Comparison of Hydrazone Heterobifunctional Cross-Linking Agents for Reversible Conjugation of Thiol-Containing Chemistry

R. James Christie, Diana J. Anderson, and David W. Grainger*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523-1872. Received January 26, 2010; Revised Manuscript Received June 12, 2010

Reversible covalent conjugation chemistries that allow site- and condition-specific coupling and uncoupling reactions are attractive components in nanotechnologies, bioconjugation methods, imaging, and drug delivery systems. Here, we compare three heterobifunctional cross-linkers, containing both thiol- and amine-reactive chemistries, to form pH-labile hydrazones with hydrazide derivatives of the known and often published water-soluble polymer, poly[*N*-(2-hydroxypropyl methacrylamide)] (pHPMA), while subsequently coupling thiol-containing molecules to the cross-linker via maleimide addition. Two novel cross-linkers were prepared from the popular heterobifunctional cross-linking agent, succinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (SMCC), modified to contain either terminal aldehyde groups (i.e., 1-(*N*-3-propanal)-4-(*N*-maleimidomethyl) cyclohexane carboxamide, PMCA) or methylketone groups (i.e., 1-(*N*-3-butanone)-4-(*N*-maleimidomethyl) cyclohexane carboxamide, BMCA). A third cross-linking agent was the commercially available *N*-4-acetylphenyl maleimide (APM). PMCA and BMCA exhibited excellent reactivity toward hydrazide-derivatized pHPMA with essentially complete hydrazone conjugation to polymer reactive sites, while APM coupled only ∼60% of available reactive sites on the polymer despite a 3-fold molar excess relative to polymer hydrazide groups. All polymer hydrazone conjugates bearing these bifunctional agents were then further reacted with thiol-modified tetramethylrhodamine dye, confirming cross-linker maleimide reactivity after initial hydrazone polymer conjugation. Incubation of dye-labeled polymer conjugates in phosphate buffered saline at 37 °C showed that hydrazone coupling resulting from APM exhibited the greatest difference in stability between pH 7.4 and 5.0, with hydrolysis and dye release increased at pH 5.0 over a 24 h incubation period. Polymer conjugates bearing hydrazones formed from cross-linker BMCA exhibited intermediate stability with hydrolysis much greater at pH 5.0 at early time points, but hydrolysis at pH 7.4 was significant after 5 h. Hydrazones formed with the PMCA cross-linker showed no difference in release rates at pH 7.4 and 5.0.

INTRODUCTION

Recent developments in nanomaterials, biotechnology, and advanced drug delivery and imaging systems have prompted innovation of new molecular building blocks and methods to attach components together to achieve advanced materials with specific functionality. For polymer-based therapeutics, in particular, the benefits of conjugating drugs to water-soluble polymers are well-known and include the following: increased circulation half-life, reduced nonspecific activity, enhanced targeting ability, and physiological solubility (*1*). While these benefits provide strong incentives for use of polymers and new particle carriers in drug delivery, methods to chemically couple therapeutic and imaging agents to such carriers have been frequently inflexible and performance limiting. Yet, control and versatility of the chemistry used to couple molecules together is crucial to their function and purpose. Most therapeutic agents are best released from carriers at the desired physiological site of drug activity to be most effective, while retaining stability in circulation until the construct reaches its therapeutic target. Many cleverly designed coupling agents and cross-linkers have therefore been developed for stable covalent attachment under one set of conditions (i.e., normal circulation) and reversible uncoupling chemistries under other sets of conditions (*2*−*4*). That these chemistries reside in a single coupling agent that responds reliably to desired stimuli (e.g., local pH, thermal or optical gradients, enzymes, electrochemical or redox inputs) to couple and uncouple connected cargo is a challenging goal.

Strategies for site-specific nanoparticle- or polymer-based agent delivery often exploit biochemical conditions intrinsic to cell internalization and processing pathways to specifically release drug into the cellular cytoplasm (*5*). Polymer and nanoparticle constructs internalized into cells by endocytosis are transported to lysosomes—membrane-encapsulated cytoplasmic organelles more acidic (pH ∼5.0) than normal physiological conditions, and containing a host of specific enzymes (*6*). Therapeutic agents with activity beyond the lysosomal compartment (i.e., most drugs) must achieve lysosomal release at sufficient dosing in order to exert their desired activity. For these reasons, polymer− and nanoparticle−drug conjugation chemistry is often designed to degrade once inside the cell via cleavage by lysosome-specific enzymes, as well as by nonspecific pH-dependent and organelle-specific mechanisms. The Gly-Phe-Lys-Gly (GFLG) peptide sequence has been shown to degrade specifically by the lysosome enzyme, cathepsin B, and is a distinguishing component in the poly[*N*-(2-hydroxypropyl) methacrylamide] (pHPMA) copolymer−doxorubicin (DOX) anticancer drug PK1, currently in clinical trials (*7*−*11*). Other degradable peptide spacers such as the dipeptides valine-citrulline, asparagine-D-lysine, and methionine-D-lysine have been used to produce antibody−drug conjugates where the drug is released by proteolysis of the peptide linker (*12, 13*). Nonspecific pH-driven hydrolytic degradation and agent de-

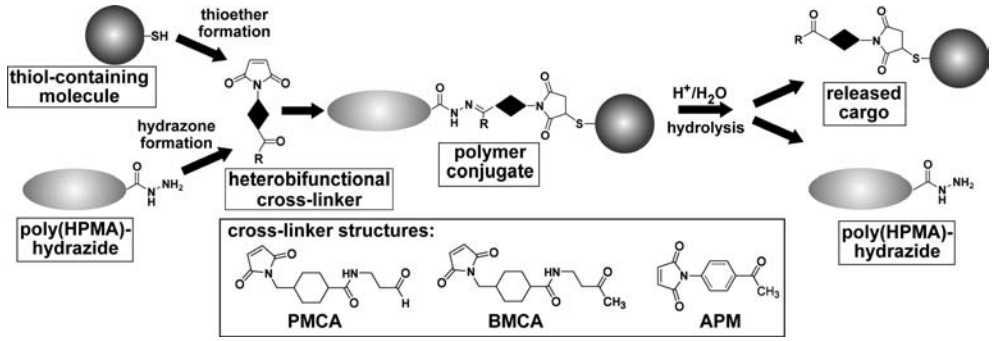

Figure 1. Design strategy for reversible coupling of thiols to pHPMA and cross-linker structures.

coupling have been demonstrated for a variety of coupling chemistries including hydrazone, acetal, carbamate, and *cis*-aconityl moieties (*14*−*17*).

More specifically, hydrazone bonds have been successfully used to generate a variety of pH-sensitive conjugates of the anticancer drug doxorubicin with various polymers, particles, micelles, and antibodies by reaction with hydrazide-derivatized carriers and cross-linkers with the 13-keto position of this drug (*15*, *16*, *18*−*24*). Hydrazone bonds are formed by condensation of hydrazides with aldehydes or ketones after elimination of the carbonyl oxygen as water, resulting in a metastable imine bond. This reaction can be performed under aqueous conditions with careful control of pH and reaction stoichiometry but is most often performed under organic conditions with an acid catalyst such as acetic acid or trifluoroacetic acid to facilitate dehydration and formation of the hydrazone bond (*19*, *25*, *26*). While certain types of hydrazone linkages are known to be stable at pH 7.4 and degrade at low pH (i.e., <5.0), chemistries adjacent to both hydrazide and ketone functionality greatly affect pH and hydrolytic stability. Hence, specific substituents have been used to achieve different bond cleavage rates and pH sensitivities (*15*, *16*). This chemistry can also be tailored to present other functional groups useful for other conjugation strategies.

This work evaluates three heterobifunctional cross-linkers designed to couple thiol-containing molecules to hydrazone-derivatized pHPMA drug carriers enjoying a long history of use (*9*, *10*, *27*). Thiol-based drug conjugation to polymer-linked hydrazones is not widely studied. Efficiency of cross-linker coupling to reactive sites on the polymer backbone, and their subsequent stability at pH 7.4 and 5.0 were investigated. While both polymer and cross-linker can be designed to provide the hydrazide functionality, we placed this functional group on the polymer carrier as previously described (*19*, *20*). Crosslinkers that facilitate reversible coupling of thiol-containing molecules to pHPMA contain ketone or aldehyde functional groups on one terminus for reaction with pHPMA hydrazide, and a maleimide functionality at the other terminus to react with sulfhydryl groups on the target adduct via a 1,4-Michael addition reaction (*19*, *20*). This thiol coupling strategy is advantageous for coupling unmodified proteins/peptides lacking aldehyde/ketone functionality, or other thiol-containing molecules, to known hydrazide-derivatized pHPMA water-soluble carriers, or analogous chemistry. Two heterobifunctional cross-linkers investigated, 1-(*N*-3-propanal)-4-(*N*-maleimidomethyl) cyclohexane carboxamide (PMCA), and 1-(*N*-3-butanone)-4-(*N*-maleimidomethyl) cyclohexane carboxamide (BMCA) were prepared from the popular commercial cross-linker succinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (SMCC), while the third was a commercially available benzene derivative, *N*-4-acetylphenyl maleimide. Illustration of the reversible coupling/release strategy and cross-linking chemistry structures involving hydrazone−thiol coupling are shown in Figure 1.

MATERIALS AND METHODS

General Procedures and Materials. All solvents were ACS-certified grade purchased from Fisher Scientific (Fair Lawn, USA) and used without further purification unless otherwise noted. Trinitrobenzene sulfonic acid (5% w/v solution in methanol) (TNBSA), cystamine hydrochloride (98%), diisopropylethylamine (DIPEA), ethyl carbazate (97%), *N*-hydroxysuccinamide (NHS) (98%), 4-(aminomethyl)cyclohexane carboxylic acid (97%), maleic anhydride (98+%), acetic anhydride, dicyclohexanecarbodiimide (DCC) (99%), hydrazine monohydrate (98%), 3-amino-1-propanol (99+%), triethyl amine (99.5%), oxalyl chloride (99+%), and glacial acetic acid were all purchased from Aldrich (St. Louis, USA). *N*-4-(Acetylphenyl) maleimide (APM) (98+%) was purchased from Lancaster Synthesis (Pelham, USA). 4-Amino-2-butanol (98%) was purchased from Acros Organics (Geel, Belgium). Reducing gel with immobilized tris(2-carboxyethyl) phosphine hydrochloride (TCEP) was purchased from Pierce (Rockford, USA). Spectra/Por 1, 6−8 kDa molecular weight cutoff dialysis tubing was obtained from Spectrum Laboratories, Inc. (Rancho Dominguez, USA). Sephadex G-25 and LH-20 size exclusion chromatography gel were purchased from Amersham Biosciences (Uppsala, Sweden). Dimethyl sulfoxide-d_6 containing 0.05% w/v tetramethylsilane was purchased from Cambridge Isotope Laboratories, Inc. (Andover, MA). 5(6)-Tetramethylrhodamine-succinimidyl ester (TAMRA-NHS) was obtained from AnaSpec (San Jose, USA). Poly(HPMA) molecular weight standards were a gift from Prof. P. Kopeckova, Univ. Utah, USA. Water was Millipore-filtered ASTM Type I quality. All NMR spectra were recorded on a Magnex Scientific Inova 400 MHz instrument in DMSO-d_6 containing 5% w/v tetramethylsilane as an internal standard. Absorbance measurements were obtained on a Varian Carey 500 Scan instrument.

4-(*N*-Maleimidomethyl)cyclohexane Carboxylic Acid (MCCA) (1). 4-(Aminomethyl)cyclohexane carboxylic acid (40.71 g, 0.26 mol, 1 equiv) was dissolved in dimethyl acetamide (DMAc, 100 mL). A solution of maleic anhydride (25.20 g, 0.26 mol, 1 equiv) was prepared in DMAc (50 mL), then added to the 4-(aminomethyl)cyclohexane carboxylic acid solution dropwise while stirring. The reaction vessel was purged with nitrogen, capped, and stirred for 24 h at room temperature. After 24 h, sodium acetate (5.00 g, 0.06 mol, 0.24 equiv) and acetic anhydride (43 mL, 0.455 mol, 1.75 equiv) were added and the reaction was continued for an additional 24 h. After 24 h, the reaction was heated to 65 °C and stirred for 5 h, then concentrated to ∼125 mL under vacuum and poured into 1 L cold water while stirring. The light-brown precipitate was collected by filtration and dried under vacuum. The aqueous portion was extracted twice with methylene chloride (500 mL), and product was isolated after evaporation of solvent. Both solid portions were combined and dissolved in methylene chloride (500 mL), then silica gel (5 g) was added to the solution and

the suspension was stirred for 30 min. The resulting colorless solution was filtered and solid product was obtained by evaporation of solvent under vacuum. Crude product was further purified by crystallization from ethyl acetate to yield a white solid. Yield: 14.70 g, 24%. ^{1}H NMR, δ ppm: 0.926 (dd, 2H), 1.22 (dd, 2H), 1.517 (m, 1H), 1.6165 (d, 2H), 1.869 (d, 2H), 2.109 (m, 1H), 3.2355 (d, 2H), 7.012 (s, 2H), 12.010 (s, 1H). ^{13}C NMR, δ ppm: 27.932, 29.112, 36.013, 42.105, 42.861, 134.273, 171.549, 176.497. MS calcd $[M + H]^+$ ($C_{12}H_{15}NO_4$): 238.107. Found: (FAB) 238.108.

1-(*N*-3-Propanol)-4-(*N*-maleimidomethyl)cyclohexane Carboxamide (2). Cross-linker precursor MCAA (3.00 g, 1.0 equiv, 13 mmol) was dissolved in methylene chloride (75 mL), purged with nitrogen, capped, and cooled to −15 °C. A suspension of NHS was prepared (1.45 g, 1.0 equiv, 13 mmol) in methylene chloride (25 mL), then cooled to −15 °C. Next, a solution of DCC was prepared (2.87 g, 1.1 equiv, 14 mmol) in methylene chloride (25 mL) and cooled to −15 °C. The DCC solution was added to the solution of MCAA, followed by addition of the NHS suspension. The reaction flask was purged with nitrogen, stirred at −15 °C for 24 h, and then filtered to remove dicyclohexylurea (DCU). The filtrate was retained and 3-amino-1-propanol (1.98 mL, 1.9 equiv, 25 mmol) was added dropwise. The reaction was purged with nitrogen, capped, and stirred at room temperature for 3 h. After 3 h, the reaction mixture was filtered to remove liberated NHS, and the filtrate was concentrated to ∼2/3 original volume under vacuum, cooled to −20 °C, and then refiltered. The resulting filtrate volume was doubled by addition of diethyl ether to form a precipitate, which was isolated by filtration. The solid product was further purified by silica gel chromatography (10 × 40 cm, 90/10 methylene chloride/methanol mobile phase) and isolated by evaporation of solvent under vacuum. Yield: 1.91 g, 51.6%, white solid. ^{1}H NMR, δ ppm: 0.886 (dd, 2H), 1.265 (dd, 2H), 1.508 (q, 3H), 1.618 (d, 2H), 1.682 (d, 2H), 1.998 (m, 1H), 2.5 (solvent overlap), 3.047 (q, 2H), 3.234 (d, 2H), 3.372 (q, 2H), 4.399 (t, 1H), 7.013 (s, 2H), 7.652 (t, 1H). ^{13}C NMR, δ ppm: 28.488, 29.349, 32.386, 35.423, 36.060, 42.980, 43.704, 58.307, 134.277, 171.188, 174.825. MS calcd $[M + H]^+$ ($C_{15}H_{22}N_2O_4$): 295.1657. Found: (FAB) 295.1654.

1-(*N*-3-Butanol)-4-(*N*-maleimidomethyl)cyclohexane Carboxamide (3). This product was obtained by an analogous procedure used to synthesize compound **2** (vida infra) with the only difference being the use of 4-amino-2-butanol (1.65 mL, 1.1 equiv, 17.3 mmol) in methylene chloride (30 mL) as the amidation reagent. Yield: 2.88 g, 60%, white powder. ^{1}H NMR, δ ppm: 0.887 (dd, 2H), 1.036 (d, 3H), 1.267 (dd, 2H), 1.521 (m, 1H), 1.620 (d, 2H), 1.686 (d, 2H), 1.998, (m, 1H), 3.065 (q, 2H), 3.240 (d, 2H), 3.585 (septet, 1H), 4.443 (d, 1H), 7.018 (s, 2H), 7.645 (t, 1H). ^{13}C NMR, δ ppm: 23.509, 28.459, 29.334, 35.489, 36.046, 38.719, 42.966, 43.694, 63.628, 134.267, 171.168, 174.776. MS calcd $[M + H]^+$ ($C_{16}H_{24}N_2O_4$): 309.1814. Found (FAB) 309.1819.

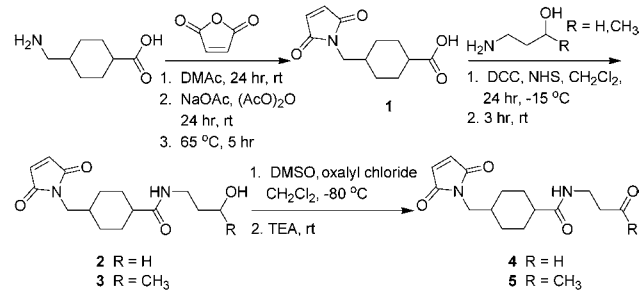
1-(*N*-3-propanal)-4-(*N*-maleimidomethyl)cyclohexane Carboxamide, PMCA (4). PMCA was prepared using the Swern procedure for oxidation of alcohols to aldehydes (*28*). The alcohol **2** (500 mg, 1.0 equiv, 1.72 mmol) was dissolved in freshly distilled methylene chloride (20 mL) and cooled to −80 °C. An activated dimethyl sulfoxide (DMSO) solution was prepared by combining DMSO (295 μL, 2.4 equiv, 4.13 mmol) and oxalyl chloride (950 μL of 2.0 M solution in methylene chloride, 1.1 equiv, 1.9 mmol) in methylene chloride (1.5 mL) at −80 °C. The alcohol solution was slowly added to the activated DMSO solution over 5 min. The reaction was allowed to proceed for 15 min at −80 °C, followed by addition of triethylamine (1.2 mL, 5.0 equiv, 8.5 mmol). The reaction was equilibrated to room temperature, and then water (15 mL) was added and the mixture was stirred for 10 min. The organic layer was separated, and the aqueous portion was re-extracted with 2 × 10 mL methylene chloride, and then all organic portions were combined. The organic portion was washed with 1 M HCl, dilute $NaHCO_3$, and H_2O, and then dried with Na_2SO_4. Product was isolated after removal of Na_2SO_4 and evaporation of solvent. Yield: 0.350 g, 66%, white powder. ^{1}H NMR, δ ppm: 0.878 (dd, 2H), 1.232 (dd, 2H), 1.507 (m, 1H), 1.636 (m, 2H), 1.976 (m, 1H), 2.502, (solvent overlap) 3.23 (d, 2H), 3.284 (q, 2H), 7.011 (s, 1H), 7.796 (t, 1H), 9.604 (t, 1H). ^{13}C NMR, δ ppm: 28.378, 29.286, 32.393, 36.037, 42.957, 43.265, 43.566, 134.274, 171.185, 174.958, 202.195. MS calcd $[M + H]^+$ ($C_{15}H_{20}N_2O_4$): 293.1501. Found (FAB) 293.1507.

1-(*N*-3-Butanone)-4-(*N*-maleimidomethyl)cyclohexane Carboxamide, BMCA (5). BMCA was prepared using the same Swern procedure described above to prepare PMCA, except starting with **3** (2.00 g, 1.0 equiv, 6.5 mmol) as the alcohol to be oxidized. Yield: 1.34 g, 68%, white powder. ^{1}H NMR, δ ppm: 0.875 (q, 2H), 1.243 (q, 2H), 1.511 (m, 1H), 1.511 (m, 1H), 1.638 (m, 4H), 1.975 (m, 1H), 2.070 (s, 3H), 2.545 (t, 2H), 3.180 (q, 2H), 3.228 (d, 2H), 7.011 (s, 2H), 7.677 (t, 1H). ^{13}C NMR, δ ppm: 28.407, 29.305, 29.752, 33.626, 36.043, 42.620, 42.962, 43.548, 134.273, 171.179, 174.796, 207.179. MS calcd $[M + H]^+$ ($C_{16}H_{22}N_2O_4$): 307.1657. Found (FAB): 307.1657.

Thiol-Containing Tetramethylrhodamine (6). Thiolated tetramethylrhodamine was prepared by reaction of TAMRA-NHS with cystamine hydrochloride activated with diisopropylethylamine (DIPEA) to form the TAMRA disulfide dimer (ssTAMRA) as previously described (*29*). Briefly, cystamine hydrochloride (9.6 mg, 0.9 equiv amines, 0.043 mmol) was activated in dimethylformamide (DMF, 2.5 mL) containing DIPEA (30 μL, 1.8 equiv, 0.17 mmol). This solution was added to TAMRA-NHS (50.0 mg, 1.0 equiv, 0.095 mmol) in DMF (1.5 mL) and stirred at room temperature in the dark for 30 min followed by addition of DIPEA (15 μL, 0.086 mmol, 1.0 equiv) and reaction for an additional hour. Product was precipitated by addition of 50 mL cold diethyl ether, washed five times, and dried under vacuum overnight. Further purification was achieved by repeat precipitation from methanol into cold ether. Yield: 24.81 mg, 54%, dark red solid. MS calcd $[M+H]^+$ ($C_{54}H_{52}N_6O_8S_2$): 977.3366. Found (FAB): 977.3348.

Poly[*N*-(2-hydroxypropyl)methacrylamide], pHPMA (7). PHPMA was synthesized to contain 5 mol % reactive nitrophenol ester terminated, nondegradable glycylglycine side chains using previously described procedures (*30*−*32*). *N*-(2-Hydroxypropyl)methacrylamide (HPMA) and methacryloyl glycylglycine nitrophenol ester (MAGGONP) monomers were prepared in house and confirmed with NMR and mass spectrometry. A detailed procedure for monomer synthesis and subsequent polymerization is provided as Supporting Information. The number of active esters in the resulting copolymer was estimated to be 2.55×10^{-4} mol/g polymer (3.8 mol %) by measuring the absorbance of released *p*-nitrophenolate anion at 400 nm ($\varepsilon = 1.74 \times 10^4$ M^{-1} cm^{-1}) following hydrolysis of ester bonds in 0.05 M sodium hydroxide for 3 h at 37 °C. No increase in absorbance after the 3 h incubation period was observed, showing complete cleavage of *p*-nitrophenol esters. Copolymer molecular weight was estimated to be 18 200 Da by size exclusion chromatography using a HP1050A HPLC equipped with a HP1047A refractive index detector and BioSil 125 column calibrated with pHPMA samples of known molecular weights. Samples were eluted at 0.5 mL/min with 0.1 M sodium phosphate, 0.05 M NaCl, pH 7.4.

Hydrazide Derivatized pHPMA (8). pHPMA copolymer was further modified to contain hydrazide-terminated side chains by reaction of *p*-nitrophenol ester-terminated MAGGONP side



chains with excess hydrazine monohydrate using methods previously described (*19*, *20*). Briefly, *p*-nitrophenol activated pHPMA (2.0 g, 1.0 equiv, 0.51 mmol active ester) was dissolved in methanol (25 mL). The pHPMA solution was added dropwise to a solution of hydrazine monohydrate (267 μL, 10.8 equiv, 5.5 mmol) in methanol (25 mL). The reaction was purged with nitrogen, capped, and stirred for 3 h at room temperature. The reaction solution turned dark yellow indicating reaction of active ester groups and release of *p*-nitrophenol. After complete reaction, the reaction mixture was dripped into cold water (50 mL) and low molecular weight byproducts were removed by dialysis against water (SpectraPore, 6−8 kDa molecular weight cutoff, 2 days). Polymer product was isolated by lyophilization. Yield: 0.120 g, 60%, white powder. Hydrazide content: 2.63×10^{-4} mol/g, 100.5% conversion.

Analysis of pHPMA Hydrazide Content. Hydrazide content was estimated using a modified trinitrobenzene sulfonic acid (TNBSA) assay and methacryloyl glycylglycine hydrazide (MAGGH) standards (see Supporting Information for details regarding synthesis of MAGGH standards). For each pHPMA hydrazide content analysis, stock solutions of 0.1% w/v TNBSA and $\sim 2 \times 10^{-4}$ M MAGGH were prepared in 0.1 M $NaHCO_3$, pH 8.5. The MAGGH solution was further diluted with 0.1 M $NaHCO_3$ to generate standards in the range $\sim(0.3-2) \times 10^{-4}$ M. Next, hydrazide derivatized pHPMA solutions in 0.1 M $NaHCO_3$ were prepared at concentrations of 0.2−0.4 mg/mL for samples prior to cross-linker reactions and 1−2 mg/mL for cross-linker reacted samples. TNBSA stock solution (0.5 mL) was combined with MAGGH standard or pHPMA solutions (1.0 mL) and incubated for 1.5 h at 37 °C. After incubation, sample absorbance was measured at 505 nm and hydrazide content was estimated from the MAGGH standard curve.

Reaction of Hydrazide-Derivatized pHPMA with Cross-Linkers (10, 11, 12). Hydrazide-derivatized pHPMA (**8**, 0.20 g, 1.0 equiv, 52 μmol hydrazide) was dissolved in 50/50 methylene chloride/methanol (2 mL), and 100 mg Na_2SO_4 was added. Cross-linker solutions (PMCA, **4**, 46.0 mg; BMCA, **5**, 48.0 mg; APM, **9**, 34.0 mg, 3.1 equiv, 160 μmol) were prepared in 50/50 methylene chloride/methanol (2 mL) and then added dropwise to the pHPMA solution at room temperature. After complete addition, acetic acid (5 μL of 34% v/v solution in methylene chloride, 0.6 equiv, 30 μmol) was added, and the reaction was stirred under nitrogen at room temperature for 24 h. The reaction was terminated by precipitation of pHPMA product into ether. Product was further purified by size exclusion chromatography (Sephadex LH-20, 1 × 15 cm, methanol mobile phase). Typical yields: pHPMA-PMCA **10**, 116 mg 59%; pHPMA-BMCA **11**, 122 mg, 61%; pHPMA-APM **12**, 126 mg, 63%; all as white powders. Hydrazide content postconjugation was determined using a TNBSA assay, as described above. Cross-linker content was determined by optical absorbance measurement at λ_{max} and using the molar extinction coefficients of corresponding ethyl carbazate cross-linker hydrazone derivatives: **10**, 297 nm, $\varepsilon = 5.5 \times 10^2$ M^{-1} cm^{-1}; **11**, 299 nm, $\varepsilon = 5.7 \times 10^2$ M^{-1} cm^{-1}; **12**, 288 nm, $\varepsilon = 1.9 \times 10^4$ M^{-1} cm^{-1} (see Supporting Information). Polymer cross-linker-bearing conjugates were analyzed by ^1H NMR to confirm maleimide presence on the polymer backbone.

Coupling Thiolated TAMRA to Maleimide Activated pHPMA (13, 14, 15). Dimeric TAMRA disulfide **6** was reduced using TCEP-immobilized gel immediately prior to reaction with cross-linker-derivatized pHPMA. TAMRA disulfide dimer (17.46 mg, 0.036 mmol, 1 equiv) was dissolved in 1 mL DMSO and added dropwise into an immobilized TCEP gel suspension (5 mL gel, ~1.1 equiv, ~0.04 mmol TCEP) in 12 mL phosphate buffer (0.1 M sodium phosphate, 0.05 M NaCl, 2.5 mM EDTA, pH 7.0). The reduction reaction was allowed to proceed for 1.25 h, followed by removal of TCEP gel by centrifugation. The gel material was washed with 6 mL buffer (pH 7.0, 2.5 mM EDTA), centrifuged, and the supernatant retained and combined with the first fraction.

Scheme 1. Thiol-Reactive Crosslinker Synthesis

Reduced TAMRA solution (3 mL,~1.1 equiv,~5.9 μmol) was added separately to pHPMA cross-linker conjugates **10**, **11**, and **12** (20.0 mg in 2 mL sodium phosphate, 0.05 M NaCl, 2.5 mM EDTA, pH 7.0, ~1 equiv, ~5.3 μmol). Reaction mixtures were degassed, purged with nitrogen, capped, and stirred at room temperature in the dark for 3 h. The coupling procedure was terminated by separation of unreacted TAMRA thiol after passage through an SEC column (Sephadex, G-25, 2 × 20 cm, H_2O mobile phase). The polymer conjugate fraction was collected as the first red band eluting from the column and lyophilized. Typical yields of TAMRA conjugated pHPMA: 15.3−19.5 mg, 76−96%. TAMRA conjugation efficiency to maleimide groups was determined by absorbance measurements at 554 nm using $\varepsilon = 6.4 \times 10^4$ M^{-1} cm^{-1}. TAMRA content (μmol/g polymer): **13** = 105.2, **14** = 47.8, **15** = 25.9.

Determination of Decoupling Hydrolysis Rates for Cross-Linkers on Conjugates 13−15. Release of free TAMRA dye from pHPMA was monitored at pH 5.0 (0.1 M sodium acetate buffer) and pH 7.4 (0.1 M sodium phosphate buffer). TAMRA-conjugated pHPMA samples (1.5−2.5 mg) were dissolved in the appropriate buffer (8.5 mL) and incubated at 37 °C in the dark while stirring. At various time points, 750 μL of polymer solution was withdrawn and free TAMRA was separated from polymer using a Sephadex G-25 SEC column (1 × 13 cm, H_2O mobile phase). The two resulting bands were collected and water was evaporated using a speed-vac. The samples were then dissolved in 500 μL water and the percentage of free TAMRA was determined by the ratio of absorbance at 554 nm that of the two fractions. For pHPMA conjugate **15**, TAMRA release was also determined after acidification (pH 3.0) of a sample incubated for 72 h at pH 7.4 (0.1 M phosphate buffer). All release experiments comprised 4 individual samples and data was analyzed using Microsoft *Excel*.

RESULTS AND DISCUSSION

Cross-Linker Design and Synthesis. Although several heterobifunctional cross-linkers are commercially available that form hydrazone bonds and also contain thiol-coupling reactivity, most are synthesized to contain hydrazide groups that react with synthetic ketone-containing drugs such as doxorubicin or oxidized sugar moieties present on biomolecules. We know of only one commercially available cross-linker that contains both ketone and maleimide functionality (APM), since hydrazide groups are not a common target for reaction with biomolecules or synthetic drugs. However, synthetic polymers, particles, surfaces, and so forth can easily be prepared with hydrazide functionality for reversible conjugation of thiolated molecules using the cross-linkers described in this work.

Synthesis of the aldehyde or methyl ketone SMCC-based heterobifunctional cross-linkers is shown in Scheme 1. The

Table 1. Summary of pHPMA−Cross-Linker Coupling Reactions[a]

polymer conjugate	cross-linker	cross-linker content[b] (μmol/g)	conversion[b] (%)	remaining hydrazide[c] (μmol/g)	conversion[c] (%)
13	PMCA	373.0 ± 21.2	141.8 ± 8.1	19.5 ± 0.1	92.6 ± 4.3
14	BMCA	248.9 ± 8.1	94.6 ± 3.1	18.6 ± 0.1	92.9 ± 5.6

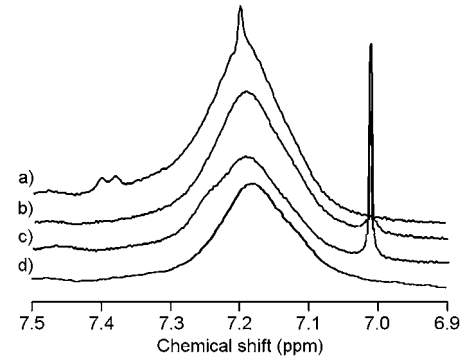
cyclohexyl SMCC core was chosen as it is known to produce a stable maleimide functional group. Maleimide groups are subject to degradation by hydrolysis and the increased hydrophobicity and lack of a conjugated aromatic system in the cyclohexyl spacer may reduce the hydrolysis rate (*2, 33*). Early attempts to synthesize these cross-linkers involved direct modification of commercially available SMCC, but synthesis of SMCC precursors in-house allowed inexpensive scale-up. Synthesis of the corresponding alcohols of SMCC was performed in a one-pot reaction after activation of carboxylic acid with NHS using well-known carbodiimide chemistry (*2*). Direct coupling of 4-amino-2-butanol and 3-amino-1-propanol to 4-(*N*-maleimidomethyl)cyclohexane carboxylic acid (**1**) following DCC activation without NHS led to a mixture of products, presumably due to addition of alcohol groups to the highly reactive DCC-activated carboxylic acid. The choice of methylene chloride as the solvent aided in product purification due to the limited solubility of NHS byproduct, which precipitated from solution and was easily removed by filtration after concentration and cooling the reaction mixture. Residual NHS was removed by aqueous extraction for cross-linker precursor **3**, but this purification strategy for **2** resulted in reduced yields due to higher water solubility. Chromatographic purification of **2** resulted in markedly increased yields.

Oxidation of alcohol groups in cross-linker precursors **2** and **3** was readily achieved using the mild oxidation conditions of the Swern procedure to yield the corresponding aldehyde- and methylketone-containing reactive cross-linkers. No side reactions were observed with other functional groups in the molecule. Other attempts to oxidize the alcohol functional groups using pyridinium chlorochromate resulted in oxidation of alcohol groups, but removal of chromium salt byproduct was difficult, resulting in low yields (data not shown).

Cross-Linker Coupling to pHPMA. Synthesis of hydrazide-derivatized pHPMA (**8**) was easily achieved by reaction of active *p*-nitrophenol esters on pendant side chains with hydrazine monohydrate as previously described (*19, 20*). This construct has been previously utilized to couple doxorubicin via a hydrazone bond to allow pH-dependent release (*19, 20*). The number of reactive sites in pHPMA was controlled by monomer feed ratios in the free radical-initiated polymerization reaction to produce pHPMA, with reactive sites kept fairly low so as to not alter the polymer solubility after cross-linker conjugation. Formation of hydrazone bonds has been reported for doxorubicin conjugates with pHPMA and poly(ethylene glycol) in polar protic conditions with methanol used as the solvent and acetic acid as the catalyst (*19, 20*). Since the hydrophobic cross-linkers used in this study were only minimally soluble in methanol, and the more hydrophilic pHPMA was only minimally soluble in solvents ideal for cross-linker solvation, a mixed solvent system was used. The best methanol-based solvent system for optimal cross-linker/polymer solubility was found to be 50/50 methanol/methylene chloride. PHPMA−cross-linker reactions showing conjugation efficiency are summarized in Table 1. With the reactive sites on the polymer controlled by monomer feed ratio, an excess of cross-linker was used to maximize conjugation to the polymer.

Reaction of cross-linkers PMCA (**4**) and BMCA (**5**) resulted in complete conversion of hydrazide groups to hydrazone conjugates as determined directly by cross-linker absorbance and indirectly by determination of remaining hydrazide groups using TNBSA measurements. Optical absorption measurements of the pHPMA−PMCA cross-linker product **10** showed the highest coupling efficiency, indicative of the higher reactivity of aldehyde functional groups. Although more than stoichiometric conversion was observed for the aldehyde cross-linker, the excess coupling was small compared to the total polymer units in the pHPMA carrier, indicating that polymer units lacking the hydrazide functionality were generally unreactive toward the aldehyde. The amount of hydrazide containing monomer units in pHPMA was ~4 mol %; thus, the ~140% coupling of the aldehyde cross-linker observed under these reaction conditions corresponds to modification of only ~2% of the polymer side chains in an unintended fashion. One possible explanation for the higher coupling rate observed for the aldehyde cross-linker is the formation of acetals with the alcohol groups contained in pHPMA side chains or mixed acetals formed by reaction with pHPMA and MeOH, as the reaction conditions used for hydrazone formation are similar to those used for acetal formation (i.e., acid catalyst and dehydrating agent). The methylketone group of **5** reacted with pHPMA hydrazide groups in a stoichiometric fashion, with absorbance and remaining hydrazide content in good agreement for conjugate **11**. This demonstrates that the less reactive methyl ketone functionality resulted in more readily controlled conjugation. The resonance stabilized APM cross-linker **9** was less reactive and did not stoichiometrically react with hydrazide-containing pHPMA **8** to produce conjugate **12**. Only 60−70% conjugation was observed in the cross-linker-derivatized product **12**, with cross-linker absorbance and remaining hydrazide measurement in good agreement. A similar result was observed in the analogous reaction of APM with ethyl carbazate (see Supporting Information). ^{1}H NMR analysis of the cross-linker polymer conjugates **10**−**12** also revealed a convenient analytical signal to confirm conjugation due to the sharp maleimide peak at 7.0−7.2 ppm, shown in Figure 2.



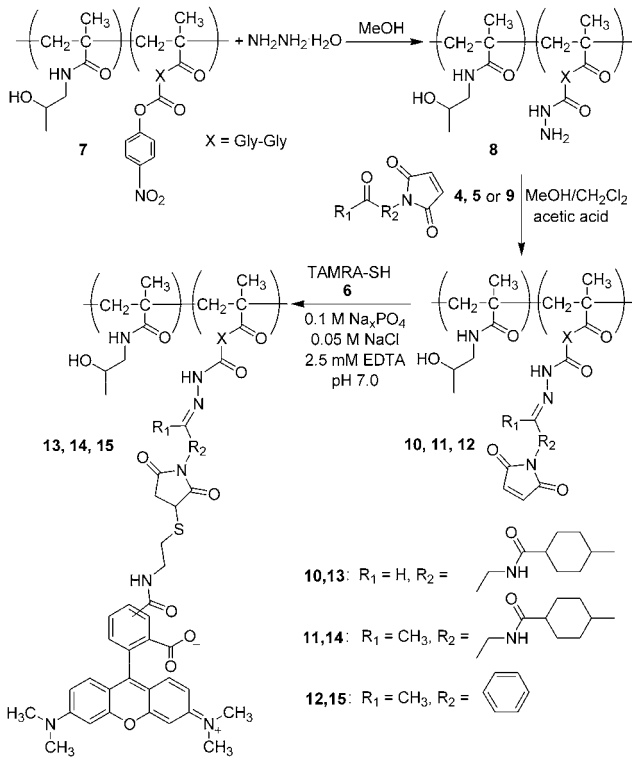


Figure 2. ^{1}H NMR spectra of pHPMA conjugates showing the pHPMA amide peak (broad) and cross-linker maleimide peak (sharp). Spectra recorded at 400 MHz, 25 °C in DMSO-d_6. (a) pHPMA−APM conjugate **12**, (b) pHPMA−BMCA conjugate **11**, (c) pHPMA−PMCA conjugate **10**, (d) pHPMA−hydrazide **8**.

For conjugates **10** and **11**, the maleimide peak appeared in an unobscured region of the ^{1}H NMR spectrum allowing easy detection. Additionally, formation of conjugate **10** was confirmed by the disappearance of the aldehyde peak present in

Scheme 2. Synthesis of pHPMA Conjugates

unreacted cross-linker **4** at 9.6 ppm. Although the maleimide signal overlapped with the polymer backbone signal for conjugate **12** containing APM, it was still visible protruding above the broad amide peak. Additionally, the ability of each cross-linker to form hydrazone linkages was modeled with the hydrazide-containing small molecule ethyl carbazate, with confirmation of hydrazone formation more analytically straightforward than with a small percentage of reactive sites in a polymer conjugate (see Supporting Information). For PMCA and BMCA, rapid, stoichiometric conversion to hydrazone product was obtained, with only a simple purification procedure needed to isolate pure hydrazone product. However, reaction of APM with ethyl carbazate resulted in formation of several products, and purification required a separation procedure for isolation, which resulted in a lower overall yield.

Attachment of Thiolated TAMRA to pHPMA and Subsequent Release. Synthesis of the pHPMA cross-linker TAMRA conjugates **13**−**15** is shown in Scheme 2. Thiol-modified TAMRA (**6**) was used as a model cargo compound to react with maleimide groups resulting from cross-linker conjugation to pHPMA. This model system was convenient, as TAMRA is fairly water-soluble, readily detected by simple absorbance measurements, and released dye is sufficiently smaller in size to allow rapid separation from the polymer-bound fraction using size exclusion chromatography. Reduction of the TAMRA disulfide **6** was performed with TCEP-immobilized gel, allowing easy separation of reducing agent. Free TCEP, DTT, or combinations of both resulted in lower conjugation of TAMRA to the polymer (data not shown). Although free TCEP is generally believed to be unreactive toward maleimide functional groups, similar observations regarding interference with maleimide coupling have been reported (*34, 35*). Reaction times of TAMRA with cross-linker-derivatized pHPMA were kept short (3 h) in this study, as degradation rates of the hydrazones were unknown. TAMRA conjugation was not efficient under these conditions, with couplings relative to cross-linker content of ∼20% observed for all pHPMA−cross-linker conjugates. Maleimide coupling efficiency for all cross-linkers

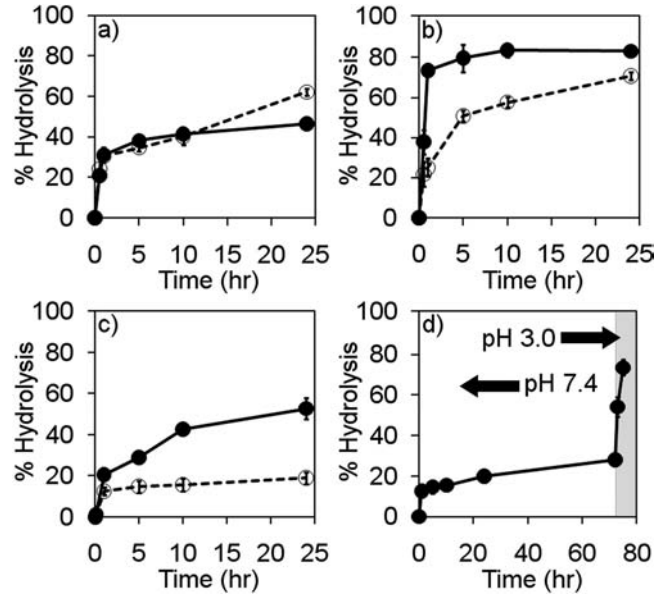

Figure 3. Hydrolysis rates for pHPMA-cross-linker-TAMRA conjugates. Graphs a−c represent hydrolysis at pH 7.4 (dashed) and pH 5.0 (solid): (a) pHPMA-PMCA-TAMRA conjugate **13**, (b) pHPMA-BMCA-TAMRA conjugate **14**, (c) pHPMA-APM-TAMRA conjugate **15**. (d) Hydrolysis of pHPMA-APM-TAMRA conjugate **15** upon acidification following 75 h incubation at pH 7.4. Each data point represents the average of 4 samples ± the standard deviation.

may increase with longer reaction times until hydrazone degradation and release from the polymer competes with thiol conjugation.

Release of conjugated TAMRA from the polymer backbone at physiologically relevant temperature and pH [pH 7.4 (circulation) and pH 5.0 (lysosomes), 37 °C] was influenced by cross-linker structure as shown in Figure 3a−c. The conditions used to observe hydrazone degradation are not physiological, only a simple approximation, as the addition of other physiologically relevant components such as serum interfere with the ability to separate released TAMRA dye from the macromolecular component of the mixture by size exclusion chromatography: TAMRA can associate with high molecular weight serum components in more complex milieu via nonspecific interactions. Ideally, for systemic administration of a drug delivery system, the hydrolytic stability of the hydrazone bond between the carrier and therapeutic agent should be stable at systemic pH (∼7.4) for the same period of time that it takes for the carrier to reach its site of activity. However, if the carrier is rapidly cleared from circulation, and the therapeutic target is also the site of rapid accumulation (i.e., kidney or liver tissue), the hydrazone does not necessarily need to exhibit extended stability at systemic pH. For carriers targeting cancer tissue by the EPR effect, the hydrazone used for preparation of the conjugate should exhibit minimal hydrolysis at pH 7.4, as accumulation into cancer tissue by the EPR effect requires a carrier with extended circulation (*36*). In this regard, the stability of the hydrazone used to couple the therapeutic agent to the carrier depends on the properties of the carrier used.

Polymer conjugates **13** and **14** containing aliphatic acyl hydrazone bonds were relatively unstable at physiological pH, with more than 30% of conjugated TAMRA released after 5 h. Release for conjugate **13** prepared with the aldehyde-containing PMCA cross-linker showed no difference between pH 7.4 and 5.0, with a maximum of 40−60% release observed after only a few hours, with little increase after 24 h. Hydrolysis of conjugate **13** rapidly plateaued at a value less than that for complete hydrolysis, which may be attributed to the reversible nature of the hydrazone bond and the closed system used to study the

release profile which could result in the highly reactive aldehyde-containing PMCA cross-linker reaching equilibrium between the aldehyde and hydrazone forms at this concentration and temperature. Alternatively, the additional PMCA attached to the polymer (~140% conjugation to pHPMA was observed) could be interfering with the observation of hydrazone bond hydrolysis, assuming that the additional conjugation resulted in a hydrolytically unstable bond (i.e., acetal). Polymer conjugate **14** formed with the BMCA cross-linker showed a marked difference in hydrazone degradation at early time points, with more than 75% of cargo released after only 2 h at pH 5.0 while only 25% of TAMRA was released at pH 7.4 in the same time frame. This difference in initial pH stability for BMCA containing conjugate **14** compared to the hydrazone formed with PMCA in conjugate **13** is likely due to increased electron donation ability of a methyl group relative to a hydrogen, which would facilitate protonation of the imine nitrogen but also sterically hinder the imine carbon electrophile toward nucleophilic attack by water. This property may be useful for targeting or delivery devices that can efficiently reach a target site of lower pH without prolonged residence in the off-target environment, with rapid release of cargo at the site of lower pH.

The desired difference in stability of polymer conjugates at pH 7.4 and 5.0 was most pronounced for the pHPMA−APM containing conjugate **15**. Polymer conjugate **15** containing the resonance-stabilized hydrazone was most stable at pH 7.4 with less than 30% of degradation occurring after 24 h, while degradation at pH 5.0 steadily increased during the same time period (Figure 3c). Increased degradation rate of conjugate **15** upon acidification after extended incubation at pH 7.4 is shown in Figure 3d; hydrolysis increased immediately upon lowering the pH. This result shows that polymer-bound payload is likely to be released within target cells in vivo following extended circulation, cellular internalization, and trafficking to acidic subcellular organelles (lysosomes).

Hydrazones investigated in this work showed the following trend for increased difference in stability at pH 7.4 and 5.0 based on the functional groups attached to the imine carbon: phenyl, CH_3 > alkyl, CH_3 > alkyl, H. A similar trend has also been observed for other hydrazone systems recently reviewed elsewhere (*15*). This trend is directly related to cross-linker reactivity toward polymer hydrazide groups, with highly reactive carbonyl groups forming hydrazone bonds with decreased pH-dependent hydrolysis. The acyl hydrazide functionality utilized on the pHPMA component of the hydrazone forming system was not varied, but the acyl hydrazide was convenient to prepare by simple aminolysis of active esters by hydrazine and also likely aided in the stability of the resulting hydrazones at pH 7.4. A recent detailed study of hydrazone stability showed that an acyl hydrazone had a first-order rate constant for hydrolysis a few hundred-fold lower relative to an alkyl hydrazone at pH 7.0 (*37*).

The pH-dependent release mechanism for hydrazone hydrolysis involves (1) protonation of the imine nitrogen, (2) nucleophilic attack of a water molecule at the imine carbon, (3) formation of a tetrahedral carbinolamine intermediate, and (4) decomposition of the carbinolamine and cleavage of the C−N bond (*15, 17, 37, 38*). The rate at which this hydrolysis occurs is influenced by substituents adjacent to the hydrazone. In general, cross-linker electron-donating groups can facilitate pH-dependent hydrolysis by encouraging protonation of the imine nitrogen, which activates the imine carbon toward nucleophilic attack from water, as the nitrogen can then accept a pair of electrons from the imine bond to form the tetrahedral carbinolamine intermediate. Electron withdrawing groups decrease pH sensitivity by decreasing electron density of the imine carbon making it more susceptible to nucleophilic attack by water (*15, 37, 39, 40*). Aromatic groups in π-bond conjugation with hydrazones have also been shown to increase their stability, due to resonance stabilization, as was observed in our results (*41*). The desired stability for controlled pH-dependent hydrolysis is dependent on a delicate balance of groups adjacent to the carbonyl and hydrazide reaction partners used to form the hydrazone.

Modification of the carbonyl portion of cross-linkers described here may result in increased stability at pH 7.4 and hydrolysis rate at pH 5.0, while retaining excellent hydrazide reactivity. For example, glyoxylyl aldehydes prepared from N-terminal serine-modified amino acids have been recently used to form pH-sensitive hydrazones with acyl hydrazides (*42*). These findings suggest that further optimization of the SMCC-based cross-linker chemistries described here could be achieved by incorporation of different chemistries on carbon atoms adjacent to the reactive ketone functionality.

CONCLUSIONS

This work demonstrates the feasibility of forming thiol-reactive pHPMA conjugates with varying coupling and decoupling stability controlled by different chemical substitution patterns in analogous heterobifunctional cross-linker chemistries. Currently, the APM cross-linker is likely the best choice for long-circulation in vivo application due to the high stability at pH 7.4, with desired increased degradation occurring in acidic conditions analogous to the lysosome environment within cells. However, although APM shows the desired release properties for a long circulating conjugate, this cross-linker has the inherent disadvantage of lower hydrazide reactivity. BMCA is attractive for use in rapid release of cargo at a target site where extended stability is not desired (i.e., conjugates that rapidly accumulate at their site of activity or those that need to be rapidly cleared after use, i.e., gadolinium imaging agents). Alternatively, modifications of chemistry contained in the hydrazide part of synthetic constructs could result in conjugates with more stable hydrazone linkages formed with PMCA and BMCA.

The utility of these thiol-reactive cross-linkers may be further extended to produce nondegradable conjugates. In this case, addition of a hydrazone reducing agent such as sodium cyanoborohydride would result in a stable amide bond. Thus, the excellent hydrazide and maleimide reactivity of PMCA and BMCA would be attractive. Additionally, hydrazide reactivity is different from amine reactivity due to the lower pK_a of hydrazides. Nonreversible conjugation of the cross-linkers described here to hydrazides in the presence of primary amines could be achieved by control of reaction pH and the use of a hydrazone reducing agent.

In summary, the thiol-reactive cross-linkers described in this work could prove to be useful new tools for preparation of bioconjugates with specific coupling/decoupling properties. Hydrazide functionality is readily incorporated into synthetic systems, while thiol functionality is readily contained in biological components targeted for conjugation and subsequent release. These cross-linkers could be used for conjugation and subsequent triggered release as described here, for nonreversible conjugation by simply changing the reaction conditions, or serve as a starting point for design of more advanced cross-linkers with specific performance features.

ACKNOWLEDGMENT

We thank Andrew Higginbotham and Dr. Mark Kerr for helpful discussion regarding organic procedures. Partial support from NIH grant EB000894 is gratefully acknowledged.

Supporting Information Available: Experimental details regarding pHPMA synthesis, synthesis of methacryloyl glycylglycine TNBSA assay standards, reaction of cross-linkers

with ethyl carbazate, and spectral properties of hydrazones formed with cross-linkers and ethyl carbazate are described. This material is available free of charge via the Internet at http://pubs.acs.org.

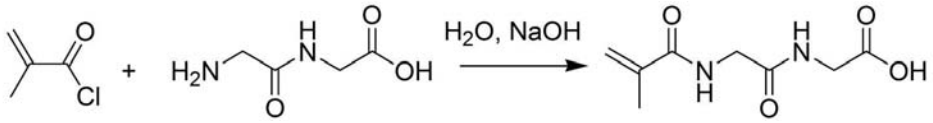
1. Synthesis of pHPMA.

1.1. HPMA monomer: N-2-hydroxypropyl methacrylamide.

N-(2-hydroxypropyl) methacrylamide (HPMA) was synthesized by reaction of DL-1-amino-2-propanol with methacryloyl chloride as shown in Scheme S1. 1-amino-2-propanol (24.3 mL, 0.311 mol, 1 eq) and sodium bicarbonate (33.6 g, 0.40 mol, 1.3 eq) was added to CH_2Cl_2 (85 mL) and the suspension was purged with N_2, capped, and placed in an ice bath. A second solution containing methacryloyl chloride (29.5 mL, 0.304 mol, 0.98 eq) in CH_2Cl_2 (40 mL) was prepared and cooled to –20 ^oC. Next, the methacryloyl chloride solution was slowly added to the 1-amino-2-propanol solution under N_2 with vigorous stirring. After complete addition the reaction was stirred for 15 min at 25 ^oC, and anhydrous Na_2SO_4 (10 g) was added. The solution was manually stirred for an additional 10 minutes and the solution was filtered through paper. Solids were washed twice with 20 mL CH_2Cl_2 and the filtrates were combined. The combined filtrates were concentrated under vacuum to ~ 50% of the original volume then placed in a –20 ^oC freezer overnight. HPMA crystals were collected by filtration and washed with cold acetone. Product was purified by repeated crystallization from acetone. Typical yield: ~15.0 g, 30%, semi-transparent white crystals. ^1H NMR, δ ppm: 1.008 (d, 3H), 1.848 (s, 3H), 3.041 (t, 2H), 3.678 (m, 1H), 4.693 (s, 1H), 5.483 (d, 2H), 7.820 (s, 1H). Mp = 72 ^oC (sharp).



Scheme S1. Synthesis of *N*-2-hydroxypropyl methacrylamide monomer (HPMA).

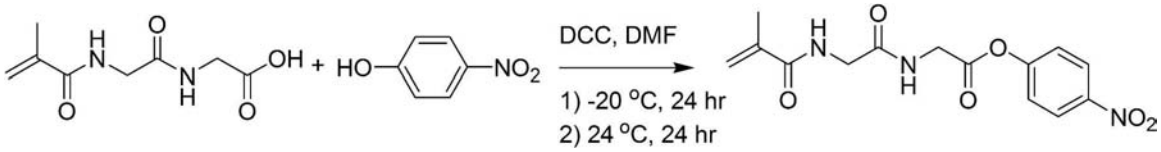
1.2. Active ester-containing monomer:methacryloyl glycylglycine 4-nitrophenyl ester (MAGGONP).

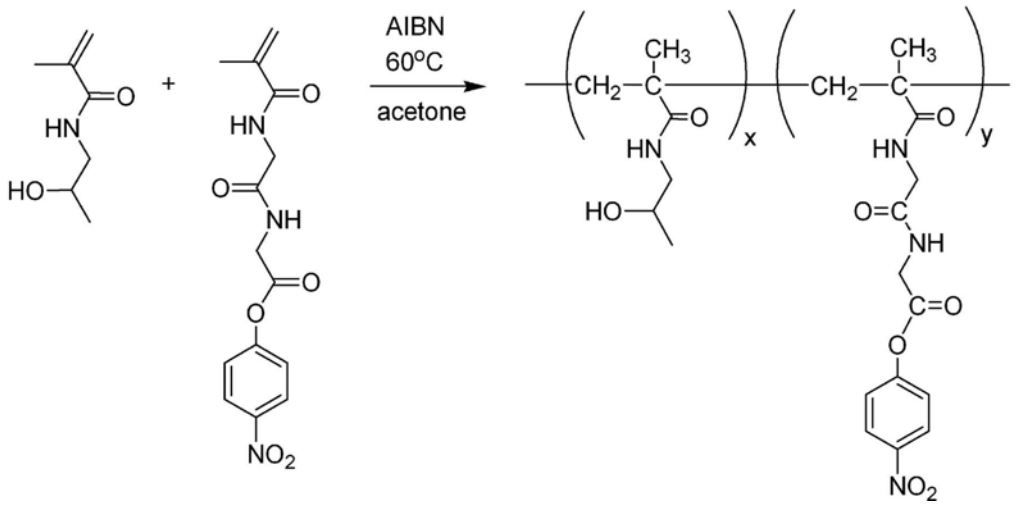


N-methacryloyl glycylglycine 4-nitrophenyl ester (MAGGONP) synthesis began with preparation of methacryloyl glycylglycine (MAGG) using the Schotten-Baumann procedure in aqueous alkaline medium as shown in Scheme S2. Glycylglycine (10 g, 76 mmol, 1 eq) was dissolved in 0.5 M NaOH (15.1 mL, 76 mmol, 1 eq) over 30 minutes then cooled to 0 ^{o}C. Methacryloyl chloride (7.5 mL, 77 mmol, 1eq) and 5.0 M NaOH (15.1 mL, 76 mmol, 1 eq) were added drop wise and simultaneously to the glycylglycine solution while stirring at 0 ^{o}C. After complete addition, the reaction was stirred for an additional hour at room temperature, then concentrated HCl was added until a dense white precipitate formed. Solids were collected by filtration and washed with cold water until the filtrate was neutral. Crude solid product was dried under vacuum and further purified by repeat crystallization from 50/50 (v/v) ethanol/water. Typical yield: ~5.0 g, 30%, small white crystals. ^{1}H NMR: (400 MHz, DMSO-d_6) δ ppm: 1.876 (s, 3H), 3.766 (d, 4H), 5.561 (d, 2H), 8.132 (t, 1H), 8.190 (t, 1H), 12.594 (s, 1H). Mp = 175-205 ^{o}C.

Scheme S2. Synthesis of methacryloyl glycylglycine (MAGG).

Methacryloyl glycylglycine (MAGG) was esterified with 4-nitrophenol using carbodiimide chemistry to yield methacryloyl glycylglycine 4-nitrophenyl ester (MAGGONP) as shown in Scheme S3. MAGG (5.23 g, 26.1 mmol, 1 eq) was dissolved in dry dimethyl formamide (DMF, 50 mL) and cooled to –15 ^{o}C. 4-nitrophenol (4.0 g, 28.71 mmol, 1.1 eq) and dicyclohexylcarbodiimide (DCC) (5.39 g, 26.1 mmol, 1.0 eq) were each dissolved in DMF (26 mL) in separate flasks and cooled to –15 ^{o}C. After all solutions were cooled, the 4-nitrophenol and DCC solutions were added drop wise to the MAGG solution sequentially while stirring. The reaction was stirred for 4 hr at –15 ^{o}C followed by 24 hr at –20 ^{o}C. Upon complete reaction, dicyclohexyl urea (DCU) byproduct was removed by filtration. The filtrate was collected and allowed to sit at room temperature for 24 hrs under N_2 and then cooled to –20 ^{o}C. The solution was again filtered to remove DCU crystals. The filtrate was retained and 100 mL cold water was added. This mixture was placed on ice for 1 hr. The pale-yellow solids were collected by filtration and dried under vacuum. Hot 50/50 water/ethanol was added to the dried solids until ~ 80% dissolved. The solution was boiled for an additional 10 minutes then filtered. Small, pale-yellow, fish-scale crystals formed slowly in the filtrate over a 3 hr

period at room temperature. Solids were collected by filtration and dried under vacuum. Typical yield ~ 2.0 g, 22%, yellow crystals. ^{1}H NMR, δ ppm: 1.884 (s, 3H), 3.809 (d, 2H), 4.176 (d, 2H), 5.577 (d, 2H), 7.435 (m,2H), 8.267 (t, 1H), 8.326 (m, 2H), 8.479 (t, 1H). Mp = 143-160 ^{o}C.

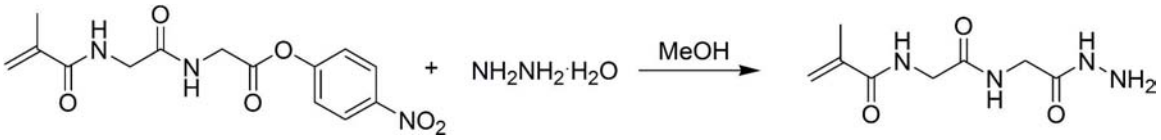


Scheme S3. Synthesis of methacryloyl glycylglycine 4-nitrophenyl ester (MAGGONP).

Reference: Kopecek J. (1977) Reactive Copolymers of N-(2-Hydroxypropyl) Methacrylamide with N-Methacryloylated Derivatives of L-Leucine and L-Phenylalanine .1. Preparation, Characterization, and Reactions with Diamines. Makromol. Chem. Macromol. Chem. Phys. *178(8)*, 2169-83.

2. Synthesis of pHPMA copolymer.

HPMA copolymer was prepared by free radical initiated polymerization as previously described using 12.5% (w/v) monomer and 0.6% initiator (AIBN) in freshly distilled acetone. Reactive side chain content in the polymer product was controlled by feed ratio of MAGGONP. The following is a typical procedure to produce an HPMA copolymer with 95 mole% HPMA units and 5 mole% MAGGONP units. HPMA monomer (3.35 g, 23.4 mmol, 1 eq), MAGGONP (0.40 g, 1.2 mmol, 0.05 eq), and AIBN (0.18 g, 1.1 mmol, 0.05 eq) were added to acetone (26 mL) in a Chemglass 50 mL pressure flask containing a magnetic stir bar. The solution was degassed by sonication under N_2 flow for 5 minutes and then capped. This solution was stirred until all solids dissolved (~ 30 minutes) and placed in a hot water bath and stirred at 60^{o}C for 24 hrs. After complete reaction, solids were collected by filtration, washed with cold acetone, and dried under vacuum. Solids were further purified by repeat precipitation from 90/10 CH_2Cl_2/MeOH (v/v) into a 10-fold excess of cold acetone. Typical yield: ~ 2.2 g, 56%, cream colored powder.

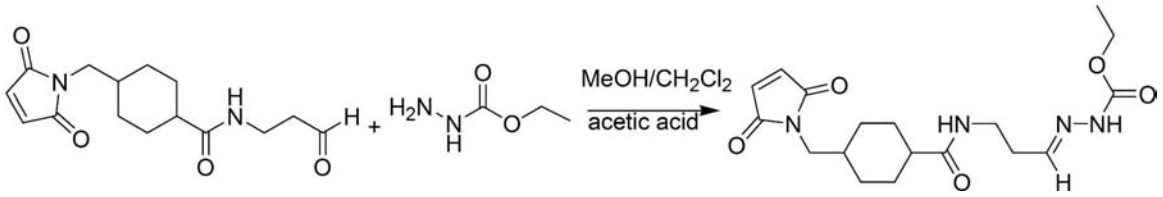


Scheme S4. Free radical initiated copolymerization of *N*-2-hydroxypropyl methacrylamide and methacryloyl glycylglycine nitrophenyl ester.

Reference: Kopecek J. (1977) Reactive Copolymers of N-(2-Hydroxypropyl)Methacrylamide with N-Methacryloylated Derivatives of L-Leucine and L-Phenylalanine. 1. Preparation, Characterization, and Reactions with Diamines. Makromol. Chem. Macromol. Chem. Phys. *178(8)*, 2169-83.

3. Synthesis of methacryloyl glycylglycine hydrazide (MAGGH).

Methacryloyl glycylglycine hydrazide (MAGGH) was synthesized to serve as a control compound in the TNBSA assay for quantification of pHPMA hydrazide functional groups. MAGGH was synthesized by reaction of MAGGONP with hydrazine monohydrate as follows: MAGGONP (750 mg, 1.0 equiv, 2.3 mmol) was dissolved in methanol (90 mL), then dripped into a solution of hydrazine monohydrate (567 µL, 5.0 equiv, 11.7 mmol) and stirred for 5 hr at room temperature under nitrogen. Solvent was removed under vacuum to yield crude solids that were then dissolved in 90/10 methylene chloride/methanol (40 mL), filtered, and loaded onto a silica gel column (2.5 x 17.5 cm) equilibrated with 90/10 methylene chloride/methanol. After the sample was loaded onto the column, the elution solvent was changed to methanol and MAGGH eluted after the visible yellow p-nitrophenol band. Yield: 0.156 g, 31%, white powder. ^{1}H NMR, δ ppm: 1.836 (s, 1H), 3.619 (d, 2H), 3.712 (d, 2H), 4.165 (d, 2H), 5.341 (d, 1H), 5.698 (d, 1H), 8.048 (t, 1H), 8.131 (t, 1H), 8.907 (s, 1H). ^{13}C NMR, δ ppm: 18.479, 40.779, 42.402, 119.752, 139.356, 167.597, 168.011, 169.204. MS calcd $[M+H]^+$ ($C_8H_{14}N_4O_3$): 215.1144. Found (FAB): 215.1147.

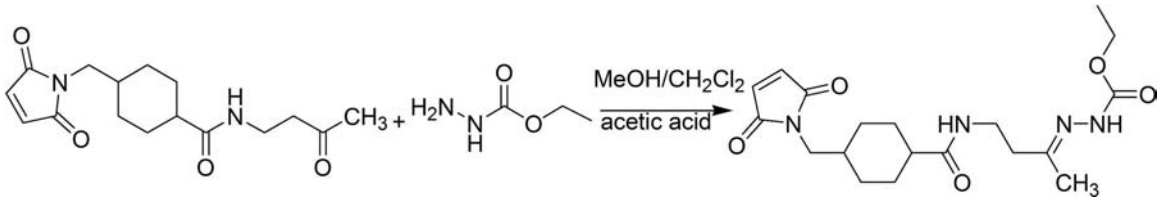


Scheme S5. Synthesis of methacryloyl glycylglycine hydrazide (MAGGH).

4. Reaction of heterobifunctional crosslinkers with model hydrazide ethyl carbazate.

The ability of each crosslinker to form hydrazone linkages was modeled with the hydrazide-containing small molecule ethyl carbazate, with confirmation of hydrazone formation being more analytically straightforward than with a small percentage of reactive sites in a polymer conjugate. For PMCA and BMCA, rapid, stoichiometric conversion to hydrazone product was obtained, with only a simple purification procedure needed to isolate pure hydrazone product. However, reaction of APM with ethyl carbazate resulted in formation of several products and purification required a separation procedure for isolation, which resulted in a lower overall yield. Although extensive analysis of reaction by-products was not performed, one by-product of the APM reaction with ethyl carbazate did show loss of maleimide functionality by ^{1}H NMR analysis.

4.1. PMCA.

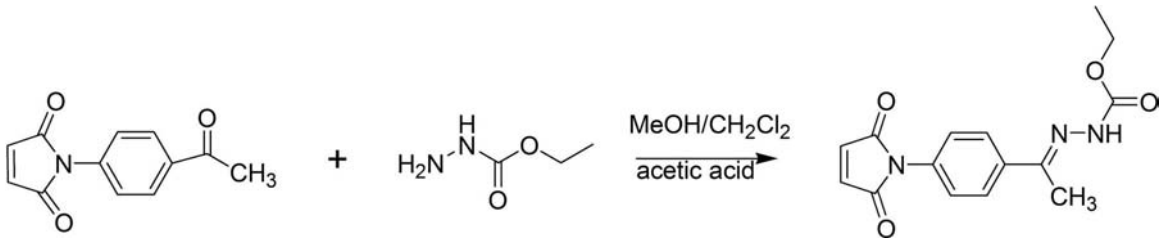


PMCA (100 mg, 0.342 mmol, 1.0 eq) was dissolved in 50/50 methylene chloride/methanol (2mL), followed by addition of Na_2SO_4 (100 mg, 0.70 mmol, 2.5 eq). Ethyl carbazate (35.6 mg, 0.342 mmol, 1.0 eq) was dissolved in 2 mL 50/50 methylene chloride/methanol (2 mL) and added to the PMCA solution drop wise. After 30 minutes acetic acid (5.0 μL, 0.087 mmol, 0.25 eq) was added and the reaction was stirred for 12 hrs under nitrogen and periodically monitored by TLC. After 12 hrs, the reaction mixture was filtered through a 0.2 μm filter, then washed with 0.1 M $NaHCO_3$. The organic layer was retained, dried with Na_2SO_4 and product was obtained after evaporation of solvent. Yield: 116.2 mg, 89.8%, white powder. ^{1}H NMR, δ ppm: 0.882 (q, 3H), 1.175 (t, 3H), 1.243 (q, 3H), 1.506 (m, 1H), 1.603 (d, 2H), 1.679 (2, 2H), 1.980 (m, 1H), 2.251 (q, 2H), 3.153 (q, 2H), 3.232 (d, 2H), 4.059 (q, CH2), 7.014 (s, 2H), 7.214 (s, 1H), 7.760 (t, 1H), 10.681 (s, 1H). 13C NMR, δ ppm: 14.516, 28.422, 29.336, 32.341, 35.698, 36.095, 42.984, 43.724, 60.021, 134.298, 145.493, 153.287, 171.211, 174.839. MS calcd $[M+H]^+$ ($C_{18}H_{26}N_4O_5$): 379.1981, found (FAB): 379.1976. Product was further analyzed by UV-Vis spectroscopy and a molar extinction coefficient was calculated using dilutions in methanol.

Scheme S6. Reaction of PMCA with ethyl carbazate.

4.2 BMCA.

BMCA (100 mg, 0.326 mmol, 1.0 eq) was dissolved in 50/50 methylene chloride/methanol (2 mL), followed by addition of Na_2SO_4 (100 mg, 0.70 mmol, 2.2 eq). Ethyl carbazate (33.9 mg, 0.326 mmol, 1.0 eq) was dissolved in 50/50 methylene chloride/methanol (2 mL) and added to the BMCA solution drop wise through a septum. After 30 minutes acetic acid (5.0 uL, 0.087 mmol, 0.27 eq) was added and the reaction was allowed to proceed for 12 hrs. After 12 hrs the reaction mixture was filtered through a 0.2 μm filter, then washed with 0.1 M $NaHCO_3$. The organic layer was retained, dried with Na_2SO_4, and product was obtained after evaporation of solvent. Yield: 116.1 mg, 91.0%, white solid. ^{1}H NMR, δ ppm: 0.873 (q, 2H), 1.193 (t, 3H), 1.232 (m, 2H), 1.501 (m, 1H), 1.595 (d, 2H), 1.673 (d, 2H), 1.777 (s, 3H), 1.963 (m, 1H), 2.250 (t, 2H), 3.190 (q, 2H), 3.228 (d, 2H), 4.083 (q, 2H), 7.015 (s, 2H), 7.669 (t, 1H), 9.653 (s, 1H). ^{13}C NMR δ ppm: 14.565, 15.917, 28.408, 29.345, 33.292, 36.080, 36.623, 42.980, 43.757, 60.245, 134.290, 154.058, 156.534, 171.194, 174.704. MS calcd $[M+H]^+$ ($C_{19}H_{28}N_4O_5$): 393.2137, found (FAB): 393.2135. Product was further analyzed by UV-Vis spectroscopy and a molar extinction coefficient was calculated using dilutions in methanol.



Scheme S7. Reaction of BMCA with ethyl carbazate.

4.3. APM.

APM (400.0 mg, 1.86 mmol, 1.0 eq) was dissolved in 50/50 methylene chloride/methanol (2 mL), followed by addition of Na_2SO_4 (528 mg, 3.72 mmol, 2.2 eq). Ethyl carbazate (176.0 mg, 1.69 mmol, 0.91 eq) was dissolved in 50/50 methylene chloride/methanol (2 mL) and added to the APM solution drop wise with stirring. After 30 minutes acetic acid (5.0 μL, 0.174 mmol, 0.1 eq) was added and the reaction was continued for 12 hrs at room temperature. After 12 hrs the reaction mixture was filtered through a 0.2 μm filter and washed with 0.1M $NaHCO_3$. The organic layer was retained, dried with Na_2SO_4, and crude

product was obtained after evaporation of solvent. Product was further purified by silica gel chromatography (50/50 methylene chloride/ethyl acetate mobile phase). Yield: 0.150 g, 27%, yellow solid. ^{1}H NMR, δ ppm: 1.262 (d, 3H), 2.234 (s, 3H), 4.177 (q, 2H), 7.197 (s, 2H), 7.368 (m, 2H), 7.827 (m, 2H), 10.173 (s, 1H). ^{13}C NMR, δ ppm: 13.782,14.545, 60.509, 126.246, 126.356, 131.830, 134.676, 137.458, 147.997, 154.097,169.744. MS calcd $[M+H]^+$ ($C_{15}H_{15}N_3O_4$): 302.1140, found (FAB): 302.1137. Product was further analyzed by UV-Vis spectroscopy, and the molar extinction coefficient was calculated using dilutions in methanol.

Scheme S8. Reaction of APM with ethyl carbazate.

5. Spectral properties of hydrazones formed with crosslinkers and ethyl carbazate.

The spectroscopic properties of hydrazones formed from crosslinker reaction with ethyl carbazate are summarized in Table S1.

Table S1. Spectral properties of crosslinkers and corresponding hydrazones formed with ethyl carbazate

crosslinker	λ_{max} (nm)	λ_{max} of hydrazone (nm)	ε ($M^{-1}cm^{-1}$) of hydrazone
PMCA	299	297	5.53×10^2
BMCA	297	299	5.66×10^2
APM	268	288	1.90×10^4

Spectral properties of PMCA and BMCA crosslinkers before and after hydrazone formation were nearly identical, preventing analysis of hydrazone formation or degradation by simple absorbance measurements. The absorbance of PMCA and BMCA at 297 nm is due to the maleimide functional group, while the more intense and red-shifted APM absorbance results from the conjugated π system. The relatively high molar extinction coefficient of APM provides a convenient analytical tool for determination of the degree of conjugation, even at low concentrations.

Neutrophil Targeting Heterobivalent SPECT Imaging Probe: cFLFLF-PEG-TKPPR-^{99m}Tc

Yi Zhang,[†] Li Xiao,[†,‡] Mahendra D. Chordia,[‡] Landon W. Locke,[†] Mark B. Williams,[†] Stuart S. Berr,[†] and Dongfeng Pan*[,†]

A new heterobivalent peptide ligand specifically targeting polymorphonuclear leukocytes (PMNs) with favorable pharmacological parameters to monitor sites of inflammation for imaging is designed. The detailed synthesis, characterization, and pharmacological evaluation of the ligands are reported here. Two separate peptide binding ligands for formyl peptide and tuftsin receptors were chosen to link together based on the high expression levels of the two receptors on activated PMNs The heterobivalency and pegylated links were incorporated in the structural design to improve the sensitivity of the detection and to improve the bioavailability along with blood clearance profile, respectively. Two chemical constructs, cFLFLF-$(PEG)_n$-TKPPR-^{99m}Tc ($n = 4$, 12), were evaluated in vitro with human PMNs for binding affinity and bioavailability. As a result, cFLFLF-$(PEG)_{12}$-TKPPR-^{99m}Tc was found to have more favorable pharmacological properties and was therefore used for further in vivo studies. Preliminary in vivo assessment of the agent was performed using single gamma emission computed tomography (SPECT) imaging of a mouse model of ear inflammation. The results of these studies indicate cFLFLF-$(PEG)_{12}$-TKPPR-^{99m}Tc may be a desirable imaging agent for binding to PMNs to identify sites of inflammation by SPECT.

INTRODUCTION

High-quality nuclear imaging can be a useful diagnostic and prognostic tool for detecting sites of inflammation. This should aid in designing therapies to control pathological conditions. However, the ability to detect and characterize inflammation has been elusive so far (*1*). One of the hallmarks of inflammation is migration and activation of leukocytes. Current leukocyte imaging techniques include ex vivo white blood cell labeling with ^{67}Ga citrate, ^{111}In, or ^{99m}Tc containing complexes and reinjection of the labeled cells back into patients. Although the utility of this method is proven, the process is laborious and involves handling of blood products, thereby increasing the risk of contamination. Tracking neutrophils by intravenous administration of highly specific radiolabeled binding probes would circumvent these limitations. As a result, numerous chemotactic peptides, such as fMLF and its analogues have been investigated as potential neutrophil imaging probes (*2, 3*). However, exhibition of undesired biological side effects and/or poor pharmacokinetic parameters have limited their clinical utility.

We have recently reported a novel PET imaging agent, cFLFLF-PEG-^{64}Cu (PEG = 3.4 kDa), which binds to the formyl peptide receptor (FPR) without prompting neutrophil activation and, in addition, has favorable pharmacokinetic characteristics such as increased hydrophilicity to minimize nonspecific liver uptake (*4, 5*). However, the high cost of PET imaging and the limited supply of the cyclotron-produced ^{64}Cu isotope may restrict its widespread application in research and clinics. A ^{99m}Tc version of the probe for single gamma emission computed tomography (SPECT) imaging of neutrophils provides an attractive alternative because of the wider availability and lower cost of ^{99m}Tc. In addition, to further enhance the detection sensitivity, binding affinity, and specificity of the ligand toward neutrophils, we designed a heterobivalent peptide, cFLFLF-PEG-TKPPR-^{99m}Tc, that simultaneously targets the FPR and tuftsin receptor. Heterobivalent ligands have demonstrated higher affinity than monovalent and symmetrical bivalent binders (homodimer) (*6, 7*).

Because of inclusion of the polar TKPPR sequence in the present heterobivalent ligand design, the size of PEG linker was reduced in comparison with the larger PEG linker reported earlier in cFLFLF-PEG-^{64}Cu (PEG = 3.4 kDa) in order to maintain roughly the same water solubility. Thus, the two binding peptide sequences were linked through either a bifunctional PEG_4 or PEG_{12} moiety. An additional lysine residue was incorporated in the construct as a handle for the HYNIC group and its coordination to radiometal (Scheme 1). We wish to report here the detailed synthetic method, the observed pharmacokinetic parameters for these new probes, and a preliminary demonstration of its application to SPECT imaging of inflammation in vivo.

EXPERIMENTAL PROCEDURES

Materials and Methods. All chemicals obtained commercially were of analytical grade and used without further purification. Na^{99m}TcO$_4$ was obtained from Cardinal Health, Inc. (Charlottesville, VA). 6-Boc-hydrazinonicotinic acid (6-Boc-HYNIC acid) was obtained from SoluLink (San Diego, CA). Fmoc-Arg-PS resin was purchased from Applied Biosystems (Foster City, CA). Fmoc-amino acids were purchase from Anaspec Inc. (Fermont, CA). N-Fmoc-amino-dPEG$^{TM}_4$ acid and N-Fmoc-amino-dPEG$^{TM}_{12}$ acid were purchased from Quanta Biodesign, Ltd. (Powell, OH). *N*-Hydroxysulfosuccinimide (Sulfo-NHS) and 1-ethyl-3-[3-(dimethylamino)-propyl]carbodiimide (EDC) were purchased from Pierce (Rockford, IL). All other chemical reagents and solvents were obtained from Sigma-

[a] Reagent and conditions: (i) standard solid phase Fmoc chemistry; (ii) (1) piperidine, (2)Fmoc-(PEG)*n*-COOH, HBTU, DIEA; (iii) standard solid phase Fmoc chemistry; (iv) (1) 2% hydrazine, (2) 6-Boc-HYNIC acid, HBTU, DIEA; (v) TFA (95%); (vi) $^{99m}TcO_4^-$, $SnCl_2$, tricine, nicotinic acid, pH 5.2.

Aldrich. For purification of peptide precursors and ^{99m}Tc labeled products, semipreparative reversed-phase high-performance liquid chromatography (RP-HPLC) was performed with an Apollo C18 reversed-phase column (5 μ, 250 $\times$ 10 mm) on a Varian system with ABI Spectroflow 783 UV detector and Bioscan NaI solid scintillation flow count radio-HPLC detector. The mobile phase was changed from 60% Solvent A (0.1% TFA in water) and 40% Solvent B (0.1% TFA in 80% aqueous acetonitrile) to 100% Solvent B at 30 min at a flow rate 3 mL/min. MALDI-TOF mass spectroscopy analysis was performed on samples of peptide products at the W. M. Keck Biomedical Mass Spectrometry Laboratory at the University of Virginia (UVa) and the data obtained on a Bruker Daltonics system (Billerica, MA). Peptides were synthesized manually by standard solid-phase method, following a conventional Fmoc strategy using 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) as the coupling agent. Lysine was used as handle to incorporate HYNIC to the peptide. High-performance liquid chromatographic (HPLC) analysis of the nonradiolabeled compounds was performed on a Varian Prostar system equipped with a ProStar 335 HPLC diode array detector. HPLC solvents were purchased from Fisher Scientific (Pittsburgh, PA) and used without further purification. Typical yields of the crude peptides were 80−85%.

Human tumor necrosis factor-α (TNF-α) was procured from Peprotech, and fMLF was purchased from Sigma. Aliquots of both samples were taken (TNF-α, 10 U/mL, and fMLF, 10 mM) and stored at −20 °C. For every assay, the solutions were thawed to ambient temperature and freshly diluted with hepatic arterial (HA) buffer before use. Multiscreen high-throughput screening (HTS) with glass fiber filter (FC) 96-well plates, type C, with 1.2 mm glass filters were purchased from Millipore. Filtration from 96- well plates was performed under vacuum on a Brandel filtration device. The membranes from each well were collected by punching with the Millipore Multiscreen punching instrument. The radioactivity from ^{99m}Tc-bound ligand was measured with Minaxi (Packard), Autogamma 5000 series (Packard), or Wallac 1420Wizard (Perkin-Elmer) γ-counters. Radioactivity was measured for 1 min per sample and was not corrected for decay.

Human neutrophils were prepared from normal heparinized (10 U/mL) venous blood by a one-step Ficoll-Hypaque separation procedure (*8, 9*), yielding approximately 98% neutrophils; greater than 95% viable as determined with trypan blue containing less than 50 pg/mL of endotoxin. After separation, neutrophils were washed with Hank's balanced salt solution with heparin (10 U/mL) 3 times. After the third wash, neutrophils were resuspended in HA buffer, which was Hank's balanced salt solution supplemented with 0.1% human albumin (Bayer Healthcare). Neutrophil experiments were completed in HA buffer.

Female FVB mice, 5 months old, were purchased from the National Cancer Institute (Frederick, MD). Mice were housed in a controlled environment (12 h light/12 h dark photoperiod, 22 ± 1 °C, 60 ± 10% relative humidity), and were provided free access to autoclaved pellet food and tap water. All procedures were in accordance with current National Institutes of Health (NIH) guidelines and were approved by the University of Virginia Animal Care and Use Committee (ACUC).

SPECT/CT imaging was performed with a microSPECT/CT scanner designed and built at UVa under NIH funding (*10*). The scanner uses an open-barrel type gantry consisting of two 38 in steel wheels connected by aluminum profile pieces. CT and SPECT scanning are performed sequentially, and the animal is translated axially from one subsystem to another between two fixed locations along a 1-in-diameter carbon fiber half-cylinder that is located at the gantry axis of rotation. Reproducibility of animal table location permits consistent and simple fusion of CT and SPECT images using stored offset parameters. The scanner can be operated with two different types of X-ray detectors: CCD-based for high spatial resolution (modulation transfer function in the reconstructed CT image of 0.1 at a spatial frequency of 14.7 mm^{-1} when used with an 8 μm X-ray source) or CMOS-based for fast readout (2 frames per second). Microfocus X-ray sources with focal spot sizes ranging between 8 and 50 μm are available. SPECT scanning can be performed using up to four gamma cameras (10 cm $\times$ 10 cm fields of view) simultaneously. Respiratory and cardiac gating are available for both CT and SPECT scanning. CT projection images are preprocessed for detector sensitivity uniformity correction and dark count subtraction using a custom-written IDL program and then are reconstructed with a Feldkamp three-dimensional filtered backprojection algorithm (COBRA, Exxim, Inc., Pleasanton, CA). SPECT data are acquired using a custom-written interface using Kmax (Sparrow Corp., Port Orange, FL) software and reconstructed using a custom-written maximum-likelihood expectation-maximization algorithm (*11*).

Synthesis of cFLFLF-PEG$_n$-K(HYNIC)TKPPR 6 and 7. (Scheme 1). Fmoc-Arg-PS resin **1** (150 mg, 0.21 mmol/g) was loaded to a peptide synthesis vessel, suspended in DMF (2 mL), and shaken at 600 rpm for 5 min and drained. Fmoc was removed by adding 2 mL of 20% piperidine−DMF solution to the synthesis vessel. The vessel was shaken on a vibrator (Labnet Shaker 20, Woodbridge, NJ) for 5 min, and the solution was

drained. The same deprotection step was repeated once again by shaking for 20 min. The deprotected resin was washed six times each with 2 mL of DMF. The resin was then coupled to the Fmoc-protected amino acid by successively adding 4 molar excess of the Fmoc-protected amino acid (0.84 mmol) in DMF (0.1 M), 4 equiv of HBTU in DMF (0.1 M), and 8-fold excess of DIEA (1.68 mmol). The reaction vessel was shaken for 90 min. The reaction solution was drained off, and the resin was washed with 3 × 2 mL of DMF. The peptide resin was subsequently capped by adding 10-fold molar excess of acetic anhydride (0.5 mL) and DIEA and shaking at 600 rpm for 30 min. After draining off the solution, the resin was washed with 6 × 2 mL of DMF and was then ready for the next cycle of coupling. To obtain the resin-bound peptide sequence **4**, the amino acids and special residues were coupled in the following order: Fmoc-Pro, Fmoc-Pro, Fmoc-Lys(*t*-Boc), Fmoc-Thr(t-Bu), Fmoc-Lys(ivDDE), *N*-Fmoc-amino-dPEG$^{TM}_4$ acid or N-Fmoc-amino-dPEG$^{TM}_{12}$ acid, Fmoc-Phe, Fmoc-(D)Leu, Fmoc-Phe, Fmoc-(D)Leu, Fmoc-Phe, and Trans-cinnamic acid. The ivDDE protecting group of **4** was removed to free the ω-NH_2 of the lysine by treatment with 2% hydrazine in DMF for 60 min. After draining, the peptide resin was repeatedly washed with DMF (2 mL) six times. To conjugate the chelating HYNIC moiety at the ω-NH_2 of the lysine, a solution of 4 molar excess of 6-Boc-HYNIC acid, 4 equiv of HBTU, and 8 equiv of DIEA in 1.6 mL of DMF was added into the reaction vessel. The vessel was shaken for 90 min, the solution was drained off, and the resin was washed with DMF (2 mL) three times. The peptide cFLFLF-PEG$_n$-K(HYNIC)TKPPR **6** or **7** was cleaved from the resin support using a 95% TFA. The crude products were purified with the HPLC conditions described above. The molecular weights of the purified precursors were verified by MALDI-TOF mass spectroscopy.

cFLFLF-PEG$_n$-TKPPR-^{99m}Tc 8 or 9. To a 1.5 mL vial was consecutively added 100 μg of cFLFLF-PEG$_n$-K(HYNIC)TKPPR **6** or **7** in 200 μL of citrate buffer (10 mM, pH 5.2), 200 μL of tricine solution (30 mg/mL in 10 mM citrate buffer, pH 5.2), 100 μL of nicotinic acid solution (10 mg/mL in 10 mM citrate buffer, pH 5.2), 37 MBq of $^{99m}TcO_4^-$ solution (370 MBq/mL in saline), and 25 μL of $SnCl_2$ solution (1.0 mg/mL in 0.1 N HCl). The reaction mixture was stirred by shaking and heated at 60 °C for 15 min. After being cooled to room temperature for 10 min, the reaction mixture was purified by the same HPLC conditions mentioned above. The observed retention times of cFLFLF-PEG$_4$-TKPPR-^{99m}Tc **8** and cFLFLF-PEG$_{12}$-THPPK-^{99m}Tc **9** were 17.8 and 16.8 min, respectively.

Partition Coefficient. Freshly HPLC purified cFLFLF-PEG$_n$-KTKPPR-^{99m}Tc **8** or **9** (~350 kBq) in 500 μL of water was mixed with 500 μL of octanol in an Eppendorf microcentrifuge tube. The tube was sonicated 10 min and then centrifuged at 4000 rpm 5 min (Fisher Scientific Marathon Micro-A). Aliquots (100 μL) of octanol and aqueous layers were carefully separated and radioactivity of samples counted. Log *P* is derived as the log of the ratio of radioactivity in octanol to radioactivity in water. The measurement was repeated in triplicate and data presented are the average of three measurements.

Neutrophil Binding. Freshly isolated human neutrophils (4 × 10^6 cells/mL) were treated with TNF-α (10 U/mL, Peprotech) twenty minutes prior to binding studies and transferred to a 96 well plate (Multiscreen HTS FC by Millipore, Billerica, MA. 1.2 μm glass filter type C, 50.0 μL, ~2.0 × 10^5 cells/well). Saturation assays were carried out using eight different concentrations of cFLFLF-PEG$_{12}$-TKPPR-^{99m}Tc ranging from 1.0 μM to 0.01 nm incubated at 25 °C for 90 min. Neutrophils were incubated with the excess radioligand at 25 °C for 90 min to obtain total binding. Following incubation, the plates were filtered rapidly under vacuum using a Brandel filtration device (Brandel Inc., Gaithersburg, MD), washed three times with cold Tris-Mg buffer (−5 °C, 10 mM, 150 μL each time/well) to remove the unbound radioligand, and dried under vacuum. The plates were then wiped with Kimwipes EX-L at room temperature, and membranes from each well were collected by Millipore multiscreen punching instrument (Billerica, MA). The bounded radioactivity remaining on the membranes was measured in a gamma counter. Specific binding was calculated as the difference between total binding and nonspecific binding at the highest concentration. Nonradioactive peptide (cFLFLF-PEG$_{12}$-TKPPR) was used in excess (100 μM) to determine nonspecific binding. Saturation experiment data (K_d and B_{max} values) were obtained by computer analysis using *Prism 4.0* (GraphPad).

Blood Clearance. Blood kinetics of cFLFLF-PEG$_{12}$-TKPPR-^{99m}Tc was studied in 3 control (non-inflamed) mice. Approximately 50 μL samples of blood from the contralateral tail vein were collected in capillary tubes at 15, 30, 45, 60, 120, and 180, and 360 min after tracer injection (0.37−0.74 MBq). The capillary tubes were placed in a vial that was weighed beforehand and afterward. Activity in each blood sample was measured in a radioisotope-calibrated well counter (CRC-15W, Capintec, Inc., NJ), decay-corrected back to the time of tracer injection, normalized for injected dose and animal body weight, and expressed as %ID/g of blood.

Serum Stability of cFLFLF-PEG$_{12}$-TKPPR-^{99m}Tc. Fifty microcuries of the cFLFLF-PEG$_{12}$-TKPPR-^{99m}Tc was added in to 100 μL of fetal bovine serum (Invitrogen, Grand Island, NY). After incubation at 37 °C for 1, 3, and 6 h, aliquots of the mixture were filtered through a 0.2 μM microspin filter. The filtrates were analyzed by reverse-phase HPLC with a Bioscan Flow Count Radio-HPLC detector. All of the newly formed γ-peaks besides the original cFLFLF-PEG$_{12}$-TKPPR-^{99m}Tc peak would be considered as degraded products.

Biodistribution. Body distribution of radioactivity was determined in control ($n = 3$) mice at 3 and 18 h after injection of the tracer. After a single blood sample had been taken from the tail vein, mice were euthanized by deep halothane anesthesia. The organs and tissues (ear, heart, lungs, muscle, bone, liver, kidney, spleen, small intestine, and stomach) were collected, rinsed with PBS, wiped with filter paper, and weighed in a preweighed vial. The radioactivity of each sample was measured in a γ-well counter and decay-corrected back to the time of tracer injection. Biodistribution values are expressed as a percentage of the injected dose (%ID) and normalized by body and organ/tissue mass.

Mouse Ear Inflammation Model. A female FVB mouse, 5 month old, with left ear inflammatory lesion was used to preliminarily assess the ability of the cFLFLF-PEG$_{12}$-TKPPR-^{99m}Tc to detect inflammation as a result of neutrophil migration and accumulation. The animal model is similar to that described by Gross et al. (*12*). Topical application of PMA (2.5 μg in 20 μL DMSO) onto the left earlobe induces acute dermatitis, manifested by local swelling, erythema, and infiltration of neutrophils (*13, 14*). The right ear served as control and received only DMSO (vehicle). The SPECT/CT imaging was correlated with myeloperoxidase (MPO) activity determined by noninvasive bioluminal-bioluminescence imaging (*12*).

Luminal-Bioluminescence Imaging of MPO. Since MPO is the most abundant protein in azurophilic granules of neutrophils, an MPO-specific luminal-bioluminescence study was carried out in support of the accumulation and activation of neutrophils in the PMA-treated ear. The mice were injected with 200 μL of luminol (5 mg/0.1 L DMF) intraperitoneally 22 h after PMA application. Immediately after luminal injection, a 40 min kinetic bioluminescence scan was performed on Xenogen

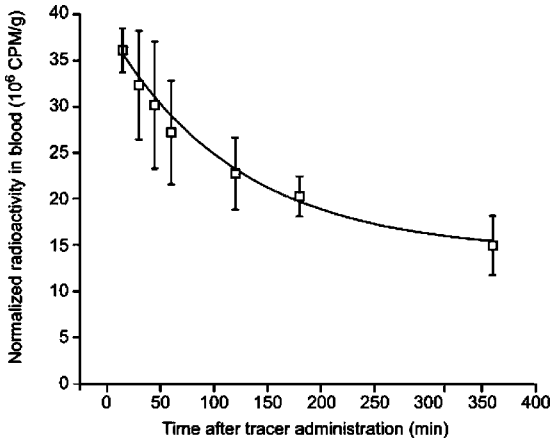

Figure 1. Monoexponential blood clearance curve of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc in control mice ($n = 3$): the normalized blood radioactivity was plotted against various time points after tail vein injection of the tracer.

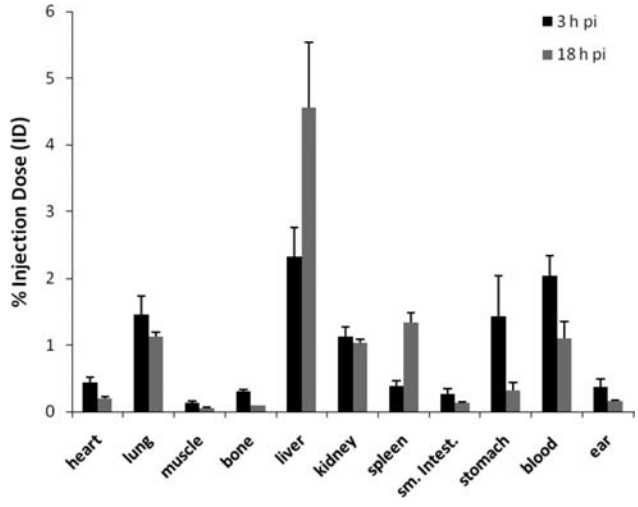

Figure 2. Tissue and organ accumulation of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc at 3 and 18 h post-injection of normal mice ($n = 3$) expressed as the percent injected dose per gram of tissue (decay corrected).

IVIS Spectrum (Caliper life science, CA) and processed on *Live Image* software (Caliper life science) with open filter and exposure time of 60 s.

SPECT/CT Imaging. Twenty-four hours after PMA challenge, 3.7 MBq (1 mCi) of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc in 200 μL of saline was administered via tail vein. Three hours later, CT/SPECT imaging was performed using the microSPECT/CT scanner described above. Anesthesia (1−2% isoflurane in oxygen) was delivered throughout the imaging procedure. CT projection data acquisition used the CMOS X-ray detector and obtained 200 evenly spaced projections spanning 240° over approximately 5 min. For SPECT scanning, 60 evenly spaced views were obtained over 180° using two opposing gamma cameras simultaneously, resulting in a total of 120 projections over 360° at an angular increment of 3°. The acquisition time was approximately 45 min. The two cameras were fitted with 0.5-mm-diameter tungsten pinholes. The reconstructed CT voxel size was $0.164 \times 0.164 \times 0.164$ mm^3 on a $320 \times 320 \times 384$ image matrix. The reconstructed SPECT voxel size was $0.4 \times 0.4 \times 0.4$ mm^3 on a $60 \times 60 \times 60$ image matrix. All SPECT images were corrected for radioactivity decay but not for gamma ray attenuation.

Image Analysis. Co-registration of SPECT and CT images was performed using *ASIPRO* software (Siemens Medical Solutions USA, Inc., Knoxville, TN) and a transformation matrix previously obtained with a dual modality phantom. To characterize the accumulation of the tracer in the ears, volume-of-interest (VOI) analysis was performed to identify the number of detected counts originating in the ears. CT images were used to identify voxels lying within the ear and the corresponding SPECT voxels were included in each VOI. Inflamed VOI was drawn tightly around the ear inflammation area on the SPECT transaxial image slice and copied to the control ear. Six slices were taken in both ears. The upper 60% signal (in counts/mL) was taken into calculation in each slice. The known gamma camera detection efficiency was used to compute the activity contained in the ears. This activity was expressed as a percentage of the injected dose per mouse body mass (%ID/g).

RESULTS AND DISCUSSION

The precursors, cFLFLF-PEG_n-K(HYNIC)TKPPR **6** and **7**, were synthesized using standard Fmoc peptide chemistry on resin. Briefly, starting from arginine residue loaded on resin at carboxyl group, the TK(*t*-Boc)PPR peptide was constructed first, an additional lysine residue [Lys(ivDDE)] was added to form intermediate **2** prior to addition of varied pegylated linker. Then, on the other side of the PEG the second cFLFLF peptide was built to produce the desired peptide sequence **4**. Finally, the removal of the ivDDE protecting group of the lysine linker using basic hydrazine conditions released the side chain ω-NH_2 derivative **5** for conjugation with HYNIC. The resin-bound HYNIC conjugated bivalent peptides **6** and **7** were cleaved with standard TFA chemistry. The two precursor peptides were purified by reverse-phase HPLC with total yield in the range 20−25%. The purified peptide constructs were characterized by mass spectroscopy for its composition. The calculated and observed MALDI-TOF-MS $[M+H]^+$ were 1905 and 1906 for cFLFLF-PEG_4-K(HYNIC)TKPPR **6** and 2258 and 2258 for cFLFLF-PEG_{12}-K(HYNIC)TKPPR **7**. The two radiolabeled cFLFLF-PEG_n-K(HYNIC)-TKPPR-^{99m}Tc **(8)** ($n = 4$) and (**9**) ($n = 12$) were obtained by conjugating **6** and **7** with stannous chloride reduced [^{99m}Tc]pertechnedate with nicotinic acid and

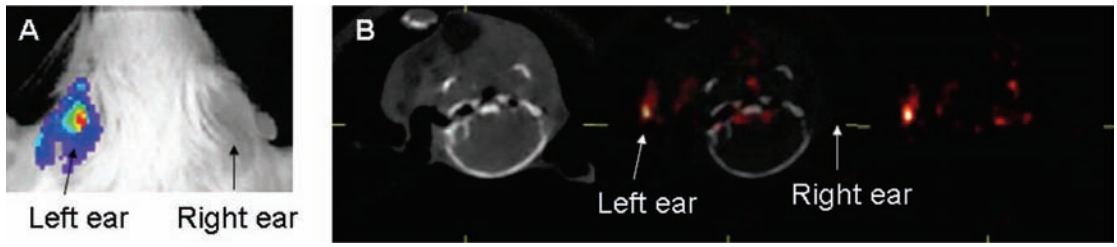

Figure 3. (A) Representative MPO-BLN image of mouse subjected to topical application of PMA on left ear for 24 h. (B) Representative transaxial images of MicroCT (left), MicroSPECT (right), and fused micro-CT and micro-SPECT (middle) of mice subjected to PMA application on left ears. Both SPECT and CT images were obtained 3 h after tail vein injection of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc. SPECT scans revealed the PMA infected ear had visually more tracer uptake compared to control ear, which was quantified by ROI analysis.

tricine as coligands, respectively. The radiolabeled peptides were purified from unlabeled precursors and other reagents by reverse-phase semipreparative HPLC with radiochemical yield of >75% and radiochemical purity of 98%. The detailed synthetic method is described in Scheme 1.

The in vitro binding studies to isolated human neutrophils exhibited K_d values 47.8 and 15.1 nM for ligands **8** and **9**, respectively. The radiolabled ligand **8** was roughly 3-fold less potent than compound **9**, possibly due to the longer PEG_{12} linker allows the simultaneous binding to both the formyl peptide and the tuftsin receptors on activated neutrophils. The purified radioligands **8** and **9** were first evaluated for their Log *P* values to estimate approximate lipophilicity of the individual compounds. The observed Log *P* values for **8** and **9** are in agreement with the expected trend as PEG12 linked was found to be more hydrophilic (−0.89) compared to PEG4 derivative (−0.77). On the basis of the better solubility in water and higher binding affinity, radioligand **9** was chosen for further in vivo studies.

The cFLFLF-PEG_{12}-TKPPR-^{99m}Tc is stable for at least 6 h in serum. HPLC analysis of serum samples mixed with ligand displayed no appreciable fragments of ^{99m}Tc labeled peptide at each time point (1, 3, and 6 h).

In order to further analyze the pharmacokinetic parameters of the ligand **9**, blood clearance studies were conducted in vivo. The data revealed a monoexponential clearance of the radiotracer as shown in Figure 1. The elimination half-life for blood clearance ($T_{1/2}$) was calculated to be about 84 min.

Biodistribution of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc in liver increases from 2.3 to 5.3%ID at 3 and 18 h post-injection which indicated the radiotracer is excreted mainly through the hepatobilliary pathway. The longer blood retention of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc, 2.1 and 1.2%ID at 3 and 18 h post-injection vs 0.2%ID (*15*) of cFLFLFK-PEG-^{64}Cu at 18 h post-injection, correlates the longer circulation time ($T_{1/2}$) of 84 vs 55 min (Figure 2). This indicates that a longer PEG moiety might be needed for fast blood clearance of cFLFLF-PEG_n-TKPPR-^{99m}Tc and, therefore, benefit the earlier imaging quality by lowering background signals from blood.

At 22 h post PMA treatment, bioluminescence as observed by MPO assay was locally emitted from PMA-treated earlobes of FVB (female) mice after luminal administration, reaching levels 7-fold over those of vehicle-treated ears. The image (Figure 2a) 21 min after luminal injection was chosen as a representative due to the highest ratio of photons emitted from inflamed ear (left) to control ear (right). At 27 h after PMA challenge and 3 h post-injection of cFLFLF-PEG_{12}-TKPPR-^{99m}Tc, CT/SPECT imaging shows that the accumulation of the tracer measured in the inflamed ear (left) is about 3.15-fold higher than in the control ear (Figure 3b).

This preliminary data suggests that in vivo detection of inflammation through neutrophil activation and migration in live animal is feasible with gamma or SPECT modalities. In a real inflammatory situation, the intensity of radiotracer signal will be dependent on the intensity of inflammation and amount of PMN accumulation at the inflammatory site.

CONCLUSION

In conclusion, we have synthesized two neutrophil-targeting heterobivalent SPECT imaging probes: cFLFLF-PEG_4-TKPPR-^{99m}Tc and cFLFLF-PEG_{12}-TKPPR-^{99m}Tc. The peptide ligands bound to neutrophils with high affinity and demonstrated stability in serum and sufficient hydrophilicity. The cFLFLF-PEG_{12}-TKPPR-^{99m}Tc is a feasible probe for in vivo imaging of acute neutrophilic inflammation. Further biologic evaluation of this novel imaging agent is ongoing, with the goal of refining the biologic properties of the agent to facilitate studies that assess the efficacy of novel anti-inflammatory therapeutic drug candidates. On the basis of preliminary in vivo imaging results and in vitro cell function assays, this peptide appears to possess properties to be a promising new radiopharmaceutical for the in vivo imaging of neutrophils.

Apoptosis and macrophage burden are believed to correlate with atherosclerotic plaque vulnerability and are therefore considered important diagnostic and therapeutic targets for atherosclerosis. These cell types are characterized by the exposure of phosphatidylserine (PS) at their surface. In the present study, we developed and applied a small micellar fluorescent annexin A5-functionalized nanoparticle for noninvasive magnetic resonance imaging (MRI) of PS exposing cells in atherosclerotic lesions. Annexin A5-mediated target-specificity was confirmed with ellipsometry and in vitro binding to apoptotic Jurkat cells. In vivo T_1-weighted MRI of the abdominal aorta in atherosclerotic ApoE$^{-/-}$ mice revealed enhanced uptake of the annexin A5-micelles as compared to control-micelles, which was corroborated with ex vivo near-infrared fluorescence images of excised whole aortas. Confocal laser scanning microscopy (CLSM) demonstrated that the targeted agent was associated with macrophages and apoptotic cells, whereas the nonspecific control agent showed no clear uptake by such cells. In conclusion, the annexin A5-conjugated bimodal micelles displayed potential for noninvasive assessment of cell types that are considered to significantly contribute to plaque instability and therefore may be of great value in the assessment of atherosclerotic lesion phenotype.

INTRODUCTION

Annexin A5, a 36 kDa protein belonging to the annexin family, is known to bind to the negatively charged phospholipid phosphatidylserine (PS) in the presence of Ca^{2+} (*1*, *2*). In almost all homeostatic cells, this phospholipid is restricted to the cytoplasmic leaflet of the plasma membrane and therefore inaccessible from the extracellular compartment (*3*). However, dying and activated cells, such as apoptotic cells, activated platelets (*4*, *5*), and activated macrophages (*6*), are known to expose PS also in the exoplasmic layer of the cell membrane. Furthermore, membrane integrity is lost during the process of necrosis, thereby allowing extracellular proteins to enter the cell (*7*). Therefore, annexin A5 has been proposed and exploited to function as a ligand to target apoptotic, necrotic, and other PS exposing cells for a variety of applications, including cell sorting, imaging, and drug targeting (*8*−*11*).

In atherosclerosis, a high occurrence of apoptosis and necrosis, as well as high macrophage burden, is believed to contribute significantly to plaque vulnerability and rupture (*12*−*15*). Consequently, identification of these markers using annexin A5-targeted noninvasive diagnostic imaging may contribute to discrimination between atherosclerotic lesions with a stable and unstable phenotype, which would be of great clinical value. To this aim, there have been a number of studies where technetium (^{99}Tc) or indium (^{111}In) -labeled annexin A5 has been used for imaging of vulnerable plaque or the effect of therapy with nuclear techniques in both experimental (*16*−*20*) and human atherosclerosis (*21*). Importantly, these studies demonstrated significant correlations between the extent of annexin A5 uptake, macrophage content, and the amount of apoptosis. Furthermore, all of these values were shown to increase with more advanced lesions, as classified according to the American Heart Association.

Although nuclear imaging is a very sensitive technique, it suffers from poor spatial resolution and the images lack detailed anatomical information. MRI is an imaging modality with a high spatial resolution and can discriminate among different plaque components (*22*). Nevertheless, MRI suffers from relatively low sensitivity (*23*). In targeted molecular MRI, the latter drawback is frequently compensated for by using high relaxivity (super)-paramagnetic imaging probes (*24*). These probes, usually nanoparticulate in nature, contain either (multiple) iron oxide crystals or a high payload of gadolinium. We and others previously reported on a number of such nanoparticles that have been successfully applied for MRI-based molecular imaging of atherosclerosis. These include target-specific lipid-based nanoparticles within the size range of 10−300 nm, such as micelles (*25*, *26*), high-density lipoproteins (HDL) (*27*), liposomes (*28*), and microemulsions (*29*), in which large numbers of Gd-DTPA moieties were incorporated in the lipid (bi)layer. Alternatively, iron oxide-based nanoparticles have been developed to enable molecular MRI of lipoproteins (*30*) or adhesion molecule expression in atherosclerotic plaques (*31*). For validation and co-localization purposes, the aforementioned nanoparticles can include additional fluorescent dyes, such as fluorescent lipids or quantum dots (*32*).

In the present study, we developed and characterized a small annexin A5-conjugated micellar nanoparticle, carrying multiple Gd-labeled lipids for MRI and fluorescent lipids for fluorescence microscopy or imaging. Target-specificity of this nanoparticle

for PS was examined with ellipsometry of PS-containing membranes, as well as CLSM of apoptotic Jurkat cells in vitro. Furthermore, in a pilot study, the nanoparticles were applied for in vivo MR imaging of phosphatidylserine exposing cells in atherosclerotic lesions of ApoE knockout ($ApoE^{-/-}$) mice. Ex vivo near-infrared fluorescence imaging of intact aortas was used to validate and quantify nanoparticle uptake in the lesions, while CLSM was employed to investigate which specific cell types bound the contrast agent.

EXPERIMENTAL PROCEDURES

Materials. 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(poly(ethylene glycol))-2000] (PEG2000-DSPE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[maleimide-(poly(ethylene glycol))2000] (Mal-PEG2000-DSPE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(poly(ethylene glycol))2000] (Amine-PEG2000-DSPE), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (Rhodamine-PE) were obtained from Avanti Polar Lipids (Albaster, AL). Cy5.5 monoreactive NHS ester was obtained from GE Healthcare Europe GmbH (Amersham CyDye value packs, Diegem, Belgium). Gd-DTPA-di(stearylamide) (Gd-DTPA-DSA) was purchased from Gateway Chemical Technology (St. Louis, MO). HEPES was purchased from Merck (Darmstadt, Germany). All other chemicals were of analytic grade or of the best grade available. A Bradford protein assay kit was purchased from Bio-Rad laboratories (Veenendaal, The Netherlands).

Cy5.5-PEG2000-DSPE. Cy5.5-PEG2000-DSPE lipid was prepared by covalent conjugation of Cy5.5 monoreactive NHS ester to micellar Amine-PEG2000-DSPE. First, Amine-PEG2000-DSPE micelles were prepared by lipid film hydration. In short, 10 μmol Amine-PEG2000-DSPE was dissolved in 0.5 mL chloroform. Subsequently, a lipid film was obtained by rotary evaporation of the solvent, followed by additional drying under nitrogen flow. Next, the film was gently hydrated in 5 mL sodium bicarbonate solution (0.1 M $NaHCO_3$, pH 8.0) at 65 °C, until a clear solution was obtained. Once micelles were formed, 5 mg Cy5.5 monoreactive NHS ester was dissolved in 100 μL dimethyl sulfoxide (DMSO) and immediately added to the micelle-containing suspension. Coupling was performed via overnight incubation at 4 °C on a moving table. The resulting micelles were sequentially concentrated and resuspended in ultrapure water, using 20 mL vivaspin concentrators (Vivascience, Sartorius Stedim Biotech, 10 000 MWCO) at 3000 × *g* and 4 °C. At least five wash cycles were required to remove nonbound Cy5.5. Following the washing procedure, the Cy5.5-PEG2000-DSPE-micelle suspension was dried with a FreeZone 4.5 L benchtop freeze−dry system for three days (Labconco). The obtained lipid powder was dissolved in a 2:1 (v/v) mixture of chloroform and methanol, to a final Cy5.5-PEG-DSPE concentration of 1 μmol/mL.

Micellar Contrast Agent. Bimodal micelles were obtained by lipid film hydration of a lipid mixture, typically containing a total amount of 50 μmol lipids. Gd-DTPA-DSA, PEG2000-DSPE, and Mal-PEG2000-DSPE were added at a molar ratio of 0.5/0.4/0.1 and dissolved in chloroform/methanol 2:1 (v/v). Next, 1 mol % Cy5.5-PEG-DSPE or Rhodamine-PE was added to the lipid mixture for near-infrared fluorescence imaging or confocal microscopy, respectively. The solvent was removed by rotary evaporation, and additional drying of the lipid film was performed under nitrogen flow. Next, the lipid film was gently dissolved in 4 mL of warm HEPES buffered saline (20 mM HEPES and 135 mM NaCl, pH 6.7, 65 °C) during continuous heating at 65 °C until a clear solution was obtained.

Annexin A5 Coupling. The micellar contrast agent was functionalized with a variant of annexin A5 that has a single cysteine residue in the N-terminal tail (annexin A5-cys). The PS and apoptotic cell binding properties of annexin A5-cys are identical to those of recombinant human annexin A5 as previously shown by ellipsometry (*1*) and flow cytometry (*33*), respectively. Annexin A5-cys (~36 kDa) was covalently conjugated to the Mal-PEG2000-DSPE-containing micelles by sulfhydryl−maleimide coupling, as previously described for other lipid-based agents (*34*). In short, annexin A5-cys was reactivated with 10 mM DTT for 1.5 h at 37 °C. Next, 10 mM EDTA was added and DTT and EDTA were removed by extensive dialysis using a 12−14 kDa membrane (Pierce). Activated annexin A5-cys was added to the micelle suspension at a final concentration of 750 μg/μmol total lipid, and coupling was performed overnight at 4 °C. Subsequently, the annexin A5-micelles (AnxA5-micelles) were concentrated and resuspended at least 5 times in HEPES buffered saline (20 mM HEPES and 135 mM NaCl, pH 6.7) to remove nonconjugated annexin A5-cys, using 20 mL vivaspin concentrators (Vivascience, Sartorius Stedim Biotech, MWCO 100 000) at 3000 × *g* and 4 °C. Untargeted micelles were concentrated using the same protocol. A schematic of the preparation procedure of the annexin A5-micelles is shown in Figure 1.

Contrast Agent Characterization. Dynamic light scattering was performed on a Malvern instrument (Zetasizer, Nano-S) to determine the hydrodynamic diameter of control and anxA5-micelles in HEPES buffered saline (20 mM HEPES and 135 mM NaCl, pH 7.4), as deduced from the intensity-weighted particle size distribution. Final micelle concentration was determined by a phosphate analysis according to Rouser (*35*) after complete destruction with perchloric acid. Protein content of the AnxA5-micelles was measured according to a modified Bradford method (*36*), which corrects for lipid-associated background absorption at 750 nm by adding equivalent concentrations of control-micelles to calibration samples containing a known amount of annexin A5-cys. Relaxivity measurements were performed on a 60 MHz table top NMR spectrometer (Bruker, Minispec), at 25 and 37 °C. Relaxivities were obtained by measuring T_1 and T_2 values for serial dilutions of the Cy5.5-labeled micelles in the range 0.4−3.4 mM total lipid. T_1 relaxation times were obtained with an inversion recovery sequence, whereas T_2 values were measured using a CPMG sequence.

In Vitro Targeting. *Ellipsometry.* The interaction of the Cy5.5-labeled annexin A5-micelles with phosphatidylserine (PS) was monitored with ellipsometry as described in detail elsewhere (*34*). Untargeted micelles and unconjugated annexin A5-cys served as a control. In short, a silica plate was coated with a lipid bilayer of PS and phosphatidylcholine (PC) at a molar ratio of 20:80. The lipid-coated silica plate was placed in a sample container, filled with 5 mL of Ca^{2+}-containing binding buffer (10 mM HEPES, 150 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 2.5 mM $CaCl_2$, pH 7.4). Micelles were added at a final concentration of 280 μM total lipid, while the final concentration of free annexin A5-cys protein was 56 nM. Binding of the particles was assessed by continuously measuring the polarization angle of the reflected elliptically polarized light. Once the polarization angle reached a steady-state value, 5 mM EDTA was added to investigate Ca^{2+}-dependent membrane association.

Apoptotic Cells. Target specificity for apoptotic cells was examined in the T-lymphoma cell line Jurkat (ATCC). Cells were grown in RPMI1640 medium (Gibco) at 37 °C in a humidified atmosphere and 5% CO_2. Medium was supplemented with 10% fetal calf serum and a mixture of antibiotics (100 units/mL penicillin and 0.1 mg/mL streptomycin; Biochrom AG). In order to induce a high level of apoptosis, Jurkat cells were resuspended to 1×10^6 cells/mL medium and treated with 200 ng/mL anti-Fas (CD95 human monoclonal antibody,

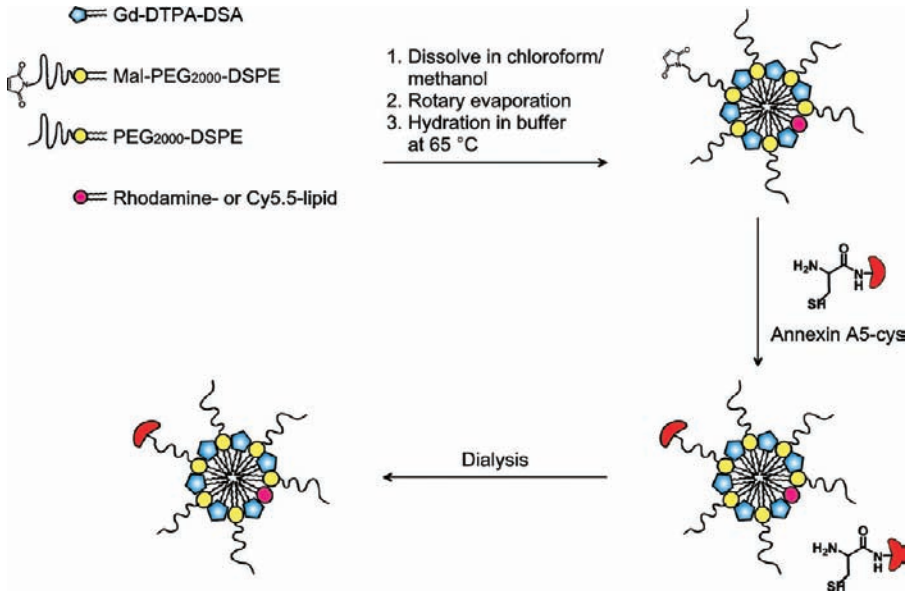

Figure 1. Schematic of nanoparticle preparation.

Beckman Coulter B.V.) for 3 h at 37 °C in a humidified atmosphere and 5% CO_2. Following this procedure, which initiated apoptosis in approximately 40−50% of the cells, cells were harvested and resuspended in Ca^{2+}-containing binding buffer to a final concentration of 2.5×10^6 cells/mL. Next, the cell suspensions were incubated with the Cy5.5-labeled annexin A5- or control-micelles for 30 min at a final concentration of 1 mM total lipid. An additional apoptotic cell sample was left untreated for comparison. Incubations were performed on a roller bench at room temperature. After the incubation procedure, cells were collected and washed at least three times in 2 mL of Ca^{2+}-containing binding buffer (300 × *g*, 5 min). Last, cells were fixed in 200 μL of 4% paraformaldehyde containing 2.5 mM $CaCl_2$.

For confocal laser scanning microscopy (CLSM), 5 μL of the resuspended fixed cell pellets were applied to poly(L-lysine) microscopy slides (Menzel-Gläser) and dried for 20 min at 55 °C. Next, the adhered cells were washed in PBS, counterstained for nuclei with DAPI (15 min; 0.1 μg/mL in PBS), washed in PBS, and mounted with Mowiol mounting medium. CLSM was performed on a Zeiss LSM 510 META NLO system (Carl Zeiss AG, Oberkochen, Germany), equipped with a multiphoton Chameleon laser and a HeNe633 laser. The Chameleon laser (780 nm) allowed excitation of DAPI, whereas the HeNe633 laser (633 nm) was used for Cy5.5 excitation. All images were obtained at 630× magnification, and imaging settings remained unchanged to allow a direct comparison of the different samples.

In Vivo Experiments. *Animals.* A total of 10 ApoE$^{-/-}$ and 2 wild-type (WT) male C57BL/6 mice were included for in vivo MRI experiments and additional ex vivo fluorescence imaging or microscopy. One additional apoE$^{-/-}$ mouse was included for ex vivo fluorescence imaging only. ApoE$^{-/-}$ mice were placed on a high-cholesterol diet (0.2% total cholesterol, Harlan Teklad, Madison, Wis) ad libitum beginning at 6 weeks until 60 to 68 weeks of age, while WT mice were maintained on a normal murine diet (Research Diets, Inc., New Brunswick, NJ). All animal experiments were approved by the ethics committee of Mount Sinai General Hospital.

MRI. In vivo MRI measurements were performed with an 89 mm vertical bore MRI system, operating at 9.4T (Bruker Instruments, Billerica, MA, USA). Mice were initially anesthetized with 4% isoflurane in oxygen (0.4 L/min) and placed head-up in a 30 mm birdcage coil for imaging (Bruker). During MRI, anesthesia was maintained using 1.5−2.0% isoflurane in oxygen (0.4 L/min) supplied through a face mask. The respiratory signal was monitored using a pressure sensor to regulate the depth of the anesthesia.

At the onset of the experiment, precontrast T_1-weighted images of the abdominal aorta in the area between the renal and aortic bifurcations were acquired using a fat-suppressed black blood spin−echo sequence with the following parameters: TR = 800 ms, TE = 8.6 ms, NEX = 16, matrix = 256 × 256, FOV = 2.6 × 2.6 cm^2, and slice thickness = 0.5 mm. For flow suppression, an inflow saturation slab of 4 mm, consisting of a 90° pulse followed by a 2 ms spoiler gradient, was positioned superior to the imaging area.

Following the precontrast scans, anesthetized mice were injected with the micellar contrast agent through the tail vein at a dose of 2.5 μmol per mouse (100 μL; 25 mM total lipid concentration). A total of 6 ApoE$^{-/-}$ mice received annexin A5-micelles fluorescently labeled with either Rhodamine-PE (n = 3) or Cy5.5-PEG2000-DSPE (n = 3). control-micelles were administrated to four ApoE$^{-/-}$ mice (Rhodamine-PE, n = 2; Cy5.5-PEG2000-DSPE, n = 2) and two WT mice received Cy5.5-labeled annexin A5-micelles.

At 24 h post-administration of the contrast agent, mice were again prepared for MR measurements. First, imaging slices were carefully matched to the precontrast images by using the unique anatomy of individual vertebrae as anatomical landmarks. Next, T_1-weighted MR images were obtained with the same parameters as used for the precontrast scans. For two ApoE$^{-/-}$ mice, the same MR protocol was additionally repeated at 48 h and 7 days after injection of the annexin A5-micelles.

Mice that underwent their last MR measurement at 24 h post-injection were immediately sacrificed by saline perfusion after the scanning procedure. Blood samples were obtained, and spleen, liver, kidney, and lung tissues were removed to investigate nanoparticle biodistribution. The abdominal aortas from mice that received Rhodamine-labeled micelles were isolated using microscopic dissection and snap-frozen in optical cutting temperature compound (Tissue Tek, Sakura Finetech) for confocal fluorescence microscopy (n = 2/group). Alternatively, whole aortas from mice that received Cy5.5-labeled micelles were excised and placed on a microscopy slide for near-infrared fluorescence imaging (NIRF, n = 2/group). For the latter procedure, the fat surrounding the abdominal aorta was carefully removed.

MR Data Analysis. Images were analyzed using *Mathematica 6* (Wolfram Research, Inc., USA). Prior to analysis, pre- and 24 h postcontrast injection measured slices were matched by the shape of the vertebrae. Slices that could not be matched were excluded from data analysis. Typically, for each ApoE$^{-/-}$ mouse 15 to 19 slices with orientations perpendicular to the abdominal aorta were analyzed. Circular regions of interest (ROIs) were drawn on the pixels in the thickened atherosclerotic vessel wall surrounding the lumen (S_w), while excluding the vessel lumen. A second ROI was drawn in a portion of the surrounding muscle (S_m). Wall signal was divided by the muscle signal to yield a normalized signal intensity $S_{norm} = S_w/S_m$ that could be compared pre- and 24 h post-contrast, as well as between mice. Signal enhancement (SE) was calculated as the average percentile difference between S_{norm} of all pre- and 24 h post-contrast slices: $[(S_{norm_post} - S_{norm_pre})/(S_{norm_pre})] \times 100\%$. WT mice were not analyzed using the above procedure, as the aortic wall in these animals could not be discriminated from surrounding tissue. Alternatively, images from WT mice were visually inspected for possible signal enhancement in the aortic wall.

Near Infrared Fluorescence Imaging. For whole-aorta near-infrared fluorescence imaging (NIRF) 1 ApoE$^{-/-}$ mouse, which received no contrast agent, was used as a control. Aortas from ApoE$^{-/-}$ mice that were injected with either control-micelles ($n = 2$) or annexin A5-micelles ($n = 2$) were collected following the in vivo MRI experiments. The dissected aortas were placed on a microscope slide and covered with gauze submerged in PBS, placed at 4 °C, and imaged within 2 h. Aortas were placed in the IVIS 200 system (Xenogen) and the Cy5.5 label was excited using a wavelength filter with a range of 615−665 nm, while the emission was recorded using a 695−770 nm filter. Fluorescent reflectance images were acquired with identical exposure times for all groups. Total photon count was determined within identical windows around the whole aorta. The mean increase in fluorescence intensity was calculated as the average percentile difference between the total photon count from the contrast-receiving group (PC_{CA}) and the total photon count from the control ApoE$^{-/-}$ mouse that received no contrast agent ($PC_{control}$): $[(PC_{CA} - PC_{control})/(PC_{control})] \times 100\%$.

Confocal Fluorescence Microscopy. 8-μm-thick frozen tissue sections were cut for confocal microscopy. Individual sections were air-dried for 10 min and blocked (PBS containing 1% BSA and 5% horse serum) for 45 min at room temperature. DNA fragmentation was detected with the TdT-mediated dUTP Nick End Labeling (TUNEL) technique, using the In Situ Cell Death Detection Kit with fluorescein isothiocyanate (FITC)-labeled dUTP (Roche, Mannheim, Germany) according to manufacturer instructions. Cells with fragmented DNA will be referred to as apoptotic. Macrophages were fluorescently stained with Alexa 647 labeled anti-CD68 antibodies (Serotec, Inc.). After washing with PBS, the sections were directly mounted with VectaShield containing 1.5 μg/mL DAPI (VectorLaboratories, Burlingame, CA) to stain cell nuclei. The sections were covered with coverslips and imaged within 12 h.

Rhodamine-labeled annexin A5-micelles and control-micelles (red) were detected and co-localized with respect to both DNA fragmentation (green) and macrophages (green) within the vessel wall 24 h after contrast agent administration using confocal laser scanning microscopy (Zeiss LSM 510 META microscope, Carl Zeiss AG, Oberkochen, Germany) in an inverted configuration. The system was equipped with four lasers and three confocal detectors, and data were captured and analyzed using Zeiss LSM 510 Meta and postprocessed with *Image Browser* software (Carl Zeiss AG, Oberkochen, Germany). All images were obtained with the same laser power and detector gain settings.

Table 1. Relaxivities of Nonspecific Control-micelles and Annexin A5-Micelles (AnxA5-micelles) in HEPES Buffered Saline at 60 MHz and Different Temperatures[a]

	25 °C		37 °C	
	r_1 (mM^{-1} s^{-1})	r_2 (mM^{-1} s^{-1})	r_1 (mM^{-1} s^{-1})	r_2 (mM^{-1} s^{-1})
Control-micelles	11.8 ± 0.1	18.5 ± 0.1	13.4 ± 0.1	20.4 ± 0.1
AnxA5-micelles	11.4 ± 0.1	19.4 ± 0.1	12.4 ± 0.1	19.9 ± 0.1

[a] Relaxivity values are based on Gadolinium concentration.

Statistics. Statistical analysis was performed for experiments with $n \geq 3$ per group. Comparisons between the two groups were performed with a Student's t test for independent samples in SPSS 16.0. $P < 0.05$ was considered significant.

RESULTS

Characterization of the Micelles. The hydrodynamic diameters of control and anxA5-micelles were 19.5 ± 0.7 nm and 22.3 ± 0.2 nm, respectively. Protein and phosphate determinations showed that on average two annexin A5-cys proteins were covalently conjugated per micelle, assuming that each micellar nanoparticle contains approximately 80 lipids (*37*). Based on the initial lipid composition, this also implies that each micelle contains approximately 1 fluorescent dye and 40 gadolinium-based lipids. The potency of a MRI contrast agent to reduce the intrinsic tissue T_1 and T_2 relaxation times, and thereby introduce tissue contrast on MR images, is described by the relaxivity values r_1 and r_2, which are expressed in mM^{-1} s^{-1}. Relaxivities r_1 and r_2 of the paramagnetic Cy5.5-labeled control-micelles and annexin A5-micelles were measured at 60 MHz and different temperatures. Importantly, similar r_1 and r_2 values were observed for the targeted versus the nontargeted micelles (Table 1). At 25 °C, the relaxivities of control-micelles were $r_1 = 11.8 \pm 0.1$ mM^{-1} s^{-1} and $r_2 = 18.5 \pm 0.1$ mM^{-1} s^{-1}, whereas for annexin A5-micelles relaxivities were $r_1 = 11.4 \pm 0.1$ mM^{-1} s^{-1} and $r_2 = 19.4 \pm 0.1$ mM^{-1} s^{-1}. These values, which are based on gadolinium concentration, are relatively high compared to clinically approved gadolinium complexes such as Gd-DTPA, for which $r_1 = 3.3$ and $r_2 = 3.9$ at 1.5 T (64 MHz) and 37 °C (*38*). An increase in temperature to 37 °C was shown to slightly elevate r_1 and r_2 for both micellar agents (Table 1).

In Vitro Targeting. Ellipsometry measurements clearly demonstrated binding of the annexin A5-micelles to a bilayer consisting of 20 mol % PS and 80 mol % phosphatidylcholine (PC), as observed by the gradually increasing polarization angle, which is known to correlate with layer thickness. The polarization angle reached a steady state at higher values compared to free annexin A5-cys (Figure 2). Binding was shown to strictly depend on annexin A5 as the polarization angle remained at baseline levels after addition of control-micelles. Furthermore, association was Ca^{2+}-dependent, as annexin A5-cys, as well as annexin A5-micelles, instantly dissociated from the bilayer upon addition of Ca^{2+}-chelating EDTA.

Micelle binding to PS-expressing cells was also examined on a Jurkat cell line using confocal laser scanning microscopy (CLSM). Apoptotic cell suspensions that were untreated (Figure 3A) or incubated with control-micelles (Figure 3B) exhibited negligible levels of Cy5.5 fluorescence, while apoptotic cells incubated with the annexin A5-micelles showed a clear cell-associated Cy5.5 signal (Figure 3C).

MRI and NIRF. In vivo precontrast T_1-weighted MR images of atherosclerotic ApoE$^{-/-}$ mice clearly revealed extensive atherosclerotic lesions in their abdominal aorta (Figure 4A,C), whereas aortas of wild-type (WT) C57BL/6 mice showed normal vessel wall morphology within the same region (Figure 4E). At 24 h post-injection of annexin A5-micelles, T_1-weighted images of the same ApoE$^{-/-}$ mice showed increased signal

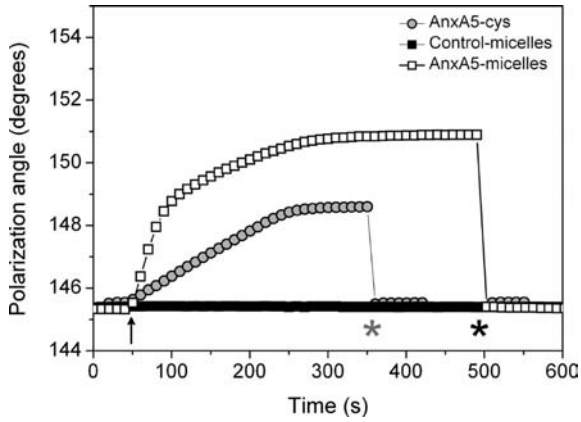

Figure 2. Ellipsometry measurements of a PS/PC (20:80) bilayer in the presence of 2.5 mM Ca^{2+} upon addition of annexin A5-cys (AnxA5-cys), annexin A5-micelles (AnxA5-micelles), and control-micelles. Micelles or protein was added at the time point indicated by the arrow. 5 mM EDTA was added at the time points indicated by the asterisks (*) to assess Ca^{2+}-dependence of binding.

intensity within the thickened aortic vessel wall (compare Figure 4C and D). Contrast enhancement within these mice persisted up to at least 7 days after injection (data not shown). Atherosclerotic lesions of $ApoE^{-/-}$ mice that were injected with control-micelles showed less signal enhancement at 24 h post-injection (compare Figure 4A and B). Moreover, no contrast changes were observed in WT mice that received annexin A5-micelles (compare Figure 4E and F).

Ex vivo near-infrared fluorescence imaging was performed on excised aortas from $ApoE^{-/-}$ mice that underwent in vivo MRI experiments and were sacrificed 24 h post-contrast agent injection. The aorta of an $ApoE^{-/-}$ mouse that received no contrast agent served as a control and showed marginal fluorescence signal due to autofluorescence (Figure 5A). In contrast, the aortas from $ApoE^{-/-}$ mice that received control-micelles (Figure 5B) or annexin A5-micelles (Figure 5C) displayed strong fluorescence signal, which was heterogeneously distributed over the entire aorta. Interestingly, aortas from mice injected with annexin A5-micelles showed multiple intense fluorescent hotspots, whereas aortas from the control micelle group revealed considerably less fluorescence in a reduced number of areas. Importantly, these hotspots were predominantly observed in areas where extensive atherosclerotic lesions were expected as described by Nakashima et al. (*39*). These areas included the aortic arch, the branching points of the renal arteries, and the aortic bifurcation (Figure 5C).

MR signal enhancement in the aortic wall also appeared highly heterogeneous throughout the examined abdominal area.

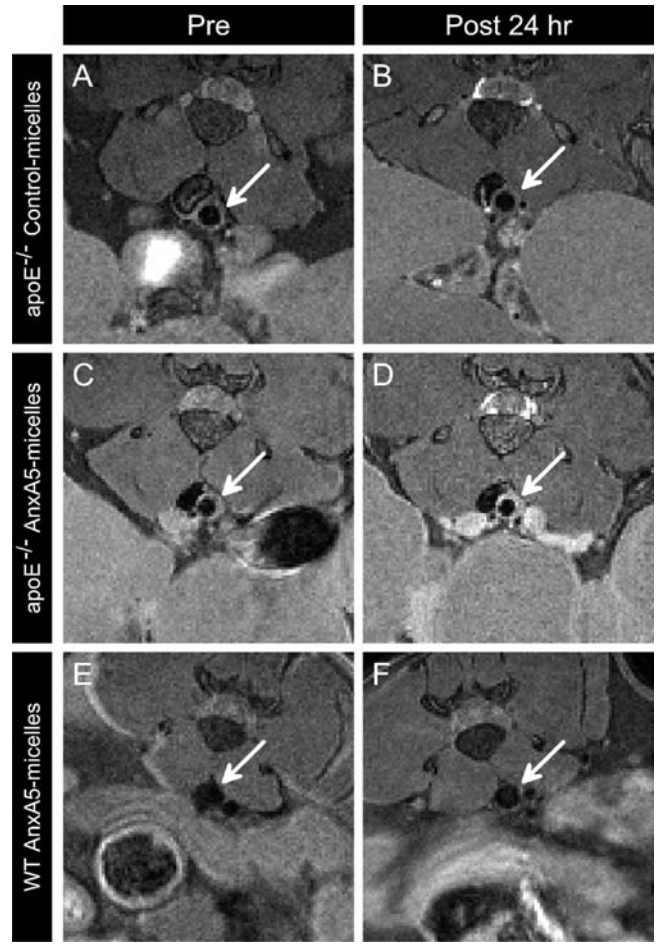

Figure 4. T_1-weighted in vivo MR images at the level of the abdominal aorta (arrow). Scans were made before (left panel) and 24 h after (right panel) contrast agent injection. $ApoE^{-/-}$ mice received either control-micelles (A,B) or annexin A5-micelles (C,D). Wild-type (WT) C57BL/6 mice only received annexin A5-micelles (E,F).

Nevertheless, all slices that were measured with in vivo MRI were used to calculate the mean signal enhancement within the vessel wall to prevent any bias by analyzing only specific slices. Mean MR signal within the examined abdominal aortic wall was calculated to be increased by $6.7 \pm 3.4\%$ and $10.7 \pm 1.7\%$ at 24 h post-administration of control or annexin A5-micelles, respectively (Figure 6A). At the same time point, the total photon count in the entire aorta was enhanced by $113.1 \pm 4.4\%$ for the control micelle group and $257.1 \pm 9.1\%$ for the annexin A5-micelle group (Figure 6B).

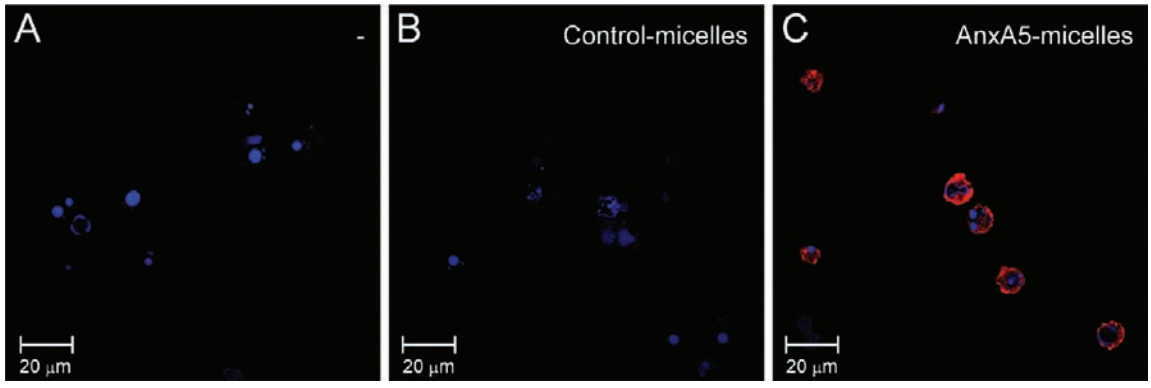

Figure 3. CLSM images of fixed apoptotic Jurkat cells after incubation with (A) no contrast agent, (B) untargeted paramagnetic control-micelles, or (C) paramagnetic annexin A5-micelles (AnxA5-micelles). Micelles contained Cy5.5-PEG2000-DSPE (red), and adhered cells were counterstained with DAPI (blue). Magnification: 630×.

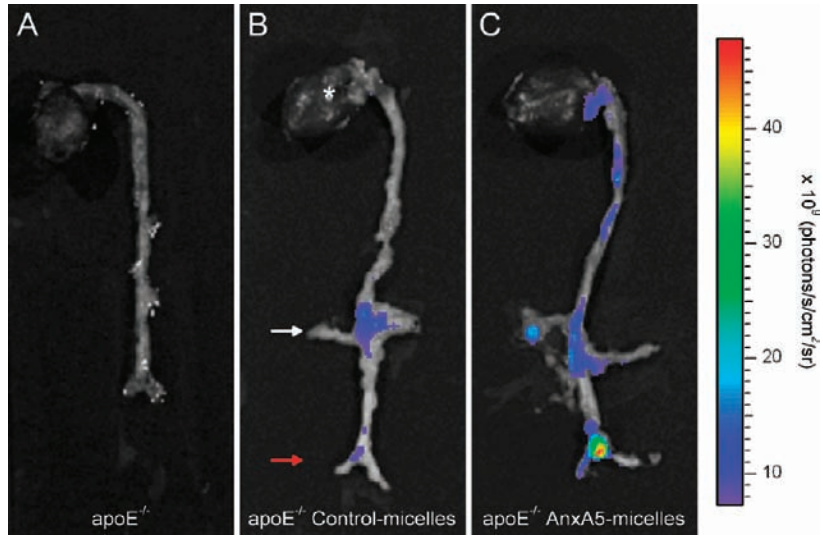

Figure 5. Ex vivo near-infrared fluorescence imaging (NIRF) of whole aortas from ApoE$^{-/-}$ mice (A) without contrast agent injection and at 24 h after injection of (B) control-micelles and (C) annexin A5-micelles. Micelles contained Cy5.5-PEG2000-DSPE. The orientation of the aorta is indicated by characteristic regions in (B), such as the heart (*), a renal branch (white arrow),and the aortic bifurcation (red arrow). In vivo MR images were acquired in the area between the white and the red arrow.

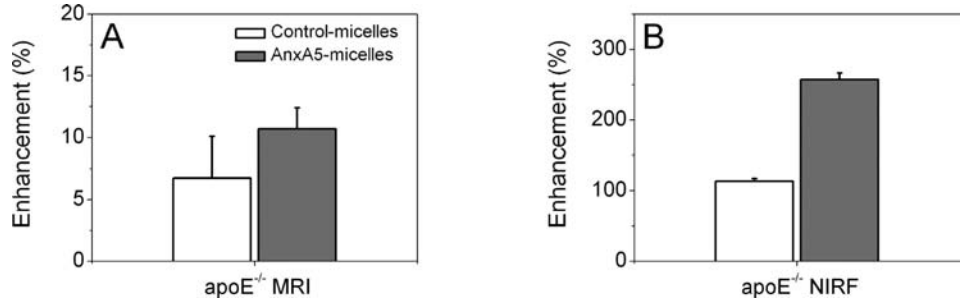

Figure 6. Quantitative analysis of MR signal enhancement in T_1-weighted images (A) and NIRF enhancement (B) at 24 h after injection of the contrast agent in ApoE$^{-/-}$ mice (B). Bars represent mean values ± SE: (A) MRI: control-micelles ($n = 4$), annexin A5-micelles ($n = 6$). NIRF: control-micelles ($n = 2$), annexin A5-micelles ($n = 2$).

Confocal Fluorescence Microscopy. Tissue sections from the abdominal aortas of the mice were examined with confocal fluorescence microscopy. Atherosclerotic lesions from ApoE$^{-/-}$ mice injected with Rhodamine-labeled control-micelles demonstrated only weak and diffuse red fluorescent signal at 24 h post-injection (Figure 7A,B), whereas bright red fluorescent hot spots were observed for ApoE$^{-/-}$ mice that received annexin A5-micelles (Figure 7C and D). In these latter mice, the annexin A5-micelles clearly colocalized with macrophages (Figure 7C) and apoptotic cells (Figure 7D) in the center of the intima. Presumably, a fraction of these macrophages are apoptotic, as previously described elsewhere (*17*). No obvious association to macrophages (Figure 7A) or apoptotic cells was observed for control-micelles (Figure 7B).

Biodistribution. At 24 h post-injection of control-micelles in ApoE$^{-/-}$ mice, the Gd content of liver and spleen was shown to be higher than that of kidneys and lungs (Figure 8A). Similar amounts of Gd were measured in the kidneys and lungs of mice that received the annexin A5-functionalized micellar contrast agent (Figure 8B). In contrast, Gd content in the liver and spleen of these mice was approximately 100% and 219% higher, respectively, compared to control-micelles. These results are in agreement with previous studies that demonstrated PS specific uptake of radiolabeled annexin A5 by the liver and spleen, while kidney accumulation appeared to be nonspecific (*40*). Importantly, preliminary studies in ApoE$^{-/-}$ mice, which were injected with the same contrast agents at equal dose, displayed similar blood clearance kinetics for control and annexin A5-micelles (data not shown). Consequently, this allows a direct comparison of the collected data from both agents.

DISCUSSION

In the current study, we developed, characterized, and evaluated the use of annexin A5-conjugated micelles for targeted MRI of atherosclerotic plaques in ApoE$^{-/-}$ mice. The micelles were composed of a paramagnetic amphiphile (Gd-DTPA-DSA) and PEGylated lipids (PEG-DSPE) in a 1:1 molar ratio. Above the so-called critical micelle concentration (CMC), PEG-DSPE forces the amphiphilic aggregation towards a micellar morphology. A near-infrared fluorophore (Cy5.5) and annexin A5 proteins were covalently conjugated to the distal ends of the PEG chains of the micelles for fluorescence imaging and target specificity, respectively. Alternatively, Rhodamine-PE, instead of Cy5.5-PEG2000-DSPE, was incorporated in the lipid monolayer for confocal fluorescence microscopy. Ellipsometry measurements on PS/PC bilayers and experiments with apoptotic Jurkat cells were performed to assess the target-specificity of the annexin A5-micelles in vitro. Furthermore, in vivo MRI of the abdominal aortas from apoA$^{-/-}$ mice and ex vivo fluorescence methods on excised aortas of the same mice were used to image the uptake of control and annexin A5-micelles in atherosclerotic lesions, as well as to validate their cellular targets following intravenous injection.

MR molecular imaging of vascular targets is usually done with nanoparticles that carry a high payload of contrast-

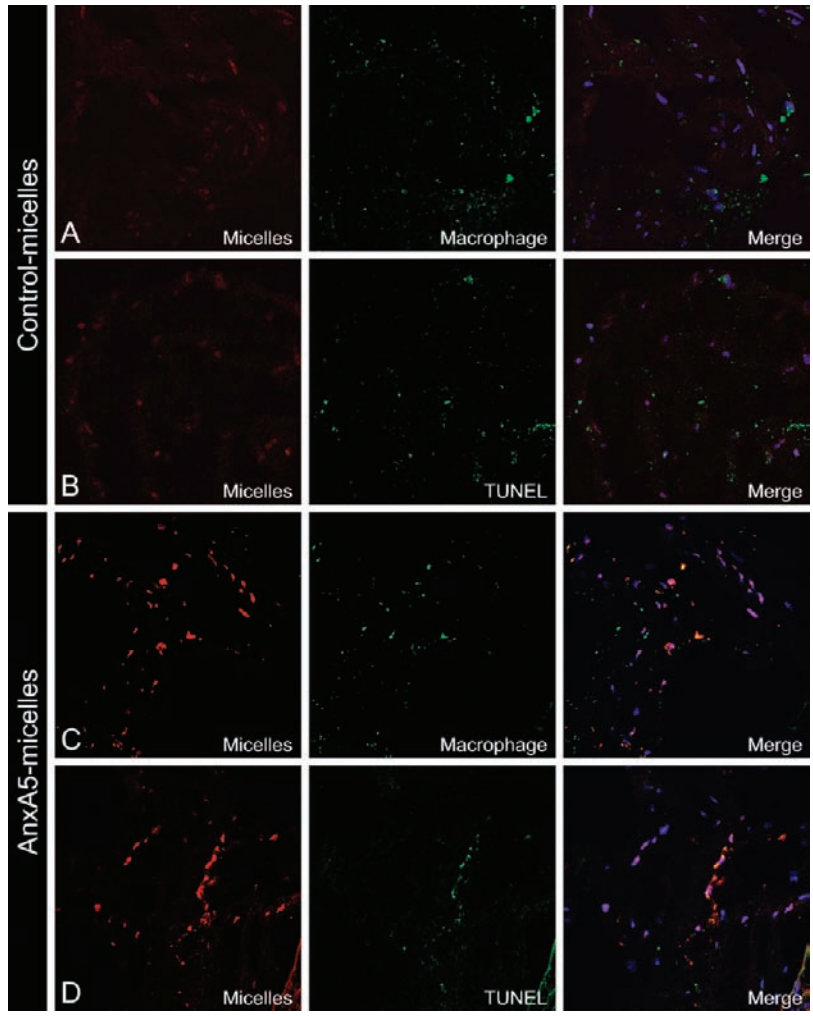

Figure 7. Confocal fluorescence microscopy of frozen sections from abdominal aortas of ApoE$^{-/-}$ mice at 24 h after administration of (A,B) control-micelles or (C,D) annexin A5-micelles (red). Sections were counterstained for (A,C) macrophages with anti-CD68 (green) or (C,D) apoptotic cells with TUNEL (green). Nuclei were stained with DAPI. Magnification: 400×.

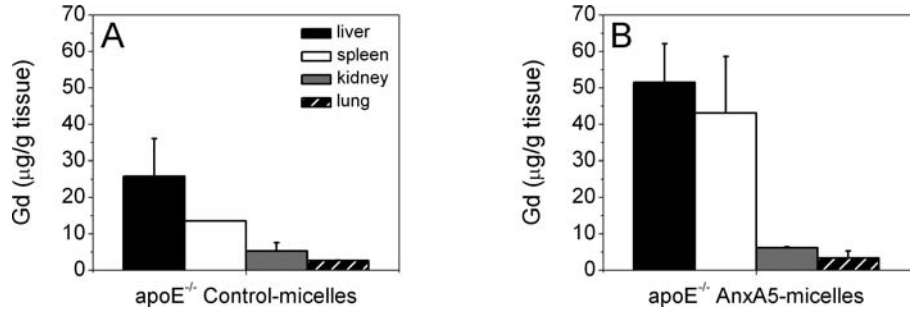

Figure 8. Biodistribution of control-micelles (A) and annexin A5-micelles (B) at 24 h post-injection in ApoE$^{-/-}$ mice, as measured by ICP-MS of Gd content indicated in micrograms per gram of tissue. Bars represent average ± SD (n = 2/group).

generating material (*41*, *42*). After intravenous administration, such nanoparticulate agents do not require extravasation from the vasculature to bind to their target, and therefore, nanoparticle size is less critical. However, when extravascular targeting is to be accomplished, e.g. in case of intraplaque targeting, a small particle size is more favorable, to allow penetration of the endothelium. Recently, Burtea et al. reported on a novel PS-specific peptide that was conjugated to a single Gd-DTPA, which successfully allowed MRI of PS exposing cells in atherosclerotic plaques (*43*). Furthermore, Schellenberger et al. reported on a PS-specific superparamagnetic iron oxide-based MRI contrast agent with a hydrodynamic diameter of approximately 15 nm, i.e. annexin A5-VSOP (*44*). However, this nanoparticle was only applied in an in vitro setting. In the current study, we developed and applied annexin A5-functionalized paramagnetic micellar nanoparticles of similar size. This relatively small size facilitates extravasation in areas with enhanced endothelial permeability, such as atherosclerotic lesions.

Ellipsometry measurements revealed a Ca^{2+}-dependent affinity of the annexin A5-conjugated micelles for a lipid bilayer that contained 20% PS, whereas nonspecific control-micelles did not bind to a similar bilayer. These results were corroborated by CLSM images of apoptotic cells, which showed abundant association of annexin A5-functionalized micelles, whereas control-micelles were barely detected.

For in vivo MRI experiments, we used a dosage that is typical for targeted MR contrast agents, i.e., 50 μmol Gd per kilogram of body weight. MRI revealed pronounced and heterogeneously distributed hyperintense areas throughout plaque-rich regions in the abdominal aorta at 24 h after administration of annexin A5-functionalized micelles. Such enhanced regions were also observed in the untargeted control micelle group, but to a lower extent. To enable comparison of both groups, the signal enhancement for each slice was calculated and averaged for all acquired imaging slices, thereby disregarding heterogeneous distribution of the contrast agent. Data analysis revealed that the mean signal enhancement throughout the abdominal aorta was nonsignificantly higher for mice that received annexin A5-micelles than for control micelle-injected mice. In both cases, the enhancement was, however, modest compared to macrophage scavenger receptor (MSR) targeted micellar contrast agents that were applied at a dose of 75 μmol Gd per kilogram of body weight (*26*).

In vivo MRI observations were compared to ex vivo fluorescence imaging of excised aortas. The mean photon count of aortas that originated from mice injected with annexin A5-micelles was at least twice that of the aortas from control micelle injected mice. In addition, near-infrared fluorescence imaging allowed us to investigate the entire aorta. The most pronounced uptake of annexin A5-micelles was observed in the aortic arch, at principal branches of the abdominal aorta, such as the renal arteries, and at the aortic bifurcation into the iliac arteries. Isobe et al. observed distinct uptake of ^{99m}Tc-labeled annexin A5 in similar regions of the aorta in ApoE$^{-/-}$ mice (*17*). Importantly, these regions are known to correspond to a high plaque burden (*39*), which was the case in this study as well. However, one should note that the in vivo MR images were acquired in the abdominal aorta in the area between the renal and aortic bifurcations. This implies that certain regions with intense uptake of the micellar contrast agent were not included in the in vivo MRI scans, which could partially explain the observed difference in signal enhancement between MRI and NIRF imaging. Future imaging studies should therefore cover a larger area of the abdominal aorta, or alternatively, another animal model could be used, with well-defined locations and phenotype of atherosclerotic plaque within the carotid artery (*45*).

Ex vivo confocal fluorescence microscopy revealed association of annexin A5-micelles to PS-expressing cells, such as apoptotic cells and macrophages, within atherosclerotic lesions in the abdominal aorta. A large fraction of these apoptotic cells are considered dying macrophages, whereas the remaining fraction most likely consists of smooth muscle cells (*46*). The annexin A5-functionalized contrast agent was most probably also associated with viable macrophages, as previously observed for biotinylated annexin A5 (*17*). Macrophages in atherosclerotic lesions are also known to nonspecifically engulf nanoparticulate agents such as USPIOs (*47*). Nevertheless, CLSM images of tissue sections from control micelle-injected mice revealed no macrophage-associated micellar fluorescence. Presumably, the cell-associated contrast agents observed in the CLSM images were internalized, which may have led to a quenched T_1 effect due to limited water exchange with the bulk (*48, 49*). Such an effect may provide a second explanation for the apparent discrepancy between the modest signal enhancement of annexin A5-micelles in the in vivo MR images and the large difference in micellar fluorescence from control and annexin A5-micelles in the ex vivo CLSM images.

At present, there is an urgent need to discriminate vulnerable atherosclerotic lesions from stable lesions. Current diagnostic methods used in the clinic are primarily focused on visualizing narrowing of the lumen but do not reveal plaque composition and thus do not predict the risk of rupture accurately (*23*). In the past decade, traditional high-resolution MRI techniques have been developed to enable plaque characterization by visualizing features such as the lipid-rich core and fibrous cap size. The biochemistry that lies at the basis of plaque formation may be investigated using MRI-based molecular imaging techniques. For example, MR imaging of the macrophage burden has been investigated with ultrasmall iron oxide nanoparticles (USPIO) (*47*), while the expression of cell adhesion molecules was visualized using VCAM-1 targeted cross-linked iron oxide nanoparticles (CLIO) (*31*). Furthermore, annexin A5-functionalized iron oxide particles were applied to image PS-expressing cells in a preliminary study on a limited number of animals (*50*). The disadvantage of such strategies is that iron oxide-based imaging relies on the use of so-called $T_2^{(*)}$-weighted MRI, in which regions of high iron oxide content appear dark. These spots are hard to localize in images that usually already have a low signal-to-noise ratio. Therefore, more recent investigations primarily focus on the application of T_1-reducing agents that appear bright in T_1-weighted MR images (*25, 29, 43*), as is the case in our study. The paramagnetic nanoparticulate agent introduced in the present study exhibited enhanced accumulation in plaque by the conjugation of annexin A5. This phenomenon may also be applied to shuttle therapeutically active compounds, such as anti-inflammatory agents or nucleotides, into plaque.

In the present study, a dose of 1.9 mg annexin A5 was administered per mouse, which was well tolerated by the animals. However, this dose is considered unfeasible in clinical studies. Ideally, small molecules such as peptides or peptidomimetics, with a high affinity for PS, need to be developed for clinical translation. Alternatively, and despite the previously mentioned disadvantages, small iron oxide nanoparticles may be employed. These nanoparticles represent a more sensitive MRI contrast agent and are typically injected at a 100-fold lower particle dose, which also decreases the Annexin A5 dose by a factor 100.

In conclusion, the present study demonstrated the potential of an annexin A5-functionalized micellar contrast agent for target-specific imaging of PS-expressing cells in atherosclerotic lesions of ApoE$^{-/-}$ mice. Such imaging strategies are of great diagnostic potential as the abundance of PS expressing cells is considered an important prognostic marker of plaque vulnerability. Interestingly, the presented nanoparticulate platform may be simultaneously exploited for therapeutic purposes, thereby facilitating a wide range of clinically relevant applications for improved diagnostics, as well as therapeutic interventions in atherosclerotic cardiovascular disease.

In this work, carboxyl-terminated PAMAM G-3.5 was covalently attached to SN38 via glycine and β-alanine spacers. The conjugates were stable at pH 7.4 and moderately hydrolyzed in cell culture media and rat plasma. Similarly to SN38 but to a lesser extent, both conjugates inhibited proliferation of human colorectal cancer HCT-116 cells, arrested the cell cycle in the G_2/M phase, and led to nuclear fragmentation. However, activity of the conjugate with glycine spacer (IC_{50} = 129 nM) was higher compared to that of the β-alanine linked conjugate (IC_{50} = 387 nM). These PAMAM-SN38 conjugates have the potential for targeted therapy of colorectal carcinoma.

INTRODUCTION

Polymeric drug carriers have emerged as promising alternatives to small molecule therapeutics due to their many advantages over parent drugs, which include enhanced aqueous solubility, reduced systemic toxicity, and improved efficacy (*1, 2*). In this context, dendrimers have emerged as promising candidates for targeted delivery of chemotherapeutics. They are nanometer-sized and have multiple surface groups and low polydispersity. The large number of functionalizable sites at the periphery of the dendrimers allows facile attachment of multiple drugs, targeting moieties, and imaging agents. Pharmaceutical compounds can also be physically encapsulated in the dendrimer interior to enhance water solubility and reduce toxicity (*3, 4*).

7-Ethyl-10-hydroxy camptothecin (SN38) is a chemotherapeutic agent belonging to the camptothecin family of high-potency topoisomerase I inhibitors (*5, 6*). It has extremely low water solubility and is not used directly for clinical applications. CPT-11 (Irinotecan) is the water-soluble prodrug of SN38 which is currently approved for colorectal cancer. However, it is 100−1000 times less active than SN38, causes gastrointestinal toxicity, and, similarly to SN38, has poor oral bioavailability (*7, 8*). Additionally, the pharmacologically important lactone ring in irinotecan is converted to the inactive carboxylate form in the presence of human plasma albumin (*9*). A promising approach to increase the solubility of SN38 and facilitate delivery to the site of action is attachment to water-soluble polymeric carriers (*10, 11*) or antibodies (*12*). Recently, we demonstrated that complexation of SN38 with amine-terminated generation 4 PAMAM (poly(amido amine)) dendrimers (G4-NH2) enhances water solubility of the drug and increases cellular uptake and transepithelial transport across Caco-2 cells (*13*). While such complexes show promise in oral drug delivery, covalent conjugation of SN38 to dendrimers can impart greater stability, prevent premature release, and facilitate targeted delivery (*14*). In addition, we have previously demonstrated in vitro that concentration, generation of dendrimer, and incubation time influence the toxicity observed with cationic PAMAM dendrimers, whereas under similar conditions, carboxyl-terminated anionic dendrimers have shown less toxicity yet maintained comparable transepithelial transport (*15, 16*). These observations, along with the inherent advantages of polymeric drug delivery systems, suggest that development of anionic PAMAM-SN38 conjugates can increase the bioavailability of the drug, increase its efficacy, and reduce toxicity. Here, we report the synthesis, characterization, and in vitro stability and activity of G3.5-SN38 conjugates in a colorectal cancer cell model.

EXPERIMENTAL PROCEDURES

PAMAM G3.5 dendrimer, *N*-(*tert*-butoxycarbonyl)glycine, *N*-(*tert*-butoxycarbonyl)beta alanine, *N*-ethyl-*N*′-(3-dimethylaminopropyl)carbodiimide (EDC), *N*-hydroxy succinimide (NHS), 4-(dimethylamino)pyridine (DMAP), *N*,*N*-diisopropylethylamine (DIPEA), and di-*tert*-butyl dicarbonate (Boc_2O) were obtained from Aldrich, (St. Louis, MO, USA). 7-Ethyl-10-hydroxy camptothecin (SN38) was obtained from AK Scientific Company (California, USA), and its purity was determined by ^{1}H NMR and HPLC. Anyhdrous dichloromethane (DCM) and dimethylsulfoxide (DMSO) were purchased and used without further purification.

^{1}H NMR of intermediates and conjugates was recorded on a Bruker 400 or Varian Unity 500 MHz spectrophotometer. Size exclusion chromatography (SEC) for characterization and purification of G3.5−drug conjugates were performed on an Akta fast protein liquid chromatography (FPLC) system, using Superose12 analytical and Hiload 16/60 Superdex 75 preparative-grade columns (GE, USA) respectively. The dendrimer peak was analyzed to determine the hydrodynamic radius using a Wyatt quasi-elastic light scattering detector (QELS), and the calculations were performed using the *Astra 5.3.4* software. All samples were run in triplicate. Reverse-phase high performance liquid chromatography (HPLC) was performed on a Hewlett Packard series 1100 instrument using an Agilent C18 column, 250 mm ×4.5 mm.

Synthesis of SN38-gly (3). The overall synthetic strategy is depicted in Scheme 1. SN38 derivatized at the 20-OH with a glycine spacer was synthesized according to a reported protocol

with modifications (*11*). Briefly, SN38 (0.8 g, 2.04 mmol) was stirred for 12 h with di-*tert*-butyl dicarbonate (0.579 g, 2.65 mmol) and anhydrous pyridine (4 mL, 42 mmol) in 40 mL of CH_2Cl_2 to obtain compound **1** (Scheme 1) in 90% yield. To a solution of **1** (0.5 g, 1.0 mmol) in CH_2Cl_2 (10 mL), *N*-(*tert*-butoxycarbonyl)glycine (0.5 g, 3.0 mmol), EDC (0.9 mL, 5.0 mmol), and DMAP (0.350 g, 3.0 mmol) were added and stirred for 2 h. Subsequently, the reaction mixture was washed with 0.5% $NaHCO_3$ and 0.1 N HCl. The crude product obtained was purified by column chromatography using 1−3% MeOH/$CHCl_3$ to obtain compound **2** (Scheme 1) in 63% yield. Deprotection of **2** (0.25 g, 0.3 mmol) in 30% TFA/DCM gave SN38-gly (compound **3**, 0.24 g, 95% yield). ^{1}H NMR (400 MHz, CD_3OD): δ 1.07 (t, 3H, $J = 5.8$ Hz), 1.34 (t, 3H, $J = 6.2$ Hz), 2.18−2.30 (m, 2H), 3.07−3.12 (m, 2H), 4.17 (d, 1H, $J = 14.4$ Hz), 4.27 (d, 1H, $J = 14.0$ Hz), 5.21 (s, 2H), 5.48 (d, 1H, $J = 13.2$ Hz), 5.63 (d, 1H, $J = 13.2$ Hz), 7.31 (s, 1H), 7.40−7.42 (m, 2H), 7.96 (d, 1H, $J = 7.2$ Hz). ESI-TOF MS: *m*/*z* Calc. for $C_{24}H_{23}N_3O_6 + H^+$: 450.17; Obsd. 450.12.

Synthesis of SN38-*βala* (5). In an analogous manner, compound **1** (0.4 g, 0.8 mmol) was reacted with *N*-(*tert*-butoxycarbonyl) *β*-alanine (0.28 g, 2.4 mmol) to obtain compound **4** (0.38 g, 70% yield), which upon deprotection with 30% TFA/CH_2Cl_2 gave compound **5** in 90% yield (Scheme 1). ^{1}H NMR (400 MHz, CD_3SOCD_3): δ 0.91 (t, 3H, $J = 5.6$ Hz), 1.28 (t, 3H, $J = 5.8$ Hz), 2.16−2.18 (m, 2H), 2.87−3.1 (m, 6H), 5.30 (s, 2H), 5.49 (s, 2H), 7.03 (s, 1H), 7.41 (s, 2H), 7.80 (bs, 3H), 8.0 (d, 1H, $J = 7.6$ Hz). ESI-TOF MS: *m*/*z* Calc. for $C_{24}H_{25}N_3O_6 + H^+$: 464.18; Obsd. 464.18.

Synthesis of G3.5-SN38 Conjugates. The methanolic solution of PAMAM G3.5 carboxylate equivalent to 250 mg (0.02 mmol) was evaporated under vacuum. The residue was dissolved in water, pH adjusted to 3.0, and lyophilized. To the acidified G3.5 in DMSO (15 mL) was added EDC (0.22 mL, 1.28 mmol) and NHS (0.28 g, 2.56 mmol) and the reaction mixture stirred for 10 min. To this solution, compound **3** or **5** (0.32 mmol) was added followed by DIPEA (0.07 mL, 0.32 mmol) (Scheme 2). The reaction mixture was stirred at room temperature for 8 h. DMSO was removed under high vacuum at 40 °C and residue redissolved in water, dialyzed using 3500 cutoff membrane, and sample lyophilized. The obtained product was further purified by SEC to remove low molecular weight impurities, unreacted dendrimer, and possible cross-linked impurities. The conjugates were obtained in ∼65% yield and characterized by SEC and ^{1}H NMR.

In Vitro Stability of Conjugates. Solutions of G3.5-gly-SN38 (0.75 mg/mL) and G3.5-*β*ala-SN38 (0.5 mg/mL) in PBS, pH 7.4, Mcyoy's 5A media (ATCC, Manassa, VA, USA) with 10% FBS, or 50% rat plasma (rat plasma was prepared by centrifuging rat whole blood for 10 min at 1000 rpm and the clear supernatant isolated as plasma) in PBS were incubated at 37 °C with shaking. At periodic intervals, samples (0.1 mL) were withdrawn and 0.1 mL acetonitrile added, vortexed for 30 s, and centrifuged at 1600 rpm to precipitate the proteins.

The clear supernatant was then extracted with 0.1 mL of chloroform, and the procedure was repeated in triplicate. The chloroform extracts were pooled, evaporated under nitrogen, redissolved in 80 μL of 1:1 DMSO/0.1 N HCl and analyzed by reverse-phase HPLC using a UV detector for SN38 detection. A gradient elution method of methanol/water in 0.1% TFA at a flow rate of 1 mL/min was used. The concentration of SN38 from each sample was determined from the peak areas observed, based on a calibration curve ($n = 3$) for SN38 in the concentration range 0.1−60 ug/mL. The calibration curves were plots of peak area as a function of SN38 concentration. For accurate determination of SN38 concentration in extracted samples, extraction efficiencies for SN38 using the above-described method were determined in each of the media, which were 100%, 103%, and 62% for PBS, cell culture media, and 50% rat plasma, respectively.

Evaluation of Cell Proliferation and Viability. HCT-116, human colorectal cancer cell line, was obtained from American Type Culture Collection (ATCC, Manassas, VA). The cells were cultured in Mcyoy's 5A medium (ATCC) containing 10% fetal bovine serum (FBS) at 37 °C. Cells were grown at 37 °C in a humidified atmosphere of 5% CO_2 (v/v) in air. Cell growth kinetics and viability were assessed by utilizing a highly water-soluble tetrazolium salt, WST-8 [2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfophenyl)-2*H*-tetrazolium, monosodium salt], as a component of Cell Counting Kit-8 from Dojindo Molecular Technologies, Inc. (Gaithersburg, MA). Cells were plated in 96 well plates (4000 cells/well) and incubated for 24 h; media was then gently aspirated, and cells were treated with different concentrations (serially diluted) of SN38, SN38-gly, SN38-βala, G3.5, G3.5-gly-SN38, or G3.5-βala-SN38 in 0.5% DMSO containing media. DMSO was used to ensure complete dissolution of SN38 in media. 0.5% DMSO did not affect cell viability. After 48 h, the cells were washed with PBS, and CCK8 reagent was added following the manufacturer's protocol. The cells were then incubated for 90 min, and absorbance at 450 nm was measured using 630 nm as reference. Cell viability was determined as percent absorbance relative to untreated control cells. Prism software (v 5.0, LaJolla, CA, USA) was used to generate the inhibition curves and IC_{50} determination.

Cell Cycle Analysis. Cell cycle progression was monitored by the flow cytometric measurement of DNA content (*17*). HCT-116 cells (0.25×10^6 cell/mL) were incubated in 6 well plates for 24 h. The cells were then exposed to free SN38 (32 nM), G3.5-gly-SN38 (240 nM), and G3.5-βala-SN38 (760 nM) for a further 24 h. Cells were then harvested, washed with 1 mL of ice-cold PBS, and fixed with 1 mL of 70% ethanol (previously frozen at −20 °C) overnight. The cells were then washed a second time with 1 mL of ice-cold PBS and treated with 0.2 mL PBS solution containing propidium iodide (Sigma-Aldrich, USA) (25 μg/mL), Triton X-100 (Sigma-Aldrich, USA) (0.05%), and RNase (Sigma-Aldrich, USA) (180 μg/mL). The solutions were incubated at room temperature in the dark for 30 min prior to analysis. Analysis of DNA content in cells stained with propidium iodide was performed using FACScan (Becton Dickinson, Mountain View, CA). The percentage of cells in each phase of the cell cycle was evaluated using the *ModFit* software (Verity Software House, Topsham, ME).

Nuclear Fragmentation Study. HCT-116 cells (0.1×10^6) were plated in 6 well plates containing coverslips and incubated for 24 h. SN38 (5 nM), G3.5-gly-SN38 (40 nM), and G3.5-βala-SN38 (120 nM) were added, and cells were incubated for 36 h. Cells were then washed with PBS three times and fixed with 4% paraformaldehyde for 10 min. Cells were again washed with PBS three times, and each coverslip was mounted on glass slide with a drop of DAPI containing mounting medium (Santacruz Biotechnology, CA, USA). Nuclear fragmentation was visualized in fixed cells stained with DAPI by a laser scanning confocal microscope Olympus FluoView FV1000 (Olympus America Corp., Center Valley, PA). The objective specifications were 60× oil immersion and numerical aperture 1.42.

Table 1. Characteristics of G3.5 PAMAM-SN38 Conjugates

compound	no. of SN38 molecules/ PAMAM[a]	wt of SN38/ wt of conjugate (%)	molecular weight[b]	elution volume (mL)	hydrodynamic radius (nm)
G3.5	-	-	12 931	13.0	1.76 ± 0.11
G3.5-gly-SN38	2.9	8.0	14 184	13.4	1.37 ± 0.06*
G3.5-βala-SN38	4.0	10.0	14 715	14.0	1.33 ± 0.05**

[a] Determined from ^{1}H NMR. [b] Determined from NMR data and reported molecular weight of PAMAM. * ($p < 0.01$) denotes significant differences of hydrodynamic radius from unconjugated G3.5. ** ($p < 0.01$) denotes significant differences of hydrodynamic radius from unconjugated G3.5.

Statistical Analysis. Statistical analysis was carried out using Student's t test with a probability value $p < 0.05$ considered statistically significant.

RESULTS AND DISCUSSION

Synthesis and Characterization. Anionic PAMAM G3.5 was covalently conjugated to SN38 via a glycine or β-alanine spacer. Amino acid linkers, particularly glycine, have been successfully used to attach SN38 and other camptothecin analogues to polymers such as poly(ethylene glycol) (PEG), poly(glutamic acid), and pegylated poly(L-lysine) dendrimer with such conjugates showing increased aqueous solubility and good in vitro and in vivo efficacy (*11*, *18*−*20*). β-Alanine differs from glycine in the presence of an additional methylene group and could thus act as a relatively extended spacer. We chose these two spacers to compare the possible effect of linker length on the extent of drug loading, rate of drug release, and activity of the conjugates. SN38 derivatives, modified at the 20-OH position via an ester linker with glycine and β-alanine, respectively, were synthesized as described in the Experimental Section (*11*). Briefly, the phenolic hydroxyl group at the 10-position of SN38 was first protected with a Boc group, and the resulting compound **1** was then reacted with N-Boc glycine to yield compound **2**. Removal of both Boc groups under acidic conditions yielded SN38-gly (compound **3**). In an analogous manner, SN38-βala (compound **5**) was also synthesized starting from SN38 (Scheme 1).

The terminal carboxyl groups of G3.5 PAMAM dendrimer were then activated using EDC/NHS and reacted with the primary amines of SN38-gly and SN38-βala, respectively, in DMSO. Thus, the dendrimer was linked via an amide bond at one end of the spacer, while the drug was attached to the same spacer via an ester bond at the other end (Scheme 2). The dendrimer was conjugated at the 20-OH end of SN38 with the aim of stabilizing the lactone form of the camptothecin derivative under physiological conditions, which is essential for antitumor activity (*9*).

The conjugates were extensively purified by dialysis followed by preparative SEC to remove low molecular weight impurities. There was an increase in the elution volume in SEC for both conjugates relative to G3.5 with the order of elution being G3.5 < G3.5-gly-SN38 < G3.5-βala-SN38. The hydrodynamic radii of both conjugates as measured by dynamic light scattering was less than that of G3.5 (Table 1). These observations suggest that, upon attachment of SN38, the dendrimer may have a more compact form to avoid unfavorable interactions between the aqueous solvent and the hydrophobic drug. It is also possible that the overall charge density on the surface of the conjugates is lowered relative to G3.5, reducing the extent of solvation in aqueous solution, which results in a lower hydrodynamic radius.

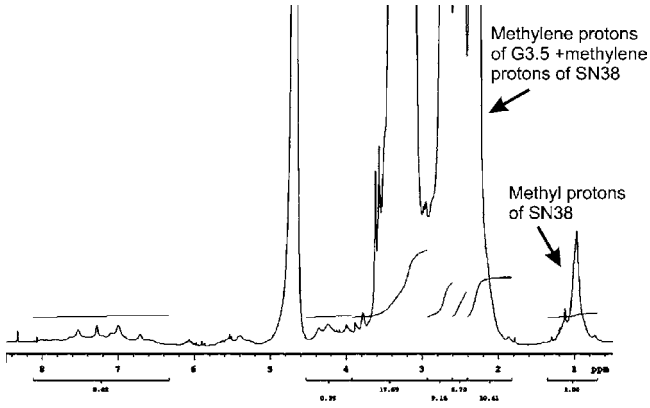

Figure 1. ^{1}H NMR spectra (500 MHz, D_2O) of G3.5-gly-SN38.

The number of drug molecules attached to the dendrimer was determined using ^{1}H NMR, by comparing the number of protons in the dendrimer to the methyl groups of SN38. The protons corresponding to PAMAM appeared between chemical shifts, 2.1−3.8 ppm, while the methyl protons appeared as a broad peak between 0.9 and 1.1 ppm (Figure 1). ^{1}H NMR was recorded at three different concentrations, 5 mg/mL, 10 mg/mL, and 25 mg/mL, and no changes in integral values corresponding to protons from the dendrimer or methyl protons of SN38 were observed. This suggested the absence of aggregation at concentrations used for NMR analysis. The drug loading per mole of dendrimer was 2.9 and 4 for G3.5-gly-SN38 and G3.5-βala-SN38, respectively (Table 1). Thus, increasing the spacer length by one methylene unit increased the drug loading slightly. For synthesis of dendrimers with the drug loadings above, 16 mol of compound gly-SN38 or βala-SN38 was used for conjugation to G3.5. Use of a further excess of drug did not improve loading, while lower stoichiometric ratios of the drug derivatives decreased loading onto PAMAM dendrimers. In order to further confirm that SN38 was covalently linked to the dendrimer, the following control experiment was performed. Acidified PAMAM G3.5 was mixed with compound gly-SN38 in DMSO and stirred under identical conditions to those of the conjugation reactions in the absence of activating reagents EDC/NHS. The resulting mixture was then purified using the same method as described for the conjugates and the isolated compound analyzed by SEC and ^{1}H NMR. The SEC profile and ^{1}H NMR were the same as for the native G3.5 PAMAM dendrimer. No peaks due to SN38 were observed in the ^{1}H NMR spectrum suggesting the absence of complexed or free drug (Supporting Information). These observations further confirm that the conjugates synthesized are not complexes and the SN38 is covalently bound to the dendrimer.

The solubility of the conjugates in water was ~140 mg/mL, which corresponds to ~10 mg/mL and ~14 mg/mL of SN38, respectively, in the cases of G3.5-gly-SN38 and G3.5-βala-SN38. SN38 has a very poor solubility of 7 μg/mL, and conjugation to the PAMAM dendrimer has considerably improved its aqueous solubility, which is higher than that of previously reported PEG-SN38 derivatives (6.7 mg/mL) (*11*).

Stability of the Conjugates. In vitro release characteristics of the conjugates was studied to assess their stability in the following physiologically relevant solutions, PBS, pH = 7.4, cell culture media: Mcyoy's 5A medium with 10% FBS and 50% rat plasma (*11*, *21*, *22*). Stability in cell culture media was studied to determine whether potential activity of the conjugates would be due to extracellular and/or intracellular release of the drug. 50% plasma was used, since in whole blood, the plasma content is about ~55%. SN38 binds strongly to plasma proteins, and the extraction efficiency in 100% rat plasma was poor (35%)

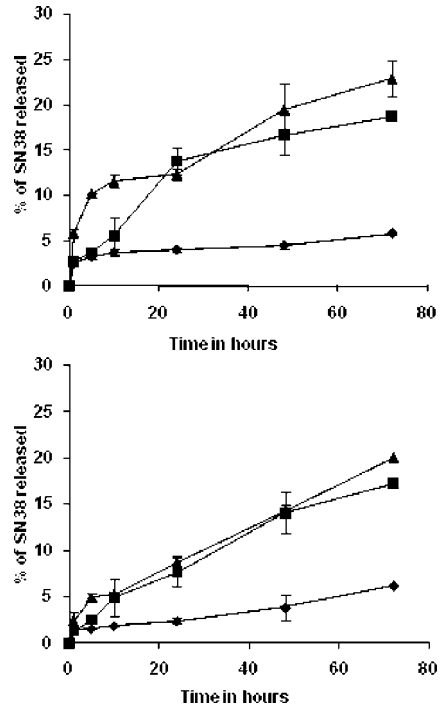

Figure 2. Stability of conjugates in different media at 37 °C. Top panel: SN38 release from G3.5-gly-SN38. Bottom panel: SN38 release from G3.5-βala-SN38. The time intervals were 0, 1, 5, 10, 24, 48, and 72 h. Each graph represents the average of two independent runs. (m ± s.d): PBS (◆), 50% rat plasma (▲), and cell culture media (■).

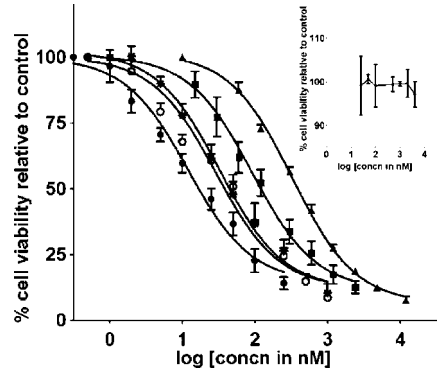

Figure 3. In vitro cytotoxicity of SN38 (•), SN38gly (○), SN38βala (*), G3.5-gly-SN38 (■), G3.5- βala-SN38 (▲) in human colorectal cancer cell line (HCT-116) after 48 h incubation. Each curve is representative of 3−5 independent experiments (m ± s.d). Inset: Inhibition curve for G3.5.

after 1 h incubation, while in 50% plasma, it was much higher (62%); and hence, the released drug could be estimated more accurately.

In PBS, both conjugates were stable with approximately 5% of the drug released in 72 h. Thus, these conjugates are more stable than the PEG-SN38 conjugates, which were reported to have a $t_{1/2}$ of only 14 h in PBS (*11*). However, in cell culture media and 50% rat plasma the extent of release was relatively higher compared to that in PBS (Figure 2). This is expected, as enzymes such as esterases are present in both plasma and 10% FBS containing media. Esterases can specifically cleave the ester bond between the spacer and the drug, whereas in PBS, the release is only due to nonspecific hydrolysis. In the case of G3.5-gly-SN38, the release in plasma was slightly higher than in cell culture medium ($p < 0.04$), but no significant difference was observed in the case of β-alanine-linked conjugate. It has been reported that increasing the length of the spacer increases the

Table 2. Cytotoxicity of Different Forms of SN38 toward Human Colorectal Carcinoma HCT-116 cells[a]

compound	IC_{50} (nM)
SN38	16 ± 3
SN38-gly	42 ± 10
SN38-βala	45 ± 6
G3.5-gly-SN38	129 ± 27*
G3.5-βala-SN38	387 ± 20**
CPT-11	$(12 \times 10^3) \pm (3.8 \times 10^3)$

[a] IC_{50} values presented as m $\pm$ s.d. of 3−5 independent experiments. * ($p < 0.001$) denotes significant difference of IC_{50} of G3.5-SN38 conjugates from SN38. ** ($p < 0.001$) denotes significant difference of IC_{50} of G3.5-SN38 conjugates from SN38.

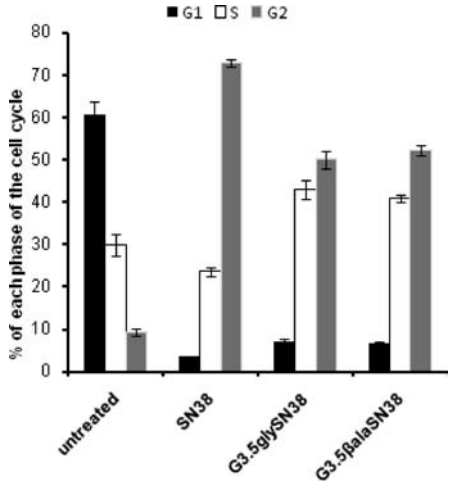

Figure 4. Effect of SN38 and G3.5-SN38 conjugates on cell cycle distribution of HCT-116 cells after 24 h incubation. Values are representative of two independent experiments, each done in duplicate (m $\pm$ s.d).

rate of hydrolysis of the ester bond due to increased accessibility to the enzyme (*22*, *23*). Upon comparing the release rates of both conjugates, we did not observe an overall, large difference in the release when increasing the linker by one methylene unit. However, it is observed that G3.5-gly-SN38 shows slightly faster release of the drug in the first 24 h than G3.5-βala-SN38 in both media and plasma ($p < 0.03$), but they return to similar rates by 48 h ($p > 0.1$). It is possible that glycine, being a natural amino acid, is a better substrate for enzymes compared to β-alanine, and hence, the glycine linked conjugate shows initially faster release rates in media containing esterases. The conjugate with glycine linker also showed a higher release of drug at pH 5 after 72 h compared to the conjugate with the β-alanine linker (see Supporting Information Figure 4). However, the dendrimer is likely to have too many different conformations in solution, such that some result in increased accessibility to the enzymes, while others lead to increased steric hindrance to ester degradation. Hence, the overall release kinetics is complex (*24*, *25*). The fact that only ~20% (Figure 2) is released even after 72 h for both conjugates in rat plasma suggests that the covalent conjugates are quite stable and hold promise as delivery systems for controlled release of the drug.

Inhibition of Cell Growth. The toxicities of the conjugates, linker modified SN38 derivatives (SN38-gly, SN38-βala), free SN38, and CPT-11 were compared upon 48 h incubation with HCT-116 cells (Figure 3). SN38 was highly toxic to the cells with IC_{50} of approximately 16 nM. It was observed that both SN38-gly and SN38-βala had similar IC_{50} values and were slightly less cytotoxic than SN38 ($p < 0.02$). This suggests that both SN38-gly and SN38-βala undergo rapid hydrolysis to release the free drug, as the IC_{50} values were only about 3 times less than that of SN38. Both conjugates were far less cytotoxic with much higher IC_{50} values compared to the free drug. However, their toxicities are still in the nanomolar range and are highly potent compared to that of CPT-11 (Table 2). PAMAM G3.5 was nontoxic in the concentration range used in the case of the conjugates (inset, Figure 3). The lower activity of the PAMAM-SN38 conjugates compared to that of SN38

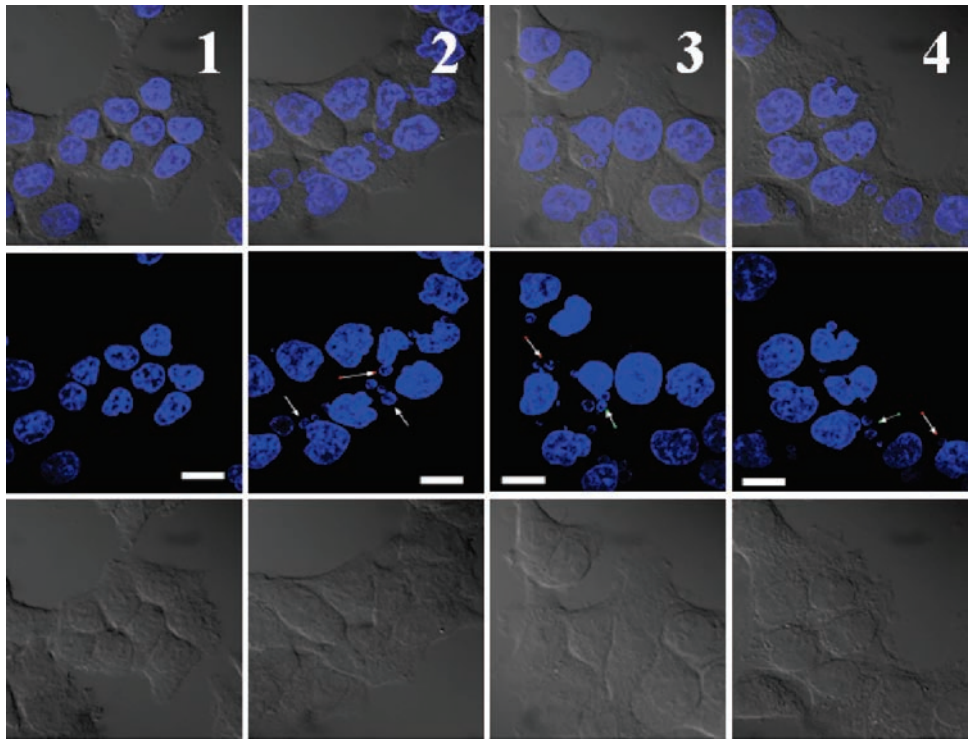

Figure 5. Nuclear fragmentation in HCT-116 cells treated with drug/conjugates. Untreated cells (column 1); 5 nM SN38 (column 2); 40 nM G3.5-gly-SN38 (column 3); 120 nM G3.5-βala-SN38 (column 4). Scale bar is 10 μm. Arrows indicate nuclear fragments. From bottom: 1st row, DIC (differential interference contrast image); 2nd row, fluorescence image; 3rd row, overlay of DIC and fluorescence images.

can be attributed to the slow release of the drug by hydrolysis of the linker from the sterically hindered dendrimer surface. G3.5-βala-SN38 exhibited lower activity as compared to G3.5-gly-SN38 ($p < 0.001$), which could perhaps be due to the observed lower initial release rate in cell culture media. There is also a possibility that the cellular uptake varies for the two different conjugates (*26*).

Induction of Cell Cycle Arrest and Nuclear Fragmentation. As both PAMAM-SN38 conjugates inhibited cell proliferation of HCT-116 cells, we further investigated the mode of action of these conjugates. SN38 is a topoisomerase I inhibitor and is known to exhibit characteristic G_2/M phase cell cycle arrest. The drug acts by covalent binding to the cleavable topoisomerase I−DNA complex, causing double-strand DNA breaks and irreversible arrest of DNA replication. These events lead to arrest in the G_2/M phase of the cell cycle (*27, 28*).

The progression of HCT-116 cells through the cell cycle after 24 h treatment with 2 × IC-50 concentration of either conjugate or free drug was evaluated using flow cytometry. As expected, SN38 caused cell cycle arrest in the G_2/M phase (73%) with considerable reduction in population of cells in the G_0/G_1 (4%) phase relative to untreated cells (61%). Upon exposure to G3.5-gly-SN38, a significant accumulation of cells in the G_2/M phase (50%) was observed with accompanying substantial decrease in G_0/G_1 (7.0%). Similarly, in the case of G3.5-βala-SN38, the accumulation of 52% cell population in the G_2 phase was observed (Figure 4). These results suggest that the dendrimer−drug conjugates have a similar mechanism of action as SN38 and the conjugates affect cells due to release of the free drug. However, compared to both conjugates, SN38 used at equitoxic 2 × IC-50 concentration induced accumulation of a larger number of cells in the G_2/M phase of the cell cycle ($p < 0.001$). This can be attributed to the slow release of drug from the conjugates.

In addition to inducing cell cycle arrest in cancer cells, anticancer drugs such as SN38 can kill cancer cells. The different modes of cell death include apoptosis, necrosis, autophagy, or mitotic catastrophe with each associated with characteristic morphological changes and biochemical markers. Few studies have shown that SN38 causes cell death mainly via an apoptotic mechanism. The morphological changes that define apoptosis include chromatin condensation, nuclear fragmentation, plasma membrane blebbing, and appearance of apoptotic bodies, while biochemical markers include formation of DNA fragment "ladders" and caspase activation (*28, 29*).

Fluorescence microscopy was used to examine and compare the effect of conjugates and free drug on cell and nuclear morphology (Figure 5). HCT-116 cells were treated for 36 h with either free SN38 or conjugates at 1/3 IC_{50}, stained with the nuclear dye, DAPI, and observed under the confocal fluorescence microscope. Untreated cells appeared mostly uniform with regularly shaped nuclei. In contrast, cells treated with either SN38 or the dendrimer−drug conjugates appeared heterogeneous. Nuclear fragments were distinctly visible, along with swollen and sparsely condensed nuclei. Mitotic cells were also occasionally seen in the treated cells. Although these observations are not conclusive evidence of apoptosis or necrosis, they do suggest that the free drug and conjugates have the same mode of action. The activity of the conjugates is due to the release of the free drug.

CONCLUSIONS

PAMAM-SN38 conjugates with ester linkers which are stable at physiological pH and in plasma with low release of drug were synthesized. Conjugation of SN38 with the dendrimer significantly increased aqueous solubility. These dendrimer−drug conjugates are potent and have IC_{50} in the nanomolar range, and show activity due to slow release of SN38. Cell cycle analysis and observed nuclear fragmentation suggest that both free drug and the drug conjugated to the dendrimer have similar mechanisms of action. These novel dendritic conjugates of SN38, coupled with our previous observations that PAMAM dendrimers are translocated across the epithelial barrier of the gut, show the potential to improve the oral bioavailability and targeted delivery of this potent drug.

We combine a novel boronate trap for F^- with a near-infrared fluorophore into a single molecule. Attachment to targeting ligands enables localization by positron emission tomography (PET) and near-infrared fluorescence (NIRF). Our first application of this generic tag is to label Lymphoseek (tilmanocept), an agent designed for receptor-specific sentinel lymph node (SLN) mapping. The new conjugate incorporates $^{18}F^-$ in a single, aqueous step, targets mouse SLN rapidly (1 h) with reduced distal lymph node accumulation, permits PET or scintigraphic imaging of SLN, and enables NIRF-guided excision and histological verification even after ^{18}F decay. This embodiment is superior to current SLN mapping agents such as nontargeted [^{99m}Tc]sulfur colloids and Isosulfan Blue, as well as the phase III targeted ligand [^{99m}Tc]SPECT Lymphoseek counterpart, species that are visible by SPECT or visible absorbance separately. Facile incorporation of ^{18}F into a NIRF probe should promote many synergistic PET and NIRF combinations.

INTRODUCTION

Different molecular imaging techniques have complementary advantages and disadvantages in spatial and temporal resolution, depth penetration, sensitivity, and cost (*1*). A powerful way to combine synergistic advantages is to construct synthetic probes that can be imaged by two or more modalities (*2*−*4*). Radiotracers and near-infrared fluorescence (NIRF) are particularly suitable combinations because both are sufficiently sensitive to enable direct visualization at receptor binding concentrations (nanomolar to picomolar). In contrast, magnetic resonance imaging (MRI) and X-ray contrast tomography require much higher elemental concentrations of the probe (*1*). The excellent penetration of γ-ray photons in positron emission tomography (PET) allows quantitative detection regardless of depth, making this technique ideal for whole-body scanning. NIRF offers much higher spatial and temporal resolution and cheaper instrumentation, but it is largely limited to superficial targets, making it ideal for image-guided surgery and histology.

Multimodality PET/optical probes under development currently include ^{18}F/quantum dot (QD) (*5*), ^{18}F/nanoparticle (*6*), bis(thiosemicarbazonato) ^{64}Cu chelates (*3, 7*), and ^{64}Cu/cypate (*4*) conjugates. PET bioconjugate radiochemistry is often limited to the physically more common radionuclides ^{64}Cu ($t_{1/2}$ = 762 min), ^{68}Ga ($t_{1/2}$ = 68 min), and ^{18}F ($t_{1/2}$ = 110 min), because they are easily manipulated and possess nuclear half-lives sufficiently long enough for chemical isotope manipulation and in vivo distribution. Unfortunately, each of these PET nuclides presents intrinsic complications. For example, ^{64}Cu (*3, 4, 8*) and ^{68}Ga (*9, 10*) chelates can suffer from impure isotope production as well as lowered specific activity because of impure isotope decay (*11*) and large chelation moieties that may alter ligand biodistribution and may also suffer from in vivo metal ion transchelation (*12*). Alternatively, traditional ^{18}F labeling methods (*5, 13*−*17*) relying on C−F bond formation are water-sensitive, multistep processes that often require harsh reaction conditions and long processing times that are poorly suited to the short half-life of ^{18}F.

To simplify PET chemistry, there has been recent interest in developing rapid, one-step labeling procedures from shelf-stable final target precursors with aqueous $^{18}F^-$, while reducing the side products and chromatographic purifications associated with traditional C−^{18}F labelings. Recent silica-based (*18*−*21*) and boron-based (*22*−*24*) aqueous ^{18}F capture technology allows direct preparation of isotopically pure PET compounds that are cleanly labeled, are easily purified, and have been shown to be stable in vivo (*19, 25*). We chose to generate [^{18}F]fluoroborates because they require less bulky hydrophobic substituents and potentially triple the F^- incorporation stoichiometry and attainable specific activity (*22*−*24*). A typical preparation of ^{18}F fluoride has a specific activity of ~10 Ci/μmol even if no carrier was deliberately added and therefore contains 170 atoms of ^{19}F for each atom of ^{18}F (*26*). Incorporation of three fluorine atoms triples the probability that at least one will be radioactive. We combine this boron-based ^{18}F capture technology [$t_{1/2}$ of B−F solvolysis = 5550 ± 1740 min (*23*)] with a NIR fluorophore to give a generally conjugatable PET/NIRF multimodality probe **1** (Figure 1A). Our first test of this probe is to help find and excise sentinel lymph nodes.

The current method for sentinel lymph node mapping in melanoma and breast cancer involves injection of a combination of Isosulfan Blue (*27*) and a ^{99m}Tc-labeled colloid radiopharmaceutical (*28, 29*). This pair allows for lymphoscintigraphy and absorbance-guided intraoperative lymph node excision (*30*). With little affinity for the sentinel lymph node, ^{99m}Tc-labeled colloids and Isosulfan Blue will travel past the sentinel node in a lymph chain restricting the surgeon to a small time-window within which to perform the mapping procedure. ^{99m}Tc-radiolabeled colloids are large particles that are nonspecifically trapped within lymphoid tissue. These agents are inefficient at entering lymph channels and, over time, reach distal lymph nodes. Distal colloid or dye uptake leads to the surgical removal of more lymph nodes than necessary, which increases the extent of the dissection, forces the pathologist to review a greater

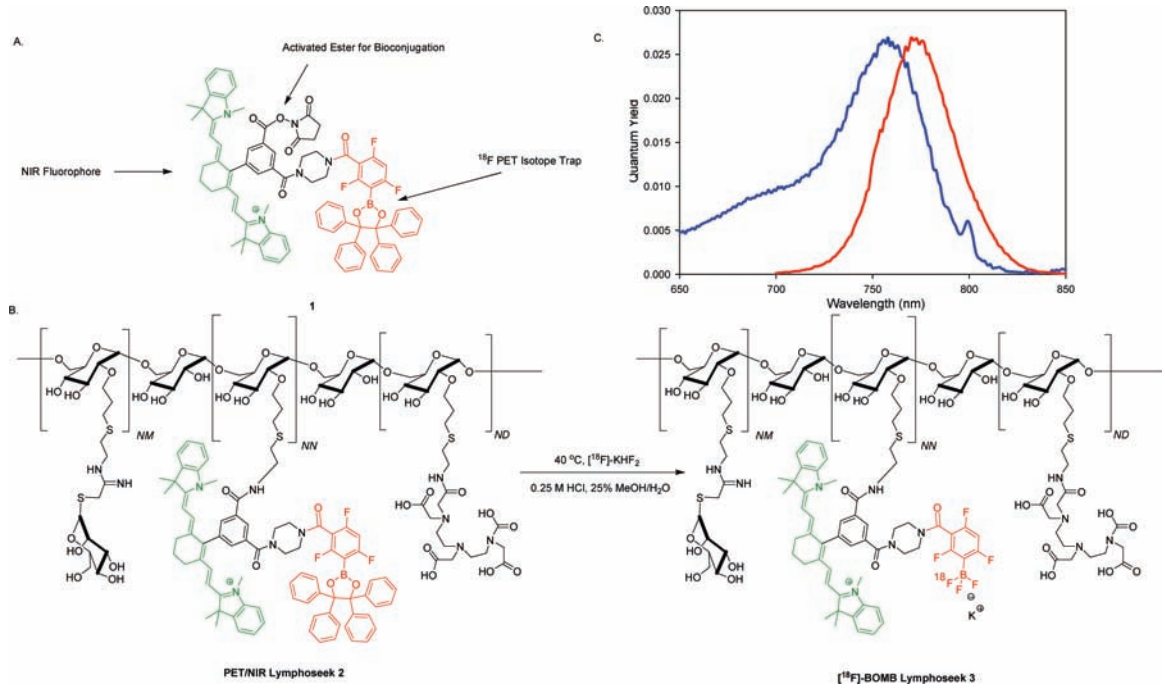

Figure 1. (A) Structure of the ^{18}F boron trap/heptamethine cyanine (C7-Cy) PET/NIR probe, [^{18}F]BOMB 1, activated as an NHS ester for general bioconjugation. The boron-based ^{18}F trap is colored red, while the NIR fluorophore is colored green. (B) Structure of PET/NIR dual probe Lymphoseek (DTPA-mannosyl-dextran) **2** and the aqueous ^{18}F labeling scheme used to generate ^{18}F-labeled [^{18}F]BOMB Lymphoseek **3**. (C) Excitation (blue) and emission (red) spectra of an aqueous solution of [^{18}F]PET/NIR-Lymphoseek **3** ($\varphi_f = 0.027$, excitation maximum = 755 nm, emission maximum = 772 nm, 1.5 μM Lymphoseek solution in water). The amine (NN), mannose (NM), and DTPA (ND) densities on Lymphoseek are 5.8, 16.5, and 4.2 mol/dextran, respectively. The average preconjugation molecular weight of Lymphoseek is 16122.

number of lymph nodes, and increases the probability of local lymphedema, a complication of lymph node resection. An alternative probe is Lymphoseek (tilmanocept), a mannosylated 16 kDa dextran conjugate, that can be labeled with ^{99m}Tc for SPECT-based imaging (*31*, *32*) and is currently in phase III clinical trials. It binds with a high affinity to cell-surface lectins [$K_D = 0.12$ nM (*33*)] and was developed specifically for sentinel lymph node mapping. ^{99m}Tc-labeled Lymphoseek has demonstrated rapid injection site clearance, a low level of distal node accumulation, a lack of local systemic toxicity, and greater specific sentinel lymph node uptake than filtered [^{99m}Tc]sulfur colloid (*32*, *34*, *35*). A version of Lymphoseek that can be viewed by both PET and NIRF would combine molecular targeting, the higher spatial resolution of PET compared to ^{99m}Tc SPECT, and the greater sensitivity and depth penetration of NIRF compared to the red absorbance of Isosulfan Blue.

Here we apply our generally conjugatable PET/NIRF probe **1** (Figure 1A) to Lymphoseek to enable multimodality-guided sentinel node visualization and excision. This [^{18}F]boron/optical multimodality beacon ([^{18}F]BOMB) is differentiated from traditional C−^{18}F PET labeling strategies (*5*, *13*−*17*) by its one-step [^{18}F]fluoride wash-in labeling. [^{18}F]BOMB Lymphoseek **3** (Figure 1B) allows rapid, receptor-specific, positive identification of the sentinel lymph node in both the NIRF and PET imaging modes while maintaining little breakthrough to distal lymph nodes. This success predicts that [^{18}F]BOMB should be generalizable to other medically relevant targets.

EXPERIMENTAL PROCEDURES

Chemical Synthesis. *PET/NIR Dual-Probe Reaction with Lymphoseek: Synthesis of PET/NIR Lymphoseek Probe **2**.* The generally conjugatable NHS ester of PET/NIR probe **1** (4 μmol) (see the Supporting Information for detailed synthesis) was added as a CH_2Cl_2 solution directly into a 1.5 mL glass vial containing 5.5 mg (0.34 μmol) of Lymphoseek bearing 5.8 amine groups per dextran (Reliable Biopharmaceuticals). This solution was concentrated to dryness and then resuspended in 100 μL of DMF. This solution was sonicated for 1 h and left to react for 18 h. The next day, 10 μL of diisopropylethylamine was added and the reaction mixture was left for an additional 2 h. The reaction mixture was then transferred to a polypropylene centrifuge tube containing 25 mL of CH_2Cl_2. A pellet of **2** was isolated following centrifugation for 20 min at 3000 rcf, washed with two more portions of CH_2Cl_2, dried under high vacuum, and resuspended in 1 mL of water. This solution was centrifuged for 2 min at 18000 rcf. Water-soluble **2** was decanted from the pellet and divided into four aliquots, which were lyophilized and stored at −78 °C. On the basis of fluorescence readings, 115.9 nmol of fluorophore-conjugated Lymphoseek **2** was isolated. On the basis of a hexose assay (*36*), 34−49 nmol of Lymphoseek was isolated as **2**. This corresponds to a 10−14% yield of **2** from unconjugated Lymphoseek. The incorporation ratio of fluorophore to Lymphoseek was 2.36 to 3.41 fluorophores per molecule of Lymphoseek. Spectrophotometric constants of a 1.5 μM solution in water were as follows: absorbance maximum = 758 nm, $\varepsilon_{758} = 110000$ cm^{-1} M^{-1} per fluorophore, excitation maximum = 757 nm, emission maximum = 777 nm, and quantum yield = 0.026.

Radiochemistry. *^{18}F-Labeled Lymphoseek **3**.* A 300−500 μL aqueous solution containing 100 mCi of $^{18}F^-$ was transferred via syringe to a 10 mL glass vial containing 0.4 μL of 0.05 M KHF_2 (40 nmol) fluoride carrier. Note that acidic solutions of H^{18}F are volatile and radioactive, and therefore, the following procedures should be performed in a vented hot cell or a fume hood with radiation shielding. This sample was heated to dryness at 140 °C under a nitrogen flow. The clear dry solid was resuspended in 5 μL of a 0.25 M HCl/25% MeOH/75% H_2O solution. This solution, containing 30 mCi, was transferred to a 600 μL microcentrifuge tube containing 10.6 nmol of lyophilized **2**. This volume was sufficient to completely solubilize **3** and was reacted at 40 °C for 1 h. Following reaction,

the reaction was quenched with 40 μL of a 1 M MOPS buffered solution (pH 7.3).

To remove unreacted [^{18}F]fluoride, 5 μL of 3.0 M KHF_2 was added, and then the entire 45 μL was transferred to a Micro Bio Spin 6 column [molecular weight cutoff of 6000 (Bio-Rad)] buffered with 10 mM Tris (pH 7.4) and centrifuged without added eluant for 4 min at 1000 rcf. To the 40 μL of eluant was added an additional 5 μL of 3.0 M KHF_2 (30 μmol) to prevent the nonspecific elution of [^{18}F]fluoride, and the solution was immediately centrifuged. This described spin column purification was repeated three more times with a fresh spin column each time. Bio-Rad P-6 columns quantitatively remove small MW organic molecule impurities (see the Supporting Information) and 93% of [^{18}F]fluoride per column (99.998% of all [^{18}F]fluoride over four columns). Chromatography took 30 min total, and the final pH of the 60 μL of Tris-buffered, eluted solution was 7−8. Fluorescence showed that 6.0 nmol of ^{18}F-labeled PET/NIRF Lymphoseek **3** was eluted from the spin columns 90 min following $^{18}F^-$ concentration. The volume was 60 μL, and the activity was 300 μCi [total preparation time (reaction and purification) of 90 min]. See the Supporting Information for final analyses.

This purified solution was divided into two 30 μL portions, each sufficient for 3 × 10 μL, 1.0 nmol injections of Lymphoseek. To one portion was added 1.0 μL of a 31 mM solution of unconjugated Lymphoseek to give enough injectate for 3 × 10 μL, 11.0 nmol injections. Injections with specific activities of 0.05 Ci/μmol for 1 nmol Lymphoseek injections and 0.005 Ci/μmol for 11 nmol Lymphoseek injections were conducted for 15−75 min following synthesis and purification (see the Supporting Information for specifics).

*^{19}F (nonradioactive) Labeling of Lymphoseek **3**.* A 10.6 nmol quantity of lyophilized **2** was dissolved in a 0.25 M HCl/25% MeOH/75% H_2O solution in a 600 μL Eppendorf tube and left to react at 40 °C for 1 h. This reaction was quenched and the solution chromatographed under conditions similar to those described above for ^{18}F labeling. Spectrophotometric constants of a 1.5 μM solution of [^{19}F]**3** in water were as follows: absorbance maximum = 756 nm, ε_{756} = 110000 cm^{-1} M^{-1} per fluorophore, excitation maximum = 755 nm, emission maximum = 772 nm, and quantum yield = 0.027 (see the Supporting Information for HPLC characterization).

In Vivo Experiments. The in vivo procedures in this study have all been approved by the University of California, San Diego, Institutional Animal Care and Use Committee. A single subcutaneous injection of **3** was made into the right rear footpad of 20−25 g, 6−8-week-old athymic nude mice (Charles River Laboratories). These mice were anesthetized 20 min prior to injection with isoflurane, taped to black cardboard, and placed in pairs on an imaging stage. Six pairs of injections were made. The injected mice received either a 1 nmol dose or a 11 nmol dose (10 μL each) of 10 mM Tris-buffered [^{18}F]Lymphoseek **3** (pH 7.3). The distribution of [^{19}F]Lymphoseek **3** proceeded for 1 h and 20 min before the mice were euthanized by isoflurane overdose followed by cervical dislocation.

Imaging. PET and CT scanning were conducted on a eXplore Vista PET scanner or eXplore Locus CT scanner from GE Healthcare. PET acquisition was conducted in a single block in static emission mode with a 100−700 keV energy window. All PET scans were 20 min unless specified otherwise. Acquisition and OSEM PET reconstruction were performed with GE Explore Vista 3.1/MMKS Image Software. This reconstructed image was fused with computed tomography (CT) images processed with GE Medical Systems eXplore Utilities. CT Image acquisition was performed at 93 μm resolution over 10 min. PET/CT image fusion was conducted with the open source program amide 0.9.1.

NIRF imaging was conducted using multiple cameras because of radioactive licensing regulations. IR image acquisition of the nonradioactive compositions in Figure 2 was performed on a Maestro small animal imaging instrument (CRI Inc.) with a 820 nm emission filter and a 710−760 nm excitation wavelength. Data were collected over a 0.5−20 s exposure. Image processing was performed with Maestro version 2.0.2 and Photoshop. The Maestro, used for Figure 2, was the best instrument for real-time, fluorescence-guided node excision, although a custom system optimized for real-time intraoperative imaging would be yet more convenient. The success of sentinel lymph node excision was 100% as determined by histology with the Maestro. Because animals containing ^{18}F could not be transported to the Maestro, NIRF in vivo image acquisition of ^{18}F-labeled compounds was performed on two systems closer to the hot cell and PET scanner. The first was an eXplore Optix (ART, Advanced Research Technologies Inc.) optical imaging system. This is a point source-detector system with a 750 nm excitation laser and a 780 nm long pass filter placed before the photomultiplier tube for single-photon fluorescence detection. The regions of interest were raster-scanned in 1.5 mm steps with laser powers ranging from 200 to 800 μW and signal integration times ranging from 200 to 1000 ms per point. Image processing was performed with Optix version 2 and Photoshop. However, the slow raster scan of the Optix made real-time, image-guided node excision difficult, so a custom full field system (*37*) was employed for faster NIRF imaging of ^{18}F-labeled compounds (Figure 3C). This system used a pulsed laser tuned to 720 nm (Mai TaiSpectraPhysics) whose output was passed through an expansion lens and diffuser for uniform area illumination. Area detection of the fluorescence intensity was acquired in reflection mode using a 780 nm fluorescence filter and standard 50 mm lens (Nikon) mounted to a microchannel plate (Picostar HRI, La Vision) for signal amplification, which was coupled to an electron-multiplying CCD camera (Andor) to capture the image. Subsequent image processing was performed with Image J and Photoshop. Both the Optix and custom systems can measure nanosecond decay kinetics to provide extra information about probe lifetime and depth, but this dimension was not exploited here.

Lymph Node Removal and Dissection. Animals were euthanized by isoflurane overdose or CO_2 inhalation followed by cervical dislocation. After the skin had been removed, fluorescent images were taken to improve the visualization of the positions of the fluorescent lymph nodes. With mice placed in prone positions, both right and left sets of lymph nodes were surgically removed in the following order: the left popliteal, the left lumbar, the right lumbar, and the right popliteal. Following excision, nodes were weighted, submersed in Optimal Cutting Temperature (OCT) Compound (Sakura Tissue-Tec # 4585) cryogenic embedding medium, and replaced next to their mouse of origin within the field of view, approximately half a centimeter below the surgical site in the corresponding mouse. In some instances where sentinel node excision was difficult, fluorescence guidance was utilized to guide surgical removal.

Following imaging, samples of blood (vena cava), liver, kidney, spleen, the hind feet (right and left), bone (contralateral femur), and muscle from the contralateral femur were collected.

Histology. Immediately following excision, lymph nodes were weighed and then coated in OCT Compound to prevent lymph nodes from becoming dehydrated during PET/CT/NIRF analysis and overnight scintillation counting. Lymph nodes were frozen at −80 °C for extended periods of time in this preservative. Frozen sections (10 μm) of the lymph nodes were imaged under NIRF conditions on a stereomicroscope (Zeiss, Lumar). Tissue was stained with hematoxylin and eosin and subsequently imaged via light microscopy (Zeiss, Axiovert). Images were

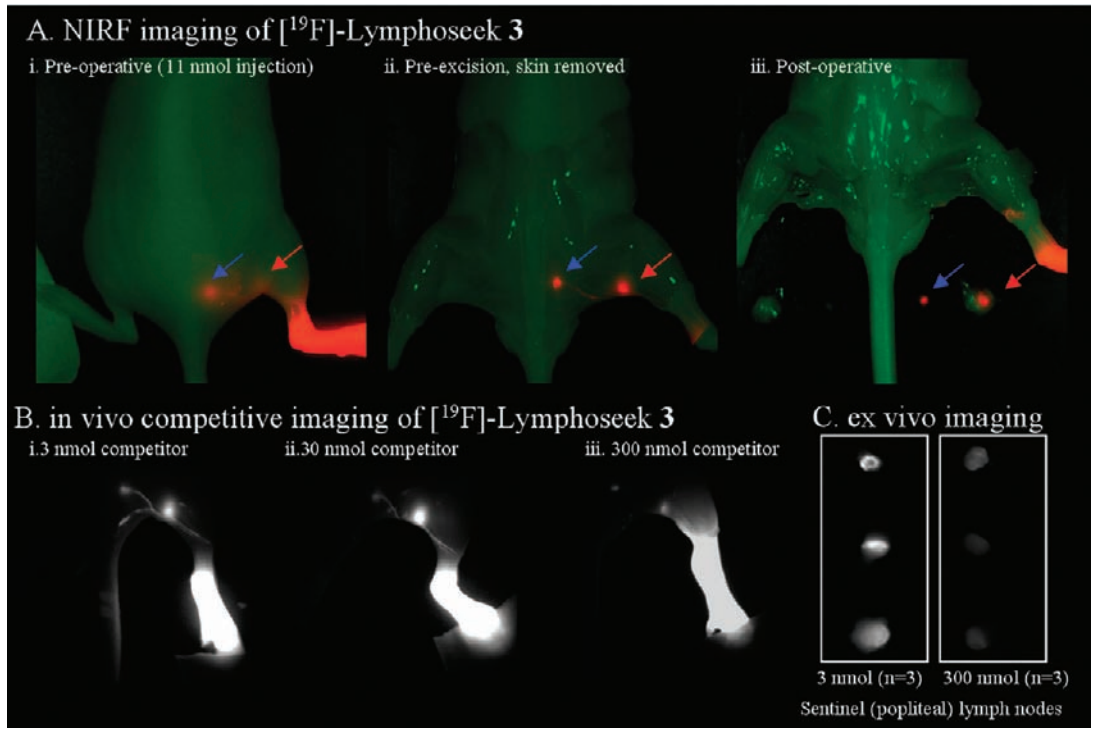

Figure 2. Nonradioactive NIRF imaging of [^{19}F]Lymphoseek **3**. (A) Typical NIRF imaging experiment of a mouse that had been injected with 1 nmol of [^{19}F]**3** diluted with 10 nmol of unconjugated Lymphoseek. The NIRF signal (colored red) is overlaid onto a bright field image (green) of a mouse. A red arrow indicates clear localization of [^{19}F]Lymphoseek **3** to the sentinel (popliteal) lymph node, while the blue arrow indicates localization to the distal (lumbar) lymph node. (i) Post-mortem skin-on image in which tissue (skin) notably interferes with the sentinel lymph node visibility. (ii) Pre-excision image (skin removed) in which the sentinel node visibility is improved and lymph drainage tracks are visible. (iii) Postoperative image in which the excised lymph nodes have been placed in the field of view. (B) In vivo imaging of [^{19}F]Lymphoseek **3**'s mannose receptor specific activity. Fluorescent [^{19}F]Lymphoseek **3** (1 nmol) was imaged in the presence of 2 (i), 29 (ii), or 300 nmol (iii) of unlabeled Lymphoseek, a competitor for lymph node mannose binding sites. Note that lymph tracks are clearly visible and that greater accumulation of fluorescent [^{19}F]Lymphoseek **3** is seen in the sentinel lymph nodes with 3 and 30 nmol injections than with 300 nmol injections because of increased competition with unlabeled Lymphoseek for sentinel lymph node mannose receptors. (C) Ex vivo imaging of [^{19}F]Lymphoseek **3**'s mannose receptor specific activity. Sentinel lymph nodes were extracted from mice and placed on a bed for analysis. Greater accumulation of fluorescent [^{19}F]Lymphoseek **3** is seen in the sentinel lymph nodes in 3 nmol injections than in 300 nmol injections (signal ratio of 3.5, $n = 3$ mice per dose, $P = 0.015$ for a two-tailed test, two-sample equal variance, quantization shown in the Supporting Information).

processed using Image J. The fluorescent histology was acquired using 710/75 nm band-pass excitation and 810/90 nm band-pass emission filters.

Biodistributions. Tissue and injectate samples of known dilutions were assayed (Gamma 9000, Beckman Instruments) for radioactivity using a 400−600 keV energy collection window.

*Nonradioactive [^{19}F]Lymphoseek **3** Dosing Experiments.* Nonradioactive [^{19}F]Lymphoseek **3** was prepared as described for its ^{18}F counterpart. This preparation was divided into 10 μL aliquots of 10 mM Tris (pH 7.3) that contained 1.0 nmol of ^{19}F-labeled Lymphoseek **3** diluted with 2, 10, 29, or 300 nmol of unlabeled Lymphoseek.

RESULTS

Synthesis and Conjugation of a General PET/NIRF NHS Probe. We appended a sufficiently electron withdrawing boronic ester (*23*) to a heptamethine cyanine, a member of a class of small-molecule dyes that possess an established safety record (*38*, *39*). Through chemistry pioneered by the Achilefu group (*40*), we modified the inexpensive synthon IR-775 (Sigma-Aldrich) into an *N*-hydroxysuccinimide (NHS)-activated pre-PET/NIRF probe **1** (Figure 1A) in three steps with a final yield of 50.7%. The resulting pre-PET/NIRF probe **1** (Figure 1A) shows long wavelength NIR fluorescence and adequate quantum yield [excitation maximum = 755 nm, emission maximum = 772 nm, and $\varphi_f = 0.027$ (Figure 1C)]. It was conjugated to Lymphoseek in a ratio of two to three molecules of fluorophore per molecule of Lymphoseek to give precursor **2** (Figure 1B). Self-quenching on **2** or **3** was not observed (see the Supporting Information).

Nonradioactive Fluorescence-Based Lymphoseek Dosing. Initial staging experiments were conducted for two purposes: (1) to determine what doses, when injected into the right rear footpad, would rapidly identify the (sentinel) popliteal lymph node and minimize flow-through to distal (lumbar) lymph nodes and (2) to determine if the conjugation of Lymphoseek to the PET/NIRF probe had altered Lymphoseek's desired pharmaceutical properties, especially mannose receptor specificity. These experiments were conducted with nonradioactive [^{19}F]Lymphoseek **3** and fluorescence equipment alone, minimizing the use of radioactivity during initial stages of this project. Lymphoseek boronate **2** (Figure 1B) was converted into fluoroborate **3**, and 1 nmol of this fluorescent material was diluted with 0, 2, 10, 29, or 300 nmol of unconjugated Lymphoseek to give 1, 3, 11, 30, or 301 nmol of total Lymphoseek but identical quantities of fluorophore. These mixtures were injected into mice (three injections per dose, 15 mice total). After 80 min, the first two lymph nodes that drain the rear-footpad injection site could be viewed by NIRF (Figure 2A,B).

In 1, 3, 11, and 30 nmol Lymphoseek injections (Figure 3 and panels Bi, A, and Bii of Figure 2, respectively), a high level of uptake in the sentinel node was observed with limited flow-through to distal lymph nodes. Injections where **3** had been diluted with 300 nmol of unlabeled Lymphoseek gave less

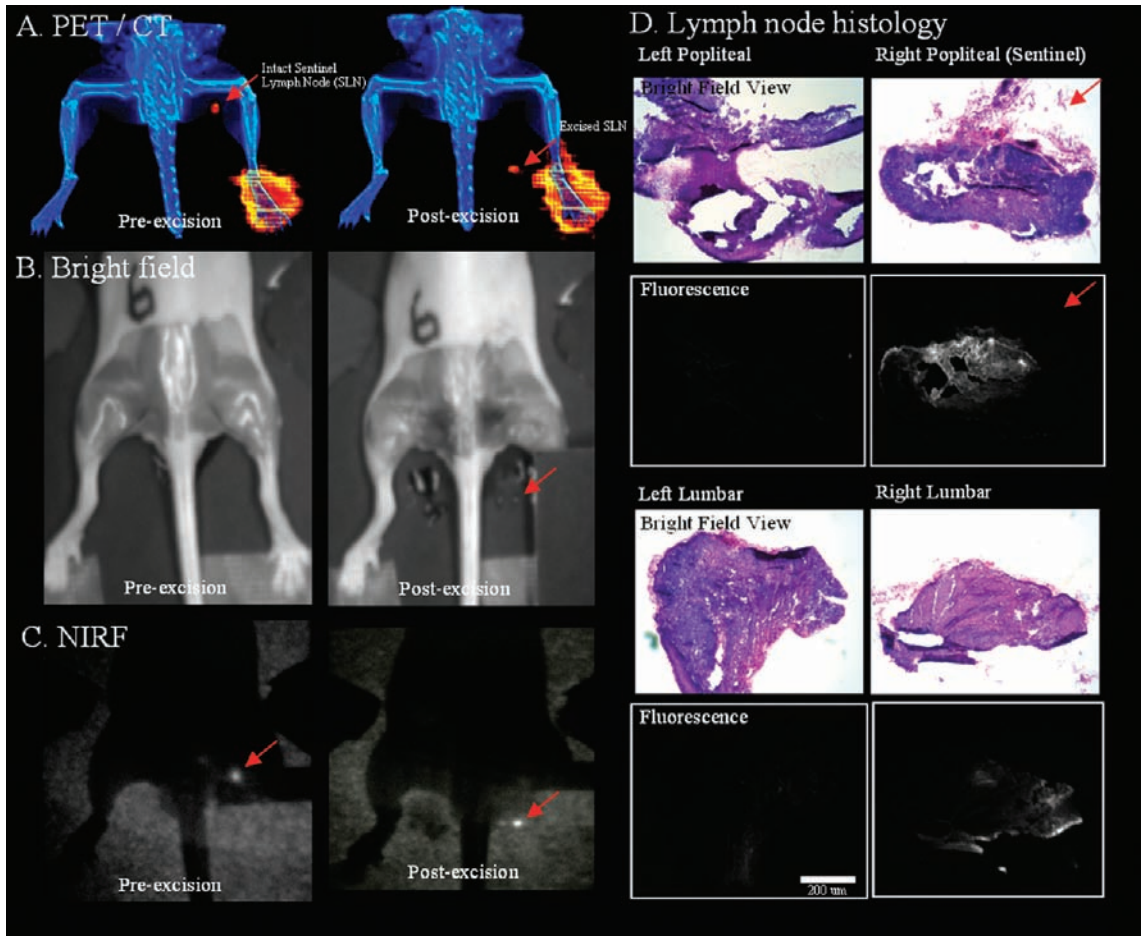

Figure 3. Multimodality imaging of a mouse injected with a 10 μL, 1 nmol, 48.1 μCi dose of ^{18}F-labeled Lymphoseek **3** (0.048 Ci/μmol). The red arrows indicates the location of the sentinel lymph node. (A) Pre-excision, live-mouse PET (red color table)/CT (blue color table) scan (left) and postoperative PET/CT scan (right) of the mouse with excised nodes (right and left lumbar and popliteal) that are placed below the excision site in the field of view. (B) Bright field images of the mouse with skin removed before (left) and after node excision (right). (C) NIRF images taken 90 min postexcision on a custom full field IR camera before (left) and after (right) lymph node excision. The injection site was covered with black cardboard to block intense signal from the foot and allow better visualization of the fluorescent lymph nodes. (D) H and E stain (top, color images) and NIRF (bottom, black and white images) histological verification of lymph node excision. A PET projection video of panel A is given as Supporting Information.

fluorescence in the sentinel lymph node of mice because of competition for SLN mannose receptors (Figure 2Biii,C). Such saturable binding of [^{19}F]Lymphoseek **3** to a limited number of SLN mannose receptors (*32, 34, 41*) suggests that conjugation to **1** does not alter Lymphoseek's mannose receptor specificity. This observation is confirmed quantitatively in separate biodistribution experiments (vide infra).

Image-guided surgical excisions of the SLN were then conducted and confirmed (Figure 2C). Real-time imaging with a NIRF camera allows for rapid and simple removal of lymph nodes, especially because the lymph tracks connecting the nodes are fully visible (Figure 2Bi,Biii). Notably, lymph tracks in mice have not been previously observed with [^{99m}Tc]Lymphoseek. The observed lymph tracks connecting injection sites and nodes should help identify the sentinel node in cases where the distinctions between distal and sentinel nodes are ambiguous.

Radiochemistry. From NIRF experiments (Figure 2), we determined that total doses of Lymphoseek of up to 30 nmol work well in imaging the SLN in mice. Using these doses, we incorporated different ^{18}F activities into **3** to determine the optimal level of radioactivity that would provide sufficient signal to image 1 nmol of Lymphoseek by PET, synthesized on a large multi-injection scale starting with only 100 mCi of $^{18}F^-$ ion. A specific activity of 1−50 Ci/mmol at the time of injection proved to be adequate for imaging ^{18}F-labeled **3** in a 20 min PET scan 1 h after injection.

Size exclusion gel chromatography in spin columns was used to remove small molecule impurities and free [^{18}F]fluoride ions from radiochemical preparations. The removal of [^{18}F]fluoride was evidenced by the absence of a bone signal in PET images (Figure 3A and Supporting Information) (*25*) and biodistribution studies (Figure 4, bone). In mouse serum, the chemical release of F^- from ^{18}F-labeled Lymphoseek **3** had a half-life of 21 h (Supporting Information), 11.6-fold slower than the radioactive decay of ^{18}F.

Multimodality PET/CT/NIRF Imaging. [^{18}F]Lymphoseek **3** was tested for in vivo multimodal imaging in 12 mice. Injections containing 1 nmol and 10−50 μCi of fluorescent **3**, with 0 or 10 nmol of added unlabeled Lymphoseek, were made into the right rear footpad of anesthetized nude mice positioned securely on trays for corroborative multimodality imaging. One hour later, a 20 min PET/CT scan was acquired (Figure 3A, left). Mice were then sacrificed by CO_2 inhalation followed by cervical dislocation; skin was removed, and NIRF images were obtained before (Figure 3C, left) and after excision of nodes, which were placed below their location of origin on the imaging tray. The bright field image of this dissection is shown in Figure 3B (before excision, left, and after excision, right). Successful node excision was confirmed by both NIRF (Figure 3C, right) and PET/CT imaging (Figure 3A, right, and Supporting Information), showing the node signal outside the body. Following image acquisition, tissues were collected for scin-

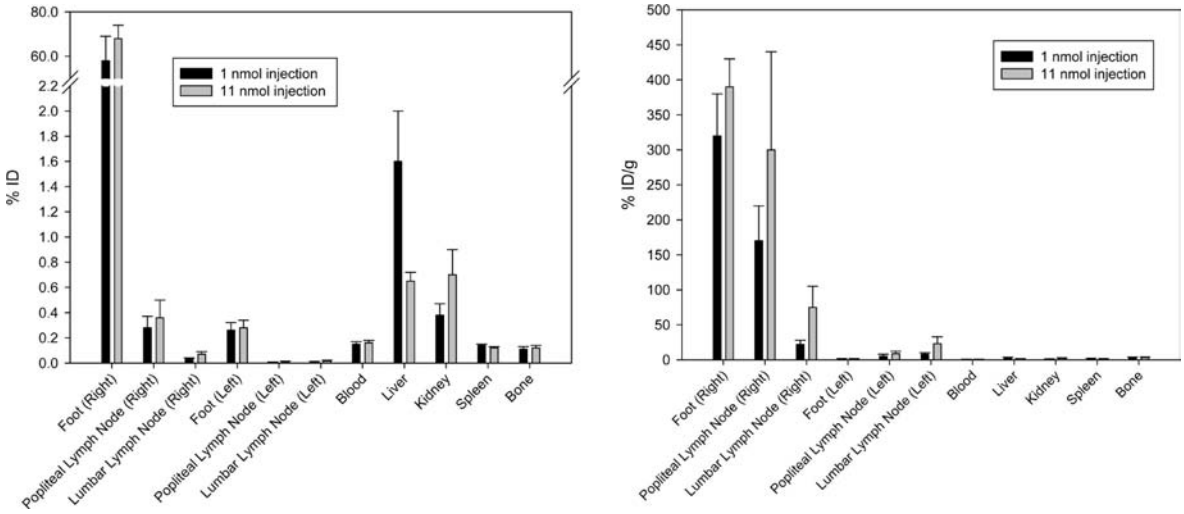

Figure 4. [^{18}F]Lymphoseek **3** tissue biodistribution in mice that were sacrificed 1 h and 20 min following injection. Units of percent injected dose (ID, left) and percent injected dose per gram (right). Biodistribution data from 12 mice were used to compile this figure.

Table 1. Distribution of Radioactive [^{18}F]Lymphoseek 3 in Mice That Were Sacrificed 80 min following Injection[a]

	percent [^{18}F]**3** activity extracted in the sentinel node	Lymphoseek in the sentinel or popliteal lymph node (pmol) (percent of detected nodal Lymphoseek)	Lymphoseek flow-through to the distal or lumbar node (pmol) (percent of detected nodal Lymphoseek)
1 nmol Lymphoseek injection	87 ± 7%	3.0 ± 0.9 (91%)	0.3 ± 0.1 (9%)
11 nmol Lymphoseek injection	74 ± 7%	40 ± 15 (83%)	8 ± 3 (17%)
t test (one-tailed two-sample unequal variance)	$P = 0.022$		$P = 0.033$

[a] Scintigraphy data from six mice were obtained per injected Lymphoseek dose (12 mice total). The percent activity extracted is defined as the difference in counts between the sentinel and distal lymph nodes minus the sum of counts in the sentinel and distal lymph nodes [(counts$_{popliteal}$ − counts$_{lumbar}$)/(counts$_{popliteal}$ + counts$_{lumbar}$)]. The percent of detected nodal Lymphoseek is defined as the amount of Lymphoseek in the lumbar lymph node divided by the sum of the Lymphoseek in both the popliteal and lumbar lymph nodes. Error = $\sigma/(n = 6)^{1/2}$.

tigraphy and histological sectioning (Figure 3D). Little or no flow-through of [^{18}F]Lymphoseek **3** to distal lymph nodes was observed in both NIRF and PET images taken under both injection conditions. PET and NIRF signals were confined to the SLN, the injection site, and, in some cases, the bladder.

Biodistribution. Scintigraphy corroborated the qualitative data observed in PET and IR images (Figure 3A,C). The [^{18}F]Lymphoseek **3** tissue distribution is shown in Figure 4 as the percent of injected dose (% ID) before (left) and after (right) normalization by tissue mass. In 1 and 11 nmol injections of Lymphoseek, the tissues of interest containing the most [^{18}F]Lymphoseek **3** are the right foot (320 ± 60 and 390 ± 40% ID/g per foot, respectively) and the right popliteal (sentinel) lymph node (170 ± 50 and 300 ± 140% ID/g per node, respectively). There is 4−7 times less [^{18}F]Lymphoseek **3** in the ipsilateral distal (lumbar) lymph nodes (22 ± 6 and 75 ± 30% ID/g, respectively) than in the sentinel lymph nodes. Much less [^{18}F]Lymphoseek accumulation is observed in contralateral nodes (5 ± 3 and 9 ± 4% ID/g for contralateral popliteal lymph nodes and 8 ± 2 and 23 ± 10% ID/g for contralateral lumbar lymph nodes, for 1 and 11 nmol injections, respectively). Nonlymphatic tissue, i.e., blood, liver, kidney, spleen, and bone, contained not more than 4% ID/g of [^{18}F]Lymphoseek **3**.

Statistical analysis verified that [^{18}F]Lymphoseek **3** retains receptor targeting properties consistent with [^{99m}Tc]Lymphoseek literature (*32*, *41*). In mice treated with 1 nmol of [^{18}F]Lymphoseek, the sentinel node extracted 87 ± 7% (Table 1) of the total lymph node accumulation, significantly greater than 74 ± 7% extracted at an 11 nmol dose. These values correspond to 3 ± 0.9 and 40 ± 15 pmol of total Lymphoseek (3 ± 0.9 and 3.6 ± 1 pmol of ^{18}F-labeled Lymphoseek **3**, respectively) in the sentinel node. These are subsaturating doses of Lymphoseek. The Lymphoseek binding capacity from a rear footpad injection in the popliteal node of mice is 49 ± 25 pmol (*41*).

Histology. NIRF histology (Figure 3D) showed that Lymphoseek **3** indeed localized to SLNs (Figure 3D), though ^{18}F activity was no longer measurable. On the basis of the specific activity of radiolabeling, the majority (>99%) of the fluorescent material was nonradioactive [^{19}F]**3** even before the ^{18}F had decayed. Hematoxylin and eosin (H and E) frozen sections of the excised lymph nodes of mice were prepared and analyzed. Specifically, lymph nodes were confirmed through the observation of an encapsulated dense mass of densely packed lymphocytes. The dense packing of these mononuclear cells includes a high nucleus:cytoplasm ratio that gives a dense basophilic/purple staining under H and E staining conditions.

DISCUSSION

We describe the novel synthesis of a small molecule NHS ester that confers both ^{18}F PET and NIRF visibility onto targeting ligands bearing free amines. Heterobifunctional adapters could easily convert the selectivity toward other reactive groups such as thiols. Because the ^{18}F is appended to the cyanine dye, only one attachment site on the targeting ligand is required. If standard NIRF and PET labels were independently affixed (*4*, *7*), at least two chemically reactive yet biologically tolerant sites on the ligand would be required. Unless regioselectivity could be tightly controlled, greater combinatorial complexity of products could result, because each site could remain unmodified or receive a NIRF or PET label. Homogeneous labeling happens not to be essential for Lymphoseek, which already contains a statistical distribution of amines, but Lymphoseek had the advantages of large-scale availability and extensive preclinical and clinical characterization. PET/NIRF-labeled Lymphoseek **3** retains the desired pharmaceutical properties of [^{99m}Tc]Lymphoseek: rapid 1 h sentinel node targeting, low level of distal lymph node accumulation, and sentinel node extraction values (1 nmol dose, 87 ± 7%; 11 nmol

dose, 74 ± 7%) that compare very well to [^{99m}Tc]Lymphoseek extraction ratios, 90 ± 10% in rabbit popliteal SLN (*31, 32*).

PET rapidly and noninvasively quantitates picomole amounts of **1** through deep tissue. An example of the superior tomographic resolution conveyed by ^{18}F PET in Figure 3A is included as an .mpg file (Supporting Information). Notably, this high-resolution projection was generated from a 20 min scan on a live mouse using only 33 μCi of activity. PET is more reliable than NIRF for imaging through deep tissue. This point is illustrated by comparing the skin-on NIRF image (Figure 2Ai) to the skin-off NIRF image (Figure 2Aii). If one were to use Figure 2Ai to evaluate Lymphoseek distribution based on relative NIRF brightness, it would incorrectly appear that the sentinel node (red arrow), buried in muscle and fat, has less Lymphoseek than the lumbar node (blue arrow), which sits next to the spine near the surface of the mouse. Following mouse sacrifice followed by skin removal (Figure 2Aii), we see that the opposite is true and that the NIRF signal is biased to tissue depth. Note that the lymph nodes seen in Figure 2 Ai would be entirely invisible by NIRF if wild-type, hair-bearing mice were used. PET is superior to NIRF in that it allows for quantitative noninvasive deep tissue three-dimensional imaging. Both the live mouse PET images shown in Figure 3 and the .mpg file included as Supporting Information illustrate this. Additional advances in PET imaging may include better CT attenuation algorithms for higher-resolution images and real-time PET reconstruction to guide surgery. If a PET scanner is not available, standard scintigraphic devices can still be used to register the positron-generated γ-rays (*42*−*44*). Consistent with previous studies of ^{18}F-labeled aryltrifluoroborates, no signal is observed in bone structure (Figures 3A and 4), demonstrating the in vivo stability of the aryl trifluoroborate to solvolysis and release of free ^{18}F (*22, 23, 45*).

The stable NIRF component on **1** also allows for NIRF-guided surgery as well as fluorescent histology long after radiotracer decay. Histological resolution (Figure 3D) and the imaging of lymph tracks (Figure 2Bi−iii) are possible only by NIRF, as these structures fall below the spatial detection limits of PET. The heterogeneous foci seen in NIRF histology (Figure 3D) identify the most probable places to find micrometastatic disease in the SLN (*46*), and their fluorescence might reduce the error in pathological evaluations. The heterogeneous distribution of **3** also suggests that only a fraction of the SLN actually filters the afferent lymph channel draining the foot. Both a 1 nmol injection of pure [^{18}F]Lymphoseek **3** and an 11 nmol injection of **3** diluted with unlabeled Lymphoseek are useful in highlighting sentinel popliteal nodes. Our use of a diluted 11 nmol injection may seem superfluous as it requires an extra step in preparation and is slightly inferior to the 1 nmol injection in terms of unwanted flow-through to distal lymph nodes (Table 1). However, the fact that the lymph node mannose receptor binding of **3** can be diluted with unlabeled Lymphoseek such that distal node flow-through is increased serves to illustrate an important trait of the dual probe, that the conjugation of targets to NHS ester **1** does not alter its target's desired diagnostic properties, in this case Lymphoseek's mannose receptor-specific targeting properties.

This PET/NIRF version of Lymphoseek **3** may improve sentinel node biopsy, because a single injection would replace the required multiple-injection combination (*47, 48*) of a radiotracer, such as [^{99m}Tc]Lymphoseek or [^{99m}Tc]sulfur colloid, with a nonspecific optical excision aid such as isosulfan blue dye. Attachment of both the positron emitter and fluorophore to a single molecularly targeted agent diminishes the risk of flow-through to distal lymph nodes and ensures perfect coregistration of the two signals, allowing PET and NIRF to complement each other. PET images would noninvasively identify sentinel nodes that drain a tumor and aid in preoperative planning. During surgery, Geiger counting of the γ-rays could help locate deeply buried nodes. Once they were exposed, higher-resolution real-time NIRF imaging would guide precision resection, including lymph tracks as well as nodes. A postoperative PET scan could confirm whether removal was complete, and NIRF would aid histological identification of metastases within the resected tissue. Successful application of PET/NIRF NHS ester **1** to a well-established, clinically interesting system suggests extension to other medically relevant targets. In previous combinations of PET and NIRF, the positron emitter and fluorophore were independently attached (*4, 7*), whereas **1** combines these capabilities in a single, versatile small molecule only slightly larger than the usual commercially available NIRF labels. It is essential that ^{18}F is incorporated into fluoroborates under mild conditions such as a weakly acidic methanol/water solution at 40 °C, because heptamethine cyanine dyes would not survive high-temperature reaction with anhydrous nucleophilic fluoride as required for traditional ^{18}F chemistries such as fluorobenzyl labeling. Despite scope for further optimization, formation of aryl fluoborate from F^- satisfies many of the criteria for "click chemistry", modularity, high yield, no offensive byproducts, mild aqueous reaction conditions, orthogonality to other functional groups, and simple product isolation (*49*). Although the B−F bond is not as chemically stable as the usual C−F bonds, appropriately substituted aryl fluoborates are stable enough that hydrolysis is negligible within the radioactive half-life of ^{18}F. Our new chemistry should facilitate the multimodality labeling of peptides, proteins, and polysaccharides, medically relevant ligands previously difficult or impossible to label by previous methods.

ACKNOWLEDGMENT

We thank Jacqueline Corbeil for excellent technical assistance with PET, CT, and NIRF imaging studies and Larry Gross for his assistance in obtaining high-resolution mass spectrometry data. IN VIVO EXPERIMENTS

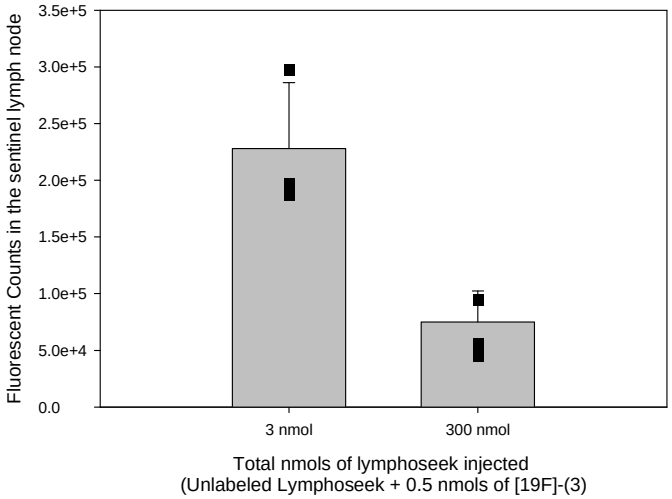
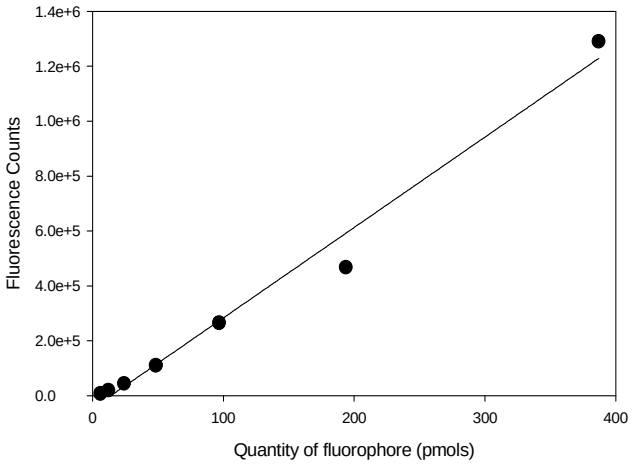
Multi Modality Imaging:

PET/CT IMAGE FUSION:



PET/CT image fusion was carried out with amide 0.9.1 open source software (http://amide.sourceforge.net). CT data in the DICOM (Digital Imaging and Communications in Medicine standard) format and PET data in .hdr (high dynamic image) format were imported into amide 0.9.1, as a new study. Inverted PET images were reflected around the x axis (right click study in study window →rotate (tab)→ change coordinate (j,y) from 1 to -1), and data was plot using a hot metal color table (right click study in study window →Colormap/Threshold (tab)→ Color Table → hot metal). Generally, PET thresholding between 1.0 and 0.0 percent was used (right click study in study window →Colormap/Threshold (tab)→ Set Max Threshold, Set Min Threshold). CT images were colormapped using a hot blue color table so that CT and PET data could be easily distinguished. Thresholding between 40 and 50 percent was sufficient to show soft tissue CT data.

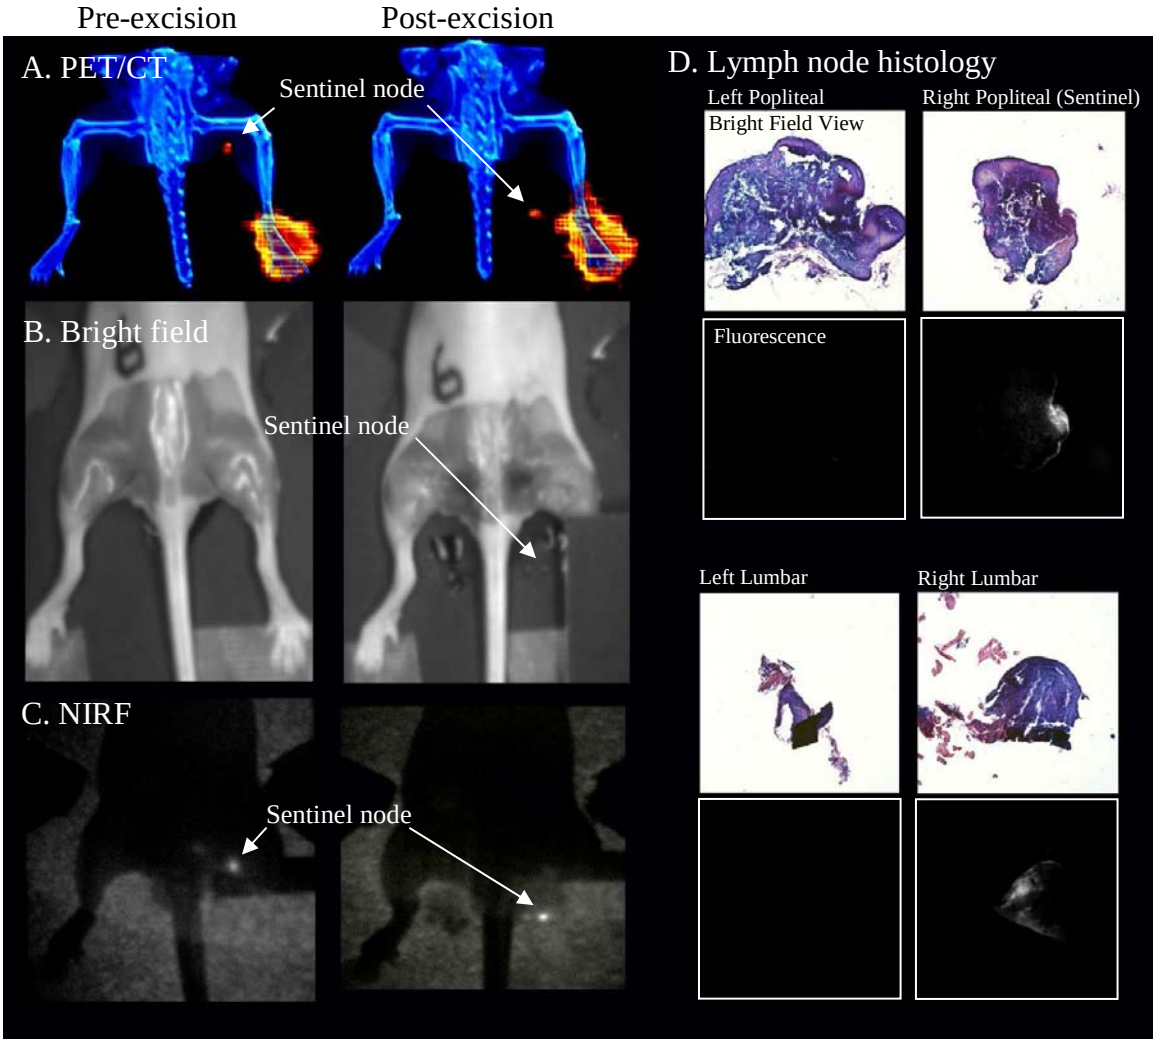
To align PET and CT images, fiducidal marks were placed at appropriate locations (generally the bladder, hind right foot, right popliteal lymph node) and the alignment wizard (Tools → Alignment Wizard) was used to reconstruct an overlaid image. The overlaid image was cropped to a single mouse using Amide's cropping tool (Tools → Crop Active Data Set) and projections were generated (View → Volume Rendering). The rendered projections were exported as .jpeg files. All displayed PET images are PET/CT fused images. A sample .XIF file (PETCT.mpg) is included with this submission (Mouse 006, 1 nmol injection of **3**, note that amide 0.9.1 available at http://amide.sourceforge.net is required to open this file. This file possesses a .mpg extension and must be renamed with an .XIF extension to open.)



Proof of [^{19}F]-Lymphoseek-3's receptor specific binding activity

E) [^{19}F]- **3** accumulation in the **SLN** at 3 and 300 nmol

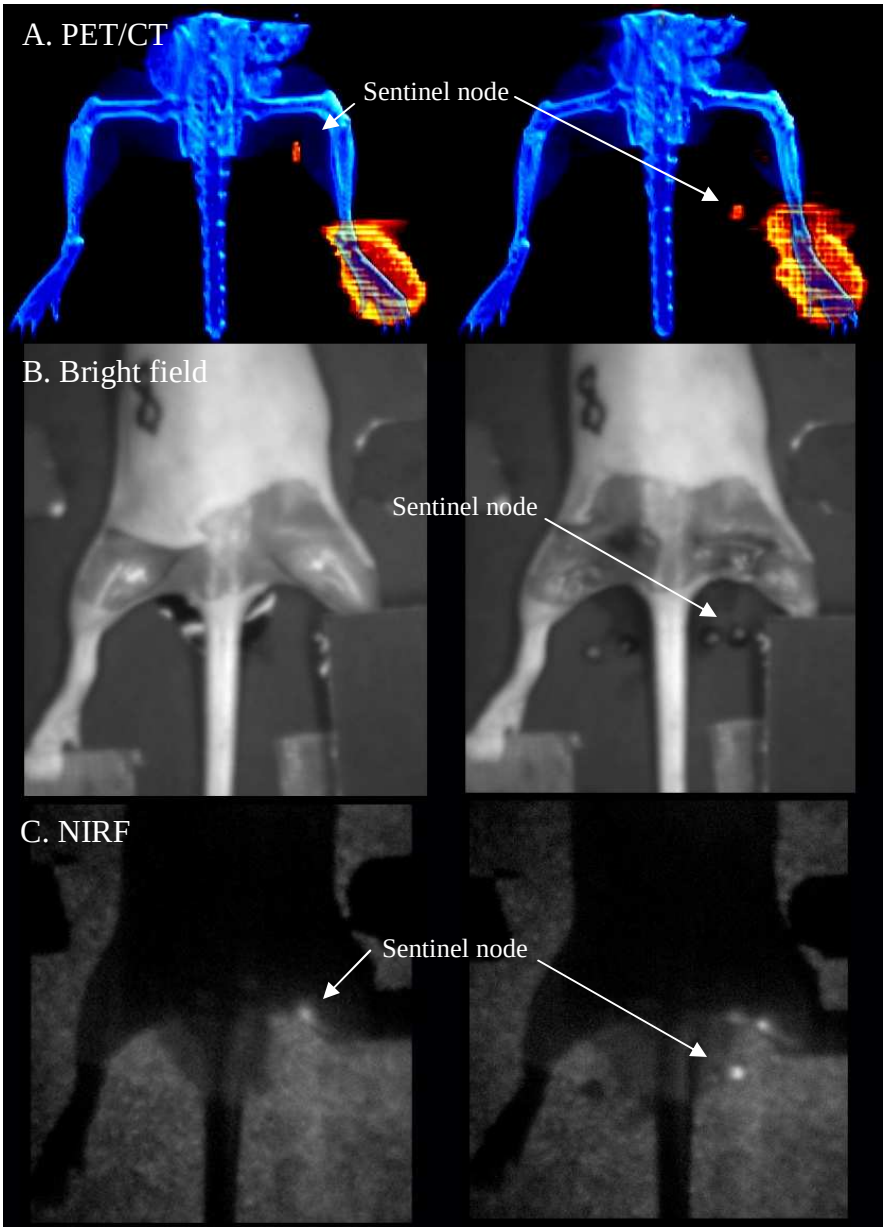
D) Standard Curve: Fluorescence Counts vs. Quantity



In vivo demonstration of [^{19}F]-Lymphoseek 3's receptor specific activity. Two solutions containing either 3 nmols (0.24 µL of a 12.5 nmol/µL solution) or 300 nmols (24 µL of a 12.5 nmol/µL solution) of unlabeled Lymphoseek were added to solutions containing 1 nmol (5 µL) of fluorescent [^{19}F]-Lymphoseek 3. These mixtures were diluted with water, injected into the rear footpad of mice at 30 µL volumes, and were allowed to distribute for 80 min. Three mice were injected at each dose. A) A 1 hour image skin-off in vivo image of [^{19}F]-Lymphoseek 3 prior to node extraction captured with a Maestro (CRi) 5 sec exposure. Note the clear visibility of the lymph tracks linking nodes to the foot's rear fat pad. B) Lymph nodes were extracted from mice and placed on a bed for analysis. The expected result, receptor specific accumulation, is observed. Greater accumulation of fluorescent [^{19}F]- Lymphoseek 3 is seen in the sentinel lymph nodes in 3 nmol injections than in 300 nmol injections due to increased competition with unlabeled Lymphoseek for sentinel lymph node mannose receptors. C) and D), Fluorescence [^{19}F]-3 standard curve generated with [^{19}F]-3 dissolved in 4 µL water droplets. Note that fluorescent photon quantization in tissue and standard curve conditions may differ due to the different media scattering properties, therefore fluorescence quantities in the standard curve are only relative representations of the fluorescence quantities within lymph nodes. The fluorescence response in the standard curve D) is linear therefore

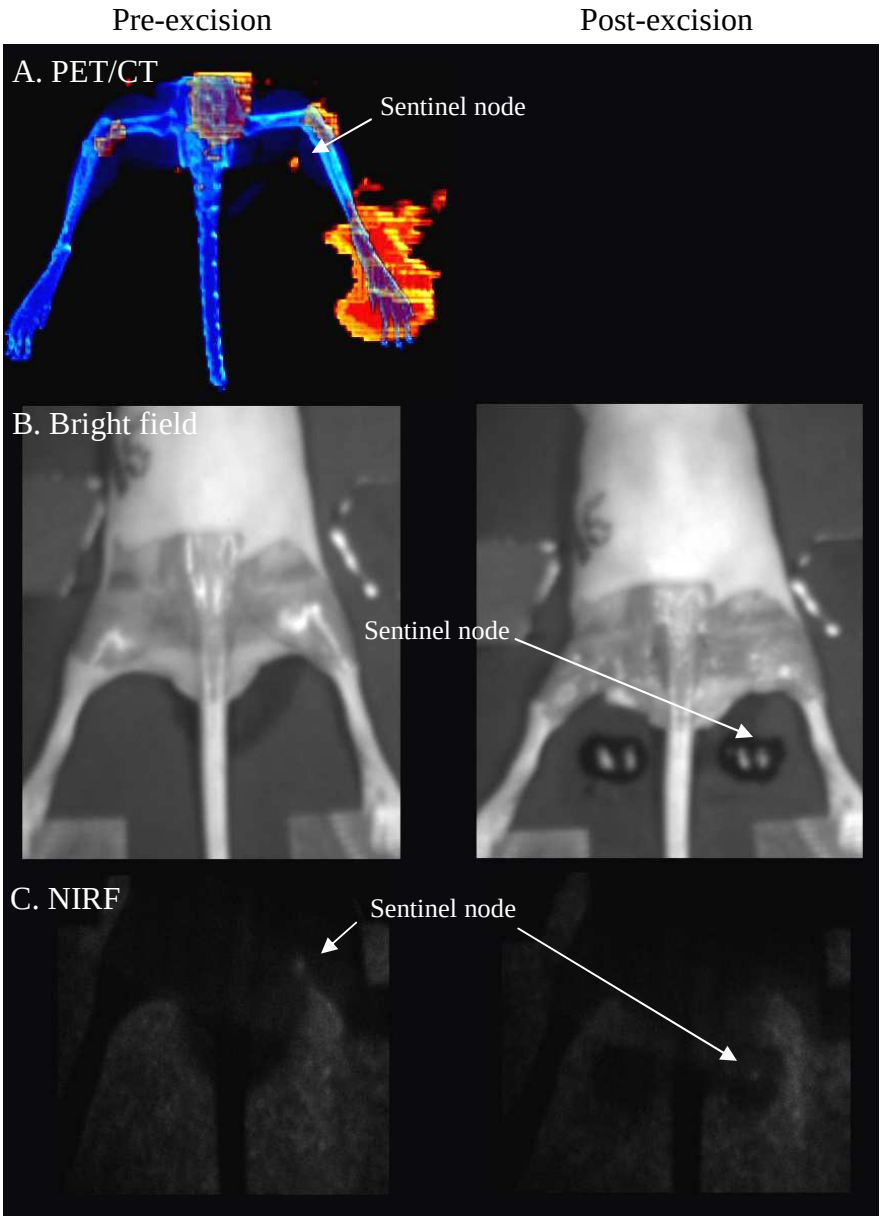
fluorescence quenching at these quantities are ruled out. E) Bar graph of Lymphoseek distribution [^{19}F]-3 in the SENTINEL NODE at 3 and 300 nmol doses of Lymphoseek. A 3.5x contrast ratio is observed between the sentinel nodes in the different injection conditions (n= 3 mice per dose, P= 0.015 two tailed, two sample equal variance). Images B-C were generated with a 4 second exposure on the CRi Maestro imaging system.

[^{18}F]- 3 EXPERIMENTAL DATA:



Low dose 1 nmol [^{18}F]-Lymphoseek **3** injections:

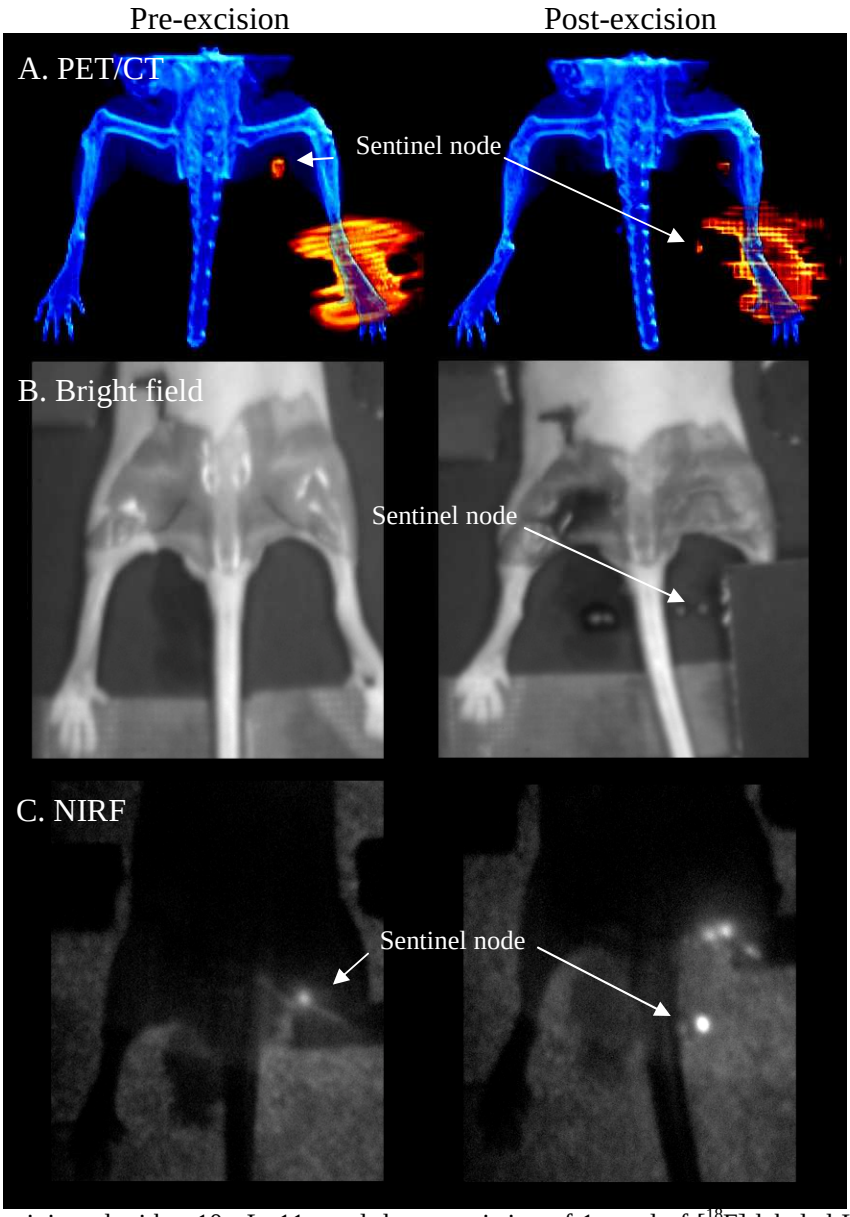
Mouse 1 of 3 low-dose 1 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 006)



Mouse 006 was injected with a 10 µL, 1 nmol dose of [^{18}F]-labeled Lymphoseek **3** corresponding to a 48.1 µCi, 0.048 Ci/µmol ^{18}F injection at 10:19 AM, the **Time Of Injection (TOI).** The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 33.0 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. 20 min PET scan was carried out 2 hours and 57 min vs. TOI on 15.8 µCi of activity (decay corrected). *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 33 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow. *D.* Fluorescent and hematoxylin and eosin stained bright field verification of lymph node excision through histological cross sectioning of the nodes excised in B.

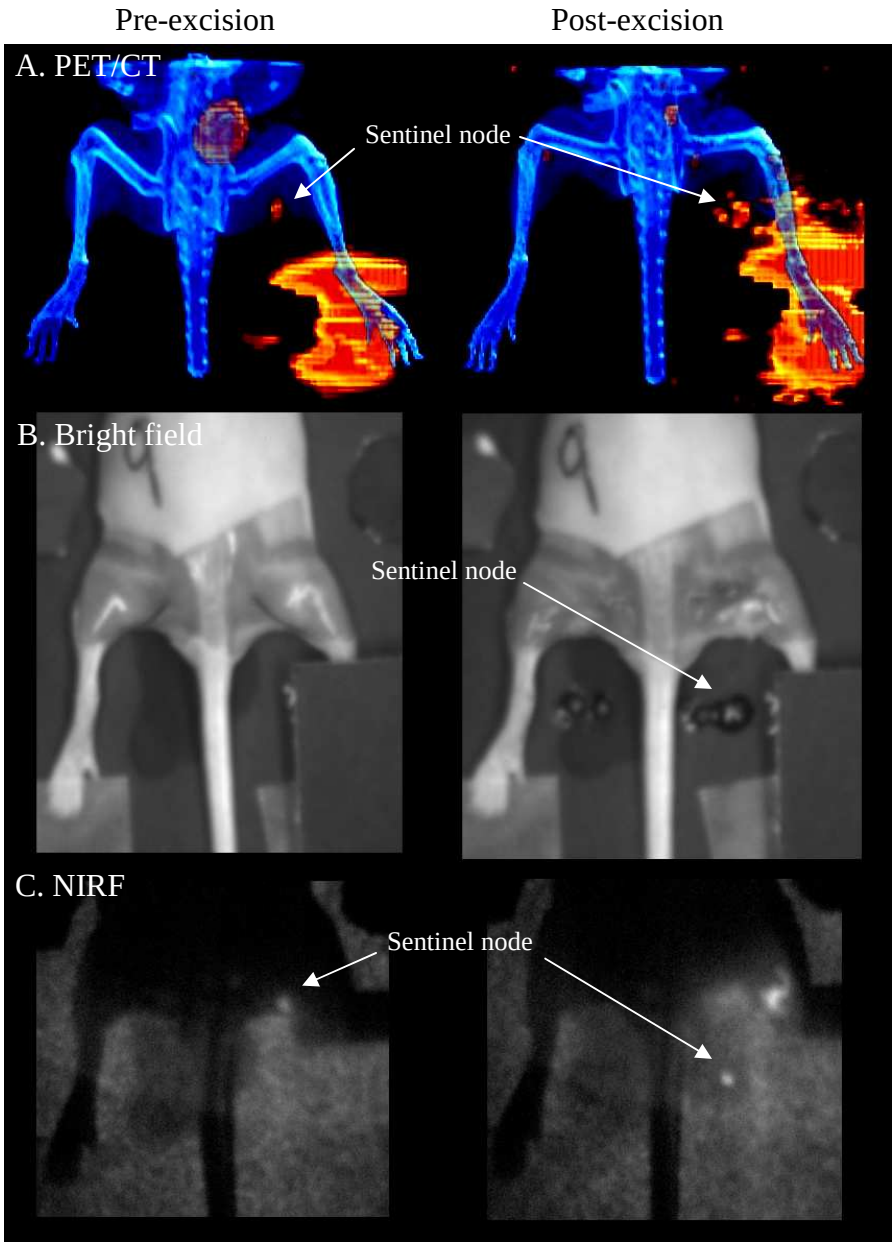
Mouse 2 of 3 low-dose 1 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 008)

Mouse 008 was injected with a 10 µL, 1 nmol dose of [^{18}F]-labeled Lymphoseek **3** corresponding to a 42.1 µCi, 0.042 Ci/µmol ^{18}F injection at 10:50 AM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 28.8 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. 20 min PET scan was carried out 3 hours and 7 min vs. TOI on 13.0 µCi of activity (decay corrected). *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 30 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.



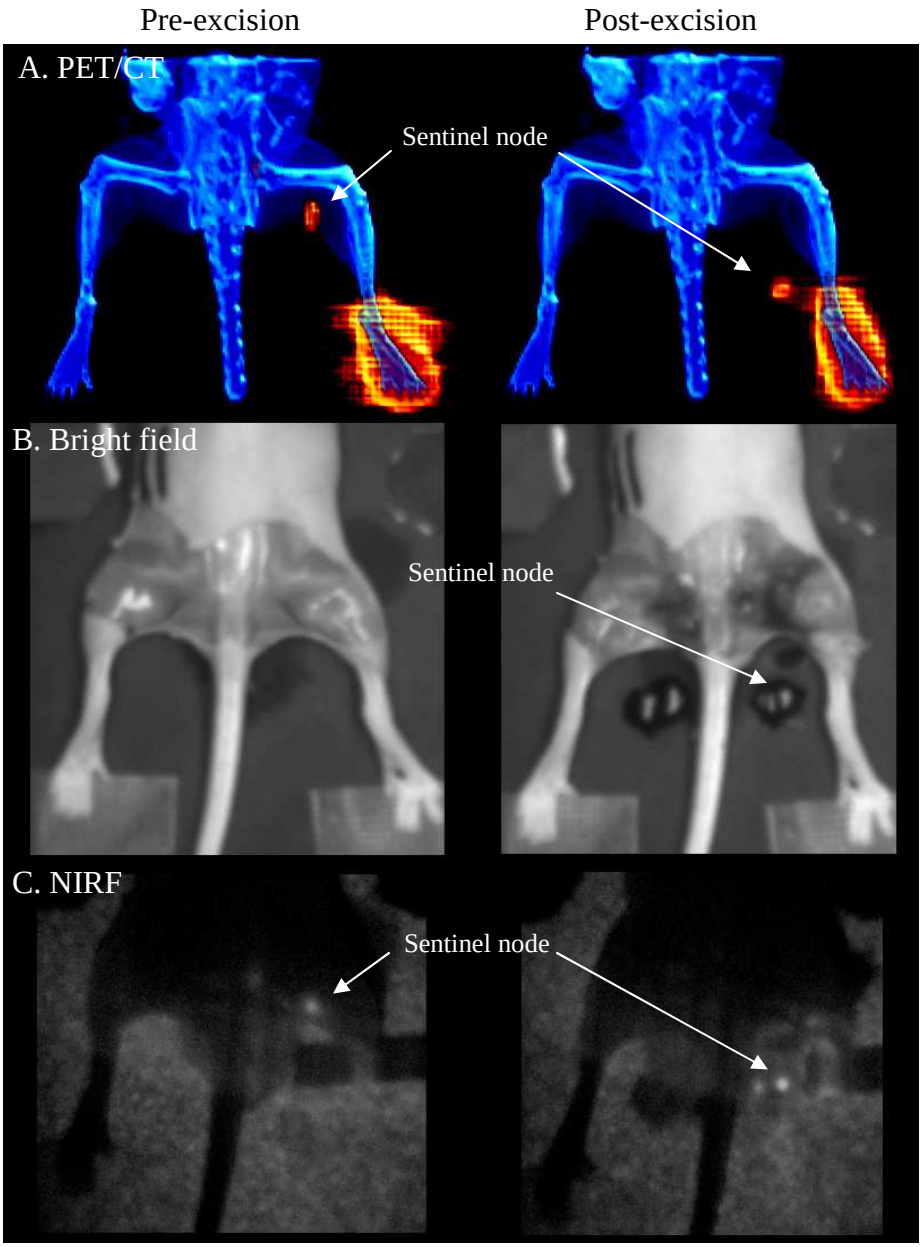
Mouse 3 of 3 low-dose 1 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 016)

Mouse 010 was injected with a 10 µL, 1 nmol dose of [^{18}F]-labeled Lymphoseek **3** corresponding to a 9.7 µCi, 0.010 Ci/µmol ^{18}F injection at 3:15 PM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 6.6 µCi of activity (decay corrected). The mouse did not possess sufficient activity for a post-excision PET scan at 3 hours and 59 min vs. TOI (2.2 µCi of activity remained, decay corrected) but sufficient activity remained in extracted nodes for scintigraphy in biodistribution studies. *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 24 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.



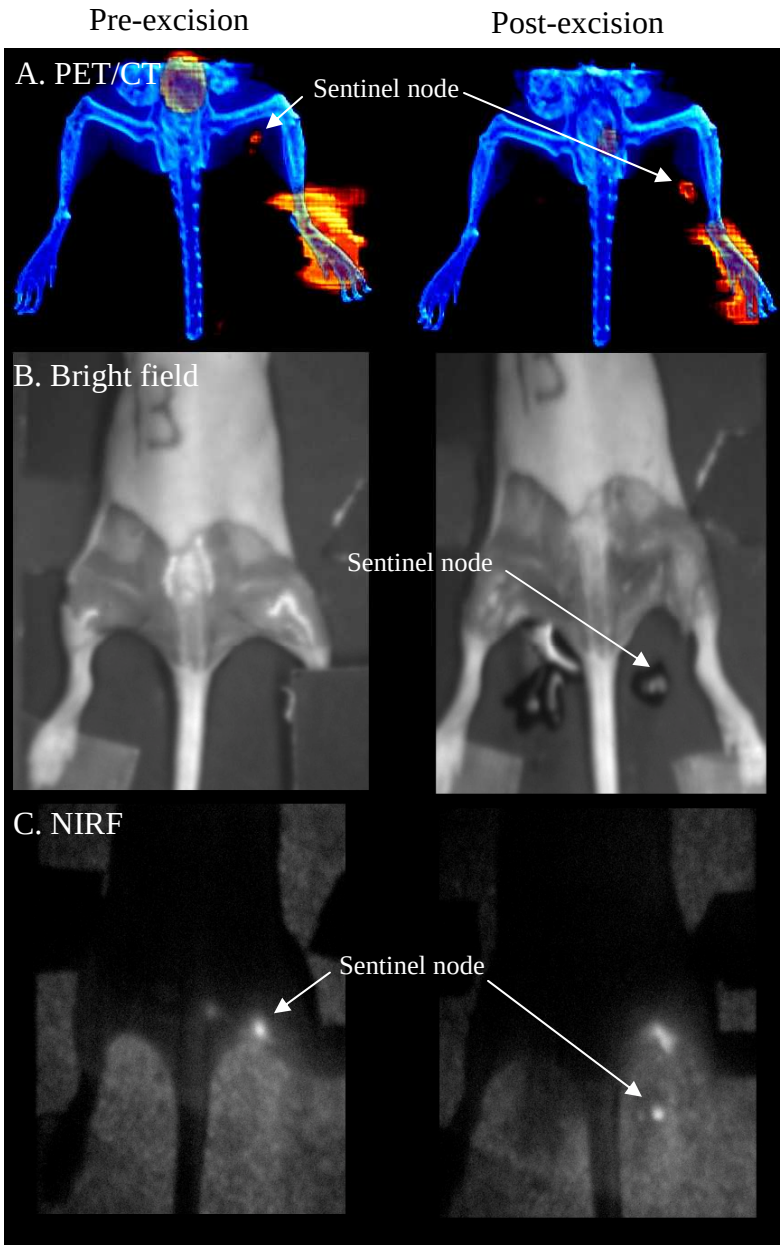
High dose 11 nmol [^{18}F]-Lymphoseek **3** injections:

Mouse 1 of 6 high-dose 11 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 007)



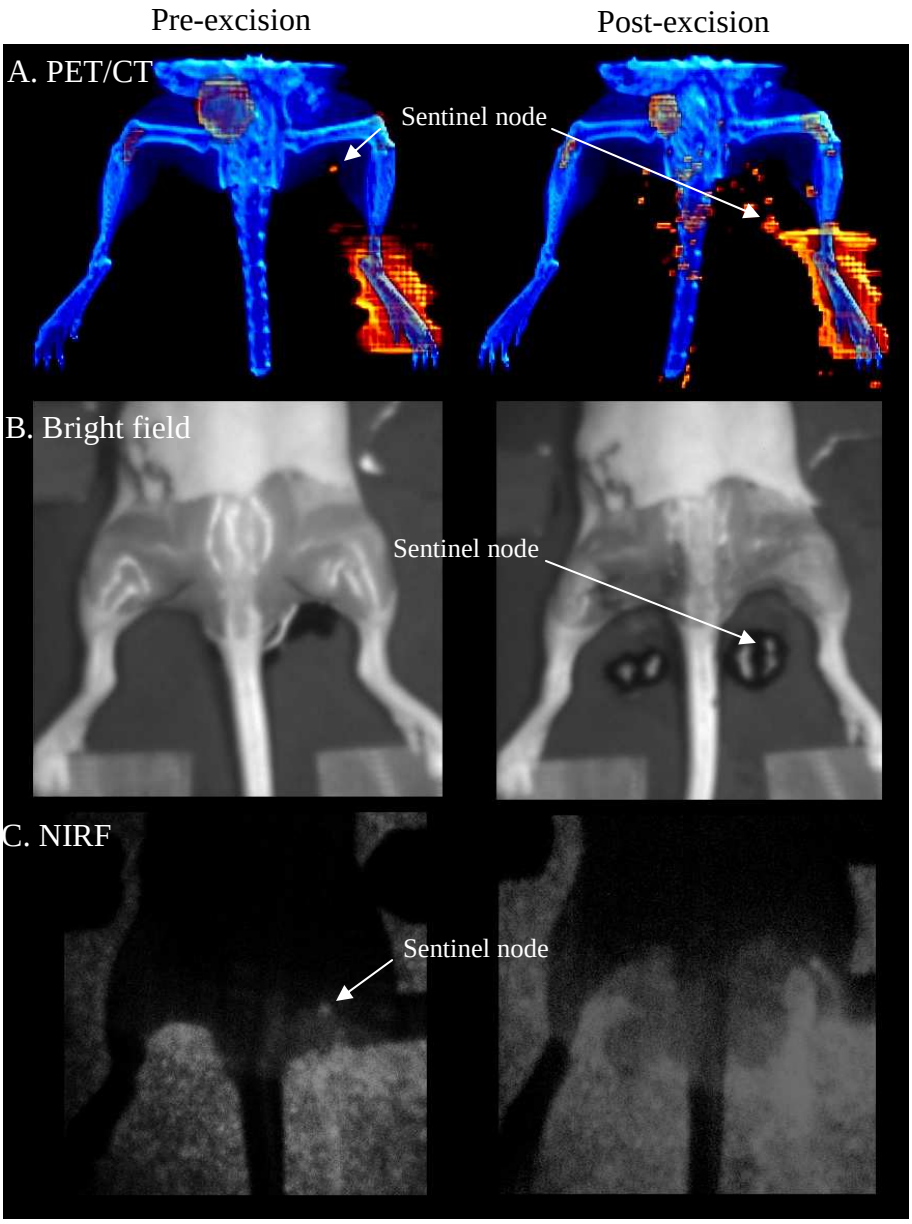
Mouse 007 was injected with a 10 µL, 11 nmol dose consisting of 1 nmol of [^{18}F]-labeled Lymphoseek **3** that had been diluted with 10 nmols of unconjugated, unlabeled Lymphoseek. This dose contained a 40.7 µCi, 0.041 Ci/µmol of ^{18}F at 10:21 AM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 27.9 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. A 20 min PET scan was carried out 2 hours and 57 min vs. TOI on 13.3 µCi of activity (decay corrected). *B.* Bright field image of the mouse with skin removed before (left) and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 33 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.

Mouse 2 of 6 high-dose 11 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 009)



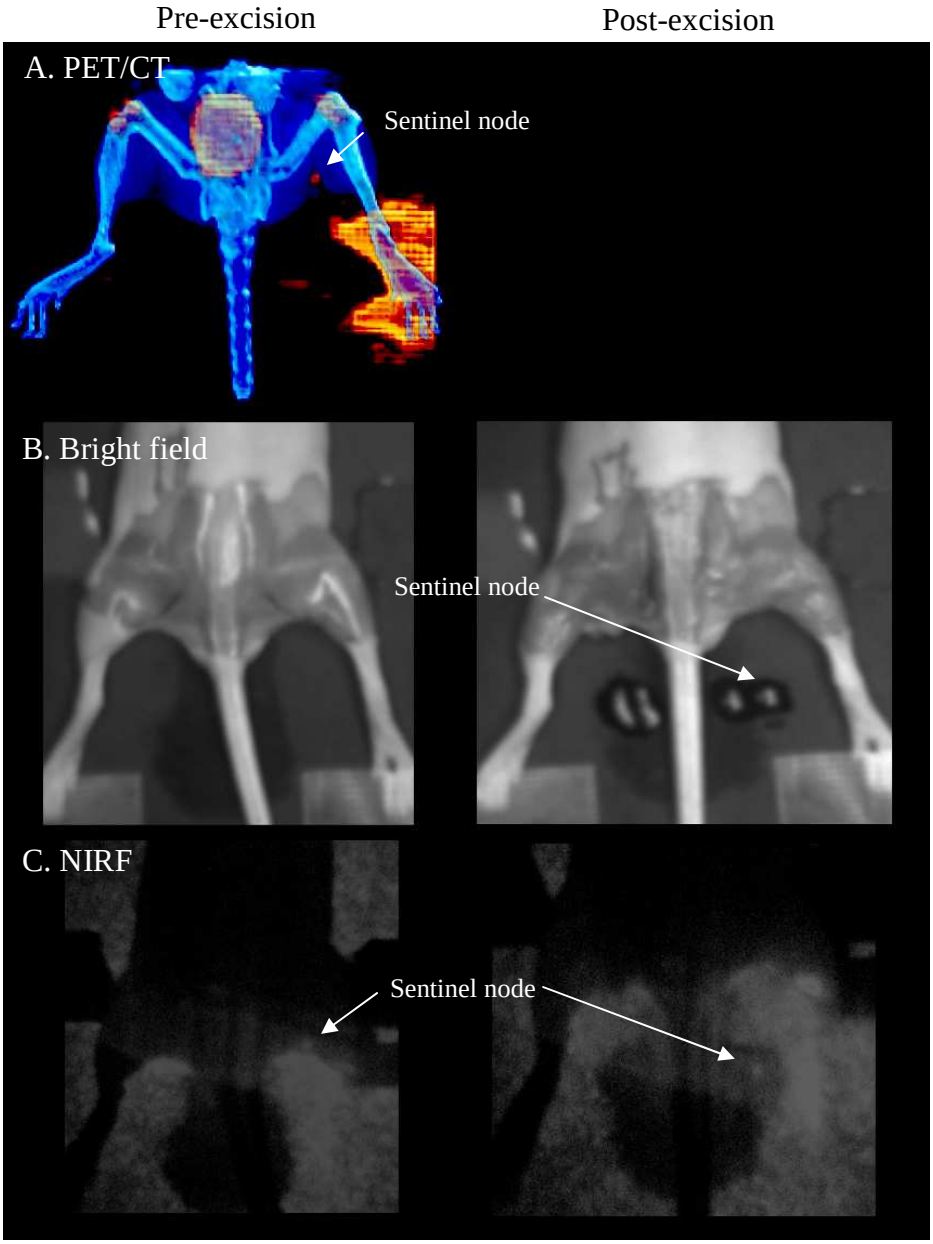
Mouse 009 was injected with a 10 µL, 11 nmol dose consisting of 1 nmol of [^{18}F]-labeled Lymphoseek **3** that had been diluted with 10 nmols of unconjugated, unlabeled Lymphoseek. This dose contained a 31.3 µCi, 0.0031 Ci/µmol of ^{18}F at 10:51 AM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 21.4 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. A 20 min PET scan was carried out 3 hours and 7 min vs. TOI on 9.6 µCi of activity (decay corrected). *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 30 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.

Mouse 3 of 6 high-dose 11 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 011)



Mouse 011 was injected with a 10 µL, 11 nmol dose consisting of 1 nmol of [^{18}F]-labeled Lymphoseek **3** that had been diluted with 10 nmols of unconjugated, unlabeled Lymphoseek. This dose contained a 23.2 µCi, 0.0023 Ci/µmol of ^{18}F at 11:19 AM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 15.9 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. 20 min PET scan was carried out 3 hours and 21 min vs. TOI on 6.5 µCi of activity (decay corrected). *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 27 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.

Mouse 4 of 6 high-dose 11 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 013)



Mouse 013 was injected with a 10 µL, 11 nmol dose consisting of 1 nmol of [^{18}F]-labeled Lymphoseek **3** that had been diluted with 10 nmols of unconjugated, unlabeled Lymphoseek. This dose contained a 14.6 µCi, 0.0015 Ci/µmol of ^{18}F at 2:11 PM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 9.9 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. 30 min PET scan was carried out 3 hours and 9 min vs. TOI on 4.4 µCi of activity (decay corrected). *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 24 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.

Mouse 5 of 6 high-dose 11 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 015)

Mouse 015 was injected with a 10 µL, 11 nmol dose consisting of 1 nmol of [^{18}F]-labeled Lymphoseek **3** that had been diluted with 10 nmols of unconjugated, unlabeled Lymphoseek. This dose contained a 11.4 µCi, 0.0011 Ci/µmol of ^{18}F at 2:45 PM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. A. top left, A 20 min pre-excision PET scan carried out 1 hour vs. TOI on 7.8 µCi of activity (decay corrected). *A. top right*, Post-excision PET scan of the mouse with resected nodes placed in the field of view. 30 min PET scan was carried out 3 hours and 19 min vs. TOI on 3.3 µCi of activity (decay corrected). The high background in this scan is due to contamination by urine and the low amount of ^{18}F activity that was used in the scan. *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 17 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.

Mouse 6 of 6 high-dose 11 nmol injections of [^{18}F]-labeled Lymphoseek 3 (Mouse 017)

Mouse 017 was injected with a 10 µL, 11 nmol dose consisting of 1 nmol of [^{18}F]-labeled Lymphoseek **3** that had been diluted with 10 nmols of unconjugated, unlabeled Lymphoseek. This dose contained an 11.0 µCi, 0.0011 Ci/µmol of ^{18}F at 3:16 PM, the time of injection (TOI). The mouse was sacrificed by isofluorane overdose at 1 hour and 20 min vs. TOI. *A. top left*, 20 min pre-excision PET scan carried out 1 hour vs. TOI on 7.5 µCi of activity (decay corrected). The mouse did not possess sufficient activity for a post-excision PET scan at 3 hours and 59 min vs. TOI (2.4 µCi of activity remained, decay corrected) but sufficient activity remained in extracted nodes for scintigraphy in biodistribution studies. *B.* Bright field image of the mouse with skin removed before *(left)* and after node resection with all resected nodes (right and left lumbar and popliteal) placed in the field of view *(right). C.* NIRF images taken at 1 hour and 24 min vs. TOI on a custom full field IR camera before *(left)* and after *(right)* lymph node resection. When identifiable, the location of the sentinel lymph node is indicated with a white arrow.

Biodistribution:

LYMPH NODE SCINTIGRAPHY DATA:

Processed count data for each mouse is shown in the table below:

Mouse #	Organ	%ID	Net Wt. (g)	%ID/g	Average %ID	Average Mass (mg)	Average %ID/g

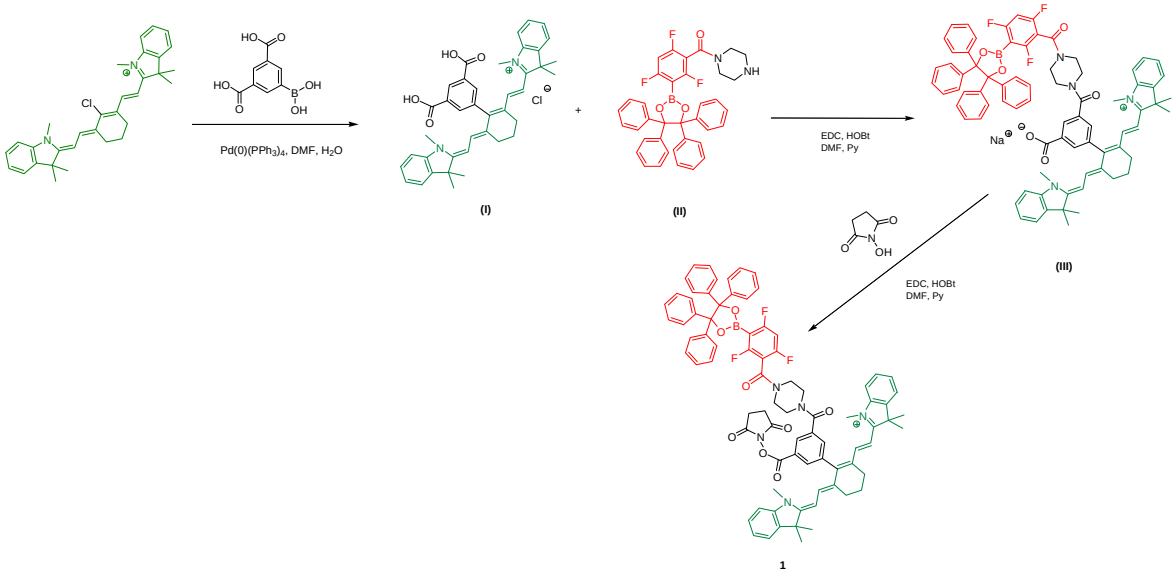
FOLD ACCUMULATION OF ^{18}F-3 IN THE SENTINEL NODE OVER THE DISTAL NODE	16 ± 10	1.5 ± 0.4	**8.3 ± 2.6**	5.0 ± 1.7	1.5 ± 0.3	**4.1 ± 1.8**
% ^{18}F-3 ACTIVITY EXTRACTED IN THE SENTINEL NODE VS. ALL EXTRACTED LYMPH NODES	87 ± 7 (%)			74 ± 7 (%)		

Tissue biodistribution of [^{18}F]- Lymphoseek 3 in mice that were sacrificed 1 hour and 20 min following injection. Biodistribution data from 12 mice were used to compile this table. Data from 6 mice were obtained per injected Lymphoseek dose. "Fold accumulation" is defined as the ratio of activity in the sentinel node to the distal node in individual mice. The "% activity extracted" is defined as the difference in counts between the sentinel and distal lymph nodes minus the sum of counts in the sentinel and distal lymph nodes ((Count $s_{popliteal}$ – Counts $_{lumbar}$)/ (Counts $_{popliteal}$ + Counts $_{lumbar}$). Error = $\sigma/(n=6)^{1/2}$. The probability associated with a student's t-test (one-tailed distribution, two-sample unequal variance) = 0.022.

CHEMICAL SYNTHESIS:

General synthetic methods:



Fluoride containing compounds were purchased from Oakwood Products. Lymphoseek was received as a gift from Reliable Biopharmaceutical. Other chemicals were purchased from Aldrich, Strem, or Combi blocks. Deuterated solvents were purchased from Cambridge Isotope Laboratories.

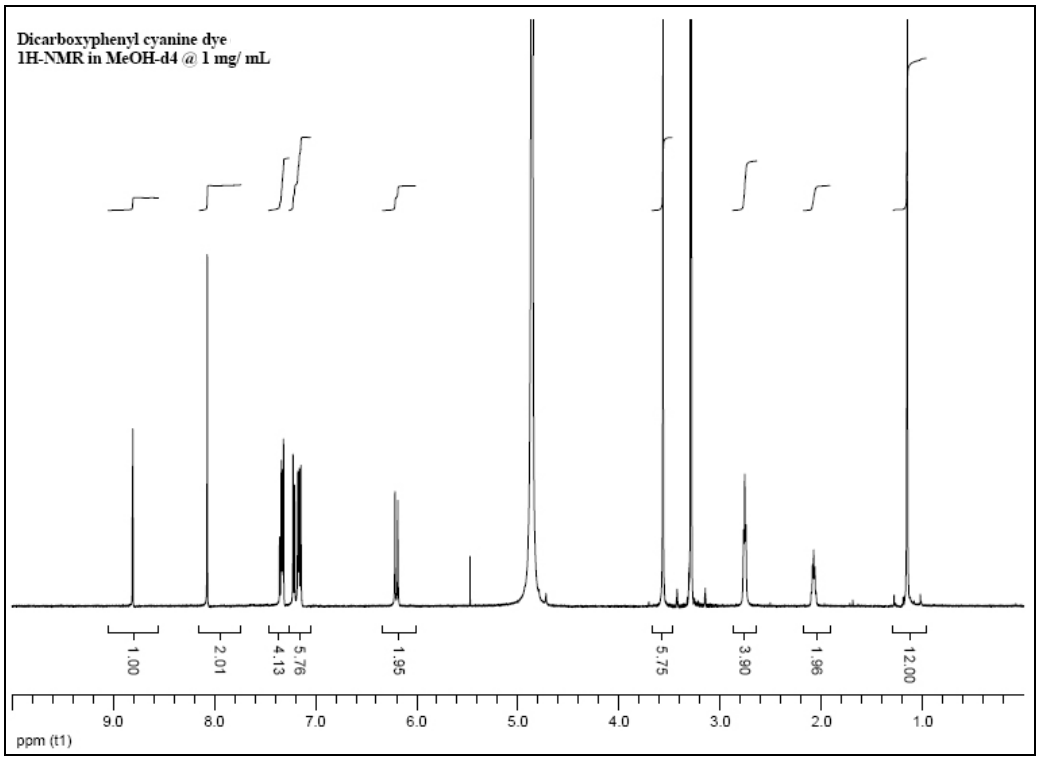
All ^{1}H Nuclear magnetic resonance (NMR) spectra were recorded at room temperature on Varian 300 or 400 MHz Mercury or 500 MHz Joel instruments. Chemical shifts are reported using the δ scale in ppm and all coupling constants (J) are reported in hertz (Hz). ^{1}H NMR spectra are referenced to the tetramethylsilane peak (δ = 0.00) and ^{19}F NMR spectra are referenced to NEAT CF_2Cl_2 (δ = 0.00). All thin layer chromatography experiments were run on Silica Gel 60 F_{254} Glass TLC plates from EMD chemicals. Fluorescence readings were made on a Fluorolog 3 spectrophotometer with Datamax v2.2 software. High resolution mass spectrometry was performed at the University of California San Diego (UCSD) Chemistry and Biochemistry Small Molecule/Chemical Mass Spectrometry Facility.

Dual Probe NHS ester synthesis:

The synthesis of the dual probe PET/NIR NHS ester **1**, was synthesized in 3 steps. The crystallization of **(i)** is the lowest yielding step in the reaction scheme (12%). **If higher product yields are desired, direct use of (i) following acidic extraction can be carried out in lieu of crystallization. In this case the final yield of 1 is 50.7 %.**

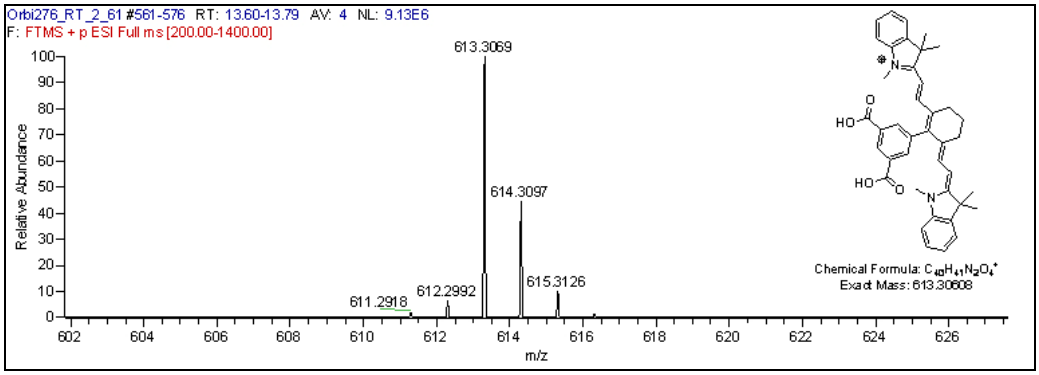
The scheme for the synthesis of the generally conjugatable PET/NIR-probe is as shown in Scheme 1:

Scheme 1. Synthetic scheme detailing the synthesis of an activated NHS ester of the ^{18}F/ heptamethine cyanine (C7-Cy) PET/NIR probe. Boron based ^{18}F trap technology is shown in red, while the NIR fluorophore is shown in green.



SYNTHESIS OF DICARBOXYPHENYL CYANINE DYE (I)

Reagents were added to a 25 mL round bottom flask charged with a magnetic stir bar in the following order: IR-775 (200 mg, 0.48 mmols, Sigma-Aldrich #544914), 3,5-Dicarboxyphenyl boronic Acid (200 mg, 0.97 mmols, Combi Blocks #BB-3936), Tetrakis(triphenylphosphine)palladium (0) (60 mg, 0.053 mmols, Strem #46-2150), 9 mL of MeOH, 1 mL of triethylamine, and 1 mL of H_2O. This reaction was stirred for 14 hours at room temperature and then concentrated to oil. **78% of all 775 nm absorbing material was converted to the product (i) as observed by LCMS.** The oil was resuspended in 100 mL of methylene chloride (CH_2Cl_2), and water soluble products were extracted with 50 mL of H_2O. The CH_2Cl_2 layer was washed with 100 mL of saturated ammonium chloride, 100 mL of 100 mM sodium bicarbonate, and then two washes of 100 mL of 1 M HCl. The product (i) could be converted to (ii) as is, but if pure product was desired for NMR, QY, or absorbance coefficient studies, (i) could be crystallized.

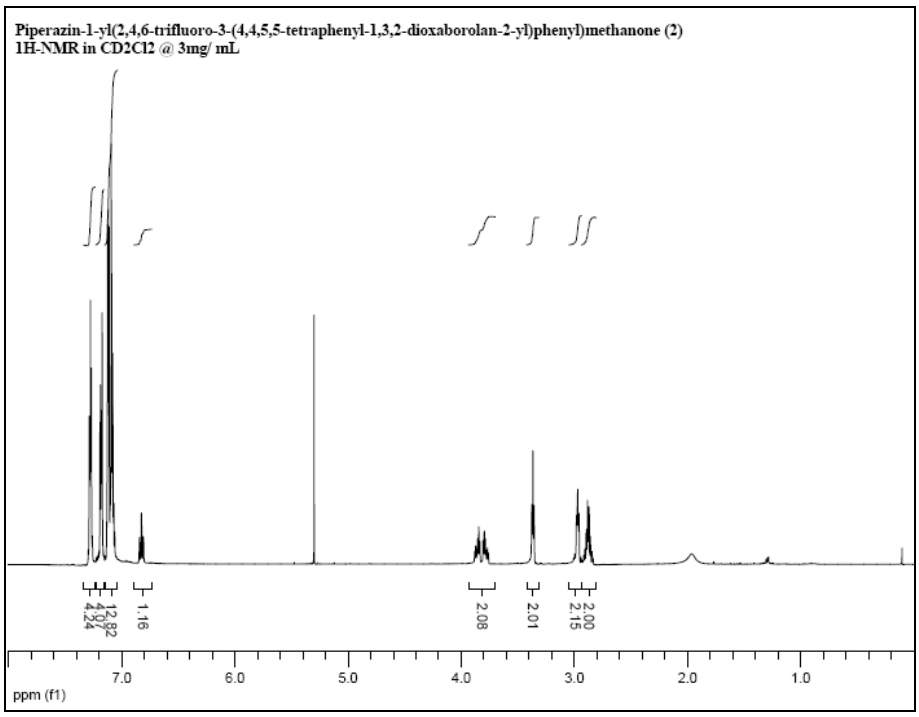


To crystallize (i), product contained in the CH_2Cl_2 layer was filtered through Whatman #5 filter paper and concentrated to ~ 5 mL at which point crystals of the **(i)** began to form. Filtration and collection of **(i)** through Whatman #5 filter paper resulted in a first crop containing 54.5 mg (0.08 mmols, 12 %) of crystalline product.

^{1}H NMR (MeOH-d4, 500 MHz, 21°C): 8.81 (*t*, J= 2 Hz, 1H), 8.07 (*d*, J= 1 Hz, 2H), 7.35-7.315 (*m*, 4H), 7.22-7.14 (*m*, 6H), 6.20 (*d*, J= 14 Hz, 2H), 3.57 (*s*, 6H), 2.76 (*t*, J= 6 Hz, 4H), 2.08 (*t*, J= 6 Hz, 2H), 1.15 (*s*, 12H). HRMS (ESI) calculated for $C_{40}H_{41}N_2O_4^+$ $(M)^+$: 613.3061, found 613.3069. Spectrophotometric constants on a 0.322 µM solution in water: λ_{max} = 749 nm, ε_{749} = 107 000 cm^{-1} M^{-1}, ex= 747 nm, em = 765 nm, and φ = 0.033.

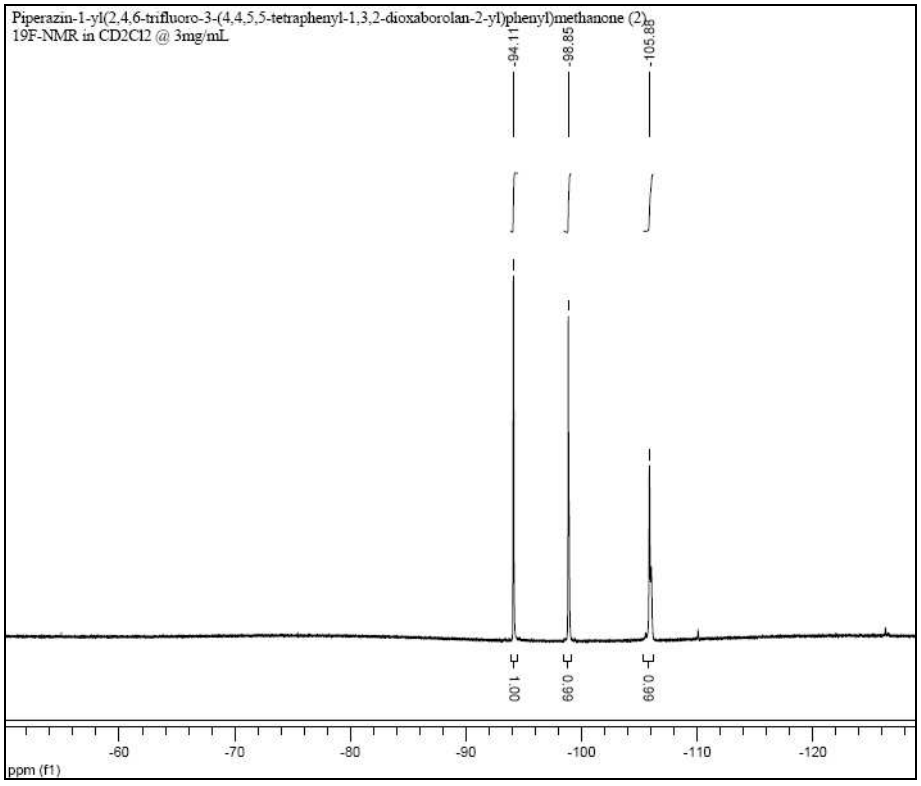
^{1}H-NMR

HRMS-ESI^{+}



PIPERAZIN-1-YL(2,4,6-TRIFLUORO-3-(4,4,5,5-TETRAPHENYL-1,3,2-DIOXABOROLAN-2-YL)PHENYL)METHANONE (II)

Reagents were added to a 25 mL vial containing 3.55 mL of DMF in the following order: piperazine (52 mg, 0.60 mmols), pyridine (133 µL, 1.56 mmols), HOBt monohydrate (61 mg, 0.40 mmols), 2,4,6-Trifluoro-3-(4,4,5,5-tetraphenyl-1,3,2-dioxaborolan-2-yl)benzoic acid (200 mg, 0.36 mmols, synthesis (1 step from commercially available reagents, synthesis and reagent sources previously described (*1*))), and N-(3-dimethylaminopropyl)-N′-ethyl carbodiimide hydrochloride (EDC) (77 mg, 0.40 mmols). This reaction was left at room temperature for 24 hours after which it was concentrated to



oil. A 100 mg amount of piperazine in 1 mL of CH_2Cl_2 was added to the oil to keep **(ii)** in its deprotonated state. The oil was loaded onto a 10 cm x 2.5 cm silica column where **(ii)** was eluted with 2 % MeOH/$CHCl_3$. Elution was monitored by TLC where **(ii)** displays an R_f of 0.30 in a 30 % MeOH/$CHCl_3$ v/v developing solution and gives a positive result in ninhydrin tests. The appropriate fractions were concentrated to give 136.8 mg of **(ii)** (a 61 % yield) as a white solid. The product, **(ii)**, is best stored as a 10 to 100 mM solution in CH_2Cl_2 at -78 °C.

^{1}H NMR (CD_2Cl_2, 500 MHz, 21 °C): 7.28-7.25 (*m*, 4H, CH), 7.22-7.19 (*m*, 4H, CH), 7.14-7.09 (*m*, 12H, CH), 6.87 (*t*, J= 9 Hz, 1H), 3.80-3.68 (*m*, 2H), 3.42-3.32 (*m*, 2H), 2.92-2.79 (*m*, 2H), 2.61-2.51 (*m*, 2H). ^{13}C NMR (MeOH-D4, 400 MHz): 164.9, 162.2, 145.2, 144.3, 130.2, 129.6, 129.1, 128.4, 128.1, 127.8, 125.6, 125.5, 118.8, 112.6, 96.8, 45.9, 45.3, 44.8, 40.8, 37.1, 31.8. ^{19}F NMR (CD_2Cl_2, 300 MHz): -94.11 (1F), -98.85 (1F), -105.88 (1F). HRMS (ESI) calculated for $C_{37}H_{31}BF_3N_2O_3^+$ $(M+H)^+$: 619.2374 m/z, found: 619.2394.

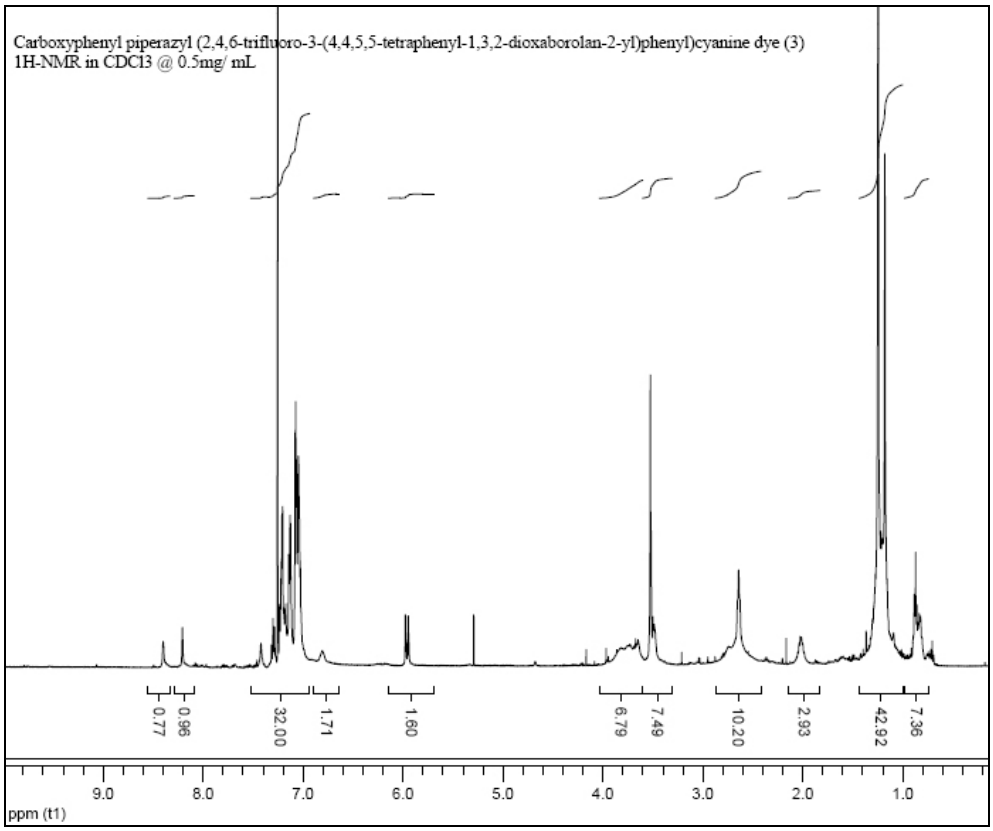
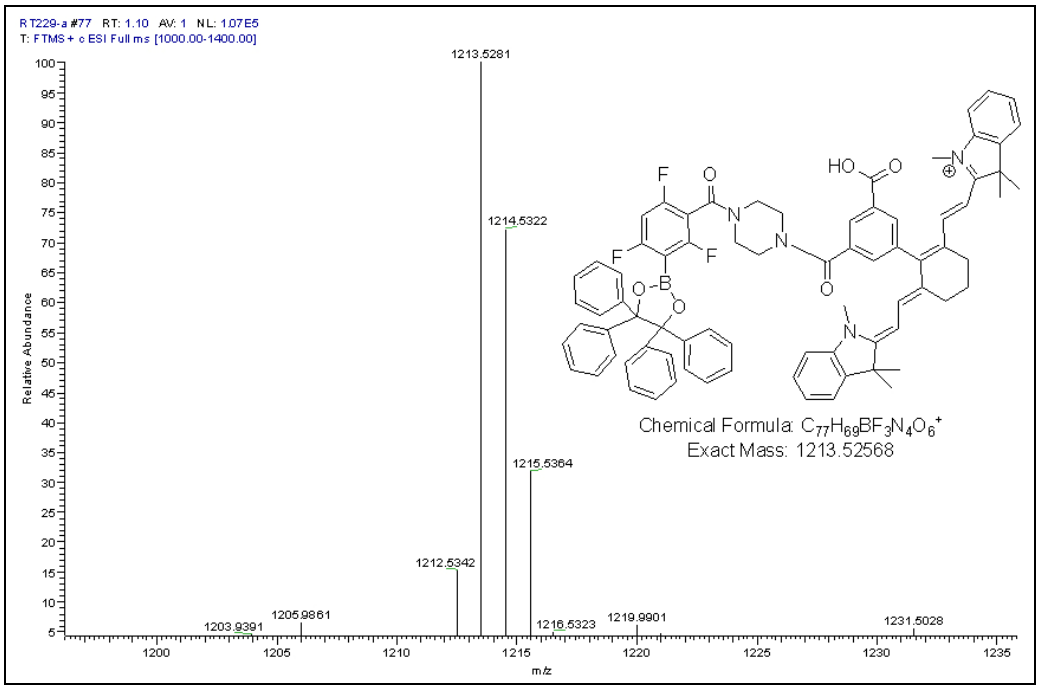
HRMS-ESI$^+$



SYNTHESIS OF CARBOXYPHENYL PIPERAZYL (2,4,6-TRIFLUORO-3-(4,4,5,5-TETRAPHENYL-1,3,2-DIOXABOROLAN-2-YL)PHENYL)CYANINE DYE (III)

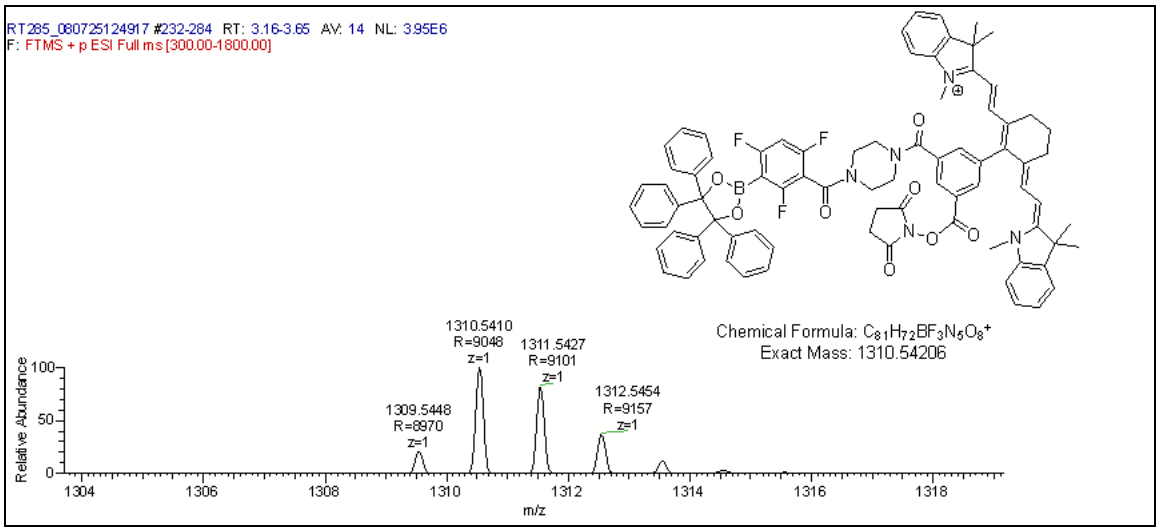


A 1.04 mL, 21.6 mM solution of **(ii)** (15 mg, 0.0225 mmols) in CH_2Cl_2 was added to **(i)** (15 mg, 0.0225 mmols). This solution was concentrated to dryness and the following reagents were added in the following order: DMF (0.9 mL), pyridine (11 µL, 0.132 mmols), HOBt monohydrate (3.45 mg, 0.0225 mmols), and N-(3-dimethylaminopropyl)-N′-ethyl carbodiimide hydrochloride (EDC) (4.5 mg, 0.0225 mmols). This reaction was sonicated for 1 hour, left at room temperature for 2 hours and then quenched with 40 mL of chloroform. This volume of chloroform was washed once with saturated aqueous ammonium chloride and twice with 40 mL of deionized water before it was concentrated. The resulting solid was loaded onto a 10 cm x 2.5 cm silica column where **(iii)** was eluted with 2 litres of 8 % MeOH/$CHCl_3$. Elution was monitored by TLC where **(iii)** displays an R_f of 0.10 with a 15 % MeOH/$CHCl_3$ v/v developing solution. The appropriate fractions were concentrated to give 17.6 mg of **(ii)** (a 65 % yield) as a stable green residue.

^{1}H NMR ($CDCl_3$, 500 MHz, 21 °C): 8.40 (*s*, 1H), 8.21 (*s*, 2H), 7.42-7.03 (*m*, 30H), 6.81 (*broad*, 1H), 5.96 (*d*, J= 7 Hz, 2H), 3.90-3.65 (*m*, 4H), 3.52 (*s*, 6H), 2.50-2.48 (*m*, 2H), 2.75-2.61 (*m*, 6H), 2.02 (*m*, 2H), 1.24-1.18 (*m*, 12H). HRMS (ESI) calculated for $C_{77}H_{69}BF_3N_4O_6^+$ $(M)^+$: 1213.5257 m/z, found: 1213.5281.

^{1}H- NMR

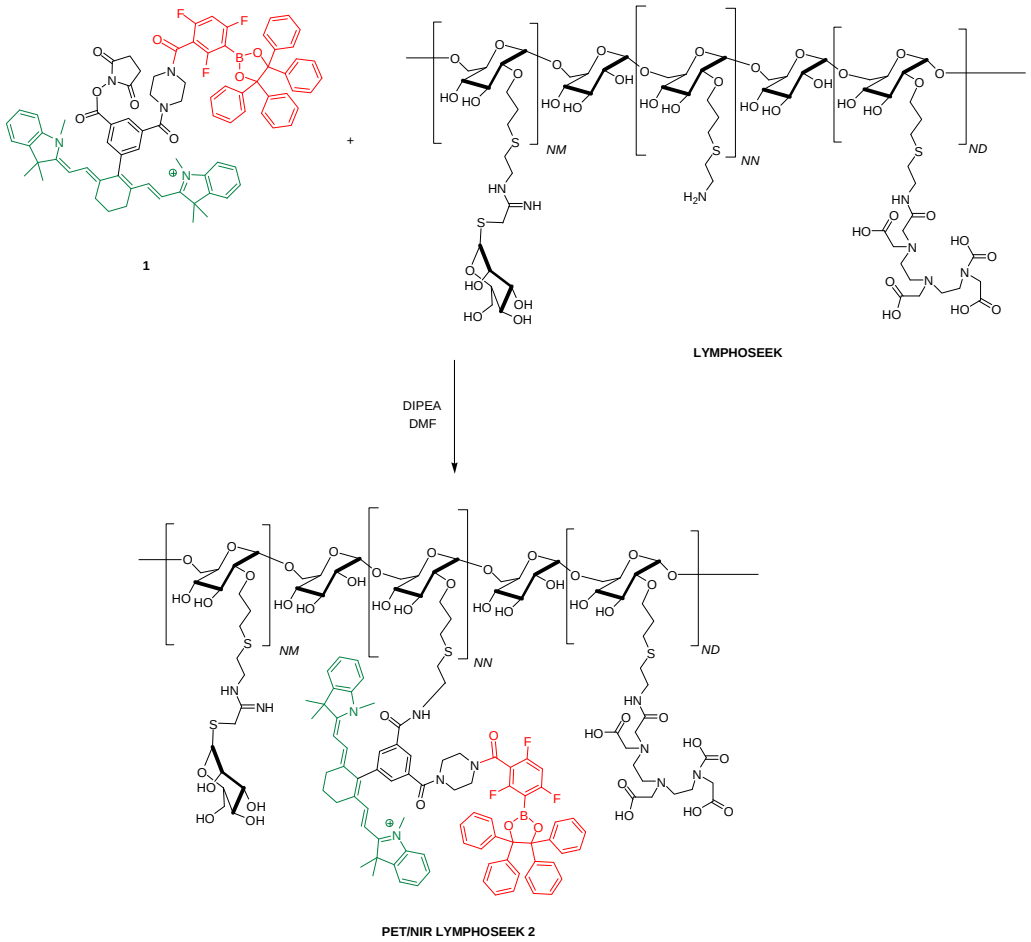
HRMS-ESI^{+}



SYNTHESIS OF N-HYDROXYSUCCINIMIDE PHENYL PIPERAZYL (2,4,6-TRIFLUORO 3-(4,4,5,5-TETRAPHENYL-1,3,2-DIOXABOROLAN-2-YL)PHENYL)CYANINE DYE 1

Reagents were added to a 1.5 mL vial in the following order: **(iii)** (8.9 mg, 7.3 µmols), N-Hydroxysuccinimide (1.2 mg, 11 µmols), HOBt monohydrate (1.7 mg, 11 µmols), DMF (144 µL), pyridine (1.2 µL, 14 µmols), and N-(3-dimethylaminopropyl)-N′-ethyl carbodiimide hydrochloride (EDC) (2.2 mg, 11 µmols). This reaction was left at room temperature for 3 hours after which it was directly diluted with 2 ml of CH_2Cl_2. The CH_2Cl_2 layer was washed 3 times with 2 mL of deionized water. The CH_2Cl_2 was decanted directly into a vial and concentrated to dryness.

As a dry, crude mixture following extraction, **1** is stable and can be used as is. Unfortunately, attempts to isolate **1** as a chloride salt for ^{1}H-NMR analysis via silica chromatography gave a disproporationation product. It is speculated that the highly acidic conditions required for transforming **1** into the chloride salt induced this reactivity.



HRMS (ESI) calculated for $C_{81}H_{72}BF_3N_5O_8^+$ $(M+H)^+$: 1310.5421 m/z, found: 1310.5410.

HRMS-ESI$^+$

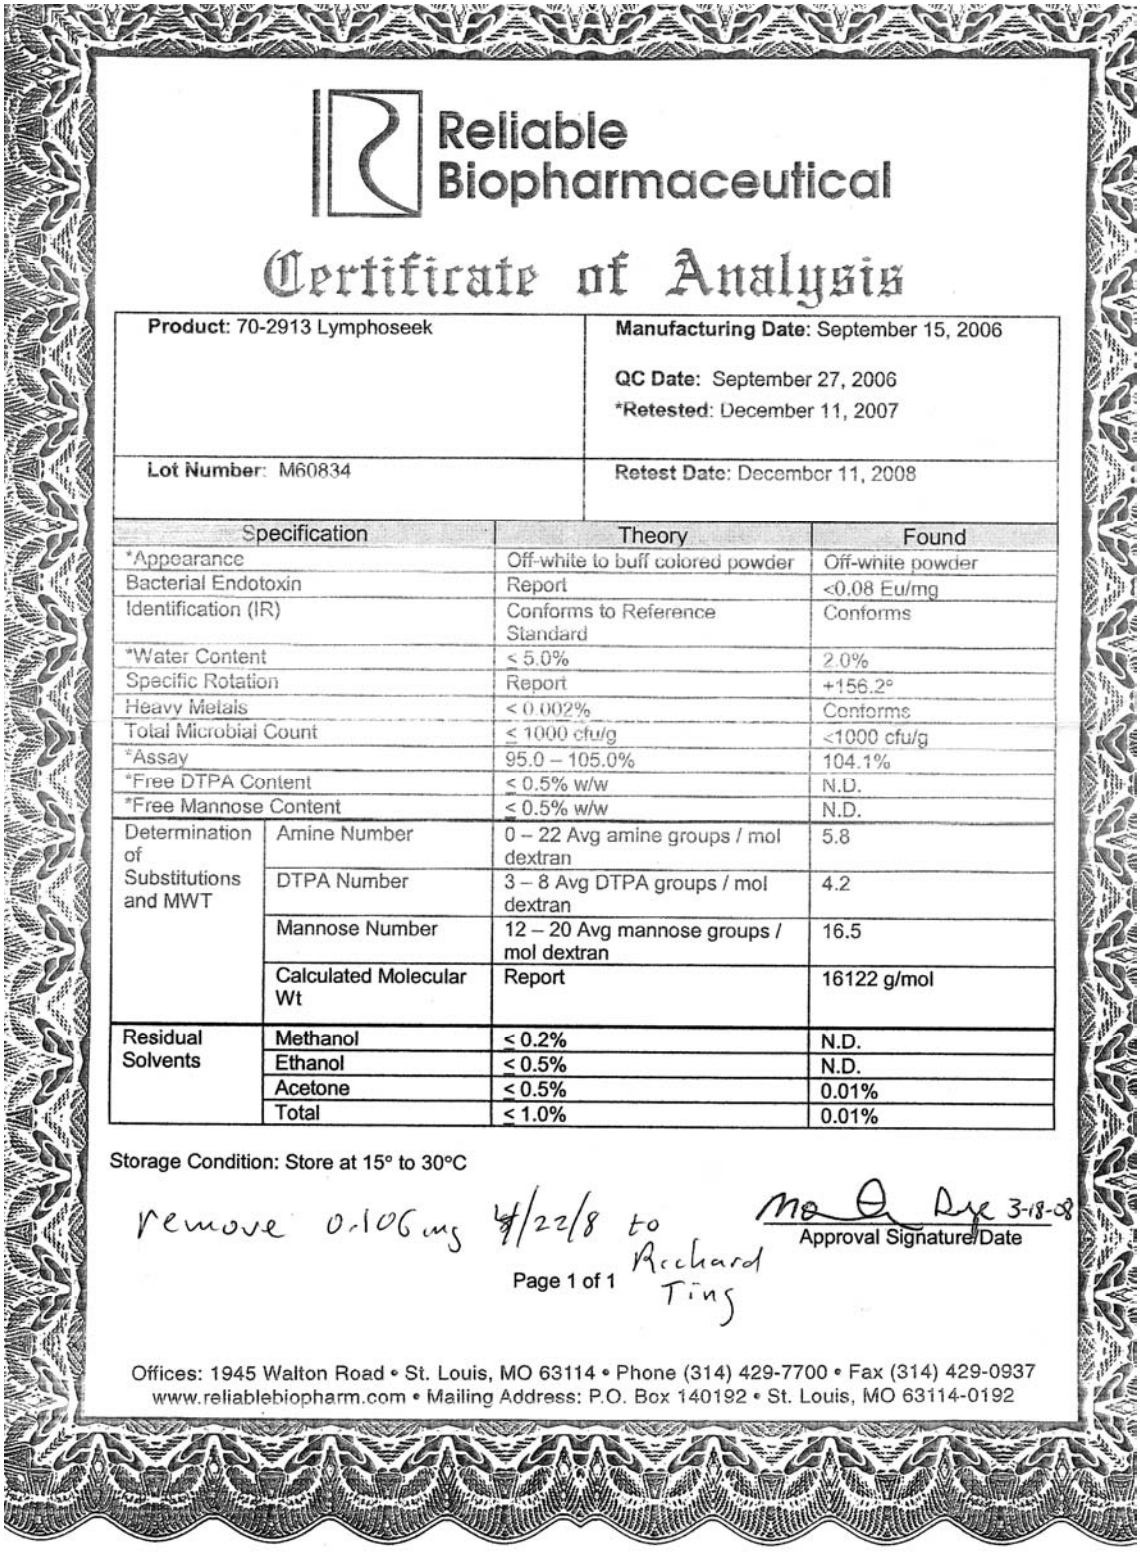
PET/NIR Dual Probe reaction with Lymphoseek:

The scheme for the conjugation of the PET/NIR-probe NHS ester to Lymphoseek is as shown in Scheme 2:

Scheme 2. Reaction of ^{18}F/ heptamethine cyanine (C7-Cy) PET/NIR NHS ester to DTPA-mannosyl-dextran amine (NN), mannose (NM), and DTPA (ND) (Lymphoseek). Densities were 5.8, 16.5, and 4.2 mol /dextran respectively. Exact densities were obtained from certificate of analysis (vide infra). Average molecular weight was 16122 g/mol. The boron based ^{18}F trap is shown in red, while the NIR fluorophore is shown in green.

SYNTHESIS OF PET/NIR- LYMPHOSEEK PROBE 2

A 5.5 mg quantity of unconjugated Lymphoseek ligand (0.34 µmols, Reliable Biopharmaceutical # 70-2913, vide infra for Certificate of Analysis) bearing 5.8 amine groups per mol dextran was used per synthesis of Lymphoseek **2**. The generally conjugatable NHS ester of the PET/NIR probe, **1**, was added as a 4 µmol solution in CH_2Cl_2 directly into a 1.5 mL glass vial containing 5.5 mg (0.34 µmols) of Lymphoseek. This solution was concentrated to dryness, after which the resulting solid was resuspended in 100 µL of DMF. This solution was sonicated for 1 hour and left to react for 18 hours. The next day, a 10 µL volume of diisopropyl ethyl amine (DIPEA) was added and the reaction was left for another 2 hours. The reaction was then transferred to a polypropylene centrifuge tube containing 25 mL of CH_2Cl_2. On an Allegra X-22R centrifuge, a pellet of **2** was isolated following 20 min of centrifugation at 3 000 rcf. The CH_2Cl_2 supernatant was decanted away from the pellet and fresh CH_2Cl_2 was added to the centrifuge tube. The pellet was triturated into a suspension and the centrifuge process was repeated two more times. The resulting pellet was dried under high vacuum and resuspended in a 1 mL of deionized water. This solution was transferred to a 1.5 mL eppendorf that was centrifuged for 2 min at 18 000 rcf. Water soluble **2** was decanted from the pellet and divided into 4.25 x 10.6 nmol aliquots in 600 µL microcentrifuge tubes. These aliquots were lyophilized and stored at -78 °C. Based on fluorescence readings, 115.9 nmols of fluorophore conjugated Lymphoseek **2** was isolated. Based on a glucose quantization assay (*2*), 49.16 to 33.63 nmols of Lymphoseek was isolated as **2.** This corresponds to a 10-14 % yield of **2** from unconjugated Lymphoseek.



CHARACTERIZATION OF LYMPHOSEEK LABELING

In order to determine the dextran yield of **2**, a sugar assay was carried out on one aliquot of **2**. To a 10 mL test tube containing a 0.500 mL solution of **2**, 0.300 mL of a 5% phenol solution followed by 1.800 mL of 18 M H_2SO_4 were added. The exothermic reaction was vortexed for one minute and allowed to cool to room temperature after which an absorbance reading at 450 nm was taken. The amount of Lymphoseek contained in an aliquot of **2** was determined from interpolation through a standardized curve prepared from glucose assays on samples with known quantities of Lymphoseek. The reactive nature of 18 M H_2SO_4 was such that no long wavelength fluorescence was observed from **2**, therefore spectroscopic interference by the fluorophore at A_{450} was not an issue. Based on this glucose assay, 49.16 to 33.63 nmols of Lymphoseek was isolated as **2.** This corresponds to a 10-14 % yield of **2** from unconjugated, commercial Lymphoseek. The estimated molar ratio of fluorophore to Lymphoseek is 2 to 3 fluorophores per molecule of Lymphoseek. Spectrophotometric constants of a 1.5 µM solution in water: λ_{max} = 757 nm, ε_{757} = 110 000 cm^{-1} M^{-1}, ex= 757 nm, em = 777 nm, and φ = 0.026.

The estimated molar ratio of fluorophore to Lymphoseek following NHS condensation is 2 to 3 fluorophores per molecule of Lymphoseek. Although there were 5.8 amines on Lymphoseek (vide infra for certificate of analysis) and **1** was added at a ratio of 4:1 of **1** per amine, the same ratio of fluorophore: Lymphoseek labeling was always achieved.

Attempts to label a greater ratio of amines by increasing the molar ratio of **1** to facilitate greater fluorophore transfer did not change the product outcome.

Lymphoseek Certificate of Analysis:

Reliable Biopharmaceutical

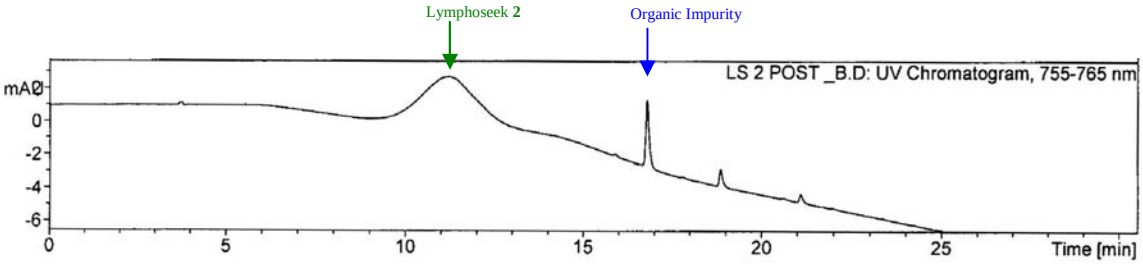
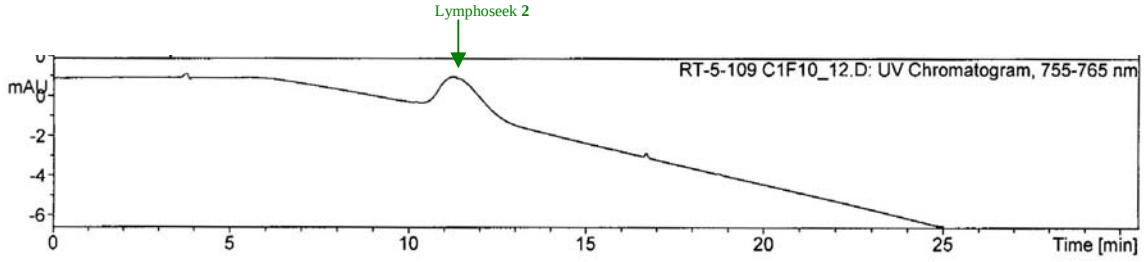
HPLC characterization of 2 and [^{19}F]-3

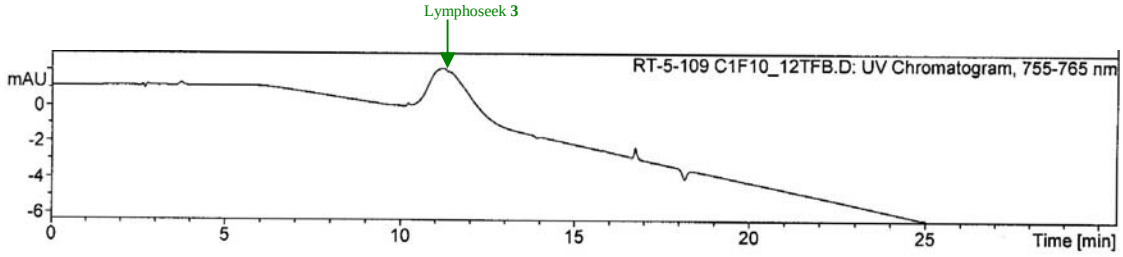
The HPLC characterization[†] of the reaction to give **2** and HPLC confirmation of the purity in both **2** and [^{19}F]-**3** following size exclusion chromatography are shown below.



The following spectra are 215 and 780 nm absorbance HPLC elution profiles of unconjugated Lymphoseek alone. Note that Lymphoseek's elution is not sharp as it is a polymeric mixture and that Lymphoseek possesses no absorbance at 760 nm.



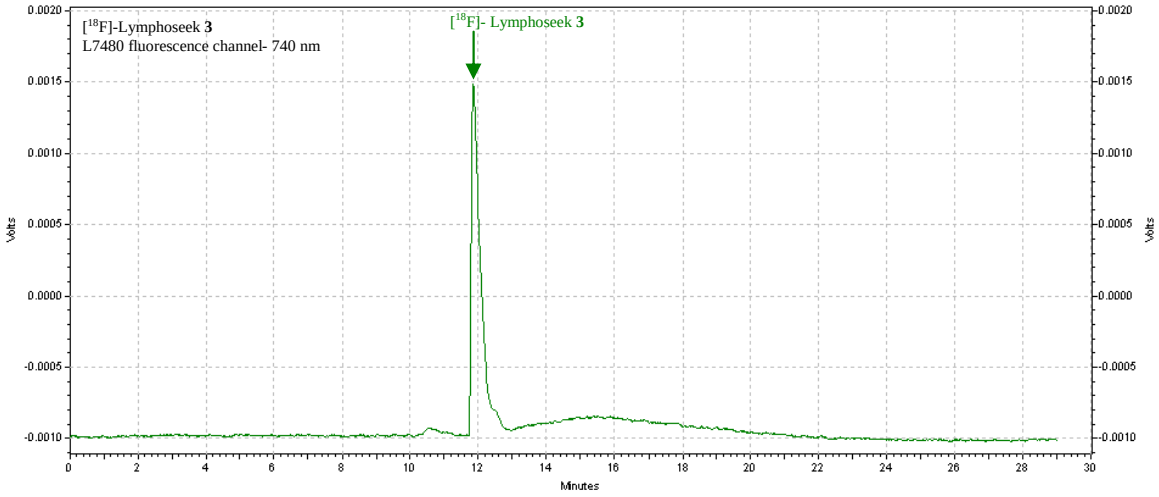
The following spectrum is the 780 nm absorbance HPLC elution profile of the crude, unpurified reaction mixture between **1** and Lymphoseek. The product, Lymphoseek **2**, absorbs at 760 nm due to labeling with **1**. Note the organic impurities at 17, 18, and 19 min from the crude, unpurified reaction mixture.



The following spectrum is the 760 nm absorbance HPLC elution profile of the crude reaction mixture containing **2** after it was extracted and passed through a single biorad-P6 size exclusion column. Note some removal of the mentioned organic impurities.

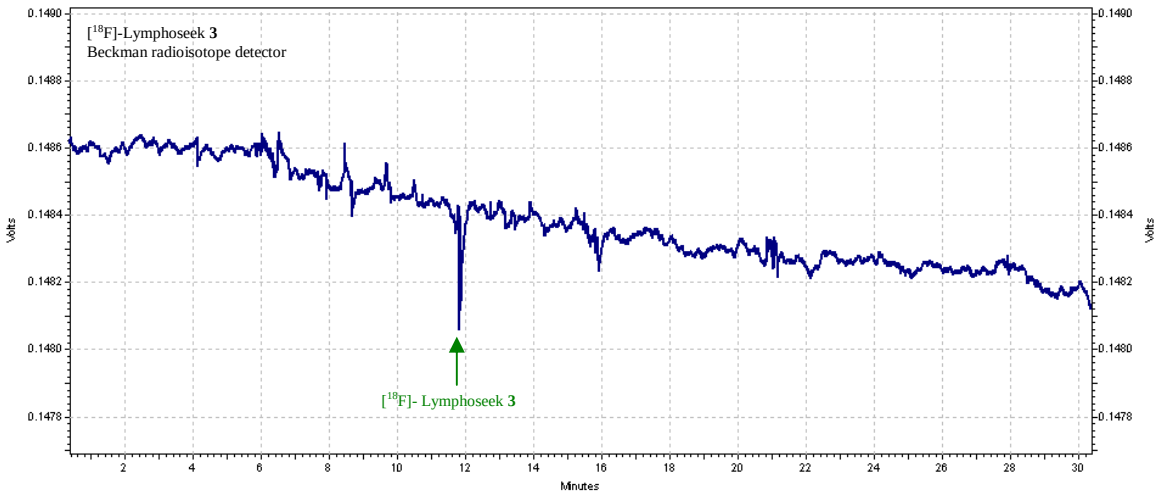
The next spectrum is the 760 nm absorbance HPLC elution profile of **2** after it was passed trough four subsequent Biorad P-6 size exclusion columns. Note the quantitative removal of organic impurities.

The final spectrum is the 760 nm absorbance HPLC elution profile of **2** after conversion to [^{19}F]-**3**, and passage trough four subsequent Biorad P-6 size exclusion columns. Again quantitative removal of organic impurities is achieved.



This section demonstrates by HPLC that Lymphoseek can be labeled with **1** to give **2**. It also demonstrates that **2** and **3** can be purified by size exclusion chromatography as described in the materials and methods. The transformation of **2** to **3** is difficult to characterize by MS due to the large mass of Lymphoseek and the fact that it is polymeric. Therefore, to demonstrate by MS that the trifluoroborate technology conveyed on **1** is generally applicable, a pure alterative target was labeled with **1**. MS characterization of this transformation follows the next section.

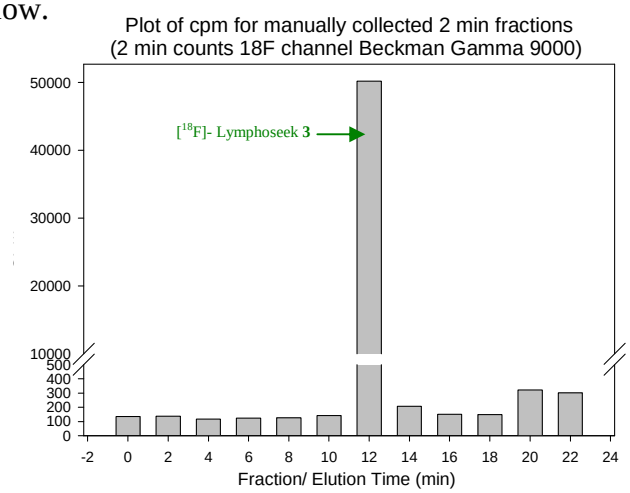
[†] HPLC Chromatography was carried out on an Agilent 1100 Series HPLC with a phenomenex Luna 5 µ C18(2) 100A 250 x 4.60 mm 5 µ column and a 1 mL/min flow rate with a 20 min, 10 to 90 % elution gradient followed by a 5 min isocratic elution with 90% acetonitrile and water where both solvents contained 0.05% trifluoroacetic acid.



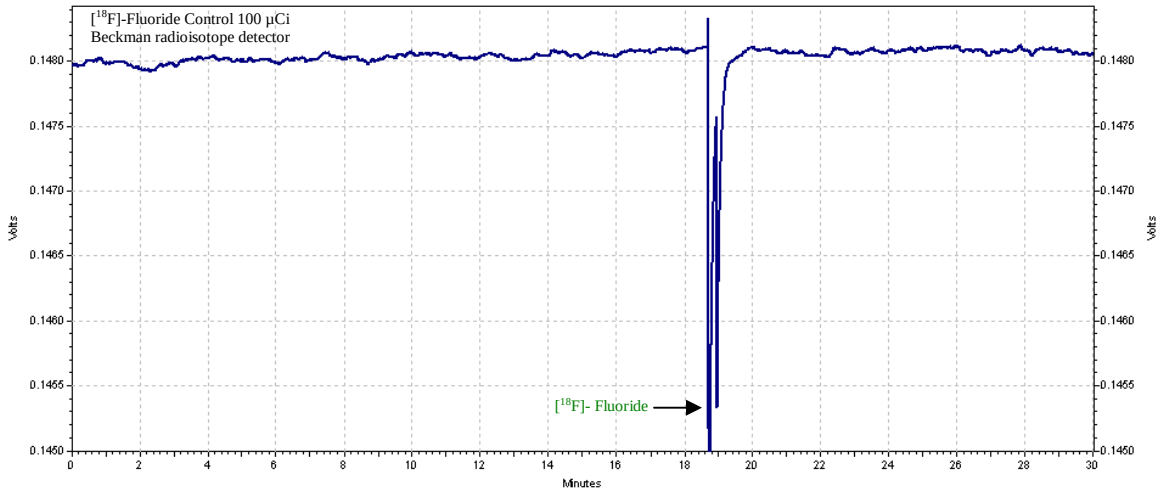
CHARACTERIZATION AND FURTHER APPLICATION

Final radiochemical analysis of [^{18}F]-3

Radiolabeled [^{18}F]-**3** was prepared as described in the materials and methods. The following HPLC analysis of [^{18}F]-**3** demonstrates its radiochemical purity. A 10 µCi amount of [^{18}F]-**3** was loaded on a Beckman Coulter System Gold HPLC equipped with a TOSOH Bioscience TSKgel G2000SW 7.8mm ID x 30 cm x 5 µ M size exclusion column, a L-7480 fluorescence detector, and a Beckman Radioisotope detector. Elution of [^{18}F]-**3** was achieved with an isocratic flow of 0.9% saline at 1 mL/min. The following figure is the elution profile of [^{18}F]-**3** as measured at 740 nm on the L7480 fluorescence detector. Note the single peak in the fluorescence channel that is indicative of a clean synthesis.



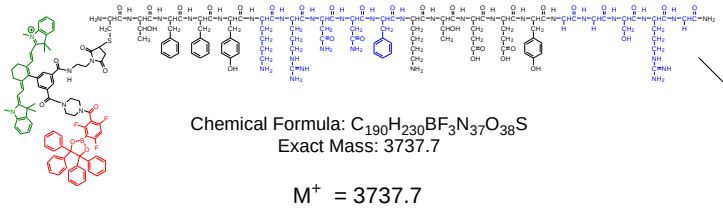
The following figure is the elution profile as observed in the Beckman radioisotope detector channel.



Unfortunately, the available Beckman radioisotope detector did not give a very good signal to noise ratio in the analysis of [^{18}F]-**3**. This detector is intended for use in high

activity syntheses and not for analytical preparations. To demonstrate that the fluorescent peak that is eluted at 12 min, corresponds to a pure sample of [^{18}F]-**3** with minimal radioactive contaminants**,** a 10 µCi sample of [^{18}F]-3 was injected and 2 min fractions were collected manually in eppendorf tubes. These samples were analyzed by scintillation counting on a Beckman Gamma 9000 scintillation counter. The elution profile is shown below.

Note that the majority of the radioactivity is contained within fractions 11-13. This is indicative of a radio-chemically pure species that possesses 740 nm fluorescence. As a control, a 100 µCi sample of [^{18}F]-fluoride was run and detected by the Beckman radioisotope detector. Minimal [^{18}F]-fluoride contamination is observed



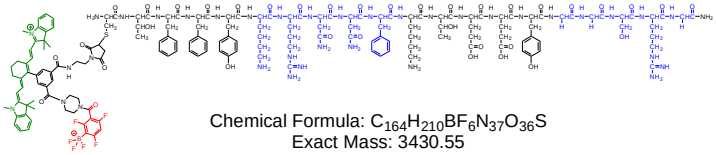
[^{18}F]-fluoride elutes at 19 min, this is consistent with the elution profile of a small molecule on a size exclusion column. The purification of [^{18}F]-**3** as described in the materials and methods gives a relatively pure compound that contains little contaminating [^{18}F]-fluoride.

General multimodality probe application and HPLC-MS analyses

The fluoridation of Lymphoseek **3**, is a perturbation that is difficult to characterize by mass spectrometry for two reasons: the large mass of the species being transformed and the polymeric nature of the species being labeled. In order to demonstrate that the trifluoroborate technology involved in transforming **2** to **3** is both clean and does not generate B-F intermediates, the following peptide was labeled with **1** and converted to a trifluoroborate under the conditions reported in this manuscript. This conversion was monitored by both MS and HPLC. The primary structure of the peptide amino acid sequence has been scrambled.

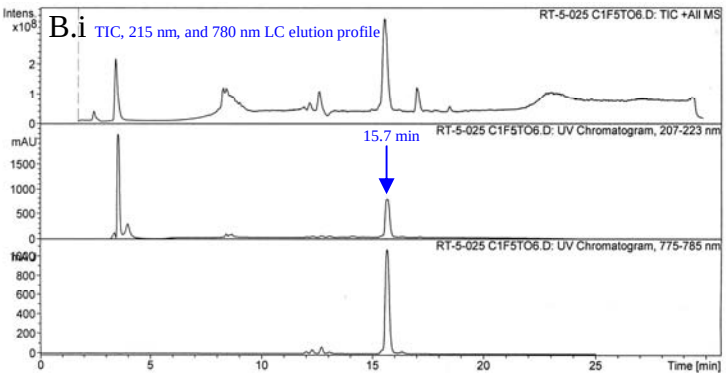
A.i

NH_2-C(FBOMB)TFFY KRNNF KTEEY GGSRG -$CONH_2$

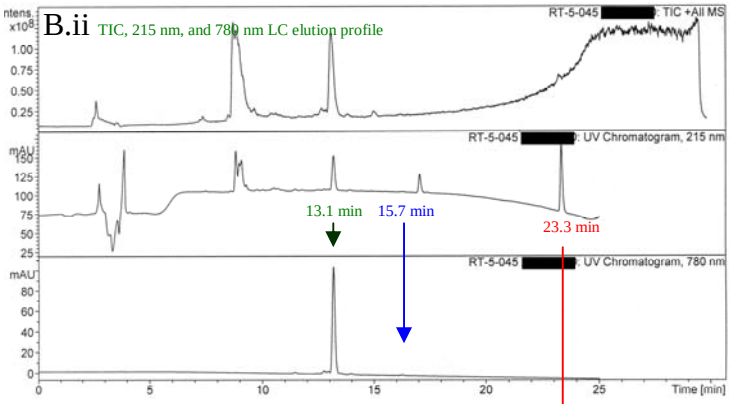


Chemical Formula: $C_{190}H_{230}BF_3N_{37}O_{38}S$
Exact Mass: 3737.7

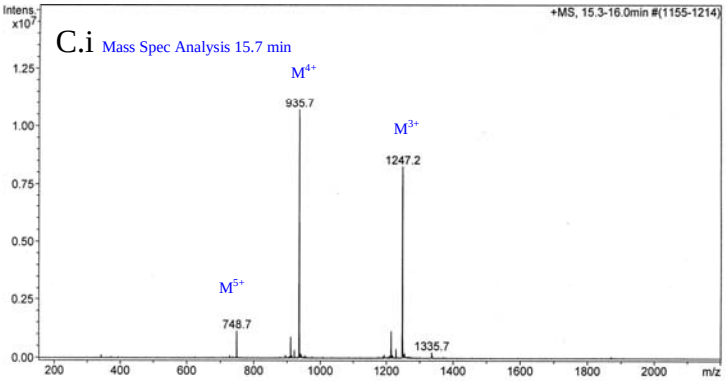
M^+ = 3737.7
M^{2+} = 1868.8
M^{3+} = 1245.9
M^{4+} = 934.4
M^{5+} = 747.5

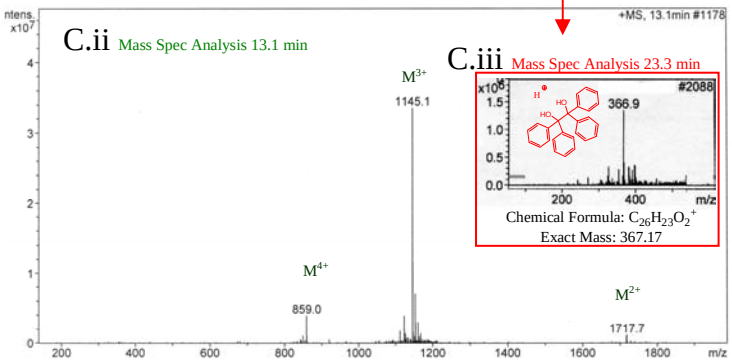


A.ii



HF
HCl, H_2O
40 °C, 1h





Chemical Formula: $C_{164}H_{210}BF_6N_{37}O_{36}S$
Exact Mass: 3430.55

M^+ = 3430.55
M^{2+} = 1715.3
M^{3+} = 1143.5
M^{4+} = 857.6

Chemical Formula: $C_{26}H_{23}O_2^+$
Exact Mass: 367.17

A peptide with the sequence, NH_2-(CTFFY KRNNF KTEEY GGSRG) -$CONH_2$ (Figure Ai, scrambled amino acid sequence), was labeled with **1** on its N-terminal cystine and was purified by preparative HPLC. The purified peptide-**1** is shown in figure B.i where the ionization current and the absorbance elution profiles at 780 nm and 215 nm are shown (vide infra for HPLC conditions)[†]. Note the characteristics indicative of purity including a single peak in both 780 nm (15.7 min) and 215 nm (15.7 min) absorbance spectra. The mass spectrometry profile of the peak eluted at 15.7 min is shown in figure Ci. Note a MS spectra indicative of relative purity, where M^{3+} (1247.2 M/z), M^{4+} (935.7 M/z), and M^{5+} (748.7 M/z) ions are observed, while unrelated masses are less abundant.

When the peptide is treated with aqueous fluoride, the trifluoroborate species shown in figure Aii is generated. HPLC analysis was carried out 10 min after fluoride treatment.[‡] This is clear in the HPLC absorbance elution profile at 215 nm (figure Bii), three peaks* in addition to the product (13.1 min) and the injection artifact 2-4 min are observed. Note the absence of a peak at 15.7 min indicating quantitative consumption of tetraphenyl pinacol peptide-**1** and production of [^{19}F]-trifluoroborate labeled peptide. This is observed in the absorbance elution profile at 780 nm, where the starting material at 15.7 min is completely converted to 780 nm absorbent material at 13.1 min. There is only a single peak at 13.1 min in the 780 nm spectra indicating that there are no B-^{19}F non-trifluoroborate intermediates produced (the boron on **1** is linked directly to a 780 nm fluorophore). The mass spectrometry profile of the peak eluted at 13.1 min is shown in figure Cii. Note a spectra indicative of relative purity, where M^{2+} (1717.7 M/z), M^{3+} (1145.1 M/z), and M^{5+} (859.0 M/z) ions are observed, while unrelated masses are not. The peak at 13.1 min can be purified by HPLC, stored at -20 °C, and reanalyzed by HPLC with no observed decomposition. All 215 nm absorbing peaks including peptide-**1** are removed when the reaction mixture Aii is passed through a Biorad-P6 spin column.

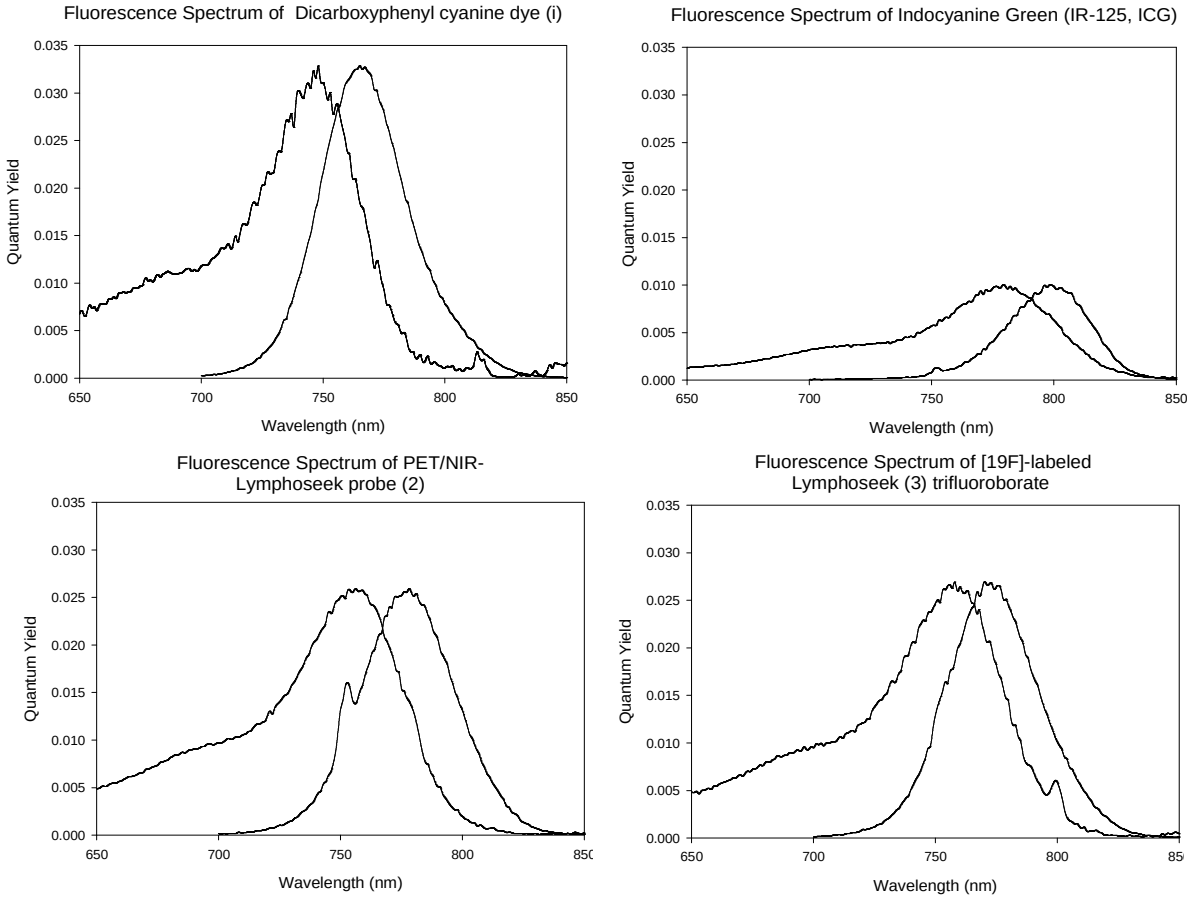
This HPLC-MS analysis demonstrates that the conditions for generating trifluoroborates reported in this manuscript: 1) produce trifluoroborates quantitatively, 2) do not produce B-F intermediates, and 3) are generally applicable to biomolecules other than polysaccharide polymers.

[†]Analysis was carried out on an Agilent 1100 Series HPLC equipped with a LC/MSD trap XCT. Chromatography was carried out on a phenomenex Luna 5 µ C18(2) 100A 250 x 4.60 mm 5 µ column with a 1 mL/min flow rate with a 20 min, 10 to 90 % elution gradient followed by a 5 min isocratic elution with 90% acetonitrile and water where both solvents contained 0.05% trifluoroacetic acid. Mass spectrometry was carried out through electrospray ionization in the positive mode with at trap focus at 1000 M/z. The traces shown were generated with Chemstation Rev.B.01.03[204].

[‡]The purification used for Lymphoseek **3** does not work when applied to the peptide in this analysis. This peptide has a molecular weight of 3432.51 g/mol, therefore it does not elute from the Biorad-P6 spin columns used to purify **3** in this manuscript (Biorad P6 MWCO, molecular weight cut-off,= 6000 g/mol). Preparative HPLC or the use of spin columns with a lower MWCO can be used instead in order to successfully purify low MW species.

* The new peak at 9 min in the 215 nm absorbance spectrum is not related to **1** or the fluoridation of **1** as it is not observed when other peptides of similar hydrophobicity and sequence are [^{19}F]-labeled (Data not shown). The peak at 23.3 min is attributed to tetraphenyl pinacol (figure Ciii) that is generated when the tetraphenylpinacol on peptide-**1** (15.7 min) is displaced by fluoride to form the trifluoroborate at 13.1 min.

Radiochemical Synthesis



The table below summarizes the results of additional radiochemical labeling experiments that were carried out on **2** prior to the 12 mouse in vivo trial of ^{18}F labeled Lymphoseek **3** described in this manuscript. These ^{18}F labelings were carried out using protocol similar to that listed in the materials and methods unless indicated otherwise.

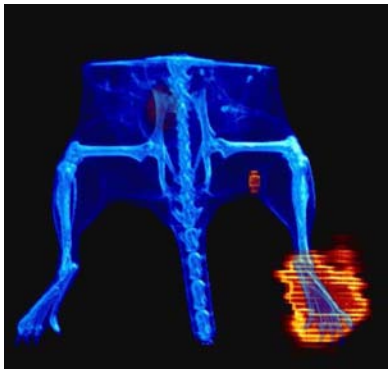
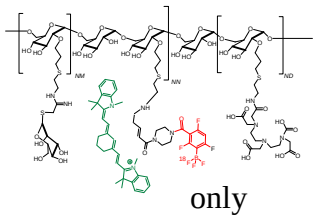
LYMPHOSEEK PLASMA STABILITY ASSAY

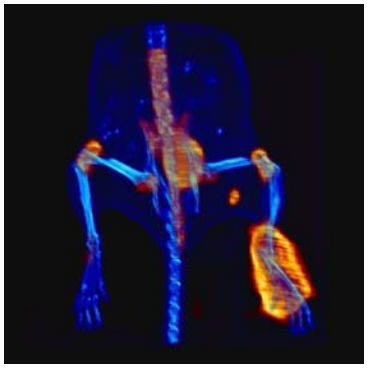


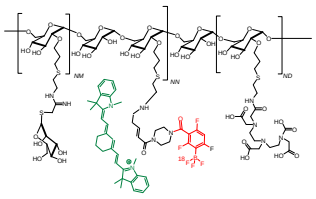
Stability plot of [^{18}F]-labeled of Lymphoseek 3. **The fraction of [^{18}F]-labeled Lymphoseek** 3 **that clears the matrix of a Bio Rad P6 size exclusion gel chromatography column (MWCO = 6000 MW) following incubation for different times in mouse serum.**



To determine the stability of [^{18}F]-labeled of Lymphoseek **3** in serum, approximately 3 nmols of labeled [^{18}F]-**3** (98 µCi @ 10:45 am) in 100 µCi of 10 mM Tris buffer pH 7.3 was added to 100 µL of mouse serum at 10:51 AM **(Start of Reaction (SOR)).** At time points corresponding to 1 min, 16 min, 44 min, 72 min, and 185 min vs. SOR, 40 µL aliquots were removed from the reaction and placed over Bio Rad Bio Gel P6 spin columns. Both the material retained in the spin column and the flow through were counted by scintillation counter. All counts were corrected for ^{18}F decay. The ratio of corrected counts obtained in the flow through divided by the sum of the counts in the flow through plus those retained in the spin column were plot against time. A non-linear regression analysis of this data was carried out using Sigma Plot 2001 v7.101. A first order decay constant of 0.00054 ± 0.00003 min^{-1} corresponding to a half-life of 1280 ± 80 min was obtained. Assuming that the material retained in the Bio Rad P6 spin column matrix represents the amount of [^{18}F]-labeled of Lymphoseek **3** that is degraded into products of molecular weight that are less than 6000 (the MWCO of the Bio Rad P6 spin columns), it can be assumed that the half-life of [^{18}F]-labeled of Lymphoseek **3** in mouse serum is 1280 ± 80 min, a value that corresponds to a very stable ^{18}F tracer considering that this value is 11.6 times that of ^{18}F nuclear decay (110 min).

EVIDENCE OF IN VIVO ^{18}F-BORON BOND STABILITY





$^{18}F^-$ only

only

+

Deliberate $^{18}F^-$ contamination

The left image is of a mouse injected with ^{18}F-Fluoride after 1 hour. Note signal accumulation in bone structures and the bladder. [^{18}F]-fluoride does not accumulate in lumbar and popliteal lymph nodes. The middle image is a 1 h image of a mouse that has been injected with ^{18}F-3 in the right rear footpad. Note that this image is different from the previous image. There is specific signal accumulation in the sentinel lymph node but no signal accumulation in the knee caps or bone structures. Right image, a 1 h image of a mouse that has been injected with a sample of ^{18}F-3 that was deliberately contaminated with ^{18}F-Fluoride. Note accumulation in the sentinel lymph node as well as in the spine and kneecaps of the mouse. If ^{18}F-3 was experiencing ^{18}F-fluoride loss from F-boron bond dissociation during the in vivo PET experiment, accumulation in the spine and kneecaps of the mouse would be an expected consequence. Because the middle image, and not the right image, is typical of PET images that are acquired with ^{18}F-3, we can qualitatively conclude that the ^{18}F-boron bond is stable on ^{18}F-Lymphoseek 3 in vivo.

Simple Fluidic System for Purifying and Concentrating Diagnostic Biomarkers Using Stimuli-Responsive Antibody Conjugates and Membranes

Allison L. Golden,[†] Charles F. Battrell,[‡] Sean Pennell,[‡] Allan S. Hoffman,[†] James J. Lai,[†] and Patrick S. Stayton*[,†]

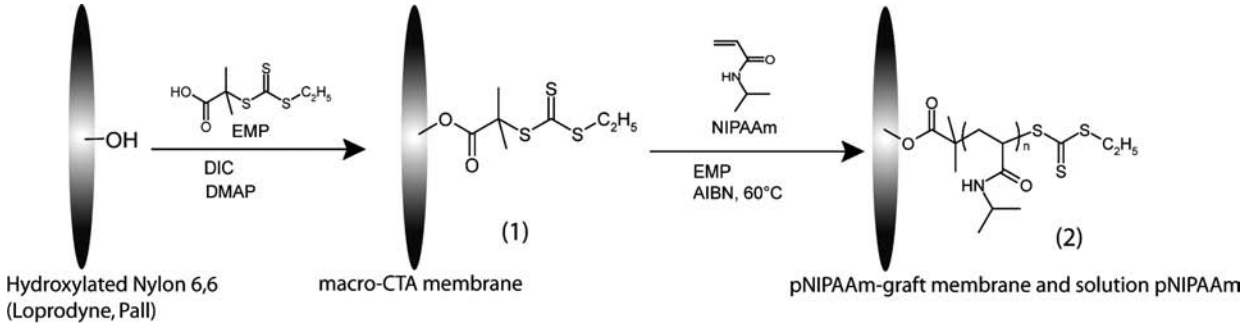
Department of Bioengineering, University of Washington, Seattle, Washington 98195, and Micronics, Inc., 8463 154th Avenue NE, Building G, Redmond, Washington, 98052. Received April 8, 2010; Revised Manuscript Received June 11, 2010

We report a simple fluidic system that can purify and concentrate diagnostic biomarkers through the capture and triggered release of stimuli-responsive polymer−antibody conjugates at porous membranes that are grafted with the same stimuli-responsive polymer. This technique is applied here to the capture and detection of a model streptavidin antigen and subsequently to clinical ranges of the malaria antigen *Plasmodium falciparum* histidine-rich protein 2 (PfHRP2) from spiked human plasma. The carboxyl end-groups of semi-telechelic poly(*N*-isopropylacrylamide) (pNIPAAm) synthesized by reversible addition−fragmentation chain transfer (RAFT) polymerization were modified with tetrafluorophenol to yield amine-reactive ester groups for conjugation to amine groups of anti-streptavidin and anti-PfHRP2 antibodies. Stimuli-responsive membranes were constructed from 1.2 μm pore-size, hydroxylated, nylon-6,6 filters (Loprodyne, from Pall Corporation). The surface hydroxyl groups on the filters were conjugated to a 2-ethylsulfanylthiocarbonylsulfanyl-2-methyl propionic acid (EMP) RAFT chain transfer agent, and the surface-grafted pNIPAAm was obtained by subsequent polymerization. The number average molecular weight (Mn) and polydispersity indices (PDI) of the surface grafts were characterized, and membranes with either 4100 and 8400 dalton pNIPAAm grafts showed greater than 80% anti-streptavidin capture efficiency. The 8400 dalton-graft membrane showed the highest release efficiency, and it was demonstrated that at 0.2 nM starting concentration the streptavidin could be concentrated approximately 40-fold by releasing into a small 50 μL volume. This concentrator system was applied to the capture and concentration of the PfHRP2 antigen, and results showed that the PfHRP2 antigen could be processed and detected at clinically relevant concentrations of this malaria biomarker.

INTRODUCTION

Biomarker testing can potentially help in the identification and epidemiological tracking of many diseases, as well as in their treatment monitoring. Achieving clinically relevant immunoassay limits of detection for biomarkers has typically required more time-consuming methods and specialized equipment found in centralized and higher-resource laboratory facilities. Rapid diagnostic tests (RDTs) based on lateral flow, flow-through, or dipstick approaches have greatly aided diagnosis in low-resource settings but have detection sensitivities that can limit their applications. As an example, tests for malaria are suitable for detecting higher levels of antigen released by parasitized red blood cells, but are not adequate for detection of low levels of parasitemia common with patients from non-endemic regions with clinical disease (*1*−*3*) or in cases of subpatent parasitemia levels that can serve as transmission reservoirs (*4, 5*). Additionally, they are limited in use for species discrimination, which can be necessary for correct treatment choice and monitoring (*6, 7*). By improving detection limits and incorporating multiplex assays, rapid diagnostic technologies can move to the forefront of providing accurate diagnosis across the spectrum of medical needs, rather than simply providing faster results for conventional methods.

Microfluidic assays have features desirable in a rapid diagnostic test including smaller input samples, shorter diffusion and reaction times, lower reagent consumption, and containment of biohazard waste products (*8*−*10*). However, simply reformatting current immunoassays to fit in a microfluidic device setting may prove to be insufficient for overcoming intrinsic sensitivity and assay limitations. While microfluidic volumes reduce diffusion distance, capture at the channel surface is confounded by the dominance of the advective laminar flow regime (*11*). Absolute quantities of antigen fall as the sample size is reduced and preconditioning of a sample can lead to further dilution. There is still a need for simple, integratable reagent systems that can both purify and concentrate diagnostic targets in microfluidic or flow-through diagnostic technologies.



Our group has been investigating the use of "smart" polymer conjugates of biomolecules to address this need for rapid and efficient biomarker processing in microfluidic devices. In the past, there have been two primary approaches that utilized either immunoconjugates that can be phase-separated in solution and captured on surfaces or stimuli-responsive surfaces for the capture of biomolecules or cells (*12*−*20*). More recently, we have been investigating the joint application of the stimuli-responsive conjugates with stimuli-responsive microfluidic channel surfaces (*16*). Here, we have grafted polymer brushes using the reversible-addition fragmentation chain transfer (RAFT) method, which allows control of properties through control of graft molecular weight and end-groups (*21*−*23*). Grafted porous membranes incorporating stimuli-sensitive polymers have been previously used to perform separations on the basis of porosity, hydrophobicity, or surface access (*24*−*33*). These stimuli-responsive grafted membranes are particularly appealing when used jointly with stimuli-responsive antibody−polymer conjugates where the diffusion of the antigen and antibody in plasma and serum is the rate-limiting step (*34*−*36*).

Temperature-responsive micro- and nanoparticles have been previously isolated in microfluidic devices, but isolation was

Scheme 1. Synthesis of pNIPAAm-Polymerized Membranes[a]

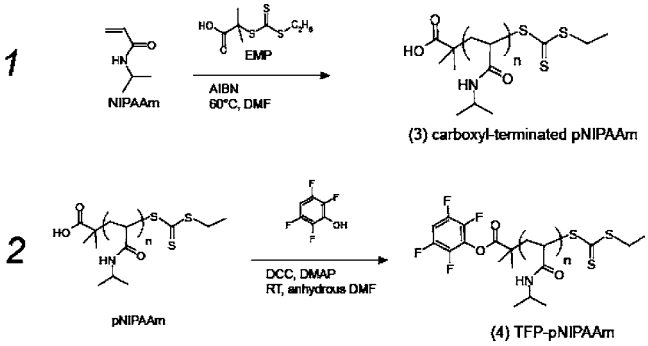
[a] Membranes were prepared by first coupling the EMP chain transfer agent via esterification to produce a macro-CTA membrane (1). Second, the membrane was immersed in a RAFT-mediated polymerization of NIPAAm with additional EMP and AIBN to yield solution homopolymer and covalently-linked surface polymer (2).

performed at microfluidic channel walls (*16, 37*−*39*). This requires migration of the particles away from the laminar flow stream. We present results showing that stimuli-responsive IgG and IgM antibody−pNIPAAm conjugates are efficiently captured and released at pNIPAAm-grafted nylon-6,6 membranes inserted into prefabricated microfluidic cards. The sharpness of the immunocomplex sandwich release after capture was shown to be strongly enhanced by the surface-polymerized pNIPAAm on the membrane surface during constant microfluidic flow. This system was also shown to be applicable to processing of malaria antigen from spiked human plasma samples, resulting in detection limits comparable to ELISA for the malaria *Plasmodium falciparum* histidine-rich protein 2 (PfHRP2) antigen.

EXPERIMENTAL SECTION

Materials. 2,2′-Azoisobutyronitirile (AIBN, Aldrich) was recrystallized from methanol. *N*-Isopropylacrylamide (NIPAAm, Aldrich, 97%) was recrystallized twice from hexane and dried under vacuum prior to use. Anhydrous dimethylformamide (DMF), anhydrous dimethylsulfoxide (DMSO), dichloromethane, anhydrous ethyl ether, 2,3,5,6-tetrafluorophenol (TFP), diisopropylcarbodiimide (DIC), and dimethylaminopyridine (DMAP) were purchased and used as received. Prepared 10 mM phosphate-buffered saline (PBS) and phosphate-buffered saline with 0.05% Tween-20 (PBS-T) dry reagents were purchased from Sigma and dissolved in distilled water. 3,3′,5,5′-Tetramethylbenzidine (TMB) substrate was purchased from KPL. Monoclonal mouse anti-PfHRP2 IgM antibody, monoclonal mouse anti-PfHRP2 peroxidase-conjugated detection IgG antibody, and recombinant PfHRP2 antigen were purchased from Immunology Consultants Laboratory. Polyclonal IgG antibodies against streptavidin were purchased from Abcam. Loprodyne hydroxylated nylon-6,6 membranes, 1.2 μm pore size, were from Pall. The chain transfer agent (CTA) 2-ethylsulfanylthiocarbonylsulfanyl-2-methyl propionic acid, EMP, was synthesized previously as described (*40*). Dialysis membranes were purchased from Spectrum laboratories. Prior to use, pooled human plasma (sodium EDTA, Valley Biomedical) was filtered using Whatman GD/X filters, to remove precipitate formed after thawing from the frozen aliquot, and stored at 4 °C for up to 1 week.

Preparation of pNIPAAm-Bound Membranes. Membranes with graft pNIPAAm were prepared as shown in Scheme 1. The CTA EMP (100 mM), DIC (100 mM), and DMAP (10 mM) were combined in 10 mL anhydrous DMF and added to vacuum-dried Loprodyne membrane. The reaction was stirred for 48 hours at room temperature. Membranes were washed extensively in acetone and ethanol, dried by vacuum at room temperature, and then stored under ambient conditions. Polymerization was mediated by chain transfer agent using the reversible addition−fragmentation chain transfer (RAFT) technique (*41*). Membrane with and without bound CTA were immersed in a solution polymerization vessel containing the following in DMF/EMP chain transfer agent (13.2 or 40 mmol), *N*-isopropylacrylamide monomer (0.2 g/mL), and (2.7 or 8 mmol) AIBN. Following nitrogen purging, polymerization proceeded at 60 °C for 18−24 h. Solution polymer was retained and analyzed and membranes were washed extensively with acetone and ethanol and soaked 48 h at 4 °C in several changes of distilled water to remove noncovalently adsorbed or entangled polymer.



Cleavage of pNIPAAm from Surface of Membranes. 1 N sodium hydroxide solution (2 mL per cm^2 of membrane) was added to membranes and heated to 70 °C for 1 h. Solutions were neutralized with 1 N hydrochloric acid, and each membrane was washed with 2 mL of distilled water. All solutions were then combined and dialyzed against several changes of distilled water for 72 h, lyophilized, and stored dry until analysis. Polymers were dissolved in DMF and treated with immobilized TCEP for 1 h prior to characterization by gel permeation chromatography.

Synthesis of Semi-telechelic (pNIPAAm) and pNIPAAm-TFP Ester. The RAFT polymerization of *N*-isopropylacrylamide monomer included the following: 13.2 mmol EMP CTA, 0.2 g/mL NIPAAm, and 2.7 mmol AIBN. After nitrogen purging, the polymerization proceeded at 60 °C for 18 hours. The resulting polymer was precipitated from DMF twice in cold ethyl ether, filtered, dried under vacuum, and analyzed by GPC. PNIPAAm of number-average molecular weight (Mn) equal to 14 500, and polydispersity index (weight average molecular weight/number average molecular weight, or M_w/M_n) equal to 1.15 was used for preparation of TFP ester. The end carboxyl group was reacted with tetrafluorophenol (Scheme 2). The reagents pNIPAAm (1 g, 13.8 mM), DIC (42 mg, 67 mM), tetrafluorophenol (56 mg, 67 mM), and DMAP (4.1 mg, 6.7 mM) were combined in 5 mL anhydrous dichloromethane at room temperature for 24 hours. Activated polymer was then precipitated with cold anhydrous ethyl ether. Precipitates were immediately dried by vacuum and stored dry at −20 °C.

Gel Permeation Chromatography. Polymer samples from solution and surface-derived polymerizations were analyzed using gel permeation chromatography (GPC) to determine their number average molecular weight (Mn) and polydispersity index (PDI = weight average molecular weight/number average molecular weight), using Viscotek model VE2001 sampler and VE3580 refractive index (RI) detector. Samples were compared against poly(methyl methacrylate) standards to determine molecular weight.

Antibody Conjugation and Purification. One milligram of polyclonal mouse IgG antistreptavidin or monoclonal mouse

Scheme 2[a]

[a] 1. Synthesis of semi-telechelic pNIPAAm through RAFT polymerization results in carboxyl terminated pNIPAAm (**3**). 2. Tetrafluorophenol is coupled with the carboxyl end of pNIPAAm to result in TFP-pNIPAAm (**4**).

IgM anti-PfHRP2 was diluted in PBS, with 100 mM sodium bicarbonate, pH 8.5 to a final concentration of 2 mg/mL. pNIPAAm-TFP ester was dissolved in anhydrous DMSO (0.2 mg/mL). Twenty-five microliters of the pNIPAAm-TFP in DMSO was added to the antibody solution, and the reaction solution was mixed gently overnight at 4 °C. Conjugates were purified from tetrafluorophenol and excess salts with a desalting column. Conjugated antibodies were separated by heating the reaction mixture to 40 °C to induce conjugate aggregation followed by centrifugation for 2 minutes at 13,000 rpm. The supernatant was removed and the polymer pellet was resolubilized in PBS, pH 7.4. Conjugates were dialyzed against 1× PBS using 100 000 MWCO dialysis membranes over several days to reduce the content of unreacted pNIPAAm. Polymer contents of the resulting solutions were measured by UV absorbance at 307 nm against polymer concentration standards. Protein contents were determined by absorbance at 280 nm with a derived correction factor for contribution of polymer content to absorbance at 280 nm. Antibody concentrations used in immunocomplex samples were based on protein content only, since an exact molecular weight of the antibody conjugate was not established. Antibody conjugates were stored at 4 °C in PBS, pH 7.4.

Microfluidic Card Assembly. Punched pieces of membrane were positioned between two-part multilayer microchannels constructed of poly(ethylene terepthalate) (PET), and poly(methyl methacrylate) (PMMA) with an adhesive layer (excluding membrane region), shown in Figure 2. Five layers contained stacked circular cutouts to serve as a membrane well area, with inner layer diameters of 2.1 mm and outer layer diameters of 3.25 mm. Membrane pieces were positioned between two of the layers and sealed. The upper and lower membrane well layers were connected on opposing sides to rectangular channels of dimensions 9.2 mm in length, 0.36 mm in width, and 0.2 mm in height. Fluid was introduced into the lower rectangular channel to flow up and through membrane and exit through the upper rectangular channel.

Immunocomplex Samples. 100 nM of anti-streptavidin IgG polyclonal antibody conjugate (total pNIPAAm concentration of 0.58 mg/mL) was mixed with 10 nM Alexa-488 labeled streptavidin. A negative control of free pNIPAAm at 0.58 mg/mL mixed with labeled streptavidin was included as a conjugate-free control. Samples were allowed to dwell 15 min prior to running through the card. For concentration from a buffer-diluted solution, a 50 μL sample of 100 nM anti-streptavidin IgG antibody conjugate and 10nM Alexa 488-labeled streptavidin was diluted 50-fold in PBS-T to 2.5 mL.

Malaria Antigen Immunocomplex Samples. PfHRP2 antigen was spiked into >99% human plasma at concentrations of 8−200 ng/mL and mixed with anti-*Pf*HRP2 IgM pNIPAAm conjugate and anti-*Pf*HRP2 horseradish peroxidase-conjugated IgG in PBS. The final concentrations were 50% plasma, PfHRP2 antigen from 4 ng/mL (68 pM) to 100 ng/mL (1.7 nM), 14 μg/mL anti-pfHRP2-pNIPAAm conjugate (14.7 nM), and 0.4 μg/mL anti-pfHRP2 peroxidase-coupled detection antibody. Final polymer concentration was 25 μg/mL. Samples were allowed to dwell 15 minutes at room temperature prior to running.

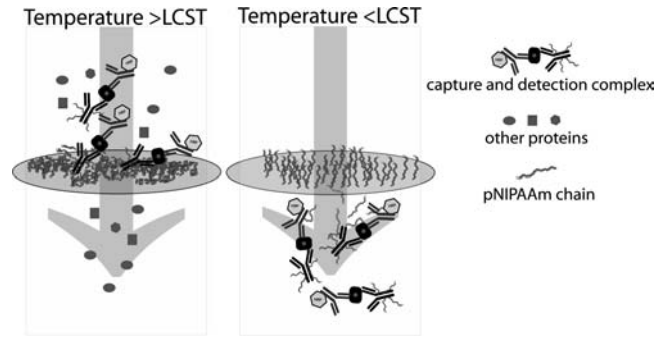


Figure 1. Schematic system design for immunocomplex capture and concentration under conditions of capture (>LCST) and release (<LCST). Covalently modified pNIPAAm-antibody, bound antigen, and detection antibody are captured at membrane during polymer aggregation above the LCST, while unconjugated plasma components flow through. When the membrane region of the device is cooled, the polymer becomes hydrophilic and molecular conjugates are released back into the flow stream, carrying their cargo of antigen and detection antibody with them.

Capture and Release in a Microfluidic Card. Capture conjugate solutions were introduced via syringe pump as a 50 μL sample plug leading wash buffer of PBS-tween (0.05%). Room-temperature samples were flowed to the membrane, wetting it, but samples did not penetrate through membrane prior to heating. For capture conditions, the entire card was heated on a solid block heater set to 40 °C. Temperature in the card was measured by a thermocouple placed through upper layer at one port. When the temperature of the thermocouple reached 35 °C (under 30 s), flow through the membrane was initiated (25 μL per minute for 2 minutes, followed by 50 μL per minute for 4 minutes), with collection of exiting 50 μL fractions. For release, the card was cooled on a 10 °C cold block until the thermocouple read 25 °C. Flow was resumed at 50 μL per minute and 15 or 50 μL fractions collected. For concentration of a diluted sample, the entire 2.5 mL sample was flowed through the membrane during heating and released upon cooling into two 50 μL fractions.

Detection of Released anti-pfHRP2 Detection Antibody. Released pfHRP2 samples were pelleted using thermal precipitation, then resuspended into 100 μL TMB substrate for color development. Reaction was stopped by 50 μL 1 N HCl. Absorbance of sample was determined using a UV−vis spectrophotometer plate reader at $A_{450\ nm} - A_{650\ nm}$. Aliquots of a dilution series of detection antibody were combined with 100 μL of TMB substrate to create a standard curve of detection antibody concentration and control for color development relative to detection antibody concentration.

RESULTS AND DISCUSSION

Construction of Stimuli-Responsive Membranes. The microfluidic system consists of two stimuli-responsive components: (1) a porous, polymer-grafted membrane and (2) antibody conjugates (Figure 1). Above the critical solution temperature (LCST), the grafted polymers on the membrane surface and the antibody conjugate polymers in the flowing solution will both phase separate, leading to capture of the antibody conjugate immunocomplex at the membrane during flow. Below the

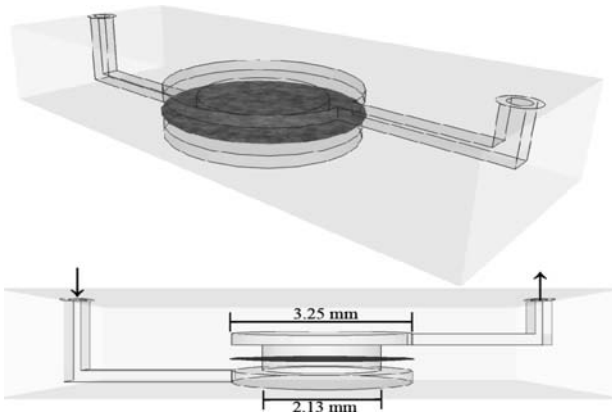

Figure 2. Schematic of microfluidic channel used in capture and release experiments, shown in isometric projection (top) and side projection (bottom) views. Stacked layers of cut poly(ethylene terepthalate) (PET) form the membrane well area, with inner layer diameters of 2.13 mm and outer layer diameters of 3.25 mm. Membrane pieces were positioned between two of the layers and sealed. The upper and lower membrane well layers are connected on opposing sides to rectangular channels of dimensions 9.2 mm in length, 0.36 mm in width, and 0.2 mm in height. Fluid is introduced into the lower rectangular channel to flow up and through membrane and exit through the upper rectangular channel.

Table 1. Chain Transfer Agent Concentration, Molecular Weight and Polydispersity Indices for Polymerization Products from Surface Grafting Reactions Used in This Study[a]

reaction	reaction EMP, mM	solution Mn (PDI)	surface Mn (PDI)
1	40 mM	3500 (1.2)	4300 (1.3)
2	13.2 mM	9500 (1.2)	8400 (1.3)
3	13.2 mM	11200 (1.2)	9000 (1.2)

[a] Solution and surface-derived polymers were analyzed by GPC. All polymerizations were performed in the presence of EMP-bound membranes, stirred at 60 °C for 18−24 h in DMF with 0.2 g/mL NIPAAm monomer and AIBN initiator equal to 0.2 times the solution EMP concentration.

LCST, the antibody conjugate immunocomplex is returned to the flow stream as the pNIPAAm chains become solvated.

As shown in Scheme 1, pNIPAAm-graft membrane material was prepared in two steps. First, the surface hydroxyl groups on 1.2 μm pore-size Loprodyne membranes were converted to RAFT CTAs using the trithiocarbonate EMP. Second, surface grafts were synthesized by immersing the macro-CTA within a polymerization solution containing additional EMP using previously identified conditions (*41*). For Mn and PDI analysis, the ester bond between the CTA and the membrane surface was hydrolyzed to cleave the grafted polymers from the membrane surface. Cleavage products derived from grafted membranes yielded milligram quantities of a soluble product per 3 cm^2 membrane material. A negative control membrane with no immobilized CTA, included in the polymerization to control for adsorbed or entangled polymer versus a covalent graft, did not yield either a measurable product or a detectable peak as analyzed by gel-permeation chromatography (GPC). By varying solution EMP concentration, molecular weights of the surface and solution polymers could be tuned. Number average molecular weight (Mn) and polydispersity indices (PDI) were analyzed for the different polymerization products (Table 1). Figure 3 shows representative GPC traces of a cleavage product with its corresponding solution polymer product. The peak shape of the surface-derived product was uniform and absent of any higher molecular weight shoulder, indicating it was not likely caused by chain−chain coupling as has been previously reported in RAFT polymerization from surfaces (*23*).

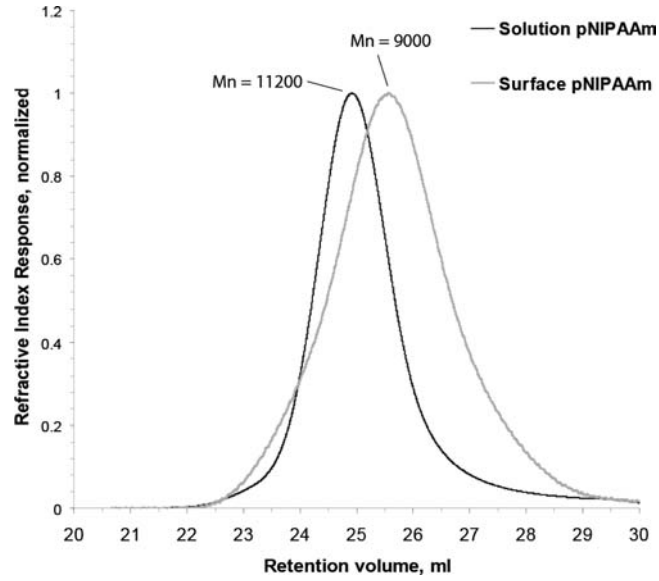

Figure 3. Analysis of grafted poly(*N*-isopropylacrylamide) and solution polymerized poly(*N*-isopropylacrylamide) by gel permeation chromatography. Normalized refractive index responses from the two syntheses are overlaid to show solution (black) and surface-cleaved (gray) polymer retention volumes, and are labeled with the calculated number-average molecular weight (Mn). Samples were derived from the same polymerization reaction containing EMP-bound 1.2 μm nylon-6,6 membranes, monomer, initiator, and solution EMP.

Covalent Antibody Conjugates. Esterification of the carboxyl end of EMP of pNIPAAm with TFP groups resulted in an amine-reactive active ester polymer (Scheme 2). Capture antibodies were reacted with the active ester polymer and the resulting product was purified from unreacted antibody through precipitation. After thermal precipitation of the reaction mixture, the pellet contained between 20% and 30% of the reacted antibody, while mock reactions with carboxyl-terminated pNIPAAm in identical quantities yielded less than 1% of the starting quantity of antibody. Reduction in polymer content after dialysis was confirmed by the decreased absorbance at 307 nm relative to the 280 nm peak, permitting quantification of both protein and polymer concentration when used in conjunction with a derived correction factor for contribution to the absorbance at 280 nm by the trithiocarbonate moiety. However, while dialysis reduced the total polymer content by over 80%, it was not complete enough based on polymer-alone dialysis (data not shown) to permit polymer-per-protein calculations.

Microfluidic Separation Efficiencies of Model Anti-Streptavidin Immunocomplex Conjugate. Fluorescently labeled streptavidin was captured with anti-streptavidin pNIPAAm antibody conjugates at membranes in microfluidic channels under flow of 50 μL per minute (Figure 4). Anti-streptavidin conjugates of pNIPAAm bound fluorescently labeled streptavidin at the membrane under heated conditions while streptavidin in a physical mixture with pNIPAAm flowed through the membrane and exited the channel as indicated by fluorescence of the flowthrough solutions. Membranes (1.2 μm pore) that were either unmodified or modified with 4100 and 8400 dalton pNIPAAm all showed greater than 80% capture efficiency. The 8400 dalton-graft membrane showed the highest release efficiency, with greater than 65% of loaded streptavidin in the first 15 μL and an overall release of approximately 80%. The immunocomplex was released from unmodified membranes much more slowly and less efficiently than from the pNIPAAm-grafted membranes, with only about 40% released in the first 15 μL. Results seen by Ebara et al. also showed slower release of pNIPAAm−streptavidin complexes from unmodified PDMS versus pNIPAAm-graft PDMS (*38*). While it was initially

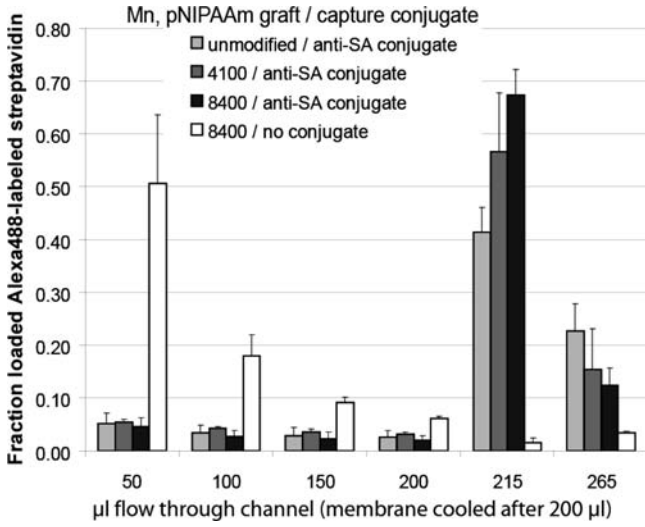

Figure 4. Anti-streptavidin antibody conjugate-bound Alexa 488-labeled streptavidin (SA) captured at membranes during heated flow (50 μL per minute) and released with cooled flow (50 μL per minute). Each 50 μL sample contained 10 nM streptavidin with either no antibody conjugate (white) or 100 nM anti-streptavidin pNIPAAm conjugate (gray to black). Membranes tested were unmodified Loprodyne (light gray), 4100 Mn-graft (medium gray), or 8400 Mn-graft (black and white) pNIPAAm-polymerized Loprodyne. Fluorescence of recovered flow fractions was measured using a plate reader fluorimeter against a standard curve.

hypothesized that the capture of conjugates with the pNIPAAm-grafted membrane would be higher than with the unmodified membrane, general hydrophobic effects and hydrogen bonding to the free amide and hydroxyl groups of the unmodified surface could explain the similar capture efficiencies. Nylon-6,6 has only a moderate affinity for dehydrated pNIPAAm, suggesting that the surface hydroxylation may play a role in the affinity (*13*, *14*). Collapse of pNIPAAm brushes on a surface is dependent on both density and molecular weight, with lower densities and smaller molecular weights exhibiting a noticeably less sharp or absent transition above the LCST (*21*, *22*). To our knowledge, no studies have been published on how such parameters affect the resolubilization of end-grafted chains. The 4100 dalton grafted membranes' release of the anti-streptavidin immunocomplex was not significantly less than that of the higher molecular weight graft membrane. However, in light of the overall trend observed, larger molecular weight graft-membranes were chosen for future work.

Capture and Enrichment of Model Antigen Using the Microfluidic Concentrator. To further test the ability of this system to concentrate antigen at the membrane surface, 100 nM anti-streptavidin conjugate and 10 nM Alexa 488-labeled streptavidin mixture were diluted 50-fold in PBS-T and flowed through heated membranes. The released antibody conjugate and antigen were concentrated approximately 40 times, from 0.2 nM to 8.5 nM in the first 50 μL released (Figure 5). The release efficiency was 84% (total released/total loaded). Evidence of concentration of the direct antibody conjugate is also seen in the reduced flowthrough concentration, indicating retention during capture conditions. The capture of the diluted solution is not expected to be mediated by particle size exclusion by the membrane pores (1.2 μm), since pNIPAAm at the concentration of the diluted solution (11.6 μg/mL) would not be expected to form particles above the nominal pore size of the membranes during the time of the capture phase, even in the absence of the antibody conjugate which would likely favor smaller particles pNIPAAm in solution (*42*). This also highlights a benefit over separation by a thermal precipitation in that much more dilute concentrations of antibody conjugate that would not be able to be separated by thermal precipitation can be efficiently separated using a membrane capture system. The mechanism of capture may be different in that the affinity between the membrane and the polymer is responsible for the capture, whereas it is a critical particle size that is responsible for precipitation in a thermal centrifugation. For the purposes of enrichment and purification of a sample, it is advantageous to reduce the need for adding additional

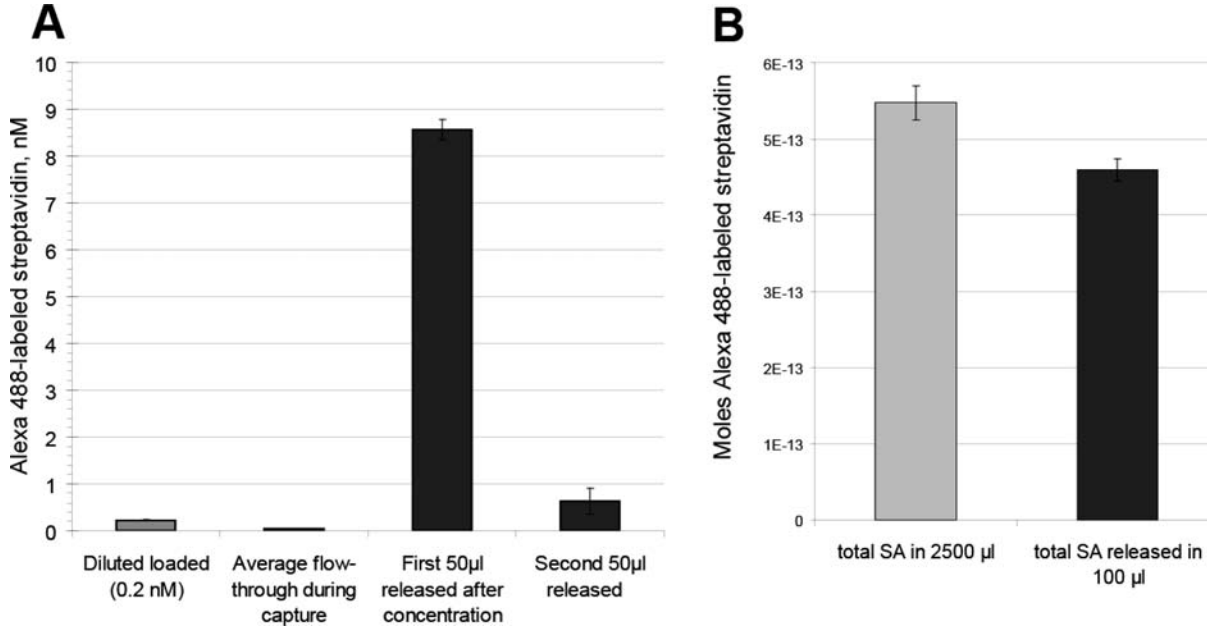

Figure 5. Concentration and enrichment of pNIPAAm-antistreptavidin immunocomplex. Samples containing 100 nM antistreptavidin antibody pNIPAAm conjugate and 10 nM Alexa 488-labeled streptavidin (SA) were diluted 50-fold into PBS-T. The entire diluted sample was flowed (100 μL per minute) through a heated membrane (pNIPAAm-modified membrane, 8400 M_n) and flow-through fractions collected (gray). After the membrane was cooled to 25 °C, 50 μL per minute flow was resumed and two 50 μL release fractions were recovered (black). (A) Concentration (nM) per 50 μL fraction was determined by measurement of fluorescence against a standard curve. (B) Right: total moles streptavidin loaded (light gray) and released (black).

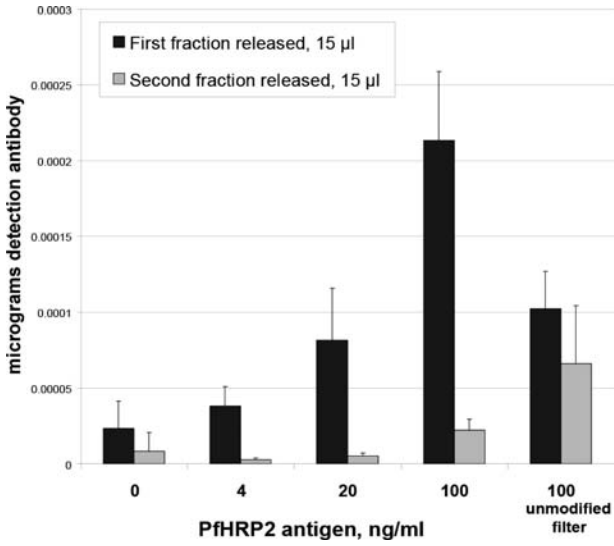

Figure 6. Released quantity of full-stack anti-PfHRP2 immunocomplex was dependent on antigen concentration and membrane modification. Samples containing anti-PfHRP2 antibody conjugate (14 μg/mL, 15 nM), PfHRP2 antigen in plasma (0−100 ng/mL range), and 0.4 μg/mL anti-PfHRP2 detection antibody were captured, washed with 400 μL PBS-T, and released into 15 μL fractions from pNIPAAm-modified membrane (M_n = 9000) or unmodified Loprodyne filter membrane. Total micrograms of peroxidase-conjugated anti-PfHRP2 detection antibody, per precipitated release fraction, was determined by measurement of TMB substrate color development against a standard curve.

polymer since it could change the solubility and viscosity of the final purified species.

Purification and Concentration of Malaria Antigen Sandwich Complex from Spiked Human Plasma. The quantity of released detection antibody was shown to be dependent on the PfHRP2 antigen concentration in the sample (Figure 6). The detection of 20 ng/mL to 100 ng/mL of PfHRP2 antigen from a 50 μL sample is within the relevant range of antigen for patient samples and comparable to the ranges detectable by standard ELISA of plasma samples (*36*). The time for the completed membrane assay was under 10 min of run time, much shorter than required for a standard ELISA, which typically consumes about 4.5 h. While the concentration of antibody−pNIPAAm conjugate used in these experiments was higher than would typically be used in a standard ELISA, this quantity could likely be reduced to a concentration similar to that used in ELISA, given the high binding affinity of the IgM antibody. The presence of pNIPAAm membrane modification resulted again in sharper release kinetics as compared to the unmodified filter membrane. Due to the concentrating capabilities of the method in this work, we expect that it may be possible to increase detection of low levels of antigen from larger plasma volumes, levels which are typically undetectable by rapid diagnostic methods and challenging as well to detect by ELISA. Data for rapid tests in terms of ng/mL concentrations of PfHRP2 antigen are not currently available. This prevents us from making any direct comparison to existing rapid assay technologies. Most literature surrounding rapid tests is expressed in parasitemia levels, which cannot be consistently correlated with PfHRP2 concentration since parasite stage and infection time would impact this number in addition to the parasite density (*43*). Future work is planned to test the performance of this system against existing malaria rapid diagnostic tests. Other candidate antigens, such as pan-*Plasmodium* lactate dehydrogenase and aldolase, may also be added for a multiplexed assay (*6*).

CONCLUSIONS

A system of stimuli-sensitive antibody conjugates and porous grafted membranes was developed for the purpose of separating and concentrating immunocomplexes within a microfluidic channel. A TFP-ester of pNIPAAm provides a facile method for conjugating pNIPAAm to amine groups on an antibody to yield phase-transition reagents suitable for capture and release of antigen. The RAFT-mediated pNIPAAm modification of a porous membrane surface results in a sharp immunocomplex release profile. We have shown this method to be capable of high-percentage capture and release of two antigens, and the ability to concentrate from dilute solutions. Full stack detection immunocomplex sandwiches identical to those used in ELISA for detection of PfHRP2 malaria antigen were separated from 50% human plasma samples. This technology has a wide range of applications for enrichment of target from samples, but can also be applied to sample preconditioning to remove specific unwanted elements from complex mixtures, such as IgG from IgM-based assays, without further diluting the sample. We have demonstrated concentration of antigen and full-stack immunocomplexes from human plasma, providing opportunities to concentrate dilute biomarkers and to expand detection ranges in microfluidic immunoassays.

China, and Department of Pharmaceutics, Utrecht Institute for Pharmaceutical Science (UIPS), Utrecht University, P.O. Box 80082, 3508 TB, Utrecht, The Netherlands. Received April 21, 2010; Revised Manuscript Received July 5, 2010

Novel reducible disulfide-containing cross-linked polyethylenimines (PEI-SS-CLs) were synthesized via click chemistry and evaluated as nonviral gene delivery vectors. First, about four azide pendant groups were introduced into a low-molecular-weight (LMW) PEI (1.8 kDa) to get an azide-terminated PEI. Then, click reaction between a disulfide-containing dialkyne cross-linker and the azide functionalized LMW PEI resulted in a high-molecular-weight disulfide-containing cross-linked PEI composed of LMW constitute via a reducible cross-linker. The synthesized polymers were characterized by ^{1}H NMR, FTIR, and size-exclusion chromatography (SEC). It was shown that the obtained disulfide-containing cross-linked PEIs were able to condense plasmid DNA into positively charged nanoparticles. The degradation of the disulfide cross-linked polymers PEI-SS-CLs induced by DTT was confirmed by a gel retardation assay and SEC analysis. In vitro experiments revealed that the reducible PEI-SS-CLs were less cytotoxic and more effective in gene transfection (in both the presence and absence of serum) than the control nondegradable 25-kDa PEI. This study demonstrates that a reducibly degradable cationic polymer composed of LMW PEI cross-linked via a disulfide-containing linker possesses both higher gene transfection efficiency and lower cytotoxicity than PEI (25 kDa). These polymers are therefore attractive candidates for further in vivo evaluations.

INTRODUCTION

Gene therapy is a promising approach to treat human genetic and acquired diseases. The key to the success of gene therapy is the availability of safe and efficient vector systems (*1, 2*). Cationic polymers, such as poly(L-lysine) (*3*), chitosan and its derivatives (*4, 5*), poly(2-(dimethylamino)ethyl methacrylate) (pDMAEMA) (*6*−*8*), and poly(ethylene imine) (PEI) (*9*), have been widely explored as nonviral gene vectors. Among them, PEI has been regarded as the "gold" standard showing relatively high transfection efficiency, particularly in vitro, due to the proton sponge effect (*10, 11*). Although transfection efficiency of PEI-based complexes increases with PEI molecular weight (*12*), cytotoxicity of PEI also simultaneously increases. High-molecular-weight (HMW) PEIs, such as 25 kDa PEI, not only are highly effective in gene transfection, but also exhibit significant cytotoxicity. Low molecular weight (LMW) PEIs, such as 1.8 kDa PEI, are less cytotoxic but less efficient (*12, 13*).

To deal with this dilemma between transfection efficiency and cytotoxicity, biodegradable cationic polymers have been designed with either hydrolytically degradable ester groups (*8, 14*) or reducibly degradable disulfide linkages (*15*−*19*). It is expected that these polymers complexed with plasmid DNA can be degraded into less toxic low-molecular-weight structures after cellular uptake, by which the polymers lose their DNA binding capacity resulting in DNA release inside target cells. Generally, ester linkages have a pH-dependent hydrolysis with half-life time of hours to days. In contrast, disulfide linkages have been shown to be stable in blood circulation (*20*), and their degradation is rapid (minutes to hours) in the presence of reductive 1,4-dithio-DL-threitol (DTT) or glutathione (GSH) mimicking the reductive intracellular environment (*20, 21*). Therefore, the introduction of disulfide bridges in the polymer main chain (*22*−*26*) or in the cross-links of polymers (*27, 28*) has been investigated for the design of polymeric gene delivery vectors (*8*). Gopferich et al. (*29*) recently published an excellent review on the redox-sensitive, disulfide-based carriers for delivery of nucleic acids. Lee et al. (*27*) first synthesized reducible PEI derivatives using 0.8 kDa PEI reacting with homobifunctional cross-linking reagents, dithiobis(succinimidylpropionate) (DSP), or dimethyl-3,3′-dithiobis-propionimidate-2HCl (DTBP). The resulting polymers showed higher transfection efficiency compared to the parent 0.8 kDa PEI and reached transfection levels close to that of 25 kDa PEI. In a similar way, 1.8 kDa PEIs cross-linked with DTBP were able to condense DNA, and the formed polyplexes were sensitive to the GSH with significantly low cytotoxicity (*30*). Also, 5-kDa PEIs cross-linked with DSP formed stable complexes with DNA which could be destabilized by a redox trigger (*31*). Kloeckner et al. (*32*) studied a library of 37 soluble polycations synthesized by oligomerization of LMW oligoamines with different cross-linkers. They concluded that the polyplexes based on 0.8 kDa PEIs cross-linked with DSP or DTBP showed negligible toxicity and efficient reporter gene transfection at high N/P ratios. Goepferich et al. (*33*) described that linear PEIs with molecular weight of 2.6, 3.1, or 4.6 kDa cross-linked with DSP or boc-cystine resulted in branched structures. Using seven different cell lines, they showed a high transfection efficiency (about 60%) and a high

Scheme 1. Synthetic Route Towards Reducible Disulfide-Contained PEI Derivatives (PEI-SS-CLs)

cell viability (>90%) of polyplexes based on the reversibly cross-linked linear PEI polymers, which was better than seven commercial transfection reagents including SuperFect, Lipofectamine, and JetPEI. It was also reported (*34*−*36*) that the disulfide cross-linked PEI derivatives using LMW PEI and DSP were highly effective as gene delivery vectors and hardly showed cytotoxicity. However, the cross-linking reaction between PEI and DSP (or DTBP) can easily lead to the formation of microgels resulting in poorly controlled molecular weight and a low yield (*35*). Peng et al. (*15*) used methylthiirane reacting with low-molecular-weight PEI to get thiolated PEIs (PEI-SHx), which were cross-linked into higher-molecular-weight PEI by oxidation of the thiol groups avoiding significantly changing the acid−base property of the PEI. However, no reducible degradation was obviously observed. They claimed that the majority of disulfide cross-links are intramolecular when the thiolation degree is high.

Recently, "click" chemistry has rapidly become a very popular method for polymer synthesis and modification due to the high selectivity and high fidelity (*8*, *37*, *38*). However, no papers using click chemistry for PEI cross-linking have been published so far. In this study, a new strategy for synthesis of disulfide cross-linked polyethylenimine (PEI-SS-CL) via click reaction is investigated, as depicted in Scheme 1. First, a LMW PEI (1.8 kDa), which has low transfection efficiency and low cytotoxicity, was modified with azide pendant groups. Then, this azide-functional PEI was reacted with disulfide-containing dialkyne cross-linker through click chemistry to obtain a reducible PEI derivative with high molecular weight. Click chemistry allows easy coupling of poly(ethylene glycol) (PEG) shielding, targeting ligands and fluorescent groups into the polyplexes for further in vivo evaluation. This paper describes the synthesis and reduction-triggered degradation of the disulfide-containing cross-linked PEI polymers and the gene transfection activities of the corresponding polyplexes.

EXPERIMENTAL PROCEDURES

Materials. Branched polyethylenimine (PEI) with molecular weight of 1.8 kDa was purchased from Alfa Aesar, and branched PEI (25 kDa) was from Sigma-Aldrich. 1,1′-Carbonyldiimidazole (CDI) (Shanghai Medpep Co., Ltd., China), propargyl alcohol (Wuhan FengFan Chemical Co., Ltd., China), cystamine dihydrochloride (Jiangsu Jintan Medicine Chemical Factory, Jiangsu, China), 1,4-dithio-DL-threitol (DTT, Shanghai Regal Biotechnology Company, China), and 3-bromopropanol (Shanghai Zhuo Rui Chemical Co., China) were used as received. *N*,*N*′-Dimethylformamide (DMF) was obtained from Shanghai Chemical Reagent Co., China, and used after distillation under reduced pressure. Plasmid pcDNA3-Luc in TE buffer with concentration of 5.0 mg/mL was from Plasmid Factory, Germany. Plasmid pEGFP encoding a red-shifted variant of wild-type green

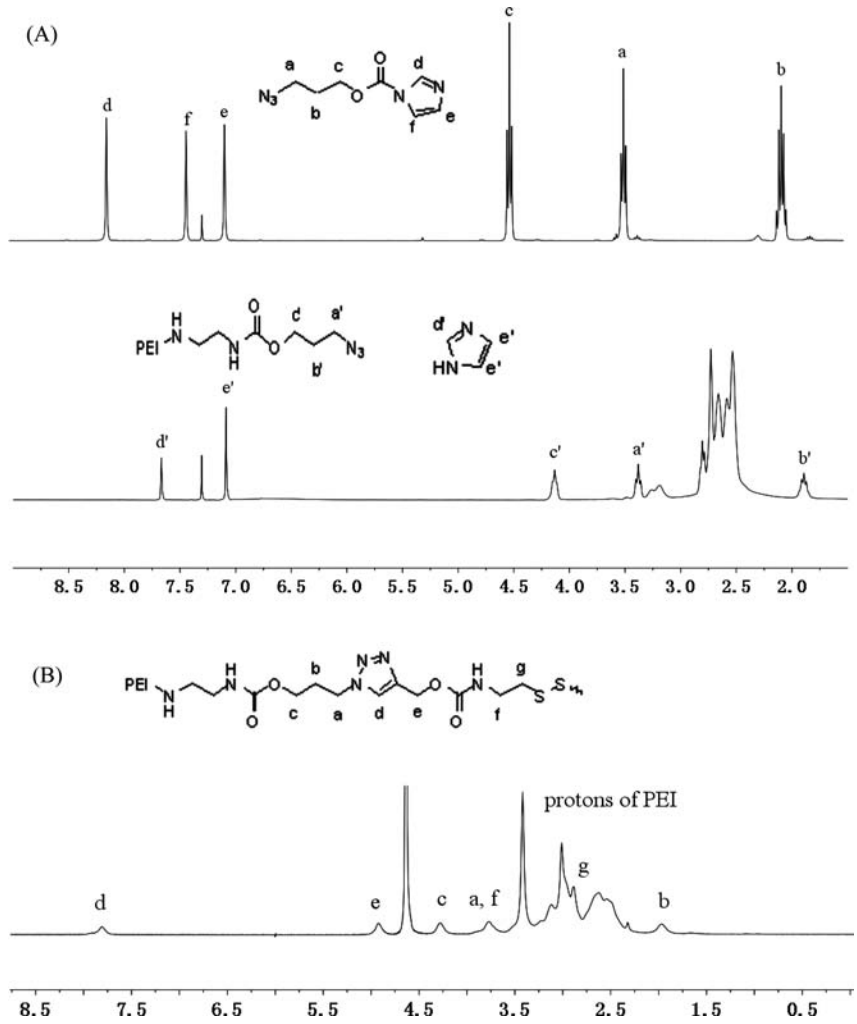

Figure 1. (A) ^{1}H NMR spectra of AP-CI and PEI-$(N_3)_4$ (with imidazole) in $CDCl_3$. (B) ^{1}H NMR spectra of PEI-SS-CL1 in D_2O.

fluorescent protein (GFP) was purchased from Clontech, Mountain View, CA, USA, and was transformed in *E. coli* DH5α and propagated in Luria−Bertani (LB) medium at 37 °C overnight. Then, the plasmids were purified by means of EndoFree plasmid purification as described previously (*39*). The purified plasmids were diluted with TE buffer solution and stored at −20 °C. The purity and concentration of plasmids were determined by ultraviolet (UV) absorbance at 260 and 280 nm. All other chemicals were analytical grade and used as received.

Synthesis of Disulfide-Containing Cross-Linked Polyethylenimine (PEI-SS-CL). *Synthesis of Bis[(Propargyl Carbamate)-Ethyl] Disulfide (BPPA-Cyst,* **2***).* Propargyl ester of carbonylimidazole (PPA-CI, **1**) was synthesized from 1,1′-carbonyldiimidazole (CDI) and propargyl alcohol (PPA) as described previously (**8**). Cystamine dihydrochloride was neutralized by 4 M NaOH and extracted with dichloromethane to yield cystamine. Then, BPPA-Cyst was synthesized from PPA-CI with the cystamine, as shown in Scheme 1. Briefly, cystamine (4.40 g, 28.52 mmol) and PPA-CI (6.93 g, 46.2 mmol) were dissolved in 50 mL dichloromethane and subsequently stirred at room temperature for 24 h. After evaporation of dichloromethane, 100 mL of 1.0 M NaH_2PO_4 (pH 4.0) was added. This aqueous solution was extracted with ethyl ether (40 mL, 3 times) to obtain, after evaporation of the solvent, BPPA-Cyst with a yield of 80.2%. ^{1}H NMR in $CDCl_3$ (Supporting Information Figure SI1): δ (ppm) 2.48 (s, 2H, ***CH***≡C), 2.82 (t, 4H, S-***CH***$_2$-C), 3.51 (app. quartet, 4H, NH-***CH***$_2$-C), 4.69(s, 4H, O-***CH***$_2$-C≡C), 5.31(s, 2H, ***NH***-C═O). IR analysis of the resulting product showed an absorption peak at 2126 cm^{-1} corresponding to the alkyne group (see Supporting Information Figure SI2, IR spectrum: 3293, 3061, 2943, 2126 ($\nu_{C\equiv C}$), and 1709 cm^{-1}).

Synthesis of 3-Azidopropyl Ester of Carbonylimidazole (AP-CI, **3***).* 3-Azidopropanol was synthesized according to the literature (*40*) with some modification. Briefly, 3-bromopropanol (3.01 g, 21.65 mmol) and sodium azide (5.62 g, 86.46 mmol) were dissolved in a mixture of 25 mL water and 10 mL acetone, stirred under reflux for 24 h in an oil bath of about 80 °C. After evaporation of acetone, the product was extracted with dichloromethane (25 mL, 3 times). The organic layer was dried over anhydrous magnesium sulfate, filtered, and evaporated to obtain colorless oil with a yield of 87.6%. ^{1}H NMR ($DCCl_3$): δ (ppm) 1.80 (app. quint, 2H, C-***CH***$_2$-C), 3.41 (t, 2H, ***CH***$_2$-N_3), 3.70 (t, 2H, **C*H*$_2$**-O).

AP-CI (**3**) was synthesized from the obtained 3-azidopropanol with carbonyldiimidazole (CDI). Briefly, a dry, round-bottomed flask was charged with CDI (4.80 g, 29.60 mmol) and 40 mL dichloromethane yielding a suspension. Next, 3-azidopropanol (1.50 g, 12.40 mmol) was added dropwise under vigorous stirring while the reaction mixture turned into a clear solution. After 4 h reaction at room temperature, the solution was washed three times with water. The organic layer was dried over anhydrous magnesium sulfate, filtered, and evaporated to obtain colorless oil with a yield of 74.3%. ^{1}H NMR in $CDCl_3$ as shown in Figure 1A: δ (ppm) 2.05 (app. quint, 2H, C-***CH***$_2$-C), 3.47 (t, 2H, N_3-***CH***$_2$), 4.50 (t, 2H, ***CH***$_2$-O), 7.06 (s, 1H, C═***CH***−N═), 7.40 (s, 1H, N−***CH***═C), 8.12 (s, 1H, N−***CH***═N).

Table 1. Characteristics of the Synthesized Disulfide Cross-Linked PEI-SS-CLs

polymers	molar feed ratios of alkyne/azide	yield(%)	M_w (kDa)	PDI
PEI-SS-CL1	1:1	59	9.4	3.12
PEI-SS-CL2	1:2	49	14.2	1.85

*Synthesis of Azide-Terminated PEI [**4**, PEI-$(N_3)_4$].* AP-CI (2.17 g, 11.13 mmol) dissolved in chloroform (20 mL) was slowly dropped (around 2 h) into a solution of 1.8 kDa PEI (5.00 g, 2.78 mmol, 29 mmol of primary amine groups, assuming that the primary amine content of the 1.8 kD PEI is 25% of the total amines (*13*) in chloroform (100 mL). Next, the reaction mixture was refluxed using an oil bath (75 °C) for 10 h. Chloroform was removed by evaporation under reduced pressure yielding a yellow liquid which was subsequently dissolved in $CDCl_3$ and characterized by ^1H NMR. No unreacted AP-CI was detected as shown in Figure 1A. The average number of azide groups per PEI molecule determined by ^1H NMR was close to 4. IR analysis of the resulting product showed an absorption peak at 2099 cm^{-1} corresponding to the asymmetric stretching vibration of the azide group (see Supporting Information Figure SI2, IR spectrum (neat): 2944, 2837, 2933, 2099 (ν_{N3}), and 1700 cm^{-1}).

Synthesis of Disulfide Cross-Linked PEI-SS-CL (5) via Click Reaction. Azide-functional PEI (PEI-$(N_3)_4$, 0.75 g, 1 equiv azide groups) and BPPA-cyst (0.16 or 0.08 g, 1 or 0.5 equiv alkyne groups) were dissolved in DMF, and CuBr (1 equiv) as catalyst was added under a nitrogen atmosphere. The reaction mixture was stirred at 50 °C for 2 days. The resulting solution was purified by dialysis against water (dialysis tube, MWCO 3.5 kDa), and the formed disulfide cross-linked PEI derivatives PEI-SS-CL1 and PEI-SS-CL2 were collected after freeze−drying. The structure of the PEI-SS-CLs was analyzed by ^1H NMR and FTIR. The molecular weights were obtained by size-exclusion chromatography−multiangle light scattering (SEC-MALLS) as described below.

Characterizations. ^1H nuclear magnetic resonance (NMR) spectra were measured with a Varian Unity 300 MHz spectrometer using $CDCl_3$ or D_2O as solvent. Fourier transformed infrared (FTIR) spectra were recorded on a Lambda Bio40 UV−vis spectrometer (Perkin-Elmer). The molecular weights and the molecular weight distributions of the polymers were evaluated by a SEC-MALLS system consisting of a Waters 2690D separations module, a Waters 2414 refractive index detector (RI), and a Wyatt DAWN EOS MALLS detector. Two chromatographic columns (Shodex OHpak SB-803 and SB-802.5, Showa Denko, Japan) with a precolumn (Shodex SB-G) were used in series. A sodium acetate (NaAc) solution was prepared by dissolving a calculated amount of sodium acetate in reverse osmosis water (0.3 M), and the pH was adjusted to 4.4 with acetic acid (*41*). A mixture of 70% 0.3 M NaAc solution, pH 4.4, and 30% acetonitrile was used as the eluent at a flow rate of 0.6 mL/min. The eluent was filtered through a 0.22 μm HPLC filter and degassed prior to use by ultrasound. The data were processed with *Astra* software (Wyatt Technology).

The reductive degradation of the disulfide cross-linked polymer PEI-SS-CL triggered by DTT was evaluated by SEC-MALLS. The polymer PEI-SS-CL (5.0 mg) was dissolved in the mobile phase (0.9 mL) followed by the addition of 0.1 mL DTT in water (1.0 mol/L). After incubation at 37 °C for 2 h, the molecular weight of the degraded polymer was determined by SEC-MALLS.

Cell Culture. Human embryonic kidney transformed (293T) cells and human cervix carcinoma (HeLa) cells were incubated in Dulbecco's Modified Eagle's Medium (DMEM) containing 10% fetal bovine serum (FBS), 100 units/mL penicillin, and 100 ug/mL streptomycin at 37 °C under a humidified atmosphere of 95% air and 5% CO_2.

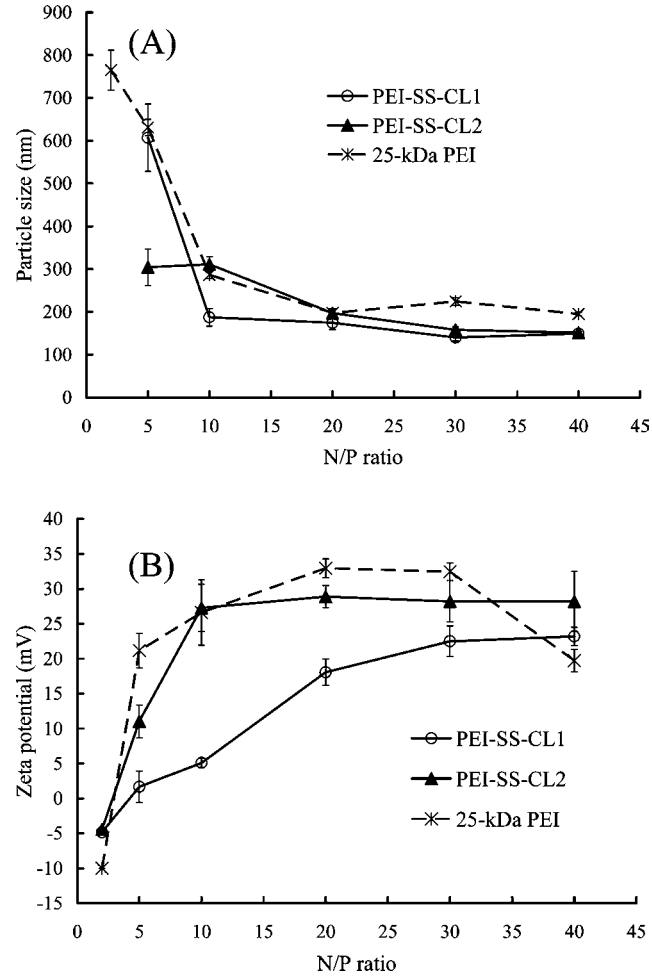

Figure 2. Size by DLS (A) and zeta potential (B) of the PEI/DNA polyplexes at various N/P ratios. Error bars are standard deviations (SD) of 3 measurements.

Cytotoxicity Assay. The cytotoxicity of the different polymers was studied using the MTT assay (*39*) on 293T cells. The cells were seeded into 96-well plates at a density of 3000 cells/well, and 100 μL DMEM containing 10% FBS was added. The cells were allowed to grow at 37 °C under a humidified atmosphere of 95% air and 5% CO_2 for 48 h. Thereafter, the medium was replaced with 100 μL of fresh medium and 100 μL solutions of PEI-SS-CLs, 25 kDa PEI and 1.8 kDa PEI, were added (final polymer concentrations ranging from 0.01 to 0.20 mg/mL). The cells were incubated for 48 h, and the medium containing polymer solution was replaced with 200 μL fresh medium. Next, the MTT reagent (20 μL in PBS, 5 mg/mL) was added to each well for further 4 h incubation at 37 °C. Then, the medium was removed and 100 μL of DMSO was added to dissolve the formed formazan crystals. The absorbance at 570 nm was recorded using a Microplate Reader (BIO-RAD 550). The relative cell viability (mean ± SD, $n = 4$) was calculated as cell viability = $(OD_{sample} - OD_{blank})/(OD_{control} - OD_{blank}) \times 100\%$, where OD_{sample} is the absorbance of solution with cells treated by polymers, $OD_{control}$ is the absorbance for untreated cells (without polymer), and OD_{blank} is the absorbance without cells.

Formation of PEI-SS-CL/DNA Polyplexes and Agarose Gel Retardation Assay. PEI-SS-CL/DNA complexes (N/P ratios ranging from 3 to 9) were prepared by addition of 5 μL polymer solution with designed concentrations in 150 mM NaCl

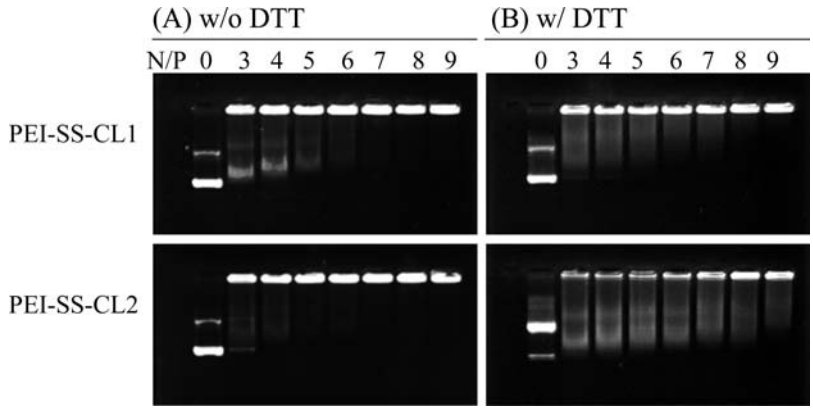

Figure 3. Agarose gel electrophoresis retardation assay of PEI-SS-CLs/DNA complexes at different N/P ratios (A) without DTT and (B) with 10 mM DTT.

(pH 7.4) to 1 μL of pcDNA3-Luc plasmid DNA (100 ng/μL in TE buffer). The resulting polyplex dispersions were incubated at 37 °C for 30 min and were then analyzed by electrophoresis in a 0.7% (w/v) agarose gel containing GelRed and in Tris-acetate (TAE) running buffer at 80 V for 60 min. DNA bands were visualized with a UV (254 nm) illuminator and photographed with a Vilber Lourmat imaging system.

The DTT triggered reductive degradation of PEI-SS-CL based polyplexes was also evaluated by agarose gel electrophoresis. To 1 mL of dispersions of PEI-SS-CL/DNA polyplexes prepared at N/P ratios ranging from 3 to 9, 100 μL of 100 mM DTT in water was added. The polyplexes were incubated at 37 °C for 30 min and were then analyzed by electrophoresis in a 0.7% (w/v) agarose gel containing GelRed and in TAE running buffer at 80 V for 60 min.

Particle Size and ζ-Potential Measurements. Polyplexes were prepared by the addition 90 μL of a PEI solution with designed concentrations (in 150 mM NaCl, pH 7.4) to 10 μL of pcDNA3-Luc plasmid DNA solution (0.1 mg/mL in 40 mM Tris-HCl buffer). The amount of polymer used was calculated on the basis of chosen N/P ratios, nitrogen atoms of the polymer over phosphates of DNA. After the complexes were incubated at 37 °C for 30 min, the polyplex dispersion was diluted with water to 1 mL prior to measurement. Particle size and ζ-potential were measured by Nano-ZS ZEN3600 (Malvern Instruments) at 25 °C.

In Vitro Transfection Activity of Polyplexes. *Luciferase Assay.* Transfection activity of polyplexes based on pcDNA3-Luc plasmid, complexed with PEI-SS-CLs, 25-kDa PEI or 1.8-kDa PEI, was evaluated in 293T and HeLa cells. The cells were seeded at a density of 70 000 cells/well in a 24-well plate. Subsequently, 1 mL of DMEM containing of 10% FBS was added, and the cells were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO_2 for 24 h. Next, the medium in each well was replaced by 0.9 mL of serum-free DMEM. The polymer/DNA polyplexes (100 μL, N/P ratios ranging from 10 to 50) prepared as described above were then added and incubated with cells for 4 h at 37 °C. The medium was replaced by fresh DMEM containing 10% FBS, and the cells were incubated for 48 h. Thereafter, the medium was removed, and the luciferase assay was performed according to manufacturer's protocols. Relative light units (RLUs) were measured with chemiluminometer (Lumat LB9507, EG&G Berthold, Germany). The total protein was measured according to a BCA protein assay kit (Pierce). Luciferase activity was expressed as RLU/mg protein.

Transfection experiments in 293T cells in the presence of serum were carried out. The protocol was the same as described above, except that the cell medium of DMEM with 10% FBS was used instead of the serum-free DMEM medium. All the transfection assays were carried out in triplicate.

Green Fluorescent Protein Assay. Transfection activity of complexes of PEI-SS-CLs with pEGFP plasmid was evaluated in 293T cells. The 293T cells were seeded at a density of 70 000 cells/well in a 24-well plate. Subsequently, 1 mL of DMEM with 10% FBS was added, and the cells were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO_2 for 24 h. Next, the cells were incubated for 4 h at 37 °C, followed by the addition of polyplexes of various N/P ratios prepared as described above. After transfection for 48 h, the cells were directly observed by an inverted microscope (Olympus IX 70). The microscopy images were obtained at the magnification of 100× and recorded using *CoolSNAP-Pro* (v 4.5.1.1) software.

RESULTS AND DISCUSSION

Synthesis and Characterization of Disulfide-Containing PEI-SS-CL. The two-step synthetic route of disulfide cross-linked polyethylenimine (PEI-SS-CL) via click reaction is illustrated in Scheme 1. First, azide pendant groups were introduced into a low-molecular-weight (LMW) PEI (1.8 kDa) to obtain PEI-(N_3)*x*, in which *x* stands for the average number of azide groups per PEI molecule. Second, the azide-functional PEI was reacted in DMF with the disulfide-containing dialkyne cross-linker BPPA-Cyst, through click chemistry with CuBr as catalyst, to obtain a reducible PEI derivative with high molecular weight.

Azide-functionalized LMW PEI was synthesized by coupling of activated azidopropanol, 3-azidopropyl ester of carbonylimidazole (AP-CI, **3**, Scheme 1), to PEI. ^{1}H NMR analysis of the obtained product (Figure 1A) shows the absence of the starting compound AP-CI (comparing the proton NMR spectra of AP-CI and PEI-(N_3)$_4$ in Figure 1A, no peaks at 8.12 (d) and 7.40 ppm (f) for PEI-(N_3)$_4$, the peaks at 4.50 (c), 3.47 (a), and 2.05 ppm (b) in AP-CI shifting to 4.09 (c′), 3.34 (a′), and 1.85 ppm (b′) for PEI-(N_3)$_4$, respectively). Also, imidazole (with one proton peak at 7.66 and two protons at 7.04 ppm) was detected in the resulting product. The IR spectrum of the resulting product shows an absorption peak at 2099 cm^{-1} corresponding to the asymmetric stretching vibration of the azide group (see Supporting Information Figure SI2). From NMR and IR analysis, it is therefore concluded that azide-functionalized PEI has been obtained. The average number of azide groups per PEI molecule (*x* in PEI-(N_3)*x*) was calculated on the basis of the ratio of the integral from 2.30 to 2.90 ppm of the PEI protons to the protons of azidopropanol at 3.34 ppm (2*H*, next to azide group), assuming that the primary amine content of the PEI (1.8 kD) is 25% of the total amines (*13, 27*). ^{1}H NMR analysis shows that *x* in PEI-(N_3)*x* is 4.1 when the AP-CI/PEI molar feed ratio was

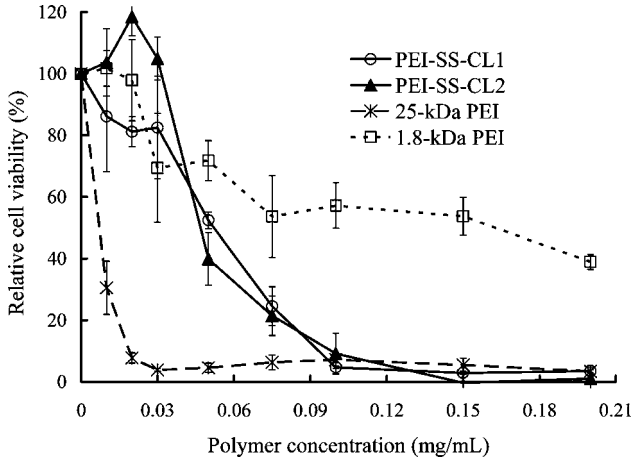

Figure 4. Cytotoxicity of cationic polymers PEI-SS-CLs and controls 1.8 kDa PEI and 25 kDa PEI to 293T cells after 48 h incubation (mean ± SD, $n = 4$).

Table 2. IC_{50} Values of PEI-SS-CLs, 1.8 kDa PEI and 25 kDa PEI

polymers	PEI-SS-CL1	PEI-SS-CL2	1.8-kDa PEI	25-kDa PEI
IC_{50} (μg/mL)	52	47	162	6

4, which indicates that AP-CI had reacted quantitatively with PEI. Because of the quantitative conversion, the reaction mixture only contains PEI-$(N_3)x$, imidazole, and solvent; no further purification was required for the next click reaction after evaporation removal of the solvent, chloroform.

The azide-functionalized LMW PEI-$(N_3)_4$ was cross-linked with disulfide-containing dialkyne BPPA-Cyst by click reaction in DMF at 50 °C for 48 h, using CuBr as catalyst, to obtain reducible HMW PEI derivative, PEI-SS-CL. Two disulfide cross-linked PEIs, named PEI-SS-CL1 and PEI-SS-CL2, were obtained with molar feed ratios of alkyne/azide of 1:1 and 1:2, respectively. Both polymers are water-soluble, which indicates that the cross-linking reactions between dialkynes and azide groups only take place within a definite number of LMW PEI molecules. However, with increasing cross-linking ratio (molar feed ratio alkyne/azide 1:0.75), microgels were formed. The soluble polymers, PEI-SS-CL1 and PEI-SS-CL2, were further investigated as gene vectors.

The structures of these soluble polymers were investigated by ^{1}H NMR and FTIR analysis. The ^{1}H NMR spectrum of PEI-SS-CL1 is shown in Figure 1B, from which it can be seen that a new peak appeared at 7.8 ppm (*H* of the triazole ring) indicating the formation of triazole groups by click reaction. The absorption peaks at 2099 cm^{-1} and 2126 cm^{-1} in the IR spectrum for polymer PEI-SS-CL1 are very weak (Supporting Information Figure SI2), which indicates that the azide groups reacted almost quantitatively with the alkyne groups.

The molecular weights and molecular weight distributions of the PEI-SS-CLs were determined by SEC-MALLS (Table 1). The weight average molecular weights of PEI-SS-CL1 and PEI-SS-CL2 were about 5 and 7 times that of the starting polymer PEI 1.8 kDa. With all ^{1}H NMR, FTIR, and SEC analysis results taken together, it can be concluded that the click reactions between BPPA-Cyst and PEI-$(N_3)_4$ were successful.

Characterization of PEI-SS-CL-Based Polyplexes. To be effective as gene delivery vectors, cationic polymers must possess the capacity to bind and condense plasmid DNA into nanoparticles which can be taken up by cells. The DNA binding and condensation properties of the starting LMW PEI (1.8 kD), the synthesized disulfide-containing PEI-SS-CLs and the branched PEI (25 kD), were investigated. It was shown by DLS measurements that 1.8 kDa PEI, even at an N/P ratio up to 50, was

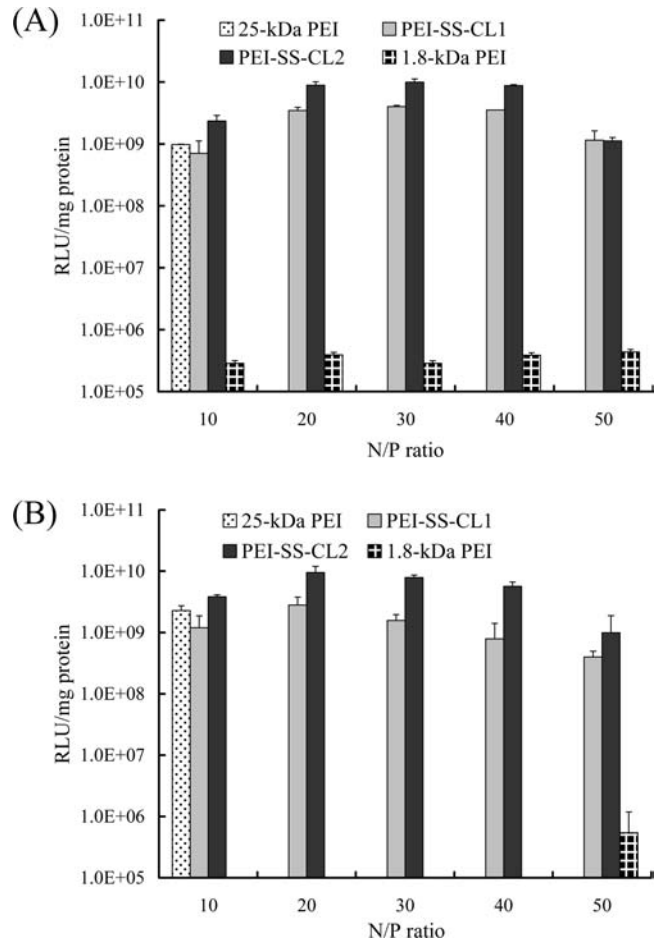

Figure 5. Luciferase expression of the PEI-SS-CL/DNA polyplexes at different N/P ratios with control 1.8 kDa PEI and 25 kDa PEI (at N/P ratio of 10) in serum-free DMEM in 293T (A) and HeLa cells (B).

unable to condense DNA. Importantly, at N/P ratios above 10, the two disulfide-containing PEI-SS-CLs prepared from the 1.8 kDa PEI were able to condense DNA into small particles with size of around 200 nm and a positive zeta potential of approximately +20 mV, similar to the 25 kDa PEI (Figure 2).

The gel retardation assay further confirmed that the two disulfide-containing PEI-SS-CLs can bind plasmid DNA efficiently and retard DNA migration at N/P ratios above 7 (Figure 3). In agreement with DLS analysis, 1.8 kDa PEI was unable to bind DNA even at an N/P ratio up to 50 (data not shown).

Reductive Degradation of the PEI-SS-CL. The DTT-induced degradation of the disulfide cross-linked PEI-SS-CLs was investigated using the agarose gel retardation assay and SEC analysis. The SEC traces of PEI-SS-CL1 and PEI-SS-CL2 in the absence and presence of DTT (Supporting Information Figure SI3) clearly show that the disulfide cross-linked polymers PEI-SS-CLs were responsive to the reductive agent DTT. After incubation with DTT for 2 h at room temperature, the weight average molecular weight of PEI-SS-CL1 decreased from 9.4 kDa (molecular weight distribution was 3.1) to 2.1 kDa (molecular weight distribution was 3.3), which is very close to M_w of PEI (1.8 kDa). Agarose gel electrophoresis (Figure 3B) shows the presence of free DNA in PEI-SS-CL/DNA polyplexes incubated with 10 mM DTT (30 min), which indicates that in a reductive environment PEI-SS-CL1 polyplexes released DNA.

In Vitro Cytotoxicity. The MTT assay for 293T cells was carried out to determine the cytotoxicity of disulfide-containing PEI-SS-CLs; 1.8 kDa PEI and 25 kDa PEI were used as controls. Figure 4 shows that the PEI-SS-CLs had a lower cytotoxicity than 25k Da PEI. The half inhibitory concentrations (IC_{50}) of

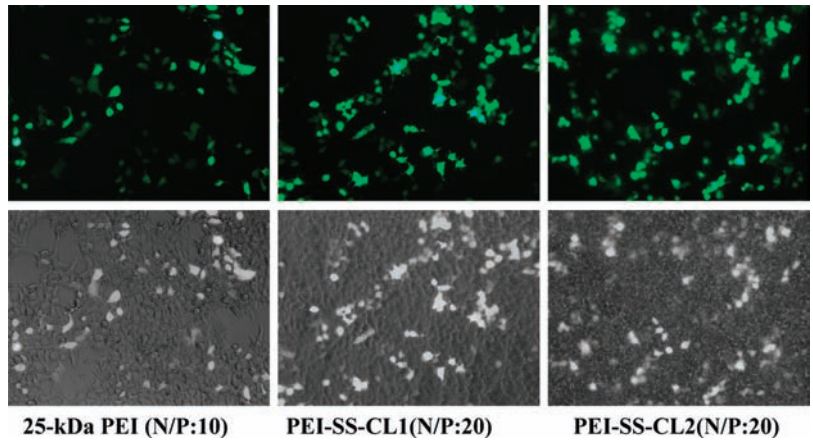

Figure 6. Fluorescent and bright-field images of enhanced green fluorescent protein expression in 293T cells for PEI-SS-CL based polyplexes (N/P ratio 20) with control 25 kDa PEI (N/P ratio 10). The images were obtained at magnification of 100×.

the polymers are summarized in Table 2 and are 52 (PEI-SS-CL1) and 47 μg/mL (PEI-SS-CL2), about 8−10× higher than that of 25 kDa PEI (6 μg/mL). The low cytocompatibility of HMW PEI is probably due to its high binding and aggregation on the cell surface and internalization, which results in significant necrosis (*13*). The low cytotoxicity of disulfide cross-linked PEI-SS-CLs indicates that, after cellular binding and internalization, they are intercellularly degraded, triggered by gluthatione, into relatively low-toxicity products.

In Vitro Transfection. The transfection activity of PEI-SS-CLs based polyplexes was evaluated in 293T and HeLa cells using the plasmid pcDNA3-Luc (expressing luciferase) and pEGFP (expressing green fluorescence) as reporter genes. Branched 25 kDa PEI and 1.8 kDa PEI, which were used for preparation of PEI-SS-CLs, were used as controls.

Figure 5 shows that PEI-SS-CL polyplexes had significantly higher transfection activity in both 293T and HeLa cells than those based on 1.8 kDa PEI. Also, incubation of cells with the PEI-SS-CL2 polyplexes resulted in about 5−10× higher luciferase expression in HeLa and in 293T cells, respectively, than polyplexes based on 25 kDa PEI, although the molecular weight of PEI-SS-CL2 is lower than that of branched PEI (25 kDa). The reason may be that PEI-SS-CLs polyplexes are degraded through cleavage of disulfide bonds inside the cells into nontoxic small PEI; DNA would be released selectively inside the cells to mediate efficient gene transfection (*15*, *25*, *27*). The transfection activity of the PEI-SS-CL2 polyplexes was higher than those of PEI-SS-CL1 at all N/P ratios studied, which can probably be ascribed to higher molecular weight of PEI-SS-CL2 .

The outstanding transfection activity of PEI-SS-CL polyplexes was visualized with a fluorescent microscope (Figure 6). The cells incubated with PEI-SS-CLs and 25-kDa PEI polyplexes showed many intracellular bright green fluorescent spots. As shown in Figure 6, substantial more fluorescent spots were observed using PEI-SS-CL1 and PEI-SS-CL2 polyplexes prepared at an N/P ratio of 20 than those based on 25-kDa PEI, which is in line with transfection data using the luciferase assay.

The transfection ability of the polyplexes of the disulfide cross-linked PEI-SS-CLs with plasmid pcDNA3-Luc in the presence of serum (10% FBS) was also investigated using 293T cells. As shown in Figure 7, the transfection efficiencies in 293T cells of the two PEI-SS-CL/DNA polyplex formulations were higher than that of the 25 kDa PEI based polyplexes in DMEM medium with 10% FBS. Especially, the PEI-SS-CL2 based polyplexes at an N/P ratio of 40 showed about an 8-fold increase in luciferase reporter gene expression compared to the control 25 kDa PEI polyplexes. This is in agreement with the reports

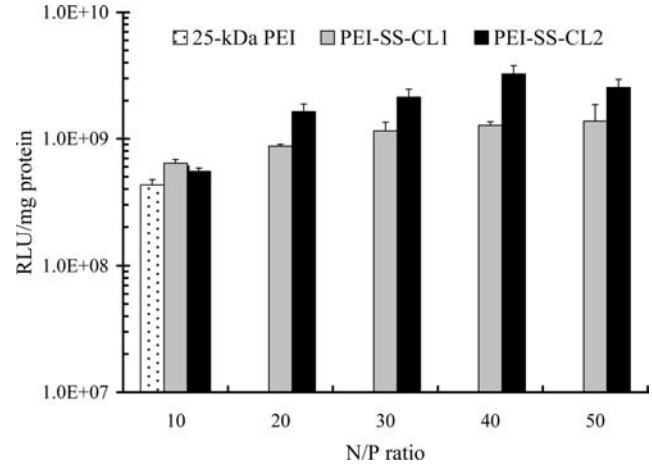

Figure 7. Luciferase expression of PEI-SS-CL/DNA polyplexes at different N/P ratios with control 25 kDa PEI (at N/P ratio of 10) in the presence of 10% FBS in 293T cells.

that the network poly(amino ester) (*42*, *43*) and disulfide cross-linked PEI (*15*) based polyplexes showed very high transfection efficiency even in the presence of serum. One possible explanation is that the cross-linked polymers have outer shells with a large proportion of the groups exposed at the surface, which may facilitate multiple simultaneous interactions with the nucleic aid phosphates and fairly maintain the stability of polymer/DNA polyplexes in the presence of serum. The other possible reason might be the introduction of reducibly cleavable disulfide bonds. Thus, importantly, the polyplexes remain active in the presence of serum proteins, which encourages further in vivo evaluation.

CONCLUSIONS

The disulfide-containing cross-linked polyethylenimine derivatives (PEI-SS-CL1 and PEI-SS-CL2) were synthesized via click reaction between disulfide-containing dialkyne cross-linker BPPA-Cyst and azide-functionalized LMW PEI. The synthesized polymers were characterized by ^{1}H NMR, FTIR, and SEC. The DNA binding and condensation properties of PEI-SS-CL were investigated for the complexes at various N/P ratios by DLS, zeta potential, and agarose gel retardation assay. We showed that the disulfide-containing PEI-SS-CLs were able to bind plasmid DNA efficiently to yield small polyplexes. The degradation of the PEI-SS-CLs in the presence of DTT was confirmed by gel retardation assay and SEC analysis. In vitro experiments demonstrated that the reducible PEI-SS-CLs not

only had much lower cytotoxicity, but also posed superior transfection activity (in both the presence and absence of serum) as compared to the control nondegradable 25 kDa PEI. Our results imply that the obtained disulfide cross-linked PEI-SS-CLs might be suitable for further in vivo gene transfection. Future work will focus on coupling of poly(ethylene glycol) (PEG) shielding, targeting ligands and fluorescent groups in the polyplexes for further in vivo evaluation.

Collections of chemical compounds, individually attached to unique DNA fragments serving as amplifiable identification bar codes, are generally referred to as "DNA-encoded chemical libraries". Such libraries can be used for the de novo isolation of binding molecules against target proteins of interest. Here, we describe the synthesis and use of a DNA-encoded library based on benzamidine analogues, which allowed the isolation of a trypsin inhibitor with an IC_{50} value of 3.0 nM, thus representing a >10 000-fold potency improvement compared to the parental compound. The novel trypsin inhibitor displayed an excellent selectivity toward other serine proteases. This study indicates that DNA-encoded libraries can be used for the facile "affinity maturation" of suboptimal binding compounds, thus facilitating drug development.

INTRODUCTION

The isolation of potent enzyme inhibitors is a frequent challenge in medicinal chemistry. Ligands with high binding affinity and specificity to a target enzyme typically allow the administration of low drug doses and minimize the risk of non-target-related side effects. The medicinal chemical optimization of lead compounds frequently improves drug potency by several orders of magnitude (*1*), but often requires the synthesis and screening of hundreds of synthetic derivatives. In order to facilitate the synthesis and screening of chemical libraries, the tagging of individual compounds with DNA fragments serving as amplifiable identification bar codes has been proposed (*2*−*18*). Indeed, both DNA-encoded chemical libraries displaying a single molecule on DNA ("single-pharmacophore" chemical libraries) (*13*−*18*) and libraries with a molecule at the extremity of duplex-forming complementary strands ("dual-pharmacophore" chemical libraries) (*6*−*12*) can be used. While the de novo isolation of binders from DNA-encoded chemical libraries represent a valuable tool for drug discovery, most frequently the pharmaceutical industry needs efficient methods for the improvement of lead compounds, a procedure often termed "affinity maturation". Trypsin is a good model to test chemical strategies for the development of inhibitors, since the function of the enzyme is very well understood at the molecular level (*19*, *20*) and proteases are a class of important pharmaceutical targets (*21*). Dual pharmacophore chemical libraries have previously been used for the improvement of benzamidine-based trypsin inhibitors (*11*). However, no affinity maturation procedures have so far been reported for single pharmacophore chemical libraries, which in principle should more rapidly yield molecules with the desired properties, as they do not require the optimization of linkers, joining the two individual binding fragments (*11*).

In this work, we describe the synthesis and use of a single pharmacophore DNA-encoded affinity maturation library based on benzamidine, from which we isolated a trypsin inhibitor with an IC_{50} value of 3.0 nM, thus representing a >10 000-fold potency improvement compared to benzamidine.

MATERIALS AND METHODS

Synthesis of BAM8000 compounds: The 8000 members of the BAM8000 library were synthesized in two-step "split and pool" amide-forming reactions. Initially, 40 Fmoc-protected amino acids containing a benzamidine moiety were chemically coupled to 5′-amino-modified 45-mer oligonucleotides following activation of the carboxylic acid in 70% (v/v) DMSO/water, with *N*-hydroxysulfosuccinimide, *N*-ethyl-*N*′-(3-dimethylaminopropyl)-carbodiimide and subsequent addition of aqueous triethylamine hydrochloride solution buffer, pH 10.0. The oligonucleotides had general structures: 5′-GGA GCT TGT GAA TTC TGG XXX XXX XXX GGA CGT GTG TGA ATT GTC-3′, where XXX XXX XXX unambiguously identifies the individual Fmoc-protected amino acid compound. All coupling reactions were stirred overnight at 30 °C. Subsequently, the reactions were quenched and simultaneously Fmoc deprotected by addition of piperidine in DMSO. The reactions were then purified by HPLC, and the desired fractions were dried under reduced pressure, redissolved in water and analyzed by LC-ESI-MS. Typical coupling yields were >39% overall. 4.0 nmol aliquots of each DNA−compound conjugate were pooled to generate a 40 member DNA encoded sublibrary. In the following split and pool step, the oligonucleotide sublibrary pool was aliquoted in 200 reaction vessels and an amide-forming reaction with a distinct amino reactive building block was performed following a very similar procedure as reported above (see Supporting Information). The identity of the compound used for the coupling reactions was encoded by annealing unique 44-mer oligonucleotides with general structure 5′-GTA GTC GGA TCC GAC CAC XXXX XXXX GAC AAT TCA CAC ACG TCC-3′ (where XXXX XXXX unambiguously identifies the individual carboxylic acid compound), partially complementary to the first oligonucleotide carrying the chemical

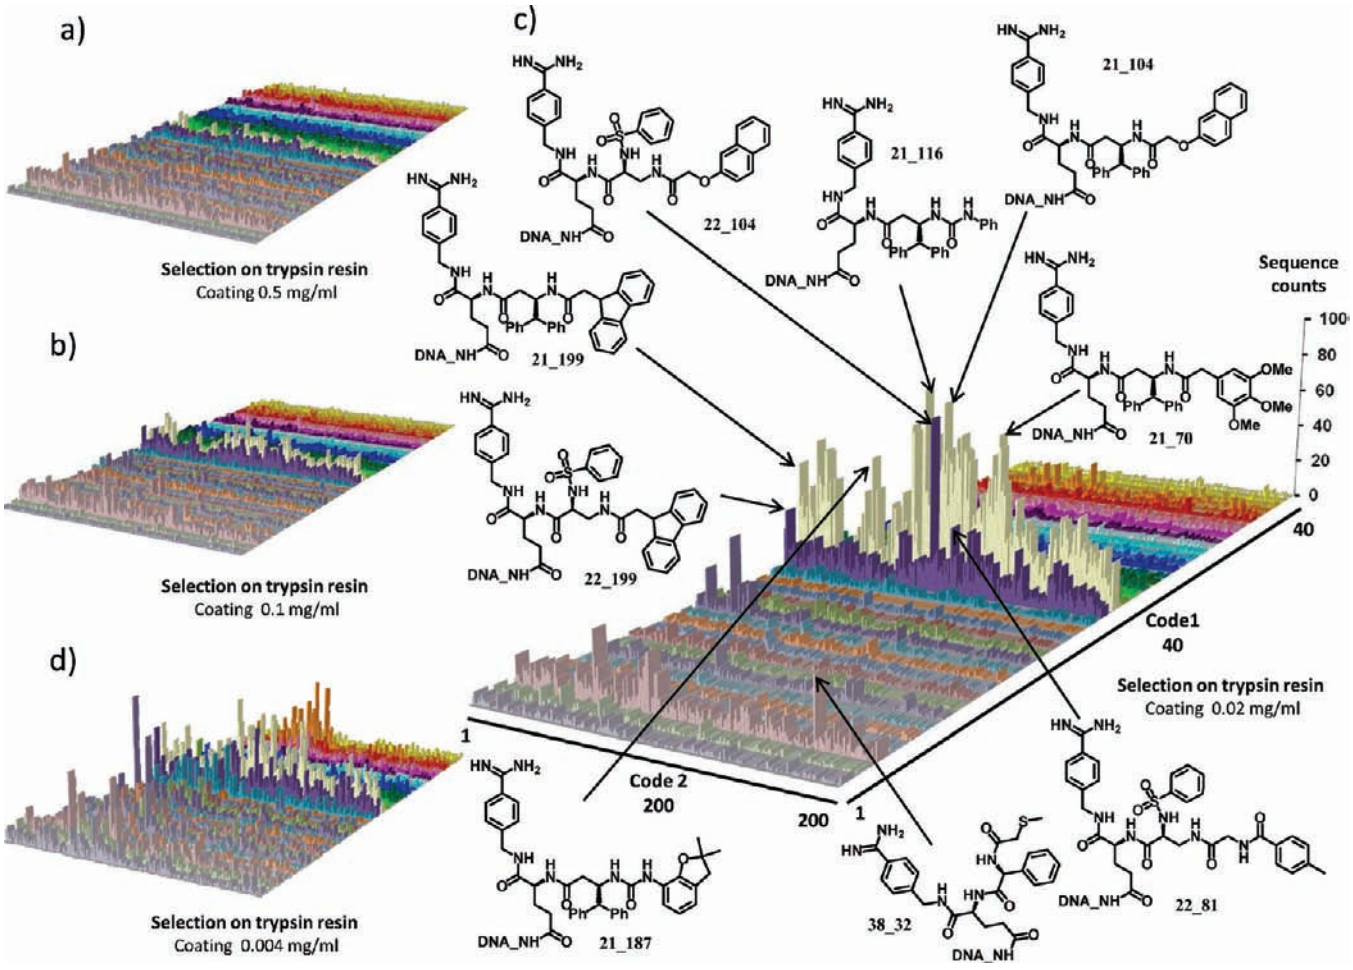
Scheme 1. Synthesis and Encoding of the BAM8000 Library[a]

[a] Initially, 40 different Fmoc-protected amino acids, containing a benzamidine moiety, were coupled to unique oligonucleotide derivatives, carrying a primary amino group at the 5′ extremity and a 9 base pair coding region. Subsequently, the oligonucleotide conjugates were pooled and coupled to 200 amino reactive building blocks (carboxylic acid, isocyanate, sulfonyl chloride, or cyclic anhydrides) in parallel reactions. The identity of each building block was encoded by means of a Klenow polymerization step, using a set of partially complementary oligonucleotides. The procedure resulted in an 8000-member library (BAM8000), in which each chemical compound was covalently attached to a double-stranded DNA fragment, containing two coding domains which unambiguously identify the compound's structure (i.e., the two chemical moieties used for compound synthesis).

modification, and subsequently incubated with Klenow polymerase at 37 °C for 1 h. After purification on chromatographic cartridges, the 200 purified reactions were dissolved in 100 μL of water each and pooled to generate the 8000 member library (BAM8000) to a final total oligonucleotide concentration of 300 nM. Details of the synthesis, analytics, and structures of the 40 Fmoc-protected amino acids as well as the structures of the 200 amino-reactive building blocks used can be found in the Supporting Information online.

Selection and decoding experiments: 50 μL of the library BAM8000 (20 nM, total oligonucleotide concentration) was added either to 50 μL trypsin−sepharose slurry (coating density as detailed in the text) or to sepharose slurry without trypsin. Both resins were preincubated with PBS and 0.3 mg/mL herring sperm DNA. After incubation for 1 h at 25 °C, the beads were washed 4 times with 400 μL PBS (20 mM NaH_2PO_4, 30 mM Na_2HPO_4, 100 mM NaCl), and used as template for PCR amplification of the selected codes. The PCR primers had the following structure: DEL_P1_A (5′-GCC TCC CTC GCG CCA TCA GGG AGC TTG TGA ATT CTG G-3′) and DEL_P2_B (5′-GCC TTG CCA GCC CGC TCA GGT AGT CGG ATC CGA CCA C-3′). The primers additionally contain at one extremity a 19 bp domain (underlined) required for high-throughput sequencing with the 454 Genome Sequencer system. The PCR products were purified with chromatographic cartridges. Subsequent high-throughput sequencing was performed on a 454 Life Sciences-Roche FLX Sequencer platform. Analyses of the codes from high-throughput sequencing were performed by an in-house program written in C++. The frequency of each code has been assigned to each individual oligonucleotide conjugate.

Synthesis of the binding molecules: In a polypropylene syringe, either 65 mg (30 μmol) of H-Gln-2-Chlorotrityl resin (Novabiochem, cat. no 04−12−2806) or 100 mg (30 μmol) of H-Ala-2-Chlorotrityl resin (Novabiochem, cat. no 04−12−2802) was suspended in a mixture of the appropriate Fmoc-protected amino acid (60 μmol, 1 mL), HBTU (120 μmol, 1 mL), and *N*,*N*-diisopropylethylamine (240 μmol, 0.5 mL) in dry DMF. After overnight incubation at 25 °C, the resin was washed 6 times with 2 mL dry DMF, and the fmoc moiety was removed by addition of 1 mL piperidine (50% in dry DMF) for 1 h at 25 °C. After washing 6 times with 2 mL dry DMF, the corresponding compound (60 μmol, 1 mL DMF) was added, and a further amide bond formation reaction was performed either as described above (carboxylic acid compounds) or by adding DIEA (Fluka, 240 μmol, 0.5 mL) in dry DMF (sulfonyl chloride and isocyanate compounds) for 6 h at rt. The resulting product was cleaved from the resin by treating the resin 5 times with 2 mL TFA (2% in CH_2Cl_2). The methylene chloride fractions were washed 3 times with water, dried on Na_2SO_4, and concentrated in vacuo. The crude carboxylic acid product was suspended in DMF (200 μL) and a solution of *N*-hydroxysulfosuccinimide



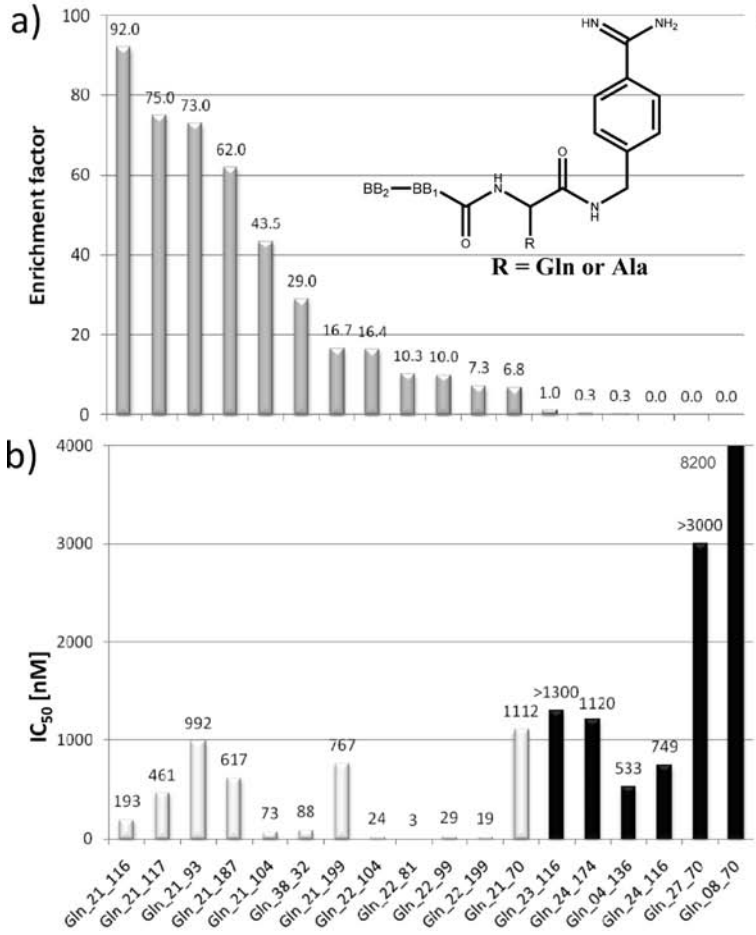


Figure 1. Plots representing the frequency (i.e., sequence counts) of the 8000 library members after selection on 4 different trypsin resins, as revealed by high-throughput 454 sequencing (*19*). The four panels are ordered from top to bottom according to decreasing protein coating density (a,b,c,d). The chemical structures of some of the most relevant trypsin binders are indicated, together with the identification number.

(36 μmol, 333 mM DMF/water, 2:1 v/v) and *N*-ethyl-*N*′-(3-dimethylaminopropyl)-carbodiimide hydrochloride (33 μmol, 100 mM DMF) was added. After 1 h at rt, 4-(aminomethyl-)benzimidamide dihydrochloride (30 μmol, ABCR, cat. no AB169853) and DIEA (180 μmol) were added. Following overnight incubation at 25 °C, HPLC purification was performed on a Synergy Prep RP18 column (5 μm, 10 × 150 mm) using a linear gradient from 20% to 100% MeCN 0.1% TFA, the desired fractions were collected and lyophilized. ESI-MS analysis confirmed the expected mass of the products. Details of the analytics can be found in the Supporting Information online.

Trypsin inhibition assay: Bovine pancreatic trypsin (1 nM) in PBS (20 mM NaH_2PO_4, 30 mM Na_2HPO_4, 100 mM NaCl [pH 7.4], containing 10% DMSO) was incubated with different concentrations of inhibitors in 384-well microtiter plates (Greiner) for 30 min at room temperature. The reaction was started by the addition of the fluorogenic substrate Z-GGR-AMC (Bachem, Bubendorf, Switzerland) dissolved in PBS and 10% DMSO to an end concentration of 0.1 mM in a total volume of 100 μL. The change of fluorescence signal (ex: 383 nm; em: 455 nm; cutoff filter: 420 nm) was recorded over 10 min using a SpectraMax microplate reader (Molecular Devices). The rate of fluorescence signal increase over time (reaction velocity v) was plotted against the corresponding inhibitor concentrations, and the IC_{50} value for the inhibitor was obtained by fitting with equation $v = a \times 0.5 \times \{-([Io] - [Eo] + IC_{50}) + [([Io] - [Eo] + IC_{50})^2 - 4 \times [Io] \times [Eo]]^{1/2}\}$; [Io] = inhibitor concentration; [Eo] = enzyme concentration = 1 nM, using the *Kaleidagraph* software package (Synergy Software, USA).

RESULTS

We have constructed a library of 8000 DNA-tagged benzamidine inhibitors based on the stepwise addition of two building blocks onto a core structure consisting of H-Glu-(4-(aminomethyl)benzamidine)-(4-(aminomethyl)benzamidine) (Scheme 1). This building block was initially coupled to 40 Fmoc-protected amino acids, and for each derivative, the side-chain carboxylic group of glutamate was deprotected and subsequently coupled to individual oligonucleotides carrying a primary amino group at the 5′ extremity. This reaction step allowed the DNA-encoding of the first building block (*13*, *15*, *16*). After Fmoc deprotection and HPLC purification (Supporting Information Table 1), the 40 oligonucleotide conjugates were pooled and split into 200 reaction vessels, where the primary amino group was covalently modified with carboxylic acids, isocyanates, sulfonyl chlorides, or cyclic anhydrides (Scheme 1). At the end of this procedure, which was already known from model reactions on oligonucleotide-tagged amines to proceed with good yields and selectivity (Supporting Information Figure 1), the second building block was encoded by hybridization of partially complementary oligonucleotides carrying an eight-base code (Scheme 1). Double-stranded DNA fragments were obtained using Klenow DNA polymerase, in full analogy to what was previously reported by our group (*13*, *15*, *16*). Fully encoded

Figure 2. Characterization of hits from trypsin selection. (a,b) Correlation of the high-throughput sequencing enrichment factor and trypsin inhibition constant. Individual compounds identified in the trypsin selection at 0.02 mg/mL protein coating density were synthesized as glutamine derivatives and incubated at different concentrations with bovine pancreatic trypsin. The reaction was started by the addition of the fluorogenic substrate Z-GGR-AMC and the change of fluorescence signal was recorded. Inhibition constants were determined by fitting. The 18 compounds are ordered on the *x*-axis from left to right according to their enrichment factor. The enrichment factor was derived by dividing the high-throughput sequencing counts of a specific code after trypsin selection by the counts obtained after selection on empty resin (see Supporting Information Figure 2). (c) Table summarizing the inhibition constants of the 21 synthesized compounds for 4 different serine proteases (trypsin, thrombin, uPA, and FXa). Three of the best trypsin inhibitors were also synthesized as alanine derivatives in order to investigate the contribution of the glutamine linker to the inhibition. The structures of the two building blocks forming the BAM8000 library compounds can be found in Supporting Information Tables 1 and 2, respectively.

library members were purified on chromatographic cartridges, pooled, and aliquoted for library use.

The library of 8000 benzamidine derivatives was panned on sepharose resins covalently modified with a series of concentrations of trypsin (0.5, 0.1, 0.02, 0.004, and 0 mg trypsin per milliliter of CNBr-activated sepharose resin). After extensive washing, the DNA-tags of the library compounds that remained attached to the resins were used as a template for PCR amplification and the resulting amplicon mixtures were characterized by high-throughput DNA sequencing, using 454 technology (*22*) (15242, 15966, 17558, 15488, and 17145 counts, respectively, could be evaluated), in order to assess the relative abundance of individual codes for the library compounds after selection under different conditions (*13*−*16*).

Figure 1 shows that the selection performed on 0.02 mg/mL trypsin coated resin yielded the best discrimination among library compounds. Indeed, it is conceivable that at high coating density all library members may efficiently be captured with the aid of the benzamidine moiety, while at low coating density, overall capture efficiency may be insufficient even for the highest-affinity binders. Similar observations have been previously made in the field of phage display library biopanning (*23*−*28*), as well as in the screening of DNA-encoded chemical libraries (*9*).

For the first building block, moieties **21** and **22** (a diphenylmethyl and a phenylsulfonamide group, respectively) dominated the trypsin selection experiments, while various groups corresponding to the second building block were selected. Representative structures indicating some of the most frequently enriched compounds are displayed in Figure 1.

Figure 2a presents the list of the 12 most enriched compounds (sorted according to their enrichment factor, calculated as a ratio of sequence counts after selection on 0.02 mg/mL resin and after selection on empty resin; see also Supporting Information Figure 2). In addition, 6 non-enriched compounds are also considered for the comparison. The 18 compounds were resynthesized in the absence of DNA as glutamine derivatives (the most similar BAM8000 library format) and were characterized in terms of their 50% inhibitory concentration (IC_{50}) of the catalytic activity of trypsin, using a fluorogenic substrate (*11*). In general, preferentially enriched compounds exhibited better IC_{50} values compared to the nonenriched counterpart (Figure 2b). The correlation between enrichment and potency was not 1:1, as other factors (e.g., reaction yields, nonspecific interactions with the resin support) may contribute to a selection bias (*23*−*25*). However, 6 out of 12 of the preferential binders exhibited an IC_{50} value of <100 nM. Compound **22_81** exhibited the most potent trypsin inhibition, with an IC_{50} value of 3.0

nM. Importantly, the newly discovered trypsin inhibitors were highly selective, as revealed by a comparative analysis of the IC_{50} values of the 18 compounds (plus 3 analogues in which the glutamine moiety was replaced by alanine) against other serine proteases (thrombin, factor Xa, urokinase-type plasminogen activator; Figure 2c). The most potent inhibitor [((*S*)-3-(2-(4-methylbenzamido)acetamido)-2-(phenylsulfonamido)propanamido)-(*S*)-(4-carbamimidoylbenzyl)-glutamamide] displayed a selectivity of >1000-fold for trypsin, compared to the other three serine proteases.

DISCUSSION

Three main lessons could be learned from this affinity-maturation project. First, libraries containing thousands of members could be rapidly synthesized with a "split and pool" approach, which allowed the unambiguous identification and quantification of individual library members with the help of the tagging with distinctive DNA fragments serving as amplifiable identification bar codes. Second, affinity selections were best performed using a variety of experimental conditions (e.g., densities of trypsin coating on resin), in order to identify the best preferential binders and minimize resynthesis work after library selections. Third and most important, a benzamidine lead compound (which displays trypsin IC_{50} values in the 100 μM concentration range; Figure 2c) could be affinity-matured to single-digit nanomolar potency, with an excellent discrimination toward related serine proteases. We anticipate that similar affinity maturation strategies can now be routinely implemented with leads against a variety of targets of pharmaceutical interest.

Supplementary Methods

General: Unless otherwise denoted, chemical compounds and proteins were purchased from Sigma-Aldrich-Fluka (Buchs, Switzerland), resin for solid phase synthesis from Novabiochem (Laufelfingen, Switzerland), enzymes from New England Biolabs (Ipswich, MA, USA) and HPLC grade lyophilized oligonucleotides were from IBA GmbH (Göttingen, Germany). SpinX columns were purchased from Corning Costar Incorporated (Acton, MA, USA) and chromatographic cartridges for DNA purification from Qiagen (Hilden, Germany), (PCR purification cat.no 28104, Nucleotides removal cat.no 28306) and used according to the protocol described by the provider. All HPLC were performed on an XTerra Prep RP_{18} column (5µm, 10x150mm) using a linear gradient from 10% to 40% MeCN in 100 mM TEAA, pH 7. LC-ESI-MS were performed on an XTerra RP_{18} column (5 µm, 4.6x20 mm) using a linear gradient from 0% to 50% MeOH in 400 mM HFIP/5 mM TEA. The mass spectra were measured from *m/z* 900 to 2000 by a Waters Quattro Micro instrument (Waters, Milford, MA, USA).

Oligonucleotide coupling reactions of 40 Fmoc-protected amino acids containing benzamidine moiety: To a reaction volume of 310 µL, containing 70% (v/v) DMSO/water, compounds were added to the respective final concentrations: Fmoc-protected amino acids DMSO solution, 30 mM; *N*-hydroxysulfosuccinimide in DMSO, 10 mM; *N*-ethyl-*N'*-(3-dimethylaminopropyl)-carbodiimide in DMSO, 4 mM; aqueous triethylamine hydrochloride solution, pH 10.0, 80 mM; oligonucleotide aqueous solution, 50 µM, (5'-GGA GCT TGT GAA TTC TGG XXX XXX XXX GGA CGT GTG TGA ATT GTC-3', XXX XXX XXX unambiguously identifies the individual Fmoc-protected amino acid compound). All coupling reactions were stirred overnight at 25 °C; residual activated species were then quenched and simultaneously Fmoc deprotected by addition of piperidine (500 mM in DMSO). Prior to HPLC purification 500 µL of 100 mM TEAA, pH 7.0, was added to the reaction mixture. The reactions were then purified by HPLC and the desired fractions were dried under reduced pressure and redissolved in 100 µL of water and analyzed by LC-ESI-MS. The samples showed the expected benzamidine Fmoc-deprotected conjugated products. Finally, 4.0 nmol of each DNA-compound conjugate were pooled to generate a 40 member DNA encoded sub-library. Typical coupling yields were between 98 % and 15% (average 56%) overall and the recoveries between 22% and 55% (average 20% overall). The structures, the matching oligonucleotide codes and the ESI-MS analysis of the 40

Fmoc-protected amino acids containing benzamidine moiety, together with the LC-MS analysis of the corresponding oligonucleotide conjugates can be found in **Supplementary Table 1**.

Coupling reactions of 200 amino reactive building blocks (carboxylic acid, isocyanate, sulfonyl chloride and cyclic anhydrides),BB2:

Carboxylic acids: To a reaction volume of 310 µL, containing 70%(v/v) DMSO/water, compounds were added to the respective final concentrations: DMSO-dissolved carboxylic acid, 30 mM; *N*-hydroxysulfosuccinimide in DMSO, 10 mM; *N*-ethyl-*N'*-(3-dimethylaminopropyl)-carbodiimide in DMSO, 4 mM; aqueous triethylamine hydrochloride, pH9.0, 80 mM; DNA-oligonucleotide sub-library pool, 1.5 µM. All coupling reactions were stirred overnight at 30 °C; residual activated species were then quenched by addition of 50 µL Tris-Cl buffer, 500 mM pH 10.0. The mixture was allowed to quantitatively precipitate by addition of 40 µL of 3 M sodium acetate buffer, pH 4.7 and 500 µL ethanol followed by 2 h incubation at -23 ºC. The DNA was centrifuged and the resulting oligonucleotide pellet was washed with ice-cold 90% (v/v) ethanol and then dissolved in 100 µL water. Test coupling reactions were also performed with the reaction conditions described above; using model 42mer 5'-Fmoc-deprotected amino acid oligonucleotide conjugates and model carboxylic acids. The reactions were analysed by HPLC and the mass of the reacted oligonucleotides detected by LC-ESI-MS. A typical reaction is reported in **Supplementary Figure 2**. The structure of the 200 compounds used as secondary building block (BB2) and the matching oligonucleotide codes are listed in **Supplementary Table 2**.

Isocyanate, sulfonyl chloride and cyclic anhydrides: To a reaction volume of 500 µL, containing 75%(v/v) DMF/water, compounds were added to the respective final concentrations: DMSO-dissolved carboxylic acid, 10 mM; $NaHCO_3$ 100 mM; DNA-oligonucleotide sub-library pool, 1.5 µM. All coupling reactions were stirred overnight at 30 °C; residual activated species were then quenched by addition of 50 µL Tris-Cl buffer, 500 mM pH 10.0. The mixture was allowed to quantitatively precipitate by addition of 40 µL of 3 M sodium acetate buffer, pH 4.7 and 500 µL ethanol followed by 2 h incubation at -23 ºC. The DNA was centrifuged and the resulting oligonucleotide pellet was washed with ice-cold 90% (v/v) ethanol and then dissolved in 100 µL water. The structure of the 200 compounds used as secondary building block (BB2) and the matching oligonucleotide codes are listed in **Supplementary Table 2**.

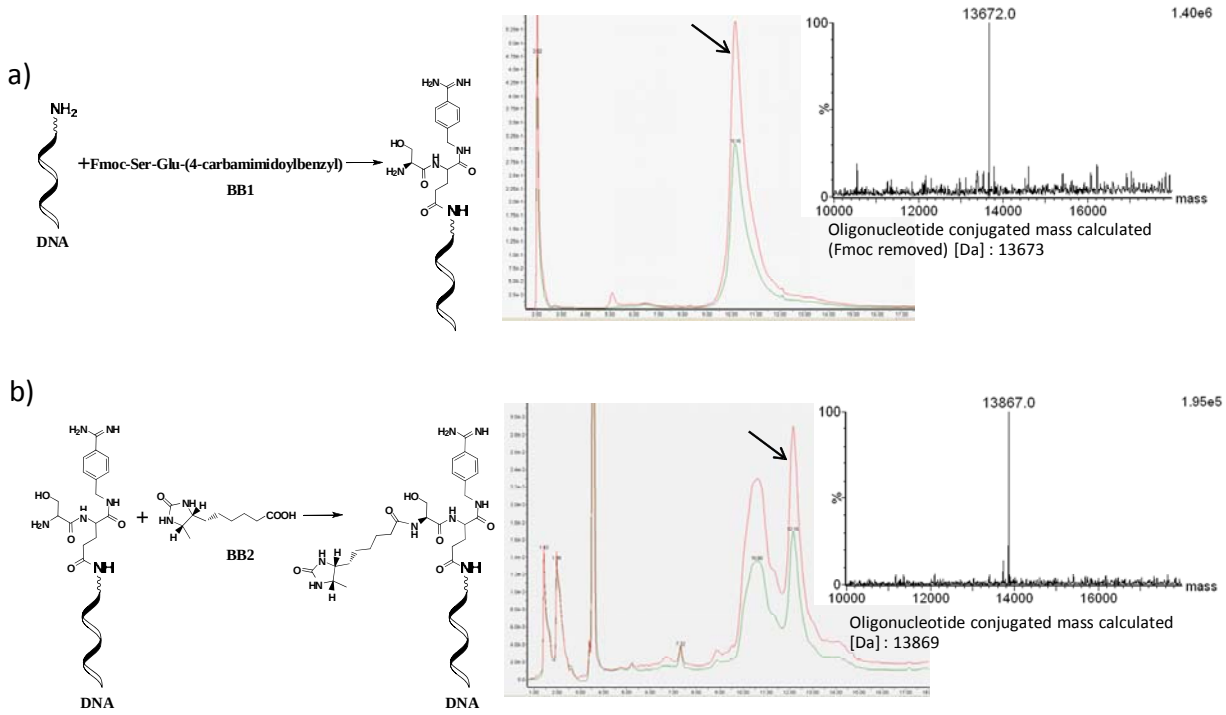
Synthesis of H-Glu(tBu)-(4-(aminomethyl)benzamidine)): To a solution of Fmoc-Glu(tBu)-OH (3.6 mmol, 1.53g, Bachem) in dry DMF (55 mL), *N*-hydroxysuccinimide (4.32 mmol, 500 mg) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (3.96 mmol, 760 mg) were added and the reaction stirred 1h at rt. Subsequently, the mixture was cooled on ice and 4-(aminomethyl)benzimidamide dihydrochloride (3.6 mmol, 800 mg) and *N,N*-diisopropylethylamine (14.4 mmol, 2.52 mL) were added. The reaction was stirred 3 h at 0 °C and then poured in 250 mL of water. The water phase was back extracted with ethylacetate (5 times, 60 mL). The pooled organic phases were washed 3 times with 10 mL of water, dried on Na_2SO_4 and concentrated *in vacuo*. The crude was dissolved in 40 mL dioxane and treated with piperidine (36 mmol, 3.57 mL) for 1h at rt. The mixture was then washed with ethylacetate (3 times, 10 mL) and the water phases concentrated at reduced pressure. The residue was purified by HPLC and the desired fractions were dried under reduced pressure (217 mg, C17H26N4O3 calculated: 334.2; measured: 334.8 [$M+H^+$]).

General synthesis for the 40 initial fmoc protected (4-(aminomethyl)benzamidine)-Glu acid derivatives (BB1): To the opportune fmoc-protected amino acid (36μmol) and *N*-hydroxysuccinimide (43 μmol, 5.0mg) in DMF (1mL), a solution of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (40 μmol, 7.7mg) in DMF (250 μL) was added. After 1h stirring at rt, the mixture was cooled on ice. Subsequently, a solution of H-Glu(tBu)-(4-(aminomethyl)benzamidine)) (36 μmol, 12mg) in DMF (1mL) and *N,N*-diisopropylethylamine (180 μmol, 31 μL) were added. The reaction was stirred over night at 4°C and then evaporated to dryness under reduced pressure. The residue was suspended 2h at rt in TFA/water (90:10, 900 μL) prior to HPLC purification. Structures of the synthesized compounds and ESI-MS characterizations can be found in **Supplementary Table 1**.

Polymerase Klenow encoding of 200 carboxylic acids reactions: To a reaction volume of 50 μL, reagents were added to the respective final concentrations: pool 40 conjugates 320 nM, 44mer oligonucleotide (5'-GTA GTC GGA TCC GAC CAC XXXX XXXX GAC AAT TCA CAC

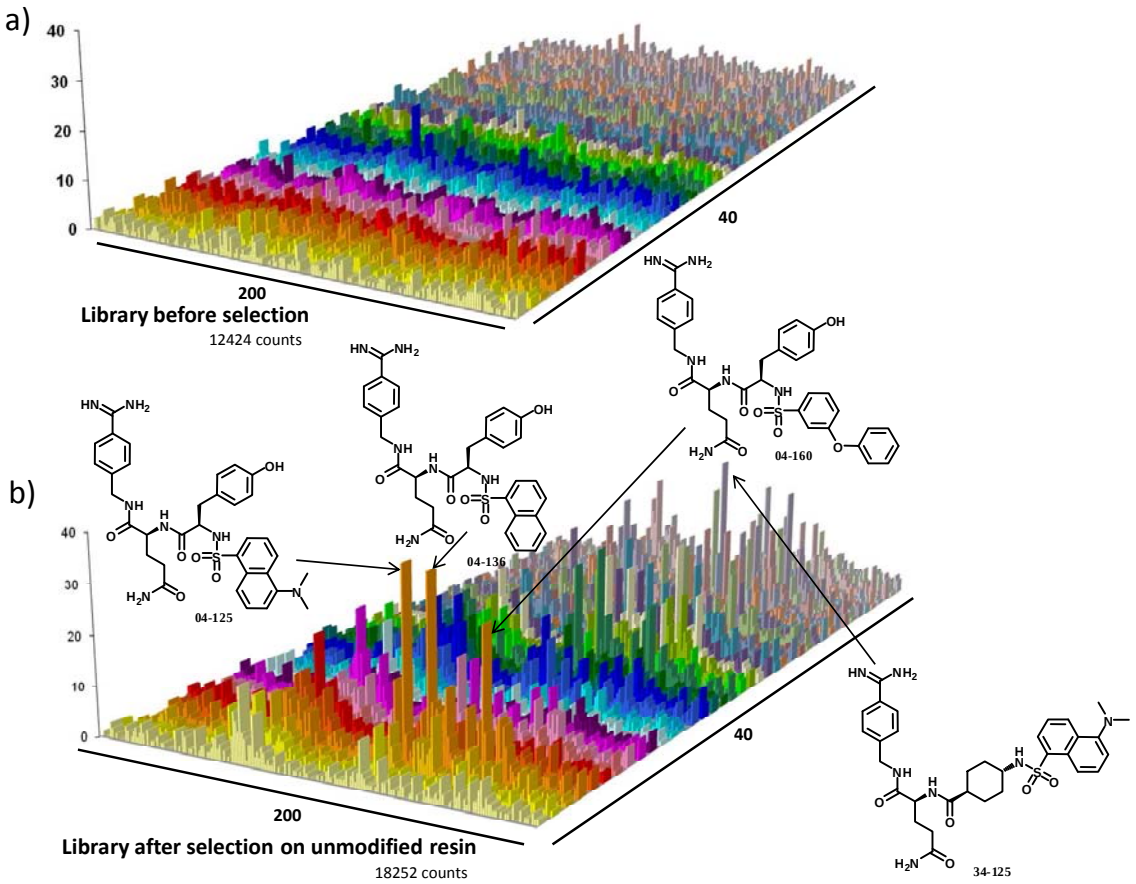
ACG TCC-3', XXXX XXXX unambiguously identifies the individual secondary building block, IBA) 600 nM, Klenow buffer (NEB, cat.no B7002S), dNTPs (Roche, cat.no 11969064001), 0.5 mM, Klenow Polymerase enzyme (NEB, cat.no M0210L), 5 units. The Klenow polymerization reactions were incubated at 37 ºC for 1 h and then purified on chromatographic cartridges (Qiagen, cat.no 28306). The 200 purified reactions were dissolved in 50 µL of water, each, and pooled to generate the 8000 member library (BAM8000) to a final total oligonucleotide concentration of 300 nM.

Trypsin coating of sepharose beads: 100mg CNBr-activated sepharose (GE Healthcare, Piscataway, NJ) was suspended in 1 mM HCl, washed, and mixed in separate tubes with the appropriate amount of pancreatic bovine trypsin (0.5, 0.1, 0.02, 0.004 and 0 mg/ml, Sigma, cat.no T4665) dissolved in 0.1M $NaHCO_{3aq}$ and 0.5 M NaCl. After 5 hours incubation at 4°C, the slurry was repeatedly and alternatively washed with 0.1 M Tris-Cl, 0.5 M NaCl, pH 8.3 and 0.1 M NaOAc, 0.5 M NaCl, pH 4 then stored in PBS (20mM NaH_2PO_4, 30 mM Na_2HPO_4,100 mM NaCl [pH 7.4]) at 4°C.



Library BAM8000 Trypsin Selections The resulting library BAM8000 (total oligonucleotide conjugate concentration 300 nM) was diluted 1:15 in PBS (20mM NaH_2PO_4, 30 mM Na_2HPO_4,100 mM NaCl [pH 7.4], 20nM final concentration). 50 µL of the library was either added to 50 µl pancreatic bovine trypsin slurry (0.5, 0.1, 0.02 and 0.004mg/ml) or to 50 µl sepharose slurry without trypsin resulting in an end concentration of 10 nM of library compounds. The resins were preincubated with PBS, 0.3 mg/mL herring sperm DNA. After incubation for 1 h at 25 ºC the mixture was transferred to a SpinX column, the supernatant was removed, and the resin washed 4 times with 400 µL PBS. After washing, the resins were resuspended in 100 µL water.

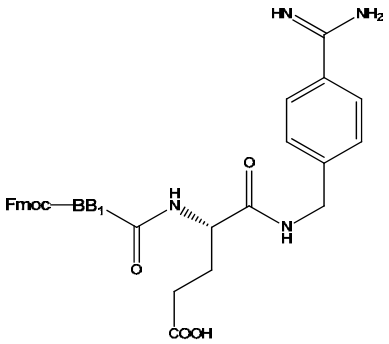
Identification of binding molecules: The codes of the oligonucleotide-compound conjugates were amplified by PCR (total volume 50 µL, 25 cycles of 1 min at 94 ºC, 1 min at 55 ºC, 40 s at 72 ºC) with either 5 µL of 100 fM BAM8000 library before selection as template, or 5 µL of each resuspended resin after selection as template. The PCR primers DEL_P1_A (5'-GCC TCC CTC GCG CCA TCA GGG AGC TTG TGA ATT CTG G-3') and DEL_P2_B (5'-GCC TTG CCA



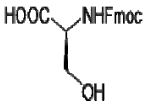
GCC CGC TCA GGT AGT CGG ATC CGA CCA C-3') additionally contain at one extremity a 19 bp domain (underlined) required for high-throughput sequencing with the 454 Genome Sequencer system. The PCR products were purified on chromatographic cartridges. Subsequent high-throughput sequencing was performed on a 454 Life Sciences-Roche FLX Sequencer platform (Sequencing by FGCZ). Analyses of the codes from high-throughput sequencing were performed by an in-house program written in C++. The frequency of each code was assigned to each individual pharmacophore.

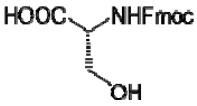
Synthesis of the binding molecules: In a polypropylene syringe, either 50 mg (30 µmol) of H-Gln-ClTrt resin (Novabiochem, cat.no 04-12-2806) or 100 mg (30 µmol) of H-Ala-ClTrt resin (Novabiochem, cat.no 04-12-2803) were suspended in a mixture of the appropriate Fmoc-protected amino acid (60 µmol, 1 mL), HBTU (Aldrich, 120 µmol, 1 mL), and DIEA (Fluka, 240 µmol, 0.5 mL) in dry DMF. After overnight incubation at 25 °C, the resin was washed 6 times with 2 mL dry DMF and the Fmoc moiety was removed by addition of 1 mL piperidine (50% in dry DMF) for 1 h at 25 °C. After washing 6 times with 2 mL dry DMF, the opportune compound (100 µmol, 1 mL DMF) was introduced and a further amide bond formation reaction was performed either as described above (carboxylic acid compounds) or adding DIEA (Fluka, 240 µmol, 0.5 mL) in dry DMF(sulfonyl chloride and isocynate compounds) for 6 hours at rt. The resulting product was cleaved by treating the resin 5 times with 2 mL TFA (2% in CH_2Cl_2). The methylenchloride fractions were evaporated to dryness. The crude product was dissolved in DMF/water (90:10, 500 µL) and a solution of *N*-hydroxysuccinimide (72 µmol, DMF/water = 90:10, 250 µL) and of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (66 µmol, 7.7 µmol) in DMF (250 µL) were subsequently added. After 2h stirring at rt, a solution of 4-(aminomethyl)benzimidamide dihydrochloride (30 µmol) and *N,N*-diisopropylethylamine (240 µmol) in DMF/water (90:10, 500 µL) were added. The pH was adjusted to pH=10 and the mixture incubated over night at rt. Prior to HPLC purification, the reaction was acidified with 250 µL of 2M HCl. The reactions were then purified by HPLC and the desired fractions were dried under reduced pressure. HPLC and ESI-MS analysis confirmed purity and the mass of the expected products (see **Supplementary Table 3**).

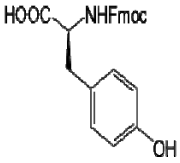
Enzyme inhibition assay: Either bovine pancreatic trypsin (1 nM, Sigma, cat.no T4665) or human plasma thrombin (5nM, Sigma, cat.no T6884) or factor Xa (25nM, Sigma, cat.no F9302 or human urokinase uPA (30nM, Accurate Chemical & Scientific Corporation, cat.no ACLENZ264) in PBS (20mM NaH_2PO_4, 30 mM Na_2HPO_4,100 mM NaCl [pH 7.4]), 5% DMSO) was incubated with different concentrations of inhibitors in 96-well microtiter plates (Greiner non-binding, cat.no 781900) for 30 min at room temperature (for the syntheses, see above). The reaction was started by the addition of the fluorogenic substrate Z-GGR-AMC (Bachem, Bubendorf, Switzerland) dissolved in PBS to an end concentration of 0.1 mM in a total volume of 60 ml. The change of fluorescence signal (ex: 383 nm; 455 nm; cutoff filter: 420 nm) was recorded over 25 min using a SpectraMax microplate reader (Molecular Devices). The rate of fluorescence signal increase over time (reaction velocity v) was plottedagainst the corresponding inhibitor concentrations, and the IC_{50} value for the inhibitor was obtained by fitting with equation v = a*0.5*(-([I_o]- [E_o]+ IC_{50})+sqrt(([I_o]- [E_o]+ IC_{50})^2-4*[I_o]*[E_o])) ; [I_o] = inhibitor concentration; [E_o] = enzyme concentration, using the Kaleidagraph software package (Synergy Software, USA).

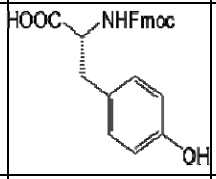


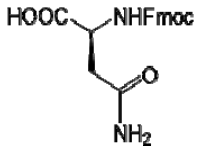
Supplementary figure 1. Typical coupling reactions using a representative 5'-amino-oligonucleotide as well as a primary and secondary building block (BB1 and BB2 respectively) to generate a model compound of the library. The HPLC chromatograms of the reactions show the traces recorded at 260nm (red) and at 280nm (green). In the side panels, the LC-ESI-MS spectrum illustrates the deconvoluted oligonucleotide conjugated masses of the products (indicated by the arrow in the chromatograms). Detailed experimental conditions are reported above in the text. a) Coupling of Fmoc-Ser-Glu-(4-carbamimidoylbenzyl) (BB1) to a representative 5'-amino-oligonucleotide. Retention time: 10.15 min, HPLC yield: 98%. b) Coupling of D-desthiobiotin (BB2) to Ser-Glu-(4-carbamimidoylbenzyl) oligonucleotide conjugated. Retention time: 12.15 min, HPLC yield 40%.

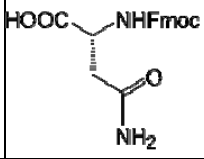


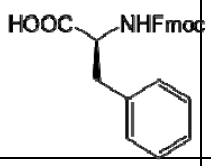


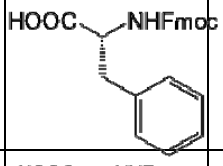


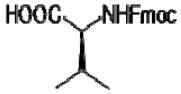


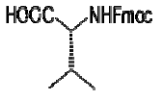


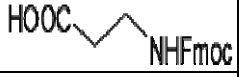


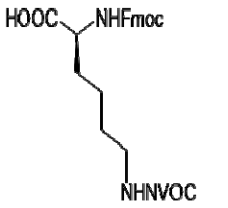


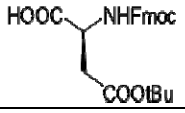


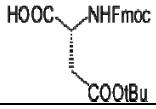


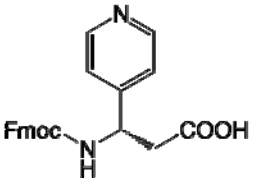


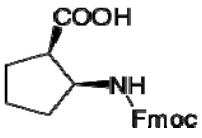


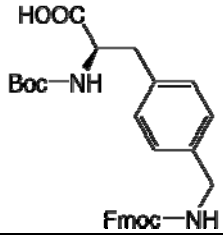


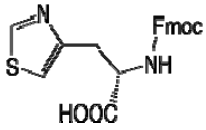




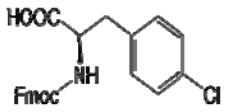


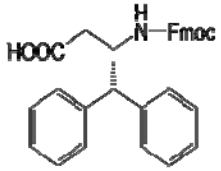


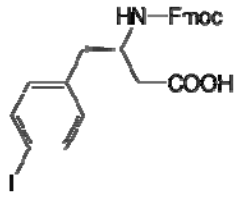


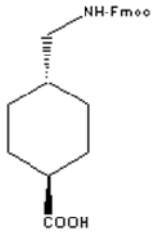


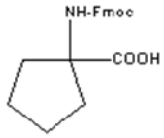
Supplementary figure 2. Plots representing the frequency (i.e., sequence counts) of the 8000 library members before selection (**a**) and after selection on unmodified resin (**b**), as revealed by high-throughput 454 sequencing.

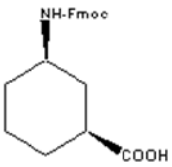




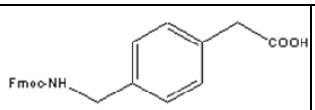


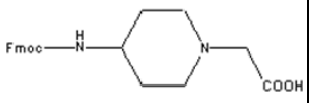


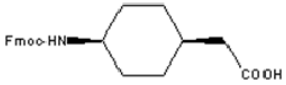


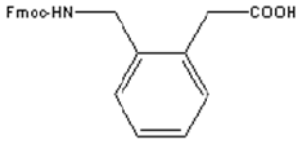


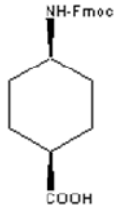
Supplemetary Table 1: The table summarizes the structures, the ESI-MS analysis and the matching oligonucleotide codes of the 40 primary building blocks (BB1) synthesized as Fmoc-protected amino acids containing benzamidine moiety. The table also contains the LC-ESI-MS analysis and the HPLC yields of the corresponding oligonucleotide conjugates used for the BAM8000 library construction.

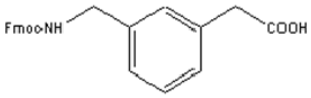


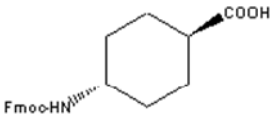


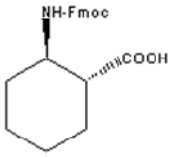


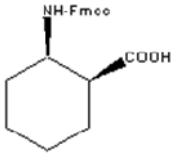


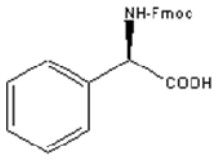


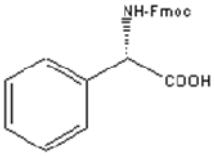


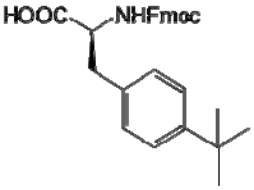


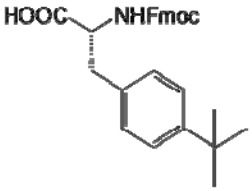












Fmoc-BB_1-Glu-(4-carbamimidoylbenzyl)

Conjugation of Synthetic *N*-Acetyl-Lactosamine to Azide-Containing Proteins Using the Staudinger Ligation

Ravi S. Loka, Christopher M. Sadek, Nikolas A. Romaniuk, and Christopher W. Cairo*

Alberta Ingenuity Centre for Carbohydrate Science, Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2. Received April 28, 2010; Revised Manuscript Received July 1, 2010

Generation of defined glycoconjugates is necessary for the study of glycoprotein function, as well as the development of therapeutics. The biosynthesis of glycoproteins produces multiple glycoforms, proteins which differ only in the structure of the attached glycan. This inherent heterogeneity complicates the study of isolated glycans and, in particular, could obscure the role of individual glycan epitopes in biological function. We present a general strategy based on the Staudinger ligation to introduce specific glycan epitopes onto azide-containing proteins. The use of a phosphane-based Staudinger reagent allows for extremely mild reaction conditions which can be applied to aqueous proteins or cells. We demonstrate that multiple carbohydrate epitopes can be incorporated onto a protein backbone, and that the resulting glycans are competent for recognition by lectins. We propose that this general strategy will allow for testing the role of specific glycan epitopes in cellular and biochemical assays and increasing the stability of protein conjugates.

INTRODUCTION

Post-translational modification can have a dramatic influence on the function and properties of proteins (*1*). The most prevalent post-translational modification found in mammalian cells is glycosylation, whether through O- or N-linkages. Mammalian glycans are known to affect the function and recognition of proteins with roles in cellular adhesion, antigen recognition, and development (*2*). A common difficulty in the study of glycobiology is the heterogeneous nature of glycan structures. Glycoproteins isolated from natural sources are typically a mixture of glycoforms—proteins that differ only in their glycan composition. The presence of glycoforms complicates the interpretation of results from these samples. Therefore, general strategies to produce synthetic glycoconjugates with uniform glycosylation continue to be of interest.

The generation of defined glycoconjugates is critical for enabling the study of glycan function and the development of therapeutics. A variety of approaches have been employed for forming protein glycoconjugates, including amine-cross-linking, native chemical ligation, solid-phase peptide synthesis, unnatural amino acid incorporation, chemoenzymatic synthesis, and chemoselective ligation (*3*–*5*). Chemoselective ligation of glycans presents an appealing approach to the bioconjugate chemist, allowing for the combination of a biologically isolated protein with a synthetic glycan (*3*, *6*, *7*). Strategies which employ chemoselective ligation, therefore, allow the incorporation of either a known homogeneous glycan *en bloc* or the introduction of specific glycan epitopes within an existing glycan. Chemoselective modifications of glycoproteins have been demonstrated using purified glycoproteins, as well as glycoproteins in the membrane of live cells and animals (*7*–*10*).

The ability to modify glycoproteins found within the glycocalyx of living cells presents the opportunity to identify the specific roles of glycan epitopes. Chemoselective modification of cell-surface glycans, referred to as glycoform remodeling, has been used to target specific cells (*11*) and to modify the function of glycoproteins (*12*). Intriguingly, modifications of cell-surface glycans have been used to alter biological responses, inducing immune-targeting and modifying cellular adhesion (*13*, *14*). These findings suggest that chemoselective strategies can form the basis of determining the roles of specific changes in glycosylation within complex biological systems. However, the introduction of complex glycan epitopes onto a protein backbone can be challenging, and chemical methods for the synthesis of glycoproteins continue to be an active area of research (*15*–*17*).

We chose to employ a popular chemoselective strategy, the Staudinger ligation, which forms a covalent linkage between an azide and a phosphane containing an intramolecular electrophilic trap (*8*). The azide component may be introduced semisynthetically (*18*) or through the metabolic incorporation of azide-containing biosynthetic precursors (*7*, *19*). The Staudinger ligation has proven to be a robust labeling chemistry, although alternative reactions that exploit the azide functional group could also be used (*20*). Here, we describe the generation of a series of mono- and disaccharide Staudinger ligation reagents that can be used to modify azide-containing proteins. We develop an efficient route to reagents able to introduce galactose (Gal), lactose (Lac, Gal-β(1,4)-Glc), and *N*-acetyl-lactosamine (LacNAc, Gal-β(1,4)-GlcNAc) glycans. We chose to target LacNAc epitopes, as this unit is part of type 2 lactosamine repeats of N- and O-linked glycans and a component of the Lewis *x* and *y* epitopes (*21*). The resulting glycoconjugates demonstrate that the reaction is efficient and can be used to study the role of specific carbohydrate epitopes within glycoproteins.

EXPERIMENTAL PROCEDURES

General Experimental Methods. Dry solvents (CH_2Cl_2, MeOH, CH_3CN, DMF) were purchased from Sigma Aldrich in capped DriSolv bottles and used without purification and stored under argon. Toluene and pyridine were dried on molecular sieves and stored under desiccated atmosphere. Reactions were conducted under a stream of argon at ambient temperature, unless otherwise noted, and monitored by TLC on silica gel G-25 UV254 (0.25 mm). Developed TLC plates were visualized under UV lamp and charred by heating plates that were dipped in cerium molybdate stain or phosphomolybdic acid stain. NMR

experiments were conducted on Varian 300, 400, or 500 MHz instruments. Chemical shifts are reported relative to the deuterated solvent peak and are in parts per million (ppm). ^{1}H NMR and ^{13}C peak assignments were made on the basis of 2D-NMR such as COSY and HSQC experiments. ESI-MS spectra were carried out on samples suspended in solvent with added NaCl. β-Lactoglobulin was obtained as a mixture of bovine A- and B-isoforms (Sigma-Aldrich) and used without further purification (*22*).

*9H-Fluoren-9-ylmethyl {2-[2-O-(2,3,4,6-Tetra-O-benzoyl-β-D-galactopyranosyl)-2-hydroxyethoxy]ethyl}carbamate (**3**).* Compound **2** (977 mg, 1.32 mmol) was dissolved in 15 mL of DCM and stirred overnight at room temperature with TMSOTf (2.34 mL, 1% in DCM, 0.13 mmol) and 9*H*-fluoren-9-yl[2-(2-hydroxy ethoxy)-ethyl]carbamate **4** (654 mg, 1.98 mmol). The solvent was removed and the product was purified by column chromatography with EtOAc/hexane (1:2) to yield 957 mg (80.1%) of **3** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.09 (d, J = 7.5 Hz, 2H), 8.05−8.01 (m, 2H), 7.98 (dd, J = 8.2, 1.1 Hz, 2H), 7.80 (dd, J = 8.3, 1.2 Hz, 2H), 7.77 (d, J = 7.6 Hz, 2H), 7.68−7.53 (m, 4H), 7.52−7.34 (m, 10H), 7.30 (t, J = 7.4 Hz, 2H), 7.27−7.21 (m, 2H), 6.01 (d, J = 3.4 Hz, 1H), 5.83 (dd, J = 10.4, 7.9 Hz, 1H), 5.65 (dd, J = 10.4, 3.5 Hz, 1H), 5.16 (s, 1H), 4.90 (d, J = 7.9 Hz, 1H), 4.70 (dd, J = 11.3, 6.5 Hz, 1H), 4.52−4.36 (m, 3H), 4.32 (t, J = 6.4 Hz, 1H), 4.23 (t, J = 6.9 Hz, 1H), 4.06 (dt, J = 11.1, 4.1 Hz, 1H), 3.87−3.67 (m, 1H), 3.61 (t, J = 4.1 Hz, 2H), 3.38 (t, J = 4.7 Hz, 2H), 3.29−2.96 (m, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 166.1, 165.6, 165.3, 156.4, 144.0, 141.3, 133.6, 133.4, 133.3, 133.29, 130.0, 129.8, 129.78, 129.7, 129.4, 129.38, 129.0, 128.8, 128.6, 128.5, 128.45, 128.3, 127.7, 127.1, 125.1, 119.9, 101.8, 71.6, 71.4, 70.2, 70.1, 69.8, 69.4, 68.1, 66.6, 62.0, 47.3, 40.8; ESIMS calculated for $C_{53}H_{47}NO_{13}Na$ $[M+Na]^+$ 928.2940, found: 928.2935.

*9H-Fluoren-9-ylmethyl {2-[2-O-(2,3,4,6-Tetra-O-benzoyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-O-benzoyl-β-D-glucopyranosyl)-2-hydroxyethoxy]ethyl}carbamate (**7**).* Compound **6** (403 mg, 0.33 mmol) was dissolved in 10 mL of DCM and stirred overnight at room temperature with TMSOTf (65 μL, 1% in DCM) and 9*H*-fluoren-9-yl[2-(2-hydroxyethoxy)ethyl]carbamate **4** (131 mg, 0.4 mmol). The solvent was removed, and the resulting solid was purified by column chromatography with EtOAc/hexane (1:1) to yield 325 mg (70.3%) of **7** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.99 (dt, J = 11.8, 7.0 Hz, 11H), 7.91 (d, J = 7.3 Hz, 2H), 7.83−7.72 (m, 4H), 7.72−7.53 (m, 6H), 7.48 (t, J = 7.7 Hz, 6H), 7.45−7.27 (m, 15H), 7.22 (t, J = 7.8 Hz, 2H), 7.14 (t, J = 7.7 Hz, 2H), 5.83 (t, J = 9.5 Hz, 1H), 5.74 (m, 2H), 5.50 (dd, J = 9.6, 8.1 Hz, 1H), 5.39 (dd, J = 10.3, 3.3 Hz, 1H), 5.19 (s, 1H), 4.86 (d, J = 7.8 Hz, 1H), 4.76 (d, J = 7.8 Hz, 1H), 4.62 (d, J = 11.4 Hz, 1H), 4.53 (dd, J = 12.1, 4.4 Hz, 1H), 4.47−4.31 (m, 2H), 4.31−4.13 (m, 2H), 4.01−3.78 (m, 3H), 3.78−3.58 (m, 3H), 3.51 (s, 2H), 3.34 (t, J = 4.6 Hz, 2H), 3.12 (t, J = 5.0 Hz, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 165.8, 165.5, 165.4, 165.38, 165.2, 164.8, 156.4, 144.0, 141.3, 133.5, 133.4, 133.3, 133.27, 133.2, 130.0, 129.8, 129.7, 129.6, 129.5, 129.4, 129.35, 128.9, 128.7, 128.6, 128.58, 128.5, 128.4, 128.3, 127.7, 127.1, 125.2, 125.1, 120.0, 101.3, 101.1, 76.1, 73.2, 72.8, 71.83, 71.8, 71.4, 70.2, 69.9, 69.88, 69.4, 67.5, 66.6, 62.4, 61.1, 47.3, 40.8; ESIMS calculated for $C_{80}H_{69}NO_{21}Na$ $[M+Na]^+$ 1402.4254, found: 1402.4256.

*9H-Fluoren-9-ylmethyl {2-[2-O-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl-(1→4)-2-acetamido-3,6-di-O-acetyl-2-deoxy-β-D-glucopyranosyl)-2-hydroxyethoxy]ethyl}carbamate (**10**).* Oxazoline **9** (355 mg, 0.58 mmol) and 9*H*-fluoren-9-yl[2-(2-hydroxyethoxy)ethyl]carbamate **4** (569 mg, 1.74 mmol) were stirred with a catalytic amount of camphor sulfonic acid (CSA) (12 mg) in 12 mL of 1,2-dichloroethane under refluxing conditions (90 °C) for 2.3 h. The reaction mixture was cooled and poured over ice water and then washed successively with aqueous saturated $NaHCO_3$, then water, and then dried over anhydrous Na_2SO_4. The solvent was evaporated under vacuum, and the residue was purified by column chromatography using EtOAc to yield 427 mg (78.0%) of **10** as a yellow solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.77 (d, J = 7.5 Hz, 2H), 7.63 (d, J = 7.3 Hz, 2H), 7.40 (t, J = 7.5 Hz, 2H), 7.31 (tt, J = 7.5, 1.2 Hz, 2H), 5.89 (d, J = 9.0 Hz, 1H), 5.60 (s, 1H), 5.34 (d, J = 2.7 Hz, 1H), 5.11 (dd, J = 10.5, 7.9 Hz, 2H), 4.97 (dd, J = 10.5, 3.5 Hz, 1H), 4.55−4.45 (m, 3H), 4.43 (d, J = 6.9 Hz, 2H), 4.24 (t, J = 6.8 Hz, 1H), 4.13 (dd, J = 11.8, 5.4 Hz, 1H), 4.11−4.00 (m, 3H), 3.94−3.81 (m, 2H), 3.77 (t, J = 8.3 Hz, 1H), 3.69−3.56 (m, 4H), 3.53 (s, 2H), 3.44−3.23 (m, 2H), 2.14 (s, 3H), 2.10 (s, 3H), 2.05 (s, 6H), 2.03 (s, 3H), 1.97 (s, 3H), 1.94 (s, 3H); ^{13}C NMR (126 MHz, $CDCl_3$) δ 170.4, 170.3, 170.1, 170.0, 169.4, 156.8, 144.0, 141.3, 127.7, 127.1, 125.1, 120.0, 100.9, 75.6, 72.7, 72.0, 70.8, 70.7, 70.3, 70.2, 69.1, 68.5, 66.6, 66.57, 62.5, 60.8, 53.0, 50.8, 47.3, 41.1, 23.2, 20.87, 20.8, 20.7, 20.62, 20.6, 20.5; ESIMS calculated for $C_{45}H_{56}N_2O_{20}Na$ $[M+Na]^+$ 967.3319, found: 967.3307.

*Methyl 2-(Diphenylphosphino)-4-[2(2-O-β-D-galactopyranosyl-2-hydroxyethoxy)ethylcarbamoyl]benzoate (**12**).* Deprotection of compound **3** (453 mg, 0.5 mmol) was achieved under Zémplen conditions by stirring in a solution of MeOH (8 mL) with 1% NaOMe/MeOH (5.6 mL) for 4 h. The solvent was removed and a solution of DCM/H_2O (20 mL, 1:1) was added. The water layer was washed with DCM (2 × 10 mL) and lyophilized to yield 111 mg of white solid. The solid (50 mg, 0.19 mmol) was then stirred with succinimidyl-3-diphenylphosphino-4-methoxy-carbonylbenzoate **11** (*23*), (106 mg, 0.23 mmol) and two drops of triethylamine in 5 mL of DMF for 2.3 h at room temperature. The DMF was removed under vacuum, and the crude product was purified by column chromatography (Iatrobeads, Mitsubishi Kagaku Iatron, Inc.) with EtOAc/MeOH (8:2) to yield 76 mg (65%) of **12** as a yellow solid containing a small amount of the corresponding phosphine oxide. ^{1}H NMR (500 MHz, CD_3OD) δ 8.04 (dd, J = 8.0, 3.6 Hz, 1H), 7.81 (dd, J = 8.0, 1.7 Hz, 1H), 7.44 (dd, J = 3.9, 1.7 Hz, 1H), 7.39−7.31 (m, 6H), 7.26 (m, 4H), 4.24 (d, J = 7.6 Hz, 1H), 3.98 (dt, J = 10.8, 4.2 Hz, 1H), 3.81 (t, J = 3.2 Hz, 1H), 3.78−3.68 (m, 4H), 3.67 (s, 3H), 3.66−3.61 (m, 3H), 3.59 (t, J = 5.5 Hz, 2H), 3.54−3.40 (m, 7H); phosphine oxide δ 8.13 (dt, J = 8.0, 1.5 Hz, 0.2H), 7.97 (m, 0.8H), 7.70−7.59 (m, 1.3H), 7.58−7.50 (m, 0.9H); ^{13}C NMR (125 MHz, CD_3OD) δ 169.5, 168.4 (d, J_{C-P} = 2.5 Hz), 142.3 (d, J_{C-P} = 27.5 Hz), 138.9, 138.6 (d, J_{C-P} = 11.3 Hz), 138.3 (d, J_{C-P} = 20.0 Hz), 135.1 (d, J_{C-P} = 21.3 Hz), 134.5, 131.6 (d, J_{C-P} = 2.5 Hz), 130.1, 129.7 (d, J_{C-P} = 7.5 Hz), 127.9, 105.1, 76.8, 75.0, 72.6, 71.3, 70.4, 70.3, 69.8, 62.6, 52.6, 41.0; phosphine oxide δ 138.3 (d, J_{C-P} = 11.3 Hz), 133.6 (d, J_{C-P} = 3.8 Hz), 133.5 (d, J_{C-P} = 7.5 Hz), 132.9 (d, J_{C-P} = 10.0 Hz), 132.7, 132.2, 131.8 (d, J_{C-P} = 7.5 Hz), 129.9 (d, J_{C-P} = 12.5 Hz), 52.9; ^{31}P NMR (202 MHz, CD_3OD) δ 35.0 (s, 0.22P), −2.8 (s, 1.00P); ESIMS calculated for $C_{31}H_{36}PNO_{10}Na$ $[M+Na]^+$ 636.1969, found: 636.1951.

*Methyl 2-(diphenylphosphino)-4-{2[2-O-β-D-galactopyranosyl-(1→4)-β-D-glucopyranosyl-2-hydroxyethoxy]ethylcarbamoyl]}-benzoate (**13**).* Deprotection of compound **7** (325 mg, 0.24 mmol) was achieved under Zémplen conditions by stirring in a solution of MeOH (6 mL) with 1% NaOMe/MeOH (6 mL) overnight. The solvent was removed and a solution of DCM/H_2O (10 mL, 1:1) was added. The water layer was washed with DCM (2 × 5 mL) and the aqueous layer was lyophilized to yield 85 mg of a white solid. A portion of the solid (32 mg, 0.08 mmol) was stirred with succinimidyl-3-diphenylphosphino-4-methoxy-carbonylbenzoate **11** (42 mg, 0.09 mmol), and two drops of triethylamine for 3 h at room temperature in DMF (5 mL). The

solvent was removed under vacuum, and the product was purified by column chromatography (Iatrobeads) with EtOAc/MeOH (8:2) to yield 36 mg (62%) of **13** as a yellow solid containing a small amount of the corresponding phosphine oxide. ^{1}H NMR (500 MHz, CD_3OD) δ 8.04 (dd, J = 8.0, 3.6 Hz, 1H), 7.80 (dd, J = 8.0, 1.7 Hz, 1H), 7.43 (dd, J = 3.9, 1.7 Hz, 1H), 7.40−7.30 (m, 6H), 7.26 (m,4H), 4.35 (d, J = 7.6 Hz, 1H), 4.32 (d, J = 7.8 Hz, 1H), 3.96 (ddd, J = 22.3, 13.3, 8.9 Hz, 1H), 3.88 (dd, J = 12.1, 2.5 Hz, 1H), 3.84−3.75 (m, 4H), 3.74−3.68 (m, 2H), 3.68 (s, 3H), 3.67−3.62 (m, 2H), 3.61−3.57 (m, 3H), 3.56−3.41 (m, 7H), 3.38 (ddd, J = 9.2, 4.2, 2.5 Hz, 1H), 3.26−3.19 (m, 1H); phosphine oxide δ 8.13 (dt, J = 8.0, 1.6 Hz, 0.1H), 7.99 (dd, J = 8.0, 3.7 Hz, 0.1H), 7.95 (dd, J = 13.8, 1.7 Hz, 0.1H), 7.72−7.59 (m, 0.7H), 7.55 (m, 0.4H); ^{13}C NMR (125 MHz, CD_3OD) δ 169.5, 168.4 (d, J_{C-P} = 2.5 Hz), 142.3 (d, J_{C-P} = 27.5 Hz), 138.9, 138.6 (d, J_{C-P} = 10.0 Hz), 138.3 (d, J_{C-P} = 20.0 Hz), 135.1 (d, J_{C-P} = 20.0 Hz), 134.5, 131.6 (d, J_{C-P} = 2.5 Hz), 130.1, 129.7 (d, J_{C-P} = 7.5 Hz), 127.9, 105.1, 104.4, 80.7, 77.1, 76.5, 76.4, 74.9, 74.8, 72.6, 71.2, 70.4, 70.3, 69.9, 62.5, 62.0, 52.6, 41.0; ^{31}P NMR (202 MHz, CD_3OD) δ 35.0 (s, 0.10P), −2.8 (s, 1.00P); ESIMS calculated for $C_{37}H_{46}PNO_{15}Na$ $[M+Na]^+$ 798.2497, found: 798.2489.

*Methyl 2-(Diphenylphosphino)-4-{2[2-O-(β-D-galactopyranosyl-(1→4)-2-acetamido-2-deoxy-β-D-glucopyranosyl)-2-hydroxyethoxy]ethylcarbamoyl]}benzoate (***14***).* Deprotection of compound **10** (183 mg, 0.19 mmol) was achieved under Zémplen conditions by stirring in a solution of MeOH (4 mL) with 1% NaOMe/MeOH (2.3 mL) for 2.3 h. The reaction mixture was neutralized with Amberlite resin 120. The resin was washed with MeOH, stirred with 10 mL of ammonia for 30 min, and filtered. The ammonia was removed by evaporation and dried overnight under vacuum to give 52 mg of a white solid. The solid (36 mg, 0.08 mmol) was dissolved in 5 mL of DMF and stirred with succinimidyl-3-diphenylphosphino-4-methoxy-carbonylbenzoate **11** (106 mg, 0.23 mmol), and two drops of triethylamine for 4 h at room temperature. The solvent was removed under vacuum, and the material was purified by column chromatography (Iatrobeads) with DCM/MeOH (3:1) to yield 43 mg (50%) of **14** as a yellow solid containing a small amount of the corresponding phospine oxide. ^{1}H NMR (500 MHz, CD_3OD) δ 8.05 (dd, J = 8.0, 3.6 Hz, 1H), 7.82 (dd, J = 8.0, 1.7 Hz, 1H), 7.44 (dd, J = 3.9, 1.7 Hz, 1H), 7.39−7.30 (m, 6H), 7.30−7.22 (m, 4H), 4.43 (d, J = 8.4 Hz, 1H), 4.37 (d, J = 7.6 Hz, 1H), 3.96−3.89 (m, 1H), 3.88 (d, J = 2.4 Hz, 1H), 3.85−3.78 (m, 2H), 3.78−3.68 (m, 3H), 3.67 (s, 3H), 3.67−3.44 (m, 13H), 3.43−3.38 (m, 1H), 3.36 (ddd, J = 9.4, 4.4, 2.5 Hz, 1H), 1.92 (s, 3H); phosphine oxide δ 8.15 (dt, J = 8.0, 1.6 Hz, 0.2H), 8.00 (dd, J = 8.0, 3.6 Hz, 0.25H), 7.95 (dd, J = 13.8, 1.7 Hz, 0.25H), 7.68−7.58 (m, 1.4H), 7.54 (m,1H); ^{13}C NMR (125 MHz, CD_3OD) δ 173.5, 169.5, 168.5 (d, J_{C-P} = 2.5 Hz), 142.3 (d, J_{C-P} = 28.8 Hz), 138.9, 138.6 (d, J_{C-P} = 10.0 Hz), 138.26 (d, J_{C-P} = 18.7 Hz), 135.1 (d, J_{C-P} = 20.0 Hz), 134.5, 131.7 (d, J_{C-P} = 2.5 Hz), 130.1, 129.7 (d, J_{C-P} = 6.3 Hz), 127.9, 105.2, 102.8, 81.1, 77.2, 76.6, 74.9, 74.2, 72.6, 71.2, 70.4, 70.3, 70.0, 62.5, 62.0, 56.7, 52.6, 41.0, 23.1; phosphine oxide δ 139.8 (d, J_{C-P} = 7.5 Hz), 138.3 (d, J_{C-P} = 11.3 Hz), 133.6, 132.9 (d, J_{C-P} = 12.5 Hz), 129.9 (d, J_{C-P} = 12.5 Hz), 53.0; ^{31}P NMR (202 MHz, CD_3OD) δ 35.00 (s, 0.21P), −2.80 (s, 1.00P); ESIMS calculated for $C_{39}H_{49}PN_2O_{15}Na$ $[M+Na]^+$ 839.2763, found: 839.2756.

Synthesis of Azidoacetic Acid Labeled β-Lactoglobulin. Protein samples of β-lactoglobulin (5 mg, 0.3 mmol) were dissolved in borate buffer (50 mM, pH 9, 1 mL). A solution of succinimidyl 2-azidoacetate **SI1**, in dioxane, was added (27 mg mL^{-1}, 70 μL, 35 equiv) and was left at room temperature for 1 h after vortexing. The labeled protein was purified using ultracentifugation (10 kDa MW cutoff). The sample was lyophilized and stored at −20 °C.

Staudinger Ligation of Azide-Labeled Protein. Samples of azide-labeled protein (200 μg) were dissolved in 100 μL of buffer (10 mM, ammonium acetate, pH 8.9). Staudinger reagents in DMSO/H_2O (1:15, 1 mg mL^{-1}; 300 μL) were added to the protein solution and allowed to react for 12 h at room temperature. The mixture was lyophilized and dissolved in 100 μL of buffer (10 mM, ammonium acetate, pH 8.9).

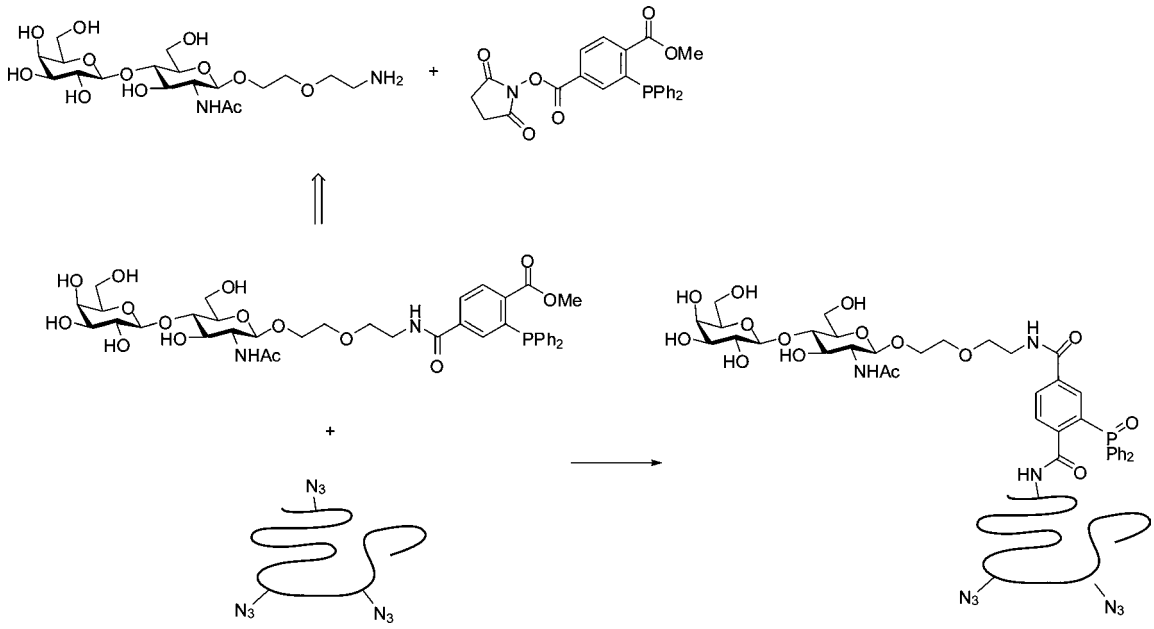
LC-MS of Glycoconjugates. The LC-MS experiments were carried out on an Agilent 6220 Accurate-Mass TOF LC/MS system (Agilent Technologies, Santa Clara, California, USA). Samples were injected on a 75 × 0.5 mm Poroshell C8 column with a particle size of 5 μm (Agilent Technologies, Santa Clara, California, USA) with an Opti-pak trap cartridge kit, 5 μL bed, C8 (Optimize Technologies, Oregon City, USA). After loading of the sample, the column was flushed for 3 min at a 0.15 mL min^{-1} flow rate with 95% mobile phase A (0.1% formic acid in water) and 5% mobile phase B (0.1% FA in acetonitrile) in order to effectively remove the salts and reagents. Elution of the protein was performed by gradually increasing the concentration of phase B in the mobile phase to 95% over a period of 11 min. The column was maintained at 70 °C. Protein molecular weight information was generated using the maximum entropy deconvolution algorithm in the Agilent Mass Hunter BioConfirm software.

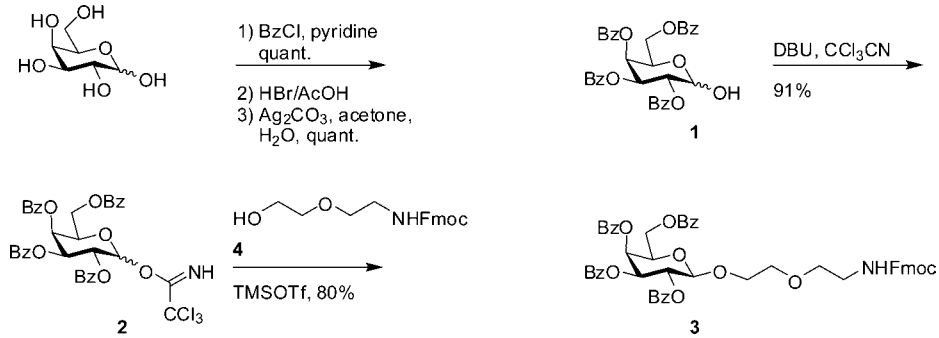
Lectin Blotting of Glycoconjugates. Labeled glycoprotein samples were separated by SDS-PAGE (5%/15%) and transferred to nitrocellulose. The membrane was blocked for 2 h with CarboFree Blocking Solution (Vector Laboratories) and incubated with biotinylated MAL-I lectin (Vector Laboratories) diluted in blocking solution (1 μg mL^{-1}) for 1 h. The membrane was washed with TTBS (Tris-buffered saline, 0.1% Tween 20) and incubated with streptavidin-HRP (Bio-Rad) in blocking solution for 1 h. The membrane was washed again with TTBS, and positive signals were then detected by enhanced chemiluminescence (Amersham). All incubations after protein transfer were performed at room temperature.

RESULTS AND DISCUSSION

Our conjugation strategy is summarized in Figure 1, and first required the development of suitable phosphane derivatives that could install the target carbohydrates onto a model protein. Although our primary interest is the incorporation of a LacNAc disaccharide, we also intended to make related carbohydrate structures to be used as controls in future experiments, such as a monosaccharide, galactose (Gal), and a disaccharide, lactose (Lac, Gal-β(1,4)-Glc). The target structures consist of a carbohydrate epitope, a linker, and a phosphane group. These reagents can react with any azide-containing biomolecule, such as a chemically or metabolically labeled protein, in an aqueous environment. We chose to introduce the phosphane late in the synthesis to avoid issues with oxidation commonly observed with this moiety (*24*). Therefore, we developed each of the carbohydrate epitopes as an amine that could be reacted with an activated ester of the phosphane under mild conditions. The amine was introduced as part of an ethylene glycol derived linker. This strategy is general and allows for the introduction of alternative amine-containing epitopes as desired.

Synthesis of Carbohydrate Epitopes with a Free Amine. To generate a suitable galactosyl-amine derivative, galactose was protected as the 2,3,4,6-tetrabenzoylated derivative, **1**, by perbenzoylation and selective deprotection of the anomeric position (see Supporting Information; Scheme 1) (*25*). Compound **1** was then converted to the trichloroacetimidate derivative (TCA), **2**, as a mixture of anomers using trichloroacetonitrile





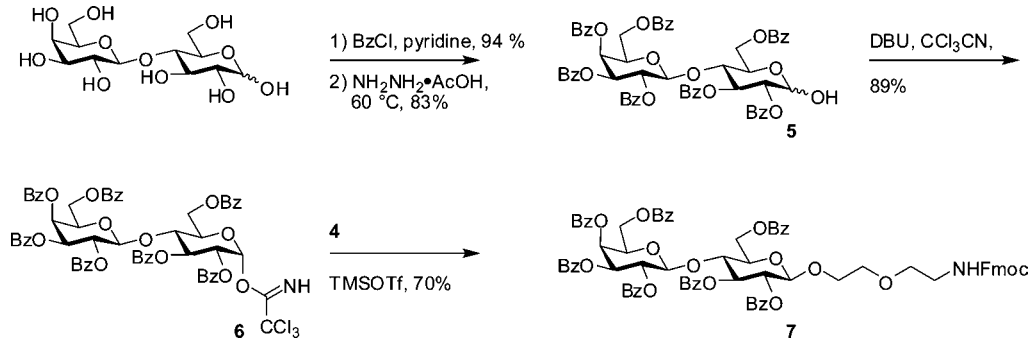


Figure 1. Glycoconjugate strategy. An azide labeled protein, generated semisynthetically or by metabolic incorporation, is reacted with a carbohydrate epitope linked to a phosphane reagent. The Staudinger ligation product is formed under mild conditions compatible with cell culture. The phosphane reagent is generated from a carbohydrate derivative containing a free amine and an NHS-ester phosphane. This strategy allows late incorporation of the phosphane, which can be sensitive to oxidation.

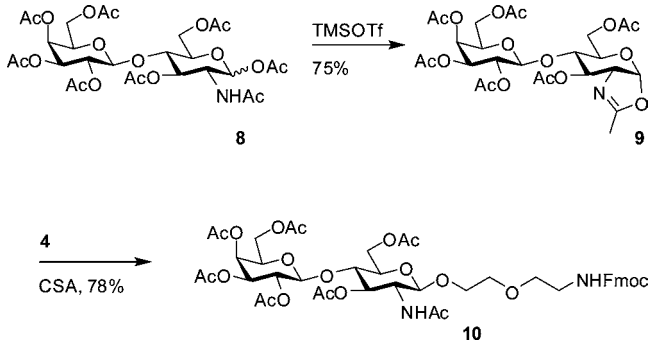
Scheme 1. Synthesis of Protected Galactose

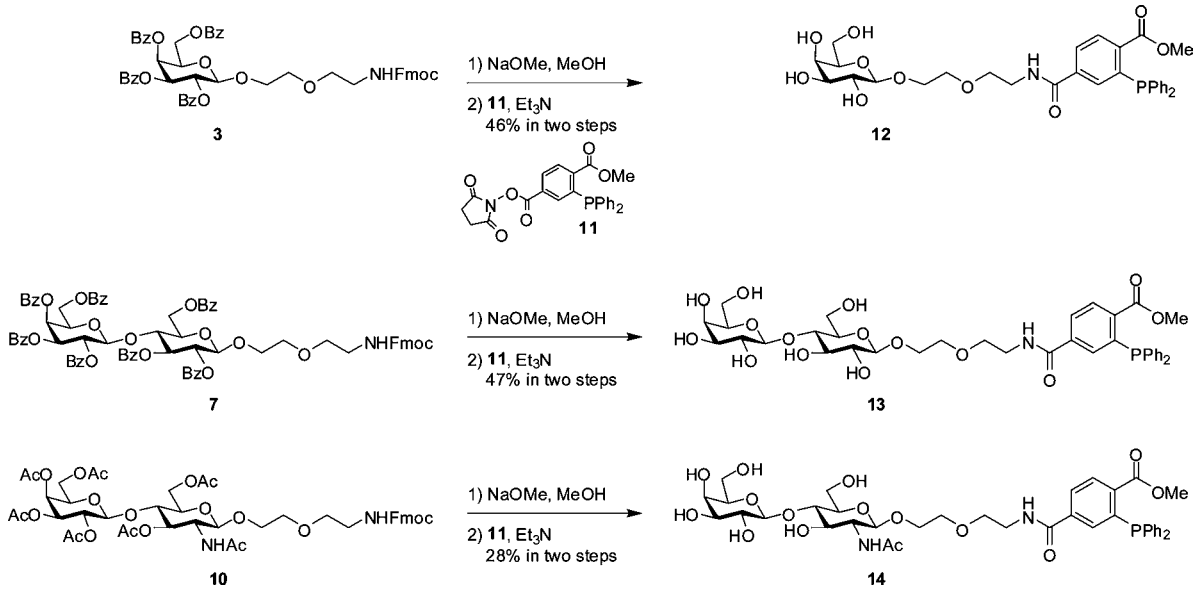


Scheme 2. Synthesis of Protected Lactose

and 1,8-diazabicycloundec-7-ene (DBU) (*25*). Glycosylation of the TCA donor, **2**, by an Fmoc-protected 2-(2-aminoethoxy)-ethanol linker, **4**, in the presence of TMSOTf proceeded in good yield, providing the fully protected compound, **3** (*26*). The lactose-containing amine was generated using a similar sequence of reactions. Perbenzoylated lactose was selectively deprotected at the anomeric position using hydrazine in acetic acid, to give compound **5** in good yield in two steps (see Supporting Information) (*27*). Treatment with DBU and trichloroacetonitrile gave the protected lactosyl-TCA derivative, **6**, as the α-anomer (*26*, *27*). Glycosylation was carried out using the protected linker (2-(2-aminoethoxy)-ethanol) **4** to provide compound **7** (Scheme 2).

The synthesis of LacNAc derivatives can be more challenging, due in part to the expense of the disaccharide as a starting material. A variety of strategies are known for generating LacNAc (*28*), either from cheaper disaccharide glycals (*29*) or from monosaccharides (*30*). We found that the method reported by Wrodnigg and Stutz (*31*, *32*) based on the Heyns rearrangement of lactulose provided excellent overall yields of lac-

Scheme 3. Synthesis of Protected LacNAc



tosamine starting material. We followed the protocol of Stutz et al. for the synthesis of lactosamine as the (1,3-dimethyl-2,4,6 (1*H*,3*H*,5*H*)-trioxopyrimidine-5-ylidene)methyl (DTPM) derivative, which was easily purified by precipitation. Subsequent removal of DTPM (*33*) and acetylation provided compound **8** as a relatively economical starting material (see Supporting Information). The acetyl-protected LacNAc (**8**) was converted to oxazolidine **9** (Scheme 3) (*34*). The oxazolidine donor, **9**, was then modified to incorporate a linker, to provide the fully protected compound **10**. With three carbohydrate epitopes in their protected forms, we proceeded to convert each of **3**, **7**, and **10** to the corresponding phosphane derivatives to be used in generating protein glycoconjugates.

Synthesis of Phosphane Labeling Reagents. To convert each of the protected carbohydrate derivatives to an azide-reactive phosphane, they were first deprotected to unmask the primary amine of the linker. Alkaline deprotection conditions simultaneously removed benzoyl or acetyl and carbamate protecting groups from compounds **3**, **7**, and **10** (*35*). Each of the resulting free amines could then be acylated to generate the desired phosphane targets. Due to sensitivity of the phosphane reagent to oxidation (*24*), we chose to avoid harsh coupling conditions. Instead, the amines were acylated using an *N*-hydroxysuccinimide ester (NHS) derived phosphane **11**. This reagent was first reported by Wang et al., and we prepared the reagent from 2-(diphenylphosphanyl)-terepthalic acid 1-methyl ester reported by Kiick et al. (*10, 23*) This convergent approach provided phosphane compounds **12**, **13**, and **14** in moderate yields from their protected saccharide precursors (Scheme 4). The purity and oxidation state of the resulting phosphane compounds were confirmed using ^{31}P and ^{1}H NMR spectroscopy. Typically, we observed minor oxidation of the phosphane (ca. ~15%) based on NMR. This minor contamination of the phosphine oxide originated from the starting NHS-ester and during purification, but did not appear to be due to the coupling conditions. The phosphine oxide is expected to be unreactive for the Staudinger ligation and should not interfere with the use of these reagents for conjugation.

Conjugation of Carbohydrates to a Model Protein. With three carbohydrate-phosphane derivatives in hand, we turned our attention to the formation of glycoprotein conjugates. We sought to determine the reactivity of the reagents on a model azide-containing protein and to confirm the availability of the incorporated glycans as recognition elements within a glycoconjugate. We selected β-lactoglobulin as a model protein, due to its small size and lack of glycosylation. The protein has 178 amino acids and a molecular weight of 18 kDa (*22*). We modified lactoglobulin by acylation with an NHS-activated azido-acetic acid derivative (succinimidyl 2-azidoacetate, **SI1**) (*36*) to generate a model azide-containing protein (see Supporting Information). The sequence contains 16 lysine residues, which in addition to the *N*-terminus of the protein provide 17 possible sites for acylation.

To confirm the reactivity of phosphane reagents **12**, **13**, and **14**, each was incubated with the azide-modified lactoglobulin. The isolated protein was then analyzed by mass spectrometry (MS) to observe the formation of the desired glycoconjugates (Figure 2). For the galactose labeling reagent, **12**, we observed clear evidence of the incorporation of between 1 and 13 saccharides. The most intense peaks observed were for 8−11 sites of incorporation. Conjugation reactions performed with the LacNAc reagent, **14**, gave similar results, with incorporation of between 2 and 13 disaccharides. The most intense peaks were seen for 8−12 sites of incorporation. Similar results were found with the lactose reagent, **13** (see Supporting Information). We concluded that the Staudinger ligation reagents were efficiently incorporating the desired carbohydrate residues into the proteins. We then turned our attention to testing the availability of the glycan residues as recognition elements as part of the glycoconjugate.

Scheme 4. Synthesis of Staudinger Ligation Reagents

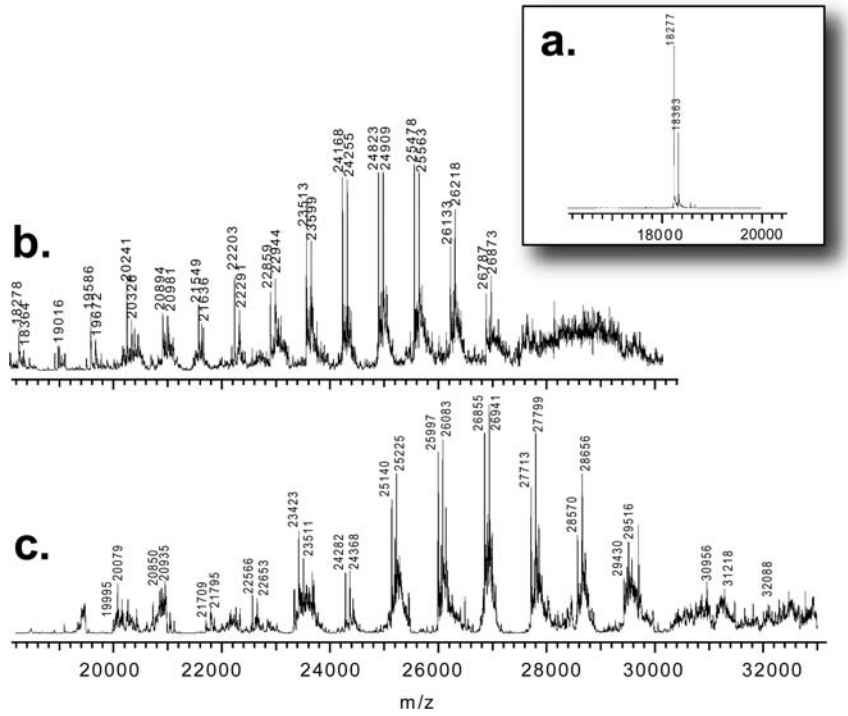


Figure 2. Mass spectral characterization of glycoconjugates. Glycoconjugates were analyzed using LC-MS to confirm the attachment of glycans. Lactoglobulin consists of A- and B-isoforms. Labeled protein samples were analyzed by LC-MS. Proteins analyzed were (a) unlabeled protein, (b) azide-labeled protein reacted with compound **12**, and (c) azide-labeled protein reacted with compound **14**. Both conjugate samples showed incorporation of as many as 13 glycans. Complete analysis of the observed peaks for all glycoconjugates are provided in Supporting Information (Tables SI1−3).

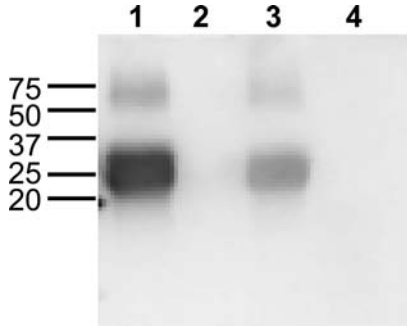

Figure 3. Lectin blotting characterization of glycoconjugates. Lactoglobulin glycoconjugates were probed with biotinylated MAL-I lectin to confirm the attachment of the desired glycans. Proteins were loaded on an SDS-PAGE gel (5−15%), transferred to nitrocellulose, and probed with MAL-I. The blot was developed with streptavidin-HRP. Lanes shown are as follows: 1, lactoglobulin-LacNAc; 2, lactoglobulin-Gal; 3, lactoglobulin-Lac; 4, azido-acetic acid labeled lactoglobulin. The expected MW for the azido-acetic acid modified lactoglobulin is 18 kDa. MW markers are 75, 50, 37, 25, and 20 kDa.

Samples of Gal-, Lac-, and LacNAc-conjugated lactoglobulin were used in a lectin-blotting experiment (*37*). The proteins were blotted onto nitrocellulose then probed with the *Maackia amurensis* lectin-I (MAL-I), which binds LacNAc and sialyl-LacNAc glycans (*38*)(Figure 3). Among the glycoconjugates studied, the lectin demonstrated a strong preference for labeling lactoglobulin which had been modified with the LacNAc reagent, **14**. Reduced staining was observed for the Lac conjugate, while neither the Gal conjugate nor the unreacted azido-lactoglobulin conjugates showed any reactivity to the lectin. These results confirm that the carbohydrate residues of the glycoconjugates are intact and capable of recognition by lectins.

Although we have only explored the use of three carbohydrate epitopes, we expect the chemistry employed here to be general and easily adapted for the incorporation of other glycan epitopes. Additionally, this modular strategy allows for only minimal development of new chemistry to generate different glycoconjugates. More complex glycans could be generated through the use of reductive amination of purified or chemoenzymatically prepared glycans (*39*). Our studies here have used purified proteins which have been acylated to incorporate azide groups. However, this approach could be adapted for the development of other protein or lipid glycoconjugates (*17, 40, 41*). An alternative strategy would be to isolate proteins or glycoproteins which have metabolically incorporated azides (*7*). This strategy could allow for selective modification of glycoproteins to test the role of specific glycan structures in biological activity. Although alternative chemistries could be employed for labeling azide-containing proteins, the Staudinger ligation strategy allows for mild conditions that are compatible with live cells.

Our group is interested in developing chemoselective strategies for increasing the proportion of specific glycan epitopes in cell-surface glycoproteins. We chose to develop chemistry for lactosamine derivatives since *N*-acetyl-lactosamine repeats are commonly found in complex N-linked glycans and O-linked glycans (*42*). Importantly, these structures can modulate the function of immunoreceptors, and the relative proportions of LacNAc incorporation can vary due to cell maturity or activation. The LacNAc epitope is essential for the recruitment of endogenous galectins to immunoreceptors, which induce cellular signals such as apoptosis and leukocyte stimulation (*42, 43*). Thus, bioconjugate methods that can modify the content of LacNAc epitopes found within glycoproteins could be used to probe the role of a single glycan epitope in biological function. Finally, the strategy described here could be used as a method

to increase the biological half-life of therapeutic proteins through attachment of defined glycans (*44–46*).

SUMMARY

We have demonstrated a general route to glycoconjugates which incorporate synthetic glycans using the Staudinger ligation. The chemistry is based on the generation of a carbohydrate epitope with a free amine, which is then acylated to incorporate a phosphane label. The resulting phosphane reagent will react with azide-containing proteins to generate a new glycoconjugate. We show that a model protein, lactoglobulin, can incorporate as many as 13 synthetic glycans, and that the resulting glycoconjugates are specifically recognized by lectins. This strategy provides a simple method of generating multisite modified glycoconjugates under extremely mild conditions which are compatible with proteins and live cells.

ACKNOWLEDGMENT

The authors would like to thank M. R. Richards, Dr. W. Peng, and Prof. T. L. Lowary (U. of Alberta) for helpful discussions and B. Reiz (U. of Alberta) for assistance with mass spectrometry. This work was funded by a grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Alberta Ingenuity Centre for Carbohydrate Sciences (AICCS). NAR was supported by a Queen Elizabeth II scholarship from the University of Alberta.

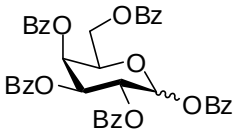
Synthetic methods:

Succinimidyl 2-azidoacetate (SI1):



SI1

Compound **SI1** was previously reported by Yu et al. (1) Sodium azide (4.182 g, 39.3 mmol) was dissolved in 12 mL of deionized water and cooled to 0° C. Bromoacetic acid (4.456g, 32.1 mmol) was then added to the reaction, and the solution was slowly warmed to room temperature and stirred for 24 h. The mixture was acidified to pH 1 with the addition of 4 mL of HCl (1:1, HCl:H_2O). The solution was extracted with diethyl ether (3 × 30 mL). The organic layers were combined and dried over Na_2SO_4 and concentrated to give azidoacetic acid as a colorless liquid. To a solution of azidoacetic acid (1.918 g, 18.98 mmol) and NHS (2.184 g, 18.98 mmol), in anhydrous DMF (26.6 mL) under argon, was added DCC (3.916 g, 18.98 mmol) at 0 °C. The solution was stirred overnight at room temperature. The reaction was filtered to remove DCU. The filtrate was concentrated, and the product was crystallized from DCM/hexanes to give **SI1** as white solid (1) (2.230 g, 59.3% yield). ^{1}H NMR (300 MHz, $CDCl_3$) δ 4.24 (s, 2H), 2.87 (s, 4H); mp 113.9-116.1 ºC.

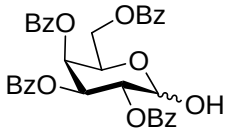
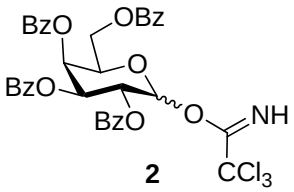
1, 2, 3, 4, 6-Penta-*O*-benzoyl-α/β-D-galactopyranoside (SI2):



SI2

Benzoyl chloride (12.6 mL, 100 mmol) was added slowly to a suspension of galactose (3 g, 16.7 mmol) in 40 mL of pyridine and stirred at room temperature for 24 h under argon. Excess benzoyl chloride was quenched by adding 30 mL MeOH with cooling. The reaction mixture was concentrated under vacuum. The crude product was dissolved in DCM (25 mL) and washed with water (3 × 30 mL). The organic layer was dried over anhydrous Na_2SO_4. The solvent was

evaporated under vacuum and the crude residue was purified by column chromatography using EtOAc/Hexane (1:2) to yield 10.5 g (90%) of **SI2** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.13 (t, *J* = 6.4 Hz, 4H), 7.97 (d, *J* = 7.3 Hz, 2H), 7.88 (d, J = 7.3 Hz, 2H), 7.83 (d, *J* = 7.3 Hz, 2H), 7.65 (td, *J* = 7.4, 1.1 Hz, 2H), 7.52 (dd, *J* = 11.9, 7.6 Hz, 5H), 7.46 (t, *J* = 7.4 Hz, 2H), 7.39 (t, *J* = 7.7 Hz, 2H), 7.29 (dd, *J* = 9.7, 8.0 Hz, 4H), 6.97 (d, *J* = 3.6 Hz, 1H), 6.21 (d, *J* = 2.2 Hz, 1H), 6.14 (dd, *J* = 10.7, 3.2 Hz, 1H), 6.05 (dd, *J* = 10.7, 3.6 Hz, 1H), 4.85 (t, *J* = 6.6 Hz, 1H), 4.65 (dd, *J* = 11.3, 6.4 Hz, 1H), 4.44 (dd, *J* = 11.3, 6.9 Hz, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 165.9, 165.7, 165.5, 165.4, 164.5, 133.9, 133.7, 133.4, 133.3, 133.2, 130.0, 129.95, 129.8, 129.76, 129.3, 129.0, 128.98, 128.9, 128.8, 128.74, 128.7, 128.42, 128.41, 128.4, 90.7, 69.5, 68.6, 68.5, 67.7, 61.9; ESIMS calculated for $C_{41}H_{32}O_{11}Na$ $[M+Na]^+$ 723.1837, found: 723.1834.



2, 3, 4, 6-Tetra-*O*-benzoyl-α/ β-D-galactopyranoside (1):

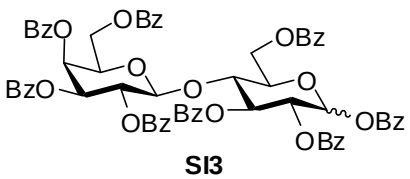
1

Penta-*O*-benzoyl galactoside, **SI2** (3 g, 4.3 mmol), was treated with 1.6 mL of HBr/AcOH (33%) in 10 mL of DCM for 1 h. The solution was washed twice with 10 mL of saturated $NaHCO_3$, NaCl, and 8 mL DI water. The DCM was evaporated and the solid was dried under vacuum. The resulting white solid was dissolved in 15 mL acetone and 0.7 mL water with Ag_2CO_3 (602 mg, 2.2 mmol). The solution was filtered through a pad of celite and dried under vacuum to yield a quantitative amount of **1** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.15 – 8.08 (m, 3H), 8.06 – 7.96 (m, 5H), 7.86 – 7.79 (m, 2H), 7.67 – 7.54 (m, 1H), 7.54 – 7.43 (m, 5H), 7.43 – 7.31 (m, 6H), 7.23 (t, *J* = 7.9 Hz, 3H), 6.16 - 6.11 (m,1H), 6.06 (s, 0.3H), 5.90 (s,1H), 5.77 (d, *J* = 3.5 Hz, 0.5H), 5.75 (d, *J* = 3.7 Hz, 1H),5.14 (t, *J* = 7.4 Hz, 0.3H), 4.89 (t, *J* = 6.8 Hz, 1H), 4.77 (d, *J* = 7.8 Hz, 0.3H), 4.71 (dd, *J* = 11.2, 6.3 Hz, 0.3H), 4.63 (dd, *J* = 11.3, 6.3 Hz, 1H), 4.47 (m, 0.3H), 4.40 (m, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 164.2, 163.8, 163.76, 163.7, 163.3, 163.2, 163.16, 131.2, 131.1, 131.05, 130.9, 130.89, 130.86, 130.8, 130.7, 127.5, 127.45, 127.4, 127.36, 127.34, 127.3, 127.26, 127.2, 126.9, 126.8, 126.75, 126.6, 126.5, 126.47, 126.2, 126.18, 126.16, 126.0, 125.95, 125.9, 125.8, 125.78, 93.7, 88.6, 69.6, 69.0, 68.8, 67.2, 66.9, 65.8, 65.7, 64.2, 59.9, 59.7; ESIMS calculated for $C_{34}H_{28}O_{10}Na$ $[M+Na]^+$ 619.1575, found: 619.1576.

2, 3, 4, 6-Tetra-*O*-benzoyl-α/ β-D-galactopyranosyl trichloroacetamidate (2):

2

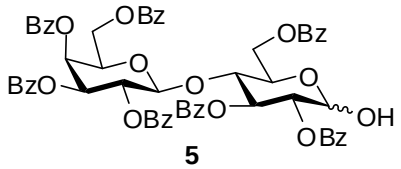
Compound **1** (1.10 g, 1.8 mmol), DBU (60 µL), and trichloroacetonitrile (2.2 mL, 4.8 mmol) were dissolved in DCM (25 mL) and stirred for 4 h at room temperature. DCM was evaporated and the residue was purified by column chromatography with EtOAc/hexane (1:2) to yield 1.214 g (91.3%) of **2** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.77 (s, 0.3H), 8.67 (s, 1H), 8.12 (dd, *J* = 8.2, 1.1 Hz, 3H), 8.08 (dd, *J* = 8.2, 1.2 Hz, 0.7H), 8.00 (ddd, *J* = 11.6, 8.3, 1.2 Hz, 4H), 7.94 (ddd, *J* = 20.6, 8.3, 1.2 Hz, 1.4H), 7.83 (dd, *J* = 8.3, 1.2 Hz, 2H), 7.69 – 7.63 (m, 1H), 7.63 – 7.58 (m, 1H), 7.58 – 7.49 (m, 6H), 7.48 – 7.27 (m, 11H), 6.96 (d, *J* = 3.7 Hz, 1H), 6.74 (s, 0.3H), 6.22 – 6.19 (m, 1H), 6.17 (dt, *J* = 7.0, 4.3 Hz, 0.4H), 6.12 (dd, *J* = 10.7, 3.3 Hz, 1H), 6.01 (dd, *J* = 10.7, 3.7 Hz, 1H), 5.82 (d, *J* = 4.2 Hz, 0.3H), 5.80 (s, 0.3H), 4.91 (dd, *J* = 8.8, 4.7 Hz, 1.3H), 4.85 – 4.73 (m, 1H), 4.65 (dd, *J* = 11.5, 6.9 Hz, 1H), 4.48 (dd, *J* = 11.5, 6.0 Hz, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 166.0, 165.9, 165.7, 165.6, 165.52, 165.51, 165.5, 165.2, 160.6, 160.3, 133.8, 133.7, 133.6, 133.4, 133.3, 133.26, 133.1, 130.05, 130.0, 129.97, 129.9, 129.86, 129.8, 129.75, 129.7, 129.5, 129.4, 129.3, 129.0, 128.9, 128.8, 128.74, 128.7, 128.5, 128.46, 128.4, 128.35, 102.9, 93.8, 91.0, 90.8, 84.6, 80.8, 77.2, 70.1, 69.8, 68.6, 68.4, 67.9, 63.4, 62.2; ESIMS calculated for $C_{36}H_{28}Cl_3NO_{10}Na$ $[M+Na]^+$ 762.0671, found: 762.0671.



9*H*-fluoren-9-ylmethyl [2-(2-hydroxyethoxy)ethyl]carbamate (4):

4

In a round bottom flask, 23 mL of 10% $NaHCO_3$ was added to 2-(2-aminoethoxy)-ethanol (700 µL, 7 mmol) in 20 mL of dioxane. The mixture was stirred for 15 min, then 9-fluorenylmethyl-*N*-succinimidyl carbonate (2.833 g, 8.4 mmol) was added. The reaction mixture was stirred overnight then extracted with DCM (60 mL). The DCM layer was washed with water (2 x 50 mL) and dried over anhydrous Na_2SO_4. The solvent was evaporated under vacuum and the residue was purified by column chromatography using EtOAc/hexane (2:1) to yield 2.203 g (92.4%) of **4** as an off-white solid. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.76 (d, *J* = 7.5 Hz, 2H), 7.59 (d, *J* = 7.4 Hz, 2H), 7.39 (t, *J* = 7.4 Hz, 2H), 7.31 (td, *J* = 7.5, 1.2 Hz, 2H), 5.37 (s, 1H), 4.43 (d, *J* = 6.7 Hz, 2H), 4.21 (t, *J* = 6.7 Hz, 1H), 3.71 (dd, *J* = 9.3, 5.5 Hz, 2H), 3.54 (d, *J* = 4.5 Hz, 4H), 3.38 (d, *J* = 5.0 Hz, 2H), 2.44 (t, *J* = 5.8 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 156.6, 143.9, 141.3, 127.7, 127.0, 125.0, 120.0, 72.3, 70.1, 66.6, 61.7, 47.3, 40.9; ESIMS calculated for $C_{19}H_{21}NO_4Na$ $[M+Na]^+$ 350.1363, found: 350.1357; mp 64.3-66.9 ºC.

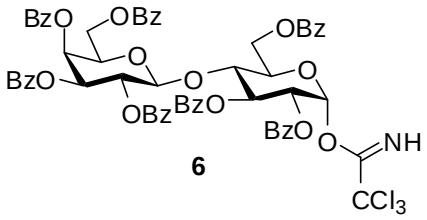


2,3,4,6-Tetra-*O*-benzoyl-β-D-galactopyranosyl-(1→4)-1,2,3,6-tetra-*O*-benzoyl-α/β-D-glucopyranose (SI3):

SI3

Benzoyl chloride was added slowly to a suspension of D-lactose (514 mg, 1.5 mmol) in 10 mL of pyridine and stirred at room temperature for 24 h under argon. Excess benzoyl chloride was quenched by adding MeOH with cooling. The reaction mixture was concentrated under high vacuum. The crude product was dissolved in DCM (25 mL) and washed with water (3 x 30 mL). The organic layer was dried over anhydrous Na_2SO_4. The solvent was evaporated under vacuum. The product was purified by column chromatography using EtOAc/hexane (1:2) to yield 1.66 g (93.9%) of **SI3** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.13 (dd, *J* = 8.2, 1.2 Hz, 1H), 8.08 – 7.97 (m, 13H), 7.96 – 7.85 (m, 5H), 7.77 – 7.71 (m, 3H), 7.69 – 7.25 (m, 28H), 7.20 (ddd, *J* = 11.4, 10.0, 5.6 Hz, 6H), 6.76 (d, *J* = 3.8 Hz, 0.3H), 6.21 (dd, *J* = 10.1, 9.3 Hz, 0.3H), 6.15 (d, *J* = 8.1 Hz, 1H), 5.95 (t, *J* = 9.3 Hz, 1H), 5.82 – 5.77 (m, 1.3H), 5.77 – 5.71 (m, 2.4H), 5.62 (dd, *J* = 10.3, 3.8 Hz, 0.3H), 5.39 (dd, *J* = 10.4, 3.4 Hz, 1H), 4.96 (d, *J* = 7.9 Hz, 0.3H), 4.91 (d, *J* = 7.9 Hz, 1H), 4.64 – 4.50 (m, 3H), 4.40 (td, *J* = 9.5, 3.0 Hz, 1.3H), 4.31 (dt, *J* = 10.2, 2.5 Hz, 0.3H), 4.08 (ddd, *J* = 9.9, 3.7, 1.9 Hz, 1H), 3.90 (t, *J* = 6.6 Hz, 1.4H), 3.85 – 3.76 (m, 1.5H), 3.76 – 3.68 (m, 1.3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 165.8, 165.77, 165.6, 165.5, 165.45, 165.43, 165.4, 165.3, 165.24, 165.2, 165.19, 164.9, 164.8, 164.5, 164.48, 133.9, 133.7, 133.5, 133.45, 133.4, 133.39, 133.37, 133.3, 133.26, 130.1, 130.07, 130.0, 129.8, 129.78, 129.76, 129.71, 129.7, 129.66, 129.65, 129.6, 129.57, 129.5, 129.43, 129.42, 129.4, 128.9, 128.86, 128.8, 128.7, 128.63, 128.6, 128.59, 128.56, 128.55, 128.5, 128.47, 128.4, 128.34, 128.3, 128.25, 101.3, 101.2, 92.6, 89.9, 75.7, 75.6, 73.9, 72.9, 72.0, 71.8, 71.4, 71.2, 70.7, 70.4, 70.1, 69.9, 69.8, 67.5, 62.1, 61.8, 61.0; ESIMS calculated for $C_{68}H_{54}O_{19}Na$ $[M+Na]^+$ 1197.3152, found: 1197.3142.

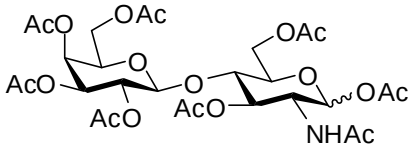
2,3,4,6-Tetra-*O*-benzoyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-benzoyl-α/β-D-glucopyranose (5):



5

Hydrazine acetic acid (220 μL) was added to a solution of **SI3** (600 mg, 0.51 mmol) in DMF (10 mL) and the mixture was stirred at 60 ^{o}C for 6 h. A white solid crashed out after addition of water (20 mL) and was filtered. The solid was dissolved in DCM (10 mL) and washed with water (2 × 15 mL). The organic layer was dried over anhydrous Na_2SO_4 and evaporated under vacuum. The crude residue was purified by column chromatography using EtOAc/hexane (1:1) to yield 455 mg (83.3%) of **5** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.07 – 7.93 (m, 15H), 7.89 (dd, *J* = 8.3, 1.2 Hz, 3H), 7.73 (dd, *J* = 8.3, 1.2 Hz, 3H), 7.66 – 7.25 (m, 28H), 7.25 – 7.13 (m, 6H), 6.15 (dd, *J* = 9.9, 9.5 Hz, 1H), 5.87 (t, *J* = 7.47, 0.3H), 5.78 – 5.69 (m, 3H), 5.63 (d, *J* = 3.6 Hz, 1H), 5.47 – 5.36 (m, 1.5H), 5.32 – 5.28 (m, 0.3H), 5.25 (dd, *J* = 10.3, 3.7 Hz, 1H), 4.95 (d, *J* = 7.8 Hz, 1.23H), 4.93 – 4.87 (m, 0.6H), 4.58 (dd, *J* = 12.3, 1.9 Hz, 1.5H), 4.53 – 4.45 (m, *J* = 12.3, 4.1 Hz, 1.6H), 4.37 (ddd, *J* = 10.1, 3.1, 2.0 Hz, 1H), 4.31 – 4.22 (m, *J* = 9.7, 4.2 Hz, 1.5H), 3.92 (q, *J* = 6.4 Hz, 1.6H), 3.89 – 3.83 (m, 1.5H), 3.83 – 3.69 (m, *J* = 29.7, 11.3,

7.0 Hz, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 166.6, 166.2, 166.1, 166.0, 165.7, 165.6, 165.5, 165.47, 165.45, 165.4, 165.3, 164.9, 133.6, 133.44, 133.4, 133.37, 133.3, 133.1, 130.0, 129.95, 129.8, 129.7, 129.6, 129.5, 129.43, 129.4, 129.38, 129.1, 129.0, 128.8, 128.7, 128.6, 128.59, 128.5, 128.4, 128.3, 101.1, 95.8, 90.3, 76.1, 76.0, 74.0, 73.3, 72.6, 72.2, 72.0, 71.8, 71.4, 70.3, 70.1, 70.0, 68.4, 67.6, 67.58, 62.5, 62.45, 61.2, 61.1; ESIMS calculated for $C_{61}H_{50}O_{18}Na$ $[M+Na]^+$ 1093.2889, found: 1093.2886.



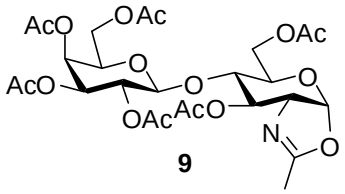
1-*O*-[2,3,4,6-Tetra-*O*-benzoyl-β-D-galactopyranosyl-(1→4)-2,3,6-tri-*O*-benzoyl-α-D-glucopyranosyl] trichloroacetimidate (6):

6

Compound **5** (430 mg, 0.4 mmol), DBU (6 µL), and trichloroacetonitrile (481 µL, 4.8 mmol) were dissolved in DCM (10 mL) and stirred for 4 h at room temperature. DCM was evaporated and the residue was purified by column chromatography with EtOAc/hexane (1:1) to yield 434 mg (89.0%) of **6** as a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.57 (s, 1H), 7.99 (dddd, *J* = 15.9, 12.8, 8.4, 1.3 Hz, 12H), 7.90 (dd, *J* = 8.3, 1.2 Hz, 2H), 7.73 (dd, *J* = 8.4, 1.3 Hz, 2H), 7.70 – 7.54 (m, 4H), 7.54 – 7.26 (m, 17H), 7.26 – 7.15 (m, 5H), 6.72 (d, *J* = 3.8 Hz, 1H), 6.20 – 6.12 (m, 1H), 5.79 – 5.71 (m, 2H), 5.55 (dd, *J* = 10.2, 3.8 Hz, 1H), 5.40 (dd, *J* = 10.3, 3.4 Hz, 1H), 4.95 (d, *J* = 7.9 Hz, 1H), 4.62 – 4.47 (m, 2H), 4.39 – 4.30 (m, 2H), 3.91 (t, *J* = 7.1 Hz, 1H), 3.83 (dd, *J* = 11.3, 6.3 Hz, 1H), 3.74 (dd, *J* = 11.3, 7.3 Hz, 1H); ^{13}C NMR (175 MHz, $CDCl_3$) δ 165.7, 165.52, 165.5, 165.4, 165.2, 165.17, 164.8, 160.7, 133.5, 133.4, 133.3, 130.0, 129.9, 129.8, 129.7, 129.65, 129.6, 129.57, 129.5, 129.4, 128.9, 128.7, 128.6, 128.57, 128.54, 128.5, 128.4, 128.3, 128.2, 101.3, 93.1, 90.7, 75.6, 71.9, 71.4, 71.35, 70.5, 70.3, 70.0, 67.5, 61.9, 61.0; ESIMS calculated for $C_{63}H_{50}Cl_3NO_{18}Na$ $[M+Na]^+$ 1236.1986, found: 1236.1997.

2-Acetamido-1,3,6-tri-*O*-acetyl-2-deoxy-4-*O*-(2,3,4,6-tetra-O-acetyl- β-D-galactopyranosyl) - α/β-D-glucopyranose (8):

8



N-[1,3-Dimethyl-2,4,6 (1H, 3H, 5H)-trioxopyrimidine-5-ylidene]methyl lactosamine **SI4** (4 g, 7.9 mmol) was prepared from lactulose as described by Stutz et al. (2) The compound was suspended in 30 mL of NH_4OH and the mixture was stirred for 40 min. White precipitate was

filtered off and washed several times with distilled water. Then filtrate was (aqueous layer, 45 mL) washed with chloroform (3 x 30 mL). The aqueous layer was concentrated and dried on high vacuum for 18 h to give lactosamine **SI5** (2.4 g, 90%) as a light yellow solid. The product was confirmed by mass spectrometry (ESIMS calculated for $C_{12}H_{24}NO_{10}$ $[M+H]^+$ 342.1395, found: 342.1397.) Lactosamine (500 mg, 1.5 mmol) was then dissolved in 10 mL of pyridine and stirred with acetic anhydride (3 mL, 31.7 mmol), and a catalytic amount of DMAP for 18 h at room temperature. Excess acetic anhydride was quenched by dropwise addition of 3 mL methanol at 0 °C under constant stirring for 30 min. The solvent was removed under vacuum and the crude mixture was purified by column chromatography with EtOAc/hexane (3:1) to yield compound **8** (923 mg, 93%) as light yellow solid. Characterization of the compound was consistent with data reported by Range et al. (3). ^{1}H NMR (498 MHz, $CDCl_3$) δ 6.07 (d, *J* = 3.6 Hz, 1H), 5.86 (d, *J* = 9.7 Hz, 0.2H), 5.65 (d, *J* = 9.1 Hz, 1H), 5.61 (d, *J* = 7.7 Hz, 0.3H), 5.34 (dd, *J* = 3.3, 1.0 Hz, 1.5H), 5.21 (dd, *J* = 11.0, 8.3 Hz, 1H), 5.14 – 5.08 (m, 1.3H), 5.07 – 5.02 (m, 0.4H), 4.99 – 4.92 (m, 1.4H), 4.51 (d, *J* = 7.9 Hz, 1H), 4.47 (d, *J* = 7.9 Hz, 0.4H), 4.43 (dd, *J* = 12.0, 3.0 Hz, 0.3H), 4.41 – 4.36 (m, 1.3H), 4.35 (dd, *J* = 3.6, 1.9 Hz, 0.5H), 4.33 (d, *J* = 3.6 Hz, 0.3H), 4.26 (td, *J* = 9.4, 7.8 Hz, 0.3H), 4.17 – 4.04 (m, 4H), 3.92 – 3.80 (m, 4H), 3.76 (ddd, *J* = 8.1, 5.7, 3.1 Hz, 1H), 3.28 (d, *J* = 7.0 Hz, 0.4H), 2.16 – 1.91 (overlapped singlets, 33H); ESIMS calculated for $C_{28}H_{40}NO_{18}$ $[M+H]^+$ 678.2240, found: 678.2239.

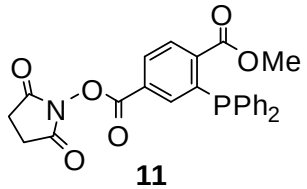
2-Methyl-{3,6-di-*O*-acetyl-1,2-dideoxy-4-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-α-D-gluco-pyrano}-[2,1-d]-oxazoline (9):



9

Peracetylated LacNAc, **8** (567 mg, 0.84 mmol), was dissolved in 10 mL of 1,2-dichloro ethane and stirred with TMSOTf (167 µL, 1.05 mmol) at 50 °C for 12 h. The reaction mixture was then warmed to room temperature. Triethylamine (0.6 mL) was added and the reaction mixture was stirred for 30 min. The solvent was removed under vacuum and the crude mixture was purified by column chromatography with toluene/EtOAc/Et_3N (100:200:1) to yield 400 mg (75%) of **9** as a yellow solid. ^{1}H NMR (498 MHz, $CDCl_3$) δ 5.90 (d, *J* = 7.3 Hz, 1H), 5.63 (s, 1H), 5.36 (d, *J* =

3.4 Hz, 1H), 5.16 (dd, *J* = 10.0, 8.3 Hz, 1H), 4.99 (dd, *J* = 10.3, 3.5 Hz, 1H), 4.64 (d, *J* = 8.0 Hz, 1H), 4.24 – 4.02 (m, 5H), 3.94 (t, *J* = 6.7 Hz, 1H), 3.64 (d, *J* = 9.5 Hz, 1H), 3.53 – 3.45 (m, 1H), 2.15 (s, 3H), 2.10 (s, 3H), 2.10 (s, 3H), 2.09 (s, 3H), 2.04 (s, 3H), 2.02 (s, 3H), 1.96 (s, 3H); ^{13}C NMR (125 MHz, $CDCl_3$) δ 170.6, 170.32, 170.3, 170.1, 169.4, 169.2, 166.8, 102.4, 99.1, 78.0, 71.0, 70.9, 70.5, 68.8, 67.5, 66.9, 65.0, 63.5, 61.1, 21.0, 20.8, 20.7, 20.66, 20.6, 20.5, 13.9; ESIMS calculated for $C_{26}H_{35}NO_{16}Na$ $[M+Na]^+$ 640.1848, found: 640.1846.

Succinimidyl 3-diphenylphosphino-4-methoxy-carbonylbenzoate (11):

11

A solution of 2-(diphenyl-phosphanyl)-terepthalic acid 1-methyl ester (1.978 g, 1 mmol), prepared according to Kiick et al. (4), was stirred with EDCI (1.244 g, 1.2 mmol) and NHS (0.684 g, 1.1 mmol) in DMF (10 mL) for one day. The reaction mixture was concentrated under reduced pressure then extracted with mixture of DCM and H_2O (50 mL). The organic layer was dried over anhydrous Na_2SO_4, and concentrated under vacuum. The residue was purified by flash column chromatography (1:1 hexane/EtOAc) to afford **11** as a yellow solid (5) (1.29 g, 52%). ^{1}H NMR (400 MHz,$CDCl_3$) δ 8.13 (s, 2H), 7.67 (d, *J* = 3.6 Hz, 1H), 7.40 – 7.26 (m, 10H), 3.76 (s, 3H), 2.84 (s, 4H);^{13}C NMR (100 MHz, $CDCl_3$) δ 168.8, 166.2 (d, J_{C-P} = 3.0 Hz), 161.0, 142.3 (d, J_{C-P} = 31.3 Hz), 139.6 (d, J_{C-P} = 19.2 Hz), 136.4 (d, J_{C-P} = 10.1 Hz), 136.0, 133.8 (d, J_{C-P} = 21.2 Hz), 130.7, 129.6, 129.1, 128.6 (d, J_{C-P} = 8.1 Hz), 127.7, 52.4, 25.5; ^{31}P NMR (162 MHz, $CDCl_3$) δ -2.9; HR-ESIMS calculated for $C_{25}H_{20}NO_6PNa(M+Na)^+$, 484.0921, found 484.0919; mp 151.2-153.6 ºC.

Received April 28, 2010; Revised Manuscript Received July 12, 2010

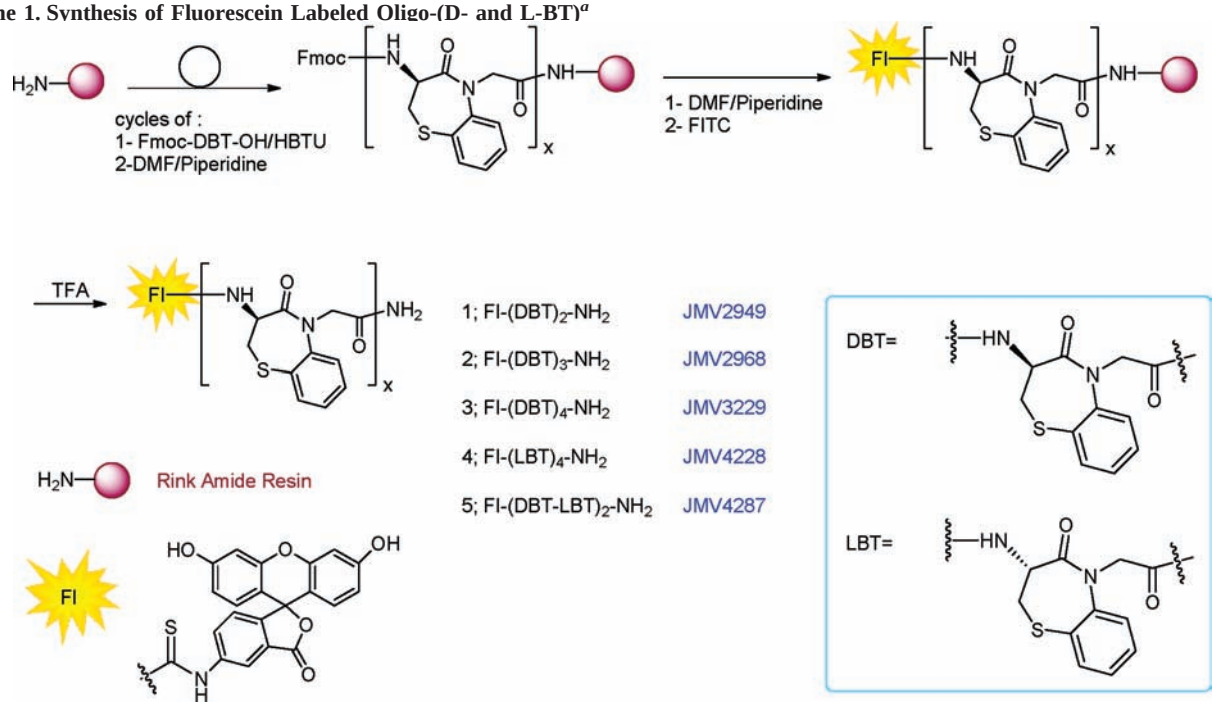
Small oligomers of constrained dipeptide mimics have been synthesized as new vectors for intracellular delivery. They are highly internalized by cells and delivered to the lysosomes by an energy-dependent pathway. This new class of vectors referred to as cell penetrating nonpeptides (CPNP) possess the distinctive feature of being noncationic.

INTRODUCTION

The delivery of drugs into cells remains a major limitation in several therapies. Peptide vectors referred to as cell-penetrating peptides (CPPs) have emerged as promising tools for the intracellular delivery of bioactive cargoes (drugs, peptides, siRNA...) (*1*−*3*). Several classes of CPPs have been reported; most of them are basic or amphipathic peptides (*4*−*8*) and often display high α-helical propensity (*9*). Hydrophobic segments from protein signal sequences or membrane translocating sequences (MTS), as well as a noncharged polyproline peptide, were also described for cell membrane transport (*10, 11*). Non-natural folded oligomers termed foldamers (*12, 13*) have emerged as an important family of versatile frameworks with the first evidence of their ability to cross the cell membrane. A large number of guanidinium rich foldamers including β-peptides (*14*) and peptoids (*5*) have been reported to deliver drugs or labeled compounds into cells. Other oligomers constructed from monomers that differ significantly from α- or β-amino acids, possessing predictable helical structure and amphipathic character were also found to efficiently enter into cells (*15*−*17*). Thanks to the possibility to control their secondary structure and their resistance against protease degradation (*18*), structured oligomers constitute a privileged platform for designing cell penetrating nonpeptide compounds (CPNP). Alternatively, it has been shown that sterol derivatives could enhance molecular uptake (*19, 20*).

Taking into account these considerations, our aim was to develop a novel class of small molecules as potential vectors to mediate cell penetration. They are based on constrained dipeptide mimic oligomers. A few years ago, we showed using molecular modeling that oligomerization of constrained β-turn dipeptide mimics could induce helix-like structures (*21*). Among the different motifs selected by this program, we particularly focused on (3-*S*)[amino]-5-(carboxymethyl)-2,3-dihydro-1,5-benzothiazepin-4(5*H*)-one (DBT) described as a β-turn mimic (*22, 23*), supposedly a favorable feature to induce structured oligomers. DBT oligomers are neither polycationic nor amphipathic oligomers unlike the majority of described vectors. By virtue of their hydrophobicity, their expected ability to achieve helical type structure and resistance against protease degradation, we hypothesized that DBT oligomers should be good candidates as translocating agents. Short oligomers were synthesized and their cellular uptake and subcellular localization studied.

EXPERIMENTAL PROCEDURES



Oligomers. They were synthesized on Rink amide resin following solid phase peptide synthesis methodology and labeled at their N-terminus with fluorescein isothiocyanate (see Supporting Information). The monomeric units Fmoc-DBT-OH and Fmoc-LBT-OH were prepared as previously described (*24*).

Cell Preparation and Treatment with Oligomers. We used 1 mM stock solutions of compounds dissolved in DMSO that were further diluted with serum-free medium to obtain a final concentration of 10^{-5} M. All compounds were protected from light during the experiments, and their fluorescence values were regularly verified. Human breast cancer MDA-MB-231 cells were maintained in monolayer cultures in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS) and 50 μg/mL gentamycin at 37 °C in 5% CO_2. One day prior to the experiment, cells were harvested using trypsin in phosphate-buffered saline (PBS), centrifuged, and resuspended with culture medium. The suspension containing 10^6 cells/mL was transferred into plastic 24-well plates (Becton Dickinson, Le Pont De Claix, France) (200 μL/well) and incubated overnight until they reached >90% confluency. On the day of the experiment, the culture medium was removed, and the cells were washed once with phenol red-free DMEM. Then, 200 μL of DMEM containing 10% FBS and 10^{-5} M of compounds was dispersed on cells. Experiments were carried out in triplicate for each compound. To determine the amount of compounds assimilated by cells, including membrane-bound fractions, cells were washed twice with PBS. To determine the amount of internalized compounds, cells were washed with PBS

[a] The scheme is given for the D series.

and then treated for 5 min with 30 μL of a solution containing 0.5 mg/mL trypsin. After trypsinization, cells were resuspended in phenol red-free DMEM and centrifuged for 5 min at 800*g*. Adherent cells or cell pellets were lysed in 200 μL of cell culture lysis reagent (Promega, Charbonnières, France). After 30 min of incubation at room temperature, 200 μL of distilled water was added before analysis on a Gemini XS spectrofluorimeter (Molecular Devices, CA, USA), with the excitation wavelength adjusted to 485 nm and emission measured at 530 nm. All fluorescence values were normalized according to the fluorescence intensity of each compound at 10^{-5} M in lysis buffer in the presence of 2×10^5 cells.

Kinetics of Internalization. One day before the experiment, 2×10^6 MDA-MB-231 cells were seeded on plastic 24-well plates. The cells were then washed with DMEM and incubated for increasing times from 1 to 24 h with 10^{-5} M oligomer at 37 °C. At the indicated time, cells were treated by trypsin and intracellular fluorescence measured as described above.

Visualization of Fluorescent Oligomers by CLSM. The day prior to the experiment, MDA-MB-231 cells were seeded onto bottom glass dishes (World Precision Instrument, Stevenage, UK) at a density of 10^6 cells per square centimeter. On the day of the experiment, cells were washed once and incubated in 1 mL phenol red-free medium containing fluorescent labeled compounds at a concentration of 10^{-5} M for 3, 16, and 24 h. Thirty minutes before the end of incubation, cells were loaded with Hoechst 33342 (Invitrogen, Cergy Pontoise, France) for nuclear staining at a final concentration of 5 μg/mL. For membrane labeling, a Vybrant lipid-raft labeling kit (Invitrogen) was used as described by the manufacturer. For endosome labeling, 20 min before the end of the experiment, 35 mg/mL of transferrin (Invitrogen) was added to the culture medium. For lysosome labeling, 3 h before the end of the experiment, 50 nM of lysotracker red DND-99 (Invitrogen) was added to phenol red-free DMEM. Before visualization, cells were washed gently with phenol red-free DMEM. Cells were then scanned with a LSM 5 LIVE confocal laser scanning microscope (Carl Zeiss, Le Pecq, France), with a slice depth (Z stack) of 0.67 μm.

RESULTS AND DISCUSSION

Design of the Target DBT Oligomers. Oligomers of different lengths were synthesized (see Supporting Information) on a solid support using Rink amide PS resin, by successive addition of N-Fmoc protected DBT (Fmoc-DBT-OH) (*24*) in the presence of HBTU as the coupling reagent (Scheme 1). In order to track their cellular internalization by fluorescence microscopy, fluorescein isothiocyanate was used to label the oligomers. The fluorescent tag was attached directly to the N-terminus of the poly(DBT) anchored to the resin (JMV2949, JMV2968 and JMV3229). The importance of the configuration and the structure of the oligomers was assessed by the preparation of the LBT derivative (JMV4228) and the D/LBT alternated oligomer (JMV4287), respectively.

Cellular Uptake of DBT Oligomers. At first, the cellular uptake in MDA-MB-231 breast cancer cells of the oligomers **1**−**5** was analyzed by fluorescence emission measurement (Figure 1) and compared to fluorescein labeled octa-arginine (*25*) (Arg_8) as a positive control and carboxyfluorescein (CF) as a negative control. In order to determine the internalized fraction of the compounds, a 5-min trypsin treatment was realized to remove membrane-bound transduction compounds (Figure 1A) (*26*). It is worth noting that the percentage of membrane-bound oligomers was not as important as in the case of the polycationic Arg_8.

The highest intracellular fluorescence intensity was found for DBT_4 (JMV3229) with a drastic decrease (>4-fold) for DBT_3 (JMV2968) and DBT_2 (JMV2949) oligomers. Thus, the cellular uptake appeared length-dependent with an increase of internalization with the oligomer size. Moreover, the amount of JMV3229 that was internalized was more significant than that of Arg_8 despite the fact that it is uncharged. Even though the increase in efficiency from DBT_2 to DBT_4 could be associated with an increase of the hydrophobicity, the high difference between DBT_3 and DBT_4 might be also attributed to a

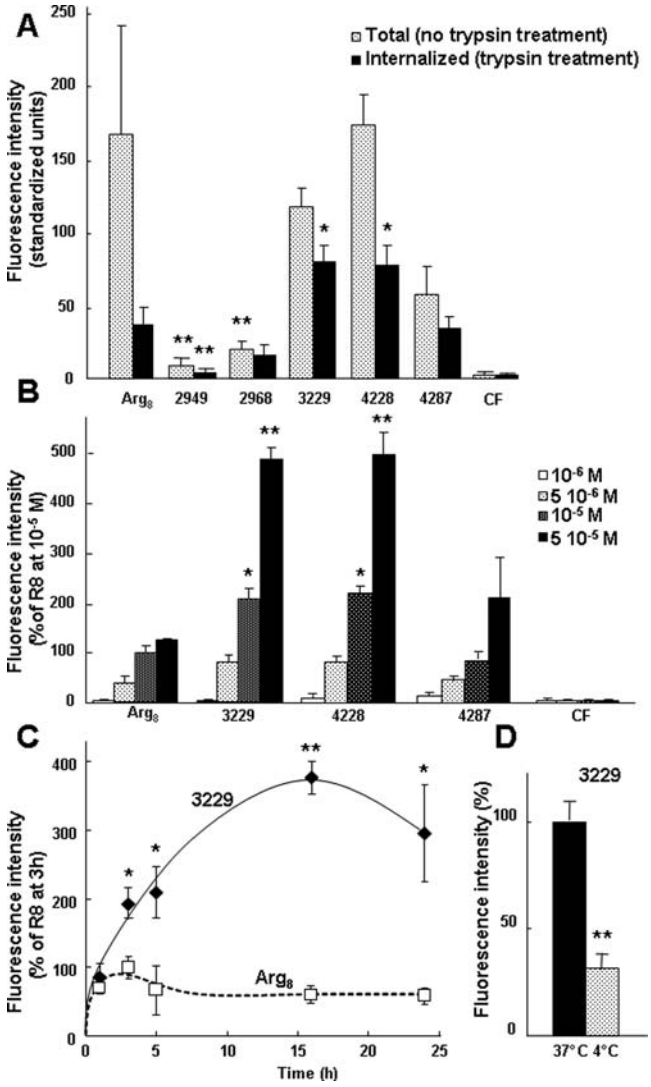

Figure 1. Uptake of Arg_8 and oligomers **1**−**5** in MDA-MB-231 cells. Data are the means ± SD from three independent experiments. In B to D, cells were treated by trypsin before fluorescence measurements. (A) Determination of total and internalized compounds after incubating cells for 3 h at 37 °C with 10^{-5} M **1**−**5**. $*p < 0.05$, $**p < 0.01$ relative to Arg_8 values with or without trypsin treatment, respectively (Student's *t* test). (B) Comparison of fluorescence emission after incubation for 3 h with several concentrations ranging from 10^{-6} to 5.10^{-5} M. $*p < 0.05$, $**p < 0.01$ relative to Arg_8 values at the same concentration (Student's *t* test). (C) Kinetics of internalization of JMV3229 and Arg_8 at 10^{-5} M. $*p < 0.05$, $**p < 0.01$ relative to Arg_8 values at the same time (Student's *t* test). (D) Effect of temperature on the cellular uptake of JMV3229 at 3 h. $**p < 0.01$ relative to Arg_8 values (Student's *t* test).

progressive organization of the oligomer structure. Compound JMV4228 constructed by oligomerization of an L-benzothiazepinone moiety was as potent as its D-counterpart suggesting that the configuration of the BT moiety was not important and that the CPNPs do not interact with a specific receptor but rather with hydrophobic plasma membrane molecules. Compound JMV4287 constructed from the alternation of D and LBT exhibited a 2-fold decreased uptake. This result could be explained by a change in the oligomer structure.

A dose−response analysis was performed to compare the uptake of the BT-oligomers with octa-arginine (Figure 1B). The penetration of all compounds appeared to be dose-dependent. However in contrast to Arg_8, uptake of JMV compounds still increased at high doses (5.10^{-5} M). The kinetics study performed with 10^{-5} M JMV3229 (Figure 1C) showed that its cellular entry was at least as efficient at 1 h as that of Arg_8. Then, JMV3229 uptake increased up to 16 h to reach a 6-fold higher concentration than Arg_8, for which maximal concentration is reached at 1 h. A temperature-dependent analysis performed at 4 and 37 °C (Figure 1D) showed that the cellular uptake exhibited a 3-fold decrease at low temperature, hence suggesting the involvement of an energy-dependent endocytotic pathway. The remaining fluorescence was most probably due to cell membrane-bound oligomers as shown in Figure 2B.

Intracellular Distribution of DBT Oligomers. Confocal laser scanning microscopy (CLSM) analyses were also performed in living cells to assess internalization and intracellular distribution. These experiments were associated with a kinetic study of DBT oligomer internalization. Figure 2A shows the internalization of JMV3229 in cellular organelles after 3 h of incubation with the highest accumulation at 16 h and an apparent decrease at 24 h in accordance with the kinetic study reported in Figure 1C. Co-staining with a membrane marker (lipid-raft labeling) indicated that this hydrophobic compound was not held in the lipid membrane. However, at 4 °C, the majority of the compound was colocalized with the membrane marker (Figure 2B) rather than internalized, confirming the temperature effect on the intracellular uptake described in Figure 1D and supporting an energy-dependent internalization mechanism.

To gain more insight into JMV3229 internalization, costainings were performed with other fluorescent markers for subcellular components such as the nucleus, endosomes, and lysosomes. The results showed that JMV3229 was mostly colocalized with an endosomal marker at 3 h (Figure 2C) and with a lysosomal marker at 16 h (Figure 2D). Similar data were obtained for the L-counterpart JMV4228 (Supporting Information). This indicated an endosomal uptake of these oligomers followed by a lysosomal accumulation.

Altogether, these data indicate the ability of these oligomers to target the endolysosomal pathway. Although most of the initial drug delivery studies aimed to avoid lysosomal addressing to prevent subsequent drug degradation, more recent studies demonstrated the relevant clinical utility to target this compartment for drug delivery in the treatment of lysosomal storage diseases, Alzheimer's disease, and cancer (*20*, *27*−*31*).

The cytotoxicity of this new class of molecules was also determined in MDA-MB-231 cells using the MTT viability assay (Supporting Information). After a 5 day-incubation, these compounds exhibited no significant effect on cell viability at the 10^{-5} M concentration used for internalization studies. These results indicated that poly-DBT could be safely used as vectors for cell drug delivery.

CONCLUSIONS

The cellular penetration efficiency of the described short DBT oligomers offers a novel class of vectors having the particularity of not being cationic. This feature should open new avenues in the field of compounds able to cross the cell membranes. The drastic increase of the cellular uptake along with the oligomer size could suggest an essential role of structuration and/or hydrophobicity for this class of compounds. Moreover, the decrease in the uptake of the D/LBT alternated oligomer should be also associated with structural features. In order to establish a relationship between their capacity to penetrate into the cell and their structural and physical features, more DBT oligomer derivatives need to be constructed. The structure of the oligomers is currently investigated using NMR spectroscopy and X-ray crystallography. The specific localization of DBT oligomers in endosomes and lysosomes has been evidenced. Studies toward the application of these CPNP as functional drug delivery vectors and the understanding of their translocation pathway are also in progress.

1- Synthesis of the oligomers JMV2949, JMV2968, JMV3229, JMV4228, JMV4287.

HBTU, DIEA, dichloromethane, methanol, acetonitrile, diethyl ether, trifluoroacetic acid, piperidine were purchased from Riedel-de Haën, Carlo Erba or Acros organics and used without purification. Fluorescein isothiocyanate (FITC) was purchased from Sigma-Aldrich, Lyon, France. Fmoc Rink amide polystyrene resin (100-200 mesh, 0.46 mmol/g) was purchased from SENN chemicals, Gentilly, France. Solvents used for HPLC and LC/MS were of HPLC grade. All final compounds were purified by reversed-phase HPLC and the purity assessed by analytical reversed-phase HPLC was found superior to 95 %

Anchoring on Rink amide-PS resin. Fmoc-Rink amide resin was conditioned for 30 minutes in DCM and submitted to the standard deprotection cycle, using DMF/ pip 80/20 solution for 30 minutes. After washing steps, the first constrained dipeptide mimetic (Fmoc-LBT-OH or Fmoc-DBT-OH) motif was loaded onto the resin through a standard coupling cycle, using HBTU (3 eq) as a coupling agent and DIEA (3 eq) as a base.

Coupling step. Coupling reaction was carried out manually in plastic syringes equipped with frits. HBTU (3 eq) as a coupling agent, DIEA (3 eq) as a base and Fmoc-DBT-OH or Fmoc-LBT-OH (3 eq) (according to resin loading) were solubilized in DMF and added to the resin. The reaction was stirred for 3 hours at room temperature. The reaction was monitored by the standard TNBS test (*1*).

Deprotection step. Fmoc deprotection was carried out using DMF/piperidine 80/20 v/v solution two times for 30 minutes.

Washing steps were performed after each coupling and deprotection steps: one time methanol, one time DCM, 3 times DMF and 3 times DCM.

FITC coupling. FITC reaction was carried out manually in plastic syringes equipped with frits. 1.5 eq of FITC and 3 eq of DIEA (according to resin loading) were solubilized in DMF and added to the resin. The reaction was stirred for 2 hours at room temperature. Due to the reddish coloration of the resin, the TNBS test was difficult to use to monitor the completion of the FITC coupling. Kaiser(*2*) test was preferred in this case.

Cleavage of Rink amide-PS resin. Oligomers were cleaved from resin for 2 hours in 99% trifluoroacetic acid. After removal of the resin by filtration, the trifluoroacetic acid was concentrated. Compounds were precipitated by addition of diethyl ether and filtrated. They were dissolved in acetonitrile/water 50/50 solution containing 0.1% TFA and freeze dried.

Purification of the compounds. All the compounds were purified by preparative HPLC (Waters 4000 apparatus) carried out on a C18 reversed-phase column (C18 Deltapak column, 100 mm x 40 mm, 15 µm, 100Å) at a flow rate of 50 mL/min of a mixture of H_2O + 0.1% TFA and CH_3CN + 0.1% TFA in gradient mode with UV detection at 214 nm.

Analysis of the compounds. HPLC: Samples were prepared in acetonitrile/water (50/50 v/v) mixture, containing 0.1% TFA. The HPLC system consisted of a Beckman 32 Karat System. All the analyses were carried out using a RP C18 VWR chromolith column, 50 mm x 3.9 mm. A flow rate of 5 mL/min and a gradient of (0–100)% B over 3 min were used. Eluent A: water/0.1% TFA; eluent B: acetonitrile/0.1% TFA. Detection was performed both at 214 nm and 254 nm.

LC/MS Analysis. Samples were prepared in acetonitrile/water (50/50 v/v) mixture, containing 0.1% TFA. The LC/MS system consisted of a Waters Alliance 2690 HPLC, coupled to a Waters-Micromass ZQ spectrometer (electrospray ionization mode, ESI+). All the analyses were carried out using a RP C18 monolithic Onyx Phenomenex 25 x 4.6 mm column. A flow rate of 3 mL/min and a gradient of (0–

100)% B over 3 min were used. Eluent A: water/0.1% formic acid; eluent B: acetonitrile/0.1% formic acid. Positive ion electrospray mass spectra were acquired at a solvent flow rate of 100–500 µL/min. Nitrogen was used for both the nebulizing and drying gas. The data were obtained in a scan mode in 0.1 s intervals; 10 scans were summed up to get the final spectrum. The yield and the purity after HPLC purification, HPLC retention time, calculated monoisotopic mass and detected mass of the compounds are reported in table 1.

Table 1.

2- Confocal Laser Scanning Microscopy of JMV4228. Distribution of JMV4228 is reported in Figure S1.

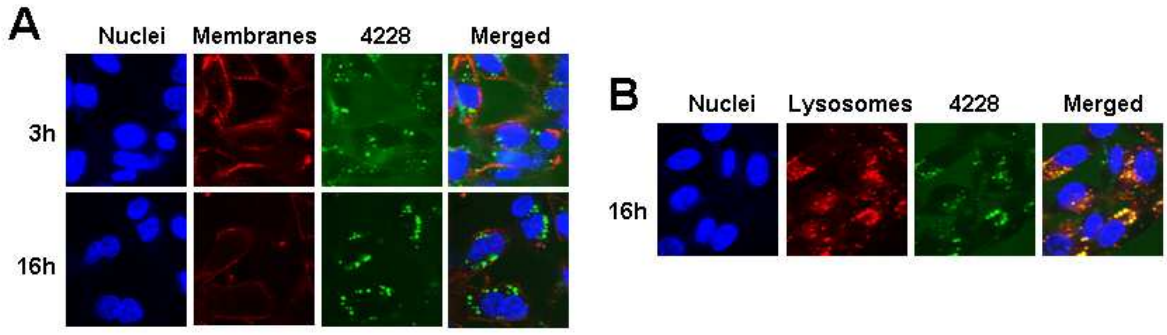

Figure S1. Confocal microscopy images of living MDA- MB-231 breast cancer cells incubated with compounds. Distribution of JMV4228 (A) at 3 h and 16 h of incubation at 37°C. To visualize

internalized compound, cells were stained with nucleus and membrane markers. Co-localization of JMV4228 (B) with the lysosome marker at 16 h at 37°C. Data are from one representative of two independent experiments.

3- MTT viability assay. Cellular toxicity of the fluorescent agents was examined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) cell viability assay. Briefly, 5000 cells were seeded in 96-well plates. Two concentrations (10-5 and 10-6 M) of compounds were tested for 5 days. Following this incubation, the cells were incubated for 4 h with 0.5 mg/mL of MTT in media. After 4 h, the MTT/media solution was removed, and the precipitated crystals were dissolved in ethanol/DMSO (1/1). The solution absorbance was read at 540 nm. We confirmed this assay to be linear and to give comparable results as total DNA quantification by diaminobenzoic acid assay(*3*).

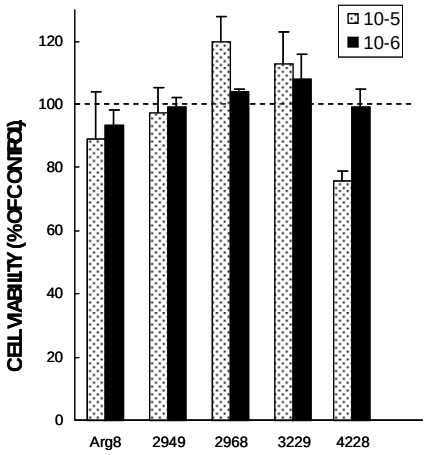

Figure S2. Cytotoxicity of compounds after a 5-day incubation at a concentration of 10^{-5} or 10^{-6} M. Values are mean ± SD of three independent experiments performed in triplicates. Values are expressed as a percentage of control cells incubated with vehicle alone (1% DMSO).

The gastrin-releasing peptide receptor (GRPR) is overexpressed on a number of human tumors and has been targeted with radiolabeled bombesin analogues for the diagnosis and therapy of these cancers. Seven bombesin analogues containing various linkers and peptide sequences were designed, synthesized, radiolabeled with ^{18}F, and characterized *in vitro* and *in vivo* as potential PET imaging agents. Binding studies displayed nanomolar binding affinities toward human GRPR for all synthesized bombesin analogues. Two high-affinity peptide candidates **6b** ($K_i = 0.7$ nM) and **7b** ($K_i = 0.1$ nM) were chosen for further *in vivo* evaluation. Both tracers revealed specific uptake in GRPR-expressing PC-3 tumors and the pancreas. Compared to **[^{18}F]6b**, compound **[^{18}F]7b** was characterized by superior tumor uptake, higher specificity of tracer uptake, and more favorable tumor-to-nontarget ratios. *In vivo* PET imaging allowed for the visualization of PC-3 tumor in nude mice suggesting that **[^{18}F]7b** is a promising PET tracer candidate for the diagnosis of GRPR-positive tumors in humans.

INTRODUCTION

Bombesin (BBS) is a 14-amino acid neuropeptide that was originally isolated from the skin of the *Bombina* frog and binds with high affinity to gastrin-releasing peptide (GRP) receptors (*1*−*4*). Four subtypes of BBS/GRP receptors have been identified. The bombesin receptor subtype 2 has been shown to be overexpressed on a variety of human tumors, including small-cell lung cancer (SCLC), prostate, breast, gastric, colon, pancreatic, and gastrointestinal cancer (*5*−*9*). Thus, radiolabeled BBS analogues having high affinity for this receptor subtype can be used as radiopharmaceuticals either for the detection or treatment of these cancers (*10*−*12*).

It has been shown that the C-terminal amino acid sequences, Trp8-Ala9-Val10-Gly11-His12-Leu13-Met14-NH_2, are necessary for retaining receptor binding affinity and preserving the biological activity of BBS-like peptides; hence, the N-terminal region of the peptide can be used for radiolabeling. A number of potent BBS analogues have been labeled with various radionuclides, such as $^{99\ m}$Tc, ^{111}In, ^{90}Y, ^{64}Cu, ^{177}Lu, ^{68}Ga, or ^{18}F, for targeting GRPR-expressing cancer cells in both animal models and human subjects (*13*−*25*). Among the available PET nuclides, ^{18}F has ideal characteristics for peptide receptor imaging studies in terms of its half-life (109.7 min) and low β^+ energy (0.64 MeV) (*26*). Current known methods of radiolabeling peptides with ^{18}F rely on using prosthetic groups such as the [^{18}F]succinimidyl 4-fluorobenzoate ([^{18}F]SFB) (*27*), [^{18}F]4-fluorobenzaldehyde (*28, 29*), and thiol-selective ^{18}F-labeling reagents (*30, 31*). Although great improvements have been achieved, the established methods have disadvantages in that the synthetic methods comprise multistep radiosyntheses and time-consuming workup procedures. Therefore, several research groups focus on new synthetic strategies that avoid the use of prosthetic groups. Recent studies have demonstrated the feasibility of labeling organoboron and organosilicon bioconjugates with ^{18}F in a single step (*32*−*35*). In our laboratories, we have successfully labeled bombesin peptides with ^{18}F in one step and applying silicon−fluorine chemistry (*36*). However, the ^{18}F-labeled silicon-based peptides showed relatively low tumor accumulation and retention as well as unfavorable hepatobiliary excretion in nude mice with PC-3 xenografts. This might be due to the introduction of the highly lipophilic di-*tert*-butyl silyl labeling moiety into the peptide. In order to improve the tumor targeting and imaging potential of ^{18}F-labeled bombesin peptides, another approach via ^{18}F-for-$^{+}N(CH_3)_3$ substitution using a less lipophilic benzonitrile labeling moiety has been exploited in our laboratories (*37*). The *in vitro* binding affinity of these fluorinated bombesin peptides toward GRPR were assessed by a competitive displacement assay using [^{125}I]-Tyr^4-bombesin as the radioligand. More than 11-fold higher binding affinity with benzonitrile as the labeling moiety was obtained compared to using di-*tert*-butyl silyl as the labeling moiety with the same peptide sequence (*36*). Therefore, in this study, several new BBS peptides were synthesized and ^{18}F-labeled via the aforementioned ^{18}F-for-$^{+}N(CH_3)_3$ substitution approach. Our efforts have been focused on improving the pharmacokinetics of BBS derivatives by using different linkers, peptide sequences, and non-natural amino acids. Two bombesin analogues, one being positively and another negatively charged, were chosen for further *in vivo* evaluation in nude mice with PC-3 xenografts.

EXPERIMENTAL PROCEDURES

General. All chemicals unless otherwise stated were purchased from Sigma-Aldrich or Merck and used without further purification. Fmoc-aminoacids were purchased from IRIS Biotech except Fmoc-Statine, FA01010, and Fmoc-Ala(SO_3Na)−OH), which were purchased from NeoMPS (now Polypeptide). The solvents were of HPLC quality. Peptide syntheses were carried out using Rink-Amide resin (0.68 mmol/g) following the standard Fmoc strategy (*29*). All amino acid residues were,

if not further specified, L-amino acid residues. FA01010 denotes (4*R*,5*S*)-4-amino-5-methylheptanoic acid, statine (Sta) denotes (3*S*,4*S*)-4-amino-3-hydroxy-6-methylheptanoic acid, Ala(SO_3H) denotes cysteine sulfonic acid, and Ava denotes 5-aminopentanoic acid. High-performance liquid chromatography (HPLC) analyses were performed using an ACE C18 column (50 × 4.6 mm, 3 μm) under the indicated conditions. Analytical HPLC chromatograms were obtained using an Agilent 1100 system with Gina software, equipped with UV multiwavelength and Raytest Gabi Star detectors. Semipreparative HPLC purifications were carried out using a semipreparative ACE C18 column (250 × 10 mm, 5 μm) under the indicated conditions. The semipreparative HPLC system used was a Merck-Hitachi L6200A system equipped with a Knauer variable wavelength detector and an Eberline radiation detector.

Solid-Phase Peptide Synthesis. Peptide synthesis was carried out using Fmoc-Rink Amide-linker functionalized polystyrene resin (0.68 mmol/g). The peptide chain was elongated in cycles of Fmoc deprotection, followed by coupling of the subsequent Fmoc amino acid. Acid-labile side chain protecting groups were used for the following amino acids: Fmoc-His(Trt)−OH, Fmoc-Trp(Boc)−OH, and Fmoc-Gln(Trt)−OH. Fmoc deprotection was achieved by shaking a suspension of the resin in 20% piperidine in DMF for 5 min and repeatedly doing so for another 20 min. The resin was subsequently washed with DMF (2×), CH_2Cl_2 (2×), and DMF (2×). A solution of Fmoc-Xaa−OH (Xaa = amino acid, 4 equiv), HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate, 4 equiv), HOBT (1-hydroxybenzotriazole, 4 equiv), DIPEA (*N*,*N*′-di-*iso*-propylethylamine, 8 equiv) in DMF was added to the resin-bound free amine peptide and shaken for 90 min at room temperature. This step was repeated with a reaction time of 60 min, and the resin was washed with DMF (2×), CH_2Cl_2 (2×), and DMF (2×). The two steps of Fmoc-deprotection and amino-acid addition were then repeated until the final elongation of the desired peptide was achieved. The peptides were typically prepared starting with 147 mg (0.1 mmol) of the resin. The amounts of reagents and building blocks in all subsequent reactions were calculated on the basis of this amount.

Procedure for the Synthesis of (4-Trimethylammonium-3-cyano-benzoyl)-Functionalized Peptide Trifluoroacetate Salts (Precursor Compounds **1a**−**7a***).* Representative procedure: *N*-methylmorpholine (NMM, 22 μL, 0.2 mmol) was added to a solution of 2-cyano-4-carboxyl-phenyl)-trimethylammonium triflate salt (71 mg, 0.2 mmol) and 4-(4,6-dimethoxy-1,3,5-triazin-2-yl)-4-methylmorpholinium tetrafluoroborate (66 mg, 0.2 mmol) in DMF (2 mL). The mixture was added to the resin-bound, side chain protected, Fmoc-deprotected peptide (0.1 mmol, based on the initial resin loading) which was prepared by following the general procedures described above. The reaction mixture was shaken intensively for 4 h. The resin was then filtered and washed with DMF (3 × 4 mL) and CH_2Cl_2 (3 × 4 mL). The coupling step was repeated. Thereafter, the resin was treated with a mixture of trifluoroacetic acid, distilled water, phenol, and tri*iso*propylsilane (85/5/5/5, 1.5 mL) for 3 h. The mixture was added to ice cold methyl *tert*-butylether, and the precipitate was separated by centrifugation. Water was added to the pellet, and the supernatant was lyophilized. The residue was purified by preparative RP-18 HPLC-MS with a gradient of 5−30% acetonitrile in 20 min and 0.1% trifluoroacetic acid as cosolvent. The desired fraction was collected and lyophilized, and the product was analyzed by HPLC-MS.

Syntheses of Fluorinated Peptides (Reference Compounds **1b**−**7b***).* Representative procedure: A solution of 3-cyano-4-fluorobenzoic acid (66 mg, 4 equiv) (*37*), HBTU (*O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate, 151 mg, 4 equiv), HOBT (1-hydroxybenzotriazole, 61 mg, 4 equiv), and DIPEA (*N*,*N*′-di-*iso*-propylethylamine, 70 μL, 4 equiv) in DMF (2 mL) was added to the resin-bound side chain protected peptide (0.1 mmol, based on the initial resin loading) which was prepared by following the general procedures described above. The reaction mixture was shaken intensively for 4 h. The resin was then filtered and washed with DMF (3 × 4 mL) and CH_2Cl_2 (3 × 4 mL). Thereafter, the resin was treated with a mixture of trifluoroacetic acid, distilled water, phenol, and tri*iso*propylsilane (85/5/5/5, 1.5 mL) for 3 h. The mixture was added to ice cold methyl *tert*-butylether, and the precipitate was separated by centrifugation. Water was added to the pellet, and the supernatant was lyophilized. The residue was purified by preparative RP-18 HPLC-MS with a gradient of 5−50% acetonitrile in 20 min and 0.1% trifluoroacetic acid as cosolvent. The desired fraction was collected and lyophilized, and the product was analyzed by HPLC-MS.

Radiolabeling. No-carrier added [^{18}F] fluoride was produced via the ^{18}O (p, n) ^{18}F nuclear reaction by irradiation of enriched [^{18}O] water. [^{18}F]Fluoride was immobilized on an anion-exchange cartridge (QMA light, Waters, AG) and eluted with a solution of Kryptofix $K_{2.2.2}$ (5 mg), Cs_2CO_3 (2.3 mg), or K_2CO_3 (1 mg) in acetonitrile (1.5 mL) and water (0.5 mL). The fluoride was dried by azeotropic distillation of acetonitrile at 110 °C under vacuum with a stream of nitrogen. The azeotropic drying was repeated three times with acetonitrile (3 × 1 mL). To the dried [^{18}F] fluoride complex, the TMA-based bombesin peptide precursor was added (2 mg, in 150 μL of DMSO). The reaction solution was heated at the indicated reaction temperatures. An aliquot was taken from the reaction mixture and analyzed by analytical HPLC. The identity of the tracer was confirmed by coinjection of the authentic standard on the same analytical HPLC system ACE C18 column (50 × 4.6 mm, 3 μm). Eluting conditions: 10 mM K_2HPO_4 in water (solvent A), 10 mM K_2HPO_4 in water/acetonitrile 3/7 (solvent B); 0−7.0 min, 5−95% B; 7.0−7.1 min, 95−100% B; 7.1−8.8 min, 100% B; 8.8−9.0 min, 100−5% B. The flow rate was 2 or 1.8 mL/min. Semipreparative HPLC purifications were carried out using a semipreparative ACE C18 column (250 × 10 mm, 5 μm). Elution system: 0.1% TFA in water (solvent A) and 0.1% TFA in acetonitrile/water 9/1 (solvent B).

*3-Cyano-4-[^{18}F]fluoro-benzoyl-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH_2 (***[^{18}F]1b***).* A solution of compound **1a** (2 mg) in anhydrous DMSO (150 μL) was added to a reaction vial containing the dry K[^{18}F]F/$K_{2.2.2}$ complex. After heating at 50 °C for 15 min, the crude reaction mixture was analyzed using an ACE C18 column. The ^{18}F-incorporation determined by HPLC was 77% (t_R = 4.92 min).

*3-Cyano-4-[^{18}F]fluoro-benzoyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH_2 (***[^{18}F]2b***).* A solution of compound **2a** (2 mg) in anhydrous DMSO (150 μL) was added to a reaction vial containing the dry Cs[^{18}F]F/$K_{2.2.2}$ complex (3.4 GBq). After heating at 70 °C for 15 min, the crude reaction mixture was analyzed using ACE C18 column. The ^{18}F-incorporation determined by HPLC was 67% (t_R = 4.87 min). The reaction mixture was diluted with water (4 mL) and injected onto an ACE semipreparative HPLC column (0.1% TFA in water (solvent A); B, 0.1% TFA in acetonitrile/water 9/1 (solvent B), 0−2.0 min, 20% B; 2.0−22.0 min, 20−60% B; 22.0−23.0 min, 60−100% B; 23.0−28.0 min, 100% B; flow rate, 3 mL/min), and the product was collected (1.1 GBq). The decay corrected radiochemical yield of the isolated product was around 47%, and radiochemical purity was greater than 99%.

*3-Cyano-4-[^{18}F]fluoro-benzoyl-Arg-βAla-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH_2 (***[^{18}F]3b***).* A solution of compound **3a** (2 mg) in anhydrous DMSO (150 μL) was added to a reaction vial containing dry K[^{18}F]F/$K_{2.2.2}$ complex (1.49 GBq). After heating at 50 °C for 15 min, the crude reaction mixture was

analyzed using an ACE C18 column. The ^{18}F-incorporation determined by HPLC was 56% (t_R = 4.78 min). The reaction mixture was diluted with water (4 mL) and injected onto an ACE semipreparative HPLC (0−5 min, 29% B; 5−25 min, 29−34% B; flow rate 3 mL/min). The desired ^{18}F-labeled product was collected (150 MBq, 21.1% d.c. RCY) with a specific activity of 72.5 GBq/μmol.

3-Cyano-4-[^{18}F]fluoro-benzoyl-Arg-Ser-Gln-Trp-Ala-Val-Gly-His(3Me)-Sta-Leu-NH$_2$ (**[^{18}F]4b**). A solution of compound **4a** (2 mg) in anhydrous DMSO (150 μL) was added to a reaction vial containing dry K[^{18}F]F/K$_{2.2.2}$ complex (2.9 GBq). After heating at 50 °C for 15 min, the crude reaction mixture was analyzed using ACE C18 column. The ^{18}F-incorporation determined by HPLC was 35% (t_R = 4.94 min). The reaction mixture was diluted with water (4 mL) and injected onto an ACE semipreparative HPLC (0−2 min, 35% B; 2−22 min, 35−55% B; flow rate 3 mL/min). The desired ^{18}F-labeled product was collected (28 MBq, 4% d.c. RCY).

3-Cyano-4-[^{18}F]fluoro-benzoyl-Arg-Ava-Gln-Trp-Ala-Val-Gly-His-FA01010-Leu-NH$_2$ (**[^{18}F]5b**). A solution of compound **5a** (2 mg) in anhydrous DMSO (150 μL) was added to a reaction vial containing dry K[^{18}F]F/K$_{2.2.2}$ complex (11 GBq). After heating at 70 °C for 15 min, the crude reaction mixture was analyzed using ACE C18 column. The ^{18}F-incorporation determined by HPLC was 63% (t_R = 5.51 min).

3-Cyano-4-[^{18}F]fluoro-benzoyl-Arg-Ava--Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH$_2$ (**[^{18}F]6b**). Radiolabeling based on the published procedure (*37*).

3-Cyano-4-[^{18}F]fluoro-benzoyl-Ala(SO$_3$H)-Ava-Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH$_2$ (**[^{18}F]7b**). A solution of compound **7a** (2 mg) in anhydrous DMSO (150 μL) was added to a reaction vial containing dry Cs[^{18}F]F/K$_{2.2.2}$ complex (20 GBq). After heating at 90 °C for 15 min, the crude reaction mixture was analyzed using ACE C18 column. The ^{18}F-incorporation determined by HPLC was 76% (t_R = 4.30 min). The reaction mixture was diluted with water (3 mL) and injected onto an ACE semipreparative HPLC column (0.1% TFA in water (solvent A), B, 0.1% TFA in acetonitrile/water 9/1 (solvent B), 0−2.0 min, 20% B; 2.0−22.0 min, 20−60% B; 22.0−23.0 min, 60−100% B; flow rate, 3 mL/min), and the product was collected (2.1 GBq). The decay corrected radiochemical yield of the isolated product was around 14%, and radiochemical purity was greater than 99%. Specific activity was 77 GBq/μmol at the end of the synthesis.

***In Vitro* Binding Affinity Studies.** The receptor binding affinities of bombesin (BBS) analogues **1b**−**7b** were determined in quadruplicate in a scintillation proximity assay (SPA) using cellular membranes transfected with human bombesin 2 receptors (GRPR) from PerkinElmer (RBHBS2M). The membranes and agglutinin-coupled SPA beads type A (PVT PEI Treated Wheatgerm, Amersham Bioscience) were mixed in assay buffer (50 mM Tris/HCl at pH 7.2; 5 mM $MgCl_2$; 1 mM EGTA; protease inhibitor (Roche Diagnostics GmbH; 1 tablet/50 mL); and 0.3% polyethylenemine) to give final concentrations of approximately 20 μg/mL protein and 8 mg/mL PVT-SPA beads. The ligand [^{125}I]-Tyr^4-bombesin (PerkinElmer; specific activity, 81.4 TBq/mmol) was diluted to 0.2 nM in assay buffer. The test compounds were dissolved in DMSO to give 1 mM stock solutions. They were further diluted in assay buffer to 2 pM−300 nM. Nonspecific binding was determined by an excess of 10 μM Tyr^4-bombesin (Sigma).

The assay was then performed as follows: First, 10 μL of compound solution to be tested for binding was placed in white 384 well plates (Lumitrac 200, Greiner). Next, 20 μL of the GRPR/PVT-SPA bead mixture and 20 μL of the ligand solution were added. After 120 min of incubation at room temperature, another 50 μL of assay buffer was added; the plate was sealed and centrifuged for 10 min at 520*g* at room temperature. Signals were measured in Top Count (Perkin-Elmer) for 1 min integration time per well. Nonspecific binding determined by an excess of bombesin was subtracted from total binding to yield the specific binding at each concentration. The IC_{50} and K_i values were calculated by nonlinear regression using *GraFit* 5 data analysis software (Erithacus Software Ltd.).

Lipophilicity: log $D_{7.4}$ Determination. The distribution coefficient D (log $D_{7.4}$) was determined by the "shake flask method" (*38*): the peptide was dissolved in a mixture of phosphate buffer (600 μL, pH 7.4) and *n*-octanol (600 μL) at 20 °C. The sample was equilibrated by shaking for 4 min followed by centrifugation. The concentrations of the peptide in each phase were measured by HPLC-UV absorption. The log D value was calculated as the log ratio of UV peak area at 254 nm in the organic and aqueous phases of the tested compound.

Biodistribution Studies. All animal experiments were performed in compliance with the current version of the German and Swiss law on the Protection of Animals. The biodistribution experiments were performed using nude mice bearing human prostate tumors (PC-3). For the induction of tumor xenografts, PC-3 cells (2×10^6 cells/mouse) were injected subcutaneously and allowed to grow for four to five weeks. Animals were injected intravenously with approximately 177 kBq of **[^{18}F]6b** and 230 kBq of **[^{18}F]7b** (100 μL). The animals were sacrificed at different postinjection time points (from 0.5 to 4 h, n = 3 for each time point). Organs and tissues of interest were collected and weighed. The amount of radioactivity was determined in the γ-counter to calculate the uptake (% injected dose per g tissue). In addition, three mice received 100 μg of bombesin coinjected with the radiolabeled compound and were sacrificed at 1 h postinjection to determine nonspecific uptake.

PET Study. Four nude mice were inoculated subcutaneously with PC-3 tumor cells (see above) next to the right shoulder. Animals were injected intravenously with 10−15 MBq of **[^{18}F]7b** and scanned in a whole body configuration from 60 to 105 min p.i. in the dedicated small-animal PET system quad-HIDAC. Two animals were coinjected with 50 μg of bombesin (1 mg/mL), while two animals received a corresponding volume of vehicle. PET data acquisition and monitoring of anesthesia were performed as described elsewhere (*39*). After the termination of the PET scan, animals were sacrificed at 107 min p.i. by decapitation for tissue sampling. PET data were reconstructed in a single 45 min time frame and normalized to the injected dose per body weight.

RESULTS AND DISCUSSION

Peptide Synthesis. On the basis of the amino acid sequence 7−14 of natural bombesin, we have designed and synthesized a series of new BBS analogues. To overcome the rapid degradation of natural BBS, some modifications were introduced at positions 13 and 14. Met14 was replaced by Leu for stabilization against aminopeptidase 3.4.11.1, and Leu13 was replaced by a non-natural amino acid (FA01010 or Sta) to prevent cleavage by neutral endopeptidase 3.4.24.11. Further modifications were the introduction of the methylated versions of His12 or Gly11. Additionally, a polar spacer, such as -Ava-, -Ava-Arg-, -Arg-βAla-, -Arg-Ser-, or -Ala(SO$_3$H)-Ava- was inserted between the labeling moiety and the binding sequence in order to further improve the pharmacokinetics and to avoid interference of the radiolabel with the binding region.

Nonradioactive peptides were synthesized by solid phase peptide synthesis (SPPS) following standard Fmoc strategies. Coupling of the resin-bound peptide with 3-cyano-4-fluoro-benzoic acid or 3-cyano-4-trimethylamino-benzoic acid afforded the corresponding nonradioactive (^{19}F) peptide standards and

[a] Isolated yields (not optimized; single syntheses) based on the amount and loading of commercial Fmoc-Rink-amide resin used for the synthesis.

precursors for ^{18}F-labeling, respectively. The nonradioactive BBS analogues served as a surrogate for ^{18}F-labeled compounds in the determination of binding affinity and as a standard reference for radio HPLC analysis. Figure 1 shows the sequences and the structures of the non-natural amino acid derivatives. All of the newly synthesized bombesin precursors and standard references were purified by reverse-phase HPLC and characterized by mass spectrometry (Table 1).

Radiolabeling. The direct ^{18}F-fluorination protocol developed previously in our laboratories was applied to these new bombesin peptide analogues. The synthetic scheme is depicted in Figure 2 using peptide **7a** as an example. Under the indicated radiolabeling conditions (Table 2), most peptides showed high ^{18}F-labeling efficiency. For peptide **4a**, which contains an Arg-Ser linker, a 29% ^{18}F-incorporation was obtained under mild radiolabeling conditions (50 °C, 15 min). For peptide **7a** containing the Ala(SO_3H)-Ava linker, a similar ^{18}F-labeling efficiency (26%, Table 2, entry 7) was achieved. These results successfully demonstrated that aromatic nucleophilic substitutions of ^{18}F-for-$^{+}$N(CH_3)$_3$ are feasible not only in the presence of histidine, tryptophan, and arginine amino acids but also in the presence of the unprotected acid and hydroxyl functionalities (serine amino acid). In addition, it was found that the ^{18}F-labeling efficiency could be dramatically improved from 26% to 75% by increasing the reaction temperature from 70 to 90 °C (Table 2, entries 7 and 8).

Concerning the stereochemistry of the peptides, similar peptides have been labeled under basic conditions (pH 8−10) and at elevated temperatures (75−100 °C); no racemization of the peptides was observed (*40*−*42*). Because most of our radiolabeling conditions (pH < 8, temperature 50−70 °C) are even milder than those previously reported, peptide racemization is not expected to occur under the above-mentioned radiolabeling conditions (Table 2). In addition, binding analysis of a ^{18}F-labeled peptide containing the same peptide sequence as **7b** revealed K_d and IC_{50} values of 1.43 nM and 0.94 nM, respectively, showing that the ^{18}F-labeled peptide still retains high binding affinity toward GRPR after heating at 90 °C for 10 min.

[a] ^{18}F-labeling was carried out in DMSO (150 μL) with a 2 mg amount of precursor using Cs_2CO_3 as the base. Conversion was determined from a radio-HPLC chromatogram representing the percentage of radioactivity area of the product related to the total radioactivity area. n.d.: not determined.

***In Vitro* Receptor Binding Affinity and Distribution Coefficient log $D_{7.4}$.** The binding affinities of the novel bombesin analogues toward the human GRPR were determined by a scintillation proximity assay using human GRPR-transfected cell membranes. All synthesized bombesin analogues showed nanomolar binding affinities toward human GRPR (Table 3). For peptide **1b** with Ava as a linker, a binding affinity of 28 nM was obtained. However, the attachment of one more hydrophilic amino acid Arg to the linker resulted in a more than 100 times higher binding affinity (Table 3; **2b**, K_i = 0.2 nM). Encouraged by these results, Arg-βAla and Arg-Ser were tested with the same peptide sequence. In both cases, binding affinities in the high nanomolar range were obtained (Table 3. K_i = 6.2 nM and 6.4 nM for **3b** and **4b**, respectively). With Arg-Ava as the linker, further investigations on the peptide sequence by exchanging Sta with FA01010 demonstrated that Sta was superior to FA01010 in terms of binding affinity. While the difference between the methylated His or the methylated Gly was not so obvious in this study (Table 3, K_i = 0.2 nM and 0.7 nM for **2b** and **6b**, respectively), the methylated Gly BBS analogue showed a 10-fold higher binding affinity than its corresponding methylated His analogue in our previous studies (*36*). Thus, the most promising peptide sequence toward human GRPR in this study was Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2. Further derivatization of the optimal peptide sequence by exchanging the linker Arg-Ava to Ala(SO_3H)-Ava yielded picomolar affinity (K_i = 0.1 nM) of this peptide candidate toward the GRPR.

The log $D_{7.4}$ values of the peptides are in the similar range (−0.8 to −1.4) with respect to the different polar linkers of Arg-Ava, Arg-βAla, or Ala(SO_3H)-Ava and peptide sequences. Compounds **6b** and **7b** gave the same log $D_{7.4}$ value of −1.1 (Table 3).

Biodistribution Studies. The biodistributions of **[^{18}F]6b** and **[^{18}F]7b** were carried out using nude mice bearing subcutaneous human prostate tumors (PC-3). The results are shown in Table 4. For **[^{18}F]6b**, the tumor uptake was 2.36 ± 0.47% ID/g at 30 min after injection, which slightly decreased to 1.80 ± 1.56% ID/g at 60 min postinjection and 1.61 ± 0.23% ID/g at 4 h postinjection. The binding of **[^{18}F]6b** toward GRPR could be blocked by around 40% in the tumor and 60% in the pancreas at 60 min postinjection, indicating that a large part of the tracer uptake in the tumor and pancreas can be attributed to specific GRPR binding. Besides the tumor and pancreas, the highest accumulation of the radiotracer **[^{18}F]6b** was found in excretory organs such as the gallbladder, intestine, kidneys, and liver. Activity uptake in the gall bladder and intestine was much higher than that in the kidneys, suggesting a preponderance of hepatobiliary elimination versus renal excretion. In the intestine there was, however, no differentiation between GRPR binding naturally expressed in intestinal smooth muscle cells and intestinal content. Furthermore, the increasing uptake in bone over time indicated that ^{18}F-fluoride represents a major radio metabolite. In comparison to the bombesin analogue **[^{18}F]6b**, the radiotracer **[^{18}F]7b** was characterized by clearly superior tumor targeting. The absolute tumor accumulation was more than double reaching about 5% ID/g at 30 min p.i., and this uptake was persistent over four hours. Tracer uptake in the GRPR-rich pancreas amounted to almost 50% ID/g at 1 h postinjection. Uptake of compound **[^{18}F]7b** in the tumor and pancreas was highly specific since accumulation could be effectively blocked by coadministration of unlabeled bombesin (83% and 97% specificity, respectively). The biodistribution of **[^{18}F]7b** was also characterized by a fast blood clearance leading to favorable tumor-to-blood ratios of >30 at 60 min postinjection and later. In line with compound **[^{18}F]6b**, the bombesin analogue **[^{18}F]7b** was mainly excreted via hepatobiliary pathways resulting in bile-to-tumor ratios of >20. It is clear that at physiological pH, Arg and Ala(SO_3H) become positively and negatively

[a] Results are expressed as % ID/g ± SD (n = 3). [b] Blockade study: animals received 100 μg of bombesin coinjected with the radiolabeled compound.

charged, respectively. Although bearing the same binding peptide sequence and having the same lipophilicity, the charge of the linker obviously plays a major role in *in vivo* pharmacokinetics. Similar results have been reported for different bombesin analogues labeled with ^{99m}Tc, ^{64}Cu, and ^{68}Ga (*43*−*46*) suggesting that a negatively charged linker has a profound effect on the biodistribution profile of bombesin analogues. Furthermore, significant *in vivo* defluorination of compound **[^{18}F]7b** was not evident from the % ID/g values in the bone.

PET Study. The excellent tumor targeting of compound **[^{18}F]7b** encouraged us to test the capability of **[^{18}F]7b** to visualize PC3 tumors *in vivo* by PET imaging. Two nude mice bearing subcutaneous PC-3 tumor xenografts next to the right shoulder were scanned from 60 to 105 min p.i. in a dedicated small-animal PET system both under baseline and blockade conditions (Figure 3). The tumor was clearly imaged under baseline conditions, whereas no tumor visualization was possible under blocking conditions. As expected from the *ex vivo*

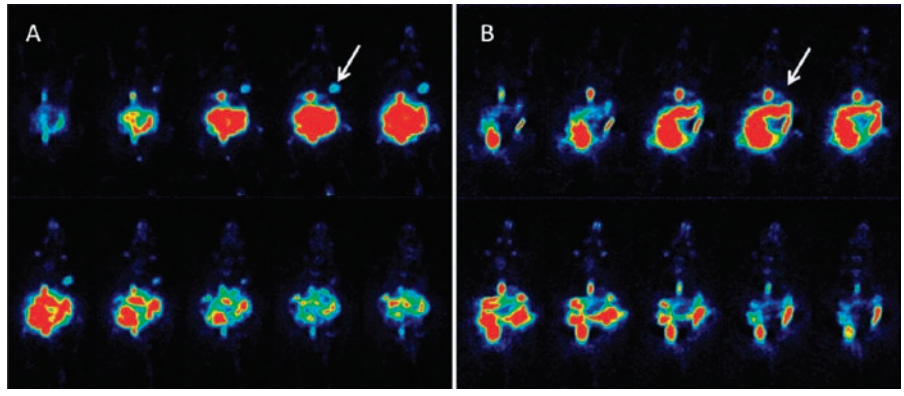

Figure 3. Series of horizontal whole body slices (ventral to dorsal) of two nude mice bearing subcutaneous PC-3 tumor xenografts next to the right shoulder (see arrows), which were injected with **[^{18}F]7b** and scanned from 60 to 105 min p.i., both under baseline (left) and blockade conditions (right). Image data were normalized to the injected dose per body weight.

biodistribution study, highest activity concentrations in the *in vivo* PET data were identified in the gall bladder and the intestine. The pancreas could not be visualized by PET due to the proximity to the bowel. Postmortem tissue sampling of these mice after PET scanning (107 min p.i.) confirmed the data which were obtained in the biodistribution study (Table 4). The absolute radioactivity uptake values in the GRPR-rich tissues were 5% ID/g for the tumor and 30% ID/g for the pancreas. The specificity of uptake amounted to 85% and 95% for the tumor and pancreas, respectively.

CONCLUSIONS

The direct ^{18}F-fluorination protocol developed previously in our lab was successfully applied to new bombesin peptide analogues. Amino acids such as histidine, tryptophan, and arginine, and non-natural amino acids such as statine and cysteine sulfonic acid in the peptide sequence did not require any protection group during radiosynthesis. *In vitro* binding studies of the synthesized bombesin analogues revealed nanomolar binding affinities toward the human GRPR. The most promising peptide sequence in this study was Gln-Trp-Ala-Val-NMeGly-His-Sta-Leu-NH_2. Two bombesin analogues containing this optimal peptide sequence, one positively (Arg-Ava) and another one negatively (Ala(SO_3H)-Ava) charged, were radiolabeled with ^{18}F and evaluated in biodistribution studies in nude mice bearing PC-3 xenografts. The comparative *in vivo* analysis of **[^{18}F]6b** and **[^{18}F]7b** showed superior characteristics for **[^{18}F]7b** with respect to (1) the total tracer accumulation in tumors and the GRPR-rich pancreas, (2) the specificity of uptake in target tissues, and (3) the target to nontarget ratios. The positive *in vivo* results of **[^{18}F]7b** suggest that this compound represents a promising PET tracer candidate for the visualization of GRPR-positive tumors in humans.

ACKNOWLEDGMENT

We thank Claudia Keller, Cindy Fischer, Selahattin, Ede, Marion Zerna, Ingo Horn, Jörg Pioch, René Zernicke, Volker Stickel, Ingolf Weber, Melanie Appel, Peter Friese, and Katrin Dinse for their excellent technical assistance.

Solid-Phase Synthesis of Azaphthalocyanine−Oligonucleotide Conjugates and Their Evaluation As New Dark Quenchers of Fluorescence

Kamil Kopecky, Veronika Novakova, Miroslav Miletin, Radim Kučera, and Petr Zimcik*

Department of Pharmaceutical Chemistry and Drug Control, Faculty of Pharmacy in Hradec Kralove, Charles University in Prague, Heyrovskeho 1203, 50005 Hradec Kralove, Czech Republic. Received May 14, 2010; Revised Manuscript Received August 30, 2010

Hydrophobic nonaggregating metal-free azaphthalocyanines (AzaPc) of the tetrapyrazinoporphyrazine type were synthesized, characterized, and used for oligonucleotide labeling. Both 3′-end and 5′-end labeling methods using solid phase synthesis suitable for automatic processes in the DNA/RNA synthesizer were developed. The hydrophobic character of AzaPc enabled the anchoring of the conjugates on reverse phase of the oligonucleotide purification cartridge, thus enabling their simple purification. AzaPc did not show any fluorescence and extremely low singlet oxygen quantum yields (Φ_Δ = 0.015−0.018 in DMF) in a monomeric state due to ultrafast intramolecular charge transfer. That is why they were investigated as a new dark quencher structural type. They profit particularly from absorption in a wide range of wavelengths (300−740 nm) that covers all fluorophores used in hybridization assays nowadays. As an example, quenching efficiency was evaluated in a simple hybridization assay using monolabeled probes. AzaPc-based probes efficiently quenched both fluorescein and Cy5 fluorescence by both resonance energy transfer and contact quenching. The results were compared with three established dark quenchers, and the AzaPc exerted better (BHQ-1 and BHQ-2) or comparable (BBQ-650) quenching efficiencies for both fluorophores.

INTRODUCTION

Modification of oligonucleotides with dyes is a commonly used procedure in genomic assays, e.g., in the monitoring of real-time polymerase chain reaction (PCR[1]). Most of the hybridization assays are based on the combination of a fluorophore with a quencher leading to the decrease of the fluorophore emission after detection of the target (*1*). The dark quenchers are a modern type of quenchers with no intrinsic fluorescence, which substantially simplifies the hybridization assays and increases their sensitivity. However, the currently used dark quenchers are based on two or three structural types, and they are often suitable only for a restricted number of fluorescent labels due to a limited spectral overlap. Therefore, the development of new highly efficient and versatile dark quenchers is desirable.

Phthalocyanines (*Pc*) and their aza-analogues azaphthalocyanines (AzaPc) are long known organic dyes with application in various areas (*2*). Despite deep investigations in *Pc* and AzaPc chemistry and applications, *Pc* conjugates with oligonucleotides were described only recently (*3*−*5*); furthermore, those using AzaPc have not been reported at all. For example, strong fluorescent properties of *Pc* were appreciated in *Pc*-oligonucleotide conjugates, and several new *Pc*-based near-infrared emitting fluorophores for DNA-hybridizations assays were developed (*6*, *7*). The use of *Pc*−oligonucleotide conjugates for a specific DNA catalytic or photosensitized modification was also described (*8*, *9*). The conjugation of *Pc* with the oligonucleotide is usually performed in a solution that requires the water solubility of the *Pc* moiety and subsequent extensive purification involving HPLC. The *Pc*−oligonucleotide labeling approaches tested until this time cover isothiocyanate (*5*) or succinimidyl methods (*6*, *10*, *11*), Huisgen cycloaddition (*12*), and reductive amination (*12*).

During our studies of AzaPc, we systematically observed that alkylamino substituted derivatives even in the strictly monomeric form are lacking any fluorescent or photosensitizing properties typical for other AzaPc derivatives (*13*). Recently, we discovered and fully explained that ultrafast intramolecular charge transfer (ICT) is responsible for the quenching of the S_1 excited state of such AzaPc (*14*). This unique mechanism of S_1 state deactivation, not yet observed at *Pc* derivatives, is responsible for the lack of fluorescence. These properties, together with strong absorption over a wide range of wavelengths, make alkylamino AzaPc ideal candidates for the modern dark quenchers. In order to confirm the hypothesis, suitable AzaPc were synthesized, simple solid-phase labeling of oligonucleotide probe was developed, and the conjugates were subjected to hybridization assays with two commonly used fluorophores.

EXPERIMENTAL PROCEDURES

All organic solvents were of analytical grade. Anhydrous butanol was stored over magnesium and distilled prior to use. Anhydrous pyridine was distilled from potassium hydroxide and stored over molecular sieves. Anhydrous tetrahydrofuran (THF) was stored over sodium and distilled prior to use. All chemicals for synthesis were obtained from established suppliers (Aldrich, Acros, Merck) and used as received. TLC was performed on Merck aluminum sheets with silica gel 60 F254. Merck

Kieselgel 60 (0.040−0.063 mm) was used for column chromatography. Long chain amino alkyl (lcaa) solid phase (500 Å controlled pore glass (CPG)) was obtained from ChemGenes Corporation (Wilmington, MA, USA). All HPLC chromatographic separations were performed on a Shimadzu chromatography system consisting of a communication bus module CBM 20A, a diode array detector SPD-M20A, two pumps LC-20AD, an autoinjector SIL-20AC, a column compartment CTO-20AC, a degasser DGU-20A_3, and a computer-based chromatographic software LC solution (Shimadzu, Tokyo, Japan). The infrared spectra were measured on IR-Spectrometer Nicolet Impact 400 in KBr pellets. The ^{1}H and ^{13}C NMR spectra were recorded on Varian Mercury-Vx BB 300 (299.95 MHz ^{1}H, and 75.43 MHz ^{13}C). The reported chemical shifts are relative to tetramethylsilane. The UV/vis spectra were recorded using a Shimadzu UV-2401PC spectrophotometer. The fluorescence spectra were obtained by an AMINCO-Bowman Series 2 luminescence spectrometer. The matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectra of compounds **1**, **2**, and **7**−**10** were collected by a Voyager-DE STR mass spectrometer (Applied Biosystems) in α-cyano-4-hydroxycinnamic acid or *trans*-2-[3-(4-*tert*-butylphenyl)-2-methyl-2-propenylidene]-malononitrile as the matrix. Mass spectra of oligonucleotide probes were obtained using a MALDI-TOF Bruker Autoflex II mass spectrometer. Compound **3** was prepared according to Mørkved et al. (*15*), and compounds **1** (*16*) and **6** (*17*) have been published by our group earlier.

Synthesis. *Azaphthalocyanine (2).* AzaPc **1** (100 mg, 0.09 mmol) in anhydrous dichloromethane (3 mL) was added to 2-cyanoethyl-*N*,*N*-diisopropylchlorophosphoramidite (102 mg, 0.36 mmol) and diisopropylethylamine (126 μL, 0.72 mmol) in anhydrous dichloromethane (5 mL) and stirred for 2 h at rt under an argon atmosphere. Progress of the reaction was monitored on TLC (dichloromethane/acetone/methanol 50:1:1; product R_f = 0.56; compound **1** R_f = 0.12). Thereafter, the solution was washed with saturated $NaHCO_3$, dried by Na_2SO_4, and evaporated to dryness. Any possible purification on a silica column failed due to the decomposition of **2** on silica. That is why the product was used directly for oligonucleotide modification without any further purification. The similar instability of phosphoramidites on silica or alumina has been described also by other researchers (*18*). The MALDI-TOF spectra of **2** showed the mass at expected *m*/*z* = 1322.6, approximately 10% of the oxidized product at *m*/*z* = 1338.6, and a fragment at *m*/*z* = 1105.6 caused by laser ionization. Yield, 105 mg; 89% as a deep purple solid. MS (MALDI-TOF) *m*/*z* = 1105.6 (55) $[M\text{-}OPN(iPr)_2OCH_2CH_2CN]^+$, 1322.6 (100) $[M]^+$, 1338.6 (10) $[M + O]^+$.

4-[(3-Chloro-5,6-dicyanopyrazin-2-yl)methylamino]benzoic Acid (4). A mixture of compound **3** (400 mg, 2 mmol) and 4-(methylamino)benzoic acid (604 mg, 4 mmol) in THF (75 mL) was refluxed for 12 h. The reaction was cooled down and filtered, and the filtrate was purified on silica with chloroform/acetone/methanol 10:1:1 as the mobile phase. The product was recrystallized from ethanol/water. Yield, 520 mg; 83% as a yellow powder; mp 208.1−211.6 °C. ^{1}H NMR (300 MHz, [D_6] acetone): δ = 8.09 (d, ^3J(H,H) = 8.5 Hz, 2H, arom. CH); 7.48 (d, ^3J(H,H) = 8.5 Hz, 2H, arom. CH_2) and 3.66 (s, N−CH_3, 3H,) ppm. ^{13}C NMR (75 MHz, [D_6] acetone): δ = 166.7, 153.5, 149.6, 141.1, 131.9, 130.7, 130.0, 125.8, 121.9, 114.3, 114.2, and 42.6 ppm. IR (KBr): ν = 3066, 2957, 2663, 2546, 2360, 2343, 2234 (CN), 1694, 1607, 1537, 1494, 1406, and 1375 cm^{-1}.

4-[(5,6-Dicyano-3-diethylaminopyrazin-2-yl)methylamino]benzoic Acid (5). Compound **4** (312 mg, 0.89 mmol) was refluxed in THF (50 mL) with diethylamine (1.3 g 18 mmol) for 2 h. The reaction was cooled down, filtered, and the solvent evaporated. The crude product was purified on silica with a mobile phase of chloroform/methanol 10:1 and finally recrystallized from ethanol/water. Yield, 324 mg; 62% of yellow powder; mp 263.3−266.2 °C (decomp.). ^{1}H NMR (300 MHz, [D_6] DMSO−): δ = 7.79 (d, ^3J(H,H) = 8.8 Hz, 2H, arom. CH_2), 7.09 (d, ^3J(H,H) = 8.8 Hz, 2H,arom. CH), 3.48 (s, 3H, N−CH_3), 3.25 (q, ^3J(H,H) = 7 Hz, 4H, N−CH_2) and 0.78 (t, ^3J(H,H) = 7 Hz, 6H, CH_2−CH_3) ppm. ^{13}C NMR (75 MHz, [D_6] DMSO): δ = 167.0, 148.5, 147.6, 143.9, 130.9, 126.0, 124.1, 120.4, 118.3, 115.4, 115.2, 42.8, 39.2, and 12.5 ppm. IR (KBr): ν = 2976, 2936, 2876, 2360, 2229 (CN), 1686, 1607, 1533, 1501, 1404, and 1292 cm^{-1}.

2-[(4-Carboxyphenyl)methylamino]-3,9,10,16,17,23,24-heptakis(diethylamino)-1,4,8,11,15,18,22,25-(octaaza)phthalocyanine (7). Metal lithium (168 mg, 24 mmol) was added to the refluxing mixture of compounds **5** (300 mg, 0.85 mmol) and **6** (700 mg, 2.57 mmol) in anhydrous butanol (20 mL) and the reflux continued for the next 3 h. The solvent was removed under reduced pressure, dilute acetic acid (50%, 50 mL) was added, and the suspension was stirred for 30 min at rt. The crude product was filtered and washed thoroughly with water. The resulting mixture of congeners was separated on silica with dichloromethane/acetone/methanol 20:1:1 as the mobile phase. The second intense purple fraction (product) was purified again on silica with dichloromethane/acetone/methanol 30:1:1. Finally, pure compound **7** was dissolved in 5 mL of dichloromethane, dropped into 200 mL of hexane, and cooled to −30 °C overnight. The precipitated fine suspension was filtered and washed with hexane. Yield, 150 mg; 15% of deep purple solid. ^{1}H NMR (300 MHz, [D_5] pyridine): δ = 13.83 (br s, 2H; central NH), 8.48 (d, ^3J(H,H) = 9 Hz, 2H; arom. CH), 7.20 (d, overlap with solvent, 2H; arom. CH), 3.96−3.86 (m, 24H, N−CH_2), 3.85 (s, 3H; N−CH_3), 3.72 (q, ^3J(H,H) = 7 Hz, 4H; N−CH_2) and 1.27−1.06 ppm (m, 42H; CH_3). ^{13}C NMR (75 MHz, [D_5] pyridine): δ = 169.0, 153.2, 151.0, 150.9, 150.5, 146.7, 146.6, 143.0, 142.9, 141.6, 140.0, 139.9, 139.7, 139.7, 131.4, 117.3, 43.8, 43.1, 43.1, 39.1, 13.2, 13.1, and 13.1 ppm (some signals were overlapped with signals of solvent). IR (KBr): ν = 2969, 2931, 2873, 1710 (CO), 1639, 1605, and 1426 cm^{-1}. UV/vis (THF): λ_{max} (ε) = 680 (80000), 654 (66500), 622sh, 597sh, 518 (54300) and 369 nm (93200 $M^{-1}cm^{-1}$). MS (MALDI-TOF): *m*/*z* = 1168.6 $[M]^+$. Anal. ($C_{60}H_{80}N_{24}O_2$ + 2 H_2O) calcd. C 59.78, H 7.02, N 27.89; found, C 60.18, H 7.30, N 27.53.

Azaphthalocyanine (8). AzaPc **7** (290 mg, 248 μmol) was dissolved in anhydrous tetrahydrofuran (40 mL). *N*,*N*′-dicyclohexylcarbodiimide (DCC) (56.2 mg, 273 μmol) and subsequently *N*-hydroxysuccinimide (NHS) (31.4 mg, 273 μmol) were added. The reaction was stirred for 72 h at rt. The precipitated solid (*N*,*N*′-dicyclohexylurea) was filtered off and washed with THF. 3-Amino-1,2-propandiol (113 mg, 1.24 mmol) in methanol was added into the THF solution, and the reaction was stirred at rt. The reaction was protected from light by aluminum foil. After 36 h, the solvent was evaporated at reduced pressure, and the rest was suspended in water, filtered, and washed thoroughly with water. Purification was performed on silica with a dichloromethane/acetone/methanol gradient from 30:1:1 to 10:1:1. Yield, 150 mg; 49% as deep purple solid. ^{1}H NMR (300 MHz, [D_5] pyridine): δ = 13.81 (br s, 2H; central NH), 9.32 (t, ^3J(H,H) = 6 Hz, 1H; NHCO), 8.32 (d, ^3J(H,H) = 9 Hz, 2H; arom. CH), 7.17 (d, overlap with solvent, 2H; arom. CH), 4.53−4.42 (m, 1H; C*H*−OH), 4.32−4.00 (m, 4H; NH−CH_2, O−CH_2), 3.97−3.84 (m, 24H; N−CH_2), 3.83 (s, 3H, N−CH_3), 3.69 (q, ^3J(H,H) = 7 Hz; 4H, N−CH_2) 1.21 (t, ^3J(H,H) = 7 Hz, 30H; CH_3), 1.14 (t, ^3J(H,H) = 7 Hz, 6H; CH_3) and 1.06 ppm (t, ^3J(H,H) = 7 Hz, 6H; CH_3). ^{13}C NMR (75 MHz, [D_5] pyridine): δ = 168.4, 153.1, 151.0, 150.9, 150.9, 150.6, 150.5, 150.0, 147.0, 146.1, 142.8, 142.7, 141.5, 140.1, 139.9, 139.8, 139.7, 139.6, 129.4, 128.9, 128.3, 126.1, 122.9, 117.9, 116.7,

IR (KBr): $\nu = 2969, 2931, 2873, 1636$ (CONH), 1607, 1506, and 1427 cm^{-1}. UV/vis (THF): λ_{max} (ε) = 681 (80000), 655 (65600), 622sh, 597sh, 518 (53500) and 370 nm (91100 $M^{-1}cm^{-1}$). MS (MALDI-TOF) m/z = 1241.3 $[M]^+$. Anal. ($C_{63}H_{87}N_{25}O_3 + 3\ H_2O$) calcd. C 58.36, H 7.23, N 27.01; found, C 58.50, H 7.33, N 26.97.

*Azaphthalocyanine (**9**).* AzaPc **8** (124 mg, 0.1 mmol), 4,4′-dimethoxytrityl chloride (DMTrCl) (44 mg, 0.13 mmol), and a catalytic amount of 4-*N*,*N*-dimethylaminopyridine were dissolved in anhydrous pyridine (20 mL) and stirred for 14 h at rt. After that time, more DMTrCl (169 mg, 0.5 mmol) was added, and the reaction was stirred further. The reaction vessel was protected from light by aluminum foil. After 24 h, TLC (dichloromethane/pyridine 40:1) indicated full conversion. The product was used directly for the subsequent reaction without any isolation. A sample was taken from the solution and analyzed using mass spectrometry. MS (MALDI-TOF) m/z 1543.7 $[M]^+$, after the addition of trifluoroacetic acid (TFA) into the matrix (deprotection of 4,4′-dimethoxytrityl (DMTr)): m/z 1241.6 $[M\text{-}DMTr]^+$.

*Azaphthalocyanine (**10**).* Succinic anhydride (100 mg, 1 mmol) was added into the previous reaction, and the mixture was heated for 12 h at 60 °C. Thereafter, the solvent was removed under reduced pressure, and the crude product was purified on silica with a step gradient: dichloromethane/pyridine 40:1, dichloromethane/pyridine 20:1, and dichloromethane/methanol/pyridine 20:1:1. Yield, 40 mg; 25% (after two steps) as a deep purple solid. ^1H NMR (300 MHz, [D_5] pyridine): δ = 13.86 (br s, 2H; central NH), 9.11 (t, ^3J(H,H) = 5 Hz, 1H; NHCO), 6.88−8.46 (m, 17H; arom. CH), 4.33−4.20 (m, 1H; C*H*-O), 3.98−3.79 (m, 26H; 1 × NH−CH_2, 12 × N−CH_2), 3.75 (s, 3H; N−CH_3), 3.73−3.56 (m, 12H; 2 × O−CH_3, 1 × O−CH_2, 2 × N−CH_2), 2.91−2.87 (m, 2H; CH_2−CO), 2.85−2.81 (m, 2H; CH_2−CO), 1.20 (t, ^3J(H,H) = 7 Hz, 30H; CH_3), 1.14 (t, ^3J(H,H) = 7 Hz, 6H; CH_3) and 1.06 ppm (t, ^3J(H,H) = 7 Hz, 6H; CH_3). ^{13}C NMR (75 MHz, [D_5] pyridine): δ = 174.4, 172.2, 167.1, 158.3, 152.4, 150.3, 150.2, 150.1, 148.5, 146.3, 145.1, 144.7, 135.7, 135.3, 134.1, 131.0, 129.9, 128.3, 127.9, 127.6, 126.4, 116.9, 113.0, 85.8, 72.4, 62.2, 54.5, 42.9, 42.4, 42.3, 38.5, 29.5, 29.3, 29.1, 12.4 ppm (some signals were overlapped with the signals of the solvent). IR (KBr): ν = 3428, 3305, 3050, 2966, 2930, 2871, 1734 (CO-O), 1640(CO-NH), 1607, 1508, 1425, and 1250 (O−CH_3) cm^{-1}. MS (MALDI-TOF): m/z = 1643.7 $[M]^+$; after the addition of TFA into the matrix, m/z = 1341.7 $[M\text{-}DMTr]^+$.

*Solid Phase Modified with Azaphthalocyanine (**11**).* AzaPc **10** (8 mg, 5 μmol), *O*-(benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU) (3 mg, 10 μmol), and anhydrous triethylamine (10 μL) were dissolved in anhydrous dimethylformamide (DMF) (2 mL), and 100 mg of lcaa CPG was added. The reaction vial was sealed, and the mixture was shaken for 24 h at rt on an orbital shaker protected from light. Thereafter, the solid phase was washed with DMF, acetonitrile, and diethylether and dried over the silica under reduced pressure. Unreacted amino groups were subsequently capped. A mixture of anhydrous THF, pyridine, and acetic anhydride (8:1:1 (v/v), 1 mL) was mixed with a 10% (m/m) solution of 1-methylimidazole in anhydrous THF (1 mL) and shaken with the solid phase **11** for 30 min at rt. Thereafter, the solid phase was washed with DMF, acetonitrile, and diethylether and dried over silica under reduced pressure. 4,4′-Dimethoxytrityl loading was determined as described in the following procedure. Approximately 2−3 mg of the support was accurately weighed out directly to the test tube, perchloric acid solution (10 mL, 51.4 mL of 70% $HClO_4$ + 46 mL of methanol) was added, and the test tube was sealed and shaken. The optical absorbance of the sample, diluted to fit an interval of 0.2−1.0 AU was measured at 498 nm in a 1 cm cuvette. The loading was calculated as given bellow:

$$\text{loading } (\mu\text{mol/g}) = (\text{absorbance at } 498) \times \text{dilution} \times 143/(\text{weight of support (mg)})$$

The loading of DMTr on solid phase **11** was determined to be 30.8 μmol/g.

Synthesis of Oligonucleotides. Oligonucleotides were synthesized on a Perkin-Elmer Applied Biosystems 394 DNA/RNA synthesizer. 3′-Labeling of the oligonucleotides was achieved by synthesis on modified solid phases (solid phase **11** and commercially obtained supports of Black Hole Quencher (BHQ) or BlackBerry Quencher (BBQ)). 5′-Labeling of the oligonucleotides was performed on the same synthesizer employing standard phosphoramidite chemistry and corresponding dye 2-cyanoethyl-(*N*,*N*-diisopropyl)-phosphoramidites (compound **2** and commercially obtained dyes). 3′-BHQ-1 CPG, 3′-BHQ-2 CPG, 5′-BHQ-1 phosphoramidite, 5′-BHQ-2 phosphoramidite, Cy5 phosphoramidite, and 5′-fluorescein phosphoramidite were supplied by Glen Research, Sterling, VA, USA. 3′-BBQ-650 CPG and 5′-BBQ-650 phosphoramidite were supplied by Berry & Associates, Inc., Dexter, MI, USA. The synthesis and purification of oligonucleotides labeled with commercially obtained dyes were performed according to the supplier's recommendations.

OPC Purification of Oligonucleotides S1−S6 Modified with AzaPc. Prepared oligonucleotides **S1**−**S6** with AzaPc were purified on oligonucleotide purification cartridges (OPCs), Puri-Pak cartridges, (ChemGenes Corp., Wilmington, MA, USA) directly after deprotection from the solid phase. The OPC was washed with acetonitrile (4 mL) and 2 M triethylammonium acetate (2 mL). A solution of oligonucleotide (2−3 mL) in deprotecting solution was loaded on the OPC repeatedly until all of the color was absorbed to the top of OPC. Thereafter, the OPC was washed with a diluted solution of ammonia (2.5%, 4 mL), then with 8% acetonitrile (4 mL) and 30% acetonitrile (2 mL). The desired sequence was obtained by freeze-drying the 30% acetonitrile fraction. Purified oligonucleotides were stored at −20 °C.

S1 (AzaPc): MS (MALDI-TOF), a cluster peaking at m/z 8805 $[M + H]^+$ and adducts with sodium and potassium. **S2** (AzaPc): MS (MALDI-TOF), a cluster peaking at m/z 10325 $[M + H]^+$ and adducts with sodium and potassium. **S3** (AzaPc): MS (MALDI-TOF), a cluster peaking at m/z 11846 $[M + H]^+$ and adducts with sodium and potassium. **S4** (AzaPc): MS (MALDI-TOF), a cluster peaking at m/z 8685 $[M + H]^+$ and adducts with sodium and potassium. **S5** (AzaPc): MS (MALDI-TOF), a cluster peaking at m/z 7400 $[M + H]^+$ and adducts with sodium and potassium. **S6** (AzaPc): MS (MALDI-TOF), a cluster peaking at m/z 5819 $[M + H]^+$ and adducts with sodium and potassium.

HPLC Analysis. A gradient elution was used to analyze **S1**−**S6** modified with AzaPc. The separation was performed on a Hypersil BDS C18 column (100 × 4.6 mm, 3 μm particle size) using a mobile phase consisting of acetonitrile and 50 mM triethylammonium acetate. Mobile phase A was 12% acetonitrile in 50 mM triethylammonium acetate, and mobile phase B was acetonitrile. The gradient time program was set as follows: 0−2 min 0%B; 2−18 min 0−85% B; 18−25 min 85% B; 25−25.5 min 85−0% B. The column was equilibrated for 4.5 min. The column temperature was maintained at 40 °C, and the flow rate was set at 0.7 mL/min. The compounds were analyzed by a diode array detector. The corresponding controls were analyzed separately to allow the determination of their elution patterns.

Unlabeled oligonucleotides were eluted with t_R of approximately 2 min and free dye (**1** or **8**) with t_R of approximately 23 min.

Hybridization Assays. *Absorption Spectra of Duplexes.* Spectra of duplexes were measured in hybridization buffer. Stock solutions of oligonucleotides **S1**, **S3**, and **S4** labeled with AzaPc and **SF** and **SFX** labeled with Cy5 were prepared to a concentration 100 μM. Hybridization buffer (1 mL) was transferred to a cuvette, the stock solution of oligonucleotide probe with the quencher (10 μL) was added, and the absorption spectrum was measured. Thereafter, the stock solution of the oligonucleotide labeled with fluorophore (10 μL) was added, and the solution was heated to 50 °C for 1 min. The absorption spectrum of the duplex was measured after 30 min when the sample cooled down to laboratory temperature. The final concentration of both oligonucleotides was 1 μM. Absorption spectra of **SF** and **SFX** were measured also separately after the addition of the stock solution (10 μL) to hybridization buffer (1 mL).

Determination of Quenching Efficiency. The method was adopted from Marras et al. (*1*). Oligonucleotides **S1**−**S6** modified with AzaPc, BHQ-1, BHQ-2, and BBQ-650 or without any quencher were dissolved in hybridization buffer to a stock concentration 10 μM. Oligonucleotide **SF** was dissolved in hybridization buffer to a concentration 0.05 μM and transferred to a cuvette (800 μL), and the fluorescence was measured at 663 and 517 nm for Cy5 and fluorescein (FAM), respectively (excitation wavelengths 651 and 492 nm for Cy5 and FAM, respectively). Subsequently, the oligonucleotide with the quencher (20 μL of stock solution; final concentration 0.25 μM) was added, and the solution was heated to 70 °C for 5 min and allowed to cool to laboratory temperature for 30 min (**S6** was cooled to 4 °C). Thereafter, the fluorescence of the duplex was measured. A similar procedure was used for oligonucleotide **SFX**. The quenching efficiency (*QE*) was calculated according to the following equation (*1*, *19*):

$$QE = (1 - F_X/F_0) \times 100$$

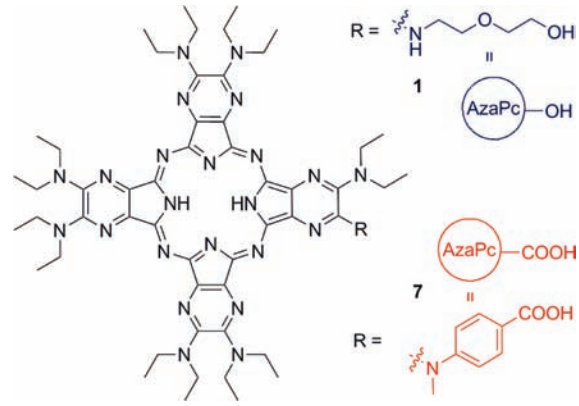
where F_0 is the fluorescence of fluorophore **SF** alone, and F_X is the fluorescence of the duplex.

Singlet Oxygen Quantum Yields and Fluorescence. Quantum yields of a singlet oxygen (Φ_Δ) of **1** and **7** were determined according to a previously published procedure (*20*) using the decomposition of 1,3-diphenylisobenzofuran in DMF. Zinc phthalocyanine (ZnPc) was used as a reference ($\Phi_\Delta = 0.56$ in DMF *21*, *22*). The absorption of the dyes in the Q-band area was set approximately to 0.1. The presented data represent the mean of three measurements.

An attempt to detect any fluorescence signals from quenchers was also made. Compounds **1** and **7** in DMF, dimethylsulfoxide (DMSO), and THF or oligonucleotides **S1**−**S6** with AzaPc in hybridization buffer were excited at the B-band (365 nm) or Q-band (650 nm). Absorption at the excitation wavelength was set to approximately 0.1. Fluorescence was monitored in a range of 550−900 nm.

RESULTS AND DISCUSSION

Synthesis. All conjugation procedures between *Pc* and oligonucleotides until now were performed in water solution with an excess of *Pc* reagent. Isolation of the desired conjugate therefore always included several steps including the final HPLC separation. Solid-phase synthesis of the conjugates allows for the reduction of the side products, and the excess of the reagent can be easily washed out. In order to further simplify the purification steps, the AzaPc labels were designed to be highly hydrophobic, and that is why the conjugates may be anchored in a short OPC allowing easy purification without the need for HPLC separation. The design of AzaPc labels was based on the following considerations: (1) the macrocycle must carry mostly hydrophobic substituents and one modifiable group; (2) the macrocycle must be substituted with alkylamino substituents in order to allow ICT to quench efficiently excited states; and (3) the hydrophobic substituents must be sufficiently bulky in order to reduce aggregation typical for planar AzaPc and *Pc* macrocycles. On the basis of these requirements, compounds **1** and **7** (Figure 1 and Schemes 1 and 2) were synthesized and further modified for both 3′- and 5′-end solid-phase labeling. Postsynthetic modification of AzaPc was easily performed because bulky *N*,*N*-diethylamino substituents reduced the aggregation to a minimum, and the typical problems with low solubility, silica binding (*22*), or tailing of AzaPc on TLC (*14*) were not observed (see Supporting Information, Figure S1).



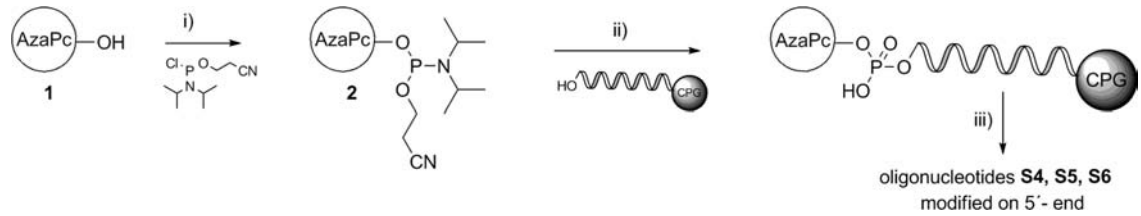


Figure 1. Structures of compounds **1** and **7**.

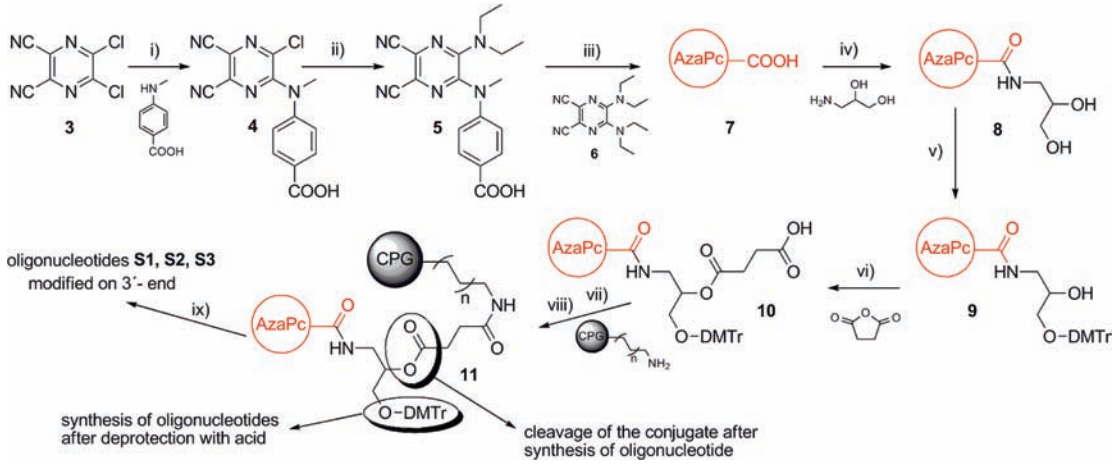
5′-End modified oligonucleotides **S4**−**S6** were prepared from **1** (*16*) via phosphoramidite **2** (Scheme 1). Phosphoramidites are highly reactive intermediates (*23*, *24*) finding their place in automatic DNA synthesis for both DNA elongation and labels attachment. Compound **2** was therefore introduced as the last step into the DNA/RNA synthesizer during solid-phase synthesis. Contrary to the in-solution conjugation methods, this approach simplifies the labeling and enables the general automatic processes to be used.



For the 3′-end labeling of oligonucleotides, the long chain aminoalkyl (lcaa) solid phase was modified by AzaPc **7** (Scheme 2) before the synthesis of the desired oligonucleotide chain (**S1**−**S3**). First, unsymmetrical AzaPc **7** was synthesized by statistical condensation of **5** and **6** and isolated from the mixture of six congeners (see Supporting Information, Figure S2) with a yield of 15%. Compound **5** was prepared by two step nucleophilic substitution of chlorine atoms in **3**. Although several selective strategies were developed for the synthesis of unsymmetrical *Pc* (*25*) including recent efforts in the improvement of solid-phase synthesis (*26*), the statistical condensation gave reasonable yields of **7** with very simple isolation of the desired congener. To verify the stability of **7** during the 3′-end labeling of oligonucleotides, the compound was subjected to the conditions occurring in the course of automated chemical oligonucleotide synthesis. It was shown to be stable in all the range of chemical conditions tested (see Supporting Information). Compound **7** was converted to dihydroxyamide **8** via an active succinimidyl ester. Protection of the primary hydroxy group with DMTrCl (**9**) allowed for selective modification of the secondary hydroxyl with succinate (**10**) and subsequent attachment of the AzaPc to lcaa solid phase (**11**). Unreacted amino groups in solid phase were capped with acetic anhydride. Solid phase **11** allows for the start of the synthesis of the DNA probe on hydroxyl after DMTr deprotection and simple cleavage of the synthesized conjugate from the solid phase by basic hydrolysis of the ester bond. Such a modified solid phase was

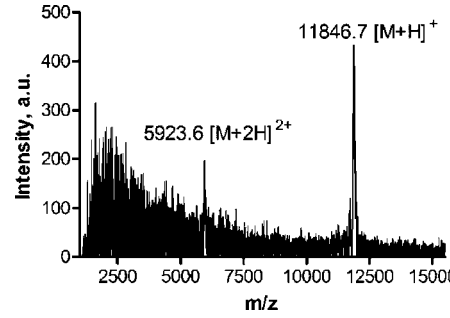

Figure 3. MALDI-TOF spectrum of oligonucleotide **S3** labeled with AzaPc.

used in a standard oligonucleotide synthesis in a DNA/RNA synthesizer. Also, this approach allows the general automatic processes in a DNA/RNA synthesizer to be used for both synthesis and cleavage of the conjugate from solid phase.

In all of the cases (**S1**−**S6**), the AzaPc conjugates cleaved from the solid phase were purified by passing through short OPC. The hydrophobic character of AzaPc labels allowed for the anchoring of the conjugates to reverse phase in OPC, and the unlabeled oligonucleotides were washed out with 8% acetonitrile. Subsequently, the increase of acetonitrile concentration to 30% released the AzaPc-oligonucleotide conjugates from OPC. The purified conjugates were analyzed by HPLC (see Figure 2), and two important peaks were detected in the chromatograms (typical retention times $t_R = 2$ min and $t_R = 17$ min). On the basis of an analysis of absorption spectra (see Supporting Information, Figure S5) and retention times of the controls, the base peak ($t_R = 17$ min) belongs to the oligonucleotide labeled with AzaPc. Unlabeled oligonucleotides were eluted in the second minute and did not exceed 4% in all cases (based on an area under the curve calculation at 254 nm). Nonconjugated AzaPc control eluted with $t_R = 23$ min and was not detected in chromatograms of AzaPc−oligonucleotide conjugates. In order to verify the composition of conjugates, MALDI-TOF spectra were recorded, and the expected mass to charge ratio was confirmed (Figure 3).

UV−Vis Spectral, Photophysical, and Photochemical Properties. Absorption spectra of AzaPc **1** and **7** were analyzed in different solvents (DMSO, THF, methanol (MeOH), DMF, and acetone). The spectra in all solvents showed the shape characteristic for monomeric species with two absorption bands typical for AzaPc or *Pc*: a high energy B-band at approximately 360 nm and a low energy Q-band at approximately 660 nm. Both compounds also showed another broad band at approximately 550 nm due to the conjugation of lone electron pairs of *N*,*N*-diethylamino substituents with a macrocyclic system (n-π^* transitions) (*14*, *27*). The Q-bands of **1** and **7** were split due to the unsymmetrical composition of the whole macrocycle because of the presence of the central hydrogens (*16*). The splitting was sharp in THF but became broad and

[a] Conjugate **S1** (for **7**) or **S5** (for **1**).

featureless in solvents with increased polarity (e.g., DMSO), and completely disappeared when the conjugates where dissolved in hybridization buffer (Figure 4), indicating considerable effect of the solvent polarity on the Q-band shape. Such spectral changes in DMSO or buffer could also be attributed to aggregation, but neither the shape of the spectra nor the extinction coefficient changed in a very wide range of concentration (in DMSO 2.5×10^{-4} M-1.0×10^{-7} M). Also, no new bands at shorter or longer wavelengths corresponding to H- (*7*, *28*) or J-dimer (*29*) formation were observed. Another support for the statement that the aggregation is not responsible for the broad Q-band is that the spectra of the conjugates did not change after hybridization with complementary oligonucleotides (see, e.g., the duplex **S4**$-$**SF** in Supporting Information, Figure S6-c).

Photophysical and photochemical parameters of AzaPc **1** and **7**, which are important for their prospective use as dark quenchers, were determined. No fluorescence of either AzaPc **1** and **7** in THF, DMF, DMSO, or the AzaPc labeled probes **S1**$-$**S6** in hybridization buffer was detected. Singlet oxygen, usually strongly produced by AzaPc after illumination (*30*), is a highly reactive species that may destroy oligonucleotide probes or the target sequence (*8, 31*), and thus, its formation is undesirable in hybridization assays. Importantly, AzaPc **1** and **7** reached very low singlet oxygen quantum yields (Φ_Δ), 0.015 and 0.018, respectively. For comparison, the Φ_Δ value for FAM, a routinely used fluorophore in hybridization assays, ranges from 0.03 to 0.1 (*32*). It must be noted that no aggregates were detected during measurements, and therefore, the lack of any detectable fluorescence can be attributed solely to the deactivation of the S_1 excited state by ICT (*14*). Spectral and photochemical data of compounds **1** and **7** are summarized in Table 1.

DNA Hybridization Assays and Quenching Efficiency. The absorption spectra of AzaPc$-$oligonucleotide conjugates **S1**$-$**S6** in hybridization buffer show a wide range of absorption from 300 to 740 nm due to the AzaPc moiety (Figure 5). Thus, it efficiently overlaps the emission spectra of all fluorophores currently used in hybridization assays. Such versatility cannot be found in any other structural type of dark quenchers and makes these compounds highly promising for future development. In order to prove the quenching ability of AzaPc, oligonucleotide **SF** labeled with two commonly used fluorophores was chosen for hybridization assays. For example, FAM (λ_{em} = 517 nm) emits at short wavelengths, while Cy5 (λ_{em} = 663 nm) emits at long wavelengths. For comparative purposes, the oligonucleotides **S1**$-$**S6** were labeled with the currently used dark quenchers BHQ-1, BHQ-2, and BBQ-650, which are highly efficient at the quenching of FAM or Cy5 (*33*).

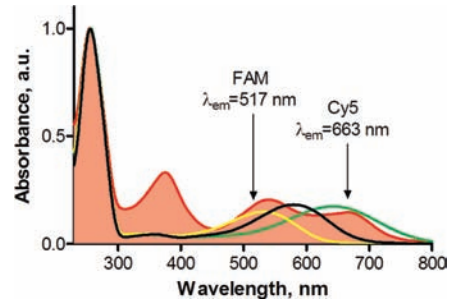

Figure 5. Absorption spectra of oligonucleotide **S1** labeled with AzaPc (red line, filled area), BHQ-1 (yellow), BHQ-2 (black), and BBQ-650 (green). The spectra were normalized to the same absorption at 254 nm (which is due to the oligonucleotides). The arrows indicate emission maxima of FAM and Cy5 fluorophores.

Figure 6. Sequences of modified oligonucleotides. F = fluorophore (FAM or Cy5), and Q = quencher (AzaPc, BHQ-1, BHQ-2, or BBQ-650).

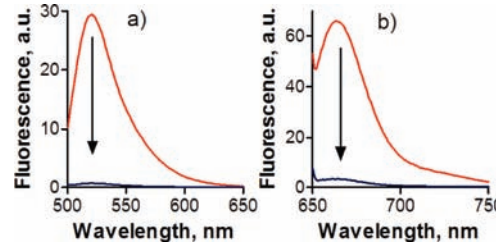

Figure 7. Fluorescence emission spectra of oligonucleotide **SF** with FAM (a) and Cy5 (b) before (red) and after (blue) the addition of the complementary oligonucleotide **S1** with AzaPc.

Oligonucleotides **S1**$-$**S6** (Figure 6) were designed to investigate both mechanisms of quenching utilized in hybridization assays. Resonance energy transfer (RET) requires the emission spectrum of a fluorophore and the absorption spectrum of a quencher to overlap with the effective distance between labeling dyes being 20$-$100 Å (*19*). During contact quenching, the fluorophore and the quencher must be very close to each other in order to form a ground-state complex that does not emit any light. Overlap of the spectra is not required in this mechanism (*19*, *34*). According to Marras et al. (*1*), the oligonucleotide **S1** can be used for the detection of the contact quenching after hybridization with **SF** because the fluorophore and the quencher may form the nonemitting heterodimer. **S3** is designed to allow purely RET quenching, and **S2** may involve both mechanisms. However, the absorption spectra of the duplex of AzaPc-labeled **S3** with Cy5-labeled **SF** revealed the presence of a certain level

[a] The mean of three measurements ± SD. The mathematical symbol minus means that fluorescence increased after hybridization.

of the heterodimer suggesting a looping of freely rotating 10T overhang (see Supporting Information, Figure S6). The heterodimer has a different absorption spectrum than a simple sum of the fluorophore and the quencher absorption spectra. Thus, **S3** cannot be used in this case for the detection of pure RET-based quenching.

In order to overcome this problem, oligonucleotides **S4**−**S6** were investigated in hybridization assays as well. The rigid double strand of their duplexes with **SF** prevents looping and thus permits the determination of pure RET quenching. At the same time, it enables the investigation of the quenching efficiency at a longer distance. The absorption spectra of the duplexes **S4**−**SF** corresponded well with a simple sum of spectra of **S4** and **SF** indicating the absence of the heterodimer (Supporting Information, Figure S6).

After hybridization, all of the prepared AzaPc-labeled oligonucleotides **S1**−**S6** efficiently decreased the fluorescence signal of **SF**, either Cy5 or FAM-containing (Figure 7). The quenching efficiency (*1*, *19*) is shown in Table 2. While all tested quenchers were highly efficient and comparable at a shorter distance (**S1**−**S3**), marked differences appeared at a longer distance between the fluorophore and the quencher (**S4**−**S6**). BHQ-1 quenched only FAM emission, BHQ-2 quenched both FAM and Cy5 emission, but its efficiency considerably decreased with distance. The AzaPc quencher was able to quench the fluorescence of both Cy5 and FAM with higher efficiency than the above-mentioned BHQ dyes and with efficiency comparable to that of the BBQ-650 quencher. This is most likely a consequence of better overlap of the AzaPc quencher absorption and fluorophore emission spectra (Figure 5).

In order to exclude nonselective quenching, two kinds of controls were involved. The decrease of **SF** fluorescence emission by the **S1**−**S3** sequence without any attached quencher was negligible (Table 2). Nonspecific quenching of fluorescence was excluded using Cy5-labeled oligonucleotide **SFX** that was not complementary to **S1**. No quenching occurred for any of the quenchers tested (Table 2).

CONCLUSIONS

In conclusion, novel highly efficient structural type of dark quenchers from the group of AzaPc with advantageous properties was described. A solid-phase method for labeling oligonucleotides by AzaPc quenchers and a simple and fast purification method without a need of HPLC separation were developed. Of particular notice is that the solid-phase conjugation presented here allows for the utilization of automatic processes in DNA/RNA synthesizers for both 3′- and 5′-end labeling by AzaPc.

The prepared AzaPc-based probes efficiently quench both FAM and Cy5 fluorescence in DNA hybridization probes by both RET and contact quenching. The AzaPc quencher profits from absorption in a wide range of wavelengths that covers all fluorophores used in hybridization assays nowadays. Thus, AzaPc may become the quenchers of choice for any kind of routinely used fluorophore and any hybridization assay. Finally, AzaPc represents flexible macrocycles with the possibility of shifting their absorption maximum over 750 nm (*17*). Therefore, they appear to have a great potential in genetic analysis, especially for the imaging of gene expression in living cells, where excitation and emission at long wavelengths is highly desired.

ACKNOWLEDGMENT

The work has been supported by grant KJB401100801 (The Grant Agency of the Academy of Sciences of the CR), by Research Project MSM0021620822, and by grant SVV-2010-261-001. We gratefully thank Jiří Kuneš for the measurements of NMR spectra.

TLC of the mixture of AzaPc congeners

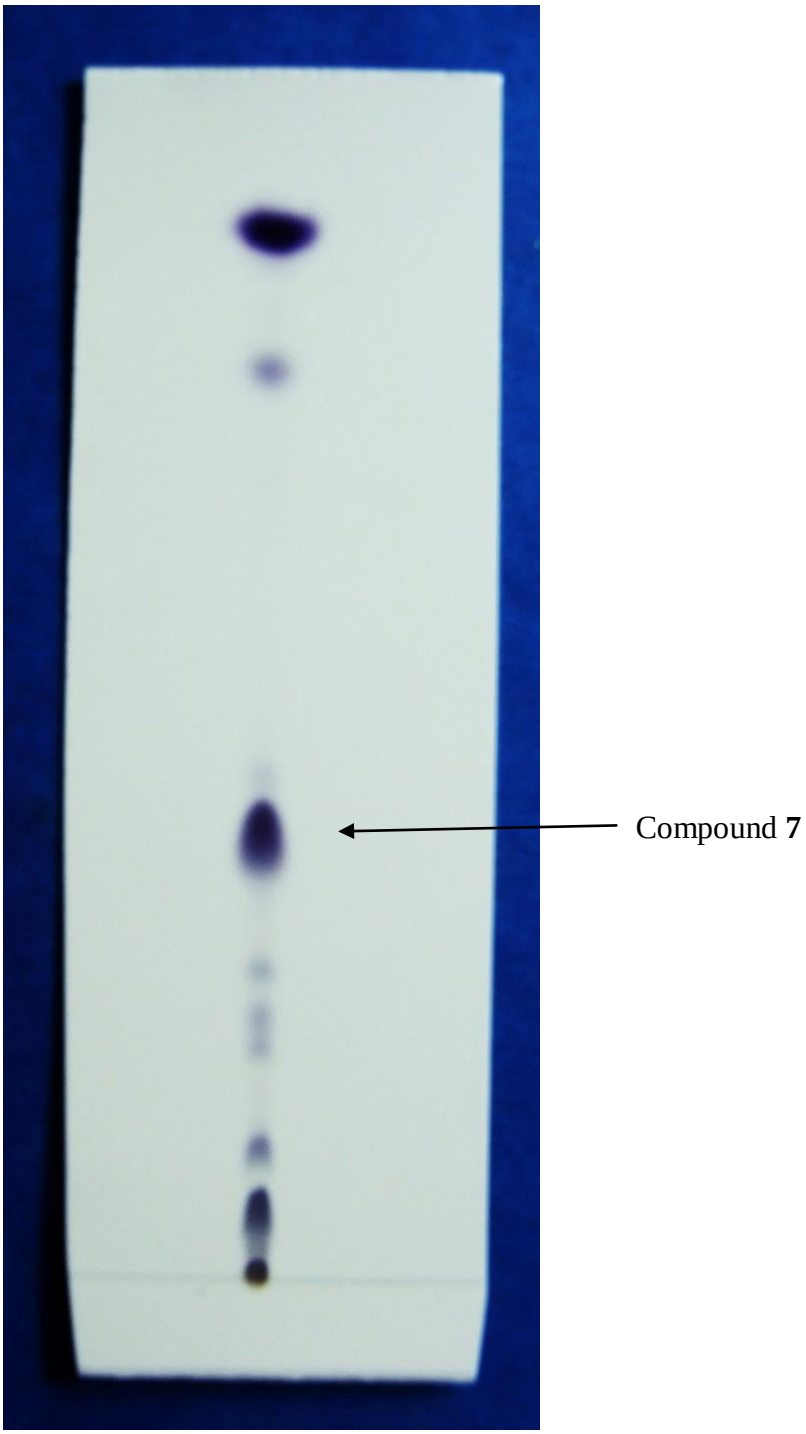

Figure S1. TLC of the mixture of AzaPc congeners after statistical condensation during synthesis of compound **7**. Note the nice round-shaped stains of AzaPc. TLC was performed on silica (Merck TLC silica gel 60 F_{254} plates) in dichloromethane/acetone/methanol 20:1:1 mobile phase.

Structures of congeners appearing in the mixture after statistical condensation

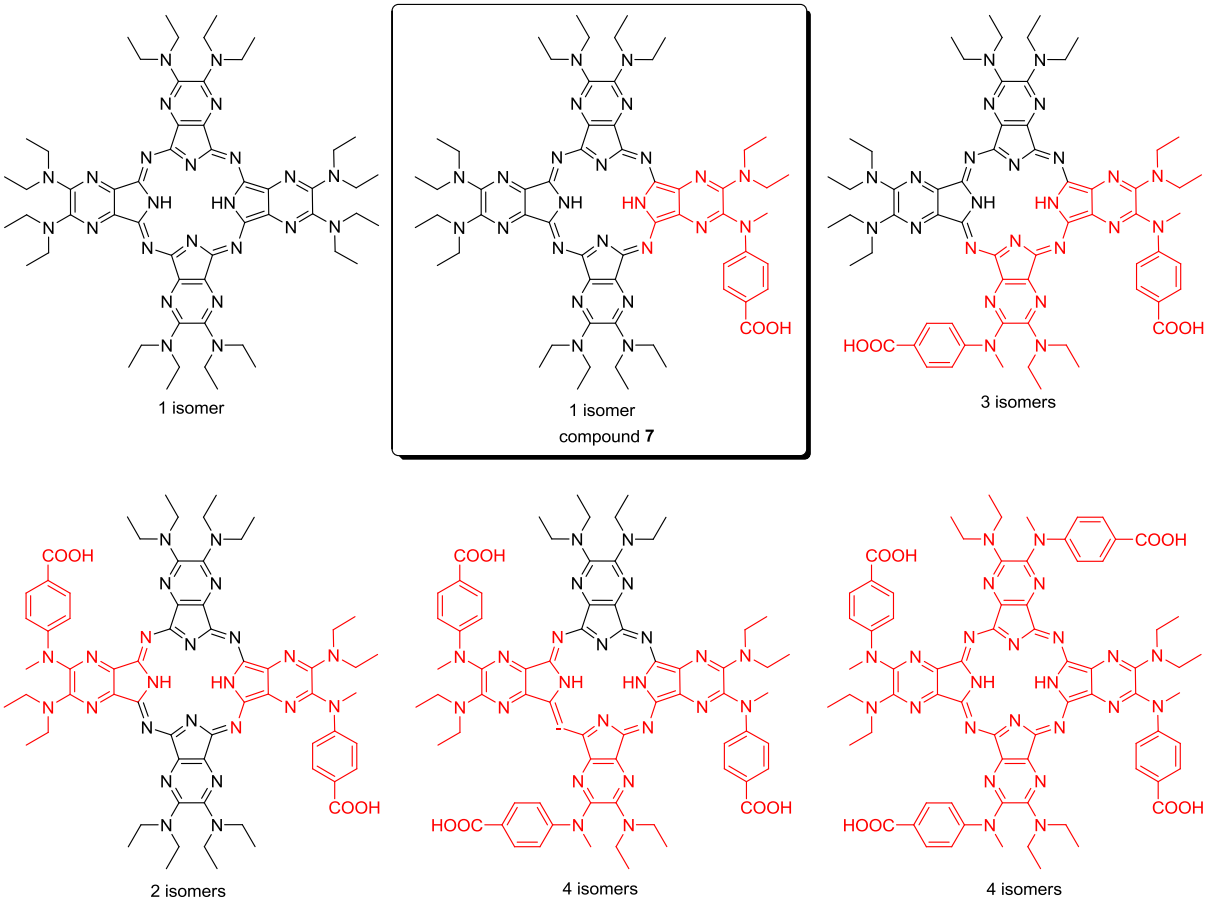

Figure S2. Possible congeners appearing in the mixture after statistical condensation during synthesis of **7**. See also Figure S1. For each congener, also number of possible structural isomers is mentioned (only one isomer is drawn).

Stability of compound 7 in reagents used during automatic DNA synthesis in DNA/RNA synthesizer.

Table S1. Reagents used in typical DNA/RNA synthesizer and typical exposure times during synthesis of standard 20-mer DNA probe.

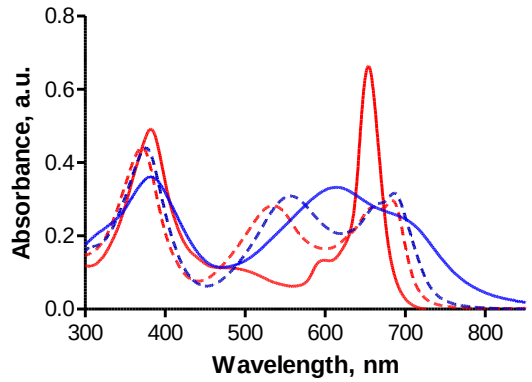
Reagent	Composition	Times (min)[c]
A	3% (m/m) trichloroacetic acid in dichloromethane	25
B	0.25 M 5-(ethylthio)-1H-tetrazole in acetonitrile	20
C[a]	10% (m/m) 1-methylimidazole in tetrahydrofuran	15
D[a]	tetrahydrofuran / pyridine / acetic anhydride 8:1:1	15
E	0.02 M iodine in tetrahydrofuran / pyridine / water 7:2:1	15
F[b]	32% ammonia / 40% methylamine 1:1	90
G[b]	0.05 M K_2CO_3 in methanol	240-720

[a] reagents C and D are mixed before the reaction. [b] Either F or G are used for deprotection of oligonucleotide and its cleavage from solid phase. [c] typical for Perkin Elmer ABI 392/394 DNA/RNA synthesizer.

Procedure: Stock solutions of the compound **7** were prepared in concentration approx. 1×10^{-5} M in dichloromethane (for reagent A), acetonitrile (reagent B), tetrahydrofuran (reagents C+D and E) and methanol (reagent G). Reagents were prepared at double concentration than used in DNA/RNA synthesizer. Reagent F was prepared at concentration used in real conditions because preparation of higher concentrations is technically impossible. For measurements, 10 ml of dye stock solution was mixed with 10 ml of the reagent to give final concentration of the dye 5×10^{-6} M and the proper concentration of the reagent (see Table S1). The solutions were stirred at r.t. during whole experiment. 2.5 ml were taken (after 0, 2, 6, 22 and 24 h) and the UV-vis spectra were measured.

Results: No changes were observed in absorption spectra of **7** in reagents B, C+D or E within 24 hours of testing. Changes in the shape of the UV-vis spectra were observed immediately after addition of the reagent A (Figure S3). Neither the shape nor the intensity of absorption changed further even after 24 h. The change is reversible and the shape of the spectra was restored to normal after washing of the tested solution with aq. NaOH. Reagent A is a strong organic acid and lead to protonation of the *N,N*-diethylamino nitrogens in the tested dye that is accompanied by changes of the absorption spectra (*1*). Similarly, reagent G as a base caused immediate spectral changes (Figure S3) due to deprotonation of acidic central NH groups (*1, 2*). Also in this case, the spectra did not shown any further progress and the change was fully reversible after addition of few drops of acetic acid. Compound **7** could not be tested in reagent F due to insolubility in water based medium. That is why, structurally similar compound **X1** (Figure S4) synthesized in our lab earlier (*3*) was tested in this medium (dissolved directly in reagent F) . Spectral changes were similar to those observed for

compound **7** in reagent G and did not indicate any decomposition even after 24 h. Stability of compounds **7** and **X1** was tested also on TLC and its examination did not indicate any decomposition. As a conclusion, the AzaPc quencher was not decomposed in any of the reagents used during automatic DNA synthesis even when the typical exposure times were exceeded several times.



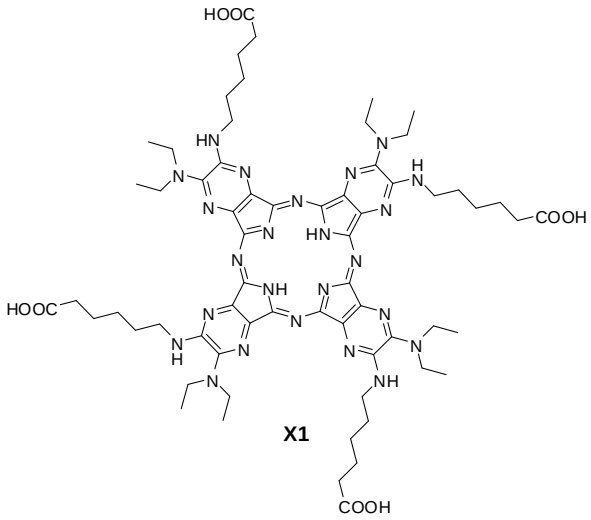


Figure S3. Absorption spectra of compound **7** in methanol (red, dotted), dichloromethane (blue, dotted), reagent A (blue, full line), reagent G (red, full line). Concentration approx. 5×10^{-6} M.

Figure S4. Structure of compound **X1**.

Absorption spectra from HPLC chromatogram

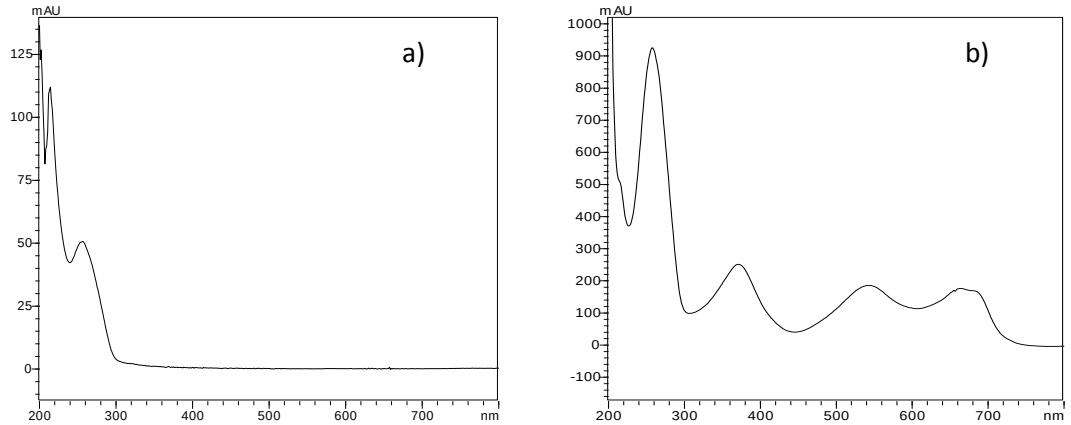

Figure S5. Absorption spectra at peaks at t_R=2.0 min (a) and t_R=16.9 min (b) of the HPLC chromatogram from Figure 2 (see article), corresponding to unlabeled oligonucleotide and AzaPc-modified oligonucleotide, respectively.

Absorption spectra of duplexes

Spectra of duplexes were measured in hybridization buffer. Stock solutions of oligonucleotides **S1**, **S3** and **S4** labeled with AzaPc and **SF** and **SFX** labeled with Cy5 were prepared to concentration 100 µM. Hybridization buffer (1 ml) was transferred to a cuvette, stock solution of oligonucleotide probe with quencher (10 µl) was added and absorption spectrum was measured. Thereafter, stock solution of oligonucleotide labeled with fluorophor (10 µl) was added and solution was heated to 50°C for 1 minute. Absorption spectrum of duplex (Figure S6) was measured after 30 minutes when the sample cooled down to laboratory temperature. Final concentration of both oligonucleotides was 1 µM. Absorption spectra of **SF** and **SFX** were measured also separately after addition of stock solution (10 µl) to hybridization buffer (1 ml).

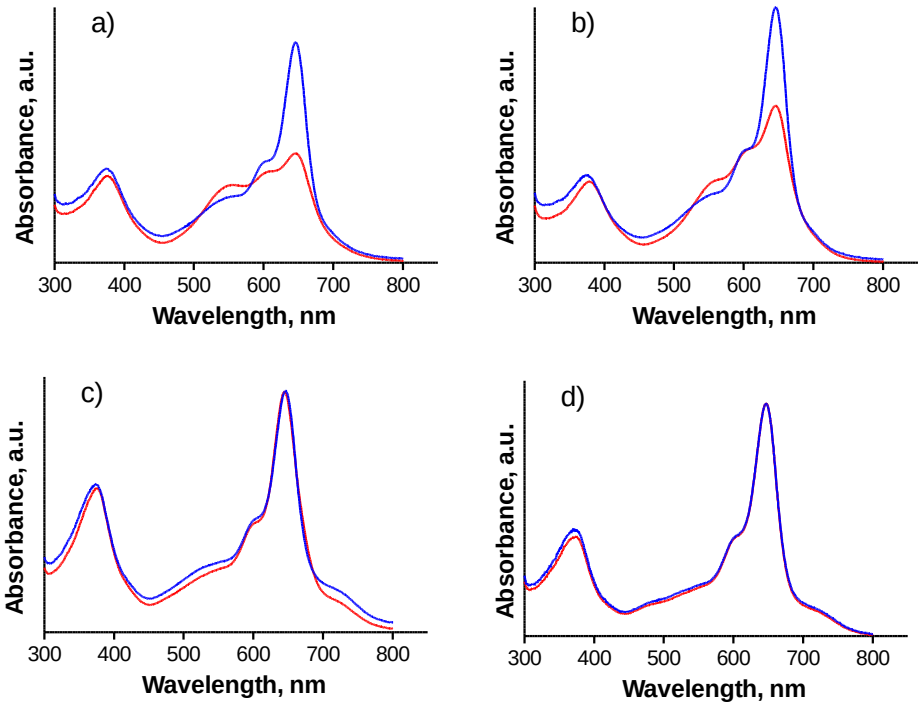

Figure S6. Red lines – measured absorption spectra of duplexes **SF** (Cy5) with **S1** (a), **S3** (b), **S4** (c) modified with AzaPc and (d) absorption spectrum of mixture of **SFX** (Cy5) with **S4** (AzaPc). Blue lines – simple sum of absorption spectra of individual oligonucleotides. In case of **S1** and **S3** the measured spectra did not correspond to calculated ones indicating presence of heterodimer Cy5-AzaPc. In case of **S4**, the heterodimers are not formed due to rigid double strand separating both dyes. Data from graph d) excludes any uncontrolled formation of the heterodimer without hybridization.

Probing the Topological Tolerance of Multimeric Protein Interactions: Evaluation of an Estrogen/Synthetic Ligand for FK506 Binding Protein Conjugate

Terry W. Moore,† Jillian R. Gunther, and John A. Katzenellenbogen*

Department of Chemistry, University of Illinois at Urbana−Champaign, 600 South Mathews Avenue, Urbana, Illinois 61801, United States. Received June 10, 2010; Revised Manuscript Received September 2, 2010

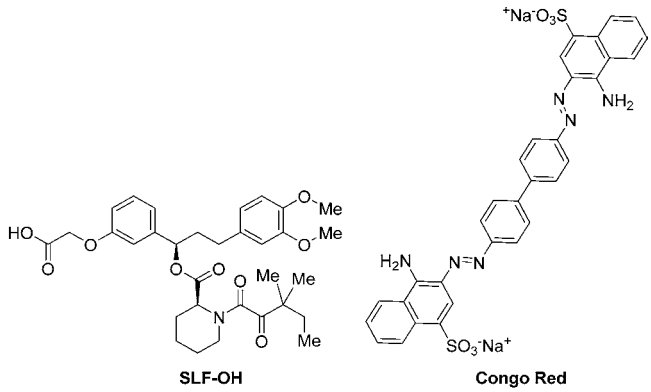
Bivalent small molecules composed of a targeting element and an element that recruits endogenous proteins have been shown to block protein−protein interactions in some systems. We have attempted to apply such an approach to disrupt the interaction of the estrogen receptor α with either its associated coactivators or its dimerization partner (i.e., another estrogen receptor). We show here that a conjugate capable of simultaneously binding both the estrogen receptor and a recruited protein (FK506 Binding Protein 12 kDa) is, however, incapable of disrupting the multimeric estrogen receptor dimer/coactivator complex both in vitro and in cell-based reporter gene assays. We postulate why it may not be possible to disrupt this particular protein−protein complex—as well as other systems having high topological tolerance—with such bivalent inhibitors.

INTRODUCTION

The estrogen receptor α (ERα) is a ligand-activated transcription factor whose activity in regulating gene expression relies on two key molecular interactions: homodimerization of the ER itself and interaction of the ER dimer with its associated coactivators (e.g., the steroid receptor coactivators (SRCs)). The monomers of ERα are linked as homodimers by hydrophobic interactions among residues on two long α-helices arranged in parallel at the dimer interface, flanked across the dimer interface by both hydrophobic and polar interactions between other helical elements. The binding affinity of ERα dimerization has been estimated to be subnanomolar (*1*). In the interaction of ER with the coactivator, one molecule of an SRC binds to an ER dimer by placing two turns of an amphipathic α-helix into a hydrophobic groove on the surface of the ligand-binding domain of each monomer of the agonist-bound ER dimer. These α-helical elements contain three conserved leucine residues arranged in an LXXLL motif (L is leucine; X is typically a polar amino acid). The affinity of each LXXLL motif for ERα is characterized by a K_D of ca. 700 nM, with the bivalent interaction once estimated to have an avidity below 30 nM (*2*) but more recently found to be ca. 1 nM, with affinity being dependent to some extent on ligand structure (M. Jeyakumar and J. A. Katzenellenbogen, unpublished). ERα interaction with SRC has strict ligand dependence; it requires that the ERs be occupied by an agonist ligand, and it is disabled when the ER is either unliganded or liganded, in most circumstances, by an antagonist ligand. By contrast, ERα dimers form in vitro whether the ER is unliganded or liganded with either an agonist or antagonist ligand, although ligand binding modulates dimerization affinity to some degree (*1*).

We and others have postulated that these two protein−protein interaction "hot-spots"—the ER/ER dimer interface or the ER/SRC interface—could serve as therapeutic targets for cancers in which the estrogen receptor is upregulated, but that are nonresponsive to traditional antagonist regimens, as is the case in antiestrogen-resistant breast cancer (*3*−*6*). In fact, it is the ER/SRC interaction that is targeted in conventional ER antagonism with antiestrogens, although this inhibition proceeds through an allosteric mechanism whereby antagonist binding in the internal ligand binding pocket induces a conformational change on the receptor surface that prevents SRC binding (*7*). Thus, targeting this interaction with small molecule inhibitors is well-validated, although those that act by a direct mechanism of inhibition are much less developed (*3, 8, 9*). Oftentimes, however, protein−protein interactions of this type are viewed as intractable targets in drug discovery, because the interactions typically occur over large surface areas, as is the case with the ER dimer interface, or may be highly dynamic, as is the case with the ER/SRC interaction (*10, 11*). Because small molecules are, by definition, low-molecular-weight compounds, they may lack sufficient steric bulk to inhibit the interaction.

Gestwicki et al. (*12*) have elaborated an interesting "Trojan horse" (or heterobivalent ligand) approach to this general problem: It involves tethering a weak protein−protein interaction inhibitor to a second ligand molecule that, after gaining access to the cell, would recruit extra steric bulk in the form of a ubiquitous, endogenous protein, thereby increasing the effective size and, consequently, the potency and/or efficacy of the inhibitor (*13*). The group demonstrated this concept by disrupting the aggregation of the Aβ peptide that leads to formation of β-amyloid, a polymer implicated in the pathologic fibrillogenesis of Alzheimer's disease. They tethered Congo Red, which, in turn, binds rather poorly to β-amyloid (i.e., $IC_{50} = 2$ μM), to SLF (synthetic ligand for FK-506 binding proteins [FKBPs]). In the presence of the ubiquitous and abundant cellular protein FKBP12, some of these conjugates (e.g., **I**, Chart 1) inhibited the aggregation of β-amyloid with IC_{50} values of 50 nM, a 40-fold increase in potency compared to Congo Red. The effect was not seen in the absence of FKBP12, suggesting that the mechanism of inhibition was dependent on the steric hindrance of FKBP12 that followed from its recruitment by the SLF element in the Congo Red conjugate. This finding was a landmark because it suggested a perhaps generalizable mechanism for inhibiting protein−protein interactions.



We saw an opportunity to use this technology in a conceptually similar yet mechanistically distinct manner to develop a ligand that would have context-dependent estrogenic properties—

Chart 1. Structures of SLF, Congo Red, and SLF-Congo Red Conjugate I

that is, a molecule that would allow ER to recruit its dimerization partner and coactivator, and thus function as an agonist, in the absence of FKBP, but that would function as an antagonist in the presence of FKBP. In addition, this novel approach to inhibition of estrogen signaling might prove more robust against the development of acquired resistance which typically develops following endocrine therapy of breast cancer with standard antagonists such as tamoxifen (*14*).

The native agonist for the estrogen receptor, 17β-estradiol (E2), is known to tolerate substitution at the 17α position without experiencing substantial loss in affinity, while retaining agonist activity for the ER (*15*, *16*). Thus, we examined whether an estradiol−SLF conjugate linked through the 17α position would by itself function as an ER agonist, engendering formation of the ER/SRC assembly, but, upon recruitment of FKBP, would place ER in an antagonized state resulting from FKBP disruption of the multimeric ER/SRC assembly. Curiously, what we have found is that the ER, when liganded with an estradiol−SLF conjugate, was not only capable of binding its dimerization partner and a coactivator fragment, but also was able to recruit FKBP, thus indicating that this multimeric protein complex exhibits a high topological tolerance. We describe the design, synthesis, and extensive biological evaluation of these compounds, and hypothesize why inhibition of this interaction might not be amenable to this Trojan horse-type strategy.

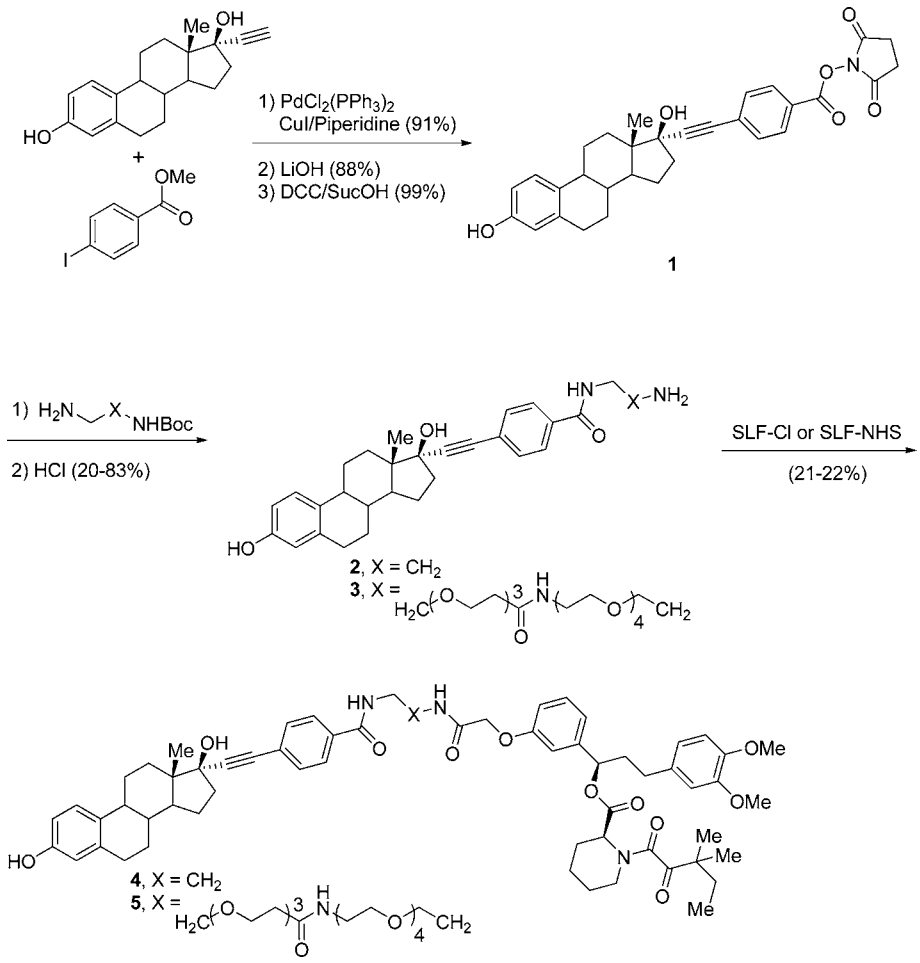
EXPERIMENTAL PROCEDURES

General Considerations. Reagents were obtained from Aldrich Chemical Co., TCI America, or Fisher Scientific and were used without further purification. Anhydrous solvents were purchased from Aldrich or obtained from a Solvent Dispensing System fabricated by J. C. Meyer, based on a design published by Pangborn et al. (*17*). Anhydrous DMF was vacuum-distilled over molecular sieves.

Reaction progress was monitored using thin-layer chromatography (TLC) on silica gel 60 F_{254} glass-backed plates from EM Science. Visualization was achieved by UV light (254 nm) or phosphomolybdic acid or potassium permanganate indicator. Flash column chromatography was performed with Woelm silica gel (0.040−0.063 mm) packing (*18*).

^{1}H and ^{13}C NMR spectra were recorded on either 400 or 500 MHz Varian FT-NMR spectrometers. Chemical shifts (δ) are reported in parts per million (ppm) by reference to proton resonances resulting from incomplete deuteration of the NMR solvent. High- and low-resolution electrospray ionization mass spectra were obtained on either a Micromass Quattro or Micromass Q-Tof Ultima mass spectrometer. Melting points were measured using a Thomas-Hoover capillary melting point apparatus and are uncorrected.

Chemical Synthesis. SLF-OH was synthesized according to a known procedure (*19*, *20*). The ethynylestradiol precursor was prepared (Scheme 1) by reacting 17α-ethynylestradiol with methyl 4-iodobenzoate using Sonagashira reaction conditions, to give, after saponification of the ester, an acid-functionalized estrogen. The acid was converted to the succinimid-1-yl ester **1** using dicyclohexylcarbodiimide as the dehydrating agent.



The estrogen prepared above was tethered to the SLF moiety by adding a monoprotected diamine to give, after deprotection of the remaining amine, amides **2** and **3**. The amines were coupled to the acid functionality of **SLF-OH**, to give conjugates **4** and **5**, by activating the acid as either the acyl chloride or an activated ester.

Succinimid-1-yl 3-(3,14-Dihydroxy-13-methyl-7,8,9,11,12,13,14,15,16,17-decahydro-6*H*-cyclopenta[*a*]phenanthren-17-ylethynyl)-benzoate (1). 17α-Ethynylestradiol (1.00 g, 1.0 equiv) was dissolved in anhydrous THF (10 mL). To this solution was sequentially added CuI (96 mg, 0.15 equiv), piperidine (0.842 mL, 2.0 equiv), methyl *p*-iodobenzoate (883 mg, 1.0 equiv), and $PdCl_2(PPh_3)_2$ (236 mg, 0.10 equiv). The solution was allowed to stir at RT for 12 h and was then heated to reflux for an additional 4 h. The crude reaction mixture was filtered through Celite and then purified using silica gel column chromatography (20% EtOAc/hexanes to 30% EtOAc/hexanes) to give a dark solid, which was recrystallized from boiling benzene to give 1.40 g (96% yield) of white flakes. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.00 (d, J = 8.1 Hz, 2 H), 7.50 (d, J = 8.1 Hz, 2 H), 7.18 (d, J = 8.6 Hz, 1 H), 6.67 (d, J = 8.6 Hz, 1 H), 6.57 (s, 1 H),4.78 (s, 1H), 3.93 (s, 3H), 2.93−2.79 (m, 2 H), 2.51−2.32 (m, 2 H), 2.30−1.69 (m, 8 H), 1.63 (s, 1 H), 1.58−1.30 (m, 5 H), 0.95 (s, 3 H); HRMS calcd for $C_{28}H_{30}O_4Na$, 453.2042; found, 453.2037.

The methyl ester (1.22 g, 1.0 equiv) prepared above was dissolved in 25 mL methanol and cooled to 0 °C. LiOH (5 mL of 2.1 M; 3.6 equiv) was added, and the solution was allowed to come to RT and was stirred for 72 h. The methanol was removed under reduced pressure, and 10 mL more water was added. HCl (1 M) was added dropwise until no more solid precipitated from solution. The white solid (1.04 g, 88% yield) was filtered and dried. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.04 (d, J = 8.1 Hz, 2 H), 7.52 (d, J = 8.1 Hz, 2 H), 7.16 (d, J = 8.6 Hz, 1 H), 6.65 (d, J = 8.6 Hz, 1 H), 6.58 (s, 1 H), 2.86−2.79 (m, 2 H), 2.49−2.30 (m, 2 H), 2.29−1.68 (m, 8 H), 1.59−1.31 (m, 5 H), 0.95 (s, 3 H); HRMS calcd for $C_{27}H_{28}O_4Na$, 439.1885; found, 439.1887.

The acid prepared above (1.00 g, 1.0 equiv), *N*-hydroxysuccinimide (1.38 g, 5.0 equiv), dicyclohexylcarbodiimide (0.90 g, 1.8 equiv) and 4-(*N*,*N*-dimethlyamino)pyridine (50 mg) were dissolved in CH_2Cl_2 and were stirred at RT. After 4 h, the solution was filtered, and the filtrate was evaporated. After dissolving the crude material in EtOAc (50 mL) and filtering again, the organic layer was washed with water (3 × 50 mL), dried ($MgSO_4$), filtered, and concentrated to give 1.23 g (99% yield) of a viscous, colorless liquid that was used without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.05 (d, J = 8.06 Hz, 2 H), 7.54 (d, J = 8.06 Hz, 2 H), 7.13 (d, J = 8.55 Hz, 1 H), 6.62 (dd, J = 8.55, 2.69 Hz, 1 H), 6.55 (d, J = 2.69 Hz, 1 H), 6.31 (t, J = 6.23 Hz, 1 H), 5.76 (br. s., 1 H), 2.98−2.70

Scheme 1. Synthesis of Estrogen−SLF Conjugates

(m, 6 H), 2.48−2.31 (m, 3 H), 2.27−1.63 (m, 8 H), 1.54−1.31 (m, 2 H), 0.94 (s, 3 H); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 169.30, 169.17, 161.33, 153.63, 138.04, 131.99, 131.85, 130.35, 129.81, 126.42, 124.15, 115.20, 112.69, 97.50, 84.88, 80.38, 49.87, 47.73, 43.55, 39.41, 38.97, 37.30, 33.79, 33.08, 29.57, 27.17, 26.38, 25.62, 25.52, 25.40, 24.82, 22.91, 12.86; HRMS calcd for $C_{31}H_{31}NO_6Na$, 536.2049; found, 536.2047.

EE2-Amine 2. The previously prepared NHS ester **1** (200 mg, 1.0 equiv) was dissolved in dry THF (0.3 mL), and diisopropylethylamine (90 μL, 1.3 equiv) was added to the solution, followed by *N*-Boc-ethylenediamine (75 mg, 1.2 equiv) in 0.5 mL dry THF. The solution was stirred at RT for 13 h, at which point another equivalent of *N*-Boc-ethylenediamine was added, because the reaction was not finished. The reaction appeared complete within 10 min after the addition of the second molar equivalent of amine. The THF was evaporated, and the gummy residue left was extracted from water (25 mL) with ethyl acetate (3 × 25 mL). The combined organic extracts were dried over $MgSO_4$, filtered, and concentrated; HRMS calcd for $C_{34}H_{43}N_2O_5$, 559.3172; found, 559.3176. The product was dissolved in ether, and then precipitated with hexanes and filtered. Then, 1 mL 4 M HCl in dioxane was added, and the product was allowed to stand at RT for 1 h. The solvents were evaporated, to give 44 mg (20% yield) of a white solid that was used without further purification. ^{1}H NMR (500 MHz, CD_3OD) δ: 7.80 (d, J = 8.3 Hz, 2 H), 7.50 (d, J = 8.3 Hz, 2 H), 7.08 (d, J = 8.5 Hz, 1 H), 6.54 (dd, J = 8.2, 2.1 Hz, 1 H), 6.47 (d, J = 1.5 Hz, 1 H), 3.44 (t, J = 6.3 Hz, 2 H), 2.83 (t, J = 6.2 Hz, 2 H), 2.80−2.72 (m, 2 H), 2.39−2.31 (m, 2 H), 2.19−1.66 (m, 8 H), 1.50−1.26 (m, 4 H), 0.91 (s, 3 H); ^{13}C NMR (125 MHz, CD_3OD) δ: 169.83, 156.13, 138.91, 135.05, 132.61, 132.50, 128.59, 128.12, 127.42, 116.21, 113.92, 97.19, 85.77, 81.00, 68.25, 51.37, 49.03, 45.31, 43.75, 42.11, 41.29, 40.06, 34.89, 34.58, 30.87, 28.78, 27.91, 26.88, 26.20, 24.01, 13.67; HRMS calcd for $C_{29}H_{35}N_2O_3$, 459.2648; found, 459.2647.

EE2-SLF Conjugate 4. SLF-OH (11.5 mg, 1.0 equiv) was converted to the acid chloride by dissolving in dry dichloromethane (0.2 mL), cooling to 0 °C, and adding thionyl chloride (3.5 mg, 1.3 equiv). After 5 min, the solvents were evaporated, and 0.2 mL more dry dichloromethane was added, the solution was cooled to 0 °C, and thionyl chloride (3.5 mg, 1.3 equiv) was again added. The reaction was allowed to come to RT and then to sit for 10 h, at which point the solvents were evaporated. Then, a solution of amine **2** (11 mg, 1.2 equiv) and diisopropylethylamine (10.7 μL, 3.0 equiv) in 0.3 mL dry DMF was added to the acid chloride, and the solution was stirred for 5.5 h at RT. The reaction mixture was then applied to a preparative thin-layer chromatography plate and eluted (CH_2Cl_2/methanol 90:10), and the topmost band was scraped from the plate. The product was extracted from the silica gel using dichloromethane/methanol (90:10) to give 4.5 mg (22% yield) of a white solid. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.68 (d, J = 8.4 Hz, 2 H), 7.46 (d, J = 8.4 Hz, 2 H), 7.42−7.19 (m, 3 H), 7.15 (d, J = 8.6 Hz, 1 H), 6.95−6.60 (m, 4 H), 6.57 (d, J = 2.4 Hz, 1 H), 5.75 (dd, J = 8.0, 5.5 Hz, 1 H), 5.26 (d, J = 5.6 Hz, 1 H), 4.51 (d, J = 4.9 Hz, 2 H), 4.12 (d, J = 8.8 Hz, 1 H), 3.84 (s, 3 H), 3.84 (s, 3 H), 3.67−3.58 (m, 4 H), 3.35 (d, J = 12.0 Hz, 1 H), 3.18−3.12 (m, 1 H), 2.85−2.78 (m, 2 H), 2.63−2.48 (m, 2 H), 2.46−2.30 (m, 3 H), 2.14−1.23 (m, 24 H), 1.20 (s, 3 H), 1.19 (s, 3 H), 0.95 (s, 3 H), 0.87 (t, J = 7.4 Hz, 3 H); LR-ESI-MS: $[M+H]^+$ = 1024.5.

EE2 Amine 3. A prepared amine (32 mg, 1.3 equiv; see Supporting Information) was dissolved in 0.2 mL dry THF, and diisopropylethylamine (12 μL, 1.4 equiv) was added to this solution. Then, NHS ester **1** (23 mg, 1.0 equiv) was added, and the solution was stirred at RT for 6 h. The reaction mixture was then applied to a preparative thin-layer chromatography plate and eluted (90:10 acetonitrile/methanol). The topmost band was scraped from the plate, and the silica gel was extracted with acetonitrile/methanol (90:10) to give 20 mg (46% yield; HRMS calcd for $C_{51}H_{76}N_3O_{13}$, 938.5378; found, 938.5367) of product, which was then subjected to 0.4 mL 4 M HCl in dioxane (6 h), which, after evaporation of the solvents, gave 15 mg (83% yield) of amine **3**. ^{1}H NMR (500 MHz, CD_3OD) δ: 7.79 (d, J = 7.3 Hz, 2 H), 7.09 (d, J = 8.6 Hz, 1 H), 6.53 (d, J = 6.6 Hz, 1 H), 6.46 (d, J = 1.9 Hz, 1 H), 3.84−3.32 (m, 30 H), 3.12 (br. s., 2 H), 2.76 (br. s., 2 H), 2.54−2.28 (m, 4 H), 2.22−1.71 (m, 8 H), 1.53−1.18 (m, 7 H), 0.92 (s, 3 H); LR-ESI-MS: $[M+H]^+$ = 838.6.

EE2-SLF Conjugate 5. SLF-OH (17 mg, 1.0 equiv), *N*-hydroxysuccinimide (7 mg, 2.0 equiv), and dicyclohexylcarbodiimide (8 mg, 1.2 equiv) were dissolved in 0.5 mL dichloromethane and were stirred together for 6 h. The product was then passed through a short plug (ca. 1 in.) of silica gel using 100% ethyl acetate as the eluant to give, after evaporation of solvents, 16 mg (80% yield) of a solid which was used immediately in the next step. The previously formed amine **3** (15 mg, 1.0 equiv) and the previously formed NHS ester **1** were dissolved in 0.2 mL dichloromethane, and diisopropylethylamine (16 μL, 3.5 equiv) was added to the solution. The mixture was stirred for 20 h, and the reaction mixture was transferred to a preparative thin-layer chromatography plate using acetonitrile/methanol (90:10) as eluant. The topmost band was scraped off of the plate, and the compound was extracted from the silica gel with acetonitrile/methanol (90:10) to give, after evaporation of the solvents, 5 mg (21% yield) of the conjugate **5**. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.78 (d, J = 8.5 Hz, 2 H), 7.49 (d, J = 8.5 Hz, 2 H), 7.35−7.28 (m, 2 H), 7.20−6.54 (m, 8 H), 5.83−5.73 (m, 1 H), 5.36−5.28 (m, 1 H), 4.51 (s, 2 H), 4.35−4.22 (m, 1 H), 3.93−3.83 (m, 8 H), 3.76−3.34 (m, 32 H), 3.23−3.14 (m, 1 H), 2.97−1.29 (m, 31 H), 1.23 (s, 3 H), 1.21 (s, 3 H), 1.19−1.06 (m, 2 H), 0.94 (s, 3 H), 0.89 (t, J = 7.4 Hz, 3 H); HR-ESI-MS: calcd for $C_{78}H_{107}N_4O_{19}$, 1403.7530; found, 1403.7504.

Estrogen Receptor Ligand-Binding Domain Expression and Labeling. N-Terminally His-tagged constructs in pET15b plasmids for ERα-417 and SRC3 were prepared as previously described. The ligand binding domain of ERα-417 (amino acids 304−554; C381,530S) with a single reactive cysteine at C417 or the nuclear receptor domain of SRC3 encompassing three nuclear receptor (NR) boxes (amino acids 627−829) was transformed into *E. coli* BL21(DE3)pLysS, grown at 37 °C to OD_{600} ~0.5, induced with 1 mM IPTG, and grown for 4 h at 28 °C, as previously reported (*21*).

For protein isolation, a cell pellet was suspended in 5 mL buffer (50 mM Tris buffer, pH 7.5, 10% glycerol, 0.1 mM TCEP) per gram and sonicated (Vibra cell sonicator with a micro probe; Sonic Materials, Inc., Danbury, CT) for 10 s at 60% power. After centrifugation for 30 min at 30 000 *g*, the supernatant was purified to near-homogeneity by batchwise adsorption onto a nickel-charged nitrilotriacetic acid-agarose resin (Ni-NTA-agarose; Qiagen Inc., Santa Clarita, CA), following standard protocols (*1, 21*).

Site-specific ER labeling was accomplished using 30 equiv of a thiol-reactive biotin derivative (MAL-dPEG4-biotin, Quanta BioDesign) while His_6-tagged ERα-417 LBD was immobilized on the Ni-NTA resin. The SRC3-NRD was likewise labeled using the recommended equivalents of a thiol-reactive Cy5 derivative (Cy5Maleimide Mono-Reactive Dye Pack, Amersham Biosciences). Labeling reactions were incubated overnight at 4 °C in Tris-glycerol buffer (50 mM Tris, pH 7.0, 10% glycerol, 0.1 mM tris(2-carboxyethylphosphine, TCEP). Excess fluorophore was removed by washing the protein-bound resin with wash buffer (50 mM Tris buffer, pH 7.5, 10% glycerol, and 10 mM mercaptoethanol) before eluting the labeled receptor using a solution of 100 mM EDTA, 0.5 M NaCl, and 20 mM Tris pH 8.0 (*1, 21*).

FKBP12 Expression and Labeling. A stab culture of *E. coli* that had been transformed with the pGEX-2T plasmid for GST-FKBP12 was obtained from the laboratory of Dr. Jie Chen at the University of Illinois at Urbana−Champaign. A 5 mL culture on a standard LB growth media supplemented with 100 μg/mL ampicillin was started by inoculating a single *E. coli* BL21 colony and agitated for approximately 16 h at 37 °C. The bacteria were diluted (1:100) into standard LB medium and grown at 37 °C until $OD_{600\ nm}$ of ~0.7. Protein expression was induced with 0.1 mM IPTG. After 4 h of incubation at 37 °C, all cells were harvested by centrifugation at 5000 × *g* for 15 min at 4 °C. The pellet was resuspended in 5 mL 1 × PBS buffer (pH 7.4) and 5 mM DTT. After addition of a 10 mg lysozyme (Sigma) per 1 g of bacteria, the resuspension was sonicated ten times for 2 s on ice. The fusion protein from the clear supernatant was batch purified using a 1 mL Glutathione Sepharose 4B (Amersham Biosciences), equilibrated in 5 mL ice-cold binding buffer (1 × PBS, pH 7.3) containing 5 mM DTT. The protein was allowed to bind for 4 h at 4 °C before elution with 300 μL 50 mM Tris-HCl, pH 8.0, containing 10 mM reduced glutathione and 5 mM DTT. The presence and purity of eluted GST-FKBP12 was evaluated by SDS-PAGE (*22*).

To produce fluorescein-labeled FKBP12, the protein was labeled nonspecifically with iodoacetamide−fluorescein (Invitrogen) while on the glutathione resin using the same protocol for labeling ER and SRC proteins as described above.

FRET Assay of Estradiol-SLF Binding to ER by Recruitment of Fluorescein-SRC3. Purified biotin-ERα-417 and fluorescein-SRC3-NRD were used in time-resolved FRET assays previously described (*23*) and adapted for the ER/FKBP system. A stock solution (5 μL) of ERα-417 (8 nM) and LanthaScreen Streptavidin-Terbium (Invitrogen) (2 nM) in TR-FRET buffer (20 mM Tris, pH 7.5, 0.01% NP40, 50 mM NaCl) was placed in separate wells of a black 96-well Molecular Devices HE high-efficiency microplate (Molecular Devices, Inc., Sunnyvale, CA). In a second 96-well Nunc polypropylene plate (Nalge Nunc International, Rochester, NY), a solution of each tested compound (0.001 M stock in DMF) was serially diluted in a 1:10 fashion into DMF. Each concentration of compound was then diluted 1:10 into TR-FRET buffer, and 10 μL of this solution or vehicle was added to the stock ER solution in the 96-well plate. After a 2 min incubation, 5 μL of 200 nM fluorescein-SRC3-NRD was added to each well. This mixture was allowed to incubate for 1 h at RT in the dark. TR-FRET was measured using an excitation filter at 340/10 nm and emission filters for terbium and fluorescein at 495/20 and 520/25 nm, respectively. The final concentrations of the reagents were as follows: ERα-417 (2 nM), streptavidin−terbium (0.5 nM), test compound (0−50 μM), SRC3-Fl (50 nM) (*9*).

FRET Assay of Estradiol-SLF Binding to FKBP. Purified FKBP12-GST and a fluorescein-labeled SLF compound were used for this time-resolved FRET assay. A stock solution (5 μL) of FKBP12-GST (20 nM) and LanthaScreen anti-GST-terbium antibody (Invitrogen) (20 nM) in TR-FRET buffer (20 mM Tris, pH 7.5, 0.01% NP40, 50 mM NaCl) was placed in separate wells of a black 96-well microplate. The test compounds were prepared as described above and added to the

protein solution. After a 2 min incubation, 5 μL of 400 nM fluorescein−SLF was added to each well. This mixture was allowed to incubate for 1 h at RT in the dark. TR-FRET was measured as described above. The final concentrations of the reagents were as follows: FKBP12-GST (5 nM), anti-GST-terbium (5 nM), test compound (0−50 μM), and SLF-Fl (100 nM).

FRET Assay of Agonist−SLF Binding to both ER and FKBP. This assay was conducted according to the protocol used for the above experiment "FRET Assay of Estradiol-SLF Binding to ER by Recruitment of Fluorescein-SRC" replacing the 50 nM SRC3-Fl with 50 nM FKBP12-Fl. All other concentrations and measures remained identical.

FRET Assay of ER-SRC Binding in the Presence of FKBP. This assay was performed in the same format as the experiment above "FRET Assay of Estradiol-SLF Binding to ER by Recruitment of Fluorescein-SRC" with the following changes. Unlabeled FKBP12 and SRC3 were each titrated into TR-FRET buffer and added to the well of a microplate. A stock solution of ERα-417 (8 nM), compound **4** (25 μM), and streptavidin−terbium (2 nM) was incubated for 10 min, and 5 μL of this solution was then added to each well of protein. Finally, 5 μL of 200 nM SRC3-Fl was added to each well and allowed to incubate for 20 min before the fluorescence was read.

FRET Assay of ER Dimerization in the Presence of FKBP. This assay was performed according to the protocol "FRET Assay of ER-SRC binding in the presence of FKBP" with the exchange of 50 nM SRC3-Fl for 50 nM ERα-Fl in the final assay concentrations. Also, both compound **2** and estradiol were used as test compounds in this assay to provide additional positive and negative controls.

Luciferase Reporter Gene Assay. Human endometrial cancer cells were maintained in culture as described and transfected in 24 well plates (*24*). A mixture of HBSS (50 μL/well), Holo-transferrin (Sigma T1408) (20 μL/well), and lipofectin (Invitrogen #18292−011) (5 μL/well) was incubated at RT for 5 min. The DNA mixture was made by adding 200 ng of pCMVβ-galactosidase as internal control, 500 ng of the estrogen-responsive reporter gene plasmid 2ERE Luc, and 100 ng of full-length ER alpha expression vector with 75 μL HBSS per well and, after addition to the first mixture, allowed to incubate for 20 min at RT. The cell media was changed to Opti-MEM (350 μL/well) and 150 μL of the transfection mixture was added to each well. The cells were incubated at 37 °C in a 5% CO_2 containing incubator for 6 h. The medium was then replaced with fresh medium containing 5% charcoal-dextran-treated calf serum and the desired treatments of compounds. Reporter gene activity was assayed at 24 h after ligand addition. Luciferase activity, normalized for the internal control β-galactosidase activity, was assayed as described (*24*).

RESULTS

Conjugate Design and Synthesis. The recruiting element/protein partner pair we chose, SLF/FKBP, was the same one used in the previously reported β-amyloid study (*12*), because of the advantages the pair confers: (a) FKBPs are ubiquitously expressed in various mammalian tissues, including breast cancer cells (e.g., FKBP52 makes up 1.0−1.5% of the total protein concentration in ER+ breast cancer cells (*25*)); (b) SLF, which is effectively one structural half of the natural product FK506, binds to FKBPs with high affinity ($K_d \approx 20$ nM) (*19, 26*) but is incapable of recruiting calcineurin, the interaction partner for FKBP, and, therefore, should have no confounding biological effects; (c) accessible methods have been described for the synthesis of SLF (*19, 20*); and finally, (d) because the SLF/FKBP pair proved effective in blocking protein−protein interactions in the β-amyloid case, we were hopeful that it would be a fruitful starting point for this project.

The position on the estradiol skeleton chosen for derivatization was the 17α position, an alteration typically known to give agonists (*15*). The NHS ester **1** was prepared by reacting 17α-ethynylestradiol with methyl 4-iodobenzoate using Sonogashira conditions, to give, after saponification of the methyl ester and activation, the NHS ester **1**. This activated ester **1** was reacted with monoprotected diamines, which after deprotection, gave the amine-functionalized estrogens **2** and **3**. Reaction of these amines with SLF electrophiles, prepared according to known methods (*19, 20*), gave the desired estrogen−SLF conjugates **4** and **5**.

Assay Design. In following the different protein−protein or protein−small molecule interactions in our studies described below, we have used various versions of a time-resolved fluorescence resonance energy transfer (TR-FRET) assay (*23*). In these assays, one of the protein partners, appropriately functionalized, is labeled with a FRET donor in one of two ways—by binding either a terbium strepavidin chelate (SA-Tb) or a terbium-labeled anti-GST antibody. The other partner, either a protein or small molecule, is labeled with the FRET acceptor fluorescein. In these experiments, an increase in FRET corresponds to a complex wherein both FRET donor and acceptor are in close proximity, meaning that both proteins are within the same complex. For further details, see our previous report (*23*).

EE2-SLF Conjugate 4 Binds ER and Recruits SRC3. As seen in Figure 1A, the short-tether EE2-SLF conjugate **4** was able to recruit a fluorescein-labeled SRC3 (SRC3-Fl) fragment to an ERα-LBD/SA-Tb complex, as judged by the dose-dependent increase in FRET signal seen with increasing concentrations of **4**. This result suggests that, as we had hoped, the conjugate **4** acts as an agonist, since antagonists are incapable of recruiting SRC to the ER in reconstituted in vitro systems. The potency of compound **4** is in general agreement with the results from a radiometric binding assay (*21, 27*), routinely carried out in our laboratories, which showed the relative binding affinity of **4** to be 1.5% that of estradiol, which corresponds to a K_D of 13 nM (data not shown).

Interestingly, conjugate **5**, having a longer tether joining the SLF and EE2 portions of the molecule, was much less capable of recruiting the SRC3 fragment to the ERα-LBD. We believe this may be due to the nonspecific interactions between the long tether and the proteins in the system that prevent the ligand from accessing the binding site.

EE2-SLF Conjugates Bind FKBP12. In a related TR-FRET experiment (Figure 1B), we showed that conjugate **4** is also capable of binding FKBP12, as judged by the dose-dependent competition of the ligand with a fluorescein-labeled SLF (SLF-Fl). In this experiment, FKBP12-GST was labeled with an anti-GST-Tb chelate. A decrease in FRET is expected if the molecule competes with SLF-Fl ($K_D = 30$ nM, data not shown) for binding to the FKBP12-Tb complex. The most potent FKBP12 binder was the unsubstituted **SLF-OH** ($IC_{50} = 200$ nM). Conjugates **4** and **5** bound to FKBP somewhat less well, with IC_{50} values of 1.7 and 1.8 μM, respectively.

EE2-SLF Conjugate 4 Binds ER and FKBP12 Simultaneously. Having established that each half of the conjugate **4** is able to independently bind to its respective partner, it was then important to establish that the conjugates were capable of binding both protein partners simultaneously. In a TR-FRET assay (Figure 1C), increasing concentrations of conjugate **4** were able to recruit fluorescein-labeled FKBP12 (FKBP12-Fl; labeled nonspecifically through available cysteine residues) to the Tb-ER complex. In this experiment, the negative control (the unfunctionalized **SLF-OH**) and the longer-tethered **5** were incapable of recruiting FKBP12 to the ER-Tb complex. This is in good agreement with the previous section, wherein **5** was

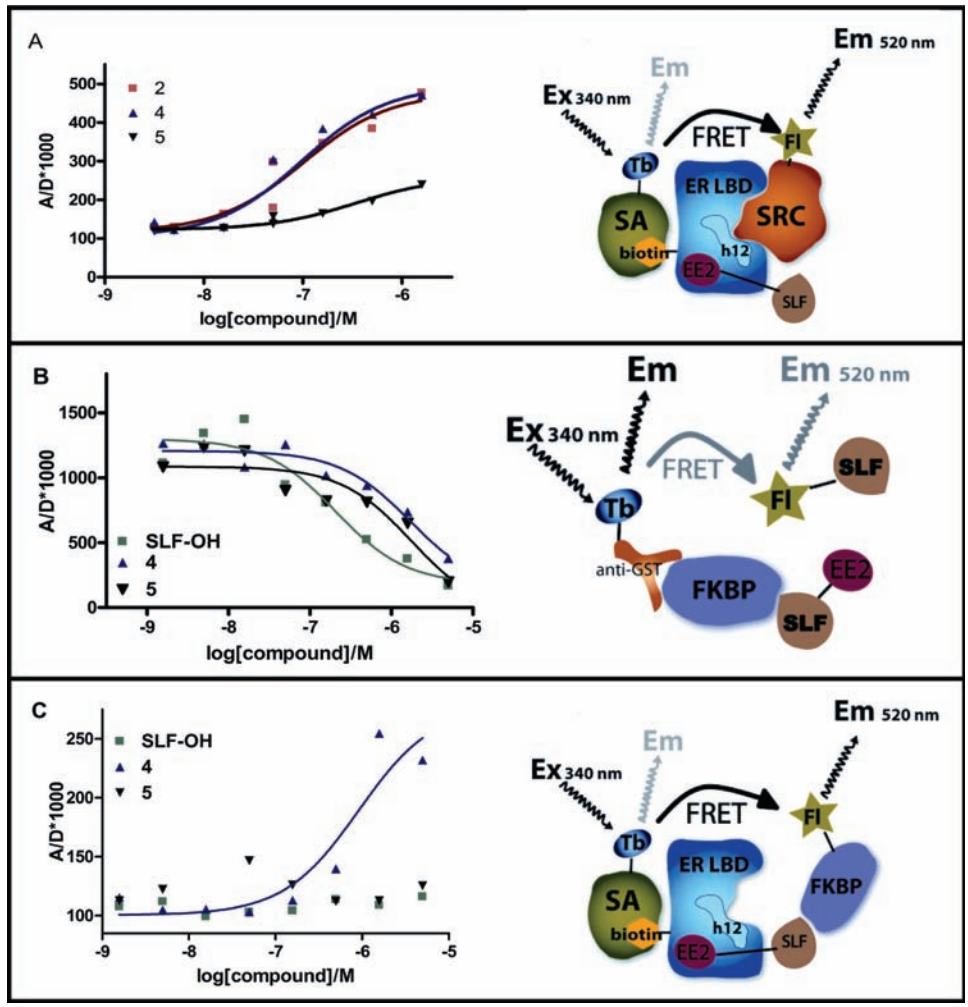


Figure 1. Time-resolved fluorescence resonance energy transfer assays. (A) Titration (ER-Tb/SRC3-Fl) of **2** (red squares), **4** (blue triangles), and **5** (black triangles) showing SRC recruitment to ER when liganded with conjugate **4**. (B) Titration (FKBP-Tb/SLF-Fl) of **SLF-OH** (green squares), **4**, and **5** showing increasing concentrations of compounds competing for SLF-Fl. (C) Titration (ER-Tb/FKBP12-Fl) of **SLF-OH**, **4**, and **5** showing recruitment of FKBP12-Fl to ER when liganded with **4**.

shown to be a poor ER binder (Figure 1A). Importantly, the results of this experiment establish that the bivalent ligand **4**, EE2-SLF, is able to bind to both of its intended protein targets, ERα and FKBP12, and bring them into one complex.

SRC3 Is Recruited to the ER/Conjugate 4/FKBP12 Complex. Conjugate **4** was capable of binding both ER and FKBP12 (Figure 1C); therefore, if it is incapable of recruiting SRC3 to ER in the presence of FKBP12, we can assume that this lack of recruitment is due to the recruited steric bulk of FKBP12. As seen in Figure 2A, ER-Tb saturated with conjugate **4** (25 μM) was capable of recruiting SRC3-Fl (high FRET), and this binding was reversible in the presence of increasing concentrations of unlabeled SRC3 (solid triangles). There was, however, no dose-dependent blockade of ER/SRC in the presence of increasing concentrations of unlabeled FKBP12 (open triangles). At the highest concentration of FKBP12 used (50 μM), no reduction is seen in the FRET signal, even though this concentration was shown to be adequate in saturating the conjugate in the previous experiment (Figure 1B). Thus, it seems that, when the ER is bound with the conjugate **4**, it can accommodate both SRC3 and FKBP12: The former is recruited due to the agonist character of the ethynylestradiol ligand (Figure 1A) and the latter can bind through the ligand component.

Conjugate 4 Is Also Incapable of Inhibiting ER Dimer Formation. In the previous experiment, ER was shown to bind a number of different proteins, but it was unclear whether a dimer or monomer of ER was responsible for this array of binding events. On the basis of structural studies of ER, dimer disruption might be more feasible than SRC inhibition, because X-ray crystallographic structures show that the 17α-phenylethynyl group of the conjugates likely exits from the binding pocket on the side of ER opposite that of the coactivator binding groove, but nearer the long helix 11, where ER dimerization takes place (*28*). If helix 11 were to be sufficiently perturbed by the recruitment of FKBP12, this could have an effect on the ability of ER to dimerize.

To probe this question, the ER-Tb complex (1 nM) was incubated with conjugate **4** (10 μM) and fluorescein-labeled ER (ER-Fl; 50 nM), such that a decrease in FRET would occur if dimer formation were to be disrupted (Figure 2B). In the positive controls, ER dimerization was disrupted (observed by a dose-dependent decrease in FRET) in the presence of increasing concentrations of unlabeled ER using either estradiol or conjugate **4**. These compounds do not, however, give this characteristic decrease in FRET in the presence of increasing concentrations of FKBP12 (open diamonds). Therefore, FKBP12 does not inhibit the formation of the ER dimer.

Conjugate 4 Is Incapable of Downregulating an ER-Regulated Reporter Gene. Regardless of its activity in in vitro assays, we thought that the conjugate might have unexpected activity in cell-based assays of ER-mediated transcription. When we treated transiently transfected HEC-1 cells with conjugate

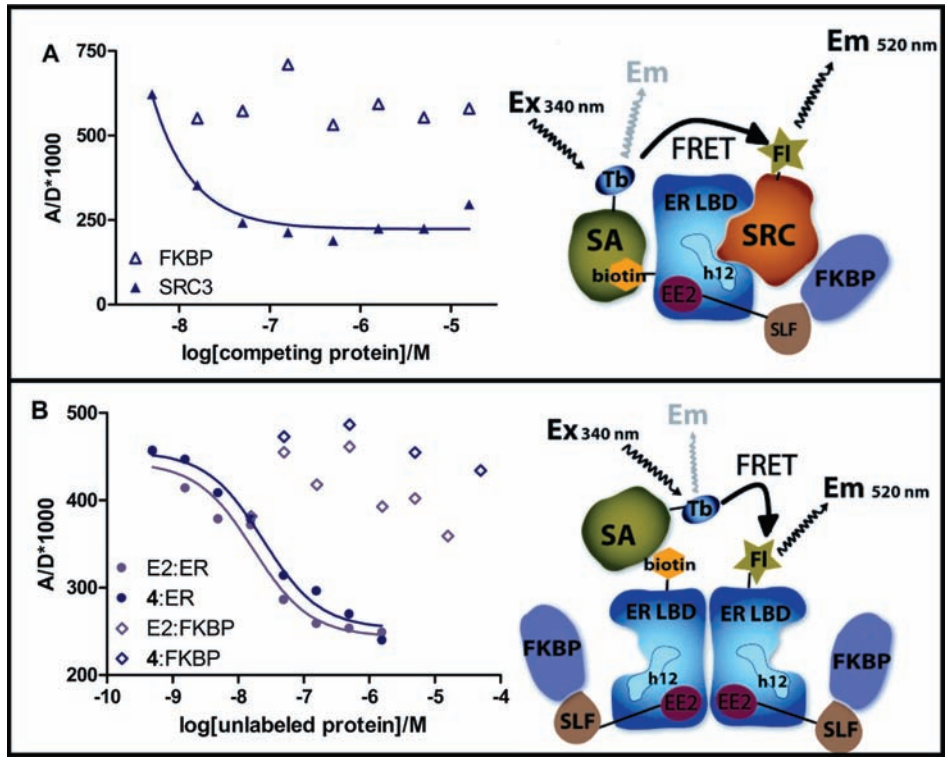

Figure 2. Time-resolved fluorescence resonance energy transfer assays. (A) Titration (conjugate **4**/ER-Tb/SRC3-Fl) of either FKBP12 (open triangles) or SRC3 (closed triangles) showing that unlabeled SRC3 displaces SRC3-Fl, but FKBP12 does not. (B) Titration (ER-Tb/ER-Fl) of conjugate **4** (blue) or estradiol (E2; purple) showing that unlabeled ER (closed circles) is able to disrupt dimer formation, but FKBP12 (open diamonds) is not.

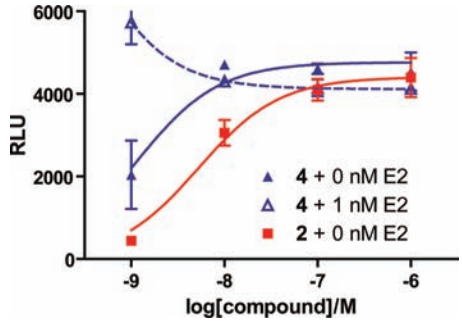

Figure 3. Luciferase reporter gene assay with **4** (closed blue triangles), **2** (closed red squares), and **4** + 1 nM E2 (open blue triangles), Increasing concentrations of **4** activate the ER-regulated luciferase gene, rather than downregulating luciferase expression.

4 (*24*), we saw, however, a dose-dependent increase in luciferase expression that was almost identical to the negative control **2**, which lacks an SLF group (Figure 3). Thus, both of these compounds behave as conventional ER agonists that are unaffected by the presence of FKBP and consistent with their ability to recruit SRC (cf. Figure 1B). When competing against 1 nM estradiol, the conjugate **4** showed no significant dose-dependent decrease in luciferase production. The small decrease in signal from −9 (1 nM) to −8 (10 nM) is most likely due to the lesser efficacy of compound **4** in comparison to estradiol as the ligands are exchanged, rather than true inhibition based on recruitment of FKBP. These data lead us to conclude that the ability of conjugate **4** to bind FKBP does not affect its efficacy, in agreement with the in vitro experiments detailed above.

DISCUSSION

The experiments detailed above yield a rather surprising finding: the ER can serve as a nexus for a remarkable number of binding events and still retain its activity, namely, binding of SA-Tb, conjugate **4**, SRC3, FKBP12, and another ER monomer occurs simultaneously and without antagonistic consequence. While this is not the finding for which we had hoped, it is an interesting one nevertheless, given that the ER-LBD is only 31 kDa, yet is able to recruit and bind approximately 145 kDa of other protein fragments simultaneously (FKBP12-GST (38 kDa), SRC3-NRD (24 kDa), streptavidin (53 kDa)). Thus, the estrogen receptor appears to be a protein with a high topological tolerance in its interactions with protein binding partners and thereby appears to be quite resistant to the disruption of its normal, functional interactions by recruitment of FKBP12 using heterobifunctional ligand−SLF conjugates.

There are a number of differences between the system we have investigated and the β-amyloid system on which this project was founded (*12*), and a comparison is instructive. Perhaps most salient is that we have not used this method to fortify the affinity of a weak, direct protein−protein interaction inhibitor, such as coactivator binding inhibitors we have studied (*8*, *9*). Rather, we have based our heterobifunctional conjugates on estradiol, a high-affinity ligand that binds to the ligand binding pocket. We were hopeful that the higher affinity of estradiol for the ligand-binding pocket of the receptor, compared to the relatively weak affinity of the known direct ER/SRC inhibitors (*8*, *9*), might serve as a better starting point for developing these types of inhibitors. Our inability to block either of these interactions with an inhibitor that binds to the ER with low nanomolar affinity, as does ours, would bode especially poorly for approaches that construct heterobifunctional conjugates from molecules that bind to the ER with only micromolar affinity, as do the currently available direct inhibitors of coactivator binding (*8*, *9*, *29*, *30*).

An additional difference between the Aβ system and ours is the size of the components involved. An oligomer of Aβ weighs only ca. 1 kDa, and its oligomerization is being inhibited by a

recruited FKBP twelve times its mass (*12*). In an in vitro sense, our system uses a 31 kDa construct of the ER-ligand binding domain and a 24 kDa SRC3 fragment. These are of comparable size to the FKBP-GST fusion protein used in our assays. Thus, it is conceivable that, although the FKBP-GST is being recruited, it is just too small to block the interaction of the larger-sized proteins. Some breast cancer cell lines, such as MCF-7, express larger FKBPs (e.g., FKBP51 or 52) that could be implemented in experiments similar to those described in this report (*25*); however, we do not believe that the steric bulk of these proteins would be significantly greater than the FKBP12-GST fusion protein (MW 38 kDa) that we have used here.

It is known that the affinities of the ER for its dimerization partner and SRC fragment are both very high ($K_d \approx$ <1 nM for both). It is not clear from the literature what the affinity of Aβ is during oligomerization, but various groups have demonstrated that appreciable oligomerization occurs at concentrations of 1−5 nM (*31, 32*), although higher concentrations (70 μM − 2 mM) are typically used when larger assemblies, such as prefibrillar and fibrillar oligomers and fibrils, are formed (*33*). The SLF-Congo Red conjugate described by Gestwicki was capable of inhibiting formation of aggregates up to ca. 28 nm^2 in size in the presence of FKBP, suggesting that the compound is not capable of disrupting the bimolecular Aβ/Aβ interaction, but rather the formation of these larger, possibly lower-affinity assemblies (*12*).

The position chosen for tethering SLF to the estradiol skeleton (17α) is an appropriate position for blocking ER dimerization, as the dimer interface occurs along the axis of helix 11 (*28*). Thus, it is surprising that the ER is able to bind its dimeric partner and FKBP simultaneously. By contrast, because SRC binds on a different face of the receptor, it might be difficult to access the ER/SRC interaction site with these types of inhibitors. It was for this reason that we created the longer-tethered conjugate **5**, in the hope that it might be able to extend further around the receptor to block the ER/SRC interaction. Unfortunately, we found that including this longer tether reduced the affinity of the molecule for the ER to levels that precluded it from being examined in our assays.

Another option in designing estrogen-SLF conjugates would be to supplement the activity of an antiestrogen by appending an SLF moiety; in fact, such a design has been reported for the androgen receptor (*34*). We have attempted to create such compounds for the estrogen receptor, but we have had difficulty in synthesizing one that has sufficient ER affinity to be examined in our assays.

More recently, heterobivalent molecules linking SLF with other ligands have been prepared (*13, 35*). These conjugates bind either to FKBP12 or to the other target protein (dihydrofolate reductase or cytochrome P450, respectively) when the two proteins are present separately, but they do not bind to both simultaneously when both are present. The steric occlusion encountered with these heterobivalent ligands is different from the behavior of the ligands, originally reported by Gestwicki et al. (*12*), that bind to FKBP and at the same time are able to interfere with the polymerization of Aβ. Our heterobivalent ligands too are able to bind to both ER and FKBP, but they do not prevent ER from interacting with other proteins (SRC or itself).

Of the heterobivalent ER ligands that have been reported in the literature, most are cytotoxic estrogens that typically contain alkylating agents tethered to estrogens (*36*−*39*); as such, they are not particularly germane to this discussion. The one exception of which we are aware is a geldanamycin-estradiol conjugate designed and synthesized by Danishefsky and coworkers (*40*). Meant to inhibit Hsp90 function and selectively degrade ER, the conjugate does seem to be selective for ER over other targets of Hsp90 inhibition (i.e., Raf-1, IGF1R) at very high concentrations (1 mM); however, no mechanistic studies were done to determine how the conjugate functions at a molecular level. It would be interesting to know whether this conjugate is also capable of simultaneously binding ER and Hsp90, whether simultaneous binding is necessary for its biological activity, and whether interruption of ER-associated protein−protein interactions contributes to its activity.

There have also been heterobivalent estrogen conjugates reported in the literature that are used in yeast-three hybrid assays, implying that the estrogen receptor is capable of binding to two different proteins simultaneously, although the interaction partner in this assay is streptavidin. This conjugate would presumably have no biological activity arising from multivalent interactions, as mammalian cells do not express avidins (*41*). We acknowledge a number of other factors (e.g., targeting element, recruiting element, tether length and composition, substitution site, enhanced affinity) one might change in creating inhibitors of the type mentioned here, but we wanted to share here our experience thus far—that a conjugate capable of binding both FKBP and ER simultaneously is incapable of inhibiting two different ER-associated protein−protein interactions.

Obviously, all of these factors merit careful consideration in the design of heterobivalent ligands, but beyond this, the overall topology of the protein−protein interaction is likely to be a critically important determinant of the feasibility and potential success of the Trojan horse approach to disruption of protein−protein interactions. The importance of the Congo Red−SLF conjugates is undeniable; however, the ER, long known as a proof-of-principle target in chemical biology experiments because of its therapeutic importance and well-studied biology, appears to have considerable topological tolerance in its interaction with its functional partner proteins (e.g., SRC). Therefore, it may not be the next logical conceptual target for this type of inhibition, and our experience suggests ways in which this Trojan horse approach may be limited.

ACKNOWLEDGMENT

The authors thank Kathryn Carlson for performing radiometric ligand-binding assays, Jie Chen for providing the FKBP12 constructs, Sung Hoon Kim for obtaining mass spectral data, and Manuel Rodriguez for assistance in synthesis. This research was supported by a grant from the National Institutes of Health (PHS 5R37 DK015556 to J.A.K.). Probing the Topological Tolerance of Multimeric Protein Interactions:

Evaluation of an Estrogen/Synthetic Ligand for FK506 Binding Protein Conjugate

by

Terry W. Moore,[a] Jillian R. Gunther and John A. Katzenellenbogen*

***tert*-Butyl 1-amino-13-oxo-3,6,9,16,19,22,25-heptaoxa-12-azaheptacosan-27-ylcarbamate:** NHS ester **26** (610 mg, 1.0 eq) was dissolved in anhydrous THF (3.0 mL) and amino alcohol **27** (500 mg, 2 eq) was added to this solution, followed by diisopropylethylamine (454 μL, 2.0 eq). This solution was stirred for 12 h, and the THF was evaporated. The compound was dissolved in ethyl acetate, and a small amount of water was added; the layers were separated, and the aqueous layer was extracted three additional times with ethyl acetate to give, after drying over $MgSO_4$ and evaporation of solvent, 550 mg (78% yield) of a viscous oil. This product was then activated as the methanesulfonate by adding in methanesulfonyl chloride (94 μL, 1.2 eq) and excess NEt_3 in dichloromethane. The solution was stirred for 4 h, and was then extracted using water and dichloromethane. The combined organic extracts were dried over $MgSO_4$ and concentrated to give 230 mg (36% yield) of the mesylate. The mesylate was then dissolved in DMF, and excess sodium azide (230 mg) was added to

the solution. The solution was stirred at RT for 4 h, and the product was extracted using ethyl acetate and brine. The organic extracts were dried over $MgSO_4$ and concentrated to give 170 mg (79% yield) of a viscous oil. Finally, the organic azide was dissolved in 20 mL methanol, and reduced for 2 h under 30 psi H_2 in a Parr shaker apparatus using 10 mol% Pd/C. The solution was filtered through celite, and the solvents were evaporated to give 150 mg (97% yield) of a viscous oil. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 3.81 - 3.74 (m, 2 H), 3.73 - 3.67 (m, 2 H), 3.65 - 3.61 (m, 2 H), 3.62 - 3.50 (m, 21 H), 3.50 - 3.43 (m, 3 H), 3.41 - 3.33 (m, 3 H), 3.23 (d, *J*=4.5 Hz, 2 H), 3.17 - 3.11 (m, 2 H), 2.51 (t, *J*=6.1 Hz, 1 H), 1.35 (s, 9 H); ^{13}C NMR (125 MHz, $CDCl_3$) δ: 171.84, 156.01, 78.92, 70.30, 70.09, 70.00, 69.90, 69.79, 69.59, 67.24, 66.41, 40.00, 39.64, 38.97, 36.38, 28.22; HR-ESI MS $[M + H^+]^+$: calcd for 540.3496; found, 540.3496.

Solid-Supported Synthesis and Click Conjugation of 4′-*C*-Alkyne Functionalized Oligodeoxyribonucleotides

Anu Kiviniemi,* Pasi Virta, and Harri Lönnberg

Department of Chemistry, University of Turku, FIN-20014 Turku, Finland. Received June 11, 2010; Revised Manuscript Received August 23, 2010

4′-*C*-[*N*,*N*-Di(4-pentyn-1-yl)aminomethyl]thymidine and 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine 3′-(2-cyanoethyl-*N*,*N*-diisopropyl)phosphoramidites (**1**, **2**) were synthesized, and one or two such monomers were incorporated into a 15-mer oligodeoxyribonucleotide. After chain assembly, azido-functionalized ligands, including appropriate derivatives of 1,4-phenylenedimethaneamine, mannose, paromamine, and neomycin, were conjugated to the alkynyl groups by the click chemistry on a solid support. The influence of the 4′-modifications on the melting temperature with DNA and 2′-*O*-methyl RNA targets was studied. Oligonucleotides containing one to four mannose ligands in the central part of the chain (up to two 4′-*C*-[*N*,*N*-di(4-pentyn-1-yl)aminomethyl]thymidine units) form equally stable duplexes with complementary 2′-OMe RNA as the corresponding unmodified DNA sequence. At high salt content, the mannose conjugation is even stabilizing. On using a DNA target, a modest destabilization occurs. All the amino group bearing conjugates stabilized the duplexes, the DNA·DNA duplexes more than the DNA·2′-*O*-methyl RNA duplexes.

INTRODUCTION

Conjugation to peptides, carbohydrates, or small molecule compounds has been extensively studied as a possible way to improve the delivery and targeting of siRNA and antisense oligonucleotides (*1*−*15*), and the synthesis of such conjugates has been recently reviewed (*16*−*21*). Both carbohydrate−carbohydrate (*22, 23*) and carbohydrate−protein interactions (*24*−*26*) are known to play a central role in cellular recognition. These interactions are multipodal; simultaneous interaction with several monosaccharide ligands is required for high-affinity binding (*27*−*30*). Accordingly, the most attention has been paid to preparation of oligonucleotide conjugates bearing a multiarmed glycocluster at either terminus of the chain (*31*−*36*). As far as glycotargeting of siRNA is concerned, another approach appears, however, possible, viz., decoration of the sense strand with sugars. A prerequisite for this approach is that the sugar ligands do not markedly destabilize the duplex. In other words, the sense strand is aimed at serving as a scaffold to which the lectin-binding sugar ligands are tethered at appropriate distances throughout the molecule. Since the carrier is simultaneously able to hybridize with the antisense strand, the latter becomes enriched at the cell surface and, hence, internalizated by receptor-mediated endocytosis.

Several examples of oligonucleotide glycoconjugates bearing the sugars at intrachain positions have been published. These cannot, however, be exploited as sense strands in siRNA, since the sugar ligands are attached either to base moieties (*37*−*41*) or to non-nucleosidic units incorporated in the sugar−phosphate backbone (*42*−*44*). Both of these conjugations markedly destabilize the duplex. In fact, the only example of conjugation that does not markedly affect the duplex stability is offered by 4′-*C*-tethered glycoconjugates obtained by subjecting a 4′-*C*-azidomethyl incorporating oligonucleotide to Cu(I) catalyzed 1,3-dipolar cycloaddition, the so-called click reaction (*45, 46*), with an alkyne-derivatized sugar (*47*). The latter approach, however, suffers from the limitation that the 4′-*C*-azidomethyl unit has to be introduced into the chain by H-phosphonate coupling, since the intramolecular Staudinger reaction prevents preparation of the phosphoramidite building block. In the present study, the corresponding alkyne-derivatized nucleosides, viz., 4′-*C*-[*N*,*N*-di(4-pentyn-1-yl)aminomethyl]thymidine and 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine monomers (**1**, **2**), have been synthesized and incorporated into oligonucleotides by phosphoramidite chemistry. The 4-pentynyl group was chosen as the alkyne spacer to provide the 4′-*C*-modified nucleoside with sufficient flexibility to ensure efficient click reaction with azides (*48*) and proper alignment of the conjugate groups upon duplex formation. A related strategy has previously been applied to solid-supported derivatization of oligonucleotides containing ω-alkynylated nucleobases (*48, 49*). Monomers **1** and **2** allowed the attachment of two or one conjugative group per modified residue, respectively (Figure 1). The ligands used for the conjugation included azido derivatives of mannose (**3**), *p*-aminomethylbenzene (**4**), and aminoglycosides paromamine (**5**) and neomycin (**6**). The effects of these conjugate groups on the melting temperature of the duplexes with cDNA and 2′-*O*-methyl RNA sequences were determined to assess the contributions of electrostatic interactions and sterical factors to the efficiency of hybrization.

EXPERIMENTAL PROCEDURES

General Remarks. The NMR spectra were recorded at 500 MHz. The mass spectra were recorded using EI or ESI ionization. The RP HPLC analyses of the oligonucleotide conjugates were performed using a Thermo ODS Hypersil C18 (250 × 4.6 mm, 5 μm) analytical column, gradient elution from 0% to 50% MeCN in 0.1 mol L^{-1} triethylammonium acetate (aq) buffer over 60 min, flow rate 1 mL min^{-1}, and detection at 260 nm.

4′-*C*-Aminomethyl-3′-*O*-(4,4′-dimethoxytrityl)thymidine (8). 4′-*C*-Azidomethyl-3′-*O*-(4,4′-dimethoxytrityl)thymidine (2.14 g, 3.6 mmol) (*47*) was dissolved in THF (24 mL). Triphenylphosphine (1.50 g, 5.7 mmol), water (64 μL), and a drop of 33% aq NH_3 (∼20 μL) was added, and the reaction was stirred overnight. The reaction mixture was evaporated to dryness and purified by silica gel chromatography (10−20% MeOH in DCM containing 0.1% triethylamine). The yield was 1.54 g (75%) as a white solid foam. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.50−7.47

ESI-MS: $[M+H]^+$ $C_{51}H_{65}N_5O_8P$ requires 906.4565, found 906.4552.

4′-*C*-[*C*-(4-Pentyn-1-yl)aminomethyl]thymidine (10). Compound **8** (0.92 g, 1.6 mmol) was dissolved in MeOH (20 mL) and 4-pentynal (0.18 g, 2.2 mmol), $NaBH_3CN$ (0.30 g, 4.8 mmol) and acetic acid (92 μL) were added on an ice bath. The reaction was allowed to proceed overnight at room temperature. To remove the 4,4′-dimethoxytrityl group, 80% aqueous acetic acid was added, and after 2 h, the reaction mixture was evaporated to dryness. The residue was purified by silica gel chromatography (5−20% MeOH in DCM), giving compound **10** in 94% yield (0.51 g) as a white powder. ^{1}H NMR (500 MHz, MeOD/CD_3Cl (1:1)) δ_{ppm} 7.61 (s, 1H), 6.38 (dd, 1H, J = 8.3 Hz, 6.3 Hz), 4.53 (dd, 1H, J = 4.0 Hz, 4.0 Hz), 3.65 (s, 2H), 3.37 (m, 1H), 3.23−3.13 (m, 3H), 2.48 (m, 1H), 2.38−2.31 (m, 3H), 2.20 (br s, 1H), 1.96 (m, 2H), 1.91 (s, 3H); ^{13}C NMR (125 MHz, MeOD/CD_3Cl (1:1)) δ_{ppm} 164.7, 151.2, 136.5, 111.4, 86.1, 85.7, 81.5, 74.1, 70.7, 65.1, 49.7, 47.8, 39.4, 24.1, 15.6, 12.0. ESI-MS: $[M+H]^+$ $C_{16}H_{24}N_3O_5$ requires 338.1711, found 338.1725.

4′-*C*-[*N*-Methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine (11). Compound **10** (0.45 g, 1.3 mmol) was dissolved in MeOH (10 mL), and paraformaldehyde (44 mg), $NaBH_3CN$ (92 mg, 1.5 mmol), and acetic acid (76 μL) were added on an ice bath. The mixture was stirred at room temperature over the weekend, and paraformaldehyde (22 mg) and $NaBH_3CN$ (50 mg, 0.8 mmol) were added to complete the reaction. The reaction was evaporated to dryness and purified by silica gel chromatography (10−20% MeOH in DCM). The yield was 0.44 g (93%). ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.48 (s, 1H), 6.40 (dd, 1H, J = 8.5 Hz, 6.0 Hz), 4.45 (dd, 1H, J = 4.5 Hz, 4.5 Hz), 3.66 (d, 1H, J = 11.5 Hz), 3.61 (d, 1H, J = 12.0 Hz), 3.41 (d, 1H, J = 14.0 Hz), 3.31 (m, 1H), 3.17 (m, 2H), 2.86 (s, 3H), 2.44−2.28 (m, 5H), 1.95−1.87 (m, 5H); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 163.7, 150.6, 136.1, 110.5, 85.9, 85.6, 82.5, 74.3, 70.1, 65.3, 59.0, 58.1, 43.6, 38.8, 23.2, 15.2, 11.6. ESI-MS: $[M+H]^+$ $C_{17}H_{26}N_3O_5$ requires 352.1867, found 352.1849.

4′-*C*-[*N*-Methyl-*N*-(4-pentyn-1-yl)aminomethyl]-5′-*O*-(4,4′-dimethoxytrityl)thymidine (13). To a solution of compound **11** (0.36 g, 1.0 mmol) in 15 mL of dry pyridine, 4,4′-dimethoxytrityl chloride (0.42 g, 1.2 mmol) was added, and the mixture was stirred overnight at room temperature. The reaction mixture was evaporated and purified by silica gel chromatography (5% MeOH in DCM + 0.1% triethylamine). The yield was 0.27 g (40%) as a white solid foam. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.49−7.45 (m, 2H), 7.37−7.31 (m, 7H), 7.26 (m, 1H), 6.92−6.87 (m, 4H), 6.29 (dd, 1H, J = 7.5 Hz, 6.5 Hz), 4.63 (dd, 1H, J = 5.5 Hz, 3.5 Hz), 3.79 (s, 6H), 3.22 (d, 1H, J = 10.0 Hz), 3.10 (d, 1H, J = 10.0 Hz), 2.85 (d, 1H, J = 14.0 Hz), 2.69 (d, 1H, J = 14.5 Hz), 2.56 (m, 1H), 2.45 (m, 1H), 2.30−2.20 (m, 5H), 2.16−2.10 (m, 3H), 1.62 (m, 2H), 1.54 (s, 3H); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 163.8, 158.8, 150.6, 144.9, 135.8, 135.7, 135.5, 130.2, 130.2, 128.1, 128.0, 127.0, 113.2, 110.1, 86.8, 86.7, 84.2, 84.1, 74.4, 68.9, 66.5, 59.9, 57.8, 55.0, 42.9, 40.4, 26.0, 15.6, 11.4. ESI-MS: $[M+Na]^+$ $C_{38}H_{43}N_3NaO_7$ requires 676.2993, found 676.2997.

3′-*O*-[(2-Cyanoethoxy)-(*N*,*N*-diisopropylamino)phosphinyl)]-4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]-5′-*O*-(4,4′-dimethoxytrityl)thymidine (2). Compound **13** (0.27 g, 0.4 mmol) was dried over P_2O_5 in a vacuum desiccator and dissolved in dry DCM (5 mL). Triethylamine (293 μL, 2.1 mmol) and 2-cyanoethyl *N*,*N*-diisopropylphosphoramidochloridite (111 μL, 0.5 mmol) were added to the reaction solution under nitrogen. After 1 h, the reaction was completed and the mixture was eluted through a short, dried silica gel column (50% ethyl acetate in hexane, 0.1% triethylamine). The faster eluting diastereomer I was partly obtained as a pure compound, while diastereomer II remained contaminated by diastereomer I (see Supporting Information). Yield was 0.31 g (87%) as a white solid foam. Diastereomer I: ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 8.89 (s, 1H), 7.54−7.49 (m, 3H), 7.40−7.32 (m, 6H), 7.28 (m, 1H), 6.92−6.88 (m, 4H), 6.24 (dd, 1H, J = 7.0 Hz, 5.0 Hz), 4.98 (ddd, 1H, J = 10.5 Hz, 7.3 Hz, 7.3 Hz), 3.80 (s, 6H), 3.75−3.59 (m, 4H), 3.42 (d, 1H, J = 10.5 Hz), 3.22 (d, 1H, J = 10.5 Hz), 2.62−2.47 (m, 6H), 2.41−2.29 (m, 2H), 2.20 (s, 3H), 2.09−2.03 (m, 3H), 1.53 (m, 2H), 1.44 (br d, 3H, J = 1.0 Hz), 1.21 (d, 6H, J = 7.5 Hz), 1.20 (d, 6H, J = 7.0 Hz); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 163.6, 158.8, 150.3, 145.1, 135.8, 135.8, 135.7, 130.3, 128.2, 127.9, 127.0, 118.6, 113.1, 110.0, 88.9, 88.8, 86.5, 84.4, 83.2, 72.7, 72.5, 68.6, 64.3, 58.7, 58.5, 58.0, 55.0, 43.4, 42.9, 38.5, 26.5, 24.0, 23.9, 20.1, 20.1, 15.6, 11.3; ^{31}P NMR (200 MHz, CD_3CN) δ_{ppm} 148.6. Diastereomer II: ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 8.94 (s, 1H), 7.52−7.48 (m, 3H), 7.38−7.31 (m, 6H), 7.27 (m, 1H), 6.91−6.87 (m, 4H), 6.27 (dd, 1H, J = 7.0 Hz, 6.0 Hz), 4.90 (ddd, 1H, J = 9.5 Hz, 7.0 Hz, 6.0 Hz), 3.87 (m, 1H), 3.79 (s, 6H), 3.77−3.56 (m, 3H), 3.43 (d, 1H, J = 10.5 Hz), 3.21 (d, 1H, J = 10.0 Hz), 2.69 (t, 2H, J = 6.0 Hz), 2.62−2.47 (m, 4H), 2.42−2.26 (m, 2H), 2.20 (s, 3H), 2.09−2.02 (m, 3H), 1.52 (m, 2H), 1.45 (br d, 3H, J = 1.0 Hz), 1.19 (d, 6H, J = 6.5 Hz), 1.12 (d, 6H, J = 6.5 Hz); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 163.5, 158.8, 150.3, 145.1, 135.8, 135.8, 135.7, 130.3, 128.2, 127.9, 127.0, 118.6, 113.1, 110.2, 88.5, 88.4, 86.6, 84.4, 83.1, 74.0, 73.9, 68.6, 64.5, 58.8, 58.2, 58.0, 54.9, 43.4, 43.0, 38.6, 26.5, 24.2, 24.1, 23.8, 23.8, 20.2, 20.1, 15.6, 11.2; ^{31}P NMR (200 MHz, CD_3CN) δ_{ppm} 148.9. ESI-MS: $[MH]^+$ $C_{47}H_{61}N_5O_8P$ requires 854.4252, found 854.4247.

***N*-[4-(azidomethyl)benzyl]-2,2,2-trifluoroacetamide (4).** *N*-[4-(Azidomethyl)benzyl]-(4-methoxytrityl)amine (**15**) was first synthesized from *N*-(4-methoxytrityl)-1,4-phenylenedimethanamine (**14**). Compound **14** (1.00 g, 2.4 mmol) was dissolved in DCM (4 mL), and an aqueous solution of K_2CO_3 (3.7 mmol)/$CuSO_4$ (15 μmol) (7 mL) and MeOH (30 mL) were added. Triflyl azide (4.9 mmol, theoretical amount calculated from trifluoromethanesulfonyl anhydride used in the preparation) was prepared as previously reported (*50*) and added to the reaction mixture. The reaction was stirred overnight at room temperature and evaporated to dryness. The residue was dissolved in ethyl acetate and extracted with water. The organic fraction was dried with Na_2SO_4, evaporated, and purified by silica gel chromatography (10−20% ethyl acetate in petroleum ether, 0.1%

triethylamine). Compound **15** was obtained in 96% yield (1.03 g) yield. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 7.57−7.52 (m, 4H), 7.47−7.40 (m, 4H), 7.32−7.24 (m, 6H), 7.22−7.17 (m, 2H), 6.85−6.81 (m, 2H), 4.32 (s, 2H), 3.79 (s, 3H), 3.34 (s, 2H), 1.84 (br s, 1H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 158.0, 146.2, 141.4, 138.1, 129.8, 128.5, 128.4, 128.3, 127.9, 126.3, 113.2, 70.5, 55.2, 54.6, 47.6. To the solution of compound **15** (0.95 g, 2.2 mmol) in 10 mL of DCM, trifluoroacetic acid (0.34 mL, 4.4 mmol) and MeOH were added. After 1 h stirring at room temperature, the reaction mixture was evaporated. Without further purification, the detritylated product was subjected to trifluoroacetylation with methyl trifluoroacetate (1.60 g, 12.5 mmol) in a mixture of triethylamine (1.6 mL) and MeOH (9 mL). After 2.5 h, the mixture was evaporated and purified by silica gel chromatography (5−50% ethyl acetate in petroleum ether). The yield was 0.50 g (88%) as a yellowish solid foam. ^{1}H NMR (500 MHz, $CDCl_3$) δ_{ppm} 7.35−7.30 (m, 4H), 6.65 (br s, 1H), 4.54 (d, 2H, J = 6.0 Hz), 4.35 (s, 2H); ^{13}C NMR (125 MHz, $CDCl_3$) δ_{ppm} 157.2, 136.0, 135.7, 128.9, 128.5, 115.8, 54.3, 43.6. ESI-MS: $[M+Na]^+$ $C_{10}H_9F_3N_4NaO$ requires 281.0621, found 281.0602.

1,3,2′-Tri-*N*-trifluoroacetylparomamine (17). Paromamine trihydrochloride (**16**) was obtained by hydrolysis of paromomycin sulfate under acidic conditions (1 mol L^{-1} HCl aq in MeOH, reflux overnight), as described previously (*51*). To the suspension of compound **16** (2.96 g, 6.8 mmol) in a mixture of MeOH (60 mL) and triethylamine (14.4 mL), methyl trifluoroacetate (8.76 g, 68.4 mmol) was added. After a few minutes, the solution cleared for a while, but soon the product began to precipitate. The reaction was stirred for 1 h at room temperature, and the precipitated product was filtered and washed with MeOH. Compound **17** was received in 76% yield (3.20 g) as a white powder. ^{1}H NMR (500 MHz, D_2O/acetone-d_6) δ_{ppm} 5.38 (d, 1H, J = 3.5 Hz), 4.02 (m, 1H), 3.90 (dd, 1H, J = 10.5 Hz, 3.5 Hz), 3.84 (m, 1H), 3.73−3.65 (m, 4H), 3.58 (dd, 1H, J = 9.5 Hz, 9.0 Hz), 3.55−3.40 (m, 3H), 1.93 (m, 1H), 1.70 (ddd, 1H, J = 12.5 Hz, each); ^{13}C NMR (125 MHz, D_2O/acetone-d_6) δ_{ppm} 97.6, 79.4, 76.9, 73.6, 73.0, 70.5, 70.0, 60.6, 54.7, 50.1, 49.3, 31.9 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{18}H_{22}F_9N_3NaO_{10}$ requires 634.1054, found 634.1052.

6′-*O*-(4,4′-Dimethoxytrityl)-1,3,2′-tri-*N*-trifluoroacetylparomamine (18). Compound **17** (1.96 g, 3.2 mmol) was dried over P_2O_5 in a vacuum and dissolved in dry pyridine (70 mL). 4,4′-Dimethoxytrityl chloride (1.09 g, 3.2 mmol) was added and the mixture was stirred overnight at room temperature. After evaporation, the residue was partitioned between ethyl acetate and saturated aq $NaHCO_3$. The organic fraction was dried with Na_2SO_4, evaporated, and purified by silica gel chromatography (10% MeOH in DCM + 0.1% triethylamine) yielding product **18** (2.00 g, 68%) as a purplish foam. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 8.07 (br d, 1H, J = 7.0 Hz), 7.54 (br d, 2H, J = 8.5 Hz), 7.52−7.49 (m, 2H), 7.39−7.32 (m, 6H), 7.26 (m, 1H), 6.92−6.88 (m, 4H), 5.30 (d, 1H, J = 3.0 Hz), 4.05−3.92 (m, 2H), 3.89−3.75 (m, 10H), 3.70−3.61 (m, 3H), 3.53 (dd, 1H, J = 9.5 Hz, 9.0 Hz), 3.49 (m, 1H), 3.42−3.34 (m, 2H), 3.27 (dd, 1H, J = 10.0 Hz, 3.5 Hz), 3.23 (dd, 1H, J = 10.0 Hz, 2.5 Hz), 2.01 (ddd, 1H, J = 13.0 Hz, 4.5 Hz, 4.5 Hz), 1.71 (ddd, 1H, J = 13.0 Hz, each); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 158.6, 145.3, 136.2, 136.2, 130.2, 128.2, 127.8, 126.7, 113.0, 98.4, 85.6, 80.1, 76.5, 73.7, 72.0, 71.5, 70.3, 62.0, 54.9, 54.8, 50.1, 49.6, 31.5 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{39}H_{40}F_9N_3NaO_{12}$ requires 936.2360, found 936.2349.

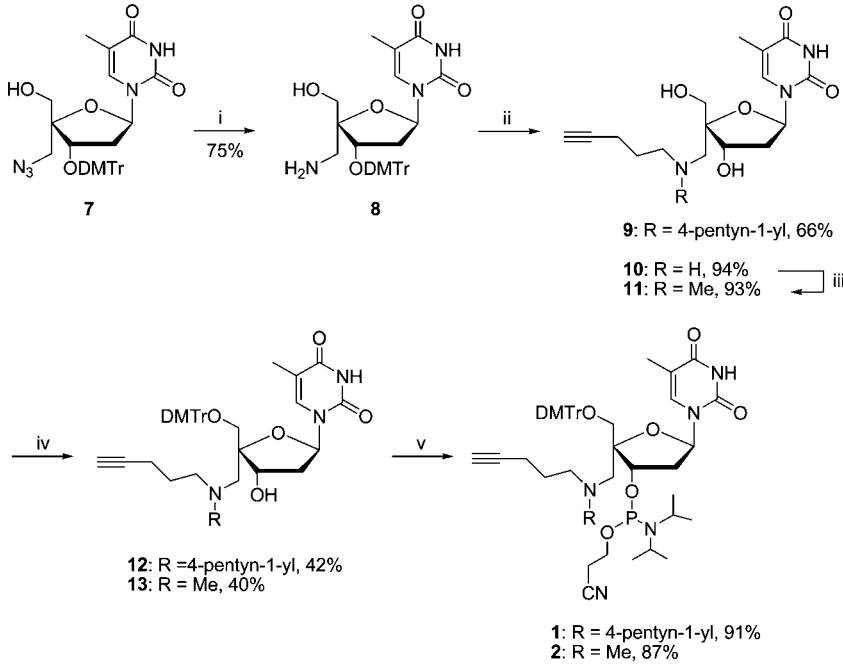
6′-*O*-(4,4′-Dimethoxytrityl)-5,6,3′,4′-tetra-*O*-acetyl-1,3,2′-tri-*N*-trifluoroacetylparomamine (19). Compound **18** (1.68 g, 1.8 mmol) was dissolved in dry pyridine and acetic anhydride (1.4 mL, 14.8 mmol), and a catalytic amount of 4-dimethylaminopyridine was added. The mixture was heated at 60 °C for 3 h and evaporated to dryness. The residue was dissolved in ethyl acetate and extracted with saturated aq $NaHCO_3$. The organic fraction was dried with Na_2SO_4, evaporated, and purified by silica gel chromatography (30% ethyl acetate in DCM + 0.1% triethylamine). The product (**19**, 1.96 g) was isolated as white foam in 98% yield.^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.72 (d, 1H, J = 9.0 Hz), 7.56 (d, 1H, J = 9.0 Hz), 7.52−7.48 (m, 2H), 7.39−7.30 (m, 7H), 7.27 (m, 1H), 6.95−6.90 (m, 4H), 5.42 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 5.36 (d, 1H, J = 3.5 Hz), 5.31 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 5.08 (dd, 1H, J = 10.0 Hz, 10.0 Hz), 5.06 (dd, 1H, J = 10.5 Hz, 10.0 Hz), 4.43 (ddd, 1H, J = 10.0 Hz, 9.5 Hz, 3.8 Hz), 4.29 (m, 1H), 4.20 (m, 1H), 4.07 (dd, 1H, J = 10.0 Hz, 10.0 Hz), 3.87 (m, 1H), 3.81 (s, 3H), 3.81 (s, 3H), 3.47 (dd, 1H, J = 10.5 Hz, 1.5 Hz), 2.83 (dd, 1H, J = 10.5 Hz, 2.5 Hz), 2.10 (ddd, 1H, J = 13.0 Hz, 4.5 Hz, 4.5 Hz), 2.02−1.94 (m, 7H), 1.92 (s, 3H), 1.71 (s, 3H); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 170.3, 170.2, 169.4, 168.7, 158.7, 158.7, 144.9, 136.1, 135.6, 130.1, 130.0, 128.1, 127.9, 126.9, 113.1, 113.0, 96.1, 85.6, 75.1, 74.6, 72.9, 70.9, 69.4, 67.4, 60.2, 55.0, 52.0, 48.6, 48.1, 31.1, 20.0, 19.8, 19.8, 19.7 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{47}H_{48}F_9N_3NaO_{16}$ requires 1104.2783, found 1104.2695.

5,6,3′,4′-Tetra-*O*-acetyl-1,3,2′-tri-*N*-trifluoroacetylparomamine (20). A solution of 3% dichloroacetic acid in DCM (30 mL) was added to compound **19** (1.90 g, 1.8 mmol) and MeOH was added. The reaction was stirred at room temperature for 4 h and evaporated to dryness. The residue was dissolved in ethyl acetate and extracted with saturated aq $NaHCO_3$. The organic fraction was dried with Na_2SO_4, evaporated, and purified by silica gel chromatography (70% ethyl acetate in petroleum ether). The product (**20**, 1.27 g) was isolated in 92% yield. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.84 (d, 1H, J = 9.0 Hz), 7.58 (d, 1H, J = 8.5 Hz), 7.30 (d, 1H, J = 9.0 Hz), 5.31 (dd, 1H, J = 9.5 Hz, 9.5 Hz), 5.27 (d, 1H, J = 4.0 Hz), 5.14 (dd, 1H, J = 10.5 Hz, 9.5 Hz), 5.07 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 5.03 (dd, 1H, J = 10.5 Hz, 10.5 Hz), 4.38−4.17 (m, 3H), 4.09 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 3.81 (ddd, 1H, J = 10.0 Hz, 4.0 Hz, 2.0 Hz), 3.66 (ddd, 1H, J = 12.5 Hz, 6.5 Hz, 2.0 Hz), 3.53 (ddd, 1H, J = 12.5 Hz, 6.0 Hz, 4.0 Hz), 2.96 (t, 1H, J = 6.3 Hz), 2.13 (ddd, 1H, J = 13.5 Hz, 4.5 Hz, 4.5 Hz), 2.04−1.96 (m, 4H), 1.96 (s, 3H), 1.95 (s, 6H); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 170.5, 170.2, 169.8, 169.4, 96.1, 75.5, 74.5, 72.9, 70.5, 70.3, 67.6, 59.7, 52.1, 48.7, 48.0, 31.2, 19.9, 19.8, 19.8, 19.7 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{26}H_{30}F_9N_3NaO_{14}$ requires 802.1476, found 802.1474.

6′-Azido-6′-deoxy-5,6,3′,4′-tetra-*O*-acetyl-1,3,2′-tri-*N*-trifluoroacetylparomamine (21). Compound **20** (0.73 g, 0.9 mmol) was dried over P_2O_5 in a vacuum and dissolved in dry DCM (6 mL). 10% DBU (1,8-diazabicyclo[5.4.0]undec-7-ene, 1.4 mL, 0.9 mmol) solution in MeCN and trifluoromethanesulfonyl anhydride (0.19 mL, 1.1 mmol) were added on an ice bath. After 30 min, the ice bath was removed, and the reaction was stirred at room temperature for 1.5 h. The reaction mixture was partitioned between ethyl acetate and water. The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (50% ethyl acetate in hexane) yielding triflate product (0.46 g, 53%), which was directly subjected to azidation step. To a solution of triflate product (0.45 g, 0.5 mmol) in dry DMF (3 mL), sodium azide (0.16 g, 2.5 mmol) was added and the mixture was stirred overnight at room temperature. The reaction mixture was partitioned between diethyl ether and water. The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (50% ethyl acetate in petroleum ether) yielding product **21** (0.39 g, 98%). ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.83 (d, 1H. J = 9.0 Hz), 7.58 (d, 1H, J = 8.0 Hz), 7.31 (d, 1H, J = 8.5

Hz), 5.32 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 5.28 (d, 1H, J = 4.0 Hz), 5.15−5.07 (m, 2H), 5.04 (dd, 1H, J = 10.5 Hz, 10.5 Hz), 4.40−4.27 (m, 2H), 4.22 (m, 1H), 4.06 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 3.92 (m, 1H), 3.56 (dd, 1H, J = 13.5 Hz, 2.5 Hz), 3.36 (dd, 1H, J = 13.5 Hz, 4.3 Hz), 2.13 (ddd, 1H, J = 13.0 Hz, 4.8 Hz, 4.8 Hz), 2.04 (ddd, 1H, J = 13.0 Hz each), 1.99 (s, 3H), 1.96 (s, 3H), 1.95 (s, 3H), 1.94 (s, 3H); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 170.4, 170.2, 169.4, 96.0, 75.8, 74.5, 72.9, 70.1, 69.3, 68.1, 52.0, 50.1, 48.7, 48.0, 31.1, 19.9, 19.8, 19.7, 19.7 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{26}H_{29}F_9N_6NaO_{13}$ requires 827.1541, found 827.1496.

6′-Azido-6′-deoxy-1,3,2′-tri-*N*-trifluoroacetylparomamine (5). To a solution of compound **21** (0.40 g, 0.5 mmol) in dry MeOH (12 mL), sodium methoxide (160 μL of 0.6 mol L^{-1} solution in MeOH) was added. After 1 h, the mixture was neutralized with a strong cation-exchange resin (Dowex 50WX8−200, H^+-form) and filtered. The solution was evaporated, yielding pure product **5** (0.28 g, 88%) as a solid powder. ^{1}H NMR (500 MHz, CD_3CN + drop of CD_3OD) δ_{ppm} 8.54 (d, 1H. J = 9.0 Hz), 8.15 (d, 1H, J = 9.0 Hz), 8.01 (d, 1H, J = 8.0 Hz), 5.21 (d, 1H, J = 3.5 Hz), 4.02 (m, 1H), 3.95 (m, 1H), 3.84 (m, 1H), 3.69 (ddd, 1H, J = 10.0 Hz, 3.0 Hz, 3.0 Hz), 3.63−3.56 (m, 2H), 3.54 (dd, 1H, J = 13.5 Hz, 2.5 Hz), 3.50 (dd, 1H, J = 9.5 Hz, 9.0 Hz), 3.47−3.41 (m, 2H), 3.34 (dd, 1H, J = 10.0 Hz, 9.5 Hz), 2.00 (ddd, 1H, J = 13.0 Hz, 4.3 Hz, 4.3 Hz), 1.68 (ddd, 1H, J = 13.0 Hz each); ^{13}C NMR (125 MHz, CD_3CN + drop of CD_3OD) δ_{ppm} 98.6, 81.2, 76.2, 73.7, 72.0, 71.0, 70.3, 54.7, 50.5, 50.1, 49.5, 31.6 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{18}H_{21}F_9N_6NaO_9$ requires 659.1119, found 659.1122.



5″-*O*-(4,4′-Dimethoxytrityl)-1,3,2′,6′,2‴,6‴-hexa-*N*-trifluoroacetylneomycin (23). Triethylamine (3.6 mL, 26 mmol) and methyl trifluoroacetate (2.6 mL, 26 mmol) were added to a mixture of neomycin trisulfate (**22**, 2.0 g, 2.2 mmol) and MeOH (10 mL). The mixture was stirred overnight at room temperature and evaporated to dryness. Saturated $NaHCO_3$ was added, and the crude product was extracted with ethyl acetate. The organic layers were combined, dried over Na_2SO_4, filtered, and evaporated to dryness. The residue was further dried by coevaporation with dry pyridine and dissolved in dry pyridine, and then 4,4′-dimetoxytrityl chloride (0.80 g, 2.4 mmol) was added to the mixture. After overnight reaction, saturated $NaHCO_3$ was added to the mixture and the product was extracted with ethyl acetate. The organic layers were combined, dried over anhydrous Na_2SO_4, filtered, and evaporated to dryness. The residue was purified by silica gel chromatography (10% MeOH, 1% triethylamine in DCM) to yield 2.35 g (73%) of the product (**23**) as white foam.^{1}H NMR (500 MHz, CD_3OD) δ_{ppm} 7.46 (m, 2H), 7.36−7.30 (m, 6H), 7.21 (m, 1H), 6.90 (m, 4H), 5.78 (d, 1H, J = 3.3 Hz), 5.16 (d, 1H, J = 4.6 Hz), 5.09 (d, 1H, J = 1.5 Hz), 4.29 (dd, 1H, J = 4.8 Hz, both), 4.21−4.20 (m, 2H), 4.14 (m, 1H), 4.11 (dd, 1H, J = 6.7 Hz, both), 4.01 (m, 1H), 3.97 (m, 1H), 3.92 (m, 1H), 3.87 (dd, 1H, J = 9.9 and 8.8 Hz), 3.80 (s, 6H), 3.75−3.63 (m, 5H), 3.60 (dd, 1H, J = 13.5 and 7.4 Hz), 3.56−3.51 (m, 2H), 3.35−3.31 (m, 3H), 3.19 (dd, 1H, J = 10.5 and 3.1 Hz), 2.00 (ddd, 1H, J = 12.9 Hz, 4.2 and 4.2 Hz), 1.77 (ddd, 1H, J = 12.7 Hz, each); ^{13}C NMR (125 MHz, CD_3OD) δ_{ppm} 157.93, 157.85, 145.0, 136.0, 135.6, 130.2, 129.9, 128.0, 127.4, 126.3, 112.7, 109.0, 97.6, 96.3, 87.4, 86.3, 81.9, 76.9, 75.6, 74.8, 73.0, 72.1, 71.5, 70.3, 69.8, 69.2, 67.1, 62.5, 54.3, 53.5, 51.3, 49.6, 49.1, 40.4, 39.6, 31.5 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{56}H_{58}F_{18}N_6NaO_{21}$ requires 1515.3260, found 1515.3239.

5″-Azido-5″-deoxy-6,3′,4′,2″,3‴,4‴-hexa-*O*-acetyl-1,3,2′,6′,2‴,6‴-hexa-*N*-trifluoroacetylneomycin (25). Compound **23** (4.60 g, 3.1 mmol) was dried over P_2O_5 in vacuum and dissolved in dry pyridine (10 mL). Acetic anhydride (3.5 mL, 37.0 mmol) and a catalytic amount of 4-dimethylaminopyridine were added, and the reaction was stirred overnight at room temperature. After evaporation, the residue was partitioned between ethyl acetate and saturated aq $NaHCO_3$. The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was dissolved in 3% dichloroacetic acid in DCM (40 mL) and MeOH was added. After stirring the reaction 3 h at room temperature, the mixture was evaporated and extracted with ethyl acetate and saturated aq $NaHCO_3$. The organic phase was dried with Na_2SO_4, evaporated to dryness, and purified by silica gel chromatography (5−10% MeOH in DCM) to yield 3.90 g (87%) of the product **24** as a white foam. ^{1}H NMR (500 MHz, $CDCl_3$ + drop of CD_3OD) δ_{ppm} 5.84 (d, 1H, J = 2.0 Hz), 5.17 (d, 1H, J = 2.5 Hz), 5.14 (dd, 1H, J = 9.5 Hz, 9.5 Hz), 4.97 (dd, 1H, J = 3.0 Hz, 3.0 Hz), 4.91 (m, 1H), 4.89−4.81 (m, 2H), 4.80 (d, 1H, J = 1.5 Hz), 4.76 (dd, 1H, J = 5.8 Hz, 2.3 Hz), 4.37−4.24 (m, 2H), 4.17−4.05 (m, 4H), 3.99 (m, 1H), 3.95 (dd, 1H, J = 9.5 Hz, 8.5 Hz), 3.78 (dd, 1H, J = 13.0 Hz, 2.5 Hz), 3.74−3.64 (m, 3H), 3.63−3.53 (m, 2H), 3.32 (dd, 1H, J = 14.3 Hz, 5.8 Hz), 3.23 (dd, 1H, J = 14.0 Hz, 9.5 Hz), 2.18 (s, 3H), 2.15 (s, 3H), 2.10 (s, 3H), 2.08−2.02 (m, 7H), 1.99 (s, 3H), 1.81 (ddd, 1H, J = 13.0 Hz each); ^{13}C NMR (125 MHz, $CDCl_3$ + drop of CD_3OD) δ_{ppm} 171.0, 170.8, 170.5, 170.3, 168.7, 168.5, 107.4, 97.4, 95.0, 82.8, 80.9, 75.1, 75.0, 74.9, 73.3, 72.3, 69.9, 69.5, 68.2, 66.8, 66.2, 59.0, 51.7, 48.6, 48.1, 47.4, 40.1, 39.9, 31.3, 20.5, 20.2, 20.2, 20.2 (peaks referring to Tfa are not listed).

Compound **24** (1.07 g, 0.7 mmol) was dried over P_2O_5 in vacuum and dissolved in dry DCM (5 mL). 10% DBU (1.1 mL, 0.7 mmol) in MeCN and trifluoromethanesulfonyl anhydride (0.15 mL, 0.9 mmol) were added on an ice bath. After 30 min, the ice bath was removed and the reaction was stirred at room temperature for 2 h. The reaction mixture was partitioned between ethyl acetate and water. The organic phase was separated, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (50−80% ethyl acetate in hexane) yielding the triflate product (0.59 g, 50%) as reddish foam. The crude product was subjected as such to azidation. Accordingly, to a solution of the triflate product (0.59 g, 0.4 mmol) in dry DMF (3.5 mL), sodium azide (0.13 g, 2.0 mmol) was added, and the mixture was stirred overnight at room temperature. The reaction mixture was partitioned between diethyl ether and water. The organic phase was collected, dried with Na_2SO_4, and evaporated to dryness. The residue was purified by silica gel chromatography (50−70% ethyl acetate in hexane) yielding **25** (0.38 g, 69%). ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 7.87 (d, 1H, J = 9.5 Hz), 7.59 (br t, 1H), 7.54 (d, 1H, J = 8.5 Hz), 7.50−7.42 (m, 2H), 7.23 (d, 1H, J = 9.5 Hz), 5.86 (d, 1H, J = 3.5 Hz), 5.24−5.17 (m, 2H), 4.99 (d, 1H, J = 3.0 Hz), 4.98−4.84 (m, 5H), 4.44−4.34 (m, 2H), 4.28 (m, 1H), 4.22 (m, 1H), 4.13−4.04 (m, 3H), 4.01 (ddd, 1H, J = 10.5 Hz, 3.5 Hz, 3.5 Hz), 3.89−3.81 (m, 2H), 3.69 (dd, 1H, J = 13.5 Hz, 3.0 Hz), 3.62 (ddd, 1H, J = 14.5 Hz, 5.0 Hz, 3.0 Hz), 3.56−3.41 (m, 4H), 2.12 (s, 3H), 2.10 (s, 3H), 2.08−2.04 (m, 4H), 2.03 (s, 3H), 2.02 (s, 3H), 2.00 (s, 3H), 1.96 (m, 1H); ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 170.4, 170.3, 170.2, 170.0, 169.2, 168.7, 107.8, 96.9, 95.5, 82.7, 79.5, 76.5, 74.8, 74.7, 74.6, 71.3, 69.9, 68.4, 68.1, 67.6, 65.5, 51.7, 50.5, 48.8, 48.5, 47.6, 39.5, 38.9, 30.8, 20.1, 20.1, 19.9, 19.8, 19.8, 19.7 (peaks referring to Tfa are not listed). ESI-MS: $[M+Na]^+$ $C_{35}H_{39}F_{18}N_9NaO_{18}$ requires 1238.2018, found 1238.2027.

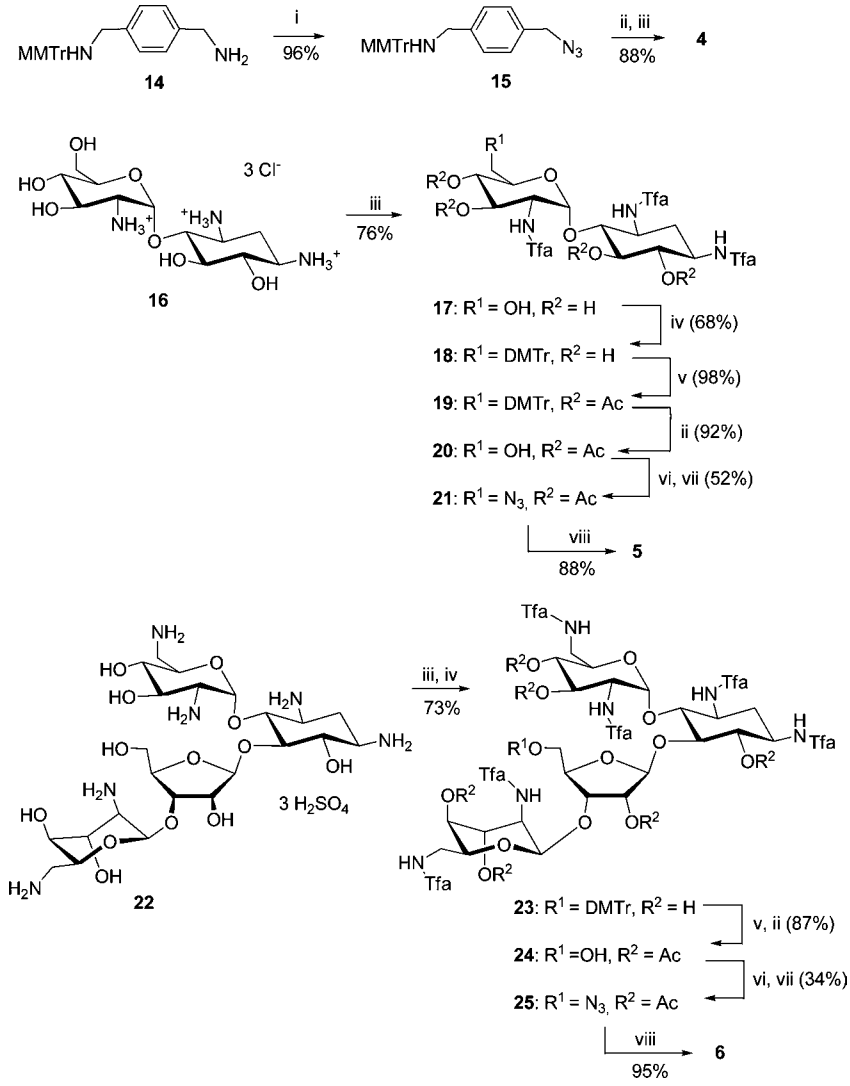
Synthesis of Oligodeoxyribonucleotides. The modified oligodeoxyribonucleotides were synthesized on an Applied Biosystems 392 DNA synthesizer in a 1.0 μmol scale using commercial 500 Å CPG-Q-adenosine support (Q = hydroquinone-*O*,*O*′-diacetate). For phosphoramidites **1** and **2** (0.13 mol L^{-1} solution in dry MeCN), a prolonged coupling time of 10 min was used. Otherwise, standard DNA protocol was applied. The oligonucleotides were released from the support with concentrated ammonia (33% aqueous NH_3) at 55 °C overnight. For the click reactions, the support-bound material **26**−**29** were treated for 5−8 min with 10% DBU in MeCN (1 mL, dried over molecular sieves), after which the support was sequentially washed with MeCN, DMF, MeOH, water, and MeOH.



Click Conjugation. Azide-functionalized ligands, **3**−**6**, were conjugated to the alkynyl groups of oligonucleotides **26**−**29**. The solutions of ligands (50 mmol L^{-1}) in MeOH were added onto the support-bound oligonucleotides as follows: 15 equiv for **27**, 30 equiv for **26** and **29**, and 40 equiv for **28**. After that, $CuSO_4$ and tris[(1-benzyl-1,2,3-triazol-4-yl)methyl]amine (TBTA-ligand) were added as a 25 mmol L^{-1} solution in a 12:3:1 mixture of water, DMSO, and 2-butanol. The amounts added were as follows: 7.5 equiv for **27**, 15 equiv for **26** and **29**, and 20 equiv for **28**. Finally, sodium ascorbate (15, 30, and 40 equiv for **27**, **26**, **29**, and **28**, respectively) as 0.1 mol L^{-1} aqueous solution was added. The mixture was shaken at room temperature for 5 h. The support was collected by filtration and washed first with water, DMF, and MeOH. To remove the copper salt and TBTA ligand as quantitatively as possible, the support was then treated for 10 min with aq EDTA solution (0.1 mol L^{-1}), washed with water, and then for another 10 min with aqueous solution of neomycin trisulfate (0.1 mol L^{-1}). Finally, the support was washed with water, DMF, DCM, MeOH, and MeCN and subjected to standard ammonolytic release. After evaporation, the oligonucleotide conjugate was purified by RP HPLC.

Melting Temperature Studies. The melting curves (absorbance versus temperature) were measured at 260 nm on a Perkin-Elmer Lambda 35 UV−vis spectrometer equipped with a multiple cell holder and a Peltier temperature-controller. The temperature was changed at a rate of 0.5 °C/min (from 20 to 90 °C). The measurements were performed in 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 mol L^{-1} or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their cDNA or 2′-*O*-methyl RNA targets were used at a concentration of 2 μmol L^{-1}. T_m values were determined as the maximum of the first derivate of the melting curve.

RESULTS AND DISCUSSION

Synthesis of 4′-*C*-[*N*,*N*-di(4-pentyn-1-yl)aminomethyl]thymidine and 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine 3′-(2-Cyanoethyl-*N*,*N*-diisopropylphosphoramidites (1, 2). 4′-*C*-Azidomethyl-3′-*O*-(4,4′-dimethoxytrityl)-thymidine (**7**) was synthesized in good yield (75%) from 4′-*C*-hydroxymethylthymidine as described previously (*47*). Because the azido group can be easily converted to amino group by Staudinger reaction, it allows further functionalization. Accordingly, 4′-*C*-aminomethyl-3′-*O*-(4,4′-dimethoxytrityl)thymidine (**8**) was obtained by the reaction of compound **7** with triphenylphosphine and water (Scheme 1). Compound **8** was then subjected to reductive alkylation in the presence of $NaBH_3CN$ under acidic conditions. On using 2 equiv of 4-pentynal (*52*), 4′-*C*-[*N*,*N*-di(4-pentyn-1-yl)aminomethyl]thymidine (**9**) was ob-

Scheme 2[a]

[a] Reagents: (i) TfN_3, K_2CO_3, $CuSO_4$, H_2O, MeOH, DCM; (ii) DCA, DCM, MeOH; (iii) TfaOMe, Et_3N, MeOH; (iv) DMTrCl, pyridine; (v) Ac_2O, DMAP, pyridine; (vi) Tf_2O, 10% DBU in MeCN, DCM; (vii) NaN_3, DMF; (viii) NaOMe, MeOH.

tained. 4′-*C*-[*N*-Methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine (**11**) was, in turn, prepared by two consecutive alkylation steps. Reaction with 4-pentynal gave 4′-*C*-[*N*-(4-pentyn-1-yl)aminomethyl]thymidine (**10**), which was then *N*-methylated with paraformaldehyde. After the reductive alkylations, the 3′-*O*-4,4′-dimethoxytrityl group was removed with 80% acetic acid. Compounds **9** and **11** were then converted to 5′-*O*-(4,4′-dimethoxytrityl) ethers (**12**, **13**) and phosphitylated to phosphoramidites **1** and **2**.

Synthesis of Ligands 3−6. The azido-functionalized ligands (**4**−**6**) used in the click conjugation were synthesized as outlined in Scheme 2. The azidation of previously synthesized (*47*) *N*-(4-methoxytrityl)-1,4-phenylenedimethanamine (**14**) was carried out by the Cu^{2+}-catalyzed diazo transfer described in the literature (*50*). The acid-labile trityl protection of the product (**15**) was changed to a base-labile trifluoroacetyl protection, removable by the conventional ammonolysis used for the release and deprotection of support-bound oligonucleotides.

Paromamine trihydrochloride (**16**) was obtained by acidic hydrolysis of commercially available paromomycin sulfate (*51*). After trifluoroacetylation of the amino groups, the primary 6′-hydroxyl group was protected as a 4,4′-dimethoxytrityl ether (**18**) and the remaining hydroxyl functions were acetylated. The 6′-position was then detritylated, sulfonated, and subjected to azidation. Since the azidation gave poor yields using mesyl esters as a starting material, conversion of the 6′-hydroxyl group to a triflate was attempted. The conventional treatment with triflic anhydride in the presence of pyridine, however, yielded a 6′-pyridinium salt instead of the desired product. Replacement of pyridine by less nucleophilic DBU then provided the desired triflate, which may be azidated to product **21** in 52% overall yield. This was finally deacetylated by methoxide ion-catalyzed transesterification in methanol to obtain product **5**, applicable to postsynthetic conjugation of the alkynylated oligonucleotides. 5″-Azido-1,3,2′,6′,2‴,6‴-hexa-*N*-trifluoroacetylneomycin (**6**) was synthesized starting from neomycin trisulfate (**22**) according to the same protocol as described for the paromamine derivative **5** above. The mannose-derived ligand, methyl 2,3,4-tri-*O*-acetyl-6-azido-6-deoxy-α-D-mannopyranoside (**3**), was prepared as previously reported (*53*).

Oligonucleotide Synthesis and Click Conjugation. 4′-*C*-[*N*,*N*-Di(4-pentyn-1-yl)aminomethyl]thymidine and 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine monomers **1** and **2** were incorporated into 15-mer oligodeoxyribonucleotides **26**−**29** using standard phosphoramidite coupling chemistry except for a prolonged 10 min coupling time. The coupling yields were 97%. Interestingly, we noticed that these modified oligonucleotides did not withstand solid-supported click con-

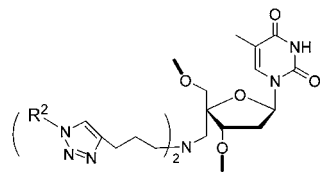
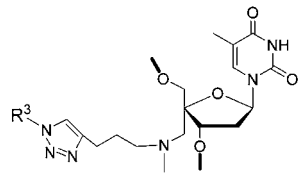
[a] In 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 mol L^{-1} or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their cDNA or 2′-*O*-methyl RNA targets were used a concentration of 2 μmol L^{-1}.

jugation as long as their phosphate groups were 2-cyanoethyl protected, but a chain cleavage took place leaving the modified monomer attached to the 5′-terminus of the support-bound oligonucleotide. By contrast, the 4-pentyn-1-yl functionalized oligonucleotides that had not been subjected to the conditions of click reaction could be isolated in intact form by conventional ammonolysis. To carry out the click reaction on a solid support, the 2-cyanoethyl groups had to be removed prior to the click reaction, which was achieved by treatment with 10% DBU in MeCN (5−8 min). Since the



succinyl linker is not fully compatible with the DBU treatment, but undergoes a premature cleavage via succinimide formation (*54*), all the conjugate syntheses were carried out on a Q-linker loaded CPG support (*55*). After exposure of the internucleosidic linkages as phosphodiesters, the azido-functionalized ligands **3**−**6** were attached by the click reaction ($CuSO_4$/TBTA/sodium ascorbate, 5 h, r.t) and the conjugates obtained were released from the support and deprotected by ammonolysis (Scheme 3). The crude products (**30**−**39**; see Table 1) were purified by RP-HPLC, and their identity was verified by ESI-MS. Figure 2 shows representative examples of the HPLC traces of the crude oligonucleotides **35**, **36**, and **39** and the homogeneous products after purification. In each case, the desired conjugate was clearly a main product.

In our previous study on oligonucleotides containing the 4′-*C*-azidomethylthymidine monomer, we were not able to achieve homogeneous products by the solid-supported click conjugation in case the ligand contained amino groups in their structure, but capillary electrophoresis revealed the presence of two peaks with the same molecular mass. When the reactions were performed in solution, this problem was not encountered. With 4′-*C*-[*N*,*N*-di(4-pentyn-1-yl)aminomethyl]thymidine and 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine monomers (**1**, **2**) used in the present study, capillary electrophoretic, HPLC, and ESI-MS data all indicated the presence of only one pure conjugate for each oligonucleotide. Accordingly, all conjugations could now be conveniently made on a solid support without complications.



Melting Temperature Studies. Melting temperatures (T_m) for the duplexes of oligonucleotides **26**−**29** and their conjugates **30**−**39** with the cDNA and 2′-*O*-methyl RNA sequences were measured at pH 7 at the ionic strength of 0.1 and 1.0 mol L^{-1} (Table 1).

B: R^1 = 4-pentyn-1-yl
D: R^1 = Me

E: R^2 = mannose (deprotected **3**)
H: R^2 = *p*-aminomethylbenzene (deprotected **4**)
J: R^2 = paromamine (deprotected **5**)

F: R^3 = mannose (deprotected **3**)
I: R^3 = *p*-aminomethylbenzene (deprotected **4**)
K: R^3 = paromamine (deprotected **5**)
L: R^3 = neomycin (deprotected **6**)

When one 4′-*C*-modified monomer, **B** (**26**) or **D** (**27**), was incorporated into the DNA strand, the stability of the duplex increased with both DNA and 2′-*O*-Me RNA. When two such monomers were incorporated in the sequence (**28**, **29**), a slight destabilization took place.

With mannose-conjugated oligonucleotides containing a single modified monomer, either **E** (**30**) or **F** (**31**), the T_m of the DNA-hybrid was again increased, but the presence of two modified units (**36**) is destabilizing. By contrast, on using a 2′-*O*-methyl RNA target, the conjugate containing two **E** monomers and, hence, four mannose residues hybridized almost as well as the corresponding unmodified 15-mer oligodeoxyribonucleotide. At high salt concentration, the hybridization was even slightly more efficient compared to the unmodified DNA sequence.

All conjugates bearing amino groups (**32**−**35**, **37**−**39**) markedly stabilized the duplex with DNA target. With the *p*-aminomethylbenzene conjugates, the DNA-hybrids incorporating one or two **H** (**32**, **37**) or **I** (**38**) monomers were stabilized by 4−5 °C/modification. Toward 2′-*O*-methyl RNA, the stabilization was less prominent. The stabilization was more marked at low ionic strength, but it still existed at high ionic strength. Undoubtedly, the major part of the stabilization results from reduced electrostatic repulsion between negatively charged sugar−phosphate backbones and positively charged amino groups present at neutral pH. This influence plays a more important role at low ionic strength.

When one paromamine derived monomer, **J** (**33**) or **K** (**34**) was incorporated into the strand, the DNA-hybrid was stabilized by 5 °C, but the second monomer (**39**) did not result in any extra stabilization. With 2′-*O*-Me RNA target, two monomers **K** were needed to achieve even a modest increase in T_m (ΔT_m = +1.0 °C). Compared to the paromamine monomers, the neomycin group (monomer **L** in **35**) was less stabilizing than the paromamine group (monomer **K** in **34**) toward DNA, and toward 2′-*O*-Me-RNA, the effect is even destabilizing. Similarly to the *p*-aminomethylphenyl ligands, the duplex stabilizing effect of the aminoglycosides ligands is more marked at low ionic strength.

The hybridization properties of the 4′-modified oligonucleotides are encouraging. Evidently the 4′-position, facing the minor groove upon hybridization, can accommodate even rather large molecule clusters without appreciable destabilization of the duplex. The 4′-*C*-[*N*,*N*-di(4-pentyn-1-yl)aminomethyl]thymidine monomer (**1**) allows attachment of two ligands per residue, which may well be useful when applying the glycotargeting concept. A short segment of the duplex may be decorated with several sugar units. The results received with the mannose conjugated oligonucleotide, **36**, lend some support to the feasibility of sugar-coated oligonucleotides as carriers of RNA-type oligonucleotides. On the other hand, 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine monomer (**2**) can be preferable for attachment of bulky ligands such as neomycin derivatives to oligonucleotides. Among the amino group-bearing ligands, the most remarkable hybridization enhancement was obtained with *p*-aminomethylphenyl conjugates (**32**, **37**, **38**). Sterically more demanding aminoglycoside ligands (**33**−**35**, **39**) stabilized the DNA·DNA duplex less, but still notably. All amino group-bearing conjugates preferred DNA over 2′-OMe RNA. Compared to the results of the present paper, the previously observed duplex stabilizations achieved with some conjugates of the 4′-*C*-azidomethylthymidine incorporating oligonucleotides are modest (*47*). This implies that the alkyl chain of the 4′-*C*-(4-pentyn-1-ylaminomethyl)thymidine monomers (**1**, **2**) allows a more flexible alignment of the triazole ring and conjugate groups upon hybridization. The tertiary amino group, which probably is protonated under physiological conditions, further stabilizes the duplex formation by diminishing the electrostatic repulsion between the complementary chains, as evidenced by the fact that the melting temperatures observed for the oligonucleotides containing 4′-*C*-(alkynylaminomethyl)thymidine units (**26**−**29**) are higher than those observed for their 4′-*C*-azidomethylthymidine counterparts.

CONCLUSION

4′-*C*-[*N*,*N*-Di(4-pentyn-1-yl)aminomethyl]thymidine and 4′-*C*-[*N*-methyl-*N*-(4-pentyn-1-yl)aminomethyl]thymidine 3′-phos-

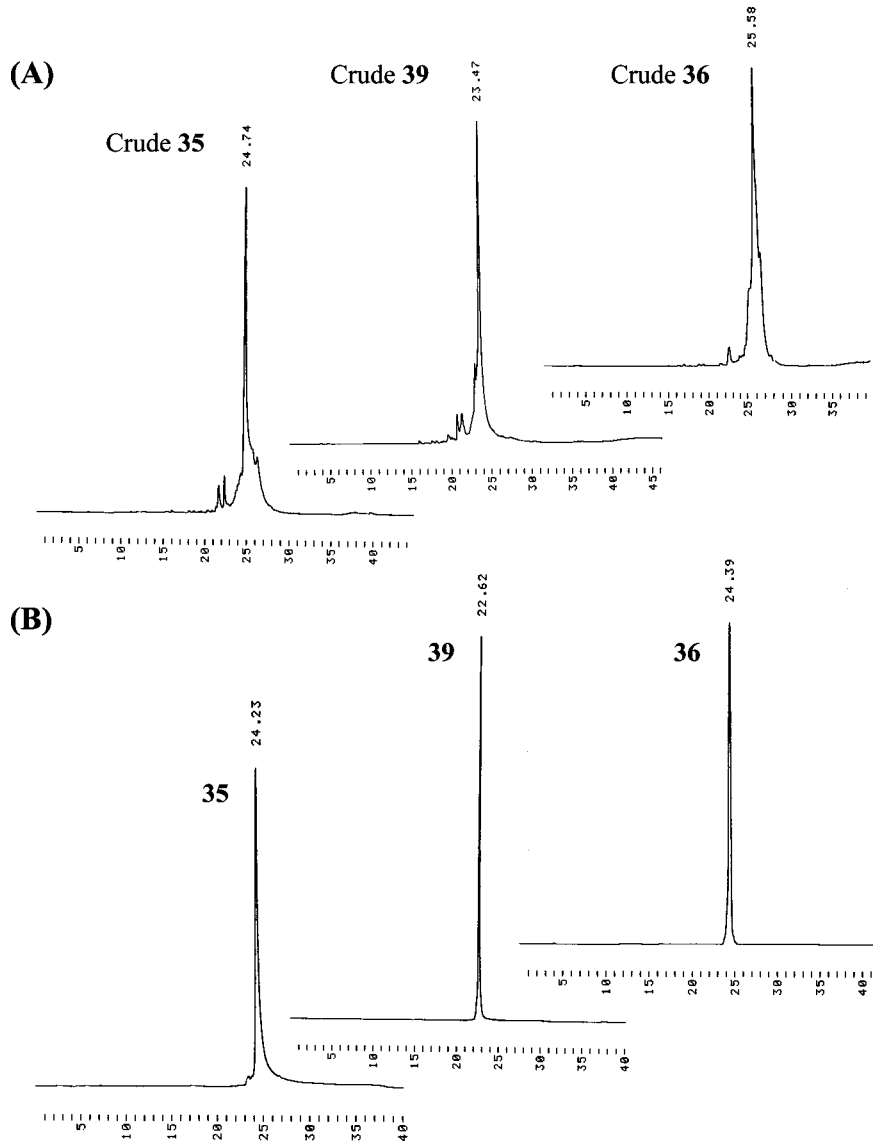


Figure 2. RP HPLC traces of the crude (A) and purified (B) oligonucleotide conjugates **35**, **36**, and **39**.

phoramidites (**1**, **2**) have been synthesized as a continuation of the previously reported preparation of 4′-*C*-azidomethylthymidine 3′-hydrogenphosphonate. Together, these building blocks enable the exploitation of the click conjugation on both ways, i.e., to have azido function present on either the oligonucleotide or ligand side. Nucleoside **1** bearing two 4-pentyn-1-yl groups is designed for high-density functionalization of modified oligonucleotides, whereas nucleoside **2** allows one-armed conjugations. Azido-derivatized ligands may be efficiently conjugated to the alkynyl groups of these monomers by the click chemistry on a solid support. However, the 2-cyanoethyl protections must be removed from the phosphates prior to the click conjugation, since the 4′-modifications used here under the click reaction conditions cause cleavage of the 5′-linked phosphate triester bond. Melting temperature studies reveal that oligonucleotides containing one to four mannose ligands in the central part of the chain (i.e., one or two modified nucleoside residue) form equally stable duplexes with complementary 2′-OMe RNA as the corresponding unmodified DNA sequence. At high salt content, the mannose conjugation is even stabilizing. The results with the space-demanding aminoglycoside ligands further demonstrate the utility of 4′-modified nucleosides **1** and **2** in glycoconjugations. All amino group-bearing conjugates stabilized the DNA·DNA duplex significantly and the DNA·2′-*O*-methyl RNA duplex notably.

ACKNOWLEDGMENT

Financial support from the Academy of Finland is gratefully acknowledged.

Supporting Information Available: NMR spectral data for **1**, **2**, **4**−**6**, **12**, and **13**. ESI-MS and RP HPLC data for oligonucleotides **26**−**39**. In addition, examples of melting temperature curves for **26**−**39** are presented. This material is available free of charge via the Internet at http://pubs.acs.org.

General procedures

The NMR spectra of **1**, **2, 4-6, 12** and **13** were recorded at 500 MHz. The mass spectra of the oligonucleotides **26-39** were recorded by ESI ionization method. RP HPLC chromatographs of pure **26-39** were performed using Thermo ODS Hypersil C18 (250 × 4.6 mm, 5 μm) analytical column, a gradient elution from 0% to 50% MeCN in 0.1 mol L^{-1} TEAA (aq) buffer over 60 min, flow rate 1 mL min^{-1} and detection at 260 nm. The melting curves (absorbance versus temperature) were measured at 260 nm on a Perkin-Elmer Lambda 35 UV-vis spectrometer equipped with a multiple cell holder and a Peltier temperature-controller. The temperature was changed at a rate of 0.5 ºC / min (from 20 to 90 ºC). The measurements were performed in 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 mol L^{-1} or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their complementary DNA or 2´-*O*-methyl RNA targets were used at a concentration of 2 μmol L^{-1}.

Synthesis and Splice-Redirecting Activity of Branched, Arginine-Rich Peptide Dendrimer Conjugates of Peptide Nucleic Acid Oligonucleotides

Amer F. Saleh,[†] Andrey Arzumanov,[†] Rachida Abes,[§] David Owen,[†] Bernard Lebleu,[§] and Michael J. Gait*[,†]

Medical Research Council, Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 0QH, United Kingdom, and UMR 5235 CNRS, Université Montpellier 2, Place Eugene Bataillon, 34095 Montpellier cedex 5, France. Received June 17, 2010; Revised Manuscript Received September 7, 2010

Arginine-rich cell-penetrating peptides have found excellent utility in cell and in vivo models for enhancement of delivery of attached charge-neutral PNA or PMO oligonucleotides. We report the synthesis of dendrimeric peptides containing 2- or 4-branched arms each having one or more R-Ahx-R motifs and their disulfide conjugation to a PNA705 splice-redirecting oligonucleotide. Conjugates were assayed in a HeLa pLuc705 cell assay for luciferase up-regulation and splicing redirection. Whereas 8-Arg branched peptide−PNA conjugates showed poor activity compared to a linear $(R\text{-Ahx-R})_4$−PNA conjugate, 2-branched and some 4-branched 12 and 16 Arg peptide−PNA conjugates showed activity similar to that of the corresponding linear peptide−PNA conjugates. Many of the 12- and 16-Arg conjugates retained significant activity in the presence of serum. Evidence showed that biological activity in HeLa pLuc705 cells of the PNA conjugates of branched and linear (R-Ahx-R) peptides is associated with an energy-dependent uptake pathway, predominantly clathrin-dependent, but also with some caveolae dependence.

INTRODUCTION

Cell-penetrating peptides (CPPs) have proven extremely valuable for enhancing the cell delivery of a range of biomolecules either as covalent conjugates or as noncovalent complexing agents (*1*). Among the biocargoes that are well-suited for CPP conjugation are antisense oligonucleotide (ON) analogues that are used to target RNAs inside cells (*2, 3*). Particularly good results have been obtained in cell delivery when CPPs are conjugated to charge-neutral peptide nucleic acid (PNA) and phosphorodiamidate morpholino oligonucleotides (PMO) that are used for non-RNase-H steric block antisense applications (*4, 5*). Such ON analogues are metabolically stable inside cells and in tissues, and retain very good sequence specificity in binding to RNA targets. Peptide conjugates of PNA and PMO are now being investigated in therapeutic applications, for example, for redirecting RNA splicing in diseases such as Duchenne muscular dystrophy (DMD) (*6, 7*).

A wide range of CPPs has been proposed for PNA and PMO conjugation, some of which are derived from small transduction domains of proteins (Tat (48−60), Penetratin), and many others are composite or synthetically designed (*2, 3*). Most CPPs are cationic, and often, they also contain regions of hydrophobic amino acids. Cationic charge helps the binding of the CPP to the cell surface glycosaminoglycans. However, the mechanisms of cell uptake following cell surface binding are diverse and in some cases have proven controversial. It is commonly recognized that in most cases at modest concentrations (1 μM or less) and, especially when conjugated to an ON cargo, endocytotic uptake mechanisms of CPPs predominate, rather than direct translocation (*2, 3*). Cationic and hydrophobic elements in the CPP are also thought to help to enhance their release from endosomes into the cytosol, but the exact spatial parameters for optimal release are not well understood.

It has become well accepted that when viewed by live-cell confocal microscopy fluorescently tagged cationic CPP-ON conjugates usually become sequestered within endosomal compartments (*8*). However, to interact with mRNA or pre-mRNA targets, ONs must reach the cytosol or nucleus, respectively. In order to better understand what parameters within an attached CPP are required to help endosomal release and thus allow the attached ON to reach its RNA target, it is necessary to utilize a biological assay that is characteristic of the cell compartment. Kole and colleagues developed such an assay for the nucleus, whereby HeLa cells contain an integrated pLuc705 plasmid coding for a firefly luciferase gene within which is embedded an aberrant β-globin intron. To produce firefly luciferase, it is necessary to deliver into the nucleus of the HeLa cells an 18-mer synthetic ON (which is targeted to the 705 site) to restore correct splicing of the pre-mRNA and hence a functional luciferase mRNA (*9*). This assay is straightforward and has a high dynamic range, which allows both high and low activity levels to be measured quantitatively as a positive luminescence readout. In addition, the EC_{50} of the splicing redirection can be assessed readily at the RNA level by an RT-PCR assay.

By use of the HeLa pLuc705 assay, we have reported that Arg-rich peptides are particularly valuable as delivery agents into cells when covalently conjugated to PNA or PMO ON cargoes in the absence of any transfection or other delivery agent. For example, we found that $(R\text{-Ahx-R})_4$-PNA705 and $(R\text{-Ahx-R})_4$-PMO705 conjugates (Ahx = aminohexanoic acid) were able to redirect splicing more efficiently than conjugates of Tat, Penetratin, or oligo-Arg classical CPPs (*10*−*12*). The interspersing of the non-natural Ahx amino acids is advantageous in providing an optimal spatial distribution of guanidinium side chains, in increasing metabolic stability, and in decreasing cytotoxicity (*13, 14*).

Further, the active fraction of such conjugates appears to enter HeLa pLuc705 cells predominantly by energy-dependent endocytosis (*10*), similarly to that found previously for PNA conjugates of Tat peptide (*15*). In addition, Arg-rich conjugates of

Published on Web 09/29/2010

PMO ONs have been shown to be highly effective in enhancing muscle cell delivery and exon skipping in a *mdx* mouse model of Duchenne muscular dystrophy (DMD), and such conjugates are in preclinical development (*6*). Other candidate Arg-rich peptides (such as Pip peptides and B-MSP) also utilize R-Ahx-R or R-β-R (β = beta-alanyl) motifs and have been used successfully to deliver PMO with even higher activity in *mdx* mice (*16, 17*).

We described recently a synthetic, Arg-rich tetramerizing peptide R10p53^{tet} where ten Arg residues were added to the *N*-terminus of the well-defined tetramerization domain of p53 protein (*18*). The peptide was conjugated close to its C-terminus to the PNA705 18-mer used in splice-redirecting studies. The splicing redirection efficiency of the PNA705 when added to HeLa pLuc705 cells was found to be much greater for the R10p53^{tet} conjugate than for R10p53^{mono}, a point mutant in the p53 domain that had been shown previously to be unable to tetramerize. The R10p53^{tet}-PNA705 conjugate was more active than any of the conjugates to CPPs previously tested by us in this assay, such as Tat (*12, 19*), Penetratin (*19*), R_6-Penetratin (*19*), and Pip2b (*16*). However, the R10p53^{tet} peptide was long (50 amino acids) and the synthetic yields were not high, and therefore, this paradigm does not seem likely to be readily adaptable for in vivo studies. Nevertheless, the principle of multivalency seemed to be highly beneficial as originally suggested (*20*).

Several years ago, Futaki and colleagues reported branched-chain arginine peptides where 4 or 8 short oligo-Arg chains were constructed based on chain branching through both the α and ε positions of Lys residues (*21*). The best translocation into HeLa cells was observed when the Arg residues were interspersed with three Gly residues (RG_3R) and placed on a four-armed structure, resulting in a branched 8-arginine configuration. This branched peptide was conjugated either directly to fluorescein or to the protein carbonic anhydrase labeled with fluorescein, and the translocation was visualized by confocal microscopy. Unfortunately, at that time confocal microscopy was carried out in the presence of a cell fixative (acetone/methanol), conditions now known to result in artifactual cell uptake and intracellular redistribution of cationic peptides (*8*). More recently, 4-branched RG_3R peptides with an Alexa fluorescent dye attached were shown to locate in endosomal compartments using live-cell imaging (*22*). However, no activity data for any attached cargo were reported.

Another recent development has been the use of a synthetic dendrimer where eight guanidine moieties were arranged to branch from a central triazine core by means of hexyl spacers (*23*). When attached to PMO oligonucleotides, the octa-guanidino dendrimer was able to enhance cell delivery of the PMO in cultured cells in the presence of serum and also enhance delivery in vivo in a wide range of tissues (*23, 24*). These conjugates are sold commercially as "Vivo-morpholinos". Thus, the concept of spacing arginine (or guanidine) moieties in a three-dimensional dendrimer configuration seemed worth exploring further.

We now describe straightforward solid-phase techniques for the chemical synthesis of 2- and 4-branched Arg-rich peptide dendrimers where such branches contain multiple (R-Ahx-R) motifs. Such branched peptides were conjugated to a charge-neutral PNA705 cargo and evaluated for their splice-redirecting activity in a HeLa pLuc705 system in comparison to equivalent linear peptides. Whereas 8-Arg branched peptide−PNA conjugates showed poor activity compared to linear peptide−PNA conjugate, 2-branched and some 4-branched 12 and 16 Arg peptide−PNA conjugates showed activities similar to those of the corresponding linear peptide−PNA conjugates. Many of the 12- and 16-Arg conjugates retained significant activity in the presence of serum. Evidence was shown that biological activity of the peptide−PNA in HeLa cells is associated primarily with an energy-dependent uptake pathway, predominantly clathrin-dependent, but that caveolae can also play a role.

EXPERIMENTAL PROCEDURES

Synthesis of Linear and Branched (R-Ahx-R)-Containing Peptides. Peptide syntheses were carried out using a CEM Liberty microwave peptide synthesizer by Fmoc chemistry. Linear peptides were synthesized starting with 100 μmol of functionalized Fmoc-PAL-PEG-PS solid support (Applied Biosystems), 2-branched peptides were synthesized starting with 50 μmol of support, and 4-branched peptides starting with 25 μmol of support. For all branched peptide syntheses, each Fmoc amino acid derivative was made up to the same concentration as if it was a standard 100 μmol-scale linear synthesis. Thus, for a 2-branched peptide, the excess activated Fmoc amino acid over growing chains in the coupling reactions after the chain branching step was 10-fold, and for a 4-branch peptide, the excess after two branching steps was 5-fold. Coupling reactions were carried out using Fmoc-amino acids in DMF activated with 0.99 equiv of PyBop in DMF and 1.98 equiv of diisopropylethylamine (DIPEA) in *N*-methylpyrrolidone (NMP). The branch point amino acid derivative was Fmoc-Lys(Fmoc)−OH (Novabiochem). Fmoc-Arg(Pbf)−OH (Novabiochem) was used for Arg couplings with the microwave double-coupling protocol previously reported (*25*). Fmoc-deprotection at each cycle was carried out using 20% piperidine in DMF containing 0.1 M hydroxybenzotriazole (HOBT). The final peptidyl resin was washed with DMF and then dichloromethane and dried in vacuo.

Cleavage and deprotection were carried out using TFA/water/ethanedithiol/triethylsilane (94:2.5:2.5:1, 20 mL) for 2 h, the resin removed by filtration and washed with TFA (ca. 5 mL) and the filtrate sparged with nitrogen to obtain a small volume. The peptide was precipitated by addition of cold diethyl ether, collected by centrifugation, and the pellet washed a further 5 times with cold ether (25 mL).

Preparative HPLC was carried out using a Phenomenex Jupiter 10 μ C18 column (250 × 10 mm): buffer A, 0.1% TFA in water; buffer B, acetonitrile containing 10% buffer A. Elution was with a linear gradient of 15−50% buffer B over 25 min. Detection was at 215/230 nm (diode array) with a flow rate of 3.5 mL min^{-1}. Analytical HPLC used the same column type (5 μ, 250 × 4.6 mm) and similar buffer and 10−40% B over 25 min gradient conditions (1.5 mL min^{-1}). Representative HPLC traces for branched peptides are shown in Supporting Information Figure 1. MALDI-TOF mass spectral analysis used a Voyager DE Pro BioSpectrometry workstation with a matrix of α-cyano-4-hydroxycinnamic acid, 10 mg mL^{-1} in acetonitrile−0.1% aqueous TFA (1:1 v/v). The accuracy of mass measurement is regarded as ±0.05%.

PNA Synthesis. NH_2-Cys(NPys)-Lys-CCTCTTACCTCAGTTACA-Lys-amide (PNA705) was synthesized by the Fmoc/Bhoc method using PNA monomers obtained from Link Technologies Ltd. (Lanarkshire, Scotland) on a Liberty microwave peptide synthesizer, purified by HPLC, and characterized by MALDI-TOF mass spectrometry as previously described (*16, 18, 26*).

Conjugation of Peptides to PNA705. Disulfide conjugation between the single Cys residue on the peptide component and the single NPys-Cys residue on the PNA705 was carried out essentially as described previously using a 2.5-fold excess of peptide over PNA705 (*16, 19, 27*). Purification of conjugates by reversed-phase HPLC was carried out using buffers identical to those used for peptide purification and linear gradients, with diode array monitoring at 215 and 260 nm. Products were obtained by lyophilization of desired HPLC fractions. Representative examples of peptide−PNA conjugate crude and puri-

fied products are shown in Supporting Information Figure 2. All conjugates were characterized by MALDI-TOF mass spectrometry as described previously (*16, 19, 27*).

Cell Culture and Splicing Redirection Assays. This was carried out similarly to that described previously (*16, 19, 27*). Peptide−PNA conjugates were incubated for 4 h in 0.35 mL OptiMEM medium with exponentially growing HeLa pLuc705 cells (1.25×10^5 cells/well seeded and cultivated overnight in 24 well plates). The medium was removed, 1 mL complete medium (DMEM plus 10% fetal bovine serum) was added, and incubation continued for 20 h. Cells were washed twice with ice-cold PBS and lysed with Reporter Lysis Buffer (Promega, Madison, WI). Luciferase activity was quantified with a Berthold Centro LB 960 luminometer (Berthold Technologies, Bad Wildbad, Germany) using the Luciferase Assay System substrate (Promega, Madison, WI). Cellular protein concentrations were measured with the BCA Protein Assay Kit (Pierce, Rockford, IL) and read using an ELISA plate reader (Dynatech MR 5000, Dynatech Laboratories, Chantilly, VA) at 550 nm. Levels of luciferase expression are shown as relative luminescence units (RLU) per microgram of protein or as fold increase in luminescence over background. All experiments were carried out in triplicate. Each data point was averaged over the three replicates.

For dose-dependence experiments, cells were treated as described above with increasing concentrations of conjugates. After carrying out the luciferase assay and BCA Protein Assay, the remaining cell lysates (about 270 μL) were transferred into 2 mL microfuge tubes, and total RNA was extracted with 1 mL TRI Reagent (Sigma). Minor changes to the manufacturer's protocol were made to accommodate the presence of Reporter Lysis Buffer. Thus, 0.3 mL of chloroform was used for extraction, and the amount of isopropanol for RNA precipitation was increased to give a 1:1 mixture with the aqueous phase. The extracted RNA was examined by RT-PCR (SuperScript III One-Step RT PCR with Platinum Taq, Invitrogen; Genius Techne Thermal cycler) with forward primer 5′-TTG ATA TGT GGA TTT CGA GTC GTC-3′ and reverse primer 5′-TGT CAA TCA GAG TGC TTT TGG CG-3′. The products were analyzed on a 2% agarose gel, which was scanned using *Gene Tools Analysis* Software (SynGene, Cambridge, UK).

Cell Culture and Splicing Redirection Assays at Low Temperature. This was carried out as described previously (*18, 19*). HeLa pLuc705 cells were preincubated for 30 min in OptiMEM at 37 or 4 °C. The conjugate was then added and incubation continued for 1 h before assay for luciferase activity was measured as above.

Cell Culture and Splicing Redirection in the Presence of Endocytosis Inhibitors. This was carried out similarly to the method described previously (*19*). HeLa pLuc705 cells were preincubated in OptiMEM at 37 °C for 20 min with one of the following inhibitors: chlorpromazine (30 μM), methyl-β-cyclodextrin (MBCD) (2.5 mM), nystatin (50 μM), or ammonium chloride (50 mM). Cells were washed twice with PBS and incubated in OptiMEM with the same concentrations of the inhibitors in the presence of 1 μM of peptide−PNA conjugate at 37 °C for 30 min. Cells were washed twice with PBS, 1 mL of DMEM complete medium was added, and incubation continued for 23 h. Each experiment was in triplicate. Luciferase expression was quantified as described above. At these concentrations of inhibitors and under the incubation conditions used, good cell viability was obtained in all cases (data not shown).

RESULTS

Synthesis of PNA705 Conjugates of Linear and Branched (R-Ahx-R)-Containing Peptides. Although the concept of chain branching through α and ε positions of Lys via use of Fmoc Lys(Fmoc)−OH was described first by Futaki (*21*), there were a number of significant differences in our methodology. First, we introduced proteolysis resistant Arg-Ahx-Arg (RXR) units as repeating units instead of oligo-Arg or Arg-$(Gly)_3$-Arg units. Second, we used the proteolysis resistant Ahx-βAla (Xβ) spacer between the branches and the C-terminal Cys residue used for conjugation to cargo, and we also varied the spacing within branches by addition of further X or β units. Third, we investigated 2-branched as well as 4-branched structures. Finally, we attached a PNA cargo via a disulfide bond and used the well-known HeLa pLuc705 cell reporter assay that is a measure of the ability of the peptide dendrimer structure to deliver the

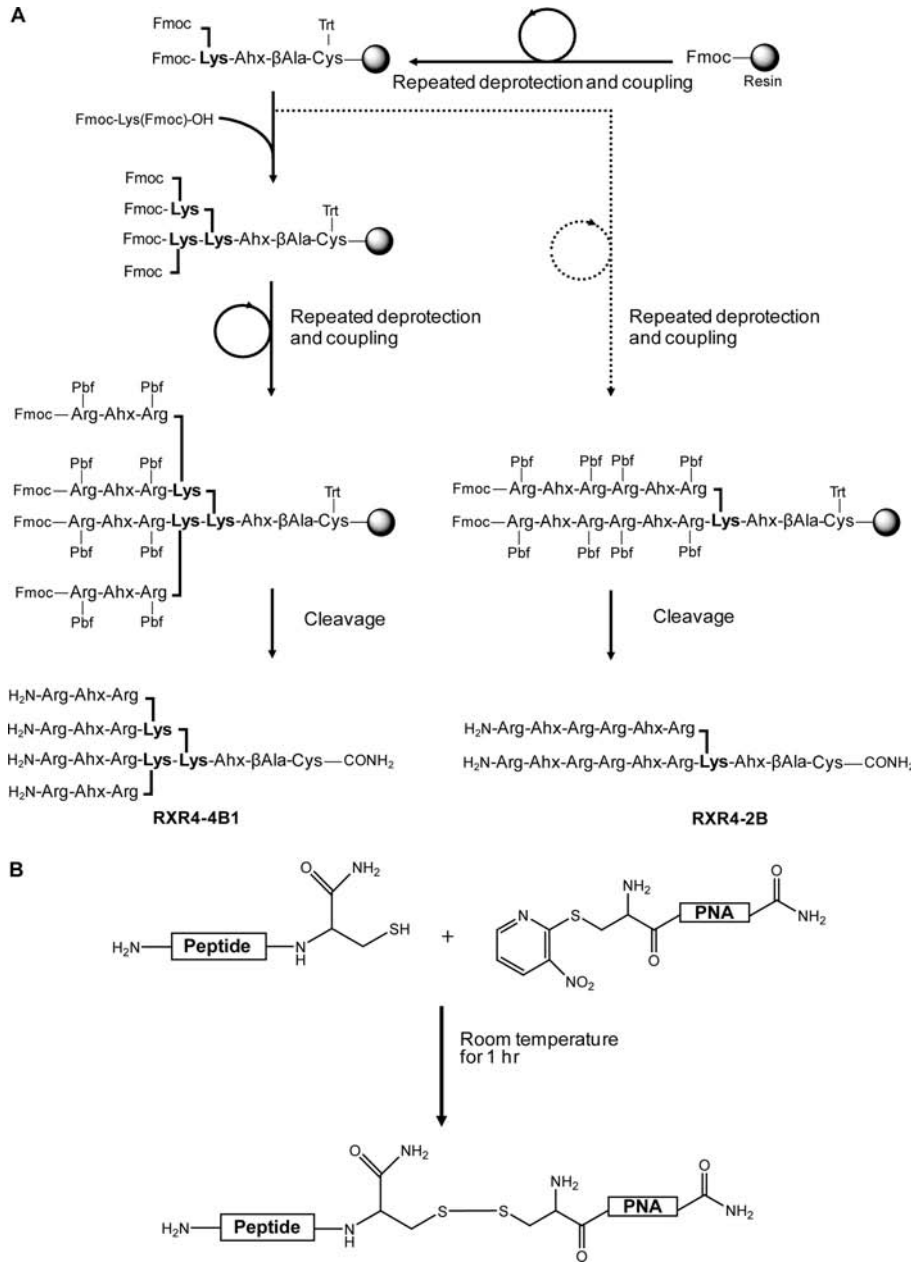

Figure 1. (A) Scheme of solid-phase peptide synthesis of branched peptides RXR4−4B1 and RXR4−2B as representative examples of the strategy of synthesis via branching with Fmoc-Lys (Fmoc)−OH and arms of R-Ahx-R units. Reagents and resin are as described in the Experimental section. (B) Scheme of the disulfide conjugation method used where the PNA contains a NPys-Cys functionality and the peptide a C-terminal free Cys functionality.

cargo to the nucleus. We compared linear (R-Ahx-R) peptides with branched analogues containing the same number of Arg residues, starting with 8-Arg residues $(R\text{-Ahx-R})_4$ and increasing the numbers of Arg residues to 12 and 16. The dendrimer structures and linear peptides RXR4, RXR6 and RXR8 are shown in Table 1.

Synthesis of branched peptide dendrimers (Figure 1A) was carried out very conveniently by microwave-aided solid-phase synthesis using the Fmoc method with a different solid support and different activation agent than reported by Futaki et al. (*21*). The coupling reactions were all very efficient, and only single couplings were needed except for Arg residues. It should be noted that we took account of the need to maintain at least a 5-fold excess of amino acids over solid-support-bound growing chains in coupling reactions at all times by reduction of the amount of solid support for 2- and 4-branched syntheses (see Experimental Procedures). The high yields and efficient syntheses are demonstrated by the HPLC traces obtained for the crude products of synthesis (Supporting Information Figure 1, showing representative 4- and 2-branched dendrimer peptide crude and purified products and MALDI-TOF analysis). Note that it was not necessary to use 5% pyridine/DMF solvent and extended (21 h) coupling times in the FmocArg(Pbf)−OH coupling reactions as previously reported (*21*). Instead, the use of microwave heating and a double coupling protocol proved highly effective (*25*).

Conjugation of purified branched and linear peptides to PNA was carried out through disulfide bond by reaction of each C-terminal Cys-containing peptide with the N-terminal Cys(N-Pys) PNA705 18-mer sequence (Figure 1B) as previously described for other linear cell-penetrating peptides (*16, 18, 19, 27*). Highly efficient conjugations were obtained with only small amounts of unconjugated peptide and PNA remaining (Supporting Information Figure 2 shows representative HPLCs for crude products and purified conjugates for RXR8−4B1-PNA705 and RXR8−2B-PNA705). Note that a disulfide linkage has the

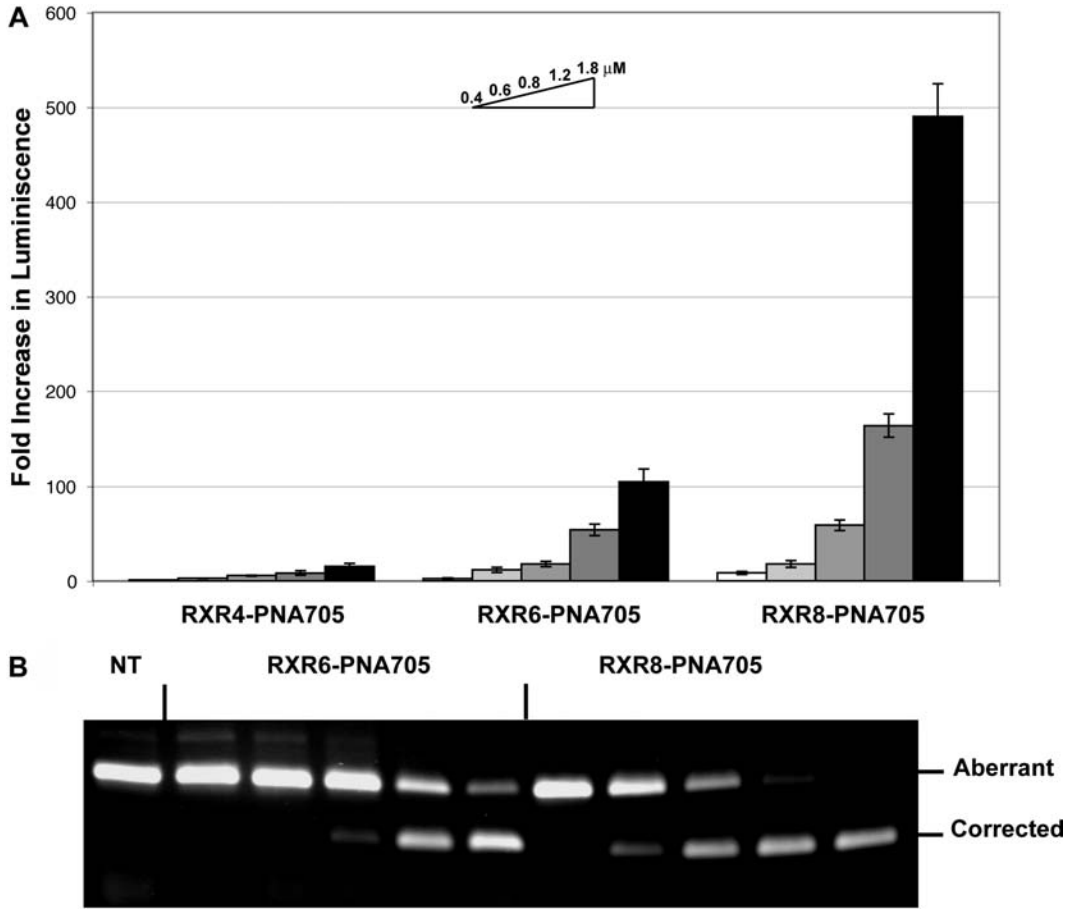

Figure 2. (A) Fold increase in luciferase expression induced by splicing redirection by incubation of RXR4-PNA705, RXR6-PNA705, and RXR8-PNA705 with HeLa pLuc705 cells. Concentrations of conjugates in each case (left to right) are 0.4, 0.6. 0.8. 1.2, and 1.8 μM. (B) RT-PCR analysis showing aberrant and redirected levels of RNA as a function of concentrations of RXR6-PNA705 or RXR8-PNA705. Concentrations of conjugates (left to right) are the same as in (A), namely, 0.4, 0.6, 0.8, 1.2, and 1.8 μM. NT = cells not treated.

advantage that, in principle, the cargo can be released from the peptide vector once inside cells because of the reducing environment, as we have used for our previous R10p53^{tet} dendrimer system (*18*).

Splice-Redirection Activity of Linear and Branched Peptide−PNA Conjugates. We reported previously the splice-redirection activity of linear $(RXR)_4$-PNA and linear $(RXR)_4$-PMO conjugates in the HeLa pLuc705 cell assay (*10, 12*). Although significantly better than $(Lys)_8$, Tat (48−60), Penetratin, and oligoArg conjugates (*12, 19, 28*), EC_{50} values using an RT-PCR assay for the amount of splice-redirected mRNA remained in the micromolar range. To our knowledge, splice-redirection of PNA conjugates to peptide containing a larger number of Arg residues has not been reported previously. We found that for the linear (R-Ahx-R) peptides an increase in the number of Arg residues to 12 (RXR6-PNA705) resulted in a significantly more active conjugate in the luciferase up-regulation assay than RXR4-PNA705, with a further increase in activity for 16 Arg residues (RXR8-PNA705) (Figure 2a). EC_{50} values (Table 1) were determined from the RT-PCR assay by scanning of the agarose gel electrophoregrams (Figure 2b). The biggest improvement in activity was between RXR4 (EC_{50} > 3 μM) and RXR6 (1.0 ± 0.1 μM), whereas a more modest improvement was seen for RXR8 (0.8 ± 0.1 μM).

PNA705 conjugates of 4-branched constructs of RXR4 where each arm contained a single RXR (RXR4−4B1), or a single RXRX (RXR4−4B2), or where additional X spacing was included between the first and second branch points (RXR4−4B3), or a 2-branch analogue with RXRRXR on each branch (RXR4−2B) all showed a dramatic loss of splice-redirecting activity, such that even at 3 μM concentration the luciferase expression activity was barely above background (Figure 3A). Likewise, a 4-branched structure containing four RXRRXβ arms (RXR6−4B) had very poor activity (Figure 3B, Table 1). By contrast, for PNA705 conjugates of RXR6 branched analogues, a 2-branched structure containing arms of RXRRXRRXR (RXR6−2B) gave rise to luciferase expression levels only a little lower than that of the linear RXR6 (Figure 3B, Table 1).

The PNA705 conjugate of RXR8 2-branched analogue (RXR8−2B) showed luciferase expression levels very similar to that for the linear RXR8 (Figure 3C), whereas the 4-branched RXR8 analogues (RXR8−4B1 and RXR8−4B2) were only slightly reduced in activity compared to the linear RXR8 (Figure 3C). The EC_{50} values (Table 1) for splice-redirected RNA measured by the RT-PCR assay in general reflected the same trends as for luciferase up-regulation results, with values for PNA705 conjugates of 2-branched peptides with 12 and 16 residues being very similar to their linear counterparts. Overall, chain branching appears to be best tolerated when the number of Arg residues is 16. For both 12 and 16 Arg residues, 2-branched structures are more active than 4-branched structures and are similar to their linear counterparts in activity. None of the 12 and 16 Arg residue conjugates showed significant toxicity, and the cell viability remained good in an MTS assay up to 3 μM with HeLa pLuc705 cells (Figure 4).

We also carried out the same luciferase and RT-PCR assays for RXR8−4B-PNA705, RXR8−2B-PNA705, and RXR8-PNA705 using a human melanoma tumor cell line containing the same integrated pLuc705 plasmid, namely, A375SM-Luc705-B cells (*29*). The results were broadly similar to the

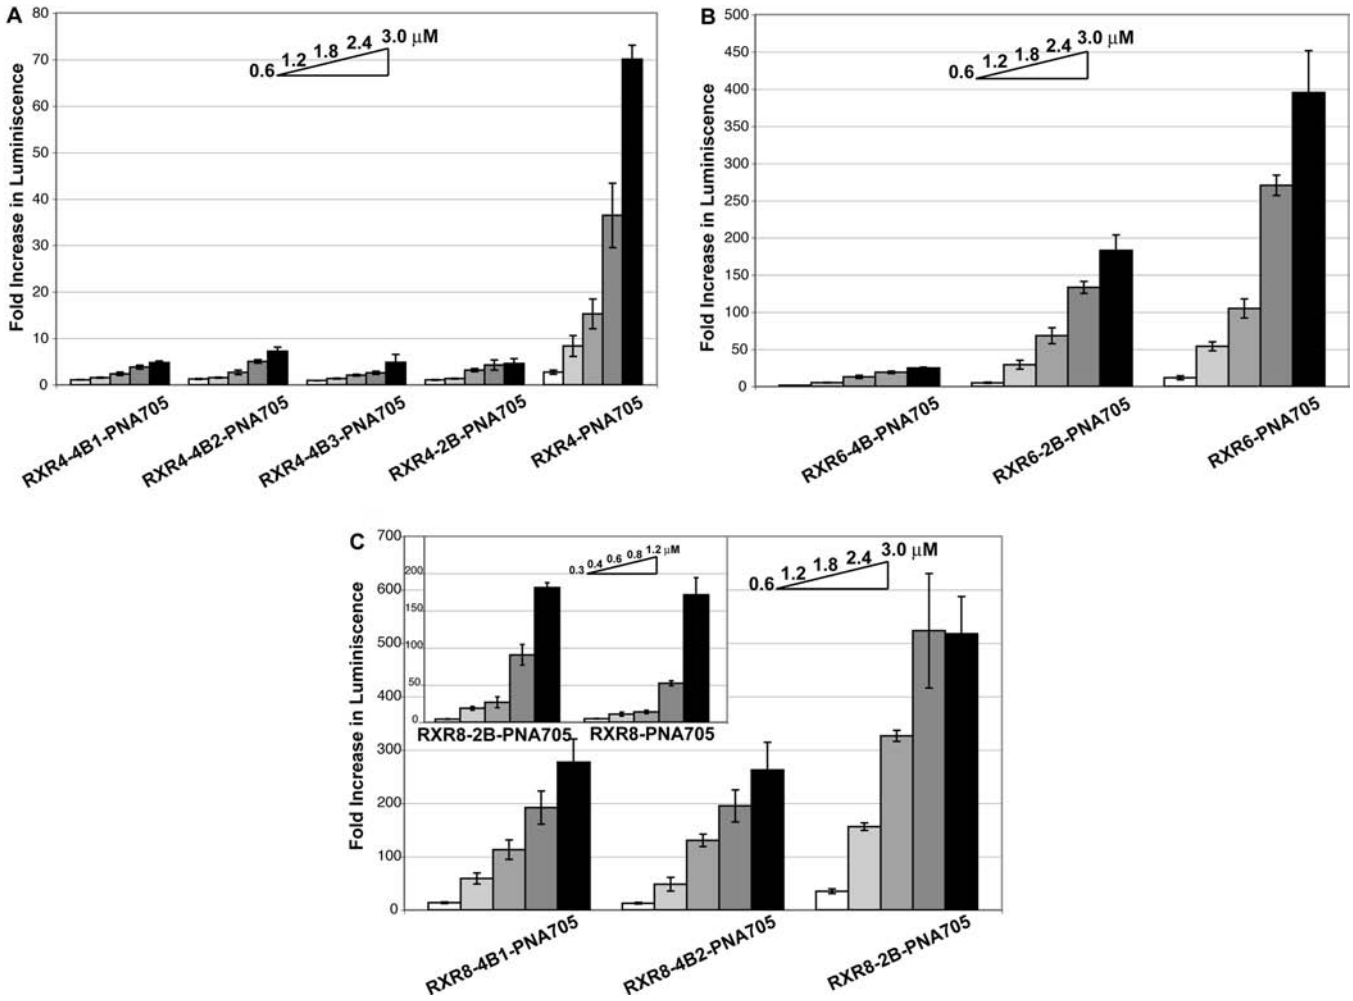

Figure 3. Fold increase in luciferase expression induced by splicing redirection in HeLa pLuc705 cells over the conjugate concentration range 0.6−3.0 μM: (A) branched and linear RXR4-PNA705 derivatives, (B) branched and linear RXR6-PNA705 derivatives, and (C) branched RXR8-PNA705 derivatives (inset shows a comparison of RXR8-2B-PNA705 and linear RXR8-PNA705 over a different concentration range 0.3−1.2 μM).

HeLa cell results in splice-redirecting activity, but in each case, the EC_{50} values in the RT-PCR assay were lower than for the HeLa cells (RXR8−4B1, 0.51 ± 0.03 μM; RXR8−2B, 0.35 ± 0.02 μM; RXR8, 0.42 ± 0.05 μM), probably reflecting a lower copy number of integrated pLuc705 plasmid in the melanoma cell line, but cell viability dropped significantly at 1 μM and higher concentrations for all these peptide−PNA conjugates (data not shown).

In addition, we carried out the HeLa pLuc705 cell luciferase assays at 1.2 μM concentration for 4 h in the presence of 10% fetal bovine serum (FBS). Interestingly, in most cases for 12 Arg and 16 Arg conjugates of PNA705 there was significant activity retained in the presence of serum, compared to serum-free media, especially for the 2-branched and the linear constructs (Supporting Information Figure 3). This is in contrast to unbranched peptide−PNA conjugates containing fewer Arg residues such as RXR4-PNA and R6Pen-PNA, where we had previously found very poor activity in the presence of serum (Arzumanov, A., Abes, R., Gait, M. J., and Lebleu, B., unpublished data).

Thus, we also synthesized a 25-mer PMO conjugate of RXR8−2B targeted to exon 23 of a mutated mouse dystrophin gene by the method previously described (*16*). At 1 μM concentration of incubation with differentiated *mdx* mouse cells in the presence of 10% FBS, but in the absence of any transfection agent, we were able to obtain >70% exon skipping in this model system, higher than for previously studied linear RXR peptide−PMO constructs (data not shown). This demonstrates that there are potential advantages of a higher number of Arg residues in the peptides in terms of activity levels in the presence of serum, which could be crucial for clinical applications.

Mechanism of Cell Uptake in HeLa pLuc705 Cells. The internalization mechanism of CPPs has been questioned ever since the first peptides were discovered. Initially, the consensus in the field was for direct translocation across the plasma membrane, but nowadays, endocytosis is considered the major pathway for many CPPs at low concentrations (*2*). We thus felt it necessary to determine whether increased biological activity of our branched peptide conjugates in comparison with the linear forms could be due to the use of a different cell uptake route. We first examined the splicing redirection activity of these peptide conjugates at low temperature of 4 °C (conditions preventing any form of endocytosis) and physiological temperature 37 °C. Cells were preincubated at 4 or 37 °C during 30 min and then incubated with the different branched peptide conjugates at 1 μM during 1 h at 4 or 37 °C. The results showed a decrease of the activity at low temperature, suggesting that the internalization of the branched peptide conjugates is predominantly energy dependent (Figure 5).

Likewise, controversies remain concerning the endocytotic pathway used for the cell internalization pathway of CPP−cargo conjugates with data advocating all three major routes (*2, 3*). We thus investigated the effects of typical inhibitors of clathrin-dependent, caveolae-dependent, and macropinocytosis pathways,

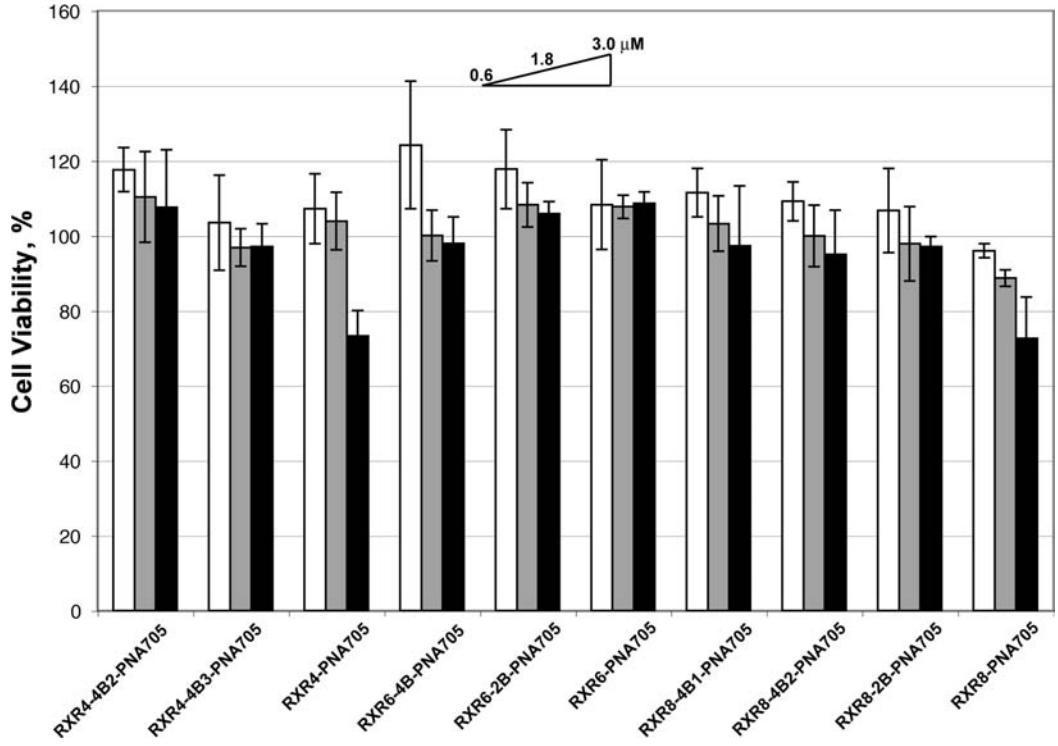

Figure 4. Percentage cell viability for branched and linear peptide-PNA705 conjugates as measured by the MTS assay. To each well of cells treated for 4 h with 0.6, 1.8, or 3.0 μM conjugate in OptiMEM (100 μL, 96 well plate) was added 20 μL of CellTiter 96 Aqueous One solution cell proliferation assay (Promega) and the color intensity measured by plate reader (Tecan, Switzerland) at 490 nm as compared to a control of cells which were not treated with conjugate. Experiments were carried out in triplicate.

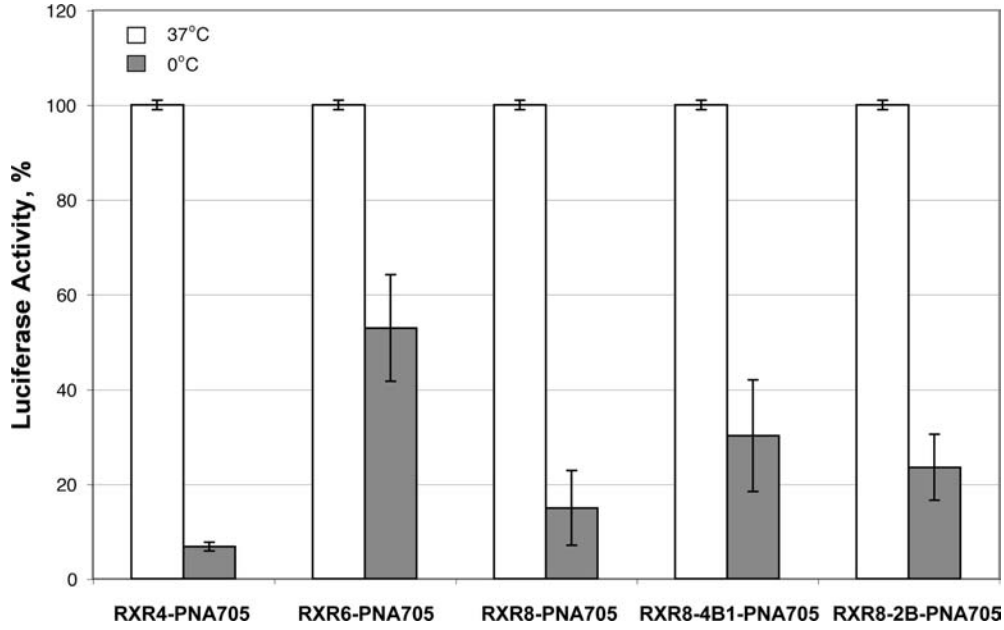

Figure 5. Low-temperature study (37 and 4 °C). Cells were preincubated at 37 °C (white bars) or 4 °C (gray bars) for 1 h and further incubated in the same conditions with PNA705 conjugates of RXR4, RXR6, RXR8, RXR8−4B1, or RXR8−2B, peptides conjugates at 1 μM. Luciferase expression assays were carried out after 24 h as indicated in the Experimental Procedures. Experiments were made in triplicate, and error bars are indicated. Data are expressed as the percentage of luciferase activity.

which are chlorpromazine, nystatin, and methyl-β-cyclodextrin (MBCD), respectively. The importance of acidification of endocytotic vesicles was evaluated with NH_4Cl. For these experiments, incubation times were reduced in order to avoid cytotoxicity of the inhibitors. Interestingly, splicing redirection efficiency by branched CPPs remained unchanged when reducing the incubation time to 30 min as compared to the 4 h incubations generally used in our studies. This is very different from the situation observed with RXR4-PMO conjugate, for example (data not shown).

Nystatin addition resulted in some reduction in the biological activity of both linear and branched peptides (Figure 6). Since nystatin complexes cholesterol and alters the structure and function of glycolipid microdomains, caveolae seem to be involved. Somewhat surprisingly, the activity increased using methyl-β-cyclodextrin, suggesting that branched peptides may

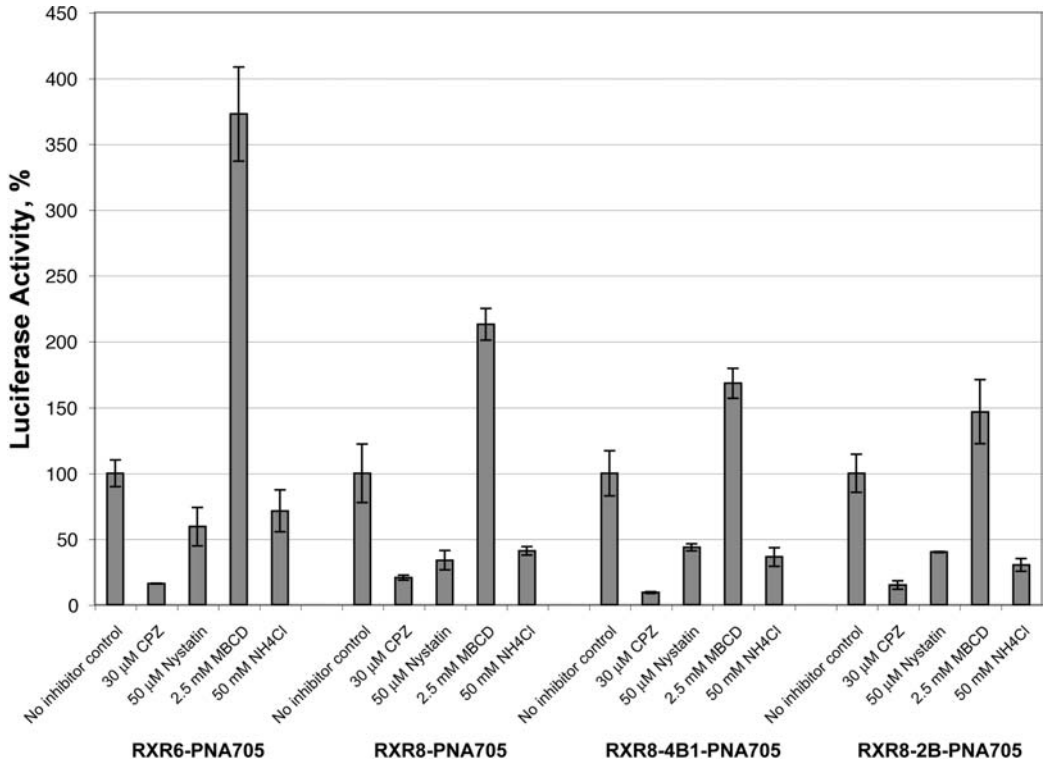

Figure 6. Luciferase activity of PNA705 conjugates of RXR6, RXR8, RXR8−4B1, or RXR8−2B using endocytosis inhibitors. Cells were preincubated at 37 °C for 20 min with chlorpromazine (30 μM), methyl-β-cyclodextrin (MBCD) (2.5 mM), nystatin (50 μM), or ammonium chloride (50 mM). Cells were further incubated in the same conditions with the peptide conjugates at 1 μM for 30 min. Luciferase expression assays were carried out after 24 h as indicated in the Experimental Procedures. Experiments were made in triplicate, and error bars are indicated. Data are expressed as the percentage of luciferase activity.

become internalized by direct membrane translocation into the cytoplasm when the membrane cholesterol is depleted, as previously reported for oligoArg (*30*). By contrast, chlorpromazine exerted a very strong effect on the biological activity with almost 90% decrease for RXR8−2B-PNA and RXR8−4B1-PNA (Figure 6). Together, these data support the notion that the clathrin-dependent uptake pathway is prominently and preferentially involved in the internalization of the branched peptides, as has already been documented for linear RXR4-PMO (*11*), Pip peptide−PNA conjugates (*16*), and Tat peptide (*15*), but with some caveolae dependence also.

Cells were also treated with NH_4Cl, which is known to neutralize the acidification of endosomal and lysosomal compartments (*31*). NH_4Cl (50 mM) caused a strong reduction in the splicing redirection activity of both linear and branched peptides with 16 Arg residues suggesting there is an accumulation in acidic compartment as shown previously for Tat−PNA conjugates (*15*) and a requirement for endosomal acidification for endosomal escape (Figure 6).

DISCUSSION

Synthesis of branched dendrimer peptides using R-Ahx-R repeating units proved very straightforward by the use of microwave-aided Fmoc solid-phase synthesis techniques. Indeed, the number of coupling steps in branched peptide syntheses is less than that for the equivalent linear peptide syntheses containing the same number of Arg residues, and the HPLC traces of the crude products all showed very high overall yields (Supporting Information Figure 1). Disulfide conjugations to PNA were just as effective as for linear peptides (Supporting Information Figure 2).

The use of a HeLa pLuc705 splice-redirecting assay for assessment of CPPs is particularly valuable to judge delivery efficacy because of its convenience, large dynamic range and its ability to measure activity in the cell nucleus for attached PNA or PMO through assays at both the RNA and protein expression levels. In our opinion, a functional assay of this type is superior to the use of fluorescent labels and observation of cell localization by confocal microscopy, because it is a true measure of the ability of a cargo to be delivered in a biologically relevant way, in this case to the cell nucleus. Thus, despite the apparently promising results of Futaki et al. for a 4-branched RG_3R peptide with 8-Arg residues in total where substantial cell uptake of the peptide was observed when a fluorescent label was attached (*21, 22*), by contrast, we found extremely poor luciferase up-regulation in the HeLa cell assay for PNA705 conjugates of both 2-branched and 4-branched peptide with only 8 Arg residues and much poorer than the linear RXR4-PNA. This suggests that branching the 8 Arg residues in this way does not trigger sufficient endosomal escape of the PNA cargo and represents a good example of how following the uptake of fluorescently labeled peptides by confocal microscopy is not predictive of subsequent biological function. We already observed a lack of correlation between cell uptake and biological activity in our SAR studies of a series of linear RXR−PMO conjugates (*13*).

As the number of Arg residues is increased to 12 and 16, however, not only does the overall level of luciferase up-regulation and splicing correction increase significantly with the number of Arg residues, but chain branching is now increasingly tolerated (Figures 2 and 3). An increase in splice-redirecting activity as the number of Arg residues is raised from 8 to 12 and 16 is not surprising, since the overall cell uptake for oligo-Arg peptides of 5 to 8 residues was shown to increase as a function of the number of Arg residues (*32*). However, the number of Arg residues and the precise three-dimensional configuration within the peptide may also affect other steps in the delivery to the nucleus. In general, we found that the longer

the run of R-Ahx-R motifs on each arm, the better the activity for the same total number of Arg residues. In the linear $(R\text{-}Ahx\text{-}R)_4$ peptide, we found previously that aminohexanoic acid spacing between guanidinium groups was optimal for splice-redirecting activity for an attached PMO oligonucleotide compared to shorter or longer spacers (*13*). Further work will be necessary to understand if this finding also holds true for the branched peptides.

However, a differential level of overall cell uptake by linear and branched peptides cannot be ruled out, especially since it has been shown for fluorescently labeled branched 8-Arg peptides that they are more dependent on interaction with membrane-associated heparan sulfate proteoglycans on the cell surface compared to linear R_8 peptides (*22*). Nevertheless, our data are consistent with the notion that the active fraction of branched Arg-rich peptide−PNAs does not use a different pathway of uptake compared to the linear R-Ahx-R peptides. This is evidenced by the very similar deleterious effects on luciferase up-regulation activity seen upon lowering the temperature of the splice correction assay to 4 °C and the similar behavior upon coincubation with endocytosis inhibitors for both branched and linear peptide−PNA constructs (Figures 5 and 6).

The very large effect of chlorpromazine on 16-Arg branched and linear peptide−PNA conjugates (Figure 6) was similar to the effects we previously observed in the same HeLa pLuc705 cells for other highly cationic peptide conjugates of PNA and PMO, such as linear RXR4-PMO (*11*), Pip peptide-PNA (*16*), and Tat peptide (*15*). We conclude as before that clathrin-dependent uptake predominates. However, the effect of nystatin on the luciferase up-regulation was much larger in the cases of both linear and branched RXR−PNA conjugates compared to the only small effects observed of nystatin on uptake and activity of the Tat peptide (*15*) and on Pip-PNA (*16*). This surprising result suggests that caveolae may play some part in uptake where there are a larger number of Arg residues, as has already been shown for Tat fusion proteins (*33*). This could account for the moderate effect of NH_4Cl in some cases, since caveolae-mediated endocytosis does not involve acidic compartments (*34*).

Our results are not entirely consistent with inhibitor experiments in the same cell assay for PNA705 conjugates of moderately cationic, Arg-containing peptides Penetratin and M918, where macropinocystosis was suggested as the major uptake pathway and clathrin-dependent endocytosis predominated only for the more hydrophobic TP10-PNA conjugate (*35*). The concentration of chlorpromazine used in our case was 30 μM, whereas in the case of Lundin et al., it was only 10 μM, and the peptide−PNA concentrations used in our case were 5-fold lower. Poon et al. reported for R_8-functionalized liposome uptake that endocytotic uptake switches from clathrin-dependent to macropinocytosis as peptide density on the liposome surface was increased (*36*), and a mechanism switch is one possible explanation for the discrepancy between our studies and those of Lundin et al. Another possibility is that the choice of uptake pathway is more subtly affected by the different relative positions of the hydrophobic and cationic elements in M918 and Penetratin as compared to the R-Ahx-R constructs. The possible sensitivity of inhibitor use to different cellular conditions, as well as possible subtle effects of amino acid composition and positioning, makes it hard to draw too definitive conclusions about the endocytosis pathways used by cationic CPPs in this class when conjugated to PNA. Further, our result that MBCD addition significantly stimulated luciferase up-regulation suggests that, when one pathway is inhibited, it is possible for cells to utilize or stimulate an alternative uptake pathway. More sophisticated cell techniques will be needed to clarify the dominant endocytotic uptake pathways for particular peptide−cargo conjugates.

A major aim of our experiments was to determine whether branched R-Ahx-R peptides could prove suitable for future development in a therapeutic context. We were particularly heartened that significant splice-redirecting activity was retained in the HeLa cell assay in the presence of 10% serum for many of the 12-Arg and 16-Arg containing conjugates (Supporting Information Figure 3), and we obtained extremely high exon skipping for RXR8−2B-PMO in a *mdx* mouse muscle cell assay that is used as a model for DMD (data not shown). However, we became concerned about the possibility of increased toxicity resulting from the use of larger numbers of Arg residues in the peptides. Although we did not observe toxicity up to 3 μM in the HeLa pLuc705 cell assay (Figure 4), we did see significant loss of cell viability at 1 μM in A375SM-Luc705-B melanoma cells for all 12 and 16 Arg conjugates (data not shown). Further, a very recent report has suggested that at high doses in both mice and monkeys some kidney toxicity is apparent when an 8-Arg peptide-PMO is injected intravenously (*6*). Thus, despite the substantial increase in cell delivery potential afforded by such dendrimeric peptide constructs, peptide conjugates with high Arg content must be used with caution in therapeutic development until the sources of these toxicities (both cellular and in vivo) can be controlled. In the case of cells, more detailed studies of membrane leakage or other specific cell toxicity assays could prove instructive.

Nevertheless, our studies have been useful in understanding some of the three-dimensional requirements for cell uptake and splice-redirecting activity of Arg-rich peptides based on an R-Ahx-R motif, and we have demonstrated that chain branching is well-tolerated when the number of Arg residues is high, especially for 2-branched peptide structures. We have shown also how such peptide chain branching is readily accessible chemically and in high yield. In principle, our methods could be used also to introduce other multiple motifs such as cell-specific uptake sequences (*17*) as conjugates of PNA or PMO cargoes. Our work expands the three-dimensional space available for CPP development.

ACKNOWLEDGMENT

We thank Rudy Juliano (University of North Carolina) for the cell line A375SM pLuc705-B. Amer Saleh was supported in part by a grant from MRC-Technology and Rachida Abes by a PhD fellowship from the Ligue Nationale contre le Cancer. We thank Donna Williams for chemical synthesis of PNA705.

Department of Chemistry and The Skaggs Institute for Chemical Biology, Department of Cell Biology and Center for Integrative Molecular Biosciences, The Scripps Research Institute, 10550 North Torrey Pines Road, La Jolla, California, Skaggs School of Pharmacy and Pharmaceutical Sciences, University of California San Diego, 9500 Gilman Drive, La Jolla, California.
Received June 17, 2010; Revised Manuscript Received August 24, 2010

The copper-catalyzed azide−alkyne cycloaddition (CuAAC) reaction, optimized for biological molecules in aqueous buffers, has been shown to rapidly label mammalian cells in culture with no loss in cell viability. Metabolic uptake and display of the azide derivative of *N*-acetylmannosamine developed by Bertozzi, followed by CuAAC ligation using sodium ascorbate and the ligand tris(hydroxypropyltriazolyl)methylamine (THPTA), gave rise to abundant covalent attachment of dye−alkyne reactants. THPTA serves both to accelerate the CuAAC reaction and to protect the cells from damage by oxidative agents produced by the Cu-catalyzed reduction of oxygen by ascorbate, which is required to maintain the metal in the active +1 oxidation state. This procedure extends the application of this fastest of azide-based bioorthogonal reactions to the exterior of living cells.

INTRODUCTION

To understand the roles of proteins, DNA, RNA, lipids, and glycans in a wide variety of cellular processes, imaging of biomolecules in their native environment using a spectroscopic probe has become increasingly popular (*1*−*3*). For proteins, genetically encoded tags such as GFP are routinely used. When smaller and less structurally perturbing labels are required, the target protein can be endowed with a peptide sequence that is selectively addressed with a small-molecule probe by either chemical or enzymatic reaction (*4*−*9*). These and other examples of chemoselective labeling of biomolecules in vivo are furthered by the development of bioorthogonal ligation reactions (*10*).

Cycloaddition reactions are attractive in this context, since they usually involve weakly polarized reactants, minimizing undesired side reactions with biomolecules. Recent examples include the reactions of strained olefins with nitrile oxides (*11*) or tetrazines (*12*), as well as unstrained olefins with photogenerated nitrile imines (*13*). Azide-based click reactions (*14*) are particularly applicable, since the azide group is stable and easy to introduce into biomolecules or probe molecules without dramatically changing their functional properties. The Staudinger ligation with phosphine esters and cycloaddition reactions with strained cyclic alkynes have been used to excellent effect, led by Bertozzi and co-workers (*15*−*19*), and augmented by others (*20, 21*).

While ligand-accelerated catalysis allows the copper-mediated azide−alkyne cycloaddition (CuAAC) reaction to achieve very high rates for in vitro bioconjugation reactions (*22*−*24*), the Cu(I) catalyst is regarded as toxic and therefore incompatible with living cells. Since both azide and alkyne groups (*25*−*27*) can be appended to biomolecules without altering their function or metabolic processing, it would be very useful if the CuAAC reaction could be adapted for this purpose. As a first step toward this goal, we describe here the application of optimized CuAAC reaction conditions (*24*) to the rapid and efficient labeling of cell-surface glycans on mammalian cells in culture.

EXPERIMENTAL PROCEDURES

Cell-Surface Labeling of Azido Glycans on HeLa and CHO Cells and Imaging by Confocal Microscopy. Cells were seeded at 1×10^5 cells/mL on glass-bottom Petri dishes (35 mm) and grown overnight at 37 °C and 5% CO_2 in growth medium (MEM medium containing 10% fetal calf serum, 1% glutamine, and 1% penstrep) with or without 50 μM Ac_4ManNAz for 2 days. The medium was gently aspirated, and the cells were washed two times with 1 mL of DPBS. In an eppendorf tube, $CuSO_4$ and THPTA in a 1:5 molar ratio were added to DPBS at 4 °C containing dye−alkynes **1** or **2** (final concn 25 μM) and aminoguanidine (final concn 1 mM). A freshly prepared stock solution of sodium ascorbate (100 mM) was added to establish a final ascorbate concentration of 2.5 mM. This reaction mixture was incubated on ice for 10 min at 4 °C before adding to the cells. After incubation at 4 °C for 1 or 5 min, the cells were washed and fixed with a mixture of 3% paraformaldehyde, 0.3% glutaraldehyde, and 1 mM $MgCl_2$ in DBPS for 10 min at room temperature. Cell nuclei were stained by adding 4′,6-diamidino-2-phenylindole (DAPI). Between each step, the slides were rinsed three times with DPBS. Slides were mounted using Vecta Shield mounting medium (Vector Laboratories, Burlingame, CA). Sections were imaged using a Biorad 2100 confocal microscope with a 60× oil objective. Data were analyzed and images were created using *ImageJ* (http://rsbweb.nih.gov/ij/). For dual labeling studies, the cells were washed twice with 1 mL of growth medium after the labeling reaction and returned to medium containing 50 μM Ac_4ManNAz for another 20 h. Optimized conditions for cell-surface labeling were 25 μM alkyne-488, $CuSO_4$ (50 μM), THPTA (250 μM), aminoguanidine (1 mM), and sodium ascorbate (2.5 mM) for 1 to 5 min in medium at 4 °C.

Cell-Surface Labeling of Azido Glycans on Jurkat Cells with Biotinylated Conjugates. Jurkat cells were grown in RPMI medium containing 10% fetal calf serum, 1% glutamine, and 1% penstrep with or without 10 μM Ac4ManNAz. Cells were collected using enzyme-free Hank's based cell

dissociation buffer, distributed in 200 μL portions at a concentration of 5×10^6 cells/mL in the wells of a 96-well V-bottom-shaped microtiter plate, pelleted (1500 $\times$ *g*, 3 min), and washed twice with 200 μL of labeling buffer DPBS. On a separate 96-well plate, premixed $CuSO_4$ and THPTA at a 1:5 molar ratio were added to DPBS at 4 °C containing biotin−alkyne **3** (final concn 50 μM) and aminoguanidine (final concn 1 mM). A freshly prepared stock solution of sodium ascorbate (100 mM, 2.5 μL) was added to establish a final ascorbate concentration of 2.5 mM. The reaction mixture was incubated on ice for 60 min before adding to the cells. After incubation for 5 min at 4 °C, the cells were washed two times with DPBS buffer containing 1 mM EDTA pH 8.0, 25 mM HEPES pH 7.5, and 1% fetal bovine serum, fixed with 2% (v/v) formaldehyde in DPBS for 10 min at room temperature, and resuspended in the same buffer containing FITC−streptavidin (1:250 dilution) for 20 min at 4 °C. Cells were analyzed using a FACS Calibur instrument (BD Biosciences, Franklin Lakes, NJ). At least 10 000 events were collected. Experiments were repeated at least twice, and triplicates of each sample were measured and data analyzed using *FlowJo 8.7.1* software (Tree Star, Inc., Ashland, OR).

Cell Viability Assay. Cells were incubated for 2 days in untreated medium or medium containing 10 μM−50 μM Ac_4ManNAz on 96-well plates. The medium was gently aspirated, and the cells were washed twice with 200 μL of DPBS. In an eppendorf tube, premixed $CuSO_4$ and THPTA at 5:1 ratio were added to DPBS at 4 °C containing aminoguanidine (1 mM) to the desired copper concentrations. Sodium ascorbate (100 mM) was added to the final concentration of 2.5 mM. The reaction mixture was incubated on ice for 10 min at 4 °C before adding to the cells. After incubation for 5 min, the cells were washed twice with the labeling buffer and returned to growth medium for 24 h. An equal volume of premixed Cell Titer-Glo Reagent from Promega was added, plates were shaken for 10 min at room temperature, and luminescence was monitored.

Synthesis of Alexa Fluor Derivatives. To a solution of the appropriate Alexa Fluor cadaverine (1.0 equiv) in DMSO (final concentration of 0.05 M) was added a solution of *N*-(4-pentynoyloxy)succinimide (10.0 equiv) and then *N*,*N*-diisopropylethylamine (10.0 equiv). The solution was stirred at room temperature overnight in the dark, diluted in 9:1 water/acetonitrile, purified by reversed-phase HPLC using water and acetonitrile, and lyophilized to a fine powder. Electrospray−ionization mass spectrometry (negative ion detection): Alexa 488-alkyne parent ion $[\mathbf{1}\cdot H^+]^-$ $(C_{30}H_{27}N_4O_{11}S_2)^-$, calcd 683.1, found 683.1; Alexa 568-alkyne parent ion $[\mathbf{2}\cdot H^+]^-$ $(C_{42}H_{43}N_4O_{11}S_2)^-$, calcd 843.2, found 843.2.

RESULTS AND DISCUSSION

While many enzymes require copper, including cytochrome oxidase, Cu/Zn superoxide dismutase, and lysyl oxidase (*28, 29*), copper ions can be harmful to cells, mostly because they catalyze the production of reactive oxygen species (ROS) from atmospheric oxygen. Therefore, free Cu is essentially absent inside cells of aerobic organisms (*30*), but the overall intracellular copper concentration is approximately 70 μM (*31*), all bound up as Cu^I among proteins that constitute a well-developed and highly conserved system for importing and distributing this essential ion (*32*).

The Cu^I oxidation state required for the CuAAC reaction is most often achieved and/or maintained by the reduction of Cu^{II} with ascorbate. The Cu/ascorbate system is a prodigious generator of oxygen radicals and other reactive species in air (*33*−*38*). We have previously shown that a water-soluble derivative of the tris(triazolylmethyl)amine family of ligands (*39*) intercepts reactive oxygen species generated in the coordination sphere of the metal and accelerates Cu-mediated peroxide degradation (*24*). The additive aminoguanidine was also shown to capture dehydroascorbate and its decomposition products before they can react with protein side chains. The combined use of these two additives gave rise to a robust protocol to label proteins, polynucleotides, and other biomolecules in aqueous buffers with high yield and efficiency in the presence of air (*24*).

The applicability of this protocol to live cells was tested by metabolic labeling using peracetylated *N*-azidoacetylmannosamine (Ac_4ManNAz), which is taken up and incorporated into cell-surface sialylated (SiaNAz) glycans (Figure 1) (*40*−*42*). In order to gauge the effect of THPTA on eliminating the toxicity of copper and sodium ascorbate, HeLa, Chinese hamster ovary (CHO), and Jurkat cells were incubated at 4 °C with these click reaction components. Preliminary exploratory experiments showed 5 min to be an incubation period in which significant protective effects from the ligand could be observed, and we knew from previous studies that the CuAAC reaction is fast enough to provide extensive labeling in this amount of time. Longer incubations gave rise to increasing cytotoxicity under

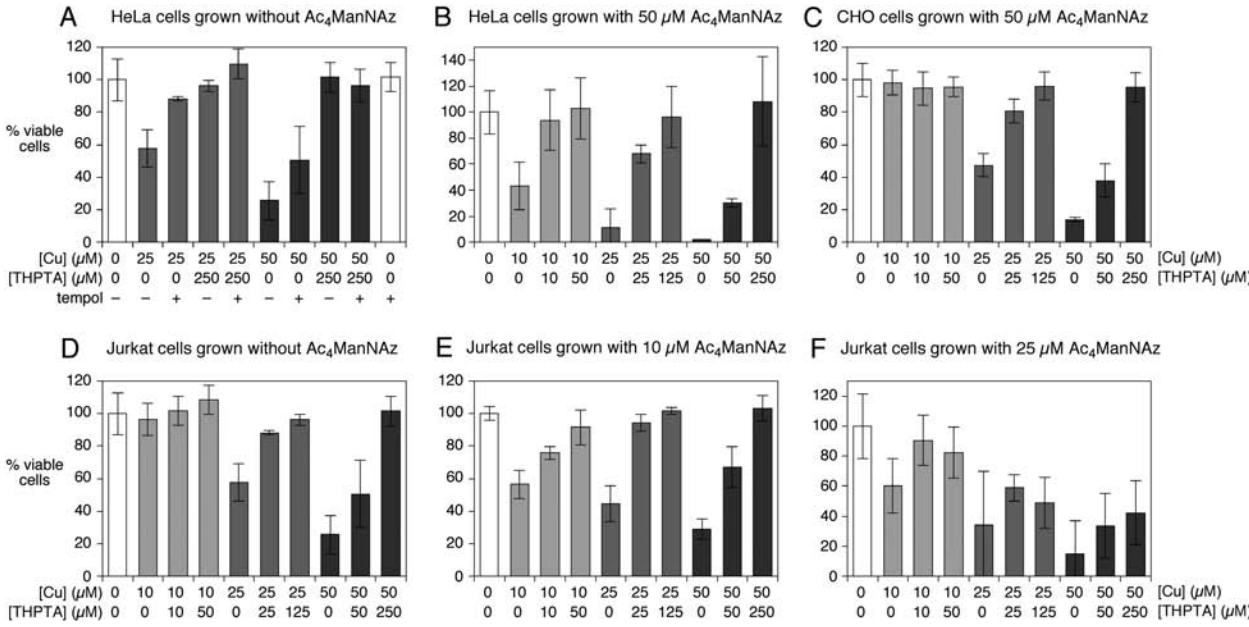

Figure 2. Viability of mammalian cells after Cu-ascorbate treatment ([$CuSO_4$] and [THPTA] as indicated, [Na ascorbate] = 2.5 mM, DPBS, 4 °C, 5 min), followed by washing in buffer and incubation in growth media for 24 h. Cell viability was determined by CellTiter-Glo Luminescent Cell Viability Assay (Promega, Madison, WI) (*43*). (B,C,E) Cells were grown for two days in the presence or absence of Ac_4ManNAz, as indicated, before Cu treatment. Error bars indicate standard deviation from the averaging of results from at least three independent experiments.

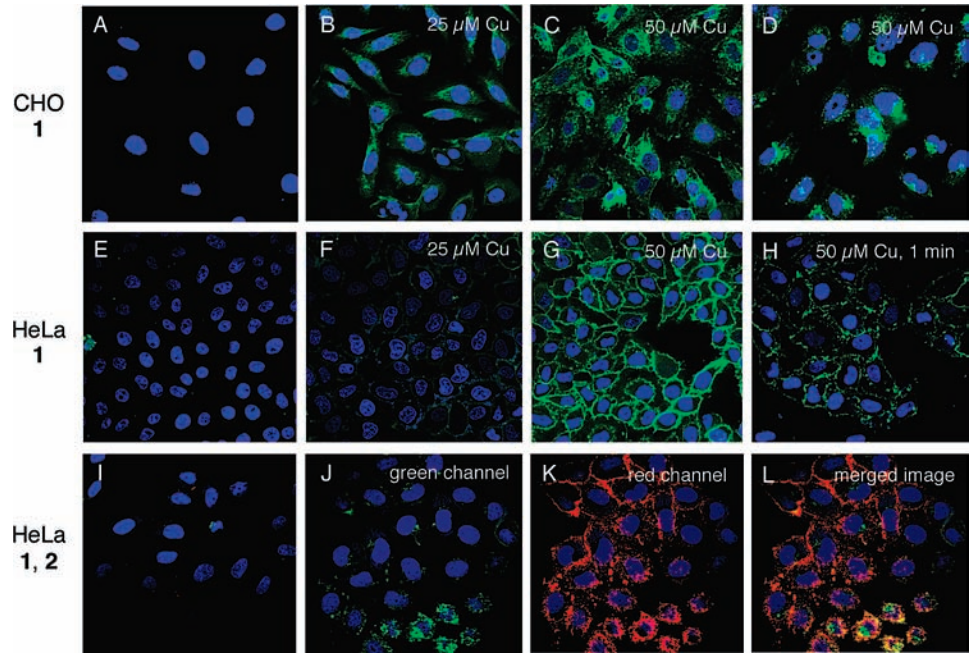

Figure 3. Representative labeling of cells (grown in the presence of 50 μM Ac_4ManNAz for 48 h) with the indicated dye−alkynes (25 μM), in the presence of Cu catalyst (5 equiv THPTA, 2.5 mM Na ascorbate, 1 mM aminoguanidine), in PBS pH 7.4 at 4 °C. The CuAAC reaction was conducted for 5 min unless otherwise noted, followed by washing in buffer and fixation for confocal microscopy imaging after incubation in fresh media for 15 min (except for panel D, for which the cells were incubated for 24 h before fixation and imaging). Nuclei were stained with DAPI (blue). Panels A, E, and I show the result of CuAAC labeling treatment with **1** on cells lacking the azido sugar, showing that nonspecific adsorption or labeling with dye does not occur. The procedure for labeling of cells shown in panels J−L is described in the text. All images are 155 × 155 μm.

most conditions. Thus, variations in Cu and ligand concentrations were explored for 5 min incubations, after which the cells were washed, placed back in media for 24 h at 37 °C and 5% CO_2, and then assessed for viability (Figure 2). In each case, the Cu/ligand/ascorbate mixture was allowed to stand for 10 min before introduction to the cells in order to allow the catalyst to quench the ROS and peroxide species generated in the reduction of dissolved oxygen (*24*).

As expected, in the absence of ligand, increasing copper concentration induced increased cell death for each cell type. Growth in the presence of the azido−sugar made the cells significantly more sensitive to Cu-ascorbate (Figure 2A vs B, D vs E,F), presumably because the health of the cells or integrity of the membrane is compromised by the incorporation of the non-natural glycan, or because the added Cu complex somehow engages the surface azide groups to the detriment of the cell.

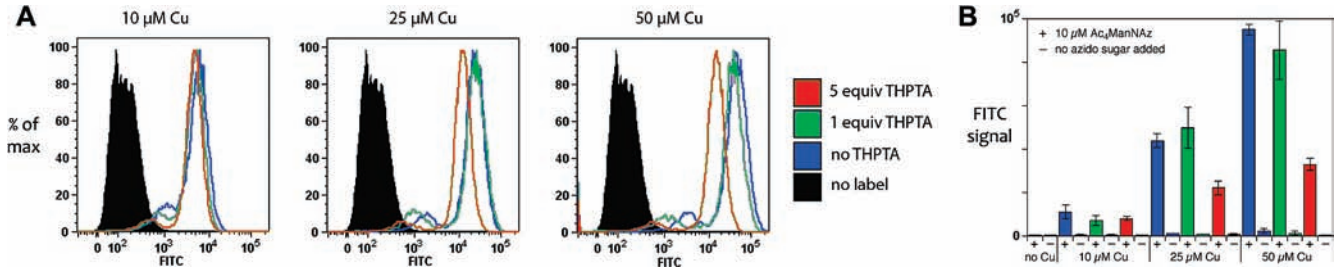

Figure 4. Flow cytometry analysis of Jurkat cells, preincubated for 48 h in growth medium containing 10 μM Ac_4ManNAz, and then labeled with **3** (50 μM) under standard conditions ($CuSO_4$ and THPTA at the indicated concentrations, 2.5 mM Na ascorbate, 1 mM aminoguanidine, in DPBS, 4 °C, 5 min). (A) All samples were analyzed in triplicate; 10 000 events were recorded in each case; and representative histograms are shown. (B) Mean fluorescence intensities with error bars representing standard deviations (statistical analysis performed using *FlowJo* software v 8.7.1).

The latter possibility is unlikely, given the fact that organic azides are not consumed by treatment with Cu^I complexes in the absence of terminal alkynes. The ligand proved to be largely protective: THPTA reversed the toxic effect of Cu-ascorbate effect in a dose-dependent manner, a 5:1 ligand:Cu ratio preserving the viability of all cell types at each Cu concentration tested (Figure 2). This is consistent with the previous observations concerning the ability of the ligand to intercept the formation of oxygen radicals with maximum efficiency (*24*).

Treatment of the Ac_4ManNAz-treated cells with dye−alkynes under the above CuAAC conditions resulted in extensive labeling, as shown in Figures 3 and 4. We chose to perform the CuAAC reactions at 4 °C to eliminate internalization of cell-surface species during this process and inhibit energy-dependent internalization of reactants. As has been previously described for in vitro bioconjugation reactions (*24*), the Cu^I•THPTA system functions best at 50 μM Cu or greater, showing much greater labeling of SiaNAz-bearing CHO and HeLa cells than 25 μM (Figure 3C vs B, G vs F). A reaction time of just 1 min gave substantial labeling, but 5 min was far better (Figure 3G vs H). In each case, evenly distributed labeling over the cell surface was observed, consistent with the expected distribution of the azido sugar throughout the exterior of the cell membrane. The viability of the cells 24 h after labeling was confirmed as above, with the same results of complete protection against ROS-induced toxicity in the presence of 5 equiv of THPTA ligand. As shown in panel D, CHO cells returned to the growth medium for 24 h after labeling showed the dye distributed in the cell interior, reflecting the expected internalization of the sialylated proteins.

The same pattern was observed in HeLa cells, which were further characterized by a two-color sequential labeling experiment. HeLa cells grown for 48 h in the presence of Ac_4ManNAz were labeled with Alexa-488 alkyne **1** at 4 °C, washed, and returned to growth media containing the azido sugar for 24 h to install additional SiaNAz residues. The cells were then labeled a second time with Alexa-568 alkyne **2** and imaged, with the results shown in Figure 3J−L. After 24 h, the initially labeled (green) sialic acid residues had trafficked largely to the inside of the cells, whereas the freshly labeled (red) sugars were distributed on the cell surface. These results suggest that the labeling protocol does not significantly perturb glycan trafficking on the time scale of the experiment.

The nonadherent Jurkat cells were analyzed by flow cytometry after the same labeling procedure described above. Ac_4ManNAz proved to be toxic to these cells at 50 μM, and cells grown in the presence of 25 μM of the sugar were more sensitive to copper than others (Figure 2F). Labeling studies were therefore performed after growth in the presence of 10 μM Ac_4ManNAz. The cells were labeled by CuAAC reaction with biotin alkyne **3**, and the label was subsequently detected with a fluorescein−streptavidin conjugate (see Experimental Section). As shown in Figure 4, labeling was most effective with 50 μM Cu, and surprisingly, the ligand could either be omitted or used in equimolar amounts with respect to Cu to achieve maximum signal. In the case of this two-step assay, however, the relationship between output signal and the degree of surface labeling may not be direct. For example, the omission of ligand could result in more cell damage and membrane permeability, and therefore in a greater signal in CuAAC labeling.

We demonstrate here a robust and general method for the surface labeling of live cells in culture using the CuAAC click reaction. The toxicity commonly attributed to copper results from the production of reactive oxygen species by Cu, ascorbate, and atmospheric oxygen. The important features of the cell labeling protocol are the use of a water-soluble accelerating ligand (THPTA) that also acts as a sacrificial reductant for oxidative species as they are produced in the coordination sphere of the metal and aminoguanidine to intercept strongly electrophilic byproducts of dehydroascorbate. The rapid nature of the reaction that allows for efficient labeling in a short time, preserving cell viability.

ACKNOWLEDGMENT

Photocleavable Peptide-Conjugated Magnetic Beads for Protein Kinase Assays by MALDI-TOF MS

Guangchang Zhou,[†,‡] Xiaoliang Yan,[†] Ding Wu,[†] and Stephen J. Kron*[,†,‡]

Ludwig Center for Metastasis Research and Department of Molecular Genetics and Cell Biology, The University of Chicago, Chicago, Illinois 60637. Received July 6, 2010; Revised Manuscript Received August 30, 2010

Peptides were immobilized onto superparamagnetic beads via photocleavable linkers. This enabled simple, rapid, and label-free protein kinase assays via MALDI-TOF MS detection of substrate peptide phosphorylation. Abltide, a model substrate for the Abl protein tyrosine kinase model, was coupled onto amine-terminated beads, incubated with ATP and recombinant c-Abl kinase, and released and further detected to determine phosphorylation. Abltide phosphorylation was found to depend significantly on the length and composition of linkers to the bead surface. Inserting a diblock spacer of poly(glycine) and poly(ethylene glycol) segments markedly enhanced phosphorylation. To validate the assay, the activity of two small-molecule kinase inhibitors, imatinib and dasatinib, which target the oncogenic mutant tyrosine kinase Bcr-Abl to treat chronic myeloid leukemia (CML), was tested. Examining inhibition of the purified c-Abl or Bcr-Abl in K562 CML cell extracts, IC_{50} values were determined to be consistent with the literature. This simple, label-free, MALDI-based protein kinase assay can be readily adapted to allow multiplexed assays of multiple peptide substrates and/or analysis of alternative post-translational modifications as a tool for drug discovery and clinical testing.

INTRODUCTION

Protein kinases play critical roles in cellular signal transduction by regulating intracellular processes such as cell growth, proliferation, differentiation, and apotosis (*1*−*3*). Deregulation of protein kinase activities and resulting perturbations of downstream targets in phosphorylation cascades have been implicated as underlying causes of a number of diseases, including cancer, diabetes, and chronic inflammation (*4*−*7*). Thus, protein kinases have emerged as a major class of drug targets, leading to several small-molecule kinase inhibitors already in use, and many more in clinical trials (*8*−*12*). Multiple technologies have been developed for analyzing protein kinase activities and screening of small molecules for inhibition of protein kinases (*13*−*23*).

A key challenge in protein kinase assays lies in the detection of the formation of the phosphorylated product by transfer of the ATP γ-phosphate to the unphosphorylated substrate. A reasonable goal is to detect the activity and inhibition of a kinase in its cellular context, but this requires extraordinary sensitivity and specificity, given the ubiquitous nature of protein phosphorylation and the expression of hundreds of different kinases in many cells. Heterogeneous kinase assays, where kinase-specific protein or peptide substrates are tethered to the surface of solid supports, have unique advantages over homogeneous assays for this purpose. The added steps of substrate immobilization and separation and/or washing are offset by enhanced sensitivity and specificity offered by ready discrimination of phosphorylated products from the many phosphorylated proteins in a cell extract. Diverse strategies are described for immobilization of peptides or proteins on solid supports, including in situ peptide synthesis (*24*, *25*), noncovalent attachment via streptavidin−biotin interaction, and covalent chemistries such as NHS−amine reaction (*26*), Diel-Alder reaction (*13*), native chemical ligation (*27*), and Michael addition (*28*−*30*). However, direct attachment of peptide substrates to the support surface may limit accessibility of kinases to their substrates. Indeed, inserting a spacer between the peptide substrate and the support surface can significantly improve phosphorylation efficiency and reduce background (*31*−*34*).

Most heterogeneous kinase assays adapted to screening exploit indirect detection of phosphorylation via labels (*35*−*37*). Traditional kinase assays based on transfer of radioactive (thio)phosphate from γ-labeled ATP to peptide or protein substrates are sensitive and quantitative but not well-suited to analysis of cell extracts. Antibodies that recognize substrate phosphopeptides offer sufficient sensitivity and specificity but require additional binding and washing steps and offer limited quantitation. An attractive label-free approach is mass spectrometry (MS), which offers independent, quantitative detection of both phosphorylated and unphosphorylated substrate, and offers potential for multiplexed assays with high sensitivity, selectivity, and speed (*38*, *39*). Direct MS analysis of kinase reaction mixtures suffers from signal suppression due to salt and detergent interference and is confounded by the complexity of cell extracts. Direct matrix-assisted laser desorption ionization (MALDI) analysis of substrates immobilized via tethering to self-assembled monolayers (*40*) or onto gold nanoparticles coated onto glass slides (*32*) has demonstrated the potential of mass spectrometry for heterogeneous kinase assays.

Photocleavable linkers offer a number of advantages, because light is easy to apply, relatively harmless to living organisms, and importantly controllable both spatially and temporally (*41*). *o*-Nitrobenzyl ether derivatives are especially convenient photocleavable moieties and have been used in a variety of fields including live cell culture and imaging due to unique properties that include stability under ambient light, clean cleavage via two-photon photolysis mechanism upon exposure to UV irradiation, and fast fragmentation reactions (within nanoseconds) upon photoexcitation (*42*−*44*). Previously, we reported a chip-based kinase assay using substrate peptides copolymerized into a hydrogel via a UV-photocleavable linker (*45*). After release by 365 nm light, peptide phosphorylation can be readily detected by

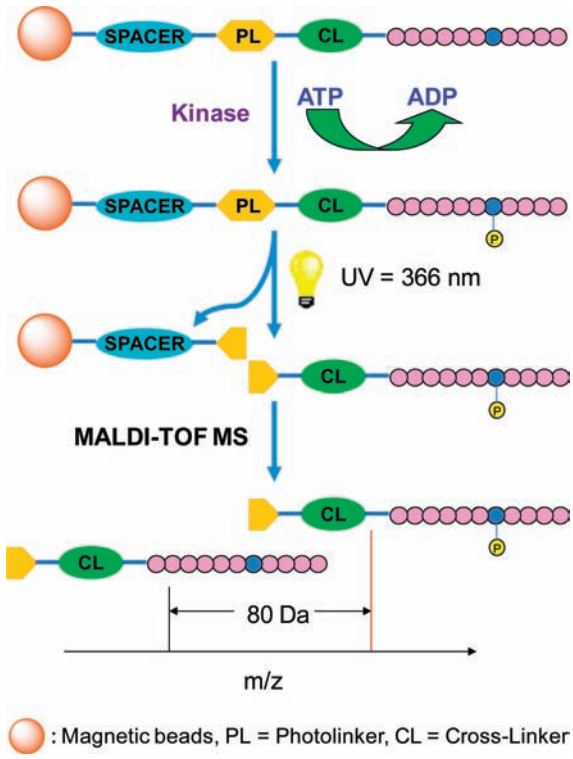

Figure 1. Schematic representation of the new label-free MALDI-based protein kinase assay technique using magnetic beads as a solid-phase analysis platform to facilitate separation and photocleavable linkers as a trigger to release peptide substrates under UV light for MALDI detection. Both phosphorylated and unphosphorylated substrate peptides can be detected by MALDI with a characteristic 80 Da difference in mass between the two peaks.

MALDI-TOF MS. Although hydrogel arrays offer a robust and inert surface that can support a high peptide density, adaptation to high-throughput screening is not straightforward. As an alternative strategy to decrease background after phosphorylation, biotin-tagged peptide substrates can be captured onto streptavidin-coated magnetic beads (*46*) prior to MALDI-TOF analysis. We recently extended this work to create a practical kinase activity screening assay and demonstrated rapid determination of IC_{50} for small-molecule kinase inhibitors (*47*). In this study, we have used Fmoc solid-phase peptide synthesis to install diblock linkers terminated by a photocleavable group onto paramagnetic particles, tethered substrate peptides, and validated these conjugates as reporters of protein kinase activity and inhibition using a MALDI-TOF readout (Figure 1). Our data suggest that this approach may be readily adapted to high-throughput, highly multiplexed analysis of kinases in whole cell lysates.

EXPERIMENTAL PROCEDURES

Materials. Fmoc-aminoethyl photolinker (4-[4-(1-(Fmoc-amino)ethyl)-2-methoxy-5-nitrophenoxy)] butanoic acid, ≥96%, Novabiochem), Fmoc-Gly-OH (N-α-Fmoc-glycine, Peptides International), HCTU coupling reagent (1-[bis(dimethylamino)methylene]-5-chlorobenzotriazolium-3-oxide hexafluorophosphate, Peptides International), 4-methylmorpholine (NMM, 99.5+%, Sigma-Aldrich), piperidine (99%, Sigma-Aldrich), *N*,*N*-dimethylformamide (DMF, anhydrous, 99.8%, Acros Organics), *N*-[*p*-maleimidophenyl]isocyanate (PMPI, Pierce), N-Fmoc-amido-dPEG$_4$-acid, N-Fmoc-amido-dPEG$_8$-acid, N-Fmoc-amido-dPEG$_{12}$-acid (Quanta Biodesign), BcMag amine-terminated magnetic beads (1 μm, Bioclone Inc.), BupH phosphate buffered saline (0.1 M sodium phosphate, 0.15 M NaCl, pH 7.2) (Pierce), and recombinant c-Abl (Upstate) were used as received. Imatinib mesylate (Novartis) was provided by Wendy Stock (The University of Chicago). Dasatinib (free base) was purchased from LC Laboratories (Woburn, MA). Cysteine-terminated G_4SG_3 Abltide substrate (CGGGGSGGGKGEAIYAAP-FAKKKG) and K562 cell lysate (human chronic myelogenous leukemia cell extract) were prepared as reported previously (*28*).

Surface Modification of Magnetic Beads. BcMag particles are uniform superparamagnetic beads consisting of silica-coated iron oxide, presenting surface primary amino groups (**MNP@NH$_2$**). The beads were washed in turn with water and DMF, and diluted to a concentration of 5 mg/mL in DMF. 500 μL of washed beads (equivalent to 0.625 μmol NH_2 groups) was added to a mixture of 100 μL of 240 mM Fmoc-Gly-OH and 900 μL of coupling reagent solution containing 0.76 M HCTU, 1.60 M NMM in DMF. The coupling reaction mixture was rotated at room temperature for 40 min; then, the beads were separated and washed with DMF three times to remove excess reactants. The Fmoc protection group was removed by treatment with 20% piperidine in DMF for 30 min. After deprotection, beads were washed with DMF three times. Four additional cycles of coupling and deprotection reactions were performed in the same manner. As a result, beads with surface poly(glycine) spacers (**MNP@Gly$_5$-NH$_2$**) were obtained and further washed with DMF.

300 μL of surface poly(glycine) spacer-modified beads (**MNP@Gly$_5$-NH$_2$**) in DMF (equivalent 0.375 μmol of free NH_2 groups) was added to a mixture of 20 μL of 400 mM N-Fmoc-amido-dPEG$_4$-acid and 780 μL of coupling reagent solution containing 0.76 M HCTU, 1.60 M NMM in DMF. The coupling reaction was again carried out at room temperature for 40 min, and deprotection for 30 min, as above. After washing with DMF, beads with surface spacers consisting of both poly(glycine) and poly(ethylene glycol) segments (**MNP@Gly$_5$-PEG$_4$-NH$_2$**) were produced.

Superparamagnetic beads with poly(ethylene glycol) spacers of different length (**MNP@PEG$_n$-NH$_2$**, n = 4, 8, 12) were prepared using three different PEG linkers (N-Fmoc-amido-dPEG$_4$-acid, N-Fmoc-amido-dPEG$_8$-acid, and N-Fmoc-amido-dPEG$_{12}$-acid) according to the above-described procedure.

Preparation of Photocleavable Abltide-Conjugated Superparamagnetic Beads. Beads with different surface spacer structures (**MNP@NH$_2$**, **MNP@Gly$_5$-NH$_2$**, **MNP@Gly$_5$-PEG$_4$-NH$_2$**, and **MNP@PEG$_n$-NH$_2$**, n = 4, 8, 12) were used for preparation of photocleavable Abltide-conjugated beads with different spacer linkers. 300 μL of each kind of bead with amino groups (equivalent to 0.375 μmol of free NH_2 groups) were added to a mixture of 60 μL of 180 mM Fmoc-aminoethyl photolinker in DMF and 540 μL of coupling reagent solution containing 0.76 M HCTU, 1.60 M NMM in DMF. The coupling reaction was carried out at room temperature for 40 min. Excess reactants were removed by washing with DMF. The removal of the Fmoc group was completed by treating the beads with 20% piperidine in DMF for 30 min. The deprotected beads were washed in turn with DMF and anhydrous DMF, and reacted with the heterobifunctional cross-linker PMPI in a 1:30 ratio of amino group to isocyanate group over 13 h. After completion of the reaction, beads were washed successively with DMF and BupH PBS buffer (pH 7.2). The maleimide-functionalized beads were reacted with the cysteine-terminated G_4SG_3 Abltide (3.33 equiv to maleimide groups) in BupH PBS buffer medium for 2.5 h. The resulting photocleavable Abltide-conjugated superparamagnetic beads were washed with water and stored in water at 4 °C.

In Vitro Kinase Assay. On-bead phosphorylation reactions by c-Abl kinase and K562 cell lysates were performed. Kinase assays using c-Abl were as reported (*47*). For kinase assays using K562 cell lyaste, a typical 50 μL kinase reaction contained 50 mM Tris-Cl (pH 7.5), 10 mM $MgCl_2$, 1 mM EGTA, 2 mM DTT, 0.01% Brij-35, 50 μM ATP, 0.50 mg/mL BSA-blocked photocleavable Abltide beads with 100 μg/mL K562 cell lysate,

and 1× complete protease inhibitor cocktail (Roche) and was incubated at 37 °C for 1 h. After the kinase reactions, beads were separated from the reaction buffer, washed twice with water, and subjected to MALDI-TOF MS analysis.

In Vitro Inhibition Assay. Dasatinib and imatinib were assayed in vitro using both recombinant c-Abl and K562 cell lysate. Assays with c-Abl or K562 cell lysate were as above with the addition of varying concentrations of inhibitors. A series of kinase reactions with 50 μM ATP and 0, 1, 10, 100, 500, 10^3, 10^4, or 10^5 nM Imatinib and 10 μM ATP and 0, 0.2, 0.5, 1, 2, 5, 10, 100, or 1000 nM Dasatinib were performed for 1 h using c-Abl at 30 °C and K562 cell lysate at 37 °C, respectively. After the kinase reactions, the beads were separated and washed with water twice, and stored in 5 μL of water at 4 °C. The degree of phosphorylation for each sample was determined by MALDI-TOF MS.

MALDI-TOF MS Analysis. Sample preparation for MALDI-TOF analysis was as described (*47*), except that the dry spotted samples were irradiated by UV light of 366 nm for 20 min prior to addition of α-cyano-4-hydroxycinnamic acid (CHCA) matrix solution onto each sample spot and analysis on a Voyager DE. The phosphorylation ratio of Abltide immobilized on magnetic beads was determined according to the previously described computational method (*47*).

RESULTS

We used solid-phase peptide synthesis to immobilize a tyrosine kinase peptide substrate with a photocleavable linker onto silica-coated superparamagnetic beads to enable simple and straightforward kinase assays (Figure 1). After the kinase reaction, both phosphorylated and unphosphorylated substrate peptide are released from the beads by UV photocleavage and then detected by MALDI-TOF MS. The phosphorylated and unphosphorylated peptide peaks are offset by 80 Da (*48*, *49*) and the degree of phosphorylation can be estimated by the relative intensities of the two peaks.

To test the new protein kinase assay technique, we chose the model system of the oncogenic protein kinase, Bcr-Abl, and a synthetic substrate peptide, Abltide. Bcr-Abl is a fusion gene product resulting from the Ph1 reciprocal 9:22 translocation (*50*, *51*), and its constitutive activity is responsible for cancer onset and progression in CML (*52*). Bcr-Abl kinase from cell extracts of the K562 cell line derived from human chronic myeloid leukemia and its counterpart recombinant c-Abl kinase were both used for this study. With this model system, Abltide was readily immobilized on magnetic beads and phosphorylated by kinases. After the reaction, MALDI-TOF MS could detect both phosphorylated and unphosphorylated peptides cleaved from the magnetic beads upon UV light exposure (λ = 366 nm).

Currently, two kinds of spacer linkers have been extensively used to distance peptides from solid supports: (i) poly(ethylene glycol) (PEG) linkers, well-known for their ability to prevent nonspecific interactions, also act as hydrophilic spacers minimizing any detrimental interaction between the attached peptide and solid surface (*53*−*55*); and (ii) glycine spacers, generally inserted into the peptide sequence, can improve the accessibility of enzymes to peptide substrates (*56*). To optimize the kinase reactions, we investigated the effect of two different linkers on

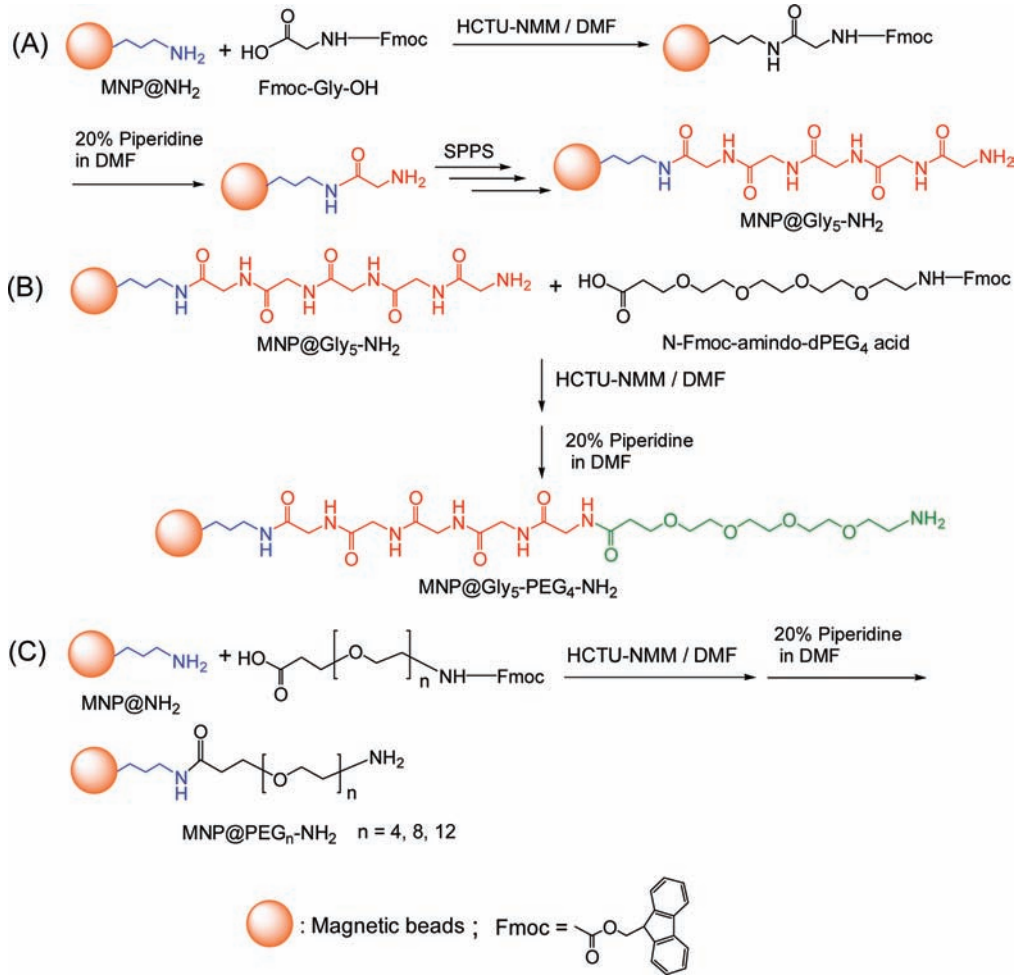

Figure 2. Structural design and synthesis of magnetic beads bearing different surface spacers via the solid-phase peptide synthesis (SPPS) technique. (A) Pentaglycine spacers. (B) Diblock spacers consisting of PEG and pentaglycine segments. (C) Single PEG spacers with different lengths.

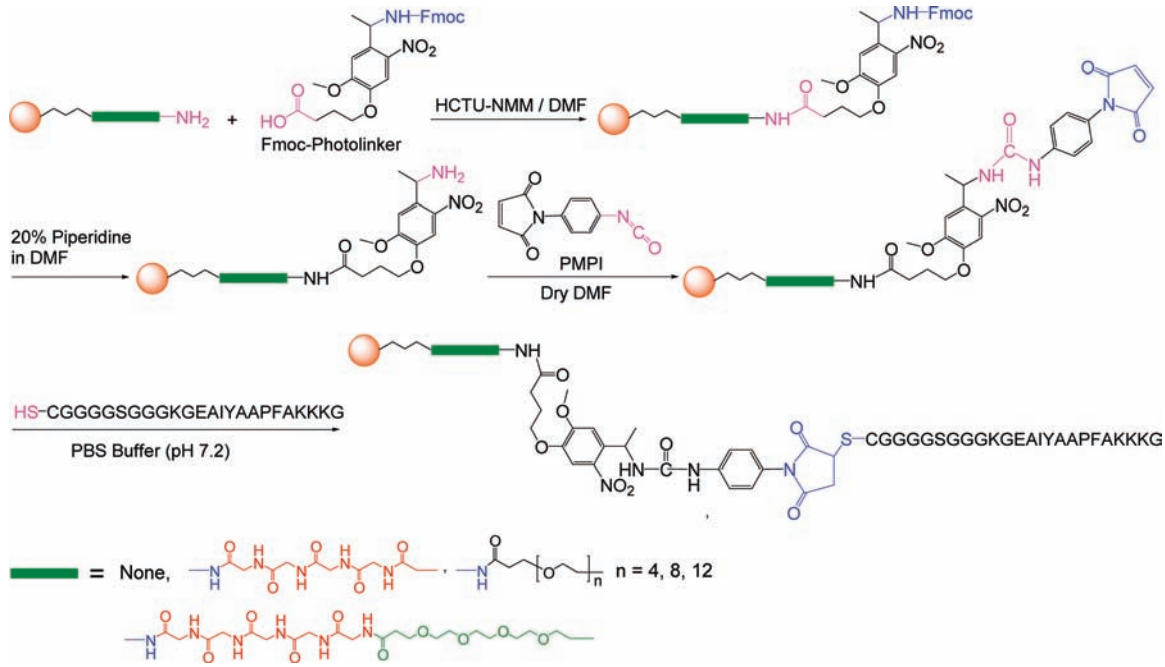

Figure 3. General synthetic route for photocleavable Abltide-conjugated magnetic beads with different surface spacer structures (pentaglycine spacer, single PEG spacers with different lengths, and diblock spacer consisting of PEG and polyglycine) through successive coupling−deprotection, amino−isocyanate, and highly selective thiol−maleimide reactions starting from magnetic beads bearing different surface spacers (denoted by the green bar).

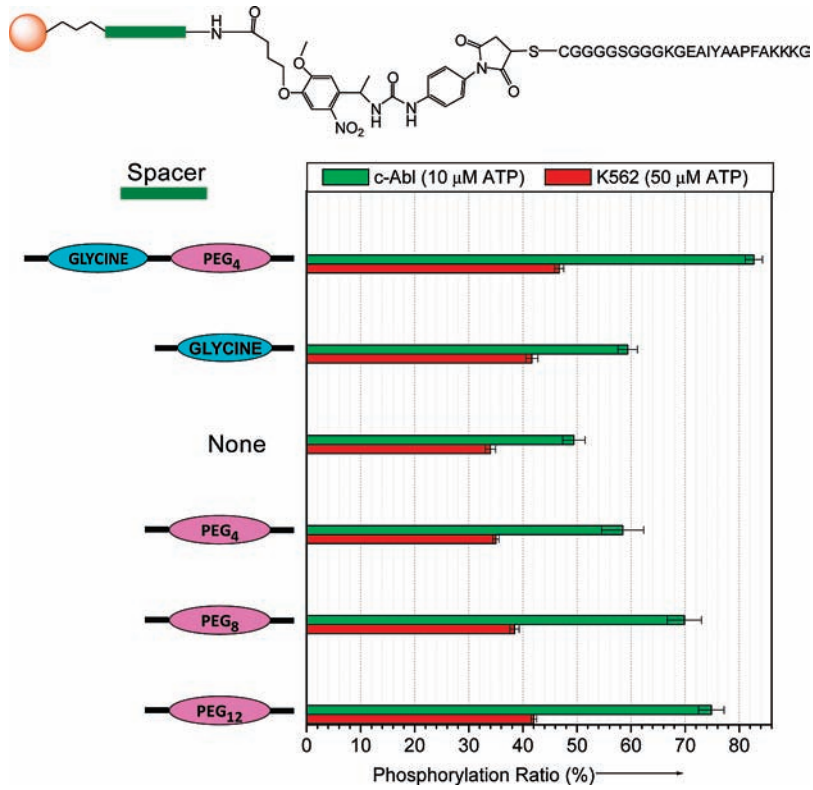

Figure 4. Effect of the surface spacer between the Abltide substrate and magnetic bead support on phosphorylation of Abltide by both c-Abl at 30 °C and K562 cell lysate at 37 °C for 1 h, respectively. The general structure of photocleavable abltide-conjugated magnetic beads was given in the upper panel, and the green bar represents different surface spacer structures shown in the lower left panel. The phosphoryaltion ratios corresponding to each surface spacer by both c-Abl and K562 cell lysate were determined by MALDI according to the intensity of phosphorylated and unphosphorylated peaks. Each experiment represented in the lower right panel was performed in triplicate.

phosphorylation of peptide substrates. First, the surface of amino-functionalized silica-coated superparamagnetic beads (**MNP@NH$_2$**) was modified by introducing a five glycine spacer (Gly_5) by a five-step standard solid-phase peptide synthesis (SPPS) procedure shown in Figure 2A. Glycine spacer-modified beads (**MNP@Gly$_5$-NH$_2$**) were further modified by insertion of a PEG linker using N-Fmoc-amino-dPEG$_4$ acid according to the standard SPPS protocol (Figure 2B). As a result, dual spacer-modified beads (**MNP@Gly$_5$-PEG$_4$-NH$_2$**) were produced. For comparison, the beads were also modified by single PEG spacers

of varying lengths (Figure 2C). The beads with different surface spacers, **MNP@NH$_2$**, **MNP@Gly$_5$-NH$_2$**, **MNP@PEG$_n$-NH$_2$**, and **MNP@Gly$_5$-PEG$_4$-NH$_2$**, were then coupled to an Fmoc-photolinker and deprotected and the amino groups reacted with *N*-[*p*-maleimidophenyl]isocyanate to form surface maleimide-functionalized beads. The maleimide-functionalized beads were then reacted with the amino-terminal cysteine on CG$_4$SG$_3$-Abltide (**C**GGGGSGGG*KEAIYAAPFAKKK*G) in PBS buffer to produce photocleavable Abltide-conjugated superparamagnetic beads with different surface spacer linkers (Figure 3). These beads were examined in kinase assays.

Abltide conjugated to superparamagnetic beads was phosphorylated in kinase buffer for 1 h with c-Abl at 30 °C or K562 cell lysate at 37 °C. The degree of phosphorylation of peptide substrates conjugated to beads via different linkers was determined by the relative intensity of phosphorylated and unphosphorylated peptide peaks in the MALDI spectrum, as summarized in Figure 4. It is clear that both single glycine and PEG spacers are able to improve the phosphorylation efficiency, most likely due to the increase in molecular mobility of the substrate peptide and kinase accessibility to peptide. The number of PEG units in the spacer had a measurable effect on phosphorylation, with longer spacers yielding a slightly higher phosphorylation ratio. We found that insertion of PEG$_{12}$ between the peptide and solid support yielded optimal phosphorylation efficiency, consistent with Katayama et al. (*33*). In particular, the diblock spacer consisting of poly(glycine) and PEG markedly increased the phosphorylation efficiency of peptide substrates, perhaps due to the complementary features of the two spacers. Therefore, the photocleavable Abltide-conjugated magnetic beads with a diblock spacer of poly(glycine) and PEG were used for the kinase inhibition assays.

A common application for assays reporting the phosphorylation of peptides is to evaluate the inhibitory ability of different drugs on protein kinases. Two clinically useful Abl kinase inhibitors, imatinib and dasatinib, have been used in the treatment of CML via targeting the oncogenic Bcr-Abl kinase. Imatinib and dasatinib were evaluated using our magnetic bead-based kinase assays. The Abltide-conjugated beads were incubated for 1 h with c-Abl kinase at 30 °C or K562 cell lysate at 37 °C with 50 μM ATP + 0−100 μM for imatinib, and with 10 μM ATP + 0−1 μM for dasatinib. The peptides were then released and analyzed by MALDI-TOF MS. Figure 5A shows a representative set of MALDI spectra of Abltide released from beads after phosphorylation by c-Abl kinase at different imatinib concentrations. The expected 80 Da increase in mass relative to the unmodified peptide was observed after peptides were phosphorylated, yielding two singly charged peaks at m/z = 2478.22 and 2398.35. With no addition of inhibitor, the Abltide substrate was 86% phosphorylated, calculated according to the relative intensity of the phosphorylated and unphosphorylated peptide ions. The c-Abl kinase activity was gradually inhibited with the increase of imatinib concentration, and fully blocked at 10 μM imatinib (Figure 5A). There is a minor peak (denoted by a star) at m/z = 2355.70 attributed to fragmentation at a site other than the site predicted for photocleavage (Figure 5B). We found that minor peak intensity depends on the completion of photocleavage prior to analysis, as well as the amount of matrix spotted and laser intensity during MALDI analysis. We found that the relative intensity ratio of the minor peaks formed from phosphorylated and unphosphorylated peptides was equal to the major ones. Therefore, the phosphorylation ratio of Abltide substrate was calculated according to the relative intensities of the major phosphorylated and unphosphorylated peaks. A dose-dependent effect on phosphorylation of Abltide by c-Abl or K562 cell lysate was observed for each inhibitor (Figure 6), and IC$_{50}$ values were calculated by fitting to sigmoidal

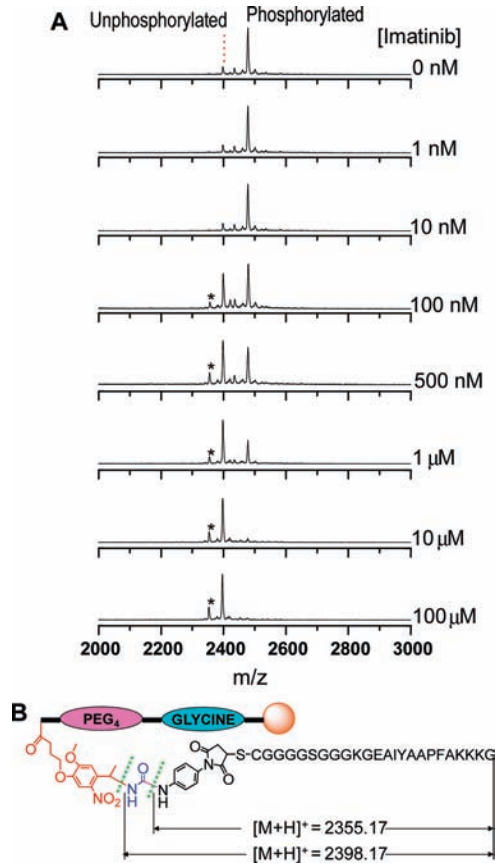

Figure 5. (A) A representative set of MALDI-TOF MS spectra of the photocleavable Abltide-conjugated magnetic beads after 1 h phosphorylation by c-Abl at different imatinib concentrations. The peaks of phosphorylated and unphorylated peptide substrates were observed at m/z = 2478.22 and 2398.35, respectively. The minor peak (denoted by a star) at m/z = 2355.70 is attributed to fragmentation at a site other than that predicted for photocleavage. (B) Predicted photocleavage and minor cleavage sites and theoretical exact mass of their corresponding generated peptide substrate fragments.

dose−response curves (Table 1). The IC$_{50}$ values of imatinib against c-Abl and K562 cell lysate were 0.53 and 1.10 μM, respectively. These values are higher than the literature IC$_{50}$ values, perhaps reflecting the use of a higher ATP concentration, 50 μM, in our experiments. However, for dasatinib, where we used 10 μM ATP, the IC$_{50}$ values against c-Abl and K562 cell lysate of 12.0 and 2.3 nM are close to reported values.

DISCUSSION

Although much progress has been made in developing protein kinase assay techniques for understanding biological regulatory pathways, many challenges still exist (*57*). Only a fraction of techniques are compatible with cell lysates or within cells (*57*). It has become clear that MALDI-based label-free heterogeneous kinase assays may have a significant application value in this field. In this study, we explored the use of magnetic beads for heterogeneous kinase assays. We chose magnetic beads as solid supports, because they can greatly facilitate on-bead preparation of peptide conjugates and rapid separation of phosphorylated products as well as being amenable to automated processing. In addition, they can promote the ionization of phosphorylated products during the process of MALDI analysis and further increase assay sensitivity (*58*). However, the immobilization of peptide substrates on the solid support plays a key role in the overall heterogeneous kinase assays. There are many strategies for immobilization of peptide substrates onto solid supports (*30*, *59*). However, our magnetic bead-based SPPS strategy has

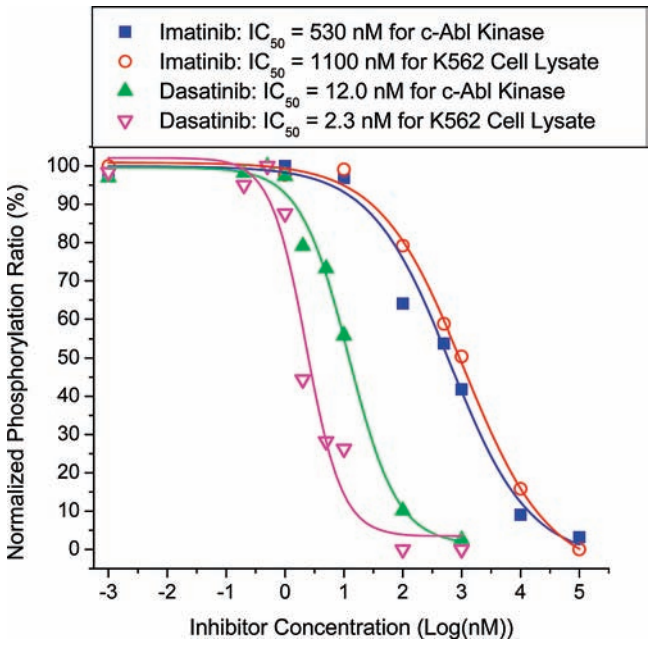

Figure 6. Inhibition assays using imatinib and dasatinib against c-Abl kinase and K562 cell lysate using the photocleavable substrate on magnetic beads, and MALDI-TOF MS analysis. The degree of phosphorylation was calculated from the ratio of phosphorylated and unphosphorylated peak intensities. Each data point is the average of three spectra. ATP concentrations for imatinib and dasatinib inhibition assays were 50 μM and 10 μM, respectively.

Table 1. IC_{50} of Inhibitors

	IC_{50} (nM), found		IC_{50} (nM), reported	
inhibitor	c-Abl	K562	c-Abl	K562
imatinib	530	1100	440 (*60*)	560 (*61*), 945 (*62*)
dasatinib	12	2.3	9 (*63*),14 (*64*)	1.0 (*65*), 16 (*62*)

shown distinct advantages over the published approaches, because it conveniently inserts different spacers between the peptide substrate and magnetic beads.

We performed a systematic study by introducing different spacers between peptide substrates and magnetic beads to understand their influence on the kinase assays. For this purpose, poly(glycine), PEG spacers, and their combinations were employed. Without spacers, the phosphorylation ratios of peptide substrates were quite low. Both the single pentaglycine spacer and PEG spacer were able to enhance the phosphorylation ratios of peptide substrates. Notably, a diblock spacer consisting of polyglycine and PEG prepared in situ by the magnetic bead-based SPPS strategy greatly improved the phosphorylation ratios as compared with the other spacers due to the synergic effects of the two types of spacers. The introduction of the diblock spacer made the MALDI-based kinase assays work well with both recombinant kinases and cell lysates. As this new kinase assay technique can rapidly quantify protein kinase activities directly from complex cellular mixtures, it provides a reasonable strategy for the development of cell-based screens for drug discovery. Unlike traditional methods, MALDI can differentiate multiple peptides and their modified forms. Thus, the use of the label-free MALDI detection tool provides this new kinase assay with the potential for quantitative evaluation of the relative potencies of a drug to different kinases.

CONCLUSIONS

We have developed a new label-free protein kinase assay technique in which magnetic beads were used as an analytical platform to immobilize peptide substrates via photocleavable linkers and released by UV light for MALDI detection. Both poly(glycine) and PEG spacers are able to improve phosphorylation efficiency and a diblock poly(glycine) and PEG spacer was found to be even more efficient than any single spacers. This simple and efficient assay technique may be adapted to high-throughput screening and generalized to a wide range of multiple post-translational modification analysis.

ACKNOWLEDGMENT

We thank Wendy Stock for kindly providing imatinib and Jonathan Goya for his helpful comments on the manuscript. This work was supported by National Institutes of Health grants HG003864, GM074691, and CA126764.

Received July 9, 2010; Revised Manuscript Received August 22, 2010

Target specific small molecules as modulators of drug delivery may play a significant role in the future development of therapeutics. Small molecules can alter the in vivo pharmacokinetics of therapeutic macromolecules leading to more efficient drug delivery with less systemic toxicity. The potential of creating a more effective drug delivery system through glycosylation has led, for instance, to the addition of galactose to increase drug delivery to the liver. However, there are many other monosaccharides with potentially useful targeting properties that require further characterization. Here, we investigate the potential of glycosylation to guide molecular therapies using five different monosaccharides conjugated to human serum albumin (HSA). Additionally, we investigate how the amount of glycosylation may alter the pharmacokinetic profile of HSA. We introduce the use of in vivo near-infrared optical imaging to characterize the effect of differential glycosylation on the pharmacokinetics of macromolecules.

INTRODUCTION

Target-organ or cell specific drug delivery can alter the pharmacokinetics of macromolecules including proteins or nanoparticles, thus changing drug catabolism and excretion with possible improvements in the therapeutic index (i.e., improved target delivery with decreased off-target toxicity). Conjugation of drugs with small molecules such as sugars, short peptides, or folic acid can dramatically alter the pharmacokinetics (*1*). Glycosylation, in particular, has been investigated for targeting hepatocytes, macrophages, vascular endothelial cells, and various cancer cells via the so-called "lectin" family of sugar receptors, commonly overexpressed on cancer cells (*2*−*5*). For example, radiolabeled galactose conjugated to albumin has been used to assess hepatocyte function. Fluorescence-labeled galactosamine conjugated albumin has recently been found to specifically bind, internalize, and visualize the peritoneal dissemination of various ovarian cancer nodules with high specificity and sensitivity (*6*). Through these studies, it becomes clear that galactose conjugation dramatically alters the biodistribution of the molecule to which it is bound. Other monosaccharides may lead to similar alterations in catabolism and excretion.

The effect of a variety of different types and amounts of monosaccharides has not been systematically studied. Here, we conjugate low (ranging 3 to 5) and high (ranging 23 to 25) numbers of various monosaccharides (galactose-β, glucose-α, mannose-α, and fucose α and β) to human serum albumin (HSA), which is also labeled with a near-infrared (NIR) fluorescent probe. These conjugates were then used to evaluate the change in pharmacokinetic and excretion using NIR fluorescence imaging.

EXPERIMENTAL PROCEDURES

Synthesis and Quality Control of Monosaccaride Conjugated Albumin. Linker-modified monosaccharides (Figure 1) were prepared as reported previously, and conjugation to HSA was carried out as reported previously for bovine serum albumin conjugates (*7*, *8*). Briefly, linker-modified monosaccharides were dissolved in a 50/50 mixture of DMF/H_2O at a final concentration of 150 mM. *N*-(3-Dimethylaminopropyl)-*N*′-ethyl-carbodiimide hydrochloride (EDC, Sigma-Aldrich, St. Louis, MO) was dissolved in a 50/50 mixture of DMF/H_2O at a final concentration of 300 mM. *N*-Hydroxysuccinimide (NHS, Sigma-Aldrich) was dissolved in DMF at a final concentration of 300 mM. The NHS ester was preformed by combining the carbohydrate, EDC, and NHS in an Eppendorf tube at a ratio of 2:1:1 and allowing the reaction to stand at room temperature with occasional gentle mixing. After 60 min, each reaction mixture was added to a solution of HSA (4 mg/mL in 10 mM sodium borate, 90 mM NaCl, pH 8.0, Sigma-Aldrich) that had been precooled to 4 °C to give a final ratio of carbohydrate to HSA of approximately 5−8:1 to produce low-density conjugates or 37−72:1 to produce high-density conjugates. After 15 min, the solution was warmed to room temperature and allowed to stand for 1 h (Figure 1). HSA conjugates were then dialyzed extensively against water containing 6 mM NaCl (SpectraPor 7, MWCO = 10 000). The extent of conjugation (Figure 2) was evaluated by measuring the average mass of each conjugate by MALDI-MS (Applied Biosystems Voyager-DE Pro time-of-flight mass spectrometer, Life Technologies Co., Carlsbad, CA) and then determining the mass shift relative to that of unmodified HSA (Table 1; also see Supporting Information Figure 1).

Synthesis of Fluorophore Conjugated Glycosylated HSA Probes. The NHS ester of IRDye 800CW (IR800) was purchased from LI-COR Co. (Lincoln, NE). Glycosylated HSA and non-glycosylated samples (6 nmol) were incubated with

NHS ester of IR800 (40 nmol for low sugar and 60 nmol for high sugar) in 0.1 M Na_2HPO_4 (pH 8.5) at room temperature for 15 min. Each mixture was purified with a Sephadex G25 column (PD-10; GE Healthcare, Piscataway, NJ) (Figure 1). The protein concentration was determined by measuring the absorption at 280 nm with a UV−vis system (8453 Value UV−visible Value System; Agilent Technologies, Santa Clara, CA). The concentration of IR800 was measured by absorption with the UV−vis system to confirm the number of fluorophore molecules conjugated to each glycosylated HSA (*9*). The number of fluorophore molecules per all HSA conjugates was ∼1.7−2.3.

In Vivo Imaging. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by the local Animal Care and Use Committee.

Forty micrograms of either high or low IR800-HSA-glucose-α (Glc-α), IR800-HSA-mannose-α (Man-α), IR800-HSA-galactose-*β* (Gal-*β*), IR800-HSA-fucose-α (Fuc-α), IR800-HSA-fucose-*β* (Fuc-*β*), or IR800-HSA (control) was injected intravenously into the tail vein of female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD) ($n = 3-4$ in each group). Mice were anaesthetized with isoflurane, and serial images of the dorsal and ventral surfaces were obtained using the Pearl Imager (LI-COR). The instrument has a light-tight chamber equipped with a cooled charge-coupled device camera. Illumination is with diode lasers, and the excitation and emission filters are specifically tuned for IR800. Images were acquired and processed using *Pearl Cam Software* v 1.0 (LI-COR). Longitudinal images were acquired at 10 min, 6 h, 24 h, and 48 h after injection of the imaging probe; and mice were anesthetized with vaporized isoflurane via nose cone for all imaging. To perform the quantification of signals, regions of interest (ROIs) of equal sizes were drawn and placed over areas representative of background, neck, liver, abdomen, and bladder. Total intensity for each ROI was normalized to the sum of the total intensity of all the ROIs drawn per animal, and the normalized values were used for statistical analysis.

Ex Vivo Organ Imaging. After imaging at the 48 h time point, the mice were euthanized with carbon dioxide inhalation, and liver, spleen, kidneys, blood, bone, bowel, stomach, and pancreas were removed. Organs were placed on a nonfluorescent black plate and imaged with the Pearl Imager. However, for all conditions except with the IR800-HSA probe, only the liver could be depicted. So, we then compared uptake of each glycosylated conjugate on an organ by organ basis.

For performing the quantitative analysis, identically sized ROIs were drawn on comparable parts of each corresponding organ. Total intensity for each ROI was used for statistical analysis. Sugar to sugar comparison was performed with a one-way analysis of variance (ANOVA) with Tukey's multiple comparisons post-test. High vs low sugar comparison was performed with an unpaired, two-tailed *t* test. All statistical analysis was performed using GraphPad *Prism* v 4.0c for Macintosh (GraphPad Software, San Diego, CA, www.graphpad.com).

RESULTS

In Vivo Biodistribution Study Using NIR Fluorescence Imaging. *Findings with HSA-IR800 (Control).* To assess the influence of IR800 conjugation on HSA biodistribution, we carried out serial in vivo imaging studies using an HSA-IR800 probe without glycosylation (Figure 3). At 10 min, diffuse distribution was observed throughout the body of the mouse. The primary location of the HSA at 10 min was in the vasculature, as demonstrated by clear visualization of the blood vessels (Figure 3). The liver was also identified, most likely due to the high blood volume in the liver. At 6 h, we observed

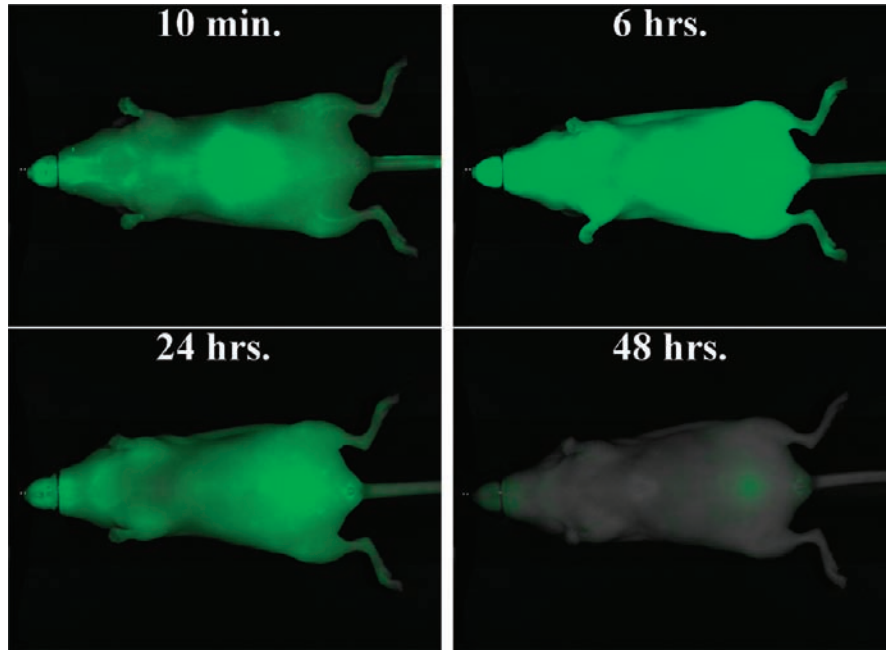

Figure 3. Time course of non-glycosylated HSA labeled with the NIR fluorophore, IR800, at 10 min, 6 h, 24 h, and 48 h after injection demonstrating a lack of targeted HSA delivery.

a diffuse signal with loss of the vessel delineation, likely representing leakage of IR800-HSA into the extracellular space and capillary beds near the skin. At 24 and 48 h, a similar diffuse pattern was observed that differed only in intensity. By 48 h, signal was barely visible.

Low Sugar-HSA-IR800 Probes. The time course of fluorescence intensity was obtained after injection of IR800-HSA labeled with low sugar numbers (3−5/HSA) of Glc-α, Man-α, Gal-β, Fuc-α, or Fuc-β (Figure 4a). Rapid accumulation of fluorescence was noted in the liver just 10 min after injection for all of the low sugar probes. Also at 10 min, the IR800-HSA low sugar probe was seen in the vessels with a minimal bladder signal. The vasculature disappeared by 6 h. At 6 h, in addition to intense liver signal, Glc-α and Gal-β labeled probes demonstrated high bowel (arrows) and some bladder signal, while Fuc-α, Fuc-β, and Man-α showed only signal in the liver and bladder (not bowel) at 6 h. Another observation is that, for all of the low sugar conjugates, the intensity of signal around the liver and abdomen was brighter at 6 h than at 10 min. At 24 h, all low sugar conjugates showed only liver signal with slight bladder signal associated with an overall decrease in fluorescence intensity. At 48 h, all sugar conjugates demonstrated minimal liver signal, although Fuc-α and Fuc-β displayed higher liver signal than Glc-α, Gal-β, and Man-α.

High Sugar-HSA-IR800 Probes. The high sugar probes (high sugar HSA-IR800) demonstrated rapid accumulation in the liver at 10 min (Figure 5a). However, unlike the low sugar probes, the blood vessels were not clearly seen 10 min after injection. Further, all high sugar probes showed some bladder signal at 10 min. At 6 h, Glc-α, Gal-β, and Fuc-β demonstrated high liver, bowel (arrow), and bladder signal. In contrast, Man-α and Fuc-α did not demonstrate bowel signal. By 24 h, the high sugar probes show only faint liver and bladder signal with Gal-β demonstrating the lowest liver signal intensity. At 48 h postinjection, the high sugar probes were no longer visible.

In the quantitative comparison of both the low (Figure 4b) and high (Figure 5b) sugar probes, the only significant difference was observed in the signal within the abdomen at 6 h. Similar results were obtained between high and low sugar probes, with Glc-α and Gal-β demonstrating the highest relative percentage of total intensity at 6 h. In both the high and low sugar groups, Gal-β abdomen intensity was statistically significantly higher compared to Man-α, Fuc-α, and Fuc-β ($p < 0.05$).

Ex Vivo Organ Analysis. Only the liver and spleen showed a difference between the probes (Figures 6 and 7). The low Gal-β probe demonstrated the lowest relative intensity of the low sugar probes at 48 h (Figure 6b). However, this difference is only statistically significant in comparison to low Glc-α ($p < 0.05$) (Figure 6d). The rest of the low sugar probes were similar in intensity. The high Gal-β probe also had the lowest relative intensity when compared to the other high sugar probes (Figure 6c). This is statistically significant in comparison to high Glc-α, Man-α, and Fuc β ($p < 0.05$) (Figure 6e). The other organ that showed a difference was the spleen. In the low sugar probes, low Man-α had the highest total intensity (Figure 7b). This increase was statistically significant relative to low Glc-α, Gal-β, and Fuc-β ($p < 0.05$) (Figure 7d). Low Fuc-α is relatively greater in intensity than low Glc-α, Gal-β, and Fuc-β, but that difference was not statistically significant. The high sugar probes have similar intensities in the spleen (Figure 7c and e).

When comparing liver signal between low and high sugar conjugates using the same sugar in ex vivo organs at 48 h, all low sugar conjugates had higher total intensity than the high sugar conjugates (Figure 6f). Low Glc-α, Man-α, Gal-β, Fuc-α, and Fuc-β all had significantly higher total intensity than the high conjugates with *P* values of 0.02, 0.03, 0.01, 0.009, and 0.01, respectively. When comparing splenic signal in ex vivo organs at 48 h, all low sugar conjugates had a relatively higher total intensity than the high sugar conjugates (Figure 7f). Low Glc-α is the only sugar conjugate that did not show statistical significance. Low Man-α, Gal-β, Fuc-α, and Fuc-β all have significantly higher total intensity than the high conjugates with *P* values of 0.0011, 0.0079, 0.014, and 0.0042, respectively.

DISCUSSION

Here, we used optical imaging to observe the biodistribution and excretion patterns associated with molecular probes composed of HSA conjugated to high and low numbers of various monosaccharides: Glc-α, Gal-β, Man-α, Fuc-α, and Fuc-β, all conjugated with identical conjugation chemistry. HSA is a

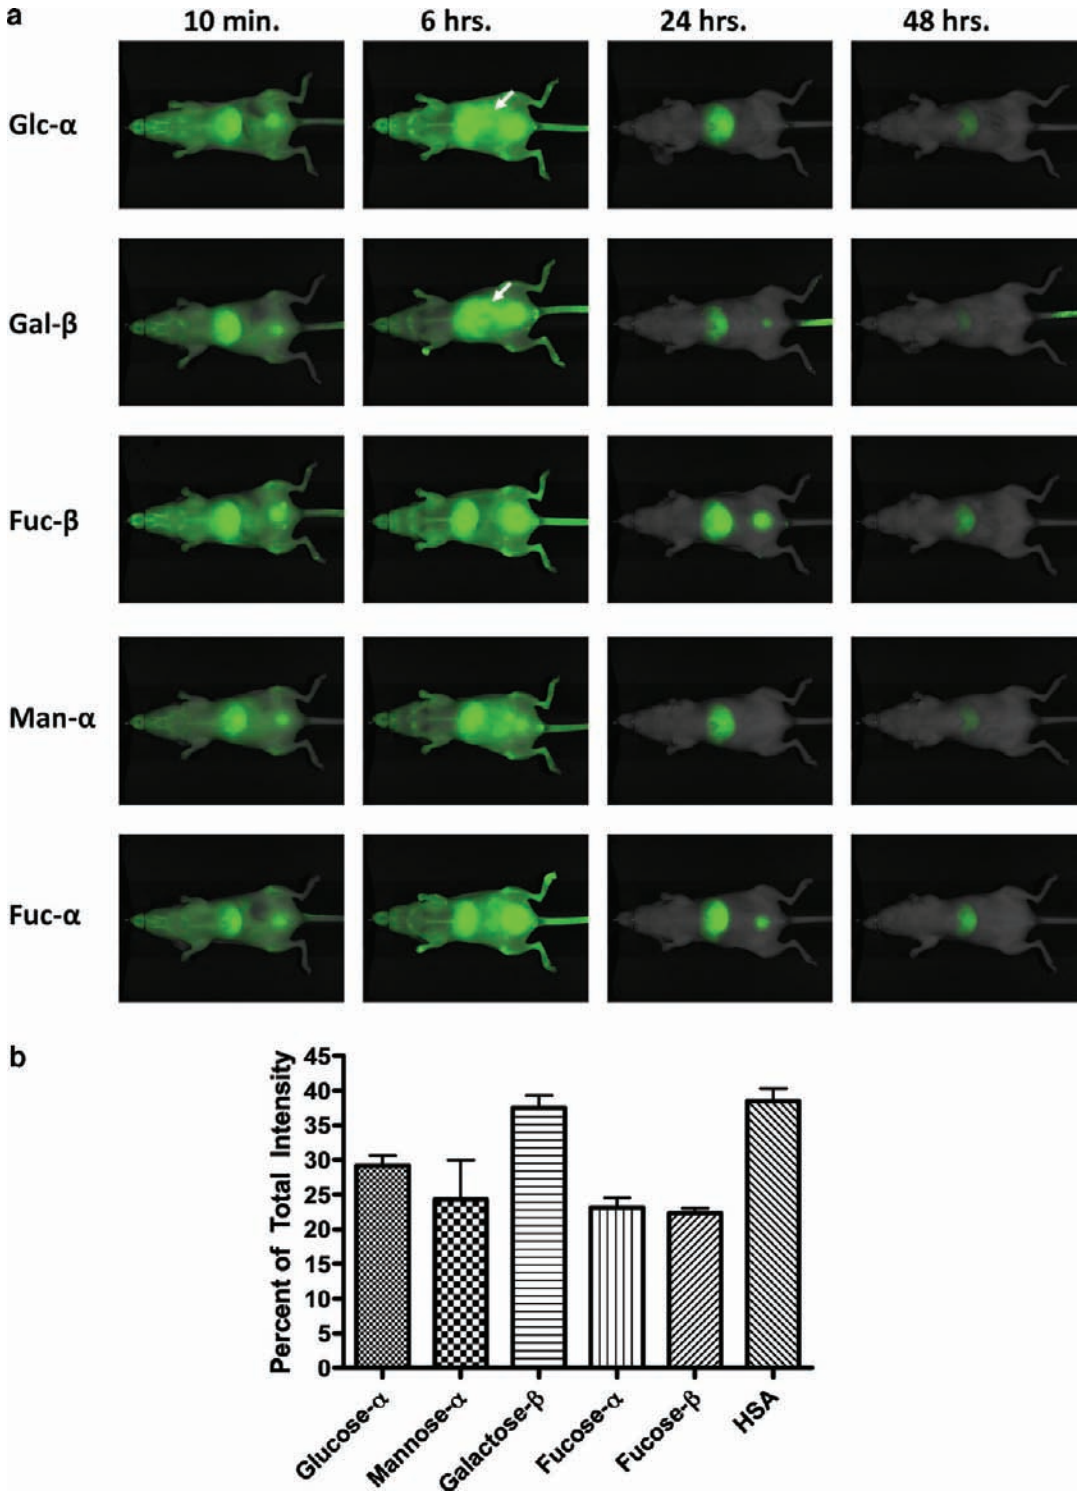

Figure 4. Time course mouse images of HSA glycosylated with a low sugar number at 10 min, 6 h, 24 h, and 48 h after injection are shown in (a). Rapid liver uptake can be appreciated as early as 10 min after injection in all sugar-conjugated albumin compared with unconjugated albumin shown in Figure 2. At 6 h, low Glc-α and Gal-β demonstrate activity present in the bowel (arrows). This is different when compared to the other sugars, and this difference is quantified and graphically represented in (b).

representative soluble protein that has high bioavailability, is nonimmunogenic, and demonstrates good in vivo stability with an average half-life of 19 days (*10*). The conjugation of IR800 to HSA demonstrated distribution throughout the body with little specificity suggesting that the addition of the NIR probe minimally changed the biodistribution of HSA. However, the conjugation of either low numbers or high numbers of sugar molecules led to rapid and specific changes in biodistribution, particularly to the liver and spleen. Similar observations have been made using radiolabeled BSA conjugated to galactose, fucose, and mannose (*11*−*13*). The effect of the amount of sugar residue conjugated to BSA on binding properties has been studied and reveals that mannosylated BSA demonstrated a higher rate of uptake as the number of mannose residues per BSA molecule increased with a plateau effect (*13*). Similarly, we found that conjugation of HSA to a low number of sugar molecules leads to slower clearance of the probe from the circulation compared to HSA conjugated to a high number of

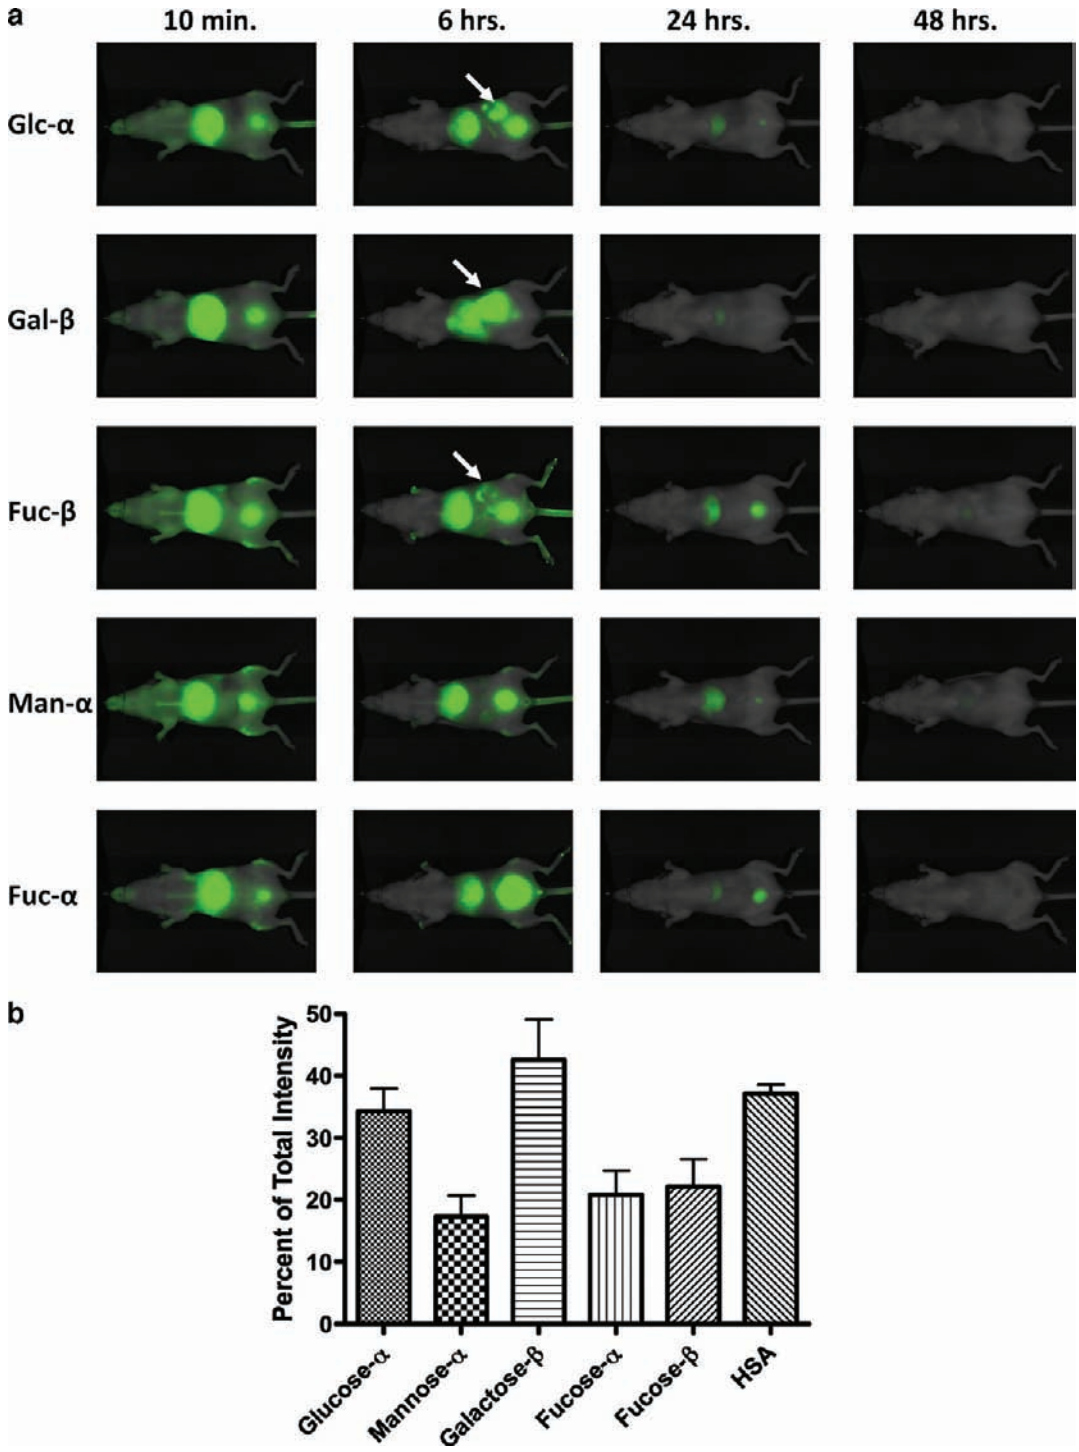

Figure 5. (a) Time course of HSA glycosylated with a high sugar number at 10 min, 6 h, 24 h, and 48 h after injection demonstrating rapid liver accumulation after just 10 min. Six hours after injection, high Glc-α, Gal-β, and Fuc-β have activity present in the bowel (arrows). (b) Graphical representation quantifying the differences in intensity of the bowel signal. Also, note that fluorescence signal is not detected at 48 h.

sugar molecules. This is demonstrated by the observation that, at 10 min, the blood vessels can still be observed in all low sugar HSA conjugates but not in high sugar HSA conjugates.

With these conjugation and labeling methods, both reactions can use amino groups at the side chain of lysine or at the N-terminal. There are 60 lysines in the HSA; therefore, theoretically 61 available conjugation sites exist in a single albumin molecule. In the previous literature, a maximum of 35 molecules of diethylenetriamine pentaacetic acid (DTPA) were conjugated with a single albumin molecule via the same amine groups for the use of macromolecular MRI contrast agents (*14*). In our experience, a maximum of 28 galactosamine and glucosamine molecules were conjugated with a single albumin molecule among 63 theoretically available carboxyl groups of glutamate using a similar direct amidation method using EDC (*15*). Therefore, although numbers of available conjugation sites are varied depending on molecules to be conjugated and conjugation chemistry, about half of the theoretically available functional groups might be practically conjugatable probably because of steric hindrance.

The current study suggests that different organs have different overall receptor specificity for different glycosylated probes. The hepatocytes, for instance, demonstrate an affinity for galactose, and this is mainly through the asialoglycoprotein receptor (*16*).

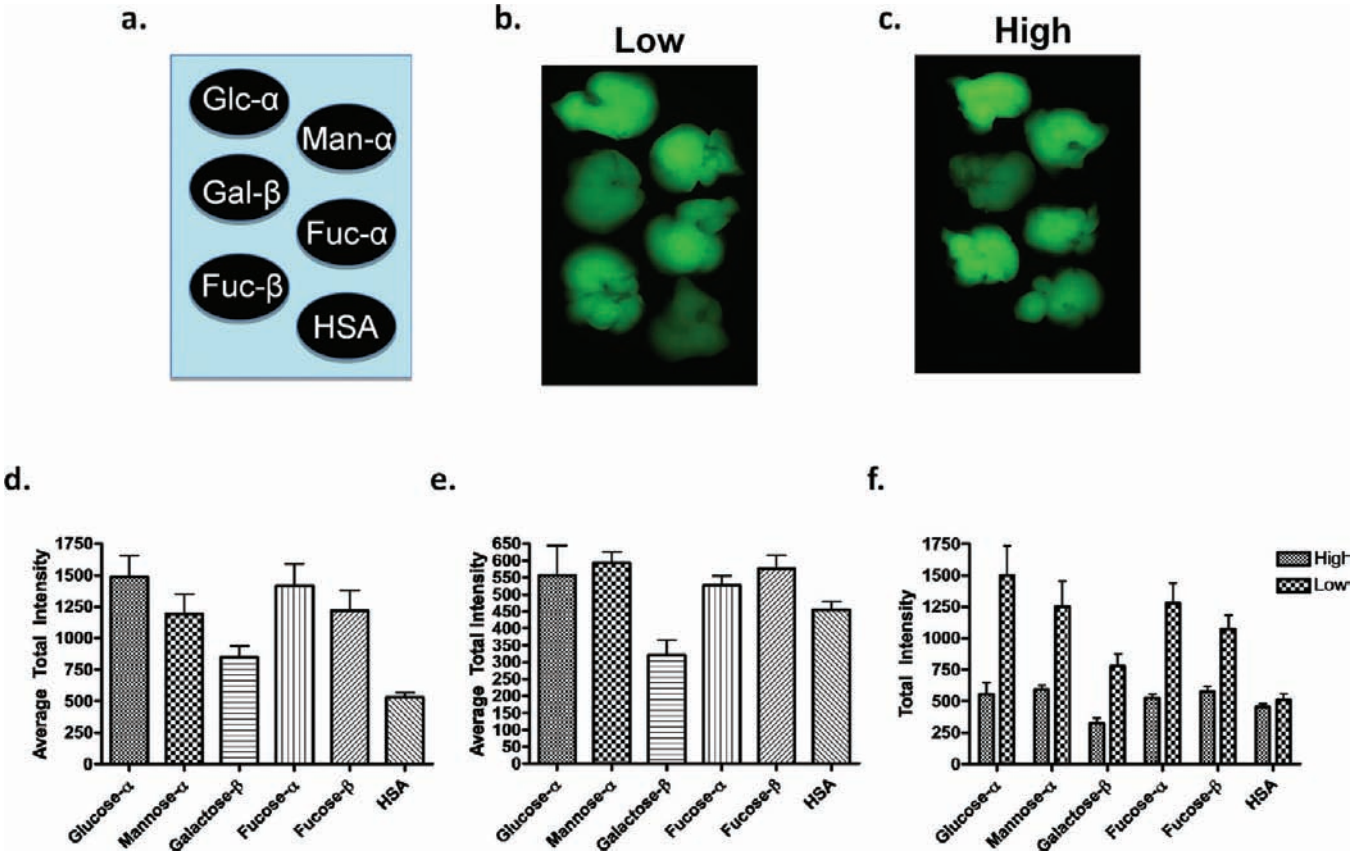

Figure 6. Ex vivo quantitation of liver intensity 48 h after injection. (a) Schematic of where (b) low or (c) high sugar conjugated HSA distributes. (d) Low and (e) high sugar quantitation is also represented graphically. (f) At 48 h, low sugar conjugates are brighter than high sugar conjugates in the liver.

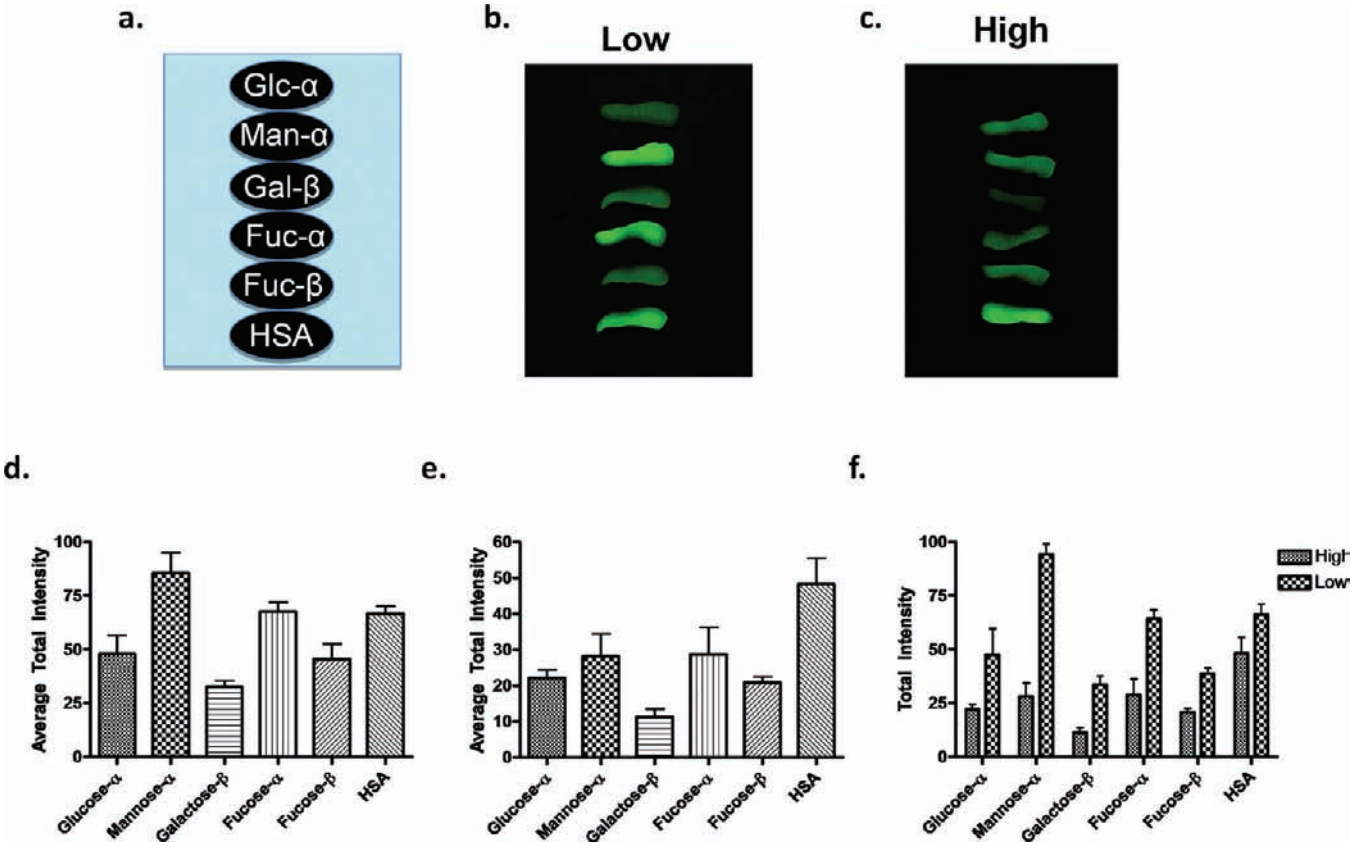

Figure 7. Ex vivo quantitation of spleen intensity 48 h after injection. (a) Schematic to illustrate where (b) low and (c) high sugar conjugated HSA is located. (d) Low and (e) high sugar quantitation is represented graphically. (f) Comparison at 48 h illustrates that low sugar conjugates are brighter than high sugar conjugates in the spleen.

Nonparenchymal cells in the liver include sinusoidal endothelial cells and Kupffer cells. Mannose receptors are expressed on both of these nonparenchymal cell types (*17*). However, there is a lectin only expressed by Kupffer cells that demonstrates high affinity for fucose and galactose but not mannose (*18*). Cultured rat sinusoidal endothelial cells and Kupffer cells were used to distinguish between the binding characteristics of BSA conjugated mannose and fucose (*17*). It was demonstrated that both mannosylated and fucosylated BSA were taken up by sinusoidal endothelial cells, and this uptake was inhibited by excess mannose or fucose but not by galactose. They further demonstrated that Kupffer cells could take up mannosylated and fucosylated BSA, but the uptake of fucosylated BSA could be inhibited by galactose (*17*).

The specific binding of glycosylated HSA molecules to cell surface receptors is supported by the excretion profiles exhibited by the different sugar conjugates. Glc-α and Gal-*β* demonstrate rapid liver uptake and excretion into the gut. This supports the concept that Glc-α and Gal-*β* may be preferentially taken up by hepatocytes, eventually culminating in hepatobiliary excretion. Man-α and Fuc-α, however, do not demonstrate gut excretion observed by Glc-α and Gal-*β*, suggesting that these sugars may lead to specific uptake into the liver via a different receptor. It would make sense that uptake of Man-α and Fuc-α by nonparenchymal cells via the mannose receptor leads to excretion by routes other than bile. Additionally, the presence of the mannose receptor on macrophages in the spleen explains the increased signal observed by low Man-α and low Fuc-α on ex vivo organ studies.

An additional challenge to using optical imaging probes is their inability to accurately quantitate signal compared with radionuclide imaging including single photon emission tomography (SPECT) and positron emission tomography (PET). This limitation is minimized with NIR probes which have much better light transmission properties in tissue than do visible range probes. Nonetheless, absolute molecule quantitation, similar to what can be done with radioisotopes, cannot be achieved using the current model. However, our semiquantitative results correlate with previous studies using radiolabeling. Quantitation with radiolabeling of albumin conjugated to sugars has some limitations, especially since catabolism in the liver or the RES may lead to separation of the radiolabel and the albumin. Moreover, this effect varies with the radioisotope employed. For instance, the difference in the biodistribution of galactosylated BSA among labeling with ^{125}I, ^{131}I, and ^{111}In (*12*) demonstrated that the choice of radioisotope alters the accuracy of quantitative pharmacokinetics. Regardless of the catabolism in hepatocytes or macrophages, radio-iodines are dehalogenated immediately after the internalization and excreted into the urine; in contrast, ^{111}In is trans-chelated and stays in the bound cells (*19*).

Unlike indocyanine green (ICG), IR800 is mostly excreted into the urine (*20*). Therefore, once macrophages catabolize the albumin conjugate, catabolized IR800 re-enters the circulation and is excreted into the urine. However, once hepatocytes catabolize the albumin conjugate, catabolized IR800 can be excreted into the bile. Therefore, we observed the intestinal activity only with Man-α and Fuc-α conjugates.

In conclusion, we demonstrate that labeling with different sugars and altering the number of sugars per molecule dramatically changes the pharmacokinetics and excretion of albumin labeled with IR800 and detected with NIR fluorescence imaging. Gal-*β* and Glc-α conjugates were excreted into the intestine suggesting uptake and catabolism by hepatocytes. In contrast, Man-α and Fuc-α conjugates were excreted into the urine suggesting that catabolism occurred mainly in macrophages. The differences of the splenic accumulation in the ex vivo organ study supported this hypothesis. The sugar conjugation might be useful for changing the catabolism and excretion route of a native compound and might lead to optimization of the dose to maximize efficacy while minimizing toxicity.

Cellular Delivery and Antisense Effects of Peptide Nucleic Acid Conjugated to Polyethyleneimine via Disulfide Linkers

Peter R. Berthold,[†] Takehiko Shiraishi,[†] and Peter E. Nielsen*[,†,‡]

Received August 6, 2010; Revised Manuscript Received August 24, 2010

Peptide nucleic acid (PNA) is potentially an attractive antisense and antigene agent for which more efficient cellular delivery systems are still warranted. The cationic polymer polyethylenimine (PEI) is commonly used for cellular transfection of DNA and RNA complexes, but is not readily applicable for PNA due to the (inherent) charge neutrality of PNA. However, PEI could function as an efficient scaffold for PNA via chemical conjugation. Accordingly, we modified PEI with the amine-reactive heterobifunctional linker agent *N*-succinimidyl-3-(2-pyridyldithio)propionate (SPDP) (with and without a PEG moiety) and further reacted this with a cysteine PNA. The level of modification was determined spectrophotometrically with high accuracy, and the PNA transfection efficiency of the conjugates was evaluated in an antisense luciferase splice-correction assay using HeLa pLuc705 cells. We find that PEI is an efficient vector for PNA delivery yielding significantly higher (up to 10-fold) antisense activity than an analogous PNA−octaarginine conjugate, even in the presence of chloroquine, which only slightly enhances the PEI-PNA activity. The PEI-PEG conjugates are preferred due to lower acute cellular toxicity. Finally, the method can be easily modified to allow for co-conjugation of other small molecules in a high-throughput screening assay that does not require a purification step.

INTRODUCTION

Peptide nucleic acids (PNAs[1]) have many of the properties desired of a gene targeting and antisense agent (*1*−*3*), but efficient cellular delivery and in vivo bioavailability are still a challenge despite the development of a variety of delivery techniques, including the use of cationic cell penetrating peptides (*4*−*7*) and cationic lipid transfection (*8*−*11*).

Polyethylenimine (PEI) is widely used as an efficient, nonviral complexation transfection agent for RNA and plasmid DNA (*12,13*), and it is commercially available in average polymer sizes ranging from ∼0.5 to 800 kDa (*14*). The high transfection efficiency of PEI is considered to arise from what has been coined the "proton sponge" effect (*12, 15*); the high amine content and buffering capacity of PEI results in endosomal import of protons, high osmotic pressure, and subsequent rupture of the endosomes. The endocytotic pathway is not yet clear but has been suggested to be caveolar, since modified PEI directed to clathrin and caveolar pathways is only effective in the latter (*16*). Furthermore, the endocytotic route and endosomal escape may be affected by the DNA/RNA cargo (*13, 17, 18*).

PEI could also be an attractive candidate for PNA delivery. However, because PNA is inherently charge neutral, chemical conjugation rather than simple complexation to PEI is required. The high primary amine content of PEI allows conjugation of a large number of (PNA) ligands using commercially available amine reactive linkers.

PEI transfection efficiency (and toxicity) is mutually correlated to the polymer size and structure, but branched PEI with a molecular weight of 25 kDa (PEI25) is an acceptable compromise between toxicity and transfection efficiency (*19*−*21*). Furthermore, several PEI derivatives with reduced toxicity but retained efficacy have been described, namely, cross-linked PEI (*22*−*24*) or grafted PEI onto less cytotoxic polymers like chitosan (*25*). Thus, we chose PEI25 as a suitable scaffold for PNA conjugation. Finally, modification of PEI with poly(ethylene glycol) (PEG) reduces toxicity of PEI in vitro (*26*−*28*) and in vivo (*29*−*31*), and we therefore decided to also include a PEG containing linker for PNA conjugation.

MATERIALS AND METHODS

Stock solutions of polyethylenimine, M_w 25 kDa (PEI25) and M_w 1.3 kDa (PEI1.3), both from Sigma, were prepared by neutralizing with HCl and accurately diluting to 50 mg/mL.

N-Succinimidyl-3-(2-pyridyldithio)propionate (SPDP) from CalBioChem and SPDP-dPEG$_8$-NHS ester (SPDP-PEG$_8$) from Quanta Biodesign were diluted in dry dimethyl sulfoxide (DMSO, Merck) immediately before use. Buffers used were as follows: 10× phosphate buffered saline (PBS) (100 mM Na_2HPO_4, 20 mM KH_2PO_4, 30 mM KCl, 1.4 M NaCl; all from Merck) adjusted to pH 7.4; HEPES buffer (Sigma), 200 mM, pH 7.4, and borate buffer (0.5 M boric acid (Sigma), pH 9.3). 2,4,6-Trinitrobenzenesulfonic acid (TNBS; Fluka) was used as 0.1 M aliquots, *o*-phthalaldehyde (OPA; Sigma) as 1 M aliquots, and dithiothreitol (DTT; BioUltra, Sigma) as 0.1 M aliquots at pH 9; all were stored at −20 °C.

PNAs were synthesized by standard t-Boc chemistry as previously described (*32*, *33*), purified by HPLC, and characterized by MALDI-TOF. Arg$_8$-PNA (PNA2787): H-(D-Arg)$_8$-Gly-CCT CTT ACC TCA GTT ACA-NH_2 (M_w: 6068.5 Da (calc:

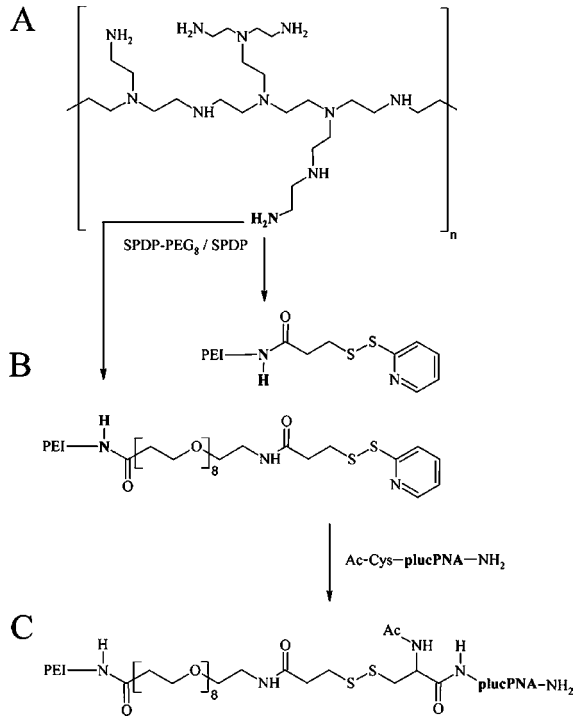

Figure 1. Synthesis and structures of PEI conjugates. Partial structure of polyethylenimine (A) and synthesis strategy. Primary amines were reacted with SPDP or SPDP-PEG_8 reagents containing an *N*-hydroxysuccinimide (NHS) ester and a sulfhydryl-reactive pyridyl disulfide group (B) which could further be reacted with a cysteine-PNA (C). PEI25 was modified to variable degrees with SPDP or SPDP-PEG_8; $n_{average}$ = ca. 15, 30, 68 (see Table 1).

6071.97). Cys-PNA (PNA3140): Ac-Cys-CCT CTT ACC TCA GTT ACA-NH_2 (M_w: 4916.15 Da (calc. 4910.59). C-teminals were amidated and N-terminal cysteine was acetylated. Cys-PNA solutions were stored at −20 °C to avoid disulfide formation.

Quantification of Polyethylenimine. PEI was quantified from primary amine content using a modified version of the TNBS assay (*34*).

PEI, diethylenetriamine (DETA), and ethylenediamine (EDA) (Sigma) were diluted to appropriate concentration in 0.1 M borate buffer, pH 9.3, containing 3% Tween 20 (Merck) and 1 mM TNBS. Following 120 min reaction, UV−vis absorbance spectra were recorded (Cary 300, Varian Inc.).

Preparation of PDP-Functionalized Polyethylenimine. Five milligrams of PEI25 (0.2 μmol) was dissolved in 1.8 mL 1× PBS, pH 7.4, and SPDP (or SPDP-PEG_8) (5 to 20 μmol in 200 μL dry DMSO) corresponding to a theoretical modification of 25−100 linkers per PEI was added. The reaction was stopped after 8 h by gel filtration using Sephadex G-25 Super Fine (G-25SF, GE Healthcare). The Sephadex was swelled according to manufacturer's protocol and preconditioned overnight with PEI1.3 and PEI25, 1 mg each/g of dry Sephadex. Seven milliliters of swelled gel was packed in handmade columns plugged with glass wool and washed thoroughly with HEPES buffer (20 mM, pH 7.4, filtered and degassed) before applying the sample. Fractions were collected in low-bind 1.5 mL polypropylene tubes using a peristaltic pump at 2.5 mL/min by elution with the HEPES buffer. Fractions containing PEI25 conjugates were pooled and dialyzed (Spectra/Por 2, MWCO 12−14 kDa, Spectrum Laboratories.) for 4 h + 12 h (250× volume, buffer change after 4 h) at 4 °C against ddH_2O. The dialysis membranes were pretreated with OPA in 50% ethanol and DETA to remove unspecified traces of sulfur, and washed thoroughly prior to dialysis.

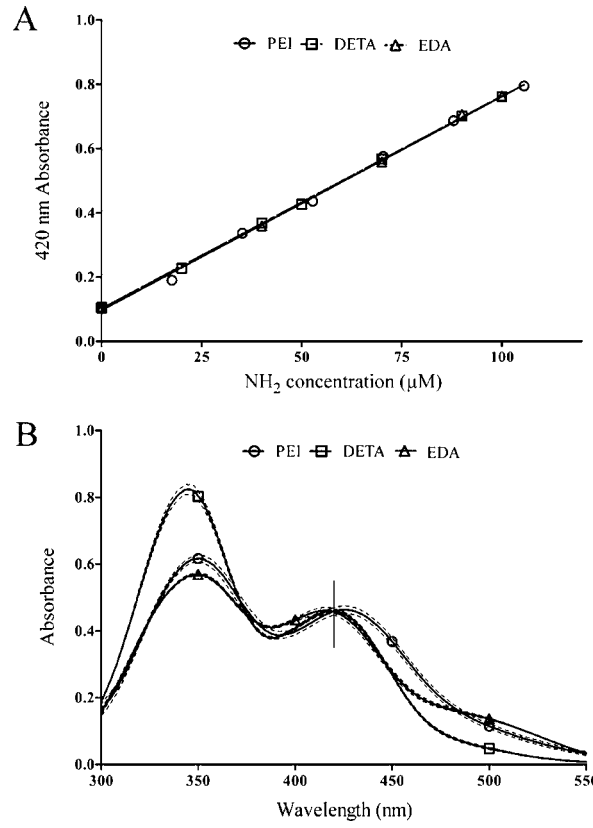

Figure 2. Standard curves (A) and absorption spectra (B) of PEI, DETA, and EDA. Absorption spectra at different concentrations of PEI, DETA, and EDA reacted with TNBS in borate buffer with 3% Tween 20 were recorded after 120 min, and absorbance at 420 nm (A) was plotted against theoretical primary amine concentration (see text for further explanation). TNBS in borate buffer with 3% Tween 20 at 120 min was used as [NH_2] = 0. (B) TNBS absorbance was subtracted from raw data and averaged spectra correspond to concentrations of 70 μM NH_2 ($n \geq 4$). Error lines (dashed) = standard deviation.

Transfection Experiments with PEI-P/PEGP. HeLa pLuc705 (Gene Tools LLC) were grown at 37 °C with 5% CO_2 in RPMI1640 medium (Sigma) supplemented with 10% fetal bovine serum (FBS) (Sigma), 1% GlutaMAX (Gibco), 100 U/mL penicillin (Gibco), and 100 μg/mL streptomycin (Gibco). The day before transfection, cells were seeded in 96-well plates (Nunc), without antibiotics, at 8×10^3 cells per well.

PEI-P/PEGP-PNA conjugates were prepared in 96-well plates; one well was prepared per triplicate transfection. Cys-PNA was left to react with PEI-P/PEGP in 20 mM HEPES in the well for 1 h. At the time of transfection, media was removed and 25 μL of the unpurified PEI-P/PEGP-PNA conjugates were diluted to 100 μL in OPTI-MEM (Gibco), and were transferred to the cells. After 6 h, cells were supplemented with 100 μL of 20% FBS and 1% GlutaMAX in RPMI-1640 and incubated for additional 18 h. For lactate dehydrogenase (LDH) leakage assays (CytoTox-ONE, Promega), 50 μL medium was recovered for analysis. After incubation, the transfection solution was removed, and then 50 μL passive lysis buffer (Promega) was added to the cells, followed by a freeze/thaw cycle, and the lysate was subjected to the further analysis. Ten microliters of lysate was diluted with 40 μL H_2O and analyzed for ATP content (CellTiter-Glo, Promega), while remaining lysate was assayed for luciferase activity (Bright-Glo, Promega). All assays were handled according to manufacturer.

RESULTS AND DISCUSSION

For conjugation to PNA, we chose to focus on PEI25, since it is a well-known standard in transfection with cationic poly-

Table 1. PEI Conjugates Used for Transfection[a]

linker	PEI25 conjugate	PDP/PEI (±SD)
SPDP	PEI-P14	14.4 ± 0.4
	PEI-P29	28.5 ± 0.9
	PEI-P68	68.4 ± 1.9
SPDP-PEG_8	PEI-PEGP15	15.5 ± 0.3
	PEI-PEGP30	29.6 ± 0.4
	PEI-PEGP66	66.1 ± 2.1

[a] Conjugates were characterized by TNBS assay and P2T release by DTT cleavage. SD = standard deviation.

mers and makes a reasonable compromise between transfection efficiency and toxicity. In order to obtain a cleavable complex, we chose to use a SPDP linker which upon reaction with cystein-containing PNA will form disulfide linkages (Figure 1B−C), and we also decided to include a PEG containing SPDP linker for possible reduction of cellular toxicity. In efforts to quantify PEI modification, we found that authentic quantification using the standard TNBS assay (*34*) was not accurate, since amine derivatives of TNBS differ significantly in reaction kinetics and extinction coefficients depend on the compounds to react with TNBS (*35*). Furthermore, trinitrophenylation of PEI caused precipitation when the majority of primary amines were reacted. However, PEI precipitation was averted by supplementing the TNBS reaction (in borate buffer at pH 9.3) with 3% Tween 20, which did not change the absorbance of the reaction products with the simple PEI model compounds EDA and DETA (*36*), as compared to borate buffer alone (not shown). Under these conditions, absorbance at 420 nm correlated linearly with primary amine content of PEI, EDA, and DETA (Figure 2A), and eq 1 was derived ($R^2 = 0.997$, valid range = [5−110 μM]) from the standard curve. The absorbance at 420 nm was used because the absorption spectra of trinitrophenylated (TNP)-PEI, -DETA, and -EDA differed significantly at 340 nm and above 430 nm with TNP-PEI being a hybrid spectrum of TNP-DETA, TNP-EDA, and TNP-$NHCH_2CH_2NR_2$ ($R \neq H$), but coalesced at 420 nm (Figure 2B).

$$[NH_2](\mu M) = \frac{(\text{Abs } 420\text{ nm}) - 85.5 \times 10^{-3}}{6.92 \times 10^{-3}} \quad (1)$$

The primary amine content of PEI25 was estimated to be ~175/polymer by comparison with TNP-DETA and TNP-EDA, which is in good agreement with the results of Harpe et al. (*14*).

Three preparations of sulfhydryl reactive 3-(2-pyridyldithio)-propionate (PDP) PEI differing in the degree of modification (14−68 per PEI) were made with both primary amine reactive SPDP and SPDP-PEG_8 linkers (Figure 1B). The conjugates were purified on Sephadex G-25SF preconditioned with PEI to block unspecific adsorption. Preconditioning the columns with PEI was critical in reducing nonspecific adsorption and significant sample loss, which was apparent when using a fluorophore-label PEI25 (not shown). We therefore assumed adsorption kinetics and capacity were analogous to those of cellulose fibers (*37*) and handled the beads accordingly, thereby reducing column loss to a minimum (as judged by control experiments using fluorescein-labeled PEI25 (results not shown).

The collected fractions were submitted to dialysis. The conjugates were characterized spectrophotometrically using the 3% Tween 20, borate buffered TNBS assay, and by measuring pyridine-2-thione (P2T) released by DTT treatment of the samples. The primary amine content ([NH_2]) was estimated from eq 1 and PEI concentration and the degree of modification

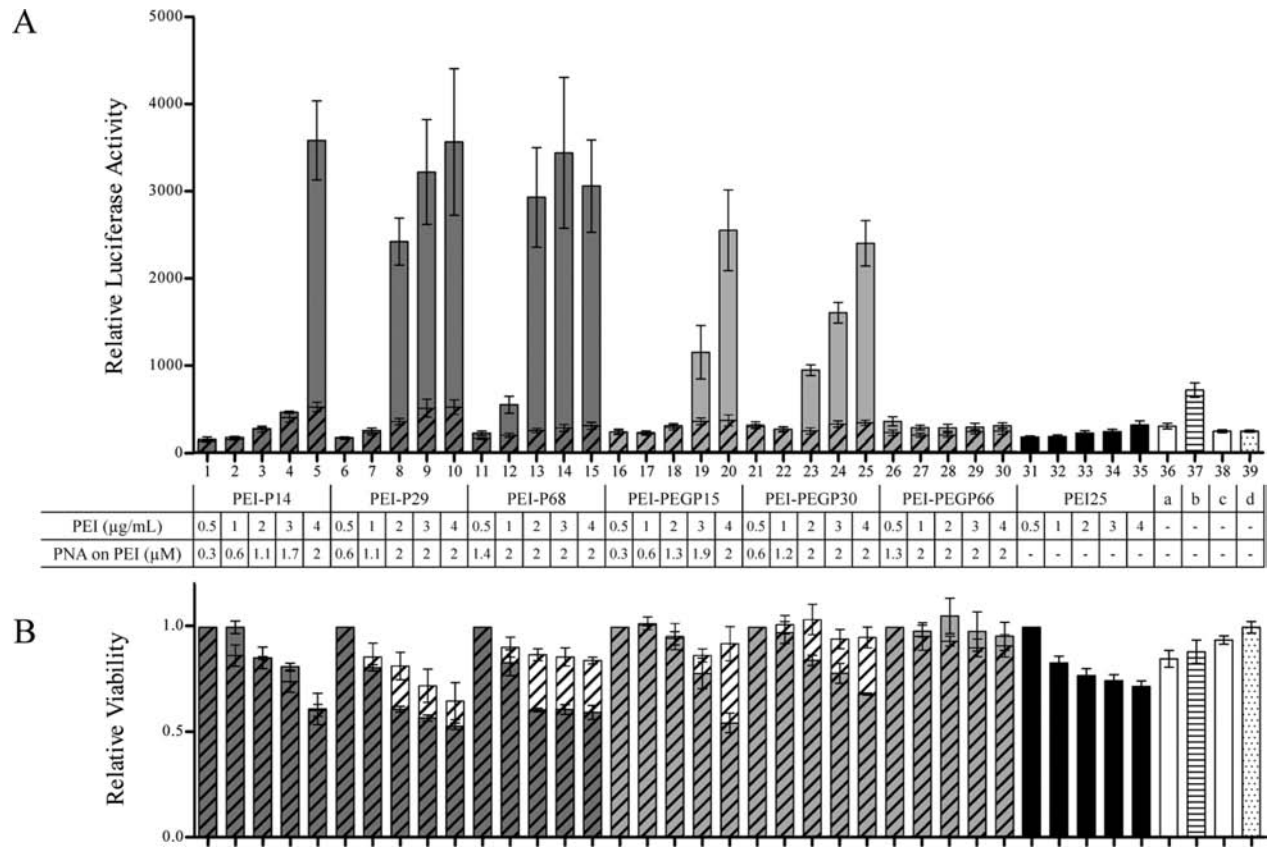

Figure 3. Effects of PEI modification. Transfections were carried out with a constant PNA concentration of 2 μM and varying concentration of functionalized PEI from 0.5 to 4 μg/mL. DTT controls were prepared for each sample (hatched overlay) in which PNA was cleaved from the PEI before transfection. Controls are 4 μM Arg_8-PNA (a), 4 μM Arg_8-PNA with chloroquine (75 μM) (b), 4 μM Cys-PNA (c), and 20 mM HEPES (1:3, v/v) in OPTI-MEM (d). Relative luciferase activity is corrected for ATP content. Error = SEM, $n = 3$.

({PDP/PEI}) from eqs 2 ([P2T] (μM) = (Δ343 nm)/(8.08×10^{-3})) and 3, respectively (Table 1).

$$[\text{PEI}] = \frac{([\text{NH}_2] + [\text{P2T}])}{175} \quad (2)$$

$$\{\text{PDP/PEI}\} = \frac{[\text{P2T}]}{[\text{PEI}]} \quad (3)$$

The modification degree and standard deviation (Table 1) were determined by unpaired comparison of triplicate TNBS and P2T release measurements, and the amine coupling efficiency (assuming 100% P2T cleavage) averaged 62%.

The PDP activated PEI was reacted with Cys-PNA (Figure 1C) in the wells in HEPES buffer and was used without further purification. Thus, samples were conveniently prepared in a 96-well format. We evaluated the transfection capacities of PEI-P/PEGP conjugates in the well-established HeLa pLuc705 splice correction assay (*38*) using a PNA targeted to the aberrant splice site (plucPNA; Ac-Cys-CCTCTTACCTCAGTTACA-NH_2), and the luciferase activity was corrected for cell viability using ATP content (rather than standard BCA assay), as this is more conveniently done in a 96-well format.

The conjugates were initially evaluated by keeping the total PNA concentration constant at 2 μM and varying the PEI concentration in the conjugation (Figure 3A). All samples were prepared with a corresponding DTT control, which was treated with 1 mM DTT prior to transfection to measure background transfection of nonconjugated PNA and PEI (Figure 3, hatched overlays). The results showed a very significant increase (up to <20-fold above background) in luciferase activity induced by the PNA upon conjugation to PEI, and this effect is virtually abolished after treatment with DTT, demonstrating the necessity of the covalent disulfide linkage for activity. The activity of the PNA-PEI conjugates is somewhat dependent on the degree of PEI modification (Figure 3A, PEI-P14, columns 1−5, vs PEI-P29 and -P68, columns 5−10 and 11−15, respectively), and the simple SPDP conjugates appear more active than the corresponding SPDP-PEG_8 conjugates (Figure 3A, PEI-P68 vs PEI-PEGP66, columns 1−15 and 16−30, respectively). In particular, the SPDP-PEG_8 conjugates are virtually inactive at the higher modification degree (Figure 3A, PEI-PEGP66, columns 26−30), although PEG-modification alleviates cellular toxicity to some extent. One possible explanation for this reduced efficiency of PEG-modified PEI is shielding of the PEI amines. Furthermore, all PEI preparations showed a dose-dependent cell toxicity (Figure 3B), and it is interesting that toxicity seems reduced upon treatment with DTT, indicating that the PNA conjugation increases the general cellular toxicity of PEI. From these results with constant PNA concentration for the conjugation (Figure 3), we found that the optimal PDP:PNA ratio was 1.2:1, which was therefore used in the dose−response experiments (Figure 4A−B).

The antisense activity of the apparently most potent and less toxic conjugates, PEI-P29, PEI-PEGP15, and PEI-PEGP30 were studied in more detail. A dose−response dependence on PNA concentration showed a close to linear relationship of all three conjugates, with the PEI-PEGP15 conjugate being twice as active as the two others most likely reflecting the reduced PEI loading and thus double PEI concentration (Figure 4A). Thus, the PEI-PEGP15 conjugate was chosen for a direct comparison with a reference CPP conjugated PNA, Arg_8-PNA (*6*−*8*) (Figure 4B). These results show that the PEI-PEGP15-PNA conjugate is about 10-fold more active than the Arg_8-PNA and up to 3−4-fold more active, even when the effect of Arg_8-PNA is enhanced with the lysosomolytic agent chloroquine (CQ) (*6*). Furthermore,

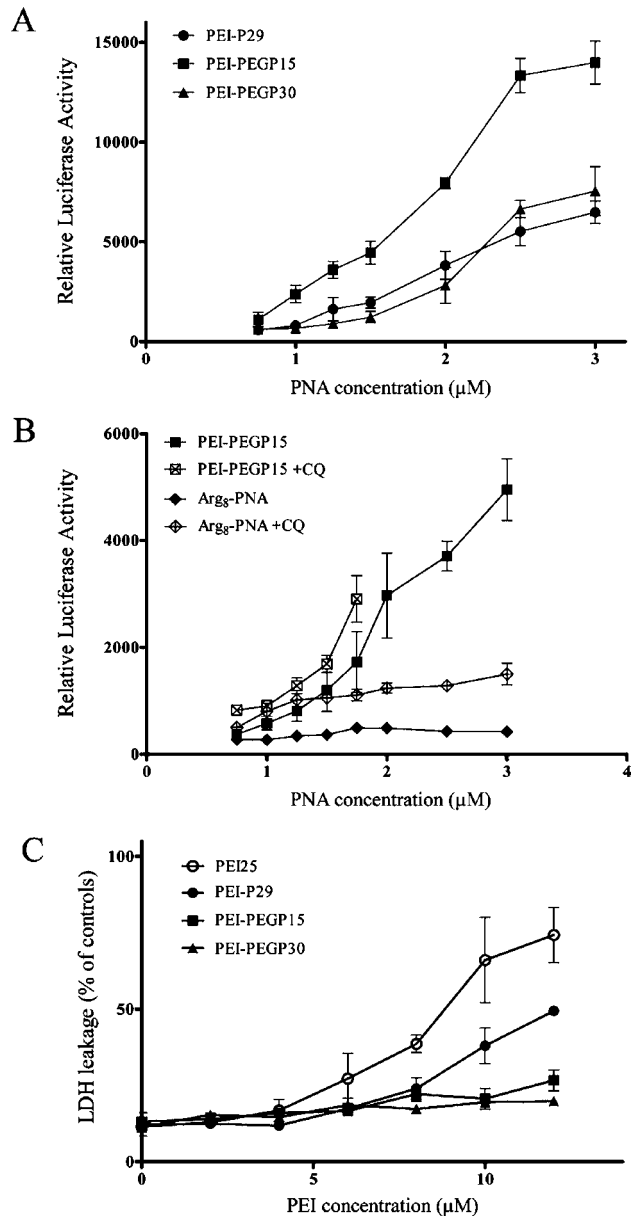

Figure 4. Dose response and acute toxicity. (A) Antisense activity of PEI-P29-, PEI-PEGP15-, and PEI-PEGP30-PNA conjugates. (B) Antisense activity of PEI-PEGP15-PNA conjugate and Arg_8-PNA in the absence or presence of chloroquine (CQ). CQ and PEI-PEGP15-PNA corresponding to PNA concentrations above 1.75 μM were highly toxic and are omitted. (C) Acute toxicity at 2 h as measured by LDH leakage. For (A) and (B), the PEI-P/PEGP concentration was determined by a PDP:PNA ratio of 1.2: 1. Relative luciferase activity is corrected for ATP content. Error = SEM, $n = 3$.

and most interestingly, the addition of chloroquine has only minimal activating effect on the PEI-PEGP15-PNA conjugate, but very significantly increases the toxicity of this (>50% for 2 μM PNA; Figure 4B).

Finally, whereas cell viability after 24 h (Figure 3B) as measured by the ATP assay did not differ much between PEI and PEI-PEG conjugates, the PEI-PEG conjugates showed significantly less acute toxicity (2 h) as measured by LDH leakage (Figure 4C). The reduced acute toxicity of SPDP-PEG_8 modified PEI25 together with the decrease in toxicity of DTT cleaved conjugates after 24 h of transfection, especially for PEI-PEGP30 and 66 (Figure 3B, columns 21−30), could indicate that the $[PEG]_8$ linker leads to reduced initial membrane damage (and possibly lower transfection efficacy when cleaved), while the delayed cytoplasmic toxicity could be caused by pertained mitochondrial damage (*19*). This is

further supported by the negligible difference between high and low modification degree with SPDP.

CONCLUSIONS

The present results clearly show that properly optimized, in terms of conjugation degree, PEI is an efficient cellular delivery agent for (antisense) PNA not requiring additional lysosomolytic activity. We also note that the experimental setup allows for high-throughput screening optimization and discovery of novel active PEI-conjugates using a variety of other bioactive ligands, such as morpholino oligomers (*39*) and minor groove binding (hairpin) polyamides (*40*). Furthermore, the system also conveniently allows for studies and optimization of heterogeneous conjugates using gene targeting agents (e.g., PNA) in combination with auxiliary agents, which have previously proven successful in improving transfection efficiency of PEI:DNA polyplexes, such as specific receptor targeting peptides (e.g., FGF) (*41, 42*), cell penetrating peptides (CPPs) (*43*−*45*), and lipids (e.g., cholesterol) (*46*), in order to optimize and tailor-make the conjugates, and exploiting the possible synergy of the agents. The ratio between the various ligands in the PEI conjugate will (to a first degree) be controlled by their ratio (as thiol derivatives) in the conjugation reaction mixture. Finally, the employment of orthogonal conjugation methods (e.g., click chemistry) would allow discrimination of ligands attached by cleavable or noncleavable linkers.

Received July 12, 2010; Revised Manuscript Received October 1, 2010

We developed a new apoptosis imaging probe with gold nanoparticles (AuNPs). A near-infrared fluorescence dye was attached to AuNP surface through the bridge of peptide substrate (DEVD). The fluorescence was quenched in physiological conditions due to the quenching effect of AuNP, and the quenched fluorescence was recovered after the DEVD had been cleaved by caspase-3, the enzyme involved in apoptotic process. The adhesion of DEVD substrates on AuNP surface was accomplished by conjugation of the 3,4-dihydroxy phenylalanine (DOPA) groups which are adhesive to inorganic surface and rich in mussels. This surface modification with DEVD substrates by DOPA groups resulted in increased stability of AuNP in cytosol condition for hours. Moreover, the cleavage of substrate and the dequenching process are very fast, and the cells did not need to be fixed for imaging. Therefore, the real-time monitoring of caspase activity could be achieved in live cells, which enabled early detection of apoptosis compared to a conventional apoptosis kit such as Annexin V-FITC. Therefore, our apoptosis imaging has great potential as a simple, inexpensive, and efficient apoptosis imaging probe for biomedical applications.

Apoptosis is an important physiological mechanism to maintain homeostasis of multicellular organisms by elimination of infected or damaged cells and regulation of cell number (*1, 2*). Various imaging techniques were developed to image this process, because it could provide a monitoring tool for therapeutic effect of cancer treatment, efficacy of new drugs, or quality of protein therapeutics produced in mammalian cell culture. In particular, the TUNEL (TdT-mediated dUTP nick end labeling) assay is a typical method to label DNA fragmentation which occurs during apoptosis. However, many reaction steps are involved in this method and internucleosomal DNA breaks were not always associated with apoptosis (*3, 4*). Annexin V/FITC (fluorescein isothiocyanate) conjugate is another widely used method for apoptosis imaging due to its binding affinity to negatively charged phosphatidylserine (PS) exposed on the apoptotic cell membrane. However, this binding is not specific to apoptosis, because PS exposure can occur in other biological situations like myotube formation and necrosis (*5, 6*). To overcome the limitation of conventional imaging methods and to enable the early diagnosis of diseases or fast evaluation of therapeutic effect, it is necessary to develop a caspase enzyme-sensitive imaging probe, because activation of caspases is the initial stage of apoptotic process and responsible for the cell changes during apoptosis such as DNA fragment, nuclear chromatin condensation, and plasma membrane blebbing (*7*).

For this reason, we synthesized a caspase-sensitive fluorescence imaging probe using gold nanoparticles (AuNPs). Caspase-3 cleavable motifs (*8*) combined with mussel-inspired adherent peptides, 3,4-dihydroxy phenylalanines (DOPA), and lysines (Gly-Asp-Glu-Val-Asp-Ala-Pro-DOPA-Lys-DOPA-Lys-DOPA, the cleavage site is between Asp and Ala) were purchased, and a near-infrared fluorescence (NIRF) dye, Cy5.5, was conjugated to the N-terminus of peptide sequence. DOPAs and lysines (DOPAK) at the C-terminus of caspase-3 cleavable motifs played an important role in adhesion of peptides on the surface of AuNP. The Cy5.5-conjugated peptide (Cy5.5-DEVD-DOPAK) was used to modified the surface of citrated-stabilized AuNPs by a simple mixing method (Scheme 1). At the N-terminus of DEVD, three 3,4-dihydroxy phenylalanines and lysines (DOPAKs) were chemically conjugated to increase the adherence between the surface of AuNP and peptide. DOPA has been known to be rich in mussel foot protein and has excellent adhesive properties to the surface of various materials (*9*). AuNP carried out a role as a quencher of Cy5.5 for its strong surface energy transfer (*10, 11*). This nanoprobe facilitated detection and monitoring of enzymatic activity of caspase, because its NIRF emission was selectively turned on after degradation of DEVD sequence by caspase-3. Our probe has unique features such as sensitive and fast imaging, direct imaging of caspase-3 enzyme activity, and real-time imaging of apoptotic cells.

For the biological application, the stability of AuNPs in the physiological condition should be guaranteed because aggregation of them impedes their long circulation and full function in the body. The stability of Cy5.5-DEVD-DOPAK coated AuNPs (DEVD-AuNPs) was confirmed through UV−vis absorption spectroscopy in caspase buffer condition (Figure 1A; see the Supporting Information for details of caspase buffer). The spectrum showed a unique surface plasmon resonance peak of DEVD-AuNPs at 523 nm, and it was no different from that of the uncoated AuNPs even in the caspase-containing buffer. However, in the case of the uncoated AuNPs, they aggregated and the UV−vis absorbance was reduced after incubation in caspase buffer. The stability of DEVD-AuNPs was also verified by observation of the morphology in the TEM images (Figure 1B). As seen in Figure 1B, DEVD-AuNPs were uniformly dispersed and no aggregation was found. The size of DEVD-

Scheme 1. Schematic Diagram of Cy5.5 and DEVD Peptide Conjugated Gold Nanoparticles (DEVD-AuNPs)[a]

[a] Blue spheres indicated quenched state of Cy5.5 and red ones represented recovered fluorescence.

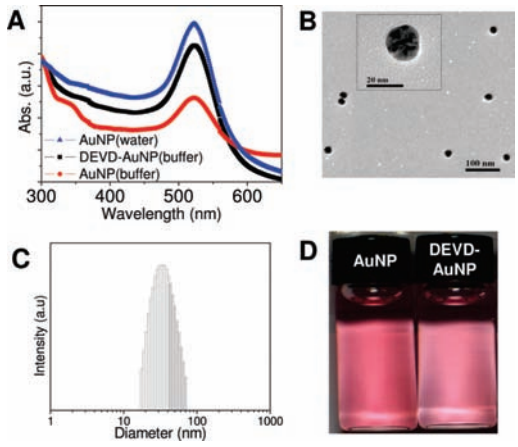

Figure 1. (A) UV−vis absorption spectrum of bare AuNP in water (blue), caspase buffer (red), and DEVD-AuNP in buffer (black). (B) TEM images of DEVD-AuNP. (C) Particle size distribution measured with DLS (D) Optical image of AuNP and DEVD-AuNP.

AuNP in the buffer was measured with dynamic light scattering, and it showed the size distribution of 37.8 ± 14.1 nm (Figure 1C). The increment of diameter was due to the hydrophilicity of peptide and not caused by aggregation of AuNPs. The enhanced stability of DEVD-AuNP was also examined by the naked eye, because it retained the unique red color during the coating process (Figure 1D). From these results of DEVD-AuNPs, it was inferred that DEVD peptide on the surface did not affect the stability of AuNPs but also stabilized AuNPs even in the caspase buffer environment. In addition, the amount of DEVD substrate bound to the AuNP surface was calculated through the measurement of UV−vis absorption of unreacted Cy5.5-DEVD during the coating process. The UV−vis absorbance at 675 nm was calibrated with a standard curve of Cy5.5, and we estimated that about 1.2×10^2 molecules of DEVD were attached to each AuNP (0.095 49 molecules/nm^2).

The feasibility of DEVD-AuNP for optical imaging probe of apoptosis was investigated. The difference of NIRF intensity of Cy5.5 was measured before and after incubation of DEVD-AuNP with caspase-3. NIRF was quenched before the addition of caspase-3 due to the nonradiative energy transfer properties of AuNP (*12*). The quenched fluorescence was recovered after the DEVD substrates on the AuNPs were degraded by caspase-3. The cleavage of DEVD increased the distance between fluorophore and AuNP, and the NIRF signal was recovered because the quenching effect of AuNP was reduced. These results were imaged with NIRF imaging system (Kodak Image Station 4000MM, New Haven, CT, USA), a function of concentration of DEVD-AuNP (Figure 2A). Due to the strong quenching effect of AuNPs, the detection of recovered fluorescence was corrupted after incubation with caspase-3 when the concentration of DEVD-AuNP had been greatly increased. For comparison, the NIRF images were obtained from the decanted solution after incubation with caspase-3 followed by centrifugation. The quantitative measurement of NIRF using a spectrofluorometer at a fixed excitation wavelength of 675 nm showed that the signal-to-background ratio could be increased by concentration of DEVD-AuNP up to 1.0 mg/mL and NIRF signal saturation appeared due to the self-quenching of Cy5.5 dyes detached from DEVD-AuNP (Figure 2B). The recovered NIRF intensity was also dependent on concentration of caspase-3 as shown in Figure 2C, and DEVD-AuNP could detect and generate fluorescence in response to only about 1 nM of caspase-3. Figure 2D shows that the fluorescence recovery of DEVD-

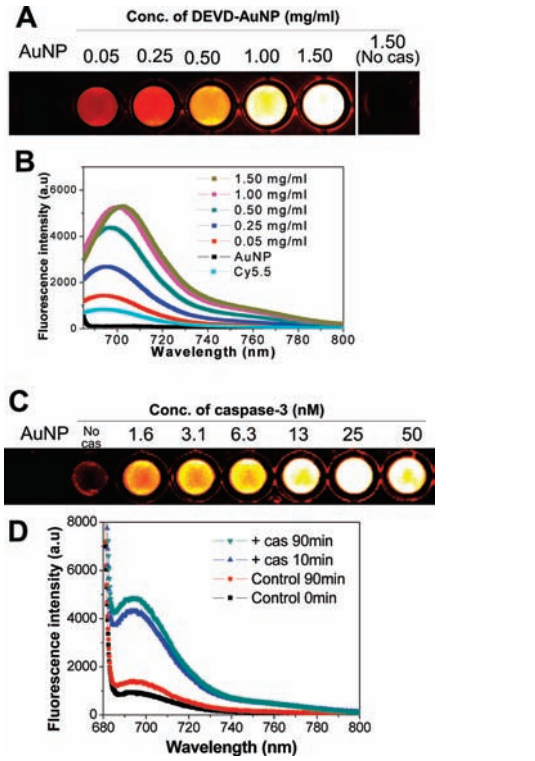

Figure 2. (A) NIRF images of DEVD-AuNP in 96-well microplate containing various concentrations of DEVD-AuNP with or without caspase-3. (B) Fluorescence spectra of DEVD-AuNP as a function of probe concentration incubated with caspase-3. (C) NIRF images of DEVD-AuNP with various concentrations of caspase-3. (D) Fluorescence spectra of DEVD-AuNP as a function of incubation time with caspase-3.

AuNP was made very quickly in response to caspase-3 and had already occurred at 10 min.

For real-time apoptosis imaging with DEVD-AuNPs in live cells, apoptosis was induced with tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) in HeLa cells. TRAIL has been known to induce apoptosis effectively in various cell lines include HeLa cells (*13*). After DEVD-AuNPs were taken up by HeLa cells by coincubation for 1 h, TRAIL was treated and the cells were observed with microscopy to obtain real-time fluorescent images. Even before the formation of apoptotic body, the NIRF signal of Cy5.5 appeared after 30 min of TRAIL treatment (Figure 3A). This signal was condensed after the apoptotic body was formed in 120 min. In contrast, NIRF signal was not observed for 120 min when the cells were not treated with TRAIL. In addition, it was seen that cell death was delayed and the NIRF intensity was reduced when the cells were exposed to the inhibitor of caspase-3 (Z-DEVD-FMK, R&D Systems, Minneapolis, MN, USA) for 30 min prior to TRAIL treatment. This result was further investigated with DAPI (4′,6-diamidino-2-phenylindole) staining, which binds strongly to DNA and forms a fluorescent complex in nuclei. It is well-known that caspase cascade is activated in the cytosol area (*1, 8*), so the recovered fluorescence of Cy5.5 in the cytosol should not overlap with that of DAPI in the nuclei as shown in Figure 3B. In addition, the existence of DEVD-AuNP was monitored through a dark-field microscope. The signal of DEVD-AuNP in the dark-field image was detected only in the cytosol area of HeLa cells, which was coincident with previous results (Figure 3C). These results clearly showed that the DEVD-AuNP probe has enhanced optical functionality and specificity against caspase enzyme and it was activated only through the caspase cascade occurring in the cytoplasm.

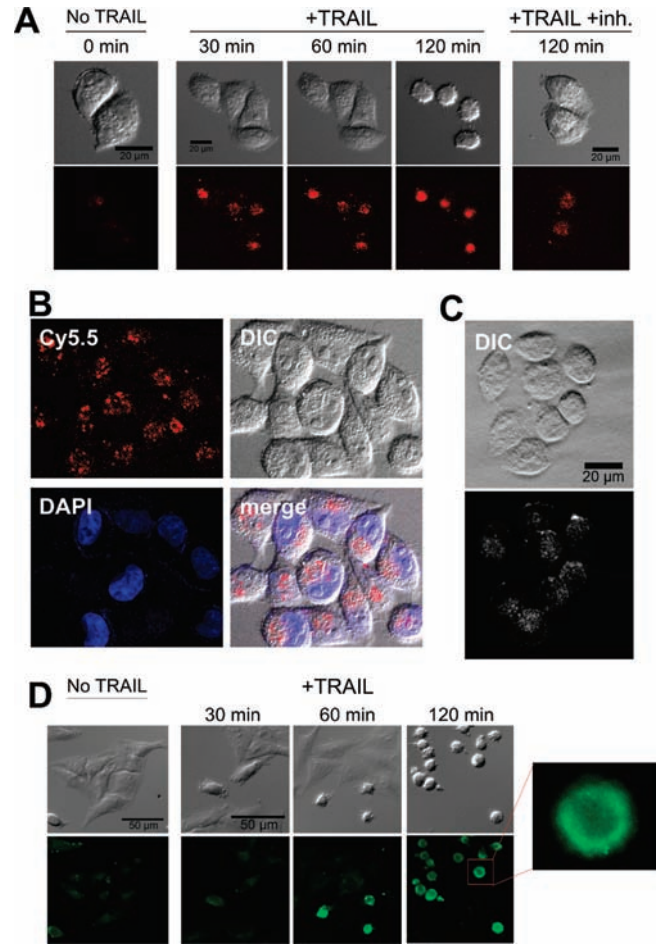

Figure 3. Microscopic images of HeLa cells after uptake of DEVD-AuNP and induction of apoptosis with TRAIL. (A) DIC and NIRF (Cy5.5) microscopic images of nonapoptotic (no TRAIL) and apoptotic (+TRAIL, +TRAIL+inh) cells treated with DEVD-AuNP. (B) DIC and fluorescence images of DEVD-AuNP treated apoptotic cells after DAPI staining (C) Dark-field images of apoptotic cell. (D) Annexin-V/FITC treated apoptotic HeLa cells before (no trail) and after (+TRAIL) treatment of TRAIL.

To show the feasibility of DEVD-AuNP for the rapid visualization and real-time detection of early apoptosis, the same experimental condition was applied to Annexin V assay (Figure 3D). The commercially available Annexin V-FITC assay was treated after induction of apoptosis in HeLa cells, but the real-time imaging was not possible because the cells should be fixed before treatment of annexin V. Even before the TRAIL was treated, a faint background fluorescenct signal of FITC was observed. After 30 min of TRAIL treatment, the morphology of the cells was slightly changed but a strong FITC signal was not detected. Strong fluorescence of FITC was seen after 60 min of TRAIL when some cells already formed apoptotic bodies. A strong FITC signal was emitted exclusively from them, which was clear 120 min after TRAIL treatment when all of the HeLa cells died from apoptotic cell death. The morphology of FITC fluorescence from the apoptotic bodies was different from that of DEVD-AuNP in Figure 3A of apoptotic HeLa cells. The NIRF of DEVD-AuNP emitted from the inside of the cell due to the uptake by HeLa cells, whereas fluorescence of annexin V was concentrated around the cell membrane because annexin V is combined with phosphatidylserine, which was exposed to the external cellular environment in apoptosis.

In conclusion, the apoptosis was successfully monitored in live cells with a molecular optical imaging technique using AuNP-based NIRF probe. It allowed rapid visualization and

detection of early apoptosis, which was not possible through the conventional apoptosis kits such as Annexin V-FITC. Moreover, the real-time monitoring of caspase activity was enabled because the fluorescence of DEVD-AuNP was activated only by caspase enzyme. In light of its simple, inexpensive, and efficient properties for an apoptosis imaging probe, DEVD-AuNP has great potential in biomedical applications.

Gold Nanoparticle for Apoptosis Molecular Imaging

In-Cheol Sun, Seulki Lee, Ick Chan Kwon, Cheol-Hee Ahn and Kwangmeyung Kim**

Supporting informations

Experimental methods

Materials. Gold nanoparticles (AuNPs, 0.05 mg Au/ml) with diameters of 20 nm were purchased from Sigma (St. Louis, MO, USA). Protected caspase-3 substrates (DEVD-DOPAKs), Gly-Asp-Glu-Val-Asp-Ala-Pro-DOPA-Lys-DOPA-Lys-DOPA and Cy5.5 mono acid were obtained from Peptron (Daejon, Korea) and Amersham Biosciences (Buchinghamshire, UK) respectively. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), Caspase-3 enzyme and its inhibitor, Z-DEVD-FMK, were bought from R&D Systems (Minneapolis, MN, USA). 1-Ethyl-3-(3-dimethylamino-propyl) carbodiimide hydrochloride (EDC), N-hydroxy succinimide (NHS; 98%), diisopropyl-ethylamine (DIPEA), Dimethyl sulfoxide (DMSO), Dimethyl-formamide (DMF), ethyl acetate (EA), HEPES sodium salt hydrate, ethylenediaminetetraacetic acid (EDTA), 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonic acid (CHAPS) and glycerol(99+%) were acquired from Sigma. Dipyrrolidino (N-succinimidyloxy) carbenium hexafluorophosphate (HSPyU) and sodium chloride (NaCl) were products form Fluka (Milwaukee, WI) and Junsei (Japan), respectively. Water (DW) used in the

experiment was double-distilled and all other chemicals were used as received without any purification.

Preparation of Cy5.5-NHS. Cy5.5 mono acid (100 mg, 0.14 mmol) was dissolved in anhydrous DMSO and DMF (50:50, 7 ml) followed by addition of DIPEA (75 µl). HSPyU (91mg, 0.22 mmol) was added to the reaction mixture and stirred at room temperature in the dark. After 30 minutes, samples were diluted with 0.1M acetic acid for characterization with HPLC (elution: 20% to 40% acetonitrile vs. 0.1M triethyl ammonium acetate (TEAA) in water over 20 minutes at a flow rate of 1.0 ml/min.) After complete activation, the Cy5.5-NHS was precipitated by adding anhydrous EA. The precipitate was washed with EA and dried in vacuum. Purity (> 95%) was confirmed by analytical reversed-phase HPLC (Agilent 1200 series, Agilent Technologies, Palo Alto, CA, USA)

Preparation of Cy5.5-labeled caspase-3 substrate (Cy5.5-DEVD-DOPAK). Cy5.5-NHS (11 mg, 11.2 µmol) was coupled to the N-terminus of the protected DEVD-DOPAK (18 mg, 8.6 µmol) in anhydrous DMF (300 µl) containing N-methyl morpholine and 4-dimethyl amino pyridine at room temperature in the dark with shaking for 2 hours. The Cy5.5-DEVD-DOPAK (protected) product was purified by semi-preparative reversed-phase HPLC; 35% to 100% acetonitrile vs. 0.1M TEAA in water over 20 minutes at a flow rate of 5.0 ml/min. The peptide of purified product was deprotected with anisol (10 µl) and DW(10 µl) in 2 ml of trifluoroacetic acid (TFA). After 1 h of stirring, TFA was evaporated and purified with HPLC under the same condition. Purity (> 95%) was confirmed by analytical reversed-phase HPLC. Eluent was removed by freeze-drying and the mass of product was analyzed with Voyage-DE™ STR matrix-assisted laser desorption ionization with time of flight (MALDI-

TOF) mass spectrometer (Applied Biosystems, Foster City, CA, USA). Mass: calculated/found, 2504/2513.

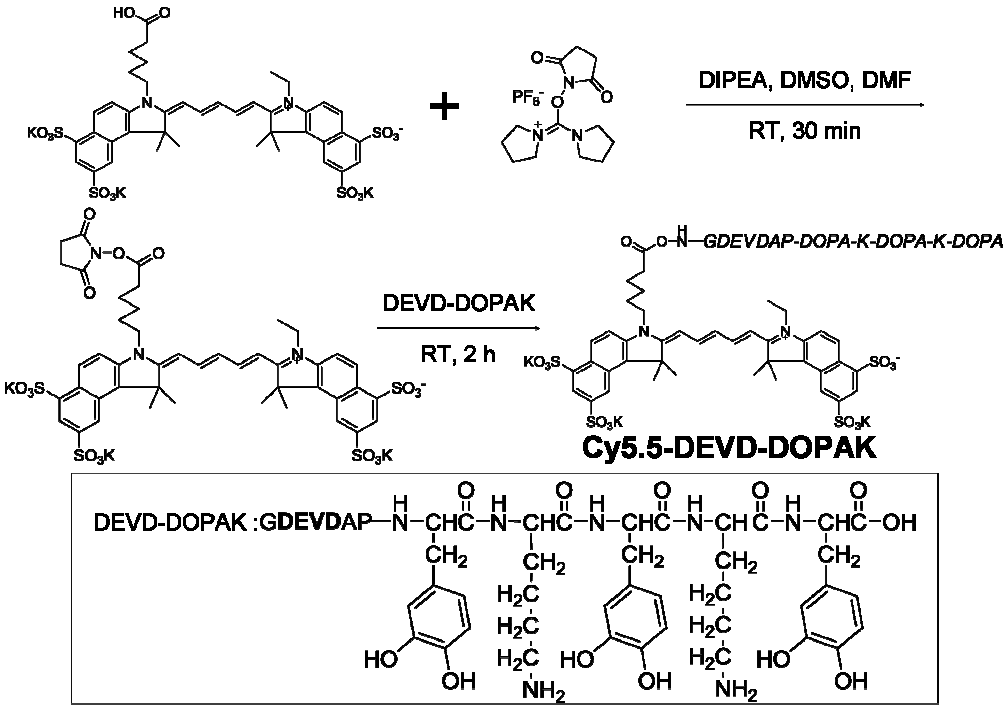

Figure S1. Schematic diagram of synthesis of Cy5.5-NHS and Cy5.5-labeled caspase-3 substrate (Cy5.5-DEVD-DOPAK)

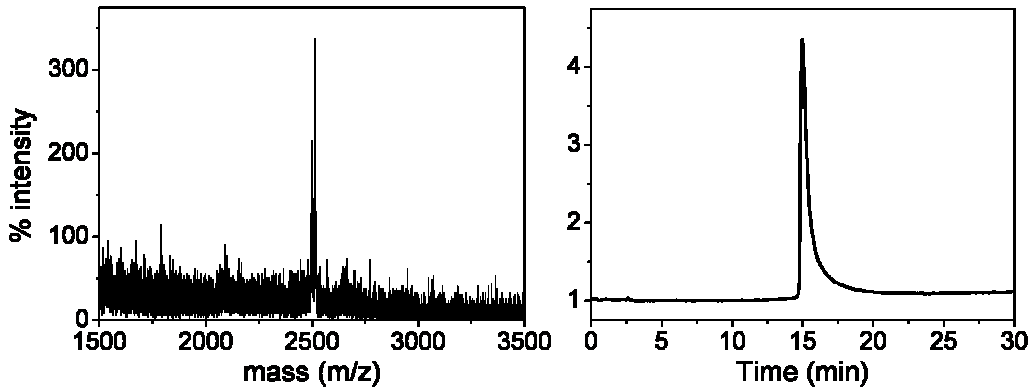

Figure S2. MALDI-TOF mass spectrum and HPLC chromatogram of Cy-DEVD-DOPAK after deprotection

Preparation of Cy5.5-DEVD-DOPAK coated AuNPs probe (DEVD-AuNPs).

Cy5.5-labeled caspase-3 substrate (Cy5.5-DEVD-DOPAK) was used to coat AuNPs by

simple mixing method. Briefly, 0.1 ml of Cy5.5-DEVD-DOPAK (100 μg/ml) solution was added dropwise to 5 ml citrated reduced gold colloid. The solution was kept in the absence of light at 25°C under stirring for 12 h. After the reaction, the solution was centrifuged (12000 rpm, 12 min) and washed with DW 3 times to remove free Cy5.5-DEVD-DOPAK. For *in vitro* enzyme test, the DEVD-AuNPs were resuspended in caspase buffer containing 50mM HEPES, 100 mM NaCl, 1 mM EDTA, 10 % glycerol and 0.1 % CHAPS and sonicated for 1 min to keep the nanoparticles uniformly dispersed. Finally the dispersed DEVD-AuNPs were stored at 4 °C before use.

Characterization of DEVD-AuNPs. The amount of Cy5.5-DEVD-DOPAK on the AuNPs surface was calculated by measuring the fluorescence signal intensity of unreacted Cy5.5-DEVD-DOPAK before and after coating process and it was compared with standard curve of Cy5.5. The fluorescence was measured with F-7000 fluorescence spectrometer (Hitachi, Tokyo, Japan). The excitation wavelength was fixed at 675 nm and emission spectra recorded from 680 to 800 nm. Under the optimal condition, 1.2×10^2 molecules of Cy5.5-DEVD-DOPAK were attached onto each AuNP particle. The spherical morphology and particle dispersion of the DEVD-AuNPs was determined by transmission electron microscopy (TEM). The TEM images were obtained from JEM-3010 (JEOL, Tokyo, Japan) operating at 300 kV. The TEM samples were prepared on the carbon-coated, 200-mesh copper grids and dried in a vacuum oven for 24 h. The size and its distributions of DEVD-AuNPs in DW were measured with dynamic light scattering (DLS) using ELS-Z2 (Otsuka, Osaka, Japan). UV-vis spectra were recorded from Optizen 2120UV (Mecasys, Daejeon, Korea) which scanned over the range of 300 ~ 700 nm.

***In vitro* enzyme test**

In vitro enzyme test was performed in caspase buffer containing HEPES (50 mM), NaCl (100 mM), EDTA (1 mM), glycerol (10% v/v) and CHAPS (0.1 % v/v) without DTT. The detection sensitivity of DEVD-AuNP probe was studied with different concentration of caspase-3 and DEVD-AuNP. DEVD-AuNP probe was examined in a 1 ml cuvette by co-incubating AuNP probe (0.5 mg Au/ml) with 1.6, 3.1, ,6.3, 13, 25 and

50 nM of caspase-3, respectively. Also 50 nM of caspase-3 enzyme was activated in 0.05, 0.25, 0.5, 1 and 1.5 mg Au/ml of DEVD-AuNP colloid. The fluorescence signal was detected with with fluorescence spectrometer. Optical NIRF imaging was performed using a Kodak Image Station 4000MM Digital Imaging System (Kodak, New Haven, CT, USA) consisting of a light-tight box equipped with a 150 W halogen lamp and an excitation filter system for Cy5.5 (Omega optical, Brattleboro, VT, USA).

Cell imaging. HeLa cells (obtained from ATCC, Rockville, MD, USA) were cultured in Dubecco's modified Eagle's medium (DMEM; Gibco, Grand Island, NY, USA) containing 10% (v/v) FBS (Gibco) and 1% (w/v) penicillin/streptomycin at 37 °C in a humidified atmosphere of 5 % CO_2. Cells were seeded at a density of 5×10^4 cells/dish in 35-mm coverglass-bottom dishes (SPL Life Sciences, Seoul, Korea) and allowed to adhere for 2 days. The cells were washed twice with phosphate-buffered saline (PBS) and 1.8 ml of DMEM (without FBS) was replenished before addition of 0.2 ml of DEVD-AuNPs (0.25 mg Au/ml). After 30 min of incubation at 37 °C, the medium was aspirated and the cells were washed twice with PBS to remove excess nanoparticles. TRAIL dissolved in DMEM (with FBS, AA) was treated to HeLa cells for induction of apoptosis. Final concentration of TRAIL and DEVD-AuNP were 300 ng/ml (13 M) and 0.025 mg Au/ml, respectively. As a control, cells were incubated with 1.34 μg (100 μM) of caspase-3 inhibitor Z-DEVD-FMK before uptake of nanoparticles. The sample was observed through IX81 fluorescence microscope (Olympus, Tokyo, Japan) equipped with a dark-field condenser.

Annexin V assay. Annexin V-FITC fluorescence microscopy kit (BD Bioscience, San Jose, CA, USA) was used according to the protocol provided by manufacturer. Briefly, apoptotic HeLa cells were washed once with Annexin V Binding Buffer after fixation. Then, the cells were stained with Annexin V-FITC solution for 10 min. The Annexin V-FITC solution was removed and washed with Binding Buffer once for the observation under the microscopy. The cells were visualized with excitation at 488 nm and emission at 530 nm.

Synthesis of N-Terminally Linked Protein and Peptide Dimers by Native Chemical Ligation

Junpeng Xiao,[†] Brian S. Hamilton,[†] and Thomas J. Tolbert*[,†,‡]

Interdisciplinary Biochemistry Graduate Program and Department of Chemistry, Indiana University, Bloomington, Indiana 47405, United States. Received August 12, 2010; Revised Manuscript Received October 6, 2010

Dimerization can be utilized to double the molecular weight of proteins and peptides and potentially increase their avidity of binding to target receptors. These dimerization effects may be utilized to increase in vivo half-lives in a manner similar to PEGylation and may also improve biological activity. In this paper, we report a new strategy for the synthesis of N-terminally linked protein and peptide homodimers utilizing native chemical ligation to conjugate a short dithioester linker to the N-terminal cysteines of protein and peptide monomers to form dimers in a single step. This strategy is general and has been applied to the production of dimers from three recombinantly expressed polypeptides, the IgG binding domain Protein G, an HIV entry inhibitor peptide C37H6, and human interleukin-1 receptor antagonist (IL-1ra). The biological activities of the C37H6 and IL-1ra dimers produced by these methods were retained or even slightly increased when compared to their corresponding monomers.

Dimeric forms of proteins and peptides play important roles in biological systems by participating in many processes including signal transduction, gene expression, enzyme regulation, and viral inhibition (*1*−*7*). One effect of dimerization of monomeric ligands is that it can increase the avidity of binding of ligands to receptors through divalent interactions, which when applied to proteins and peptides can contribute to increased biological activity (*2*). For example, anti-HIV infection activity has been enhanced by dimerization of protein ligands which bind to the HIV envelope glycoprotein gp120, such as the synthetic CD4-mimetic miniprotein CD4M9 (*8*) and the recombinant mannose binding protein cyanovirin-N (*9*). In addition to increasing avidity of binding, dimerization of proteins and peptides also doubles their molecular weight, and consequently can increase their in vivo half-lives in a manner similar to PEGylation. Although PEGylation can dramatically increase the circulation half-life of protein and peptide drugs (*10, 11*), it also has some drawbacks. PEGylation often results in a loss of binding affinity and biological activity due to steric interference of the PEG polymer (*12, 13*). Also, accumulation of large quantities of PEG in vivo can induce the formation of anti-PEG antibodies, which accelerate the clearance of PEGylated proteins (*14, 15*), and may also have long-term detrimental effects (*16*). In contrast to PEGylation, dimerization of proteins and peptides with a short synthetic linker can potentially increase in vivo half-lives by doubling molecular weight, while also maintaining or even increasing biological activity through divalent interactions. Replacement of a large PEG modification with a short linker also minimizes the potential for anti-PEG antibody formation. Because of this, there is significant interest in the development of general methods for the synthesis of dimeric proteins and peptides.

Several solid-phase peptide synthesis based approaches have been developed to form peptide dimers and even dendrimers through triazole (*17*), oxime (*18*), disulfide (*19*), thioether (*8, 20*), and thiazolidine forming reactions (*21*). However, triazole and oxime formation requires non-natural amino acids, and disulfide and thioether formation has no selectivity on proteins which contain multiple cysteine residues. Although thiazolidine formation is selective for N-terminal cysteines, the reaction is usually performed at acidic pH in an organic/water cosolvent for best efficiency, and under these reaction conditions, proteins may be denatured (*21, 22*). Consequently, the application of these approaches is limited to small synthetic peptides and single cysteine containing proteins. To expand dimer formation beyond small synthetic peptides, Kent and co-workers have utilized chemoselective thioester formation and disulfide bond formation to produce chemically synthesized tethered dimers of HIV-1 protease, where the C-terminus of one monomer is linked to the N-terminus of the second monomer through a disulfide bond (*23*). They have recently expanded this methodology by applying native chemical ligation in a convergent synthesis to link four synthetic peptides to form a "covalent dimer" of HIV-1 protease where the monomers are linked C to N with native peptide bonds (*24*). The C to N linkages of the HIV-1 protease dimers produced by the Kent lab are the same linkages that would occur in a recombinantly expressed dimer, but with the possibility of incorporating synthetic modifications selectively into the protein backbone (*25*). Dimer formation has also been applied to large recombinant proteins which contain multiple cysteine residues by utilizing expressed protein ligation (*26*) to prepare C-terminally conjugated recombinant protein dimers or dendrimers (*27, 28*). This approach produces C-terminally linked dimers, but not all proteins and peptides are suitable for conjugation at the C-terminus. For instance, conjugation at the C-terminus of HIV entry inhibitor peptide T20 significantly decreased its antiviral activity, whereas retention of antiviral activity was observed when it is conjugated at the N-terminus (*29*).

Previously, we reported a strategy to produce N-terminally linked expressed protein dimers and trimers using a combination of native chemical ligation and Cu(I)-catalyzed azide−alkyne cycloaddition click chemistry (CuAAC) (*30*). This strategy is useful for the synthesis of expressed protein heterodimers that are usually difficult to prepare using other strategies, but it also has some disadvantages. First, it requires two steps: (1) incorporation of azide and alkyne groups onto a protein's

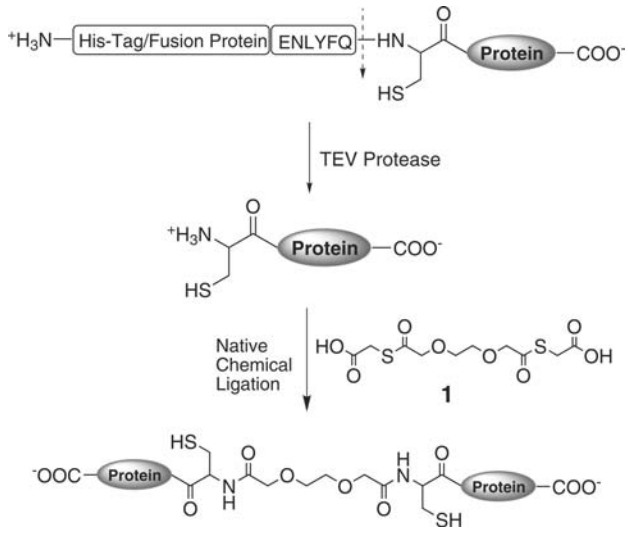

Figure 1. Strategy for the synthesis of expressed protein dimer.

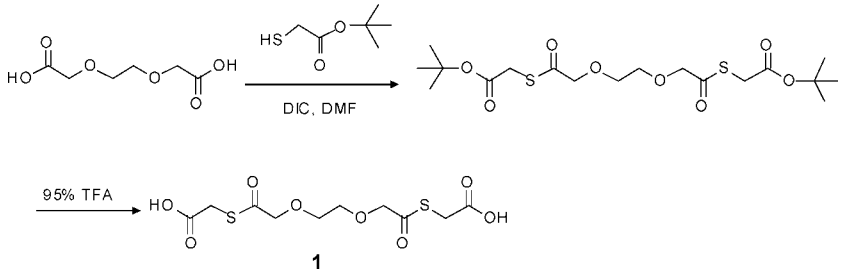
N-terminus using native chemical ligation and (2) coupling of the azide and alkyne monomers together through CuAAC to form the triazole linked dimer. A second disadvantage is the use of copper in CuAAC, which may cause methionine oxidation and which we have also observed to cause difficulties when applied to triazole formation with proteins containing multiple cysteine residues (unpublished observations). Herein, we develop a more general and straightforward single-step strategy for the synthesis of N-terminally linked protein homodimers using native chemical ligation. This strategy utilizes native chemical ligation (*31*) to conjugate a monoethylene glycol dithioester linker to the N-terminal cysteines of two protein monomers forming a dimer linked together by stable peptide bonds. Native chemical ligation is a highly selective reaction between a thioester and a N-terminal cysteine, and internal cysteines do not interfere with this reaction. Thus, this strategy is general and can be applied to both small peptides and large proteins containing multiple cysteines.

In our strategy, a target protein is first recombinantly expressed as a fusion protein that contains a tobacco etch virus NIa (TEV) protease cleavage sequence between a His-tag or fusion partner and the target protein. TEV protease cleavage of the fusion protein produces the target protein with a N-terminal cysteine (*32*). The N-terminal cysteines of two protein monomers are then conjugated together with a monoethylene glycol dithioester linker via native chemical ligation to form the N-terminally linked homodimer (Figure 1). During native chemical ligation, the internal cysteines are unreactive, and therefore, our strategy can be applied to expressed peptides and proteins containing single or multiple cysteine residues.

A sequential two-step ligation strategy (ligation of one protein onto one end of the dithioester linker first, purification, and then ligation of the second protein onto the other end) is not suitable for the dithioester linker because thioester moieties are hydrolytically labile. Because of this, the second thioester would be hydrolyzed to a carboxylic acid before it could be utilized to form a dimer. Thus, a one-step synthesis strategy was investigated for dimer formation using dithioester linkers. In this strategy, excess protein rather than the dithioester linker was used to force the protein to be ligated onto the both ends of the dithioester linker simultaneously.



Synthesis of the monoethylene glycol dithioester linker **1** was accomplished by coupling 3,6-dioxaoctanedioic acid with 4 equiv of *t*-butyl mercaptoacetate using 4 equiv of 1,3-diisopropylcarbodiimide as the coupling reagent. This formed a *t*-butyl protected dithioester linker, which was purified by flash chromatography. The *t*-butyl protecting group was then removed by treatment with 95% trifluoroacetic acid and purified by reverse-phase HPLC to afford the dithioester linker **1** with an overall 28% yield (Scheme 1).

To work out the one-step dimer synthesis strategy, a small protein, the C2 domain of Protein G, which is an immunoglobulin-binding protein found in group G streptococci (*33*), was chosen as a model protein. Protein G was expressed as a fusion protein with a TEV protease cleavable His-tag in *E. coli* (*34*). After purification by Ni^{2+}-NTA affinity chromatography, the fusion protein was concentrated to 6 mg/mL (0.5 mM) and treated with TEV protease at room temperature for 24 h to generate the desired Protein G with a N-terminal cysteine. The cleaved Protein G was then dialyzed against ligation buffer (5 mM betaine, 20 mM sodium phosphate at pH 7.5) at 4 °C overnight and used directly in the dimer formation reaction without further purification.

The dimer formation reaction was carried out by incubation of 4 mL of 0.5 mM cleaved Protein G solution with 0.25 equiv of dithioester linker **1** (50 μL of 10 mM stock solution) and 30 mM sodium 2-mercaptoethanesulfonate at room temperature. The reaction was quenched by addition of 10 mM DTT after 24 h. The resulting Protein G dimer was separated from the excess Protein G monomer by size exclusion chromatography. After purification, 4.2 mg of Protein G dimer was obtained, giving a 62% yield based on the amount of **1** as the limiting reagent. The Protein G dimer was characterized by SDS-PAGE and ESI-MS analysis. On the SDS-PAGE gel (Figure 2, lane 2), only one band appeared after size exclusion chromatography, indicating that the protein G dimer is pure after size exclusion chromatography. The expected molecular weight of the Protein G dimer is 13 615 Da. Although the Protein G dimer migrated between the 20.0 kDa and 14.3 kDa protein markers on the SDS-PAGE gel, the ESI-MS analysis of the Protein G dimer gave a molecular weight of 13 614 Da, which is consistent with the expected molecular weight (Figure 3A and Supporting Information Figure S4). All these results indicated that the desired Protein G dimer was formed and was pure.

Since the one-step dimer synthesis strategy worked well on the small model Protein G, we went further and applied this strategy to a smaller biologically active peptide, C37H6, and a larger biologically active protein, interleukin-1 receptor antagonist (IL-1ra). C37H6 is an HIV entry inhibitor peptide derived

Scheme 1. Synthesis of the Monoethylene Glycol Dithioester Linker 1

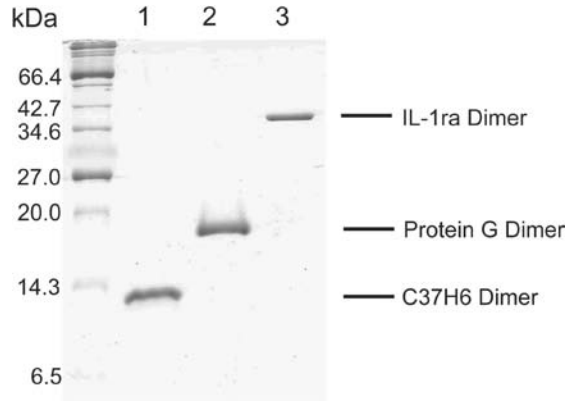


Figure 2. SDS-PAGE of purified dimers: (lane 1) C37H6 dimer, (lane 2) Protein G dimer, (lane 3) IL-1ra dimer.

from the HIV gp41 (*35*, *36*). IL-1ra is an inhibitor of the proinflammatory action of interleukin-1 and has been used as a drug for the treatment of rheumatoid arthritis (*37*, *38*). The cys-IL-1ra protein used in this paper also contains four cysteine residues and so allowed us to test this one-step dimer synthesis approach with a multicysteine containing protein.

The C37H6 peptide was expressed and purified as a fusion protein with xanthine-guanine phosphoriboysyltransferase (GPRT) as described previously (*36*). After purification, the GPRT-C37H6 fusion protein was concentrated to 12 mg/mL (0.5 mM) and treated with TEV protease to generate N-terminal cysteine containing C37H6. Next, 4 mL of the 0.5 mM cleaved C37H6 was incubated for 24 h with 0.25 equivalents of **1** (50 μL of 10 mM stock solution) in the presence of 30 mM sodium 2-mercaptoethanesulfonate. The resulting C37H6 dimer was purified by size exclusion chromatography, yielding 3.2 mg of the C37H6 dimer (56% yield). ESI-MS analysis (Figure 3B and Supporting Information Figure S5) of the C37H6 dimer gave only one molecular weight of 11 397 Da, which is consistent with the expected molecular weight of 11 398 Da. The SDS-PAGE gel also showed only one band that migrated to the approximate mass of the product. Thus, the desired, pure C37H6 dimer was also produced using this strategy.

In a manner similar to that for Protein G, the IL-1ra protein was also expressed and purified as a fusion protein with a TEV protease cleavable His-tag and concentrated to 0.5 mM (11 mg/mL). TEV protease cleavage and the dimer formation reaction to form an IL-1ra dimer were carried out as reported for Protein G. However, size exclusion chromatography purification did not separate the IL-1ra dimer from monomer well. Therefore, a SP-sepharose anion exchange column was applied twice to completely separate the IL-1ra dimer from the excess monomer and resulted in 4.9 mg of purified product (28% yield). ESI-MS analysis (Figure 3C and Supporting Information Figure S6) of IL-1ra dimer gave a molecular weight of 35 061 Da, which is consistent with the expected molecular weight of 35 057 Da. The SDS-PAGE gel also demonstrated that the IL-1ra dimer was pure. All these results demonstrated that our protein dimer synthesis strategy can be applied to both expressed small peptides and large proteins.

To determine if dimer formation altered the biological activities of C37H6 and IL-1ra, biological assays of HIV entry inhibition and IL-1ra antagonism of the IL-1 receptor were conducted. The inhibitory activities of the C37H6 monomer and dimer were examined using a luciferase based cell−cell fusion inhibition assay (*39*). In this assay, fusion between HL2/3 cells and TZM-bl cells was inhibited by C37H6 peptides which resulted in a decrease of luciferase activity (Figure 4A). On the basis of three independent assays, the C37H6 dimer showed an IC_{50} value of 2.33 ± 0.08 nM, which is 1.9-fold more potent

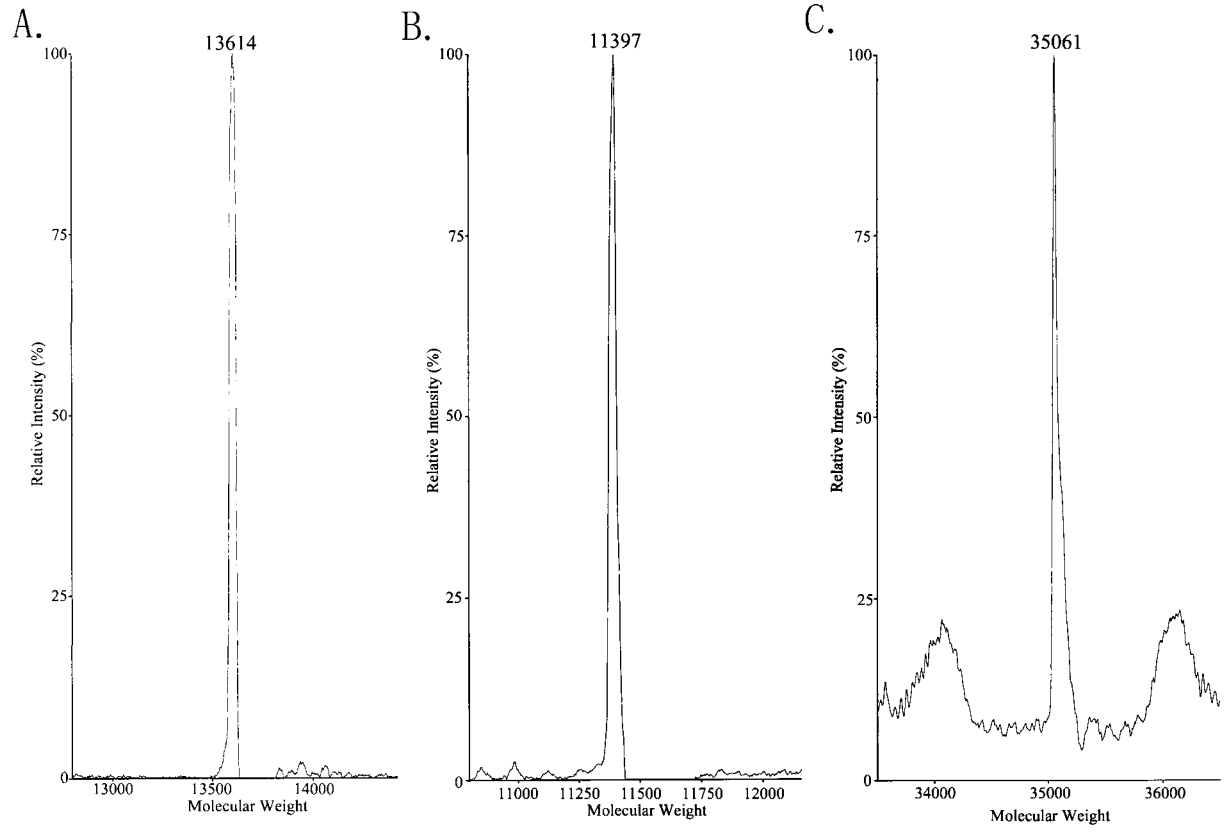

Figure 3. Reconstructed ESI mass spectra of (A) Protein G dimer, calcd 13 615 Da, found 13 614 Da; (B) C37H6 dimer, calcd 11 398 Da, found 11 397 Da; (C) IL-1ra dimer, calcd 35 057 Da, found 35 061 Da.

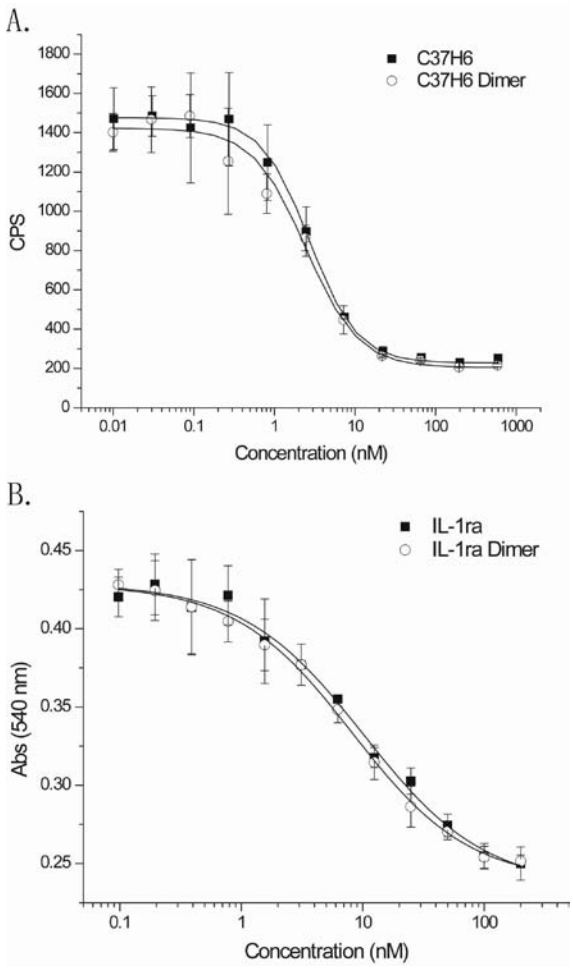

Figure 4. (A) Results from a typical cell−cell fusion inhibition assay of C37H6 monomer (solid square) and C37H6 dimer (open circle); (B) results from a typical competition assay of interleukin-1β induced proliferation with the IL-1ra monomer (solid square) and IL-1ra dimer (open circle).

than the C37H6 monomer (IC_{50}: 4.40 ± 0.10 nM). The biological activities of the IL-1ra monomer and dimer were determined using a proliferation assay, in which the interleukin-1β induced proliferation of the mouse D10.G4.1 T cell line was inhibited by IL-1ra proteins (Figure 4B) (*40*). The IL-1ra dimer resulted in an IC_{50} value of 7.63 ± 0.62 nM and the activity is similar (1.2-fold more potent than) to the monomeric IL-1ra (IC_{50}: 9.02 ± 1.11 nM). The dimer formation only slightly increased the activity of the C37H6 and IL-1ra dimers, which might due to the short linker length of **1**. Their activities might be improved more by using longer PEG linkers. Additionally, dimer formation doubled their molecular weights from 5628 Da and 17 458 Da to 11 398 Da and 35 057 Da for C37H6 and IL-1ra, respectively. In the case of IL-1ra, the increased molecular weight of the IL-1ra dimer could potentially slow down the glomerular filtration by the kidney and consequently increase its in vivo half-live.

In conclusion, a strategy for the synthesis of N-terminally linked dimeric expressed proteins and peptides was developed. This one-step strategy utilizes native chemical ligation to conjugate the N-terminal cysteine of two proteins together through a monoethylene glycol dithioester linker with a stable peptide bond linkage. The strategy is highly efficient in aqueous solution at neutral pH and can be applied to both small peptides and large proteins. It also works with proteins that contain multiple cysteine residues, as demonstrated by the synthesis of the IL-1ra dimer. Slightly increased activity of the dimeric forms of C37H6 and IL-1ra were observed in bioassays. Although the activities of the C37H6 dimer and IL-1ra dimer were not increased greatly, the linker could be easily altered by using a longer PEG linker to potentially improve their biological activities. Moreover, dimer formation doubles the molecular weight of bioactive peptides and proteins with a minimal ethylene glycol synthetic modification, which could potentially increase in vivo half-lives of proteins without forming anti-PEG antibodies.

Materials. 3,6-Dioxaoctanedioic acid, 1,3-diisopropylcarbodiimide (DIC), betaine, and sodium 2-mercaptoethanesulfonate were purchased from Sigma-Aldrich. Anhydrous solvents were purchased and used without purification. Dulbecco's modified Eagle's medium (DMEM), RPMI 1640 medium, fetal bovine serum (FBS), penicillin, and streptomycin were obtained from Hyclone Laboratories, Inc. ^{1}H and ^{13}C NMR spectra were recorded on a 300 MHz Varian Gemini 2000 NMR spectrometer. High resolution CI mass spectrometry was performed on a Thermo Electron Corporation MAT 95XP-Trap. Low resolution ESI mass spectrometry was performed on a PE Sciex API III.

Synthesis of Mono-Ethylene Glycol Dithioester Linker 1, 4,11-Dioxo-6,9-dioxa-3,12-dithiatetradecane-1,14-dioic acid. 3,6-Dioxaoctanedioic acid (178 mg, 1.0 mmol), *t*-butyl mercaptoacetate (*1*) (593 mg, 4.0 mmol) and DIC (505 mg, 4.0 mmol) were dissolved in DMF anhydrous (10 mL). After stirring at room temperature for 24 h under N_2, the solvent was removed by rotavapor. The residue was purified by flash chromatography (ethyl acetate/hexane 20:80). After removal of solvents, the residue was dissolved in 95% TFA (10 mL) and stirred at room temperature for 30 min. The TFA and water were then azeotroped with toluene by rotavapor and the residue was purified by C18 reverse phase HPLC (Alltech Hyper Prep C18 column, 10 mm I.D., 250 mm length, gradient 5-75% acetonitrile in H_2O, 0.1% TFA over 40 min with a flow rate of 4 mL/min, detection at 220 nm), affording 90 mg of the dithioester PEG linker **1** as a colorless oil (28% yield). ^{1}H NMR (300 MHz, D_2O): δ 4.21 (s, 4H), δ 3.71 (s, 4H), δ 3.61 (s, 4H; ^{13}C NMR (300 MHz, D_2O): δ 202.53,

173.50, 75.56, 71.49, 30.91; HR-CI-MS (m/z): calcd for $C_{10}H_{15}O_8S_2$ $(M+H)^+$ 327.0203, obsd 327.0205.

Expression and Purification of GRT-C37H6 and Protein G Fusion Protein. The GPRT-C37H6 fusion protein and His-tag fused Protein G fusion protein were expressed and purified as described previously (*2, 3*). After purification, the GPRT-C37H6 and Protein G fusion proteins were concentrated to 0.5 mM (12 mg/mL and 6 mg/mL, respectively) by centrifugation at 12,390 g using a centrifugation vial containing a 10,000 Da molecular weight cutoff membrane (Amicon/Millipore).

Cloning of IL-1ra Fusion Protein. Primers were designed based on the human gene sequence (ATCC # 10658607, MGC-10430) of interleukin-1 receptor antagonist (IL-1ra). An EcoR I restriction site sequence, TEV protease site sequence, and codons for a Cys followed by four Gly residues were added to the IL-1ra DNA sequence in the 5'-primer (gaaaacctgtattttcagtgcggtggaggtggacgaccctctgggagaaaatcc). A Not I restriction site sequence was added to the 3'-primer after IL-1ra encoding DNA (gcggccgcctactcgtcctcctggaagtagaa). The IL-1ra gene was subcloned into the bacterial expression vector pET28a (Novagen) by digestion of complementary restriction sites and subsequent ligation using T4 DNA ligase (New England Biolabs). The ligation mixture was electroporated (BioRad micropulser) into Top 10 f' *E. coli* (Invitrogen) using a 0.1 cm electroporation cuvette. The resulting bacterial solution was selected on a LB (50 μg/mL kanamycin) plate. The successful insertion and absence of mutations for a selected bacterial colony was determined by DNA sequencing. The resulting

construct was named Cys-ILra-pet28a. The Cys-ILra-pet28a construct was transformed into Rosetta-gami2 (DE3) *E. coli* for protein expression.

Expression and Purification of IL-1ra Fusion Protein. An IL-1ra expressing bacterial colony was inoculated into 5 mL of Luria-Bertani (LB) media containing kanamycin (50 μg/mL), chloroamphenicol (34 μg/mL), and tetracycline (10 μg/mL). The 5 mL culture was incubated, with shaking overnight at 37º C. The dense 5 mL culture was transferred into 50 mL of LB media containing the antibiotics described above and incubated, with shaking overnight at 37º C. The dense 50 mL culture was then transferred into 1 L of LB media containing the antibiotics described above and incubated at 37º C, with shaking until the OD_{600nm} reached 0.9. IL-1ra expression was induced by the addition of 0.5 mM β-D-1-thiogalactopyranoside (IPTG) and incubated, with shaking for 12 hr at 25º C before harvesting. The bacteria culture was pelleted by centrifugation at 12,390 g for 20 min (Beckman Coulter, J2-HS). The pellet was resuspended in 30 mL of buffer A (50 mM tris, pH = 7.8) and lysed by sonication. The cell debris was then pelleted by centrifuged at 38,720 g for 20 min. The resulting solution was then loaded onto a (pre-equilibrated with buffer A, 5 mL bed volume) Ni^{2+} NTA agarose resin column and washed with buffer B (50 mM tris, 300 mM NaCl, 1 mM imidazole, pH = 7.8) to remove nonspecifically bound proteins. IL-1ra was eluted with buffer C (50 mM tris, 250 mM imidazole, pH = 7.8) and collected into 2 mL fractions. The IL-1ra containing fractions, as assessed by SDS-PAGE, were pooled and concentrated to 11 mg/mL (0.5 mM) by centrifugation at 12,390 g using a centrifugation vial containing a 10,000 Da molecular weight cutoff membrane

(Amicon/Millipore).

General Procedure for TEV Protease Cleavage. TEV protease was obtained by bacterial expression (*4*). 0.5 mM of fusion protein was placed into a 3,500 Da molecular weight cutoff dialysis bag and 200 units of TEV protease were added. The dialysis bag was placed into 1 L of buffer D (20 mM sodium phosphate buffer pH 7.5, 2 mM β-ME). The TEV protease cleavage reaction was gently stirred and incubated at room temperature for 24 h to generate the N-terminal cysteine containing protein.

General Procedure for Dimer Formation by Native Chemical Ligation. 4 mL of TEV protease cleaved protein (0.5 mM) was dialyzed into 1 L of ligation buffer (5 mM betaine, 20 mM sodium phosphate at pH 7.5) at 4 °C for 12 h using 3,500 Da molecular weight cutoff dialysis bag and then transferred into a 15 mL centrifuge tube for native chemical ligation. The ligation reaction was initiated by adding 50 μL of 10 mM dithioester linker **1** (0.25 equiv) and 450 μL of 300 mM sodium 2-mercaptoethanesulfonate (30 mM final concentration) into the protein solution, and this mixture was incubated at room temperature. After 24 h incubation, the dimerization reaction was quenched by adding 10 mM DTT.

Purification of C37H6 Dimer and Protein G Dimer. The C37H6 dimer and Protein G dimer were purified using the same procedure described below. The dimerization reaction mixture was dialyzed into 1 L of buffer D at 4 °C overnight using 6,000-8,000 Da molecular weight cutoff dialysis bag. The protein sample was then applied to a size exclusion column (100 mL bed volume of Bio-Gel P-10, Bio-Rad, pre-equilibrated with buffer D). Buffer D was used to elute the column and 2 mL

fractions were collected throughout the purification. The protein dimer containing fractions, as assessed by SDS-PAGE, were pooled together. 1 mg samples of the purified protein dimers were desalted by C18 (Alltech, 250 mm x 4.5 mm) reverse phase HPLC (10-80% acetonitrile in H_2O, 0.1% TFA) and were then analyzed by low resolution ESI mass spectrometry.

Purification of IL-1ra Dimer. The IL-1ra dimerization reaction mixture was dialyzed overnight in buffer E (10 mM potassuim phosphate, 1 mM β-mercaptoethanol, pH = 6.0) using 6,000-8,000 Da molecular weight cutoff dialysis bag. The protein sample was then loaded onto a SP-sepharose anion exchange column (40 mL bed volume, Sigma, pre-equilibrated with buffer E). Dimeric IL-1ra was then eluted using a 500 mL gradient (0-0.25 M NaCl) and collected in 15 mL fractions. The IL-1ra containing fractions, as assessed by SDS-PAGE, were then pooled and dialyzed overnight in buffer E. The protein sample was then reapplied to the SP-sepharose column to completely separate the IL-1ra dimer from the monomer. The same method described above was used for the elution of the dimer. The IL-1ra dimer was then concentrated to 0.5 mg/mL using an ultrafiltration vial containing a 30,000 Da molecular weight cutoff membrane (Amicon/Millipore). A 1 mg sample of the purified IL-1ra dimer was desalted by C18 (Alltech, 250 mm x 4.5 mm) reverse phase HPLC (10-80% acetonitrile in H_2O, 0.1% TFA) and was then analyzed by low resolution ESI mass spectrometry.

Cell-Cell Fusion Inhibition Assay of C37H6. The luciferase-based cell-cell fusion assay was performed as described previously (*5*). HL2/3 and TZM-bl cells were

obtained from the NIH AIDS Research and Reference Reagent Program. The HL2/3 cell line stably expresses HIV Gag, Env, Tat, Rev and Nef proteins. The TZM-bl indicator cell line stably expresses large amount of CD4 and CCR5, and contains integrated copies of the luciferase genes under control of the HIV-1 promoter. Both of the cells were cultured in DMEM medium containing 10% FBS, 100 U/ml penicillin, and 100 U/ml streptomycin in 37 °C, 5% CO_2 incubator. The TZM-bl cells were seeded in a 96-well plates (40 μL per well, 2.5×10^4 cells per well) and incubated in 37 °C, 5% CO_2 incubator for overnight. Then, the HL2/3 cells were added into the plate (40 μL per well, 2.5×10^4 cells per well) and co-cultured with the TZM-bl cells in 37 °C, 5% CO_2 incubator for 6 h in the absence or presence of various peptide concentrations in duplication (20 μL per well). The cell-cell fusion was measured by a luciferase enzyme assay using the Steady-Glo Luciferase Assay System and following the instruction of the manufacturer (Promega, Madision, WI, USA). Background luminescence in TZM-bl was measured without the addition of HL2/3 cells in the plate. The data were obtained by a DTX 880 multimode detector (Beckman Coulter) and the IC_{50} values were calculated by Origin using sigmoidal fit. The final presented IC_{50} values represent the average of three independent assays.

Cloning, Expression and Purification of Interleukin-1β. Primers were designed based on the human gene sequence (MGC-9216) of interleukin-1β (IL-1β). An Nco I restriction site was added to the 5'-primer (ccatggcagcacctgtacgatcactgaactgcacgc) and a EcoRI restriction site was the 3'-primer (gcggccgcttaggaagacacaaattgc). The IL-1β gene was subcloned into the bacterial expression vector pET28a by digestion with

complimentary restriction sites and subsequent ligation using T4 DNA ligase. The resulting reaction mixture was transformed into Top 10 f' *E. coli* by electroporation using a 0.1 cm electroporation cuvette. The resulting bacterial solution was selected on LB plates containing kanamycin (50 μg/mL). The successful insertion and absence of mutations of a selected bacterial colony was determined by DNA sequencing. The resulting construct was named IL1-pet28a.

IL1-pet28a was electroporated into Rosetta-gami2 (DE3) *E. coli* for protein expression. The protein expression methods described above were used for the production of IL-1β. The cells were pelleted by centrifugation at 12,390 g for 20 min and resuspended in 30 mL of buffer F (10 mM potassium phosphate, pH = 6.0) and lysed by sonication. The cell debris was pelleted by centrifugation at 38,720 g for 20 min and the supernatant was dialyzed overnight in buffer F using 3,500 Da molecular weight cutoff dialysis bag.

The protein solution was loaded onto a (30 ml bed volume, pre-equilibrated with buffer F) DEAE (Toyopearl, Tosoh) cation exchange column and washed with buffer F. IL-1β passed through the column, which allowed for separation from the proteins that bound to the DEAE column. The IL-1β containing solution was then loaded onto a (40 mL bed volume, pre-equilibrated with buffer F) SP-sepharose column and eluted using a 500 mL (0-0.5 M NaCl) gradient where 15 mL fractions were collected. The IL-1β containing fractions, as assessed by SDS-PAGE, were pooled and concentrated to 5 mL by centrifugation at 12,390 g using a centrifugation vial containing a 10,000 Da molecular weight cutoff membrane. The sample was then dialyzed overnight in buffer F

using 3,500 Da molecular weight cutoff dialysis bag. The IL-1β containing solution was then loaded onto a (150 mL bed volume, pre-equilibrated with buffer F) size exclusion column (HiPrep, S-100) and eluted using buffer F at a flow rate of 0.5 mL/min. The IL-1β containing fractions, as assessed by SDS-PAGE, were pooled and loaded onto a (pre-equilibrated with H_2O, 5 mL bed volume) endotoxin removing column (Detoxi-Gel, Thermo Scientific) and washed with H_2O. IL-1β passed through the column and so the flow through and column wash were collected and concentrated to 10 mL by centrifugation at 12,390 g using a centrifugation vial containing a 10,000 Da molecular weight cutoff membrane. The IL-1β solution was then sterilized using a 0.2 micron filter in preparation for cell culture.

Biological Assay of IL-1ra. The mouse T cell line, D10.G4.1 (ATCC # TIB-224) was used to determine the inhibitory effect of IL-1β dependent proliferation of both monomeric and dimeric IL-1ra. The cells were cultured in RPMI 1640 medium containing 10% FBS, 100 U/ml penicillin, 100 U/ml streptomycin, 500 pM IL-1β, and 10% T-STIM (BD Biosciences) in 37 °C, 5% CO_2 incubator. The methods for conducting the competition assay were followed as described previously (*6*). The final presented IC_{50} values represent the average of three independent assays.

Received January 15, 2010; Revised Manuscript Received July 12, 2010

Vinblastine is a widely used anticancer drug with undesired side effects. Its conjugation with carrier molecules could be an efficient strategy to reduce these side effects. Besides this, the conjugate could exhibit increased efficiency against resistant cells, e.g., due to the altered internalization pathway. Oligoarginines, as cell-penetrating peptides, can transport covalently attached compounds into different kinds of cells and enhance the efficiency of those compounds. We report here the coupling of vinblastine through its carboxyl group at position 16 with the *N*-terminal amino function of L-Trp methyl ester. After hydrolysis of the ester group, 17-desacetylvinblastineTrp was conjugated to the *N*-terminal amino group of oligoarginine via the *C*-terminal carboxyl group of the Trp moiety in solution. The antitumor effect of conjugates was studied on sensitive and resistant human leukemia (HL-60) cells in vitro. Our data suggest that all conjugates investigated possess an antiproliferative effect against the studied cells. However, the effect was dependent on the number of Arg residues in the conjugates: $Arg_8 > Arg_6 \gg Arg_4$. The conjugate with Arg_8 exhibited similar efficicacy as compared with free 17-desacetylvinblastineTrp. The in vitro studies also showed that the tubulin binding ability of vinblastine was essentially preserved even in the octaarginine conjugate. We also observed that two isomers were formed during conjugation. These isomers showed different levels of activity against tubulin polymerization in vitro and in vivo. The 17-desacetylvinblastineTrp-Arg_8-1 isomer conjugate possessed high selectivity against the mitotic spindles. HRMS and NMR data suggest that 17-desacetylvinblastineTrp-Arg_8-1 and 17-desacetylvinblastineTrp-Arg_8-2 are epimers at the tryptophan α carbon atom.

INTRODUCTION

Vinca-alkaloids (e.g., vincristine, vinblastine) are widely used antitumor drugs isolated first from the leaves of *Catharanthus roseus* (L.) G. Don. They cause a cytotoxic effect by disturbing the dynamics of the microtubular system (*1, 2*). In vivo, these compounds interact with tubulin at the ends of microtubules in mitotic spindles and promote microtubule instability (*3*). They are bisindole alkaloids containing a rearranged catharanthine and a vindoline moiety. Vindoline, a major alkaloid of *Catharanthus roseus*, constitutes the most complex half of vinblastine, and it is both a biosynthetic and synthetic precursor of the natural product. Upon studying the tubulin binding ability of the two parts separately, it turned out that only the catharanthine part could bind to tubulin, but this interaction is weaker than that for the bisindole alkaloids (*4*). It was concluded that the indole part of catharanthine could be responsible for the binding of vinblastine/vincristine to tubulin and the vindoline moiety could function as an anchoring residue.

The structure of vinblastine and vincristine differs only in the nature of the substituent, a methyl or a formyl group, respectively, on the vindoline *N*-atom, but this "minor" difference leads to different antitumor efficacies, potencies, and toxicities. Vinblastine is in clinical use with success in the treatment of testicular cancer, non-Hodgkin's lymphoma, and breast cancer. However, vincristine is more effective against Hodgkin's disease and pediatric solid tumors. Vinblastine treatment can result in leucopenia, while vincristine might be neurotoxic. These differences indicate that there is a marked relationship between the chemical structure and the biological effect of these alkaloids. To eliminate or reduce the side effects of these potent vinca-alkaloids, much effort has been directed toward the synthesis of new derivatives.

In the first experiments, Barnett et al. synthesized 17-desacetylvinblastine-amide (vindesine) by modifying the methyl ester group at position C-16 of the vindoline part. Vindesine and vincristine exhibited very similar biological activity spectra in animal experiments, but the neurotoxicity of the former was lower (*5*). Further compounds were prepared by modification of the amide group by incorporating different alkyl groups (*6*) or amino acids (*7*). Among the amino acid derivatives, the hydrophobic amino acid (Leu, Ile, Val, and Trp) containing derivatives showed pronounced activity. The Trp-OEt derivative had an outstanding effect on P388 and L1210 leukemias implanted intravenously in DBA_2 mice (*7*).

Various bioconjugates of vinblastine derivatives were also prepared for targeting. Conjugates with tumor-specific antibodies (*8*), for example, KS1/4 (*9*), carcinoembryonic antigen (CEA) (*10*), epidermal growth factor receptor (*11*), or PF1/D, a squamous carcinoma-reactive monoclonal antibody (*12*), were also produced and tested extensively. In other experiments, 17-desacetylvinblastine monohydrazide was coupled with folic acid

Published on Web 10/25/2010

as a targeting unit via a peptide spacer (*13, 14*). The conjugate could bind to the folate receptor positive cells and produced specific, dose-responsive activity in vitro. In vivo tests confirmed the activity of the conjugate in both syngeneic and xenograft models with minimal to moderate toxicity.

Oligoarginines are members of the cell-penetrating oligopeptide family. These synthetic or natural peptides permeate the cell membrane and transport the covalently attached cargoes into the cytosole. Among oligoarginines, hexa-, hepta-, and octaarginine showed the most effective internalization (*15, 16*). Different oligoarginines were used efficiently to transport genetically or chemically attached protein, peptide, and noncovalently bound plasmid DNA into cells (*17*). Oligoarginines can also be used to transport covalently coupled small molecules into cells, like cyclosporin A (*18*), ferrocene (*19*), and daunomycin (*20*) derivatives or bisubstrate-analogue inhibitors of basophilic protein kinases (adenosine, 5′-adenosine-carboxic acid) (*21*).

In this work, we report on the synthesis of oligoarginine (Arg_n, where $n = 4$, 6, or 8) conjugates with the Trp-derivative of vinblastine via amide bond formation in solution. We observed and isolated two isomers after conjugation. The effect of these compounds on sensitive and resistant HL-60 (human leukemia) cells was studied. Furthermore, we described our findings on the influence of conjugates on the in vitro and in vivo tubulin polymerization. Data suggest that the cytotoxicity of the conjugates was dependent on the chain length of the peptides. Moreover, only the 17-desacetylvinblastineTrp-Arg_8-1 conjugate exhibited the capability to destroy only the mitotic spindle and cause the apoptosis of the cells that are in mitosis. On the basis of HRMS and NMR data, we also report on the structure identification of the isomers proposing that 17-desacetylvinblastineTrp-Arg_8-1 and 17-desacetylvinblastineTrp-Arg_8-2 are epimers at the α-carbon atom of the Trp residue.

EXPERIMENTAL PROCEDURES

Fmoc-Arg(Pbf)-OH was purchased from Novabiochem (Läufelfingen, Switzerland), while thioanisole, 1,2-ethanedithiol (EDT), *N*-diisopropyl-ethylamine (DIEA), 1-hidroxybenztriazole (HOBt), *N,N′*-diisopropylcarbodiimide (DIC), trifluoracetic acid (TFA), phenol, ninhydrine, piperidine, 1,8-diazabicyclo[*5.4.0*]undec-7-ene (DBU) were Fluka (Buchs, Switzerland) products. The Rink-amid MBHA resin was from Novabiochem (Läufelfingen, Switzerland). Reagents and solvents used in the biological assays were purchased from Sigma-Aldrich Ltc (Budapest, Hungary). Solvents (dimethyl formaide (DMF), dichloromethane (DCM), diethyl ether, acetonitrile (AcN)) for syntheses and purification were obtained from Reanal (Budapest, Hungary).

General Procedures. Analytical RP-HPLC was performed on a Knauer (Herbert Knauer GmbH, Berlin, Germany) system using a Phenomenex SYNERGI MAX-RP column (250 × 4.6 mm I.D., 4 μm silica, 80 Å pore size) (Torrance, CA, USA) as a stationary phase. Linear gradient elution (0 min 0% B; 5 min 0% B; 50 min 90% B) was generated using 0.1% TFA in water as eluent A and 0.1% TFA in acetonitrile−water (80:20, V/V) as eluent B. Flow rate of 1 mL/min was applied at ambient temperature. The samples were dissolved in eluent B. The crude products were purified on a semipreparative Phenomenex Jupiter C18 column (250 × 10 mm I.D., 10 μm silica, 300 Å pore size) (Torrance, CA, USA). The flow rate was 4 mL/min. Peaks were detected at λ=220 nm. Positive ion electrospray ionization mass spectrometric analysis was performed on a Bruker Esquire 3000 plus (Germany). The samples were dissolved in acetonitrile−water (50:50, V/V), containing 0.1% acetic acid. High-resolution MS measurements were carried out on a Thermo LTQ FT Ultra mass spectrometer using ESI (source voltage, 4.2 kV; capillary voltage, 43 V; capillary temperature, 200 °C; sheath gas flow rate, 10 arb; aux gas flow rate, 2 arb; sweep gas flow rate, 2 arb; solvent, MeOH/H_2O 1:1 + 1 v/v % cc. AcOH) ionization technique.

All NMR measurements were performed on a Varian 800 MHz NMR spectrometer equipped with a ^{13}C enhanced HCN cold probe. $^1H-^1H$, direct $^1H-^{13}C$, long-range $^1H-^{13}C$ scalar, and dipolar spin−spin connectivities were established from ^1H, 2D-GHSQCAD, GCOSY, 2D-GHMBCAD, and 2D-ROESY NMR experiments, respectively. All pulse sequences were applied by using the standard spectrometer software package.

Synthesis of Oligoarginines. Oligoarginines (tetra-, hexa-, and octaarginine) were synthesized manually by solid-phase methodology on Rink-amide resin (0.3 g, 0.69 mmol/g) using Fmoc/^{t}Bu strategy. The side chain of Arg was protected with 2,2,4,6,7-pentamethyldihydrobenzofuran-5-sulfonyl group. N^{α}-Fmoc group was removed with 2% piperidine plus 2% DBU in DMF (2 + 2+5 + 10 min) followed by washing with DMF (8 × 0.5 min). For coupling, the Arg derivative and DIC and HOBt dissolved in DMF were used in 3-fold molar excess for the resin capacity. The reaction proceeded at RT for 60 min. Then, the resin was washed (DMF 2 × 0.5 min, DCM 3 × 0.5 min). The efficiency of coupling was checked by ninhydrin assay (*22*). The amount of resin was divided into three parts during the synthesis. After assembly, the peptide was cleaved from the resin by 10 mL of TFA using 0.75 g of phenol, 0.5 mL of distilled water, 0.5 mL of thioanisole, and 0.25 mL of 1,2-ethandithiol as scavengers. The crude product was precipitated by dry diethyl ether, dissolved in 10% acetic acid, and freeze−dried. Purification was done by RP-HPLC as described above. The following gradients were applied for purification: 0 min 0% B; 5 min 0% B; 50 min 50% B.

Synthesis of Conjugates. First, 17-desacetylvinblastineTrp was prepared by coupling the unprotected 17-desacetylvinblastine to Trp as described earlier (*7*) with some modifications. Briefly, vinblastine was refluxed in an ethanol−chloroform mixture with 98% hydrazine monohydrate instead of anhydrous hydrazine used in the published paper mentioned above. The corresponding acid azide was prepared with sodium nitrite in the presence of hydrochloric acid. The latter compound, without isolation, was allowed to react with L-Trp methyl ester in dichloromethane at 4 °C to give the Trp derivative of 17-desacetylvinblastine (*23*). After hydrolysis of the carboxylic ester, the corresponding 17-desacetylvinblastineTrp carboxylic acid (3 mg, 3.15 μmol) was coupled to oligoarginines (Arg_n, where $n = 4$, 6, or 8) (6.3 μmol) by DCC (1.3 mg, 6.3 μmol); HOBt (1 mg, 6.3 μmol) in the presence of DIEA (1.1 μL, 6.3 μmol) in 0.5 mL DMF. The reaction proceeded at RT for 4 h. The DMF was evaporated and conjugates were purified by RP-HPLC using the following gradient: 0 min 5% B; 5 min 5% B; 50 min 80% B as described above.

Cell Cultures. HeLa (ATCC, CCL-2) cells were grown in DME/F-12 medium supplemented with 10% FCS, 1 mM sodium pyruvate, 100 U/mL streptomycin, and 100 μg/mL penicillin (all from Sigma) (complete medium) in a humidified 37 °C incubator with 5% CO_2. The sensitive and resistant HL-60 human leukemia cells (ATCC: CCL-240) were cultured in RPMI-1640 medium supplemented with 10% FCS, 2 mM L-glutamine, and 160 μg/mL gentamycin. The cell culture was maintained at 37 °C in a humidified atmosphere with 5% CO_2.

MTT Assay. For cytostatic studies, sensitive and resistant HL-60 cells were placed in a 96-well plate with each well containing 5 × 10^3 cells. After incubation at 37 °C for 24 h, the cultured cells were treated with the solution of conjugates in serum-free RPMI-1640 medium for 3 h. Compounds were used at the $c = 2 \times 10^{-3}$ to 8 × 10^2 μM range. In control experiments, cells were treated with serum-free medium at 37 °C for 3 h. After incubation, cells were washed with serum-

free medium three times, and serum-containing medium was added to the cells. After 3 days at 37 °C, the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay was carried out. The yellow solution of MTT at a concentration of 0.2 mg/mL was added to each well. The obtained purple crystal was dissolved in DMSO, and the optical density (OD) of the samples was measured at $\lambda = 540$ nm using ELISA Reader (Labsystems MS Reader, Finland). The percentage of the antitumor effect was calculated using the following equation:

$$\text{antitumor effect } \% = (1 - \text{OD}_{\text{treated}}/\text{OD}_{\text{control}}) \times 100$$

where $\text{OD}_{\text{treated}}$ and $\text{OD}_{\text{control}}$ correspond to the optical densities of the treated cells and the control cells, respectively, at $\lambda = 540$ nm. Results obtained from in vitro cytotoxicity measurements were analyzed using sigmoidal curve fitting.

Tubulin Preparation. Microtubule-associated protein (MAP)-depleted tubulin was purified from bovine brain by the method of Na and Timasheff (*24*) and stored in 10 mM phosphate buffer, pH 7.0, containing 1 M of sucrose, 0.5 mM of $MgCl_2$, and 1 mM of GTP at −80 °C. Purified tubulin showed no contamination with MAPs on overloaded SDS-PAGE. Before use, stored tubulin was dialyzed against 50 mM of 4-morpholine ethanesulfonic acid (MES) buffer, pH 6.8, at 4 °C for 3 h and then centrifuged at 100 000 *g* at 4 °C for 20 min.

Polymerization Assay. Ten micromoles of tubulin was assembled to microtubules at 37 °C in polymerization buffer (50 mM of MES buffer, pH 6.6, containing 1 mM of dithioerythritol, 1 mM of $MgCl_2$, 1 mM of EGTA (ethylene glycol tetraacetic acid), and 100 mM of KCl. The polymerization was initiated with 20 μM of paclitaxel at 37 °C. Vinblastine, 17-desacetylvinblastineTrp, and 17-desacetylvinblastineTrp−octaarginine conjugates in the 0.05−2 μM concentration range were incubated with tubulin at 37 °C for 5 min before starting the polymerization. For turbidity measurements, the absorbance was monitored at $\lambda = 350$ nm with a Cary 100 spectrophotometer (Varian, Mulgrave, Victoria, Australia). The error margin of the turbidity measurements was ±5% within a series of experiments.

Immunocytochemistry. For microscopic studies, HeLa cells were grown on 12 mm diameter coverslips. The vinblastine, 17-desacetylvinblastineTrp, and 17-desacetylvinblastineTrp−octaarginine conjugates were added to the complete medium of the cells in the 0.25−5 μM concentration range for 24 h and then were fixed with ice-cold methanol for 15 min and immunostained for α-tubulin as described by Lehotzky et al. (*25*). Nuclei were counterstained with 4′,6-diamidino-2-phenylindole (DAPI) after coverslips were mounted on an Aqua Poly/Mount medium (Sigma). Images were taken on a Leica DMLS microscope (Leica Microsystems, Wetzlar, Germany) equipped with a cooled CCD camera (Spot, Digital Instruments, Sterling Heights, MI, USA). Statistical analysis was performed manually by investigating random microscopic fields. Data were analyzed with Microsoft *Excel*. Images were processed with *ImageJ* software.

RESULTS AND DISCUSSION

To avoid the undesired effect of antitumor drugs and to increase their efficiency against resistant cells is a difficult task to achieve. The conjugation of small drug molecules to carriers could be considered as a potential strategy for utilization. In this paper, we describe the synthesis and in vitro antitumor effect of oligoarginine conjugates of the Trp derivative of 17-desacetylvinblastine. The influence of these compounds on the tubulin polymerization was also studied in vitro and in vivo.

Synthesis of Conjugates. Among the amino acid ester derivatives of viblastine, the tryptophan derivative showed the highest antitumor effect in mice (*7*). Accordingly, for the present studies 17-desacetylvinblastineTrp (*7*, *23*, *26*) was prepared with a modified procedure using 17-desacetylvinblastine (*26*), as the major metabolite of vinblastine in humans considering its pharmacological equivalency with vinblastine (*27*) (Scheme 1).

Scheme 1. Synthesis of 17-DesacetylvinblastineTrp

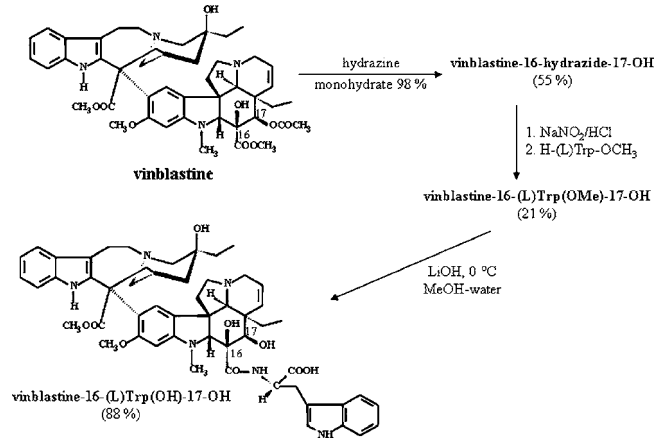

Table 1. Characteristics of 17-DesacetylvinblastineTrp−Oligoarginine Conjugates

conjugate	R_t[a] (min)	$[M+H]^+$,[b] cal. [meas.]
17-desacetylvinblastineTrp-Arg_4-1	27.9	1564.9 (1564.3)
17-desacetylvinblastineTrp-Arg_4-2	26.3	1564.9 (1564.3)
17-desacetylvinblastineTrp-Arg_6-1	26.0	1877.3 (1876.7)
17-desacetylvinblastineTrp-Arg_6-2	26.3	1877.3 (1876.7)
17-desacetylvinblastineTrp-Arg_8-1	26.3	2189.6 (2189.1)
17-dezacetylvinblasztinTrp-Arg_8-2	26.6	2189.6 (2189.1)

[a] RP-HPLC retention time, column: Phenomenex SYNERGI MAX-RP (250 × 4.6 mm I.D., 4 μm silica, 80 Å pore size). Linear gradient elution 0 min 0% B; 5 min 0% B; 50 min 90% B using 0.1% TFA in water as eluent A and 0.1% TFA in acetonitrile−water (80:20, V/V) as eluent B. [b] ESI-MS.

17-DesacetylvinblastineTrp was conjugated with tetra-, hexa-, or octaarginine in solution. First, the oligoarginines were built up on Rink-amide resin by Fmoc/^{t}Bu strategy, and after cleavage from the resin by TFA, the unprotected and purified *C*-terminal peptide amides were used for the conjugation. 17-DesacetylvinblastineTrp was coupled to the peptides by the active ester method using DCC/HOBt coupling reagents in DMF in the presence of DIEA as base. The conjugates were characterized by analytical RP-HPLC and ESI-MS (Table 1 and Figure 1 in Supporting Information).

The conjugation reaction resulted in two isomers with different retention times, but with the same molecular mass in all three cases. The isomers were separated, isolated, and characterized, and their biological effects were examined. To identify the structure of the two isomer conjugates, these compounds were studied by high-resolution MS and NMR.

Identification of the Structure of the Two Isomers of the Octaarginine Conjugates. The two compounds (17-desacetylvinblastineTrp-Arg_8-1 and 17-desacetylvinblastineTrp-Arg_8-2) obtained during the preparation of the 17-desacetylvinblastineTrp octaarginine conjugate were investigated after HPLC separation.

High-Resolution Mass Spectrometry. In the direct ESI mass spectra of the samples 17-desacetylvinblastineTrp-Arg_8-1 and 17-desacetylvinblastineTrp-Arg_8-2 multiply charged ions of $[M+4H]^{4+}$, $[M+5H]^{5+}$ and $[M+6H]^{6+}$ can be detected. The monoisotopic mass values were obtained by the deconvolution of the mass spectra (using Xtract in *Xcalibur 2.0.7*): 17-DesacetylvinblastineTrp-Arg_8-1: *m*/*z* 2188.29693, calculated value for $C_{102}H_{161}O_{16}N_{39}$: 2188.29780 ($\delta$ −0.4 ppm). 17-

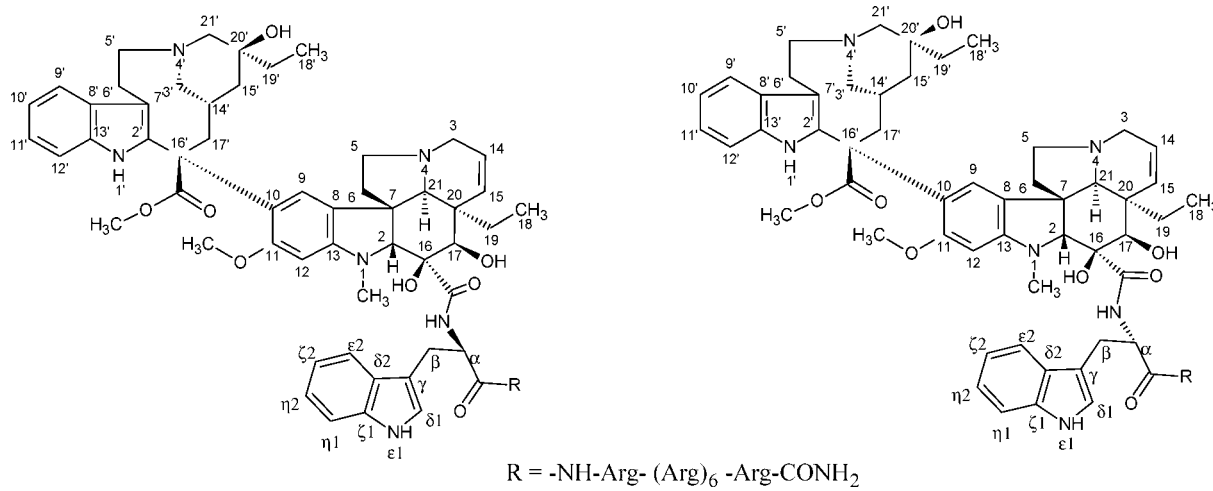

Figure 1. Structures proposed for the two isomeric Arg8 conjugates of 17-desacetylvinblastineTrp: 17-desacetylvinblastineTrp-Arg$_8$-1 (left) and 17-desacetylvinblastineTrp-Arg$_8$-2 (right).

DesacetylvinblastineTrp-Arg$_8$-2: *m/z* 2188.29728, calculated value for $C_{102}H_{161}O_{16}N_{39}$: 2188.29780 ($\delta$ −0.2 ppm).

The most intense $[M+5H]^{5+}$ ion peaks were fragmented by CID (collision induced dissociation) at a normalized collision energy of 25%. The monoisotopic mass values of the main fragment ions in the deconvoluted MS-MS spectra are the following: 17-DesacetylvinblastineTrp-Arg$_8$-1: *m/z* 2129.25013, 2015.17064, 1876.09619, 1702.96880, 1660.94691, 1537.91516, 1501.89406, 1348.74426, 1234.66543, 1192.64356, 1174.63301, 1078.56404, 648.36752, 523.28346. 17-DesacetylvinblastineTrp-Arg$_8$-2: *m/z* 2129.25155, 2015.17057, 1876.09677, 1234.66544, 1192.64463, 1174.63280, 953.63348, 894.46857, 708.38901, 648.36785.

On the basis of the accurate mass values of the fragment ions in the MS−MS spectra, elemental compositions were calculated using the *Xcalibur 2.0.7* software. In the range of 0.2−1.5 ppm mass accuracy, plausible elemental compositions could be obtained for all of the fragment ions. All of these elemental compositions are in agreement with the expected 17-desacetylvinblastineTrpArg$_8$ chemical structure. However, when comparing the MS-MS spectra of the two samples some differences can be noticed regarding the obtained fragment ions and their relative abundance values. Most of the fragment ions were obtained by the cleavage of the Arg$_8$ part of the molecule for both samples. In the case of 17-desacetylvinblastineTrp-Arg$_8$-1, more fragment ions were produced by the cleavage of the vindoline C ring (cleavage of the C_2-C_{16} and $C_{17}-C_{20}$ bonds), while exclusively for 17-desacetylvinblastineTrp-Arg$_8$-2, a single minor fragment ion was observed in the deconvoluted mass spectrum, which can originate from a C−C cleavage beside the carbonyl group of the Tryptophan. According to these MS data, compounds 17-desacetylvinblastineTrp-Arg$_8$-1 and 17-desacetylvinblastineTrp-Arg$_8$-2 are two stereoisomers of 17-desacetyvinblastineTrpArg$_8$.

NMR. Since both compounds 17-desacetylvinblastineTrp-Arg$_8$-1 and 17-desacetylvinblastineTrp-Arg$_8$-2 were available only in a limited amount for NMR measurements, only limited spectroscopic information could be obtained on an affordable time scale even on our ultrasensitive 800 MHz NMR spectrometer. Furthermore, due to their conformational dynamics both compounds gave broad ^{1}H NMR resonances in all common NMR solvents (such as DMSO-d_6, $CDCl_3$, ACN-d_3, MeOD-d_4, or D_2O), which prohibited easy access to the desired spectroscopic information (see Supporting Information Figure 2 as an example) in this concentration. Finally, a solvent mixture containing ACN-d_3 and D_2O in a one-to-one ratio was chosen as the most suitable medium. Although most of the resonances (mainly those belonging to the vindoline half of the two molecules) were still significantly broadened in this solvent mixture, structurally informative spectral information could nevertheless be obtained. In accordance with the HRMS results, these data suggest that 17-desacetylvinblastineTrp-Arg$_8$-1 and 17-desacetylvinblastineTrp-Arg$_8$-2 are epimers at the tryptophan α-carbon atom (Figure 1).

Partial ^{1}H and ^{13}C NMR assignments (determined from ^{1}H, 2D-GHSQCAD, GCOSY, 2D-GHMBCAD, and 2D-ROESY NMR spectra) that are indicative of the proposed epimeric structures are listed in Table 1 in Supporting Information. These structures are supported via the following argument. The chemical shifts of the catharantine parts of 17-desacetylvinblastineTrp-Arg$_8$-1 and 17-desacetylvinblastineTrp-Arg$_8$-2 (note that an almost complete assignment could be achieved for the catharantine moieties) are practically the same, telling us that the structural difference is located elsewhere in the two molecules.

Due to the low sample concentrations and to the significant broadening of some of the resonances belonging to the vindoline half of the molecules, assignments for this part of the compounds could not be given completely. Nevertheless, the similarity of the signals due to the detectable and assignable functional groups [the C(14)═C(15) double bond, the C(20)-Et, C(11)-OMe, and N(1)-Me functions], as well as those belonging to the aromatic resonances (*8, 9*) of the indole part, indicate that the vindoline parts also remained intact during the formation of the conjugates.

The most significant differences were detected in signals belonging to the tryptophan moieties, especially those belonging to the Trp α and β protons of these residues. Not only do the chemical shifts of the Trp α (5.09 and 4.84 ppm in 17-desacetylvinblastineTrp-Arg$_8$-2 and 17-desacetylvinblastineTrp-Arg$_8$-1, respectively) and β protons (3.73 ppm in 17-desacetylvinblastineTrp-Arg$_8$-2 and 3.58 and 3.72 ppm in 17-desacetylvinblastineTrp-Arg$_8$-1) differ significantly, but the coupling patterns differ as well (Figure 3 in Supporting Information). In 17-desacetylvinblastineTrp-Arg$_8$-2, the Trp α proton resonance appears as a triplet with a coupling constant of 5.9 Hz, while that in 17-desacetylvinblastineTrp-Arg$_8$-1 is a doublet of doublet with coupling constants of 10.4 and 5.6 Hz. These findings indicate that during the formation of the Arg conjugates inversion of the Trp α carbon occurred. The Trp moieties are expected to be in different conformational states in the two epimers, which accounts for the observed difference in the coupling patterns of the Trp α proton resonances.

In order to identify the two epimers, we recorded the ^{1}H NMR spectra of two smaller model systems containing only the

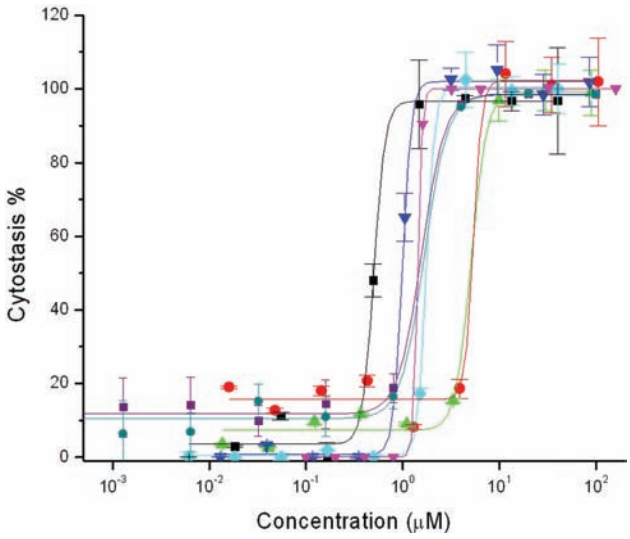

Figure 2. Cytostatic activity of vinblastine sulfate, 17-desacetylvinblastine, and its conjugates on sensitive HL-60 cells. The cells were incubated with the compound for 3 h, after growth in serum-containing medium for 3 days. The IC_{50} values were determined by MTT assay as described in the text: black -■-, 17-desacetylvinblastineTrp, $IC_{50} = 0.49$ μM; magenta -▼-, vinblastine sulfate, $IC_{50} = 1.26$ μM; red -●-, 17-desacetylvinblastineTrp-Arg_4-1, $IC_{50} = 5.25$ μM; green -▲-, 17-desacetylvinblastineTrp-Arg_4-2, $IC_{50} = 4.97$ μM; cyan -◆-, 17-desacetylvinblastineTrp-Arg_6-1, $IC_{50} = 0.97$ μM; blue -▼-, 17-desacetylvinblastineTrp-Arg_6-2, $IC_{50} = 1.75$ μM; purple -■-, 17-desacetylvinblastineTrp-Arg_8-1, $IC_{50} = 1.61$ μM; teal -●-, 17-desacetylvinblastineTrp-Arg_8-2, $IC_{50} = 1.59$ μM.

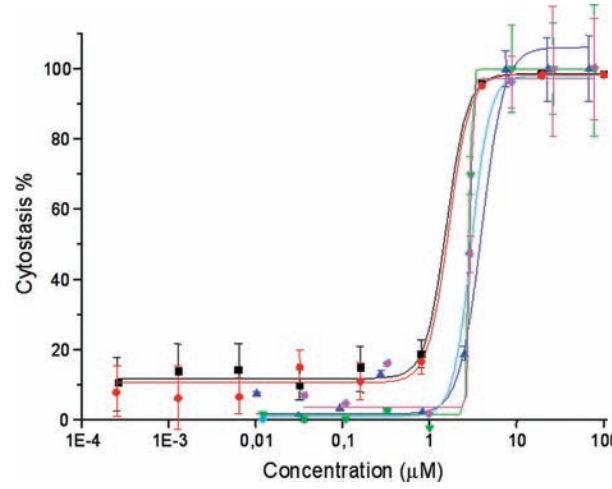

Figure 3. Cytostatic activity of 17-desacetylvinblastineTrp-Arg_8 conjugates on sensitive and resistant HL-60 cells. The cells were incubated with the compound for 3 h, after grown in serum-containing medium for 3 days. "vindoline" half bound to D- and L-tryptophan (unpublished synthetic results), having the structures shown in Figure 4 in Supporting Information. In the vindoline−L-tryptophan model, the α proton appears as a triplet (5.8 Hz) similarly to epimer 17-desacetylvinblastineTrp-Arg_8-2, while in the vindoline−D-tryptophan model, it appears as a doublet of doublets (8.9 and 4.8 Hz) similarly to epimer 17-desacetylvinblastineTrp-Arg_8-1 (Figure 5 in the Supporting Information). These similarities indicate that 17-desacetylvinblastineTrp-Arg_8-2 and 17-desacetylvinblastineTrp-Arg_8-1 contain the L- and D-tryptophan moieties, respectively.

Additional synthetic and spectroscopic investigations are in progress to further verify the proposed structures as well as to explore the nature of and reasons behind the observed epimerization of Trp octaarginine during its coupling to 17-desacetylvinblastine.

Cytostatic Effect of Conjugates on HL-60 Human Leukemia Cells. The cytostatic effect of conjugates as well as of the control compounds was studied on sensitive and resistant HL-60 cells using MTT assay. The cells were treated with vinblastine sulfate, 17-desacetylvinblastineTrp, and its conjugates at different concentrations for 3 h, and then, the number of living cells was determined after 72 h. Data are summarized in Figure 2. In contrast to vinblastine sulfate ($IC_{50} = 1.26$ μM), the 17-desacetylvinblastine has more marked activity on sensitive HL-60 cells ($IC_{50} = 0.0043$ μM). The presence of Trp residue in the amino acid conjugate decreased the activity by 2 orders of magnitude ($IC_{50} = 0.49$ μM), but it is still more effective than vinblastine sulfate. On sensitive HL-60 cells, the increasing number of Arg residues enhanced the cytostatic effect of the conjugate. The octa- and hexaargininеTrp conjugate isomers have slightly higher activity ($IC_{50} = 1.61$ μM and 1.59 μM, for octaargininеTrp conjugate and $IC_{50} = 0.97$ μM and 1.75 μM for hexaargininеTrp conjugates) as compared to the tetraargininеTrp conjugates ($IC_{50} = 5.25$ μM and 4.97 μM). It is interesting to note that the octa- and hexaargininеTrp conjugate isomers almost preserve the activity of 17-desacetylvinblastineTrp, and these values are comparable with those of vinblastine sulfate ($IC_{50} = 0.97-1.75$ μM for octa- and hexaargininеTrp conjugates and $IC_{50} = 1.26$ μM for vinblastine sulfate).

The activity of compounds was studied on HL-60/MDR1 and HL-60/MRP1 resistant cells, too. The effect of vinblastine sulfate on resistant HL-60/MRP1 cells ($IC_{50} = 1.31$ μM) is similar to that of sensitive HL-60 cells ($IC_{50} = 1.26$ μM), but its efficacy was somewhat lower in the case of resistant HL-60/MDR1 cells ($IC_{50} = 2.96$ μM).

The effect of 17-desacetylvinblastine decreased markedly ($IC_{50} = 1.78$ for MDR1 and 0.24 μM for MRP1), showing that it is a good substrate of the MDR1 and MRP1 transporter proteins, somewhat better than vinblastine sulfate. The efficiency of the Trp derivative diminished dramatically in the presence of the MDR1 protein ($IC_{50} = 59.6$ μM), but the effect of the MRP1 protein was less marked ($IC_{50} = 3.98$ μM).

The antitumor effect of the conjugates increased with the number of Arg residues present in the conjugates on both resistant cell lines, but the IC_{50} values are somewhat higher than in the case of the sensitive cells. The two isomer conjugates (except the compounds with four Arg residues) show similar effects on the resistant cells. The IC_{50} values of octaarginine conjugates are shown in Figure 3.

Our results show that 17-desacetylvinblastine significantly inhibits the division of sensitive human leukemia cells. This effect, which is higher than that of vinblastine sulfate, decreases if the molecule is modified by a Trp. The conjugation of 17-desacetylvinblastineTrp to oligoarginine resulted in an antitumor effect which is dependent on the number of Arg residues. The presence of hexa- and octaarginine in the conjugates has almost no effect—these compounds exhibit essentially the same level of antitumor activity. However, tetraarginine reduces the activity significantly.

17-Desacetylvinblastine has significant cytotoxicity, higher than that of vinblastine. While the attachment of Trp dramatically decreases the effect of 17-desacetylvinblastine, this derivative still has a similar activity to vinblastine. The IC_{50} values of octa- and hexaargininеTrp conjugates suggest that these

compounds exhibit in vitro an antitumor effect similar to that of vinblastine.

In the case of resistant cells, the effect of 17-desacetylvinblastine is dramatically decreased, and the activity of both the Trp derivative and its octaarginine conjugate is similar in the case of HL-60/MRP1. The HL-60/MDR1 cells pump out the Trp derivative so effectively that its activity decreases to one tenth, while the octaarginineTrp conjugates show comparable effect with 17-desacetylvinblastine. Interestingly, the effect of vinblastine sulfate is reduced only by MDR1 proteins and only to a little extent. The biggest effect is measured in the presence of the MDR1 protein when the cells are treated by vinblastine derivatives. In the case of conjugates, the MRP1 proteins result in a bigger reduction in the activity. These results show that 17-desacetylvinblastine is a very good substrate of the transporter proteins. Considering the decreased effect of the conjugates, it is attractive to speculate that the transport proteins can also pump out the conjugated 17-desacetylvinblastine from the cells. The extent of efflux increased in the case of conjugates with a shorter oligoarginine, which could suggest that the character of conjugates became similar to that of the drug. On the other hand, the efficacy of the MRP1 protein to 17-desacetylvinblastineTrp is increased by the conjugation. In the resistant cells, the proteins pump out the compounds and the resulting concentration reduction inhibits the effect of the drugs. Because the cytotoxicity of 17-desacetylvinblastine and the octaarginineTrp conjugate are almost similar on resistant cells, it can be supposed that the reason for the significant difference in the case of the sensitive cells is the difference between the concentrations of active 17-desacetylvinblastine in the cells. In the case of 17-desacetylvinblastine, the achieved effective intracellular concentration is determined only by the diffusion rate. However, with the conjugates at least two different processes are involved, namely, the internalization of the conjugates and the interaction of the released (free) or conjugated drug with the microtubular system at the site of action. In order to analyze the influence of the presence of oligoarginine, the effect of the conjugates was studied on tubulin polymerization in vitro and in vivo.

In Vitro and in Vivo Effect of Vinblastine Derivatives on Tubulin Polymerization. In order to characterize the effect of vinblastine and its conjugate derivatives on a microtubule assembly, the polymerization of tubulin heterodimers was investigated in vitro at different drug concentrations.

Figure 4 shows that vinblastine and its derivatives inhibit paclitaxel-induced tubulin polymerization; however, this effect was dependent upon the nature of the derivatives. The dose−response curves obtained by plotting the polymerization rate as a function of drug concentrations reveal that the inhibitory effects of 17-desacetylvinblastineTrp and the 17-desacetylvinblastineTrp-Arg_8-2 conjugates are comparable to those of vinblastine in the polymerization assay. However, the inhibitory potency of the 17-desacetylvinblastineTrp-Arg_8-1 conjugate on the microtubule assembly was less pronounced. It should be noted that with the mixture of the two Trp-Arg_8-containing isomers (before their HPLC separation) we obtained a lower inhibitory effect than with 17-desacetylvinblastineTrp-Arg_8-2, but a higher effect than with 17-desacetylvinblastineTrp-Arg_8-1. This result suggests that the 17-desacetylvinblastineTrp-Arg_8-1 conjugate is not a potential antimitotic agent. However, the effect observed in an in vitro system with purified tubulin cannot provide information on the specificity of the drugs. Specificity, i.e., the antimicrotubular activity of the drug, was studied at a cellular level using HeLa cells by investigating both the interphase and spindle microtubules in parallel.

The majority of the eukaryote cells are at interphase, and only the minority are in mitosis—at a certain point in time—even

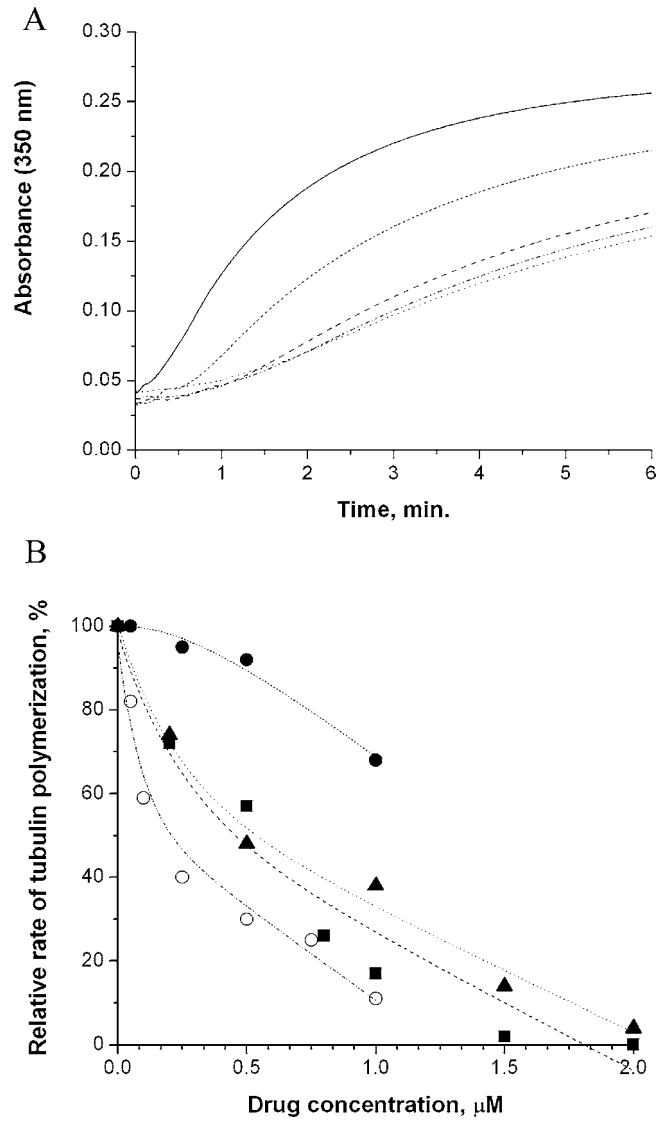

Figure 4. Effect of vinblastine and its conjugate derivatives on tubulin polymerization. (A) Turbidimetric assay. The paclitaxel-induced tubulin polymerization was followed at $\lambda = 350$ nm. The concentration of vinblastine and its derivatives was 1 μM. Tubulin control (solid line), vinblastine (dashed line), 17-desacetylvinblastineTrp (dotted line), 17-desacetylvinblastineTrp-Arg_8-1 (short dashed line), 17-desacetylvinblastineTrp-Arg_8-2 (dash-dot-dotted line). (B) The relative effect of vinblastine and its derivatives on tubulin polymerization as a function of drug concentration. (■, dashed line) vinblastine, (▲, dotted line) 17-desacetylvinblastineTrp, (●, short dashed line) 17-desacetylvinblastineTrp-Arg_8-1, (○, dash-dot-dotted line) 17-desacetylvinblastineTrp-Arg_8-2.

in cancer cells, which are characterized by rapid proliferation. Therefore, if a drug specifically targets the mitotic microtubule spindle, this effect is not necessarily reflected at a cellular level by the cytotoxicity index.

In order to characterize the antimicrotubule activities of vinblastine and its conjugate derivatives at a cellular level, we performed comparative studies in human cervical carcinoma (HeLa) cells. The drugs were added to the medium of the growing cells at different concentrations. After 24 h, the microtubular network of the cells was immunostained with antitubulin antibody and visualized by immunofluorescence microscopy.

Figure 5 shows that the interphase microtubular network can be characterized by three well-defined stages: (i) Normal stage (Figure 5a): the microtubular network is assembled into bundled fibers of highly ordered fashion. The fibers originate from the

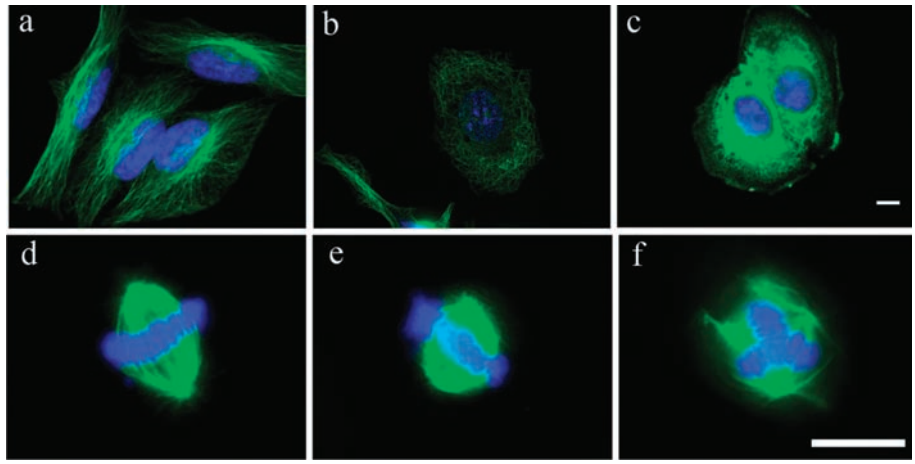

Figure 5. Characteristic pictures for interphase (a−c) and mitotic (d−f) microtubule network formations in HeLa cells immunostained for α-tubulin (green); normal, control (a and d), fragmentated (b) induced by 2.5 μM 17-desacetylvinblastineTrp, depolymerized (c) induced by 2.5 μM vinblastine, asymmetric (e) induced by 0.25 μM, and multipolar (f) induced by 2.5 μM 17-desacetylvinblastineTrp treatment. [a] HeLa cells were treated with the drugs at different concentrations for 24 h. The percentage distribution of the aberrant mitotic spindle among all cells in the phase of mitosis was quantified by investigating random microscopic fields. The structure of the interphase and mitotic microtubules was visualized by immunofluorescence microscopy using monoclonal antitubulin antibody. [b] n.d: not defined.

microtubule organizing center and are concentrated around the nucleus. Their free ends radiate outward toward the cell membrane, forming a network. In drug-treated cells, microtubules undergo significant reorganizations. (ii) Fragmented stage (Figure 5b): long bundles of microtubules are fragmented into short, disorganized fibers which radiate to the cell periphery in a criss−cross fashion. In the vicinity of nuclei, the microtubules acquire an amorphous appearance. The microtubule organizing centers are no longer apparent. (iii) Depolymerized stage (Figure 5c): all microtubules are disassembled; the depolymerized microtubules show homogeneous cytosolic distribution.

We also studied the changes of the spindle structures in parallel with those of the interphase at various drug concentrations. Treatment of the cells with vinblastine or its derivatives caused significant alterations in the spindle structures. Typical structures visualized in the drug-treated samples are shown in Figure 5: normal, symmetric (Figure 5d), asymmetric (Figure 5e), and multipolar (Figure 5f).

For evaluation of the specificity of the vinblastine derivatives, we quantified the relative amount (%) of the aberrant mitotic spindles as compared to all mitotic cells. In addition, the ultrastructures of the interphase microtubules were visualized and ranked according to the categories presented in Figure 5.

According to the data summarized in Table 2, vinblastine, even at the lowest concentration used in this study, depolymerized the microtubular network completely; the tubulin homogeneously distributed within the cytosol corresponding to Figure 5c. 17-DesacetylvinblastineTrp causes much less damage to the microtubular network than vinblastine, and 47% of the mitotic cells are aberrant at 0.25 μM. The two Trp-Arg$_8$ conjugates displayed distinct effects, while the 17-desacetylvinblastineTrp-Arg$_8$-2 isomer conjugate caused significant fragmentation of the interphase microtubule at 2.5 μM, the 17-desacetylvinblastineTrp-Arg$_8$-1 isomer conjugate did not affect them at all even at a 5 μM concentration. These results clearly show that the 17-desacetylvinblastineTrp-Arg$_8$-1 isomer conjugate is highly selective against the mitotic spindles and destroys only these structures in the mitotic cells. As among tumor cells there are more cells in mitosis at a certain time point than among normal cells, these data suggest that the 17-desacetylvinblastineTrp-Arg$_8$-1 isomer conjugate may have a selective cytotoxic effect against tumor cells and may thus have lower side effects. As the isomers are different in the configuration of Trp, further studies are needed to rationalize this selectivity.

CONCLUSIONS

Vinblastine is an efficient antitumor agent, but its side effects and resistance can restrict its use. A promising approach to avoid the harmful effects is its conjugation with an appropriate partner compound. The coupling of 17-desacetylvinblastineTrp with cell-penetrating oligoarginines results in conjugates whose biological effectiveness correlates with the chain length of peptides. The octa- and hexaarginine conjugates preserve the cytotoxicity of the original drug on both sensitive and resistant HL-60 cells. Moreover, the 17-desacetylvinblastineTrp-Arg$_8$-1 isomer conjugate preferentially destroys the mitotic spindle, at least in the case of cancerous HeLa cells, resulting in cell cycle inhibition. Further studies should be performed to demonstrate that this conjugate can exclusively target the tumor cells and is less toxic to normal cells in many other cases.

Istituto di Ricerche Chimiche e Biochimiche G. Ronzoni, via G. Colombo, 81, 20133, Milano, Italy, and Area of Oncology Research and Development, Sigma-Tau, Pomezia, Roma, Italy. Received February 24, 2010; Revised Manuscript Received September 30, 2010

Eight conjugates of a novel camptothecin derivative (Namitecan, NMT) with RGD peptides have been synthesized and biologically evaluated. This study focused on factors that optimize the drug linkage to the transport vector. The different linkages investigated consist of heterofunctional glycol fragments and a lysosomally cleavable peptide. The linkage length and conformation were systematically modified with the purpose to understand their effect on receptor affinity, systemic stability, cytotoxicity, and solubility of the corresponding conjugates. Among the new conjugates prepared, **C6** and **C7** showed high receptor affinity and tumor cell adhesion, acceptable stability in murine blood, and high cytotoxic activity ($IC_{50} = 8$ nM). The rationale, synthetic strategy, and preliminary biological results will be presented.

INTRODUCTION

The antitumor efficacy of clinically used anticancer drugs is limited by their nonspecific toxicity to normal cells, resulting in a low therapeutic index. Therefore, great efforts are being devoted to the aim of targeting therapeutics preferentially to tumors, sparing physiological tissues and decreasing side effects. In late years, several different approaches to this problem have been studied, which mainly focused on conjugating cytotoxic agents with macromolecules such as monoclonal antibodies (mAbs) or polymeric materials (*1*−*5*). First successes have been achieved with mAbs immunoconjugates, and some of them are currently in clinical trials. However, there are factors restricting the scope of this approach: the antigen-dependent drug delivery to target tumor cell population can be limited by the cell surface density of expressed antigens and by saturation of the receptors with immunoconjugates that are endocytosed at a given rate. The new generation immunoconjugates have incorporated drugs that are considerably more potent than the standard anticancer agents. Among them, the anti-CD33-calicheamicin (Mylotarg) has been approved by FDA for treatment of acute myeloid leukemia (*6*).

During the past two decades, the understanding of many receptors overexpressed by tumor cells during proliferation has given impetus to the development of low-molecular-weight selective ligands. Therefore, following a trend toward replacing the antibody scaffolds with small molecules, several peptides have been proposed as tumor-targeting tools, to be used as receptor imaging or as therapeutics when conjugated with antitumor agents; for recent reviews on this topic, see ref 7, 8. Small receptor-binding peptides offer the advantage of being easily synthesized, modified, and characterized in order to optimize their affinity to specific receptors.

Cyclic peptides containing the RGD (Arg-Gly-Asp) sequence are well-known as specific ligands of the $\alpha_v\beta_3$ integrin cell surface receptor. This integrin has a predominant role in tumor-induced angiogenesis and is overexpressed on the activated endothelial cells in several tumor forms, but expressed at a low level on normal and mature endothelial cells. Inhibition of angiogenesis has been shown to prevent tumor growth and even cause tumor regression in various experimental models (*9*). However, antiangiogenic therapy usually is not sufficient to eradicate tumors in the late stage. Thus, combination of antiangiogenic agents with either chemo or radiation therapy has demonstrated enhanced activity in multiple tumor systems (*10*). Ruoslathi et al. first raised the idea of conjugating a cytotoxic agent with RGD-containing peptides (*11*−*13*). Later on, many RGD peptides have been evaluated for their potential as antiangiogenic agents or integrin-targeted radiotracers and/or therapeutics (*14*−*19*).

We were interested in studying the effect of RGD cyclopeptides in conjugation with a new potent antitumoral drug belonging to the camptothecin family, Namitecan, NMT (*20*). A number of camptothecin prodrugs and delivery systems have been developed to improve the pharmacokinetic profile of this anticancer drug (*21*−*23*). We have previously reported on the synthesis and biological evaluation of a number of RGD−NMT conjugates (*24*), where the targeting RGD peptide was attached to the drug by either amide or hydrazone bond; in theory, both linkages should be potentially stable at physiological pH, whereas the main difference between them lies in the acid stability. During that study, we demonstrated that the amide bond-containing conjugates maintained good affinity to integrin receptors and accumulated in tumor cells after internalization, but showed no appreciable activity both in vitro and in vivo, indicating that the amide bond is too stable to promptly release the drug into the tumor cells. On the contrary, the hydrazone bond-containing conjugates exhibited high in vitro cytotoxicity, but their stability at pH 7.4 was much lower than expected; as a consequence, their activity has been mostly attributed to the NMT prematurely liberated within the cell culture medium. Thus, it was concluded that both types of linkage are not suitable for these low-molecular-weight conjugates. Moreover, all conjugates prepared were not soluble enough for a complete in vivo study, likely because the proximity of ligand and drug

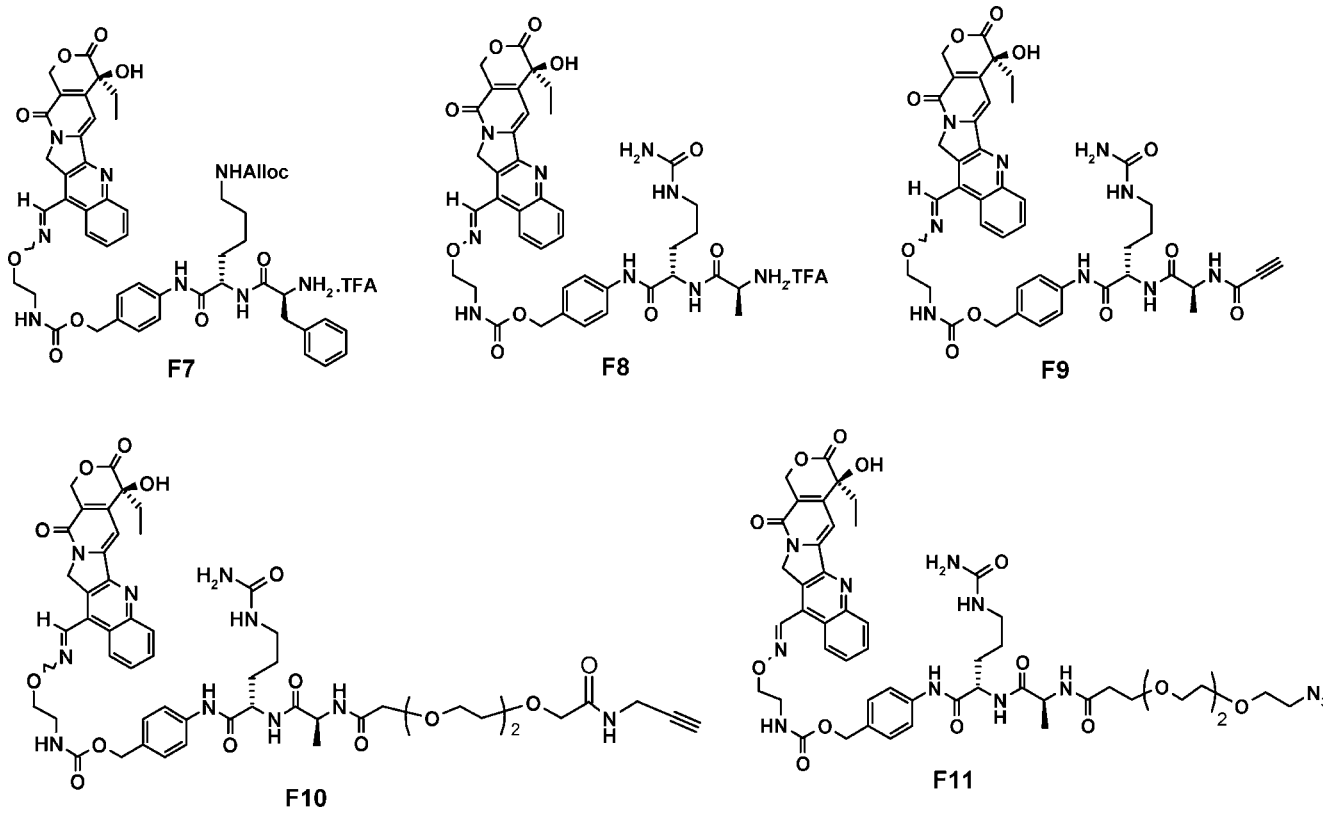
forms efficient intramolecular stacking interactions. Inspired by these results, we sought to verify another interesting approach, proposed in the literature and based on the introduction of selective protease-sensitive peptides into tumor-targeted conjugate spacers. These peptides have been claimed to be specific substrates of enzymes overexpressed within the lysosomal compartment of tumor cells, but rather stable to proteases in the systemic circulation (*25*−*28*).



Because of our interest in the potential of this approach, we have undertaken the development of a series of tumor-targeted conjugates containing an $\alpha_v\beta_3$ integrin recognition moiety connected to NMT by different molecular bridges as spacers. The structure of these spacers include a peptide, that is enzymatically cleavable, but stable enough in the systemic circulation, and a number of glycol residues, whose length and conformation were systematically modified, in order to enhance solubility, without disturbing the binding of the RGD ligand to the receptor.The objective of the work described in this article was to study the effect of the spacer modifications on receptor affinity, stability in murine blood, cytotoxicity, and solubility of the new conjugates.

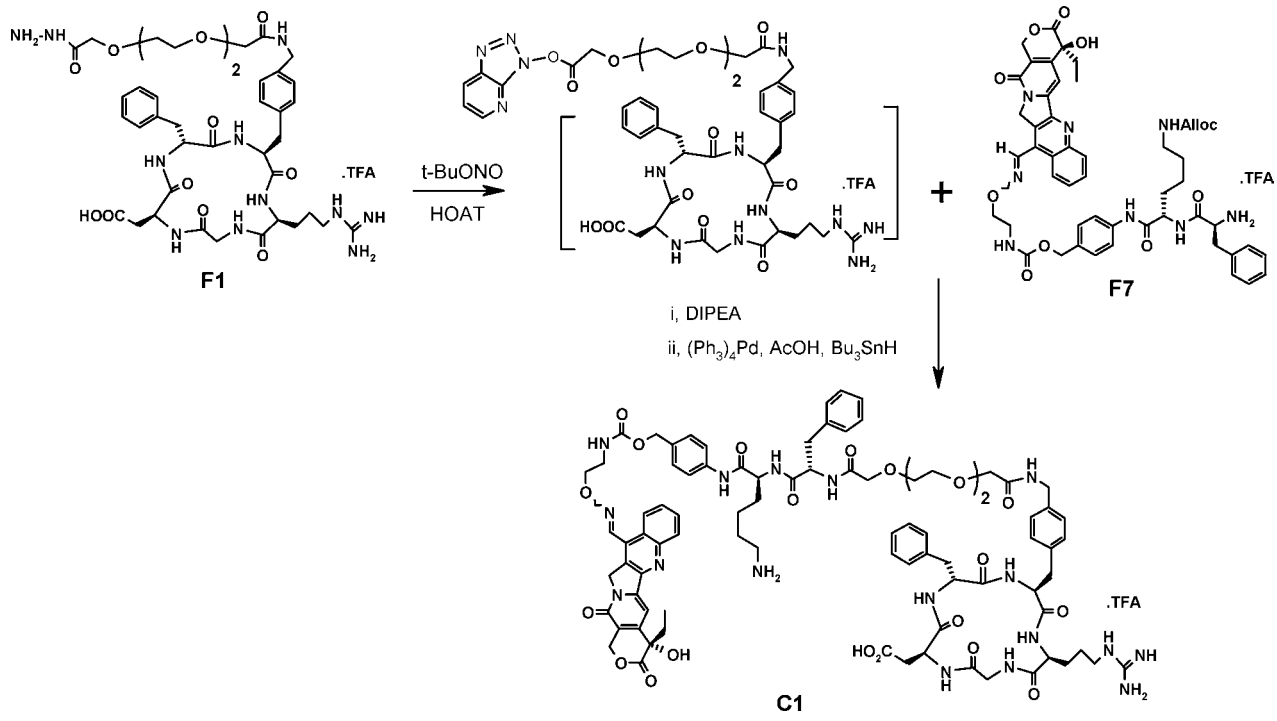
Among a series of RGD cyclopeptide analogues of Cilengitide (*29*), designed and synthesized in our laboratories for the purpose of this study, we identified **P1** and **P2** to be used as targeting ligands, owing to their optimal stability and affinity to α_v integrins (*30*). Peptide ligands, camptothecin derivative NMT, and conjugate structures are illustrated in Chart 1. The structure of the fragments used for assembling the conjugates is illustrated in Charts 2 and 3. Each pair of fragments, which were coupled together to obtain the desired conjugate, is described in Table 1.

EXPERIMENTAL PROCEDURES

Materials and Instruments. All reagents and solvents were reagent grade and were distilled prior to use. All natural amino

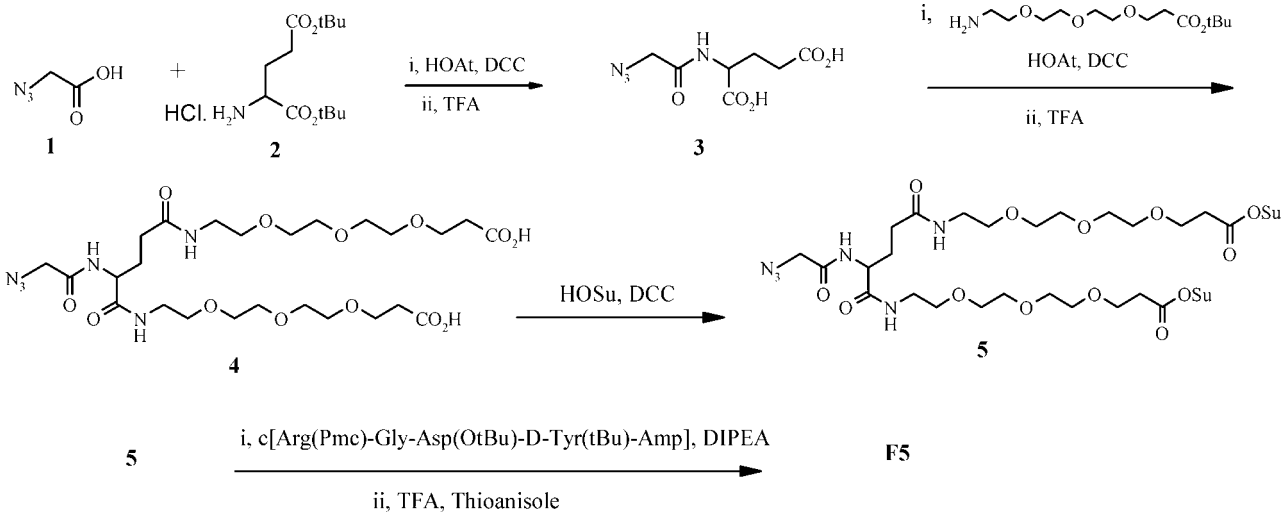
Chart 3. Structure of Fragments F7−F11, Containing the Cytotoxic Drug NMT

acids and resin were purchased from Bachem (Switzerland). Fmoc-4-aminomethyl-phenylalanine (Amp) was purchased from PepTech Corporation, Burlington, MA, USA; the corresponding building blocks, Fmoc-Amp-glycol-R (where R can be amino, hydrazido, or azido group), were easily synthesized by standard methods. PEG derivatives were purchased from Iris Biotech GMBH (Germany). Namitecan (ST1968) was synthesized in Sigma-Tau laboratories (*20*). Microwave-assisted reactions were performed on a CEM MW instrument. Compounds were purified and characterized by a RP-HPLC 600 Waters instrument, equipped with a semipreparative column Alltima, Alltech, RP18, 10 μ, 22 × 250 mm, or an analytical column Gemini, Phenomenex, C18, 5 μ, 4.6 × 250 mm, at $\lambda = 220$ nm, using acetonitrile/water with 0.1% trifluoroacetic acid as mobile phase. ^{1}H NMR spectra were recorded on an AC300 Bruker instrument. Mass spectra were recorded on Bruker Autoflex Maldi-Tof or Micro-Tof Q instruments. Flash chromatography was carried out on silica gel Merck 230−400 mesh.



Synthesis of Conjugate C1. (Method A) As described in Scheme 1, fragment **F1** (350 mg, 0.319 mmol) and HOAT (259 mg, 1.91 mmol) were dissolved with 7 mL DMF; then, *t*-butyl nitrite (45 μL, 0.383 mmol) was added and the mixture left under stirring at room temperature. After 30 min, 1 equiv of DIPEA was added, and the reaction mixture was poured into a solution containing fragment **F7** (337 mg, 0.319 mmol) in 2 mL DMF; pH was adjusted to 7.5 with DIPEA and the mixture left under stirring at room temperature, protected from light. After 2 h, an additional equivalent of the activated ester, prepared in situ as described above, was added, pH adjusted at 7.5, and left overnight. The solvent was removed at reduced pressure, and the residue was purified by preparative HPLC (40% CH_3CN in H_2O + 0.1% TFA). To remove the *N*-Alloc group, the compound was dissolved in 1 mL DMF, under argon, together with 2.5 mg of $(Ph_3P)_4Pd$, AcOH (12 μL), and Bu_3SnH (25 μL), and stirred for 1 h. The final conjugate **C1** was obtained after repeated precipitations with cool diethyl ether followed by lyophilization, with 97% purity.

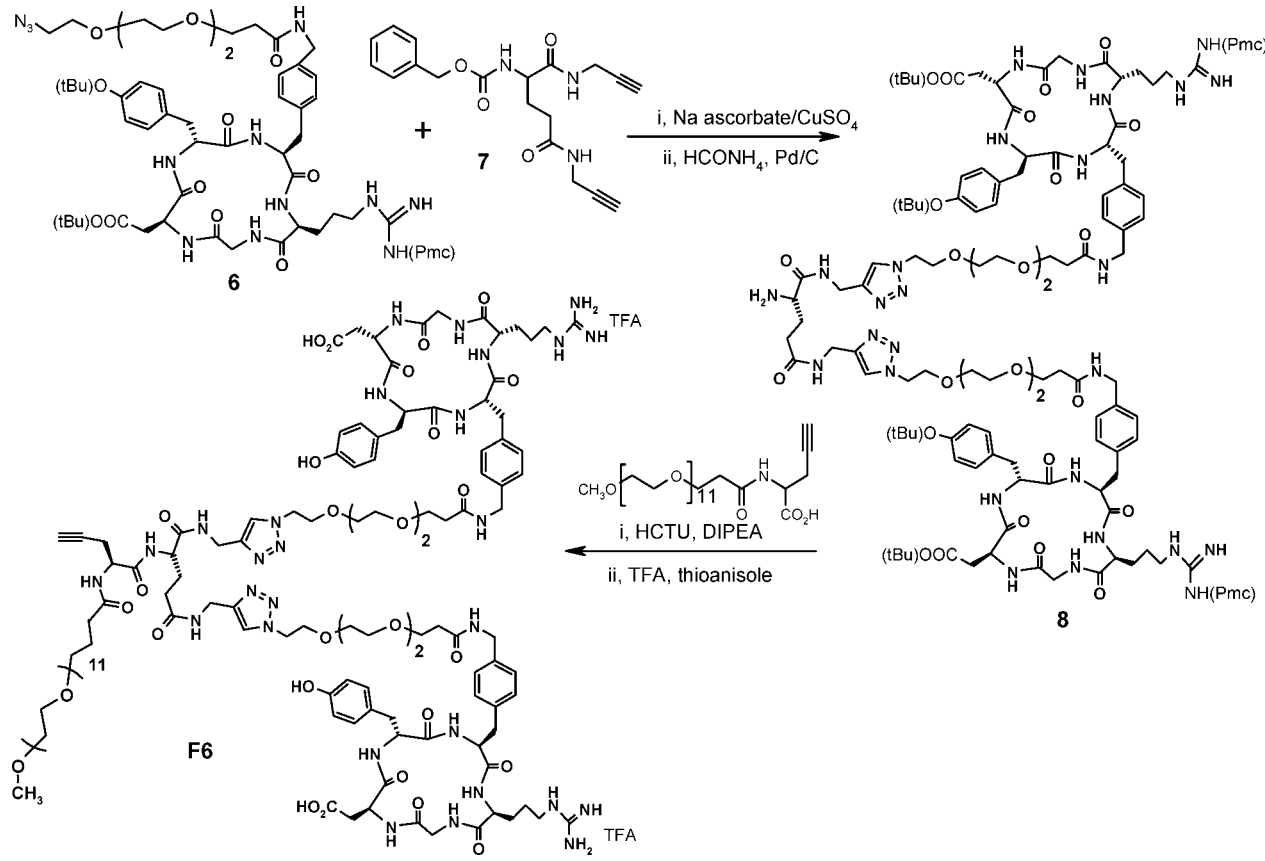
Synthesis of Conjugate C2. Coupling between fragments **F1** and **F8** was performed following the procedure described for conjugate **C1**. After purification by preparative HPLC and lyophilization, the compound was obtained with 97.6% purity.



Synthesis of Conjugates C3−C7. (Method B) General procedure. Two fragments, containing an alkyne and an alkylazido group, respectively, were assembled by Huisgen 1,3-dipolar cycloaddition. Equimolar amounts of the two desired fragments were dissolved in DMF. Aqueous solutions of sodium ascorbate (1 equiv) and $CuSO_4 \cdot 5H_2O$ (0.1 equiv) were added, pH was adjusted to 6 by addition of NaOH, and the suspension was stirred at room temperature overnight. When necessary to speed up the reaction, the mixture was submitted to microwave irradiation, 90 W for 2 min (T_{max} obs 120 °C) once or twice until completion of the reaction, as monitored by HPLC. Final conjugates were obtained with >98% purity, after preparative HPLC and lyophilization.

MW-Assisted Solid-Phase Synthesis of Cyclopeptides. *General Procedure.* Solid-phase synthesis followed the standard Fmoc-protocol, starting from Fmoc-Gly-SASRIN. The amino acids (2 equiv) were added in the following order: Fmoc-Arg(Pmc)-OH, Fmoc-Amp(building block)-OH, Fmoc-D-Phe-OH (or Fmoc-D-Tyr(tBu)-OH), and Fmoc-Asp(OtBu)-OH. At each step, Fmoc deprotection was carried out with 20% piperidine. Energy applied: 30 W for 5 min (t_{max} obs. 70 °C) for couplings and 25 W for 3 min (t_{max} obs. 40 °C) for deprotections. For cleavage of the peptides, the resin was treated with 1% TFA in DCM during 15 min for 5 times and the filtrates immediately neutralized with pyridine. The collected filtrates were taken to dryness under vacuum, and the linear peptides were dissolved with acetonitrile containing 1% DIPEA to obtain a 1.5×10^{-3} M solution, then added with 3 equiv TBTU/HOBT and stirred for 1 h, until complete cyclization, as monitored by HPLC. After evaporation of the solvent, the cyclopeptides were

Scheme 1. Synthesis of the Conjugate C1



Scheme 2. Synthesis of Fragment F5

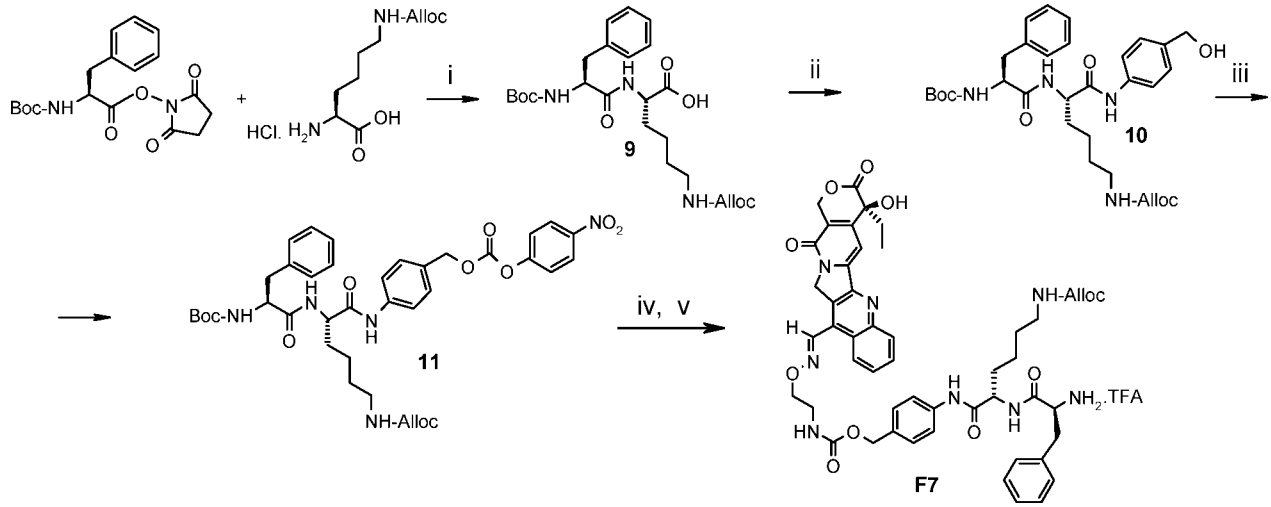
dissolved with DCM and washed (water, 0.1 N HCl, water). The organic phase, after drying with Na_2SO_4, was concentrated and the residue purified by flash chromatography (mobile phase, 95:5 → 85:15 DCM/MeOH). Removal of the protecting groups was performed with 95:5 TFA/H_2O within 1 h. After concentration to small volume, the products were further purified by repeated precipitations with dry and cold diethyl ether. Total yields were around 50%, calculated on the amount of starting resin.The cyclopeptides prepared with this method differ from each other for the presence of D-Phe **(P1)** or D-Tyr (**P2**) at position 4 and for the Amp-building blocks at position 5.

Synthesis of Fragment F5. As described in the Scheme 2, DCC (84 mg, 0.405 mmol) was added to a cold solution of azidoacetic acid **1** (41 mg, 0.405 mmol), glutamic acid di-*tert*-butyl ester. HCl **2** (100 mg, 0.338 mmol), HOAT (0.405 mmol), and DIPEA (127 mL, 0.744 mmol) in 5 mL DCM. The reaction was stirred at room temperature for 2.5 h and after filtration was diluted up to 30 mL and washed with water, 0.1 N HCl, 5% $NaHCO_3$, and water. After removing the solvent, the residue was treated with 3 mL of TFA for 1 h to afford 2-(2-azidoacetylamino)-pentanedioic acid **3**, which was dissolved with 45 mL of 8:1 DCM/DMF and coupled with *tert*-butyl 12-amino-4,7,10-trioxadodecanoate (281 mg, 1.01 mmol), HOAT (137 mg, 1.014 mmol), DIPEA (174 mL), and DCC (209 mg, 1.014 mmol) by the standard method to give a crude product that was purified by flash chromatography (95:5 DCM/MeOH) to obtain 175 mg of a solid white powder. Yield 68% (calc. for 3 steps). After deprotection with TFA, the bis-carboxylic intermediate **4** (0.234 mmol**)** was dissolved with 5 mL of DMF and treated with *N*-hydroxysuccinimide (108 mg, 0.936 mmol) and DCC (145 mg, 0.700 mmol) by stirring overnight. Solvent was removed and the succinimide **5**, dissolved with 8 mL DCM, was added to a solution of the partially protected cyclopeptide c[Arg(Pmc)-Gly-Asp(OtBu)-D-Tyr(tBu)-Amp], 728 mg, 0.66 mmol and DIPEA (113 μL, 0.66 mmol) in 14 mL of DMF. After 1.5 h, solvent was removed and the residue purified by preparative HPLC (69% CH_3CN). Yield 48%. Total deprotection was performed with 1:1 TFA/DCM containing 220 equiv of

Scheme 3. Synthesis of Fragment F6

thioanisole. The pure fragment **F5** was obtained as a white solid after evaporation of the solvents and subsequent precipitations from cold diethyl ether. Yield 79%.

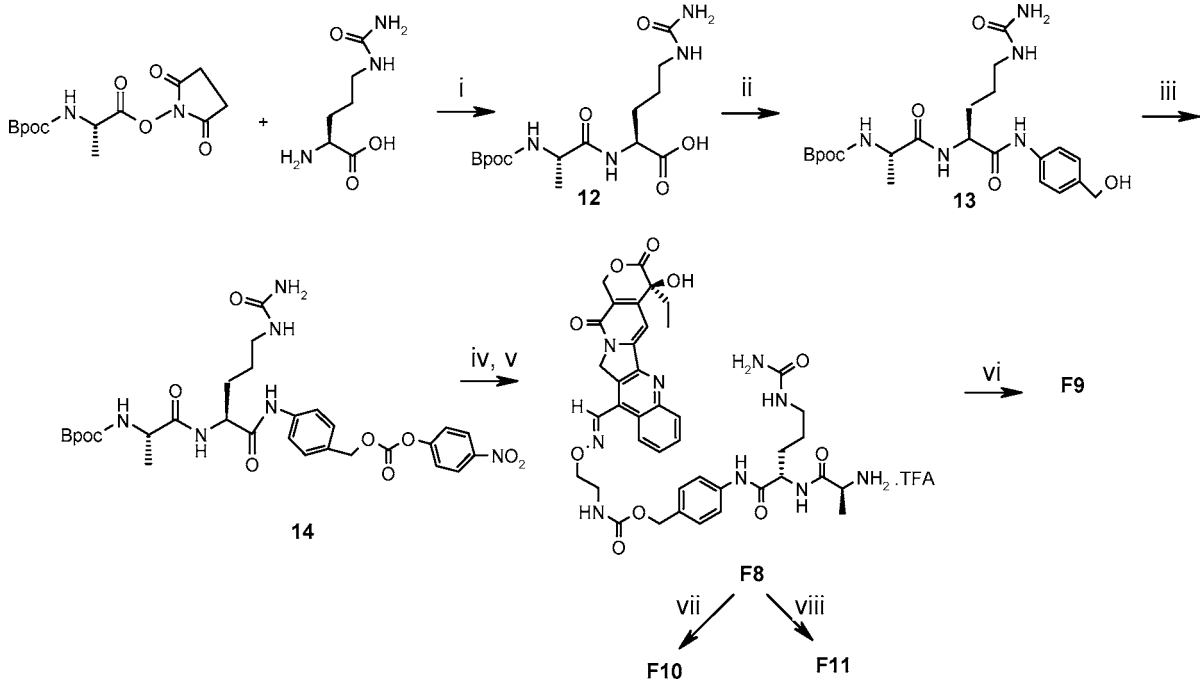
Synthesis of Fragment F6. As reported in Scheme 3, the totally protected cyclopeptide c{Arg(Pmc)-Gly-Asp(OtBu)-D-Tyr(OtBu)-Amp[CO-$(CH_2)_2$-(O-CH_2-CH_2)-O-$(CH_2)_2$-N_3]} **6** (572 mg, 0.448 mmol) and 1,3-bis-(prop-2-ynylcarbamoyl-propyl)-carbamic acid benzyl ester **7** (72.5 mg, 0.206 mmol) were dissolved with 12 mL of 7:5 DMF/H_2O. Then, 2.5 M sodium ascorbate (90 μL) and 0.5 M $CuSO_4 \cdot 5H_2O$ (45 μL) were added, and the mixture submitted to microwave irradiation (90 W, T_{max} obs. 121 °C). The same operation was repeated three times until complete disappearance of the starting material, which was monitored by HPLC (35% CH_3CN). After removing the solvent under reduced pressure, the crude residue was purified by flash chromatography (93:7 → 90:10 → 80:20 DCM/MeOH). Yield 71%. ESI mass: 1453.6 (*m*/*z* 2+), 969.4 (*m*/*z* 3+). 406 mg of this product was dissolved with 3:5 DMF/MeOH and orthogonally deprotected by means of ammonium formate (44 mg, 0.7 mmol) and Pd/C (200 mg). After 3 h stirring, the reaction was filtered, and the filtrate concentrated to give the intermediate **8**, which was dissolved with 3 mL DMF and used for the next step. *N*-(Methyl-PEG_{11}-carboxy)-propargylglycine (102 mg, 0.149 mmol in 4.5 mL DCM) followed by HCTU (62 mg, 0.149 mmol) and DIPEA (51 μL, 0.298 mmol) were added, and the resulting solution stirred for 2 h. After evaporation, the residue was redissolved with 300 mL of DCM and washed with water (2 × 50 mL).The organic phase was evaporated, and the fragment fully deprotected by means of a mixture of TFA/DCM/thioanisole (1:1:0.3). After taking to dryness, the residue was purified by repeated precipitations from TFA with cold diethyl ether, to afford 245 mg of fragment **F6**, with 41% yield (calculated from 3 steps).



Conjugates Binding to $\alpha_v\beta_3$ Integrin, Tumor Cell Adhesion, and in Vitro Cytotoxicity. These assays were performed following the experimental procedures already published (*24*), and the results are reported in the Tables 5 and 7.

Conjugate Stability in Murine Blood. The blood of untreated healthy mice was collected in tubes containing 2% EDTA.The sample molecules were added to obtain a concentration of 5 μM.The tubes were incubated at 37 °C under rotation for different sampling times during an interval of 3 h. At each time point, the samples were centrifuged at 1000*g* for 10 min, and the supernatants transferred in new tubes and stored at −20 °C. Plasma (100 μL) was processed by adding 700 μL of a cold mixture of 0.1% acetic acid and methanol (1:5 v/v). After vortexing, samples were kept at 20 °C for 10 min and then centrifuged at 14 000*g* for 10 min at 4 °C. The supernatants were analyzed by RP-HPLC-FL Beckman; column, Discovery HS-F5, 100 × 4.6 mm, 5 μ, Supelco; mobile phase, A = 0.1 M AcOH + 0.1% TEA, B = CH_3CN; flow rate, 1 mL/min; spectrofluorometric detector, RF-10AXL Shimadzu; wavelengths, λ_{ex} 370 nm and λ_{em} 510 nm. A gradient elution was employed ranging from 25% to 33% B within 30 min. Data were acquired by computer system and processed by 32Karat Software, Beckman. Calibration curves were performed in plasma, and peak areas were used to calculate each calibration curve intercept and the slope of each calibration curve equation by weighted least-squares method, using l/*y* as weighting factor. All peaks were well-resolved from impurities of plasma and methods were linear in the tested range ($r^2 > 0.985$), with results suitable for quantification. Results are reported in Table 6 as a percentage of residual amounts found at each sampling time versus time zero (calculated using mean values of triplicate samples).

RESULTS



Synthesis. Two groups of fragments have been prepared: the fragments **F1**−**F6** of the first group (Chart 2) contain one or

Scheme 5. Synthesis of Fragments F8−F11[a]

[a] Reagents and conditions: (i) LiOH·H_2O; (ii) 4-aminobenzylalcohol, HOAT, DCC; (iii) 4-nitrophenylchloroformate, py; (iv) NMT, TEA; (v) 0.5% TFA in trifluoroethanol, 30 min, total yield 56.2%; (vi) propiolic acid, HOAT, DCC; yield 72.6%; (vii) HCC-CH_2-NH-CO-CH_2-O-(CH_2-CH_2O)$_2$-CH_2-COOH, DCC, yield 63.5%; (viii) N_3-$(CH_2)_2$-O-(CH_2-CH_2-O)$_2$-$(CH_2)_2$-COOH, DCC, yield 62.8%.

two RGD cyclopeptides, which differ from each other for the amino acid in position 5 bearing glycol chains of different length and conformation. These fragments were built with good yields by MW-assisted SPPS, following cyclization in solution. In the case of the dimeric fragments **F5** and **F6**, two cyclopeptides were connected in solution through a dendron based on glutamic acid. The experimental procedures are given in detail and illustrated in Schemes 2 and 3. Fragments **F7**−**F11** of the second group (Chart 3) contain the camptothecin derivative and the lysosomally cleavable dipeptide sequence.The dipeptide is connected to the *N*-terminal of the drug through 4-aminobenzylalcohol (PABA). PABA is a known self-immolative entity (*31*) that accomplishes a double function, to increase the distance between peptide and cytotoxic drug, allowing a better recognition by the endopeptidases, and to guarantee prompt release of the parent drug through a 1,6-elimination mechanism, only after the enzymatic hydrolysis. The fragments belonging to the latter group were all prepared with similar synthetic procedures, except for minor modifications. In fact, during the synthesis of the first fragment **F7** (Scheme 4), deprotection of the terminal *N*-Boc caused a loss of about 10% of NMT, even reducing the TFA treatment to a few minutes. Therefore, *N*-Bpoc protection was used for fragments **F8**−**F11** (Scheme 5), because it can be removed with 0.5% TFA in trifluoroethanol without any cleavage of the carbamate bond.

In each fragment of both groups, a unique amino, hydrazido, azido, or alkyne function was introduced for further reaction with the corresponding counterpart to give the desired conjugates **C1**−**C7** (Chart 1). Each pair of fragments used for the synthesis of each conjugate is indicated in Table 1. The formation of

[a] Method A. [b] Method B.

conjugates needs a chemoselective synthesis. In fact, the reacting fragments must be used in a totally deprotected form, because the carbamate bond between NMT and the rest of the molecule is very sensitive to all late deprotection conditions. Two different methods were used: the conjugates **C1** and **C2** were synthesized via the acylazide method from the initial hydrazide, using the transfer active ester condensation procedure (TAEC) introduced by Ramage et al. (*32*), as described in Scheme 1 (Method 1). Later on, for conjugates **C3−C7**, we found more convenient the use of Huisgen 1,3-dipolar reaction (*33*), (Method B). In fact, this cycloaddition affords cleaner products, because of its mild nature; moreover, grafting of the residual alkyne with the azide-terminated molecule enables the use of equivalent amounts of the two fragments, whereas the acylazide reaction requires two equivalents of the RGD counterpart. In the case of the bulkier conjugates, MW irradiation was applied to accelerate the reaction. Physico-chemical characterization of all fragments and conjugates is reported in the Tables 2, 3, and 4.

Effect of Spacer on the Conjugate Receptor Affinity, Tumor Cell Adhesion, and Stability in Murine Blood. The effects of spacer modifications on the behavior of the conjugates RGD−NMT are illustrated in Tables 5, 6, and 7. All spacers contain the dipeptide alanine-citrulline as a lysosomally cleavable sequence, except for **C1**, which contains phenylalanine-lysine. Within the series **C2−C5**, the spacers differ from each

Table 2. Physico-Chemical Characterization of Conjugates C1−C7

other for the length and disposition of the hydrophilic glycol chains, whereas the spacers of conjugates **C6** and **C7** contain two RGD ligands connected to the drug through multiple glycol chains in a branched conformation. In Table 5, the conjugate affinity to $\alpha_v\beta_3$ integrin and their tumor cell adhesion is reported in parallel with the ligand cyclopeptides and the drug alone. **C1**−**C3**, bearing a short glycol between ligand and drug, showed very poor solubility and lost affinity to the receptor if compared with the ligand alone, most probably due to steric hindrance induced by the drug. However, when the glycol spacers were elongated in **C4**−**C5**, affinity and solubility improved, but the stability decreased, as it is possible to observe in Table 6. This is consistent with the results reported in Table 7: as stability decreased, cytotoxicity increased, obviously due to some amounts of the free drug in the culture media. Only the dimeric conjugates **C6** and **C7** exhibited good receptor affinity and cytotoxicity, together with sufficient stability and optimal solubility.

Cell adhesion of the conjugates resulted generally increased with respect to RGD peptides alone, and this may be attributed to cooperative adhesion of the whole molecule.

DISCUSSION

In the present work, RGD peptides as targeting moieties were conjugated to the cytotoxic agent Namitecan through

different spacers, consisting of linear or branched glycol residues and a peptide suitable for releasing the drug by enzymatic hydrolysis inside the tumor cell. The products were evaluated for their in vitro tumor cell-targeting efficacy, stability in murine blood, solubility, and cytotoxicity, with the purpose of studying their structure−activity relationship. Since the spacers between carrier and drug play the main role in the fate of small targeted drug conjugates, we systematically modified these molecular bridges in a continuing effort to reach a fine balance between sufficient systemic stability and cleavability inside the tumor cells, while preserving high receptor affinity and solubility of the whole conjugate. In the first conjugate **C1**, a spacer containing the Phe-Lys dipeptide was introduced, because this sequence had been proposed by Dubowchick et al. (*26, 27*) for rapid lysosomal hydrolysis and high human plasma stability. However, we assisted at the total cleavage of **C1** within one hour in the murine blood. In a search for more stable peptides, we evaluated other peptide sequences (such as D-Ala-Phe-Lys, Val-Cit, Aib-Cit, Tic-Cit), but with negative results (Dal Pozzo, A., Ni, M., and Bucci, F. Data not published. We also confirmed with our representative examples that compounds lacking the PABC self-immolative group do not release CPT, probably because of the steric crowding of the bulky drug), even though some of them have been used with success in the literature, mainly for immunoconjugates. Finally, the Ala-Cit dipeptide was found to have a significantly longer life in murine blood, together with sufficient cleavability by tumor cell associated proteases, as demonstrated by the cytotoxic activity of the corresponding conjugates; thus, Ala-Cit was adopted in all subsequent conjugate spacers. However, the stability was greatly influenced by the rest of the molecule, and this is observable with conjugates **C3**−**C5**, where elongation of the hydrophilic glycol chains led to a decrease of the half-life in the murine blood (see Table 6). To improve the solubility, we chose to substitute the commonly used large poly(ethylene glycol)s (PEGs) with a number of small glycol chains. In fact, PEGs, which are unique water-solubilizing agents currently employed for bioactive systems, are commercially available as polydisperse oligomers, and would yield undesirable heterogeneous products; moreover, because of their conformational flexibility, they tend to create bulky loops that can interfere with the ligand binding to the receptor. On the contrary, short glycols can be distributed on strategical positions of the molecular construct with respect to both the targeting and cleavable peptides. At first, we introduced in the spacers short glycol fragments connected in series through citrulline residues, which, beyond increasing hydrophilicity, should impart rigidity to the chain by their amide bonds, without shielding the ligand from recognition. Nevertheless, this strategy proved unsuccessful: in fact, as solubility improved, stability decreased, and cytotoxicity increased, due to the presence of significant amounts of the parent drug. This behavior indicates that the cleavable peptide is more exposed to the blood proteases. A deshielding effect is also observable in the conjugate **C3**, where the rigid triazole linkage orients the spacer chain away from the cleavable dipeptide moiety, where it is more accessible. On the other hand, solubility issues are a potentially negative aspect that could be a serious obstacle for preclinical development, and introduction of hydrophilic moieties is unavoidable. In an attempt to increase pegylation, while maintaining plasma stability and affinity to the receptor, we designed dimeric conjugates containing two RGD linked to a dendron unit bearing different glycol chains, to obtain a multifunctional platform where different pendant domains can be strategically allocated, without disturbing each other. Moreover, this approach exploits the multivalency effect on the ligand affinity (*16, 18, 34*). In this way, we could find conjugates **C6** and **C7**, endowed with the desired characteristics (increased avidity for the receptor together with appreciable stability and solubility), which demonstrated superior in vitro efficacy.

CONCLUSION

Our study highlights the crucial role of the spacer between targeting device and drug in tumor-targeted conjugates. Unlike immunoconjugates (where the bulky nature of the targeting molecule is less sensitive to the influence of the drug and spacer counterparts, and can shield and stabilize the connecting bond from premature hydrolysis), engineering conjugates with low-molecular-weight ligands is a most challenging problem, its success depending on a plateau of different factors. In fact, the small targeting molecule must retain tumor binding after substitution with molecules, that may be of similar or larger size, and the addition of new domains results in the modification of existing domains affecting their properties. Accordingly, careful selection of the enzymatically cleavable peptide and the length and disposition of the hydrophilic chains shoud be necessary for

the development of each single small targeting molecule for therapeutic application, since the strategy is not generalizable. We tried to help bring order to this sometimes unruly subject, and optimized the properties of our conjugates after a systematic in vitro study. Our results demonstrate the potential of tumor-targeted delivery of conjugates based on the specific recognition of the integrin RGD ligands and selective release of the drug by tumor-associated enzymes. However, we are aware of possible in vivo problems, such as the following: (1) Partial distribution of free drug generated through extracellular proteases cannot be ruled out. (2) The hydrophilic compounds synthesized may undergo rapid renal clearance, and larger PEGs would be needed to enhance the retention time in the circulation and allow proper tumor accumulation. Nevertheless, an improved therapeutic index could be expected by tumor specific delivery of at least a part of the targeted drug, resulting in lower and therefore less toxic systemic doses necessary to obtain the antitumor effect. Further evaluation of conjugates **C6** and **C7** in preclinical animal models for tumor growth inhibition and acute toxicity studies are currently in progress.

Multiphoton-Absorption-Induced-Luminescence (MAIL) Imaging of Tumor-Targeted Gold Nanoparticles

Matthew B. Dowling,[†] Linjie Li,[‡] Juhee Park,[‡] George Kumi,[‡] Anjan Nan,[§] Hamid Ghandehari,[||] John T. Fourkas,[‡,⊥] and Philip DeShong*[,†,‡]

Department of Bioengineering, Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland 20742-2111, United States, School of Pharmacy, University of Maryland, Baltimore, Maryland 21201, United States, and Department of Bioengineering, University of Utah, Salt Lake City, Utah 84101, United States. Received March 3, 2010; Revised Manuscript Received September 16, 2010

We demonstrate that multiphoton-absorption-induced luminescence (MAIL) is an effective means of monitoring the uptake of targeted nanoparticles into cells. Gold nanoparticles (AuNPs) with diameters of 4.5 and 16 nm were surface-functionalized with monocyclic RGDfK, an RGD peptide analogue that specifically targets the $\alpha_v\beta_3$ integrin, a membrane protein that is highly overexpressed in activated endothelial cells during tumor angiogenesis. To determine whether cyclic RGD can enhance the uptake of the functionalized AuNPs into activated endothelium, human umbilical vein endothelial cells (HUVECs) were used as a model system. MAIL imaging of HUVECs incubated with AuNPs demonstrates differential uptake of AuNPs functionalized with RGD analogues: RGDfK-modified nanoparticles are taken up by the HUVECs preferentially compared to AuNPs modified with linear RGD (GRGDSP) conjugates or with no surface conjugates. The luminescence counts observed for the AuNP-RGDfK conjugates are an order of magnitude greater than for AuNP-GRGDSP conjugates. Transmission electron microscopy shows that, once internalized, the AuNP-RGDfK conjugates remain primarily within endosomal and lysosomal vesicles in the cytoplasm of the cells. Significant aggregation of these particles was observed within the cells. MAIL imaging studies in the presence of specific uptake inhibitors indicate that AuNP-RGDfK conjugate uptake involves a specific binding event, with $\alpha_v\beta_3$ integrin-mediated endocytosis being an important uptake mechanism.

INTRODUCTION

The development of techniques for targeting of multifunctional nanostructures to specific locations in vivo is a major goal in nanomedicine (*1*−*4*). Once these nanostructures reach their destination, they should be able to perform additional tasks, such as releasing a payload or being taken up into specific cells via endocytosis. The design of effective nanovectors for targeting applications (diagnostics, imaging, or drug delivery) would benefit greatly from methods that allow the direct probing of these processes. Within the field of single molecule/particle tracking, there are two classes of probes, (1) organic fluorophores and (2) quantum dots, which have generated the majority of the interest. However, despite the clear advances in their associated imaging techniques, both classes present major disadvantages that limit their practical applications as trackable probes within biological systems. Organic fluorophores are subject to photobleaching within time scales that are much shorter than many important biological processes (*5, 6*). Quantum dots experience blinking upon sustained excitation, and they are synthesized from cytotoxic materials (*7, 8*). Additionally, the chemistries involved in attaching targeting agents and/or therapeutic molecules to quantum dots are generally complex and not well-understood (*9, 10*).

Noble metal nanostructures such as gold and silver represent a third major class of nanovectors for direct probing. Unlike organic fluorophores or quantum dots, these structures do not experience photobleaching or blinking upon sustained excitation (*5*). Furthermore, the chemistries of noble metals are well-understood, and they present minimal toxicity and/or inflammatory concerns. Hence, photoinduced luminescence from noble metals has attracted attention for use in biomedical imaging, particularly as this method has become increasingly efficient over the past few decades. In 1986, Boyd et al. discovered that gold surfaces exhibit a 10^6-fold enhancement in luminescence intensity when subjected to two-photon excitation as opposed to single-photon excitation (*11*). More recently, it has been demonstrated that noble metal nanoparticles also exhibit efficient luminescence upon multiphoton excitation. Farrer et al. demonstrated that multiphoton-absorption-induced luminescence (MAIL[1]) from AuNPs is generated efficiently with 800 nm laser intensities that are lower than those typically used for two-photon imaging of living cells (*5*). For AuNPs, this luminescence spans the visible spectrum and was shown to arise from three-photon absorption when excited with 800 nm light (*5*). Similar results have been found for silver nanoparticles (*12*). We have recently shown, by correlating MAIL intensity with SEM

Published on Web 10/21/2010

images, that aggregates of AuNPs show even stronger MAIL signals than individual particles (*13*).

MAIL from gold nanostructures shows considerable promise for biomedical applications. Durr et al. have shown that luminescence from gold nanorods can be orders of magnitude brighter than autofluorescence from cancer cells (*14*). Wang et al. were able to image gold nanorods within cancer cells in vitro and flowing in a mouse ear blood vessel in vivo using MAIL (*15*). Park et al. used MAIL to perform three-dimensional imaging of gold nanoshells within mouse tumor tissue (*16*). Qu et al. have used MAIL to image AuNPs targeted to lymphoma cells (*17*). In addition, Nagesha et al. have used MAIL to visualize AuNPs in *Dictyostelium discoideum* cells and murine embryonic stem cells (*6*).

Here, we also use MAIL, but instead to monitor the targeting and endocytosis of AuNPs of different sizes to human umbilical vein endothelial cells (HUVECs), which serve as an in vitro model for the activated endothelium of tumor angiogenesis. The targeting moiety of interest in this study is RGDfK, a cyclic RGD analogue. This peptide has a large binding affinity for the $\alpha_v\beta_3$ integrin, a membrane protein that is overexpressed in the activated endothelium and thus represents a potential target for chemotherapy (*18*−*23*). Fani et al. showed that free RGDfK peptide displays approximately 4-fold preferential uptake into tumor tissue as compared to a linear RGD control peptide (*24*). Additionally, we have previously shown that water-soluble polymers with side chains terminated in RGDfK localize efficiently within solid tumors in vivo (*19*−*23*). A number of other groups have demonstrated that the RGD peptide is generally an effective targeting moiety for therapeutic molecules and nanoparticles to the activated endothelium (*25*−*28*).

AuNPs provide a platform for targeted drug delivery and tumor ablation. However, the fate of AuNP-RGDfK systems in endothelial cells is unknown (*18, 23*). In this study, we conjugate AuNPs with the targeting peptide RGDfK or, as a control, with a linear RGD peptide. AuNPs are attractive for targeting applications because they are highly stable and biocompatible, have well-established surface chemistry, and can exhibit strong MAIL signals. We demonstrate that MAIL imaging methodology can monitor the uptake of AuNPs functionalized with RGD peptide analogues. The collected images indicate that the AuNPs undergo differential uptake into HUVECs based upon both particle size and surface conjugate, and that the uptake is largely a receptor-mediated process. In addition, we benchmark the MAIL imaging with transmission electron microscopy, and demonstrate that the two techniques give complementary results. This suggests that MAIL may be used for rapid, routine screening of the efficacy of a given targeting moiety attached to AuNPs. It is also worth noting that the MAIL imaging reported in this manuscript uses low power and thus is capable of real-time, 3D imaging of living cells.

EXPERIMENTAL PROCEDURES

Chemicals. Linear GRGDSP was obtained from Calbiochem, Inc. (La Jolla, CA). RGDfK (M_w 604.5) was obtained from Anaspec, Inc. (San Jose, CA). Fibrinogen, sodium azide, bovine serum albumin, paraformaldehyde, MTT, and doxorubicin were each purchased from Sigma. Hydrogen tetrachloroaurate (III) was obtained from Alfa Aesar. All chemicals for the preparation of AuNPs and surface functionalization with peptide conjugates were purchased from commercial suppliers and used without further purification unless noted otherwise. Milli-Q water (Millipore, 18 MΩ) was used throughout.

Preparation of Citrate-Stabilized AuNPs. Water-soluble AuNPs were prepared according to the method reported by Natan (*29*) for 4.5 nm size and a modification of the method reported by Frens (*30*) for 16 nm size.

4.5-nm-Diameter Gold Nanoparticles. A solution of $HAuCl_4$ (1.00 mL, 29.4 mM in H_2O, Alfa Aesar) was added into 90 mL of H_2O at room temperature. After the solution had been stirred for 1 min, a solution of sodium citrate (2.00 mL, 38.8 mM in H_2O) was added, followed by a fresh solution of $NaBH_4$ (1.00 mL, 0.075% in 38.8 mM of sodium citrate). The red colloidal suspension was stirred for 10 min and stored at 4 °C.

16-nm-Diameter Gold Nanoparticles. To a refluxing solution of $HAuCl_4$ (100 mL, 1.47 mM in H_2O) was added a solution of sodium citrate (2.00 mL, 0.340 M in H_2O). The resulting red colloidal suspension was stirred at reflux for 20 min, cooled to room temperature, and stored at 4 °C.

General Procedure for the Synthesis of RGD Peptide Conjugates. Peptide conjugates were prepared using a modification of the reported conjugation procedure developed in the DeShong lab (*31*). A solution of RGD peptide (1.0 equiv) in HEPES buffer (0.1 M, pH 7.4) was mixed with a solution of the *N*-hydroxy succinimidyl thioctic ester (1.3 equiv) in acetone. The resulting mixture was stirred at room temperature for 24 h, and the acetone was removed in vacuo. The aqueous layer was acidified with aq HCl (0.2 M) to pH 3, washed with organic solvent (EtOAc or ether), and neutralized with aq NaOH (0.2 M). The remaining organic solvent was removed in vacuo, and the final solution was filtered through a 200 nm membrane filter. This RGD peptide conjugate solution in HEPES buffer was used for the surface functionalization of AuNPs without further purification.

Linear RGD Peptide Conjugate. Linear RGD peptide (5.0 mg, GRGDSP, Calbiochem) in 4.0 mL of buffer was treated with *N*-hydroxy succinimidyl thioctic ester (3.4 mg) in 2.0 mL of acetone. After purification as described above in the General Procedure, the final solution was filtered with a total volume of 5.0 mL.

Cyclic RGD Peptide Conjugate. Cyclic RGD peptide (2.4 mg, RGDfK, Anaspec) in 2.0 mL of buffer was treated with *N*-hydroxy succinimidyl thioctic ester (1.6 mg) in 2.0 mL of acetone. After purification as described above in the General Procedure, the final solution was filtered as described above with a total volume of 7.0 mL.

General Procedure for the Surface Functionalization of AuNPs with RGD Peptide Conjugates. A solution of citrate-stabilized AuNPs was mixed with a solution of RGD peptide conjugate. Self-assembly of peptide conjugate onto the surface of AuNPs was accomplished by leaving the solution at room temperature for 24 h. The functionalized particles were then purified by centrifugal filtering (Centriplus YM-30, Amicon). The process was repeated two times with H_2O. The residue in the centriplus filter was additionally purified by gel filtration (prepacked column, PD-10, GE Healthcare). The final volume of particle solution was adjusted with H_2O and stored at 4 °C.

4.5-nm-Diameter AuNPs Functionalized with Linear RGD Peptide. To a solution of citrate-stabilized AuNPs (5.0 mL) was added a solution of linear RGD peptide conjugate in HEPES buffer (0.25 mL). After purification as described above in the General Procedure, the final volume of purified functionalized nanoparticle solution is 5.0 mL in H_2O.

4.5-nm-Diameter AuNPs Functionalized with Cyclic RGD Peptide. To a solution of citrate-stabilized AuNPs (5.0 mL) was added a solution of cyclic RGD peptide conjugate in HEPES buffer (0.50 mL). After purification as described above in the General Procedure, the final volume of purified functionalized nanoparticle solution is 5.0 mL in H_2O.

16-nm-Diameter AuNPs Functionalized with Linear RGD Peptide. A solution of linear RGD peptide conjugate in HEPES buffer (0.5 mL) was diluted with HEPES buffer (7.5 mL, 20 mM, pH 7.4), and the resulting solution was then mixed with a solution of citrate-stabilized AuNPs (4.0 mL). After purification

as described above in the General Procedure, the final volume of purified functionalized nanoparticle solution is 16 mL in H_2O.

16-nm-Diameter AuNPs Functionalized with Cyclic RGD Peptide. A solution of cyclic RGD peptide conjugate in HEPES buffer (0.5 mL) was diluted with HEPES buffer (3.5 mL, 20 mM, pH 7.4), and the resulting solution was then mixed with a solution of citrate-stabilized AuNPs (2.0 mL). After purification as described above in the General Procedure, the final volume of purified functionalized nanoparticle solution is 8.0 mL in H_2O.

Characterization of AuNPs. UV−visible absorption spectra were recorded using an Ocean Optics USB 2000 spectrometer. Transmission electron microscopy (TEM) measurements were performed using a ZEISS EM10 CA. Samples were prepared by drop casting 5 μL of the sample onto a Formvar coated copper grid. The distribution of particle sizes was determined using *ImageJ*.

Cell Lines. HUVECs (human umbilical vein endothelial cells, [Lonza] Cambrex Biosciences, Walkersville, MD) were cultured in endothelial growth media at 37 °C in a humidified atmosphere of 5% CO_2 (v/v). The growth media consisted of 500 mL of endothelial cell basal media (EBM) supplemented with 10 ng/mL recombinant epidermal growth factor (hEGF), 1 μg/mL hydrocortisone, 12 μg/mL bovine brain extract, 25 U/mL heparin, 50 μg/mL amphotericin B, and 2% fetal bovine serum. The cells were detached and harvested using 0.05% trypsin/0.02% EDTA in PBS.

Cell Viability. To determine cell cytotoxicitiy/viability, the cells were plated at a density of 1×10^4 cells/well in a 96-well plate at 37 °C in 5% CO_2 atmosphere. After 24 h of culture, the medium in the wells was replaced with fresh medium containing nanoparticles in varying concentrations. After 24 h, 100 μL of MTT solution (5 mg/mL in phosphate buffer pH 7.4, MTT Sigma-Aldrich) was added to each well. After 3 h incubation at 37 °C and 5% CO_2 for exponentially growing cells and 15 min for steady-state confluent cells, the medium was removed and formazan crystals were solubilized with 100 μL of DMSO, and the solution was vigorously mixed to dissolve the reacted dye. The absorbance of each well was read on a microplate reader at 560 nm. The spectrophotometer was calibrated to zero absorbance, using culture medium without cells. The relative cell viability (%) related to control wells containing cell culture medium without nanoparticles was calculated by $[A]_{test}/[A]_{control} \times 100$. As a positive control, 100 μM doxorubicin (DOX) was added to an extra set of plated culture wells in conjunction with each test sample.

Transmission Electron Microscopy (TEM) of Cells. The medium containing the gold nanoparticles not taken up by the cells was discarded, and the cells were thoroughly washed with PBS buffer. Cells were scraped from the culture dish and centrifuged at 5000 *g* for 5 min, and the supernatant was removed. The cell pellets were fixed in a 0.1 M PBS solution containing 2.5% glutaraldehyde and 4% paraformaldehyde for 1 h. The pellets were then rinsed with 0.1 M PBS, embedded in 2% agarose gel, postfixed in 4% osmium tetroxide solution for 1 h, rinsed with distilled water, stained with 0.5% uranyl acetate for 1 h, dehydrated in a graded series of ethanol (30%, 60%, 70%, 90%, and 100%), and embedded in epoxy resin. The resin was polymerized at 60 °C for 48 h. Ultrathin sections (50−70 nm) obtained with a LKB ultramictrotome were stained with 5% uranyl acetate and 2% aqueous lead citrate and imaged via transmission electron microscopy. One representative image out of 30 captured images at the same magnification (61600×) is shown in the results and discussion sections for each experimental condition studied.

Amino Acid Analysis. Amino acid content analysis of the AuNP−peptide conjugates was performed by Commonwealth Biotechnologies, Inc. (Richmond, VA), by chromatographic measurement of derivatized peaks after hydrolysis of the sample in 6 N HCl at 110 °C for 20 h.

MAIL Imaging of Cells. Cells were plated at a density of 5×10^4 cells/mL in four-chamber tissue culture slides (BD Falcon); each chamber had been treated with 1 mL of fibrinogen (200 μg/mL) for 24 h at 4 °C prior to seeding the cells. After 24 h of culture, the medium in the chambers was replaced with fresh medium containing nanoparticles of three varieties, separately: (1) bare Au citrate NPs, (2) linear RGD conjugated AuNPs, and (3) monocyclic RGD conjugated AuNPs. One chamber per slide was refilled with fresh media containing no nanoparticles to serve as a control. After incubation for a particular time interval (e.g., 2 h, 6 h, 24 h), the media were removed from the chambers and cells were fixed by treatment with paraformaldehyde (4% v/v in PBS) for 10 min. The cells were then washed twice with 25 mM glycine in PBS to remove unreacted paraformaldehyde. Again, one representative image out of a set of 30 captured images at the same magnification (40×) is displayed in the results and discussion section for each experimental condition studied.

Apparatus. The multiphoton microscope has been described in detail previously (*32*), and so we present only brief details here. The excitation source was a Coherent Mira 900-F Ti:sapphire laser that produced pulses with a duration of approximately 150 fs at a center wavelength of 800 nm. The laser was focused into the sample through a 40× microscope objective with a numerical aperture of 0.75 (Zeiss Plan Neofluar). An excitation power of 1.5 mW was used. MAIL emission was collected by the same objective and was detected by single-photon-counting avalanche photodiodes. Light with wavelengths of 750 nm and longer was filtered out before detection. Images were collected by scanning the laser beam across the sample using a pair of galvanometric mirrors. A program written in LabView was used to control the scanning and to monitor the luminescence counts as a function of position on the sample. In the resulting MAIL images, a color is assigned to each pixel based upon the luminescence counts collected at that pixel position. Hence, the images give an immediate indication of the location and intensity of AuNP structures present within the captured frame.

Integration of MAIL Image Intensities. In order to generate semiquantitative data from each MAIL image, pixel values were integrated in a program written in LabView. The program discarded values lower than 15, which were considered to be random noise present even on sample chamber slides to which no gold had been added. All remaining pixel values were summed and assigned to the corresponding image.

Blocking of AuNP Uptake into HUVECs. Cells were cultured in fibrinogen-treated four-chamber slides for 24 h. After that period, three wells were treated with different blocking agents and one was left as an untreated control. The blocking agents used were sodium azide (0.1%), bovine serum albumin (3%), and free cyclic RGDfK (1 μM). Cells were treated with blocking agent for 10 min and then washed twice with PBS. AuNPs with surface-conjugated RGDfK were added to all wells in 1 mL of growth media. After an additional 24 h, cells were fixed with paraformaldehyde and subsequently imaged by MAIL.

RESULTS AND DISCUSSION

We studied AuNPs of two different diameters, 4.5 and 16 nm, to determine whether the size of the particle, and correspondingly the number of peptide conjugates attached, would have an effect on the uptake results. Figure 1 shows TEM images of these particles ex vivo and corresponding UV absorption spectra. Figures 1b and 1e show the cyclic RGD conjugates for 4.5 and 16 nm particles, respectively, demonstrat-

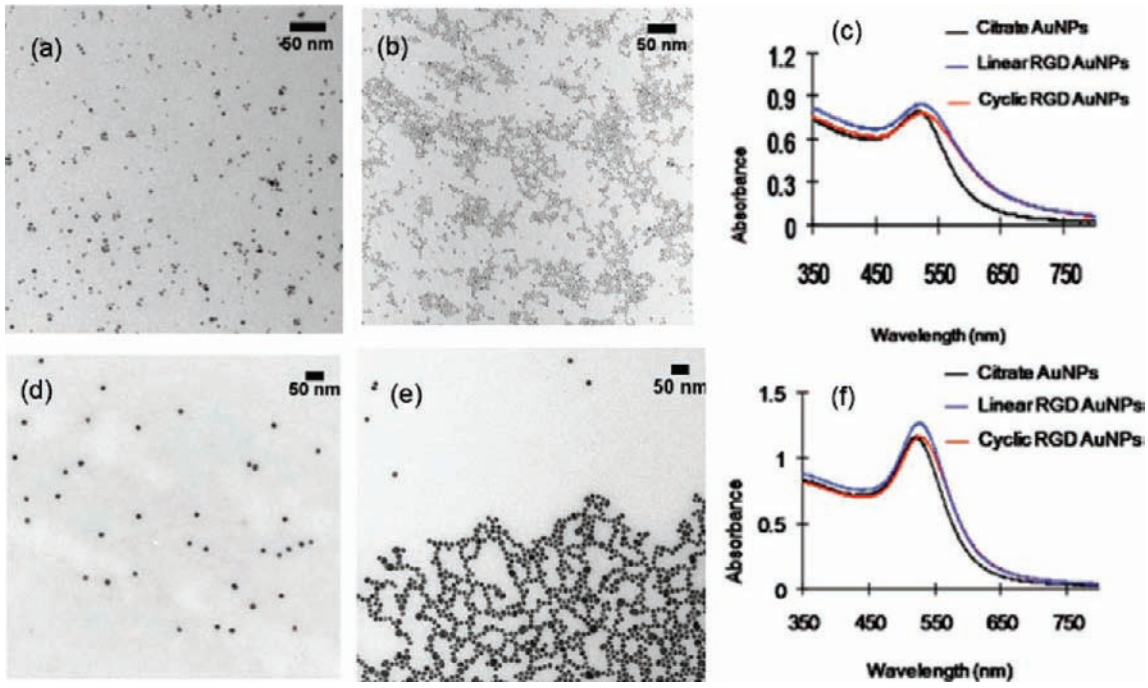

Figure 1. TEM images and UV−vis absorption spectra of AuNPs: (a) citrate-stabilized AuNPs (average diameter, 4.5 ± 1.4 nm); (b) cyclic RGD peptide-functionalized AuNPs; (c) 4.5 nm citrate-stabilized AuNPs (in black, λ_{max} = 520 nm), linear RGD peptide-functionalized AuNPs (in blue, λ_{max} = 523 nm), and cyclic RGD peptide-functionalized AuNPs (in red, λ_{max} = 523 nm); (d) citrate-stabilized AuNPs (average diameter, 15.8 ± 1.6 nm); (e) cyclic RGD peptide-functionalized AuNPs; (f) 15.8 nm citrate-stabilized AuNPs (in black, λ_{max} = 520 nm), linear RGD peptide-functionalized AuNPs (in blue, λ_{max} = 526 nm), and cyclic RGD peptide-functionalized AuNPs (in red, λ_{max} = 526 nm).

ing a significant amount of aggregation relative to their bare citrate counterparts in Figures 1a and 1d. The increased aggregation of the peptide-functionalized AuNPs can be attributed to hydrogen bonding occurring between surface conjugates on adjacent particles, as water was removed from the system by vacuum prior to TEM analysis. Aggregation of functionalized AuNPs on TEM grids has been observed for many derivatives. Analysis of the solutions prior to deposition by dynamic light scattering indicated that aggregation in solution is minimal.

The wavelength of maximum absorption for both particle sizes remains constant at 525 nm for bare citrate AuNPs, linear RGD conjugated AuNPs, and cyclic RGD conjugated AuNPs, although the absorbance values increase slightly over the measured wavelength range for both the linear and cyclic RGD-conjugated AuNPs. Absorption peaks for aggregated samples are broadened and shifted significantly to longer wavelengths. As our observed UV absorbance peaks are sharp and are consistent with values reported previously for stable AuNP suspensions, aggregation in solution is likely to be insignificant. Furthermore, it has been previously demonstrated that AuNPs do not aggregrate in serum-completed cell growth media (*33*).

Figure 2 summarizes the results of the MTT cytotoxicity assay for 4.5 nm AuNPs incubated with HUVECs. Even at a concentration of 39 μg/mL of AuNPs, which is significantly higher than what would be possible in a biologically relevant setting, the AuNPs were nontoxic to the HUVECs. However, DOX mixed with any AuNP sample diminishes cell survival to below 2%. There are two key points to take from the results of this experiment. First, 4.5 nm AuNPs, which are comparable in size to many cellular proteins, do not harm the target cells. Second, the addition of targeting peptides to the surfaces of the AuNPs does not lead to measurable toxicity of the nanovector under the conditions used in this study. This preliminary toxicological screening result is promising for the potential use of surface-functionalized particles as in vivo targeting agents. We also note that similar results were found for the 16 nm

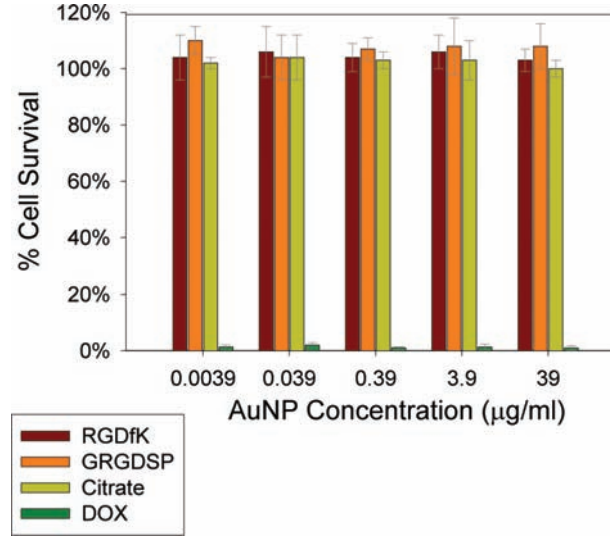

Figure 2. MTT assay of peptide-targeted AuNPs incubated with HUVECs.4.5 nm particles of three different types, (1) AuNP-RGDfK conjugates (maroon bars), (2) AuNP-GRGDSP conjugates (orange bars), and (3) bare citrate-stabilized AuNPs (gold bars), were each incubated with HUVECs for a 72 h MTT assay. Doxorubicin (DOX; 100 μM) was incubated with the HUVECs as a positive control (green bars).

AuNPs, both bare and with the targeting peptides conjugated to the particle surfaces (data not shown for brevity).

Table 1 summarizes the results of amino acid analysis on the AuNP−peptide conjugates for the 4.5 nm AuNPs. The grafting density of linear RGD peptides on the AuNPs was approximately 5 times as large as that of cyclic RGD peptides. This finding is reasonable, since the cyclic peptide conjugate takes up a significantly larger effective area than the linear peptide counterparts. Since the peptide conjugates were reacted with the AuNPs in large excess, it is assumed that saturation of the particle surfaces was achieved, and so the greater surface

Table 1. Amino Acid Analysis of Peptide-Conjugated AuNPs (4.5 nm)[a]

conjugate type	(avg no. of conjugated peptides)/particle	(avg no. of conjugated peptides)/nm^2
cyclic RGD peptide	124.6 ± 29.3	2.0 ± 0.5
linear RGD peptide	610.7 ± 92.9	9.6 ± 1.5

[a] Particle/peptide conjugates were treated in highly acidic conditions to hydrolyze the bound amino acids, whose mass was subsequently measured. It is shown that the average number of peptide conjugates per particle is nearly five times as high for the linear RGDs as compared to the cyclic RGDfKs (indicated error is s.d.).

density of linear peptides resulted. The average number of conjugated peptides per unit area for 4.5 nm AuNPs is shown in Table 1, and the surface densities for 16 nm AuNPs are expected to be similar, but were not determined in this study.

MAIL Detection of Particle Uptake into Cells. MAIL imaging was performed on HUVECs incubated for 6 and 24 h with 4.5 nm AuNPs and with 16 nm AuNPs. Note that all MAIL images in this study show one representative cell from a single image out of the correspondingly treated cell population, although many images were collected. Shown in Figure 3 are MAIL images and corresponding transmission optical images at 6 h incubation with 4.5 nm AuNPs. Figure 4 shows HUVECs incubated with the same AuNPs for 24 h. The cells incubated with the AuNPs with cyclic RGD conjugates (Figures 3a and 4a) exhibit a greater luminescence signal than those cells

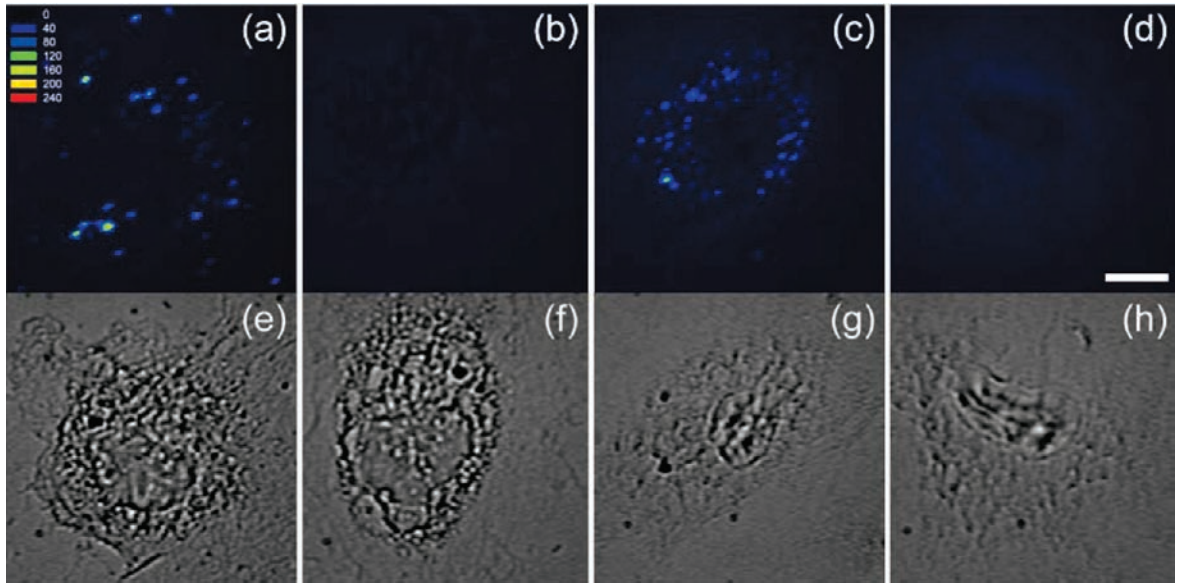

Figure 3. MAIL/transmission optical (40×) images for 6 h uptake of targeted 4.5 nm AuNPs into HUVECs. (a) MAIL image of 4.5 nm AuNPs with cyclic RGD conjugates; (b) MAIL image of 4.5 nm AuNPs with linear RGD conjugates; (c) MAIL image of bare citrate 4.5 nm AuNPs; (b) MAIL image of controls, i.e., no AuNPs incubated with HUVECs; (e) transmission image of 4.5 nm AuNPs with cyclic RGD conjugates; (f) transmission image of 4.5 nm AuNPs with linear RGD conjugates; (g) transmission image of bare citrate 4.5 nm AuNPs; (h) transmission image of control sample. The scale bar is 10 μm.

The scale bar is 10 μm.

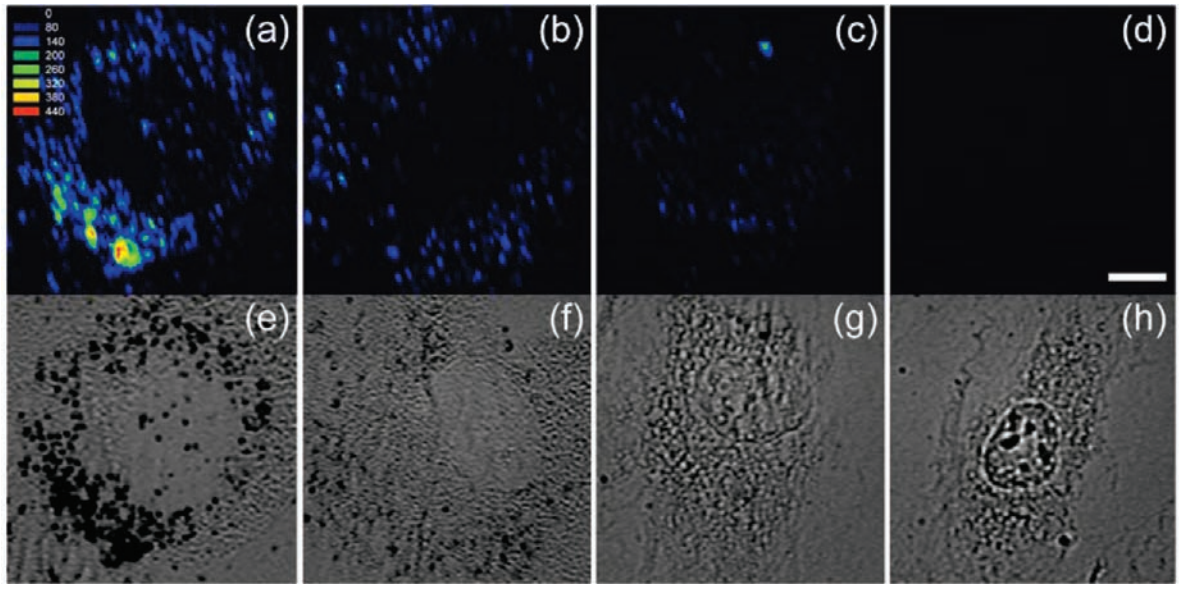

Figure 6. MAIL/transmission optical (40×) images for 24 h uptake of targeted 16 nm AuNPs into HUVECs. (a) MAIL image of 16 nm AuNPs with cyclic RGD conjugates; (b) MAIL image of 16 nm AuNPs with linear RGD conjugates; (c) MAIL image of bare citrate 16 nm AuNPs; (b) MAIL image of controls, i.e., no AuNPs incubated with HUVECs; (e) transmission image of 16 nm AuNPs with cyclic RGD conjugates; (f) transmission image of 16 nm AuNPs with linear RGD conjugates; (g) transmission image of bare citrate 16 nm AuNPs; (h) transmission image of control sample. The scale bar is 10 μm.

incubated with either AuNPs functionalized with linear RGD conjugates (Figures 3b and 4b) or bare citrate AuNPs (Figures 3c and 4c).

Figures 5 and 6 show images of HUVECs incubated with 16 nm AuNPs after 6 h and 24 h of incubation, respectively. Again, a greater luminescence signal is observed in the samples containing the AuNPs with cyclic RGD conjugates (Figures 5a and 6a), and uptake increases significantly over the 24 h period. The MAIL signals for 16 nm AuNPs are stronger than those for 4.5 nm AuNPs. This effect could be intrinsic to the AuNPs or could be due to a more effective exocytotic mechanism for smaller particles by the HUVECs. Note that the concentration of particles incubated with the HUVECs was 39 μg/mL, which was the upper limit value for the 72 h MTT assay. Thus, a large number of the targeted AuNPs are getting into the cells, but they do not appear to harm the cells in any significant way.

Figure 7 displays a histogram of the integrated MAIL counts from treated cell populations corresponding to representative images displayed in Figures 3−6. While the intensity values in this figure do not give an absolute quantitative measure of the number AuNPs within the cell, the data clearly indicate that differential uptake is observed among the experimental conditions. The 16 nm AuNP−RGDfK conjugates at 24 h displayed the highest intensity value (1.31×10^6) among the tested samples. The data also indicate that large increase in intensity was observed over an 18 h period (between the 6 and 24 h test points) for the 4.5 nm AuNP−RGDfK conjugates and the 16 nm AuNP−RGDfK conjugates at 12.36-fold and 13.17-fold,

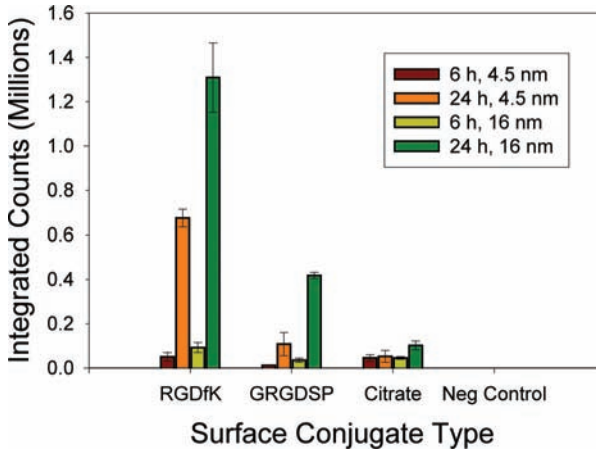

Figure 7. Integrated counts from MAIL images of targeted AuNPs (Corresponding representative images shown in Figures 3−6).

respectively. Again, as anticipated from the images at 24 h, the AuNP−RGDfK conjugate samples had significantly higher average luminescence counts (1.31×10^6 [16 nm] and 6.75×10^5 [4.5 nm]) than the AuNP−GRGDSP (4.18×10^5 [16 nm] and 1.08×10^5 [4.5 nm]) or citrate-stabilized AuNP (1.01×10^5 [16 nm] and 5.23×10^4 [4.5 nm]) controls of the same particle size. For the 6 h time interval, preferential uptake of the 4.5 nm citrate-stabilized AuNPs compared to the 4.5-nm AuNP−GRGDSP conjugate was unexpected. There are three possible explanations for this observation. First there should be a large difference in zeta potential (surface charge) between the functionalized and unfunctionalized gold nanoparticles that may influence uptake. Alternatively, preferential uptake of the citrate nanoparticles may arise from the saturation of the linear RGD peptide on surface of the gold nanoparticles, which would interfere with single peptide−receptor binding events via steric hindrance. Finally, the 4.5 nm particles may be more susceptible to exocytosis mechanisms during the initial uptake period (*33*). At this point, it is not possible to differentiate among these three explanations without significant experimentation. These additional studies are underway and will be reported in due course.

Determination of the Cellular Uptake Mechanism. Figures 8 and 9 show HUVEC cells incubated with AuNP−RGDfK conjugates for 24 h in the presence of different uptake-blocking agents for 4.5 and 16 nm AuNPs, respectively. The leftmost images are controls in which the HUVECs have not been treated with a blocking agent. We observe significantly greater luminescence in these images (Figures 8a and 9a), indicating that the blocking agents alter the uptake of the AuNP−RGDfK conjugates. In Figures 8b and 9b, the cells have been treated with 0.1 wt % sodium azide, an endocytosis inhibitor, for 10 min prior to addition of AuNP−RGDfKs. The luminescence signal is diminished significantly for both 4.5 and 16 nm AuNPs, although some small patches of signal are still observed for these samples.

The cells in Figures 8c and 9c have been treated for 10 min with 3% BSA, which blocks nonspecific binding to the cells. For both samples, a smaller luminescence signal was observed, although this signal was more comparable to that of the untreated controls. This inhibition study indicates that a large fraction of the functionalized AuNPs is taken up into the cells via specific binding to a cell-surface receptor followed by receptor-mediated endocytosis. Figures 8d and 9d demonstrate that treatment of the cells with 1 μM RGDfK to block $\alpha_v\beta_3$ integrins significantly decreases the intensity of the luminescent signals relative to the untreated controls. This result implies that the majority of uptake must involve endocytosis via the $\alpha_v\beta_3$ integrin.

Figure 10 displays a histogram of the integrated MAIL counts from the treated cell populations corresponding to the representative images shown in Figures 8 and 9. As expected, the untreated HUVEC samples had the highest integrated counts at 5.28×10^5 and 1.09×10^6 for 4.5 and 16 nm AuNPs, respectively. AuNP−RGDfK conjugates taken up into HUVECs pretreated with 3% BSA displayed the next highest intensity values, with a 64% drop-off in intensity for 4.5 nm AuNP−RGDfKs (1.91×10^5 counts) and a 68% drop-off in intensity for 16 nm AuNP−RGDfKs (3.54×10^5 counts) relative to the untreated HUVEC controls. For both 4.5 nm and 16 nm

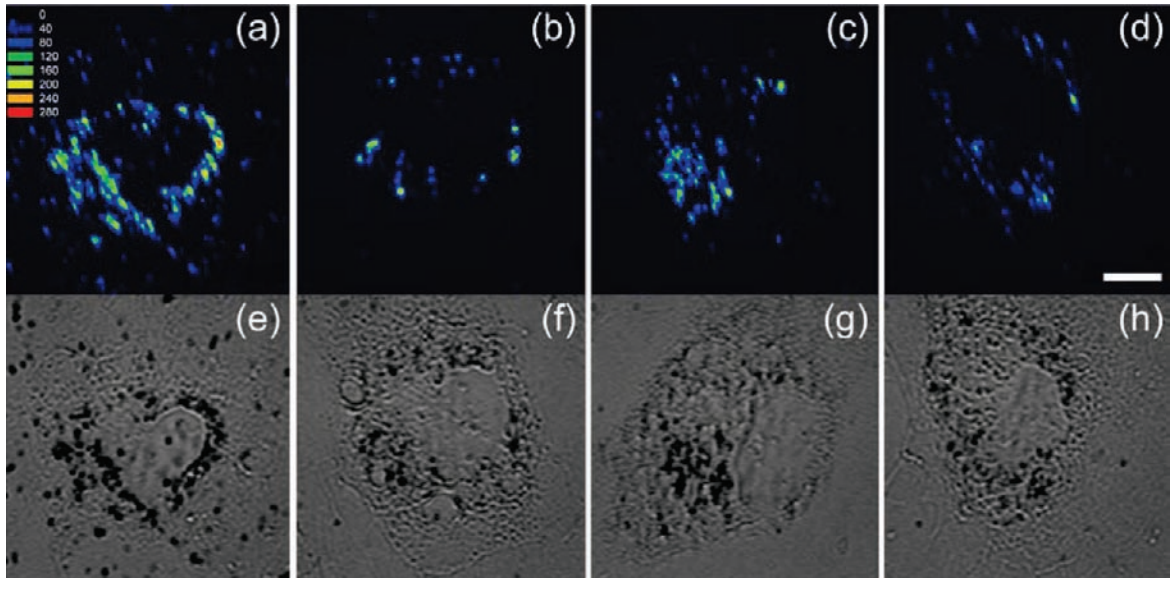

Figure 8. MAIL/transmission optical (40×) images for 24 h uptake of targeted 4.5 nm AuNPs into HUVECs. (a) MAIL image 4.5 nm AuNPs with cyclic RGD conjugates (no treatment); (b) MAIL image of 4.5 nm AuNPs with cyclic RGD conjugates, HUVECs treated with sodium azide; (c) MAIL image of 4.5 nm AuNPs with cyclic RGD conjugates, HUVECs blocked with BSA; (d) MAIL image of 4.5 nm AuNPs with cyclic RGD conjugates, HUVECs treated with free RGDfK; (e) transmission image of 4.5 nm AuNPs with cyclic RGD conjugates (no treatment); (f) transmission image of 4.5 nm AuNPs with cyclic RGD conjugates, HUVECs treated with sodium azide; (g) transmission image of 4.5 nm AuNPs with cyclic RGD conjugates, HUVECs blocked with BSA; (h) transmission image of 4.5 nm AuNPs with cyclic RGD conjugates, HUVECs treated with free RGDfK. The scale bar is 10 μm.

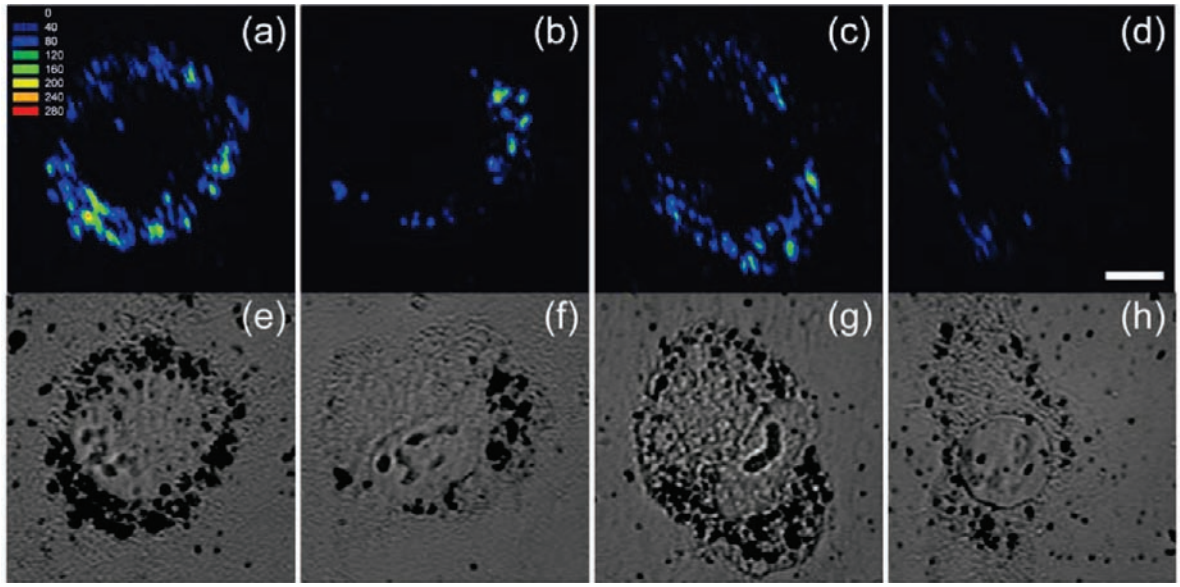

Figure 9. MAIL/transmission optical (40×) images for 24 h uptake of targeted 16 nm AuNPs into HUVECs. (a) MAIL image 16 nm AuNPs with cyclic RGD conjugates (no treatment); (b) MAIL image of 16 nm AuNPs with cyclic RGD conjugates, HUVECs treated with sodium azide; (c) MAIL image of 16 nm AuNPs with cyclic RGD conjugates, HUVECs blocked with BSA; (d) MAIL image of 16 nm AuNPs with cyclic RGD conjugates, HUVECs treated with free RGDfK; (e) transmission image of 16 nm AuNPs with cyclic RGD conjugates (no treatment); (f) transmission image of 16 nm AuNPs with cyclic RGD conjugates, HUVECs treated with sodium azide; (g) transmission image of 16 nm AuNPs with cyclic RGD conjugates, HUVECs blocked with BSA; (h) transmission image of 16 nm AuNPs with cyclic RGD conjugates, HUVECs treated with free RGDfK. The scale bar is 10 μm.

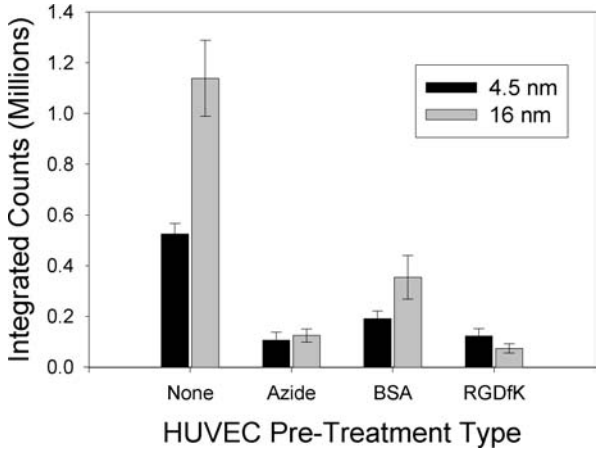

Figure 10. Integrated counts from MAIL images of AuNP−RGDfK conjugates pretreated with blocking agents (corresponding representative images in Figures 8−9, a−d).

AuNP−RGDfKs taken up in HUVECs pretreated with BSA, intensity values 2.5 to 4 times higher were measured relative to the sodium azide and free RGDfK pretreated HUVECs incubated with the same AuNPs. The individual values suggest that this preferential uptake is due to a specific binding event between the AuNP−RGDfKs and cell surface receptors, while smaller amounts of signal may be attributed to nonspecific uptake (free RGDfK blocking) and nonspecific binding to the cell surface (free RGDfK blocking and sodium azide treatment).

Detection of Particle Uptake into Cells via TEM imaging. Figure 11 shows TEM images of HUVECs incubated with 4.5 and 16 nm AuNPs with surface conjugated RGDfK for a period of 72 h. These images demonstrate that the nanoparticles are taken primarily into endosomal and lysosomal vesicles. Aggregation of the AuNPs is observed within the vesicle. This intracellular destabilization may arise from ligand exchange reactions within the cell, as suggested by Rotello et al., (*35*) or may be the result of digestion of the ligand shell by proteases within the endosomes and lysosomes, a mechanism proposed by Nativo et al. in an AuNP uptake study on human fibroblasts

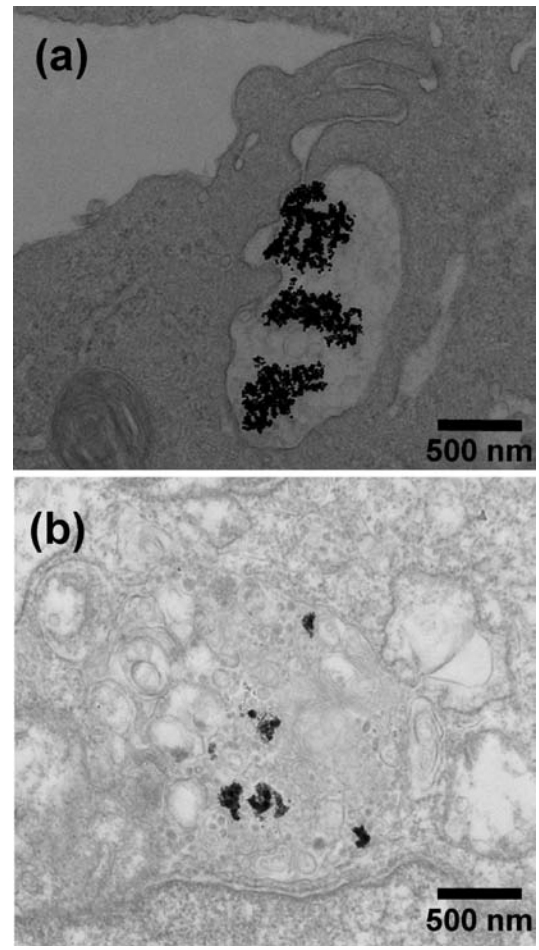

Figure 11. TEM images of AuNPs taken up by HUVECs. (a) 16 nm AuNPs with surface conjugated cyclic RGD peptide incubated with HUVECs for 72 h; AuNPs are seen to be uptaken into an endosomal compartments. (b) 4.5 nm AuNPs with surface conjugated cyclic RGD peptide incubated with HUVECs for 72 h; AuNPs are also observed clustered within endosomal compartments.

(*36*). These TEM studies serve as a benchmark to demonstrate that MAIL imaging can provide similar information to electron microscopy, but with the potential of performing imaging in real time and on live cells.

CONCLUSIONS

We have shown via MAIL imaging that AuNPs of two different diameters, 4.5 and 16 nm, can be targeted specifically to activated endothelial cells by covalent conjugation of RGD peptides to the surface of the nanoparticle. Detected signal from these particles within the cells depended on two factors: (1) the size of the particle, 4.5 nm vs 16 nm, and (2) the structure of the RGD analog. AuNP−RGDfK conjugates exhibit highly differential nanoparticle uptake when compared to AuNPs conjugated with linear RGD or bare AuNPs. The integrated counts for MAIL images of the targeted HUVECs were an order of magnitude higher for the AuNP−RGDfK conjugates than for the AuNP−GRGDSP controls. Also, cells incubated with 16 nm AuNPs exhibit significantly higher MAIL signals than those incubated with the smaller 4.5 nm AuNPs. Additional experiments in which uptake into HUVECs was blocked with BSA, sodium azide, or free RGDfK, indicated that AuNP−RGDfK conjugates are internalized following a specific binding event and that $\alpha_v\beta_3$ integrin-mediated endocytosis is an important uptake mechanism. Results from MAIL studies were verified by comparison to TEM images, which revealed that the endocytosed AuNPs remain primarily within endosomal and lysosomal vesicles.

The studies reported here demonstrate that MAIL is a powerful tool for monitoring targeting and determining uptake mechanisms of surface-functionalized nanostructures. Given the capability of MAIL for rapid, three-dimensional imaging with high resolution, this technique shows great promise for applications in nanomedicine.

Self-Protecting Bactericidal Titanium Alloy Surface Formed by Covalent Bonding of Daptomycin Bisphosphonates

Chang-Po Chen and Eric Wickstrom*

Department of Biochemistry and Molecular Biology, Thomas Jefferson University, Philadelphia, Pennsylvania 19107, United States.
Received March 12, 2010; Revised Manuscript Received September 24, 2010

Infections are a devastating complication of titanium alloy orthopedic implants. Current therapy includes antibiotic-impregnated bone cement and antibiotic-containing coatings. We hypothesized that daptomycin, a Gram-positive peptide antibiotic, could prevent bacterial colonization on titanium alloy surfaces if covalently bonded via a flexible, hydrophilic spacer. We designed and synthesized a series of daptomycin conjugates for bonding to the surface of 1.0 cm^2 Ti6Al4V foils through bisphosphonate groups, reaching a maximum yield of 180 pmol/cm^2. Daptomycin-bonded foils killed 53 ± 5% of a high challenge dose of 3×10^5 cfu *Staphylococcus aureus* ATCC 29213.

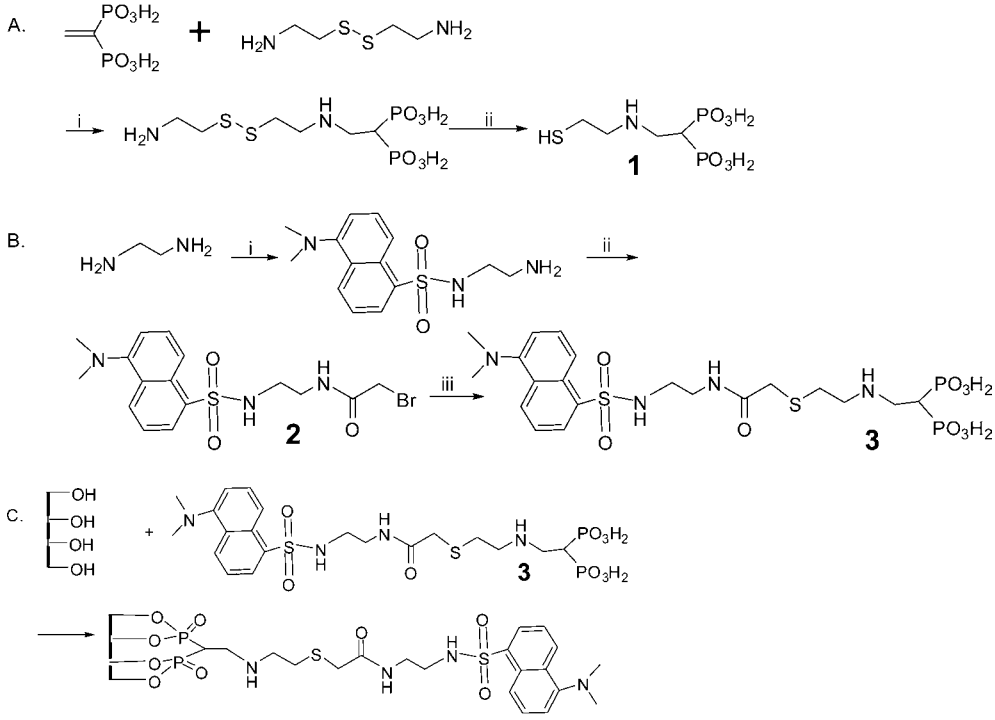
INTRODUCTION

The introduction of medical implants has revolutionized the field of medicine. Orthopedic implants, dental implants, vascular grafts, heart valves, and stents have extended life spans and the quality of life (*1*). However, implant-associated infections are serious complications of all those medical devices (*2*). The current arthroplasty infection rate ranges 1−5%, but the infection rate is much higher in trauma patients and in populations at risk for infection (*3*). Implant removal is usually the only clinical option because bacterial biofilm formation on the surface of the implant protects the microorganisms from the immune system and antibiotic therapy (*4, 5*). A number of local antibiotic delivery systems, such as antibiotic-containing poly(methyl methacrylate) cement (*6*) or biopolymers (*7*), have been developed to prevent orthopedic implant-associated infections. These approaches suffer from the limitation that the antibiotics can only be released to the surroundings over a short time. In some cases, the porous material holding the antibiotics has to be removed by a second surgery (*2*).

In order to address the problems faced by local delivery systems, covalent modification of orthopedic implants has been investigated with a variety of antibacterial materials. Quaternary ammonium salts, such as poly(4-vinyl-*N*-alkylpyridinium bromide) and 3-(trimethoxysilyl)propyldimethyloctadecyl ammonium chloride, were covalently bonded to glass, metal, and polymer surfaces to provide bactericidal activity (*8, 9*). An antimicrobial peptide LL-37 has also been attached to the surface of titanium alloy implants to prevent infections (*10, 11*). The peptide has a broad-spectrum activity against bacteria and fungi through peptide−membrane interactions leading to membrane permeation. Ampicillin has been used to modify the surface of polytetrafluoroethylene to effect surface antibiotic activity (*12, 13*).

Recently, we reported the covalent modification of titanium powder and titanium alloy pins by vancomycin, a Gram-positive peptide antibiotic that blocks peptidoglycan cross-linking (*14*), via a flexible, hydrophilic spacer (*15, 16*). The surfaces of the titanium alloy pins were uniformly oxidized with a hydrogen peroxide/sulfuric acid mixture, then functionalized with aminopropyltriethyoxysilane. After amide bonding of two aminoethoxyethoxyacetates to the surface aminopropyl groups, vancomycin was coupled to the titanium alloy surface via a third amide bond. The covalently attached vancomycin prevented *Staphylococcus aureus* (*17*) and *S. epidermidis* (*18*) colonization and biofilm formation on the titanium alloy surfaces.

This approach should be effective against most Gram-positive infections today, since resistance to vancomycin is relatively rare. Nevertheless, resistance to vancomycin is becoming more prevalent (*19, 20*), and we must prepare for the time when vancomycin will be much less effective. Treatment with daptomycin, a recently discovered antibacterial cyclic lipopeptide (*21*), might be a candidate for a second-generation antibiotic, as there have been no reports yet of resistance. Daptomycin appears to function by penetrating the bacterial cell membrane and causing rapid depolarization, resulting in a loss of membrane potential, leading to inhibition of protein, DNA, and RNA synthesis, thereby killing the bacteria (*22*).



Bisphosphonates bind strongly to metal surfaces and bone tissue (*23, 24*), and have been successfully integrated into bone-specific drug delivery systems to target protein, peptide, estrogen, antibiotics, antitumor and radioactive pharmaceutics to bone tissue (*25*). Recently, bisphosphonate has been conjugated with poly(ethylene glycol) or alkanes to directly modify titanium surfaces (*26*), and an RGD[1]peptide was bound to the titanium implants by conjugating with four phosphonic acid groups (*27*). Because of the strong and selective affinity of phosphonates to the oxidized surface of titanium (*25*), we hypothesized that a phosphonate derivative of daptomycin could bond readily to the surface of Ti6Al4V titanium alloy to form an antibiotic monolayer. This approach could reduce the number

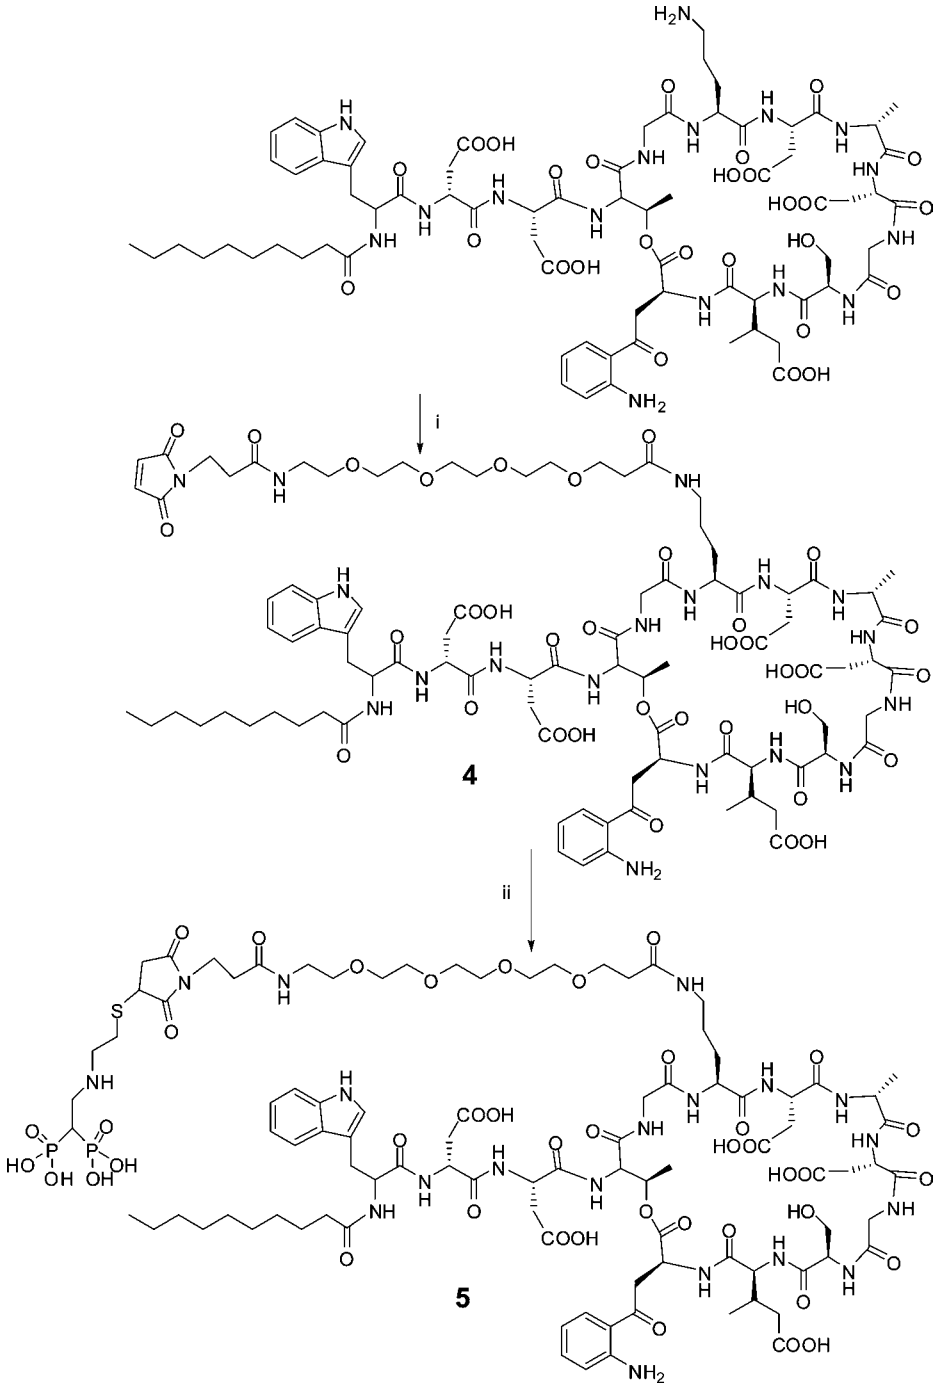
of chemical synthetic steps required, relative to our vancomycin construct (*16*), and make sterilization feasible during production.

MATERIALS AND METHODS

Materials. Daptomycin was purchased from Cubist Pharmaceuticals. Fmoc-Lys(εBoc)-OH and HATU were purchased from Novobiochem. Bromoacetic acid, CF_3CO_2H, CH_2Cl_2, CH_3CN, DCC, Et_2O, EtOAc, hexane, H_2NEtNH_2, iPr_2NEt, iPrOH, iPr_3SiH, Me_2NCHO, and MeOH were purchased from Sigma-Aldrich. Müller-Hinton broth was purchased from Becton-Dickinson. Mal-dPEG4 NHS ester (#10214) (succinimidyl-TEG-maleimide) was purchased from Quantum Biodesign Ltd. 2-(2-Mercaptoethylamino) ethylidene-1,1-bisphosphonic acid (**1**), prepared as described (*28*) (Scheme 1), was the generous gift of Dr. Ivan S. Alferiev of the Children's Hospital of Philadelphia.

Chromatography. Normal-phase flash chromatography of crude products was carried out on a 2.5 × 60 cm silica gel column eluted with 75% hexane/25% EtOAc or 95% CH_2Cl_2/5% MeOH.



Preparative reversed-phase high-performance liquid chromatography (HPLC) of intermediates was performed on an Alltech Alltima C_{18} 5 μ column, 250 × 22 mm, coupled to a UV detector at 254 nm, eluted with a linear gradient of 10−50% CH_3CN in water containing 0.1% CF_3CO_2H in 30 min at a flow rate 6 mL/min. The analysis was performed with a Waters 600E system, using Alltech C18 5 μ, 250 × 4.6 mm column coupled to a Waters 486 detector at 254 nm. Sample was eluted with a linear gradient of 20−70% CH_3CN in water containing 0.1% CF_3CO_2H in 30 min with a flow rate of 1 mL/min. Thin layer chromatography of intermediates was done on Baker Si250F silica gel TLC plates developed with MeOH/CH_2Cl_2 solvent system, then visualized with a Mineralight 254 nm lamp.

Apparatus. ^{1}H NMR spectra were recorded with a Varian INOVA 400 MHz spectrometer (Palo Alto, CA). Molecular weight analysis was performed on an Ettan MALDI-TOF mass spectrometer (GE Healthcare, Piscataway, NJ). Lyophilization was performed using a Christ Alpha 2−4 freeze-dryer (Martin Christ, Osterode am Harz, Germany) equipped with a Pfeiffer Vacuum Pump (Asslar, Germany). Fluorescence readings were performed on a QuantaMaster double monochromator fluorimeter (Photon Technologies, Birmingham, NJ). Deionized water was produced using a Milli-Q water purification system (Millipore, Bedford, MA).

Synthesis. *1-Bromoacetyl-2-dansyl-ethylenediamine (**2**).* To 20 mL of H_2NEtNH_2 was added dansyl chloride (1.079 g, 4 mmol) in 30 min under stirring (Scheme 1). The reaction was stirred for 2 h at room temperature, followed by removal of unreacted H_2NEtNH_2 under reduced pressure. The residual syrup was dissolved in 20 mL EtOAc, washed with saturated aqueous Na_2CO_3 solution (3 × 5 mL), and water (3 × 5 mL). The organic phase was dried with Na_2SO_4, filtered, and the solvent removed by rotary evaporation. The residual product was redissolved in dry EtOAc, followed by addition of bromoacetic acid (555.6 mg, 4 mmol) and DCC (824 mg, 4 mmol). The mixture was stirred at room temperature for 3 h, after which the precipitate was removed by filtration. The filtrate was then washed with saturated aqueous Na_2CO_3 solution (3 × 5 mL), and water (3 × 5 mL). The organic phase was dried with Na_2SO_4. The desired product (*2*) was purified by flash chromatography on a silica gel column eluted with 75% hexane/25% EtOAc. Yield: 1.57 g (94.7%). ^{1}H NMR (400 MHz, $CDCl_3$), δ = 8.62 (d, 1H), 8.25−8.30 (m, 2H), 7.55−7.62 (m, 2H), 7.25 (br, 1H), 6.71 (br, 1H), 5.33 (br, 1H), 3.69 (s, 1H), 3.33−3.37 (m, 2H), 3.07−3.11 (m, 2H), 2.94 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$), δ = 166.8, 155.0, 153.6, 134.5, 130.8, 130.0, 129.6, 128.8, 123.7, 118.6, 115.7, 45.8, 43.2, 40.1, 28.8. MALDI-TOF MS, calc. 414.32 Da, found 414.52 Da.

*Dansyl-bisphosphonic Acid (**3**).* 2-(2-Mercaptoethylamino)-ethylidene-1,1-bisphosphonic acid (**1**) (265 mg, 1 mmol) was dissolved in 5 mL of 67% Me_2NCHO/33% water and adjusted to pH 7.0 with NaOH under the protection of argon. Then, 1-bromoacetyl-2-dansyl-ethylenediamine (**2**) (414 mg, 1 mmol)

Scheme 2. Synthesis of Daptomycin-TEG-bisphosphonic Acid (5)[a]

[a] (i) 1.1 equiv of succinimidyl TEG maleimide, Me_2NCHO, r.t. (ii) 2-(2-Mercaptoethylamino) ethylidene-1,1-bisphosphonic acid (**1**), 50% Me_2NCHO/50% water.

was dissolved in 2 mL Me_2NCHO and added dropwise to (**1**) under the protection of argon (Scheme 1). The mixture was stirred at room temperature for 2 h. The solvent was then removed by rotary evaporation under vacuum. Finally, the residue was dissolved in 10% aqueous CH_3CN and purified by preparative reversed-phase HPLC. The eluent peak corresponding to the product 2-(9-dansyl-6,9-diaza-5-oxo-3-thia-nonanyl)-ethylidene-1,1-bisphosphonic acid (**3**) was pooled, concentrated, and lyophilized. ^{1}H NMR (400 MHz, Me_2SO), δ = 8.48 (d, 1H), 8.29 (d, 1H), 8.13−8.11 (m, 2H), 8.05 (t, 1H), 7.67−7.60 (m, 2H), 7.29 (d, 1H), 3.34−3.27 (m, 2H), 3.22 (t, 2H), 3.12−3.09 (m, 4H), 2.85 (s, 6H), 2.85−2.83 (m, 4H), 2.52−2.51 (m, 1H), 2.44−2.36 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$), δ = 169.0, 157.9, 151.3, 135.7, 129.5, 129, 128.3, 127.9, 123.7, 119.1, 115,2, 45.6, 45.1, 44.3, 41.7, 40.3, 35.5, 33.5, 27.7. ^{31}P NMR (Me_2SO): δ = 17.15 (^{1}H decoupled: s). MALDI-TOF MS, calc. 598.57 Da, found 598.86 Da. Yield: 546 mg (91%).

*Daptomycin-TEG-maleimide (**4**).* Daptomycin (100 mg, 0.062 mmol) was dissolved in 1 mL Me_2NCHO and added to 1.1 equiv of succinimidyl-TEG-maleimide (Scheme 2). The mixture was stirred at room temperature overnight. The product was precipitated by Et_2O and purified by analytical reversed-phase HPLC. The eluent peak corresponding to the product daptomycin-TEG-maleimide (**4**) was pooled, concentrated, and lyophilized. The purified sample was characterized by analytical HPLC (Figure 4B). MALDI-TOF MS, calc. for $C_{90}H_{126}N_{18}O_{35}$ 2020.01 Da, found $[M+H]^+$ 2021.53 Da. Yield: 112 mg (89%).

*Bisphosphonic Acid Derivative of Daptomycin (**5**).* To a solution of daptomycin-TEG-maleimide (**4**) (100 mg, 49.5 μmol) in 1 mL water was added 14.4 mg of 2-(2-mercaptoethylamino)ethylidene-1,1-bisphosphonic acid (**1**) in 1 mL water (pH 7.0, adjusted by sodium hydroxide) under the protection of argon (Scheme 2). The mixture was stirred at room temperature for 1 h. The sample was purified by analytical reversed-phase HPLC. The eluent peak corresponding to the product daptomycin-TEG-bisphosphonic acid (**5**) was pooled, concentrated, and lyophilized. The purified sample was characterized by analytical HPLC (Figure 4C). MALDI-TOF MS calc. for $C_{94}H_{139}N_{19}O_{41}P_2S$ 2285.24 Da, found $[M+H]^+$ 2286.13 Da. Yield: 105 mg (93%).

*Dansyl-Lys(εBoc)-OH (**6**).* To a solution of α-H_2N-Lys(εBoc)-OH (492.6 mg, 2 mmol) in CH_2Cl_2 (5 mL) was added 10 mmol of iPr_2NEt, followed by addition of 2.1 mmol of dansyl chloride (dissolved in 2 mL CH_2Cl_2) dropwise over 10 min (Scheme 3). The mixture was stirred at room temperature for 2 h. The solvent was removed by rotary evaporation, and the residue was dissolved in 10 mL EtOAc, washed with water, and then dried with Na_2SO_4. The solvent was evaporated, and the resulting product dansyl-Lys(εBoc)-OH (**6**) was purified with flash chromatography with 95% CH_2Cl_2/5% MeOH ($R_f = 0.12$). ^{1}H NMR (400 MHz, Me_2SO), δ = 8.53 (d, 1H), 8.32−8.38 (m, 1H), 8.27 (d, 1H), 7.59−7.49 (m, 2H), 7.20 (d, 1H), 5.93 (s, 1H), 4.43 (s, 1H), 3.97−3.89 (m, 2H) 2.89 (s, 6H), 2.8−2.7 (m, 2H), 1.68−1.6 (m, 2H), 1.38 (s, 9H), 1.22−1.1 (m, 4H). ^{13}C NMR (100 MHz, $CDCl_3$), δ = 174.2, 158.1, 156.2, 151.6, 134.1, 130.7, 129.8, 129.7, 128.4, 123.2, 119.3, 115.3, 81.1, 55.5, 45.8, 39.9, 32, 28.4, 21.7. MALDI-TOF MS calc. for $C_{23}H_{33}N_3O_6S$ 479.59 Da, found $[M+H]^+$ 480.62 Da. Yield: 765 mg (87%).

*Dansyl-Lys-daptomycin (**7**).* Dansyl-Lys(εBoc)-OH (**6**) (23.6 mg, 49 μmol), NHS (7.4 mg, 55 μmol), and DCC (11.2 mg 54 μmol) were dissolved in 5 mL anhydrous EtOAc in darkness. After stirring for 2 h at room temperature, the precipitate was removed by filtration, and the solvent was evaporated. The resultant NHS active ester was dissolved in 1 mL anhydrous Me_2NCHO and added to a solution of 100 mg daptomycin in 1 mL Me_2NCHO (Scheme 3). The mixture was stirred at room temperature overnight. The product was precipitated by Et_2O, sedimented, and dried under vacuum. The residue was incubated with 2 mL 95% CF_3CO_2H/2.5% water/2.5% iPr_3SiH at room temperature for 1 h to deprotect the Boc group. The deprotected derivative was precipitated by Et_2O and purified by analytical reversed-phase HPLC. The eluent peak corresponding to the product dansyl-Lys-daptomycin (**7**) was pooled, concentrated, and lyophilized. The purified sample was characterized by analytical HPLC and MALDI-TOF MS. Calc. for $C_{90}H_{125}N_{19}O_{27}S$, 1937.13 Da, found $[M+H]^+$ 1938.09 Da. Yield: 105 mg (88%).

*Dansyl-Lys-daptomycin-TEG-maleimide (**8**).* Dansyl-Lys-daptomycin (**7**) (120 mg, 0.062 mmol) was dissolved in 1 mL Me_2NCHO and added to 1.1 equiv of succinimidyl-TEG-maleimide in 1 mL Me_2NCHO (Scheme 3). The mixture was stirred at room temperature overnight. The product was precipitated by Et_2O and purified by analytical reversed-phase HPLC. The eluent peak corresponding to the product dansyl-Lys-daptomycin-TEG-maleimide (**8**) was pooled, concentrated, and lyophilized. The purified sample was characterized by analytical HPLC and MALDI-TOF MS. Calc for $C_{108}H_{149}N_{21}O_{38}S$, 2381.52 Da, found $[M+H]^+$ 2383.10 Da. Yield: 128 mg (87%).

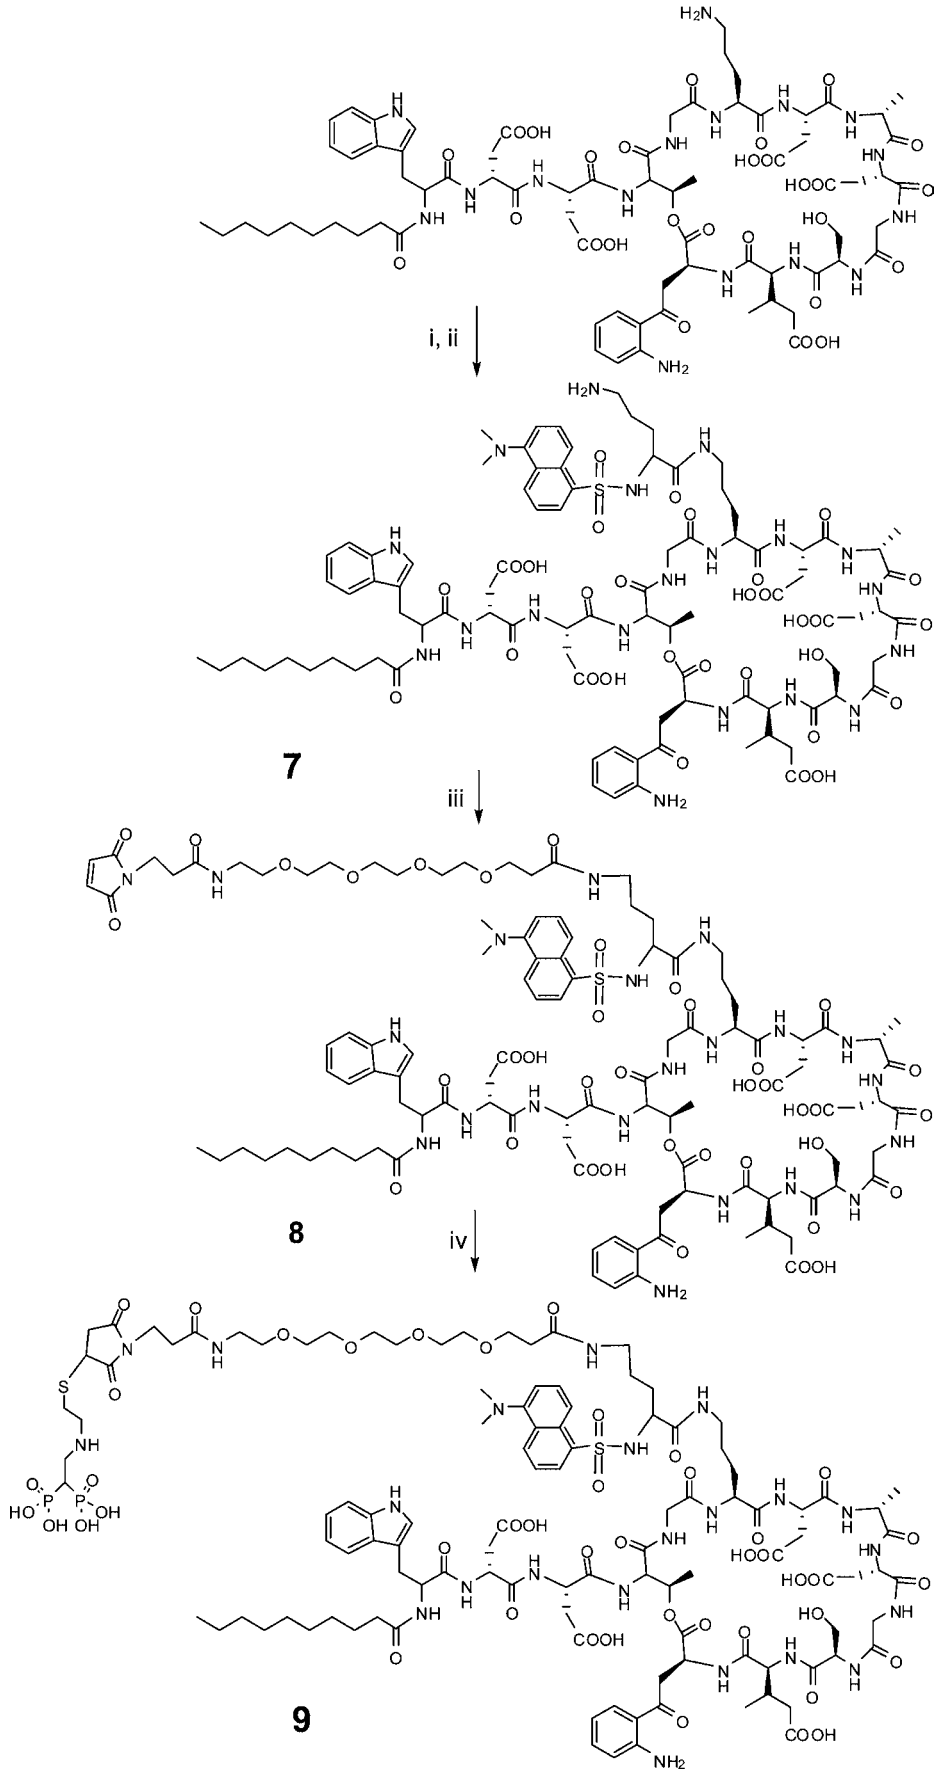
*Dansyl-Lys-daptomycin-TEG-bisphosphonic Acid (**9**).* The conjugation of 2-(2-mercaptoethylamino)-ethylidene-1,1-bisphosphonic acid (**1**) with **8** to give the dansyl-Lys-daptomycin-TEG-bisphosphonic acid derivative (**9**) (Scheme 3) was carried out according to the procedure described above for preparing **5**. The purified dansyl-Lys-daptomycin-TEG-bisphosphonic acid (**9**) was characterized by analytical HPLC (Figure 4D). MALDI-TOF MS: calc. for $C_{112}H_{162}N_{22}O_{44}P_2S_2$ 2646.68 Da, found $[M+H]^+$ 2648.02 Da.

Methods. *Oxidation of Ti6Al4V Foil Surface.* Ti6Al4V foil (0.6 mm thickness) was cut into 1 × 1 cm squares and washed twice with acetone, then once each with double-deionized water, saturated aqueous Alconox, and 0.1 M NaOH. Finally, the foils were washed with 50% concentrated HCl/50% MeOH at room temperature for 30 min with sonication every 5 min, followed by three washes with double-deionized water. The cleaned foil surfaces were then oxidized in 50% H_2O_2/50% concentrated H_2SO_4 at 4 °C for 4 h. The oxidized foils were washed four times with water, Me_2NCHO, and water, dried overnight under vacuum, and placed in the argon atmosphere chamber of an MO-20M glovebox (*29*).

*Attachment of Dansyl-bisphosphonic Acid (**3**) to Ti6Al4V Foils.* 2-(9-Dansyl-6,9-diaza-5-oxo-3-thia-nonanyl)-ethylidene-1,1-bisphosphonic acid (**3**) (5 mg/mL) was incubated with oxidized Ti6Al4V foils in water (pH was adjusted to 7.0 using 1 M NaOH) at room temperature for 16 h (Scheme 1) with intermittent shaking.

Stability of Dansyl-bisphosphonic Acid (3) on the Surface of Titanium Foil. After washing with water and PBS, the dansyl-bisphosphonate foils were immersed in PBS, pH 7.4, and kept at 37 °C to investigate the stability of the linkage between titanium and dansyl. The dansyl-bisphosphonate residues released into the solution were measured by total fluorescence (λ_{ex} 337 nm and λ_{em} 520 nm) (*30*) at several time points over one month.

After one month of incubation at pH 7.4, 1 M NaOH was added to the PBS buffer to adjust the pH to 12, and the foils were incubated with the basic solution for 4 h at room temperature, with intermittent sonication, to release all the remaining dansyl moieties from the surface of the foils, as described (*30*). Dansyl moieties in solution were measured by fluorescence as before. In each batch of foils, the total fluorescence stripped from the foil was treated as 100%.



*Attachment of Daptomycin-TEG-bisphosphonic Acid (**5**) to Ti6Al4V Foils.* Daptomycin-TEG-bisphosphonic acid (**5**) (2 mg, 0.88 μmol) was dissolved in 1 mL water, and the pH was adjusted to 7.0 with 1 M NaOH. Six foils (1 × 1 × 0.06 cm^3) were immersed in the solution and kept at room temperature for 16 h with intermittent gentle shaking, avoiding foil-to-foil contact. The solution was removed, and the foils were washed with water (3 × 1.5 mL), Me_2NCHO (3 × 1.5 mL), and water (3 × 2 mL). The foils were dried under vacuum at room temperature.

Fluorescent Quantitation of Daptomycin Derivatives on the Titanium Foil Surface. Dansyl-Lys-daptomycin-TEG-bisphosphonic acid (**9**) (5 mg/mL) was incubated with 20 Ti6Al4V foils at pH 7 at room temperature for 16 h, followed by washing with water, Me_2NCHO, and water. The modified foils were then incubated with 0.01 M NaOH at room temperature for 4 h. The fluorescence was recorded with λ_{ex} 337 nm and λ_{em} 520 nm (*30*), quantitated against a standard curve of known dansyl concentrations, as before (*16*).

Minimum Inhibitory Concentrations. Minimum inhibitory concentrations (MIC) were determined by broth microdilution according to NCCLS guidelines (*31*) except that the Müller-Hinton Broth was supplemented to 50 mg/L Ca^{2+} and all assays were performed at 37 °C with *S. aureus* ATCC 29213.

Antibacterial Activity Assay on Daptomycin-TEG-bisphosphonate-Ti6Al4V Foils. Each dried foil was adhered in place in an individual well of a 24-well plate by low-melting-point wax with the upper surface uncovered (Figure 1). The upper

[a] (i) Dansyl-Lys (Boc)-NHS ester, Me_2NCHO, r.t, overnight. (ii) CF_3CO_2H/water/iPr_3SiH (95:2.5:2.5), rt, 1 h. (iii) succinimidyl-TEG-maleimide, Me_2NCHO, rt, overnight. (iv) 2-(2-Mercaptoethylamino)ethylidene-1,1-bisphosphonic acid, 50% Me_2NCHO/50% water.

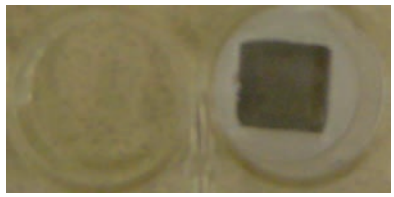

Figure 1. Each dried Ti6Al4V foil was adhered in place in an individual well of a 24-well plate by low-melting-point wax for antibiotic activity evaluation with the upper surface uncovered. Left, empty well; right, one piece of Ti6Al4V foil adhered in the well using low-melting-point wax.

surfaces of the foils were sterilized with 70% iPrOH for 30 min at room temperature, followed by rinsing with sterile broth three times. Then, 200 μL aliquots of Müller-Hinton broth (complemented with Ca^{2+}) containing 3×10^5 cfu were transferred into each well containing a foil and incubated at 37 °C for 16 h (same time point with that used in MIC test). The broth in the wells was diluted with 800 μL of fresh Müller-Hinton broth, and the optical density at 600 nm was recorded. The experiment was carried out with nonimmobilized daptomycin-modified foils and immobilized blank foils as controls.

Statistical Analysis. Data were expressed as mean ± SE. The significance of differences between means of experimental groups was determined by using Student's *t* test.

RESULTS

Design and Synthesis of Dansyl-bisphosphonic Acid (3) as a Fluorescent Model for Ti6Al4V Bonding. The reaction of dansyl chloride with a large excess of H_2NEtNH_2 provided dansylamidoethylamine as the main product, and the residual H_2NEtNH_2 could be collected for further use (Scheme 1). The reaction of dansylamidoethylamine and bromoacetic acid gave 1-bromoacetyl-2-dansyl-ethylenediamine (**2**). The dansyl-bisphosphonic acid derivative (**3**) was prepared by selective reaction of 1-bromoacetyl-2-dansyl-ethylenediamine (**2**) with 2-(2-mercaptoethylamino)ethylidene-1,1-bisphosphonic acid (**1**) under basic conditions (Scheme 1).

Attachment of Dansyl-bisphosphonic Acid (3) to Ti6Al4V Foils. 2-(9-Dansyl-6,9-diaza-5-oxo-3-thianonanyl)-ethylidene-1,1-bisphosphonic acid (**3**) (5 mg/mL) was incubated with oxidized Ti6Al4V foils in water (pH was adjusted to 7.0 using 1 M NaOH) at room temperature for 16 h (Scheme 1) with intermittent shaking. The time course of attachment is shown in Figure 2. Coupling was largely complete by 1 h, and leveled off by 10 h.

Stability of Dansyl-bisphosphonic Acid (3) on the Surface of Titanium Foil. The dansyl-bisphosphonate residues released into the pH 7.4 PBS solution at 37 °C were measured by total fluorescence (λ_{ex} 337 nm and λ_{em} 520 nm) (*30*) at several time points over one month (Figure 3). In each batch of foils, the total fluorescence stripped from the foil was treated as 100%. The data showed that about 25% percent of the dye was released in the first 10 h of incubation in pH 7.4 phosphate saline buffer. No more dansyl was released to the buffer in one month. It seems likely that the rapidly eluted dansyl moieties were only adsorbed, not covalently bonded. The results imply that the covalently attached dansyl-bisphosphonic acid was stable on the surface of titanium foils in PBS at 37 °C.

Design and Synthesis of of Bisphosphonic Acid Derivative of Daptomycin (5) for Bonding to Ti6Al4V Foils. Daptomycin is a cyclic lipopeptide antibiotic with one primary amino group, four carboxylic acid groups, and one sensitive indole ring (*21*). A study of N-acylated ornithine analogues of daptomycin indicated that acylation of the ε-amino group on ornithine did not significantly influence the antibacterial activity (*32, 33*). Only the ε-amino group on ornithine reacted with NHS active esters. Electron density on the aromatic amine of the daptomycin anthraniloyl residue is more delocalized than usual by the neighboring carbonyl function. The resulting low nucleophilicity greatly disfavors reaction with NHS esters.

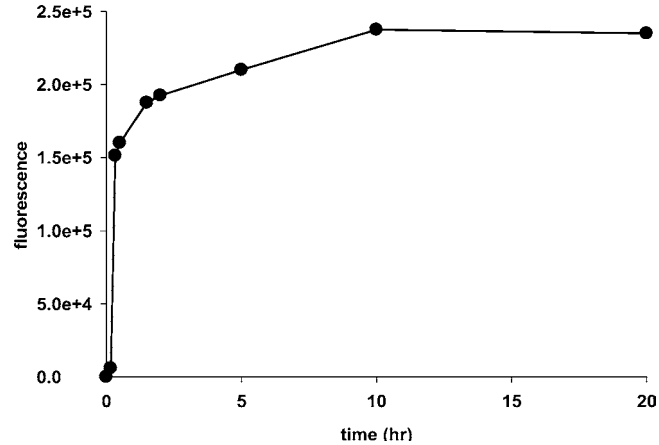

Figure 2. Time course of attachment of dansyl bisphosphonic acid bound to the surface of Ti6Al4V foils at different time points. The passivated foils were incubated with dansyl bisphosphonic acid (pH 7.4, 2.5 mg/mL) at room temperature. The foils were removed from the solution at a series of time points and then washed with Me_2NCHO and water, followed by incubation with 1 mL 0.01 M NaOH at room temperature for 3 h. The fluorescence in the NaOH solution was recorded with λ_{ex} 337 nm and λ_{em} 520 nm (*30*).

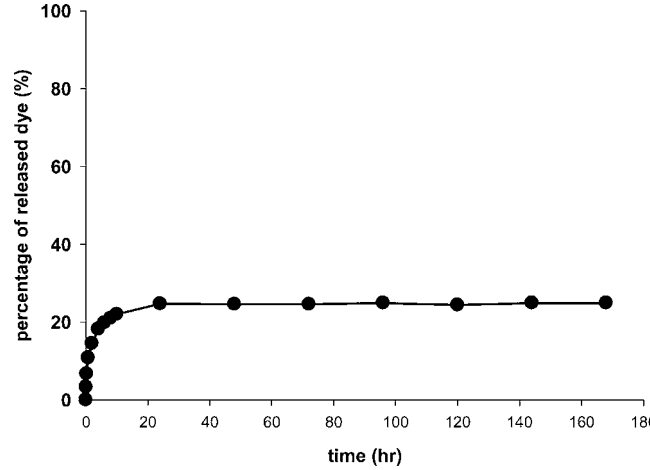

Figure 3. Release kinetics of dansyl bisphosphonic acid on the surface of Ti6Al4V foil. The foil was incubated in 1 mL phosphate buffer (pH 7.4) at 37 °C. Dansyl fluorescence was recorded with λ_{ex} 337 nm and λ_{em} 520 nm. The data were expressed as release % = $(F_{sample} - F_0)/(F_{final} - F_0)$. F_{sample}, the fluorescence at a certain time point; F_0, background of phosphate buffer; F_{final}, fluorescence of the loading dansyl bisphosphonic acid.

In order to increase the flexibility of attached daptomycin on the surface of titanium foil, bifunctional TEG with maleimide and NHS groups was selected to conjugate with daptomycin to form daptomycin-TEG-maleimide (**4**) overnight in Me_2NCHO, after which the maleimide specifically reacted with sulfhydryl group of 2-(2-mercaptoethylamino)ethylidene-1,1-bisphosphonic acid daptomycin-TEG-maleimide (**1**) at pH 7.0 with a yield of 93% (Scheme 2).

Dansyl-Lys-daptomycin-TEG-bisphosphonic Acid (9). The antimicrobial activity of daptomycin prompted us to prepare dansyl-daptomycin bisphosphonates to enable fluorescent monitoring of foil bonding. In order to introduce the dansyl group, the ε-amine of lysine was coupled with dansyl, while the

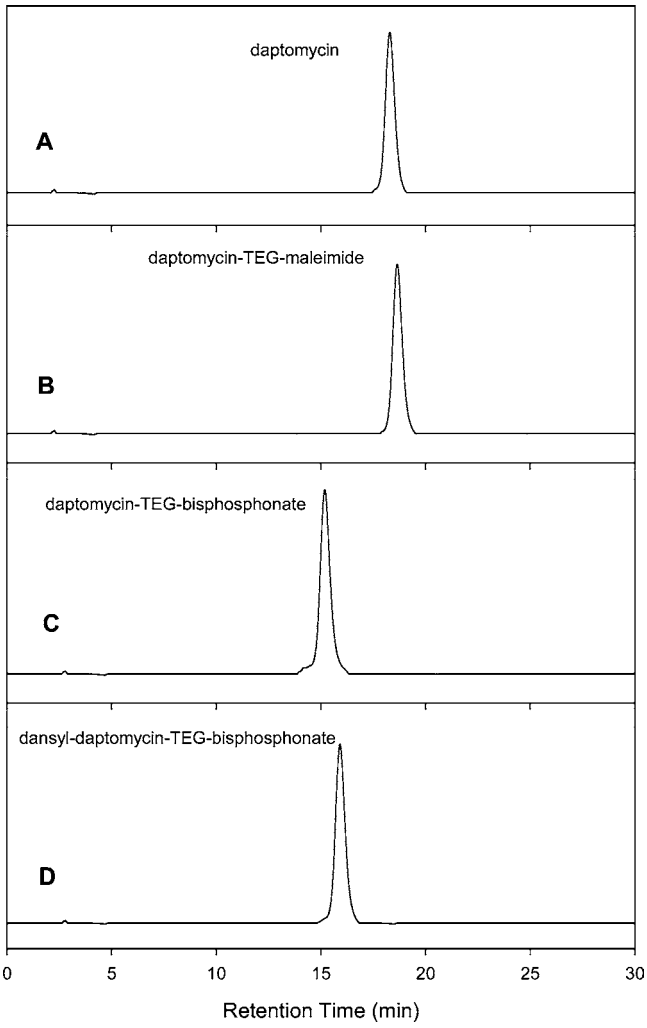

Figure 4. Analytical HPLC of daptomycin (A), daptomycin-TEG-maleimide (B), daptomycin-TEG-bisphosphonate (C), and dansyl-daptomycin-TEG-bisphosphonate (D). The analysis was performed with a Waters 600E system, using Alltech C18 5 μ, 250 $\times$ 4.6 mm column coupled to a Waters 486 detector at 254 nm. Sample was eluted with a linear gradient of 20−70% CH_3CN in water containing 0.1% CF_3CO_2H in 30 min with a flow rate of 1 mL/min. The retention times for the peaks in A, B, C, and D were 18.3, 18.4, 15.5, and 15.9 min, respectively.

ε-amine side chain of lysine was protected with Boc (Scheme 3). To prepare dansyl-Lys-daptomycin (**7**), the α-dansyl-Lys-εBoc (**6**) was converted to a succinimidyl active ester and used to acylate the ornithine residue of daptomycin (Scheme 3). The deprotected lysine ε-amino side chain in **7** was reacted with succinimidyl-TEG-maleimide to give dansyl-Lys-daptomycin-TEG-maleimide (**8**). The conjugation of 2-(2-mercaptoethylamino)ethylidene-1,1-bisphosphonic acid (**1**) with **8** to give the dansyl-Lys-daptomycin-TEG-bisphosphonic acid derivative (**9**) (Scheme 3) was carried out according to the procedure described above for preparing **5**. The purified dansyl-Lys-daptomycin-TEG-bisphosphonic acid (**9**) was characterized by analytical HPLC (Figure 4D).

Fluorescent Quantitation of Daptomycin Derivatives on the Titanium Foil Surface. After confirming the antibacterial activity of attached daptomycin on the surface of titanium foils, dansyl-Lys-daptomycin-TEG-bisphosphonic acid (**9**) was synthesized and was used as a model to investigate how much daptomycin was coupled to the solid surface. The daptomycin loading fell in the range 0.06−0.18 nmol/cm^2, below the theoretical maximum of adducts that could be coupled to the surface of titanium foil, 0.22 nmol/cm^2 (*34*).

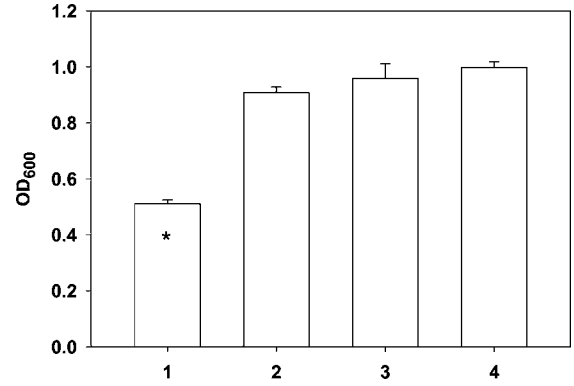

Figure 5. Histogram of antibacterial activity of daptomycin bisphosphonic acid covalently bound to the surface of Ti6Al4V foils. 1, daptomycin modified foils adhered by wax, covered by 200 μL of broth containing 3 $\times$ 10^5 cfu *S. aureus*; 2, nonadhered daptomycin modified foils floating in 200 μL of broth containing 3 $\times$ 10^5 cfu *S. aureus*; 3, adhered blank foils incubated with 200 μL of broth containing 3 $\times$ 10^5 cfu *S. aureus*; 4, 200 μL of broth containing 3 $\times$ 10^5 cfu *S. aureus.* Symbol * indicates statistically significant differences ($p < 0.05$) from the other groups. The *y*-axis is the optical density of the bacteria-containing broth at 600 nm.

Antibacterial Activity of Surface-Tethered Daptomycin. The MIC of DAP-TEG-bisphosphonic acid (**5**) was 8.0 μg/mL with *S. aureus* ATCC 29213 as the model bacterium in calcium-complemented Müller-Hinton broth, compared with an MIC of 0.8 μg/mL for daptomycin (Supporting Information). The mass of daptomycin attached to a single 1.0 cm^2 Ti6Al4V foil at the maximum observed yield of 0.18 nmol/cm^2 is 0.83 μg. If that amount of **5** was released into the 200 μL of broth applied to each foil, the concentration of **5** in solution would only be 4.2 μg/mL, lower than 8.0 μg/mL (MIC of daptomycin-TEG-bisphosphonic acid).

However, the covalently bound daptomycin on the solid-phase foil surfaces killed 53 $\pm$ 5% of the high challenge dose of 3 $\times$ 10^5 cfu in the 200 μL of broth applied to each foil (Figure 5). The data showed that there was a significant difference (p = 0.000 01) between the bacterial growth inhibition activities of the DAP-TEG-bisphosphonate surface and the nonmodified control surfaces. No significant antibacterial activity difference (p = 0.20, 0.49, 0.20) was observed among the nonmodified or nonadhered control surfaces.

DISCUSSION

The gold standard for implants is titanium because of its biocompatibility and osseointegrating ability (*35*). Much effort has been paid to the surface modification of titanium implants to enhance osseointegration, and biofuctionalization of the titanium implant surface by attaching therapeutic proteins, peptides, or antibiotics has attracted the attention of scientists from metallurgy and medicinal chemistry (*36*). We have linked vancomycin to titanium powder and pins by aminopropylation of the surface with aminopropyltriethoxysilane and attaching the antibiotics to the functionalized surface via a pair of di(ethylene glycol) spacers to extend the drug away from the metal surface. The attached antibiotics significantly inhibited the growth of bacteria on the metal surface (*15, 16*). The extensive chemical manipulations and the incompatibility of metallurgy and organic chemistry prompted us to investigate a more convenient and compatible method. In fact, functionalization of titanium alloy surfaces using a "dip and rinse" protocol that combines the goals of efficacy and convenience is being sought by those working in this area (*27*).

Bisphosphonate binds strongly to metal surfaces and bone tissue (*23, 24*), so it became our first choice in the design and

preparation of a daptomycin conjugate to be attached to Ti6Al4V alloy through the "dip and rinse" process. The preparation reported here of dansyl-TEG-bisphosphonic acid and its stable attachment to the surface of oxidized Ti6Al4V demonstrates the practicality of "dip and rinse" modification by daptomycin−bisphosphonate conjugates. The bioactivity and stability results indicated that bisphosphonate derivatives of daptomycin could effectively attach to Ti6Al4V foils and provide significant antibacterial activity. It is inevitable that some daptomycin bisphosphonates will dissociate from the metal surfaces over time. However, the dissociated daptomycin bisphosphonates are likely to be trapped by the surrounding bone tissue, thereby reducing systemic distribution, because of the bone-targeting activity of bisphosphonates after systemic administration of drug−bisphosphonate conjugates (*25*). By changing the number of phosphonates linked with the drugs, the stability might be adjustable in order to meet different requirements.

The selection of antibiotics to be covalently attached to the surface of implants is key to surface antibacterial activity. Current strategies to prevent implant-related infections include antibiotic-eluting bioceramics, drug-impregnated bone cements, and natural and synthetic polymers loaded with antimicrobials (*37*). Erythromycin, tobramycin, gentamicin, cephalexin, norfloxacin, sulbactam-cefoperazone, sulbactam-ampicillin, and antimicrobial peptides have been used in the delivery system. These materials deliver active drugs only from the time of implantation, lasting at most only through the immediate postoperative period, and deliver a relatively low solution concentration.

Covalent attachment of antibiotics to the surface of implants is the new direction in the development of self-protecting bactericidal implants. Amipicillin (*38*), vancomycin (*15*), and antimicrobial peptides (*11*) have been reported to be attached to the surface of implant materials such as polytetrafluoroethylene and titanium alloys. There are several factors that should be taken into consideration to select the antibiotics to be attached to the surface of an implant. The antimicrobial should ideally act at the bacterial cell surface, such as β-lactams, vancomycin, quaternary ammonium, or antimicrobial peptides. If the site of action is inside the bacterium, permanent bonding would significantly reduce bioactivity. We observed that phenomenon previously when we explored the attachment of minocycline to the surface of Ti6Al4V foils through an acid-labile linkage that could be broken in response to the lower pH caused by a local bacterial infection (*39*). It will also be valuable to investigate the effect of longer or shorter spacers.

The second important characteristic is that the interaction of the antimicrobial with the bacteria should be noncovalent, so that the antibiotic remains unchanged and active after each bacterial challenge. Even though ampicillin and other β-lactam antibiotics were effective against Gram-positive and some Gram-negative bacteria, the β-lactam interaction with bacterial transpeptidases opens the lactam ring to covalently modify the enzyme, so that the antibiotics can only be used once. Daptomycin, however, acts in the bacterial membrane, leading to a change in cell polarity and permeability that kills the bacteria (*22*). The interaction of daptomycin with bacteria depends only on physical binding. As a result, daptomycin could retain its structural integrity and bactericidal activity against successive bacterial challenges, as we observed with vancomycin bound to titanium alloy surfaces (*15, 17, 18*).

The daptomycin bonded to the Ti6Al4V surfaces killed 53 $\pm$ 5% of the high challenge dose of bacteria suspended in a drop of broth applied to each foil. Under the conditions of our experiments, the surface was exposed to 1.5×10^6 cfu/mL, many more than in clinical practice, where most circulating bacteria will be suppressed by systemic antibiotics, and only a limited number of opportunistic bacteria first attack an implant.

In conclusion, bisphosphonic acid derivatives of daptomycin were synthesized. The conjugates were stably attached to Ti6Al4V surfaces and provided antibacterial activity against high doses of *S. aureus*. The antibiotics can stay bonded to the alloy for an extended period to prevent infections on the surfaces of implants. The integration of bisphosphonates with antibiotics opens a new way for covalent protection of implants.

ACKNOWLEDGMENT

We thank Dr. Richard Wassell and Mr. Zhixian Lu of the Thomas Jefferson University Proteomics Center for assistance in mass spectrometry, and Dr. Ivan S. Alferiev of Division of Cardiology, the Children's Hospital of Philadelphia, for his generous gift of 2-(2-mercaptoethylamino) ethylidene-1,1-bisphosphonic acid. This work was supported by a grant from Cubist Pharmaceuticals to E.W. and a grant from the National Institutes of Health (AR051303) to Dr. Irving Shapiro. Conflicts of interest: E.W. is a cofounder of SecureImplant LLC, which might ultimately benefit from the results of this investigation, but did not support the work.

Minimum inhibitory concentrations. Minimum inhibitory concentrations (MIC) were determined with *Staphylococcus aureus* strain 25923 (ATCC, Germantown, MD), by broth microdilution according to NCCLS guidelines (*1*) for aerobic Gram-positive organisms. *S. aureus* were maintained in Müller-Hinton broth supplemented with 50 mg/L calcium chloride, according to the Cubist Pharmaceuticals protocol, at a final *S. aureus* titer of 5×10^5 cfu/ml, using daptomycin (**1**) as the positive control. All assays were performed in triplicate at 37˚C.

Table 1. MIC of daptomycin and its derivatives

Compound Name	MIC, μg/ml
Daptomycin **1**	0.8
DAP-TEG-bisphosphonic acid, **5**	8.0

An ultrasensitive fluorescence immunoassay method for quantitative detection of single molecules is developed on the basis of counting single magnetic nanobeads (MNBs) with combined amplification of DNA and dye/DNA conjugate. Highly amplified fluorescence signal and low background signal are achieved by using mutilabel bioconjugates made by linking multiple dye/DNA conjugates to streptavidin-coated magnetic nanobeads (SA-MNBs) and magnetic separation. In this method, human IgG (Ag) is captured on the silanized glass substrate surface, followed by immunoreaction with biotinylated mouse antihuman antibody (BT-Ab). Then, SA-MNBs are attached to the BT-Ab through the biotin/streptavidin interaction at a ratio of 1:1. Subsequently, a 30 base pair double-stranded oligonucleotide terminated with biotin (BT-dsDNA) is conjugated to the SA-MNBs. The resultant Ag-BT-Ab-SA-MNBs/BT-dsDNA/SYBR Green I is achieved after a fluorescent DNA probe, SYBR Green I, is added to the substrate and bound to the oligonucleotide at high ratios. Finally, epifluorescence microscopy coupled with a high-sensitivity electron multiplying charge-coupled device is employed for human IgG fluorescence imaging and detection. The number of fluorescent spots corresponding to single protein molecules on the images is counted. It is found that the number of fluorescent spots resulting from the SA-MNBs/BT-dsDNA/SYBR Green I immuotargeted on the glass slides is correlated with the concentration of human IgG target antigen in the range 3.0−50 fM.

INTRODUCTION

Recently, single-molecule detection (SMD), based on the analysis of individual molecules, has attracted a great deal of attention in the area of analytical chemistry and life science (*1, 2*). In analytical chemistry, single-molecule detection (SMD) is the ultimate limit of detection (*3*). Fluorescence detection techniques combined with capillary or microchannels (*4*−*8*), confocal fluorescence microscopy (*9*−*16*), total internal reflection fluorescence microscopy (TIRFM) (*17*−*23*), and epifluorescence microscopy (EFM) (*24, 25*) are the most popular techniques in SMD. Of these SMD studies with fluorescence quantitative detection, all research performed the counting of single fluorescence molecules for quantitative analysis at the single-molecule level. The SMD quantitative research technique relies on directly counting one by one the number of target molecules rather than measuring signal intensity to quantitative analysis of the concentration, which is suitable for ultralow concentrations of target biological macromolecule identification and detection. As for SMD-based quantitative research, on the assumption of target biological macromolecules being identified, the most important advantage of the quantitative technique that relies on counting single molecules is that the detected signal intensity is not important, which guarantees the reliability of the quantitative determination (*3*). To ensure that the target biological macromolecule can be identified, a better signal-to-noise (*S*/*N*) ratio is needed, which can improve the sensitivity.

Fluorescent antibodies have been widely used in single-molecule fluorescence immunodetection. The fluorescent labels for the labeling of antibodies, which provide exquisite sensitivity (*26*) and guarantee the reliability of quantitative determination, should be bright and stable enough in single-molecule fluorescence detection. Usually, a fluorescent dye molecule is coupled to the target molecules to generate a detectable signal. However, two major difficulties limit the sensitivity when these fluorophores are used. The first difficulty is the relatively low fluorescence signal intensity. Because one antibody can only be labeled with one or a few fluorophores, the fluorescence signal is too weak to be detected when the target concentration is low. The second difficulty is the poor photostability of many fluorophores. Most organic dyes suffer serious photobleaching. To improve the sensitivity of single-molecule fluorescence immunodetection by using highly fluorescent and photostable fluorescence labels, quantum dots (QDs) have been developed and explored as novel signal labels for single-molecule fluorescence immunodetection (*23, 26*−*29*). Although QDs have many unique prominent properties, there are many problems involved in using QDs as fluorescence labels, such as the stability of multifunctionalized QDs in different reaction systems, the toxity of heavy metal ions, and the blinking and physical adsorption (*27, 30*). Thus, efforts to develop novel fluorescence labels to reduce the background signal from nonspecific adsorption of labels and increase fluorescence signal intensity have gained considerable momentum in single-molecule fluorescence detection.

Along with the efficient magnetic particle amplification strategy for sensitive detection of biomolecules (*31, 32*), a magnetic particle amplification strategy could be also applied to single-molecule immunodetection. The magnetic particle acts as a carrier and a bridge when functionalized magnetic particles are used as signal labels. On one hand, the significant signal intensity could be gained from the application of amplification strategy. On the other hand, the background signals from nonspecific adsorption of labels could be reduced because of the application of magnetic particles. Recently, Jin's group (*3*)

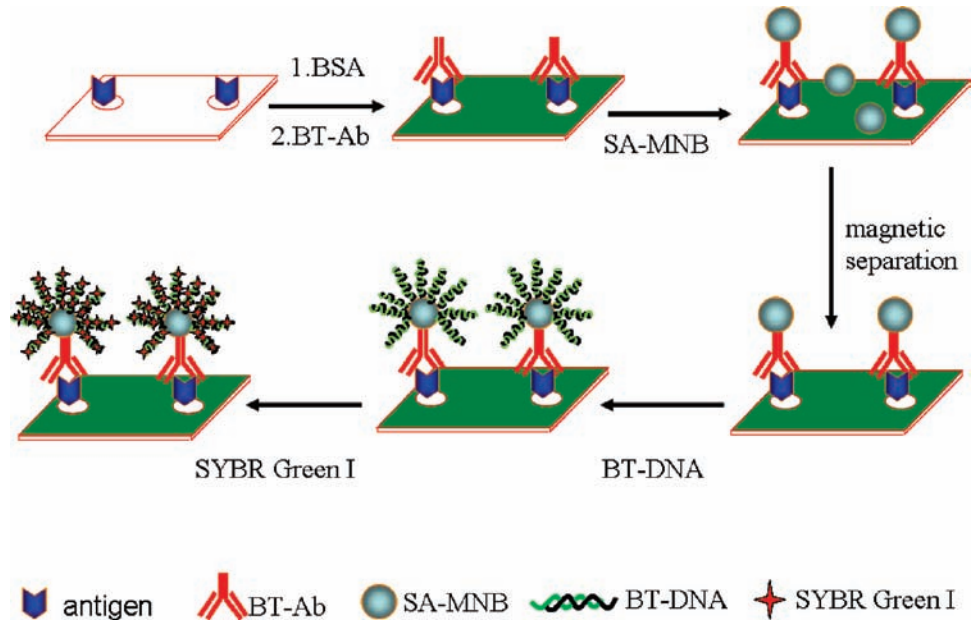

Figure 1. Schematic representation of the process of immunoassay labeling format by using the conjugate SA-MNBs/BT-dsDNA/SYBR Green I label.

developed an electrochemical immunoassay strategy for quantitative detection of single molecules based on counting the magnetic nanobeads released from a substrate with the combination of DNA amplification and enzyme amplification. If SA-MNB does not need to be dissociated, further sensitivity improvement may be obtained by directly counting the number of functionalized magnetic nanobeads attached to single antibodies for quantitative detection of single molecules in a fluorescence image.

In this work, we present an ultrasensitive fluorescence immunoassay method for quantitative detection of single molecules based on counting of single magnetic nanobeads with combined amplification of DNA and DNA/SYBR Green I conjugate. The principle of this method is shown in Figure 1. In this method, we employed a streptavidin-coated magnetic nanobead as a carrier for the conjugation of multiple fluorescent BT-dsDNA/SYBR Green I conjugates. It was attached to a biotin-modified mouse antihuman antibody through the high-specificity, high-affinity biotin−streptavidin interaction at a ratio of 1:1. Human IgG captured on the silanized glass substrate surface was detected by its immunoreaction with biotinylated mouse antihuman antibody. EFM with EMCCD was employed for human IgG fluorescence imaging and detection. In this case, only one MNB is bound to one single protein. Each fluorescent spot corresponds to one SA-MNB/BT-dsDNA/SYBR Green I immuotargeted on the glass slides. Finally, the number of fluorescent spots corresponding to single protein molecules on the images was counted. It is found that the number of fluorescent spots resulting from the SA-MNBs/BT-dsDNA/SYBR Green I immuotargeted on the glass slides could be applied to the quantitative detection of human IgG target antigen.

EXPERIMENTAL SECTION

Materials and Instrumentation. Human immunoglobulin G (IgG), monoclonal antihuman IgG-Biotin conjugate (Clone HP-6017), 3-glycidyloxypropyltrimethoxysilane, and bovine serum albumin were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Strand A, biotin-5′-TTT TTT TTT GCG GGT AAC GTC AAT ATT AAC TTT ACT CCC-3′, and strand B, 5′-GGG AGT AAA GTT AAT ATT GAC GTT ACC CGC-3′, were obtained from the Genscript Corporation (Nanjing, China). Streptavidin−MNBs (350 nm diameter, 1.343 g mL^{-1}, aqueous suspension containing 0.1% bovine serum albumin (BSA), 0.05% Tween-20, and 10 μM EDTA at a concentration of 3.324×10^{11} beads mL^{-1}) from Bangs Laboratories Inc. (Fishers, IN), Tris (>99.8%) from Amresco Inc. (Solon, OH), and Tween-20 from Sigma (St. Louis, MO) were used in the work. Other chemicals (analytical grade) were obtained from standard reagent suppliers. Microscope cover glasses (22×22 mm^2) were purchased from Cole-Parmer (Illinois, USA).

The physiological buffer saline (PBS) consisted of 0.15 M NaCl, 7.6 mM NaH_2PO_4, and 2.4 mM Na_2HPO_4 (pH 7.4). PBS−T buffer consisted of 0.15 M NaCl, 7.6 mM Na_2HPO_4, 2.4 mM NaH_2PO_4, and 0.05% Tween-20 (pH 7.4). TE buffer consisted of 10 mM Tris−HCl and 1.0 mM Na_2EDTA (pH 8.0). TTL buffer consisted of 0.10 M Tris−HCl (pH 8.0), 0.1% Tween-20, and 1.0 M LiCl. TT buffer consisted of 0.25 M Tris−HCl (pH 8.0) and 0.1% Tween-20. TTE buffer consisted of 0.25 M Tris−HCl (pH 8.0), 0.1% Tween-20, and 20 mM Na_2EDTA (pH 8.0). A phosphate buffer (pH 7.0) containing 1% BSA was used as a buffer for blocking.

We used an inverted microscope (model IX81, Olympus, Tokyo, Japan) equipped with a high-numerical-aperture 40× objective lens (PlanApo, Olympus, Tokyo, Japan), a mercury lamp (OSRAM, HBO, 103w/2, Germany), a mirror unit consisting of a 470−490 nm excitation filter (BP470−490), a 505 nm dichromatic mirror (DM 505), a 510−550 nm emission filter (IF510−550), and a 16 bit thermoelectrically cooled EMCCD (Cascade 512B, Tucson, AZ, USA). The EMCCD was used for collecting the fluorescent images. Imaging acquisition and data analysis were performed using the *MetaMorph* software (Universal Imaging, Downingtown, PA, USA).

DNA Hybridization. A 30 base pair biotinylated double-stranded oligonucleotide (BT-dsDNA) was obtained by hybridizing two complementary single-stranded oligonucleotides. The two oligonucleotides were mixed in 2 × SSC buffer, denatured at 95 °C for 5 min (*33*), annealed at 72 °C for 10 min, and naturally cooled down to 48 °C for 6 h.

Substrate Preparation and Antigen Coating. The epoxy-functionalized glass surfaces were prepared according to the modification described in the literature (*27*). The freshly prepared substrate surface was coated with 100 μL human IgG

solutions of various concentrations (50, 30, 10, 8.0, 5.0, 3.0 fM). The substrate was immediately placed in a sealed Petri dish at 37 °C for 5 h. After that, the substrate was washed three times with PBS-T washing buffer to remove unbound human IgG and impurities.

Blocking. We used a phosphate buffer containing 1% BSA as a blocking buffer. To the substrate of antigen coating was added 100 μL of blocking, and then, the substrate was incubated for 3 h. After that, the substrate was washed three times with PBS-T washing buffer.

Immunoreaction. Antihuman IgG-Biotin solution was 40-fold diluted with a phosphate buffer (pH 7.4) before being used, and 100 μL of the diluted solution of various concentrations (2, 1.2, 0.4, 0.32, 0.2, 0.12 pM) was then added to the substrate. The biotinylated monoclonal antihuman IgG (BT-Ab) molecule was bound to the human IgG through the immunoreaction. After that, the substrate was deposited hermetically for 2 h at 37 °C. Finally, nonspecifically absorbed antibodies were washed by PBS-T washing buffer.

Binding of SA-MNBs to BT-Ab. Five microliters of streptavidin-MNB suspension (3.324×10^{11} beads/mL) was washed five times with 400 μL of TTL buffer to remove surfactants. Then, 50 μL of TTL buffer was added. Subsequently, streptavidin−MNB was conjugated to the biotinylated monoclonal antihuman IgG molecules by adding 16 μL of streptavidin−MNB suspension (0.52×10^9 beads) and incubating for 2 h at 37 °C. After the incubation, the redundant MNB were separated magnetically from the substrate using a neodymium−boron (Nd−B) magnet that produced an inhomogeneous magnetic field on the top of the sample cell for 5 min. Then, the substrate of the cell was gently rinsed eight times with 200 μL of PBS-T by drawing these solutions out along the wall of the cell. Finally, nonspecifically absorbed SA-MNBs were removed with magnetic separation.

Modification of SA-MNBs with BT-DNA. 100 μL of 0.14 μM BT-DNA solution was added to the substrate, and then the substrate was incubated hermetically for 2 h at 37 °C. Double-stranded oligonucleotides terminated with biotin (BT-dsDNA) were conjugated to the streptavidin−MNBs. Finally, the unreacted biotin−dsDNA was washed away with 400 μL PBS-T washing buffer. Then, the substrate was washed twice with 400 μL of TT buffer and twice with 400 μL of TTE buffer.

SYBR Green I Adding and Fluorescence Image Detection. 100 μL 2.0 μM of SYBR Green I was added to the substrate and incubated for 10 min. SYBR Green I was bound to the oligonucleotide at high ratios by the specific binding interaction with the oligonucleotide. The resultant Ag-BT-Ab-SA-MNBs/BT-dsDNA/SYBR Green I was formed. All images were taken using an Olympus IX81 microscope (40× objective) equipped with a 16 bit thermoelectrically cooled EMCCD. The fluorescence images were obtained by the excitation light within the wavelength 470−490 nm of the mercury lamp and exposure time of 100 ms. Thirty images on the coverslip substrate were acquired one by one by moving the coverslip. Finally, the bright spots corresponding to single protein molecules on all the images were counted.

RESULTS AND DISCUSSION

Binding one MNB to One IgG onto the Substrate. Human IgG was captured on the epoxy-functionalized glass surfaces as the substrate by the covalent cross-linking reaction. The basic assumption in this method is that one protein brings one MNB onto the substrate. This assumption can be satisfied when the distance between two adjacent proteins captured on the substrate is larger than that between two adjacent MNBs. Thus, the concentration of protein should be low enough. It can be roughly calculated that 0.52×10^9 MNBs with a diameter of 350 nm can completely occupy the substrate within an area of 50 mm^2. This means that the amount of protein should be lower than 86 fM. In our experiments, 100 μL of human IgG solutions with concentrations lower than 50 fM was used. Thus, if all proteins are captured on the substrate, the average distance between two proteins is longer than the diameter of the MNB. Although there are many streptavidin binding sites on each MNB, it is not possible that one MNB is bound to more than two human IgG molecules because the space between two adjacent human IgG molecules is big enough. In order to prove this assumption, we measured the average distance between two adjacent proteins using EFM that can take a single-molecule image. To do so, the antigen captured on the substrate was labeled with QDs using biotin−antibody and SA-QDs. The fluorescence image for 50 fM target protein is shown in Figure 2. In the image, each bright spot corresponds to a target protein. It is obvious that the interspot distance is greater than 4 μm, which is much bigger than the diameter between two adjacent MNBs. Thus, we can conclude that one target protein should bring one MNB onto the substrate when the concentration of target protein is lower than 50 fM. This conclusion was demonstrated by a control experiment, in which the target protein solution was replaced by a buffer. In this case, only 10−11 bright spots were observed in 25 images, i.e., < 0.5 spot appeared in an image on average, which was in accordance with the result mentioned in Jin's literature (*3*).

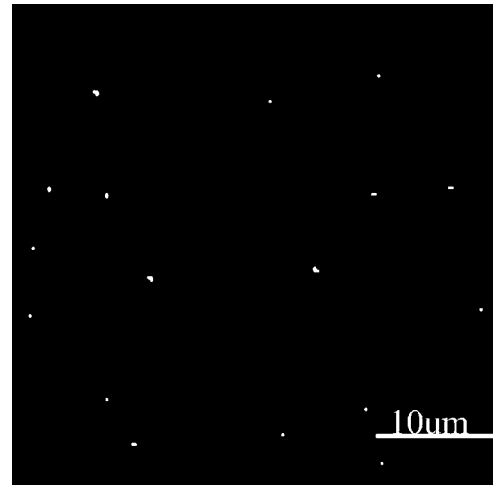

Figure 2. EFM fluorescence image of single QD-labeled human IgG on the substrate using 50 fM human IgG.

Reducing the Background Signal with Magnetic Separation. In this experiment, it has been roughly calculated that 0.52×10^9 MNBs with a diameter of 350 nm could completely occupy the substrate within an area of 50 mm^2. 100 μL of human IgG solutions with concentrations lower than 50 fM was used. This means that the amount of protein is lower than the number of MNB. Through the irreversible interaction between streptavidin and biotin, the 350-nm-diameter SA-MNB was conjugated to BT-Ab. Along with reducing the amount of protein, the MNB was far more than the antigen. The BT-dsDNA/SYBR Green I conjugate that was subsequently added to the substrate was easily bound to the redundant MNB on the substrate, leading to the background effect. To address this problem, we employed magnetic separation to remove the unbound MNB on the substrate. With the same experimental conditions, the fluorescence intensity images of the substrate of negative experiments for 50 fM target proteins without and with magnetic separation are shown in Figure 3, which indicated that the redundant MNB could be removed from the substrate with magnetic separation.

Multilabel Amplification. The high available surface-to-volume ratio of the streptavidin magnetic bead provides more

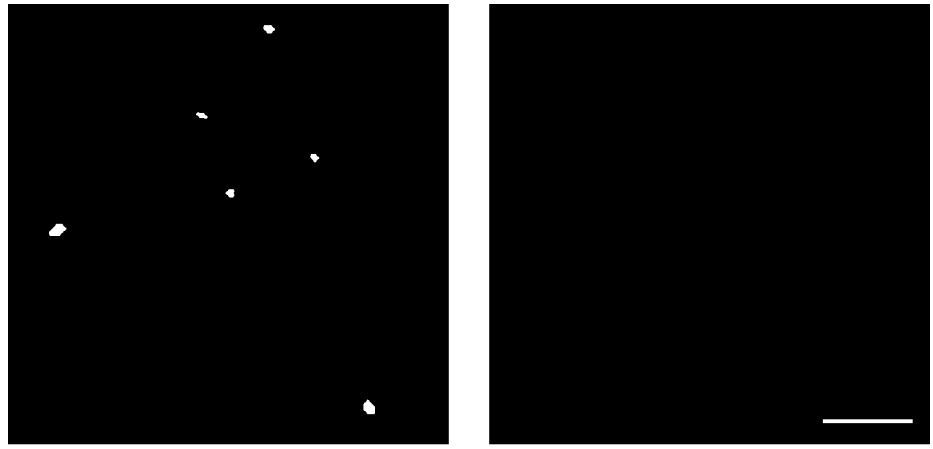

Figure 3. Fluorescent intensity subframe image of negative experiment for 50 fM target proteins in solution. Conditions: (A) without magnetic separation, (B) with magnetic separation. Scale bar, 30 pixel.

binding sites for analysis. We attached multiple BT-DNA/SYBR Green I conjugates to the streptavidin magnetic bead surfaces to increase fluorescence intensity and to improve the sensitivity. The biotinylated double-stranded oligonucleotide (BT-dsDNA) was obtained by hybridizing two complementary single-stranded oligonucleotides. The BT-dsDNA has a sequence with 9 thymine nucleotides at the biotin end acting as a spacer to reduce the steric hindrance between BT-dsDNA and the surface-confined streptavidin of MNB interaction. Through the irreversible interaction between streptavidin and biotin ($K_a = 10^{15}/M^{-1}$) with rapid binding kinetics and strong affinity, biotin−dsDNA combines with the 350 nm diameter streptavidin−MNB and produces the resultant Ag-BT-Ab-SA-MNB/BT-dsDNA. In this method, the primary amplification factor of the final detection fluorescence intensity is correlated with the number of BT-dsDNA on one MNB. The average number biotin binding sites on the surface (*m*) of one streptavidin−MNB was calculated using the equation reported in the manufacture's instructions of MagPrep streptavidin beads (Bangs Laboratories Inc., Fishers, IN). With the binding capacity (*g*) of the streptavidin-coated magnetic bead, the molecular weight (*M*) of biotin−FITC and the number (*C*) of magnetic beads per milligram, *m* could be estimated to be 2.25×10^4. The average biotin binding sites on the surface of one streptavidin−MNB is ∼30 000 based on the data provided in the manufacturer's instructions. In order to ensure all binding sites on the surface of one streptavidin−MNB conjugated with biotin-dsDNA, the amount of biotin-dsDNA used for reaction here is 10 times over the biotin binding sites.

The amount of BT-dsDNA per unit weight of magnetic beads was determined by measuring the concentration of DNA solution added and washed down after magnetic separation, which was determined by the absorbance at 260 nm using ultraviolet spectrophotometry. According to the difference at the two concentrations, we worked out the number of BT-dsDNA per magnetic bead to be ∼3000, which was in accordance with the data mentioned in Jin's report (*3*), implying an amplification factor of ∼3000 for DNA amplification. Although the measured value was different from that offered by the manufacturer's instructions, the large amplification factor was achieved. Magnetic beads of diameter 350 nm provided a very high number of labels on the surface and gave better sensitivities and detection limits.

Assembly of Fluorescent DNA Nanotags. In the systems reported here, DNA nanostructures serve as a template for assembling the intercalating dyes into fluorescent arrays. High densities of fluorophores are assembled in a very small region

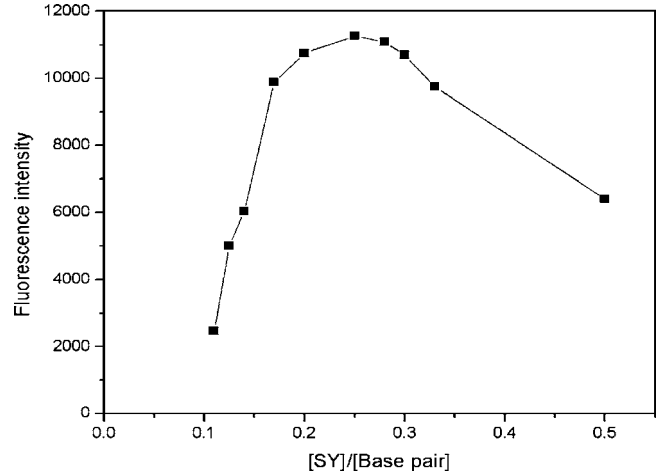

Figure 4. Dependence of maximum fluorescence intensity on ratio of intercalating SY groups per DNA base pair. Conditions: 13.9 nM dsDNA.

of base pairs in the DNA helix, yet the DNA template keeps them far enough away from each other to prevent self-quenching. A common feature of organic dyes is that they tend to aggregate in aqueous solution, which usually leads to self-quenching of fluorescence. Steric constraints impede multiple dyes from binding at the same intercalation site. As illustrated in Figure 4, the fluorescence increased monotonically when the fluorescence probe was titrated into the BT-DNA solution at increasing dye-to-base pair ratios (dbpr), the fluorescence saturated at approximately 0.25 dye/base pair. The quenching observed for SYBR Green I at ratios in excess of 0.25 is likely the result of alternative, nonintercalative binding that can occur at relatively high loading. Nevertheless, working at a ratio of 0.25 or lower yields highly fluorescent DNA-templated dye arrays.

Fluorescence Imaging Analysis. For the optimal fluorescence image, the study was optimized at a variety of imaging conditions. First, the effects of exposure time and intensifier gain were investigated, and the optimized setting values were 100 ms and 2000, respectively. In this case, the optimal fluorescence image was obtained. Second, in the experiment, the fluorescence intensity must be uniform. The intensity of the excitation light on the area illuminated by the mercury lamp through the objective was not uniform inside an area of $201 \times 201\ \mu m^2$ (512×512 pixels), as shown in Figure 5A. The light

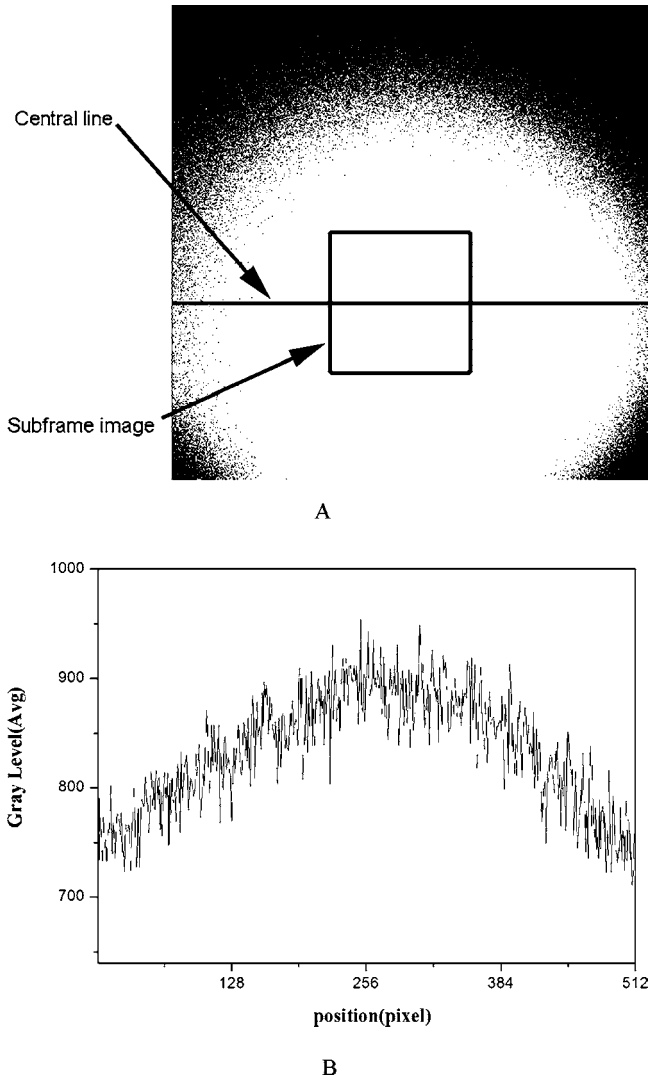

Figure 5. (A) Blank image and (B) distribution of light intensity along the central line of the bright region indicated in A in the *x* direction. Conditions: laser power of 103 W/2 mW; excitation wavelength 470−490 nm; emission wavelength of 510 nm; exposure time of 100 ms.

intensity dispersed from the center. The distribution of the fluorescence intensity corresponding to the central line in the χ direction of the light spot was given in Figure 5B. It was obvious that the light intensity dispersed from the center. In order to solve this problem, we chose a 150 × 150 pixel subregion at the center of the light spot for measuring the fluorescence intensity image. The intensity deviation inside an area of 59 × 59 μm^2 (150 × 150 pixels) at the center of the light spot was less than 5%. The threshold for image acquirement was chosen at a value of 3 times the standard deviation of the background noise for 10 blank images. For each concentration, 30 (three images of each location) images were obtained from location to location on the substrate surface, which was performed by moving the *XY* sample stage, as shown in Figure 6.

The typical fluorescence subframe images of SA-MNB/BT-dsDNA/SYBR Green I conjugate at different concentrations of human IgG in the range from 3.0 to 50 fM were shown in Figure 6. At the higher concentration, it was noted that the fluorescence intensities of some bright spots were 2−3 times higher than the mean intensity of a bright spot corresponding to a single MNB, which was obtained in lower concentrations (<10 fM) for IgG. A possible reason was that the steric hindrance among SA-MNBs made the number of BT-dsDNA per magnetic bead

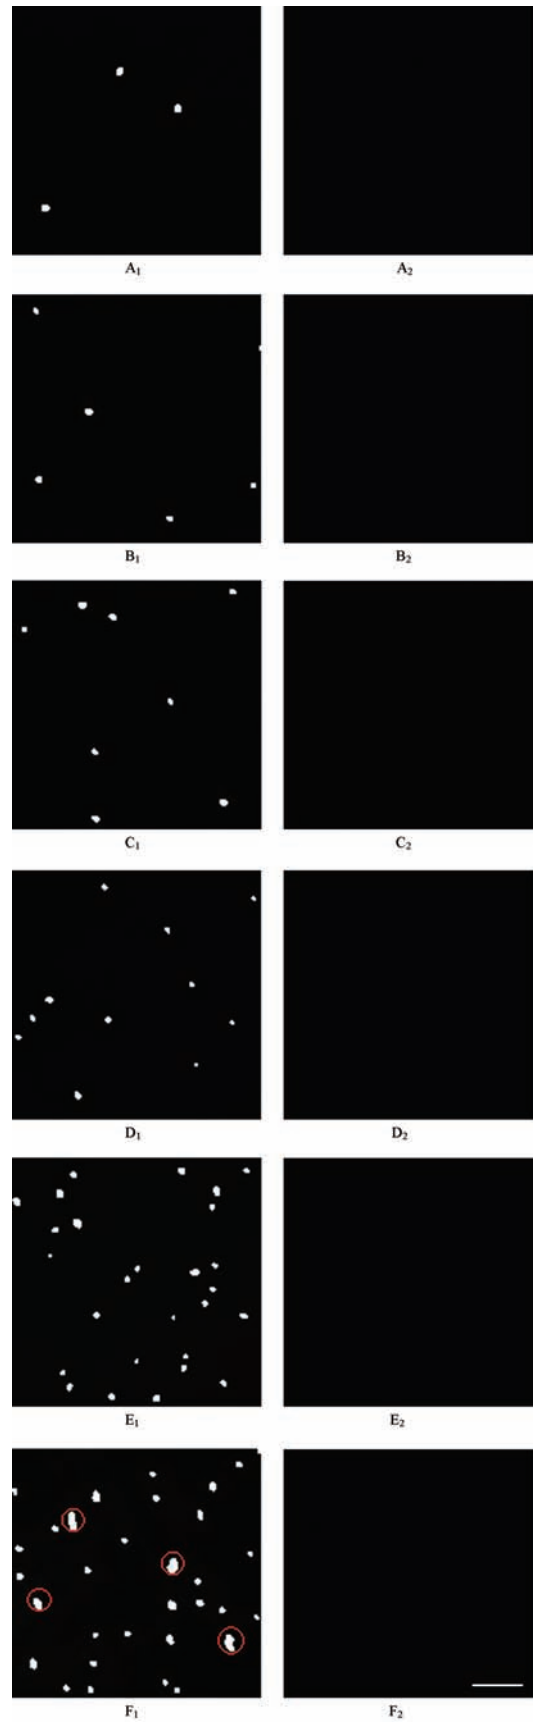

Figure 6. Fluorescent subframe image of human IgG molecules in solution at different concentrations. Conditions: human IgG concentration (fM): (A_1) 3.0, (B_1) 5.0, (C_1) 8.0, (D_1) 10, (E_1) 30, (F_1) 50, (A_2, B_2, C_2, D_2, E_2, F_2,) the corresponding negative control experiment. The bright spots of two nearest-neighbor MNBs aggregated one brighter spot (marked with red circle) in (F_1). Scale bar, 30 pixels.

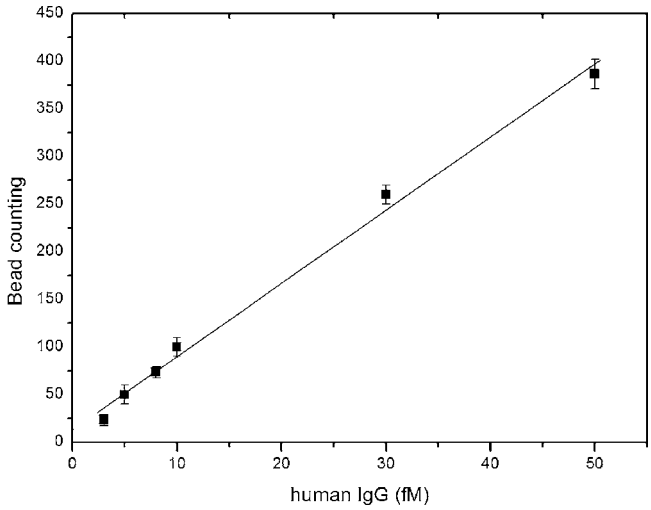

Figure 7. Linear relationship between the number of beads and the concentration of human IgG ($n = 3$). Conditions: Each data point represents an average of 3 measurements (each error bar indicates the standard deviation).

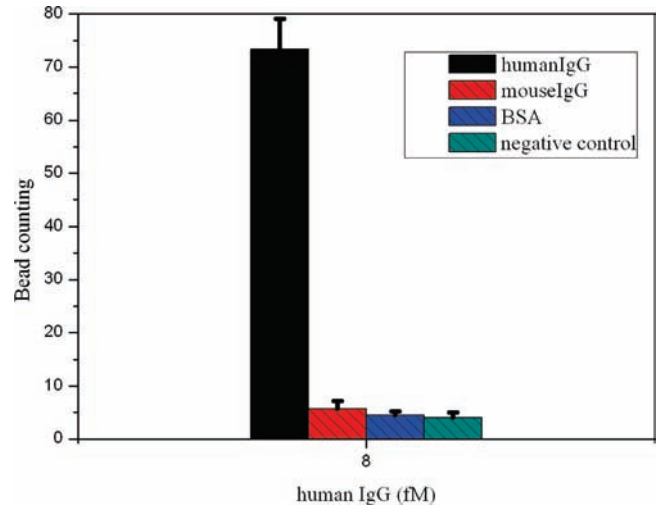

Figure 8. Comparison of fluorescence immunoassay for human-IgG (black column), mouse IgG (red column), BSA (blue column), and negative control (green column) on a silanized glass subframe using the SA-MNBs/BT-dsDNA/SYBR Green I conjugate label. Conditions: Each data point represents an average of 3 measurements (each error bar indicates the standard deviation); 10 images each measurement.

slightly different. Another possible reason was that, when the distance of two neighbor MNBs was small, the bright spots of two nearest-neighbor MNBs aggregated at one brighter spot due to diffraction of the fluorescence image. In the lower concentration, the fluorescence intensity of bright spots was rather uniform. However, as to the SMD-based quantitative methods, when the condition that one MNB was bound to one human IgG molecule onto the substrate was satisfied, the detected signal intensity was rather unimportant.

Quantification of Human IgG by SA-MNB/BT-dsDNA/SYBR Green I Conjugate. Human IgG concentration was quantified by counting the number of bright spots corresponding to single molecules on the fluorescence subframe images. Under the optimal conditions, the number of bright spots was proportional to the human IgG concentration. The typical fluorescence subframe images of Ag-BT-Ab-SA-MNB/BT-dsDNA/SYBR Green I at different concentrations in the range from 3.0 to 50 fM are shown in Figure 6. At the higher concentrations, it was noted that the fluorescence intensities of some bright spots were 2−3 times higher than the mean intensity of a bright spot corresponding to a single MNB. To solve this problem, the 30 positive images taken by the EMCCD were investigated in lower concentrations (<10 fM) for IgG. It was found that the bright spots on the subframe images were dispersive and each bright spot corresponding to a single MNB took up roughly a 6×6 pixel area, meaning that a fluorescence spot from a single functionalized MNB corresponding to a single human IgG molecule occupied roughly a 6×6 pixel area. While some bright spots in higher concentrations (>30 fM) exceed the 6×6 pixel grid of the image, taking the number of pixels occupied by the bright spots as the number of single IgG molecules was more accurate than taking the number of bright spots, even if the calibration was somewhat rough. The fluorescence intensity of bright spots (marked with red circle) in higher concentrations (>30 fM) that exceeded a 6×6 pixel area was assumed to come from two nearest-neighbor MNBs. When the concentrations exceeded 30 fM, the distance of two neighbor MNBs was small. The bright spots of two nearest-neighbor MNBs aggregated to one brighter spot due to diffraction of the fluorescence image. Figure 7 showed the linear relationship between the number of beads and human IgG concentration in the range 3.0−50 fM. The linear regression equation for human IgG in the range 3.0−50 fM was determined to be $y = 13.135 + 7.684 \times 10^{15}x$ ($R = 0.996$). The present approach improved the sensitivity by 4 orders of magnitude compared to the IgG(H+L)-Alexa Fluor 488 labeling for adsorption equilibrium strategy (*23*) and by 1.5 orders of magnitude approximately compared to the biotinylated monoclonal antihuman IgG molecules immobilized on the glass substrate surface by the streptavidin-coated quantum dot labeling strategy (*27*, *30*). A major factor in increased sensitivity is likely to be that highly amplified fluorescence signal and low background signal are achieved by using mutilabel bioconjugates made by linking multiple dye/DNA conjugates to streptavidin-coated magnetic nanobeads (SA-MNBs) and magnetic separation. The improved photostability is likely to be the number of dsDNA/SYBR Green I bound per bead in the labeling development step. By comparison, the SA-MNB/dsDNA/SYBR Green I conjugate approach reported in this paper uses all the common reagents such as biotin, oligonucleotides, streptavidin-coated magnetic nanobead, and fluorescent DNA probes.

To evaluate the specificity of the assay for human IgG, an experiment was carried out in which the surface-immobilized protein was replaced with either mouse IgG or BSA, while keeping the protein concentration the same as that for human IgG. The subsequent assay procedure was also the same as for human IgG. As illustrated in Figure 8, at a protein concentration of 8.0 fM, 30 images were obtained from location to location on the substrate surface. The fluorescence spots of either mouse IgG or BSA sample are very low by comparison with that of human IgG. The result indicates that the immunoassay is highly specific for human IgG.

CONCLUSION

In this paper, we reported an ultrasensitive fluorescence immunoassay for quantitative detection of single protein molecules based on counting of single magnetic nanobeads corresponding to single proteins with combined amplification of DNA and BT-DNA/SYBR Green I conjugate. As described above, the method offers several significant advantages. First, our strategy is to use a magnetic nanobead as a bridge carrier to attach multiple BT-DNA/SYBR Green I conjugates to an antibody at a single site, that is to say, many multiple BT-DNA/SYBR Green I conjugates are attached to an antigen to generate a strong detectable signal. Second, such a low background is attributed to a blocking step and extensive washing steps with

magnetic separation. Third, the BT-DNA/SYBR Green I conjugate is not pre-synthesized, but rather formed in situ as part of the immunoassay. A fluorescent DNA probe was bound to the oligonucleotide at high ratio. The binding stoichiometry is preferably high to ensure the high ratio, and the quantum yield of SYBR Green I is also high. The unbound probe does not emit fluorescence, and measurements can be performed without a wash step. Fourth, the multiple labeling approach uses readily available reagents and MNBs that are commercially available.

Surface-Bound Cytomimetic Assembly Based on Chemoselective and Biocompatible Immobilization and Further Modification of Intact Liposome

Yong Ma, Hailong Zhang, and Xue-Long Sun*

Department of Chemistry, Cleveland State University 2121 Euclid Avenue, Cleveland Ohio 44115, United States. Received May 5, 2010; Revised Manuscript Received September 20, 2010

A surface-bound cytomimetic assembly based on chemically selective and biocompatible immobilization and further modification of intact liposome is described. Liposomes carrying PEG-triphenylphosphine were chemoselectively immobilized onto azide-modified glass slides through Staudinger ligation, followed by modification with azide-modified lactose as a model biomolecule through Staudinger ligation to afford the surface-bound cytomimetic assembly. The intact liposome immobilized and modified and its protein binding activity were confirmed by fluorescence imaging, fluorescent dye releasing kinetics, and AFM techniques. The resultant surface-bound cytomimetic assembly showed sustained stability and fluorescent dye releasing kinetics and specific protein binding activity. The reported method provides a robust platform for preparation of a complex immobilized liposome system with multifunctional components, which mimics the cell surface in both geographical and content features and thus will find important biomedical applications.

INTRODUCTION

Cell surface biomolecules, especially glycans, have become attractive biomimetic targets for potential biomedical applications, since they act as receptors for a variety of protein ligands and are involved in a wide range of biological processes, including immune recognition events (*1*) and virus and bacterial invasion (*2*), as well as tissue growth and repair (*3*). On the other hand, cell surface glycosylated molecules play a significant role in maintaining the nonadhesive/nonthrombogenic property of the native intravascular luminal wall (*4*). Therefore, mimicking cell surface glycan structure by immobilizing glycan onto solid surface, namely, glycosurface has been explored extensively for biosensors and functional and biocompatible biomaterial surface engineering applications (*5, 6*). However, in most cases, glycans are directly conjugated onto the solid surfaces, which lack cell surface glycoconjugates' three-dimensional (3D) structure properties and cell lipid membrane's supplement effect and thus showed lower activity in both affinity and selectivity points and had limited success.

For cell surface mimetic engineering, surface chemistry characterized by the type of cell-binding ligand (carbohydrates, proteins, etc.) and their surface density (*7*), spatial distribution (*8*), and conformation (*9*) have been demonstrated to be important surface cues. Immobilization of liposome onto solid surface has shown great potential in biological and biomedical research and applications (*10*). This discipline has been inspired by the fact that liposome structurally retains the properties inherent in natural lipid membranes and functionally can serve as a biomembrane model and can encapsulate both hydrophobic and hydrophilic compounds such as drug and gene for delivery applications (*11*). For example, immobilized liposomes have been investigated as model systems presenting lipid membranes for bioseparation (*12*), biosensor (*13*), and nanobioreactor (*14*) applications. Recently, immobilized liposomes have been explored for medical device surface functionalization for sustained drug elution at the site of interest (*15*). Crucial to the further development of immobilized liposomes for practical application is their stability and the immobilization methods that allow chemoselective and biocompatible attachment of the intact liposomes with multifunctional components. Early studies using physisorptive entrapment (*12, 15*) for liposome immobilization suffered from their low reproducibility and stability due to their nonspecific interaction features. In response to these problems, biotin−streptavidin/avidin (*13, 14*) and oligonucleotide-based specific binding (*16*), histidine-nickel (*17*), and covalent immobilization strategies such as using glutaraldehyde (*18*), disulfide linkage (*19*), carbamate (*20*), and carbodiimide (*21*) chemistry have been explored. The major limitations to all these approaches lie in the fact that the immobilized liposomes tend to unravel, rupture, and fuse with other surrounding liposomes during and after the immobilization process, as well as nonselective and harsh reaction conditions. In addition, to the best of our knowledge, there has been no report on further covalent modification of the immobilized liposome. Herein, a chemically selective and biocompatible immobilization and further modification of intact liposome was investigated for preparation of a surface-bound cytomimetic assembly. The immobilized and functionalized liposome-based system mimics the cell surface in both geographical and content features and thus is expected to have high biological activity. Specifically, liposomes carrying PEG-triphenylphosphine were chemoselectively immobilized onto azide-PEG-modified glass slides through Staudinger ligation and were further modified with azide-modified glycans through Staudinger ligation with triphenyphosphine localized on the immobilized liposome exterior surface (Figure 1). This strategy fulfills the following important design criteria: (1) PEG spacers on both glass side and liposome surface will stabilize the immobilized liposome (*22*); (2) the azide group tolerates a diverse array of other functionalities in the complex and undergoes chemoselective Staudinger ligation with triphenylphosphine under mild conditions. Several research groups have demonstrated the superior chemoselectivity and biocompatibility of Staudinger ligation, for example, in the recently highlighted metabolic engineering of cell surface (*23*), microarray (*24*), and liposome surface functionalization (*25*) applications. In addition, Staudinger ligation is a catalyst-free

coupling reaction and thus does not bring in any residue to the immobilized liposome during the reaction. Therefore, the reported method will provide a robust platform for preparation of a complex immobilized liposome system with multifunctional components for a variety of biological and biomedical research and practices.

MATERIALS AND METHODS

Materials. 1,2-Distearoyl-*sn*-glycero-3-phosphocholine (DSPC) and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (ammonium salt) (DSPE-Rodamine) were purchased from Avanti Polar Lipids (Alabaster, AL, USA). Cholesterol, 5,6-carboxyfluorescein, and lectin (Arachis hypogae, FITC-labeled) were purchased from Sigma (USA). All other solvents and reagents were purchased from commercial sources and were used as received, unless otherwise noted. Deionized water was used as a solvent in all experiments. DSPE-PEG_{2000}-triphenylphosphine, MeO-PEG_{2000}-triphenylphosphine, azide-PEG_6-Glass slide, and 2-azideethyle-lactoside were synthesized as described in the Supporting Information.

General Measurement. The fluorescence imaging experiments of the immobilized liposomes on a glass slide were performed by using Typhoon 9410 variable mode imager (Amersham Biosciences, USA). A two-channel stage-scanning fluorescent image was used. Channel 1 used 521 nm output (526 nm) from laser blue 2 to selectively excite 5,6-CF encapsulated inside the liposome, and Channel 2 used 571 nm output (580 nm) from laser green to selectively excite Liss Rhod-DSPE embedded in the lipid membrane. AFM imaging experiments of the immobilized liposomes on a glass slide were performed by using PicoPlus 3000 (Molecular Imaging, USA).

Liposome Preparation. DSPC (15 mg, 20.4 μmol), cholesterol (4 mg, 10.2 μmol), and DSPE-PEG_{2000}-Triphenylphosphine (0.9 mg, 0.3 μmol) (2:1:1% molar ratio) were dissolved in 3.0 mL of chloroform. The solvent was gently removed on an evaporator under reduced pressure to form a thin lipid film on the flask wall, which was kept in a vacuum chamber overnight. The lipid film was swelled with 2.5 mL of PBS (pH 7.4) buffer containing 5,6-carboxyfluorescein (50 mM for fluorescence imaging or 85 mM for releasing study) to form the multilamellar vesicle suspension, followed by 10 freeze−thaw cycles involving quenching in liquid N_2 and then immersion in a 65 °C water bath. The lipid suspension thus formed was extruded through polycarbonate membranes (pore size 600, 200, and 100 nm, gradually) to afford small unilamellar vesicles (SUVs). Non-entrapped CF was separated from the 5,6-CF-encapsulated vesicles with Sephadex G-50 gel chromatography (1.5 × 20 cm column) using PBS (pH 7.4) buffer as eluent. For fluorescence imaging study, 1 mol % of DSPE-Rodamine was embedded in the lipid membrane as the same liposome preparation above. For liposome size determination, 20 μL of extruded liposome sample was diluted to 2 mL with PBS (pH 7.4) buffer and then measured with a 90plus particle size analyzer (Brookhaven Co., USA).

Staudinger Immobilization of Liposome. The liposome prepared above was diluted to desired lipid concentration (2.0 mg/mL, total lipid concentration) by PBS (pH 7.4) buffer and then was incubated on an azide-PEG6-functionalized glass slide for 2.0 h at room temperature. Next, MeO-PEG_{2000}-triphenylphosphine was added (20 μg/mL) to quench the azide group left on the glass slide for 2 h at room temperature, followed by removing the glass slide from the reaction solution. Finally, the liposome-immobilized glass slide was washed by rinsing with PBS (pH 7.4) buffer for 2.0 h, repeated three times.

Staudinger Glyco-Functionalization of Immobilized Liposome. The immobilized liposome carrying triphenylphosphine was incubated with 2-azidoethyllactoside in PBS buffer (pH 7.4, 40 mg/mL) at room temperature for 2.0 h, followed by removing the glass slide from the reaction solution. The glass slide was washed by rinsing with PBS (pH 7.4) buffer for 2.0 h, repeated three times.

Specific Lectin Binding onto Lactosylated Immobilized Liposome. The lactosylated liposomes immobilized onto a glass slide were incubated with lectin (Arachis hypogae, FITC-labeled, Sigma) in PBS (pH 7.4) buffer solution (50 μg/mL) at room temperature for 2.0 h, followed by removing the glass slide from the reaction solution. The glass slide was washed by rinsing with PBS (pH 7.4) buffer for 2.0 h, repeated three times. The control experiment was performed with lectin-FITC presaturated with free lactose (0.1 mM in PBS (pH 7.4) buffer).

Measurement of Release of 5,6-CF from Liposome. 5,6-CF released from free liposomes, immobilized liposomes, and glycosylated immobilized liposomes in PBS (pH 7.4) buffer at room temperature was measured over time. The excitation and emission wavelengths of 5,6-CF were 497 and 520 nm, respectively. The variation of the fluorescent intensity with release time was calculated according to the equation below

$$\text{fraction of CF remaining in liposomes} = 1 - F/F_0$$

where F is the fluorescent intensity measured at any time during the experiment and F_0 is the total fluorescent intensity measured

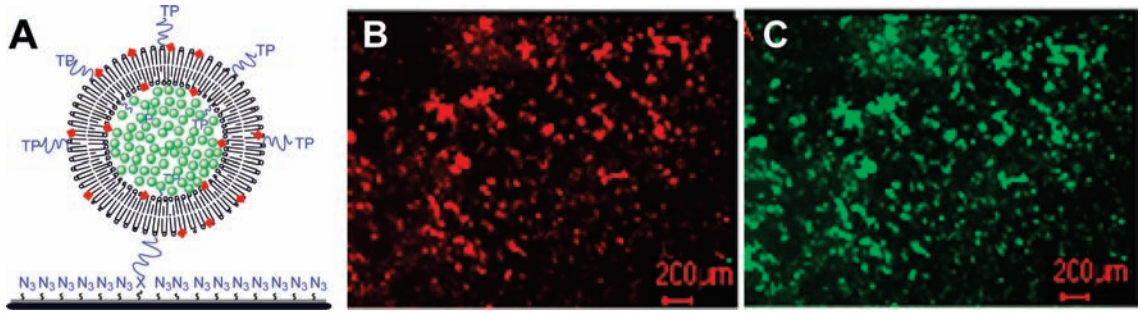

Figure 2. Fluorescent-labeled immobilized liposome (A); fluorescence images of immobilized liposomes obtained for selectively exciting PE-Rhodamine embedded in the liposome membrane (B) and for selectively exciting 5,6-CF encapsulated in the liposome (C). Bar size: 200 μm.

after disrupting liposomes completely with 0.5% Triton X-100 in PBS (pH 7.4) buffer.

RESULTS AND DISCUSSION

The synthesis of surface-immobilized liposomes starts with the synthesis of anchor group modified liposomes followed by attachment onto a solid surface carrying a counterpart group of the anchor group on the liposome surface. The anchor lipid DSPE-PEG_{2000}-Triphenylphosphine was synthesized by amidation of commercially available DSPE-PEG_{2000}-NH_2 (Avanti Polar Lipid, Inc.) with 3-diphenylphosphino-4-methoxycarbonylbenzoic acid NHS active ester (see the Supporting Information). Small unilamellar vesicles composed of DSPC and cholesterol (2:1 mol ratio) and 1.0 mol % of the anchor lipid in PBS (pH 7.4) buffer were prepared by rapid extrusion through polycarbonate membrane with pore size of 600, 200, and 100 nm diameter, sequentially at 65 °C. In the present study, DSPC was used as a model lipid; different lipids such as unsaturated lipids will be used to mimic the real cellular surface in continued study. This produced small unilamellar vesicles show an average mean diameter of 120 $\pm$ 5 nm as determined by dynamic light scattering (see Supporting Information). On the other hand, the azid-PEG_6-glass slide was used as model surface and was prepared by amidation of commercially available amine glass slide (Xenopore, Co) with azido-PEG_6-COO-NHS (see the Supporting Information). Next, immobilization of the preformed liposomes was performed by incubating azide-PEG-glass slides with preformed liposomes in PBS (pH 7.4) buffer (2 mg/mL of total lipid concentration) for 2.0 h at room temperature, followed by addition of MeO-PEG_{2000}-triphenylphosphine (20 μg/mL) to quench the azide group left on the glass slide for 2 h at room temperature. Finally, removing the glass slide from the reaction solution followed by washing with PBS (pH 7.4) buffer three times to remove the unreacted liposomes afforded immobilized liposomes.

To confirm the intact liposome immobilized on the glass slide surface, a fluorescence imaging study was conducted first. DSPE-Rodamine (1 mol %, Avanti Polar Lipid, Inc.) was doped in the liposomes so as to label the lipid membrane, and 5,6-carboxyfluorescein (5,6-CF, Sigma) (50 mM) was encapsulated into the liposome so as to image the inner compartment of the liposome (Figure 2A). As a result, detecting either Rhodamine (Figure 2B) or 5,6-CF (Figure 2C) yielded a fluorescence image of the immobilized liposome for an azide-PEG glass slide treated with liposomes carrying anchor group triphenylphosphine, while there was no apparent fluorescence image observed for an azide-PEG glass slide treated with liposomes without anchor group triphenylphosphine (data not shown). These results indicated that the immobilization of intact liposomes was achieved through Staudinger ligation. Both fluorescence images were not so uniform. This might be due to non-uniform functionalization of the glass slide surface or the original glass slide surface being bumpy.

To examine whether the immobilization reaction condition could provoke liposome disruption, fluorescent dye releasing kinetics from the liposome during immobilization reaction was investigated. Briefly, we have exposed our standard conditions to the same type of liposomes but with encapsulated self-quenching concentration (85 mM) of 5,6-CF. On the basis of the fluorescence quenching determinations (Figure 3A), we could demonstrate that less than 7.2% leakage of the total loading was triggered during the immobilization reaction (2.0 h) compared with 5.2% leakage for the same liposome during storage without reaction (2.0 h). The leakage percentiles were calculated by destroying liposomes with surfactant 0.5% Triton X-100 in PBS (pH 7.4) buffer to release all 5,6-CF encapsulated after 2.0 h reaction. These results indicated that the immobilization reaction condition is harmless for liposome integrity. Continually, the subsequent fluorescent dye releasing kinetics over time for the non-destroyed immobilized liposomes was examined to verify the stability of the intact immobilized liposome in PBS (pH 7.4) buffer at room temperature. It was found that immobilized liposome showed a constant leakage of approximately 25%/day for three days (Figure 3B), whereas free liposome in PBS (pH 7.4) solution showed a leakage rate of approximately 20%/day (Figure 3C), which is slightly less than that of immobilized liposome. The extended fluorescent dye releasing results further demonstrated that intact liposomes had been successfully immobilized onto the glass slide and showed sustained stability as well.

Furthermore, atomic force microscopy (AFM) was used to confirm the intact liposomes immobilized on the glass slide surface, since it is a powerful tool for investigating surface-related physical and chemical properties in the nanoscale. Typical AFM images of immobilized liposomes were observed on the azide-PEG glass slide treated with liposomes carrying anchor group triphenylphosphine (Figure 4B), while there were no immobilized liposomes observed for the azide-PEG glass slide treated with liposomes without anchor group triphenylphosphine (Figure 4A). These results further indicated the successful immobilization of intact liposomes via Staudinger ligation.

Lactose was chosen as a model glycan for chemoselective modification of the immobilized liposome since it serves as ligand for lectin (*26*) and cells such as hepatocytes that express galactose-specific binding receptor asialoglycoproteins on the surface (*27*). Briefly, glyco-modification was performed by incubation of the immobilized liposomes carrying triphenylphosphine on the exterior surface with 2-azidoethyllactoside (*28*) in PBS buffer (pH 7.4) at room temperature under an argon atmosphere for 2 h. Similarly, fluorescent dye releasing kinetics from the glycosylated immobilized liposome was examined by using liposome encapsulating self-quenching concentrations (85 mM) of 5,6-CF (Figure 3D). It was found that the 5,6-CF releasing kinetics from the glycosylated immobilized liposome is slower than that of its precursor, but slightly faster than that

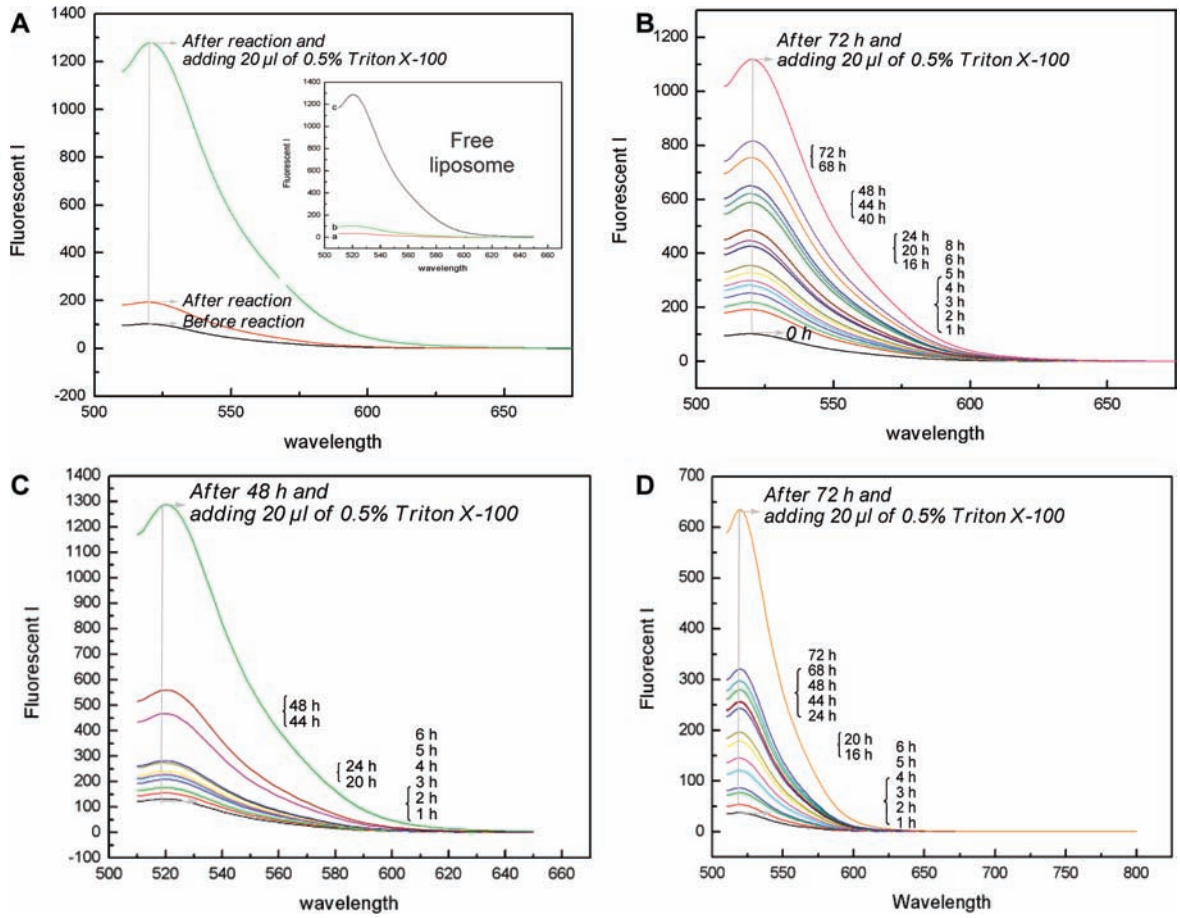

Figure 3. 5,6-CF releasing from liposome during the immobilization reaction: before reaction, after reaction, and after adding 20 μL of 0.5% Triton X-100 (A); the 5,6-CF releasing kinetics from immobilized liposome (B); the 5,6-CF releasing kinetics from free liposome (C); and the 5,6-CF releasing kinetics from glycosylated immobilized liposome (D) during storage in PBS (pH 7.4) buffer at rt during 0−72 h, and after adding 20 μL of 0.5% Triton X-100 at the final point.

of free liposome (Figure 5A), which indicated that glycosylated immobilized liposome showed sustained stability. It can be explained by the fact that liposome surface glycans prevent 5,6-CF release and stabilize the immobilized liposome. Furthermore, the glyco-stabilizing function was defined by a detergent rupturing experiment (*29*), in which the immobilized liposomes were ruptured by adding surfactant 0.5% Triton X-100 immediately after immobilization and glycosylation reaction, respectively. As shown in Figure 5B, 90% of encapsulated 5,6-CF was released from the non-glycosylated immobilized liposomes in 30 min, while it took 120 min for the glycosylated immobilized liposomes. In other words, the glycosylated immobilized liposomes released encapsulated 5,6-CF much more slowly than its precursor did. This result demonstrated the capacity of the surface glycans to protect liposomes against the action of surfactant, which is consistent with the literature report (*29*).

Next, to determine whether the grafted lactose residues are easily accessible at the surface of the immobilized liposomes, specific lectin binding assay was conducted by incubating lactosylated immobilized liposomes in the presence of β-galactose binding lectin (*Arachis hypogae,* 120 kDa, FITC-Labeled, Sigma) in PBS (pH 7.4) buffer at room temperature for 2.0 h. As shown in Figure 6, the specific binding of fluorescent-labeled lectin was observed on the lactosylated immobilized liposome (Figure 6A), while no fluorescent image was observed on non-glycosylated immobilized liposomes treated with the same lectin (Figure 6B). Furthermore, lectin binding was not observed when lactose-saturated lectin was used (Figure 6C). These results indicated specific binding of lectin onto the lactosylated immobilized liposomes. Finally, AFM images were investigated to confirm lactosylated immobilized liposomes as well as its lectin binding. As result, there is no apparent size change after lactosylation of the immobilized liposomes (Figure 4C); however, morphological change was observed after lectin binding to the lactosylated immobilized liposomes (Figure 4D). This phenomenon can be explained as the glycosylated immobilized liposome might be ruptured due to specific multivalent binding interaction between grafted lactoses on the immobilized liposome surface and lectin. These results further demonstrated the successful glyco-functionalization of the immobilized liposome and its lectin binding capacity.

CONCLUSION

A surface-bound cytomimetic assembly was demonstrated by chemically selective and biocompatible immobilization and further glyco-modification of intact liposome through Staudinger ligation and PEG chemistry. The integrity and stability of the intact glycosylated immobilized liposomes and its specific lectin binding were confirmed by fluorescence imaging, fluorescent dye releasing kinetics, and AFM techniques. The high specificity and efficiency and biocompatible reaction conditions make the present approach an attractive alternative to all currently used protocols for liposome immobilization and modification. Continued study on maximum and optimized density of immobilized liposomes and the glycans on the surface of the immobilized liposomes correlating to its stability and biological activity are under investigation and will be reported accordingly. The reported method will provide a robust platform for preparation of immobilized liposome systems with multifunctional compo-

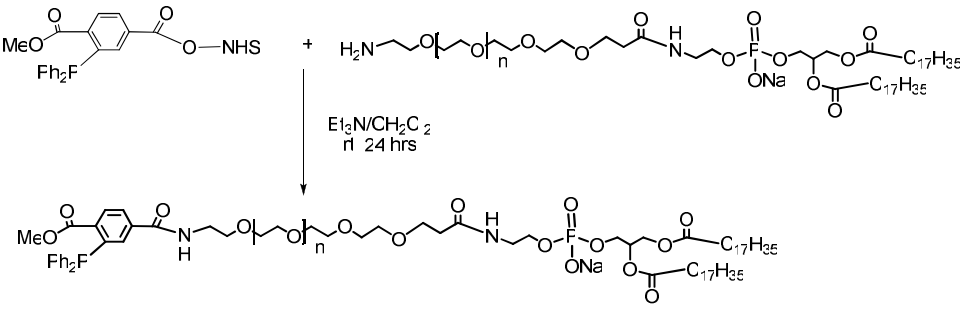
Surface-Bound Cytomimetic Assembly Based on Chemoselcetive and Biocompatible Immobilization and Further Modification of Intact Liposome

Yong Ma, Hailong Zhang and Xue-Long Sun*

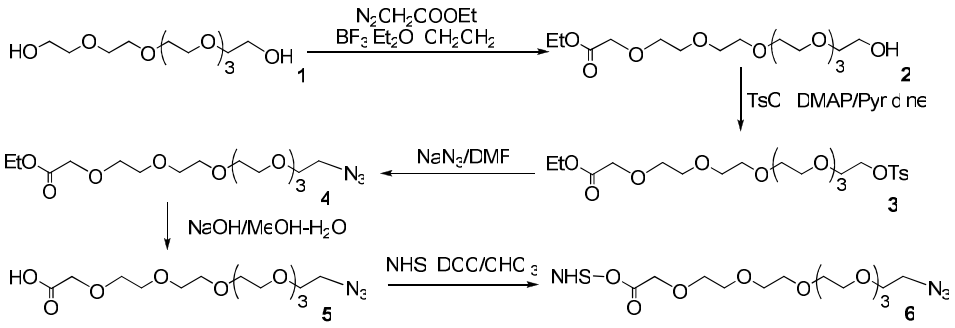


Supporting Information

Materials. All solvents and reagents were purchased from commercial sources and were used as received, unless otherwise noted. Deionized water with a resistivity of 18Ω was used as a solvent in all polymerization reactions.

Method. Thin-layer chromatography (TLC) was performed on Whatman silica gel aluminum backed plates of 250 μm thickness on which spots were visualized with UV light or by charring the plate after dipping in 10% H_2SO_4 in methanol. ^{1}H NMR spectra were recorded with a Varian INOVA 300 MHz spectrometer. In all cases, the sample concentration was 10 mg/mL, and the appropriate deuterated solvent was used as an internal standard.

1. 1-Succinimidyl 3-diphenylphosphino-4-methoxycarbonylbenzoate was synthesized as literature method.[1]



2. Synthesis of DSPE-PEG$_{2000}$-Triphenylphosphine

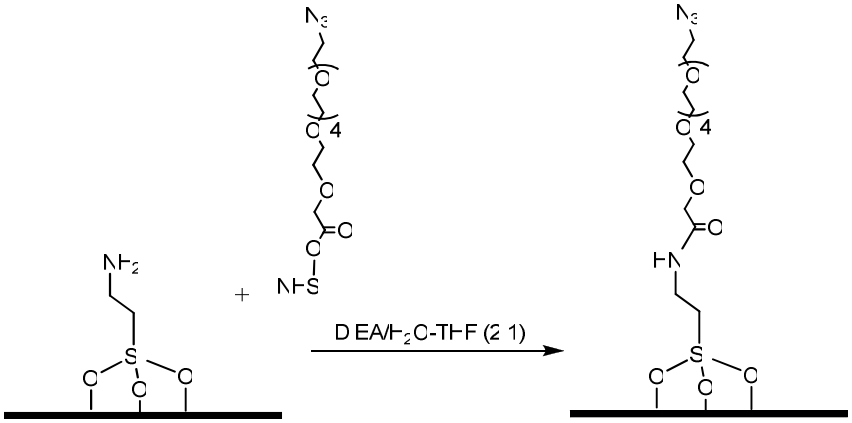
Scheme 1. Synthesis of DSPE-PEG$_{2000}$-Triphenylphosphine

DSPE-PEG2000-NH_2 (100 mg, 35.8 μmol) was dissolved in 20 mL of CH_2Cl_2, and 0.2 mL of Et_3N was added. After stirring for 30 min at room temperature, a solution of succinimidyl 3-diphenylphosphino-4-methoxycarbonylbenzoate (33 mg, 71.6 μmol) in 5 mL of CH_2Cl_2 was added. The reaction mixture was stirred at room temperature for 24 h and then concentrated under vacuum to give a residue, which was purified by silica gel chromatography using chloroform/methanol (4:1, v/v) as elute to afford DSPE-PEG$_{2000}$-Triphenyphosphine (45 mg, 42%), ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 8.06 (m, 1H), 7.79 (m, 1H), 7.66 (m, 2H), 7.52-7.42 (m, 2H), 7.28-7.34 (m, 8H), 6.64 (m, 1H), 5.19 (s, 1H), 4.34-4.20 (m, 3H), 3.95-3.80 (m, 3H), 3.80-3.50 (br. S, 100H, O-CH_2-CH_2-O), 3.40-3.20 (m, 3H), 2.28 (br.s, 4H), 1.58 (br.s, 4H), 1.36-1.20 (s, 32H), 0.89 (t, *J*, 6.9 , 6H) ppm, ^{31}P NMR ($CDCl_3$, 121 MHz) δ: -2.70 ppm.

3. Synthesis of Azido-PEG$_6$-COO-NHS ester

Scheme 2. Synthesis of Azido-PEG6-COO-NHS ester

Synthesis of Hexa (ethylene glycol) monoester (2): Ethyl diazoacetate (0.47 mL, 4.42 mmol) was added dropwise to a solution of hexa(ethylene glycol) (10 g, 35.3 mmol) and BF_3•Et_2O (0.056 mL, 0.442 mmol) in dichloromethane (12 mL) at 0 ^oC. The reaction mixture was allowed to proceed for 15 min at room temperature and then saturated NH_4Cl (6 mL) was added. The reaction solution was placed in a separatory funnel and was extracted with dichloromethane (3 × 20 mL). The combined organic phase was concentrated in vacuum to afford yellow oil, which was purified with silica gel chromatography (3:1 (v/v) EtOAc:hexanes → EtOAc) to afford **2** as a clear oil (2.90 g, 23%). ^{1}H-NMR ($CDCl_3$, 300 MHz) δ: 4.16 (q, *J* = 7.14 Hz, 2H), 4.10 (s, 2H), 3.62-3.70 (m, 22H), 3.56 (t, *J* = 4.24 Hz, 2H), 2.78 (br, s, 1H), 1.23 (t, *J* = 7.14 Hz, 3H) ppm.



Synthesis of O-Toluenesulfonyl-hexa(ethylene glycol) ethyl ester (3): *P*-toluenesulfonyl chloride (2.25 g, 11.80 mmol) and DMAP (65 mg, 0.54 mmol) were added to a solution of **2** (2.90 g, 7.84 mmol) in 1:1 (v/v) of pyridine/dichloromethane (25 mL). After 5 hr, the reaction solution was poured into ice-cold water (50 mL), and the aqueous phase was extracted with dichloromethane (3 × 40 mL). The combined organic phases were washed with NH_4Cl (20 mL) and brine (20 mL), dried over Na_2SO_4, and concentrated. The resultant yellow oil was chromatographed on silica gel (EtOAc: *n*-Hexanes, 3:1, v/v) to afford **3** as a clear oil (1.56 g, 40%). ^{1}H-NMR ($CDCl_3$, 300 MHz) δ: 7.73 (d, *J* = 8.30 Hz, 2H), 7.28 (d, *J* = 8.30 Hz, 2H), 4.14 (q, *J* = 7.14 Hz, 2H), 4.08 (s, 2H), 3.52-3.68 (m, 22H), 2.39 (s, 3H), 1.22 (t, *J* = 7.14 Hz, 3H) ppm.

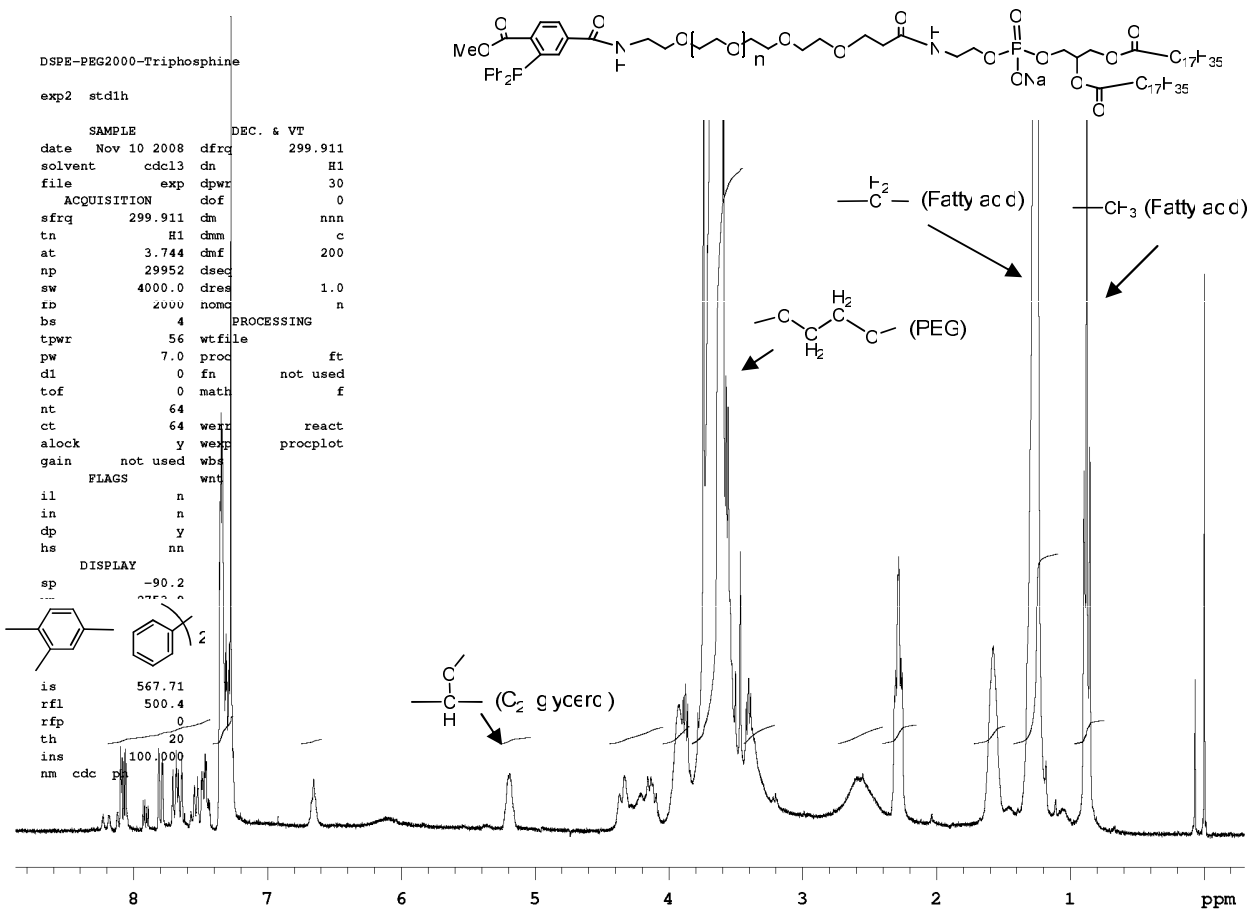
Synthesis of Ethyl 14-azido-3, 6, 9-hexaaoxatetradecan-1-oate (4): Sodium azide (0.400 g, 6.16 mmol) was added to a solution of **3** (0.78 g, 1.53 mmol) in DMF (20 mL). The reaction mixture was stirred at 70 ^oC overnight then cooled to room temperature, water (10 mL) was added and extracted with Et_2O (3 × 20 mL). The combined Et_2O layer was backwashed by saturated NaCl (2 × 10 mL). The diethyl ether extraction was dried by anhydrous Na_2SO_4 and concentrated to afford crude yellow oil, which was purified with silica gel chromatography with Hexane/Ethyl aceate (1:4, v/v) as elute to afford **4** (0.48 g, 80%) as near colorless oil. ^{1}H-NMR ($CDCl_3$, 300 MHz) δ: 4.14 (q, *J* = 7.2 Hz, 2H), 4.07 (s, 2H), 3.70-3.55 (m, 22H), 3.31 (t, *J* = 5.0 Hz, 2H), 1.20 (t, *J* = 7.1 Hz, 3H), 1.20 (t, *J* = 7.1 Hz, 3 H) ppm.

Synthesis of 14-azido-3, 6, 9-hexaaoxatetradecan-1-oic acid (5): The azide compound **4** (0.48 g, 1.22 mmol) was dissolved in 5 mL of methanol. 4.5 mL of 1N NaOH was added to the solution at 0 °C and the mixture was stirred for 21 h at room temperature. Then reaction solution was concentrated under reduced pressure to obtain a residue. 1N HCl was added to the residue until pH 2, and then was extracted with chloroform (3 x 20 mL). The organic phase was washed once by a saturated saline solution, and dried with an anhydrous Na_2SO_4. The organic phase was concentrated under reduced pressure to obtain a colorless liquid serving as compound **5** (0.40 g, 90%). ^{1}H-NMR ($CDCl_3$, 300 MHz) δ: 4.16 (s, 2H), 3.68 (m, 22H), 3.41 (t, *J* = 6.1 Hz, 2H) ppm.

Synthesis of Azido-PEG$_6$-COO-NHS ester (6): 400 mg (1.0 mmol) of azide-PEG6-COOH (5) and 271 mg (1.30 mmol) of DCC were dissolved in 10 mL $CHCl_3$ and then stir at 0 °C for 30 min. After adding 152 mg (1.30 mmol) of *N*-hydroxysuccinimide, the mixture was stirred at room temperature over night. The chloroform was evaporated to provide the yellow crystalline product, which was purified by a silica gel column ($CHCl_3$ → EtOAc) to afford pure product **6** (620 mg, 89%). ^{1}H-NMR ($CDCl_3$, 300 MHz) δ 3.71-3.52 (m, 22H), 3.37 (m, 4H), 3.28 (m, 2H), 2.81 (s, 2H) ppm.

4. Preparation of Azide-PEG$_6$-Glass slide

Scheme 3. Preparation of Azide-PEG$_6$-Glass slide



N_3-PEG$_6$-NHS (10 mg) was dissolved in 4.0 mL of THF, 0.5 mL of *N*,*N*-disopropylethyl-amine (DIEA) was added and then diluted to 8.0 mL by H_2O, followed by incubation of amine functionalized glass slide for 8 h at room temperature. The glass slide was rinsed with THF (3 times, 5 min each), water (3 times, 5 min each), then dried under N_2 atmosphere.

5. 2-azidoethyl-lactoside was synthesized as literature method.[2]

20 μL of extruded liposome sample was diluted to 2 mL with PBS (pH 7.4) buffer and then measured with 90plus particle size analyzer (Brookhaven Co., USA).

Influence of the Backbone Structure on the Release of Bioactive Volatiles from Maleic Acid-Based Polymer Conjugates

Damien L. Berthier,* Nicolas Paret, Alain Trachsel, and Andreas Herrmann*

Firmenich SA, Division Recherche et Développement, B.P. 239, CH-1211 Genève 8, Switzerland. Received May 7, 2010; Revised Manuscript Received September 22, 2010

Poly(maleic acid monoester)-based β-mercapto ketones were synthesized and investigated as potential delivery systems for the controlled release of bioactive, volatile, α,β-unsaturated enones (such as damascones and damascenones) by retro 1,4-addition. The bioconjugates were prepared in a one-pot synthesis using 2-mercaptoethanol as a linker. The thiol group of 2-mercaptoethanol adds to the double bond of the enone to form a β-mercapto ketone, which was then grafted via nucleophilic ring-opening of the remaining alcohol function onto a series of alternating copolymers of maleic anhydride and 1-octadecene, ethylene, isobutylene, and methyl vinyl ether. The influence of copolymer backbones on the release of δ-damascone was investigated in buffered aqueous solution as a function of pH and time. In the presence of a cationic surfactant, the polymer conjugates were transferred from an aqueous medium to a cotton surface. The deposition and the release of δ-damascone from the cotton surface as a function of the polymer backbone structure were measured by fluorescence spectroscopy and dynamic headspace analysis, respectively. All polymer conjugates were found to deliver higher amounts of the volatile into the headspace than the reference consisting of unmodified δ-damascone. Polymers with a hydrophobic backbone were generally efficiently deposited on the cotton surface, but released δ-damascone only moderately in solution. Conjugates with a more hydrophilic backbone release the active compound more efficiently in water, but are deposited to a lower extent onto the target surface. A good balance of the hydrophobicity and hydrophilicity of the polymer backbone is the key factor to maximize the deposition of the conjugates on the target surface and to optimize the release of the bioactive volatiles.

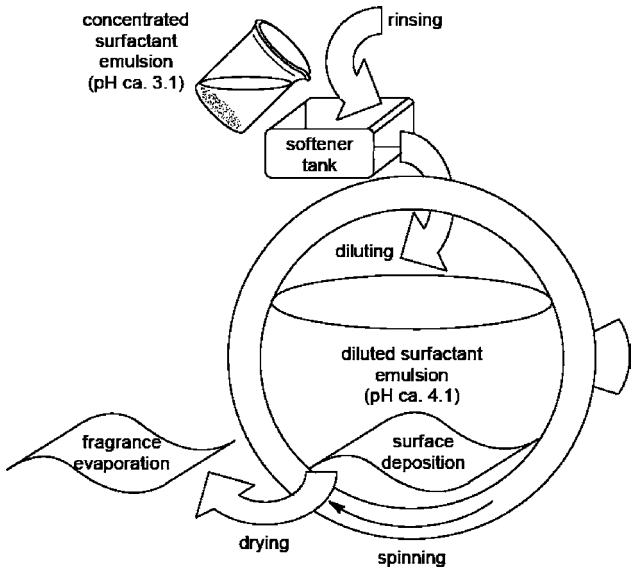
INTRODUCTION

Semiochemicals are highly volatile, biologically active organic compounds that serve for interspecies communication via evaporation and transportation through the air by diffusion (*1–3*). Many of these compounds have been used as fragrances since antiquity (*4, 5*), and advances in organic synthesis have resulted in the introduction of new volatile compounds to the palette of the modern perfumer (*6–9*). As a consequence of their high volatilities (vapor pressures) (*10, 11*), the perception of these compounds is usually transient. Bearing in mind that the longevity of fragrance perception is an important factor in the appreciation of perfumed consumer articles (*12*), and that perfumes are generally complex mixtures of fragrance ingredients having different volatilities, water solubilities, and chemical functions (*4, 6–9*), the stability of these ingredients during storage, their efficient delivery, and their resilience in application are very important.

Physical (encapsulation-based) (*13, 14*) or chemical (precursors) (*15*) delivery systems have been developed to improve substantivity, which is defined as the ability to be deposited on different substrates and the retention of volatile perfumery ingredients. Because of their particular physicochemical properties, a broad variety of polymers (*12, 16–20*) and polymer conjugates (*15, 21–30*) have been described as suitable carrier materials to control the release of fragrances. These materials can disperse hydrophobic volatile molecules in aqueous media and enhance their deposition on various substrates.

Physical delivery systems are based on the preparation of polymer matrices (*12, 16–19*) or core−shell structures (*20*), which stabilize sensitive compounds whose slow diffusion out of the encapsulating matrix or capsule improves the duration of fragrance perception.

In contrast, chemical delivery systems, so-called profragrances, use mild ambient conditions to cleave the covalent bond of the volatile conjugated to a precursor substrate (*15*). Reaction conditions allowing the cleavage of a chemical bond between a substrate and a targeted molecule comprise changes in temperature, hydrolysis or change of pH, oxidation, and exposure to daylight or enzymes. Because of their macromolecular structure, polymer conjugates were generally found to slow down the release of volatiles compared with the corresponding monomeric, low-molecular-weight analogues (*22–29*). Changes in the polymer structure with respect to the hydrophilicity or hydrophobicity of the polymer backbone (*28–30*), as well as the presence of specific chemical functionalities in close proximity to the release unit (*29*), were found to strongly influence the release rates of the volatiles from their precursors.



Endo and co-workers prepared a series of amphiphilic poly(methacrylate) copolymers with different ratios of hydrophobic fragrance-releasing acetal side chains and hydrophilic poly(ethylene glycol) (PEG) side chains (*30*). They found that the polymers aggregate to micelles, which strongly influenced the cleavage of the acid-labile acetal side chain and thus the release of the fragrance. With the polymer aggregation being temperature dependent, application of heating and cooling cycles allowed control of the rate of fragrance release from the polymeric profragrances.

Recently, Fehr and Galindo (*31*) reported the Michael-type 1,4-addition of carboxylic acids or thiols to enones, such as damascones or damascenones, the so-called rose ketones (*32, 33*). The β-mercapto ketone obtained by condensation of 1-dodecanethiol and δ-damascone was especially found to be very

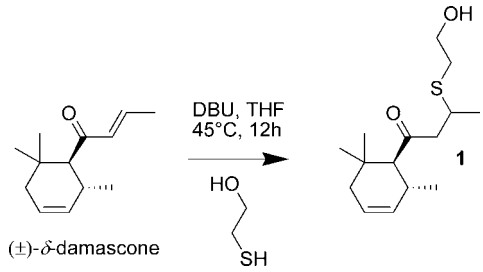
Scheme 1. Fabric Softening Process in a Washing Machine



efficient as a fragrance precursor and has now been commercialized (*31*). From these results, we became interested in preparing polymeric fragrance delivery systems that released rose ketones by retro 1,4-addition and in investigating the influence of structural modifications on the surface deposition of the polymers from an aqueous environment and the release efficiency of the bioactive volatile.

A recent study reported the pH-dependent release of δ-damascone from amphiphilic random copolymers of a β-acyloxy ketone derivative of δ-damascone and methacrylic acid (*28*). Poly(methacrylate)-based profragrances were synthesized via an aldol condensation of the corresponding methyl ketone with acetaldehyde, followed by esterification of the resultant β-hydroxy ketones with methacrylic acid (*28, 31*). Subsequent copolymerization with methacrylic acid, at different molar ratios to adjust the polarity of the polymer backbone, controlled the surface adsorption/deposition of the polymer on various substrates and its dispersion in aqueous media. Although this procedure provided access to a very efficient pH-dependent delivery system for δ-damascone by retro 1,4-addition, the preparation of the intermediate 3-hydroxy ketone of δ-damascone is costly and difficult to scale up.

Because alternating copolymers of maleic anhydride can be easily modified by ring-opening of the reactive anhydride unit with alcohols or amines (*34, 35*), these are suitable substrates for the grafting of bioactive compounds and, at the same time, for fine-tuning the physicochemical properties of the resulting conjugate. Accordingly, various maleic acid monoesters were prepared by reaction with monomeric or polymeric alcohols (*36–41*) to afford a series of versatile, biocompatible delivery systems (*42, 43*).

To be perceived, fragrance molecules have to be evaporated from a surface. In fine perfumery, surface deposition is easily achieved by spraying the volatiles together with a solvent onto the target surface (e.g., skin, fabric). However, in other types of application, surface deposition is less evident and becomes an important issue to control the release of volatiles. Scheme 1 shows a typical fabric softening process in a washing machine. A concentrated surfactant emulsion, serving as the softening agent, is rinsed into a larger volume of water corresponding to a dilution by a factor of ca. 300. The active agent is then deposited from this diluted surfactant emulsion onto the fabric (cotton) surface. After stirring for a short time, the emulsion is withdrawn and the fabric dried. To achieve a controlled release effect, it is important to understand and control the release

Scheme 2. Preparation of β-Mercapto Ketone 1 by 1,4-Addition of 2-Mercaptoethanol to δ-Damascone

properties of the delivery system in aqueous solution (during the washing cycle), the amount of its deposition onto the fabric, as well as the evaporation kinetics on dry fabric (after the washing cycle).

In this study, we thus prepared a series of maleic anhydride-based δ-damascone conjugates in an easy one-pot, two-step process using 2-mercaptoethanol as a linker. 1,4-Addition of the thiol group to the enone double bond of δ-damascone gave β-mercapto ketone **1** (Scheme 2), which then reacted by nucleophilic ring-opening with poly(maleic anhydride) copolymers.

The release of the fragrances by retro 1,4-addition was investigated in solution as a function of pH by solvent extraction. The copolymer conjugates were labeled with pyren-1-ylmethanol (*44*) to quantify their deposition from an aqueous dispersion onto a cotton surface in the presence of a cationic surfactant. Finally, the influence of the polymer backbone structure on the amount of polymer deposition and release of δ-damascone was investigated by dynamic headspace analysis (*45–47*) on dry cotton.

EXPERIMENTAL PROCEDURES

General. Commercially available reagents and solvents were used without further purification if not stated otherwise. Reactions were carried out in standard glassware under N_2 or Ar, and yields were not optimized. Demineralized H_2O: Millipore-Synergy-185 water purifier. IR Spectra: Perkin-Elmer-1600-FTIR spectrometer; $\tilde{\nu}$ of weak (w), medium (m), or strong (s) bands in cm^{-1}. ^1H and ^{13}C NMR spectra: Bruker-DPX-400 spectrometer; δ in ppm downfield from Me_4Si as internal standard, J in Hz. High-resolution mass spectra (HRMS) were recorded in the multimode (MM) on an Agilent 1200 RR high-performance liquid chromatograph, equipped with an Agilent Eclipse Plus C18 column (2.1 × 100 mm inner diameter (i.d.)), eluted at 0.5 mL min^{-1} with a gradient of water (containing 0.1% of formic acid)/acetonitrile at 50 °C and coupled to a MSD TOF HR G3250A mass spectrometer (MM source, dual mode positive) at 250 °C, with the N_2 flow at 5 mL min^{-1}, the nebulizer pressure at 40 psi, the capillary voltage at 3000 V, and the fragmentor voltage at 140 V.

Analytical Size-Exclusion Chromatography (SEC). SEC analyses were carried out at room temperature (ca. 22 °C) with a system composed of a Thermo Finnigan Surveyor vacuum online degasser, quaternary LC pump, autosampler, and UV/vis detector, combined with a Thermo Separation Products (tsp) Spectra System IR 150 refractometer and a Viscotek 270 Dual Detector viscometer. Samples were eluted from a Macherey Nagel Nucleogel GPC 104-5 column (300 × 7.7 mm i.d., particle size 5 μm) at a flow rate of 1.0 mL min^{-1} by using HPLC-grade tetrahydrofuran (THF) from SDS. Universal calibrations were performed with the viscometer and the RI detector using commercial poly(styrene) standards from Fluka. Ca. 40 mg of the polymer standard was accurately weighed and dissolved in 10 mL of THF; then 50 μL aliquots of those solutions were injected for the calibration. Molecular weights of poly(maleic anhydrides) were given by the manufacturer to

be M_n = 30 000−50 000 g mol^{-1} (**2**), M_w = 60 000 g mol^{-1} (**3**), M_w = 100 000−500 000 g mol^{-1} (**4**), and M_w = 200 000 g mol^{-1} (**5**).

3-(2-Hydroxy-ethylsulfanyl)-1-(2,6,6-trimethyl-cyclohex-3-enyl)-butan-1-one (1). (*E*)-1-(2,6,6-Trimethylcyclohex-3-enyl)-but-2-en-1-one (δ-damascone, 10.0 g, 52.1 mmol) and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU, 0.78 mL, 5.21 mmol) were dissolved in THF (50 mL) prior to the dropwise addition of a solution of 2-mercaptoethanol (3.5 mL, 50 mmol) in THF (20 mL) at 45 °C; the mixture was then stirred for 12 h. Treatment with 5% aqueous HCl, extraction with Et_2O, and consecutive washing of the organic phase with a saturated aqueous solution of $NaHCO_3$ and a saturated solution of NaCl afforded an organic phase which was dried (Na_2SO_4), filtered, and concentrated to give a colorless oil (13.8 g, 99%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.53 (m, 1H), 5.45 (m, 1H), 3.77 (m, 2H), 3.35 (sext., 6.9 Hz, 1H), 2.96 (m, 1H), 2.88 (m, 1H), 2.86−2.63 (m, 3H), 2.60−2.45 (m, 2H), 2.23 (m, 1H), 1.97 (m, 1H), 1.70 (m, 1H), 1.31 (m, 3H), 1.02 (m, 1H), 0.96 (m, 5H), 0.92 (d, 6.9 Hz, 2H), 0.88 (d, 6.9 Hz, 1H) ppm. ^{13}C NMR (100.6 MHz, $CDCl_3$): δ 212.76 (s), 212.61 (s), 131.81 (d), 131.68 (d), 124.23 (d), 124.13 (d), 67.96 (t), 62.89 (d), 61.15 (t), 61.13 (t), 55.13 (t), 41.75 (t), 41.70 (t), 36.48 (q), 34.38 (t), 34.27 (t), 34.05 (d), 33.98 (d), 33.20 (q), 33.13 (q), 31.75 (d), 31.69 (d), 31.44 (d), 31.38 (d), 29.85 (q), 29.75 (q), 25.60 (t), 22.32 (q), 22.14 (q), 20.75 (q), 20.73 (q), 19.92 (q), 19.88 (q) ppm. IR (neat): 3415w, 3018w, 2956m, 2928m, 2871m, 2830w, 1703s, 1667m, 1625w, 1457m, 1430w, 1386m, 1366s, 1286w, 1250w, 1212w, 1153m, 1115m, 1044s, 999s, 953w, 932w, 895w, 843w, 690s cm^{-1}. General Procedure to Prepare Alternating Copolymers of Maleic Acid-Based Profragrances. δ-Damascone (2.68 g, 13.94 mmol), 2-mercaptoethanol (1.08 g, 13.80 mmol), and 2,3,4,6,7,8,9,10-octahydropyrimido[1,2-*a*]azepine (0.21 mL, 1.39 mmol) were dissolved in acetone (50 mL) to give a colorless solution. The solution was stirred at 45 °C for 2 h. Thin layer chromatography (TLC) in ethyl acetate showed a complete conversion; no more 2-mercaptoethanol was detected (rf = 0.15). Pyren-1-ylmethanol (31.70 mg, 0.14 mmol) was added to the solution before one of the copolymers **2**−**5** (13.94 mmol of maleic anhydride unit) in acetone (30 mL) was added dropwise. The reaction mixture was stirred at 45 °C for 48 h. Copolymers **6**−**9** were obtained by precipitation from pentane or diethyl ether, filtered, and dried under vacuum at 50 °C for 24 h.

Alternating Copolymer of 1-Octadecene and Maleic Acid Mono-{2-[1-methyl-3-oxo-3-(2,6,6-trimethyl-cyclohex-3-enyl)-propylsulfanyl]ethyl} Ester Labeled with Pyren-1-ylmethanol (6). Precipitation afforded a white solid (4.82 g, 70%, conversion (of **1**) 51%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.46−8.22 (br. m, 0.08H), 7.02 (br. m, 0.01H), 5.52 (m, 1H), 5.46 (m, 1H), 4.09 (m, 1.5H), 3.51 (m, 1H), 3.28 (m, 6H), 2.96 (s, 6H), 2.74 (m, 4H), 2.59 (m, 1.5H), 2.43−2.15 (br. m, 4H), 1.93 (m, 3H), 1.63 (m, 5H), 1.18 (m, 60H), 0.96 (m, 4H), 0.82 (m, 13H) ppm. ^{13}C NMR (DMSO-d_6, 100.6 MHz): δ 162.64 (s), 131.54 (d), 124.13 (d), 62.97 (d), 61.37 (t), 54.45 (t), 45.33 (t), 40.97 (t), 36.42 (q), 33.88 (t), 32.52 (t), 31.41 (t), 31.34 (d), 31.02 (q), 29.24 (t), 22.09 (t), 21.40 (q), 20.52 (q), 20.36 (q), 19.34 (q) ppm. IR (neat): 3634 to 2324m, 3018w, 2922s, 2852s, 2605w, 2498w, 1778w, 1726m, 1710m, 1649m, 1625w, 1567m, 1464m, 1397w, 1386m, 1366m, 1323w, 1167s cm^{-1}. M_w = 68 600 g mol^{-1}. M_n = 28 000 g mol^{-1}.

Alternating Copolymer of Isobutylene and Maleic Acid Mono-{2-[1-methyl-3-oxo-3-(2,6,6-trimethyl-cyclohex-3-enyl)-propylsulfanyl]ethyl} Ester Labeled with Pyren-1-ylmethanol (7). Precipitation afforded a white solid (1.91 g, 65%, conversion (of **1**) 20%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.63−8.19 (br. m, 0.05H), 7.71 (m, 0.01H), 7.04 (m, 0.03H), 5.54 (m, 1H), 5.46 (m, 1H), 4.95 (m, 3H), 4.08 (m, 2H), 3.61 (m, 2H), 3.54 (m, 6H), 3.48 (m, 6H), 3.30 (m, 3H), 2.68 (m, 9H), 2.31 (m, 9H), 1.97 (m, 18H), 1.06 (br. m, 24H) ppm. ^{13}C NMR (DMSO-d_6, 100.6 MHz): δ 165.31 (s), 162.25 (s), 131.56 (d), 124.13 (d), 61.45 (d), 41.77 (d), 23.40 (br. d) ppm. IR (neat): 3768 to 2495w, 2959m, 2937w, 2879m, 1786s, 1731s, 1646s, 1585w, 1469m, 1394m, 1371m, 1321m, 1175s cm^{-1}.

Alternating Copolymer of Ethylene and Maleic Acid Mono-{2-[1-methyl-3-oxo-3-(2,6,6-trimethyl-cyclohex-3-enyl)propylsulfanyl]ethyl} Ester Labeled with Pyren-1-ylmethanol (8). Precipitation afforded a white solid (3.27 g, 89%, conversion (of **1**) 50%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.52−8.16 (br. m, 0.17H), 5.54 (m, 1H), 5.47 (m, 1H), 4.09 (m, 2H), 3.52 (m, 4H), 3.25 (m, 3H), 3.01 (m, 2H), 2.87 (m, 10H), 2.71 (m, 4H), 2.32 (m, 3H), 2.12 (m, 3H), 1.93 (m, 3H), 1.63 (m, 5H), 1.43 (m, 5H), 1.24 (m, 4H), 0.95 (m, 3H), 0.84 (m, 6H) ppm. ^{13}C NMR (DMSO-d_6, 100.6 MHz): δ 211.93 (s), 176.46 (s), 131.53 (d), 124.15 (d), 63.02 (t), 61.31 (t), 60.96 (d), 54.36 (t), 54.19 (t), 53.25 (d), 49.64 (t), 42.72 (d), 37.53 (d), 34.00 (s), 32.52 (d), 31.57 (d), 31.13 (d), 31.03 (t), 28.16 (t), 25.82 (t), 23.27 (q), 21.49 (q), 21.30 (q), 20.31 (q), 19.38 (q), 18.82 (q), 9.36 (q) ppm. Alternating Copolymer of Methoxyethylene and Maleic Acid Mono-(α-methoxy-poly(ethylene oxide)) And Mono-{2-[1-methyl-3-oxo-3-(2,6,6-trimethyl-cyclohex-3-enyl)propylsulfanyl]ethyl} Esters Labeled with Pyren-1-ylmethanol (10). Copolymer **5** (10 mmol) was dissolved in acetone (40 mL) prior to the dropwise addition of a solution of **1** (8 mmol), pyren-1-ylmethanol (0.01 mmol), and α-methoxy-poly(ethylene glycol) (2 mmol, M_n = 550 g mol^{-1}) in acetone (30 mL) and a solution of triethylamine (10 mmol) and 4-dimethylaminopyridine (DMAP, 61 mg, 0.5 mmol) in acetone (30 mL) at 0 °C. The mixture was heated at 40 °C for 24 h. The cooled mixture was then diluted with dichloromethane and extracted with aqueous HCl (5%), dried (Na_2SO_4), filtered, concentrated, and precipitated from pentane to afford a red solid (4.69 g, 88%, conversion (of **1**) 75%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.46−8.02 (br. m, 0.09H), 7.22 (m, 0.02H), 5.54 (m, 1H), 5.45 (m, 1H), 4.78 (m, 0.3H), 4.57 (m, 0.3H), 4.09 (m, 1.8H), 3.51 (m, 15H), 3.33 (m, 28H), 2.88 (m, 1.3H), 2.74 (m, 3H), 2.61 (m, 2H), 2.32 (m, 2H), 1.94 (m, 2H), 1.65 (m, 3H), 1.24 (m, 3H), 0.94 (m, 3H), 0.83 (m, 6H) ppm. ^{13}C NMR (DMSO-d_6, 100.6 MHz): δ 211.71 (s), 165.31 (s), 131.51 (d), 124.10 (d), 71.16 (t), 69.66 (t), 63.18 (d), 61.30 (s), 60.99 (t), 40.99 (q), 37.54 (d), 34.02 (d), 33.85 (s), 32.57 (t), 32.51 (t), 31.64 (t), 31.14 (t), 31.02 (t), 29.04 (s), 27.81 (t), 21.45 (br. q), 20.45 (q), 19.33 (q) ppm. IR

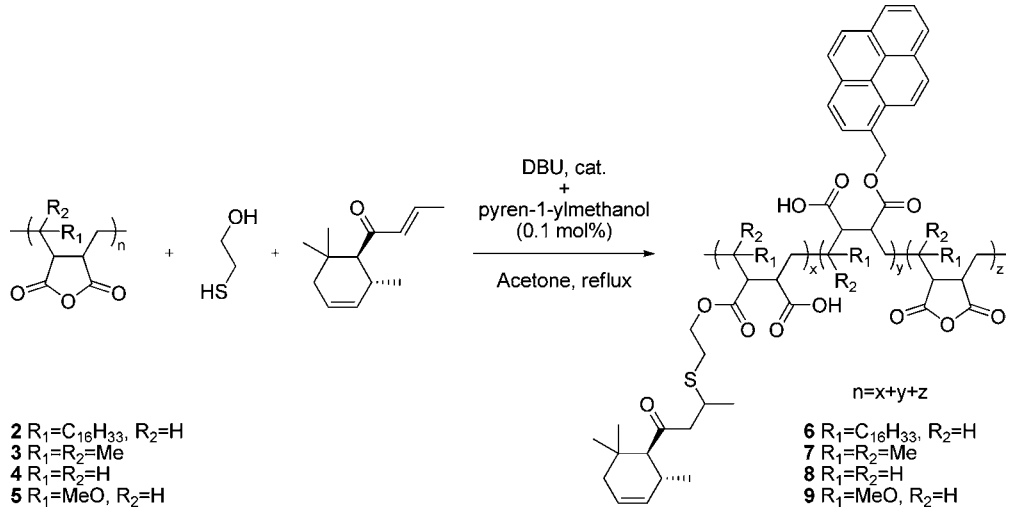
(neat): 3675 to 2323m, 2953m, 2930m, 2884m, 2831w, 1727s, 1705s, 1648m, 1587w, 1453m, 1386w, 1365m, 1323w, 1172s cm^{-1}.

Controlled Release of δ-Damascone From Copolymers 6−10 in Buffered Solutions. According to the molecular mass of their repeat unit, copolymers **6**−**10** were dispersed in a buffered aqueous solution (CertiPUR from Merck, 5 mL) at pHs 4, 7, and 10, respectively. The solutions thus contained equimolar concentrations of δ-damascone (0.045 mmol mL^{-1} or 8.7 mg mL^{-1}). Samples were stirred for 1 h to obtain a solution or a homogeneous dispersion. Each solution or dispersion was divided into four samples of 1 mL and mixed with 1 mL of a solution of 1,4-dibromobenzene at 150 mg L^{-1} (internal standard) in a mixture of isooctane/diethyl ether (9:1). The samples were stirred at 25 °C in a water bath for 1, 3, and 6 days. The δ-damascone content in the organic phase was analyzed by gas chromatography (GC) using a GC 7890A system equipped with an auto sampler 7683 series from Agilent Technologies (1 μL injected) and a HP-5 column (30 m, i.d. 0.32 mm, film thickness 0.25 μm). The volatiles were analyzed by GC at 100 °C for 1 min and then heated to 170 at 10 °C min^{-1}, for a total run time of 8 min. Helium was the mobile gas phase; the split ratio was 50:1. A calibration curve was measured and used to quantify δ-damascone. All samples were analyzed in triplicate.

Thermogravimetric Analysis (TGA). Solid contents were measured by thermogravimetry using an organic phase solution (20 μL) and placed with a precision syringe (Hamilton - Bonaduz, Switzerland, 25 μL) inside an aluminum pan (Mettler-Toledo ME-26763 40 μL) that had been previously weighed on a precision balance (Mettler-Toledo XP204S). Measurements were carried out under a constant nitrogen flow (20 mL min^{-1}) with a thermogravimetric analyzer (Mettler-Toledo TGA/SDTA851ᵉ) equipped with a microbalance (accuracy: 1 μg) and an accurate oven having an internal volume of 35 mL. Temperatures were increased from 25 to 80 °C at 10 °C min^{-1} and kept at 80 °C for 25 min and 30 s. All measurements were performed in triplicate.

The stability of copolymers **6** and **9** (data not shown) was measured by thermogravimetry. Solids were placed inside an aluminum pan that had been previously weighed on a precision balance. Temperatures were increased from 20 to 270 at 10 °C min^{-1} under a constant nitrogen flow (20 mL min^{-1}).



Preparation of Aqueous Surfactant Emulsions. A cationic surfactant containing emulsion with the following composition was prepared: Stepantex VK90 (Stepan) 16.5%, calcium chloride 0.2%, water 83.3%. A total of 1.0% to 5.5%, depending on the δ-damascone content of the polymers, of poly(maleic acid)-based copolymers was added to the softener formulation. All values are given in % by weight.

Procedure for Polymer Deposition on Cotton. The fabric softening process in a washing machine as illustrated in Scheme 1 was transferred to a laboratory scale. In a beaker (1 L), poly(maleic acid)-based copolymers **6**−**10** (**6**, 43.6 mg (2.4%) in THF (3 mL); **7**, 48.3 mg (2.7%) in methanol (5 mL); **8**, 23.5 mg (1.3%) in methanol (5 mL); **9**, 348.7 mg (10% in dipropylene glycol (DIPG), 1.9%); **10**, 312.5 mg (10% in DIPG, 1.7%), all of which can release a total amount of 8.7 mg of δ-damascone) were added to the aqueous concentrated surfactant emulsion (1.80 g, pH ca. 3.1), respectively, and the resulting mixtures stirred for 18 h. The emulsions were then placed in a beaker (1 L) and diluted with demineralized cold tap water (600 g). One cotton sheet (Eidgenössische Materialprüfanstalt (EMPA, Switzerland), cotton test cloth Nr. 221, cut to ca. 12 × 12 cm^2 sheets (average mass ca. 3.5 g) and prewashed with an unperfumed detergent powder (perfumery application laboratories)) was added in a beaker to the diluted surfactant emulsion (pH ca. 4.1) and manually stirred for 3 min, left standing for 2 min, and then wrung out by hand and weighed (average mass ca. 7 g) to estimate the quantity of residual water and to ensure that each cotton sheet was loaded with the same amount of diluted surfactant emulsion. As a reference sample, a solution (1 mL) containing an equimolar amount of unmodified δ-damascone (87.2 mg in 10 mL of acetone) was added to another 1.80 g of the original fabric softener formulation, which was treated as described above. All cotton sheets were line dried for 3 days.

Procedure for Fluorescence Measurements. Poly(maleic acid)-based copolymers **6**−**10** were added to the aqueous surfactant emulsion and diluted with demineralized cold tap water as described above. Several aliquots of the emulsions were pipetted off (1.0, 0.5, and 0.1 mL) and adjusted to 1.0 mL with the diluted aqueous surfactant emulsion. For the verification of the linearity of the fluorescence intensity with respect to the copolymer concentration, additional points using 0.75 and 0.25 mL of the emulsion were recorded. All samples were then further diluted with demineralized water by a factor of 100 and analyzed by fluorescence spectroscopy. Measurements were carried out on a Jobin Yvon Fluorolog-3 spectrometer equipped with DataMax software. The average spectra of three scans were recorded between 370 and 400 nm, with an excitation wavelength of 334 nm, increment 0.5 nm, integration time 0.5 s, slit excitation 1.5 nm, and slit emission 1.5 nm. Data were analyzed at 378, 384, 389, and 398 nm. The fluorescence intensity measured for the 1.00 mL aliquot served as the reference corresponding to 0% of deposition and the other aliquots as external standard calibration of the corresponding polymer. Then, one cotton sheet (see above) was added to each beaker containing the diluted emulsions with the copolymer, and manually stirred for 3 min, left standing for 2 min, and then wrung out by hand, and line-dried for 3 days (see above). The remaining emulsion (1.00 mL) was diluted by a factor of 100 and analyzed by fluorescence spectroscopy as described above to determine the amount of remaining nondeposited copolymer. The missing amount with respect to the first fluorescence measurement was assumed as being deposited on the fabric surface. All measurements were carried out in duplicate.

Procedure for Dynamic Headspace Sampling. One of the dry cotton sheets was put into a headspace sampling cell (internal volume ca. 160 mL), thermostatted at 25 °C, and exposed to a constant airflow (200 mL min^{-1}), respectively (*48*). The air was filtered through active charcoal and aspirated through a saturated solution of NaCl, corresponding to a constant humidity of ca. 75% (*49*). For 15 min, the volatiles were adsorbed onto a waste Tenax cartridge and then for 15 min onto a clean Tenax cartridge. The sampling was repeated seven times every 60 min (45 min trapping on the waste cartridge and 15 min on a clean cartridge) (*48*); the waste cartridges were discarded. The cartridges with the volatiles were desorbed on a Perkin-Elmer TurboMatrix ATD 350 desorber coupled to a Perkin-Elmer Autosystem XL gas chromatograph equipped with a J&W Scientific DB1 capillary column (30 m, i.d. 0.25 mm, film thickness 0.25 μm) and a Perkin-Elmer Turbomass Upgrade mass spectrometer. The volatiles were analyzed by GC using a two-step temperature gradient starting from 70 to 130 °C at 3 °C min^{-1} and then heating to 260 at 25 °C min^{-1}. The injection temperature was at 240 °C and the detector temperature at 260 °C. External standard calibrations were carried out using six different concentrations of δ-damascone in acetone (varying between 1.96×10^{-6} and 9.26×10^{-4} mol L^{-1}). Each calibration solution (2 μL) was injected with a microliter syringe onto three clean Tenax cartridges, respectively. All the cartridges were desorbed immediately under the same conditions as those resulting from the headspace sampling (see above). Because

Scheme 3. Preparation of Poly(maleic acid monoester)-Based δ-Damascone Conjugates 6 ($x = 55$, $y = 0.1$, $z = 50$), 7 ($x = 65$, $y = 0.3$, $z = 260$), 8 ($x = 640$, $y = 1$, $z = 640$), and 9 ($x = 320$, $y = 1$, $z = 750$)

the quantities of released compounds were monitored at very low concentrations, the calibration curve was forced through the origin of the coordinate system. Plotting the concentrations (in ng L^{-1}) against the peak areas gave a straight line with a correlation coefficient of $r^2 > 0.9990$. All experiments were carried out in duplicate.

RESULTS AND DISCUSSION

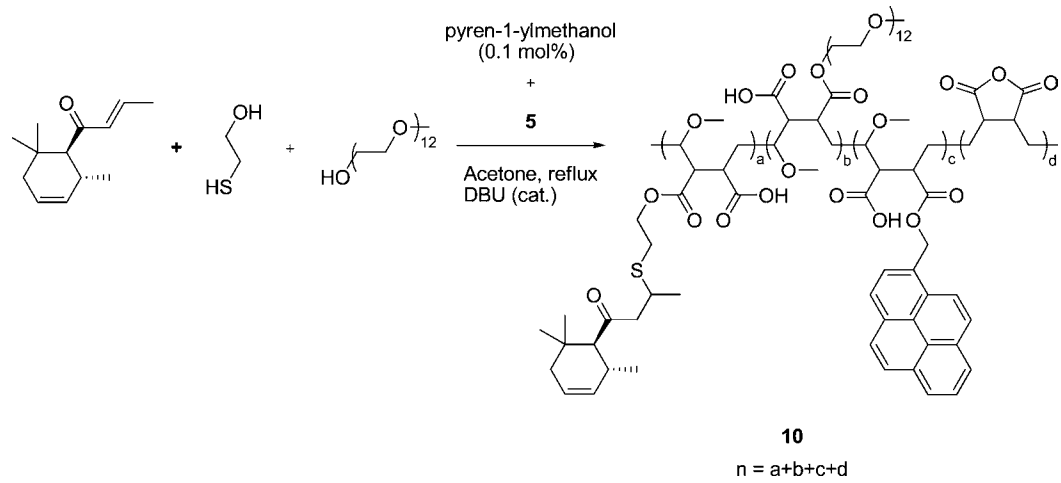
Preparation of Poly(maleic acid)-Based Profragrances. Poly(maleic acid)-based conjugates of δ-damascone were prepared in a one-pot procedure consisting of two reaction steps. In the first step, 2-mercaptoethanol, serving as a linker (*50*), was reacted with a slight excess of δ-damascone to give 1,4-addition product **1** in very good yields (Scheme 2). This reaction step was carried out in the presence of catalytic amounts of DBU as a base (*31*). β-Mercapto ketone **1** was isolated for full characterization. ^{1}H NMR analysis showed the disappearance of the enone double bond and the appearance of two signals corresponding to the formation of the thioether (a sextuplet at 3.3−3.4 ppm for the CH group of the rose ketone moiety and a multiplet at 2.5−2.8 for the CH_2 group of the ethylene linker), whereas the signals of the other double bonds remained unchanged.

After complete reaction of the mercaptoethanol, as shown by TLC in ethyl acetate, one of the commercially available poly(maleic anhydride) copolymers **2**−**5**, respectively, was added as the second reaction step to react with the primary alcohol function of **1** upon ring-opening of the maleic anhydride function (Scheme 3).

Copolymers **2**−**5**, obtained by copolymerization of maleic anhydride with 1-octadecene, isobutylene, ethylene, or methyl vinylether, respectively, are commercially available. Alternating copolymer **5**, for example, is supplied by ISP Technologies under the trade name Gantrez and used as an ingredient in toothpaste and various pharmaceutical products (*43*).

Depending on the solubility of the copolymers, different solvents (DMF, THF, or acetone) were used for the reaction with β-mercapto ketone **1**. Four different bases, namely, pyridine, tributylamine, triisobutylamine, and triethylamine (Et_3N), with a catalytic amount of DMAP, were tested to open the maleic anhydride moiety of **2**−**5** with **1** to give polymer conjugates **6**−**10** (Scheme 3); triethylamine led to the best conversions (*36*–*41*).

In this work, the one-pot two-step preparation of copolymers **6**−**10** was carried out in acetone, which is a convenient solvent for an industrial scaleup. Intermediate **1** was synthesized in situ by adding 2-mercaptoethanol to δ-damascone in the presence of DBU as catalyst. When the conversion was completed, the acetone solutions of copolymers **2**−**5** were added to **1**. We observed that the presence of DBU as a base was sufficient to reach acceptable conversion (see Experimental Procedures).



Grafting a fluorescent marker onto the polymer backbone (*44*) is convenient to measure the deposition on various surfaces. We labeled our polymer conjugates by adding pyren-1-ylmethanol to the reaction mixture (*51*). Its concentration was limited to 0.1 mol % to avoid saturation of the fluorescent signal and to keep the physical properties of copolymers **6**−**10**. Amphiphilic polymer conjugates are known to aggregate in surfactant emulsions (*52*). However, this aspect was not studied in the context of this work because it requires higher grafting of the fluorescence moiety.

The conversion of the grafting reaction was analyzed by ^{1}H NMR spectroscopy by integrating the signals of the cyclohexene double bonds (between 5.45 and 5.85 ppm) of alcohol **1** and comparing them with characteristic resonances from the different copolymers **2**−**5**, such as the signal of the methyl group of the alkyl chain of 1-octadecene in **2** (at 0.87 ppm), the signal of the dimethyl group of the isobutylene unit in **3** (at 1.07 ppm), the broad signal of the poly(ethylene) backbone in **4** (1.40 to 2.15 ppm), and the signal of the methyl ether (at 3.36 ppm) of copolymer **5**.

Despite the fact that ring-opening of maleic anhydride creates carboxylic acid functions that increase the polarity of the polymer backbone, this effect was counterbalanced by the introduction of the rather hydrophobic rose ketone release unit. In contrast to copolymer **9**, conjugates **6**−**8** were found to be almost insoluble in aqueous media and gave only dispersions. This solubility profile indicates that minor structural modifications of the copolymer structure have an important influence on the physicochemical properties of the resulting conjugate (*28*, *29*). The release of δ-damascone from the thioether conjugate is pH dependent. Although relatively stable under acidic conditions, the precursors slowly release the bioactive compound at pH values above 6 (*31*). Furthermore, for an efficient release, the polymer must be soluble, or at least well-dispersed, in water (*28*).

To fine-tune the water solubility, we grafted poly(ethylene glycol) side chains onto the polymer backbone by using the same one-pot synthesis described above. PEG is a water-soluble and biocompatible polymer that has already been used to modify

different poly(maleic anhydride) copolymers of styrene (*53*), 1-hexene (*54*), and methyl vinyl ether (*55*). We thus prepared a PEG-modified analogue of copolymer **9** by adding a mixture of a poly(ethylene glycol) monomethyl ether (20 mol % with respect to the maleic anhydride unit) and **1** (80 mol %) to polymer **5** to afford conjugate **10** (Scheme 4). The grafting of the PEG chains on **5** was complete, and conversion of **1** was estimated at 75 mol %.

Measurement of the Controlled Release of δ-Damascone from Poly(Maleic Acid)-Based Conjugates in Buffered Solutions at pH 4, 7, and 10 as a Function of Time. In technical applications or under physiological conditions, Michael-type 1,4-addition of thiols to α,β-unsaturated ketones can be reversible, as described for the reaction of prostaglandins with various thiols (*56*). In the present study, the release of δ-damascone from copolymers **6**−**10** is presumably also controlled by this mechanism (Scheme 5).

The influence of the copolymer structure on the release of δ-damascone from conjugates **6**−**10** was first studied in buffered aqueous solution at different pH values. The pH influences the kinetics of the retro 1,4-addition. Furthermore, the solubility of the different delivery systems in aqueous media is impacted by the pH because the carboxylic acid functions can be deprotonated under neutral or alkaline conditions (*28*). The amount of each polymer was chosen to release the same concentration of δ-damascone in all samples, that is to say, 8.7 mg mL^{-1} or 8700 ng μL^{-1}. In order to prevent equilibration, a nonmiscible organic solvent, a mixture of isooctane/diethyl ether (9:1), was added to the system to continuously extract the released δ-damascone (*30*). Organic and water phases were gently stirred so as not to mix with each other at pH 4 (the pH of fabric softener applications), 7, and 10 (the pH of liquid detergent applications) for different times. The quantity of δ-damascone released into the organic phase was analyzed by GC. Results were plotted as a function of pH for copolymers **6**−**10** after 1, 3, and 6 days (Figures 1a−d).

In solution, the release of δ-damascone is strongly influenced by the polymer backbone. When the polymer contained methyl groups or hydrogen atoms, as in copolymers **7** and **8**, respectively, the solubility in the buffered solutions was very limited, especially at low pH. Both copolymers **7** and **8** gave stable dispersions at pH 4 and 7, and were soluble only at pH 10. They released only 253.9 and 325.2 ng μL^{-1} of δ-damascone at pH 10 after 6 days, which corresponded to 2.9% and 3.7% of δ-damascone grafted on the copolymers, respectively.

When the comonomer of the backbone contained a methoxy group, the resulting copolymer **9** was soluble at all pH values. A faster release was observed with a δ-damascone concentration of 999.5 ng μL^{-1} measured at pH 10 after 6 days. This trend suggests that the higher solubility of a copolymer facilitates the release by retro 1,4-addition. This result was confirmed at the example of copolymer **10**, which was modified with PEG side

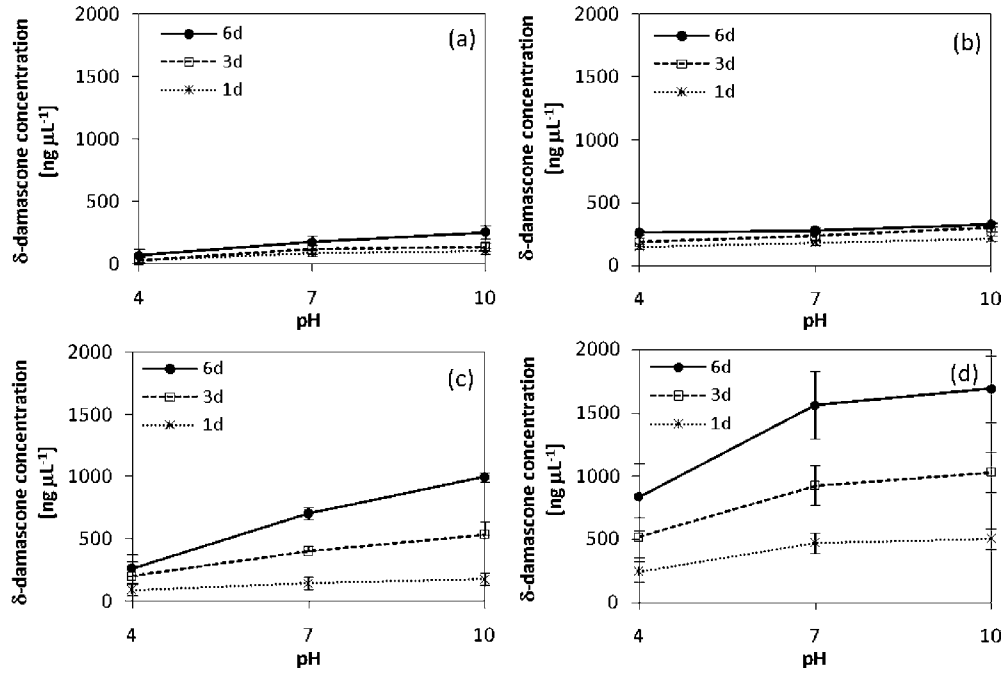

Figure 1. a−d. Concentrations of δ-damascone released from copolymers **7** (a, $R_1 = R_2 =$ Me), **8** (b, $R_1 = R_2 =$ H), **9** (c, $R_1 =$ MeO), and **10** (d, $R_1 =$ MeO + PEG chain ester) as a function of pH after 1, 3, and 6 days as determined by GC analysis.

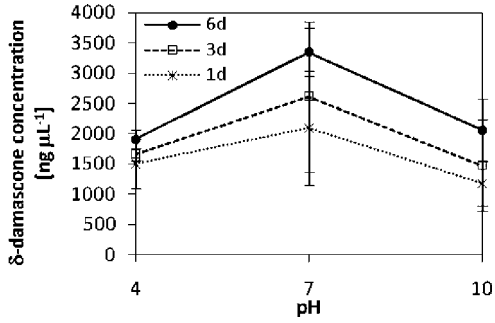

Figure 2. Concentrations of δ-damascone released from copolymer **6** as a function of pH after 1, 3, and 6 days as determined by GC analysis.

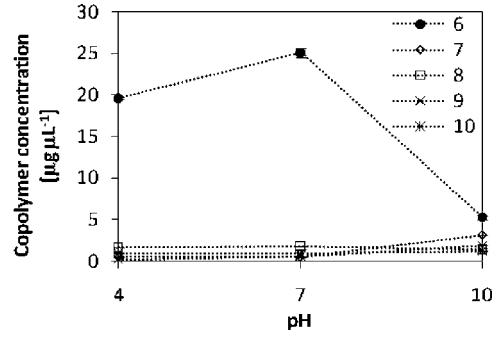

Figure 3. Concentrations (in mg mL^{-1}) of copolymers **6−10** extracted from buffered aqueous solutions into the organic phase as a function of pH after 1 day as determined by thermogravimetric analysis.

chains. Its solubility was significantly improved, and the amount of δ-damascone released from copolymer **10** increased faster than in the case of the unmodified copolymer **9**, even at pH 4 (Figure 1d). The measured δ-damascone concentrations varied between 836.2 ng μL^{-1} at pH 4 and 1689.9 ng μL^{-1} at pH 10, corresponding to a release of 19.4%.

Nonetheless, high water solubility might prevent an efficient deposition of the copolymers on a fabric surface. Therefore, we were also interested in understanding the release from more hydrophobic structures, such as copolymer **6** with a hexadecyl side chain. As observed with copolymers **7−10**, the release of δ-damascone from **6** increased with time at different pH values (Figure 2). However, after 1 and 3 days, we observed a more important δ-damascone release at pH 4 than at pH 10. These results are different from those obtained with copolymers **7−10** and in contradiction with the mechanism of release (Scheme 5). In addition, high variability of the data was observed, indicating an uncontrolled process.

In comparison with copolymers **7−10**, the presence of the hexadecyl side chain should change the solubility profile of copolymer **6**, and we expected that a large part of the copolymer was dissolved in the organic phase. The solubility of all copolymers was thus estimated by thermogravimetry. We placed 20 μL of the organic phase (isooctane/diethylether 9:1) inside an aluminum pan, which was dried in a thermogravimeter at 80 °C for 30 min. A plateau was reached, indicating that the samples were dried. The experiment was repeated with the pure extraction solvent, which served as the reference. The difference between both plateaus corresponds to the concentration of polymer in the organic phase. Data obtained from measurements performed after one day are reported in Figure 3.

Concentrations of copolymers were measured at different pH values as a function of time (Table 1). As expected, the concentrations of copolymers **7−10** in the organic phase are relatively low. The concentration of copolymer **7** in the organic phase was at maximum 1−2%. The concentration of copolymer **8** leveled off at around 6−7%, indicating a saturation of the organic phase, even after 1 day. Solubilization of copolymers **9** and **10** in the organic phase increased slowly with time but did not exceed 8% and 7%, respectively.

In contrast, 45% and 58% of copolymer **6** were detected in the organic phase at pH 4 and 7, respectively (Table 1). These concentrations increased with time to reach a maximum at about 78% at pH 7 after 6 days and decreased to 12% at pH 10. At this pH, the carboxylic acid functions of the copolymer are mostly deprotonated, which makes the polymer less soluble in the organic phase. Furthermore, the release of δ-damascone increases the polarity of the polymer and thus decreases its solubility in the organic phase.

Table 1. Concentrations (in μg μL^{-1} and %) of Copolymers 6−10 in the Organic Phase as a Function of pH and Time

		copolymers dissolved in organic phase [μg μL^{-1}] ([%])				
pH	day #	**6**	**7**	**8**	**9**	**10**
	1	19.63 (45.2)	0.50 (1.0)	1.62 (6.9)	0.22 (0.6)	0.97 (2.2)
4	3	22.08 (50.9)	0.14 (0.3)	1.51 (6.4)	0.44 (1.3)	2.67 (6.1)
	6	24.00 (55.3)	0.29 (0.6)	1.35 (5.7)	2.71 (7.8)	1.78 (6.7)
	1	25.13 (57.6)	0.52 (1.1)	1.79 (7.5)	0.55 (1.6)	0.90 (2.1)
7	3	31.75 (73.2)	0.48 (1.0)	1.69 (7.2)	0.73 (2.1)	1.35 (3.1)
	6	33.70 (77.7)	0.67 (1.4)	1.35 (5.7)	1.43 (4.1)	1.27 (4.0)
	1	5.25 (12.1)	0.35 (0.7)	1.41 (6.0)	1.87 (5.4)	1.20 (2.8)
10	3	1.00 (2.3)	0.19 (0.4)	1.44 (6.1)	0.68 (2.0)	1.42 (3.3)
	6	0.91 (2.1)	0.31 (0.7)	1.48 (6.3)	1.84 (5.3)	2.22 (7.0)

These results suggest that a large part of copolymer **6** was dissolved in the organic phase at pH 4 and 7. Its concentration in buffered aqueous solution must thus have decreased, which then slowed down the release of δ-damascone (Figure 2). The concentration of δ-damascone extracted from the aqueous phase was determined by GC analysis using a calibrated flame ionization detector (FID). The presence of copolymer **6** in the organic phase suggests that, at an injection temperature of 250 °C, additional amounts of δ-damascone and other volatiles might be generated by thermal degradation of the polymer conjugate. Therefore, we measured the stability of the copolymer at this temperature by using TGA. Pure copolymer **6** was placed inside an aluminum pan, which was transferred into the TGA. The temperature was increased from 25 to 270 at 10 °C min^{-1} and the mass loss measured as a function of time (Figure 4). A significant mass loss was detected in the range from 150 to 270 °C, corresponding to 38% of the total polymer mass. The same experiment was carried out with the starting copolymer **2**, and a mass loss of only 8% was measured in this case. This result demonstrated that copolymers of maleic acid were not stable at 250 °C (injector temperature represented by a dotted line in Figure 4) and that they degraded (*57*). We assume that this degradation first releases precursor **1**, which then further degrades (Scheme 6). This was confirmed by TGA analysis of **1** for which a complete mass loss was measured at 270 °C, suggesting either evaporation or degradation of **1**. With the boiling point of δ-damascone being 253 °C, we thus assume that copolymer **6** degrades, in fact, in two steps, as illustrated in Scheme 6. The thermal degradation of copolymer **6** extracted into the organic phase thus explains the large amount of δ-damascone detected in our GC measurements.

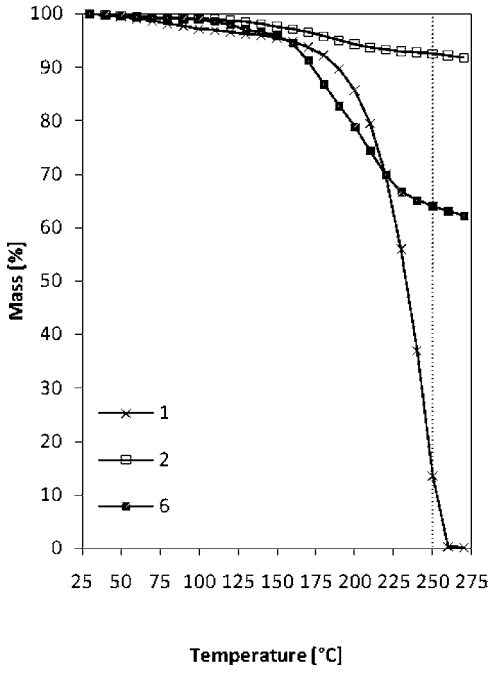

Figure 4. Thermogravimetric analysis of β-mercapto ketone **1** and copolymers **2** and **6** from 25 to 270 °C at 10 °C min^{-1}.

With the ester bond being much more stable than the β-mercapto ketone moiety (*15*), we did not expect the release of 2-mercaptoethanol under the mild reaction conditions found in the targeted application. This was confirmed by the fact that no smell arising from sulfur compounds was detected in the applications.

However, even if we were not able to accurately measure the release of δ-damascone from **6** at pH 4 and 7, the low concentration of this copolymer in the organic phase at pH 10 (Table 1), combined with the high concentration of released δ-damascone, suggested that copolymer **6** might nevertheless be a suitable δ-damascone delivery system in practical applications. The efficient release of δ-damascone at pH 10 emphasizes the importance of the polarity of the backbone on the release rate. The tendency observed at pH 10 was confirmed (at lower extent) at pH 4, which is the pH of our model application.

Deposition of the Copolymers from an Aqueous Environment onto Cotton. To test the potential of the different δ-damascone conjugates for practical applications in functional perfumery, we investigated the release of the active volatile in a fabric softening composition. Fabric softeners are particularly interesting in the context of this project, as they are usually acidic (pH ca. 3.1), which means that the polymer conjugates are expected to be stable during storage. In use (e.g., during a normal washing cycle), the fabric softener is diluted with water, resulting in an increase of pH to ca. 4.1, which should trigger the release of the damascone. Fabric softener formulations typically consist of about 16% by weight of a cationic surfactant in water, such as a quaternized triethanolamine ester of a fatty acid (TEA-esterquat) (*58*, *59*). Cationic surfactants are efficiently deposited onto cotton surfaces (*58*–*61*) and therefore facilitate the transport of apolar organic molecules such as fragrances from an aqueous environment onto textiles (*62*–*65*). It can be expected that the polymer conjugates are also deposited with the surfactant onto cotton surfaces. To ensure that the quantity of polymer deposited onto the cotton depends on the polymer structure and not on the deposition process, the amount of the diluted surfactant emulsion deposited on the cotton sheet was controlled (by weighing a constant amount of remaining water). As outlined above, the polymer deposition should depend on the copolymer structure and should thus be influenced by the nature of the comonomer (*28*). The polarity of the copolymer is expected to be further influenced by the pH of the system.

Besides the choice of the linker (*66*) and efficient deposition on the target surface, the amount of δ-damascone released into the headspace also depends on the release kinetics of the active compound from the corresponding polymer conjugate; these are dependent on the water solubility of the polymer, as previously shown for a series of poly(methacrylate) derivatives (*28*). At acidic pH, as in the softener formulation, the carboxylic acid functions of polymers **6**−**10** are protonated. The pK_a of the maleic acid units is a function of the degree of dissociation and

Scheme 6. Proposed Mechanism of Degradation of Copolymer 6 ($x = 55$, $y = 0.1$, $z = 50$) at 250°C in the GC Injector

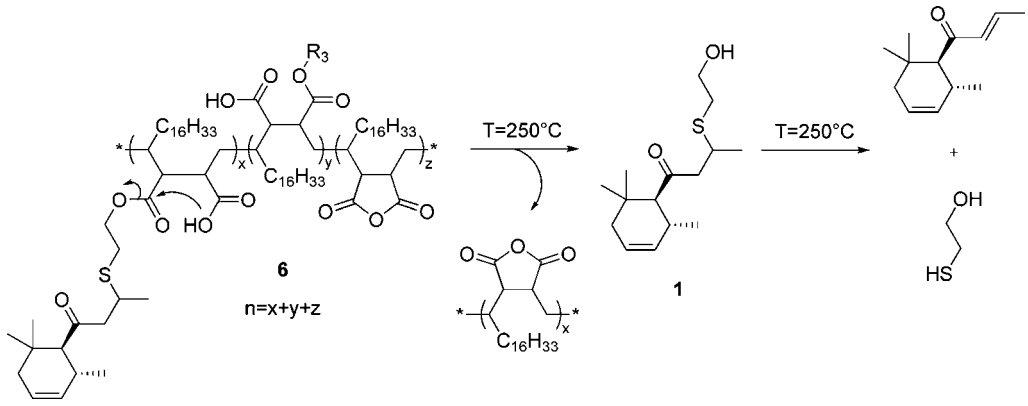

Table 2. Amount of Deposition of Pyrene-Labeled Poly(maleic acid)-Based δ-Damascone Conjugates 6−10 on Cotton as Determined by Fluorescence Spectroscopy (data recorded at 389 nm, excitation at 334 nm)

copolymer	deposition determined with respect to reference [%]	deposition determined by external standard calibration [%]	average deposition [%]	amount of conjugated δ-damascone deposited onto the cotton surface [%]
6	44	43	44	3.83
7	28	41	35	3.05
8	40	50	45	3.92
9	29	32	31	2.70
10	23	25	24	2.09

has been reported to be between 4 and 8 (*67*). Therefore, upon dilution during the application, the pH increases and the polymers become partially deprotonated, which results in an increased solubility of the conjugates in the aqueous medium. With the release being pH dependent (Figure 1) and triggered at a pH of ca. 6.5 and above (*31*), additional carboxylic acid functions are generated on the polymer backbone (Scheme 5). The water solubility of the polymer still increases, which should then accelerate the release of the active volatile.

The amount of polymer deposition on the cotton surface was determined with the help of the fluorescence label of copolymers **6**−**10**. In a typical experiment, equimolar amounts of copolymers with respect to the total amount of active compound to be released were solubilized in an appropriate solvent and pipetted into an aqueous emulsion of a TEA-esterquat, corresponding to a total of ca. 1.0−5.5% by weight of polymer in the surfactant emulsion. After the emulsion was stirred for several hours, it was diluted with tap water and a small aliquot pipetted off. The measured fluorescence intensity served as the reference, corresponding to 0% of deposition. Then, one cotton sheet was added and stirred manually for 5 min (to allow for the deposition of the surfactant and the polymer conjugate onto the cotton surface). The cotton sheet was removed before another aliquot of the surfactant emulsion was pipetted off, and then the cotton sheet was wrung out by hand and line-dried for 3 days. The measured fluorescence intensity reflected the quantity of the remaining nondeposited copolymer in the surfactant emulsion. The missing amount with respect to the reference measurement was assumed as being deposited on the fabric surface. The release of δ-damascone from the dry cotton surface was then analyzed by dynamic headspace analysis as described below.

Despite the fact that the fluorescence label corresponded to only about 0.1 mol % by weight of the total mass of the copolymer, its concentration in the surfactant emulsion was by far too high for accurate fluorescence measurements. A nonlinear fluorescence response was obtained by diluting the sample by a factor varying between 2 and 10. The surfactant emulsions were thus diluted by a factor of 100 and the fluorescence spectra recorded between 370 and 400 nm with an excitation at 334 nm. Additionally, the difference in fluorescence intensity measured at different wavelengths before and after addition of the cotton sheet was compared with data obtained by external standard calibration. Data were analyzed at 378, 384, 389, and 398 nm. The dependence of the fluorescence intensity at the different wavelengths with respect to the amount of polymer in the emulsion, after dilution by a factor 100, was verified with the example of δ-damascone conjugate **9**.

At all wavelengths, a linear relationship was observed when varying the polymer concentration over 1 order of magnitude, thus covering a range corresponding to 0−90% of deposition. Extrapolation of the fluorescence intensities to zero polymer concentration revealed some remaining fluorescence at 378 nm, whereas at the other wavelengths, the fluorescence decreased to a fluorescence intensity value close to zero. With the curve recorded at 389 nm having the steepest slope, we selected this wavelength for further analysis.

Table 2 lists the data obtained for the deposition of poly(maleic acid)-based δ-damascone conjugates **6**−**10** on cotton and indicates the total amount of conjugated δ-damascone transferred to the cotton surface. Our measurements confirmed the expected dependence of the polymer structure on the amount of surface deposition.

According to the copolymer structures, different amounts of the conjugates were deposited on the cotton surface, varying between 24% for the more hydrophilic polymer **10** and 45% for the more apolar structures **6** and **8**, thus confirming an inverse correlation of the deposition with the ease of dispersion of the materials in an aqueous environment, which was also reported previously for a series of poly(methacrylate) derivatives (*28, 30*).

Nevertheless, for practical application, the amount of δ-damascone to be delivered from the target surface is the most important factor to be considered for the efficiency of a delivery system. Increasing the deposition on the target substrate is the first step of optimization; controlling the rate of the covalent bond cleavage reaction is another parameter to be considered. The latter strongly depends on the local environment of the release site (*28–30*). As the next step, we thus determined the release of δ-damascone from the different poly(maleic acid) conjugates by dynamic headspace analysis after deposition of the polymers from an aqueous environment onto a cotton

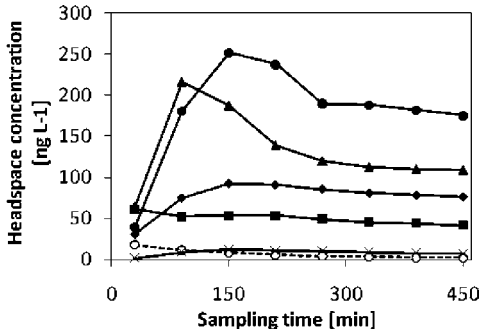

Figure 5. Headspace concentrations (in ng L^{-1} of air) measured for the evaporation of δ-damascone from poly(maleic acid)-based conjugates **6** (-◆-), **7** (-×-), **8** (-■-), **9** (-•-), and **10** (-▲-) on dry cotton after 3 days with respect to unmodified δ-damascone as the reference (---○---).

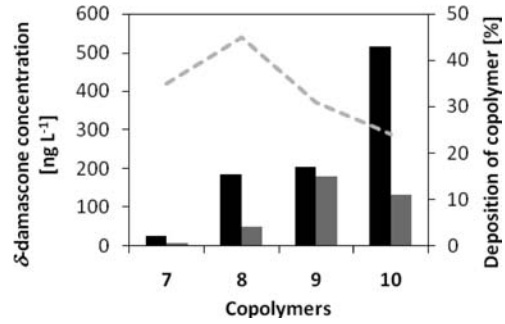

Figure 6. Correlation of δ-damascone concentrations measured in buffered aqueous solution (pH 4, after 3 days, black bars), in the headspace above the cotton surface (after 3 days of line-drying, gray bars) with the amount of polymer deposited onto the surface (dotted line) for copolymers **7**−**10**.

surface, and we tried to correlate the amount of deposition with the release efficiency.

Dynamic Headspace Analysis of the Controlled Release of δ-Damascone from Poly(maleic acid)-Based Conjugates on Dry Cotton. δ-Damascone conjugates **6**−**10** were deposited from a TEA-esterquat emulsion onto the cotton surface as described above. After line-drying for 3 days, one of the dry towels was put into a headspace sampling cell that was controlled for temperature and relative humidity of the air (*48*). A constant flow of air of ca. 200 mL min^{-1} was continuously pumped across the cell. After equilibrating the system, the volatiles were adsorbed onto a clean Tenax cartridge for 15 min and then onto a waste cartridge for 45 min. The sampling was repeated seven times at constant time intervals every 60 min. At the end of the experiment, the sample cartridges were thermally desorbed and the volatiles quantified by GC analysis (*48*). The absolute headspace concentrations of δ-damascone were determined by external standard calibration. All experiments were carried out in duplicate and compared with a reference sample composed of unmodified δ-damascone, which was prepared and analyzed under the same conditions as the polymer conjugates. The measured headspace concentrations of δ-damascone released from polymers **6**−**10** or from the reference sample on dry cotton after 3 days are illustrated in Figure 5.

The data show that the headspace concentrations were higher when δ-damascone was released from either one of the polymeric precursors **6**−**10** as compared with the unmodified δ-damascone used as the reference, thus confirming the expected resiliency of fragrance release. The release of δ-damascone was found to be particularly efficient from polymer conjugates **6**, **9**, and **10**, with increased headspace concentrations (measured at the end of the experiment after 450 min, Figure 5) by a factor of 30, 75, or 50, respectively, with respect to the δ-damascone reference. With a human group olfactory threshold for δ-damascone of 0.021 ng L^{-1} air (*32, 33*), all detected concentrations lie above the human detection limit and are therefore easily perceived by humans (Figure 5).

The observed constant increase of some of the concentration curves of δ-damascone released from the precursors at the beginning of the experiment may result from the changing conditions at the cotton surface from the line-drying to the headspace sampling cell (*48*). A constant airflow at ca. 75% of humidity was aspirated through the headspace sampling cell. Although the ambient humidity during the line-drying of the fabric was estimated as being quite high, the cotton sheets may still take up some humidity during the experiment, which in return may trigger some fragrance release. After ca. 200 min, a constant or slightly decreasing amount of δ-damascone was released from the samples. Due to the fact that the headspace above the cotton surface, and thus the δ-damascone evaporated from the surface, was constantly removed, the system is not at equilibrium. The observed constant release at the end of the measurements thus corresponds to a constant release rate over time.

Comparison of the release rates observed by dynamic headspace analysis (Figure 5) with those from solution measurements (Figure 1) generally showed a good correlation. With the exception of copolymer **6** (which was extracted into the organic phase and thermally degraded in the GC injector), the relative amount of δ-damascone released was found to low for copolymer **7** as compared to copolymers **8**−**10**. This was the case for both headspace analysis and solution experiments. Despite its better deposition, copolymer **8** released less δ-damascone than copolymers **9** and **10**, which correlates to a less efficient release in solution. In contrast, copolymer **10** with a faster release in solution released less δ-damascone into the headspace than copolymer **9** due to its lower deposition on the cotton surface.

Considering the amount of deposition of the different polymers (Table 2) and the efficiency of release observed in solution (Figure 1), one can see that these two parameters have an opposite influence on the amount of δ-damascone released into the headspace. In solution, polymer conjugate **10** with hydrophilic PEG chains near the releasing unit was found to release the highest amount of δ-damascone of the series of compounds tested in this work. However, as a result of a limited deposition on the cotton surface, its final performance was found to be comparable to copolymer **6** with hydrophobic alkyl side chains. The latter is suspected to release the volatile less efficiently in solution, at pH between 4 and 7, but was better deposited onto cotton.

Our measurements carried out in aqueous-buffered solution have shown that the structure of the polymer influences the rates of release, independently of other parameters such as the surface deposition. We therefore expected that copolymer **10** should give rise to a higher release of δ-damascone than copolymers **7**−**9**. The headspace concentrations of δ-damascone released from the polymers on the cotton surface were then measured after line-drying for 3 days. These concentrations correspond to the momentaneous release at the given time. The total amount released over time was influenced by the polymer structures (release efficiency) and depended on the amount of polymer deposited onto the surface (maximum amount to be released). The maximum amount of δ-damascone that can be released into the air (as required for the practical application) was estimated from measurement of the deposition of the polymers on the target surface (Table 2). Figure 6 correlates the concentrations of δ-damascone released in solution (at pH 4 after 3 days, Figure 1) and the momentaneous headspace concentration measured

above the cotton surface (constant value measured after 3 days of line-drying and 450 min of sampling, Figure 5) together with the deposition (data determined by fluorescence measurements, Table 2) for polymers **7**−**10** (horizontal axis).

Accordingly, a well-adjusted balance between hydrophobicity (deposition) and hydrophilicity (solubility, release kinetics) is presumably the most important criterion for the choice of the appropriate delivery system with respect to the targeted application. The presence of PEG side chains favors the release but not the deposition. Therefore, polymer conjugate **9** seems to represent the best structural compromise of the delivery systems investigated in this work by giving rise to the highest headspace concentrations of δ-damascone after 3 days. The ease of structural modifications, allowing fine-tuning of the physicochemical properties of bioconjugates, makes polymeric delivery systems particularly interesting for the controlled release of bioactive compounds in various applications.

CONCLUSION

Besides prolonging the duration of evaporation, polymeric bioconjugates have additional advantages as delivery systems for bioactive volatiles such as fragrances. Labile covalent bonds to be cleaved in the conjugate to release bioactive compounds can be stabilized by the encapsulating polymer matrix, and thus, degradation can be (partially) prevented during storage in harsh media. Furthermore, the ease of structural modification by choosing suitable co-monomers allows preparation of copolymers with enhanced surface deposition and/or better dispersion in aqueous media.

Damascones or damascenones, the so-called rose ketones, are important fragrance raw materials frequently used in perfumery. With 2-mercaptoethanol as a linker, α,β-unsaturated enones such as δ-damascone form the corresponding β-mercapto ketone, which then reacts under mild conditions with poly(maleic anhydride) copolymers to afford the corresponding conjugates in a two-step, one-pot procedure with very good yields and high conversions.

The release of δ-damascone from the polymer conjugates by retro 1,4-Michael-type addition was investigated in buffered aqueous solution as a function of pH and time, as well as after deposition onto a cotton surface in the presence of a cationic surfactant. Grafting a fluorescence label to the polymer backbone allowed quantification of polymer deposition from an aqueous environment on a cotton surface.

The most efficient release of δ-damascone was achieved for a polymer conjugate representing a well-balanced compromise of hydrophilicity (giving rise to high release rates) and hydrophobicity (increased surface deposition) of the polymer backbone. Our data thus show that the detailed understanding of the influence of the polymer structure on the deposition and the reactivity of the conjugates is the most important prerequisite toward the design of new polymer-based bioconjugates.

Poly(maleic acid)-based copolymers were found to be particularly suitable as profragrances because they can be easily modified to cover a broad range of polarity and structural functionality within the polymer backbone. A series of these compounds with different backbone functionalities are widely available and thus allow easy access to a broad variety of structures. Therefore, the polymer conjugates described in this work (*68*) might be easily adapted for the release of bioactive compounds in various biomedical applications.

ACKNOWLEDGMENT

The authors thank Philippe Chevalier for his assistance with the polymer synthesis, Daniel Grenno for recording the high-resolution mass spectra, and Dr. Roger Snowden for constructive comments on the manuscript.

HEHEHE-Tagged Affibody Molecule May Be Purified by IMAC, Is Conveniently Labeled with $[^{99m}Tc(CO)_3]^+$, and Shows Improved Biodistribution with Reduced Hepatic Radioactivity Accumulation

Vladimir Tolmachev,*[,†,‡] Camilla Hofström,[§] Jennie Malmberg,[†] Sara Ahlgren,[‡] Seyed Jalal Hosseinimehr,[†,||] Mattias Sandström,[⊥] Lars Abrahmsén,[#] Anna Orlova,[†] and Torbjörn Gräslund[§]

Division of Biomedical Radiation Sciences, Rudbeck Laboratory, and Division of Nuclear Medicine, Department of Medical Sciences, Uppsala University, Uppsala, Sweden, Department of Molecular Biotechnology, Royal Institute of Technology, Stockholm, Sweden, Department of Radiopharmacy, Faculty of Pharmacy, Mazandaran University of Medical Sciences, Sari, Iran, Hospital Physics, Department of Oncology, Uppsala University Hospital, Uppsala, Sweden, and Affibody AB, Stockholm, Sweden. Received May 20, 2010; Revised Manuscript Received September 23, 2010

Affibody molecules are a class of small (ca. 7 kDa) robust scaffold proteins suitable for radionuclide molecular imaging of therapeutic targets in vivo. A hexahistidine tag at the N-terminus streamlines development of new imaging probes by enabling facile purification using immobilized metal ion affinity chromatography (IMAC), as well as convenient $[^{99m}Tc(CO)_3]^+$-labeling. However, previous studies in mice have demonstrated that Affibody molecules labeled by this method yield higher liver accumulation of radioactivity, compared to the same tracer lacking the hexahistidine tag and labeled by an alternative method. Two variants of the HER2-binding Affibody molecule $Z_{HER2:342}$ were made in an attempt to create a tagged tracer that could be purified by immobilized metal affinity chromatography, yet would not result in anomalous hepatic radioactivity accumulation following labeling with $[^{99m}Tc(CO)_3]^+$. In one construct, the hexahistidine tag was moved to the C-terminus. In the other construct, every second histidine residue in the hexahistidine tag was replaced by the more hydrophilic glutamate, resulting in a HEHEHE-tag. Both variants, denoted $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$, respectively, could be efficiently purified using IMAC and stably labeled with $[^{99m}Tc(CO)_3]^+$ and were subsequently compared with the parental H_6-$Z_{HER2:342}$ having an N-terminal hexahistidine tag. All three variants were demonstrated to specifically bind to HER2-expressing cells in vitro. The hepatic accumulation of radioactivity in a murine model was 2-fold lower with $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6 compared to $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, and more than 10-fold lower with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$. These differences translated into appreciably superior tumor-to-liver ratio for $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ compared to the alternative conjugates. This information might be useful for development of other scaffold-based molecular imaging probes.

INTRODUCTION

Malignant transformation of cells is often associated with overexpression of cell surface proteins, such as different growth factor receptors. The use of antitumor agents with the ability to selectively target such overexpressed proteins increases the specificity of cancer treatment, resulting in improved therapy (*1*−*3*). Obviously, only tumors with the relevant alteration on the cell surface respond to the targeted therapy. For this reason, molecular profiling of tumors is necessary to select suitable patients. The commonly used biopsy-based methods are associated with false-negative findings due to inter- and intratumoral heterogeneity of cell surface protein exposure (*4*, *5*). An attractive alternative is in vivo radionuclide molecular imaging (RMI), which is global, minimally invasive, and less sensitive to target expression heterogeneity, and may be used repeatedly to follow the course of the disease (*6*−*8*). The precondition of successful application of RMI is high sensitivity and specificity of the imaging agent, which is provided by high accumulation in tumors and low uptake in healthy organs and tissues. High tumor uptake and rapid clearance of nonbound radiolabeled scaffold proteins provide high imaging contrast, increasing the sensitivity of imaging.

Previous studies with antibody-based imaging agents have demonstrated that imaging contrast is favored by a small size of the targeting probe (*9*). This prompted the development of protein-based imaging agents smaller than the smallest binding antibody fragment (*10*). One example is the Affibody molecules, containing only 58 amino acids (approximately 7 kDa), based on a single polypeptide, three-helix bundle domain derived from staphylococcal protein A. They lack backbone cysteines and are capable of rapid folding. Affibody molecules with high affinity and selectivity for different targets have previously been selected by phage display from libraries made by randomizing 13 surface-exposed residues on helices 1 and 2, i.e., the 2 N-terminal helices (*11*). The successful development of Affibody-based imaging agents is exemplified by $Z_{HER2:342}$, which binds to human epidermal receptor type 2 (HER2) with high affinity (K_D 22 pM) (*12*). HER2 is a relevant target for RMI since it is overexpressed in a significant fraction of many carcinomas, and since different HER2-targeted therapeutics are available (*13*).

Technetium-99m ($T_{1/2}$ = 6.0 h) is widely used in radionuclide diagnostics because of favorable energy of emitted γ-quanta

Figure 1. Sequences of studied proteins.

and low radiation absorbed dose burden to patients, combined with low price and a wide availability of $^{99}Mo/^{99m}Tc$ generators. An attractive approach for obtaining a protein-based imaging agent suitable for labeling with technetium-99m is to produce the tracer protein recombinantly with a hexahistidine-tag. This tag can be used both for efficient purification by immobilized metal ion affinity chromatography (IMAC) and for chelation of ^{99m}Tc-tricarbonyl ($[^{99m}Tc(CO)_3]^+$) (*14*). This very elegant labeling technique has been applied on a number of targeting proteins (*15*−*18*) to provide stable and site-specific labeling, giving uniform conjugates with reproducible chemical and pharmacological proprieties. Importantly, no additional coupling of chelators is required, and the proteins can be labeled directly after purification. This simple procedure is suitable for development of protein-based imaging agents binding new molecular targets, facilitating comparison of alternative variants of the tracer protein. However, evaluation of the dimeric His_6-$(Z_{HER2:4})_2$ anti-HER2 Affibody molecule demonstrated that $[^{99m}Tc(CO)_3]^+$-His_6-$(Z_{HER2:4})_2$ yielded high accumulation of radioactivity in the liver (*19*). Since the liver is a major metastatic site for many carcinomas, a high liver uptake is an undesirable property of any imaging agent, and hence, correct assessment of this property is very important when comparing alternative variants of a labeled tracer.

Previous studies have shown that different chelators and labeling chemistry may influence the excretion pathway and hepatic uptake of Affibody molecules. For example, increasing the hydrophilicity of the chelator reduced the hepatobiliary excretion of ^{99m}Tc-radioactivity, when the peptide-based N_3S chelators mercaptoacetyl-X-X-X (maXXX, where X is Gly, Ser, Glu, or Lys) were located at the N-terminus (*20*−*23*). In contrast, alternative amino acids in the C-terminal chelating sequence X-X-Cys (where X is Val, Asp, Ser, or Glu) yielded a similar level of hepatobiliary excretion of the radioactivity from ^{99m}Tc (*24*, *25*). Taken together, these data suggested that the properties of the N-terminal portion of the molecule are more crucial for hepatic uptake and hepatobiliary excretion than the properties of the C-terminus when chelating ^{99m}Tc by an N_3S chelator. Furthermore, comparison of the same Affibody molecule with or without an N-terminal hexahistidine tag and site-specifically labeled at the C-terminus with ^{111}In (by maleimido-DOTA) or ^{99m}Tc (by cysteine-containing peptide-based N_3S chelator) clearly showed that the presence of the hexahistidine tag led to much higher accumulation of radioactivity in the liver (*24*, *26*). Thus, the presence of an N-terminal hexahistidine tag leads to a higher uptake in the liver.

The present study was performed to test the hypothesis that the problem with high accumulation of radioactivity in the liver might be solved by either relocating the hexahistidine tag or making it more hydrophilic. The hypothesis was tested by constructing two novel affibody tracers. In the first construct, the tag was moved from the N-terminus to the C-terminus. In the second construct, the hydrophilicity of the N-terminal tag was increased by replacing three of the six histidine residues by glutamic acid residues, resulting in a HEHEHE-tag (Figure 1). Both molecules denoted $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$, respectively, could be purified by IMAC and labeled with $[^{99m}Tc(CO)_3]^+$, and both constructs yielded less radioactivity in the liver in a murine model: 2-fold and more than 10-fold less than the parent tracer, respectively. This was reflected in a significant improvement of tumor-to-liver ratio in tumor xenograft-bearing mice.

MATERIALS AND METHODS

General. Buffers were prepared using common methods from chemicals supplied by Merck (Darmstadt, Germany). High-quality Milli-Q water (resistance higher than 18 MΩ/cm) was used for preparing solutions. The IsoLink labeling kit was purchased from Covidien. NAP-5 size exclusion columns were from GE Healthcare, Uppsala, Sweden. ^{99m}Tc was obtained as pertechnetate from an Ultra-TechneKow generator (Covidien) by elution with sterile 0.9% NaCl. The yield, radiocolloid content, and radiochemical purity of the labeled Affibody constructs were analyzed using 150−771 DARK GREEN, Tec-Control Chromatography strips from Biodex Medical Systems (New York, USA) as described (*20*). Cells used during in vitro experiments were detached using trypsin−EDTA solution (0.25% trypsin, 0.02% EDTA in buffer, Biochrom AG, Berlin, Germany). For in vivo experiments, Ketalar (50 mg/mL, Pfizer, NY, USA), Rompun (20 mg/mL, Bayer, Leverkusen, Germany), and Heparin (5000 IE/mL, Leo Pharma, Copenhagen, Danmark) were used. Data on cellular uptake and biodistribution were assessed by an unpaired, two-tailed Student's *t*-test using GraphPad *Prism* (v 4.00 for Windows GraphPad Software, San Diego, California, USA) in order to determine any significant differences ($p < 0.05$).

Instrumentation. The radioactivity was measured using an automated gamma-counter with a 3 in. NaI(Tl) detector (1480 WIZARD, Wallac Oy, Turku, Finland). The distribution of radioactivity along the thin layer chromatography strips and SDS-PAGE gels was measured on a Cyclone Storage Phosphor System and analyzed using the *OptiQuant* image analysis software. Cells were counted using an electronic cell counter (Beckman Coulter).

Production and Purification of Affibody Molecules, $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$. The gene encoding $Z_{HER2:342}$ was PCR amplified from vector pAY1069-$(Z_{HER2:342})_2$ (*12*) to introduce the amino acid sequence GSHHHHHH at the C-terminus (denoted $Z_{HER2:342}$-H_6) or the amino acid sequence MHEHEHE at the N-terminus (denoted $(HE)_3$-$Z_{HER2:342}$). PCR fragments were fitted with the restriction sites for *Hin*dIII and NdeI, which were subsequently used to subclone the fragments into the expression vector pET21a(+), containing a T7 promoter (Novagen, Darmstadt, Germany). Correct DNA sequences were verified by cycle sequencing using an ABI Prism 3700 Analyzer (Applied Biosystems, CA).

The H_6-$Z_{HER2:342}$ Affibody molecule having a His_6-tag at N-terminus was produced as described by Orlova and co-workers (*12*). The molecules $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ were produced in *Escherichia coli* strain BL21(DE3) essentially as previously described for other Affibody molecules (*27*). After fermentation, cells were harvested by centrifugation, and cell pellets were resuspended in washing buffer (50 mM Na_2HPO_4, 300 mM NaCl, pH 7). Cells were disrupted by sonication, and cell debris was removed by centrifugation.

The $Z_{HER2:342}$-H_6 Affibody molecule was recovered by IMAC purification on a Talon Metal Affinity Resin (BD Bioscience, San Jose, CA) column under native conditions essentially as recommended by the manufacturer, using acid elution (50 mM sodium acetate, 300 mM NaCl, pH 4.8).

The cleared cell lysate containing $(HE)_3$-$Z_{HER2:342}$ was heat-treated (60 °C for 10 min) followed by centrifugation (35 000 *g*, 20 min, 4 °C). The supernatant was subsequently filtered through a 0.45 μm filter (Sartorius Stedim Biotech, Aubagne

Cedex, France) before loading onto a column containing Chelating Sepharose Fast Flow (GE Healthcare, Uppsala, Sweden) with immobilized Ni^{2+}-ions. The protein was recovered by IMAC purification under native conditions using an imidazole gradient (0−500 mM) for elution, according to the manufacturer's instructions. The process was monitored using an ÄKTA explorer 100 system (GE Healthcare).

Eluted fractions containing Affibody molecules were pooled and concentrated using Vivaspin2 centrifugal concentrators (Vivascience, Hannover, Germany). The buffer was changed to PBS (137 mM NaCl, 8 mM Na_2HPO_4, 1.5 mM KH_2PO_4, 2.7 mM KCl, pH 7.4) by dialysis overnight at 4 °C using SnakeSkin Pleated Dialysis Tubing (Pierce, Rockford, IL). Protein concentrations were determined from the absorbance at 280 nm and by amino acid analysis (Amino Acid Analysis Center, Uppsala University).

Sample Purity Analysis. Analytic reverse-phase high-performance liquid chromatography (RP-HPLC) was used to investigate sample purity and the retention times of $Z_{HER2:342}$-H_6, $(HE)_3$-$Z_{HER2:342}$, and H_6-$Z_{HER2:342}$ using a C18 column on an Agilent 1200 HPLC system (Agilent Technologies, Santa Clara, CA). Samples containing 0.2 mg Affibody molecule were injected sequentially onto the column and eluted using a 20 min gradient of 20−65% B (A, 0.1% trifluoroacetic acid (TFA) in H_2O; B, 0.1% TFA in CH_3CN), with a flow rate of 0.8 mL/min. Each integrated peak area corresponding to the Affibody molecule was compared to the area of all peaks to calculate the purity.

Mass Spectrometry Analysis. The molecular mass of $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ was determined by mass spectrometry analysis using a 6520 Accurate-Mass Q-TOF LC/MS instrument (Agilent Technologies, Santa Clara, CA). The molecular masses were retrieved using Agilent *MassHunter B.02.00* software (Agilent Technologies) yielding the isotopic and charge state information.

Biosensor Analysis. Affinity constants were measured by real-time biospecific interaction analyses using a Biacore 2000 instrument (Biacore AB, Uppsala, Sweden). The extracellular portion of human HER2 fused to the Fc region of human IgG (R&D Systems, Minneapolis, MN) was immobilized (∼1000 RU) on a flow-cell surface of a CM5 sensor chip (Biacore Life Science, GE Healthcare, Uppsala, Sweden) by amine coupling, according to the manufacture's instructions. Another sensor chip was activated and deactivated for use in the reference flow-cell. Dilution series consisting of five different concentrations were prepared for each Affibody construct and injected in duplicates over the flow-cells with a flow rate of 50 μL/min. The concentration ranges used were 90 pM to 1.5 nM for $Z_{HER2:342}$-H_6, 65 pM to 1 nM for $(HE)_3$-$Z_{HER2:342}$, and 200 pM to 2.9 nM for H_6-$Z_{HER2:342}$. After each sample injection, the flow-cell surface was regenerated by 20 μL of 15 mM HCl. The dissociation equilibrium constant (K_D), the association rate constant (k_a), and the dissociation rate constant (k_d) were calculated using *BIAevaluation 3.2* software (Biacore Life Science, GE Healthcare, Uppsala, Sweden), assuming a one-to-one interaction model.

Melting Point Analysis. Variable temperature measurements of $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ were performed using a JASCO J-810 spectropolarimeter instrument (JASCO, Tokyo, Japan). Samples were diluted to a concentration of 60 μM in PBS, and the absorbance was measured at 221 nm during a temperature gradient increasing 5 °C/min ranging from 20 to 90 °C. Circular dichroism spectra were also recorded from 250 to 195 nm at 20 °C, before and after each variable temperature measurement.

Labeling of H_6-$Z_{HER2:342}$, $Z_{HER2:342}$-H_6, $(HE)_3$-$Z_{HER2:342}$. Labeling of H_6-$Z_{HER2:342}$, $Z_{HER2:342}$-H_6, and $(HE)_3$-$Z_{HER2:342}$ with $[^{99m}Tc(CO)_3]^+$ was performed as described by Orlova and co-workers (*19*). Briefly, 500 μL (350 MBq-2 GBq) of $^{99m}TcO_4^-$-containing generator eluate was added to a vial with the IsoLink kit. The mixture was incubated at 100 °C during 20 min. Thereafter, 40 μL of mixture were transferred to a tube containing 50 μg (∼6.8 nmol) Affibody molecule in 40 μL PBS and incubated at 50 °C. The labeling yield after incubation for 10, 20, 40, and 60 min was monitored by ITLC to assess labeling kinetics. When the ITLC strips were eluted with PBS pertechnetate, as well as carbonyl and histidine complexes of ^{99m}Tc migrated with the eluent front (R_f = 1.0), while Affibody molecules do not migrate under these conditions (R_f = 0.0). To determine the presence of reduced hydrolyzed technetium, ITLC was eluted with pyridine/acetic acid:water (5:3:1.5). When this eluent was used, the technetium colloids stayed at the application point (R_f = 0.0), while radiolabeled Affibody molecules, as well as pertechnetate and carbonyl complexes of ^{99m}Tc, migrated with the solvent front (R_f = 1.0). The experiments were performed in quadruplicate. In addition, blank experiments were performed, where the Affibody molecules were omitted.

For in vitro and in vivo studies, labeling during 60 min was selected. The labeled Affibody molecules were purified using NAP-5 desalting columns (GE Healthcare), pre-equilibrated and eluted with PBS. The purity of each preparation was evaluated using thin layer chromatography.

To evaluate storage stability (shelf life), the purified radiolabeled conjugates were kept at ambient temperature (23 °C) and analyzed after 1, 2, 6, and 24 h. To predict in vivo stability of the ^{99m}Tc-label, a histidine challenge (*14*) of conjugates was performed. Briefly, a 500- and 5000-fold excess of histidine was added to the conjugate. After incubation at 37 °C during 1 h, the mixture was analyzed using radio-ITLC. The incubation time was selected on the basis of previous data on the biodistribution of Affibody molecules, showing that more than 95% of Affibody-related radioactivity was cleared from the blood 1 h after injection, irrespectively of label (*21*, *26*, *28*). SDS-PAGE analysis was performed to confirm the stability test data. Two samples of each labeled conjugate were incubated at 37 °C with 5000-fold excess of histidine during 1 h. After incubation, samples were analyzed by SDS-PAGE on NuPAGE 4−12% Bis-Tris Gel (Invitogen) in MES buffer (200 V constant). To facilitate interpretation of the result, a sample of ^{99m}Tc-pertechnetate and a sample of the same conjugate not treated with histidine were analyzed in parallel with the test samples on the same gel. Distribution of radioactivity along the SDS-PAGE gels was measured using a Cyclone Storage Phosphor System.

In Vitro Studies. The in vitro HER2 specificity of the ^{99m}Tc-labeled Affibody molecules was evaluated using SKOV-3 ovarian carcinoma cell line and two prostate cancer cell lines, DU-145 and PC-3. All cell lines were purchased from American Type Tissue Culture Collection (ATCC) via LGC Promochem, Borås, Sweden. SKOV-3 was selected because it has a high level of HER2 expression (1.2×10^6 receptors per cell) (*29*) and was used in our earlier studies on radiolabeled Affibody molecules. Prostate cancer cell lines (both expressing $\sim 5 \times 10^4$ receptors per cell, A. Orlova and J. Malmberg, unpublished results) were selected because of our intention to visualize HER2-expression in prostate cancer in future studies. In vitro specificity testing was performed according to the methods described earlier (*24*). Briefly, a solution of each conjugate (concentration 0.2 nM) was added to six Petri dishes (ca. 10^6 cells in each). A 1000-fold excess of nonlabeled recombinant $Z_{HER2:342}$ was added 5 min before the radiolabeled conjugates to saturate the receptors in blocking experiments. The cells were

incubated during 1 h in a humidified incubator at 37 °C. Thereafter, the media were collected, the cells were detached by trypsin−EDTA solution, and the radioactivity in cells and media was measured to calculate the fraction of cell-bound radioactivity.

The cellular retention and internalization of radioactivity were evaluated as described by Wållberg and Orlova (*22*) using the SKOV-3 cell line. Tumor cells were incubated with radiolabeled conjugate (1 nM) for 1 h at 4 °C. Thereafter, the incubation media was discarded and the cells were washed three times using ice-cold serum-free medium. After addition of 1 mL complete medium, the cells were further incubated at 37 °C. Three dishes were analyzed for cell-associated radioactivity at predetermined time points, up to 24 h. Medium was collected, and the cells were washed three times with ice-cold serum-free medium—these two steps were omitted for the zero time point—and treated with 0.5 mL of 4 M urea solution in 0.2 M glycine buffer, pH 2.5, for 5 min on ice. The acid fraction was collected, and cells were washed with another 0.5 mL acid solution. The radioactivity in the acid wash fraction was considered to be membrane-bound radioactivity. After addition of 0.5 mL of 1 M NaOH, the cells were incubated at 37 °C for at least 0.5 h and the basic wash solution collected. Dishes were washed with an additional 0.5 mL of basic solution. The radioactivity in the alkaline fractions was considered to be internalized radioactivity.

The antigen-binding capacity (ABC) was analyzed according to the method described and validated by Wållberg and co-workers (*30*). The SKOV-3 cells were scraped from culture flasks, and three cell pellets containing 10^7 cells were formed by gentle centrifugation. A solution of radiolabeled Affibody molecules in cell culture medium (1 mL, 0.26 pmol) was added to each pellet to provide approximately a 100-fold molar access of receptor over conjugate. The cells were gently resuspended and incubated for 1 h at 4 °C under gentle shaking. After incubation, cells were pelleted and 0.5 mL of the supernatant was transferred to new tubes. The radioactivity of the samples was measured, and the ABC was calculated as

$$\mathrm{ABC} = (A_{\mathrm{pellet+media}} - A_{\mathrm{media}})/(A_{\mathrm{pellet+media}} + A_{\mathrm{media}}) \times 100\%$$

In Vivo Studies. All animal experiments were planned and performed in accordance with national legislation on laboratory animals' protection and were approved by the Local Ethics Committee for Animal Research.

Male NMRI mice (18 weeks old, weight 32.4 ± 1.7 g) were used in the biodistribution studies. The animals were intravenously injected with 520 kBq (1 μg, 0.125 nmol) of $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, or $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ diluted in 100 μL PBS. Mice were sacrificed and dissected at 4 or 24 h after injection.

The mice were euthanized at predetermined time points by an intraperitoneal injection of Ketalar-Rompun solution (20 μL of solution per gram body weight: Ketalar, 10 mg/mL; Rompun, 1 mg/mL) followed by heart puncture with a 1 mL syringe rinsed with Heparine (5000 IE/mL). Blood and organ samples—lung, liver, spleen, stomach, kidneys, salivary gland, thyroid, muscle, bone, intestines (with content)—and the remaining carcass were collected, weighed, and the radioactivity measured as described above. The organ uptake values are expressed as percent of injected dose per gram of tissue (% ID/g), except for the intestines and the remaining carcass where values are expressed as % ID per whole sample.

Male outbreed NMRI *nu*/*nu* mice were used in tumor targeting experiments. Approximately 10^6 LS174T colon adenocarcinoma cells (ATCC) (expressing ~6×10^4 receptors per cell; A. Orlova, unpublished results) were subcutaneously implanted in the right hind leg. At the time of the biodistribution experiment, the average tumor size was 0.74 ± 0.39 g.

Animals were randomized into groups of four and injected intravenously with 1 μg $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, or $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ conjugate (40 kBq) in 100 μL PBS. To verify the specificity of targeting by $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, HER2 receptors were presaturated in one additional group of mice by a subcutaneous injection with 500 μg of unlabeled H_6-$Z_{HER2:342}$ 45 min before injection of the labeled conjugate. The animals were euthanized at 4 h p.i., and the biodistribution was studied as described above.

For gamma camera imaging, two mice bearing LS174T xenografts were injected with 1.5 MBq (1 μg) $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ or an equal amount of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, respectively. The animals were euthanized at 4 h p.i. by overdosing Ketalar/Rompun. After euthanasia, the urinary bladders were dissected. Imaging of both mice was performed simultaneously at the department of Nuclear Medicine at Uppsala University Hospital using a Millenium VG gamma camera (General Electric) equipped with a low-energy, high-resolution (LEHR) collimator. Acquisition of static images was performed with a 256 × 256 matrix and a zoom factor of 3. The energy window settings were 140 keV, 15%.

RESULTS

Production and Purification of Affibody Molecules with Different Histidine Tags. The affibody tracers were produced recombinantly in *Escherichia coli* followed by cell disruption by sonication. $Z_{HER2:342}$-H_6 was directly purified from the lysate by IMAC using a column with immobilized Co^{2+}. Purification of $(HE)_3$-$Z_{HER2:342}$ was performed by heat-treating the lysate at 60 °C for 10 min to precipitate endogenous *E. coli* proteins followed by centrifugation and purification by IMAC using a column with immobilized Ni^{2+}. Purification of $Z_{HER2:342}$-H_6 resulted in an essentially pure protein of the expected molecular mass (Figure 2). Samples taken after the different steps in the purification of $(HE)_3$-$Z_{HER2:342}$ were analyzed by SDS-PAGE and showed that the heat-treatment resulted in reduction of endogenous *E. coli* proteins and that the pooled and concentrated material after IMAC was essentially pure with only one band having the expected molecular mass (Figure 2).

Analysis of Physical Properties of Purified Affibody Constructs. Analytic RP-HPLC analysis showed a purity for both $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ of over 90% (Table 1). The molecular masses of $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ were determined by mass spectrometry analysis and showed a good correlation with the theoretical values (Table 1). The K_D value for H_6-$Z_{HER2:342}$ interacting with HER2 was determined to be 23 pM, essentially identical to the previously determined 22 pM (*12*). The K_D values obtained for $Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ were similar, 20 and 18 pM, respectively (Table 1), indicating that neither the location nor the composition of the histidine tag influenced the HER2 binding.

$Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$ were also analyzed by circular dichroism, showing that both molecules had a melting temperature of 65 °C (Table 2), correlating well with the previously reported value for H_6-$Z_{HER2:342}$ (63 °C) (*12*). Also, both Affibody molecules gave CD spectra showing high α-helical content, similar to those previously determined for H_6-$Z_{HER2:342}$. The spectra recorded for both constructs before and after heating to 90 °C were highly similar, indicating that both molecules refolded efficiently (Figure 2).

Labeling of H_6-$Z_{HER2:342}$, $Z_{HER2:342}$-H_6, $(HE)_3$-$Z_{HER2:342}$. The use of labeling conditions optimized by Orlova and co-workers (*19*) enabled efficient labeling, resulting in a radiochemical yield of more than 80% after 60 min of incubation with $[^{99m}Tc(CO)_3(H_2O)_3]^+$ for all conjugates (Figure 3). Labeling of H_6-$Z_{HER2:342}$ was somewhat more efficient than labeling of

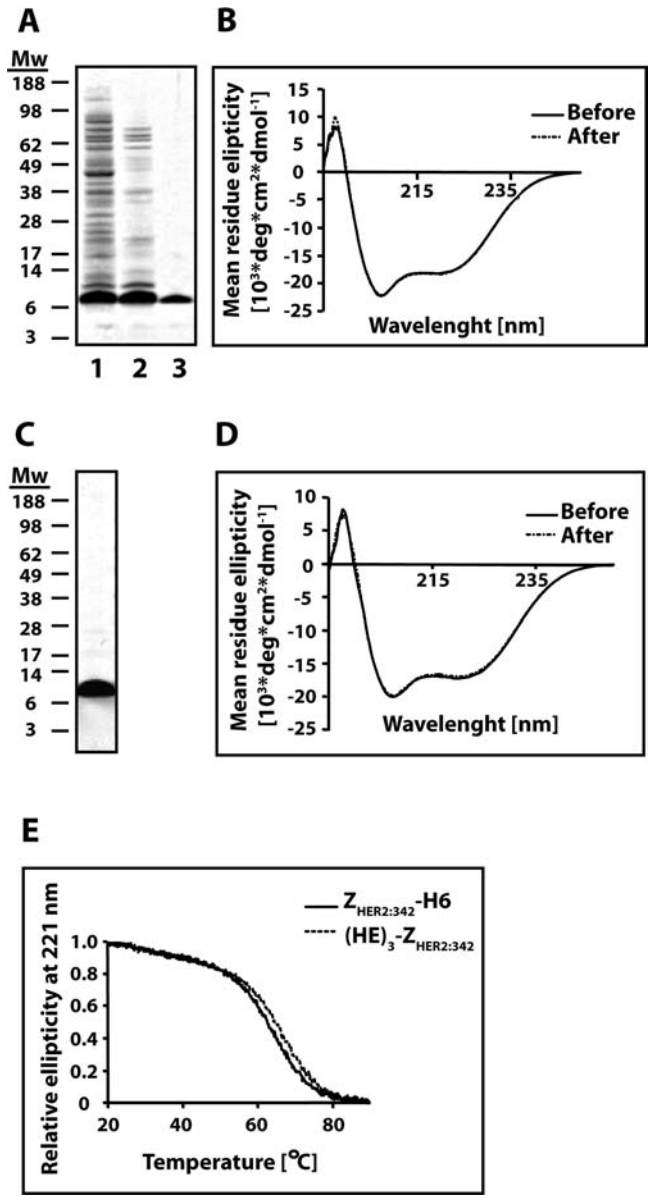

Figure 2. Analysis of $Z_{HER2:342}$-H6 and HEHEHE-$Z_{HER2:342}$ Affibody molecules. SDS-PAGE analysis of samples taken during the purification of HEHEHE-$Z_{HER2:342}$ is shown in panel A. Lane 1, sample after cell lysis and initial clarification; lane 2, sample after heat-treatment; lane 3, sample after IMAC purification. Panel B: an overlay of CD-spectrum recorded before and after thermal unfolding (as in panel E) of HEHEHE-$Z_{HER2:342}$. Panel C: SDS-PAGE analysis of a sample of the eluted material after IMAC purification of $Z_{HER2:342}$-H6. Panel D: an overlay of CD-spectrum recorded before and after thermal unfolding (as in panel E) of $Z_{HER2:342}$-H6. Panel E: overlay of the relative ellipticity measured by CD-spectrometry at 221 nm as a function of temperature for HEHEHE-$Z_{HER2:342}$ and $Z_{HER2:342\text{-}H6}$.

$Z_{HER2:342}$-H_6 and $(HE)_3$-$Z_{HER2:342}$. A simple purification using a disposable desalting column provided isolated yield of 75 ± 7%, 71 ± 12%, and 77 ± 4% for $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, and $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, respectively (mean ± standard deviation, $n = 3$). The radiochemical purity was over 95%, and the specific radioactivity was in the range 1.7−2 MBq/μg (14−15.8 GBq/μmol). Radiocolloid formation was very low, less than 1.5% with all three constructs.

Table 2. In Vitro Stability of $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, and $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$[a]

[a] Each data point represents an average from three samples ± standard deviation.

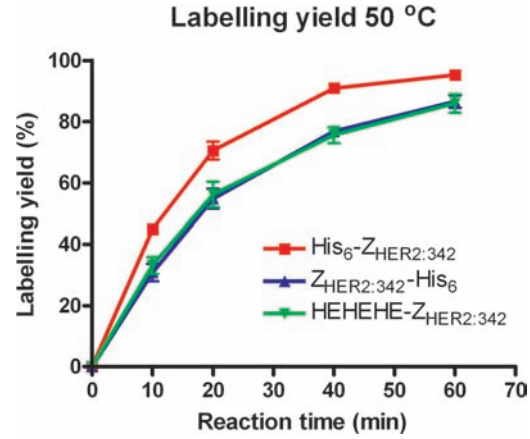

Figure 3. Labeling kinetics of Affibody molecules using IsoLink at 50 °C. $[^{99m}Tc(CO)_3(H_2O)_3]^+$ was added to 50 μg of Affibody molecules in 40 + l PBS. After 10, 20, 40, and 60 min of incubation, samples of the reaction mixture were analyzed using thin-layer chromatography. Labeling yields are presented as an average from four independent experiments with the error bars corresponding to ±1 standard deviation.

The results from the stability tests are presented in Table 2 and Figure 4, showing that all conjugates demonstrated a remarkably high stability. The loss of radioactivity was about 1% after 24 h incubation in PBS at room temperature. All constructs showed a high stability of label attachment in the histidine challenge; the release of technetium-99m was only minor and independent of the excess of free histidine. The results were comparable with previously published data for ^{99m}Tc His-tag-labeled compounds (*14, 19*). Figure 4 shows a representative radioactivity pattern after SDS-PAGE analysis of a sample from 60 min incubation of ($[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$) with 5000-fold excess of histidine at 37 °C. ^{99m}Tc-pertechnetate and a control sample incubated in PBS at room temperature were included for comparison. The main peak corresponds to migration of a monomeric Affibody molecule. The only other radioactivity peak corresponds to low-molecular-weight compounds, such as ^{99m}Tc-pertechnetate. This peak did not contain more than 1.1% of the total activity after the challenge, showing high stability of the complex.

In Vitro Studies. Binding specificity tests (Table 3) indicated that the binding of all ^{99m}Tc-labeled Affibody constructs to living HER2-expressing cells was receptor mediated; saturation of the

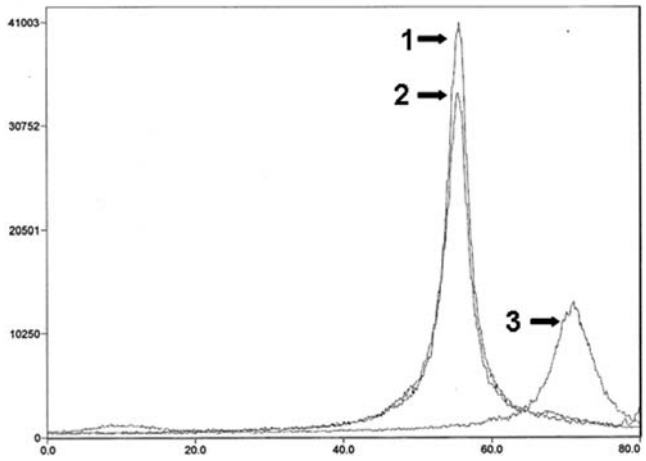

Figure 4. SDS-PAGE analysis of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ stability under histidine challenge. Distribution of radioactivity along lanes was visualized and quantified using Cyclone Storage Phosphor System. 1, $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ control sample, which was incubated in PBS at room temperature for 1 h; 2, $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ sample, which was incubated in 5000-fold excess of histidine at 37 °C for 1 h; 3, ^{99m}Tc-pertechnetate was used as a marker for low-molecular-weight compounds.

$[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6	6.8 ± 1.0	3.4 ± 0.2	<0.005
$[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$	3.0 ± 0.2	0.8 ± 0.1	<0.0005

[a] The test was performed on the ovarian cancer cell line, SKOV-3 (high expression level) and prostate cancer cell lines, DU-145 and PC-3 (both with low expression level). For pre-saturation of antigens, a 1000-fold molar excess of nonradioactive Affibody molecules was added. Data are presented as mean values of percent added radioactivity that is cell-bound from three cell dishes and standard deviations.

receptors by preincubation with nonlabeled $Z_{HER2:342}$ significantly decreased the binding of the radiolabeled Affibody molecules. The level of cell-associated radioactivity was appreciably lower for both prostate cancer cell lines PC-3 and DU-145 compared to the ovarian carcinoma cell line SKOV-3, reflecting the lower expression level of HER2.

The cellular retention and internalization test showed that all conjugates were efficiently retained by HER2-expressing cells (Figure 5). The cellular retention of total radioactivity was generally high, with 80.1 ± 0.5%, 47.7 ± 0.1%, and 65.3 ± 1.1% cell-associated after 24 h of incubation at 37 °C, for $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, and $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, respectively. In contrast, the internalization rate differed, being highest for $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ and lowest for $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6. The overall cellular retention correlated directly with the internalization rate of the conjugates.

The antigen binding capacity after labeling was retained to a very high extent. The fraction of conjugate bound to approximately 100-fold receptor excess was 79.6 ± 0.6%, 80.5 ± 0.4%, and 70.3 ± 7.3% for $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, and $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, respectively. These values are similar to those previously observed for ^{99m}Tc-labeled Affibody molecules (*21*, *22*).

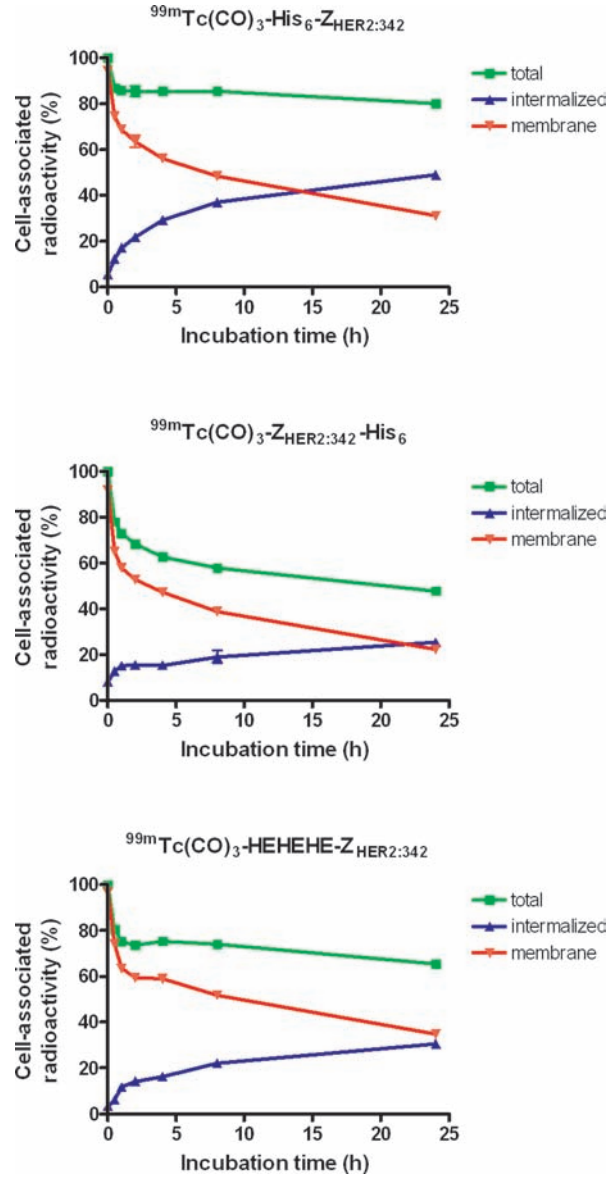

Figure 5. Cell-associated radioactivity as a function of time after interrupted incubation of SKOV-3 cells with $[^{99m}Tc(CO)_3]^+$-H6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H6, or $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$. The cell-associated radioactivity at time zero after the interrupted incubation was defined as 100%. The radioactivity that was removed from cells by treatment with 4 M urea solution in 0.2 M glycine buffer, pH 2.0, was considered membrane-bound and the rest internalized. Data are presented as an average value from 3 dishes ± standard deviation. Due to the small standard deviation, not all error bars are visible behind the symbols.

In Vivo Studies. Data on the comparative biodistribution of $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6, and $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ in male NMRI mice at 4 and 24 h after intravenous injection are presented in Table 4 and Table 5, respectively. The general pattern of all three conjugates was typical for Affibody molecules, with rapid clearance from blood, nonspecific compartments, and the carcass. The renal clearance was accompanied by reabsorption, which resulted in an appreciable accumulation of radioactivity in the kidneys (80−100% ID/g at 4 h after injection). The average radioactivity in the gastrointestinal tract, including content, was below 5% for all

conjugates, showing minimal excretion of conjugates or their radiocatabolites via the bile. The radioactivity uptake in stomach, salivary gland, and thyroid was low for all three conjugates, indicating that no pertechnetate was released in vivo. However, some differences in biodistribution were seen between conjugates (see Table 4 and Table 5). For example, the blood clearance of $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ was the most rapid. However, the most remarkable difference in biodistribution was the large difference in hepatic accumulation of radioactivity. Four hours after injection, the concentration of radioactivity in the liver was 2-fold lower with $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6 than with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ (5.3 ± 1.1% ID/g compared to 10.3 ± 2.8% ID/g; $p < 0.05$). At the same time point, the concentration of radioactivity in the liver with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ was more than 10-fold lower than with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ (0.93 ± 0.15% ID/g; $p < 0.0005$), and nearly 6-fold lower than with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ ($p < 0.0005$).

Comparison of biodistribution data for 4 and 24 h pi shows 1.5−1.8-fold decrease of hepatic radioactivity and 1.8−2-fold decrease of renal radioactivity, suggesting a moderately residualizing character of all labels.

The biodistribution data from nude NMRI mice bearing tumor xenografts (4 h pi) and the results of their statistical treatment are presented in Tables 6 and 7. The data are in very good agreement with the data from immunocompetent mice at the same time point (taking into account strain-to-strain variability and difference in animal size). The uptake of radioactivity in normal organs and tissues followed the pattern found in normal NMRI mice. The accumulation of radioactivity in the liver was again the lowest with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, 9.2-fold lower than with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ and 4.9-fold lower than with $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6. Accordingly, the hepatic uptake in the case of $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6 was nearly 2-fold lower than the uptake seen with the counterpart having an N-terminally located hexahistidine tag. At the same time, the clearance of radioactivity from blood was the slowest for $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6. Overall, $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ provided the most rapid clearance from normal organs and tissues. Preinjection of a large amount of H_6-$Z_{HER2:342}$ significantly reduced tumor uptake of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, demonstrating targeting specificity. There was no significant difference in the tumor uptake between the conjugates. However, the lower accumulation in normal tissue provided appreciable better tumor-to-organ ratio with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ compared to the two other conjugates (except from the kidneys) (Table 7). The most spectacular difference seen between the conjugates was the tumor-to-liver ratio: the value was 0.29 ± 0.04 with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ (i.e., negative contrast) and 3.0 ± 0.5 with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$.

Gamma-camera imaging, performed at 4 h pi (Figure 6), confirmed the results of the biodistribution experiments. The most prominent sites of radioactivity accumulation with both $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ and $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ were in the kidneys. The HER2-expressing tumor xenografts were visualized using both conjugates. However, a high liver accumulation exceeding the accumulation in tumor was observed for $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, but not with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$.

DISCUSSION

Development of imaging agents often requires in vivo comparison of several variants with similar properties (*12, 16*). The evaluation procedure is appreciably facilitated by the use of a technique that enables labeling of the different variants without additional modification, i.e., coupling of a chelator or prosthetic group. A hexahistidine tag allows for facile labeling with $^{99m}Tc(CO)_3^+$ and may also be used for easy and highly efficient purification. The drawback with an N-terminal hexahistidine tag on an Affibody molecule is high hepatic accumulation of radioactivity. Our hypothesis was that hepatic accumulation of the radioactivity is caused by high uptake of the tracer in the liver, which in turn is caused by the relatively hydrophobic nature of the tag labeled with $^{99m}Tc(CO)_3^+$ (*31*). Indeed, there are several observations of higher hepatic uptake of $[^{99m}Tc(CO)_3]^+$-labeled hexahistidine-labeled imaging agents compared to what was expected with the corresponding protein (*32, 33*) or compared to what had been seen with an alternative labeling method (*15, 19*). Interestingly, Ruscowski and coauthors (*34*) have previously suggested that the handling of proteins in the liver is more influenced by the presence of "hydrophobic patches", i.e., areas with high density of hydrophobic side chains, than the overall lipophilicity of the protein. Although histidine is not generally considered hydrophobic, it can most likely not balance the hydrophobic nature of technetium tricarbonyl.

Thus, the $^{99m}Tc(CO)_3^+$ labeled hexahistidine tag may create a "hydrophobic" patch at the N-terminal end of the Affibody molecule which promotes uptake of the tracer in the liver. This is further supported by previous observations of large effect of single amino acid substitutions in the N-terminus of the affibody molecule on biodistribution properties (*20*−*23*). However,

Planar gamma-camera images were acquired 4 h after administration of the tracers. Arrows point to tumors (T), liver (L), and kidneys (K).

similar amino acid replacements in the C-terminus gave only small effects (*24*−*26*). Since the C-terminus is spatially distant from the N-terminus in this antiparallel triple helical protein, we therefore hypothesized that placing hexahistidine tag at the C-terminus instead of at the N-terminus might make a difference in the biodistribution properties, without changing the overall hydrophobicity of the protein. The results from the present study confirmed this hypothesis, showing that the $[^{99m}Tc(CO)_3]^+$-labeled $Z_{HER2:342}$-H_6 yielded a 2-fold lower hepatic radioactivity concentration compared to the parent $[^{99m}Tc(CO)_3]^+$-labeled H_6-$Z_{HER2:342}$, in both normal and tumor-bearing mice. However, the positive effect of the C-terminal location of hexahistidine tag on overall biodistribution was modest and associated with some negative effects, such as appreciably elevated blood radioactivity concentration. The latter is not due to lower stability, as shown by histidine challenge. The concentration of radioactivity in the intestine and carcass is also slightly higher, which may indicate not only that the favorable lowering of the hepatic radioactivity concentration is due to reduced uptake of $[^{99m}Tc(CO)_3]^+$-labeled $Z_{HER2:342}$-H_6, but also that lower hepatic retention of radioactivity might be involved. More detailed studies are needed to fully elucidate this issue.

The other approach investigated to reduce liver uptake was to increase the hydrophilicity in the N-terminal portion of the tracer, by introducing charged residues in the hexahistidine tag, while retaining the possibility for IMAC purification and labeling with $[^{99m}Tc(CO)_3]^+$. Previous studies of N-terminally located N_3S chelators consisting of the sequence mercaptoacetyl-X-X-X (where X is Glu, Ser, or Lys) have shown that the overall biodistribution is more favorable if glutamate is included compared to lysine (*35*). Therefore, the negatively charged amino acid glutamate was chosen to increase the hydrophilicity. Furthermore, labeling with $[^{99m}Tc(CO)_3]^+$ seems only to require an H-X-H-motif (*36*) indicating that every second histidine in the hexahistidine tag could be substituted for glutamate without affecting its chelating properties. We therefore chose to add the motif H-E-H-E-H-E to the Affibody tracer. Like the His_6-tag, this motif will probably also be surface exposed allowing purification by IMAC, for example, by a resin containing immobilized iminodiacetic acid (IDA)/Ni^{2+}-ions. The results exceeded expectations, and this tracer could be efficiently purified by IMAC and labeled by $[^{99m}Tc(CO)_3]^+$, and when used in vivo, the hepatic concentration of radioactivity was more than 10-fold lower with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ compared to that with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, both at 4 and 24 h. A slightly slower blood clearance could be seen with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$, but the concentration of radioactivity was lower in all tissues already at 4 hour after injection, and much lower at 24 hours after injection. Besides a low uptake value for the liver, rapid clearance was also reflected in lower values in the carcass and intestine, disregarding the intestine at 4 h after injection of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ where no reliable value was obtained. Importantly, the HEHEHE tag is not less stable toward histidine challenge than the hexahistidine tag, supporting the conclusion that the effects seen are directly related to much lower hepatic uptake of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-

$Z_{HER2:342}$. Furthermore, no correlation could be seen between the retention time of Affibody molecules on reversed-phase HPLC (Table 1) and liver uptake. This suggests that the observed differences in hepatic uptake are due to differences in local rather than overall hydrophobicity. This observation is in agreement with the hypothesis of Ruscowski and coauthors (*34*) concerning the importance of "hydrophobic patches" for hepatic uptake of radiolabeled peptides.

Taken together, purification on IMAC worked equally well for all three constructs. Labeling using $[^{99m}Tc(CO)_3]^+$ was nearly as efficient with Z_{HER2}-H_6 and $(HE)_3$-Z_{HER2} as labeling of H_6-$Z_{HER2:342}$, and all three labeled constructs were equally stable in PBS and toward a histidine challenge. Furthermore, specific binding to HER2-expressing cells was seen with all three labeled tracer, at levels in agreement with the receptor density of the selected cell-lines (Table 3.). Significant differences were only seen in the biodistribution of radioactivity, believed to be primarily due to differences in the uptake of the labeled tracers by the liver, as outlined above. The renal excretion and retention seem to be virtually identical; for example, a 2-fold decrease of kidney values between 4 and 24 h were seen with all three variants of $Z_{HER2:342}$. This suggests that all three labels possess similar, moderately residualizing properties. This provides further support for the assumption that hepatic uptake, not hepatic retention, differs among the labeled tracers. Radioactivity uptake with $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ at 4 h pi (a time point relevant for imaging using ^{99m}Tc) was significantly lower in lungs, spleen, stomach, salivary gland, and muscles in comparison with $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ and $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6.

The findings from biodistribution experiments in normal mice were confirmed in an experiment on tumor-bearing mice. The data for normal organs and tissues were in very good agreement. All conjugates were capable of targeting LS174T xenografts with moderate expression of HER2 in these cells. One might expect somewhat higher uptake of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ in the tumor because of increased bioavailability. However, this did not happen, possibly because of better retention of $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$ by cancer cells (Figure 5). Nevertheless, the favorable biodistribution properties of $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ provided the best tumor-to-organ ratios in comparison with the other conjugates. The most important difference was in the tumor-to-liver ratio, determining the sensitivity of liver metastasis detection. In the case of $[^{99m}Tc(CO)_3]^+$-H_6-$Z_{HER2:342}$, the concentration of radioactivity in the tumor was only one-third of the concentration in the liver. Relocation of the hexahistidine tag to the C-terminus improved the tumor-to-liver ratio, and $[^{99m}Tc(CO)_3]^+$-$Z_{HER2:342}$-H_6 might provide a positive contrast over the liver for tumors with a higher level of HER2 expression. $[^{99m}Tc(CO)_3]^+$-$(HE)_3$-$Z_{HER2:342}$ gave a positive contrast (tumor-to-liver ratio of 3.0 ± 0.5) in the present experiment using low HER2 expressing LS174T xenografts.

In conclusion, this study demonstrated that both the position and composition of a histidine tag may influence the hepatic uptake of $[^{99m}Tc(CO)_3]^+$-labeled Affibody molecules in vivo. The use of the hydrophilic and negatively charged HEHEHE-tag provided by far the lowest level of hepatic uptake, as well as the lowest accumulation of radioactivity in other organs and tissues. In fact, the biodistribution data obtained with this ^{99m}Tc-labeled variant of $Z_{HER2:342}$ are in line with the data obtained with the best nonhistidine tag containing constructs labeled with ^{99m}Tc (*22*, *24*, *25*). Thus, this molecule might be a good clinical imaging agent, not just an example of a favorable procedure for evaluating alternative variants of a novel tracer. We hope that these observations can also be helpful for development of other targeting scaffold proteins for in vivo radionuclide imaging.

Chemically Modified Firefly Luciferase Is an Efficient Source of Near-Infrared Light

Bruce R. Branchini,* Danielle M. Ablamsky, and Justin C. Rosenberg

Department of Chemistry, Connecticut College, New London, Connecticut 06320, United States. Received June 5, 2010; Revised Manuscript Received September 14, 2010

Bioluminescence and bioluminescence resonance energy transfer (BRET) are two naturally occurring light emission phenomena that have been adapted to a wide variety of important research applications including in vivo imaging and enzyme assays. The luciferase enzyme from the North American firefly, which produces yellow−green light, is a key component of many of these applications. Recognizing the heightened interest in the potential of near-infrared (nIR) light to improve these technologies, we have demonstrated that spectral emissions with maxima of 705 and 783 nm can be efficiently produced by a firefly luciferase variant covalently labeled with nIR fluorescent dyes. In one case, an outstanding BRET ratio of 34.0 was achieved emphasizing the importance of selective labeling with fluorescent dyes and the efficiency provided by the intramolecular BRET process. Additionally, we constructed a biotinylated fusion protein that similarly produced nIR light. This novel material was immobilized on solid supports containing streptavidin, demonstrating, in principle, that it may be used for receptor-based imaging. Also, the matrix-bound labeled fusion protein was used to measure factor Xa activity at physiological concentrations in blood. We believe this to be the first report of bright nIR light sources produced by chemical modification of a beetle luciferase.

INTRODUCTION

A wide variety of biological organisms emit light spanning the visible spectrum. Bioluminescence emission maxima ranging from 450 to 625 nm have been recorded (*1*) for species of crustaceans and beetles. Moreover, the 705 nm peak luminescence emanating from the light organs of several dragonfish (*2*) extends bioluminescence beyond human vision into the near-infrared (nIR) 700−1000 nm. In the dragonfish, the emitter is likely a secondary pigment (*2*) excited via bioluminescence resonance energy transfer (BRET), the natural process responsible for the green glow of the aequorin−GFP complex (*3, 4*). BRET-based assays, in which a bioluminescence donor excites a fluorescent acceptor, have been developed for a variety of applications (*5*) including measuring protease activity (*6*) and detecting protein−protein interactions (*7*−*9*). In the field of in vivo imaging, there is heightened interest in the nIR region because it can enable deeper imaging owing to lower background and minimized signal loss from light absorption and scattering (*10*). Promising BRET-based imaging results have been reported with quantum dot (QD)-*Renilla* luciferase (rLuc) conjugates (*11, 12*), including a recently described bioinorganic hybrid structure that emits at ∼800−1050 nm (*13*), and with a *Cypridina* luciferase (cLuc) containing fusion proteins modified with an indocyanine dye emitting at 675 nm (*14*).

Our interest is in developing new biomaterials with photonic properties that may be suitable for improved biomarker and biosensor applications focusing on the firefly luciferase system from *Photinus pyralis* (Luc). The firefly enzyme produces yellow−green light (Figure 1a) through a series of reactions that require substrates firefly (beetle) luciferin (LH_2), Mg-ATP, and oxygen. This process is generally considered to have the highest known quantum yield (41 ± 7.4%) (*15*) of any bioluminescence system based on the conversion of substrate (luciferin) into photons. Additional advantages of working with Luc are the superior stability and relatively low cost of LH_2. While notable applications of BRET-based red sources have been reported (*11, 12, 14*), we have developed Luc-based BRET systems with greater BRET efficiencies that provide improved signal-to background ratios. The efficiency of BRET is dependent on the spectral overlap, relative orientation, and the distance between the bioluminescence donor and the fluorescence acceptor. We set out to determine whether the Luc system could be used to produce efficient BRET-based sources of nIR light. Our strategy was to optimize spectral overlap with the long-wavelength acceptor absorption spectra typical of nIR fluorescent dyes by starting with a recombinant *P. pyralis* luciferase containing the mutations Thr214Ala, Ala215Leu, Ile232Ala, Ser284Thr, Phe295Leu, Arg330Gly, Ile351Val, and Phe465Arg (Ppy RE8), our recently developed (*16*) thermostable Luc variant, which emits red light (617 nm) (Figure 1b). We investigated two acceptors, the Alexa Fluor nIR dyes AF680 and AF750 with excitation maxima of 680 and 750 nm and emission maxima of 705 and 780 nm, respectively. Using versions of these dyes containing maleimide groups, we covalently attached the nIR dyes to Ppy RE10, a variant of Ppy RE8 containing two surface Cys residues at positions 169 and 399, and achieved highly efficient nIR emission by an intramolecular BRET process that minimized donor−acceptor distance. We report here the design, construction, and characterization of soluble and immobilized Luc-based sources of nIR light. Additionally, we demonstrate that the novel materials can be applied to the assay of factor Xa activity and we provide information from model studies with blood designed to assess the potential advantage of nIR transmittance. The measurement of factor Xa activity has become increasingly common in clinical laboratories, because it is an effective means to monitor heparin

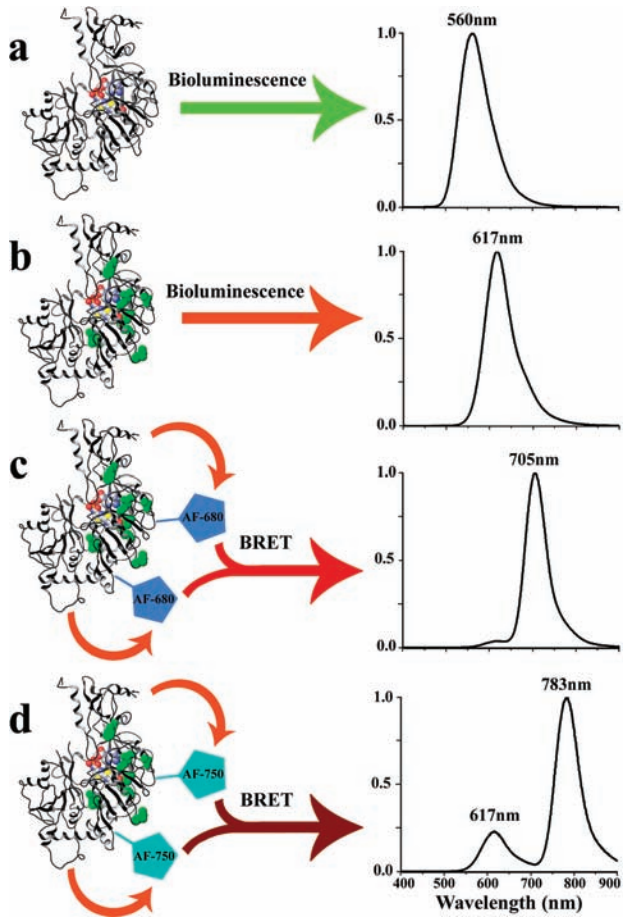

Figure 1. Normalized bioluminescence and BRET emission spectra of (a) Luc, (b) Ppy RE8, and Ppy RE10 labeled with (c) AF680 or (d) AF750. Reactions were initiated by the addition of LH_2 and Mg-ATP at pH 7.8. Ribbon diagrams are based on a Luc-DLSA crystal structure (Branchini, B. R., Southworth, T. L., and Gulick, A. M. Unpublished results) (*25*) showing mutated residues (green) and DLSA as CPK models.

anticoagulant therapy used for treatment and prevention of thromboembolic disease (*17*).

EXPERIMENTAL PROCEDURES

Materials. The following materials were obtained from the sources indicated: Mg-ATP (bacterial source) from Sigma-Aldrich (St. Louis, MO); Alexa Fluor 680 C2-maleimide (AF680) and Alexa Fluor 750 C5-maleimide (AF750) dyes from Invitrogen (Carlsbad, CA); NanoLinK streptavidin magnetic microspheres from SoluLinK Biosciences (San Diego, CA); and Streptavidin agarose resin from Thermo Scientific (Rockford, IL). The recombinant GST-fusion proteins Ppy RE8 (*16*) and Ppy RE10 were expressed and purified as previously reported (*16, 18*−*21*). LH_2 was a generous gift from Promega (Madison, WI), and the pET-KBPT-Luc plasmid (*22*) was a generous gift from E. S. Yeung, Iowa State University.

General Methods. Concentrations of unlabeled proteins were determined using the Bio-Rad Protein Assay system using BSA as the standard. Unless otherwise specified, specific activity measurements, heat inactivation studies, and steady-state kinetics constants were determined as previously reported (*18, 19, 21, 23*). Mass spectral analyses were performed by tandem HPLC−electrospray ionization mass spectrometry (LC/ESMS) using a ThermoFinnigan Surveyor HPLC system and a ThermoFinnigan LCQ Advantage mass spectrometer. The found molecular masses (Da) of the newly reported luciferase variants were within the allowable experimental error (0.01%) of the calculated values (in parentheses): Ppy RE8-Thr169Cys, 61000 ± 6 (60998); Ppy RE8-Phe368Cys, 60961 ± 6 (60956); Ppy RE8-Ser399Cys, 61021 ± 6 (61016); and Ppy RE10, 61020 ± 6 (61014).

Covalent Labeling of Luciferase Enzymes with Alexa Fluor Maleimide Dyes. Stock solutions (10 mM, determined by UV−vis spectroscopy) of the AF680 ($\varepsilon_{684\ nm} = 175\ 000\ M^{-1}\ cm^{-1}$) and AF750 ($\varepsilon_{753\ nm} = 290\ 000\ M^{-1}\ cm^{-1}$) dyes (*24*) were prepared in sterile deionized water, divided into 30 μL aliquots, lyophilized, and stored at −20 °C. All labeling reactions were performed at 10 °C in 20 mM sodium phosphate buffer, pH 7.2 containing 150 mM NaCl, 5 mM EDTA and 0.8 M ammonium sulfate (PBSA buffer). Using Slide-A-Lyzer 10K MWCO dialysis cassettes (Thermo Scientific, Rockford IL), stock luciferase solutions (~2 mg/mL) in 20 mM Tris-HCl (pH 7.0) containing 150 mM NaCl, 1 mM EDTA, and 1 mM DTT were dialyzed against PBSA buffer (5 changes, 1 L each) to remove DTT and introduce 0.8 M ammonium sulfate. The inclusion of ammonium sulfate in PBSA effectively reduced noncovalent dye incorporation that can result from hydrophobic interactions between the dyes and the proteins. Labeling reactions were initiated by the addition of 1 mL of 30 μM enzyme in PBSA buffer to a lyophilized aliquot of AF680 or AF750 (final concentration 300 μM) and gently mixed for 15 min. Reactions were quenched by addition of 20 μL of 100 mM glutathione in PBSA buffer, incubated for 15 min, and dialyzed against PBSA buffer (8 changes, 1 L each). The nIR dye-labeled proteins could be stored in PBSA buffer at 5 °C for at least 6 weeks without the loss of more than 10% activity. For long-term storage, labeled and unlabeled proteins were dialyzed into 20 mM sodium phosphate buffer, pH 7.2, containing 150 mM NaCl and 5 mM EDTA, flash-frozen in liquid N_2, and stored at −80 °C with complete retention of activity.

Determination of Fluorescent Dye Labeling Stoichiometry. The degree of nIR dye labeling was estimated by UV−vis spectroscopy by measuring the micromoles of dye (using the molar absorptivity coefficients above) bound to micromole samples of labeled luciferases. A Micro BCA Protein Assay Kit (Thermo Scientific, Rockford IL) was used to determine the quantity of enzyme with readings taken at 540 nm to avoid interference with dye absorption bands. Additionally, LC/ESMS analysis of the labeled luciferases was performed using a BioBasic-C4 (100 × 1 mm) column eluted at a flow rate of 50 μL/min using an acetonitrile gradient of 10%/min. Elution was monitored by absorbance at 260 and 680 nm or 750 nm. With all labeled enzymes, long-wavelength absorption associated with the Alexa Fluor dyes was only observed coeluting with protein indicating the absence of any noncovalently attached label. If present, fluorescent dyes not covalently attached to protein would be observed eluting prior to the covalently labeled enzymes (Supporting Information Figure S1). Dye/protein incorporation ratios were determined from the observed masses of each covalently labeled protein. Protein mass increases of 979 Da (AF680) and 1048 Da (AF750) were taken as 1:1 dye/protein incorporation ratios, while mass increases of 1958 Da (AF680) and 2096 Da (AF750) corresponded to 2:1 dye/protein incorporation ratios. Postrun data analysis was performed using ThermoFinnigan *BioWorks Browser 3.0* deconvolution software.

Identification of Ppy RE10 Residues Labeled with Fluorescent Dyes. Samples (200 μg) of Ppy RE10 labeled as described above with AF680 or AF750 were digested with thermolysin (protease/protein, 1:10, w/w) in 50 mM ammonium bicarbonate, pH 8.0, for 6 h at 37 °C. Peptides were separated on a Gemini-NX 5 μ C18 110 Å column (50 × 2.00 mm) at a flow rate of 50 μL/min using 0.1% aqueous TFA containing linear gradients of acetonitrile: 5% (v/v) initially for 5 min, 50%

after 90 min, and 95% after 110 min. Elution was monitored by absorbance at 214 nm, 260 nm, and either 680 or 750 nm for AF680 or AF750 labeled peptides, respectively. Each digest of nIR dye-labeled enzyme produced two major peaks with long-wavelength absorbance attributable to the dyes. For the AF680-labeled luciferase, masses of 1199 ± 0.1 and 1344 ± 0.1 Da were found corresponding to the mass of the dye plus Val168Cys169 and Ile397Met398Cys399, respectively. For the AF750-labeled enzyme, masses of 1268 ± 0.1 and 1413 ± 0.1 Da were observed that were consistent with the mass of the dye plus Val168Cys169 and Ile397Met398Cys399, respectively. While the presence of Val80Cys81 is a potential source of ambiguity, Ppy RE8, which lacks Cys at position 169, did not incorporate the Alexa Fluor dyes. Additionally, the labeled peptide sequences were confirmed by MS/MS analysis in which masses of 1100 ± 0.1 and 1169 ± 0.1 Da, corresponding to Cys covalently bound to AF680 and AF750, respectively, were observed. Upon prolonged standing at room temperature, proteolysis mixtures produced additional peaks corresponding to mass additions of 18, suggesting hydrolytic ring-opening of the maleimide group. Since the dyes are presumably attached through thioether linkages, maleimide ring-opening would not release the dyes.

Bioluminescence and BRET Emission Spectra. Bioluminescence emission spectra were obtained using a Horiba Jobin-Yvon iHR imaging spectrometer equipped with a liquid N_2 cooled CCD detector and the excitation source turned off. Data were collected at 25 °C (in a 0.8 mL quartz cuvette) over the wavelength range 400−935 nm with the emission slit width set to 25 nm and were corrected for the spectral response of the CCD using a correction curve provided by the manufacturer. Reactions (0.525 mL final volume) were initiated by addition of 5 μL aliquots of luciferase in PBSA buffer (0.2−0.3 μM final concentration) to solutions containing LH_2 (150 μM) and Mg-ATP (2 mM) in 25 mM glycylglycine buffer, pH 7.8. The pH values of the reaction mixtures were confirmed before and after spectra were obtained. BRET ratios were calculated from emission spectra by dividing the area under the BRET emission peak by the area under the residual bioluminescence peak.

Immobilization of BXRE-680 onto Streptavidin Supports. Biotinylated BXRE10, the fusion protein consisting of an N-terminus hexa-His tagged biotin binding domain (BBD) joined to Ppy RE10 through the peptide linker GSGSIEGRGSGS, was chemically modified with AF680 as described above yielding BXRE-680, the corresponding biotinylated fusion protein with AF680 covalently bound in a 2:1 dye/protein ratio. Streptavidin-coated magnetic microspheres and agarose resin were each prepared by aliquoting 0.1 mL portions of bead slurry, separating and removing the supernatant (via magnet for magnetic beads, quick desktop centrifugation for agarose resin), and washing three times with 0.1 mL portions of PBSA buffer. The supernatant was removed, and the beads were stored on ice. BXRE-680 was bound to the supports by adding 0.1 mL of an ∼1.5 mg/mL protein solution in PBSA to the prewashed beads, which were then incubated with gentle mixing for 10 min on ice. The supernatant was removed, and the immobilized BXRE-680 beads were washed five times with 0.1 mL portions of PBSA buffer. The materials were resuspended in PBSA buffer to a total volume of 0.1 mL and stored in PBSA buffer at 5 °C. An equally effective procedure to prepare immobilized BXRE-680 was to add the streptavidin-coated supports to labeling mixtures of nIR dye and BXRE10 (see above), followed by washing with ten 0.1 mL aliquots of PBSA. Excess label and unreacted glutathione were effectively removed while avoiding the exhaustive dialysis step. Alternatively, biotinylated BXRE10 can be bound to the insoluble supports and then labeled with AF680 followed by repeated washing with PBSA buffer.

Estimation of Specific Activities of Immobilized Fusion Proteins. Integrated specific activities of bead-bound fusion protein samples were estimated using a Horiba Jobin-Yvon Fluorolog-3 with the excitation source shunted. A "flea"-sized magnetic stir bar was used to suspend the immobilized material throughout the 15 min measurement. A volume of bead solution equivalent to ∼2 μg of protein was mixed with 0.4 mL of 0.6 mM LH_2 in a 0.8 mL quartz cuvette. The reactions were initiated at 25 °C by injection of 120 μL of 18 mM Mg-ATP solution through a modified lid. Signal intensity was measured over 15 min by centering the emission monochromator to the appropriate peak wavelength (617 nm for BXRE10, 706 nm for BXRE-680). The emission slit width was set to the maximum of 29.4 nm, and emission intensities were corrected for the spectral response of the R928 photomultiplier tube, and for the relative percentage of the overall emission profile observable through the 29.4 nm window.

Transmittance of Bioluminescence through Blood. Solutions (5 mL) of 2 mM Mg-ATP and 0.60 mM LH_2 in PBS, pH 7.3, were diluted with equal volumes of PBS or citrated human blood, and the pH of each was adjusted to 7.3. Aliquots (520 μL) of PBS- or blood-containing solutions were added to cuvettes, and bioluminescence was initiated by addition of 3 μg of luciferase at 25 °C. After 10 s, bioluminescence emission was recorded with a CCD detector as described above. Percent light transmittance through 50% blood solution was calculated from the ratio of the integrated intensities of the signals transmitted through blood and PBS.

Factor Xa Assay. Assays of factor Xa activity from a commercial sample of authentic material were performed in either PBSA buffer or citrated human blood. The specific activity of the sample was confirmed by assay with the chromogenic substrate Bz-Ile-Glu(γ-OR)-Gly-Arg-pNA·HCl (Kabi Diagnostica, Stockholm, Sweden). A sample of BXRE-680 immobilized onto agarose beads (Agarose-SA:BXRE-680), prepared as described above, was divided into 0.1 mL aliquots that were briefly centrifuged. The supernatants were removed and replaced with 0 to 20 μg/mL of factor Xa in 0.1 mL of either PBSA or blood. The solutions were resuspended and gently mixed while incubating at 25 °C. At various time intervals, the suspensions were briefly centrifuged, 5 μL aliquots were withdrawn, and incubation was continued after the mixtures were resuspended. To simulate performing the bioluminescence measurements in blood, assay solutions containing 0.25 mL of blood and 0.25 mL of 1.0 mM Mg-ATP and 0.3 mM LH_2 in PBS were used. Light reactions were initiated by the addition the 5 μL aliquots of supernatant and were monitored with a liquid N_2 cooled CCD as described above. Emission intensity was determined by integrating the resulting bioluminescence emission spectra. Light reactions performed in PBSA (no added blood) were monitored using a photomultiplier tube as described above.

RESULTS AND DISCUSSION

Ppy RE8 Cysteine Variants. With the goal of developing efficient intramolecular BRET-based sources of nIR light using the firefly luciferase system, we initiated our studies with the recently developed thermostable Luc variant Ppy RE8 (*16*), which emits red light (617 nm) (Figure 1b) with 63% bioluminescence specific activity compared to wild-type Luc (Ppy WT) (Table 1). The red-shifted emission of Ppy RE8 provided better donor−acceptor overlap with the nIR fluorescent dyes AF680 and AF750 than was possible with Luc, 59% with AF680 and 29% with AF750 compared to 40% and 15%, respectively (Figure 2). The commercially available AlexaFluor dyes afford nIR fluorescence with good quantum yields of 0.36 (AF680) and 0.12 (AF750) (*24*), and excellent labeling specificity for Cys residues provided by the appended maleimide groups.

Table 1. Properties of Firefly Luciferase Variants

enzyme	relative specific activity[a]	decay time[b] (min)	K_m (μM)		bioluminescence λ_{max} (nm, fwhm[c])	thermal inactivation[d] (h)
			LH_2	Mg-ATP		
Ppy WT	100	0.10	15 ± 2	160 ± 20	560 (73)	0.26
Ppy RE8	63	0.26	77 ± 8	391 ± 39	617 (73)	3.50
Ppy RE8/C169	78	3.10	138 ± 9.6	450 ± 45	617 (72)	4.00
Ppy RE8/C368	84	3.90	105 ± 13	523 ± 50	617 (72)	1.10
Ppy RE8/C399	94	2.30	113 ± 13	517 ± 48	617 (71)	3.50
Ppy RE10	97	1.70	175 ± 16	422 ± 41	617 (71)	3.60

[a] Specific activity based on 15 min integration assays performed as previously described (*23*). The error of the triplicate measurements was less than 10% of the measured value. [b] Time for maximum signal intensity to decay to 15% of the initial value. [c] Full width at half-maximum intensity. [d] Time for the maximum initial activity to decay to 50% at 37 °C.

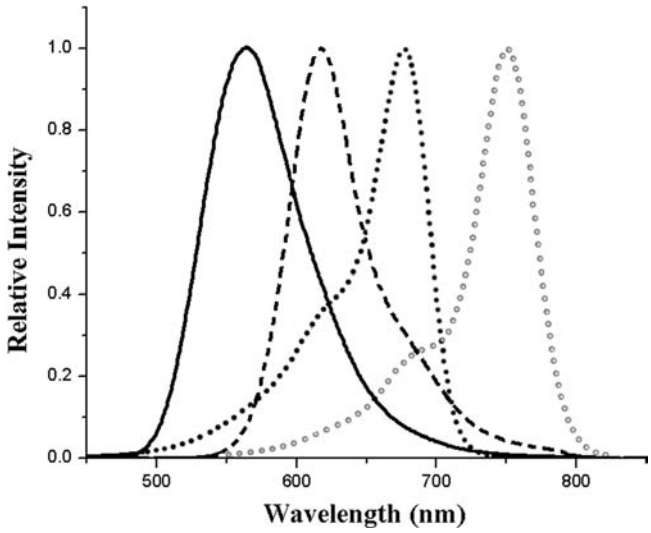

Figure 2. Overlap of normalized bioluminescence emission spectra of Luc (solid line), Ppy RE8 (dashed line), and Ppy RE10 (dashed line) with the normalized excitation (absorption) spectra of AF680 (closed circles) and AF750 (open circles).

Although Ppy RE8 contains four native Cys residues, molecular modeling based on a crystal structure (*1*) of Luc in complex with the inhibitor DLSA (*25*), an N-acylsulfamate analogue of LH_2-AMP, indicated that the thiols were not in solvent-exposed surface positions. As anticipated, control experiments with Ppy RE8 and the AlexaFluor nIR dyes produced neither measurable BRET signals nor any covalent incorporation of dye as determined by LC/ESMS (data not shown). Next, molecular modeling was used to select residues Thr169, Ser185, Ser307, Phe368, and Ser399 for mutation to Cys based on their surface locations, proximity to (but not part of) the active site, and, with the exception of Phe368, structural similarity to Cys. The single Cys Ppy RE8 variants were obtained as pure proteins in yields of 5−10 mg/0.25 L culture, and the characterization of the bioluminescence properties of the three most promising ones is presented in Table 1. Significantly, the introduction of a single Cys residue at positions 169, 368, or 399 produced luciferases with bioluminescence emission maxima of 617 nm, a value identical to that of the template enzyme Ppy RE8. The K_m values of the single Cys mutants were slightly elevated up to 2.3-fold for LH_2 and 1.3-fold for Mg-ATP, while the specific activities determined from 15 min integrated light emission were somewhat enhanced. Since the overall stability of the Cys368 enzyme, estimated from 37 °C thermal inactivation data (Table 1), was significantly lower than that of Ppy RE8 and the other Cys variants, we did not study it further. Instead, we added both the T169C and S399C mutations to Ppy RE8 and expressed and purified the resulting Ppy RE10 protein obtaining 7 mg from 0.25 L culture. The protein has 1.4-fold enhanced specific activity and is otherwise quite similar to Ppy RE8.

Covalent Labeling of Luciferases with Alexa Fluor Maleimide Dyes Produces nIR BRET Emission. The Ppy RE8 Cys169 and Cys399 enzymes along with Ppy RE10 were covalently labeled with AF680 and AF750 by incubating 30 μM protein solutions in PBSA buffer with a 10-fold molar excess of dye for 15 min at 10 °C. Ppy RE8/C169 and Ppy RE8/C399 have similar activity and thermostability properties (Table 1) and nIR dye labeling produced BRET emission at ~705 nm (with AF680) and ~780 nm (with AF750). However, the BRET efficiencies obtained with these proteins were quite different (Table 2). The BRET ratios of the position 399 labeled enzymes were ~5- to 9-fold greater than those of the corresponding position

Table 2. Properties of Luciferase Variants and Fusion Proteins Labeled with Alexa Fluor nIR Dyes

enzyme[a]	relative specific activity[b]	decay time[c] (min)	thermal inactivation[d] (h)	BRET λ_{max} (nm, fwhm[e])	BRET ratio[f]	labeling stoichiometry[g]
Ppy WT	100	0.10	0.26		-	-

[a] AF750 and AF680 refer to the fluorescent dyes covalently attached to the respective enzymes. [b] Specific activity based on 15 min integration assays performed as previously described (*23*). The error of the triplicate measurements was less than 10% of the measured value. [c] Time for maximum signal intensity to decay to 15% of the initial value. [d] Time for the maximum initial activity to decay to 50% at 37 °C. [e] Full width at half-maximum intensity. [f] BRET ratios were calculated from emission spectra by dividing the area under the BRET emission peak by the area under the residual bioluminescence peak. [g] The number of dye molecules incorporated per molecule of enzyme was calculated by UV−vis absorption as described in the Experimental Procedures. The error in the UV−vis based determination is ~20%. The ratios in parentheses are based on the masses associated with the only peaks detected using LC/ESMS. [h] Contains bound biotin. [i] The BXRE-680 LC peak contained a second minor mass indicative of 1:1 dye/protein labeling.

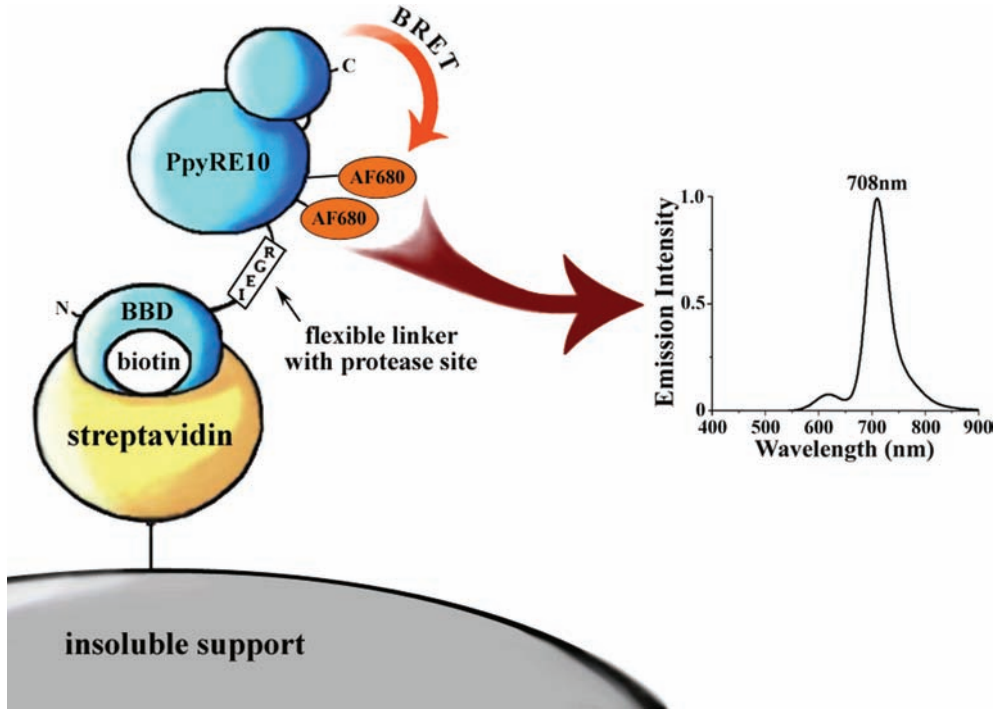

Figure 3. BRET emission spectrum of BXRE-680 immobilized on Agarose-SA. The fusion protein contains biotin bound to a biotin binding domain that is connected through a 12 amino acid linker (containing a factor Xa protease site) to Ppy RE10 labeled with AF680. The emission spectrum was recorded by suspending an aliquot of the immobilized material in a pH 7.8 buffer containing LH_2 and Mg-ATP.

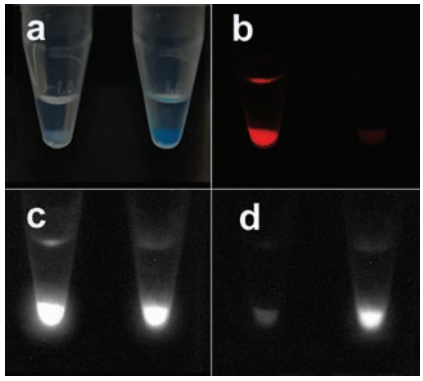

Figure 4. Visible and nIR light emission produced by unlabeled and labeled immobilized fusion proteins. In each panel, the tubes contain ~20 μL of Agarose-SA bound substrate (right tubes, BXRE-680; and left tubes, the immobilized fusion protein with no AF680 attached) that settled from 70 μL pH 7.8 buffered suspensions after brief centrifugation. The protein concentrations in the 20 μL of settled resin are ~40 μM. In panels (a) and (b), photographs were taken with a Nikon D80 equipped with a stock IR filter (a) in ambient light prior to addition of LH_2 and Mg-ATP and (b) in the dark at 15 s exposure following addition of the substrates and showing only visible light emission. In panels (c) and (d) photographs were taken with an iGen NV 20/20 camera with night vision (infrared) capability (c) capturing total light emission; and in (d) using a Schott 695 nm long-pass filter showing only nIR emission.

169 enzymes (Table 2). Since the dyes attached to Cys399 are estimated to be 15 Å closer (20 Å versus 35 Å) to the emitter oxyluciferin, the higher BRET ratios associated with the labeling of Cys399 are expected, because resonance energy transfer efficiency is inversely proportional to and heavily weighted by the distance between the donor and the acceptor.

We reproducibly and quantitatively labeled milligram quantities of Ppy RE10 by attaching AF680 or AF750 to both the Cys169 and Cys399 residues (Table 2). Thermolysin proteolysis and LC/ESMS analyses verified the covalent attachment of the nIR dyes to the expected Cys169 and Cys399 residues (Experimental Procedures), presumably through thioether linkages. The dye-modified luciferases displayed emission maxima shifted to 705 and 783 nm with BRET ratios of 35.0 and 4.1, respectively (Figure 1c and d). Integrated light emission was 4.0-fold greater for Ppy RE10 labeled with AF680 compared to the AF750 labeled enzyme, representing a 1.7-fold increase and 2.4-fold decrease with respect to the Ppy RE10 template. The nIR dye-labeled Ppy RE10 enzymes provided an excellent combination of high BRET ratios, retention of enzyme activity, minimal nonspecific dye incorporation, long-wavelength emission maxima, and extended glow kinetics. Importantly, the two additional engineered Cys residues did not alter the 617 nm bioluminescence maximum of precursor Ppy RE8, nor did they adversely affect specific activity.

While the BRET ratio of 4.0 with the attached AF750 label is very good and is similar to results obtained with quantum dot (QD)−rLuc mutant conjugates (*12*), the 34.0 value obtained with AF680 is extraordinary. Moreover, the bioluminescence maximum of Luc has been red-shifted 223 nm by the combined effects of mutagenesis (57 nm) and BRET (166 nm) in the AF750 labeled enzyme. The nIR dye-labeled Ppy RE10 enzymes were stable for at least 6 weeks when stored in solution at 5 °C, and they could be flash frozen, stored at −80 °C, and thawed without loss of activity. Additionally, the BRET activity was retained at levels greater than 50% for ~3 h at 37 °C. To the best of our knowledge, this is the first report of bright nIR light sources produced by chemical modification of a beetle luciferase. The outstanding BRET ratio (34.0) achieved with AF680 labeling of Ppy RE10 emphasizes the importance of selective labeling with fluorescent dyes.

We considered the basis of the appreciably different labeling results, particularly the 4.0-fold higher specific activity and 8.5-fold greater BRET ratio obtained with Ppy RE10 labeled with AF680 and AF750, respectively (Table 2). Since the dyes are approximately the same size, have similar chemical structures (preliminary structure assignments based on HRMS and NMR) and are attached to the same Ppy RE10 thiols, distances from the emitter can be ruled out, although differences in spatial

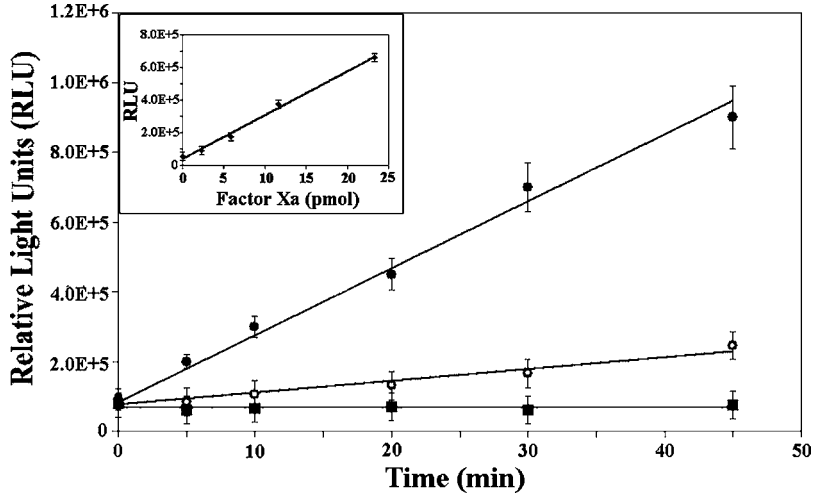

Figure 5. Bioluminescence assays of factor Xa activity in whole blood. Stirred suspensions of aliquots of Agarose-SA:BXRE-680 in whole blood (0.1 mL) were incubated at 20 °C with factor Xa: (filled squares) 0 μg/mL; (open circles) 2.5 μg/mL; and (filled circles) 10 μg/mL. Aliquots (5 μL) were withdrawn and assayed at the times shown as described in detail in the Experimental Procedures. The inset shows bioluminescence end point assay data collected 30 min after incubation of factor Xa in stirred substrate suspensions of Agarose-SA:BXRE-680.

orientation of the dyes may be a contributing factor. Instead, it is likely that the variation in the specific activities can largely be accounted for by the 3-fold higher fluorescence quantum yield of AF680 (0.36) compared to AF750 (0.12) (*24*). That is, even if the energy transfer efficiencies were identical, the AF680 labeled enzyme would be expected to produce ~3-fold more BRET emission than the AF750 labeled protein. While the difference in the quantum yields of the nIR dyes also contributes to the superior BRET ratio of the AF680 labeled Ppy RE10, the 2-fold greater spectral overlap of Ppy RE10 bioluminescence with the AF680 excitation spectrum is also an important contributing factor. Additionally, the AF680 labeled enzymes produced integrated specific activities (based on total photons emitted) that were greater than that of Ppy WT (Table 2). This is most likely due to improved turnover. Under the assay conditions employed in the measurement of the integration-based activities, Luc is inhibited by the formation of dehydroluciferyl-AMP, a side product naturally formed during the oxidation of LH_2 (*26*−*28*), that binds tightly and dissociates very slowly (K_D = 0.5 nM) from the active site. Possibly, the binding of AF680 on the surface of the Luc variants results in conformational changes that caused an increase in the K_D of the inhibitor.

Immobilized AF680-Labeled Ppy RE10 Fusion Proteins. To demonstrate that a Luc-based BRET source could be applied where nIR emission would be advantageous, e.g., in receptor-based imaging and for enzyme assays in whole blood, we constructed the fusion protein BXRE-680 and immobilized it to streptavidin (SA) bound to agarose or magnetic microspheres (Figure 3). Modeled after a similar fusion protein containing Luc immobilized on magnetic beads (*22*), BXRE-680 contains biotin bound to a biotin binding domain connected to AF680-labeled Ppy RE10 through a12 amino acid residue linker sequence that includes the IleGluGlyArg factor Xa protease site. Reaction of AF680 with the biotinylated fusion protein BXRE10 produced BXRE-680 with an ~2-fold greater specific activity, likely resulting from the slower decay of luminescence (Table 2). The linker peptide and BBD do not contain Cys residues and LC/ESMS analysis of BXRE-680 confirmed the incorporation of 2 nIR dyes/fusion protein. After attachment to both agarose and magnetic microspheres through the strong streptavidin (SA)−biotin interaction (*29*), matrix-bound BXRE-680 produced BRET ratios of 13.7 (708 nm maximum) and 11.0 (706 nm maximum), respectively (Table 2). While immobilization reduced specific activity 1.5- and 3.4-fold for the agarose and magnetic bead bound materials, respectively, the materials are bright sources of red and nIR light as illustrated with Agarose-SA:BXRE-680 (Figure 4). Yeung and co-workers reported (*22*) making a biotinylated fusion protein of Luc with an attached BBD that was then immobilized on SA-containing beads. The modified beads were attached to cell surfaces and employed to image ATP release from live astrocyte cells upon addition of LH_2 using a CCD camera (*22*). The construction of the biotinylated BXRE-680 fusion protein and demonstration that it efficiently emits nIR light while immobilized through the streptavidin−biotin interaction (Figures 3 and 4) established, in principle, that our material can be applied similarly for receptor imaging of genetically encoded streptavidin sites. However, one drawback of the chemical labeling approach used to produce our materials is that they cannot be genetically encoded, thereby limiting their usefulness for in vivo applications. Nevertheless, Ohmiya and co-workers recently demonstrated (*14*) the targeting and tumor imaging capabilities of a biotinylated nIR dye labeled-cLuc conjugate in live mice. This was accomplished by first linking the labeled cLuc conjugate to an avidin-monoclonal antibody against a cell surface tumor marker. Injection of this biotin−avidin complex, followed by injection of the cLuc substrate coelenterazine produced BRET signals (λ_{max} = 675 nm) that enabled tumor detection and imaging (*14*). These interesting results strongly support the feasibility of applying BXRE-680 fusion proteins for similar purposes. Moreover, since the cited applications (*14, 22*) employ CCD cameras, the longer wavelength emission and superior BRET ratio of BXRE-680 (e.g., 40- to 50-fold greater than the cLuc-containing material) may provide enhanced sensitivity in environments containing interfering visible light absorbing substances. However, additional experiments must be undertaken to determine whether the potential advantages of BXRE-680 can be realized.

Factor Xa Assays with Agarose-SA:BXRE-680. We also explored the use of the agarose bound BXRE-680 material (Figure 3) as a substrate for assaying factor Xa activity. Briefly, various concentrations (1−20 μg/mL) of commercial factor Xa were incubated at 25 °C in citrated human blood containing the resin-bound substrate. The assay principle is that factor Xa cleavage of BXRE-680 releases AF680-labeled Ppy RE10 from the matrix into the blood medium. Physiologically significant levels of factor Xa activity were proportional to the light intensity produced by the solubilized BRET source (after brief centrifugation to separate unreacted matrix-bound substrate) upon addition of substrates LH_2 and Mg-ATP (Figure 5). The advantage provided by the nIR source was that there was

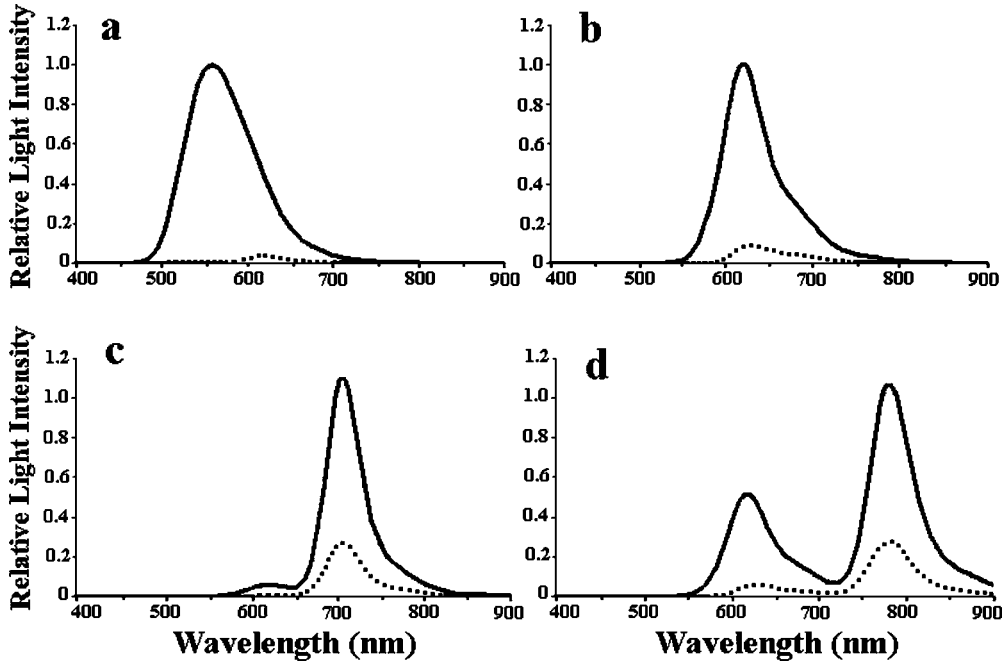

Figure 6. Relative transmittance of bioluminescence through citrated human blood. The emission spectra shown in all panels were initiated by addition of solutions of Mg-ATP (2 mM) and LH_2 (0.60 mM) in PBS to citrated human blood (dashed lines) or PBS (solid lines) containing (a) Ppy GR-TS (*18*); (b) Ppy RE10; (c) Ppy RE10-AF680; and (d) PpyRE10-AF750 as described in detail in the Experimental Procedures.

sufficient sensitivity to detect 1 μg/mL of factor Xa from aliquots of blood diluted only 1:1 with substrate solution. Emission spectra showing the attenuation of green (Ppy GR-TS), red (Ppy RE10), and nIR (Ppy RE10-AF680 and Ppy RE10-AF750) signals by whole human blood diluted 1:1 with an isotonic buffer are presented in Figure 6. Since the bioluminescence measurements were made with the proteins in direct contact with the blood components, attenuation may result not only from the absorption of light emission, but also from nonspecific effects, e.g., adsorption of the enzymes, and from quenching of bioluminescence and/or fluorescence of the nIR dyes. Strong hemoglobin absorption (*30*) is likely an important factor in the nearly complete loss (~97%) of the green signal (Figure 6a) and the 550−600 nm component of the Ppy RE10 emission (Figure 6b). However, interference of Ppy RE10 bioluminescence also occurs as the total bioluminescence signal has been attenuated ~90%. The loss of Ppy RE10 bioluminescence intensity no doubt contributes to the reduced intensity of the nIR signals produced by BRET (Figure 6c,d); however, the relative intensities produced by the AF-680 and AF-750 labeled enzymes in blood were ~23% and ~25%. This result very likely reflects the greater transmission of nIR light in a medium containing hemoglobin. Immobilized versions of the fusion protein with linkers containing other specific cleavage sites should provide new substrates for protease assays as demonstrated with factor Xa, possibly in media like blood where interference with visible light is a serious problem. Additional potential applications (*31*) include immunoassays and biosensors.

1. Materials and General Methods

Materials. The following materials were obtained from the sources indicated: Mg-ATP (bacterial source) from Sigma-Aldrich (St. Louis, MO); Glutathione Sepharose 4B media and pGEX-6P-2 expression vector from GE Healthcare (Piscataway, NJ); pQE30 expression vector from Qiagen (Valencia, CA); QuikChange® Lightning Site-Directed Mutagenesis kit from Stratagene (La Jolla, CA); Alexa Fluor® 680 C2-maleimide (AF680) and Alexa Fluor® 750 C5-maleimide (AF750) dyes from Invitrogen (Carlsbad, CA); NanoLinK™ streptavidin magnetic microspheres from SoluLinK Biosciences (San Diego, CA); and Streptavidin agarose resin from Thermo Scientific (Rockford, IL). The recombinant GST-fusion proteins Ppy RE8 (S1) (*15*) and Ppy RE10 were expressed and purified as previously reported (S1-S5) (*15-19*). LH_2 was a generous gift from Promega (Madison, WI) and the pET-KBPT-Luc plasmid (S7) (*20*) was a generous gift from E. S. Yeung, Iowa State University.

General Methods. Concentrations of unlabeled proteins were determined using the Bio-Rad Protein Assay system using BSA as the standard. DNA sequencing to verify all mutations, insertions and ligation sites was performed at the W. M. Keck Biotechnology Laboratory at Yale University. Unless otherwise specified, specific activity measurements, heat inactivation studies and steady-state kinetics constants were determined as previously reported (S2, S3, S5, S6) (*16, 17, 19, 21*).

2. Cloning of Ppy RE8 Variants.

Starting with the DNA encoding Ppy RE8 in the pGEX-6P-2 vector (S2), the QuikChange Lightning Site-Directed Mutagenesis kit was used to introduce the following single mutations using the indicated primers and their respective reverse complements: Thr169Cys 5´- CAG TCG ATG TAC ACG TTC GTC TGC TCT CAT CTA CCT CCC GGT TTT AAT G - 3´ [AleI]; Phe368Cys, 5´ - GGT AAA GTT GTT CCA TGT TTT GAA GCC AAG GTT GTG GAT CTG - 3´ [BstXI]; and Ser399Cys 5´-T GTC AGA GGG CCC ATG ATT ATG TGC GGT TAT GTA AAC AAT CCG - 3´ [ApaI] (bold represents the mutated codons, underline represents silent changes to create a unique screening

endonuclease site and brackets indicate the screening endonuclease). The gene encoding Ppy RE10 was made by sequential introduction of the Thr169Cys and Ser399Cys changes into the Ppy RE8 DNA.

3. Cloning of Fusion Protein BXRE10.

The vector containing the gene encoding a fusion protein (BXRE10), consisting of an N-terminus hexa-His tagged biotin binding domain joined to Ppy RE10 through the peptide linker –GSGSIEGRGSGS-, was constructed as follows. First the Qiagen pQE30 plasmid was modified to enable the insertion of the gene for Ppy RE10 flanked by BamHI and XhoI sites in the pGEX-6P-2 vector (see above). The existing XhoI site in the pQE30 plasmid was removed and a new one was created in the multiple cloning site downstream of the already present BamHI site using the following primers and their respective reverse complements: 5´- ACG AGG CCC TTT CGT CTT CAC CTG GAG AAA TCA TAA AAA - 3´and 5´- CAC GGA TCC GCA TGC GAG CTC GAG ACC CCG GGT CGA CCT - 3´, respectively. The gene encoding Ppy RE10 was isolated from the pGEX-6p-2 plasmid by digestion with BamHI and XhoI and was then ligated into the modified pQE30 vector, which had been digested with the same restriction enzymes. The modified pQE30 plasmid containing the Ppy RE10 gene was further altered by introducing the PmlI and SpeI restriction sites upstream of the luciferase gene to enable insertion of the DNA encoding the biotin binding domain (BBD, residues Met12-Val76 in the pET-KPBT-Luc plasmid) using the following primer and its respective reverse complement: 5´ - CAC CAT CAC CAT CAC GTG AGC ACT AGT GGA TCC ATG GAA GAC - 3´ (bold represents the inserted codons and the PmlI and SpeI endonuclease sites are underlined). The BBD was amplified from the pET-KPBT-Luc plasmid by PCR (initial denaturation at 95 °C for 2 min; a 60-cycle amplification of 95 °C for 30 s, 55 °C for 30 s and 68 °C for 1.75 min; and a final extension at 68 °C for 5 min) with the primers 5´- CAT CAT CAC GTG ATG GCT AGA GTC GAC GTC AGC - 3´ and 5´- CCA CCA GTA CTA GTA GTA ACG GCC GCC AGT GTG C - 3´ (bold represents the introduced endonuclease sites for insertion of the BBD). The PCR product was cleaned with the Qiagen QIAquick PCR purification kit, digested with PmlI and SpeI and ligated into the modified pQE30 vector

containing the Ppy RE10 DNA, which had been treated with the same restriction endonucleases, yielding pQE30-BBD-RE10. Using the primer 5´ - A CTG GCG GCC GTT ACT ACT GGA TCC GGA TCC ATC GAA GGT CGT GGA AGT GGA TCC AT - 3´ (bold represents the inserted codons) and its reverse complement, a 12 amino acid linker containing the factor Xa protease site IleGluGlyArg was inserted between the BBD and Ppy RE10 genes yielding pQE30-BXRE10. This plasmid encodes the fusion protein BBD-GSGSIEGRGSGS-Ppy RE10 containing a hexa-His-tag at the N-terminus (BXRE10).

3. Expression and Purification of Biotinylated Fusion Protein BXRE10.

Cultures (250 mL of Luria-Bertani media supplemented with 100 mg/mL ampicillin, 25 mg/mL kanamycin and 50 mM biotin) of transformed E. coli BL21 (pREP4) cells containing the pQE30-BXRE10 plasmid were grown in 1 L flasks at 37 °C to mid log phase ($A_{600\ nm}$ ~ 0.6), moved to a 22 °C incubator, allowed to equilibrate for 10 min, induced with 0.1 mM IPTG and incubated at 22 °C for 16-18 h. Cells were harvested by centrifugation at 4 °C and then frozen at -80 °C for 15 min. The cell pellet was resuspended in 25 mL of 150 mM sodium chloride, 100 mM sodium phosphate buffer, pH 7.3 (PBS) containing 0.1 mM phenylmethylsulfonyl fluoride and 5 mM imidazole. After the addition of 2.5 mL lysozyme (10 mg/mL in PBS), the cells were lysed by sonication and treated with DNase (5 mg/mL) and RNase (10 mg/mL) for 5 min on ice. Triton X-100 was added (1% final volume) and the whole-cell extracts were isolated by centrifugation at 20000 x g for 45 min. The biotinylated His-tagged fusion protein was purified using Ni-NTA agarose (Qiagen) affinity chromatography according to the manufacturer's instructions. Fractions eluted with 250-500 mM imidazole were pooled (2 mL) and dialyzed (2 changes, 1 L each) against 20 mM sodium phosphate buffer, pH 7.2 containing 150 mM NaCl, 5 mM EDTA and 0.8 M ammonium sulfate (PBSA buffer). Biotinylation was confirmed by LC/ESMS analysis showing a single eluting peak of 74592 ± 7 Da corresponding to the predicted mass of BXRE10 plus biotin (74348 + 244 = 74592 Da). The protein was stored at 5 °C in PBSA buffer (~2mg/mL) and retained 90% activity for at least 6 weeks.

Received June 8, 2010; Revised Manuscript Received August 23, 2010

We have devised and estimated a new strategy to prolong the residence time of radiolabeled antibodies in tumor in which an octaarginine peptide (R_8) was used as an anchoring molecule to fix antibodies against CD20 (NuB2; IgG2a) on tumor cells. Conjugation of R_8 with antibodies was performed by maleimide−thiol chemistry using thiol groups generated by reducing the disulfide bonds of the antibody. The R_8-conjugated NuB2 was then reacted with succinimidyl *meta*-[^{125}I]iodobenzoate to prepare [^{125}I]SIB-NuB2$_I$ (0.92 R_8/NuB2) and [^{125}I]SIB-NuB2$_{III}$ (3.38 R_8/NuB2). Both SIB-NuB2$_I$ and SIB-NuB2$_{III}$ exhibited size-exclusion HPLC elution profiles and immunoreactivity to CD20-positive cells similar to those of NuB2. NuB2$_I$ also possessed isoelectric focusing (IEF) profile similar to NuB2. However, NuB2$_{III}$ registered a broad IEF band toward higher pI. When incubated with CD20-positive cells, [^{125}I]SIB-NuB2$_I$ and [^{125}I]SIB-NuB2$_{III}$ exhibited 1.4 and 4.0 times higher cell-associated radioactivity than [^{125}I]SIB-NuB2. After the cells were washed and reincubated in a fresh medium for 3 h, [^{125}I]SIB-NuB2$_I$ and [^{125}I]SIB-NuB2$_{III}$ exhibited significantly higher cell-associated radioactivity than [^{125}I]SIB-NuB2. In biodistribution studies in normal mice, while both [^{125}I]SIB-NuB2$_I$ and [^{125}I]SIB-NuB2 exhibited similar biodistribution profiles, [^{125}I]SIB-NuB2$_{III}$ showed faster clearance from the blood and higher hepatic radioactivity levels than [^{125}I]SIB-NuB2. In SCID mice bearing CD20-positive xenografts, [^{131}I]SIB-NuB2$_I$ exhibited significantly higher radioactivity in xenografts than those of [^{125}I]SIB-NuB2 with no significant increase being observed in other tissues. The findings indicate that appropriate R_8 modification of antibodies satisfies both specific targeting ability of antibody and strong cell-association property of R_8, which was reflected in the increased radioactivity levels in tumor. These findings supported the applicability of this approach to enhance target-specific accumulation of radiolabeled antibodies.

INTRODUCTION

Radioimmunotherapy (RIT) is a cancer therapeutic modality that combines the specific tumor targeting of immunotherapeutics and cytotoxic radiation mechanisms. Encouraging results have been reported in patients with hematologic malignancies treated with ^{90}Y- and ^{131}I-labeled antibodies against CD20 (*1*−*4*), due to their intrinsic high radiosensitivity and relatively good access of the radiolabeled antibodies to the cancer cells (*5*, *6*). Despite numerous efforts, the treatment of solid tumors with radiolabeled antibodies resulted in limited success, due to poor localization of radiolabeled antibodies in the tumors (*7*−*9*). Thus, the enhancement of tumor accumulation and retention of radiolabeled antibodies constitutes a prime requisite for successful RIT.

Numerous factors have been presented as being responsible for tumor accumulation and retention of radiolabeled antibodies (*8*). Since the mechanism of accumulation of radiolabeled antibodies is based on their specific but reversible binding to antigens in tumor tissues, a strategy that shifts the equilibrium to antigen association was considered of prime importance to enhancing tumor accumulation. The use of antibodies internalized to target cells would prolong residence time in the tumor, since these molecules will be resistant to being cleared by washout. The conjugation of arginine-rich cell-penetrating peptides (AR-CPPs) to antibodies has been conducted as a means to facilitate internalization of antibodies and to increase tumor accumulation. Indeed, a prior study reported an increase in tumor accumulation of AR-CPP-conjugated antibodies in vitro (*10*). However, in vivo studies showed increased accumulation in nontarget tissues such as the liver with decreased accumulation in tumors. A prior study also described that the tumor targeting ability of an antibody construct (scFv) was completely abolished following conjugation with AR-CPP (*11*).

Meanwhile, an increase in avidity of antibodies constitutes another strategy to enhance tumor accumulation, as observed in antibody constructs with multivalent binding domains (*8*, *12*, *13*). An increase in tumor uptake was also observed with divalent radiolabeled haptens in pretargeting strategy (*14*). These studies suggested that chemical modification of antibodies with anchoring molecules that possess strong interaction with cell surface molecules or cell membrane may also be useful to shift the equilibrium to antigen association in tumor tissues.

Scheme 1

The AR-CPPs possess strong interaction with phosphate groups, sulfates, and carboxylates on cellular components (*15*−*18*). The electrostatic interaction between AR-CPPs and cell membrane is so strong that complete removal of AR-CPPs from the cell surface is difficult to perform (*19*−*21*). Such characteristics render AR-CPPs applicable as an anchoring molecule to shift the equilibrium to antigen association for prolonged retention of radiolabeled antibodies in tumors. In addition, the strong electrostatic interaction between AR-CPPs and cellular components suggested that AR-CPPs would exert their anchoring ability at conjugation levels much lower than those used for facilitating internalization.

In this study, an octaarginine peptide was selected as an anchoring molecule, and the peptide was derivatized with a maleimide group to conjugate with a relevant or irrelevant antibody against CD20 (Scheme 1). After radiolabeling of the modified antibodies with succinimidyl *meta*-[$^{125/131}$I]iodobenzoate ([$^{125/131}$I]SIB), the effect of the octaarginine conjugation on specific binding to target cells, dissociation rates from the cells, and biodistribution was determined with special emphasis being laid on the relationship between the anchoring ability of R_8 and the number of R_8 molecules attached per molecule of the antibody. The applicability of the new approach using an AR-CPP as an anchoring molecule to prolong residence time of radiolabeled antibodies in tumor will be discussed.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. Na[^{125}I]I and Na[^{131}I]I were obtained from MP Biomedicals (Irvine) and Perkin-Elmer (Yokohama, Japan), respectively. The stannyl precursor of the radioiodination reagents, *N*-succinimidyl-3-(tri-*n*-butylstannyl)-benzoate (ATE) was synthesized as reported previously (*22*). Size-exclusion high-performance liquid chromatography (SE-HPLC) was performed using a Cosmosil Diol-300 (7.5 × 600 mm, Nacalai Tesque, Kyoto, Japan) column at a flow rate of 1 mL/min with 0.1 M phosphate buffer (PB, pH 6.8) as an eluent. Each eluent was collected with a fraction collector (RediFlac, GE Healthcare Bioscience, Tokyo, Japan) at 1 min intervals. The radioactivity counts in each fraction (1 mL) were determined with an autowell γ counter (ARC-380M, Aloka, Tokyo). TLC analyses were performed with silica plates (Silica Gel 60 F_{254}, Merck, Tokyo). Isoelectric focusing (IEF) was conducted using a Tefco STC808 mini electrophoresis cell (Tefco, Tokyo) with a precast polyacrylamide gel isoelectric focusing (IEF-PAGE) mini isocratic gel (pH 3−10) (Tefco, Tokyo). Other reagents were of reagent grade and were used as received.

Cells and Antibodies. The CD20 positive human peripheral lymphocyte line RPMI 1788 cells were incubated with RPMI-1640 medium (Sigma-Aldrich Co, St. Louis, MO, USA) supplemented with 10% fetal calf serum and were used for the studies.

The monoclonal antibodies used in this study were a murine monoclonal antibody (NuB2; IgG2b) that reacts specifically with CD20 as a relevant antibody and a murine monoclonal antibody (8E1; IgG2a) specific to a neural protein as an irrelevant one, respectively, since both subclasses possess similar quaternary structures and the interchain disulfide bonds are the primary sites of chemical reduction for both antibodies (*23*). Both antibodies were kindly supplied from Immuno-Biological Laboratories Co, Ltd., (Takasaki, Japan).

Synthesis of Mal-(Acp)$_2$-(D-Arg)$_8$-(D-Tyr) (R_8). We employed D-octaarginine peptide as an AR-CPP, and the peptide with N-terminal bis-aminocaproate linker was coupled with *N*-(4-maleimidebutyryloxy)succinimide for antibody conjugation (Scheme 1).

The peptide chain of R_8 was constructed by Fmoc (9-fluorenylmethyloxycarbonyl) solid-phase peptide synthesis on a TGS-RAM resin (Shimadzu, Kyoto) using Shimadzu PSSM8 peptide synthesizer (Shimadzu, Kyoto) with its standard protocol. A 1-[bis(dimethylamino)methylene]-1*H*-benzotriazolium 3-oxide hexafluorophosphate/1-hydroxybenzotriazole/*N*,*N*-diisopropylethylamine coupling system was employed as the coupling system. As amino acid derivatives, Fmoc-Acp, Fmoc-D-Arg(Pdf), and Fmoc-D-Tyr(^{t}Bu) were used (Acp = 6-aminocaproic acid). The peptide resin was then treated with *N*-(4-maleimidobutyryloxy)succinimide (3 equiv) and *N*-methylmorpholine (3 equiv) in DMF at 37 °C for 20 min to yield a peptide resin bearing a maleimide moiety on its N-terminus. The final deprotection of the peptide resin using trifluoroacetic acid (TFA)−H_2O (95:5) at room temperature for 3 h followed by reverse-phase HPLC purification with a Cosmosil Protein-R (10 × 250 mm, Nacalai Tesque, Kyoto) at a flow rate of 1 mL/min with a gradient mobile phase starting from 14% A (H_2O containing 0.1% TFA) and 86% B (CH_3CN containing 0.1% TFA) to 44% A and 56% B in 15 min. The product was ascertained by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS, Voyager-DE STR, Applied Biosystems, Tokyo). MALDI-TOFMS: 1822.14 [Calcd for $(M + H)^+$: 1822.16].

Preparation of R_8-Modified Antibodies. Two R_8-modified NuB2s with different R_8-conjugation levels ($NuB2_I$ and $NuB2_{III}$) were prepared by reducing the disulfide bonds of NuB2 as reported previously with some modifications (Scheme 1) (*22*). Briefly, NuB2 was concentrated in a nitrogen atmosphere to 6.0 mg/mL in well-degassed 0.1 M PB (pH 7.0) containing 2 mM EDTA. The antibody (1.0 mL) was allowed to react with 2-mercaptoethanol (2-ME, 1000 molar excess) by gently stirring at room temperature for 30 min. Excess 2-ME was then removed

by a centrifuged column procedure using Sephadex G-50 Fine (GE Healthcare, Tokyo) equilibrated and eluted with 0.1 M PB (pH 6.0) containing 2 mM EDTA. A small aliquot of the filtrate was sampled, and the number of exposed thiol groups was determined with 2,2-dipyridyl disulfide (*24*). The filtrate was then added to a reaction vial containing 1.5-fold R_8 (42.8 μL, 85.7 μg) for $NuB2_I$ or 5-fold R_8 for $NuB2_{III}$ in 0.1 M PB (pH 6.0). After the reaction mixture was agitated gently for 1.5 h at 25 °C, 500-fold molar excess of iodoacetamide (269 μL, 2.68 mg) in 0.1 M PB (pH 6.0) was added. The reaction mixture was further incubated for 30 min to alkylate the unreacted thiol groups. $NuB2_I$ and $NuB2_{III}$ were finally purified by the centrifuged column procedure, equilibrated, and eluted with PBS (0.01 M, pH 7.4; Wako, Tokyo). Both $8E1_I$ and $8E1_{III}$ were prepared according to the procedure described above except for using 8E1 in place of NuB2.

Preparation of [$^{125/131}$I] *N*-Succinimidyl 3-Iodobenzoate (SIB)-Labeled Antibodies. *N*-Succinimidyl 3-(tri-*n*-butylstannyl)benzoate (ATE) was synthesized and radio-iodinated in the presence of *N*-chlorosuccinimide (NCS) as described previously (*25*). Briefly, ATE was dissolved in methanol containing 1% acetic acid (0.45 mg/mL), and 16.2 μL of this solution was mixed with 4.4 μL of NCS in methanol (0.5 mg/mL) in a sealed vial, followed by addition of Na[^{125}I]I (2 μL). After incubation at room temperature for 45 min, the reaction was quenched with aqueous sodium bisulfite (2.2 μL, 0.72 mg/mL). The radiochemical yield of [^{125}I]SIB was determined by TLC developed with ethyl acetate. The solvent was removed under a stream of N_2 prior to subsequent conjugation reaction with the antibodies. Conjugation of [^{125}I]SIB with antibodies was performed according to our previous procedure (*22*), with slight modifications as follows: A solution of $NuB2_I$, $NuB2_{III}$, $8E1_I$, or $8E1_{III}$ (120 μL, 2.5 mg/mL) in 0.2 M borate buffer (pH 8.5) was added to the dried residue of crude [^{125}I]SIB. After gentle incubation for 1 h at room temperature, [^{125}I]SIB-labeled antibodies were purified by the centrifuged column procedure, equilibrated, and eluted with PBS. Radioiodination of ATE with Na[^{131}I]I was performed as described above except for using Na[^{125}I]I in place of Na[^{131}I]I. Radiochemical purities of radiolabeled antibodies were also determined by SE-HPLC and TLC developed with 80% methanol/H_2O.

Preparation of ^{125}I-NuB2. Direct radioiodination of NuB2 was performed by the chloramine T method (*22*). To a solution of NuB2 (0.25 mg/mL; 200 μL) in 0.3 M PB (pH 7.5) was added 5 μL of Na[^{125}I]I. Chloramine T (0.1 mg/mL, 25 μL), freshly prepared in the same buffer, was then added. After incubation of the mixture for 10 min at room temperature, the reaction was terminated by an addition of 6 μL of aqueous sodium bisulfite (0.7 mg/mL). ^{125}I-NuB2 was purified by the centrifuged column procedure. The radiochemical purity was determined by SE-HPLC and TLC developed with 80% methanol/H_2O.

Preparation of Fluoresced Antibodies. NuB2, $NuB2_I$, and $NuB2_{III}$ were also labeled with Alexa Fluor 488 (AF, Molecular Probes, Tokyo). The fluorophore was dissolved in dimethylformamide at a concentration of 10 mg/mL, and the conjugation reaction was performed with a 5-fold molar excess of the fluorophore in 0.1 M sodium carbonate−sodium bicarbonate buffer (pH 9.0). After 1 h at room temperature, the reaction was terminated by an addition of freshly prepared 1.5 M hydroxylamine, and the fluorescent antibodies were purified by the centrifuged column procedure. The protein concentration in the purified conjugates was determined spectrophotometrically by subtracting 0.11 $A_{495\ nm}$ of the fluorophore from the $A_{280\ nm}$ of the antibody. The degree of labeling was calculated by dividing the $A_{495\ nm}$ of the fluorophore by the molar concentration of the antibodies and the dye extinction coefficient of 71 000 M^{-1} cm^{-1}.

Immunoreactivity. The immunoreactivity of radiolabeled NuB2s was assessed by the competitive immunoassay (*26*). To minimize nonspecific binding of radioiodinated antibodies to plastic tubes, the tubes were presaturated with a freshly prepared solution of 1% bovine serum albumin in PBS for 30 min, followed by three washes with PBS (*27*). Nonradioactive SIB-NuB2, SIB-$NuB2_I$, and SIB-$NuB2_{III}$ were prepared by experimental procedures similar to those used for [^{125}I]SIB-labeled antibodies, except that nonradioactive NaI was used in place of Na[^{125}I]I. A mixed solution of 50 μL ^{125}I-NuB2 and 50 μL nonradioactive SIB-NuB2, SIB-$NuB2_I$ or SIB-$NuB2_{III}$ (0.05−10 μg) was incubated in the presence of 1×10^6 RPMI 1788 cells suspended in 100 μL of PBS at 37 °C for 1 h. After centrifugation at 10 000 × *g* for 5 min, supernatant was discarded and the cell-associated radioactivity was determined using an auto γ counter.

RPMI 1788 Cell Binding and Retention. The cell binding of [^{125}I]SIB-labeled antibodies was also evaluated according to the procedure of Foulon et al. with slight modification (*28*). Approximately 1 μg each of [^{125}I]SIB-labeled antibodies was incubated with 1×10^6 RPMI 1788 cells for 1 h at 37 °C. Aliquots of cells in triplicate were removed, centrifuged, and washed with cold media. Then, the cell-associated radioactivity was determined as described above. Similar studies were conducted in the presence of 1000-fold excess of unlabeled NuB2.

The rest of the cells were resuspended in RPMI 1640 media containing 10% fetal bovine serum and 20 mM HEPES to a density of 3×10^6 cells/mL. After incubation for 1 and 3 h, aliquots of cells in triplicate were removed, centrifuged, and washed twice with cold media, and the cell-associated radioactivity was determined.

Confocal Microscopy. For each assay, 6×10^6 cells were plated into 35 mm glass-bottomed dishes. The cells were then incubated at 37 °C for 1 h with a fresh solution of NuB2, $NuB2_I$, or $NuB2_{III}$ (60 μL, 0.1 mg/mL) in cold RPMI 1640 media containing 10% FCS and 20 mM HEPES. The cells were washed twice with the same medium at 4 °C. The acidotropic dye LysoTracker Red DND-99 (Molecular Probes, Eugene, OR) was diluted in DMSO. The cells were resuspended in prewarmed (37 °C) medium containing 50 nM LysoTracker Red for 30 min. For live-cell imaging, aliquots of cells in 35 mm glass-based dishes were analyzed by confocal microscopy using a Fluoview FV500 (Olympus, Tokyo). Images were obtained at low-power laser (0.3−3.0% laser) using the 488 nm line of an argon laser. All images were obtained as 10 μm thicknesses of one planar (*xy*) section. The cells were maintained at 37 °C in a temperature-controlled box.

In Vivo Studies. Animal studies were conducted in accordance with our institutional guidelines and were approved by Chiba University Animal Care Committee. Biodistribution studies were performed by intravenous administration of a PBS solution of [^{125}I]SIB-NuB2, [^{125}I]SIB-$NuB2_I$, or [^{125}I]SIB-$NuB2_{III}$ to 6-week-old male ddY mice (Japan SLC Inc., Shizuoka, Japan). Groups of five mice, each receiving 0.3 μCi (20 μg/100 μL) of the antibodies, were used for the experiments. Organs of interest were removed and weighed, and the radioactivity counts were determined with an autowell γ counter at 1, 3, and 24 h postinjection.

Severe combined immunodeficiency (SCID) mice (C.B-17/IcrCrj-scid, Charles River Japan, Kanagawa, Japan) bearing xenograft of RPMI 1788 cells were also treated with a mixed solution of [^{131}I]SIB-$NuB2_I$ and [^{125}I]SIB-NuB2. The biodistribution of radioactivity after i.v. administration of the mixture

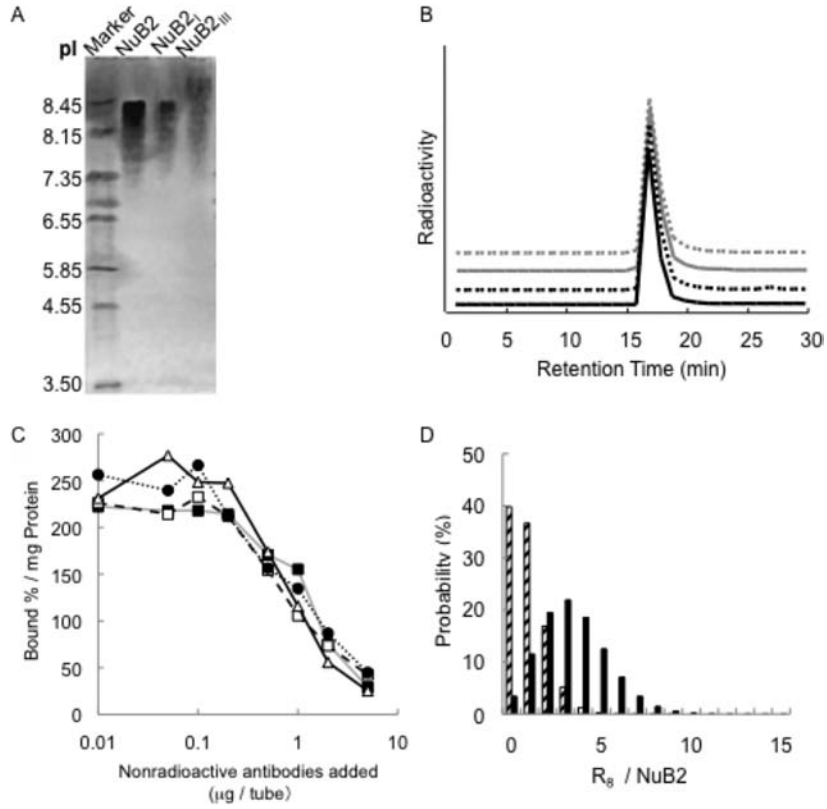

Figure 1. Characterization of R_8-conjugated antibodies ($NuB2_I$ and $NuB2_{III}$). (A) Isoelectric focusing. While both NuB2 and $NuB2_I$ showed similar profiles, a wider band toward higher pI was observed with $NuB2_{III}$. (B) Size-exclusion HPLC profiles. ^{125}I-NuB2: black solid line. [^{125}I]SIB-NuB2: black broken line. [^{125}I]SIB-$NuB2_I$: gray solid line. [^{125}I]SIB-$NuB2_{III}$: gray broken line. All the radioiodinated NuB2s exhibited similar elution profiles. (C) Competitive immunoassay to RPMI 1788 cells. Increasing concentrations of nonradioactive iodine-labeled NuB2s (NuB2 (solid square), SIB-NuB2 (square), SIB-$NuB2_I$ (circle), SIB-$NuB2_{III}$ (triangle)) and 1×10^6 RPMI 1788 cells were incubated in the presence of [^{125}I]-labeled NuB2. No significant differences were observed among the four NuB2s. (D) Poisson distribution profiles of $NuB2_I$ (hatched column) and $NuB2_{III}$ (solid column).

to 8-week-old SCID mice was monitored at 24, 48, 72, and 96 h postinjection. Groups of 5−7 mice, each receiving 0.3 μCi (10 μg each) of antibodies, were used for the experiments. Organs of interest were removed and weighed, and the radioactivity counts were determined with an autowell γ counter. A window from 29 to 97 keV was used for counting ^{125}I, whereas one from 280 to 440 keV was used for ^{131}I. Correlation factors to eliminate crossover of ^{131}I activity into ^{125}I were determined by counting ^{131}I standard in each window. The crossover of ^{125}I into the ^{131}I channel was negligible.

Statistical Analysis. Data are expressed as means ± standard deviation where appropriate. Results were statistically analyzed with an unpaired Student's *t*-test using the Microsoft *Excel* program. Differences were considered statistically significant when the *p* value was less than 0.05.

RESULTS

Preparation of Conjugates. Conjugation of NuB2 or 8E1 with R_8 was performed by maleimide−thiol chemistry using thiol groups generated by reducing the disulfide bonds of the antibody molecule. The numbers of R_8 molecule attached per molecule of NuB2 were determined to be 0.92 for $NuB2_I$ and 3.38 for $NuB2_{III}$. Similar procedures were employed for the preparation of $8E1_I$ and $8E1_{III}$ where the number of R_8 per molecule of 8E1 was estimated to be 0.98 and 3.85, respectively. The pI values of NuB2, $NuB2_I$, and $NuB2_{III}$ were determined by the isoelectric focusing and found to be 7.5−8.6, 7.5−8.6, and 7.5−9.0, respectively (Figure 1A). All [$^{125/131}$I]SIB-labeled antibodies had radiochemical purities over 95% when determined by the SE-HPLC (Figure 1B) and TLC. ^{125}I-NuB2 was prepared by the chloramine T method with radiochemical purity of 99%. AF-NuB2, AF-$NuB2_I$, and AF-$NuB2_{III}$ were labeled with Alexa Fluor 488 with a conjugation level of 3.67, 3.89, and 3.57 molecules of the fluorophore per molecule of each antibody.

Immunoreactivity Measurement. Figure 1C shows the RPMI 1788 cell binding of ^{125}I-NuB2 in the presence of unlabeled NuB2, nonradioactive SIB-conjugated NuB2, SIB-$NuB2_I$, and SIB-$NuB2_{III}$. Unlabeled NuB2 almost completely inhibited the binding of ^{125}I-NuB2 to RPMI 1788 cells, and no significant differences were observed in the inhibitory curves among the nonradioactive SIB-NuB2, SIB-$NuB2_I$, and SIB-$NuB2_{III}$. Similar results were observed with AF-labeled antibodies (data not shown).

Localization of the Antibodies in RPMI 1788 Cells. Figure 2A shows the localization of NuB2, $NuB2_I$, and $NuB2_{III}$ in living cells when determined by confocal microscopy. All AF-labeled antibodies (green) were present on the cell membrane. Under the conditions, LysoTracker (red) was observed in acidic compartment of the cells such as endosome and lysosome.

In Vitro Cell Binding and Retention. When the radiolabeled antibodies were incubated with the RPMI 1788 cell at 1 h at 37 °C, [^{125}I]SIB-$NuB2_I$ and [^{125}I]SIB-$NuB2_{III}$ showed 1.4 and 4.3 times higher cell-associated radioactivity than [^{125}I]SIB-NuB2 (Figure 2B). When the radiolabeled antibodies were incubated in the presence of 1000-fold excess of NuB2, significant reduction in the cell-associated radioactivity was observed with [^{125}I]SIB-NuB2 and [^{125}I]SIB-$NuB2_I$. However, [^{125}I]SIB-$NuB2_{III}$ still registered high cell-associated radioactivity. Similarly, higher cell-associated radioactivity was observed

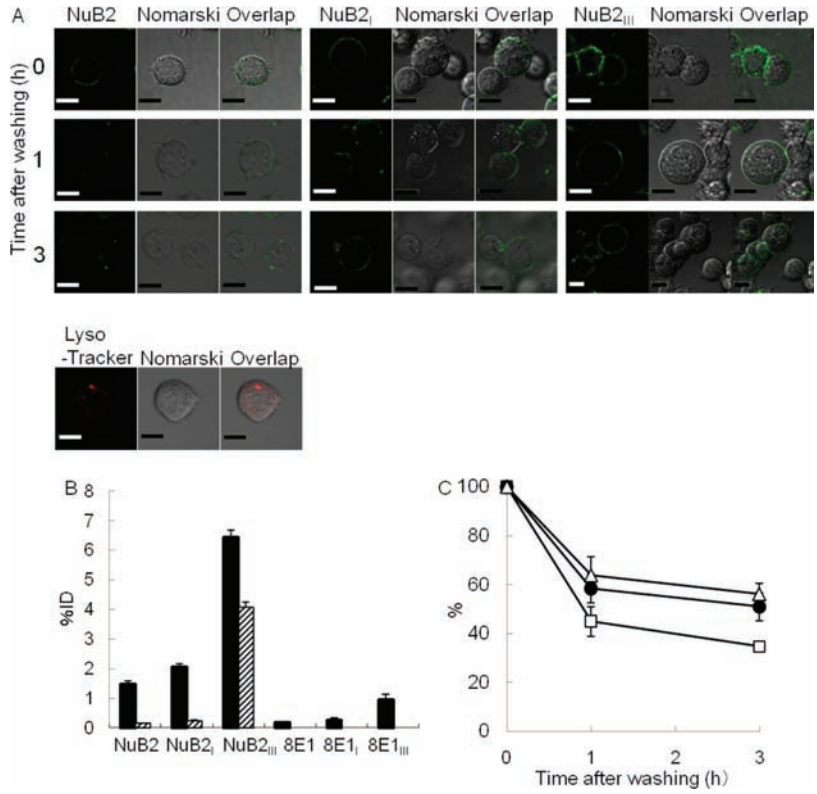

Figure 2. Cellular processing of [^{125}I]SIB-NuB2s. (A) Confocal microscopy to detect NuB2s localization (green) in RPMI 1788 cells as a function of incubation intervals at 37 °C; bars, 10 μm. (B) RPMI 1788 cell-associated radioactivity after 1 h incubation of [^{125}I]SIB-NuB2s at 37 °C (solid column). Similar experiments were performed in the presence of 1000-fold excess of NuB2 (hatched column). (C) Retention of [^{125}I]SIB-labeled NuB2s ([^{125}I]SIB-NuB2 (square), [^{125}I]SIB-NuB2$_I$ (solid circle), [^{125}I]SIB-NuB2$_{III}$ (triangle)) on RPMI 1788 cells after washing and reincubation in a fresh medium for 1 and 3 h (average of triplicates and SD).

in [^{125}I]SIB-8E1$_{III}$ when compared with [^{125}I]SIB-8E1 and [^{125}I]SIB-8E1$_I$.

Figure 2C shows the retention of [^{125}I]SIB-NuB2, [^{125}I]SIB-Nub2$_I$, and [^{125}I]SIB-NuB2$_{III}$ from RPMI 1788 cells as a function of reincubation times. While [^{125}I]SIB-NuB2 showed 44.3% and 34.2% of the initial radioactivity levels at 1 and 3 h postincubation, [^{125}I]SIB-NuB2$_I$ exhibited the cell-bound radioactivity of 59.1% and 51.2% at the same postincubation times. [^{125}I]SIB-NuB2$_{III}$ showed radioactivity levels of 67.8% and 61.3% at 1 and 3 h postincubation, respectively.

In Vivo Studies. The biodistribution of radioactivity after intravenous injection of [^{125}I]SIB-NuB2, [^{125}I]SIB-NuB2$_I$, and [^{125}I]SIB-NuB2$_{III}$ to normal mice is summarized in Table 1. Both [^{125}I]SIB-NuB2 and [^{125}I]SIB-NuB2$_I$ showed similar radioactivity levels in the blood, liver, kidney, and intestine. However, [^{125}I]SIB-NuB2$_{III}$ exhibited faster clearance of the radioactivity from the blood with higher radioactivity levels in the liver throughout the postinjection time examined. As a result, [^{125}I]SIB-NuB2$_{III}$ exhibited higher liver-to-blood ratios of the radioactivity.

Table 2 shows the biodistribution of the radioactivity after simultaneous injection of [^{125}I]SIB-NuB2 and [^{131}I]SIB-NuB2$_I$ in SCID mice bearing RPMI 1788 cells. [^{131}I]SIB-NuB2$_I$ exhibited significantly higher radioactivity levels in the tumor than those observed with [^{125}I]SIB-NuB2 from 48 to 96 h postinjection. [^{131}I]SIB-NuB2$_I$ exhibited similar radioactivity levels in other tissues such as the blood, liver, kidney, and intestine when compared with [^{125}I]SIB-NuB2.

Table 1. Biodistribution of Radioactivity after Intravenous Injection of [^{125}I]SIB-NuB2, [^{125}I]SIB-NuB2$_I$, and [^{125}I]SIB-NuB2$_{III}$ in Normal Mice[a]

DISCUSSION

In this study, we estimate the ability of an octaarginine peptide, R_8, as an anchoring molecule to enhance target accumulation of radiolabeled antibodies. The spatial location of the anchoring molecules attached to an antibody was considered of importance to maintain antigen binding properties, specific binding, and biodistribution profiles of the parental

[a] Tissue radioactivity is expressed as percent of injected dose per gram of wet tissue. Results are expressed as means (SD) of five to six animals for each point. [b] Expressed as percent injected dose. Significances determined by unpaired Student's *t*-test. * $p < 0.05$ compared to [^{125}I]SIB-NuB2. ** $p < 0.01$ compared to [^{125}I]SIB-NuB2.

antibodies. It was speculated that the attachment of anchoring molecules close to an antibody molecule may cause less interaction with cell surface molecules or cell membrane of target cells, whereas attachment of linkers that place the anchoring molecules at a distance from the antibody molecule may increase nonspecific binding. We selected a butyryl-bis(aminocaproate) linkage between a maleimide moiety and an octaarginine peptide with an expectation that the octaarginine moiety would not interact directly with a cell but interact strongly after the specific binding of antibody takes place. Since the importance of the density of AR-CPP molecules in an antibody was well-documented (*10, 11*), two R_8-conjugated antibodies holding different numbers of R_8 per molecule of the antibody were prepared (Scheme 1).

The R_8 conjugation and subsequent iodination reactions did not affect the SE-HPLC profiles of NuB2 (Figure 1B). The three SIB-labeled NuB2s possessed similar immunoreactivity to the antigen-positive tumor cells (Figure 1C). However, the heavy conjugation of R_8 to NuB2 increased the bandwidth of isoelectric focusing and raised pI of the resulting NuB2$_{III}$ (Figure 1A). The reaction of R_8 derivatives and an antibody can be better understood by considering the example of a perfectly random reaction (*29*). Poisson distribution can be used to predict how the R_8 molecules will be distributed among the individual antibody molecules. According to the calculation (Figure 1D), the majority of NuB2$_I$ contained up to 2 molecules of R_8 per molecule of NuB2. On the other hand, NuB2$_{III}$ consisted of a variety of conjugates ranging from 1 to 7 R_8 molecules per molecule of NuB2 with over 65% of NuB2$_{III}$ containing more than 3 R_8 molecules per molecule of NuB2, which accounts for the wide bandwidth of the isoelectric focusing.

The effect of R_8 conjugation levels on the target cell binding was assessed using CD20 positive cells. [^{125}I]NuB2$_{III}$ exhibited high cell-bound radioactivity levels even in the presence of a 1000-fold excess of cold NuB2. Since the cell-bound radioactivity levels of [^{125}I]SIB-8E1$_{III}$ were much lower than those of [^{125}I]SIB-NuB2$_{III}$, the majority of the cell-associated radioactivity of [^{125}I]NuB2$_{III}$ would be attributable to the specific antigen binding, followed by the strong interaction of the R_8 moieties with the cell. The low cell-bound radioactivity of [^{125}I]SIB-NuB2$_I$ in the presence of excess NuB2 suggested slower interaction kinetics of R_8 moieties with the cell, following the specific binding. However, when the dissociation rates from the cells were compared, not only [^{125}I]SIB-NuB2$_{III}$ but also [^{125}I]SIB-NuB2$_I$ exhibited much longer residence times in the CD20 positive tumor cells than [^{125}I]SIB-NuB2 (Figure 2C). The confocal microscopy confirmed that both NuB2$_I$ and NuB2$_{III}$ were present on the cell membrane (Figure 2A). These studies supported the hypothesis that the conjugation of anchoring molecules that possess strong interaction with cell surface molecules or cell membrane prolonged the retention of radiolabeled antibodies on tumor cells by fixing the antigen-bound antibodies on target cells, although the binding kinetics of anchoring molecules with the cell was affected by their density. This also suggested that further improvement of spatial location of the R_8 molecule may increase the binding kinetics.

Despite favorable anchoring ability, the heavy conjugation of R_8 affected biodistribution profiles of the parental antibody. As shown in Table 1, [^{125}I]SIB-NuB2$_{III}$ displayed faster clearance from the blood and higher accumulation in the liver in normal mice, as also observed in prior studies (*30*). On the other hand, both [^{125}I]SIB-NuB2 and [^{125}I]SIB-NuB2$_I$ displayed similar biodistribution (Table 1). These results reinforced the importance of the number of R_8 molecules attached per molecule of an antibody to retain its in vivo behavior (*10, 11*) and showed that the present conjugation of up to 2 R_8 molecules per molecule of NuB2 did not induce any significant changes in biodistribution. Recently, we have observed that the biodistribution of PAMAM dendrimers is predominantly determined by their net molecular charge as measured by both zeta potential and pI values (*31*). The present study also suggests that the determination of net molecular charge of AR-CPP-modified antibodies may be useful to predict their pharmacokinetics.

The biodistribution studies in tumor-bearing SCID mice were investigated with [^{125}I]SIB-NuB2 and [^{131}I]SIB-NuB2$_I$ since they exhibited similar pharmacokinetics in normal mice. To minimize individual differences, the biodistribution studies were conducted after injection of a mixed solution of [^{131}I]SIB-NuB2$_I$ and [^{125}I]SIB-NuB2. As shown in Table 2, the role played by R_8 conjugation on tumor accumulation was clearly demonstrated in the biodistribution studies, where [^{131}I]SIB-NuB2$_I$ exhibited significantly higher radioactivity levels in the xenograft than those of simultaneously administrated [^{125}I]SIB-NuB2 with no significant increase being observed in the radioactivity levels of blood, liver, and other tissues between the two. When considering the in vitro studies, these results would be attributable to the delayed dissociation rates of [^{131}I]SIB-NuB2$_I$ from the target cells in vivo.

In conclusion, the findings in this study indicated that the conjugation of anchoring molecules to an antibody that possesses a strong interaction with cell surface molecules or cell membrane enhanced accumulation in target tissues by fixing antigen-bound antibodies on target cells. This study also showed that conjugation of up to 2 molecules of R_8 per molecule of NuB2 satisfied both target-specific binding of antibodies and strong cell binding property of R_8. Further optimization of the conjugation chemistry would be required to provide uniform conjugates with appropriate linkage structure between R_8 and an antibody. These findings strongly suggested the application of AR-CPP to enhance specific accumulation of antibodies in target for more effective RIT.

ACKNOWLEDGMENT

The authors appreciated to Immuno-Biological Laboratories Co, Ltd., for supplying the relevant and irrelevant antibodies. Y. Azuma is grateful for the JSPS Research Fellowship for Young Scientists. This work was supported in part by a Grant-in-Aid for Scientific Research (B), for Exploratory Research,

for Development of Systems and Technology for Advanced Measurement and Analysis, and by Special Funds for Education and Research (Development of SPECT Probes for Pharmaceutical Innovation) from the Ministry of Education, Culture, Sports, Science, and Technology, Japan. This work was dedicated to our distinguished colleague, the late Mr. Yuichiro Taira.

Structural Requirements of the ASBT by 3D-QSAR Analysis Using Aminopyridine Conjugates of Chenodeoxycholic Acid

Xiaowan Zheng,[‡] Yongmei Pan,[‡] Chayan Acharya,[†] Peter W. Swaan, and James E. Polli*

Department of Pharmaceutical Sciences, School of Pharmacy, University of Maryland, 20 Penn Street, Baltimore, Maryland 21201, United States. Received June 17, 2010; Revised Manuscript Received August 26, 2010

The human apical sodium-dependent bile acid transporter (ASBT) is a validated drug target and can be employed to increase oral bioavailability of various drug conjugates. The aim of the present study was to investigate the chemical space around the 24-position of bile acids that influences both inhibition and uptake by the transporter. A series of 27 aminopyridine and aminophenol conjugates of glutamyl-chenodeoxycholate were synthesized and their ASBT inhibition and transport kinetics (parametrized as K_i, K_t, and J_{max}) measured using stably transfected ASBT-MDCK cells. All conjugates were potent ASBT inhibitors. Monoanionic conjugates exhibited higher inhibition potency than neutral conjugates. However, neutral conjugates and chloro-substituted monoanionic conjugates were not substrates, or at least not apparent substrates. Kinetic analysis of substrates indicated that similar values for K_i and K_t implicate substrate binding to ASBT as the rate-limiting step. Using 3D-QSAR, four inhibition models and one transport efficiency model were developed. Steric fields dominated in CoMFA models, whereas hydrophobic fields dominated CoMSIA models. The inhibition models showed that a hydrophobic or bulky substitute on the 2 or 6 position of a 3-aminopyridine ring enhanced activity, while a hydrophobic group on the 5 position was detrimental. Overall, steric and hydrophobic features around the 24 position of the sterol nucleus strongly influenced bile acid conjugate interaction with ASBT. The relative location of the pyridine nitrogen and substituent groups also modulated binding.

INTRODUCTION

Bile acids are primarily absorbed in the terminal ileum via the apical sodium-dependent bile acid transporter (ASBT; SLC10A2) (*1*, *2*), which displays high transport capacity and efficiency (*3*). This transporter may also be employed as a prodrug target for enhancing oral drug bioavailability of poorly permeating compounds, where drug is conjugated to bile acid and bile acid allows for the conjugate to be taken up by ASBT (*3*). However, the lack of knowledge of ASBT substrate requirements has impeded progress in rational prodrug design to target ASBT. Structure−activity studies have largely employed ASBT inhibition rather than substrate uptake, perhaps due to inhibition studies being more facile. Various transport studies have been performed over 30 years using animal tissues and organs, but the interpretability of the bile acid transport by ASBT has been confounded by other intestinal and hepatic transporters (*4*).

Our laboratory previously developed a stably transfected ASBT-MDCK monolayer to evaluate ASBT-mediated transport of solutes (*5*). Using a series of native bile acids to evaluate ASBT binding properties, we found that chenodeoxycholate (CDCA) was the most potent inhibitor among native bile acids and conjugation through C-24 of CDCA with taurine or glycine enhanced binding affinity (*6*). A series of C-24 CDCA conjugates were then synthesized using glutamic acid or lysine as a linker, and the results showed that only conjugates with one negative charge and a single bulky ester substituent proximal or distal to the C-24 region were ASBT substrates (*7*). Furthermore, a C-24 bile acid prodrug of valacyclovir enhanced oral bioavailability by 2-fold, compared to acyclovir in rats (*8*). Overall, ASBT permits bile acid conjugates with substitutions at the C-24 side chain region, but the chemistry space extending beyond the C-24 region needs to be further explored, especially for ASBT substrates. In fact, several quantitative structure−activity relationships studies have been reported for general ASBT inhibition. Thus, we sought to apply 3D-QSAR approaches to elucidate the substrate requirements in the space extending beyond the C-24 region using comparative molecular field analysis (CoMFA) (*9*) and comparative molecular similarity indices analysis (CoMSIA) (*10*). These algorithms are particularly useful when the structure of a target protein is unknown and may be applied for lead compound optimization (*11*).

The objective of this study was to synthesize and characterize substrate uptake and inhibition properties of C-24 bile acid probe moiety conjugates, and subsequently develop comprehensive 3D-QSAR models to elucidate the substrate requirements on positions beyond C-24 region. Pyridine and phenol are common chemical scaffolds in drug structures (*12*). Therefore, C-24 aminopyridine and aminophenol conjugates of glutamyl-CDCA were synthesized and their inhibition and uptake kinetics were evaluated. Pyridine and phenol probes were functionalized using different ring substitutions in order to study chemical substituent effect on ASBT inhibition and uptake. Using a combination of inhibition and uptake studies, we differentiate ASBT inhibitors from substrates and developed 3D-QSAR models for both classes of bile analogues. These studies provide new insight into the substrate requirements for ASBT uptake and shed light on the design of bile acid conjugates that can increase intestinal drug permeability and bioavailability.

EXPERIMENTAL PROCEDURES

Materials. [^{3}H]-Taurocholic acid was purchased from Perkin-Elmer (Waltham, MA). Taurocholic acid was purchased from Sigma (St. Louis, MO). CDCA was obtained from TCI America

Approach 2.

[a] X = N, H; Y = H, CH_3, OCH_3, NH_2, OH, Cl, F, Br; Z = H, CH_3.

(Portland, OR). Protected glutamic acid analogues were from Novabiochem (Gibbstown, NJ). Aminopyridine analogues were purchased from Sigma Aldrich (St. Louis, MO) and Matrix Scientific (Columbia, SC). Fetal bovine serum (FBS), trypsin, and Dulbecco's modified Eagle's medium (DMEM) were purchased from Invitrogen Corporation (Carlsbad, CA). All other reagents and chemicals were of the highest purity commercially available.

Synthetic Procedures. A series of aminopyridines were conjugated to CDCA using glutamic acid as a linker. Two synthetic approaches were employed (Scheme 1). Among the native bile acids, CDCA was selected on the basis of its favorable transport across ASBT-MDCK monolayers (*6*).

*N-Hydroxybenzotriazole (HOBT) Esters of CDCA (**II**).* CDCA **I** (5 g) was activated with HOBT (0.5 equiv) and HBTU (1.2 mmol) in 20 mL of anhydrous dimethylformamide (DMF) along with 1.2 equiv of triethylamine (TEA) at RT for 4 h to form CDCA-OBt ester **II**. The reaction was terminated by adding 50 mL of water. Subsequently, the reaction mixture was extracted with ethyl acetate (EtOAc) (3×). The combined organic layer was washed with brine (1×), dried with anhydrous sodium sulfate, filtered, and evaporated under vacuum to yield a white fluffy solid CDCA-OBt ester **II** (90% yield). Mass spectrometry (MS) showed appropriate peaks: $[M+H]^+$ 510.81, $[M+Na]^+$ 532.81. **II** was used in approaches A and B.

*Synthesis of CDCA-α-Benzyl-Glutamyl Probe (**V**).* Approach 1 was applied as shown in Scheme 1. **II** (5.0 g) was reacted with to 0.8 equiv of L-α-benzyl glutamic acid **III** in 30 mL of anhydrous DMF along with 1 equiv of TEA at 60 °C overnight. Reaction was terminated by adding 50 mL of water. The reaction mixture was extracted with EtOAc (3×). The combined organic layer was washed with 1 N HCl (3×) and brine (1×). Then, the organic extract was dried with anhydrous sodium sulfate, filtered, and evaporated under vacuum to yield off-white solid glutamyl-CDCA conjugates **IV** (75% yield). MS showed appropriate peaks: $[M+H]^+$ 612.81, $[M+Na]^+$ 634.81.

IV (1.0 g) was activated with 1.2 equiv of HBTU in 15 mL of anhydrous DMF along with 1.2 equiv of TEA for 10 min followed by addition of appropriate aminopyridine or aminophenol probes at 60 °C overnight. Reaction was terminated by adding 30 mL of water. The reaction mixture was extracted with EtOAc (3×). The combined organic layer was washed with 1 N HCl (3×), 1 N NaOH (3×), and brine (1×). Then, the organic extract was dried with anhydrous sodium sulfate and filtered. The EtOAc extract was evaporated under vacuum to yield thick, yellow oil. The crude product was further purified by silica gel column chromatography using a mobile phase of EtOAc and hexane (95:5). Fractions were collected and solvent evaporated to yield the neutral conjugate **V**. Purity of the conjugate was characterized by TLC and MS techniques.

Approach 2 was applied as shown in Scheme 1. First, 2.0 g of N-boc-α-benzyl-glutamic acid **VII** was coupled to aminopyridine or aminophenol probes (1.1 equiv) using HBTU (1.2 equiv) as coupling reagents in 10 mL of anhydrous DMF along with of 2.2 equiv of TEA at 70 °C overnight. Reaction was terminated by adding 30 mL of water. The reaction mixture was extracted with EtOAc (3×). The combined organic layer was washed with 1 N HCl (3×), 1 N NaOH (3×), and brine (1×). Then, the organic extract was dried with anhydrous sodium sulfate, filtered, and evaporated under vacuum to yield orange oil. The crude product was further purified by silica gel column chromatography using a mobile phase of EtOAc and hexane (90:10). Fractions were collected and solvent evaporated to give a solid, white intermediate. Purity of the intermediate conjugates was characterized by TLC and MS techniques. The intermediate was then selectively N-deprotected using 25% trifluoroacetic acid (TFA) in anhydrous dichloromethane (DCM) at RT for 1−2 h. Solvent was evaporated under vacuum to yield off-white solid **VIII**.

VIII (1.0 g) was reacted with 1.2 equiv of CDCA-OBt ester **II**, along with 1 equiv of TEA in 15 mL of anhydrous DMF at RT overnight. Reaction was terminated by adding 50 mL of water. The reaction mixture was purified as described above (see synthetic approach **I**) to yield the neutral conjugate **V**.

Synthesis of CDCD-Glutamyl Probe (VI). The neutral conjugates **V** were subjected to catalytic hydrogenation for the removal of the benzyl ester using 10% Pd/charcoal in ethanol at 50 psi overnight. Suspension was filtered through Celite and solvent evaporated under vacuum to yield the final conjugates **VI**. For chloro- and bromo-substituted neutral conjugates **V**, the benzyl ester was removed in 10 mL 33% hydrobromic acid in acetic acid at RT for 2 h. Reaction was terminated by adding 30 mL of EtOAc. The reaction mixture was extracted with water (3×). The organic layer was washed with brine (1×), dried with anhydrous sodium sulfate, filtered, and evaporated under vacuum to yield the final conjugates **VI**.

Characterization of Conjugates. Identity and purity of bile acid conjugates was characterized by TLC, MS, and ^{1}H NMR (proton, COSY). MS was performed on a LCQ ESI-MS (Thermo Fisher Scientific Inc., Waltham, MA). ^{1}H NMR spectra were recorded on a Varian Inova 500 MHz (Varian Inc., Palo Alto, CA). The mass spectra in all cases gave a molecular ion in agreement with the calculated mass of the conjugates. No CDCA impurity was detected in any final conjugate (*13*). LC-MS/MS and ^{1}H NMR results are compiled in Supporting Information Table S1. The chemical shifts are reported in parts per million (ppm) relative to tetramethylsilane (TMS) ($\delta = 0.0$ ppm).

Cell Culture. Stably transfected ASBT-MDCK cells were grown as previously described (*14*). Briefly, cells were grown at 37 °C, 90% relative humidity, 5% CO_2 atmosphere and fed every two days. Media comprised DMEM supplemented with 10% FBS, 50 units/mL penicillin, and 50 μg/mL streptomycin. Cells were passaged after reaching 90% confluency.

Inhibition Study. To characterize compound binding affinities to ASBT, cis-inhibition studies of taurocholate uptake were conducted as previously described (*15*). Briefly, cells were seeded in 12 well cluster plates (Corning; NY) at a density of 1.5 million cells/well. Inhibition studies were performed on the fifth day in Hank's Balance Salts Solution (HBSS). Cells were exposed to donor solution containing 2.5 μM taurocholate (spiked with 0.5 μCi/mL [^{3}H]-taurocholate) in the presence of a conjugate at eight concentrations (0−100 μM) for 10 min. Cells were lysed using NaOH. Cell lysate was counted for taurocholate radioactivity using a liquid scintillation counter (Beckmann Instruments, Inc., Fullerton, CA). For neutral conjugates, 2.5% DMSO was included in transport buffer, which has been shown to not affect ASBT kinetics (*16*).

Uptake Study. The uptake of conjugates by ASBT, representing cellular absorption mediated by the transporter, was evaluated. Cells were seeded as above for inhibition studies. Uptake studies employed HBSS buffer or modified HBSS buffer (i.e., sodium-free). Since ASBT is a sodium-dependent transporter, studies using sodium-free buffer enabled passive permeability measurement of conjugate. Cells were exposed to donor solution contain eight different conjugate concentrations (1−500 μM). Subsequently, cells were lysed as previous described (*16*) by adding 0.25 mL acetonitrile to each well, following evaporation at RT. A solution (1 mL) containing 50% water and 50% acetonitrile was added to each well for 10 min. Sample was stored in −80 °C until analysis by LC-MS/MS. Taurocholate uptake was measured on each study occasion as a control.

Analytical Methods. The conjugate was quantified by LC-MS on a Thermo Finnigan Surveyor HPLC system, equipped with a Thermo Finnigan Surveyor autosampler and a Thermo TSQ quantum mass spectrometer (Thermo Fisher Scientific Inc., Waltham, MA). The column used was a Phenomenex Luna C8 (50 × 2.0 mm, 3 μm; Phenomenex; Torrance, CA, USA) heated to 45 °C. The mobile phase was A, 0.1% formic acid in water; and B, 0.1% formic acid in acetonitrile, with a flow rate of 0.4 mL/min. The injection volume was 10 μL. Detection was achieved under positive ion electrospray tandem mass spectrometry using $[M+H]^+$ peak for all conjugates. The mobile phase and retention time for each conjugate are detailed in Supporting Information Table S1. The limit of quantification for all conjugates was between 1 and 2.5 nM.

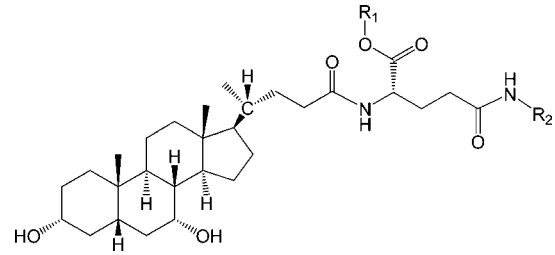

Figure 1. General structure of CDCA-glutamyl-probe (pyridines, phenol) conjugates. Database alignment employed the sub-structure CDCA-glutamate.

Kinetic Analysis. Inhibition data were analyzed in terms of inhibition constant K_i and used a modified Michaelis−Menten competitive inhibition model, as previously described, taking into account aqueous boundary layer (ABL) resistance (*17*).

Uptake data were analyzed in terms of K_t, J_{max}, $normJ_{max}$, and P_p, where J_{max} is the transport capacity; $normJ_{max}$ is normalized conjugate J_{max} against taurocholate J_{max} from the same occasion; K_t is the Michaelis−Menten coefficient for ASBT-mediated transport; and P_p is the conjugate passive permeability coefficient. For **18**, estimated K_t was less than 0.1 μM, such that K_t was assigned a value of 0.1 μM, due to the limited ability to accurately estimate potent K_t values (*17*). Data were analyzed using WinNonlin Professional (Pharsight Corporation; Mountain View, CA).

3D-QSAR Analysis. 3D-QSAR models were developed for K_i and $normJ_{max}/K_t$. The inhibition constant K_i reflects compound binding affinity to ASBT, with smaller values denoting greater binding. $normJ_{max}/K_t$ reflects the efficiency of conjugate translocation by ASBT.

The implementation of the CoMFA and CoMSIA techniques was performed as described previously (*18, 19*). Briefly, conjugates were sketched with *Sybyl 7.2* (Tripos Inc., St. Louis, MO). Each structure was minimized using the Powell method and Tripos force field (*20*) with maximum iterations of 2000 steps and termination gradient of 0.001 kcal/mol. Partial atomic charges were computed by the Gasteiger-Hückel method (*21*). Conjugates were aligned via "database alignment" based on a template structure in Figure 1. The reference compound during alignment was **12** for K_i models and **15** for the $normJ_{max}/K_t$ model. A regularly placed grid of 2.0 Å was created around aligned molecules. An sp^3 carbon atom with charge +1.00 was used as a probe atom. The steric and electrostatic fields were truncated at +30.00 kcal/mol. In contour maps of models, areas with above 80% favorability among the fields being viewed were regarded as beneficial for the biological activity, while those with field values below 20% were regarded as detrimental. The attenuation factor was 0.3. Models were obtained using the partial-least-squares (PLS) analysis (*22*). Leave-one-out cross validation (LOO) was performed to determine the optimum number of components, and nonvalidation PLS was applied to obtain the final model. Models were evaluated by the cross-validated standard coefficient q^2 and correlation coefficient r^2. A model with high q^2 (above 0.5), high r^2, low standard error of prediction (SEP), and low standard error of estimate (SEE) was considered to possess good predictability. Models were also evaluated using a test set of four randomly selected conjugates.

RESULTS AND DISCUSSION

Synthesis. A series of aminopyridine and aminophenol conjugates of glutamyl-CDCA were synthesized. The general

[a] Data were summarized as mean (±SEM) of three measurements. [b] To correct for variation in ASBT expression levels across studies, J_{max} of each bile acid was normalized against taurocholate J_{max} from the same occasion. [c] **2**, **18**, **22**, and **25** were used as the test set. The other 23 compounds were used as the training set. [d] Not determinable owing to high passive permeability. [e] Not measurable due to lack of transportation by ASBT.

structure is depicted in Figure 1, and all conjugate structures are drawn in Table 1. The synthetic strategy was based on coupling the carboxyl group at the C-24 position of CDCA to the amino group of the common drug scaffolds pyridine or phenol, using glutamic acid as a linker (Scheme 1). A negative charge around the C-24 region was designed to promote ASBT translocation (*7, 23*). The corresponding neutral analogues with α-benzyl protection on the glutamic acid linker were also synthesized. Unsubstituted, monosubstituted, and disubstituted pyridine and phenol were employed as functioned probe moieties that yielded conjugates with varying chemistry in the region beyond C-24.

ASBT Inhibition. Table 1 lists K_i values of the 27 conjugates, which included 24 pyridine-based conjugates and 3 phenol-based conjugates. Neutral conjugates with α-benzyl protection on C-24 were poorly water-soluble. Therefore, among the 24 neutral conjugates that were synthesized, only **11**, **13**, and **17** allowed K_i to be measured.

All 24 monoanionic conjugates were potent inhibitors with K_i ranging from 1.51 to 23.6 μM with CDCA-glutamyl-3-aminopyridine **2** being the most potent inhibitor. They are in the range of native bile acids. The three neutral conjugates were less potent than their corresponding monoanionic conjugates by approximately 10−20-fold.

ASBT Uptake. While all 27 conjugates exhibited high inhibition potency, only 22 showed to be substrates. Table 1 lists kinetic parameters K_t, *norm*J_{max}, *norm*J_{max}/K_t, and P_p. K_t represents transporter affinity. To accommodate variation in ASBT expression levels across studies, J_{max} of each bile acid was normalized against taurocholate J_{max} from the same occasion yielding *norm*J_{max}. The *norm*J_{max}/K_t value represents the ASBT mediated transport efficiency. Neutral compound **17** exhibited a high passive permeability, such that it was not able to be assessed as a substrate or not. The other two neutral compounds, **11** and **13**, were not further evaluated. Results from **17** were consistent with previous findings that a negative charge around the C-24 region is required for translocation (*7*).

K_t values ranged from 0.1 μM for **18** to 92.2 μM for **12**. *norm*J_{max} ranged from 0.0791 for **5** to 2.67 for **18**. *norm*J_{max}/K_t ranged from 0.00388 μM^{-1} for **6** to 26.7 μM^{-1} for **18**. P_p ranged from 1.19×10^{-7} cm/s for **5** to 100×10^{-7} cm/s for **22**. Figure 2A shows the uptake profile of **18**, which was the most potent substrate in terms of both K_t and *norm*J_{max}; Figure 2B shows the nonsubstrate **23**.

Ring substituent position had an important effect on transport efficiency. For example, for 3-aminopyridine conjugates, substitution at position 2 led to more potent substrate compared to other positions, e.g., **5** (11.2 μM) vs **7** (21.2 μM), and **18** (0.1 μM) vs **19** (4.30 μM) when substitution is moved from 2 to 5 position. Substitution at position 6 significantly decreased activity, when **8** (24.6 μM) is compared with **5** and **7**; **20** (11.7 μM) is compared with **18** and **19**; **12** (92.2 μM) is compared with **5**; **22** (83.6 μM) is compared with **21** (33.0 μM). The type of substituent group also influenced K_t. For example, all fluoro-substituted conjugates were potent substrates, bromo-substituted conjugates were weak substrates, while chloro-substitution abolished uptake.

Comparison of Inhibition Kinetics vs Transporter Kinetics. Transporter-mediated translocation minimally involves substrate binding to the transporter, transporter conformation changes involving substrate translocation, dissociation of substrate from transporter, and transporter conformation restoration.

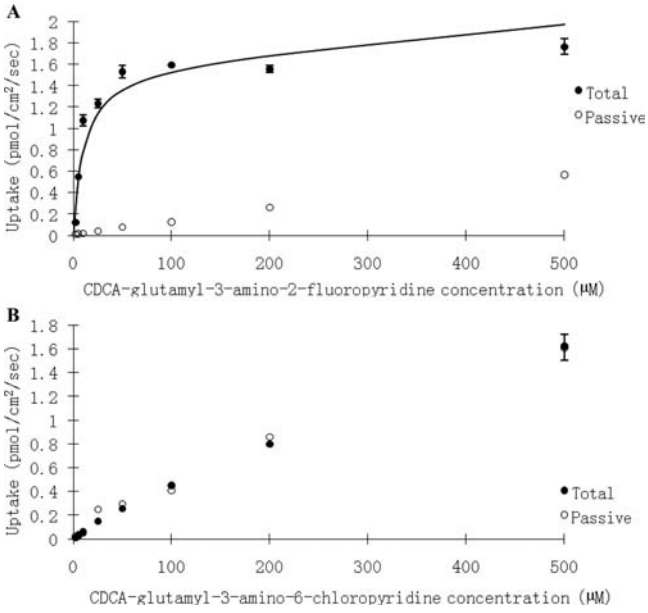

Figure 2. Concentration-dependent uptake of (A) CDCA-glutamyl-3-amino-2-fluoropyridine **18** and (B) CDCA-glutamy-3-amino-6-chloropyridine **23** into ASBT-MDCK monolayers. The conjugate was measured at varying concentrations (2.5−500 μM) in the presence and absence of sodium to delineate ASBT-mediated and passive uptake components. Data indicate total uptake in the presence of sodium (•) and passive uptake in the absence of sodium (○). Uptake of **18** was several-fold higher in the presence of sodium than in the absence of sodium, reflecting ASBT-mediated uptake. Uptake of **23** was the same in the presence and absence of sodium; passive uptake was high, such that the compound was either not a substrate or not measurable as a substrate due to high passive permeability.

The initial binding step is assessed by K_i. Results show that ASBT inhibition requirements were different from the ASBT-mediated transport requirements. A potent inhibitor may be a weak substrate, such as **6**, **12**, and **22**. Figure 3A illustrates the relationship of transporter affinity K_t and inhibition potency K_i for all 22 substrates. Figure 3B excludes **6**, **12**, and **22**, where K_t was notably weaker than K_i. For these 19 conjugates in Figure 3B, there was a modest association between K_t and K_i with linear slope = 0.995, $r^2 = 0.403$, and $p = 0.003$. Qualitatively, most conjugates yielded similar potency of K_t and K_i, suggesting that conjugate binding was broadly the slow kinetic step for conjugate translocation. These results agree with previous native bile acid findings (*6*). It should be noted that **14** and **18** yielded K_t values that were over 7-fold more potent than K_i although they both were potent inhibitors and substrates (e.g., K_i and K_t < 10 μM). For **6**, **12**, and **22**, where K_t was far less potent than K_i, postbinding events were rate-limiting.

Figure 4 shows that transport capacity was not associated with inhibitory potency. Capacities of most conjugates spanned a narrow range and were less than taurocholate. However, $normJ_{max}$ of **15**, **18**, **22**, and **25** were higher than that of taurocholate. Supporting Information Figures S1 and S2 show that transport capacity and transport efficiency were not related to K_t or K_i, respectively.

ASBT Inhibition 3D-QSAR Models. Figure 5 shows the superimposition of all 27 compounds for inhibition model development. Twenty-three compounds were included in the training set. The remaining, randomly selected four compounds (i.e., **2**, **18**, **22**, and **25**) were used as the test set. Four 3D-QSAR models, including one CoMFA and three CoMSIA models, were developed using pK_i data (Table 2). CoMSIA-1 included electrostatic and steric fields, whereas CoMSIA-2 included an additional hydrophobic field. CoMSIA-3 included the three molecular descriptors from models 1 and 2, as well as hydrogen bond donor and acceptor fields.

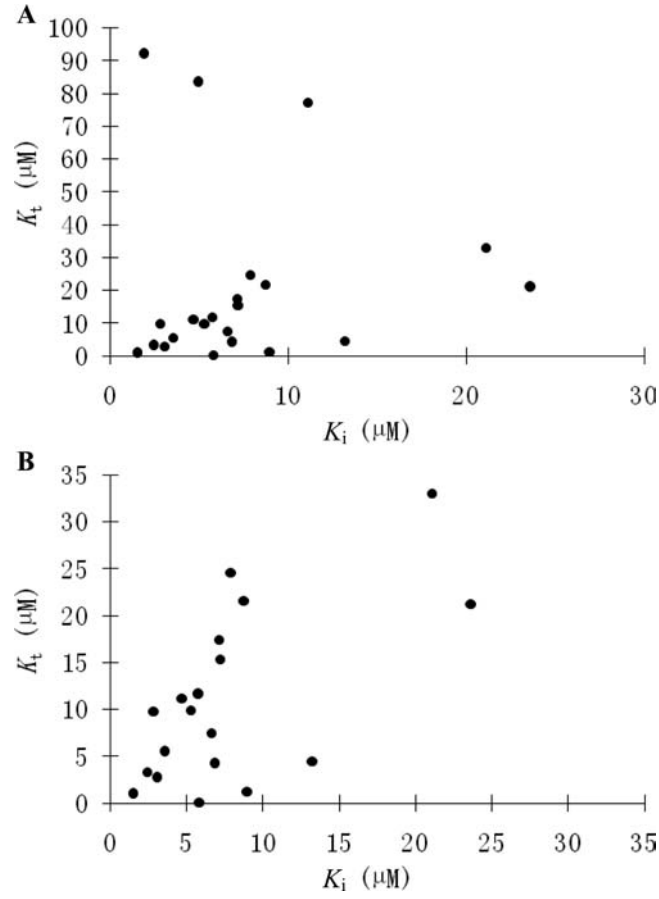

Figure 3. Relationship of K_t and K_i. (A) For all 22 bile acid conjugates that were substrates, K_t vs K_i are plotted. **6**, **12**, and **22** exhibited several-fold higher K_t values than K_i values. (B) With **6**, **12**, and **22** removed, most conjugates yielded similar K_t and K_i. Linear regression showed slope = 0.995, $r^2 = 0.403$, and $p = 0.003$. **14** and **18** yielded $K_t \ll K_i$, although all were <10 μM.

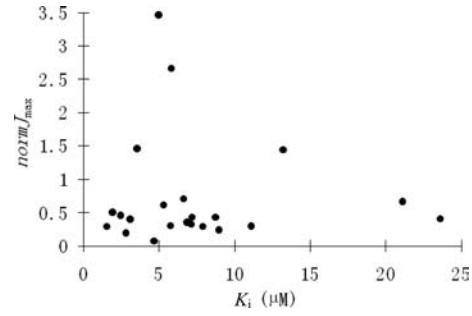

Figure 4. Relationship between $normJ_{max}$ and K_i. Transporting capacity was not associated with inhibition potency. Linear regression showed a slope of -0.008 μM^{-1} and $r^2 = 0.003$. **15**, **18**, **22**, and **25** yielded J_{max} higher than taurocholate. All other conjugates exhibited J_{max} less than taurocholate J_{max}, and ranged from 0.0791 to 0.716.

CoMFA and CoMSIA models were comparable in terms of their predictability of pK_i, with CoMFA-1 ($q^2 = 0.675$, $r^2 = 0.965$) and CoMSIA-3 ($q^2 = 0.612$, $r^2 = 0.958$) being the best inhibition models (Table 2). Figure 6 shows the relationship of observed versus predicted pK_i for training set and test set of CoMFA-1 and CoMSIA-3. The corresponding data are listed in Supporting Information Table S2. Both models accurately predicted activities of three out of the four test compounds. **2** was underpredicted by both models, where the observed K_i was 1.51 μM and predicted K_i were 8.13 μM and 11.7 μM by CoMFA-1 and CoMSIA-3, respectively.

Table 2 also shows the relative contributions of specific fields to the inhibition activities. For CoMFA-1, the steric feature

[a] Models for pK_i. [b] Model for log($normJ_{max}/K_i$). [c] SEP: standard error of prediction; SEE: standard error of estimate; NOC: number of components.

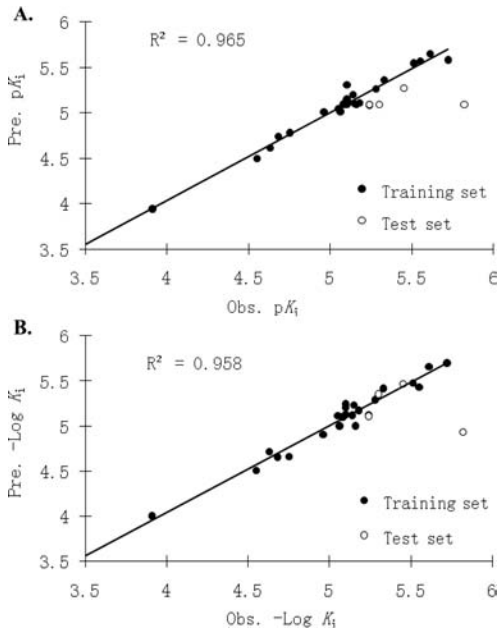

Figure 6. Observed versus predicted pK_i plot of the CoMFA-1 (A) and CoMSIA-3 (B) using 23 training set conjugates (•) and 4 test set conjugates (○). The solid line is the regression for the training set. The regression line has a slope = 0.965 and r^2 = 0.965 for CoMFA-1, and 0.959 and 0.958 for CoMSIA-3, respectively.

dominated (73.1% contribution) the electrostatic feature. For all CoMSIA models, the steric feature was less important than the electrostatic feature. For example, the contributions of steric and electrostatic features in CoMSIA-1 were 37.7% and 62.3%, respectively. The different effects of steric and electrostatic fields between CoMFA and CoMSIA are attributed to their energy function forms. The contribution of the steric feature in CoMSIA is further reduced when the hydrophobic field was added, with 12.0% and 8.4% for CoMSIA-2 and CoMSIA-3, respectively. For these two models, the hydrophobic was the most determining feature that contributed 50.2% and 40.8%, respectively. Considering the improved q^2 in CoMSIA-2 and CoMSIA-3 vs CoMSIA-1, the hydrophobic feature was the major contributor to improve pK_i predictability. Hydrogen bond donor and acceptor in CoMSIA-3 contributed 13.1% and 17.3%, respectively, and account for the slight q^2 increase from 0.572 in CoMSIA-2 to 0.612 in CoMSIA-3.

3D-QSAR Contour Maps for Inhibition. Figures 7 and 8 illustrate features of the CoMFA-1 and CoMSIA-3 models, respectively. Contour maps were drawn relative to CDCA-glutamyl-3-amino-2,6-dimethylpyridine **12**.

CoMFA Contour Maps. The steric contours from CoMFA-1 (Figure 7A) reveal that bulky groups at the 2 or 6 position (green region) of 3 aminopyridine afford beneficial steric interactions for inhibition, whereas bulky substitutes on position 5 (yellow region) are detrimental. The contours explain the higher activity of 2,6-dimethyl-substituted **12** (K_i = 1.94 μM) over 2-methyl substituted **8** (7.87 μM) and 6-methyl substituted **5** (4.66 μM). The two green regions also accounted for the higher activity of **5** and **8** than **6** (11.1 μM) and **7** (23.64 μM), where the methyl group is moved from 2 or 6 to 4 or 5. The same pattern is evident for bromo substitution. When bromine is moved from position 6 in **22** to 5 in **21**, the activity decreased from 4.96 to 21.1 μM. The electrostatic contour from CoMFA-1 (Figure 7B) indicates that an electropositive group near the −COO (blue region) will be favorable. Considering that a hydroxyl hydrogen on a carboxylic group bears a positive charge, this blue area reflects that a carboxylic acid near C-24 improved inhibition more than the corresponding conjugates with α-benzyl protection. Inhibition potency decreased from 6.61 to 122 μM comparing **10** to **11**, from 1.94 to 28.1 μM comparing **12** to **13**, and from 3.07 to 17.78 μM comparing **16** to **17**. These findings agree with previous observations that a negative charge near C24 region is preferred (*7*). In Figure 7B, the red contour region behind the 2 position and a blue contour region near the 6 position of the 3-aminopyridine ring indicate that an electronegative or electropositive group enhanced inhibition.

CoMSIA Contour Maps. Steric contour maps from CoMSIA-3 (Figure 8A) reveal that the green regions are patterned similarly to those from CoMFA-1 (Figure 7A). However, CoMSIA-3 provides two additional yellow contours above the carboxylate group indicating that a steric interaction near −COO is unfavorable. The yellow areas are consistent with the blue electrostatic contour of CoMFA-1 (Figure 7B), where α-benzyl protection of the carboxylate decreased the inhibition potency (i.e., **10** vs **11**, **12** vs **13**, and **16** vs **17**). Electrostatic contours (Figure 8B) are consistent with the patterns observed in CoMFA-1 (Figure 7B), e.g., red and blue regions around 2 and 6 position of the 3-aminipyridine ring. Hydrophobic contour plots (Figure 8C) indicate that hydrophobic substitution on the 2 or 6 position enhances inhibition (orange regions), whereas such substitution on the 5 position reduces potency (white contour). This result is consistent with steric contours of CoMFA-1 (Figure 7A). Hydrogen bond donor contours (Figure 8D) suggest that a −OH in the carboxyl group can be regarded as a hydrogen bond donor. The cyan area near the −COO group agrees with the steric (Figure 8A) and hydrophobic contours (Figure 8C), indicating that the α-benzyl group on −COO remarkably reduced the inhibition activities. The purple area near the pyridine ring indicates that a hydrogen-bond donor

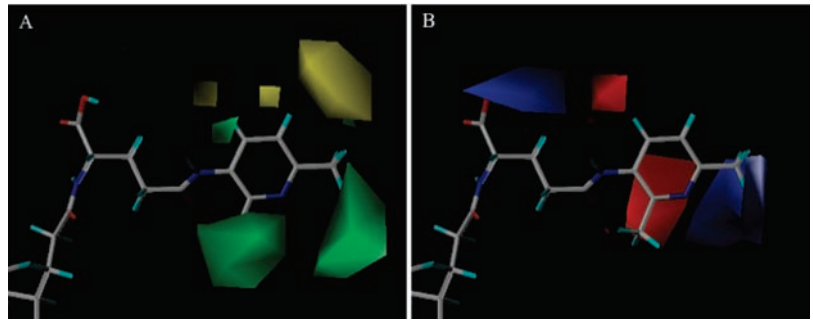

Figure 7. Steric (A) and eletrostatic (B) contour maps around compound CDCA-glutamyl-3-amino-2,6-dimethylpyridine **12** for CoMFA-1 inhibition model. In panel A, green contours show where bulky substitute favored inhibition, while yellow contours were disfavored. In panel B, blue region represents favorable electropositive interaction for inhibition, while red shows disfavored electropositive character.

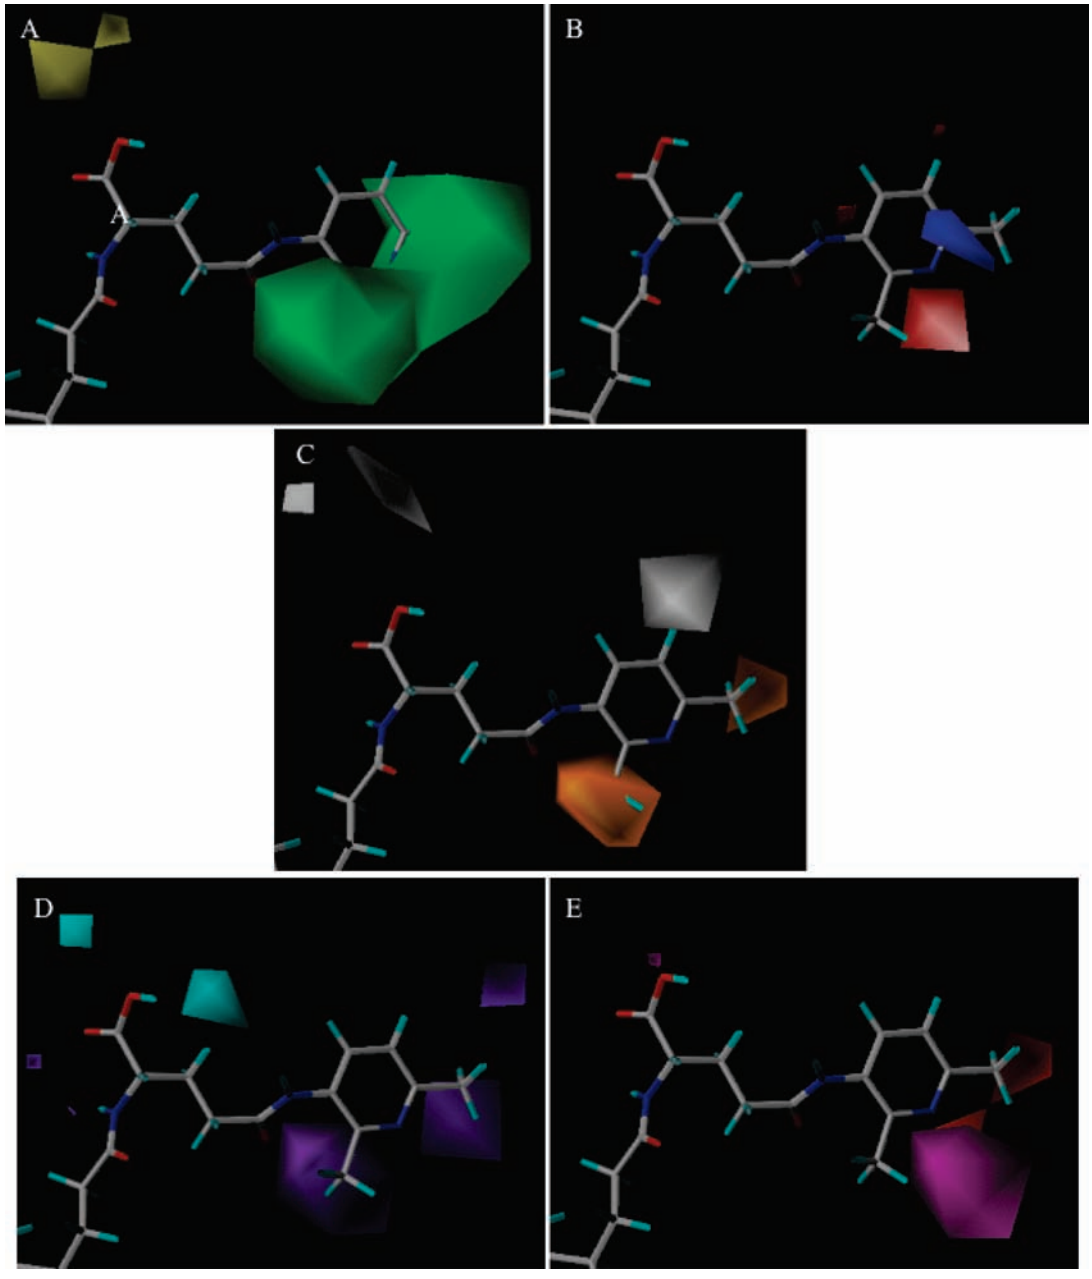

Figure 8. Steric (A), electrostatic (B), hydrophobic (C), hydrogen bond donor (D), and hydrogen bond acceptor (E) contour maps around CDCA-glutamyl-3-amino-2,6-dimethylpyridine **12** for CoMSIA-3 inhibition model. In panel A, green and yellow contours represent favorable and unfavorable bulky substituent interaction regions for inhibition. In panel B, blue and red contours represent regions that favor electropositive and electronegative groups, respectively. In panel C, orange and white contours are areas where hydrophobic groups enhance and diminish activity. In panel D, cyan and purple contours indicate regions where an inhibitor's hydrogen bond donor is favored and disfavored, respectively. In panel E, magenta and red contours represent favorable and unfavorable hydrogen-bond acceptor regions, respectively.

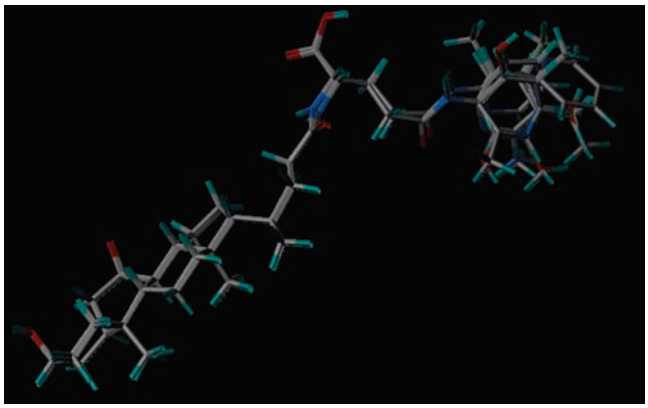

Figure 9. Superimposition of training set and test compounds for transport efficiency model development.

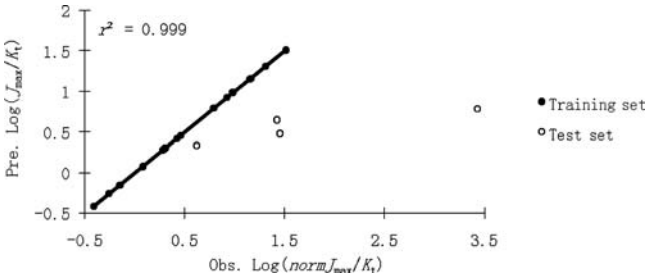

Figure 10. Observed vs predicted log($normJ_{max}/K_t$) plot of the CoMFA-2 using 18 training set conjugates (•) and 4 test set conjugates (○). The solid line is the regression for the training set. The regression line has slope = 1.00 and r^2 = 0.999.

behind the 2 and 6 positions of the 3-aminopyridine ring is detrimental. Hydrogen bond acceptor contours (Figure 8E) determine favorable (magenta) areas near the pyridine nitrogen and a red (disfavored) area around the 6 position on 3-aminopyridine ring, reflecting the decreased activity from 2.43 to 7.18 μM when a hydroxyl group is moved from the meta position in **26** to the para in **27** on the phenol ring.

Comparison of CoMFA and CoMSIA Models for Inhibition. CoMFA-1 possessed slightly greater predictability than CoMSIA-3 in terms of q^2 (0.675 and 0.612, respectively). However, the advantage of CoMSIA is the employment of a Gaussian-type energy calculation and additional molecular descriptors, including hydrophobic fields, hydrogen bond acceptor, and hydrogen bond donor. For example, the influence of the α-benzyl group is not accommodated by the steric contour of CoMFA-1 (Figure 7A), but is accommodated by the steric and hydrophobic contours of CoMSIA-3 (Figure 8A,B). The hydrophobic contour of CoMSIA-3 had a similar pattern to the steric contour of CoMFA-1, indicating that the hydrophobic field of CoMSIA-3 may share common features with the steric field of CoMFA-1. The similarity is not surprising, because a large hydrophobic substitution may have significant steric effects.

ASBT Transport Efficiency Model. As with the inhibition models, **2**, **18**, **22**, and **25** were reserved as test compounds for transport efficiency modeling. Figure 9 shows the superimposition of all 22 compounds for transport efficiency model development. No QSAR model was derived from K_t data with significant q^2.

A comprehensive CoMFA model (CoMFA-2) was derived from log($normJ_{max}/K_t$) (Table 2). The q^2 and r^2 values were 0.538 and 0.999, respectively. Similar to CoMFA-1, steric fields dominated the electrostatic fields for transport efficiency with contributions of 61.2% and 38.8%, respectively. Figure 10 shows the relationship between observed and predicted uptake efficiencies of the training and test set (corresponding data in Supporting Information Table S2). The uptake efficiencies of test sets **22** and **25** were underestimated by 2- and 6-fold, respectively. **2** and **18** were significantly underestimated by approximately 9- and 400-fold, respectively. A potential contributing factor to the prediction error of **18** is that its uptake efficiency was over 100-fold greater than that of all other conjugates. The underestimated activity of compound **2** might be due to chemical or physical features beyond the predictive capacity of CoMFA and CoMSIA models.

CoMFA Model Contours for Transport Efficiency. Figure 11 shows steric and electrostatic contours of CoMFA-2 relative to CDCA-glutamyl-2,6-diaminopyridine **15**, the most efficient ASBT substrate within the training set ($normJ_{max}/K_t$ = 0.324 μM^{-1}). As above, a large green contour near positions 5 and 6 on the pyridine ring in Figure 11A indicates that a bulky group is beneficial. Compared to other position 6 substituents, transport efficiency of **14** with a methoxy group at position 6 on the 3-aminopyridine ring ($normJ_{max}/K_t$ = 0.202 μM^{-1}) was high compared to **8** (methyl substituted, 0.0119 μM^{-1}), **20** (fluoro, 0.0262 μM^{-1}), and **22** (bromo, 0.0415 μM^{-1}). The other green region near 1 and 6 positions on the pyridine ring of **15** indicates that steric interaction is favorable. A yellow contour between 4 and 5 positions indicates that a steric substituent will decrease efficiency. For example, fluoro substitution exhibited higher efficiencies than corresponding bromo substitution (**19** vs **21**). Figure 11B shows the electrostatic contour. The large blue region near the 4 and 5 positions on the 2,6-aminopyridine ring reflects the lower efficiency of the para hydroxyl in **27** compared to the ortho hydroxyl in **25** or the meta hydroxyl in **26**. The small blue region under the 6 position of **15** agrees with its high efficiency, compared to compounds lacking a 6-amino substitute such as **1**. The red region near the 4 position of **15** indicates that an electronegative substitute at the 4 position on 2-aminopyridine could enhance the transport efficiency.

LogP Effects on ASBT Inhibition and Transport. Partition coefficient (LogP) is a measurement of compound solubility and lipophilicity (*24*). Since CoMFA and CoMSIA models indicated that steric and hydrophobic features strongly influenced conjugate interaction with ASBT, LogP may explain inhibition or transport efficiency. Calculated LogP (CLogP) was computed

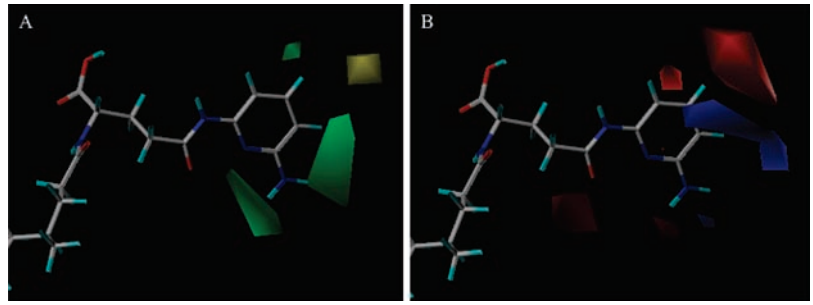

Figure 11. Steric (A) and eletrostatic (B) contour maps around CDCA-glutamyl-2,6-diaminopyridine **15** for CoMFA-2 transport efficiency model. In panel A, green contours show where bulky substitute favored inhibition, while yellow contours were disfavored. In panel B, the blue region represents favorable electropositive interaction for inhibition, while red shows disfavored electropositive character.

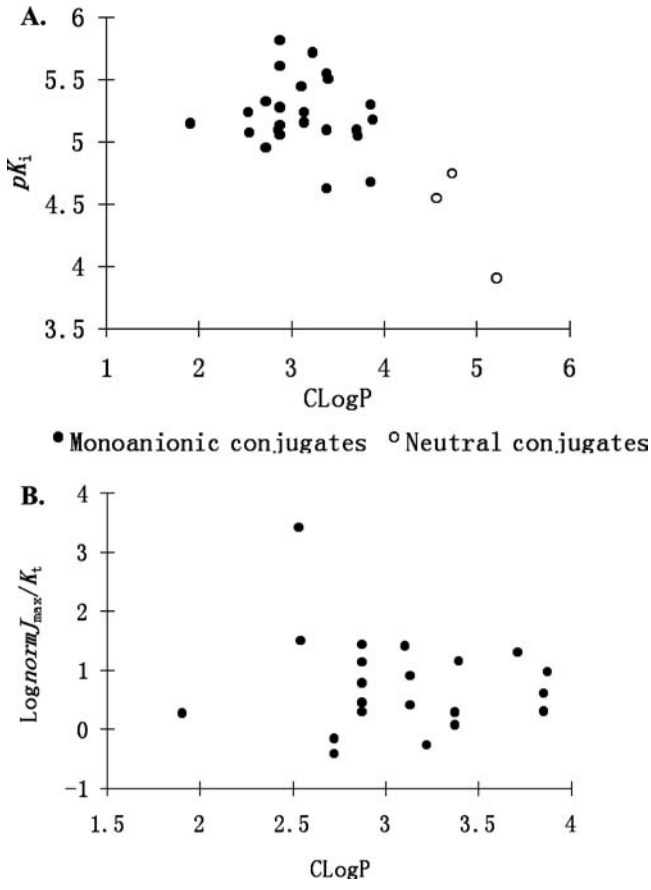

Figure 12. Influence of LogP on ASBT inhibition (A) and transport efficiency (B). (A) Observed pK_i vs ClogP shows a fairly negative correlation between pK_i and CLogP (slope = −0.331, $r^2 = 0.367$, and $p = 0.0008$). However, there was no simple correlation ($r^2 = 0.021$) among the 24 monoanionic conjugates when the three neutral conjugates (i.e., the α-benzyl substituted conjugates **11**, **13**, and **17**) were eliminated. (B) Observed log($normJ_{max}/K_t$) vs ClogP shows no relationship between log($normJ_{max}/K_t$) and CLogP with $r^2 = 0.015$ and $p = 0.586$.

using SYBYL according to Hansch and colleagues (*24, 25*) (Table 1). Plots of observed pK_i vs CLogP (Figure 12A) shows a fairly negative correlation between pK_i and CLogP with $r^2 = 0.367$ and $p = 0.0008$ (i.e., lipophilicity reduced binding potency). Comparison of α-benzyl-substituted conjugates to their nonsubstituted counterparts (**11** vs **10**, **13** vs **12**, and **17** vs **16**) essentially accounted for this trend. However, elimination of these three neutral conjugates (open circles in Figure 12A) leads to no relationship between pK_i and CLogP ($r^2 = 0.021$) among the 24 monoanionic conjugates (filled circles in Figure 12A). This lack of simple correlation between inhibition and CLogP is supportive of COMFA and COMSIA findings that hydrophobicity played differing roles in conjugate binding (i.e., hydrophobic or bulky substitute on the 2 or 6 position of a 3-aminopyridine ring enhanced activity, while a hydrophobic group on the 5 position was detrimental).

There was no correlation between Log($normJ_{max}/K_t$) and CLogP, with $r^2 = 0.015$ (Figure 12B). Additionally, no correlation was observed between K_t vs CLogP and $normJ_{max}$ vs CLogP as well with $r^2 = 0.037$ and 0.005, respectively. The lack of correlation between transport parameters and CLogP indicates that other physicochemical and structural variables impact transport beyond hydrophobicity, and further suggests a greater complexity in conjugate translocation compared to conjugate binding.

Comparison to Previous ASBT Models. Several computational models have been developed to study structural requirements of ASBT inhibition. Baringhaus and co-workers (*26*) explored the chemical features of ASBT inhibitors with 3D pharmacophore using structurally diverse molecules. 3D pharmacophore and Bayesian models were derived and applied by our lab to identify novel ASBT inhibitors among commercial drugs (*15*). However, the above studies do not systemically involve C-24 conjugated bile acid analogues, nor do they address the more complex process of ASBT-mediated uptake. Swaan and colleagues (*27*) applied CoMFA analysis on a series of bile acid−peptide analogues and found that inhibition was favored by an electron donor group between C-24 and C-27 and steric bulk at the end of the side chain. These results corroborate our present findings.

3D-QSAR models using a conformationally sampled pharmacophore (CSP) approach were developed for inhibition requirements using C-24 bile acid conjugates that employed piperidines as probe moieties (*28*). Results here using pyridines and phenols as probe moieties in part agree with these piperidine findings, where hydrophobicity favored inhibition activity. In contrast to piperidine findings, the results showed a position effect, where the relative location of the pyridine nitrogen and substituent groups modulated the conjugate ASBT inhibition and translocation.

C-24 bile acid conjugates have previously been shown to be ASBT substrates (*7, 29−31*). One of these studies was a SAR study involving a series of C-24 cholic acid conjugates and found that the C-24 side chain can be 14 Å in length or longer for translocation and that large hydrophobic moieties increase binding to ASBT (*29*). In another study, C-24 conjugation with glutamic acid and lysine also found that charge and hydrophobicity around the 24 position influenced translocation (*7*). Results of this study are in agreement with these prior findings that a negative change near C-24 promotes substrate translocation and that steric bulk at certain positions of the aminopyridine ring beyond C-24 also favors translocation.

CONCLUSION

With the view that bile acid conjugates can serve as prodrugs that target ASBT to increase oral drug permeability and bioavailability, a series of aminopyridine or aminophenol conjugates of glutamyl-bile acids were synthesized. Their ASBT inhibition and transport efficiency were evaluated to investigate their interaction beyond the C-24 region of CDCA with ASBT. Similar values for K_i and K_t indicate that substrate binding to ASBT was generally the rate-limiting step in overall substrate transport. 3D-QSAR models were developed for ASBT inhibition. The steric field dominated in the CoMFA model, whereas the hydrophobic field dominated other features in the CoMSIA models. Monoanionic conjugate exhibited higher inhibition potency than neutral conjugate. A hydrophobic or bulky substituent on the 2 or 6 position of a 3-aminopyridine ring enhanced inhibition, while a hydrophobic group on the 5 position was detrimental. Both inhibition models predicted test set inhibition. Recently, the value of inhibition-only QSAR models for drug transporters has been questioned (*32*), which prompted us to also develop ASBT models for transport efficiency. 3D-QSAR has not previously been applied to ASBT substrate studies. Similar to the inhibition models, the steric field was the predominant contributor; however, we demonstrate that steric contributions to ASBT transport cannot be explained simply by lipophilicity. Overall, these 3D-QSAR models provide new insight into the substrate requirements for ASBT uptake and shed light on the design of bile acid conjugates that can increase intestinal drug permeability and bioavailability.

ACKNOWLEDGMENT

This work was support in part by National Institutes of Health grants DK67530 (to J.E.P.) and DK61425 (to P.W.S.). The

author gratefully acknowledges Dr. Gasirat Tririya and Rana Rais for their assistance in chemical synthesis and Dr. Guoyun Bai for NMR assignment assistance.

[a] Calculated monoisotopic mass.

[b] Q1 and Q3 mass are experimental mass $[M+H]^+$.

[c] The mobile phase was A, 0.1% formic acid in water; and B, 0.1% formic acid in acetonitrile. The gradient times were listed as percent organic phase, B%. 0–0.2 (X%), 0.2–3.0 (X–95%), 3.0–4.0 (95%), 4.0–4.2 (95-X%), and 4.2–7.0 min (X%)

[d] Only characteristic peaks are shown, CDCA region and methylene peaks are not shown; values are in ppm relative to TMS; β indicates assignment to proton peaks in R_1; α indicates assignment to protons in R_2; γ indicates assignment to protons in amide, θ indicates the proton in α carbon.

[c] **2**, **18**, **22**, and **25** were used as test set.

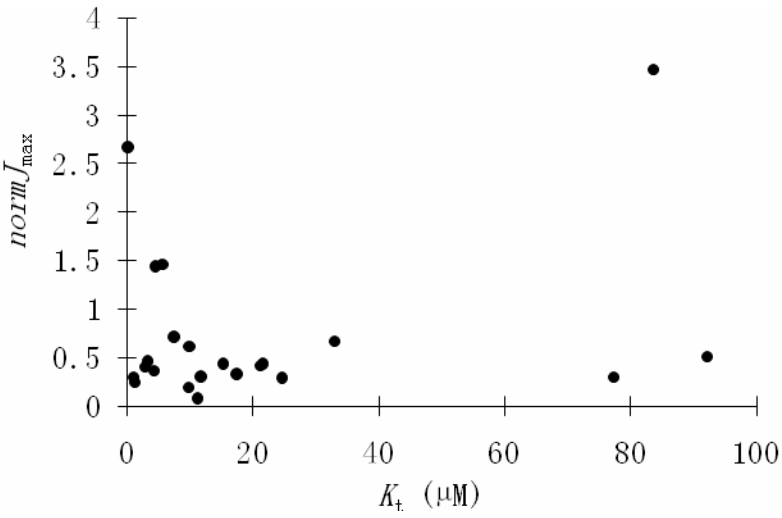

Figure S1. Relationship between $normJ_{max}$ and K_t. Transporting capacity was not associated with transporter affinity. Linear regression showed a slope of 0.008 μM^{-1} and r^2 of 0.064. **15**, **18**, **22**, and **25** yielded J_{max} higher than taurocholate. All other conjugates exhibited J_{max} less than taurocholate J_{max}, and ranged from 0.0791 to 0.716.

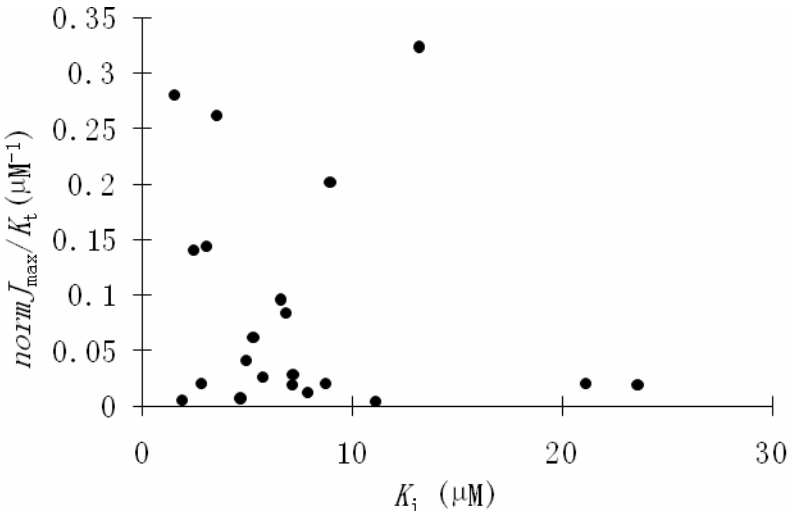

Figure S2. Relationship between $normJ_{max}/K_t$ and K_t. Linear regression showed a slope of -0.003 μM^{-2} and r^2 of 0.028. Transporting efficiency was not associated with inhibition potency. **18** was removed from the plot due to its high $normJ_{max}/K_t$ value of 26.7.

Active Accumulation of Gold Nanorods in Tumor in Response to Near-Infrared Laser Irradiation

Gold nanorods, rod-shaped gold nanoparticles, have strong absorbance in the near-infrared region, and the absorbed light energy can be converted to heat, the so-called photothermal effect. The gold nanorods were coated with thermoresponsive polymers, which have different phase transition temperatures that were controlled by adding comonomers, *N*,*N*-dimethylacrylamide (DMAA) or acrylamide (AAm) to *N*-isopropylacrylamide (NIPAM). The phase transition temperatures of poly(NIPAM-DMAA) and poly(NIPAM-AAm)-coated gold nanorods were 38 and 41 °C, respectively, while polyNIPAM-coated gold nanorods showed phase transition at 34 °C. Irradiation of the coated gold nanorods using the near-infrared laser induced a decrease in their sizes due to a phase transition of the polymer layers. Poly(NIPAM-AAm)-coated gold nanorods stably circulated in the blood flow without a phase transition after intravenous injection. Irradiation of near-infrared light at a tumor after the injection resulted in the gold specifically accumulating in the tumor. This novel accumulation technique which combines a thermoresponsive polymer and the photothermal effect of the gold nanorods should be a powerful tool for targeted delivery in response to light irradiation.

INTRODUCTION

Gold nanorods, rod-like shaped gold nanoparticles, have attracted increasing attention in recent years. Gold nanorods show unique optical properties, including two absorption bands corresponding to the transverse and longitudinal surface plasmon oscillations of free electrons in the visible (∼520 nm) and near-infrared (∼900 nm) regions, respectively (*1, 2*). Furthermore, absorbed light energy is converted efficiently into heat via the so-called photothermal effect (*3*). Since near-infrared light is ideally suited for in vivo imaging and laser therapy due to its high tissue penetration (*4*), gold nanorods are expected to act both as contrast agents for bioimaging and as thermal converters for photothermal therapy (*5, 6*).

Thermoresponsive polymers such as *N*-isopropylacrylamide (NIPAM) show a discontinuous volume phase transition, and their hydrophobicity changes in response to temperature increases (*7, 8*). These properties have been applied in the design of controlled drug release systems (*9*−*11*). Raucher et al. reported that the resulting hydrophobicity induced the uptake of the polymers to tumor cells in vitro (*12*). After intravenous injection of the polymers into tumor-bearing mice, they were accumulated in the tumor where it was locally heated (*13*). If thermoresponsive polymers can be conjugated to gold nanorods, the photothermal effect of gold nanorods actuated by irradiating the near-infrared light can induce the phase transition of the polymers. Gorelikov et al. prepared submicrometer-sized spheres of poly(NIPAM-*co*-acrylic acid) gels containing gold nanorods stabilized by cationic surfactant (*14*). Volume phase transition in response to near-infrared laser light was observed. Wei et al. prepared poly(NIPAM) (PNIPAM)-modified gold nanorods by surface-initiated atom transfer radical polymerization (*15*). They loaded norvancomycin, a widely used glycopeptide antibiotic against methicillin-resistant *Staphylococcus aureus*, into the PNIPAM layer on the gold nanorod. The PNIPAM layer retained the norvancomycin, and near-infrared laser irradiation enhanced its release, which was monitored by absorption at 260 nm.

Recently, our group succeeded in coating a PNIPAM gel on the surface of the gold nanorods, named PNIPAM-coated gold nanorods (*16*). They showed reversible shrinking of the gel layer triggered by near-infrared laser irradiation. The core−shell structure of PNIPAM-coated gold nanorods was prepared by colloid-template polymerization. After intravenous injection of PNIPAM-coated gold nanorods into mice, near-infrared laser light was irradiated to the right kidney for 10 min. At 30 min after the injection, significant accumulation of the gold nanorods was observed in the irradiated kidney. Thus, active accumulation mediated by the photothermal effect of the gold nanorods was confirmed. However, larger amounts of the injected gold nanorods were detected in the lungs in addition to the irradiated kidney (*16*). This is likely due to the phase transition of the PNIPAM layer which typically occurs at about 34 °C, which is lower than the body temperature of mice (37 °C). Therefore, after the injection, the hydrophobicity of the PNIPAM layer increased, and then, the gold nanorods were trapped in the capillary vessels in the lungs.

To maintain the stability of the gold nanorods in the circulating blood and demonstrate phase transition above the body temperature of the mice, the phase transition temperature should be adjusted to include a relevant range between 37 °C to represent a typical body temperature and 43 °C to account for a situation where the tissue is thermally damaged. Some research groups have succeeded in controlling the phase transition temperature of PNIPAM by adding a hydrophilic monomer such as *N*,*N*-dimethylacrylamide (DMAA) (*17*) or acrylamide (AAm) (*18*). Resultant copolymers, P(NIPAM-DMAA) and P(NIPAM-AAm), showed higher phase transition temperatures than the PNIPAM, because the hydrophilic units impede aggregation of NIPAM units in the polymer. In this

study, we prepared thermoresponsive polymer-coated gold nanorods that show phase transition at temperatures above the normal body temperature of mice. Active accumulation of the gold nanorods to the tumor site triggered by the near-infrared laser irradiation was observed.

EXPERIMENTAL PROCEDURES

Materials. Gold nanorods were supplied by Mitsubishi Materials Corp. (Tokyo, Japan) and Dai Nippon Toryo Co. Ltd. (Osaka, Japan). The gold nanorods dispersed by cetyltrimethylammonium bromide (CTAB) were prepared by our previous methods (*19*). The average length and width of the as-supplied gold nanorods were 48.8 ± 7.9 nm and 9.0 ± 1.2 nm, respectively (aspect ratio: 5.4). Thiol-terminated poly(ethylene glycol) (PEG) (MW ca. 20 000 Da) was purchased from NOF Co., Ltd. (Tokyo, Japan). Tetraethyl orthosilicate (TEOS) was purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan). 3-(Methacryloxy) propyl triethoxysilane (MPS) was purchased from Gelest, Inc. (Morisville, PA, USA). *N*-Isopropylacrylamide (NIPAM), *N*,*N*-dimethylacrylamide (DMAA), sodium dodecyl sulfate (SDS), 25% ammonia solution, and ethanol (99.5%) were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Acrylamide (AAm) and *N*,*N*′-methylenebisacrylamide (MBA) were purchased from Nacalai Tesque, Inc. (Kyoto, Japan). Potassium persulfate (KPS) was purchased from Sigma-Aldrich, Inc. (Missouri, USA). Phosphotungstic acid was purchased from TAAB Laboratories Equipment Ltd. (Berkshire, UK).

Preparation of Silica-Coated Gold Nanorods. PEG-modified gold nanorods were prepared by a method previously reported (*20*). A solution of gold nanorods containing CTAB was centrifuged at 14 000 × *g* for 10 min, decanted, and resuspended in distilled water to remove excess CTAB. A total of 10 mL of a solution of 1 mM gold nanorods (concentration of gold atom) was added to 2 mL of 1 mM thiol-terminated PEG (MW ca. 20 000 Da). The mixture was stirred overnight at room temperature and was dialyzed. PEG-modified gold nanorods were coated with a silica layer using the modified Stöber method, which is based on the hydrolysis of TEOS in ethanol/water mixture in the presence of gold nanorods, which act as seeds (*21, 22*). A solution of the prepared PEG-modified gold nanorods was concentrated by centrifugation. A total of 1 mL of a solution of 10 mM PEG-modified gold nanorods (as gold atoms) was diluted with 7.8 mL of ethanol. The mixture was added to 200 μL of 5% ammonia solution, and 1 mL of 50 mM TEOS was added. The reaction was allowed to proceed for 24 h at room temperature. The reaction mixture was added to 1 mL of 100 mM MPS to graft methacryl groups on the surface. The mixture was stirred for 24 h and dialyzed against ethanol/water solution (9/1) to remove excess MPS.

Preparation of Thermoresponsive Polymer-Coated Gold Nanorods. Thermoresponsive polymer-coated gold nanorods were prepared by following our previous report (*16*). All thermoresponsive polymer-coated gold nanorods were prepared by free radical precipitation polymerization. The resulting solution of the silica-coated gold nanorods grafted with MPS was centrifuged and resuspended in water. In the polymerization procedure, silica-coated gold nanorods grafted with MPS were used as seeds for the precipitation polymerization of NIPAM, 16 mol % of either comonomer (DMAA and AAm), and MBA using SDS as a stabilizer and KPS as an initiator. The mixture was bubbled through nitrogen for 10 min to remove residual oxygen. The reaction was allowed to proceed for 4 h at 70 °C. Then, the reaction mixture was dialyzed to remove the remaining monomers and initiator.

Characterization and Measurements. Absorption spectra of gold nanorods from the visible to near-infrared light region were measured with a spectrophotometer, Jasco V-670 (Tokyo, Japan). Morphologies of gold nanorods were observed with a transmission electron microscope (TEM) JEOL JEM-2010 (Tokyo, Japan) after staining with 1% phosphotungstic acid. Sizes of thermoresponsive polymer-coated gold nanorods in water were evaluated by the dynamic light scattering analysis with the Malvern Zetasizer Nano ZS (Worcestershire, UK). *Z*-average was used as an average diameter. Thermoresponsive polymer-coated gold nanorod solutions were diluted to 0.6 μg/mL (as gold weight) to avoid aggregate formation of the particles, and temperature of the sample was increased in a stepwise manner by 2 °C from 20 to 60 °C. After increasing the temperature by 2 °C, the sample was allowed to equilibrate at temperature for 5 min before data collection of scattered light from a He−Ne laser (633 nm). Photothermally driven size change of thermoresponsive polymer-coated gold nanorods was also measured with the Zetasizer Nano ZS. The thermoresponsive polymer-coated gold nanorod solutions (6 μg/mL (as gold weight; it is still enough to avoid aggregate formation), 700 μL) were irradiated using a near-infrared continuous-wave diode laser of wavelength at 807 nm (2.5 W/cm^2) (Alfalight Corporation, Madison, WI, USA). The laser was irradiated from the top of the solution in a cuvette for the dynamic light scattering analysis. The laser was turned off during the measurements because the effects of scattered light produced by the laser disturbed the measurements.

Animals. Male ddY mice (Kyudo Co., Ltd., Saga, Japan) were used in all experiments. Five-week old mice were maintained in a temperature controlled environment at 24 °C with a 12 h light/dark cycle and were provided with drinking water and food ad libitum. Animal experiments were performed according to the Guidelines for Animal Care and Use Committee, Kyushu University.

Implantation of Tumor Cells into Mice. Mouse rectum carcinoma colon-26 cells were cultured in RPMI-1640 containing 10% fetal bovine serum and 60 μg/mL kanamycin sulfate. The dishes containing cells were maintained at 37 °C in an incubator under a 5% CO_2 atmosphere. Tumor-bearing mice were prepared as follows. Colon-26 cells were injected subcutaneously into the right and left sides of the abdomen of a mouse (ddY, male, 5 weeks, 23−26 g) at a dose of 1 × 10^6 cells in 100 μL Hank's balanced salt solution per injection, then allowed to grow for 5 days, after which time the tumors had reached a size of 5−10 mm in diameter.

Biodistribution of P(NIPAM-AAm)-Coated Gold Nanorods in Mice. Normal mice and mice having two tumors at the right and left sides of the abdomen were anesthetized, then P(NIPAM-AAm)-coated gold nanorods (120 μg/mL (as gold weight), 10 μL/g of mice weight) were injected intravenously into the mice. In the case of the tumor-bearing mice, at 1 min after the injection, a near-infrared laser light (wavelength, 807 nm; power, 3.8 W/cm^2) irradiated the right tumor for 10 min. Mice were sacrificed at 30 min and 72 h after injection. Blood and major organs (liver, lung, spleen, kidney, and tumor) were collected. The samples were added to approximately 4 mL aqua regia and then heated overnight at 95 °C. The organic compounds were completely oxidized, and the gold was ionized. Finally, the samples were condensed to less than 0.5 mL by further heating at 120 °C for 2 h. The residues were diluted to 10 mL of 0.5 M HCl and sonicated for 10 min. Quantitative analysis of gold was performed by inductively coupled plasma mass spectrometry (ICP-MS) using the Agilent 7500c model ICP-MS (Agilent, CA, USA).

RESULTS AND DISCUSSION

Preparation of Thermosensitive Polymer-Coated Gold Nanorods. First, the gold nanorods stabilized by CTAB as shown in Figure 1A were modified with PEG, and then, the

Table 1. Composition of Reaction Mixtures to Prepare Thermoresponsive Polymer-Coated Gold Nanorods, Which Have Different Phase Transition Temperatures

coated polymer	NIPAM (mM)	DMAA (mM)	AAm (mM)	MBA (mM)	SDS (mM)	KPS (mM)
PNIPAM	50			5	1	1
P(NIPAM-DMAA)	41	9		5	1	1
P(NIPAM-AAm)	41		9	5	1	1

PEG-modified gold nanorods were coated with a silica layer using a modified Stöber method. Thickness of the resultant silica layer on the gold nanorods was 50−60 nm. This corresponded to that of the PEG layer of the original PEG-modified gold nanorods (Figure 1B). After coating with silica shells, the gold nanorods were dispersed without forming aggregates in a solution of 90% ethanol in water and were used in the following step. The silane-coupling agent MPS was used to modify the surface of the silica-coated gold nanorods with methacryl groups. Silica-coated gold nanorods grafted with MPS were modified with thermoresponsive polymers which have different phase transition temperatures. To alter the phase transition temperature of the PNIPAM, a hydrophilic monomer, 16 mol % of DMAA or AAm, was added to reaction mixtures of NIPAM polymerization as shown in Table 1. Figure 1C−H shows TEM images of the polymer-coated gold nanorods. The single core of a silica-coated gold nanorod modified with a single shell of the thermoresponsive polymer was observed in each case. There was no difference in the morphology among these variations, PNIPAM-coated gold nanorods (Figure 1C,D), P(NIPAM-DMAA)-coated gold nanorods (Figure 1E,F), and P(NIPAM-AAm)-coated gold nanorods (Figure 1G,H). After modifying the gold surface with the silica layer, a slight red shift of the absorption in the near-infrared light region (∼900 nm) was observed (Figure 2). Modifications with the thermoresponsive polymers caused a blue shift of the absorption. This is likely due to changes in the local refractive index around the gold nanorods produced by the silica shells and the thermoresponsive polymer layers (*23*). The increase of absorption in the visible region (∼500 nm) would be due to light scattering of the polymer layers.

Temperature-Induced Size Change of the Thermoresponsive Polymer-Coated Gold Nanorods. Size changes in the thermoresponsive polymer-coated gold nanorods induced by increasing their temperatures were measured by dynamic light scattering (DLS) (Figure 3). To avoid aggregation, experiments were performed at a low concentration (0.6 μg/mL of gold weight) of the gold nanorods. All thermoresponsive polymers showed discontinuous phase transition behavior. The volume phase transition of PNIPAM-coated gold nanorods occurred at about 34 °C, in agreement with a previous study (*16*). The phase transition temperatures of copolymerized thermoresponsive

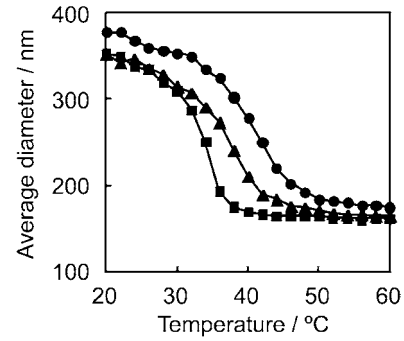

Figure 3. Temperature dependence of hydrodynamic diameters of thermoresponsive polymer-coated gold nanorods. Squares: PNIPAM-coated gold nanorods. Triangles: P(NIPAM-DMAA)-coated gold nanorods. Circles: P(NIPAM-AAm)-coated gold nanorods.

polymers, P(NIPAM-DMAA) and P(NIPAM-AAm)-coated gold nanorods, were about 38 and 41 °C, respectively. P(NIPAM-DMAA) and P(NIPAM-AAm)-coated gold nanorods showed slightly broader phase transition curves than PNIPAM-coated gold nanorods. Interruption of PNIPAM chain segments by other monomers would cause broadening of the phase transition of the polymers (*24*). Considering that the phase transition temperature is lowered by about 2.5 °C in the blood, i.e., physiological conditions (osmotic pressure maintained by ionic concentration equivalent to 150 mM NaCl) (*25*), P(NIPAM-AAm)-coated gold nanorods are expected to show phase transition at the desired range 38−42 °C in blood after intravenous injection.

Laser Irradiation-Induced Change in Size of the Thermoresponsive Polymer-Coated Gold Nanorods. We examined the phase transition behavior of the thermoresponsive polymer-coated gold nanorods by irradiation using a focused near-infrared laser at a wavelength of 807 nm (Figure 4). The PNIPAM-coated gold nanorods shrank from ∼330 to ∼130 nm after laser irradiation (2.5 W/cm^2) for 10 min, corresponding to a ∼95% decrease in the total volume of the coated gold nanorods. P(NIPAM-DMAA)-coated gold nanorods shrank from ∼330 to ∼170 nm, corresponding to a ∼86% decrease in the volume. P(NIPAM-AAm)-coated gold nanorods shrank from ∼350 to ∼230 nm, corresponding to a ∼70% decrease in the volume, which was lower than P(NIPAM-DMAA)- and PNIPAM-coated gold nanorods. The sizes of the polymer-coated gold nanorods after the light irradiation corresponded to those at about 44 °C as shown in Figure 3 indicating that temperatures of the samples were increased to about 44 °C after the laser irradiation for 10 min. Actually, the temperature of the samples after light irradiation for 10 min was between 45 and 47 °C (data not shown). If thermal damage of tissue is desired, as in the case of hyperthermia, the temperature increase is sufficient. A cycle of shrinkage and swelling

induced by switching the laser on and off could be repeated. This result indicated that the optical property of the gold nanorods and characters of the thermoresponsive polymer layers were not affected by the laser irradiation.

Biodistribution of P(NIPAM-AAm)-Coated Gold Nanorods. Since P(NIPAM-AAm)-coated gold nanorods are expected to maintain the hydrophilic surface at the body temperature of a mouse (37 °C) and undergo phase transition after laser irradiation in the temperature range 38−42 °C, P(NIPAM-AAm)-coated gold nanorods were employed for examination of biodistribution after intravenous injection. P(NIPAM-AAm)-coated gold nanorods were systemically injected into normal mice, and then blood and major organs were collected at 30 min after the injection. The amount of the gold (% injected dose) in the organs was evaluated by inductively coupled plasma mass spectrometry (ICP-MS) (Figure 5A). A total of 66% of the injected dose of gold was found in the blood. As we already reported in the previous paper (*16*), in the case of PNIPAM-coated gold nanorods, about 1% of the injected dose of gold was detected in the blood at 30 min, and about 45% of the injected dose of gold was found in the lung. It was believed that phase transition of the PNIPAM layer on the gold nanorods was induced by the body temperature after the injection and then the surface hydrophobicity caused aggregation of the gold nanorods. Finally, the gold nanorods became trapped in the capillary vessels in the lungs and/or interacted with the cellular surface through hydrophobic interactions. In contrast, P(NIPAM-AAm)-coated gold nanorods that have a higher phase transition temperature than the body temperature showed stable circulation in the blood flow at least 30 min after the intravenous injection. The amount of the gold per gram of tissue was calculated from

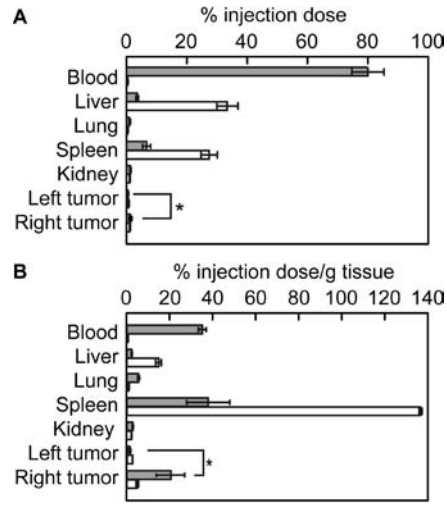

Figure 6. Biodistribution of P(NIPAM-AAm)-coated gold nanorods at 30 min (gray bars) and 72 h (open bars) after intravenous injection to mice that have two tumors at their abdomen. A near-infrared laser light at a power density of 3.8 W/cm^2 was applied to tumor for 10 min after the injection. Amounts of gold in blood and tissues were evaluated by ICP-MS. Panels A and B indicate % injected dose and % injected dose per gram of tissue, respectively. Data represent mean values for $n = 3$ and bars are standard errors of the mean. $^*P < 0.05$.

the data shown in Figure 5A (Figure 5B). The highest accumulation of the gold nanorods was found in the spleen, likely because nanoparticles larger than 200 nm like the P(NIPAM-AAm)-coated gold nanorods are known to be trapped by splenic physical filtration (*26*−*28*). Very small amounts of gold were observed in other organs.

Next, we examined the active accumulation of P(NIPAM-AAm)-coated gold nanorods in a tumor irradiated by the near-infrared laser light in vivo. P(NIPAM-AAm)-coated gold nanorods were intravenously injected into mice that have two tumors at the abdomen. The right tumor was irradiated using the near-infrared laser (807 nm, 3.8 W/cm^2) for 10 at 1 min after the injection. Organs were collected at 30 min and 72 h after the injection, and the amounts of the gold nanorods (% injected dose) in the organs were evaluated by ICP-MS (Figure 6A). A total of 80% of the injected dose of gold was found in the blood at 30 min. In the case of the normal mice without laser irradiation, 66% of the gold was observed (Figure 5A). Although existence of the tumor may affect the biodistribution of the gold nanorods in mice, the volumes of the tumors used in this study would be too small (less than 1% of body weight) to affect it. Furthermore, it is also supposed that the laser power used (807 nm, 3.8 W/cm^2, 10 min) would not affect the blood circulation of the mice. Therefore, this inconsistency would be due to experimental error. In the irradiated right tumor, a significantly larger amount of the gold (1.1 ± 0.4%) was detected compared with the left tumor (0.06 ± 0.03%), although the absolute amount of gold was lower than that of the spleen (6.5 ± 1.3%). At 72 h, a small amount of gold was observed in the blood, while most of the gold accumulated in the liver and the spleen. In the left tumor, the amount of gold was increased to 0.42 ± 0.05%. This may be due to the EPR effect; however, the absolute amount of the gold was extremely low. In the irradiated right tumor, 0.88 ± 0.09% of gold was detected. This was not significantly different from the accumulation at 30 min (1.1 ± 0.4%), indicating that most of the gold was retained in the right tumor for 72 h.

The calculation of the amount of gold per gram of tissue (Figure 6B) indicates a clear difference in the accumulations between the right and left tumors at 30 min, and the accumulation in the right tumor (20%/g tissue) was higher than the case

of the PEG-modified gold nanorods accumulating in the tumor by EPR effect (15%/g tissue), which was enough to show photothermal tumor damage (*29*). On the other hand, the accumulation in the right tumor was comparable to that in the blood and the spleen. As described previously, the mechanism of the accumulation is believed to involve the hydrophobic surface of the P(NIPAM-AAm)-coated gold nanorods after the phase transition induced by the photothermal effect of the gold nanorods triggered aggregate formation at the light irradiated site. For example, in the case of the right tumor, the gold nanorods became trapped in the capillary vessels in the tumor and/or interacted with the cellular surface and the extracellular matrix through the hydrophobic interactions. At 72 h, the amount of the gold per gram of tissue in the right tumor was lower than that at 30 min. The reason the value was decreased is that the tumor had grown for 72 h without a decrease in the absolute amount of gold in the tumor.

Although further optimization of several factor, e.g., inject does of the polymer-coated gold nanorods, condition of the laser irradiation, and further surface modification to improve the accumulation in the tumor, are required, this novel accumulation technique which combines a thermoresponsive polymer and the photothermal effect of the gold nanorods will be a powerful tool for targeting the gold nanorods for purposes of photothermal therapy. As well, this technique may be useful for targeted delivery and controlled release of drugs at the site of light irradiation if drugs can be successfully encapsulated in the polymer layer as previously reported by Wei et al. (*15*).

CONCLUSION

Thermoresponsive polymer-coated gold nanorods with different phase transition temperatures were prepared by adding comonomers, DMAA and AAm, to the polymerization of NIPAM. P(NIPAM-AAm)-coated gold nanorods underwent phase transition at temperatures above the normal body temperature of mice. Active accumulation of the gold nanorods in the tumor in response to the near-infrared light irradiation was demonstrated in tumor-bearing mice after intravenous injection. This combination of a thermoresponsive polymer and the photothermal effect of the gold nanorods should provide clues for the development of novel therapeutic techniques controlled by light.

Synthesis, Characterization, and Thermodynamic Study of a Polyvalent Lytic Peptide−Polymer Conjugate As Novel Anticancer Agent

Jieying Zhong[†] and Ying Chau*[,‡]

Bioengineering Graduate Program and Department of Chemical and Biomolecular Engineering, The Hong Kong University of Science and Technology. Received June 25, 2010; Revised Manuscript Received September 27, 2010

We designed and synthesized a new polyvalent lytic peptide−polymer conjugate as a novel chemotherapeutic agent capable of overcoming multidrug resistance. A hexapeptide (KWKWKW or $(KW)_3$) was designed and conjugated to dextran in multiple copies to afford a polyvalent conjugate. A robust synthesis procedure involving click chemistry and the detailed characterization of the conjugate were reported here. The conjugate Dex-$(KW)_3$ exhibited significantly enhanced anticancer potency in vitro by up to 500-fold compared to monomeric $(KW)_3$. The LC_{50} value was comparable to that of conventional lytic peptides which have more than 20 residues. No hemolytic activity was shown by the conjugates up to 300 μM. Thermodynamic study indicated that the binding of conjugates was predominantly entropy-driven while the binding of free peptides was mainly enthalpy-driven, implying a deeper penetration of conjugate into the core of lipid bilayer. The binding affinity of conjugate to neutral membrane is much higher than that to free peptide ($K_{conj} \approx 8822.9\ M^{-1}$, $K_{pep} \approx 1884.7\ M^{-1}$). In binding to negatively charged membrane, the conjugate surpassed free peptides at high concentrations when the binding of free peptides became saturated. The higher binding capability, attributed to the high local concentration of peptides mounted on a polymer backbone, explains the superior anticancer activity of polyvalent Dex-$(KW)_3$.

INTRODUCTION

For cancers that are homological or metastatic, chemotherapy is almost the only choice of treatment. However, multidrug resistance remains an impediment to successful chemotherapy (*1*). Resistant cancer cells can diminish or even neutralize the therapeutic effect by increasing the efflux and/or reducing the uptake of drug, thus greatly impair the effectiveness of conventional chemotherapeutics. This problem brings a strong demand for novel chemotherapeutics. In antibiotic research, another field also facing the problem of drug resistance, a group of antimicrobial peptides are considered promising (*2*). More recently, their potential as anticancer agents is being recognized (*3, 4*).

These peptides widely exist in nature as an important component of innate immune system against infection (*5*). Their action is fast, direct, and broad-spectrum, complementary to the adaptive immune system, which is specific but requires more time to mobilize. The cytotoxicity of peptides is mediated by the disruption of cytoplasmic membrane. Models on the mechanism have been proposed (*6, 7*). Most of these peptides are amphipathic and cationic. The cationic charge allows peptides to accumulate on the membrane surface, and the side chains of hydrophobic residues subsequently insert into the outer layer of the membrane. The expansion of the outer layer places lateral pressure on the lipid bilayer to bend inward. It is important to have sufficient peptides in close proximity to create enough strain on the curvature of the lipid layer to break down the membrane. When the number of inserted peptides is above a certain limit, the formation of pores or the global decomposition of membrane leads to cell death. The activity of lytic peptides is independent of the extracellular recognition or intracellular uptake. Its target is not any specific molecule or pathway but the cell membrane, which is a relatively conservative structure so that resistance cannot be easily acquired. This unique feature renders this family of molecules an advantage in overcoming multidrug resistance.

However, lytic peptides require a minimal length and local concentration to be effective. Though the effective length varies from sequence to sequence, these peptides usually have more than 10 residues. For peptides without modification, the critical concentration at the target site can only be driven by high bulk concentration at which peptides may cause unwanted toxicity such as hemolysis. Besides, peptides may suffer from degradation by proteases, inactivation by serum proteins, and fast elimination in the blood circulation. These create additional hurdles to achieving effective concentration at the target sites. Therefore, antibiotic peptides succeeded in clinical trials only as topical agents. Another issue accompanying long sequences and low efficiency is high cost. The strategy of polyvalency was employed by several studies for it is known to be able to increase the avidity of weak monomeric ligands dramatically (*8*). Antimicrobial potency was significantly enhanced by mounting multiple copies of lytic peptides to a core or a scaffold (*9*−*11*). These reports support the hypothesis that clustering and sufficient local concentration are essential to the activity of lytic peptides, suggesting polyvalent design as a solution to fulfill the therapeutic promise of membrane lytic peptides.

In this study, we aim to demonstrate that polyvalency increases the anticancer potency of membrane lytic peptides. We will address the underlying mechanism via the thermodynamics measurement of the interaction between cell membranes and peptides. To these ends, a peptide−polymer conjugate was synthesized by coupling multiple copies of short lytic sequences to a dextran backbone. With this design, we expect not only an enhanced effectiveness due to polyvalency, but also an improve-

ment in stability, tumor targeting, and pharmacokinetic properties due to polymeric conjugation (*12*).

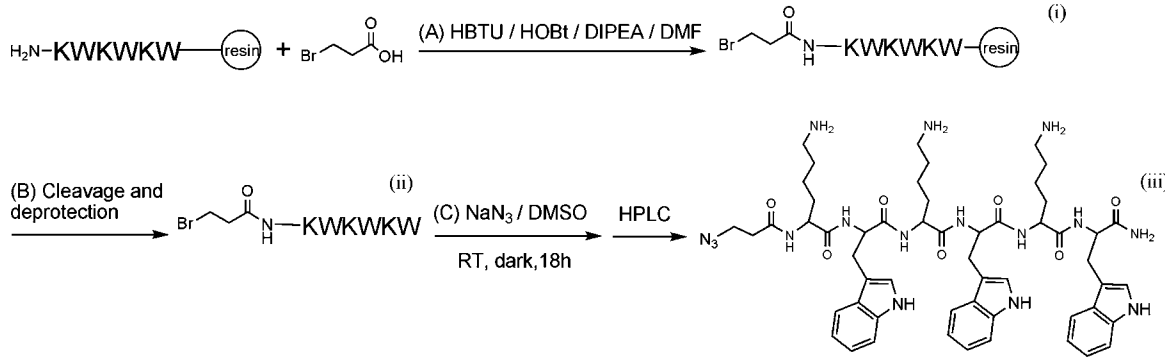
MATERIALS AND METHODS

Reagents. Dextran T-70, *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide (EDC), 2,4,6-trinitrobenzene sulfonic acid (TNBSA), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), 1,2-dioleoyl-*sn*-glycero-3-phospho-*rac*-(1-glycerol) sodium salt (DOPG), trifluoroacetic acid (TFA), sodium azide, copper sulfate, and deuterium oxide were purchased from Sigma (St. Louis, USA). Propargylamine, 3-bromopropionic acid, and Gly-Gly were from Fluka (St. Louis, USA). DMSO, chloroacetic acid, and ascorbic acid sodium were obtained from Acros (Geel, Belgium). Acetonitrile was from Duksan (Gyeonggi-do, Korea). 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) and all the cell culture reagents were bought from Invitrogen (Carlsbad, USA). Human breast cancer cell line MCF-7 and prostate cancer cell line PC-3 were kindly provided by Prof. Kathy Luo (Nanyang Technological University, Singapore) and Prof. Patrick Ling (The University of Hong Kong, Hong Kong), respectively.

Synthesis. *Preparation of Azido Peptide.* The peptides were synthesized based on the solid-phase peptide synthesis procedure. Briefly, Fmoc- Amide AM resin was mixed in DMF in a plastic peptide vessel (1 h), then subjected to Fmoc-deprotection and coupling. The Fmoc-protection group was removed by incubating resin in a piperidine/DMF mixture (25:75, v/v, 10 mL/g of resin) under agitation for 15 min. The vessel was drained via vacuum and washed with DMF (6×). The Fmc-protected amino acid (5 equiv), HBTU (4.5 equiv), and HOBT (4.5 equiv) were dissolved in DMF (5 mL/g of resin) followed by the addition of DIPEA (10 equiv). This mixture was quickly added to the resin and agitated for 3 h. After coupling, the resin was washed with DMF (3×). The Fmoc-deprotection and coupling were repeated for each amino acid until the desired sequence was assembled. At the end of peptide prolongation, the N-terminal was capped with 3-bromopropionic acid with the same coupling method as amino acid. The resin was then thoroughly washed with DMF, DCM, and methanol (3× each) and dried in high vacuum overnight. The resulting sequence was then deprotected and cleaved from resin by adding a cleavage cocktail (TFA/TIPS/water, 95:2.5:2.5, v/v) to the vessel. After 3 h incubation with agitation, the mixture was filtered. The filtrate was concentrated under a nitrogen stream. Cold diethyl ether was added to the filtrate to precipitate raw peptide $Br(CH_2)_2CONH\text{-}KWKWKW\text{-}NH_2$. The terminal bromine was converted to azide after overnight incubation in DMSO containing sodium azide (25 mg/mL) at room temperature in the dark. Purification was performed on a silica C18 column (1 × 25 cm, Grace Vydac 218TP) connected to an HPLC delivery system equipped with a UV detector (Waters, Milford, USA). The chromatographic separation was run at 5 mL/min using water and acetonitrile, both supplemented with 0.1% TFA, as mobile phases A and B, respectively. After sample injection, the column was rinsed with 5% mobile phase B for 10 min, followed by a gradient from 5% B to 30% B in 10 min and then to 80% B in 60 min. Absorbance at 220 and 280 nm was monitored. Eluted fractions were collected. Peptide identity was confirmed by MALDI mass spectroscopy analysis (Calc.: 1056.6, found: 1056.7). Analytical HPLC indicated that the purity was higher than 95%.

Preparation of Carboxymethyl Dextran (CM-Dextran). Dextran T-70 (2 g) was dissolved in 6 M sodium hydroxide solution (10 mL) to yield a clear solution. Chloroacetic acid (116.5 mg) was then added. The resulting mixture was held at 90 °C with vigorous stirring for 3 h. HCl (5 M) was added to neutralize and terminate the reaction. The product was purified by ultrafiltration against DI water. Briefly, the reaction mixture as aqueous solution was put in a cup-like ultrafilter equipped with a semipermeable membrane (cutoff: 10 000 Da) (SINAP Membrane Science & Technology Co., Ltd., Shanghai, China). Hydrostatic pressure was applied by connecting the interior of ultrafilter to compressed nitrogen. Salt, catalyst, and unreacted reagents passed through the membrane with water while polymers were retained. DI water was refilled before the solution was too concentrated. The ultrafiltration was stopped when the volume of filtrate was six times the volume of the original mixture. The lyophilized polymer appeared as a fluffy white powder.

Preparation of Alkynyl Dextran. Carboxylmethyl groups were further modified with alkynyl groups according to the procedure below. CM-dextran (2 g, 0.244 mmol carboxylmethyl) and propargyl amine (0.63 mL, 9.8 mmol) were dissolved in water (20 mL). The pH of the mixture was tuned to 5 with HCl. EDC (2.35 g, 12.25 mmol in total) was added to the mixture in 5 aliquots in 48 h. Excessive amounts of propargyl amine and EDC were used to drive the completeness of conversion. The reaction was held at room temperature. The polymer was purified by ultrafiltration as previously described and lyophilized for storage.



Preparation of Conjugate Dex-$(KW)_3$. Propargyl dextran (91.2 mg, 0.011 mmol alkyne) and azido $(KW)_3$ (17.7 mg, 0.017 mmol) were dissolved in DI water and mixed thoroughly. Copper sulfate pentahydrate (2.77 mg, 0.011 mmol) and sodium ascorbate (4.4 mg, 0.022 mmol) were subsequently added to the mixture. The reaction was carried out in a nitrogen atmosphere at 40 °C for 48 h. The product was then dialyzed against DI water using cellulose dialysis membrane tubing (Spectrum Laboratories, Rancho Dominguez, CA, USA) with a molecular weight cutoff at 3000−8000 Da for 3 days. On the second day of dialysis, the solution was taken out and centrifuged at 4500 rpm for 10 min to remove the insoluble copper ions. The supernatant was then dialyzed again. A white fluffy powder was obtained after lyophilization.

NMR Spectroscopy. ^1H NMR spectra were recorded on 400 MHz spectrometer (JNM EX-400, JEOL Ltd., Tokyo, Japan). All samples were dissolved in D_2O for spectral acquisition.

Determination of Peptide Loading (TNBSA assay). TNBSA reacts readily and exclusively with primary amine at pH 8 to form yellow adducts which can be monitored at 335−345 nm (*13*). Since there are plenty of primary amines at the side chain of lysine in the sequence, we used this method to quantify the loading of $(KW)_3$ on conjugate. Dipeptide Gly-Gly was used as a standard. A concentration series of Gly-Gly and conjugates were prepared in 0.1 M sodium bicarbonate. The volume of each standard and sample was 0.5 mL. To each standard and sample was added 0.25 mL of TNBSA (0.01% w/v, in 0.1 M sodium bicarbonate). After incubation in a 37 °C water bath for two hours, 0.25 mL of SDS (10% w/v, in water) and 0.125 mL of HCl (1 M) were added and mixed thoroughly. Absorbance was measured at 335 nm with a microplate reader (Varian Cary 50, Palo Alto, USA). A standard curve was constructed by plotting the amine concentration of Gly-Gly standards against the absorbance reading.

Cell Culture. Human breast cancer cell line MCF-7 was maintained in MEM. Prostate cancer cell line PC-3 was maintained in RPMI 1640 medium. Mouse embryo fibroblast NIH/3T3 was maintained in DMEM. The drug-resistant cell line MES-SA/Dx5 and its parental cell line MES-SA were cultured in McCoy's 5A medium. All media were supplemented with 10% fetal bovine serum, except the medium for NIH/3T3 was supplemented with 10% bovine calf serum. Cells were cultured at 37 °C in 5% CO_2 atmosphere.

Scheme 1. Synthesis Procedure of Azide-Terminated Lytic Peptide[a]

[a] Reactants and products: (i) bromine-terminated $(KW)_3$ on resin; (ii) bromine-terminated $(KW)_3$; (iii) azide-terminated $(KW)_3$. Reaction conditions: (A) HBTU/HOBT/DIPEA coupling in DMF; (B) dilute trifluoroacetic acid cleavage from resin and deprotection of peptide side chains; (C) substitution of bromine by azide in DMSO and purification by reversed-phase HPLC. Typical yield of step C is ∼70%.

In Vitro Cytotoxicity Test (MTT assay). Cells were seeded on a 96-well plate at a density of 15 000 (PC-3, MCF-7, and NIH/3T3) or 20 000 (MES-SA and MES-SA/Dx5) cells per well. After overnight incubation, the growth medium was replaced with 100 μL of serum-free medium containing peptides or conjugates at the indicated concentrations. After 3 h of incubation, 10 μL of MTT was added to each well to achieve a final concentration of 0.5 mg/mL. The plate was then incubated at 37 °C for 4 h. 100 μL of SDS solution (10% w/v in 0.01 M HCl) was added to each well to dissolve the purple crystals of formazan. After overnight incubation, the absorbance at 595 nm was measured with a plate reader (Wallac Victor^3 1420, PerkinElmer, MA, USA). The percentage viability was calculated as follows:

$$\text{viability}(\%) = (A_s - A_0)/(A_c - A_0) \times 100\%$$

where A_s is the absorbance value of sample, A_c is the absorbance of control where cells were untreated, and A_0 is the absorbance of cell-free background. Each experiment was repeated three times independently.

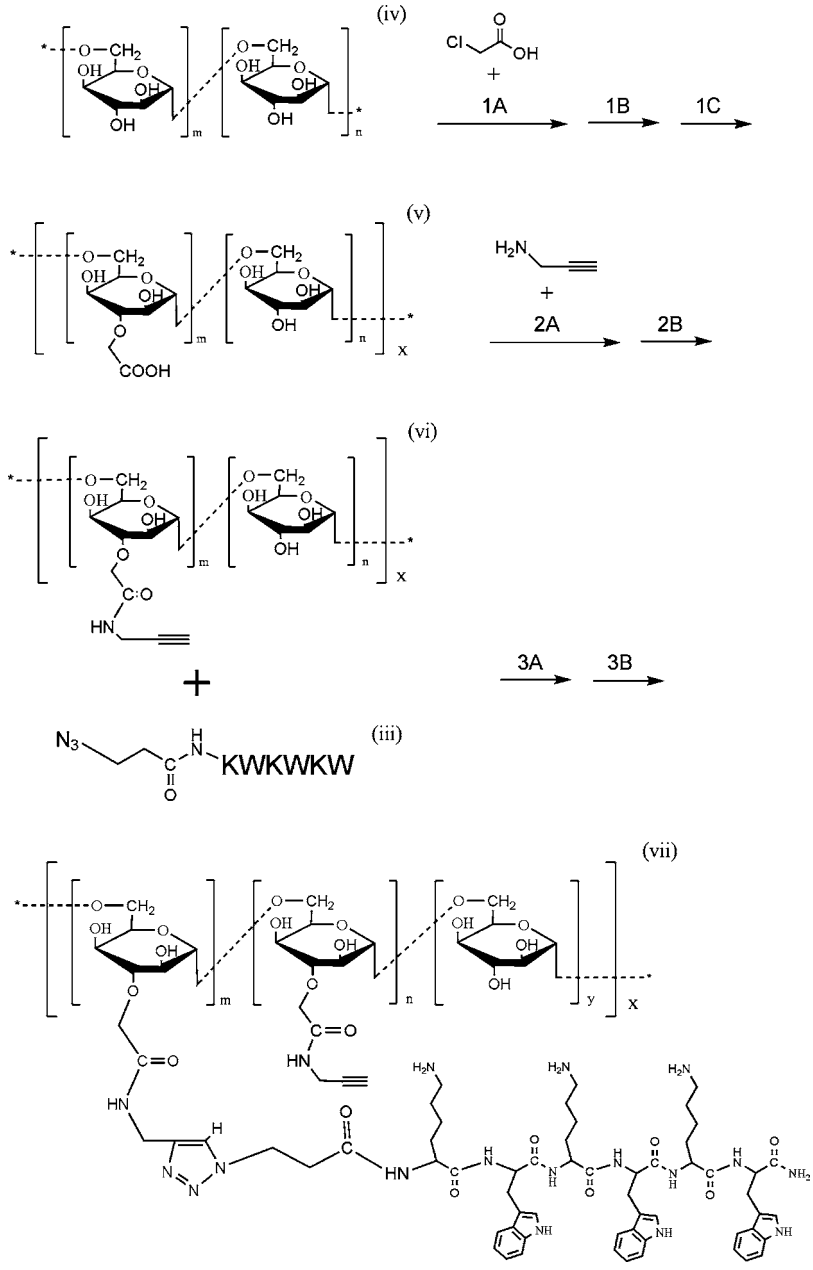
Hemolysis Assay. Heparinized fresh rabbit blood was centrifuged at 2000 rpm for 10 min. The supernatant was removed. The red blood cells were then resuspended in warm PBS. The procedure was repeated three times to rinse the red blood cells prior to use. Peptides were added to erythrocyte suspension to obtain the designated peptide concentrations and a final erythrocyte concentration of 4% (v/v). The resulting suspensions were incubated at 37 °C for 1 h at 300 rpm agitation. Samples were then centrifuged at 2000 rpm for 10 min. The absorbance of supernatant at 540 nm was measured to examine the release of hemoglobin and the damage of erythrocyte membrane. Zero hemolysis and 100% hemolysis consisted of erythrocyte suspended in PBS and 1% Triton X-100, respectively. The percentage of hemolysis was determined as follows:

$$\text{hemolysis}(\%) = (A_s - A_0)/(A_{100} - A_0) \times 100\%$$

where A_s is the absorbance value of the sample, A_{100} is the absorbance of completely lysed RBC in 1% Triton X-100, and A_0 is the absorbance of zero hemolysis. Each experiment was repeated at least three times independently.

Small Unilamellar Vesicles (SUVs) Preparation. The phospholipid DOPC and DOPG were dissolved in dichloromethane and mixed in a 75/25 molar ratio. The mixture was dried under a nitrogen stream and subsequently under a high vacuum overnight. The weight of the mixed lipid was measured. For DOPC SUV, lipid was directly weighed and used. The dry film was dissolved in phosphate buffer (20 mM, 100 mM NaCl, pH 7.4) to obtain a final lipid concentration of 10 mM. The suspension was then vortexed rigorously for 2 h for hydration. Sonication was applied with a probe tip-type sonicator (Sonifier 450, Branson, Danbury, CT, USA). The lipid suspension was sonicated in an ice bath (output = 5, duty cycle = 35) until a clear solution was obtained. Debris was removed by centrifugation at 14 000 rpm for 10 min. The concentration of SUV suspension was calculated according to the weight of lipid measured prior to preparation.

Particle Size and Potential Measurement by Dynamic Light Scattering (DLS). The particle size and surface potential of lipid vesicles, polymers, and conjugates were measured by laser-light scattering with a zeta potential analyzer (ZetaPlus, Brookhaven Instruments Corporation, NY, USA). All the samples were prepared in PBS (20 mM, 100 mM NaCl, pH7.4). Polymers and conjugates were measured at 10 mg/mL. SUV samples were measured at a lipid concentration of 5 mM.



Isothermal Titration Calorimetry. Experiments were performed using an isothermal titration calorimeter (VP-ITC, MicroCal, NJ, USA) at 25 °C. PBS (20 mM, pH 7.4, 100 mM NaCl) was used as the working buffer. All the samples were degassed prior to use. SUV suspension (10 mM lipid concentration) was injected in 6 μL increments into a solution of peptides or conjugates (2 or 10 μM equivalent peptide concentration according to the respective affinity) in the calorimeter cell (cell volume = 1.4561 mL). The heat liberated from the binding of peptides to lipids in each injection was recorded. The titration continued until the released heat approached zero. The heat of dilution was determined by the titration of SUV suspension into buffer. Heats of dilution were relatively small but nevertheless subtracted. Binding isotherms were constructed as described (*14*). The procedure was summarized in the Supporting Information.

RESULTS

Design and Synthesis of Lytic Peptide−Polymer Conjugate Dex-$(KW)_3$. A hexapeptide, Lys-Trp-Lys-Trp-Lys-Trp ($(KW)_3$), was designed as the lytic sequence based on the principle of amphipathicity. Tryptophan is a hydrophobic amino acid with a bulky ring at the side chain. The importance of tryptophan to lysing activity has been reported by previous studies (*15, 16*). Lysine and arginine were widely used as the source of positive charge in synthetic antimicrobial peptides. The lysine-containing sequence is less cationic but prone to inducing membrane disruption instead of penetration compared to an arginine-containing analogue (*17*). With consideration of the aim of this work, lysine was selected.

Since there are multiple active amine groups at both the N-terminal and side chains, a conjugation method that can be restricted at the terminal is required. Moreover, because the

Scheme 2. Synthesis Procedure of Dextran-$(KW)_3$ Conjugate[a]

[a] Reactants and products: (iv) Dextran of MW 70 000 Da; (v) carboxylmethyl dextran; (vi) alkynyl dextran; (vii) conjugate Dex-$(KW)_3$. Reaction conditions and step yields: 1A, carboxylmethyl modification in 6 M NaOH solution at 90 °C; 1B, termination and neutralization with 5 M HCl; 1C, ultrafiltration against water, yield of step 1 = ~80%; 2A, coupling with propargyl amine under catalysis of EDC in water; 2B, ultrafiltration against water, yield of step 2 = ~90%; 3A, conjugation by Cu(I)-catalyzed cycloaddition; 3B, dialysis against DI water, yield of step 3 = ~70%.

resulting conjugates are going to be tested in vitro, the minimized use of organic solvent and harsh conditions will be preferred. Cu(I)-catalyzed Huisgen 1,3-dipolar cycloaddition between azide and alkyne was adopted for conjugation. As one of the click chemistry reactions, it provides the advantages of high specificity and mild conditions.

Azide-terminated peptide was prepared according to Scheme 1. The sequence $(KW)_3$ was synthesized on resins, and the N-terminal was capped with 3-bromopropionic acid at the end of peptide prolongation. Since positive charge is essential to peptide activity, the C-terminal was amidated to mask the negatively charged carboxyl group. After cleavage from resins, the terminal bromine was substituted with azide for subsequent conjugation. The reaction yield was ~70%.

Dextran T-70 was modified with pendant carboxymethyl (Scheme 2 reaction 1). The reaction was examined by ^{1}H NMR. In the spectrum, the peak of the C1 proton of glucose structural units (-O−C*H*−O-, δ = 5.0 ppm) shifts upon carboxylmethyl modification (-O−C*H*−O-, δ = 5.2 ppm) (Supporting Information Figure S1(A)). The substitution degree of carboxylmethyl groups could be tuned by adjusting the feed ratio of chloroacetic acid.

CM-dextran was further converted to alkynyl dextran (Scheme 2 reaction 2). Because unmasked carboxyl groups may impair the activity of lytic sequence, to which positive charge is important, an excessive amount of propargyl amine was added to drive the completeness of reaction. The success of the reaction was confirmed by the signal of alkyne proton (C*H*≡C-, δ = 2.65 ppm) in the ^{1}H NMR spectrum (Supporting Information Figure S1(B)). The alkyne proton was estimated and compared with the C1 proton of carboxylmethyl glucose structural units

Table 1. Summary of the Characterization Results of Polymers and Conjugate

	loading of functional group or peptide (mmol/gram)	zeta potential (mV)	diameter (nm)
dextran T-70	−	1.29 ± 2.51	9.48 ± 0.25
carboxylmethyl−dextran	∼0.122	-7.02 ± 2.11	14.59 ± 0.35
alkynyl−dextran	∼0.122	0.35 ± 2.03	11.57 ± 0.24
Dex-$(KW)_3$	∼0.05	8.13 ± 2.63	8.19 ± 0.42

The loading of carboxylmethyl and alkynyl groups on dextran was estimated by comparing the signals of the functional groups to the signal of glucose units in the ^{1}HNMR spectrum. The loading of peptides on dextran was calculated by measuring the primary amine groups on peptide side chains with a colorimetric assay. All the samples for DLS were prepared in PBS buffer (20 mM, 100 mM NaCl, pH 7.4). Polymers and conjugates were measured at 10 mg/mL. SUV samples were prepared at a lipid concentration of 5 mM.

(-O−C*H*−O-, $\delta = 5.2$ ppm). The result suggested that the conversion was close to 100%.

Cu(I)-catalyzed Huisgen 1,3-dipolar cycloaddition was applied to graft $(KW)_3$ to dextran (Scheme 2 reaction 3). The occurrence of conjugation was indicated by the decrease of alkyne proton signal at δ 2.65 ppm and the appearance of peptide amine protons and triazole proton signal in the range δ 7−8 ppm in the ^{1}H NMR spectrum of the conjugate (Supporting Information Figure S1(C)). Not all the triple bonds were reacted since the alkyne proton signal, though decreased, could still be detected. The conversion from alkyne to triazole linkage was ∼50%.

Conjugate Characterization: Peptide Loading, Particle Size, and Charge. According to ^{1}H NMR, the amount of pendant carboxylmethyl in structure v (Scheme 2) and alkynyl groups in structure vi (Scheme 2) was around 0.122 mmol per gram of polymer. The precise peptide loading was measured by TNBSA assay. The loading was around 0.05 mmol peptide per gram of conjugate (Scheme 2 structure vii). The variation of loading was within 10% from batch to batch. The degree of modification, size, and charge of polymers and conjugate were summarized in Table 1.

Cytotoxicity against Cancer Cells. Dex-$(KW)_3$ was tested for its anticancer activity in vitro and compared with free peptide Ac-$(KW)_3$-$CONH_2$. The conjugate and free $(KW)_3$ were tested at equivalent peptide concentrations in human prostate cancer cells PC-3 and breast cancer cells MCF-7 (Figure 1A,B). Free $(KW)_3$ exhibited toxicity only at extremely high concentrations with LC_{50} higher than 500 μM. However, Dex-$(KW)_3$ was much more active toward both cell lines with LC_{50} less than 10 μM. This value is comparable to most conventional lytic peptides of more than 20 residues (*18*). The result showed that a polyvalent presentation significantly enhanced the potency of a short lytic peptide by 50- and 500-fold, respectively, in PC-3 and MCF-7. We also constructed a conjugate analogue Dex-$(KW)_4$ to study the effect of increasing the length of peptide on cytotoxicity (Figure 1B). Dex-$(KW)_4$ and free $(KW)_4$ were subjected to the same test. Dex-$(KW)_4$ was slightly more active at low concentrations than Dex-$(KW)_3$, but free $(KW)_4$ acquired moderate activity with an extra (KW) unit with LC_{50} between 30 and 100 μM. In systemic administration, peptides prematurely detached from the conjugate can interact with nontargeted cells before they are directed to tumor tissues. To avoid undesirable side effects, an ideal lytic sequence should be inactive in free form and exhibit high potency when conjugated. $(KW)_3$ was preferred, because it showed a larger contrast in activity between its free form and conjugated form.

Ability to Overcome Multidrug Resistance. After confirming the anticancer activity, we further investigated the potential of Dex-$(KW)_3$ in killing cancer cells that have acquired drug resistance. MES-SA is a human uterine sarcoma cell line that is sensitive to chemotherapeutic agents. MES-SA/Dx5 is a subline of MES-SA with multidrug resistance, established by growing parental MES-SA cells in the presence of doxorubicin of gradually increased concentration over a prolonged period. MES-SA/Dx5 exhibits a marked cross-resistance to a number of chemotherapeutics. We confirmed the drug resistance of MES-SA/Dx 5 in our lab and found that the IC_{50} of doxorubicin was 10-fold higher in MES-SA/Dx5 than in MES-SA (data not shown). Dex-$(KW)_3$ and free peptide were applied to both cell lines, and their activities were measured by MTT assay (Figure 2). The result indicated that the cytotoxicity profiles were very similar in the cells with and without resistance. It suggested that the anticancer activity of the new conjugate was not affected by multidrug resistance, consistent with previous reports about lytic peptides. Again, the potency of conjugates was significantly increased compared with free peptides.

To exclude the possibility that the toxicity resulted from the polymer backbone or the unmasked alkynyl groups, cell lines were exposed to alkynyl dextran at equivalent polymer concentration to that of the conjugate. The result confirmed that the polymer was nontoxic to all the cancer cells used in this study at tested concentrations and therefore not the reason for the observed cytotoxicity (Supporting Information Figure S2).

Effect of Dex-$(KW)_3$ on Noncancer Cells. Hemolysis is one of the potential risks when lytic peptide-based therapeutics are administrated systemically. To investigate the effect of the new conjugate on red blood cells, Dex-$(KW)_3$ was incubated with a red blood cell suspension under agitation to mimic the situation in the circulation system. Free $(KW)_3$ and alkynyl dextran were subjected to the same test. Over the concentration range tested (5−300 μM), the percentages of hemolysis in all the samples were less than 3% (Table 2). The cytotoxicity test was also conducted on a fibroblast cell line NIH/3T3 to examine the effect of conjugate on normal cells. The activity profile was similar to the one against cancer cells, though the potency was slightly lower (Supporting Information Figure S3).

Isothermal Titration Calorimetry. Small unilamellar vesicle (SUV) was used as a model of the cell membrane to investigate the interaction between conjugates and cell membranes. Neutral DOPC vesicles and negatively charged DOPC/DOPG (75:25) vesicles were prepared. Their size and zeta potential were measured prior to titration. The measurement showed that vesicles were approximately 30 nm in diameter. The zeta potentials of DOPC and DOPC/DOPG vesicles were 3.28 ± 1.23 mV and -19.48 ± 1.61 mV, respectively.

Because the disruption of lipid vesicles will generate extra heat flow, which is difficult to dissect from the heat of binding, the concentrations of lipids, conjugates, and peptides were carefully chosen prior to the titration experiments to ensure that the vesicles would remain intact even at the highest peptide/lipid molar ratio during the first injection (Supporting Informations Table S1). In this way, the measurement reflected only the binding interaction of the conjugates or free peptides with the membrane.

Lipid vesicle suspensions were titrated into the conjugate or free peptide solution. The heat flow in each injection was recorded. As the titration proceeded, the amount of peptide available for binding decreased. Therefore, the measured heat of binding decreased with consecutive lipid injections (Supporting Information Figure S4). The titration continued until the enthalpy change approached zero.

Binding isotherms was constructed by plotting the binding degree (X_b: molar ratio of bound peptide to lipid) as a function of the equilibrium concentration of unbound peptide in the solution (C_f) (Figure 3A). In the titration of negatively charged DOPC/DOPG (75:25) SUVs, the isotherm of free $(KW)_3$ is a smooth curve with decreasing slope. Consistent with previous

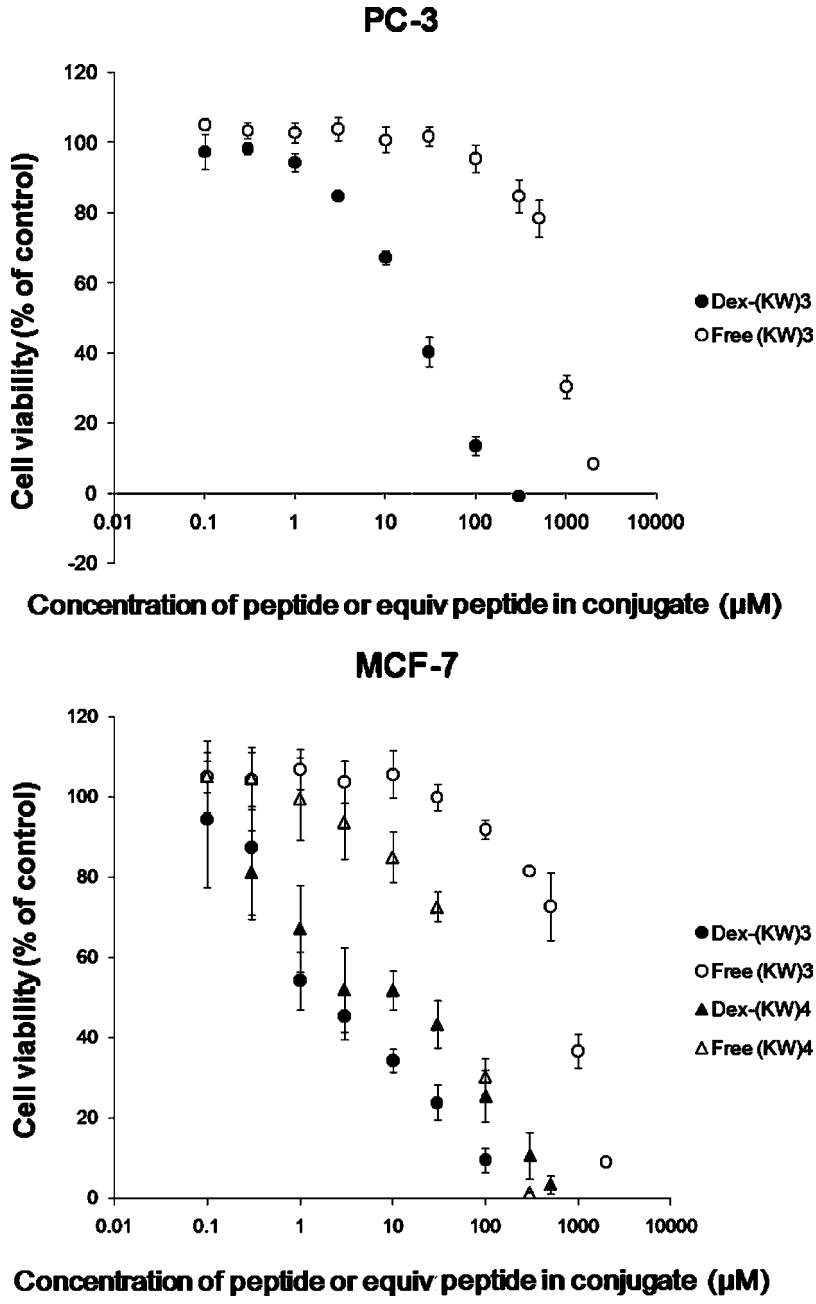


Figure 1. In vitro cytotoxicity against cancer cells. Dex-$(KW)_3$ was applied to (A) human prostate cancer cells PC-3 and (B) breast cancer cells MCF-7 at indicated equivalent peptide concentrations and incubated for 3 h. The cytotoxicity was determined by MTT assay. Free $(KW)_3$ was subjected to the same procedure for comparison. Dex-$(KW)_4$ and free $(KW)_4$ were tested on MCF-7 to investigate the effect of peptide length on anticancer activity. Cell viability was normalized by control and shown as the percentage of viability. The result is an average of at least three independent tests.

reports (*19*), the apparent binding constant (K_{app}) of free $(KW)_3$ decreased with increasing peptide concentration. This is because binding was predominantly driven by the electrostatic interaction between cationic peptides and the negative membrane surface. As the peptide concentration increased and the binding proceeded, the negatively charged surface of lipid vesicle was gradually screened by bound peptides. The weakened attraction is translated into a lowered binding constant. In contrast to free $(KW)_3$, the conjugate gave a relatively steady binding constant over the course of titration. Therefore, the conjugate eventually surpassed the free peptide in binding affinity at high concentrations. The isotherm of the conjugate was roughly treated as a straight line, and an apparent binding constant of 9728 M^{-1} was obtained from linear regression. This approach for estimating binding constant is not applicable to the whole isotherm of free peptides, but apparent binding constants in the ranges of initial binding (20 574 M^{-1}) and saturated binding (2254 M^{-1}) were calculated. It was found that the apparent binding constant of free $(KW)_3$ decreased by almost 1 order of magnitude from the beginning to the end of titration.

To further investigate the binding thermodynamics in the absence of electrostatic attraction, neutral DOPC SUVs were employed. Dex-$(KW)_3$ yielded an isotherm similar to the one with DOPC/DOPG SUVs and gave a binding constant of 8822.8 M^{-1} (Figure 3B). However, for the free $(KW)_3$, the isotherm was remarkably different upon removal of electrostatic interaction. The isotherm is almost linear, and the binding constant was estimated to be 1884.7 M^{-1}, significantly lower than the conjugate. It should be noted that the end of titration was defined as the point where all the peptides or conjugates were consumed for binding and the release of heat approached zero. In the previous three titration experiments, 10 μM was used as the

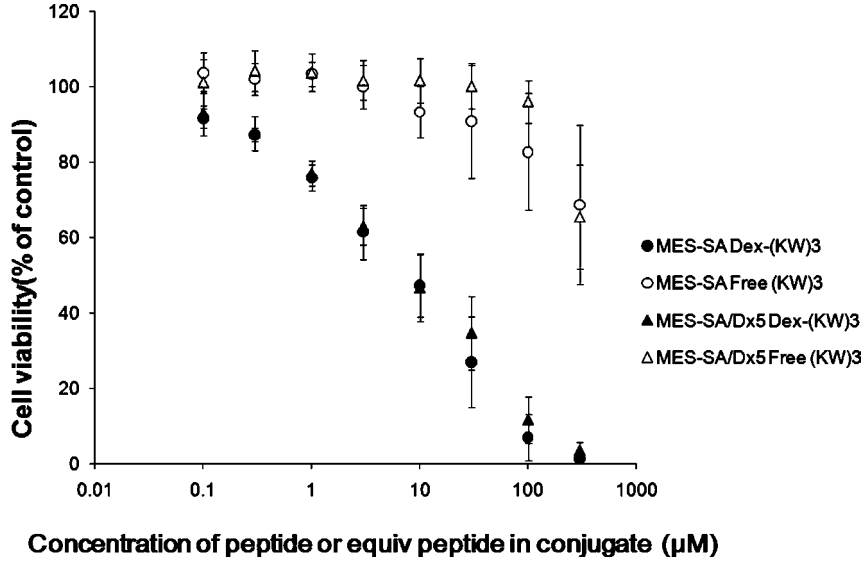

Figure 2. Ability to overcome multidrug resistance. Dex-$(KW)_3$ was applied to human uterine sarcoma cell line MES-SA and its resistant subline MES-SA/Dx5 at indicated equivalent peptide concentrations and allowed for 3 h incubation. Cytotoxicity was measured by MTT assay. Free $(KW)_3$ was subjected to the same procedure for comparison. Cell viability was normalized by control and shown as the percentage of viability. The result is an average of at least three independent tests.

Table 2. Values of % Hemolysis at the Highest Tested Concentration of Conjugate, Free Peptide, and Corresponding Precursor Polymer

	Dex-$(KW)_3$	free $(KW)_3$	alkynyl dextran
% hemolysis	1.9 ± 0.2%	1.2 ± 0.9%	2.0 ± 0.9%

Fresh rabbit red blood cell suspension (4% v/v in PBS) was incubated with Dex-$(KW)_3$, free $(KW)_3$, and alkynyl dextran for 2 h in agitation prior to the measurement of released hemoglobin. Data in Table 2 show the percent hemolysis at 300 μM peptide concentration (equiv peptide concentration for Dex-$(KW)_3$ and equiv polymer concentration for alkynyl dextran). Results are the average of three independent assays.

initial peptide concentration in the reaction cell. Because free $(KW)_3$ showed low affinity and slow binding rate with neutral membranes, we used 2 μM as the initial concentration of free $(KW)_3$ in DOPC SUVs titration to ensure that the titration can be completed in a reasonable number of injections. This is the reason the isotherm of free $(KW)_3$-DOPC binding covers a smaller concentration range in Figure 3B.

From the ITC experiments, thermodynamic parameters related to the membrane binding can be calculated (Table 3). By comparison of the change of free energy (ΔG), there is a trend among different combinations of titrant and titrand: peptide (low conc.)/DOPC/G < conjugate/DOPC/G ≈ conjugate/DOPC < peptide (high conc.)/DOPC/G ≈ peptide/DOPC. Though in all the titrations the binding is favored by both enthalpy and entropy, there is a substantial difference in the relative contributions of these two components to ΔG. Generally speaking, the conjugate has a more negative entropy component ($-T\Delta S$) and free peptide has a more negative enthalpy term (ΔH) regardless of the type of SUVs (Figure 4).

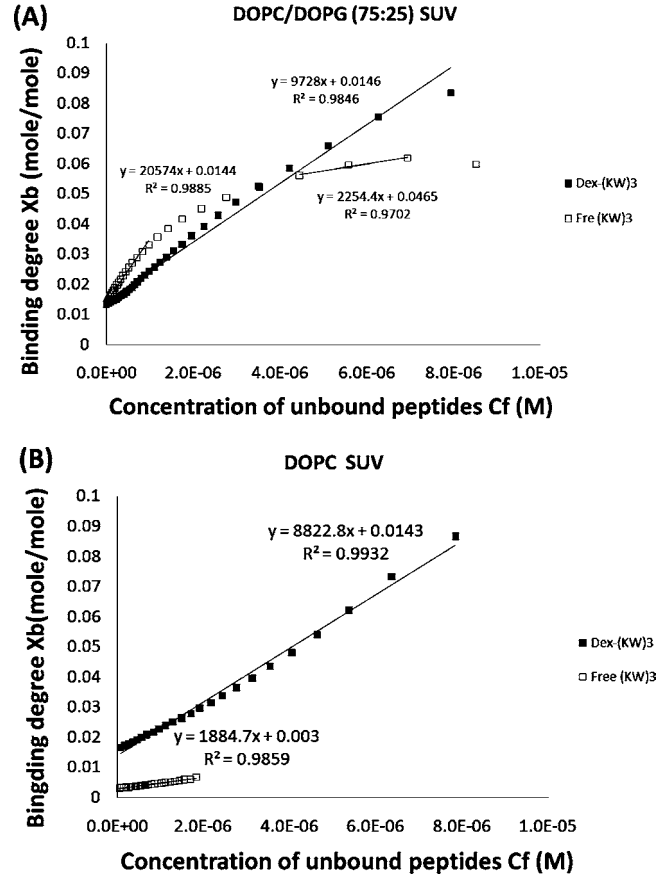

Figure 3. Binding isotherms of lipid−conjugate interaction and lipid−peptide interaction Conjugate Dex-$(KW)_3$ and free peptide $(KW)_3$ were titrated into the suspension of negatively charged lipid vesicles (A) and neutral lipid vesicles (B). The binding isotherm was obtained by plotting the degree of binding X_b against the concentration of unbound peptide C_f as described in Supporting Information. The straight lines are linear regression of the binding isotherms. The slope gave an estimation of the apparent binding constants (K_{app}).

DISCUSSION

A procedure was developed to synthesize a new lytic peptide−polymer conjugate. The lytic sequence $(KW)_3$ was chosen based on previous structure−activity relationship studies about the critical structural requisite of an active lytic peptide (*20*−*22*). Despite the high variability in the peptide sequence, there are two determinants of membrane activity: (1) the presence of cationic charge and hydrophobic residues in a balanced ratio and (2) the capability to rearrange the residues in an amphipathic way by segregating basic and hydrophobic residues on the opposite sides of peptide surface. Lysine was used to provide the positive charge necessary for membrane absorption, and tryptophan with a bulky, lipophilic indole ring

Table 3. Thermodynamic Parameters for Conjugate−SUV and Peptide−SUV Binding

condition	sample	SUV	ΔH (kcal/mol)	ΔG (kcal/mol)	ΔS (cal/(mol*K))	$-T\Delta S$ (kcal/mol)	K(1/M)
1	Dex-$(KW)_3$	DOPC	−1.33	−7.76	21.57	−6.43	8822.8
2	Dex-$(KW)_3$	DOPC/DOPG (75:25)	−3.57	−7.81	14.23	−4.24	9728.0
3	free $(KW)_3$	DOPC	−4.20	−6.84	8.86	−2.64	1884.7
4	free $(KW)_3$ (high conc.)	DOPC/DOPG (75:25)	−6.00	−6.95	3.19	−0.95	2254.4
5	free $(KW)_3$ (low conc.)	DOPC/DOPG (75:25)	−6.00	−8.26	7.58	−2.26	20574.0

ΔH values were calculated from the sum of corrected heats of reaction. Typically, 6 μL of SUV suspension (c_l = 10 mM) was injected into a peptide or conjugate solution (c_p or equiv c_p = 10 μM, except in condition 3, c_p = 2 μM) at 25 °C. Apparent binding constants (K_{app}) were estimated from the corresponding binding isotherm. The changes of free energies (ΔG) and entropies (ΔS) were calculated using the equations $\Delta G = -RT \ln 55.5K$ and $\Delta G = \Delta H - T\Delta S$. The factor 55.5 is the molar concentration of water. $K^* = 55.5K_{app}$ is the binding constant if the concentration of peptide is referenced to 1 mol H_2O (*19*).

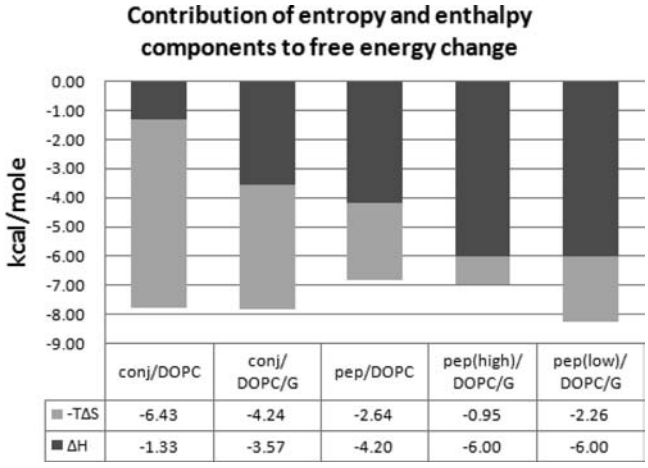

Figure 4. Relative contribution of entropy ($-T\Delta S$, dark column) and enthalpy (ΔH, light column) components to free energy change ($\Delta G = \Delta H - T\Delta S$, stacked column) is shown in a stacked column chart and the values are summarized in the table below. Abbreviations: conj, Dex-$(KW)_3$; pep, free $(KW)_3$; DOPC, small unilamellar vesicles composed of DOPC; DOPC/G, small unilamellar vesicles composed of DOPC and DOPG (75:25).

was employed for the insertion and perturbation to membrane lipid matrix. Since the amino acid residues can rotate along peptide backbone, we expected $(KW)_3$ to be capable of rearranging the side chains in a way to exhibit amphipathicity (Scheme 1). 1,3-Dipolar cycloaddition between alkyne and azide, known as one of the "click" reactions, was applied for conjugation (Scheme 2), though the reaction efficiency (~50%) was not as high as expected. The conjugate is about 8 nm in diameter, within the size range suitable for passive tumor targeting according to the effect of enhanced permeation and retention (EPR) (*12*).

The effect of polyvalency on anticancer activity of conjugates was investigated in different cancer cell lines. $(KW)_3$ is designed to be a potential membrane-lytic sequence. The in vitro test indicated that the hexapeptide was mild unless at extremely high concentrations (LC_{50} > 500 μM), which may be due to the short length. However, the potency of the conjugate was greatly enhanced by around 50-fold in PC-3 and even higher in MCF-7 with an increase up to 500-fold (Figure 1A,B). According to the compatibility test of the precursor polymer, the cytotoxicity was not caused by the polymer backbone. The enhancement of activity should be mainly attributed to the polyvalency of peptides on conjugation. The activity of free peptide was length-dependent. An analogue sequence $(KW)_4$ showed moderate activity with an extra (KW) unit. The potency of Dex-$(KW)_4$ was only slightly increased compared with that Dex-$(KW)_3$ (Figure 1B). $(KW)_3$ is a better choice because shorter length means a reduced risk of immunogenicity. Most importantly, $(KW)_3$ gave a better contrast between conjugate and free peptide, which helps to lower the risk of nonspecific toxicity caused by prematurely detached peptides in the systemic administration without compromising the conjugate activity.

One of the motivations for developing membrane-active anticancer peptides is to overcome the problem of multidrug resistance in chemotherapy. We examined the activity of Dex$(KW)_3$ in drug-resistant cancer cells MES/SA-Dx5 and the drug-sensitive counterpart MES/SA, then compare the results (Figure 2). The anticancer activity of the conjugate was not impaired by the drug resistance phenotype. This result is consistent with previous reports on antimicrobial peptides and anticancer peptides. The target of most lytic peptides is cytoplasmic membrane, the outermost structure of a cell, and the lytic activity does not rely on any specific signal pathway. As a result, the efflux pump of resistant cells cannot diminish the peptide activity. Besides, membrane is a conservative cellular structure so that acquiring resistance by genetic mutation is much more difficult.

The enhancement in membrane activity of polyvalent antimicrobial peptides has been reported by several groups (*9*−*11*). In the current study, we also observed similar trends in anticancer effects. Hints all point to an idea that the polyvalent presentation of peptides should surmount the hurdle of assembly by prenucleating on a scaffold (polymer). However, this hypothesis has not been experimentally verified and this motivates us to perform a thermodynamic analysis to compare monomeric peptide and polyvalent conjugate in the capability of binding with lipid membranes. To focus on the binding step, the lipid vesicles were kept intact by keeping the peptide concentration below the threshold for lysis.

According to the Shai-Matsuzaki-Huang (SMH) model, the interaction of peptides and the membrane goes through two sequential stages before lysis actually happens (*5*). The initial association is mediated by the electrostatic interaction. At this "absorption" stage, peptides associate with the membrane either superficially or embedded just below the aqueous interface (*23*). The basic residues form a hydrogen bond and/or a salt bridge with the lipid head groups, which contribute to the negative ΔH. This is supported by the result of our thermodynamic study. When the vesicles are negatively charged, the increase of electrostatic interaction is always accompanied with a more negative ΔH for both conjugates and free peptides (Figure 4). A lack of hydrophobic interaction is involved at this stage, and the lipids remain well-packed. As the peptide concentration continues to increase, the binding enters the "integration" stage where the nonpolar side chains insert into the hydrophobic core of the membrane and perturb the lipid matrix. In this stage, the entropy takes the lead in driving the binding. There are two reasons for entropy contribution to dominate in this stage. First, the packing of the lipid layer is greatly impaired; and second, large amounts of water originally organized around the hydrophobic side chains are released upon the burial of side chains in the core of the membrane ("solvation" effect (*8*)). The "absorption" and "integration" represent different depth in binding.

In our system, the binding of peptide and conjugate with the membrane also went through these two stages. The contribution of entropy and enthalpy to free energy was summarized in Figure 4. Regardless of the type of vesicle, it was found that the binding of conjugates is mainly entropy-driven, while the binding of free peptides is mainly enthalpy-driven. We hypothesize that conjugates were primarily in the "integration" stage with deeper penetration into the phospholipid bilayer. Under the same conditions, most free peptides tended to be in the "absorption" stage where peptides were in a shallow location and less disturbance to the membrane was caused. Since peptide concentration is the force that drives binding and lysing to proceed, the high local concentration of peptide mounted on a polymer scaffold leads to a deeper penetration of conjugate and enhances the lysing activity. The prenucleation or preassembly of the conjugated peptides is another reason for the more positive ΔS of Dex-$(KW)_3$. Upon binding to the membrane, peptides become more restricted, and this loss of freedom contributes to a decrease of entropy, a situation that applies to both conjugated and free peptides. Because the peptides in the conjugate were in an initial status of higher order, the entropy penalty is accordingly smaller compared to that of free peptides.

From the isotherm of free peptide−DOPC/DOPG SUV binding (Figure 3A), the binding capability of free $(KW)_3$ was significantly weakened at high concentrations due to electrostatic repulsion, and binding became almost saturated even though the vesicles were still intact. In contrast, the binding behavior of the conjugate was barely affected by the electrostatic effect. It is probably because the initially bound peptides can bring the rest of the peptides on the same polymer backbone into the vicinity of cell membrane. The polyvalent design thus facilitates the subsequent binding and counteracts the effect of repulsion.

Interestingly, though the enhanced activity of Dex-$(KW)_3$ was shown in both cytotoxicity and thermodynamic studies, the hemolysis activity of the conjugate was almost negligible at the concentrations tested (5−300 μM) (Table 2). In other multivalent lytic peptides as antibiotics, the relatively low hemolytic activity compared to antibacterial activity was also observed (*10*, *11*). The erythrocyte membrane is known for a high content of cholesterol compared to other cell types (*24*). It has been reported that there is an inverse relationship between the rate of hemolysis and the cholesterol content in the membrane (*25*). The stability of the erythrocyte membrane is mainly responsible for the selectivity. Considering that the conjugate binding is entropy driven, we reason that it may suffer from a greater loss of activity when exposed to a less fluid membrane due to increased resistance against deep peptide penetration. This property of the conjugate is advantageous to systemic administration as the risk of hemolysis is minimized. In a fibroblast cell line NIH/3T3, which is a normal cell but shares more similarity with cancer cells in structure than erythrocyte, the activity of Dex-$(KW)_3$ is comparable to those observed in cancer cells (Supporting Information Figure S3). The lack of selectivity resulted from the subtle differences between transformed and nontransformed cells in the plasma membrane. Though it has been reported that acidic components such as phosphatidylserine and O-glycosulated mucin increased in and around the cancer cell membrane (*26*), which leads to increased membrane potential and thus preferential interaction of cancer cells with cationic lytic peptides, these differences were not significant enough to provide robust specificity. A tumor-targeting conjugate is currently being constructed in our lab to address the selectivity issue.

To conclude, a polyvalent lytic peptide−polymer conjugate Dex-$(KW)_3$ was designed, synthesized, and characterized. The new conjugate showed significantly enhanced activity against cancer cells compared to monomeric peptides, and the anticancer activity was not affected by the acquisition of multidrug resistance in cancer cells. The detrimental effect on erythrocytes was negligible. The encouraging in vitro data showed the potential of this new conjugate for systemic treatment against drug-resistant cancer. For the first time, the mechanism of polyvalency-mediated activity enhancement of lytic peptides was investigated by quantitative thermodynamic study. At the same bulk concentration, the polyvalent conjugate caused a stronger perturbation of membrane structure, which should be attributed to the increased local concentration of peptides in a polyvalent conjugate.

ACKNOWLEDGMENT

Peptides were synthesized using solid-phase synthesis by Dr. Sunny Cheung, the University of Hong Kong. Dr. Zhongyu Li in our group provided advice on the conjugation chemistry. Clara Eng, California Institute of Technology, contributed to the ITC investigation as part of her undergraduate summer research project. Hong Kong Research Grant Council (Earmarked Research Grant HKUST 6407/06M) provided financial support to this project.

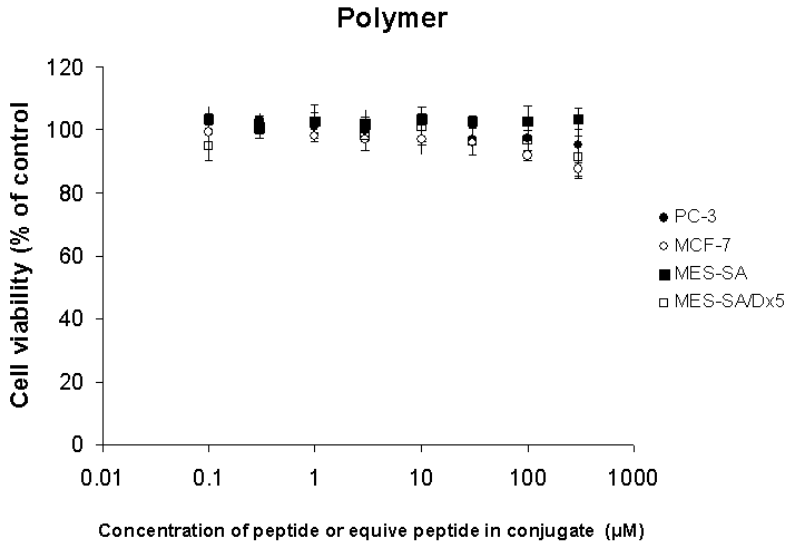

Figure S2. Effect of precursor polymer on cell viability

Alkynyldextran of equivalent polymer concentration to conjugate was applied to all the cancer cell lines that have been used in this study. The effect of precursor polymers on cell viability was measured by MTT assay after 3-hour incubation. Cell viability was normalized by control and shown as the percentage of viability. The result is the average of three independent tests.

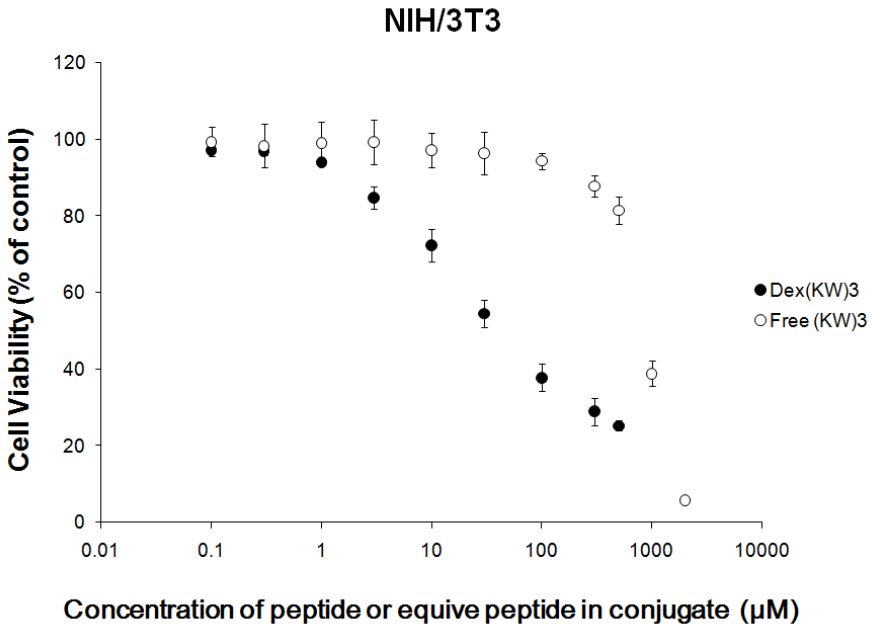

Figure S3. Effect of Dex-$(KW)_3$ on non-cancer fibroblast cell line NIH/3T3

Dex-$(KW)_3$ was applied to non-transformed fibroblast cell line NIH/3T3 at indicated equivalent peptide concentrations and allowed for 3-hour incubation. Cytotoxicity was measured by MTT assay. Free $(KW)_3$ was subjected to the same procedure for comparison. Cell viability was normalized by control and shown as the percentage of viability. The result is an average of at least three independent tests.

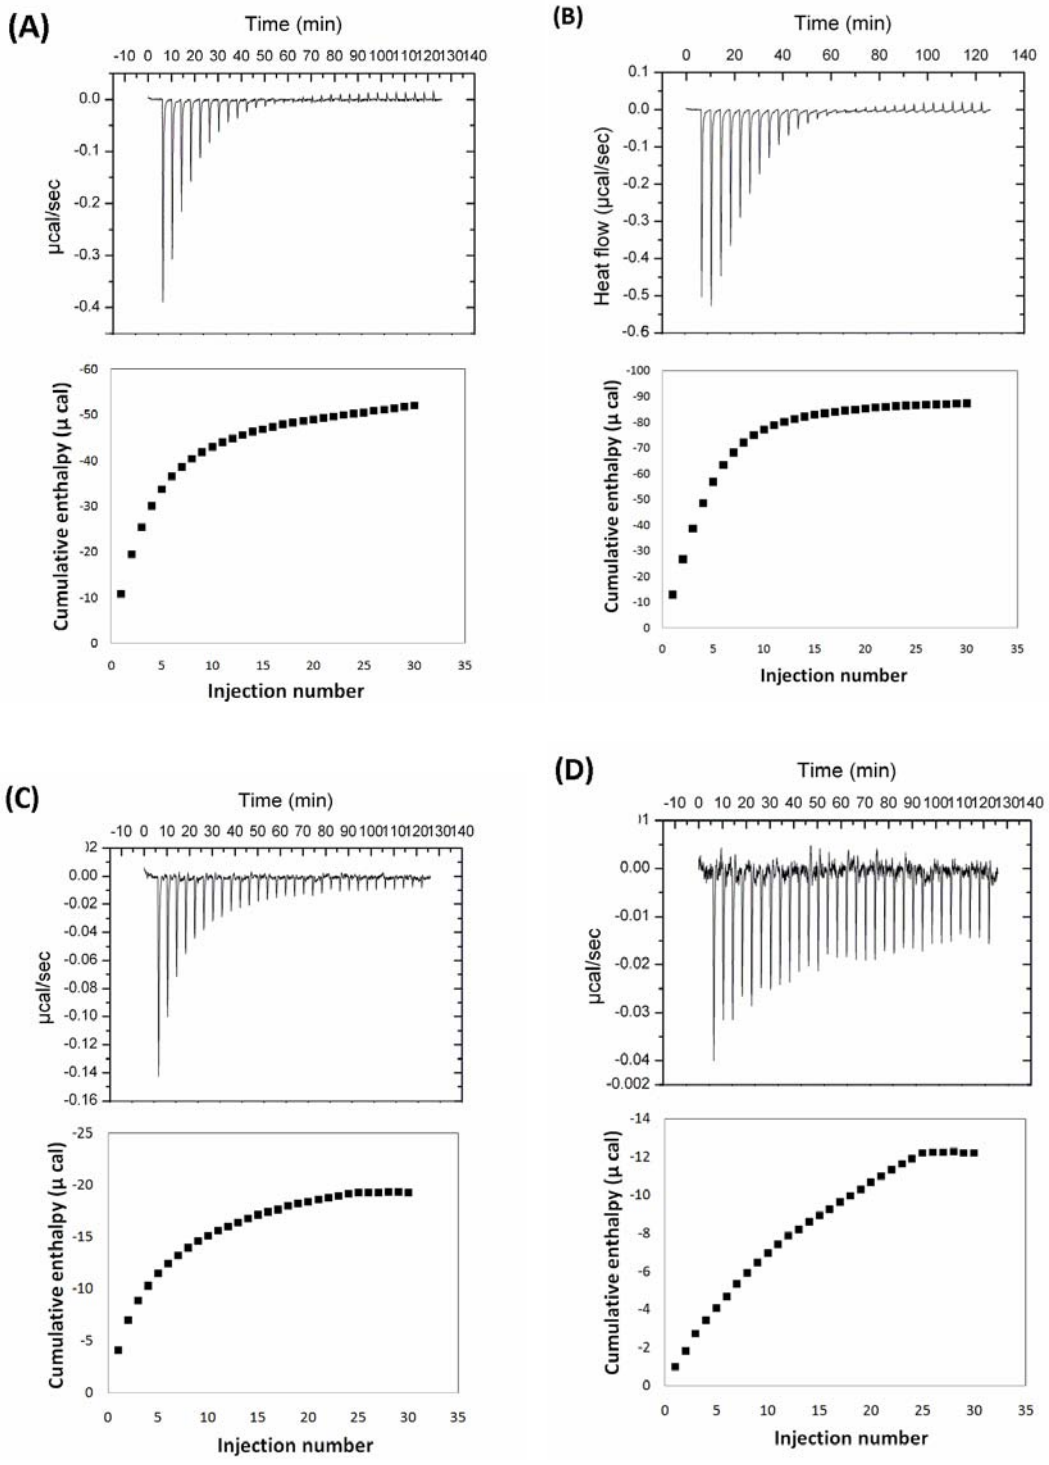

Figure S3. Isothermal titration calorimetry of Dex-$(KW)_3$ and free $(KW)_3$ with lipid vesicles.

The upper panel of each figure shows the calorimeter traces. Each peak represents an injection of 6 µL of small unilamellar vesicles suspension (lipid concentration = 10

mM) into the calorimeter cell containing conjugate or free peptide solution (equivalent peptide concentration = 10 μM, except (D) where peptide concentration = 2 μM). The lower panel shows the cumulative reaction enthalpy（$\sum_1^k \Delta h_k$）after each injection. (A) DOPC/DOPG(75:25) SUV/Dex-$(KW)_3$; (B) DOPC/DOPG(75:25) SUV/free $(KW)_3$; (C) DOPC SUV/ Dex-$(KW)_3$; (D) DOPC SUV/ free $(KW)_3$.

Table S1. Diameter of lipid vesicles at the highest peptide/lipid ratio in isothermal titration

	DOPC SUV	**DOPC/DOPG SUV (75:25)**
Buffer	32.2 ± 2.7 nm	26.2 ± 3.3 nm
Dex-$(KW)_3$	31.5 ± 0.4 nm	31.0 ± 1.2 nm
	31.2 ± 0.8 nm	31.0 ± 4.4 nm
	31.3 ± 0.6 nm	33.1 ± 2.3 nm
Free $(KW)_3$	33.0 ± 4.1 nm	31.0 ±11.9 nm
	30.1 ± 1.1 nm	28.7 ± 9.6 nm
	30.0 ± 1.4 nm	29.6 ± 7.3 nm

SUVs (41.2 μM lipid concentration) were mixed with conjugate and free peptide (10 μM equiv peptide concentration) respectively. The mixture resembles the condition in the reaction cell of isothermal titration calorimeter after the first injection of SUVs, when the ratio of lipid/peptide has the highest value. The diameter of SUVs in buffer indicates the original size of vesicles. Vesicles were subjected to particle sizing by dynamic light scattering (DLS). The effect of conjugate and peptide on vesicle integrity at the particular titration conditions were evaluated by comparing the size of lipid vesicles in the presence and absence of peptide or conjugate. MeasurementS were repeated three times for conjugate or peptide treated vesicles.

Isotherm construction

The experimentally measured heat of reaction at the kth injection is denoted as Δh_{k}, while $\sum_1^{\mathrm{k}} \Delta h_k$ is the cumulative heat of the first k injections and $\sum_1^{\mathrm{n}} \Delta h_{\mathrm{n}}$ is the total heat of all injections (provided $\Delta h_{\mathrm{n}} = 0$). After k injections, the fraction of peptide bound to the lipid membrane is given by

$$X_{\mathrm{p}}^{(k)} = n_{\mathrm{p}}^{(k)}/n_{\mathrm{p}} = \sum_1^k \Delta h_k \;/\; \sum_1^n \Delta h_k$$

Here $n_{\mathrm{p}}^{(k)}$ is the molar amount of bound peptide after k injections and $\mathrm{n_p}$ is the total amount of peptide in the calorimeter cell. $X_{\mathrm{p}}^{(k)}$ approaches its maximal value 1 at the end of titration since all the peptides have bound to the membrane. The

concentration of peptide free for binding $c_f^{(k)}$ after each injection can be calculated according to

$$c_f^{(k)} = c_p^o \left(1 - X_p^{(k)}\right)$$

where c_p^o is the initial peptide concentration in calorimeter cell. The lipid concentration after kth injection $n_L^{(k)}$ can be calculated by

$$n_L^{(k)} = k \cdot V_{inj} \cdot c_L^o$$

where V_{inj} is the injection volume per titration step and c_L^o is the concentration of stock lipid solution in the needle. Usually peptides cannot interact with the lipids inside, only the lipid molecules in the outer leaflet are available for peptide binding. It was reported that for the SUVs produced by sonication with the diameter about 30 nm, the molar fraction of lipid molecules in the outer leaflet is about 60% (*1*). The degree of binding after *k*th injection $X_b^{(k)}$ is defined as the molar ratio of bound peptide and total available lipid as below

$$X_b^{(k)} = n_p^{(k)} / \left(n_L^{(k)} \cdot 0.6\right)$$

where 0.6 is the correction factor that takes into account the accessible lipid on the outside layer. The isotherm is obtained by plotting the degree of binding $X_b^{(k)}$ as a function of the concentration of peptide free for binding $c_f^{(k)}$. The apparent binding constant, K_{app}, is given by the slope of the curve.

$$K_{app} = X_b / C_f$$

The change of free energy and entropy were calculated by

$$\Delta G = -RT(\ln 55.5K)$$

$$\Delta G = \Delta H - T\Delta S$$

where R is the gas constant, factor 55.5 is the molar concentration of water, $K^* = 55.5K_{app}$ is the binding constant if the concentration of peptide is referred to 1 mol H_2O.

Bishydrazides are versatile linkers for attaching glycans to substrates for lectin binding and pathogen detection schemes. The α,ω-bishydrazides of carboxymethylated hexa(ethylene glycol) (**4**) can be conjugated at one end to unprotected oligosaccharides, then attached onto carrier proteins, tethered onto activated carboxyl-terminated surfaces, or functionalized with a photoactive cross-linking agent for lithographic patterning. Glycoconjugates of bishydrazide **4** can also be converted into dithiocarbamates (DTCs) by treatment with CS_2 under mild conditions, for attachment onto gold substrates. The immobilized glycans serve as recognition elements for cell-surface lectins and enable the detection and capture of bacterial pathogens such as *Pseudomonas aeruginosa* by their adsorption onto micropatterned substrates. A detection limit of 10^3 cfu/mL is demonstrated, using a recently introduced method based on optical pattern recognition.

INTRODUCTION

Pathogenic microorganisms are an omnipresent threat to global biosecurity, and effective biodetection strategies are necessary to control the spread of infectious diseases. One viable approach to pathogen detection is to develop diagnostic technologies based on "immutable" recognition of ligands presented on cell surfaces, a vital first step in the cycle of infection. These recognition elements are often low molecular weight molecules such as glycans, which are exploited by pathogens for gaining entry into their host cells. Pathogens must maintain this ligand affinity in order to remain virulent, as those which undergo mutations that disable recognition can no longer infect their target cells. Glycan-based strategies have proven to be particularly successful in detecting bacteria that use lectins for adhesion to host cell membranes (*1*−*8*). Furthermore, the immutability of this functional recognition provides an important advantage over antibody-based detection schemes, which are susceptible to nonfunctional mutations that are often irrelevant to pathogen virulence.

Glycoconjugates are also of considerable importance for high-throughput diagnostics or screening of carbohydrate-binding proteins associated with various biological functions or disease states (*9*−*12*). Several different covalent chemistries have been successfully implemented for surface functionalization, such as thiol−ene and thiol−maleimide additions (*13*−*16*), Diels−Alder or Cu-catalyzed Huisgen cycloadditions (*17*−*19*), nucleophilic addition to epoxides and isothiocyanates (*20, 21*), amide bond ligation (*22, 23*), and Staudinger ligation (*24*). However, many of these methods require that glycans be in a protected form prior to linker installation and may involve multiple synthetic or purification steps.

Chemoselective coupling of bifunctional linkers to underivatized glycans is an attractive option, particularly if the reducing-end sugar can be retained in its native cyclized form. Traditional methods involve covalent attachment to the free hemiacetal via reductive amination or glycation, but while the conditions are mild, they sacrifice the reducing-end sugar by generating an open-chain structure (*25, 26*). However, weakly basic nucleophiles like aminooxy ethers (H_2NO-R, MeHNO-R) and hydrazides (H_2NNHCO-R) have been shown to condense with hemiacetals in aqueous solutions for efficient glycoconjugation (*27*−*39*). Hydrazides have been widely used for bioconjugation onto aldehyde- or carboxyl-presenting surfaces (*25*); conversely, hydrazides can also be presented on substrates for the specific generation of carbohydrate microarrays.

Here, we investigate α,ω-bishydrazides as bifunctional linkers for conjugating underivatized glycans onto various substrates and present several surface functionalization methods with application toward the binding of lectins and pathogenic bacteria. Bishydrazides can be useful as chelating agents or as supramolecular recognition motifs (*40, 41*), but are most often applied as polymer or biopolymer cross-linking agents (*42*−*44*). At first glance, bishydrazides appear to be an unlikely choice for heterofunctionalization; however, we find that they can be selectively monofunctionalized and are versatile linkers for glycoconjugate chemistry.

In this work, we use glycan-bishydrazide conjugates to target specific lectins and adhesins found in *Pseudomonas aeruginosa*, an opportunistic, Gram-negative bacteria often found in hospital settings. Nosocomial *Pseudomonas* infections have become increasingly drug-resistant and can be especially pernicious in immunocompromised patients or those suffering from cystic fibrosis, so there is a strong need to develop detection platforms against this pathogen. Epidemiological studies suggest that the risk of *Pseudomonas* infections in healthy individuals increases with environmental pathogen counts above 10^3 cfu/mL (*45, 46*).We aim to address this important public health concern by focusing on glycan recognition as a mechanism for detecting virulent pathogens such as *Pseudomonas* at densities as low as 10^3 cfu/mL, the estimated threshold for nosocomial infection.

EXPERIMENTAL PROCEDURES

General Procedures. All starting materials and reagents were obtained from commercial sources and used as received unless otherwise noted. Fuc(α1→2)Gal(β1→4)Glc (2′-fucosyllactose

3) was purchased from V-laboratories, Inc., and GalNAc(β1→4)-Gal(β1→4)Glc (pulmonary trisaccharide **2**) was prepared by multistep synthesis (see below). Bovine serum albumin (BSA), galactose-binding lectin from *Arachis hypogaea* (peanut lectin), antilectin rabbit IgG, and FITC-labeled antirabbit goat IgG were purchased from Sigma and used as received. *Pseudomonas aeruginosa* (PA01 strain) was obtained from ATCC and grown overnight on agar plates (15 g/L of Bacto Agar, 8 g/mL of Difco Nutrient Broth) at 37 °C. CS_2, CH_2Cl_2, and CH_3CN were freshly distilled from CaH_2 before use; anhydrous and anaerobic MeOH and THF were passed through activated alumina and dipensed from a solvent purification system (MBraun). Reactions were carried out in oven-dried glassware under an inert atmosphere, and solvents were freshly distilled from CaH_2 prior to use. ^1H and ^{13}C NMR spectra were recorded on a Bruker DRX 400 spectrometer operating at 400 and 100 MHz respectively. Chemical shifts (δ) are reported in ppm and referenced to the solvent used ($CDCl_3$, δ 7.24 and 77.23; CD_3OD, δ 3.31 and 49.15; D_2O, δ 4.80), with coupling constants (*J*) reported in Hz. Deionized water with a resistivity of >18 MΩ·cm was obtained from an ultrafiltration system (Milli-Q, Millipore) and passed through a 0.22 μm filter to remove particulate matter. Silica gel chromatography was performed using ICN SiliTech 32−63 D; reverse-phase HPLC was performed using a Phenomenex Synergi C-18 column (250 × 21.2 mm, 4 μM, 80 Å) with UV detection at 214 nm, using an aqueous CH_3CN solvent gradient with a linear flow rate of 10 mL/min.

Neoglycoprotein Formation. In a typical experiment, a freshly prepared solution of BSA (10 mg) in phosphate buffered solution (PBS, pH 7.4, 200 μL) was treated with 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (EDC·HCl, 3 mg in 50 μL PBS) and gently stirred at rt for 1 h. The activated protein solution was then treated with pulmonary trisaccharide−hydrazide conjugate **7** (5.1 mg) in 200 μL PBS, then stirred for another 2 h, followed by membrane dialysis and passage through a 0.45 μm filter to remove aggregates and particulate matter. These BSA glycoconjugates could be stored safely at 4 °C for several months.

In Situ Dithiocarbamate (DTC) and Monolayer Formation (*47, 48*). In a typical experiment, a 10 mM solution of lactose−bishydrazide conjugate **6** in deaerated methanol (1.5 mg in 200 μL) was treated with 10 mM solutions of CS_2 (200 μL) and Et_3N (200 μL), then stirred at rt for 1 h in a capped vial prior to use (see below). In situ DTC formation was monitored by diluting aliquots of the reaction mixture in deionized water, then measuring increases in characteristic absorption peak intensities at 250 and 292 nm using a Cary-50 spectrophotometer (cell path length = 1 cm).

DTC-anchored monolayers (DAMs) were produced from a freshly prepared solution of **6**-DTC, diluted 10-fold with deionized water to a final concentration of 1 mM. A 30 μL aliquot of this stock solution was spread across a lightly oxidized PDMS stamp, then patterned onto Au substrates by microcontact printing (see below). Lactose-terminated DAMs were treated with a solution of peanut lectin (50 μg/mL) and visualized by fluorescence immunostaining. The robustness of the patterned DAMs was evaluated by measuring changes in relative emission intensities over time, with exposure to 2-mercaptoethanol (10 or 100 μM) in PBS. Mean luminosity values and standard deviations were taken from selected regions on the printed substrate using Photoshop v.7.0.1 (Adobe Systems).

UV Photolithography. Glass substrates coated with a 50 nm Au layer (1.2 × 1.2 cm^2, Reichert) were cleaned with a piranha solution (2 parts 18 M H_2SO_4, 1 part 30% H_2O_2) for 3 min, then thoroughly rinsed with deionized water and dried under a stream of argon. (Caution: Piranha solution is a strong oxidizing agent, and should be handled with extreme care.) Freshly cleaned substrates were coated with BSA by soaking in a 1 wt % solution in PBS for several hours at rt, followed by immersion in a solution of photoactive glycoconjugate (20 mM in 2:1 MeOH/CH_2Cl_2) for 5 min. The dried films were covered by a quartz photomask having linewidths of 10 or 15 μm and grating periods of 20 μm (Advanced Reproductions Corp.), then exposed to a short-wave ultraviolet lamp (Spectroline, ENF-240C) operating at 254 nm for 25 min, followed by a rinse with MeOH. Microcontact printing (see below) could also be used for patterning photoactive glycoconjugates onto BSA-coated glass slides.

Microcontact Printing (μCP). A freshly prepared poly(dimethylsiloxane) (PDMS) stamp (grating period a = 20 μm; line width = 15 μm) was lightly oxidized by a 15 s exposure in a plasma cleaner, then coated with 30 μL of an aqueous solution of **6**-DTC for 2 min (see above for preparation of stock solution). The PDMS stamp was dried in air after blotting excess solution, then pressed lightly onto a roughened Au substrate (see below) at an applied pressure of 6 kPa for 3 s, as measured by a mechanical stamper developed in our laboratories. A brass plate was placed at the top of the stamp for even distribution of pressure, and the stamp remained in conformal contact with the substrate for an additional 5 min.

Similar μCP conditions were used to pattern BSA glycoconjugates onto smooth Au substrates. A 30 μL aliquot of a 1 wt % BSA−lactose hydrazide conjugate (**6**-BSA) in PBS was cast onto a lightly oxidized PDMS stamp as described above and allowed to sit for 2 min prior to blotting. The PDMS stamp was dried in air, pressed lightly onto the substrate at an applied pressure of 6−12 kPa for 3 s, and then allowed to remain in conformal contact without added pressure for another 5 min. The micropatterned substrate was washed sequentially with PBS, PBS containing 0.05% Tween-20, and then deionized water. The patterned substrate was further incubated with a 5% BSA solution in PBS for 2 h, then washed as above prior to use.

Glycan-Directed Affinity Binding and Imaging. Micropatterned glycoconjugates were exposed to either soluble lectins or to live bacterial cultures and visualized by immunofluorescent staining (bound lectin) or darkfield microscopy (bound bacteria) using an upright microscope (Olympus BH2-RFL-T3) equipped with a darkfield condensor, a high-pressure Hg lamp and filter set for FITC emission, and a DP70 camera for image acquisition. Fluorescence imaging was performed either on glass or on roughened Au substrates; the latter were prepared by immersing clean Au substrates into a solution of $AgNO_3$ (3.7 mM) and hydroquinone (120 mM) in 1.3 M citric acid buffer (pH 3.5) for 1.5 min, followed by a quick rinse with deionized water and immersion in an aqueous $HAuCl_4$ solution (0.5 mM) for 30 min. Roughened Au substrates were dried in air, prior to use.

For affinity patterning with proteins, micropatterned substrates were incubated with a dilute solution of lectin from *Arachis hypogaea* (peanut lectin, 50 μg/mL in PBS) for 2 h at 4 °C. The chip was washed with PBS, then treated with a solution of antipeanut lectin rabbit IgG (1 μg/mL in PBS) for 2 h at 4 °C, then washed again and treated with a solution of FITC-labeled antirabbit goat IgG (1 μg/mL in PBS) for another 2 h at 4 °C. The chip was washed with PBS, deionized water, and then dried under a stream of air prior to fluorescence imaging.

For affinity patterning with bacteria, *Pseudomonas aeruginosa* (PA01 strain, ATCC) was cultured in NB broth containing choline (0.2% w/v), the latter being necessary for the ectopic expression of fucose-binding lectin PA-IIL (*49*). Micropatterned substrates were incubated with suspensions of live *Pseudomonas* for 1 h at room temperature, at concentrations ranging from 10^8 to 10^2 cfu/mL. After incubation, the chip was washed with PBS and deionized water prior to darkfield imaging. The density

of live *Pseudomonas* was estimated by correlating turbidity measurements (ca. 10^9 cfu/mL at O.D. 1) with colony counts obtained by plating serial dilutions. Fluorescent staining of active cultures (SYTO 9/propidium iodide (PI) stains, Invitrogen) confirmed that >90% of the bacteria were alive prior to their exposure to glycan-patterned substrates.

Darkfield images were subjected to fast Fourier transform (FFT) for pattern demodulation to reveal characteristic peaks in reciprocal lattice space ($k = 1/a$) indicating pathogen capture, according to a recently established protocol (*50*). Standard sizes and magnification were established for each micropatterned image, so that the units defining periodicity (in μm) were correctly translated into reciprocal lattice units (in μm^{-1}) in the spectra derived from the FFT images. Signal-to-noise (*S*/*N*) levels were determined as the ratio of the peak value at 0.05 μm^{-1} (after background subtraction) to the standard deviation of background intensity; signal qualities were considered acceptable above $S/N = 3$.

Glycoconjugate-Lectin Binding Immunoassays. Each incubation was performed for 2 h at rt, followed by rinsing three times with PBS to remove excess proteins prior to the next step. 96-well microtiter plates were coated with **6**-BSA conjugate (10 mg/mL), blocked with a 1% BSA solution to minimize nonspecific protein adsorption, and then incubated with increasing concentrations of peanut lectin in the presence or absence of 100-fold excess lactose. Wells were then treated with antilectin rabbit IgG (1 μg/mL), followed by antirabbit horseradish peroxidase (HRP) IgG (1 μg/mL). The optical absorbances of the wells were analyzed using a microplate reader (VERSA$_{max}$, Molecular Devices) following addition of the HRP substrate (100 μL). Untreated and antilectin rabbit IgG treated wells (without primary antibody) in PBS served as negative controls.

For flow cytometry, carboxylic acid functionalized microspheres were conjugated to lactose−bishydrazide **6** via standard EDC coupling for 16 h at rt, followed by multiple washes with PBS. The lactose-conjugated microspheres were dispersed in PBS (1.2 mL) and split into several Eppendorf tubes, which were incubated with increasing concentrations of peanut lectin in the presence or absence of 100-fold excess lactose. After incubating for 2 h at rt, tubes were rinsed and subjected to sequential incubation with antilectin rabbit IgG and antirabbit FITC IgG as described above. The microspheres were then analyzed for fluorescent immunolabeling using a flow cytometer (Cytomics F500, Beckman Coulter, 10^4 microspheres/sample). Untreated and antilectin rabbit IgG (without primary antibody) treated microspheres in PBS served as negative controls.

*Hexa(ethylene glycol)-Linked Bishydrazide (**4**).* A solution of hexa(ethylene glycol) (5.0 g, 17.70 mmol) in dry THF (50 mL) at room temperature was treated portionwise with potassium *tert*-butoxide (9.92 g, 88.54 mmol) at rt, then stirred for 30 min. The reaction mixture was treated dropwise with ethyl bromoacetate (20 mL, 170 mmol), then stirred at reflux for 20 h. The reaction mixture was cooled to rt, filtered and concentrated, and then purified by silica gel chromatography (EtOAc/hexanes 1:1) to yield pure diethyl ester as a colorless oil (5.5 g, 68%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 4.62 (s, 4H), 4.17 (q, 4H, J = 7.2 Hz), 3.71−3.69 (m, 4H), 3.66−3.63 (m, 8H), 3.61−3.59 (m, 12H), 1.23 (t, 6H, J = 7.2 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ 170.01, 167.44, 71.01, 70.85, 70.63, 68.88, 68.36, 61.60, 60.79, 14.16. MS (ESI) calcd for $C_{20}H_{38}O_{11}[M]^+$ *m*/*z* 454.24; found: *m*/*z* 454.98.

The hexa(ethylene glycol)-linked diester (1.0 g, 2.2 mmol) was dissolved in MeOH (20 mL) passed through an activated alumina column (MBraun) and treated with anhydrous hydrazine (0.34 mL, 11.0 mmol). The reaction mixture was stirred at rt for 24 h, then concentrated followed by the azeotropic removal of hydrazine using toluene (3 × 10 mL), and finally dried in vacuo to afford a light yellow oil (0.92 g, 98%). The resulting bishydrazide could be used to prepare glycoconjugates without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.61 (br s, 2H), 4.06 (s, 4H), 3.74−3.58 (m, 28H). ^{13}C NMR (100 MHz, CD_3OD) δ 173.72, 171.15, 73.66, 72.10, 71.51, 71.44, 71.75, 62.12. MS (ESI) calcd for $C_{16}H_{34}N_4O_9Na$ $[M+Na]^+$ *m*/*z* 449.44; found: *m*/*z* 449.02.

*Heptanediol-Linked Bishydrazide (**5**).* Heptane-1,7-diol (1.1 g, 7.56 mmol) was treated with ethyl bromoacetate (4.35 mL, 37.82 mmol) as described above, followed by workup and silica gel purification (EtOAc/hexanes 1:2) to yield the pure diester as a colorless oil (0.92 g, 36%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 4.15 (t, 4H, J = 6.7 Hz), 3.81 (s, 4H), 3.61 (t, 4H, J = 6.1 Hz), 1.63 (quint, 4H, J = 6.4 Hz), 1.53 (quint, 4H, J = 6.7 Hz), 1.34 (3, 6H), 1.26 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 167.52, 66.54, 63.04, 32.77, 29.10, 28.48, 26.13, 25.87, 25.76.

Anhydrous hydrazine (0.185 mL, 5.91 mmol) was treated with heptanediol-linked diester (0.36 g, 1.18 mmol) in methanol (10 mL), according to the reaction conditions described above. After azeotropic removal of the volatiles using toluene, bishydrazide **5** was obtained as an oil (0.32 g, 92%) and could be used to prepare glycoconjugates without further purification. ^{1}H NMR (400 MHz, CD_3OD) δ 3.40 (t, 4H, J = 6.4 Hz), 1.40 (quint, 4H, J = 6.6 Hz), 1.25−1.21 (m, 10H). ^{13}C NMR (100 MHz, CD_3OD) δ 173.73, 172.39, 62.94, 33.57, 30.38, 26.90. MS (ESI) calcd for $C_{11}H_{24}N_4O_4$ $[M]^+$ *m*/*z* 276.17; found 276.76.

*Hexa(ethylene glycol)-Linked Lactose-Bishydrazide Conjugate (**6**).* A mixture of lactose (10 mg, 0.029 mmol) and bishydrazide linker **4** (124.6 mg, 0.29 mmol) in NaOAc buffer (1 mL, pH 4.2) was stirred at 70 °C for 2 days. The reaction mixture was evaporated under reduced pressure, then purified by reverse-phase HPLC (1−30% aq CH_3CN gradient over 60 min) to afford **6** as colorless oil (18.9 mg, 86%). ^{1}H NMR (400 MHz, CD_3OD) δ 4.62 (s, 1H), 4.34 (d, 1H, J = 7.5 Hz), 4.14 (d, 1H, J = 8.6 Hz), 4.09−4.03 (m, 3H), 3.98 (dd, 1H, J = 4.0, 12.0 Hz), 3.92 (dd, 1H, J = 4.0, 8.0 Hz), 3.84−3.79 (m, 2H), 3.78−3.74 (m, 2H), 3.70−3.65 (m, 22H), 3.59−3.52 (m, 6H), 3.49−3.46 (m, 2H). ^{13}C NMR (100 MHz, CD_3OD) δ 172.32, 171.81, 105.10, 91.89, 80.45, 77.76, 77.11, 76.63, 74.81, 73.66, 73.53, 72.51, 72.14, 72.07, 71.54, 71.31, 70.75, 70.29, 62.48, 62.21, 62.12. MS (ESI) calcd for $C_{28}H_{54}N_4O_{19}Na$ $[M+Na]^+$ *m*/*z* 773.32; found: *m*/*z* 773.37.

*Hexa(ethylene glycol)-Linked Pulmonary Trisaccharide-Bishydrazide Conjugate (**7**).* This compound was prepared according to the procedure above, starting from pulmonary trisaccharide **2** (32 mg, 0.058 mmol) and bishydrazide linker **4** (60.0 mg, 0.14 mmol). Purification by RP-HPLC (1−30% aq CH_3CN gradient over 60 min) yielded glycoconjugate **7** as a light-yellow oil (32 mg, 58%). ^{1}H NMR (400 MHz, CD_3OD) δ 4.61 (d, 1H, J = 8.3 Hz), 4.32 (d, 1H, J = 7.6 Hz), 4.14 (d, 1H, J = 5.5 Hz), 4.08−3.97 (m, 10H), 3.89−3.47 (m, 36H), 2.05 (s, 3H). ^{13}C NMR (100 MHz, CD_3OD) δ 180.31, 175.05, 105.05, 104.44, 93.98, 78.18, 76.80, 76.23, 75.98, 74.69, 74.14, 73.57, 73.07, 72.60, 71.44, 69.53, 62.61, 61.72, 55.05, 24.15, 23.18. MS (ESI) calcd for $C_{36}H_{67}N_5O_{24}Na$ $[M+Na]^+$ *m*/*z* 976.40; found: *m*/*z* 976.18.

*Hexa(ethylene glycol)-Linked 2′-Fucosyllactose-Bishydrazide Conjugate (**8**).* This compound was prepared according to the procedure above, starting from commercially available 2′-fucosyllactose (2.5 mg, 5.1 μmol) and bishydrazide linker **4** (21.8 mg, 51 μmol). Purification by RP-HPLC (1−40% aq CH_3CN gradient over 60 min) yielded glycoconjugate **8** as a colorless oil (2.9 mg, 51%). ^{1}H NMR (300 MHz, D_2O) δ 5.17 (d, 1H, J = 3.1 Hz), 4.38 (d, 1H, J = 7.7 Hz), 4.10 (m, 1H), 4.02−3.98 (m, 4H), 3.82 (m, 1H), 3.75−3.71 (m, 2H), 3.67−3.43 (m, 41H), 3.29 (m, 1H), 3.23 (m, 1H), 1.09 (d, 1.7H,

J = 6.6 Hz), 1.03 (d, 1.3H, J = 6.6 Hz). MS (ESI) calcd for $C_{34}H_{64}N_4O_{23}Na$ $[M+Na]^+$ *m/z* 919.38; found: *m/z* 919.70.

*Heptanediol-Linked Lactose-Bishydrazide Conjugate (**9**).* This compound was similarly prepared as that described above, starting from lactose (50 mg, 0.146 mmol) and 1,7-heptanediol bishydrazide **5** (201 mg, 0.736 mmol). Purification by RP-HPLC (1−50% aq CH_3CN gradient over 45 min) yielded glycoconjugate **9** as a light-yellow oil (54 mg, 62%). ^1H NMR (400 MHz, CD_3OD) δ 4.30 (d, 1H, J = 7.6 Hz), (d, 1H, J = 8.2 Hz), (d, 1H, J = 4.4 Hz), 3.97 (s, 2H), 3.83−3.77 (m, 2H), 3.67−3.59 (m, 4H), 3.54−3.45 (m, 4H), 3.41−3.35 (m, 2H), 3.22−3.19 (m, 1H), 1.92−1.69 (m, 14H). ^{13}C NMR (100 MHz, CD_3OD) δ 181.97, 173.86, 103.51, 89.97, 78.93, 76.39, 75.95, 75.52, 73.09, 71.55, 70.84, 69.18, 61.66, 61.01, 60.84, 23.98, 20.65, 20.44, 20.37. MS (ESI) calcd for $C_{23}H_{45}N_4O_{14}$ $[M+H]^+$ *m/z* 601.28; found: *m/z* 601.09.

*2-Deoxy-3,4,6-tri-O-acetyl-2-trichloroacetamido-β-D-galactopyranosyl-(1→4)-2,4,6-tri-O-benzyl-β-D-galactopyranosyl-(1→4)-1,2,3,6-tetra-O-benzyl-D-glucopyranose (**12**).* D-Galactosamine thiophenyl glycoside **10** (*51*) (36.8 mg, 0.066 mmol) and lactose derivative **11** (*52*) (43.0 mg, 0.044 mmol) were stirred under argon in dry CH_2Cl_2 (2 mL) for 30 min at rt in the presence of freshly activated, powdered 4 Å molecular sieves. The reaction mixture was cooled to −70 °C, then treated with *N*-iodosuccinimide (NIS, 17.8 mg, 0.079 mmol) and a catalytic amount of triflic acid (TfOH, 2.0 mg, 0.0132 mmol). The reaction mixture was slowly warmed to 0 °C, then stirred for an additional 4 h at rt. The reaction mixture was then neutralized with a few drops of triethylamine and filtered over a pad of Celite with rinsing by CH_2Cl_2. The mixture was washed with a 10% Na_2SO_3 solution followed by water, and the aqueous layer was extracted twice with CH_2Cl_2. The organic phases were collected and dried over anhydrous Na_2SO_4 and concentrated then purified by silica gel chromatography (EtOAc/hexanes 2:3) to afford trisaccharide **12** as a yellow oil (52.2 mg, 84%). ^1H NMR (400 MHz, $CDCl_3$) δ 7.44−7.25 (m, 35H, ArH), 6.23 (d, 1H, J = 10 Hz, NH), 5.26 (d, 1H, J = 2.8 Hz), 4.97 (d, 2H, J = 12.0 Hz), 4.94 (d, 2H, J = 12.0 Hz), 4.88 (d, 2H, J = 8.0 Hz), 4.85 (d, 2H, J = 8.0 Hz), 4.81 (d, 2H, J = 9.6 Hz), 4.78 (d, 2H, J = 8.0 Hz), 4.71 (d, 2H, J = 8.0 Hz), 4.66 (d, 2H, J = 12.0 Hz), 4.51 (d, 1H, J = 8.0 Hz), 4.49 (d, 1H, J = 8.0 Hz), 4.44 (d, 2H, J = 12.0 Hz), 4.13−3.98 (m, 5H), 3.90 (dd, 2H, J = 6.0, 11.2 Hz), 3.74−3.67 (m, 2H), 3.62−3.59 (m, 1H), 3.56 (d, 2H, J = 9.2 Hz), 3.49 (t, 1H, J = 7.6 Hz), 3.36 (d, 1H, J = 9.6 Hz), 2.09 (s, 3H), 2.03 (s, 3H), 1.99 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ 170.49, 170.44, 170.30, 162.00, 139.15, 138.66, 137.84, 137.56, 129.00, 128.88, 128.57, 128.42, 128.30, 128.16, 128.00, 127.94, 127.83, 127.70, 127.59, 102.77, 99.51, 92.53, 82.53, 81.76, 82.53, 81.76, 76.11, 75.43, 75.06, 74.32, 73.88, 71.29, 70.64, 69.95, 68.20, 66.31, 60.87, 53.43, 20.87, 20.78, 20.68. RESULTS AND DISCUSSION

Synthesis and Reactivity of Bishydrazide Glycoconjugates. The preparation of bishydrazide cross-linkers have been previously reported in the literature, but with little detail regarding their purification (*53*). We found bis(carboxymethyl) esters to be practical intermediates for bishydrazide formation, but hydrazinolysis should be performed under strictly anhydrous conditions to avoid the generation of byproducts during glycoconjugate formation. Bishydrazide linkers **4** and **5** were synthesized from their corresponding α,ω-diols by base-promoted carboxymethylation with ethyl bromoacetate in THF, followed by treatment with excess hydrazine in anhydrous methanol under an inert atmosphere. The bishydrazides prepared in this manner could be collected in nearly quantitative yields simply by removing all volatiles by azeotropic drying with toluene, then used to generate glycoconjugates without further purification.

Glycan−bishydrazide conjugates were prepared by adapting the conditions reported by Shin and co-workers (Scheme 1) (*20, 21*). After an extensive evaluation of reaction conditions using hexa(ethylene glycol)-linked bishydrazide **4** and commercial-grade lactose, we determined that the highest yields were obtained by treating 1 equiv of glycan in AcOH/NaOAc buffer (pH 4.2) with 10 equiv of bishydrazide linker at 70 °C for 48 h. The glycoconjugates were readily separated from the excess linker by preparative reverse-phase HPLC using an aqueous CH_3CN gradient. ^{13}C NMR analysis of lactose−bishydrazide conjugate **6** indicated the anomeric carbons to have the expected chemical shifts for *O,O*- and *N,O*-acetals (δ_c 105.10 and 91.89 ppm, respectively), confirming the pyranosidic nature of the reducing-end sugar. ^{1}H NMR coupling constant analysis indicated that the bishydrazides form β-glycoside linkages, in accord with earlier reports (*54*−*57*). It should be noted that the formation of bishydrazide glycoconjugates **7** and **8** is not always complete after 48 h under these conditions; on the other hand, the formation of glycan dimers is negligible, circumventing the need for heterobifunctional linkers.

Glycan−bishydrazide conjugates **7** and **8** were prepared using GalNAc(β1→4)-Gal(β1→4)Glc (**2**) and 2′-fucosyllactose (Fuc-(α1→2)Gal(β1→4)Glc, **3**), with the former obtained through multistep organic synthesis (see below). Trisaccharide **2** is a common substructure in the glycans presented on the epithelial lining of the pulmonary tract and is a high-affinity ligand for adhesins presented on the pili of virulent *Pseudomonas* (*58, 59*). Fucose-presenting glycans such as **3** have been shown to be potent ligands for the lectin PA-IIL, also expressed by *Pseudomonas* (*60, 61*). These glycans presented us an opportunity to evaluate the bishydrazide glycoconjugate chemistry in the context of bacterial pathogen detection.

Briefly, pulmonary trisaccharide **2** was synthesized by the coupling of *N*-trichloroacetyl-protected GalNAc donor **10** (*51*) with lactose-derived acceptor **11** (*52*) and *N*-iodosuccinimide-triflic acid activation conditions, yielding the desired β-glycoside **12** in 86% yield (Scheme 2, see Experimental Procedures section for details). Reductive dechlorination with tributyltin hydride, followed by methanolic deacetylation and global debenzylation, yielded trisaccharide **2** in excellent overall yields.

The glycan−bishydrazide conjugates react readily with standard labeling and bioconjugation reagents. Fluorescent glycoconjugate **14** was generated by treatment of 2′-fucosyllactose-bishydrazide **8** with fluorescein isothiocyanate (FITC), whereas photoreactive glycoconjugates **15**−**17** were produced by coupling bishydrazide-linked glycans **6**−**8** with *N*-(5 azido-2-nitrobenzoyloxy)succinimide (ANB-NOS) (Figure 1). In both of these cases, hydrazide coupling was most efficient in anhydrous polar solvents such as DMF and MeOH, using *N,N*-diisopropylethylamine as the base (see Experimental Procedures section for details). Neoglycoproteins could also be formed in phosphate-buffered saline (PBS) solutions at physiological pH using typical EDC coupling conditions (*39*), and stored at 4 °C for several months.

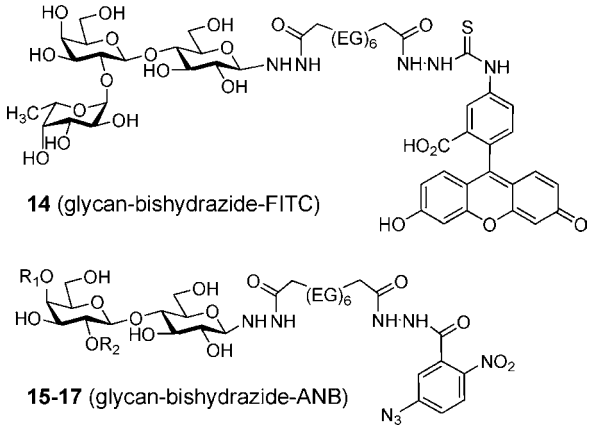

Figure 1. Glycan−bishydrazide conjugates labeled with fluorescent or photoreactive chromophores. $(EG)_6 = -O(CH_2CH_2O)_6-$. **15**: R_1, R_2 = H. **16**: R_1 = β-D-GalNAc, R_2 = H. **17**: R_1 = H, R_2 = α-L-Fuc.

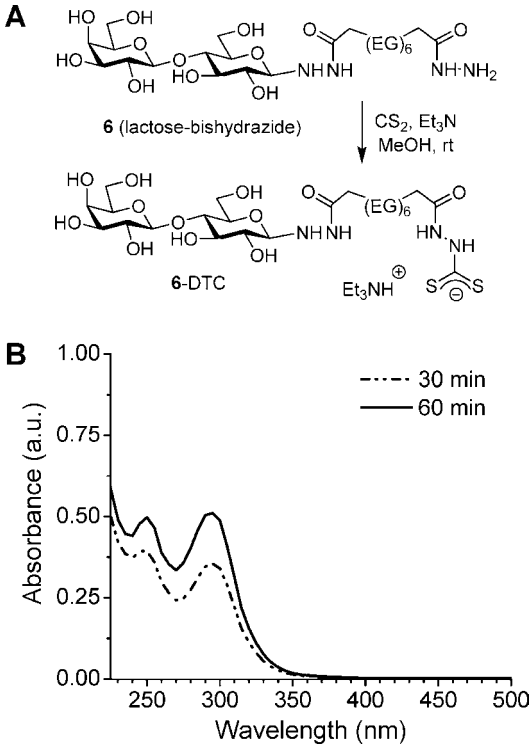

Figure 2. (A) In situ DTC formation starting from lactose−bishydrazide conjugate **6**; $(EG)_6 = O(CH_2CH_2O)_6$. (B) UV absorption spectra of **6**-DTC in dilute aqueous solution, taken during in situ DTC formation. No further increases in peak intensities were observed after 60 min.

The hydrazide-terminated glycoconjugates are also amenable to in situ dithiocarbamate (DTC) formation, a recently established method for anchoring amine-terminated ligands onto metal surfaces (*47*, *48*, *62*−*69*). DTCs are conveniently prepared by the addition of nucleophilic amines to CS_2 in polar organic or aqueous media and exhibit a strong binding affinity for gold and several types of inorganic oxides. Bishydrazide−DTCs can be prepared in a similar fashion: in this work; an equimolar mixture of lactose−bishydrazide conjugate **6**, CS_2, and Et_3N in methanol resulted in essentially quantitative formation of DTC triethylammonium salt within 1 h under ambient conditions (**6**-DTC, Figure 2). The reaction time was determined by using UV absorption spectroscopy to monitor hydrazide−DTC formation based on increases in characteristic peak intensities at 250 and 292 nm (*70*).

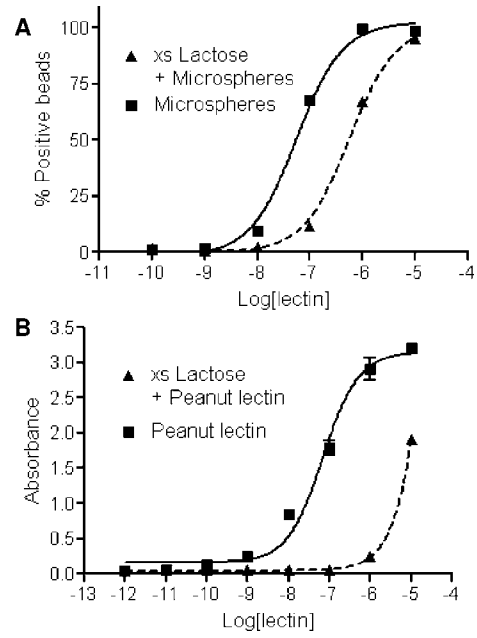

Figure 3. (A) Affinity and lactose competition assay of peanut lectin binding to microspheres conjugated with lactose−bishydrazide **6** using flow immunocytometry. (B) ELISA and competition assay of peanut lectin binding to immobilized **6**-BSA.

Lectin and Bacterial Binding by Bishydrazide Glycoconjugates. Bishydrazide glycoconjugates can be directly attached onto surface-active substrates for the selective capture of lectins and subsequent binding immunoassays. For example, lactose−bishydrazide **6** was attached onto NHS-activated latex microspheres in order to measure the binding affinity of peanut lectin by flow immunocytometry (K_d = 50 nM), using a FITC-labeled secondary antibody for fluorescence detection (Figure 3A and Supporting Information Figure S1). Selective binding was established by a competition assay against 1 mM lactose, which increased K_d by 10-fold. However, in some cases the use of carrier proteins such as BSA is more convenient for surface functionalization by simple physisorption. An ELISA of **6**-BSA conjugate indicates its affinity for peanut lectin to be the same as that measured for lactose-conjugated microspheres.

Glycoconjugates can also be covalently tethered onto protein layers and other organic substrates by photo-cross-linking, which provides opportunities to create glycan microarrays and micropatterns by photolithography (*71*−*75*). Au substrates coated with a monolayer of BSA were immersed in a solution of lactose-bishydrazide-ANB conjugate **15**, then dried in air and exposed to UV irradiation through a photomask. The intermediate nitrenes that are generated upon UV irradiation (*76*) presumably insert into the amino acid side chains of the immobilized BSA, resulting in a patterned array of glycans after washing away the unexposed ligands. Incubation with peanut lectin followed by fluorescence immunostaining revealed well-defined line patterns, defined by the photomask features (Figure 4).

A similar approach was used to generate photopatterned arrays of the pulmonary trisaccharide and 2′-fucosyllactose on BSA-coated substrates, using glycan-bishydrazide-ANB conjugates **16** and **17**, respectively. These micropatterned substrates were exposed to the opportunistic pathogen *Pseudomonas aeruginosa* at 10^6−10^8 cfu/mL, then washed and imaged by optical darkfield microscopy to visualize patterns of glycan-immobilized bacteria in a label-free manner (Figure 5 and Supporting Information Figures S2 and S3). Specificity for **16** and **17** was confirmed by introducing *Pseudomonas* to control substrates patterned with lactose−bishydrazide conjugate, which resulted in no apparent binding. Furthermore, only live *Pseudomo-*

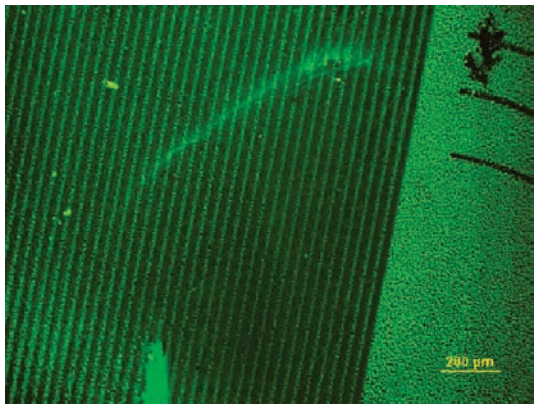

Figure 4. Fluorescence immunostaining of peanut lectin bound to lactose-bishydrazide-ANB conjugate **15**, photopatterned onto a BSA-coated substrate by UV irradiation ($\lambda = 254$ nm) through a quartz mask.

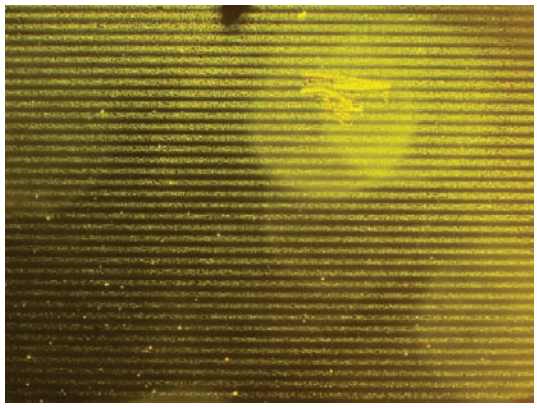

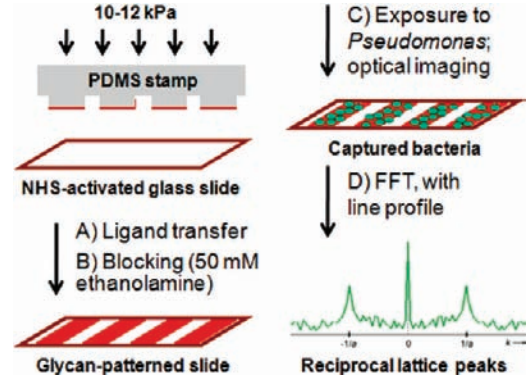

Figure 5. Capture of *Pseudomonas* on BSA-coated substrates with photopatterned glycan-bishydrazide-ANB conjugate, imaged by darkfield microscopy. Bacterial capture mediated by 2′-fucosyllactose conjugate **17** at 10^8 cfu/mL; grating period $a = 20$ μm. Additional images in Supporting Information (Figures S2−S4).

nas were captured by the trisaccharide ligands; exposing the bacteria to UV irradiation for 2 h prior to their introduction resulted again in no observable pattern (Supporting Information Figure S4). We note that the patterns formed by bacterial adhesion at lower pathogen densities can be well below saturation levels; however, our pathogen detection method only requires a fill factor of a few percent for pattern recognition, as will be demonstrated shortly.

Glycan−bishydrazide conjugates could also be patterned onto substrates by microcontact printing (μCP), a well-established "soft lithography" technique based on microfabricated polydimethylsiloxane (PDMS) stamps for the physical transfer of organic or biomolecular ligands, including glycans (*77*−*81*). Stamps imprinted with 20 μm gratings were coated with solutions of **7**-BSA or **8**-BSA in phosphate buffer, then dried in air and placed in conformal contact with activated glass slides under lightly applied pressure (see Scheme 3 and Experimental Procedures section). The substrates were blocked then exposed for 1 h to *Pseudomonas* at 10^2−10^8 cfu/mL, then evaluated for evidence of patterned pathogen capture (Figure 6). On average, we find the pattern transfer of **7**-BSA by μCP to be more consistent than that produced by photolithography, and remarkably reliable for mediating bacterial adhesion at low pathogen densities.

Visual inspection of the patterned glycan slides can indicate *Pseudomonas* capture at a concentration of 10^5 cfu/mL (Figure 6D). However, image processing by fast Fourier transform

Scheme 3[a]

[a] (A,B) Glycan-patterned slides by microcontact printing of BSA glycoconjugates onto NHS-activated glass substrates, followed by a blocking step. (C) Patterned capture slides were exposed to *Pseudomonas* at variable concentrations, then imaged under darkfield condtions. (D) Image processing by FFT analysis produced reciprocal lattice peaks at $k = \pm 1/a$ in spectral format; central peak ($k = 0$) scales with spatially averaged intensity of original image; noise from nonspecific binding is dispersed throughout *k*-space.

allows the linear array of scattering signals to be analyzed as reciprocal lattice peaks, enabling much lower limits of detection (*50*). These demodulated signals are largely separated from background noise and can be presented with much greater contrast than the original darkfield images (Figure 6A−H, insets). As a result, we find that slides patterned with **7**-BSA can detect *Pseudomonas* capture in a label-free manner, with acceptable signal-to-noise (*S*/*N*) ratios down to 10^3 cfu/mL (Figure 6F).

Interestingly, we observe that our *Pseudomonas* cultures have a much lower avidity for 2′-fucosyllactose **8** than for pulmonary trisaccharide **7**, which are recognized by adhesins that are constitutively presented at the tips of bacterial pili (*82*). Whereas affinity for **7**-BSA is robust and minimally affected by the presence of competing GalNAc or lactose up to 100 mM (Supporting Information, Figure S5), affinity for **8**-BSA is observed only when the bacteria has been cultured in the presence of choline (*49*). It has been shown that the expression of the fucose-binding lectin PA-IIL is regulated by quorum sensing circuitry (*las* and *rhl*), which are activated in an environmentally dependent (paracrinal) fashion (*83, 84*).

Presentation of Glycan-Bishydrazides on Metal Surfaces by in Situ Dithiocarbamate Formation. Biosensor applications are often performed with gold substrates, like those based on surface plasmon resonance (SPR) and quartz crystal microbalance (QCM) (*85*, *86*). For short-term biosensing studies, it is often appropriate to employ chemisorptive ligands such as ω-functionalized alkanethiols, which are well-known to form self-assembled monolayers (SAMs) on gold surfaces (*87*). However, alkanethiol-based SAMs can have limited stability when exposed to even mildly oxidizing conditions (*88*), so it is worth considering other types of chemisorptive ligands that can support robust surface functionalization under variable environments or in physiological settings.

DTC-anchored monolayers (DAMs) are useful alternatives to thiol-based SAMs, as they have been shown to have greater resistance to surface desorption or oxidative degradation (*47*). Although earlier studies involving in situ DTC and DAM formation have been conducted with alkyl- and dialkylamines (*47*, *48*, *62*−*69*), hydrazide−DTCs can be formed just as easily and may also serve as chemisorptive ligands. Lactose−bishydrazide **6** was thus converted into the corresponding DTC (Figure 2), then diluted in water and deposited onto a PDMS stamp for pattern transfer onto a chemically roughened Au surface by μCP. The

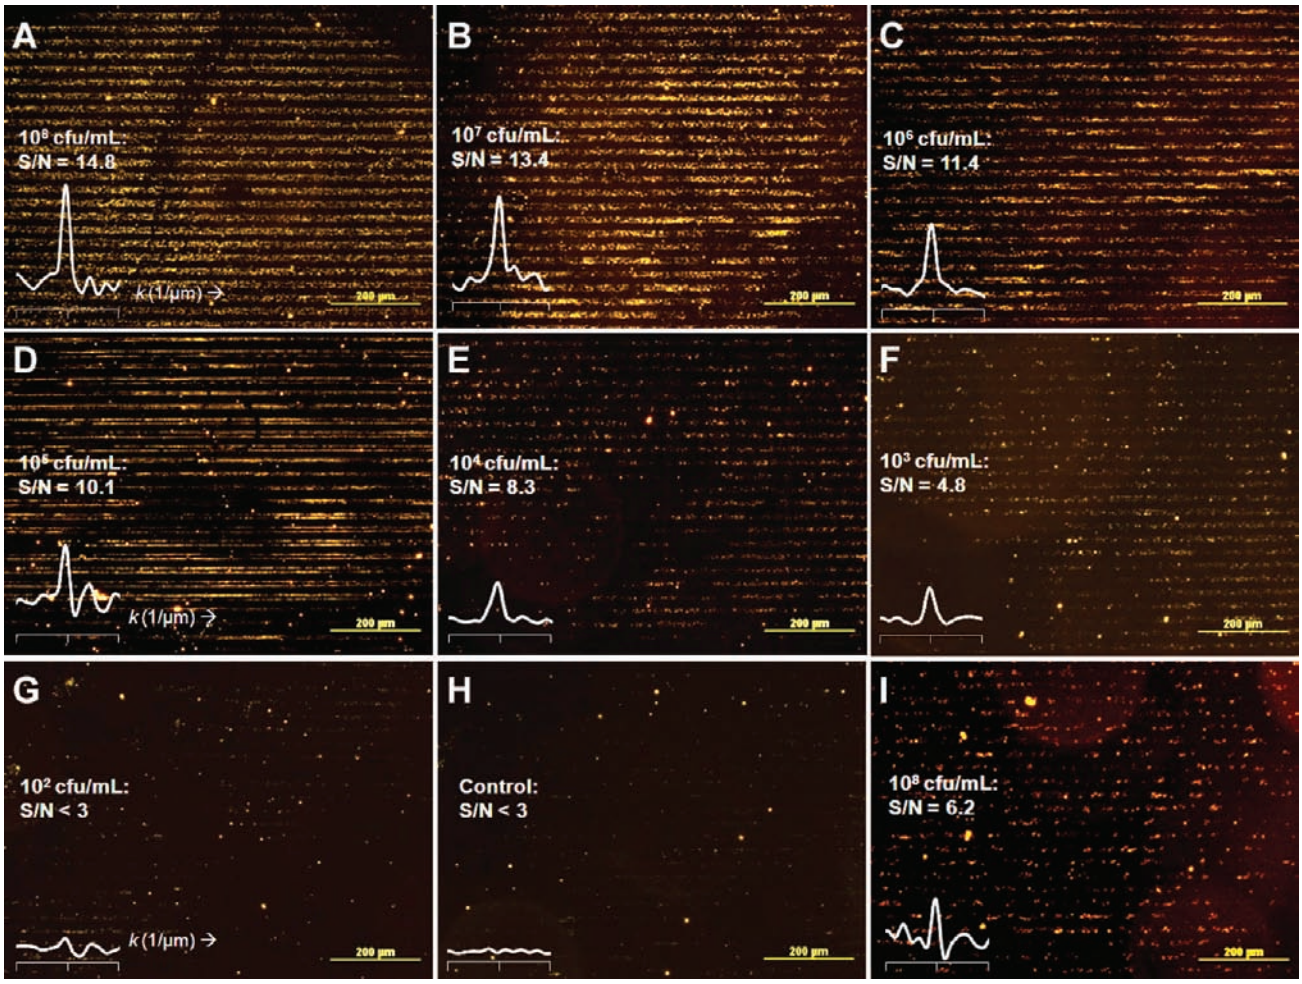

Figure 6. Capture of live *Pseudomonas* on glass substrates patterned with BSA−glycan bishydrazide conjugates using μCP, as imaged by darkfield microscopy. (A−G) Substrates patterned with pulmonary trisaccharide conjugate **7**-BSA after a 1-h exposure to *Pseudomonas*, at concentrations ranging from 10^8 to 10^2 cfu/mL. Pattern contrast correlates with signal-to-noise (*S*/*N*) ratio defined by reciprocal lattice peak produced by FFT ($k = 0.05\ \mu m^{-1}$). (H) Substrate patterned with **7**-BSA without exposure to bacteria (control). (I) *Pseudomonas* capture mediated by 2′-fucosyllactose conjugate **8**-BSA, in the presence of choline (10^8 cfu/mL).

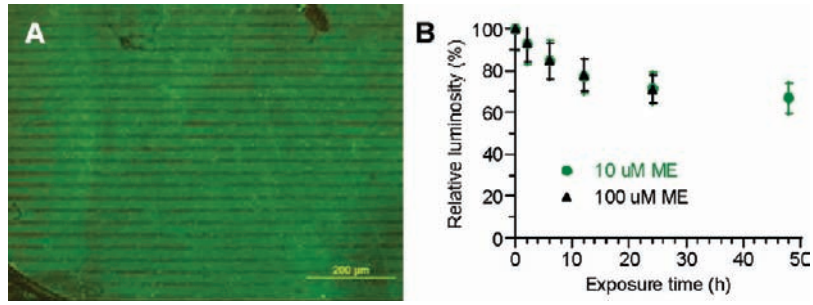

Figure 7. (A) Fluorescence immunostaining of peanut lectin bound to lactose conjugate **6**-DTC, presented as DAMs on Au substrates by μCP. (B) Stability profile of hydrazide−DTC patterns on roughened Au in PBS containing ME (10 or 100 μM), based on changes in relative luminosity.

patterned substrates were blocked by BSA and incubated with peanut lectin, whose binding to lactose-terminated DAMs was visualized by immunofluorescent staining (Figure 7). It is important to note that Au substrates are often incompatible with fluorescence imaging due to their propensity to quench emission; however, radiative decay rates can be accelerated on roughened Au substrates by coupling with local plasmon modes and may even produce a net gain in emission (*89*).

As expected, the oriented presentation of **6**-DTC on Au surfaces is well-suited for the immobilization of multivalent lectins, and patterned substrates can be soaked in PBS for extended periods without concern for degradation. To further establish whether glycan−bishydrazide DAMs are capable of providing robust support as carbohydrate microarrays for protein screening or pathogen binding, we investigated their stability in the presence of 2-mercaptoethanol (ME), a polar thiol that is frequently used to displace alkanethiol-based SAMs from Au surfaces (*90*). This displacement assay is important in the context of physiological sensing, as biogenic thiols such as cysteine and glutathione can also be considered as competing adsorbates. The immunofluorescent patterns on roughened Au substrates were thus exposed to 10 μM or 100 μM ME in PBS at room temperature for 2 days, with monitoring of selected regions at different exposure times by fluorescence microscopy (Supporting

Information, Figure S6). Both conditions produced very gradual decay profiles, with an estimated halflife of over 80 h (Figure 7B). It should be mentioned that displacement assays with millimolar levels of ME could not be performed in this case, as this was sufficient to cause degradation of the roughened Au substrates themselves. Nevertheless, exposure of **6**-DTC ligands to ME at these levels has minimal detrimental effect on DAM stability and merits further investigation. A direct comparison between SAMs and DAMs is in progress and will be reported in due course.

CONCLUSIONS

α,ω-Bishydrazides are useful and versatile linkers for attaching glycans onto substrates for bacterial pathogen detection and lectin profiling. Unprotected glycans are conjugated straightforwardly to bishydrazides with retention of the native pyranose conformation at the reducing end, and can be further conjugated to amine-reactive substrates, carrier proteins, and to metal surfaces by in situ DTC formation. With respect to the latter, glycan-bishydrazide-DTCs form robust attachments to roughened gold substrates and are able to withstand displacement by competing thiols under physiologically relevant conditions. Glycan−bishydrazide conjugates can be subsequently employed in microfabrication schemes involving photolithography or PDMS-based microcontact printing for the facile detection of glycan-binding proteins and pathogens, as demonstrated by the patterned adsorption of peanut lectin and *Pseudomonas*. We anticipate using this methodology to support real-time biosensing applications involving protein biomarker or pathogen detection.

ACKNOWLEDGMENT

The authors gratefully acknowledge financial support from the National Institutes of Health (GM-069862), the National Science Foundation (CHE-0243496), the Department of Defense (W911SR-08-C-0001) administered through the U.S. Army RDECOM (Edgewood Contracting Division), and the Center for Sensing Science and Technology at Purdue University. We thank David Lyvers and Ron Reifenberger for their contributions toward FFT analysis, and Youngsoon Kim and James Newton for helpful discussions and assistance with microcontact printing, bacteria culture, and quantitative bacterial cell culture analysis.

Supporting Information Available: Representative data from flow immunocytometry (Figure S1); control experiments for specificity of pathogen capture (Figures S2−S5); additional immunofluorescence images of lectins bound to DTC-anchored glycan bishydrazides on Au substrate (Figure S6); ^{1}H and ^{13}C NMR spectra of all new compounds. This material is available free of charge via the Internet at http://pubs.acs.org.

Surface Functionalization Using Catalyst-Free Azide−Alkyne Cycloaddition

Alexander Kuzmin,[†] Andrei Poloukhtine,[†] Margreet A. Wolfert,[‡] and Vladimir V. Popik*,[†]

Department of Chemistry and Complex Carbohydrate Research Center, University of Georgia, 315 Riverbend Road, Athens, Georgia 30602, United States. Received July 6, 2010; Revised Manuscript Received September 29, 2010

The utility of catalyst-free azide−alkyne [3 + 2] cycloaddition for the immobilization of a variety of molecules onto a solid surface and microbeads was demonstrated. In this process, the surfaces are derivatized with aza-dibenzocyclooctyne (ADIBO) for the immobilization of azide-tagged substrates via a copper-free click reaction. Alternatively, ADIBO-conjugated molecules are anchored to the azide-derivatized surface. Both immobilization techniques work well in aqueous solutions and show excellent kinetics under ambient conditions. We report an efficient synthesis of aza-dibenzocyclooctyne (ADIBO), thus far the most reactive cyclooctyne in cycloaddition to azides. We also describe convenient methods for the conjugation of ADIBO with a variety of molecules directly or via a PEG linker.

INTRODUCTION

Surface immobilization of biomolecules is a very important step in the manufacturing of biosensors, microbeads, biochips, probe arrays, medical implants, and other devices (*1*−*5*). The key requirements for this process are the preservation of biochemical properties of immobilized substrates and robustness of the linkage. Copper(I)-catalyzed Huisgen 1,3-dipolar cycloaddition of azides to terminal acetylenes has emerged as one of the most convenient methods for the functionalization of various surfaces (*3, 5*−*10*). The triazol linker formed in the azide "click" reaction has excellent chemical stability due to the aromatic character of the heterocycle. Azide tags can be incorporated into biomolecules using a variety of different strategies, such as postsynthetic modification (*11*−*13*), in vitro enzymatic transfer (*14, 15*), the use of covalent inhibitors (*16*), and metabolic labeling by feeding cells a biosynthetic precursor modified with azido functionality (*17*). While conventional copper(I)-catalyzed click chemistry has become commonplace in surface derivatization, as well as in polymer and materials synthesis (*6*−*10, 18*−*20*), the use of metal catalyst often limits the utility of the method. Copper ions are cytotoxic (*21*), can cause degradation of DNA molecules (*22, 23*), and induce protein denaturation (*24*). In addition, the use of catalysts complicates kinetics of the immobilization process, requires polar solvents, and can alter surface properties (*25*).

Conventional copper-catalyzed azide click coupling methods employ terminal acetylenes, since internal alkynes react with azides only at elevated temperatures. Cyclooctynes, on the other hand, are known to form triazoles without a catalyst under ambient conditions, albeit at a rather slow rate (*26*). The triple bond incorporated into an eight-membered ring is apparently already bent into a geometry resembling the transition state of the cycloaddition reaction, thus reducing its activation barrier (*27*). Recently developed cyclooctyne derivatives are substantially more reactive toward azides and offer a convenient metal-free alternative to the copper-catalyzed click reaction (*28*−*33*). Metal-free click chemistry has been successfully employed for the modification of luminescent quantum dots (*25*) and protein labeling and purification (*34*−*37*), as well as for the introduction of fluorescent tags into live cells (*25, 38, 39*) and organisms (*40, 41*).

Among reactive cyclooctyne derivatives, dibenzocyclooctynes are synthetically more accessible (*42*). The major limitation of these click reactants is the relatively low rate of azide cycloaddition (ca. 0.05 M^{-1} s^{-1}) (*34*−*37*). Substitution of one of the saturated carbons in the cyclooctyne ring for a nitrogen atom not only improves its reactivity, but also simplifies the synthesis (*28*−*33*). To extend the arsenal of bioorthogonal copper-free click reagents, we have developed an efficient synthesis of aza-dibenzocyclooctyne-containing compounds for azide-coupling reactions. In the present report, we describe a novel approach to efficient surface-functionalization using a catalyst-free azide click reaction. This method allows for the site-specific covalent anchoring of proteins and other substrates to various surfaces. The same metal-free click reaction is employed for the PEGylation of nonfunctionalized areas of the surface. Such treatment allows for a dramatic reduction or complete elimination of nonspecific binding. The copper-free click immobilization strategy discussed in the present report can be applied to the preparation of various types of arrays, as well as to the derivatization of microbeads and nanoparticles.

EXPERIMENTAL PROCEDURES

Materials and Methods. Purification of products by column chromatography was performed using 40−63 μm silica gel. All NMR spectra were recorded on a 400 MHz instrument in $CDCl_3$ and referenced to TMS unless otherwise noted. Images of fluorophore-patterned slides were recorded, and fluorescence intensity was quantified using a Typhoon 9400 variable mode imager (GE Healthcare) at an excitation/emission setting appropriate for fluorescein (488/520 nm) or Lissamine rhodamine B (532/580 nm) fluorophores in PBS solution; images of fluorescent microbeads were obtained using Zeiss Observer AX10 inverted microscope with an X-cite series 120 fluorescent light source and Chroma Technology filters. The relative fluorescent intensity (spot/background) was quantified using *ImageJ* program (NIH).

Tetrahydrofuran was distilled from a sodium/benzophenone ketyl; ether and hexanes were distilled from sodium; *N*,*N*-dimethylformamide (DMF) was dried by passing through an alumina column. Biotin-dPEG3+4-azide and Biotin-PEG4-acid were purchased from Quanta BioDesign; fluorescein SE, Oregon Green SE, Lissamine rhodamine B sulfonyl chloride, and FITC-Avidin were obtained from Invitrogen; (3-glycidyloxypropyl)-

dimethoxymethylsilane was purchased from TCI America; 0.0067 M phosphate buffered saline (PBS) with pH 7.4 was obtained from Thermo Scientific. Bovine serum albumin (BSA) was obtained from Fisher BioReagents. Other reagents were purchased from Aldrich or VWR and used as received unless otherwise noted. Polished glass slides were obtained from VWR; NanoLink streptavidin magnetic microspheres (1% aqueous suspension) were purchased from SoluLink Biosciences. Aza-dibenzocycloctyne **6** conjugates with fluorescein (ADIBO-fluor, **10**), Oregon green (ADIBO-OG, **11**), and Lissamine rhodamine B (ADIBO-Rhodamine, **12**) were prepared by treating **6** with equimolar amounts of fluorescein SE, Oregon Green SE, Lissamine rhodamine B sulfonyl chloride, respectively, in DMF in the presence of DIEA (ethyldiisopropylamine). Oregon green azide (**13**) and Lissamine rhodamine B azide (**14**) were prepared by reacting equimolar amounts of Oregon green SE or Lissamine rhodamine B sulfonyl chloride with 3-azidopropyl amine in DMF in the presence of DIEA. Conjugates **10**−**14** were purified by chromatography ($CHCl_3$/MeOH/AcOH 100:5:0.5) and their purity was confirmed by HPLC analysis. 1-Amino-11-azido-3,6,9-trioxaundecane (AminoPEG_4azide) (*43*) and 6-azidohexylamine (*44*) were prepared according to literature procedures.

*5,6-Dihydrodibenzo[b,f]azocine (**2**).* A solution of dibenzosuberenone (25 g, 121 mmol) and hydroxylamine hydrochloride (6.81 mL, 164 mmol) in pyridine (70 mL) was refluxed for 20 h. The reaction mixture was concentrated and poured into 5% aqueous hydrochloric acid (with crushed ice), stirred for 20 min, filtered, and dried in the air to provide 28.1 g of crude dibenzosuberenone oxime, as a white precipitate. Dibenzosuberenone oxime (16 g, 72.3 mmol) was added to 250 mL polyphosphoric acid at 125 °C; the reaction mixture was stirred for 60 min at this temperature, poured onto crushed ice (∼700 mL), stirred for another 30 min, and filtered. The filter cake was washed with water and dried under vacuum to provide crude dibenzo[*b*,*f*]azocin-6(5H)-one **1** (11.6 g, 52.4 mmol, 73%) as a gray powder.

A suspension of **1** (7.4 g, 33.4 mmol) and lithium aluminum hydride (2.494 mL, 66.9 mmol) in anhydrous ether (200 mL) was refluxed for 15 h. The reaction mixture was quenched by water and filtered, and the filter cake was washed with ether. The filter cake was dispersed in ether (100 mL), stirred for 10 min, and filtered. The combined organic layers were dried over $MgSO_4$, solvent was removed under vacuum, and the product was purified by chromatography (hexanes/ethyl acetate 2:1) to provide 4.04 g (19.49 mmol, 58%) of 5,6-dihydrodibenzo[*b*,*f*]-azocine (*2*). ^{1}H NMR: δ 7.27−7.23 (m, 1 H), 7.2−7.1 (m, 3 H), 6.96−6.9 (m, 1 H), 6.9−6.8 (m, 1 H), 6.65−6.55 (m, 1 H), 6.54−6.48 (m, 1 H), 6.40 (d, J = 8 Hz, 1 H), 6.38−6.29 (m, 1 H), 4.51 (d, J = 6.8 Hz, 2 H), 4.2 (br s, 1 H). ^{13}C NMR: δ 147.3, 139.3, 138.3, 134.9, 132.7, 130.3, 129.0, 128.1, 127.8, 127.6, 127.5, 121.8, 118.1, 117.9, 49.6. HRMS (ESI+) calcd for $C_{15}H_{14}N$ $[M+H]^+$ 208.1126, found 208.1120.

*N-(6-(Dibenzo[b,f]azocin-5(6H)-yl)-6-oxohexyl)trifluoroacetamide (**3**).* 6-(Trifluoroacetamido)hexanoyl chloride (*45*) (0.984 g, 4.52 mmol) was added to a solution of **2** (0.75 g, 3.62 mmol) and pyridine (0.859 g, 10.86 mmol) in CH_2Cl_2 (ca. 10 mL) at rt and stirred for 30 min. The reaction mixture was diluted with CH_2Cl_2 (ca. 20 mL), washed with water (2 × 30 mL), and dried over anhydrous $MgSO_4$, and the solvent was removed under reduced pressure. The residue was purified by chromatography (hexanes/ethyl acetate 2:3) to provide 1.064 g (2.56 mmol, 71%) of **3** as yellowish oil. ^{1}H NMR: δ 7.32−7.22 (m, 4 H), 7.19−7.11 (m, 4 H), 6.77 (d, J = 13.2 Hz, 1 H), 6.58 (d, J = 13.2 Hz, 1 H), 5.46 (d, J = 14.8 Hz, 1 H), 4.20 (d, J = 14.8 Hz, 1 H), 3.29−3.15 (m, 2 H), 2.09−2.02 (m, 1 H), 1.93−1.85 (m, 1 H), 1.51−1.32 (m, 4 H), 1.25−1.04 (m, 2 H). ^{13}C NMR: δ 172.7, 157.5, 141.1, 136.1, 135.8, 134.8, 132.4, 131.8, 130.5, 128.5, 128.2, 128.1, 128.0, 127.3, 127.2, 117.5, 114.6, 54.8, 39.6, 34.3, 28.2, 25.9, 24.3. HRMS (ESI+) *m*/*z* calcd for $C_{23}H_{24}F_3N_2O_2$ $[M+H]^+$ 417.1790, found 417.1783.

*N-(6-Trifluoroacetamidohexanoyl)-5,6-dihydro-11,12-didehydrodibenzo[b,f]azocine (**5**).* Pyridine hydrobromide perbromide (0.948 g, 2.97 mmol) was added to a solution of **3** (1.05 g, 2.70 mmol) in CH_2Cl_2 (4 mL) at rt, and the reaction mixture was stirred overnight. The reaction mixture was diluted with CH_2Cl_2 (20 mL), washed with 5% aqueous hydrochloric acid (20 mL), dried over $MgSO_4$, and solvent removed under vacuum. The residue was passed through a short pad of silica gel (CH_2Cl_2) to give 1.2 g of crude *N*-(trifluoroacetamidohexanoyl)-5,6,11,12-tetrahydro-11,12-dibromodibenzo[*b*,*f*]azocine (*4*) as an oil. A solution of crude **4** (1.2 g, 2.08 mmol) in THF (5 mL) was added to a solution of potassium *t*-butoxide (0.584 g, 5.21 mmol) in THF (10 mL) at rt; the reaction mixture was stirred for 1 h, diluted with ethyl acetate (20 mL), washed with 5% aqueous hydrochloric acid and brine, then dried over $MgSO_4$, and the solvent was removed under reduced pressure. The crude product was purified by chromatography (hexanes/ethyl acetate, 2:1 to 1:1) to afford 0.76 g (1.83 mmol, 88%) of **5** as brown oil. ^{1}H NMR: δ 7.68 (d, J = 7.6 Hz, 1 H), 7.45−7.21 (m, 7 H), 6.79 (br s, 1 H), 5.16 (d, J = 14.4 Hz, 1 H), 3.67 (d, J = 13.6 Hz, 1 H), 3.22−3.14 (m, 1 H), 3.11−3.02 (m, 1 H), 2.24−2.16 (m, 1 H), 1.41−1.22 (m, 4 H), 1.11−0.9 (m, 2 H). MS: *m*/*z* 414 $[M^+]$. Calcd for $C_{23}H_{21}F_3N_2O_2$ 414.

*N-(6-Aminohexanoyl)-5,6-dihydro-11,12-didehydrodibenzo-[b,f]azocine (ADIBO-C6-amine, **6**).* A solution of K_2CO_3 (2 g, 14.47 mmol) in 15 mL of water was added to a solution of *N*-(6-trifluoroacetamido hexanoyl)-5,6-dihydro-11,12-didehydrodibenzo[*b*,*f*]azocine (**5**, 2.95 g, 7.12 mmol) in MeOH (30 mL) at rt and stirred overnight. Solvents were removed under reduced pressure, the residue was redissolved in CH_2Cl_2/ethyl acetate (1:4), then washed with brine and water. The organic layer was dried over anhydrous Na_2SO_4 and concentrated in vacuum. The crude product was purified by chromatography (CH_2Cl_2/MeOH 10:1 to 10:4) to provide 1.31 g (4.11 mmol, 58%) of **6** as slightly yellow oil. ^{1}H NMR: δ 7.71 (d, J = 7.6 Hz, 1 H), 7.45−7.21 (m, 7 H), 5.18 (d, J = 14.4 Hz, 1 H), 3.63 (d, J = 13.6 Hz, 1 H), 3.32 (br, 2 H), 2.67 (t, J = 5.6 Hz, 1 H), 2.52 (t, J = 5.6 Hz, 1 H), 2.21−2.19 (m, 1 H), 1.95−1.90 (m, 1 H), 1.45−1.35 (m, 2 H) 1.28−1.20 (m, 2 H), 1.11−0.9 (m, 2 H). ^{13}C NMR: δ 173.3, 151.8, 147.8, 132.3, 132.1, 128.9, 128.2, 128.0, 127.8, 127.5, 126.5, 122.1, 123.0, 114.8, 107.9, 55.8, 41.4, 34.7, 31.9, 26.0, 24.8. HRMS (ESI+) *m*/*z* calcd for $C_{21}H_{23}N_2O$ $[M+H]^+$ 319.1810, found 319.1799.

*N-(3-Aminopropionyl)-5,6-dihydro-11,12-didehydrodibenzo[b,f]azocine (ADIBO-C3-amine, **7**).* **7** was prepared following the same protocol as the preparation of **6**. ^{1}H NMR (500 MHz): δ 7.68 (d, J = 7.5 Hz, 1 H), 7.45−7.33 (m, 5 H), 7.29 (t, J = 7.5 Hz, 1 H), 7.25 (t, J = 7 Hz, 1 H), 5.15 (d, J = 14 Hz, 1 H), 3.16 (d, J = 14 Hz, 1 H), 2.82−2.67 (m, 2H), 2.45−2.35 (m, 1 H), 2.01−1.92 (m, 1 H), 1.6−1.4 (br s, 2 H). ^{13}C NMR: δ 172.14, 151.48, 148.01, 132.12, 129.08, 128.29, 128.21, 127.99, 127.63, 127.01, 125.43, 122.85, 122.57, 114.97, 107.66, 55.25, 38.25, 38.15. HRMS (ESI+) calcd for $C_{18}H_{17}N_2O$ $[M+H]^+$ 277.1341, found 277.1339.

*Aza-dibenzocyclooctyne−Biotin Conjugate (ADIBO-biotin, **8**).* HBTU (1.916 g, 5.05 mmol) was added to a solution of biotin-PEG4-acid (1.9 g, 3.87 mmol) and DIEA (0.647 g, 5.61 mmol) in CH_2Cl_2 (15 mL) at rt and stirred for 15 min. A solution of **7** (1.238 g, 4.48 mmol) in CH_2Cl_2 (2 mL) was added dropwise, the reaction mixture was stirred for 3 h and concentrated under reduced pressure. The product was purified by chromatography (CH_2Cl_2 to CH_2Cl_2/MeOH 20:1 to 100:15) to provide 2.44 g (3.26 mmol, 87%) of **8** as colorless semisolid. ^{1}H NMR (500 MHz, $CDCl_3$): δ 7.66 (d, J = 7 Hz, 1 H),

7.42−7.3 (m, 7 H), 7.28−7.25 (m, 1 H), 7.05−6.99 (m, 1 H), 6.79−6.75 (m, 1 H), 6.61 (br s, 1 H), 5.13 (d, J = 14 Hz, 1 H), 4.5−4.45 (m, 1 H), 4.32−4.25 (m, 1 H), 3.68 (d, J = 14 Hz, 1 H), 3.65−3.45 (m, 17 H), 3.44−3.36 (m, 2 H), 3.32−3.22 (m, 2 H), 3.15−3.07 (m, 2 H), 2.9−2.82 (m, 1 H), 2.75−2.65 (m, 1 H), 2.55−2.46 (m, 1 H), 2.33 (q, J = 6 Hz, 2 H), 2.2 (t, J = 7.5 Hz, 2 H), 2.0−1.92 (m, 1 H), 1.75−1.6 (m, 4 H), 1.45−1.35 (m, 5 H). ^{13}C NMR: δ 173.51, 171.99, 171.13, 164.01, 151.1, 148.09, 132.13, 129.14, 128.68, 128.21, 127.83, 127.19, 125.58, 123.07, 122.45, 114.72, 107.86, 70.45, 70.43, 70.39, 70.3, 70.17, 70.03, 69.98, 97.17, 61.83, 60.26, 55.69, 55.52, 53.67, 42.0, 40.52, 39.14, 36.79, 35.89, 35.26, 34.71, 28.29, 28.11, 25.63, 18.59, 17.44, 11.88. HRMS (ESI+) m/z calcd for $C_{39}H_{53}N_5O_8S$ $[M+H]^+$ 750.3537, found 750.3542.

*Aza-dibenzocyclooctyne-PEG$_4$-Amine (ADIBO-PEG$_4$-amine, **9**).* EDC (0.75 g, 4.68 mmol) was added to a solution of Boc-NH-$(CH_2CH_2O)_4$-$CH_2CH_2CO_2H$ (*46*) (1.57 g, 4.32 mmol) in CH_2Cl_2 (15 mL) and DIEA (0.7 g, 5.4 mmol) at rt and stirred for 15 min. A solution of ADIBO-amine **7** (1 g, 3.6 mmol) in CH_2Cl_2 (1 mL) was added to the reaction mixture and stirred for 4 h, at which time the solvent was removed under reduced pressure and the crude product purified by chromatography (ethyl acetate/hexanes 1:1 to 9:1) to provide 1.8 g (2.8 mmol, 80%) of crude *N*-Boc-protected ADIBO-PEG$_4$-amine (9-Boc) as yellow oil.

A solution of TFA (0.48 g, 4.2 mmol) in THF (15 mL) was added to a solution of **9-Boc** (1.8 g, 2.8 mmol) in THF (30 mL) at rt. The reaction mixture was stirred overnight, and the solvent was removed under reduced pressure. The residue was purified by chromatography (CH_2Cl_2/MeOH 10:1 to 10:4) to provide 1.15 g (2.2 mmol, 79%) of ADIBO-PEG$_4$-amine (**9**) as slightly yellow oil. ^{1}H NMR (500 MHz): δ 7.67 (d, J = 7.5 Hz, 1 H), 7.43−7.34 (m, 5 H), 7.31 (t, J = 7.5 Hz, 1 H), 7.29−7.24 (m, 1 H), 6.95−6.88 (m, 1 H), 5.13 (d, J = 14 Hz, 1 H), 4.45−4.2 (br s, 2 H), 3.7−3.5 (m, 22 H), 3.37−3.2 (m, 3 H), 2.68 (t, J = 5 Hz, 2 H), 2.57−2.42 (m, 1 H), 2.4−2.32 (m, 2 H), 2.02−1.92 (1 H). ^{13}C NMR (100 MHz, $CDCl_3$): 172.13, 171.21, 151.20, 148.16, 129.3, 129.2, 128.78, 128.44, 128.31, 127.9, 127.29, 127.25, 125.68, 123.16, 122.55, 114.81, 107.92, 70.46, 70.39, 70.35, 70.32, 70.30, 70.26, 70.1, 55.62. 48.86, 36.69, 35.41, 34.67. HRMS (ESI+) m/z calcd for $C_{29}H_{38}N_3O_6$ [M+H] 524.2761, found 524.2756. (Note: Integration of ^{1}H spectra of compounds containing PEG commonly overestimates the number of protons due to the presence of tightly bound water and/or hydroxylic solvents.)

Cleaning and Activation of Glass Slide Surfaces. All glass slides were sonicated for 30 min in methanol, rinsed with acetone, and dried in an oven at 145 °C for 1 h. Piranha solution (90 mL) was prepared by the addition of H_2O_2 (25 mL of 35% v/v) in one portion to 65 mL of conc H_2SO_4 in a 100 mL Pyrex beaker, which was kept in a water bath (**Caution:** Piranha solution reacts violently with organic compounds and should be handled with extreme care. Wear thick plastic gloves, lab coat, and safety glasses. Any piranha solutions should be handled in a fume hood at all times). The solution was carefully stirred with a glass rod, followed by inserting glass slides into the solution. After 1 h, slides were removed from the solution and rinsed with copious amounts of distilled water, then acetone, and dried in an oven for 20 min at 145 °C. Glass slides prepared in this fashion were submitted to derivatization procedures immediately.

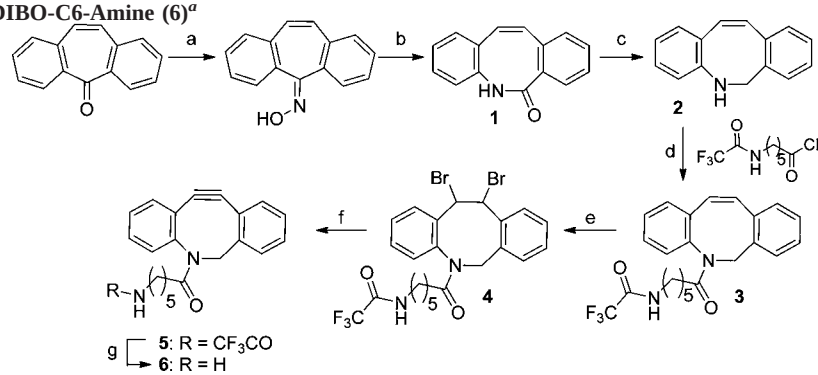
Preparation of Epoxy-Derivatized Glass Slides. Freshly activated glass slides were immersed in a solution of freshly distilled (3-glycidyloxypropyl)dimethoxy-methylsilane (1% v/v) and DIEA (1% v/v) in dry toluene (100 mL) at 25 °C for 16 h. Slides were sonicated two times in methanol for 15 min, thoroughly rinsed with acetone, and dried under a stream of nitrogen.

Preparation of Aza-dibenzocyclooctyne (ADIBO, 6)-Coated Glass Slides. Freshly prepared epoxy-coated glass slides were placed in a solution of aza-dibenzocyclooctyne amine **6** (75 mg) and DIEA (1 mL) in DMF (100 mL) and incubated overnight at rt. Slides were then rinsed with acetone, sonicated for 15 min in methanol, rinsed with acetone, and dried under a stream of nitrogen.

Preparation of Azide-Coated Glass Slides. Freshly prepared epoxy-coated glass slides were immersed in a solution of 6-azidohexylamine (1 mL) and DIEA (1 mL) in DMF (100 mL) overnight at rt. The slides were then sonicated for 15 min in methanol, rinsed with acetone, and dried under a stream of nitrogen.

Patterned Derivatization of Glass Slides with Aza-dibenzocyclooctyne 6. One microliter drops of a 10 mM PBS solution of dibenzocyclooctyne **6** were spotted using a micropipet on a freshly prepared epoxy-coated slide, followed by incubation in a humidity chamber containing PBS buffer for 12 h at rt. The slide was washed with copious amounts of acetone, then water, and sonicated in DMF for 30 min.

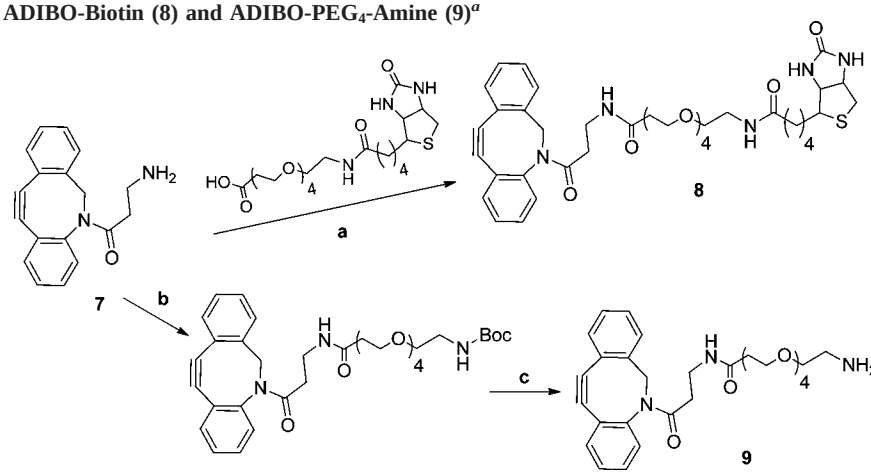
Patterned Immobilization of Fluorescent Dyes on ADIBO-Coated Slides. Solutions of Oregon green azide (**13**, 0.1 mM and 1 mM in PBS) or Lissamine rhodamine B azide (**14**, 0.1 mM) were spotted using a pipet (2 μL) on a freshly prepared dibenzocyclooctyne plate and incubated in a humidity chamber for various periods of time (vide infra). Slides were rinsed with acetone, then sonicated for 15 min in methanol, rinsed with acetone, and dried under a stream of nitrogen.



Patterned Immobilization of Avidin on ADIBO-Coated Slides. One microliter drops of biotin-dPEG3+4-azide PBS solutions of different concentrations (10 mM, 1 mM, and 0.1 mM) were spotted on a ADIBO-coated glass slide. Slides were incubated in a humidity chamber for 1 h at rt, rinsed with copious amounts of acetone, then water, and sonicated in DMF for 30 min. Slides were then immersed in a blocking solution containing 1% aminoPEG$_4$azide in DMF and incubated overnight at rt. The slides were then rinsed with acetone, sonicated in DMF for 30 min, and rinsed with distilled water, followed by immersion into a solution of avidin-FITC (50 μL of 2 mg/mL in 10 mL of PBS) at 2 °C for 15 min. The slides were sonicated in PBS containing 0.1% Tween 20 for 30 min, washed with distilled water, incubated in PBS containing 0.1% of BSA for 12 h at 2 °C, sonicated again in PBS (1% of Tween 20) for 30 min, and rinsed with distilled water.

Patterned Immobilization of Fluorescent Probes on Azide-Coated Slides. One microliter drops of 1 mM of ADIBO-fluor (**10**) solution in PBS were spotted on an azide plate, followed by incubation in a humidity chamber for 12 h at rt. Slides were rinsed with acetone, then sonicated for 15 min in methanol, rinsed with acetone, and dried under a stream of nitrogen.

For two-color derivatization, azide-coated slides patterned with ADIBO-fluor (**10**) spots as described above were immersed in a solution of ADIBO-Rhodamine (**12**, 1 mM in PBS) and incubated for 3 h at rt. Slides were rinsed with acetone, then sonicated for 15 min in methanol, rinsed with acetone, and dried under a stream of nitrogen.



Patterned Immobilization of Avidin on Azide-Coated Slides. One microliter drops of ADIBO-biotin (**8**) solutions of different concentrations (10 mM, 1 mM, 0.1 mM, and 0.01 mM in PBS) were spotted on an azide-coated glass slide. Slides were incubated in a humidity chamber for 1 h at rt, rinsed with copious amounts of acetone, then water, and sonicated in DMF for 30 min. Slides were then immersed in a blocking solution containing 0.1% ADIBO-PEG4-amine (**9**) in DMF and incu-

[a] Reagents and conditions: (a) $NH_2OH.HCl$, pyridine, 60%; (b) PPA, 125 °C, 73%; (c) $LiAlH_4$, ether, 58%; (d) pyridine, CH_2Cl_2, 71%; (e) pyridinium tribromide, 78%; (f) *t*-BuOK, THF, 88%; (g) K_2CO_3, aq MeOH, 58%.

Scheme 2. Synthesis of ADIBO-Biotin (8) and ADIBO-PEG_4-Amine (9)[a]

[a] Reagents and conditions: (a) HBTU, DIEA, CH_2Cl_2, 89%; (b) Boc-NH-$(CH_2CH_2O)_4$-$CH_2CH_2CO_2H$, EDC, DIEA, CH_2Cl_2, 80%; (c) TFA, THF, 79%.

bated overnight at rt. The slides were rinsed with acetone, sonicated in DMF for 30 min, and rinsed with distilled water, followed by immersion into a solution of avidin-FITC (50 μL of 2 mg/mL in 10 mL PBS) at 2 °C for 15 min. The slides were sonicated in a PBS solution containing 0.1% Tween 20 for 30 min, washed with distilled water, incubated in PBS containing 0.1% BSA for 12 h at 2 °C, sonicated again in PBS (1% Tween 20) for 30 min, and rinsed with distilled water.

Preparation of ADIBO-Coated Magnetic Beads. A solution of ADIBO−biotin conjugate (**8**) (25 μL, 10 mM in PBS) was added to a suspension of streptavidin-coated magnetic beads (25 μL of 10 mg/mL) in 450 μL PBS. The resulting mixture was stirred by shaking for 2 h at rt. The reaction mixture was centrifuged at 11 000 rpm for 2 min, the supernatant liquid was decanted, and the pellet resuspended in PBS (450 μL). The washing step was repeated two times.

Preparation of Azide-Coated Magnetic Beads. A solution of Biotin-dPEG3+4-azide (25 μL, 10 mM in PBS) was added to a suspension of streptavidin-coated magnetic beads (25 μL of 10 mg/mL) in 450 μL PBS. The resulting mixture was stirred by shaking for 2 h at rt. The reaction mixture was centrifuged at 11 000 rpm for 2 min, the supernatant liquid was decanted, and the pellet resuspended in PBS (450 μL, pH 7.4). The washing step was repeated twice.

Fluorescent Labeling of ADIBO-Coated Magnetic Beads. A solution of Oregon Green-azide (**13**) (10 mM in PBS) was added to a suspension of ADIBO-coated magnetic beads (25 μL of 10 mg/mL) and incubated for 3 h at rt. Beads were centrifuged at 11 000 rpm for 1 min, the supernatant liquid was decanted, and the pellet was resuspended in 450 μL PBS containing 0.1% Tween 20, centrifuged, washed with PBS, centrifuged, and resuspended in 450 μL PBS for fluorescent microscopy imaging.

Fluorescent Labeling of Azide-Coated Magnetic Beads. A solution of ADIBO-fluor (**10**, 25 μL of 10 mM in PBS) was added to a suspension of azide-coated magnetic beads (25 μL of 10 mg/mL) in 450 μL PBS and incubated for 3 h at rt. Beads were centrifuged at 11 000 rpm for 1 min, the supernatant liquid was decanted, and the pellet was resuspended in 450 μL PBS containing 0.1% of Tween 20, centrifuged, washed with PBS, centrifuged, and resuspended in 450 μL PBS for fluorescent microscopy imaging.

RESULTS AND DISCUSSION

Synthesis of Aza-dibenzocyclooctyne−Amine Conjugate (ADIBO-amine, 6). The efficient preparation of ADIBO-amine developed in our lab is outlined in Scheme 1. It starts with the polyphosphoric acid-catalyzed Beckman rearrangement of dibenzosuberenone oxime, which is readily prepared by treating commercially available dibenzosuberenone with hydroxylamine. The lactam **1** produced in this reaction is then reduced with lithium aluminum hydride to give dihydrodibenzo[*b*,*f*]azocine (**2**). The secondary amino group in **2** is converted to amide **3** by reacting with 1.25 equiv of 6-(trifluoroacetamido)hexanoyl chloride in the presence of pyridine. The olefin in **3** is smoothly converted into an acetylene moiety via a bromination−dehydrobromination procedure to give aza-dibenzocyclooctyne **5** in excellent yield (88%). Saponification of the trifluoroacetamide moiety with potassium carbonate in aqueous methanol gives

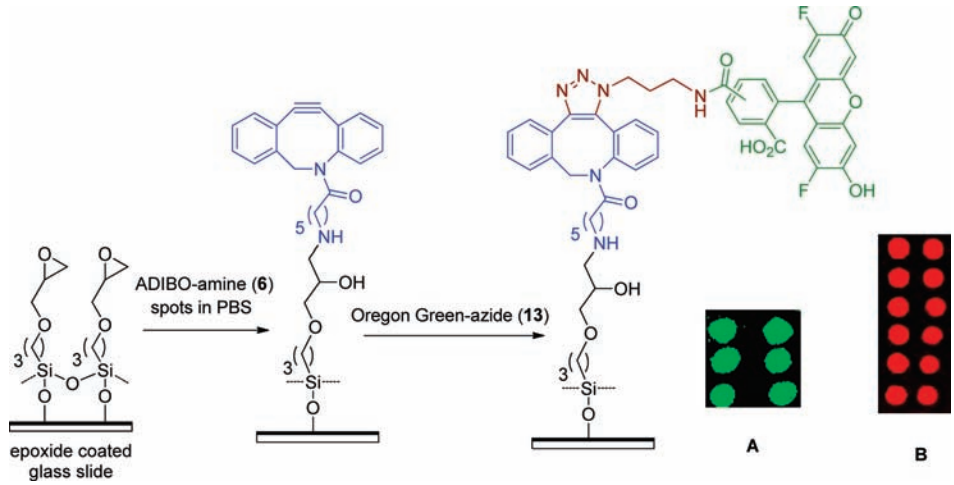

Figure 1. Schematic representation of ADIBO derivatization of an epoxy-coated slide followed by copper-free click immobilization of Oregon green dye. Inserts show fluorescent images ADIBO slides patterned with (A) Oregon green azide (**13**) and (B) Lissamine rhodamine B azide (*14*).

target ADIBO-C6-amine (**6**). ADIBO-amine with a shorter aminoakyl side chain, ADIBO-C3-amine (**7**), was prepared following the same synthetic sequence by replacing 6-(trifluoroacetamido)hexanoyl chloride in step "d" with 3-(trifluoroacetamido)propionyl chloride.

Aza-dibenzocyclooctyne−Biotin Conjugate (ADIBO-biotin, 8). 8 was prepared by HBTU (1-[bis(dimethylamino)methylene]-1*H*-benzotriazolium-3-oxide hexafluorophosphate)-promoted coupling of ADIBO-C3-amine (*7*) with biotin-PEG4-acid (Scheme 2). EDC-induced coupling of compound **7** with *N*-Boc-15-amino-4,7,10,13-tetraoxapentadecanoic acid, followed by trifluoroacetic acid-catalyzed removal of *N*-Boc protection gave Aza-dibenzocyclooctyne-PEG_4-amine (ADIBO-PEG_4-amine, **9**, Scheme 2).

ADIBO and Azide Functionalization of Glass Slides. Derivatization experiments were performed on glass surfaces due to the ready availability, low cost, high mechanical stability, low intrinsic fluorescence, and easy surface modification techniques of the glass substrate. Freshly prepared epoxide-coated slides were incubated in a DMF solution of ADIBO-amine **6** or 6-azidohexylamine in the presence of Hünig's base (*N*-ethyl-*N*,*N*-diisopropylamine) overnight and washed with acetone, then methanol (Figures 1 and 5).
