-selective reagents has often been employed (*1*−*4*). Native chemical ligation, such as N-terminally introduced Cys-specific modification, is a more sophisticated strategy due to its being N-terminal-specific (*5, 6*). One obstacle is the difficulty associated with producing Cys-introduced proteins due to the formation of inclusion bodies or incorrect disulfide bridges.

Enzymatic approaches to site-specific protein modification have attracted much attention because the substrate specificity of an enzyme enables "site-specific" protein modification (*7, 8*). Several kinds of transglutaminases have been used for protein modification with primary amine-containing molecules such as fluorescence probes or PEG (*9*−*11*). Briefly, a short substrate sequence for transglutaminase is genetically introduced at the N- or C-terminus of the target protein. The expressed protein is modified with a small primary amine-containing molecule. Sortase has also been used for protein modification (*12*−*16*). The most studied one is Sortase A (SrtA), a transpeptidase from *Staphylococcus aureus*. Wild-type SrtA consists of 206 amino acids (23.5 kDa). N-Terminal 59-amino-acid truncated SrtA (17 kDa and pI = 6.8) has been used in many studies (*13*−*16*). SrtA recognizes the LPXTG sequence, cleaves between the Thr and Gly residues, and subsequently links the carboxyl group of Thr to an amino group of N-terminal glycine oligomers by a native peptide bond (*17, 18*). Recombinant soluble SrtA has been used for peptide−protein or protein−protein ligation in vitro because of its greater substrate specificity (*19*−*21*). The advantages of this enzymatic protein modification strategy are that it is highly selective and mild compared to conventional methods.

Antibody−protein conjugates have been widely used in various areas because of their remarkable molecular recognition properties. Generally, a Cys-based modification strategy is employed; however, site-specific modification of antibodies is not always achieved and the yield of modified antibody is not yet high enough. Although short peptide tag sequences should be introduced into antibodies in order to apply the enzymatic modification strategy, the establishment of a recombinant antibody production system is too difficult and is less versatile (*22*−*24*).

Here, we demonstrate site-specific antibody−protein conjugation using SrtA. We focused on an antibody-binding domain called the ZZ domain. The ZZ domain has high affinity to the Fc region of various kinds of antibodies, and its genetic manipulation and mass production is very easy (*25, 26*). The strategy of this study is shown in Figure 1A. ZZ domains were site-specifically conjugated with other proteins using sortase, and then the desired antibody−ZZ-protein conjugates were created by simply mixing the antibodies and ZZ−protein conjugates. We genetically introduced the LPETG sequence to the C-terminus of a ZZ domain (ZZ-LPETG). As model of partner proteins, alkaline phosphatase (*27*), luciferase (*28, 29*), and glucose oxidase (*30*) were used (Figure 1B). Pentaglycine appended alkaline phosphatase (Gly5-AP), luciferase (Gly5-Luc), and triglycine appended glucose oxidase (Gly3-GOD) were prepared (Figure 1B). ZZ-LPETG and Gly5-AP were site-specific conjugated by a SrtA-mediated reaction. In addition, Gly5-Luc and Gly3-GOD were also conjugated with ZZ-

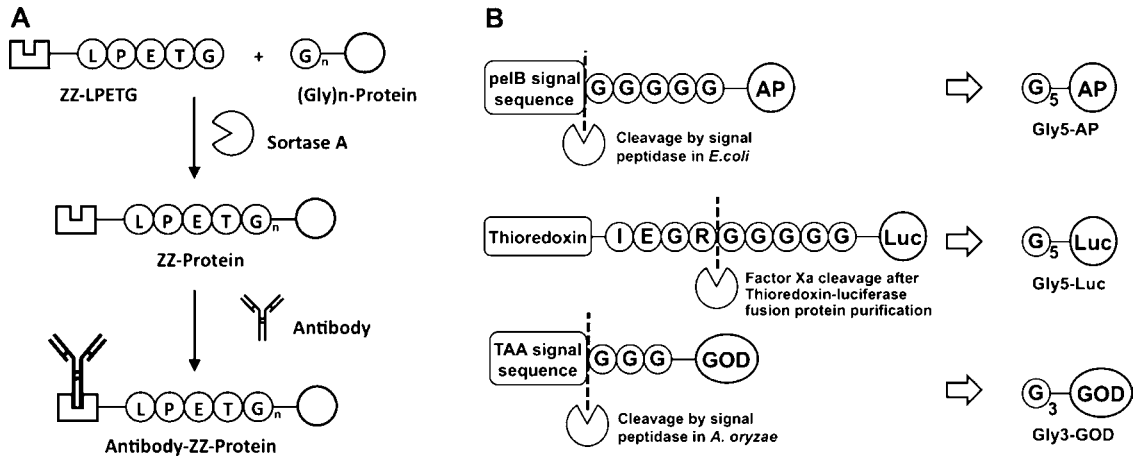

Figure 1. (A) Schematic illustration of antibody-ZZ-protein conjugation using Sortase A. ZZ-LPETG and (Gly)*n*-protein are site-specifically conjugated by Sortase A. The resultant ZZ−protein is simply mixed with whole antibody, and antibody-ZZ-protein is obtained due to the affinity between Fc region of ZZ and Fc region of antibody. (B) N-Terminal glycine appended proteins used in this study. Alkaline phosphatase and glucose oxidase were expressed with pelB signal sequence and Taka amylase (TAA) signal sequence, respectively. The moiety of signal sequence was cleaved by signal peptidase in each host cells; the N-terminal glycine exposed proteins were obtained. In the case of luciferase, Factor Xa cleavage between thioredoxin and luciferase could expose the N-terminal glycine of luciferase.

LPETG. Finally, we successfully demonstrated target molecule detection using antibody-ZZ-protein conjugates.

EXPERIMENTAL PROCEDURES

Plasmid Construction. The plasmid for pentaglycine appended alkaline phosphatase expression was constructed as follows. The gene encoding alkaline phosphatase (AP) from *E. coli* was amplified by PCR using *E. coli* genomic DNA as a template with the following primers: 5′-C CGT CAT ATG AAA TAC CTG CTG CCG ACC GCT GCT GCT GGT CTG CTG CTC CTC GCT GCC CAG CCG GCG ATG GCC GGC GGT GGA GGT GGA TCC ACA CCA GAA ATG CCT GTT CTG GAA AAC C-3′ and 5′-TTA ACT CGA GTG CGG CCG CTT TCA GCC CCA GAG CGG CTT TCA TGG-3′. (pelB leader sequence is underlined.) The amplified fragment was subcloned into the *Nde*I/*Xho*I sites of pET22b (Novagen). The resultant plasmid was named pET22b-Gly5-AP. The pelB leader sequences were cleaved during expression (*31*), and N-terminal glycine was exposed (Figure 1B).

The plasmid for LPETG sequence appended ZZ domain expression was constructed as follows. The gene encoding ZZ was amplified by PCR using pGLDLd33-ZZ (*32*) as a template using the following primers: 5′-GC GGT ACC GGA TCC GGT ATT GAG GGT CGC GGC GGT GGA GGT GGT GCG CAA CAC GAT GAA GCC GTA GAC-3′ and 5′-GC GAG CTC CTA GAA TTC ACC GCC AGT CTC AGG CAG GCC GCC GCC GGA GGA CTC TTT CGG CGC CTG AGC ATC ATT TAG C-3′. The amplified fragment was ligated into the *Kpn*I/*Sac*I sites of pBAD-Gly5-EGFP (*15*). The resultant plasmid was named pBAD-ZZ-LPETG. The plasmid for pentaglycine appended luciferase (Luc) expression was constructed as follows. The gene encoding Luc was amplified by PCR using pCBG68-Basic Vector (Promega) as a template using the following primers: 5′-GCG GTA CCG GAT CCG GTA TTGAGG GTC GCG GCG GTG GAG GTG GTG ACT ACA AGG ATG ACG ACG ACA AGA TGG TGA AAC GCG AAA AGA ACG TGA TCT ACG G-3′ and 5′-GCG AGC TCC TAG CCG CCA GCT TTT TCG AGG AGT TGC TTC AGC-3′. The amplified fragment was ligated into the *Kpn*I/*Sac*I sites of pBAD-Gly5-EGFP (*15*). The resultant plasmid was named pBAD-Gly5-Luc.

The plasmid for triglycine appended glucose oxidase (GOD) expression was constructed as follows. The gene encoding GOD was amplified by PCR using *Aspergillus niger* genomic DNA as a template using the following primers: 5′-GC CTC GAG AAA AGA GGC GGT GGA CAC CAC CAC CAC CAC CAC AGC AAT GGC ATT GAA GCC AGC CTG GTG ACT GAT CCC-3′ and 5′-G CAT AGC GGC CGC TCA CTG CAT GGA AGC ATA ATC TTC CAA-3′. The second PCR was carried out using the amplified fragment as a template using the following primers: 5′-G CAT ACT AGT AAA AGA GGC GGT GGA CAC CAC CAC CAC CAC CAC-3′ and 5′-G CAT AGC GGC CGC TCA CTG CAT GGA AGC ATA ATC TTC CAA-3′. The amplified fragment was ligated into the *Spe*I/*Not*I sites of pISI-EGFP (*33*). The resultant plasmid was named pISI-Gly3-GOD. In the case of Gly3-GOD, secretion signal sequence derived from taka amylase (*33*) were cleaved during secretion, and N-terminal glycine was exposed (Figure 1B).

The plasmid for myc sequence appended luciferase (Luc) expression was constructed as follows. The gene encoding Luc was amplified by quick change using the pBAD-Gly5-Luc Vector as a template using following primers: 5′-GAC TAC AAG GAT GAC GAC GAC AAG GAA CAA AAG TTG ATC AGC GAA GAG GAC CTC ATG GTG AAA CGC GAA AAG AAC GTG-3′ and 5′-CAC GTT CTT TTC GCG TTT CAC CAT GAG GTC CTC TTC GCT GAT CAA CTT TTG TTC CTT GTC GTC GTC ATC CTT GTA GTC-3′. The resultant plasmid was named pBAD-Gly5-myc-Luc.

The plasmid for pentaglycine and FLAG sequence appended red fluorescence protein (RFP) expression was constructed as follows. The gene encoding RFP was amplified by PCR using pmRFP-N1 (Clontech) as a template using the following primers: 5′-CGG GGT ACC ATT GAG GGT CGC GGC GGT GGA GGT GGT AGC GAT TAC AAG GAT GAC GAC GAT AAG AGC GAC AAC ACC GAG GAC GTC ATC AAG GAG TTC-3′ and 5′-GAG CTC CTA GCT AGC ATA ATC TGG AAC ATC ATA TGG ATA GCT GGA GCC GGA GTG GCG GGC CTC GGC GTG CTC-3′. The amplified fragment was ligated into the *Kpn*I/*Sac*I sites of pBAD-Gly5-EGFP (*15*). The resultant plasmid was named pBAD-Gly5-FLAG-RFP.

Protein Expression and Purification. SrtA and green fluorescence protein (GFP) were expressed and purified according to a previous report (*15*). The expression and purification of Gly5-AP was conducted as follows. Plasmid pET22b-Gly5-AP was transformed into *E. coli* BL21 (DE3) (Novagen). The cells were grown in LB medium to an OD (600 nm) value of 0.8, at which time expression of protein was induced by the addition of isopropyl-β-D-thiogalactopyranoside (IPTG) to a final concentration of 0.5 mM. After growth for an additional 16 h

at 25 °C, the cells were harvested by centrifugation. The cell pellets were resuspended in 50 mM Tris-HCl, 300 mM NaCl, pH 7.5, and lysed by sonication. Gly5-AP was purified from the soluble fraction of the lysate by TALON metal affinity resins (Clontech) according to the manufacturer's protocol and dialyzed against 50 mM Tris-HCl, 300 mM NaCl, pH 7.5. Protein concentration was determined using a BCA protein assay kit (Pierce).

Plasmids pBAD-ZZ-LPETG, pBAD-Gly5-Luc, pBAD-Gly5-myc-Luc, and pBAD-Gly5-FLAG-RFP were induced in *E. coli* Top10 (Invitrogen) by the addition of 0.1% L-arabinose and subsequent incubation for 16 h at 25 °C. ZZ-LPETG, Gly5-Luc, Gly5-myc-Luc, and Gly5-FLAG-RFP were purified using TALON metal affinity resin as described above. In the case of Gly5-Luc, Factor Xa (New England Biolabs) cleavage was carried out according to manufacturer's procedure to expose the N-terminal glycine (Figure 1B). After cleavage, Factor Xa was removed by Benzaimidine Sepharose 4 Fast Flow (GE Healthcare), and the cleaved thiredoxin moiety was also removed by TALON metal affinity resin.

The *Aspergillus oryzae* niaD mutant (strain IF4), derived from wild-type *A. oryzae*, OSI1031, was used as the GOD expression host. Czapek-Dox (CD) medium plates (2% glucose, 0.3% $NaNO_3$ (CD-NO_3), 0.2% KCl, 0.1% KH_2PO_4, 0.05% $MgSO_4 \cdot 7H_2O$, and 0.8 M NaCl, pH 6.0) containing 1.5% agar were used as the minimal medium to select the fungal transformants. GPY medium (3% glucose, 0.2% KCl, 0.1% KH_2PO_4, 0.05% $MgSO_4 \cdot 7H_2O$, 1% peptone, and 0.5% yeast extract, pH 6.0) was used for growing the transformants and for GOD expression. The transformation of *A. oryzae* was carried out according to the method described by Gomi et al. (1987). The resultant transformants were subcultured on a CD-NO_3 medium plate three times for obtaining the stable expression transformants. Then, the transformants were seeded on 250 mL of GPY medium and cultivated for 6 days at 30 °C. The culture supernatants were separated using Mira cloth (Millipore), and the secreted GOD was purified using TALON metal affinity resin according to the manufacturer's procedure.

SrtA Reaction between ZZ-LPETG and Pentaglycine Appended Proteins. The reaction between ZZ-LPETG (10 μM) and Gly5-AP (25 μM), Gly5-Luc (10 μM), and Gly3-GOD (10 μM) was initiated by the addition SrtA (35 μM). The reaction was carried out in 20 mM Tris-HCl, 150 mM NaCl, 0.5 mM $CaCl_2$, pH 7.5 at 24 °C. After incubation for 15 h, the reaction was terminated by mixing with SDS-PAGE sample buffer (50 mM Tris-Cl, 2% SDS, 6% 2-mercaptoethanol) and boiling. The samples were then subjected to SDS-PAGE, and the gels were stained with Coomassie brilliant blue R-250 (Nacalai Tesque).

AP Activity Analysis. In order to evaluate AP activity, luminescence was determined using CDP-Star (Applied Biosystems) after the SrtA reaction. Gly5-AP (25 μM), ZZ-LPETG (10 μM), and SrtA (35 μM), creating a ZZ-AP conjugate, were placed in each well of a 96-well microplate. After the addition of CDP-Star, the luminescence intensity in each well was measured at room temperature with a Wallac 1420 ARVOsx Multi Label Counter (Perkin-Elmer).

Luciferase Activity Analysis. In order to evaluate Luc activity, the luminescence was determined using Bright-Glo (Promega) after the SrtA reaction. Gly5-Luc (10 μM), ZZ-LPETG (10 μM), and SrtA (35 μM), creating a ZZ-Luc conjugate, were placed in each well of a 96-well microplate. After the addition of Bright-Glo, the luminescence intensity in each well was measured at room temperature with a Wallac 1420 ARVOsx Multi Label Counter.

GOD Activity Analysis. In order to evaluate GOD activity, the absorbance was determined using glucose and peroxidase and a coloring reagent (Nacalai Tesque) after the SrtA reaction. Gly3-GOD (10 μM), ZZ-LPETG (10 μM), and SrtA (35 μM), creating a ZZ-GOD conjugate, were placed in each well of a 96-well microplate. After the addition of glucose (0.5 M), peroxidase (1 mg/mL), and coloring reagent (100 μL), the absorbance at 450 nm in each well was measured at room temperature with a Wallac 1420 ARVOsx Multi Label Counter.

ELISA Using Antibody-ZZ-Protein Conjugates. BSA was Gly5-FLAG-RFP (10 μg/mL in PBS) were placed in each well of a 96-well microplate and incubated for 15 h at 4 °C to allow adsorption to the surface of the wells. At the same time, 15 μM ZZ-AP conjugate and 6 μM ZZ-Luc conjugate were added with anti-FLAG antibody 20 μg/mL (Sigma) and incubated for 1 h at 4 °C. Each well was washed three times with PBS. Then, anti-FLAG antibody-ZZ-AP conjugate and anti-FLAG antibody-ZZ-Luc conjugate were added to each well and incubated for 1 h at 4 °C, followed by washing three times with PBS. After the addition of CDP-Star (Applied Biosystems) and Bright-Glo (Promega), the luminescence intensity in each well was measured using a Wallac 1420 ARVOsx Multi Label Counter.

BSA or Gly5-myc-Luc (10 μg/mL in PBS) was placed in each well of a 96-well microplate and incubated for 15 h at 4 °C to allow adsorption to the surface of the wells. At the same time, 6 μM ZZ-GOD conjugate was added with antimyc antibody 20 μg/mL (Bethyl Laboratories) and incubated for 1 h at 4 °C. Each well was washed three times with PBS. Then, antimyc antibody-ZZ-GOD was added to each well and incubated for 1 h at 4 °C, followed by washing three times with PBS. After the addition of glucose, peroxidase, and coloring reagent (Nacalai Tesque), the absorbance at 450 nm in each well was measured using a Wallac 1420 ARVOsx Multi Label Counter.

In order to evaluate the applicability of the ZZ-Luc conjugate, ELISA for GFP was carried out. Different amounts of GFP (0, 0.25, 0.5, 2.5, 5, 6.25, 12.5, 25 nM in PBS) were placed in each well of a 96-well microplate and incubated for 15 h at 4 °C to allow adsorption to the surface of the wells. At the same time, 6 μM ZZ-Luc conjugate was added with anti-GFP antibody 20 μg/mL (Medical & Biological Laboratories) and incubated for 1 h at 4 °C. Each well was washed three times with PBS. Then, anti-GFP antibody-ZZ-Luc conjugate was added to each well and incubated for 1 h at 4 °C, followed by washing three times with PBS. After the addition of Bright-Glo, the luminescence intensity in each well was measured using a Wallac 1420 ARVOsx Multi Label Counter.

RESULTS AND DISCUSSION

Site-Specific Conjugation between ZZ-LPETG and Pentaglycine Appended Proteins Using SrtA. Figure 1A shows the effect of SrtA treatment on ZZ-LPETG and Gly5-AP. When Gly5-AP, ZZ-LPETG, and SrtA were mixed, a ZZ-AP conjugate (ca. 75 kDa) was clearly observed (Figure 2A, lane 7). ZZ-LPETG and Gly5-AP themselves were not susceptible to SrtA treatment (Figure 2A, lanes 5, 6), In addition, when ZZ-LPETG and AP without the pentaglycine tag at its N-terminus were mixed, the ZZ-AP conjugate was not observed, in spite of SrtA treatment (Figure 2B). These results suggest that site-specific ZZ-LPETG and Gly5-AP conjugation were carried out through the tag sequences. The yield of ZZ-AP was about 65% of the Gly5-AP, as evaluated by the ratio of the Gly5-AP band intensity before conjugation (Figure 2A, lane5) to that after conjugation (Figure 2A, lane 7). The ZZ-AP conjugates were also stable for more than one week even in the presence of the Sortase A, which is confirmed by SDS-PAGE (data not shown).

To expand the versatility of this strategy, we carried out site-specific protein conjugation between ZZ-LPETG and other proteins. Firefly luciferase and glucose oxidase were employed

as reporter proteins. Firefly luciferase is widely used as a detection enzyme in ELISA, as well as in reporter gene assays. Luciferase was expressed as a thioredoxin-tag fusion protein using *E. coli* as a host. Then, N-terminal pentaglycine was exposed by protease (Factor Xa) digestion, and the thioredoxin tag was removed. Glucose oxidase is also widely used as a detection enzyme due to its high sensitivity against glucose. However, glycosylation is required for GOD activity, and hence, GOD cannot be expressed using *E. coli*. Other hosts such as *Aspergillus oryzae* or yeast are required.

Figure 3A shows the effect of SrtA treatment of ZZ-LPETG and Gly5-Luc. Gly5-Luc and Gly3-GOD were successfully expressed and purified using appropriate hosts. The smeared bands of GOD were caused by glycosylation. As expected, the ZZ-Luc conjugate (ca. 100 kDa) was successfully obtained after SrtA treatment (Figure 3A, lane 7). Figure 3B shows the effect of SrtA treatment of ZZ-LPETG and Gly3-GOD. The ZZ-GOD conjugate (ca. 110 kDa) was also successfully obtained after SrtA treatment (Figure 3B, lane 7). Neither Luc nor GOD was susceptible to SrtA because of its high substrate specificity. The yield of ZZ-GOD conjugates estimated with Gly3-GOD band intensity was about 65%, suggesting that the reactivity of SrtA was not affected by the target protein and/or protein modification such as glycosylation.

Evaluation of Enzymatic Activity after the Sortase Reaction. Figure 4 shows the enzymatic activity after SrtA treatment. The enzymatic activity of AP was almost the same when Gly5-AP was mixed with ZZ-LPETG or SrtA (Figure 4A, columns 1, 4, 5). This clearly shows that AP activity was not affected by other proteins. After SrtA treatment, the produced ZZ-AP conjugate retained its activity at almost the same level as Gly5-AP (Figure 4A, column 7). The other conjugates, ZZ-Luc and ZZ-GOD, both had enzymatic activity after SrtA treatment (Figure 4B,C, columns 1, 7). These data clearly show that SrtA enables conjugation of proteins without significant loss of their functions. Several previous reports have shown that protein activity after enzymatic conjugation is retained (*10*−*16*). Our results are consistent with these reports and demonstrate the superiority of the enzymatic protein conjugation method.

Detection of Target Molecules Using Antibody-ZZ-Protein Conjugates. Encouraged by these findings, we carried out the detection of target molecules using antibody-ZZ-protein conjugates. A moiety of the FLAG tag sequence in

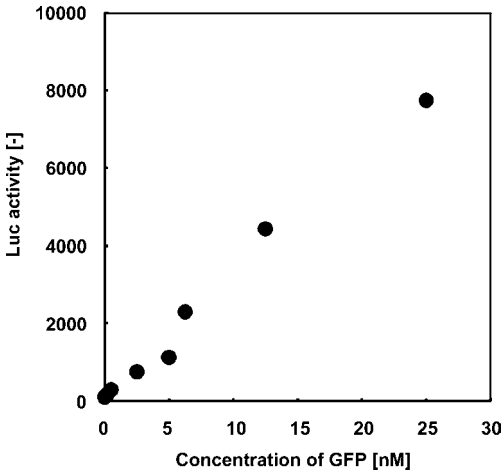

Figure 6. ELISA with anti-GFP antibody-ZZ-Luc conjugate. The signal intensities of wells containing varying concentrations of the antigen, GFP, were measured. Data are averages from three independent experiments and SD are indicated.

in Figure 5A, Gly5-FLAG-RFP was successfully detected using the anti-FLAG antibody-ZZ-AP conjugate (Figure 5A, column 7). No signal was observed against BSA, and no signal was observed without the ZZ-AP conjugate or by using a mixture of ZZ and AP (Figure 5A, columns 1−6). We also utilized the anti-FLAG antibody to ZZ-Luc conjugate. As shown in Figure 5B, Gly5-FLAG-RFP was successfully detected using the anti-FLAG antibody-ZZ-Luc conjugate (Figure 5B, column 7). No signal was observed against BSA, and no signal was observed without the ZZ-Luc conjugate (Figure 5B, columns 1−6).

The *S*/*N* (signal-to-noise) ratio was 40 in the presence or absence of Gly5-FLAG-RFP, which is 7-fold higher than that of ZZ-AP. This is due to the higher activity of luciferase compared to AP.

Additionally, Gly5-myc-Luc was employed as a model target molecule. ZZ-GOD and antimyc antibody (whole IgG) were simply mixed and antimyc antibody-ZZ-GOD conjugates were produced. As a negative control, BSA was employed. As shown in Figure 5C, Gly5-myc-Luc was successfully detected using the antimyc antibody-ZZ-GOD conjugate (Figure 5C, column 7). No signal was observed against BSA, and no signal was observed without the ZZ-GOD conjugate (Figure 5C, columns 1−6).

ELISA was also carried out to test the applicability of antibody-ZZ-Luc conjugate as immunoassay reagent. As shown in Figure 6, signal intensity was increased in response to the concentration of GFP administrated, and the detection limit of GFP with anti-GFP antibody-ZZ-Luc conjugates was found to be around 2.5−5 nM. In the case of using anti-HA antibody-ZZ-Luc conjugate, no signal observed against GFP and no signal was increased in response to the GFP concentration, as expected (data not shown). These results showed that antibody-ZZ-protein conjugate is able to be utilized for immunoassay because of its bifunctionality.

In conclusion, ZZ-LPETG and some enzymes were site-specifically conjugated by a SrtA-mediated reaction. These conjugates retained both the enzymatic activity of AP, Luc, or GOD and the IgG binding activity of ZZ after SrtA treatment. Because genetic engineering of the whole antibody is very difficult, ZZ−protein conjugate can be one of the ways to produce a bifunctional antibody by only mixing with whole antibody. Sortase A also can ligate between proteins and functional small molecules site-specifically (*13*−*16*), suggesting the extension of this ZZ-protein conjugate to ZZ-functional molecule conjugate, for example, fluorescent dyes and/or quantum dot (*14*−*16*). Also notable is that the additional short sequences (i.e., LPETG or GGGGG) may have little effect on the protein expression and refolding, which is possible to allow the ligation of ZZ-LPETG to tag-introduced proteins after refolding. Our strategy is highly useful and versatile for producing antibody−protein conjugates.

An optical encoder is a device that uses an interrupted light source−sensor pair to map linear or rotational motion onto a periodic signal. Simple, inexpensive optical encoders are used for precise positioning in machines such as desktop printers, disk drives, and astronomical telescopes. A strand of DNA labeled with a series of Förster resonance energy transfer acceptor dyes can perform the same function at the nanometer scale, producing a periodic fluorescence signal that encodes the movement of a single donor-labeled molecular motor with high spatial and temporal resolution. Previous measurements of this type have employed encoders limited to five acceptor dyes, and hence five signal periods, restricting the range of motion that could be followed. Here we describe two methods for synthesizing double-stranded DNA containing several to hundreds of regularly spaced dyes on one strand. Distinct functional groups incorporated at the encoder ends enable tethering for single-molecule measurements.

INTRODUCTION

Single-molecule Förster resonance energy transfer (FRET) (*1*, *2*) is a powerful technique for measuring nanoscale distances between two fluorophores. Its high sensitivity in the range of approximately 2−10 nanometers is ideal for the study of structural rearrangements in biological macromolecules (*3*−*5*). Until recently, single-molecule FRET measurements of processive motor proteins on DNA (*6*−*9*) have been limited by the presence of only one or a few dye pairs to examination of a restricted range of motion. Furthermore, it remains difficult to obtain accurate distances from measured FRET efficiencies (*10*−*13*).

Precise measurements of macroscopic motion are often made by mapping distance and velocity onto the phase and frequency of a periodic signal. This can be done using an optical encoder, in which a light source and sensor move with respect to a mask containing regularly spaced transparent windows. As the source and sensor move, the window pattern modulates the sensor output, producing the desired signal. We recently implemented a nanoscale encoder (*2*, *14*) using FRET between a moving donor fluorophore and a series of acceptors attached to one strand of a DNA molecule at 69 base pair (bp) intervals. As a donor-labeled helicase traveled along the FRET encoder, a periodic acceptor fluorescence signal was observed.

We synthesized the original five-period FRET encoders from 12 unique self-assembling DNA oligonucleotides. While this scheme has the advantage of producing a well-defined product, its cost and complexity both increase with the length of the encoder. To follow translocation over long distances, observe many cycles of the same molecular motor, and collect multiple periods of any signal modulation (*14*), it is desirable to have encoders many times longer than would be practical to synthesize using our original scheme. Here we demonstrate two methods that produce FRET encoders with lengths ranging from several to hundreds of periods.

The first method employs polymerization-driven self-assembly (*15*, *16*). We designed two synthetic oligonucleotides that, when annealed, form a double-stranded DNA monomer with two complementary cohesive ends. Upon annealing, the monomers undergo a step polymerization reaction that rapidly produces a wide distribution of encoder lengths.

The second method exploits rolling circle amplification (*17*) (RCA), a process used in the replication of many bacterial plasmids (*18*), in bacterial conjugation (*19*), and by many retroviruses (*20*) and bacteriophages (*21*). In RCA (Figure 4), a suitable polymerase binds to a primed single-stranded circular template. DNA synthesis begins from the 3′ terminus of the primer and proceeds around the circle, generating a linear complement to the circular template. After the polymerase completes one revolution around the template, the newly synthesized strand is removed by a cooperating helicase, or by the polymerase itself, so that the process can continue. Because of its extreme processivity and strand displacement ability, DNA polymerase from the ϕ29 bacteriophage is particularly suitable for RCA (*22*).

RCA has found many uses in nanotechnology (*23*), mutation detection (*24*), and immunoassays (*25*). Recently, two groups (*26*, *27*) used RCA to generate periodic double-stranded DNA templates, on which they assembled arrays of gold nanoparticles. We have adapted this technique to synthesize FRET encoders with more than 200 periods, terminated with biotin and digoxigenin groups for site-specific immobilization in single-molecule experiments.

EXPERIMENTAL PROCEDURES

Buffers and Reagents. All solutions were prepared in distilled deionized water (DDI). DNA was stored in 10 mM Tris-HCl (pH 8.0) with 1 mM EDTA (TE buffer). Gels were cast and run in 40 mM Tris-acetate and 1 mM EDTA. Fluorescence measurements were performed in a fluorescence buffer containing 50 mM Tris-HCl (pH 7.9), 1 mM EDTA, 10 mM NaCl, 10 mM $MgCl_2$, 4 mM dithiothreitol, and an enzymatic oxygen-scavenging system consisting of 35 μg/mL

Table 1. FRET Encoder Single-Stranded Oligonucleotide Sequences[a]

name	nucleotide sequence (5′ → 3′)
a-b	TTCTTGCACCAGTGTCCTCTCCGCGTCGTCCTACAG TGACTAGTCTGGAACGTATAGTATAAGC
A-B	GACACTGGTGCAAGAAGCTTATACTATACGTTCCA GACTAGTCACTGTAGGACGACGCGGAGAG
a-z-p	TTCTTGCACCAGTGTCCAATATGCAGAACGATCCAA GACGCAATAGCTCC
a-b10	TTCTTGCACCAGTGTCCTCTCCGCGT

[a] The primer−template complex (A-B−a-b10) melts at 74 °C in 100 mM NaCl.

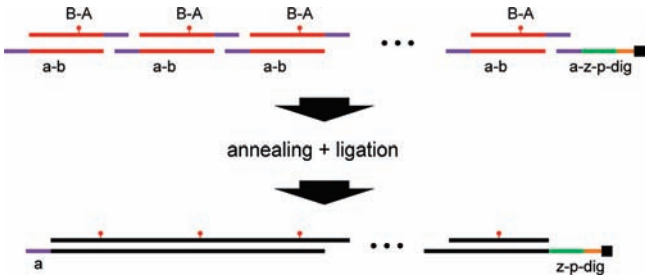

Figure 1. Schematic representation of the polymerizing FRET encoder. The fully assembled encoder consists of a series of regularly spaced FRET acceptor dyes on a double-stranded DNA scaffold. The acceptors are located between bases 32 and 33 of oligo A-B (read 5′ to 3′), and in the final product are spaced by 64 base pairs, approximately four times the Förster radius (R_0) when used with a typical donor dye. An increase in the amount of oligo a-z-p, which binds to unoccupied "A" sites and leaves an unmatched 34-nucleotide cohesive end, will limit the degree of polymerization.

catalase (Sigma-Aldrich C100), 0.2 mg/mL glucose oxidase (Sigma-Aldrich G2133), 0.8% (w/v) D-glucose (Sigma-Aldrich G8270), and 1.2 mM Trolox antioxidant (Sigma-Aldrich 238813) (*28*). Reaction buffers for T4 ligase, ϕ29 polymerase, and terminal transferase were supplied by the manufacturer (New England Biolabs, Ipswich, MA).

DNA Sequences. Sequences for the single-stranded oligonucleotides used in both synthesis schemes are listed in Table 1. All DNA was purchased from Integrated DNA Technologies (Coralville, IA). Oligos A-B and a-b were PAGE purified, and oligo A-B-Cy5, identical to oligo A-B except for a Cy5 fluorophore between bases 32 and 33, was purified by HPLC. All sequences other than a-z-p and a-b10 (the primer for rolling circle amplification reactions) have a 5′ phosphate to enable ligation. To allow for attachment of completed encoders in single-molecule experiments, oligo a-b10 has a 5′ biotin modification, and the terminating oligo a-z-p has a 3′ digoxigenin.

FRET Encoder Synthesis by Polymerization. For polymerization-driven self-assembly, we designed the two partially complementary 64-base oligonucleotides a-b and A-B listed in Table 1. Together they form a 48 bp double-stranded DNA monomer with two 16-base 5′ cohesive ends (Figure 1). The average molecular weight of the product was controlled by the terminator oligonucleotide a-z-p, which anneals at one end of the growing chain, preventing further polymerization from its binding site. The terminating oligo can be designed to incorporate a binding site for a particular motor protein at one end of the encoder, as well as a hapten or biotin for site-specific immobilization.

To synthesize the encoders, we annealed 50 pmol of oligo a-b, 100 pmol of oligo A-B, and a selected ratio of a-z-p to a-b (Figure 2) in a total volume of 8 μL of TE buffer containing

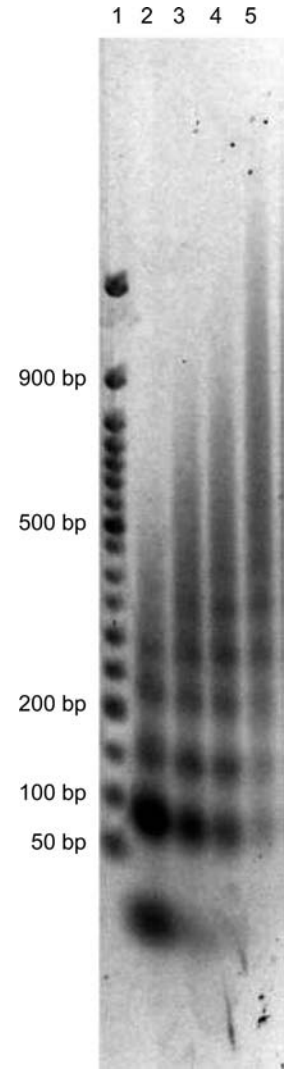

Figure 2. Tuning the molecular weight distribution with a terminator oligonucleotide. The left lane contained a 50 bp DNA marker ladder. The encoders in lanes 2, 3, 4, and 5 were annealed and ligated with 10:1, 2:1, 1:1, and 1:5 molar ratios of oligo a-z-p to monomers, respectively.

100 mM NaCl. When the ratio of a-b to A-B was varied (Figure 3), 50 pmol of a-b was used and the a-z-p terminator was omitted until after the encoders had been separated by size and purified. The mixtures were heated to 65 °C and then cooled to room temperature over the course of approximately 5 min. We connected discontinuous backbone strands in the resulting encoders by adding 1 μL (400 units) of T4 DNA ligase and 1 μL of 10× T4 ligase reaction buffer and incubating overnight at room temperature.

Polymerization results in a broad distribution of FRET encoder lengths. We separated the ligated polymer mixture on a 1.2% (w/v) agarose gel at 160 V for 4.5 h, alongside a 50 bp DNA marker ladder (New England Biolabs). The gel was poststained in a 0.5 μg/mL ethidium bromide solution for 30 min, destained for 30 min in DDI, and visualized using a UV transilluminator. Gel slices were purified using the Wizard Gel Clean-Up kit (Promega, Madison, WI) following the manufacturer's instructions, except that the gel slice was dissolved at room temperature. Heating of the ligated encoders was avoided to prevent melting. Because the DNA sequences are periodic, melting and subsequent reannealing could result in a relative frame shift between the two strands of some integral number of periods.

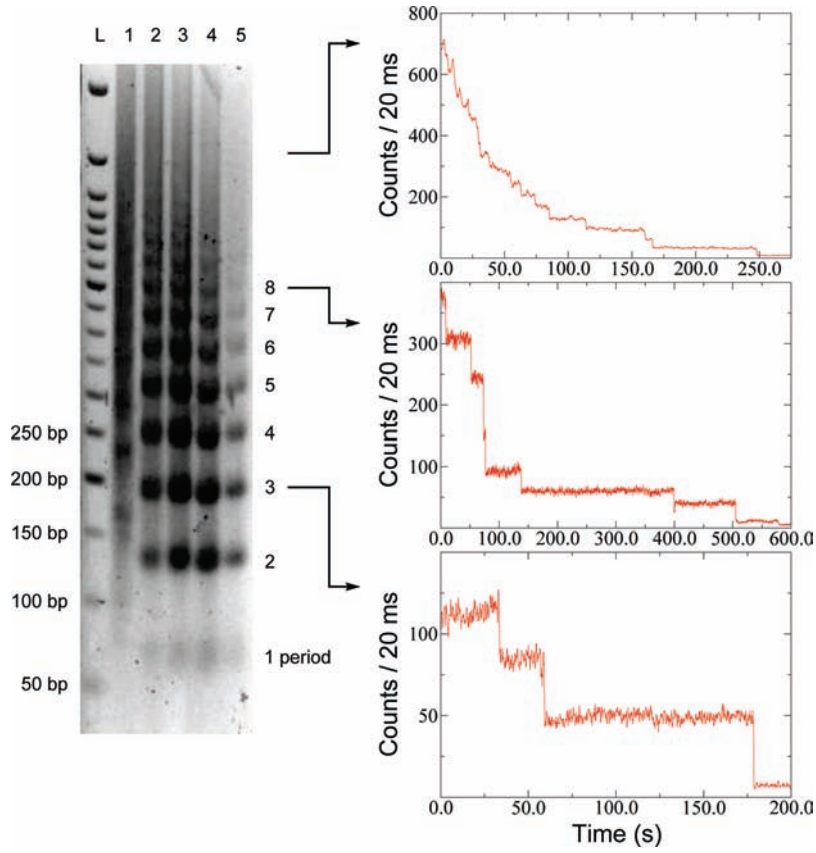

Figure 3. Characterization of polymerized FRET encoders. Agarose gel electrophoresis resolves discrete encoder lengths up to approximately 10 periods. Lane L contained a 50 bp DNA marker ladder. Encoders in lanes 1, 2, 3, 4, and 5 were synthesized with 1:1, 1:2, 1:3, 1:4, and 1:5 ratios of oligo A-B to a-b, respectively. An excess of one monomer oligo over the other improves resolution while preventing the growth of excessively long encoders. Photobleaching traces are shown for FRET encoder DNA extracted from the three- and eight-period bands, and from a position in the gel corresponding to approximately 15 periods. Random temporary drops in the signal are expected from dye blinking (*30*). In the eight-period event, two steps occur near 75 s, while the eighth, smaller step, occurs around 575 s.

FRET Encoder Synthesis by Rolling Circle Amplification. The procedure for RCA patterning is summarized in Figure 4. We formed rolling circle templates by combining 2 μL of 100 μM A-B oligo and 2 μL of 100 μM a-b10 primer in 200 μL of TE buffer containing 100 mM NaCl. We annealed the DNA by heating the solution to 65 °C and then cooling it to room temperature over the course of several hours. This step fully melts undesirable secondary structures in the component oligos, the most stable of which melts at 36.2 °C in 100 mM NaCl. We ligated nicks in the circular templates by adding 1 μL (400 units) of T4 DNA ligase and 21.2 μL of a 10× concentrate of the T4 DNA ligase reaction buffer.

After 3 h of ligation, 30 μL of 10× ϕ29 polymerase reaction buffer, 6 μL of 10 mg/mL bovine serum albumin, 30 μL of 10 mM dNTPs, 30 units of ϕ29 polymerase, and 9 μL of H_2O were added. The reaction mixture was incubated at 31 °C for 3 h, followed by a 10 min 65 °C heat inactivation of the polymerase. The single-stranded RCA product was separated from free nucleotides and the circular templates using a centrifugal filter device (Millipore Ultracel YM-100, 100 kDa NMWL cutoff, Fisher Scientific catalog no. 42412). The 300 μL reaction mixture was diluted to 500 μL with TE buffer and then concentrated to approximately 15 μL. This process was repeated twice more before the DNA was diluted to a final concentration of 75 μL. According to the filter manufacturer's specifications, encoder DNA recovery is expected to be greater than 95%, with more than 99% free nucleotide removal. Preparations for single-molecule measurements select for properly tethered molecules with significant fluorescence. Small residual impurities are either washed out of the flow cell prior to observations or remain undetected.

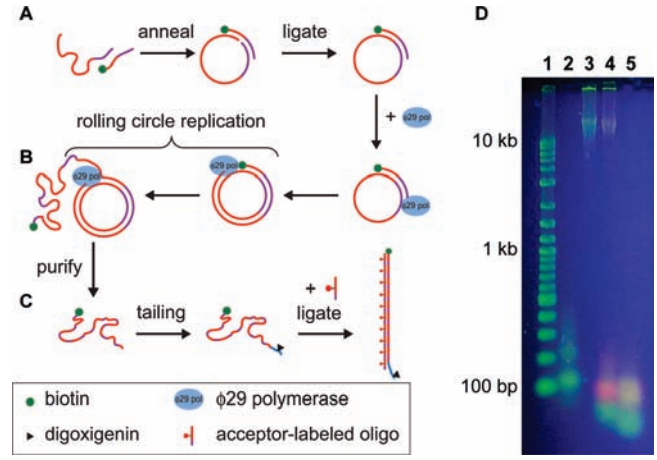

Figure 4. Rolling circle amplification for FRET encoder synthesis. After cyclization of the template by ligation in the presence of a primer (A), an RCA step (B) produces a long concatemer of the complement to the circular template. A tail is appended to the single-stranded product with terminal transferase using dTTP and digoxigenin-labeled dUTP, and subsequent annealing and ligation with the dye-labeled version of the circular template completes a long, bifunctionalized FRET encoder (C). (D) Lane 1 contained a 2 log DNA marker ladder. Lane 2 contained the circular template−primer complex, dimers and trimers of which are also visible. Lane 3 contained the single-stranded RCA product, while lane 4 contained the final annealed and ligated encoder. SpeI, a restriction enzyme that cuts the encoder DNA once per period, was added to the sample from lane 4, which was then run in lane 5. The disappearance of the ≈13 kb double-stranded DNA demonstrates that the encoder is periodic.

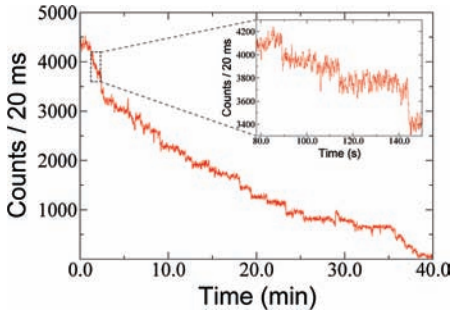

Figure 5. Photobleaching of an immobilized RCA FRET encoder. By eye, we can discern approximately 33 steps. Upward steps, such as those near 29 min and in the inset, are likely caused by the return of a single acceptor (Cy5) from a dark state (*30*). The horizontal position of the focus was adjusted manually in 10 nm increments every few minutes to correct for instrument drift, so that the encoder would remain centered during the 40 min measurement. A 10 nm displacement is only 2.7% of the measured beam waist at the sample plane (data not shown) and could not produce the observed steps.

We appended a digoxigenin-labeled tail to the RCA product by reacting it with terminal transferase in the presence of dTTP and digoxigenin-labeled dUTP. Terminal transferase is a template-independent polymerase that catalyzes the addition of nucleotides to the 3′ end of a strand of DNA. Supplying terminal transferase with a 5−10:1 mixture of dTTP and dig-dUTP produces a tail containing several digoxigenins spaced sufficiently far apart to allow multiple anti-digoxigenins to bind.

For the tailing reaction, 1.7 μg of the purified single-stranded RCA product was combined with 2.5 μL of 10× terminal transferase reaction buffer, 2.5 μL of 2.5 mM $CoCl_2$, 0.25 μL of 100 mM dTTP, 5 μL of 1 mM dig-dUTP, 100 units of terminal transferase (New England Biolabs), and sufficient DDI to yield a total solution volume of 25 μL. The reaction mixture was incubated at 37 °C for 2 h, then heated to 70 °C for a 10 min inactivation.

After the tailing reaction was complete, 12.5 μL of reacted solution was mixed with 10 μL of 100 μM A-B-Cy5 oligo, heated to 65 °C, and then cooled over several hours to room temperature so that dye-labeled oligos would anneal to the long single-stranded template. Once annealed, double-stranded DNA was purified using a PCR spin column (Invitrogen K3100-01) according to the manufacturer's instructions. Finally, nicks in the double-stranded DNA were closed with T4 ligase as described above, and the product was purified again with the same type of spin column.

Fluorescence Measurements. We characterized assembled and purified FRET encoders from both synthesis schemes with a single-molecule photobleaching assay described in detail previously (*14*). We tethered encoders sparsely to the inner surface of a fused-silica flow cell by incubating 50 pM encoder DNA and 1 nM anti-digoxigenin in fluorescence buffer in the cell for 20 min. Excess DNA was then flushed out with fluorescence buffer.

A 633 nm laser, reduced to 1 μW using absorptive neutral density filters, was focused at the fused-silica surface while a piezoelectric stage supporting the cell was scanned in a raster pattern to search for immobilized encoders. When the fluorescence intensity exceeded a designated threshold, indicating the presence of an encoder in the confocal detection volume, the scan was stopped, and the focal position was optimized using an automated centration algorithm (*29*). The encoder was then excited continuously while fluorescence intensity was measured by photon counting and recorded until all dye molecules had been photobleached. Data processed with a 420 ms (21-point) median filter are shown in Figures 3 and 5.

RESULTS AND DISCUSSION

As can be seen in Figure 2, the polymerization scheme produces a distribution of discrete encoder lengths that can be tuned by varying the amount of terminator oligo a-z-p. Figure 3 shows representative photobleaching measurements of polymerized encoders. Sudden, irreversible downward steps in the fluorescence data, each corresponding to the bleaching of a single dye molecule, are clearly evident, and the numbers of dyes counted in this manner correspond to the gel bands from which the encoders were extracted. It is difficult or impossible to identify discrete bands corresponding to lengths beyond 10 periods; however, photobleaching traces for encoders extracted from the high-molecular weight end of the gel indicate that lengths up to at least 15 periods are produced. The typical yield of purified five-period encoder DNA was approximately 1 pmol, making this reaction on the order of 10 times more efficient for this length alone than that described in ref *14*.

Figure 4 shows an agarose gel electrophoresis analysis of the RCA FRET encoders. Lane 2 contained the annealed primer−template complex. Monomeric and multimeric forms, which arise from primer-mediated cross-linking of the template DNA, are visible. The RCA product derived from any of these substrates will contain the same periodic sequence. The gel indicates that the RCA FRET encoders are approximately 13 kb (200 periods) long on average (lanes 3 and 4), and digestion with SpeI, a restriction enzyme that cuts the encoders once per period, demonstrates that they are periodic (lane 5). The red hue of the long DNA in lane 4 arises from annealing with the dye-labeled oligo, the vast excess of which is clearly visible at the bottom of the lane. In lane 5, the 64 bp DNA appears yellow because the stain more efficiently intercalates double-stranded DNA (the mixture of green stain fluorescence and red acceptor fluorescence produces yellow). In lanes 4 and 5, the lower-most band is an unlabeled truncation product left over from the synthesis of the dye-labeled oligo. As it is not fully complementary to oligo a-b, it does not interfere with assembly of the RCA encoder.

Photobleaching data from an RCA encoder are shown in Figure 5. The length of this encoder (approximately 4.4 μm) greatly exceeds the axial extent of the confocal volume. No refocusing was done during the measurement, so the ≈30 observed steps, corresponding to ≈650 nm of encoder contour length, match our expectation for the number of dyes within the region from which fluorescence was collected.

One could envision extending both of the synthesis schemes we have presented to create polymers with much longer repeat lengths. Several synthetic oligonucleotides could be annealed and ligated to form monomers hundreds of base pairs long, and these could be polymerized as described above. Alternatively, an extended substrate for the rolling circle amplification scheme could be fashioned from two or more single-stranded oligos, cyclized by an equal number of primers. Modification of all but one of the primers with 3′ terminal dideoxynucleotides would allow the origin of the RCA reaction to be specified. FRET encoders assembled in this manner could prove useful for measurements taking advantage of multiple acceptors with distinct spectra, or for studying the effects of specific sequences on transcription.

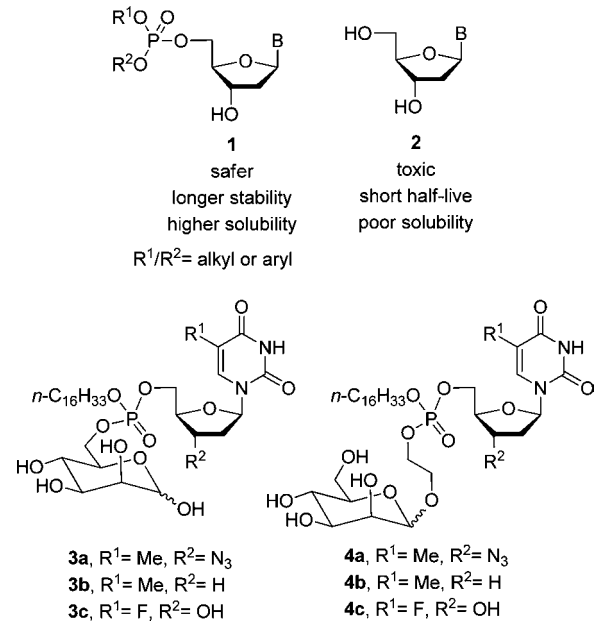
Chemoenzymatic Syntheses and Anti-HIV-1 Activity of Glucose−Nucleoside Conjugates as Prodrugs

Tatiana Rodríguez-Pérez,[†] Susana Fernández,[†] Yogesh S. Sanghvi,[‡] Mervi Detorio,[§] Raymond F. Schinazi,[§] Vicente Gotor,*[,†] and Miguel Ferrero*[,†]

Departamento de Química Orgánica e Inorgánica and Instituto Universitario de Biotecnología de Asturias, Universidad de Oviedo, 33006-Oviedo (Asturias), Spain, Rasayan Inc., 2802 Crystal Ridge Road, Encinitas, California 92024-6615, United States, and Center for AIDS Research, Department of Pediatrics, Emory University School of Medicine/Veterans Affair Medical Center, Decatur, Georgia 30033, United States. Received May 3, 2010; Revised Manuscript Received October 18, 2010



Phosphodiester linked conjugates of various nucleosides such as d4U, d4T, IdUrd, ddI, ddA, virazole, *ara*-A, and *ara*-C containing a glucosyl moiety have been described. These compounds were designed to act as prodrugs, where the corresponding 5′-monophosphates may be generated intracellularly. The synthesis of the glycoconjugates was achieved in good yields by condensation of a glucosyl phosphoramidite **7** with nucleosides in the presence of an activating agent. It was demonstrated that the glucose conjugates improve the water solubility of the nucleoside analogues, for example, up to 31-fold for the *ara*-A conjugate compared to that of *ara*-A alone. The new conjugates were tested for their anti-HIV-1 activity in human lymphocytes. These derivatives offer a convenient design for potential prodrug candidates with the possibility of improving the physicochemical properties and therapeutic activity of nucleoside analogues.

INTRODUCTION

Chemically modified nucleosides are widely used as therapeutic agents to treat cancer, fungal, bacterial, and viral infections (*1*−*5*). Similarly, carbohydrates are of paramount importance in intercellular recognition, bacterial and viral infection processes, and inflammation events making them an attractive target for drug development (*6*−*8*). Consequently, a conjugate of these two classes of molecules may offer an avenue to design and develop novel therapeutics with improved biological functions. The use of a phosphate ester linkage for conjugation is widely practiced because of its natural occurrence in cellular physiology and as a backbone for DNA and RNA molecules. The culmination of these attributes motivated us to use natural phosphate linkage to conjugate a biologically active nucleoside with a carbohydrate unit anticipating that we could modulate the therapeutic effects of known nucleosides in a favorable manner.

Several modified nucleosides (AZT, d4T, 3TC, ddI, ddC, and abacavir) have been approved by the US FDA as anti-HIV drugs. Although these drugs are effective for the treatment of HIV, some of the limitations such as toxicity, short half-life, and dependence on cellular enzymes preclude their wider use. In order to overcome these limitations and to improve the therapeutic potential of these nucleosides, several phosphate-based prodrug strategies have been developed (*9*−*16*). The prodrug approach appears to be a promising way to improve the anti-HIV activity of the approved nucleosides, reduce their cellular toxicity, enhance cellular uptake, and prevent viral resistance (*17*−*19*). The 5′-phosphate analogues of nucleosides have been extensively studied as prodrugs. For example, nucleoside glycoconjugate prodrugs (**1**, Chart 1) are able to penetrate cellular membranes as a result of their higher lipophilicity and are also able to improve the efficacy of antiviral and anticancer nucleoside analogues **2** (*20*). Phosphate derivatives of AZT (**3a**,**4a**), ddT (**3b**,**4b**), and FdUrd (**3c**,**4c**) with a D-mannose as a conjugating moiety were prepared as membrane soluble prodrugs directed toward cells carrying mannosyl receptors (*21*, *22*). Previously, glyco-conjugates of oligonucleotides have been reported to demonstrate improved anti-HIV activity (*23*).

Chart 1. Prodrugs of Phosphorylated Nucleosides

The main methods described in the literature for the preparation of nucleoside−carbohydrate phosphodiesters are the condensation of protected sugar monophosphates with nucleosides in the presence of an activating agent (*21*, *22*, *24*) or by coupling of a nucleoside phosphate with a protected glycosyl donor (*25*).

Among the various protocols available for conjugation, the phosphoramidite chemistry offers the best yields (*16*). Recently, it has been demonstrated that the solid-phase synthesis of a dinucleoside and a nucleoside−carbohydrate phosphodiester and thiophosphodiester using polymer-bound oxathiophospholanes as the phosphitylating agents is a viable way for the synthesis of conjugates (*14*).

As a part of our ongoing efforts in the discovery and design of therapeutic nucleoside analogues (*26*−*28*), we embarked on a path to synthesize nucleoside−carbohydrate conjugates linked via the phosphate backbone. We believe that these conjugates will act like prodrugs where the corresponding 5′-monophosphate could be liberated intracellularly by cellular phosphodiesterases. With this objective in sight, we elected to develop conjugation chemistry that will permit the convenient attachment of glucose 6-phosphate (*29*) to a nucleoside analogue of therapeutic value. For this study, we have utilized highly efficient phosphoramidite chemistry to create the conjugates of interest. Herein, we describe the synthesis, anti-HIV-1 activity, and cytotoxicity of novel glucose−nucleoside conjugates.

MATERIALS AND METHODS

Candida rugosa lipase (CRL, Type VII, 1410 U/mg) was purchased from Sigma. *Pseudomonas cepacia* lipase (PSL-C, Amano PS-C II, 1195 U/g) was purchased from Aldrich. *Candida antarctica* lipase B (CAL-B, Novozym 435, 7300 PLU/g) was a gift from Novo Nordisk Co. Synthesis of α-**5** and **6** have been previously described (*29*). Unless otherwise specified, flash chromatography was performed over silica 60 Å (230−400 mesh). 1*H*-Tetrazole was prepared according to the procedure previously described (*30*). The nucleosides **8c**, **8d**, **8f-i**, **14**, **15**, **17-19**, **21**, and **22** were isolated as amorphous solids upon concentration of the solutions. The melting range of these solid compounds was determined by the melting point Gallenkamp apparatus.

Synthesis of 2-Cyanoethyl-*N*,*N*-diisopropyl-(1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranoside-6-yl)phosphoramidite (*7*). 2-Cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite (1.1 mL, 3.45 mmol) and pyridinium trifluoroacetate (*31*) (673 mg, 3.45 mmol) was added to a stirred solution of **6** (1 g, 2.89 mmol) in anhydrous CH_2Cl_2 (7 mL) and the mixture stirred for 3 h at room temperature. Upon the complete consumption of the starting material (TLC), the solvent was evaporated and the residue purified by flash chromatography using silica 60 Å (32−63 μm). Elution with 33% EtOAc/hexane afforded **7** as a clear oil in 91% yield. For flash chromatography, silica was pretreated with 33% EtOAc/hexane containing 1% Et_3N (300 mL) and then with 33% EtOAc/hexane (300 mL). ^{1}H NMR ($CDCl_3$, 600 MHz): δ 1.13 (s, 3H, Me-^{i}Pr), 1.14 (s, 3H, Me-^{i}Pr), 1.15 (s, 6H, Me-^{i}Pr), 1.16 (s, 3H, Me-^{i}Pr), 1.17 (s, 6H, Me-^{i}Pr), 1.18 (s, 3H, Me-^{i}Pr), 1.99 (s, 3H, CH_3), 2.00 (s, 6H, CH_3), 2.02 (s, 3H, CH_3), 2.03 (s, 6H, CH_3), 2.14 (s, 3H, CH_3), 2.15 (s, 3H, CH_3), 2.62 (t, 4H, $H_{2'}$, $^3J_{HH}$ 6.4 Hz), 3.60 (m, 6H, H_6+ $H_{1''}$), 3.79 (m, 6H, $H_{1'}$ + H_6), 4.05 (m, 2H, H_5), 5.03 (m, 2H, H_2), 5.09 (t, 1H, H_4,$^3J_{HH}$ 10.1 Hz)), 5.15 (t, 1H, H_4,$^3J_{HH}$ 9.7 Hz), 5.44 (t, 2H, H_3,$^3J_{HH}$ 9.2 Hz), 6.31 (t, 2H, H_1,$^3J_{HH}$ 3.3 Hz). ^{31}P NMR ($CDCl_3$, 242.9 MHz): δ 149.64, 149.91. MS (ESI^+, *m*/*z*): 549 [$(M + H)^+$, 10%], 571 [$(M + Na)^+$, 100%].

Synthesis of 5-Iodo-3′-*O*-levulinyl-2′-deoxyuridine (8c). A suspension of **11** (200 mg, 0.56 mmol), *O*-levulinyl acetonoxime (*32*) (291 mg, 1.70 mmol), and PSL-C (600 mg) in anhydrous THF (5.7 mL) under nitrogen was stirred at 30 °C and 250 rpm for 24 h. The enzyme was filtered off and washed with CH_2Cl_2 and THF. The solvents were distilled under vacuum, and the residue was washed with Et_2O to afford **8c** as a white solid in 95% yield. Melting range: 164−166 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 2.36 (s, 3H, CH_3), 2.52 (m, 2H, $H_{2'}$), 2.77 (t, 2H, CH_2-Lev, $^3J_{HH}$ 6.7 Hz), 3.01 (t, 2H, CH_2-Lev, $^3J_{HH}$ 6.5 Hz), 3.99 (m, 2H, $H_{5'}$), 4.29 (m, 1H, $H_{4'}$), 5.50 (m, 1H, $H_{3'}$), 6.43 (apparent q, 1H, $H_{1'}$, $^3J_{HH}$ 5.8 Hz), 8.72 (s, 1H, H_6). MS (ESI^+, *m*/*z*): 475 [$(M + Na)^+$, 100%].

Synthesis of 5-Iodo-5′-*O*-levulinyl-2′-deoxyuridine (8d). A suspension of **11** (200 mg, 0.56 mmol), *O*-levulinyl acetonoxime (*32*) (291 mg, 1.70 mmol), and CAL-B (200 mg) in anhydrous THF (5.7 mL) under nitrogen was stirred at 30 °C and 250 rpm for 24 h. The enzyme was filtered off, washed with CH_2Cl_2 and THF, and the solvents distilled under vacuum. The residue was purified by flash chromatography using 5% ^{i}PrOH/CH_2Cl_2 and the resulting solid washed with Et_2O to afford **8d** as a white solid in 78% yield. Melting range: 140−143 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 2.37 (s, 3H, CH_3), 2.49 (m, 2H, $H_{2'}$), 2.87 (t, 2H, CH_2-Lev, $^3J_{HH}$ 6.3 Hz), 3.03 (t, 2H, CH_2-Lev, $^3J_{HH}$ 6.6 Hz), 4.28 (m, 1H, $H_{4'}$), 4.46 (m, 1H, $H_{5'}$), 4.55 (m, 2H, $H_{3'}$ + $H_{5'}$), 6.39 (apparent t, 1H, $H_{1'}$, $^3J_{HH}$ 6.5 Hz), 8.72 (s, 1H, H_6). MS (ESI^+, *m*/*z*): 475 [$(M + Na)^+$, 65%].

Synthesis of N^6-(Dimethylamino)methylene-2′,3′-dideoxyadenosine (8f). A mixture of **12** (149 mg, 0.63 mmol) and *N*,*N*-dimethylacetamide dimethyl acetal (824 μL, 6.3 mmol) in anhydrous DMF (3.2 mL) was stirred at room temperature for 4 h. The mixture was evaporated and the residue purified by flash chromatography using 8% MeOH/CH_2Cl_2 to afford **8f** as a white solid in 97% yield. Melting range: 61−64 °C (unstable compound, decomposes easily). ^{1}H NMR (MeOH-d_4, 300 MHz): δ 2.38 (m, 2H, $H_{2'}$ or $H_{3'}$), 2.72 (m, 2H, $H_{2'}$ or $H_{3'}$), 3.42 (s, 3H, Me), 3.43 (s, 3H, Me), 3.85 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 12.2 Hz, $^3J_{HH}$ 3.9 Hz), 4.05 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 12.2 Hz, $^3J_{HH}$ 3.1 Hz), 4.45 (m, 1H, $H_{4'}$), 6.51 (apparent t, 1H, $H_{1'}$, $^3J_{HH}$ 5.6 Hz), 8.59 (s, 1H, H_8), 8.70 (s, 1H, H_2), 9.07 (s, 1H, HC═N). MS (ESI^+, *m*/*z*): 291 [$(M + H)^+$, 100%].

Synthesis of 1-(2′,3′-Di-*O*-acetyl-β-D-ribofuranosyl)-1*H*-1,2,4-triazole-3-carboxamide (8g). To a solution of **15** (295 mg, 0.9 mmol) in chloroform (30 mL) was added formic acid (3−4 drops). After being stirred at room temperature for 18 h, the mixture was neutralized with 1 N KOH, and the solution was concentrated. The residue was purified by flash chromatography using 1−50% MeOH/CH_2Cl_2 as the elution gradient to yield **8g** as a white solid in quantitative yield. Melting range: 75−77 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 2.29 (s, 3H, CH_3), 2.31 (s, 3H, CH_3), 2.28 (s, 3H, CH_3), 3.92 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 12.5 Hz, $^3J_{HH}$ 3.7 Hz), 4.03 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 12.5 Hz, $^3J_{HH}$ 3.1 Hz), 4.52 (q, 1H, $H_{4'}$,$^3J_{HH}$ 5.1 Hz), 5.79 (t, 1H, $H_{3'}$, $^3J_{HH}$ 5.3 Hz), 5.96 (dd, 1H, $H_{2'}$, $^3J_{HH}$ 5.1, 3.9 Hz), 6.43 (d, 1H, $H_{1'}$, $^3J_{HH}$ 3.9 Hz), 8.73 (br s, 1H, NH), 9.02 (s, 1H, H_5). MS (ESI^+, *m*/*z*): 351 [$(M + Na)^+$, 90%].

Synthesis of N^6-Benzoyl-9-(2′,3′-di-*O*-acetyl-β-D-arabinofuranosyl)adenine (8h). A 4 M solution of hydrogen chloride in 1,4-dioxane (1.1 mL) was added to a stirred solution of **19** (330 mg, 0.44 mmol) in CH_2Cl_2 (8.8 mL) at −50 °C. After 15 min, the reaction was quenched by adding a solution of pyridine/MeOH (1:1, v/v) at −50 °C. The mixture was poured into saturated aqueous $NaHCO_3$ solution and extracted with CH_2Cl_2. The combined organic fractions were dried (Na_2SO_4) and concentrated under vacuum. The crude was purified by flash chromatography using 1−10% MeOH/CH_2Cl_2 as the elution gradient to yield **8h** as a white solid in 76% yield. Melting range: 165−167 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 1.96 (Me), 2.33 (Me), 4.09 (m, 2H, $H_{5'}$), 4.38 (m, 1H, $H_{4'}$), 5.79 (m, 2H, $H_{2'}$ + $H_{3'}$), 6.89 (d, 1H, $H_{1'}$, $^3J_{HH}$ 5.3 Hz), 7.69−7.85 (m, 3H, H_m + H_p), 8.26 (d, 2H, H_o, $^3J_{HH}$ 8.5 Hz), 8.86 (s, 1H, H_8), 8.89 (s, 1H, H_2). MS (ESI^+, *m*/*z*): 478 [$(M + Na)^+$, 100%] and 494 [$(M+K)^+$, 5].

Synthesis of N^4-acetyl-1-(2′,3′-di-*O*-acetyl-β-D-arabinofuranosyl)cytosine (8i). Acetic acid (57 μL, 1 mmol) and TBAF (2 mL, 1 M in THF, 2 mmol) were added to a solution of **22** (330

mg, 0.68 mmol) in anhydrous THF (6.8 mL), and the reaction was stirred at room temperature for 2 h. The mixture was concentrated and the residue purified by flash chromatography using 8% MeOH/CH_2Cl_2 for elution affording **8i** as a white solid in 82% yield. Melting range: 173−175 °C. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.92 (s, 3H, Me), 2.14 (s, 3H, Me), 2.30 (s, 3H, Me), 3.88 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 12.3 Hz, $^3J_{HH}$ 4.9 Hz), 3.96 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 12.3 Hz, $^3J_{HH}$ 3.9 Hz), 4.83 (q, 1H, $H_{4'}$, $^3J_{HH}$ 4.8 Hz), 5.22 (m, 1H, $H_{3'}$), 5.58 (dd, 1H, $H_{2'}$, $^3J_{HH}$ 3.9, 2.2 Hz), 6.31 (d, 1H, $H_{1'}$, $^3J_{HH}$ 4.2 Hz), 7.58 (d, 1H, H_5, $^3J_{HH}$ 7.4 Hz), 8.26 (d, 1H, H_6, $^4J_{HH}$ 7.1 Hz), 9.9 (br s, 1H, NH). MS (ESI$^+$, *m*/*z*): 370 [(M + H)$^+$, 5%] and 392 [(M + Na)$^+$, 100].

General Procedure for the Synthesis of Phosphotriesters 9a−i. To a stirred solution of nucleoside **8** (1.07 mmol) and **7** (0.72 mmol) in anhydrous MeCN (8 mL) was added 1*H*-tetrazole (112.7 mg, 1.61 mmol). After the reaction was stirred at room temperature for 5 min, 5.1 mL of a 1 M solution of I_2 in Py/H_2O (9:1, v/v) was added to the mixture. After being stirred at room temperature for 5 min, the mixture was poured into $Na_2S_2O_3$ (5% aqueous solution) and extracted with CH_2Cl_2. The combined organic fractions were dried (Na_2SO_4) and concentrated under vacuum. The crude was purified by flash chromatography using 60 Å silica (32−63 μm) at pH 7 and 0−50% MeOH/EtOAc as the elution gradient to yield **9** as a white hygroscopic foam.

2-Cyanoethyl-(2′,3′-didehydro-2′,3′-dideoxyuridin-5′-yl)-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9a). 89% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.14 (s, 3H, Me), 2.15 (s, 3H, Me), 2.16 (s, 3H, Me), 2.17 (s, 3H, Me), 2.21 (s, 3H, Me), 2.22 (s, 3H, Me), 2.34 (s, 3H, Me), 2.35 (s, 3H, Me), 3.05 (t, 4H, $H_{2'''}$, $^3J_{HH}$ 6.1 Hz), 4.31−4.48 (m, 14H, $H_{5''}$ + $H_{6''}$ + $H_{5'}$ + $H_{1'''}$), 5.23 (m, 4H, $H_{2''}$ + $H_{4'}$), 5.34 (m, 2H, $H_{4''}$), 5.61 (m, 2H, $H_{3''}$), 5.88 (d, 1H, H_5, $^3J_{HH}$ 8.0 Hz), 5.91 (d, 1H, H_5, $^3J_{HH}$ 8.1 Hz), 6.18 (m, 2H, $H_{2'}$), 6.45 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.7 Hz), 6.47 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.7 Hz), 6.62 (m, 2H, $H_{3'}$), 7.12 (m, 2H, $H_{1'}$), 7.72 (d, 1H, H_6, $^3J_{HH}$ 8.1 Hz), 7.74 (d, 1H, H_6, $^3J_{HH}$ 8.1 Hz). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −2.11, −2.19. MS (ESI$^+$, *m*/*z*): 696 [(M + Na)$^+$, 100%].

2-Cyanoethyl-(2′,3′-didehydro-2′,3′-dideoxythymidin-5′-yl)-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9b). 88% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.07 (d, 3H, H_7, $|^4J_{HH}|$ 1.1 Hz), 2.08 (d, 3H, H_7, $|^4J_{HH}|$ 1.1 Hz), 2.16 (s, 3H, Me), 2.17 (s, 3H, Me), 2.18 (s, 3H, Me), 2.19 (s, 3H, Me), 2.20 (s, 6H, Me), 2.37 (s, 3H, Me), 2.38 (s, 3H, Me), 3.08 (q, 4H, $H_{2'''}$, $^3J_{HH}$ 7.2 Hz), 4.36−4.53 (m, 14H, $H_{5''}$ + $H_{6''}$ + $H_{5'}$ + $H_{1'''}$), 5.25 (m, 4H, $H_{2''}$ + $H_{4'}$), 5.35 (m, 2H, $H_{4''}$), 5.65 (m, 2H, $H_{3''}$), 6.19 (d, 2H, $H_{2'}$, $^3J_{HH}$ 6.0 Hz), 6.46 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.8 Hz), 6.49 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.8 Hz), 6.64 (m, 2H, $H_{3'}$), 7.15 (m, 2H, $H_{1'}$), 7.58 (d, 1H, H_6, $|^4J_{HH}|$ 1.1 Hz), 7.60 (d, 1H, H_6, $|^4J_{HH}|$ 1.1 Hz). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −1.99, −2.11. MS (ESI$^+$, *m*/*z*): 710 [(M + Na)$^+$, 100%].

2-Cyanoethyl-(3′-*O*-levulinyl-5-iodo-2′-deoxyuridin-5′-yl)-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9c). 80% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.18 (s, 6H, Me), 2.19 (s, 3H, Me), 2.20 (s, 6H, Me), 2.21 (s, 3H, Me), 2.26 (s, 3H, Me), 2.37 (s, 3H, Me), 2.38 (s, 6H, Me), 2.64 (m, 4H, $H_{2'}$), 2.79 (t, 4H, CH_2-Lev, $^3J_{HH}$ 6.2 Hz), 3.04 (t, 4H, CH_2-Lev, $^3J_{HH}$ 6.1 Hz), 3.14 (t, 4H, $H_{2'''}$, $^3J_{HH}$ 5.8 Hz), 4.40−4.61 (m, 16H, $H_{5''}$ + $H_{6''}$ + $H_{4'}$ + $H_{5'}$ + $H_{1'''}$), 5.27−5.50 (m, 4H, $H_{2''}$ + $H_{4''}$), 5.56 (m, 2H, $H_{3'}$), 5.65 (t, 2H, $H_{3''}$, $^3J_{HH}$ 9.8 Hz), 6.42 (m, 2H, $H_{1'}$), 6.48 (t, 2H, $H_{1''}$, $^3J_{HH}$ 4.1 Hz), 8.24 (s, 1H, H_6), 8.31 (s, 1H, H_6). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −1.59, −1.95. MS (ESI$^+$, *m*/*z*): 938 [(M + Na)$^+$, 100%].

2-Cyanoethyl-(5′-*O*-levulinyl-5-iodo-2′-deoxyuridin-3′-yl)-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9d). 81% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.19 (s, 3H, Me), 2.20 (s, 6H, Me), 2.21 (s, 3H, Me), 2.22 (s, 3H, Me), 2.26 (s, 3H, Me), 2.37 (s, 3H, Me), 2.38 (s, 6H, Me), 2.39 (s, 3H, Me), 2.72 (m, 2H, $H_{2'}$), 2.88 (m, 6H, $H_{2'}$ + CH_2-Lev), 3.06 (m, 4H, CH_2-Lev), 3.12 (t, 4H, $H_{2'''}$, $^3J_{HH}$ 7.1 Hz), 4.40−4.67 (m, 16H, $H_{5''}$ + $H_{6''}$ + $H_{4'}$ + $H_{5'}$ + $H_{1'''}$), 5.32 (m, 4H, $H_{2''}$ + $H_{3'}$), 5.42 (m, 2H, $H_{4''}$), 5.65 (m, 2H, $H_{3''}$), 6.41 (m, 2H, $H_{1'}$), 6.50 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.6 Hz), 6.51 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.8 Hz), 8.28 (s, 1H, H_6), 8.29 (s, 1H, H_6). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −2.76, −2.99. MS (ESI$^+$, *m*/*z*): 938 [(M + Na)$^+$, 100%].

2-Cyanoethyl-(2′,3′-dideoxyinosin-5′-yl)-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9e). 80% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.17 (s, 3H, Me), 2.18 (s, 3H, Me), 2.19 (s, 3H, Me), 2.20 (s, 3H, Me), 2.22 (s, 3H, Me), 2.23 (s, 3H, Me), 2.36 (s, 3H, Me), 2.37 (s, 3H, Me), 2.42 (m, 4H, $H_{3'}$), 2.80 (m, 4H, $H_{2'}$), 3.05 (t, 4H, $H_{2'''}$, $^3J_{HH}$ 6.1 Hz), 4.30−4.55 (m, 14H, $H_{5''}$ + $H_{6''}$ + $H_{5'}$ + $H_{1'''}$), 4.62 (m, 2H, $H_{4'}$), 5.24 (m, 2H, $H_{2''}$), 5.35 (t, 1H, $H_{4''}$, $^3J_{HH}$ 9.8 Hz), 5.37 (t, 1H, $H_{4''}$, $^3J_{HH}$ 8.0 Hz), 5.63 (m, 2H, $H_{3''}$), 6.44 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.7 Hz), 6.47 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.8 Hz), 6.52 (apparent t, 2H, $H_{1'}$, $^3J_{HH}$ 5.3 Hz), 8.26 (s, 2H, H_2), 8.44 (br s, 2H, H_8). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −1.77, −1.79. MS (ESI$^+$, *m*/*z*): 700 [(M + H)$^+$, 100%].

2-Cyanoethyl-[N^6-(dimethylamino)methylen-2′,3′-dideoxyadenosin-5′-yl]-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9f). 60% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.17 (s, 3H, Me), 2.18 (s, 3H, Me), 2.19 (s, 3H, Me), 2.20 (s, 3H, Me), 2.22 (s, 3H, Me), 2.23 (s, 3H, Me), 2.36 (s, 3H, Me), 2.37 (s, 3H, Me), 2.45 (m, 4H, $H_{3'}$), 2.81 (m, 4H, $H_{2'}$), 3.05 (t, 4H, $H_{2'''}$, $^3J_{HH}$ 6.1 Hz), 3.45 (s, 6H, Me-N), 3.48 (s, 6H, Me-N), 4.26−4.72 (m, 16H, $H_{5''}$ + $H_{6''}$ + $H_{4'}$ + $H_{5'}$ + $H_{1'''}$), 5.21 (m, 2H, $H_{2''}$), 5.35 (q, 2H, $H_{4''}$, $^3J_{HH}$ 9.2 Hz), 5.61 (t, 2H, $H_{3''}$, $^3J_{HH}$ 10.2 Hz), 6.42 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.6 Hz), 6.44 (d, 1H, $H_{1''}$, $^3J_{HH}$ 3.8 Hz), 6.57 (apparent t, 2H, $H_{1'}$, $^3J_{HH}$ 5.9 Hz), 8.62 (s, 2H, H_8), 8.67 (s, 2H, H_2), 9.28 (s, 1H, HC=N), 9.30 (s, 1H, HC=N). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −2.18, −2.21. MS (ESI$^+$, *m*/*z*): 754 [(M + H)$^+$, 100%].

2-Cyanoethyl-[2′,3′-di-*O*-acetyl-1′-(3-carbamoyl-1,2,4-triazoyl)-β-D-ribofuranos-5′-yl]-1,2,3,4-tetra-*O*-acetyl-α-D-glucopyranos-6-yl phosphate (9g). 89% yield. ^{1}H NMR (MeOH-d_4, 600 MHz): δ 2.17 (s, 3H, Me), 2.18 (s, 3H, Me), 2.19 (s, 3H, Me), 2.20 (s, 3H, Me), 2.23 (s, 3H, Me), 2.24 (s, 3H, Me), 2.29 (s, 3H, Me), 2.30 (s, 3H, Me), 2.31 (s, 3H, Me), 2.32 (s, 3H, Me), 2.37 (s, 3H, Me), 2.38 (s, 3H, Me), 3.09 (t, 4H, $H_{2'''}$, $^3J_{HH}$ 5.9 Hz), 4.36−4.63 (m, 14H, $H_{5''}$ + $H_{6''}$ + $H_{1'''}$ + $H_{5'}$), 4.71 (m, 2H, $H_{4'}$), 5.28 (m, 2H, $H_{2''}$), 5.37 (m, 2H, $H_{4''}$), 5.64 (m, 2H, $H_{3''}$), 5.91 (dd, 2H, $H_{3'}$, $^3J_{HH}$ 5.7 Hz), 5.97 (t, 1H, $H_{2'}$, $^3J_{HH}$ 9.4, 5.1 Hz), 6.49 (m, 4H, $H_{1''}$ + $H_{1'}$), 8.91 (s, 2H, H_5). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ −2.37, −2.60. MS (ESI$^+$, *m*/*z*): 833 [(M + H)$^+$, 100%].

General Procedure for the Synthesis of Phosphodiesters 10a−d. A solution of **9a−d** (0.30 mmol) in 6 mL of NH_4OH/MeOH (1:1, v/v) was stirred at room temperature overnight. The solution was concentrated in vacuum, and the residue was dissolved in water and treated with DOWEX 50WX8 (H^+ form). After stirring for 20 min, the resin was filtered, washed with water, and the filtrate concentrated. The residue was purified by reversed-phase HPLC with a Tracer Excel ODSA column (250 × 10 mm, 5 μm), flow rate 3 mL/min, 0.1% CF_3CO_2H/H_2O (1% MeCN) for elution, to afford **10a−d** as a hygroscopic white solid.

2′,3′-Didehydro-2′,3′-dideoxyuridine 5′-(α/β-D-glucopyranos-6-yl) phosphate (10a). 47% yield. ^{1}H NMR (D_2O, 400 MHz): δ 3.30 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.44−4.78 (m, 6H), 4.00 (m, 3H), 4.11 (m, 5H, $H_{5'}$), 4.68 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 7.9 Hz), 5.16 (m, 2H, $H_{4'}$), 5.28 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.8 Hz), 5.91 (d, 1H, H_5, $^3J_{HH}$ 8.1 Hz), 5.93 (d, 1H, H_5, $^3J_{HH}$ 8.1 Hz), 6.03 (m, 2H, $H_{2'}$), 6.56 (m, 2H, $H_{3'}$), 7.01 (m, 2H, $H_{1'}$), 7.85 (d, 1H, H_6, $^3J_{HH}$ 7.9 Hz), 7.88 (d, 1H, H_6, $^3J_{HH}$ 8.1 Hz). ^{31}P NMR (MeOH-d_4, 161.9 MHz): δ 0.64. MS (ESI$^-$, *m*/*z*): 451 [(M − H)$^-$, 100%].

2′,3′-Didehydro-2′,3′-dideoxythymidine 5′-(α/β-D-glucopyranos-6-yl) phosphate (10b). 45% yield. ^{1}H NMR (D_2O, 600 MHz): δ 1.89 (s, 6H, H_7), 3.23 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.3 Hz), 3.37−4.52 (m, 5H), 3.68 (m, 1H, $^3J_{HH}$ 9.8 Hz), 3.87−4.07 (m, 8H), 4.60 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 5.09 (m, 2H, $H_{4'}$), 5.18 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.5 Hz), 5.96 (d, 2H, $H_{2'}$, $^3J_{HH}$ 6.3 Hz), 6.48 (m, 2H, $H_{3'}$), 6.95 (m, 2H, $H_{1'}$), 7.60 (d, 1H, H_6, $|^4J_{HH}|$ 1.2 Hz), 7.61 (d, 1H, H_6, $|^4J_{HH}|$ 1.1 Hz). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ 0.38. MS (ESI$^-$, *m*/*z*): 465 [(M − H)$^-$, 100%].

2′-Deoxy-5-iodouridine 5′-(α/β-D-glucopyranos-6-yl) phosphate (10c). 40% yield. ^{1}H NMR (D_2O, 400 MHz): δ 2.41 (m, 4H, $H_{2'}$), 3.25 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.8 Hz), 3.45−3.74 (m, 6H), 3.94 (m, 1H), 4.07−4.26 (m, 10H), 4.59 (m, 2H, $H_{3'}$), 4.64 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 7.8 Hz), 5.19 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.7 Hz), 6.29 (apparent t, 2H, $H_{1'}$, $^3J_{HH}$ 6.9 Hz), 8.27 (s, 1H, H_6), 8.28 (s, 1H, H_6). ^{31}P NMR (D_2O, 161.9 MHz): δ 0.46. MS (ESI$^-$, *m*/*z*): 595 [(M − H)$^-$, 100%].

2′-Deoxy-5-iodouridine 3′-(α/β-D-glucopyranos-6-yl) phosphate (10d). 43% yield. ^{1}H NMR (D_2O, 400 MHz): δ 2.48 (m, 2H, $H_{2'}$), 2.67 (m, 2H, $H_{2'}$), 3.29 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.34−4.27 (m, 15H), 4.30 (m, 2H, $H_{4'}$), 4.70 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 7.9 Hz), 4.81 (m, 2H, $H_{3'}$), 5.28 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.8 Hz), 6.32 (apparent t, 2H, $H_{1'}$, $^3J_{HH}$ 6.8 Hz), 8.38 (s, 1H, H_6), 8.39 (s, 1H, H_6). ^{31}P NMR (D_2O, 161.9 MHz): δ 0.42. MS (ESI$^-$, *m*/*z*): 595 [(M − H)$^-$, 100%].

General Procedure for the Synthesis of Phosphodiesters 10e−i. A solution of **9e−i** (0.30 mmol) in 6 mL of NH_4OH/MeOH (1:1, v/v) was stirred overnight at room temperature (at 50 °C for **10f** and **10h**). The solution was concentrated in vacuum, and the residue was purified by reversed-phase HPLC to afford the ammonium salt of **10e−i** as a hygroscopic white solid.

2′,3′-Dideoxyinosine 5′-(α/β-D-glucopyranos-6-yl) phosphate (10e). 39% yield. HPLC conditions: Waters XBridge C18 column (150 × 19 mm, 5 μm), flow rate 1.5 mL/min, and H_2O for elution. ^{1}H NMR (D_2O, 400 MHz): δ 2.29 (m, 4H, $H_{3'}$), 2.65 (m, 4H, $H_{2'}$), 3.27 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.40−3.61 (m, 6H), 3.74 (t, 1H, $^3J_{HH}$ 9.4 Hz), 3.85−4.44 (m, 8H), 4.54 (m, 2H), 4.65 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 7.9 Hz), 5.22 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 7.9 Hz), 6.43 (dd, 2H, $H_{1'}$, $^3J_{HH}$ 6.6, 3.4 Hz), 8.27 (s, 2H, H_2), 8.46 (br s, 2H, H_8). ^{31}P NMR (MeOH-d_4, 161.9 MHz): δ 0.71. MS (ESI$^-$, *m*/*z*): 477 [(M − H)$^-$, 100%].

2′,3′-Dideoxyadenosine 5′-(α/β-D-glucopyranos-6-yl) phosphate (10f). 37% yield. HPLC conditions: Waters XBridge C18 column (150 × 19 mm, 5 μm), flow rate 1.5 mL/min, and H_2O for elution. ^{1}H NMR (D_2O, 600 MHz): δ 2.25 (m, 4H, $H_{3'}$), 2.58 (m, 4H, $H_{2'}$), 3.23 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.40 (m, 6H), 3.73 (m, 4H), 3.95 (m, 3H), 4.1 (m, 2H), 4.49 (m, 2H, $H_{4'}$), 4.57 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 7.7 Hz), 5.14 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.7 Hz), 6.32 (dd, 2H, $H_{1'}$, $^3J_{HH}$ 6.6, 3.1 Hz), 8.20 (s, 2H, H_8), 8.39 (s, 2H, H_2). ^{31}P NMR (MeOH-d_4, 242.9 MHz): δ 0.35. MS (ESI$^-$, *m*/*z*): 476 [(M − H)$^-$, 100%].

1′-(3-Carbamoyl-1,2,4-triazoyl)-β-D-ribofuranose 5′-(α/β-D-glucopyranos-6-yl) phosphate (10g). 44% yield. HPLC conditions: Mediterránea Sea 18 column (250 × 10 mm, 5 μm), flow rate 1.1 mL/min, and H_2O for elution. ^{1}H NMR (D_2O, 600 MHz): δ 3.17 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.36−3.49 (m, 7H), 3.79−4.11 (m, 10H), 4.51 (m, 2H, $H_{3'}$), 4.55 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 4.62 (m, 2H, $H_{2'}$), 5.11 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.5 Hz), 6.01 (d, 2H, $H_{1'}$, $^3J_{HH}$ 3.5 Hz), 8.73 (s, 2H, H_5). ^{31}P NMR (D_2O, 242.9 MHz): δ 0.50. MS (ESI$^-$, *m*/*z*): 485 [(M − H)$^-$, 100%].

1′-Adeninyl-β-D-arabinofuranose 5′-(α/β-D-glucopyranos-6-yl) phosphate (10h). 35% yield. HPLC conditions: Waters XBridge C18 column (150 × 19 mm, 5 μm), flow rate 1.5 mL/min, H_2O for elution. ^{1}H NMR (D_2O, 600 MHz): δ 3.29 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.42−3.65 (m, 6H), 3.90 (m, 1H), 4.04 (m, 2H), 4.13 (m, 1H), 4.25 (m, 6H), 4.52 (m, 2H, $H_{3'}$), 4.65 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 8.4 Hz), 4.68 (m, 2H, $H_{2'}$), 5.22 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.7 Hz), 6.49 (dd, 2H, $H_{1'}$, $^3J_{HH}$ 6.49 Hz, $|^4J_{HH}|$ 1.6 Hz), 8.31 (s, 2H, H_8), 8.48 (s, 2H, H_2). ^{31}P NMR (D_2O, 242.9 MHz): δ 0.23. MS (ESI$^-$, *m*/*z*): 508 [(M − H)$^-$, 100%].

1′-Cytosinyl-β-D-arabinofuranose 5′-(α/β-D-glucopyranos-6-yl) phosphate (10i). 49% yield. HPLC conditions: Mediterránea Sea 18 column (250 × 10 mm, 5 μm), flow rate 1.1 mL/min, and H_2O for elution. ^{1}H NMR (D_2O, 400 MHz): δ 3.28 (t, 1H, $H_{2''}$ β anomer, $^3J_{HH}$ 8.1 Hz), 3.49−3.61 (m, 5H), 3.74 (t, 1H, $^3J_{HH}$ 9.4 Hz), 4.05−4.29 (m, 12H), 4.53 (m, 2H, $H_{2'}$), 4.66 (d, 1H, $H_{1''}$ β anomer, $^3J_{HH}$ 8.0 Hz), 5.24 (d, 1H, $H_{1''}$ α anomer, $^3J_{HH}$ 3.7 Hz), 6.27 (d, 2H, $H_{1'}$, $^3J_{HH}$ 5.4 Hz), 6.30 (d, 1H, H_5, $^3J_{HH}$ 7.8 Hz), 6.32 (d, 1H, H_5, $^3J_{HH}$ 7.8 Hz), 8.17 (d, 1H, H_6, $^3J_{HH}$ 8.1 Hz), 8.18 (d, 1H, H_6, $^3J_{HH}$ 8.1 Hz). ^{31}P NMR (D_2O, 161.9 MHz): δ 0.41. MS (ESI$^-$, *m*/*z*): 484 [(M − H)$^-$, 100%].

Synthesis of 1-(5′-*O*-dimethoxytrityl-β-D-ribofuranosyl)-1,2,4-triazole-3-carboxamide (14). 4,4′-Dimethoxytrityl chloride (417 mg, 1,23 mmol), Et_3N (171 μL, 1.23 mmol), and DMAP (catalytic amount) are added to a solution of **13** (150 mg, 0.62 mmol) in anhydrous pyridine (3.1 mL), and the reaction is stirred at room temperature during 24 h. The mixture was poured into $NaHCO_3$ (5% aqueous solution) and extracted with EtOAc. The combined organic fractions was dried (Na_2SO_4) and concentrated under vacuum. The crude was purified by flash chromatography using 2% MeOH/CH_2Cl_2 for elution to yield **14** as a yellow solid in 83% yield. Melting range: 111−113 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 3.48 (m, 2H, $H_{5'}$), 3.86 (s, 6H, OMe), 4.39 (m, 1H, $H_{4'}$), 4.65 (t, 1H, $H_{2'}$ or $H_{3'}$, $^3J_{HH}$ 5.6 Hz), 4.85 (t, 1H, $H_{2'}$ or $H_{3'}$, $^3J_{HH}$ 3.4 Hz), 6.13 (d, 1H, $H_{1'}$, $^3J_{HH}$ 3.1 Hz), 6.91 (d, 4H, H_m, $^3J_{HH}$ 8.9 Hz), 7.35 (m, 7H, $H_m + H_o + H_p$), 7.53 (d, 2H, H_o, $^3J_{HH}$ 8.2 Hz), 8.82 (s, 1H, H_5). MS (ESI$^+$, *m*/*z*): 569 [(M + Na)$^+$, 100%].

Synthesis of 1-(2′,3′-di-*O*-acetyl-5′-*O*-dimethoxytrityl-β-D-ribofuranosyl)-1,2,4-triazole-3-carboxamide (15). To a solution of **14** (404 mg, 0.74 mmol) in anhydrous pyridine (5.2 mL) at 0 °C was added acetic anhydride (350 μL, 3.7 mmol). After being stirred at room temperature for 16 h, the mixture was poured into saturated aqueous $NaHCO_3$ solution and extracted with CH_2Cl_2. The combined organic fractions were dried (Na_2SO_4) and concentrated under vacuum. The crude was purified by flash chromatography using 1% MeOH/CH_2Cl_2 for elution to yield **15** as a white solid in 78% yield. Melting range: 99−101 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 2.24 (s, 3H, CH_3), 2.28 (s, 3H, CH_3), 3.48 (m, 1H, $H_{5'}$), 3.60 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 11.9, $^3J_{HH}$ 3.2 Hz), 3.92 (s, 6H, OMe), 4.53 (q, 1H, $H_{4'}$, $^3J_{HH}$ 3.9 Hz), 5.89 (t, 1H, $H_{3'}$, $^3J_{HH}$ 5.3 Hz), 6.20 (dd, 1H, $H_{2'}$, $^3J_{HH}$ 5.1, 3.9 Hz), 6.43 (d, 1H, $H_{1'}$, $^3J_{HH}$ 3.8 Hz), 6.97 (d, 4H, H_m, $^3J_{HH}$ 8.8 Hz), 7.38 (m, 7H, $H_m + H_o + H_p$), 7.58 (d, 2H, H_o, $^3J_{HH}$ 8.3 Hz), 8.75 (br s, 1H, NH), 8.98 (s, 1H, H_5). MS (ESI$^+$, *m*/*z*): 653 [(M + Na)$^+$, 100%].

Synthesis of 9-(β-D-Arabinofuranosyl)-N^6-benzoyladenine (17). Compound **16** was evaporated with anhydrous pyridine (3 × 10 mL). To a solution of **16** (400 mg, 1.5 mmol) in anhydrous pyridine (7.5 mL) was added trimethylsilyl chloride (1.4 mL, 11.2 mmol). Upon the complete consumption of the starting material, benzoyl chloride (870 μL, 7.5 mmol) was added, and the reaction was stirred at room temperature for 2 h. The mixture was then cooled at 0 °C, and 2 mL of water was added. After 5 min, 3 mL of aqueous ammonia was added, and the mixture was stirred at this temperature for 30 min. The reaction was concentrated and the residue washed with water and EtOAc to give **17** as a white solid in 90% yield. Melting range: 185−187 °C. ^{1}H NMR (DMSO-d_6, 300 MHz): δ 3.68 (m, 2H, $H_{5'}$), 3.83 (q, 1H, $H_{4'}$, $^3J_{HH}$ 4.8 Hz), 4.23 (m, 2H, $H_{2'}$ + $H_{3'}$), 5.15 (s, 1H, OH), 5.61 (d, 1H, OH, $|^4J_{HH}|$ 3.9 Hz), 5.74 (d, 1H, OH, $|^4J_{HH}|$ 5.2 Hz), 6.42 (d, 1H, $H_{1'}$, $^3J_{HH}$ 5.1 Hz), 7.57 (m, 3H, $H_m + H_p$), 8.04 (d, 1H, H_o, $^3J_{HH}$ 8.4 Hz), 8.53 (s, 1H, H_8), 8.73 (s, 1H, H_2). MS (ESI$^+$, *m*/*z*): 372 [(M + H)$^+$, 100%].

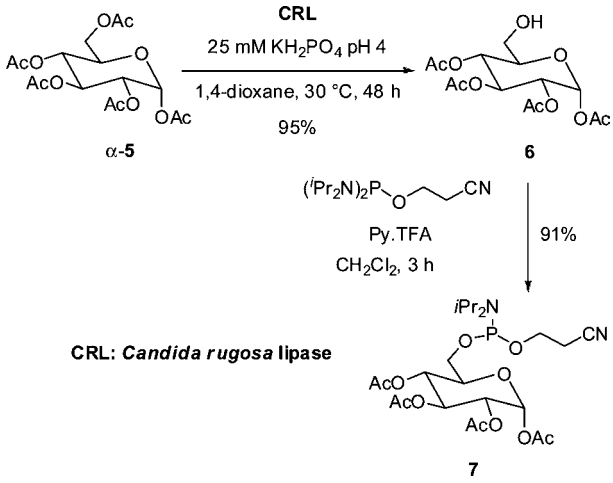
Synthesis of N^6-Benzoyl-9-(5′-*O*-dimethoxytrityl-β-D-arabinofuranosyl)adenine (18). A procedure similar to that described for **14** afforded **18** as a yellow solid in 70% yield. Melting range: 147−149 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 3.68 (m, 2H, $H_{5'}$), 3.88 (s, 6H, MeO), 4.29 (m, 1H, $H_{4'}$), 4.57 (m, 2H, $H_{2'}$ + $H_{3'}$), 6.73 (d, 1H, $H_{1'}$, $^3J_{HH}$ 4.1 Hz), 6.96 (d, 4H, H_m, $^3J_{HH}$ 8.2 Hz), 7.33−7.77 (m, 12H, $H_m + H_o + H_p$), 8.21 (d, 2H, H_o, $^3J_{HH}$ 7.2 Hz), 8.67 (s, 1H, H_8), 8.82 (s, 1H, H_2). MS (ESI$^+$, *m*/*z*): 696 [(M + Na)$^+$, 100%].

Synthesis of N^6-Benzoyl-9-(2′,3′-di-*O*-acetyl-5′-*O*-dimethoxytrityl-β-D-arabinofuranosyl)-adenine (19). A procedure similar to that described for **15** afforded **19** as a white solid in 83% yield. Melting range: 88−90 °C. Flash chromatography was performed using 2% MeOH/CH_2Cl_2 for elution. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 1.76 (s, 3H, Me), 2.27 (s, 3H, Me), 3.71 (m, 2H, $H_{5'}$), 3.94 (s, 6H, OMe), 4.49 (q, 1H, $H_{4'}$, $^3J_{HH}$ 4.1 Hz), 5.75 (dd, 1H, $H_{3'}$, $^3J_{HH}$ 5.4, 4.3 Hz), 5.91 (dd, 1H, $H_{2'}$, $^3J_{HH}$ 5.3, 4.2 Hz), 6.85 (d, 1H, $H_{1'}$, $^3J_{HH}$ 5.4 Hz), 7.03 (d, 4H, H_m, $^3J_{HH}$ 8.9 Hz), 7.37−7.65 (m, 12H, $H_m + H_p + H_o$), 7.82 (d, 2H, H_o, $^3J_{HH}$ 7.2 Hz), 8.62 (s, 1H, H_8), 8.77 (s, 1H, H_2). MS (ESI$^+$, *m*/*z*): 779 [(M + Na)$^+$, 100%].

Synthesis of 1-(5′-*O*-*tert*-Butyldimetylsilyl-β-D-arabinofuranosyl)cytosine (21). *tert*-Butyldimetylsilyl chloride (342 mg, 2.3 mmol), anhydrous Et_3N (287 μL, 2.2 mmol), and DMAP (38 mg, 0.15 mmol) were added to a solution of **20** (500 mg, 2.1 mmol) in anhydrous DMF (10.3 mL) and anhydrous CH_2Cl_2 (5.2 mL). The mixture was stirred at room temperature for 17 h. Next, the solvents were concentrated and the residue purified by flash chromatography using 10% MeOH/CH_2Cl_2 for elution affording **21** as a white solid in 82% yield. Melting range: 162−164 °C. ^{1}H NMR (MeOH-d_4, 300 MHz): δ 0.16 (s, 3H, Me-Si), 0.17 (s, 3H, Me-Si), 0.95 (s, 9H, Me_3C), 4.12 (m, 3H, $H_{4'}$ + $H_{5'}$), 4.33 (m, 1H, $H_{2'}$ or $H_{3'}$), 4.46 (m, 1H, $H_{2'}$ or $H_{3'}$), 5.93 (d, 1H, H_5, $^3J_{HH}$ 7.5 Hz), 6.16 (d, 1H, $H_{1'}$, $^3J_{HH}$ 3.7 Hz), 7.85 (d, 1H, H_6, $^4J_{HH}$ 7.5 Hz). MS (ESI$^+$, *m*/*z*): 358 [(M + H)$^+$, 100%].

Synthesis of N^4-Acetyl-1-(2′,3′-di-*O*-acetyl-5′-*O*-*tert*-butyldimetylsilyl-β-D-arabinofuranosyl)-cytosine (22). A procedure similar to that described for **15**, except that 10 equivalents of acetic anhydride were used, afforded **22** as a white solid in 85% yield. Melting range: 229−231 °C. Flash chromatography was performed using 50−100% EtOAc/hexane as the elution gradient. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 0.12 (s, 3H, Me-Si), 0.13 (s, 3H, Me-Si), 0.94 (s, 9H, Me_3C), 1.93 (s, 3H, Me), 2.11 (s, 3H, Me), 2.30 (s, 3H, Me), 3.90 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 10.7 Hz, $^3J_{HH}$ 4.1 Hz), 3.94 (dd, 1H, $H_{5'}$, $|^2J_{HH}|$ 11.3 Hz, $^3J_{HH}$ 3.9 Hz), 4.06 (q, 1H, $H_{4'}$, $^3J_{HH}$ 3.9 Hz), 5.28 (dd, 1H, $H_{3'}$, $^3J_{HH}$ 4.5, 3.4 Hz), 5.58 (dd, 1H, $H_{2'}$, $^3J_{HH}$ 4.5, 2.5 Hz), 6.35 (d, 1H, $H_{1'}$, $^3J_{HH}$ 4.7 Hz), 7.44 (d, 1H, H_5, $^3J_{HH}$ 7.5 Hz), 8.12 (d, 1H, H_6, $^4J_{HH}$ 7.5 Hz). MS (ESI$^+$, *m*/*z*): 484 [(M + H)$^+$, 100%].

Solubility Assays. The experiments were carried out taking 1 or 2 mg of the corresponding compound and then adding consecutive amounts of water with a micropipet. After each addition, a vigorous shaking of the solution was done. Then, the solution was checked for insoluble material with a magnifying glass.



Antiviral Assays. The procedures for the antiviral assays in human peripheral blood mononuclear (PBM) cells were reported previously (*45*). Briefly, uninfected phytohemagglutinin (PHA)-stimulated human PBM cells were infected with HIV-1_{LAI} [about 63,000 disintegrations of reverse transcriptase (RT) activity per min per 10^7 cells per 10 mL of medium]. The nucleoside analogues or prodrugs were then added to duplicate or triplicate cultures. Uninfected and untreated PBM cells were grown in parallel at equivalent cell concentrations as controls. The cultures were maintained in a humidified 5% CO_2−95% air incubator at 37 °C for 6 days after infection, at which point all cultures were sampled for supernatant RT activity. The supernatant was clarified, and the viral particles were then pelleted at 40,000 rpm for 30 min by using a rotor and suspended in virus-disrupting buffer. The RT assay was performed in 96-well microdilution plates by using $(rA)_n \cdot (T)_{12-18}$ as the template primer. The RT results were expressed in disintegrations per minute per milliliter of originally clarified supernatant.

Cytotoxicity Assays. The nucleoside analogues and prodrugs were evaluated for their potential toxic effects on uninfected PHA-stimulated human PBM cells and also in CEM (lymphoblastoid) and Vero (African green monkey kidney) cells as described previously (*46*). PBM cells were obtained from whole blood of healthy HIV-1 and hepatitis B virus-seronegative volunteers and collected by single-step Ficoll-Hypaque discontinuous gradient centrifugation. CEM (CEM-CCRF) cells were a T-lymphoblastoid cell line that was obtained from the American Type Culture Collection, Rockville, MD. The CEM cells were maintained in RPMI 1640 medium supplemented with 20% heat-inactivated fetal bovine serum, penicillin (100 U/mL), and streptomycin (100 μg/mL). The PBM and CEM cells were cultured with and without drug for 6 days, at which time portions were counted for cell proliferation and viability by the trypan blue exclusion method. Only the effects on cell growth are reported since these correlated well with cell viability. The toxicity of the compounds in Vero cells was assessed after 3 days of treatment with a hemacytometer.

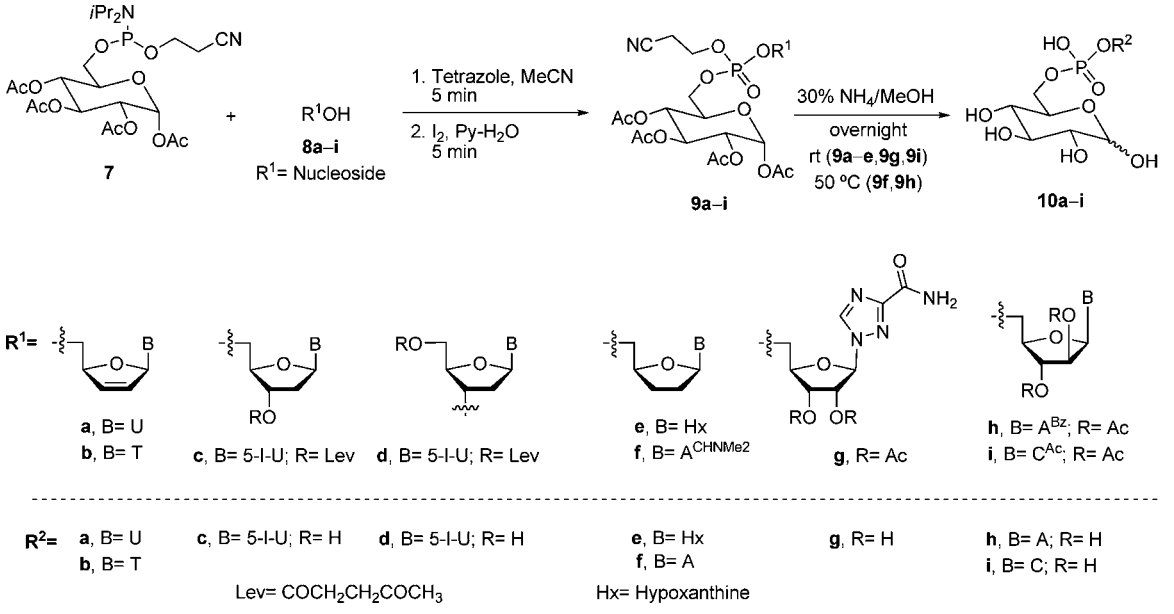
RESULTS AND DISCUSSION

We envisioned phosphoramidite **7** as the key building block for the synthesis of the target nucleoside−carbohydrate prodrugs for several reasons. First, phosphoramidite chemistry offers

Scheme 1. Synthesis of D-Glucose Phosphoramidite

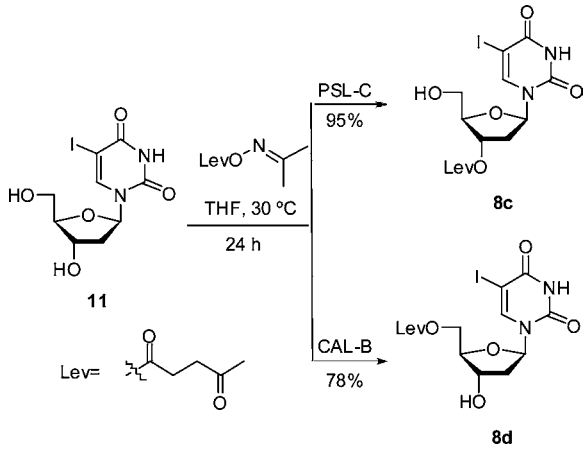
excellent yield during solution-phase coupling of various nucleosides (*33*). Second, phosphoramidite compounds are reasonably stable and easy to handle during synthesis. Third, glucose−amidite **7** would be an ideal molecule offering a versatile conjugation unit for the attachment of glucose to a wide range of nucleosides.

A major challenge faced by carbohydrate or nucleoside chemists is to orchestrate selective transformation of hydroxyl groups with similar reactivity in a single molecule. Gratifyingly, enzyme-catalyzed reactions have provided selective modifications with high selectivity and efficiency (*34*). The synthesis of glucosyl phophoramidite **7** was accomplished in few steps via a regioselective enzymatic hydrolysis of 1,2,3,4,6-penta-*O*-acetyl-α-D-glucopyranose (**5**, Scheme 1).



Commercial *Candida rugosa* lipase (CRL) was found to be an efficient catalyst for both regio- and chemoselective deacetylation of the primary hydroxyl group in the peracetylated α-D-glucose, furnishing the 6-OH derivative **6** in excellent yield after crystallization from diethyl ether/*n*-hexane (4:1) (*29*). The synthesis of phosphoramidite **7** was carried out by phosphitylation of **6** with 2-cyanoethyl-*N*,*N*,*N*′,*N*′-tetraisopropylphosphoramidite and pyridinium trifluoroacetate as the activator in high yield (*31*). The stability of phosphoramidite **7** was determined both in solution and as a neat product. A solution of **7** in $CDCl_3$ was found to be stable for six months (by ^{31}P NMR). Similarly, neat amidite **7** was stored for 18 months in the freezer (−24 °C) under nitrogen without any noticeable degradation.

The conjugation of glucosyl phosphoramidite **7** was practiced with a model nucleoside **8a** (d4U). Following standard amidite coupling conditions, **7** was first activated with 1*H*-tetrazole, and the resulting intermediate was oxidized *in situ* using an iodine/pyridine/water solution to give the phosphotriester derivative **9a** in 89% isolated yield after flash chromatography. As expected, the presence of P-diastereoisomers, due to the phosphorus stereocenter, was apparent from two signals at −2.11 and 2.19 ppm in the ^{31}P NMR spectrum. Next, the acetyl groups and the cyanoethyl group were removed simultaneously from **9a** by treatment with a 1:1 (v/v) mixture of aqueous ammonia and MeOH. The residue was purified on a DEAE Sephadex-A25 column with a linear gradient of triethylammonium hydrogen carbonate buffer (0.1−1.0 M) and the product lyophilized. However, this purification protocol resulted in a lower purity of the product with a significant amount of TEA salt. Alternatively, the crude residue was mixed with a Dowex 50WX8 hydrogen form exchange resin, and after filtration, the free acid was subjected to reverse-phase HPLC purification with a tracer excel 120 ODS-A column using H_2O (0.1% TFA, 1% MeCN) for elution. This technique allows for the isolation of phosphodiester **10a** in high purity and 47% yield. The two α/β-anomeric products corresponding to the glycosyl unit were observed in the ^1H NMR spectrum.



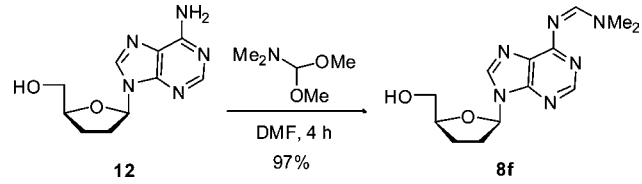
Having established an efficient protocol for the glucose−nucleoside conjugate, we were ready to synthesize the glucose conjugates of seven biologically active nucleosides (d4T, ddI, IdUrd, ddA, virazole, *ara*-A, and *ara*-C) that we selected for this study. Since d4T has only one reactive site, the synthesis of conjugate **10b** was easily accomplished from **8b** in two convenient steps (Scheme 2). Pronucleotide **10b** was purified by HPLC, and the structure was elucidated by NMR spectroscopy.

For the synthesis of the IdUrd-glucose phosphodiester derivative **10c**, coupling of sugar phosphoramidite **7** with the 5′-hydroxyl group of the parent nucleoside required the masking of the 3′-hydroxyl group. The selective protection of the 3′-secondary alcohol in **11** was accomplished with acetonoxime levulinate catalyzed by *Pseudomonas cepacia* lipase (PSL-C) in THF at 30 °C (Scheme 3). Under these conditions, facile

Scheme 2. Synthesis of Nucleosyl D-Glucopyranosyl Phosphodiesters

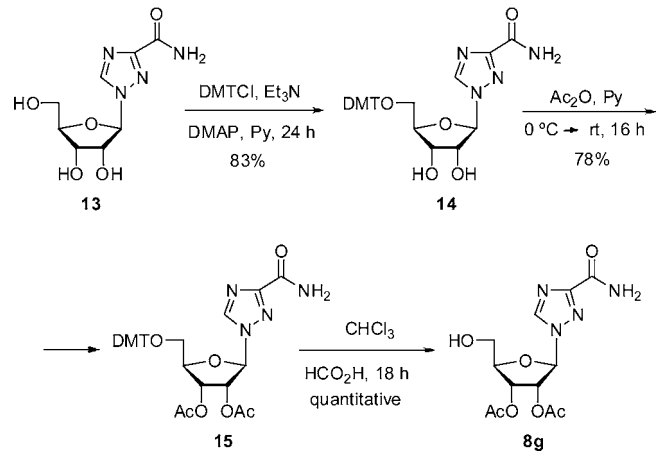
Scheme 3. Enzymatic Synthesis of 3′- and 5′-*O*-Lev-IdUrd

regioselective 3′-*O*-acylation of **11** was observed within 24 h, exclusively furnishing 3′-*O*-levulinyl derivative **8c** in 95% yield. Importantly, pure 3′-*O*-Lev-IdUrd **8c** was isolated via precipitation without a need for column chromatography.



The protected nucleoside **8c** was coupled with phosphoramidite **7** according to the procedure summarized in Scheme 2. After oxidation, the coupled product was purified by column chromatography to afford the phosphotriester **9c** in 80% yield. Next, the 3′-*O*-levulinyl group was cleaved by treatment of **9c** with 1 M hydrazine hydrate in pyridine−acetic acid (3:2 v/v) at room temperature without affecting the phosphate protecting group, thereby establishing the orthogonality of these two protecting groups. However, this reaction resulted in a lower yield due to the troublesome purification of the final product. Therefore, **9c** was first deprotected at the phosphate group with Et_3N−MeCN (1:1, v/v) to furnish the free phosphate in 90% yield, and then the levulinyl group was removed, leading to compound **10c**. Nevertheless, the yield did not improve. Finally, the phosphodiester derivative **10c** was obtained in satisfactory yield by treatment of **9c** with a 1:1 (v/v) mixture of aqueous ammonia and MeOH (*35*). These conditions allowed for the deprotection of both the cyanoethyl and levulinyl groups simultaneously furnishing **10c** in 40% yield after HPLC purification.

In order to determine the relationship between biological activity and site of conjugation, we decided to synthesize a 3′-*O*-conjugate prodrug **10d** starting with IdUrd. Preparation of the 5′-*O*-protected IdUrd derivative **8d** was performed with acetonoxime levulinate catalyzed by *Candida antarctica* lipase (CAL-B) (Scheme 3). Acylation takes place with high selectivity at the 5′-hydroxyl group providing **8d** in 78% yield. Coupling of phosphoroamidite **7** and nucleoside **8d** followed by *in situ* oxidation and cleavage of the blocking groups yielded glucoconjugate **10d** with 43% overall yield.

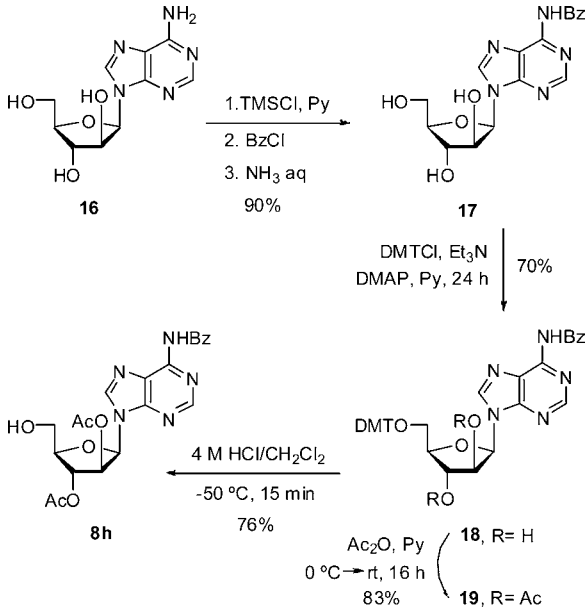


Next, glucoconjugates of nucleosides having purine bases were synthesized. Synthesis of glucosyl-ddI phosphodiester **10e** was accomplished in manner similar to that described above. Condensation of **7** and **8e** with 1*H*-tetrazole and iodine oxidation gave phosphotriester **9e** in 80% yield. To release the free phosphate, **9e** was treated with NH_4OH, and the crude product was purified by HPLC (see Materials and Methods) in 39% yield.

In order to synthesize the glucose conjugate of ddA (**12**, Scheme 4), it is essential that the N^6-amino group is masked appropriately, avoiding the interference with highly reactive amidite **7**. Conventional protection of the N^6-amino group in **12** following the Jones protocol (*36*) resulted in low yields, perhaps due to facile depurination of ddA. Therefore, formamidine was chosen as the protecting group for the amino group

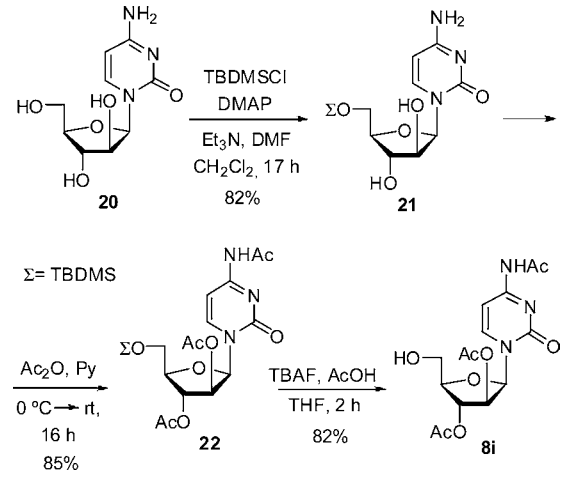
Scheme 4. Synthesis of Formamidine Base Protected ddA

Scheme 5. Synthesis of the Virazole Nucleoside Precursor



that is installed under neutral conditions following the protocol described by Minamoto (*37*).

Treatment of ddA (*12*) with DMF-dimethyl acetal generated the dimethylaminomethyleneamino compound **8f** in quantitative yield. Coupling of 1*H*-tetrazole activated phosphoramidite **7** with **8f**, followed by the oxidation of the resulting phosphite triester afforded the desired phosphotriester **9f** in 60% yield. The modest yield of the coupling and oxidation steps can be explained in terms of possible side reactions. The formamidine group is more labile than the benzoyl group, and degradation of the formamidine into formamide was observed (*37*). Subsequently, the phosphate moiety, the acetyl groups, and the formamidine group were simultaneously cleaved by aqueous ammonium at 50 °C, which gave the phosphodiester **10f** as its ammonium salt. Purification of **10f** was achieved by HPLC (see Materials and Methods).



Prior to the conjugation of amidite **7** to the antiviral drug virazole **13**, masking of the 2′- and 3′-hydroxyl groups was essential. Our first attempt was based on the simultaneous protection of 2′- and 3′-hydroxyl groups of **13** as an acetal using acetone, copper(II) sulfate, and sulphuric acid resulted in less than 40% yield of the desired product. The yield could not be improved when **13** was treated with 2,2-dimethoxypropane in acetone. Next, we attempted the acylation of the secondary hydroxyl groups of **13** with acetonoxime levulinate in the presence of *Pseudomonas cepacia* (PSL-C) (*38*−*40*). Unfortunately, the mixture of acylated products and low conversions (<10%) were observed after 4 days at 50 °C. The conversion of **13** was improved by employing vinyl acetate as the acylating agent. However, 3′,5′-di-*O*-acetyl nucleoside was obtained as the major product, in addition to the 2′,5′-di-*O*-acetyl and the triacetyl derivatives. Additionally, we attempted the selective enzymatic hydrolysis of peracylated virazole anticipating the formation of **8g** (*41*). Multiple enzymes (*Candida antarctica* lipase B, porcine pancreas lipase, subtilisine) were employed, but we could not achieve the desired regioselectivity.

These failures directed our attention to a more traditional three-step approach described in Scheme 5. Selective protection of the primary hydroxyl group was easily achieved by the treatment of virazole (**13**) with dimethoxytrityl chloride, Et_3N,

Scheme 6. Synthesis of the *ara*-Adenosine Precursor

Scheme 7. Synthesis of the *ara*-Cytidine Precursor

and DMAP in pyridine. Product **14** was then subjected to acetylation with acetic anhydride in pyridine to provide 2′,3′-di-*O*-acetyl-5′-*O*-DMT nucleoside **15** in 78% yield. Deprotection of the 5′-hydroxyl group by formic acid in chloroform led to the desired precursor **8g** in quantitative yield. The protected nucleoside **8g** was coupled as described above, and the resulting phosphotriester **9g** was deprotected with a 1:1 (v/v) mixture of aqueous ammonia and MeOH. Phosphodiester **10g** was purified by reverse-phase HPLC on a C18 column.

Vidarabine is an *ara*-nucleoside drug with a wide range of antiviral activity. However, vidarabine is toxic and metabolically unstable (rapid deamination). Therefore, 5′-conjugates of vidarabine have been synthesized as prodrugs (*42*). In this vein, we decided to extend our study toward the synthesis of glycoconjugate **10h**. First, *ara*-adenosine (**16**) was *N*-benzoylated following the transient Jones protocol to furnish N^6-benzoyl-*ara*-adenosine (**17**) in 90% yield (Scheme 6). Transformation of **17** into **19** proceeded well yielding the corresponding 2′,3′-di-*O*-acetyl-5′-*O*-DMT derivative. Traditional deprotection of the dimethoxytrityl group of **19** with formic acid in $CHCl_3$ resulted in low yield and the formation of depurinated products. Milder deprotection of **19** was accomplished with 4 M HCl in CH_2Cl_2 at −50 °C furnishing a cleaner product, **8h**.

Coupling of phosphoramidite **7** with protected *ara*-adenosine **8h** and subsequent oxidation gave the compound **9h** in 70% yield after column chromatography. Deprotection of **9h** by aqueous ammonium at 50 °C and purification of the reaction product by reverse-phase HPLC led to phosphodiester **10h**.

Ara-cytidine is yet another drug that is poorly soluble in water, and prodrug approaches have been utilized to improve the oral bioavailability (*43*, *44*). We believe that the synthesis of a glucose conjugate **10i** would offer increased solubility for **20** in water. Preparation of the protected *ara*-cytidine precursor **8i** was accomplished as depicted in Scheme 7. The primary hydroxyl group in **20** was protected as silyl ether by reaction with *tert*-butyldimethylsilyl chloride, Et_3N, and DMAP in DMF and CH_2Cl_2 to afford **21** in 82% yield. Peracetylation was then performed using acetic anhydride in pyridine furnishing protected **22**. Subsequent treatment with tetrabutylammonium fluoride removed the TBDMS group and afforded the 2′,3′-protected nucleoside **8i** in 57% overall yield from *ara*-cytidine. Phosphotriester **9i** was prepared in 96% isolated yield by the coupling of **7** and **8i** followed by *in situ* oxidation. Finally, compound **10i** was purified by reverse-phase HPLC. On the basis of their NMR data, all conjugates **10a**−**i** were prepared in the furanose form.

In order to determine the impact of conjugating the glucose moiety onto the nucleosides, we compared the solubility of prodrugs **10a**−**i** with unprotected nucleosides (Figure 1). Solubility assays revealed that all conjugates **10a**−**i** prepared in this study were more soluble in water than the parent nucleosides. It is noteworthy that the phosphodiester of *ara*-adenosine **10h** was found to be 31 times more soluble in water than *ara*-adenosine. Also, the 3′-*O*- and 5′-*O*-conjugate derivatives of IdUrd **10c** and **10d** displayed markedly increased solubility in water (25 and 20 times more soluble, respectively). More importantly, poorly soluble nucleoside derivatives IdUrd and *ara*-A showed significant improvement in water solubility after conjugation with glucose. Clearly, such carbohydrate conjugates may lead to improved oral bioavailability of the drugs that lack water solubility.

Biological Evaluation. *Antiviral Assays.* Nine glucose conjugates **10a**−**i** were tested against HIV-1 with AZT (zidovudine) used as a positive control. All of the anti-HIV assays were performed in human PBM cells (*27*). We also included the unprotected starting materials used for the synthesis of conjugates and a representative commercial sample of the same product in the assay as additional controls. A stock solution (40 mM) of the conjugates **10a**−**i** and various controls were prepared in sterile DMSO and then diluted to the desired concentration in growth media.

An overall summary of the data expressed as the effective concentration required for the inhibition of viral replication by 50% (EC_{50}) and 90% (EC_{90}) is summarized in Table 1. The anti-HIV activity of the conjugates tested was in the order of **10b** > **10f** > **10i** > **10g** > **10e** > **10h** > **10c**. The traditional anti-HIV nucleosides d4T and ddI after conjugation showed moderate activity indicating that the potency of **10b** and **10e** could be attributed to the free nucleosides. A similar pattern of anti-HIV activity was observed with ddA before and after conjugation. The improved activity of the ddA conjugate **10f** compared to that of the conjugate of ddI **10e** may be due to the efficient deamination of **10f** to liberate ddI intracellularly. Furthermore, both virazole conjugate **10g** and *ara*-A conjugate **10h** exhibited better activity than their nucleoside counterpart, thus indicating that the glucose conjugates are possibly a good design for developing prodrugs. Most importantly, the conjugation of glucose to the nucleosides via a phosphate linkage did not abolish the antiviral activity of the parent nucleosides. The retention of modest anti-HIV activity exhibited by the new conjugates is encouraging and warrants further studies.

[a] The HIV drug susceptibility assay was done as previously described in ref *45*. [b] The cytotoxicity assays in PBM, CEM, and Vero cells were done as previously described in ref *46*. ND = not determined.

Cytotoxicity Assays. The new conjugates were evaluated for their potential toxic effects using three different cell lines. First, the PBM cells were selected because of their slow growth and also being host cells for the anti-HIV assay. Second, we included lymphocytic CEM cells due to their quick replication and its common use for anti-HIV-1 assays. Third, Vero cells were utilized due to their rapid growth and because they were anchored on the surface. The screening of new conjugates in three cell types will enable us to distinguish the observed anti-HIV-1 activity from the toxicity. Among the various conjugates tested, the most potent anti-HIV-1 compound was **10b** with EC_{50} of 0.34 μM demonstrating no cytotoxicity in PBM and Vero cells and marginal IC_{50} of 76.8 μM in CEM cells. However, the ddA conjugate **10f** was found to be relatively more cytotoxic in all three cell lines. Overall, the new conjugates were found to be somewhat more cytotoxic in CEM cells compared to those in the PBM and Vero cells.

In summary, the anti-HIV-1 and cytotoxicity assays with conjugates **10a**−**i** reported herein confirm that the modification of various nucleosides with the glucose−phosphate conjugate did not completely abolish the original activity of the parent nucleosides. No significant toxicity was observed for the conjugates tested in this study with the exception of *ara*-C, which was found to be more cytotoxic when in the form of a glyco-conjugate than as a simple nucleoside.

CONCLUSIONS

Glycoconjugates of biologically active nucleoside analogues have been prepared as potential prodrugs since they can be cleaved intracellularly to the corresponding nucleosides and nucleotides. We have shown that the phosphoramidite approach is a convenient method that allows for the synthesis of stable glycosyl-nucleoside phosphodiester compounds. We demonstrated that glucosyl 6-phosphoramidite **7** is easily accessible in high yield through a regioselective chemoenzymatic strategy. Furthermore, we established that the phosphodiesters of d4T, IdUrd, ddI, ddA, virazole, *ara*-A, and *ara*-C exhibited higher solubility in water compared to their parent nucleosides. These water soluble conjugates of nucleosides may improve their oral bioavailability and increase the intestinal absorption as reported

for other carbohydrate conjugates (*47*, *48*). The anti-HIV-1 data is encouraging and expected to offer new opportunities in designing therapeutic nucleosides via a straightforward chemical conjugation approach. We anticipate that amidite **7** will find wider applications for other therapeutic agents that require enhanced water solubility.

ACKNOWLEDGMENT

This work is dedicated to Professor Francisco Palacios on the occasion of his 60th birthday. Financial support of this work by the Spanish Ministerio de Educación y Ciencia (MEC) (Project MEC-CTQ-2007-61126) is gratefully acknowledged. R.F.S. is supported in part by NIH grants 5P30-AI-50409 (CFAR), 5R37-AI-025899, and 5R37-AI-041980 and by the Department of Veterans Affairs.

Supporting Information Available: ^{1}H and ^{13}C NMR spectral data; the level of purity is indicated by the inclusion of copies of ^{1}H and ^{13}C NMR spectra; in addition, some 2D NMR experiments are shown, which were used to assign the peaks. This material is available free of charge via the Internet at http://pubs.acs.org.

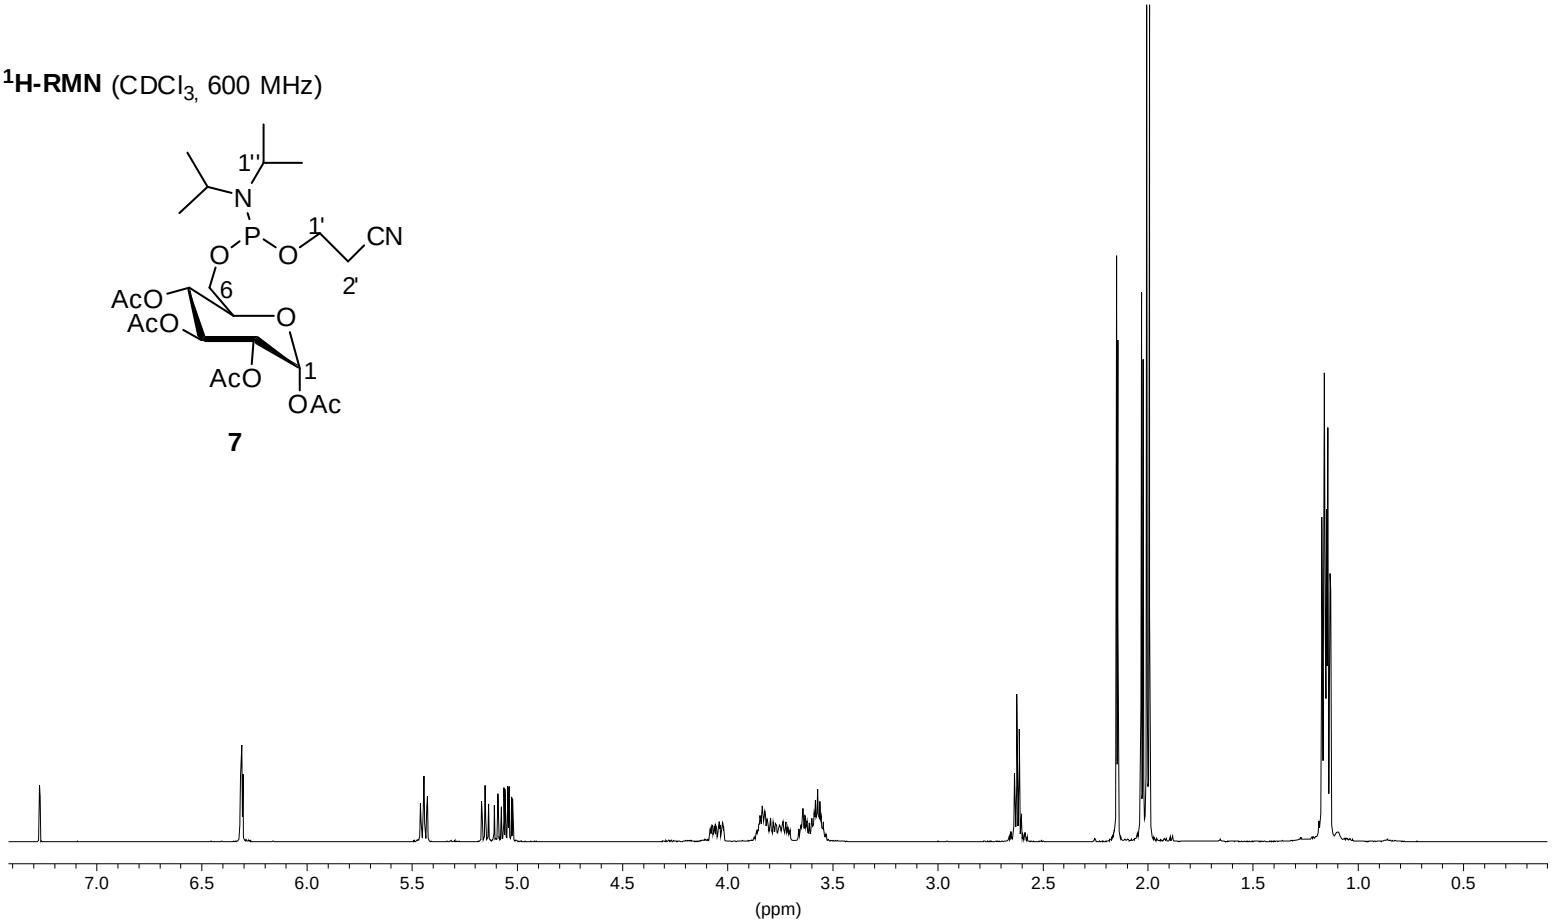
ELECTRONIC SUPPLEMENTARY INFORMATION (page 1 of 153 pages)

Contents:

Copies of ^{1}H, ^{13}C, DEPT, and some 2D NMR spectra of compounds **3**, **5**, **7**, **9**, and **10**:

- ^{1}H NMR of **7** (S4)
- ^{13}C NMR of **7** (S5)
- DEPT NMR of **7** (S6)
- ^{31}P NMR of **7** (S7)
- COSY of **7** (S8)
- HSQC of **7** (S9)
- HMBC of **7** (S10)
- NOESY of **7** (S11)
- ^{1}H NMR of **8c** (S12)
- ^{13}C NMR of **8c** (S13)
- DEPT NMR of **8c** (S14)
- COSY of **8c** (S15)
- ^{1}H NMR of **8d** (S16)
- ^{13}C NMR of **8d** (S17)
- DEPT NMR of **8d** (S18)
- ^{1}H NMR of **8f** (S19)
- ^{13}C NMR of **8f** (S20)
- DEPT NMR of **8f** (S21)
- ^{1}H NMR of **8g** (S22)
- ^{13}C NMR of **8g** (S23)
- DEPT NMR of **8g** (S24)
- ^{1}H NMR of **8h** (S25)
- ^{13}C NMR of **8h** (S26)
- DEPT NMR of **8h** (S27)



- ^{1}H NMR of **8i** (S28)
- ^{13}C NMR of **8i** (S29)
- DEPT NMR of **8i** (S30)
- ^{1}H NMR of **9a** (S31)
- ^{13}C NMR of **9a** (S31)
- DEPT NMR of **9a** (S33)
- ^{31}P NMR of **9a** (S34)
- ^{1}H NMR of **9b** (S35)
- ^{13}C NMR of **9b** (S36)
- DEPT NMR of **9b** (S37)
- ^{31}P NMR of **9b** (S38)
- COSY of **9b** (S39)
- HSQC of **9b** (S40)
- HMBC of **9b** (S41)
- ^{1}H NMR of **9c** (S42)
- ^{13}C NMR of **9c** (S43)
- DEPT NMR of **9c** (S44)
- ^{31}P NMR of **9c** (S45)
- COSY of **9c** (S46)
- HSQC of **9c** (S47)
- HMBC of **9c** (S48)
- ^{1}H NMR of **9d** (S49)
- ^{13}C NMR of **9d** (S50)
- DEPT NMR of **9d** (S51)
- ^{31}P NMR of **9d** (S52)
- COSY of **9d** (S53)
- HSQC of **9d** (S54)
- HMBC of **9d** (S55)
- ^{1}H NMR of **9e** (S56)
- ^{13}C NMR of **9e** (S57)
- DEPT NMR of **9e** (S58)
- ^{31}P NMR of **9e** (S59)
- COSY of **9e** (S60)
- HSQC of **9e** (S61)
- HMBC of **9e** (S62)
- ^{1}H NMR of **9f** (S63)
- ^{13}C NMR of **9f** (S64)
- DEPT NMR of **9f** (S65)

Scavenger Receptors Mediate Cellular Uptake of Polyvalent Oligonucleotide-Functionalized Gold Nanoparticles

Pinal C. Patel,[†,§] David A. Giljohann,[†,§] Weston L. Daniel,[‡,§] Dan Zheng,[†,§] Andrew E. Prigodich,[†,§] and Chad A. Mirkin*[,‡,§]

Mammalian cells have been shown to internalize oligonucleotide-functionalized gold nanoparticles (DNA-Au NPs or siRNA-Au NPs) without the aid of auxiliary transfection agents and use them to initiate an antisense or RNAi response. Previous studies have shown that the dense monolayer of oligonucleotides on the nanoparticle leads to the adsorption of serum proteins and facilitates cellular uptake. Here, we show that serum proteins generally act to inhibit cellular uptake of DNA-Au NPs. We identify the pathway for DNA-Au NP entry in HeLa cells. Biochemical analyses indicate that DNA-Au NPs are taken up by a process involving receptor-mediated endocytosis. Evidence shows that DNA-Au NP entry is primarily mediated by scavenger receptors, a class of pattern-recognition receptors. This uptake mechanism appears to be conserved across species, as blocking the same receptors in mouse cells also disrupted DNA-Au NP entry. Polyvalent nanoparticles functionalized with siRNA are shown to enter through the same pathway. Thus, scavenger receptors are required for cellular uptake of polyvalent oligonucleotide functionalized nanoparticles.

INTRODUCTION

Polyvalent DNA-functionalized gold nanoparticles (DNA-Au NP) are structures with a gold nanoparticle core and a high surface density of DNA ligands (*1*). As a result of this dense functionalization, these hybrid nanostructures have demonstrated applications in programmable materials crystallization (*2, 3*) and nonenzymatic biodiagnostic assays (*4*). Furthermore, the tailorable recognition properties of DNA and the catalytic and plasmonic properties of Au NPs have been used synergistically in a variety of highly sensitive and selective nucleic acid, small molecule, metal ion, and cancer cell detection strategies (*5*−*11*).

Recently, it was reported that DNA-Au NPs enter a wide variety of cell types (over 50 cell types examined to date) surprisingly readily without the aid of transfection agents (*12, 13*). These structures have properties that make them particularly attractive as intracellular gene regulation agents. They resist nuclease degradation (*12, 14*), exhibit enhanced target binding (*15*), show minimal interferon β response (*16*), and enter cells rapidly and efficiently (*17*). Consequently, they have been used for antisense (*12, 18*) and siRNA (*19*−*21*) based post-transcriptional gene regulation, intracellular detection of biologically relevant molecules (*22, 23*), and intracellular delivery of MRI contrast agents (*24*), as well as chemotherapeutic agents (*25*). Given the fundamental ability of these nanomaterials to readily enter cultured cells, the mechanism of cellular uptake is of significant interest. It has shown that subtle changes in surface functionalities can lead to drastic changes in cellular internalization ability of nanoparticles (*26, 27*). We have shown that the densely functionalized shell of polyanionic DNA (19 pmol/cm^2 for 13 nm gold particle) is a primary contributor to the cellular uptake of DNA-Au NPs (*17*), despite the conventional wisdom that negatively charged materials will not enter cells efficiently.

When material surfaces are exposed to biological environments, they are often modified by the adsorption of biomolecules, such as proteins (*28*). It has been shown that adsorption of proteins to a surface causes conformational changes in the proteins. These changes may expose hidden epitopes that cause unpredictable behavior and result in unusual properties (*29*). Protein adsorption on a nanoparticle surface has been implicated in facilitating uptake of various nanomaterials, including single-walled nanotubes, nanosized amorphous silica, and citrate capped gold nanoparticles (*30*−*32*). Indeed, we have previously shown that serum proteins are adsorbed to the dense monolayer of DNA on the Au NP surface, and that increasing the density of DNA on the Au NP surface increased the number of proteins adsorbed to DNA-Au NPs (*17*), as well as intracellular concentration of DNA-Au NPs.

In this paper, we explore the role of certain adsorbed serum proteins (BSA and transferrin) in the cellular internalization of the highly negatively charged DNA-Au NPs. We show that the adsorbed serum proteins reduce the cellular uptake of DNA-Au NPs, and that DNA-Au NP uptake is highest in serum-free conditions. Furthermore, using pharmacological methods, we identify scavenger receptors as the membrane proteins primarily responsible for facilitating the cellular uptake of DNA-Au NPs. We show that other oligonucleotide-functionalized nanoparticles, such as siRNA-Au NPs, also follow the same pathway of internalization. For DNA-Au NPs, the density of DNA on nanoparticles determines the extent of their cellular uptake. This entry pathway is conserved in mouse cells and may be a general mechanism of cellular entry of nanomaterials displaying dense monolayers of oligonucleotides.

EXPERIMENTAL PROCEDURES

Synthesis of Gold Nanoparticles, DNA, and RNA. Citrate-stabilized gold nanoparticles (13 ± 1 nm diameter) were prepared as described previously (*33*). DNA oligonucleotides were synthesized on an Expedite 8909 Nucleotide Synthesis

System (ABI) using standard solid-phase phosphoramidite synthesis techniques. RNA oligonucleotides were synthesized using TOM-RNA reagents (Glen Research) on a MerMade 6 system (Bioautomation) using manufacturer-recommended cleavage and deprotection stategy. All oligonucleotides were purified using reverse-phase high-performance liquid chromatography (RP-HPLC) on a Varian Microsorb C_{18} column (10 μm, 300 $\times$ 10 mm) with 0.03 M triethylammonium acetate (TEAA), pH 7, and a 1%/min gradient of 95% CH_3CN/5% 0.03 M TEAA at a flow rate of 3 mL/min, while monitoring the UV signal of the nucleic acids at 254 nm. After purification, the oligonucleotides were lyophilized and stored at −80 °C until use. The following oligonucleotide sequences were synthesized: RNA sequences: 5′-ACC CUG AAG UUC AUC UGC ACC ACC G-(hexa(ethylene glycol))$_2$-propylthiol-3′,5′-CGG UGG UGC AGA UGA ACU UCA GGG UCA-3′. DNA sequences: 5′-AGT AGA GGC AGG GAT GAT G AAA AAA AAA A-propylthiol-3′,5′-Fluorescein-AGT AGA GGC AGG GAT GAT G AAA AAA AAA A-propylthiol-3′,5′-TTT TGG GGT TTT GGG GTT TTG GGG TTT TGG GG-propylthiol-3′,5′-TTT TGG GGT TTT GGG GTT TTG GGG TTT TGG GG-3′,5′ (DTPA) AAA AAA AAA AGT AGT AGG GAC GGA GAT GA 3′ and 5′ (Tosyl-T)-AAA AAA AAA A (S−S) TCA TCT CCG TCC CTA CTA CG 3′. Tosyl-modified thymidine phosphoramidite was synthesized as described previously (*34*) and added to the oligonucleotide manually as described previously (*35*). DNA or RNA functionalized gold nanoparticles were prepared following published methods (*12*, *19*). Mixed monolayer nanoparticles with variable DNA density were prepared following a published protocol (*17*) but with following modified oligonucleotide as diluent strand: 5′ (Propyl Spacer)$_{19}$-AAA AAA AAA A-propylthiol-3′. DNA loading onto mixed monolayer nanoparticles was determined using a fluorescein-modified DNA strand.

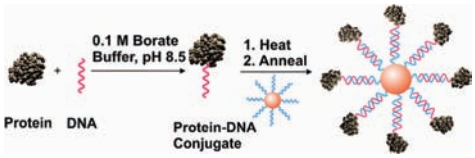
Preparation of Protein−DNA Conjugates. All proteins used in this study were purchased from Sigma Aldrich and/or Fisher Scientific. The protein was mixed with the tosyl-modified oligonucleotide at a 3-fold molar excess in 0.1 M borate buffer, pH 8.5. The mixture was shaken at room temperature overnight. Unreacted oligonucleotides were separated from protein−DNA conjugates using 30 000 MWCO spin columns (Chemicon).

Preparation of Gold Nanoparticle Conjugates with Variable Protein Loading. Oligonucleotide-modified gold nanoparticle conjugates were made as described previously (*1*). DNA-Au NPs were loaded with various amounts of proteins by mixing with variable volumes of protein−DNA conjugates in phosphate buffered saline (PBS) (Hyclone), heating the mixture to 65 °C, and cooling it to room temperature. The conjugates were centrifuged at 4 °C and redispersed in 1× PBS three times to remove excess protein−DNA conjugate. The average number of protein molecules per gold nanoparticle was determined using previously published methods (*17*). Briefly, the protein-loaded Au NPs were dissolved with potassium cyanide (KCN, 2 mM final concentration). The KCN-digested samples were treated with a Quant-iT fluorescent reagent (Invitrogen) as described by the manufacturer. The resulting fluorescence was measured at room temperature using a fluorescence microplate reader (Fluo Dia T70, Photal) with excitation at 486 nm and recording emission at 570 nm. Estimation of the number of proteins in solution was calculated by comparing the fluorescence values of these unknowns to those obtained from a standard curve of known protein concentrations under the same assay conditions. Finally, the average number of proteins per nanoparticle was calculated by dividing this number by the initial nanoparticle concentration prior to KCN digestion.

Cell Culture. The uptake of gold nanoparticles (DNA-Au NPs or siRNA-Au NPs) was studied using a model cell line. HeLa (human cervical carcinoma) cells were obtained from American Type Culture Collection (ATCC) and maintained in minimum essential medium (EMEM) supplemented with 10% heat-inactivated FBS and 1% penicillin/streptomycin at 5% CO_2 and 37 °C. In the serum-free conditions, FBS was omitted from the EMEM formulation. HeLa cells were acclimated to serum-free culture by slowly reducing serum concentration from 10% to 0%. Mouse C166 cells (ATCC) were cultured in DMEM with 10% FBS at 5% CO_2 and 37 °C.

Serum Preincubation of DNA-Au NPs. DNA-Au NPs were prepared as described above. The nanoparticle conjugates were added to MEM buffer containing 10% FBS and incubated at 37 °C for at least 12 h. Following the incubation, excess serum was removed by three centrifugation, supernatant removal, and redispersion steps. The nanoparticle conjugates were added to HeLa cells in serum-containing and serum-free MEM to measure cellular uptake.

Cellular Uptake Studies and Nanoparticle Calculations. Hela cells were added to 96-well plates (25 000 cells/well) 24 h prior to nanoparticle addition. Filter sterilized nanoparticle conjugates were added directly to the cell culture media of adherent cells in 5 and 10 nM concentrations. 48 hours after nanoparticle addition, the cells were washed twice with PBS, collected, counted, and their viability measured using the Guava Viacount reagent on an EasyCyte flow cytometer (Millipore). The gold content of the cell digest was determined by inductively coupled plasma mass spectrometry (ICP-MS) (Thermo-Fisher). To prepare samples for ICP-MS, the cells were dissolved with nitric acid at 60 °C overnight, diluted in a matrix consisting of 2% HNO_3, 2% HCl, and 1 ppb indium (internal standard). The number of nanoparticles in each sample was calculated based on the concentration of Au found in the sample.



Treatments with Chemical Inhibitors. All chemicals were purchased from Sigma-Aldrich. HeLa cells were treated with different concentrations of methyl-β-cyclodextrin (MβCD), cytochalasin D (CytoD), or bafilomycin A (Baf A) for 60 min. DNA-Au NPs were then added in the presence of these chemicals. Controls include incubations of DNA-Au NPs in the presence of the solvent dimethylsulfoxide (DMSO) and in the absence of any chemicals. To probe the role of scavenger receptors, cells were similarly incubated in the presence of known ligands of scavenger receptors, polyinosinic acid (Poly I) and Fucoidan. Compounds that are not known to inhibit scavenger receptors, polyadenosinic acid (Poly A), galactose, lipopolysacchride (LPS), and untreated cells were used as controls. 24 hours after the addition of nanoparticles, cells were washed with phosphate buffered saline, trypsinized, counted using Viacount (Millipore) reagent, and prepared for ICP-MS.

Knockdown of Scavenger Receptors. HeLa cells were plated in 48-well plates at 50 000 cells/well. The cells were transfected with commercially bought siRNA (100 nM, 50 nM, and 25 nM) against scavenger receptors A and scavenger receptors B1 (Santa Cruz) with Dharmafect (Dharmacon) following the manufacturer's protocol. After 48 h, the media was replaced with DNA-Au NP containing media (10 nM) for 24 h. An equal volume of lipofectamine was used as delivery agent control. The cells were prepared for ICP-MS to determine the cellular gold content as described above.

RESULTS AND DISCUSSION

Serum Proteins Reduce Cellular Uptake of DNA-Au NPs. Previous work has shown that the cellular uptake of DNA-Au NPs correlates positively with the density of oligonucleotides on the nanoparticles and that, when DNA-Au NPs are added to serum containing media, they are coated with serum proteins (*17*). We hypothesized that, if adsorption of serum protein promotes cellular uptake, then covalent attachment of serum

Scheme 1. Stable Loading of Proteins on DNA Functionalized Gold Nanoparticles[a]

[a] The proteins are covalently attached to tosyl-modified oligonucleotides, which are then hybridized to nanoparticles functionalized with a complementary sequence. The variable loading of proteins is achieved by using different ratios of protein−DNA conjugate to DNA-Au NPs.

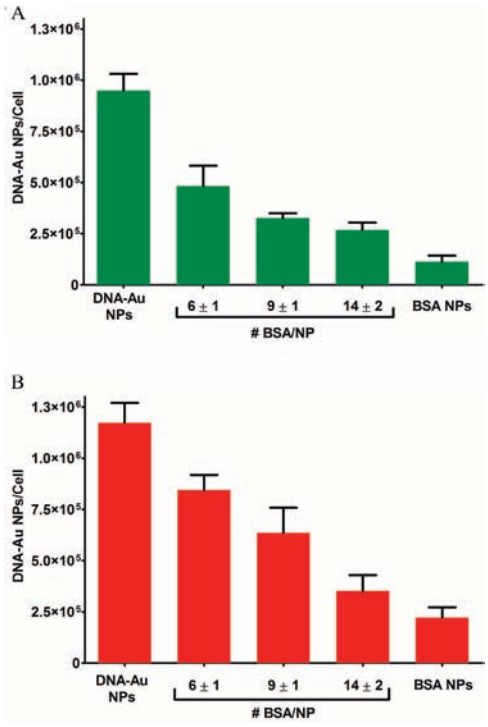


Figure 1. Cellular internalization of DNA-Au NPs when coated with increasing amounts of BSA. The method for loading a variable number of proteins on DNA-Au NPs is shown in Scheme 1. Cells were grown in media containing 10% FBS with 5 nM (A) and 10 nM (B) of DNA-Au NPs.

proteins may increase uptake even further. To test this hypothesis, we attached bovine serum albumin (BSA) and transferrin, two highly abundant serum proteins, through DNA hybridization on DNA-Au NPs. BSA is also the most abundant protein in serum and is known to coat polymer nanoparticles in complex media (*36*). Protein−DNA conjugates were made by covalently linking a tosyl-terminated oligonucleotide to amine groups on BSA or transferrin. These conjugates were then mixed at different ratios with DNA-Au NPs functionalized with the complementary oligonucleotide sequence to load variable numbers of proteins around the nanoparticles (Scheme 1). These nanoconjugates loaded with the same number of oligonucleotides but different numbers of proteins were then added to HeLa cells, and their cellular internalization was measured by ICP-MS (see Experimental Procedures).

The results show that, as BSA loading onto DNA-Au NPs increases, the number of nanoparticles taken up by cells decreases (Figure 1 and Supporting Information). For example, as the number of BSA molecules per DNA-Au NP increased from 0 to 14 ± 2, the number of DNA-Au NPs internalized by cells in serum-containing conditions decreased by up to 80%, from $1.0 \times 10^6 \pm 0.1 \times 10^6$ to $2.5 \times 10^5 \pm 0.7 \times 10^5$ Au NPs per cell. A 70% decrease was observed when transferrin was used to coat DNA-Au NPs instead of BSA (Supporting Information, Figure 1). These results suggest that the most abundant components of serum reduce uptake when they are bound strongly to DNA-Au NPs. These results are surprising, since previously we observed that the high density of DNA on nanoparticles resulted in increased adsorption of proteins, as well as cellular uptake, and when DNA density was reduced with oligo(ethylene glycol) (OEG) passivation, protein adsorption and cellular uptake were reduced (*17*). One explanation of this apparent discrepancy is that the dense monolayer of DNA on nanoparticles may generally promote both cellular uptake and protein adsorption. However, adsorbed serum proteins do not necessarily promote cellular uptake and may be displaced by some cellular proteins that affect nanoparticle uptake. When nanoparticles are functionalized with lower density of DNA, their binding to all proteins is reduced, as is their cellular uptake. In this experiment, since serum proteins are strongly bound to nanoparticles, they cannot be easily displaced by cellular proteins that affect nanoparticle uptake. Furthermore, preincubation of DNA-Au NPs in serum and subsequent addition to cell culture also reduced cellular uptake by a similar amount (Supporting Information, Figure 2a). Thus, it is unlikely that the binding of other less abundant serum proteins promotes cellular uptake of nanoparticles. Overall, these results suggest that serum protein generally reduce cellular uptake of DNA-Au NPs and point to other factors as positive regulators of cellular entry.

DNA-Au NP Uptake Is Highest in Serum-Free Culture. To confirm that serum proteins generally reduce nanoparticle uptake, we performed previously described experiments in serum-free media and compared the results to the results from normal serum-containing cultures. In all cases, the number of DNA-Au NPs internalized by cells in serum-free conditions was significantly higher than in serum-containing conditions. For example, at a 5 nM DNA-Au NP solution concentration, $2.5 \times 10^6 \pm 0.02 \times 10^6$ DNA-Au NPs/cell were internalized in serum-free conditions, while $1.0 \times 10^6 \pm 0.1 \times 10^6$ DNA-Au NPs/cell were internalized when the media contained 10% serum, a 150% increase (Supporting Information, Figure 2b). Furthermore, this increase was observed for DNA-Au NPs that were preincubated with serum or DNA-Au NPs loaded with covalently immobilized BSA (Figure 2) or transferrin (Supporting Information, Figure 3).

While the number of DNA-Au NPs internalized is still high in serum-containing media, a 150% or higher uptake is observed in serum-free cultures for all of the particles tested, with the exception of fully BSA- or transferrin-coated nanoparticles that contained no oligonucleotides, which did not exhibit such an increase. These results are consistent with the conclusion that serum proteins are responsible for decreasing the uptake of DNA-Au NPs. Since it was shown previously that serum proteins adsorb to DNA-Au NPs (*17*), it is likely that the adsorbed proteins compete with the binding interactions required for nanoparticles to be internalized by cells. These binding interactions between oligonucleotides on the DNA-Au NPs and cellular proteins may promote internalization through receptor-mediated endocytosis.

Pharmacological Inhibitors of DNA-Au NP Uptake Machinery. DNA-Au NP entry was explored using a pharmacological approach that tested the effect of inhibitors of cellular uptake mechanisms on nanoparticle uptake. Bafilomycin A (Baf A) can inhibit the acidification of endosomes, thus preventing their maturation and fusion into lysosomes (*33*). Baf A treatment did not inhibit nanoparticle uptake (Figure 3C). Therefore, the endosomal−lysosomal acidification process is not critical for nanoparticle entry in HeLa cells. Similarly, methyl-β-cyclodextrin (MβCD) and cytochalasin-D, inhibitors of caveolae-

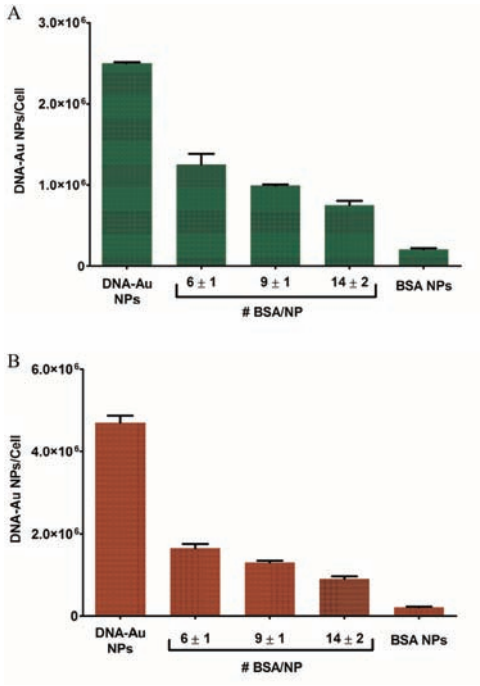

Figure 2. (A) Cellular uptake of DNA-Au NPs loaded with varying numbers of BSA molecules at 5 nM (A) and 10 nM (B) solution concentrations of DNA-Au NPs in serum-free conditions. Serum-free conditions yield a significantly higher number of nanoparticles per cell (150% increase) compared with normal 10% serum cultures (shown in Figure 1).

mediated endocytosis and phagocytosis, respectively, largely did not affect nanoparticle entry into cells (Figure 3D; Supporting Information Figure 4A). Cytochalasins cause the depolymerization of the actin cytoskeleton and inhibit uptake through the caveolae and macropinocytosis without affecting clathrin-mediated endocytosis, whereas MβCD inhibits phagocytosis by the disruption of lipid rafts (*32*). These experiments suggest that the broader classes of endocytotic process such as caveolae-mediated endocytosis, macropinocytosis, or phagocytosis are not the primary modes of entry of DNA-Au NPs into HeLa cells.

DNA-Au NP Uptake is Blocked by Agonists of Pattern-Recognition Receptors. The role of pattern-recognition receptors in DNA-Au NP uptake was evaluated using a chemical approach. Scavenger receptors are a group of structurally unrelated molecules known to mediate the endocytosis of certain polyanionic ligands, including nucleic acids (*37*), and are implicated in uptake of phosphorothioate-modified oligonucleotides in animals (*38*). We examined whether molecules known to interact with scavenger receptors competed for binding of the DNA-Au NPs, and thus inhibited cellular uptake. Poly I and fucoidan, well-known ligands of the scavenger-receptor family, inhibited nanoparticle uptake by >60% as measured by ICP-MS (Figure 3A,B). In contrast, chemically related molecules that interact with other receptors, but do not inhibit scavenger receptors (such as lipopolysacchrides (LPS), polyadenylic acid (poly A), ssDNA, or the monosaccharide galactose), did not affect DNA-Au NP uptake (Supporting Information, Figure 4). There was a slight decrease in viability of cells when treated with the highest concentrations of poly I and fucoidan. However, this decrease in viability was not correlated with decrease in cellular uptake as treatments with related chemicals that cause similar drop in viability, poly A and lipopolysaccharides, did not lead to a decrease in uptake (Supporting Information, Table 1). Thus, the decrease in cellular uptake of nanoparticles is most likely caused by binding of poly I and fucoidan to scavenger receptors, which prevents DNA-Au NPs from binding to the same receptors. We also measured the stability of DNA-Au NPs in poly I and fucoidan solutions to rule out any possibility of drop in stability of nanoparticles causing the decrease in uptake (Supporting Information, Figure 9).

While RNAi down-regulation of class A (SR-A) or class B (SR-B1) scavenger receptors (Supporting Information, Figure 10) did not result in inhibition of nanoparticle uptake (Supporting Information, Figure 5), the inhibition observed by the pharmacological treatments suggests that multiple types of scavenger receptors with overlapping functions participate in DNA-Au NP uptake. To explore this possibility, mixed siRNAs targeting

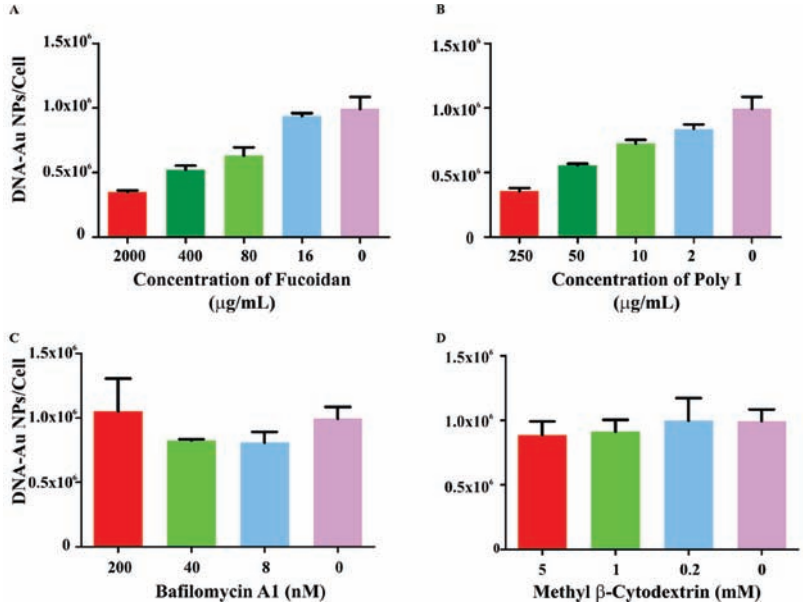

Figure 3. Endocytotic uptake of DNA-Au NPs in HeLa cells is mediated by scavenger receptors. Treatment with agonists of scavenger receptors, fucoidan (A) and polyinosinic acid (poly I, B), prior to nanoparticle addition results in up to 60% inhibition of the cellular uptake of DNA-Au NPs. Pharmacological agents that inhibit other modes of cellular entry, such as bafilomycin A1 and methyl β-cytodextrin, did not inhibit nanoparticle uptake (C, D, Supporting Information, Figure 4).

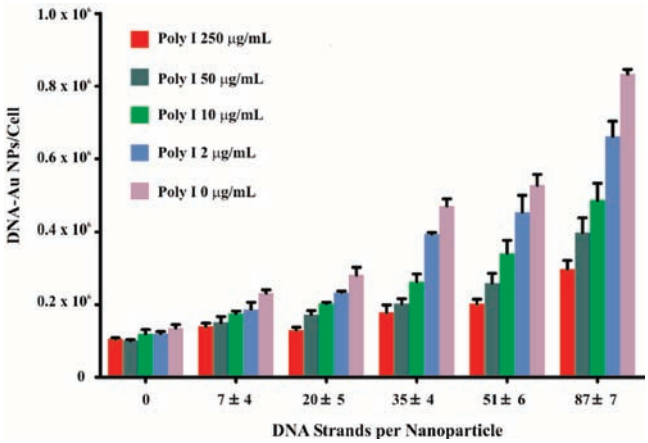

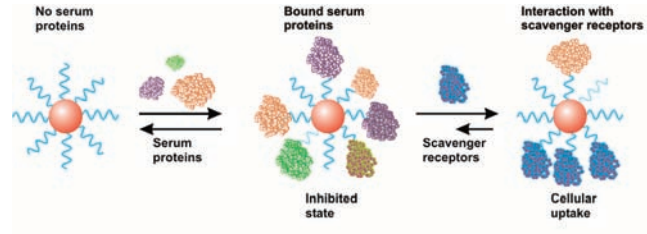

Figure 4. Polyinosinic acid dependent inhibition of DNA-Au NPs is dependent on the density of DNA on nanoparticles. When the cellular uptake of DNA-Au NPs is lowered with decreasing DNA density, the ability of Poly I to inhibit cellular internalization of DNA-Au NPs is lowered as well.

SR-A and SR-B1 were transfected into HeLa cells. This mixture did not result in a significant reduction in nanoparticle uptake. Recent reports have shown that long dsRNA is internalized by scavenger receptor-mediated endocytosis in S2 cells (*39*, *40*). However, these reports were also unable to show that down-regulation of individual scavenger receptors significantly reduced dsRNA uptake or resultant RNAi. It is possible that simultaneously targeting the two classes of receptors by RNAi is not effective enough to impair the DNA-Au NP binding to the remaining receptors. It is also possible that unidentified members of this family of transporter proteins are responsible for this uptake function.

DNA Density on Nanoparticles Determines the Extent of Inhibition. We next sought to understand the molecular basis of binding of DNA-Au NPs to scavenger receptors. It has been shown that poly I forms complex quadraplex-like structures at physiologic temperatures and that the binding of polynucleotides to scavenger receptors depends on the formation of stable four-stranded structures (*41*, *42*). Thus, it is likely that other polynucleotide sequences predicted to fold into a structure that can bind scavenger receptors would lower cellular uptake of nanoparticles. Indeed, treatment with telomere-like DNA sequences (which are predicted to fold into quadraplex-like structures) prior to addition of DNA-Au NPs reduced cellular uptake of nanoparticles (Supporting Information, Figure 6). Higher concentrations of this synthetic ligand were necessary to inhibit nanoparticle entry, which is likely due to the weaker binding of the synthetic DNA strand to scavenger receptors compared to Poly I or fucoidan.

Thus, we hypothesized that the dense monolayer of DNA on the nanoparticle surface mimics the complex structure that Poly I forms in order to bind to scavenger receptors. Indeed, reducing the density of DNA on nanoparticles decreased the Poly I dependent inhibition of nanoparticle uptake (Figure 4). However, since we also reduced the ability of nanoparticles to bind scavenger receptors, the total nanoparticles internalized by the cell decreased as well. Interestingly, the extent of inhibition was greater for nanoparticles with higher surface density of DNA. For nanoparticles with 87 ± 7 DNA per nanoparticle, the cellular uptake decreased 64% (from 8.33×10^5 to 2.98×10^5 DNA-Au NPs per cell) as Poly I concentration increased from 0 to 250 μg/mL. By contrast, for the nanoparticles with 7 ± 4 DNA per nanoparticle, the cellular uptake decreased 38% (from 2.32×10^5 to 1.42×10^5 DNA-Au NPs per cell) with the same Poly I treatment. This difference suggests that the nanoparticles with higher density of oligonucleotides are more dependent on scavenger receptors and thus show more inhibition over the range of concentrations of Poly I that competes for binding to the same receptors.

Scheme 2. Proposed Mechanism of Cellular uptake of DNA-Au NPs[a]

[a] In serum-containing media, DNA-Au NPs are coated with proteins which reduce nanoparticle interactions with scavenger receptors. Cellular uptake is mediated by the displacement of serum proteins by these receptors. In the absence of serum proteins, these interactions are more easily facilitated, resulting in greater uptake as a result of high DNA density. If the binding to scavenger receptors is inhibited by addition of competitive ligands, then the cellular uptake of nanoparticles is also reduced.

These experiments strongly suggest that the dense monolayer of DNA on nanoparticles mimics the complex structures of other polynucleotides, such as Poly I or long dsRNA, and serves as a ligand for scavenger receptors. This hypothesis is further strengthened by experiments showing that the cellular uptake of siRNA-Au NPs is inhibited by fucoidan and Poly I but not by the other pharmacological treatments (Supporting Information, Figure 7). For siRNA-Au NPs, the inhibition was >85% versus that of the untreated samples at highest concentrations of the agonists, suggesting that these nanomaterials depend on scavenger receptor binding for cellular entry. Identical experiments in a mouse cell line also yielded the same results suggesting that the entry pathway in mouse cells is conserved (Supporting Information, Figure 8). Recently, our group has shown that iron oxide nanoparticles also enter cells with high efficiency when functionalized with a dense monolayer of oligonucleotides (*43*). Therefore, it is likely that nanomaterials displaying a dense monolayer of oligonucleotides can engage these receptors and be internalized by mammalian cells using the scavenger receptor pathway.

CONCLUSIONS

We have shown that serum proteins act to reduce the cellular uptake of oligonucleotide-functionalized nanoparticles and that highest nanoparticle uptake is observed in serum-free cultures. Using a pharmacological approach, we demonstrated that scavenger receptors mediate the cellular entry of oligonucleotide-functionalized gold nanoparticles. We have shown that the interaction of DNA-Au NPs and scavenger receptors is dependent on the density of oligonucleotides on nanoparticles. This interaction can be partially blocked by synthetic polynucleotides that mimic the structures of other ligands of scavenger receptors. Thus, our results show that a determining factor for cellular uptake of DNA-Au NPs is the polyvalent interaction of DNA-Au NPs with scavenger receptors on the cell surface (Scheme 2) suggesting a general mechanism by which nanostructures with dense monolayers of oligonucleotides can be internalized by cells.

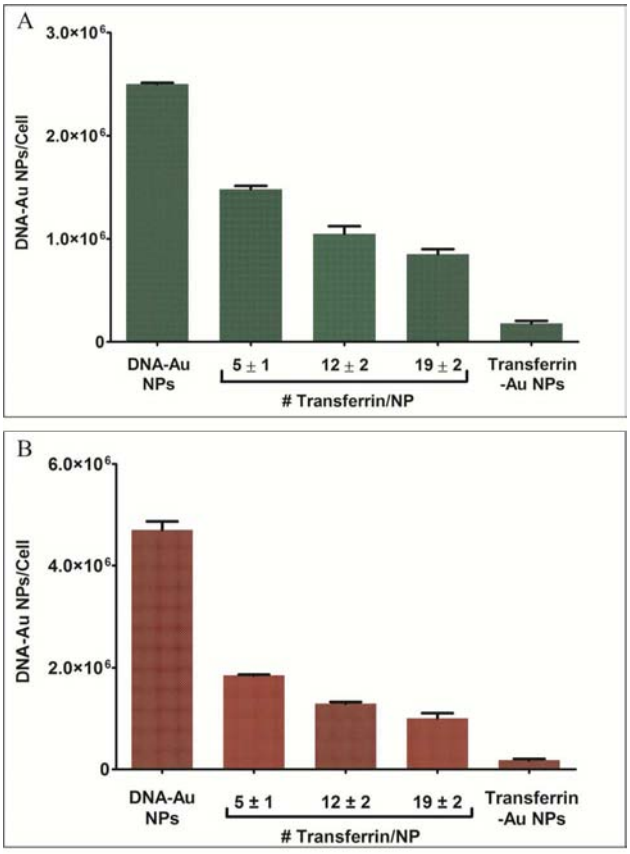
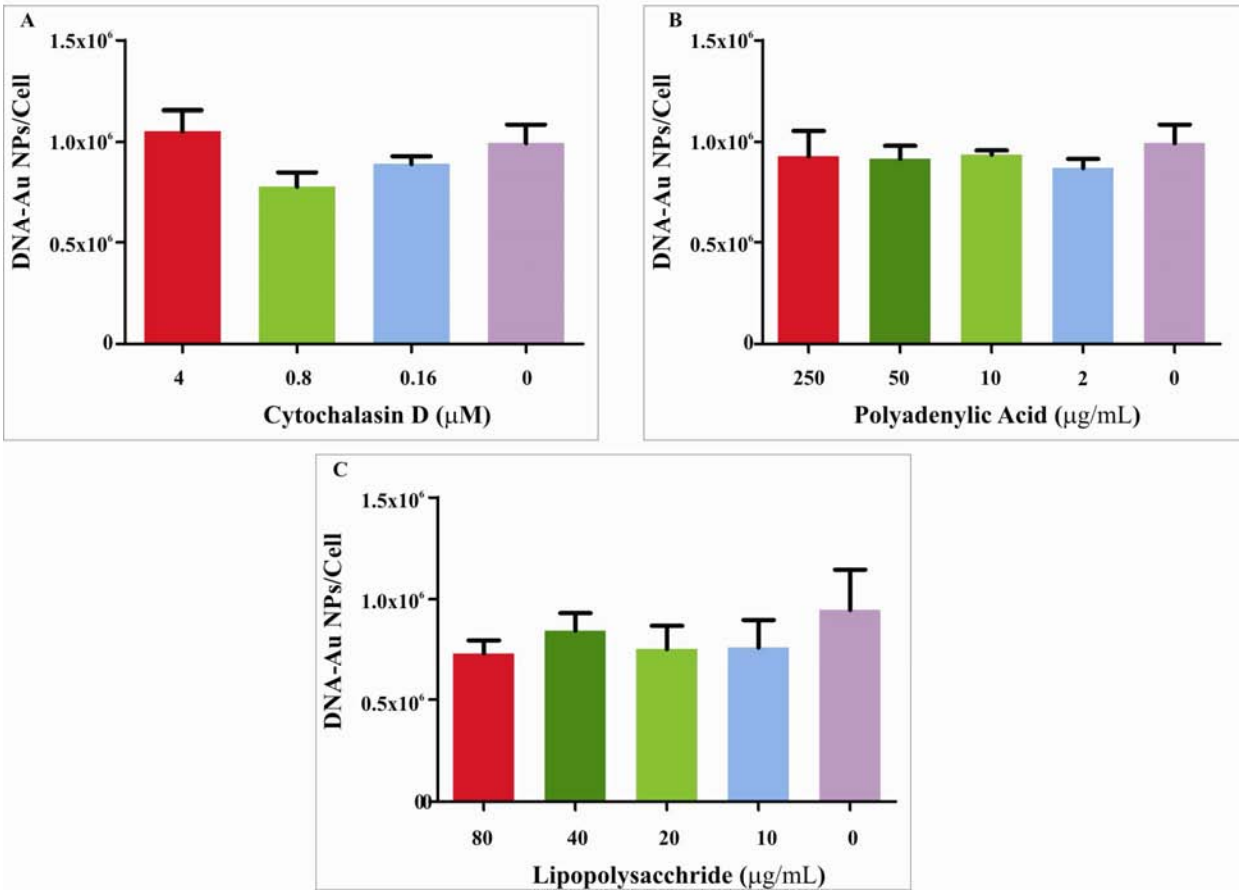
EXPERIMENTAL PROCEDURES

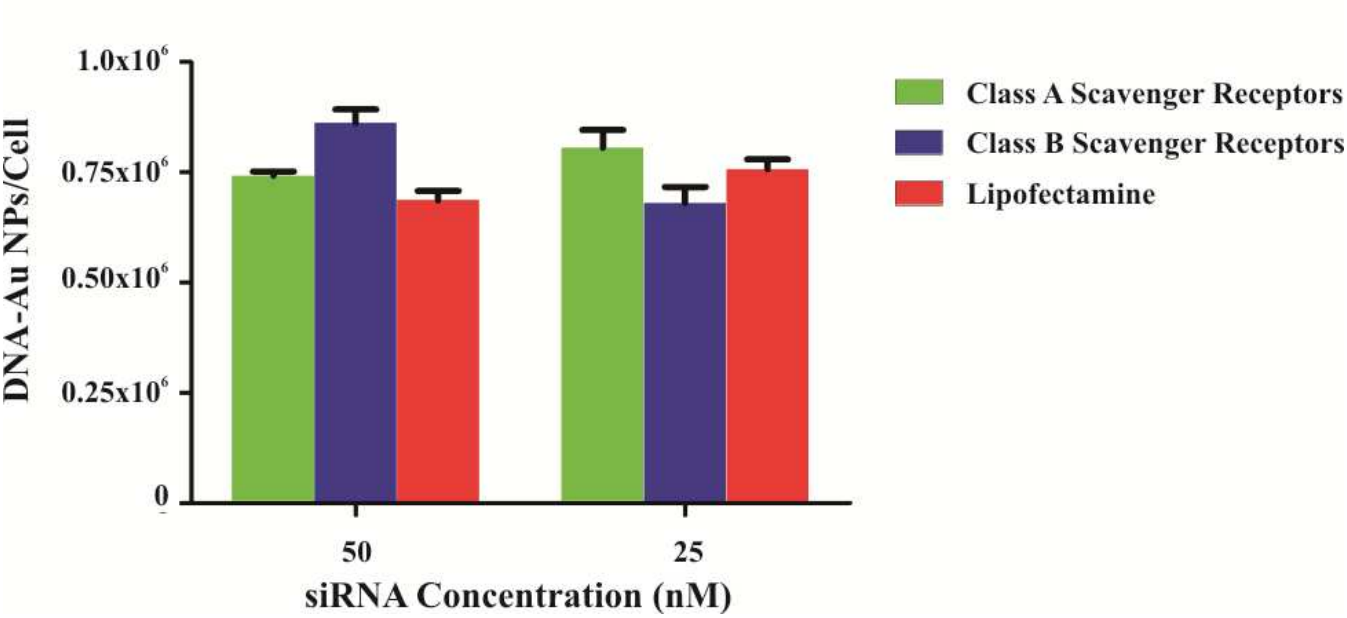
Nanoparticle stability in poly I and fucoidan solutions. DNA and siRNA functionalized gold nanoparticles were prepared as described in experimental procedures. Poly I and fucoidan solutions were prepared in phosphate buffered saline. DNA-Au NPs and siRNA-Au NPs were incubated with poly I and fucoidan at solution concentration of 10nM for 24 hours at 37°C. Nanoparticles without any additional chemicals were used as controls. Following the incubation, the stability of nanoparticles was measured using Cary 5000 UV-VIS-NIR instrument, scanning between 400-700nm wavelengths. The resultant spectra were normalized to the gold SPR peak.



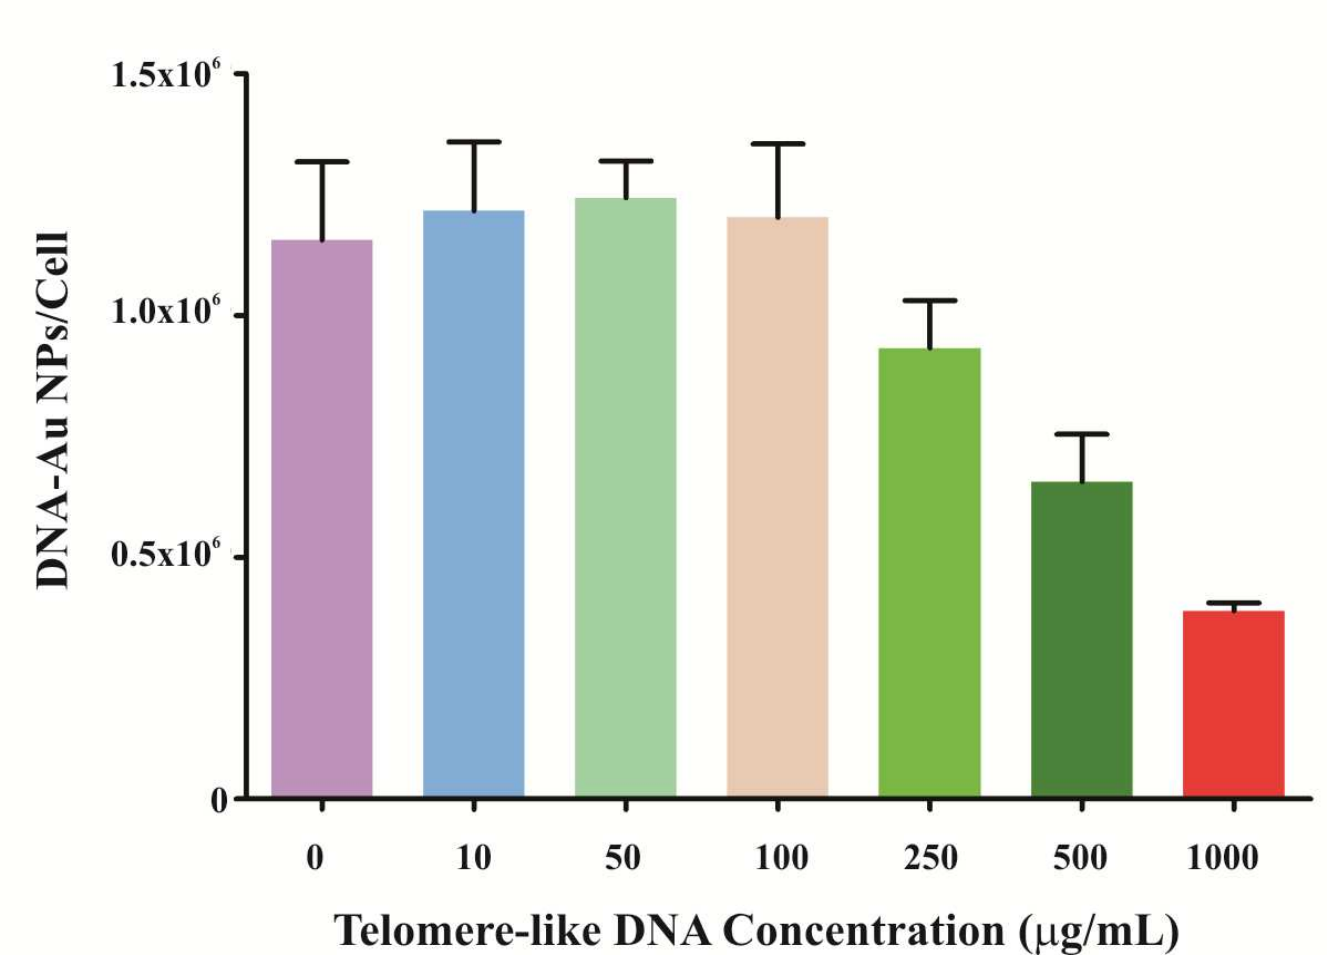
Quantitative real-time polymerase chain reaction. HeLa cells were plated in 48-well plate at density of 25000 cells/well. Following overnight incubation, the cells were treated with 25nM and 50nM of siRNAs targeting scavenger receptors A and B1 (Santa Cruz) using lipofectamine transfection reagent. After 24 hours, the siRNA containing medium was replaced with regular growth medium, EMEM with 10% FBS. The cells were allowed to grow for another 24 hours after which the experiment was terminated. Total RNA was extracted using TRIzol (Invitrogen) following manufacturer's recommended protocol. One μg of this RNA was used for cDNA synthesis using Taqman Gold RT-PCR kit (Applied Biosystems). Real-time PCR was performed on a Roche 480 Lightcycler. Hydrolysis probes (Roche) were used to measure the relative abundance of each target mRNA. These values were normalized to actin expression and compared to cells treated with lipofectamine alone to determine the change in mRNA levels. The primers used in these experiments were, SR-A left, 5' -TTT GAT GCT CGC TCA ATG AC- 3', SR-A right, 5' -TGA AGG GAA GGG CTG TTT TT- 3', SR-B1 left, 5' -CAT CAA GCA GCA GGT CCT TA- 3', SR-B1 right, 5' – CGG AGA GAT AGA AGG GGA TAG G- 3'. Actin primers are probes were purchased as single reagent from Roche.



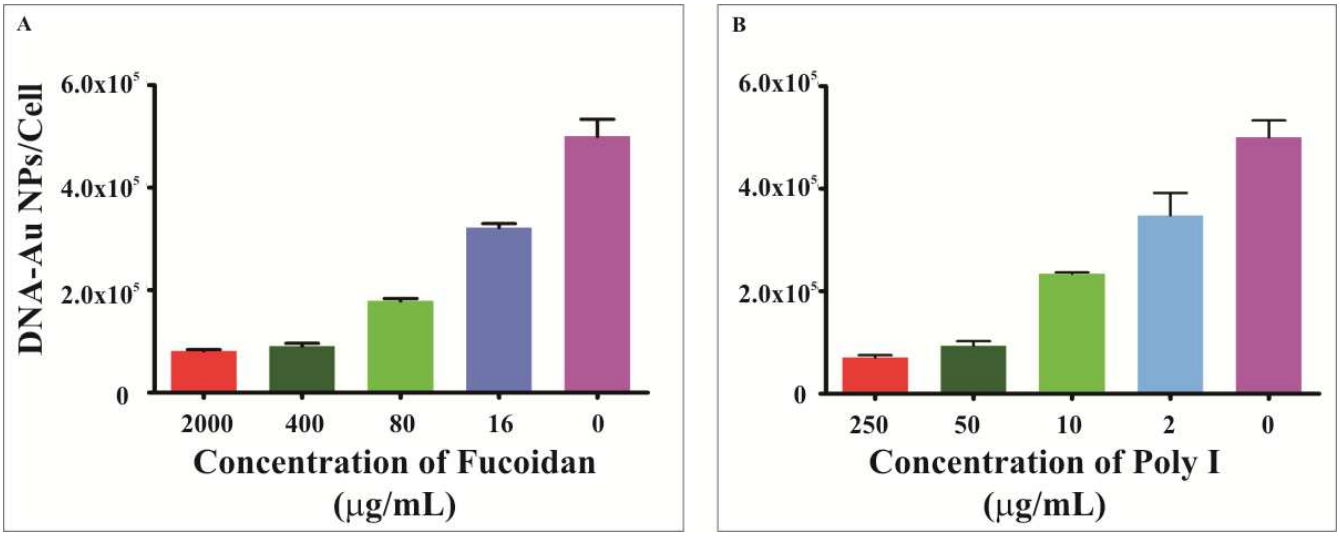
Supporting Figure 1. Cellular uptake of DNA-Au NPs coated with varying numbers of transferrin molecules. The method for loading a variable number of proteins on DNA-Au NPs is shown in Scheme 1. Cells were grown in media containing 10% FBS with 5 nM (green) or 10 nM (red) concentration of nanoparticles.



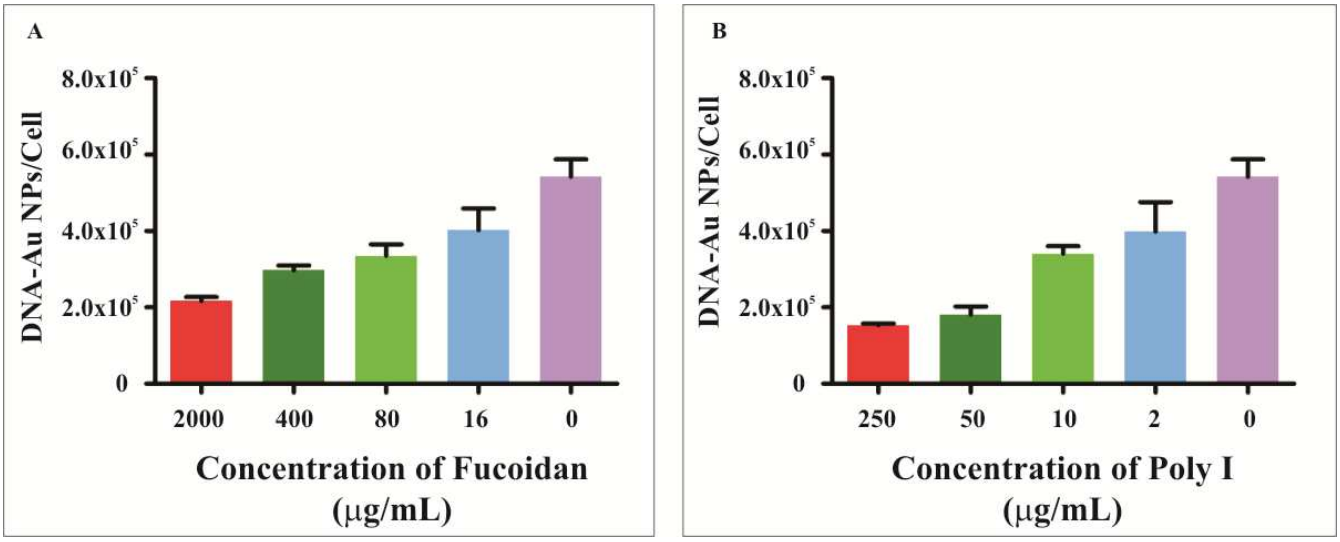
Supporting Figure 2. (A) Cellular uptake of DNA-Au NPs (5nM) with or without serum pre-incubation in normal culturing conditions (EMEM+10% FBS). Pre-incubation of DNA-Au NPs with serum reduces cellular uptake by 76% when compared direct addition without pre-incubation. (B) Comparison of cellular uptake of DNA-Au NPs in serum-free and normal 10% FBS cultures. The serum-free conditions yield 150% higher nanoparticle uptake.



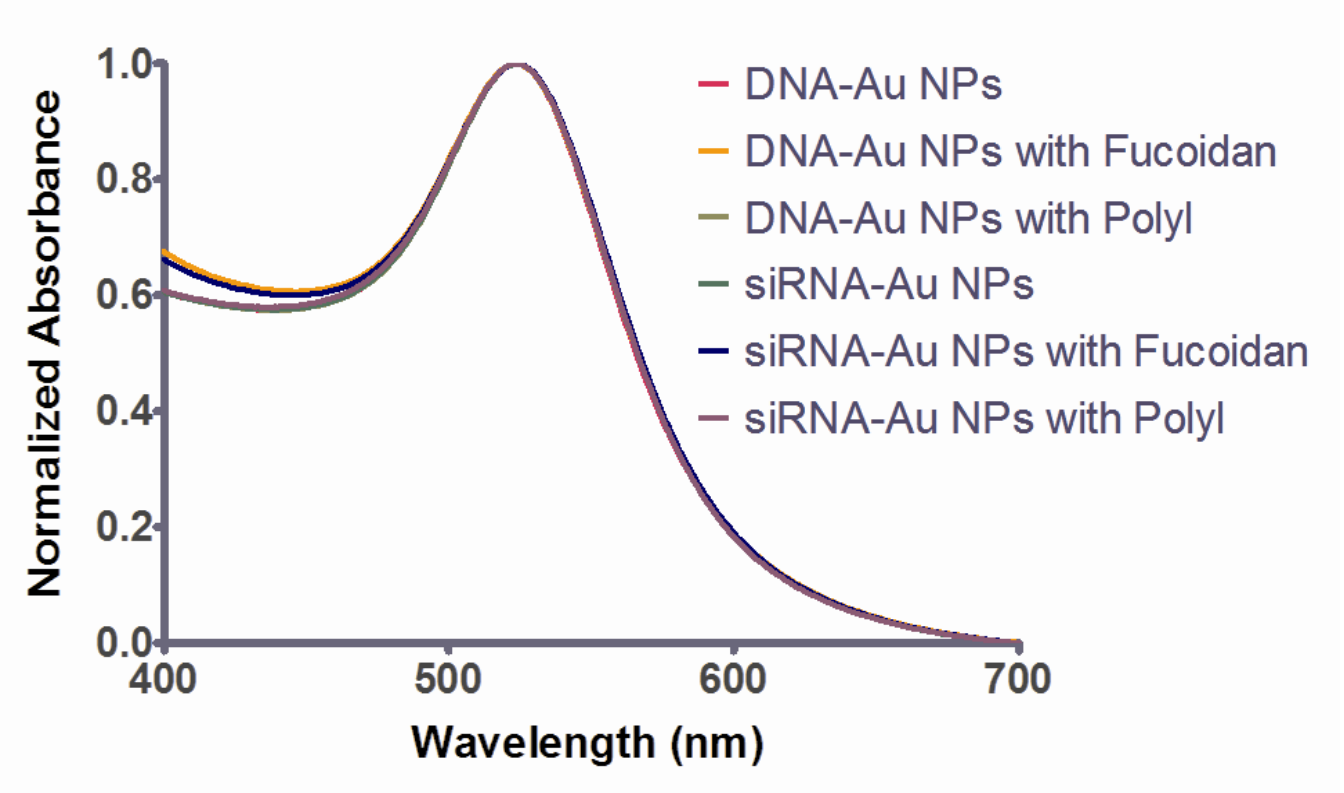
Supporting Figure 3. Cellular uptake of DNA-Au NPs when coated with varying numbers of transferrin molecules. The method for loading variable number of proteins on DNA-Au NPs is shown in Scheme 1. Cells were grown in serum-free conditions with 5 nM (green) or 10 nM (red) concentration of nanoparticles. Nanoparticle uptake is significantly higher than in normal serum culturing conditions (Supp. Figure 1).



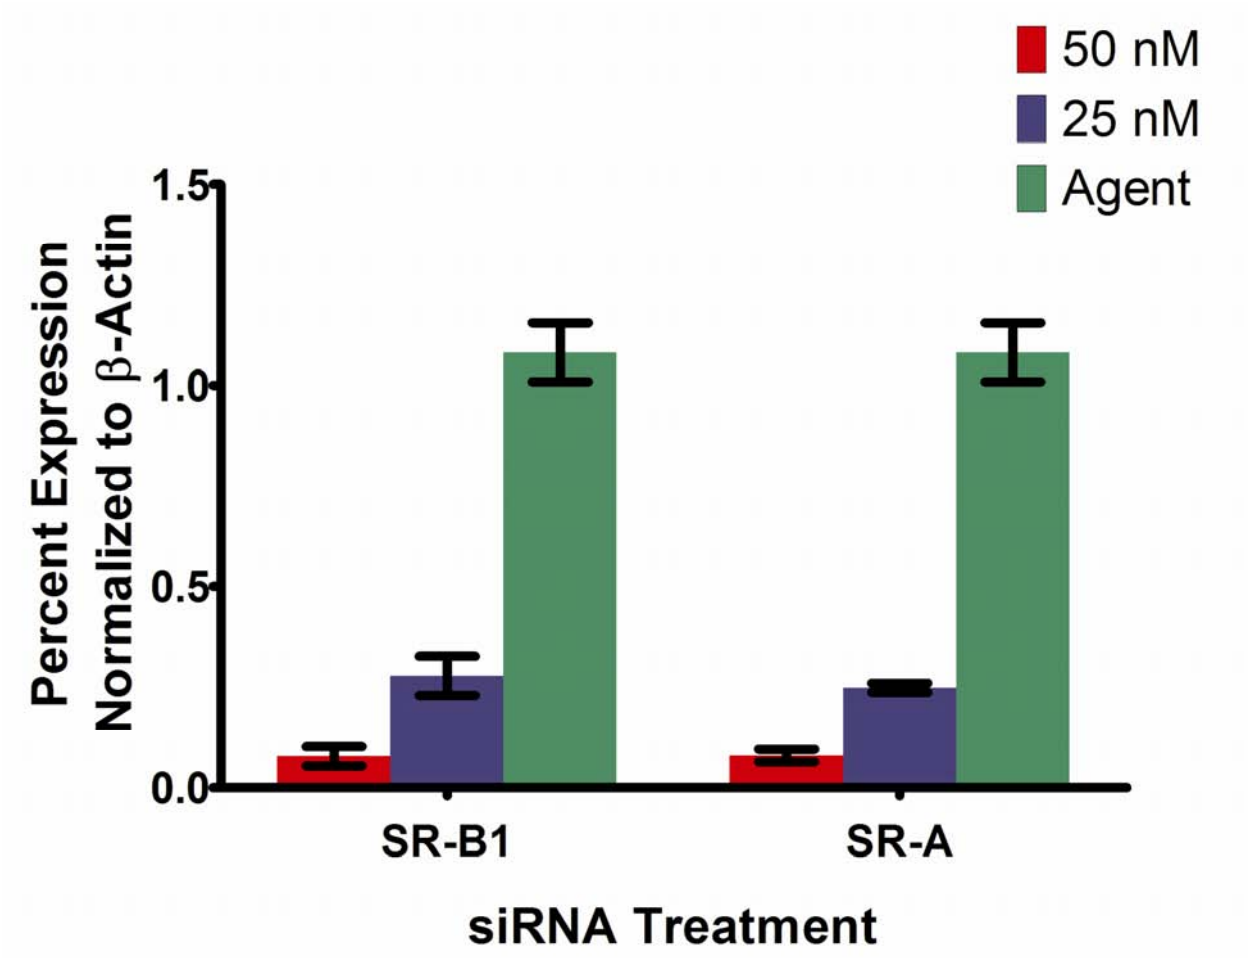
Supporting Figure 4. Cellular uptake of DNA-Au NPs in HeLa cells treated with inhibitors of endocytotic pathways. High cellular uptake in the presence of Cytochalasin D (A) suggests that DNA-Au NPs do not depend on phagocytosis as the primary mode of cellular entry. The cellular entry is inhibited in the presence of agonists of scavenger receptors, such as fucoidan and polyinosinic acid but not in the presence of chemically related molecules that do not bind scavenger receptors, such as polyadenylic acid (B) and lipopolysacchrides (C).



Supporting Figure 5. RNAi mediated knockdown of class A and class B scavenger receptors have no significant effect on cellular entry of DNA-Au NPs. Identical volumes of lipofectamine were used as control for each siRNA concentration. Equal volume of the two siRNA pools had no significant effect on nanoparticle uptake (data not shown).



Supporting Figure 6. Synthetic ligands of scavenger receptors inhibit cellular entry of DNA-Au NPs in HeLa cells. Telomere-like DNA is theorized to form complex quadraplex-like structure that may mimic solution structure of polyinosinic acid. Higher concentration of telomere-like DNA is needed to inhibit nanoparticle entry into HeLa cells.



Supporting Figure 7. Cellular uptake of siRNA-functionalized nanoparticles (siRNA-Au NPs) is strongly inhibited by ligands of scavenger receptors. Both polyinosinic acid and fucoidan reduced siRNA-Au NPs entry into HeLa cells. The extent of inhibition was greater for siRNA-Au NPs than for DNA-Au NPs.

Supporting Figure 8. Cellular uptake of DNA-Au NPs in mouse cells (C166) is inhibited by ligands of scavenger receptors.

Supporting Figure 9. Stability of DNA and siRNA functionalized gold nanoparticles in the presence of Fucoidan (2000μg/mL) and Poly I (250μg/mL). The nanoparticles were incubated with the chemicals at 37°C for 24 hours. The spectra are normalized to the SPR peak at 522nm.

Supporting Figure 10. RNAi mediated knockdown of class A and class B scavenger receptors as measured by quantitative real-time PCR. Beta actin is used as an internal control and the results are normalized to cell treated with lipofectamine treatment.

CHEMICAL TREATMENT	% CELLVIABILITY
Lipopolysacchrides (80 μg/mL)	91.7 ± 0.42
Fucoidan (2000 μg/mL)	91.9 ± 2.9
Poly I (250 μg/mL)	93.2 ± 1.3
Poly A (250 μg/mL)	93.5 ± 1.1
Untreated Cells	99.2 ± 0.85

Supporting Table 1. Cell viability as a result of treatment with highest concentration of various chemicals. Untreated cells were not given any chemicals or nanoparticles. Poly I and Poly A are similar polymers and show comparable effects on cell viability as do LPS and Fucoidan. Poly A and LPS treatments do not inhibit cellular uptake of DNA-Au NPs whereas Poly I and Fucoidan treatments inhibit internalization of DNA-Au NPs.

Impact of Epidermal Growth Factor Tethering Strategy on Cellular Response

In an effort to evaluate the impact of various epidermal growth factor (EGF) grafting strategies upon cell surface receptor activation and cell adhesion, we generated low-fouling surfaces by homogeneously grafting carboxymethylated dextran (CMD) on amino-coated glass substrate. By preventing nonspecific cell adhesion while providing reactive groups facilitating subsequent protein grafting, CMD allowed achieving specific cell/tethered EGF interactions and therefore deriving unambiguous conclusions about various EGF grafting strategies. We demonstrate here that A-431 cell response to immobilized EGF is highly dependent on the bioactivity of the tagged protein being tethered, its proper orientation, and its surface density. Among all the approaches we tested, the oriented tethering of fully bioactive EGF via a *de novo*-designed coiled-coil capture system was shown to be the most efficient. That is, it led to the most intense and sustained phosphorylation of EGF receptors as well as to strong A-431 cell adhesion, the latter being comparable to that observed with amino-coated surfaces in the absence of CMD.

INTRODUCTION

Bioengineered implants are becoming extremely promising with respect to the development of biocompatible surfaces aiming at promoting and sustaining tissue regeneration. Within the last three decades, in an effort to mimic nature's mechanisms that are involved in tissue development and healing processes, the immobilization of growth factors on various substrates has been extensively studied by several groups (*1–3*). Such an interest from the scientific community may be ascribed to the direct implication of growth factors in almost all fundamental cellular processes, including cell survival, proliferation, migration, differentiation, and apoptosis. Furthermore, growth factor immobilization is believed to limit their clearance through endocytosis/degradation pathways and their diffusive mobility, thus restraining delivery to the local implant region (*4*). In that context, the epidermal growth factor (EGF), a soluble 6 kDa polypeptide that mediates its biological function by promoting the oligomerization (*5, 6*) and the phosphorylation (*7–9*) of cell surface EGF receptors (EGFRs), has attracted a lot of attention and has already shown great promises for the generation of smart corneal implants promoting re-epithelialization (*10, 11*) as well as for *ex vivo* stem cell expansion (*12–15*).

Nonspecific adsorption of EGF on substrate has been demonstrated to drastically diminish EGF bioactivity, most likely due to the occurrence of adsorption-induced conformational changes or inappropriate orientation of EGF (*4*). In contrast, covalent immobilization strategies via photoimmobilization or wet chemistry route resulted in unambiguous effects upon cell adhesion, phenotypic changes, and DNA synthesis (*4, 16*). However, for human EGF (hEGF), amine chemistry has been acknowledged to be suboptimal since the lysine side chains of hEGF extensively contribute to receptor binding; their involvement in the generation of an amide bound during EGF immobilization has been shown to greatly decrease its bioactivity (*4, 17, 18*). To counteract this caveat, oriented and stable tethering of hEGF has been successfully achieved through the use of recombinant EGF chimeras. That is, EGF has been fused to various tags or domains including the Fc region of immunoglobulin G (*19*), poly histidine (*12*), or coil peptide tags (*18*), in order to subsequently tether these chimeras on surfaces on which Protein A/G, nitrilotriacetate (NTA), or complementary coil peptide had been immobilized in a covalent fashion, respectively. Although the noncovalent but stable capture of EGF via tags hold great promise, this strategy should be examined with caution. We indeed recently demonstrated that the nature and the position of the tags both influence EGF bioactivity (*20*). More specifically, an Fc tag was shown to have a deleterious effect on EGF bioactivity when fused at its N- or C-terminus, as deduced from the ability of these constructs to induce A-431 cell receptor phosphorylation *in vitro*. In this assay, EGFR phosphorylation was not detected when the cells were treated with soluble Fc-EGF, while EC_{50} values of 17 nM versus 4.3 nM for EGF-Fc and EGF, respectively, were determined when these ligands were provided to the cells in their soluble forms. In stark contrast, EGF being N-terminally tagged with a short (i.e., 35 amino-acid-long) peptide (the Ecoil) was found to be as active as untagged EGF (EC_{50} of 5.5 nM). The effect of these various tags upon EGF signaling, when captured in an oriented fashion, has never been rigorously compared, although several independent studies have demonstrated that the EGF moiety of these chimeric proteins was able to promote a cellular response.

Another point to be considered with great care in growth factor immobilization resides in the choice of the spacer arm ensuring proper display and attachment of the growth factor of interest. So far, homo- (*21*) and heterobifunctional (*22*) polyethylene glycol (PEG) chains have been extensively used. However, as outlined by Kuhl et al. (*4*) and Klenkler et al. (*21*),

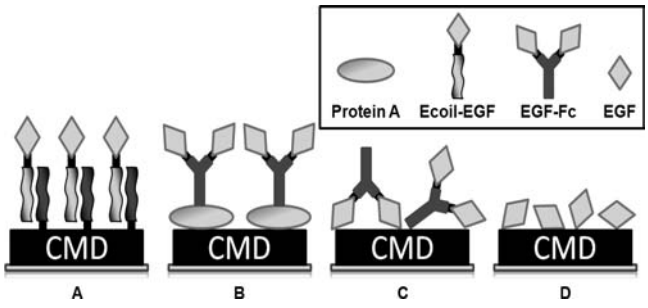

Figure 1. Strategies for EGF immobilization on CMD. (A) Ecoil−EGF capture on a covalently attached Kcoil peptide layer, (B) EGF−Fc capture on a covalently attached Protein A layer, and random covalent attachment of (C) EGF−Fc and (D) untagged EGF on CMD layer.

PEG grafting often results in heterogeneous surface coverage that does not totally block nonspecific adsorption of the growth factor under investigation or of other proteins present in the medium. Furthermore, as already mentioned, subsequent hEGF chemical linkage to activated PEG also leads to heterogeneous EGF display. Hence, results from *in vitro* cell culture experiments performed on PEG surfaces being derivatized with growth factors may not only reflect the effect of the tethered protein but may also be attributed to more complex phenomena being triggered by the combination of suboptimally immobilized and adsorbed species.

As an alternative to PEG, synthetic or natural polymers presenting functionalities such as amine (e.g., chitosan and polyvinylamine), or carboxyl (e.g., carboxymethylated dextran (CMD)) groups distributed homogeneously along their chains are often used as a linker to facilitate the attachment of specific proteins and thus further tailor material surface properties (*1*). In addition to introducing desired reactive groups at the material surface for subsequent protein grafting, the added polymeric layer *per se* can also affect the macroscopic surface properties (hydrophilicity, roughness) and modulate cell and protein affinity for the engineered material surface (*22–24*).

The aim of this work was to compare various controlled constructions of EGF-coated surfaces within the same study (Figure 1) in order to further investigate the impact of the tags (nature and size), the immobilization strategy (i.e., random immobilization versus oriented tethering) upon EGFR activation, and cell adhesion. A-431 cells were cultured on various EGF-derivatized surfaces to correlate the type of EGF display with cell adhesion and EGFR activation. In that effort, a homogeneous polymeric layer of CMD was selected as a polymeric spacer for its ability to provide sufficient reactive groups homogeneously distributed on the surface and because of its low-fouling properties (*25–27*). By preventing nonspecific cell adhesion, CMD allowed us to achieve specific cell interactions with immobilized EGF and therefore derive unambiguous conclusions about the impact of our various EGF grafting strategies upon receptor activation and cell adhesion.

MATERIALS AND METHODS

Chemicals and Reagents. Native silicon wafers (Prime Si P/Boron) were obtained from University Wafer (South Boston, MA), and amino-coated glass slides (10 × 10 mm) were from Erie Scientific Co. (Portsmouth, NH). Anhydrous 3-aminopropyltriethoxysilane (APTES, 99% purity), cysteine (99+% purity), monochloroacetic acid (99+% purity), sodium hydroxide (98+% purity), sodium monobasic phosphate (99+% purity), and sodium chloride (99.99% purity) were purchased from Sigma-Aldrich Canada, Ltd. (Oakville, ON). Hydrogen peroxide (30% v/v), chlorhydric acid (37% v/v), chloroform (99.8% purity), sulfuric acid (98% purity), dimethyl sulfoxide (DMSO, 99+% purity) and toluene (99.5% purity) were purchased from VWR International, Inc. (Mont-Royal, Qc, Canada). All solvents were distilled under strict anhydrous conditions prior to use. Milli-Q quality water (18.2 MΩ·cm; total organic compounds (TOC) = 4 ppb) was generated with a Millipore Gradient A 10 purification system. Cysteine-tagged Kcoil peptides were synthesized by the peptide facility at the University of Colorado (Denver, CO) (*28*). Untagged hEGF and EGFRED-Fc (artificially dimerized EGFR ectodomain through the Fc portion of an IgG_1) was purchased from R&D Systems (Minneapolis, MN). All the surface plasmon resonance (SPR) experiments were performed using a Biacore T100 instrument (GE Healthcare, Baie d'Urfé, Qc, Canada). CM4 sensor chips, *N*-hydroxysuccinimide (NHS), ethyl-*N*′-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), ethanolamine, 2-(2-pyridinyldithio)ethaneamine hydrochloride (PDEA), and borate buffer (pH 8.5) were also purchased from GE Healthcare. Dextran (70 kDa) was obtained from Pharmacosmos A/S (Holbaek, Denmark).

Dextran Carboxymethylation and Characterization. Dextran carboxymethylation and characterization was performed by adapting previously reported protocols (*29*). Briefly, 400 mg of dextran was dissolved in 10 mL of 3 M NaOH containing 1 M monochloroacetic acid. The solution was stirred for 2 h at room temperature (RT). The reaction was stopped by the addition of 40 mg of NaH_2PO_4 followed by pH adjustment to neutral using 18 M H_2SO_4. The solution was then filtered through a 0.2 μm PTFE filter, dialyzed five times against Milli-Q water for 1 h in order to remove reagents and salts, and finally lyophilized. CMD powder was stored at 4 °C until use.

The carboxymethylation degree of our product was assessed using ^{1}H NMR spectroscopy. Spectra for CMD were recorded with a Varian Unity Inova 400 MHz NMR spectrometer equipped with a 5-mm indirect probe, operating at a frequency of 399.95 MHz. Samples were examined as solutions in D_2O at 323.1 K. Water signal was suppressed by pulse sequences (72.4°). Chemical shifts are given relative to external tetramethylsilane (TMS = 0 ppm).

Ecoil-Tagged and Fc-Tagged EGF Production. Ecoil−EGF, EGF−Fc, and Fc−EGF were produced in HEK293-6E cells, purified, and quantified as previously described (*20*). Purified recombinant proteins were then aliquoted and stored at −80 °C until use.

Surface Preparation. Glassware was carefully cleansed by overnight immersion in a bath of KOH-saturated isopropyl alcohol followed by intensive rinsing with Milli-Q water. Prior to layer grafting, silicon and amino-coated glass surfaces were washed to remove any adsorbed organic compounds. The silicon surfaces (10 × 10 mm) were cleansed according to the Piranha method, i.e., the surfaces were immersed in a 3:1 mixture of sulfuric acid and hydrogen peroxide for 10 min at 100 °C. After intensive rinsing with Milli-Q water, the surfaces were dried in air at RT and then introduced in a dried Schlenk. To ensure anhydrous conditions, two cycles of vacuum/dry argon were performed in the Schlenk. The amino-coated glass surfaces (10 × 10 mm) were cleansed in an ultrasonic bath for 1 min in distilled chloroform and then dried in air at RT.

Grafting Procedures. *APTES Grafting on Silicon Surfaces.* Amino groups were generated on silicon surfaces using a silanization procedure as previously reported (*18, 30*). Briefly, APTES was first dissolved in anhydrous toluene at a concentration of 10 mM. The solution was injected through a 0.2 μm PTFE filter in dry Schlenk tubes each containing one silicon surface. After a reaction time of 3 h at RT, the surfaces were taken out from the Schlenk tubes, dried in air for 1 min, and placed in an oven at 120 °C for 30 min. The surfaces were then rinsed by soaking them in freshly distilled toluene for 5 min.

CMD Grafting on Amino-Coated Silicon and Glass Surfaces. CMD was covalently attached onto amino-coated surfaces using water-soluble carbodiimide chemistry. CMD solutions (2 mg/mL) were prepared in Milli-Q water. Once dissolved, NHS-activation of CMD was performed by adding 150 μL of 0.4 M EDC in Milli-Q water and 150 μL of 0.1 M NHS in Milli-Q water to the CMD solutions. The amino-coated surfaces were covered with 150 μL of NHS-activated CMD solution for 2 h at RT. The surfaces were finally washed in a 10 mM phosphate buffer solution (pH 7.4) in ultrasonic bath for 2 min, rinsed by soaking them in 10 mM phosphate buffer (pH 7.4) and rinsing three times in fresh Milli-Q water.

Kcoil Peptide Grafting on CMD-Coated Surfaces. Kcoil peptides were immobilized on CMD-coated surfaces using PDEA cross-linker. CMD-coated surfaces were first activated with 100 μL of 0.2 M EDC and 0.05 M NHS in Milli-Q water for 15 min at RT and rinsed in fresh Milli-Q water for 5 min. One hundred microliters of 10 mg/mL PDEA in borate buffer (10 mM disodium tetraborate, 1 M NaCl, pH 8.5) was deposited on each surface for 15 min at RT. The surfaces were rinsed by soaking them in Milli-Q water for 5 min. The thiol-reactive surfaces were then reacted with 100 μL of 10 μM cysteine-tagged Kcoil (5 heptad repeats (*28*)) in 10 mM acetate buffer (pH 5.5) for 2 h at RT. The surfaces were finally rinsed by soaking them in 5 M guanidium hydrochloride solution, 10 mM phosphate buffer, and in Milli-Q water for 5 min each. Unreacted PDEA sites were blocked using 100 μL of 50 mM cysteine solution (1 M NaCl in 0.1 M sodium acetate, pH 4.0) followed by rinsing with Milli-Q water for 5 min.

Kcoil Peptide Grafting on Amino-Coated Glass Surfaces. Kcoil peptides were immobilized onto amino-coated surfaces via *N*-succinimidyl-6-(3'-(2-pyridyldithio)-propionamido)-hexanoate (LC-SPDP) linker, as previously described (*18*). Briefly, the surfaces were covered with 150 mL of 2 mM LC-SPDP in 100 mM phosphate buffer (10% DMSO) for 2 h at RT. The surfaces were rinsed by soaking them in Milli-Q water for 5 min. Then, the LC-SPDP-coated surfaces were covered with 150 mL of 10 mM cysteine-tagged Kcoil peptides in 10 mM phosphate buffer for 2 h at RT. The surfaces were rinsed in 10 mM phosphate buffer (pH 7.4) and in Milli-Q water. One hundred fifty microliters of 50 mM cysteine solution (1 M NaCl in 0.1 M sodium acetate, pH 4.0) was used to block unreacted LC-SPDP sites. The surfaces were rinsed by soaking them in Milli-Q water for 5 min.

Ecoil-Tagged EGF Tethering and Removal. Surfaces harboring covalently bound Kcoil were covered with 150 μL of 600 nM Ecoil-EGF in 10 mM phosphate buffer (pH 7.4) for 2 h at RT. The surfaces were rinsed in 10 mM phosphate buffer and Milli-Q water for 5 min. When necessary, removal of the Ecoil-tagged EGF was performed by soaking the surfaces in a 5 M guanidium hydrochloride solution, followed by rinsing in 10 mM phosphate buffer and Milli-Q water for 5 min each.

Nonoriented EGF Covalent Immobilization on CMD-Coated Surfaces. CMD-coated surfaces were treated with 100 μL of 0.2 M EDC and 0.05 M NHS in Milli-Q water for 15 min at RT and rinsed in fresh Milli-Q water for 5 min. 100 μL of 600 nM untagged hEGF or Fc-tagged EGF in 10 mM acetate buffer (pH 4.5) were deposited on NHS-activated CMD surfaces for 2 h at RT. The surfaces were then rinsed by soaking them in 10 mM phosphate buffer and Milli-Q water for 5 min each.

Fc-Tagged EGF Capture via Immobilized Protein A. CMD-coated surfaces were activated with 100 μL of 0.2 M EDC and 0.05 M NHS in Milli-Q water for 15 min at RT and rinsed in fresh Milli-Q water for 5 min. 100 μL of 10 μM Protein A in 10 mM acetate buffer (pH 4.5) were reacted with NHS-activated CMD surfaces for 1 h at RT. The surfaces were rinsed in 10 mM phosphate buffer and Milli-Q water for 5 min each. The surfaces were then covered with 100 μL of 1 μM Fc-tagged EGF in 10 mM phosphate buffer (pH 7.4) for 2 h at RT. The surfaces were finally rinsed by soaking them in 10 mM phosphate buffer and Milli-Q water for 5 min each.

Contact Angle and Ellipsometric Measurements. Contact angle and ellipsometric measurements were performed as previously described (*18*).

SPR Assays. SPR experiments were conducted at 25 °C using HBS-T (10 mM HEPES pH 7.4, 150 mM NaCl, 3.4 mM EDTA, 0.05% Tween 20) as running buffer.

Kcoil Immobilization on CMD Sensorchip. All the covalent immobilization steps were carried out at a flow rate of 10 μL/min. The carboxylic groups of the CMD matrix of biosensor chips were first activated by injecting 0.05 M NHS mixed with 0.2 M EDC (7 min). The NHS-activated carboxylic groups were then reacted with PDEA cross-linker (10 mg/mL in borate buffer, 7-min injection) to end-graft cysteine-labeled Kcoil (10 μM Kcoil in 10 mM acetate buffer (pH 5.5), 20-s injection). Finally, freshly prepared cysteine solution (50 mM in 0.1 M acetate buffer, 1 M NaCl, pH 4.0) was injected (7 min) to block all unreacted PDEA-activated sites. For each Kcoil-functionalized surface, a mock surface was also generated by applying the same procedure but replacing Kcoil peptide injection by buffer injection.

Ecoil-EGF Capture and Subsequent Injections of EGFRED-Fc. Ecoil-EGF capture and subsequent injections of EGFRED-Fc to test Ecoil-EGF bioactivity were performed at a flow rate of 50 μL/min. Regeneration of the sensorchip (i.e., removal of Ecoil-EGF) was accomplished by two pulses of guanidium hydrochloride (50 μL, 100 μL/min, 5M).

Immobilized EGF Quantification. Commercially available DuoSet ELISA kit (DY-236, R&D Systems, Minneapolis, MN) was used to quantify EGF and Ecoil-EGF concentrations in solution before and after immobilization/capture on surfaces according to the manufacturer recommendations and using a Victor (*3*) V ELISA plate reader (PerkinElmer Inc., Woodbridge, ON). Standard curves were generated with tagged and untagged EGF proteins depending on the protein to be quantified.

Cellular Assays. *Cell Culture.* A-431 cells were maintained in 175 cm^2 flasks in Dulbecco's modified Eagle's medium (DMEM, GIBCO/BRL, Burlington, ON) supplemented with 10% fetal bovine serum (Invitrogen, Burlington, ON) at 37 °C with 5% CO_2 until 85−90% confluence was reached.

A-431 Seeding. Prior inoculations onto our various surfaces, A-431 cells were washed with phosphate buffered saline (PBS) and incubated overnight in DMEM medium without serum. After trypsinization (5 min, 37 °C), A-431 cells were washed by centrifugation and resuspended in DMEM (no serum). Then, A-431 cells were distributed at 1×10^6 cells/mL, 1 mL/well, in 24-well plates containing aminated glass surfaces, Kcoil functionalized glass surfaces where Ecoil−EGF had previously been immobilized via coiled-coil interactions, CMD-coated glass surfaces in the presence or absence of soluble EGF (4 nM), CMD-coated glass surfaces where Ecoil−EGF had been previously immobilized via coiled-coil interactions, CMD-coated glass surfaces where EGF−Fc had been previously captured via Fc/protein A interactions, and CMD-coated glass surfaces where EGF and EGF−Fc had been covalently immobilized via amine chemistry (nonoriented immobilization).

Cell Adhesion. DMEM medium was removed 4 h after inoculation and adhered cells were washed three times with DMEM (serum-free). Cells were observed using inverted microscope Axiovert S100TV (Carl Zeiss Canada, North York, ON). Images were processed with a QICAM Fast 1394 camera (QImaging) and cell count was achieved using Northern Eclipse image acquisition software (Empix imaging).

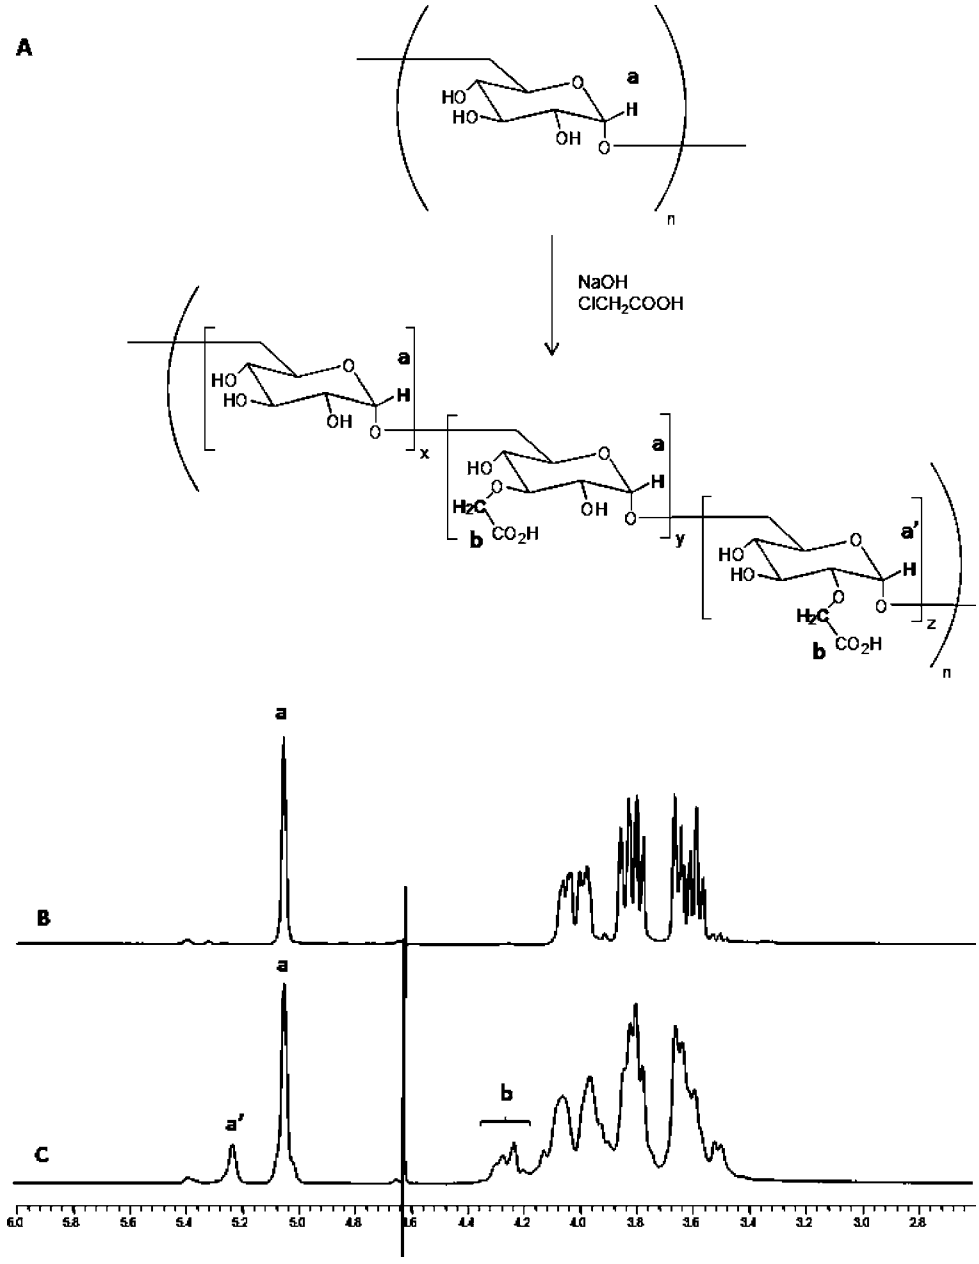

Figure 2. 70 kDa dextran carboxymethylation. Chemical reaction scheme (A) and ^{1}H NMR spectra of dextran (B) and product of dextran carboxymethylation (C). Letters in bold correspond to the protons borne by the anomeric carbons (**a** and **a′**) or by the methyl groups (**b**) added by the chemical reaction.

Phosphorylation Assays and Cell Lysis. DMEM medium was removed 2, 3, 4, and 5 h after inoculation, and A-431 cells were washed three times with PBS supplemented with sodium-orthovanadate (1 mM, Sigma) and extracted with lysis buffer (50 mM HEPES pH 7.4), 150 mM NaCl, 1% Thesit, 0.5% Na Deoxycholate, Complete protease inhibitor cocktails (Roche, Laval, Qc)) supplemented with 0.1 mM Na_3VO_4, 20 mM β-glycerophosphate, 10 mM $Na_4P_2O_7 \cdot 10\ H_2O$ and 0.5 μM microcystin). Insoluble material was removed by centrifugation at 10 000 *g* for 5 min at 4 °C. Protein phosphorylation was then analyzed by Western blotting as previously described (*18*).

RESULTS AND DISCUSSION

Dextran Carboxymethylation and Grafting on Amino-Coated Glass Surfaces. To introduce carboxylic groups, 70-kDa dextran chains were first transformed into negatively charged CMD (Figure 2A). $-CH_2-COOH$ groups were introduced in the chain by reaction of monochloroacetic acid with the hydroxyl groups held by the glucopyranose rings of dextran without degrading the polysaccharidic backbone (as opposed to methods relying on periodate oxidation) (*25*). Although the carboxymethylation protocol we used is known to kinetically favor the modification of hydroxyl groups held by the C_2 carbon, modifications may also occur on all the $-OH$ groups of the glucopyranose cycle (*25*). Dextran modification was confirmed by ^{1}H NMR spectroscopy. As shown in Figure 2, the product of the carboxymethylation reaction exhibited two distinct peaks within the spectral region corresponding to an anomeric proton signal (Figure 2C). By comparing this spectrum to that of unmodified dextran (Figure 2B), peaks at $\delta = 5.04$ ppm and $\delta = 5.23$ ppm were attributed to the anomeric protons of glucopyranose units being unsubstituted (**a**) or bearing a carboxymethyl group (**a′**) at their C_2 position, respectively. Also, the spectrum corresponding to the carboxymethylation product was characterized by the presence of new peaks within the 4.17−4.35 ppm δ region (denoted **b** within Figure 2C). These

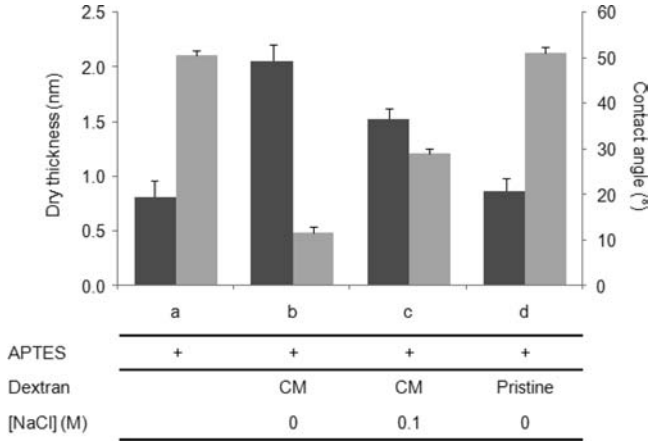

Figure 3. Ellipsometric and water contact angle characterization of CMD grafting on aminated silicon surfaces. APTES layer grafted on silicon surfaces (a) and subsequent grafting of carboxymethylated (CM) dextran in the absence of salt (b) or dissolved in 0.1 M NaCl solution (c). As a comparison, the characterization of pristine (unmodified) dextran incubation on APTES-coated surfaces is also presented. The dark and light gray bars correspond to dry thickness and contact angle measurements, respectively. The reference was set as (0 nm, 0°) for a cleaned silicon surface. The successive grafting reactions were performed as described in the Materials and Methods section and summarized in the table below the graph. Values are given as mean value ± standard deviation ($n = 5$).

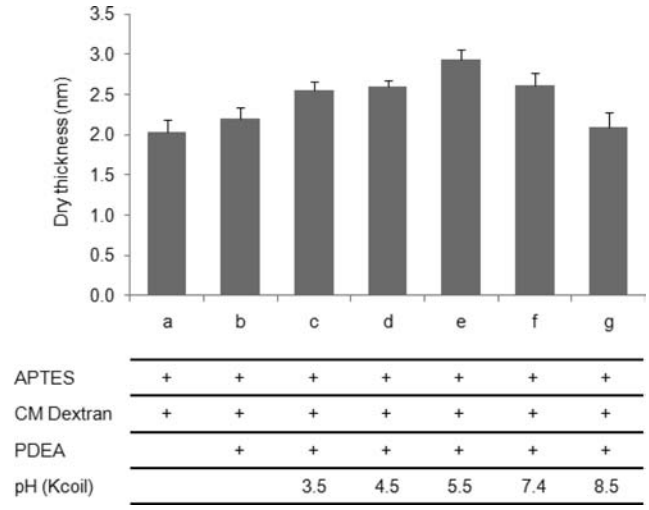

Figure 4. Ellipsometric characterization of Kcoil peptide covalent immobilization on CMD surfaces. PDEA grafting (b) and subsequent immobilization of cysteine-tagged Kcoil peptide (c−g) on CMD-coated silicon surfaces (a). Cysteine-tagged Kcoil was reacted on PDEA-covered surfaces at pH 3.5 (c), pH 4.5 (d), pH 5.5 (e), pH 7.4 (f) and pH 8.5 (g). The reference was set as 0 nm for a cleaned silicon surface. The grafting reactions were performed as described in the Materials and Methods section and summarized in the table below the graph. Values are given as mean value ± standard deviation ($n = 5$).

peaks corresponded to the $-CH_2$ protons of the added carboxymethyl group. The degree of carboxymethylation was thus determined from the ratio of the areas corresponding to the $-CH_2$ signals of the CH_2-COOH groups (**b** region within Figure 2C) to the areas corresponding to the anomeric proton signals (**a** and **a′** peaks within Figure 2C). Under our experimental conditions, the carboxymethylation degree of our 70-kDa dextran was estimated to be 22%.

In a second step, silicon surfaces were chosen as substrate to investigate CMD grafting to aminated substrate. Ellipsometric and water contact angle measurements were performed to evaluate the effect of salt upon our grafting protocol. In that endeavor, amine groups were first generated on silicon surfaces via a silanization reaction occurring between APTES and silanol groups that are naturally exposed on the surfaces (*18*). As illustrated in Figure 3 (condition a), the layer of deposited APTES appeared to be thin and homogeneous as deduced from ellipsometric thickness (0.8 ± 0.15 nm) and water contact angle (51 ± 2°) measurements, both in excellent agreement with those we determined in a previous study (*18*). CMD chains were then grafted on these amino-functionalized surfaces using EDC and NHS as coupling agents. In this way, NHS-activated carboxyl groups of CMD chains were reacted with free amine groups on the surface to create a stable amide bound. In an effort to maximize CMD grafting on amino-coated surfaces, the coupling reaction was carried out both in the absence and presence of salt (0.1 M NaCl) in the CMD solution (Figure 3, conditions b and c). We reasoned that salt addition would decrease the electrostatic repulsions that may occur within and between the charged CMD chains. We thus expected to obtain more compact individual CMD chains in solution and therefore denser grafted CMD layers. Whereas a dense and hydrophilic polymeric layer was grafted (net dry thickness of 1.3 nm and water contact angle of 11 ± 2°) in the absence of salt, the addition of 0.1 M NaCl resulted in a 53% lower net dry thickness (0.7 nm). As a negative control, when the same reaction was performed with pristine dextran, only minor variations in surface characteristics were observed when compared to APTES-coated silicon surfaces (+ 0.05 nm and +0.5° for dry thickness and contact angle values, respectively). The negative impact of salt upon CMD grafting has previously been reported by others (*31*). This effect is most likely related to a drastic loss of NHS-activated carboxyl groups via hydrolysis, the latter being promoted by high salt concentrations (*32*).

EGF Grafting. The covalent immobilization as well as the stable tethering of several EGF variants were then studied on optimized CMD-grafted surfaces by applying the oriented and nonoriented strategies described in Figure 1. That is, two distinct tag systems were independently evaluated (coil and Fc tags) and compared to the nonoriented but covalent immobilization of EGF or EGF−Fc onto CMD.

Coiled-Coil-Mediated EGF Tethering. The first tethering strategy consisted in covalently grafting cysteine-tagged Kcoil peptides on CMD-covered surfaces, followed by the capture of Ecoil-tagged proteins via E/K coiled-coil interactions. Cysteine-tagged Kcoil peptides were first grafted on CMD using PDEA as a bifunctional linker (*28*). NHS-activated CMD chains were reacted with the free amine group of PDEA linker to form an amide bond. The resulting film showed an ellipsometric thickness of 2.2 ± 0.2 nm (Figure 4, condition b). The other extremity of PDEA linker, terminated by a pyridyl disulfide group, was then reacted with the thiol group of cysteine-terminated Kcoil peptide to create a covalent disulfide bond. In an effort to maximize Kcoil grafting density, the coupling reaction was studied at various pHs ranging from 3.5 to 8.5 (Figure 4, conditions c−g). Maximal effective thickness, i.e., 0.7 ± 0.1 nm (Figure 4, condition e), was obtained for Kcoil peptides reacted at pH 5.5. Cysteine was then used to block unreacted pyridyl disulfide group of PDEA linkers and therefore prevent the undesired attachment of other molecules containing thiol groups. No significant changes in surface characteristics were observed before (Figure 4, conditions b and e) and after (Figure 5, conditions a and d) cysteine-mediated PDEA deactivation. The ability of our CMD surfaces, when functionalized with Kcoil peptides, to recruit N-terminally Ecoil-tagged EGF chimera was then tested. As can be seen in Figure 5, the incubation of Ecoil−EGF on Kcoil peptides previously bound to CMD surfaces, followed by extensive rinsing to elute unbound material, led to a net increase in dry thickness of 0.8 ± 0.2 nm. Further treatment of surfaces on which Ecoil−EGF

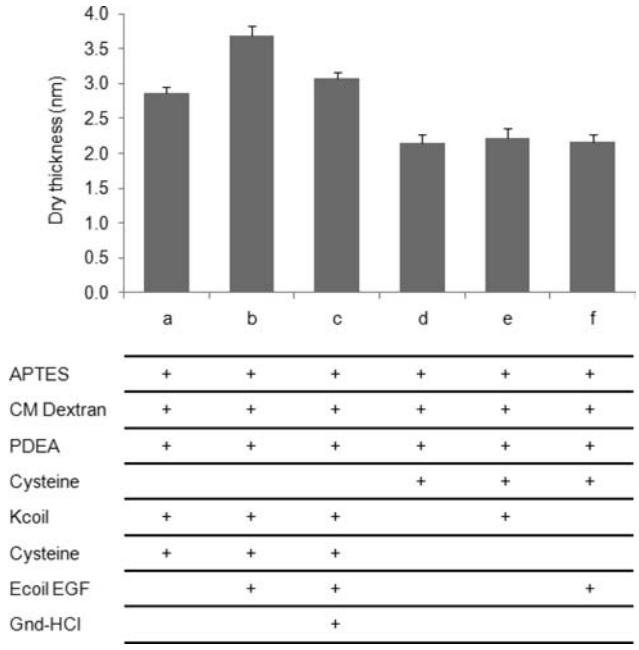

Figure 5. Ellipsometric characterization of Ecoil-tagged EGF tethering on Kcoil-coated CMD surfaces. Dry thickness measurements corresponding to silicon surfaces sequentially treated with APTES, CMD, PDEA, Kcoil (pH 5.5) and cysteine solutions (a) that were incubated with Ecoil−EGF (b) and then exposed to a 5 M guanidium hydrochloride (Gnd-HCl) solution (c). As negative control, the incubation of Kcoil peptides (e) and Ecoil−EGF proteins (f) on cysteine-blocked PDEA layers (d) are presented. The reference was set as 0 nm for a cleaned silicon surface. The successive grafting reactions were performed as described in the Materials and Methods section and summarized in the table below the graph. Values are given as mean value ± standard deviation ($n = 5$).

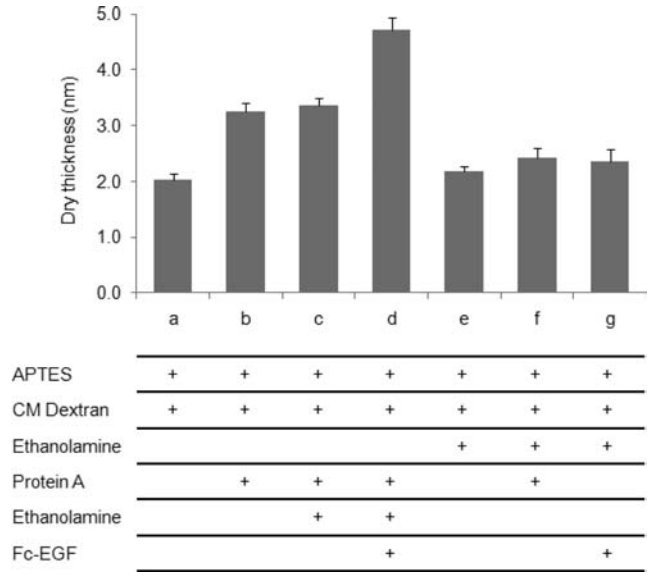

Figure 6. Ellipsometric characterization of EGF−Fc tethering on Protein A-coated surfaces. Dry thickness measurements corresponding to silicon surfaces sequentially treated with APTES and CMD (a) on which covalent coupling of Protein A had been achieved by amine chemistry (b), and for whom remaining activated group had been blocked by ethanolamine (c). EGF−Fc capture on (c) is shown as (d). As negative control, the incubation of Protein A (f) and EGF−Fc (g) on ethanolamine-blocked CMD layers (e) are presented. The reference was set as 0 nm for a cleaned silicon surface. The successive grafting reactions were performed as described in the Materials and Methods section and summarized in the table below the graph. Values are given as mean value ± standard deviation ($n = 5$).

had been captured, with 5 M guanidium hydrochloride, a strong chaotropic agent known to disrupt coiled-coil interactions (*28*), induced a decrease in dry thickness of 0.6 nm, which confirmed the reversibility of the coiled-coil interaction. Finally, when Ecoil−EGF or cysteine-tagged Kcoil were incubated on cysteine-deactivated PDEA/CMD layers (Figure 5, conditions e and f, respectively), no significant changes in dry thickness values were observed when compared to those measured prior incubation (Figure 5, condition d), hence demonstrating that nonspecific adsorption of Ecoil−EGF and Kcoil peptides on dextran-coated surfaces was negligible.

Fc-Mediated EGF Tethering. The second EGF capture strategy was based on the covalent attachment of Protein A to CMD, followed by the oriented capture of C-terminally Fc-tagged EGF proteins (EGF−Fc) via Protein A/Fc interactions (*33*). To do so, NHS/EDC coupling agents were used to activate grafted CMD surfaces. Ten micromolar Protein A diluted in 10 mM acetate buffer (pH 4.5) was found to be the best condition among those we tested for Protein A covalent grafting on NHS-activated CMD (data not shown). The resulting film displayed a dry thickness of 3.3 ± 0.1 nm (Figure 6, conditions b). After Protein A grafting, the remaining NHS-reactive groups were deactivated using ethanolamine as blocking agent in order to prevent any undesired attachment of amine-containing molecules. The ethanolamine-mediated NHS deactivation did not induce any significant change in the layer thickness (Figure 6, compare conditions b and c). Fc-tagged EGF proteins were then tethered on the Protein A layer, giving rise to final dry thickness of 4.7 ± 0.2 nm after extensive rinsing to remove any unbound material. As negative control, Protein A and EGF−Fc were incubated on ethanolamine-deactivated CMD (Figure 6, conditions f and g, respectively). Minor variations in dry thickness values were noticed when compared to that of deactivated dextran layer (Figure 6, condition e). This observation suggested that Protein A was mainly attached via covalent amide bonds to CMD-coated surfaces while Fc−EGF nonspecific adsorption on CMD was negligible.

Altogether, the negative controls shown in Figures 5 and 6 demonstrated that the experimental protocol we optimized to generate our low-fouling CMD layer was successful. This conclusion is in total agreement with those drawn by Monchaux and Vermette who reported very low levels of serum protein adsorption on similar CMD surfaces (*31*).

EGF Covalent Immobilization. For the sake of comparison, covalent immobilization of EGF was also performed on CMD surfaces using untagged hEGF and EGF−Fc proteins. In that approach, available amine groups of EGF or Fc tag (displayed on lysine residue side chains or at the N-terminus of the proteins) were used to create amide bonds with NHS-activated CMD layer. One micromolar of hEGF or EGF−Fc dissolved at pH 4.5 (10 mM acetate buffer) was found to be the optimal condition to obtain thick and homogeneous grafted layers on CMD surfaces (data not shown) that were characterized by effective dry thicknesses of 1.1 and 0.9 nm, respectively. In contrast to both oriented capture approaches we described earlier, our EGF covalent immobilization protocol required the use of acetate buffer at acidic pH far from physiological values. In order to assess if such a pH difference might have induced EGF unfolding, additional SPR biosensing experiments were performed as follows. Kcoil peptide was first immobilized at the surface of commercially available biosensor chips harboring a CMD layer, using the same chemistry protocol as the one we previously described for Kcoil covalent grafting on CMD-coated silicon surfaces (650 RU of immobilized Kcoil peptide). Ecoil−EGF (43 μM) was either freshly diluted in biosensor running buffer (HBS, pH 7.4, 1/430 dilution) or diluted in acetate buffer (pH 4.5, 1/12 dilution), let for 2 h at RT then further

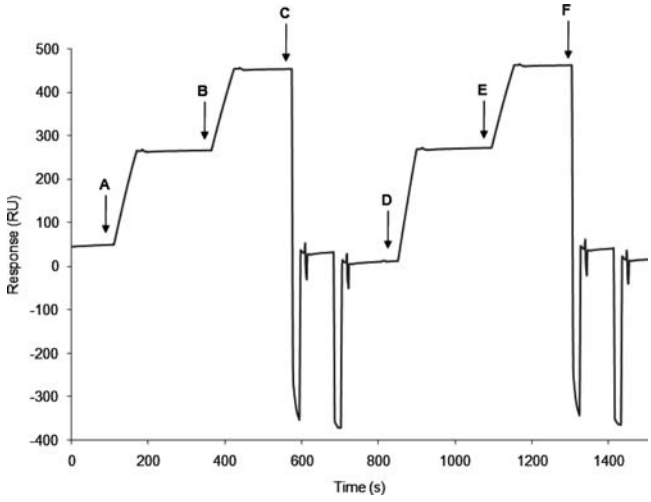

Figure 7. Acidic pH does not affect EGF bioactivity during immobilization procedure. Control-corrected sensorgrams corresponding to the sequential capture of Ecoil−EGF chimera that has been directly diluted in running buffer (A, pH 7.4), followed by EGFR−Fc injection (B) and 5 M Gnd-HCl pulses (C) to remove coil-tagged EGF. In order to evaluate the impact of acidic pH upon EGF bioactivity, Ecoil−EGF that had been kept for 2 h at pH 4.5, was diluted in running buffer prior biosensor surface capture (D), EGFR−Fc injection (E, same as B) and regeneration (F). Note that EGFR−Fc binding to captured Ecoil−EGFs (B and E) gave identical responses.

diluted in HBS buffer (pH 7.4, 1/36 dilution to get a final 1/432 dilution of EGF stock solution). The bioactivity of both Ecoil−EGF preparations was then assessed by capturing Ecoil−EGF onto Kcoil-functionalized biosensor surface and then injecting the soluble extracellular domain of EGFR being artificially dimerized through the Fc portion of an antibody (namely, EGFR−Fc). As can be seen in Figure 7, a 2-h incubation of Ecoil−EGF in acidic buffer did not alter its ability to bind to its receptor ectodomain since similar SPR responses were obtained when injecting EGFR−Fc over the same amount of coiled-coil captured EGF that had been either incubated in acetate or freshly dissolved at physiological pH prior to capture. It is thus most likely that the use of acetate buffer at acidic pH in our immobilization protocol does not alter *per se* EGF or EGF−Fc bioactivity.

Quantification of EGF Surface Densities. EGF surface densities were evaluated by ELISA for all our immobilization/capture strategies. Ecoil−EGF (600 nM) incubated on Kcoil layers previously generated on amino-coated (no dextran) and on CMD-coated silicon surfaces resulted in EGF densities of 30.7 ± 3.6 and 31.5 ± 3.5 pmol/cm^2, respectively. When EGF−Fc had been incubated at 600 nM on Protein A layers (previously grafted on CMD), an EGF density of 13.4 ± 2.3 pmol/cm^2 was obtained. In parallel, covalent coupling of EGF proteins (i.e., untagged EGF and EGF−Fc, 600 nM) on NHS-activated CMD layers resulted in EGF grafting densities of 37.5 ± 1.6 and 9.3 ± 2.4 pmol/cm^2, respectively. Dry thickness measurements were also performed to evaluate the impact of soluble tagged EGF concentration upon resulting amount of captured EGF. As shown in Figure 8, EGF surface density could be easily controlled over a wide range by varying soluble concentrations during incubation. Similar apparent thermodynamic dissociation constant (K_D) of 15 and 30 nM were deduced for Ecoil−EGF binding to immobilized Kcoil peptide and EGF−Fc binding to immobilized Protein A, respectively, assuming that Ecoil−EGF/Kcoil and EGF−Fc/Protein A interactions are well-depicted by a Langmuirian isotherm. These results thus indicate that the compact coil tag is an interesting alternative to bulkier Fc tag since the former allowed higher EGF surface density to be reached without any compromise on affinity.

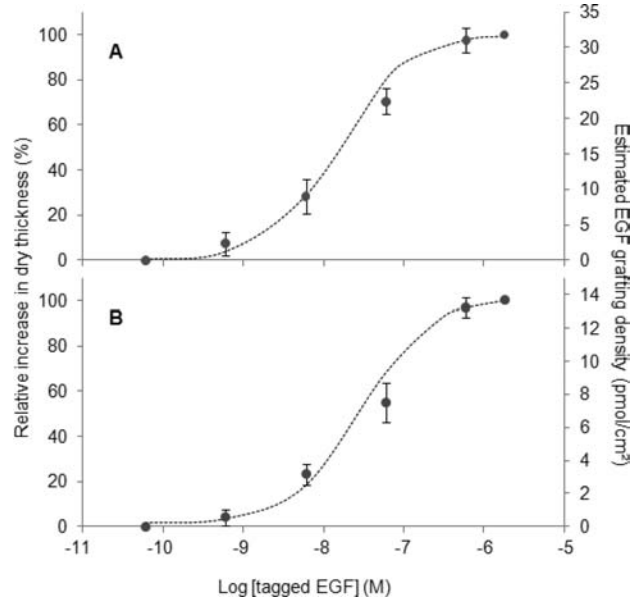

Figure 8. The amount of tagged EGF being captured on CMD layers via coiled-coil or Fc−Protein A interactions is controllable. Variation of the effective dry thickness as a function of tagged EGF concentration when Ecoil−EGF was incubated on Kcoil layers grafted on CMD (A) or when EGF−Fc was incubated on Protein A layers grafted on CMD (B). Surface density (pmol/cm^2) was deduced by ELISA assay for the maximal Ecoil−EGF or EGF−Fc concentrations. Each dot corresponds to values obtained for three independent measurements while the dotted line corresponds to data fitting using a simple Langmuirian isotherm (K_D = 15 and 30 nM for panels A and B, respectively).

EGFR Phosphorylation Assays. EGF-dependent cellular response is mediated through EGF binding to its cell surface receptors, which in turn lead to receptor intracellular kinase activation via a trans-autophosphorylation mechanism (*6*). Phosphorylation levels of A-431 cell EGFR were thus assayed at different time points by Western blot analysis (Figure 9). As expected, no phosphorylation of EGFR was observed for aminated glass surfaces that were coated or not with CMD. Also, Fc−EGF (a chimeric protein in which EGF is fused to the C-terminus of the Fc portion of an IgG), when captured onto Protein A surfaces did not lead to any significant EGFR phosphorylation. This result was expected since this chimeric construct was shown to poorly interact with EGFR ectodomain (*20*). When the cells were treated with soluble EGF, EGFR phosphorylation was found to be transient (maximal phosphorylation levels occurred after 2 h and no more phosphorylation could be observed after 4 h). These results sharply contrasted with those related to covalently immobilized or stably captured EGF conditions, for which sustained phosphorylation (i.e., at least 5 h after cell seeding) was always observed.

Of interest, the stable capture of EGF in an oriented fashion (via Fc−Protein A or coiled-coil interactions) resulted in increased EGFR activation when compared to all the nonoriented immobilization strategies we tested. That is, phosphorylation signals were found to be more intense for surfaces where Ecoil−EGF or EGF−Fc had been captured via coiled-coil or Fc−Protein A interactions than for surfaces where EGF or EGF−Fc had been covalently immobilized in a random fashion (compare "nonoriented immobilization" to "oriented capture" panels in Figure 9). Since comparable levels of coil-tagged EGF (31.5 ± 3.5 pmol/cm^2) or untagged EGF (37.5 ± 1.6 pmol/cm^2) had been captured or covalently immobilized, respectively, these results unambiguously confirmed that hEGF grafting strategies relying on covalent coupling through amine chemistry negatively impact its bioactivity, as previously reported (*17, 18*). This loss of bioactivity cannot be attributed to the acidic

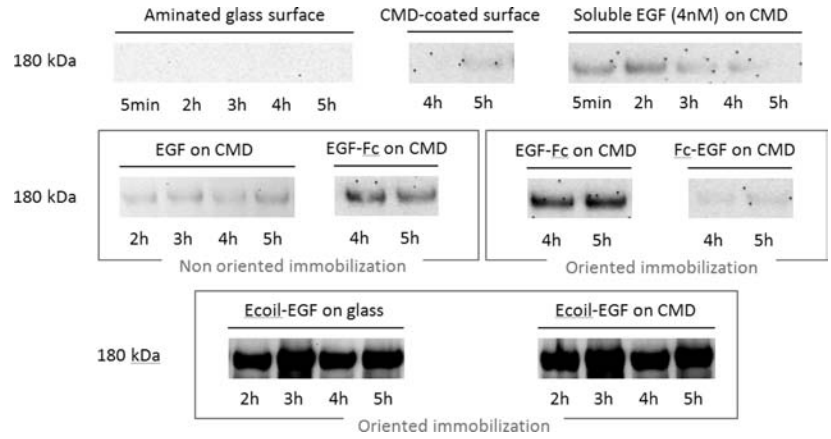

Figure 9. Phosphorylation of A-431 cell surface EGFRs. The phosphorylation of EGFRs on A-431 cells was monitored at different times by Western blot. The 180 kDa band immunoreactive to anti-pTyr antibody (corresponding to EGFR) was captured using a Kodak 440cf imager. Surface type and mode of EGF supply is indicated for each panel.

conditions that were used for covalent grafting (see previous SPR results, Figure 7), but most likely results from the involvement of the EGF lysine side-chains in the grafting reaction. This conclusion holds true when examining the phosphorylation levels (Figure 9) for EGF−Fc that was captured via Protein A/Fc interactions (13.4 ± 2.3 pmol/cm^2) to those related to randomly immobilized EGF−Fc (9.3 ± 2.4 pmol/cm^2).

Finally, Ecoil−EGF tethering via coiled-coil interactions on surfaces previously coated with CMD was the approach that induced the most intense activation of EGFR. In that specific case, phosphorylation levels were comparable to those obtained when Ecoil−EGF was directly tethered on amino-coated surfaces via coiled-coil interactions (Figure 9). This maximal response can be attributed to the fact that (i) the EGF moiety within the Ecoil−EGF chimera is fully bioactive, as opposed to EGF−Fc (*20*), (ii) that the coiled-coil strategy allowed capturing almost 3-fold more EGF when compared to strategies relying on Protein A/Fc interactions (most likely due to the compactness of the coiled-coil structure), and (iii) that the use of a coil tag linked to the EGF moiety thanks to a glycine linker, enhanced EGF mobility when compared to that of untagged EGF being directly coupled.

Tethered EGF Increases A-431 Cell Adhesion on Low-Fouling CMD. The effect of CMD layer, combined to our various strategies aiming at immobilizing/tethering EGF, upon A-431 cell adhesion was then investigated. For this purpose, A-431 cells were directly seeded on aminated glass surfaces (control), on Kcoil functionalized glass surfaces to which Ecoil−EGF had been captured via coiled-coil interactions, on CMD-coated glass surfaces in the presence or absence of soluble EGF (4 nM), on CMD-coated glass surfaces on which Ecoil−EGF had been immobilized via coiled-coil interactions or via Fc-Protein A interactions and on CMD-coated glass surfaces where EGF and EGF−Fc were covalently immobilized via amine chemistry (nonoriented immobilization) (Figure 10). As expected from the low-fouling properties of dextran (*26*), CMD layers drastically limited A-431 cell adhesion when compared to aminated surfaces (110 versus 2177 cells/mm^2). The nonoriented immobilization of EGF (native EGF or EGF−Fc) on CMD only resulted in a less than 3-fold increase of A-431 cell adhesion (299 and 277 cells/mm^2, respectively) and to levels comparable to those determined when signaling-incompetent Fc-EGF had been tethered via its interaction with Protein A (283 cells/mm^2). In stark contrast, a marked increase of A-431 cell adhesion was observed for Ecoil−EGF being tethered via coiled-coil interaction on CMD-coated surfaces (2182 cells/mm^2). In that specific case, adhesion was determined

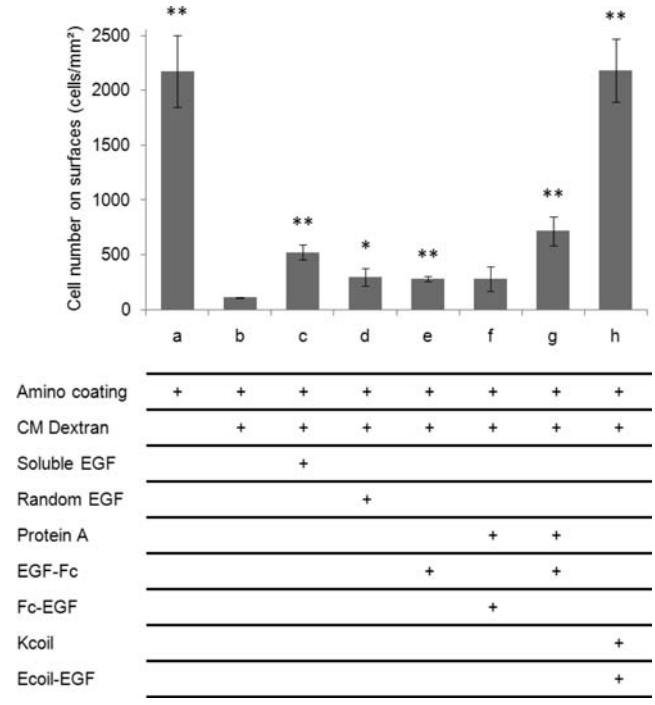

Figure 10. Cell adhesion assays. A-431 cells were incubated for 4 h on glass surfaces being amino-coated only (a), or coated with CMD both in the absence (b) or presence of soluble EGF (c). Conditions (d−h) correspond to approaches leading to EGF covalent immobilization (d,e) or to its tag-driven capture (g,h). Condition f corresponds to the negative control for condition g. The successive grafting reactions were performed as described in the Materials and Methods section and summarized in the table below the graph. Values are given as mean value ± standard deviation ($n = 5$). In order to compare each condition to condition b, statistical analysis was performed by independent two-sample t test with equal variances. Values of $p < 0.05$ and $p < 0.001$ were considered to be statistically significant and are identified by * and **, respectively.

to be as strong as for amino-coated surfaces (no CMD, Figure 10). Statistically significant but lower increases of cell adhesion were also observed for EGF−Fc being tethered via Fc/Protein A interactions (716 cells/mm^2) or with soluble EGF supply (522 cells/mm^2). These results are in excellent agreements with those from Kempiak et al. demonstrating that local activation of EGFR with EGF-coated beads caused a rapid actin polymerization response and lamellipod extrusion (*34*), two traits of A-431 cellular adhesion. Additionally, EGF grafting has also been shown to increase 3T3 Swiss (*19*) and human corneal epithelial

(*35*) cell adhesion, most likely due to the sustained activation of various downstream signaling pathways (e.g., ERK 1/2 and Akt), in turn leading to increased production of extracellular matrix proteins.

Altogether, the results presented in Figures 9 and 10 demonstrate that a strong EGF-induced A-431 cell adhesion on CMD surfaces can only be achieved when EGF is presented to the cells in a nondiffusible way, while preserving its biological activity. Indeed, EGF tethering on CMD surfaces via coiled-coil interactions (which corresponded to the most intense and sustained phosphorylation of A-431 cell surface receptors on CMD coating; Figure 9), was the only experimental condition that lead to adhesion levels similar to those obtained on control aminated surfaces (Figure 10). In stark contrast, only limited, but yet significant, increase in cell adhesion was observed (Figure 10, conditions c-g) when the grafting strategies altered EGF bioactivity (as demonstrated by low levels of EGFR phosphorylation, Figure 9) or when only transient phosphorylation of EGFR was triggered by diffusible EGF (Figure 9).

CONCLUSION

In the context of tissue engineering and regenerative medicine, EGF immobilization at the surface of implants has attracted a lot of attention. Here we show that fully bioactive EGF being tethered on carefully engineered surfaces may play, *per se*, a significant role in promoting cell adhesion, in addition to cell survival and proliferation as already demonstrated by several research groups. Among all the approaches we tested, the oriented tethering of EGF via coiled-coil interactions was shown to be the most efficient on low-fouling CMD surfaces. This most likely resulted from the many advantages of this capture system. First, it permitted the adequate display of captured EGF, and in turn the maximal biological effect as opposed to random covalent coupling. While we previously showed that the Ecoil peptide had no impact on EGF bioactivity (in contrast to the Fc tag), the relatively small size of the coiled-coil structure allowed achieving levels of captured EGF 3-fold higher than those obtained with a bulkier Fc/Protein A capture system. Altogether, coiled-coil tethered EGF led to the most intense and sustained phosphorylation of A-431 cell EGFRs as well as to strong cell adhesion. Of interest, the latter was comparable to that observed with an amino-coated surface. Our results thus highly suggest that CMD may be an interesting alternative to PEG for the generation of surfaces limiting nonspecific adhesion, and that these surfaces could be further tailored through growth factor capture via coiled-coil interactions.

Magnetic resonance imaging (MRI) has long been used clinically and experimentally as a diagnostic tool to obtain three-dimensional, high-resolution images of deep tissues. These images are enhanced by the administration of contrast agents such as paramagnetic Gd(III) complexes. Herein, we describe the preparation of a series of multimodal imaging agents in which paramagnetic Gd(III) complexes are conjugated to a fluorescent tetrapyrrole, namely, a porphyrazine (pz). Zinc metalated pzs conjugated to one, four, or eight paramagnetic Gd(III) complexes are reported. Among these conjugates, Zn-Pz-8Gd(III) exhibits an ionic relaxivity four times that of the monomeric Gd(III) agent, presumably because of increased molecular weight and a molecular relaxivity that is approximately thirty times larger, while retaining the intense electronic absorption and emission of the unmodified pz. Unlike current clinical MR agents, Zn-Pz-1Gd(III) is taken up by cells. This probe demonstrates intracellular fluorescence by confocal microscopy and provides significant contrast enhancement in MR images, as well as marked phototoxicity in assays of cellular viability. These results suggest that pz agents possess a new potential for use in cancer imaging by both MRI and near-infrared (NIR) fluorescence, while acting as a platform for photodynamic therapy.

INTRODUCTION

In the past decade, magnetic resonance imaging (MRI) has become a powerful diagnostic tool in clinical uses such as brain imaging, angiography, and tumor detection. The strength of MRI lies in its ability to produce 3-D anatomical information of human structures noninvasively with exceptional soft tissue contrast (*1*–*3*). Typically, MR contrast agents are applied to enhance the image contrast. Clinical MR contrast agents are primarily Gd(III) complexes that can effectively reduce the relaxation time of water protons, rendering a locally brighter region in an MR image (T_1 weighted). Low sensitivity and the lack of cell specificity, however, remain as barriers to realizing the potential of MR probes.

One approach to improve MR agents is through co-registration of cells and tissues by creating a multimodal agent. Exploiting the strengths of two different imaging modalities, such as MRI and near-infrared (NIR) fluorescence imaging, can increase the accuracy of analysis (*4*–*8*). Conjugating probes that are detectable by different techniques creates agents of multimodality. For example, covalent attachment of a fluorescent probe to an MR agent results in a conjugate that reports cellular and subcellular localization via fluorescence while providing deep anatomical information by MRI (*9*, *10*). In this report, we focus on employing a class of NIR molecules known as the porphyrazines (pzs) to serve as the platform for the attachment of Gd(III) MR contrast agents.

Porphyrazines, or tetraazaporphyrins, resemble the porphyrins in structure, but the *meso*-CH groups linking the pyrrole rings are replaced by nitrogen atoms. The pzs are prepared via a different synthetic route than the porphyrins; this synthetic pathway enables the pzs to be more easily functionalized than the porphyrins (*11*). Pzs exhibit intense optical absorption ($\varepsilon > 10^5$) and fluorescence at short wavelengths (~300−400 nm) and NIR wavelengths (~700−900 nm) (*12*). The NIR emission bands of pzs appear beyond the absorption of hemoglobin ($\lambda \approx 700$ nm) and before the onset of absorption by water ($\lambda \approx 900$ nm), minimizing interference in the imaging of tissues (*13*). In addition, certain pzs accumulate preferentially in tumor tissues and show marked phototoxicity due to their excellent quantum yield of singlet oxygen generation. These properties make pzs extremely attractive as potential tumor optical imaging and photodynamic therapy (PDT) agents (*14*–*17*).

Herein, we exploit the structural flexibility of pzs and apply click chemistry to covalently attach a specific number of Gd(III) complexes to the periphery of zinc metalated pzs. The photophysical properties that make pzs advantageous for biological applications are preserved upon the attachment of Gd(III) complexes, and the resulting Zn-Pz-Gd(III) conjugates have improved magnetic relaxivities relative to current clinical MR contrast agents. Furthermore, these modified Zn-Pz-Gd(III) complexes exhibit enhanced water solubility compared to previously studied pz agents and can be tailored to exhibit selective cellular uptake. Thus, they represent a promising new

class of multimodal and multifunctional diagnostic agents for tumor imaging and therapy.

EXPERIMENTAL PROCEDURES

Materials. All solvents and chemicals were of reagent-grade quality, purchased from Sigma-Aldrich Chemical Co., and used without further purification unless otherwise noted. Thin-layer chromatography (TLC) and column chromatography were performed with 25 DC-Plastikfolien Kieselgel 60 F254 (Merck), and Baxter silica gel 60 Å (230−400 mesh), respectively.

Instrumentation. Nuclear magnetic resonance (NMR) spectra were obtained using a Varian Inova 500 MHz spectrometer. Matrix-assisted laser desorption ionization time-of-flight mass spectra (MALDI-TOF-MS) were recorded on a PE Biosystems Voyager System 6050, using 2,5-dihydroxybenzoic acid as the matrix. High-performance liquid chromatography (HPLC) analyses and preparation were performed on a Varian Prepstar system (Varian Instruments Inc., USA) using a reverse-phase HPLC column (Atlantis C18, Waters, USA). Electrospray ionization mass spectra (ESI-MS) were recorded using a Micromass Quattro II Electronic HPLC/MS/MS mass spectrometer. UV−vis spectra were recorded on an Agilent 8453 UV−vis spectrometer. Fluorescence measurements were conducted on a Hitachi F-4500 fluorescence spectrophotometer. Relaxivity was measured on a Bruker 60 MHz, at 37 °C. Doubly distilled deionized water was obtained from a Millipore-Q system to 18 MΩ·cm resistivity.

Synthesis. 1-Azido-3-aminopropane, Gd(III)-DOTA derivative (MW = 595 g/mol, **Gd595**), and Pzs **1** and **11** were prepared according to literature (*18–20*).

Pz-1acid. *H_2[Pz(A_2); (SC_4O_2Pr)$_3$(SC_4O_2H)$_1$], A = 3,6 Bis(isopropyloxy)-1,2-benzo (***5***).* Thirty milliliters of 0.4 M LiOH aqueous solution was added to a solution of pz **1** (260 mg, 0.20 mmol) in 20 mL THF and stirred at room temperature for 1.5 h. THF was removed by rotary evaporation, and 0.1 M HCl(aq) was added dropwise until the solution was acidic, followed by extraction with CH_2Cl_2. The organic phase was dried with Na_2SO_4 and evaporated under reduced pressure. The resulting residue was purified by column chromatography on silica gel (eluent AcOEt/CH_2Cl_2 = 5:95, MeOH/CH_2Cl_2 = 1/99) to give **5** as a green solid (50 mg, 20%). 145 mg starting material **1** was recovered from the column chromatography. ^{1}H NMR (400 MHz, $CDCl_3$) δ −0.52 (br s, 2H), 0.73 (m, 9H), 1.40 (m, 6H), 1.79 (m, 24H), 1.98 (m, 8H), 2.57 (m, 8H), 3.83 (m, 6H), 4.21 (m, 8H), 5.26 (sept, J = 5.6 Hz, 4H), 7.71 (d, J = 5.6 Hz, 4H); APCI-MS m/z 1245.5 (M + H$^+$) calcd for $C_{61}H_{81}N_8O_{12}S_4$ 1245.5.

Pz-1azide. *H_2[Pz(A_2); (SC_4O_2Pr)$_3$($SC_4ONHC_3N_3$)$_1$], A = 3,6 Bis(isopropyloxy)-1,2-benzo.* Pz-1acid **5** (40 mg, 0.032 mmol), *N*-hydroxysuccinimide (NHS) (18 mg, 0.16 mmol), and *N,N′*-dicyclohexylcarbodiimide (DCC) (33 mg, 0.16 mmol) were dissolved in 5 mL of THF and stirred at room temperature overnight. The mixture was concentrated to dryness and redissolved in CH_2Cl_2. The mixture was filtered, and the solid was washed with CH_2Cl_2. The filtrate and washings were combined, evaporated to dryness under reduced pressure, and dissolved in 4 mL of THF. 1-Azido-3-aminopropane (16 mg, 0.16 mmol), dissolved in 1 mL of THF, was added, and the mixture was stirred at room temperature for 2 h. The final mixture was concentrated and purified by TLC on silica gel (eluent CH_3OH/CH_2Cl_2 = 5/95) to give **Pz-1azide** as a green solid (34 mg, 80%). ^{1}H NMR (500 MHz, $CDCl_3$) δ −0.52 (br s, 2H), 0.75 (m, 9H), 1.45 (m, 8H), 1.81 (m, 24H), 2.00 (sept, J = 7.0 Hz, 8H), 2.57 (t, J = 7.5 Hz, 6H), 2.61 (t, J = 7.5 Hz, 2H), 3.01 (m, 4H), 3.85 (m, 6H), 4.01 (t, J = 6.5 Hz, 2H), 4.22 (t, J = 7.0 Hz, 4H), 4.29 (t, J = 7.0 Hz, 2H), 5.30 (m, 4H), 6.35 (t, J = 6.0 Hz, 1H), 7.59 (m, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 10.5, 22.0, 23.01, 23.03, 23.1, 25.8, 28.9, 30.0, 33.0, 33.2, 34.9, 35.0, 36.9, 49.2, 66.1, 66.3, 72.5, 72.6, 73.6, 118.8, 118.6, 118.4, 120.1, 128.7, 137.6, 139.2, 140.0, 149.4, 149.9, 150.4, 173.0, 173.3, 173.5; MALDI-MS m/z 1327.6 (M + H$^+$) calcd for $C_{64}H_{87}N_{12}O_{11}S_4$ 1327.5.

Zn-Pz-1acid. *Zn[Pz(A_2); (SC_4O_2Pr)$_3$($SC_4ONHC_3N_3$)$_1$], A = 3,6 Bis(isopropyloxy)-1,2-benzo (***6***).* **Pz-1azide** (34 mg, 0.026 mmol) and 10 equiv of zinc chloride were dissolved in 5 mL of DMF. The solution was stirred at room temperature under nitrogen. The metalation procedure was monitored by UV−vis spectroscopy (24−36 h). The mixture was evaporated to dryness under reduced pressure, dissolved in CH_2Cl_2, and twice washed with H_2O. The organic phase was concentrated and purified by TLC on silica gel (eluent CH_3OH/CH_2Cl_2 = 5/95) to give **6** as a green solid (28 mg, 86%). ^{1}H NMR (500 MHz, $CDCl_3$) 0.71 (m, 9H), 1.40 (m, 8H), 1.82 (m, 24H), 1.98 (m, 8H), 2.51 (m, 8H), 3.34 (m, 4H), 3.67 (m, 6H), 4.16 (m, 8H), 5.31 (m, 4H), 6.15 (s, 1H), 7.79 (d, J = 5.0 Hz, 2H), 7.56 (s, 2H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 10.4, 10.5, 22.0, 22.96, 23.04, 23.1, 25.8, 25.9, 30.0, 33.1, 35.0, 36.3, 48.5, 66.1, 66.2, 72.2, 72.4, 73.6, 128.9, 130.0, 140.9, 149.7, 149.9, 150.6, 172.7, 173.55, 173.61; ESI-MS m/z 1389.8 (M + H$^+$) calcd for $C_{64}H_{85}N_{12}O_{11}S_4Zn$ 1389.5.

Zn-Pz-1Gd(III). *Zn[Pz(A_2); (SC_4O_2Pr)$_3$(SC_4ONHC_3Gd)$_1$], A = 3,6 Bis(isopropyloxy)-1,2-benzo.* Gd595 (17.0 mg, 0.029 mmol), copper sulfate (1.9 mg, 0.012 mmol), sodium ascorbate (3.4 mg, 0.044 mmol), and pz **6** (13.0 mg, 0.009 mmol) were dissolved in 4 mL of water/DMF (v/v = 1:1). The reaction mixture was heated in an oil bath at 70 °C overnight. After cooling, the reaction mixture was loaded into a dialysis bag with MWCO 100 and dialyzed for 48 h against Millipore water. The final reaction mixture was reconcentrated and passed through a sephadex LH20 column using MeOH as the eluent to give **Zn-Pz-1Gd(III)** as a green solid (86.1%). MALDI-MS m/z 1985.8 (M + H$^+$) calcd for $C_{83}H_{113}GdN_{17}O_{18}S_4Zn$ 1985.6.

Pz-4azide. *H_2[Pz(A_2); ($SC_4ONHC_3N_3$)$_4$], A = 3,6 Bis(isopropyloxy)-1,2-benzo.* Pz **2** (44 mg, 0.039 mmol), *N*-hydroxysuccinimide (NHS) (90 mg, 0.79 mmol), and *N,N′*-dicyclohexylcarbodiimide (DCC) (55 mg, 0.79 mmol) were dissolved in 10 mL of THF and stirred at room temperature overnight. The mixture was concentrated to dryness and redissolved in CH_2Cl_2. The resulting suspension was filtered, and the solid was washed with CH_2Cl_2. The filtrate and washings were combined, evaporated to dryness under reduced pressure, and redissolved in 5 mL of THF. 1-Azido-3-aminopropane (53 mg, 0.79 mmol) in 5 mL of THF was added, and the mixture was stirred at room temperature for 2 h. The mixture was concentrated and purified by column chromatography on silica gel (eluent CH_3OH/CH_2Cl_2 = 2/98) to give **Pz-4azide** as a green solid (31 mg, 54%). ^{1}H NMR (500 MHz, $CDCl_3$) δ −0.54 (br s, 2H), 1.49 (m, 8H), 1.79 (d, J = 6.5 Hz, 24H), 1.96 (m, 8H), 2.53 (t, J = 7.5 Hz, 8H), 3.01 (m, 16H), 4.15 (m, 8H), 5.26 (sept, J = 6.0 Hz, 4H), 6.36 (s, 4H), 7.57 (s, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 22.1, 23.1, 26.2, 28.8, 30.0, 35.0, 35.5, 37.0, 49.3, 73.2, 119.5, 129.0, 139.1, 149.9, 172.9; ESI-MS m/z 1447.9 (M + H$^+$) calcd for $C_{64}H_{87}N_{24}O_8S_4$ 1447.6.

Zn-Pz-4azide. *Zn[Pz(A_2); ($SC_4ONHC_3N_3$)$_4$], A = 3,6 Bis(isopropyloxy)-1,2-benzo, (***3***).* **Pz-4azide** (29 mg, 0.019 mmol) and 10 equiv of zinc chloride were dissolved in 5 mL of DMF. The resulting solution was heated to 70 °C under nitrogen. The metalation procedure was monitored by UV−vis spectroscopy (24−36 h). The mixture was evaporated to dryness under reduced pressure and redissolved in CH_2Cl_2. The solution was washed with equal volumes of brine twice. The organic phase was dried over Na_2SO_4, concentrated under reduced pressure, and purified by TLC on silica gel (eluent CH_3OH/CH_2Cl_2 = 5/95) to give **3** as a green solid (26 mg, 86%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 1.12 (m, 8H), 1.37 (m, 8H), 1.71 (d, J = 6.0

Hz, 24H), 2.00 (m, 8H), 2.51 (m, 8H), 2.83 (t, $J = 6.0$ Hz, 8H), 3.75 (m, 8H), 5.27 (sept, $J = 6.0$ Hz, 4H), 6.29 (t, $J = 5.5$ Hz, 4H), 7.52 (s, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 23.0, 25.7, 28.4, 34.4, 35.2, 36.8, 49.0, 73.3, 119.1, 129.2, 149.7, 154.6, 156.1, 172.8; ESI-MS *m/z* 1509.3 ($M + H^+$) calcd for $C_{64}H_{85}N_{24}O_8S_4Zn$ 1509.5.

Zn-Pz-4Gd(III). *Zn[Pz(A$_2$); (SC$_4$ONHC$_3$Gd)$_4$], A = 3,6 Bis-(isopropyloxy)-1,2-benzo.* Gd595 (44 mg, 0.074 mmol), copper sulfate (3.8 mg, 0.024 mmol), sodium ascorbate (8.7 mg, 0.044 mmol). and Zn-Pz-4azide **3** (25.0 mg, 0.017 mmol) were dissolved in 8 mL of a water/DMF (v/v = 1:1) mixture. The reaction mixture was heated in an oil bath at 70 °C overnight. After cooling, the reaction mixture was loaded into a dialysis bag with MWCO 100 and dialyzed for 48 h against Millipore water. The resulting solution was reconcentrated and run through a Chelax column to ensure the complete removal of copper ions. Finally, the product was purified with reverse-phase HPLC using a water/acetonitrile gradient to give **Zn-Pz-4Gd** as a green solid (40 mg, 62%). MALDI-TOF-MS *m/z* 3893.1 ($M + H^+$) calcd for $C_{140}H_{197}Gd_4N_{44}O_{36}S_4Zn$ 3894.0.

Bis(2-azidoethyl) Amine. A solution of bis(2-chloroethyl) amine hydrochloride (3.57 g, 20.0 mmol) and sodium azide (7.80 g, 120 mmol) in 20 mL H_2O was heated to 80 °C for 15 h. After removing the water by distillation, the reaction mixture was cooled in an ice bath. Diethyl ether (20 mL) and KOH (pellets 1.6 g) were added in small portions. The solution was stirred at room temperature for 2 h. After separation of the organic phase, the aqueous layer was extracted with diethyl ether. The combined organic layers were dried over Na_2SO_4, concentrated, and purified by column chromatography (eluent AcOEt/CH_2Cl_2 = 5/95) to give **6** as a pale yellow liquid (2.05 g, 66%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 1.56 (s, 1H), 2.81 (t, $J = 6.0$ Hz, 4H), 3.42 (t, $J = 6.0$ Hz, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 48.4, 51.6, 53.7; ESI-MS *m/z* 156.2 ($M + H^+$) calcd for $C_4H_9N_7$ 156.1.

Pz-8azide. *H$_2$[Pz(A$_2$); (SC$_4$ON(C$_2$N$_3$)$_2$)$_4$], A = 3,6 Bis(isopropyloxy)-1,2-benzo.* Pz **2** (64 mg, 0.057 mmol), 1-hydroxybenzotriazol hydrate (HOBT) (62 mg, 0.46 mmol), dicyclohexylcarbodiimide (DCC) (94 mg, 0.46 mmol), and **6** (178 mg, 1.15 mmol) were dissolved in 10 mL of THF and stirred at room temperature for 2 days. The suspension was filtered and washed with cold THF. The combined filtrates were evaporated to dryness and purified by column chromatography on silica gel (eluent CH_3OH/CH_2Cl_2 = 2/98) followed by TLC (eluent CH_3OH/CH_2Cl_2 = 2/98) to give **Pz-8azide** as a green solid (53 mg, 56%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 0.53 (br s, 2H), 1.80 (d, $J = 6.0$ Hz, 24H), 1.97 (m, 8H), 2.66 (t, $J = 7.0$ Hz, 8H), 3.33 (m, 32H), 4.28 (t, $J = 6.5$ Hz, 8H), 5.27 (sept, $J = 6.0$ Hz, 4H), 7.58 (s, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 23.1, 25.6, 31.5, 35.2, 46.4, 48.2, 49.5, 50.1, 72.8, 128.8, 129.9, 138.9, 149.9, 173.0; ESI-MS *m/z* 1667.5 ($M + H^+$) calcd for $C_{68}H_{91}N_{36}O_8S_4$ 1667.7.

Zn-Pz-8azide. *Zn[Pz(A$_2$); (SC$_4$ON(C$_2$N$_3$)$_2$)$_4$], A = 3,6 Bis(isopropyloxy)-1,2-benzo, (**4**).* **Pz-8azide** (37 mg, 0.022 mmol) and 10 equiv of zinc chloride were dissolved in 5 mL DMF. The solution was heated to 70 °C under nitrogen protection. The metalation procedure was monitored by UV−vis spectroscopy (24−36 h). The mixture was evaporated to dryness under reduced pressure and redissolved in CH_2Cl_2. The solution was washed with equal volumes of H_2O twice. The organic phase was concentrated and purified by thin-layer chromatography on silica gel (eluent CH_3OH/CH_2Cl_2 = 5/95) to give **4** as a green solid (33 mg, 86%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 1.71 (m, 8H), 1.79 (d, $J = 6.5$ Hz, 24H), 2.44 (m, 8H), 2.95 (m, 16H), 3.10 (m, 16H), 4.10 (m, 8H), 5.33 (sept, $J = 6.0$ Hz, 4H), 7.58 (s, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ 23.0, 25.5, 31.3, 35.2, 46.2, 48.1, 49.2, 49.8, 72.5, 128.9, 149.8, 154.6, 155.8, 173.0; ESI-MS *m/z* 1729.8 ($M + H^+$) calcd for $C_{68}H_{89}N_{36}O_8S_4Zn$ 1729.6.

Zn-Pz-8Gd(III). *Zn[Pz(A$_2$); (SC$_4$ON(C$_2$Gd)$_2$)$_4$], A = 3,6 Bis-(isopropyloxy)-1,2-benzo.* Gd595 (97 mg, 0.16 mmol), copper sulfate (5.6 mg, 0.035 mmol), sodium ascorbate (19 mg, 0.098 mmol), and Zn-Pz-8azide **5** (31.0 mg, 0.019 mmol) were dissolved in 10 mL of water/DMF (1:1) mixture. The reaction mixture was heated in an oil bath at 70 °C overnight. After cooling, the reaction mixture was loaded into a dialysis bag with MWCO 100 and dialyzed for 48 h against Millipore water. The resulting solution was reconcentrated and run through a Chelex column to ensure the complete removal of copper ions. The product was purified with reverse-phase HPLC using water/acetonitrile gradient to give **Zn-Pz-8Gd** as a green solid (60 mg, 50%). MALDI-TOF-MS *m/z* 6496.5 ($M + H^+$) calcd for $C_{220}H_{313}Gd_8N_{76}O_{64}S_4Zn$ 6498.6.

Relaxivity (r_1). Solutions of Zn-Pz-*n*Gd(III) conjugates were prepared in 500 μL of Millipore water for T_1 acquisition. T_1 (spin−lattice relaxation time) was determined at 60 MHz (1.41 T) and 37 °C using an inversion recovery pulse sequence on a Bruker mq60 minispec NMR spectrometer with 4 averages, 15 s repetition time, and 10 data points (Bruker Canada; Milton, Ontario, Canada). The starting and final Gd(III) concentrations of the solutions were determined using inductively coupled plasma-mass spectrometer (ICP-MS). The inverse of the longitudinal relaxation time ($1/T_1$, s^{-1}) was plotted against Gd(III) concentration (mM) and fitted to a straight line with $R^2 > 0.99$. The slope of the fitted line was recorded as the relaxivity, r_1.

General Cell Culture. Cell lines were obtained from American Type Culture Collection (Manassas, VA, USA), and all media, Dulbecco's phosphate buffered saline (DPBS), and 0.25% trypsin/EDTA solutions were purchased from Invitrogen (Carlsbad, CA, USA). Human pulmonary adenocarcinoma cell line (A549) and a SV40 transformed embryonic cell line (WI-38 VA13) were used in this study. The A549 cell line was grown in RPMI 1640 media supplemented with 10% fetal calf serum heat inactivated at 56 °C for 30 min, 2 mM L-glutamine, 100 μg/mL streptomycin, 100 U/mL penicillin, and 2.5 μg/mL Amphotericin B solution. The WI-38 VA13 cell line was grown in Minimum Essential Medium (MEM) with Earle's salts supplemented with 10% fetal calf serum heat-inactivated at 56 °C for 30 min, 2 mM L-glutamine, 100 μg/mL streptomycin, 100 U/mL penicillin, and 2.5 μg/mL Amphotericin B solution, as well as 100 μM MEM nonessential amino acids and 1 mM sodium pyruvate. All experiments were performed in the aforementioned cell-specific media in a 5.0% CO_2 incubator operating at 37 °C.

Confocal Laser Scanning Microscopy (CLSM). Cells were seeded on glass coverslips in round 10 cm^2 plates and allowed to grow to 60−80% confluency. Media solutions for staining cells were prepared from a 5 mM solution in water for Zn-Pz-4Gd(III) and Zn-Pz-8Gd(III), in DMSO for Zn-Pz-1Gd(III). After 24 h incubation with pz-Gd(III) complexes, coverslips were rinsed twice with PBS and placed onto microscope slides with imaging buffer for live cell imaging. The imaging buffer used for live-cell imaging was prepared using a literature procedure (*21*). Images were acquired on a Zeiss LSM 510 inverted microscope (computer controlled using Zeiss Zen software) equipped with a mode-locked Mai Tai DeepSee Ti: sapphire two-photon laser (Spectra Physics, Mountain View, CA, USA). Specifically, pz-Gd(III) conjugates were excited using the 750 nm wavelength of the two-photon laser and imaged with a PMT through a band-pass 390−465 nm emission filter. Images of cells stained with pz-Gd(III)s and associated vehicle controls were taken at the same gain and amplitude settings.

MR Imaging. For cell phantoms, ~1.5 × 10^6 cells were incubated with 50 or 100 μM [Gd(III)] concentrations of Pz-Gd(III) conjugates for 18 h at 37 °C, rinsed three times with DPBS buffer, and harvested with trypsin. After the addition of complete media (1.0 mL total volume), cells were added to flame-sealed 53/4″ Pasteur pipettes and centrifuged at 4.0 °C and 100 × *g* for 5 min to form pellets with a diameter of approximately 1 mm.

Cell pellets were arranged around a tube of water and imaged on a 4.7 T (200 MHz) Bruker Biospec 4740 MR imager (Bruker Corporation, Billerica, MA). The radiofrequency coil used was a volume coil with 38 mm internal diameter (Rapid MR International, Columbus, OH). Images were acquired by a standard T_2-weighted multislice multiecho sequence with TR = 750 ms, TE ranging from 15−60 ms, matrix size 128 × 128, FOV = 25 × 25 × 1 mm^3.

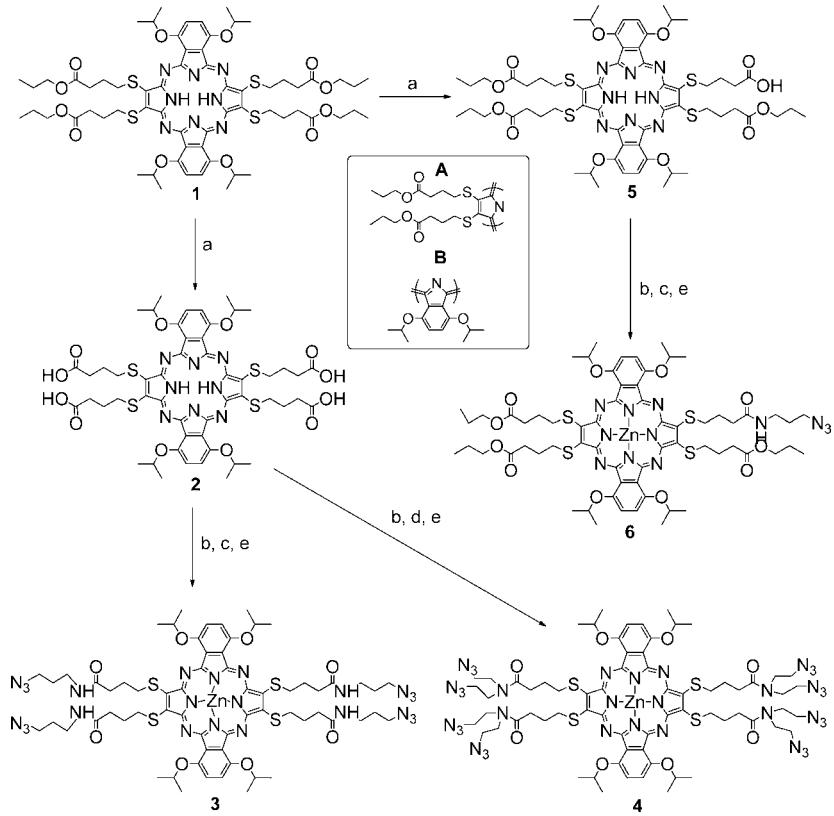
Inductively Coupled Plasma−Mass Spectrometry (ICP-MS). ICP-MS was performed on either a computer-controlled (*Plasmalab* software) Thermo PQ ExCell ICP-MS (Thermo Fisher Scientific, Waltham, MA) equipped with a CETAC 500 autosampler or a computer-controlled (*Plasmalab* software) Thermo X series II ICP-MS equipped with an ESI SC-2 autosampler (Omaha, NE, USA). Each sample was acquired using 1 survey run (10 sweeps) and 3 main (peak jumping) runs (100 sweeps). The isotopes selected were ^{156,157}Gd for acquisition, with ^{115}In, ^{165}Ho, and ^{209}Bi as internal standards for data interpolation and machine stability.

Cell Viability Assays. Zn-Pz-*n*Gd(III) solutions were prepared as 5 mM stock solutions in either DMSO [Zn-Pz-1Gd(III)] or H_2O [Zn-Pz-4Gd(III), Zn-Pz-8Gd(III)]. A549 and WI-38 VA13 cells were seeded into 96-well microtiter plates and grown until they were approximately 70% confluent. The plates were treated in the dark with 50, 25, or 12.5 μM pz-Gd(III) or a volume of DMSO or H_2O equivalent to the volume of compound added at these concentrations. The plates were incubated for 72 h, after which the media was removed and replaced with 100 μL of a 2 g/L solution of 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) in DPBS. The plates were then incubated for 5 h. During this incubation, purple formazan crystals formed because of the cleaving of the tetrazolium ring of the MTT molecules by the mitochondrial dehydrogenases of viable cells. Following the 5 h incubation, the supernatant was removed and 100 μL of DMSO was added to each well to dissolve the remaining formazan crystals. A SpectraMax Plus 384 spectrophotometer (Molecular Devices, Sunnyvale, CA, USA) was used to record the absorbance at 540 nm for each well. Each data point represents the average of at least four microtiter wells for each plate, and a minimum of two independent trials were carried out for each experiment. Data was normalized and averaged such that the final reported values represent at least eight independent values for each reported condition, for each cell line. Data points lying outside of two standard deviations from the mean were removed.

Phototoxicity Assays. Zn-Pz-*n*Gd(III) solutions were prepared as 5 mM stock solutions in either DMSO [Zn-Pz-1Gd(III)] or H_2O [Zn-Pz-4Gd(III) and Zn-Pz-8Gd(III)]. Two identical 96-well microtiter plates were seeded with A549 and WI-38 VA13 cells; the cells were established to ~70% confluency. The cells were treated with 50 μM Pz-Gd(III), and the plates were incubated for an additional 24 h. A volume of DMSO or H_2O equivalent to 50 μM were used as negative controls, and Photofrin (HpD, 50 μM) was used as a positive control. Following the 24 h incubation, aluminum foil was wrapped around the sides and top of the first plate, leaving the bottom of the plate uncovered for illumination. The second plate was completely wrapped in aluminum foil to inhibit light from reaching the cells and served as the dark control. The two plates were then placed on top of a standard X-ray illuminator (consisting of four 15 W bulbs, ~3600 total lumens) and exposed to 10 min of white light. The plates were placed back into the incubator for an additional 24 h, after which time MTT cytotoxicity assays were performed as described above. Each data point represents the average of at least four microtiter wells for each plate. Data was normalized and averaged such that the final reported values represent at least four independent values for each reported condition and for each cell line. Data points lying outside 2 standard deviations from the mean were removed.

RESULTS AND DISCUSSION

Synthesis. Since the synthesis of the first optical/MRI contrast agent, a monomeric Gd(III) complex conjugated with tetramethylrhodamine (*22*), polymeric MR-optical agents were developed based on polylysine and dextran to increase the sensitivity of the agents (*10, 23*). Conjugation of Gd(III) complexes with polymer backbones was carried out under peptide coupling conditions in most cases (*24*). These methods, however, normally resulted in a polydispersed mixture with poor batch-to-batch reproducibility, rendering the determination of the Gd(III)-to-fluorophore ratio difficult. In the present work, the coupling procedure adopts click chemistry where multiple Gd(III)-alkyne complexes are simultaneously attached to a pz-azide in high yield to produce monodispersed MR-optical agents (*19, 25, 26*). This click chemistry approach provides a facile means to generate new MRI contrast agents with high relaxivities and discrete molecular weights.



The synthesis starts with A_2B_2 pz **1**, prepared following literature procedures, where A has an appended sulfide moiety and B is a fused benzo group (Scheme 1) (*20*). Hydrolysis with excess LiOH(aq) affords **2** with four terminal acids, while sub-stoichiometric hydrolysis produces **5** with one terminal acid. Peptide coupling of **2** and **5** with 1-azido-3-aminopropane followed by metalation with zinc chloride yields Zn-Pz-4azide **3** and Zn-Pz-1azide **6**, respectively. In a similar fashion, coupling of **2** with bis(2-azido ethyl)amine yields Zn-Pz-8azide **4**.

Initial attempts to apply click chemistry to metal-free azido-pzs showed that pzs would sequester copper ions, resulting in a mixture of metalated and nonmetalated products. Therefore, the pz azides were metalated with zinc(II) prior to conjugation with Gd(III) complexes via click chemistry. Trans-metalation of Zn-Pzs in the presence of catalytic copper salts was not observed. In later attempts, stoichiometric copper salt was used to ensure that pzs were fully metalated and Cu-Pz-*n*Gd(III) (*n* = 4, 8) conjugates were characterized. Cu-Pz and Zn-Pz possess different optical properties, but their Gd(III) conjugates exhibit similarities in relaxivity (Table 2 and Supporting Information, Table SI-1).

Click chemistry between the Gd(III) alkyne analogue, Gd595, and pz substrates **3**, **4**, and **6** was carried out in a DMF/water (v/v = 1:1) mixture (Scheme 2). The reaction was highly efficient in conjugating one, four, and eight Gd595 molecules at the pz periphery in 50−60% yield. The resulting Zn-Pz-4Gd(III) and Zn-Pz-8Gd(III) complexes are freely water-soluble suggesting that the conjugates could be administered intravenously without the addition of a co-solvent. Zn-Pz-1Gd(III) exhibited limited water solubility but could be dissolved in a water/DMSO mixture.

UV Absorption and Fluorescence. The electronic absorption and emission features of Zn-Pz-*n*Gd(III) (*n* = 1, 4, 8) are summarized in Table 1. Similar to previously reported pzs, Zn-Pz-*n*Gd(III) conjugates display an intense Soret band (340 nm) and a pair of Q-bands (~670 nm, ~780 nm). Both Zn-Pz-

4Gd(III) and Zn-Pz-8Gd(III) exhibit dual fluorescence in water (Table 1 and Supporting Information Figure SI-5). Short-wavelength fluorescence was observed at $\lambda \approx 440$ nm, and long-wavelength near-infrared (NIR) fluorescence occurred at $\lambda \approx 815$ nm. With Zn-Pz-1Gd(III), both emission peaks were present in DMSO solution, but the 813 nm emission peak was quenched in aqueous solution (Figure 1 and Supporting Information Figure SI-6).

The NIR emission from a hydrophobic pz such as **1** is typically sensitive to the local polar environment and is quenched by water due to a combination of hydrogen bonding and aggregation (*27*). The observation of NIR fluorescence in water from Zn-Pz-*n*Gd(III) ($n = 4, 8$) compounds suggests that the hydrophilic Gd(III) complexes tethered to the pz periphery protect the pz core from interaction with water and consequent quenching. According to the Lippert-Mataga relationship, a fluorophore's stokes shift increases with the polarity of its local environment (*28*). The stokes shift of the pz-Gd(III) conjugates decrease with added Gd(III)-chelates to the periphery with Zn-Pz-8Gd(III) exhibiting the smallest effective stokes shift (in H_2O). This is in agreement with the notion that appended Gd(III) complexes protect the pz core from nonradiative de-excitation in aqueous solutions. Cu-Pz-*n*Gd(III) ($n = 4, 8$) conjugates showed weak, if any, NIR fluorescence, presumably due to enhanced spin−orbit coupling to the triplet state by the paramagnetic Cu(II). This characteristic of Cu-Pz-Gd(III) limits application in fluorescence imaging (see Supporting Information Table SI-2, Figure SI-5). However, Cu-Pz-Gd(III) conjugates can serve as model compounds for the preparation of MR-PET (positron emission topography) agents, that use ^{64}Cu as the radionuclide.

Relaxivity Properties. The efficiency of a contrast agent in reducing the longitudinal relaxation time of water protons is measured by the property known as relaxivity ($mM^{-1}\ s^{-1}$). Several major parameters influence the relaxivity, including the number of coordinated water molecules, *q*; rotational correlation time, τ_R; and mean water residence time, τ_m. Solomon-Bloembergen-Morgan theory predicts that an increase in rotational correlation time, τ_r, by slowing down the molecular tumbling of an agent in solution will result in an increase in relaxivity (*29*). A common approach to reduce molecular tumbling is by attaching small Gd(III) complexes to a macromolecule through rigid linkages (*19*, *25*, *30*).

The relaxivities of Zn-Pz-*n*Gd(III) ($n = 1, 4, 8$) at 60 MHz, 37 °C, are summarized in Table 2. As expected, the molecular relaxivities of these conjugates increase nonlinearly with the number of appended Gd(III) complexes, presumably because of increased molecular weights. Zn-Pz-1Gd(III) showed an ionic relaxivity of 4.2 $mM^{-1}\ s^{-1}$ per Gd(III), which is slightly higher than the monomeric Gd595. Zn-Pz-4Gd(III) and Zn-Pz-8Gd(III) exhibited enhanced ionic relaxivities of 10.5 $mM^{-1}\ s^{-1}$ and 12.8 $mM^{-1}\ s^{-1}$, respectively. These ionic relaxivities are ∼3−4 times higher than that of the clinically employed agent DOTA-Gd(III) at the same magnetic field strength (Dotarem, $r_1 = 2.7-3.1$ $mM^{-1}\ s^{-1}$ at 60 MHz, 37 °C; DOTA = 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid), while the molecular relaxivities range up to more than 30-fold greater (*30*). A slight difference in relaxivities was observed between Cu-Pz-*n*Gd(III) and Zn-Pz-*n*Gd(III) ($n = 4, 8$) which is likely due to the paramagnetism of Cu(II) (Supporting Information Table SI-1). Overall, these conjugates exhibit similar relaxivities to the polymer-Gd(III) conjugates reported in the literature (*32*–*34*).

Confocal Fluorescence Microscopy. Initial cellular localization and uptake studies of Zn-Pz-*n*Gd(III) conjugates were performed using confocal fluorescence microscopy in WI-38

VA13 cells, a non-tumorigenic, embryonic fibroblast-like human cell line. Cells were incubated with 50 μM Zn-Pz-*n*Gd(III) ($n = 1, 4, 8$) for 24 h and imaged for both short-wavelength (390−465 nm) and NIR (>700 nm) fluorescence. Cells that were stained with Zn-Pz-1Gd(III) displayed the short-wavelength pz fluorescence but very little NIR emission (Figure 2). This result revealed that Zn-Pz-1Gd(III) is incorporated inside the cells. Intracellular pz fluorescence is not observed from Zn-Pz-*n*Gd(III) ($n = 4, 8$) under the same condition, suggesting no cellular uptake of these two conjugates (see Supporting Information Figure SI-7).

Although the mechanism for cellular uptake and subcellular localization of the pz-Gd(III) conjugates has not been investigated, evidence has shown that low-density lipoprotein (LDL) can facilitate cellular uptake of pz analogues (*17*). In these previous studies, the hydrophobic portions of pzs were found to interact with LDL, leading to receptor-mediated cellular uptake. It is likely that Zn-Pz-1Gd(III) follows a similar uptake mechanism, involving the hydrophobic pz core of the compound. The fact that Zn-Pz-*n*Gd(III) ($n = 4, 8$) showed no observable cellular uptake further indicates that introducing a higher number of Gd(III) complexes can prohibit cellular uptake, because of either the hindered interaction of the pz with LDL or the

[a] Measured in DMSO/water, v/v = 1:5.

increased hydrophilicity. Therefore, MR imaging of cell pellets was carried out with Zn-Pz-1Gd(III).

MR Imaging and Cell Uptake. Cell pellets labeled with the Zn-Pz-1Gd(III) over a range of concentrations were imaged on a Bruker Biospec 4.7 T MR imager. Each cell pellet imaged was ~1 mm in diameter and contained ~1.5 × 10^6 cells. Image contrast was highly dependent on the incubation concentration (Figure 3A), with cells incubated at 100 μM of Zn-Pz-1Gd(III) producing a more pronounced contrast enhancement than those incubated at 50 μM in the T_1 weighted image.

To quantify the Gd(III) content in each cell pellet, ICP-MS was employed to determine the amount of Gd(III) per cell. As shown in Figure 3B, Gd(III) per cell increases linearly with the increase in cell incubation concentration. In addition, we have compared the cellular uptake between Zn-Pz-1Gd(III) and DOTA-Gd(III), which is known to be exogenous (Supporting Information Figure SI-8). The result shows that WI-38 VA13 cell uptake was 10-fold greater for Zn-Pz-1Gd(III) than for DOTA-Gd(III) when treated under the same conditions. This finding is consistent with cellular incorporation of Zn-Pz-1Gd(III).

Cellular Viability. MTT assays were performed with WI-38 VA13 cells exposed to varying concentrations of Zn-Pz-*n*Gd(III) (n = 1, 4, 8) over a 72 h period (Figure 4). Control cells were exposed to water or DMSO according to the solvent of the pz-Gd(III) stock solutions. Zn-Pz-*n*Gd(III) (n = 4, 8) showed little effect on cell viability at all three concentrations, namely, 12.5, 25, 50 μM, over 72 h (~90% viable vs control). Zn-Pz-1Gd(III) exhibited dose-dependent toxicity where only 60% of cells remained viable upon 50 μM exposure for 72 h.

Phototoxicity was measured by exposing cells to the conjugates followed by irradiation with white light for 10 min (Figure 5). Given that the Zn-Pz-*n*Gd(III) all contain the same core structure, it would be expected that all three compounds would generate similar levels of singlet oxygen and therefore exhibit similar phototoxicity effects when incorporated into cells. However, only Zn-Pz-1Gd(III) was found to show phototoxicity. Approximately 50% of the cells were killed upon treatment of Zn-Pz-1Gd(III) for 24 h and white light for 10 min. In contrast, nearly all of the cells were killed upon exposure to Photofrin under the same

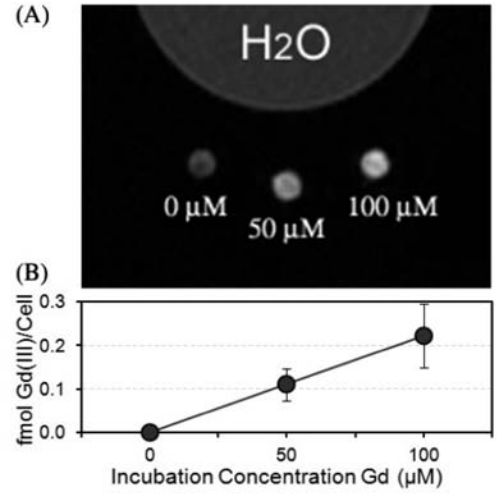

Figure 3. (A) T_1 weighted MR image of WI-38 VA13 cells incubated with 0, 50, and 100 μM of Zn-Pz-1Gd(III) for 24 h at 4.7 T. (B) Cellular uptake of Zn-Pz-1Gd(III) measured by ICP-MS corresponding to the cell pellets in the MR image of (A).

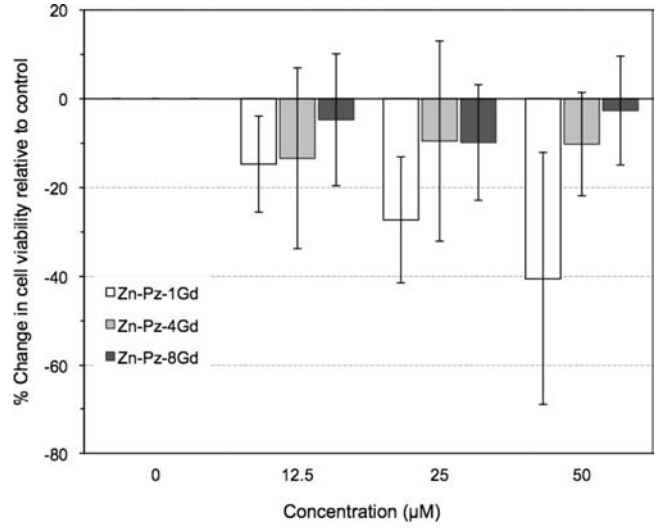

Figure 4. Concentration-dependent dark toxicity of Zn-Pz-*n*Gd(III) (n = 1, 4, 8) in WI-38 VA13 cells. Cells were incubated for 72 h for all three agents.

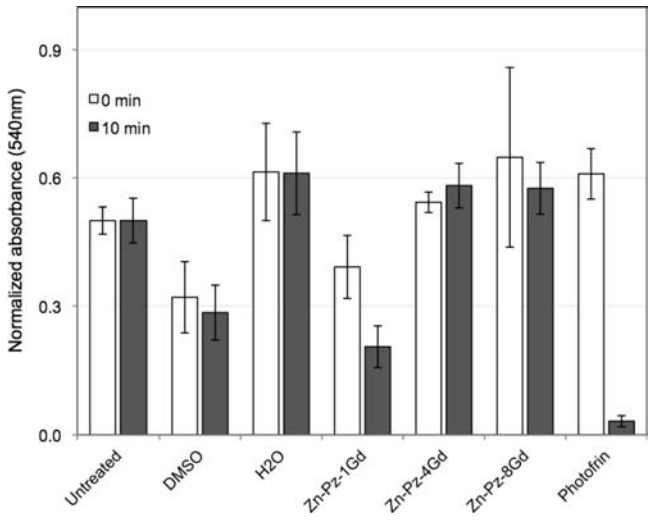

Figure 5. Phototoxicity of Zn-Pz-*n*Gd(III) ($n = 1, 4, 8$) in WI-38 VA13 cells upon 50 μM pz exposure for 24 h, followed by 0 or 10 min of white light exposure. Photofrin was used as a positive control. It is notable that Zn-Pz-1Gd(III) is the only pz-Gd(III) conjugate showing significant phototoxicity.

conditions. The lack of phototoxicity observed for Zn-Pz-4Gd(III) and Zn-Pz-8Gd(III) corresponds to our observation with confocal microscopy and MR contrast that these two conjugates are not taken up by cells, whereas Zn-Pz-1Gd(III) is.

CONCLUSION

The measurements of Pz-based-MRI multimodal probes described herein highlight numerous properties of this unique class of complexes that make them superior to Gd(III)-based MR contrast agents and optical probes. Unlike previously developed polymeric MR-optical multimodal agents, the pzs can be characterized and possess strict batch-to-batch consistency. Furthermore, the photophysical properties that make the pz class of molecules attractive for biological applications are preserved upon addition of the Gd(III) complexes, and the water solubility properties of these compounds are enhanced by the addition of the hydrophilic Gd(III) moieties. The Pz-Gd(III) conjugates possess improved ionic and molecular relaxitivites relative to well-known single-molecule MRI agents. Perhaps most importantly, we show that the biological properties of the conjugates can be tailored to achieve cellular uptake of an MR agent, as exhibited by Zn-Pz-1Gd(III).

These studies show that we have the potential to create a single pz [containing Gd(III) complexes] that can not only function as an MRI agent, but also possess a second moiety that can be used to target specific cell types (i.e., tumors). Furthermore, changing the core pz structure and/or metal ion allows us to control the antitumor functionality of the compound, suggesting that these compounds could be used as PDT agents. Thus, multimodal and multifunctional pzs, such as those described herein, have the potential to serve as dual MRI-NIR/antitumor therapeutic agents capable of targeting specific tumor types.

Experimental Procedure:

Cu-Pz-8Gd(III). Cu[Pz(A_2); ($SC_4ON(C_2Gd)_2)_4$], A = 3,6 Bis(isopropyloxy)-1,2-benzo. Gd595 (22 mg, 0.037 mmol), copper sulfate (1.3 mg, 0.008 mmol), sodium ascorbate (4.4 mg, 0.022 mmol) and Pz-8azide (7.0 mg, 0.004 mmol) were dissolved in 3 ml of water/DMF (1:1) mixture. The reaction mixture was heated in an oil bath at 70 ºC overnight. After cooling, the reaction mixture was loaded into a dialysis bag with MWCO 100 and dialyzed for 48 hrs against Millipore water. The resulting solution was re-concentrated and run through a Chelex column to ensure the complete removal of copper ions. Finally the product was purified with reverse phase HPLC using water/acetonitrile gradient to give **Cu-Pz-8Gd(III)** as a green solid (16 mg, 59%). MALDI-TOF-MS *m/z* 6497.6 ($M + H^+$) calcd for $C_{220}H_{313}CuGd_8N_{76}O_{64}S_4$: 6497.3.

Cu-Pz-4Gd(III). Cu[Pz(A_2); ($SC_4ONHC_3Gd)_4$], A = 3,6 Bis(isopropyloxy)-1,2-benzo (7). Gd595 (9.1 mg, 0.015 mmol), copper sulfate (0.8 mg, 0.005 mmol), sodium ascorbate (1.8 mg, 0.009 mmol) and PZ-4 azide (5.0 mg, 0.004 mmol) were dissolved in 2 ml water/DMF (1:1). The reaction mixture was heated in an oil bath at 70 ºC overnight. After cooling down, the reaction mixture was loaded into a dialysis bag with MWCO 100 and dialyzed for 48 hrs against Millipore water. The resulting solution was re-concentrated and run through a Chelex column to ensure the complete removal of copper ions. Finally the product was purified with reverse phase HPLC using water/acetonitrile gradient to give **Cu-Pz-4Gd(III)** as a green solid (9 mg, 67%). MALDI-TOF-MS *m/z* 3894.9 ($M + H^+$) calcd for $C_{140}H_{197}CuGd_4N_{44}O_{36}S_4$ 3893.0.

(B)

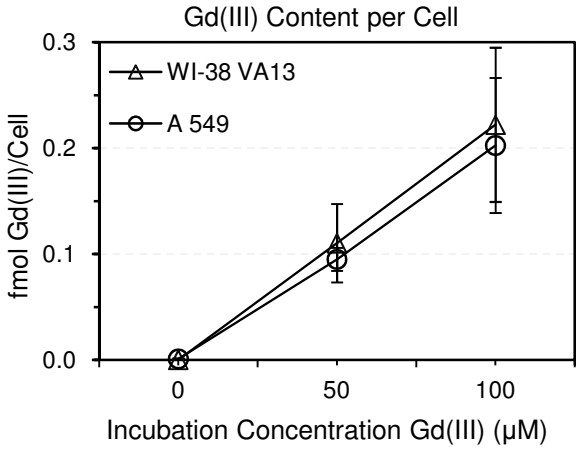

Figure SI-9. Cellular uptake of Zn-Pz-1Gd(III) measured by ICP-MS in WI-38 VA13 cells and A549 cells corresponding to the MR images in Figure SI-7. (A) Total Gd(III) content per cell pellet. (B) Gd(III) content per cell in the cell pellets.

Explanation for Figure SI-8 and Figure SI-9:

In Figure SI-8, images on the left are T_1-weighted images which were acquired with short TE (15 ms) for minimal T_2-weighting, and images on the right are T_2-weighted images which were acquired with a long TE (40 ms) to demonstrate the signal dropout due to the presence of Gd(III).

Generally in a T_1-weighted image, a higher local concentration of Gd(III) will induce higher brightness, which was observed in the T_1-weighted images of WI-38 VA13 cell pellets. However, the result with A549 cells was counter-intuitive, as the T_1 weighted images appeared darker in pellets prepared with increasing incubation concentration of Gd(III). This was due to a strong T_2-shortening effect caused by an overwhelming amount of Gd(III) in the given volume under these imaging conditions. Therefore, the high concentration of local Gd(III) caused dark images for the A549 cell pellets and the bright images for the WI-38 VA13 pellets.

Interestingly, ICP-MS studies showed that the Gd(III) count per cell was similar for both cell lines when subjected to the same incubation concentration. This result indicated that both cell lines were taking up similar amounts of Gd(III) per cell (see Figure SI-9B). Further study showed that the A549 cell pellets contained twice the amount of Gd(III) per pellet than the W-I38 VA13 cell (Figure SI-9A). Based on this evidence, we concluded that in the A549 cell pellets, twice the number of cells was packed into approximately the same volume as that of the WI-38 VA13 cells during the spin-down cell pellet preparation. Therefore, the local Gd(III) concentration was higher in A549 cell pellets and induced the T_2 effect.

The T_2-weighted image is more straightforward in Figure SI-8. Because of the increasing concentration of Gd(III), the labeled cells appeared markedly darker compared to the control cells pellets. The higher the incubation concentration of Gd(III), the darker

the pellets appeared in the image. The maximum signal dropout occurred with the A549 cells incubated at 100 μM of Zn-Pz-1Gd(III), which is consistent with the ICP-MS data showing the highest Gd(III) content in the sample (see Figure SI-7B).

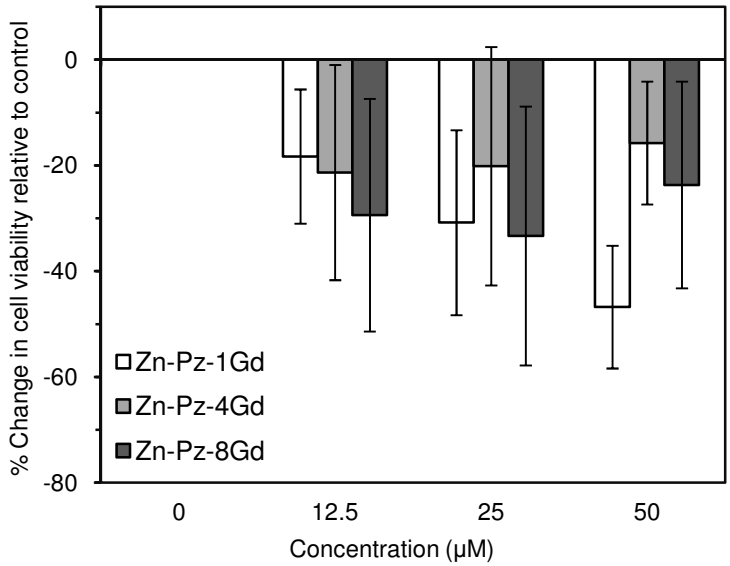

Figure SI-10. Concentration dependent dark toxicity of Zn-Pz-nGd(III) in A549 cells (n=1,4,8). Cells were incubated for 24 h for all three agents. Control for Zn-Pz-1Gd(III): cells + DMSO; control for Zn-pz-4Gd(III) or Zn-Pz-8Gd(III): cells + H_2O.

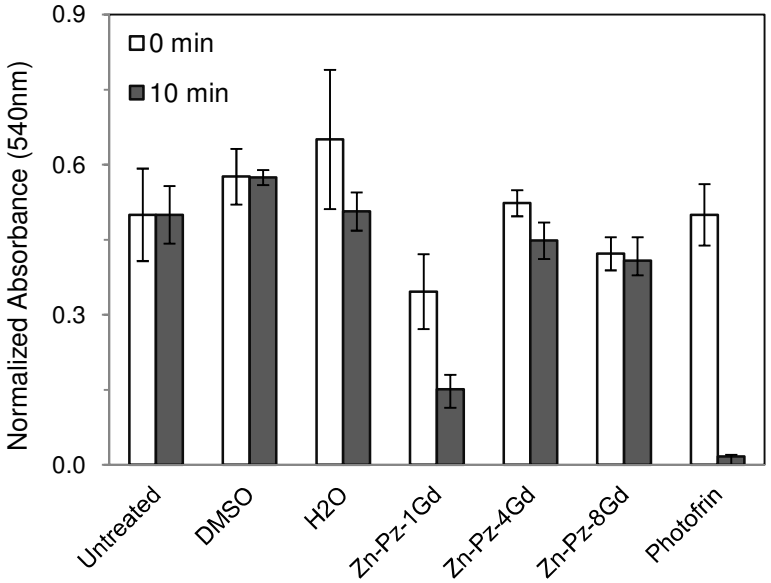

Figure SI-11. Phototoxicity of Zn-Pz-nGd(III) conjugates (n=1, 4, 8) with A549 cells at 50 μM incubation concentration. Photofrin was used as a positive control. Control for Zn-Pz-1Gd(III): cells + DMSO; control for Zn-pz-4Gd(III) or Zn-Pz-8Gd(III): cells + H_2O.

ECHO-LNA Conjugates: Hybridization-Sensitive Fluorescence and Its Application to Fluorescent Detection of Various RNA Strands

Kaori Sugizaki[†] and Akimitsu Okamoto*[,‡]

RIKEN Advanced Science Institute, 2-1 Hirosawa, Wako, Saitama 351-0198, Japan, and PRESTO, Japan Science and Technology Agency, 4-1-8 Honcho, Kawaguchi, Saitama 332-0012, Japan. Received June 30, 2010; Revised Manuscript Received August 23, 2010

Hybridization-sensitive fluorescent DNA probes containing the nucleotide units of locked nucleic acid (LNA) have been developed. Exciton-controlled hybridization-sensitive fluorescent oligonucleotide (ECHO) probes that incorporated LNA nucleotides achieved high thermostability of the hybrid with target RNA strands. The appropriately designed ECHO-LNA chimeric probes exhibited an effective on−off switching property of fluorescence depending on hybridization with RNA and facilitated fluorescent detection of the TAR RNA strand forming a hairpin structure and distinction of one base difference in PLAC4 RNA sequence.

INTRODUCTION

Ribonucleic acid (RNA) is one of many essential biomolecules responsible for the expression, maintenance, and control of cell functions. RNA is highly diverse in terms of size, structure, mass, function, location, and expression timing, as well as in sequences (*1*). In particular, the structural and sequential diversity of RNA, such as higher-ordered structure formation and one-base mutations, plays an important role in characterizing the function of RNA. Therefore, effective detection of such RNA strands is very important for understanding the cell functions.

Many fluorescent nucleic acid probes have been developed for observation of the functions of target nucleic acids (*2*−*4*). In particular, much effort has been invested in the rational design of hybridization-sensitive fluorescent probes to detect effectively the target nucleic acid using on−off switching of fluorescence depending on hybridization (*5*−*9*). However, the functions of these probes are insufficient for effective detection of a variety of RNA molecules, because accessing the RNA sequence that forms a higher-ordered structure and distinguishing the target RNA sequence from the one-base mutants are often thermodynamically difficult for fluorescent nucleic acid probes.

Incorporation of the nucleotide units of locked nucleic acid (LNA) into hybridization-sensitive probes may provide one of the more effective methods for solving such problems (*10*). Chimeric probes having select positions modified with LNA nucleotides have been reported to enhance duplex stability (*11*). In addition, LNA trinucleotides enhance the thermostability of the duplex formed with the complementary sequences, whereas the duplex stability with mismatched sequences is much lower (*12*−*14*). Incorporation of LNA nucleotides into hybridization-sensitive fluorescent DNA probes would make fluorometric detection of a variety of RNA molecules more effective. However, the bridged sugar structure of LNA nucleotides may diminish the function of hybridization-sensitive on−off switching of fluorescence. To choose the correct course for design of the fluorescent probe sequence including LNA nucleotides, the effect of LNA incorporation on the fluorescence intensity of probes needs to be estimated through several model experiments.

In this paper, we report fluorescence properties of hybridization-sensitive fluorescent probes possessing LNA nucleotides. Incorporation of LNA nucleotides into hybridization-sensitive fluorescent DNA probes provided higher thermostability with the complementary RNA strand compared with probes consisting of only 2′-deoxyribonucleotides. In addition, fluorescent detection of the RNA strand forming a hairpin structure and distinction of a one-base difference in an RNA sequence were facilitated by LNA-incorporated fluorescent probes.

EXPERIMENTAL PROCEDURES

General. Reverse-phase HPLC was performed on Chemcobond 5-ODS-H columns (10 × 150 mm) with a Gilson Chromatograph, model 305, using a Jasco multiwavelength detector, MD-2015Plus. MALDI-TOF mass spectra were measured with a Bruker Daltonics Reflex apparatus. Absorption and fluorescence spectra were recorded on a Shimadzu UV-2550 spectrophotometer and RF-5300PC spectrofluorophotometer, respectively.

Probe Synthesis. Oligonucleotides containing both LNA nucleotides and a diamino-modified nucleotide, which is a precursor of the D_{514} nucleotide, were synthesized by Gene Design (Osaka, Japan). RNA was synthesized by Japan Bio Service. DNA oligomers were synthesized by a conventional phosphoramidite method on a DNA/RNA synthesizer. Oligonucleotides containing a diamino-modified nucleotide and a 2′-*O*-methyl RNA nucleotide were synthesized through a conventional phosphoramidite method by using an H-8 DNA/RNA autosynthesizer (Nihon Techno Service). The diamino-modified nucleoside phosphoramidite was synthesized according to our previous report (*15*). The synthesized oligonucleotides were cleaved from the support with 28% aqueous ammonia and deprotected at 25 °C for 16 h. After removal of ammonia from the solution under reduced pressure, the DNA was purified by reverse-phase HPLC, followed by elution with a solvent mixture of 0.1 M triethylammonium acetate (TEAA) (pH = 7.0) and linear gradient over 20 min from 5% to 30% acetonitrile at a flow rate of 3.0 mL/min. The concentration of the oligonucleotides was determined by absorption at 260 nm.

A solution of the *N*-hydroxysuccinimidyl ester of thiazole orange pentanoic acid (*15*) (40 mM, 22 equiv to an active amino

group of an oligonucleotide) in DMF was added to a deprotected oligonucleotide solution (164 μM) in 100 mM sodium carbonate buffer (pH = 9.0) and incubated at 25 °C for 30 min. The reaction mixture was diluted with ethanol. After centrifuging at 4 °C for 20 min, the supernatant liquid was removed. The residue was dissolved in a small amount of water, and then the solution was passed through a 0.45 μm filter. The product was purified by reverse-phase HPLC on a 5-ODS-H column, elution with a solvent mixture of 0.1 M TEAA (pH = 7.0) and linear gradient over 30 min from 5% to 30% acetonitrile at a flow rate of 3.0 mL/min. The product was subsequently desalted by reverse-phase HPLC on a 5-ODS-H column, elution with a solvent mixture of deionized water, and linear gradient over 20 min from 0% to 100% acetonitrile at a flow rate of 3.0 mL/min. The concentration of the oligonucleotides was determined by absorption at 260 nm. The oligonucleotides were identified by MALDI-TOF mass spectrometry. (Here, the molecular weight of the counteranions of dyes was not included in the value of *M*, and D_{514} denotes a doubly thiazole orange-labeled deoxynucleotide. Lower-case and lower-case italic characters represent LNA and 2′-*O*-methyl RNA nucleotides, respectively. The LNA nucleotide "c" denotes a 5-methylcytosine LNA nucleotide, and the 2′-*O*-methyl RNA nucleotide "*u*" denotes a uracil 2′-*O*-methyl RNA nucleotide.): **DNA(0)**, CGCAATD$_{514}$TAACGC, calcd for $C_{180}H_{217}N_{56}O_{78}P_{12}S_2$ ([M − H]$^+$) 4848.8, found 4851.4; **LNA(−4)**, CGcAATD$_{514}$TAACGC, calcd for $C_{182}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4891.8, found 4891.3; **LNA(−3)**, CGCaATD$_{514}$TAACGC, calcd for $C_{181}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4877.8, found 4878.9; **LNA(−2)**, CGCAaTD$_{514}$TAACGC, calcd for $C_{181}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4877.8, found 4878.0; **LNA(−1)**, CGCAAtD$_{514}$TAACGC, calcd for $C_{181}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4877.8, found 4880.0; **LNA(+1)**, CGCAATD$_{514}$tAACGC, calcd for $C_{181}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4877.8, found 4879.8; **LNA(+2)**, CGCAATD$_{514}$TaACGC, calcd for $C_{181}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4877.8, found 4878.9; **LNA(+3)**, CGCAATD$_{514}$TAaCGC, calcd for $C_{181}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4877.8, found 4878.3; **LNA(+4)**, CGCAATD$_{514}$TAAcGC, calcd for $C_{182}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4891.8, found 4893.9; **OMe(−4)**, CG*c*AATD$_{514}$TAACGC, calcd for $C_{181}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4879.8, found 4879.1; **OMe(−3)**, CGC*a*ATD$_{514}$TAACGC, calcd for $C_{181}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4879.8, found 4879.2; **OMe(−2)**, CGCA*a*TD$_{514}$TAACGC, calcd for $C_{181}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4879.8, found 4879.6; **OMe(−1)**, CGCAA*u*D$_{514}$TAACGC, calcd for $C_{180}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4865.8, found 4865.5; **OMe(+1)**, CGCAATD$_{514}$*u*AACGC, calcd for $C_{180}H_{218}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4865.8, found 4865.3; **OMe(+2)**, CGCAATD$_{514}$T*a*ACGC, calcd for $C_{181}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4879.8, found 4880.6; **OMe(+3)**, CGCAATD$_{514}$TA*a*CGC, calcd for $C_{181}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4879.8, found 4879.9; **OMe(+4)**, CGCAATD$_{514}$TAA*c*GC, calcd for $C_{181}H_{220}N_{56}O_{79}P_{12}S_2$ ([M − H]$^+$) 4879.8, found 4879.5; **LNA(anti-TAR)**, GCtCcCaGGCD$_{514}$CAGaT, calcd for $C_{213}H_{256}N_{67}O_{101}P_{15}S_2$ ([M − H]$^+$) 5899.4, found 5902.0; **DNA(anti-TAR)**, GCTCCCAGGCD$_{514}$CAGAT, calcd for $C_{208}H_{254}N_{67}O_{97}P_{15}S_2$ ([M − H]$^+$) 5773.4, found 5771.4; **LNA(anti-PLAC4-C)**, AGD$_{514}$TAGacgA, calcd for $C_{157}H_{183}N_{50}O_{62}P_9S_2$ ([M − H]$^+$) 4105.3, found 4107.3; **DNA(anti-PLAC4-C)**, AGD$_{514}$TAGACGA, calcd for $C_{153}H_{181}N_{50}O_{59}P_9S_2$ ([M − H]$^+$) 4007.3, found 4008.5; **LNA(anti-PLAC4-T)**, AGD$_{514}$TAGatgA, calcd for $C_{157}H_{182}N_{49}O_{63}P_9S_2$ ([M − H]$^+$) 4106.3, found 4106.8; **DNA(anti-PLAC4-T)**, AGD$_{514}$TAGATGA, calcd for $C_{154}H_{182}N_{49}O_{60}P_9S_2$ ([M − H]$^+$) 4022.3, found 4022.8.

Melting Temperature. The melting temperature (T_m) values of duplexes (1.0 μM) were measured in 50 mM sodium phosphate (pH = 7.0) containing 100 mM sodium chloride. The absorbance of the samples was monitored at 260 nm from 10 to 90 °C with a heating rate of 0.5 °C min^{-1}. From these profiles, first derivatives were calculated to determine the value of T_m.

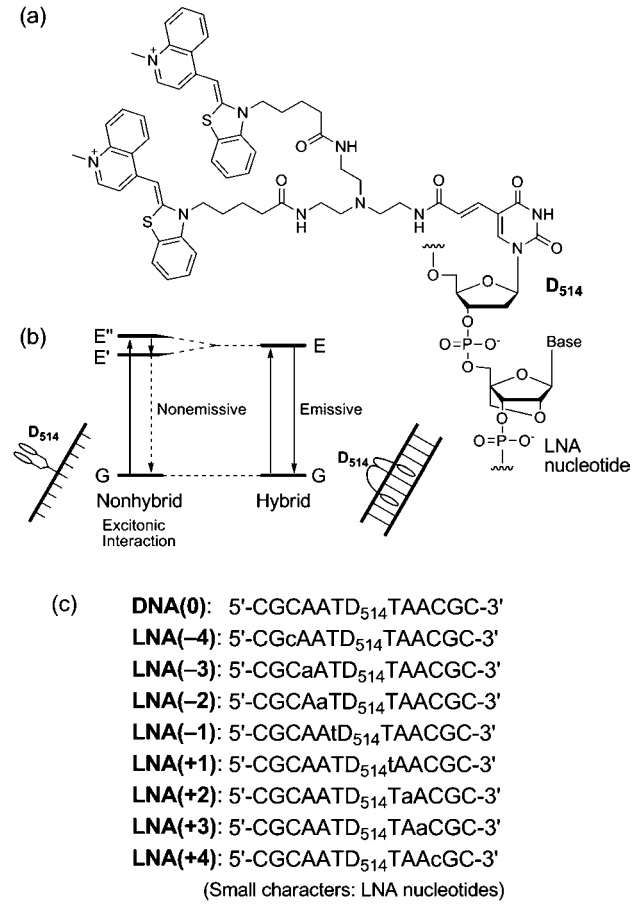

Figure 1. Structures and functions of the fluorescent probes. (a) A hybridization-sensitive fluorescent nucleotide D_{514} and an LNA nucleotide. (b) Schematic representation of the energy levels of the single- and double-stranded states of the hybridization-sensitive fluorescent DNA probe controlled by excitonic interaction between the fluorescent dyes of D_{514}. (c) Probe sequences in this study.

Absorption and Fluorescence Spectra. Absorption and fluorescence spectra of the fluorescent probes (0.4 μM) in the absence or presence of the target RNA (0.4 μM) were measured in 50 mM sodium phosphate (pH = 7.0) containing 100 mM sodium chloride using a cell with a 1 cm path length. The excitation and emission bandwidths were 1.5 nm. A water circulator EYELA NCB-1200 was connected to the spectrofluorophotometer for programmed temperature control in Figures 5 and 6.

CD Spectra. CD spectra of the fluorescent probes (2.5 μM) in the absence or presence of the target RNA (2.5 μM) were measured in 50 mM sodium phosphate (pH = 7.0) containing 100 mM sodium chloride using a cell with a 0.1 cm path length.

RESULTS AND DISCUSSION

ECHO-LNA Chimeric Probe. We prepared a hybridization-sensitive fluorescent probe including an LNA nucleotide. Exciton-controlled hybridization-sensitive fluorescent oligonucleotide (ECHO) probes have been developed for the function of hybridization-sensitive on−off switching of fluorescence (Figure 1) (*15*, *16*). This DNA probe is a new type of hybridization-sensitive probe, which has a doubly fluorescence-labeled nucleotide to achieve high fluorescence intensity for a hybrid with the target nucleic acid and effective quenching of a single-stranded probe (*17*−*22*). An excitonic interaction between the fluorescence dyes linked covalently to a single

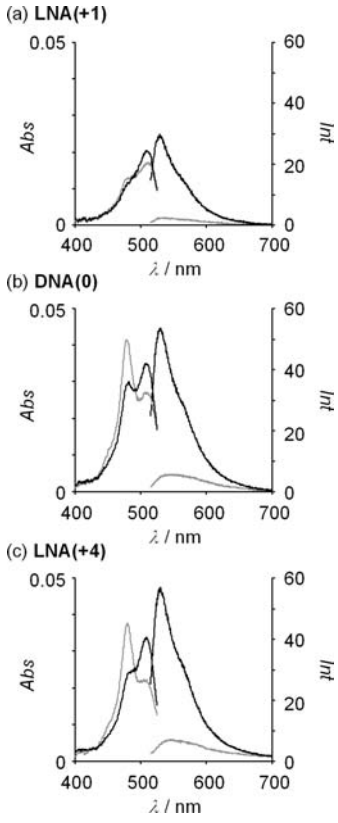

Figure 2. Absorption and emission spectra of ECHO probes. Gray lines, probes before hybridization; black lines, probes hybridized with the corresponding complementary RNA. Emission spectra were recorded with excitation at 488 nm.

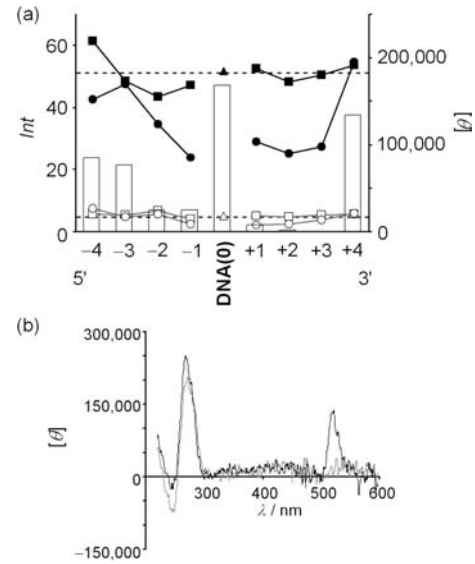

Figure 3. Effect of site incorporating LNA on the intensity of fluorescence emission and induced CD. (a) Intensity of fluorescence emission at 532 nm and induced CD at 520 nm. The fluorescence intensities of LNA-incorporated probes (open circles), and their hybrids with complementary RNA (closed circles), 2′-*O*-methyl RNA-incorporated probes (open squares), and their hybrids with complementary RNA (closed squares) are presented, together with the fluorescence intensity of the probe with an unmodified DNA backbone, **DNA(0)** (an open triangle and an accompanying dot line), and its hybrid with the complementary RNA (a closed triangle and an accompanying dotted line). The intensities of the induced CD of LNA-incorporated probes are shown by the height of the bars at each LNA incorporation site. (b) Typical CD spectra showing a strong or negligible induced CD signal. Gray and black lines are CD spectra of **LNA(+1)** and **LNA(+4)** hybridized with the complementary RNA, respectively.

nucleotide in a probe was produced by the formation of an H-aggregate between dyes, and as a result, emission from the probe was suppressed through splitting of the excited state (*23*). Dissociation of dye aggregates by hybridization with the complementary RNA resulted in disruption of the excitonic interaction and a strong emission from the hybrid.

We initially synthesized a probe with an LNA nucleotide incorporated next to the thiazole orange dye-labeled nucleotide (D_{514}). The chimeric probe **LNA(+1)** showed hybridization-sensitive fluorescence emission at 531 nm when hybridized with the complementary RNA, but the fluorescence emission of the probe itself was much weaker (Figure 2a). A shift in the absorption band, which is characteristic for H-aggregation of dyes, was also observed. The absorption shift and fluorescence switching suggest that the fluorescence emission of ECHO probes modified by an LNA nucleotide was controlled by excitonic interaction between fluorescence dyes. However, the fluorescence intensity of the **LNA(+1)**-RNA hybrid at 531 nm was only about half that of the **DNA(0)**-RNA hybrid, which includes no LNA nucleotides (Figure 2b), although the T_m of the **LNA(+1)**-RNA hybrid (52 °C) was 5 °C higher than that of the **DNA(0)**-RNA hybrid. In addition, the absorbance of **LNA(+1)** was lower than that of **DNA(0)**. These weak photophysical signals of **LNA(+1)** may suggest that the intercalation or aggregation of thiazole orange dyes linked to **LNA(+1)** was incomplete, as reported in the studies on the photophysics of free thiazole orange dye (*24, 25*). The reason for these photophysical behaviors of **LNA(+1)** was not the existence of an LNA nucleotide in the probe, but the location of LNA incorporation. Another LNA probe **LNA(+4)** showed high fluorescence intensity after hybridization with RNA (Figure 2c), as well as formation of a highly thermostable hybrid (58 °C). The photophysical behavior of **LNA(+4)** was close to that of the **DNA(0)**. Incorporation of an LNA nucleotide into a different site in the probe resulted in different absorption and fluorescence spectra.

Effect of Location of the Incorporated LNA Nucleotide. In the case of **LNA(+1)**, incorporation of an LNA nucleotide into ECHO probes induced a decrease in the fluorescence intensity of the hybrid with complementary RNA, although the hybrid showed higher stability and maintained its hybridization-sensitive emission property. The design of the probe containing LNA nucleotides, i.e., determination of where we should insert LNA nucleotides, is a key point for obtaining an effective fluorescent probe. We next prepared several chimeric probes with LNA nucleotides incorporated at different sites in the probe sequence (Figure 1c). The T_m values of the hybrids formed by the ECHO-LNA probes and the complementary RNA were 4−11 °C higher than that of the **DNA(0)**-RNA hybrid. The incorporation of an LNA nucleotide made the duplex with the complementary RNA more stable, regardless of the incorporation site. In contrast, the fluorescence intensities of the hybrids of chimeric probes and complementary RNA strongly depended on the LNA insertion site. The fluorescence intensities of the hybrid with RNA by **LNA(−2)**, **LNA(−1)**, **LNA(+2)**, and **LNA(+3)** were low, and likewise for the **LNA(+1)**-RNA hybrid (Figure 3a). On the other hand, **LNA(−4)**, **LNA(−3)**, and **LNA(+4)**, where an LNA nucleotide was located at the site far from the dye nucleotide D_{514}, showed high fluorescence intensity after hybridization with RNA, close to the fluorescence intensity of the **DNA(0)**-RNA hybrid. Fluorescence of ECHO probes has been reported to be induced by dissociation of H-aggregation and intercalation of dyes into stacking base pairs (*15, 16*). Incorporation of LNA nucleotides into the sites close to D_{514} may be unfavorable for the binding of two dyes of D_{514} to the hybrid structure.

LNA would slightly change the duplex structure from the structure of the **DNA(0)**-RNA hybrid, because the fixed puckering of LNA bridged ribose (C3′-*endo*) is close to that of RNA ribose but not DNA 2′-deoxyribose (C2′-*endo*) (*26*). However, sugar puckering may be unimportant for fluorescence intensity in the present case. The chimeric probes in which LNA nucleotides were replaced with a 2′-*O*-methyl RNA nucleoside (C3′-*endo*) kept the high fluorescence intensity of the hybrid with complementary RNA regardless of the site of 2′-*O*-methyl RNA nucleoside incorporation. Therefore, the effect of partial conformational change by sugar puckering on the fluorescence intensity in an ECHO probe was not large.

The CD spectra of LNA-containing probes provided us with key information on the intercalation of D_{514} thiazole orange dyes. The CD spectra of the hybrid of **LNA(+4)** with RNA showed a strong positive Cotton effect at 520 nm (Figure 3b), which was also observed for the **DNA(0)**-RNA hybrid. On the other hand, the hybrid formed by RNA and **LNA(+1)**, containing an LNA nucleotide located close to a D_{514} nucleotide, showed a very weak induced CD signal. These weak signals indicated that binding of D_{514} thiazole orange dyes was unsuccessful in the hybrid, suggesting that incorporation of an LNA nucleoside made the dye intercalation from the major groove side inefficient. The rigidity of the LNA sugar unit is disadvantageous for dye intercalation because dye intercalation requires the flexibility of sugar−phosphate backbones to extend the distance between base pairs (*27*). Actually, hybrids of the probes containing a lowly rigid 2′-*O*-methyl RNA nucleoside and complementary RNA showed an induced CD at 520 nm regardless of incorporation sites. Intercalation of D_{514} dyes into the hybrid structure is a key factor for dissociation of the dye aggregate and fluorescence emission. As shown in Figure 3a, the LNA incorporation sites of the probes showing a weak CD signal were consistent with the LNA incorporation sites of the probes showing low fluorescence intensity. Therefore, the rigidity of the LNA sugar unit resulted in a decrease in the fluorescence intensity of the probe through intercalation inhibition. The LNA incorporation sites where the fluorescence intensity of the hybrid decreased were not distributed symmetrically around D_{514} (two nucleotides of 5′ side of D_{514} and three of 3′ side) (Figure 4). This asymmetry can be explained by considering the distance that the dyes can reach through a linker in the right-handed double helical structure of the hybrid. To obtain an effective ECHO-LNA conjugate with high fluorescence intensity, LNA nucleotides should be incorporated into the probe, avoiding the positions marked with closed triangles in Figure 4.

Fluorescence Detection of RNA with Higher-Ordered Structure: The Example of HIV-1 TAR RNA. Insertion of LNA nucleotides into the hybridization-sensitive fluorescent probes would facilitate analysis of higher-ordered structures (*28*). HIV-1 TAR RNA, which is the transactivation responsive element located at the 5′-end of HIV-1 mRNA (*29*), is a small RNA hairpin consisting of a stem-loop structure with a three-nucleotide bulge, which is essential for Tat protein recognition and activity (*30, 31*). We designed the 16-mer ECHO probe (**LNA(anti-TAR)**) for fluorescent detection of the TAR RNA stem-loop structure (T_m = 57 °C) (Figure 5). Four LNA nucleotides were incorporated into the probe to gain high binding affinity to TAR RNA. These LNA nucleotides lay at least three nucleotides apart from D_{514} to not lose the strong fluorescence of hybrid by LNA incorporation as described above. **LNA(anti-TAR)** before hybridization showed low fluorescence intensity, which was at the same level as that of a DNA probe **DNA(anti-TAR)**. On the other hand, **LNA(anti-TAR)** showed more effective on−off switching of fluorescence emission, and the fluorescence intensity of **LNA(anti-TAR)** was higher after

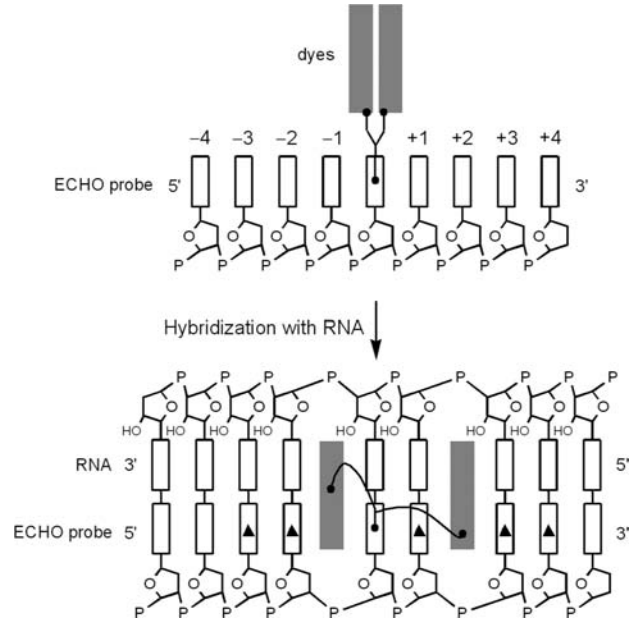

Figure 4. Binding site of D_{514} thiazole orange dyes proposed from fluorescence intensities and induced CD spectra of the hybrid with RNA. Thiazole oranges are represented by gray rectangles. The replacement by LNA nucleotides in the positions indicated with closed triangles resulted in hybrids with low fluorescence intensity and low induced CD signals.

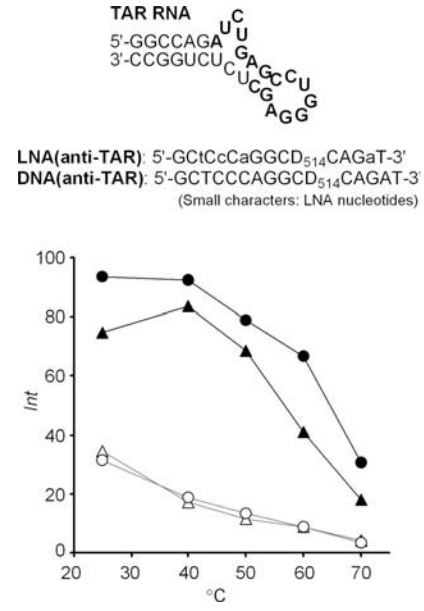

Figure 5. Fluorescence intensities of ECHO probes binding to TAR RNA. The fluorescence intensities at 531 nm at different temperatures are plotted with open circles for **LNA(anti-TAR)**, closed circles for its hybrid with TAR RNA, open triangles for **DNA(anti-TAR)**, and closed triangles for its hybrid with TAR RNA.

hybridization with TAR RNA than that of **DNA(anti-TAR)**. The T_m of the hybrid of **LNA(anti-TAR)** and TAR RNA was 56 °C, i.e., 11 °C higher than that of the hybrid of **DNA(anti-TAR)** and TAR RNA (45 °C). Thus, the largest difference in their fluorescence intensities was observed for the fluorescence measurement at 60 °C, which was close to the T_m values observed for a stem-loop TAR RNA and an **LNA(anti-TAR)**-TAR hybrid. The higher fluorescence intensity of the hybrid formed by a well-designed LNA-incorporating probe suggested that use of LNA nucleotides and temperature control was

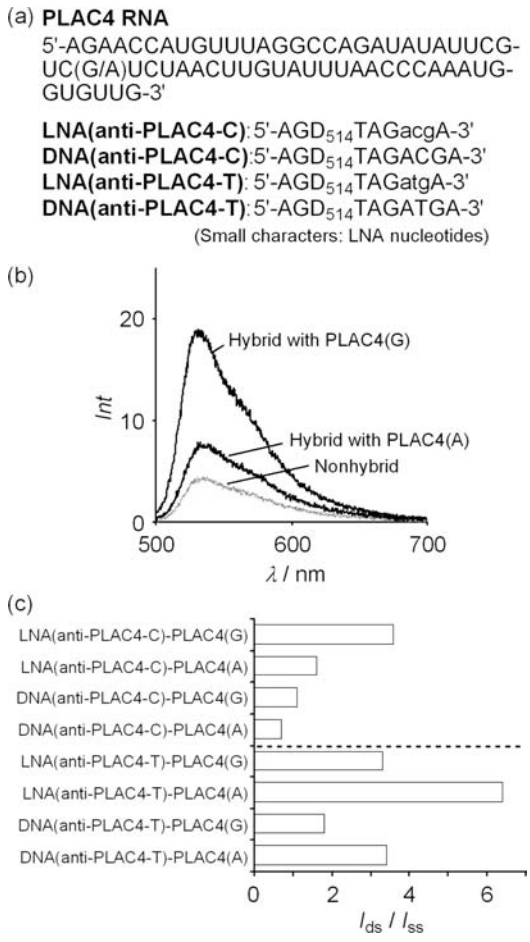

Figure 6. Fluorometric detection of the single nucleotide polymorphism (SNP) of PLAC4 RNA. (a) Sequences of a PLAC4 RNA fragment including a G/A SNP site and ECHO probes for detection of PLAC4 RNA. (b) Fluorescence spectra of **LNA(anti-PLAC4-C)**. The temperature was 50 °C, and excitation wavelength was 488 nm. (c) Ratio of the fluorescence intensities of hybrids (I_{ds}) to that of probe alone (I_{ss}). The temperature was 50 °C for LNA probes and 25 °C for DNA probes.

effective for clearer on−off fluorescence observation of an RNA strand with a higher-ordered structure.

Fluorescence Detection of Single Nucleotide Alteration of RNA: The Example of PLAC4 RNA. LNA is also effective for mismatch discrimination. A one-base difference in a genome sequence is well-known as a single-nucleotide polymorphism (SNP), and this sequence variation is among the very important research targets for progress of gene diagnosis and personalized medicine. LNA trinucleotides have been reported as being useful for recognition of one-base alteration (*32*). We next designed the ECHO probe for fluorescent SNP detection. The target SNP was placenta-specific 4 (PLAC4) rs130833, which is an SNP located in the transcribed regions of placental-expressed mRNA in maternal plasma (*33*, *34*). We designed ECHO-LNA conjugates, in which the LNA trinucleotide recognizes the target SNP site of PLAC4 RNA, and compared the SNP selectivity of fluorescence emission with DNA probes. ECHO-LNA conjugate probes, **LNA(anti-PLAC4-C)** and **LNA(anti-PLAC4-T)**, showed high T_m values for hybridization with matched PLAC4 RNA sequences (61 and 55 °C, respectively) but much lower T_m values with mismatched sequences (34 and 44 °C, respectively). On the other hand, the gap in T_m values of DNA probes for hybridization with matched and mismatched RNA was less than 3 °C, although the matched hybrid was only slightly more thermostable. The large gap between T_m values of matched and mismatched hybrids observed for LNA-incorporating probes meant that appropriate temperature control was effective for clear fluorescence detection of SNP. When the fluorescence intensity was measured at 50 °C, i.e., between the T_m values of the matched and mismatched hybrids of LNA-containing probes and PLAC4 RNA, the emission at 531 nm was selective for matched hybrids (Figure 6). LNA-containing probes distinguished a one-nucleotide difference of the target RNA more sensitively compared with DNA probes. Combination of a hybridization-sensitive fluorescent probe and an SNP-recognizing LNA trinucleotide was effective for mix-and-read fluorescent SNP typing.

In conclusion, we have designed ECHO probes showing sequence-selective fluorescence for higher-ordered RNA and RNA SNPs through the incorporation of LNA nucleotides into appropriate sites of the probes. This probe achieved high thermostability of the hybrid with target RNA strands and fluorescence detection of higher-ordered RNA and single base alteration. Although further aspects remain to be examined toward an easier-to-use intracellular RNA analysis, such as molecular design for higher sensitivity and selectivity of a small amount of the target RNA, we anticipate that this new concept of the hybridization-sensitive fluorescent probe supported by the nucleic acid chemistry and photochemical basis will be the starting point for the development of a practical assay for detection of RNAs in vivo.

ACKNOWLEDGMENT

We thank Dr. Takehiro Suzuki (RIKEN) for the MALDI-TOF mass spectrometry and Dr. Shuji Ikeda (RIKEN) for valuable discussions on the present study.

[a] Small characters present LNA nucleotides. The LNA nucleotide "c" denotes a 5-methylcytosine LNA nucleotide. [b] All T_m values of probe-RNA duplexes (1.0 μM) were taken in in 50 mM sodium phosphate (pH = 7.0) containing 100 mM sodium chloride. Short complementary RNAs, 5'-UCAUCUAACU-3' for **PLAC4(A)**, 5'-UCGUCUAACU-3' for **PLAC4(G)**, were used in only the T_m measurements. [c] Photophysical data were collected at 50 °C for LNA probes and 25 °C for DNA probes. [d] Fluorescent quantum yield measured using 0.4 μM probe solution in 50 mM sodium phosphate (pH = 7.0) containing 100 mM sodium chloride excited at 488 nm. [e] Ratio of the fluorescence intensities of hybrids (ds) and nonhybridized probes (ss) at λ_{em} 531 nm.

Synthesis of N_4'-[^{18}F]Fluoroalkylated Ciprofloxacin as a Potential Bacterial Infection Imaging Agent for PET Study

Syntheses and evaluation of fluoroalkylated ciprofloxacin analogues are described. Among these analogues, N_4'-3-fluoropropylciprofloxacin (**16**) showed the most efficient antibacterial activity against *E. coli* strains (DH5α and TOP10) and a high binding affinity for DNA gyrase of bacteria. To develop bacteria-specific infection imaging agents for positron emission tomography (PET), no-carrier-added N_4'-3-[^{18}F]fluoropropylciprofloxacin ([^{18}F]**16**) was prepared in two steps from N_4'-3-methanesufonyloxypropylciprofloxacin, resulting in a 40% radiochemical yield (decay corrected for 100 min) via the *tert*-alcohol media radiofluorination protocol with high radiochemical purity (>99%) as well as high specific activity (149 ± 75 GBq/μmol). The agent was stable (>90%), as shown by an in vitro human serum stability assay. A bacterial uptake and blocking study of [^{18}F]**16** using authentic compound **16** in TOP10 cells demonstrated its high specific bacterial uptake. The results suggest that this radiotracer holds promise as a useful bacterial infection radiopharmaceutical for PET imaging.

INTRODUCTION

Fluoroquinolones, such as ciprofloxacin (**1**) and enrofloxacin (**2**), as an important class of antibiotics are commonly prescribed because of their broad spectrum of activity against Gram-negative and Gram-positive bacteria (*1*). It is known that their effect is due to the interaction of fluoroquinolones with bacterial DNA gyrase, thus inhibiting DNA uncoiling and subsequent DNA synthesis (*2, 3*).

Radiolabeled fluoroquinolones are used as radiotracers for single-photon emission computed tomography (SPECT) or positron emission tomography (PET) and have been developed as shown in Figure 1. They have received much attention in the clinical field because they can differentiate between bacterial infection and nonbacterial infection or sterile inflammation (*4*−*9*). ^{99m}Tc-ciprofloxacin as a SPECT imaging agent has been widely used for this purpose in clinical studies (*4, 5*). However, the chemical structure of ^{99m}Tc-ciprofloxacin has been not determined, and it has been shown to have very low specific activity (*6*−*9*). Since the use of PET as a noninvasive nuclear imaging approach allows the measurement of nano- or picomolar-level concentrations of molecules in the tissues of virtually all organs with higher spatial and temporal resolutions than SPECT (*10*−*12*), many researchers have shown an interest in ciprofloxacin analogues labeled with a positron emitter for PET such as [^{18}F]ciprofloxacin (*13*), [^{18}F]COPCA (*14*), and N_4'-[^{11}C]methylciprofloxacin (*15*). However, [^{18}F]ciprofloxacin also has low specific activity (which can decrease PET imaging quality), because it is [^{18}F]radiolabeled via an ^{18}F- by ^{19}F-exchange reaction from ciprofloxacin in nature; consequently, it is difficult to prepare and results in poor radiochemical yield (*13, 16*). [^{18}F]COPCA was developed to increase specific activity, and this radiotracer has no specific binding to bacteria and is difficult to purify (*14*). Due to short imaging time (the short half-life of carbon-11; $t_{1/2}$ = 20.4 min), N_4'-[^{11}C]methylciprofloxacin is not preferred as a PET radiotracer for pharmacokinetics analysis (*15, 10*). It is widely accepted that fluorine-18 is the most desirable PET radionuclide due to its ideal physical properties ($t_{1/2}$ = 110 min) (*17*).

According to previous structure−activity relationship (SAR) studies, an introduction of short alkyl chains such as ethyl and *n*-propyl groups at the N-4′ position of ciprofloxacin could maintain or increase the antibacterial potency of the ciprofloxacin analogues (*18*−*22*). On the basis of this knowledge, we designed N_4'-[^{18}F]fluoroalkylated ciprofloxacin analogues, which have a high specific activity, for the development of a promising bacteria-specific infection imaging agent for PET. In this report, we describe the preparation and evaluation of N_4'-[^{18}F]fluoroalkylciprofloxacins.

EXPERIMENTAL SECTION

General. Unless otherwise noted, all reagent and solvents were commercially available from Sigma-Aldrich. Reaction progress was followed by TLC on 0.25 mm silica gel glass plates containing F-254 indicator. Visualization on TLC was monitored by UV light or radio-TLC scanner. Flash chromatography was performed using a 230−400 mesh silica gel (Merck KGaA). ^{1}H NMR spectra were recorded on a 600 MHz spectrometer (JEOL, Japan). Chemical shifts were reported in δ units (ppm) relative to tetramethylsilane, and coupling constants were reported in hertz. ^{13}C NMR spectra were acquired at 125 MHz. Low- and high-resolution electron impact (EI, 70 eV) spectra were obtained. [^{18}F]Fluoride ion was produced from a cyclotron (KIRAMS 13 MeV, South Korea) using the ^{18}O(p,n)^{18}F nuclear reaction with 19 MeV proton irradiation of an enriched [^{18}O]H_2O target. High-performance liquid chromatography (HPLC) was performed with spectra system (Thermo Scientific, Waltham, MA) using semipreparative column (C18 silica gel, 10 μm, 10 × 250 mm, Hypersil gold) and analytic column (C18 silica gel, 5 μm, 4.6 × 250 mm, Hypersil gold, 10 mM aqueous phosphoric acid/ethanol = 88:12). The eluant was simultaneously monitored by a UV detector (215 nm) and a NaI(Tl) radioactivity detector. Radioactivity was measured in a dose calibrator.

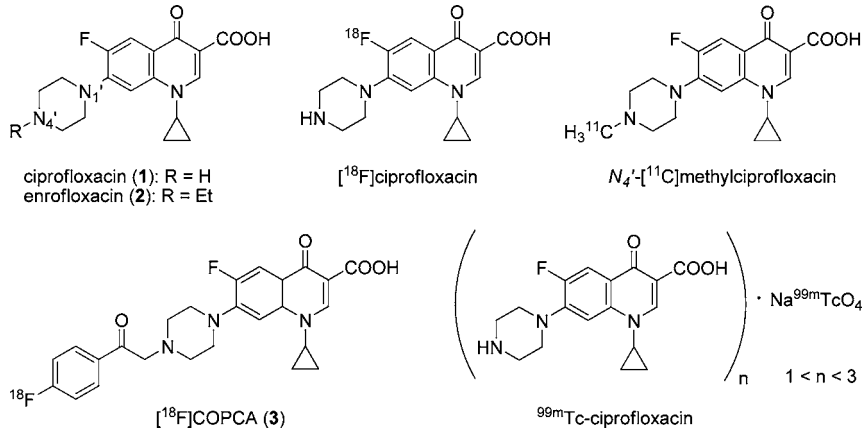

Figure 1. Structure of the radiolabeled ciprofloxacin derivatives.

Ciprofloxacin Methyl Ester (4). To a stirred solution of ciprofloxacin (Fluka, >98.0%, 200 mg, 0.60 mmol) in methanol (20 mL) was added *p*-toluenesulfonic acid (172 mg, 0.89 mmol). The mixture was refluxed for 16 h at 100 °C and then cooled to room temperature. The reaction mixture was dissolved in a $NaHCO_3$ solution (100 mL) and extracted from the aqueous phase with CH_2Cl_2 (100 mL × 3). The organic layer was dried over sodium sulfate and evaporated under reduced pressure. The residue was purified by flash column chromatography (5% MeOH/CH_2Cl_2) to obtain 166 mg (81%) of ciprofloxacin methyl ester (**4**) as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.13−1.15 (m, 2H), 1.30−1.34 (m, 2H), 3.0−3.1 (m, 4H), 3.22−3.24 (m, 4H), 3.41−3.45 (m, 1H), 3.91 (s, 3H), 7.26 (d, J = 7.0 Hz, 1H), 8.04 (d, J = 13.7 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.20, 34.59, 46.06, 51.25 (d, J = 4.0 Hz), 52.11, 104.80 (d, J = 2.9 Hz), 110.09, 113.30 (d, J = 23.0 Hz), 123.00 (d, J = 7.2 Hz), 138.10, 145.10 (d, J = 11.4 Hz), 148.40, 153.53 (d, J = 247.0 Hz), 166.51, 173.17; MS (EI) *m*/*z* 345 (M^+), 303 (100); HRMS (EI) *m*/*z* calcd for $C_{18}H_{20}N_3O_3F$ (M^+) 345.1489, found 345.1486.

General Procedure for *N*-Alkylation Reaction. To a mixture of **4** (1.44 mmol) and potassium carbonate (4.32 mmol) in acetonitrile (20 mL) was added each $Br(CH_2)_nOH$ (2.88 mmol). The mixture was stirred at 100 °C for 12 h. The reaction mixture was dissolved in water (100 mL) and extracted from the aqueous phase with CH_2Cl_2 (100 mL × 3). The organic layer was dried over sodium sulfate and evaporated under reduced pressure. Flash column chromatography (5% MeOH/CH_2Cl_2) gave each N_4'-hydroxyalkyl ciprofloxacin methyl ester compound.

N_4'-2-Hydroxyethylciprofloxacin Methyl Ester (5). According to the general procedure for *N*-alkylation reaction with **4** (500 mg, 1.44 mmol), potassium carbonate (600 mg, 4.32 mmol), and 2-bromoethanol (360 mg, 2.88 mmol), **5** (390 mg, 69%) was obtained as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.13−1.16 (m, 2H), 1.31−1.34 (m, 2H), 2.66 (t, J = 10.3 Hz, 2H), 2.74−2.76 (m, 4H), 3.29−3.30 (m, 4H), 3.41−3.45 (m, 1H), 3.68 (t, J = 19.0 Hz, 2H), 3.91 (s, 3H), 7.27 (d, J = 9.0 Hz, 1H), 8.05 (d, J = 14.8 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 7.16, 34.92, 49.35 (d, J = 4.4 Hz), 50.74, 53.06, 58.54, 59.95, 105.55 (d, J = 2.9 Hz), 108.68, 111.57 (d, J = 24.4 Hz), 121.73 (d, J = 5.7 Hz), 138.40, 144.77 (d, J = 10.0 Hz), 153.40 (d, J = 247.0 Hz), 165.23, 173.73; MS (EI) *m*/*z* 389 (M^+), 358 (100); HRMS (EI) *m*/*z* calcd for $C_{20}H_{24}N_3O_4F$ (M^+) 389.1751, found 389.1753.

N_4'-3-Hydroxypropylciprofloxacin Methyl Ester (6). According to the general procedure for *N*-alkylation reaction with **4** (275 mg, 0.80 mmol), potassium carbonate (550 mg, 3.98 mmol), and 3-bromopropanol (221 mg, 1.59 mmol), **6** (300 mg, 93%) was obtained as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.12−1.15 (m, 2H), 1.30−1.33 (m, 2H), 1.77−1.81 (m, 2H), 2.73 (t, J = 11.0 Hz, 2H), 2.76 (m, 4H), 3.27 (m, 4H), 3.40−3.43 (m, 1H), 3.85 (t, J = 10.3 Hz, 2H), 3.91 (s, 3H), 7.26 (d, J = 6.8 Hz, 1H), 8.05 (d, J = 13.0 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.24, 27.18, 34.61, 50.08 (d, J = 4.3 Hz), 52.15, 53.14, 58.80, 64.67, 104.97 (d, J = 2.9 Hz), 110.20, 113.42 (d, J = 23.0 Hz), 123.33 (d, J = 5.7 Hz), 138.07, 144.54 (d, J = 10.0 Hz), 148.48, 153.53 (d, J = 247.0 Hz), 166.54, 173.15; MS (EI) *m*/*z* 403 (M^+), 358 (100); HRMS (EI) *m*/*z* calcd for $C_{21}H_{26}N_3O_4F$ (M^+) 403.1907, found 403.1912.

N_4'-4-Hydroxybutylciprofloxacin Methyl Ester (7). According to the general procedure for *N*-alkylation reaction with **4** (600 mg, 1.74 mmol), potassium carbonate (720 mg, 5.21 mmol), and 4-bromobutanol (530 mg, 3.47 mmol), **7** (475 mg, 63%) was obtained as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.12−1.14 (m, 2H), 1.30−1.33 (m, 2H), 1.74 (m, 4H), 2.51 (t, J = 7.0 Hz, 2H), 2.76 (m, 4H), 3.31 (m, 4H), 3.38−3.42 (m, 1H), 3.62 (t, J = 5.5 Hz, 2H), 3.91 (s, 3H), 7.27 (d, J = 8.8 Hz, 1H), 8.05 (d, J = 13.0 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.26, 25.39, 32.61, 34.63, 49.60 (d, J = 4.3 Hz), 52.14, 52.68, 58.63, 62.84, 105.11 (d, J = 2.9 Hz), 110.19, 113.39 (d, J = 23.0 Hz), 123.38 (d, J = 7.2 Hz), 138.06, 144.43 (d, J = 10.0 Hz), 148.48, 153.57 (d, J = 247.0 Hz), 166.54, 173.16; MS (EI) *m*/*z* 417 (M^+), 358 (100); HRMS (EI) *m*/*z* calcd for $C_{22}H_{28}N_3O_4F$ (M^+) 417.2064, found 417.2063.

General Procedure for Hydrolysis. To a solution of each methyl ester compound (0.41 mmol) in methanol/water (4:1, 50 mL) was added LiOH (2.04 mmol). The mixture was stirred at room temperature for 8 h. The reaction solution was acidified (pH 5−6) with acetic acid and dissolved in water (100 mL). The reaction mixture was extracted from the aqueous phase with CH_2Cl_2 (100 mL × 3). The organic layer was dried over sodium sulfate and evaporated under reduced pressure. Flash column chromatography (10% MeOH/CH_2Cl_2) gave each acid compound.

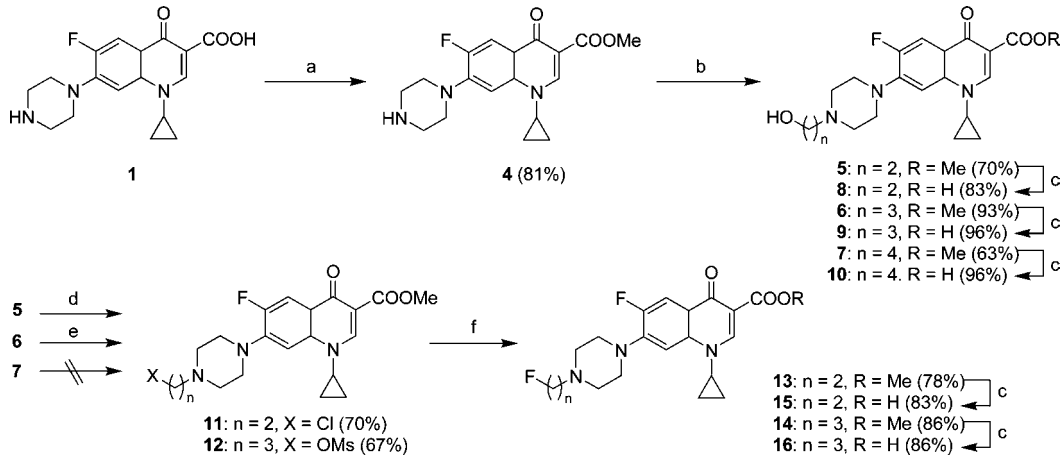
N_4'-2-Hydroxyethylciprofloxacin (8). According to the general procedure for hydrolysis reaction with **5** (100 mg, 0.26 mmol), LiOH (30 mg, 1.28 mmol), **8** (80 mg, 83%) was obtained as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.19−1.22 (m, 2H), 1.38−1.41 (m, 2H), 2.67 (t, J = 10.3 Hz, 2H), 2.76−2.78 (m, 4H), 3.36−3.38 (m, 4H), 3.52−3.56 (m, 1H), 3.70 (t, J = 8.3 Hz, 2H), 7.36 (d, J = 7.0 Hz, 1H), 8.04 (d, J = 13.1 Hz, 1H), 8.78 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.37, 35.37, 49.95 (d, J = 5.7 Hz), 52.63, 57.92, 59.38, 104.86 (d, J = 1.8 Hz), 108.19, 112.44 (d, J = 23.0 Hz), 120.05 (d, J = 7.2 Hz), 139.15, 145.90 (d, J = 11.5 Hz), 147.49, 153.57 (d, J = 247.0 Hz), 167.08, 177.13; MS (EI) *m*/*z* 375 (M^+), 344 (100); HRMS (EI) *m*/*z* calcd for $C_{19}H_{22}N_3O_4F$ (M^+) 375.1594, found 375.1592.

***N*$_4$′-3-Hydroxypropylciprofloxacin (9).** According to the general procedure for hydrolysis reaction with **6** (135 mg, 0.33 mmol), LiOH (40 mg, 1.67 mmol), **9** (125 mg, 96%) was obtained as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.19−1.22 (m, 2H), 1.37−1.41 (m, 2H), 1.78−1.81 (m, 2H), 2.73 (t, J = 11.0 Hz, 2H), 2.78 (m, 4H), 3.34 (m, 4H), 3.51−3.54 (m, 1H), 3.85 (t, J = 10.3 Hz, 2H), 7.36 (d, J = 6.8 Hz, 1H), 8.02 (d, J = 13.0 Hz, 1H), 8.78 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.34, 27.22, 35.37, 49.91 (d, J = 4.3 Hz), 53.00, 58.71, 64.59, 105.02 (d, J = 2.8 Hz), 108.31, 112.57 (d, J = 23.0 Hz), 120.21 (d, J = 7.2 Hz), 139.31, 145.86 (d, J = 10.0 Hz), 147.57, 152.81 (d, J = 247.0 Hz), 167.06, 177.22; MS (EI) *m/z* 389 (M^+), 344 (100); HRMS (EI) *m/z* calcd for $C_{20}H_{24}N_3O_4F$ (M^+) 389.1751, found 389.1755.

***N*$_4$′-4-Hydroxybutylciprofloxacin (10).** According to the general procedure for hydrolysis reaction with **7** (170 mg, 0.41 mmol), LiOH (50 mg, 2.04 mmol), **10** (125 mg, 96%) was obtained as a white solid. ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.18−1.21 (m, 2H), 1.37−1.410 (m, 2H), 1.74 (m, 4H), 2.52 (t, J = 7.0 Hz, 2H), 2.76−2.78 (m, 4H), 3.37−3.38 (m, 4H), 3.50−3.53 (m, 1H), 3.62 (t, J = 5.5 Hz, 2H), 7.37 (d, J = 7.5 Hz, 1H), 8.04 (d, J = 13.0 Hz, 1H), 8.78 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.35, 25.33, 32.55, 35.41, 49.47 (d, J = 4.3 Hz), 52.73, 58.58, 62.85, 105.17 (d, J = 2.5 Hz), 108.24, 112.45 (d, J = 23.0 Hz), 120.16 (d, J = 7.2 Hz), 139.10, 145.82 (d, J = 10.1 Hz), 147.54, 153.82 (d, J = 247.0 Hz), 167.05, 177.19; MS (EI) *m/z* 403 (M^+), 344 (100); HRMS (EI) *m/z* calcd for $C_{21}H_{26}N_3O_4F$ (M^+) 403.1907, found 403.1909.

***N*$_4$′-2-Chloroethylciprofloxacin Methyl Ester (11).** To a mixture of **5** (300 mg, 0.77 mmol) and *p*-toluenesulfonylchloride (293 mg, 1.54 mmol) in CH_2Cl_2 (15 mL) was added triethylamine (0.32 mL, 2.31 mmol). The mixture was stirred at 25 °C for 30 h. The reaction mixture was dissolved in water (50 mL) and extracted from the aqueous phase with CH_2Cl_2 (50 mL × 3). The organic layer was dried over sodium sulfate and evaporated under reduced pressure. The residue was purified by flash column chromatography (5% MeOH/CH_2Cl_2) to obtain 235 mg (74%) of N_4′-2-chloroethylciprofloxacin methyl ester (**11**) as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.12−1.15 (m, 2H), 1.30−1.35 (m, 2H), 2.74−2.76 (m, 4H), 2.38 (t, J = 13.7 Hz, 2H), 3.29−3.30 (m, 4H), 3.40−3.44 (m, 1H), 3.46 (t, J = 13.1 Hz, 2H), 3.91 (s, 3H), 7.27 (d, J = 10.0 Hz, 1H), 8.05 (d, J = 13.1 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.22, 34.58, 41.00, 49.95 (d, J = 4.3 Hz), 52.15, 52.94, 55.71, 104.92 (d, J = 3.2 Hz), 110.18, 113.39 (d, J = 23.0 Hz), 123.21 (d, J = 5.7 Hz), 138.08, 144.65 (d, J = 10.0 Hz), 153.52 (d, J = 247.0 Hz), 165.55, 173.13; MS (EI) *m/z* 407 (M^+), 149 (100); HRMS (EI) *m/z* calcd for $C_{20}H_{23}N_3O_3FCl$ (M^+) 407.1412, found 407.1411.

***N*$_4$′-3-Methanesulfonylpropylciprofloxacin Methyl Ester (12).** To a mixture of **6** (0.39 g, 0.97 mmol) and methane sulfonylchloride (0.09 mL, 1.16 mmol) in CH_2Cl_2 (10 mL) was added triethylamine (0.174 mL, 1.16 mmol) at 0 °C. The mixture was stirred at 25 °C for 2 h. The reaction mixture was dissolved in water (25 mL) and extracted from the aqueous phase with CH_2Cl_2 (25 mL × 3). The organic layer was dried over sodium sulfate and evaporated under reduced pressure. The residue was purified by flash column chromatography (5% MeOH/CH_2Cl_2) to obtain 310 mg (66%) of N_4′-3-methanesulfonylpropylciprofloxacin methyl ester (**12**) as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.12−1.15 (m, 2H), 1.30−1.34 (m, 2H), 1.95−2.00 (m, 2H), 2.56 (t, J = 13.7 Hz, 2H), 2.65−2.67 (m, 4H), 3.03 (s, 3H), 3.26−3.28 (m, 4H), 3.40−3.44 (m, 1H), 3.91 (s, 3H), 4.35 (t, J = 13..0 Hz, 2H), 7.26 (d, J = 7.0 Hz, 1H), 8.04 (d, J = 13.1 Hz, 1H), 8.54 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.24, 27.18, 34.61, 49.95, 51.97 (d, J = 4.4 Hz), 59.14, 62.62, 104.97 (d, J = 3.3 Hz), 110.20, 113.42 (d, J = 23.0 Hz), 123.74 (d, J = 5.7 Hz), 138.07, 142.21 (d, J = 11.5 Hz), 148.48, 153.78 (d, J = 247.0 Hz), 166.54, 173.15; MS (FAB) *m/z* 482 (M + H), 386 (100); HRMS (FAB) *m/z* calcd for $C_{22}H_{29}N_3O_6F$ (M + H) 482.1758, found 482.1761.



***N*$_4$′-2-Fluoroethylciprofloxacin Methyl Ester (13).** To a solution of **11** (135 mg, 0.25 mmol) in *t*-amyl alcohol (5 mL) was added TBAF (130 mg, 0.50 mmol). The mixture was stirred at 80 °C for 6 h. The reaction mixture was dissolved in water (10 mL) and extracted from the aqueous phase with ethyl acetate (10 mL × 3). The organic layer was dried over sodium sulfate and evaporated under reduced pressure. The residue was purified by flash column chromatography (5% MeOH/CH_2Cl_2) to obtain 76 mg (78%) of N_4′-2-fluoroethylciprofloxacin methyl ester (**13**) as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.12−1.15 (m, 2H), 1.30−1.35 (m, 2H), 2.77−2.78 (m, 4H), 2.82 (t, J = 9.6 Hz, 2H), 3.30−3.32 (m, 4H), 3.41−3.44 (m, 1H), 3.91 (s, 3H), 4.62 (dt, J = 47.4, 4.7 Hz, 2H), 7.27 (d, J = 7.0 Hz, 1H), 8.05 (d, J = 13.1 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.20, 34.57, 49.98 (d, J = 4.3 Hz), 52.11, 53.32, 58.21 (d, J = 20.1 Hz), 81.96 (d, J = 166.6 Hz), 104.89 (d, J = 3.2 Hz), 110.16, 113.36 (d, J = 23.0 Hz), 123.15 (d, J = 7.2 Hz), 138.08, 144.65 (d, J = 10.0 Hz), 153.51 (d, J = 248.0 Hz), 165.54, 173.13; MS (EI) *m/z* 391 (M^+), 315 (100), 358; HRMS (EI) *m/z* calcd for $C_{20}H_{23}N_3O_3F_2$ (M^+) 391.1707, found 391.1711.

***N*$_4$′-3-Fluoropropylciprofloxacin Methyl Ester (14).** Prepared from mesylate precursor **12** by the method used to prepare the fluorocompound **13**, 200 mg (86%) of N_4′-3-fluoropropylciprofloxacin methyl ester (**14**) was obtained as a white solid; ^{1}H NMR (600 MHz, $CDCl_3$) δ 1.12−1.15 (m, 2H), 1.30−1.33 (m, 2H), 1.89−1.98 (m, 2H), 2.57 (t, J = 14.4 Hz, 2H), 2.67−2.69 (m, 4H), 3.28−3.29 (m, 4H), 3.40−3.44 (m, 1H), 3.91 (s, 3H), 4.55 (dt, J = 46.7, 5.8 Hz, 2H), 7.27 (d, J = 7.5 Hz, 1H), 8.04 (d, J = 13.1 Hz, 1H), 8.55 (s, 1H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 8.20, 27.96 (d, J = 20.1 Hz), 34.57, 50.05 (d, J = 4.3 Hz), 52.12, 53.04, 54.25 (d, J = 5.7 Hz), 84.41 (d, J = 163.7 Hz), 104.80 (d, J = 3.8 Hz), 110.17, 113.37 (d, J = 23.0 Hz), 123.08 (d, J = 7.2 Hz), 138.10, 144.65 (d, J = 11.5 Hz), 148.41, 153.51 (d, J = 248.0 Hz), 166.57, 173.15; MS (EI) *m/z* 405 (M^+), 358 (100); HRMS (EI) *m/z* calcd for $C_{21}H_{25}N_3O_3F_2$ (M^+) 405.1864, found 405.1868.

Procedure for Labeling [^{18}F]16. [^{18}F]fluoride was produced in a cyclotron by the ^{18}O(p, n)^{18}F reaction. A volume of 200−400 μL of [^{18}F]fluoride (370−666 MBq) in water was added to a vacutainer containing *n*-Bu$_4$NHCO$_3$ (40% aq, 15 μL, 20.3 μmol). The azeotropic distillations were conducted with 200 μL aliquots of CH$_3$CN at 75 °C under a stream of nitrogen. A [^{18}F]fluoride displacement reaction of **12** (10 mg, 20.8 μmol) with *n*-Bu$_4$N[^{18}F]F in *tert*-amyl alcohol (500 μL) was carried out in a reaction vial at 100 °C for 20 min. After the reaction, the vial was cooled in an ice bath. The solvent was removed under a gentle stream of nitrogen at room temperature. For hydrolysis of the ester group, the residue was treated with LiOH (5 mg, 217 μmol) in 3 mL of MeOH/H$_2$O (4:1) at 100−110 °C for 20 min. After cooling the reaction mixture, the reaction mixture was acidified with acetic acid (pH = 5−6). The solvent was removed with a gentle stream of nitrogen. The crude compound was injected onto reverse-phase HPLC with 10 mM aqueous phosphoric acid (1 mL, pH 2.2) and purified. The desired compound was collected from HPLC (t_R = 10.6 min; C18 silica gel, 10 μm, 10 × 250 mm; 10 mM aqueous phosphoric acid/ethanol = 88:12 (v/v); pH 2.3; 215 nm; 4 mL/min). After the HPLC solvent was removed (70−75 °C) using a gentle stream of nitrogen, N_4'-3-[^{18}F]fluoropropylciprofloxacin ([^{18}F]**16**) was obtained for biological study. For the identification of the radioproduct, the collected HPLC fraction was coinjected with the cold compound **16**. The total reaction time of [^{18}F]**16** was 100 min, and the overall decay-corrected radiochemical yield was approximately 40%. Specific activity at the end of synthesis was calculated by relating radioactivity to the mass associated with the UV absorbance (215 nm) peak of cold compound. Specific radioactivity of [^{18}F]**16** (149 ± 75 GBq/μmol, n = 3) was obtained on an HPLC column.

In Vitro Antibacterial Activity Analysis Studies. The antibacterial activity analysis was determined from the lowest concentration to the high concentration of test compounds that resulted in a complete inhibition of visible growth in the medium. In vitro antibacterial activity analysis was studied according to previously published procedures (*23*). Ciprofloxacin and tested compounds were dissolved (mg/mL) in 10 mM phosphoric acid, and the mixture was adjusted to pH 7. Serial dilutions (ranging from 0 μg/mL to 500 μg/mL of test compounds) were made using LB broth (BD Bioscience, San Jose, CA). *E. coli* DH5α or TOP10 (5 × 10^6/mL) (Invitrogen, Carlsbad, CA) was added to tubes containing the diluted test compounds. Each tube was incubated in a shaking incubator at 37 °C for 18 h, and optical density was measured at 600 nm (Amersham biosciences, Ultraspec 2100 pro, Piscataway, NJ). Antibacterial activities were carried out in quintuple. The MIC$_{50}$ (ng/mL) of the test compounds and ciprofloxacin were determined. The MIC$_{50}$ was defined as the 50% concentration of an antibacterial agent that inhibited visible growth after incubation at 37 °C for 18 h.

Table 1. In Vitro Antibacterial Activity and Inhibitory Activity against DNA Gyrase of N_4'-Substituted Ciprofloxacin Derivatives[a]

			MIC$_{50}$ (ng/mL)[b]		IC$_{50}$ (μg/mL)
compound	*n*	X	DH5α	TOP10	DNA gyrase
ciprofloxacin	-	-	13.9 ± 2.7	0.40 ± 0.06	3.20 ± 0.8
8	2	OH	6.76 ± 0.55	3.80 ± 0.96	16.8 ± 3.4
9	3	OH	35.7 ± 0.58	6.66 ± 1.0	ND
10	4	OH	40.0 ± 2.1	21.3 ± 3.5	ND
15	2	F	346 ± 18	3.16 ± 0.23	12.6 ± 4.4
16	3	F	157 ± 4.0	3.13 ± 0.20	9.63 ± 3.6

[a] Data are expressed as mean ± SD. ND = not determined. [b] MIC$_{50}$ for 50% of strains tested.

DNA Gyrase Inhibition Studies. Measurement of minimum inhibitory concentration (MIC) was done as described previously (*24*). DNA supercoiling activity was assayed with relaxed pHOT-1 DNA as a substrate (TopoGEN, Inc., FL, USA) according to the manufacturer's protocol. The standard reaction mixture (20 μL) contained 35 mM Tris-Cl, pH 7.5, 24 mM KCl, 4 mM MgCl$_2$, 2 mM dithiothreitol, 1.8 mM spermidine, 1 mM ATP, 6.5% glycerol, 0.1 mg/mL BSA, 167 ng/μL relaxed pHOT-1, and *E. coli* DNA gyrase. The reaction mixture was incubated at 37 °C for 1 h and was terminated by addition of a stop buffer (5% Sarkosyl, 0.125% bromophenol blue, 25% glycerol) and a chloroform/isoamyl alcohol (24:1) mixture. After a brief vortex, the blue aqua phase was analyzed by electrophoresis in 0.8% agarose. The IC$_{50}$ was defined as the drug concentration that reduced the enzymatic activity observed with drug-free controls by 50%.

In Vitro Stability Study of [^{18}F]16. For the labeling stability test, [^{18}F]**16** (0.74 MBq/100 μL) was incubated with human

Scheme 2. Radiosynthesis of N_4'-[^{18}F]Fluoropropylciprofloxacin in tert-Alcohol Medium[a]

[a] Reagents and conditions: (g) [^{18}F]TBAF, *t*-amyl alcohol or CH_3CN, 100 °C, 20 min; (h) LiOH, MeOH:H_2O (4:1), 100 °C, 30 min.

serum (0.5 mL) at 37 °C water bath for 5 h and then analyzed by chromatography on ITLC-sg strips eluted with 5% methanol/methylene chloride ([^{18}F]**16**, $R_f = 0.79$; serum bound [^{18}F]**16**, $R_f = 0$). After they were developed, the chromatographic strips were scanned on an automatic TLC scanner (Bioscan, Washington, DC, USA). TLC was performed at various time points. All the experiments were done in triplicate.

Competitive Bacteria Uptake Experiments of [^{18}F]16 and Cold Authentic Compound. Bacterial uptake test was performed with TOP10. TOP10 (5×10^7) was incubated with [^{18}F]**16** (2.96 MBq) for 30 min at 37 °C. For the blocking studies, [^{18}F]**16** was co-treated with **16** (25 nmol) as a blocker to the TOP10 (5×10^7) sample for 30 min at 37 °C. These blocker concentrations did not affect TOP10 survival. This was verified at 400 nm before starting the test. After incubation, TOP10 was washed with PBS buffer twice and counted on a γ-counter (Packard, Meriden, CT). The experiment was carried out in triplicate. The values were expressed as mean ± SD.

RESULTS AND DISCUSSION

The synthesis of non-radiolabeled N_4'-fluoroalkylated and hydroxyl ciprofloxacin derivatives were achieved via a versatile and efficient synthetic route from commercially available ciprofloxacin (**1**), as shown in Scheme 1. According to structure−activity relationship (SAR) studies, it should be noted that variation at the N-4′ substituent of fluoroquinolones with alkyl groups plays an important role in antibacterial activity (*6*). On the basis of this information, we introduced various fluoroalkyl groups at the terminal nitrogen of the piperazine of ciprofloxacin (N-4′ position). After the esterification of **1** to the methyl ester **4** for the protection of the acid group (*19*), the alkylation of **4** with 2-bromoethanol, 3-bromopropanol, and 4-bromobutanol under reflux conditions in CH_3CN yielded the N_4'-2-hydroxyethyl, 3-hydroxyproyl, and 4-hydroxybutyl ciprofloxacin methyl esters (**5**−**7**), respectively, in reasonable yields (63−93%). Hydrolysis of **5**−**7** with LiOH in methanol/water produced N_4'-hydroxyalkyl ciprofloxacin derivatives **8**−**10**. The chloride precursor **11** was prepared by the chlorination of the alcohol compound **5** with *p*-toluenesulfonyl chloride and triethylamine (TEA) in CH_2Cl_2 at 70% yield. Similarly, the mesylate precursor **12** was prepared by treating the alcohol compound **6** with methanesulfonylchloride and TEA. Unfortunately, the precursor produced by the methanesulfonylation or chlorination reaction of N_4'-3-hydroxybutyl ciprofloxacin methyl ester (**7**) could not be obtained because the precursor product immediately converted to its five-membered intracyclization salt compound during the reaction process. The *tert*-alcohol media nucleophilic fluorination (*25*−*27*) of precursors **11** and **12** using tetrabutylammonium fluoride (TBAF) proceeded selectively producing the desired fluoro-products in high yields (**13**, 78%; and **14**, 86%, respectively) without intracyclic or alkene byproducts (*20, 21*). N_4'-2-Fluoroethyl ciprofloxacin (**15**) and N_4'-3-fluoropropylciprofloxacin (**16**) were produced by hydrolysis of methyl esters **13** and **14**, respectively.

To investigate the antibacterial potency of the N_4'-substituted ciprofloxacin derivatives, including the N_4'-fluoroalkylated ciprofloxacin derivatives (**15** and **16**), we measured the EC_{50} values of these derivatives (**8**, **9**, **10**, **15**, and **16**) for their in vitro antibacterial activity against two *E. coli* DH5α and TOP10 strains, as shown in Table 1. Whereas N_4'-fluoroalkylated ciprofloxacin derivatives **15** and **16** exhibited less potent in vitro antibacterial activity against the DH5α strain than did the N_4'-hydroxyalkylated ciprofloxacin derivatives (**8**−**9**), they showed good antibacterial activity against the TOP10 strain compared with these N_4'-hydroxyalkylated compounds **8** and **9**. Next, we evaluated the inhibition potencies of the three selected derivatives (**8**, **15**, and **16**) and the inhibition potentials of ciprofloxacin in the presence of DNA gyrase of *S. aureus*. Among the compounds tested, N_4'-3-fluoropropylciprofloxacin (**16**) exhibited the best ability to inhibit the target enzyme, DNA gyrase, as well as the greatest antibacterial activity against the TOP10 strains. In this in vitro study, the introduction of a 3-fluoropropyl group onto the N-terminal of the piperazinyl moiety in ciprofloxacin maintained both high binding affinity for the enzyme and a antibacterial potency comparable to that of the parent compound, ciprofloxacin. On the basis of the in vitro study results, we selected **16** as the compound of choice for further investigation and prepared N_4'-3-[^{18}F]fluoropropylciprofloxacin ([^{18}F]**16**) as a potential bacterial infection imaging agent for PET study.

N_4'-3-[^{18}F]fluoropropylciprofloxacin ([^{18}F]**16**) was generated by a two-step procedure consisting of *tert*-alcohol media [^{18}F]radiofluorination (*27*) and subsequent hydrolysis of the methyl ester compound [^{18}F]**14**, as shown in Scheme 2. The first radiolabeling step, [^{18}F]radiofluorination reaction of the mesylate precursor **12** with [^{18}F]TBAF in *tert*-amyl alcohol at 100 °C, produced the labeled compound [^{18}F]**14** at high radiochemical yield (RCY) compared with [^{18}F]radiofluorination reaction in conventional solvent—CH_3CN. After the basic hydrolysis of [^{18}F]**14**, the final product compound, [^{18}F]**16**, was isolated by reverse-phase HPLC purification, as described in the Experimental Section. Figure 2A shows a representative semipreparative HPLC chromatogram of the crude reaction mixture, which indicates that [^{18}F]**16** could be obtained with high specific activity (an average specific activity of 149 ± 75 GBq/μmol when starting from a relatively low amount (370−666 MBq) of [^{18}F]fluoride) compared to that of the previous radiolabeled ciprofloxacins (0.43 ± 0.2 GBq/μmol) (*13*). The radiochemical purity of [^{18}F]**16**, which coeluted on analytical HPLC with an authentic sample of unlabeled **16** (Figure 2B), was >99%. The overall radiosynthesis of [^{18}F]**16** resulted in a decay-corrected RCY of approximately 40% with a total synthesis time (including the HPLC purification) of 100 min from the end of bombardment in two steps; the RCY of overall radiosynthesis of [^{18}F]**16** using the radiofluorination reaction in CH_3CN showed 24%.

The radiotracer (0.74 MBq) was incubated, and the percentage of the remaining [^{18}F]**16** ($R_f = 0.79$) was greater than 90% after 5 h when incubated in human serum at 37 °C, indicating the relatively high in vitro stability of the radiotracer as shown in Figure 3. On the other hand, serum-bound [^{18}F]**16** ($R_f = 0$) was less than 10% after 5 h postlabeling. This result demonstrated

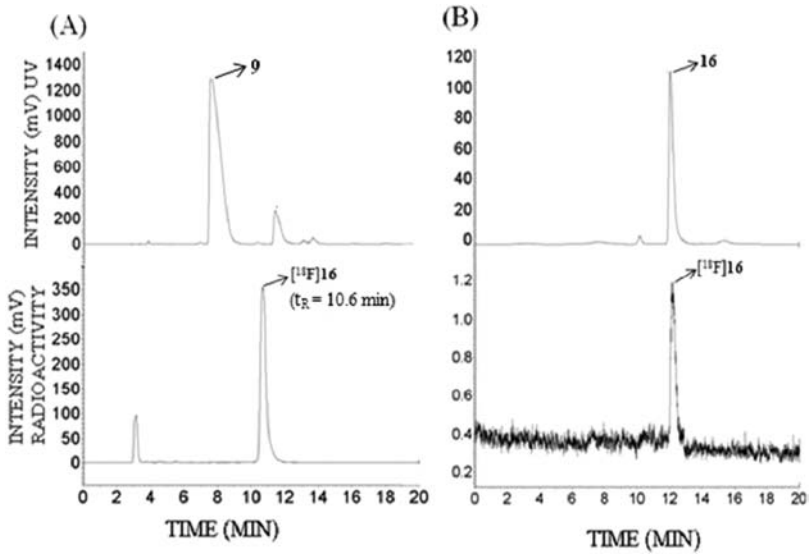

Figure 2. (A) Purification of [^{18}F]**16** on HPLC. The reaction mixture was injected on a semipreparative C18 column and was eluted with 10 mM aqueous phosphoric acid/EtOH (88:12) at a flow rate of 4.0 mL/min. (B) Representative analytical HPLC chromatogram of [^{18}F]**16** coinjected with its non-radioactive analogue **16**.

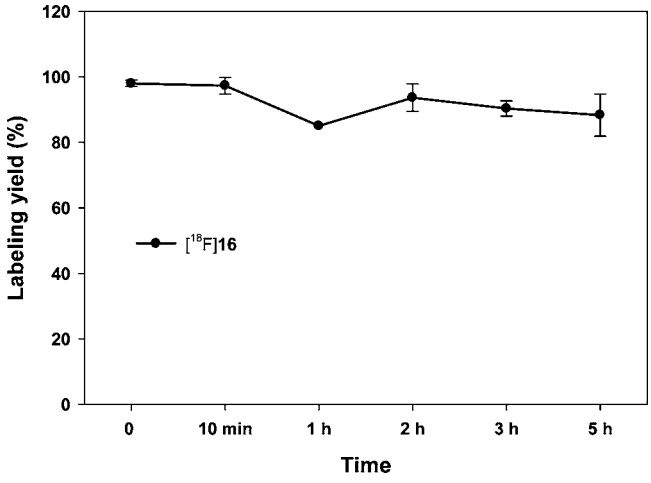

Figure 3. In vitro human serum stability of [^{18}F]**16**.

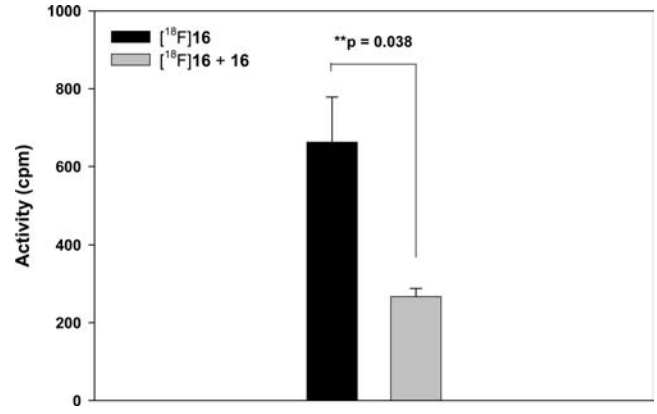

Figure 4. Bacterial uptake and blocking of [^{18}F]**16** in TOP10 ($n = 3$). TOP10 was incubated with [^{18}F]**16** and the authentic compound **16** (25 nmol) as inhibitor. The data are presented as the mean ± SD ($P < 0.05$).

that the [^{18}F]fluoropropyl moiety in the radiotracer is quite stable in human serum.

Competitive bacterial binding assays were carried out on the TOP10 with a cold authentic compound **16**, as shown in Figure 4. Bacterially bound levels decreased by 59% of control levels in the presence of 25 nmol of cold authentic compound **16**. This inhibition study demonstrated high specificity of [^{18}F]**16** binding to the DNA gyrase of TOP10; these results illustrate that this radiotracer has great potential as an imaging agent to detect bacterial infections or to evaluate pharmacokinetics of quinolone antibacterial drugs through its high specific bacterial uptake.

CONCLUSION

In summary, we present syntheses and evaluation of fluoroalkylated ciprofloxacin derivatives to investigate bacterial infection radiopharmaceuticals for PET. The SAR study suggests that the introduction of a 3-fluoropropyl group onto the N-4′ position in ciprofloxacin should have little influence on either high binding affinity to the DNA gyrase of bacteria or antibacterial potency; we prepared no-carrier-added N_4'-3-[^{18}F]fluoropropylciprofloxacin ([^{18}F]**16**) in two steps starting from its mesylate precursor using the *tert*-alcohol media radiofluorination method with good radiochemical yield. The competition bacterial binding study and high specific activity of [^{18}F]**16** suggest that it may have potential as a useful PET radiopharmaceutical agent for the differentiation between bacterial infection and nonbacterial infection or sterile inflammation. Further studies to evaluate the utilities of this radiotracer for PET bacterial infection in vivo imaging are in progress in our laboratories.

Received July 13, 2010; Revised Manuscript Received October 18, 2010

The synthesis, radiolabeling, and initial evaluation of new silicon-fluoride acceptor (SiFA) derivatized octreotate derivatives is reported. So far, the main drawback of the SiFA technology for the synthesis of PET-radiotracers is the high lipophilicity of the resulting radiopharmaceutical. Consequently, we synthesized new SiFA-octreotate analogues derivatized with Fmoc-NH-PEG-COOH, Fmoc-Asn(Ac_3AcNH-β-Glc)-OH, and SiFA-aldehyde (SIFA-A). The substances could be labeled in high yields (38 ± 4%) and specific activities between 29 and 56 GBq/μmol in short synthesis times of less than 30 min (e.o.b.). The in vitro evaluation of the synthesized conjugates displayed a sst2 receptor affinity (IC_{50} = 3.3 ± 0.3 nM) comparable to that of somatostatin-28. As a measure of lipophilicity of the conjugates, the log P_{ow} was determined and found to be 0.96 for SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate and 1.23 for SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate, which is considerably lower than for SiFA-Tyr^3-octreotate (log P_{ow} = 1.59). The initial in vivo evaluation of [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate revealed a significant uptake of radiotracer in the tumor tissue of AR42J tumor-bearing nude mice of 7.7% ID/g tissue weight. These results show that the high lipophilicity of the SiFA moiety can be compensated by applying hydrophilic moieties. Using this approach, a tumor-affine SiFA-containing peptide could successfully be used for receptor imaging for the first time in this proof of concept study.

INTRODUCTION

Fluorine-18 (^{18}F, $t_{1/2}$ = 109.7 min) is the most important radionuclide for imaging by means of positron emission tomography (PET), a noninvasive imaging modality which found its way into human diagnostic imaging more than 30 years ago. The introduction of 2-[^{18}F]FDG, a ^{18}F-labeled sugar derivative, has pushed nuclear medicine forward, and 2-[^{18}F]FDG today accounts for the majority of human PET scans in a variety of human afflictions such as cancer and neurological diseases. Further stimulated by the introduction of PET/CT, it is very likely that the number of PET-scans will continue to rise within the next years particularly as the single-photon-emission-tomography (SPECT) technology has recently suffered from radioisotope shortages and thus impaired reliability (*1, 2*). One apparent drawback of the PET technology is the often complicated synthesis of the respective imaging agents, a circumstance which, despite best efforts, has not yet been alleviated. Especially for larger molecules, such as peptides and proteins, simple one-step labeling procedures have been evasive despite several advancements in the field (*3*−*7*). Although direct labeling via nucleophilic substitution has recently been shown to be a possible route for the ^{18}F-labeling of some selected peptides with nonacidic side chain functionalities (*8*), this path lacks general applicability to more complex and temperature-sensitive peptides. A further drawback of all the described methods for the radiolabeling of peptides and proteins based on the formation of a carbon-^{18}F bond is the necessity for intricate purification methods (e.g., HPLC) (*9*). Recently, our group and Ametamey et al. independently described the synthesis of sterically hindered silicon-^{18}F building blocks used as prosthetic groups in the synthesis of radiolabeled peptides and proteins (*10*−*13*). Our method was coined SiFA chemistry (SiFA: Silicon-Fluoride-Acceptor), whose concept is based on a simple isotopic exchange reaction, yet yielding compounds of high specific activity. Single-step labeling as well as two-step labeling procedures were described, and the first true ^{18}F-kit labeling procedure for proteins emerged from these efforts (*14*−*16*). Despite this success for protein labeling, the initial application of silicon-^{18}F derivatized peptides for tumor imaging unambiguously revealed a pronounced lipophilicity imparted by the Si−F building blocks, leading to a high unspecific liver and low tumor uptake (*17, 13*). In order to circumvent this problem, we report here the application of our SiFA chemistry together with hydrophilic PEG spacers and carbohydrates in the syntheses of octreotate derivatives in order

to obtain compounds with improved properties for the in vivo imaging of somatostatin receptor positive tumors (*18*−*20*). The peptides Tyr^3-octreotate as well as Tyr^3-octreotide (an alcohol derivative of Tyr^3-octreotate) are analogues of the peptide hormone somatostatin and have a preferentially high affinity to the somatostatin receptor subtype 2, which is highly overexpressed on the cell surface of several neuroendocrine tumors. Thus, these peptides represent ideal compounds for receptor-mediated tumor targeting and imaging (*21*−*23*). As of now, the radiolabeling of somatostatin analogues with ^{18}F is complicated and time-consuming, as it necessitates a two-step procedure for (i) the synthesis of a secondary labeling precursor (which has in most cases to be purified by HPLC) and (ii) the subsequent reaction with the peptidic compound. Thus, a more simple and efficient method for the introduction of ^{18}F into peptides is highly desirable. A promising approach is the use of the SiFA technology, as this would allow the introduction of ^{18}F into peptides in a one-step reaction. Thus, the aim of this work was to demonstrate that (i) the introduction of hydrophilic groups in combination with the SiFA moiety into peptides yields radiofluorinated products retaining their binding affinity to the target receptor while (ii) simultaneously displaying improved in vivo behavior for PET imaging compared to radiofluorinated peptides using silicon-fluoride building blocks alone, and that furthermore (iii) one-step synthesis of these radiotracers is feasible.

EXPERIMENTAL SECTION

Materials. Commercially available chemical compounds were purchased in highest purity and used without further purification. The resin for peptide synthesis (Fmoc-Thr(tBu)-Wang resin), Fmoc-protected amino acids, Fmoc-8-amino-3,6-dioxaoctanoic acid (Fmoc-NH-PEG-COOH), *N*-α-Fmoc-*N*-*β*-[3,4,6-tri-*O*-acetyl-2-(acetylamino)-deoxy-2-*β*-glucopyranosyl]-L-asparagine (Fmoc-Asn(Ac_3AcNH-*β*-Glc)-OH), and bis-Boc-aminooxy acetic acid (Bis-boc-Ao-OH) were purchased from NovaBiochem (Nottingham, UK). 4-(Di-*tert*-butylfluorosilyl) benzaldehyde (silicon-fluoride-acceptor aldehyde, SiFA-A) (**1**) as well as [^{18}F]-SiFA-Tyr^3-octreotate (**[^{18}F]-2**) were synthesized according to a published procedure (*11*). SepPak C-18 cartridges were obtained from Waters Corporation (Milford, MA, USA), Chromafix PS-HCO_3 cartridges from GE-Healthcare Europe (Freiburg, Germany).

Instruments. The analytical and semipreparative HPLC system used was an Agilent 1200 system equipped with a Raytest Gabi Star radioactivity detector together with an analytical Chromolith Performance column (RP-18e, 100 × 4.6 mm, Merck, Germany) at a flow rate of 4 mL/min and a semipreparative Chromolith column (RP-18e, 100 × 10 mm, Merck, Germany) at a flow rate of 8 mL/min, respectively. ESI mass spectra were obtained by using a Finnigan MAT95Q. The PET scans were performed using a Siemens Inveon 120 small animal PET system (Siemens Preclinical Imaging, Knoxville, TN, USA) or a Philips MOSAIC small animal scanner (Philips Healthcare, Eindhoven, The Netherlands). Gamma counting was performed using a Packard Canberra apparatus.

*Peptide Synthesis. Synthesis of Aoa-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**3**).* Tyr^3-octreotate was synthesized on solid support applying standard Fmoc solid-phase peptide synthesis as described by Wellings et al. (*24*) on a Fmoc-Thr(tBu)-Wang resin (standard coupling procedure: 4 equiv amino acid, 3.9 equiv HBTU, 4 equiv DIPEA in DMF; Fmoc-cleavage: 50% piperidine in DMF). After cyclization of the Tyr^3-octreotate peptide sequence (Fmoc-D-Phe-Cys(Acm)-Tyr-D-Trp-Lys-Thr-Cys(Acm)-Thr-Wang) by incubating the resin with Tl(III)-trifluoroacetate in DMF for 45 min, the terminal Fmoc protecting group was removed. Subsequently, Fmoc-NH-PEG-COOH, Fmoc-Asn(Ac_3AcNH-*β*-Glc)-OH, and Bis-boc-Aoa-OH were successively coupled using standard coupling conditions. The peptide was cleaved from the resin by incubation with a mixture of TFA (trifluoroacetic acid)/TIS (triisopropylsilane)/H_2O (95:2.5:2.5, 1.5 mL) for 45 min, precipitated in diethyl ether, washed twice with diethyl ether, and dried. For cleavage of the carbohydrate acetyl protecting groups, the dried crude peptide was dissolved in methanol (1 mL), and a sodium methanolate solution in methanol (0.5M) was added until the pH of the mixture reached 12−13 (approximately 0.6 mL; pH determined on moistened pH indicator strips). After 30 min reaction at room temperature, the mixture was acidified with neat TFA (approximately 50 μL) and purified by semipreparative HPLC using a gradient of 15−40% MeCN + 0.1% TFA over 5 min. The product was isolated as white solid after lyophilization (23.2 mg, 14.6 μmol, 19% yield).

HR-ESI-MS (*m*/*z*) for $[M+H]^+$ (calculated) 1584.63 (1584.64); (*m*/*z*) for $[M+2H]^{2+}$ (calculated) 792.82 (792.82).

*Synthesis of SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**4**).* The intermediate Aoa-Asn(AcNH-*β*-Glc)-Tyr^3-octreotate was synthesized by reacting fully protected Tyr^3-octreotate on resin with Fmoc-Asn(Ac_3AcNH-*β*-Glc)-OH and Bisboc-Aoa-OH and cleaved from the resin as described before for the synthesis of **3**. The deprotection of the O-acetyl protecting groups was also performed analogously to **3** by reacting the peptide for 30 min with sodium methanolate solution in methanol. When the reaction was finished, the volatile components of the mixture were evaporated, the obtained solid was dissolved in phosphate buffer (0.5 M, pH = 4.0, 400 μL) and reacted with SiFA-A (**1**) dissolved in acetonitrile by adding SiFA-A in small amounts until an excess of SiFA-A could be detected by analytical HPLC (gradient of 0−100% MeCN + 0.1% TFA over 5 min) after reaction times of 5 min. The crude product was purified by semipreparative HPLC using a gradient of 10−50% MeCN + 0.1% TFA over 5 min. The product was isolated as white solid after lyophilization (5.5 mg, 3.3 μmol, 13.3%).

HR-ESI-MS (*m*/*z*) for $[M+H]^+$ (calculated): 1686.70 (1686.69).

*Synthesis of SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**5**).* For the oxime formation, a modified protocol from that described by Poethko et al. was used (*25*). A solution of Aoa-Asn(AcNH-*β*-Glc)-PEG-Tyr^3-octreotate (**3**, 10 mg, 6.3 μmol) in phosphate buffer (0.25 M, pH = 4.0, 400 μL) was added to a solution of SiFA-A (**1**, 2.1 mg, 7.9 μmol, 1.25 equiv) in acetonitrile (500 μL). The pH was adjusted to 4.0 by adding phosphate buffer (0.5 M, pH = 4.0, ∼50 μL). The mixture was incubated for 5 min at ambient temperature, and subsequently, the product was purified by semipreparative HPLC using a gradient of 40−80% MeCN + 0.1% TFA over 4 min. The product was isolated as a white solid after lyophilization (9.3 mg, 5.1 μmol, 80%).

HR-ESI-MS (*m*/*z*) for $[M+H]^+$ (calculated) 1832.02 (1832.77); (*m*/*z*) for $[M+2H]^{2+}$ (calculated) 917.39 (917.88).

*Radiolabeling. Preparation of a Stock Solution Containing [^{18}F]F$^-$/Kryptofix 2.2.2/K$^+$ Complex for the Labeling of SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**4**) and SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**5**).* Aqueous [^{18}F]fluoride (4000−7500 MBq) that had been produced by the ^{18}O(p,n)^{18}F nuclear reaction on an enriched [^{18}O]water (95%) target was loaded onto a Chromafix PS-HCO_3 cartridge and eluted with a mixture of acetonitrile (800 μL), water (200 μL), potassium oxalate solution (1 M, 10 μL), and Kryptofix 2.2.2 (12.5 mg). The solvents were removed by coevaporation to dryness under reduced pressure (650 mbar) using a stream of helium at 87 °C for 4 min. The drying step was repeated twice with CH_3CN (0.8 mL) (3 min) and full vacuum (∼10 mbar) was applied in the final drying step (4 min). The dried [^{18}F]F$^-$/Kryptofix 2.2.2/K$^+$ complex was

dissolved in dry DMSO (500−1000 μL) and used as stock solution for labeling.

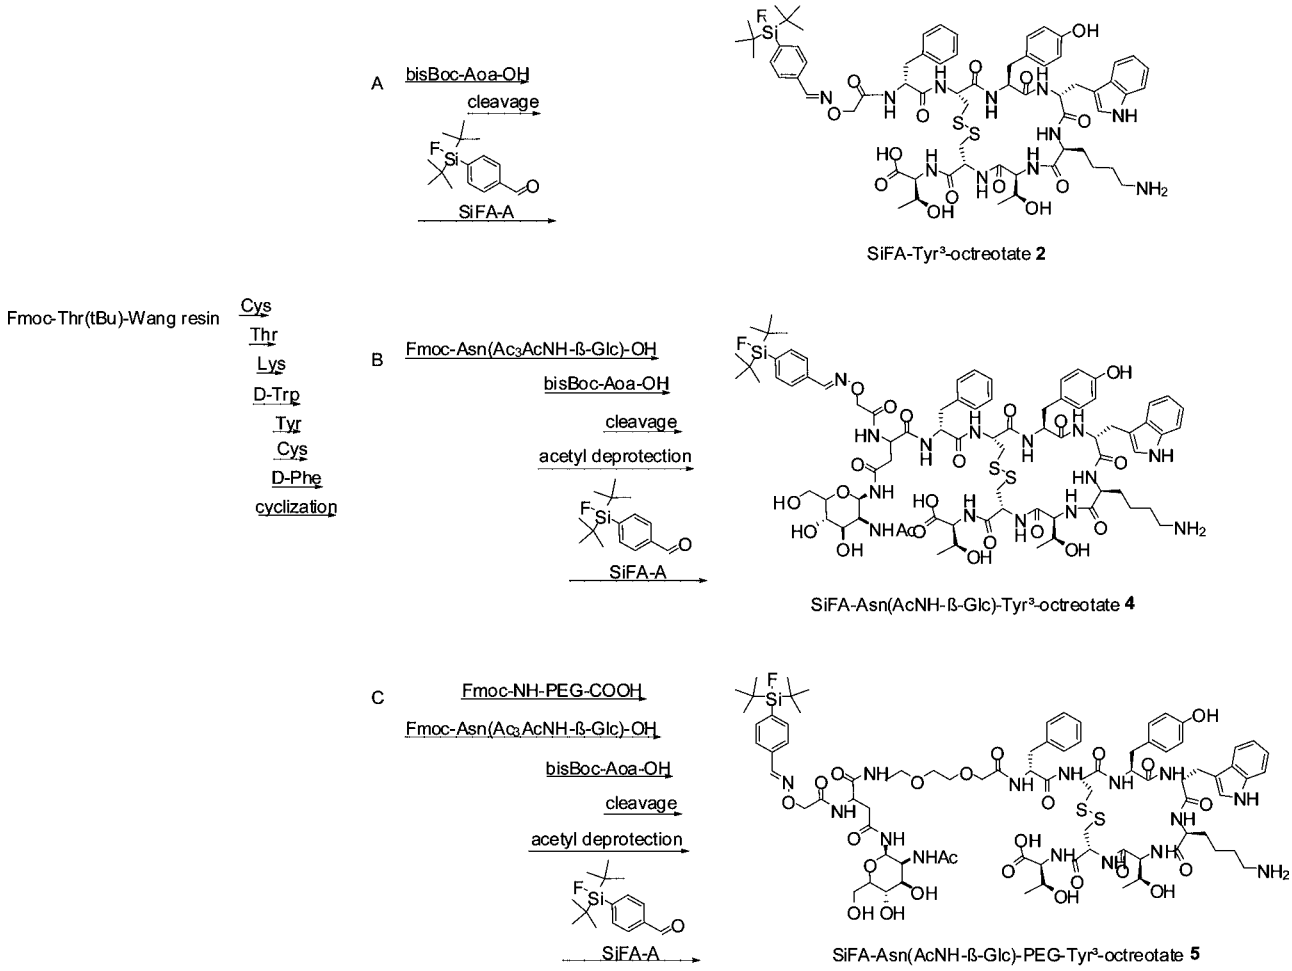
*Radiosynthesis of [^{18}F]SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**[^{18}F]-4**) and [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**[^{18}F]-5**).* The SiFA containing peptides **4** and **5** (10−25 nmol, 10−25 μL of a 1 mmol/L stock solution in dry DMSO) were added to 450−500 μL of the stock solution containing [^{18}F]F$^-$/Kryptofix 2.2.2/K$^+$ complex (2−3 GBq) in dry DMSO and reacted at ambient temperature for 5 min without stirring. Subsequently, the reaction mixture was added to HEPES buffer (0.1 M, pH 4, 9 mL) and loaded on a Waters SepPak C-18 light cartridge, previously conditioned by subsequent rinsing with ethanol (5 mL) and water for injection (10 mL). The trapped [^{18}F]SiFA-peptides were washed with water for injection (5 mL), eluted from the cartridge with ethanol (200 μL), and diluted with isotonic saline solution (2 mL). The solution was filtered sterile for further use. The overall synthesis time was 15 min. Reverse-phase HPLC revealed radiochemical purities ranging from 92% to 96%. ^{18}F-fluoride impurities were in all cases <1%. The syntheses yielded 0.7 to 1.4 GBq of **[^{18}F]-4** and **[^{18}F]-5** starting from 2−3 GBq of the [^{18}F]F$^-$/Kryptofix 2.2.2/K$^+$ complex of the used stock solution. The products could be obtained in specific activities between 29 and 56 GBq/μmol and radiochemical yields (RCY) of 38 ± 4%.

Plasma Stability. [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate **[^{18}F]-5** (100 MBq) in injectable solution obtained as described before) was added to human plasma (500 μL) at 37 °C. At certain time points (5, 10, 40, 60, and 120 min), 75 μL of this mixture were taken and added to acetonitrile (250 μL). The samples were stored on ice for 5 min for complete precipitation of plasma proteins. The precipitate was removed by centrifugation, and the supernatants were analyzed by radio-HPLC. Radioactivity in precipitate and supernatant was measured.

Lipophilicity. 1−2 MBq of [^{18}F]SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**[^{18}F]-4**) or [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**[^{18}F]-5**) was added to a mixture of 1-octanol (900 μL) and phosphate buffer (0.05 M, pH = 7.4, 900 μL) and the mixtures were vigorously vortexed for 5 min. After subsequent centrifugation at 14 000 rpm for 2 min, aliquots of 100 μL were taken from each phase and measured in a gamma-counter. As a control, the experiment was repeated by partinioning the organic layer from the aqueous layer. The organic layer was added to the same amount of fresh phosphate buffer and again treated as described before.

In Vitro Evaluation. Receptor subtype affinity of the synthesized peptides to the somatostatin receptor subtypes 1−5 (sst1−5) was determined as described in detail previously (*26*). In brief, sections of cell membrane pellets on microscopic slides were used. These cell membrane pellets were prepared from different cell types expressing the somatostatin receptor as described before (*27*). Displacement experiments were performed by incubating the sections for 2 h at room temperature using the somatostatin radioligand [Leu^8, D-Trp^{22}, [^{125}I]-Tyr^{25}]somatostatin-28 and increasing concentrations of the unlabeled peptides ranging from 0.1 to 1000 nM. After 2 washing steps, the sections were dried quickly and exposed to a radiosensitive film (Biomax MR; Kodak) for 7 days. IC$_{50}$ values were calculated after quantification of the data using a computer-assisted image processing system as described previously (*27*). Tissue standards (Autoradiographic [^{125}I] and/or [^{14}C] microscales, GE Healthcare, Little Chalfont, UK) that contain known amounts of isotope, cross-calibrated to tissue-equivalent ligand concentrations, were used for quantification (*28*).

In Vivo Biodistribution of [^{18}F]SiFA-PEG-Asn(AcNH-β-Glc)-PEG-Tyr^3-Octreotate **[^{18}F]-5** *in AR42J Tumor-Bearing Nude Mice (CD 1 nu/nu).* Mice were housed according to German animal protection laws and protocols of the local committee. To establish a tumor model with high expression of sst2, the rat pancreatic tumor cell line AR42J was utilized (*29*). In brief, nude mice (CD 1 nu/nu, female, 6−8 weeks) were injected with 100 μL of a cell suspension (containing (2.5−5) × 10^6 cells) of AR42J cells s.c. into the right flank (*30, 31*). The biodistribution experiments were performed 10 to 14 days after tumor inoculation under inhalation anesthesia (oxygen 1.2 L/min, isofluran 1.5 vol %) and appropriate warming to prevent hypothermia. For in vivo biodistribution experiments, 4−5 animals per group bearing AR42J tumors (200−900 mg) on the right flank were used. 1.0−1.8 MBq of [^{18}F]SiFA-PEG-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**[^{18}F]-5**) were administered i.v. The animals were sacrificed after 10 and 60 min. The tissues of interest were dissected and weighed, and the incorporated radioactivity was measured using a gamma counter. For the small animal PET imaging experiment evaluating **[^{18}F]-5**, 7.86 MBq of the radiotracer was injected i.v. List mode data were acquired over 90 min using the Siemens Inveon 120 small animal PET system (Siemens Preclinical Imaging, Knoxville, TN, USA) and divided into temporal frames of increasing length varying from 20 s to 20 min for the assessment of temporal changes in regional tracer accumulation. For the small animal PET imaging experiment evaluating **[^{18}F]-2**, 35 MBq of the radiotracer were injected i.v. List mode data were acquired over 90 min using the Philips Mosaic III small animal PET Scanner (Philips Healthcare, Amsterdam, The Netherlands) and divided into 18 frames of 5 min for the assessment of temporal changes in regional tracer accumulation.



RESULTS AND DISCUSSION

Synthesis of PEG and Glucose Derivatized Octreotate Derivatives 4 and 5. In order to obtain Tyr^3-octreotate derivatives showing a lower lipophilicity and therefore a more favorable in vivo biodistribution, our synthesis strategy was to introduce groups of high hydrophilicity such as carbohydrates and polyethylene glycols (PEGs) into the peptide sequence compensating the high lipophilicity of the SiFA building block (Scheme 1). This approach was shown to result in peptide derivatives with improved in vivo behavior by Schottelius et al. (*18, 19*) and Antunes et al. (*32*).

The synthesis of the less lipophilic peptide derivatives started with of Tyr^3-octreotate obtained by standard Fmoc solid-phase peptide synthesis methods (*24*). In the synthesis of SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**4**) and SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**5**), Tyr^3-octreoate was synthesized on solid support and further reacted with the PEG spacer Fmoc-NH-PEG-COOH (in case of **5**), the glucose-derivative Fmoc-Asn(Ac$_3$-Ac-NH-βGlc)-OH and bis-Boc-aminooxyacetic acid (Bis-boc-Aoa) (Scheme 1). After cleaving the peptides from solid support and purification via semipreparative HPLC, the acetyl-protecting groups of the glucose-hydroxyl functions were cleaved by incubating the intermediates with sodium methanolate in methanol at pH 12−13. Analytical HPLC revealed the maximum achievable yields after 30 min at ambient temperature to be around 40%. Longer deprotection times resulted in a significant decomposition of the peptides complicating the subsequent HPLC-purification. Aoa-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate **3** could be isolated after semipreparative HPLC purification and lyophilization in ∼20% yield. The corresponding Tyr^3-octreoate derivative Aoa-Asn(AcNH-β-Glc)-Tyr^3-octreotate could not be purified by means of HPLC due to the side-products which were formed in the acetyl-deprotection step and was therefore used without further purification for the subsequent coupling of the SiFA moiety via oxime formation reaction.

For further derivatization of the peptides with the SiFA ^{18}F-acceptor moiety, both peptides were reacted with SiFA-A (**1**)

Scheme 1[a]

Synthesis of the SiFA-conjugated octreotate-derivatives SiFA-Tyr^3-octreotate **2** (route A), SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate **4** (route B), and SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate **5** (route C).

[a] After a standard Fmoc solid-phase synthesis of Fmoc-Tyr^3-octreotate, the on resin cyclization was carried out using Tl(III)trifluoroacetate. For the synthesis of the SiFA-derivatized peptides, Tyr^3-octreotate was further reacted on resin with Fmoc-NH-PEG-COOH (C), Fmoc-Asn(Ac_3AcNH-*β*-Glc)-OH (B, C), and bis-boc-aminooxyacetic acid (A, B, C) prior to the cleavage from resin and semipreparative HPLC-purification. After the acetyl deprotection of the carbohydrated intermediates using sodium methanolate (B, C), the oxime formation (A, B, C) was carried out in an acetonitrile buffer mixture reacting the intermediates with SiFA-A (**1**) at pH 4 for 5 min following a strategy described by Poethko et al (*25*).

in a mixture of phosphate buffer and acetonitrile via oxime formation (Scheme 1) (*25*). The coupling reaction was carried out at pH 4.0 giving the desired products in high yields after reaction times of only 5 min at room temperature. The overall yields for **4** and **5** were 13.3% and 15.2% after final HPLC purification, respectively. These two compounds represent the direct, unprotected labeling precursors for the one-step ^{18}F-labeling reaction.

Radiolabeling. In general, a drawback of the isotopic exchange reaction for radiolabeling is the limited specific activity (SA) because the precursor cannot be separated from the final product. As a result of its overall inefficiency, the precursor amount used for isotopic ^{19}F−^{18}F exchange is in the micromolar range. In order to achieve higher SA, the amount of labeling precursor used must be minimized. A high SA of the radiotracer for in vivo receptor imaging with PET is a prerequisite, as imaging probes being of low SA insufficiently delineate the target tissue as a result of direct binding competition of nonradioactive ^{19}F-compound. For SiFA-Tyr^3-Octreotate (**2**), we found 75 nmol to be the smallest possible amount for a direct labeling procedure to introduce 350−400 MBq (∼10 mCi) of ^{18}F, resulting in specific activities of 3−5 GBq/μmol (*10*). This SA would normally not be sufficient for PET-imaging. To obtain labeled peptides with much higher specific activities, we developed a two-step labeling procedure. The first step using this approach was the radiolabeling reaction in amounts of down to 3.75 nmol of SiFA-aldehyde (SIFA-A) and the subsequent reaction with an aminooxy-derivatized Tyr^3-octreotate, resulting in specific activities of up to 680 GBq/μmol (*11*). However, using this synthesis route, a HPLC-purification step was required to separate the final products from the precursors and intermediates, extending the synthesis time and diminishing the benefits of the fast reaction kinetics of the SiFA approach.

To circumvent a two-step labeling approach and HPLC-purification steps, we intended to find radiolabeling conditions resulting in the formation of the desired peptidic products **[^{18}F]-4** and **[^{18}F]-5**, even when small amounts of the new and more hydrophilic precursors SiFA-Asn(AcNH-*β*-Glc)-Tyr^3-octreotate (**4**) and **5** of ≤25 nmol were used. The resulting octreotate derivatives should then be obtained in high specific activities allowing their use in animal PET imaging applications.

When starting from stock solutions of dried [^{18}F]F$^-$/Kryptofix 2.2.2/K$^+$ complex in DMSO, the labeling experiments with both **4** and **5** displayed a ^{18}F-incorporation of about 40% and 60%

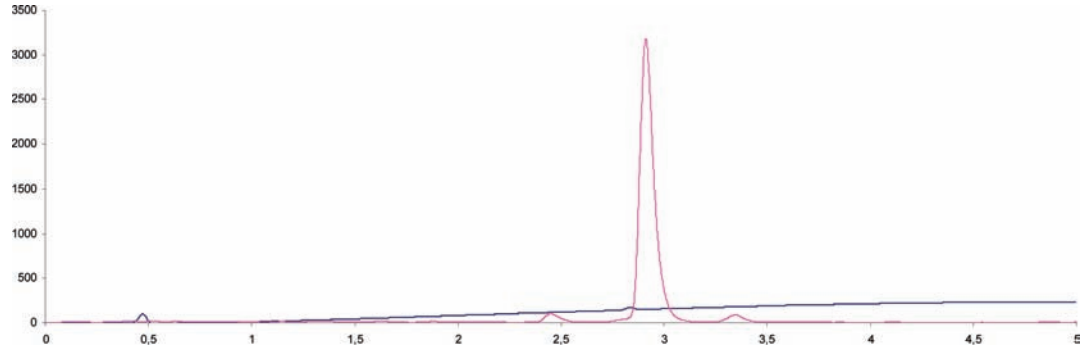


Figure 1. Typical UV/Radio-HPLC chromatogram of [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate **[^{18}F]-5** purified by solid-phase extraction, blue = UV trace at 214 nm, magenta = radioactivity trace (R_t (**[^{18}F]-5**) = 2.9 min).

when 10 nmol and 25 nmol of precursor were used, respectively. As the SiFA-modified peptides are labeling precursors and labeled products at the same time, the advantage of the SiFA-labeling technique is the absence of a labeling precursor chemically different from the product requiring a HPLC-purification. The SiFA-isotopic exchange labeling is performed under very mild conditions preventing the occurrence of radioactive side products. Only unreacted ^{18}F has to be removed using a reversed-phase (RP) cartridge. The cartridge purification also removes DMSO and Kryptofix 2.2.2 after a final washing step with water, retaining the respective peptides. Final elution of the cartridge with ethanol and dilution with sterile buffer yielded compound **[^{18}F]-5** in 38 ± 4% RCY as an injectable solution after sterile filtration. After this simple RP-cartridge purification step, analytical HPLC revealed a radiochemical purity of the products of 92−96% (Figure 1). The chemical purity of **[^{18}F]-5** was determined by HPLC at 214 nm and showed no side products.

The resulting specific activities of **[^{18}F]-4** and **[^{18}F]-5** ranged between 29 and 56 GBq/μmol—assessed from the precursor amount used for the synthesis—thus being in a suitable range for imaging sst-positive tumors. The labeling reaction and cartridge purification of [^{18}F]SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**[^{18}F]-4**) and [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**[^{18}F]-5**) were completed in less than 15 min (30 min overall synthesis time, including the preparation of the [^{18}F]F$^-$/Kryptofix 2.2.2/K$^+$ complex).

Thus, this labeling method is highly efficient, proceeding in very short time spans in only one reaction step and requiring only one final cartridge purification.

Stability Studies. The chemical batch stability of **[^{18}F]-5** was determined over 4 h at room temperature by analytical radio-HPLC. Within this time span, compound **[^{18}F]-5** displayed no observable decomposition. In addition, the plasma stability was determined over 2 h displaying no degradation of the product as well. In this experiment, more than 86% of the radioactivity was found in the supernatant. These findings are in accordance with the data published for several silicon-derivatized peptides comprising huge, sterically hindered substituents (*10, 33*).

Lipophilicity. We and other groups found bulky, lipophilic substituents are a prerequisite to stabilize the Si−F bond against hydrolysis. The resulting high lipophilicity represents, however, a problem for in vivo application of SiFA-containing peptides. To determine whether our concept of introducing hydrophilic moieties such as carbohydrates and PEG spacers has a positive effect on the lipophilicity of the obtained Tyr^3-octreotate derivatives, making them ultimately better-suited for in vivo application, we determined the lipophilicity of the radiolabeled compounds [^{18}F]SiFA-Tyr^3-octreotate (**2**), [^{18}F]SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**4**), and [^{18}F]SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**5**). By determining the 1-octanol/phosphate buffered saline (PBS) partition coefficient P_{ow} and the lipophilicity log P_{ow}, we found for SiFA-TATE (**2**), (**4**), and (**5**) log P_{ow} values of 1.59, 1.23, and 0.96, respectively (Table 1). This displays a significant increase in hydrophilicity of the derivatized peptides **4** and **5** compared to SiFA-TATE (**2**) (*10*).

Table 1. Lipophilicity of SiFA-Derivatized Octreotate Derivatives (n = 3, values are mean ± SD)

peptide	log P_{ow}
SIFA-Tyr^3-octreotate (**2**)	1.59 ± 0.01
SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**4**)	1.23 ± 0.05
SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**5**)	0.96 ± 0.07
[^{125}I]-Tyr^3-octreotide[a]	0.18 ± 0.03[a]

In Vitro Evaluation. The new compounds SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**4**) and SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**5**) were tested for their affinity toward the human somatostatin receptor subtypes (sst1−sst5) (Table 2). Both display affinities to the sst2—the most important receptor subtype for imaging—which are comparable to the affinity of Tyr^3-octreotide, a physiologically stabilized derivative of the natural ligand somatostatin-28. Tyr^3-octreotide was the lead compound for the development of several SPECT and PET radiotracers for receptor scintigraphy of sst-postive tumors in human studies. Comparing the PEGylated (**5**) and the non-PEGylated derivative (**4**), we found an increased affinity of the former compound to the somatostatin receptor subtype 2 (sst2), being in the same range as for Tyr^3-octreotide, which might be explained by the higher distance of the peptide to the highly lipophilic SiFA moiety using a PEG spacer in addition to the carbohydrated asparagine derivative. In comparison to Tyr^3-octreotide, compound **5** displayed the same binding affinity to sst2. Antunes and co-workers (*32*) used different hydrophilic spacers to derivatize the somatostatin-binding peptide NOC (Nal^3-octreotide) and found only marginal changes in the binding affinities to sst2, which is in contrast to our own findings. We assume that, for the compounds presented here, the observed larger variations in specific binding affinities that are achieved by using different spacers can be attributed to the more substantial decrease in the overall lipophilicity (Table 1).

In Vivo Biodistribution. In our initial in vivo experiment which was done using [^{18}F]SiFA-Tyr^3-octreotate (**[^{18}F]-2**) in a tumor model published by Fottner et al. (*31*), the animal PET images revealed no tumor uptake after 90 min but a significant radioactivity accumulation in liver and intestines. This experimental outcome is in accordance with data published for the biodistribution of ^{18}F-labeled silicon-modified bombesin derivatives suffering from the same shortcomings (*13*). Since affinity data for this compound are not available, we speculate that the faint tumor uptake can be attributed to an unfavorably high lipophilicity resulting in fast blood clearance, high liver uptake, and high unspecific binding.

Table 2. Affinity Profiles (IC_{50}) to the Human sst1−sst5 Receptors, Determined for Compounds 4 and 5 Using [Leu^8, D-Trp^{22}, ^{125}I-Tyr^{25}]somatostatin-28 as the Radioligand[a]

Table 3. Tissue Distribution [ID/g] of ^{18}F-SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-Octreotate ([^{18}F]-5) in AR42J Tumor-Bearing Mice

tissue	10 min p.i.[a]	60 min p.i.[b]
blood	13.43 ± 2.58	5.92 ± 1.52
lung	8.30 ± 2.96	5.82 ± 1.59
liver	29.55 ± 7.04	16.11 ± 3.80
pancreas	5.64 ± 1.22	11.99 ± 2.89
spleen	3.94 ± 0.87	2.72 ± 0.48
stomach	4.36 ± 0.85	14.46 ± 2.14
large intestine	1.59 ± 1.16	2.14 ± 1.15
small intestine	2.93 ± 0.45	6.90 ± 1.10
kidney	6.67 ± 1.11	6.35 ± 0.98
adrenals	6.14 ± 2.46	3.92 ± 1.13
muscle	0.89 ± 0.19	0.59 ± 0.21
femur	1.88 ± 1.15	3.79 ± 1.24
tumor	3.25 ± 1.06	7.73 ± 1.90

[a] Group of 4 mice. [b] Group of 5 mice. Values are mean ± SD injected dose per gram tissue (% ID/g).

As ^{18}F-SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-Octreotate (**[^{18}F]-5**) showed the most promising in vitro evaluation profile and the most favorable properties with regard to hydrophilicity, we evaluated the compound in vivo in AR42J tumor-bearing nude mice. The tissue distribution after 10 and 60 min postinjection is shown in Table 3.

As expected, and despite the hydrophilic derivatization, the lipophilicity of **[^{18}F]-5** leads to a high accumulation of 30% and 16% ID/g tissue in the liver after 10 and 60 min, respectively. The radioactivity concentration in the blood decreases from ~13.4% (10 min p.i.) to 6% (60 min p.i.), displaying a relatively high plasma half-life of the derivative. The accumulation in pancreas, stomach, and intestines increases by the factor 2−3 over time.

In Vivo Animal PET Data for a Silicon-^{18}F Derivatized [^{18}F]SiFA-Octreotate of High Lipophilicity Lacking PEG and/or Glucose Moieties. Initial laboratory results for the in vivo evaluation of the SiFA-derivatized octreotate derivative [^{18}F]SiFA-Tyr^3-octreotate (**[^{18}F]-2**), the radiosynthesis of which was published by our group in 2007 (*11*) as well as the results published by Höhne et al. (*13*) for the in vivo evaluation of an ^{18}F−Si derivatized bombesin derivative revealed only a negligible uptake in the tumor tissue of the corresponding mouse model (Figure 2A).

These findings can most probably be attributed to the high lipophilicity of the evaluated compounds which lead to an extraordinarily high uptake of the radiolabeled peptides in the liver and gallbladder. This high lipophilicity is a result of the *tert*-butyl substituents of the SiFA-moiety, which are necessary to stabilize the silicon-based fluoride acceptor systems against hydrolysis.

In contrast to these preliminary data found for the small animal PET study of ^{18}F-SiFA-Tyr^3-octreotate **[^{18}F]-2**, we found an uptake of 7.7% ID/g of ^{18}F-SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate (**[^{18}F]-5**) in the tumor after 60 min p.i.. Compared to the uptake of radioiodinated octreotide and octreotate derivatives in tumor tissue, these findings are comparable to the uptake of a radioiodinated octreotide derivative already used for in vivo imaging, but display significantly lower uptake than the respective radioiodinated octreotate derivative (*18, 35*).

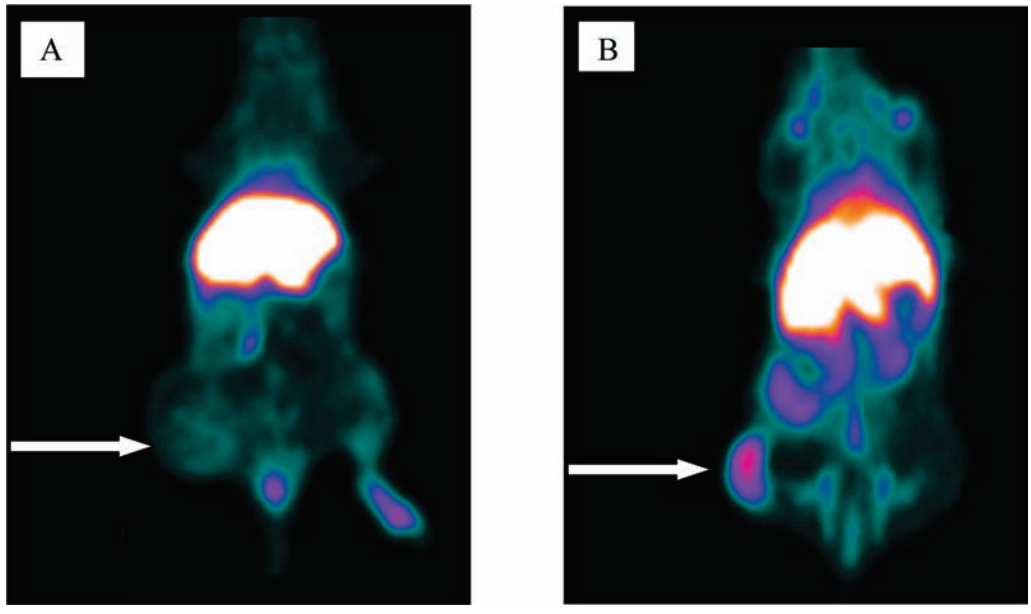

Figure 2. Small animal PET evaluation of nonmodified **[^{18}F]-2** (A) and modified **[^{18}F]-5** (B) in AR42J tumor-bearing nude mice (CD1 nu/nu). Both images show coronal slices (sum from 50 to 90 min p.i.). (A) In vivo small animal PET evaluation of ^{18}F-SiFA-Tyr^3-Octreotate (**[^{18}F]-2**) in a tumor bearing nude mouse model was carried out using a Philips Mosaic small animal scanner. The site of the tumor is indicated by an arrow. (B) In vivo evaluation of ^{18}F-SiFA-Asn(AcNH-β-Glc)-PEG-Tyr^3-octreotate **([^{18}F]-5)** was carried out using a Siemens Inveon small animal PET-scanner in the same tumor model showing the uptake of the radiotracer in the tumor tissue (arrow).

Though giving no optimal results, this is the first approach demonstrating the applicability of silicon-based building blocks (SiFAs) for the one-step ^{18}F-radiolabeling of a receptor-affine peptide for PET and a successful in vivo imaging of a receptor-positive tumor (Figure 2 B). According to these encouraging findings, one part of further developments will now focus on the remaining challenge of the SiFA-approach, namely, the still intrinsically high lipophilicity deriving from the SiFA-building blocks developed so far. Even the introduction of a small PEG-spacer and a carbohydrate as presented in this work could not fully compensate the high lipophilicity of the SiFA building block. In order to further reduce the lipophilicity of SiFA-derivatized peptides, we intend to introduce larger sugar moieties, such as maltotriose or cellobiose (*19*), or charged chemical groups, such as phosphates and quarternary ammonia groups, into the peptides or to use more hydrophilic silicon building blocks stable against hydrolysis.

CONCLUSION

This study demonstrates the feasibility of silicon-fluoride building blocks for the labeling of glucose and glucose/PEG derivatized octreotate derivatives. The SiFA moiety can easily be introduced via chemoselective oxime formation between the aminooxy-derivatized octreotate derivatives and the aldehyde group of SiFA-A (**1**). The conjugates can be radiolabeled with $^{18}F^-$ in a simple one-step isotopic exchange reaction at ambient temperature within 5 min, yielding radiofluorinated octreotate derivatives with reduced lipophilicity suitable for in vivo PET-imaging of sst-positive tumors in mice.

We further demonstrated that the PEG- and carbohydrate-derivatized SiFA-octreotate derivatives can be radiolabeled in high specific activities of 29−56 GBq/μmol. In contrast to other studies using Si−F building blocks, no HPLC purification was required for the isolation of ^{18}F-SiFA-Asn(AcNH-β-Glc)-Tyr^3-octreotate (**[^{18}F]-4**) and ^{18}F-SiFA-Asn(AcNH-β-Glc)-Tyr^3- PEG-octreotate (**[^{18}F]-5**) from the reaction mixture. Although substantial chemical modifications have been made to the original octreotate, both derivatized octreotate conjugates display preserved binding affinities to the sst2 subtype. Compound **[^{18}F]-5** could be used for a successful visualization of a sst2-positive tumor in vivo in an AR42J tumor mouse model with a high tumor uptake of 7% after 60 min.

In conclusion, we progressed significantly toward a feasible application of the SiFA labeling technique for PET tracer development demonstrating that a reduction of the inherent high lipophilicity of the SiFA building block is the key to successful in vivo imaging.

Radiosynthesis and Biodistribution of a Prosthetic Group (^{18}F-FENMA) Conjugated to Cyclic RGD Peptides

Dag Erlend Olberg,*[,†] Alan Cuthbertson,[‡] Magne Solbakken,[‡] Joseph M. Arukwe,[‡] Hong Qu,[§] Alexandr Kristian,[||] Skjalg Bruheim,[||] and Ole Kristian Hjelstuen[†,‡]

Department of Pharmaceutics & Biopharmaceutics, University of Tromsø, Norway, GE Healthcare Medical Diagnostics R&D, Oslo, Norway, Centre for Molecular Biology and Neuroscience (CMBN), University of Oslo, Norway, and Department of Tumour Biology, Institute of Cancer Research, Rikshospitalet, Oslo, Norway. Received July 16, 2010; Revised Manuscript Received October 21, 2010

We have recently reported a new *N*-methylaminooxy-based prosthetic group for the site-selective introduction of ^{18}F-fluorine under mild acidic aqueous conditions into model peptides functionalized with a Michael acceptor moiety. To further investigate the utility of this methodology, the radiosynthesis of two cyclic RGD peptides was carried out, and in vivo biodistribution and microPET studies were performed in tumor-bearing mice. A cyclic RGD peptide was functionalized with the Michael acceptors *trans*-β-nitrostyrene carboxylic acid and 3-vinylsulfonylpropionic acid. Radiolabeling was then performed with the prosthetic group *O*-(2-(2-[^{18}F]fluoroethoxy)-ethyl)-*N*-methylhydroxylamine (^{18}F-FENMA) yielding the ^{18}F-conjugates in moderate yields (8.5−12%). Biodistribution, blocking, and microPET imaging studies were performed in a mouse xenograft model. The vinylsulfonyl-modified conjugate demonstrated good in vitro plasma stability. Biodistribution and microPET studies revealed excellent tumor uptake with low background in key organs and renal elimination as the predominant route of excretion. Blocking studies with coinjected nonlabeled RGD peptide confirmed the in vivo specificity for the integrin $\alpha_v\beta_3$. On the other hand, ^{18}F-FENMA-nitrostyrene-RGD, although stable at conjugation pH 5, was found to rapidly degrade at physiological pH through loss of the ^{18}F-prosthetic group.

INTRODUCTION

Positron emission tomography (PET) has become an important functional imaging modality in diagnostic medicine due to the high sensitivity, high resolution, and ability to quantify the radioactive concentration in tissues (*1*). Fluorine-18 is a particularly attractive radionuclide due to the favorable nuclear and chemical properties (*2*), as well as its availability from medical cyclotrons in high specific activity (*3, 4*). The low positron energy of 0.64 MeV results in low radiation doses and short tissue range, and the relatively long 109.7 min half-life allows both multistep radiosynthesis and extended scanning protocols (*5*).

Although numerous drug-like molecules have been successfully labeled with fluorine-18, optimization of the radiolabeling route to complex molecules such as peptides and proteins still offers significant challenges to the radiochemist. Direct incorporation of [^{18}F]fluoride at high specific radioactivity into macromolecules is hampered by the harsh reaction conditions, and as a consequence, peptide and protein labeling is usually carried out by adopting a prosthetic group strategy (*6*). This methodology, also referred to as radiolabeling using bifunctional labeling agents, involves first ^{18}F incorporation into a small organic molecule, which is then conjugated to the macromolecule under mild conditions in a second step. The variety of chemistries exploited for the conjugations includes acylation, Huisgen 1,3-dipolar cycloaddition (click chemistry), alkylation, and oxime or hydrazone forming reactions (*7*−*10*). Each approach has its own advantages and limitations affecting the radiolabeling yields and biodistribution profile of the tracer. For example, increasing the lipophilicity of the prosthetic group changes the physicochemical properties of the drug product leading to increased hepatobiliary excretion (*11*). In order to control excretion routes, peptides are often modified with poly(ethylene glycol) (PEG) units or other pharmacokinetic modifiers (PKMs) (*12, 13*) to counteract the lipophilic nature of the prosthetic group. As an alternative, hydrophilic prosthetic groups are therefore considered desirable.

Recently, we reported a novel prosthetic group *O*-(2-(2-[^{18}F]fluoroethoxy)ethyl)-*N*-methylhydroxylamine (^{18}F-FENMA) utilizing the site-selective reactivity of the *N*-methylaminooxy functionality with peptides modified with a Michael acceptor (*14, 15*). Further extension of this approach is reported in this study using the RGD peptide **1** modified with either 4-[(*E*)-2-nitrovinyl-]benzoic acid or a 3-vinylsulfonylpropionyl group. The nitrostyrene−peptide **2** showed rapid reaction kinetics with ^{18}F-FENMA forming a more hydrophobic peptide as evidenced by radio-HPLC. The 3-vinylsulfonylpropionyl−peptide **3** formed the more hydrophilic conjugate [^{18}F]**5** but with slower reaction kinetics. The ultimate aim of this study was to determine the radiochemical yields, in vitro stability, biodistribution, and tumor targeting properties of the peptide conjugates in osteosarcoma xenograft bearing mice.

EXPERIMENTAL PROCEDURES

Materials. All chemicals were of analytical grade and obtained commercially. No carrier added [^{18}F]F^- was produced via the ^{18}O(p,n)^{18}F reaction by bombardment of an isotopically enriched [^{18}O]water target with 16.5 MeV protons using a GE PETtrace 6 cyclotron (Uppsala, Sweden). NMR spectra were run on a Bruker Avance III 400 spectrometer (Fällanden, Switzerland) equipped with a 5 mm BBFO PFG probe.

Preparative reversed-phase HPLC was performed on a Shimadzu LC-8A (Bergman, Oslo, Norway) system using a Phenomenex Luna C18(2) column (Teknolab, Oslo, Norway) (250 mm × 21.2 mm, 5 μm), flow rate 10 mL/min, with gradients 0−30% solvent B (Preparative Method 1) or 0−40% solvent B (Preparative Method 2) over 60 min (solvent A, water/0.1% TFA; solvent B, acetonitrile/0.1% TFA). LC-MS spectra were recorded on a LCQ DECA XP MAX instrument using electrospray ionization (ESI) or a Waters LCT-TOF (Instrument teknikk AS, Oslo, Norway) instrument (for high-resolution mass spectrometry (HRMS)) using a Phenomenex Luna (Teknolab) C18(2) column (20 mm × 2 mm, 3 μm), flow rate 0.6 mL/min with gradient 0−30% B. UV detection was in all instances at 214 and 254 nm. Synthesis of the tosylate precursor and labeling with [^{18}F]fluoride yielding *O*-(2-(2-[^{18}F]fluoroethoxy)ethyl)-*N*-methylhydroxylamine (abbreviated ^{18}F-FENMA) was carried out as described previously (*14*). The cyclic RGD peptide NC100717, was supplied by GE Healthcare (Oslo, Norway) (*16*). Boc-protected cysteic acid (*N*-Boc-L-cysteic acid) was prepared according to Jia et al. (*17*).

Chemistry and Radiochemistry. *Synthesis of Peptide (**1**).* To a stirred solution of NC100717 (100 mg, 97 μmol) in DMF (3 mL) was added Boc-L-cysteic acid (32 mg, 115 μmol) preactivated with tetramethylfluoroformamidiniun hexafluorophosphate (TFFH) (31 mg, 115 μmol) and *N*,*N*-diisopropylethylamine (DIPEA) (101 μL, 0.58 mmol). After 2 h, solvent was removed in vacuo, and the crude residue was treated with trifluoroacetic acid (TFA) (5 mL) for 5 min. TFA was removed under reduced pressure. The two-step cycle described above was repeated to introduce and deprotect the second cysteic acid residue. The crude mixture was then subjected to purification by preparative HPLC (Method 1), and after removal of the organic solvents under reduced pressure, the pure product (>95%) was isolated by lyophilization. Yield: 26 mg (17% based on NC100717). LC-MS found $m/z = 1560.5$ $[M+H]^+$ calculated for $C_{56}H_{89}N_{17}O_{25}S_5$ 1559.48.

Synthesis of 3-(Vinylsulfonyl)propionic Acid. To a stirred solution of 3-(2-chloro-ethanesulfonyl)propionic acid methyl ester (100 mg) in dichloromethane (5 mL) was added 3 equiv of triethylamine at room temperature, and the reaction mixture was allowed to stand overnight. After removal of solvents under reduced pressure, the residue was purified by normal-phase flash chromatography (gradient 0−50% ethyl acetate in hexane). Purified intermediate was dissolved in 0.1 M HCl (20 mL) and refluxed overnight. The aqueous phase was evaporated off, and the residue was dissolved in dichloromethane and dried over Na_2SO_4 for 1 h. After filtration and removal of solvents, 3-(vinylsulfonyl)propionic acid was obtained as a white powder (59 mg, 77%). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) 6.65 (dd, $J_1 = 9.7$ Hz, $J_2 = 16.7$ Hz, 1H), δ 6.49 (d, $J = 16.7$ Hz, 1H), δ 6.22 (d, $J = 9.7$ Hz, 1H), δ 3.34 (t, $J = 7.4$ Hz, 2H), δ 2.87 (t, $J = 7.4$ Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) 173.8, 135.8, 131.5, 49.2, 27.0.

*Synthesis of Nitrostyrene-RGD (**2**) and Sulfonyl-RGD (**3**).* 4-[(*E*)-2-Nitrovinyl]benzoic acid was synthesized as previously described (*18*). To a stirred solution of **1** (13 mg, 7.9 μmol) in DMF (3 mL) was added either 4-[(*E*)-2-nitrovinyl]benzoic acid or 3-vinylsulfonylpropionic acid (12 μmol) preactivated with TFFH (3.2 mg, 12 μmol) and DIPEA (10 μL, 0.60 μmol). The reaction mixtures were placed in a sonication bath for 1 h and product formation was monitored by LC-MS. If necessary, the above procedure was repeated until complete conversion was achieved. Reaction mixtures were subjected to purification by preparative HPLC (method 2 compound **2**, method 1 compound **3**), and products were isolated from fractions by lyophilization. Nitrostyrene-RGD (**2**): Yield 8.2 mg (60%), LC-MS found $m/z = 1735.7$, $[M+H]^+$ calculated for $C_{65}H_{94}N_{18}O_{28}S_5$ was 1734.5. Sulfonyl-RGD (**3**): Yield 7.4 mg (55%), LC-MS found $m/z = 1706.7$, $[M+H]^+$ calculated for $C_{61}H_{95}N_{17}O_{28}S_6$ was 1705.5.

*Synthesis of Nonradioactive Reference Standard FENMA Conjugates **4** and **5**.* To a solution of *O*-(2-(2-fluoroethoxy)-ethyl)-*N*-methylhydroxylamine (1 mg, 4 μmol) in acetate buffer 0.4 M pH 5 (1 mL) was added either **2** or **3** (0.9 μmol). Conversion to **4** was completed after only 15 min at room temperature, whereas **5** was formed in >90% yield with heating to 60 °C for 60 min. Reaction mixtures were subjected to purification by preparative HPLC (method 2), and the pure products were isolated from fractions by lyophilization. (**4**): Yield 1.4 mg (85%), LC-HRMS found $m/z = 1870.5868$, $[M-H]^-$ calculated for $C_{70}H_{106}FN_{19}O_{30}S_5$ was 1871.5941. (**5**): Yield 1.3 mg (80%), LC-HRMS found $m/z = 1841.5627$, $[M-H]^-$ calculated for $C_{66}H_{107}FN_{18}O_{30}S_6$ was 1842.5709.

*Radiosyntheses of [^{18}F]**4** and [^{18}F]**5**.* Peptide precursors **2** and **3** were radiolabeled by reaction with ^{18}F-FENMA in acetate buffer pH 5 with a specific activity of 40−50 GBq/μmol (after formulation) as determined by comparison of the radiochromatogram with a calibration curve of authentic reference standards. The radiosynthesis and purification of ^{18}F-FENMA was carried out as previously described (*14*). In short, a solution of **2** or **3** (1.2 μmol) in acetate buffer 0.4 M pH 5 (0.8 mL) was added to the reaction vial containing purified ^{18}F-FENMA. Conjugation conditions were 40 °C for 15 min and 70 °C for 60 min for [^{18}F]**4** and [^{18}F]**5**, respectively. Postconjugation, the reaction mixture was diluted with water (4 mL) before purification by C18 reversed-phase liquid chromatography using both radiometric detection and UV detection at 214 nm. The HPLC fraction containing the radioactive material was diluted with water and passed through a Waters C18 Sep-Pak light cartridge preactivated with ethanol (2 mL) and water (5 mL). The cartridge with bound drug product was washed with water (5 mL), and the product was eluted into a sealed sterile vial with 1 mL absolute ethanol. The ethanol was removed under a stream of nitrogen at 70 °C. The radioactive residue was reconstituted in isotonic saline (adjusted to pH 4 for compound [^{18}F]**4**) for use in the animal experiments. The identities of [^{18}F]**4** and [^{18}F]**5** were confirmed by coelution with the corresponding nonradioactive reference compounds.

Integrin Receptor-Binding Assay. The binding affinity and specificity of **4** and **5** for $\alpha_v\beta_3$ integrin were assessed in a competitive cell binding assay using ^{125}I-echistatin and membrane preparations from the human endothelial adenocarcinoma cell line EA-Hy926 as previously described (*16*). K_i values were calculated from the binding curves using *Graphpad Prism* software.

In Vitro Stability in Mice Plasma. Approximately 2 MBq each of either [^{18}F]**4** and [^{18}F]**5** in saline (50 μL) was added to freshly collected mouse plasma (0.5 mL total volume) and the samples incubated at 37 °C. After 30 min, 1 and 2 h aliquots (100 μL) were collected, diluted 1:1 with phosphate buffered saline (PBS), and the mixtures filtered (Ultrafree filter unit 5000 NMWL, Millipore) at 14 000 rpm for 15 min. The resulting filtrate was diluted with water/0.1% TFA and analyzed by C18 reversed-phase radio-HPLC.

Octanol/Water Partition Coefficient. Approximately 50 kBq of [^{18}F]**5** in 30 μL PBS was diluted with 470 μL of PBS and added to 500 μL of *n*-octanol in an Eppendorf cup ($n = 4$). After vortexing for 3 min, the cups were centrifuged (10 300 rpm; 6 min), and the radioactivity of 100 μL aliquots of the PBS and *n*-octanol phases was counted in a gamma counter.

Animals and Tumor Model. Housing and handling of animals were performed according to protocols approved by the Animal Care and Use Committee, in compliance with the National Committee for Animal Experiments guidelines on animal welfare. Female Balb/c nu/nu mice, bred at the

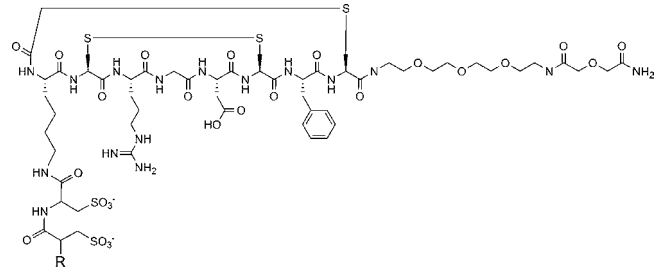
nude rodent facility at the Norwegian Radium Hospital, were maintained under specific pathogen-free conditions with food and water supplied ad libitum. The xenografts have previously been established by direct implantation of patient tumor specimens in nude mice (*19*). The xenografts were established by subcutaneous injection of human osteosarcoma cells (3×10^6) in 100 μL of PBS solution into distal part of mouse right flank when animals were 4−6 weeks of age. When the average tumor diameter was about 5−10 mm (14−21 days after implant), the mice underwent biodistribution and microPET imaging experiments. Visualization of neovascularization in the tumor tissue was performed by immunohistochemistry with a rat antimouse-CD31 monoclonal antibody (clone MEC 13.3; BD Pharmigen).

Biodistribution and MicroPET Studies. *Biodistribution.* Nude mice bearing subcutaneously xenografted human OHS tumors were injected intravenously with approximately 1 MBq of [^{18}F]**5**. Animals were euthanized and sacrificed at 5 min and 2 h post-injection (3 or 4 per time point). Blood, tumor, and the major organs and tissues were collected, wet-weighed, and their radioactivity counted in a gamma counter (MINAXI 5000 series, United Technologies Packard, Zurich, Switzerland). The percentage of injected dose per gram (%ID/g) was calculated for each sample. For each mouse, the amount of radioactivity present in the tissue samples was calibrated against a calibration curve of the injectate. Values are expressed as mean ± standard deviation (SD) for a group of 3−4 animals. For the receptor blocking experiment, [^{18}F]**5** was coinjected with 10 mg/kg of NC100717 in tumor bearing mice. Biodistribution was determined as described above at 2 h post-injection.

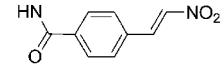
MicroPET. PET scans and image analysis were performed using a microPET F120 scanner (Siemens Medical Solutions). Tumor-bearing mice were injected via a tail vein with 4−7 MBq of [^{18}F]**5**. Static PET images were acquired for 15 min in mice under isoflurane anesthesia 105 min post-injection. For dynamic PET scans, mice were prepositioned in the microPET scanner under isoflurane anesthesia, injected with tracers, and imaged continuously from time 0 to 120 min.

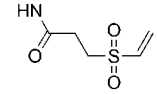
The images were reconstructed using a three-dimensional ordered subsets expectation maximization/maximum a posteriori/(OSEM3D/MAP) algorithm, and no correction was applied for attenuation and scatter.

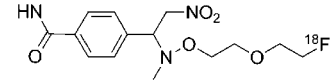
Statistical Analysis. The data are expressed as means ± SD. One-way analysis of variance (ANOVA) was used for statistical evaluation. A *P*-value of <0.05 was considered significant.

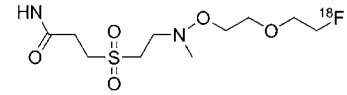


RESULTS









The structures of **1**, **2**, **3**, [^{18}F]**4**, and [^{18}F]**5** are shown in Table 1. Synthesis of tosyl precursor and radiosynthesis of the prosthetic group *O*-(2-(2-[^{18}F]fluoroethoxy)ethyl)-*N*-methylhydroxylamine (^{18}F-FENMA) and its site-selective ligation in aqueous buffer with model peptides has been described previously (*14*, *15*).

In order to provide good solubility of the peptide precursors in the relatively concentrated aqueous acetate buffer (0.4 M) which was required for conjugation reaction with ^{18}F-FENMA, the core peptide NC100717 was modified with two cysteic acids.

The modification of NC100717 was accomplished by reacting *N*-Boc-protected L-cysteic acid activated with TFFH to the free ε-amine of lysine in two synthetic steps. TFFH was used in this reaction, as it generally gave cleaner reaction mixtures and higher yields compared to more traditional coupling reagents *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(7-azabenzotriazol-1-yl)uronium hexafluorophosphate (HATU) and (7-azabenzotriazol-1-yloxy)tripyrrolidinophosphonium hexafluorophosphate (PyAOP). After HPLC purification and isolation by lyophilization, peptide **1** was obtained in moderate yield (17%) calculated from starting peptide NC100117. Reaction of the Michael acceptor moieties, 4-[(*E*)-2-nitrovinyl]benzoic acid or 3-vinylsulfonylpropionic acid, with the amino terminus using TFFH gave the peptide precursors **2** and **3** in good yields. The conjugation reaction of FENMA with **2** and **3** proceeded smoothly in acetate buffer pH 5. Differences in the reaction kinetics between the two systems were clearly observed. After addition of FENMA to the nitrostyrene peptide **2**, the reaction was essentially complete in 15 min at room temperature. In contrast, the vinylsulfone **3** required heating at 60 °C for 1 h with FENMA to achieve yields above 90% as analyzed by HPLC.

[^{18}F]**5**	

The radiosynthesis time for ^{18}F-FENMA-nitrostyrene-RGD ([^{18}F]**4**) after formulation was about 2 h with a decay-corrected yield of 6−7% ($n = 3$) based on [^{18}F]fluoride. Extended reaction times were required for the radiosynthesis of ^{18}F-FENMA-sulfonyl-RGD ([^{18}F]**5**), being produced in 2−4% ($n = 5$) radiochemical yield (decay-corrected postformulation) with 165 min reaction time using 2 mg of precursor peptide. Experiments using higher peptide concentrations, however, clearly demonstrated the dependence of synthesis yield on peptide quantity. Using 5 mg of peptide precursor, the overall yields increased, ranging from to 8.5% to 12% (decay-corrected postformulation). Importantly, unreacted peptide precursor could readily be separated from ^{18}F-labeled peptides to yield both [^{18}F]**4** and [^{18}F]**5** with a radiochemical purity >98% based on analytical HPLC and a specific activity of 40−50 GBq/μmol. As expected, the retention time for [^{18}F]**4** (11.1 min) was significantly higher than for [^{18}F]**5** (9.75 min), reflecting the higher lipophilicity of [^{18}F]**4** compared to that of [^{18}F]**5**.

The stability of [^{18}F]**4** and [^{18}F]**5** was determined following incubation in mouse plasma at 37 °C over 2 h with samples collected for analysis by radio-HPLC at 30 min, 1 h, and

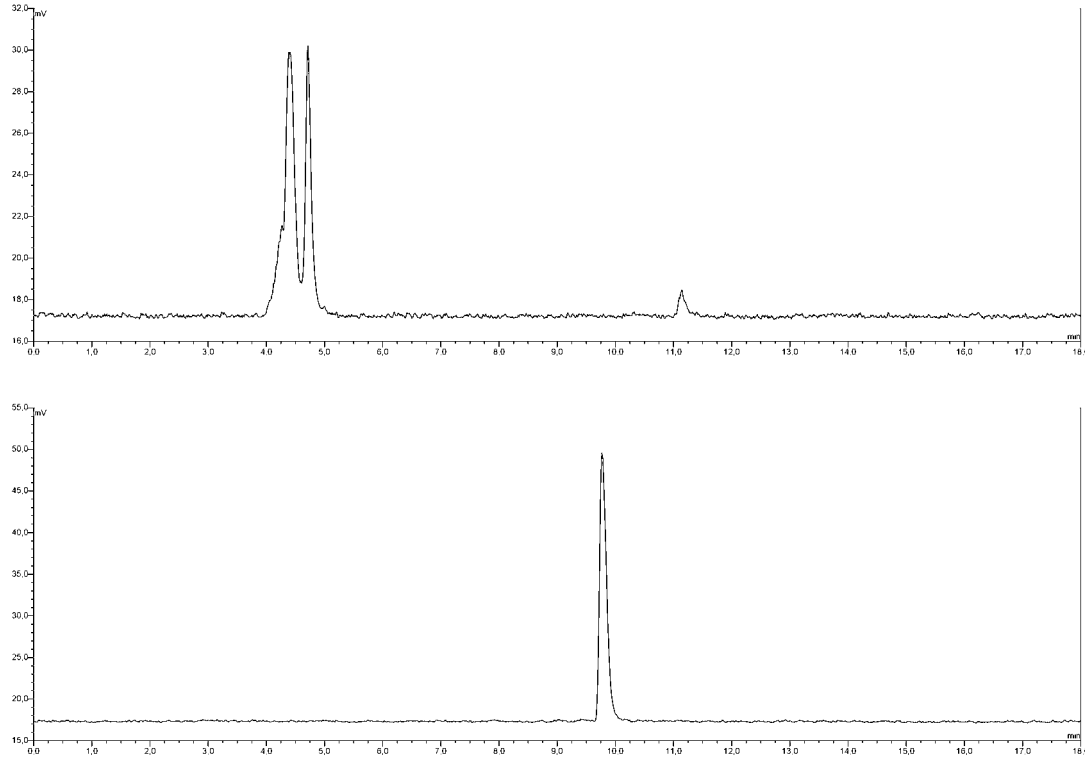

Figure 1. Above chromatogram: [^{18} F]**4** following incubation in mouse plasma after 1 h. Right peak at t_R = 11 min is intact [^{18} F]**4**. Lower chromatogram: [^{18} F]**5** incubation in mouse plasma after 1 h. Main peak is intact [^{18} F]**5**.

2 h. Plasma studies with [^{18}F]**5** revealed no detectable degradation over 2 h. On the other hand, conjugate [^{18}F]**4** demonstrated poor stability in plasma with only 5% of the intact tracer remaining after 2 h (Figure 1). Subsequent studies of **4** in phosphate buffer at different pH values revealed that the stability was pH-dependent. At pH 7.3, 17% of **4** remained intact after 60 min, while at pH 6, 50% remained intact after 60 min. At pH 4, no degradation of **4** was observed within the time frame of the study (2 h). The observed degradation was attributed to the retro-Michael addition of the prosthetic group favored at higher pH. LC-MS studies supported this assumption with reappearance of peptide precursor **2** being confirmed in a stock solution of **4** stored at pH 7 (data not shown) (*20*). Since [^{18}F]**4** proved to be unstable in mice plasma, log *P* experiments were conducted only for [^{18}F]**5**. The log *P* (octanol/water) for [^{18}F]**5** was -2.61 ± 0.01 confirming the hydrophilic nature of the compound.

The affinity of compound **5** for $\alpha_v\beta_3$ integrin was determined in a competitive binding assay with ^{125}I-echistatin. Binding of ^{125}I-echistatin to $\alpha_v\beta_3$ was competed out by **5** in a concentration-dependent manner with a measured K_i value of 3.0 nM as shown in Figure 2. This suggests that attachment of the prosthetic group to the peptide had no effect on receptor binding, with the reported K_i for NC100717 being 6.8 nM (*16*). The unstable nature of **4** precluded an accurate interpretation of the K_i for this compound.

Despite its poor plasma stability, dynamic microPET scans were performed with [^{18}F]**4** in three tumor-bearing mice. We rationalized that, due to low interstitial pH caused by hypoxia and metabolic activity in the lesion, any intact [^{18}F]**4** distributed to the local tumor environment would display greater stability (*21*−*23*). The more rapid degradation of background [^{18}F]**4** at normal physiological conditions would result in a more rapid excretion of the prosthetic group improving the signal-to-noise ratios. Lewis et al. have also

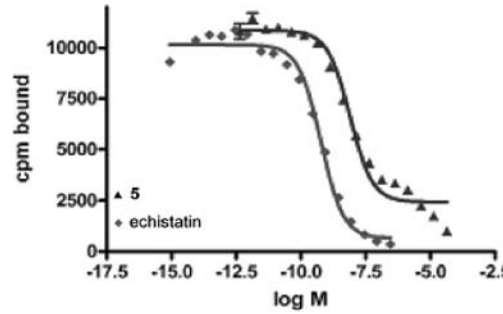

Figure 2. Competition of ^{125}I-echistatin by **5** (K_i = 3 nM) on EA-Hy926 cell membranes (▲). Echistatin for reference (♦).

conducted similar studies with a labile maleimidocysteineamido-DOTA side chain (*24*, *25*). However, this hypothesis proved to be incorrect with the rapid degradation in blood preventing tumor accumulation, and thus, [^{18}F]**4** was not evaluated further.

The results of the biodistribution of [^{18}F]**5** in mice with subcutaneously implanted OHS tumors are shown in Figure 3. The tracer cleared rapidly from the blood (0.18% ID/g, 2 h post-injection) and had good tumor uptake (3.48% ID/g) 2 h post-injection, low bone uptake indicating little or no defluorination, and a favorable biodistribution profile. At 120 min post-injection, the tumor to blood and tumor to muscle ratios were 19 and 5, respectively. The systemic clearance was predominately by renal excretion.

In a separate experiment addressing specificity, mice were coinjected with [^{18}F]**5** and 10 mg/kg of nonradioactive RGD peptide NC100717. The blocking study demonstrated a >10-fold reduction in tumor uptake at 120 min post-injection (3.48% ID/g vs 0.25% ID/g, $P < 0.05$) indicating $\alpha_v\beta_3$-mediated tumor binding. Uptake in nontarget organs was also reduced in the presence of excess unlabeled RGD peptide, indicating that the uptake in these tissues was at least partly $\alpha_v\beta_3$-mediated;

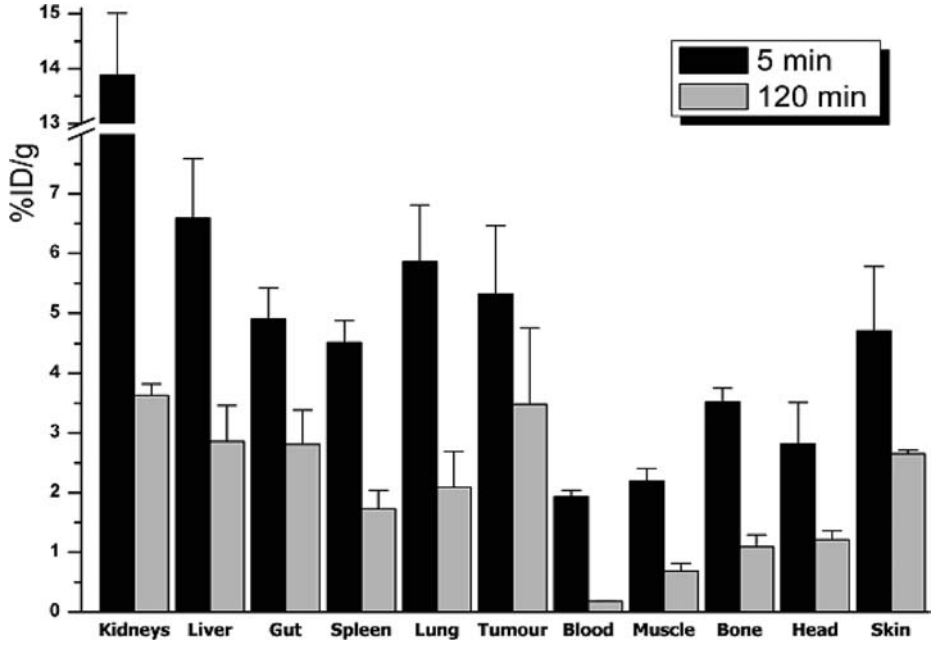

Figure 3. Radioactivity expressed as percentage injected dose per gram tissue in the tumor and key organs of the subcutaneous human OHS xenograft mouse model 5 and 120 min after intravenous injection of approximately 1 MBq [^{18}F]**5** at. ($n = 4$ for each time point).

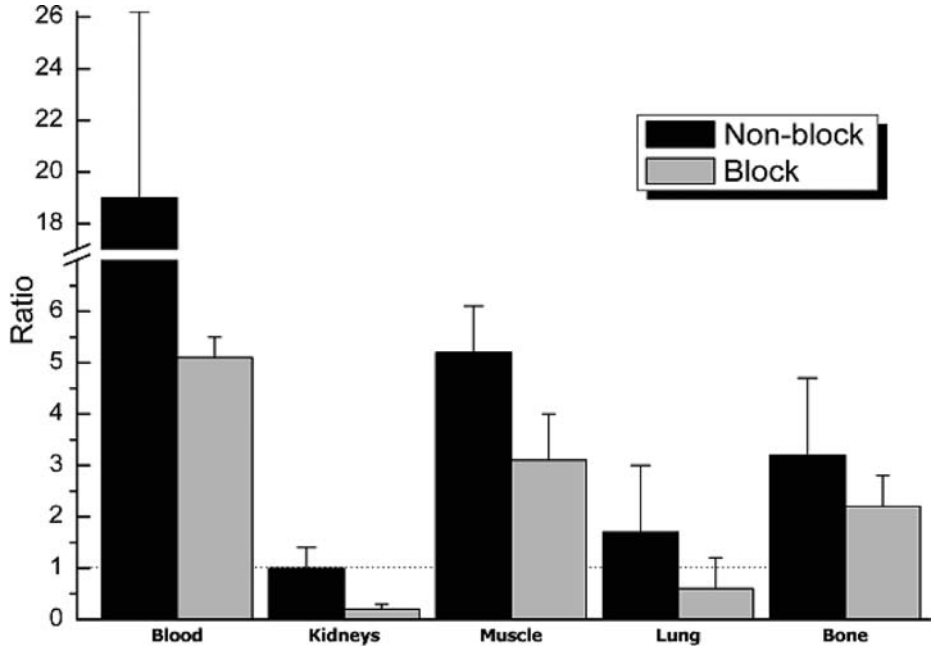

Figure 4. Tumour to nontarget ratios of key organs for [^{18}F]**5** without and in the presence of coinjected excess NC100717.

however, tumor uptake was reduced most markedly (Figure 4). Similar observations have been reported with other radiolabeled RGD peptides (*26*−*29*).

MicroPET images (15 min static single frame) were taken at 105 min of one mouse bearing an OHS tumor injected with 5.2 MBq [^{18}F]**5** as shown in Figure 5. The tumor was clearly visible with high tumor to background activity ratio. Highest uptake of radioactivity was seen in the kidneys and to a lesser extent in the liver/GI region, which is in agreement with the data obtained from direct tissue sampling. In a similar study, the specificity of [^{18}F]**5** for the $\alpha_v\beta_3$ integrin in vivo was confirmed by a blocking experiment where the tracer was coinjected with nonlabeled cyclic RGD peptide (10 mg/kg). As can be seen from Figure 6, uptake in OHS tumor in the presence of nonradiolabeled RGD peptide was clearly lower than without RGD blocking, which is in good agreement with the biodistribution studies.

DISCUSSION

There have been several reports on the use of various ^{18}F-prosthetic groups for labeling of peptides for in vivo PET studies (*30*, *31*). However, many of these strategies are dependent on acylation reactions (*32*−*34*) which, for peptide sequences containing more than one free amino group, lead to the formation of a multitude of products. Site-selective chemistries are available using, for example, click chemistry, oxime bond formation, and alkylation reactions with thiols (^{18}F-maleimide, ^{18}F-thiols), which produce a single radiolabeled product (*35*, *36*). However, all the above approaches have their limitations. The click chemistry requires a copper catalyst and

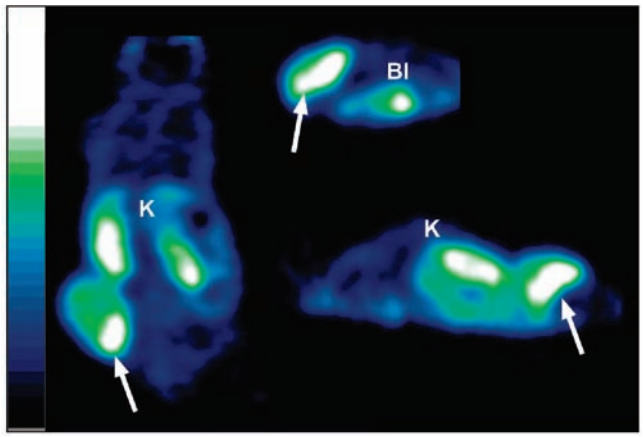

Figure 5. Coronal (left), transaxial (upper right), and sagittal (lower right) microPET images (15 min static single frame) at 105 min post-injection of an OHS tumor-bearing mouse injected with 5.2 MBq [^{18}F]**5**. K = kidneys. Bl = bladder. White arrow indicates tumor.

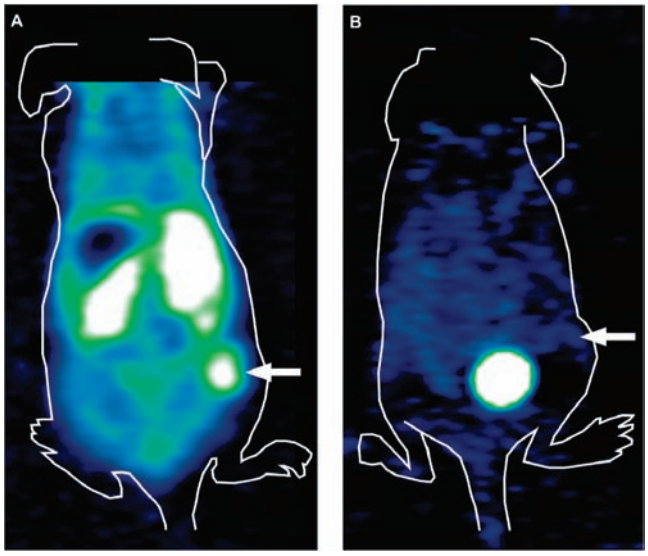

Figure 6. Coronal microPET images of OHS tumor-bearing mice at 105 min post-injection of [^{18}F]**5** without (A) and with (B) coinjection of nonradioactive RGD peptide (10 mg/kg). Tumors are indicated by white arrows.

is complicated by a distillation step which is nontrivial with respect to automation. Free sulfhydryl groups are relatively uncommon in most peptides and are furthermore susceptible to oxidation and disulfide formation.

In this study, the site-selective introduction of an ^{18}F-*N*-methylaminooxy prosthetic group into an RGD peptide was explored, with the peptide component bearing two different types of Michael acceptor moiety. The ^{18}F-FENMA-nitrostyrene-RGD ([^{18}F]**4**) conjugate displayed pH-dependent degradation with poor stability in the physiological to alkaline pH range. Improved stability was observed at lower pH values with no observable degradation of the conjugate at pH 4. The hypothesis of enhanced product stability in the tumor interstitia combined with rapid clearance from the background was tested (vide supra), but no tumor uptake was observed. The reason for this was likely a rapid retro-Michael addition of the ^{18}F-FENMA from the nitrostyrene in vivo. It remains to be explored whether substituents other than the nitro group on the styrene moiety can render sufficient stability to the conjugates.

The conjugation kinetics of ^{18}F-FENMA with the vinylsulfone peptide **3** were slower than for the nitrostyrene derivative, requiring a 60 min reaction time; however, using 5 mg of precursor **3** a yield of 8.5−12% (decay-corrected postformulation) of the drug product [^{18}F]**5** was obtained. In contrast to [^{18}F]**4**, [^{18}F]**5** demonstrated excellent stability in mouse plasma over two hours, and was more hydrophilic as reflected by a shorter HPLC retention time. However, for clinical utility of this methodology, further optimization with respect to synthesis yield and shorter synthesis time is a prerequisite.

The two cysteic acid residues in the peptide precursor contribute to the high hydrophilicity of the conjugate as the side-chains remain deprotonated at physiological pH. Biodistribution studies with [^{18}F]**5** demonstrated that the tracer was excreted mainly through the renal system reflecting its hydrophilic nature. As a further demonstration of in vivo stability, the initial low uptake and subsequent wash-out of radioactivity over time in the femurs of the mice suggested that no significant defluoridation of [^{18}F]**5** was taking place. Uptake in nontarget organs was most pronounced in kidney, followed by liver, gut, and skin. The high kidney uptake may be $\alpha_v\beta_3$ mediated, as rodent kidneys have been found to express integrin in the endothelial cells of the small vessels in the glomerulus (*37*). The data presented herein are similar to those published for the ^{18}F-galacto-RGD studied in osteosarcoma-bearing mice with higher uptake values for organ and tumor for [^{18}F]**5**. The slight differences in biodistribution may be a result of the higher log *P* of [^{18}F]**5** compared to that of ^{18}F-galacto-RGD (−2.61 and −3.17, respectively), which increases the relative retention of this peptide in vivo (*38*).

The xenograft model used in this study was an osteosarcoma model derived from human tissue. Direct immunohistochemical staining of $\alpha_v\beta_3$-integrin expression was not possible due to the absence of a suitable antibody specific for mice (*39*). Staining with CD31 demonstrated vascularization of the tumors. The assumption that [^{18}F]**5** was able to target the neovasculature via the $\alpha_v\beta_3$ receptors expressed on endothelial cells was supported by the work of Pasqualini et al. who demonstrated that tumor vessels are the structural elements predominantly targeted by the RGD sequence (*40*).

Tracer uptake was significantly higher in nonblocked animals than those coinjected with 10 μg/g nonradioactive RGD peptide, suggesting a specificity for $\alpha_v\beta_3$ expression in the human OHS osteosarcoma. This was in accordance with published data from other groups working with alternative osteosarcoma mouse model where the tumors were induced using ^{90}Sr (*38*, *27*).

The relatively large standard deviations in tumor uptake observed at 2 h post-injection (±1.27% ID/g) compared to nontarget organs (±0.28% ID/g) may reflect the difference in tumor sizes among the mice (0.1−0.4 g) used in the study. Tumor size is likely to impact the degree of neovascularization and $\alpha_v\beta_3$ expression, as new blood vessels are required to supply oxygen and nutrients when the lesion reaches a diameter of around 1−2 mm (*41*). Although the data set was not large enough to reach full statistical significance, plots of tumor uptake (%ID/g) of the tracer against tumor weight indicated a sufficient correlation ($R = 0.79$). Similar observations have been reported previously in the literature with $\alpha_v\beta_3$ specific radioligands (*28*).

CONCLUSION

In conclusion, the prosthetic group *O*-(2-(2-[^{18}F]fluoroethoxy)ethyl)-*N*-methylhydroxylamine (^{18}F-FENMA) was found to have promising characteristics for in vivo use in combination with a vinylsulfonyl modified RGD peptide in human OHS xenograft bearing mice. In vitro studies demonstrated high integrin $\alpha_v\beta_3$ binding affinity and good in vitro plasma stability. MicroPET showed good visualization of tumor along with good tumor-to-background ratios. The excretion of ^{18}F[**5**] was predominately by the renal route.

ACKNOWLEDGMENT

Many thanks to Prof. Erik Dissen and Ph.D. student Per Christian Sæther (Dept of Anatomy, University of Oslo) for giving us access to the gamma counter and the included excellent technical support.

Improved Speciation Characteristics of PEGylated Indocyanine Green-Labeled Panitumumab: Revisiting the Solution and Spectroscopic Properties of a Near-Infrared Emitting anti-HER1 Antibody for Optical Imaging of Cancer

Aaron Joseph L. Villaraza, Diane E. Milenic, and Martin W. Brechbiel*

Radioimmune and Inorganic Chemistry Section, Radiation Oncology Branch, National Cancer Institute, National Institutes of Health, 10 Center Drive, Bethesda, Maryland 20892-1002, United States. Received July 23, 2010; Revised Manuscript Received October 26, 2010

A water-soluble amine-reactive PEGylated analogue of near-infrared emitting dye indocyanine green (**5**) was synthesized and used to label the anti-HER1 antibody panitumumab (Vectibix) at various equivalents. These conjugates were compared with non-PEGylated analogue conjugate products and the solution speciation analyzed with UV−vis spectrophotometry, size exclusion HPLC, and SDS-PAGE. PEGylation of the bioconjugates was successful in preventing aggregation in solution, a phenomenon observed with the non-PEGylated bioconjugates presumably due to the hydrophobicity of indocyanine green. Competitive radioimmunoassay demonstrated that the targeting moiety of the PEGylated bioconjugates was conserved. Fluorescence microscopy also demonstrated membrane binding of the bioconjugate to HER1-expressing A431 cells. Hence, these bioconjugates are suitable candidates for the in vivo optical imaging of HER1-expressing tumors.

INTRODUCTION

There has been a great amount of interest in near-infrared (NIR) dyes as reporter groups for bioconjugate probes as NIR light (700−1000 nm) is relatively transparent to tissue (*1*). The many applications of NIR dyes for in vivo fluorescence biological imaging has been reviewed in detail elsewhere (*2, 3*). Chief among this class of reporter groups are the water-soluble cyanine (Cy) dyes designed to react selectively with either sulfhydryl or amine groups present on biomolecules (*4*−*8*).

However, excessive loading of Cy dye on proteins results in quenching of fluorescence, a phenomenon more pronounced in the longer-chain cyanine dyes, such as Cy5 and Cy7 (*9*). Indeed, dye−dye-mediated self-quenching was found to be more evident in the Cy dyes than in other commercially available NIR dyes, such as the AlexaFluor dyes (*10*). This phenomenon has led to the development of particular applications such as enzyme-responsive NIR-protein bioconjugates which fluoresce upon enzymatic cleavage of the bioconjugate (*11*−*13*). Cy dyes have also been used to label monoclonal antibodies (mAbs) targeting tumor-associated antigens (*14*−*17*), with Cy7 demonstrating a fluorescence response with the deepest tissue penetration (*14*). More recently, mAbs labeled with both a Cy dye and a radioactive reporter have been described toward the development of multimodal diagnostic agents (*18, 19*).

Indocyanine green (ICG) (**1**) is an FDA-approved cyanine dye first described in the construction of dilution curves for cardiovascular physiological studies (*20*). The absorption and emission characteristics of this dye at the near-infrared end of the spectrum further extended its application to fluorescence angiography (*21*), necessitating a thorough investigation of the effects of solvent on the absorption and emission spectra of ICG in blood plasma in comparison with ICG dissolved in commonly used laboratory solvents (*22, 23*). In general, it has been observed that dye-aggregation, whether due to the nature of the solvent, the concentration of the dye, or combinations of both, results in the quenching of ICG fluorescence.

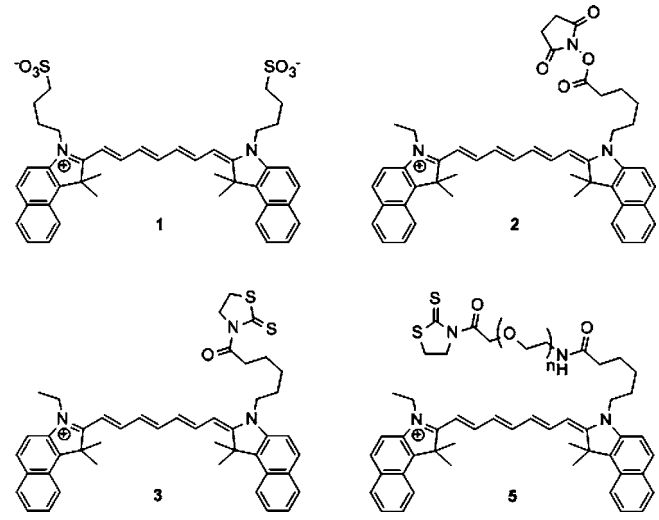

Figure 1. (**1**) ICG, (**2**) ICG-OSu, (**3**) ICG-ATT, (**5**) ICG-PEG-ATT.

Monoclonal antibody conjugates with amine-reactive ICG (*24, 25*) (**2** and **3**) (Figure 1) have been used in immunohistochemical staining of gastric microcancers (*26*−*29*) and as an in vivo probe for tumor imaging (*30*−*32*). Interestingly, some examples of these ICG-mAb bioconjugates were found to be nonfluorescent in PBS, but became fluorescent either in vitro when in the presence of denaturing agents such as 5% SDS and β-mercaptoethanol (β-ME), or upon internalization in tumor cells (*31, 32*). The exact mechanism for this observed fluorescence activation was not elucidated, though the authors suggest aggregation as the cause of fluorescence quenching. Further-

more, these conjugates also exhibited significant uptake and retention in the liver.

The studies herein describe an amine-reactive PEGylated ICG analogue (**5**) and its conjugation to the mAb panitumumab. Panitumumab (Vectibix) is an FDA-approved mAb which binds to HER1 (*33*), a surface antigen which is overexpressed in a variety of cancers. These conjugates were compared with mAb conjugates of non-PEGylated analogues **2** and **3**, and their solution speciation characterized spectroscopically and chromatographically. The immunoreactivity of the mAb postmodification was evaluated by radioimmunoassay using purified antigen and by fluorescence microscopy. PEGylation was found to render ICG water-soluble, thereby obviating the need for intermediary solvents such as DMSO or DMF in the conjugation reaction. The PEGylated ICG-mAb was hypothesized to exhibit improved solubility and pharmacokinetic characteristics and to minimize or eliminate aggregation of the conjugation product in comparison with the non-PEGylated analogue. Furthermore, PEGylation of biologically active molecules, antibodies, and antibody fragments has been found to reduce their immunogenicity and improve in vivo clearance (*34*, *35*).

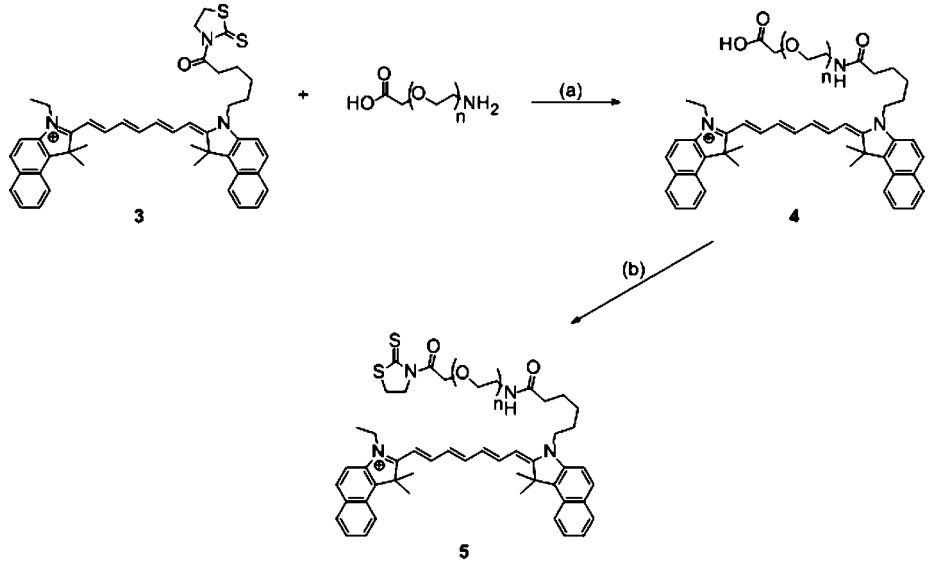
MATERIALS AND METHODS

Compounds **2** and **3** were synthesized as previously described (*24*, *25*). NH_2-PEG-CM-3400 (average molecular weight 3250) was purchased from Laysan Bio Inc. (Arab, AL). 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC) and 2-mercaptothiazoline (ATT) were obtained from TCI America (Portland, OR) and 4-dimethylaminopyridine (DMAP) was purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Sephadex G-25 Medium was purchased from GE Healthcare (Piscataway, NJ). Panitumumab (AMGEN Inc., Thousand Oaks, CA) was purchased through the Veterinary Resources Pharmacy, NIH.

^{1}H and ^{13}C NMR spectra were obtained using a Bruker Avance 300 MHz instrument, and chemical shifts are reported in ppm on the δ scale relative to TMS or residual solvent. Proton chemical shifts are annotated as follows: ppm (multiplicity, coupling constant (Hz), integration). Reaction progress was also monitored by Silica Gel 60 thin layer chromatography (Merck, Germany).

Absorbance spectra were recorded on an Agilent 8453 spectrophotometer (Santa Clara, CA). Size exclusion HPLC (SE-HPLC) was performed on a Waters HPLC system (Milford, MA) using a TOSOH TSK4000SW column (Tokyo, Japan) with 67 mM Na_3PO_4/100 mM KCl buffer (pH 6.8) as eluent (flow rate 0.5 mL/min). Radioactivity was measured using a Wizard One Perkin-Elmer γ-scintillation counter (Shelton, CT).

ICG-PEG-COOH (4). NH_2-PEG-CM-3400 (1.0 g, 0.31 mmol) was dissolved in MeCN (50 mL) and stirred in the presence of Et_3N (50 μL, 0.36 mmol) over ice. Compound **3** (0.24 g, 0.34 mmol) was added, and the solution stirred over ice for 1 and 18 h at room temperature. The reaction mixture was diluted with $CHCl_3$ (50 mL) and washed with 0.1 M HCl (50 mL). The aqueous layer was extracted further with $CHCl_3$ (2 × 50 mL). The organic portions were pooled together and dried over anhydrous $MgSO_4$. The mixture was filtered and the filtrate evaporated under reduced pressure. The dye−polymer conjugate was purified by passing through a Sephadex G-25 size exclusion column previously equilibrated with water. The volume of the pure fraction was brought up to ~50 mL with water, acidified with 0.1 M HCl, and extracted into $CHCl_3$ (3 × 50 mL). The organic portions were pooled together, dried over anhydrous $MgSO_4$, filtered, and the filtrate evaporated under reduced pressure. The dark green oily residue was triturated with diethyl ether, the supernatant decanted, the resulting solid washed with more diethyl ether, and the residue dried under reduced pressure to yield a dark green powder (0.91 g, 77%). R_f = 0.5 ($CHCl_3$/MeOH 9:1); ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.5 (t, J = 7.2 Hz, 3H), 1.6−2.4 (m, 6H), 2.0 (s, 12H), 3.4−3.5 (m, 5H), 3.6−3.8 (m, 307H), 3.9 (t, J = 6.2 Hz, 3H), 4.1−4.4 (m, 4H), 4.2 (s, 2H), 6.3 (d, J = 13.1 Hz, 1H), 6.4 (d, J = 12.9 Hz, 1H), 6.8 (m, 2H), 7.3−8.2 (m, 15H); ^{13}C NMR ($CDCl_3$, 300 MHz) δ 12.74, 25.22, 26.50, 27.58, 36.15, 39.08, 44.66, 50.90, 59.53, 68.97, 69.72, 70.23, 71.27, 81.61, 110.09, 110.56, 122.18, 124.81, 124.99, 127.70, 128.20, 128.33, 130.00, 130.55, 130.66, 131.63, 131.78, 133.54, 133.75, 139.25, 139.53, 171.42, 173.08; λ_{max} = 783 nm (PBS).



ICG-PEG-ATT (5). Compound **4** (0.76 g, 0.20 mmol) was dissolved in DCM (20 mL) and cooled over ice. EDC (45 mg, 0.22 mmol) and DMAP (27 mg, 0.22 mmol) were added and the solution stirred for 30 min. Afterward, ATT (26 mg, 0.22 mmol) was added, and the reaction was stirred over ice for 1 h and at room temperature for 18 h. The reaction mixture was then washed successively with 0.1 M $NaHCO_3$ (1 × 50 mL) and 0.1 M HCl (2 × 50 mL). The organic portions were pooled together, dried over anhydrous $MgSO_4$, filtered, and the filtrate evaporated under reduced pressure. In a similar manner as with **4**, the residue was triturated with diethyl ether and then dried under reduced pressure to yield a dark green powder (0.64 g, 84%). R_f = 0.8 ($CHCl_3$/MeOH 9:1); ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.5 (t, J = 7.0 Hz, 3H), 1.6−2.4 (m, 6H), 2.0 (s, 12H), 3.4−3.5 (m, 5H), 3.6−3.8 (m, 295H), 3.9 (m, 3H), 4.0 (t, J = 7.8 Hz, 2H), 4.1−4.4 (m, 4H), 4.6 (t, J = 7.2 Hz, 2H), 5.1 (s, 2H), 6.3 (d, J = 13.1 Hz, 1H), 6.4 (d, J = 12.9 Hz, 1H), 6.8 (m, 2H), 7.3−8.2 (m, 15H); ^{13}C NMR ($CDCl_3$, 300 MHz) δ 12.78, 25.27, 26.44, 27.61, 29.56, 33.75, 36.19, 39.12, 44.68, 50.92, 51.60, 55.48, 59.50, 60.00, 70.54, 74.00. 81.58, 110.16, 110.67, 122.22, 125.07, 127.77, 128.21, 130.03, 130.62, 131.64, 133.48, 133.71, 139.22, 139.51, 171.97, 173.12, 201.13; λ_{max} = 783 nm (PBS).

Conjugation of Antibodies. Solutions of mAb (typically 10 mg, 66.7 nmol) were incubated with 2, 4, or 8 equiv of **2**, **3**, or **5** in 0.1 M $NaHCO_3$ (pH 8.5) buffer for 1 h at 37 °C with stirring at 750 rpm. The mAb solution was vortexed as the amine-reactive dye was added dropwise to ensure homogeneity of the reaction. All conjugation reactions were made up to a total volume of 1 mL. In particular, **5** was added as a 200 μL aliquot in buffer, while **2** and **3** were added as a 200 μL aliquot in DMSO. After incubation, the reaction was transferred to a 3 mL Slide-A-Lyzer Dialysis Cassette G2 (Thermo Fisher Scientific, Rockford, IL) and dialyzed against PBS buffer at 4 °C for three days with nine buffer changes (9 L total). Protein recovery during conjugation was determined by measuring the UV absorption at 280 nm.

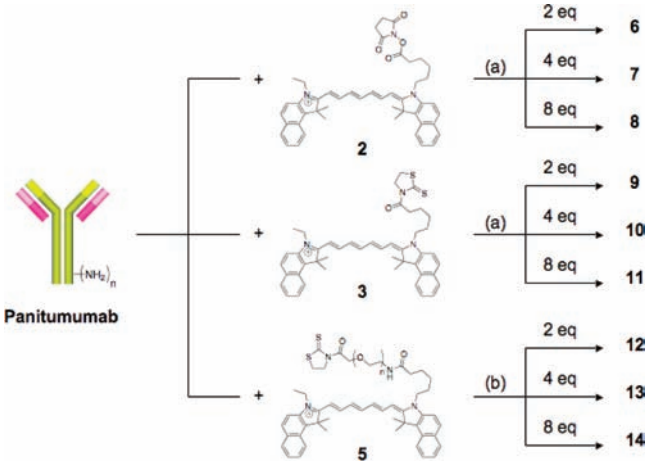
Absorbance Measurements. The extinction coefficient of **3** was determined in DMF and in 9:1 PBS/DMF solution, while the extinction coefficient of **5** was determined in DMF, in 9:1 PBS/DMF solution, and in PBS. The absorbance spectra of 50 μg/mL samples of the bioconjugates were measured in PBS and in 9:1 PBS/DMF. On the basis of a previously described procedure (*22*), the changes in the shape of the spectra as a function of concentration were monitored by preparing 500, 100, 50, and 10 μg/mL samples of bioconjugate. The absorbance spectra of 500 μg/mL and 50 μg/mL samples were measured in a 2 mm cuvette, while 100 μg/mL and 10 μg/mL samples were measured in a 10 mm cuvette. The spectra of samples whose product of concentration c and path length b were the same (i.e., $A = \epsilon bc$ where bc = constant) where superimposed. These measurements were performed in PBS and in 8:2 PBS/DMSO.

Competition Radioimmunoassay (General Procedure). The immunoreactivities of immunoconjugates were evaluated using a competition radioimmunoassay. Fifty nanograms of

Scheme 1[a]

[a] Synthesis of **5**: (a) Et_3N, MeCN, 0 °C, (b) DCM, EDC, DMAP, ATT, 0 °C.

human epidermal growth factor receptor (hEGFR) (Sigma-Aldrich, St. Louis, MO) in 50 μL of PBS containing Mg^{2+} and Ca^{2+} was added to each well of a 96-well plate and incubated overnight at 4 °C. The excess antigen was removed, 150 μL of 1% bovine serum albumin in PBS (BSA/PBS) was added to each well, and the plate allowed to sit at ambient temperature for 1 h. The wells were then aspirated and serial dilutions (1000−0.02 ng in 50 μL BSA/PBS) of the immunoconjugates were added to the wells in triplicate (leaving one set of wells as a blank, i.e., no competitor), followed by ^{125}I-panitumumab (*36*) (~50 000 cpm in 50 μL BSA/PBS). The plate was then incubated at 37 °C for 4 h. Afterward, the wells were emptied and washed with BSA/PBS (3 × 200 μL), the bound radioactivity removed with 100 μL 0.2 M NaOH, absorbed into cotton filters, placed in 12 × 75 mm tubes, and counted in a γ-scintillation counter. The percent inhibition was calculated and plotted. Unconjugated panitumumab was included in the assay as well as a negative mAb HuM195 (kindly provided by M. McDevitt, Memorial Sloan Kettering Cancer Center), which reacts with human CD33.



SDS-Polyacrylamide Gel Electrophoresis. The immunoconjugates were analyzed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE) both with and without reduction by β-ME using 4−20% precast Tris-Glycine polyacrylamide gels, respectively (Invitrogen, Carlsbad, CA). Five micrograms of the immunoconjugates was added to each lane, and the gels were run according to the method of Laemmli (*37*). Lanes containing 5 μg of panitumumab were included as a comparison.

Fluoresence Microscopy. HER1-positive A431 cells were utilized for fluorescence microscopy to demonstrate tumor targeting and specificity of the PEGylated panitumumab−ICG conjugate. The cells were obtained from ATCC (Manasass, VA) and grown in RPMI 1640 media (Lonza, Walkersville, MD) supplemented with 10% FetalPlex (Gemini Bioproducts, Woodland, CA), 1 mM nonessential amino acids, and 2 mM glutamine. The fluorescence microscopy study was performed by adding A431 cells (2.5×10^4) to each chamber of an 8 chamber slide and incubated for 72 h. The chambers were washed 3 times with phosphate-buffered saline (PBS, pH 7.2) and fixed for 10 min at room temperature with 4% paraformaldehyde. After 3 more washes with PBS, 0.5 mL of PBS containing 1% bovine serum albumin was added to each chamber. Following 1 h incubation at ambient temperature, the 1% BSA/PBS was removed and 1 μg of **12** or **15** (negative control) was added to a chamber and incubated for 1 h at 37 °C. The chambers were then washed 3 times with PBS, the chambers removed, and the slide mounted with a coverslip using FluorSave (Calbiochem, La Jolla, CA). Fluorescence microscopy was performed using an Olympus BX61 microscope (Olympus America, Inc., Center Valley, PA) equipped with the following filters: excitation wavelength 672.5 to 747.5 nm, emission wavelength 765 to 855 nm. Transmitted differential interference contrast (DIC) images were also collected.

RESULTS AND DISCUSSION

Amine-reactive ICG dyes **2** and **3** were synthesized in good yields. To produce ICG-PEG conjugate **4**, compound **3** was chosen to react with NH_2-PEG-CM-3400 as the aminolysis of 3-acylthiazolidine-2-thione activated esters to form amides has been thoroughly demonstrated to be efficient (*38*, *39*). Furthermore, the reactivity of **3** itself has been tested with a variety of amino acids and primary amines under different conditions and found to be efficient (*25*). The benefits of PEGylating ICG were expected to be threefold: first, the dye−polymer conjugate **4** would be dramatically more water-soluble than **3**; second, the increase in molecular weight would promote simplified purification of the resulting dye−polymer conjugate **4** by size-exclusion chromatography (indeed, due to the differences in molecular weight and solubility between the starting materials and product, unreacted dye was retained at the top of the Sephadex column while the dye−polymer eluted); third, since the molecular weight of the polymer is significantly greater than that of the dye, the resulting mass of **4** is much higher relative to the amount of **3** used in the reaction, which again facilitates handling. This bodes well if the same reaction scheme is to be applied to the synthesis of dye−polymer conjugates using commercially available Cy dyes, which are relatively expensive and sold only in small amounts. Interestingly, **4** could, in fact, be extracted back into chloroform upon slight acidification of the purified fraction. Synthesis of activated ester **5** was chosen over a succinimidyl ester analogue in order to be able to compare mAb labeling efficiencies with **3** (Scheme 1). The formation of the activated ester was easily monitored by thin layer chromatography. Finally, both PEGylated and non-PEGylated amine-reactive dyes were found to "stick" to the flask, but trituration in diethyl ether dislodged both products, thereby maximizing reaction yields.

Scheme 2[a]

[a] Conjugation of **2**, **3**, and **5** with panitumumab: (a) 25% DMSO in 0.1 M $NaHCO_3$ buffer, (b) 0.1 M $NaHCO_3$ buffer.

Amine-reactive dyes **2**, **3**, and **5** were added to panitumumab in increasing equivalents of 2, 4, and 8 per mAb to (1) compare their respective labeling efficiencies and (2) determine the effect of increased labeling on the immunoreactivity of the resulting conjugates (Scheme 2). As **5** proved to be water-soluble, the conjugation reaction was performed solely in buffered aqueous solutions as described above. However, the insolubility of **2** and **3** in aqueous solutions required dissolution in DMSO before addition to the buffered protein solution. Prior to the conjugation reactions with the ICG compounds, the maximum percentage of DMSO in buffer that panitumumab could tolerate without loss of immunoreactivity was determined to be 25% DMSO in reaction buffer (data not shown). Hence, the conjugation reactions involving **2** and **3** were performed with the desired equivalents being added as a 200 μL DMSO solution to 800 μL buffered protein solution, resulting in a final reaction volume of 1 mL. All conjugates were purified via extensive dialysis against PBS and recovered in good yield on a protein basis.

A previous study on the UV−vis absorption properties of ICG noted the following: (1) the characteristics of the absorbance spectrum of ICG are dependent upon its concentration in solution and the nature of the solvent; (2) at relatively low concentrations, the absorbance maximum of the dye is red-shifted when comparing spectra taken in water versus plasma; and (3) a continuous increase in ICG concentration results in a collapse of the absorbance maximum at ~780 nm accompanied by simultaneous growth of a peak within the range 700−720 nm (*22*). The presence of this peak is a clear indication of the formation of dye aggregates in aqueous solvent due to the hydrophobicity of ICG (*40*). Indeed, analogous solvent- and concentration-dependent formation of dye aggregates has been observed for other cyanine dyes as well (*41*). The formation of aggregates alters the optical density of the dye, and correspondingly, the extinction coefficient ε. This change has profound implications on the use of ICG as a fluorescent probe in biological applications, as the optical density determines the fluorescence intensity. This occurrence is underlined by the inconsistency of reported ICG quantum yields in the literature, which were also found to be both solvent- and concentration-dependent (*23, 42*).

The extinction coefficients of **3** and **5** were determined in different solvents at micromolar concentrations. Compounds **3** was insoluble in PBS, but soluble in a 10% DMF in PBS solution and in DMF alone. The calculated extinction coefficients were drastically different, being a fifth lower in PBS/DMF than in just DMF. On the other hand, the calculated extinction coefficients of **5** were independent of the three solvents used (Table 1). However, a slight red-shift from 783 to 790 nm was observed when comparing the absorbance maxima ranging from aqueous to organic solvent (Figure 2).

Table 1. Comparison of Optical Properties of 3 and 5 in Different Solvents

	compound			
	3		**5**	
solvent	λ_{max}	ε (μM^{-1} cm^{-1})	λ_{max}	ε (μM^{-1} cm^{-1})
PBS	---	---	783	0.155
9:1 PBS/DMF	800	0.034	785	0.154
DMF	790	0.170	790	0.158

More critically, the effect of solvent on the extinction coefficient of the dye has important implications in the determination of the dye-to-protein (D/P) ratio of resulting ICG-labeled proteins. D/P ratios can be determined spectrophotometrically by calculating the concentration of dye based on its absorbance at its λ_{max}, and likewise the protein concentration from its absorbance at 280 nm. These calculations require the construction of a calibration curve for each separate component (i.e., dye and protein) measured in an ideal aqueous solvent such as PBS. As both **2** and **3** are insoluble in PBS, no such calibration curve could be constructed, and therefore D/P ratios for proteins labeled with them cannot be determined. On the other hand, a protein calibration curve in 9:1 PBS/DMF is meaningless, as this solvent combination does not mimic physiological conditions. Indeed, in previous reports (*31, 32*) the D/P ratios of a variety of ICG-labeled mAbs were determined under denaturing conditions, i.e., in the presence of 5% SDS and β-mercaptoethanol. Applying the same argument, such results and measurement are at best questionable, as these solvent conditions do not reflect the physiological state of the antibody conjugates under study.

However, as the extinction coefficient of **5** is consistent throughout the range of solvents described, the concentrations of panitumumab and ICG can be accurately determined from the absorbances of the conjugates at 280 and 783 nm (Figure 3a) in PBS. Using this method, the D/P ratios for the PEGylated dye−protein conjugates **12**, **13**, and **14** were calculated to be 0.73, 1.74, and 3.38, respectively. HuM195 was also reacted with **5** to form conjugate **15**, and its D/P ratio was determined to be 1.05. The challenge of determining D/P ratios in dye-labeled proteins is not limited to ICG conjugates; for example, it has been addressed previously in antibody conjugates of rhodamine B, a relatively hydrophobic dye (*43, 44*). The importance of accurately establishing the D/P ratio of a fluorescently labeled antibody cannot be overstated, as high loading of dye molecules onto a single antibody has been shown to result in fluorescence quenching rather than fluorescence enhancement, observed especially in the longer-chain Cy dyes due to their relative hydrophobicity (*9, 10*).

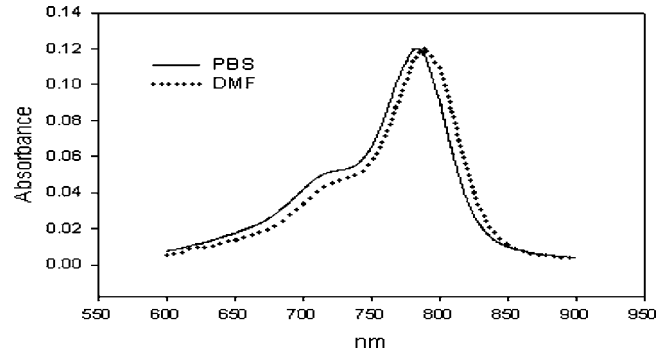


Figure 2. A slight red shift in the λ_{max} of **5** is observed when in aqueous solvent (PBS) vs organic solvent (DMF).

Table 2. SE-HPLC Data of Conjugates[a]

sample	% HMW	% IgG
6	9.2	90.8
7	15.7	84.3
8	26.0	74.0
9	5.3	94.7
10	12.2	87.9
11	19.9	74.0
12	0	100
13	0	100
14	0	100

[a] IgG (Panitumumab): t_R = 19.9 min. HMW species (**6**−**8**): t_R = 11.2 and 16.9−18.4 min. HMW (**9**−**11**): t_R = 11.2. Molecular weight standards: 158 kDa (20.5 min), 232 kDa (19.3 min), 440 kDa (16.5 min), Blue Dextran (11.2 min).

Absorption spectra of 50 μg/mL samples of all bioconjugates were measured; for brevity, the spectral range corresponding to dye absorption of **8**, **11**, and **14** are presented (Figure 3b,c). As discussed earlier, the depression of the absorbance peak at 790 nm, the shift and broadening of the λ_{max} to around 800 nm, and the increase of the absorbance within the 700−720 nm range in the spectra of **8** and **11** in PBS are all indicators of dye aggregation in these conjugates, characteristics which are much less pronounced in the spectrum of the PEGylated conjugate **14** (Figure 3b). Similar to previously published absorption spectra of ICG-mAb bioconjugates (*27*), the spectra of **8**, **11**, and **14** when measured in 9:1 PBS/DMF show suppression of the 720 peak and growth in the 790 nm peak (Figure 3c) relative to that measured in PBS alone, suggesting that the presence of DMF prevents or reduces dye aggregation. Again, however, this solvent combination is not representative of physiological conditions, and therefore, absorbance measurements performed in it do not reflect the true absorption properties of these conjugates, particularly when translated to an in vivo environment. On the other hand, the absorption spectra of the PEGylated conjugates suggest that they are more stable against dye aggregation, a result of the increased hydrophilicity of **5** due to the water-soluble PEG polymer.

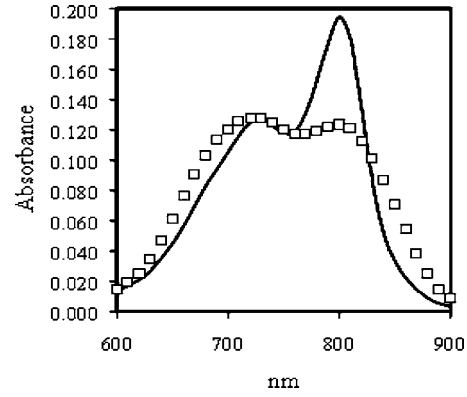

Figure 5. Absorption spectra of (□) aggregate HMW fraction and (−) pure IgG fraction.

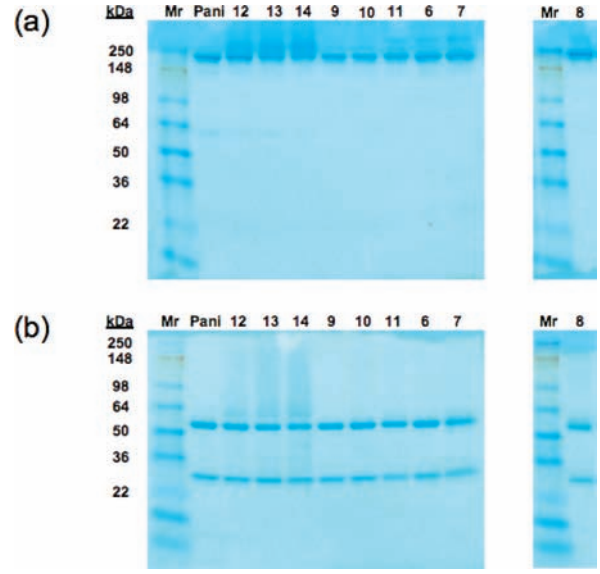

Figure 6. SDS-PAGE of ICG-labeled panitumumab bioconjugates under (a) nondenaturing and (b) denaturing conditions with β-ME.

To determine if aggregation is an effect of concentration, the absorption spectrum of **11** was measured at different concentrations (ranging from10 to 500 ng/mL) in PBS (Figure 4a,b). Furthermore, to determine if the solvent also had an effect, the same measurements were performed in 20% DMSO in PBS

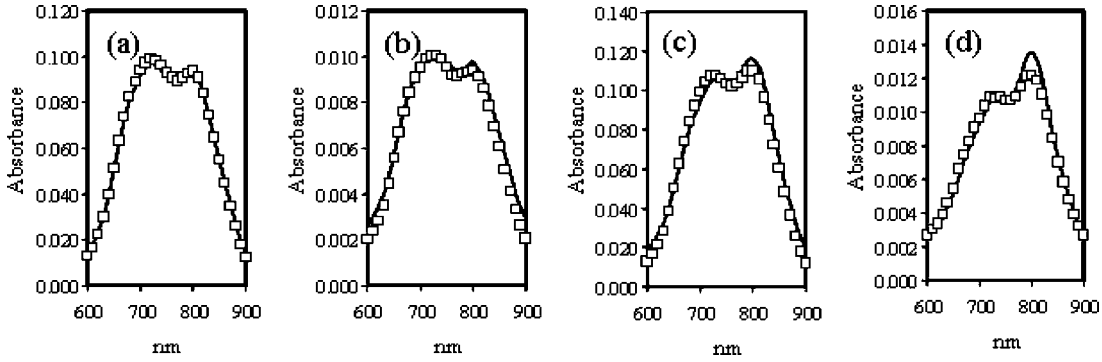

Figure 4. (a) and (b) **11** in PBS, (c) and (d) **11** in 2:8 DMSO:PBS at (□) 0.5 mg/mL and (−) 0.1 mg/mL.

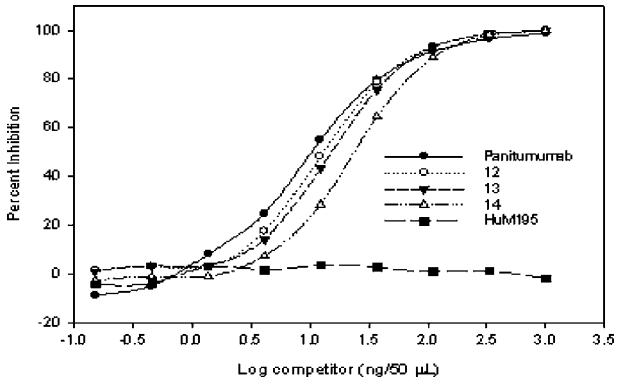

Figure 7. Competition RIA of **12**, **13**, and **14** with ^{125}I-Panitumumab.

(Figure 4c,d). No change was observed in the spectra measured in PBS regardless of the sample concentration. However, for the samples measured in 2:8 DMSO/PBS, the data suggest that aggregation is reduced upon dilution of the sample in the presence of an organic cosolvent, indicated once again by the suppression of the peak at 720 nm and the growth of the peak at 790 nm.

The SE-HPLC data demonstrated that the aggregation occurs on a macromolecular level, as evidenced by the formation of high molecular weight (HMW) species with conjugates **8**−**11** which were clearly observable by chromatography (Table 2). Aggregates were formed only in those conjugates which were labeled with non-PEGylated dye. Furthermore, the degree of aggregation is directly related to the amount of dye loaded onto the protein. Interestingly, previous studies which describe the synthesis of ICG-mAb conjugates fail to report any SE-HPLC data, stating only that purification of the conjugation reaction mixture involved elution through a desalting PD-10 column (*24*,*26*−*32*) to remove any excess or unreacted dye. However, this method is incapable of discriminating between the labeled mAb and any aggregates. The assumptions were that the eluted fraction was a pure product. The SE-HPLC analysis presented in this study demonstrates that this assumption cannot be made. The SE-HPLC data clearly demonstrates that the PEGylated conjugates (**12**−**14**) were void of aggregate formation. Indeed, it has been reported many times in the literature that PEGylation of mAbs and mAb fragments is useful in preventing their aggregation in solution (*35*).

To determine if aggregation was an equilibrium-based process, conjugate **8** was purified by SE-HPLC, the aggregate was separated from the IgG fraction, and the corresponding fractions pooled together and concentrated. Measurement of absorption spectra in PBS confirmed their identities (Figure 5). These repurified products were allowed to sit at 4 °C for three weeks, after which time an aliquot was taken and characterized by SE-HPLC. No formation of aggregates was observed, suggesting that the bioconjugate is stable and therefore the observed aggregation is not an equilibrium-based process but a result of the amount of dye loaded in the conjugation reaction.

All bioconjugates under study were analyzed by SDS-PAGE under both nondenaturing (Figure 6a) and denaturing (Figure 6b) conditions. Under nondenaturing conditions, the band patterns for conjugates **6**−**11** suggest that the presence of SDS was sufficient to disassociate any aggregates present. Furthermore, since all samples under study exhibit the same band pattern as that of native panitumumab in the presence of β-ME, it can be inferred that the aggregates observed in SE-HPLC are associated purely by supramolecular forces; i.e., no covalent cross-linking between antibody molecules during the conjugation reaction occurred. A slight smearing of bands is observed for the PEGylated compounds **12**−**14** under both conditions, a

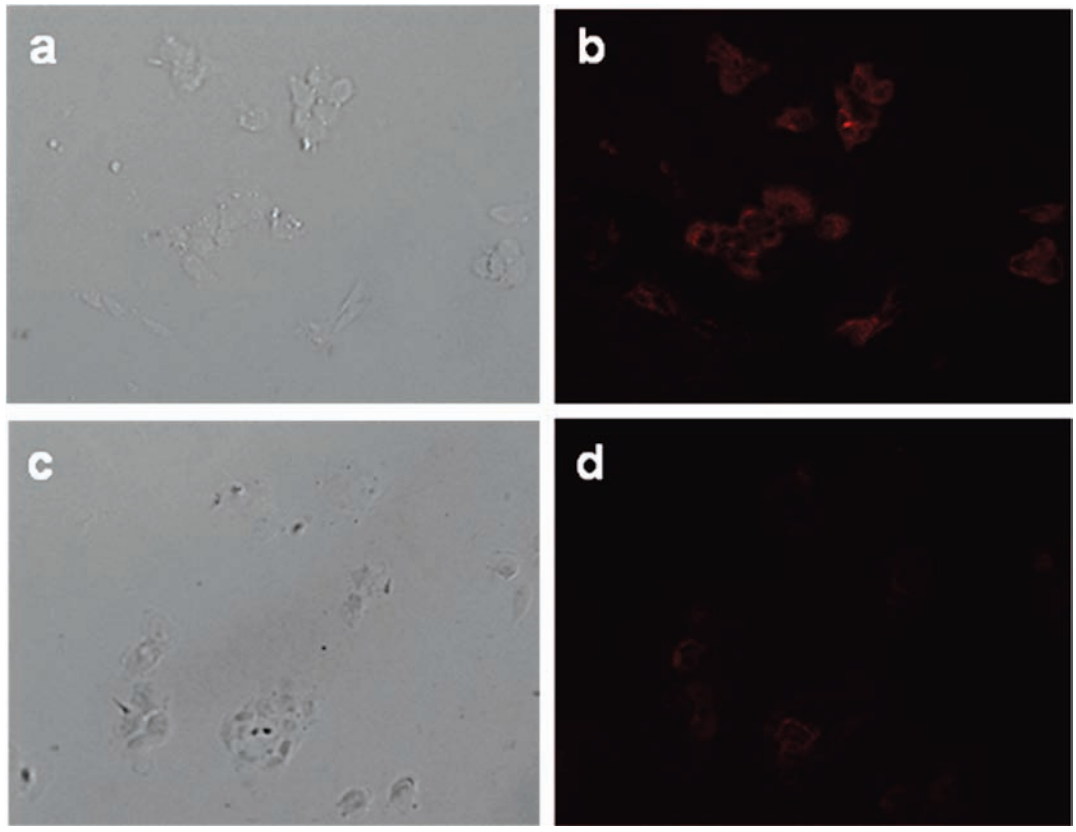

Figure 8. HER1-positive A431 fixed cells incubated with 1 μg of test antibody for 1 h at 37 °C. (a) DIC and (b) fluorescence image of cells stained with **12**. (c) DIC and (d) fluorescence image of cells stained with **15** (negative control).

behavior observed previously in other PEGylated antibodies and antibody fragments (*35*).

The SDS-PAGE data suggest that the mechanism of fluorescence activation previously described for other ICG-labeled mAbs in vitro in the presence of 5% SDS and β-ME or upon cell internalization, and in vivo with mouse cancer xenografts (*31*, *32*), could actually be the result of dye disaggregation of the dye−mAb conjugate. On the other hand, no such problem is anticipated for PEGylated compounds **12**−**14**, as they form no aggregates; furthermore, the linear polymer can serve as an effective spacer to minimize dye−dye interactions.

PEGylated mAbs **12**−**14** were analyzed by competition radioimmunoassay against ^{125}I-labeled panitumumab (Figure 7). The amount of bioconjugate required for 50% inhibition increased with the degree of labeling: 14 ng (**12**), 15 ng (**13**), 23 ng (**14**) vs 10 ng (native panitumumab). Though **12** and **13** exhibit comparable affinities, **14** showed the least amount of affinity among the samples under study, indicating a threshold value had been reached. Therefore, modification of panitumumab with **5** with a resulting D/P ratio less than 3 did not significantly compromise the immunoreactivity of the mAb.

Finally, **12** and **15** (negative control) were used to stain HER-1 expressing A431 cells and their fluorescence monitored by confocal microscopy. The images taken of fixed cells show that the panitumumab-based bioconjugate binds to the cell membranes (Figure 8). Fluorescence of the probe is observed even without internalization into the cell. This reinforces the previously described mechanism of fluorescence activation upon internalization into cells to be one of disaggregation of the dye−mAb conjugate. Fluorescence images of viable cells were also taken and showed similar binding of the fluorescent probe to the cell membranes (Supporting Information Figure 5).

In summary, a PEGylated amine-reactive derivative of NIR-emitting cyanine dye ICG has been successfully synthesized. This was used to label the anti-HER1 antibody panitumumab, and the resulting bioconjugate was characterized alongside previously reported non-PEGylated analogues. UV−vis spectrophotometry and SE-HPLC demonstrate that PEGylation prevents aggregation of the bioconjugate from occurring, in comparison with the non-PEGylated analogues. SDS-PAGE analysis of the bioconjugates show that the presence of SDS is sufficient to disassociate any aggregates formed, and denaturation with β-ME also shows that aggregation is not the result of covalent cross-linkage. These results suggest that the previously reported mechanism of fluorescence activation in ICG-labeled mAbs probably occurs via dye disaggregation. Competitive radioimmunoassay demonstrated that PEGylation of panitumumab with 2 equiv of **5** did not significantly reduce immunoreactivity of the mAb. This result was demonstrated further by fluorescence microscopy of HER1-expressing A431 cells stained with the PEGylated mAb, showing fluorescence on the cell membrane without internalization. This study highlights the fact that, though many protocols for the purification of bioconjugates are well-established and tools for these are commercially available as kits, the need to thoroughly characterize novel bioconjugates using classical methods is necessary to have a proper understanding of their solution properties and speciation.

It is hoped that the PEGylated bioconjugates described here would exhibit not only improved fluorescence properties in vivo but also better pharmacokinetic behavior in visualizing HER1-expressing tumor lesions. Indeed, the benefits of PEGylating proteins for therapeutic purposes have been described thoroughly in the literature, namely, that PEGylation increases the in vivo circulation half-life of the protein thereby enhancing its bioavailability, and that the modified protein exhibits a reduced immunogenicity and antigenicity coupled with increased plasma stability as the steric hindrance introduced by the water-soluble polymer masks it from proteolytic enzymes and other degrading agents (*45*−*47*). Hence, future work involving these single-modality imaging agents will include in vivo testing in animal models to determine their biodistribution and other pharmacokinetic characteristics. Futhermore, it is of immediate interest to this group to assess if PEGylation will improve the solution and in vivo biodistribution properties of our previously reported dual-modality optical/SPECT imaging agents (*18*, *19*), as PEGylation of a radiolabeled protein for SPECT imaging has previously been shown to possess improved pharmacokinetic behavior in the noninvasive monitoring of tumor response to applied therapy (*48*).

ACKNOWLEDGMENT

This research was supported by the Intramural Research Program of the NIH, National Cancer Institute, Center for Cancer Research. We would like to acknowledge the assistance of Dr. Kwamena Baidoo for supplying the ^{125}I-labeled panitumumab for the radioimmunoassay and Dr. Hisataka Kobayashi for the use of the confocal fluorescence microscope.

Supporting Information Available: NMR spectra of compounds **4** and **5**, and in vitro confocal microscopy images of compounds **12** and **15** with viable A431 cells. This material is available free of charge via the Internet at http://pubs.acs.org.

Synthesis and Evaluation of 15-(4-(2-[^{18}F]Fluoroethoxy)phenyl)pentadecanoic Acid: A Potential PET Tracer for Studying Myocardial Fatty Acid Metabolism

Zhude Tu, Shihong Li, Terry L. Sharp, Pilar Herrero, Carmen S. Dence, Robert J. Gropler, and Robert H. Mach*

Division of Radiological Sciences, Washington University School of Medicine, 510 South Kingshighway Blvd. St. Louis, Missouri 63110, United States. Received July 27, 2010; Revised Manuscript Received October 12, 2010

15-(4-(2-[^{18}F]fluoroethoxy)phenyl)pentadecanoic acid ([^{18}F]**7**) was synthesized as a PET probe for assessing myocardial fatty acid metabolism. The radiosynthesis of [^{18}F]**7** was accomplished using a two-step reaction, starting with the corresponding tosylate ester, methyl 15-(4-(2-(tosyloxy)ethoxy)phenyl)pentadecanoate (**5**), and gave the radiolabeled fatty acid, [^{18}F]**7** in a radiolabeling yield of 55−60% and a specific activity of >2000 Ci/mmol (decay corrected to EOB). The biological evaluation of [^{18}F]**7** in rats displayed high uptake in heart (1.94%ID/g at 5 min), which was higher than the uptake (%ID/g) in blood, lung, muscle, pancreas, and brain. MicroPET studies of [^{18}F]**7** in Sprague−Dawley rats demonstrated excellent images of the myocardium when compared with [^{11}C]palmitate images in the same animal. Moreover, the tracer kinetics of [^{18}F]**7** paralleled those seen with [^{11}C]palmitate, with an early peak followed by biphasic washout. When compared to [^{11}C]palmitate, [^{18}F]**7** exhibited a slower early clearance (0.17 ± 0.01 vs 0.30 ± 0.02, $P < 0.0001$) and a significantly higher late clearance (0.0030 ± 0.0005 vs 0.0006 ± 0.00013, $P < 0.01$). These initial studies suggest that [^{18}F]**7** could be a potentially useful clinical PET tracer to assess abnormal myocardial fatty acid metabolism.

INTRODUCTION

Fatty acid metabolism is the major source of energy production in the normal myocardium contributing 90% of aerobic metabolism through the β-oxidation pathway (*1*−*3*). Abnormalities in myocardial fatty acid metabolism play a central role in a variety of cardiac diseases such as obesity, diabetes mellitus, dilated cardiomyopathy, and myocardial ischemia (*1*, *4*). An overdependence on fatty acid metabolism typifies obesity and diabetes mellitus. This increase in fatty acid use can initiate a cascade of events such as worsening myocardial insulin resistance, impaired energetics, and an increase in oxidative stress and lipid accumulation, all of which have detrimental effects on myocellular health and can lead to reduced cardiac function (*5*−*7*). In contrast, a reduction in fatty acid metabolism leading to an overdependence on glucose use occurs in left ventricular hypertrophy, dilated cardiomyopathy, and myocardial ischemia. This metabolic pattern can impair cardiac function through a variety of mechanisms including reduced energy production, increased oxidative stress, and accelerated cell death (*8*, *9*). The importance of altered fatty acid metabolism in these various cardiac disease processes is highlighted by the robust development of new therapeutics designed to favorably manipulate myocardial fatty acid use such as the peroxisome proliferator-activated receptor alpha (PPARα) agents and partial fatty acid oxidation inhibitors (*10*−*12*).

Detection of these different patterns in myocardial fatty acid metabolism may have important diagnostic, prognostic, and therapeutic implications in the management of the cardiac patient. However, to achieve this goal requires the availability of an accurate and widely applicable noninvasive method to image myocardial fatty acid metabolism. To this end, investigators have focused on optimizing the structures of the fatty acids to identify radioligands that have extended retention time in heart and suitable pharmacokinetic properties for use as positron emission tomography (PET) or single photon emission computed tomography (SPECT) imaging probes (Figure 1) (*13*−*16*). However, because PET has higher sensitivity and higher spatial and temporal resolution compared to SPECT, developing a suitable PET probe which is capable of accurately quantifying myocardial fatty acid metabolism is highly desirable. Currently, [^{11}C]palmitate (Figure 1) is the most accurate PET radiotracer for measuring myocardial fatty acid metabolism. However, the short half-life of carbon-11 ($t_{1/2} = 20$ min) limits the use of [^{11}C]palmitate in the study of cardiovascular disease to imaging centers having the capability to produce the radiotracer onsite. Therefore, a number of groups have focused on developing fluorine-18 labeled PET tracers which are capable of imaging fatty acid uptake in the heart.

In this regard, two different strategies have been pursued: (1) developing radiotracers such as [^{11}C]palmitate whose kinetics closely track those of unlabeled fatty acids and thus reflect all aspects of myocardial fatty acid oxidation and storage (*7*, *16*−*19*); and (2) developing radiolabeled tracers that will be trapped within the myocardium and can thus reflect a specific aspect of fatty acid metabolism such as cellular uptake (*16*, *20*−*28*). For the first strategy, the advantages are the assessment of various aspects of myocardial fatty acid metabolism, such as uptake, oxidation, and storage, with appropriate mathematical modeling techniques capable of quantifying fatty acid metabolism in each pathway. In contrast, trapped fatty acid tracers offer the potential of higher image quality, but are not capable of discriminating between the oxidation and storage pathways. A prime example of the latter approach is the radiotracer, 14-(*R*,*S*)-[^{18}F]fluoro-6-thia-heptadecanoic acid ([^{18}F]FTHA) (Figure 1) (*20*, *21*). Imaging studies of [^{18}F]FTHA showed high uptake and retention in the myocardium in various diseases (*23*−*25*), but this radiotracer lacked sensitivity to measure the inhibition of β-oxidation by myocardium under conditions of hypoxia (*14*).

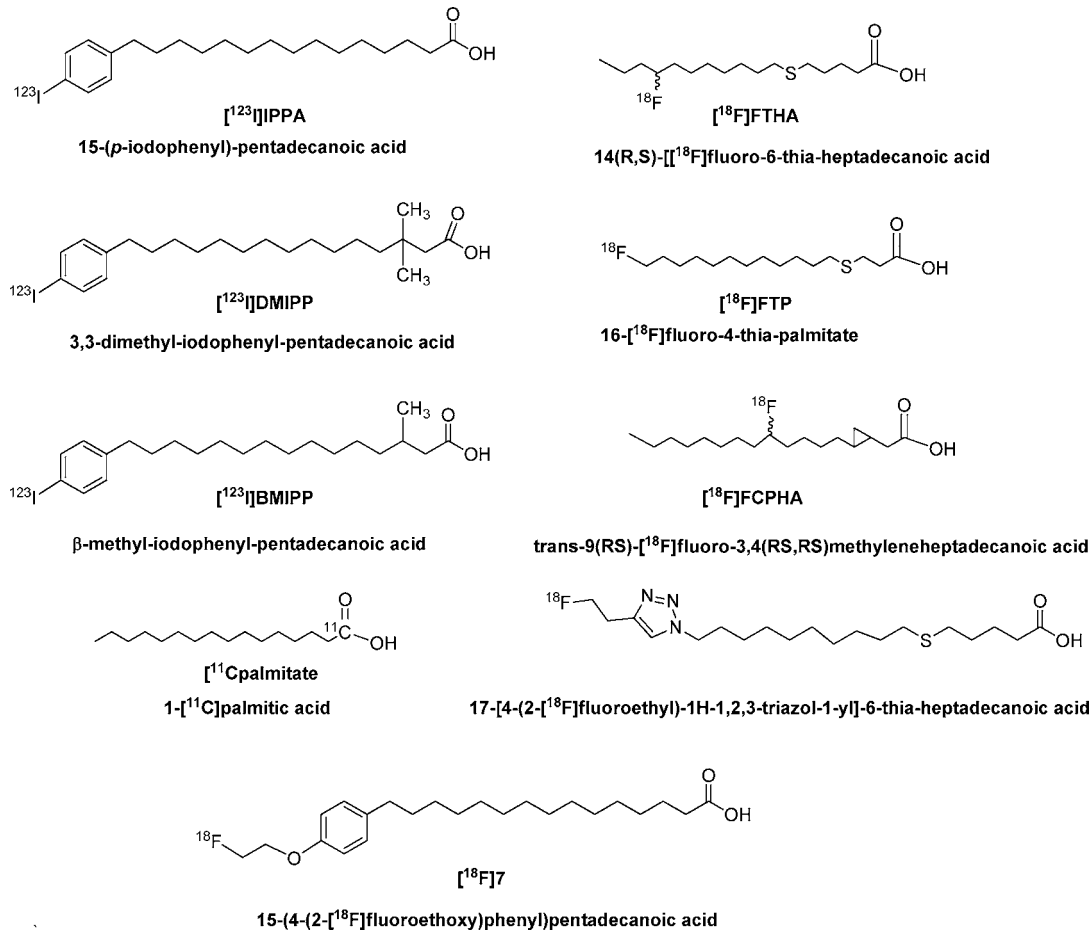

Figure 1. Radiolabeled fatty acid analogues used in PET and SPECT imaging studies.

Subsequently, 16-[^{18}F]fluoro-4-thia-palmitate ([^{18}F]FTP) (Figure 1) was developed, and its metabolic trapping function was proportional to β-oxidation under normal oxygenation and hypoxic conditions (*22*). However, it is not clear if [^{18}F]FTP can accurately differentiate between fatty acid oxidation and esterification (*27*).

Recently, trans-9-(*RS*)-[^{18}F]fluoro-3,4-(*RS*,*RS*) methylene heptadecanoic acid ([^{18}F]FCPHA) (Figure 1), which incorporates a cyclopropyl group at C3−C4 to block β-oxidation, was reported as a radiolabeled fatty acid analogue (*26*). The uptake of [^{18}F]FCPHA in rat myocardium reached approximately 1.5%ID/gram tissue at 5 min and displayed little change over a period of 60 min. However, the impact of altered plasma substrate levels, cardiac workload, and myocardial blood flow on the pharmacokinetics of [^{18}F]FCPHA is not known. It is also not clear if the kinetics of [^{18}F]FCPHA will be able to differentiate among fatty acid uptake, oxidation, and esterification. Currently, both [^{18}F]FTP and [^{18}F]FCPHA are being evaluated in phase 1 clinical trials (*4*). In 2009, 17-[4-(2-[^{18}F]fluoroethyl)-1*H*-1,2,3-triazol-1-yl]-6-thia-heptadecanoic acid, a "click-labeling" analogue of [^{18}F]FTHA, was reported as a potential PET agent for visualizing fatty acid metabolism in myocardium (*28*). However, the same issues apply to this radiotracer regarding the ability to differentiate between fatty acid oxidation and storage mechanisms in the heart.

The goal of our research was to identify an ^{18}F-labeled fatty acid analogue which is capable of mimicking [^{11}C]palmitate with regard to its ability to measure fatty acid uptake, β-oxidation, and storage as triglycerides. The lead compound for our studies was 15-(*para*-iodophenyl)-pentadecanoic acid (IPPA) (Figure 1), which was developed over twenty years ago as a SPECT myocardial imaging agent. In this case, the *p*-iodine atom of IPPA was replaced with a 2-fluoroethoxy group to make 15-(4-(2-fluoroethoxy)phenyl)pentadecanoic acid (**7**) (Figure 1). IPPA was chosen as the lead compound for developing a PET radiotracer because its kinetics closely match those of [^{11}C]palmitate but are too rapid to be imaged with clinical SPECT scanners.

In this article, we report the synthesis and radiosynthesis of [^{18}F]**7**, and our initial results measuring myocardial uptake in rats. MicroPET imaging studies of [^{18}F]**7** were also performed in Sprague−Dawley rats and its pharmacokinetics were compared with that of [^{11}C]palmitate.

EXPERIMENTAL PROCEDURES

General Chemistry. All analytical-grade chemicals and reagents were purchased from Sigma-Aldrich (Milwaukee, WI) and were used without further purification unless otherwise specified. Flash column chromatography was conducted using Scientific Adsorbents, Inc., silica gel, 60 Å, "40 Micron Flash" (32−63 μm). Melting points were determined using MEL-TEMP 3.0 apparatus and uncorrected. ^{1}H NMR spectra were recorded at 300 MHz on a Varian Mercury-VX spectrometer with $CDCl_3$ as solvent and tetramethylsilane (TMS) as the internal standard. All chemical shift values are reported in ppm (δ). Elemental analyses (C, H) were determined by Atlantic Microlab, Inc. (Norcross, GA).

Methyl 15-Bromopentadecanoate (2). A 2.0 M solution of trimethylsilyl diazomethane in hexane (3.4 mL, 6.8 mmol) was added to the solution of 15-bromopentadecanoic acid **1** (1 g, 3 mmol) in THF/MeOH (v/v, 7/2) (18 mL), and the reaction mixture was stirred at room temperature for 2 h. The solvent was removed under reduced pressure. Chloroform (80 mL) was

used to dissolve the residue, and the solution was washed with water (2 × 30 mL) and brine (2 × 30 mL). The organic solution was dried over sodium sulfate. After the solvent was removed under reduced pressure, it afforded **2** as colorless syrup (0.99 g, 99%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.2−1.36 (m, 20H); 1.36−1.48 (2H, m); 1.58−1.78 (m, 2H); 1.79−1.92 (m, 2H); 2.26−2.34 (t, 2H); 3.36−3.48 (t, 2H); 3.67 (s, 3H).

Methyl 15-(4-(Benzyloxy)phenyl)pentadecanoate (3). A solution of compound **2** (400 mg, 1.2 mmol) in 2-methyl-2-butanol (5 mL) was added to a round-bottom flask (25 mL) that contained 4-benzyloxyphenylboronic acid methyl ester (408 mg, 1.79 mmol), $Pd(OAc)_2$ (26.8 mg,12 mmol), [HP(t-Bu)$_2$Me]BF_4 (62.7 mg, 0.25 mmol), and potassium *tert*-butoxide (KO-t-Bu) (53.5 mg, 0.48 mmol), and the reaction mixture was stirred overnight at ambient temperature. The reaction was quenched with ethyl acetate (60 mL), water (13 mL), and glacial acetic acid (2 mL). The organic layer was separated and washed with brine (3 × 10 mL). The organic solution was dried over sodium sulfate, and the solvent was removed under reduced pressure. The product was purified by silica gel column chromatography using ethyl acetate/hexane (1/10, v/v) as the eluent to afford the intermediate compound, 15-(4-(benzyloxy)-phenyl)pentadecanoic acid, as a white solid (240 mg, 45%), mp: 95−96 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.38−1.18 (m, 20H), 1.70−1.50 (m, 2H), 2.34 (t, 2H), 5.04 (s, 2H), 2.54 (t, 2H), 6.93−6.87 (m, 2H), 7.12−7.05 (m, 2H), 7.50−7.30 (m, 5H). 0.5 mL of concentrated sulfuric acid was added into a solution of 15-(4-(benzyloxy)phenyl)pentadecanoic acid (230 mg, 0.54 mmol) in 30 mL methanol. The reaction mixture was stirred at reflux overnight and quenched with a saturated aqueous solution of sodium bicarbonate. After removing the methanol under reduced pressure, the residue was partitioned between dichloromethane and brine. The organic layer was dried over sodium sulfate, filtered, and concentrated under reduced pressure. The crude product was purified by silica gel column chromatography using ethyl acetate/hexane (v/v, 1/10) as the eluent to afford **3** (185 mg, 78%) as a white solid: mp 56−57 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.18−1.40 (m, 20H); 1.50−1.68 (4H, m); 2.26−2.36 (t, 2H); 2.48−2.58 (t, 2H); 3.66 (s, 3H); 5.04 (s, 2H); 6.86−6.94 (m, 2H); 7.06−7.13 (m, 2H); 7.28−7.46 (m, 5H). Elemental analysis $C_{29}H_{42}O_3$ calcd: C, 79.41; H, 9.65. Found: C, 79.14; H, 9.81.

Methyl 15-(4-Hydroxyphenyl)pentadecanoate (4). Palladium (10 wt % on activated carbon; 50 mg) was added under a nitrogen atmosphere to a solution of compound **3** (185 mg, 0.42 mmol) in ethyl acetate (10 mL). Hydrogen was added into the system to reach 6 pounds per square inch (psi) pressure, and the mixture was stirred for over 5 h. The reaction mixture was filtered through Celite and washed with ethyl acetate (5 mL). After removing excess solvent, the product was purified by silica gel column chromatography using ethyl acetate/hexane (v/v, 1/5) as the eluent to afford **4** as a white solid (111 mg, 75%): mp 75−76 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.30−1.47 (m, 20H); 1.50−1.68 (m, 4H); 2.26−2.36 (t, 2H); 2.49−2.58 (t, 2H); 3.67 (s, 3H); 6.72−6.78 (m, 2H); 7.04−7.09 (m, 2H). Elemental analysis $C_{22}H_{36}O_3$ calcd: C, 75.82; H, 10.41. Found: C, 75.71; H, 10.46.

Methyl 15-(4-(2-(Tosyloxy)ethoxy)phenyl)pentadecanoate (5). Compound **4** (106 mg, 0.30 mmol) and ethylene glycol-1,2-bistosylate (338 mg, 0.91 mmol) were dissolved into anhydrous acetonitrile (20 mL), and then potassium carbonate (42 mg, 0.30 mmol) was added into the reaction mixture. The reaction mixture was stirred at reflux under a nitrogen atmosphere for 18 h until thin layer chromatography (TLC) indicated the reaction was complete. After removing the solvent, dichloromethane (10 mL) was used to dissolve the residue. The organic layer was washed with brine (10 mL), dried over sodium sulfate, filtered, and concentrated under reduced pressure. The residue was purified by silica gel column chromatography using ether/hexane (v/v, 1/2) as the eluent to afford compound **5** as a white solid (145 mg, 87%): mp 44−45 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.18−1.40 (m, 20H); 1.46−1.68 (4H, m); 2.26−2.36 (t, 2H); 2.45 (s, 3H); 2.48−2.56 (t, 2H); 3.66 (s, 3H); 4.09−4.15 (2H); 4.32−4.38; 6.66−6.74 (m, 2H); 7.01−7.08 (m 2H); 7.30−7.37 (m, 2H); 7.78−7.853 (m, 2H). Elemental analysis $C_{31}H_{46}O_6S \cdot 4H_2O$ calcd: C, 60.17; H, 8.80. Found: C, 60.03; H, 8.44.

Methyl 15-(4-(2-Fluoroethoxy)phenyl)pentadecanoate (6). Compound **4** (104 mg, 0.3 mmol), 1-bromo-2-fluoroethane (227 mg, 1.8 mmol), and potassium carbonate (246 mg, 1.8 mmol) were added into a flask containing acetone (40 mL). The reaction mixture was stirred at reflux under a nitrogen atmosphere for 18 h. Volatiles were removed under reduced pressure, and the residue was partitioned between ethyl acetate (60 mL) and water (20 mL). The organic layer was washed with brine, dried over sodium sulfate, filtered, and concentrated under reduced pressure. The residue was purified by silica gel column chromatography using ethyl acetate/hexane (v/v, 1/10) as the eluent to afford compound **6** as a white solid (115 mg, 98%): mp 66−67 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.18−1.40 (m, 20H); 1.50−1.68 (m, 4H); 2.26−2.37 (t, 2H); 2.49−2.58 (t, 2H); 3.67 (s, 3H); 4.12−4.18 (t, 1H), 4.22−4.27 (t, 3H); 4.64−4.70 (t, 1H); 4.80−4.85 (t, 1H); 6.82−6.88 (m, 2H); 7.06−7.13 (m, 2H). Elemental analysis $C_{24}H_{39}FO_3$ calcd: C, 73.06; H, 9.96. Found: C, 73.30, H, 10.14.

5-(4-(2-Fluoroethoxy)phenyl)pentadecanoic Acid (7). Compound **6** (110 mg, 0.28 mmol) and NaOH (180 mg, 4.5 mmol) were dissolved into 11 mL of dichloromethane/methanol/water (5/5/1), and the reaction mixture was stirred at ambient temperature for 18 h. Solvents were removed under reduced pressure; the residue was acidified to pH 2.0 with 1 N aqueous HCl and extracted into ethyl acetate (3 × 20 mL). The organic layer was dried over sodium sulfate, filtered, and concentrated under reduced pressure to afford compound **7** as a white solid (95 mg, 89%): mp 84−85 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.18−1.40 (m, 20H); 1.50−1.708 (m,4H); 2.30−2.39 (t, 2H); 2.49−2.58 (t, 2H); 4.12−4.17 (t, 1H), 4.21−4.37 (t, 3H); 4.64−4.70 (t, 1H); 4.80−4.85 (t, 1H); 6.81−6.88 (m, 2H); 7.06−7.13 (m, 2H). Elemental analysis $C_{23}H_{37}FO_3$ calcd: C, 75.29; H, 9.80. Found: C, 72.77; H, 9.82.

Radiochemistry. *Production of [^{18}F]Fluoride.* $H_2{}^{18}O$ was purchased from Rotem Industries (Israel). [^{18}F]Fluoride was produced in our institution by proton irradiation of enriched ^{18}O water (95%) [reaction: ^{18}O(p, n)^{18}F] using a Siemens Eclipse Cyclotron (Siemens Medical Systems, Inc., Knoxville, TN). ^{18}F-enriched $H_2{}^{18}O$ (up to 1500 mCi) was delivered from the Eclipse Cyclotron and transferred to the reaction vial through an anion-exchange column, Sep-Pak Light QMA. [^{18}F]fluoride was eluted from the Sep-Pak by addition of an aqueous solution of potassium carbonate (2 mg of K_2CO_3 in 0.5 mL of water) into the reactor vessel.

15-(4-(2-[^{18}F]fluoroethoxy)phenyl)pentadecanoic Acid ([^{18}F]7). [^{18}F]Fluoride (100−150 mCi) was added to a 10 mL Pyrex screw cap tube containing 5−6 mg of Kryptofix 2.2.2 and 1−2 mg of K_2CO_3. HPLC-grade acetonitrile (3 × 1.0 mL) was used to remove the water by azeotropic evaporation from this reaction vessel at 110 °C under a stream of nitrogen. After all the water was removed, a solution of precursor **11** (1−2 mg) in 0.25−0.30 mL acetonitrile was added. The tube was capped and heated at 110−115 °C for 5−10 min. This solution was diluted with 1.0 mL acetonitrile and passed through a silica gel Sep-Pak (Alltech Associates, Inc., Deerfield, IL) into a collection vial. An additional 2 mL of acetonitrile was used to rinse out the remaining radioactive product from the Sep-Pak into the above collection vial. Radio-thin-layer chromatography (radio-TLC) showed that the

radiochemical purity was >95% on a Bioscan System 2000 system (Bioscan, Inc., Washington, DC). The acetonitrile was removed by a stream of nitrogen gas at 80−85 °C. [^{18}F]**6** was used directly in the next step, without further purification. 0.5 mL of ethanol and 0.2 mL of a 2 N NaOH aqueous solution were added into the above collection vessel containing dried [^{18}F]**6**. The vessel was heated at 80 °C for 2 min, and then 0.4 mL of 1 N aqueous HCl was added into the reaction mixture to neutralize the mixture to pH = 7.0. Acetonitrile (2 mL) was added, and the reaction mixture was loaded through a 0.45 μm filter into a high-performance liquid chromatography (HPLC) system equipped with an Alltech Econosil C18 reverse-phase column (10 × 250 mm) and eluted with acetonitrile/0.1 M ammonium formate buffer (v/v, 85/15) at a flow rate of 4.0 mL/min. A vial was used to collect the radioactive product from 24 to 25.5 min. The HPLC mobile-phase solution was concentrated under reduced pressure, and the residue was azeotroped with ethanol (2 × 1 mL) to remove the residual mobile phase. The labeled fatty acid [^{18}F]**7** was formulated in 6 mL of 3% human serum albumin (HSA) preincubated at 45 °C for 3 min and passed through 0.22 μm Millex-GP sterile syringe filter (cat no. SLMP025SS, Millipore, Billerica, MA) into a final dose vial. The dose sample was authenticated by coinjection with the corresponding cold standard onto an analytical HPLC system, which included an Alltech Econosil C18 column (10 μm, 250 mm × 4.6 mm), using acetonitrile/0.1 M ammonium formate buffer (v/v, 90/10) as mobile phase, 1.5 mL/min flow rate, and 274 nm UV wavelength. Under these conditions, the retention time of the product [^{18}F]**7** was 7.4 min. The total radiosynthesis took ~2 h; the labeling yield ranged 50−60% (decay corrected to EOB), radiochemical purity >95%, and specific activity >2000 Ci/mmol (decay corrected to EOB).

Biodistribution Studies. All animal experiments were conducted in compliance with the NIH Guidelines for the Care and Use of Research Animals under IACUC approved protocols reviewed by the Washington University School of Medicine Animal Studies Committee. The biodistribution of [^{18}F]**7** was performed in adult male Sprague−Dawley rats (170−250 g). Rats were anesthetized with 2−3% isoflurane/O_2, and [^{18}F]**7** (approximately 20−25 μCi/100 μL) was injected via the lateral tail vein. Rats were euthanized under anesthesia at 5, 30, 60, and 120 min post-injection, 4−8 rats for each time point. Samples of blood, lung, liver, kidney, spleen, muscle, heart, brain, and pancreas were removed from each rat, weighed, and counted in a Beckman Gamma 8000 counter. Bone and fat were taken only for the 5 and 60 min time points from 4 rats. A standard dilution of the injectate was counted with the samples from each animal. The biodistribution results were calculated as percent injected dose per gram of tissue (%ID/g) and are presented in Table 1.

MicroPET Studies. MicroPET imaging studies were performed in fasted male Sprague−Dawley rats using a microPET Focus 220 scanner. The rats were secured using a custom-designed acrylic restraining device, and placed inside the field of the window of the microPET Focus 220 scanner (*29, 30*). After a bolus injection of radiotracer via the right jugular catheter, microPET imaging studies of each rat were performed using 1 h dynamic data acquisition. The microPET studies were first conducted with [^{11}C]palmitate (0.30−0.40 mCi/150 μL). After a 1 h period for biological clearance and radioactive decay, [^{18}F]**7** (0.30−0.40 mCi/150 μL) was administered into the same rat, and a second microPET dynamic imaging scan was acquired. [^{11}C]Palmitate and [^{18}F]**7** blood time−activity curves were generated from dynamic PET images by placing one 3 × 3 voxel region of interest (ROI) on the left ventricle. Myocardial ROIs encompassing the anteriolateral myocardium were drawn on three consecutive PET slices as shown in Figure 2C,D.

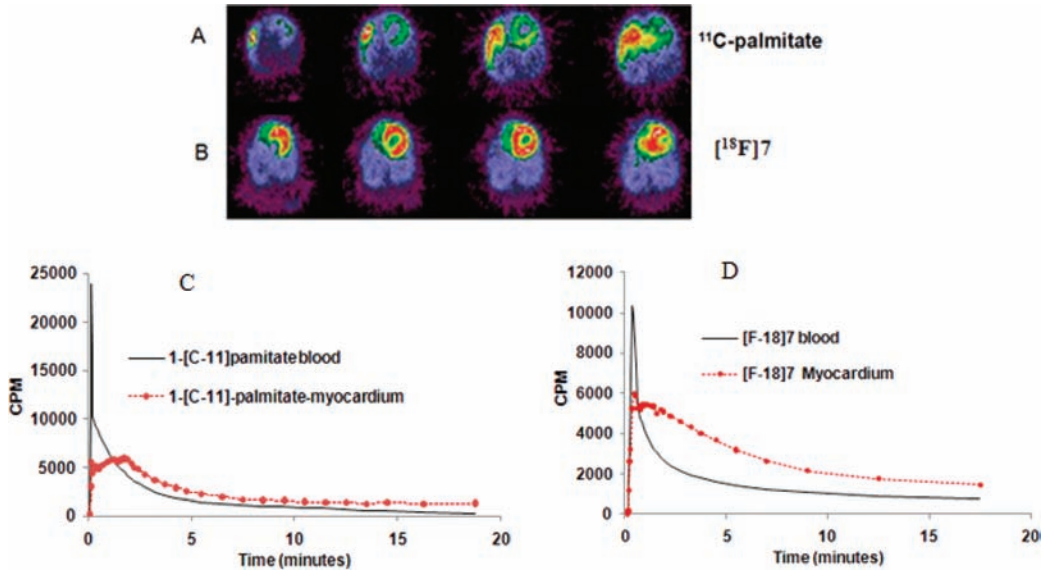
RESULTS AND DISCUSSION

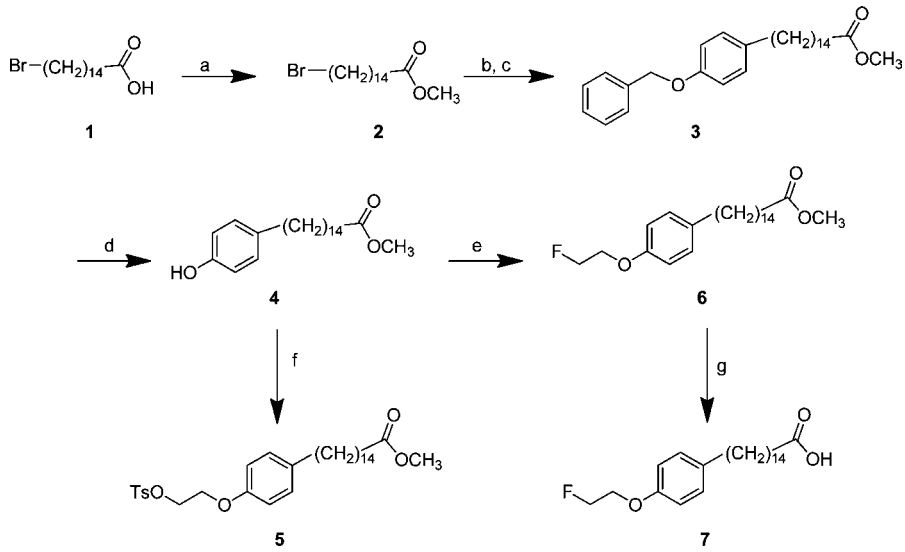
Chemistry. The synthesis of compound **7** is shown in Scheme 1. The ester **2** was made via O-alkylation of 15-bromopentadecanoic acid, **1**, with trimethylsilyl diazomethane in tetrahydrofuran as described in the literature (*31*). The Suzuki cross-coupling of **2** with 4-benzyloxyphenyboronic acid gave 15-(4-(benzyloxy)phenyl)pentadecanoic acid in modest yield (45%). The methyl group was removed from the ester **3**, because potassium *tert*-butoxide (KO-t-Bu) is a strong Lewis base that led to the hydrolysis of intermediate ester, methyl 15-(4-(benzyloxy)phenyl)pentadecanoate. It is of interest to note that, when the Suzuki cross-coupling reaction was directly performed between 15-bromopentadecanoic acid and 4-benzyloxyphenyboronic acid, no product was obtained. Esterification of 15-(4-(benzyloxy)phenyl)pentadecanoic acid in methanol with concentrated sulfuric acid as a catalyst afforded compound **3** in 78% yield. Removal of the benzyl group of **3** was accomplished by hydrogenolysis over 10% palladium-activated carbon to afford **4** in 75% yield. O-alkylation of the phenol group of **4** with 1-bromo-2-fluoroethane in acetone using potassium carbonate as the base afforded the fluoroethoxy ester **6** in high yield (98%). Hydrolysis of the ester group afforded the target compound **7** in 89% yield. Compound **5**, the precursor for making [^{18}F]**7**, was prepared via O-alkylation of **4** with ethylene glycol-1,2-bistosylate in acetonitrile using potassium carbonate as the base (87% yield) as shown in Scheme 1.

Radiochemistry. The radiosynthesis of the target compound [^{18}F]**7** was made using the two-step reaction sequence shown in Scheme 2. First, nucleophilic displacement of the tosylate group of ester **5** with [^{18}F]KF/Kryptofix 2.2.2 in acetonitrile afforded [^{18}F]**6**. Hydrolysis of the ester with aqueous sodium hydroxide followed by neutralization with aqueous hydrochloric acid and semipreparative HPLC gave the target fatty acid analogue, [^{18}F]**7**. The identity of the target compound was confirmed by coinjection with the cold standard **7** using an analytical HPLC system. Radiosynthesis and formulation of [^{18}F]**7** took approximately 2 h, with the yield ranging from 50% to 60%, the specific activity was >2000 mCi/μmol (decay corrected to the end of synthesis), and the radiochemical and chemical purities were >95% (n = 10). The radiosynthesis is straightforward and can be easily adapted to an automated synthesis module.

Radiosynthesis of [^{11}C]palmitate was performed as previously described (*32*).

Biodistribution Studies. The tissue distribution of [^{18}F]**7** in adult male Sprague−Dawley rats is shown in Table 1. At 5 min post-i.v. injection, the uptake of [^{18}F]**7** in the heart (2.00 ± 0.44%ID/g) and liver (2.71 ± 0.37%ID/g) was higher than that of any other tissues sampled. The ratio of activity in heart/nontarget tissues was 2.55:1 for blood and 8.3:1 for skeletal muscle. The brain had the lowest initial uptake of [^{18}F]**7**, 0.11 ± 0.01%ID/g; tracer uptake in fat activity was also very low, 0.14 ±





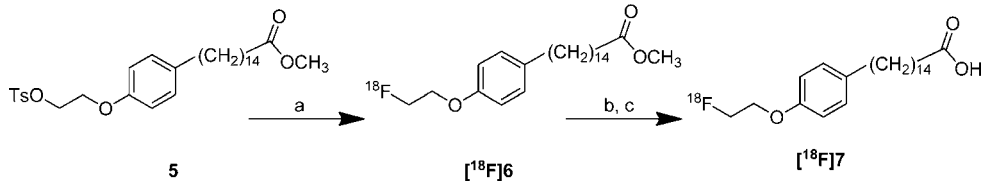


Figure 2. MicroPET imaging studies of [^{11}C]palmitate (panel A) and [^{18}F]**7** (panel B) in male Sprague−Dawley rats. Images are displayed on the transaxial axis and represent data acquired 20−30 min postinjection of the radiotracer. [^{18}F]**7** images display excellent quality and higher tracer accumulation than the [^{11}C]palmitate images. Tissue time−activity curve are shown in panel C for [^{11}C]palmitate and panel D for [^{18}F]**7**. Both radiotracers display biphasic washout kinetics, but some differences are noted. For example, when compared to [^{11}C]palmitate, [^{18}F]**7** exhibited an early plateau followed by a slower early tracer clearance (0.17 ± 0.01 vs 0.30 ± 0.02, $P < 0.0001$) and a significantly higher late clearance (0.0030 ± 0.0005 vs 0.0006 ± 0.00013, $P < 0.01$).

Synthesis of the precursor for radiolabeling and the HPLC standard.

Scheme 2[a]

[a] Reagents and conditions: (a) [^{18}F]F-, Kryptofix 2.2.2, K_2CO_3, CH_3CN, 80 °C; (b) 2 N NaOH/MeOH, H_2O; (c) 1 N HCl Radiosynthesis of [^{18}F]**7**.

0.02%ID/g. [^{18}F]**7** has a calculated log *P* value of 5.56 (ACD, Log D/suite 7.0). Consequently, this high lipophilicity will make it difficult to passively cross the blood−brain barrier, which explains the low uptake of [^{18}F]**7** in the brain. The 5 min uptake of [^{18}F]**7** in liver was 2.71 ± 0.37%ID/g, the only organ with higher uptake than that seen in heart. By 30 min post-injection, the uptake of [^{18}F]**7** in heart had decreased to 35% of the 5 min activity and remained stable between 30 and 60 min (0.72 ± 0.10 and 0.86 ± 0.28%ID/g, respectively). At 120 min, the uptake of [^{18}F]**7** in the heart remained 0.34 ± 0.04%ID/g, which

was approximately 1.4-fold higher than that in blood (0.26 ± 0.06% ID/g) at 120 min. Between 30 and 60 min, activity in blood, liver, and kidney continued to decrease, while activity levels in lung, heart, spleen, muscle, pancreas, and brain remained fairly stable. The increase in mean uptake of [^{18}F]**7** in lung and heart from 30 to 60 min was within experimental error and was not significant (*P* values comparing the 30 and 60 min time points using the Students *t* test were 0.56 for lung and 0.66 for heart). Bone and fat were taken only at the 5 and 60 min time points. Although the activity in fat increased 20% (from 0.14 ± 0.02 to 0.17 ± 0.01%ID/g, Student's *t* test *P* value = 0.04), there was no significant accumulation of [^{18}F]**7** activity in bone between 5 and 60 min (from 0.28 ± 0.01 to 0.33 ± 0.06%ID/g, Student's *t* test *P* value = 0.14). These data indicate that there was no significant metabolic defluorination during the period of time needed for PET data acquisition.

MicroPET Studies. MicroPET imaging studies in adult male Sprague−Dawley rats ($N = 3$) were also conducted in order to compare the myocardial uptake of [^{18}F]**7** with that of [^{11}C]palmitate. Representative myocardial microPET images obtained from same rat are displayed in Figure 2A when using [^{11}C]palmitate and Figure 2B when using [^{18}F]**7**. Images are displayed on the transaxial axis and represent data acquired 20−30 min postinjection. [^{18}F]**7** images displayed excellent quality and higher tracer activity than the corresponding [^{11}C]palmitate images. PET images were consistent with the biodistribution data and showed no evidence of accumulation in bone. Because the biological half-life of [^{11}C]palmitate in human heart is short, a tissue time−activity curve for 0−20 min provides sufficient information for measuring the kinetics of fatty acid metabolism (*33*). To be consistent, Figure 2C,D displays 0−20 min tissue time−activity curves for both radiotracers. [^{18}F]**7** exhibited significant tracer uptake in the heart and a rapid biphasic washout. However, some differences were noted when the data were compared with the time−activity curves of [^{11}C]palmitate. For example, [^{18}F]**7** exhibited an early plateau followed by a slower early tracer clearance (0.17 ± 0.01 vs 0.30 ± 0.02, $P < 0.0001$) and a significantly higher late clearance (0.0030 ± 0.0005 vs 0.0006 ± 0.00013, $P < 0.01$). Studies to determine if the differences in washout kinetics of [^{18}F]**7** versus [^{11}C]palmitate reflect a difference in fatty acid metabolism or are due to the position of the radiolabel (C-1 position in [^{11}C]palmitate vs *p*-position of the benzene ring in [^{18}F]**7**) are currently ongoing in our group.

CONCLUSION

We have successfully synthesized the fatty acid analogue [^{18}F]**7** with good yield, high radiochemical purity, and high specific activity. The initial biodistribution and microPET imaging studies of [^{18}F]**7** in rats indicate that [^{18}F]**7** displays a high uptake in heart and good contrast vs blood and other tissues. The initial microPET studies of [^{18}F]**7** in male Sprague−Dawley rats indicated that the tissue time−activity of [^{18}F]**7** displays rapid biphasic washout kinetics similar to that of [^{11}C]palmitate.

There is a compelling need for widely applicable radiotracer method that provides accurate and comprehensive measurements of myocardial fatty acid metabolism in humans. Current radiotracers are limited by their lack of quantitative capability (e.g., [^{123}I]BMIPP),[1] inability to track various aspects of fatty acid metabolism (e.g., ([^{18}F]FTHA or [^{18}F]FTP) or widespread applicability (e.g., [^{11}C]palmitate). The availability of [^{18}F]**7** combined with appropriate image analysis tools should overcome these limits. The availability of these methods will facilitate the identification of relevant fatty acid metabolic biomarkers predictive of the presence and/or progression of cardiac disease and to evaluate specific therapeutic strategies. Once these data are obtained, the usefulness of this radiotracer technique in the clinical management of patients could be determined. Moreover, PET studies with [^{18}F]**7** could be used to measure fatty acid metabolism in other organs such as skeletal muscle and liver. Thus, the impact on human health of an ^{18}F-labeled radiotracer for measuring fatty acid metabolism could be further expanded by enabling the study of other common diseases where alterations in cellular fatty acid metabolism are central to disease pathophysiology, such as insulin resistance syndrome and nonalcoholic fatty liver disease.

Multicolor Protein Labeling in Living Cells Using Mutant β-Lactamase-Tag Technology

Shuji Watanabe,[†] Shin Mizukami,[†,‡] Yuichiro Hori,[†] and Kazuya Kikuchi*[,†,‡]

Division of Advanced Science and Biotechnology, Graduate School of Engineering, and Immunology Frontier Research Center, Osaka University, 2-1 Yamadaoka, Suita, Osaka, 565-0871, Japan. Received July 29, 2010; Revised Manuscript Received September 21, 2010

Protein labeling techniques using small molecule probes have become important as practical alternatives to the use of fluorescent proteins (FPs) in live cell imaging. These labeling techniques can be applied to more sophisticated fluorescence imaging studies such as pulse-chase imaging. Previously, we reported a novel protein labeling system based on the combination of a mutant β-lactamase (BL-tag) with coumarin-derivatized probes and its application to specific protein labeling on cell membranes. In this paper, we demonstrated the broad applicability of our BL-tag technology to live cell imaging by the development of a series of fluorescence labeling probes for this technology, and the examination of the functions of target proteins. These new probes have a fluorescein or rhodamine chromophore, each of which provides enhanced photophysical properties relative to coumarins for the purpose of cellular imaging. These probes were used to specifically label the BL-tag protein and could be used with other small molecule fluorescent probes. Simultaneous labeling using our new probes with another protein labeling technology was found to be effective. In addition, it was also confirmed that this technology has a low interference with respect to the functions of target proteins in comparison to GFP. Highly specific and fast covalent labeling properties of this labeling technology is expected to provide robust tools for investigating protein functions in living cells, and future applications can be improved by combining the BL-tag technology with conventional imaging techniques. The combination of probe synthesis and molecular biology techniques provides the advantages of both techniques and can enable the design of experiments that cannot currently be performed using existing tools.

INTRODUCTION

Recent prominent advances in fluorescence imaging techniques enabled investigations of direct localization and trafficking of biomolecules in living cells. Genetic engineering has also been progressing dramatically and provides methods for expressing various proteins in specific organelles in cells. Fusion proteins prepared by linkage of fluorescent proteins (FPs) can be used to obtain tools for imaging any protein of interest (POI) (*1*). However, it is difficult to use FPs in pulse-chase imaging studies for investigating protein function over time within the space inside a living cell and to optimize fluorescence properties such as emission and excitation wavelengths, extinction coefficients, and photostability for various experiments. Moreover, certain FPs tend to form protein aggregates that affect the function and/or localization of the target POIs (*2, 3*).

Protein labeling methods using small molecule probes have attracted great attention because they may have the ability to overcome the limitations of FPs. Several methods for labeling proteins with small molecules have been commercialized, including Lumio-tag (*4*−*6*), HaloTag (*7*), SNAP-tag (*8*−*10*), and DHFR-based tag (*11*). Lumio-tag, using FlAsH or ReAsH, is based upon a fluorescent biarsenical dye that reacts with tetracysteine peptide and generates strong fluorescence. HaloTag is a modified haloalkane dehalogenase designed to covalently react with synthetic haloalkyl ligands. SNAP-tag utilizes human O^6-alkylguanine-DNA-alkyltransferase (hAGT) as the protein tagged with synthetic benzylguanine derivatives. DHFR-based tag employs the noncovalent interaction between *Escherichia coli* dihydrofolate reductase and fluorescently labeled methotrexate. Other protein labeling methods based on biotin ligase (*12*), transglutaminase (*13*), hexahistidine (*14*), and tetraaspartic acid (*15*) have also been reported.

The advantages of synthetic fluorescent probes are tunable switches for changes in fluorescence characteristics. These probes have intense fluorescence properties and provide a wide range of choices in fluorophores. Meanwhile, the advantages of using protein expression systems are provided by specific expression in cellular components and tissues, convenient experimental procedures, and the potential for in vivo studies using transgenic mice. Combining the advantages of both techniques is expected to provide enhanced methods for exploring molecular functions in biological systems.

For incorporation of the tunable switches in expressed protein tags, we previously reported a specific protein labeling system with an off/on fluorescence switch that employs a mutant enzyme and its specific substrate. The system involves covalent modification of a mutant β-lactamase (BL-tag) with a rationally designed fluorogenic probe based on fluorescence resonance energy transfer (FRET) (*16*). β-Lactamases are members of a family of bacterial enzymes that efficiently cleave β-lactam moieties within compounds such as penicillins and cephalosporins (*17*). Since the activity of β-lactamases is not observed in eukaryotic cells, these proteins have been widely exploited as reporter enzymes in living mammalian cells (*18*−*20*). Furthermore, their three-dimensional structures, catalytic mechanism, and inhibitors have been widely studied because of their clinical importance (*21*). A well-characterized isoform is the 29 kDa TEM-1 β-lactamase from *Escherichia coli* categorized as a class A β-lactamase (*22*).

Scheme 1. Reaction Mechanism of Wild-Type (WT) and Mutant (E166N) TEM-1 β-Lactamase

The reaction of wild-type (WT) TEM-1 with β-lactams involves acylation and deacylation steps (Scheme 1). Nucleophilic attack on the β-lactam ring by Ser70 leads to the covalent acyl-enzyme intermediate. In WT TEM-1, Glu166 acts as a base to catalyze hydrolysis of the intermediate (*23*), resulting in release of the product and regeneration of WT TEM-1. In ^{E166N}TEM, Asn166 is ineffective as a base; hence, the intermediate accumulates as a stable covalent adduct (*24*).

According to the above-mentioned mechanism, we have reported a novel protein labeling system with an off−on fluorescence switch based on a combination of a mutant β-lactamase (BL-tag) and coumarin-based substrates. Owing to the rational design of both the tag protein and the labeling probes, this system enabled us to simultaneously achieve specific and fluorogenic labeling of the target protein on living cells (*16*). In our previous report, we designed and synthesized both a simple fluorescent labeling probe, designated CA, and a fluorogenic probe, designated CCD. CA is a 7-hydroxycoumarin−ampicillin conjugate and CCD includes three main components; 7-hydroxycoumarin, cephalosporin, and DABCYL. The fluorescence of CCD is largely quenched by intramolecular FRET from coumarin to DABCYL. Cleavage of the cephalosporin β-lactam ring produces a free amino group, which triggers spontaneous elimination of any leaving group previously attached to the 3′ position (*25*). Consequently, fluorogenic labeling with CCD of fusion proteins of ^{E166N}TEM (BL-tag) was successfully performed in vitro and on the surfaces of living cells.

In this paper, we demonstrated the broad applicability of this labeling technology for live cell imaging experiments by developing a series of labeling probes with various fluorophores. We also show that this technology has a low interference with respect to the functions of EGFR and is orthogonal to another currently used protein labeling method.

EXPERIMENTAL PROCEDURES

Fluorometric Analysis. The slit width was 2.5 nm for both excitation and emission, and the photomultiplier voltage was 700 V. All fluorescent probes were dissolved in DMSO to obtain 10 mM stock solutions, and these solutions were diluted to the desired final concentrations with an appropriate aqueous buffer solution. Relative fluorescence quantum yields of the compounds were obtained by comparing the area under the emission spectrum of the sample with that of an EtOH solution of rhodamine B, which has a quantum efficiency of 0.97 when excited at 545 nm (*26*), and with that of a 100 mM NaOH solution of fluorescein, which has a quantum efficiency of 0.85 when excited at 492 nm (*27*).

Calculation of Förster Distance (R_0) and Energy Transfer Efficiency (E). For evaluation of R_0 and E, a revised version of the Förster formula was used (*28*)

$$R_0 = 9.78 \times 10^3(\Phi_D \kappa^2 n^{-4} J)^{1/6} \quad \left(J = \int_0^\infty f_D(\lambda)\varepsilon_A\lambda^4\, d\lambda\right)$$

$$E = R_0^6/(R_0^6 + R^6)$$

where R_0 is expressed in Å units, κ^2 is the orientation factor, Φ_D is the donor quantum yield in the absence of acceptor, n is the refractive index of the medium, $f_D(\lambda)$ is the normalized donor emission spectrum, $\varepsilon_A(\lambda)$ is the acceptor molar absorption coefficient in M^{-1} cm^{-1} units, and R is the donor−acceptor distance. The wavelength is expressed in nanometer units. The value $\kappa^2 = 2/3$, which corresponds to a dynamic isotropic regime, was assumed and $n = 1.33$ was applied. The molar absorption coefficient (ε) of DABCYL was 25 500 ($\lambda = 462$ nm) in 100 mM HEPES buffer (pH 7.4). R_0 values were calculated for the CA-DABCYL pair for CCD, the FA-DABCYL pair for FCD, and the RA-DABCYL pair for RCD. The quantum yields (Φ_D) of the compounds were 0.40 for CA, 0.71 for FA, and 0.49 for RA. The donor−acceptor distance (R) was evaluated by using the integrated molecular modeling packages *Maestro* v 8.5 and *MacroModel* v 9.6.

HPLC Analysis. HPLC analyses were performed with an Inertsil ODS-3 (4.6 × 250 mm) column (GL Sciences Inc.) using an HPLC system that comprises a pump (PU-2080, JASCO) and a detector (MD-2010 or FP-2020, JASCO). Preparative HPLC was performed with an Inertsil ODS-3 (10.0 × 250 mm) column (GL Sciences Inc.) using an HPLC system that comprises a pump (PU-2087, JASCO) and a detector (UV-2075, JASCO).

Fluorescence Microscopy. Fluorescence microscopic images were recorded using a IX71 fluorescence microscope (Olympus), a Cool Snap HQ cooled CCD camera (Roper Scientific), and a USH-103OL mercury lamp (Olympus). The filter sets used were Olympus BP330-385, DM455, and BA455 for Hoechst 33342 and coumarin derivatives; BP470-495, DM505, and BA510-550 for fluorescein derivatives; and BP510-550, DM575, and BA575-625 for rhodamine derivatives. *MetaMorph* imaging software (Universal Imaging Corporation) was used for imaging and data analysis.

Detection of Protein Labeling by SDS-PAGE. WT TEM-1 or ^{E166N}TEM (*16*) (20 μM) was added to a solution of probes (30 μM) in 100 mM HEPES buffer (pH 7.4) at 25 °C. After 30 min, the labeled protein was denatured in 2 × SDS gel loading buffer (100 mM Tris−HCl buffer (pH 6.8), 2.5% SDS, 20%

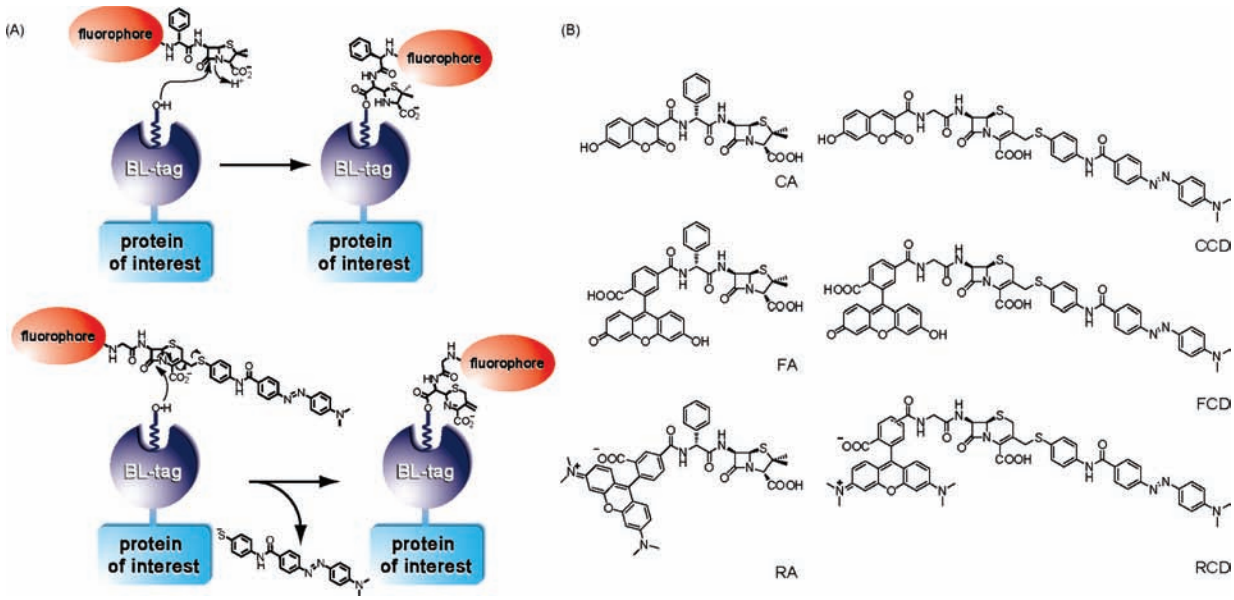

Figure 1. (A) General labeling mechanisms of the ampicillin- and cephalosporin-based probes. (B) Structures of β-lactam derivatives used for fluorescence labeling of BL-tag fusion proteins.

glycerol, and 10% mercaptoethanol) and resolved by NuPAGE (12% bis-Tris gel, Invitrogen). The fluorescence images of the gels were captured using a digital camera (Nikon COOLPIX P6000). The gels were stained with Coomassie Brilliant Blue prior to the capture of images.

Labeling of Cell Surface pcDNA3.1(+)-^{E166N}TEM-EGFR (BL-EGFR) with Various Probes. HEK293T cells maintained in 10% FBS in DMEM (Invitrogen) at 37 °C under 5% CO_2 were transfected with a plasmid coding for BL-EGFR, which was prepared as described previously (*16*), using Lipofectamine 2000 (Invitrogen). After 5−6 h, the culture medium was replaced with DMEM (without phenol red), and the cells were incubated at 37 °C for 24 h. The cells were then washed three times with DMEM (without phenol red) and incubated with 10 μM labeling probes in a CO_2 incubator for 30 min for CA, FA, and RA, or for 2 h for CCD and FCD. The cell nuclei were co-stained with Hoechst 33342 (100 ng mL^{-1}). After washing with DMEM containing 10% FBS, cells were incubated with HBSS, and the fluorescence images were captured with appropriate filter sets for each of the fluorophores.

Analysis of Fluorescence Images. Labeled cell images with CA, CCD, FA, and RA were acquired according to the above-mentioned procedure. 256 × 256 pixels area, where cells were confluently cultured, was selected at random from the acquired fluorescence images. The average fluorescence intensity of different colors per pixel was computed from the selected area using *MetaMorph* imaging software.

Multilabeling of Cells with BL-tag and SNAP-tag. Plasmids coding for BL-EGFR and COX8-2-SNAP were co-transfected into HEK293T cells. The cells were then incubated with FA, SNAP-Cell TMR Star, and Hoechst 33342 in a CO_2 incubator for 30 min (final concn of FA, 10 μM; SNAP-Cell TMR Star, 0.8 μM; Hoechst 33342, 100 ng mL^{-1}), and the fluorescence images were captured. The detailed procedure was the same as the procedure followed for the single protein labeling.

Western Blot Analysis of EGFR and BL-EGFR Expressed in HEK293T Cells after EGF Stimulation. HEK293T cells were transfected with BL-EGFR or pcDNA3.1(+)-EGFR using Lipofectamine 2000. After 5−6 h, the culture medium was replaced with DMEM, and the cells were incubated at 37 °C for 24 h. Prior to EGF addition, the cells were incubated overnight in the medium containing 0.5% serum. The cells were then washed once with PBS (−) and treated with EGF (100 ng mL^{-1}, Sigma, E9644) for 10 min at 25 °C. After one rinse with PBS (−), the cells were lysed with 200 μL of 1× SDS gel loading buffer (50 mM Tris−HCl buffer (pH 6.8), 1.3% SDS, 10% glycerol, and 5% mercaptoethanol). After scraping, the lysates were boiled at 95 °C for 3 min. Subsequently, samples were electrophoresed in a 7.5% or 10% SDS-polyacrylamide gel and transferred to PVDF membranes for Western blot. Membranes were blocked by 1 h incubation with TBST buffer (0.01% Tween 20, 138 mM NaCl, 20 mM Tris, pH 7.6) containing 5% skim milk (for anti-EGFR, anti-β-lactamase, and anti-β-actin antibodies) or 3% BSA (for anti-EGFR-pY1197 antibody) at room temperature. Then, anti-EGFR (1:500 dilution), anti-β-lactamase (1:5000 dilution), anti-EGFR-pY1197 (1:500 dilution), or anti-β-actin (1:5000 dilution) antibodies were added to each membrane. After incubation for 16 h at 4 °C with shaking, the membranes were washed three times with TBST buffer, incubated with horseradish peroxidase-linked secondary antibody, washed with TBST buffer, and visualized using ECL Western blotting detection reagents.

Immunofluorescence Detection of the Tyrosine Phosphorylation on BL-EGFR after EGF Stimulation. Transfected HEK293T cells were prepared and treated with EGF according to the above-mentioned procedure. After one rinse with PBS(−), the cells were fixed with 3.7% formaldehyde/PBS(−) at 25 °C for 20 min. After two rinses with PBS(−), the cells were blocked with blocking buffer (PBS containing 5% Goat Serum (Invitrogen) and 0.05% NaN_3) at 25 °C for 1 h. Anti-EGFR-pY1197 antibody, followed by fluorescein-conjugated goat antimouse antibody, was used to stain BL-EGFR or EGFR. After mounting, microscopic images were acquired using a filter set for fluorescein.

RESULTS AND DISCUSSION

Design and Synthesis of Fluorophores for the Labeling of BL-tag Fusion Proteins. Although it was previously shown that BL-tag fusion proteins can be specifically labeled with 7-hydroxycoumarin-conjugated β-lactam probes (Figure 1), the fluorescence was found to be dim and the excitation wavelength was short and hindered by the intrinsic autofluorescence of mammalian cells. The use of brighter and longer-excitation wavelength fluorophores is advantageous for various functional

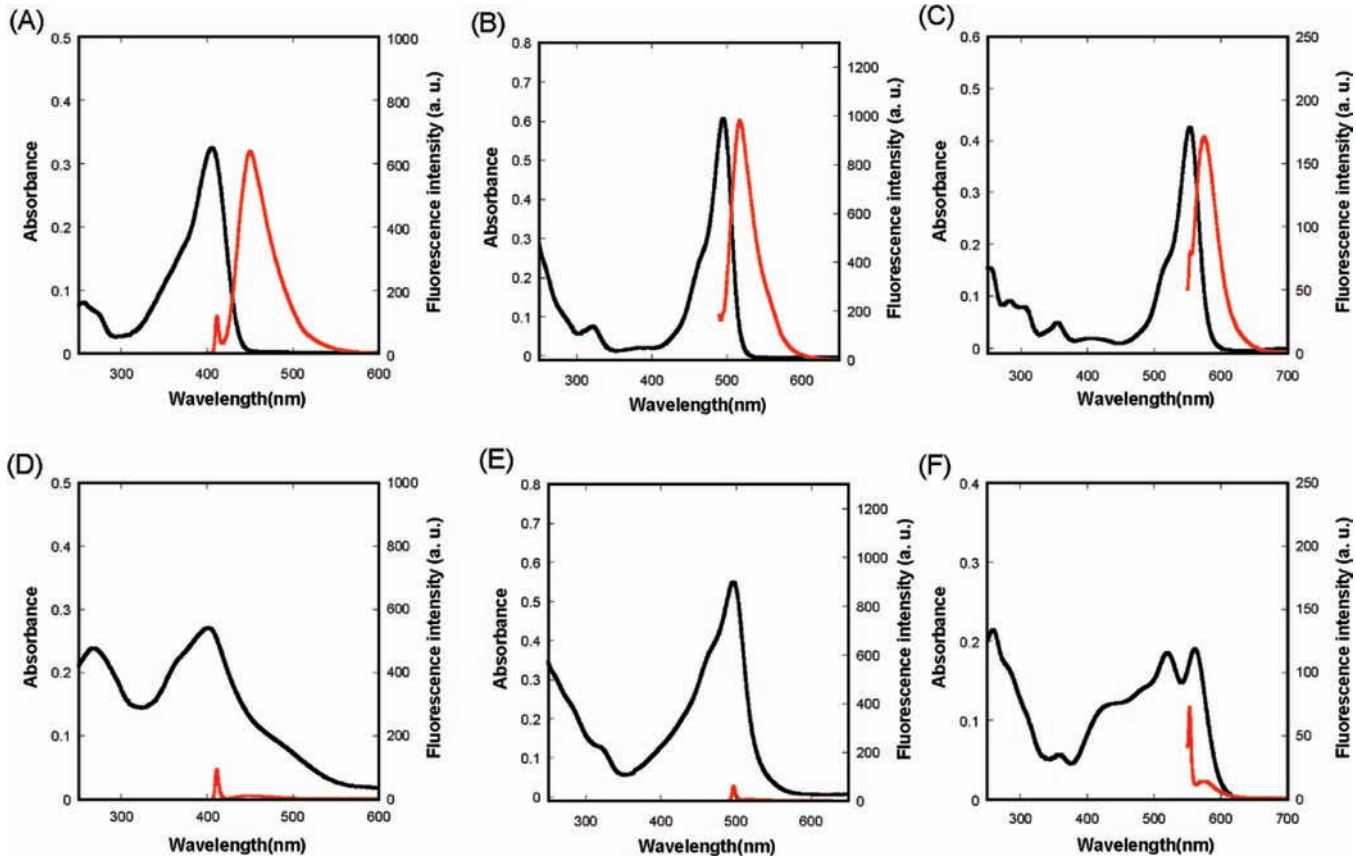

Figure 2. Absorption (black line) and emission spectra (red line) of (A) CA, (B) FA, (C) RA, (D) CCD, (E) FCD, and (F) RCD in 100 mM HEPES buffer (pH 7.4). In the absorption measurements, the probe concentrations were 5 μM for FA, FCD, RA, and RCD and 10 μM for CA and CCD. In the absorption measurements, the probe concentrations were 0.5 μM for FA, FCD, RA, and RCD and 1 μM for CA and CCD. Excitation wavelengths were 405 nm for CA and CCD, 492 nm for FA, 496 nm for FCD, and 553 nm for RA and RCD.

Table 1. Spectroscopic Properties and Calculated Values for FRET of Labeling Probes in 100 mM HEPES Buffer (pH 7.4)

compound	$\lambda_{abs,\ max}$/nm	$\lambda_{em,\ max}$/nm	fluorescence quantum efficiency (Φ)	Förester distance[a] (R_0)/Å	donor−acceptor distance[b] (R)/Å	energy transfer efficiency[c] (E)
CA	405	453	0.40	–	–	–
CCD	400	450	0.006	44.2	26.3	0.96
FA	492	517	0.71	–	–	–
FCD	496	520	0.005	43.4	27.8	0.93
RA	553	575	0.49	–	–	–
RCD	525, 565	573	0.07	19.6	27.7	0.12

[a] R_0 values were derived from the overlap integral between the absorption spectrum of DABCYL and the fluorescence spectrum of CA for CCD, FA for FCD, and RA for RCD. [b] R values were evaluated from the farthest distance between the fluorophore and DABCYL by using the molecular modeling software. [c] Energy transfer efficiencies were calculated from the equation $E = R_0^6/(R_0^6 + R^6)$.

studies using living cells. Therefore, β-lactam probes conjugated to fluorescein or tetramethylrhodamine (TAMRA) were designed and synthesized (Figure 1B). The fluorescence labeling probes FA and RA were synthesized in one step from ampicillin and activated esters of the corresponding fluorophores. FCD and RCD, which were designed to be fluorogenic as well as CCD, were also synthesized. RCD was synthesized from the activated ester of the 5(6)-TAMRA isomers and used for the experiments without separation of the 5(6)-isomers (see Figure S1 in Supporting Information).

Absorption and emission spectra of all β-lactam labeling probes are shown in Figure 2, and the spectroscopic properties are summarized in Table 1. FA and RA exhibited similar spectroscopic properties to fluorescein and TAMRA, respectively. From the Förster radii caluculated from their spectra and the simulated donor−acceptor distances, the FRET efficiency was estimated (Table 1). We predicted that FCD fluorescence would be quenched sufficiently from the FRET efficiency value. Indeed, FCD was largely quenched by intramolecular FRET from coumarin to DABCYL ($\Phi = 0.005$). In contrast, RCD fluorescence would theoretically not be quenched because of the limited overlap between the absorption spectrum of DABCYL and the emission spectrum of TAMRA. Nevertheless, RCD fluorescence was considerably quenched ($\Phi = 0.07$). This quenching of RCD fluorescence can be ascribed to the intramolecular association between TAMRA and DABCYL moieties. We previously reported that, if two hydrophobic dyes are located in close proximity, self-quenching occurs due to the close contact of the two dyes in aqueous solution (*29*). The fluorescence intensities of FCD and RCD were recovered by the addition of WT TEM-1 and BL-tag in a time-dependent manner (see Figure S2 in Supporting Information). These results indicate that elimination of the DABCYL moieties occurs by the enzymatic cleavage of the β-lactam in both cases. The labeling capabilities of all compounds with BL-tag were confirmed by SDS-PAGE (see Figure S3 in Supporting Information).

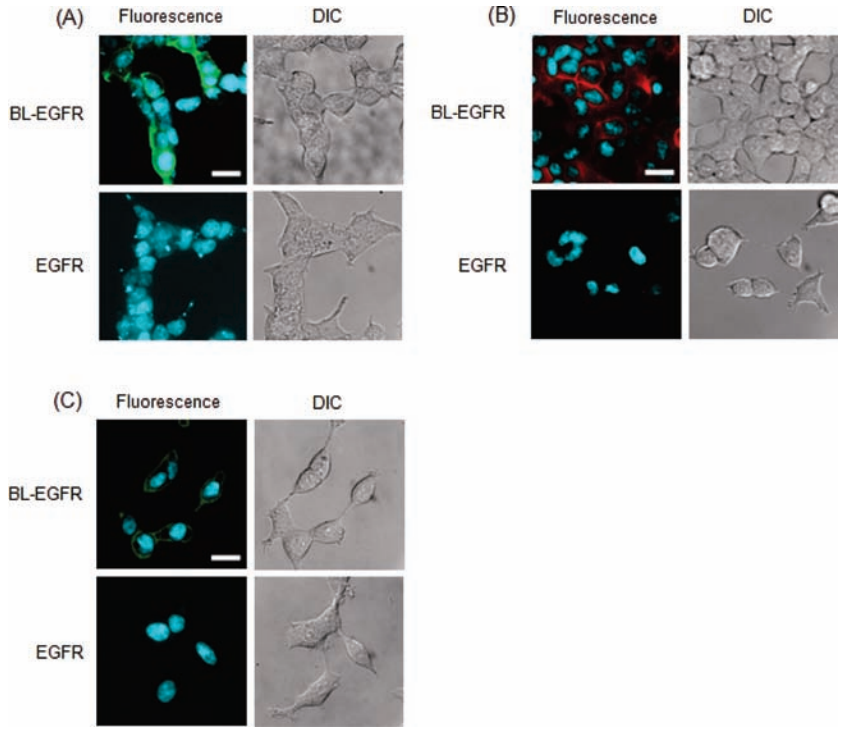

Figure 3. Labeling of BL-tag fusion proteins with (A) FA, (B) RA, and (C) FCD. HEK293T cells were transfected with a plasmid encoding BL-EGFR or EGFR. The cell nuclei were costained with Hoechst 33342. For fluorescence microscopic images, the cells were excited at 330−385 nm for Hoechst 33342, 460−490 nm for FA, and 510−550 nm for RA. Scale bar: 20 μm.

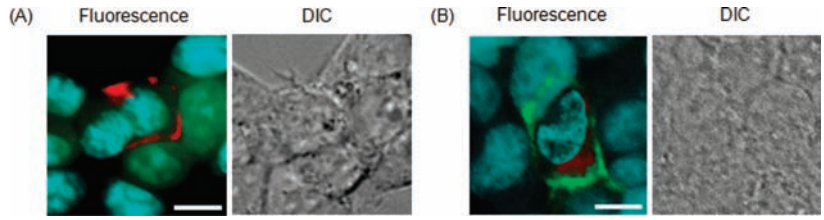

Figure 4. (A) Multicolor imaging of HEK293T cells expressing BL-EGFR. BL-EGFR, nuclei, and cytosol were labeled with RA (red), Hoechst 33342 (cyan), and CellTracker Green (green), respectively. (B) Multiprobe labeling of HEK293T cells expressing BL-EGFR and COX8-2-SNAP. BL-EGFR was labeled with FA, COX-8-2-SNAP with SNAP-Cell TMR-STAR, and nuclei with Hoechst 33342. Fluorescence microscopic images were excited at 330−385 nm, 460−490 nm, and 510−550 nm. Scale bar: 10 μm.

Fluorescence Labeling of BL-tag Fusion Proteins by the Synthesized Probes. BL-tag was fused to the N-terminus of epidermal growth factor receptor (EGFR), and the fusion protein BL-EGFR was expressed on cell surfaces of HEK293T cells by transfection with a plasmid encoding BL-EGFR. The cells were incubated with FA or RA, washed three times, and observed using a fluorescence microscope. The cells generating BL-EGFR clearly emitted green or red fluorescence at the plasma membrane (Figure 3A,B). We calculated the average fluorescence intensity per pixel from BL-EGFR expressing cells and negative control cells, and compared with each other (see Figure S4 in Supporting Information). As a result, the fluorescence signal from labeled cells by FA or RA was clearly enhanced compared with the background signal (about 1.8 times), while the fluorescence signal of cells labeled by CA or CCD was about 10% higher than the background signal. Therefore, the signal-to-background ratio was largely improved by FA and RA relative to CA and CCD. Subsequently, the labeling properties of FCD were investigated. The cells generating BL-EGFR were labeled by FCD in a labeling procedure similar to the procedure used for FA and RA (Figure 3C).

Multicolor Imaging by Simultaneous Labeling with BL-tag and SNAP-tag. We applied BL-tag technology to multicolor imaging of cells in order to demonstrate its wide versatility. After transfection of HEK293T cells with a plasmid encoding BL-EGFR, Hoechst 33342, CellTracker Green, and RA were incubated. Cells were then imaged using different fluorophores with appropriate filter sets. Each organelle was confirmed by multicolor fluorescence imaging (Figure 4A). In addition, BL-tag fusion proteins were found to be labeled with different color fluorophores (Figure 3). This property is beneficial for pulse-chase fluorescence imaging experiments used for tracing protein trafficking after various stimulations (*30, 31*).

Next, multicolor fluorescence labeling of two different target proteins was performed with another specific protein labeling system known as SNAP-tag technology. In this experiment, SNAP-tag was applied as a COX8-2-SNAP fusion plasmid encoding COX8-2 (subunit 8-2 protein of cytochrome c oxidase) cloned upstream of SNAP-tag. Cytochrome c oxidase is a terminal enzyme of the respiratory transport chain and localized at the inner mitochondrial membrane (*32*). The COX8-2-SNAP fusion proteins provide fluorescence in mitochondria when labeled with SNAP-Cell TMR-Star.

HEK293T cells were co-transfected with BL-EGFR and COX8-2-SNAP plasmids. The cells were incubated with FA, SNAP-Cell TMR-Star, and Hoechst 33342, and then washed three times with DMEM containing 10% FBS prior to imaging with a fluorescence microscope. Though the co-expression

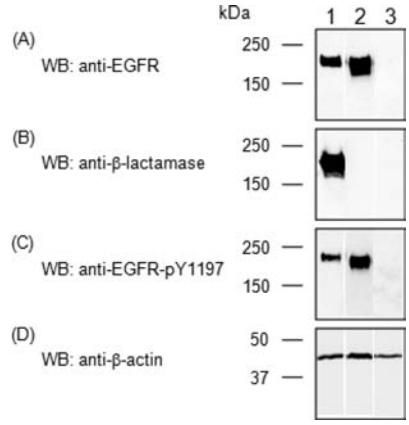

Figure 5. Western blot analysis of the EGFR and BL- EGFR expressed in transfected HEK293T cells after EGF stimulation. (A) Detection of EGFR with polyclonal anti-EGFR antibody. (B) Detection of TEM-1 with polyclonal anti-β-lactamase antibody. (C) Detection of phosphorylated tyrosine at 1197 position with monoclonal anti-EGFR-pY1197 antibody. (D) Detection of β-actin cytoskeleton with monoclonal anti-β-actin antibody. Lane 1: BL-EGFR-expressing cells. Lane 2: EGFR-expressing cells. Lane 3: Cells transfected with an empty plasmid vector.

efficiencies were not very good in this experiment, green fluorescence derived from FA was observed along the plasma membrane and red fluorescence from SNAP-Cell substrates in mitochondria was observed in the same cells (Figure 4B). This result distinctly indicates that BL-tag and SNAP-tag have nonoverlapping substrate specificity and can be used simultaneously in single cells.

Ligand-Induced Activation of the BL-tag Fusion Protein. Finally, we demonstrate the low interference of BL-tag with the function of the target protein EGFR. EGFR is a 170 kDa transmembrane glycoprotein that belongs to a tyrosine kinase receptor family comprising four members. The intracellular trafficking behavior and ligand-dependent dimerization of EGFR has attracted great attention (*33*). It was, however, reported that the expression and trafficking of EGFR was greatly disrupted as a result of extracellular GFP fusion and appropriate expression of the fusion protein was not detected by Western blot analysis with anti-GFP antibody (*34*) due to the fact that the fluorophore formation of GFP strongly depends upon the structural integrity of the protein (*3*). The identity of the BL-EGFR fusion protein was characterized by Western blot analysis with anti-β-lactamase, anti-EGFR, and anti-EGFR-pY1197 phosphorylation site-specific antibodies. Specific ligand binding on the extracellular domain of EGFR results in dimerization of the receptor and subsequent autophosphorylation of the tyrosine residues, the most predominant of which is pY1197 (*35*).

HEK293T cells were transfected with fusion proteins or EGFR plasmids, followed by incubation under serum-starved conditions. The cells were then stimulated with EGF and analyzed by Western blot. Naive (nontransfected) HEK293T cells express extremely low levels of endogenous EGFR as demonstrated in cells transfected with a control plasmid vector probed with an anti-EGFR antibody (lane 3 in Figure 5A) (*36*). When lysates of the cells transfected with EGFR plasmids were probed with an anti-EGFR antibody, one major band was visible with a molecular weight of about 170 kDa, corresponding to EGFR (lane 2 in Figure 5A). A single band was also detected from cells transfected with BL-EGFR. This band appeared in the slightly upper position of that of EGFR. This is consistent with the increase of the molecular weight as a result of fusion of BL-tag to EGFR (lane 1 in Figure 5A). On the other hand, when the membrane was probed with an anti-β-lactamase antibody, the immunoblotted band was observed only in the lane of the lysate containing BL-EGFR fusion protein (Figure 5B). These results suggest that the BL-EGFR fusion protein was properly expressed in HEK293T cells.

After stimulation by EGF, phosphorylation of Y1197 was confirmed using an anti-EGFR-pY1197 antibody. A single band shows that phosphorylation was observed in the lanes of cell lysates containing BL-EGFR or EGFR (lanes 1 and 2 in Figure 5C). In addition, we compared the distribution of BL-EGFR and EGFR after EGF stimulation by immunofluorescence staining with anti-EGFR-pY1197 antibody. Cells expressing BL-EGFR and EGFR gave the same distribution pattern of fluorescence responses that demonstrate phosphorylation in the cells (see Figure S5 in Supporting Information). From these results, it is evident that the phosphorylation function of EGFR can be preserved after introduction of the BL-tag to the extracellular domain of EGFR. All of the results discussed herein suggest that BL-tag has lower interference than GFP with respect to the function of EGFR.

In conclusion, we have designed and synthesized various labeling probes for BL-tag. These new probes have superior spectroscopic properties relative to the previously reported probes, CA and CCD. FA and RA can specifically label BL-tag in living cells, while FCD and RCD possess fluorogenic properties based on FRET or intramolecular stacking interaction which provides a useful switching mechanism for protein labeling probes, as we recently reported (*37*). The function of EGFR was found to be considerably preserved after the fusion of BL-tag to the extracellular domain. This low interference with the function of the target protein can provide a great advantage relative to fusion to GFP and should be suitable for studying the function or trafficking of POIs. Furthermore, BL-tag technology can be simultaneously used with other protein labeling methods such as SNAP-tag technology. Orthogonality of the substrate specificity between BL-tag and SNAP-tag was also shown.

In the future, a series of labeling probes with various fluorophores for BL-tag can be applied to a pulse-chase experiment that can distinguish between young and old copies of proteins by labeling at different time points with different fluorophores. Moreover, protein labeling techniques can be used not only for fluorescence imaging, but also for inducers of protein−protein interactions. Techniques based on multiple protein labeling methods are quite useful for studying and controlling protein−protein interactions (*38, 39*). Thus, we have provided a potential tool for practical biological applications. BL-tag technology can be exploited with conventional protein labeling methods for the specific labeling of two or more different proteins within a single cell. Furthermore, combinations of BL-tag technology with other imaging methods such as MRI or NIR are expected to contribute to the clarification of various protein−protein interactions.

ACKNOWLEDGMENT

This work was supported in part by the Grant-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology (MEXT) of Japan, by the Grant-in-Aid from the Ministry of Health, Labour and Welfare (MHLW) of Japan, and by the New Energy and Industrial Technology Development Organization (NEDO) of Japan. 1. Materials and Instruments

Materials. General chemicals for organic synthesis were of the highest grade available supplied by Tokyo Chemical Industries, Wako Pure Chemical, and Aldrich Chemical Co, and were used without further purification. 7-Amino-3-chloromethyl-3-cephem-4-carboxylic acid *p*-methoxybenzyl ester hydrochloride (ACLE·HCl) was obtained from Otsuka Chemical Co. Ltd. COX8-2-SNAP plasmid and SNAP-Cell^{TM} TMR-Star were purchased from New England Biolabs Inc. (E9100S). Anti-EGFR antibody was purchased from Abcam (ab2430), anti-β-lactamase antibody was purchased from Millipore (ab3738), anti-β-actin antibody was purchased from Sigma (A5441) and anti-EGFR-pY1197 antibody was purchased from DACO (M7299). Horseradish peroxidase-linked secondary antibody was purchased from GE Healthcare (anti-rabbit NA934, anti-mouse NA931). ECL Western Blotting Detection Reagents were purchased from GE Healthcare (RPN2109). Fluorescein-conjugated goat anti-mouse antibody was purchased from Bethyl Laboratories (A90-116F). 5 (6)-Carboxytetramethylrhodamine succinimidyl ester was purchased from Invitrogen (C1171). All probes were dissolved in DMSO (biochemical grade, Wako) before fluorescence measurements in order to facilitate solubilization in aqueous solvents. Silica gel column chromatography was performed using BW-300 (Fuji Silysia Chemical Ltd.).

Instruments. NMR spectra were recorded on a JEOL JNM-AL400 instrument at 400 MHz for ^{1}H and at 100.4 MHz for ^{13}C NMR, using tetramethylsilane as an internal standard. Mass spectra were measured on a JEOL JMS-700 mass spectrometer for FAB and on a Waters LCT-Premier XE mass

spectrometer for ESI. Fluorescence spectra were measured using a Hitachi F4500 spectrometer. UV-visible absorbance spectra were measured using a Shimadzu UV1650PC spectrometer. Fluorescence images of SDS-PAGE were visualized using an AE-6935B VISIRAYS-B (ATTO) for fluorescein derivatives, or BSPEBV001 EtBr viewer (Biospeed) for rhodamine derivatives.

2. Syntheses of Compounds

Syntheses of compounds 1–4

Syntheses of these compounds were reported in our previous paper (*S1*).

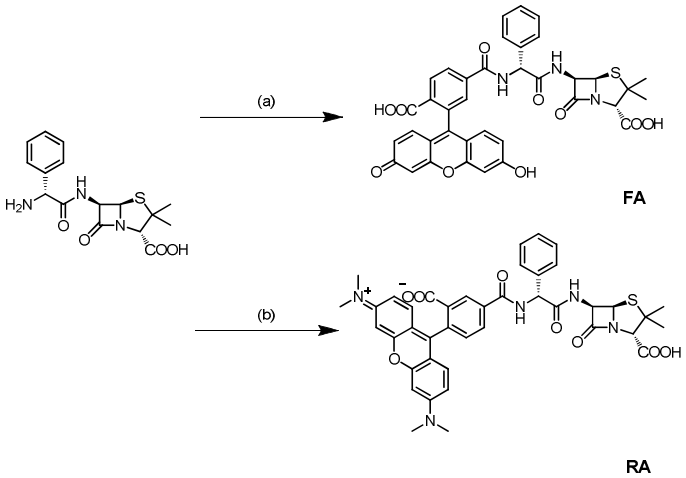
Synthesis of FA.

Ampicillin (44 mg, 127 μmol) was dissolved in DMF (500 μL), then TEA (13 mg, 127 μmol) and 6-carboxyfluorescein-succinimidyl ester (20 mg, 42 μmol) were added at 0 °C. The mixture was stirred for 12 h, and AcOEt was then added to the reaction mixture. The organic phase was washed with 10% citric acid aq. and water, and then dried with brine and sodium sulfate. After removal of the solvent, the residue was purified with reversed-phase HPLC and eluted with H_2O/acetonitrile containing 0.1% formic acid to yield FA (13 mg, y. 32%). ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.37 (s, 3H), 1.43 (s, 3H), 4.17 (s, 1H), 5.30 (d, 1H, J = 4.0 Hz), 5.50 (dd, 1H, J = 3.9 Hz, 7.3 Hz), 5.87 (d, 1H, J = 7.3 Hz), 6.54–6.68 (m, 4H), 6.90 (s, 2H), 7.27–7.43 (m, 5H), 7.84 (s, 1H), 8.07 (d, 1H), 8.23 (dd, 1H, J = 1.0, 7.6 Hz), 9.04 (d, 1H, J = 7.3 Hz), 9.22 (d, 1H, J = 7.6 Hz), 10.1 (brs, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 26.5, 30.4, 56.7, 58.3, 63.6, 67.2, 70.2, 83.5 102.2, 109.1, 109.2, 112.7, 122.8,

124.7, 127.6, 127.7, 128.2, 128.6, 129.2, 130.1, 137.1, 140.1, 151.8, 152.3, 159.6, 164.8, 168.0, 168.8, 169.8, 173.1; HRMS (FAB^+) *m*/*z*: 708.1649 (Calcd for $[M+H]^+$: 708.1652).

Synthesis of RA.

Ampicillin (30 mg, 85 μmol) was dissolved in DMF (500 μL). TEA (8.6 mg, 85 μmol) and 5 (6)-carboxytetramethylrhodamine-succinimidyl ester (15 mg, 28 μmol) were then added at 0 °C. The mixture was stirred for 12 h, and the solvent was lyophilized. The residue was purified with reversed-phase HPLC and eluted with H_2O/acetonitrile containing 0.1% formic acid to yield RA (6 mg, y. 28%). ^1H NMR (400 MHz, DMSO-d_6) δ 1.37 (s, 3H.), 1.43 (s, 3H), 2.95 (s, 12H), 4.22 (s, 1H), 5.44 (d, 1H, *J* = 4.0 Hz), 5.57 (dd, 1H, *J* = 3.9, 7.8 Hz), 5.95 (d, 1H, *J* = 8.3 Hz), 6.51 (m, 6H), 7.30–7.55 (m, 6H), 8.26 (d, 1H, *J* = 7.8 Hz), 8.57 (s, 1H), 9.12 (d, 1H, *J* = 7.8 Hz), 9.34 (d, 1H, *J* = 7.8 Hz); ^{13}C NMR (100 MHz, DMSO-d_6) δ 26.6, 30.4, 56.8, 58.3, 63.7, 67.3, 70.3, 84.7, 98.0, 105.6, 109.0, 124.1, 126.7, 127.7, 128.2, 128.4, 129.0, 135.0, 135.5, 137.4, 152.0, 152.2, 155.0, 163.1, 165.1, 168.3, 168.9, 169.9, 173.3; HRMS (FAB^+) *m*/*z*: 762.2595 (Calcd for $[M+H]^+$: 762.2598).



Synthesis of FCD.

Compound **4** (30 mg, 47 μmol) was dissolved in DMF (500 μL), then DIEA (30 mg, 230 μmol) and 6-carboxyfluorescein-succinimidyl ester (26 mg, 56 μmol) were added at -20 °C. The mixture was stirred for 16 h, and the solvent was evaporated followed by the addition of 100 mM ammonium formate aq. (15 mL). The precipitate was collected and washed thoroughly with 100 mM ammonium formate aq. and water to afford pure FCD (18 mg, y. 39%). ^1H NMR (400 MHz, DMSO-d_6) δ 3.07 (s,

A class of reactive DNA circuits was adapted as erasable molecular imaging probes that allow fluorescent reporting complexes to be assembled and disassembled on a biological specimen. Circuit reactions are sequence-dependent and therefore facilitate multiplexed (multicolor) detection. Yet, the ability to disassemble reporting complexes also allows fluorophores to be removed and new circuit complexes to be used to label additional markers. Thus, these probes present opportunities to increase the total number of molecular targets that can be visualized on a biological sample by allowing multiple rounds of fluorescence microscopy to be performed.

INTRODUCTION

In situ imaging of molecular markers has become increasingly important to advancements in the biological and biomedical sciences (*1*−*5*). These approaches offer advantages over bulk analyses, since they allow spatially dependent expression patterns of RNA and proteins to be delineated in cells and tissues. Several antibody and nucleic acid-based fluorescent probe technologies have been developed for marker imaging, and the sensitivity of these probes has been continually improved (*5*−*8*). Yet, many contemporary cytological studies now require increasingly comprehensive molecular pathway analyses to characterize the network-level properties of cells and resolve functional relationships between cell phenotypes and their tissue distribution (*9*−*11*). In such cases, the number of markers one seeks to examine can easily exceed the number of probes that can be used simultaneously for detection due to the spectral overlap of the reporting dye molecules. Thus, various biological studies stand to benefit from methods that allow a greater number of molecular markers to be visualized.

The number of markers that can be evaluated on an individual biological sample could be increased if it were possible to remove fluorescent probes from cells such that new markers could be labeled and detected using the same fluorescent reporting molecules. However, dye molecules are typically attached covalently to probes that are engineered specifically to bind their targets with high affinity. Probe removal therefore requires the use of harsh chemical and/or physical treatments that can disrupt cell and tissue morphology and compromise subsequent marker analyses.

To overcome these limitations, we adapted a new class of DNA circuit technologies as molecular imaging probes that allow fluorophores to be sequentially coupled to, and removed from, molecular markers using exceptionally mild processing conditions. Derived from "entropically driven" circuits developed by Zhang et al. (*12*), these probes operate using principles distinct from those of fluorescence in situ hybridization (FISH) probes and molecular beacons. Whereas these latter technologies rely on more classical, sequence-dependent hybridization reaction mechanisms for target recognition, the different complexes that make up the entropically driven circuits are designed to react with one another via a process called strand-displacement: the selective exchange of individual oligonucleotides between different complexes of DNA (*13*−*16*). These reactions proceed in a sequence-dependent fashion, and hence, multiple circuits can be employed simultaneously to label different targets. Yet, the total number of matched base pairs that are formed through these reactions does not necessarily have to increase for them to proceed efficiently (i.e., reactant and product complexes can be isoenergetic). As a result, strand displacement reactions can be used to assemble, isolate, and disassemble stable intermediate-state complexes of multistep reaction cycles. Herein, we show that such capabilities can be harnessed to create erasable molecular imaging probes that can function at ambient temperatures and in mild, nondenaturing buffers (e.g., Tris-based buffers). Thus, while the circuit-based probes facilitate multiplexed (simultaneous multicolor) detection, they should also allow the same-colored dye molecules to be used reiteratively to label different markers on an individual sample of fixed cells.

EXPERIMENTAL PROCEDURES

General Methods. Oligonucleotides were purchased from Integrated DNA Technologies (IDT). The recombinant target protein GFP-Z_E, was designed with C-terminal leucine zipper (Z_E) and 6× Histidine tag (6xHis) for purification using standard cloning procedures. Artificial proteins were labeled with catalyst DNA as described in ref *17*.

DNA Circuit Design and Characterization. The DNA circuit sequences were designed as previously described (*12*). Fluorophores and quenchers were incorporated into substrate complexes as shown in Supporting Information Table S1. Strands outfitted with fluorophores or quenchers were purchased HPLC-purified. DNA complexes were formed via a thermal annealing procedure: strands were mixed together at a 1:1 stoichiometry in TAE/Mg^{2+} buffer at a final concentration of 3 μM. The temperature of this solution was then raised to 95 °C and reduced to 25 °C over 90 min. DNA complex formation was verified by 12% nondenaturing PAGE gel analyses using SYBR-Gold staining (Invitrogen).

Microarray Procedures. The DNA microarrays were printed on Vantage silyated aldehyde slides (CEL Associates) using SMP3 pins (ArrayIt) and a custom fabricated microcontact

printer. Arrays were fabricated by spotting solutions of 3′-amine labeled C strands (10, 5, 1, 0.5, 0.1, and 0.05 μM stocks for gradient experiments and 2 μM stocks for all others) in PBS (pH 6.6) containing 30% glycerol. Afterward, the slides were incubated in a humidity chamber for 6 h. Free aldehyde groups on the slides were then quenched for 5 min in a sodium borohydride solution (3:1 PBS/EtOH 2.5% $NaBH_4$). Slides were blocked for 2 h in 4× SSPE buffer (600 mM NaCl, 40 mM NaH_2PO_4, and 5 mM EDTA) containing 0.1% BSA, washed 3 times with 4× SSPE buffer with 0.1% SDS, rinsed with milli-H_2O, and dried under nitrogen.

Microarray labeling/activation and dye removal/deactivation reactions were performed using a static incubation procedure or with a hybridization station (TrayMix2: ArrayIt) that provides active mixing of reagents over the slide. For static incubation, Gene frames (AbGene) were affixed over the arrays to create a reaction chamber containing 5 pmol substrate and OC1 consumption complex in TAE w/Mg^{2+}. The arrays were incubated overnight. The Gene frames were then removed and slides were washed 3 times in 4× SSPE buffer, rinsed again in milli-H_2O, and dried under a nitrogen stream. Deactivation and reiterative labeling experiments were performed similarly by affixing new Gene frames to the slides and repeating the incubation procedure. Microarray analysis was performed using *ImageJ* (http://rsbweb.nih.gov/ij/).

Cell Culture and Labeling. HeLa cells were cultured in an 8-chambered coverslips (Lab-Tek) for 24 h in DMEM supplemented with 10% FBS, 50 μg/mL penicillin, and 50 μg/mL of streptomycin. For GFP labeling experiments, the media was replaced and the cells were transfected with GFP-Z_E DNA using Fugene (Roche) transfection reagent under the manufacturer's protocol.

To label cells, coverslips were washed once with PBS and fixed with freshly prepared 4% paraformaldehyde (PFA) solution for 30 min. The cells were then washed twice for 2 min with PBS, permeabilized for 5 min with 0.2% Triton X-100, washed twice again with PBS, and stored overnight at 4 °C. Prior to circuit labeling experiments, the cells were washed again with PBS and then incubated for 2 h with a blocking solution (1% BSA, 1 mg/mL denatured Herring sperm DNA, and 0.5 μM polyT DNA in PBS). For GFP labeling experiments, the cells were also incubated with 400 nM of Z_R-ELS_6-Cat1 in PBS for 2 h. Excess polymer was then removed by washing twice with PBS prior to circuit-based labeling.

Circuit labeling reactions were carried out by incubating the cells for 1.5 h with 100 nM substrate complex and then washing twice with PBS for 2 min. Dye removal was performed similarly using 1 μM fuel. Before imaging experiments, slides were washed twice with PBS and then mounted on a glass slide using rubber cement.

Fluorescence Imaging and Analyses. All images were collected using a Zeiss Axioplan epifluorescence microscope and are contrasted identically in each figure. Correlations between GFP and Cy5-circuit signals and Cy5 signals produced during sequential labeling of cells (ON_1 and ON_2) were analyzed using a custom program written in *Matlab*.

RESULTS AND DISCUSSION

An illustration depicting our use of entropically driven circuits as imaging probes is shown in Scheme 1. Adopting the nomenclature of Zhang et al. (*12*), these circuits are composed of three main components: a single-stranded "catalyst" strand (C), a three-strand DNA complex called the "substrate" (S), and a "fuel" strand (F). In the circuit reaction cycle, the binding of C to a 6 nucleotide "toehold" domain at one end of S initiates a strand displacement reaction that releases an "output" strand (O1) and produces an intermediate-state complex (I_R) that possesses a new, internal 4 bp toehold domain. The binding of F to this toehold then initiates a second strand displacement reaction that releases C from the I_R complex and produces a "waste" product (W). To convert these complexes into imaging probes, catalyst strands can be appended to targeting agents that bind to specific molecular markers. The circuit substrates are modified by incorporating fluorescent dye (Cy3 or Cy5) and quencher (Iowa Black) molecules that are positioned such that the reaction of S with C results in an I_R complex that contains an unquenched fluorophore. The dye-bearing strand within I_R can then be removed from the marker and rendered inactive in the waste product by incubation with a modified F strand that carries a second quencher molecule. Overall, the use of quenched substrates and waste products should reduce background fluorescence resulting from potential nonspecific binding of either complex to a sample. Finally, we note that, in contrast to prior work where C truly functioned as a catalyst (*12*), marker labeling and removal in the present application is achieved by performing partial circuit reactions while using C for targeting. We therefore use the term catalyst only for continuity with previous reports.

To evaluate the efficiency of the circuit-based labeling and dye removal reactions, we first examined distributions of product complexes that were formed upon incubations of S and C, as well as S, C, and F via native PAGE-gel analyses (Figure 1a). After a partial circuit reaction of S with C, the catalyst strand is bound to the I_R complex through a total of 22 matched base pairs. This complex is therefore stable at room temperature and can be isolated on a gel. Yet, the free energy difference between S and I_R is small (ΔG ~0.4 kcal/mol). As a result, the reaction of S and C, when performed using equimolar concentrations, results in an equilibrium distribution of circuit components possessing near-equivalent concentrations of S, I_R, and free,

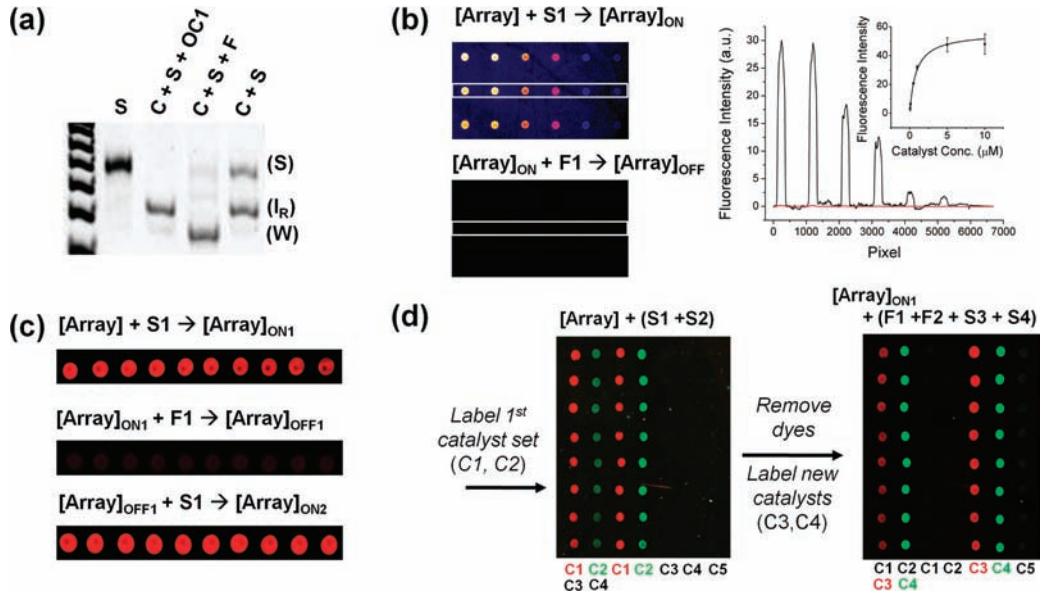

Figure 1. Multiplexed and reiterative fluorescence labeling of ssDNA catalyst. (a) Native PAGE-gel displaying DNA circuit reaction products: all components were reacted at a concentration of 200 nM. (b) A catalyst microarray possessing a gradient of spot concentrations (using 10, 5, 1, 0.5, 0.1, and 0.05 μM stock solutions) that was first labeled and then erased via the sequential addition of S (top image) and a fuel strand (bottom image). Images are rendered as heat maps. Plots of the averaged intensity profile of the boxed regions for the labeling (black line) and dye removal (red line) reactions are shown. Average spot intensities can be approximated by the Langmuir equation (inset). (c and d) Reiterative labeling of an individual (c) and multiple (d) arrayed catalysts. The reactions performed on the arrays are indicated above each image.

"unlabeled" catalyst (Figure 1a, lane 5). While this result is not optimal for marker labeling, this reaction can be driven forward by adding a second complex (OC1) that consumes (O1) once it is liberated from S (boxed reaction in Scheme 1). As demonstrated in other strand displacement systems (*18*), the sequestration of O1 shifts the equilibrium distribution of the reaction significantly toward the I_R state (Figure 1a, lane 3). Alternatively, this distribution can also be shifted using an excess of S relative to C, which should often be the case when labeling catalysts (markers) that are immobilized on a specimen. Nevertheless, the ability to drive strand displacement reactions forward through output sequestration will likely be useful for optimizing dye-labeling kinetics or when local target concentrations within a sample are high.

The removal of dyes from a sample via the reaction of I_R and F constitutes an equally important step in our marker imaging procedure. Here, the use of three-strand S and I_R complexes, as opposed to somewhat simpler two-strand complexes, allows dye-bearing strands to be displaced from the reporting I_R complex without output sequestration (Figure 1a, lane 4), since two strands (C and O2) must react simultaneously with final circuit product W for the reverse reaction W + O2 + C → I_R + F to occur. Hence, the dye removal reaction is effectively irreversible.

We next performed a series of DNA microarray experiments that were designed to evaluate the use of DNA circuit complexes as molecular imaging probes (Figure 1). In these experiments, amine-modified C strands are arrayed on the surfaces of glass slides, and the reaction of S with C produces a fluorescent I_R complex that is anchored to the slide surface and can be detected using a fluorescence microarray scanner. Analyses of arrays where a catalyst was printed at variable spot concentrations confirm that the I_R complex of the circuit can function as a reliable reporter of the levels of immobilized catalyst (Figure 1b, top). Here, spot intensity profiles can be approximated by the Langmuir adsorption equation, as is commonly found with DNA microarrays (*19*, *20*). Furthermore, after the same slide is incubated with a fuel strand, each spot disappears and cannot be detected over background autofluorescence signals of the slide (Figure 1b, bottom).

Our microarray experiments also allowed us to demonstrate the use of DNA circuit probes for both multiplexed and reiterative marker labeling. We found that immobilized C strands can be labeled with dyes multiple times via sequential reactions of arrays with S, F, and then a second solution of S complexes (Figure 1c). Each labeling reaction produced arrays possessing near identical spot intensities. We also demonstrated that multiple C targets could be labeled and/or erased simultaneously using multiple S and F complexes in a single reaction step (Figure 1d). In these experiments, five different C strands were printed both as mixtures of two strands and individually on the surface of the slide. The array was then reacted with two different substrate complexes (S1-Cy5 and S2-Cy3), yielding a spot pattern that corresponded directly to the positions of the printed catalysts (C1 and C2). Subsequently, in a single incubation step, this pattern was erased with F1 and F2, and a new spot pattern was generated through a reaction with a second set of substrates (S3-Cy5 and S4-Cy3); spotted lanes where C3 and C4 were printed appear in the scanned image. Throughout this procedure, the fifth printed catalyst strand of the array (C5) remains unlabeled in both scanned images. Thus, these experiments confirm that DNA circuitry can be used for multiplexed and reiterative imaging: two fluorescent dye molecules and two spectral channels of an imaging system are used to detect four distinct markers on the same sample. Importantly, all labeling and removal reactions in these assays were performed using mild processing conditions (room temperature and Tris buffer supplemented with 12.5 mM Mg^{2+}).

We next performed a series of imaging experiments that show DNA circuit complexes can be used to selectively label molecular markers on fixed and permeablized HeLa cells. Background circuit reactivity was first tested by incubating cell samples with a quenched S complex (100 nM) for 1.5 h. The resulting images show no discernible fluorescence signals and possess signal to background ratios of 1 (Figure 2a), implying that the substrate complexes have exceptionally low background reactivity with cells. We attribute this property to the high stability of the duplexed substrate complex, the enhanced sequence specificity of strand exchange over a classical hybridization mechanism (*21*), and the ability to place dye and

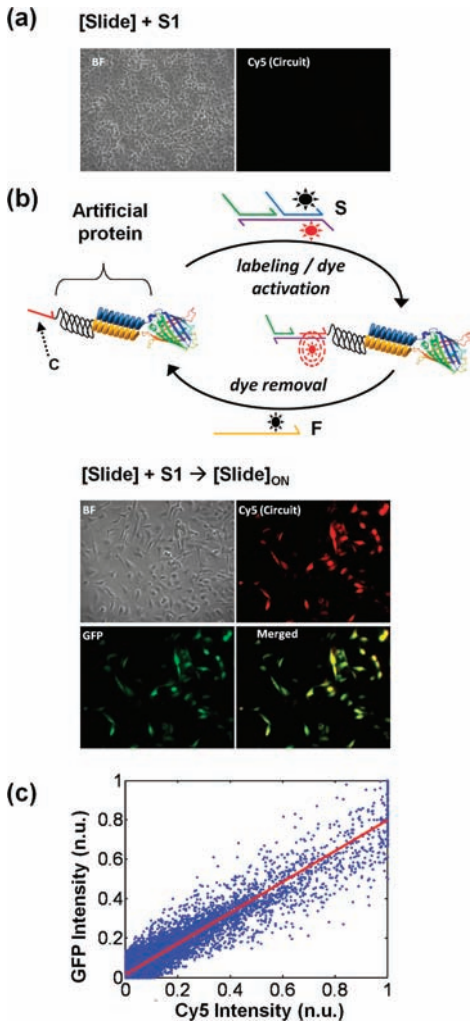

Figure 2. Selective targeting of an exogenously expressed GFP protein marker. (a) Bright field (BF) and fluorescence images of paraformaldehyde-fixed and permeablized HeLa cells reacted with a substrate complex that incorporates a Cy5 and a quencher (Iowa Black). (b) Circuit-based labeling of GFP-Z_E transfected HeLa cells. The catalyst is attached to the GFP marker via a DNA-conjugated artificial protein (Z_R-ELS_6-ssCat) that is introduced postfixation. (c) Intensity correlation analyses of GFP-Z_E and DNA circuit (Cy5) signals. The correlation coefficient, *r*, for the fitted line is 0.95.

quencher molecules in close proximity to one another within the substrate complex.

To label markers on cells, we chose to target the DNA circuit complexes to a transfected and expressed green fluorescent protein construct (GFP-Z_E) so that circuit labeling and dye removal efficiencies could be benchmarked directly against an internal standard (Figure 2b). The catalyst strand was coupled to the GFP using DNA-conjugated artificial-protein-based polymers (Z_R-ELS_6-ssCat) that we have previously developed for protein−DNA labeling (*17*). These polymers associate with the GFP-Z_E via a heterodimeric leucine zipper complex (Z_E/Z_R: $K_D \sim 10^{-15}$ M). Thus, after incubating GFP-Z_E transfected HeLa cells with Z_R-ELS_6-ssCat and then washing the samples to remove unbound polymer, GFP-Z_E transfected cells can be labeled by a reaction of a circuit substrate complex that carries a Cy5 dye and a quencher. As seen in Figure 2b, cells that were successfully transfected with GFP-Z_E reacted with S to produce fluorescent signals in the Cy5 channel of the microscope. While cells that were not transfected did not exhibit fluorescence, clear linear correlations are observed between GFP-Z_E and circuit labeling intensities, yielding a correlation coefficient $r = 0.95$.

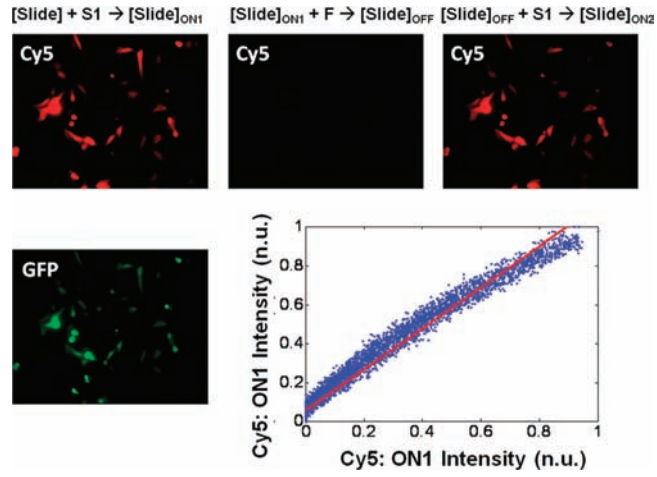

Figure 3. Reiterative circuit labeling of GFP-Z_E transfected cells. Sequential images of GFP-Z_E transfected cells where circuit complexes were used to label (ON1), erase (OFF), and relabel (ON2) the same sample of HeLa cells are shown. The pixel intensities in both Cy5 images (Cy5/ON1 and Cy5/ON2) are linearly correlated; fitted slope = 1.1, $r = 0.92$.

We also tested whether molecular markers could be labeled multiple times on a single sample of cells without loss of fluorescence signal intensities (Figure 3). After a first round of circuit labeling and imaging, fuel strands were added to remove Cy5 dyes from a sample of GFP-Z_E transfected cells. As in our microarray experiments, dye removal reactions are found to be efficient and yield signal to background ratios of 1. In addition, the transfected cells could be labeled and imaged a second time by incubating the sample with a fresh solution of substrate. Bright field imaging showed that a small portion of the cells detached from the slide surface during our manual washing and coverslip mounting procedures. Nevertheless, GFP and Cy5 signals remain highly correlated on a pixel-by-pixel basis after both rounds of fluorescence labeling ($r > 0.95$). Furthermore, strong correlations were found between cell images collected after the first and second dye labeling reactions are performed (i.e., between the ON1 and ON2 images in Figure 3 bottom). The Cy5 intensities of both images are linearly correlated and can be approximated by a line possessing a slope of 1.1. We therefore conclude that the Cy5 dyes can be coupled to the GFP-Z_E markers with near-identical efficiencies through sequential rounds of circuit-based labeling.

CONCLUSION

In summary, we have demonstrated that DNA circuit complexes can be used as erasable molecular imaging probes. Here, the sequence-dependent specificity of the DNA circuit reactions facilitates multiplexed marker detection. The use of strand displacement mechanisms also allows fluorescence reporting complexes to be disassembled, and hence, new reporting complexes can be created and used to image additional sets of molecular markers. Importantly, these reactions can be carried out at ambient temperature and in mild buffering conditions to minimize potential perturbations to a biological specimen. While such capabilities should offer opportunities to increase the number of molecular markers that one can examine on a single biological sample via fluorescence microscopy by at least a factor of 2 or 3, the next challenge will also be to develop diverse sets of molecular targeting agents (e.g., monovalent DNA-conjugated antibodies) that can facilitate efficient molecular marker recognition and react with the DNA circuitry reliably. Efforts to optimize syntheses of such agents are currently underway.

Time-Dependent Enzyme Activity Dominated by Dissociation of J-Aggregates Bound to Protein Surface

Kenji Watanabe and Koji Kano*

Department of Molecular Chemistry and Biochemistry, Doshisha University, Kyotanabe, Kyoto, 610-0321, Japan. Received August 3, 2010; Revised Manuscript Received October 18, 2010

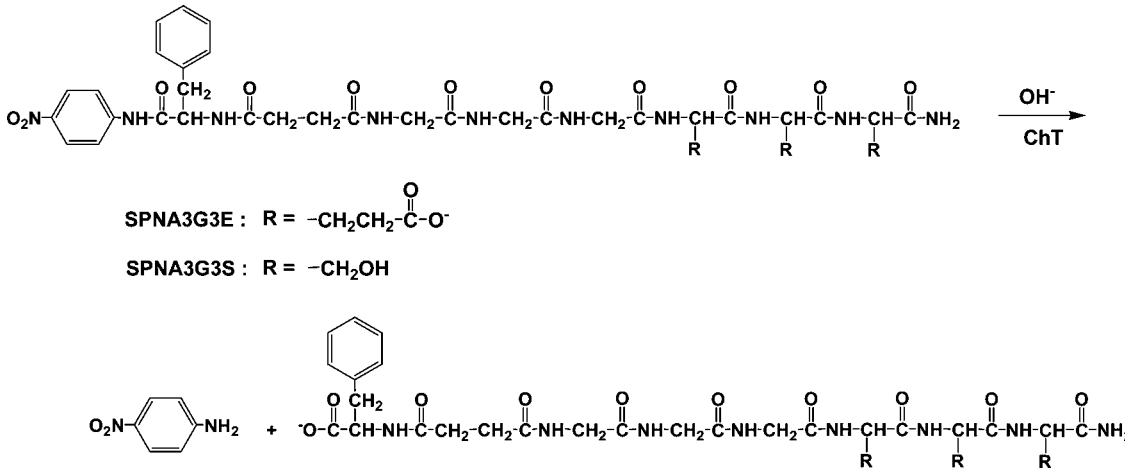
J-Aggregates of diprotonated 5,10,15,20-tetrakis(4-sulfonatopheny)porphyrin (H_4TPPS^{2-}) were stabilized even in a neutral aqueous solution (pH 7.0) containing per-*O*-methylated β-cyclodextrin by binding to the surface of α-chymotrypsin (ChT). The large J-aggregates covered the active site of ChT and completely inhibited the hydrolysis of the peptides. However, enzyme activity was gradually restored with the dissociation of the J-aggregates attached to the protein surface to monomers. After the completion of dissociation of the aggregates, the enzyme activity was almost completely restored, though the structure of ChT significantly changed. Circular dichroism spectroscopy suggested that the microscopic structure at the active site of ChT was scarcely affected by the J-aggregates, but the binding of J-aggregates to ChT increased the content of the random coils in the enzyme. The present study showed a new type of effector for controlling the function of ChT.

INTRODUCTION

Modulation of protein functions by artificial means is an important challenge in the fields of biochemistry, chemical biology, medicinal chemistry, and medical chemistry. Pseudosubstrates that selectively bind to the enzyme active sites have been used as strong inhibitors and can be used to suppress the propagation of viruses (*1*−*3*). Artificial receptors that recognize protein surfaces might also be useful for the inhibition of protein−protein and/or protein−substrate interactions. Hamilton et al. designed and prepared several artificial receptors based on calixarene, porphyrin, and G-quartet scaffolds, which recognize the surfaces of proteins such as α-chymotrypsin (ChT) and cytochrome c (cyt c) (*4*−*14*). Rotello et al. used functionalized gold nanoparticles to regulate the function of ChT (*15*−*25*). These artificial receptors of proteins have larger molecular size than that of pseudosubstrates and, therefore, cover a wider area on the protein surface. Most of these protein receptors are anionic and can nonspecifically recognize the surfaces of basic proteins such as ChT and cyt c. An artificial protein receptor primarily binds to the surface of the protein. If the receptor covers the active site of the protein, it inhibits the activity of the protein. If the receptor causes alteration in protein structure, such receptors act as the denaturant. In the former case, detachment of the receptor from the protein surface restores the protein function. Kano et al. used 5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrinato iron(III) ($Fe^{III}TPPS^{3-}$) as a receptor of ChT that resulted in inhibition of the hydrolysis of an amide substrate (*26*). They found that the ChT function is recovered by detaching $Fe^{III}TPPS^{3-}$ from ChT using heptakis(2,3,6-(tri-*O*-methyl)-β-cyclodextrin (TMe-β-CD), which forms a very stable inclusion complex with the porphyrin. In the latter case, refolding of the denatured protein is so difficult that, in most cases, the function of the protein is permanently lost.

In the present study, we have introduced a concept of spontaneous restoration of enzyme activity, whose function is initially inhibited by a protein receptor. Recently, we found that J-aggregates of diprotonated H_2TPPS^{4-} (H_4TPPS^{2-}) are stabilized by ferric myoglobin (metMb) in aqueous solution at pH 7.0 and 25 °C (*27*). The average half-life of the J-aggregates bound to metMb is approximately 3 h. The J-aggregates gradually dissociate to monomers and the native metMb structure was restored. The results of our previous study prompted us to investigate the time-dependent recovery of ChT activity that is initially inhibited due to covering of the ChT active site by H_4TPPS^{2-} J-aggregates. There have been very few studies on time-dependent changes in enzyme activity. Hamilton's group reported time-dependent inhibition of ChT activity by 4 peptide loops attached to the upper rimes of calix[4]arene and G-quartet scaffolds (*4*−*6*). Similar time-dependent inhibition of ChT activity by functionalized gold nanoparticles has also been reported (*15*). These phenomena were attributed to the slow binding of receptors to ChT. Meanwhile, we explained the similar inhibition by $Fe^{III}TPPS^{3-}$ as time-dependent irreversible denaturation of ChT (*26*). At any rate, the enzyme activity lowered by the protein receptors is hardly restored. In the present study, we examined the self-restoration of ChT activity that is initially inhibited by the J-aggregates of H_4TPPS^{2-}.

EXPERIMENTAL PROCEDURES



Materials. $H_2TPPS \cdot nH_2O$ (acidic form, >98%, Tokyo Chem. Ind. Co.) was purchased and used without further purification. The concentration of H_2TPPS^{4-} was determined by measuring the absorbance at 414 nm in aqueous NaOH (6 mM) solution using the molar extinction coefficient of $\varepsilon_{414} = 5.33 \times 10^5\ M^{-1}\ cm^{-1}$ (*28*). ChT from bovine pancreas (Sigma-Aldrich Japan) was used as received. The concentration of ChT was determined by measuring the absorbance at 280 nm using the molar extinction coefficient of $\varepsilon_{280} = 5.06 \times 10^4\ M^{-1}cm^{-1}$ (*29*). The building blocks of the substrates, Fmoc-Gly-OH, Fmoc-Glu(^{t}Bu)-OH, and Fmoc-Ser(^{t}Bu)-OH, were purchased from Peptide Institute Inc. (Osaka, Japan). *N*-Succinyl-L-phenylalanine *p*-nitroanilide (SPNA) was obtained from Sigma-Aldrich Jap. Other reagents and solvents were commercially available and used without further purification. Water was purified using a Millipore Simpack 1 (Nihon Millipore, Tokyo, Japan).

Instruments. Absorption and fluorescence spectra were recorded on a Shimadzu UV-2100 spectrophotometer and a Shimadzu RF-5300PC spectrofluorometer, respectively. Circular

dichroism (CD) spectra were measured using a Jasco J820 spectropolarimeter. MALDI-TOF MS measurements were performed by using an Shimadzu AXIMA-CFRplus system. A Horiba F-52 pH meter was used to adjust the pH values of the solutions.

Synthesis. SPNA3G3E (p-NA-Phe-Suc-Gly-Gly-Gly-Glu-Glu-Glu-$CONH_2$): The SPNA3G3E peptide (Scheme 1) was prepared by Fmoc solid-phase peptide synthesis on the TGS-RAM resin (Shimadzu, Kyoto, Japan). Fmoc deprotection was achieved by treatment with 30% (v/v) piperidine in DMF. Each coupling reaction involved the reaction of the NH_2 group on the resin with a carboxy group of Fmoc-amino acid (10 equiv) in DMF containing HBTU (1.2 equiv), HOBt (1.2 equiv), and DIEA (2.4 equiv). The N-terminus of the peptide was conjugated with SPNA (4 equiv) using the coupling agents HBTU (4 equiv), HOBt (4 equiv), and DIEA (4 equiv) in DMF. After the reaction, the peptide was cut off from the resin using a mixture of trifluoroacetic acid/1,2-ethandiol/thioanisole/triisopropylsilane/water (86:5:5:1.5:2.5, v/v) and precipitated with diethyl ether. The crude peptide was purified using an ÄKTApurifier FPLC system (GE Healthcare Jpn. Co., Tokyo, Japan) equipped with a Wakosil-II 5C18 AR reverse phase column (Wako Pure Chem. Ind., Osaka, Japan). The purity of the peptide was confirmed by the FPLC analysis (Supporting Information, Figure S1). Yield 21 mg (76%). MS (MALDI-TOF, α-cyano-4-hydroxycinnamic acid) *m/z*: calcd for $[M - H]^-$ 940.8; found 941.3.

SPNA3G3S (p-NA-Phe-Suc-Gly-Gly-Gly-Ser-Ser-Ser-$CONH_2$): The SPNA3G3S peptide (Scheme 1) was synthesized according to the procedure similar to that followed for SPNA3G3E synthesis. The purity of the peptide was confirmed by FPLC analysis (Supporting Information, Figure S2). Yield 19 mg (79%). MS (MALDI-TOF, α-cyano-4-hydroxycinnamic acid) *m/z*: Calcd for $[M + Na]^+$ 839.3; found 838.6. Calcd for $[M + K]^+$ 855.3; found 855.6.

Sample Preparation. A stock solution of the J-aggregates of H_4TPPS^{2-} (2.0×10^{-3} M as the monomer) was prepared by dissolving $H_2TPPS \cdot nH_2O$ (acidic form) into phosphate buffer (pH 7.0, 5.0×10^{-3} M) and the solution was allowed to stand for a night in dark. Because the buffering effect of the system was not enough, the pH value of the resulting solution decreased to 2.8 due to dissociation of the acidic SO_3H groups of the porphyrin. The main species in this solution were the J-aggregates of H_4TPPS^{2-} (>80%) as confirmed by the UV−visible absorption spectrum (Supporting Information, Figure S3).

RESULTS AND DISCUSSION

Stabilization of J-Aggregates by ChT. Since the pH of the stock solution of H_4TPPS^{2-} ($pK_a = 4.8$) (*30*) was 2.8, the J-aggregates were formed through electrostatic interactions between the SO_3^- groups in the periphery and diprotonated tetrapyrroles of H_4TPPS^{2-} (*31*−*35*). The aggregation numbers of the J-aggregates have been estimated to be tens to hundreds thousands by resonance light scattering (RLS) (*36, 37*). When a stock solution of H_4TPPS^{2-} (2.0×10^{-3} M of H_2TPPS^{4-} monomer) was injected into a neutral phosphate buffer solution (pH 7.0, 1.0×10^{-2} M) to achieve the apparent porphyrin concentration of 1×10^{-6} M, the J-aggregates of H_4TPPS^{2-} immediately dissociated to H_2TPPS^{4-} monomers. In the presence of ChT (1.0×10^{-6} M), however, the dissociation of the J-aggregates was strongly slowed down even in a neutral aqueous solution. Figure 1 (in black) shows the UV−visible spectrum of the resulting solution measured immediately after sample preparation. The characteristic narrow and strong absorption bands at 491 and 706 nm were ascribed to the J-aggregates of H_4TPPS^{2-}, and the coexisting band at 413 nm was due to the monomer of H_2TPPS^{4-} (*31*−*35*). These results indicate that ChT stabilizes the J-aggregates of H_4TPPS^{2-} in neutral aqueous solution. Similar stabilization of the J-aggregates was observed in the H_4TPPS^{2-}/metMb system (*27*). An image of the H_4TPPS^{2-}J-aggregate/ChT complex is shown in Figure

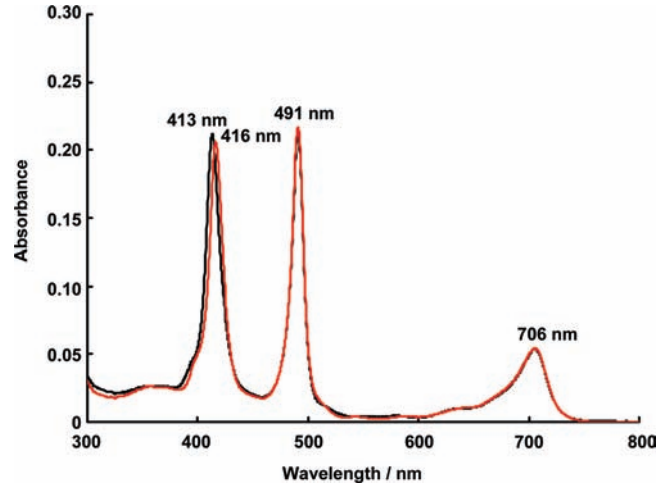

Figure 1. UV−visible spectrum of a sample (sample A) prepared by injecting a stock solution of the J-aggregates of H_4TPPS^{2-} (2.0×10^{-3} M as monomer) into 4 mL of phosphate buffer (pH 7.0, 1.0×10^{-2} M) containing ChT (1.0×10^{-6} M) at 25 °C (black solid line) and the spectrum of a sample (spectrum B) prepared by subsequent addition of TMe-β-CD (8.0×10^{-6} M) to sample A (red solid line).

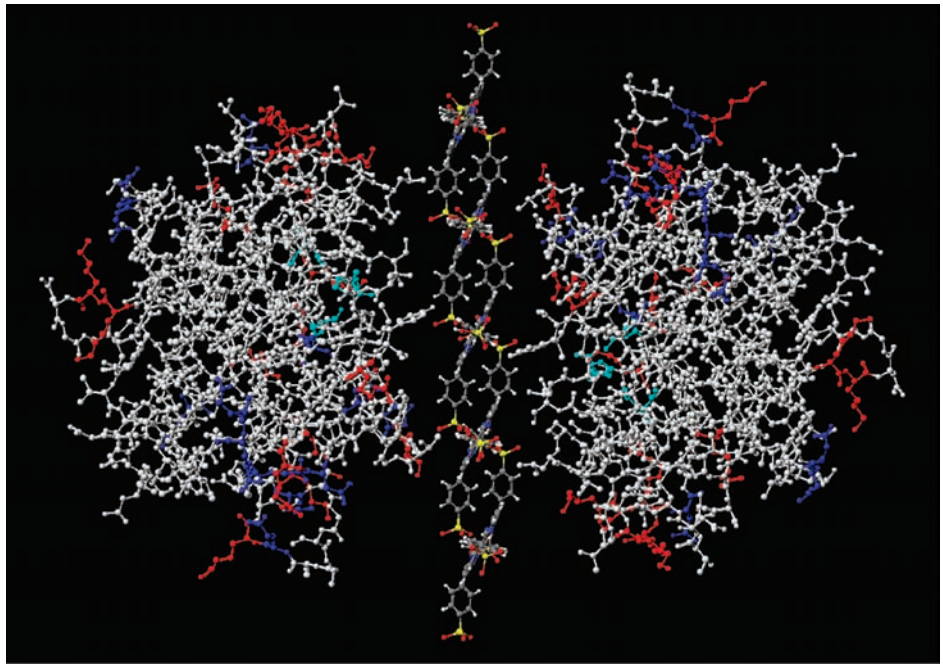

Figure 2. Image of the complex of J-aggregate of H_4TPPS^{2-} with ChT (PDB code 4CHA) drawn by using BioMed CAChe V6. The cationic and anionic amino acid residues of ChT are shown in the red and blue colors, respectively. The light blue color represents the active site of ChT.

2. The J-aggregates stabilized by ChT gradually dissociated to monomers with a $t_{1/2}$ of 27.2 ± 5.5 min (Supporting Information, Figure S4).

We previously found that the $Fe^{III}TPPS^{3-}$ monomer strongly binds with ChT ($K = (4.8 \pm 0.3) \times 10^5\ M^{-1}$) and inhibits its activity (*26*). The H_2TPPS^{4-} monomer also formed a fairly stable complex with ChT ($K = (1.8 \pm 0.4) \times 10^5\ M^{-1}$) (Supporting Information, Figure S5). To prevent the interaction between the H_2TPPS^{4-} monomer and ChT, we externally added TMe-*β*-CD, which forms an extremely stable 2:1 inclusion complex with H_2TPPS^{4-} (*38*), to the system. In the presence of TMe-*β*-CD (8.0×10^{-6} M), the absorption maximum of the monomer band ($\lambda_{max} = 413$ nm) shifted to 416 nm due to the formation of the 2:1 TMe-*β*-CD and H_2TPPS^{4-} complex (Figure 1, in red), but the absorption band of the J-aggregates was not affected at all. The dissociation of the J-aggregates in the presence of TMe-*β*-CD was analyzed by UV−visible spectroscopy (Figure 3). The $t_{1/2}$ in the presence of TMe-*β*-CD was 26.1 ± 2.9 min, which was similar to that in the absence of TMe-*β*-CD, indicating that the dissociation of the J-aggregates was not accelerated by TMe-*β*-CD. Pasternack et al. extensively studied the formation of self-aggregates (not J-aggregates) of a cationic porphyrin (5,10-diphenyl-15,20-bis(*N*-methylpyridinium)porphyrin) (t-$H_2P_{agg}^{2+}$) on a polyanionic DNA double strand (*39*−*41*). They reported that the cationic porphyrin molecules are detached from the DNA after the addition of *β*-cyclodextrin (*41*). The inconsistency in the effects of cyclodextrins between the J-aggregates on ChT and the self-aggregates on DNA might be due to the difference in the regularity of the arrangements of these aggregates. In the case of the J-aggregates, the H_4TPPS^{2-} molecules are highly ordered so that the insertion of a cyclodextrin molecule into the aggregate is difficult. However, the t-$H_2P_{agg}^{2+}$ molecules on DNA are arranged in a relatively disordered manner, and therefore, a cyclodextrin molecule can include the phenyl group of the porphyrin (*41*).

Effect of J-Aggregates on Enzyme Activity. ChT is a proteolytic enzyme that catalyzes the hydrolysis of an amide linkage at the C-terminus of a protein. Because ChT recognizes the aromatic moieties of amino acid residues such as Phe, Tyr, and Trp, we introduced a Phe residue into the substrates

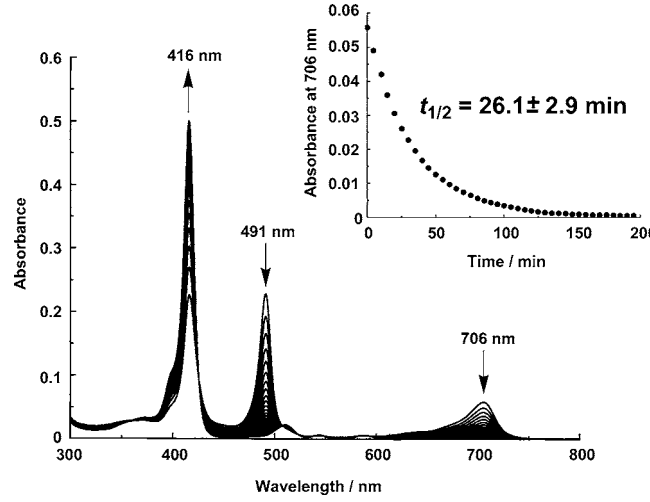

Figure 3. Decomposition of the J-aggregates of H_4TPPS^{2-} bound to ChT into the TPPS/TMe-*β*-CD inclusion complex. The spectra were collected with 5 min intervals. Inset: Progressive change in absorbance at 706 nm due to the J-aggregates. The total concentration of the porphyrin in the system was 1.0×10^{-6} M.

(SPNA3G3E and SPNA3G3S, Scheme 1) used in this study. SPNA3G3E and SPNA3G3S are the anionic and nonionic substrates, respectively. SPNA3G3E with a GluGluGlu sequence was designed to allow recognition of the Phe residue by ChT at the C-terminus and to enhance electrostatic repulsion with the J-aggregates. The hydrolysis of the substrate was monitored by following the changes in the absorbance of released *p*-nitroaniline at 355 nm that correspond to the isosbestic point in the UV−visible spectral changes of the H_4TPPS^{2-} J-aggregates to the H_2TPPS^{4-}/TMe-*β*-CD inclusion complex (Supporting Information, Figure S6).

Figure 4a (in black) shows the progressive changes in the absorbance at 355 nm in the hydrolysis of SPNA3G3E (3.0×10^{-4} M) catalyzed by ChT (1.0×10^{-6} M) in phosphate buffer (pH 7.0, 1.0×10^{-2} M) at 25 °C. The result at the initial stage of hydrolysis, where less than 16% of the substrate molecules were hydrolyzed, is shown in Figure 4. The absorbance at 355

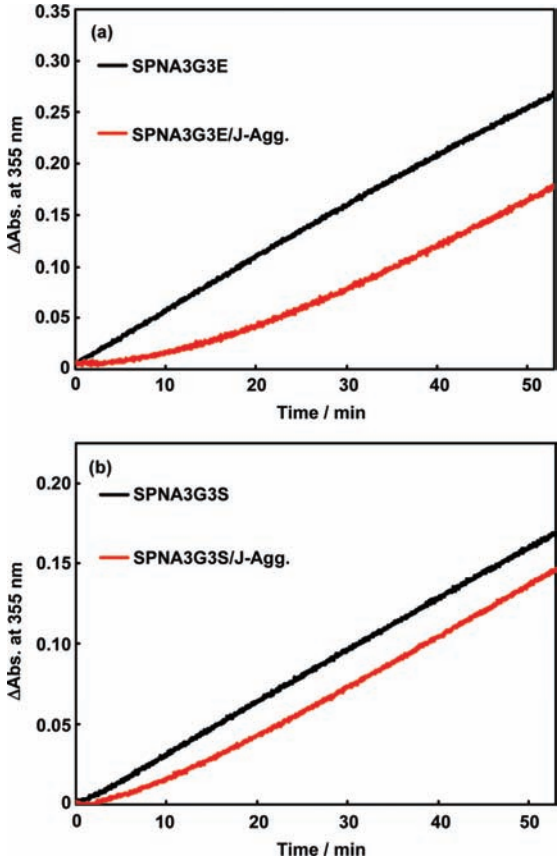

Figure 4. Hydrolysis profiles of SPNA3G3E (3.0×10^{-4} M) (a) and SPNA3G3S (3.0×10^{-4} M) (b) catalyzed by ChT (1.0×10^{-6} M) in the absence (black) and the presence (red) of both the J-aggregates of H_4TPPS^{2-} ($[H_2TPPS^{4-}] = 1.5 \times 10^{-5}$ M) and TMe-β-CD (1.2×10^{-4} M) in phosphate buffer (pH 7.0, 1.0×10^{-2} M) at 25 °C.

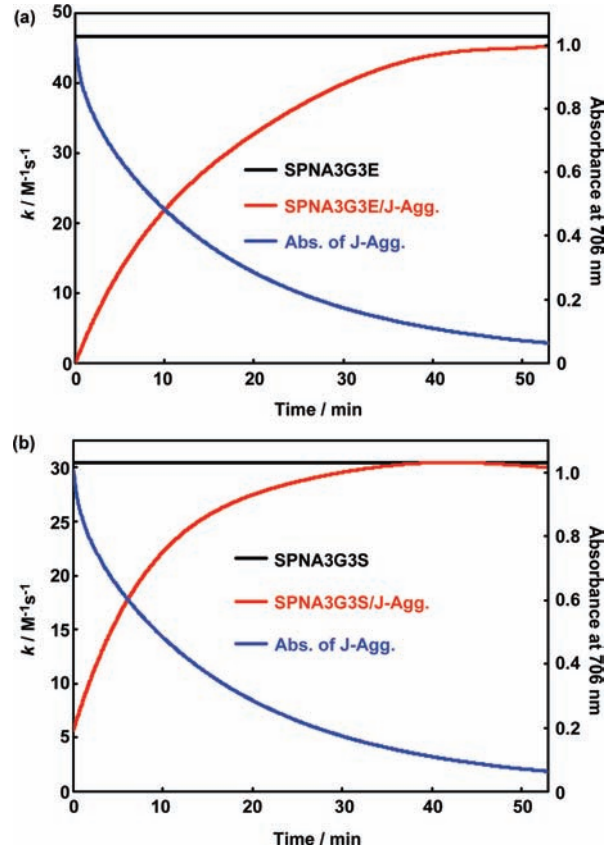

Figure 5. Progressive changes in the rate constants for the ChT-catalyzed hydrolyses of SPNA3G3E (a) and SPNA3G3S (b) in the absence (black) and the presence (red) of both the J-aggregates and TMe-β-CD. The progressive change in the absorbance at 706 nm due to the J-aggregates of H_4TPPS^{2-} (blue) is also shown.

nm appeared to increase linearly in the case of ChT-catalyzed hydrolysis of SPNA3G3E in the absence of the J aggregates. Meanwhile, the ChT-catalyzed hydrolysis of SPNA3G3E in the presence of both H_4TPPS^{2-} J-aggregates (1.5×10^{-5} M as the monomer) and TMe-β-CD (1.2×10^{-4} M) showed a characteristic reaction profile which suggested that the hydrolysis was completely inhibited by the J-aggregates during initial 2 min and the reaction rate gradually increased until 50 min from the start. The inhibition effect depended on the amount of H_4TPPS^{2-} added to the system (Supporting Information, Figure S7). TMe-β-CD itself as well as the 2:1 complex of TMe-β-CD and H_2TPPS^{4-} did not affect the hydrolysis at all. These results clearly indicate that the J-aggregates of H_4TPPS^{2-} play a role in the time-dependent inhibition of ChT-catalyzed hydrolysis of SPNA3G3E.

The results in Figure 4a were analyzed by the following equations. The change in the absorbance at 355 nm (ΔA) is represented as

$$\Delta A = (\varepsilon_S C_S l + \varepsilon_P C_P l) - \varepsilon_S C_{S0} l \quad (1)$$

where ε_S and ε_P are the extinction coefficients of the substrate and the product, respectively, at 355 nm, C_{S0} is the initial concentration of the substrate, C_S and C_P are the concentrations of the substrate and the product, respectively, at time t, and l is the optical length. Since $C_P = (C_{S0} - C_S)$, the C_P can be expressed as

$$C_P = \Delta A/(\varepsilon_P - \varepsilon_S)l \quad (2)$$

The C_P−time profiles obtained for the systems in the absence and the presence of both the J-aggregates and TMe-β-CD fitted well with the linear and six-order polynomial equations (eq 3) using the least-squares method. We arbitrarily selected the six-order polynomial equation. The degrees of fittings were evaluated from the R^2 values that were over 0.999.

$$C_P = f(t) = \sum_{m=0}^{n} a_m t^m \quad (n = 1 \text{ or } 6) \quad (3)$$

Equation 3 was differentiated with time (t) to obtain velocity ($v(t)$) at time t.

$$v(t) = \frac{df(t)}{dt} = \sum_{m=1}^{n} a_m m t^{m-1} \quad (4)$$

The second-order rate constant at t was obtained from eq 5 where the enzyme and substrate concentrations were assumed

$$k(t) = v(t)/[E][S] \quad (5)$$

to be the same as their respective initial concentrations.

Figure 5a shows the rate constants as a function of time for the ChT-catalyzed hydrolyses of SPNA3G3E in the absence and the presence of both the J-aggregates and TMe-β-CD. In the absence of the J-aggregates, the $k(t)$ value was constant until 50 min from the start (Figure 5a, in black). In the presence of a large excess of the substrate, ChT-catalyzed hydrolysis appeared to proceed linearly at the initial stage. Meanwhile, the $k(t)$ value in the presence of the J-aggregates and TMe-β-CD gradually increased and reached the value obtained in the absence of the J-aggregates (Figure 5a, in red). The progressive change in the $k(t)$ was in good agreement with the decrease in

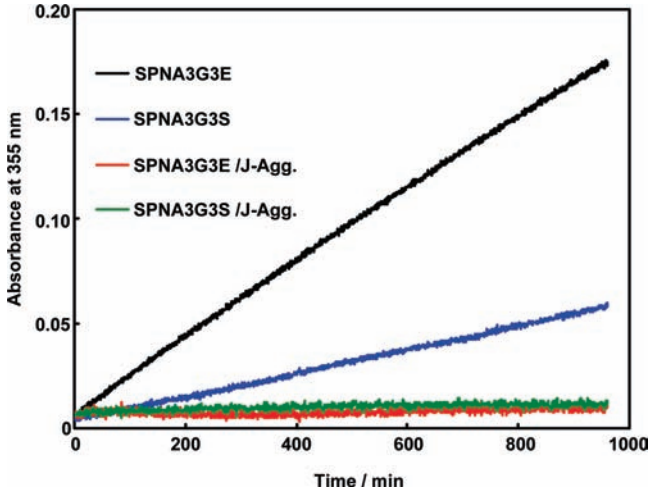

Figure 6. Hydrolysis profiles of SPNA3G3E (3.0×10^{-4} M; black and red) and SPNA3G3S (3.0×10^{-4} M; blue and green) catalyzed by ChT (1.0×10^{-6} M) in the absence and the presence of both the J-aggregates of H_4TPPS^{2-} ($[H_2TPPS^{4-}] = 1.5 \times 10^{-5}$ M) and TMe-β-CD (1.2×10^{-4} M) in succinic acid buffer (pH 4.0, 1.0×10^{-2} M) at 25 °C.

the absorbance at 706 nm due to the dissociation of the J-aggregates (Figure 5a, in blue). These results clearly indicate that the enzyme activity of ChT was inhibited by the J-aggregates and that it gradually recovered to the original value with the progressive dissociation of the J-aggregates. The restoration of the enzyme activity was 98% at 50 min from the start of the dissociation of the J-aggregates.

Inhibition Mechanism. The following three mechanisms are proposed for the inhibition of ChT activity by the J-aggregates of H_4HPPS^{2-}: (1) electrostatic repulsion between the anionic groups of SPNA3G3E and the J-aggregates, (2) covering of the active site of ChT by the J-aggregates, and (3) structural changes in ChT caused by the J-aggregate.

To study the contribution of electrostatic interaction to the inhibition of the hydrolysis of anionic SPNA3G3E, we used a neutral SPNA3G3S (Scheme 1) as the substrate. The reaction profile is shown in Figure 4b, which exhibits that the J-aggregates inhibit the hydrolysis of the neutral substrate in the manner similar to that of the anionic substrate, though the inhibitory effect in the case of neutral SPNA3G3S is not as remarkable as that in the case of SPNA3G3E. The degrees of inhibition by the J-aggregates at 500 s from the start were 83% and 35% for SPNA3G3E and SPNA3G3S, respectively. It can be concluded, therefore, that electrostatic repulsion between the polyanionic J-aggregates and anionic SPNA3G3E is one of the important factors that reduces the hydrolysis of this anionic substrate.

Since the hydrolysis of the neutral substrate was inhibited by the J-aggregates, the covering effect might also influence the hydrolysis. To this end, we evaluated the inhibition effect of the J-aggregates in aqueous solution at pH 4.0, wherein the J-aggregates do not dissociate to a marked extent. The results are shown in Figure 6. Since the optimum pH range of ChT activity is 8−9, the rates of the hydrolyses of both SPNA3G3E and SPNA3G3S at pH 4.0 were much less than those at pH 7.0. The hydrolyses of both the substrates were completely suppressed in the presence of the J-aggregates. The results clearly show that the J-aggregates of H_4TPPS^{2-} cover the active site of the enzyme and block the binding of the substrate leading to complete inhibition of the hydrolysis. At pH 7.0, the partial dissociation of the J-aggregates occurs from the start of the reaction, freeing the active site to interact with the substrate. In this stage, electrostatic interactions influence the approach of the substrate to the open active site of ChT.

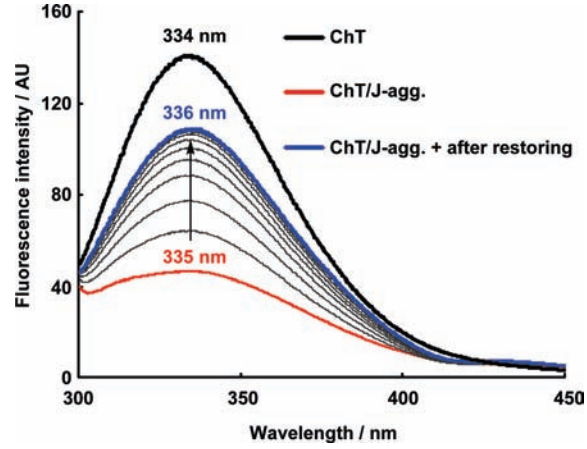

Figure 7. Fluorescence spectra of ChT (1.0×10^{-7} M) before (black) and after (red) the addition of both J-aggregates of H_4TPPS^{2-} ($[H_2TPPS^{4-}] = 1.5 \times 10^{-6}$ M) and TMe-β-CD (1.2×10^{-5} M) (red solid line) in phosphate buffer (pH 7.0, 1.0×10^{-2} M) at 25 °C. The fluorescence intensity gradually recovered to the spectrum indicated in a blue line. The spectra were recorded with 5 min intervals.

Finally, we studied the effect of the J-aggregates on changes in the protein structure of ChT. ChT possesses eight Trp residues, which are located in the core and the surface of the protein (*42*). The Trp residues exhibit fluorescence and are useful to probe changes in the protein structure, because the fluorescence of these residues greatly depends on the microenvironment (*43, 44*). Figure 7 shows the fluorescence spectral changes of ChT after the addition of J-aggregates. The fluorescence intensity at 334 nm markedly decreased immediately after the addition of the J-aggregates and gradually recovered with the dissociation of the J-aggregates from the protein surface. The fluorescence maximum of ChT scarcely shifted though the fluorescence intensity markedly diminished, suggesting that the Trp residues in the interior of the protein are not exposed on the protein surface upon binding with the J-aggregates. ChT appears to change its conformation upon binding with J-aggregates without undergoing distinct denaturation. The change in the conformation of ChT might cause enhanced fluorescence quenching of the Trp fluorescence by other amino acid residues (*44*). The fluorescence was not completely recovered, meaning occurrence of permanent change in the structure of ChT, although the enzyme activity was almost completely restored after the complete dissociation of the J-aggregates (see Figure 5).

CD spectra also revealed structural changes in ChT after the addition of J-aggregates (Figure 8). Since the CD measurement required about 10 min, the observed spectrum did not reflect the structure of ChT immediately after binding with the J-aggregates. Upon addition of the J-aggregates, the negative CD bands of ChT at 203 nm shifted to 201 nm along with enhancement of the negative Cotton effect. Meanwhile, the band at 230 nm scarcely changed. The CD spectrum of ChT further changed during the dissociation of the J-aggregates and the CD band finally shifted to 198 nm. The negative CD signal at 198 nm indicates the formation of a random coil structure. The negative band at 230 nm was retained in the final CD spectrum. The negative CD band at 230 nm is characteristic of the Trp 141 that is located close to the His 57 and Ser 195 at the active site of ChT (*18, 45*). This band has been used as a probe for predicting the enzyme activity of ChT (*18, 45*). Reduction in the band at 230 nm indicates lowering of the enzyme activity. If the band is not affected by any perturbation, the enzyme activity will be maintained (*46*). The CD spectral data is

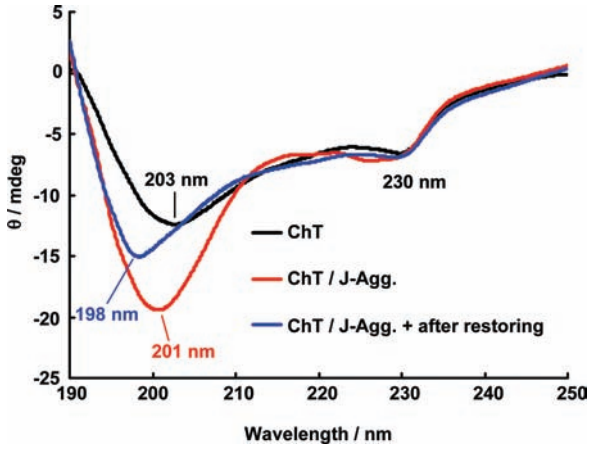

Figure 8. CD spectra of ChT (1.0×10^{-6} M) before (black) and after the addition (red) of the J-aggregates of H_4TPPS^{2-} ($[H_2TPPS^{4-}] = 1.5 \times 10^{-5}$ M) and TMe-β-CD (1.2×10^{-4} M) in phosphate buffer (pH 7.0, 1.0×10^{-2} M) at 25 °C. A spectrum in blue was recorded after complete dissociation of the J-aggregates.

consistent with the fact that the enzyme activity is restored after complete dissociation of the J-aggregates from the surface of ChT.

CONCLUSION

The J-aggregates of H_4TPPS^{2-} are stabilized by ChT even in neutral aqueous solution. These aggregates cover the active site of the enzyme and completely inhibit the enzyme activity. However, the enzyme activity is restored almost completely with the dissociation of the J-aggregates. The J-aggregates induce a progressive change in enzyme activity from complete inhibition to complete restoration without the aid of a secondary additive.

On the basis of the findings of this study, it is possible to develop a "dream drug" with the following features: (1) The drug specifically binds to a target protein. (2) The drug inhibits protein function for a desired time period. (3) The function of the protein is completely restored after the drug has performed its work. (4) The used drug is removed from the body.

The present study shows that J-aggregates of H_4TPPS^{2-} partially fulfill these requirements. The polyanionic J-aggregates selectively bind with a basic protein and do not interact with polyanionic DNA and RNA. The large J-aggregates cover the protein surface and inhibit substrate binding or protein−protein interaction. The J-aggregates spontaneously dissociate to monomers, gradually restoring the protein function. The monomer of H_2TPPS^{4-} forms an extremely stable 2:1 inclusion complex with TMe-β-CD that is easily excreted in urine (*47*). The J-aggregates of H_4TPPS^{2-} cannot be actually used as drugs because of difficulty in administration to a living body. However, the present study introduces the concept of preparing a dream drug in the future.

Gene Silencing Activity of siRNA Polyplexes Based on Thiolated *N,N,N*-Trimethylated Chitosan

Amir K. Varkouhi,[†] Rolf J. Verheul,[†] Raymond M. Schiffelers,[†] Twan Lammers,[†,‡] Gert Storm,[†] and Wim. E. Hennink*[,†]

Department of Pharmaceutics, Utrecht Institute for Pharmaceutical Sciences, Faculty of Science, Utrecht University, Sorbonnelaan 16, 3584 CA Utrecht, The Netherlands, and Department of Experimental Molecular Imaging, RWTH - Aachen University, Pauwelsstrasse 30, 52074 Aachen, Germany. Received August 20, 2010; Revised Manuscript Received October 10, 2010

N,N,N-Trimethylated chitosan (TMC) is a biodegradable polymer emerging as a promising nonviral vector for nucleic acid and protein delivery. In the present study, we investigated whether the introduction of thiol groups in TMC enhances the extracellular stability of the complexes based on this polymer and promotes the intracellular release of siRNA. The gene silencing activity and the cellular cytotoxicity of polyplexes based on thiolated TMC were compared with those based on the nonthiolated counterpart and the regularly used lipidic transfection agent Lipofectamine. Incubation of H1299 human lung cancer cells expressing firefly luciferase with siRNA/thiolated TMC polyplexes resulted in 60−80% gene silencing activity, whereas complexes based on nonthiolated TMC showed less silencing (40%). The silencing activity of the complexes based on Lipofectamine 2000 was about 60−70%. Importantly, the TMC-SH polyplexes retained their silencing activity in the presence of hyaluronic acid, while nonthiolated TMC polyplexes hardly showed any silencing activity, demonstrating their stability against competing anionic macromolecules. Under the experimental conditions tested, the cytotoxicity of the thiolated and nonthiolated siRNA complexes was lower than those based on Lipofectamine. Given the good extracellular stability and good silencing activity, it is concluded that polyplexes based on TMC-SH are attractive systems for further in vivo evaluations.

INTRODUCTION

Cationic polymers have been studied for nucleic acid delivery both in vitro and in vivo (*1*−*4*). Due to their positive charge, these polymers are able to complex with anionic nucleic acid molecules to form polyplexes which are able to cross cellular barriers and reach their intracellular targets (*5*−*8*). However, the complexes based on many of these cationic polymers are insufficiently stable in biological fluids and consequently do not protect the DNA/siRNA molecules against enzymatic degradation by nucleases (*9, 10*). Moreover, insufficient uptake by target cells, poor intracellular release properties, and considerable cellular toxicity are other limiting factors for pharmaceutical and therapeutic application of these polymers. Therefore, the search for effective and nontoxic vectors is currently of prime interest (*11*−*13*).

N,N,N-Trimethylated chitosan (TMC) is a biodegradable polymer emerging as a promising nonviral vector for nucleic acid and protein delivery (*14*−*16*). This polymer is a partially quaternized chitosan derivative which, as compared to chitosan, has improved solubility in aqueous solution at neutral pH, safety, and effectiveness (*17, 18*). The beneficial ability of TMC to reversibly open tight junctions between epithelial cells, which facilitates the uptake of therapeutics, its muco-adhesive properties, and relatively low toxicity, make TMC a valuable polymer for several drug delivery applications (*19, 20*).

Introduction of thiol groups into several carrier systems has been shown to enhance their delivery properties. This is due to the formation of reducible disulfide bonds between thiol groups, leading to increased extracellular stability and improved intracellular release properties (*21*−*23*). Therefore, introduction of thiol groups in TMC likely enhances the stability of its complexes with nucleic acids and also allows further chemical derivatization with targeting ligands and PEG making use of unreacted SH groups (*24*−*26*). Moreover, the thiol groups in TMC-SH can promote its muco-adhesive potential due to formation of disulfide bonds between the polymer and mucin glycoproteins on the cell membrane, which might lead to enhanced cellular uptake (*27, 28*).

Recently, considerable research effort has been dedicated to the use of small interfering RNAs (siRNA) as novel biotherapeutics (*29*). These double-stranded RNA molecules are rapidly degraded by nucleases present in biological fluids and are not able to enter the cytoplasm, where the RNA interference (RNAi) machinery is located (*30, 31*). Therefore, a key challenge to the effective and widespread use of this new class of biotherapeutics is their cytosolic delivery (*32*−*34*).

Our group recently reported on thiolated TMC and the formation of nanoparticles based on this polymer (*24*). In the present study, thiolated and nonthiolated TMC (Figure 1) were investigated for siRNA delivery and gene silencing. The silencing activity and the cellular toxicity of polyplexes based on these biodegradable polymers were compared with those based on the regularly used lipidic transfection agent Lipofectamine (*35*).

EXPERIMENTAL PROCEDURES

Materials. The double-stranded siRNA which specifically targets firefly luciferase (used against mRNA from pGL3; structure below), was obtained from Dharmacon Bioscience (Lafayette, LA, USA), and anti-EGFP siRNA as nonspecific

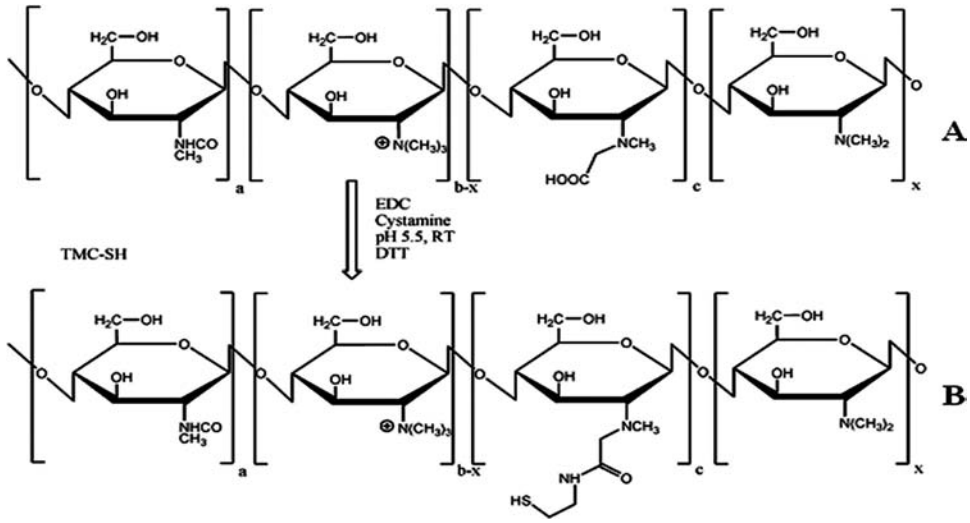

Figure 1. Structure of nonthiolated (A) and thiolated *N,N,N*-trimethylated chitosan (TMC) (B).

siRNA and Fluc-TYE563- labeled siRNA were obtained from Integrated DNA Technologies BVBA (Leuven, Belgium).

Sense strand: 5′- GAU UAU GUC CGG UUA UGU A UU. Antisense strand: UU CUA AUA CAG GCC AAU ACA U P-5′.

Thiolated TMC (TMC-SH) with different extents of thiol modification of 2%, 5%, and 7% and molecular weights of 180, 215, and 144 kDa, respectively, and nonthiolated TMC (MW = 100 kDa) and thiolated HA (HA-SH, 40 kDa) with 21% thiol modification were synthesized and purified as described previously (*24*). The degree of quaternization and acetylation of the studied TMCs were 25% and 17%, respectively. Sodium heparin was obtained from Sigma Aldrich (Zwijndrecht, The Netherlands); and Lipofectamine 2000 and LysoTrackerR Green DND-26 were obtained from Invitrogen (Breda, The Netherlands). Luciferase assay reagent and reporter lysis buffer were obtained from Promega (Leiden, The Netherlands). DRAQ5 was obtained from Biostatus Limited (Leicestershire, UK).

Physicochemical Characterization of Polyplexes. Polyplexes were prepared at different polymer to siRNA ratios (expressed as *N*/*P* ratios, where *N* is the moles of cationic nitrogens in the polymer and *P* is moles of phosphate in siRNA) between 0.5 and 14 by adding a siRNA solution (200 μL, 40 μg/mL) in HEPES (5 mM, pH 7.4) to polymer solutions (200 μL, various concentrations) in the same buffer. The resulting solutions were vortexed for 10 s. After 3 h incubation at room temperature, *Z*-average diameters were measured with dynamic light scattering at 25 °C with a Malvern 4700 system using an argon-ion laser (488 nm) operating at 10.4 mW (Uniphase) and *PCS* (photon correlation spectrometry) software for Windows v 1.34 (Malvern, UK). Viscosity and refractive index of water at 25 °C were used. Calibration was done with an aqueous dispersion of polystyrene particles with a diameter of 100 nm. Particle size distribution is characterized by the polydispersity index (PDI), ranging from 0 for a monodisperse to 1 for a heterodisperse preparation. The zeta potential of the polyplexes prepared in HEPES (5 mM, pH 7.4) was determined at 25 °C in a DTS5001 cell using a Zetasizer 2000 unit (Malvern). The instrument was calibrated with a polystyrene dispersion with known zeta potential. To study the formation of covalent disulfide bonds in the polyplexes based on TMC-SH and their effect in the stability of the complexes, in some experiments after adding the siRNA solution (200 μL, 40 μg/mL) in HEPES (5 mM, pH 7.4) to polymer solutions (200 μL, various concentrations) in the same buffer, immediately 50 μL of either thiolated (*24*) or nonthiolated hyaluronic acid (1 mg/mL) solution in HEPES (5 mM, pH 7.4) was added to the complex and incubated for 3 h at room temperature.

Agarose Gel Electrophoresis. The complexation of siRNA with the thiolated and nonthiolated TMC as well as the L-glutathione/heparin-induced destabilization of the polyplexes was investigated using agarose gel electrophoresis. The agarose gels (NuSieve GTG Agarose, Lonza, Rockland, ME, USA) were made at a concentration of 4% (w/v) in Tris-acetate-EDTA (TAE) running buffer and contained 0.5 μg/mL ethidium bromide. Polyplexes of TMC's with the siRNA and thiolated or nonthiolated HA made at *N*/*P* ratio of 8 were prepared as described above. Naked siRNA was used as a control. Polyplex dispersions with or without heparin (1.5 USP/μg siRNA; molar ratio of amine groups of the polymer and sulfate groups of heparin was 0.5 (N/S)) were incubated for 5 min at room temperature. In another experiment, polyplex dispersions were incubated for 30 min at 37 °C with L-glutathione (5 mM) and subsequently incubated with or without heparin (N/S: 0.5) for 5 min at room temperature. Polyplexes (15 μL, corresponding to 15 pmol siRNA) were applied in the starting slot of the gel and electrophoresis was performed at 60 V for 50 min. The siRNA bands, stained with ethidium bromide, were detected on a UV transilluminator (ImaGo compact imaging system, B&L Systems, The Netherlands).

Gene Silencing and Cytotoxicity Experiments. The human lung cancer cell line H1299 which expresses firefly luciferase was used to study the gene silencing activity of the TMC formulations. The cell line was maintained in RPMI 1640 medium with HEPES and L-glutamine (PAA laboratories GmbH, Pasching, Austria, catalog no. E15-842) completed with fetal bovine serum (FBS) (final concentration 10% v/v) and cultured at 37 °C at 5% CO_2 humidified atmosphere. The cells (8×10^3 cells/well) were seeded into 96-well plates and cultured overnight. The anti-Luciferase siRNA polyplexes were added to the cells in the presence or absence of serum in the medium and incubated at 37 °C for 24 h. Then, the medium was removed, and fresh medium was added. Subsequently, the cells were incubated at 37 °C for 1 day, after which the luciferase protein expression was analyzed using Luciferase reporter gene assay (Promega). The cytotoxicity of the polyplexes was measured using the XTT colorimetric viability assay as previously described (*36*). Complexes of either specific or nonspecific siRNA with Lipofectamine 2000 were prepared by gently mixing 50 μL siRNA (20 μg/mL) in HEPES (5 mM, pH 7.4) with 3.7 μL Lipofectamine 2000 in 50 μL HEPES (5 mM, pH

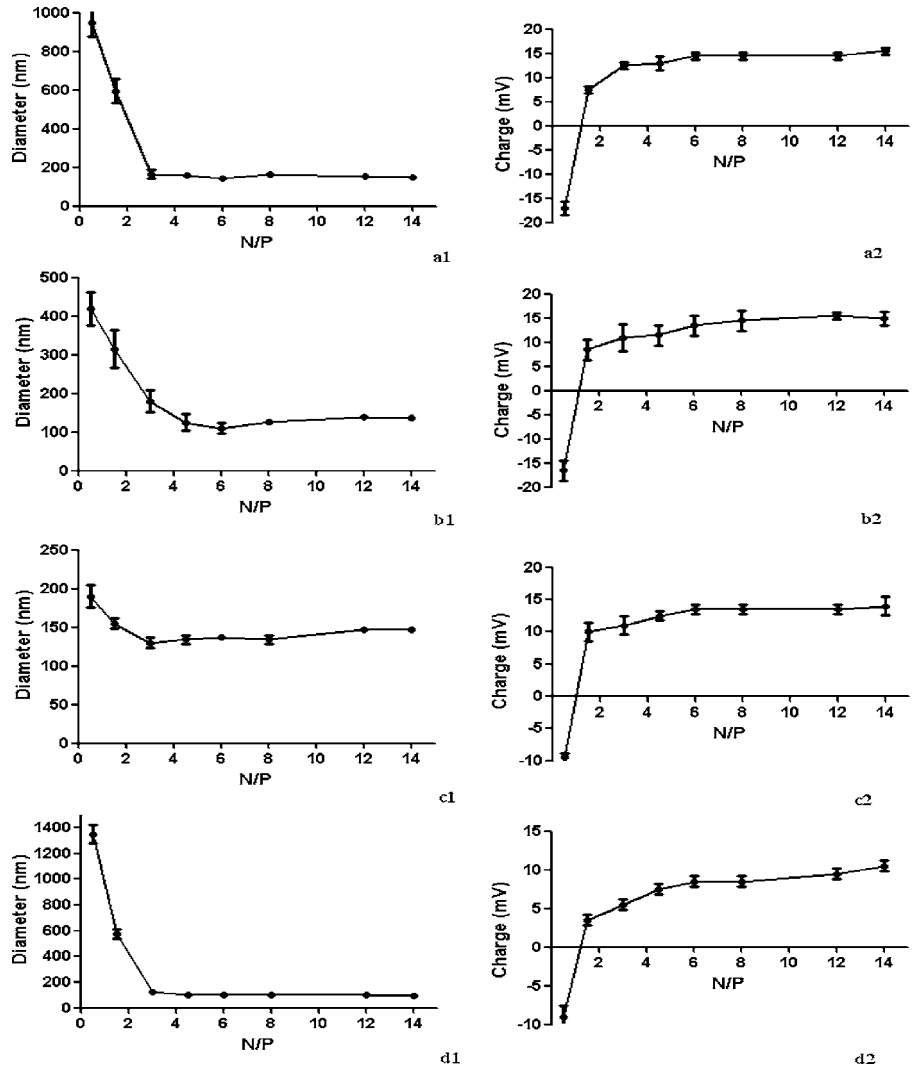

Figure 2. Average diameter and zeta potential of polyplexes prepared at different *N*/*P* ratios. (a1, a2) TMC-SH 2%. (b1, b2) TMC-SH 5%. (c1, c2) TMC-SH 7%. (d1, d2) Nonthiolated TMC (mean ± standard deviation ($n = 3$)).

7.4) followed by 30 min incubation at room temperature and then were incubated with cells.

Determination of Luciferase Activity. Luciferase activity was measured after removal of the growth medium and lysis of the cells by the addition of 100 μL reporter gene lysis buffer. After a freeze/thaw cycle at −80 °C/room temperature, 50 μL of luciferase assay reagent was added to 50 μL of the cell lysate, and relative light units (RLU) were measured for 10 s at room temperature using a FLUOstar OPTIMA microplate-based multidetection reader with a microinjector.

Confocal Laser Scanning Microscopy (CLSM). The cellular uptake of polyplexes was investigated with CLSM. In short, 8×10^3 cells were seeded in Fluorodish cell culture dish (WPI, Sarasota, NY, USA). The cells were cultured for 24 h at 37 °C and subsequently incubated with Fluc TYE563-labeled siRNA lipo/polyplexes for 4 h. Then, the cells were washed with PBS and incubated for 5 min with medium containing 40 μM DRAQ5 for nuclear staining and 75 nM LysoTracker Green DND-26 for endosomal/lysosomal staining. The cells were subsequently analyzed on a Leica TCS-SP confocal laser scanning microscope (Leica, Heidelberg, Germany) equipped with three lasers: 488 nm argon, 568 nm krypton, and 647 nm HeNe laser.

RESULTS AND DISCUSSION

Physicochemical Characterization of Polyplexes. The average diameter of the polyplexes prepared at different *N*/*P* ratios was measured by dynamic light scattering (Figure 2). Both thiolated and nonthiolated TMC were capable of forming complexes with siRNA over the whole *N*/*P* range 0.5−14. The average size of the particles decreased with increasing *N*/*P* ratio, with small-sized nanoparticles of ≤200 nm being formed at *N*/*P* ratio of ≥3. This can probably be ascribed to an increased polymer amount in the formulations which leads to tighter complexes. There was no significant difference in size of the nanoparticles based on thiolated and nonthiolated TMCs. Furthermore, a polydispersity index (PDI) of ≤0.3 was observed for all polyplex formulations made at *N*/*P* ratio of ≥3, which indicates a rather narrow size distribution.

At *N*/*P* of 0.5, the polyplexes had a negative zeta potential (about −10 to −25 mV), which can be explained by the excess of siRNA present in the complexes. At *N*/*P* ≥ 1.5, positively charged particles for the different TMC-SH based formulations (zeta potential +5 to +15 mV) and nonthiolated TMC (+5 to +10 mV) were formed (Figure 2). The average diameter and zeta potential of the particles based on TMC-SH and nonthiolated TMC (*N*/*P*: 8) in combination with thiolated hyaluronic acid (HA-SH) and the nonthiolated one (HA) were measured. The particles based on TMC-SH/siRNA/HA-SH had an average diameter of 170 ± 10 nm and an average zeta potential of 10 ± 2 mV, whereas the other formulations (with nonthiolated TMC instead of TMC-SH) led to formation of particles of ≥1000 nm.

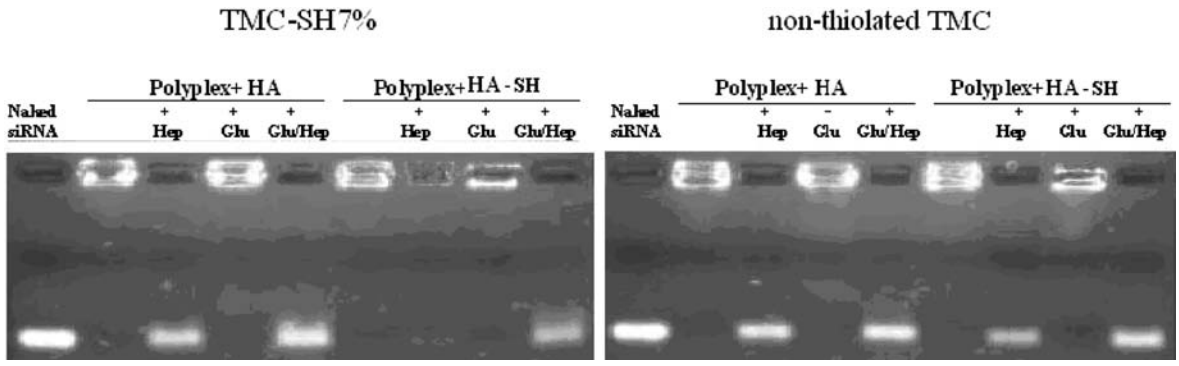

Figure 3. Agarose gel electrophoresis. Polyplexes of TMC-SH and nonthiolated TMC with siRNA made in 5 mM HEPES buffer (pH 7.4) at *N*/*P* ratio 8, containing either nonthiolated hyaluronic acid (HA) or HA-SH were applied on a 4% agarose gel. By adding heparin (*N*/*S* = 0.5, *N* is the moles of cationic nitrogens in the polymer and *S* is moles of sulfate in siRNA) release of siRNA was observed for all complexes, except for those based on TMC-SH/siRNA/HA-SH, which is probably due to disulfide bond formation in the complex. Incubation of the complexes with L-glutathione (5 mM) for 30 min at 37 °C did not lead to release of the siRNA Complexes based on TMC-SH/siRNA/HA-SH only showed release of the siRNA after incubation with L-glutathione and heparin sequentially.

Agarose Gel Electrophoresis. Binding of TMC-SH to siRNA molecules and subsequent complex formation are essential for protection of siRNA against degradation by nucleases. Moreover, formation of covalent disulfide bonds between thiolated molecules likely increases the stability of the particles which avoids the dissociation of the siRNA from the complex in the extracellular matrix by anionic macromolecules such as proteins and polysaccharides (*37, 38*). On the other hand, polyplex destabilization still needs to occur in the cytosol to achieve gene silencing due to released siRNA.

TMC-SH and HA-SH as another thiolated polymer were formulated with siRNA and the stability of the formed particles was studied. As control formulations, polyplexes based on TMC-SH and nonthiolated HA and additionally polyplexes based on nonthiolated TMC in combination with HA-SH were prepared.

Figure 3 shows that siRNA remains in the starting slots of the gel for all the polyplexes prepared at *N*/*P* = 8, indicating that siRNA is stably associated with the cationic TMC. To monitor the sensitivity of these complexes for dissociation and release of siRNA, complexes were incubated with heparin, which is commonly used as a model anionic polyelectrolyte able to dissociate siRNA (*39, 40*). Figure 3 shows that, after incubation of the complexes with heparin, siRNA is released from all complexes, except from those based on TMC-SH/siRNA/HA-SH, demonstrating that siRNA is stably encapsulated in these particles. SiRNA is released from these particles only after incubation with L-glutathione and heparin, which indicates that siRNA can only be released after the disulfide bonds in the particles are cleaved by L-glutathione. These observations indicate an enhanced stability of the polyplexes based on TMC-SH/HA-SH likely due to formation of disulfide bonds between TMC-SH and HA-SH molecules. As a result, release of the siRNA from these complexes is expected to occur in two steps: (1) after cellular internalization of the particles, cleavage of the disulfide bonds between thiolated molecules inside the complex occurs, due to the relatively high concentrations of reducing agenst in the cytosol, and subsequently followed by (2) dissociation of the complexes and release of siRNA is likely due to competition with the negatively charged macromolecules such as proteins and mRNA (*41*) present in the cytosol.

Silencing Activity and Cell Viability. Human lung cancer cells (H1299) expressing luciferase were used for gene silencing studies. SiRNA polyplexes based on thiolated and nonthiolated TMC polymers prepared at *N*/*P* ratios of 8 were selected for silencing studies, because these particles showed binding to the siRNA (Figure 3), and upon complexation had a positive mean zeta potential and small average size (Figure 2). TMC-SH with highest degree of thiolation (7%) was selected for the silencing/

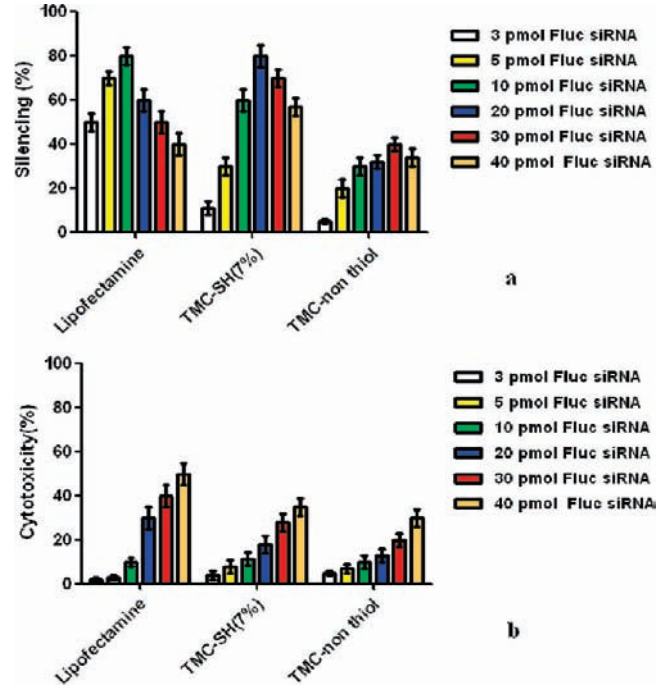

Figure 4. (a) Dose response effect of the siRNA complexes in Luciferase gene silencing after incubation with H1299 cells for 24 h in serum-free medium. (b) Cell viability as measured by XTT assay after incubation of H1299 cells for 24 h with siRNA complexes in serum-free medium (mean ± standard deviation (n = 3)).

cytotoxicity experiments, because the most stable particles can be expected using this polymer. The silencing activity and cytotoxicity of these complexes were compared to those based on Lipofectamine 2000, and in all cases, the silencing results were corrected for cytotoxicity.

Figure 4a shows that increasing the dose of the TMC-SH polyplexes from 3 to 20 pmol siRNA content per well resulted in a significant enhancement of the silencing activity from 10% to above 80%, whereas doses higher than 20 pmol siRNA led to a gradual decrease in silencing activity of the complexes due to the increased cytotoxicity (Figure 4b). In case of the nonthiolated TMC, by increasing the dose of the siRNA, a gradual increase in silencing activity from 5% up to 40% was observed. In terms of silencing activity and cytotoxicity, the efficiency of TMC-SH polyplexes in gene silencing is substantially higher than those based on Lipofectamine 2000 (approximately 60% at a dose of 20 pmol siRNA) and nonthiolated TMC (approximately 30% at a dose of 20 pmol).

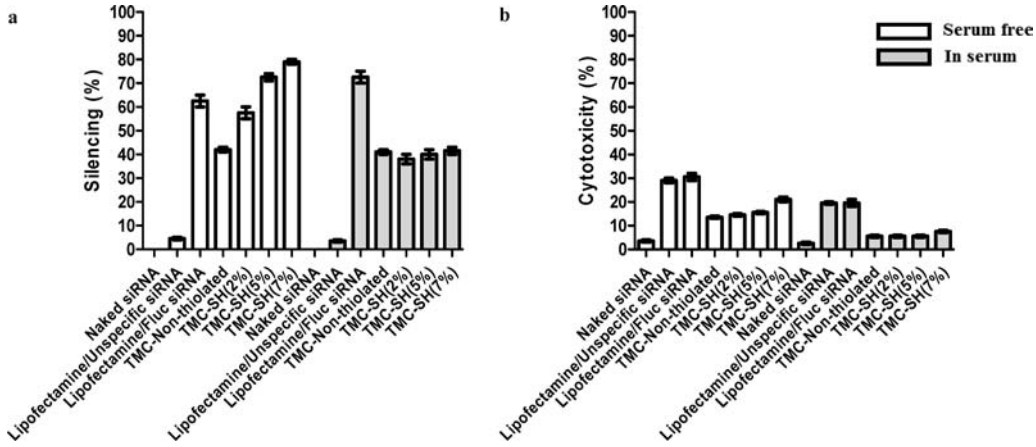

Figure 5. (a) Luciferase gene silencing after incubation of H1299 cells with siRNA complexes in serum-free medium and in the presence of serum. (b) Cell viability as measured by XTT assay after incubation of H1299 cells with siRNA complexes in serum-free medium and in the presence of serum (mean ± standard deviation ($n = 3$)).

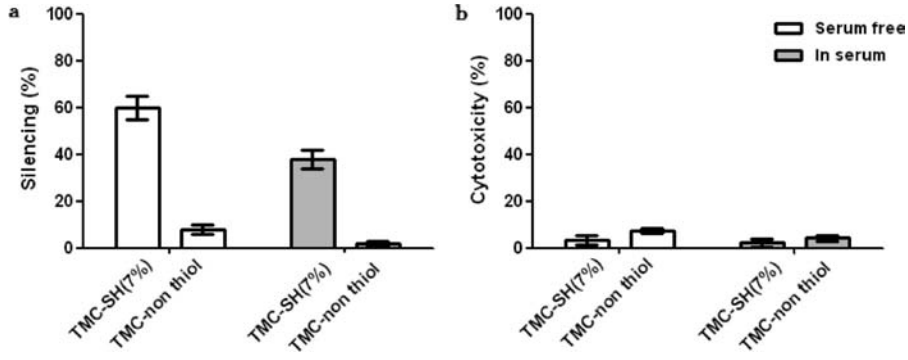

Figure 6. (a) Effect of hyaluronic acid (HA) (0.5 mg/mL) on Luciferase gene silencing activity of siRNA complexes based on TMC-SH (7%) and nonthiolated TMC. (b) Effect of HA on cell viability as measured by XTT assay after incubation of H1299 cells with siRNA complexes (mean ± standard deviation ($n = 3$)).

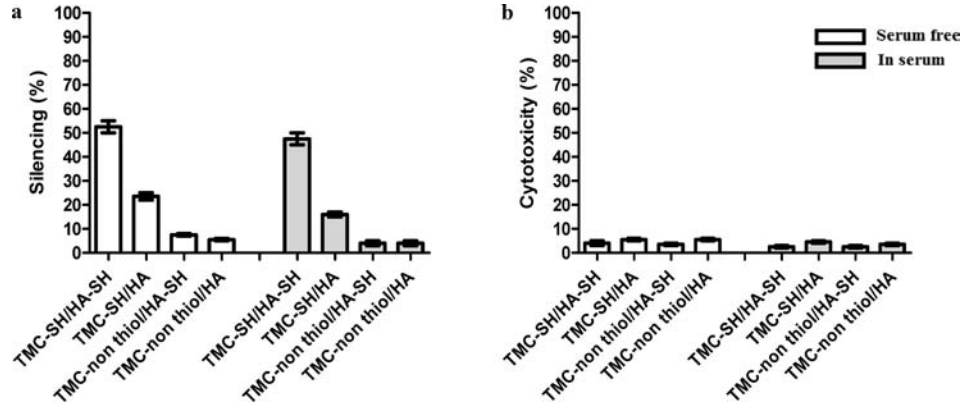

Figure 7. (a) Luciferase gene silencing after incubation of H1299 cells for 24 h with siRNA complexes in serum-free medium and in the presence of serum. (b) Cell viability as measured by XTT assay after incubation of H1299 cells with siRNA complexes in serum-free media and in the presence of serum (mean ± standard deviation ($n = 3$)).

Figure 4b shows that the cytotoxicity of TMC-SH/siRNA formulation is lower than that of the standard transfection system Lipofectamine 2000. In addition, TMCs have substantially lower cytotoxicity than other cationic polymers (*42, 43*). On the basis of these results, a dose of 20 pmol siRNA per well was selected as the dose for further gene silencing studies.

Figure 5a shows that, in the absence of serum, incubation of cells with polyplexes based on TMC-SH polymers containing 2%, 5%, and 7% thiol groups resulted in 60−80% silencing activity, whereas incubation with nonthiolated TMC complexes showed about 40% gene silencing. These results show that, by introduction of thiol groups in TMC structure, the gene silencing activity of the polyplexes is substantially increased. This might be due to the increased stability of the polyplexes of thiolated TMC.

The differences in gene silencing activity of the lipofectamine formulations in the absence and presence of serum are small (~60% and ~70%, respectively). It has been reported that the in vitro transfection activity of complexes increases once they aggregate in serum, due to more intense contact with cells (*44*). In the presence of 10% FBS, gene silencing activity of the siRNA polyplexes based on TMC-SH polymers decreased to 45%, whereas the gene silencing activity of the nonthiolated TMC remained the same as in serum-free conditions. This

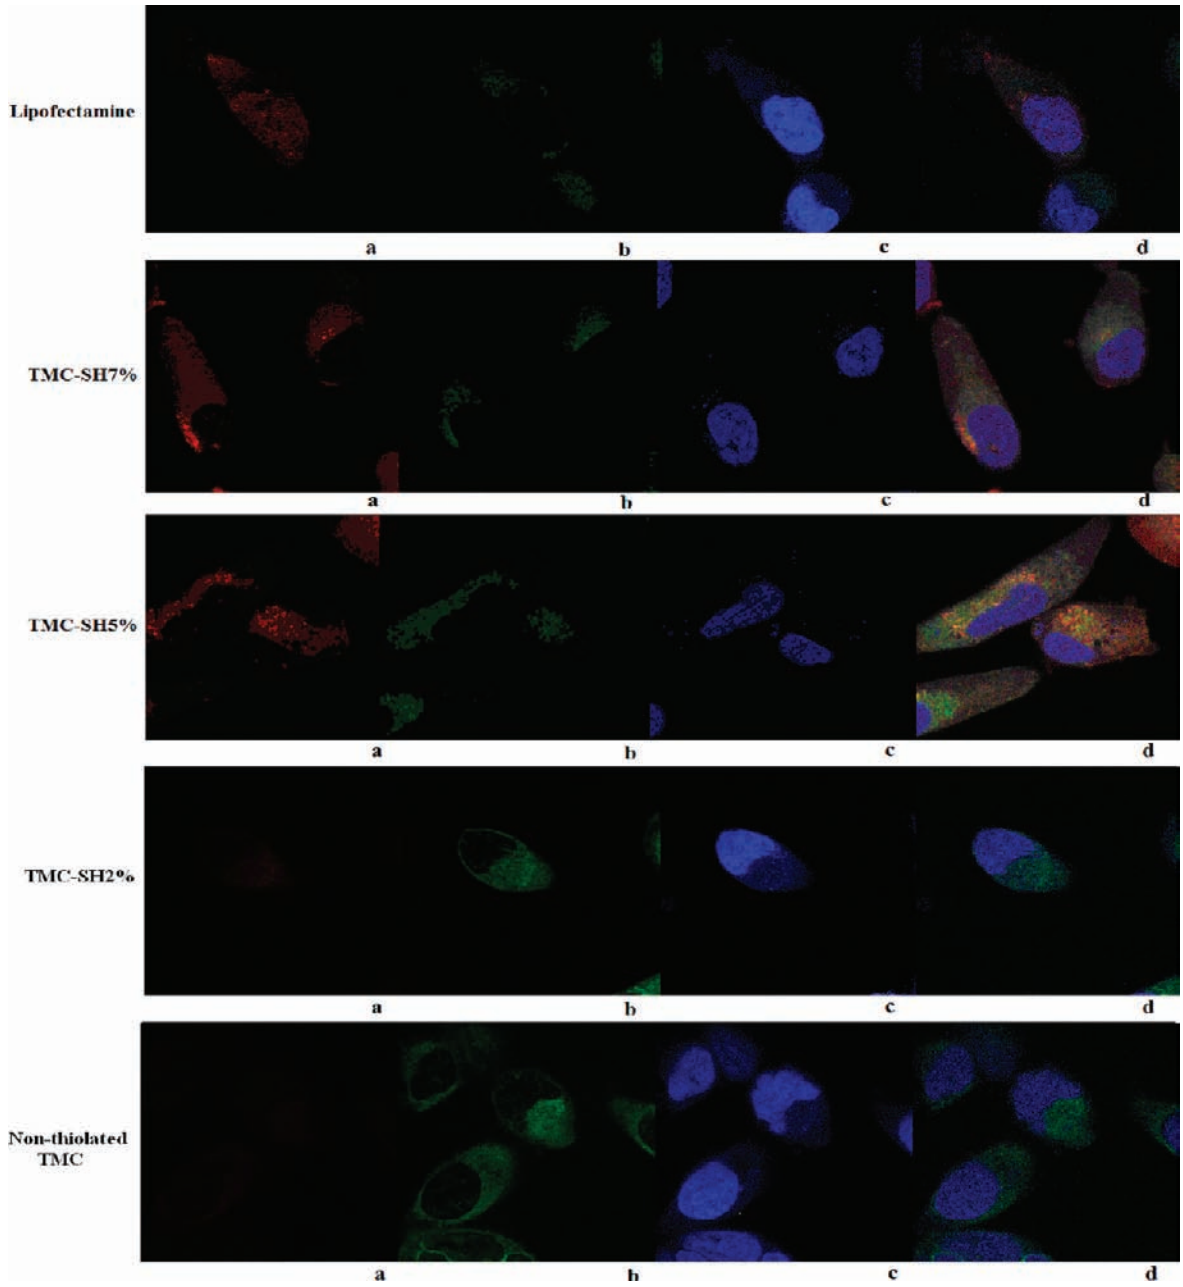

Figure 8. Confocal laser scanning microscopy images of H1299 cells incubated with complexes prepared with TYE563-labeled siRNA. Images (a): Pattern of intracellular TYE563-labeled siRNA. Images (b): Endosomes/lysosomes stained with LysoTracker Green DND-26. Images (c): Nuclei of cells stained with DRAQ5. reduction in silencing effect might be partly explained by the inhibitory effect of serum proteins on the uptake of nanoparticles (Figure 5a) (*45*).

Figure 5b shows low cytotoxicity of both thiolated and nonthiolated TMC/siRNA formulations made at an *N*/*P* ratio of 8 (<20%) compared to Lipofectamine with a cytotoxicity about 30%. Moreover, in the presence of serum, the cytotoxicity of the polyplexes was slightly lower than that of the complexes incubated with the cells in medium without serum. This effect is in line with the literature suggesting that serum proteins can mask the cytotoxicity of cationic polyplexes (*46, 47*). No significant differences in cytotoxicity of thiolated and nonthiolated TMCs were observed (Figures 4b and 5b).

The gene silencing efficiency of the polyplexes based on thiolated and nonthiolated TMC polymers was further investigated in the presence of hyaluronic acid (HA), which is an polyanionic macromolecule present in biological fluids that has been shown to inhibit the transfection activity of pDNA/cationic polymer nanoparticles (*48*, *49*).

In the presence of 0.5 mg/mL HA, TMC-SH/siRNA complexes showed up to 60% silencing activity, whereas the silencing activity of nonthiolated TMC polyplexes was less than 10%. In the presence of both HA and serum in the growth medium, the silencing activity of the TMC-SH polyplexes was decreased to 40%, whereas nonthiolated TMC polyplexes hardly showed any silencing (Figure 6a). These results illustrate the key role of disulfide bonds present in the TMC-SH polyplexes which enhance the stability of the complexes against competitor macromolecules present in biological fluids.

Furthermore, the silencing activity of the polyplexes based on TMC-SH and nonthiolated TMC in combination with either HA-SH or nonthiolated HA was studied. In the absence and presence of serum in the growth medium, siRNA complexes based on TMC-SH/HA-SH showed >50% gene silencing activity

(Figure 7a), whereas the gene silencing activity of the other formulations is ≤20% (Figure 7a). These results are in line with Figure 3, indicating better stability of the polyplexes based on TMC-SH/HA-SH due to formation of disulfide bonds between TMC-SH and HA-SH molecules, which consequently results in a higher gene silencing activity of this formulation compared to the other formulations. The XTT cell viability assay showed low cytotoxicity of the studied complexes (Figure 7b).

Confocal Laser Scanning Microscopy (CLSM). Confocal laser scanning microscopy (CLSM) was used to study the cellular uptake and internalization of siRNA complexes using fluorescently labeled siRNA. Figure 8 shows that red spots originating from the labeled siRNA (images a and d) were intracellularly observed after incubation of the cells with the various siRNA formulations investigated in this study, demonstrating that the complexes were internalized. The images of cells treated with Lipofectamine/siRNA complexes do visualize the presence of siRNA into both the cytosol and the nucleus, in agreement with previous observations (*23, 50*). In the case of TMC-SH 7% and TMC-SH 5% based complex-treated cells, the intensity of the internalized siRNA (images a and d) is considerably higher than in the case of the other groups, which is in agreement with the gene silencing results (Figure 5a). Furthermore, in the case of TMC-SH 7%, a diffuse pattern of the siRNA inside the cytosol is observed, while the lipofectamine and TMC-SH 5% treated cells mostly show a punctuated pattern of the siRNA. The yellow dots in panel d represent the colocalization of the siRNA with fluoresecent markers for endosomes/lysosomes. We speculate that these observations reflect the enhanced level of cellular uptake for the complexes based on TMC-SH with higher extent of thiol modification (5% and 7%), which might be related to their enhanced muco-adhesive properties (*27, 28*) and stability in the extracellular environment.

CONCLUSION

This study reports on TMC-SH as a promising vector for siRNA delivery. As compared to the nonthiolated TMC and Lipofectamine-based complexes, the gene silencing activity of the siRNA complexes based on thiolated TMC was substantially higher. Importantly, the polyplexes based on TMC-SH retained their silencing activity in the presence of hyaluronic acid, while nonthiolated TMC polyplexes hardly showed any silencing activity. Furthermore, the cytotoxicity profiles of TMC-SH and nonthiolated TMC were the same and more favorable compared to that of Lipofectamine. The results of this study suggest enhanced stability of the TMC-SH polyplexes, which is likely due to formation of the reducible disulfide bonds in the complex. These features make TMC-SH an attractive candidate for further development and evaluation in animal studies.

ACKNOWLEDGMENT

This project was funded by MEDITRANS, an Integrated Project funded by the European Commission under the "Nanotechnologies and Nano-sciences, Knowledge-based Multifunctional Materials and New Production Processes and Devices" (NMP), thematic priority of the Sixth Framework Program. We would like to thank Miss Esther van't Veld from the Centre for Cell Imaging (Faculty of Veterinary Medicine, Utrecht University) for technical assistance with the CLSM and Prof. Thomas Kissel and Dr Olivia Merkel from Marbourg University, Germany, for provding the H1299 cell line.

Photophysical Characterization of a FRET System Using Tailor-Made DNA Oligonucleotide Sequences

Roman Flehr,[†] Andrea Kienzler,[‡] Willi Bannwarth,[‡] and Michael U. Kumke*[,†]

University of Potsdam, Institute of Chemistry (Physical Chemistry), Karl-Liebknecht-Str. 24-25, 14476 Potsdam-Golm, Germany, and Albert-Ludwigs University of Freiburg, Institute of Organic Chemistry and Biochemistry, Albertstr. 21, 79104 Freiburg, Germany. Received August 31, 2010; Revised Manuscript Received October 19, 2010

We have carried out a detailed photophysical study of the FRET D/A pair consisting of a carbostyril donor and a Ru(II)bathophenanthroline complex acceptor in double-stranded synthetic DNA. Altogether 13 different double-stranded 30 base pair DNAs showing small incremental differences in the distances between donor and acceptor were synthesized. Using the fluorescence of the donor as well as of the acceptor, D/A separations were determined and compared to those derived from a well-established model for DNA distance calculations. The model calculations and anisotropy studies revealed that the donor can nearly be seen as a free rotator allowing the application of the established FRET data evaluation.

INTRODUCTION

In life sciences, the fundamental principle of fluorescence resonance energy transfer (FRET) is widely applied to study macromolecules, especially with respect to their intra- and intermolecular interactions (*1*−*4*). In clinical diagnostics, FRET-based immunoassays successfully compete with radio immunoassays, and moreover, biochemical processes can even be investigated on a single molecule level making use of this principle (*5*−*8*). Due to increasing demand and the growing number of applications in life sciences and medical application, there is an ongoing search for novel dyes with tailor-made spectroscopic properties to create FRET systems with special characteristics (e.g., making use of dyes absorbing and emitting in the far-red to NIR spectral range in order to minimize disturbances arising from biological samples) (*9*−*13*). Depending on the analytical problem to be solved, different FRET systems are required (*14*). In order to use FRET-based analysis as a "molecular ruler", well-characterized reference systems are needed showing under "working conditions" a clear relationship between the distance of donor−acceptor and the resulting FRET efficiencies.

For a specific donor−acceptor (D/A) pair, the Förster radius R_0 determines the working range with respect to analytically accessible distances between donor (D) and acceptor (A). As a rule of thumb, a specific D/A pair can be used for distance determinations within a range of $R_0/2 < R < 2R_0$. Therefore, for a powerful tailor-made FRET system two aspects are of major importance: (i) The spectroscopic properties of the D and A dye molecules need to be matched in order to adjust R_0 to the required needs, and (ii) from a synthetic point of view, an easy and robust labeling protocol should allow an exact (strategic) positioning of the dye molecules in the macromolecular system under investigation. With respect to (i), major prerequisites are a high donor fluorescence quantum yield Φ_D, a large molar extinction coefficient ε_A of A and an intensive spectral overlap between the emission spectrum of D and the absorption spectrum of A (*15*). In addition to matching the spectroscopic properties, an important factor is the relative orientation of the transition dipole moments of D and A (*16*−*18*). Coupling to a macromolecule may influence the overall performance of a D/A pair due to changes in the spectroscopic properties and/or due to limitations in the rotational freedom of the dyes. The latter may arise from specific interactions between the dye molecules and the macromolecule (e.g., H-bonding) and has to be considered by adapting the orientation factor κ in the calculations properly. In addition, at short D/A distances additional dye−dye quenching may occur, which needs to be accounted for (*19*).

In the past, polyprolines with different numbers of proline units as well as DNA fragments with a variable number of base pairs were used as scaffold. Double-stranded DNA fragments show a clear relationship between the number of base pairs (bp) and overall length with a large persistence length of about 50 nm (*16*, *17*, *19*−*23*). In contrast, polypeptides may build secondary and even ternary structures depending on the peptide sequence making their use as reference systems, in which a systematic variation of the separation between donor and acceptor is desired, more demanding, e.g., additional information from complementary analytical techniques such as X-ray structure analysis may be needed to determine the molecular distances. It turned out that in solution model systems based on polyproline spacers are not completely rigid, leading to deviations between calculated and measured values for R_0 (*24*). Subsequently, the observed distance distribution of D and A may limit the overall spatial resolution of the FRET system, and proper calibration factors such as for the sequence-dependent bending of the DNA sequence are needed to correctly estimate D/A distances (*16*−*18*).

For dyes attached to DNA, intercalation of the dye molecule or other specific binding interactions (such as H-bonding) between dye and DNA are of major concern (*18*, *25*). In order to minimize limitations due to rotational hindrance of the donor and acceptor dyes, flexible linker entities were suggested (*26*, *27*). FRET pairs consisting of dyes like tetramethylrhodamine, Cy3, or R6G have already been applied in DNA as donors in combination with Cy5 or JA133 as acceptor (*19*, *28*, *29*).

In the present paper, a FRET system based on a carbostyril (quinolin-2(1*H*)-one) chromophore as donor and a (bathophenanthroline)ruthenium(II)-complex as acceptor (Figure 1) bound to double-stranded DNA was systematically character-

ized. Feasibility studies for the FRET system were first carried out in peptides (*30*, *31*) and later also in synthetic DNA (*32*, *33*). In comparison to other FRET systems, this D/A pair has several benefits. The donor is very robust with respect to its chemical stability and can be directly incorporated as a building block into DNA during its automated assembly on solid support allowing exact positioning within any desired DNA sequence.

The acceptor (**2**) can be coupled to the donor-labeled DNA on solid support directly after synthesis via an amide bond formation (*33*). The Ru-complex (**2**) outmatches other reported acceptors due to its thermodynamic stability, its chemical inertness, its straightforward synthetic accessibility (*34*), and the possibility of time-gated detection as a result of the long luminescence decay time (*34*−*38*).

The unique combination of chemically robust dye-labeled building blocks and remarkable spectroscopic properties of the FRET system prompted us to perform a detailed study concerning synthetic DNA, in which the distance between donor and acceptor was systematically varied by the number of separating base pairs. On the basis of the evaluation of the donor as well as acceptor related emission, the energy transfer efficiencies (D/A separations) were determined and compared to a well-established model for DNA distance calculations evaluating under "working conditions" the "molecular ruler" properties.

MATERIALS AND METHODS

In the present study, 13 different DNA fragments **3**−**15** all bearing the Ru-complex (A) at the 5′-end and the carbostyril donor (D) at different distance intervals defined by the number of separating base pairs (Δbp) between donor and acceptor were prepared (Figure 2). In addition, we have also prepared the complementary sequences **16**−**21**. Due to the attachment of A at the 5′-position of 2′-deoxyuridine, the hybridization to the complementary strand is not hampered.

General. Oligonucleotide syntheses were carried out on an Expedite 8909 Nucleic Acid Synthesis system on a 1 μmol scale using phosphoramidite chemistry and standard protocols. Phosphoramidites as well as nucleosides coupled to solid support (CPG) were obtained from Proligo/Sigma Aldrich. Cleavage of the modified and unmodified oligonucleotides from the solid support and deprotection was performed by a 25% NH-solution followed by vortexing overnight at room temperature. After exchanging NH_4^+ with K^+, the oligonucleotide samples were desalted by size exclusion chromatography using NAP-10 columns. Purification of the modified oligonucleotides was performed by preparative polyacrylamide gel electrophoresis (PAGE). The oligonucleotides were visualized at 366 nm, and bands containing the desired DNA were isolated and extracted with water. The resulting oligonucleotide samples were again desalted on NAP-10 columns. All oligonucleotides were analyzed by analytical PAGE after staining with Stains-All (Fluka). Quantification was done by UV-measurements on a Perkin-Elmer-Lambda-35-UV/Vis spectrometer. H, C, and P NMR spectra were measured on AC 250, AM 400, and DRX 500 from Bruker, as well as a Mercury VX 300 from Varian using $CDCl_3$, CD_3CN, or d-DMSO as solvent. Column chromatography was performed on silica gel type 60 ACC 35−70 μm.

Compounds **22** and **23** were synthesized according to ref *33*. Spectroscopic data were in accordance to literature data (*32*, *33*).

Synthesis of Modified Oligonucleotides 3−**15.** The two modified building blocks **22** and **23** (67 μmol/mL in MeCN) were incorporated during automated synthesis using standard cycles. For the attachment of the Ru-complex **2**, the MMT-protecting group was cleaved after complete assembly on the synthesizer using standard detritylation conditions. Then, a mixture of HBTU (54.6 mg, 143 μmol), HOBT (24.5 mg, 181 μmol), and Ru-complex **2** (50.8 mg, 42.4 μmol) was dissolved in DMF (960 μL) followed by the addition of DIEA (65.6 μL). After vortexing for 10 min, it was added to the DNA attached to the solid support (16 mg, ∼0.4 μmol) in an Eppendorf reaction vessel (*39*). The slurry was slowly shaken at room temperature overnight. After removal of the supernatant, the solid support was washed with DMF (2 × 1 mL) and MeCN (2 × 1 mL). Cleavage from solid support and deprotection was performed according to standard protocols. Purification was done by preparative gel.

Hybridization (Preparation of FRET Constructs). To the donor and acceptor-labeled DNA (0.1 OD in 1 μL H_2O), 1.3 equiv. of the corresponding unmodified DNA-strand (0.1 OD in 1 μL H_2O) were added and the solvent removed in vacuum. The precipitate was dissolved in phosphate buffer (5 mM, pH 7) and thermal hybridization was performed by heating the sample to 90 °C for 2 min and then cooling it slowly to room temperature yielding dye-labeled double-stranded DNA (FRET constructs).

Photophysical Characterization. The absorption and fluorescence spectra were recorded on a Lambda 750 UV/Vis spectrometer (Perkin-Elmer) and a Fluoromax3 spectrometer (Jobin Yvon). In the time-resolved emission measurements, the frequency doubled output (second harmonic generation, SHG) with a vertical polarization plane of a Titan sapphire laser (Tsunami 3960; Spectra Physics; $\lambda_{TiSa} = 720$ nm, $\lambda_{SHG} = 360$ nm, pulse width (fwhm) 120 fs) was used for excitation. The repetition rate of 80.2 MHz was reduced to 4 MHz to 50 kHz with a Pulse Picker (Pulse Select; APE). The luminescence was detected in a right angle configuration to the incoming beam. The emission polarizer was set to 0°, 90°, and 55° with respect to the polarization plane of the laser. For the detection, a multichannel plate (ELDI EM1−132/300; Europhoton GmbH) coupled to a FL920 fluorescence lifetime spectrophotometer (Edinburgh Instruments) was used. The time-resolved emission was recorded in the time-correlated single photon counting

mode. The fluorescence quantum yields were measured on a PL Quantum Yield measurement system C9920−02 with an integrating sphere (Hamamatsu, Japan).

Data Analysis. For the energy transfer efficiency E, the distance R_{DA} between D and A is of fundamental importance. For DNA, the distance R_{DA} at different Δbp can be calculated according to eq 1 (*40*). In this model, the geometrical parameters of a B-form double-stranded (ds) DNA helix in solution are applied (diameter 20 Å, 3.4 Å rise, and 36° turn per base pair) to calculate R_{DA}.

$$Q = L_D^2 + L_A^2 - 2L_D L_A \cos(\Omega + 36\Delta\text{bp})$$

$$R_{DA} = \sqrt{(K + 2.4\Delta\text{bp})^2 + Q} \tag{1}$$

In eq 1, Δbp represents the number of base pairs separating D and A, K is the theoretical relative distance of D and A in the case in which both dyes are attached to the same base (Δbp = 0). L_D and L_A are the distances between the dyes and the helical axis for D and A, respectively. Ω is the interdye angle for Δbp = 0.

On the basis of eqs 2 and 3, the critical Förster distance R_0 [Å] was calculated from experimental spectroscopic data.

$$R_0^6 = \frac{(9000 \ln 10)\kappa^2 \Phi_D}{128\pi^5 n^4 N_A} J(\lambda) \tag{2}$$

$$J(\lambda) = \int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 \, d\lambda \tag{3}$$

In eq 2, Φ_D is the fluorescence quantum efficiency of D, and κ^2 represents the orientation factor describing the relative orientation of the transition dipole moments of emission and absorption for D and A, respectively. The refractive index of the solvent is taken into account by n. $J(\lambda)$ is the spectral overlap integral calculated from the area-normalized fluorescence spectrum of D and the absorption spectrum of A (see eq 3).

Using eq 1, the mean distance R_{DA} of D and A for each FRET construct can be calculated. In addition, theoretical energy transfer efficiencies E_{theo} were calculated using eqs 4 and 1 to fit experimentally obtained E_{exp} based on the measured emission data (vide infra).

$$E_{theo} = \frac{1}{1 - \left(\frac{R_{DA}}{R_0}\right)^6} \tag{4}$$

The experimental energy transfer efficiencies E_{exp} were determined from the following equations.

(i). Donor Fluorescence Signal. On the basis of eq 5:

$$E_{exp,D} = 1 - \frac{I_{DA}}{I_D} \tag{5}$$

In eq 5, I_{DA} is the fluorescence signal of D in the presence of A and I_D in the absence of A.

(ii). Ratio Method. According to eq 6 introduced and applied by Clegg et al. from the fluorescence excitation spectra (*20, 40−43*)

$$E_{exp,D} = 1 - \frac{F_{ex,D}(\lambda_{em,D})}{F_{ex,A}(\lambda_{em,A})} \cdot \frac{\varepsilon_A(\lambda_A)}{\varepsilon_D(\lambda_D)} \tag{6}$$

where $F_{ex,D}$ and $F_{ex,A}$ are the emission signals in the excitation spectrum (for D in the spectral range of 325 nm < λ_{ex} < 415 nm at λ_{em} = 435 nm and for A in the spectral range of 410 nm < λ_{ex} < 600 nm at λ_{em} = 620 nm), ε_D and ε_A are the molar extinction coefficients of D and A at their respective absorption maxima.

(iii). Increased Acceptor and Decreased Donor Emission (44).

$$E_{exp,A} = \frac{I_A}{I_D + \frac{\Phi_A}{\Phi_D} I_A} \tag{7}$$

In eq 7, I_A is the fluorescence of the acceptor corrected for contribution from direct excitation, I_D the fluorescence of the donor (I_D, 375 nm < λ_{em} < 550 nm; I_A, 560 nm < λ_{em} < 690 nm), and Φ_D and Φ_A are the quantum yields of the donor and acceptor, respectively. $E_{exp,A}$ is often used to calculate the energy transfer efficiencies in single molecule experiments, but it has also been successfully applied to data of batch emission measurements (*28*).

Time-dependent fluorescence anisotropy measurements $r(t)$ were carried out to determine the rotational mobility of the donor dye in the FRET constructs. The anisotropy decay was calculated according to eq 8 by measuring the fluorescence decay with the emission polarizer set in a vertical ($I_{VV}(t)$) and horizontal ($I_{VH}(t)$) position relative to the excitation polarization (*45*).

$$r(t) = \frac{I_{VV} - I_{VH}G}{I_{VV} + 2I_{VH}G} \tag{8}$$

In eq 8, G is the instrumental correction factor and the subscipts V and H refer to the vertical or horizontal orientation of the polarizers for the excitation and emission. The G-value was determined according to ref *46*.

$$r(t) = \sum_n r_{0n}\, e^{-t/\varphi_n} \quad \text{with } n \leq 2 \tag{9}$$

The obtained anisotropy decay curves were fitted using eq 9, where r_{0n} and φ_n are the limiting anisotropy and decay times associated with the rotations of the dye (*27*). For the free donor, n was set to 1, and for donor−DNA construct, n was set to 2.

RESULTS AND DISCUSSION

Basic Spectroscopic Properties: Absorption, Emission, and Anisotropy. In the absorption spectra of the FRET constructs, the absorption maximum of the donor was found at $\lambda = 360$ nm, that of the acceptor at $\lambda = 450$ nm, and that of the oligonucleotides at $\lambda = 260$ nm, respectively. Compared to the parent compounds, the absorption spectra of D and A were not altered due to the covalent binding to DNA.

An advantage of this D/A pair is the complementary donor and acceptor absorption characteristics. The absorption maximum of D is located at the minimum of the acceptor absorption, resulting in a desired low direct excitation of A. Therefore, all samples were excited at $\lambda_{ex} = 355$ nm, corresponding to the absorption minimum of the Ru-complex (A).

The fluorescence spectra of the FRET constructs containing D and A show a "dual" fluorescence corresponding to the emission of the donor and acceptor part at $\lambda_{em} = 430$ nm and at $\lambda_{em} = 620$ nm, respectively. Figure 4 shows the fluorescence emission spectra of the FRET constructs with Δbp = 5, 9, 13, 19, and 28. Spectral shifts of neither the donor- nor the acceptor-related emission were observed for the FRET constructs. Especially, the fact that at small D−A distances (low Δbp) the emission spectra are free of spectral changes indicates that no strong electronic coupling between the electronic systems of D and A is operative. Weak electronic coupling is a prerequisite for the application of the FRET formalism. The emission curves intersect at a single point, which indicates a direct correlation between the decrease of donor fluorescence and the increase of acceptor fluorescence. This is also expected for FRET.

In contrast to the spectral characteristics, the emission intensities of the donor and acceptor fluorescence were strongly correlated with Δbp. With decreasing Δbp, the donor emission was decreased, and at the same time, for the corresponding acceptor fluorescence an increase was observed.

The fluorescence excitation spectra recorded at the emission wavelength of the acceptor ($\lambda_{em} = 620$ nm) show a distinct increase under indirect excitation at $\lambda_{ex} = 365$ nm of the Ru-complex (A) with decreasing Δbp (see Figure 5). It clearly shows that energy is transferred from the carbostyril (D) to the Ru-complex (A) and emphasizes the occurrence of FRET in the DNA constructs.

From time-resolved anisotropy measurements of the free donor dye, a rotational correlation time φ_1 of about 0.5 ns was determined. For the corresponding DNA constructs, the donor anisotropy showed two rotational correlation times: $\varphi_1 \approx 0.5$ ns and $\varphi_2 \approx 7$ ns (see Table 1). φ_1 and φ_2 can be tentatively attributed to the rotation of the donor itself and to the overall rotation of the donor-DNA strand (*47*). For the acceptor, anisotropy measurements were not performed because of its very long luminescence decay time (τ_A in degassed aqueous solution was determined to be 5 μs (*48*)) rendering anisotropy measurements meaningless, since the rotation of A as well as the DNA strands occurs on a much shorter time scale (few nanoseconds or less; see Table 1).

Determination of FRET Parameters. An important parameter for the evaluation of a D/A FRET pair is the critical Förster distance R_0 (see eqs 2 and 3). The fluorescence spectrum of the carbostyril (D) and the absorption spectrum of the Ru-complex (A) show a large spectral overlap, which is a prerequisite for a large R_0. In Figure 6, the absorption spectrum $\varepsilon_A(\lambda)$ and the area normalized (area = 1) fluorescence spectrum F_D are shown. On the basis of the experimental spectral data, a spectral overlap integral $J = 1.05 \times 10^{15}$ l·mol^{-1}·cm^{-1}·nm^4 was calculated. Using a value of $\Phi_D = 0.17$ for the donor fluorescence quantum efficiency, the refractive index of water ($n = 1.4$), and setting the orientation factor $\kappa^2 = 2/3$, the $R_{0,spec} = (37 \pm 3)$ Å was calculated according to eq 2.

From the fluorescence emission and excitation spectra the FRET efficiencies $E_{exp,D}$ and $E_{exp,A}$ were determined according to methods (i)−(iii) (vide supra). The data sets of the donor-based $E_{exp,D}$ and acceptor-based $E_{exp,A}$ show the same dependency on Δbp (see Figure 7). After a first increase of the experimentally observed energy transfer efficiency upon increasing Δbp up to 7, E_{exp} decreases at larger Δbp. The comparison between $E_{exp,D}$ and $E_{exp,A}$ shows a small difference with respect to the corresponding uncertainties of the data. Especially at larger Δbp, an increase in the experimental error of the determined energy transfer efficiencies is found and can be attributed to the increasing relative contribution of noise for

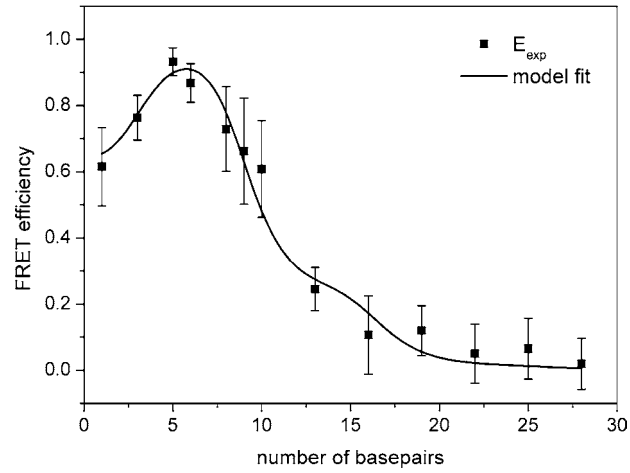

Figure 8. Experimental and theoretical FRET efficiencies (according to eq 4 with $R_{DA,cal}$ from eq 1). From the data analysis, the following parameters were obtained: $L_A = (4 \pm 1)$ Å, $L_D = (28 \pm 1)$ Å, $K = (-13 \pm 2)$ Å, and $\Omega = (134 \pm 15)$, respectively.

decreasing signals. For the acceptor signal, this is more effective because of a lower absolute signal and also because of smaller absolute changes in the signal intensity.

From eq 1, the absolute distances between D and A (see Figure 7, top *x*-scale) can be determined. It can be seen that the observed energy transfer efficiency depends on the absolute number of base pairs between D and A (Δbp) as well as the relative orientation between D and A in space (same or opposite side of the DNA helix), which can be concluded from the comparison of the experimentally determined and calculated data based on the model. In Figure 8, experimentally determined FRET efficiency E_{exp} calculated as an average of all $E_{exp,X}$ (X = A, D) and theoretically expected efficiencies E_{theo} are compared. The latter were calculated using eq 1 for the determination of the theoretical distance between D and A assuming an ideal DNA helix and transforming those distances subsequently into an energy transfer efficiency based on eq 4. In the calculation, the Förster distance R_0 determined from the spectral data was used and the parameters K, L_D, L_A, and Ω were varied to fit the model to the experimental FRET efficiencies. It can be seen that the experimental data can be nicely fitted with the model, especially at distances $R_{DA} \leq R_0$ ($\Delta bp \leq 10$). At larger R_{DA} (Δbp), the differences between experimentally determined and model-based FRET efficiencies become larger.

It is striking that in the beginning—with increasing numbers of separating base pairs—an increase of the energy transfer efficiency is observed, which—after passing a maximum at around $\Delta bp = 7$—is decreasing again for larger Δbp. This trend, which is also predicted by the model, can be attributed to the turn of the DNA helix. The "in-space" distance between D and A is dependent on their relative position with respect to each other. In the case in which D and A are on the same side of the DNA helix, a shorter overall distance is expected compared to a situation in which D and A are located at opposite sides. Hence, due to the turn of the DNA helix a damped sinusoidal oscillation of the energy transfer efficiency with a maximum every $\Delta bp = 10$ (for a full turn of the DNA helix, ten base pairs are required) is predicted by the model.

From the fitted parameters, Ω is especially intriguing, as it represents an interdye angle. From the data fitting, a Ω-value of $(134 \pm 15)°$ was obtained. This interdye angle may explain that for the FRET constructs the maximum energy transfer efficiency is observed around $\Delta bp \approx 5$, which corresponds to a situation of D and A aligned on the same side of the DNA strand.

The applied model also predicts a small second maximum for E at $\Delta bp \approx 16$ (next full turn of DNA helix), which is not

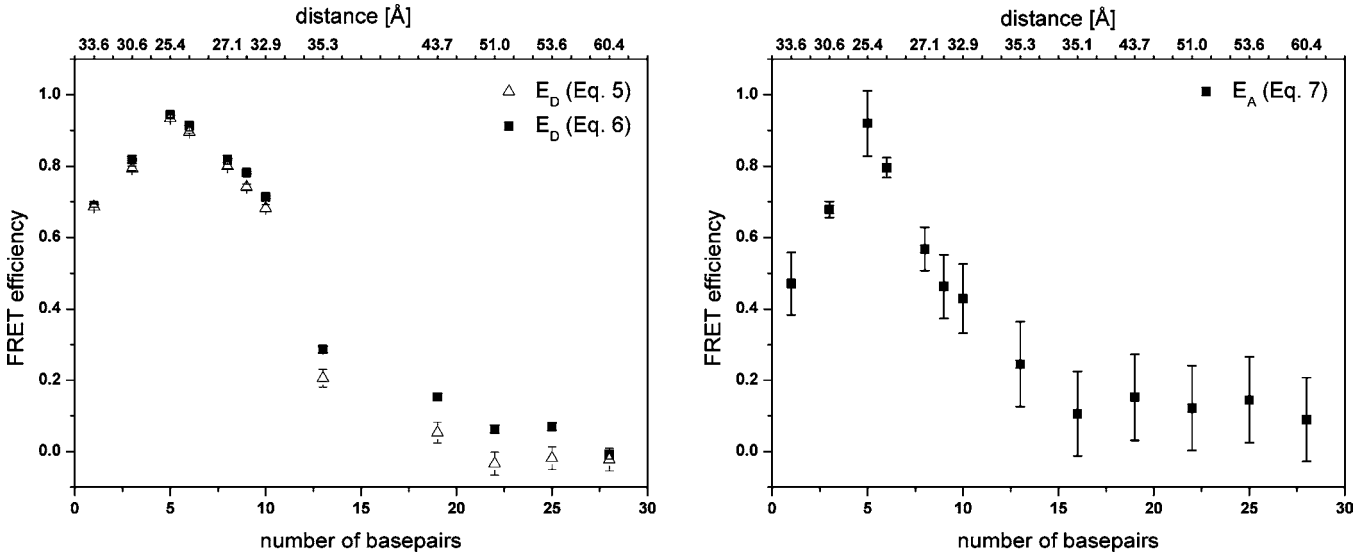

Figure 7. Experimental FRET efficiencies for donor (left) and acceptor (right) at increasing numbers of separating base pairs (Δbp).

found in the experimental data. Here, the increasing uncertainty of the determined energy efficiencies at large distances ($R \geq 2R_0$) may be seen as an explanation. For such large distances between D and A, only minor changes in the donor fluorescence due to very low FRET efficiencies are expected, making the exact determination of E rather challenging.

The setting of the orientation factor $\kappa^2 = 2/3$ is often used in distance calculations, but has been questioned especially for dyes bound to macromolecules, since in this case, the rotational motion of D and/or A can be hindered due to interactions such as H-bonding between the dye and the macromolecule. In these cases, κ^2 may differ from 2/3. As a consequence, the expected and measured energy transfer efficiencies (and subsequently the distances) can be significantly different. For the FRET constructs, setting κ^2 to 2/3 seems to be a good approximation judged by the fit according to eq 4 (see Figure 8) and by the results of the time-resolved anisotropy measurements (see Table 1). Both results strongly suggest that the donor when attached to the DNA is free to rotate and is not hindered due to specific dye−DNA interactions. The acceptor is attached to the 5′-end of the DNA, and due to the excellent agreement between model and experimental data, it seems reasonable to assume that it is also not hindered in its rotational motion.

CONCLUSION

The FRET system, based on a carbostyril (quinolin-2(1*H*)-one) chromophore as donor and the (bathophenanthroline)ruthenium(II) complex as FRET acceptor attached to double-stranded DNA fragments with different separating base pairs between D and A, was characterized with respect to its photophysical properties. The distance dependency of the energy transfer efficiencies for different Δbp was experimentally determined and could be well-described by a model, which considers the turn of the DNA helix as well as the relative orientation of D and A. It was shown that, for small numbers of separating base pairs (Δbp < 5), a decrease in the experimental energy transfer efficiency was observed. Such a phenomenon was described in earlier publications, and additional quenching of the donor emission for short D/A distances due to specific interactions was suggested (*28*), e.g., the dyes are hindering each other at short D−A distances, thereby limiting the free rotation (which may result in $\kappa^2 \neq 2/3$). However, in the present work it is shown that for the FRET constructs the distance dependence of FRET is well-described by taking into account Δbp as well as the relative positions of D and A in space (by the angle Ω between D and A). Moreover, anisotropy measurements support the assumption that no hindrance of the free rotation for the donor is present for the FRET constructs. Our results show that such FRET constructs are well-suited to serve as a construction kit in the design and characterization of novel FRET pairs. Distances between D and A can be tailor-made by adjusting Δbp and taking the operative in-space distance into account. The latter can be predicted and calculated using eq 1.

The difference between model and experimental data especially at large D/A distances ($R_{DA} < 2R_0$) also demonstrate the need for advanced FRET systems. The "simple" approach of maximizing R_0 will make the system "blind" at shorter distances. In more sophisticated concepts, two FRET systems are coupled; here, an acceptor serves as the donor for the second (triple-color FRET). In such systems, the potential of high spatial resolution at short and medium distances is retained, while the sensing of larger distances is improved. Work is in progress to implement such a multichromophor FRET system for DNA analysis using the carbostyril and the (bathophenanthroline)ruthenium(II)-unit as central building blocks.

Radiofluorinated Rhenium Cyclized α-MSH Analogues for PET Imaging of Melanocortin Receptor 1

Gang Ren, Shuanlong Liu, Hongguang Liu, Zheng Miao, and Zhen Cheng*

Molecular Imaging Program at Stanford (MIPS), Department of Radiology and Bio-X Program, Canary Center at Stanford for Cancer Early Detection, Stanford University, Stanford, California, 94305-5344, United States. Received September 1, 2010; Revised Manuscript Received October 18, 2010

In order to accomplish *in vivo* molecular imaging of melanoma biomarker melanocortin 1 receptor (MC1R), several α-melanocyte-stimulating hormone (α-MSH) analogues have been labeled with *N*-succinimidyl-4-^{18}*F*-fluorobenzoate (^{18}F-SFB) and studied as positron emission tomography (PET) probes in our recent studies. To further pursue a radiofluorinated α-MSH peptide with high clinical translation potential, we utilized 4-nitrophenyl 2-^{18}*F*-fluoropropionate (^{18}F-NFP) to radiofluorinate the transition metal rhenium cyclized α-MSH metallopeptides for PET imaging of MC1R positive malignant melanoma. Metallopeptides Ac-d,Lys-ReCCMSH(Arg^{11}) (two isomers, namely **RMSH-1** and **RMSH-2**) were synthesized using conventional solid phase peptide synthesis chemistry and rhenium cyclization reaction. The two isomers were then conjugated with ^{19}F-NFP or ^{18}F-NFP. The resulting cold or radiofluorinated metallopeptides, **$^{18/19}$F-FP-RMSH-1** and **$^{18/19}$F-FP-RMSH-2**, were further evaluated for their *in vitro* receptor binding affinities, *in vivo* biodistribution, and small-animal PET imaging properties. The binding affinities of **^{19}F-FP-RMSH-1** and **^{19}F-FP-RMSH-2** were determined to be within low nanomolar range. *In vivo* studies revealed that both ^{18}F-labeled metallopeptides possessed good tumor uptake in the B16F10 murine model with high MC1R expression, while possessing much lower uptake in A375M human melanoma xenografts. Moreover, **^{18}F-FP-RMSH-1** displayed more favorable *in vivo* performance in terms of higher tumor uptake and much lower accumulation in the kidney and liver, when compared to that of **^{18}F-FP-RMSH-2** at 2 h postinjection (p.i.). **^{18}F-FP-RMSH-1** also displayed lower liver and lung uptake when compared with that of the same peptide labeled with ^{18}F-SFB (named as **^{18}F-FB-RMSH-1**). Small animal PET imaging of **^{18}F-FP-RMSH-1** in mice bearing B16F10 tumors at 1 and 2 h showed good tumor imaging quality. As expected, much lower tumor uptake and poorer tumor/normal organ contrast were observed for A375M model compared to those of the B16F10 model. **^{18}F-FP-RMSH-1** also exhibited higher tumor uptake and better tumor retention when compared with **^{18}F-FB-RMSH-1**. **^{18}F-FP-RMSH-1** demonstrates significant advantages over **^{18}F-FB-RMSH-1** and **^{18}F-FP-RMSH-2**. It is a promising PET probe for imaging MC1R positive melanoma and MC1R expression *in vivo*.

INTRODUCTION

The incidence of malignant melanoma in western countries has kept increasing in the last two decades. According to the National Cancer Institute, there will be an estimated 68,000 new cases and 8,650 deaths in the United States in 2010. Although melanoma represents only 5% of all skin cancer subtypes, it contributes to more than 50% of deaths related to skin cancer (*1, 2*). Melanoma is an aggressive disease with high metastatic potential and resistance to cytotoxic agents. Currently, early diagnosis and accurate staging of melanoma remain crucial for the improvement of management of melanoma patients (*3, 4*).

Melanocortin type 1 receptor (MC1R[1]) is a G-protein coupled receptor and has been found to be overexpressed in many types of murine and human melanomas, making it an attractive target for receptor based melanoma imaging and therapy (*5, 6*). Over the last two decades, a wide variety of alpha-melanocyte-stimulating hormone (α-MSH) peptides have been developed and extensively studied for MC1R targeted melanoma imaging and treatment (*7, 8*). To date, two classes of α-MSH analogues have shown the most promising results for *in vivo* targeting of MC1R positive melanoma. One class is the linear α-MSH, Ac-Nle-Asp-His-d,Phe-Arg-Trp-Gly-Lys-NH_2 (referred to as NAPamide) and its analogues (*9*−*12*); the other is transition metal rhenium cyclized α-MSH, ReO[Cys^{3,4,10}, d,Phe^{7}, Arg^{11}]α-MSH_{3-13} [referred to as ReCCMSH(Arg^{11})] based metallopeptides (*13*−*18*).

In our previous research, both NAPamide and ReCCMSH(Arg^{11}) analogues had been synthesized and radiolabeled with a well-established radiofluorination synthon, *N*-succinimidyl-4-^{18}F-fluorobenzoate (^{18}F-SFB), for positron emission tomography (PET) imaging of melanoma (*12, 19*). The resulting ^{18}F-probes exhibited good tumor imaging contrast as early as 1 h postinjection (p.i.) in B16F10 tumor mouse models. Compared with ^{18}F-SFB labeled NAPamide, ^{18}F-SFB conjugated ReCCMSH(Arg^{11}) peptides displayed higher tumor uptake and retention, suggesting the advantages of rhenium cyclized CCMSH(Arg^{11}) as a scaffold for developing MC1R PET imaging agents (*19*). Overall, these pioneer studies highlight that ^{18}F-SFB labeled α-MSH peptides can efficiently target malignant melanoma with overexpression of

MC1R in mice and that they can be promising candidates for MC1R targeted melanoma PET imaging.

However, ^{18}F-SFB conjugated ReCCMSH (Arg^{11}) peptides also show moderate liver and lung uptake and relatively high uptake in the gallbladder, which is unfavorable for clinical translation (*19*). In this research, we aimed to further optimize the *in vivo* behavior of ^{18}F labeled α-MSH metallopeptides for melanoma PET imaging. 4-Nitrophenyl-2-[^{18}F]fluoropropionate (^{18}F-NFP) is a small prosthetic group with less hydrophobicity and has been widely used for the radiofluorination of many peptides (*20*). The ^{18}F-NFP conjugated galacto-RGD peptide has even been evaluated in patients of different solid tumors for tumor angiogenesis imaging (*21*−*23*). The promising results suggested NFP as an attractive labeling moiety. Herein, we report the radiosynthesis of ^{18}F-NFP labeled Ac-d,Lys-ReCCMSH(Arg^{11}) peptides (two isomers, abbreviated as **RMSH-1** and **RMSH-2**, respectively) (Figure 1). The resulting probes **^{18}F-FP-RMSH-1** and **^{18}F-FP-RMSH-2** were then evaluated in C57BL/6 mice bearing subcutaneous murine B16F10 melanoma tumors with high levels of the MC1R and Foxn1 nude mice bearing human A375M melanoma with low levels of the MC1R.

MATERIALS AND METHODS

General. ^{125}I-(Tyr^2)-[Nle^4,D-Phe^7]-α-MSH [^{125}I-(Tyr^2)-NDP] was purchased from Perkin-Elmer (Waltham, MA). All N-α-Fmoc-protected amino acids were purchased from Advanced Chemtech (Louisville, KY). Dimethylformamide (DMF) and methylene chloride were from Fisher Scientific (Fair Lawn, NJ). Piperidine (20%) in DMF and 0.4 M *N*-methylmorpholine in DMF were from Protein Technologies Inc. (Tucson, AZ). Trifluoroacetic acid (TFA), *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluoro-phosphate (HBTU), and 4-(2′,4′-dimethoxyphenyl-Fmoc-aminomethyl)-phenoxy resin **(**Rink amide resin LS, 100−200 mesh, 1% DVB, 0.2 mmol/g) were from Advanced Chemtech. Pyridine, acetic anhydride, acetic acid, and anhydrous ether were from J.T.Baker (Phillipsburg, NJ). Triisopropylsilane (TIPS), *N*,*N*′-diisopropylethylamine (DIPEA), and 1,2-ethanedithiol (EDT) were purchased from Sigma-Aldrich (Milwaukee, WI). High performance liquid chromatography (HPLC) grade acetonitrile (CH_3CN) and Millipore 18 mΩ water were used for peptide purifications. 4-Nitrophenyl 2-fluoropropionate (^{19}F-NFP) was synthesized as previously reported (*24*). All other standard synthesis reagents were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). All the other general materials (cell lines, mice, etc.) and instruments [reverse phase HPLC, radioactive dose calibrator, and electrospray ionization mass spectrometry (ESI-MS), or matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS)] are the same as previously reported (*12*). The A375M cell line was a generous gift from Dr. M. Kolodny, University of California, Los Angeles, CA, and B16/F10 murine melanoma cells were obtained from American Type Tissue Culture Collection (Manassas, VA). C57BL/6 and Fox Chase SCID mice were purchased from Charles River Laboratories (Boston, MA).

Synthesis of RMSH and ^{19}F-FP-RMSH. The rhenium cyclized metallopeptide, RMSH, was synthesized as previously reported using the Ac-d,Lys-CCMSH(Arg^{11}) peptide (amino acid sequence: Ac-kCCEHdFRWCRPV-NH_2) and rhenium-gluco-heptonate transchelation reaction (*19*). Two major products (isomers **RMSH-1** and **RMSH-2**) with identical molecular weights (MW) but different HPLC retention times were obtained. The reference standards **^{19}F-FP-RMSH-1** and **-2** were then prepared by a reaction of the metallopeptides with ^{19}F-NFP (*24*). Briefly, **RMSH-1** or **-2** (1 μmol) in DMSO (100 μL) was added to ^{19}F-NFP (5 μmol) in DMSO (100 μL), followed by the addition of DIPEA (5 μL). The mixture was heated at 60 °C for 2 h. After it cooled down to room temperature, the reaction solution was quenched by adding TFA (50 μL) and injected into a semipreparative HPLC for purification. The flow rate was 3 mL/min, with the mobile phase starting at 95% solvent A and 5% solvent B (0−3 min), going to 35% solvent A and 65% solvent B at 33 min, then going to 15% solvent A and 85% solvent B and maintaining this solvent composition for another 3 min (36−39 min), and returning to initial solvent composition after 42 min had elapsed. Fractions containing the product were collected, lyophilized, and characterized by ESI-MS or MALDI-TOF-MS.

Radiosynthesis of ^{18}F-FP-RMSH-1 and -2. The radiofluorination synthon, ^{18}F-NFP, was prepared on the basis of the procedure reported previously (*23*, *25*). ^{18}F-NFP (specific activity of 0.4−1.0 Ci/μmol or 14.7−37 GBq/μmol) dissolved in acetonitrile (100 μL) was then added to the peptide (**RMSH-1** or **-2**; 100 μg) dissolved in DMSO and reacted for 20 min at 60 °C. After adding TFA (50 μL) to quench the reaction, the reaction solution was injected into a semipreparative HPLC using the same elution gradient as the one used in the synthesis of cold **^{19}F-FP-RMSH** (**1** or **2**). The HPLC fractions containing the radiolabeled product were subsequently collected, combined, and evaporated with a rotary evaporator to dryness. The radiolabeled peptide was reconstituted in phosphate-buffered saline (PBS, 0.01 M, pH 7.4) and passed through a 0.22 μm Millipore filter into a sterile vial for *in vitro* and animal experiments.

***In Vitro* Cell Binding Assay.** B16F10 murine melanoma cells were cultured in Dulbecco's modified Eagle's high-glucose medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and penicillin and streptomycin. The cells were maintained at 37 °C in a 5% CO_2 humidified incubator. The receptor binding affinity studies of **^{19}F-FP-RMSH-1** and **-2** for the MC1R were performed using B16F10 cells. Briefly, 0.5×10^6 cells were resuspended in Dulbecco's modified Eagle's medium containing 25 mM HEPES, 0.2% BSA, and 0.3 mM 1,10-phenanthroline. The cells were then incubated at 37 °C for 90 min with either **^{19}F-FP-RMSH-1** or **-2** (peptide concentration varying from $10^{-12}-10^{-6}$ M) and approximately 40,000 counts per minute (cpm) of ^{125}I-(Tyr^2)-NDP. Cells were washed three times with ice-cold PBS, and the radioactivity of the cells was measured. Data was analyzed by Graphpad Prism 5.0 (Northampton, MA). The IC_{50} values, the concentration of competitor required to inhibit 50% of the radioligand binding, of the peptides were calculated.

Biodistribution Studies. All animal experiments were performed in compliance with a protocol approved by Stanford University Institutional Animal Care and Use Committee. Five- to six-week old male C57BL/6 mice were implanted with 1×10^6 B16F10 murine melanoma cells, and Foxn1 nude mice were inoculated with 3×10^6 A375M human melanoma cells in the right flank. When the diameters of the tumors reached around 8 mm, approximately 110−130 μCi (4.07−4.81 MBq) of **^{18}F-FP-RMSH-1** or **-2** was injected into each mouse through the tail vein. After injection of the radiotracer, the B16F10 mice ($n = 3$) were sacrificed at 1, 2, and 4 h p.i., while A375M ($n = 3$) mice were sacrificed at 2 h p.i. by carbon dioxide. Tumors, blood, and major organs of interest were harvested, weighed, and counted in a Wallac 1480 automated γ-counter (Perkin-Elmer, Waltham, MA). The radioactivity uptake in tumors and normal tissues was expressed as a percentage of the injected radioactive dose per gram of tissue (% ID/g).

Small-Animal PET Imaging Studies. PET imaging of tumor bearing mice was performed on a small-animal PET R4 rodent model scanner (Siemens Medical Solutions USA, Inc., Knoxville, TN). The mice bearing B16F10 or A375M tumors were injected with 110−130 μCi (4.07−4.81 MBq) of **^{18}F-FP-RMSH-1** or **-2** through the tail vein. At 1 and 2 h p.i., the mice were anesthetized with 2% isofluorane and placed in the prone position near the central field of view in the small-animal PET. Five-minute static scans were obtained, and images were reconstructed by a two-dimensional ordered subsets expectation maximum (OSEM) algorithm. Regions of interest (ROIs) were then drawn over the tumor or organ of interest on decay-corrected whole-body coronal images. The mean counts per pixel per minute were obtained from the ROI and converted to counts per milliliter per minute by using a calibration constant. By assuming a tissue density of 1 g/mL, the ROIs were converted to counts$\cdot g^{-1}\cdot min^{-1}$. An image ROI-derived % ID/g of tissue was then determined by dividing counts per gram per minute with injected dose (ID). No attenuation correction was performed.

Statistical Methods. Statistical analysis was performed using the Student's *t*-test for unpaired data. A 95% confidence level was chosen to determine the significance between groups, with $P < 0.05$ being significantly different.

RESULTS

Chemistry, Radiochemistry, and IC_{50}. The linear peptide, Ac-d,Lys-CCMSH(Arg^{11}), could react with rhenium-glucoheptonate to produce two major products (**RMSH-1** and **RMSH-2**) with same molecular weight (MW) and similar binding affinities to MC1R, which was reported previously (*19*). The nonradioactive fluorinated metallopeptides were then prepared by conjugation with cold ^{19}F-NFP to allow for characterization of the ^{18}F labeled counterparts. Under the HPLC gradient (5−65% over 30 min) used in the study, the retention times for **^{19}F-FP-RMSH-1** and **-2** were found to be 16.6 and 18.1 min, respectively (Figure 2). The desired products were purified by semipreparative HPLC (>90% yield and >95% purity) and characterized by MALDI-TOF-MS. For all of the metallopeptides prepared above, the measured MW was consistent with the expected MW: $m/z = 1878.1$ for $[M + H]^+$ ($C_{73}H_{104}FN_{23}O_{17}ReS_3$, calculated MW = 1878.2). The receptor binding assay showed that the IC_{50} values of **^{19}F-FP-RMSH-1** and **-2** were 6.1 and 33.7 nM, respectively (Table 1).

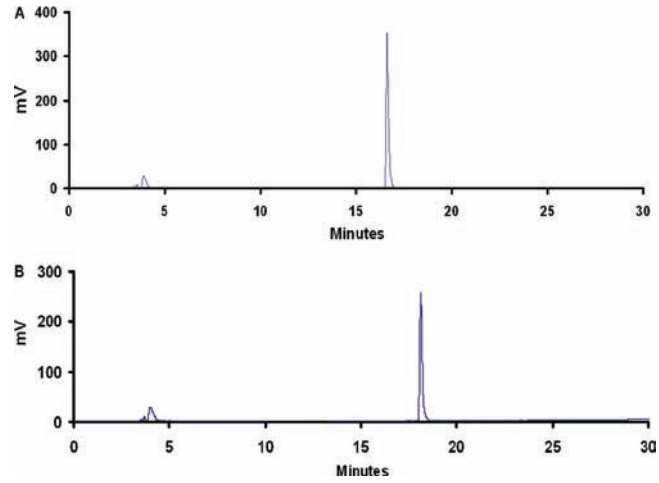

Figure 2. HPLC profiles of **^{19}F-FP-RMSH-1** (A) and **2** (B).

Table 1. IC_{50} Values of the Fluorinated α-MSH Analogues and Their Expected and Measured Molecular Weights (M.W.) for $[M + H]^+$ by ESI-MS or MALDI-TOF-MS

peptides	expected M.W.	measured M.W.	IC_{50} (nM)
^{19}F-FP-RMSH-1	1878.2	1878.1	6.1 ± 0.6
^{19}F-FP-RMSH-2	1878.2	1878.1	33.7 ± 3.0

Similarly, **^{18}F-FP-RMSH-1** and **-2** were prepared by the conjugation of **RMSH-1** or **-2** with the radioactive ^{18}F-NFP. On the basis of the retention times acquired from the nonradioactive fluorinated peptides, the radiofluorinated products were identified and collected using the same HPLC gradient. The total radiosynthesis time for making the radiopeptide took about 100 min. The decay-corrected radiochemical yields of **^{18}F-FP-RMSH-1** and **-2** were based on ^{18}F-NFP and were 12.0% ± 2.7% and 10.5% ± 1.8% ($n = 4$), respectively, at the end of synthesis (EOS). The radiochemical purities of the labeled peptides were over 95%, as verified by analytical radio-HPLC. Since the difference in retention times of radiolabeled and unlabeled peptide was greater than 1.5 min, the radiofluorinated **RMSH-1** and **-2** were easily separated from their nonradiolabeled counterparts by HPLC. The specific activity of the two **^{18}F-FP-RMSH-1** and **-2** were estimated to be ~20 GBq/μmol (decay corrected) on the basis of the labeling agent ^{18}F-NFP.

***In Vivo* Biodistribution of ^{18}F-FP-RMSH-1 and -2.** The *in vivo* biodistribution studies of both **^{18}F-FP-RMSH-1** and **-2** were examined in B16F10 murine allograft and A375M human xenograft melanoma bearing mice. As shown in Table 2, for **^{18}F-FP-RMSH-1**, the uptake in the B16F10 tumor with high expression of MC1R was 1.80 ± 0.18, 2.12 ± 1.08, and 1.09 ± 0.23% ID/g at 1, 2, and 4 h p.i., respectively, suggesting good tumor uptake and retention of this PET probe. **^{18}F-FP-RMSH-1** also displayed rapid blood clearance and low uptake in muscle, resulting in decent tumor/blood and tumor/muscle ratios (3.80 ± 0.89 and 9.36 ± 3.98, respectively) at 2 h p.i. It was also noted that **^{18}F-FP-RMSH-1** displayed a much lower

Table 2. Biodistribution Data for ^{18}F-FP-MSH-1 and -2 in C57BL/6 Mice Bearing Subcutaneously Xenotransplanted B16F10 Murine Melanoma and Foxn1 Nude Mice Bearing A375M Human Melanoma[a]

[a] Data were expressed as the mean ± SD, indicating the percentage administered activity (injected dose) per gram of tissue (%ID/g) after intravenous injection of 110−130 μCi (4.01−4.87 MBq) tracers ($n = 3$). $P < 0.05$ when compared with **^{18}F-FP-RMSH-1** at 2 h.

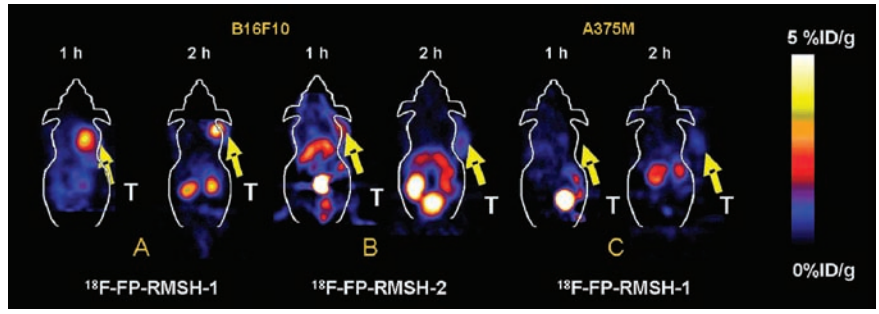

Figure 3. Representative decay-corrected coronal small-animal PET images of mice bearing B16F10 tumors on the right shoulder at 1 and 2 h after tail vein injections of **^{18}F-FP-RMSH-1** (A) and **-2** (B) ($n = 3$ for each group). T stands for tumor. (**C**) Representative decay-corrected coronal small-animal PET images of A375M tumor bearing mice at indicated time points after a tail vein injection of **^{18}F-FP-RMSH-1**.

uptake in the lung and liver (0.80 ± 0.03 and 0.78 ± 0.05, respectively) compared with **^{18}F-FB-RMSH-1** (*19*). Also compared with **^{18}F-FB-RMSH-1**, **^{18}F-FP-RMSH-1** showed lower kidney uptake in B16F10 tumor bearing mice ($P < 0.05$). The level of accumulation in the kidney was 8.82 ± 0.76 and 6.76 ± 0.82% ID/g at 1 and 2 h p.i., respectively, for **^{18}F-FP-RMSH-1**. For the A375M model, tumor uptake of **^{18}F-FP-RMSH-1** was only 0.84 ± 0.39% ID/g at 2 h p.i., which was significantly lower than that in B16F10 tumors ($P < 0.01$).

For **^{18}F-FP-RMSH-2**, the uptake in the B16F10 tumor model was 0.78 ± 0.10% ID/g at 2 h p.i., which was much lower than that of **^{18}F-FP-RMSH-1** ($P < 0.05$). Meanwhile, **^{18}F-FP-RMSH-2** showed much higher kidney uptake of 15.13 ± 0.88% ID/g at 2 h p.i. ($P < 0.05$). In addition, **^{18}F-FP-RMSH-2** demonstrated a higher uptake in the liver when compared to that of **^{18}F-FP-RMSH-1**. For other major organs including the lung, spleen, pancreas, and stomach, **^{18}F-FP-RMSH-2** exhibited an uptake similar to that of **^{18}F-FP-RMSH-1** ($P > 0.05$). Lastly, **^{18}F-FP-RMSH-2** revealed very low tumor uptake (0.63 ± 0.19% ID/g), but high uptake (13.45 ± 0.91% ID/g) was observed in the kidneys at 2 h p.i in the A375M tumor model.

Small-Animal PET Imaging. Small-animal PET imaging of mice bearing B16F10 using **^{18}F-FP-RMSH-1** and **-2** was performed, and the imaging results were compared (Figure 3A,B). Visual examination showed that **^{18}F-FP-RMSH-1** uptake in the tumor was higher than that of **^{18}F-FP-RMSH-2** at both 1 and 2 h p.i. Both probes showed moderate to high uptake in the liver and kidney. Further quantification analysis of small-animal PET images demonstrated that **^{18}F-FP-RMSH-2** had a much higher uptake in the kidney than that of **^{18}F-FP-RMSH-1** ($P < 0.01$) at 1 and 2 h p.i. (Figure 4). Improved quality of PET images was also observed at 2 h p.i. for **^{18}F-FP-RMSH-1**. On the basis of the above findings, **^{18}F-FP-RMSH-1** was selected as a PET probe for further evaluation.

^{18}F-FP-RMSH-1 was then imaged in the nude mice bearing A375M melanoma with low MC1R expression at 1 and 2 h (Figure 3C). Compared with B16F10 tumor bearing mice, much lower tumor uptake and poor tumor-to-background ratio were observed in A375M tumors at both time points. The A375M tumor was barely discernible, while high activity accumulation in kidneys was still observed.

DISCUSSION

It has been reported that overexpression of MC1R may correlate with the prognosis of malignant melanoma (*26*, *27*). Peptide based radioactive probes have been extensively studied for tumor receptor targeted imaging and therapy (*28*−*30*). Recently, a number of studies have also been performed to develop molecular probes that specifically target MC1R in melanoma (*12*, *19*). However, ^{18}F-SFB labeled **RMSH** has its own limitations such as suboptimal tumor uptakes and relatively high uptakes in the liver and lung. Thus, the major goal of this research is to study whether we can further optimize the *in vivo* profile of ^{18}F-labeled **RMSH** analogues by using a different

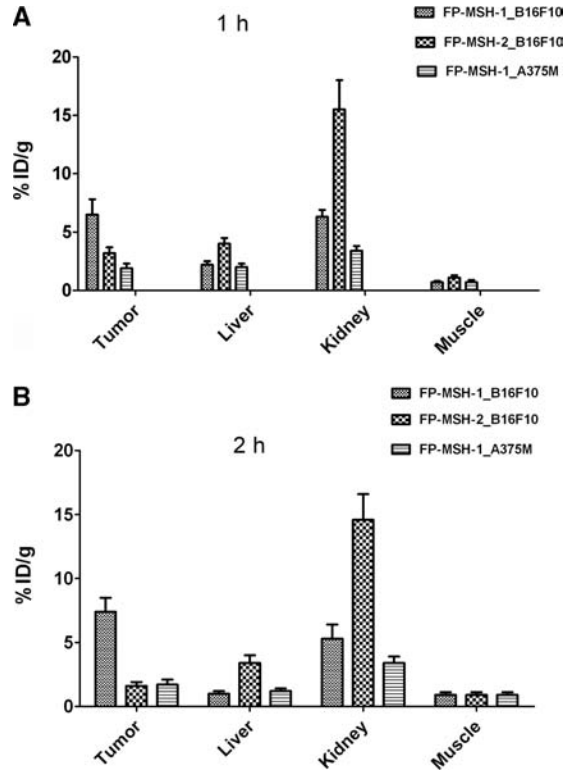

Figure 4. PET quantification of the tumor and other major organ uptakes derived from 1 (**A**) and 2 h (**B**) after tail vein injections of **^{18}F-FP-RMSH-1** or **-2**. Data are shown as the mean ± SD % ID/g ($n = 3$).

radiofluorination synthon, ^{18}F-NFP. The resulting PET probe, **^{18}F-FP-RMSH**, was also studied for its ability to image melanoma and differential MC1R expression in tumor mice models.

The two isomers of rhenium cyclized Ac-d,Lys-CCMSH-(Arg^{11}), **RMSH-1** and **-2**, were reproducibly formed in previous studies and proved to possess high MC1R binding affinity in the nanomolar (nM) range. Further modification of **RMSH** with the small prosthetic group ^{19}F-NFP only slightly reduced their affinities, as evidenced by *in vitro* cell binding assays (Table 1). The NFP conjugation to **RMSH** did not change the binding capability to B16F10 cells which overexpress MC1R. In addition, **^{19}F-FP-RMSH-1** displays much higher MC1R binding affinity than **^{19}F-FP-RMSH-2** (6.1 vs 33.7 nM), which is consistent with the study of the ^{19}F-SFB conjugated **RMSH** peptides (*19*). Since the affinities of both compounds are in the low nanomolar range and thus very encouraging, further *in vivo* evaluation of the ^{18}F-NFP labeled metallopeptides is warranted.

In biodistribution studies in the B16F10 tumor mice model, a higher tumor uptake of **^{18}F-FP-RMSH-1** can be observed compared to that of **^{18}F-FP-RMSH-2** along with much lower kidney and liver uptake for **^{18}F-FP-RMSH-1** at 2 h ($P < 0.05$). The higher tumor uptake with lower kidney uptake was further evidenced by small-animal PET imaging as well as quantification analysis of PET images. For **^{18}F-FP-RMSH-1**, B16F10 tumors are clearly delineated over the background at 1 and 2 h p.i., while **^{18}F-FP-RMSH-2** shows a much less prominent tumor uptake (Figure 3A,B). The quantification analysis of small-animal PET images further reveals significant differences in the tumor, liver, and kidney uptake between the two probes ($P < 0.01$) (Figure 4). **^{18}F-FP-RMSH-2** exhibits a much lower tumor uptake but higher kidney uptake than those of **^{18}F-FP-RMSH-1** at both 1 and 2 h in B16F10 tumor bearing mice. In the A375M model, the tumor uptake is low for both **^{18}F-FP-RMSH-1** and **-2**. Interestingly, the higher uptake in the liver and kidney for **^{18}F-FP-RMSH-2** compared with that of **^{18}F-FP-RMSH-1** ($P < 0.05$) may further suggest the different clearance time of these two isomers. Overall, **^{18}F-FP-RMSH-1** clearly displays more favorable *in vivo* properties, which suggests that it could be a better candidate for imaging MC1R *in vivo*.

^{18}F-FP-RMSH-1 exhibits longer retention times in the B16F10 tumor than all other normal organs but the kidney (Table 2). The tumor-to-blood and tumor-to-muscle ratios reach the highest levels at 4 h. More importantly, it is noticed that **^{18}F-FP-RMSH-1** displays high tumor-to-background ratios, for example, tumor-to-blood and tumor-to-muscle ratios at 4 h are 7.45 ± 0.69 and 16.97 ± 1.73, respectively. While for another two radiofluorinated α-MSH peptides reported previously, **^{18}F-FB-NAPamide** and **^{18}F-FB-RMSH-1**, their tumor-to-blood ratios at 4 h are only 3.60 ± 0.37 and 1.65 ± 0.11, respectively, and their tumor-to-muscle ratios at 4 h are 7.46 ± 2.68 and 5.24 ± 1.43, respectively (*12*, *19*). These increased tumor-to-background ratios as well as tumor residence time would make longitudinal observation of the malignant melanoma with overexpression of MC1R more feasible when using NFP conjugated **RMSH-1** as PET probes. For the A375M tumor model, the tumors are barely noticeable and show background uptake at 1 and 2 h p.i., when the mice were injected with **^{18}F-FP-RMSH-1** (Figure 3C). This low uptake is likely caused by nonspecific uptake. The better PET imaging quality in the B16F10 tumor compared to that in the A375M suggests that **^{18}F-FP-RMSH-1** could differentiate melanoma with different MC1R expression in living subjects.

More importantly, compared with previous ^{18}F-SFB conjugated **RMSH-1** (**^{18}F-FB-RMSH-1**) that possesses moderate lung and liver uptake in the B16F10 tumor model (*19*), **^{18}F-FP-RMSH-1** shows similar tumor uptake at 1 and 2 h, but the uptake gets significantly higher than that of **^{18}F-FB-RMSH-1** at 4 h ($P < 0.05$). The background uptake, particularly in the liver and lung, is much lower for **^{18}F-FP-RMSH-1**. Much higher tumor-to-blood and tumor-to-muscle ratios are also observed for **^{18}F-FP-RMSH-1** than that of **^{18}F-FB-RMSH-1**. Furthermore, the liver and lung uptakes are lower for **^{18}F-FP-RMSH-2** when compared with that of **^{18}F-FB-RMSH-2** in both models ($P < 0.05$). All of these observations highlight that different radiofluorination methods have significant impact in this metallopeptide's *in vivo* properties. Additionally, these observations further suggest that the uptake in the liver and lung are due to nonspecific accumulation.

Taken together, ^{18}F-NFP shows advantages over ^{18}F-SFB for labeling of **RMSH** peptides. Compared to **^{18}F-FB-RMSH-1**, **^{18}F-FP-RMSH-1** is more promising for translation into melanoma MC1R PET imaging in clinics. The relatively low liver and lung uptakes of **^{18}F-FP-RMSH-1** also validate the possibility of using it as a potential PET probe for the early detection of malignant melanoma metastasis in these regions. **^{18}F-FP-RMSH-1** seems by far the best radiofluorinated probe reported for imaging MC1R expression *in vivo*.

CONCLUSIONS

In summary, radiofluorinated rhenium cyclized α-MSH analogue, **^{18}F-FP-RMSH-1** and **-2**, were successfully synthesized. Their characteristics including binding affinities and *in vivo* profiles were investigated in this study. **^{18}F-FP-RMSH-1** demonstrates significant advantages over **^{18}F-FB-RMSH-1** and **^{18}F-FP-RMSH-2**. **^{18}F-FP-RMSH-1** displays favorable *in vivo* pharmacokinetics in MC1R overexpressing tumor mice models. It is a promising PET probe for imaging MC1R positive melanoma and MC1R expression *in vivo*.
