Alkyne–Azide Click Patterning. Recently, Bowman and co-workers demonstrated 3D patterning of hydrogels via pCuAAC.[32] The transient generation of Cu(I) facilitates spatial and temporal control of the CuAAC reaction. PEG hydrogels were first synthesized by a thiol-yne reaction, ensuring a stoichiometric excess of alkynes. Postgelation, a solution of photoinitiator (Irgacure 2959), copper sulfate, and an azide-labeled fluorophore was swollen into the gel. Upon irradiation with a photomask, Cu(I) is generated within the irradiated areas, catalyzing the pCuAAC reaction between the azide-fluorophore and the pendant alkynes in the polymer network, ultimately producing a spatially defined fluorescent pattern within the hydrogel. The authors note that future work is required to translate this system to biological systems.

Thiol–Ene Click Patterned Scaffolds. Immobilization of bioactive growth factors via thiol conjugation has become increasingly popular given the ease of cysteine incorporation within a peptide, making the thiol–ene click reaction particularly relevant for 3D patterning. Anseth and co-workers developed a sequential click protocol relevant to both hydrogel synthesis and postgelation modification.[30,31,74] Click cross-linked PEG hydrogels were first formed via CuAAC, as an extension of the method taken by Malkock et al.[22] To enable photopatterning of their PEG hydrogels, multifunctional photoreactive polypeptide sequences were included within the network structure by incorporating the non-natural amino acid, Fmoc-Lys(alloc)-OH.[74] The allyloxycarbonyl (alloc) protecting group contains a vinyl functional group capable of reacting with any thiol-containing compound, such as cysteine. Upon exposure to UV light, thiyl radicals are generated via the photocleavage of a hydrogen-abstracting initiator, thereby using light to achieve spatial and temporal control of thiol–ene functionalization within the network. To illustrate this technique, a fluorescently labeled cysteine containing peptide was patterned within PEG hydrogels via transparency-based photolithographic patterning techniques.

This thiol−ene photopatterning method was later employed to immobilize peptides and proteins within PEG hydrogels cross-linked via SPAAC (Figure 4).[30] Spatial and temporal

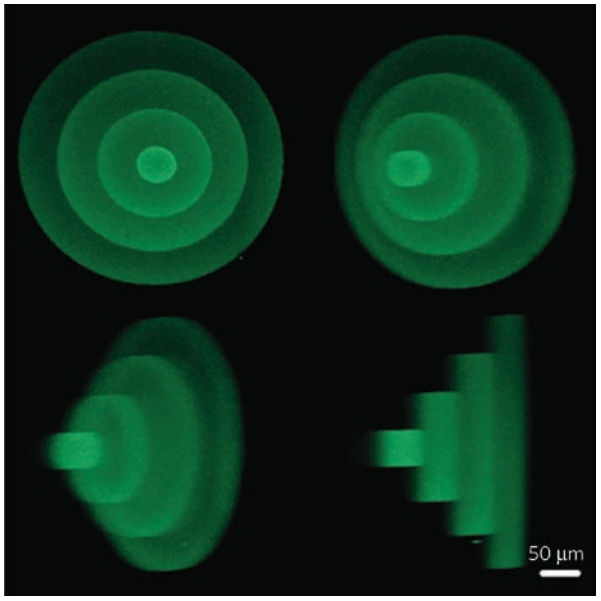

Figure 4. 3D biochemical patterning of PEG hydrogels via thiol−ene photocoupling.[30] Fluorescently tagged peptides were patterned within SPAAC cross-linked networks. (Copyright Macmillan Publishers Limited, reproduced with permission.[30])

control was validated by selectively exposing certain locations within the hydrogel matrix to light, and by controlling light intensity and exposure time. Furthermore, the thiol−ene reaction was confirmed to be cytocompatible, as 3T3 cells encapsulated within the hydrogel maintained high viability throughout patterning (>90% at 24 h post encapsulation), and thiol−ene immobilization of RGD within the network was shown to influence cell morphology. In a follow-up study, DeForest et al. verified that patterning concentration within the hydrogel is directly proportional to the dosage of light, as well as the photoinitiator concentration.[31] Using this system, they were able to construct well-defined 3D biochemical gradients of multiple peptides, offering potential promise to elucidate fundamental biological processes essential to regenerative medicine such as induced cell migration.

Thiol−Maleimide Click Patterning. The thiol−maleimide reaction exemplifies a variation of the thiol-Michael click reaction. Shoichet and co-workers have exploited this click reaction for 3D patterning of agarose hydrogels.[68,72,75,76] Covalent modification of agarose with S-2-nitrobenzyl-cysteine (S-NBC) renders a photolabile matrix, which upon UV irradiation releases free thiols capable of reacting with any thiol-reactive biomolecule through Michael addition. Thiol channels were created on exposure to a focused laser beam, and reacted with a maleimide-terminated RGD peptide. This immobilized RGD channel volume promoted neurite extension and cell migration.[72] This system was also applied to study the effect of immobilized platelet derived growth factor AA (PDGF-AA) on neural stem/progenitor cell (NSPC) differentiation.[68] Hydrogels with immobilized RGD and PDGF-AA supported NSPC adhesion and preferential differentiation to oligodendrocytes.

In order to advance this click technology toward more sophisticated architectures that better mimic the native extracellular matrix, agarose was later modified with a coumarin derivative, which upon exposure to a pulsed infrared laser yields free thiols.[75] The use of this photolabile group allows for intricate 3D control by way of multiphoton excitation. Aizawa et al. exploited this coumarin multiphoton patterning technique to immobilize a gradient of the angiogenic factor, VEGF165, within agarose hydrogels.[76] Primary endothelial cells responded to this immobilized gradient by displaying tip and stalk cell morphology, eventually forming tubule-like structures as they migrated in response to the VEGF gradient (Figure 5).

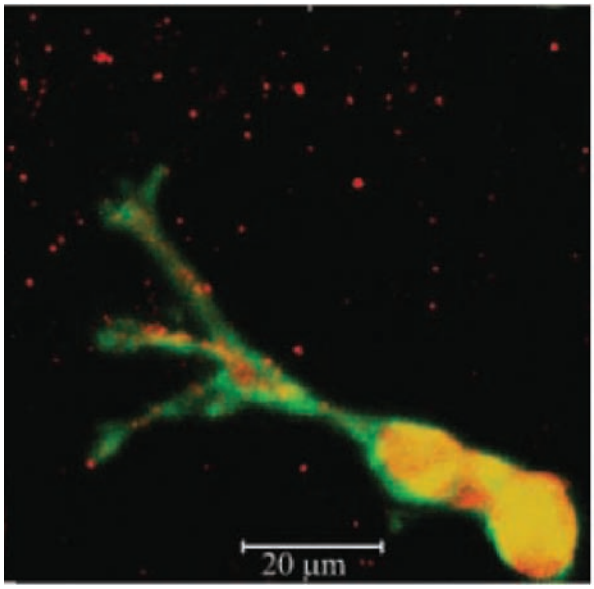

Figure 5. Primary endothelial cells guided in 3D patterned agarose hydrogel.[76] VEGF165 was immobilized in a concentration gradient within the scaffold using the thiol-maleimide click reaction. (Copyright Wiley-VCH Verlag GmbH & Co. KGaA; reproduced with permission.[76])

The "click" nature of thiol addition to a maleimide unit was also exercised by Kosif et al.[77] with the immobilization of proteins in PEG-methacrylate based hydrogels. Hydrogel synthesis was achieved using AIBN initiated thermal polymerization, by which they directly incorporated a furan-protected maleimide containing monomer. This furan-protected maleimide represents a DA adduct which is susceptible to thermal cycloreversion. Postgelation, a thermal cycloreversion step activated the maleimide group to its thiol-reactive form. To evaluate this system as a potential template for bioconjugation, thiolated-biotin was covalently attached to the hydrogels, and its affinity for streptavidin investigated. This system is particularly intriguing as it incorporates the retro-DA click reaction, which is not commonly applied in regenerative biomaterials.

■ CONCLUDING REMARKS

Click chemistry has long been recognized as a powerful tool within biotechnology applications, and has since begun to gain popularity for the preparation of functionalized materials applicable in regenerative medicine strategies. These elegant, versatile reactions represent attractive building blocks for engineered hydrogel networks, decorated 2D cell culture

surfaces, and patterned 3D biomimetic scaffolds. Click chemistry is particularly compelling for hydrogel formation and modification because it is water-based chemistry. Moreover, the click reaction provides impeccable control over the conformation of the protein or peptide immobilized, thereby maximizing its bioactivity. With the formation of stable covalent bonds, one can be confident of a well-defined system with which to study cellular response.

Each click reaction, however, has limitations that warrant consideration. The obvious shortcoming of CuAAC is the copper requirement. Copper has been shown to be cytotoxic, and increased copper intake has been linked to hepatitis, Alzheimer's disease, and other neurological disorders.[78] Another disadvantage of CuAAC is alkyne homocoupling. Although rare, alkynes may react with another alkyne instead of an azide.[9] The evolution of SPAAC has played a substantial role in catalyzing the development of click reactions beyond CuAAC; however, the difluorinated cyclooctynes can be difficult to synthesize[14] thereby complicating what would normally be a simple reaction. Collaboration between chemists and bioengineers, as well as increased commercial access to starting materials, will overcome some of these synthetic limitations.

The DA click cycloaddition is a "reagent-free" click reaction that does not require catalyst, photoinitiator, or radical initiation. Moreover, the DA reaction is accelerated in aqueous solutions, an ideal characteristic for biomaterial design. Despite these strengths, the DA click reaction has been much less explored relative to the CuAAC and thiol-click reactions, perhaps due to longer reaction times. Although it has not been specifically reported, the reaction time for the formation of HA hydrogels via Diels–Alder click chemistry is likely greater than 8 h since hydrogels are allowed to form overnight.[42] The rate of reaction can be accelerated with heat or photoinitiation if required. DA adducts can also undergo cycloreversion, but this is only relevant at higher temperatures, and thus should not pose a problem to biomaterials used *in vitro* or *in vivo*.

Recently, the thiol–click reaction has emerged as a prominent reaction within the field of regenerative biomaterials, particularly as a tool for protein conjugation, given the simplicity of immobilization via functional groups common to proteins. However, it is difficult to control protein immobilization via thiol-Michael addition due to cross-reactivity. In terms of 3D patterning, this can be avoided by spatially controlling where free thiols are exposed within a photolabile matrix using two-photon laser technology. The anionic chain process of thiol-Michael click reactions is thought to reduce its efficiency and rate. On the other hand, the photoinitiated thiol–ene click reaction occurs by free-radical addition, offering enhanced spatial and temporal control. However, this method often requires a photoinitiator, which can be cytotoxic and hence reduce the biocompatibility of the material. Finally, free thiols are susceptible to disulfide bond formation via oxidation, which further limits the efficiency of thiol–ene click reactions.

What other bioorthogonal reactions are likely to emerge within the field of regenerative medicine? Popik and co-workers have recently developed a photoinducible azide–alkyne cycloaddition reaction circumventing the copper catalyst requirement.[82] Generation of a dibenzocyclooctyne from a photoprotected cyclopropenone provides spatial and temporal control over the reaction under ambient conditions. While this chemistry has not been applied to biomaterials to date, use of this reaction would harness spatial and temporal control to the already bioorthongal reactants without the use of a copper catalyst. A highly effective click reaction for protein immobilization is the Staudinger ligation.[83] The simple nature of this chemistry makes it an excellent candidate for the synthesis of 2D substrates used to study stem cell proliferation/differentiation. While we have reviewed several examples of thiol–ene and thiol–Michael click reactions applied to regenerative biomaterials, the thiol–yne reaction not yet been tested in regenerative medicine. This reaction is capable of consecutive reaction with two thiol functional groups.[84] Application of this chemistry to hydrogel synthesis would provide scaffolds with high cross-link densities. Finally, while not traditionally defined as "click", the orthogonal chemistry of peptide binding pairs has recently been used to design hydrogels with 3D immobilized proteins.[85] Physical binding pairs, barnase–barstar and streptavidin–biotin, were exploited to simultaneously immobilize differentiation factors within an agarose hydrogel. Application of this technology in the future will avoid multistep protocols, while preserving protein bioactivity.

In a short period of time, the use of click chemistry within the field of regenerative medicine has exploded. The ability to synthesize biomaterials with pristine definition and architecture to ultimately control cell fate is unprecedented. To this day, click reactions continue to evolve with the identification of new orthogonal chemistries. Bioengineers will continue to translate these improved chemoselective methodologies to their regenerative materials. Already, we have seen a considerable increase in the use of click reactions for biochemically patterning 3D hydrogels, which we anticipate will increase further. Sequential click reactions will likely emerge as a key approach to design sophisticated biomaterials in a simplistic manner.

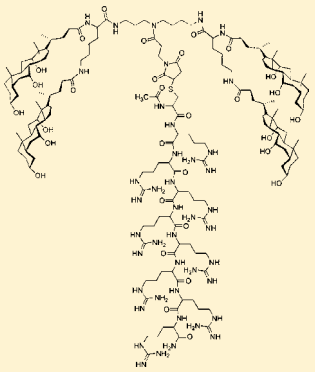
Supporting Information

ABSTRACT: A series of diwalled and tetrawalled molecular umbrellas have been synthesized using cholic acid, spermidine, and lysine as starting materials. Coupling of these molecular umbrellas to an octaarginine peptide afforded agents that were capable of promoting the transport of small interfering RNA to HeLa cells, as judged by the knockdown of enhanced green fluorescent protein expression. The efficiency of this knockdown was found to increase with an increasing number of facially amphiphilic walls present, and also when a cleavable disulfide linker was replaced with a noncleavable, maleimido moiety; i.e., a group that is not susceptible to thiolate-disulfide interchange. The knockdown efficiency that was observed for one tetrawalled molecular umbrella–octaargine conjugate was comparable to that observed with a commercially available transfection agent, Lipofectamine 2000, but the conjugate showed less cytotoxicity.



The ability of small interfering RNA (siRNA) to silence gene expression has generated considerable interest in recent years because of its potential as a chemotherapeutic agent and a biological tool.[1−4] One of the major goals in this area has been to improve the delivery of siRNA directly to the cytosol to allow for more efficient incorporation into the RNA-induced silencing complex (RISC), a key step in the silencing process.[2] To date, most approaches that have been used to deliver siRNA appear to rely on endocytotic pathways. Because endosomal release is known to be inefficient, a more direct means of delivery would be highly desirable. In particular, if siRNA could be transported into the cytosol via passive diffusion, significant improvement in their efficacy should be possible. With this ultimate goal in mind, we have begun to explore molecular umbrellas as delivery agents for siRNA.[5] Here, we report our results with first-generation molecular umbrellas bearing a pendant octaarginine peptide moiety for binding to siRNA.

As discussed elsewhere, molecular umbrellas are conjugates composed of two or more facial amphiphiles (i.e., "walls") that are attached to a central scaffold.[5] When immersed in a hydrophilic environment, these molecules create a hydrophilic exterior. Conversely, when immersed in a hydrophobic environment, they create a hydrophobic exterior. Recently, we have shown that the transport properties of molecular umbrellas in model membranes do not follow the classic size/lipophilicity rule.[6] Specifically, bilayer transport rates were found to increase with increasing numbers of umbrella walls and increasing facial hydrophilicity. This is exactly the opposite of what is expected on the basis of existing drug transport theory.[7] In addition, we and other researchers have shown that molecular umbrellas can readily enter live HeLa cells and that passive transport may play a significant role in this entry.[8,9] On the basis of these features, molecular umbrellas offer an opportunity for promoting the passive transport of biologically active agents across cell membranes in ways that have not previously been possible.

As a first step in exploring molecular umbrellas for siRNA delivery, we examined a series of molecular umbrella–octaarginine conjugates for their ability to reduce (i.e., "knock down") gene expression of enhanced green fluorescent protein (eGFP) in HeLa cells. Octaarginine was chosen because of its contiguous array of positive charges for binding to siRNA through electrostatic interactions and hydrogen bonding. Our working hypothesis was that such conjugates would create a "slide" within a plasma membrane for the passage of siRNA and/or a "sheath" that shields the siRNA as it crosses the bilayer (Figure 1). A related mechanism that can also be envisioned is one in which the conjugates act like "ferries" to shuttle the cargo across the membranes (not shown). In this study, our primary aim was fourfold: (i) to determine whether molecular umbrella–octaarginine conjugates can promote siRNA-induced knockdown of eGFP expression beyond that of octaarginine itself, (ii) to test whether knockdown efficiency

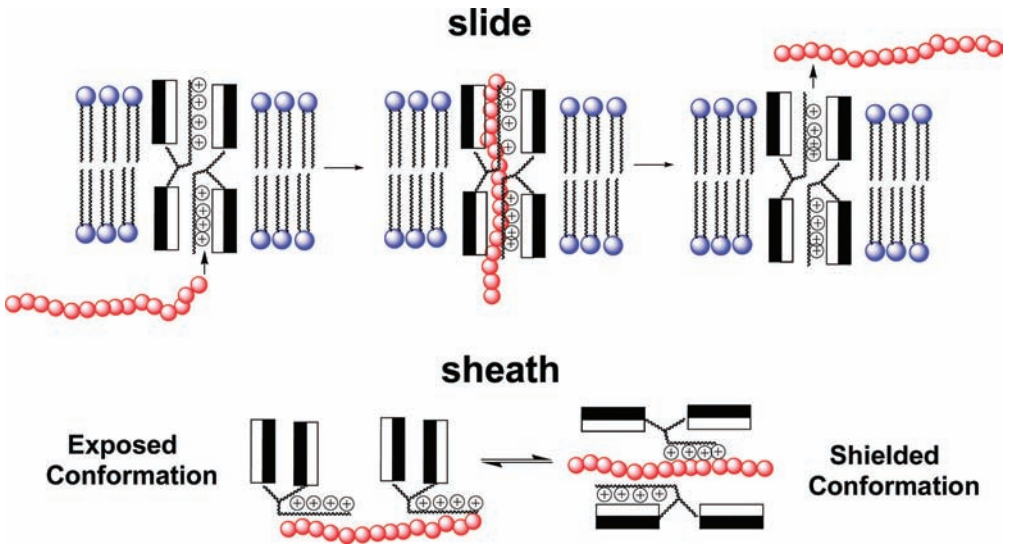

Figure 1. Hypothetical slide created by two diwalled molecular umbrella–oligoarginine conjugates inserting into a plasma membrane (top) vs a sheath (bottom), affording an exposed or shielded conformation. The black and white rectangles represent lipophilic and hydrophilic faces of the umbrella, respectively, and the red spheres represent individual units of the siRNA.

is dependent on the size of the umbrella that is used, (iii) to determine whether the introduction of a cleavable linker into a molecular umbrella–octaarginine conjugate can improve knockdown efficiency, and (iv) to judge the potential importance of a slide versus a sheath mechanism of delivery.[2]

With this purpose in mind, five agents were chosen as synthetic targets for this work, that is, conjugates **1**–**5** (Figure 2). Thus, comparison of **1** with **2** and comparison of **3** with **4** address the question of how umbrella size may influence siRNA delivery. Comparison of **1** with **3** and comparison of **2** with **4**, bearing a cleavable disulfide or a noncleavable maleimido moiety for conjugation, address the question of conjugate lability on knockdown efficiency. As a control for investigating the role that only the peptide portions of these conjugates play in siRNA delivery, we synthesized an octaarginine analogue (**5**), which contains a 2-mercaptoethanol moiety instead of a molecular umbrella. To place the knockdown efficiencies of these agents in perspective, we have compared them with that found using Lipofectamine 2000, a proprietary formulation that is widely used as a "gold standard" for transfection.

The synthetic method that was used to prepare conjugate **1** is shown in Scheme 1. In brief, Boc protection of the terminal amino groups of spermidine with 2-(Boc-oxyimino)-2-phenylacetonitrile (Boc-ON) to give **6**, followed by acylation with *N*-[*O*-1,2,3-benzotriazin-4(3*H*)onyl]-3-(2-pyridyldithio)-propionate (BPDP), afforded **7**.[10] Subsequent deprotection to give **8** followed by acylation with the *N*-hydroxysuccinimide ester of cholic acid (Ch-NHS) afforded **9**, which was then reacted with the free thiol form of **5** (designated as Pep-SH) to give **1**. The synthesis of **2** was conducted in a similar manner (Scheme 2). In this case, lysine dicholamide was first activated with *N*,*N*,*N*′,*N*′-tetramethyl-*O*-(*N*-succinimidyl)uronium tetrafluoroborate (TSU) and then used to acylate **8** to give **10**.[11] Conjugate **4** was synthesized by first acylating both terminal amino groups of spermidine with lysine dicholamide, followed by acylation of its secondary amine with 3-maleimidopropanoic acid and conjugated addition of Pep-SH (Scheme 3). The analogous diwalled conjugate, **3**, was synthesized by a similar route (note shown). Finally, the control peptide, **5**, was obtained by reacting Pep-SH with 2-(2-pyridyldithio)ethanol (not shown).

Using procedures described in the Supporting Information and 50 nM eGFP siRNA, knockdown efficiencies were determined with concentrations of **1**–**5** that varied from 100 to 2000 nM. In control experiments, in which HeLa cells were treated with only eGFP siRNA or with eGFP siRNA and **5**, no significant knockdown was observed (Figure 3). Because a primary aim of this work was to compare the efficacy of **5** with those of corresponding molecular umbrella conjugates under similar experimental conditions, no effort was made to find other conditions under which **5** shows significant activity, e.g., by using higher concentrations of **5**. In contrast, when the siRNA was first incubated with **1**, the extent of knockdown increased on going from 100 to 1000 nM; however, at a concentration of 2000 nM, the extent of knockdown was found to decrease. This corresponds to the concentration at which cytotoxicity began to occur. Similar results were observed with **2** except that the knockdown efficiency was found to be significantly greater (Figure 3). Thus, an increase in the number of umbrella walls resulted in a significant increase in transport activity.[6] Compared with that of Lipofectamine 2000, however, the ability of **2** to induce eGFP knockdown was significantly weaker. Also reported in Figure 3 are the corresponding cytotoxicities of these delivery agents, as determined by a standard MTS assay. None of the conjugates displayed any decrease in cell viability until a concentration of 1000 nM was reached. This can be compared to the case of Lipofectamine 2000, which shows 76.8% cell viability using optimal conditions described by the manufacturer.

To judge the consequences that a cleavable linker has on molecular umbrella-assisted transport of siRNA, we examined the relative activities of **3** and **4** (Figure 4). Similar to **1**, the diwalled analogue **3** showed very low activity. However, for the tetrawalled conjugate that contained the maleimido linkage (i.e., **4**), its activity was significantly greater than that of its cleavable counterpart, **2**, and it compared favorably to that of Lipofectamine 2000. Control experiments conducted with **4**, alone, showed no knockdown and no cytotoxicity at 500 nM.

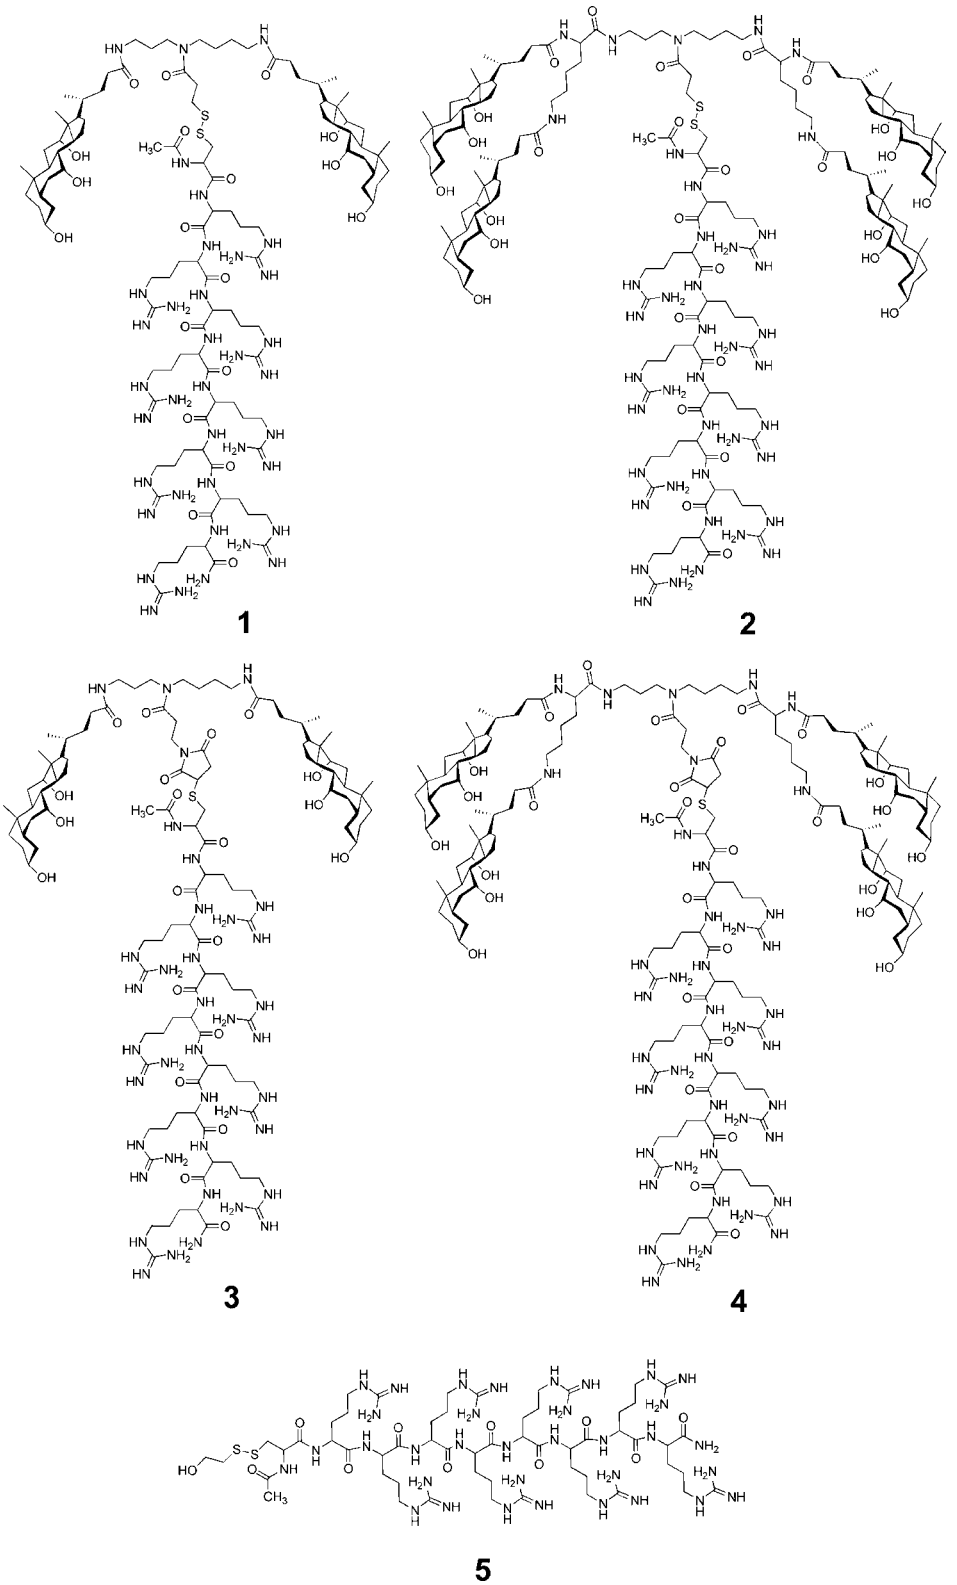

Figure 2. Molecular structures of umbrella−octaarginine conjugates **1**−**4** and control peptide **5**.

Although we hypothesized that the cleavable analogues might exhibit greater activity because of a greater ability to release siRNA into the cytoplasm, the exact opposite was observed. We presently suspect that cleavage on the outer surface of the HeLa cells via neighboring cysteine groups of membrane proteins may be responsible for this difference. It is also noteworthy that under optimized conditions (i.e., using 500 nM molecular umbrella conjugate), **4** exhibited no significant decrease in cell viability, whereas the use of Lipofectamine 2000 resulted in a moderate decrease in cell viability.

In an effort to judge the potential importance of a slide versus a sheath mechanism of transport, we conducted

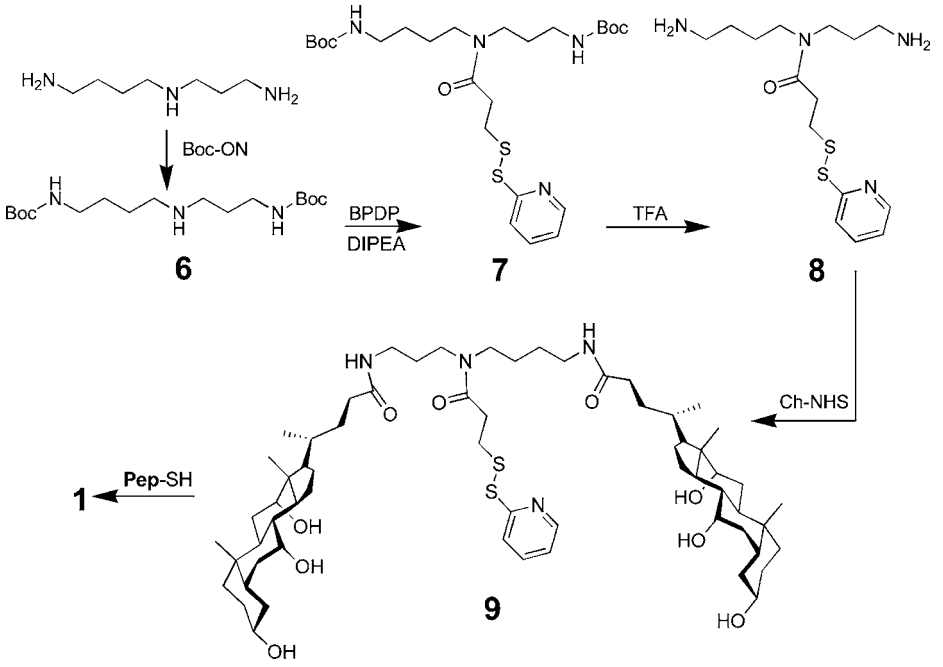
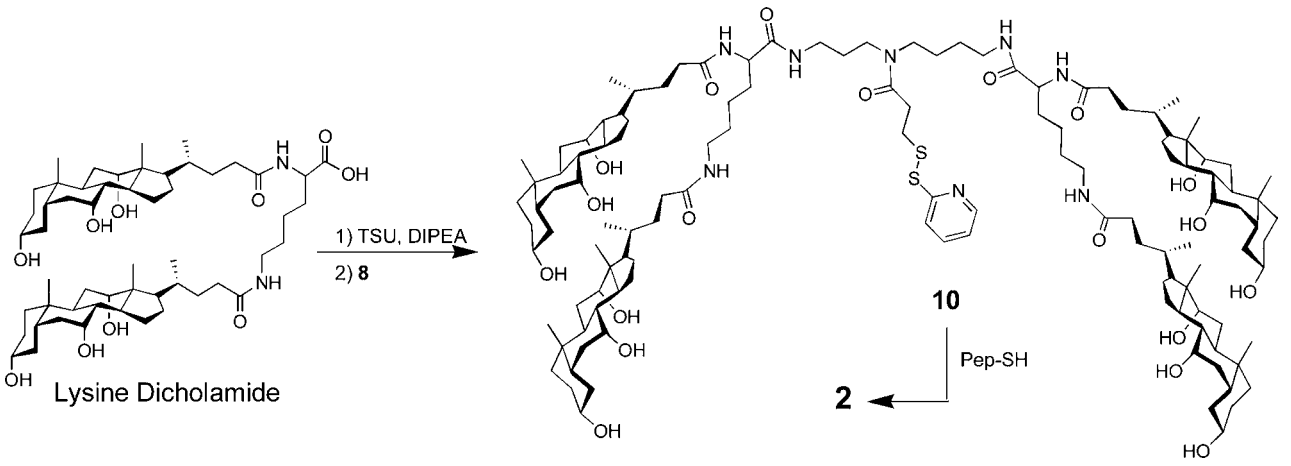


Scheme 2. Synthesis of 2



knockdown experiments with **4** in two different ways: (i) by incubating HeLa cells with the conjugate prior to the addition of siRNA and (ii) by incubating **4** with the siRNA followed by incubation with the HeLa cells. As shown in Figure 5, the latter (where the umbrella conjugate is premixed with the eGFP siRNA) clearly results in a greater knockdown efficiency. These results suggest that contributions from a sheath mechanism of delivery are likely to be more important than those from a slide mechanism (Figure 5).

To judge the consequences that a cleavable linker has on molecular umbrella-assisted transport of siRNA, we examined the relative activities of **3** and **4** (Figure 4). Similar to **1**, the diwalled analogue **3** showed very low activity. However, for the tetrawalled conjugate that contained the maleimido linkage (i.e., **4**), its activity was significantly greater than that of its cleavable counterpart, **2**, and it compared favorably to that of Lipofectamine 2000. Control experiments conducted with **4**, alone, showed no knockdown and no cytotoxicity at 500 nM.

These findings demonstrate the feasibility of applying molecular umbrella chemistry to siRNA transport. They also show that significant improvements are possible in the case of molecular umbrella–octaargine conjugates by increasing the number of umbrella walls and increasing the stability of the linker used to connect both components. The fact that the knockdown efficiency of **4** is at a level that is comparable to that of Lipofectamine 2000 while **4** exhibits reduced cytotoxicity provides considerable incentive for exploring molecular umbrellas more broadly in this context. It should be noted, in this regard, that this comparison is based on experiments in which HeLa cells were transfected for 4 h with the siRNA complexes in serum-free media prior to changing to serum-containing media. When serum was present throughout the entire course of the transfection, the activity of **4** was reduced by ~50% (Supporting Information). In contrast, serum had a negligible effect on the activity of Lipofectamine 2000. Whether further changes in the composition and structure of such molecular umbrella conjugates can minimize such reduction in activity remains to be established.

Efforts currently in progress are focused on (i) the synthesis of related conjugates in which the sense strand of a double-

stranded siRNA has been covalently attached to the handle of a molecular umbrella, thereby circumventing the need for a pendant octaarginine moiety, and (ii) gaining insight into the probable contributions made from passive transport and endocytotic pathways for cellular entry. The results of these studies will be reported in due course.

Supporting Information

Methods and Materials. ^{1}H NMR spectra were recorded in either CD_3OD or $CDCl_3$ using a Bruker 500 spectrometer and the solvent as a reference. Silica gel 60 (Fluka, particle size 0.035~0.070 mm, 220-440 mesh) was used for all column chromatographic purifications. Thin-layer chromatography (TLC) was performed on a glass plate precoated with silica gel and a fluorescence indicator (EMD). Detection on TLC was made by use of sulfuric acid 10% in water, iodine or UV (254 or 365 nm). All reagents and chemicals were obtained from commercial sources and used upon as received unless otherwise stated. All molecular umbrella-octaarginine conjugates were purified by preparative reverse phase (RP)-HPLC and characterized by ^{1}H NMR and high resolution mass spectrometry (HRMS).

High glucose containing Dulbecco's modified Eagle's medium (DMEM-H), DEPC-treated water, trypsin-EDTA solution, G 418 disulfate salt, and antibiotic antimycotic solution were purchased from Sigma Aldrich (St. Louis, MO). Lipofectamine™ 2000, fetal bovine serum (FBS), and OPTI-MEM reduced serum media were obtained from Invitrogen (Carlsbad, CA). **Pep**-SH (i.e., Ac-CRRRRRRRR-NH_2) was custom-

synthesized by GenScript USA, Inc. (Piscataway, N.J). Duplexed and desalted siRNA was purchased from ThermoScientific Dharmacon siRNA Technologies (Lafayette, CO) with the sense and antisense sequences 5'-GACGUAAACGGCCACAAGUdTdT and 5'-ACUUGUGGCCGUUUACGUCdTdT, respectively. HeLa cells that stably expressed enhanced green fluorescent protein (HeLa eGFP cells) were obtained from Professor Juliano's laboratory (University of North Carolina, Chapel Hill, NC). The cells were maintained in normal growth medium containing DMEM-H with 10% FBS, 400 µg/mL G 418, and 1% antibiotic antimycotic solution and grown at 37°C and 5% CO_2. A Cell Titer 96 Aqueous non-radioactive cell proliferation assay (MTS assay) was purchased from Promega (Madison, WI).

Boc-protected Spermidine (6). To a solution that was prepared from 0.26 g (1.79 mmol) of spermidine, 15 mL of CH_3OH and 0.545 g (5.38 mmol) of triethylamine was added 0.974 g (3.96 mmol) of 2-(Boc-oxyimino)-2-phenylacetonitirile) ("Boc-ON"). After stirring the resulting solution at room temperature for 24 h, the solvent was then removed under reduced pressure. Subsequent purification of the residue by column chromatography [silica gel, using a gradient starting from $CHCl_3/CH_3OH$ (10/1, v/v) and ending in $CHCl_3/CH_3OH/NH_4OH$ (75/20/3, v/v/v)] afforded 310 mg (50 %) of **5** having ^{1}H NMR (500 MHz, CD_3OD, 298K): 3.19(m,2H); 3.11(t,2H); 2.66(m,2H); 2.60(m,2H); 1.64(m,2H); 1.52(m,4H); 1.44(bs,18H).

Conjugate 7. To a solution that was made from 155 mg (0.45 mmol) of **6**, 2 mL of DMF and 156 µL (0.9 mmol) of N,N-diisopropyl-N-ethylamine (DIPEA) was added 162 mg

(0.9 mmol) of *N*-[O-1,2,3-benzotriazin-4(3H) one-yl]-3,(2-pyridyldithio)propionate (BPDP), directly as solid. For the synthesis of BPDP, see: Sarinya Shawaphun, S.; Janout; V.; Regen; S. L. (1999) Transbilayer movement of molecular umbrellas. *J. Amer. Chem. Soc. 121,* 5860-5865.

After stirring this solution for 18 h at room temperature, the solvent was removed under reduced pressure. Subsequent trituration with aqueous $NaHCO_3$ followed by water, and purification by column chromatography [silica gel, $CHCl_3/CH_3OH/NH_4OH$ (300/10/1, v/v/v) afforded 123 mg (50 %) of **7** having ^{1}H NMR (500 MHz, CD_3OD, 298 K): 8.40 (d, 1H); 7.81(m,2H); 7.22(d, 1H); 3.35(t, 2H); 3.25(t, 2H); 3.05(m, 6H); 2.79(t, 2H); 1.68(m, 2H); 1.54(m, 4H); 1.42(d,18H).

Deprotection of 7 to give 8. Deprotection was carried out by dissolving 122 mg (2.25 mmol) of **7** in a solution made from 4.5 mL of $CHCl_3$ plus 1.5 mL of CF_3CO_2H (TFA), followed by stirring for 2.5 h at room temperature. Removal of the solvents under reduced pressure, followed by drying (16 h, 23°C, 1 mm Hg) afforded 76.8 mg (100%) of **8** having ^{1}H NMR (500 MHz, CD_3OD, 298 K): 8.45 (d, 1H); 7.88(m, 2H); 7.28(d, 1H); 3.47(t, 2H); 3.30(m, 2H); 3.09(t, 2H); 2.87(m, 6H); 1.90(m, 2H); 1.63(m, 4H).

Umbrella Conjugate 9. To a solution derived from cholic acid 200 mg (0.489 mmol), 3 mL of DMF and 65.7 mg (0.509 mmol) of DIPEA was added 156 mg (498 µmol) of N_1,N_1,N_2,N_2-tetramethyl-N-[O-succinimidyl]-uronium tetrafluoroborate TSU. After stirring the mixture for 2 h at room temperature, a solution of 83.3 mg (0.244 mmol) of **8** in 1.0 mL DMF and 0.4 mL (2.3 mmol) DIPEA was added and resulting solution stirred

for an additional 18 h at room temperature. Removal of solvents under reduced pressure at 50°C gave a crude product that was washed, sequentially, with 5% $NaHCO_3$ and water. The crude product was then dissolved in 5 mL of CH_3OH and this solution then added to 1% $NaHCO_3$ to precipitate a crude product. After centrifuging washing with water, and freeze drying, the product was purified by preparative thin layer chromatography [silica gel, $CHCl_3$/CH_3OH/water/NH_4OH (70/20/1, v/v/v/v) to give 199 mg (74%) of **9** having ^{1}H NMR (500 MHz, CD_3OD, 298K): 8.40 (d, 2H); 7.84(m, 2H); 7.23(d, 1H); 3.93(s, 4H); 3.78(d, 4H); 3.36(m, 8H); 3.18(m, 8H); 3.06(m, 2H); 2.78(m, 2H); 0.71-2.35(m, 138H); 0.70(s, 12H). This ^{1}H NMR spectrum was identical to that previously reported: Sarinya Shawaphun, S.; Janout; V.; Regen; S. L. (1999) Transbilayer movement of molecular umbrellas. *J. Amer. Chem. Soc. 121,* 5860-5865.

Umbrella-Peptide Conjugate 1. To a solution that was made from 6.5 mg (5.9 μmol) of **9** in 500 μL of CH_3OH was added solution of 9.10 mg (6.4 μmol) of **Pep**-SH in 500 uL of CH_3OH. After stirring at room temperature under an argon atmosphere for 48 h the mixture was subjected, directly, to purification by reverse phase HPLC [C18 column, 0.06% TFA in water/CH_3CN/$(CH_3)_2CHOH$] using a gradient that started with 80/10/35, v/v/v and ended with 5/10/85, v/v/v. Concentration under reduced pressure at 45°C, followed by freeze drying for 48 h afforded 12.0 mg (81%) of **1** having ^{1}H NMR (500 MHz, D_2O, 298 K) δ: 4.70 (t, 1H); 4.40 (m, 8H), 3.92(bs, 2H); 3.72(bs, 2H), 3.36 (m, 2H); 3.27(m, 4H), 3.12(bs, 16H), 3.08(m, 4H); 2.90 (m, 2H); 2.75 (m, 2H); 0.79-2.20 (m, 100H); 1.98 (s, 9H); 0.58(s, 6H); MALDI-TOF MS m/z (MH+) Calcd. for $C_{111}H_{204}N_{37}O_{19}S_2$: 2423.5570. Found: 2423.5488.

Synthesis of Conjugate 10. To a solution derived from lysine dicholamide 219 mg (0.236 mmol) and 3 mL of DMF was added 87.3 mg (250 µmol) O-3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl-N,N,N',N'-tetramethyl-uronium tetrafluoro borate (DBTU) and 37.5 mg (0.290 mmol) of DIPEA. After stirring the mixture for 3 h at room temperature, a solution of 36.9 mg (0.108 mmol) of **8** in 1.5 mL of DMF and 0.2 mL (1.15 mmol) of DIPEA was added and resulting solution stirred for an additional 18 h at room temperature. Removal of solvents under reduced pressure at 50°C gave a crude product that was washed, sequentially, with 5% $NaHCO_3$ and water. The crude product was then dissolved in 5 mL of CH_3OH and this solution then added to 1% $NaHCO_3$ to precipitate crude product. After centrifuging, washing with water, and freeze drying, the product was purified by preparative thin layer chromatography [silica gel, $CHCl_3$/CH_3OH/water/NH_4OH (85/25/2/1, v/v/v/v) to give 126 mg (54%) of **10** having ^1H NMR (500 MHz, CD_3OD, 298K): 8.39 (d,2H); 7.80(m,2H); 7.21(d,1H); 4.26(m,2H); 3.93(s,4H); 3.78(d,4H); 3.36(m,8H); 3.18(m,8H); 3.06(m,2H); 2.78(m,2H); 0.71-2.35(m, 138H); 0.70(s,12H). HRMS: for $C_{133}H_{202}N_8O_{19}S_2Na$ calc.: 2182.4420 ; found: 2182.4408

Umbrella-Peptide Conjugate 2. To a solution that was made from 15.0 mg (7.0 µmol) of **10** in 1mL of CH_3OH was added solution of 9.2 mg (6.51µmol) of **Pep**-SH in 500 µL of CH_3OH. After stirring at room temperature under and argon atmosphere for 48 h the mixture was subjected, directly, to purification by reverse phase HPLC [C18 column, 0.06% TFA in water/CH_3CN/iso-propylalcohol, using a gradient that started with

40/5/35, v/v/v and ended with 5/10/95, v/v/v. Concentration under reduced pressure at 45°C, followed by freeze drying for 48 h afforded 11.80 mg (33%) of **2** having ^{1}H NMR (500 MHz, D_2O, 298 K) δ: 4.70 (t, 1H); 4.40 (m, 8H), 3.92(bs, 2H); 3.72(bs, 2H), 3.36 (m, 2H); 3.27(m, 4H), 3.12(bs, 16H), 3.08(m, 4H); 2.90 (m, 2H); 2.75 (m, 2H); 0.79-2.20 (m, 100H); 1.98 (s, 9H); 0.58(s,6H); MALDI-TOF MS m/z (MH+) Calcd. for $C_{171}H_{304}N_{41}O_{29}S_2$: 3460.2010. Found: 3460.3106 .

Synthesis of Conjugate 11. To a solution that was made from 200 mg (0.215 mmol) of lysine dicholamide, 1.4 mL of DMF and 42 µL of DIPEA was added 82.0 mg (0.235 mmol) of N,N,N',N'-tetramethyl-O-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-yl) uranium tetrafluoroborate (DBTU). After stirring for 18 h at room temperature, a solution made from 15.7 mg of spermidine (0.108 mmol) plus 400 µL of DMF and 100 µL of DIPEA was then added. Further stirring for 18 h at room temperature in closed flask, followed by concentration under reduced pressure, afforded a crude product that was purified by column chromatography [silica gel, $CHCl_3/CH_3OH/NH_4OH$ (80/35/7, vol/vol/vol) to give 46 mg (22%) of the N_1,N_3-bisconjugate of spermidine and lysine dicholeamide having ^{1}H NMR (CD_3OD, δ): 4.21(m, 2H); 3.94(s, 4H); 3.79(s, 4H); 3.40(m, 6H); 3.16(m, 8H); 2.64(m, 4H); 0.9-2.30(m, 138H); 0.69(s, 12H).

To a solution that was made from 6.0 mg (35.4 µmol) of 3-maleimido-propanoic acid, 0.3 mL of DMF and 6.3 µL of DIPEA (0.0353mmol) was added 13.0 mg (0.0373 µmol) of DBTU. After stirring for 3 h at room temperature, a solution that was made from 0.5 mL of DMF, 30 µL DIPEA (0.168 mmol) of 58.0 mg (29.5 µmol) of the N_1,N_3-bisconjugate of spermidine and lysine dicholeamide and 20 µL DIPEA was added. The

resulting mixture was stirred for an additional 18 h at room temperature. The product mixture was then concentrated under reduced pressure and the crude oily produce was washed with 5% $NaHCO_3$, followed by freeze drying. The crude product was then purified by RP HPLC [C18 column, using solvents A: EtOH/CH_3CN/water (10/5/90, v/v/v), B: EtOH/CH_3CN/water (96/8/4, v/v/v) starting at A/B=30/70, ending A/B=0/100) to give 42.2 mg (68%) of **11** having ^{1}H NMR (500 MHz, CD_3OD, 298 K): 6.28(s,2H); 4.28 (m,2H);3.94(s,4H);3.79(m, 6H);3.37(m, 6H)'3.15(m, 10H); 2.60(m, 2H);, 0.8-2.35(m,138H);,0.70(s,12H).

Umbrella-Peptide Conjugate 4. To a solution that was made from 9.8 mg (4.64 µmol) of **11** in 500 µL of CH_3OH was added solution of 8.71 mg (6.17 µmol) of **Pep**-SH in 1.2mL of MeOH at room temperature. After stirring under an argon atmosphere for 48 h, the mixture was subjected, directly, to purification by reverse phase HPLC [C18 column, 0.06% TFA in water/CH_3CN/$(CH_3)_2CHOH$ (using a gradient that started with 80/10/35, v/v/v and ended with 5/10/85, v/v/v. Concentration under reduced pressure at 45°C, followed by freeze drying for 48 h afforded 12.42 mg (76%) of **4** as a white solid, which was dissolved in pure water and dialyzed against pure water using a 100 Dalton cut-off. The resulting product exhibited ^{1}H NMR (500 MHz, CD_3OD, 298 K) δ: 4.70 (m, 1H); 4.34(m,8H); 4.22 (m, 2H); 3.95(s, 4H); 3.72(m, 6H); 3.36(m, 8H); 3.20(m,27H); 2.502.73(m,4H);0.85-2.35(m, 170H); 2.05(s, 3H); 0.69(s, 12H). MALDI-TOF MS m/z (MH+) Calcd. for $C_{176}H_{308}N_{41}O_{29}S_2$: 3524.3323. Found: 3524.3135.

2-Mercaptoethanol-Peptide Conjugate 5. To a solution of 15.0 mg (0.0761 mmol) of 2-[2-hydroxyethyldithio]-pyridine in 500 µL of CH_3OH was added 5.01mg (3.5 µmol) of **Pep**-SH. After stirring under an argon atmosphere for 48 h, the mixture was diluted by adding 10 mL H_2O and subjected to dialysis using MWCO 500 Da. Concentration under reduced pressure at 45°C, followed by freeze drying for 48 h afforded 4.85 mg (93%) of **5** having ^{1}H NMR (500 MHz, D_2O, 298 K) δ: 4.70 (t, 1H); 4.37(m,8H); 3.82(t,2H); 3.19(m, 16H); 3.00(m,2 H);, 2.86(t,2H); 2.03(s,3H); 1.60(m,32H). MALDI-TOF MS m/z. $C_{58}H_{11}N_{34}O_{11}S_2$ MH+ calc.: 1487.8608; found: 1487.8572

siRNA Transfection. HeLa eGFP cells were seeded into a 24-well plate at a density of 20,000 cells/well and grown for 24 h in DMEM-H medium with 10% FBS added. Cells were grown without antibiotics or G 418 present for at least one cell passage prior to transfection. Molecular umbrella-oligoarginine conjugates **1** and **2** were dissolved in DEPC-treated water and these stock solutions (250 µM) then stored at 5°C; conjugates **3** and **4** were stored as solids at -80°C and were dissolved immediately prior to use. The duplexed siRNA was also dissolved in DEPC-treated water (75 µM) and stored in 50 µL aliquots at -80º C. The concentration of siRNA was determined using UV absorption at 260 nm. Prior to transfection, molecular umbrella-oligoarginine stocks were diluted with OPTI-MEM buffer (4, 8, 20, 40, and 80 µM) and the siRNA diluted with OPTI-MEM buffer (2 µM). The resulting two solutions were then combined (1/1, vol/vol) and incubated at room temperature for 30 min. Growth medium was removed and the cells then rinsed with warm OPTI-MEM. To each well was added 950 µL of fresh OPTI-MEM medium and 50 µL of molecular umbrella-siRNA complex mixture. The cells

were incubated at 37°C and 5% CO_2 for 4 h. Medium was then removed and replaced with DMEM-H with 1.5% FBS added and the cells incubated at 37°C and 5% CO_2 for 72 h. The cells were rinsed with PBS and incubated for 5 min with 1x trypsin-EDTA solution (0.3 mL). OPTI-MEM containing 10% FBS (1 mL) was added to each well, and the solution was vigorously pipetted to remove cells from the bottom of the plate. The cells were pelleted by centrifugation for 5 min at 750 rpm. The pellet was then resuspended in 0.5 mL PBS and analyzed for eGFP fluorescence using a BD FACS CANTOII flow cytometer. Lipofectamine™ 2000 was used as a reference, following optimum procedures as described by the manufacturer. The percent knockdown of eGFP expression was determined using the BD FACSDiva software and correcting for eGFP fluorescence in untreated cells.

Cell Viability Measurements. The cell viability of the eGFP-expressing HeLa cells after treatment with the molecular umbrella-siRNA complexes was determined using the MTS assay (CellTiter 96® AQ_{ueous} Non-Radioactive Cell Proliferation Assay provided by Promega). Cell viability was determined at the conclusion of the transfection experiment (72 h after exposure to the complexes). In brief, cells were treated with trypsin-EDTA solution (0.3 mL) for 5 min after which OPTI-MEM media containing 10% FBS (1 mL) was added. The cell suspension was vigorously mixed to remove all cells from the bottom of the plate, and a 130 µL aliquot was transferred to a 96-well plate. At this time, 25 µL of the MTS/PMS solution was added to each well and the plate incubated at 5% CO_2 for 2 h (37°C). The UV-VIS absorbance of each sample (total volume of 155 µL) was analyzed at 492 nm using a Labsystems Multiskan Ascent microplate reader. Cell viability was expressed by the following equation: cell viability (%) = ($Abs_{sample}/Abs_{control}$)

x 100%, where Abs_{sample} was the absorbance of the cell solution when treated with molecular umbrella-siRNA complexes and $Abs_{control}$ was the absorbance of untreated cells. All absorbance values were corrected for background signal of the solution with no cells present.

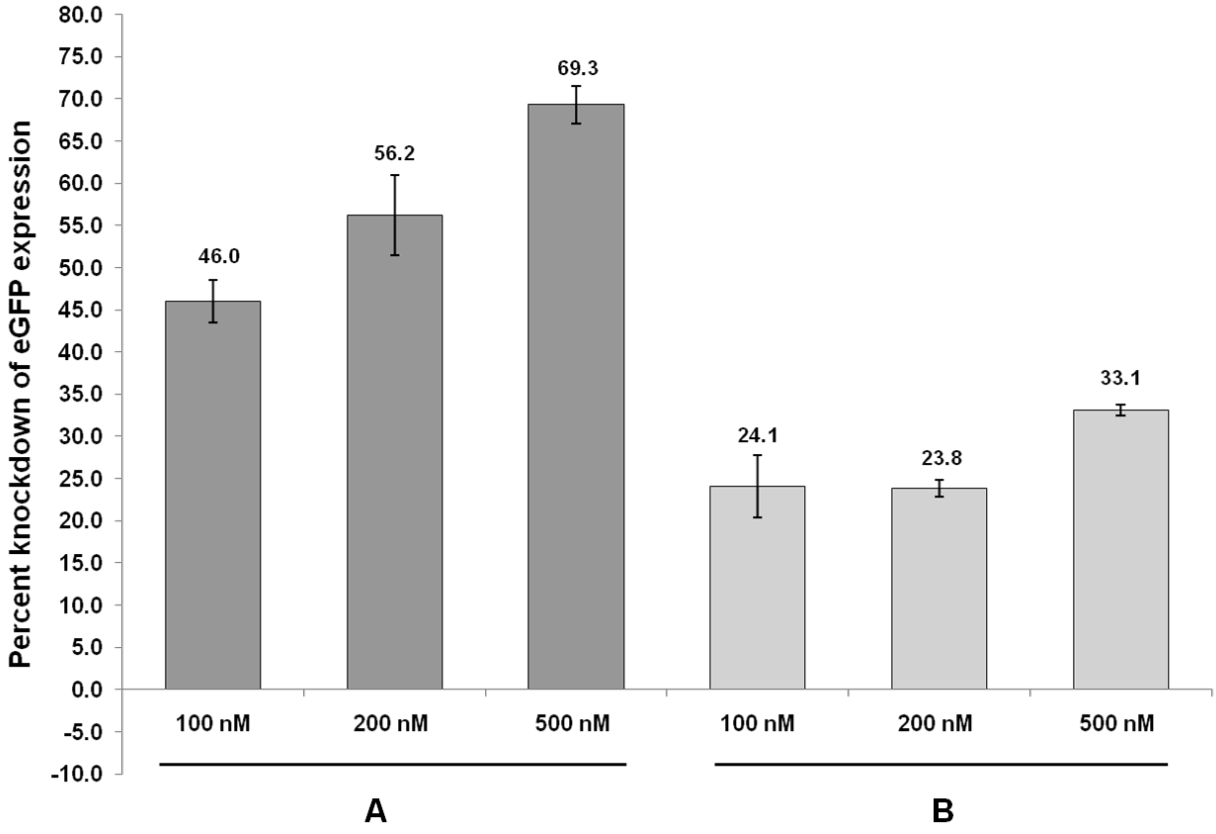

Figure S1. Percentage of eGFP knockdown for 4 when the 4 h siRNA transfection asssay was (A) done without fetal bovine serum (FBS) present in the OPTI-MEM buffer, or (B) done with 10% FBS added to the OPTI-MEM buffer. Values for percent

knockdown of eGFP expression are given above each column and represent the average of a typical experiment done in triplicate. Error bars represent the standard deviation of these values.

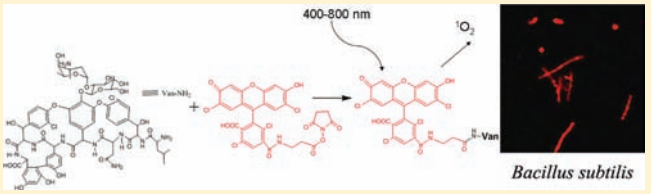
Supporting Information

ABSTRACT: A simple and unique conjugation of norvancomycin–fluorescein (VanF) has been achieved. It was characterized by UV–vis and fluorescence spectra and confirmed by MALDI-TOF mass spectrum. The photodynamic assay indicated that VanF effectively inactivated the Gram-positive *Bacillus subtilis* (ATCC 6633) from clinic with inactivation rate of 30–70% within 1–7.5 μM. In vitro, VanF showed low antimicrobial activity with value of >128 μg/mL, binding affinity with value of 180 nM per 10^8 cells/mL against the bacteria strains. The fluorescence imaging showed that VanF could label the *B. subtilis strain*, but not the *Escherichia coli* (ATCC 25922), *Enterococcus faecalis* (ATCC 51299, VanD), and VRE strains from clinic.



Glycopeptide antibiotics, such as vancomycin and norvancomycin, were used to combat infection of the Gram-positive bacteria by inhibiting the bacterial cell wall synthesis.[1] However, the overuse of glycopeptide antibiotics in the clinical setting has resulted in the vancomycin-resistant *Enterococcus* (VRE), which is typically due to the mutation of peptidoglycan sequence from *N*-acyl-D-Ala-D-Ala to *N*-acyl-D-Ala-D-Lac, resulting in the substantial decrease of binding affinity to vancomycin.[2,3] There are no useful antibiotics for treatment of vancomycin-resistant bacteria,[4] but photodynamic therapy (PDT) may have such potential. PDT is a photochemistry-based emerging technology that relies on the wavelength-specific light activation of certain nontoxic photosensitizers (PSs) to produce active molecular species that are toxic to surrounding logical targets.[5,6] PSs have been conjugated to antibodies or peptide for treatment of the area of bacteria infection, but the molecules of these targets are so big and labeling PS to antibodies or peptide is relatively complicated.[7] So, developing easier and smaller targets is very necessary. Xing and co-workers reported a simple and specific conjugation of vancomycin–porphyrins to use for fluorescent imaging and antibacterial studies of VRE.[2]

Eosin has been employed as PS to treat basal cell carcinoma.[8] The chlorinated fluoresceins, synthesized by us earlier,[9–11] has the same parent structure as eosin (Figure 1). The similarity suggests that the new compound could be linked to antibiotic to construct an efficient conjugation of drug–fluorescein that may apply to a biological target. On the basis of this idea, we constructed a novel compound norvancomycin-chlorinated fluorescein (VanF), and explored photodynamic inactivation experiments, as well as antimicrobial activity, binding affinity, and fluorescence imaging against *B. subtilis*.

VanF was prepared according to Scheme 1. Norvancomycin hydrochloride (32 mg) and chlorinated fluorescein[11] (18 mg) were dissolved in 2 mL 0.1 M phosphate-buffered saline (PBS) buffer (pH 8.5). The pH of the resulting mixture was adjusted to 9.5 and stirred for 20 h at 4 °C; the reaction mixture was loaded onto a silica gel column, eluted with methanol, collected, and the fractions containing the target compound (monitored by UV–vis) pooled, concentrated, and loaded onto a Sephadex G-25 column to offer the purified VanF with yield 54%.

VanF was characterized by UV–vis and fluorescence spectra and confirmed by MALDI-TOF (matrix-assisted laser desorption ionization, time-of-flight) mass spectrum, the peak at m/z 2023.15 $[M+Na-2H]^-$ corresponding to VanF was clearly observed (Figure 2). The spectroscopic characterization showed that VanF had a nearly 4-fold decrease in fluorescence emission and a nearly 40% decrease in absorbance compared to chlorinated fluorescein (Figure 3).

The photodynamic inactivation of VanF against the Gram-positive bacteria *B. subtilis* was assayed as previously described.[12] Briefly, the *B. subtilis* culture was washed with PBS buffer, incubated with the tested compounds in the dark at 37 °C for 20 min with shaking, and illuminated by light with wavelength of 400–800 nm (350 mW), which was produced by Xenon lamp and isolated by means of the optical filters, for 5 min to offer the phototreated samples. The assays showed that the phototreated VanF effectively inactivates *B. subtilis*; with the increase of VanF concentration, the bacterial lethality increased (Figure 4a). When the concentration of VanF was 7.5 μM, the bacterial lethality

reached to 70%. Also, the bacterial lethality was dependent on the irradiation time; with the increase in irradiation time, the bacterial lethality increased (Figure 4b), and it reached 68% after 5 min irradiation with concentration of 5 μM VanF. Eosin and fluoresceins could successfully produce the singlet oxygen ($^1O_2$) to inactivate the living cells;[13] this suggests that the photodynamic inactivity of VanF against *B. subtilis* is due to the effect of the singlet oxygen species.[14,15]

Furthermore, we tested VanF with the Gram-negative bacteria *Escherichia coli*, which contained the antibiotic-resistant plasmid; it was induced with IPTG to produce the metallo-β-lactamase CcrA (B1 subgroup),[16] ImiS (B2 subgroup),[17] and L1 (B3 subgroup),[18] respectively. The results showed that VanF had no obvious photodynamic inactivation toward the tested bacteria. This may be ascribed to the large fluorescence group, which blocked VanF from attaching to the bacteria, or the outer membrane of Gram-negative bacteria, which blocked PS from entering the bacteria.[15]

In vitro antimicrobial activities of VanF were evaluated by determination of MIC according to the Clinical and Laboratory Standards Institute (CLSI) macrodilution (tube) method.[19] The MIC value of VanF against *B. subtilis* (ATCC 6633) was larger than that of norvancomycin (Table 1), indicating that the antimicrobial efficacy of VanF decreased. The decreased activity of VanF implied that chlorinated fluorescein conjugated to norvancomycin (Figure 1), in which the large fluorescence group blocked VanF to bind to the peptidoglycan sequence

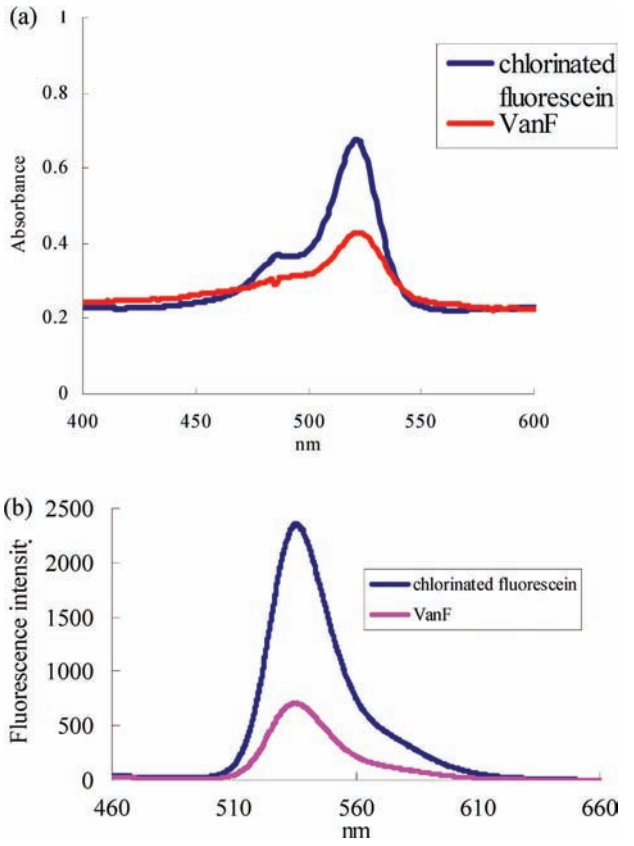

Figure 3. UV−vis (a) and fluorescence (b) spectra of VanF and chlorinated fluorescein. The concentrations of the tested compounds were 8 μM (for UV−vis spectra) and 3.75 μM (for fluorescence spectra) in 10 mM PBS buffer at pH 7.5 (λ_{ex} = 400 nm).

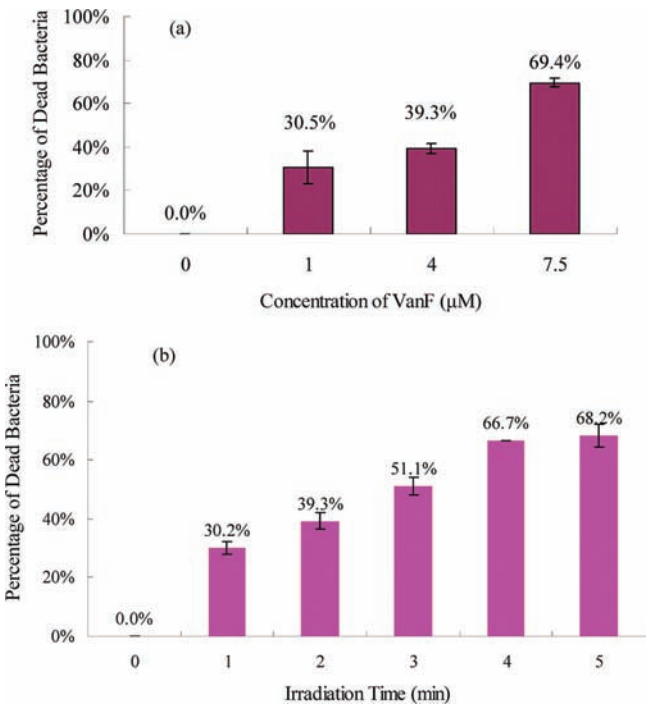

Figure 4. (a) Photodynamic inactivation of *B. subtilis* strains with different concentrations of VanF. (b) Time-dependent bacterial lethality with incubation of 5 μM VanF.

Table 1. MIC Values of VanF and Norvancomycin

compounds	*B. subtilis*
norvancomycin	4 μg/mL
VanF	>128 μg/mL

N-acyl-D-Ala-D-Ala. Further, the binding affinity of VanF to *B. subtilis* was quantified. The results showed that both VanF (7.5 μM, saturation concentration) and chlorinated fluorescein (3.75 μM, saturation concentration) weakly bond to the bacteria (Figure 5) with values of 180 and 46 nM per 10^8 cells/mL,

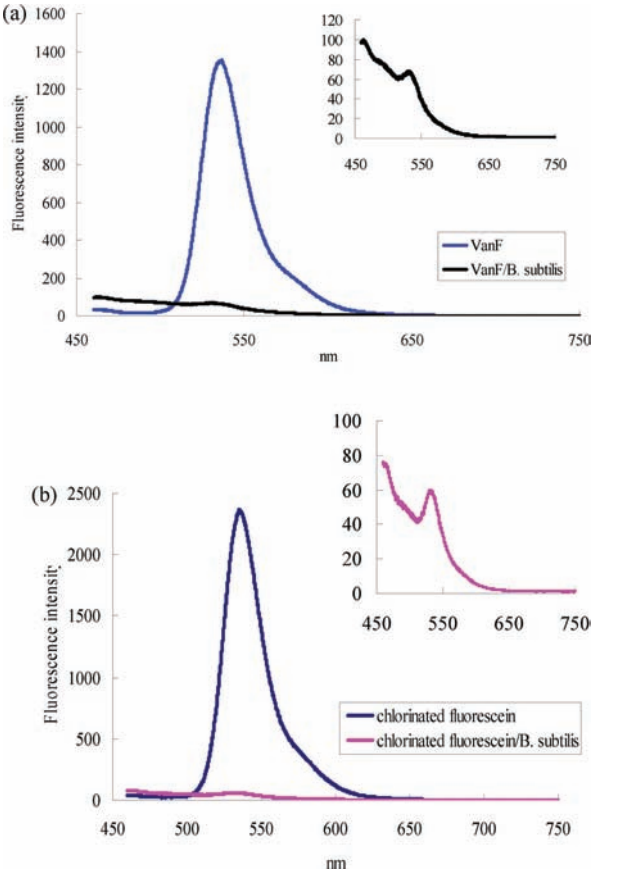

Figure 5. Binding abilities of VanF (a) and chlorinated fluorescein (b) to *B. subtilis*. The concentration of VanF was 7.5 μM in 10 mM PBS buffer at pH 7.5 and the concentration of chlorinated fluorescein was 3.75 μM in 10 mM PBS buffer at pH 7.5. Both the concentrations of VanF and chlorinated fluorescein are saturation concentration.

respectively, while VanF had 4-fold stronger binding ability than the chlorinated fluorescein. In this investigation, the low antimicrobial activity and low binding affinity of VanF are consistent.

Imaging was conducted using VanF (Figure 6). Both VanF and chlorinated fluorescein showed obvious fluorescent imaging of *B. subtilis*, indicating that both of them could be used as fluorescent probes. Meanwhile, VanF was also tested to label the *Escherichia coli* (ATCC 25922), *Enterococcus faecalis* (ATCC 51299, VanD), and VRE from clinic, but the results indicated that it could label neither Gram-negative bacteria nor vancomycin-resistant bacteria.

In conclusion, we successfully constructed a novel fluorescence antibiotic VanF by conjugation of the chlorinated

Supporting Information

A Novel Conjugation of Norvancomycin-fluorescein for Photodynamic Inactivation of *Bacillus subtilis*

General: Muller-Hinton Broth was obtained form Beijing Aoboxing Biotech. Company Ltd. Norvancomycin hydrochloride was obtained from North China Pharmaceutical Company, LTD. Other chemical reagents were purchased from commercial supplies. UV-vis spectra were recorded on Agilent 8453 UV-Vis spectrometer. The fluorescence emission spectra were recorded on HITACHI F-4500 Fluorescence spectrophotometer. Fluorescence imaging studies were carried out on Olympus FluoView FV1000 Confocal Microscope. MALDI-TOF-MS were acquired on an AXIMA-CFR time-of-flight (TOF) mass spectrometer.

MIC test:

Norvancomycin hydrochloride was dissolved in dd H_2O to obtain 1280 μg/ml stock solution and VanF was dissolved in 0.01M PBS buffer (pH 7.5) to obtain the same 1280 μg/ml stock solution. The chosen bacteria were ***Bacillus subtilis*** (ATCC 6633). The MICs were determined by the Clinical and Laboratory Standards Institute (CLSI) macrodilution (tube) broth method.[1]

Bacterial strain and preparation of cultures:

Single colony of ***B. subtilis*** (ATCC 6633) on solid Luria-Bertani (LB) plates were transferred to 10 ml of LB culture medium and were grown at 37 ˚C overnight. The bacteria were harvested by centrifuging (4˚C, 4000 rpm for 10 min) and washed with 0.01M PBS buffer (pH 7.5) three times. The supernatant was discarded and the remaining bacteria were re-suspended in the same PBS buffer and adjusted to O. D. 600 of 0.5-0.6.

Evaluation of photodynamic inactivation of bacterial strains:

Photodynamic experiments were performed according to the methods previously described.[2] Exactly, bacterial cells suspension were incubated with different concentrations of VanF in the dark for 20 min at 37 □ in a shaker. All samples were illuminated with white light (400-800 nm, 350 mW) isolated from the emission of a Xemon lamp for 5 minutes. Bacterial suspensions were centrifuged (4000 rpm for 10 min, at 4 ˚C). The supernatant was removed directly, the bacterial pellet was suspended and serially diluted (5×10^4)-fold in 0.01M PBS buffer (pH 7.5). A 75 μL portion of the diluted bacterial cells was spread on the advance prepared solid LB agar plate and incubated overnight at 37 ˚C. The single colonies formed were counted. The percentage of dead bacteria was evaluated by dividing the number of colony-forming units between the samples incubated with photosensitizers with light illumination and the controls without light illumination.

Binding affinity experiments

Suspensions of ***B. subtilis*** (ATCC 6633) in PBS were incubated with VanF (7.5 μM) or chlorinated

fluorescein (3.75 μM) at 37 °C for 40 min in the dark in a shaker. Then, the cultures were centrifuged (4000 rpm for 10 min) and the supernatant was removed directly. The bacterial pellet was suspended in 1.5 mL of 2% SDS, incubated overnight at 4 °C, and then sonicated for 30 min. The concentration of chlorinated fluorescein and VanF was determined by fluorescence intensity. Emission spectra of chlorinated fluorescein and VanF without ***B. subtilis*** were taken as controls. The fluorescence values of samples were referred to the samples labeling ***B. subtilis***.

Imaging test:

Imagining test was performed according to the methods previously described.[3] Equivalent 10 μM of VanF or chlorinated fluorescein and the bacterial cells suspensions were mixed together and then incubated in the dark for 1 hour at 37 ˚C in a shaker. After three times 0.01M PBS buffer (pH 7.5) washing, the bacterial cells were spotted on glass slides, immobilized by the coverslips, and the cell imaging tests were conducted with a Olympus FluoView FV1000 Confocal Microscope.

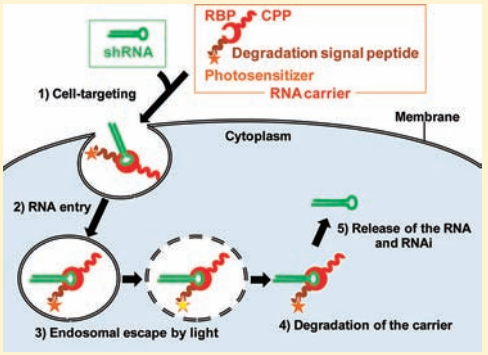
Department of Bioscience and Biotechnology, Okayama University, 3-1-1 Tsushimanaka, Okayama 700-8530, Japan

Supporting Information

ABSTRACT: RNA interference (RNAi) is being widely explored as a tool in functional genomics and tissue engineering, and in the therapy of intractable diseases, including cancer and neurodegenerative diseases. Recently, we developed a photoinducible RNAi method using photosensitizing carrier proteins, named CLIP-RNAi (CPP-linked RBP-mediated RNA internalization and photoinduced RNAi). Novel carrier proteins were designed for this study to establish a highly efficient delivery system for small interfering RNA (siRNA) or short hairpin RNA (shRNA) and to demonstrate light-dependent gene silencing. In addition, the results suggested that the dissociation of the siRNA (or shRNA) from carrier proteins in the cytoplasm is a critical event in CLIP-RNAi-mediated gene silencing.



INTRODUCTION

RNA interference (RNAi)-mediated gene silencing is a valuable method for investigating gene function and for use in clinical applications.[1,2] To deliver small interfering RNAs (siRNAs) and short hairpin RNAs (shRNAs) efficiently into the cytosol, many RNA carriers, including lipids, nanoparticles, polymers, and viral vectors, have been developed.[3] However, there is much room for improvement with respect to target gene specificity and the ability to regulate gene expression.

In this regard, Shah et al. recently developed caged siRNAs, which enabled a spatially and temporally controlled RNAi.[4] In this method, the attachment of photolabile protecting groups (caging groups) to siRNA blocks gene silencing activity in the absence of light, while the removal of the caging groups from the siRNA with an external light trigger results in the induction of the RNAi. A great variety of photolytic compounds capable of attaching themselves to RNAs have been identified, although their widespread use is limited by the optical wavelength for deprotection, which must be around 350 nm.[5]

Previously, we reported that the utilization of a fluorescent dye attached to an RNA carrier protein enabled light-dependent gene silencing.[6−8] We designed a cell-permeable RNA-binding protein (TatU1A) labeled with a fluorescent dye (TatU1A-dye) as an RNA carrier. TatU1A is a fusion protein between a TAT-derived cell-penetrating peptide (CPP)[9] and the U1A RNA-binding protein (RBP).[10] The TatU1A-dye could undertake the specific delivery of an shRNA containing a U1A binding sequence in its loop region.[6,7] The complexes formed between the TatU1A-dye and shRNA (TatU1A-dye/shRNA) were internalized by cells via an endocytotic pathway. TatU1A-dye/shRNA complexes were entrapped in endosomes before photoirradiation, while after irradiation they were released into the cytosol where they mediated gene silencing. This delivery system was named "CLIP-RNAi (CPP-linked RBP-mediated RNA internalization and photoinduced RNAi)", and in this study, its use is demonstrated with newly designed carrier proteins (CPP-RBPs).

EXPERIMENTAL PROCEDURES

Plasmid Construction. Double-stranded DNA encoding the flock house virus (FHV) coat peptide (residues 35 to 49) (RRRRNRTRRNRRRVR) was prepared by primer extension using the following primers, 5′- CCGCCCATGGGCAGCA-GCCATCATCATCATCATCACAGCAGCGGCCGCCGTC-GCCGCAACCGCACCCGCCG-3′ (sense, *Nco*I site underlined) and 5′-CGCCGCTAGCGTAATCCGGAACATCG-TATGGGTAGCCGCGCACGCGACGGCGGTTGCGGCG-GGTGCGGTTGCG-3′ (antisense, *Nhe*I site underlined), and cloned into the *Nco*I-*Nhe*I site of the previously constructed pET-TatU1A-C plasmid,[6] yielding pET-FHVU1A-C. The DNA segment encoding the Tat peptide (YGRKKRRQRRR) of pET-TatU1A-C was converted to the cytoplasmic transduction peptide 512 (CTP512) (YGRARRRRRRR) using the QuikChange Site-Directed Mutagenesis Kit (Stratagene) with the following primers: 5′-GCAGCGGCTACGGCCGCGCGCGTCGCCG-CCGTCGCCGTCGCGGCTACCC-3′ (sense) and 5′-GGGTA-GCCGCGACGGCGACGGCGGCGACGCGCGCGGCCGTAG-CCGCTGC-3′ (antisense).

The coding sequence for the RNA-binding domain of *Drosophila* Sex lethal protein (*Sxl*), was amplified with the

primers 5′-CCGCTCGAGTTAGGATCCCTTGCCATGCTCCTCAG-3′ (sense, *Xho*I site underlined) and 5′-CGCGCTAGCGGCGCAAGCAACACCAACCTG-3′ (antisense, *Nhe*I site underlined) from the *Drosophila Sxl* cDNA clone, EDM1133−6921617 (Open Biosystems). Double-stranded DNA encoding the bacteriophage λ N peptide (λN) was amplified using the following primers: 5′-CCGCTCGAGTTAGGATCCAGGGCGGTTAACTGGTTTTGCGCTTACCCCAACCAACAGGGGATTTGCTGCTTCCATTG-3′ (sense, *Xho*I site underlined) and 5′-CGCGCTAGCGGCCTGGATGCACAAACACGCCGCCGCGAACGTCGCGCAGAGAAACAGGCTCAATGGAAAGCAGCAAATCC-3′ (antisense, *Nhe*I site underlined). The coding sequences for *Sxl* or λN were cloned into the *Xho*I-*Nhe*I site of pET-TatU1A-C,[6] yielding pET-TatSxl-C, and pET-TatλN-C, respectively.

Double-stranded DNA encoding the degradation signal peptide CL1 (ACKNWFSSLSHFVIHL) was prepared by primer extension using the following primers: 5′-CCGCGGATCCGCTTGCAAGAACTGGTTCAGTAGCTTAAGCCACTTTGTGA-3′ (sense, *Bam*HI site underlined) and 5′-CGGCCTCGAGTTAGCAGCTGTTAAGGTGGATCACAAAGTGGCTTAAGCTA-3′ (antisense, *Xho*I site underlined), and cloned into the *Bam*HI-*Xho*I site of pET-TatU1A-C,[6] yielding pET-TatU1A-CL1-C. All of the constructs contained a C-terminal Cys residue for later modification with Alexa Fluor 546 (Alexa546) C5 maleimide (Molecular Probes). The coding sequences of the above-mentioned plasmid vectors were confirmed by sequencing analysis with an ABI PRISM 310 genetic analyzer.

Purification and Fluorescent Labeling of Proteins. The CPP-RBP plasmids described above were introduced into *Escherichia coli* BL21(DE3). Transformants were grown at 37 °C, and expression of CPP-RBPs was induced by the addition of isopropyl-β-D-thiogalactopyranoside (1 mM), followed by growth at 30 °C for 16 h. CPP-RBP proteins were purified as described previously,[6] except for the TatU1A-CL1 protein, which was purified from the insoluble fraction.

The carrier proteins were labeled with Alexa546 as previously described.[6,7] Protein concentration was determined using a Protein Assay Kit (Bio-Rad), and the labeling efficiencies were calculated by measuring the absorbance of Alexa546 with a NanoDrop 1000 Spectrophotometer (Thermo Scientific). In all experiments, the labeling efficiencies were adjusted to 30% using separately prepared unlabeled carrier proteins.

Preparation of siRNAs and shRNAs. The shRNA sequence used was as follows: 5′-GGCUACGUCCAGGAGCGCACAUUGCACUCCGUCGCGUCCUGGACGUAGCCUU-3′ (U1A binding sequences underlined).[6,7] This shRNA and the 3′-FAM-labeled shRNA were from JBioS (Japan).

To construct siRNA-type cargo RNAs, antisense and sense strands were dissolved in distilled water at final concentrations of 20 μM and were annealed by incubation at 90 °C for 1 min followed by a 60 min incubation at 37 °C. The target sequence in the enhanced green fluorescent protein (EGFP) mRNA was 5′-UGCGCUCCUGGACGUAGCCUU-3′. The sense strands contained 5′ short extensions, which bound to their respective RBPs, to make *U1A*-siRNA (5′-GGGCAUUGCACUCCGCCCUCUGGCUACGUCCAGGAGCGCAUU-3′), *Sxl*-siRNA (5′-GGUUGUUUUUUUUCUGGCUACGUCCAGGAGCGCAUU-3′), and *λN*-siRNA (5′-GGCCCUGAAAAAGGGCCUCUGGCUACGUCCAGGAGCGCAUU-3′). The RBP binding sequences are underlined. The 3′-FAM-labeled antisense strand was purchased from JBioS and annealed with the sense strands to make FAM-labeled siRNAs.

Cell Culture. Chinese hamster ovary (CHO) cells and destabilized EGFP stably expressing CHO (EGFP-CHO) cells[6] were cultured in Ham's F-12 medium (Sigma) supplemented with 10% fetal bovine serum (Biowest), 100 units/mL penicillin, and 100 μg/mL streptomycin (Gibco, Invitrogen, US).

Cellular RNA Delivery by Carrier Proteins. The FAM-labeled RNA (200 nM) and carrier protein (2 μM) were mixed in T buffer [20 mM HEPES-KOH (pH 7.4), 115 mM NaCl, 5.4 mM KCl, 1.8 mM $CaCl_2$, 0.8 mM $MgCl_2$, and 13.8 mM glucose] and incubated at 37 °C for 10 min. CHO cells were grown on a 96-well plate to 70% confluence and were treated for 2 h with the carrier/RNA complex mentioned above. After washing, the cells were visualized using a fluorescence microscope (Olympus, Japan). For endosomal escape of the carrier/RNA complex, cells were irradiated at 540 ± 10 nm for 11 s with a 100 W halogen lamp (Olympus USH-1030 L) passed through the 40× objective lens as described previously.[6,7]

Induction of RNAi-Mediated EGFP Gene Silencing and Analysis of EGFP Gene Expression. EGFP-CHO cells were grown on a 96-well plate to 70% confluence and treated for 2 h with the unlabeled RNA/carrier protein complex. The RNA was delivered to the cells by the carrier protein, and photoaccelerated endosomal escape was induced by irradiation at 540 ± 10 nm for 64 s with a 100 W halogen lamp passed through the 4× objective lens as described above. After 20 h of irradiation, cells were recovered from dishes and resuspended in PBS. The EGFP mean fluorescence intensities (MFIs) were analyzed by flow cytometry using FACSCalibur and *CellQuest* software (BD Biosciences). Data were acquired from 10 000 cells in all experiments.

RESULTS AND DISCUSSION

Design of Carrier Proteins (CPP-RBPs). We previously demonstrated CLIP-RNAi-mediated EGFP silencing using CPP-RBP protein (TatU1A) as an RNA carrier, and the silencing efficiency was 60−70%.[6,7] The insufficient RNAi efficacy may be due to insufficient RNA delivery efficiency that relates to the cell-targeting activity of the CPP moiety of CPP-RBP or the size and RNA binding efficiency of the RBP moiety, or may be due to inhibition of the activity of the RNA with tightly bound CPP-RBP. To establish a highly efficient siRNA or shRNA delivery system, a series of CPP-RBP proteins was constructed and purified (Figure 1).

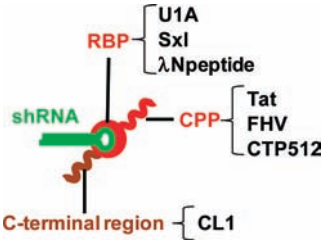

Figure 1. RNA carrier protein design. Schematic diagram of the RNA carrier proteins used in this study. CPP, cell-penetrating peptide; RBP, RNA-binding protein. The C-terminal cysteine was labeled with Alexa546 as a photosensitizer.

First, CPP-U1A variants were prepared to examine whether changing the CPP moiety of TatU1A significantly improved the RNA delivery efficiency. An FHV coat peptide and a CTP512 peptide were selected as the CPP moiety. Recently, it was reported that the cellular uptake of the FHV peptide was higher than that of the

dx.doi.org/10.1021/bc200095a | *Bioconjugate Chem.* 2011, 22, 2222−2226

Tat peptide.[11] The FHV peptide was internalized by various cell types about 15- to 21-fold more efficiently than the Tat peptide. Cytoplasmic transduction peptides (CTPs) were designed to ensure efficient cytoplasmic delivery using computer-based molecular modeling.[12] The CTP512 peptide was evaluated as the leading CTP as it possessed a transduction capacity approximately 5-fold that of the Tat peptide.

Next, Tat-RBP variants were prepared. A partial sequence of the *Drosophila* Sex lethal protein and the bacteriophage λ N protein were used for the RBP moiety. Sex-lethal protein has two RNA-binding domains (RBDs), which are required for specific RNA binding.[13−15] In this study, the protein region (173 amino acids), which included the two RBDs, was used and is hereafter referred to as Sxl. The dissociation constant (K_d) of the Sxl/RNA complex (~5 pM) is lower than that of the U1A/RNA complex (20 pM);[16,17] therefore, high RNAi efficiency due to increased RNA delivery efficiency might be expected from the Sxl/RNA interaction. In addition, the N-terminal region (36 amino acids) of the bacteriophage λ N protein, which included a relatively small RNA binding motif, was employed, and is hereafter referred to as λN. The high specificity and affinity of the complex between λN and the target RNA (K_d = 5 nM) have been demonstrated previously.[18,19] The small size of λN may offer advantages over the internalization of other carrier proteins.

Furthermore, to investigate whether the dissociation of the carrier protein from shRNA or siRNA in the cytoplasm accelerated RNAi-mediated gene silencing, a C-terminally extended TatU1A bearing the degradation signal peptide CL1 (TatU1A-CL1) was designed. The CL1 peptide is known to act as a degradation signal peptide via the ubiquitin−proteasome pathway,[20,21] and the degradation of carrier proteins is thought to promote the release of free shRNA or siRNA into the cytoplasm.

Effects of CPPs on RNAi Efficiency. To examine the effects of CPPs on RNAi efficiency, three CPP-U1A variants (TatU1A, FHVU1A, and CTP512U1A) were constructed and purified. The CPP-U1As were labeled with Alexa546 and were tested to determine whether they carried the shRNA into cells and whether the carrier/shRNA complexes were released from the endosome by photostimulation. FAM-labeled shRNAs were used to visualize RNA localization. As shown in Figure 2, in all cases, the Alexa546 and FAM fluorescence signals showed punctuate distributions before irradiation, indicating that the carrier/shRNA complexes were trapped in endosomes, as reported previously.[6,7] After irradiation at 540 ± 10 nm, the Alexa546 and FAM signals for all three variants were dispersed throughout the cytosol. Moreover, there was no significant difference in FAM fluorescence intensity between TatU1A and FHVU1A, suggesting that they had almost equal transfection efficiencies. Quantitative fluorescence image analysis of microscopic images in Figure 2 using *cellSens Dimension* software (Olympus) indicated that mean FAM intensity with CTP512U1A was about 45% lower than that with TatU1A.

Next, the RNAi efficiencies with the CPP-U1A carriers were examined by evaluating the knockdown of EGFP expression in EGFP-CHO cells. EGFP silencing at 20 h after photostimulation was assessed by flow cytometry. As is clearly shown in Figure 3A, a dramatic light-dependent reduction in EGFP MFI was observed with TatU1A-Alexa. The treatment of cells with the TatU1A-Alexa/shRNA(anti-EGFP) complex followed by photostimulation induced a 70% decrease in MFI when compared with the control cells treated with T-buffer only, while without irradiation, no decrease in MFI was observed in cells treated with the carrier/shRNA complex (Figure 3A). Similarly, treatment with the

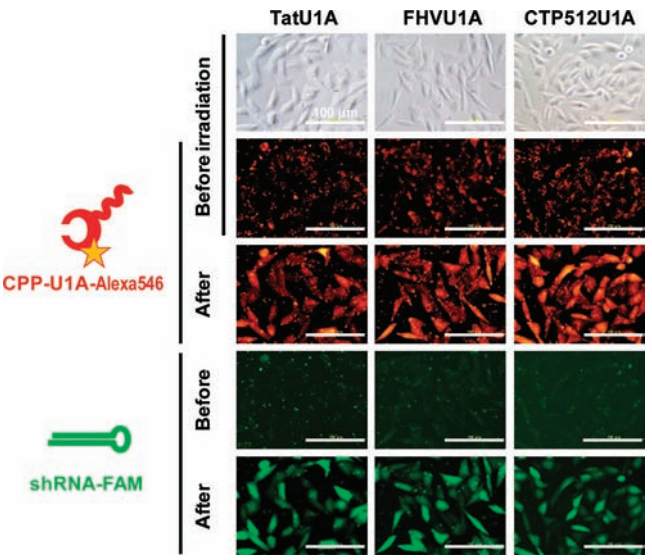

Figure 2. Translocation of the CPP-U1A/shRNA complexes via endocytosis. CHO cells were treated with CPP-U1A-Alexa546/shRNA-FAM complexes for 2 h at 37 °C and irradiated (540 ± 10 nm light passed through a 40× objective lens for 11s) as described in Experimental Procedures. Images were taken before and 2 min after irradiation.

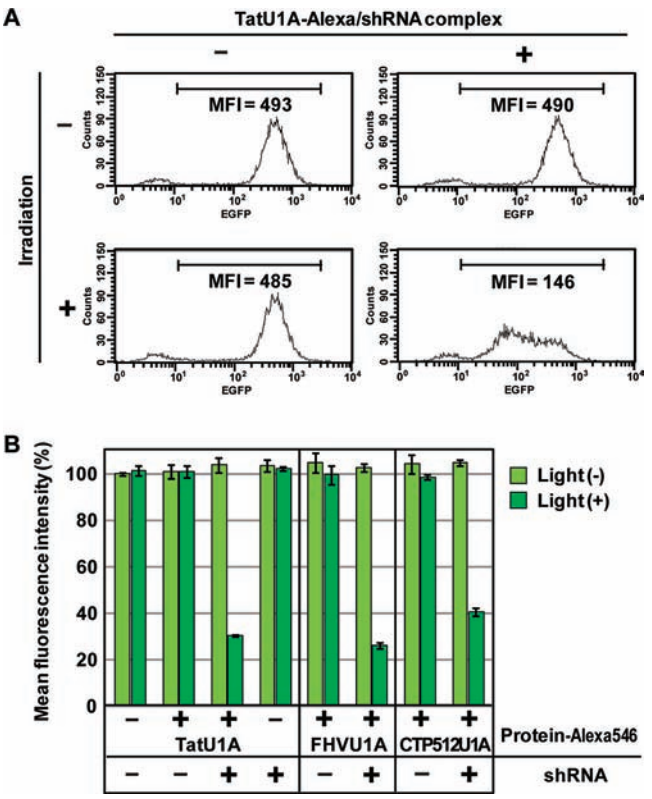

Figure 3. EGFP silencing by CPP-U1A-Alexa/shRNA complexes. The shRNA has an anti-GFP sequence and a U1A-binding sequence. (A) Flow cytometric analysis of EGFP-expressing cells treated with TatU1A-Alexa546/shRNA complexes and irradiated (540 ± 10 nm light passed through a 4× objective lens for 64 s). Cells were collected for flow cytometric analysis at 20 h after irradiation. The silencing effect was assessed by measuring EGFP mean fluorescence intensity (MFI). (B) Comparison of CPP-U1A proteins in EGFP silencing. EGFP MFIs of cells treated with different CPP-U1A-Alexa546/shRNA complexes are compared to control cells treated with T-buffer only.

dx.doi.org/10.1021/bc200095a | *Bioconjugate Chem.* 2011, 22, 2222−2226

FHVU1A-Alexa/shRNA or CTP512U1A-Alexa/shRNA complexes induced a 74% and 59% decrease in MFI, respectively (Figure 3B). These data indicate that the three CPP-U1A variants had a similar effect on EGFP silencing, although the RNAi efficiency of the CTP512U1A-Alexa/shRNA complex was slightly lower than the other two. We suggest that the low RNAi efficiency with CTP512U1A was due to the lower delivery efficiency of CTP512U1A compared to that of the other two variants.

Effects of RBPs on RNAi Efficiency. Next, the RNAi efficiencies of the Tat-RBP variants (TatU1A, TatSxl, and TatλN) were compared to investigate the effects of the RBPs. As shown in Figure 4A, the siRNAs carried by TatU1A-Alexa

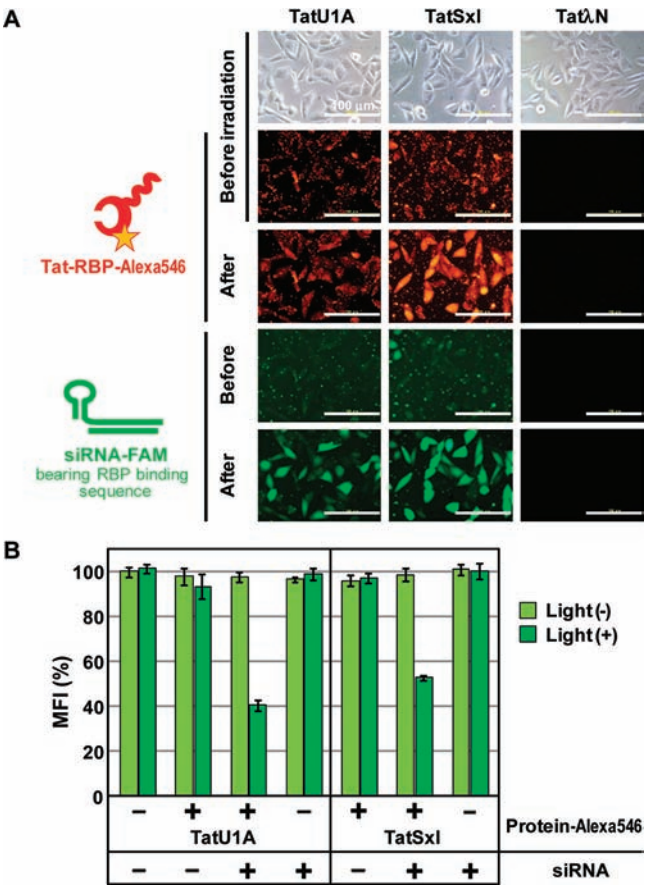

Figure 4. Comparison of Tat-RBP proteins with respect to cellular delivery and EGFP silencing. (A) Translocation of the Tat-RBP-Alexa546/siRNA. The sense strand of the siRNA contained 5′ short extensions for the binding to U1A, Sxl, or λN. Transfection and fluorescence microscopy were carried out as described in the legend to Figure 2. (B) Comparison of Tat-RBP proteins with respect to EGFP silencing. The silencing effects were calculated as described in the legend to Figure 3.

and TatSxl-Alexa diffused into the cytoplasm in a photo-dependent manner. However, in the case of TatλN, cellular uptake of the carrier protein and the siRNA was not observed, irrespective of irradiation. Hence, only the effects of the two carrier proteins, TatU1A-Alexa and TatSxl-Alexa, on RNAi efficiency were investigated. Unexpectedly, TatSxl-Alexa exhibited a lower RNAi efficiency (47% decrease in MFI compared to the control) than TatU1A-Alexa (59% decrease in MFI compared to the control) (Figure 4B), although quantitative fluorescence image analysis of microscopic images of Figure 4A indicated that the cellular uptake of siRNA with TatSxl-Alexa was higher than that with TatU1A (data not shown). Given that the dissociation constant of the Sxl/RNA complex is reportedly one order lower than that of the U1A/RNA complex,[16,17] these results suggested that the dissociation of carrier proteins from shRNA or siRNA in the cytoplasm might be important for RNAi efficiency.

Importance of RBP/RNA Dissociation on RNAi Efficiency. To investigate this possibility further, the influence of the CL1 peptide on the RNAi efficiency was examined using CHO cells. As shown in Figure 5 and Supporting Information

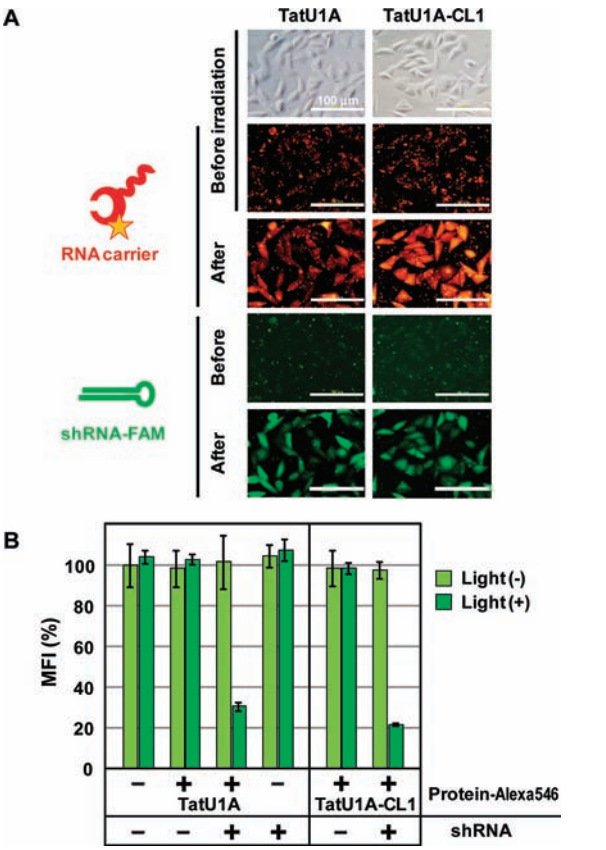

Figure 5. Influence of the CL1 peptide on cellular delivery and EGFP silencing. (A) Translocation of the TatU1A-CL1-Alexa546/shRNA. Transfection and fluorescence microscopy were carried out as described in the legend to Figure 2. (B) Comparison of TatU1A-CL1 with TatU1A in EGFP silencing. The silencing effects were calculated as described in the legend to Figure 3.

Figures S1 and S2, although the internalization efficiency and the light-dependent diffusion of TatU1A-CL1-Alexa with the shRNA to the cytoplasm was equivalent to that of TatU1A-Alexa, the use of TatU1A-CL1-Alexa increased the RNAi efficiency (78% decrease in MFI) compared to TatU1A-Alexa (69% decrease in MFI). This tendency was also confirmed in other cell types (Figure S3). EGFP-silencing using the TatU1A-CL1-Alexa/shRNA complex was also confirmed by analyzing the EGFP level on a SDS-PAGE gel (Figure S4A). The EGFP silencing level was dependent on the size of the area irradiated (Figure S4A and B), and the cells treated with the complex were not damaged by photostimulation (Figure S4C). These results suggest that the dissociation of the shRNA from the carrier protein in the cytoplasm is a critical event in CLIP-RNAi-mediated gene silencing.

dx.doi.org/10.1021/bc200095a | Bioconjugate Chem. 2011, 22, 2222–2226

CONCLUSION

The results presented here demonstrated that the three CPP-U1A variants, TatU1A, FHVU1A, and CTP512U1A, possessed similar carrier qualities and suggested that U1A was superior to Sxl as the RBD moiety of the Tat-RBP. Attachment of the degradation signal peptide, CL1, accelerated RNAi-mediated gene silencing, suggesting that the dissociation of the carrier protein and RNA due to the degradation of the carrier in the cytosol is important for mediating RNAi activity. TatU1A-CL1, which showed almost 80% RNAi efficiency, is an excellent candidate RNA carrier protein for the CLIP-RNAi method. CLIP-RNAi performed with the new carrier protein designed for this study would be available for clinical and cell-engineering applications.

Supporting Information

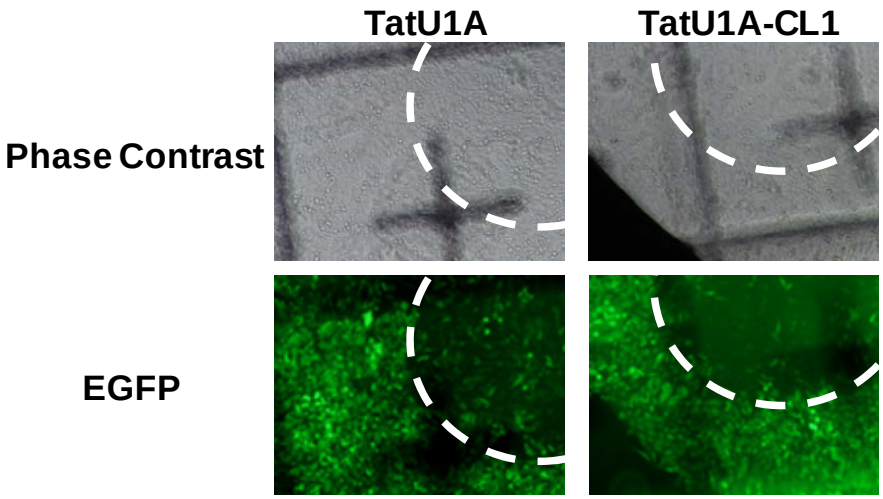

Fig. S1. EGFP silencing in EGFP-CHO cells. Anti-EGFP shRNA (200 nM) was mixed with TatU1A-Alexa546 or TatU1A-CL1-Alexa546 for complex formation, added to EGFP-CHO cells, and incubated at 37ºC for 2 h. After 20 h of irradiation (540 ± 10 nm light passed through a 4× objective lens for 64 s), fluorescent images were evaluated. The irradiated area is to the right of the dotted line.

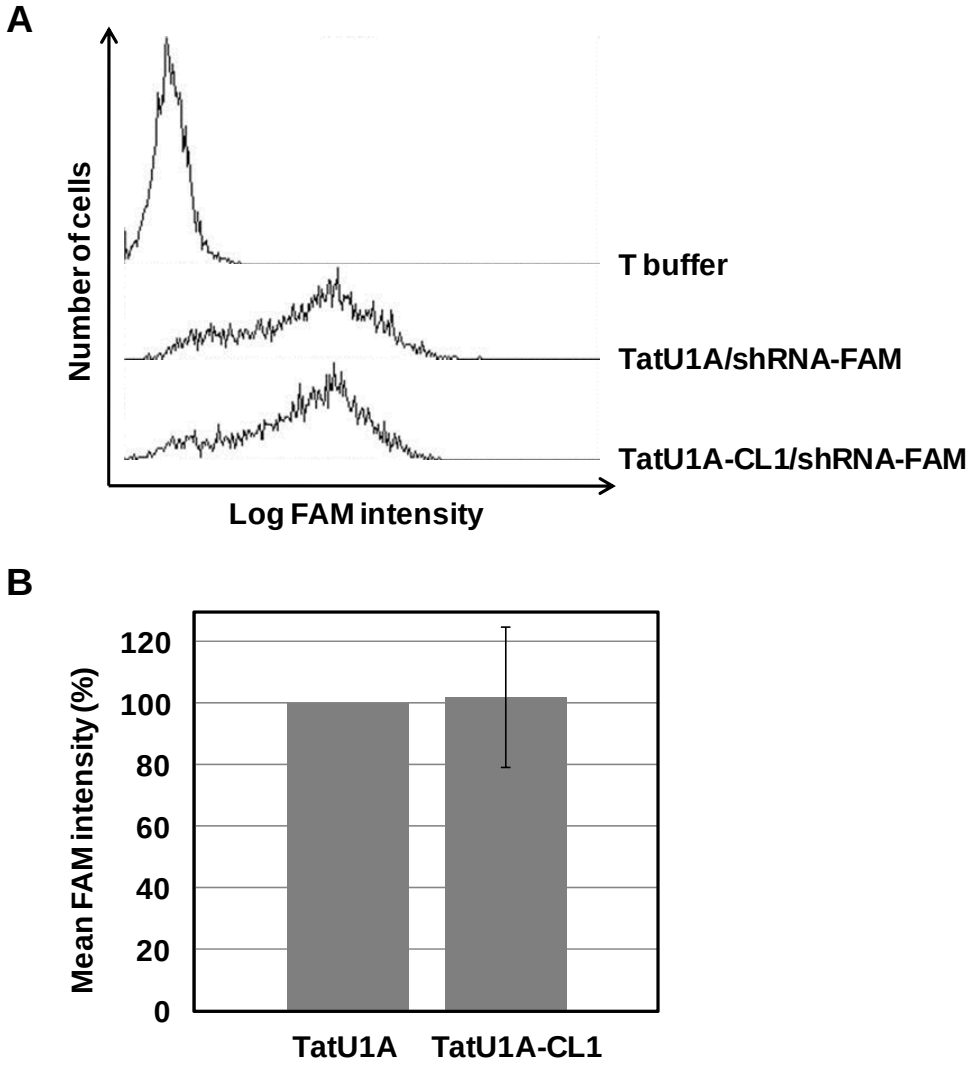

Fig. S2. Cellular FAM intensities after incubation of CHO cells with TatU1A-Alexa/shRNA-FAM or TatU1A-CL1-Alexa/shRNA-FAM. (**A**) The FAM intensities of the cells were evaluated by flow cytometry using FACSCalibur (BD Bioscience). (**B**) Mean FAM intensities with TatU1A and TatU1A-CL1 were analyzed using Cell Quest software (BD Bioscience).

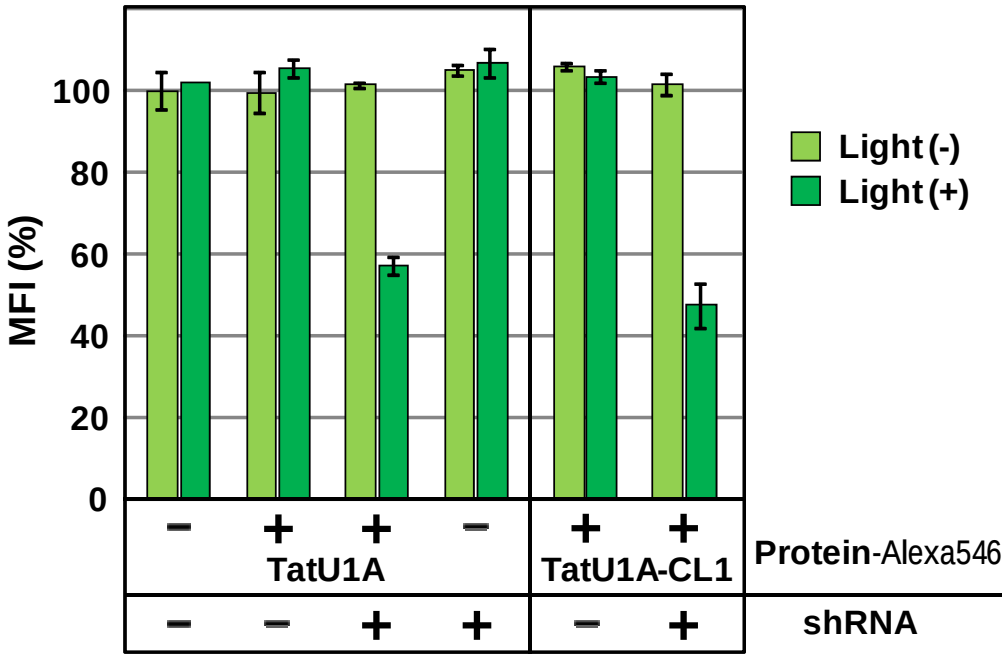

Fig. S3. Evaluation of the knockdown of EGFP expression in EGFP stably-expressing human malignant mesothelioma cells. Cells were treated with TatU1A-Alexa546/shRNA or TatU1A-CL1-Alexa546/shRNA complexes and irradiated (540 ± 10 nm light passed through a 4× objective lens for 64 s). Cells were collected for flow cytometric analysis at 20 h after irradiation. The silencing effect was assessed by measuring EGFP MFI.

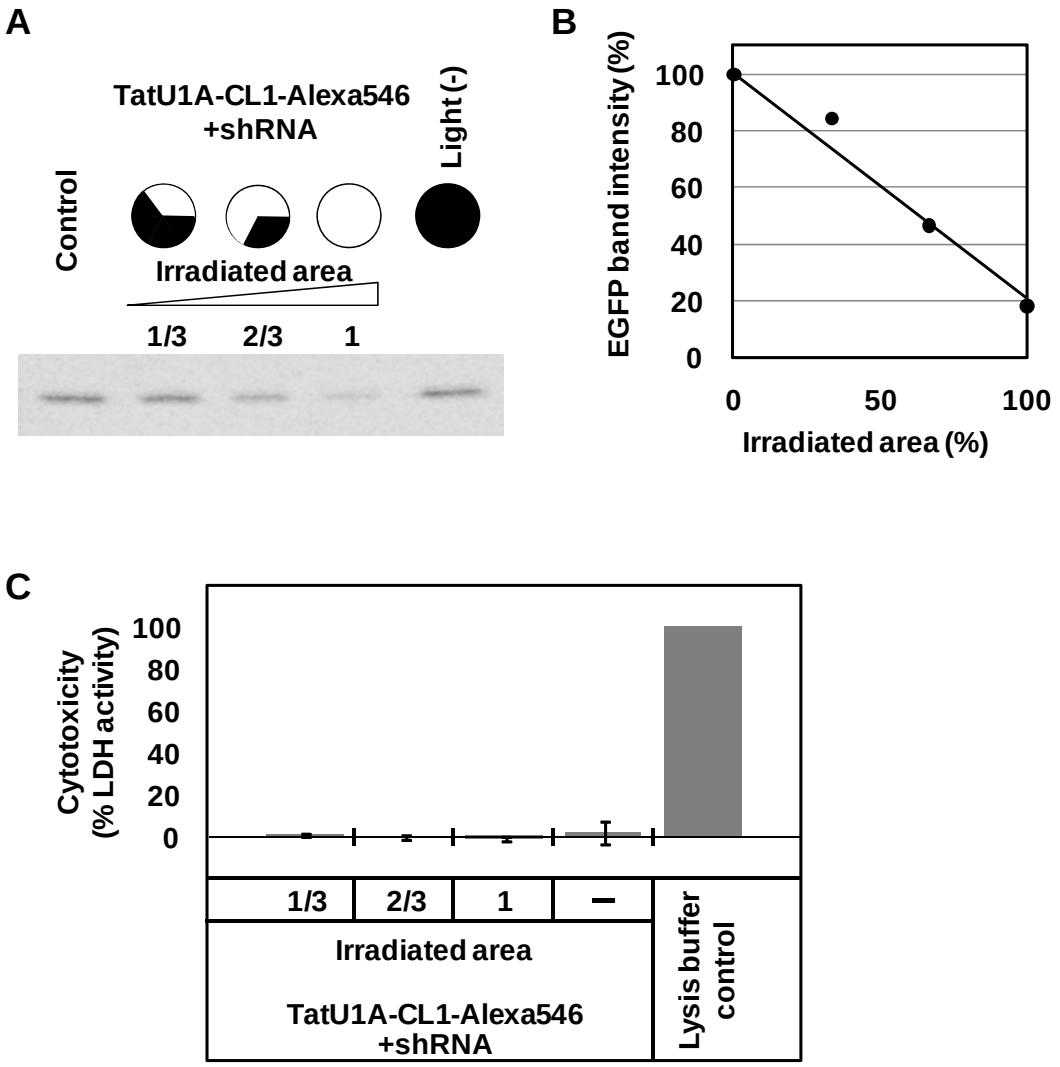

Fig. S4. Partial photoinduction of EGFP silencing. (**A**) Photomasking films were prepared to enable partial photostimulation of cells in the microwells of a 96-well plate, as described previously (Endoh *et al.* J. Controlled Release 137, 241-5, 2009). The photomasking film was attached to the bottom of the culture plate, and the cells were irradiated using a 4× objective lens. Cell lysates were obtained 20 h after photostimulation, and were applied to a 15 % SDS-polyacrylamide gel without boiling. Since EGFP maintains its fluorescence under this condition, EGFP was imaged by using a fluorescence image scanner (HITACHI FMBIO-SC01). (**B**) The EGFP intensity in the

partially irradiated wells. The EGFP intensity decreased depending on the size of the photostimulation area while the amount of total protein remained almost constant. As judged by the band intensity, the EGFP intensity decreased to 18% when the entire area was subjected to photostimulation. (**C**) Cytotoxicity after treatment with the TatU1A-CL1-Alexa546/shRNA complex and photostimulation. At 20 h after photostimulation, cytotoxicity was evaluated using the Cytotoxicity Detection Kit (LDH) (Roche, Switzerland), as described previously (Endoh *et al.* Bioconjug. Chem. 19, 1017-24, 2008).

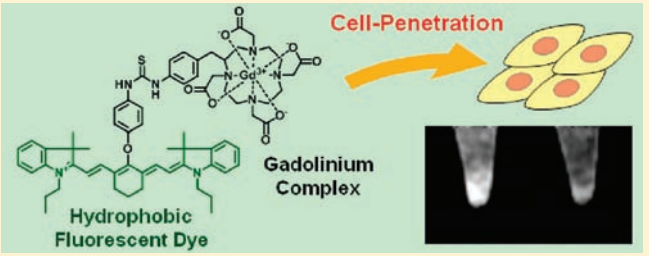
Supporting Information

ABSTRACT: Gadolinium ion (Gd^{3+}) complexes are commonly used as magnetic resonance imaging (MRI) contrast agents to enhance signals in T_1-weighted MR images. Recently, several methods to achieve cell-permeation of Gd^{3+} complexes have been reported, but more general and efficient methodology is needed. In this report, we describe a novel method to achieve cell permeation of Gd^{3+} complexes by using hydrophobic fluorescent dyes as a cell-permeability-enhancing unit. We synthesized Gd^{3+} complexes conjugated with boron dipyrromethene (**BDP-Gd**) and Cy7 dye (**Cy7-Gd**), and showed that these conjugates can be introduced efficiently into cells. To examine the relationship between cell permeability and dye structure, we further synthesized a series of **Cy7-Gd** derivatives. On the basis of MR imaging, flow cytometry, and ICP-MS analysis of cells loaded with **Cy7-Gd** derivatives, highly hydrophobic and nonanionic dyes were effective for enhancing cell permeation of Gd^{3+} complexes. Furthermore, the behavior of these **Cy7-Gd** derivatives was examined in mice. Thus, conjugation of hydrophobic fluorescent dyes appears to be an effective approach to improve the cell permeability of Gd^{3+} complexes, and should be applicable for further development of Gd^{3+}-based MRI contrast agents.



INTRODUCTION

Many imaging techniques, such as X-ray computed tomography (CT), ultrasonography (US), positron emission tomography (PET), and magnetic resonance imaging (MRI), are currently available for the diagnosis of diseases.[1] On the other hand, MRI is useful not only for clinical diagnosis, but also for in vivo imaging in basic research.[2] MRI is based on the NMR signals derived from protons of water molecules, and can provide three-dimensional images of internal body structures noninvasively with high resolution. Gadolinium ion (Gd^{3+}) complexes are commonly used as MRI contrast agents. Paramagnetic Gd^{3+} ions greatly shorten the longitudinal relaxation time (T_1) of water protons by interaction with nearby water molecules.[3] As a result, MR signals of tissues in which Gd^{3+} ions have accumulated show high intensities in T_1-weighted MR images. More recently, sensors based on Gd^{3+} complexes enable us to visualize lesions which are otherwise difficult to detect, as well as biological processes such as gene expression and enzymatic reaction inside the body.[4,5]

On the other hand, Gd^{3+} complexes are generally cell-impermeable, because of their high hydrophilicity, and are distributed only extracellularly. Recently, attempts have been made to develop cell-permeable Gd^{3+} complexes; for example, the attachment of cell-penetrating peptides (CPPs) such as polyarginines or HIV-1 tat peptides is a well-known method to internalize Gd^{3+} complexes or other molecules into cells.[6−9] CPPs consist of positively charged amino acids such as arginine or lysine, and it is reported that electrostatic interactions between the cationic CPPs and the anionic cell-membrane trigger cell-penetration of the CPPs.[10,11] The internalization pathways of CPPs are thought to be endocytosis and macropinocytosis, and its mechanism is highly dependent on incubation conditions or conjugated molecules.[12−14] However, in the case of MRI contrast agents, entrapment of CPPs in endosomes and/or lysosomes might lead to problems such as relaxivity quenching. On the other hands, there is a report that polyarginine-conjugated Gd^{3+} complexes easily leaked from cells;[6] therefore, the increased cell retention via disulfide bond incorporation was also reported.[15,16] Because of the relatively low sensitivity of MRI, it is often difficult to detect small amounts of the Gd^{3+} complexes by MRI; therefore, an efficient method to internalize and retain Gd^{3+} complexes inside cells is still needed in order to extend the applicability of MRI contrast agents.

For this purpose, we focused on fluorescent dyes, because some fluorescent dyes can easily permeate the cell membrane, and the cell permeation property should be controllable by modification of their chemical structures. So, we anticipated that the conjugation of fluorescent dyes to cell-impermeable Gd^{3+} complexes would endow the complexes with cell membrane permeability. The chemical structures of a few fluorescent dye-Gd^{3+} complex conjugates (**dye-Gd**s) have been reported so far. One report described the cell permeation of the Cy5.5-Gd^{3+} complex conjugate in the presence of LDL, but the cell permeation ability was derived from the LDL.[17] Another report described a rhodamine-Gd^{3+} complex conjugate (**Gd(Rhoda-DOTA)**), but when **Gd(Rhoda-DOTA)** was introduced into cells by injection, no MRI contrast enhancement was obtained.[18] Furthermore, Parker et al. reported cell-permeable fluorescent lanthanide complexes, but they did not examine the utility of their Gd^{3+} complexes as MRI contrast agents.[19,20] On the other hand, Mishra et al. reported DO3A-ethylamine-derived contrast agents such as biotin-conjugated, maleimide-bearing, and FITC-coupling Gd^{3+} complexes, and the FITC-conjugated contrast agent was used for MRI and optical labeling of NIH-3T3 cells by the incubation for 18 h.[21]

Here, we report a novel approach to develop cell-permeable Gd^{3+} complexes by using hydrophobic fluorescent dyes as a cell-permeability-enhancing unit. We also examined the relaxivity of **dye-Gd**s, the relationship between cell permeability and dye structure, and the distribution of **dye-Gd**s inside cells. Furthermore, the behavior of cell-permeable and cell-impermeable **dye-Gd**s in mouse was also examined by MRI.

EXPERIMENTAL SECTION

Materials. *p*-NH_2-Bn-DOTA (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetate) and DOTA-mono[*N*-(2-aminoethyl)ethanamide]-tris(*t*-butyl ester) were purchased from Macrocyclics (Dallas, Texas, USA). All other reagents and solvents were purchased from Tokyo Chemical Industry Co. (Tokyo, Japan), Wako Pure Chemical Industries (Osaka, Japan), Dojindo Laboratories (Kumamoto, Japan), Invitrogen (Carlsbad, CA), or Aldrich Chemical Co. (St. Louis, MO) and were used without further purification. Silica gel column chromatography was performed by using Chromatorex-NH (Fuji Silysia Chemical, Kasugai, Japan) or Silica Gel 60 (Spherical) (Kanto Chemical Co., Tokyo, Japan).

Instruments. ^1H and ^{13}C NMR spectra were recorded by using a JEOL JNM-LA300 or JNM-LA400 spectrometer. Mass spectra (ESI) were measured by using a JEOL JMS-T100LC AccuTOF spectrometer. UV−visible spectra were obtained on a Shimadzu UV-1650 spectrophotometer. Fluorescence spectroscopic studies were performed on a Hitachi F-4500 spectrofluorometer. Longitudinal water proton relaxation time (T_1) was measured by using an NMR instrument operating at 20 MHz, 0.47 T (Minispec mq20, Bruker, Germany). HPLC analyses were performed on an Inertsil ODS-3 column (GL Sciences Inc.; 4.6 mm × 250 mm) using an HPLC system composed of a pump (PU-2080, JASCO) and a detector (MD-2015 or FP-2025, JASCO). HPLC purifications were performed on an Inertsil ODS-3 column (GL Sciences Inc.; 10.0 × 250 mm) using an HPLC system composed of a pump (PU-2080, JASCO) and a detector (MD-2015 or FP-2025, JASCO).

Fluorometric Analysis. Excitation slit width, emission slit width, and photomultiplier voltage were 10 nm, 10 nm, and 400 V for **Cy7-Gd** derivatives, and 2.5 nm, 2.5 nm, and 700 V for other **dye-Gd**s, respectively. The spectra of **dye-Gd**s were measured in an aqueous solution buffered to pH 7.4 (100 mM HEPES buffer) at room temperature. Relative fluorescence quantum efficiencies of **dye-Gd**s were determined by comparing the area under the emission spectrum of the sample (on an energy scale) with that of fluorescein in 0.1 M NaOH aqueous solution (Φ = 0.85, for **BDP-Gd** and **FL-Gd**), rhodamine B in ethanol (Φ = 0.97, for **Gd(Rhoda-DOTA)**) or indocyanine green (ICG) in DMSO (Φ = 0.13, for **Cy7-Gd** derivatives).

Relaxivity Measurements. The longitudinal water proton relaxation times (T_1) of aqueous solutions of **dye-Gd**s were measured in phosphate-buffered saline (PBS, Dulbecco's phosphate-buffered saline, pH 7.4) with or without 4% human serum albumin at 37 °C, 20 MHz, 0.47 T (Minispec mq20, Bruker). T_1 values were measured from 30 points generated by using the standard inversion−recovery procedure. The r_1 relaxivities (mM^{-1} s^{-1}) of **dye-Gd**s were determined from the slope of the plot of $1/T_1$ versus concentration of **dye-Gd**s (0.50, 0.20, 0.10, 0.05, and 0 mM) except **Cy7-Gd**. The r_1 relaxivity of **Cy7-Gd** was determined at different concentrations of **Cy7-Gd** (0.10, 0.075, 0.05, 0.025, and 0 mM), because of its low solubility.

Cell Culture. HeLa cells (human cervical cancer cells) and NIH-3T3 cells (mouse fibroblasts) were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% (v/v) fetal bovine serum, penicillin (100 units/mL), and streptomycin (100 units/mL) at 37 °C in a humidified incubator containing 5% CO_2 in air. SHIN3 cells (human ovarian cancer cells) were cultured in Roswell Park Memorial Institute (RPMI) 1640 medium supplemented with 10% (v/v) fetal bovine serum, penicillin (100 units/mL), and streptomycin (100 units/mL) at the same condition with HeLa cells or NIH-3T3 cells.

Fluorescence Microscopic Imaging of Cells. Cells were plated onto 35 mm poly(L-lysine)-coated glass-bottomed dishes (MatTek Corporation, Ashland, MA) and cultured for 2 days. The medium was removed, then **dye-Gd**s in medium (10 μM, containing 0.1% DMSO as a cosolvent) were added and incubation was continued for 2 h. The stained cells were washed twice with PBS, and fluorescence microscopic images were captured in PBS. We used an inverted microscope (IX 71, Olympus) with a 60× objective lens (PlanApo 60× /1.40 oil, Olympus) and *MetaFluor 6.1* software (Universal Imaging, Media PA). The fluorescence images were observed through a filter cube (NIBA for **BDP-Gd** and **FL-Gd**, WIG for **Gd(Rhoda-DOTA)**, and Cy7 for **Cy7-Gd**, Olympus).

MR Imaging of Cells. HeLa cells were plated onto 90 mm noncoated dishes (Fast Gene) and cultured for 3 days. The medium was removed, and then **dye-Gd**s in DMEM (100 μM, containing 0.1% DMSO as a cosolvent) were added and incubation was continued for 2 h. The stained cells were washed once with PBS buffer. The cells were harvested with trypsin-EDTA solution (GIBCO, 0.25% trypsin, 1 mM EDTA·Na), and DMEM was added. The cells were transferred to a 15 mL centrifuge tube, and centrifuged at 1000 rpm, 4 °C for 3 min. After removal of the supernatant, DMEM was added and the cells were transferred to a micro test tube, then centrifuged at 6200 rpm for 3 min. The tube was filled with DMEM, and MR imaging was performed using a 4.7 T MRI scanner (Biospec 47/40, Bruker) with 100 mT/m actively shielded gradient coils equipped with a transmit/receive birdcage coil (od/id: 255/197 nm, Bruker). T_1-weighted MRI

parameters were as follows: fast spin echo sequence, repetition time (TR), 323 ms; echo time (TE), 14 ms; matrix size, 384 × 384; field of view (FOV), 88 × 88 mm^2; slice thickness, 1.5 mm; in-plane resolution, 0.23 × 0.23 mm^2; number of signals averaged, 40; scan time, 15.5 min. Dunnett's test was used to assess differences in the MR signal intensities between sample and control cells. $p < 0.05$ was considered statistically significant.

ICP-MS Measurements. **Dye-Gd**-labeled HeLa cells used in MR imaging were resuspended and transferred to a 15 mL centrifuge tube, then 20% sodium dodecyl sulfate solution (SDS, 3 mL) was added, and the cells were incubated for 2 days. The solution was diluted to 10 mL with ultrapure water, and concentrations of Gd^{3+} ion in the diluted solutions were measured by ICP-MS. Tukey's test (Figure 3c) and Student's *t* test (Figure 6c) were used to assess the significance of differences in the concentrations of Gd^{3+} ion between different groups of cells.

Flow Cytometric (FCM) Analyses. HeLa cells were plated onto 35 mm poly(L-lysine)-coated glass-bottomed dishes (MatTek Corporation) and cultured for 3 days. After removal of the medium, **Cy7-Gd** derivatives in DMEM (10 μM, containing 0.1% DMSO as a cosolvent) were added and incubation was continued for 2 h. The stained cells were washed 3 times with PBS buffer, then incubated with trypsin-EDTA solution (GIBCO, 0.25% trypsin, 1 mM EDTA·Na), and DMEM was added to the dishes. The cells were transferred to a 15 mL centrifuge tube, and centrifuged at 1000 rpm for 3 min. The supernatant was removed. The cells were resuspended in 0.5 mL of PBS, and fluorescence analyses were performed using a BD LSR II Flow Cytometer (Beckman Coulter; 633 nm laser excitation and a 750−810 nm emission filter). Each analysis was performed with 10 000 cells.

Co-Staining with Organelle-Specific Fluorescent Dyes. HeLa cells were plated onto 35 mm poly(L-lysine)-coated glass-bottomed dishes (MatTek Corporation, Ashland, MA) and cultured for 2 days. (i) Dextran-Alexa488 conjugate, which accumulates in lysosomes, was prepared from Alexa Fluor488 5-SDP ester (Invitrogen) and dextran, and purified on a PD-10 column (GE Healthcare). Dextran-Alexa488 conjugate in PBS (1 mg/mL) was mixed with the same quantity of DMEM, and then added to the dish, after removal of the medium. After incubation for 4 h, the stained cells were washed three times with PBS. The medium was replaced with DMEM and incubation was continued for 20 h. After removal of the medium, **dye-Gd**s in DMEM (10 μM, containing 0.1% DMSO as a co-solvent) were added and incubation was continued for 2 h. The stained cells were washed twice with PBS, and confocal fluorescence microscopy images were captured in PBS. (ii) Mitotracker Red, which accumulates in mitochondria, and **dye-Gd**s in DMEM (100 nM and 10 μM, respectively, containing 0.1% DMSO as a co-solvent) were added after removal of the medium, and incubation was continued for 2 h. The stained cells were washed twice with PBS, and confocal fluorescence microscopy images were captured in PBS. (iii) BODIPY TR ceramide, which accumulates in Golgi apparatus, in DMEM (5 μM, containing 0.5% DMSO as a co-solvent) was added after removal of the medium, and incubation was continued for 30 min. The stained cells were washed three times with PBS. The medium was replaced with DMEM and incubation was continued for 30 min. After removal of the medium, **dye-Gd**s in DMEM (10 μM, containing 0.1% DMSO as a co-solvent) were added and incubation was continued for 2 h. The stained cells were washed twice with PBS and confocal fluorescence microscopy images were captured in PBS. We used a confocal imaging system (TCS-SP5, Leica) equipped with a white light laser, Leica Application Suite Advanced Fluorescence (LAS-AF), and a 40× objective lens (HSX PL APO 40×/1.25−0.75 oil CS, Leica). The excitation wavelength and the fluorescence emission wavelength were 495 nm and 505−530 nm for **BDP-Gd** and dextran−Alexa488 conjugate, 552 nm and 600−620 nm for **Gd(Rhoda-DOTA)**, 600 nm and 650−680 nm for BODIPY TR ceramide, and 670 nm and 750−800 nm for **Cy7-Gd** and **6**, respectively.

Fluorescence Imaging of Mice. All procedures were approved by the Animal Care and Use Committee of the University of Tokyo. BALB/cAJcl-*nu*/*nu* (male, 8-week-old) were purchased from CLEA Japan, Inc. Mice were anesthetized by intraperitoneal injection of pentobarbital (Nembutal, Dainippon Sumitomo Pharma Co., 50 mg/kg). A solution of **1** or **6** in saline (100 μM, 100 μL) was administered to the mice via the orbital vein, and fluorescence images were captured with a Maestro In-Vivo Imaging System (CRi Inc., Woburn, MA). The excitation wavelength was 670−710 nm, and fluorescence emission (780−900 nm) was obtained. After imaging at each time point, the mice were sacrificed with CO_2 gas, and blood was collected immediately from the heart. After incision of the femoral vein, PBS was injected from the heart to wash out residual blood, and organs were harvested. Fluorescence images of isolated organs and blood were captured.

MR Imaging of Mice. This experiment complied with the rules for animal experiments of The University of Tokyo. Mice were fixed on a custom-made cradle and anesthetized continuously with a mixture of oxygen and 1.5−2.0% isoflurane (Forane, Abbott Japan). MR imaging was performed before the injection of **dye-Gd**s. Then, compound **1**, **6**, or Gd-DTPA in saline (5 mM, 100 μL) was administered to the mice via the orbital vein, and MR imaging was performed from 10 min after the injection. For MRI experiments, we used a 4.7 T MRI scanner (Biospec 47/40, Bruker, Germany), 100 mT/m actively shielded gradient coils equipped with a transmitter birdcage coil (od/id: 255/197 nm, Bruker), and a receiver surface coil (35 mm, Takashima Seisakusho, Japan). T_1-weighted MR images were obtained with the following parameters: sequence, fast spin echo; repetition time (TR), 300 ms; echo time (TE), 9.8 ms; matrix size, 256 × 256; field of view (FOV), 64 × 64 mm^2; slice thickness, 1.0 mm; in-plane resolution, 0.25 × 0.25 mm^2; number of signals averaged, 3. T_1 maps were obtained with the following parameters: repetition time (TR), 7000, 2000, 1000, 600, 300, 200, 150, 100 ms; echo time (TE), 9.8 ms; matrix size, 128 × 128; field of view (FOV), 80 × 50 mm^2; slice thickness, 1.0 mm; in-plane resolution, 0.63 × 0.30 mm^2; number of signals averaged, 1; scan time, 12.1 min. Mice were kept warm at 37 °C with a heating pad during MR imaging. The experiments were carried out twice for each compound. T_1 values of mouse liver were measured within two regions of interest (ROI) in the left and right sides of the liver, respectively. (The T_1 values of the center of the liver were unclear because of the presence of the aorta.) Each ROI contained 102 voxels, and the T_1 values of the liver were calculated by averaging T_1 values of voxels in both the left and right ROIs. Student's *t* test was used to assess the significance of the differences in T_1 values of the liver between pre- and postinjection of **1**, **6**, or Gd-DTPA.

Fluorescence Microscopic Imaging of Liver Slices. This experiment complied with the rules for animal experiments of

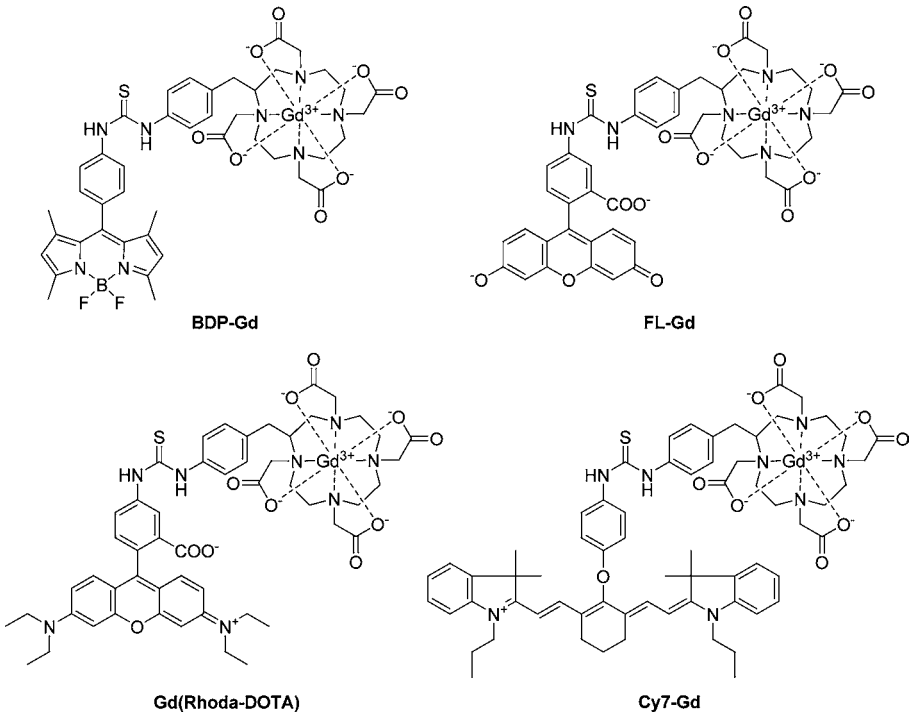

Figure 1. Structures of **dye-Gd**s and Gd-DTPA.

The University of Tokyo. Mice were anesthetized by intraperitoneal injection of pentobarbital (50 mg/kg), and a solution of **1** or **6** in saline (5 mM, 100 μL) was administered via the orbital vein. After 30 min, the mice were sacrificed with CO_2 gas. After incision of the femoral vein, PBS was injected from the heart to wash out the blood. Then, the liver was harvested, washed three times with PBS, embedded in OCT compound (Tissue-Tek), frozen on 2,2-dimethylbutane cooled with liquid N_2, and cut into 5-μm-thick frozen sections. Fluorescence images of the sections were captured on a confocal imaging system (TCS-SP5, Leica) equipped with a white light laser, Leica Application Suite Advanced Fluorescence (LAS-AF), and a 63× objective lens (HSX PL APO 63×/1.40−0.60 oil CS, Leica). The excitation wavelength and the fluorescence emission wavelength were 670 nm and 700−800 nm, respectively.

RESULTS AND DISCUSSION

First, we carried out screening to identify fluorescent dyes which can promote entry of Gd^{3+}-DOTA complexes into cells. We chose boron dipyrromethene (BODIPY), fluorescein, rhodamine B, and Cy7 dye, which have different chemical properties such as hydrophilicity, positive or negative charge, molecular weight, and so forth. The chemical structures of prepared **dye-Gd**s are shown in Figure 1. These **dye-Gd**s were synthesized by conjugation of fluorescent dye isothiocyanates to *p*-NH_2-Bn-DOTA, and the conjugates were subsequently coordinated to Gd^{3+} ion. Fluorescein isothiocyanate and rhodamine B isothiocyanate were commercial products, while BODIPY isothiocyanate and Cy7 isothiocyanate were synthesized by the reaction of the aniline compounds and thiophosgene. **Gd(Rhoda-DOTA)** was previously reported in ref 18 where it was stated not to show contrast enhancement in MR imaging of *Xenopus* embryos.

The fluorescence properties and r_1 relaxivities of **dye-Gd**s are summarized in Table 1. In particular, the r_1 relaxivities of

Table 1. Chemical Properties of dye-Gds

	r_1 (mM^{-1} s^{-1})[a]				
	PBS	4% albumin	λ_{abs} (nm)[b]	λ_{em} (nm)[b]	Φ_{fl}[b,c]
BDP-Gd	22	24	497	509	0.16
FL-Gd	4.1	5.9	493	518	0.63
Gd(Rhoda-DOTA)	6.3	17	557	582	0.28
Cy7-Gd	32	32	768	786	0.063

[a]Data were measured at 20 MHz in PBS. [b]Data were measured in 0.1 M HEPES buffer (pH 7.4). [c]Φ_{fl} is the relative fluorescence quantum yield determined by using fluorescein in 0.1 M NaOH aqueous solution (0.85, for **BDP-Gd**, **FL-Gd**), rhodamine B in EtOH (0.65, for **Gd(Rhoda-DOTA)**), or indocyanine green in DMSO (0.13, for **Cy7-Gd**) as a fluorescence standard.

BDP-Gd and **Cy7-Gd** in PBS were about 5 and 8 times larger than that of Gd-DTPA (DTPA: diethylenetriamine-*N,N,N′,N″,N″*-pentaacetic acid; the r_1 relaxivity of Gd-DTPA was 4.1 mM^{-1} s^{-1} under the same conditions), which is a widely used Gd^{3+} complex.[22] We think that these high relaxivities are derived from the high hydrophobicity of BODIPY and Cy7 dye. **BDP-Gd** and **Cy7-Gd** seem to exhibit stacking in aqueous solution, based on the low fluorescence quantum yields and their spectra, and the resulting increment of apparent molecular weight may lead to enhancement of the r_1 relaxivity because of the slow molecular rotation of the Gd^{3+} complex.[22,23] However, additional effect of albumin was hardly observed about **BDP-Gd** and **Cy7-Gd**. Only **Gd(Rhoda-DOTA)** showed a large increment of the r_1 relaxivity in 4% albumin solution, and this may be due to the interaction with albumin molecules.

Next, we examined the cell permeability of **dye-Gd**s. HeLa cells were incubated with 10 μM **dye-Gd**s for 2 h, then fluorescence images of the cells were captured. No toxicity was observed under these conditions. Fluorescence microscopic

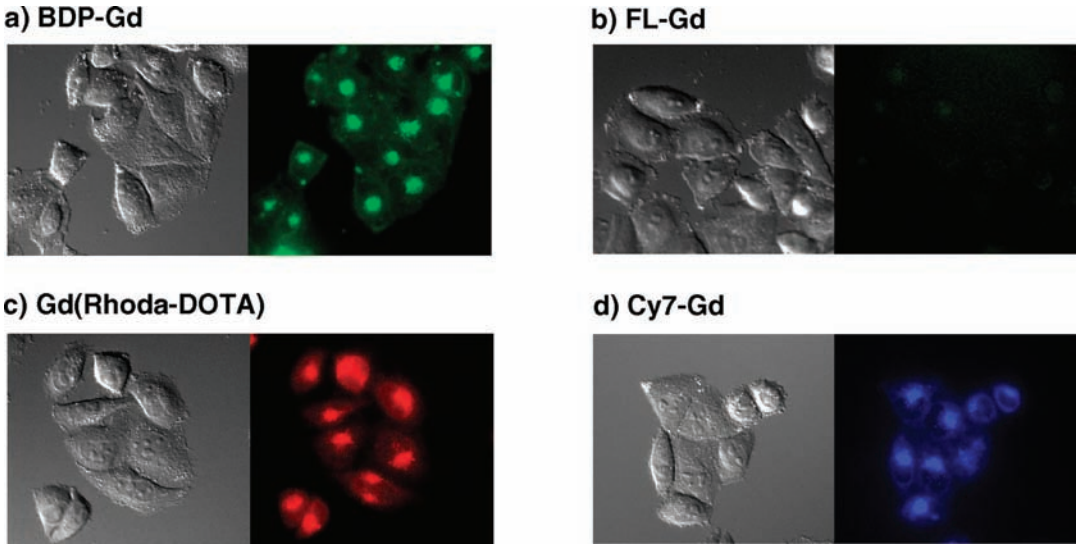

Figure 2. Fluorescence images of HeLa cells incubated with **dye-Gd**s (10 μM). The left and right panels show differential interference contrast (DIC) and fluorescence micrographs of HeLa cells, respectively. (a) **BDP-Gd**, (b) **FL-Gd**, (c) **Gd(Rhoda-DOTA)**, (d) **Cy7-Gd**.

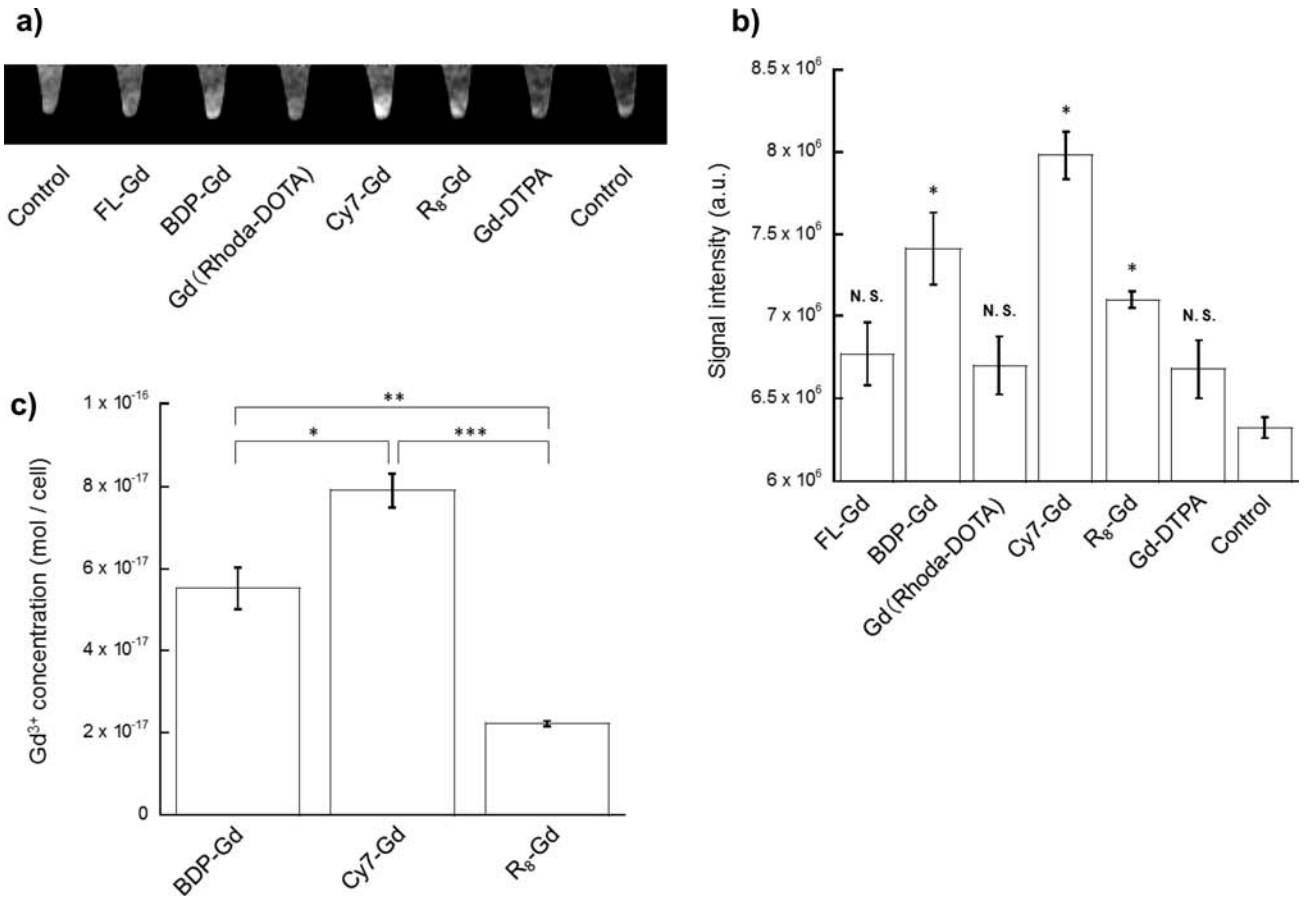

Figure 3. (a) T_1-weighted MR image of HeLa cells incubated with **dye-Gd**s, **R_8-Gd**, and Gd-DTPA (100 μM) for 2 h. (b) MR signal intensities in T_1-weighted MR image of HeLa cells incubated with **dye-Gd**s (n = 3). *p < 0.05. N.S., not significant. (c) Concentrations of Gd^{3+} ion in HeLa cells measured by ICP-MS (n = 3). In the cases of **FL-Gd**, **Gd(Rhoda-DOTA)**, and Gd-DTPA, the concentrations of Gd^{3+} ion could not be measured because the apparent values were too small. *p < 0.05, **p < 0.01, and ***p < 0.001. Error bars show standard error.

analysis demonstrated efficient cell permeation of **BDP-Gd**, **Gd(Rhoda-DOTA)**, and **Cy7-Gd**, whereas **FL-Gd** was not taken into the cells at all (Figure 2). Fluorescein is anionic and relatively hydrophilic compared with the other dyes. According to the results of costaining with organelle-specific fluorescent dyes, each **dye-Gd** showed a different distribution inside cells (Supporting Information Figure S1). **BDP-Gd** showed good overlap with BODIPY TR ceramide, which specifically accumulates in Golgi apparatus, and **Cy7-Gd** was accumulated in lysosomes and mitochondria. In addition, we examined the

dx.doi.org/10.1021/bc200127t | *Bioconjugate Chem.* 2011, 22, 2227–2236

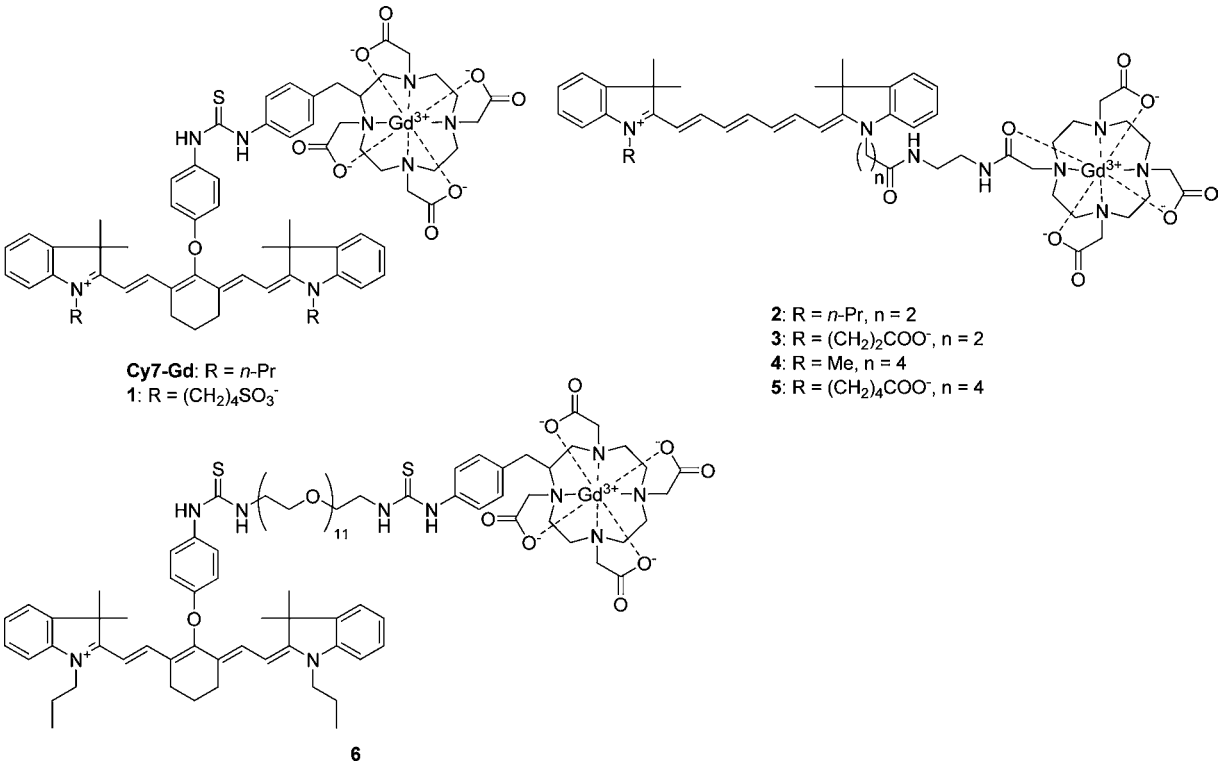

Figure 4. Structures of **Cy7-Gd**s.

contrast effect of **dye-Gd**s by MR imaging of live cells (Figure 3a,b). In the T_1-weighted MR images, **BDP-Gd**, **Cy7-Gd**, and $\mathbf{R_8}$**-Gd**, a cell-permeable octaarginine-conjugated Gd^{3+} complex[6] exhibited significant enhancement of the MR signal of HeLa cells. On the other hand, significant enhancement was not observed with cell-impermeable **FL-Gd** or Gd-DTPA. Moreover, **Gd(Rhoda-DOTA)** also did not produce a significant change of the MR signal, although its fluorescence was observed in fluorescence microscopy. When we compared the efficiency of cell permeation of **dye-Gd**s by using ICP-MS, **BDP-Gd** and **Cy7-Gd** showed higher cell permeation than $\mathbf{R_8}$**-Gd**, while the quantity of **Gd(Rhoda-DOTA)** in the cells was much lower than those of the other cell-permeable **dye-Gd**s (Figure 3c). Thus, **BDP-Gd** and **Cy7-Gd** showed good cell permeability and acted as MRI contrast agents. Furthermore, we examined the cell permeability of **BDP-Gd** and **Cy7-Gd** using other cell lines (Supporting Information Figure S2). **BDP-Gd** and **Cy7-Gd** were taken into both NIH/3T3 cells and SHIN3 cells, and the fluorescence intensities of the cells were equivalent to that in the case of HeLa cells.

To further examine the relationship between the chemical structure of Gd^{3+} complexes and the cell permeability, we synthesized various **Cy7-Gd** derivatives (**Cy7-Gd**s) (Figure 4). We chose **Cy7-Gd**s as a basic scaffold because structural elaboration is easier than in the case of **BDP-Gd**. Compound **1** has two anionic sulfo groups, and **2**, **3**, **4**, and **5** have asymmetric structures. Compound **6** has a poly(ethylene glycol) (PEG) chain between the Cy7 dye and Gd^{3+} complex. All of compounds **1**−**6** showed higher solubility in water than did **Cy7-Gd**. The fluorescence properties and r_1 relaxivities of these **Cy7-Gd**s are summarized in Table 2. Compounds **1** and **6** showed high r_1 relaxivities, whereas compounds **2**−**5** showed low r_1 relaxivities, almost the same as that of Gd-DTPA. It is considered that these differences arise from differences in the degree of stacking of these compounds on the basis of the low fluorescence quantum yields. Alternatively, hydrophobicity and/or flexibility of linker of **1** and **6** such as thiourea-phenyl moiety might change the local rotational dynamics of the Gd^{3+} complex and the r_1 relaxivities. Moreover, additional effect of albumin was hardly observed about **1** and **6**, while compounds **2**−**5** showed the high r_1 relaxivities in 4% albumin solution by their interactions with albumin molecules.

Table 2. Chemical Properties of Cy7-Gds

	r_1 (mM^{-1} s^{-1})[a]				
	PBS	4% albumin	λ_{abs} (nm)[b]	λ_{em} (nm)[b]	Φ_{fl}[b,c]
Cy7-Gd	32	32	768	786	0.063
1	20	25	769	785	0.072
2	4.0	12	743	762	0.14
3	4.9	11	743	763	0.12
4	4.6	13	741	761	0.14
5	5.0	12	745	765	0.14
6	18	20	771	786	0.078

[a]Data were measured at 20 MHz in PBS. [b]Data were measured in 0.1 M HEPES buffer (pH 7.4). [c]Φ_{fl} was determined by using indocyanine green in DMSO (0.13) as a fluorescence standard.

Cell permeation of **Cy7-Gd**s was examined by means of fluorescence microscopy and FCM analysis (Figure 5). When cells were incubated with **1** bearing sulfo groups, no fluorescence was observed in the cells by fluorescence microscopy (Figure 5b). On the other hand, **6** showed stronger fluorescence intensity than that of **Cy7-Gd** (Figure 5c). In FCM analysis, compounds **2**−**5** were less well taken into the cells than **Cy7-Gd**, and cell permeation of **3** and **5**, bearing a carboxy group in the Cy7 scaffold was lower than that of **2** and **4**, which have no carboxy group. Thus, as was expected, these results showed that anionic compounds were less effective for

dx.doi.org/10.1021/bc200127t | *Bioconjugate Chem.* 2011, 22, 2227−2236

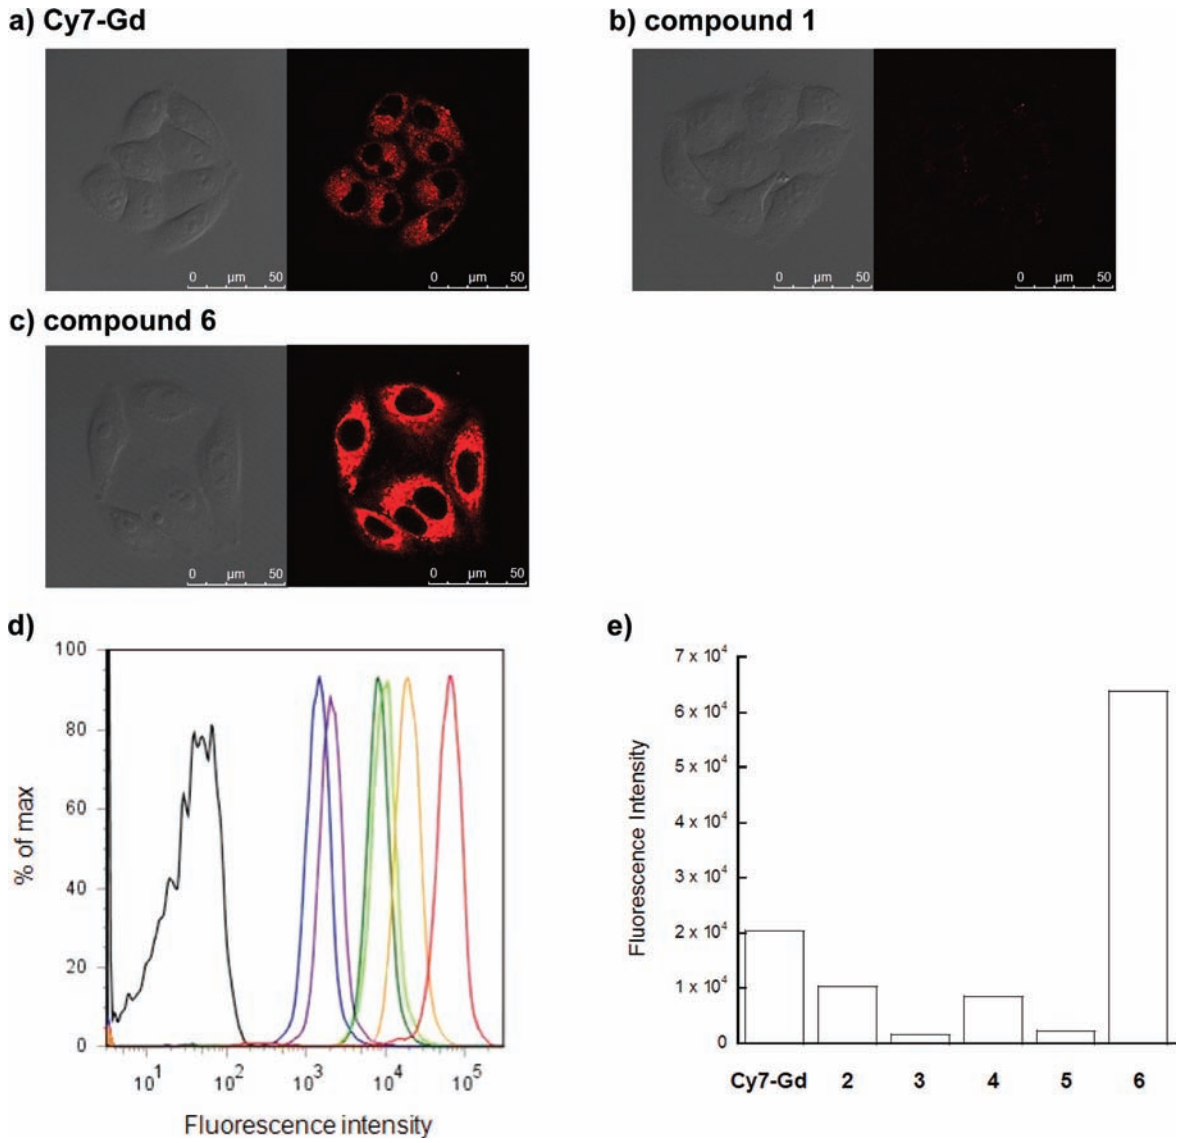

Figure 5. Confocal fluorescence microscopic images of HeLa cells incubated with (a) **Cy7-Gd**, (b) **1**, and (c) **6**. Left and right panels show DIC and fluorescence images, respectively. (d,e) FCM analysis of HeLa cells incubated with **Cy7-Gd** derivatives (10 μM). Each analysis was performed with 10 000 cells. Yellow, **Cy7-Gd**; light green, **2**; blue, **3**; deep green, **4**; purple, **5**; red, **6**; black, control.

cell permeation.[24] Compound **6** showed the highest fluorescence intensity among the **Cy7-Gd**s examined in FCM analysis, and was accumulated in mitochondria on the basis of the confocal fluorescence images (Supporting Information Figure S3). Furthermore, we examined the contrast effects of cell-permeable **6** and cell-impermeable **1** in MR imaging of live cells. Compound **6** showed a significant signal enhancement of live cells in MR imaging, whereas no significant enhancement was observed in the case of **1** (Figure 6a,b). In addition, a higher Gd^{3+} concentration of **6** was also observed in the cells on ICP-MS measurement (Figure 6c). From these results, PEG chains are thought to improve both cell permeation and water solubility,[25] and **6** was the best cell-permeable contrast agent among the **Cy7-Gd**s synthesized here.

We next examined the behaviors of cell-permeable **6** and cell-impermeable **1** in in vivo MR imaging of mice. These two compounds showed sufficient water solubility for MR imaging and had high r_1 relaxivities. First, compound **1** or **6** dissolved in saline (100 μM, 100 μL) was administered intravenously to nude mice, and then, the accumulation in various organs was observed by means of fluorescence imaging. Each compound accumulated mostly in the liver (Supporting Information Figure S4). The reason **1** and **6** accumulate in the liver is considered to be as follows. Indocyanine green (ICG), which is a tricarbocyanine dye, is accumulated specifically in the liver when it is administered, because it binds to serum protein such as albumin and lipoprotein, and is carried to the liver.[26] Therefore, ICG is used as a diagnostic agent to evaluate hepatic function (Diagnogreen Daiichi Sankyo). ICG is taken into hepatocytes via Na^+-independent basolateral membrane transport systems, such as organic anion transporting polypeptide 1 (OATP1) and organic anion transporter LST-1.[27,28] Compounds **1** and **6** also have tricarbocyanine structures, and therefore might be taken into the liver via the same pathways as ICG.

We also evaluated the MRI contrast effect of **1** and **6** in vivo. Cell-impermeable **1** or cell-permeable **6** in saline (5 mM, 100 μL) was administered intravenously to mice, and T_1-weighted MR images and T_1 maps of the body were measured (Figure 7). After the injection of **6**, MR signals of the liver were enhanced

dx.doi.org/10.1021/bc200127t | *Bioconjugate Chem.* 2011, 22, 2227–2236

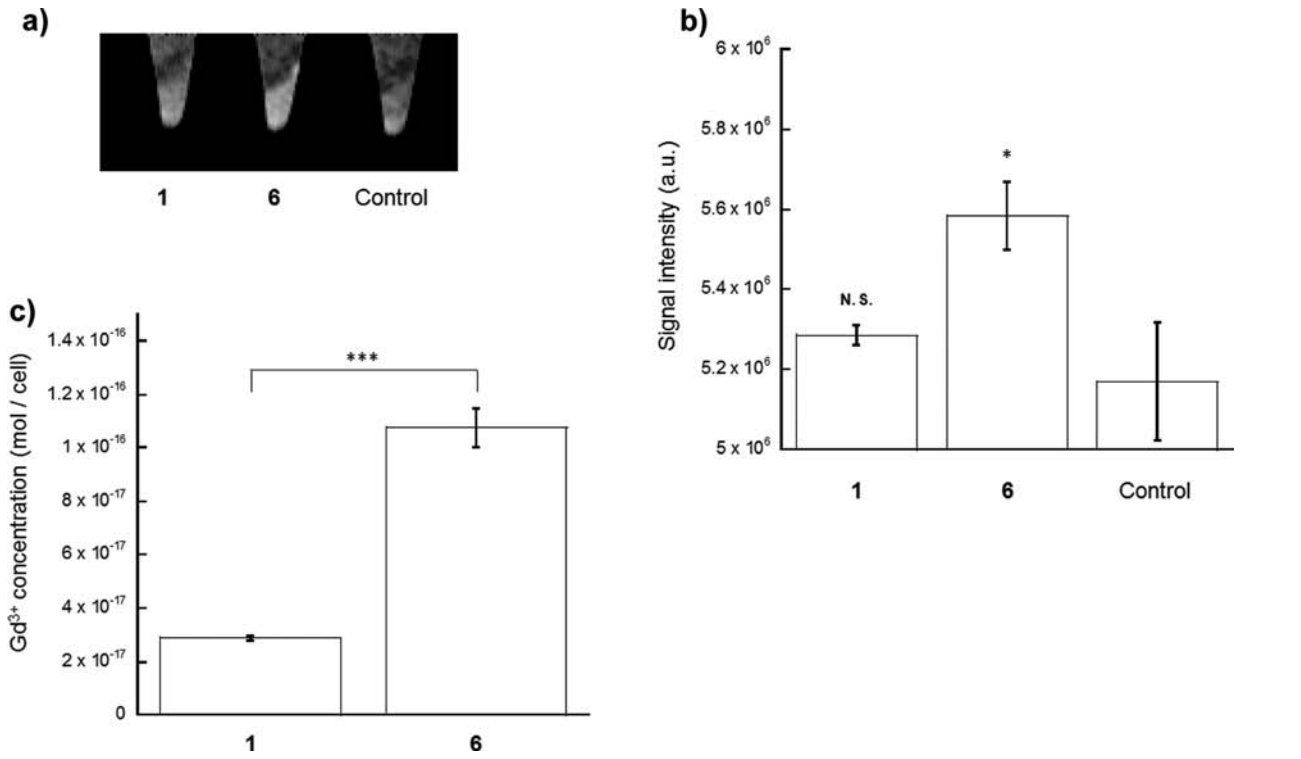

Figure 6. (a) T_1-weighted MR image of HeLa cells incubated with **Cy7-Gd**s (100 μM). (b) MR signal intensities in T_1-weighted MR image of HeLa cells (n = 3). *p < 0.05. N.S., not significant. (c) Concentrations of Gd^{3+} in HeLa cells (n = 3). ***p < 0.001. Error bars show standard error.

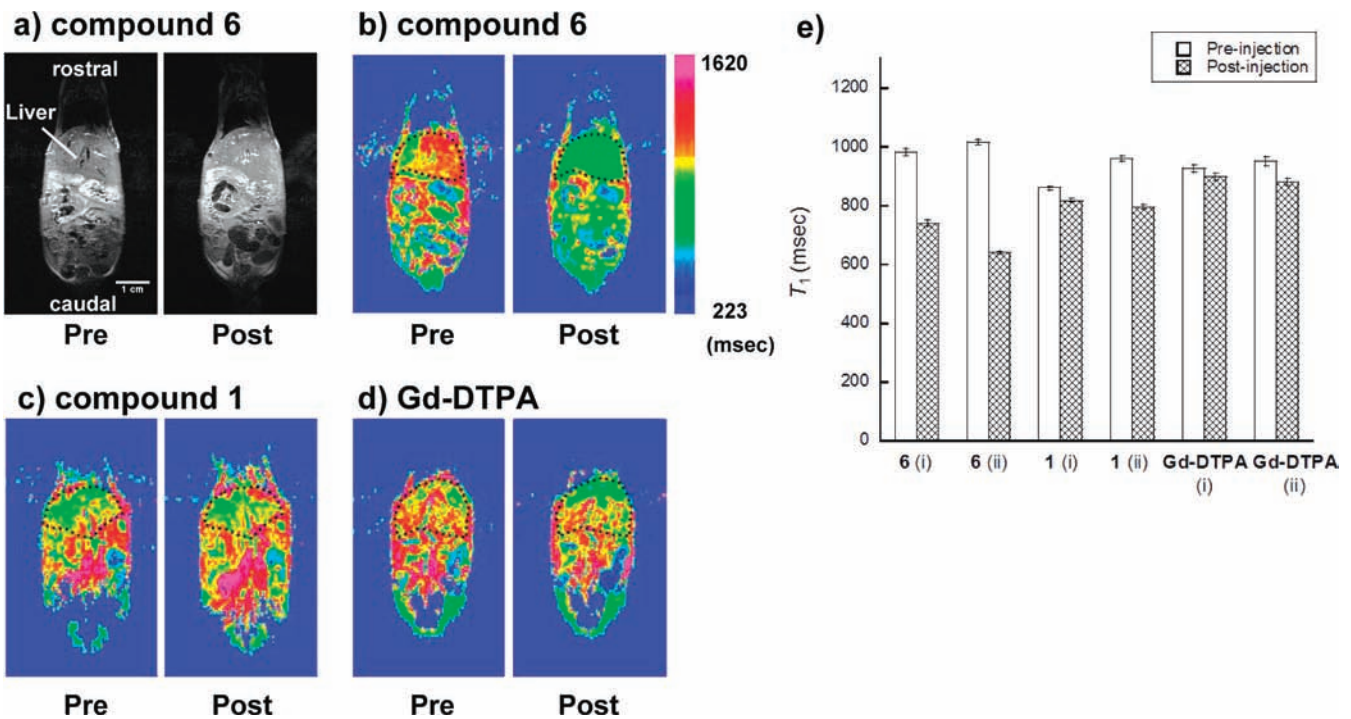

Figure 7. T_1-weighted MR images and T_1 maps of mice before (left) and after (right) the injection of **1**, **6**, or Gd-DTPA (5 mM, 100 μL). (a) T_1-weighted MR image of mouse injected with **6**. (b,c,d) T_1 maps of mice injected with (b) **6**, (c) **1**, and (d) Gd-DTPA. Dotted frames show the position of the liver. (e) The T_1 values in mouse liver in each experiment. Error bars show standard error (204 voxels). All changes of the T_1 values in each experiment were statistically significant (p < 0.001).

in T_1-weighted MR images, and the T_1 value of the liver decreased. Larger changes of the T_1 value in the liver were observed in the experiments with **6** (ΔT_1 = 241 and 353 ms) than in those with **1** (ΔT_1 = 70 and 151 ms), although accumulation of both compounds in the liver was observed in the fluorescence images (Supporting Information Figure S4). The changes of the T_1 values in the liver were small when Gd-DTPA was administered (ΔT_1 = 38 and 99 ms), and it was

dx.doi.org/10.1021/bc200127t | *Bioconjugate Chem.* 2011, 22, 2227–2236

considered that Gd-DTPA is nonspecifically distributed all over the body and rapidly eliminated through the kidney.

To clarify the reason **6** showed a higher MR signal in the liver than **1**, we observed the fluorescence images of mouse liver slices by means of confocal fluorescence microscopy. At 30 min after injection of **1** or **6** (5 mM, 100 μL, the same dose used in MRI), mice were sacrificed, and the livers were harvested. Frozen sections were prepared, and fluorescence microscopic images were obtained. Interestingly, the fluorescence intensity of hepatocytes of the mouse injected with **6** was much higher than that in the case of **1** (Figure 8), although

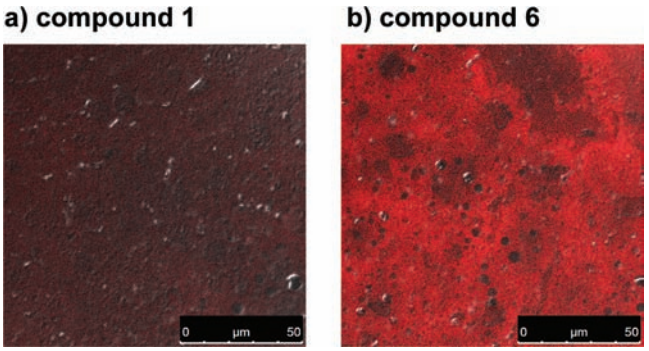

Figure 8. Fluorescence images of liver slices from mice injected with (a) **1** and (b) **6** (5 mM, 100 μL). Ex: 670 nm, Em: 700−800 nm.

the fluorescence intensities of the liver were almost the same after injection of the two compounds at low dose (100 μM, 100 μL, Supporting Information Figure S4). These results indicated that cell-permeable **6** is accumulated in hepatocytes more efficiently than cell-impermeable **1** at high dose (5 mM, 100 μL), and the difference of the MR signal would reflect the difference in the amount of **1** or **6** in the liver due to their biodistribution/excretion pathways.

CONCLUSION

In conclusion, we have developed a novel method for enhancing the cell permeation of Gd^{3+} complexes by using hydrophobic fluorescent dyes as a cell-permeation-promoting unit. We designed and synthesized various fluorescence dye−Gd^{3+} complex conjugates, and found that the Gd^{3+} complexes conjugated with BODIPY and Cy7 dye were efficiently accumulated into cells. We further examined the relationship between cell permeability and chemical structure in a series of **Cy7-Gd**s, and the results showed that a hydrophobic and nonanionic scaffold is favorable for the development of cell-permeable Gd^{3+} complexes. Among the synthesized **Cy7-Gd**s, compound **6** was the best cell-permeable MRI contrast agent. In addition, the behavior of **Cy7-Gd** derivatives in mice was also examined. Our method has the further advantage of enabling easy and detailed observation of the distribution of Gd^{3+} complexes inside cells or tissues by means of fluorescence imaging. This design strategy should be useful for further development of various MRI contrast agents.

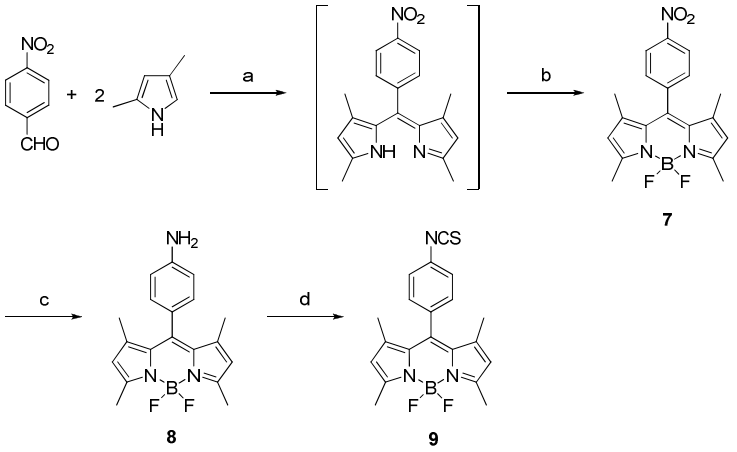
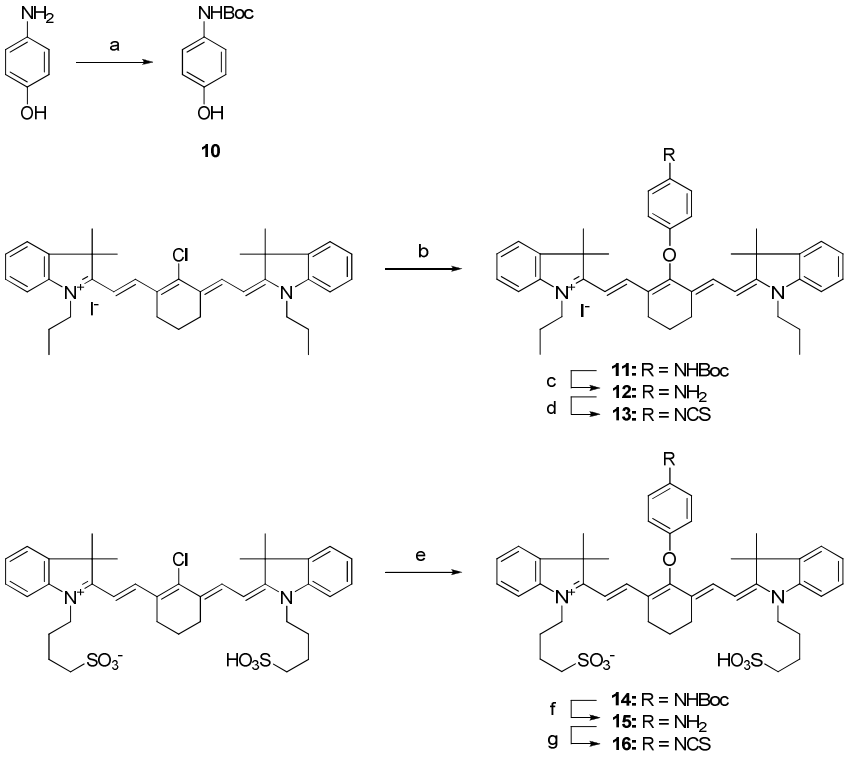
Experimental Procedures and Characterization of Compounds



Scheme S1. Synthesis of BODIPY isothiocyanate. (a) (1) TFA, CH_2Cl_2, r.t., (2) chloranil, r.t.; (b) $BF_3 \cdot Et_2O$, TEA, toluene, r.t.; (c) Pd/C, CH_2Cl_2/MeOH, r.t., under H_2; (d) thiophosgene, Na_2CO_3, DMF, 0 ºC to r.t.

Synthesis of compounds 7 and 8: see reference S1.

Synthesis of compound 9: Compound **8** (101 mg, 0.30 mmol) and Na_2CO_3 (151 mg, 1.4 mmol) were dissolved in 25 mL of DMF. The resulting mixture was cooled at 0 ºC, and thiophosgene (100 μL, 1.3 mmol) was added dropwise under an argon atmosphere. The reaction mixture was warmed to room temperature and stirred for 2 h. The solvent was removed by evaporation, and the residue was purified by column chromatography (silica gel 60, CH_2Cl_2/hexane, 1:2) to afford compound **9** as an orange solid (113 mg, 99%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.40 (s, 6H); 2.56 (s, 6H); 6.00 (s, 2H); 7.30 (d, 2H, ***J*** = 8.8 Hz); 7.37 (d, 2H, ***J*** = 8.8 Hz); ^{13}C NMR (100 MHz, $CDCl_3$): δ 14.6, 14.7, 121.5, 126.5, 129.6, 131.1, 132.3, 134.0, 137.1, 139.8, 142.8, 156.0; HRMS (ESI^+): Calcd for $[M+H]^+$, 382.1361; Found, 382.1326.



Scheme S2. Synthesis of Cy7 isothiocyanate. (a) Boc_2O, TEA, MeOH, r.t.; (b) **10**, NaH, DMF, r.t.; (c) TFA, CH_2Cl_2 / MeOH, r.t.; (d) thiophosgene, Na_2CO_3, DMF, 0 ºC to r.t.; (e) **10**, NaH, DMF, r.t.; (f) TFA, r.t.; (g) thiophosgene, Na_2CO_3, DMF, 0 ºC to r.t.

Synthesis of compound 10: 4-Aminophenol (327 mg, 3.0 mmol) and triethylamine (TEA, 630 μL, 4.5 mmol) were dissolved in 15 mL of MeOH. Boc_2O (786 mg, 3.6 mmol) was added, and the mixture was stirred for 4 h at room temperature. The solvent was removed by evaporation, and the residue was purified by column chromatography (silica gel 60, CH_2Cl_2/MeOH, 19:1) to afford compound **10** as a colorless solid (615 mg, 98%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.51 (s, 9H), 5.54 (s, 1H), 6.36 (br s, 1H), 6.75 (d, ***J*** = 8.8 Hz, 2H), 7.18 (d, ***J*** = 8.8 Hz, 2H); ^{13}C NMR (75 MHz, CD_3OD): δ 28.7, 80.5, 116.2, 122.2, 132.3, 154.4, 155.9; HRMS (ESI$^-$): Calcd for [M-I]$^-$, 208.0974; Found, 208.0982.

Synthesis of compound 11: Compound **10** (126 mg, 0.60 mmol) was dissolved in 15 mL of DMF. Sodium hydride (60% in oil, 24 mg, 0.60 mmol) was added, and the mixture was stirred for 10 min at room temperature under an argon atmosphere. IR-780 iodide (Aldrich, 200 mg, 0.30 mmol) was added to the mixture, and stirring was continued overnight. The solvent was removed by evaporation, and the residue was purified by column chromatography (NH silica, CH_2Cl_2/MeOH, 19:1) to afford **11** as a purple solid (184 mg, 73%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.05 (t, ***J*** = 7.4 Hz, 6H), 1.36 (s, 12H), 1.50 (s, 9H), 1.87 (sex, ***J*** = 7.4 Hz, 4H), 2.05 (t, ***J*** = 5.5 Hz, 2H), 2.72 (t, ***J*** = 5.5 Hz, 4H), 4.05 (t, ***J*** = 7.4 Hz, 4H), 6.05 (d, ***J*** = 14.3 Hz, 2H), 6.80 (br s, 1H), 6.99 (d, ***J*** = 9.0 Hz, 2H), 7.09 (d, ***J*** = 7.7 Hz, 2H), 7.20 (d, ***J*** = 7.7 Hz, 2H), 7.27 (d, ***J*** = 6.8 Hz, 2H), 7.34 (d, ***J*** = 6.8 Hz, 2H), 7.47 (d, ***J*** = 9.0 Hz, 2H), 7.91 (d, ***J*** = 14.3 Hz, 2H); ^{13}C NMR (75 MHz, $CDCl_3$): δ 11.6, 20.8, 21.1, 24.6, 27.9, 28.3, 46.1, 49.0, 80.4, 100.0, 110.5, 114.8, 120.6, 122.2, 122.5, 125.0, 128.6, 133.4, 141.0, 142.1, 153.0, 155.5, 164.5, 172.0; HRMS (ESI$^+$): Calcd for [M−I]$^+$, 712.4478; Found, 712.4478.

Synthesis of compound 12: Compound **11** (118 mg, 0.14 mmol) was dissolved in 2.5 mL of CH_2Cl_2, then 0.5 mL of trifluoroacetic acid (TFA) was added, and the mixture was stirred for 2 h at room temperature. The solvent was removed by evaporation. The residue was purified by column chromatography (NH silica, CH_2Cl_2/MeOH, 9:1) to afford **12** as a purple solid (99 mg, 95%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.03 (t, ***J*** = 7.4 Hz, 6H), 1.38 (s, 12H), 1.86 (sex, ***J*** = 7.4 Hz, 4H), 2.02 (t, ***J*** = 5.8 Hz, 2H), 2.67 (t, ***J*** = 5.8 Hz, 4H), 4.00 (t, ***J*** = 7.4 Hz, 4H), 6.01 (d, ***J*** = 14.3 Hz, 2H), 6.70 (d, ***J*** = 8.8 Hz, 2H), 6.85 (d, ***J*** = 8.8 Hz, 2H), 7.06 (d, ***J*** = 7.6 Hz, 2H), 7.19 (d, ***J*** = 7.6 Hz, 2H), 7.27 (d, ***J*** =

6.4 Hz, 2H), 7.34 (td, ***J*** = 7.6, 1.2 Hz, 2H), 7.96 (d, ***J*** = 14.3 Hz, 2H); ^{13}C NMR (75 MHz, $CDCl_3$): δ 11.6, 20.7, 21.1, 24.4, 27.9, 45.9, 49.0, 99.7, 110.5, 115.0, 116.7, 122.1, 122.6, 124.9, 128.5, 141.0, 141.7, 142.2, 142.4, 153.2, 165.3, 171.9; HRMS (ESI^+): Calcd for $[M-I]^+$, 612.3954; Found, 612.3963.

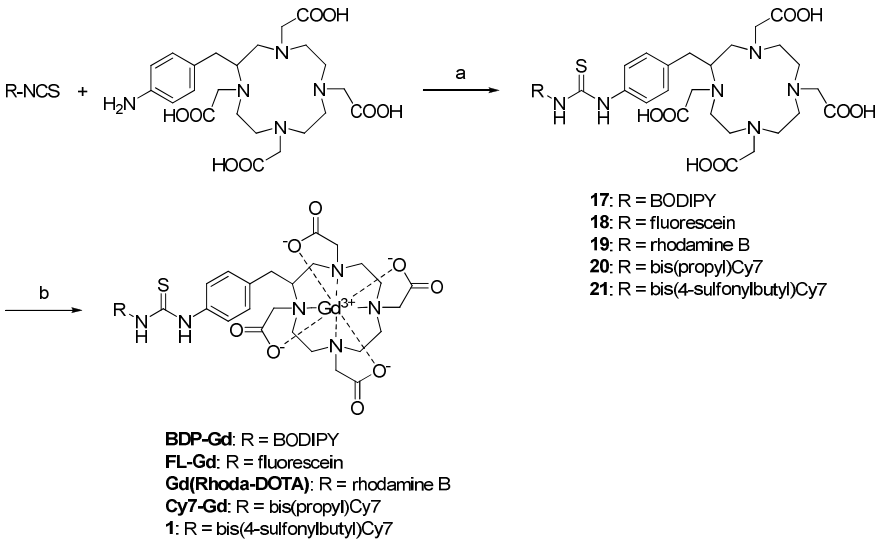
Synthesis of compound 13: Synthetic procedure was the same as for **9**. Purification of the reaction mixture was carried out by column chromatography (silica gel 60, CH_2Cl_2/MeOH, 9:1) to afford **13** as a purple solid (34 mg, 75%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.04 (t, ***J*** = 7.4 Hz, 6H), 1.35 (s, 12H), 1.86 (sex, ***J*** = 7.4 Hz, 4H), 2.04 (t, ***J*** = 5.8 Hz, 2H), 2.72 (t, ***J*** = 5.8 Hz, 4H), 4.07 (t, ***J*** = 7.4 Hz, 4H), 6.13 (d, ***J*** = 14.3 Hz, 2H), 7.06 (d, ***J*** = 8.8 Hz, 2H), 7.09 (d, ***J*** = 8.8 Hz, 2H), 7.17-7.28 (m, 6H), 7.36 (t, ***J*** = 7.6 Hz, 2H), 7.79 (d, ***J*** = 14.3 Hz, 2H); ^{13}C NMR (100 MHz, DMSO-$\boldsymbol{d}_6$): δ 11.1, 20.4, 20.6, 23.7, 27.2, 44.9, 48.6, 100.5, 111.4, 115.9, 121.1, 122.5, 123.9, 124.9, 128.3, 128.5, 132.6, 140.3, 140.9, 142.1, 158.4, 161.5, 171.8; HRMS (ESI^+): Calcd for $[M-I]^+$, 654.3518; Found, 654.3503.

Synthesis of compound 14: Synthetic procedure was the same as for **11**. Purification of the reaction mixture was carried out by column chromatography (Silica gel 60, CH_2Cl_2/MeOH, 2:1) to afford **14** as a purple solid (176 mg, 89%). ^{1}H NMR (300 MHz, CD_3OD): δ 1.26 (s, 12H), 1.39 (s, 9H), 1.83 (br s, 8H), 1.93 (br s, 2H), 2.65 (br s, 4H), 2.78 (t, ***J*** = 6.8 Hz, 4H), 4.03 (br s, 4H), 6.08 (d, ***J*** = 14.3 Hz, 2H), 6.93 (d, ***J*** = 9.2 Hz, 2H), 7.09 (t, ***J*** = 7.3 Hz, 2H), 7.18 (d, ***J*** = 7.7 Hz, 2H), 7.24-7.33 (m, 6H), 7.90 (d, ***J*** = 14.3 Hz, 2H), 8.79 (s, 1H); ^{13}C NMR (75 MHz, CD_3OD): δ 22.5, 23.6, 25.2, 27.2, 28.2, 28.7, 44.8, 50.2, 51.8, 80.7, 101.1, 112.0, 115.9, 121.7, 123.3, 123.6, 126.1, 129.7, 135.4, 142.5, 143.5, 143.6, 155.3, 157.0, 165.6, 173.6; HRMS (ESI^+): Calcd for $[M+Na]^+$, 944.3566; Found, 944.3530.

Synthesis of compound 15: Compound **14** (176 mg, 0.19 mmol) was dissolved in 2.5 mL of TFA, and the solution was stirred for 30 min at room temperature. TFA was removed by evaporation, and the residue was purified by column chromatography (silica gel 60, CH_2Cl_2/MeOH, 7:3) to afford **15** as a purple solid (168 mg, quant.). ^{1}H NMR (300 MHz, CD_3OD): δ 1.27 (s, 12H), 1.82 (br s, 8H), 1.92 (t, ***J*** = 5.3 Hz, 2H), 2.63 (t, ***J*** = 5.3 Hz, 4H), 2.76 (t, ***J*** = 6.8 Hz, 4H), 4.02 (t, ***J*** = 6.8 Hz, 4H), 6.08 (d, ***J*** =

14.3 Hz, 2H), 6.89 (d, ***J*** = 9.2 Hz, 2H), 6.93 (d, ***J*** = 9.2 Hz, 2H), 7.09 (t, ***J*** = 7.5 Hz, 2H), 7.19 (d, ***J*** = 7.5 Hz, 2H), 7.25 (d, ***J*** = 7.5 Hz, 2H), 7.27 (d, ***J*** = 7.5 Hz, 2H), 7.89 (d, ***J*** = 14.3 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 22.5, 23.6, 25.3, 27.2, 28.2, 44.9, 50.3, 51.8, 101.1, 112.1, 116.8, 121.6, 123.3, 123.6, 126.1, 129.8, 136.5, 142.4, 143.4, 143.7, 157.4, 165.6, 173.6; HRMS (ESI$^+$): Calcd for $[M+Na]^+$, 844.3042; Found, 844.3006.

Synthesis of compound 16: Synthetic procedure was the same as for **13**. Purification of the reaction mixture was carried out by column chromatography (Silica gel 60, CH_2Cl_2/MeOH, 2:1) to afford **16** as a purple solid (114 mg, >99%). ^{1}H NMR (300 MHz, DMSO-***d*$_6$**): δ 1.22 (s, 12H), 1.67 (br s, 8H), 1.88 (br s, 2H), 2.44 (br s, 4H), 2.67 (br s, 4H), 4.08 (br s, 4H), 6.19 (d, ***J*** = 14.3 Hz, 2H), 7.14 (t, ***J*** = 7.0 Hz, 2H), 7.20 (d, ***J*** = 8.4 Hz, 2H), 7.31 (t, ***J*** = 7.5 Hz, 2H), 7.35 (d, ***J*** = 8.4 Hz, 2H), 7.45 (d, ***J*** = 7.5 Hz, 4H), 7.67 (d, ***J*** = 14.3 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 22.4, 23.6, 25.2, 27.2, 28.2, 44.9, 50.3, 51.8, 101.4, 112.2, 117.3, 123.1, 123.4, 126.2, 126.8, 128.9, 129.8, 136.7, 142.5, 142.9, 143.6, 160.0, 164.3, 173.7; HRMS (ESI$^+$): Calcd for $[M+Na]^+$, 886.2606; Found, 886.2579.



Scheme S3. Synthesis of **dye-Gd**s. (a) DIEA or TEA, MeOH or DMF, r.t.; (b) $GdCl_3$, 1.0 M HEPES buffer (pH 7.4), r.t.

Synthesis of compound 17: Compound **9** (101 mg, 0.27 mmol) and ***N*,*N***-diisopropylethylamine (DIEA, 92 μL, 0.53 mmol) were dissolved in 30 mL of

DMF. A solution of ***p***-NH_2-Bn-DOTA (160 mg, 0.32 mmol) in 10 mL of DMF was added, and the mixture was stirred for 24 h at room temperature. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B = 50/50 to 0/100, 20 min, solvent A: H_2O with 0.1% TFA; solvent B: CH_3CN/H_2O = 80/20 with 0.1% TFA) to afford **17** as an orange solid (222 mg, 94%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.49 (s, 6H); 2.48 (s, 6H); 2.54-4.91 (m, 25H); 6.06 (s, 2H); 7.28 (d, 2H, ***J*** = 8.8 Hz); 7.32 (d, 2H, ***J*** = 8.3 Hz); 7.49 (d, 2H, ***J*** = 8.8 Hz); 7.72 (d, 2H, ***J*** = 8.3 Hz); ^{13}C NMR (100 MHz, CD_3OD): δ 14.6, 15.0, 32.8, 49.7, 49.8, 50.1, 51.3, 52.8, 53.8, 55.0, 57.1, 57.3, 57.5, 57.7, 116.6, 119.5, 122.2, 122.5, 125.8, 126.2, 129.6, 129.7, 130.7, 132.6, 132.8, 139.5, 141.8, 143.3, 144.7, 156.7, 182.2; HRMS (ESI^+): Calcd for $[M+H]^+$, 891.3846; Found, 891.3889.

Synthesis of compound 18: Fluorescein isothiocyanate (40 mg, 0.10 mmol), ***p***-NH_2-Bn-DOTA (55 mg, 1.1 mmol) and TEA (142 μL, 1.0 mmol) were dissolved in 4 mL of MeOH, and the mixture was stirred for 24 h at room temperature. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B = 80/20 to 0/100, 30 min) to afford **18** as a yellow solid (62 mg, 65%). ^{1}H NMR (400 MHz, CD_3OD): δ 2.58-4.32 (m, 25H), 6.57 (dd, ***J*** = 8.8, 2.4 Hz, 2H), 6.67(d, ***J*** = 8.8 Hz, 2H), 6.68 (d, ***J*** = 2.4 Hz, 2H), 7.19 (d, ***J*** = 8.4 Hz, 1H), 7.33 (d, ***J*** = 8.3 Hz, 2H), 7.50 (d, ***J*** = 8.3 Hz, 2H), 7.83 (dd, ***J*** = 8.3, 2.0 Hz, 1H), 8.21 (d, ***J*** = 2.0 Hz, 1H); ^{13}C NMR (100 MHz, CD_3OD): δ 103,5, 111.6, 113.9, 120.8, 125.8, 126.4, 129.0, 130.4, 130.7, 132.4, 142.6, 154.4, 161.8, 171.0; HRMS (ESI^+): Calcd for $[M+H]^+$, 899.2922; Found, 899.2919.

Synthesis of compound 19: Rhodamine B isothiocyanate (mixture of isomers, 59 mg, 0.11 mmol), ***p***-NH_2-Bn-DOTA (51 mg, 0.10 mmol) and TEA (138 μL, 1.0 mmol) were dissolved in 8 mL of MeOH, and the mixture was stirred for 24 h at room temperature. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B = 70/30 to 0/100, 30 min). The desired isomer was eluted after another isomer (elution time: 11.0 min and 12.2 min). Compound **19** was obtained as a red solid (29 mg, 59%). ^{1}H NMR (300 MHz, CD_3OD): δ 1.30 (t, ***J*** = 7.0 Hz, 12H), 2.58-4.32 (m, 25H), 3.67 (q, ***J*** = 7.0 Hz, 8H), 6.97(d, ***J*** = 2.4 Hz, 2H), 7.04 (dd, ***J*** = 9.6, 2.4 Hz, 2H), 7.25 (d, ***J*** = 9.6 Hz, 2H), 7.35 (d, ***J*** = 6.8 Hz, 2H), 7.36 (d, ***J*** = 8.3 Hz, 1H),

7.54 (d, ***J*** = 6.8 Hz, 2H), 8.07 (dd, ***J*** = 8.3, 2.4 Hz, 1H), 8.18 (d, ***J*** = 2.4 Hz, 1H); ^{13}C NMR (100 MHz, CD_3OD): δ 12.8, 46.8, 97.2, 115.0, 115.3, 119.6, 122.8, 126.3, 130.7, 131.7, 132.5, 132.6, 132.8, 157.1, 159.3, 161.0, 162.6, 162.9, 167.8, 182.3; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1009.4494; Found, 1009.4471.

Synthesis of compound 20: Synthetic procedure was the same as for **18**. Purification of the reaction mixture was carried out by preparative HPLC (gradient, A/B = 60/40 to 0/100, 30 min) to afford **20** as a green solid (42 mg, 62%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.01 (t, ***J*** = 7.4 Hz, 6H), 1.39 (s, 12H), 1.83 (sex, ***J*** = 7.4 Hz, 4H), 2.05 (t, ***J*** = 5.8 Hz, 2H), 2.60-4.30 (m, 25H), 2.74 (t, ***J*** = 5.8 Hz, 4H), 4.07 (t, ***J*** = 7.4 Hz, 4H), 6.16 (d, ***J*** = 14.3 Hz, 2H), 7.12 (d, ***J*** = 8.8 Hz, 2H), 7.20 (t, ***J*** = 7.6 Hz, 2H), 7.24-7.49 (m, 12H), 8.01 (d, ***J*** = 14.3 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 11.6, 21.8, 22.4, 25.2, 28.5, 46.4, 50.4, 101.1, 112.1, 115.8, 123.1, 123.3, 126.2, 126.3, 128.7, 129.7, 130.7, 135.3, 142.5, 143.3, 143.7, 159.0, 173.9, 182.7; ; HRMS (ESI^+): Calcd for $[M+H]^+$, 1163.6004; Found, 1163.5995.

Synthesis of compound 21: Synthetic procedure was the same as for **18**. Purification of the reaction mixture was carried out by preparative HPLC (gradient, A/B = 60/40 to 0/100, 30 min) to afford **21** as a green solid (20 mg, 46%). ^{1}H NMR (300 MHz, DMSO-***d*$_6$**): δ 1.31 (s, 12H), 1.69 (br s, 8H), 1.93 (br s, 2H), 2.43-4.37 (m, 37H), 6.22 (d, ***J*** = 14.3 Hz, 2H), 7.11-7.25 (m, 6H), 7.32-7.49 (m, 10H), 7.82 (d, ***J*** = 14.3 Hz, 2H), 7.45 (d, ***J*** = 7.5 Hz, 4H), 9.75 (s, 1H), 9.77 (s, 1H); ^{13}C NMR (100 MHz, DMSO-***d*$_6$**): δ 20.8, 22.5, 23.8, 26.0, 27.3, 27.5, 43.6, 48.6, 50.8, 100.3, 111.4, 114.1, 121.6, 122.3, 123.4, 124.7, 126.2, 128.5, 129.2, 134.0, 138.1, 140.8, 141.0, 142.1, 156.4, 162.7, 171.5, 179.6; HRMS (ESI⁻): Calcd for $[M-H]^-$, 1349.5297; found, 1349.5247.

General synthetic procedure of dye-Gds: The conjugate of fluorescent dye and DOTA was dissolved in 1.0 M HEPES buffer (pH 7.4). $GdCl_3 \cdot 6H_2O$ (1.5−2.0 eq.) was added to the solution, and the mixture was stirred at room temperature overnight. The reaction mixture was purified by preparative HPLC.

BDP-Gd: Orange solid (27 mg, 12%). HRMS (ESI^-): Calcd for $[M-H]^-$, 1044.2696; Found, 1044.2738; HPLC analysis: retention time, 14.7 min; purity, 99.7% integrated

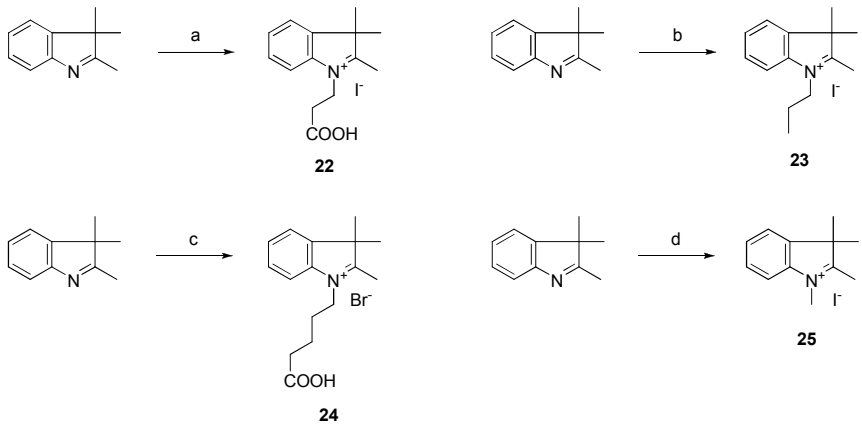
intensity (eluent: A/B = 80/20 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 500 nm).

FL-Gd: Yellow solid (9.9 mg, 87%). HRMS (ESI^-): Calcd for $[M-H]^-$, 1052.1772; Found, 1052.1819; HPLC analysis: retention time, 9.2 min; purity, 99.9% integrated intensity (eluent: A/B = 80/20 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 450 nm).

Gd(Rhoda-DOTA): Red solid (10.0 mg, 40%). HRMS (ESI^-): Calcd for $[M-H]^-$, 1162.3343; Found, 1162.3362; HPLC analysis: retention time, 12.2 min; purity, 99.6% integrated intensity (eluent: A/B = 80/20 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 550 nm).

Cy7-Gd: Green solid (7.0 mg, 62%). HRMS (ESI^-): Calcd for $[M+CF_3COO^-]^-$, 1430.4782; found, 1430.4831; HPLC analysis: retention time, 15.1 min; purity, 99.8% integrated intensity (eluent: A/B = 50/50 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 780 nm).

Compound 1: Green solid (8.9 mg, 46%). HRMS (ESI^-): Calcd for $[M-H]^-$, 1504.4303; found, 1504.4348; HPLC analysis: retention time, 11.4 min; purity, 99.7% integrated intensity (eluent: A/B = 80/20 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 780 nm).



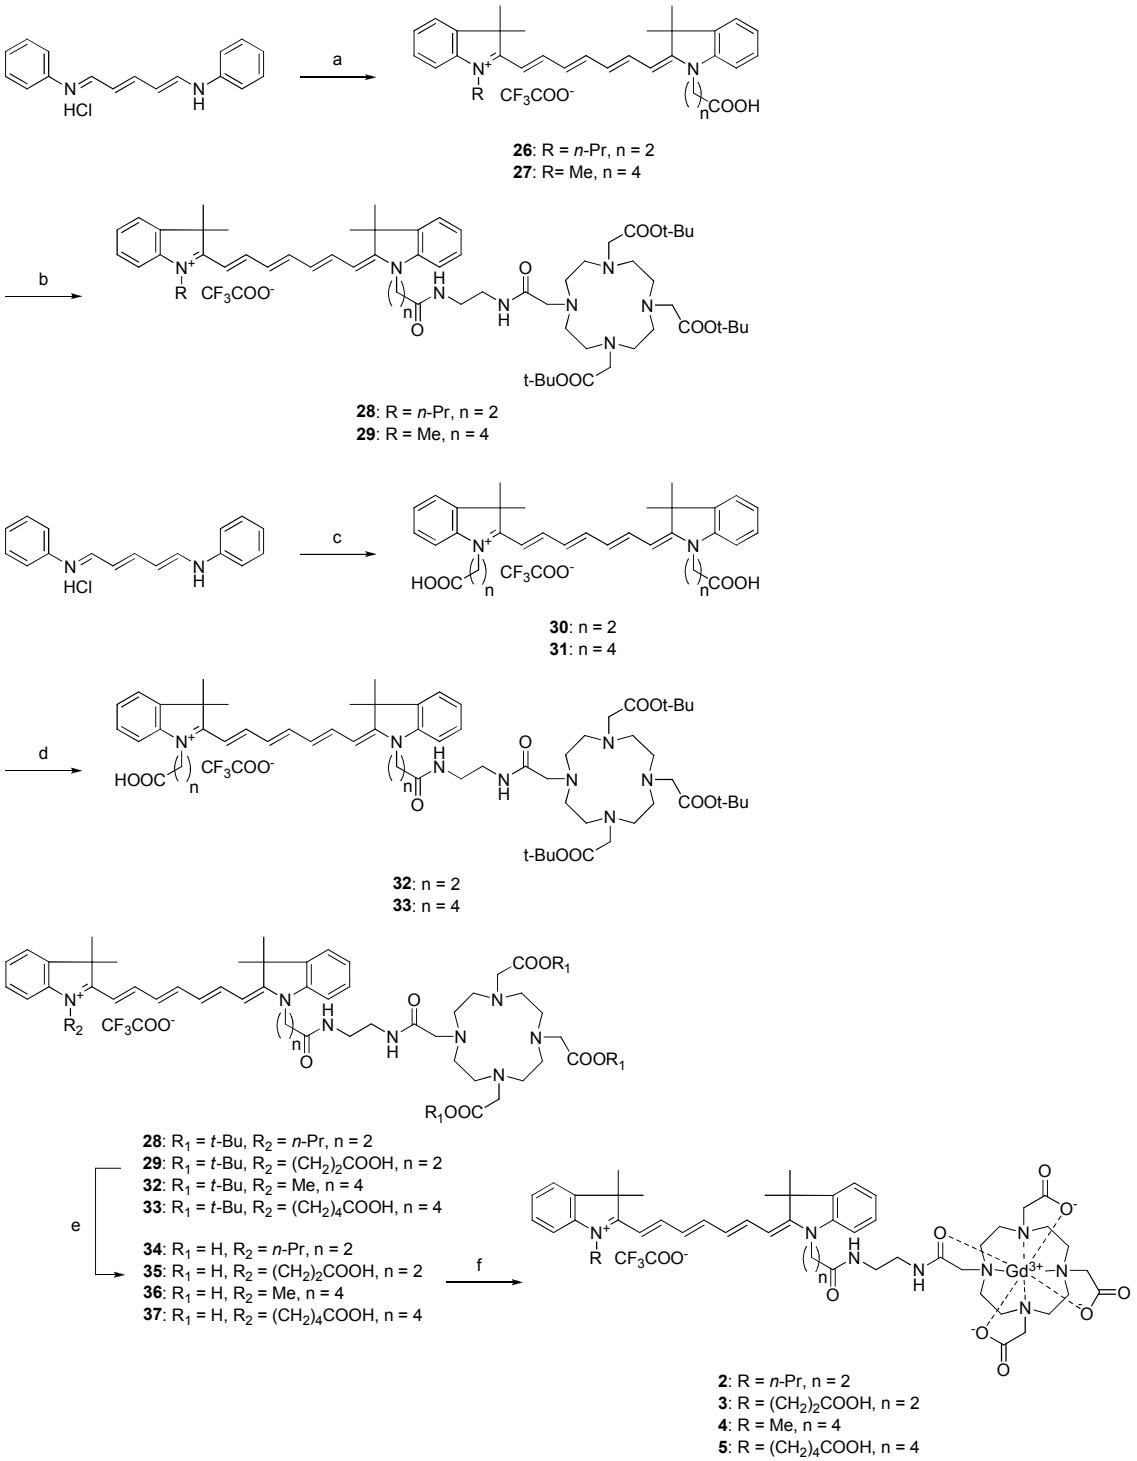
Scheme S4. Synthesis of indolenium salts. (a) 3-iodopropanoic acid, neat, 95 ºC; (b) 1-iodopropane, $CHCl_3$, reflux; (c) 5-bromovaleric acid, neat, 100 ºC; (d) iodomethane, $CHCl_3$, reflux.

Synthesis of compound 22: Neat 2,3,3-trimethylindolenine (3.22 mL, 20 mmol) and 3-iodopropanoic acid (4.0 g, 20 mmol) were stirred for 5 h at 95 ºC. The reaction mixture was cooled to room temperature, and the product was reprecipitated from acetone and diethyl ether to afford **22** as pale yellow plates (5.8 g, 80%). ^{1}H NMR (300 MHz, DMSO-***d*$_6$**): δ 1.53 (s, 6H), 2.87 (s, 3H), 2.98 (t, ***J*** = 7.0 Hz, 2H), 4.65 (t, ***J*** = 7.0 Hz, 2H), 7.62 (dd, ***J*** = 5.9, 2.9 Hz, 2H), 7.85 (dd, ***J*** = 5.9, 2.9 Hz, 1H), 8.00 (dd, ***J*** = 5.9, 2.9 Hz, 2H), 12.75 (br s, 1H); ^{13}C NMR (75 MHz, DMSO-***d*$_6$**): δ 14.4, 21.9, 31.1, 43.5, 54.3, 115.6, 123.5, 128.9, 129.3, 140.8, 141.7, 171.6, 197.9; HRMS (ESI$^+$): Calcd for $[M-I]^+$, 232.1338; found, 232.1374.

Synthesis of compound 23: 2,3,3-Trimethylindolenine (3.22 mL, 20 mmol) and 1-iodopropane (1.94 mL, 20 mmol) were dissolved in 6 mL of $CHCl_3$, and the mixture was heated to reflux in the dark under an argon atmosphere. The reaction mixture was stirred overnight, then cooled to room temperature, and the solvent was removed by evaporation. The residue was reprecipitated from acetone and diethyl ether to afford **23** as pale yellow needles (4.8 g, 73%). ^{1}H NMR (300 MHz, DMSO-***d*$_6$**): δ 1.00 (t, ***J*** = 7.3 Hz, 3H), 1.55 (s, 6H), 1.89 (sex, ***J*** = 7.3 Hz, 2H), 2.87 (s, 3H), 4.46 (t, ***J*** = 7.3 Hz, 2H), 7.62-7.65 (m, 2H), 7.85-7.87 (m, 1H), 7.99-8.03 (m, 1H); ^{13}C NMR (75 MHz, DMSO-***d*$_6$**): δ 10.7, 14.0, 20.7, 22.0, 48.8, 54.1, 115.5, 123.5, 128.9, 129.4, 141.0, 141.8, 196.5; HRMS (ESI$^+$): Calcd for $[2M+I]^+$, 531.2236; found, 531.2221.

Synthesis of compound 24: Neat 2,3,3-trimethylindolenine (3.22 mL, 20 mmol) and 3-iodovaleric acid (3.6 g, 20 mmol) were stirred overnight at 100 ºC. The reaction mixture was cooled to room temperature, and the product was recrystallized from CH_3CN to afford **24** as a pale red solid (2.1 g, 31%). ^{1}H NMR (300 MHz, DMSO-***d*$_6$**): δ 1.54 (s, 6H), 1.65 (quin, ***J*** = 7.3 Hz, 2H), 1.86 (quin, ***J*** = 7.3 Hz, 2H), 2.31 (t, ***J*** = 7.3 Hz, 2H), 2.85 (s, 3H), 4.49 (t, ***J*** = 7.3 Hz, 2H), 7.60-7.66 (m, 2H), 7.82-7.89 (m, 1H), 7.97-8.02 (m, 1H); ^{13}C NMR (75 MHz, DMSO-***d*$_6$**): δ 14.0, 21.4, 22.0, 26.6, 33.0, 47.2, 54.1, 115.4, 123.5, 128.9, 129.4, 141.1, 141.9, 174.0, 196.6; HRMS (ESI^+): Calcd for $[M-I]^+$, 260.1651; found, 260.1634.

Synthesis of compound 25: 2,3,3-Trimethylindolenine (3.22 mL, 20 mmol) and iodomethane (1.25 mL, 20 mmol) were dissolved in 6 mL of $CHCl_3$, and the mixture was heated to reflux in the dark under an argon atmosphere. The reaction mixture was stirred for 4 h, then cooled to room temperature, and the solvent was removed by evaporation. The residue was washed with acetone to afford **25** as a pale red solid (4.1 g, 69%). ^{1}H NMR (300 MHz, DMSO-***d*$_6$**): δ 1.54 (s, 6H), 2.78 (s, 3H), 3.98 (s, 3H), 7.59-7.66 (m, 2H), 7.82-7.85 (m, 1H), 7.90-7.93 (m, 1H); ^{13}C NMR (75 MHz, DMSO-***d*$_6$**): δ 14.1, 21.6, 34.7, 53.9, 115.1, 123.2, 128.7, 129.2, 141.5, 142.0, 195.9; HRMS (ESI^+): Calcd for $[2M+I]^+$, 475.1610; found, 475.1590.



Scheme S5. Synthesis of Cy7-DO3A conjugates. (a) (1) **22** or **24**, AcOH, Ac_2O, reflux, (2) **23** or **25**, AcOK, Ac_2O, r.t.; (b) (1) DCC, NHS, DMF, r.t., (2) 2-aminoethyl-mono-amide-DOTA-tris(***t***-Bu ester), r.t.; (c) **23** or **25**, AcOK, Ac_2O, r.t.; (d) 2-aminoethyl-mono-amide-DOTA-tris(***t***-Bu ester), DCC, HOBt, DIEA, DMF, r.t.; (e) TFA, r.t.; (f) $GdCl_3$, 1.0 M HEPES buffer (pH 7.4), r.t.

Synthesis of compound 26: Glutaconaldehyde dianil monohydrochloride (1.79 g, 6.3 mmol) was dissolved in 20 mL of AcOH and 20 mL of Ac_2O. Compound **22** (2.2 g, 6 mmol) was added to the mixture, and whole was heated to reflux under an argon atmosphere. The reaction mixture was stirred for 30 min, then cooled to room temperature, and the solvent was removed by evaporation. The residue was dissolved in 25 mL of Ac_2O, and **23** (2.17 g, 6.6 mmol) and potassium acetate (2.0 g, 20 mmol) were added. The mixture was stirred overnight at room temperature. The solvent was removed by evaporation, and the residue was purified by column chromatography (NH silica, gradient, CH_2Cl_2 to CH_2Cl_2/MeOH, 19:1) and preparative HPLC (gradient, A/B, 50/50 to 0/100, 30 min) to afford **26** as a red solid (943 mg, 32%). ^{1}H NMR (400 MHz, DMSO-***d*$_6$**): δ 0.95 (t, ***J*** = 7.3 Hz, 3H), 1.61 (s, 6H), 1.63 (s, 6H), 1.73 (sex, ***J*** = 7.3 Hz, 2H), 2.67 (t, ***J*** = 7.3 Hz, 2H), 4.08 (t, ***J*** = 7.3 Hz, 2H), 4.24 (t, ***J*** = 7.3 Hz, 2H), 6.30 (d, ***J*** = 13.7 Hz, 1H), 6.47 (d, ***J*** = 13.2 Hz, 1H), 6.51 (t, ***J*** = 13.2 Hz, 1H), 6.56 (t, ***J*** = 13.2 Hz, 1H), 7.17 (t, ***J*** = 7.3 Hz, 1H), 7.26 (t, ***J*** = 7.3 Hz, 1H), 7.31 (d, ***J*** = 7.3, 1H), 7.35 (t, ***J*** = 7.3 Hz, 1H), 7.40 (t, ***J*** = 7.3 Hz, 1H), 7.44 (d, ***J*** = 7.3, 1H), 7.53 (d, ***J*** = 7.3, 1H), 7.60 (d, ***J*** = 7.3, 1H), 7.75 (t, ***J*** = 13.2 Hz, 1H), 7.82 (t, ***J*** = 13.2 Hz, 1H), 7.92 (t, ***J*** = 13.2 Hz, 1H), 12.54 (br s, 1H); ^{13}C NMR (100 MHz, DMSO): δ 11.0, 20.6, 27.1, 27.3, 31.4, 45.0, 48.3, 49.0, 103.1, 104.7, 104.8, 110.6, 111.5, 122.3, 122.5, 124.1, 125.1, 125.4, 125.6, 128.3, 128.5, 140.6, 141.3, 142.0, 142.1, 150.3, 152.1, 170.0, 172.0, 172.6; HRMS (ESI^+): Calcd for $[M+H]^+$, 495.3012; Found, 495.3016 .

Synthesis of compound 27: Glutaconaldehyde dianil monohydrochloride (900 mg, 3.2 mmol) was dissolved in 10 mL of AcOH and 10 mL of Ac_2O. Compound **24** (1.2 g, 3.0 mmol) was added to the mixture, and the whole was heated to reflux under an argon atmosphere. The reaction mixture was stirred for 30 min, then cooled to room temperature, and the solvent was removed by evaporation. The residue was dissolved in 15 mL of Ac_2O, and **25** (900 mg, 3.0 mmol) and potassium acetate (1.2 g, 12 mmol) were added. The mixture was stirred overnight at room temperature. The solvent was removed by evaporation, and the residue was dissolved in CH_2Cl_2. This solution was washed with water and brine, dried over Na_2SO_4, filtered through paper filter and evaporated. The residue was purified by column chromatography (NH silica, gradient, CH_2Cl_2 to CH_2Cl_2/MeOH, 4:1) and preparative HPLC (gradient, A/B, 50/50 to 0/100, 30 min) to afford **27** as a red solid (231 mg, 16%). ^{1}H NMR (300 MHz, CD_3OD): δ 1.69

(s, 12H), 1.71-1.90 (m, 4H), 2.40 (t, ***J*** = 7.0 Hz, 2H), 3.60 (s, 3H), 4.09 (t, ***J*** = 7.0 Hz, 2H), 6.27 (d, ***J*** = 13.9 Hz, 1H), 6.28 (d, ***J*** = 13.6 Hz, 1H), 6.55 (t, ***J*** = 12.7 Hz, 2H), 7.20-7.28 (m, 4H), 7.39 (t, ***J*** = 7.7 Hz, 1H), 7.40 (t, ***J*** = 7.7, 1H), 7.47 (d, ***J*** = 7.3 Hz, 2H), 7.59 (t, ***J*** = 12.7 Hz, 1H), 7.92 (t, ***J*** = 12.8 Hz, 1H), 7.94 (t, ***J*** = 13.2 Hz, 1H); ^{13}C NMR (100 MHz, CD_3OD): δ 9.2, 23.2, 27.8, 27.9, 28.0, 31.4, 34.2, 44.6, 50.2, 104.6, 111.66, 111.75, 116.4, 119.3, 123.3, 123.4, 125.9, 126.1, 127.0, 129.7, 142.37, 142.40, 143.7, 144.4, 152.9, 153.1, 157.7, 162.0, 162.4, 172.9, 173.9, 176.9; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 495.3012; Found, 495.3014.

Synthesis of compound 28: Compound **26** (50 mg, 0.10 mmol), dicyclohexyl carbodiimide (DCC, 41 mg, 0.20 mmol), and ***N***-hydroxysuccinimide (23 mg, 0.20 mmol) were dissolved in 5 mL of DMF, and the mixture was stirred overnight at room temperature. 2-Aminoethyl-mono-amide-DOTA-tris(***t***-Bu ester) (74 mg, 0.12 mmol) was added to the mixture, and stirring was continued for 2 days. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B = 60/40 to 0/100, 30 min) to afford **28** as a green solid (33 mg, 30%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.05 (t, ***J*** = 7.3 Hz, 3H), 1.45 (s, 18H), 1.54 (s, 9H), 1.68 (s, 6H), 1.71 (s, 6H), 1.86 (sex, ***J*** = 7.3 Hz, 2H), 2.67 (t, ***J*** = 6.8 Hz, 2H), 2.97-4.20 (m, 26H), 4.31 (t, ***J*** = 6.8 Hz, 2H), 6.22 (d, ***J*** = 13.2 Hz, 1H), 6.41 (d, ***J*** = 13.2 Hz, 1H), 6.52 (t, ***J*** = 13.2 Hz, 1H), 6.59 (t, ***J*** = 12.7 Hz, 1H), 7.19 (t, ***J*** = 7.3 Hz, 1H), 7.23 (d, ***J*** = 7.8 Hz, 1H), 7.30 (t, ***J*** = 7.3 Hz, 1H), 7.35 (d, ***J*** = 7.8 Hz, 1H), 7.36 (t, ***J*** = 7.8 Hz, 1H), 7.43 d, ***J*** = 7.3 Hz, 1H), 7.43 (t, ***J*** = 7.3 Hz, 1H), 7.52 (d, ***J*** = 7.8 Hz, 1H), 7.60 (t, ***J*** = 12.7 Hz, 1H), 7.88 (t, ***J*** = 13.2 Hz, 1H), 8.00 (t, ***J*** = 13.2 Hz, 1H); ^{13}C NMR (100 MHz, DMSO): δ 11.5, 22.0, 27.9, 28.2, 28.5, 34.6, 39.8, 40.3, 41.3, 46.6, 49.7, 49.8, 50.8, 52.9, 54.9, 56.1, 83.1, 85.9, 103.8, 106.1, 111.3, 112.5, 123.3, 123.5, 125.4, 126.8, 127.0, 127.4, 129.6, 129.9, 142.0, 142.8, 143.5, 143.6, 151.7, 154.3, 157.8, 166.7, 171.3, 172.2, 172.4, 172.7, 175.0; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1091.7273; found, 1091.7292.

Synthesis of compound 29: Synthetic procedure was the same as for **28**. Compound **29** was obtained as a green solid (60 mg, 55 %). ^{1}H NMR (400 MHz, CD_3OD): δ 1.44 (s, 18H), 1.52 (s, 9H), 1.677 (s, 6H), 1.682 (s, 6H), 1.71-1.83 (m, 4H), 2.29 (t, ***J*** = 6.8 Hz, 2H), 2.94-4.18 (m, 28H), 6.24 (d, ***J*** = 14.4 Hz, 1H), 6.28 (d, ***J*** = 14.4 Hz, 1H), 6.54 (t, ***J*** = 12.4 Hz, 1H), 6.55 (t, ***J*** = 12.4 Hz, 1H), 7.20-7.29 (m, 4H), 7.38 (t, ***J*** = 7.6 Hz, 1H),

7.40 (t, ***J*** = 7.6 Hz, 1H), 7.46 (t, ***J*** = 6.6 Hz, 2H), 7.58 (t, ***J*** = 12.4 Hz, 1H), 7.91 (t, ***J*** = 14.4 Hz, 1H), 7.94 (t, ***J*** = 14.4 Hz, 1H); ^{13}C NMR (100 MHz, CD_3OD): δ 24.0, 27.8, 28.0, 28.1, 28.5, 31.5, 36.5, 39.6, 40.4, 44.5, 50.1, 50.3, 53.0, 54.9, 56.2, 82.9, 85.9, 104.1, 105.1, 111.6, 111.8, 123.3, 123.4, 125.8, 126.2, 126.9, 127.0, 129.7, 129.8, 142.35, 142.41, 143.8, 144.3, 152.6, 153.3, 157.7, 166.7, 172.2, 172.6, 174.3, 175.8; HRMS (ESI$^+$): Calcd for $[M-CF_3COO^-]^+$, 1091.7273; Found, 1091.7263.

Synthesis of compound 30: Compound **22** (1.44 g, 4.0 mmol), glutaconaldehyde dianil monohydrochloride (570 mg, 2.0 mmol) and potassium acetate (785 mg, 8.0 mmol) were dissolved in 40 mL of Ac_2O, and the mixture was stirred under an argon atmosphere overnight. The solvent was removed by evaporation, and the residue was purified by column chromatography (Silica gel, gradient, CH_2Cl_2 to CH_2Cl_2/MeOH, 1:1) and preparative HPLC (gradient, A/B, 60/40 to 0/100, 30 min) to afford **30** as a green solid (346 mg, 33%). ^{1}H NMR (300 MHz, CD_3OD): δ 1.60 (s, 12H), 2.79 (t, ***J*** = 7.0 Hz, 4H), 4.37 (t, ***J*** = 7.0 Hz, 4H), 6.34 (d, ***J*** = 13.2 Hz, 2H), 6.58 (t, ***J*** = 13.7 Hz, 2H), 7.24 (t, ***J*** = 7.5 Hz, 2H), 7.31 (d, ***J*** = 7.5 Hz, 2H), 7.40 (t, ***J*** = 7.3, 2H), 7.47 (d, ***J*** = 7.3 Hz, 2H), 7.61 (t, ***J*** = 12.7 Hz, 1H), 7.95 (t, ***J*** = 13.2 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 29.0, 32.6, 40.9, 50.3, 105.1, 111.9, 123.4, 126.1, 127.5, 129.7, 142.4, 143.3, 153.3, 158.1, 173.3, 173.9; HRMS (ESI$^+$): Calcd for $[M-CF_3COO^-]^+$, 525.2753; Found, 525.2786.

Synthesis of compound 31: Compound **24** (1.21 g, 3.0 mmol), glutaconaldehyde dianil monohydrochloride (427 mg, 1.5 mmol) and potassium acetate (589 mg, 6.0 mmol) were dissolved in 30 mL of Ac_2O, and the mixture was stirred under an argon atmosphere overnight. The solvent was removed by evaporation, and the residue was purified by column chromatography (Silica gel, gradient, CH_2Cl_2 to CH_2Cl_2/MeOH, 1:1) and preparative HPLC (gradient, A/B, 50/50 to 0/100, 30 min) to afford **31** as a green solid (955 mg, >99%). ^{1}H NMR (300 MHz, CD_3OD): δ 1.69 (s, 12H), 1.71-1.90 (m, 8H), 2.39 (t, ***J*** = 7.0 Hz, 4H), 4.10 (t, ***J*** = 7.0 Hz, 4H), 6.29 (d, ***J*** = 13.6 Hz, 2H), 6.56 (t, ***J*** = 12.7 Hz, 2H), 7.24 (t, ***J*** = 7.5 Hz, 2H), 7.27 (d, ***J*** = 7.5 Hz, 2H), 7.39 (t, ***J*** = 7.5 Hz, 2H), 7.47 (d, ***J*** = 7.5 Hz, 2H), 7.60 (t, ***J*** = 12.1 Hz, 1H), 7.93 (t, ***J*** = 13.0 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 23.2, 27.8, 28.0, 34.2, 44.6, 50.3, 111.8, 123.4, 126.0, 127.1, 129.8, 142.4, 143.7, 153.1, 157.9, 162.5, 173.2, 176.9; HRMS (ESI$^+$):

Calcd for $[M-CF_3COO^-]^+$, 581.3379; found, 581.3378.

Synthesis of compound 32: Compound **30** (52.5 mg, 0.10 mmol), DCC (31 mg, 0.15 mmol), HOBt·H_2O (15 mg, 0.10 mmol), 2-aminoethyl-mono-amide-DOTA-tris(t-Bu ester) (74 mg, 0.12 mmol), and DIEA (35 μL, 0.20 mmol) were dissolved in 5 mL of DMF, and the mixture was stirred overnight at room temperature. The reaction mixture was purified by preparative HPLC (gradient, A/B, 50/50 to 0/100, 30 min) to afford **27** as a green solid (23 mg, 20%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.45 (s, 18H), 1.54 (s, 9H), 1.69 (s, 6H), 1.69 (s, 6H), 2.68 (t, ***J*** = 6.8 Hz, 2H), 2.80 (t, ***J*** = 7.3 Hz, 2H), 2.92-4.20 (m, 28H), 4.35 (t, ***J*** = 6.8 Hz, 2H), 4.39 (t, ***J*** = 7.3 Hz, 2H), 6.31 (d, ***J*** = 13.7 Hz, 1H), 6.37 (d, ***J*** = 13.2 Hz, 1H), 6.56 (t, ***J*** = 12.4 Hz, 1H), 6.58 (t, ***J*** = 12.4 Hz, 1H), 7.22-7.29 (m, 3H), 7.32-7.49 (m, 5H), 7.62 (t, ***J*** = 12.4 Hz, 1H), 7.94 (t, ***J*** = 12.7 Hz, 1H), 7.97 (t, ***J*** = 12.7 Hz, 1H); ^{13}C NMR (100 MHz, CD_3OD): δ 28.0, 28.1, 28.5, 32.7, 34.6, 39.8, 40.3, 41.0, 41.6, 50.29, 50.33, 52.9, 54.9, 56.0, 83.3, 85.6, 104.8, 111.90, 111.94, 123.4, 126.08, 126.12, 127.4, 129.7, 142.4, 143.30, 143.35, 153.1, 153.2, 157.9, 172.47, 172.52, 173.2, 173.4, 173.9; HRMS (ESI^+): Calcd for $[M]^+$, 1121.7015; found, 1121.6976.

Synthesis of compound 33: Synthetic procedure was the same as for **32**. Compound **33** was obtained as a green solid (47 mg, 40%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.45 (s, 18H), 1.53 (s, 9H), 1.69 (s, 6H), 1.70 (s, 6H), 1.72-1.84 (m, 8H), 2.29 (t, ***J*** = 7.1 Hz, 2H), 2.39 (t, ***J*** = 7.1 Hz, 2H), 2.88-4.25 (m, 28H), 4.06-4.14 (m, 4H), 6.25 (d, ***J*** = 13.6 Hz, 1H), 6.32 (d, ***J*** = 13.2 Hz, 1H), 6.51-6.60 (m, 2H), 7.21-7.31 (m, 4H), 7.36-7.49 (m, 4H), 7.60 (t, ***J*** = 12.9 Hz, 1H), 7.92 (t, ***J*** = 13.2 Hz, 1H), 7.96 (t, ***J*** = 13.2 Hz, 1H); ^{13}C NMR (100 MHz, DMSO-$\boldsymbol{d}_6$): δ 21.7, 22.3, 26.5, 26.6, 27.2, 27.7, 31.3, 33.3, 34.8, 37.8, 43.2, 47.7, 48.2, 48.6, 48.7, 50.9, 53.1, 54.4, 54.6, 81.2, 83.5, 110.9, 111.1, 112.2, 115.1, 118.1, 122.5, 124.6, 124.7, 128.5, 141.0, 141.0, 142.17, 142.20, 169.7, 169.74, 169.85, 171.5, 172.1, 174.3; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1177.7641; found, 1177.7591.

General synthetic procedure of Cy7-DO3A: TFA (2 mL) was added to the conjugate of Cy7 dye and DO3A ***t***-Bu ester (18-57 μmol), and the mixture was stirred for 2 h at room temperature. TFA was removed by evaporation, and the residue was purified by

preparative HPLC.

Compound 34: Blue solid (14 mg, 55%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.05 (t, ***J*** = 7.3 Hz, 3H), 1.68 (s, 6H), 1.70 (s, 6H), 1.86 (sex, ***J*** = 7.3 Hz, 2H), 2.69 (t, ***J*** = 6.8 Hz, 2H), 3.18-4.12 (m, 30H), 4.32 (t, ***J*** = 7.3 Hz, 2H), 6.27 (d, ***J*** = 13.7 Hz, 1H), 6.37 (d, ***J*** = 13.7 Hz, 1H), 6.55 (t, ***J*** = 13.7 Hz, 1H), 6.58 (t, ***J*** = 13.7 Hz, 1H), 7.19 (t, ***J*** = 7.6 Hz, 1H), 7.25-7.44 (m, 6H), 7.51 (d, ***J*** = 7.6 Hz, 1H), 7.59 (t, ***J*** = 12.9 Hz, 1H), 7.89 (t, ***J*** = 12.9 Hz, 1H), 7.98 (t, ***J*** = 12.9 Hz, 1H); ^{13}C NMR (100 MHz, CD_3OD): δ 11.5, 22.0, 27.9, 28.1, 34.6, 39.9, 40.2, 41.4, 46.5, 49.9, 50.6, 51.2, 51.7, 54.8, 55.6, 111.5, 112.4, 123.3, 123.4, 125.5, 126.5, 127.0, 127.2, 129.6, 129.8, 142.1, 142.7, 143.6, 152.0, 152.1, 153.9, 154.0, 157.7, 171.9, 172.9, 174.5; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 923.5395; found, 923.5421.

Compound 35: Blue solid (13 mg, 78%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.68 (s, 6H), 1.69 (s, 6H), 2.72 (t, ***J*** = 6.8 Hz, 2H), 2.78 (t, ***J*** = 6.8 Hz, 2H), 3.24-3.88 (m, 28H), 4.34-4.39 (m, 2H), 6.31 (d, ***J*** = 13.7 Hz, 1H), 6.37 (d, ***J*** = 13.7 Hz, 1H), 6.56 (t, ***J*** = 12.4 Hz, 1H), 6.57 (t, ***J*** = 12.4 Hz, 1H), 7.21-7.47 (m, 8H), 7.60 (t, ***J*** = 12.4 Hz, 1H), 7.90-7.98 (m, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 28.0, 32.6, 34.7, 39.9, 40.2, 40.9, 41.6, 50.2, 50.4, 51.8, 54.5, 55.7, 104.9, 111.6, 111.8, 123.4, 126.0, 126.2, 127.4, 129.7, 142.3, 142.4, 143.3, 153.0, 153.4, 158.0, 172.7, 172.9, 173.5, 174.0; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 953.5137; found, 923.5132.

Compound 36: Blue solid (36 mg, 73%). ^{1}H NMR (300 MHz, CD_3OD): δ 1.69 (s, 12H), 1.69-1.86 (m, 4H), 2.30 (t, ***J*** = 6.6 Hz, 2H), 3.45-4.05 (m, 28H), 3.61 (s, 3H), 4.07 (t, ***J*** = 6.6 Hz, 2H), 6.25 (d, ***J*** = 13.6 Hz, 1H), 6.28 (d, ***J*** = 13.6 Hz, 1H), 6.54 (t, ***J*** = 12.7 Hz, 1H), 6.55 (t, ***J*** = 12.7 Hz, 1H), 7.20-7.29 (m, 4H), 7.36-7.49 (m, 4H), 7.59 (t, ***J*** = 12.7 Hz, 1H), 7.87-7.99 (m, 2H); ^{13}C NMR (100 MHz, (CD_3OD): δ 24.0, 27.8, 27.99, 28.03, 31.5, 36.4, 39.7, 40.4, 44.6, 50.2, 50.3, 51.3, 54.8, 55.6, 104.3, 111.7, 123.3, 123.4, 125.9, 126.2, 126.90, 129.7, 142.4, 143.8, 144.3, 152.7, 153.2, 157.6, 172.8, 174.1, 176.0; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 923.5395; found, 923.5406.

Compound 37: Blue solid (20 mg, 89%). ^{1}H NMR (400 MHz, CD_3OD): δ 1.68 (s, 12H), 1.71-1.84 (m, 8H), 2.32 (t, ***J*** = 6.8 Hz, 2H), 2.39 (t, ***J*** = 7.1 Hz, 2H), 3.23-3.89 (m,

28H), 4.06-4.12 (m, 4H), 6.27 (d, ***J*** = 13.2 Hz, 1H), 6.29 (d, ***J*** = 12.7 Hz, 1H), 6.51-6.58 (m, 2H), 7.21-7.29 (m, 4H), 7.36-7.48 (m, 4H), 7.58 (t, ***J*** = 12.7 Hz, 1H), 7.90-7.96 (m, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 23.2, 24.0, 27.8, 27.98, 28.01, 34.3, 36.4, 39.6, 40.3, 44.6, 44.7, 50.28, 50.33, 51.3, 54.6, 55.3, 55.6, 104.8, 111.9, 123.4, 126.0, 126.1, 127.0, 129.8, 142.5, 143.7, 152.9, 153.1, 157.8, 173.1, 173.3, 176.0, 176.9; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1009.5763; found, 1009.5742.

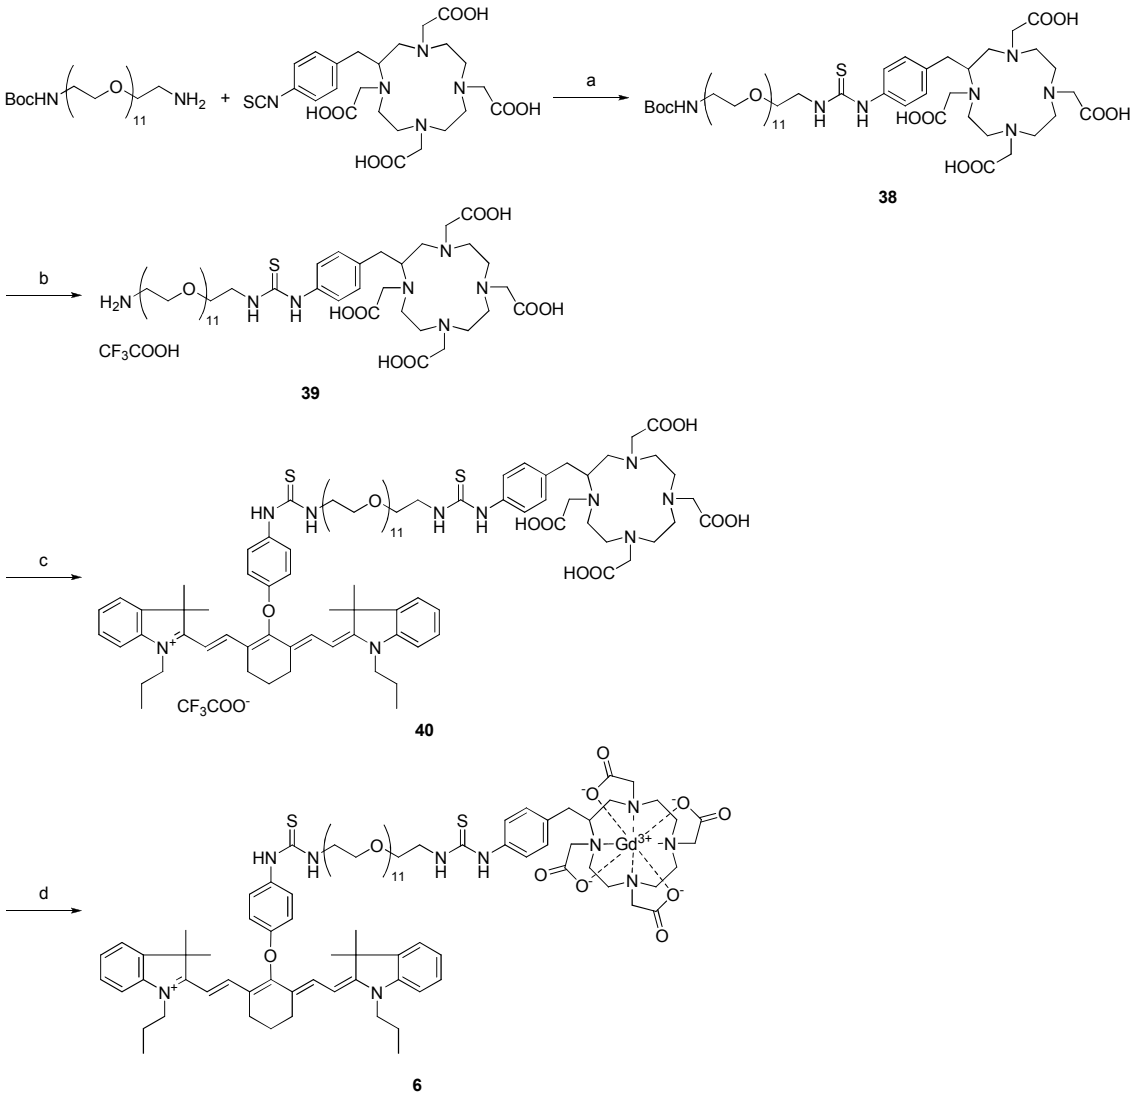
Synthesis of Cy7-Gd derivatives: Synthetic procedure was the same as for **dye-Gd**s.

Compound 2: Blue solid (8.7 mg, 54%). HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1078.4401; found, 1078.4356; HPLC analysis: retention time, 12.7 min (eluent: A/B = 50/50 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 750 nm).

Compound 3: Blue solid (9.4 mg, 62%). HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1108.4143; found, 1108.4110; HPLC analysis: retention time, 11.3 min (eluent: A/B = 50/50 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 750 nm).

Compound 4: Blue solid (26 mg, 63%). HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1078.4401; found, 1078.4376; HPLC analysis: retention time, 12.5 min (eluent: A/B = 50/50 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 750 nm).

Compound 5: Blue solid (16 mg, 72%). HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1164.4769; found, 1164.4720; HPLC analysis: retention time, 12.3 min (eluent: A/B = 50/50 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 750 nm).



Scheme S6. Synthesis of compound **6**. (a) DIEA, DMF, r.t.; (b) TFA, CH_2Cl_2, r.t.; (c) **13**, DIEA, DMF, r.t.; (d) $GdCl_3$, 1.0 M HEPES buffer (pH 7.4), r.t.

Synthesis of compound 38: ***O***-(2-Aminoethyl)-***O′***-[2-(Boc-amino)ethyl]decaethylene glycol (Aldrich, 161 mg, 0.25 mmol) and DIEA (435 μL, 2.5 mmol) were dissolved in 2 mL of DMF. A solution of ***p***-SCN-Bn-DOTA (Macrocyclics, 154 mg, 0.28 mmol) in 2.5 mL of DMF was added, and the mixture was stirred for 2 days at room temperature. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B, 99/1 to 0/100, 30 min) to afford **38** as a colorless solid (281 mg, 94%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.44 (s, 9H), 2.01-4.66 (m, 73H), 7.22-7.31 (m, 4H); ^{13}C NMR (100 MHz, $CDCl_3$): δ 28.8, 32.7, 41.3, 45.4, 49.6, 49.9, 50.2, 51.3, 52.8, 53.8, 55.0, 55.8, 57.1, 67.9, 70.3, 70.7, 70.95, 71.02, 71.1, 71.2, 71.3, 71.5, 80.1, 125.7, 130.8,

134.7, 139.4, 158.4, 169.0, 182.7; HRMS (ESI^+): Calcd for $[M+H]^+$, 1196.6224; found, 1196.6234.

Synthesis of compound 39: Compound **38** was dissolved in 8 mL of CH_2Cl_2, and 5 mL of TFA was added to the solution. The mixture was stirred for 2 h at room temperature. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B, 99/1 to 0/100, 30 min) to afford **39** as a colorless solid (227 mg, 89%). ^1H NMR (400 MHz, CD_3OD): δ 2.04-4.96 (m, 73H), 7.30 (d, ***J*** = 8.3 Hz, 2H), 7.41 (d, ***J*** = 8.3 Hz, 2H); ^{13}C NMR (100 MHz, CD_3OD): δ 32.7, 40.6, 45.3, 50.0, 51.2, 52.8, 53.7, 54.8, 55.6, 57.1, 57.5, 67.9, 70.3, 70.7, 70.9, 71.1, 71.16, 71.23, 71.29, 71.33, 71.42, 71.43, 125.7, 130.8, 134.7, 182.7; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1096.5699; found, 1096.5696.

Synthesis of compound 40: Compound **13** (69 mg, 105 μmol) and DIEA (174 μL, 1.00 mmol) were dissolved in 4 mL of DMF. A solution of compound **39** (110 mg, 100 μmol) in 4 mL of DMF was added, and the mixture was stirred overnight at room temperature. The solvent was removed by evaporation, and the residue was purified by preparative HPLC (gradient, A/B, 60/40 to 0/100, 30 min) to afford **40** as a green solid (53.8 mg, 31%). ^1H NMR (300 MHz, $CDCl_3$): δ 0.92 (t, ***J*** = 7.5 Hz, 6H), 1.30 (s, 12H), 1.74 (sex, ***J*** = 7.5 Hz, 4H), 1.95 (s, 2H), 2.51-4.19 (m, 6H), 6.07 (d, ***J*** = 13.9 Hz, 2H), 7.03 (d, ***J*** = 9.2 Hz, 2H), 7.12 (t, ***J*** = 7.5 Hz, 2H), 7.18 (t, ***J*** = 7.7 Hz, 4H), 7.26-7.35 (m, 8H), 7.91 (d, ***J*** = 13.9 Hz, 4H); ^{13}C NMR (100 MHz, DMSO): δ 11.1, 20.4, 23.7, 27.4, 43.5, 44.9, 48.6, 68.6, 69.6, 69.8, 100.3, 111.3, 114.2, 115.2, 118.1, 121.5, 122.4, 124.8, 128.5, 129.3, 140.8, 141.0, 142.2, 157.9, 158.3, 162.8, 164.0, 171.7, 181.0; HRMS (ESI^+): Calcd for $[M-CF_3COO^-]^+$, 1749.9139; found, 1749.9185.

Synthesis of 6: Synthetic procedure was the same as for **Cy7-Gd** derivatives. Compound **6** was obtained as a green solid (17 mg, 86%). HRMS (ESI^-): Calcd for $[M+H]^+$, 1904.8145; found, 1904.8111; HPLC analysis: retention time, 15.6 min; purity, 99.7% integrated intensity (eluent: A/B = 50/50 to 0/100, 20 min; flow rate = 1.0 mL/min; detection wavelength, 780 nm).

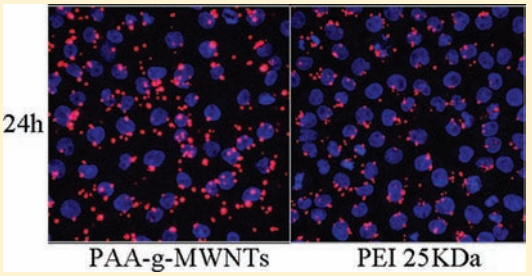
Supporting Information

ABSTRACT: Functionalized multiwalled carbon nanotubes (*f*-MWNTs) are of great interest and designed as a novel gene delivery system. In this paper, we presented synthesis of polyamidoamine-functionalized multiwalled carbon nanotubes (PAA-*g*-MWNTs) and their application as a novel gene delivery system. The PAA-*g*-MWNTs, obtained from amide formation between PAA and chemically oxidized MWNTs, were stable in aqueous solution and much less toxic to cells than PAA and PEI 25KDa. More importantly, PAA-*g*-MWNTs showed comparable or even higher transfection efficiency than PAA and PEI at optimal w/w ratio. Intracellular trafficking of Cy3-labeled pGL-3 indicated that a large number of Cy3-labeled pGL-3 were attached to nucleus membrane, the majority of which was localized in nucleus after incubation with cells for 24 h. We have demonstrated that PAA modification of MWNTs facilitate higher DNA uptake and gene expression *in vitro*. All these facts suggest potential application of PAA-*g*-MWNTs as a novel gene vector with high transfection efficiency and low cytotoxicity.



INTRODUCTION

Since application of viral vectors was restricted by their drawbacks such as high immunogenicity, high toxicity, low gene loading rate, and so on, researchers in this field have developed many types of nonviral gene vectors.[1−4] Recently, multiwalled carbon nanotubes (MWNTs) have been explored as an efficient novel gene delivery system due to their unique structure and properties. However, the as-prepared carbon nanotubes are water-insoluble, chemical modification of MWNTs is desired for their application in gene delivery.[5−12]

Dendrimer-grafted MWNTs have been developed as gene delivery vectors.[13−15] Dendrimers containing large numbers of surface primary amine groups can effectively improve water solubility of MWNTs; meanwhile, the surface primary amines can condense DNA via electrostatic interaction and then deliver foreign DNA into cells. Yao group[16,17] designed and synthesized several kinds of dendrimer-functionalized MWNTs, the obtained PAMAM-MWCNT possessed much lower cytotoxicity and higher transfection efficiency. However, the properties of dendrimers are mainly dependent on the number of their generations and the synthesis is usually complicated.[18]

Recently, linear polyamidoamine (PAA), which can be easily synthesized via one-step polyaddition of primary monoamines or bis(secondary amine) to bisacrylamines, has attracted much attention from researchers.[19] In a previous work, secondary and tertiary amines were introduced to the side chains to improve water solubility and transfection efficiency.[20] However, polymers with primary amino groups often show higher stability in saline solution and better transfection activity.[21] To date, there are few reports on PAA with pendant primary amine groups for gene delivery.[22]

Herein, we report a novel gene delivery system based on MWNTs grafted with PAA. In our strategy, PAA with pendant primary amine groups was synthesized via Michael polyaddition of N-Boc-protected diamine to *N,N*-methylenebis(acrylamide). Next, PAA was conjugated to MWNTs (PAA-*g*-MWNTs) through EDC chemistry. The composition, morphology, surface properties, and cytotoxicity of PAA-*g*-MWNTs were characterized by FT-IR spectroscopy, thermogravimetric analysis (TGA), scanning electron microscopy (SEM), zeta potential, and WST measurement. Finally, using pGL-3 as a reporter gene, we investigated the ability of PAA-*g*-MWNTs to deliver foreign luciferase gene, including transfection efficiency and intracellular trafficking.

EXPERIMENTAL PROCEDURES

Materials. MWNTs and EDAC were obtained from domestic suppliers. PAA (M_w = 1.8 × 10^4) was synthesized as described previously.[22] Branched PEI 25KDa was purchased from Sigma-Aldrich and used as received. *N*-Hydroxysuccinimide

(NHS) was purchased from Alfa Aesar. Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), 0.25% Trypsin-EDTA, Opti-MEM, and Hoechst 33258 were purchased from Gibco BRL (Grand Island, NY). Label IT Cy3 Nucleic Acid Labeling Kit was obtained from Mirus Bio Corporation. Luciferase assay system was obtained from Promega Corporation. COS-7 and HeLa cell lines were purchased from China Center for Type Culture Collection (CCTCC) (Wuhan University) and cultured in DMEM supplemented with 10% FBS at 37 °C in a humidified air atmosphere containing 5% CO_2.

Amplification and Purification of Plasmid DNA. pGL-3 was used as the luciferase reporter gene and transformed in *E. coli* JM109. pEGFP-N1 was used as the green fluorescent protein gene and transformed in *E. coli* DH5R. Both plasmids were amplified in LB at 37 °C for 12−16 h at 250 rpm, and purified by QIAfilter plasmid Giga kit according to the manufacturer's protocol. The quantity and quality of plasmid DNA was analyzed by spectrophotometric analysis at 260 and 280 nm and by electrophoresis in 0.7% (w/v) agarose gel. The purified plasmid was dissolved in TE buffer and stored at −20 °C.

Synthesis and Characterization of PAA-*g*-MWNTs. Carboxylic acid groups were introduced onto MWNTs by acid treatment following a previous protocol.[23] Next, 10 mg of MWNTs-COOH obtained from the above step was dispersed into 10 mL of aqueous solution (pH = 6) of EDC (9.6 mg) and NHS (5.7 mg) via sonication. After sonication for 3 h, 40 mg of PAA was added to the above solution and changed the solution pH to 9. The mixture was then sonicated for further 4 h and stirred at room temperature overnight. Finally, the solution was dialyzed against distilled water (MWCO = 50 000) to remove the unreacted PAA. Next, the solution was centrifuged at 12 000 rpm for 30 min, the supernatant was sterile-filtered (Millipore 220 nm) and stored as a stock solution.

The structure and composition of the purified PAA-*g*-MWNTs were characterized by FTIR and TGA. TGA was performed by scanning from 100 to 800 °C under nitrogen at a heating rate of 20 °C min^{-1} by using TG/DTA 6200.

Morphology of the PAA-g-MWNTs/pEGFP-N1 complexes was characterized by SEM (FEI Quanta 400). The complexes at optimal w/w ratio of 15 were prepared as described above, followed by vortexing for 5 s and incubating for 30 min at room temperature. Afterward, a drop of the solution was deposited onto a glass slide and stored in a desiccator overnight.

Cytotoxicity Assay. The cytotoxicity of PAA-*g*-MWNTs to HeLa and COS-7 cells was evaluated by WST assay, in which PAA was also tested as a control. HeLa and COS-7 cells were seeded into 96 well plate at a density of 6000 and 5000 cells/well in 100 μL complete DMEM. When cells achieved about 50% confluence after incubation for 24 h, 100 μL aliquots of PAA-*g*-MWNT solutions in DMEM at different concentrations were added to a 96 well plate and incubated for another 24 h. Then, the DMEM was replaced with 100 μL fresh DMEM, and 10 μL of WST solution was added to each well except for the background wells and incubated for further 2 h. The absorbance at 450 nm was measured using a microplate reader (Perkin-Elmer Victor X4). The percent relative viability in reference to control wells containing complete DMEM without the added PAA-*g*-MWNTs was calculated by the following equation:

$$\text{relative cell viability (\%)} = 100 \times (A_{\text{test}} - A_0)/(A_{\text{control}} - A_0)$$

where A is absorbance at 450 nm, A_0 represents absorbance of the solution containing cells and complete DMEM without WST and PAA-*g*-MWNTs.

Preparation of PAA-*g*-MWNTs/DNA Complexes and Agarose Gel Retardation Assay. PAA-*g*-MWNTs/DNA complexes were freshly prepared in 150 mmol L^{-1} NaCl by mixing PAA-*g*-MWNTs with pEGFP-N1 at desired w/w ratios, followed by vortexing for 5 s and incubation for 30 min at room temperature.

The complexes for agarose gel retardation assay were prepared at w/w ratios of 1.5:1, 3:1, 4.5:1, 6:1, 9:1, 12:1, and 15:1 as described above. Gel electrophoresis was carried out in TAE buffer in 0.7% (w/v) agarose gel at 80 V for 80 min. The gel was visualized with a Fujifilm LAS-4000 image analyzer.

Zeta Potential Measurement. The zeta potential of samples was measured with Zetasizer Nano-ZS (Malvern Instruments) at 25 °C. The PAA-*g*-MWNTs/pEGFP-N1 complexes at various w/w ratios were freshly prepared as described above. After incubating for 30 min, the solution was diluted to 1 mL with pure water for zeta potential measurement.

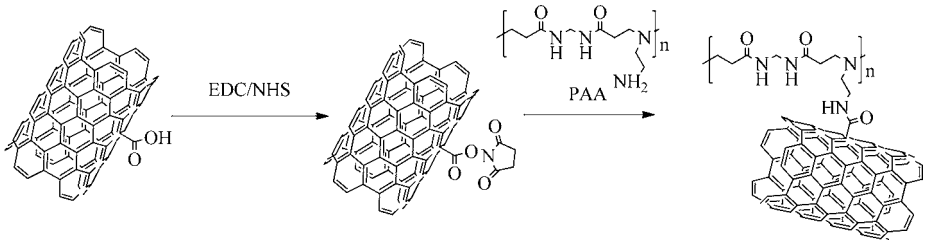
In Vitro Transfection. In vitro transfection efficiency of complexes was evaluated on HeLa and COS-7 cells, pGL-3 was used as the report gene. Branched PEI 25KDa and PAA were used as a control. HeLa and COS-7 cells were separately seeded into 24 well plates at an appropriate density (6×10^4 for HeLa cells, and 5×10^4 for COS-7 cells) with 1 mL of complete DMEM. When the cells were incubated to 50−60% confluence in the 24 well plate, the medium was replaced with 400 μL of Opti MEM, and then, 100 μL aliquots of PAA-*g*-MWNT/DNA complexes at various w/w ratios were added to each well. After incubation for 4 h at 37 °C, the culture media was then replaced with 1 mL of complete DMEM, and the cells were incubated for further 48 h. All of the transfections were performed in duplicate. For luciferase expression, after 48 h of incubation, the medium was replaced with 200 μL of cell lysis buffer and freeze−thawed twice. The lysate was centrifuged at 12 000 rpm for 3 min, 20 μL of supernatant was mixed with 100 μL of the luciferase assay substrate (Promega), and light emission was measured with a Lumat 9507 luminometer (Berthold Germany) for 10 s. The relative light units (RLU/mg protein) were normalized against the total protein concentration in the cell extracts, which was determined using a BCA assay kit (Pierce).

To evaluate the effect of serum on gene delivery, we used Opti MEM containing 10% FBS for transfection of cells with PAA-*g*-MWNTs/DNA complexes. For transfection in the presence of serum, when the cells achieved 50−60% confluence, the medium was replaced with fresh Opti MEM containing 10% FBS, and then, complexes at various w/w ratios were added to each well. The other procedure was the same as that described above.

Intracellular Trafficking. pGL-3 was labeled by Label IT Cy3 Nucleic Acid Labeling Kit according to the manufacturer's protocol. Then, PAA-*g*-MWNTs at optimal w/w ratio (w/w ratio = 15) was screened through the evaluation by luciferase expression. PEI 25KDa at optimal w/w ratio (w/w = 1.3) was used as a control.

COS-7 cells were seeded onto a coverslip in a 24 well plate at a density of 4×10^4. After incubation for 24 h, the cells achieved 40−50% confluence, the medium was replaced with 400 μL of Opti MEM, and then PAA-*g*-MWNTs with labeled pGL-3 at w/w ratio of 15 were added to each well. After incubating for 4 h, the medium was replaced with 1 mL

Scheme 1. Synthesis Route of PAA-Functionlized MWNTs



complete DMEM. At the end of each incubation period (4 h and 24 h), the medium was removed, and the coverslip was taken out and fixed with 4% formalin for 10 min. Then, the cells were rinsed with PBS twice, and 100 μL of Hoechst 33258 (5 μg/mL) was added onto the coverslip and incubated for 10 min. Finally, the coverslip was washed with PBS and mounted on a microscopic slide. Intracellular localization of Cy3-labeled DNA was visualized by Nikon confocal system with excitation at 405 and 543 nm for Hoechst and Cy3, respectively. Image analysis was used to determine whether Cy3-labeled DNA was localized inside or over the nucleus, 5−10 of *Z*-series images at 1 μm interval containing blue fluorescence (nucleus) were selected. DNA nucleus localization was confirmed by evidence of the colocalization of blue and red fluorescence.

RESULTS

Synthesis and Characterization of PAA-g-MWNTs. PAA was conjugated to the carboxyl groups on the surface of MWNTs, which is shown in Scheme 1. After purification, the obtained PAA-*g*-MWNTs were then characterized by FT-IR. For comparison purpose, IR spectra of PAA, MWNTs-COOH, and PAA-*g*-MWNTs are shown in Figure S1 (see Supporting Information). The CONH group formed between PAA and MWNTs-COOH shows IR bands at about 3400, 1650, and 1535 cm^{-1}, suggesting successful formation of PAA-*g*-MWNTs complexes.

The relative amount of PAA grafted onto the surface of MWNTs was evaluated by thermogravimetric analysis (TGA). As shown in Figure 1, MWNT-COOH was thermally stable up to 600 °C, while PAA and PAA-*g*-MWNTs began to degrade at about 300 °C. At 500 °C, PAA and PAA-*g*-MWNTs showed about 75.4% and 72.2% weight losses, respectively; thus, PAA-*g*-MWNTs contained about 95.7% PAA.

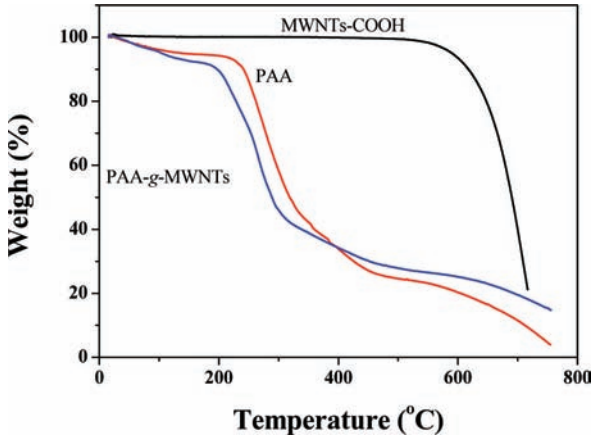


Figure 1. TGA curves of MWNTs, PAA, and PAA-g-MWNTs.

Cell Viability Assay. The relative cellular viabilities of PAA-*g*-MWNTs and PAA are presented in Figure 2. The cytotoxicity of PAA-*g*-MWNTs was found to be concentration dependent, which meant that the cell viability decreased with increasing concentration of PAA-*g*-MWNTs. Figure 2A shows the cytotoxicity of PAA-*g*-MWNTs against COS-7 cells; the viability of COS-7 cells incubated with the solution of PAA was about 40% at a concentration of 80 μg/mL, while the viability of COS-7 with PAA-*g*-MWNTs was about 80% at the same concentration, suggesting much lower cytotoxicity of PAA-*g*-MWNTs than that of PAA. Figure 2B gives the cytotoxicity of PAA-*g*-MWNTs against HeLa cells. The viability of HeLa cells against PAA-*g*-MWNTs and PAA at a concentration of 80 μg/mL was about 50% and 20%, respectively. The result is similar to that observed for COS-7 cells.

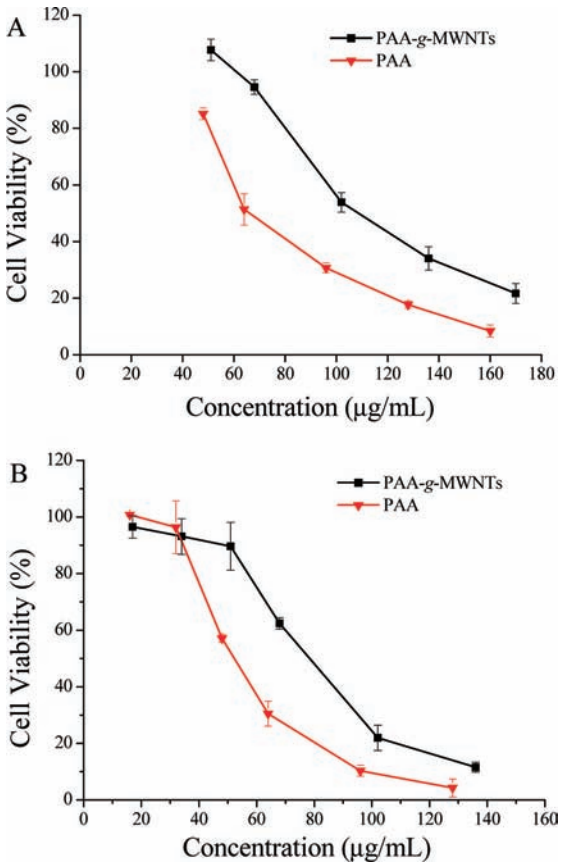

Figure 2. In vitro cytotoxicity of PAA-*g*-MWCNTs in COS-7 (A) and HeLa (B) cells. PAA was used as a control.

Agarose Gel Retardation. Agarose gel retardation assays were performed to study the condensation ability of PAA-*g*-MWCNTs. As shown in Figure 3, DNA was entirely retained in

dx.doi.org/10.1021/bc200189f | *Bioconjugate Chem.* 2011, 22, 2237−2243

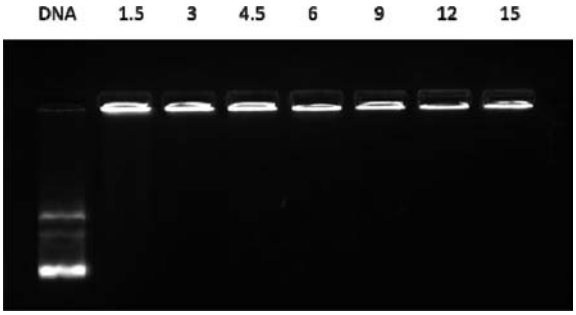

Figure 3. Agarose gel electrophoresis retardation assay of PAA-*g*-MWNTs/DNA complexes at various w/w ratios. Lane 1, naked DNA; lanes 2−8, w/w ratios of 1.5:1, 3:1, 4.5:1, 6:1, 9:1, 12:1, and 15:1, respectively.

the wells at w/w ratio above 1.5, suggesting high DNA binding ability at low w/w ratios.

Zeta Potential Measurement. It is well-known that positive surface charge of polymer/DNA complexes can facilitate the nonspecific attachment of complex nanoparticles to the negatively charged cellular membranes and the uptake of polycation/DNA complexes by cells. The zeta potential of PAA-*g*-MWNTs/DNA complexes was measured to assess their surface charge. As shown in Figure 4, at w/w ratios below 3, the

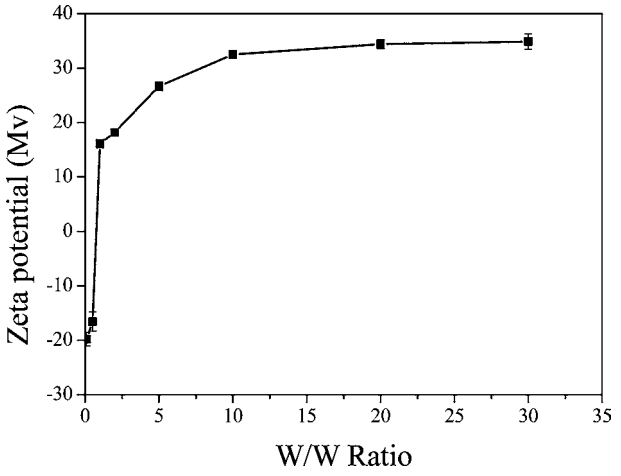

Figure 4. Zeta potentials of PAA-*g*-MWNT/DNA complexes at w/w ratios ranging from 0.5 to 30 in 10 mmol L^{-1} NaCl aqueous solution.

zeta potential of the complexes is negative, indicating incomplete complexation. With increase of the w/w ratio, the zeta potential increased rapidly and reached a plateau of about 35 mV.

In Vitro Transfection. In vitro transfection was conducted on COS-7 and HeLa cells to evaluate the ability of the PAA-*g*-MWNTs to deliver foreign DNA into cells. PAA and branched PEI 25KDa at the optimal w/w ratio were used as positive controls, and pGL-3 was used as the report gene.

The transfection results in Figure 5A reveal that PAA-*g*-MWNTs showed excellent transfection efficiency in COS-7 cells at w/w ratios from 2 to 30, which is comparable or higher than that of branched PEI 25KDa. Luciferase expression (RLU/mg protein) was related to the w/w ratio, with the w/w ratio increasing, the luciferase expression increased obviously. Optimized luciferase expression (RLU/mg protein) in COS-7 cells with PAA-*g*-MWNTs/pGL-3 complexes was a little higher than that with PEI/pGL-3 complexes. The high transfection

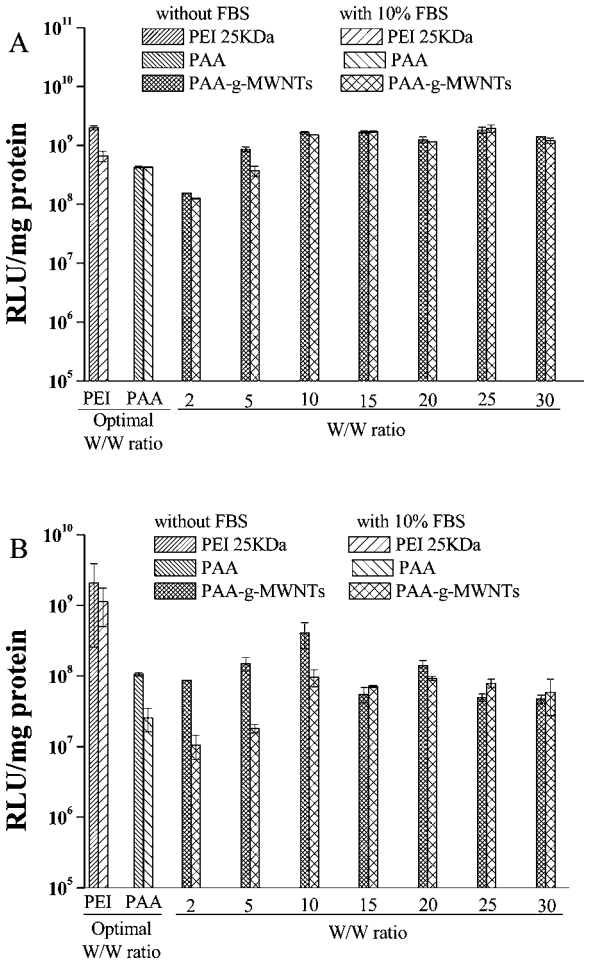

Figure 5. Transfection efficiencies of PAA-*g*-MWNTs/pGL-3 complexes in COS-7 (A) and HeLa (B) cells. PAA and branched PEI 25KDa were used as positive control.

efficiencies of PAA-*g*-MWNTs should be related to the combinational factors including low cytotoxicity, strong DNA binding ability and small particle size.

Similarly, the transfection results (Figure 5B) indicate that PAA-*g*-MWNTs still express high transfection efficiencies in HeLa cells, and the luciferase expression at optimal w/w ratio was comparable to that of PEI/pGL-3 complexes.

Serum protein can hinder cellular uptake and promote aggregation, often leading to reduction of the transfection efficiency. To understand the effect of serum on the DNA transfection, a transfection experiment was then performed with COS-7 cells in the presence of 10% FBS. As shown in Figure 5A, 10% of serum inhibited luciferase expression in COS-7 cells with each polycation tested in this work including PEI and PAA-*g*-MWNTs. The results illustrated that luciferase expression in COS-7 cells only slightly decreased at low w/w ratios; specifically, with the w/w ratio increasing, the luciferase expression could not be effectively prohibited by serum, indicating that the PAA-*g*-MWCNTs/DNA complexes were less serum-sensitive for in vitro transfection. Similar results were obtained in the case of HeLa cells.

Intracellular Trafficking of Cy3-Labeled pGL-3. Intracellular trafficking of Cy3-labeled pGL-3 was analyzed by CLSM and the result is shown in Figure 6. The optimal w/w ratio for PAA-*g*-MWNTs and PEI 25KDa was determined to be 15 and 1.3, respectively. In order to distinguish the nucleus and

dx.doi.org/10.1021/bc200189f | *Bioconjugate Chem.* 2011, 22, 2237−2243

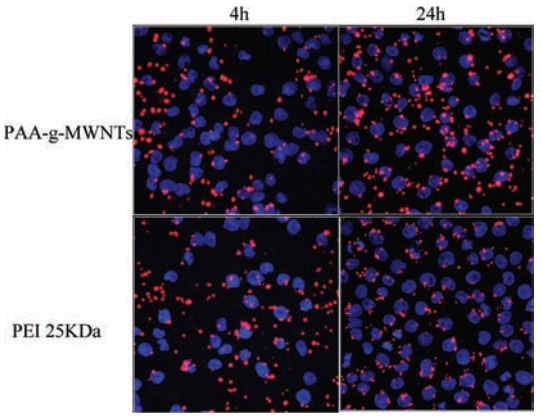

Figure 6. Intracellular trafficking of Cy3-labeled pGL-3 (red) when combined with PAA-*g*-MWNTs and PEI 25KDa at optimal w/w ratio. The localization of fluorescent particles in COS-7 cells was visualized at 4 and 24 h post-transfection. Nucleus (blue) was stained with Hoechst 33258.

DNA, Hoechst 33258 was used to stain the nucleus, which appeared to be blue fluorescence; meanwhile, the Cy3-labeled pGL-3 appeared to be red fluorescence.

As shown in Figure 6, after transfection for 4 h, Cy3-labeled pGL-3 was clearly visible. For PAA-*g*-MWNTs and PEI, a large amount of Cy3-labeled pGL-3 was dispersed in the cytoplasm and only a few red fluorescence particles were found interacting with the nucleus membrane. Meanwhile, very little Cy3-labeled pGL-3 was observed in the nucleus. After 24 h of transfection, significant differences appeared within each group: most of the red fluorescence particles were found aggregating in the nucleus. For PAA-*g*-MWNTs, lots of red fluorescence particles around the nucleus were observed, and almost all of the cells in the field of view showed DNA nucleus localization. Similar results were observed for PEI: there was no obvious difference with distribution of Cy3-labeled pGL-3 between PAA-*g*-MWNTs and PEI, except that cells transfected by PEI showed relatively lower fluorescence density in nuclear localization.

DISCUSSION

In our experiment, the carboxyl groups on the surface of MWNTs were first converted to succinimide-terminated (Scheme 1); after the carboxyl groups were activated, the cationic PAA was then added to the solution above, thus leading to the formation of PAA-*g*-MWNTs. Similar procedures were also reported previously.[24] The obtained aqueous solution of PAA-*g*-MWNTs was stable at room temperature without any precipitation for up to 6 months, as shown in Figure S2 (see Supporting Information); however, the aqueous solution of MWNTs-COOH precipitated rapidly, usually within a few hours.

The size and morphology of MWNTs-COOH, PAA-*g*-MWNTs, and PAA-*g*-MWNTs/DNA were characterized by SEM. Figure 7A,B shows the image of raw MWNTs-COOH and PAA-*g*-MWNTs. Obviously, after grafting with PAA, the morphology of MWNTs did not change significantly. Figure 7C presents the image of PAA-*g*-MWNTs/DNA. The SEM analysis did not reveal significant differences in size among the MWNTs-COOH, PAA-*g*-MWNTs, and PAA-*g*-MWNTs/DNA. A similar result was also reported by Gao and colleagues.[30]

Cytotoxicity of carriers is a very important factor in gene delivery. Previous work[25,26] demonstrated that polycations first combined with cell membrane via electrostatic interaction between positively charged polycations and negatively charged sites on the cells, which induced polycations to aggregate on the cell membrane and lead to cell death. Functionalization of carbon nanotubes has proven to be very useful for reducing their cytotoxicity.[27−29] Our results indicated that PAA-*g*-MWNTs showed no significant cytotoxicity to COS-7 cells at low concentration. However, with the concentration increasing, the cytotoxicity increased slowly. The IC_{50} values of PAA-*g*-MWNTs and PAA in COS-7 cells were estimated to be 108 and 66 μg/mL, respectively, much lower than that of PEI (IC_{50} = 10 μg/mL).[22] The IC_{50} values of PAA-*g*-MWNTs and PAA to HeLa cells are 78 and 52 μg/mL, respectively, which is similar to the case of COS-7 cells. Since PAA contains primary and tertiary amine groups, PAA-*g*-MWNTs may behave as a polycation molecule, and thus cause certain cytotoxicity.

The ability of vectors to condense DNA into small-sized particles is another important factor in gene delivery. To facilitate efficient gene expression, cationic polymers should strongly condense DNA to protect the DNA against digestion by enzymes, and thus improve transfection efficiency. The interaction of PAA-*g*-MWNTs with the pEGFP-N1 plasmid was investigated by gel retardation assay, zeta potential measurement, and SEM.

Gel retardation assay was performed to explore whether PAA-*g*-MWNTs could effectively bind DNA. The result in Figure 3 reveals that PAA-*g*-MWNTs could efficiently condense DNA, and entirely retain DNA at w/w ratio above 1.5. The zeta potential reached a plateau of about 35 mV, while the PAA/DNA complexes reached a plateau of about 20 mV,[22] which was much lower than that of PAA-*g*-MWNTs/DNA complexes. PAA-*g*-MWNTs with high zeta potential would facilitate electrostatic interaction between cationic PAA-*g*-MWNTs and polyanionic DNA.

Transfection efficiency is the most important factor in gene delivery. In our work, PAA-*g*-MWNTs could deliver foreign DNA into COS-7 and HeLa cells, with the transfection

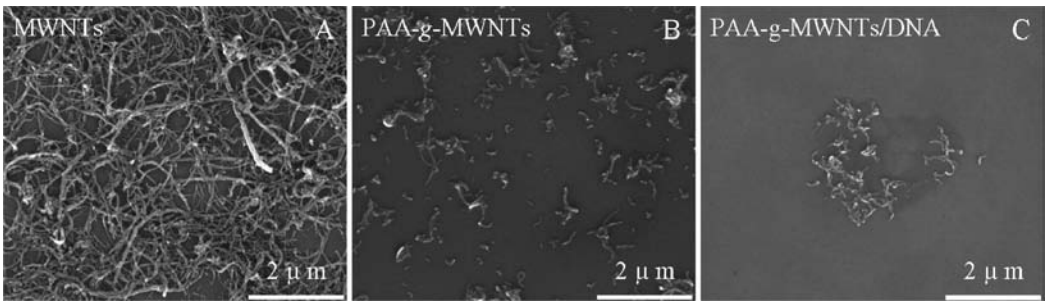

Figure 7. SEM images of MWNTs-COOH, PAA-*g*-MWNTs, and PAA-*g*-MWNTs/DNA.

efficiencies comparable or even higher than that of PEI 25KDa at optimal w/w ratio. Many factors are considered to affect transfection efficiencies, among which w/w ratio is the most important factor. With increasing of w/w ratio, the transfection efficiency rosed up steeply, then reached a plateau, and finally decreased. With the w/w ratio increasing, the cytotoxicity increased, leading to decrease in the cell viability and transfection efficiency. In addition, changing the w/w ratios would also alter the surface charge of PAA-*g*-MWNTs/DNA complexes, which could influence the DNA binding ability, and in turn, the transfection efficiency. Previous work has demonstrated that complexes with positive charge and small size are beneficial for cellular uptake and intracellular trafficking. In our study, PAA-*g*-MWNTs/DNA complexes possess high positive charge (35 mV), the average length is about 300 nm, and the diameter about 30−40 nm.

Cellular uptake and nuclei localization of PAA-*g*-MWNTs were studied by delivery of Cy3-labeled pGL-3 to cells. Besides the extracellular and cellular obstacles which reduced gene expression, nuclear envelope is recognized as one of the most important intracellular barriers. CLSM results in Figure 6 indicate that, for PAA-*g*-MWNTs and PEI, a majority of red fluorescence particles were attached to nucleus membrane within 4 h incubation, and some of them had already localized in the perinuclear region and localized in nucleus after 24 h incubation. On the basis of the results, intracellular trafficking and cellular uptake of Cy3-labeled pGL3 displayed that PAA-*g*-MWNTs showed superior DNA delivery ability to COS-7 nucleus than others.

CONCLUSIONS

In summary, PAA-grafted multiwalled carbon nanotubes were successfully prepared to deliver foreign DNA to cells. In comparison to PAA and PEI 25 KDa, PAA-*g*-MWNTs showed significantly low cytotoxicity and strong ability to condense DNA. Transfection efficiency results revealed that PAA-*g*-MWNTs possessed comparable or even higher luciferase expression than PAA and PEI at optimal w/w ratio. Intracellular trafficking of Cy3-labeled pGL-3 also displayed that PAA-*g*-MWNTs showed superior ability to deliver foreign DNA into cell nucleus. The current study may provide useful insight into design of novel nanovectors for efficient and nontoxic gene delivery.

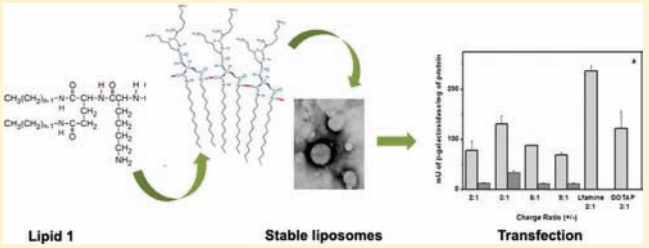
ABSTRACT: In the design of new cationic lipids for gene transfection, the chemistry of linkers is widely investigated from the viewpoint of biodegradation and less from their contribution to the biophysical properties. We synthesized two dodecyl lipids with glutamide as the backbone and two lysines to provide the cationic headgroup. Lipid 1 differs from Lipid 2 by the presence of an amide linkage instead of an ester linkage that characterizes Lipid 2. The transfection efficiency of lipoplexes with cholesterol as colipid was found to be very high with Lipid 1 on Chinese Hamster Ovary (CHO) and HepG2 cell lines, whereas Lipid 2 has shown partial transfection efficiency on HepG2 cells. Lipid 1 was found to be stable in the presence of serum when tested in HepG2 and CHO cells albeit with lower activity. Fluorescence-based dye-binding and agarose gel-based assays indicated that Lipid 1 binds to DNA more efficiently than Lipid 2 at charge ratios of >1:1. The uptake of oligonucleotides with Lipid 1 was higher than Lipid 2 as revealed by confocal microscopy. Transmission electron microscopy (TEM) images reveal distinct formation of liposomes and lipoplexes with Lipid 1 but fragmented and unordered structures with Lipid 2. Fusion of Lipids 1 and 2 with anionic vesicles, with composition similar to plasma membrane, suggests that fusion of Lipid 2 was very rapid and unlike a fusion event, whereas the fusion kinetics of Lipid 1 vesicles was more defined. Differential scanning calorimetry (DSC) revealed a high T_m for Lipid 1 (65.4 °C) while Lipid 2 had a T_m of 23.5 °C. Surface area–pressure isotherms of Lipid 1 was less compressible compared to Lipid 2. However, microviscosity measured using 1,6-diphenyl-1,3,5-hexatriene (DPH) revealed identical values for vesicles made with either of the lipids. The presence of amide linker apparently resulted in stable vesicle formation, higher melting temperature, and low compressibility, while retaining the membrane fluid properties suggesting that the intermolecular hydrogen bonds of Lipid 1 yielded stable lipoplexes of high transfection efficiency.



INTRODUCTION

Cationic lipid-based formulations offer attractive solutions for *in vitro* delivery of nucleic acids.[1−4] Liposomes containing cationic lipids electrostatically bind with the polyanionic nucleic acids resulting in a lipoplex that protects nucleic acids from degradation and facilitates endosomal uptake.[5,6] Structurally, cationic lipids are amphiphilic with a hydrophilic cationic headgroup connected with a linker to hydrophobic tails, usually alkyl chains.[7−9] Extensive investigations on chemistry and transfection efficiency of cationic lipids suggest that a wide variety of molecules are suitable when appropriate amphiphilicity is maintained.[5,6] Alkyl chains [8,10] and steroid molecules[11] are a few examples that were found suitable as hydrophobic groups, while a large variety of cationic groups such as primary or tertiary amines together with polyamine and quarternary ammonium,[12,13] guanidino groups,[14] and amino acids[15] were found to enhance transfection efficiency. The enhancement in transfection efficiency in the presence of a neutral lipid or a colipid such as phosphatidylethanolamine or cholesterol was the prime motivation to successfully test a large number of cationic lipids with colipids.

Transfection efficiency by cationic lipids is strongly dependent on the cell type and inclusion of colipids in formulations.[16−18] To obtain insight into the relationship between transfection efficiency and the properties such as size, charge, stability, and interaction with the biological membranes, cationic lipids have been extensively investigated.[15] These studies indicated that compact, fluid, and positively charged lipoplexes overcome serum destabilization, enhanced cellular associations, and eventual escape from the endosomes by fusion.[19] Amino acids or short peptides have been used, especially as headgroup moieties, in the design of cationic lipids.[15] Cationic amino acids lysine and arginine have been extensively used to provide the cationic headgroup[15] to facilitate complexation with the nucleic acids. The pK_a properties of amino acid histidine have been used successfully[20] to cause endosomolysis after uptake of lipoplex. However, use of amino acids as backbone for the cationic lipid has not been investigated. Earlier, we reported

synthesis and transfection efficiencies of pyridinium-based cationic lipids with glutamide as the backbone.[21] In the design of cationic lipids, linkers are used to connect the headgroup or the hydrophobic portion to the backbone, for example, glycerol.[22−24] This is to provide biodegradability and thereby safety due to decreased toxicities. Ester linkages are preferred over ether linkers[25] primarily for their biodegradability. In some reports, the linkers are designed to enhance the release of the nucleic acid from the lipoplex in response to a change in conditions inside the cell. For example, low pH labile bonds are used to dissociate the headgroup from the lipid in the endosomal compartment and release the plasmid DNA.[13] Reduction of linkers with disulfide bonds in the cytoplasmic milieu destabilizes the complex[26] thereby separating the nucleic acid from the liposomes. Recently, in an otherwise chemically similar lipid, the linker orientation was shown to have dramatic effect on the transfection properties of the lipid.[24] We report in this study two lysinated-glutamide lipids which differ from each other only in their linker chemistry, i.e., either amide or an ester designated as Lipid 1 and Lipid 2, respectively. Lipid 1 with an amide linker melts at a higher temperature and has higher transfection efficiency than the low melting counterpart Lipid 2 with the ester linker. This striking structural difference between the two lipids motivated further investigations to address whether the linker has any role in determining the transfection efficiency.

EXPERIMENTAL PROCEDURES

Materials. In this work, all chemicals and solvents were purchased and used without further purification. The chemical structures of the lipids were identified by melting point, FTIR, ^{1}H NMR, and elemental analysis. Melting points were determined on a micro melting point apparatus. FTIR spectra were performed on a JASCO FT/IR-4000 spectrometer. ^{1}H NMR spectra were recorded by a JEOL JNM-EX400 spectrometer using tetramethylsilane as an internal standard. Elemental analyses were performed with a Yanaco CHN Corder MT-3. ESI-HRMS was performed on a QSTAR XL hybrid MS/MS system (Applied Biosystems/MDS sciex), equipped with an ESI source.

1,6-diphenyl-1,3,5-hexatriene, ethidium bromide, NBD-DHPE, and Rhodamine −DHPE were purchased from Molecular Probes (USA). 1,2-Dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE), cholesterol, L-α-phosphatidylglycerol (PG), and 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC) were purchased from Avanti Polar Lipids (USA). Fluorescein (FAM) Labeling Kits were sourced from Ambion. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and other reagents were purchased from Sigma Co.

Synthesis of Z-Lys(Z)-Lys(Z)-OH. *(A). Z-Lys(Z)-Lys(Z)-OMe.* Z-Lys(Z)-OH (3.42 g, 9.06 mmol), H-Lys(Z)-OMe·HCl (3.0 g, 9.06 mmol), and triethylamine (2.76 g, 27.1 mmol) were dissolved in chloroform. The solution was cooled to 0 °C, and DEPC (1.97 g, 1.09 mmol) was added to the solution and stirred for 30 min at this temperature. After stirring for 1 day at room temperature, the solution was concentrated *in vacuo*, and the residue was dissolved in chloroform. The solution was washed with 0.2 N HCl, 5 wt % $NaHCO_3$, and water. The solution was dried over Na_2SO_4, concentrated, and finally added to diethyl ether, which gave a white solid powder: yield 4.56 g (73%, 6.5 mmol); mp 103−105 °C; FT-IR (KBr) 3316, 2942, 1741, 1690, 1650, and 1542 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 1.37 (m, 4H, C*HCH$_2$CH_2), 1.49 (m, 4H, CH_2CH_2NH), 1.62 (m, 2H, CHCH_2(CH$_2$)$_3$NH), 1.83 (q, 2H, $CH_3OC(=O)C^*HCH_2$), 3.08−3.18 (m, 4H, C*H-(CH$_2$)$_3$CH_2NHC(=O)), 3.68 (s, 3H, CH_3), 4.18 (s, 1H, $CH_3OC(=O)C^*H$), 4.53 (s, 1H, NHC(=O)C*HNHC(=O)), 5.07 (m, 6H, C*H_2Ph), 7.35 (d, 15H, C_6H_5). Anal. Found: H, 6.77%; C, 63.4%; N, 7.97%. Calcd. for $C_{37}H_{46}N_4O_9$: H, 6.71%; C, 64.3%; N, 8.11%.

(B). Z-Lys(Z)-Lys(Z)-OH. Z-Lys(Z)-Lys(Z)-OMe (4.6 g, 6.60 mmol) and 1 N NaOH 19 mL (19 mmol) were dissolved in 100 mL methanol, stirred for 1 h at room temperature, and pH was adjusted to 2 by 1 N HCl. After removing methanol from the solution *in vacuo*, the residue was added to ethanol. The obtained white precipitate was removed by filtration, and the solution was concentrated and added to *n*-hexane to give a white precipitate. The precipitate was collected by filtration and dried *in vacuo*: yield 4.30 g (95% 6.35 mmol) mp 145−147 °C; FT-IR (KBr) 3322, 2941, 2863, 1692, 1652, and 1541 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 1.35 (m, 4H, C*HCH$_2$CH_2), 1.47 (m, 4H, CH_2CH_2NH), 1.63−1.86 (br, 4H, C*HCH_2), 3.10 (d, 4H, C*H(CH$_2$)$_3$CH_2NHC(=O)), 4.26 (s, 1H, HOC(=O)C*H), 4.50 (s, 1H, NHC(=O)C*HNHC(=O)), 5.06 (m, 6H, CH_2Ph), 7.29 (d, 15H, C_6H_5). Anal. Found: H, 6.86%; C, 63.44%; N, 8.08%. Calcd. for $C_{36}H_{44}N_4O_9$: H, 6.55%; C, 63.9%; N, 8.28%.

Synthesis of Lipid 1 (2C$_{12}$-Gln-Lys-Lys). *(A). Synthesis of 2C$_{12}$-Gln.* Synthesis of 2C$_{12}$-Gln was described earlier (*Bioconjugate Chem.* **2006**, *17*, 1530).

(B). 2C$_{12}$-Gln-Lys(Z)-Lys(Z)-Z. 2C$_{12}$-Gln (0.93 g, 1.93 mmol), Z-Lys(Z)-Lys(Z)-OH (1.30 g, 1.92 mmol), and triethylamine (0.37 g, 3.84 mmol) were dissolved in dry THF (100 mL). The solution was cooled to 0 °C, and DEPC (0.52 g, 2.88 mmol) was added to the solution and stirred for 1 day at room temperature. After stirring, the solution was concentrated *in vacuo*, and the lipid was recrystallized from ethanol, which gave a white solid powder: yield 1.07 g (50%, 0.94 mmol); mp 184−187 °C; FT-IR (KBr) 3295, 2925, 2853, 1693, 1637, and 1543 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.86−0.89 (t, 6H, CH_3), 1.25 (m, 36H, CH$_3$(CH_2)$_9$), 1.33 (s, 4H, CH_2CH$_2$NHC(=O)), 1.48 (br, 6H, C*H(CH_2)NHC(=O)), 1.58−2.40 (s, 8H, C*HCH$_2$CH_2CH$_2$, C*HCH$_2$CH$_2$CH_2), 2.44 (m, 2H, C*HCH$_2$CH_2C(=O)), 3.16−3.23 (br, 8H, CH_2NHC(=O), CH_2NHC(=O)O), 4.11 (s, 1H, C*HNHC(=O)), 4.35 (s, 1H, C*HNHC(=O)), 4.51 (s, 1H, C*HNHC(=O)), 4.92−5.15 (br, 6H, CH_2Ph) 7.28−7.34 (m, 15H, C_6H_5). Anal. Found: H, 8.94%; C, 68.3%; N, 8.56%; Calcd. for $C_{65}H_{101}N_7O_{10}$: H, 8.93%; C, 68.5%; N, 8.60%.

(C). 2C$_{12}$-Gln-Lys-Lys. 2C$_{12}$-Gln-Lys(Z)-Lys(Z)-Z (0.93 g, 0.82 mmol) was dissolved in 100 mL ethanol with heating, and Pd/carbon (0.5 g) was added to the solution. H_2 gas was bubbled slowly into the solution for 14 h at 70 °C. Pd/carbon was removed by filtration, and the solution was dried *in vacuo* to give a solid powder: yield 0.34 g (52%, 0.43 mmol, as a trihydrate); mp 104−107 °C; FT-IR (KBr) 3289, 2920, 2851, 1639, and 1557 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ 0.87−0.90 (t, 6H, CH_3), 1.28 (m, 36H, CH$_3$(CH_2)$_9$), 1.52−2.17 (br, 20H, CH_2CHNHC(=O), CH_2C*H, CH_2CH$_2$C*H, CH_2(CH$_2$)$_2$C*H), 3.12−3.35 (br, 8H, CH_2-NHC(=O), CH_2NHC(C=O)O), 4.31−4.56 (br, 3H, C*HNHC(=O)). Anal. Found: H, 10.9%; C, 64.9%; N, 11.4%. Calcd. for $C_{41}H_{89}N_7O_7$: H, 11.3%; C, 62.2%; N, 12.4%. ESI-HRMS: m/z = +738.6569 (calcd value for $C_{41}H_{84}N_7O_4$ = 738.6584).

Synthesis of Lipid 2 (2C$_{12}$Glu-Lys-Lys). *(A). Didodecyl-L-Glutamate Toluene-p-Sulfonate (2C$_{12}$L-Glu TosOH).* L-Glutamic acid (6.0 g, 40.0 mmol), *p*-toluenesulfonic acid

(6.82 g, 48.0 mmol), and 1-dodecanol (17.8 g, 96.0 mmol) were dissolved in toluene (250 mL), and refluxed for 5 h by use of Dean−Stark apparatus. The solution was concentrated in vacuo, and the residue was dissolved in 200 mL of diethyl ether, and refrigerated to 4 °C for 1 day, which gave a white solid powder: yield 13.1 g (49%), mp 65−66 °C. Anal. Found: H, 9.93; C, 65.4; N, 2.40; Calcd. for $C_{36}H_{65}NO_7S$: H, 9.99; C, 65.9; N, 2.14. FT-IR (KBr) 2921 cm^{-1} (ν_{C-H}), 2850 cm^{-1} (ν_{C-H}), 1743 cm^{-1} (ν_{ester}), 1533 cm^{-1} (δ_{NH}), 1182 cm^{-1} (ν_{C-O}). ^1H NMR ($CDCl_3$, internal reference: tetramethylsilane) δ 0.86−0.90 (m, 6H, CH_3) δ 1.26 (m, 36H, CH_3-$(CH_2)_9$), δ 1.55 (m, 4H, $CH_2CH_2OC(=O)$), δ 2.15−2.25 (m, 2H, $C^*HCH_2CH_2C(=O)$), δ 2.34 (s, 1H,CH_3Ph), δ 2.43−2.58 (m, 2H, $C^*HCH_2CH_2C(=O)$), δ 3.95−4.11 (m, 4H, $CH_2CH_2OC(=O)$), δ 7.12−7.14 (d, 2H, C_6H_5), δ 7.72−7.74 (d, 2H, C_6H_5).

(B). $2C_{12}$Glu-Lys(Z)-Lys(Z)-Z. $2C_{12}$Glu-Lys(Z)-Lys(Z)-Z was synthesized by similar method with $2C_{12}$Gln-Lys(Z)-Lys(Z)-Z: yield 1.20 g (51%); mp 130−131.5 °C; FT-IR (KBr) 3307 cm^{-1} 2924 cm^{-1} (ν_{C-H}), 2853 cm^{-1} (ν_{C-H}), 1732 cm^{-1} ($\nu_{C=O(ester)}$), 1688 cm^{-1} ($\nu_{C=O(urethan)}$), 1640 cm^{-1} ($\nu_{C=O(amide)}$), 1543 cm^{-1} (δ_{N-H}), ^1H NMR ($CDCl_3$) δ 0.86−0.90 (m, 6H, CH_3), δ 1.26 (m, 40H, CH_3-$(CH_2)_9$, $C^*HCH_2CH_2CH_2$), δ 1.49 (m, 4H, $CH_2CH_2NHC(=O)$), δ 1.56 (m, 4H, $CH_2CH_2OC(=O)$), δ 1.68−1.88 (br, 4H, $CH_2C^*HNHC(=O)$), δ 1.94−2.01(m, 1H, $C^*HCH_2CH_2C(=O)$), δ 2.11−2.16 (m, 1H, $C^*HCH_2CH_2C(=O)$), δ 2.36 (m, 2H, $C^*HCH_2CH_2C(=O)$), δ 3.16 (m, 4H, $CH_2CH_2NHC(=O)$), δ 4.03 (m, 4H, $CH_2CH_2OC(=O)$), δ 4.15 (m, 1H, $CH_2OC(=O)C^*HNH$ $C(=O)$), δ4.38 (q, 1H, $NHC(=O)C^*HNH$ $C(=O)$), δ 4.53 (q, 1H, $NHC(=O)C^*HNH$ $C(=O)OCH_2Ph$), δ 5.07 (m, 6H, $PhCH_2OC(=O)$), δ 7.31 (d, 15H, C_6H_5). Anal. Found: H, 8.69; C, 67.8; N, 6.20; Calcd. For $C_{65}H_{99}N_5O_{12}$: H, 8.73; C, 68.3; N, 6.13.

(C). $2C_{12}$-Glu-LysLys. $2C_{12}$Glu-LysLys was synthesized by similar method with $2C_{12}$Gln-LysLys: yield 0.40 g (49%, 0.47 mmol, as a hexahydrate); FT-IR (KBr) 3307 cm^{-1} and 2925 cm^{-1} (ν_{C-H}), 2854 cm^{-1} (ν_{C-H}), 1737 cm^{-1} ($\nu_{C=O(ester)}$), 1654 cm^{-1} ($\nu_{C=O(amide)}$), 1557 cm^{-1} (δ_{N-H}), ^1H NMR ($CDCl_3$) δ 0.86−0.90 (m, 6H, CH_3), δ 1.27 (m, 36H, $CH_3(CH_2)_9$), δ 1.50−2.27 (br, 18H, CH_2), δ 2.51 (m, 2H, $C^*HCH_2CH_2C(=O)$), δ 3.15 (m, 4H, CH_2-NH_2), δ 4.14−4.20 (m, 4H, $CH_2CH_2OC(=O)$), δ 4.30−4.57 (br, 3H, $C^*HNHC(=O)$). Anal. Found: H, 9.4; C, 58.1; N, 8.00. Calcd. for $C_{41}H_{93}N_5O_{12}$: H, 11.1; C, 58.1; N, 8.26. ESI-HRMS: m/z = +740.6245 (calcd value for $C_{41}H_{82}N_5O_6$ = 740.6265).

Preparation of Liposomes. Cationic amphiphiles Lipid **1**, **2**, and the colipid cholesterol were dissolved in chloroform and mixed in glass vials at 1:1 mol ratio. Chloroform was then removed with a thin flow of nitrogen and the dried lipid film was kept under vacuum for 4−5 h. Subsequently, deionized water was added to the dried lipid film for overnight rehydration. The vial was vortexed thoroughly at RT to produce multilamellar vesicles (MLVs). MLVs were sonicated until clarity to obtain small unilamellar vesicles (SUV).

DNA-Binding Assay. *Agarose Gel Electrophoresis.* Plasmid $pGFPN_3$ was complexed with cationic lipids at charge ratios varying from 0.3:1 to 3:1 (lipid/DNA) to measure the DNA binding ability. In a typical binding assay, 0.6 nmol of DNA, corresponding to 200 ng of plasmid DNA, was complexed with the lipids, at indicated charge ratios, in 10 mM phosphate buffer (pH 7.5), deionized water or 0.5× PBS in a volume of 20 μL and incubated at room temperature for 30 min. After addition of the tracking dye bromophenol blue, samples were directly loaded on a 1% agarose gel with TAE buffer and electrophoresed at 80 V for approximately 2 h. The gel was stained with ethidium bromide (EtBr), post electrophoresis, and visualized under a transilluminator. DNA binding was also carried out by EtBr fluorescence titrations as described.[27]

Ethidium Bromide (EtBr) Fluorescence Quenching. The binding of DNA with Lipid **1** and **2** was studied using EtBr as the fluorescent probe. The lipids were reconstituted with colipids DOPE or cholesterol in deionized water using standard protocols. Bound EtBr was expelled from the DNA−EtBr complexes by the lipid. This displacement of EtBr is reflected as a drop in the fluorescence signal, since unbound EtBr does not fluoresce. All fluorescence measurements were carried out using a Hitachi F-4500 fluorescence spectrophotometer. The excitation wavelength, λ_{ex}, was 516 nm and the emission wavelength was kept at 598 nm (slit width 5 × 5 nm^2). Briefly, 2.3 μg of pCMV-β-gal plasmid DNA was added to 500 μL of 20 mM Tris−HCl buffer (pH 7.4) in a fluorescence cuvette. EtBr 0.23 μg, from a diluted stock solution, was added to DNA and the baseline fluorescence was determined. The fluorescence intensity obtained upon each addition of lipid was normalized relative to the fluorescence signal of DNA−EtBr complex, in the absence of the lipid, which was taken as 100%. The binding of DNA by the lipid was recorded after each addition at time intervals of 5 min.

Transfection. CHO, HepG2, cells were plated at a density of 10 000 cells per well in a 96-well plate on the previous day. Plasmid DNA pCMVβ-gal was purified by using the Qiagen Kit (endotoxin free) using the manufacturer's protocol and also by CsCl−EtBr density gradient ultracentrifugation using standard protocols. Plasmid (0.9 μg corresponding to 2.72 nmol) was complexed with varying amounts of Lipid **1** and **2**, formulated with cholesterol at 1:1 mol ratio, to obtain charge ratios varying from 1:1 to 9:1, DNA/Lipid, in DMEM without serum and incubated at RT for 30 min. Complexes were added to cells after appropriate dilution with DMEM to achieve 0.3 μg per well, and incubated for 3 h. The medium was then replaced with complete medium containing 10% serum.

Serum stability experiments were performed as described[21] in CHO and HepG2 cells. Briefly, transient transfections, *in vitro*, were done in the presence of fetal calf serum. Lipid/DNA complexes were prepared in the absence of serum and incubated for a period of 30 min at room temperature. Serum was then added to the complex to obtain the 10% final concentration and then added to the cells, seeded on a 96-well plate and the charge ratios varied from 2:1 to 12:1 Lipid/DNA. Data is represented as β-gal activity/well (20 000 cells). Reporter gene assay was carried out 48 h post transfection and efficiency depicted as relative β-gal activity. In these assays, cells were washed with PBS and lysed in 50 μL of lysis buffer (0.25 M Tris.HCl, pH 8.0, and 0.5% NP40). β-Gal activity was estimated by adding 50 μL of 2× substrate (1.33 mg/mL ONPG, 0.2 M sodium phosphate, pH 7.15, and 2 mM magnesium chloride) to an equal volume of the lysate in a fresh 96-well plate and incubated at 37 °C. Absorption at 405 nm was converted to β-gal units by using a standard curve generated with pure commercial enzyme.

Differential Scanning Calorimetry. Thermal transitions in Lipids **1** and **2** were performed using VP-DSC MicroCal calorimeter (VP-ITC model). The calorimetry was performed using Lipids **1** and **2** (8.8 mg/mL) vesicles prepared in deionized water as described above except the sonication step. All samples (250 μL) were degassed before acquiring the scans

which were performed between 10 °C and 95 ° C at a scan rate of 60 deg/h. Water or buffer baselines were obtained and subtracted from lipid scans.

Fluorescence Anisotropy Measurements. These measurements were carried out using Fluorolog 3−22 Fluorescence Spectrophotometer (Jobin Yvon,USA). Lipids **1** and **2** were prepared from chloroform stocks by the appropriate addition of the fluorescent probe DPH (1,6-diphenyl-1,3,5-hexatriene) at 300:1 mol ratio of Lipid/DPH, to obtain 2 mM stock of the lipid. This mixture was then dried under nitrogen gas. The residual chloroform was then removed in a vacuum for 4 h. Lipid films were then hydrated in 1 mL of buffer (Tris. HCl, pH 7.4, 100 mM) overnight, vortexed, and sonicated prior to the scans between 15 and 90 °C with 2.5 °C increments. Fluorescence anisotropy was measured by recording the DPH fluorescence values (excitation at 354 nm and emission at 427 nm) in parallel and perpendicular polarizer positions. Anisotropy values were calculated by instrument software.

Membrane Fusion. Membrane fusion between cationic lipid vesicles and anionic vesicles was monitored by Förster resonance energy transfer (FRET) between NBD-PE and Rhodamine DHPE. The liposomes containing the fluorophores were prepared with the following composition: DOPC:DOPE:egg PG:NBD-PE:Rh-PE at a mole ratio of 75:20:5:0.8:0.8. Cationic liposomes were prepared with Lipid **1** and **2** along with cholesterol in a mole ratio of 50:50. The fusion was initiated by mixing 50 nmol of cationic lipid vesicles with 10 nmol of fluorescent lipids in phosphate buffered saline (10 mM sodium phosphate buffer, pH 7.4, with 150 mM of sodium chloride) at 25 °C in stirring conditions. The increase in fluorescence was monitored in a Hitachi F4300 spectrofluorimeter by exciting the sample at 460 nm and collecting the emission at 530 nm. The total fluorescence was measured by adding Triton X-100 at a final concentration of 0.15%. The small but measurable quenching due to Triton X-100 was corrected. Anionic vesicles were also prepared using phophatidic acid instead of PG at the same mole ratio, and we obtained similar results.

Surface Area−Pressure Isotherms. The measurements were made on a Langmuir trough manufactured by Nima (model 622D) using high-purity water as subphase. Lipids **1** and **2** were prepared as stocks in chloroform and spread at the air−water interface in less than 5 μL. The pressure−area isotherms were obtained at compression rates of 50 cm^2 per minute. Since the surface area available with the trough does not allow us to monitor the collapse point of the monolayer, only the rate of change of the surface pressure for change in molecular area was used in the study.

Transmission Electron Microscopy. SUVs of Lipids **1** and **2** (2 mM) were prepared as described earlier. The vesicle solution was cast on the poly(vinyl acetate)-coated copper grid and stained with 1.0 wt % uranyl acetate aqueous solution. The TEM images were recorded by JEM-2000EX/FX (JEOL, Co. Ltd.) with 80 kV accelerating voltage.

Live Uptake of DNA by Confocal Microscopy. Chambered cover glass was plated with 20 000 cells (CHO) and incubated with lipoplexes (with 6:1 lipid/DNA charge ratio) prepared with Lipids **1** and **2** in 300 μL of DMEM containing Oregon Green-labeled plasmid pCMVβ-gal plasmid DNA prepared as described. After the incubation period of 3 h, DMEM was removed, and the cells were washed with PBS twice before obtaining images (Leica TCS S52). The cells containing labeled DNA (ChromaTide Oregon Green 488−5′dUTP): RhDHPE-labeled lipid complexes were visualized using the 488 nm excitation of argon laser, 405 nm excitation of diode while Rhodamine was detected using HeNe excitation wavelength of 543 nm. The emission collection wavelengths were 500−540 nm for Oregon Green, 415−485 nm for Hoechst 33258, and 560−615 nm for Rhodamine. In each panel, 5 slices of 0.5 μm were combined. Last panel indicates overlaid images depicting nuclear staining with Hoechst 33258.

Toxicity Assay. Cytotoxicity of the Lipids **1** and **2** were assessed in CHO cells using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT). Complexes prepared with lipid, were evaluated for their toxicity to cells by performing the MTT assay as described[27] in 96-well plates at charge ratios used in the transfection experiments. Cells were incubated with transfection complexes for 3 h at 37 °C in serum-free DMEM. Soon after transfection, cells were washed with PBS and replaced with 100 μL DMEM+25 μL MTT (2 mg/mL in PBS) for 3 h. The medium was removed and replaced with 100 μL DMSO/methanol 1:1 (v/v) and mixed to dissolve the formazan crystals. Absorbance was then measured at 540 nm with untreated cells serving as controls. Results were expressed as percent viability. [A540 (treated cells) − background/A540 (untreated cells) − background] × 100.

Small Angle X-ray Diffraction of the Lipid Vesicles. Vesicles of Lipids **1** and **2** with cholesterol were prepared as described above. The lipid concentration for SAXS studies was 5 mM and vesicles were used without sonication. Diffraction data were collected on a S3-MICROpix attached to a Dectris 100K Platus detector (Hecus Xray Systems, Graz, Austria) located 300 mm from the sample. Detector was precalibrated with silver behenate. Samples were filled in 1 mm thin-walled quartz-glass capillaries in tight thermal contact with a programmable Peltier unit. Samples were equilibrated for 10 min at each temperature before measurement. The data were fitted using *Fit2d* software.[28]

RESULTS

Synthesis of the Lipids. To investigate the role of the amide and ester linker in a cationic lipid on transfection properties, $2C_{12}$Glu and $2C_{12}$-Gln were synthesized and later coupled to Z-Lys (Z)-Lys(Z)-OH. The schemes for the synthesis of Lipid **1** (amide lipid) and Lipid **2** (ester lipid) is given in Scheme 1A,B. The purity was assessed by HPLC and chemical nature of the compounds was confirmed by FTIR, ^{1}H-NMR, and elemental analysis.

DNA Binding Properties of Lipid 1 and 2. *Agarose Gel Retardation Assay.* We initially investigated the DNA-binding ability of Lipid **1** and **2** by a gel-based assay. Both lipids formulated with cholesterol bind to plasmid DNA, pEGFPN$_3$ (Figure 1A). Formation of a complex and its retardation was observed with Lipids **1** and **2** with cholesterol as the colipid at 0.3:1 charge ratio. At charge ratios greater than 2:1, the complexes were either retained in the well or not amenable to EtBr binding after electrophoresis. The binding of lipids with the plasmid was found to be ratio-dependent. The binding of Lipid **1** was more avid compared to Lipid **2** when formulated with DOPE (data not shown). Therefore, only formulations with cholesterol were taken up for further biophysical investigations and cell biological activity *in vitro*.

Fluorescence Quenching. Binding strengths of cationic lipids with DNA are important to correlate the transfection properties of lipids to its chemical structure. Exclusion of EtBr

from DNA upon the addition of cationic lipid, and consequent enhancement of fluorescence, provides a sensitive and quantitative measurement for DNA binding. Figure 1B shows the DNA binding pattern of Lipid **1** in comparison to Lipid **2**, which was similar at lower charge ratios. However, at charge ratios above 1:1, Lipid **1** shows a slightly stronger binding with ~25% drop in the fluorescence intensity when compared to ~17% decrease with Lipid **2**.

Uptake of Lipoplexes in CHO Cells. We examined the cellular uptake of lipoplexes prepared with Lipid **1** and Lipid **2** formulated with cholesterol in CHO cells. An Oregon-Green labeled plasmid probe (green) was mixed with an equal proportion of unlabeled DNA to prepare lipoplexes labeled with 0.5 mol % of fluorescent lipid (RhDHPE), at the charge ratios indicated and added to CHO cells followed by incubation at 37 °C for 3 h. After thorough washes with DMEM, live cells were viewed by confocal microscopy. The upper panel, i.e., Lipid **1** (Figure 2), exhibited particulate bright red fluorescence originating from the Rhodamine-labeled lipid that colocalized with the labeled-plasmid DNA. Uptake of Lipid **2** was comparatively less (see merged panel of this figure). Quantitative analysis of the confocal image was done by measuring mean fluorescence intensity (MFI) per cell using *LAS AF* software. When compared with Lipid **2**, we observed a 3-fold increase in the MFI measured either by OG-labeled DNA or Rhodamine-labeled liposomes in the uptake of lipoplexes prepared with Lipid **1**/Chol.

Biophysical Characterization of the Lipids. *Determination of the Melting Temperature of the Lipids.* Hydrated lipid samples with and without the colipid, cholesterol, were subjected to thermal transitions in a differential scanning calorimeter (DSC). The heat capacity changes in the lipid phase as a function of temperature were plotted in Figure 3. The transition midpoints were found to be 65.4 and 23.5 °C for Lipid **1** and **2**, respectively. Similar transition midpoints was also found for these lipids in the presence of cholesterol. The transition midpoint for lipids is known to be determined by the chain length of the alkyl group. Since both lipids have identical chain length (C12) and identical head groups, the higher

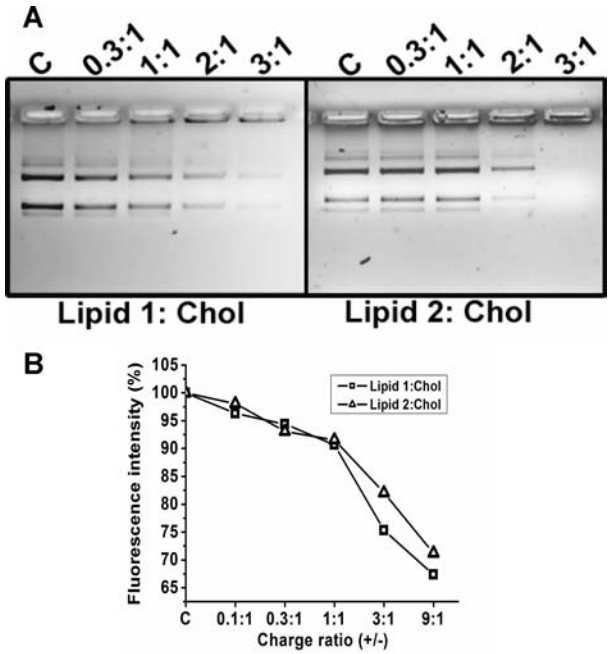

Figure 1. Binding of DNA with Lipids **1** and **2** in the presence of the colipid cholesterol: (A) 1% Agarose gel electrophoresis of plasmid pCMVβ-gal complexed with Lipids **1** and **2** at charge ratios varying from 0.3:1 to 3:1 Lipid/DNA, indicated above each well. Samples were electrophoresed using TAE buffer (pH 8.0) and visualized post-electrophoresis by staining with EtBr. Control in each panel denoted as "C" pertains to naked plasmid DNA. (B) Fluorescence quenching by EtBr exclusion assay of Lipids **1** and **2** formulated with colipid cholesterol. Fluorescence titration curves depict quenching of fluorescence due to release of EtBr from pCMVβ-gal plasmid DNA upon lipid binding in a buffer containing 20 mM Tris·HCl (pH 7.4).

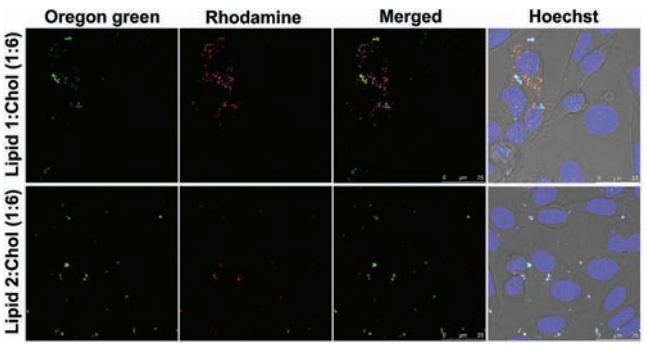

Figure 2. Uptake of lipoplexes and analysis by confocal microscopy: Transfection complexes with the corresponding lipid were added to cells in the absence of serum and incubated for 3 h. Lipid **1**/Chol at 6:1 DNA/Lipid (top) and Lipid **2**/Chol at 6:1 DNA/Lipid (bottom). DNA was labeled with Oregon-Green while liposomes were labeled with Rhodamine DHPE at 0.5 mol %. The merged panel indicate colocalization of the fluorophores. Cell nuclei were stained with Hoechst (blue). Panels on the extreme right depict images merged with the transmission channel. Five optical sections in the middle region, each of 0.5 μm thickness, were combined to generate the images.

melting temperature of Lipid **1** may have been due to additional interactions in Lipid **1**. To confirm the phase transitions, we used identical preparations of Lipid **1** and **2** with a fluorescent probe diphenyl hexatriene (DPH) at 300:1 ratio (lipid/DPH, mol/mol). Anisotropy of DPH is sensitive to the microviscosity of its location. DPH resides at the center of the bilayer and its

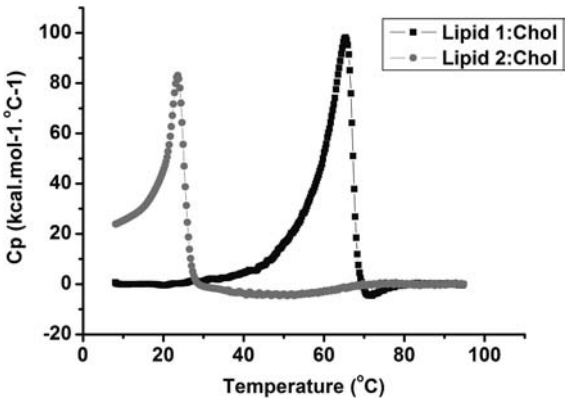

Figure 3. Differential scanning calorimetric scans of lipid vesicles: Thermograms of Lipid **1** and Lipid **2** formulated with equimolar amounts of cholesterol. Vesicles were prepared as described in methods.

anisotropy has been extensively used to estimate the phase transition temperatures of lipid assemblies. Lipid **1** exhibited a sharp phase transition around 67 °C, whereas Lipid **2** had a shallow transition at lower temperatures (Supporting Information Figure 1S). Thus, a higher melting temperature of Lipid **1** was confirmed by two independent methods.

Transmission Electron Microscopy (TEM). Having determined the melting temperature of liposomes of Lipids **1** and **2**, we sought to examine the structural features of these liposomes by transmission electron microscopy (TEM). The images obtained with Lipid **1** vesicles prepared with cholesterol or DOPE as the colipid at charge ratio 3:1 revealed the formation of very well-defined spherical structures with a clear inside–outside demarcation. The average size of the vesicles was between 100 and 200 nm in diameter. In contrast, liposomes prepared with Lipid **2** with either of the colipids resulted in supramolecular assemblies that were fragmented and poorly defined (Figure 4). The liposomal preparation with Lipid **2** resulted in structures with long continuous layers that were not discrete. Liposomes of Lipid **1** had unaltered morphology when the particles were prepared either in water or in the presence of PBS (ionic strength = 0.154) (data not shown).

To confirm our observations further, we subjected both the liposomal samples to small angle X-ray scattering (SAXS). SAXS provides information on characteristics of long-range-ordered structures and has been extensively used in identifying the phase properties of the lipids in membranes. The SAXS pattern of Lipids **1** and **2** as shown in Figure 5 indicated defined scatter peaks for Lipid **1** with ordered assembly, and the simulation fitted the scatter to ordered lamellar structures. The scatter profile of liposomes prepared with Lipid **2** resulted in a broad scatter peak indicative of an amorphous material. The peak distances in the scattergram were used to calculate the d_1 (thickness of the membrane). We obtained 3.58 nm for the thickness of the Lipid **1**. We obtained similar distance for Lipid **2** though the peak peak intensities were significantly smaller in case of this lipid. The thickness saturated phosphatidylcholine of 12-carbon chains gives a thickness of 3.0 nm, which is comparable with Lipid **1**. The results of SAXS confirm the absence of organized structure in the liposomes of Lipid **2**.

Compressibility of Lipid Monolayers. With a view to investigate the higher melting temperature of Lipid **1**, we spread both lipids on water subphase and monitored the changes in surface pressure as a function of area occupied by the molecule

dx.doi.org/10.1021/bc2002874 | *Bioconjugate Chem.* 2011, 22, 2244–2254

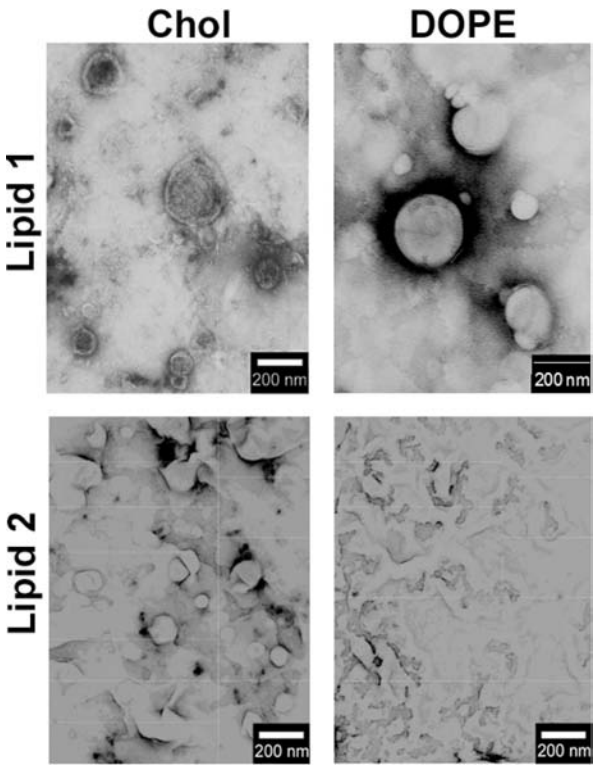

Figure 4. Transmission electron micrographs of Lipids **1** and **2**: Lipids formulated with DOPE or cholesterol were complexed with plasmid pCMVβ-gal DNA in 1× PBS buffer at Lipid/DNA 6:1 charge ratio. Lipoplexes were stained with uranyl acetate as described.

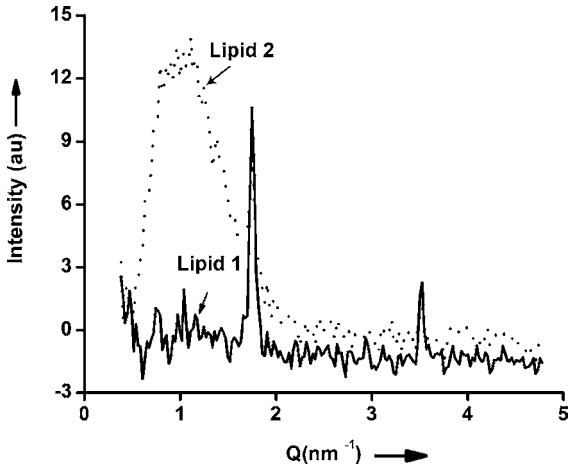

Figure 5. Small-angle X-ray diffraction of lipid vesicles: Vesicles of Lipids **1** and **2** formulated with cholesterol were prepared. The lipid concentration was kept at 5 mM and used without sonication. Diffraction data were collected and fitted using *Fit2d* software.

(Figure 6). Surface pressure vs area isotherms of monolayers of lipids provides information on the surface areas and intermolecular interactions. The slow compressibility of Lipid **1** compared to that of Lipid **2** suggested that the Lipid **1** monolayer experiences additional resistance to compression compared to Lipid **2**. This resistance may possibly be attributed to additional interactions between molecules.

Fusion Properties with Anionic Liposomes. Fusion of the membrane components of the lipoplex membrane with the

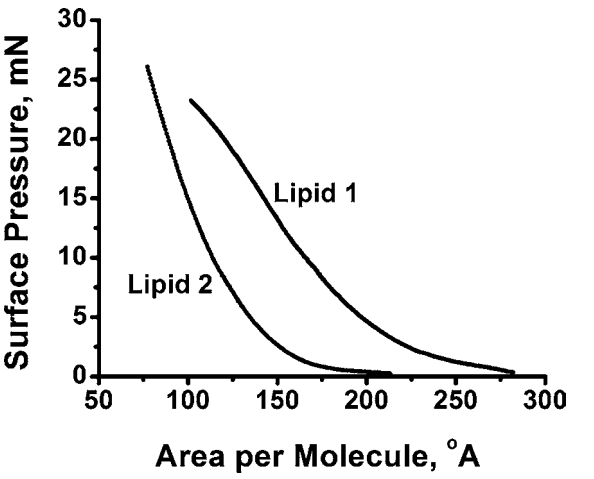

Figure 6. Surface pressure isotherms of Lipids **1** and **2** were generated in the presence of high-purity water as the subphase. Isotherms are representative of four independent measurements with very good reproducibility between the isotherms.

cellular membrane is critical for release of DNA. We monitored the fusion between cationic liposomes of both lipids along with the anionic vesicles prepared with a composition similar to the plasma membrane. The fusion kinetics was monitored using FRET between the donor, NBD-PE, and the acceptor, Rh-PE. Lipid **2** as seen in Figure 7 showed rapid increase in fluorescence

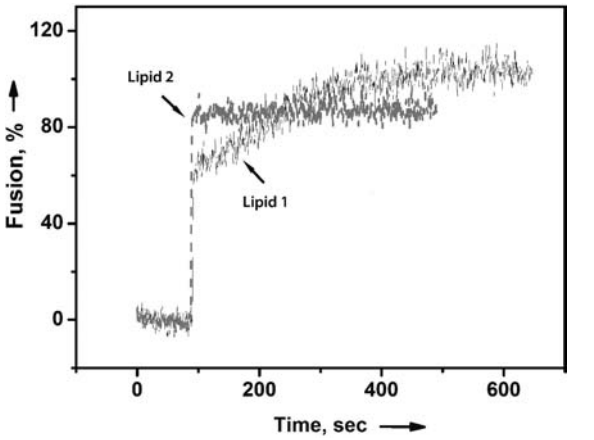

Figure 7. Membrane fusion kinetics: Membrane fusion between anionic vesicles with Lipid **1** or Lipid **2** was monitored by fluorescence resonance energy transfer between NBD-PE and Rhodamine PE, as described.

signal and reached a value representative of complete mixing, i.e., in the presence of Triton X-100, within 1 min. Many variations employed in the experimental design such as the ratio of labeled and unlabeled vesicle and composition of the labeled vesicles did not change the kinetics. Since Lipid **2** has poorly defined vesicles as seen in TEM, it is possible that these vesicles were unstable, hence show very rapid increase in fluorescence that was not typical of a fusion process. On the other hand, Lipid **1** shows comparatively slower kinetics of fusion with labeled vesicles. The fusion kinetics was similar when the labeled vesicles were prepared with phosphatidic acid instead of phosphatidylserine (data not reported).

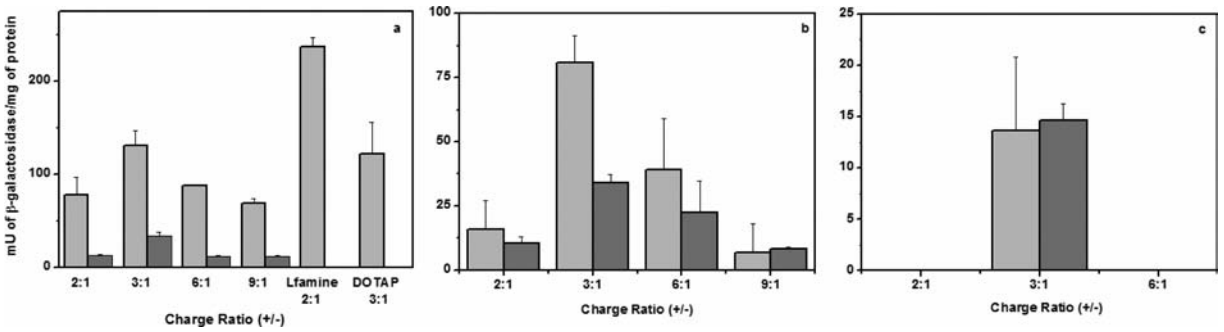

Figure 8. Transient transfection *in vitro*: (a) Transfection of CHO cells with Lipid **1** formulated with equimolar amounts of the colipid, cholesterol, at charge ratios varying from 2:1 to 9:1 Lipid/DNA in the absence (light gray) and presence of serum (dark gray) and normalized to milligrams protein. Graph depicts reporter gene activity at various charge ratios. Standards such as Lipofectamine (Lfamine) and DOTAP at 2:1 and 3:1 charge ratio, respectively, were included for comparison. Lipid **2** did not show any detectable reporter gene activity on CHO cells and was not plotted. (b) Transfection in HepG2 cells with Lipid **1**/Chol at the indicated charge ratios in the absence (light gray) and presence of serum (dark gray). (c) Transfection in HepG2 cells with Lipid **2**/Chol at the indicated charge ratio in the absence (light gray) and presence of serum (dark gray).

Biological Activity and Stability in Serum. *Transient Transfection in CHO and HepG2 Cells.* The lipids initially characterized for their DNA-binding properties were then tested for transfection efficiency in four cell lines, namely, CHO, HepG2, MCF-7, and HeLa. Both the lipids were formulated with DOPE or cholesterol as colipid and tested for transfection efficiency. Formulations with DOPE as colipid were consistently lower than formulations with cholesterol as colipid (data not shown), when tested in CHO cells. Hence, in all further studies only cholesterol-containing liposomes were used. Transient transfections of the two lipids at varying charge ratios from 2:1 to 9:1 Lipid/DNA, using pCMVβ-gal as the reporter gene, were performed as described in CHO cells (Figure 8a) and HepG2 cells (Figure 8b and c). When compared with the cationic lipid standards, i.e., DOTAP/DOPE and polycationic lipid, Lipofectamine, we observed slightly better transfection than DOTAP, and the efficiency was 50% of the transfection observed with Lipofectamine. We also tested the 14- and 16-carbon analogues of Lipid **1**, which is 12-carbon, and found that Lipid **1** has shown higher transfection than the 14- and 16-carbon analogues, >3-fold, Supporting Information Figure 2S. As in the case of HepG2, Lipid **1** (Figure 8b) exhibited much higher activity than Lipid **2** (Figure 8c). Lipid **2** was inefficient in all cell lines tested. The biological activity of Lipid **1** with the amide linkage was consistently higher than that of Lipid **2** that is ester-based in both HeLa cells Supporting Information Figure 3S and MCF-7 (data not reported). In all cell lines, maximal activity was observed at 3:1 Lipid/DNA with Lipid **1** formulated with cholesterol.

Although lipids bind DNA by charge−charge interaction, these may not protect DNA sufficiently from degradation by nucleases. Stability in serum is an important property when developing protocols for *in vivo* gene transfer. To assess the serum stability of Lipid **1**, serum was included in the medium, to a final concentration of 10%, at the time of incubation of cells with the complexes. As evident from Figure 8a−c, compared to the controls, i.e., in the absence of serum, Lipid **1** retained approximately 25% of its transfection efficiency in the presence of serum at 10% final concentration in CHO and 40−57% in the case of HepG2 cells at all charge ratios. Transfection decreased further in the presence of serum concentrations greater than 10%. Lipid **2** has observable but low transfection in HepG2 cells at 3:1 charge ratio and good stability in the presence of serum (Figure 8c). Overall, the transfection efficiency in the presence and absence of serum has a similar bell-shaped curve as a function of charge ratio.

Toxicity. Toxicity is an important issue to be dealt with while generating formulations useful for gene delivery protocols. We performed MTT-based cell viability assays at various charge ratios, i.e., 1:1 to 9:1 in CHO cells. Percent cell viabilities upon treatment with Lipid **1** at charge ratios 3:1 is ∼70% (Figure 9).

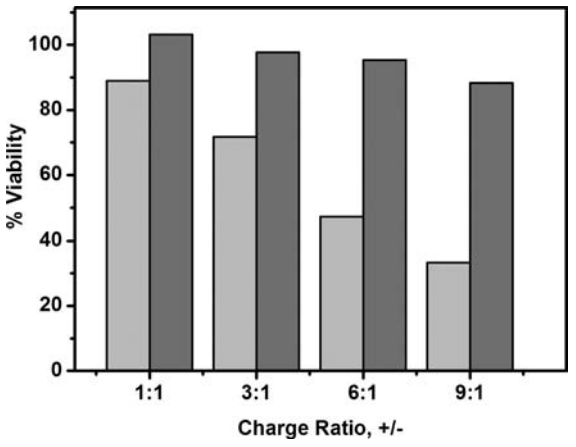

Figure 9. Determination of cell viability in CHO cells. Lipid **1** and **2**: DNA:Lipid complexes of Lipids **1** and **2** formulated with cholesterol was evaluated for cytotoxicity at the indicated charge ratios varying from 1:1 to 9:1 N/P. Following 3 h incubation, the MTT assay was performed. Percent cell viability represents experiments performed in triplicate as described in Materials and Methods. The absorption values obtained using reduced formazan, in the absence of lipids, were taken to be 100.

In contrast, Lipid **2** is inefficient at this charge ratio, although nontoxic. The utility of Lipid **1**/cholesterol offsets the observed toxicity making it effective *in vitro*.

DISCUSSION

Two glutamic acid-based lipids that have identical head groups and acyl chains were synthesized. These lipids differ from each other with respect to the chemistry of the linker connecting the acyl chains to glutamide. Lipid **1** with the amide linker exhibited high transfection efficiency in four different cell lines,

dx.doi.org/10.1021/bc2002874 | *Bioconjugate Chem.* 2011, 22, 2244−2254

when compared to Lipid **2** with an ester linker. Among the popular colipids such as DOPE and cholesterol, both lipids exhibited higher transfection efficiency with cholesterol compared to DOPE. The binding of lipids to DNA in EtBr exclusion assay showed identical profiles, however, at charge ratios >1:1, Lipid **1** shows stronger displacement of EtBr. Similar charge ratio dependency was also observed in gel retardation assay with these lipids. Electron microscopy images of the lipoplexes prepared using Lipids **1** and **2** along with the colipids cholesterol and DOPE showed clearly that Lipid **1** lipoplexes have a defined morphology, whereas Lipid **2** aggregates were irregular and amorphous. Lack of defined liposomal structure of Lipid **2** vesicles was also confirmed by broad scattering profile in SAXS. It is apparent that the stronger binding and formation of defined stable complexes are important in the interaction of Lipid **1** with cells and eventually in their uptake. The higher uptake of the lipoplexes with Lipid **1**, as seen from confocal microscopy may consequently be responsible for observed higher transfection efficiency. Lipid **1** has also demonstrated efficient transfection in the presence of serum when tested in both CHO and HepG2 cells. The benefits of serum in transfection protocols have been reported.[29,30] Stability in serum suggests the potential of these lipids for DNA delivery *in vivo*.

Biophysical Basis for Higher Transfection Efficiency with Lipid 1. DNA binding being a prerequisite for achieving good transfection efficiency, it must be condensed prior to cell uptake. Cationic lipids bind electrostatically to the DNA.[3,30] This process results in condensation and protection of the DNA and leads to the formation of complexes that are particulate in nature.[3,31] DNA present in a particle is more efficiently taken up by the cell and endocytosed than free DNA. Characterization of lipoplexes at varying charge ratios revealed that transfection efficiency sharply increases with DNA condensation, change in zeta potential from negative to positive value, and observations of ordered lipoplexes in electron micrographs.[32] Although DNA was found to be condensed below optimal charge ratios, DNA was accessible to nucleases leading to decrease in transfection. Stability of the lipoplex is critical for protecting the DNA during transfection and also enhancing the uptake of the lipoplex by the cells.[32] Though binding of Lipid **2** with the DNA was comparable to Lipid **1**, the packing of the DNA into lipoplexes may be inefficient leading to particles that may be large and variable in size. Thus, Lipid **2**, a 12-carbon lipid, does not provide sufficient stability for the formation of liposomes; hence, its uptake by cells and subsequent transfection is poor. Though Lipid **1** has same chain length and headgroup as Lipid **2**, its melting temperature was nearly 40 °C higher. Melting temperature of lipids depends strongly on the length of the acyl chains and increases with the increase in chain lengths. Since Lipids **1** and **2** have identical chain lengths, the higher melting temperature may be due to additional interactions between the molecules. The stabilizing effect of the intermolecular hydrogen bond was observed between the headgroups in phosphatidylethanolamines (PE), which increases the melting temperature of PEs by nearly 20 °C compared to phosphatidylcholines of similar alkyl chain length.[33] Such intermolecular hydrogen bonding was observed in Gemini quaternary ammonium surfactants that contain an amide linker but not in ester-containing surfactants.[34] In addition, the data on polarization of DPH, an indicator of microviscosity of the membrane, suggests that both lipids possess similar microviscosity values, corroborating the observations that the higher melting temperature of Lipid **1** does not originate from the hydrophobic portion of the molecule. The addition of the slow compression rate of Lipid **1** monolayers compared to Lipid **2** also points to the fact that Lipid **1** monolayers experience additional intermolecular interactions. Since the head groups of both lipids are identical, the altered isotherm may originate intermolecular interactions. The amine linkers of Lipid **1** possibly form a hydrogen bond with carbonyl group of the adjacent lipid in a liposome, thus providing additional stability necessary for a stable lipoplex (Figure 10). In our opinion, this is the first report

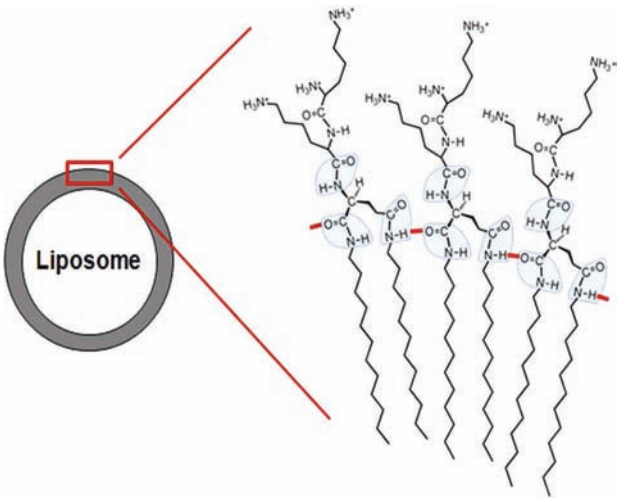

Figure 10. Intermolecular interactions of Lipid **1**. Model depicting stabilization of Lipid **1** through intermolecular interactions generated through hydrogen bonding.

of an approach to increase the stability and transfection of cationic liposomes by designing features favoring intermolecular hydrogen bonding.

Unsaturated lipids, predominantly oleic acid, containing cationic lipid formulations showed higher transfection efficiency than formulations with saturated lipids. Investigation of transfection efficiency with a given cationic lipid (DOTAP) along with phosphatidylethanolamine lipids with various acyl chains with different lengths indicated that unsaturated PEs are essential compared to saturated PEs for efficient transfection.[35] Hydrophobic moiety of cationic lipids strongly modulates their transfection activity. A study on the chain length variants of DOTAP suggests that DLTAP (*N*-[1-(2,3-dilauroyloxy)-propyl]-*N*,*N*,*N*-trimethylammonium methylsulfate) was least efficient in transfection.[36] In this context, the observation of higher transfection efficiency of Lipid **1**, despite having higher melting temperature, is interesting. It is observed that higher melting points of long acyl chain containing lipids do not mix with other membranes easily. Fusion between vesicles occurs readily above the phase transition temperature of the lipids. Below the phase transition temperature, the lipids are in crystalline phase and have restricted fluidity, essential for mixing of the membrane contents.[37] Within a cell, transfection processes involve membrane−membrane interactions between lipoplex and endosomal membrane and fusion.[38] Fusion is essential for dissociation of the cationic lipids from the DNA and release the DNA into the cytoplasm. Though Lipid **1** has higher melting temperature, its microviscocity as measured by DPH, is still in the range of 12-carbon lipids.

dx.doi.org/10.1021/bc2002874 | *Bioconjugate Chem.* 2011, 22, 2244−2254

Hence, the miscibility of Lipid **1** may not restrict fusion with other membranes. Amide linkers have been used in the design of cationic lipids and were found to be biodegradable and stable.[39] DOGS is a popular amide linker containing cationic lipid, where the amide linker is between the backbone and the headgroup.[40] A series of cationic lipids with amide and ester linkers to a pyridinium headgroup were synthesized. Amide linker containing lipids were found to be superior in transfection compared to the ester containing pyridinium lipids.[41] However, the amide containing lipids melt at slightly lower temperatures than the ester lipids. In another study, a series of detergents were synthesized with amide or ester linkers to amino acid head groups. The amide detergents bound to the oligonucleotides more efficiently than the ester containing detergents.[42] In Lipid **1**, the amide linker provides stability to the liposome and the lipoplex by forming an intermolecular hydrogen bond which did not seem to influence the membrane interactions crucial for transfection. Incorporating intermolecular interactions, such as hydrogen or ionic bonds, in cationic lipids offers yet another strategy to design efficient cationic lipids.

CONCLUSIONS

Stability of a lipoplex is important for achieving good transfection efficiencies. This is dependent on the nature of the cationic headgroup and DNA interactions and the hydrophobic volume of the lipid. The overview of lipid/DNA interactions and lipid properties of the two lipids, different in their linker chemistry, suggests that stable formation of liposomes with Lipid **1** was critical for superior transfection properties compared to Lipid **2**. Formulations made with Lipid **1** were stable in serum, thereby implying its utility for in vivo experimentation. Since the two lipids are identical in all aspects except for the linker, the stability of amide linker containing Lipid **1** is due to the presence of intermolecular hydrogen bonds leading to stable vesicles. This observation is supported by higher transition temperatures, TEM, SAXS, and monolayer studies. Incorporation of intermolecular interactions may be yet another way to increase the stability of the liposomes and thereby transfection.

Supporting Information

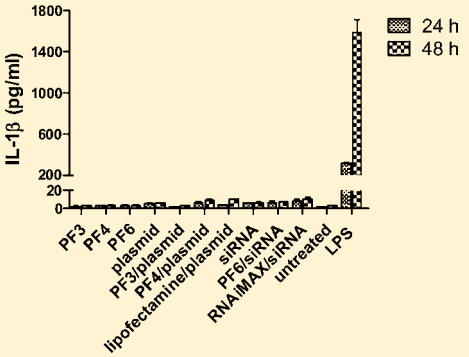
ABSTRACT: Cell-penetrating peptide based vehicles have been developed for the delivery of different payloads into the cells in culture and in animals. However, several biological features, among which is the tendency to trigger innate immune response, limit the development of highly efficient peptide-based drug delivery vectors. This study aims to evaluate the influence of transportan 10 (TP10) and its chemically modified derivatives, PepFects (PFs), on the innate immune response of the host system. PFs have shown high efficiency in nucleic acid delivery *in vitro* and *in vivo*; hence, the estimation of their possible toxic side effects would be of particular interest. In this study, we analyzed cytotoxic and immunogenic response of PF3, PF4, and PF6 peptides in monocytic leukemia and peripheral blood mononuclear cell lines. In comparison with amphipathic PFs, TP10, TAT, stearyl-$(RxR)_4$ peptides, and the most widely used transfection reagents Lipofectamine 2000 and Lipofectamine RNAiMAX were also analyzed in this study. IL-1β, IL-18, and TNF-α cytokine release was detected using highly sensitive enzyme-linked immunosorbent assay (ELISA). Cell viability was detected by measuring the activity of cellular enzymes that reduce water-soluble tetrazolium salts to formazan dyes and apoptosis was evaluated by measuring the levels of caspase-1 and caspase-3/7 over untreated cells. All peptides were found to be nontoxic and nonimmunogenic *in vitro* at the concentrations of 10 μM and 5 μM, respectively, and at a dose of 5 mg/kg *in vivo*, suggesting that these CPPs exhibit a promising potential in the delivery of therapeutic molecules into the cell without risks of toxicity and inflammatory reactions.



INTRODUCTION

Efficient internalization of therapeutic agents into target cells is very important to gain the desired therapeutic effect. However, since the plasma membrane limits the internalization of high molecular weight molecules into the cell, therapeutic applications of nucleic acids and proteins have been restricted.[1] Several techniques have been used to promote efficient drug delivery, for instance, electroporation, encapsulation in polymers or liposomes, viral delivery systems, and so forth. However, these approaches have several serious drawbacks, including complex manipulation, limited efficiencies in *in vitro* and *in vivo* systems, cytotoxicity, and undesired immunogenic effects.[2,3]

Cell-penetrating peptides (CPPs) have proven their ability to deliver various drug molecules, DNA, RNA, and proteins in cultured cells.[4] Synthetic CPPs were designed with predetermined structures and they maintain the parent peptide's functions. This enables different chemical modifications of the CPPs as well as expression with specific proteins or application together with other delivery vectors, which gives an advantage for the construction of novel, more efficient therapeutic agents.[5] Several modifications of CPPs have been investigated in order to improve gene delivery. In particular, stearic acid modification of different membrane-permeable relatively short peptides, such as TAT,[6] transportan,[7,8] octa-arginine (R_8),[9] and $(RxR)_4$, was shown to substantially increase their transfection efficiency.[6,8,10] It has been shown that stearic acid modification enhances CPP-mediated plasmid DNA delivery, promoting more efficient endosomal escape,[10] enhanced cellular association, as well as higher nuclear delivery.[9] Lysosomotropic agents such as chloroquine and methylamine are also capable of improving the release of therapeutic molecules from acidic endosomal compartments, raising the pH, and performing proteolytic cleavage;[11,12] however, their application *in vivo* for therapeutic use is limited, due to their toxicity.[13,14]

Although therapeutic protein agents and peptides used in clinical settings are generally considered nontoxic, antitherapeutic protein antibodies can develop during the treatment. Antitherapeutic protein antibodies or antidrug antibodies might neutralize or otherwise compromise the clinical effect of therapeutics and can also be associated with serious adverse events related to cross-reactivity with autologous proteins of the host organism.[15] Immune response to therapeutic proteins is categorized by activation of the immune system by foreign

proteins, resembling immune response against pathogens or vaccines, involving T-cells, B-cells, and the innate immune system.[15]

The size, surface charge, surface hydrophilicity, surface morphology, and the amino acid sequence of the peptides can significantly affect the immunogenicity of the peptide/nucleic acid complexes and their clearance by the macrophages.[16] Additionally, undesired toxicity can be mediated through interactions of the oligonucleotides with the proteins. These effects can be sequence-dependent, such as interaction with Toll-like receptors (TLRs), or sequence-independent.[17] For example, RNA molecules can also affect TLRs 3, 7, and 8, eliciting undesired immune stimulation that manifests as hyperplasia in lymphoid organs and mononuclear cell infiltrates in nonlymphoid organs.[18,19] Therefore, development of suitable delivery system will depend not only on the efficiency of delivery vectors to transport therapeutic agents through the biological barriers, but also on their risks of producing side effects: toxicity and undesired immunogenicity.[20−22]

In the previous study, stearyl and chloroquine modifications introduced in the TP10 structure were successfully used to overcome the problem of endosomal entrapment of therapeutic agents.[5,23] The introduction of the stearyl moiety at different positions led to PF3 and PF4 peptides (Table 1), which enabled luciferase plasmid (pGL3) delivery at the concentration of 2 μM (Table 2).[23] Covalently bound chloroquine analogue[24] and stearyl moiety in different positions improved the activity of TP10 in serum,[8] generating the PepFect 6 (PF6) peptide, which promoted an efficient siRNA-delivery *in vitro* using only 50 nM siRNA and 2 μM PF6 peptide (Table 2).

In this study, we tested PepFect peptides and PepFect/nucleic acid complexes for the undesired toxicity and immunogenicity both *in vitro* and *in vivo* using the concentrations and similar complex formation conditions, which have been previously reported and indicated to gain the best therapeutic effect. Possible toxic and immunogenic effects of TP10, PF3, PF4, and PF6 peptides were compared with the immunogenic activities of unmodified TP10, well-studied cationic peptides TAT and stearyl-$(RxR)_4$,[25] and the most widely used Lipofectamine transfection reagents. Our results show that PF peptides are efficient nontoxic and nonimmunogenic peptide-based vectors for nucleic acid delivery both *in vitro* and *in vivo,* suggesting promising perspectives for their future therapeutic applications without any risks of inflammation.

EXPERIMENTAL PROCEDURES

Synthesis of Cell-Penetrating Peptides. The peptides were synthesized in a stepwise manner at a 0.1 mmol scale on an automated peptide synthesizer (Applied Biosystemsmodel 433A) using *N*-Fmoc (*N*-fluorenylmethyloxycarbonyl) solid-phase peptide synthesis strategy. All the solvents and reagents used for the peptide synthesis were purchased from Sigma-Aldrich, Germany. Stearyl-modified peptides were prepared according to previously reported protocol,[8] and chloroquine modification from PF6 peptide was performed as described by El Andaloussi et al.[5] (Table 1). Peptides were purified by preparative reversed-phase HPLC (Agilent 1200) using C4 column (Phenomenex Jupiter C4, 5 μm, 300 Å, 250 × 10 mm) using a gradient of 5−100% acetonitrile/water containing 0.1% TFA. Molecular weights of the peptides were analyzed by MALDI-TOF mass-spectroscopy (The Voyager-DE PRO Biospectrometry System). The mass spectra were acquired in positive ion reflector mode using α-cyano-4-hydroxycinnamic acid as a matrix (Sigma−Aldrich), and purity was about 95% as determined by analytical HPLC. The molar concentrations of the peptide solutions were determined based on dilutions of accurately weighed substances.

HPRT1 siRNA. HPRT1 (hypoxanthine phosphoribosyltransferase 1) siRNA was provided by Peter Guterstam.[26] 500 μM stock solutions of siRNA were stored at −20 °C. Sequences of HPRT1 siRNA are as follows: sense 5′-GCCAGACUUU-GUUGGAUUUGAAATT and antisense 5′-AAUUUCAAAUC-CAACAAAGUCUGGCUU.

Plasmid pEGFP-C1. Plasmid pEGFP-C1 (Clontech Laboratories, Inc., USA), 4.7 kb, encodes a red-shifted variant of wild-type green fluorescent protein, GFP, which has been optimized for brighter fluorescence and higher expression in mammalian cells (excitation maximum at 488 nm and emission maximum at 507 nm). Plasmid was propagated and purified using Qiagen plasmid DNA purification kit (QIAGEN Group, USA), according to manufacturer's protocol.

Cell Cultures. THP-1, human acute monocytic leukemia cells (CLS, Germany), and PBMC, human peripheral blood mononuclear cells, isolated from healthy donor by standard density gradient centrifugation and washed in PBS to remove platelets were kindly provided by Dr. Alar Aints, were grown at 37 °C, 5% CO_2 in RPMI 1640 medium with glutamax supplement, 0.1 mM nonessential amino acids, 1.0 mM sodium

Table 2. Transfection Efficiencies of the PF Peptides

pyruvate, 10% fetal bovine serum, 100 U/mL penicillin, and 100 mg/mL streptomycin (PAA Laboratories GmbH, Germany) further named as complete medium.

PF3/pEGFP-C1 and PF4/pEGFP-C1 Complex Formation. Complexes of peptides with plasmid DNA (pEGFP-C1) were prepared as described previously.[5] Briefly, 0.5 μg of green fluorescent protein expressing pEGFP-C1 plasmid was mixed with PF3 or PF4 at different plasmid/peptide charge ratios (CRs) 1:1 and 1:5 in MQ water in 1/10th of the final treatment volume (i.e., 30 μL). CRs were calculated theoretically, taking into account the positive charges of the peptide and negative charges of the plasmid. Final concentration of PF3 or PF4 was 0.75 μM at CR 1:1 and 3.75 μM at CR 1:5 (Table 3). Complexes were incubated for 1 h at room temperature.

Table 3. Layout of the Peptide/Nucleic Acid Complexes

CPP	pEGFP-C1 plasmid		HPRT1 siRNA	
PF3	CR 1:1	CR 1:5		
PF4	CR 1:1	CR 1:5		
PF6			MR 30, 100 nM siRNA	MR 40, 50 nM siRNA

PF6/siRNA Complex Formation. PF6 (100 μM stock solution) was mixed with HPRT1 siRNA (10 μM stock solution) in MQ water in 1/10th of final treatment volume (i.e., 30 μL), using peptide/siRNA molar ratios (MRs) 40 and 30, siRNA 50 nM and 100 nM, respectively, and were formed as described previously.[5] Complexes were incubated for 1 h at room temperature. In the case of Lipofectamine 2000 and Lipofectamine RNAiMAX (Invitrogen, Sweden), complexes were formed according to the manufacturer's protocol.

Formation and stability of all the peptide/nucleic acid complexes in the presence or absence of serum was confirmed by agarose gel (2%) stained with EtBr (0.5 μg/mL).

MTS Proliferation Assay. Long-term toxicity was evaluated using MTS proliferation assay (Promega, Sweden), which measures the activity of mitochondrial dehydrogenases to convert tetrazolium salts into formazan. 2×10^4 THP-1 cells were seeded into 96-well plate and treated with PF3, PF4, and PF6 peptides at the following concentrations: 1, 5, and 10 μM and peptide/nucleic acid complexes (PF3 or PF4 and pEGFP-C1 complexes at CR 1:1 and CR 1:5; PF6 and siRNA complexes at MR 40, 50 nM siRNA and at MR 30, 100 nM siRNA) for 24 h in complete medium. Thereafter, MTS proliferation assay was performed according to the manufacturer's protocol. Untreated cells were defined as 100% viable. The results are the means of three independent experiment performed in duplicate.

Cytokine Detection from Cell Culture Supernatants and Mouse Serum. THP-1 or PBMC cells were stimulated with 15 ng/mL of PMA (Phorbol 12-myristate 13-acetate (Sigma)) one day before experiment and then 1×10^6 cells were seeded into 24-well plates. Thereafter, the cells were incubated for 24 and 48 h with PF3, PF4, and PF6 at the concentration of 5 μM. In parallel, the cells were treated with plasmid/PF3 or plasmid/PF4 at CR 1:1 and 1:5 and HPRT1 siRNA/PF6 complexes at MR 40, 50 nM siRNA for 4 h in serum-free medium followed by addition of 1 mL complete medium. LPS (10 μg/mL) and poly (i:c) (0.1 μg/mL) were used as positive controls. Supernatants were collected after 24 and 48 h and applied on IL-1β, IL-18, and TNF-α ELISA kits according to manufacturer's protocol (Quantikine kit, R&D Systems, Inc., Minneapolis, MN, USA). The remaining cells were used for the preparation of the extracts, which were applied to the caspase-1 and caspase-3/7 activity assays. Optical density of supernatants from each well was determined using a Tecan Sunrise absorbance plate reader at wavelength of 450 nm with correction at 540 nm. Obtained absorbance values were directly proportional to cytokine concentration in each well. The results are the means of three independent experiment performed in duplicate.

Caspase Activity Assay. Extracts from 1×10^6 THP-1 or PBMC cells were prepared by lysing the cells with Lysis Buffer (R&D Systems, Inc., Minneapolis, MN, USA) for 40 min on ice, followed by incubation with caspase fluorogenic substrates (WEHED-AFC or Z-DEVD-R110 substrate for caspase-1 or caspase-3/7 activity detection, respectively) for 2 h at 37 °C. Measured fluorescence signals are proportional to enzyme activity and monitored over time using a fluorescence plate reader, set for excitation at 400 nm and emission at 505 nm according to manufacturer's protocol. Results are normalized by the cell count in each well and expressed as fold increase in caspase activity of apoptotic cells over untreated cells. The

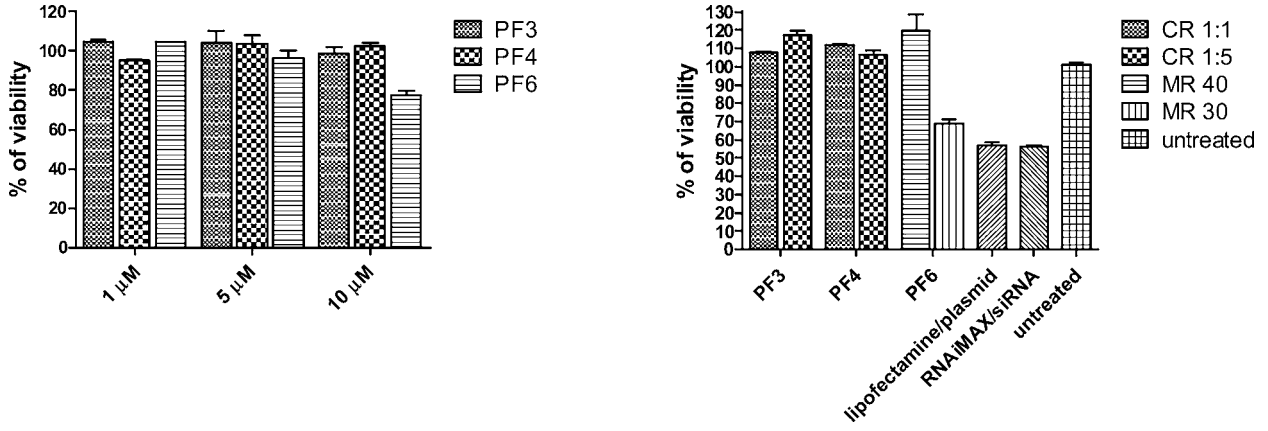

Figure 1. Cell proliferation test. THP-1 cells were incubated with PF3, PF4, and PF6 peptides for 24 h at concentrations of 1, 5, and 10 μM (a). Cells were treated with peptide/nucleic acid complexes: pEGFP-C1/PF3, pEGFP-C1/PF4, at CR 1:2 and 1:3 and HPRT siRNA/PF6, at MR 40, 50 nM siRNA and at MR 30, 100 nM siRNA for 24 h (b). All incubations were performed in complete medium. The values represent the mean of at least three independent experiments performed in duplicate (mean ± SEM).

dx.doi.org/10.1021/bc200293d | Bioconjugate Chem. 2011, 22, 2255–2262

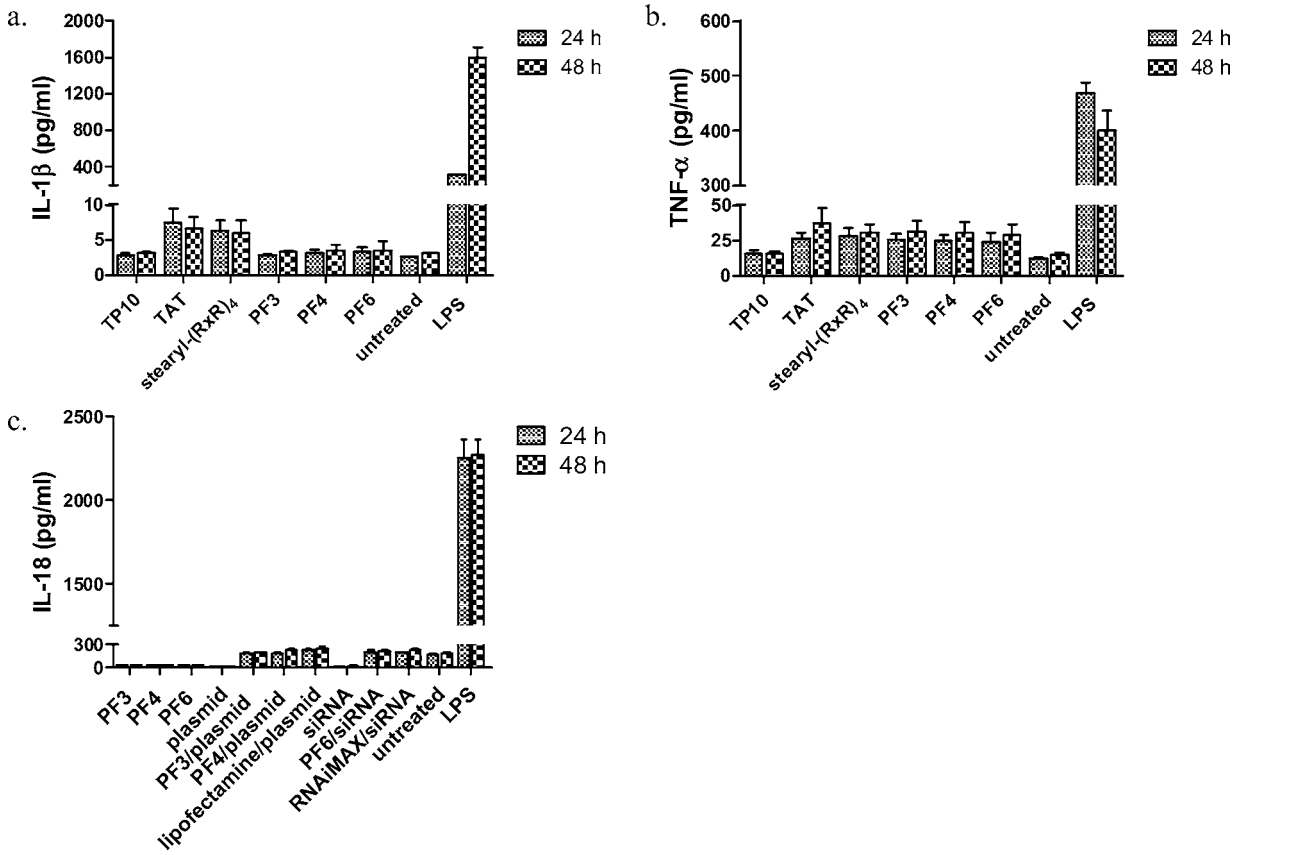

Figure 2. Cytokine release (pg/mL) in THP-1 cell culture supernatants were measured by ELISA assay. IL-1β (a) and TNF-α (b) release in cell culture supernatants were measured after 24 and 48 h of incubation with TP10, TAT, stearyl-$(RxR)_4$, PF3, PF4, and PF6 peptides. IL-18 (c) release was measured after incubation with PF3, PF4, and PF6 peptides, pEGFP-C1/PF3, pEGFP-C1/PF4, HPRT1 siRNA/PF6 and Lipofectamine 2000/pEGFP-C1 and Lipofectamine RNAiMAX/siRNA complexes. LPS (10 μg/mL) was used as a positive control. The values represent the mean of at least three independent experiments performed in duplicate (mean ± SEM).

results are the means of three independent experiment performed in duplicate.

***In Vivo* Toxicology.** C57BL/6 male and female animals (8−10 weeks old at the beginning of the experiments) were used for toxicity and immunogenicity assessments. Cytokine levels in serum were analyzed at 24 and 48 h after i.v. injections of 1 and 5 mg/kg of TAT (48−60) and their equimolar doses of 0.01 and 0.06 μmol per animal of TP10, stearyl-$(RxR)_4$, PF3, PF4, and PF6, respectively. Some animals received LPS (10 μg i.p.). Blood samples were collected via heart puncture, and serum was separated using serum gel-separation tubes (Terumo). Ketamine (75 mg/kg (Vetoquinol, Bioketan)) and dexmedetomidine (1.0 mg/kg (Laboratorios SYVA S.A.U., Dorbene)) in saline solution were applied via i.p. injection and used for anesthesia. Liver, kidney, lung, and spleen were dissected immediately after blood sample collection and rapidly frozen in 2-methylbutan at −60 °C. The cryosected slices were fixed in formalin and stained with hematoxylin and eosin. Slices were analyzed for pathological deviation. Two mice were used per group in three independent experiments.

Statistical Analysis. Values in all experiments are represented as mean ± SEM of three independent experiments done in duplicate. In toxicity measurements, decrease in viability was considered significant at $p < 0.001$ using ANOVA Dunnett's multiple comparison test.

RESULTS

***In Vitro* Toxicity and Immunogenicity.** Aiming to estimate possible toxic and immunogenic effects of PF3, PF4, and PF6 peptides we measured activity levels of caspases-1, 3, and 7 and interleukin IL-1β, IL-18, and TNF-α cytokine production by THP-1 and PBMC cells after 24 and 48 h of treatment. *In vitro* cell viability test showed no toxic effects in THP-1 cells treated with the peptides PF3, PF4, and PF6 at concentrations of 1, 5, and 10 μM and incubated for 24 h in complete medium (Figure 1a). Moreover, treatment with plasmid/peptide complexes at CR 1:1 and 1:5 or with peptide/siRNA complexes at MR 40, 50 nM siRNA also did not show any toxic effects. At the same time, treatment with peptide/siRNA complexes at MR 30, 100 nM siRNA reduced cell viability up to 30%. Therefore, only CPP/siRNA complexes at MR 40, 50 nM siRNA were preferred for the further *in vitro* experiments. Toxic effects were observed during the treatment with the lipofectamine/nucleic acid complexes, whereas only 55% of the cells remained viable after 24 h of incubation (Figure 1b). Estimation of the cytokine levels showed no enhanced interleukine release induced by PF3, PF4, and PF6 peptides in THP-1 or in PBMC cell lines (Figure 2a,b,c; Supporting Information Figure S1a). In parallel, we measured and analyzed the immunogenic influence of cationic peptides: TAT, stearyl-$(RxR)_4$, and chimeric amphipathic TP10. We found no influence of these peptides on THP-1 and PBMC cells (Figure 2 a,b; Figure S2) and the results were similar to

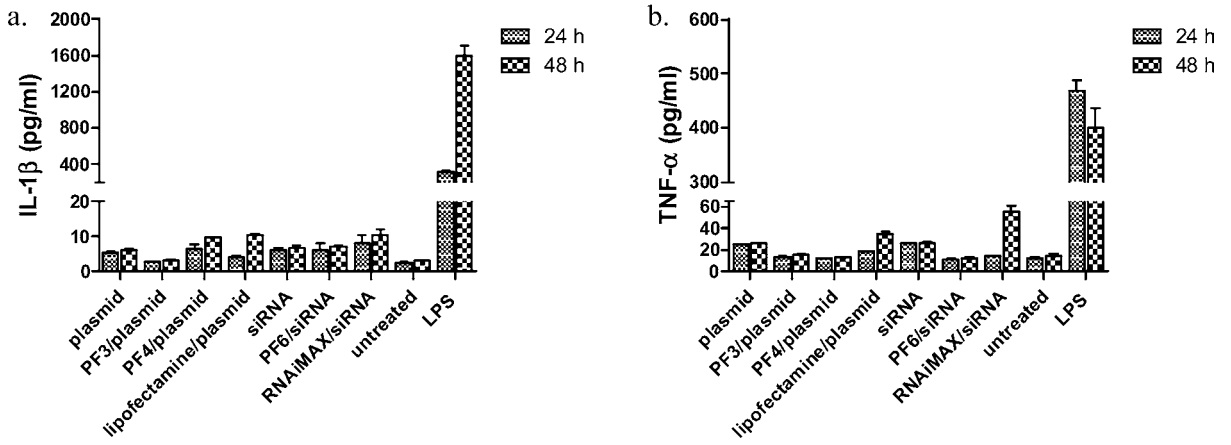

Figure 3. Cytokine release (pg/mL) in THP-1 cells treated with PF peptides/nucleic acid complexes. IL-1β (a) and TNF-α (b) measured by ELISA assay after 24 and 48 h of incubation with pEGFP-C1 plasmid (0.5 μg), siRNA (50 nM), pEGFP-C1/PF3, pEGFP-C1/PF4, HPRT1 siRNA/PF6, and Lipofectamine 2000/pEGFP-C1 and Lipofectamine RNAiMAX/siRNA complexes. LPS (10 μg/mL) was used as a positive control. The values represent the mean of at least three independent experiments performed in duplicate (mean ± SEM).

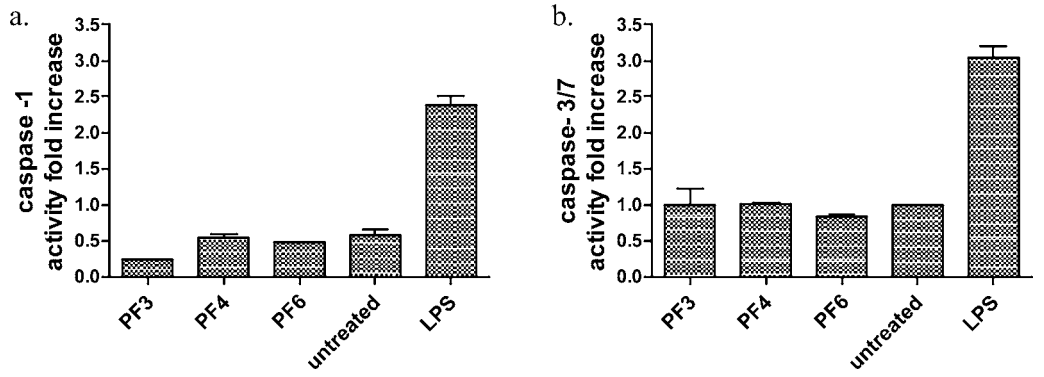

Figure 4. Caspase activity measured in THP-1 cell line. Caspase-1 (a) and caspase-3/7 (b) activity were measured in cells incubated with PF3, PF4, and PF6 peptides for 48 h as described previously. The results are expressed as fold increase in caspase activity of apoptotic cells over noninduced cells. The values represent the mean of at least three independent experiments performed in duplicate (mean ± SEM).

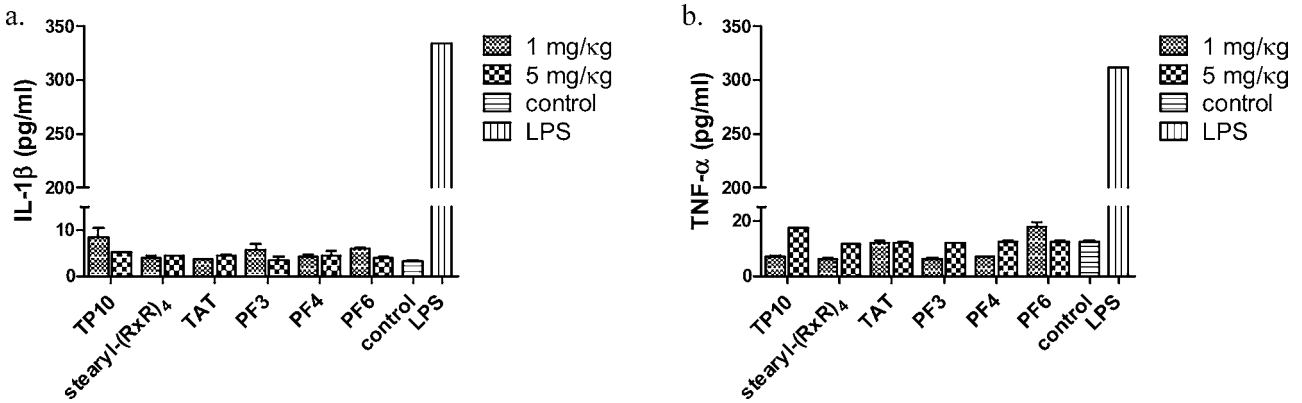

Figure 5. IL-1β and TNF-α cytokines level detection *in vivo*. Immunocompetent mice were treated with TP10, TAT, stearyl-$(RxR)_4$, PF3, PF4, and PF6 peptides at the dose of 0.01 or 0.06 μmol per animal (corresponding to 1 mg/kg and 5 mg/kg, respectively). Serum samples were collected 24 h after i.v. injections and applied to the ELISA assay. IL-1β (a) and TNF-α (b) levels were measured by a TECAN absorbance plate reader. The values represent the mean of at least three independent experiments performed in duplicate (mean ± SEM).

the effects exhibited by PF peptides. Modest increase in cytokine activity triggered by TAT and stearyl-$(RxR)_4$ was considered not statistically significant. Indicated influence on the release of IL-1β, TNF-α, and IL-18 was insignificant if compared to lipopolysaccharide (LPS) or poly (i:c) (used in this study as positive control for PBMC cells) after 24 and 48 h of incubation. Next, we analyzed whether the peptide/nucleic acid complexes formed at different charge ratios are able to trigger the cytokine release. No evidence of increased cytokine level was noticed in both THP-1 and PBMC cell lines in response to treatment with plasmid/peptide and siRNA/peptide complexes (Figure 3a,b; Figure S1b,c) at CR 1:5 for

dx.doi.org/10.1021/bc200293d | *Bioconjugate Chem.* 2011, 22, 2255–2262

plasmid and for siRNA at 50 nM concentration, which is the highest effective dose of siRNA used in the previous studies.[5] Thereafter, we estimated the caspase-1 and caspase-3/7 activity in the cells treated with 5 μM PF peptides and peptide/nucleic acid complexes measuring the rate of hydrolysis of a fluorogenic substrate in the cell lysates. Caspase activity rates 2-fold over those of noninduced cells or higher were considered to be significant caspase activity of apoptotic cells in these studies. Measured caspase-1 and caspase-3/7 activity was similarly compared with the caspase activity of the untreated cells (Figure 4a,b). The results showed that the peptides used in the current study lack apoptotic activity *in vitro*.

***In Vivo* Immunogenicity.** In order to confirm the *in vitro* data, the peptides were administrated to immunocompetent mice via i.v. injection followed by collection of the blood samples after 24 and 48 h. Mice that received 10 μg LPS were used in this study as a positive control. Similarly to the results obtained from *in vitro* studies, ELISA analyses of the separated serum samples also showed no evidence of enhanced IL-1β or TNF-α cytokine production after 24 or 48 h of treatment with PF3, PF4, PF6, TP10, TAT, and stearyl-$(RxR)_4$ peptides at doses of 0.01 and 0.06 μmol per animal (corresponding to 1 mg/kg and 5 mg/kg, respectively, as it is shown in Figure 5a,b). Indicated release of IL-1β and TNF-α cytokines was insignificant if compared to lipopolysaccharide (LPS). Additionally, no pathological deviations were observed in liver, kidney, lung, and spleen dissected from animals, which received 1 mg/kg and 5 mg/kg of PFs, TP10, TAT, and stearyl-$(RxR)_4$ peptides (data not shown).

DISCUSSION

Application of CPPs has evolved as an attractive tool to solve the problems of drug delivery.[27] However, successful usage of the drug carriers in clinics has been mostly limited by their possible undesired side effects, namely, immunogenicity and *in vivo* toxicity. The main goal of the current study was to evaluate the influence of the PepFect delivery agents on the immune activity *in vitro* and *in vivo*, which is a novel aspect of the PF peptide-based delivery system investigation. Despite the fact that CPPs contain fewer than 30 amino acids[28] and contain no evidence for oncogene activation,[27] the research on biological side effects of cationic and amphipathic peptides has still been receiving great attention.[20] Several independent experiments on cell viability, membrane integrity, as well as toxicity analyses suggested that amphipathic peptides such as TP10 affect cellular metabolism at the concentrations ranging from 5 to 10 μM, whereas the cationic CPPs penetratin, TAT, and nonaarginine showed no toxic effect at similar concentration range.[29] As PF peptide design is based on the TP10 peptide sequence with minor chemical modifications, we could not eliminate the possibility that they could induce undesired toxic and inflammatory effects *in vitro* and *in vivo*. It has been shown that TAT peptide induces no cytotoxicity *in vitro* even at the concentration up to 400 μM. In the same work, toxicity was evaluated *in vivo* by applying peptides to the rabbit's cornea 4 times daily for 7 days. At doses 1000 times the IC_{50} values, penetratin peptide showed no toxicity *in vivo* and TAT caused some mild eyelid swelling.[30] Similarly, polyarginine peptides also did not induce any cellular toxicity at siRNA/peptide ratio of negative/positive charges of 40.[30−32] These studies indicate that the use of TAT peptide for anticancer therapy, for instance, does not induce a measurable immune response, although long-term toxicity studies have not been performed yet.[3]

Chloroquine has been used for a long time in the treatment or prevention of malaria. Due to its immunosuppressive activity, chloroquine is applied for treatment of autoimmune disorders, such as rheumatoid arthritis and lupus erythematosus.[33] Recently, chloroquine was used to overcome the problems of endosomal escape of the entrapped and deactivated therapeutic molecules *in vitro*. The coaddition of chloroquine in solution enhances endosomal release of peptide-based delivery vehicles.[8] In order to promote endosomal escape and increase the transfection efficiency the chloroquine moieties were introduced in the PF6 structure.[5] At the same time, chloroquine has been associated with several toxicity cases, including retinal injury and skin irritations particularly when provided at high doses for a long time range.[34,35] Toxic side effects and the ability of chloroquine to influence immune system limit therapeutic application of this lysosomotropic agent *in vivo*.

In the current study, we investigated possible toxic and immunogenic activity of the PF peptides and compared them with the widely used cationic CPPs such as TAT, stearyl-$(RxR)_4$, and amphipathic TP10, trying to bring out the differences or possible enhanced influence of PF peptides on the activation of the immune system. During the analyses, the greatest attention received the peptide/nucleic acid complexes with the highest charge and molar ratios that proved to be stable in serum and showed a particular effectiveness in case of different cell line transfections.[5] Our results demonstrated the lack of viability reduction in THP-1 cell line, as well as no indication of primary inflammatory effects after 24 or 48 h of incubation with PF peptides. Peptides showed no toxic influences on THP-1 cell viability even at concentration of 10 μM, although this was observed mainly in serum containing complete medium (Figure 1 a,b). Moreover, lipofectamine agents exhibited strong cytotoxic effect, reducing cells viability up to 55%. None from the measured IL-1β, IL-18, and TNF-α cytokines were overexpressed in the THP-1 cells in response to TP10, TAT, stearyl-$(RxR)_4$, or PF peptide treatment (Figure 2 a,b,c).

Similarly, no evidence of enhanced *in vitro* IL-1β production was observed also in noncancer PBMC cell line (Figure S1a, Figure S2). The peptides were applied at the concentration of 5 μM dose, which corresponds to the peptide amount used for complex formation. As expected, the cells treated with the peptide/nucleic acid complexes similarly showed no increase in cytokine release if compared with the peptide-treated or untreated cells (Figure 3a,b; Figure S1b,c). None of the lipofectamine reagents induced the increased cytokine production at the recommended manufacturer̀s dose *in vitro* (Figure 2c; Figure 3a,b; Figure S1b,c). At the same time, cells incubated with LPS demonstrated increased cytokine level in growth medium, more then 100 times higher than in the untreated cells (Figure 2 a,b,c; Figure 3a,b; Figure S1 a,b,c).

Thereafter, we estimated if PF peptides could possibly trigger apoptotic events in immune cells. We performed total caspase-1 and caspase-3/7 activity measurements *in vitro*. Caspases are crucial mediators of programmed cell death (apoptosis).[36] Among them, caspase-3 is a frequently activated death protease, catalyzing the specific cleavage of many key cellular proteins, initiating apoptosis.[37] Caspase-1 or ICE (interleukin-1β converting enzyme) is an essential regulator of inflammatory responses through its capacity to process and activate proIL-1β, proIL-18, and proIL-33.[38,39] Therefore, caspase-1 is considered "inflammatory" caspase. We measured caspase-1 and caspase-3/

7 activity in the immune cells treated with PF3, PF4, and PF6 peptides. No activation of the measured caspases was detected in the cells, compared to LPS, suggesting that these peptides lack caspase-dependent apoptotic activity (Figure 4a,b).

In summary, we found that PFs peptides are not toxic or immunogenic at tested concentrations *in vitro*, and we proceeded with testing PF3, PF4, and PF6 peptides *in vivo*. Similar to the results from *in vitro* studies, none of the peptides induced an increase of the cytokine levels in blood serum (Figure 5a,b) or caused pathological deviations in liver, kidney, lung, and spleen of the treated animals (data not shown). PF peptides, which were obtained by chemically modifying the TP10 peptide sequence, exhibited similar effects with TP10, and also with TAT and stearyl-$(RxR)_4$ peptides, showing no influence on the host system. The peptide dose used for i.v. injections in current *in vivo* immunogenicity study, 5 mg/kg, was much higher than the dose used for *in vivo* nucleic acid delivery in the previous study.[5] Having evaluated the data obtained with TP10, TAT, stearyl-$(RxR)_4$ peptides and compared then with the results of PF peptides, we conclude that the peptides have no evidence of inflammatory effects *in vivo*. PF peptides resemble the effects shown by TP10, suggesting that introduced stearyl and chloroquine groups in TP10 sequence do not interfere with cellular immunogenicity.

Although the novel TP10 analogues used in this study were found not to be toxic and immunogenic *in vitro* and *in vivo*, long-term toxicity studies have not been performed yet to confirm the data. The current study confirms that PF3, PF4, and PF6 peptides have indeed a promising potential in plasmid and siRNA delivery without evidence of undesired toxicity and inflammation.

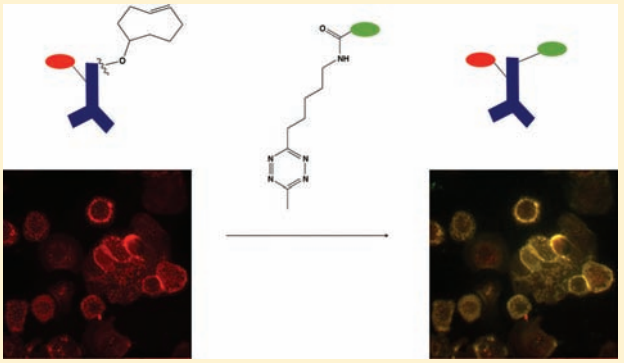
Center for Systems Biology, Massachusetts General Hospital and Harvard Medical School, 185 Cambridge Street Suite 5.210, Boston, Massachusetts 02114, United States

Supporting Information

ABSTRACT: 1,2,4,5-Tetrazines have been established as effective dienes for inverse electron demand [4 + 2] Diels–Alder cycloaddition reactions with strained alkenes for over 50 years. Recently, this reaction pair combination has been applied to bioorthogonal labeling and cell detection applications; however, to date, there has been no detailed examination and optimization of tetrazines for use in biological experiments. Here, we report the synthesis and characterization of 12 conjugatable tetrazines. The tetrazines were all synthesized in a similar fashion and were screened in parallel to identify candidates most ideally suited for biological studies. In depth follow-up studies revealed compounds with varying degrees of stability and reactivity that could each be useful in different bioorthogonal applications. One promising, highly stable, and water-soluble derivative was used in pretargeted cancer cell labeling studies, confirming its utility as a bioorthogonal moiety.



INTRODUCTION

Bioorthogonal 'click' chemistry reactions are a powerful tool for exploring different aspects of biological systems. The ability to perform these chemical reactions in cellular environments (*in cellulo* chemistry) and host organisms (*in vivo* chemistry) without interference from biological components allows for selective 'tagging' of cellular targets and provides a means to image or track biochemical components and interactions. The most widely used and well-known bioorthogonal reaction is the azide and alkyne [3 + 2] cycloaddition.[1] The use of ring strain to promote this reaction was a major development in the field allowing for the [3 + 2] cycloaddition to proceed at room temperature without the need for catalysts.[2] Notable accomplishments utilizing this chemistry have involved the labeling of cell surface glycoconjugates,[3] cell membrane lipids,[4] and glycans in living organisms,[5,6] among others.[7,8] Another bioorthogonal reaction using a similar concept, but employing 1,2,4,5-tetrazines and strained alkenes for [4 + 2] inverse electron demand cycloadditions, has emerged more recently.[9−11] This reaction has gained popularity due to the potential for extremely fast cycloaddition kinetics with *trans*-cyclooctene (TCO) as the dienophile. Applications have included fluorescent cancer cell labeling,[12,13] *in vivo* cancer imaging with ^{111}In,[14] ^{18}F radiolabeling,[15−17] as well as cancer cell detection applications.[18,19]

The effectiveness of the strained alkene–tetrazine reaction is clear, but there has been little detailed investigation on optimizing the reactant properties for bioorthogonal use. However, there is a wealth of reactivity data in nonaqueous media, beginning with the observation in the late 1950s that tetrazines can react with unsaturated compounds.[20] Following this publication, much progress was made in synthesizing different tetrazines for reactions with various dienophiles[21,22] including kinetic analysis of this cycloaddition reaction with different dienophiles by Sauer.[23−25] Sauer reported a range of [4 + 2] cycloaddition reactivity based on the nature of the dienophile that spans 9 orders of magnitude with 1,2,4,5-tetrazines including the first use of norbornene and TCO, which have been the primary dienophiles used in recent bioorthogonal literature.[25,26] TCO has proven to be a much faster reactant than norbornene for bioorthogonal applications,[9,10] but the latter is more stable and commercially available. No reported attempts at improving the dienophile reactivity for bioorthogonal use with tetrazines were published until a recent article emerged describing a new derivative of TCO.[27] The large cycloaddition rate differences seen by changing the chemical nature of the dienophile are equaled by changing the substituents in the 3 and 6 positions of 1,2,4,5-tetrazines.[28] However, only a few tetrazines have been employed in biological environments for bioorthogonal labeling. The primary tetrazines used for this application found in recent literature are the 3,6-monoaryl as well as the diaryl-*s*-tetrazines shown in Figure 1. Tetrazine **A** and carboxylic acid modified versions of this compound shown in Figure 1 have

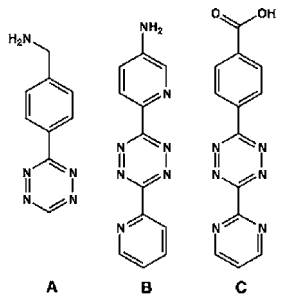

Figure 1. Chemical structures of tetrazines used in reported bioorthogonal applications. (A) (4-(1,2,4,5-tetrazin-3-yl)phenyl)-methanamine, (B) 6-(6-(pyridin-2-yl)-1,2,4,5-tetrazin-3-yl)pyridin-3-amine, (C) 4-(6-(pyrimidin-2-yl)-1,2,4,5-tetrazin-3-yl)benzoic acid.

been employed for many applications by our lab,[12,13,15,17−19] whereas tetrazines **B** and **C** have been reported elsewhere and were used for various purposes including the postsynthetic modification of DNA as well as for the synthesis of a 'BioShuttle' that effectively assists in transporting cargo into cells.[9,11,14,29−31] These tetrazines fall within the mid-range of reported cycloaddition reactivity with dienophiles mainly because some of the tetrazines with the fastest kinetics are not stable in water.[32] With such a large range of reactivity, many substituents are likely to be suitable for bioorthogonal use and could have a significant impact on the kinetics of the reaction. In dealing with bioorthogonal reactions, another parameter besides the rate constant that should be considered is aqueous solution stability. Here, we report the design, synthesis, and characterization of a series of 12 conjugatable tetrazines with varying functional groups. We demonstrate a variety of solution stabilities and reaction rates and validate the bioorthogonal use of a new highly stable and water-soluble tetrazine.

EXPERIMENTAL PROCEDURES

General Considerations. All chemicals and reagents were purchased from commercial sources and used without further purification. (*E*)-Cyclooct-4-en-1-yl (2,5-dioxopyrrolidin-1-yl) carbonate (TCO−carbonate) was synthesized as previously described.[13] NMR spectra were collected on a Varian 500 MHz spectrometer. ^{1}H and ^{13}C NMR spectra were referenced to residual solvent peaks or TMS (0.00 ppm). All phosphate buffered saline (PBS) solutions used were composed of 0.01 M phosphate buffer, 0.0027 M potassium chloride, and 0.137 M sodium chloride, pH 7.4. HyClone DBPS/Modified was used for DPBS. HyClone USDA tested fetal bovine serum was used in FBS stability studies. Herceptin (trastuzumab) was purchased from Genentech. Analytical high-performance liquid chromatography (HPLC) and liquid chromatography−mass spectrometry (LCMS) were performed on a Waters 2695 HPLC equipped with a 2996 diode array detector, a Micromass ZQ4000 ESI-MS module, and a Varian 100 × 2.0 mm RPC$_{18}$ column at a flow rate of 0.3 mL/min. Preparative HPLC was performed on a Varian ProStar model 210 instrument equipped with a model 335 diode array detector, a model 701 fraction collector, and a Varian 250 × 21.2 mm RPC$_{18}$ column at a flow rate of 21 mL/min. HPLC buffers contained: buffer A (0.1% trifluoroacetic acid (TFA) in H_2O) and buffer B (acetonitrile with 10% H_2O and 0.1% TFA). Three to five milligram portions of all compounds were weighed 3× on a Mettler Toledo AB265-S/Fact balance with an accuracy of 0.03 mg in the preparation of stock solutions. Mass spectrometry measurements for exact mass were performed by the Department of Chemistry Instrumentation Facility at the Massachusetts Institute of Technology using a Bruker Daltonics 4.7 T Fourier Transform Ion Cyclotron Mass Spectrometer (FTMS).

Synthesis. *General Tetrazine Synthesis Procedure.* Compounds **1**−**12** were synthesized by mixing 2 mmol of 4-(aminomethyl)benzonitrile, ethyl 6-aminohexanimidate dihydrochloride, or 4-cyanobenzoic acid with 10 mmol of formamidine acetate, acetamidine hydrochloride, 2-cyanopyridine, or pyrimidine-2-carbonitrile under N_2. Anhydrous hydrazine (2 mL) was then added slowly to the solid mixture with stirring (Note: This procedure should be carried out in a well-ventilated fume hood due to the formation of ammonia gas). Reactions were then stirred at room temperature or with heat for 30 min to 2 h. Sodium nitrite (10 mmol) in water was added to the reaction mixture followed by dropwise addition of 2% aqueous HCl until the solution reached approximately pH 3. The solution turned red and stopped bubbling indicating that the dihydrotetrazines were oxidized to the tetrazines (Note: This procedure should be carried out in a well-ventilated fume hood due to the formation of nitrogen oxide gases). The crude aqueous mixtures were then subjected to one of two general workups.

Workup A (compounds **1**−**8**): The oxidized acidic solutions were extracted with dichloromethane (DCM) until the organic layer was colorless. The organic fractions were discarded and the aqueous layer was then saturated with NaCl and basified by addition of solid $NaHCO_3$ (compounds **1**−**4**) or Na_2CO_3 (compounds **5**−**8**) and immediately extracted with DCM. The organic layers were then dried with $MgSO_4$, filtered, and the solvent was removed by rotary evaporation (alternatively, approximately 300 μL of TFA was added prior to rotary evaporation) to yield a crude product mixture.

Workup B (compounds **9**−**12**): The oxidized acidic solutions yielded a pink/red precipitate, which was filtered or separated by centrifugation and washed with 2% aqueous HCl to afford a crude product mixture.

The crude mixtures of all compounds (**1**−**12**) were then purified by HPLC, using the appropriate gradient of buffer A and buffer B, and lyophilized (Note: in some cases, especially with the pyridyl and pyrimidyl substituted compounds, multiple rounds of HPLC purification were necessary due to poor resolution of the product peak). The resulting TFA salts of amine containing compounds **1**−**8** were then dissolved in 0.1% HCl, loaded onto Waters Sep-Pak Vac 10 g C_{18} cartridges and flushed with approximately 10 column volumes of 0.1% HCl. The hydrochloride salts of purified compounds **1**−**8** were then eluted with a mixture of 0.1% HCl and MeCN and either dried in vacuo or lyophilized to dryness.

Synthesis of Ethyl 6-Aminohexanimidate Dihydrochloride. 6-Aminohexanenitrile (50 mmol) was dissolved in anhydrous EtOH (30 mL). Excess HCl gas was bubbled into the solution on an ice bath with stirring for 1 h. The ice bath was removed and HCl bubbling was continued for 24 h. The solvent was then removed by rotary evaporation giving a crystalline solid that was then stirred in cold *i*PrOH (30 mL), filtered, and washed with cold *i*PrOH (2 × 10 mL). After drying in vacuo, pure ethyl 6-aminohexanimidate dihydrochloride salt (9.05 g, 78%) was obtained as a white solid. ^{1}H NMR (500 MHz, DMSO-d_6) δ 1.35 (5H, pentet, J = 15.5 Hz), 1.54−1.66 (4H, m), 2.63 (2H, t, J = 7 Hz), 2.72−2.78 (2H, m), 4.42 (2H, quartet, J = 21 Hz), 8.11 (3H, s, N−H); ^{13}C NMR (125 MHz, DMSO-d_6) δ 179.37, 69.33, 38.75, 32.55, 26.76,

25.32, 24.72, 13.84 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_8H_{19}N_2O]^+$ 159.1492, found 159.1489.

*(4-(1,2,4,5-Tetrazin-3-yl)phenyl)methanamine Hydrochloride (**1**).* The reaction time was 30 min at 80 °C. The title compound as the TFA salt was purified by HPLC using a 0−50% buffer B gradient. A red crystalline solid was obtained after anion exchange to the hydrochloride salt (17% yield, 76 mg). ^{1}H NMR (500 MHz, D_2O) δ 4.37 (2H, s), 7.75 (2H, d, J = 8.0 Hz), 8.54 (2H, d, J = 8.0 Hz), 10.43 (1H, s); ^{13}C NMR (125 MHz, D_2O) δ 169.11, 160.39, 140.49, 134.95, 132.62, 131.84, 45.60 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_9H_{10}N_5]^+$ 188.0931, found 188.0934.

*(4-(6-Methyl-1,2,4,5-tetrazin-3-yl)phenyl)methanamine Hydrochloride (**2**).* The reaction time was 30 min at 80 °C. The title compound as the TFA salt was purified by HPLC using a 0−50% buffer B gradient. A red/purple crystalline solid was obtained after anion exchange to the hydrochloride salt (17% yield, 81 mg). ^{1}H NMR (500 MHz, D_2O) δ 3.11 (3H, s), 4.36 (2H, s), 7.74 (2H, d, J = 8.5 Hz), 8.48 (2H, d, J = 8.0 Hz); ^{13}C NMR (125 MHz, D_2O) δ 170.36, 166.71, 140.06, 134.89, 132.61, 131.44, 45.59, 23.00 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_{10}H_{12}N_5]^+$ 202.1087, found 202.1090.

*(4-(6-(Pyridin-2-yl)-1,2,4,5-tetrazin-3-yl)phenyl)-methanamine Hydrochloride (**3**).* The reaction time was 2 h at 80 °C. The cooled reaction mixture was suspended in a mixture of 25 mL of MeCN, 10 mL of MeOH, and 4 mL of TFA giving a clear yellow-orange solution. Solid $NaNO_2$ (10 mmol) was then added and the reaction was allowed to stir for 15 min. After removing the solvent by rotary evaporation, the residue was washed with DCM and the organics were discarded, leaving an oil. The oil was then dissolved in water (50 mL), saturated with solid $NaHCO_3$, and extracted with DCM. The combined DCM fractions were concentrated and the title compound as the TFA salt was purified by HPLC using a 0−25% buffer B gradient. A red crystalline solid was obtained after anion exchange to the hydrochloride salt (22% yield, 132 mg). ^{1}H NMR (500 MHz, DMSO-d_6) δ 4.19 (2H, s), 7.53 (1H, t, J = 5 Hz), 7.83 (2H, d, J = 8 Hz), 8.19 (1H, t, J = 8 Hz), 8.56−8.64 (3H, m), 8.95 (1H, d, J = 5 Hz); ^{13}C NMR (125 MHz, DMSO-d_6) δ 163.17, 163.03, 150.33, 149.87, 138.85, 137.99, 131.55, 129.85, 127.89, 126.57, 124.01, 41.73 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_{14}H_{13}N_6]^+$ 265.1196, found 265.1190.

*(4-(6-(Pyrimidin-2-yl)-1,2,4,5-tetrazin-3-yl)phenyl)-methanamine Hydrochloride (**4**).* The reaction time was 2 h at 80 °C. The cooled reaction mixture was treated as in **3**. The title compound as the TFA salt was purified by HPLC using a 0−25% buffer B gradient. A red crystalline solid was obtained after anion exchange to the hydrochloride salt (17% yield, 102 mg). ^{1}H NMR (500 MHz, D_2O) δ 4.35 (2H, s), 7.74 (2H, d, J = 8.5 Hz), 7.86 (1H, t, J = 5 Hz), 8.58 (2H, d, J = 8.0 Hz), 9.13 (2H, d, J = 5.5 Hz); ^{13}C NMR (125 MHz, D_2O) δ 167.32, 164.79, 161.60, 160.45, 141.00, 134.30, 132.78, 132.14, 126.75, 45.60 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_{13}H_{12}N_7]^+$ 266.1149, found 266.1140.

*5-(1,2,4,5-Tetrazin-3-yl)pentan-1-amine Hydrochloride (**5**).* The reaction time was 2 h at room temperature. The title compound as the TFA salt was purified by HPLC using a 0−25% buffer B gradient. A pink crystalline solid was obtained after anion exchange to the hydrochloride salt (6% yield, 24 mg). ^{1}H NMR (500 MHz, D_2O) δ 1.53 (2H, pentet, J = 15.5 Hz) 1.75 (2H, pentet, J = 15.5 Hz), 1.99 (2H, pentet, J = 15.5 Hz) 3.02 (2H, t, J = 7.5 Hz), 3.39 (2H, t, J = 7.5 Hz), 10.36 (1H, s); ^{13}C NMR (125 MHz, D_2O) δ 175.63, 160.63, 42.25, 37.13, 29.71, 29.35, 27.99 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_7H_{14}N_5]^+$ 168.1244, found 168.1241.

*5-(6-Methyl-1,2,4,5-tetrazin-3-yl)pentan-1-amine Hydrochloride (**6**).* The reaction time was 2 h at room temperature. The title compound as the TFA salt was purified by HPLC using a 0−100% buffer B gradient. A purple crystalline solid was obtained after anion exchange to the hydrochloride salt (21% yield, 92 mg). ^{1}H NMR (500 MHz, D_2O) δ 1.51 (2H, pentet, J = 15.5 Hz) 1.73 (2H, pentet, J = 15 Hz), 1.95 (2H, pentet, J = 15 Hz) 3.02 (2H, t, J = 7.5 Hz), 3.34 (2H, t, J = 7.5 Hz), 4.77 (3H, s); ^{13}C NMR (125 MHz, D_2O) δ 172.49, 170.45, 42.21, 36.42, 29.78, 29.29, 27.91, 22.97 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_8H_{16}N_5]^+$ 182.1400, found 182.1405.

*5-(6-(Pyridin-2-yl)-1,2,4,5-tetrazin-3-yl)pentan-1-amine Hydrochloride (**7**).* The reaction time was 30 min at 80 °C. The title compound as the TFA salt was purified by HPLC using a 0−50% buffer B gradient. An orange/red crystalline solid was obtained after anion exchange to the hydrochloride salt (10% yield, 55 mg). ^{1}H NMR (500 MHz, DMSO-d_6) δ 1.48 (2H, pentet, J = 15 Hz), 1.66 (2H, pentet, J = 15.5 Hz), 1.96 (2H, pentet, J = 15 Hz), 2.72−2.82 (2H, m), 3.35 (2H, t, J = 7), 7.70−7.76 (1H, m), 8.16 (1H, t, J = 7.5 Hz), 8.53 (1H, d, J = 7.5 Hz), 8.91 (1H, d, J = 5 Hz); ^{13}C NMR (125 MHz, DMSO-d_6) δ 169.78, 163.19, 150.23, 150.00, 137.98, 126.46, 123.83, 38.39, 33.82, 26.60, 26.54, 25.11 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_{12}H_{17}N_6]^+$ 245.1509, found 245.1503.

*5-(6-(Pyrimidin-2-yl)-1,2,4,5-tetrazin-3-yl)pentan-1-amine Hydrochloride (**8**).* The reaction time was 30 min at 80 °C. The title compound as the TFA salt was purified by HPLC using a 0−50% buffer B gradient. A red crystalline solid was obtained after anion exchange to the hydrochloride salt (2% yield, 12 mg). ^{1}H NMR (500 MHz, D_2O) δ 1.59 (2H, pentet, J = 15 Hz) 1.80 (2H, pentet, J = 15.5 Hz), 2.08 (2H, pentet, J = 15.5 Hz) 3.05 (2H, t, J = 8 Hz), 3.52 (2H, t, J = 8 Hz), 7.86 (1H, t, J = 5.5 Hz), 9.14 (2H, d, J = 5.5 Hz); ^{13}C NMR (125 MHz, D_2O) δ 174.31, 165.18, 161.60, 160.45, 126.71, 42.19, 36.87, 29.68, 29.30, 27.99 ppm. HRMS−ESI $[M + H]^+$ m/z calcd for $[C_{11}H_{16}N_7]^+$ 246.1462, found 246.1465.

*4-(1,2,4,5-Tetrazin-3-yl)benzoic Acid (**9**).* The reaction time was 30 min at 80 °C. The title compound was purified as a pink solid by HPLC using a 0−100% buffer B gradient (18% yield, 73 mg). ^{1}H NMR (500 MHz, DMSO-d_6) δ 8.22 (2H, d, J = 8.0 Hz), 8.62 (2H, d, J = 8.5 Hz), 10.66 (1H, s); ^{13}C NMR (125 MHz, DMSO-d_6) δ 166.58, 164.98, 158.16, 135.62, 134.22, 130.11, 127.88 ppm. HRMS−ESI $[M - H]^-$ m/z calcd for $[C_9H_5N_4O_2]^-$ 201.0418, found 201.0416.

*4-(6-Methyl-1,2,4,5-tetrazin-3-yl)benzoic Acid (**10**).* The reaction time was 30 min at 80 °C. The title compound was purified as a purple solid by HPLC using a 0−100% buffer B gradient (11% yield, 48 mg). ^{1}H NMR (500 MHz, DMSO-d_6) δ 3.03 (3H, s), 8.20 (2H, d, J = 9.0 Hz), 8.58 (2H, d, J = 8 Hz); ^{13}C NMR (125 MHz, DMSO-d_6) δ 167.84, 167.17, 163.30, 136.18, 134.43, 130.67, 128.06, 21.36 ppm. HRMS−ESI $[M - H]^-$ m/z calcd for $[C_{10}H_7N_4O_2]^-$ 215.0574, found 215.0574.

*4-(6-(Pyridin-2-yl)-1,2,4,5-tetrazin-3-yl)benzoic Acid (**11**).* The reaction time was 90 min at 80 °C. The title compound was purified as a purple solid by HPLC using a 0−100% buffer B gradient (3% yield, 17 mg). ^{1}H NMR (500 MHz, DMSO-d_6) δ 7.74 (1H, t, J = 6.5 Hz), 8.17 (1H, d, J = 7.5 Hz), 8.24 (2H, d, J = 9.0 Hz), 8.62 (1H, d, J = 8.0 Hz), 8.69 (2H, d, J = 8.5 Hz), 8.95 (1H, d, J = 3.5); ^{13}C NMR (125 MHz, DMSO-d_6) δ

165.57, 162.02, 161.99, 149.46, 148.89, 136.78, 134.39, 133.16, 129.14, 126.92, 125.57, 123.09 ppm. HRMS–ESI $[M + H]^+$ m/z calcd for $[C_{14}H_{10}N_5O_2]^+$ 280.0829, found 280.0827.

*4-(6-(Pyrimidin-2-yl)-1,2,4,5-tetrazin-3-yl)benzoic Acid (**12**).* The reaction time was 90 min at 80 °C. The title compound was purified as a red solid by HPLC using a 0–100% buffer B gradient (2% yield, 12 mg). ^{1}H NMR (500 MHz, DMSO-d_6) δ 7.78 (1H, t, J = 5.0 Hz), 8.19 (2H, d, J = 8.5 Hz), 8.64 (2H, d, J = 8.5 Hz), 9.14 (2H, d, J = 5.0 Hz); ^{13}C NMR (125 MHz, DMSO-d_6) δ 167.15, 163.64, 163.36, 159.48, 159.00, 135.82, 134.94, 130.73, 128.83, 123.51 ppm. HRMS–ESI $[M + H]^+$ m/z calcd for $[C_{13}H_9N_6O_2]^+$ 281.0781, found 281.0784.

*Synthesis of AF750–Tetrazine Conjugate (AF750–**6**).* The succinimidyl ester of AlexaFluor-750 (AF750, Invitrogen, 2.5 mg) was dissolved in 10 mM phosphate buffer, pH 8.3. Excess (approximately 10-fold molar excess, 4 mg) tetrazine **6** was then added immediately and the solution was allowed to stir at room temperature in the dark for 5 h. The product was identified by LCMS and purified by HPLC using a 0–100% buffer B gradient. The resulting fractions containing the desired compound were neutralized with NaOH, desalted by flushing with deionized water after loading on Waters Sep-Pak Vac 10 g C_{18} cartridges, eluted with a mixture of water/MeCN, frozen, and lyophilized to yield purified product as determined by analytical HPLC (see Supporting Information Figure S1).

Kinetics. *Tetrazine Kinetics with Norbornene.* Cycloaddition kinetics were monitored using a Tecan Safire2 microplate reader in clear flat-bottomed 96-well plates. Norbornene carboxylic acid ((1*S*,2*S*,4*S*)-bicyclo[2.2.1]hept-5-en-2-ylacetic acid) (NB) was used in excess as the dienophile at 1, 2, 3, 4, and 5 mM concentrations with each of the 12 tetrazines (100 μM) in triplicate. Stock solutions of reactants in DMSO were diluted in PBS pH 7.4 to a final concentration of 5% DMSO. The decrease of the tetrazine absorbance measured at 515 nm was monitored at 37 °C (NB PBS solutions were allowed to pre-equilibrate at 37 °C in the instrument for 10 min before addition of the tetrazine). The k_{obs} (s^{-1}) values were then calculated using the Prism software package, averaged, and plotted against the concentration of NB to yield the second order rate constants (k_2, M^{-1} s^{-1}) from the slope of the line. Trials for each tetrazine were done in duplicate. The relative (to tetrazine **1**) rate constants for each of the 12 tetrazines can be seen in Supporting Information Figure S2.

Tetrazine Kinetics with TCO. Kinetics were performed with the major isomer of (*E*)-cyclooct-4-enol (TCO) and selected tetrazines using an Applied Photophysics Stopped-Flow spectrophotometer. Stock solutions of reactants in DMSO were diluted in PBS pH 7.4 to a final concentration of 1% DMSO. Solutions of TCO and tetrazine were loaded into the individual chambers of the spectrophotometer and equilibrated to 37 °C for 10 min. Samples were then mixed by the instrument in a 1:1 (v/v) ratio and the decrease of the tetrazine absorbance measured at 515 nm was monitored at regular intervals. Final concentrations of reactants were 1.0, 1.5, 2.0, and 2.5 mM for TCO and 50 mM for the tetrazines. Baseline corrected k_{obs} (s^{-1}) values were calculated using Prism and the results of 4 runs were averaged for each concentration of TCO using the standard deviation as the error. The average k_{obs} values were then plotted against the concentration of TCO to yield the second order rate constants (k_2, M^{-1} s^{-1}) from the slope of the line and the error from the standard deviation in the slope calculated in Prism.

Tetrazine Stability Studies. *Stability in Phosphate Buffered Saline.* The stability of tetrazines **1**–**12** in PBS was measured using a Tecan Safire2 microplate reader in clear flat-bottomed 96-well plates. DMSO stocks of tetrazines were diluted in PBS pH 7.4 to 0.2 mM and a final DMSO concentration of 1%. The decrease of the tetrazine absorbance measured at 515 nm was monitored for 14 h at 37 °C. Three independent trials (containing three wells for each tetrazine) were conducted and the average of the three wells for each tetrazine was calculated for each trial. The PBS corrected averages from each of the three trials were themselves averaged and the relative (to tetrazine **1**) percent tetrazine remaining can be seen in Supporting Information Figure S3 where the error is the standard deviation of the three trials.

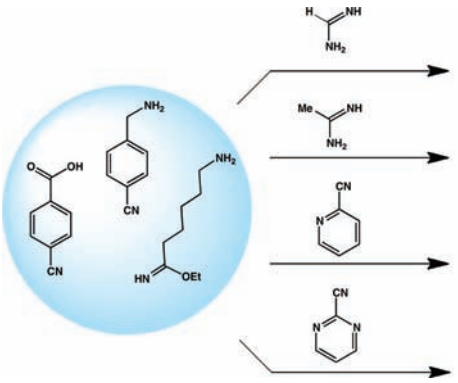
Stability in Serum (FBS). The stabilities of selected tetrazines in 100% fetal bovine serum were measured using an Agilent 8453 UV–visible spectrophotometer. The compounds were added to pre-equilibrated serum at 37 °C in a capped quartz cuvette at a final concentration of 1 mM and 1% DMSO. A higher concentration of tetrazine was used as compared to the PBS stability measurements due to a small but significant baseline drift over time from the FBS resulting in absorbance that overlaps with the tetrazine absorbance at 515 nm. The decrease of the tetrazine absorbance measured at 515 nm was monitored for 10 h at 37 °C. This procedure was repeated three times and the serum only corrected percent decreases were averaged and the standard deviation was used as the error.

Antibody Labeling. Herceptin (5 mg) was dissolved in 10 mM $NaHCO_3$ pH 8.4 buffer before adding approximately 3 mol equiv (0.25 mg) AlexaFluor-568 succinimidyl ester (AF568, Invitrogen). The reaction was allowed to shake at room temperature overnight in the dark. HerceptinAF568 was then purified from unconjugated fluorophore using an Amicon centrifugal filter (3K MWCO, Millipore) and determined to have approximately 1–2 fluorophores/antibody by absorbance using 91 300 M^{-1} cm^{-1} as the extinction coefficient for AF568. Fluorophore labeled Herceptin was further labeled with excess TCO–succinimidyl carbonate as described previously.[19]

Cell Studies. *Flow Cytometry.* Confluent SKBR-3 cells were suspended using 0.05% Trypsin/0.53 mM EDTA, washed by centrifugation with DPBS, and placed in microcentrifuge tubes. HerceptinAF568 only (control) or HerceptinAF568–TCO were then added separately to individual tubes to a final concentration of 10 μg/mL in 100 μL total volume of DBPS. After incubating for 30 min at room temperature, cells were washed by centrifugation with DPBS (3 × 1 mL). AF750–**6** in DMSO was then added to give a final concentration of 10 μM in 100 μL of DBPS and was allowed to incubate for 30 min at room temperature (the final DMSO concentration was 1%). Cells were then washed by centrifugation with DBPS (4 × 1 mL) before resuspension in DPBS containing 5% FBS. AF568 and AF750 fluorescence was then assessed with a Becton Dickinson LSRII flow cytometer using the PE and APC-Cy7 channels, respectively. Data collected was analyzed using the FlowJo software package.

Microscopy. SKBR-3 Human breast cancer cells were cultured in breakaway glass chamber slides. HerceptinAF568–TCO labeled antibody (HerceptinAF568 only for controls) was incubated with the cells at a final concentration of approximately 10 μg/mL for 30 min in growth media (McCoy's 5A containing 10% FBS 1% L-Glutaimine 1% Penstrep and 2% $NaHCO_3$). Cells were then washed 4× with media before

Scheme 1. Synthesis of Tetrazines 1−12



Tetrazine	R_1	R_2
1	-($BzNH_2$)	H
2	-($BzNH_2$)	Me
3	-($BzNH_2$)	2-Pyridyl
4	-($BzNH_2$)	2,6-Pyrimidyl
5	-$(CH_2)_5NH_2$	H
6	-$(CH_2)_5NH_2$	Me
7	-$(CH_2)_5NH_2$	2-Pyridyl
8	-$(CH_2)_5NH_2$	2,6-Pyrimidyl

10	4-(carboxy)phenyl-	Me
11	4-(carboxy)phenyl-	2-Pyridyl
12	4-(carboxy)phenyl-	2,6-Pyrimidyl

incubating with 10 μM AF750−**6** for 30 min in growth media. The cells were then washed 4× with DPBS and fixed by incubating with Cytofix fixation buffer (BD Biosciences) for 20 min. After washing 4× with DPBS, the chambers were removed and the cells were preserved with ProLong Gold (Invitrogen). Images were taken using a Nikon Eclipse 80i fluorescence microscope and imaged in the Y-2E/C and INDO CY GR channels for AF568 and AF750, respectively. Identical image acquisition settings were used for both the control and experimental data sets. Images were analyzed using ImageJ applying identical leveling adjustments to control and experimental data across the individual channels.

RESULTS AND DISCUSSION

Synthesis of Tetrazines. A series of 1,2,4,5-tetrazines was synthesized with the goal of testing the effects different substituents have on the solution stability and cycloaddition kinetic properties of these compounds. A total of 12 tetrazines were synthesized based on three conjugatable scaffolds and four different substituent groups. The substituents used varied in both size and electronic properties. Tetrazines **1**−**12** were all synthesized in a similar manner as shown in Scheme 1. After the appropriate carbonitrile/imidate ester/amidine pair was allowed to react in hydrazine, the crude reaction mixtures containing the dihydrotetrazine intermediates were oxidized with $NaNO_2$ in water and 2% aqueous HCl. The crude tetrazine mixtures were then purified and characterized by NMR (^{1}H and ^{13}C) and HRMS in yields ranging from 2 to 22%. Several of the pyrimidyl and pyridyl substituted tetrazines proved difficult to purify resulting in lower reported yields. It was often the case that material of approximately 80−85% purity could be obtained in much higher yields, but subsequent and often multiple rounds of chromatography to obtain ≥95% purity substantially lowered the overall yield of several of these compounds.

Tetrazine Kinetics with Norbornene and PBS Stability. With the goal of narrowing down the number of tetrazines used for in depth follow-up studies, the synthesized compounds **1**−**12** were screened initially in parallel. In 96-well plates, tetrazines **1**−**12** were incubated with norbornene carboxylic acid ((1*S*,2*S*,4*S*)-bicyclo[2.2.1]hept-5-en-2-ylacetic acid) (NB) to determine their relative inverse electron demand [4 + 2] cycloaddition kinetics (Supporting Information Scheme S1 depicts the generic reaction). NB was used in these initial screens due to its previous bioorthogonal utility in this reaction,[10,33] as well as its commercial availability. In all cases, NB was used in excess (at least 10-fold) and the disappearance of the visible absorption band of the tetrazine ring was monitored spectrophotometrically to obtain the pseudo-first-order rate constants (k_{obs} s^{-1}). Reactions had varying half-lives ranging from 1.5 to 60 min and were monitored until completion of the cycloaddition at 37 °C. The k_{obs} values at each concentration of NB were then used to calculate the relative second-order rate constants for all tetrazines. In general, tetrazines with stronger electron withdrawing groups (**4** and **8**) attached to the tetrazine ring showed faster kinetics, whereas electron donating groups (**2**, **6**, and **10**) resulted in slower cycloaddition reactions when compared to hydrogen substituted tetrazine **1** (see Supporting Information Figure S2). This is consistent with the general [4 + 2] inverse electron demand reaction in that more electron deficient dienes result in faster cycloadditions.[28] However, it is also important to note that hydrogen substituted tetrazines resulted in faster kinetics than would be predicted based on their 'neutral' character suggesting other parameters such as sterics may play an important role in the rate of this reaction.

The solution stability of the tetrazines in PBS pH 7.4 at 37 °C was investigated. This screen was done in parallel in which the compounds were incubated in 96-well plates and the absorbance of the tetrazine at 515 nm was used to determine the percent tetrazine remaining after 14 h. The relative stabilities compared to tetrazine **1** can be seen in Supporting Information Figure S3. In general, compounds with stronger electron withdrawing groups showed lower stability than hydrogen substituted tetrazines and the electron donating alkyl substituted tetrazines exhibited the highest stability.

In addition to these observed trends in kinetics and stability, other factors such as aqueous solubility and ease of synthesis/purification were also considered before selecting tetrazines for more in depth follow-up studies. Overall, 3,6-diaryl tetrazines demonstrate lower aqueous solubility than those with methyl or hydrogen substituents. For example, 3,6-diphenyl tetrazine is not soluble to any measurable amount in 100% water and **12** is not soluble above 0.2 mM, whereas **6** readily dissolves at concentrations above 500 mM. Taking all these data into account, tetrazines **1**−**9** were chosen for further evaluation.

Tetrazine Kinetics with TCO and Serum Stability. The selected tetrazines were tested for their cycloaddition kinetics against the highly reactive dienophile TCO. A stopped-flow spectrophotometer was used to follow the decrease of the absorption at 515 nm of each tetrazine when mixed with excess TCO at 37 °C in PBS pH 7.4. Reactions had varying half-lives ranging from 9 to 3000 ms and were monitored until completion of the cycloaddition at 37 °C. As with NB,

dx.doi.org/10.1021/bc200295y | *Bioconjugate Chem.* 2011, 22, 2263−2270

second-order rate constants were calculated for cycloaddition reactions of the tetrazines with TCO (Table 1). These data

Table 1. Second Order [4 + 2] Cycloaddition Rate Constants of Selected Tetrazines with TCO in PBS at 37°C[a]

tetrazine	k_2 ($M^{-1}s^{-1}$)	error
1	26000[a]	500
2	820	70
3	5300	400
4	22000	2000
5	4900	100
6	210	20
7	2300	300
8	4400	300
9	30000	3000

[a]Discrepancies between the rate constant reported here for **1** and TCO of 26 000 M^{-1} s^{-1} and a previous report from our lab[13] of 6000 M^{-1} s^{-1} may be explained by the methods used. The current method herein evaluated the kinetics of the free molecules in solution directly by absorbance of the tetrazine, whereas the previous study was conducted using TCO modified antibody physically absorbed to a surface and fluorescence readout after incubation with a tetrazine–fluorophore conjugate.

again show that hydrogen substituted tetrazines demonstrate exceptionally fast kinetics up to 30 000 M^{-1} s^{-1} for **9**. Interestingly, tetrazine **4**, which displayed faster kinetics than **1** and **9** with NB, while still relatively fast, was slightly slower than the reaction of these two tetrazines with TCO as the dienophile. This is perhaps due to steric interference between the 3,6-diaryl **4** and TCO that was not encountered with monosubstituted **1** and **9**. Even the slowest measured tetrazine **6** at 210 M^{-1} s^{-1} is still much faster than any of the reactions with NB, which was previously shown to be sufficient for pretargeted cell labeling studies.[10] Together with the NB kinetics, these data suggest a rate advantage for hydrogen substituted tetrazines over more bulky aryl substituents. To test the effect pH has on the reaction kinetics, another physiologically relevant pH was chosen, pH 5.0, approximating what is expected to occur within lysosomes. At this pH, representative compounds **1** and **3** showed no significant change in second-order rate constant compared to the reaction at pH 7.4.

As tetrazines continue to become increasingly important moieties in biological labeling/detection studies, a more physiologically relevant stability experiment was conducted with the selected compounds. Tetrazines were incubated in pure fetal bovine serum (FBS) at 37 °C and the decrease in absorbance at 515 nm was measured. The average percent remaining over 10 h can be seen in Figure 2. The most stable tetrazine was **6**, with greater than 96% remaining after 10 h, followed by the other alkyl substituted tetrazines and ending with the least stable electron withdrawing group containing tetrazine **4**. These results mimic the data observed in the previous PBS stability studies in that tetrazines with electron donating groups were the most stable. Depending on the individual application, any one of the tetrazines analyzed in this manuscript could be of importance. For example, if the tetrazine is to be employed where rapid reaction kinetics are desired, a faster compound that also has a good balance of chemical stability such as **1** or **9** would be a logical choice. Many applications of **1** have already been demonstrated (vide

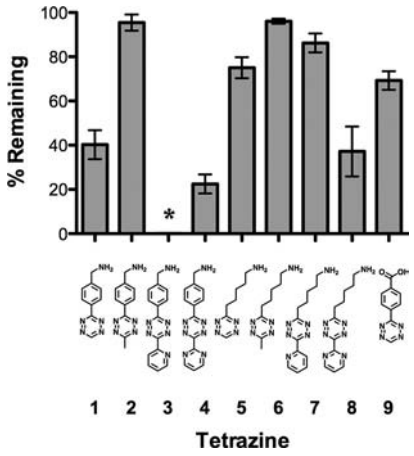

Figure 2. Stability of selected tetrazines in FBS at 37 °C after 10 h. *It was not possible to measure the serum stability of tetrazine **3** due to formation of a precipitate after incubation in FBS for approximately 1.5–2 h.

supra) including conjugation to proteins and nanoparticles.[19,33] However, in applications where rapid cycloaddition kinetics may not be as critical and improved chemical stability would be more beneficial, a tetrazine able to withstand more harsh chemical environments or endure long-term solution storage such as **2** or **6** may be of more value.

Cancer Cell Labeling. To confirm the biological utility of the new tetrazine derivatives, **6** was chosen as a representative compound for validation in pretargeted labeling studies with live SKBR-3 human breast cancer cells. Since we have already used the much faster tetrazine **1** in a similar experiment,[13] we wanted to demonstrate that the slowest tetrazine from this study was still a practical cycloaddition partner with TCO for bioorthogonal use. Despite showing the slowest reaction kinetics, tetrazine **6** demonstrated the best serum stability, was extremely water-soluble, and was synthesized/purified in relatively high yield. SKBR3 cells overexpress HER2/neu receptors and have been shown previously to be useful in pretargeted cell labeling assays with a tetrazine–norbornene system.[10] The HER2/neu antibody, Herceptin, was labeled with AF568 and TCO through sequential incubations with the dye succinimidyl ester and then TCO–succinimidyl carbonate. The fluorescent labeling allows tracking of the antibody, and in order to follow the cycloaddition reaction, the free amine of tetrazine **6** was reacted with the succinimidyl ester of AF750 to afford AF750–**6**. For confirmation of cycloaddition reactivity in a biological environment, SKBR3 cells were incubated with labeled antibodies HerceptinAF568–TCO or HerceptinAF568 (control). After washing, antibody labeled cells were then incubated with AF750–**6**, washed again, and analyzed by flow cytometry. Histograms showing the antibody labeling of cells incubated with both the control and TCO labeled Herceptin can be seen in Figure 3A. This figure indicates that the TCO loaded antibody shows identical affinity for the cells as the AF568 only loaded Herceptin. Figure 3B demonstrates that cells labeled with HerceptinAF568–TCO react with AF750–**6** through the significant shift in near-infrared fluorescence of these cells compared to the HerceptinAF568 labeled control cells. This study confirms the effectiveness of our selected tetrazine for bioorthogonal labeling.

To corroborate the flow cytometry data, we looked at the same HerceptinAF568–TCO reaction but using AF750–**6**

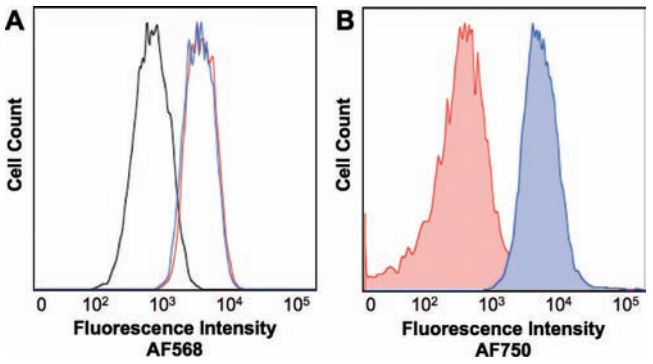

Figure 3. Flow cytometry histograms of SKBR3 cells. (A) AF568 fluorescence of cells only (black), cells incubated with HerceptinAF568 (red), or HerceptinAF568–TCO (blue) followed by AF750–**6**. incubated individually with the labeled antibodies, followed by washing, subsequent incubation with AF750–**6**, and imaging (Figure 4). As can be seen in this figure, cells labeled with

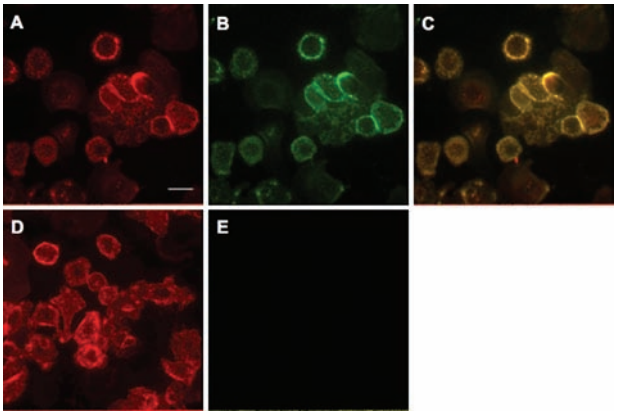

Figure 4. Fluorescent microscopy images of SKBR3 cells. Cells were treated with HerceptinAF568–TCO (A–C) or control HerceptinAF568 (D and E) followed by AF750–**6** for 30 min. Displayed is fluorescence from (A) AF568, (B) AF750, (C) AF568/AF750 merge, (D) AF568, (E) AF750. Scale bar (top left): 50 μm.

HerceptinAF568–TCO are also labeled with AF750–**6**, but cells incubated with control HerceptinAF568 showed no fluorescence in the 750 nm channel. This study further demonstrates that our selected tetrazine is useful in bioorthogonal labeling on par with previously reported compounds.

CONCLUSIONS

The series of 12 1,2,4,5-tetrazines was synthesized with a combination of four substituent groups and three conjugatable handles. Upon initial screening for reactivity and solution stability of these compounds, several were chosen for more in depth follow-up studies. These studies revealed a considerable range of serum stabilities and cycloaddition reactivities with TCO. Overall, tetrazines substituted with electron donating groups tended to be more stable, but had slower cycloaddition kinetics, and hydrogen substituted tetrazines, such as **1** and **9**, demonstrated a good balance of solution stability and fast reaction kinetics compared to compounds that would electronically be more favorable suggesting these tetrazines may react faster due to less steric interference with the dienophile. On the basis of these data along with ease of synthesis/purification, a tetrazine (**6**) was selected with exceptional chemical stability for biological evaluation. This selected tetrazine, despite demonstrating relatively slow kinetics, was then shown to be suitable for bioorthogonal use based on pretargeted cancer cell labeling studies using flow cytometry and fluorescence microscopy. The presented tetrazines add more compounds to the inverse electron demand [4 + 2] cycloaddition arsenal that can be chosen from for different bioorthogonal labeling applications depending on the desired chemical properties.

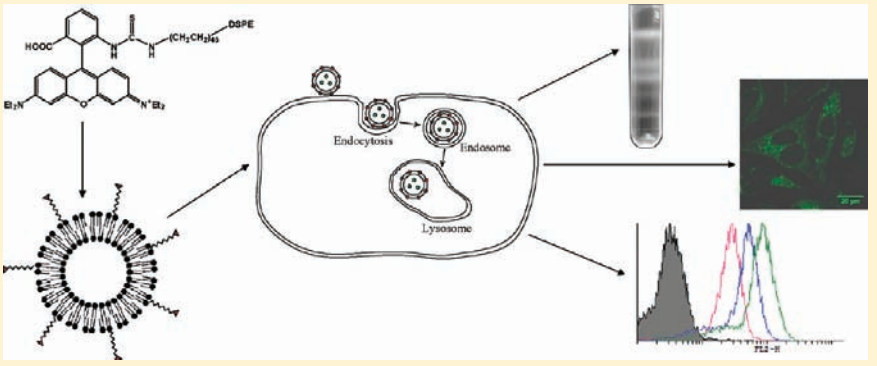
Screening and Optimization of Ligand Conjugates for Lysosomal Targeting

Igor Meerovich, Alexander Koshkaryev, Ritesh Thekkedath, and Vladimir P. Torchilin*

Center for Pharmaceutical Biotechnology & Nanomedicine, Northeastern University, 312 Mugar Hall, 360 Huntington Avenue, Boston, Massachusetts 02115, United States

ABSTRACT:



The use of lysosome-targeted liposomes may significantly improve the delivery of therapeutic enzymes and chaperones into lysosomes for the treatment of lysosomal storage disorders. The aim of this research was to synthesize new potentially lysosomotropic ligands on a base of Neutral Red and rhodamine B and to study their ability to enhance specific lysosomal delivery of surface-modified liposomes loaded with a model compound, fluorescein isothiocyanate-dextran (FD). The delivery of these liposomes and their content to lysosomes in HeLa cells was investigated by confocal immunofluorescent microscopy, subcellular fractionation, and flow cytometry. Confocal microscopy demonstrated that liposomes modified with derivatives of rhodamine B provide a good rate of colocalization with the specific lysosomal markers. The comparison of fluorescence of FD in lysosomes isolated by subcellular fractionation also showed that the efficiency of lysosomal delivery of the liposomal load by liposomes modified with some of synthesized ligands was significantly higher compared to that with plain liposomes. These results were additionally confirmed by flow cytometry of the intact cells treated with liposomes loaded with 5-dodecanoylaminofluorescein di-β-D-galactopyranoside, a specific substrate for the intralysosomal β-galactosidase, using a number of cell lines, including macrophages with induced phenotype of lysosomal enzyme deficiency; two of the synthesized ligands—rhodamine B DSPE-PEG_{2k}-amide and 6-(3-(DSPE-PEG_{2k})-thioureido) rhodamine B—demonstrated enhanced lysosomal delivery, in some cases, higher than that for commercially available rhodamine B octadecyl ester, with the best results (the enhancement of the lysosomal delivery up to 75% greater in comparison to plain liposomes) shown for the cells with induced lysosomal enzyme deficiency phenotype. Use of liposomes modified with rhodamine B derivatives may be advantageous for the development of drug delivery systems for the treatment of lysosome-associated disorders.

INTRODUCTION

Many pharmaceutical agents, including various large (enzymes, antibodies, other polypeptides) and small molecules, must be delivered specifically to particular cell organelles in order to efficiently exert their therapeutic action. Such delivery is still mainly an unresolved problem,[1] although some attempts have been made to target mitochondria and nuclei using liposomes modified with mitochondriotropic[2] or nucleotropic agents.[3]

Lysosomes represent one of the important intracellular targets. In a number of inherited human metabolic disorders, the lysosomal storage disorders (LSDs), defects in the lysosomal enzymes, lead to a progressive accumulation of unmetabolized substrates.[4] LSD symptoms may vary widely depending on the particular mutations inherited and the specific metabolic pathways affected; LSD clinical manifestations typically include deterioration of neurological function (50% of LSDs are associated with central nervous system (CNS) disorders), as well as pulmonary, hepatic, splenic, cardiovascular, and renal dysfunction. Other tissues and functions also often affected in LSDs include the immune system, bone, connective tissue, skeletal and cardiac muscle, dermis, and ocular function.[5,6] The clinical course and the severity of individual LSDs usually correlate with levels of residual enzyme activity.

The most extensively used strategy for treatment of LSDs is enzyme replacement therapy (ERT), based on the exogenous

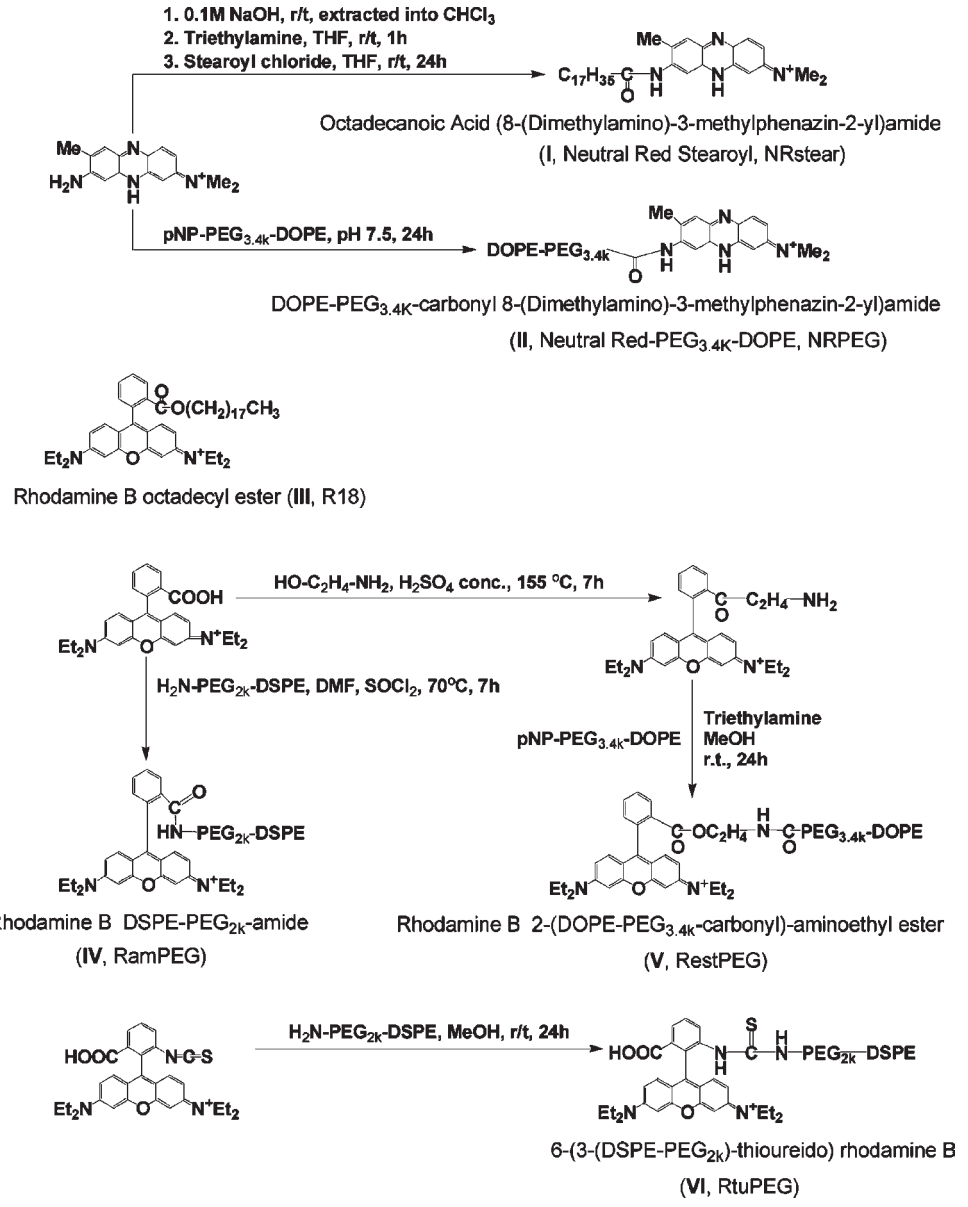

Figure 1. Synthesis of derivatives of Neutral Red and rhodamine B.

administration of active enzymes.[7] Also, among the potential advances in LSD treatment is the so-called "chaperone therapy", also called "enzyme enhancement therapy", aimed at the improperly folded mutant proteins, that are stabilized by the exogenously administered small molecules, resulting in an increase in the levels of functional enzyme. It was shown to be a promising treatment strategy for several LSDs including Gaucher disease, the GM1 and GM2 gangliosidoses, and Fabry disease.[8] However, this procedure remains limited and expensive because of the instability, poor delivery, and rapid degradation of the administered enzymes.

The use of liposome-immobilized enzymes introduced more than 30 years ago new opportunities for enzyme therapy, especially in the treatment of diseases localized to liver cells which are natural targets for liposomes.[9] Still, these liposome-based preparations are not in general clinical use for ERT, and a clear need to sharply increase the efficiency of the delivery of the liposomal enzymes to lysosomes inside cells still exists. Improvement in liposome-based enzyme delivery can be achieved by using liposomes specifically targeted to lysosomes.

Another important aspect related to the lysosomal targeting for drug delivery is the involvement of lysosomes in the treatment of cancer via the activation of the lysosome-dependent cell death pathway.[10] It has been proven that the moderate permeabilization of lysosomal membranes can result in cell apoptosis. On the other hand, secreted lysosomal cathepsins degrade protein components of the extracellular matrix and thus contribute actively to tumor angiogenesis.[11] Thus, it may be useful to develop a delivery system with specific lysosomal targeting that can provide inhibition of lysosomal enzymatic activity in cancer cells or deliver lysosome-destabilizing agents that will cause cancer cell apoptosis.

A large variety of small molecules have been identified which specifically target and accumulate in lysosomes. Among them, Neutral Red and rhodamine B are routinely used for the visualization of lysosomes and other acidic organelles in live

dx.doi.org/10.1021/bc200336j |*Bioconjugate Chem.* 2011, 22, 2271–2282

cells.[12,13] The commercially available rhodamine B octadecyl ester is used widely to monitor membrane fusion[14] and for the study of lysosomal metabolism.[15] As shown by Vult von Steyern et al.,[16] rhodamine B accumulates specifically in the lysosomes of denervated skeletal muscle. Huth et al. have shown a preferential build-up of the liposomes within lysosomes, when the liposomal membrane was labeled with rhodamine B-phosphoethanolamine.[17] With this in mind, we originally proved the general concept of the possibility to prepare the lysosome-targeted liposomes based on the use of commercially available Rhodamine B octadecyl ester.[18]

The aim of the current work was to synthesize different ligands based on Neutral Red (NR) and rhodamine B (RhB) with short and long poly(ethylene glycol) spacers suitable for introduction into the lipid bilayer and compare their ability to enhance the lysosomal delivery of these ligand-modified liposomes loaded with the model compound FITC-dextran.

MATERIALS AND METHODS

Materials. Egg phosphatidylcholine (ePC), cholesterol (Chol), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(polyethylene glycol)-2000] (DSPE-PEG_{2k}-amine) and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (DOPE) were purchased from Avanti Polar Lipids (Alabaster AL, USA). Fluorescein isothiocyanate-dextran (FD) with molecular weight (MW) of 4400, Neutral Red (NR), rhodamine B (RhB), rhodamine B octadecyl ester (R18), rhodamine B isothiocyanate (RhB-ITC), polyoxyethylene(MW 3400)-bis(*p*-nitrophenyl carbonate) ($PEG_{3.4k}$-$(pNP)_2$), triethylamine (TEA), β-galactosidase (product number G0413), protease inhibitor cocktail (PIC), phorbol myristate acetate (PMA), and conduritol B epoxide (CBE) were purchased from Sigma-Aldrich (St. Louis MO, USA). *p*-Nitrophenylcarbonyl-(polyethylene glycol-3400)-dioleylphosphatidylethanolamine (pNP-$PEG_{3.4k}$-DOPE) was prepared and purified according to the method in ref 19. Bio-Gel A-1.5 m sorbent was purchased from Bio-Rad (Hercules CA, USA). Lysosome Enrichment Kit, Coomassie-based protein assay kit, and DyLight 350-conjugated goat antimouse IgG were obtained from Pierce Biotechnology (Rockford IL, USA). Fluorescein di-β-D-galactopyranoside (FDG), dodecanoylamino fluorescein di-β-D-galactopyranoside (C_{12}FDG), and 5-(pentafluorobenzoylamino) fluorescein di-β-D-glucopyranoside (PFB-FDGlu) were purchased from Invitrogen/Molecular Probes, Inc. (Eugene OR, USA). Mouse monoclonal (H4B4) anti-lysosome-associated membrane protein antibody (anti-Lamp2) was purchased from Abcam (Cambridge MA, USA). Fluoromount-G mounting medium was purchased from SouthernBiotech (Birmingham AL, USA). Cell cultures of human epithelial cervical cancer CCL-2 (HeLa), mouse melanoma CRL-6475 (B16(F10)), mouse Lewis lung carcinoma CRL-1642 (LLC), mouse embryo fibroblasts CRL-1658 (NIH/3T3), rat myocardium myoblasts CRL-1446 (H9c2), and human monocytes (U-937[20]) were purchased from the American Type Culture Collection (ATCC, Manassas VA, USA). Cell culture media and supplements were from CellGro (Kansas City MO, USA). All other chemicals and buffer components were analytical-grade preparations. Distilled and deionized water was used in all experiments.

Conjugates of Neutral Red and Rhodamine B. The studied cnojugates and paths of their synthesis are shown in Figure 1. Substances were synthesized from commercially available Neutral Red, rhodamine B, and rhodamine B isothiocyanate, except for rhodamine B octadecyl ester (R18, as ligand **III**), which also was commercially available.

Synthetic Procedures. *Synthesis of Octadecanoic Acid (8-(Dimethylamino)-3-methylphenazin-2-yl)amide (**I**, NRstear).* **I** was made starting with the Neutral Red acid−base indicator (NR), according to procedure developed by Suzuki et al.[21] Neutral Red (120 mg) was dissolved in distilled water, and 0.1 M aqueous NaOH was added. The desalted Neutral Red was extracted with chloroform. The organic fraction was dried over Na_2SO_4 and evaporated, resulting in 68.6 mg of free-base form of Neutral Red. The intermediate product and 75 mg of triethylamine (TEA, 7.4 mmol) were dissolved together in 22.5 mL of tetrahydrofuran (THF) and the mixture was stirred for 1 h at room temperature. Stearoyl chloride (128 mg, 0.42 μmol) of was dissolved with 0.75 mL of THF and added to the reaction mixture, which was stirred for 24 h at room temperature. The THF was evaporated and the residue obtained was dissolved in 20 mL of chloroform. The chloroform phase was washed twice with 20 mL of 1 N HCl and 1 N NaOH, and once with the same deionized water, dried over Na_2SO_4, and evaporated. The residue was purified by silica gel column chromatography with *n*-hexane−ethyl acetate (1:3, R_f = 0.83) as the eluent to yield the final product (18.4 mg of purified product, yield 13%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 0.83−0.91 (m, 3H, −CH_3), 1.22−1.43 (m, 30H, −CH_2−), 1.53−1.61 (m, 2H, −CH_2CH_2CO−), 1.75−1.84 (m, 3H, Ar−CH_3), 2.17 (s, 1H, Ar−N*H*−Ar), 3.19 (s, 6H, Ar═$N^+(CH_3)_2$), 3.96−4.00 (m, 1H, Ar−*H*), 4.19−4.24 (t, *J* = 6.05 Hz), 4.64 (s, 1H, Ar-*H*), 4.72 (s, 1H, Ar−*H*), 5.04 (s, 1H, Ar−*H*), 7.06 (d, *J* = 7.06 Hz, 1H, Ar−*H*), 7.39 (s, 1H, Ar−*H*), 7.53 (dd, *J* = 9.64 Hz, 1H, Ar−*H*), 7.70, 7.90 (s, 1H, Ar−*H*), 7.98 (d, *J* = 9.61 Hz, 1H, Ar−*H*).

*Synthesis of DOPE-$PEG_{3.4K}$-carbonyl 8-(Dimethylamino)-3-methylphenazin-2-yl)amide (**II**, NRPEG).* **II** was made from NR by reaction with *p*-nitrophenylcarbonyl-(polyethylene glycol-3400)-dioleylphosphatidylethanolamine (pNP-$PEG_{3.4k}$-DOPE), according to ref 19 using less basic conditions (pH 7.5) to avoid precipitation of NR that occurs at pH above 8.0. pNP-$PEG_{3.4k}$-DOPE (6 mg, 1.37 μmol) of was dissolved in 2 mL of phosphate buffered saline with pH adjusted to 7.5 containing a 3-fold excess of NR (1.2 mg; 4.15 μmol). After fully dissolving the pNP-$PEG_{3.4k}$-DOPE, the resultant mixture was sparged with nitrogen and stirred for 24 h at room temperature. The excess of NR was separated by dialysis against deionized water using Spectra/Por cellulose ester dialysis membranes (Spectrum Laboratories, Rancho Domingues, CA, USA) with a molecular weight cutoff size of 2000 Da. Product was purified from the nonconjugated DOPE-$PEG_{3.4k}$-COOH by silica gel column chromatography with chloroform−methanol (4:1, R_f = 0.65) as the eluent to yield the final product (yield of purified product 2.3 mg, 38%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.87−0.89 (m, 6H, −CH_3 of fatty acid chains), 1.00−1.50 (m, 44H, −CH_2− of fatty acid chains), 1.5−1.8 (s, 4H, −COO−CH_2−CH_2−), 1.90−2.14 (m, 8H, −CH_2−CH_2−CH═), 2.20−2.50 (m, 4H, CH_2−CH_2−COO− of fatty acid chains), 3.18 (s, 6H, Ar═$N^+(CH_3)_2$), 3.20−3.50 (m, 2H, −CH_2−CH_2−NH_2CO), 3.53−3.78 (m, PEG chains), 3.78−3.85 (m, 2H, CH_2−CH_2−O−), 4.20−4.48 (m, 2H, −O−CH_2−CH−(CH_2−/O−), 5.07−5.18 (m, 1H, −O−C*H*(CH_2−)$_2$), 5.19−5.41 (m, 4H, −CH═C*H*−), 6.90−8.00 (m, 5H, Ar−*H*), 8.06−8.32 (m, 1H, Ar−N*H*−CO).

*Synthesis of Rhodamine B DSPE-PEG_{2k}-amide (**IV**, RamPEG).* **IV** was made from rhodamine B by amidification with

dx.doi.org/10.1021/bc200336j |*Bioconjugate Chem.* 2011, 22, 2271–2282

DSPE-PEG_{2k}-amide. Rhodamine B (7.7 mg, 16.1 μmol) was dissolved in 2 mL of dimethylformamide (DMF). Thionylchloride (2.0 mg, 16.2 μmol; used as catalyst) was added to the rhodamine B and the mixture was stirred at 55 °C for 40 min. DSPE-PEG_{2k}-amine (15 mg, 5.37 μmol) was added dropwise to the stirred solution of activated rhodamine B, and the resulting mixture was stirred for additional 7 h at 70 °C under a reverse condenser. The resulting mixture was diluted with deionized water 1:5, and the nonreacted rhodamine B was separated by dialysis against deionized water using Spectra/Por cellulose ester dialysis membranes with cutoff size of 2000 Da. Product was purified from the nonconjugated DSPE-PEG_{2k}-amine by silica gel column chromatography with chloroform−methanol (4:1, R_f = 0.62) as the eluent to yield the final product (yield of purified product 2.0 mg, 11%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.87−0.89 (t, 6H, $-CH_3$ of fatty acid chains), 1.15−1.70 (m, 60H, $-CH_2-$ of fatty acid chains, + 6H, Ar−N-$(CH_2CH_3)_2$), 2.22−2.44 (q, 4H, CH_2-CH_2-COO- of fatty acid chains), 3.18−3.42 (m, 2H, $OPO_3-CH_2-CH_2-NH_2CO-Ar{=}N^+(CH_3)_2$), 3.20−3.50 (m, 2H, $-CH_2-CH_2-NH_2CO-$), 3.43−4.50 (m, $-CH_2-CH_2-O-$ of PEG chains), 5.07−5.18 (m, 1H, $-O-CH(CH_2-)_2$), 6.78 (m, 2H, Ar−*H*), 7.00 (m, 2H, $Ar-CONH_2-CH_2$), 7.53 (td, 1H, Ar−*H*), 8.02 (m, 1H, Ar−*H*).

*Synthesis of Rhodamine B 2-(DOPE-$PEG_{3.4k}$-carbonyl)-aminoethyl Ester (**V**, RestPEG).* **V** was synthesized starting with the rhodamine B 2-aminoethyl ester, synthesized from rhodamine B as described by Derkacheva et al.[22] and generously provided by the authors. Rhodamine B 2-aminoethyl ester (2.6 mg, 4.6 μmol) was dissolved in 0.5 mL of methanol and activated by adding 0.47 mg (4.6 μmol) of TEA. pNP-$PEG_{3.4k}$-DOPE (6 mg, 1.37 μmol) was dissolved in an activated rhodamine B 2-aminoethyl ester solution. The resultant mixture was sparged with nitrogen and stirred for 24 h at room temperature. The excess of rhodamine B 2-aminoethyl ester was separated by dialysis against deionized water using Spectra/Por cellulose ester dialysis membranes with a cutoff size of 2000 Da. Product was purified from the nonconjugated DOPE-$PEG_{3.4k}$-COOH by silica gel column chromatography with chloroform−methanol (4:1, R_f = 0.52) as the eluent to yield the final product (yield of purified product 4.0 mg, 62%). ^{1}H NMR ($CDCl_3$, 400 MHz) δ 0.84−0.91 (m, 6H, $-CH_3$ of fatty acids), 1.09−1.20 (m, 6H, Ar−$N(CH_2CH_3)_2$), 1.23−1.37 (m, 32H, $-CH_2-$ of fatty acids), 1.40−1.43 (m, 6H, $Ar{=}N^+(CH_2CH_3)_2$), 1.54−1.62, 1.66−1.84 (m, 4H, $-CH_2-CH_2-COO-$), 1.97−2.04 (m, 8H, $-CH_2-CH{=}CH-$), 2.24−2.31 (m, 6H, $-CH_2-CO-$), 3.30−3.38 (m, 2H, $-CH_2-NH-COO-$), 3.44−3.48 (m, 4H, Ar−$N(CH_2-CH_3)_2$), 3.54 (s, 2H, $-CH_2-NH-CO-$), 3.58−3.84 (m, PEG chains), 3.92−4.00, 4.10−4.17 (m, 4H, $-PO_4-CH_2-$), 4.18−4.22 (m, 2H, $-CH_2-O-CO-$), 4.36−4.42 (m, 4H, $-O-CH(CH_2-O-)_2$), 5.18−5.23 (m, 2H, Ar−*H* and $-O-CH(CH_2-O-)_2$), 5.29−5.38 (m, 4H, $-CH{=}CH-$ of fatty acids), 5.84−5.90 (s, 1H, Ar−*H*), 6.80−6.93 (m, 1H, Ar−*H*), 7.04−7.20 (m, 2H, Ar−*H*), 7.27−7.34 (m, 1H, Ar−*H*), 8.33 (dd, *J* = 27.89 Hz, 1H, Ar−*H*).

*Synthesis of 6-(3-(DSPE-PEG_{2k})-thioureido) Rhodamine B (**VI**, RtuPEG).* **VI** was made starting with a rhodamine B isothiocyanate (mix of isomers, from Sigma). Rhodamine B isothiocyanate (7.7 mg, 16.1 μmol) was dissolved in 1 mL of methanol, and the solution was used to dissolve 15 mg (5.38 μmol) of DSPE-PEG_{2k}-amine; the resultant mixture was sparged with nitrogen and stirred for 48 h at room temperature. After the reaction, the excess of Rhodamine B isothiocyanate was separated by dialysis against deionized water using Spectra/Por cellulose ester dialysis membranes with a cutoff size of 2000 Da. Product was purified from the nonconjugated DSPE-PEG_{2k}-amine by silica gel column chromatography with chloroform−methanol (4:1, R_f = 0.56) as the eluent to yield the final product (yield of purified product 5.8 mg, 33%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 0.77−0.99 (m, 6H, $-CH_3$ of fatty acids), 1.03−1.51 (m, 6H, Ar−$N(CH_2CH_3)_2$), 1.57−1.72 (m, 4H, $-CH_2COO-$ of fatty acids), 2.01, 2.28−2.39 (m, 4H, $-CH_2COO-$ of fatty acids), 3.21−3.35 (m, 2H, $-CH_2-CH_2-NHCOO-$) 3.41−3.45 (m, 4H, Ar−$N(CH_2CH_3)_2$), 3.50−4.25 (m, PEG chains), 5.00−5.18 (m,1H, Ar−*H*), 6.23−6.26 (dd, *J* = 6.26 Hz, 1H, Ar−*H*), 6.60, 6.80−6.94 (m, 1H, Ar−*H*), 7.26 (m, 1H, Ar−*H*), 7.51−7.56 (s, 1H, $-CH_2-NH-CS-NH-$), 7.69−7.74 (m, 1H, Ar−*H*), 7.81−7.87 (d, *J* = 7.83 Hz, 1H, Ar−*H*).

Preparation of Liposomal Formulations. Plain and ligand-modified FD-loaded liposomes were obtained from lipid films prepared by evaporating the solvent from mixtures of chloroform solutions of egg phosphatidylcholine (ePC) and cholesterol (7:3 molar ratio) in chloroform,[19] optionally supplemented with respective ligands (1 mol %) in ethanol or chloroform. After removing the solvent on a rotary evaporator followed by freeze−drying on a Freeze-Dry System Freezone 4.5 (Labconco, Kansas City, MO), films were redissolved in chloroform and re-dried. The films were hydrated by vigorous vortexing with phosphate-buffered saline (PBS: 137 mM NaCl, 8 mM Na_2HPO_4, 2.7 mM KCl, 1.5 mM KH_2PO_4, pH 7.4) or PBS supplemented with FD (molecular weight 4400, 45 mg/mL) to produce a total lipid content of 10 mg/mL. The hydrated lipid films were extruded 21 times through Nuclepore polycarbonate membranes with 200 nm pore size (Whatman, Clifton, NJ) using an Avanti Mini-Extruder device (Avanti Polar Lipids, Alabaster, AL). Liposomes were separated from non-incorporated FD by gel-filtration on a BioGel 1.5 M column (0.7 × 24 cm). Final lipid content in the liposomal fraction was calculated from the ratio of volumes of loaded formulation and the eluted fraction. Effective inclusion of FD into liposomes was evaluated using the BioTek Synergy HT microplate reader (BioTek, Winooski, VT) by measuring fluorescence (ex/em: 485/528 nm) of liposomes diluted 1/100 with PBS (pH 7.4) supplied with 0.2% Triton X-100 (to avoid a possible FRET effect), and calculating FD concentration according to a preliminary calibration made under the same conditions, with subsequent normalization to total lipid content.

Alternatively, for the evaluation of lysosomal uptake of the liposomal load by flow cytometry, both plain and ligand-modified liposomes were produced with a load of C_{12}FDG, a 12-carbon lipophilic variant of fluorescein di-β-D-galactopyranoside (FDG).[23] C_{12}FDG solubilized in DMSO was added to a mixture of ePC, Chol, and ligand dissolved in chloroform, at 1.5% molar to total lipids. After evaporation of the solvents, the lipid film was redissolved in chloroform. After a second chloroform evaporation and freeze−drying of the film, C_{12}FDG-loaded liposomes were prepared by hydration of the lipid film in PBS with subsequent extrusion and separation from non-incorporated ligands and C_{12}FDG as described above. To estimate C_{12}FDG loading, C_{12}FDG-liposomes were resuspended in PBS at 150 μg/mL and incubated with or without recombinant β-galactosidase (0.635 μg/mL) for 24 h at 37 °C. After the liposome dissolution with 0.2% Triton X-100 (to avoid a possible FRET effect), the fluorescent intensity of the C_{12}-fluorescein produced by enzymatic hydrolysis of C_{12}FDG was measured on a BioTek Synergy HT microplate reader (ex/em: 485/528 nm) and normalized for lipid content.

Characterization of Liposomes. Liposome size distribution was determined by dynamic light scattering using a Coulter N4MD Submicrometer Particle Size Analyzer (Beckman-Coulter, Fullerton, CA). Zeta-potential of liposomal preparations was measured at 25 °C in 0.1 mM KCl solution (diluted to a lipid content of 0.2−0.3 μg/mL) using the Zeta-Plus Instrument (Brookhaven Instruments, Holtsville, NY).

Cell Cultures. The fluorescent microscopy and subcellular fractionation studies were done on HeLa cells, used for experiments up to passage 16. For the cell experiments, HeLa cells were grown at 37 °C at 5% CO_2 and 95% humidity in Dulbecco Modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM glutamine. To reseed the cell cultures or harvest them for subcellular fractionation or flow cytometry studies, cells were detached by trypsinization with 0.5% trypsin in PBS containing 0.025% EDTA. B16(F10), LLC, NIH/3T3, and H9c2 cells were grown and treated according to the same general protocol.

The U-937 monocytes, that were used for modeling the phenotype of lysosomal enzyme deficiency disorder, were grown in flasks suspended in RPMI-1640 medium supplemented with 10% FBS, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mM glutamine. To induce the needed phenotype, the cells were first seeded in 6-well plates 5×10^6 cells per well in complete RPMI-1640 and cultured for 48 h in the presence of 10nM phorbol myristate acetate (PMA; Sigma-Aldrich).[24] The mature attached macrophages were washed twice with the sterile PBS and cultured for an additional 72 h in complete RPMI-1640, supplied with 200 μM of conduritol B epoxide (CBE; Sigma-Aldrich).[25,26] To harvest the macrophages for flow cytometry studies after the incubation with liposomes, the cells were detached using 4 mg/mL lidocaine in PBS containing 0.025% EDTA.

Lysosomal β-Glucocerebrosidase Enzymatic Activity Assay. The efficiency and stability of the induction of the lysosomal enzyme deficiency phenotype in U-937 cells were evaluated by the residual enzymatic activity of the lysosomal β-glucocrebrosidase after the treatment of the cells with PMA and CBE immediately, as well as after different recovery times after the removal of the CBE-containing medium replaced by the fresh complete RPMI-1640 medium. For this evaluation, the cells were seeded and subsequently treated with PMA and CBE as described above. At specific time points after removal of the CBE, the cells were detached using lidocaine and EDTA, dispersed in 300 μL of PBS (pH 7.4), supplemented with 50 μM of specific β-glucocerebrosidase substrate, 5-(pentafluorobenzoylamino) fluorescein di-β-D-glucopyranoside (PFB-FDGlu), and incubated for 1 h at 37 °C. Residual enzymatic activity, resulting in the formation of the fluorescent fluorescein derivative, was evaluated from the intensity of the green fluorescence determined at the emission wavelength of 520 nm (channel FL-1) by flow cytometry, with macrophages not treated with the CBE as a control.

Interaction of Liposomes with Cells *in Vitro*. Cells grown to the needed extent of confluence were incubated with liposomes added at amounts calculated to provide the same FD or C_{12}FDG load to cells for every liposomal formulation, in their respective serum-free media for 4 h, then washed twice with medium to remove nonbound liposomes and used for studies. When required, cells treated with liposomes for 4 h were washed twice with fresh medium to remove nonbound liposomes and incubated for an additional chase period of 20 h at 37 °C in 5% CO_2 in complete liposome-free medium (denoted further in the text as 4 + 20 h incubation).

Immunofluorescence Microscopy. Intracellular trafficking and localization of FD-loaded ligand-modified liposomes were preliminarily tested using a fluorescent microscope Nikon Eclipse E400 (Japan) equipped with a 6 V-20W halogen lamp, filter blocks for blue (EX/DM/BA 330−380/400/435 nm), green (465−495/505/515−565), and red (528−553/565/600−600) spectral channels and 100× oil-immersion objective. After the initial evaluation, the samples obtained by incubation of cells with liposomes that provided better colocalization with lysosomes were re-evaluated using a Zeiss LSM 700 upright confocal microscope (Thornwood, NY) equipped with a 63×, 1.4-numerical aperture plan-apochromat oil-immersion objective. HeLa cells were grown on microscope coverslips in 6-well plates seeded in complete DMEM medium at 10^4 cells per well. When cells reached 40−50% confluence, plain and ligand-modified liposomes were added to cells in amounts providing an equal FD load for all formulations with an average concentration of total lipids 50 μg/mL and incubated as described. After incubation, cells were washed with PBS and fixed with 4% paraformaldehyde in PBS (pH 7.4) for 15 min at room temperature (RT), followed by a PBS wash, quenching with $NaBH_4$ in PBS for 5 min, and another PBS wash. The cells were then permeabilized by incubation with 0.2% saponin and 1% BSA in PBS for 10 min at RT, washed three times with a blocking solution (1% BSA in PBS, pH 7.4), and kept for 30 min in the same buffer. The cells were stained with the mouse antihuman Lamp2 mAb diluted with blocking solution (1:50) for 60 min at RT, and washed five times with the blocking solution. Visualization was achieved by cell incubation with DyLight 350-conjugated goat antimouse IgG (1:100 dilution) for 60 min at RT followed with five washes with the blocking solution. Individual coverslips were mounted cell-side down onto fresh glass slides with fluorescence-free glycerol-based mounting medium (Fluoromount-G; Southern Biotechnology Associates, Inc.) and studied under bright light and under epifluorescence with UV, Rhodamine/TRITC, and Fluorescein/FITC filters. Co-localization of liposomes and lysosomal markers was characterized for individual cells (N = 8 to 20 for different liposomal formulations) by Pearson's correlation coefficient (PCC) and Manders' overlap coefficient (MOC),[27] calculated using *ImageJ* 1.42 software (National Institutes of Health, Bethesda, MD) with MBF bundle of plug-ins (McMaster University, Hamilton, ON, Canada).

Evaluation of Lysosomal Delivery by Subcellular Fractionation. Hela cells were grown to 90% confluence under the above-described conditions and incubated with liposomes added at amounts calculated to provide the same FD load on cells for all formulations in complete DMEM for 4 + 20 h.

In order to isolate the lysosome-enriched fractions, the cells ($(\sim 0.7-1.0) \times 10^8$ cells per sample) were collected by trypsinization and washed with ice-cold PBS. The cell pellet was resuspended in 1 mL of the reagent A of the Lysosome Enrichment Kit (Pierce Biotechnology, Rockford IL, USA) complemented with 1% (v/v) of a protease inhibitor cocktail. After 2 min incubation on ice, the cells were lysed by sonication (20 bursts, 3 s each, at 6 W). The cell lysate was treated with 1 mL of the reagent B of the same kit. The mixture was gently shaken several times and centrifuged at 500 g for 10 min at 4 °C to pellet nuclei and any remaining intact cells. The postnuclear supernatant was then adjusted with OptiPrep gradient medium

Table 1. Composition and Properties of Plain and Ligand-Modified Liposomal Formulations

	composition (mol %)

(Pierce Biotechnology; 60% v/v solution of Iodixanol) to 15% of Iodixanol, loaded onto the top of discontinuous density gradient with the following steps from top to bottom: 17%, 20%, 23%, 27%, and 30% of Iodixanol (by respective dilutions of OptiPrep), and subjected to ultracentrifugation at 145 000 *g* for 2 h at 4 °C using Beckman Coulter Optima XL ultracentrifuge equipped with SW41Ti swinging bucket rotor (Beckman Coulter, Krefeld, Germany). A total of 5 resultant fractions were collected from the top of the tube, diluted with PBS to the equal total volume of 6 mL, pelleted at 30 000 *g* for 30 min at 4 °C using Beckman Coulter Optima TLX Tabletop equipped with TLA-100.3 fixed angle rotor (Beckman Coulter, Krefeld, Germany), and then resuspended in equal volumes of cold PBS. All collected fractions were evaluated for lysosomal β-galactosidase activity and analyzed for protein, FD, and ligand content.

Protein concentration in each fraction was determined using a Coomassie protein assay in triplicate by measuring absorption at 595 nm using BioTek Synergy HT microplate reader (BioTek Instruments, Winooski, VT, USA). FD and ligand content in fractions were determined by measuring the fluorescence intensity of equal volumes of each fraction in triplicate, using the same microplate reader at 485/528 nm and 530−590 nm (ex/em), respectively. The quantity of FD in each subcellular fraction was calculated using a calibration by standard FD solutions in PBS.

The lysosomal β-galactosidase activity was evaluated by dispersing 50 μL of each fraction in 150 μL of PBS supplemented with 15 μM of fluorescein di-β-D-galactopyranoside (FDG) and incubating the mix for 18 h at 37 °C. The intensity of fluorescence of the resultant product was measured using a microplate reader at 485/528 nm.

Measured and calculated values for each ligand, FD, and relative β-galactosidase activity were normalized to the protein content, and their fractional distribution was calculated as a percent of the normalized value in each fraction to the total sum of all fractions.

Flow Cytometry Analysis. The binding of plain and rhodamine-based ligand-modified liposomes to cultured cells was evaluated by flow cytometry. Control (untreated) HeLa cells or cells treated with liposomes were washed twice with DMEM and trypsinized. The harvested cells were washed twice with PBS, resuspended in 1 mL of ice-cold PBS, and their fluorescence determined using a fluorescence-activated cell sorter (FACS). Data acquisition was performed on a Becton Dickinson FACScan (Becton Dickinson, San Jose, CA), and the data were analyzed using *CellQuest* software (Becton Dickinson). The green and red fluorescence were determined respectively at the emission wavelengths of 520 and 580 nm (channels FL-1 and FL-2). To eliminate possible overlap of rhodamine fluorescence with channel FL-1, the compensation between FL-1 and FL-2 channels was applied using the cells incubated with nonloaded ligand-modified liposomes as an additional control.

The data were tested for statistical significance using the Student's paired *t* test. *P*-values were considered significant at $p \leq 0.05$.

RESULTS

All liposomal formulations were characterized for size, zeta-potential, and FD or relative C_{12}FDG content (see Table 1).

In all cellular studies *in vitro*, liposomes were added for incubation with cells at dilutions providing the same FD or C_{12}FDG load to cells for all liposomal formulations.

Intracellular Localization of Ligand-Modified Liposomes. The lysosomotropic ability of ligands was initially tested by fluorescent microscopy of HeLa cells incubated with plain or ligand-modified FD-loaded liposomes, fixed and treated as described in Methods.

Both derivatives of Neutral Red showed low or no colocalization of liposomal FD with antibody-marked lysosomes (PCC/MOC for Lip-NRstear-FD and Lip-NRPEG-FD liposomes were, respectively, −0.032/0.007 and 0.403/0.567) and were excluded from further study, while samples of cells incubated with rhodamine B derivatives showed elevated colocalization of liposomal load in comparison to plain Lip-FD liposomes under the same conditions and were reanalyzed using the more accurate method of confocal microscopy.

Figures 2 and 3 show representative confocal fluorescence micrographs of HeLa cells incubated with plain or ligand-modified

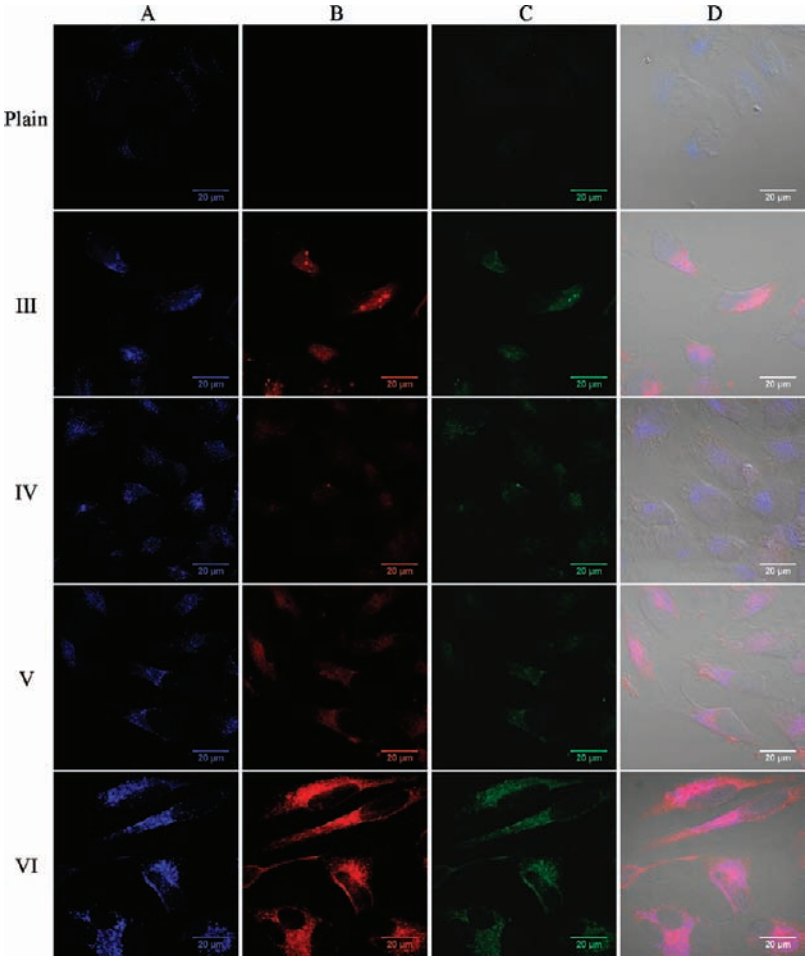

Figure 2. Confocal microscopy images of the intracellular distribution of FD-loaded liposomes modified with rhodamine B derivatives (incubation 4 h). Rows: "Plain" — cells incubated with plain Lip-FD liposomes (as control), rows III to VI — cells incubated, respectively, with Lip-R18-FD, Lip-RamPEG-FD, Lip-RestPEG-FD, and Lip-RtuPEG-FD liposomes. Columns: A (blue channel) — fluorescence of anti-Lamp2 antibody-stained lysosomes; B (red channel) — fluorescence of RhB-derivative modified liposomes; cells incubated with plain liposomes were not observed under this regime, respective position Plain-B is filled with a blank panel; C (green channel) — fluorescence of FITC-dextran; D — Overlay of A, B, and C images with their respective DIC image. Scale bar = 20 μm.

FD-loaded liposomes for 4 h, without and with an additional chase period of 20 h.

Estimation of colocalization of ligand-modified liposomes with lysosome-specific marker (Table 2) after 4 h of incubation showed that liposomes with rhodamine B derivatives provided a much higher rate of lysosomal localization in comparison to such for plain FD-loaded liposomes (MOP = 0.410; PCC = 0.619).

An additional chase period of 20 h after the 4 h incubation of cells with liposomes generally decreased the colocalization of FITC-dextran with anti-Lamp2 mAb-labeled lysosomes for both plain and ligand-modified liposomes. However, lysosomal colocalization of FD delivered by rhodamine-conjugated liposomes remained significantly higher than for plain Lip-FD liposomes (Figure 3, Table 2).

Evaluation of Intracellular Distribution of FD-Loaded Ligand-Modified Liposomes Incubated with Cultured HeLa Cells, by Subcellular Fractionation. To study the organelle distribution of ligand-modified liposomes and their FD load by subcellular fractionation, the cultured HeLa cells were incubated for 4 + 20 h with liposomes diluted to provide the same FD load on cells, originally chosen to keep the average liposomal lipid load of 50 μg/mL and then kept at the same level (9.8 μg/mL).

As shown by β-galactosidase activity assay, about 60% of the lysosomal β-galactosidase was concentrated in fraction 1 with a minor part (about 20%) in fraction 2 and negligible amounts in other fractions.

The fractional distribution of each ligand was calculated as a percent of the fluorescence measured at 530/590 nm (ex/em) for each fraction and normalized to the protein content to the total sum of normalized fluorescent intensities of fractions 1 to 5. Results shown in Figure 4A demonstrate that most of all rhodamine B-based liposome-attached ligands accumulated in the lysosome-enriched fractions (about 50% in fraction 1 or 60−70% in fractions 1 + 2).

The fractional distribution of absolute protein-normalized content of FD is demonstrated in Figure 4B. The absolute accumulation of FD in the first fraction compared with the value for the same fraction from fractionation of cells incubated with plain FD-loaded liposomes showed statistical significant difference for Lip-R18-FD (p = 0.05) and Lip-RtuPEG-FD (p = 0.005), with more moderate enhancement for Lip-RamPEG-FD

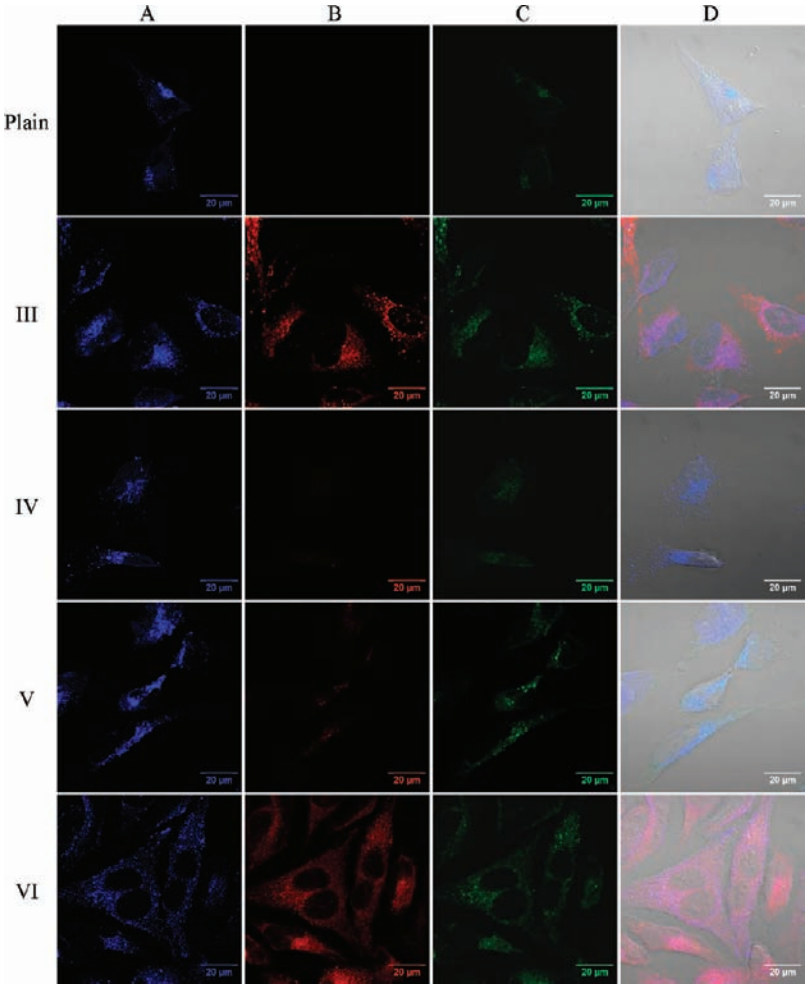

Figure 3. Confocal microscopy images of the intracellular distribution of FD-loaded liposomes modified with rhodamine B derivatives (incubation 4 + 20 h). Rows: "Plain" — cells incubated with plain Lip-FD liposomes (as control), rows III to VI — cells incubated respectively with Lip-R18-FD, Lip-RamPEG-FD, Lip-RestPEG-FD, and Lip-RtuPEG-FD liposomes. Columns: A (blue channel) — fluorescence of anti-Lamp2 antibody-stained lysosomes; B (red channel) — fluorescence of RhB-derivative modified liposomes; cells incubated with plain liposomes were not observed under this regime, respective position Plain-B is filled with blank panel; C (green channel) — fluorescence of FITC-dextran; D — Overlay of A, B, and C images with their respective DIC image. Scale bar = 20 μm.

Table 2. Averaged Coefficients of Colocalization of Ligand-Modified Liposomes and Liposomal FD Load with Anti-Lamp2 mAb Labeled Lysosomes, Determined from Micrographs Obtained by Confocal Immunofluorescent Microscopy[a]

	incubation 4 h				incubation 4 + 20 h

Lip-RtuPEG-FD (VI)	0.816	0.877	0.862***	0.902***	0.695	0.805	0.632**	0.767**

[a] PCC — Pearson's correlation coefficient, MOC — Mander's overlap coefficient. Values are presented as mean for N cells (N = 8 to 20 for different liposomal formulations). $^{*}p < 0.05$. $^{**}p < 0.01$. $^{***}p < 0.001$.

and absence of FD delivery enhancement for Lip-RestPEG-FD liposomes (Table 3). The observed increase of FD fluorescence was not determined by a possible overlap of RhB and FITC spectral channels as was shown previously for liposomes modified with rhodamine B octadecyl ester[18] by comparing the green channel fluorescence of fractions obtained from nontreated cells

or cells incubated with ligand-modified liposomes without a FD load.

Thus, liposomes modified with R18, RtuPEG, and RamPEG which demonstrated enhancement of lysosomal delivery of their FD load were chosen for further studies.

Flow Cytometric Evaluation of General Uptake of Ligand-Modified Liposomes by Cell. The general interaction of cells with FD-loaded liposomes modified with rhodamine-based ligands (R18, RtuPEG, and RamPEG) was evaluated with tumor (HeLa and B16(F10)) and normal (NIH/3T3 and H9c2) cell lines using the flow cytometry method.

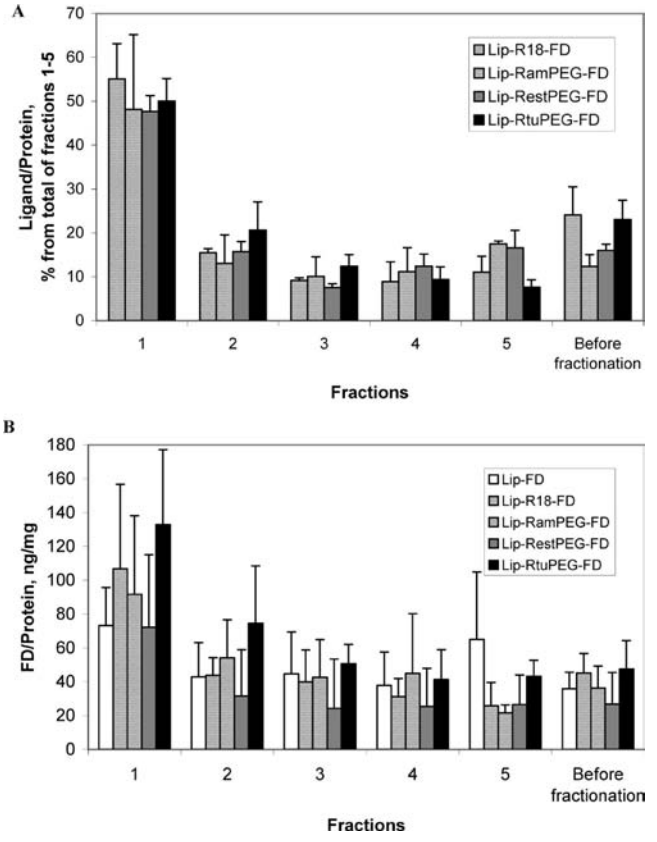

Figure 4. Relative fractional distribution of protein-normalized fluorescence of rhodamine B derivatives (A) and fractional distribution of protein-normalized FD content (B) in fractionated HeLa cells incubated with different ligand-modified liposomes for 4 + 20 h (number of experiments $n = 6$).

Liposomes were added to cells in amounts calculated to provide the same total FD content in cell medium (originally chosen to have average lipid load on cells 100 μg/mL, then kept the same) of 36.44 μg/mL. After incubation with liposomes for 4 h, cells were harvested as described in Methods and used for measurements. Since used cell lines had different autofluorescence, results were presented as relative FL-1 fluorescence values normalized to the value of FL1 for nontreated cells.

Results are shown in Table 4. In most cases, cells incubated with FD-loaded liposomes surface-modified with rhodamine B derivative ligands showed a significant increase of FL-1 channel fluorescence in comparison to plain FD-loaded liposomes.

Evaluation of Lysosomal Targeting by Flow Cytometry Using Liposomes Loaded with C_{12}FDG. To additionally confirm and compare the ability of liposomes modified with rhodamine B derivatives to specifically target lysosomes, we evaluated their specific lysosomal targeting by flow cytometric analysis of live cells using liposomes loaded with C_{12}FDG, a lipophilic substrate for the lysosomal β-galactosidase, as was proposed in ref 18, assuming FL1 fluorescence will be emitted only by product of its hydrolysis by lysosomal β-galactosidase (C_{12}-fluorescein).

The plain and ligand-modified liposomal formulations were prepared, loaded with C_{12}FDG and characterized as described in Methods. Despite the introduction of C_{12}FDG into the lipid bilayer of the liposomes, its effective load (evaluated by β-galactosidase cleavage of C_{12}FDG localized on the surface of the intact liposomes) varied between plain and ligand-modified liposomes. Because of this, we studied the lysosomal uptake of ligand-modified liposomes with intact cultured cells, adding the liposomal formulations to cells in amounts that provided the same total load of C_{12}FDG as plain C_{12}FDG-loaded liposomes at concentration of 200 μg/mL by total lipids.

The lysosomal uptake was evaluated on a number of cultured tumor and normal cell lines including HeLa, B16(F10) melanoma, LLC carcinoma, NIH/3T3 fibroblasts, and H9c2 myoblasts.

Considering the general purpose of the study, the enhancement of the lysosomal load was also specially evaluated on U-937 monocytes matured to macrophages with induced phenotype of lysosomal enzymatic deficiency disorder.[24−26] The acquisition of the lysosomal enzyme deficiency phenotype by the cells was confirmed by evaluation of the residual lysosomal β-glucocerebrosidase enzymatic activity (see Methods) immediately as well as 24, 48, and 72 h after the removal of the CBE-containing medium. It was observed that, immediately after the removal of the CBE, the cells retained about 35% of the β-glucocrebrosidase activity of the control (macrophages without CBE treatment).

Table 3. Characterization or Intracellular Distribution of Liposomal FD Delivered by Different Ligand-Modified Liposomes

liposomal formulation	relative content of FD in fraction 1 (% from total sum of fractions 1 to 5)	content of FD in fraction 1 (ng/mg proteins)	content of FD in loaded lysate, (ng/mg proteins)	paired t test of FD content in fraction 1 against the fraction 1 of sample incubated with plain FD-loaded liposomes (P-value)	ratio of FD contents in fraction 1 and loaded nuclei-free lysate

	Paired *t* test of Averaged Normalized Lysosomal Uptake of C_{12}FDG Provided by Ligand-Modified Liposomes in Comparison with the Value for Plain Liposomes (*P*-value)					
Lip-R18-C_{12}FDG	0.013	0.024	0.00002	0.073	0.014	0.149
Lip-RamPEG-C_{12}FDG	0.017	0.38	0.001	0.001	0.020	0.0074
Lip-RtuPEG-C_{12}FDG	0.035	0.003	0.021	0.005	0.007	0.0004

[a] Due to different autofluorscence of cell lines, values of FL1 fluorescence of cells incubated with liposomes were used normalized to the respective values for nontreated cells. Number of experiments n = 3 to 6.

The enzymatic activity recovered to 47−49% of control by 24−48 h post-CBE removal and to 62% after 72 h. All experiments with flow cytometric evaluation of the lysosomal delivery of liposomal load with activated U-937 cells were performed within a short time range after induction of the lysosomal deficiency by adding the liposome-containing medium immediately after removal of CBE.

The results presented in Table 5 show that, for all tested cell lines, the cells incubated with C_{12}FDG-loaded liposomes modified with rhodamine B derivatives used demonstrated significantly increased C_{12}FITC fluorescence compared to the cells treated with the plain liposomes, for at least two out of three ligands. The extent of the enhancement of the lysosomal targeting of the model substance (and the ligand providing the best enhancement) differed among cell lines, achieving the maximum values for cells with the induced phenotype of lysosomal disorder.

DISCUSSION

In our earlier paper,[18] we demonstrated that liposomes modified with rhodamine B octadecyl ester acquire the ability to specifically target lysosomes and allow for an increased delivery of a liposome-entrapped model substance (FITC-dextran with a relatively high molecular mass of 4400 Da) to these organelles.

In the current study, we attempted to develop and study other potential lysotropic ligands based on commercially available rhodamine B and Neutral Red, routinely used for the visualization of lysosomes in live cells.[12,13] A number of liposomal formulations with a ligand-modified surface were prepared using synthesized RhB and NR derivatives and loaded with FD. Their interaction with cultured cells and the ability to deliver FD to lysosomes were investigated using fluorescent microscopy, subcellular fractionation, and flow cytometry in comparison to plain FD-loaded liposomes and previously studied liposomes modified with rhodamine B octadecyl ester.

The fluorescent microscopy studies have demonstrated that liposomes modified with RhB derivatives generally show an elevated colocalization of both the liposome-attached ligand and loaded FD with a specific lysosomal marker Lamp2 (visualized using anti-Lamp2 monoclonal antibodies), while liposomes modified with derivatives of NR show much less effect. Additional study by subcellular fractionation of cells incubated with FD-loaded liposomes modified with rhodamine B derivatives and comparison of the fluorescence of lysosome-enriched fractions

with those for the cells treated with control nonmodified liposomes confirmed the lysosome-targeting ability of three rhodamine B derivatives.

Since methods such as cell staining for microscopy or subcellular fractionation of cell lysates are considered disruptive, this tendency was checked on intact live cells of several cell lines by flow cytometry, proving both an increased general accumulation of rhodamine-modified liposomes by cells and their increased delivery into the lysosomes, thus confirming the data obtained by microscopy and subcellular fractionation methods.

The evaluation of the specific lysosomal delivery of a model drug substance by liposomes modified with rhodamine B derivatives showed the best results for the cells with an induced phenotype of a lysosomal enzyme deficiency disorder (the enhancement of the lysosomal uptake of C_{12}FDG by different rhodamine B-based conjugates in the range 35−75% in comparison to nonmodified liposomes). Still, it should be noted that the development of drug delivery systems for specific LSDs, such as Gaucher disease, GM1 and GM2 gangliosidoses, and Fabry disease, requires evaluation of the efficiency of lysosomal delivery by those systems using the respective specific cell lines and animal models.

CONCLUSION

The study has demonstrated that modification of the liposomal surface with Rhodamine B-based ligands increases the delivery of liposomal FITC-dextran to lysosomes. Liposomes modified with two of the synthesized ligands—rhodamine B DSPE-PEG_{2k}-amide and 6-(3-(DSPE-PEG_{2k})-thioureido) rhodamine B—enhance lysosomal delivery of model drug load *in vitro*, in some cases, higher than commercially available rhodamine B octadecyl ester and can be used for further investigation and potentially for development of drug forms for the treatment of the lysosomal storage disorders. The choice of the optimal rhodamine B-based ligand and the extent of the lysosomal delivery enhancement *in vitro* depend on the cell line. Still, the best results (the enhancement of the lysosomal delivery up to 75% greater in comparison to plain liposomes) has been shown for the cells with induced lysosomal enzyme deficiency phenotype.

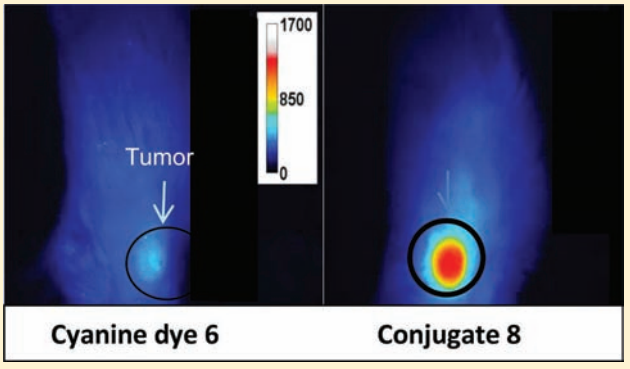
Supporting Information

ABSTRACT: Purpurinimide methyl esters, bearing variable lengths of N-substitutions, were conjugated individually to a cyanine dye with a carboxylic acid functionality. The results obtained from *in vitro* and *in vivo* studies showed a significant impact of the linkers joining the phototherapeutic and fluorescence imaging moieties. The photosensitizer−fluorophore conjugate with a PEG linker showed the highest uptake in the liver, whereas the conjugate linked with two carbon units showed excellent tumor-imaging and PDT efficacy at 24 h postinjection. Whole body imaging and biodistribution studies at variable time points portrayed enhanced fluorescent uptake of the conjugates in the tumor compared to that in the skin. Interestingly, the conjugate with the shortest linker and the one joining with two carbon units showed faster clearance from normal organs, e.g., the liver, kidney, spleen, and lung, compared to that in tumors. Both imaging and PDT efficacy of the conjugates were performed in BALB/c mice bearing Colon26 tumors. Compared to the others, the short linker conjugate showed poor tumor fluorescent properties and as a corollary does not exhibit the dual functionality of the photosensitizer−fluorophore conjugate. For this reason, it was not evaluated for *in vivo* PDT efficacy. However, in Colon26 tumor cells (*in vitro*), the short linker was highly effective. Among the conjugates with variable linkers, the rate of energy transfer from the purpurinimide moiety to the cyanine moiety increased with deceasing linker length, as examined by femtosecond laser flash photolysis measurements. No electron transfer from the purpurinimide moiety to the singlet excited state of the cyanine moiety or from the singlet excited state of the cyanine moiety to the purpurinimide moiety occurred as indicated by a comparison of transient absorption spectra with spectra of the one-electron oxidized and one-electron reduced species of the conjugate obtained by spectroelectrochemical measurements.



1. INTRODUCTION

Current treatment modalities for patients afflicted by cancer include surgery, radiation therapy, chemotherapy, and a relatively novel option called photodynamic therapy (PDT).[1−5] Surgery is used to excise abnormal growths and surrounding tissue, but the procedure is invasive and may be complicated by relapse of the cancer if not all of the tumor cells are removed. Chemotherapy employs different cytotoxic chemicals to attack or block specific cellular and molecular mechanisms that aid tumor growth. Unfortunately, patients on chemotherapeutics suffer from side effects due to adverse drug toxicities. Radiation uses ionizing energy to attack neoplastic cells, but it is nonspecific and may cause damage to surrounding healthy tissue, which can lead to the occurrence of secondary cancers. PDT uses a drug known as a photosensitizer, light, and oxygen to destroy tumors and their surrounding vasculature.

PDT has several advantages in that (i) there is no systemic, organ, or tissue toxicity, (ii) it is noninvasive, and (iii) it can be used repeatedly as a primary or adjuvant treatment.[6–9] With the current advent of imaging technologies to monitor tumor responses to treatment, we have shown that the utilization of a certain photosensitizer–cyanine dye conjugate which contains the tumor-avid photosensitizer 3-(1′-hexyloxyethyl)-pyropheophorbide-a (HPPH) for treatment and a fluorophore cyanine dye for optical imaging could be highly advantageous to treat deeply seated tumors and monitor the treatment response.[10] The ability to image real time events using fluorescence has made optical imaging an attractive modality to study cellular and molecular events[11] and to visualize events *in vivo*, especially in tumors.[12] Noninvasive in nature, optical imaging instruments are simpler and less expensive to operate and can allow precise assessment of the location and size of a tumor, providing

dx.doi.org/10.1021/bc200345p | *Bioconjugate Chem.* 2011, 22, 2283–2295

information on its invasiveness in adjacent tissue.[13,14] The work discussed herein describes the synthesis, molecular modeling, photophysical, electrochemical, tumor-imaging, and the photodynamic therapeutic potential of a series of longer wavelength photosensitizer (purpurinimides, 700 nm) joined to a cyanine dye with variable lengths of linkers. Among the near-infrared (NIR) dyes, cyanine dyes in general have shown enormous potential for optical imaging.[15−19]

2. RESULTS AND DISCUSSION

2.1. Chemistry. For the synthesis of purpurinimide-*N*-substituted cyanine dye conjugates, purpurin-18 methyl ester **1** was synthesized from chlorophyll-a by following the literature procedure, which was converted into mesopurpurin-18 methyl ester **2** by following the standard methodology.[20] Reaction of **2** with hydrazine hydrate gave N-amino mesopurpurin-18 methyl ester **3** in 50% yield.[21] By following a similar approach, **1** was individually reacted with diethyl diamine and carbamic acid to produce the corresponding N-substituted analogues **4** and **5** both with 89% yield. Reaction of these N-substituted purpurin-18 methyl esters with a cyanine dye **6** containing a carboxylic acid functionality (obtained in 80% yield by reacting commercially available IR820 with *p*-thiol-benzoic acid) gave purpurinimide−cyanine dye conjugates **7**−**9** in which two chromophores (photosensitizer and fluorophore) are joined at variable linker lengths with yields ranging from 32 to 37%. The reaction sequences for the preparation of the conjugates and the cyanine dyes are shown in Schemes 1 and 2.

Structures of the intermediates and the final products were confirmed by ^{1}H NMR and CHN/mass spectrometry (including HRMS) analysis. The purity of the final conjugates (compounds **7**−**9**) was determined by HPLC analysis.

2.2. Molecular Modeling. In order to examine the effects of linker lengths joining the two chromophores (conjugates **7**, **8**, and **9**) in photophysical, electrochemical, tumor-imaging and photodynamic efficacy, a molecular modeling study was performed. The three-dimensional model of the conjugates were built with the molecular modeling software SYBYL (Tripos Inc., St. Louis, MO) followed by the energy minimization with the PM3 semiempirical molecular orbital theory using the Spartan 02 software package (Wave function Inc., Irvine, CA). Figure 1 shows the resulting structures of the conjugates **7**, **8**, and **9** (Scheme 1) in extended conformation. The distances between the nitrogen atom in the purpurinimide ring system and the sulfur atom adjacent to the cyanine dye of the conjugates were calculated and are displayed in Figure 1. As expected, the smaller the linker length, the shorter the observed distance between two chromophores.

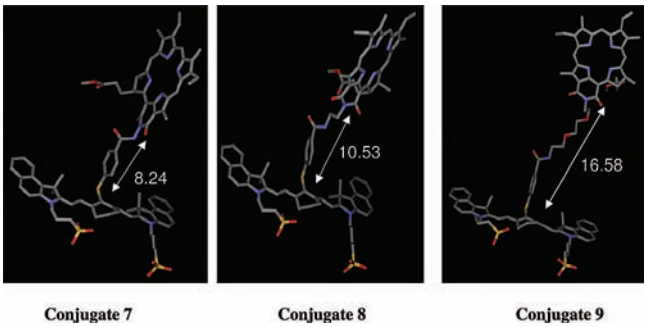

Figure 1. Three-dimensional representation of the conjugates with different lengths between the cyanine dye and the purpurinimide in extended conformation obtained from molecular modeling and energy optimization with PM3.

Since the above structures are appropriate for single molecules in gas phase, they may not be relevant to the structures of the conjugates in solution, in cells, or *in vivo* environments where physical properties and biological activities of these conjugates are examined. In order to gain some insights, the conformational flexibility of these conjugates were examined with the stochastic search module of MOE software using the MMFFs force field and charges (Chemical Computing Group, Montreal, Quebec, Canada). Again, the distance between two chromophores was measured for some of the resulting low energy conformers as shown in Figure 2.

As can be seen from the Figure 2 caption, the distances between the two chromophores remain more or less constant for conjugates **7** and **8**, while it shows a large variation for conjugate **9**. It is reasonable considering the length of the linker for these conjugates. Although the mean distances are similar between conjugates **7** and **8**, closer inspections reveal the significant difference between these conjugates. First, the standard deviation is much smaller for conjugate **7** than for **8**, reflecting the limited flexibility of **7**. Second, this limited flexibility is also the source of the limited range in the relative orientation of two chromophores for conjugate **7** as shown in Figure 2a where various low energy conformers of conjugate **7** are superimposed using the purpurinimide ring as a reference. It clearly shows that the cyanine dye and the linker can assume many different conformations but that they cannot assume a conformation that brings two chromophores close together. Thus, the purpurinimide ring remains exposed to its surroundings for this conjugate. Compared to conjugate **7**, some part of the purpurinimide ring is covered by the cyanine dye or thiophenol group in conjugate **8**, as shown in Figure 2b. Although there are a large variety of conformers for conjugate **9**, there are some conformers where a large portion of the purpurinimide ring is covered by the cyanine dye and/or thiophenol group as shown in Figure 2c. Photophysical experiments clearly indicated that intramolecular energy transfer occurred from the singlet excited state of the purpurinimide moiety to the cyanine moiety with the rate of transfer increasing with decreasing linker distance. This is an opposite trend from the linker length dependence on the *in vitro* PDT efficacy. The photophysical results are consistent with the distance dependence of energy transfer, while the conformational flexibility may explain the excellent *in vitro* PDT efficacy of conjugate **7** and the decrease of efficacy with increasing linker length. If the purpurinimide rings are not exposed to the environment, the compound may not be able to produce singlet oxygen because it cannot interact with water molecules. Alternatively, even if singlet oxygen is produced, it may not reach to the cellular target because the singlet oxygen produced may interact with the closely seated cyanine dye before it reaches the target site(s).

2.3. Photodynamics. In order to examine the photodynamics of purpurinimide, cyanine, and the conjugates, time-resolved transient absorption spectra were recorded by femtosecond laser flash photolysis in deaerated DMSO solutions as shown in Figure 3. Transient absorption bands of purpurinimide **4** observed at 500 and 530 nm taken at 2 ps after femtosecond laser excitation (Figure 3a) are assigned as the singlet excited state of **4** (^{1}**4***). The transient absorption of ^{1}**4*** decreased as the absorption band of the triplet excited state

Figure 2. (a) Various conformers for conjugate **7** with limited flexibility in the linker are superimposed using the purpurinimide ring as reference. Standard color for each atom type is used. The purpurinimide ring (shown in the left portion of this figure) is exposed to surroundings. (b) Examples of the low energy conformer for conjugate **8**. The purpurinimide moiety is shown in orange and the cyanine dye−thiophenol moiety in cyan, and the linker regions are based on standard atom type based color. There are some overlaps between the purpurinimide ring and the cyanine dye ring. (c) Example of the low energy conformer for conjugate **9**. The same color scheme as that in panel b is used. Because of the flexibility of the long linker, diverse conformations are possible, and some of the low energy conformers show an extensive interaction between the purpurinimide ring and the cyanine dye−thiophenol moiety. Mean distance between the two moieties in panel a (conjugate **7**) = 8.18 Å (SD 0.10); in panel b (conjugate **8**) = 8.55 Å (SD 0.51); and in panel c (conjugate **9**) = 9.85 Å (SD 2.27).

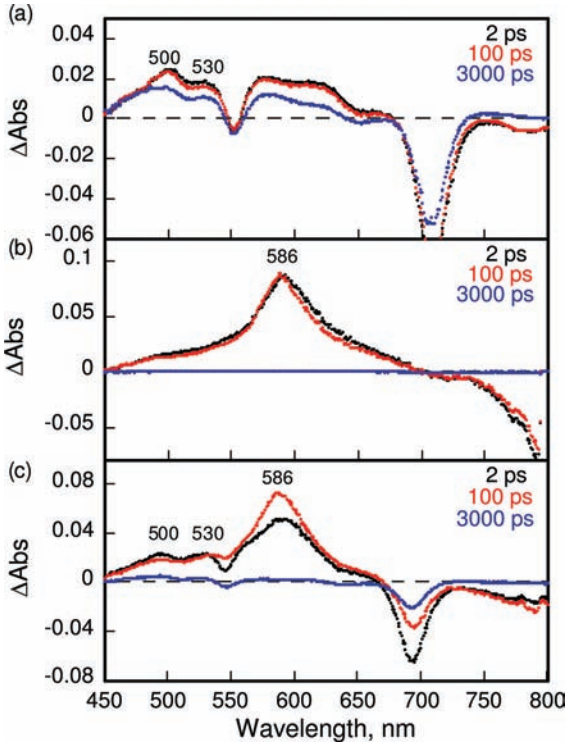

Figure 3. Transient absorption spectra of purpurinimide **4**, cyanine **6**, and conjugate **7** in deaerated DMSO taken at 2, 100, and 3000 ps after femtosecond laser flash excitation at 410 nm.

of **4** appeared. The transient absorption band of the singlet excited state of cyanine **6** is observed at 586 nm as shown in Figure 3b. The lifetimes of the singlet excited state of **4** and **6** were determined from decays of the absorption at >3 ns and 500 ps, respectively. In the case of conjugate **7** shown in Figure 3c, the transient absorption bands due to both singlet excited states of purpurinimide and cyanine were observed at 500, 530, and 586 nm at 2 ps because both moieties were excited by laser flash excitation at 410 nm. The absorption bands at 500 and 530 nm due to the singlet excited state of the purpurinimide moiety decreased, accompanied by an increase in the absorption band at 586 nm due to the singlet excited state of the cyanine moiety. This indicates that energy transfer from the singlet excited state of purpurinimide to the cyanine moiety occurs efficiently to afford the singlet excited state of cyanine. The energy transfer dynamics in **7** were determined from the rise of the absorption band at 586 nm as shown in the left panel of Figure 4a. The energy transfer rate constant was determined to be 6.7×10^{11} s^{-1}. Similarly, the energy transfer rate constants of conjugates **8** and **9** were also determined from the rise of the absorption band at 586 nm in Figure 4b and c to be 1.4×10^{11} and 1.3×10^{11} s^{-1}, respectively. The energy transfer rate constant increases with decreasing distance between the energy donor and acceptor estimated from the theoretical calculations (*vide supra*). The decay time profiles at 586 nm are shown on the right side of Figure 4. The decay rate constants of **7**−**9** agree well with the value of the cyanine reference **6** due to intersystem crossing to the triplet excited state. An energy transfer from the singlet excited state of the purpurinimide moiety to the cyanine moiety is feasible because the singlet energy of the purpurinimide (1.76 eV) is higher than that of the cyanine (1.41 eV), which were obtained from the absorption and fluorescence maxima, λ_{abs} = 689 nm and λ_{fl} = 720 nm for **4**, and λ_{abs} = 849 nm and λ_{fl} = 915 nm for **6**, respectively. Thus, in the purpurinimide−cyanine systems, intramolecular energy transfer at the singlet excited state occurs efficiently from the purpurinimide moiety to the cyanine moiety, followed by intersystem crossing to the triplet excited state of the cyanine moiety. No electron transfer from the purpurinimide moiety to the cyanine moiety was observed as expected from the disfavored energetics as indicated by the redox potentials of the conjugates (*vide infra*).

2.4. Electrochemical Properties. Cyclic voltamograms of **7**−**9** are illustrated in Figure 5, which also includes the reference compounds **4** and **6**. The first one-electron oxidation potentials of **7**−**9** (E_{ox}) are all located at $E_{1/2}$ = 0.52 V vs SCE, which is similar to the E_{ox} value of compound **6** (0.56 V vs SCE). The first one-electron reduction potentials of **7**−**9** (E_{red1}) are also identical at $E_{1/2}$ = −0.55 V vs SCE, which agrees with the E_{red1} value of cyanine **6** (−0.56 V vs SCE). The second one-electron reduction potentials of **7**−**9** (E_{red2}) are also nearly the same and range from −0.64 to −0.69 V vs SCE, which agree with the E_{red1} value of compound **4** (−0.69 V vs SCE). Thus, there seems to be little or no interaction between the purpurinimide and cyanine moieties in the conjugates **7**−**9**, irrespective of the difference in the distance between them.

The second one-electron oxidation of the purpurinimide moiety of the conjugates **8** and **9** is irreversible, and the peak potential ranges from 0.89 to 0.92 V vs SCE, which is similar to that of **4** (0.94 V). The energy of the charge-separated state of **7**−**9** to be produced by electron transfer from the purpurinimide moiety to the singlet excited state of the cyanine

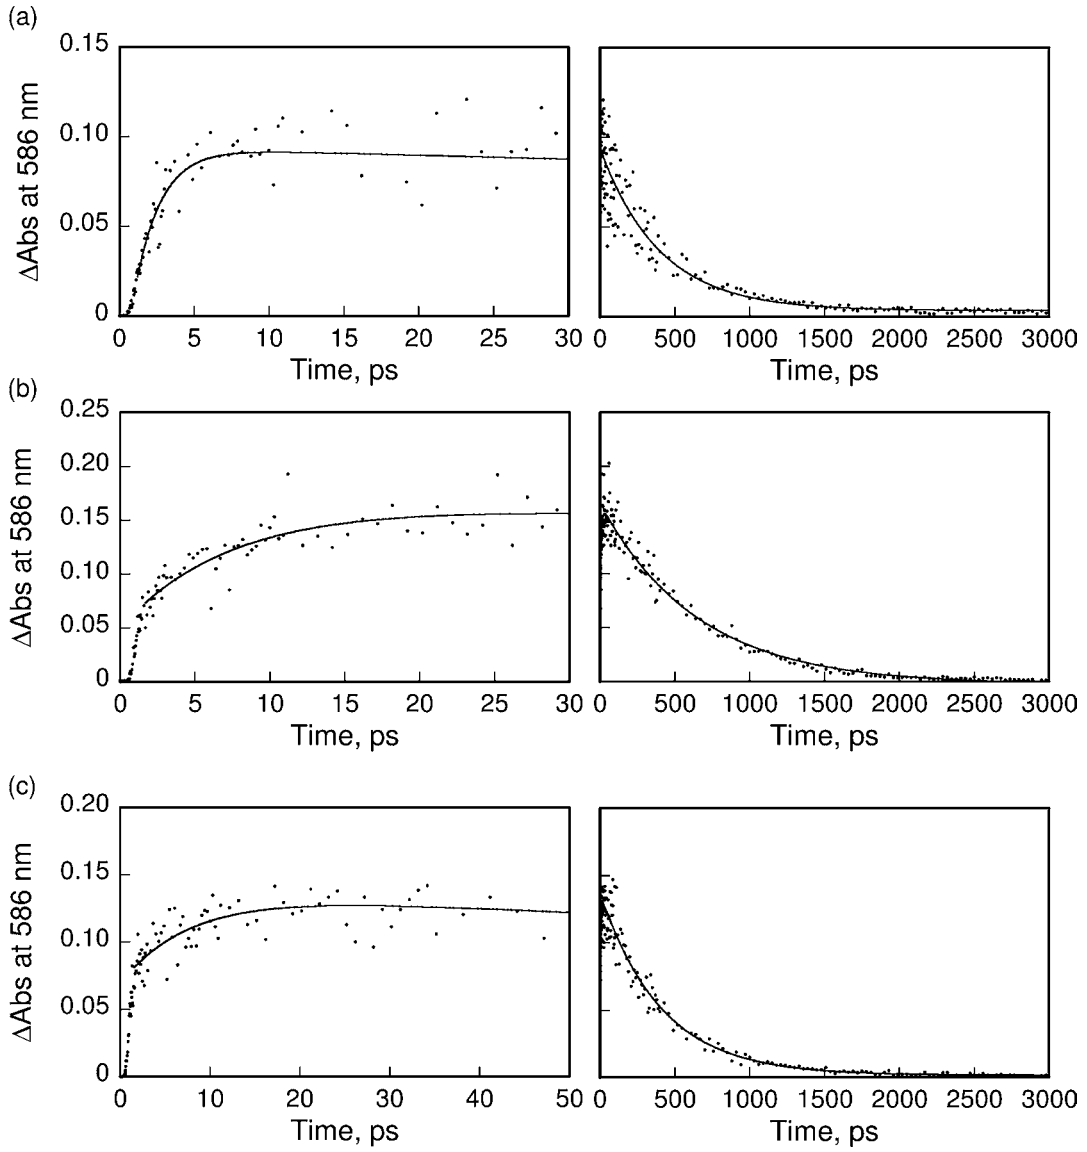

Figure 4. Rise and decay time profiles of the absorbance at 586 nm of (a) **7**, (b) **8**, and (c) **9** in deaerated DMSO after femtosecond laser excitation at 410 nm. Left panels: short time range. Right panels: long time range.

moiety is roughly estimated to be 1.6 eV, which is higher than the energy of the singlet excited state of cyanine (1.41 eV). The energy of the charge-separated state of **7**−**9** in the reverse direction from the singlet excited state of the cyanine moiety to the purpurinimide moiety is also estimated to be 1.74 eV, which is higher than the energy of the singlet excited state of cyanine (1.41 eV). Thus, electron transfer from the singlet excited state of the cyanine moiety to the purpurinimide moiety is energetically feasible. However, no electron transfer occurred from the purpurinimide moiety to the singlet excited state of the cyanine moiety as shown in Figure 3. This indicates that the intersystem crossing from the singlet excited state of the cyanine moiety to the triplet excited state is much faster than the electron transfer.

The absence of a charge-separated state of **7**−**9** was further confirmed by measuring the purpurinimide radical cation and the cyanine radical anion by use of a spectroelectrochemistry (*vide infra*). Figure 6a shows the spectral changes (in blue) which occurred during the one-electron reduction of cyanine **6** at an applied potential of −0.70 V. A new absorption maximum at 531 nm, which is assigned to the cyanine radical anion, appears, and this was accompanied by a disappearance of absorption bands at 773 and 849 nm due to cyanine. A clean isosbestic point is seen in this transfer. The radical anion can be further reduced to the dianion at an applied potential of −1.60 V vs SCE. A similar spectral change is observed for the first one-electron reduction of conjugate **7** (Figure 6b), where the radial anion of the cyanine moiety has an absorption band at 533 nm. Figure 6c shows the spectral changes upon the one-electron reduction of purpurinimide **4** at an applied potential of −0.90 V, in which the Soret band at 417 nm and the visible band at 689 nm are decreased in intensity, while an obvious radical band appears at 593 nm. These spectral changes shown in red are quite similar to the second reduction of conjugate **7** at −0.80 V also shown in red (see Figure 6b). A comparison of the spectral change for **6**, **7**, and **4** during each reduction illustrates the similarity between conjugates **7**, cyanine **6**, and purpurinimide **4**, also suggesting that the purpurinimide and cyanine moieties in **7** are almost independent of each other during electron transfer processes.

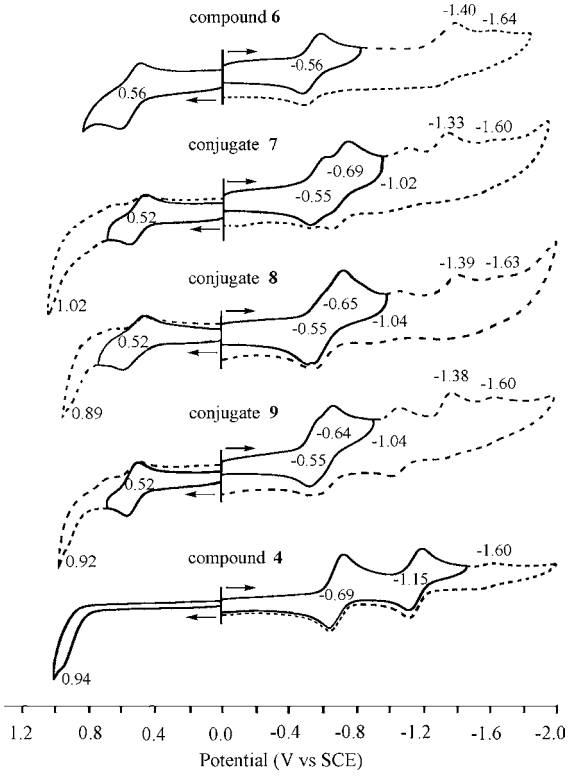

Figure 5. Cyclic voltammograms of compounds **4** and **6**–**9** in DMSO containing 0.1 M TBAP at a scan rate of 0.1 V/s.

Figure 7a shows the spectral changes which occur upon the one-electron oxidation of cyanine **6** at an applied potential of 0.70 V. A new absorption maximum appears at 650 nm, which is assigned as due to the cyanine radical cation. The absorption band due to the cyanine radical cation in conjugate **7** is slightly blue-shifted to 637 nm (Figure 7b). The purpurinimide radical cation could not be observed by spectroelectrochemistry because of irreversible oxidation, as shown in Figure 7c, where the absorption band due to **4** only disappears at an applied potential of 1.0 V vs SCE. The absence of an absorption band at 533 nm due to the radical anion of cyanine (Figure 6b) or the absorption band at 637 nm due to the radical cation of the cyanine (Figure 7b) confirms that there is no electron transfer from the purpurinimide moiety to the singlet excited state of the cyanine moiety or from the singlet excited state of the cyanine moiety to the purpurinimide moiety in the conjugate.

2.5. Biological Studies. *2.5.1. In Vitro PDT Efficacy.* Because of the insoluble nature of conjugates **7**–**9**, various formulations were used to dissolve the compounds in appropriate concentrations. Among all the formulations, reasonable solubility was obtained in both 1% Tween 80 in 5% dextrose–water solution.[22] The *in vitro* PDT efficacy of conjugates **7**–**9** was determined in Colon26 cells by following the standard MTT assay[23] (for details, see the Experimental Procedures). In brief, the cells were incubated for 24 h with **7**, **8**, and **9** at variable concentrations and then exposed to laser light (1.0 J/cm^2) at 695, 713, and 710 nm (the longest absorption wavelengths corresponding to the purpurinimide portion for the respective conjugates). The PDT efficacy (cell

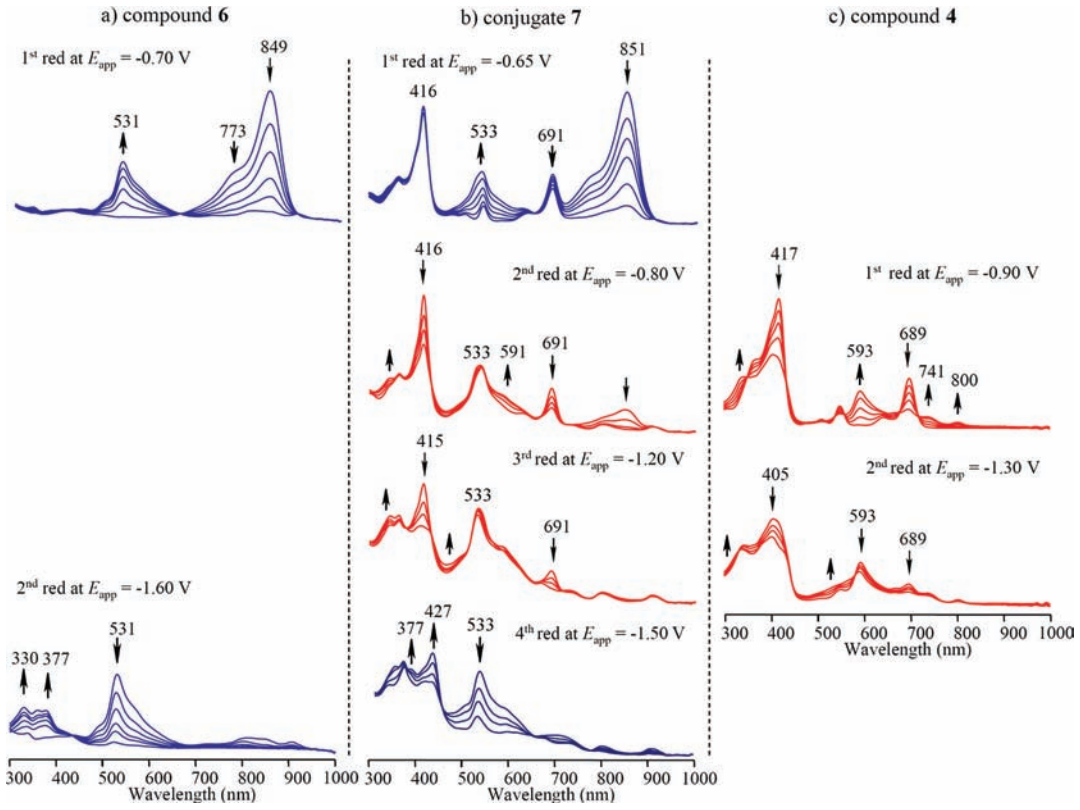

Figure 6. Thin-layer UV–visible spectra of (a) **6**, (b) **7**, and (c) **4** upon the controlled reducing potentials in DMSO containing 0.1 M TBAP. The blue spectral changes in conjugate **7** correspond to a reduction on the cyanine dye moiety. The red spectral changes are assigned at the reduction at the purpurinimide unit of the conjugate.

kill) was calculated from 4 replicate wells in 3 separate experiments, and each standard error is representative of 3 separate experiments. The results, summarized in Figure 8 and

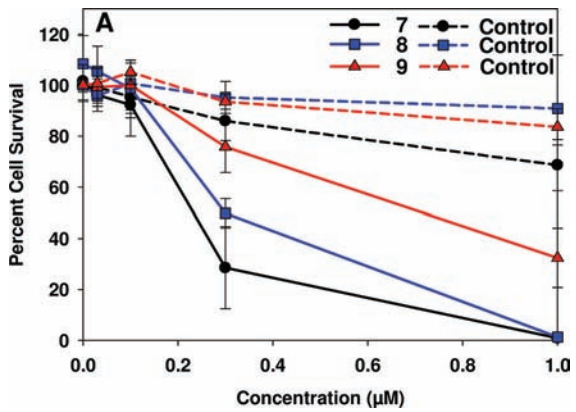

Figure 8. MTT plotted assay of **7**, **8**, and **9** incubated for 24 h at various concentrations with Colon26 cells followed by a light dose of 1.0 J/cm^2 at a dose rate of 3.2 mW/cm^2.

Table 1. IC_{50} (50% Cell Kill) Concentrations of Conjugates 7, 8, and 9[a]

conjugate	IC_{50} (μM)	distance (Å) between the two moieties
7 (short linker)	0.22	8.18
8 (medium linker)	0.32	8.55
9 (long linker)	0.69	9.85

[a]Average distance of various conformers is shown in the caption to Figure 2.

Table 1, show that increasing the distance between the photosensitizer and cyanine dye decreases the *in vitro* PDT efficacy. The LD_{50}s of the conjugates were determined by the best fit curves (plotted in Sigmaplot) to the dose–response data. The IC_{50} values confirmed a decreased *in vitro* PDT efficacy in this series of conjugates by increasing the linker length between the purpurinimide and the cyanine dye.

2.5.2. In Vivo Fluorescence Imaging. Cyanine dye **6** has the required photophysical properties (long wavelength absorption with significant Stokes shift), for fluorescence imaging but was not tumor-avid.[24] To investigate the use of tumor-avid purpurinimides as vehicles to deliver the nontumor-avid cyanine dye to the tumor, we used fluorescence imaging as a tool to investigate the effect of the linker *in vivo*.[25] Compared to the therapeutic dose, the imaging dose was quite low, and therefore, we were able to evaluate the imaging potential of the three conjugates **7**–**9**. Each conjugate was injected i.v. via the tail vein at a dose of 0.03 μmol/kg into BALB/c mice (9 mice/group) bearing Colon26 tumors on the shoulder.

Figure 9 represents fluorescent images of the tumors at 24, 48, and 72 h postinjection of conjugates **7**, **8**, and **9** (3 mice/time point) after each drug was injected. The color scale represents fluorescence intensity, where blue is the lowest intensity, and red/white is the highest. After imaging, the mice at each time point were sacrificed, and the organs were removed and imaged *ex vivo* to demonstrate the distribution and clearance rates of the conjugates. Conjugate **8** exhibited the highest fluorescent intensity in the tumors of all the compounds at 24 h and was gradually clear from the tumor by 72 h. Conjugate **9** showed a moderate but lower fluorescence intensity than compound **8**, which cleared from the tumor at a much faster rate. Interestingly, conjugate **7** gave low, barely noticeable fluorescence intensity in the tumor, which could either indicate poor fluorescence quantum yield for the cyanine dye portion of this compound or low tumor selectivity.

The *ex vivo* fluorescence intensities of various organs (ear, heart, kidney, liver, lung, muscle, small intestine, spleen, stomach, and tumors) are shown in Figure 10. As expected, conjugate **9** in which the photosensitizer is joined with the cyanine dye via a PEG linker exhibited highest fluorescence (high uptake) in the liver compared to **7** and **8**. The high affinity for this compound to the liver could be due to the more

dx.doi.org/10.1021/bc200345p | *Bioconjugate Chem.* 2011, 22, 2283–2295

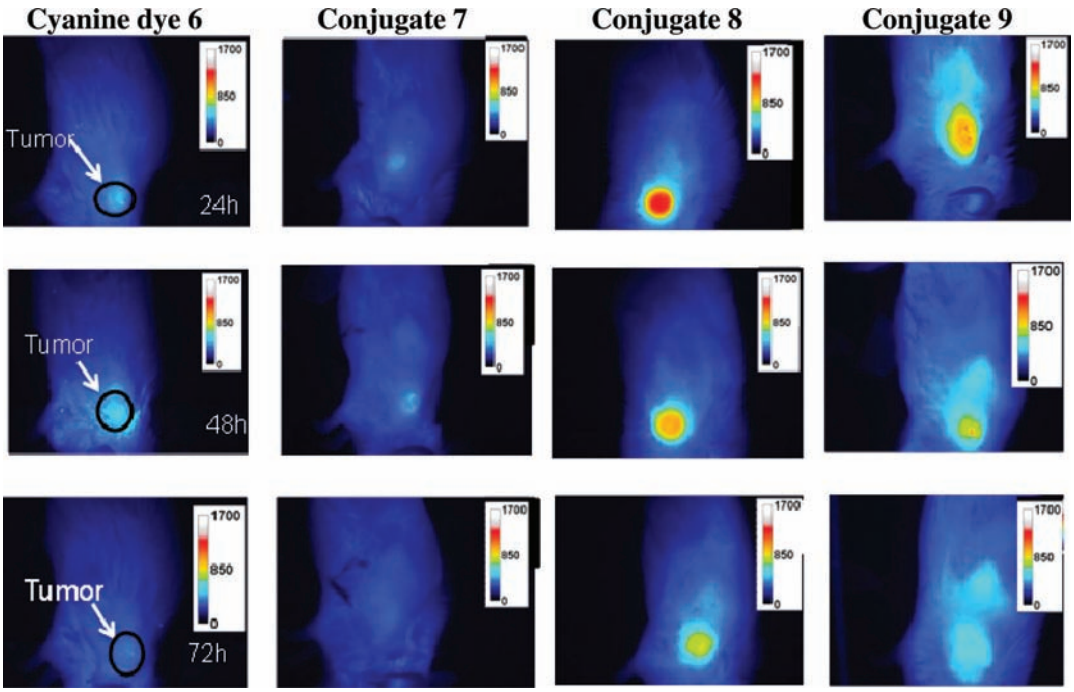

Figure 9. Comparative whole body images of conjugates **7**–**9** along with cyanine dye **6** (dose: 0.03 μmol/kg) in BALB/c mice bearing Colon26 tumors. Images were taken at 24, 48, and 72 h postinjection using a 12 bit Nuance camera (CRI, Worburn, MA) with a 782 continuous wave laser for excitation and a 800 and 830 nm long pass filter to collect fluorescence. Images were then analyzed using Image J software.

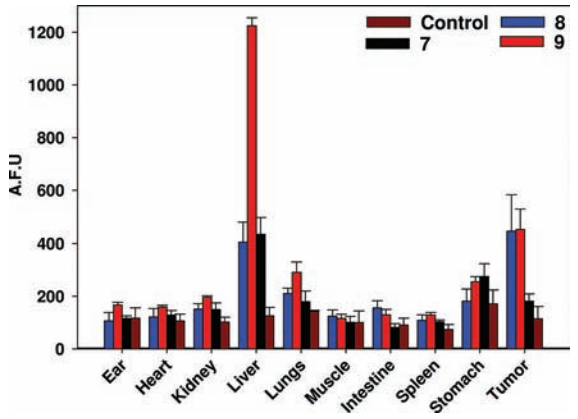

Figure 10. Fluorescence biodistribution of conjugates **7**–**9** and various organs [3 mice (BALB/c bearing Colon26 tumors]. Organs from the mice were removed and then imaged/analyzed at 24 h postinjection (dose: 0.03 μmol/kg). The fluorescence intensity of each organ was analyzed by Image J software.

lipophilic nature of the linker connecting the purpurinimide and cyanine dye. Interestingly, the PEG linker also showed comparable tumor avidity. Since the purpose of this study is to create a molecule that can act as both a fluorescent imaging and a therapeutic agent *in vivo*, conjugate **7** was not examined any further due to its weak uptake in tumors compared to that of the other two conjugates, determined by fluorescence imaging. However, further studies at lower time points may produce improved efficacy, and these studies with this and other agents are currently in progress.

2.5.3. Comparative In Vivo Tumor Uptake of the Conjugates. *In vivo* reflectance spectroscopy was used to determine the maximum uptake of the conjugates at various time points.[26] Mice were injected through the orbital venous plexus, the reflectance in tumors was measured at 24 and 48 h, and the drug concentrations were determined (see Figure 11). This approach was extremely useful in providing the knowledge of the pharmacokinetic characteristics (especially the clearance from the tumor) of the conjugates and also the shift in their *in vivo* absorption. Under a similar dose of the drug (2.5 μmol/kg), conjugate **8** showed maximum tumor uptake (BALB/c mice bearing Colon26 tumors) at 24 h postinjection, which decreased over the next 24 h. Conjugate **9** showed a small increase in uptake at 48 h compared to that at 24 h.

Comparatively, conjugate **8** showed a higher tumor uptake than **9** at both 24 and 48 h. Since our objective has been to develop a candidate with both imaging and therapy capabilities and conjugate **7** showed limited PDT efficacy, it was decided not to explore its imaging potential.

2.5.4. In Vivo Photosensitizing Efficacy. Preliminary *in vivo* PDT efficacy of conjugates **8** and **9** was measured by tail vein injection into BALB/c mice (5 mice/group) bearing Colon26 tumors (average tumor volume 27 mm^3) at a dose of 2.5 μmol/kg (which gave approximately 50% tumor cure with the HPPH–cyanine dye conjugate, our lead compound).[10] The tumors were illuminated with light (135 J/cm^2, 74 mW/cm^2) at 24 h postinjection, with the best time point for the maximum photosensitizer uptake in the tumor determined by fluorescence imaging and *in vivo* reflectance spectroscopy. From the preliminary results summarized in Figure 12A, it can be seen that compared to **8**, the conjugate **9** exhibited limited long-term efficacy and that all mice showed tumor regrowth at 10–12 days post-treatment. Under similar treatment parameters, conjugate **8** showed 100% tumor cure, and no tumor growth was observed at day 60. We further investigated the efficacy of conjugate **8** at variable doses (1.5, 2.0, and 2.5 μmol/kg), and the light dose was kept the same (135 J/cm^2, 75mW/cm^2). From the results summarized in Figure 12B, it can be seen that at the lowest dose of 1.5 μmol/kg, conjugate **8** showed limited efficacy, but at higher doses, a significant PDT response was

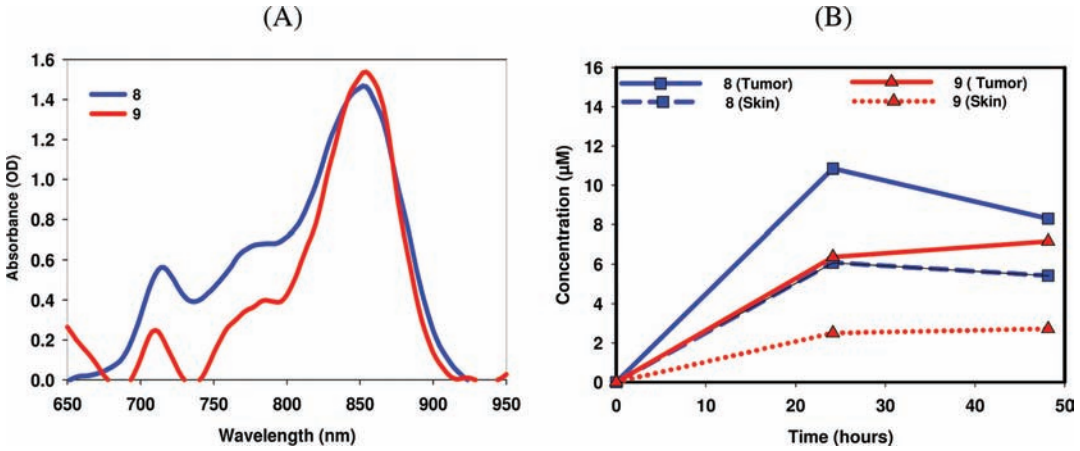

Figure 11. (A) *In vivo* absorption spectra of conjugates **7** and **8** determined by *in vivo* reflectance spectroscopy in a Colon26 tumor implanted in BALB/c mice at 24 h postinjection. (B) Tumor vs skin uptake of the conjugates at 24 and 48 h postinjection (drug dose: 2.5 μmol/kg).

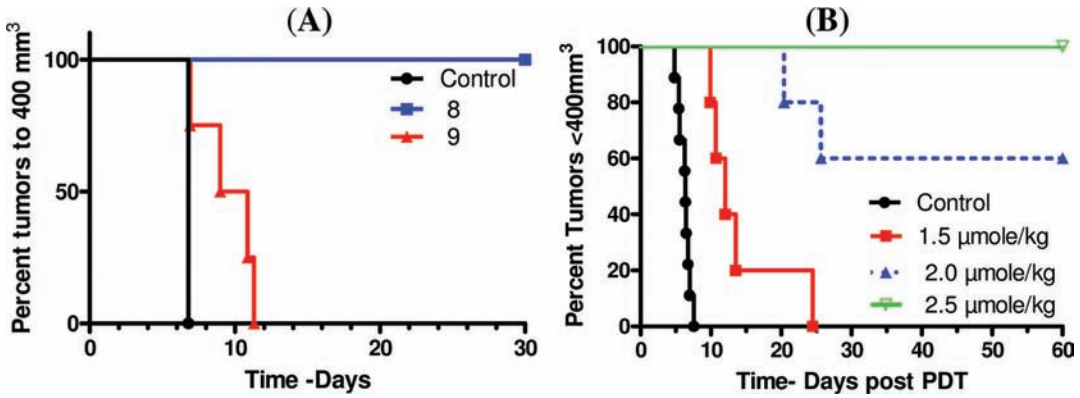

Figure 12. (A) Comparative *in vivo* photosensitizing efficacy of conjugates **8** and **9** in BALB/c mice (5 mice/group) bearing Colon26 tumors at a dose of 2.5 μmol/kg, and (B) *in vivo* efficacy of **8** at variable drug doses. The tumors were exposed to light (135 J/cm^2 and 75mW/cm^2) at their longest wavelength absorption at 24 h postinjection (i.v.) of the photosensitizers. The tumor growth was measured daily. Under the treatment parameters used, the mice treated with conjugate **8** at a dose of 2.5 μmol/kg did not show any tumor regrowth, and the tumors were flat on day 60 post-treatment.

observed (2.0 μmol/kg, 3/5 mice, and at 2.5 μmol/kg, 5/5 mice, were tumor free on day 60).

3. CONCLUSIONS

An efficient synthetic pathway was developed to create purpurinimide−cyanine dye dual functional agents. *In vitro* results suggested that increasing the carbon chain length from a short linker to a long linker decreases the PDT efficacy of the compounds. Fluorescence imaging showed that **7** (short linker) had poor imaging capabilities compared to that of **8** (medium linker) and **9** (long linker) and was not studied further. Conjugate **9** exhibited the highest liver fluorescent values. This may be due to the more lipophilic nature of the linker connecting the two molecules, which shows higher affinity to the liver. *In vivo* reflectance spectroscopy showed that conjugate **8** exhibited higher tumor uptake than **9** and should therefore produce *in vivo* PDT efficacy. The comparative *in vivo* PDT confirmed the higher efficacy of conjugate **8** over **9** and produced 100% tumor response (5/5 BALB/c mice bearing Colon26 tumors were tumor free after day 60 post-treatment), whereas **9**, under similar treatment parameters showed limited PDT activity. This study with a small number of conjugates indicates that conjugate **8** with a medium length of linker shows potential for both tumor imaging and therapy. However, further studies with a larger group of compounds should help in selecting the best candidates, and the synthesis of the related analogues is underway. The low PDT and imaging capabilities of conjugate **7** could be due to its faster *in vivo* clearance. Therefore, further studies with conjugate **7** at shorter time intervals between the injection of the drug and light treatment are also in progress.

4. EXPERIMENTAL PROCEDURES

All chemicals were of reagent grade and used as such. All reagents were purchased from Aldrich chemical company and were used as received. All photophysical experiments were carried out using spectroscopic grade solvents. Solvents were dried using standard methods unless stated otherwise. Reactions were carried out under nitrogen atmosphere and were monitored by precoated (0.20 cm) silica TLC plastic sheet (20 cm × 20 cm) strips (POLYGRAM SIL N-HR) and or/UV−visible spectroscopy. UV−visible spectra were recorded on a Varian Cary 50 Bio UV−visible spectrophotometer using dichloromethane/methanol as solvent unless otherwise specified. ^{1}H NMR spectra were recorded on Varian 400 spectrometers at 303 K in $CDCl_3$ or ∼10% of CD_3OD in $CDCl_3$ or DMSO-d_6. Proton chemical shifts (δ) are reported in parts per million (ppm) relative to $CDCl_3$ (7.26 ppm), CD_3OD

dx.doi.org/10.1021/bc200345p | *Bioconjugate Chem.* 2011, 22, 2283−2295

(3.34 ppm) or TMS (0.00 ppm). Coupling constants (J) are reported in Hertz (Hz), and s, d, t, q, p, m, and br refer to singlet, doublet, triplet, quartet, pentet, multiplet, and broad, respectively. Mass spectral data (Electro Spray Ionization, ESI, by fusion) were obtained from Biopolymer Facility, Roswell Park Cancer Institute, Buffalo, NY, and HRMS data were obtained from the Mass Spectrometry Facility, Michigan State University, East Lansing, MI. Elemental analysis were done at Midwest Microlab LLC., Indianapolis, IN.

4.1. *N*-Amino Purpurinimide Methyl Ester (3). Mesopurpurin-18 methyl ester (**2**) (0.138 mmol, 80 mg) was dissolved in 15 mL of anhydrous pyridine and stirred under argon. Hydrazine anhydrate (1.3 mmol, 42 mg, 42 μL) was added to 2 mL of anhydrous pyridine, which was then added slowly to the stirring mixture. The completion of the reaction was checked by UV−vis in regular intervals until the wavelength intensity at λ_{max} of 701 nm was maximal. After 4 h, 1 N HCl (25 mL) and dichloromethane (20 mL) were added, and the stirring was continued for another 1.5 h. The reaction mixture was then transferred into a separation funnel. Additional dichloromethane (200 mL) was added, the organic layer was washed with water (200 mL × 3). The dichloromethane (DCM) layer was separated, dried over anhydrous sodium sulfate, and filtered.. The crude reaction product obtained after evaporating DCM was purified on an alumina column by eluting with a 1% MeOH/DCM solvent system to afford a purple/magenta crystal of **3**[21] (42.4 mg, 50% yield). UV−vis λ_{max} (in CH_2Cl_2): 359 nm (ε = 5.8 × 10^4), 416 (ε = 10.0 × 10^5), 548 (ε = 1.9 × 10^5), 643 (ε = 8.60 × 10^3), 700 (ε = 4.94 × 10^4) . ^{1}H NMR (400 MHz, 3 mg/1 mL $CDCl_3$, δ ppm) 9.07, 8.95, and 8.42 (each s, 1H for 5H, 10H and 20H), 5.72 (broad s, N−NH_2), 5.29 (m, 1H, for 17H), 4.33 (m, 1H for 18H), 3.63 (q, 2H for 8^1CH_2) 3.62 (s, 3H for $12CH_3$), 3.61 (s, 3H for $17^2CO_2CH_3$), 3.33 (m, 2H for 3^1CH_2) 3.18 (s, 3H for $2CH_3$), 3.00 (s, 3H for $7CH_3$), 2.78 and 1.978 (m, 2H for 17^1 CH_2), 2.46 (m, 2H for 17^2 CH_2) 1.76 (d J = 7.2 Hz, 3H for $18CH_3$), 1.66 (t, J = 7.2 Hz, 3H for 8^2CH_3), 1.50 (m, 3H for 3^2CH_3). EIMS (m/z): 595 (M + H). Elemental Anal. Calcd. for $C_{34}H_{38}N_6O_4$: C, 68.67; H, 6.44; N, 14.13. Found: C, 68.70; H, 6.43; N, 14.01.

4.2. *N*-Boc Diethlyene Purpurinimide Methyl ester (4a). Purpurin-18 methyl ester (50 mg, 0.0865 mmol) (**1**) was added to a dry 100 mL round bottomed flask and put under house vacuum for 20 min. N-Boc ethylenediamine (48.50 mg, 0.30275 mmol) was placed under nitrogen for 10 min and then added to the flask containing Purpurin-18 using a long needle. Under a nitrogen atmosphere, 5−10 mL of anhydrous DCM was added to the reaction mixture, which was stirred for 39 h, monitoring with UV−vis. A wavelength of 665 nm indicated the opening of the six-membered anhydride ring system. It was then treated with diazomethane, the intermediate amide, as methyl ester was not isolated, and immediately treated with a catalytic amount of KOH/MeOH. The base catalyzed intramolecular cyclization afforded the desired analogue exhibiting the long wavelength absorption at 707 nm. The reaction mixture was purified by preparative plates using a 5% MeOH/DCM solvent system, and the desired band was scratched off and resuspended in 5% methanol/dichloromethane. The silica was removed by filtration. Solvents were evaporated, and the residue **4a** was precipitated with DCM/*n*-hexane (60 mg, 86% yield). UV−vis λ_{max} (in CH_2Cl_2): 365 nm, 418 nm, 550 nm, 707 nm. ^{1}H NMR (400 MHz, 3 mg/1 mL $CDCl_3$, δ ppm) 9.40, 9.20, and 8.56 (each s, 1H for 5H, 10H and 20H); 7.83 (dd, J = 11.6, 5.2 Hz 1H, $3^1CH{=}CH_2$); 6.24 (d, J = 16.4 Hz, 1H, trans $3^2CH{=}CH_2$), 6.12, (d, J = 8.4 Hz, 1H cis $3^2CH{=}CH_2$); 5.46 (br s, 1H, N-*H*-CH_2−CH_2−N-Boc); 5.37 (d, J = 4 Hz, 1H for 17H), 4.62 (m, 2H, NH−C*H*$_2$−CH_2−N-Boc); 4.37 (q, 1H for 18H); 3.59 (s, 3H, $17^2CO_2CH_3$); 3.49 (q, 2H for NH−CH_2−C*H*$_2$-N-Boc); 3.79 (d, J = 5.2 Hz, 1H for 8^1CH_2); 3.73 (s, 3H for $12CH_3$) ; 3.33 (s, 3H for $2CH_3$); 3.04 (s, 3H for 7 CH_3); 2.72, 2.46, 2.44, and 2.06 (each m, 1H for 2 × 17^1H and 2 × 17^2H); 1.79 (d, J = 8 Hz, 3H for 18^1 CH_3); 1.60 (t, J = 7.6 Hz 3H for 8^2 CH_3); −0.128 and −0.215 (br s, 1H for 2NH). EIMS (m/z): 721 (M + H).

4.3. Diethlyene Amino Purpurinimide Methyl Ester (4). *N*-Boc diethlyene purpurinimide methyl ester (**4a**) was treated with a 4:1 ratio of TFA/dry DCM and stirred for 2 h. The TFA was removed by high vacuum for 5 h, and the remainder was purified on an alumina column with 5% MeOH/DCM as the solvent system. The resulting compound was isolated as a dark purple liquid, compound **4**, which was concentrated by evaporating the liquid under vacuum to afford dark purple crystals (54 mg, 89% yield) UV−vis λ_{max} (in CH_2Cl_2): 365 nm (ε = 4.5 × 10^4), 419 nm (ε = 1.18 × 10^5), 551 nm (ε = 4.6 × 10^4), 706 nm (ε = 4.2 × 10^4). ^{1}H NMR (400 MHz, 3 mg/1 mL $CDCl_3$, δ ppm) 9.65, 9.44, 8.78 (each s, 1H for 5 H, 10H and 20H); 8.03 (dd, J = 17.6, 11.6 Hz, 1H, $3^1CH{=}CH_2$), 6.45 (d, J = 18.0, 1H, *trans* $3^2CH{=}CH_2$), 6.34 (d, J = 11.6, 1H *cis* $3^2CH{=}CH_2$), 5.58 (d, J = 8.4 Hz, 1H for 17H); 4.81 (t, J = 6.8 Hz, 2H for N−C*H*$_2$-CH_2−N), 4.58 (q, J = 7.2 Hz, 1H for 18H), 3.95 (s, 3H, $12CH_3$), 3.81 (s, 3H, $17^2CO_2CH_3$), 3.80 (q, J = 7.6 Hz, 2H, 8^1CH_2), 3.54−3.59 (m, 5H, $2CH_3$ and N−CH_2-C*H*$_2$-N), 3.27 (s, 3H, $7CH_3$), 2.96, 2.67, 2.62, and 2.22 (each m, 1H, 2 × 17^1H and 2 × 17^2H), 2.00 (d, J = 7.2 Hz, 3H, $18CH_3$), 1.82 (t, J = 7.6 Hz, 3H, 8^2CH_3) 0.08 and 0.00 (each br s, 1H, 2NH). EIMS (m/z): 621.1 (M + H). Elemental Anal. Calcd. for $C_{40}H_{48}N_6O_6$: C, 69.66; H, 6.50; N, 13.54. Found: C, 68.63; H, 6.51; N, 12.88.

4.4. *N*-Boc Glycol Purpurinimide Methyl Ester (5a). *N*-Boc-2,2′-(ethylene-1,2-dioxy) bisethylamine was prepared by following the literature procedure.[10] It (50 mg, 0.2015 mmol) was dissolved in 5 mL of dry DCM. This was added to a stirring mixture of purpurin-18 methyl ester (50 mg, 0.0865 mmol) in 10 mL of dry DCM. The reaction was stirred for 39 h under a nitrogen atmosphere with UV−vis monitoring (a shift from 700 nm to 665 nm). The reaction was then treated with diazomethane/KOH/MeOH until a red shift to 707 nm indicated the reaction was complete. A preparation scale TLC separation was done with a 5% MeOH/DCM solvent system, and the desired band was scratched off, and the desired product was isolated by following the method as discussed above to yield compound **5a** (60 mg, 86% yield). UV−vis λ_{max} (in CH_2Cl_2): 365.1 nm, 419 nm, 549 nm, 707 nm. ^{1}H NMR (400 MHz, 3 mg/1 mL $CDCl_3$, δ ppm) 9.58, 9.32, and 8.56 (each s, 1H for 5 H, 10H and 20H), 7.88 (dd, J = 8.0, 10.4 Hz 1H, $3^1CH{=}CH_2$); 6.24 (d, J = 16.0 Hz, 1H, trans $3^2CH{=}CH_2$); 6.14 (d, J = 11.6, 1H cis $3^2CH{=}CH_2$);5.32 (m, 1H for 17H); 5.10 (br s, 1H for N−CH_2-CH_2−(O−CH_2)$_2$-N*H*Boc); 4.73 (t, J = 8.0 Hz, 2H for N−C*H*$_2$-CH_2−(O−CH_2)$_2$-NHBoc); 4.34 (q, 1H for 18H); 2.70, 2.40, 2.35, and 1.98 (each m 1H, 2 × 17^1H and 2 × 17^2H); −0.05 and −0.15 (br s, 1H for 2NH). EIMS (m/z): 809 (M + H).

4.5. *N*-Glycol Purpurinimide Methyl Ester (5). Purpurin-18-*N*-Boc-glycol-imide (**5a**) was treated with a 4:1 ratio of TFA/Dry DCM and stirred for 2 h. The reaction was concentrated by evaporating under vacuum. The crude mixture

was purified on an alumina column with 5% MeOH/DCM as the solvent system. The resultant compound after the standard workup afforded dark purple crystals of **5** (54 mg, 89% yield). UV−vis λ_{max} (in CH_2Cl_2): 365 nm ($\varepsilon = 4.5 \times 10^4$), 419 nm ($\varepsilon = 1.18 \times 10^5$), 551 nm ($\varepsilon = 2.1 \times 10^5$), 707 nm ($\varepsilon = 4.30 \times 10^4$). ^{1}H NMR (400 MHz, 3 mg/1 mL $CDCl_3$, δ ppm) 9.58, 9.34, and 8.56 (each s, 1H for 5H, 10H and 20H); 7.90 (dd, J = 11.6, 11.6 Hz, 1H for 3^1CH═CH_2); 6.30 (d, J = 16.4 Hz, 1H for *trans*-3^2CH═CH_2); 6.15(d, J = 10.4 Hz, 1H for *trans*-3^2CH═CH_2); 5.33 (m, 1H for 17H); 4.73 (t, J = 1.6 Hz, 2H for N−CH_2-CH_2−(O−CH_2)$_2$-NH_2); 4.63 (q, 1H for18H); 4.07 (m, 2H for N−CH_2-CH_2-(O−CH_2)$_2$-NH_2); 3.85 (m, 2H for N-(O−CH_2)$_2$-CH_2-CH_2−NH_2); 3.79(s, 3H for 12CH_3); 3.70 (t, J = 36 Hz, N-(CH_2)$_2$−O-CH_2-CH_2−O-(CH_2)$_2NH_2$); 3.62 (q, 2H for 8^1CH_2); 3.56 (s, 3H for $17^2CO_2CH_3$) ; 3.51 (m, 2H for N-(CH_2)$_2$−O-CH_2-CH_2−O-(CH_2)$_2NH_2$); 3.34 (s, 3H for 18 CH_3); 3.14 (s, 3H for 7CH_3); 2.80, 2.70, 2.40, and 1.99 (each m 1H, 2 × 17^1H and 2 × 17^2H); 1.95 (m, 2H for N-(O−CH_2)$_2$-CH_2−CH_2-NH_2); 1.86 (broad s, 2H for NH_2); 1.74 (d, J = 7.2 Hz, 3H for 18CH_3); 1.65 (t, J = 7.6 Hz, 3H for 8^2 CH_3); 0.059 and −0.146 (broad s, 1H for 2NH). EIMS (m/z): 709 (M + H). Elemental Anal. Calcd. for $C_{40}H_{48}N_6O_6$: C, 67.78; H, 6.83; N, 11.86. Found: C, 67.59; H, 6.60; N, 10.90.

4.6. Cyanine Dye (6). To a dry round bottomed flask containing IR-820 (342 mg, 0.402 mmol) stirring in anhydrous DMF was added 4-carboxythiophenol (186.2 mg, 1.20 mmol), and the mixture was stirred overnight under a nitrogen atmosphere. The crude reaction product obtained after the standard workup was purified over a silica column using a 5−25% DCM/MeOH solvent system, and a green liquid was collected. The liquid was concentrated by evaporation under vacuum and scratched to afford dark green crystals of **6** yield (270 mg, 80%). UV−vis λ_{max} (in MeOH) 835 nm ($\varepsilon = 1.96 \times 10^5$); ^{1}H NMR (400 MHz, 3 mg/1 mL MeOH, δ ppm) 8.87 (d, 2H, J = 14 Hz), 8.15 (d, 2H, J = 14 Hz), 8.79−7.99(m, 6H), 7.57−7.63 (m,4H), 7.44 (t, 2H, J = 7.2 Hz), 7.36 (d, 2H, J = 8.4 Hz), 6.40 (d, 2H, J = 14 Hz), 4.27 (t, 4H, J = 7.6 Hz), 2.85−2.92(m, 8H), 1.93−2.10 (m, 10 H), 1.77 (s, 12H). EIMS (m/z): 989.4 (M^+ + 2Na). HRMS: Calcd. for $C_{53}H_{56}N_2O_8S_3Na$: 967.3097. Found: 967.3127.

4.7. Conjugate 7. In a dry round bottomed flask containing cyanine dye **6** (121.62 mg, 0.1289 mmol), DMTMM (39.25 mg, 1.1 equiv) was stirred in 5 mL of anhydrous DMF under a nitrogen atmosphere for 2 h. *N*-Amino purpurinimide methyl ester **3** (80 mg, 0.1289 mg) was stirred in 5 mL of anhydrous DMF in a separate round bottomed flask and was added to the flask containing the cyanine dye after 2 h. The reaction was stirred overnight and was purified by a preparative silica TLC plate using a 20% MeOH/DCM solvent system. The desired band was collected and resuspended in 5% methanol dichloromethane. It was then filtered, and the solvents were concentrated. The residue was crystallized/precipitated as dark purple crystals; yield (40 mg, 32%). UV−vis λ_{max} (in MeOH): 361 nm ($\varepsilon = 3.9 \times 10^4$), 412 ($\varepsilon = 9.6 \times 10^4$), 544 ($\varepsilon = 1.7 \times 10^4$), 693 ($\varepsilon = 4.5 \times 10^4$), 837 ($\varepsilon = 1.5 \times 10^5$). ^{1}H NMR (400 MHz, 3 mg/1 mL MeOH, δ ppm) 9.72, 9.37, 8.81 (each s, 1H, for 5H, 10H and 20H); 8.78 (d, J = 2.4 Hz, 2H, cyanine dye F); 8.29 (d, J = 8 Hz, 2H, cyanine dye B); 8.09 (m, 6H, cyanine dye H and D); 7.81 (d, J = 8.8 Hz, 2H, cyanine dye G); 7.64 (t, J = 12 Hz, 4H, cyanine dye C); 7.51(t, J = 8 Hz, 2H, cyanine dye A); 6.50 (d, J = 16 Hz, 3H, cyanine dye E); 5.01 (m, 2H cyanine dye SO_3H), 4.91 (m, 1H for 17H); 4.35 (m, 4H for cyanine dye H and 1H for 18H); 3.80(br doublet, 4H, 2H for 3^1 CH_2 and 2H for 8^1CH_2); 3.75 (d, 7H, 4H for $17^2CO_2CH_3$ and 3H); 3.35 (H_2O peak and hidden 3H for 12CH_3 singlet peak); 3.335 and 3.225 (s, 4H, 3 for 7CH_3 and 1H); 2.90 (m, 5H for cyanine dye K and L); 2.50 (m, 2H, 17^2CH_3 within DMSO peak); 2.32 (m, 2H for 17^1CH_2); 2.06−1.52 (many multiplets, 41H, 12H for cyanine dye J and N, 3H for cyanine dye M, 9H for 3^2CH_3, 18^1CH_3 and 8^2CH_3, and 17 H). EIMS (m/z): 1520 (M − H). HRMS: Calcd. for $C_{87}H_{92}N_8O_{11}S_3$: 1520.6048. Found: 1520.6048.

4.8. Conjugate 8. In a dry round bottomed flask, cyanine dye **6** (92.4 mg, 0.098 mmol) and DMTMM (30 mg, 0.1078 mmol) were stirred in 5 mL of anhydrous DMF in a nitrogen atmosphere for 2 h. Diethlyeneaminopurpurinimide methyl ester **4** (70 mg, 0.098 mmol) was stirred in 5 mL of anhydrous DMF in a separate round bottomed flask and was added into the flask containing the cyanine dye after 2 h. The reaction was stirred overnight and was purified on a preparation scale TLC plate using a 20% MeOH/DCM solvent system. The desired fraction was collected, and the residue obtained after evaporating the solvent was crystallized/precipitated with DCM/hexane as dark purple crystals; yield (35 mg, 37%). UV−vis λ_{max} (in MeOH): 365 nm ($\varepsilon = 3.8 \times 10^4$), 418 nm ($\varepsilon = 8.2 \times 10^4$), 549 nm ($\varepsilon = 1.6 \times 10^4$), 707 nm ($\varepsilon = 4.6 \times 10^4$), 842 nm ($\varepsilon = 1.6 \times 10^5$). ^{1}H NMR (400 MHz, 3 mg/1 mL MeOH, δ 9.59, 9.42, and 8.86 (each s, 1H for 5H, 10H and 20H); 8.61 (d, 2H for cyanine dye f, J=14 Hz); 8.16 (dd, J = 8 Hz,40 Hz, 1H, 3^1CH═CH_2); 8.06 (d, 2H for cyanine dye B, J=8.4 Hz); 7.98−7.95 (m, 4H for cyanine dye H and D); 7.73−7.67(m, 4H for cyanine dye G and C); 7.47 (t, 2H for cyanine dye A, J = 7.2 Hz); 7.34 (d, 2H for cyanine dye E, J = 8.4 Hz); 6.38 (t, 3H, 2H for cyanine dye E, 1H for trans 3^2CH═CH_2, J = 14 Hz); 6.20 (d, 1H for cis 3^2CH═CH_2, J = 11.6); 5.12 (d, 1H for 17H, J = 1.2 Hz); 4.53−4.40(m, 3H, 1H for 18H and 2H for N−CH_2-CH_2−N); 4.24 (broad s, 3H for cyanine dye I); 3.81 (s, 3H for 12 CH_3); 3.69 (m, 1H for NH); 3.60 (s, 3H for $17^2CO_2CH_3$); 3.39−3.31 (m, 2H for 8^1CH_2, 3H for 2CH_3 and 2H for N−CH_2-CH_2-N, 8H for cyanine dye K and L); 3.13(s, 3H for 7 CH_3); 2.33−2.20 (each m, 1H for, 2 × 17^1H and 2 × 17^2H); 2.10−2.08 (each m, 8H for cyanine dye J and N); 1.925 (m, 3H for 18 CH_3); 1.74−1.52 (m, 15 H, 3H for 8^2CH_3 and 12 H for cyanine dye M); −0.35 and −0.41 (each br s, 1H for 2NH). EIMS (m/z): 1546 (M − H). HRMS Calcd. for $C_{89}H_{94}N_8O_{11}S_3$: 1546.6204. Found: 1546.6244.

4.9. Conjugate 9. In a dry round bottomed flask, cyanine dye **6** (142.7 mg, 0.151 mmol) and DMTMM (45.96 mg, 0.1661 mmol) were stirred in 5 mL of anhydrous DMF in a nitrogen atmosphere for 2 h. *N*-Glycolpurpurinimide methyl ester **5** (90 mg, 0.151 mmol) stirred in 5 mL of anhydrous DMF in a separate round bottomed flask was added to the flask containing the cyanine dye after 2 h. The reaction was stirred overnight and was purified on a preparation scale TLC plate using a 20% MeOH/DCM solvent system as discussed for the foregoing compound. The desired fraction was collected and concentrated, crystalized with DCM/hexane to afford dark purple crystals; yield (40 mg, 32%). UV−vis λ_{max} (in MeOH): 366 nm ($\varepsilon = 4.5 \times 10^4$), 416 nm ($\varepsilon = 1.0 \times 10^5$), 549 nm ($\varepsilon = 2.7 \times 10^4$), 707 nm ($\varepsilon = 5.8 \times 10^4$), 842 nm ($\varepsilon = 2.1 \times 10^5$). ^{1}H NMR (400 MHz, 3 mg/1 mL MeOH): δ 9.67,9.46 and 8.88 (each s, 1 H for 5H, 10H and 20H); 8.62 (d, 2H for cyanine dye f, J = 14 Hz); 8.10 (d, 4H, cyanine dye j, J = 11.6 Hz);7.85 (m, 4H, cyanine dye M); 7.79 (d, 2H for cyanine dye a, J = 7.2 Hz); 7.40 (d, 2H for cyanine dye b, J = 7.2 Hz); 6.39 (m, 3H, 1H for 3^1CH═CH_2 and 2H for cyanine dye e); 6.19 (d, 1 H

for $3^2CH{=}CH_2$, J = 7.6 Hz); 5.18 (m, 1H for *cis*-$3^2CH{=}CH_2$); 4.4 (m, 1H for 18H); 4.2 (m,1H for 17H); 3.75 (s,3H for 12 CH_3);3.51 (s, 3H for 2 CH_3); 3.30(s, 3H for $17^2CO_2CH_3$);3.15 (s, 3H for 7 CH_3); 2.80 (m, 8H for cyanine dye i and j); 2.60, 2.55, 2.40, and 2.36 (each m, 1H for, 2 × 17^1H and 2 × 17^2H); 1.90 (m, 5H for cyanine dye c and h); 1.63(s, 3H for 18 CH_3); 1.50 (t, 3H for 8^2CH_3, J=7.2 Hz); −0.35 and −0.41 (each br s, 1H for 2NH). EIMS (m/z): 1634 (M − H); HRMS Calcd. for $C_{93}H_{103}N_8O_{13}S_3$: 1634.6746. Found: 1634.6729.

4.10. *In Vivo* Fluorescence Imaging. Fluorescence imaging was performed using approved protocols in accordance with the Guide for the Use of Laboratory Animals. A 12 bit Nuance camera (CRI, Worburn, MA) was used to image the conjugates *in vivo* using a 782 continuous wave laser for an excitation source. The fluorescence was collected after filtering through two 600 nm long pass filters in series and 800 and 830 nm long pass filters. Prior to imaging, BALB/c mice bearing Colon26 tumors on the shoulder with an average diameter of 4−5 mm were shaved and depilated with Nair cream to remove the hair over the tumor and the surrounding skin. Conjugates **7**, **8**, and **9** were injected via the tail vein at 0.03 μmol/kg. At 24, 48, and 72 h postinjection, mice were anesthetized with ketamine/xylene (100/10 mg/kg), placed in the light box, and imaged. The localization and biodistribuition of the conjugates were determined by sacrificing 3 mice/time points and imaging the organs. The images were processed using an image calculator.[27]

4.11. *In Vivo* Photosensitizing Efficacy. BALB/c mice (5 mice/group) were implanted subcutaneously in the right shoulder with 1 × 10^6 Colon26 cells per 50 μL of RPMI-1640 medium. When tumors grew to 4−5 mm diameter, mice were injected with 2.5 μmol/kg of **8** and **9** via tail vein injection. Twenty-four hours postinjection, the mice were restrained within Plexiglas holders, and exposed tumors were treated with laser light for 135 J/cm^2 at 75mW/cm^2. Following treatment, tumor growth was monitored daily and measured with calipers along the length and width of the tumors. Tumor volumes were calculated by using the formula $V = LXW^2/2$. Mice were considered cured if no palpable tumor grew within 30 days of being treated, or they were euthanized when the tumor volume reached 400 mm^3.

4.12. Molecular Modeling. *4.12.1. Conjugate Structures.* The three-dimensional structures of purpurinimide−cyanine dye conjugates (**7**−**9**) were built with SYBYL molecular modeling software, version 8.0 (Tripos Inc., St. Louis, MO). The purpurinimide moiety was taken from previous studies[28] utilizing appropriate crystal structure. The cyanine dye moiety was built from a SYBYL fragment library and standard geometry using the extended conformation. Both moieties were fully energy optimized with a semiempirical molecular orbital method, PM3, using the Spartan 02 software (Wave function Inc., Irvine, CA). Finally, energy optimized moieties were joined with specific linkers with standard geometry using SYBYL software. Each conjugate as a whole was again energy optimized with PM3 using Spartan software.

4.12.2. Conjugate Conformations. The PM3 energy optimized structure for each conjugate was used as the initial conformation for limited conformational search to explore the conformational flexibility of these conjugates. Because of the size of molecules, molecular mechanics instead of the molecular orbital method was used for this study. The stochastic conformational search was performed using Molecular Operating Environment (MOE) software, version 2010.10, from Chemical Computing Group (Montreal, Quebec, Canada). Standard MMFFs force field and charges were used for the stochastic conformational search where the dihedral angles were randomly modified, followed by energy minimization in dihedral angles first, then energy minimization in Cartesian space. During the conformational search, the chiral centers were maintained as the original structure. No attempt was made to perform an exhaustive conformational search due to uncertainty in the environment of the conjugate in the cell or in an *in vivo* situation.

4.13. Photophysical Properties. Femtosecond transient absorption spectroscopy experiments were conducted using an ultrafast source, Integra-C (Quantronix Corp.), an optical parametric amplifier, TOPAS (Light Conversion Ltd.), and a commercially available optical detection system, Helios, provided by Ultrafast Systems, LLC. The source for the pump and probe pulses were derived from the fundamental output of Integra-C (780 nm, 2 mJ/pulse and fwhm = 130 fs) at a repetition rate of 1 kHz. Seventy-five percent of the fundamental output of the laser was introduced into TOPAS, which has optical frequency mixers resulting in a tunable range from 285 to 1660 nm, while the rest of the output was used for white light generation. Prior to generating the probe continuum, a variable neutral density filter was inserted in the path in order to generate a stable continuum, then the laser pulse was fed to a delay line that provides an experimental time window of 3.2 ns with a maximum step resolution of 7 fs. In our experiments, a wavelength between 350 to 450 nm of TOPAS output, which is the fourth harmonic of signal or idler pulses, was chosen as the pump beam. As this TOPAS output consists of not only desirable wavelength but also unnecessary wavelengths, the latter were deviated using a wedge prism with a wedge angle of 18°. The desirable beam was irradiated at the sample cell with a spot size of 1 mm diameter where it was merged with the white probe pulse in a close angle (<10°). The probe beam after passing through the 2 mm sample cell was focused on a fiber optic cable, which was connected to a CCD spectrograph for recording the time-resolved spectra (410−1600 nm). Typically, 2500 excitation pulses were averaged for 5 s to obtain the transient spectrum at a set delay time. Kinetic traces at appropriate wavelengths were assembled from the time-resolved spectral data. All measurements were conducted at room temperature, 295 K.

The fluorescence measurements were carried out with an absolute PL quantum yield measurement system (Hamamatsu photonics Co., Ltd., C9920-02) with excitation at 680 nm.

4.14. Electrochemical Measurements. Cyclic voltammetry was carried out with an EG&G Model 173 potentiostat/galvanostat. A homemade three-electrode cell was used and consisted of a glassy carbon working electrode, a platinum wire counter electrode, and a saturated calomel reference electrode (SCE). The SCE was separated from the bulk of the solution by a fritted-glass bridge of low porosity which contained the solvent/supporting electrolyte mixture. All potentials are referenced to the SCE.

UV−visible spectroelectrochemical experiments were performed with an optically transparent platinum thin-layer electrode of the type described in the literature.[29] Potentials were applied with an EG&G Model 173 potentiostat/galvanostat. Time-resolved UV−visible spectra were recorded with a Hewlett-Packard Model 8453 diode array rapid scanning spectrophotometer.

Tetra-*n*-butylammonium perchlorate (TBAP, ≥ 99%) was recrystallized from ethyl alcohol and dried under vacuum at 40 °C for at least one week prior to use. Dimethylsulfoxide (DMSO, ≥ 99.9%) were obtained from Sigma-Aldrich Chemical Co. and used without further purification.

Contents

***In Vitro* Phototoxicity Assay (MTT Assay):** To determine the *in vitro* efficacy of the compounds the following procedure was performed. Colon-26 cells were grown in RPMI 1640 with 10% FCS, 2mM L-Glutamine, 50 IU penicillin/50 µg/ml streptomycin. Cells were maintained in 5 % CO_2 and 95% air at 100% humidity. For phototoxicity studies, Colon-26 cells were plated in 96 well plates at a density of 3500 cells/well in complete medium. 4 h later, compounds were added at concentrations ranging from 0.003 to 1 µM. After 24 h incubation in the dark at 37 °C, the cells were irradiated with laser light from an argon pumped dye laser using fluences of 0-2 J/cm^2 at a dose rate of 3.2 mW/cm^2 with light adjusted to the specific maximum wavelength of each drug. The light treatment is shown in Figure 13. After irradiation, the cells were incubated for 48h. After 48 h, 15 µL/well of 4 mg/ml 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide MTT in PBS was added, and cells were incubated for a further 4 h. MTT is a yellow water soluble tetrazolium salt that is taken up by cells, reduced to water insoluble purple formazan crystals by metabolically active (viable) cells. The MTT-containing media was removed, and 100µl DMSO was added to solubilize the formazan crystals. The absorbance of the wells was read on a microtiter plate reader at a wavelength of 560 nm. The results were plotted as percent growth of control (untreated) cells *vs.* concentration range for each individual drug.

***In Vivo* Reflectance Spectroscopy:** *In vivo* reflectance spectroscopy is a non-invasive method of following the pharmacokinetics and measuring the concentration of a photosensitizer in an experimental animal. By measuring the light diffusely reflected from tissue containing the dye, the time at which the concentration is at its maximum can be determined and the light treatment can be delivered at the optimal tumor to normal tissue ratio, for the greatest selectivity. As described in reference 9, monochromatic light was delivered through a quartz fiber which was placed perpendicular to and touching the tissue. At a measured distance (3-5 mm) from the delivery fiber, a pick up fiber is also placed in contact with the tissue. Light is delivered at optical power levels of about 1µW to avoid any potential PDT effects during measurement. Light

$$C = \frac{1}{2 * \varepsilon}\left\{\left\{-\sqrt{{\mu_s}^2 + \frac{4}{3}{\alpha_0}^2} + \sqrt{{\mu_s}^2 + \frac{4}{3}\left(\frac{OD}{r} + {\alpha_0}^2\right)^2}\right\}\right. \qquad \text{Equation 1}$$

that enters the pickup fiber was conducted to a silicon photodiode detector that measured the photocurrent linear in power over 7-8 orders of magnitude. The wavelength was varied from 650-1000 nm and a spectrum of diffusely scattered photons was recorded. The concentration *C* was calculated using the formula in equation 1. Where ε is the molar extinction coefficient, α0 is the intrinsic tissue coefficient, OD is diffuse optical density, μ_3 is the reduced scattering coefficient, r is the distance from the detector to the pickup fiber. Molar extinction coefficient (ε) is measured using the Beer- Lambert law (A= ε lc).

HPLC Analysis

Method: HPLC analysis of conjugates # **7**, # **8**, and # **9** was carried out using a Waters Delta 600 System consisting of the 600 Controller, 600 Fluid Handling Unit and 996 Photodiode Array Detector equipped with a Waters Symmetry C18 column, 5 micron, with dimensions 4.6 x150mm. The mobile phase flow program was as follows: flow rate of 1.0 ml / min; mobile phase composition - 75% Methanol/ 25% water from 0 to 20 minutes , then a linear gradient to 100% Methanol from 20 minutes to 30 minutes, maintained at 100% Methanol from 30 minutes on.. Data collected and spectrally monitored from 300 nm to 799 nm. Percent purity of compounds based on 416 nm channel.

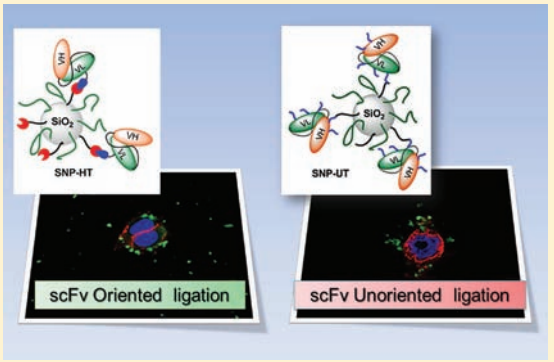
Supporting Information

ABSTRACT: Spherical silica nanoparticles (SNP) have been synthesized and functionalized with anti-HER-2 scFv800E6 antibody by both localized histidine-tag recognition, leading to an oriented protein ligation, and glutaraldehyde cross-linking, exploiting a statistical reactivity of lysine amine groups in the primary sequence of the molecule. The targeting efficiency of nanocomplexes in comparison with free scFv was evaluated by flow cytometry using a HER-2 antigen-positive MCF-7 breast cancer cell line, exhibiting a 4-fold increase in scFv binding efficacy, close to the affinity of intact anti-HER-2 monoclonal antibody, which suggests the effectiveness of presenting multiple scFv molecules on nanoparticles in improving antigen recognition. Unexpectedly, the conjugation method did not affect the binding efficacy of scFv, suggesting a structural role of lysines in the scFv molecule. Confocal laser scanning microscopy confirmed the binding of nanocomplexes to HER-2 and also provided evidence of their localization at the cell surface.



INTRODUCTION

Monoclonal antibodies (mAbs) are versatile and unique molecules that have found applications in the investigation, diagnosis, and treatment of many diseases, including cancer.[1] Although mAbs display high affinity and selectivity for the target, antibody-based therapies are often less effective toward solid tumors, because only a small amount of mAbs can indeed accumulate at the tumor tissue, due to their high immunogenicity and low penetration. Moreover, mAbs remain circulating for an extended time because their large size prevents excretion by renal clearance.[2] Recently, recombinant antibodies with modified properties have been designed in order to improve tissue penetration and biodistribution.[3] Among them, small antibody fragments consisting of the variable V_H and V_L regions connected through a synthetic loop, called single-chain fragment variable recombinant antibodies (scFv), hold great promise.[4] Target-specific scFvs are usually obtained through genetic engineering by phage display technology.[5] ScFv display has improved biodistribution compared to intact IgGs due to small size (typically in the 20−30 kDa range) and absence of a highly immunogenic stem. However, a poor retention time and a decreased affinity and specificity caused by their monovalent binding strongly limit their application in cancer immunotherapy. Hence, while immunogenicity is remarkably reduced and scFv clearance is accelerated, the binding efficacy is often reduced compared to their parent mAb resulting in a remarkably lower affinity for the receptor.

Multimerization has been recently envisaged as a strategy to enhance the functional affinity (avidity) of scFv increasing the k_a by 2−3 orders relative to the monovalent fragment.[6−8] Different multimerization strategies have been proposed to couple monovalent domains to produce multivalent antibodies, by chemical manipulation or using protein engineering approaches, including formation of diabodies, tribodies, tetrabodies, and minibodies.[9,10] Multimerized scFvs combine features from mAb and scFv that improve tumor penetration, as low immunogenicity and high affinity toward their receptor, and increase circulation time due to their large size, which prevents renal excretion.[10] So far, the conjugation of antibody fragments to nanoparticles has been seldom exploited. It has been observed that scFv having low affinity toward the epidermal growth factor receptor, when present in multiple copies on a liposome, allowed for tight receptor binding, thus filling the affinity gap between scFv and a high-affinity mutant obtained by molecular evolution.[11] However, functionalization

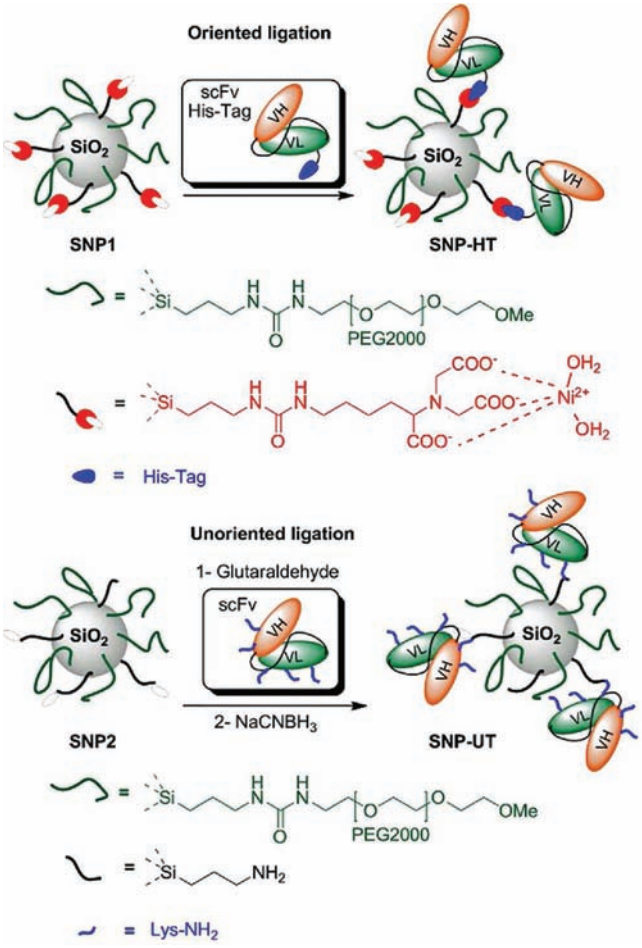
of immunoliposomes does not offer a suitable control of number and orientation of the scFv ligand displayed on their surface. Such control of scFv presentation could be better optimized by using inorganic nanoparticles.[12−14] Here, we present a strategy to enhance scFv target binding efficacy that makes use of silica nanoparticles as a multimerization scaffold. As proof of concept, we chose scFv800E6 produced in *Pichia pastoris*, that recognizes the breast cancer membrane marker HER-2.[15] Among the numerous examples of inorganic nanoparticles available so far, silica nanoparticles have been extensively studied, due to their broad application and the ease of synthesis and stable functionalization with organic ligands.[16,17] In this work, we have explored synthesis and surface functionalization of silica nanoparticles (SNP) in order to immobilize scFv800E6 by two different approaches (Scheme 1): (1) the first method exploits a localized histidine tag recognition leading to an oriented ligation of scFv; (2) the second involves a reductive amination strategy *via* glutaraldehyde cross-linking on the nanoparticle exploiting a statistical reactivity of lysine amine groups on the primary sequence of the scFv molecule.

Scheme 1. Mechanism of "Oriented" and "Unoriented" Immobilization of scFv800E6 on Functionalized Silica Nanospheres[a]



[a]Method 1: SNP1 functionalized with Ni-NTA groups tightly and specifically interact with scFv histidine tag leading to an oriented protein immobilization (SNP-HT). Method 2: the available amino groups of lysine residues of scFv bind to SNP2 via the aldehydic groups, which have been generated on the surface of nanoparticles by glutaraldehyde addition, resulting in a random ligation (SNP-UT).

EXPERIMENTAL PROCEDURES

Materials and Methods. All reagents and solvents were purchased from Sigma-Aldrich (St. Louis, MO), Fluka (St. Gallen, Switzerland), and Riedel-de Haën (Seelze, Germany) and used as received without further purification. Water was deionized and ultrafiltered by a Milli-Q apparatus (Millipore Corporation, Billerica, MA). Ultrasounds were generated by S15H Elmasonic Apparatus (Elma, Singen, Germany). TEM images of nanoparticles were obtained by a Zeiss EM-109 microscope (Oberkhochen, Germany) operating at 80 kV. Dynamic light scattering (DLS) measurements were performed at 90° with a 90 Plus Particle Size Analyzer from Brookhaven Instrument Corporation (Holtsville, NY) working at 15 mW of a solid-state laser (λ = 661 nm). Zeta-potential measurements were elaborated on the same instrument equipped with AQ-809 electrode and data were processed by *ZetaPlus* software. UV−vis spectra were recorded by using a Nanodrop 2000C spectrophotometer (Thermo Fisher Scientific, Wilmington, Germany) in a range of wavelengths from 190 to 600 nm.

Synthesis of SNP. Monodisperse silica nanospheres were obtained as described in previous work.[18] Briefly, a 25% NH_4OH solution in water (12.5 mL) and ethanol (250 mL) were mixed under magnetic stirring at 300 rpm. To the above solution was added a mixture of TEOS (6.25 mL, 28 mmol) dissolved in ethanol (7 mL) at a rate of 1 mL min^{-1} through a dropping funnel. The reaction was stirred for 20 h at room temperature (RT). At the end of the reaction, the solution became milky and the product was collected from the suspension by centrifugation at 8300 × *g* for 30 min. The white particulate was washed several times with ethanol (4 × 100 mL). Next, SNP (1.5 g) was dried under vacuum. SNP (100 mg) was redispersed in ethanol at a concentration of 4 mg mL^{-1} for further experiments.

Synthesis of Fully PEG-Coated SNP (SPEG). In a dried round-bottom flask, *O*-(2-aminoethyl)-*O*′-methylpolyethylene glycol 2000 (100 mg, 50 μmol) was dissolved in anhydrous CH_2Cl_2 (1 mL); subsequently, Et_3N (8 μL, 55 μmol) and (3-isocyanatopropyl)triethoxysilane (15 μL, 60 μmol) were added and the reaction run overnight at RT with magnetic stirring under argon atmosphere. When the reaction was completed, the solution was filtered and the clear filtrate was evaporated under reduced pressure. The resultant yellow pale oil was redissolved in a minimum amount of CH_2Cl_2 (300 μL), and cold Et_2O (10 mL) was added to precipitate the product as a white solid. The product was washed twice with Et_2O (10 mL) and finally dried under vacuum. APTS-PEG2000 (98 mg) was used immediately without further purification. The conjugation reaction was performed as follows.[18,19] A suspension of SNP in EtOH (20 mL, 1 mg mL^{-1}) was warmed at 60 °C; next, 25% NH_4OH (50 μL) and APTS-PEG2000 (20 mg, 10 μmol) were added and the resultant mixture was subjected to vigorous magnetic stirring at 60 °C overnight. The particulate was collected by centrifugation at 8300 × *g* for 15 min and washed with EtOH (2 × 10 mL) and water (10 mL). The resultant SPEG were redispersed in water (10 mL) for analyses.

Synthesis of SNP1. N^{α},N^{α}-Bis(carboxymethyl)-L-lysine (NTA) was synthesized according a previous work.[20] NTA (100 mg, 380 μmol) was suspended in anhydrous CH_2Cl_2 (8 mL) and THF (3 mL). Subsequently, Et_3N (211 μL, 1.52 mmol) and (3-isocyanatopropyl)triethoxysilane (113 μL, 456

dx.doi.org/10.1021/bc200352x | *Bioconjugate Chem.* 2011, 22, 2296−2303

μmol) were added and the reaction run overnight at RT with magnetic stirring under argon atmosphere. The resulting suspension was filtered, and the clear filtrate was evaporated under reduced pressure. The pale yellow oil was redissolved in a minimum amount of MeOH (500 mL) and cold Et_2O (10 mL) was added to precipitate the product as a white solid. The product was washed twice with Et_2O (10 mL) and finally dried under vacuum. APTS-NTA (132 mg) was used immediately without further purification.

For the conjugation reaction,[18,19] a suspension of SNP in EtOH/H_2O 1:1 (20 mL, 1 mg mL^{-1}) was warmed at 60 °C; 25% NH_4OH (50 μL), APTS-NTA (10 mg, 20 μmol), and APTS-PEG2000 (10 mg, 5 μmol) were added, and the mixture was left under vigorous stirring at 60 °C overnight. Next, the particulate was collected by centrifugation at 8300 × *g* for 15 min and washed with EtOH (2 × 10 mL) and water (10 mL). Nanoparticles were resuspended in water (20 mL) for further chelation with nickel ions. A green solution of 0.1 M $NiCl_2 \cdot 6H_2O$ in deionized water (2 mL) was added to the above suspension of nanoparticles; the pH was adjusted to pH 8.0 with 0.1 N NaOH, and the resultant mixture were kept under magnetic stirring for 30 min at RT. Then, particles were collected by centrifugation and the pale blue supernatant was discarded. The pale green particulate was washed thrice with water (10 mL) and, finally, SNP1 were resuspended in water (5 mL) and stored for further conjugation with His-tagged scFv800E6.

Synthesis of SNP2. The conjugation reaction[18,19] was performed as follows. A suspension of SNP in EtOH (20 mL, 1 mg mL^{-1}) was warmed at 60 °C; then, 25% NH_4OH (50 μL), APTS (5 μL, 20 μmol), and APTS-PEG2000 (10 mg, 5 μmol) were added and the resultant mixture was kept under vigorous magnetic stirring at 60 °C overnight. The particulate was collected by centrifugation at 8300 × *g* for 15 min and washed with EtOH (2 × 10 mL) and water (10 mL). The resultant SNP2 were stored in water (10 mL) for further conjugation with scFv.

Determination of Amine Groups on SNP2. Following a method described in the literature,[21] an aqueous mixture containing 1 M picrylsulfonic acid TNBS (10 μL) and 0.05 M $Na_2B_4O_7$ (1.5 mL) was added to a sample of aminated SNP2 (6 mg). The suspension was sonicated for 1 min and then heated at 70 °C for 10 min. At the end of reaction, the mixture was allowed to cool to RT; SNP2 was then separated from the supernatant by centrifugation at 11 200 × *g* and washed with water (1 mL), 50% acetone in water (1 mL), 100% acetone (1 mL), and water (2 × 1 mL). SNP2 was then suspended in NaOH 1 M (5 mL) and heated to 70 °C under vigorous stirring for 10 min. The suspension was cooled to RT and SNP2 were separated by centrifugation. An aliquot of the particle-free supernatant (1 mL) was then withdrawn and its absorbance read at 410 nm. Each particle contained silica (d = 2.2×10^6 g m^{-3}) with an average radius of 40 nm = 4.0×10^{-8} m. The average volume and mass of SiO_2 nanoparticles were 2.68×10^{-22} m^3 and 5.90×10^{-16} g, respectively. Hence, 1 mg of SiO_2 contained 1.02×10^{14} particles. By determination of residual absorbance due to picric acid released from reaction (Supporting Information Scheme S4), we established that 0.012 μmol of ligand APTS were immobilized on the particle surface corresponding to about 708 NH_2 groups/particle.

Dynamic Light Scattering and ζ-Potential Measurements. Viscosity and refractive index of deionized water were used to characterize the solvent. Nanoparticles were dispersed in water under sonication for several minutes before analyses; sporadically, to avoid the formation of large aggregates, the suspension was filtered through a 0.45 μm cellulose acetate filter. The final sample concentration used for measurements was typically 0.025 mg mL^{-1} (Figure S1). The same procedure was followed for hydrodynamic size distribution behavior of nanoparticles in deionized water by different Na^+ concentrations (1 mM to 20 mM) (Figure S2).

Strains and Plasmids. *P. pastoris* KM71H (*arg4; aox1::ARG4*) (Invitrogen) was used as host for expressing scFv800E6 gene. Plasmid pPICZαA (Invitrogen) was used for constructing plasmid vector, as previously described.[15]

Purification of scFv800E6. The clone KM71H-pPICZαA-scFv800E6-4 was grown in 10 mL YPD medium (1% yeast extract, 2% peptone, 2% dextrose) at 30 °C overnight with shaking at 250 rpm. The cultures were centrifuged at 1500 × *g* for 4 min, and then, the pellets were resuspended in 200 mL of BMMY (1% yeast extract, 2% peptone, 100 mM potassium phosphate pH 6.0, 1.34% YNB, 0.00004% biotin, 0.5% methanol) with 0.8% glycerol yielding an initial OD 600 value of 10. The culture was induced by daily addition of methanol to a final concentration of 0.5%. After 48 h of methanol treatment, the culture supernatant was filtered through 0.22 μm filters and dialyzed overnight in 50 mM sodium phosphate pH 8.0, 300 mM NaCl. The dialyzed medium was loaded at a flow rate of 0.5 mL/min onto a Ni-NTA Agarose (Qiagen) column (bed volume 0.5 mL) pre-equilibrated with 50 mM sodium phosphate pH 8.0, 300 mM NaCl, and 10 mM imidazole. The column was washed with 50 mM sodium phosphate pH 8.0, 300 mM NaCl, 20 mM imidazole, and the protein eluted with a stepwise imidazole gradient, 100 mM to 200 mM, in the same buffer. Fractions were collected and analyzed by SDS-PAGE. SDS-PAGE was performed according to Laemmli,[22] using 12% (v/v) polyacrylamide gels. The proteins were detected by Coomassie Brilliant Blue R-250 staining. Protein content was determined both by measuring absorbance at 280 nm and by using the Coomassie Plus Protein Assay Reagent (Termo Fisher Scientific) and bovine plasma immunoglobulin G as the standard protein.

Conjugation of His-tag scFv800E6 (SNP-HT). In a plastic tube, SNP1 (1 mg) were incubated with purified scFv800E6 (50 μg) in phosphate-buffered saline (PBS; EuroClone) in a final volume of 1000 μL and the mixture was stirred on an orbital shaker for 10 min at RT. SNP-HT were isolated from unreacted scFv800E6 by centrifugation at 11 200 × *g* for 5 min and the supernatant was discarded. Nanoparticles were washed three times with PBS (500 μL) and stored in PBS at 4 °C for further experiments. By measuring the absorbance at 280 nm, we determined an amount of scFv800E6 immobilized on nanoparticles of 26 μg per mg of SNP-HT.

Unoriented Conjugation of scFv800E6 (SNP-UT). Particle-glutaraldehyde cross-linking,[23] followed by imine reduction[24] with $NaCNBH_3$ were performed as follows. In a plastic tube, amino SNP2 (1 mg) was dispersed in borate buffer pH 7.6 (600 μL). A 5 mM glutaraldehyde solution in the same buffer (400 μL, 20 μmol) was added under stirring at RT. After 2 h, particles were isolated by centrifugation and washed once with borate buffer pH 7.6 (1 mL) and twice with PBS pH 7.4 (1 mL). At the end of the washing, nanoparticles were resuspended at a concentration of 1 mg mL^{-1} in the same buffer (1 mL) and the suspension cooled at 4 °C with an ice bath. scFv800E6 (50 μg in PBS) was added to the suspension

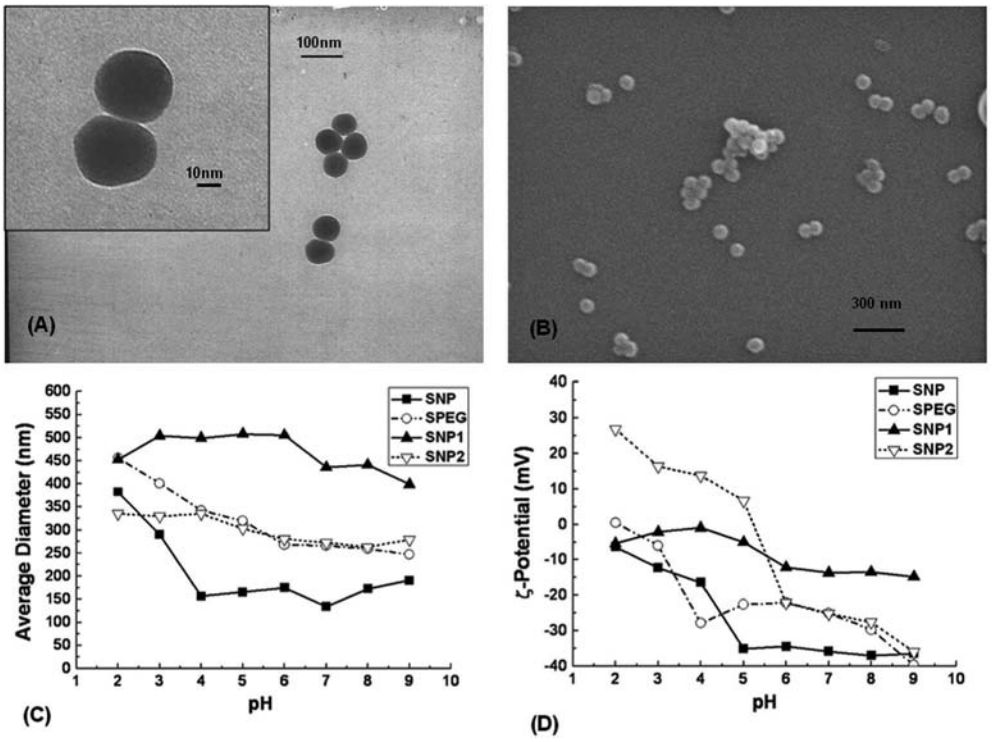


Figure 1. Characterization of modified silica nanoparticles: (A) TEM (Inset: magnification) and (B) SEM images of as-synthesized SNP. (C) DLS and (D) ζ-potential measurements of SNP, SPEG, SNP1, and SNP2 as a function of pH in aqueous solution.

and the resultant mixture was stirred on the orbital shaker for 3 h at 4 °C. ScFv-functionalized nanoparticles were recovered after centrifugation and washed twice with PBS (1 mL). Subsequently, a $NaBH_3CN$ solution (10 μL, 1 mg mL^{-1}) in PBS buffer pH 7.4 was added to the nanoparticle suspension in the same medium (1 mL) and incubated for 3 h at 4 °C. After centrifuging, SNP-UT were washed several times with PBS (3 × 1 mL) and finally were stored in the same buffer at 4 °C for further experiments. By measuring the absorbance at 280 nm, we determined an amount of scFv800E6 of 43 μg per mg of SNP-UT.

Dot Blot Assay. Dot blot was performed by filtering proteins and/or nanoparticles onto PVDF membranes, utilizing a Manifold I dot blot apparatus (GE Healthcare), and incubating in blocking solution (5% skim milk in PBS, Tween 0.05%) for 1 h at RT. The membrane was then probed for 1 h at RT in blocking solution using rabbit anti-Myc-HRP antibody (Invitrogen) at a 1:5000 dilution. Membranes were rinsed thrice in 0.05% Tween in PBS for 10 min. Immunoreactive spots were revealed using ECL Western blotting reagent (GE Healthcare).

Cell Cultures. MCF-7 and MDA cell lines were used as HER-2 positive and HER-2 negative targets, respectively. Cells were cultured in 50% Dulbecco's Modified Eagle's Medium (DMEM) and 50% F12, supplemented with 10% fetal bovine serum, L-glutamine (2 mM), penicillin (50 UI mL^{-1}), and streptomycin (50 mg mL^{-1}) at 37 °C and 5% CO_2 in a humidified atmosphere and subcultured prior to confluence using trypsin/EDTA. Cells culture medium and chemicals were purchased from EuroClone.

Flow Cytometry. Cells were cultured on a multiwell dish until subconfluence. Then, equal aliquots were incubated 15 min at 37 °C in the presence of one of the following: (i) 5 μg mL^{-1} scFv, (ii) 25.6 μg mL^{-1} TZ, (iii) SNP-HT, and (iv) SNP-UT. For each sample, 0.171 nmole of antibody, either free or immobilized on nanoparticles, was used. After incubation time, cells were washed twice with PBS and treated with typsin for 3 min. Digestion with trypsin was stopped with culture medium, cells were transferred in FACS tubes and washed twice with PBS. Then, cells were incubated for 30 min at 4 °C in blocking solution (PBS, 2% Bovine Serum Albumin) and immunodecorated with 1 μL of FITC-conjugated antibody to whole murine IgG (MP Biomedicals) for 30 min at 4 °C. The excess secondary antibody was removed by washing cells six times with PBS. Labeled cells were resuspended with 0.5 mL of PBS and analyzed on a FACS Calibur flow cytometer (Becton Dickinson). Ten thousand events were acquired for each analysis, after gating on viable cells, and isotype-control antibodies were used to set the appropriate gates.

Stability Assay of scFv Conjugation on SNP-HT. Five micrograms of scFv immobilized on SNP-HT was incubated at 37 °C with 0.1 mL of culture medium. After incubation time, SNP-HT was centrifuged 15 min at 15 000 × *g* at 4 °C, and supernatants (S1, S4, S24, and S48) were filtered onto a PVDF membrane utilizing a Manifold I dot blot apparatus (GE Healthcare). The membrane was incubated in blocking solution (5% skim milk in PBS, Tween 0.05%) for 1 h at RT, then probed 1 h at RT in blocking solution using rabbit anti-Myc-HRP antibody (Invitrogen) at a 1:5000 dilution. Membranes were rinsed thrice in 0.05% Tween in PBS for 10 min. Immunoreactive spots were revealed using ECL Western blotting reagent (GE Healthcare). Five micrograms of scFv immobilized on SNP-HT and 0.1 mL of culture medium were used, respectively, as positive and negative control.

Confocal Laser Scanning Microscopy. Cells were cultured on collagen (Sigma) precoated coverglass slides until subconfluence. Cells were incubated 1 h at 37 °C with 20 μg/mL of free-scFv800E6, and with equal amounts of scFv800E6

immobilized on SNP-HT and SNP-UT. Then, cells were washed with PBS, fixed for 10 min with 4% paraformaldehyde (Sigma), and treated for 10 min with 0.1 M glycine (Sigma) in PBS. A blocking step was performed for 1 h at RT with a solution containing 2% bovine serum albumin (Sigma) and 2% goat serum in PBS. ScFv was revealed by a FITC-conjugated antibody to whole murine IgG (MP Biomedicals) at a 1:300 dilution by incubating for 2 h at RT. Nuclei were stained with DAPI (4′,6-diamidino-2-phenylindole, Invitrogen) at 0.2 μg mL^{-1} in PBS with 0.1% Saponin (Sigma) for 20 min at RT. Membranes were stained with DiD oil (Invitrogen) at a 1:300 dilution by incubating 30 min at 37 °C. Microscopy analysis was performed with a Leica SP2 AOBs microscope confocal system. Images were acquired with 63× magnification oil immersion lenses at 1024 × 1024 pixel resolution.

RESULTS AND DISCUSSION

Uniform 60 nm spherical SNPs were synthesized by hydrolysis and condensation of tetraethyl orthosilicate (TEOS) in a 25% NH_4OH ethanolic solution.[18] In method 1, previously prepared APTS-PEG2000-OMe[25] and APTS-NTA in a 1:1 molar ratio were co-condensed on SNP in alkaline ethanol resulting in NTA-functionalized SNP1 (Schemes S1,2 in SI).[19] According to previous reports,[26] PEG chains enhanced the nanoconjugate solubility in buffered media and prevented nonspecific adsorption of proteins. ScFv800E6 protein containing a 6 × His-affinity tag was produced in *P. pastoris*, secreted in culture medium, and purified through affinity chromatography, as previously described.[15] Subsequent Ni^{2+} chelation by nitriloacetic acid groups of SNP1 promoted the active Ni^{2+}-NTA affinity-oriented immobilization of His-tagged scFv (SNP-HT) by incubation at room temperature. In method 2, APTS-PEG2000-OMe and APTS in a 1:1 molar ratio were co-condensed on SNP (Scheme S3 in SI).[23] Next, the covalent attachment of scFv was performed via glutaraldehyde cross-linking resulting in functional SNP2, stabilized by reduction of the diimine intermediate with $NaCNBH_3$,[27] to give SNP-UT. In Figure 1, TEM (A) and SEM (B) images show that the core size of SNP was 60 ± 5 nm indicating a homogeneous formulation of silica nanospheres. The hydrodynamic diameter of SNP in ethanol was 78.3 ± 2.2 nm, as determined by dynamic light scattering (DLS, Figure S1 in SI). The pH-dependent behavior of SNP, SNP1, SNP2, and fully PEG-coated nanosilica (SPEG) was investigated by DLS in the 2−9 pH range (Figure 1C). All the nanosilica tested did not exhibit the formation of critical aggregates between pH 4 and 9. Zeta potential (ζ) of SNP, SPEG, SNP1, and SNP2 in water in the 2−9 pH range was also investigated (Figure 1D). From pH 5 to 9, SNP were strongly negatively charged (−35.85 ± 0.64 mV), whereas at pH 4 and lower, the charge approached neutrality (−6.40 ± 1.77 mV). Similar behavior was also observed for SPEG, although they were only −25.01 ± 0.38 mV at pH 7 because of the charge-shielding effect of the PEG layer on the nanoparticle surface. In contrast, SNP1 exhibited a remarkably low surface charge at pH 7 (−13.64 ± 0.74 mV), in accordance with the presence of the Ni^{2+} chelates on the external carboxylic groups of NTA. This charge did not appreciably change in the pH range tested. SNP2 were negatively charged (−25.23 ± 1.03 mV) at pH 7−9. However, below pH 5, a gradual shift of the charge to positive values (+16.39 ± 1.35 mV at pH 3) was observed, in line with the presence of protonated amino groups of APTS in acidic conditions.

After conjugation, the amount of scFv800E6 on SNP-HT and SNP-UT was quantified by protein assay of supernatants at 280 nm using a calculated $\varepsilon_{280\ nm}$ of 55 600 M^{-1}. The immobilization of scFv on SNP-HT was also confirmed by dot-blot assay (Figure 2). SNP-HT (5 μg) and free scFv (0.5, 0.2, 0.1, and 0.05 μg) were filtered onto a polyvinylidene fluoride (PVDF) membrane and then probed with an anti-Myc-HRP antibody. Intensities of immunoreactive spots of SNP-HT and 0.1 μg of free scFv were comparable. This reasonably fits with the amount of bound scFv that we inferred from the determination of unbound protein, i.e., 0.125 μg.

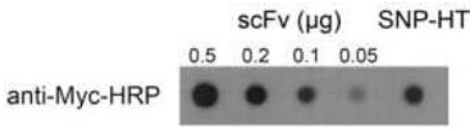

Figure 2. Dot-blot assay of SNP-HT conjugated with scFv. Different amounts of scFv800E6 (0.5, 0.2, 0.1, and 0.05 μg) and an aliquot of SNP-HT were filtered on a PVDF membrane, then probed with anti-Myc-HRP antibody and revealed with an ECL substrate.

To assess the effect of multivalent presentation of scFv on silica nanoparticles, SNP-HT and SNP-UT binding toward HER-2 receptor in breast cancer cells was evaluated by flow cytometry. Free scFv, the commercial anti-HER-2 mAb (trastuzumab, TZ), SNP-HT, and SNP-UT, containing equal amounts of conjugated scFv, were incubated 15 min with HER-2-positive MCF-7 cells.[28] Flow cytometry evidenced a right-shift of fluorescence signal accounting for an increase in scFv binding efficacy upon multimerization due to SNP conjugation (Figure 3). Values reported in Figure 3B show a 3-fold increase in mean fluorescence intensity of SNP-UT sample in comparison with free scFv at the same scFv concentration. Moreover, scFv multimerized on SNP *via* glutaraldehyde cross-linking (SNP-UT) exhibited a mean fluorescence intensity value very close to that of intact TZ, indicating that there was a significant improvement in receptor binding capability, which can be attributed to avidity effect. However, the conjugation strategy exploited for scFv multimerization on SNP surfaces (method 1 vs method 2) did not prove to be crucial in enhancing scFv binding efficiency. Indeed, SNP-HT and SNP-UT exhibited similar fluorescence intensities when assessed by flow cytometry. To account for this unexpected result, we inspected the localization of lysines in scFv sequence. Multiple sequence alignment of scFv800E6 with other scFv sequences available in the NCBI database revealed that all lysine residues are highly conserved. This clearly indicates that these residues are not directly involved in HER-2 binding. Instead, quite likely they only play a structural role. Therefore, an involvement of this residue in glutaraldehyde cross-linking is not expected to interfere significantly with HER-2 binding.

Moreover, to exclude the release of scFv from SNP-HT and assess the stability of this conjugation method, we have incubated SNP-HT for 1, 4, 24, and 48 h at 37 °C and 5% CO_2 atmosphere. Supernatants of incubation were then filtered on PVDF membrane and probed with an anti-Myc-HRP antibody. Release of scFv800E6 in cell culture medium was not observed under the conditions tested, confirming that scFv conjugation on SNP-HT was stable within 48 h of incubation at 37 °C (Figure 4).

To validate flow cytometry data, the specificity of binding between SNP-HT or SNP-UT and HER-2 was assessed by

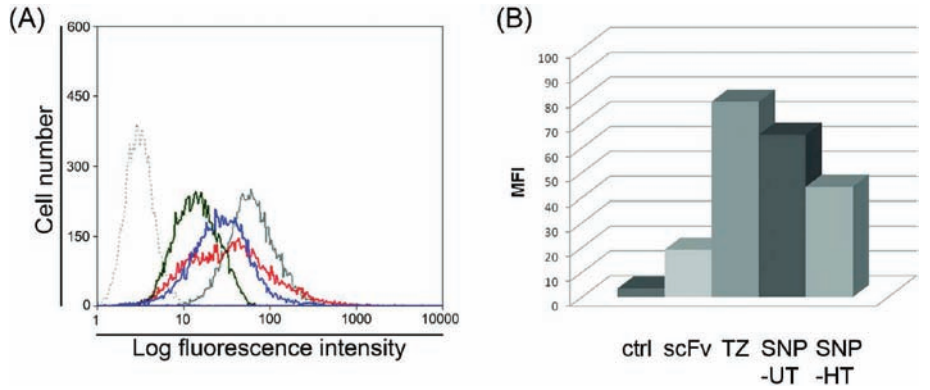

Figure 3. Multivalent presentation of scFv800E6 onto SNP-HT and SNP-UT enhances binding avidity toward HER-2 receptor. (A) MCF-7 cells were incubated with scFv (black), SNP-HT (blue), SNP-UT (red), or trastuzumab (TZ; gray continuous) and processed by flow cytometry. ScFv incubation with HER-2 cells as negative control (gray dashed line). (B) Mean fluorescence intensity (MFI).

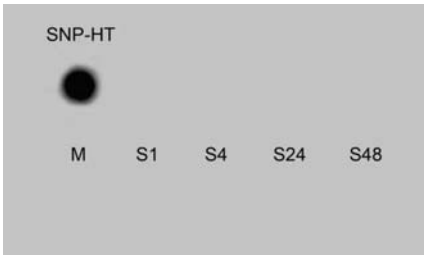

Figure 4. Stability assay of scFv conjugation on SNP-HT. 5 μg of scFv immobilized on SNP-HT was incubated at 37 °C with 0.1 mL of culture medium. After incubation time, SNP-HT were centrifuged 15 min at 15 000 × *g* at 4 °C and supernatants (S1, S4, S24, and S48) were filtered on a PVDF membrane. Membranes were then probed with anti-Myc-HRP antibody and revealed with an ECL substrate. 5 μg of scFv immobilized on SNP-HT was used as a positive control. 0.1 mL of culture medium (M) was used as negative control.

confocal laser scanning microscopy (Figure 5). As HER-2 is a transmembrane receptor, we expected an accumulation of SNP-HT and SNP-UT at the level of the cell membrane of HER-2-positive cells only, which would confirm that nanoparticle capture occurs via specific membrane receptor-mediated internalization. HER-2 positive MCF-7 cells (Figure 5) were treated with scFv to assess HER-2 expression and cellular surface distribution. SNP-HT and SNP-UT were incubated in parallel with both MCF-7 and MDA cells (Figure 6) at a scFv concentration of 25 μg mL^{-1} of culture medium for 1 h at 37 °C. In order to discriminate between specific binding to the membrane receptor and a possible nonspecific adsorption of SNP, we revealed scFv, SNP-HT, and SNP-UT with FITC-labeled antiwhole mouse secondary antibodies (green), instead of exploiting intrinsically fluorescent silica nanospheres (Figures 5A,6A). Nuclei were stained with DAPI (Figures 5B,6B) while membranes were stained with DiD oil (Figures 5C,6C). As expected, both SNP-HT and SNP-UT (Figure 5A) were observed on HER-2-positive MCF-7 cell surface but not on HER-2-negative MDA cells (Figure 6A), which demonstrates that they are actually capable of specifically targeting their transmembrane receptor. Merged images in Figure 5D also show that SNP-UT and SNP-HT were mostly localized on cell membrane after 1 h incubation, although a small amount of nanoparticles were already internalized.

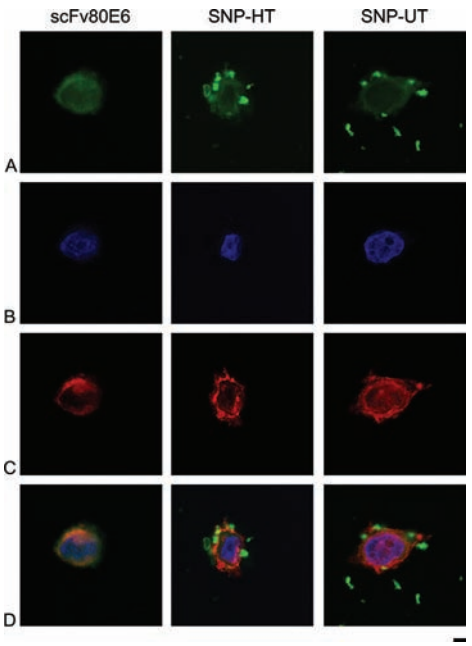

Figure 5. Assessment of HER-2 target efficacy of SNP-HT and SNP-UT on HER-2 positive cells. SNP-HT and SNP-UT were incubated with MCF-7 cells at a scFv concentration of 25 μg mL^{-1}. Free scFv was used as a positive control. ScFv, SNP-HT, and SNP-UT were revealed with FITC-labeled antiwhole mouse secondary antibodies (green, A). Nuclei were stained with DAPI (B), membranes (MB) with DiD oil (C). Merge images are shown in D. Scale bar: 10 μm.

CONCLUSION

In summary, we present a nanoparticle-based multimerization strategy aimed at enhancing the functional affinity of scFv toward cancer cell receptors. So far, the increase in binding efficiency of an antibody fragment has been primarily obtained by either chemically linking the individual scFv units or constructing multivalent variants by connecting antibody fragment with oligomerization domains. Our strategy lead to the facile and reliable development of nanoparticles allowing for multiple presentation of scFv molecules on a rigid nanosized spherical surface, which proved very effective and selective in binding the specific transmembrane receptor in living cells, as assessed by flow cytometry and confocal microscopy. These results suggest that the use of size- and shape-controlled inorganic nanoparticles as a multimerization scaffold is capable

Supporting Information

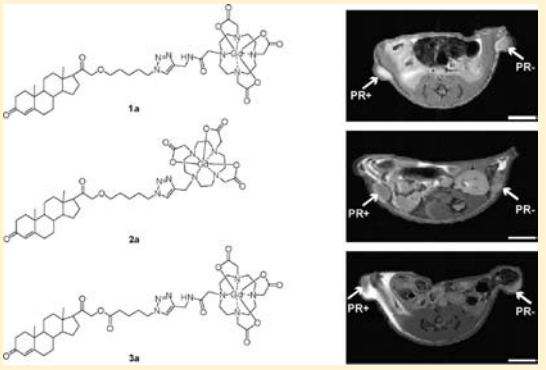
ABSTRACT: Progesterone receptor (PR) is strongly associated with disease prognosis and therapeutic efficacy in hormone-related diseases such as endometriosis and breast, ovarian, and uterine cancers. Receptor status is currently determined by immunohistochemistry assays. However, noninvasive PR imaging agents could improve disease detection and help elucidate pathological molecular pathways, leading to new therapies and animal disease models. A series of water-soluble PR-targeted magnetic resonance imaging (MRI) probes were synthesized using Cu(I)-catalyzed click chemistry and evaluated *in vitro* and *in vivo*. These agents demonstrated activation of PR *in vitro* and preferential accumulation in PR(+) compared to PR(-) human breast cancer cells with low toxicity. In xenograft tumor models, the agents demonstrated enhanced signal intensity in PR(+) tumors compared to PR(-) tumors. The results suggest that these agents may be promising MRI probes for PR(+) diseases.



INTRODUCTION

Biomedical imaging has traditionally focused on detecting abnormalities in gross anatomical structures.[1] However, there has been a recent increase in the interest of developing targeted agents that noninvasively provide information about physiological and pathological processes on a molecular level.[1−4] In this regard, steroid receptors have emerged as particularly attractive targets for molecular imaging due to their role in promoting the growth of breast, ovarian, uterine, and prostate cancers.[5]

Previous attempts to image steroid receptors have focused on positron emission tomography (PET).[1,6] PET imaging of estrogen receptor (ER) in breast cancer and androgen receptor (AR) in prostate cancer has been successful.[7−10] However, imaging of progesterone receptor (PR) has been limited in humans due to rapid metabolism of the tracers by 20-hydroxysteroid dehydrogenase.[11−13] In addition, PET suffers from the disadvantages of low spatiotemporal resolution and requirements of a nearby cyclotron and radiochemistry facilities.[2]

Magnetic resonance imaging (MRI) offers excellent spatiotemporal resolution without exposure to harmful radiation or the need for specialized radiochemistry equipment.[2] Although the sensitivity of PET imaging agents far surpasses that of any other modality, MRI contrast agents can be optimized to enhance the otherwise low sensitivity of these probes.[2,14,15] Therefore, MRI is an excellent alternative to PET for detecting steroid receptors and, in particular, PR.

Several PR-targeted MRI contrast agents have been previously developed.[16−18] One of these agents, referred to as ProGlo, preferentially accumulated and enhanced MR signal in tissues and tumors with high PR expression.[19] In contrast to the PR-targeted PET imaging agent, ProGlo may be less rapidly metabolized due to the steric hindrance from the Gd(III) chelate preventing binding to 20-hydroxysteroid dehydrogenase.[20]

Due to the low solubility of ProGlo in aqueous media, *in vivo* delivery of this agent was limited to subcutaneous or intraperitoneal injection routes rather than intravenous injections.[19] Furthermore, the effect of hydrophobicity on nonspecific interactions with biomolecules and the correlation between hydrophobicity and toxicity have been well-documented in numerous drugs.[21−23] The association of ProGlo with toxicity when intraperitoneally injected into athymic nude mice was, therefore, not surprising, and is likely a consequence of its hydrophobic properties and nonspecific interactions, necessitating the development of water-soluble contrast agents. Minimizing lipophilicity in

imaging agents has been reported to decrease background signal by reducing nonspecific interactions in tissues.[1] In addition, imaging breast cancers, as opposed to tumors that form in the peritoneal space, should be significantly improved by intravenous imaging agent delivery, which can take advantage of leaky vasculature to accumulate and remain inside those tumors specifically expressing PR.

The current work describes the synthesis of a novel series of water-soluble PR-targeted MR probes. These new agents demonstrated activation of PR *in vitro* with lower cytotoxicity than ProGlo. Higher cellular Gd(III) accumulation was observed in comparison to a nontargeted agent, particularly in PR(+) cells. Finally, these agents preferentially enhanced signal intensity in PR(+) tumors compared to PR(-) tumors and were not associated with toxicity in preliminary *in vivo* studies.

EXPERIMENTAL SECTION

General Methods. Unless noted, materials and solvents were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO) and used without further purification. $GdCl_3 \cdot 6H_2O$ and 1,4,7,10-tetraazacyclododecane (cyclen) were purchased from Strem Chemicals (Newburyport, MA) and used without further purification. Unless noted, all reactions were performed under a nitrogen or argon atmosphere. DMSO, *N*,*N*-dimethylformamide, and methanol were purified using a Glass Contour Solvent system. Deionized water was obtained from a Millipore Q-Guard System equipped with a quantum Ex cartridge (Billerica, MA). Thin-layer chromatography (TLC) was performed on EMD 60F 254 silica gel plates. Visualization of the developed chromatogram was performed by CAM stain and platinum stain. Standard grade 60 Å 230−400 mesh silca gel (Sorbent Technologies) was used for flash column chromatography. ^{1}H and ^{13}C NMR spectra were obtained on a Bruker 500 MHz Avance III NMR Spectrometer with deuterated solvent as noted. Electrospray ionization mass spectrometry (ESI-MS) spectra were taken on a Varian 1200 L single-quadrupole mass spectrometer. High-resolution mass spectrometry data were acquired on an Agilent 6210 LC-TOF (ESI, APCI, APPI). Analytical reverse-phase HPLC-MS was performed on a Varian Prostar 500 system with a Waters Atlantis C18 column (4.6 × 250, 5 μm). This system is equipped with a Varian 380 LC ELSD system, a Varian 363 fluorescence detector, a Varian 335 UV−vis detector, and a Varian 1200 L Quadrupole MS detector. Preparative runs were performed on a Waters Atlantis C18 column (19 × 250, 10 μm). Mobile phase consisted of water (solvent A) and HPLC-grade acetonitrile (solvent B).

Synthesis. *{1,4,7-Tris(carboxymethyl)-10-[10-(6-(2-((10R,13S,17S)-10,13-dimethyl-3-oxo-2,3,6,7,8,9,10,11,12,13,14,15,16,17-tetradecahydro-1H-cyclopenta[a]phenanthren-17-yl)-2-oxoethoxy)hexyl]-1,4,7,10-tetraazacyclododecanato}Gd(III) (ProGlo).* The synthesis and purification of ProGlo were performed as previously described.[17]

*2-(10,13-Dimethyl-3-oxo-2,3,6,7,8,9,10,11,12,13,14,15,16,17-tetradecahydro-1H-cyclopenta[a]phenanthren-17-yl)-2-oxoethyl 5-bromopentanoate (**8**).* A solution of 21-hydroxyprogesterone (300 mg, 1.36 mmol), 5-bromovaleric acid (111 mg, 0.613 mmol), diisopropyl carbodiimide (DIC) (122 μL, 0.786 mmol), and 4-(dimethylamino)pyridinium-4-toluenesulfonate (DPTS) (207 mg, 0.666 mmol) in anhydrous dichloromethane (1.1 mL) was stirred for 16 h at room temperature. The reaction mixture was diluted in dichloromethane and washed with water three times. The organic layer was dried over sodium sulfate and concentrated by rotary evaporation. The crude residue was purified by flash chromatography with hexanes/ethyl acetate (1:1) as the eluent to afford **8** as a white solid (348 mg, 75%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.65 (1H, s, 4-H), 4.68 (1H, d, J = 17, $COCH_2O$), 4.45 (1H, d, J = 17, $COCH_2O$) 3.36 (2H, t, J = 6.5, CH_2Br), 2.47−0.80 (complex, 26H), 1.12 (3H, s, CH_3), 0.63 (3H, s, CH_3); ^{13}C NMR (125 MHz, $CDCl_3$) δ 203.77, 199.80, 172.71, 171.17, 124.18, 69.34, 59.31, 56.41, 53.79, 51.04, 44.91, 38.81, 38.56, 35.94, 35.77, 34.16, 33.39, 32.98, 32.1, 32.2, 24.71, 23.62, 23.07, 21.22, 17.59, 13.43; ESI-MS m/z $[M + H]^+$ observed: 494.8, calculated: 495.2.

*2-(10,13-Dimethyl-3-oxo-2,3,6,7,8,9,10,11,12,13,14,15,16,17-tetradecahydro-1H-cyclopenta[a]phenanthren-17-yl)-2-oxoethyl 5-azidopentanoate (**10**).* To a solution of **8** (325 mg, 0.639 mmol) in anhydrous *N*,*N*-dimethylformamide (7 mL) was added sodium azide (415 mg, 6.39 mmol). The reaction mixture was heated to 65 °C and stirred overnight. Excess sodium azide was filtered off and the solvent was removed by rotary evaporation. The crude residue was dissolved in ethyl acetate and washed with water three times. The organic layer was dried over sodium sulfate and concentrated followed by flash chromatography in hexanes/ethyl acetate (4:3) to give **10** (206 mg, 71%). ^{1}H NMR (500 MHz, CD_3CN) δ 5.62 (1H, s, 4-H), 4.72 (1H, d, J = 17, $COCH_2O$), 4.53 (1H, d, J = 17, $COCH_2O$), 3.31 (2H, t, J = 6.5, CH_2N_3), 2.55−0.99 (complex, 26H), 1.17 (3H, s, CH_3), 0.64 (3H, s, CH_3); ^{13}C NMR (125 MHz, CD_3CN) δ 204.49, 199.18, 173.04, 171.81, 123.86, 69.81, 59.25, 56.55, 54.21, 51.43, 44.95, 39.12, 38.60, 36.20, 35.94, 34.28, 33.36, 32.96, 32.52, 28.46, 24.79, 23.62, 23.07, 21.46, 17.35, 13.20. ESI-MS m/z $[M + Na]^+$ observed: 478.3, calculated: 478.3.

*17-(2-((5-Bromopentyl)oxy)acetyl)-10,13-dimethyl-6,7,8,9,10,11,12,13,14,15,16,17-dodecahydro-1H-cyclopenta[a]phenanthren-3(2H)-one (**7**).* A mixture of 21-hydroxyprogesterone (200 mg, 0.605 mmol), 1,5-dibromopentane (1.65 mL, 12.1 mmol), 40% KOH (300 μL), and tetrabutylammonium hydroxide (60 μL) was stirred for 16 h at room temperature. The reaction mixture was diluted in dichloromethane and washed with water three times. The organic layer was dried over sodium sulfate and concentrated by rotary evaporation. The crude residue was purified by flash chromatography with hexanes/ethyl acetate (2:1) as the eluent to afford **7** as a colorless oil (125 mg, 43%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 5.67 (s, 1H), 3.96 (q, J = 17.2 Hz, 2H), 3.41 (t, J = 6.4 Hz, 2H), 3.38−3.31 (m, 2H), 2.56 (t, J = 9.1 Hz, 1H), 2.40−2.09 (m, 6H), 1.96 (m, 1H), 1.90−1.74 (m, 5H), 1.72−1.16 (m, 14H), 1.12 (s, 3H), 1.05−0.86 (m, 2H), 0.65−0.58 (m, 3H). ^{13}C NMR (125 MHz, $CDCl_3$) δ 207.55, 198.50, 169.94, 122.92, 75.79, 70.34, 61.56, 57.43, 55.12, 52.51, 43.53, 37.54, 34.61, 32.85, 31.74, 31.47, 30.82, 28.69, 27.74, 23.77, 23.47, 21.81, 19.97, 16.34, 12.55. ESI-MS m/z $[M + H]^+$ observed: 481.1, calculated: 481.2.

*17-(2-((5-Azidopentyl)oxy)acetyl)-10,13-dimethyl-6,7,8,9,10,11,12,13,14,15,16,17-dodecahydro-1H-cyclopenta[a]phenanthren-3(2H)-one (**9**).* To a solution of **7** (125 mg, 0.261 mmol) in anhydrous *N*,*N*-dimethylformamide (7 mL) was added sodium azide (169 mg, 2.61 mmol). The reaction mixture was heated to 65 °C and stirred overnight. Excess sodium azide was filtered off and the solvent was removed by rotary evaporation. The crude residue was dissolved in ethyl acetate and washed with water three times. The organic layer was dried over sodium sulfate and concentrated followed by flash chromatography in hexanes/ethyl acetate (2:1) to give **9** (78 mg, 68%). ^{1}H NMR (500 MHz, CD_3OD) δ 5.61 (d, J = 4.9 Hz, 1H), 3.39 (t, J = 6.4 Hz, 2H), 3.25−3.17 (m, 4H), 2.60 (t, J = 9.1 Hz, 1H), 2.45−2.33 (m, 2H), 2.25−2.15 (m, 2H), 2.12−2.03 (m, 1H), 1.99 (m, 1H), 1.89−1.76 (m, 2H), 1.70−1.29 (m, 15H), 1.29−1.15 (m, 2H),

1.13 (d, J = 11.0 Hz, 4H), 1.04−0.87 (m, 2H), 0.60 (s, 3H). ^{13}C NMR (125 MHz, CD_3OD) δ 210.81, 202.29, 174.92, 124.24, 78.00, 72.34, 62.71, 59.71, 57.39, 55.16, 52.43, 45.67, 39.99, 39.72, 36.81, 34.72, 33.90, 33.20, 30.15, 29.75, 25.52, 24.46, 24.17, 23.76, 22.15, 17.67, 13.96. ESI-MS m/z $[M + Na]^+$ observed: 464.2, calculated: 464.3.

General Procedure for Click Chemistry. All click chemistry reactions were run in 1:1 methanol/water or 1:1 DMSO/water solutions. The steroid derivative (1 equiv) and Gd(III) or Eu(III) chelate (1.1 equiv) were dissolved and N_2 gas was bubbled through the solution to remove oxygen. Sodium ascorbate (1 equiv), $CuSO_4$ (0.167 equiv), and [(1-benzyl-1*H*-1,2,3-triazol-4-yl)methyl]amine (TBTA) (0.02 equiv) were added and the reaction mixture was stirred at 60 °C for 24 h. The crude residue was purified by reverse-phase preparative HPLC using a ramp from 0% to 100% B over 20 min. Analytical HPLC traces of the purified complexes are given in the Supporting Information.

*{2,2′,2″-(10-(2-(((1-(5-(2-(10,13-Dimethyl-3-oxo-2,3,6,7,8,9,10,11,12,13,14,15,16,17-tetradecahydro-1H-cyclopenta[a]phenanthren-17-yl)-2-oxoethoxy)pentyl)-1H-1,2,3-triazol-4-yl)methyl)amino)-2-oxoethyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetate}gadolinium (**1a**).* HRMS (ESI) m/z $[M + H]^+$ observed: 1034.4231, calculated: 1034.4267 for $C_{45}H_{68}GdN_8O_{10}$.

Relaxivity. Solutions of **1a**, **2a**, **3a**, **4a**, **5a**, and **6a** were prepared in 500 μL of Millipore water for T_1 and T_2 acquisition. T_1 and T_2 relaxation times were measured on a Bruker mq60 NMR analyzer equipped with *Minispec v 2.51* rev. 00/NT software (Billerica, MA, USA) operating at 1.41 T (60 MHz) and 37 °C. T_1 relaxation times were measured using an inversion recovery pulse sequence using the following parameters: 4 scans per point, 10 data points for fitting, monoexponential curve fitting, phase cycling, 10 ms first pulse separation, and a recycle delay and final pulse separation of $\geq 5T_1$. The Gd(III) concentration of each solution was determined using ICP-MS. The inverse of the relaxation time ($1/T_1$, s^{-1}) was plotted against Gd(III) concentration (mM) and fitted to a straight line with $R^2 > 0.99$. The slope of the fitted line was recorded as the relaxivity, r_1.

Octanol−Water Partition Coefficients. Approximately 1 mg of each compound was dissolved in 1 mL of a 1:1 mixture of water/1-octanol. After shaking the sample tube vigorously for 30 s, the tube was placed on a rotator for gentle mixing over 4 h. The tube was then removed from the rotator and allowed to sit for 10 h to ensure complete separation of the aqueous and organic phases. 50 μL was removed from each layer and subjected to ICP-MS to determine the Gd concentration in each layer. The partition coefficient was calculated from the following equation: $\log_{10} P = \log_{10}(C_o/C_w)$, where $\log_{10} P$ is the logarithm of the partition coefficient, C_o is the concentration of Gd in the 1-octanol layer, and C_w is the concentration of Gd in the water layer.

Determination of *q*. The Eu(III) complexes were dissolved in D_2O and H_2O. The emission was monitored at 614 nm with excitation at 395 nm on a Hitachi F4500 fluorescence spectrophotometer operating in phosphorescence lifetime mode. Twenty-five scans were averaged and fit to a monoexponential decay ($R^2 > 0.98$) to give the phosphorescent lifetimes which were entered into this equation (corrected for one amide oscillator): $q = 1.0\ (k_{H2O} - k_{D2O} - 0.25 - 0.075)$.[24,25]

Receptor Binding to nPR. The progesterone receptor A ligand binding domain (amino acids 675−933) fused to GST (PR-LBD-GST; 80 nM), a fluorescently tagged PR ligand (fluoromone green PL; 4 nM), and progesterone, ProGlo, **1a**, or **3a** (several concentrations) were incubated in PR screening buffer with 4 mM dithiothreitol (DTT) in a total volume of 100 μL for 4 h at room temperature according to the manufacturer's protocol (Invitrogen, Carlsbad, CA, USA). Each sample was measured using the Beacon 2000 fluorescence polarization analyzer (Invitrogen, Carlsbad, CA) located in the Northwestern University Keck Facility. The machine was used in static mode, batch blank, no delay, with an average of 1 read per cycle, at 22 °C. A sample containing only buffer and PR-LBD-GST with no fluorescent PL was used as the blank to eliminate background signal from the protein or buffer. A sample with no competitor was used to determine 100% binding capacity of the PR-LBD-GST for the PL ligand. Curve fitting and error calculation was performed using *Prism* software from GraphPad Software, Inc. (La Jolla, CA).

General Cell Culture. Dulbecco's modified phosphate buffered saline (DPBS), media, sera, and dissociation reagents were purchased from Invitrogen (Carlsbad, CA). Cell culture consumables (flasks, plates, etc.) were purchased from VWR (Radnor, PA). Charcoal dextran stripped FBS was purchased from Atlanta Biologicals (Lawrenceville, GA). MDA-MB-231 cells were cultured using phenol red free α-MEM (modified to contain 20 ng/mL insulin) supplemented with 10% FBS (characterized) or with 10% charcoal dextran stripped FBS. T47D cells were cultured using phenol red free RPMI 1640 (modified to contain 1.0 mM sodium pyruvate, 1.0 mM HEPES, and 4.5 g/L glucose) supplemented with 10% FBS or 10% charcoal dextran stripped FBS. Prior to all experiments, cells were plated in the appropriate medium containing noncharcoal dextran stripped FBS. After plating, this medium was replaced with medium containing the stripped FBS and allowed to sit for 24 h, at which point the medium was replaced with fresh stripped medium and the cells were allowed to sit for another 24 h prior to

beginning the experiment. MDA-MB-231 and T47D cells were harvested by incubation with 0.25% TrypLE for 10 min at 37 °C in a 5.0% CO_2 incubator. All incubations were carried out at 37 °C in a 5.0% CO_2 incubator unless otherwise specified.

Cell Counting and Percent Cell Viability Determination Using Guava EasyCyte Mini Personal Cell Analyzer (PCA) System. After cell harvesting, an aliquot (15 or 30 μL) of the cell suspensions were mixed with Guava ViaCount reagent (final sample volume of 150 μL) and allowed to stain at room temperature for at least 5.0 min (no longer than 20 min). Stained samples were then vortexed for 10 s, after which cells were counted and percent cell viability determined via manual analysis using a Guava EasyCyte Mini Personal Cell Analyzer (PCA) and ViaCount software module. For each sample, 1000 events were acquired with dilution factors that were determined based upon optimum machine performance (~25−70 cells/μL). Instrument reproducibility was assessed daily using GuavaCheck Beads and following the manufacturer's suggested protocol using the Daily Check software module.

Cellular Uptake Studies. Contrast agents were dissolved in the appropriate medium (containing stripped FBS) for each cell line (T47D and MDA-MB-231) at concentrations of 2, 1, 0.5, 0.25, and 0.125 mM of contrast agent. For concentration-dependent cellular uptake, cells were incubated with 2, 1, 0.5, and 0.25 mM of each contrast agent for 4 h. For the time dependent cellular uptake, cells were incubated with 0.125 mM contrast agent for 1, 4, 10, and 24 h. After incubation, the media was removed, and the cells were rinsed twice with PBS and trypsinized. An aliquot was used for cell counting and the remaining portion was analyzed for Gd(III) content by ICP-MS. Each condition was done in triplicate.

Fractionation of Nuclear, Cytoplasmic, and Membrane Components. T47D and MDA-MB-231 cells were incubated with 0.250 mM of contrast agent (in the appropriate medium containing stripped FBS) for 10 h. After incubation, the cells were rinsed twice with PBS, trypsinized, pelleted (500*g* for 5 min), and resuspended in PBS. A portion was removed for cell counting, and the rest was pelleted (500*g* for 5 min) and the PBS removed. Cytoplasmic and nuclear fractions were extracted using a NE-PER Nuclear and Cytoplasmic Extraction Kit according to manufacturer protocol (Pierce, Rockford, IL). The remaining pellet after cytoplasmic and nuclear extraction was assumed to consist mainly of membrane. Each fraction was analyzed for Gd(III) content by ICP-MS.

Cytotoxicity. The CellTiter 96 AQ_{ueous} Non-Radioactive Cell Proliferation Assay (Promega, Madison, WI) was used to measure cell viability. Cells were plated at 5000 cells/well in 96 well plates and maintained in medium containing stripped serum for 48 h before beginning the experiment. ProGlo, progesterone, **1a**, **2a**, **3a**, and **4a** were dissolved in varying concentrations in media. After 24 h of incubation, the assay was run according to manufacturer protocol. Absorbance was measuring using a Biotek Synergy4 microplate reader in the High Throughput Analysis Facility at Northwestern University.

Luciferase Assay for nPR Activation. T47D cells were grown in phenol-free medium, and cells were trypsinized and plated in 24-well plate (50 000 cells/well). Incubation of cells with the pPRE-luciferase plasmid (100 ng/well, construct provided by Dr. Ken Korach, NIEHS, NIH), RSV-β-galactosidase (100 ng/well, provided by Dr. William T. Beck, University of Illinois at Chicago), and Lipofectamine 2000 (1 μL per well, Invitrogen, Carlsbad, CA) in Opti-MEM was performed overnight at 37 °C inside a humidified incubator. The cells were treated with **1a**, **2a**, **3a**, and **4a** for an additional 24 h.

To measure luciferase production, cells were lysed in 100 μL GME buffer (25 mM glycylglycine at pH 7.8, 15 mM $MgSO_4$, 4 mM EGTA, 1 mM dithiothreitol, and 1% Triton X-100) and lysates were added to assay buffer (GME buffer, 16.5 mM KPO_4, 2.2 mM ATP, and 1.1 mM dithiothreitol). Luciferase substrate was injected followed by a 30 s read by a FLUOstar OPTIMA (BMG Lab Tech, Offenburg, Germany). LacZ activity (50 μL lysate) was measured from cleavage of ONPG. The sample results were normalized to β-galactosidase to account for transfection efficiency by dividing the sum of the luciferase activity by the sum of the β-galactosidase activity. Fold change was calculated by taking the luciferase value, dividing by the β-galactosidase activity, and then dividing by the solvent control, which was set equal to one.

RT-PCR. Total RNA was isolated using Qiagen RNA easy columns with on column DNase added according to the manufacture (Qiagen, Valencia, CA). RNA samples (2 μg) were then primed with random hexamers and reverse transcribed with M-MLV Reverse Transcriptase (Promega, Madison, WI) according to manufacturer's instructions. From the original RT reaction, 1 μL was subjected to PCR amplification in a 25 μL volume with Taqman Universal PCR SYBR Green Master Mix (Applied Biosystems, Foster City, CA) under the following conditions: 50 °C hold 2 min, 95 °C hold for 10 min, the 40 cycles of 95 °C for 15 s, 65 °C for 30 s, and 72 °C for 1 min. The primers used were designed using Integrated DNA technologies primer quest for ZBTB16 forward 5′TGTTTGAGATCCTCTTCCACCG-CA3′ and reverse 5′ TCTCCAGCATCTTCAGGCACTGTT3′ and normalized to GAPDH forward 5′ ATGGGGAAGGTGAA-GGTCG3′ and reverse 5′GGGGTCATTGATGGCAACAATA3′.

ICP-MS Sample Preparation and Instrument Parameters. For octanol−water partition coefficients, relaxivity, and cell studies, ACS reagent grade nitric acid (70%) was added to solutions of the agent in water or 1-octanol, cell suspensions, and media (for a 1.0:1.0 v/v sample/nitric acid) in 15 mL conical tubes and placed at 65 °C for at least 4.0 h to allow for complete sample digestion. For samples in 1-octanol, tubes were vented every 30 min due to buildup of pressure. Nanopure H_2O and internal standard (either indium or multielement) were added to produce a final solution of 3.0% nitric acid (v/v) and 5.0 ng/mL internal standard. Gd(III) standards were prepared at 0.10, 0.25, 0.50, 1.0, 5.0, 10, 25, and 50 ng/mL concentrations with 3.0% nitric acid (v/v) and internal standard final concentrations.

ICP-MS was performed on a computer-controlled Thermo (Waltham, MA) X Series II inductively coupled plasma mass spectrometer equipped with a CETAC 260 autosampler. Each sample was acquired using 1 survey run and 3 main (peak jumping) runs. The isotopes selected were ^{156,157}Gd, as well as ^{115}In and ^{165}Ho (as internal standards for data interpolation and machine stability).

Animal Experiments. Female Balb/C athymic nude mice were acquired from Harlan (Indianapolis, IN) and housed under pathogen free conditions. All animal studies were conducted at Northwestern University in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals and established institutional animal use and care protocols. Due to low circulating estradiol levels in nude mice, a 17β-estradiol pellet (Innovative Research of America, Sarasota, FA, 70-day release, 0.72 mg/pellet) was implanted subcutaneously in the nape of the neck to ensure growth of estrogen-dependent

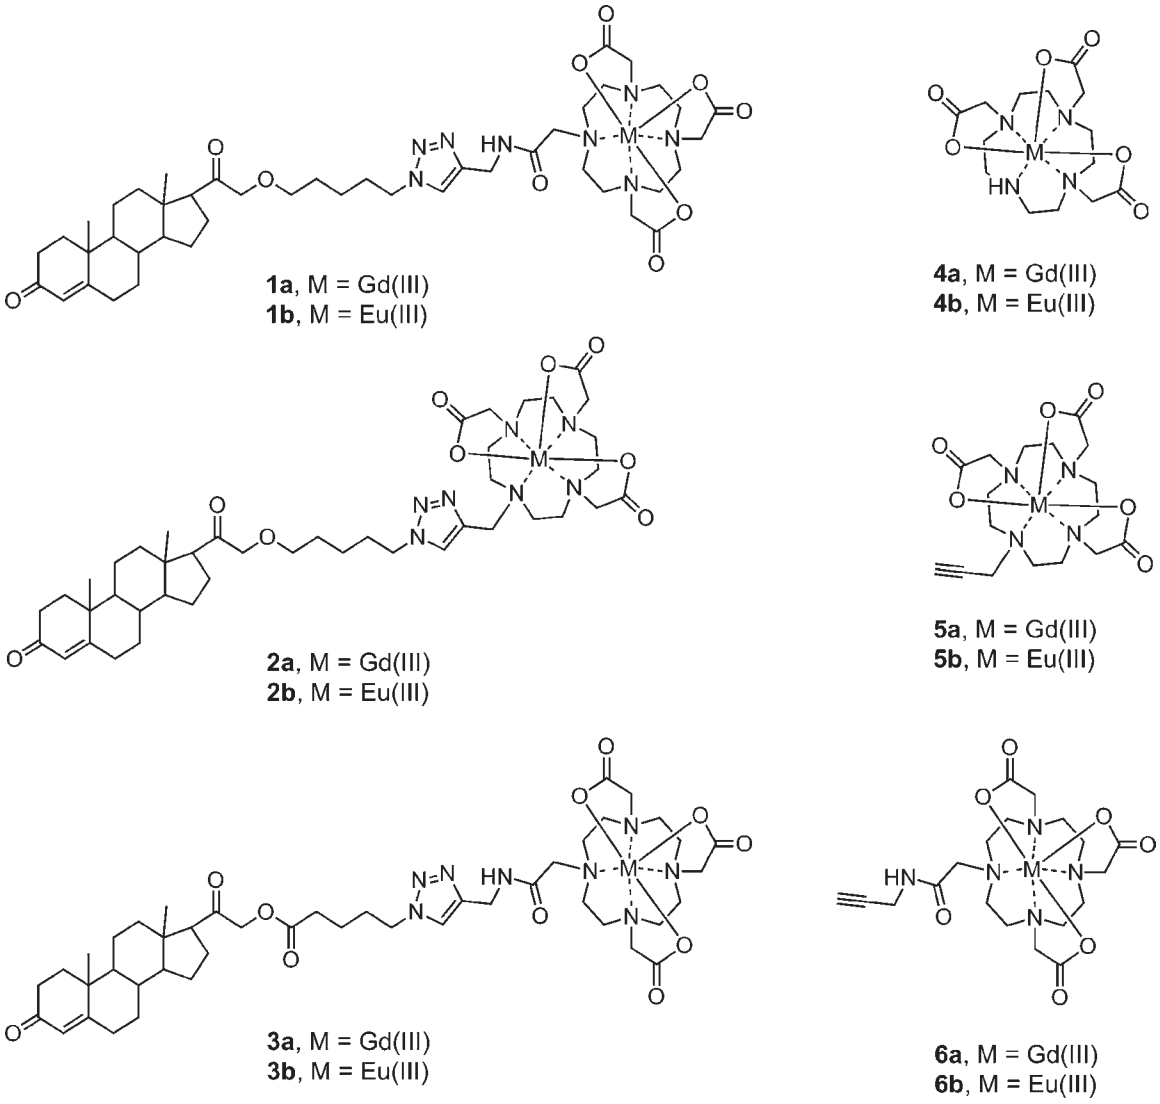

Figure 1. Chemical structures of the PR-targeted agents (**1**−**3**) and the nontargeted control agents (**4**−**6**) used in this study.

T47D cells. Two to seven days later, T47D and MDA-MB-231 ($(1-2) \times 10^6$) cells were suspended in Matrigel (1:1 volume) and injected subcutaneously into the rear flank (T47D cells on the right side and MDA-MB-231 cells on the left). Mice were monitored for tumor growth every two to three days after injection of cells. Mice were imaged two to three weeks after xenografting when tumors were palpable with a minimum weight of 20 mg (determined after tumor removal postimaging).

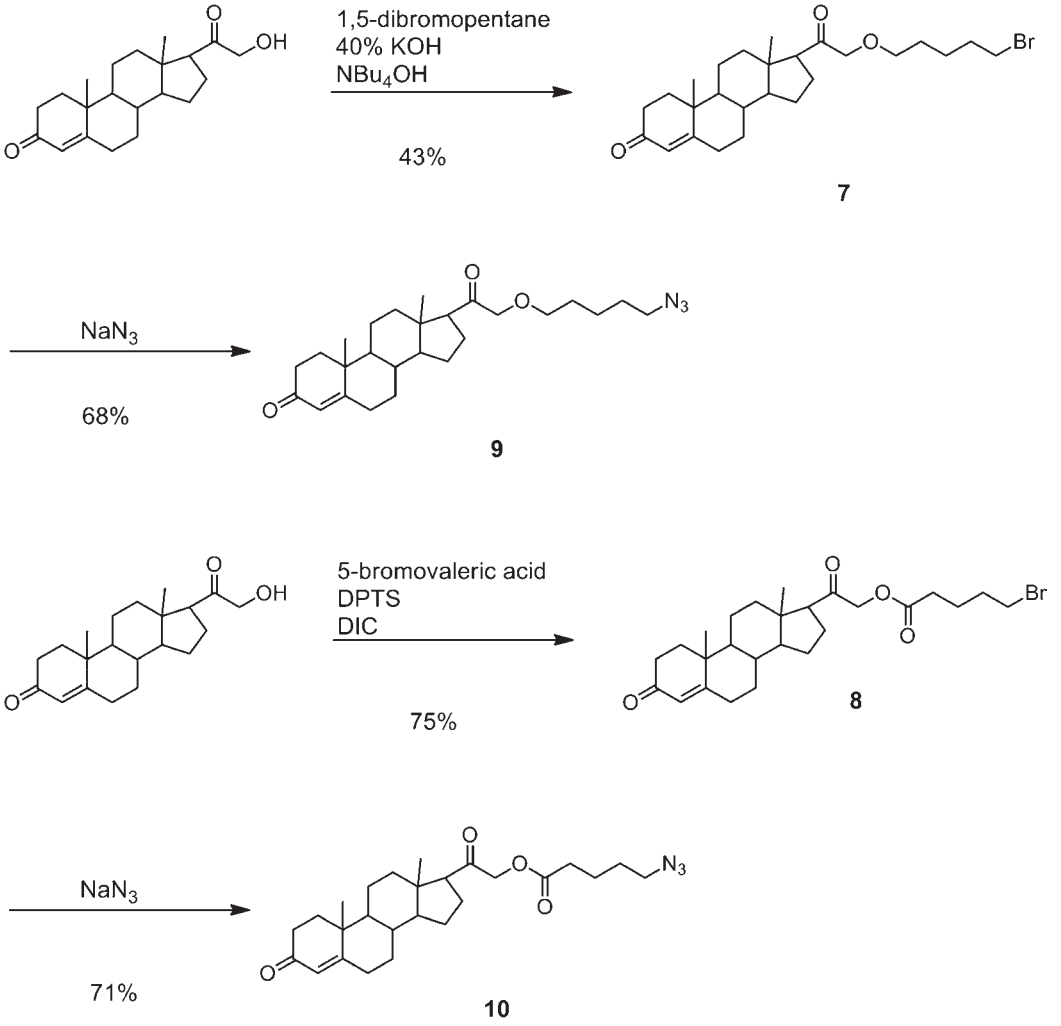
***In Vivo* MR Imaging.** Xenografted nude mice were injected intraperitoneally (n = 1 per compound) with each agent (0.15 mmGd/kg) dissolved in 50 μL DMSO. During imaging, mice were maintained under anesthesia (1−3% isoflurane) but were allowed to wake up and recover between imaging time points. Tubing containing heated water was positioned under the mouse to keep a constant body temperature. All MR imaging was performed on a 89 mm bore size PharmaScan 7.05 T MR imager fitted with shielded gradient coils (Bruker BioSpin, Billerica, MA, USA) using a RF RES 300 1H 089/038 quadrature transmit receive volume coil (Bruker BioSpin, Billerica, MA, USA).

Standard T_1-weighted multislice multiecho (MSME) scans with fat suppression were used for imaging the uterus, ovaries, and xenografts: TR = 700 ms, TE = 10.635 ms, FOV = 35 × 35 mm, matrix size = 256 × 256, slice thickness = 1.0 mm, contiguous slices. Images were analyzed using *ImageJ*. Contrast-to-noise ratio (CNR) was calculated using the equation $CNR = (SI_{Tissue} - SI_{Muscle})/\sigma_{noise}$ where SI_{Tumor} is the signal intensity in the tumor, SI_{Muscle} is the signal intensity in the muscle, and σ_{noise} is the standard deviation of the noise. CNRs were averaged over two to three axial slices in which the tumors were clearly demarcated.

RESULTS

Click Chemistry Synthesis of Water-Soluble PR-Targeted MRI Contrast Agents. ProGlo was proven to be a successful PR-targeting MRI contrast agent *in vitro* and *in vivo*.[17,19] However, its insolubility in aqueous media resulted in a degree of toxicity and limited *in vivo* delivery.[19] In order to increase the solubility of ProGlo while attempting to retain its biological properties, the core structure of the targeting steroid and the Gd(III) chelate were maintained while the linker was modified. The structures of the new PR-targeted agents and nontargeted control agents used in this study are presented in Figure 1.

Scheme 1. Synthesis of the Azide Derivatives of Progesterone (9 and 10)[a]



[a] These were synthesized and coupled to the alkyne-functionalized Gd(III) or Eu(III) chelates via Cu(I)-catalyzed click chemistry.

The synthesis of each water-soluble PR-targeted agent began with the coupling of 1,5-dibromopentane or 5-bromovaleric acid to 21-hydroxyprogesterone off the 21-hydroxyl group because PR is known to accommodate bulky substituents on the D ring of the progesterone.[17,26,27] Reaction with sodium azide yielded the azido derivative of these steroids (Scheme 1). Using copper-catalyzed click chemistry (Scheme 2),[28,29] these steroid derivatives were attached to alkyne-functionalized Gd(III) chelates, **5a** and **6a**, which were synthesized using modifications of previously reported procedures.[19,30−34]

Relaxivities, Hydration Numbers, and Octanol−Water Partition Coefficients of Progesterone-Conjugated MRI Probes. The longitudinal relaxivities of the PR-targeted agents and **4a** are similar to those reported for clinically used contrast agents, about 4−5 mM^{-1} s^{-1} (Table 1).[35,36] Like most clinically used contrast agents, each of the PR-targeted agents has approximately one water molecule bound to the Gd(III), as determined by analysis of hydration number (q) on the Eu(III) analogues of these agents (Table 1). For complex **2b**, the coordination of one water molecule, rather than two, indicates that the triazole ring from the click reaction coordinates to the Gd(III), an effect that was previously reported.[33] For **3b** and **1b**, the q of one is due to the coordination of the amide group back to the metal.

Octanol−water partition coefficients (log P) were measured to determine the hydrophobicity of these agents, which correlates to the cellular permeability and tissue distribution (Table 1).[21,37] The negative log P value for **4a** was characteristic of its high water solubility. The log P values of these water-soluble PR-targeted agents are between the values for ProGlo and **4a**, indicating an intermediate hydrophobicity.

High Receptor Binding Affinity is Maintained by Progesterone-Modified Gd(III) Chelates. The new water-soluble agents were expected to have receptor binding affinities similar to that of ProGlo because the chemical modification occurred at the same position on the steroid. Compounds **1a** and **3a** were chosen to compare the effect of the ether to an ester linker in terms of PR binding (**2a** was not tested because this molecule has the same linker as **1a**). The relative binding affinities (RBAs) of these agents and of ProGlo were measured (Table 1). Both **1a** and **3a** have RBAs similar to that of ProGlo and about 100-fold less than that of progesterone. These results are consistent with previously published data that demonstrated approximately 100-fold lower binding affinity of ProGlo compared to unmodified progesterone.[17] Although **3a**

Table 1. Characterization of the Water-Soluble PR-Targeted Agents and Nontargeted Control Agents

agent[a]	r_1 (mM^{-1} s^{-1})[b]	r_2 (mM^{-1} s^{-1})[b]	q	log P	RBA
1	4.16 ± 0.05	4.78 ± 0.26	0.75	−0.37 ± 0.09	0.40%
2	4.16 ± 0.50	4.48 ± 0.33	1.03	−0.59 ± 0.04	n.d.[c]
3	4.26 ± 0.13	4.90 ± 0.14	1.24	−0.27 ± 0.08	0.29%
ProGlo	5.35 ± 0.74	6.14 ± 0.81	n.d.	1.40 ± 0.08	0.45%
4	4.05 ± 0.018	4.75 ± 0.35	2.13	−2.96 ± 0.35	n.d.
5	4.98 ± 0.069	5.64 ± 0.24	2.16	n.d.	n.d.
6	3.36 ± 0.11	3.89 ± 0.20	1.21	n.d.	n.d.

[a] Gd(III) complexes (**1a**−**6a**) were used for measuring relaxivities, log P, and RBA; Eu(III) complexes (**1b**−**6b**) were used for measuring q. [b] 1.41 T, 37 °C. [c] n.d. = not determined.

demonstrated a minimal decrease in binding affinity (likely due to the presence of the additional carbonyl), the RBAs of these agents indicate that the modifications made to the linker did not significantly affect their ability to bind PR as compared to ProGlo.

Progesterone-Conjugated MRI Probes Demonstrate Enhanced Cellular Association. To determine the cell permeability of the compounds, PR(+) (T47D) and PR(-) (MDA-MB-231) human breast cancer cells were incubated with **1a**, **2a**, **3a**, and **4a**. Time- and concentration-dependent experiments were performed to identify the optimal dose and incubation times of the agents (Figure 2). Each agent demonstrated increased cellular Gd(III) accumulation with increased incubation concentrations in both cell lines. However, time-dependent accumulation was observed only for **2a** in the PR(+) cells. The uptake of **1a** in the PR(+) cells increased slightly after 1 h and then stabilized, while the Gd(III) levels in PR(+) cells incubated with **3a** had decreased by 24 h in comparison to earlier time points. No time dependence in uptake was seen in PR(-) cells as the Gd(III) levels

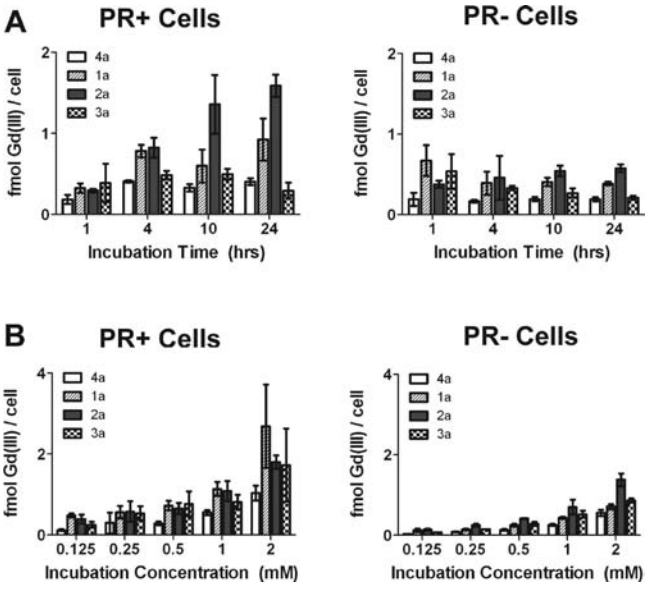

Figure 2. Cellular uptake of PR-targeted agents and nontargeted control. (A) Time-dependent cellular uptake of Gd(III) in PR(+) versus PR(-) cells after incubation with **4a**, **1a**, **2a**, and **3a**. (B) Concentration-dependent cellular uptake of Gd(III) in PR(+) versus PR(-) cells after incubation with **4a**, **1a**, **2a**, and **3a**. Error bars represent mean ± standard deviation.

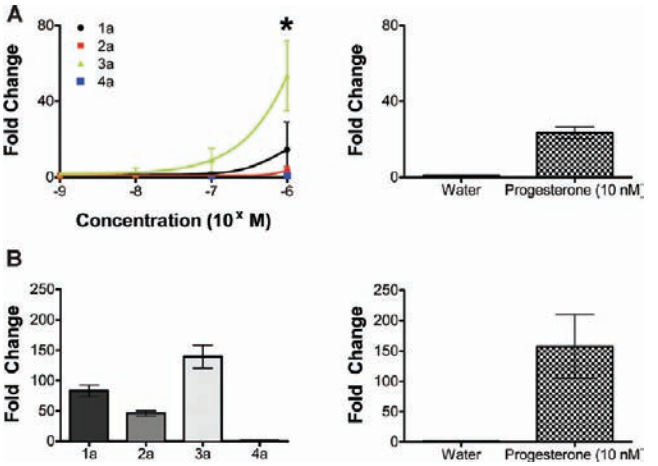

Figure 3. Progesterone Gd(III) chelates initiate gene transcription. (A) Incubation with **3a** resulted in the greatest transcriptional activation of luciferase reporter gene, while incubation with **4a** resulted in no transcriptional activation (left). The asterisk denotes a significant difference in activation after incubation with **3a** compared to **1a** (at the highest incubation concentration, $p < 0.05$, Student's t test). Activation with water or 10 nM progesterone is shown as a control (right). (B) Endogenous gene transcription is consistent with the luciferase assay. Induction of ZBTB16 was normalized to GAPDH. Error bars represent mean ± standard deviation.

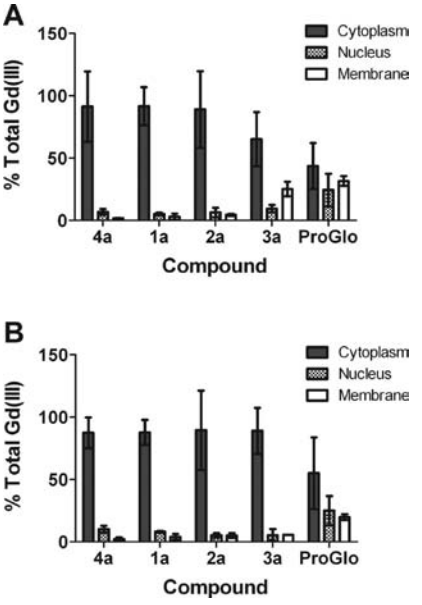

Figure 4. Subcellular localization of the water-soluble PR-targeted agents, ProGlo, and nontargeted **4a**. (A) Subcellular localization in PR(+) T47D cells. (B) Subcellular localization in PR(-) MDA-MB-231 cells. Error bars represent mean ± standard deviation. The water-soluble agents predominantly localized to the cytoplasm, whereas ProGlo was distributed in significant levels in the nucleus and membrane.

remained constant at all time points or even decreased (for **3a**). The uptake of the steroid-conjugated agents was higher than that of **4a** at all time points and cell lines, except for **3a**, which showed equal or lower Gd(III) than **4a** at the 24 h time point in both cell lines. These results indicate that the presence of the steroid moiety encourages cellular uptake of the targeted contrast agents when compared to the nonfunctionalized Gd(III) chelate.

Importantly, the Gd(III) accumulation of the PR-targeted agents was significantly higher in PR(+) than in PR(-) cells. While the uptake of **4a** was higher in PR(+) cells than in PR(-) cells, the difference in uptake was lower than for the progesterone-conjugated agents (particularly **1a** and **2a**). These data indicate that conjugation with progesterone increases the ability of Gd(III) contrast agents to associate with cells. In addition, the increased Gd(III) accumulation in PR(+) cells compared to PR(-) cells suggests that PR likely plays a role in the accumulation and retention of these progesterone-conjugated agents.

Water-Soluble PR-Targeted Agents Cross the Cell Membrane and Activate PR. Progesterone receptors bind to a region of DNA referred to as the progesterone response element (PRE).[17] This DNA element was ligated to the luciferase gene and used to verify the ability of the compounds to cross the cell membrane and interact with PR to form a functional transcription complex. The change in luciferase activity at increasing incubation concentrations of each PR-targeted contrast agent is shown in Figure 3a (left graph). The graph on the right in Figure 3 shows the change in luciferase activity when cells were incubated with either water or 10 nM progesterone as a positive control. As expected, the control compound **4a** did not induce PRE-mediated transcription to any significant extent. However, incubation with each of the progesterone derivatives resulted in luciferase activity, indicating that these compounds entered the cells and bound to PR as agonistic ligands. Interestingly, **3a** was the most effective agent despite its low cell uptake and lower relative binding affinity for PR *in vitro* compared to **1a** and **2a**. Compound **2a** demonstrated the lowest efficacy of the three progesterone-conjugated agents.

To further investigate the ability of the contrast agents to activate transcription, PR-regulation of the gene ZBTB16 was examined based on previous reports of its induction in T47D

cells (Figure 3b). The increase in ZBTB16 transcription in response to **1a**−**4a** and progesterone was measured and normalized to GAPDH. Each progesterone-conjugated agent activated transcription after incubation at 10 nM, providing further evidence that these agents cross the cell membrane and bind to PR. Furthermore, the transcriptional activation demonstrated the same relative potency as the luciferase assays in that **3a** demonstrated the highest activation of endogenous gene transcription. As expected, control agent **4a** did not result in transcription of endogenous ZBTB16.

Water-Soluble MRI Contrast Agents Localize to the Cytoplasm. To examine the cellular distribution of the water-soluble PR-targeted agents as compared to **4a** and ProGlo, PR(+) and PR(-) cells incubated with each agent were subjected to a nuclear cytoplasmic fractionation kit (Figure 4). The pellet remaining after isolation of the nuclear and cytoplasmic fractions was assumed to contain material that was primarily associated with cell membrane proteins.

As expected, the majority of each agent was found in the cytoplasm of each cell type. However, the fraction of agent in the cytoplasm was lowest for ProGlo in both PR(+) and PR(-) cells. For **4a** and the water-soluble PR-targeted agents, the fraction of agent in the cytoplasm was around 80−90% in both cell lines except for **3a**, which showed a lower fraction in the cytoplasm of the PR(+) cells. The fraction of Gd(III) in the nucleus and membrane was similar for **4a** and the water-soluble agents in both cell lines, although **3a** had a higher presence in the pellet fraction in the PR(+) cells. ProGlo was found in high levels (relative to **1a**−**4a**) in the pellet and in the nucleus in both cell lines.

The majority of PR resides in the cytoplasm, but it was expected that incubation with the targeted contrast agents would result in translocation of a fraction of the total cytoplasmic receptor to the nucleus, leading to higher levels of Gd(III) in the nucleus after incubation with the targeted agents compared to **4a**. While the luciferase assays and real-time PCR indicated that PR was activated, the difference in levels of progesterone-conjugated agents versus **4a** that translocated to the nucleus was likely too low to detect using ICP-MS. However, the cell fractionation data indicate that in cells incubated with the water-soluble contrast agents, the majority of the Gd(III) associated with these cells is intracellular and not interacting within the membrane. While this was true for cells incubated with ProGlo, 20−30% of the total ProGlo was detected in the remaining membrane pellet fraction. The hydrophobicity of ProGlo likely increased nonspecific interaction with nontargeted biomolecules and could explain high levels of the agent in the membrane, as well as the higher levels in the nucleus compared to fractions from cells incubated with the water-soluble agents.

Water-Soluble Agents Demonstrate Lower Cytotoxicity than ProGlo. To determine the toxicity profile of the agents, a MTS assay of cell viability was conducted after incubating T47D or MDA-MB-231 cells with varying concentrations of each agent for a 24 h period. The toxicities of the water-soluble agents were compared to that of progesterone, ProGlo, and the nontargeted **4a**, and the data are presented in Figure 5.

As expected, in PR(+) T47D cells, the water-soluble PR-targeted agents were less toxic than ProGlo at all concentrations except for the lowest concentration tested. In addition, progesterone was more toxic than the water-soluble agents at the highest concentration tested (2.5 mM), but reached similar levels at 1.25 mM and lower. Control agent **4a** was nontoxic at all concentrations tested. In PR(-) MDA-MB-231 cells, all agents had similar toxicity profiles, including **4a**. While the effect on cell viability in both cell types was similar for ProGlo and progesterone, **4a** and the water-soluble PR-targeted agents were surprisingly more toxic in the MDA-MB-231 cells than in the T47D cells. **3a** was the most toxic of the water-soluble agents in both cell lines.

Water-Soluble Progesterone-Conjugated MRI Contrast Agents Specifically Enhance Contrast in PR(+) Preliminary Xenograft Images. To determine whether the water-soluble progesterone-conjugated agents would increase the contrast-to-noise ratio (CNR) of PR(+) tumors relative to PR(-) tumors *in vivo*, athymic nude mice with PR(+) and PR(-) xenografted tumors were injected intraperitoneally with **1a**, **2a**, or **3a** dissolved in DMSO and imaged at 2 and 6 h postinjection. Intraperitoneal injection was chosen over subcutaneous injection because it yielded more consistent results in previous studies, and the parent compound, ProGlo, has been more extensively studied for its biodistribution after intraperitoneal injection.[19] In addition, while these agents are water-soluble, they were dissolved in DMSO to compare back to previous *in vivo* imaging with the insoluble ProGlo and the control agent **4a**.[19]

After injection of each of the PR-targeted agents, the PR(+) tumor exhibited significantly higher CNR than the PR(-) tumor at 6 h postinjection with **2a**, 2 and 6 h postinjection with **1a**, and 2 h postinjection with **3a** (Figure 6A, top graphs). At all other time points, the CNRs in the PR(+) and PR(-) were not significantly different. This is in contrast to the CNRs after injection with nontargeted **4a**, in which the CNRs of the PR(+) and PR(-) tumors were not significantly different at any time point.[19] The uptake of these agents in the different tumor types can be partially attributed to PR-independent mechanisms, which would explain the presence of contrast agent in the PR(-) tumors. However, the increased CNR in the PR(+) compared to the PR(-) tumor is seen only with the progesterone-functionalized agents, indicating that the agents used here are targeting PR *in vivo*. Most likely, the higher accumulation in the PR(+) tumors is a result of accumulation and retention due to interaction with PR as previously reported[17] rather than PR-driven uptake of the agents.

Analysis of the xenograft images revealed that the PR-targeted agents each increased the CNR in both tumors over the preinjection CNR levels, particularly after injection of **1a** and **3a** (Figure 6A, bottom graphs). Injection with ProGlo was previously reported to similarly increase CNR several-fold in both tumors, while injection with Gd-DO3A resulted in only minimal increases in CNR over time. Furthermore, the fold changes in CNR (compared to the preinjection CNR) in the PR(+) tumors after injection with **1a** and **3a** were 16% and 34% higher, respectively, at the 2 h time point than with ProGlo.[19] Injection with **3a** resulted in the highest overall increase in CNR of the three agents, but **1a** demonstrated a several-fold increase in CNR along with higher CNR in the PR(+) tumor than the PR(-) tumor at both the 2 and 6 h time points. These data provide evidence that the water-soluble PR-targeted probes function better as tumor imaging agents compared to nonfunctionalized **4a**, and they preferentially target PR(+) cancer cells over PR(-) cancer cells (in similar fashion to ProGlo). Of the three water-soluble agents tested, **1a** provided an optimal balance between tumor uptake and specificity for PR(+) cells compared to PR(-) cells. Representative images of the xenografts at each time point are shown in Figure 6B.

Importantly, there was no observed toxicity associated with mice that were intraperitoneally injected with these water-soluble

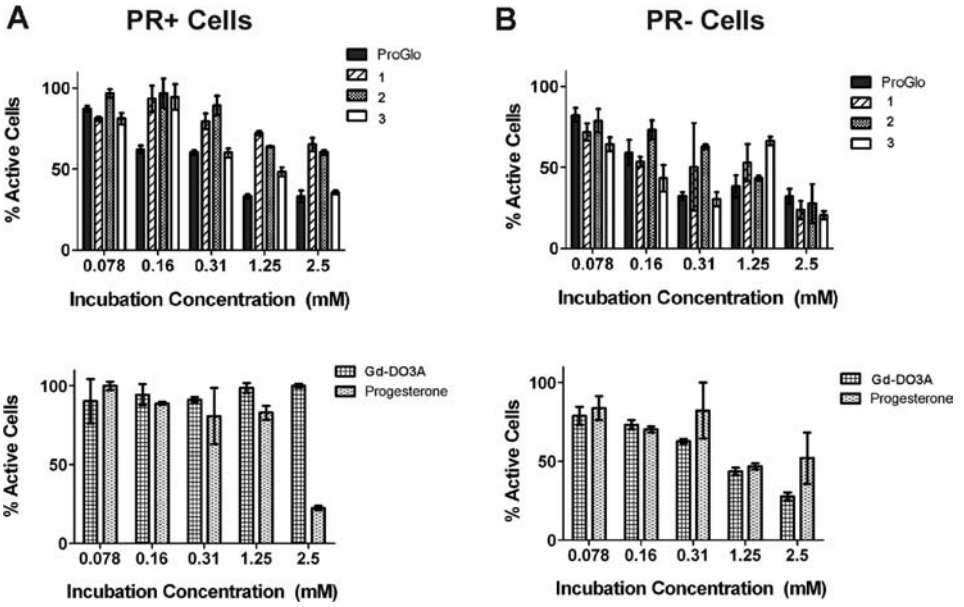

Figure 5. Cytotoxicity of the PR-targeted agents (top graphs) compared to progesterone and nontargeted **4a** (bottom graphs). (A) Cell viability in PR(+) T47D cells. (B) Cell viability in PR(-) MDAMB-231 cells. The water-soluble PR-targeted agents are associated with lower toxicity than ProGlo in both cell lines.

PR-targeted agents. Intraperitoneal injection with ProGlo had previously been associated with toxicity (xenografted mice injected with ProGlo in this manner became lethargic after the 6 h time point and did not survive to 24 h).[19] The mice injected with the water-soluble agents, however, remained active and survived to 24 h after injection with no changes in behavior.

DISCUSSION

Steroid receptors such as PR correlate with disease prognosis and therapeutic efficacy in breast cancer.[5,38] Receptor status is currently determined by immunohistochemistry assays of tumor biopsy samples, but noninvasive PR imaging agents would allow for improved molecular characterization, treatment decisions, and repeat analyses.[12] The hydrophobic PR-targeted ProGlo previously described demonstrated accumulation in, and consequent enhancement of, CNRs in PR-rich organs and tumors *in vivo*.[19] Here, we have described the synthesis and biological testing of several new water-soluble ProGlo derivatives. These agents were associated with lower toxicity than ProGlo, but retained the ability to target PR *in vitro* and in preliminary *in vivo* experiments.

ProGlo is preferentially taken up by and retained in PR(+) cells and enhances the signal intensity of PR-rich tissues *in vitro* and *in vivo*. However, this agent was associated with toxicity both *in vitro* and *in vivo*[19] due to its hydrophobic nature.[21−23] To decrease toxicity while maintaining PR targeting and biological activity, the structure of ProGlo was modified by using click chemistry to introduce a 1,2,3-triazole ring into the linker between progesterone and the Gd(III) chelate, which resulted in increased solubility. 1,4-Disubstituted 1,2,3-triazole are known to possess a large dipole moment, and the nitrogen atoms act as hydrogen bond acceptors, which improves the solubility in water.[39] In addition, this triazole is spaced several carbons away from the steroid and did not interfere with receptor binding, as evidenced by the similar RBAs for these novel agents as compared to ProGlo.

The induction of luciferase and endogenous progesterone-regulated ZBTB16 by each PR-targeted agent indicates that these agents crossed the cell membrane and bound to PR at biologically significant amounts. While **3a** was not taken up well by cells, the ester may have hydrolyzed (due to the presence of esterases or via other mechanisms) to release 21-hydroxyprogesterone. This cleavage product would bind more strongly to PR and could explain the higher transcriptional activity observed after incubation with **3a**.

The water-soluble progesterone-conjugated agents were less toxic than ProGlo due to their hydrophilic nature. The reduced toxicity is partially explained by decreased nonspecific interactions with these water-soluble agents as compared to ProGlo, as demonstrated by the cell fractionation experiments. ProGlo was distributed almost evenly across all the compartments analyzed, while the water-soluble agents were primarily located in the cytoplasm, indicating more nonspecific interaction between Proglo and off-target biomolecules. Incubation with **3a** resulted in Gd(III) accumulation in the membrane of the PR(+) cells, possibly due to ester hydrolysis and subsequent production of a Gd(III) chelate with a pentanoic acid tail that could insert in cell membranes. This ester cleavage might explain the high signal intensity surrounding the PR(+) tumor in the *in vivo* images taken 2 h after injection with **3a**, as well. In addition, ester hydrolysis would release 21-hydroxyprogesterone, which would enter the cells at high levels and could explain the higher cytotoxicity observed after incubation with this agent.

Studies in tumor xenografts demonstrated that **1a**, **2a**, and **3a** preferentially enhanced CNR in PR(+) tumors as compared to PR(-) tumors at 2 and/or 6 h after injection. Injection of control agent **4a**, by contrast, resulted in minimal changes in CNR at 2 and 6 h postinjection and no difference between the PR(+) and PR(-) tumors. Of these PR-targeted agents, **1a** was the most promising in that it resulted in higher CNR in the PR(+) tumor than the PR(-) tumors at both 2 and 6 h postinjection. In addition, the fold change in CNR compared to preinjection levels

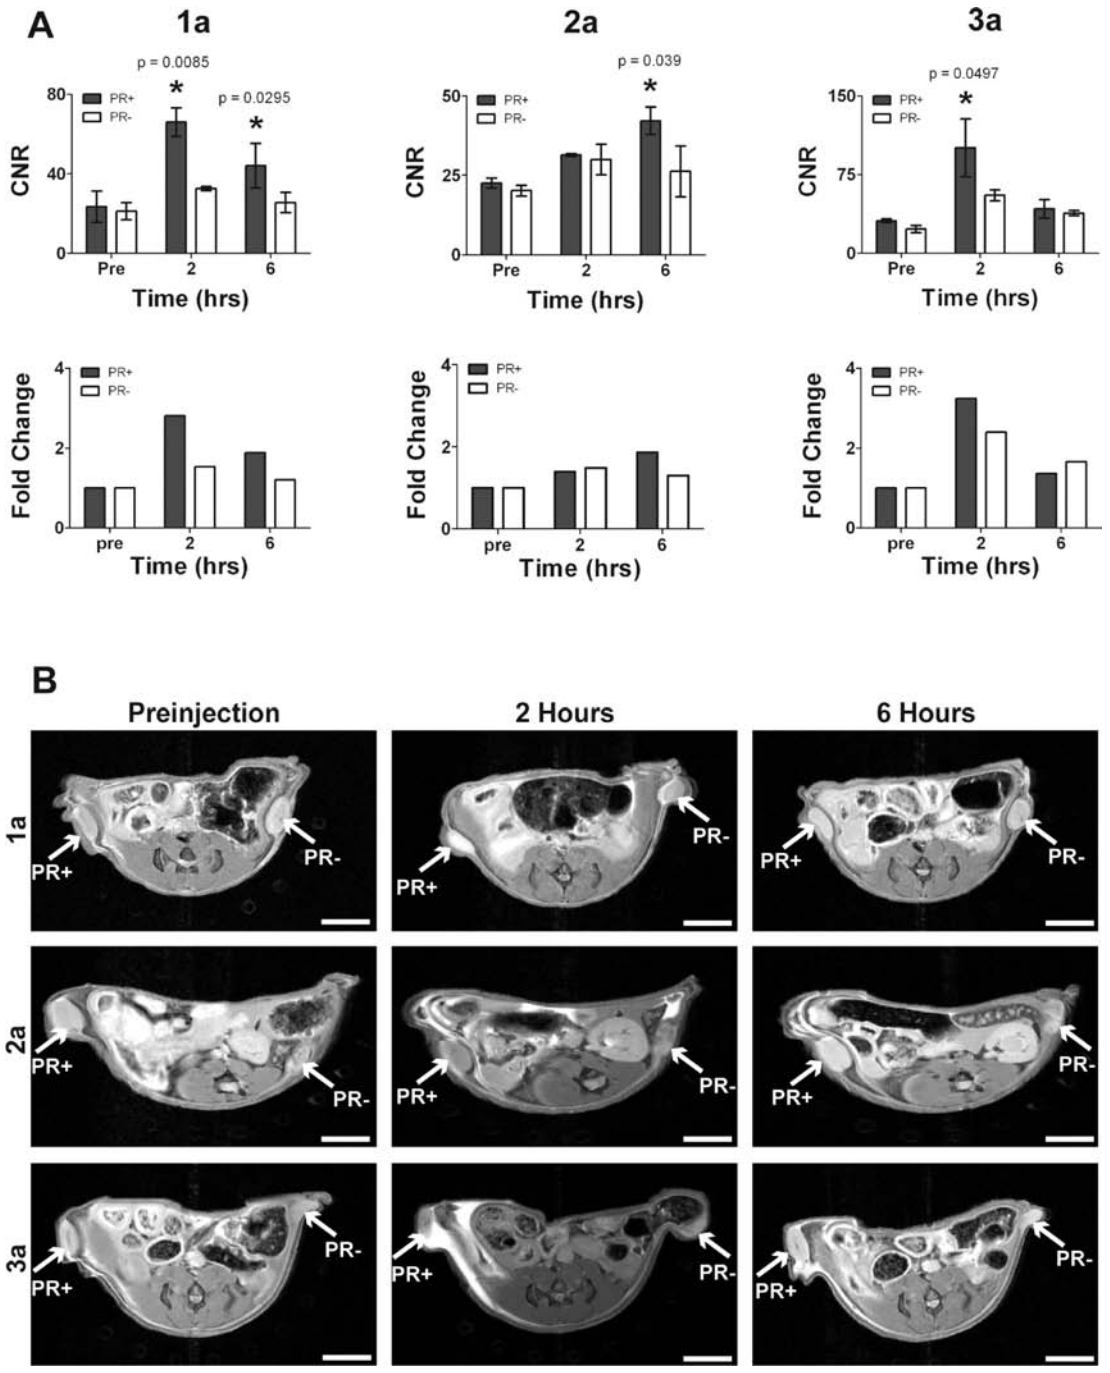

Figure 6. Xenograft images before and after injection of water-soluble agents. (A) Changes in contrast-to-noise ratio (CNR) in individual mice after intraperitoneal injection of **1a**, **2a**, or **3a** (top graphs) and fold change in CNRs compared to preinjection CNR levels (bottom graphs). The water-soluble progesterone-conjugated agents preferentially enhanced CNR in the PR(+) tumors compared to the PR(-) tumors (asterisks, Student's *t* test $p < 0.05$). Error bars represent ± standard deviation of the mean. (B) Representative images of xenografted mice injected subcutaneously with **1a** (top panels), **2a** (middle panels), or **3a** (bottom panels). White scale bars represent 5 mm.

was higher in the PR(+) tumor than the PR(-) tumor at both time points after injection. The accumulation of Gd(III) in these tumors may have been time-dependent. Injection with **1a** and **3a** increased CNR by 2 h, but CNR had decreased by 6 h. Injection with **2a**, however, resulted in a slow increase in CNR over time. Interestingly, this pattern corresponded to the cellular accumulation in cells where **2a** was the only agent tested that demonstrated time-dependent accumulation in PR(+) cells. Studies are ongoing to determine the optimal postinjection imaging time points for each of these agents.

The changes in CNR in the PR(+) tumor after injection of the water-soluble PR-targeted agents were comparable to or greater than the changes seen after injection of ProGlo previously demonstrated.[19] The difference between CNRs of the PR(+) and PR(-) tumors was greater after injection of these water-soluble agents than after intraperitoneal injection of ProGlo,

indicating that these agents possibly have more bioavailability due to their enhanced solubility. Finally, these water-soluble agents were associated with less *in vivo* toxicity than ProGlo. The enhanced solubility and bioavailability combined with the decreased toxicity might both be attributed to the less hydrophobic nature of these agents. Further *in vivo* investigations are being conducted to determine biodistribution of these agents and the optimal mode of injection.

Recent reports have asserted that, although there has been a focus on developing drugs that accumulate in cancer cells, this accumulation might actually prevent drugs from penetrating deep within tumors and decrease their efficacy.[40−42] Drugs that accumulate quickly within cells tend not to penetrate deeper areas of tumors, while less cell-permeable drugs travel further within the tumor and are more effective.[42] This indicates that decreasing lipophilicity of the agent would reduce cellular accumulation and allow for improved tumor penetration. The ability to inject water-soluble agents intravenously would also increase tumor penetration, as the angiogenic vasculature of the tumor would likely leak the agent allowing for accumulation. For imaging agents, this property of tumor penetration would be essential in terms of measuring receptor levels in a tumor with heterogeneous receptor distribution.[43] The PR-targeted agents described here would likely penetrate tumors better than ProGlo and increase signal intensity of the entire tumor rather than the surface especially since it can only be administered intraperitoneally or subcutaneously. Thus, in future work, the water-soluble PR-targeted agents might prove to be excellent tumor targeted contrast agents *in vivo*.

In conclusion, a series of water-soluble PR-targeted MRI contrast agents were designed and synthesized. These agents crossed cell membranes PR(+) T47D cells and activated PR at biologically relevant levels but exhibited lower *in vitro* and *in vivo* toxicity than the more hydrophobic ProGlo. Finally, these progesterone-conjugated agents enhanced CNR in PR(+) tumors as compared to PR(-) tumors in preliminary imaging studies in xenografts, warranting further *in vivo* investigations to prepare PR-targeted MR agents for noninvasive diagnosis of hormone related cancers and for elucidating the molecular pathways involved in these diseases.

Synthesis and Biological Evaluation of Water-soluble Progesterone-Conjugated Probes for Magnetic Resonance Imaging of Hormone Related Cancers

Preeti A. Sukerkar[1], Keith W. MacRenaris[1], Taryn R. Townsend[1], Roshan A. Ahmed[2], Joanna E. Burdette[2*], Thomas J. Meade[1*]

Synthesis and Characterization:

Synthesis and characterization of compound **4a** was previously described,[1] and compound **4b** was synthesized similarly. Compounds **4b**, **5a**, **5b**, **6a**, and **6b** were synthesized using modified literature procedures.[1-6]

General Procedure for Click Chemistry

All click chemistry reactions were run in 1:1 methanol:water or 1:1 DMSO:water solutions. The steroid derivative (1 eq) and Gd(III) or Eu(III) chelate (1.1 eq) were dissolved and N_2 gas was bubbled through the solution to remove oxygen. Sodium ascorbate (1 eq), $CuSO_4$ (0.167 eq), and [(1-benzyl-1H-1,2,3-triazol-4-yl)methyl]amine (TBTA) (0.02 eq) were added and the reaction mixture was stirred at 60^o C for 24 hours. The crude residue was purified by reverse phase preparative HPLC using a ramp from 0 to 100% B over 20 minutes.

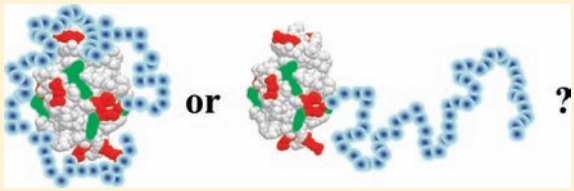
Supporting Information

ABSTRACT: Covalent conjugation of poly(ethylene glycol) or "PEGylation" has proven an effective strategy to improve pharmaceutical protein efficacy by hindering recognition by proteases, inhibitors, and antibodies and by retarding renal clearance. Because it determines the strength and range of intermolecular steric forces and the hydrodynamic properties of the conjugates, the configuration of protein-conjugated PEG chains is the key factor determining how PEGylation alters protein in vivo circulation time. Mono-PEGylated proteins are typically described as having a protective PEG shroud wrapped around the protein, but recent dynamic light scattering studies suggested that conjugates adopt a dumbbell configuration, with a relatively unperturbed PEG random coil adjacent to the globular protein. We used small-angle neutron scattering (SANS) to distinguish between the dumbbell model and the shroud model for chicken-egg lysozyme and human growth hormone covalently conjugated to a single 20 kDa PEG chain. The SANS contrast variation technique was used to isolate the PEG portion of the conjugate. Scattering intensity profiles were well described by the dumbbell model and inconsistent with the shroud model.



INTRODUCTION

Covalent conjugation of poly(ethylene glycol) (PEG) to proteins, PEGylation, has proven to be an effective strategy to increase in vivo circulation times of protein therapeutics, with consequent improvements in pharmaceutical efficacy.[1] The benefits derive from decreased renal clearance rates, decreased proteolytic degradation, and decreased immune response.[1−4] Decreased renal clearance is attributed to the larger hydrodynamic radius of the conjugates that hinders glomerular filtration. Protective effects are attributed to steric and hydration repulsions between PEGylated proteins and other activity-degrading proteins, [5] including immunoproteins, proteases, or inhibitors. These protective effects can accrue without loss of protein biological activity, depending on the number, molecular weight, and location of the attached PEG chains on the protein. PEGylation may also enhance protein thermal stability, making some conjugates more resistant to unfolding than their unmodified counterparts.[6] Examples of PEGylated proteins that have been approved for therapeutic use by the U.S. Food and Drug Administration include PEGasys (interferon α-2a; Genentech USA, Inc.), PEG-Intron (interferon α-2b; Merck & Co., Inc.), Neulasta (granulocyte colony-stimulating factor; Amgen), Adagen (adenosine deaminase; Sigma-Tau Pharmaceuticals, Inc.), Oncaspar (L-asparaginase; Sigma-Tau Pharmaceuticals, Inc.), and Somavert (growth hormone; Pfizer).[7] Recent work in this laboratory and others[8−11] indicates that PEG conjugation may also significantly improve the preservation of protein native structure and bioactivity during sustained release from biodegradable depots, in part by modifying the damaging interactions between the conjugates and the interfaces that they encounter during encapsulation and release.

Understanding the configuration of PEG chains when conjugated to proteins is necessary to interpret the steric protective effect and hindered renal clearance for circulating proteins in vivo and conjugate adsorption and associated denaturation in sustained-release delivery devices. Additionally, this information is important for interpreting filtration behavior[12] and chromatographic behavior[13,14] of PEGylated proteins during purification operations.

The commonly presumed structure of mono-PEGylated proteins is the shroud model, according to which an attached

PEG chain wraps around the protein to create a shielding effect.[5,7,13−21] Lacking direct probes of the grafted PEG conjugate structure, investigators have relied on the shroud model to interpret hydrodynamic or thermodynamic measurements. For example, Fee and Van Alstine analyzed the size exclusion chromatographic behavior of PEG-conjugated proteins in terms of the protein shroud model.[13] Using three proteins (α-lactalbumin, β-lactoglobulin dimer, and bovine serum albumin), each conjugated with one or more PEG chains having one of three different molecular masses (2.4, 5.6, or 22.5 kDa), the authors concluded that the protein and conjugated PEG interacted to create a spheroid complex in which the PEG formed a layer surrounding the protein; this morphological model and corresponding geometrically based predictions did represent size exclusion chromatography retention times well for both mono-PEGylated and poly-PEGylated conjugates.[13] García-Arellano et al. used the shroud model to interpret data on the thermal stability of horse heart cytochrome *c* singly or multiply modified with 0.35, 0.75, or 2 kDa PEG;[15] the authors presumed that the PEG acts as a cage and coils around the protein surface.[15] Manjula et al. used molecular dynamics simulations to predict the configuration of 5, 10, and 20 kDa PEG chains attached to hemoglobin; they concluded that instead of passively extending from the surface of the protein, the PEG chain folds upon itself in a separate domain on the surface of the protein.[14] While the shroud model may be appropriate for multiple PEG chains attached to a protein, we investigate the conformation of one PEG chain attached to a protein as motivated by the current pharmaceutical relevance of mono-PEGylated species. Early development of PEGylated protein therapeutics was based on grafting several low molecular weight PEG chains (5 kDa); however, the trend is toward grafting a smaller number of larger PEG chains, such as 20 kDa linear PEG or 40 kDa branched PEG grafts that provide improved performance relative to the multiply conjugated proteins.[5,19] The current work is motivated by a competing model for the configuration of protein-conjugated PEG chains in mono-PEGylated species: the dumbbell model wherein the PEG conjugate exists as a relatively unperturbed random coil adjacent to, but not surrounding, the protein.

The configuration of a random coil polymer chain in solution is dictated by polymer segment excluded volume interactions and the configurational entropy of the chain. We contend that the entropic cost of wrapping a PEG chain around a globular protein that has a radius of gyration that is comparable to that of the PEG would be prohibitive. It should be noted that absent a large externally applied pressure, PEG chains do not adsorb to proteins, so there is little or no enthalpic driving force to wrap the PEG around the protein. Using dynamic light scattering (DLS), we determined that the hydrodynamic diameter of a monoPEG−lysozyme conjugate was comparable to the sum of the individual diameters of a single lysozyme plus a single 20 kDa PEG. The diffusion coefficient determined by DLS could be interpreted in terms of a cylinder having a length equal to the sum of the unperturbed PEG and lysozyme hydrodynamic diameters.[9] The same trend was observed previously in our group for ribonuclease A (RNase A) and monoPEG−RNase A.[8] Because the protein and polymer have similar dimensions in solution, it is unlikely that a single 20 kDa PEG chain would be able to wrap around these proteins. The DLS data for the monoPEG−protein conjugates support a dumbbell model. Similarly, in a study of partition coefficients obtained from size exclusion chromatography data for PEG, proteins, and the corresponding PEGylated proteins, Molek and Zydney determined that the effective spherical volume of PEGylated proteins could be estimated as the sum of the volumes of the protein and free PEG. The sieving coefficients were consistent with the conjugated PEG chains behaving as a random coil.[12] Fee later showed that these estimates hold true for systems where the PEG chain is substantially larger than the protein itself.[22] He et al. compared small-angle X-ray scattering (SAXS) and small-angle neutron scattering (SANS) data in order to draw conclusions about the shape of di-PEGylated human galectin; their findings support the dumbbell model.[23] The authors found a slight compression of the random coils with increased solution concentration of the PEGylated protein.[23] Finally, Svergun et al. used SAXS to study PEG-conjugated hemoglobin and reported that the major part of the PEG chain protrudes away from hemoglobin.[24] The authors also stated that a portion of the PEG chain interacts with the protein.[24]

The distinction between the shroud and the dumbbell models remains unresolved, because the effective conjugate sizes that would be predicted by the two models fall within the margin of error for the conventional macromolecular sizing techniques available. Thus, purely size-based methods, which are inherently indirect methods of characterizing polymer configuration, are incapable of adequately discriminating between the two prevailing conjugate models.

We used SANS as a direct method to discriminate between the dumbbell and the shroud models. This approach takes particular advantage of the unique ability to contrast match the aqueous medium with individual portions of the conjugate to exclusively probe the conformation of the remainder of the conjugate. This is not possible with X-ray or light scattering in aqueous systems. Here, we report the configuration of a single 20 kDa PEG chain grafted to either 14 kDa chicken-egg lysozyme or 22 kDa human growth hormone (HGH), grafted predominantly at the N terminus. Using mixtures of D_2O and H_2O to isolate the scattering from the PEG portion of the conjugate, we conclude that a single conjugated PEG chain exists as a random coil with dimensions similar to those of the free PEG chains in solution. The contrast-matched SANS data were well described by the random coil form factor, confirming the suitability of the dumbbell model for these conjugates. This conclusion was further supported by the inability to fit SANS data to a core−shell form factor model that would capture a polymer shell wrapped around a protein core, without resorting to unphysical model parameters. Because of its relevance to protein therapeutics, we also investigated the configuration of the PEG conjugate in a plasmalike, high oncotic pressure environment, finding similar configurations for the PEG conjugates in dilute solution and in the model plasmalike environment.

EXPERIMENTAL PROCEDURES

Materials. Chicken-egg lysozyme (Sigma-Aldrich Co., catalog no. L-6876) and deuterium oxide (Cambridge Isotopes, D > 99%) were used without further purification. HGH was donated by Genentech Inc. Methoxy-PEG−propionaldehyde (mPEG−PA), 20.7 kDa, was donated by Dr. Reddy's Laboratories (Cambridge, United Kingdom) and used without further purification. A sample of 22.2 kDa perdeuterated mPEG−PA (*d*mPEG−PA) was synthesized by the Center for Structural Molecular Biology (CSMB) Bio-Deuteration Laboratory at Oak Ridge National Laboratory and used without further purification. The molecular weights of the hydrogenated and deuterated mPEG−PA samples were determined by matrix-assisted laser desorption/ionization (MALDI) mass

spectrometry (PerSeptive Voyager STR MS, Applied Biosystems). The average degrees of polymerization for the hydrogenated mPEG−PA and the deuterated mPEG−PA were 470 and 461, respectively. Conjugation reaction and conjugate purification buffers were prepared from sodium phosphate monobasic and dibasic anhydrous salts (Fisher Scientific, 99% pure) and sodium chloride (Sigma-Aldrich Co., 99% pure). Sodium cyanoborohydride (Sigma-Aldrich Co., 95% pure) and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES, Sigma-Aldrich Co., ≥ 95% pure) were used as received. All water was purified by reverse osmosis followed by treatment to 18 MΩ/cm resistivity using a Barnstead NANOpure Diamond system. Synthesis of *d*mPEG−PA is described in the Supporting Information, S1.

Protein PEGylation and Conjugate Characterization. We reacted lysozyme with either the ∼20 kDa hydrogenated mPEG−PA (*h*mPEG−PA) or the deuterated mPEG−PA (*d*mPEG−PA) (1:6 mol ratio) in a pH 5.1, 100 mM sodium phosphate buffer containing 20 mM sodium cyanoborohydride, conditions established to strongly favor N-terminal PEGylation of the protein, [25] and fractionated the product into monoPEGylated and diPEGylated samples by size exclusion chromatography as described in detail previously.[9] We used MALDI mass spectrometry to determine the number of PEG molecules attached to lysozyme in each collected fraction, as described previously.[9] The location of the PEG modification was determined previously to be primarily the N-terminal lysine, with slight modification at lysine residues 33 and 97.[9] To obtain an appropriate concentration, we pooled together the purified monoPEG−lysozyme fractions from eight separate PEGylations, for both the *h*mPEG−PA and the *d*mPEG−PA. The pooled monoPEG−lysozyme samples then underwent several rounds of buffer exchange into 10 mM HEPES, pH 7.4, using a diafiltration technique with 3000 MWCO centrifugal filter units (Millipore, catalog no. UFC900324). HGH was reacted with *d*mPEG−PA (1:6 mol ratio), separated, and buffer exchanged in the same manner described above for lysozyme.

The secondary structures of the lysozyme conjugates were characterized to determine if PEGylation resulted in structural perturbations using circular dichroism (CD) spectroscopy (J-810 Spectropolarimeter, Jasco, Inc.). Far UV CD spectra of unmodified lysozyme and hydrogenated monoPEG−lysozyme and deuterated monoPEG−lysozyme indicate that the secondary structure of lysozyme was not significantly altered upon PEGylation (Figure S1 in the Supporting Information, S2). The CD spectra were further analyzed using CD Pro software[26] to provide quantitative estimates of secondary structure contents (Table S1 in the Supporting Information, S2). Results indicate that conjugate secondary structure estimates were consistent with those of the unmodified protein. Finally, all samples, in pH 7.4 10 mM HEPES buffer, were dried on a lyophilizer (Unitrap II, VirTis) before transporting them with ice packs to be reconstituted for SANS experiments. Lyophilization did not significantly impact the secondary structure of the lysozyme conjugates, as determined by CD (data not shown).

SANS. SANS experiments were performed at the National Institute of Standards and Technology (NIST) Center for Neutron Research (NCNR) using the 30 m SANS instrument NG3[27] and at Oak Ridge National Laboratory (ORNL) using the 30 m Bio-SANS instrument at the High Flux Isotope Reactor (HFIR). Each lyophilized sample was suspended in the appropriate medium (H_2O, D_2O, or H_2O−D_2O mixture) at room temperature and immediately loaded into quartz cells with a 1 mm path length. At NIST, a neutron wavelength of 6 Å was used at three detector distances (1.3, 4, and 13 m) to gather scattering profiles. At ORNL, two detector distances, 0.3 and 6 m, were used to gather scattering profiles. The SANS data were fully reduced by referencing an open beam neutron flux and subtracting the background incoherent scattering. All scattering profiles were analyzed using IGOR Pro macros developed at NIST.[28]

The H_2O−D_2O composition points of minimum scattering intensity for lysozyme and HGH were first determined using contrast variation on pure lysozyme and pure HGH samples in solutions containing various hydrogen isotope ratios (D/H). The ratio at which the scattering length densities of lysozyme and buffer were matched and therefore lysozyme did not contribute to the scattering signal was determined as 46% D_2O, which agreed well with the reported value in the literature for lysozyme.[29] The ratio for HGH was determined as 48% D_2O. These ratios were used for all subsequent contrast-matched samples to mask the lysozyme or HGH and probe only the PEG portion of the PEG−protein conjugates. Lysozyme, HGH, and mPEG−PA were measured in 100% D_2O at dilute concentrations. Hydrogenated and deuterated monoPEG−lysozyme samples were measured in 100% D_2O and 46% D_2O, respectively. Deuterated monoPEG−HGH was measured in 48% D_2O. All samples that were originally lyophilized in pH 7.4 10 mM HEPES were resuspended into a volume of the appropriate water solvent to recover a pH 7.4 10 mM HEPES solution.

RESULTS AND DISCUSSION

SANS data are analyzed first in terms of a pair-distance distribution function (PDDF), which has the advantage of being model-independent, followed by the Guinier analysis that yields a more quantitative description of the distribution of mass in the scattering particle, followed by data fits to form factor models that discriminate between candidate structures.

PDDF. A first order classification of the shape of a scattering particle is obtained directly from $P(r)$, the PDDF.[30] $P(r)$ is related to the frequency of interatomic vector lengths, r, within the particle.[31] $P(r)$ functions were calculated for all samples from the entire scattering curve [$(I(q)$, to be shown below] using model-free inverse Fourier transformation.[30] Figure 1 displays the $P(r)$ analysis for lysozyme, unconjugated *h*mPEG−PA (hydrogenated mPEG propionaldehyde), and mono-*h*mPEG−lysozyme in 100% D_2O. The distance at which $P(r)$ falls to zero indicates the largest distance spanned by the scattering particle. This maximum dimension for mono-*h*mPEG−lysozyme, 21.20 ± 0.08 nm, is larger than the sum of the maximum dimension of lysozyme, 3.44 ± 0.06 nm, plus that of unconjugated *h*mPEG−PA, 13.33 ± 0.06 nm, where the latter dimensions are taken from the corresponding $P(r)$ functions. The statistical error bars correspond to 95% confidence limits.

Guinier Analysis. The Guinier approximation provides the radius of gyration, R_G, of the scattering particle. For low values of the scattering vector q, R_G can be extracted from the slope of ln I versus q^2, as $\ln I(q) = \ln I(0) - [(R_G^2)/3]q^2$ provided the approximation is applied in the limit of $qR_G \ll 1$. The scattering vector q is defined as $(4\pi/\lambda)\sin(\theta)$ where λ is the wavelength of the incident neutrons and 2θ denotes the scattering angle.[32,33] Values for R_G thus determined are listed in Table 1. Values for R_G for lysozyme and *h*mPEG−PA in 100% D_2O are comparable to those reported previously.[9,34] As was the case with $P(r)$, R_G for mono-*h*mPEG−lysozyme,

dx.doi.org/10.1021/bc2003583 | Bioconjugate Chem. 2011, 22, 2317−2323

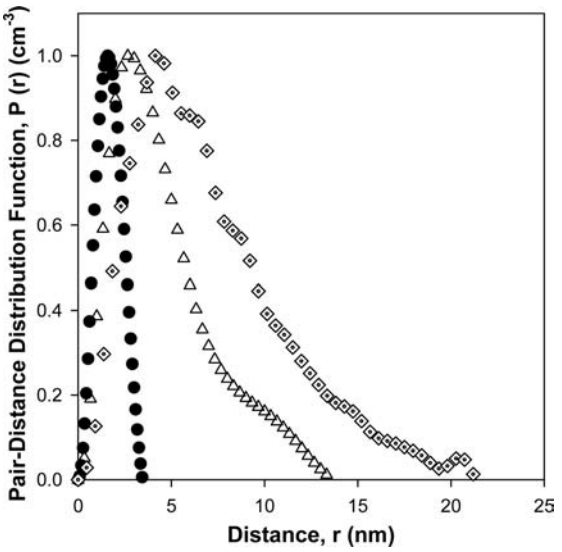

Figure 1. PDDFs, $P(r)$, for lysozyme (closed circles), hydrogenated mPEG−PA (open triangles), and hydrogenated monoPEG−lysozyme (dotted diamonds) in 100% D_2O containing 10 mM HEPES. The $P(r)$ maximum for each species is scaled to unity. The maximum extension of each particle is the point at which the function crosses the abscissa. The maximum extension of lysozyme, 3.44 ± 0.02 nm, plus the maximum extension of mPEG−PA, 13.33 ± 0.06 nm, is comparable to the maximum extension of monoPEG−lysozyme, 21.20 ± 0.08 nm. The statistical error bounding values correspond to 95% confidence limits.

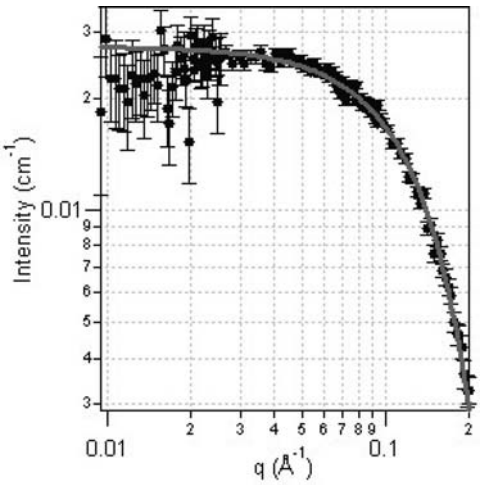

Figure 2. Comparison of the experimental scattering curve of lysozyme in 100% D_2O (filled circles), containing 10 mM HEPES, with the theoretical smeared curve of the sphere model for a monodisperse spherical particle with uniform scattering length density (solid line). Error bars represent the standard deviation of the intensity at each q value. For the fit, the scattering length density of the sphere was fixed at 2.56×10^{-6} Å $^{-2}$, and the scattering length density of the solvent was fixed at 6.33×10^{-6} Å $^{-2}$. The best fit generated a radius of 1.549 ± 0.001 nm. The statistical error bounding values correspond to 95% confidence limits.

6.8 ± 0.5 nm, is larger than the sum of R_G for lysozyme, 1.4 ± 0.2 nm, plus R_G for *h*mPEG−PA, 3.4 ± 0.3 nm. The statistical error bounding values correspond to 95% confidence limits.

Data Reduction and Form Factor Analysis. Using macros developed at NIST, all data were reduced and analyzed as $I(q)$ versus q using IGOR Pro software (WaveMetrics, Inc.).[28] Figures 2 and 3 permit comparison of the experimental scattering intensity profiles of lysozyme in 100% D_2O, containing 10 mM HEPES, and perdeuterated homopolymer mPEG−PA (*d*mPEG−PA) in 46% D_2O, containing 10 mM HEPES, with the theoretical smeared model curves for monodisperse spheres (sphere model[33]) and linear random coil polymer chains (Debye model[32]), respectively. A *d*mPEG−PA sample was used to increase the signal-to-noise ratio when employing the contrast variation technique to measure the scattering profile of deuterated monoPEG−lysozyme (mono-*d*mPEG−lysozyme) in 46% D_2O, containing 10 mM HEPES. This is the ratio of D_2O necessary to contrast match the lysozyme, determined experimentally, allowing only the PEG portion of the conjugate to be probed. Lysozyme was well described by the sphere model with radius R = 1.549 ± 0.001 nm (Figure 2), and the unconjugated *d*mPEG−PA was well described by the random coil Debye model with R_G = 3.718 ± 0.003 nm (Figure 3). The statistical error bounding values correspond to 95% confidence limits. The

Table 1. Dimensions Generated for All Species for All Data Analysis Methods[a]

species[b]	solvent with 10 mM HEPES (% D_2O)	data analysis method			
		DLS R_H (nm)[cd]	PDDF (nm)[ef]	Guinier R_G (nm)[gh]	model fitting (nm)[ij]
unmodified lysozyme	100	2.0 ± 0.9	max. ext. = 3.44 ± 0.02	1.4 ± 0.2	1.549 ± 0.001 (sphere, R_H)
*h*mPEG−PA	100	3.5 ± 1.4	max. ext. = 13.33 ± 0.06	3.4 ± 0.3	3.591 ± 0.001 (Debye, R_G)
mono-*h*mPEG− lysozyme	100	5.8 ± 2.6	max. ext. = 21.20 ± 0.08	6.8 ± 0.5	N/A

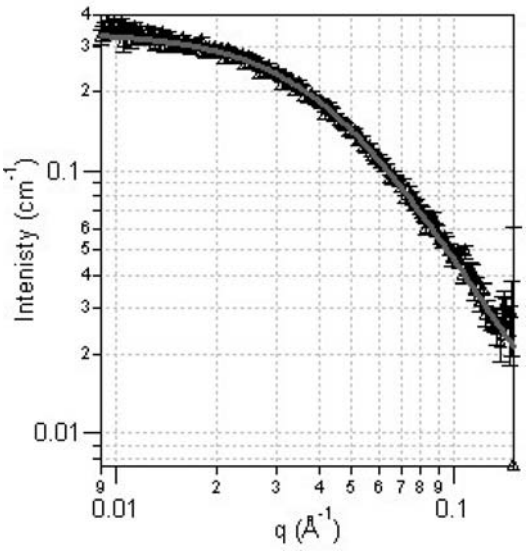

Figure 3. Comparison of the experimental scattering curve of deuterated mPEG–PA in 46% D_2O (open triangles), containing 10 mM HEPES, with the theoretical smeared curve of the Debye model for a random coil (solid line). Error bars represent the standard deviation of the intensity at each q value. The best fit generated a radius of gyration, R_G, of 3.718 ± 0.003 nm. The statistical error bounding values correspond to 95% confidence limits.

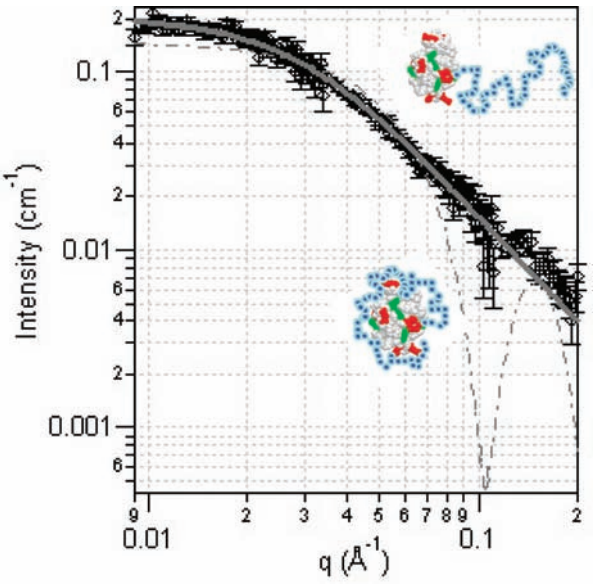

Figure 4. Comparison of the experimental scattering curve for deuterated monoPEG–lysozyme in 46% D_2O (dotted diamonds), containing 10 mM HEPES, with the theoretical smeared curve of the Debye model for a random coil (solid line) and the theoretical smeared core–shell model for a spherical particle of uniform scattering length density, surrounded by a shell having a different scattering length density (dashed line). Error bars represent the standard deviation of the intensity at each q value. The best fit generated a radius of gyration, R_G, of 5.135 ± 0.006 nm. The statistical error bounding values correspond to 95% confidence limits. Schematics qualitatively illustrate the dumbbell configuration (upper right) if the PEG chain followed the Debye model and the shroud configuration (lower left) if the PEG chain followed the core–shell model. Because of the contrast matching conditions, the protein is "invisible" to the neutrons in these measurements.

fitted radius of gyration for *d*mPEG–PA is somewhat smaller than the 6.7 nm *z*-average root-mean-square radius of gyration predicted by a light scattering correlation for PEG at 25 °C where $\langle R_G^2 \rangle = 4.08 \times 10^{-18} M_w^{1.16}$ cm^2.

To first test the suitability of the dumbbell model, the experimental scattering profile $I(q)$ of mono-*d*mPEG–lysozyme in 46% D_2O was compared to the theoretical smeared curve for a linear random coil polymer chain (Debye model). The quality of the random coil fit of the contrast-matched data in Figure 4 indicates that the conjugated PEG chain behaves as a random coil adjacent to the protein, supporting the dumbbell model.

As a counter-argument, the experimental scattering profile of mono-*d*mPEG–lysozyme in 46% D_2O, containing 10 mM HEPES, was then also compared to the theoretical smeared core–shell model for a spherical core of uniform scattering length density, surrounded by a shell having a different scattering length density; a successful fit to such a model would be consistent with the shroud model. The core–shell fit was applied in two different manners to attempt to achieve a satisfactory fit. In both cases, the scattering length densities of the core and solvent were set to be equal since the protein core was contrast-matched. In case 1, no other fitting constraints were applied, and the model fit generated a core radius of 2.98 ± 0.15 nm, a shell thickness of 0.08 ± 0.3 nm, and a shell scattering length density of $\rho_{shell} = 1.59 \times 10^{-6}$ Å^{-2}; this scattering length density falls outside the range of the solvent ($\rho_{solvent} = 2.56\times 10^{-6}$ Å^{-2}) and pure *d*PEG ($\rho_{dPEG} = 5.73 \times 10^{-6}$ Å^{-2}) and is therefore nonphysical for a mixture of *d*PEG and solvent. In case 2, the core radius was set to 1.55 nm, as previously determined by applying the sphere model to lysozyme SANS. The model then generated a shell thickness of 2.236 ± 0.002 nm, and the fitted scattering length density of the shell, $\rho_{shell} = 2.32 \times 10^{-6}$ Å^{-2}, was again nonphysical. The fringes predicted by the fit to the smeared core–shell model were absent in the experimental data. The statistical error bars correspond to 95% confidence limits.

On the basis of the agreement of contrast-matched SANS data for mono-*d*mPEG–LYZ with the random coil (Debye) model and not the core–shell model, we conclude that the conjugate adopts a dumbbell configuration (Figure 4) with the PEG chain forming an independent random coil domain rather than a shroud "wrapped" around the protein. As seen in Table 1, R_G for the lysozyme-conjugated *d*mPEG–PA chain is approximately 30% larger than that measured for free *d*mPEG–PA in 100% D_2O, containing 10 mM HEPES. This is expected because this PEG is end-anchored to the protein surface. As an isolated, nonadsorbing but end-grafted chain, configurational entropy dictates that it would be elongated relative to the unconjugated chain.[35]

Extension to Additional Proteins. The measurements described in the previous section were extended to include a protein of pharmaceutical interest, HGH, covalently conjugated to a single ~20 kDa *d*mPEG–PA chain. The contrast variation technique was again employed to measure the scattering profile of mono-*d*mPEG–HGH in 48% D_2O, containing 10 mM HEPES, the experimentally determined D_2O content to contrast match HGH in buffer. The excellent agreement of the experimental scattering profile of mono-*d*PEG–HGH with the Debye model (Figure S2 in the Supporting Information, S3) again is consistent with the grafted PEG chain existing as a random coil adjacent to the protein, that is, adopting the dumbbell configuration.

dx.doi.org/10.1021/bc2003583 | *Bioconjugate Chem.* 2011, 22, 2317–2323

Determining the Configuration of the PEG Chain in Plasmalike Environments. All measurements described thus far were in dilute solution, but blood has a large oncotic pressure that may influence the PEG conformation in a PEGylated therapeutic protein. To determine the behavior of the conjugated PEG chain as it might exist in blood, we mimicked the oncotic pressure of plasma by dissolving the mono-*d*mPEG−lysozyme (20 kDa *d*mPEG−PA) in a 15 mg/mL solution of unconjugated lysozyme, the concentration of lysozyme necessary to create an oncotic pressure typical of mammalian plasma, ∼2500 Pa, in 46% D_2O, containing 10 mM HEPES, to contrast-match lysozyme. The data are again well described by the random coil model, consistent with the dumbbell configuration, but now, R_G for the PEG conjugate, 3.238 ± 0.002 nm, is about 15% smaller than that for an unconjugated *d*mPEG−PA chain in 46% D_2O, containing 10 mM HEPES, 3.718 ± 0.003 nm (Figure S3 in the Supporting Information, S4). The statistical error bounding values correspond to 95% confidence limits. Evidently, competition for water in the plasmalike environment causes a small decrease of the excluded volume of the conjugated PEG chain but does not alter the tendency to adopt a random coil configuration. This is consistent with the effect of high conjugate concentration noted by He et al. [23]

Implications. It is well established that the covalent attachment of PEG increases in vivo blood circulation times for protein therapeutics. The implications of the dumbbell configuration for the steric protection of a conjugated protein can now be considered. In the case of a single grafted PEG chain per protein, the dumbbell configuration leaves part of the protein unprotected, but it does provide a locally strong steric repulsion force to protect the conjugated part of the molecule. In contrast, the shroud configuration, if it occurred, would have spread its protective effect over a larger fraction of the protein surface. Yet, by spreading a limited polymer mass over a large area, the local segmental density in any one region would be rather low and would afford only a weak and short-range steric repulsion, since the range of steric forces imparted by grafted polymer chains is dictated by the normal extension of the chain away from the surface and the magnitude scales with the local segment density. The random coil dumbbell configuration offers strong but more highly localized protection of the protein. For example, the nearer the site of PEGylation is to a binding epitope, the more effective its protection would be. Similar considerations come into play concerning the degree to which a conjugated PEG chain could disrupt access to a protein active site.

CONCLUSION

SANS was employed with a contrast variation technique to probe only the PEG portion of the PEG−protein conjugate to directly determine the configuration of a single ∼20 kDa PEG chain covalently attached to lysozyme or HGH. Analyses of the scattering data in terms of the pairwise distance distribution function, the Guinier analysis of conjugate radius of gyration, and model fitting to the Debye random coil polymer scattering form factor are consistent with a dumbbell model in which the PEG chain behaves as a random coil adjacent to the protein and directly challenge the more commonly presumed shroud configuration in which the PEG chain wraps around the protein, creating a shielding effect.

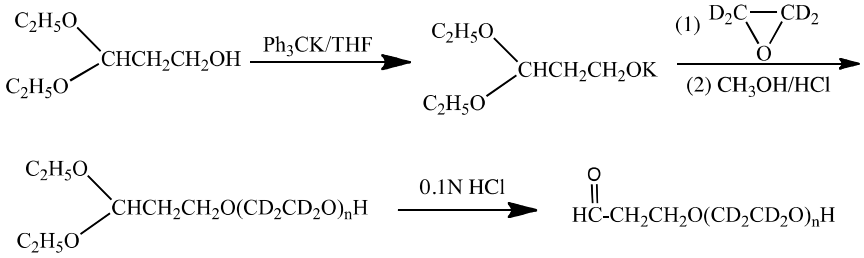
Supporting Information S1: Synthesis of Deuterated Methoxy-PEG-propionaldehyde

The synthesis of protected aldehyde-functionalized deuterated PEO (Scheme 1) was achieved using custom-made glass reactors with constrictions and breakseal techniques.[1] All reagents were purchased from Aldrich and purified by standard procedures for high vacuum anionic polymerizations. In a typical polymerizing reaction, 0.3 mmol of 3,3-diethoxy-1-propanol were reacted with 0.3 mmol of potassium triphenylmethane ($(C_6H_5)_3CK$) in THF for 30 min. at room temperature. Then 6.2 grams of EO-d4 was added to the reactor and then the mixture was allowed to react for 2 days at 45°C. The polymerization was terminated by introducing degassed acidic methanol. After precipitating into hexanes and filtering, PEO-d4 polymer was obtained and then dried under vacuum to constant weight.

Scheme S1. Synthesis aldehyde-functionalized deuterated PEO.



Transformation of the acetal group at the polymer end to the desired aldehyde group was carried out by stirring 3.13 grams of the as-synthesized PEO-d4 in 60 mL deionized water containing 15 mL of 0.1 N HC1 for overnight. Then the solution was dialyzed against deionized water for 2 days and the polymer was recovered using freezing drying.

Size exclusion chromatography (SEC) and nuclear magnetic resonance (^{13}C-NMR) were used to determine the molecular weights, polydispersities of the polymers. SEC determinations were performed on a Waters system equipped with a Waters 2695 pump, a Waters 2414 differential refractive index and Wyatt MiniDawn light scattering detectors, and 3 Polymer Lab Mixed-B columns with effective molecular weight range from 1,000 to 1,000,000 g/mol. THF was used as the eluent, and the flow rate was 1.0 mL/min at 30 °C. The system was calibrated using monodispersed linear polystyrene standards. ^{13}C-NMR spectra were obtained on a Varian Vnmr 500 spectrometer in $CDCl_3$. The molecular weight was estimated from the intensities of 3,3-diethoxy-1-propyl and EO-d4. The aldehyde functionality was confirmed by the ^{13}C-NMR peak appeared at 201.1ppm from the deprotected PEO-d4 sample.n

Supporting Information S2: Protein PEGylation and Conjugate Characterization

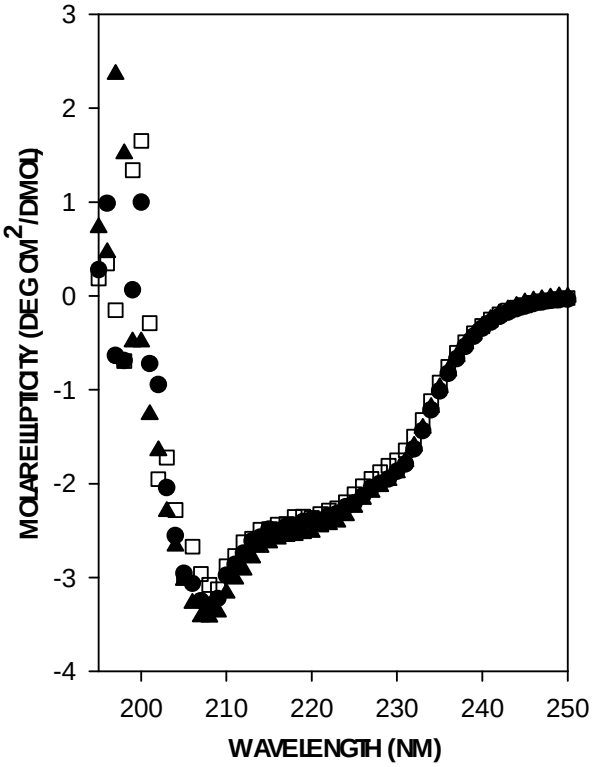


Figure S1. Circular dichroism spectra of unmodified lysozyme (filled circles), hydrogentated monoPEG-lysozyme (filled triangles) and deuterated monoPEG-lysozyme (open squares) in pH 7.4 10 mM HEPES buffer.

Table S1. Secondary structure fractions of unmodified lysozyme and monoPEG-lysozyme with both hydrogenated and deuterated mPEG-PA.

Species	**Secondary Structure Fractions**[a]					
	α-helix		**β-sheet**			
	regular	**distorted**	**regular**	**distorted**	**Turns**	**Unordered**
Unmodified Lysozyme	0.17 ± 0.04	0.15 ± 0.03	0.13 ± 0.01	0.062 ± 0.001	0.21 ± 0.04	0.27 ± 0.02
Hydrogenated monoPEG-Lysozyme	0.15 ± 0.04	0.18 ± 0.04	0.09 ± 0.03	0.07 ± 0.02	0.23 ± 0.02	0.27 ± 0.03
Deuterated monoPEG-Lysozyme	0.15 ± 0.06	0.15 ± 0.05	0.15 ± 0.03	0.08 ± 0.02	0.19 ± 0.03	0.28 ± 0.04

[a]Error values are the standard deviations of fraction values determined by three regression algorithms (SELCON3, CDSSTR, and CONTIN/LL) used to quantify secondary structure in CDPro[2].

Supporting Information S3: Contrast-Matched SANS Analysis of PEGylated Human Growth Hormone

The measurements described in the main paper for PEGylated lysozyme were extended to include an additional protein, human growth hormone (HGH), covalently conjugated to a single 20 kDa ***d***mPEG-PA chain. The contrast variation technique was once again employed to measure the scattering profile of deuterated monoPEG-hGH in 48% D_2O containing 10 mM HEPES buffer, the experimentally determined D_2O content to contrast match HGH. Figure S2 displays the experimental scattering profile of the ***d***monoPEG-hGH in 48% D_2O, with the Debye model fit. The excellent agreement of the experimental scattering profile of ***d***monoPEG-HGH with the Debye model (Figure S2) again confirms that the grafted PEG chain exists as a random coil adjacent to the protein and leading the conjugate to adopt a dumbbell configuration.

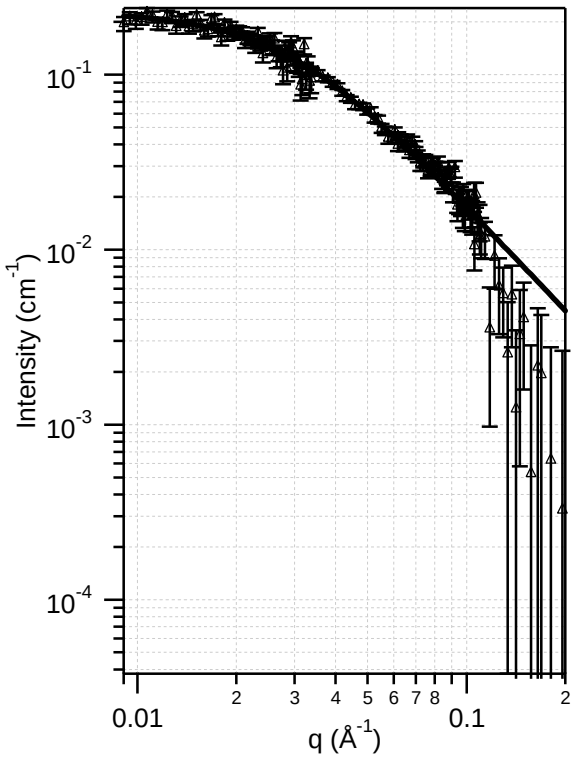

Figure S2. Comparison of the experimental scattering curve for deuterated monoPEG-HGH in 48% D_2O (open triangles), containing 10 mM HEPES, with the theoretical smeared curve of the Debye model for a random coil (solid line). Error bars represent the standard deviation of the intensity at each q value. The best fit generated a radius of gyration, R_G, of 5.012 ± 0.008 nm. The statistical error bars correspond to 95% confidence limits. A lack of fringes in the data over this ***q*** range indicates inconsistency with the core-shell model.

Supporting Information S4: Determining the Configuration of the Conjugated PEG Chain in Plasma-Like Environments

In order to predict the behavior of the conjugated PEG chain in blood, we mimicked the oncotic pressure of blood plasma by dissolving the mono-***d***PEG-lysozyme (20 kDa ***d***mPEG-PA) in a 15 mg/ml solution of unconjugated lysozyme to achieve an oncotic pressure similar to that of typical mammalian blood plasma , ~2500 Pa . This was dissolved in 46% D_2O, containing 10 mM HEPES, to contrast match lysozyme. Figure S3 displays the experimental contrast matched SANS ***I(q)*** for the conjugated ***d***PEG chains on mono-***d***PEG-lysozyme in these plasma-like conditions, along with the Debye model fit . The data were again well described by the random coil model, consistent with the dumbbell configuration. Here, $\boldsymbol{R_G}$ for the PEG conjugate, 3.239 ± 0.002 nm, was somewhat smaller than that for an unconjugated ***d***mPEG-PA chain in pure 46% D_2O, 3.718 ± 0.003 nm.

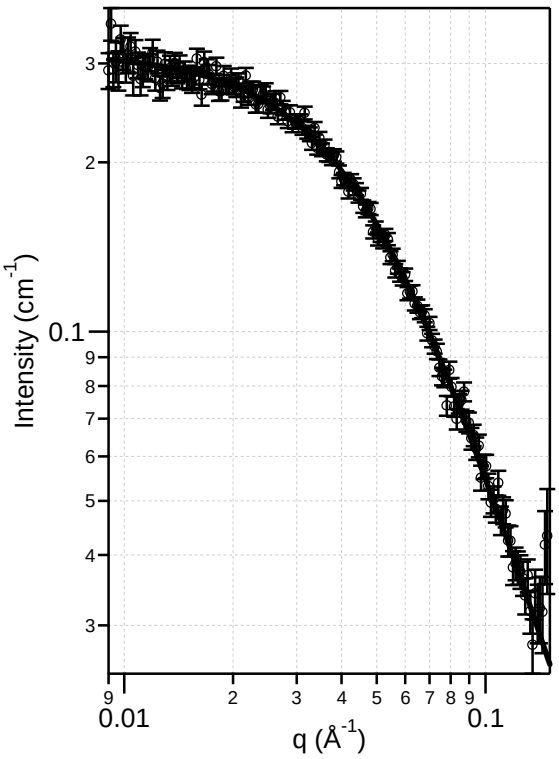

Figure S3. Comparison of the experimental scattering curve for deuterated monoPEG-lysozyme in a solution of 46% D_2O, with 10 mM HEPES, containing 15 mg/ml lysozyme (open circles) with the theoretical smeared curve of the Debye model for a random coil (solid line). Error bars represent the standard deviation of the intensity at each $\boldsymbol{q}$ value. The best fit generated a radius of gyration, $\boldsymbol{R_G}$, of 3.239 ± 0.002 nm. The statistical error bars correspond to 95% confidence limits. A lack of fringes in the data over this $\boldsymbol{q}$ range indicates inconsistency with the core-shell model.

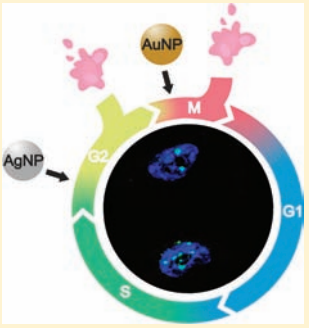
Supporting Information

ABSTRACT: Plasmonic nanoparticle research has become increasingly active due to potential uses in biomedical applications. However, little is known about the intracellular effects these nanoparticles have on mammalian cells. The aim of this work is to investigate whether silver nanoparticles (AgNPs) conjugated with nuclear and cytoplasmic targeting peptides exhibit the same intracellular effects on cancer cells as peptide-conjugated gold nanoparticles (AuNPs). Nuclear and cytoplasmic targeting spherical AgNPs with a diameter of 35 nm were incubated in a cancer (HSC-3) and healthy (HaCat) cell line. By utilizing flow cytometry, confocal microscopy, and real-time dark field imaging, we were able to analyze how targeting AgNPs affect the cell cycle and cell division. These experiments demonstrated that nuclear-targeting AgNPs cause DNA double-strand breaks and a subsequent increase in the sub G1 (apoptotic) population in our cancer cell model at much lower concentrations than previously reported for nuclear targeting AuNPs. Unlike the M phase accumulation seen in cancer cells treated with AuNPs, an accumulation in the G2 phase of the cell cycle was observed in both cell models when treated with AgNPs. Additionally, real-time dark field imaging showed that cancer cells treated with nuclear targeting AgNPs did not undergo cell division and ultimately underwent programmed cell death. A possible explanation of the observed results is discussed in terms of the chemical properties of the nanoparticles.



INTRODUCTION

Plasmonic nanoparticles (NPs) have been heavily studied due to their small size and unique optical and photothermal properties.[1,2] Their nanometer size allows NPs to permeate the cellular membrane and interact with biomolecules inside the cell, which can lead to disruption of cellular functions.[3−6] Cancer cells, which overexpress a certain ligand receptor, have the ability to be selectively targeted by NPs that have undergone surface conjugations to the respective receptor's complementary ligand.[7−9] Conjugated NPs also have the ability to intracellularly target specific organelles and/or locations within the cell.[8,10−14] A heavily targeted organelle within the cell is the nucleus. The nucleus houses the cell's genetic material and is responsible for maintaining proper cellular activities.[15] Any alteration to the nucleus and its genetic material could result in improper regulation of the cell cycle and cell death. The nucleus is most commonly targeted through the conjugation of a nuclear localizing signal (NLS) to the surface of the NPs.[8,12−14] This signal is known to interact with cytosolic factors forming stable complexes that are docked at the nuclear pore complex (NPC) in the nuclear membrane.[8] Our group's recent work has provided evidence that nuclear targeting of gold nanoparticles (AuNPs) in cancer (HSC-3) cells results in DNA damage, cytokinesis (M phase) arrest, and ultimately cell death.[14] Although this work demonstrates the alteration of the cell cycle in the presence of nuclear targeting AuNPs, it is still unknown if different nuclear targeting metallic nanoparticles, such as silver nanoparticles (AgNPs), will exhibit the same effect.

AgNPs have been extensively used in antimicrobial applications,[16,17] but little is known about the behavior and resulting cellular response when they are targeted to different organelles of mammalian cells. AgNPs are known for their active generation of reactive oxygen species (ROS).[18,19] ROS are a major source of oxidative stress within a cell and can cause damage to several cellular components. Disruption to DNA replication and ribosomal subunit protein expression after introduction of AgNPs into cells has been reported.[18] This disruption was attributed to the Ag^+ release from the surface oxidation of the AgNPs after they have been introduced into culture media and internalized in the cells. The resulting induction of DNA damage and subsequent cell death has potential applications in cancer and disease therapeutics.

In the present work, we systematically studied the cell cycle and cell division of cancer and healthy human cells in the presence of 35 nm pegylated and peptide-conjugated AgNPs. The results suggest that AgNPs localized at the nucleus cause DNA double-strand breaks and an increase in the sub G1 (apoptotic) population in the cancer cell model. G2 accumulation was also seen in both cancer and healthy cell

lines. The ROS generation from AgNPs is considered the main cause of the cell cycle alteration.

EXPERIMENTAL SECTION

AgNP Synthesis. Citrate-stabilized AgNPs with an average diameter of 35 nm were synthesized by the reduction of silver ions ($AgNO_3$) with sodium citrate.[20] Briefly, a 100 mL solution of 0.2 mM $AgNO_3$ and 0.3 mM trisodium citrate was brought to a boil under continuous stirring. After 30 min, boiling and stirring were discontinued and the solution was cooled to room temperature. TEM and DLS analysis showed an average particle diameter of 35 nm (Figure 1 and Table 1). The surface plasmon resonance band showed a peak absorbance at 430 nm (Figure 1). TEM images were taken on a JEOL 100CX-2 transmission electron microscope and the average diameter was determined using *ImageJ*.

Table 1. Hydrodynamic Diameters and Zeta Potentials of AgNPs

sample	hydrodynamic diameter (nm)	zeta potential (mV)
Citrate-AgNPs	35	−41
PEG-AgNPs	55	−18
NLS/RGD-AgNPs	57	14
RGD-AgNPs	56	16

AgNP Peptide Conjugation. The citrate-stabilized AgNPs were then pegylated to inhibit aggregation before peptide conjugation. A 1.0 mM solution of mPEG-SH 5000 (Laysan Bio, Inc.) diluted with DI water was added to a AgNP solution to achieve a 10^3 times greater concentration of mPEG-SH 5000 than AgNPs. The PEG-AgNP solution was allowed to incubate at room temperature overnight, and excess PEG was removed by centrifugation (13 500 rpm, 8 min). The PEG-AgNPs were redispersed in PBS. The pegylated particles were further conjugated with peptides following a previously established method.[13] For RGD peptide (RGDRGDRGDRGDPGC) and PEG-AgNP conjugation, a 1.0 mM RGD solution diluted in DI water was added to the PEG-AgNP solution to attain 10^3 molar excess of the RGD peptide than PEG-AgNPs. For NLS peptide (CGGGPKKKRKVGG) and PEG-AgNP conjugation, a 5 mM NLS peptide solution was added to a PEG-AgNP solution, so the NLS peptide was in 10^4 times molar excess. Last, conjugation of PEG-AgNPs with both RGD and NLS peptides was achieved by adding the peptides in 10^3 and 10^4 times molar excess, respectively, compared to the PEG-AgNPs. All peptide−particle solutions were allowed to shake overnight at room temperature and excess peptides were removed by centrifugation (13 500 rpm, 8 min). Particles were redispersed in PBS. The conjugation with PEG and the peptides was characterized by UV−vis spectroscopy and DLS analysis (Figure 1 and Table 1). To achieve the desired final concentrations (0.1 nM and 0.4 nM), the peptide-conjugated AgNPs were further diluted with DMEM cell culture medium.

Cell Culture. HSC-3 (human oral squamous cell carcinoma), a malignant epithelial cell line, and HaCat (human karatinocytes), a nonmalignant epithelial cell line, were cultured in Dulbecco's Modified Eagle's Medium (DMEM) (Mediatech) supplemented with 4.5 g/L glucose and sodium pyruvate, 10% v/v fetal bovine serum (FBS) (Mediatech), and 1% antimycotic solution (Mediatech). Cell cultures were kept at 37 °C in a 5% CO_2 humidified incubator.

Dark Field Imaging Overlays. Cells were cultured on collagen-coated 18-mm-diameter glass coverslips for 24 h and incubated for 24 h with 0.1 nM peptide−AgNP solutions diluted in DMEM. The coverslips were then washed with DPBS buffer and fixed with 4% paraformaldehyde. Images were obtained with an inverted Olympus IX70 microscope with a dark field condenser (U-DCW). A 100×/1.35 oil Iris objective (UPLANAPO) was used to collect the scattered light from the AgNP-treated samples.

AgNP Uptake Assay. HSC-3 and HaCat cells were cultured for 24 h in DMEM and then incubated for another 24 h with 0.1 nM peptide−AgNP solutions diluted in DMEM. Particle solutions were removed and the solution's OD values at 430 nm were taken using a microplate reader (SpectraMax Plus). Cells were counted using an inverted Olympus IX70 microscope with a 10× objective. Particle uptake values were normalized to the number of cells and are reported as a relative percent uptake. Statistical significance was determined from the

comparison of cancer (HSC-3) treated cells and healthy (HaCat) treated cells.

Cell Cycle Analysis with Flow Cytometry. Cells were grown for 24 h in culture medium (DMEM) and then incubated with AgNPs in culture medium (DMEM) for 24 h. After AgNP incubation, cells were fixed with −20 °C cold ethanol (70%) until analysis. To prepare for flow cytometry analysis, fixed cell suspensions were centrifuged at 1250 rpm for 12 min, and the cell pellet was redispersed in PBS. Cells were treated with 200 μg/mL RNase (Sigma) for 30 min at 37 °C. Following RNase treatment, DNA staining with 100 μg/mL of propidium iodine (Sigma) was conducted at room temperature for 15 min. A BD LSR II (BD Biosciences) with a 488 nm excitation laser and fluorescence detection in the PE channel was used to run flow cytometry. The obtained cell cycle data was analyzed using *FloJo* (Tree Star Inc.), a flow cytometry analyzing software.

Cell Synchronization. Nocodozale, a mitoic inhibitor, was used to synchronize HSC-3 and HaCat cells in the prometaphase (M phase). Cells were grown for 14 h in the presence of 80 ng/mL nocodazole, and mitoic cells were collected by shake-off. The motoic cells were released in fresh culture medium (DMEM) and collected at the indicated time points. Cells were then washed three times with PBS and fixed with −20 °C cold ethanol (70%) for further analysis by flow cytometry.

Confocal Microscopy and DNA Damage Test. HSC-3 and HaCat cells were grown on 18-mm-diameter glass coverslips and treated with their respective peptide−AgNP concentration. Cell fixation was conducted with 2% paraformaldehyde for 15 min, and cells were washed in PBS for 3 × 10 min. Cells were then permeabilized for 5 min on ice in 0.2% Triton X-100 and blocked in PBS with 1% BSA for 3 × 10 min at room temperature. Blocked cells were incubated with anti-γ-H2AX antibody (Bethyl Laboratories, Inc.) for one hour, washed in PBS with 1% BSA for 3 × 10 min at room temperature, and then incubated for 1 h at room temperature with FITC-conjugated goat antirabbit secondary antibody (Bethyl Laboratories, Inc.). Last, cells were washed in PBS with 1% BSA for 3 × 10 min at room temperature and stained with 4,6-diamidino-2-phenylindole (DAPI) for 5 min. Confocal images were taken using a Zeiss LSM 510 NLO META multiphoton excitation confocal microscope.

Real-Time Dark Field Imaging. A homemade setup was based on the modification of an inverted Olympus IX70 microscope.[21] The samples were grown in 35 mm culture plates for 24 h and then incubated with peptide-conjugated AgNPs in culture medium (DMEM) for 24 h. Samples were placed inside a mini cell chamber that was mounted on the stage of the microscope. The mini cell chamber allowed the sample to maintain a temperature of 37 °C and a carbon dioxide concentration of 5% CO_2. The scattered light from the sample was collected using a long working distance 40× objective. A Nikon D200 digital camera was used to capture the dark field pictures every two minutes.

Statistical Analysis. Statistical analysis of experimental values are conveyed as mean ± standard deviaion of at least three independent experiments. The data were analyzed using the *t test calculator* (GraphPad Software, GraphPad Software, Inc.), and statistical significance was determined from untreated (control) to treated (AgNPs incubation) samples unless otherwise noted. Data were considered statistically significant if the P value was <0.05.

RESULTS AND DISCUSSION

Synthesis and Conjugation of AgNPs. The silver nanoparticles (AgNPs) used in this work were synthesized by the reduction of silver nitrate with trisodium citrate.[20] The relatively monodispersed AgNPs had an average diameter of 35 nm, as shown by TEM (Figure 1). UV−vis spectroscopy further confirmed the synthesis of 35 nm silver particles, as the spectra showed the characteristic surface plasmon resonance (SPR) peak at 430 nm (Figure 1). Table 1 shows measurements of the hydrodynamic diameter (HD) and the zeta potential of the synthesized AgNPs.

The citrate-capped AgNPs were then conjugated with poly(ethylene glycol) (PEG) in order to increase their stability in the culture medium and prevent nonspecific binding of proteins to the surface of the particles.[22] The PEG-stabilized AgNPs were further conjugated with arginine-glycine-aspartic acid (RGD) and nuclear localization signal (NLS) peptides. RGD is known to target $\alpha v\beta 6$ as well as other αv integrins on the cell surface and assists in receptor-mediated endocytosis in cancer cells.[23−25] NLS has a characteristic lysine-lysine-lysine-arginine-lysine (KKKRK) sequence. Biomolecules labeled with this nuclear tag are known to bind to importin α and β in the

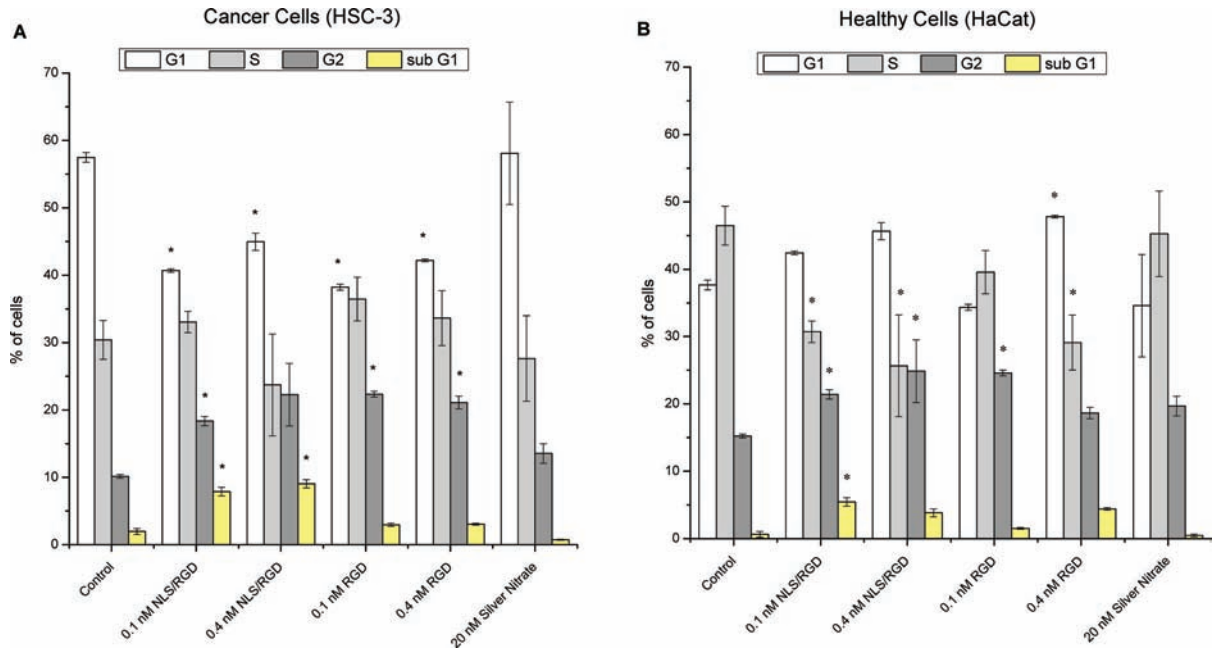

Figure 3. Complete cell cycle analysis of cancer and healthy cells by using flow cytometry. Cancer cells show a significant increase in the sub G1 (DNA deficient) population after treatment with NLS/RGD-AgNPs when compared to the control (A). G2 accumulation is seen in both cell models when treated with peptide-conjugated AgNPs. Asterisks (*) indicate a P value of <0.05.

cytoplasm and be actively transported into the nucleus through the nuclear pore complex (NPC).[26] The bioconjugation with the NLS and RGD peptides was confirmed through UV−vis spectroscopy and dynamic light scattering (DLS) measurements. The UV−vis spectra in Figure 1 show a slight red shift in the particles after conjugation with the peptides. The red shift was attributed to the change in the dielectric constant of the surrounding environment of the AgNPs. The DLS measurements, reported in Table 1, show the HD of AgNPs increased 20 nm after conjugation with the surface ligands. A change in the zeta potential of the particles was also observed after conjugation.

Additionally, the stability of the peptide-conjugated particles was investigated after 24 h of incubation in culture medium. The UV−vis spectra of the incubated AgNPs did not show a significant alteration in the SPR indicating that nanoparticle aggregation did not occur and the particles were stable in the biological environment (data not shown).

Localization and Relative Uptake of AgNPs in Cells. A major advantage of using silver nanoparticles in biomedical applications is their enhanced light scattering, which allows their localization and distribution to be imaged in different biological environments.[1] In this experiment, we wanted to determine the localization and relative uptake of the pegylated and peptide-conjugated AgNPs in two different cell lines. The cell lines used were human oral squamous cells carcinoma (HSC-3) and human keratinocytes (HaCat) cells, which modeled cancer and healthy cells, respectively. HSC-3 cells have been reported to express αv integrins (i.e., $\alpha v\beta 3$ and $\alpha v\beta 5$) and overexpress $\alpha v\beta 6$ integrins, an RGD receptor, on their cell surface.[27,28] We hypothesized that RGD conjugation would enhance the uptake of AgNPs by cancer cells since our healthy cell line has not been shown to overexpress $\alpha v\beta 6$ integrins unless induced by transforming growth factor-$\beta 1$ (TGF$\beta 1$).[29] To investigate the uptake and localization of NLS/RGD-AgNPs, RGD-AgNP and PEG-AgNP dark field imaging was utilized. The dark field image overlays seen in Figure 2A show that AgNPs conjugated with the nuclear targeting signal (NLS) are localized at the nucleus of both cell models, while RGD-AgNPs and PEG-AgNPs were dispersed within the cytoplasm. Figure 2A images also reveal that cancer cells show an apparent overall increase in AgNP uptake when compared to healthy cells.

To quantify the uptake of the different AgNPs in the cancer and healthy cell lines, the relative percent uptake of particles was determined. AgNP uptake, as reported in Figure 2B, was calculated through the normalization of the data to the number of cells present in each sample well. Cancer cells showed a statistically significant ($P < 0.05$) higher relative percent uptake of all conjugated AgNPs when compared to heatlhy cells. Furthermore, NLS/RGD-AgNPs exhibited the greatest relative percent uptake in both cell lines. The increased uptake in cancer cell lines is thought to be due to the overexpression of $\alpha v\beta 6$ integrins on their cellular membrane;[27] however, other αv integrins on the cell surface could have also contributed to the trend seen.[24,25] The cause for the differences between RGD and NLS/RGD particle uptake in both cell lines is still unclear; however, the overall surface charge of the particles could enhance/hinder the particle's ability to undergo receptor-mediated endocytosis.

Cell Cycle Analysis and Cell Synchronization of AgNP Treated Cells. After it was shown that NLS/RGD-AgNPs did localize at the nucleus, we investigated whether this localization caused cell cycle disruption in both cell models. To determine the effects of the peptide-conjugated AgNPs on cancer and healthy cells, complete cell cycle analysis was performed using flow cytometry. The complete cell cycle analysis of cancer and healthy cells treated with 0.1 nM and 0.4 nM conjugated AgNPs for 24 h, as to allow successful uptake of the particles, is shown in Figure 3. Cancer cells treated with 0.1 nM and 0.4 nM NLS/RGD-AgNP showed a statistically significant ($p < 0.05$) increase in the sub G1 (DNA deficient[30]) population (Figure

dx.doi.org/10.1021/bc200386m | Bioconjugate Chem. 2011, 22, 2324−2331

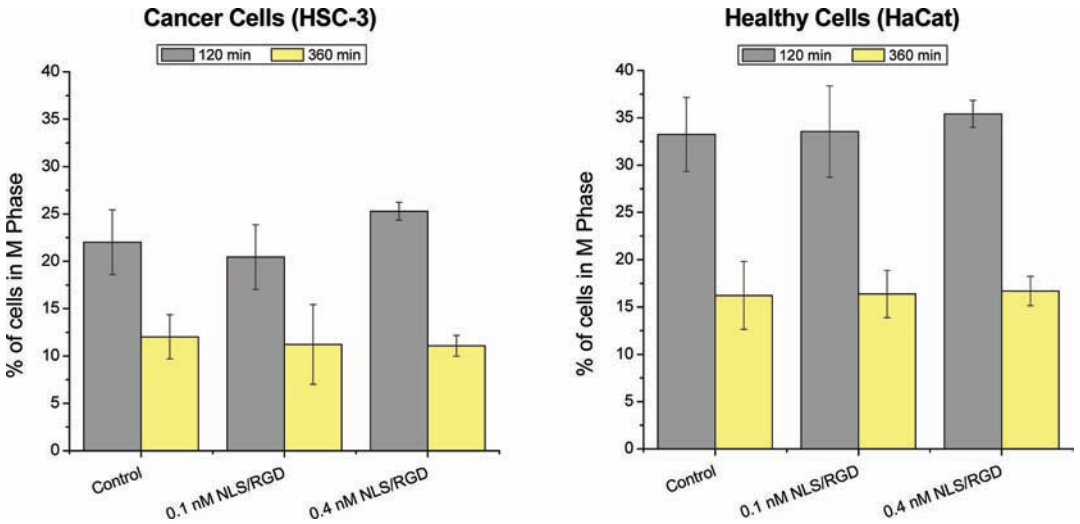

Figure 4. Cell synchronization of NLS/RGD-AgNPs treated cells. Significant M phase accumulation was not seen between control and NLS/RGD-AgNP treated cells in both cancer (A) and healthy (B) cells. Cells were synchronized with nocodazole in the prometaphase (M phase), and cell cycle analysis was conducted at 120 and 360 min. Statistical significance was determined from a P value of <0.05.

3A). The sub G1 population resulting from incubation with 0.1 nM nuclear-targeting AgNPs suggested that there was an increased toxicity of AgNPs in our cancer cell model when compared to AuNPs.[14] The sub G1 population also appears to increase as the concentration of nuclear-targeting AgNPs introduced into the cancer cells increases from 0.1 nM (~8.0%) to 0.4 nM (~9.0%). Additionally, cancer cells treated with NLS/RGD-AgNPs showed an accumulation in the G2/M phase of the cell cycle indicating the presence of nuclear targeting AgNPs disrupted the transition of G2/M or M/G1.

Contrary to the results seen with nuclear-targeting AuNPs, a significant sub G1 population was also seen in healthy cells when treated with NLS/RGD-AgNPs for 24 h (Figure 3B). It is believed that the lack of overexpression of $\alpha v\beta 6$ integrins[29] on their cell surface and reduced uptake of nuclear-targeting AgNPs contributes to the reduced sub G1 population in healthy cells when compared to our cancer cell model. Nevertheless, the presence of the DNA deficient population in healthy cells provides further evidence of the harmful, toxic effects AgNPs have when compared to AuNPs. Moreover, healthy cells show G2/M accumulation upon treatment with NLS/RGD-AgNPs indicating that the presence of nuclear-targeting AgNPs prevents normal transitions between the different phases of the cell cycle.

To ensure that the NLS peptide was necessary to induce significant sub G1 populations in cancer and healthy cells, we examined the effect that RGD and PEG conjguated AgNPs had on the cell cycle. Cancer and healthy cells treated with RGD-AgNPs did not show a significant increase in the sub G1 population when compared to their controls but did show G2/M accumulation. The G2/M accumulation seen in our work is consistent with work reported from AshaRani et al., as they observed similar G2 accumulation in human glioblastoma cells (U251) and normal human lung fibroblast cells (IMR-90) when treated with starch-coated AgNPs.[31] However, their starch-coated particles did not produce DNA-deficient populations. This suggests that alteration of the cell cycle occurs in the presence of AgNPs, but the observed increase in apoptotic populations is only induced when AgNPs are localized at the nucleus. Moreover, cell cycle analysis of cancer and healthy cells treated with 0.1 nM and 0.4 nM PEG-AgNP showed no significant increase in the sub G1 or apoptotic population when compared to untreated cells (SI Figure S2).

The two main reported causes for the appearance of an apoptotic population upon treatment with AgNPs are the leaching of Ag^+ ions from the AgNPs and the generation of reactive oxygen species (ROS) from nano metal oxide materials (AgNPs can oxidize easily to form Ag_2O).[31,32] To determine if the alteration in the cell cycle was due to free Ag^+ ions alone, cancer and healthy cells were incubated for 24 h with 20 nM $AgNO_3$ and their cell cycles were analyzed. Neither cell model showed significant ($P < 0.05$) cell cycle alteration (Figure 3) when compared to their controls. This result suggested that the apoptotic population is not solely due to the leaching of Ag^+ ions and could be partly due to the generation of ROS from the silver metal oxide inside the cancer cells.[33] ROS species are known to cause oxidative stress and DNA damage inside cells, which is a leading cause of apoptosis.[34−37] Additionally, it has been reported that upregulation of p53, a protein that is overexpressed when DNA damage occurs and causes cell cycle arrest and apoptosis, was seen after cells were incubated with unconjugated AgNPs.[38] It is possible that incubation with NLS/RGD-AgNPs also causes upregulation of p53 and signals for programmed cell death in our cancer cell model.

To further investigate alterations to the cell cycle, cell synchronization experiments were conducted to determine whether M phase arrest was seen after incubation with NLS/RGD-AgNPs. Nocodozale, a mitotic inhibitor, was used to synchronize cancer and healthy cells in the prometaphase (M phase).[39,40] On the basis of our group's previous work with nuclear-targeting AuNPs,[14] which showed abscission of two daughter cells occurring in ~2 h for untreated cells and ~4 h for particle treated cells, we chose 120 and 360 min for points of analysis. As seen in Figure 4, there was no significant M phase accumulation in the cancer or healthy cells after treatment with NLS/RGD-AgNPs. These results differ from NLS/RGD-AuNPs, as M phase accumulation in cancer cells was seen.[14] Since complete cell cycle analysis revealed an increase in the G2/M population, and the cell cycle synchronization experiment did not show M phase accumulation, it is proposed that the arrest has taken place in the G2 phase. This suggests that cancer cells treated with NLS/RGD-

AgNPs were unable to pass through the G2 checkpoint of the cell cycle, the cell's last opportunity to evaluate its genetic material before entering mitosis,[41] and resulted in apoptosis if their DNA was unable to be repaired. Furthermore, these experiments indicate that irreversible DNA damage occurs at different phases in the cell cycle when different plasmonic nanoparticles are used (Figure 5).

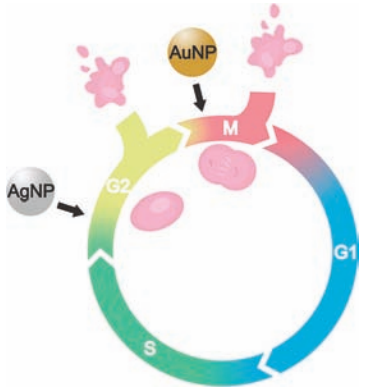

Figure 5. Summary of the difference in the effect of spherical nuclear-targeting AgNPs and AuNPs on the cell cycle. Cell cycle accumulation was seen in the G2 phase when cancer and healthy cells were treated with peptide-conjugated AgNPs. It has been reported[13] that nuclear-targeting AuNPs show cell cycle accumulation in the M phase of the cell cycle.

Confocal Microscopy and DNA Damage Test. DNA damage, in cancer and healthy cells treated with nuclear targeting AgNPs, was suggested from the sub G1 population and G2 accumulation in the flow cytometry experiments. To further investigate whether DNA damage was a result of incubation with nuclear-targeting AgNPs, treated cells were tested for double-strand breaks (DSBs) in DNA by confocal microscopy. Confocal images of untreated and treated cancer cells are shown in Figure 6. The nuclei have been stained blue with DAPI and DSBs as indicated by bright green FITC fluorescence foci. DNA DSBs are seen in cancer cells treated with 0.1 nM and 0.4 nM NLS/RGD-AgNPs (Figure 6B,C). When cancer cells were treated with 0.1 nM and 0.4 nM NLS/RGD-AuNPs, DNA DSBs were only seen after incubation with the 0.4 nM concentration.[14] This provides supplementary evidence that AgNPs exhibit more harmful effects on cancer cells than AuNPs. Confocal images of healthy cells treated with the highest concentration of NLS/RGD-AgNPs showed no DSBs (SI Figure S3). The absence of DSBs is due to the lower nanoparticle concentration at the nucleus in healthy cells compared to cancer cells. We attributed the decreased nanoparticle concentration at the nucleus to the reported lack of overexpression of $\alpha v\beta 6$ integrins, an RGD receptor, in our healthy cell line when compared to our cancer cell line.[27,29] These images confirm that NLS/RGD-AgNPs induce irreversible DNA damage in cancer cells, leading to an increased sub G1 (apoptotic) population. The confocal images further suggested that the selective targeting facilitated by the RGD peptide conjugation caused an increased vulnerability to DNA damage in cancer cells compared to healthy cells.

Real-Time Dark Field Imaging of AgNP Treated Cancer Cells. We also wanted to investigate in real time whether the presence of nuclear targeting AgNPs in our cancer cell model interferes with proper cellular division. The dynamics of cell division were monitored by long-term live-cell plasmonic scattering imaging.[21] Figure 7 displays representative real-time dark field images of cell division in our cancer cell model. Untreated cancer cells underwent proper division and showed no cell death. However, when cancer cells were incubated with varying concentrations of NLS/RGD-AgNPs normal cell division was not observed (Figure 7) and cell death resulted. These images differs from our group's previous work when using NLS/RGD-AuNPs, which showed cytokinesis (M phase) arrest in cancer cells after incubation with nuclear-targeted AuNPs.[14] The inability of cells treated with NLS/RGD-AgNPs to reach cytokinesis (M phase) provides further evidence that cells have arrested and accumulated in the G2 phase of the cell cycle due to the increased cytotoxicity of AgNPs compared to AuNPs.

CONCLUSIONS

The cell cycle and cell division of cancer (HSC-3) and healthy (HaCat) cells in the presence of conjugated AgNPs were systematically studied. DNA damage and apoptosis were seen in cancer cells that were treated with nuclear-targeting AgNPs. Real-time dark field imaging suggested that cancer cells treated with NLS/RGD-AgNPs are unable to successfully divide and ultimately undergo cell death. Complete cell cycle analysis showed a significant increase in the sub G1 population of

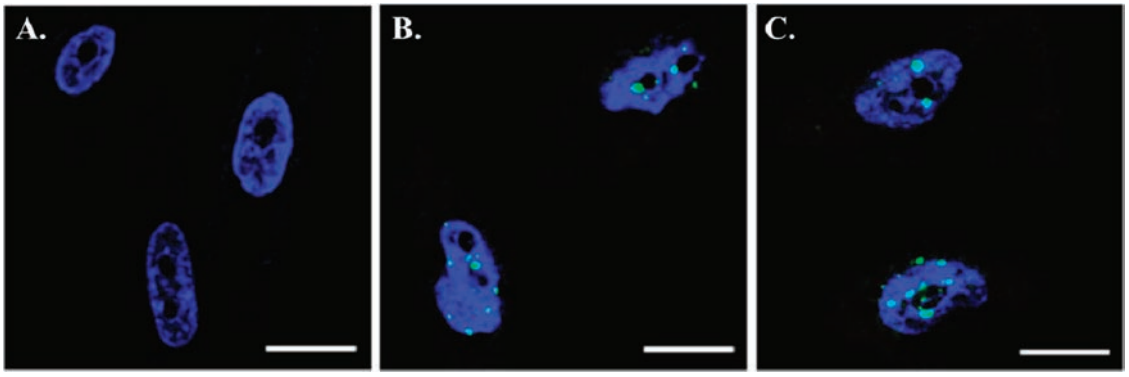

Figure 6. Confocal images of DNA damage in cancer cells resulting from incubation with NLS/RGD-AgNPs. The cells' nuclei were stained with DAPI (blue), and DNA double-strand breaks (DSBs) were stained with FITC (green). No DNA damage was seen in untreated cancer cells (A). DNA double-strand breaks (green foci) were seen in cells treated with (B) 0.1 nM and (C) 0.4 nM NLS/RGD-AgNPs. Cells were incubated with nuclear-targeting AgNPs for 24 h. Scale bar: 10 μm.

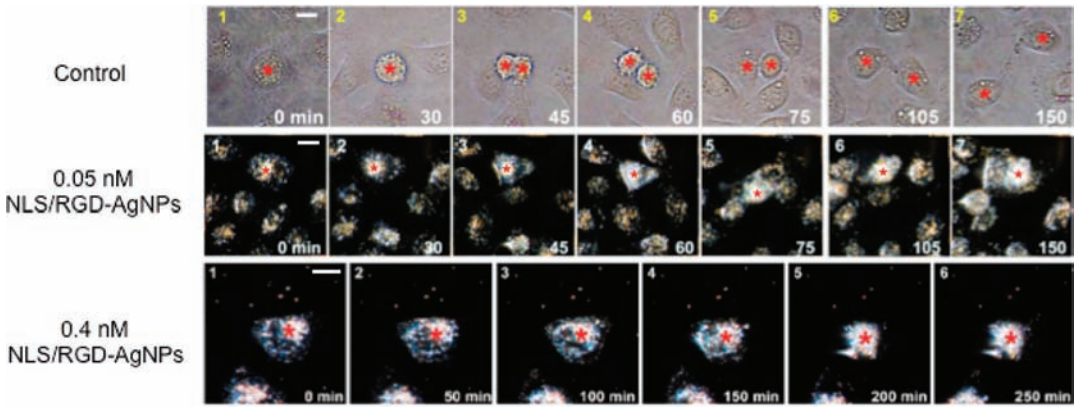

Figure 7. Real-time dark field images of cancer cells. Untreated cells (top) showed proper cell division while cells treated with 0.05 nM (middle) and 0.4 nM (bottom) nuclear-targeting AgNPs were unable to successfully divide and resulted in programmed cell death. The red stars indicate the cells of interest. Scale bar: 10 μm.

cancer cells after treatment with nuclear-targeting AgNPs. G2 accumulation was also seen in cancer and healthy cells during cell cycle analysis. The resulting G2 accumulation in cells treated with varying concentrations of AgNPs differed from the M phase accumulation in cells treated with 0.4 nM NLS/RGD-AuNPs. In cancer cells, the G2 accumulation accompanied by the increase in the sub G1 population suggests cells were unable to pass through the G2 checkpoint and the G2-M transition has been affected. The cause of the altered cell cycle was attributed to DNA damage, as seen with confocal microscopy. The basis for the observed DNA damage could potentially be a result of ROS generation from the AgNPs, as we eliminated leaching Ag^+ ions as the sole reason. These results demonstrate the importance of systematically studying the intracellular effects of each surface ligand and plasmonic nanoparticle combination to ensure the desired biomedical function and cytotoxicity are achieved.

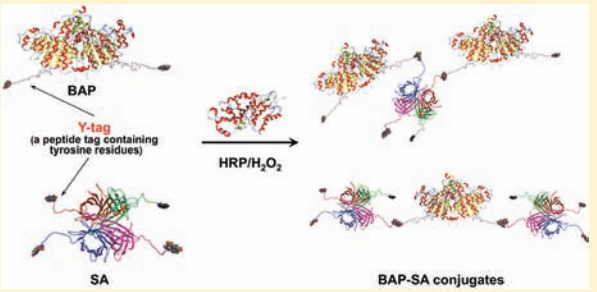
ABSTRACT: Combining different proteins can integrate the functions of each protein to produce novel protein conjugates with wider ranges of applications. We have previously introduced a peptide containing tyrosine residues (Y-tag) at the C-terminus of *Escherichia coli* alkaline phosphatase (BAP). The tyrosine residues in the Y-tag were efficiently recognized by horseradish peroxidase (HRP) and were site-specifically cross-linked with each other to yield BAP homoconjugates. In this study, the HRP-catalyzed tyrosine coupling reaction was used for protein heteroconjugation. Streptavidin (SA) was selected as the conjugation partner for BAP. The Y-tag (GGGGY) was genetically introduced to the C-terminus of SA. Prior to heteroconjugation, the reactivity of the Y-tagged SA was examined. The Y-tagged SA cross-linked to form an SA homoconjugate upon HRP treatment, whereas wild-type SA remained essentially intact. In the heteroconjugation reaction of BAP and SA, the Y-tagged BAP and SA were efficiently cross-linked with each other upon HRP treatment. The functions of the BAP-SA conjugates were evaluated by measuring the BAP enzymatic activity on a biotin-coated plate. The BAP-SA conjugate tethered to the plate showed BAP enzymatic activity, indicating that both BAP and SA retained their functions following heteroconjugation. The BAP-SA conjugate prepared from both Y-tagged BAP and SA showed the highest enzymatic activity on the biotin-coated plates. This result illustrates the advantage of the protein conjugation reaction in which multiple numbers of proteins can be conjugated at the same time.



INTRODUCTION

There is significant interest in the heteroconjugation reaction of different proteins because this reaction combines distinct protein functionalities, thereby increasing the integrative functions of conjugated proteins and providing an alternative use of proteins in many fields.[1−4] Many approaches to achieve protein heteroconjugation have been proposed. The most straightforward approach is to genetically fuse two proteins, producing so-called fusion or chimeric proteins.[5−7] This technique enables the production of homogeneous protein conjugates by controlling sophisticated protein expression systems of living organisms. Protein expression systems have been extensively used for the purpose of protein production and purification[5,6] and in *in vivo* imaging.[7] By using this method, it is possible to theoretically conjugate any set of proteins; however, there is the risk of protein misfolding which results in the loss of protein function or the formation of insoluble inclusion bodies.

Post-translational protein modification (PTM) has general versatility to produce protein heteroconjugates, because PTM works with mature proteins thereby avoiding the problems associated with the expression of fusion proteins. Heterobifunctional linkers, which cross-link primary amino groups including an N-terminal amino acid and the side-chain of lysine, and/or the thiol group of cysteine, have been widely used to produce antibody-based heteroconjugates because antibodies possess cysteine residues available for this purpose.[8−10] Although the reaction is simple and easy to apply, the hereroconjugation reaction using heterobifunctional linkers is limited between two proteins, because one protein must have an available cysteine and the other protein should contain no cysteines. Moreover, the cross-linking reaction must be conducted in two steps, including the reduction of disulfide bonds and purification. Self-labeling proteins, such as the SNAP-tag and Halo-tag, have become powerful protein modification tools to introduce small molecules site-specifically to proteins.[11,12] These techniques should offer the potential to produce protein−protein heteroconjugates; however, negligible effort has been made using this method, probably because the introduction of small chemical substrates to target proteins is required.[11] Intein-mediated protein ligation is also applicable to protein heteroconjugation, but problems associated with the misfolding of the intein-fusion protein can arise.[5,13]

Enzymatic post-translational modifications represent the most promising way to produce protein−protein heteroconjugates.[3,14−17] Transglutaminase (TGase) has been studied and used in site-specific protein modifications including protein heteroconjugation, because the cross-linking of different pairs of natural amino acids, glutamine, and lysine residues is

possible.[3,15] The transpeptidase from *Staphylococcus aureus*, Sortase A (SrtA), is another enzyme that has been employed for site-specific protein−protein conjugations.[14,16,17] SrtA catalyzes the heteroconjugation reaction of two proteins. In this reaction, one protein possesses the C-terminal LPXTG sequence and the other protein has an N-terminal oligoglycine sequence. SrtA cleaves the peptide bond between the threonine and glycine residues of the LPXTG sequence and forms a peptide bond between the C-terminal end of the threonine residue and the N-terminal end of the oligoglycine.[14] Protein conjugations mediated by these enzymes require only the addition of short peptide tags, which are composed of natural amino acids. The problems associated with using these enzymes are that TGase has relative broad substrate recognition of amino substrates and the reaction efficiency of SrtA-catalyzed transpeptidation is not high because of competitive hydrolytic cleavage reactions.

Besides these well-studied enzymes, various oxidoreductases, including tyrosinase, laccase, and peroxidase, have also been employed for the purpose of protein modifications.[18−22] These enzymes catalyze the oxidation reaction of tyrosine and form *o*-quinone and phenoxy radicals in the side-chains. These activated tyrosine species are subsequently conjugated with primary amino groups[20,21] or other tyrosine residues.[18,19,22] Tyrosine residues can be found in modified forms, including dityrosine and trityrosine, in various kinds of structural proteins in nature,[23−26] suggesting the potential use of tyrosine as a target for PTM. As a target for protein modification, tyrosine residues have several advantages over common targets such as primary amino groups, carboxylic acid groups, or the thiol group. Tyrosine is a hydrophobic amino acid, and hence, the number of tyrosine residues exposed on a protein surface is generally lower than the hydrophilic amino acids, implying higher site-specificity in targeting tyrosine compared with other amino acids. Tyrosine is rather stable in physiological conditions, and therefore, it is not readily involved in common nucleophilic reactions such as amine coupling, indicating that selective modification of tyrosine residues is orthogonal to other common protein modification strategies.

We have recently reported site-specific protein cross-linking using the horseradish peroxidase (HRP) mediated oxidative tyrosine-coupling reaction.[27] In this previous report, peptide tags containing tyrosine residues (Y-tags) were genetically introduced at the C-terminus of *Escherichia coli* alkaline phosphatase (BAP). We demonstrated that as a proof-of-concept study the Y-tagged BAP became reactive to the enzymatic reaction of horseradish peroxidase (HRP), which resulted in the formation of site-specifically cross-linked BAP via the Y-tag.

Here, we explored the protein heteroconjugation of a Y-tagged BAP with a functional protein by the HRP-mediated tyrosine coupling reaction. Streptavidin (SA) derived from *Streptomyces avidinii* was selected as a promising conjugation partner. SA is a tetrameric protein, and each subunit binds to one water-soluble vitamin, biotin, with extraordinarily strong affinity.[28] SA has been extensively used in multiple fields such as biochemical, pharmaceutical, and biophysical applications.[29,30] The heteroconjugate of SA and alkaline phosphatase (AP) is applicable to the enzyme-linked immunosorbent assay (ELISA), staining of cells and tissues, and Western blotting. SA-AP conjugates are thus commercially available from several chemical companies. Unlike other enzyme-mediated protein conjugation reactions, the HRP catalyzed tyrosine-coupling reaction can cross-link a multiple number of SA and BAPs in one step, which results in the formation of $(BAP)_n$-$(SA)_m$ conjugates. In this report, the Y-tag was genetically introduced to the C-terminus of SA and BAP and the heteroconjugation of BAP and SA was demonstrated to prepare BAP-SA conjugates by the HRP-catalyzed tyrosine coupling reaction.

EXPERIMENTAL PROCEDURES

Materials and Instruments. Wild-type BAP (WT-BAP) and Y-tagged BAP (CY1-BAP) bearing the thrombin cleavage sequence (LVPRGS) and Y-tag (GGGGY) at the C-terminus were prepared according to our previous report.[27] The plasmid coding the core streptavidin (127 a.a.) was synthesized by the Codon Device (Cambridge, MA, USA). HRP-type VI (250−330 units/mg solid using pyrogallol) was purchased from Sigma Aldrich Co. H_2O_2 (30 wt %) was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). All other reagents were purchased and used as received. A cation exchange column (HiTrap SP HP 1 mL) and a desalting column (PD-10) were purchased from GE Healthcare Bio-Sciences. A size-exclusion chromatography column (TSKgel G4000SW) was purchased from Tosoh Co. All chromatography experiments for the purification of SAs were conducted on a BioLogic DuoFlow Chromatography System (Bio-Rad Laboratories, Inc.).

Gene Construction of SA. The gene coding the core SA was amplified by PCR to introduce the Y-tag (GGGGY) to the 3′ terminal end, and the restriction enzyme sequences of *Nde*I and *Hind*III were also appended to the 5′ and 3′ termini, respectively. The PCR products were digested with *Nde*I and *Hind*III and cloned into the *Nde*I and *Hind*III sites of the pET22b + plasmid followed by transformation into *E. coli* JM109 to yield an expression plasmid coding for Y-tagged SA (abbreviated as CY1-SA). Wild-type SA (abbreviated as WT-SA) was also prepared in the same manner as the Y-tagged SA, but without the addition of the Y-tag sequence at the C-terminus.

Expression and Purification of the Recombinant SAs. The general purification process of SAs was carried out as previously described.[31,32] The expression of SA was carried out in *E. coli* BL21(DE3). After transformation, single colonies were selected from the agar plates containing 100 μg/mL of ampicillin and inoculated into 5 mL of LB medium containing 100 μg/mL of ampicillin. The medium was precultured overnight at 37 °C. The precultured medium was then poured into 500 mL of LB medium containing 100 μg/mL ampicillin and grown until the OD_{600} reached ∼0.9. Isopropyl β-D-thiogalactoside (IPTG) was added to the medium to a final concentration of 100 mg/L to induce the expression of the target SA. All protein expressions were performed for 4 h at 37 °C. The cells were then collected by centrifugation at 5000 *g* for 20 min at 4 °C. The cell pellets were washed with the pellet wash buffer (10 mM Tris-HCl, 1 mM EDTA, and 100 mM NaCl, pH 8.0) twice and subsequently resuspended in 30 mL of the inclusion body wash buffer (30 mM Tris-HCl, 2 mM EDTA, 0.1% Triton-X100, pH 8.0). The cell suspensions were frozen with liquid nitrogen and stored at −80 °C until purification. For the purification of SAs, the frozen cell suspensions were completely thawed on ice and 10 mg of lysozyme, 100 μL of 1 mg/mL DNase I and RNase A, and 120 μL of 1 M $MgCl_2$ were added. The suspensions were then incubated on ice for 30 min and then sonicated for 3 min to lyse cells. The supernatant and the insoluble materials containing inclusion bodies of SAs were separated by centrifugation at 5800 *g* for 10 min at 4 °C. The insoluble materials were thoroughly resuspended in 30 mL of the inclusion body wash buffer by pipetting and the inclusion bodies were collected at 5800 *g* and 4 °C.

This washing process was repeated until the inclusion bodies became white in color. This involved repeating the wash steps at least four times. The obtained inclusion bodies were further washed three times in the same manner using the pellet wash butter to remove the surfactant, Triton-X100. The inclusion bodies were then dissolved into 750 μL of a 6 M guanidinium hydrochloride solution (pH 1.5) and centrifuged at 20,800 *g* for 15 min at 4 °C. The supernatant containing the unfolded SA was dropped into vigorously stirred 50 mL of TBS (25 mM Tris-HCl, 137 mM NaCl, 2.68 mM KCl, pH 7.4) at 4 °C and then stirred gently overnight to refold SAs. The following day, 12.58 g of well-ground ammonium sulfate was gradually added to the TBS solution and stirring was continued for a further three hours. The generated settlings in the solution were removed using No. 2 filter paper. The SA in the solution was precipitated by adding a further 11.8 g of ammonium sulfate and stirring was continued at 4 °C overnight. The precipitated SA was collected by centrifugation at 20 800 *g* for 10 min and dissolved into 2.5 mL of TBS. The SA solution was filtrated using a 0.2 μm membrane filter and the buffer was exchanged to the cation chromatography binding buffer (100 mM succinic acid, 10 mM EDTA, pH 4.2) using PD 10 Sepharose columns. The SA solution was applied to a cation exchange column that was pre-equilibrated with the binding buffer. The column was washed with five column bed volumes of the binding buffer. SAs were eluted by a salt gradient of the elution buffer (100 mM succinic acid, 10 mM EDTA, 1 M NaCl, pH 4.4) from 0% to 35% with five column bed volumes, and 0.5 mL fractions were collected. A small portion of each fraction was taken and mixed with a HABA (2-(4′-hydroxyazobenzene)-benzoic acid) solution to determine the presence of SAs. The fractions containing SA were gathered and concentrated into a volume of ~0.9 mL using an ultrafiltration membrane (MWCO 10 kDa). The SA solution was next purified using a SEC column equilibrated with the SEC mobile phase (20 mM Tris-Acetate pH 7.2). All of the BAP solutions were applied to the SEC column using a 1 mL sample loop, and size-exclusion chromatography was carried out at flow rate of 0.5 mL/min. Fractions containing SA were collected and finally desalted into 10 mM Tris-HCl (pH 8.0) on PD 10 Sepharose columns. The concentrations of the obtained SA solutions were measured using the BCA assay and bovine serum albumin (BSA) as the standard. The purities of the SA samples were determined by SDS-PAGE analysis. The purification procedure was used for the production of all SA constructs.

Heteroconjugation Reaction of BAP and SA. BAP, SA, and HRP were dissolved in 10 mM Tris-HCl (pH 8.0) at final concentrations of 0.2 mg/mL, 0.2 mg/mL, and 0.1 mg/mL, respectively. The sample solutions were incubated at 37 °C, and the heteroconjugation reaction of BAP and SA was conducted by adding 1 μL of a 500 μM H_2O_2 solution five times every 10 min to a final concentration of 50 μM. After overnight incubation, the sample solutions were analyzed by SDS-PAGE and native-PAGE analyses. Prior to native-PAGE analyses, biotin-4-fluorescein was added to the sample solutions at a final concentration of 50 μM and incubated for 1 h at 4 °C.

Thrombin Treatment of CY1-BAP-SA Conjugates. CY1-BAP bears a thrombin cleavage site between BAP and the Y-tag; however, the CY1-SA construct does not have this protease site. Therefore, it is possible to cleave the Y-tag of CY1-BAP selectively. For the purpose of analyzing how CY1-BAP and SAs are conjugated to each other, (CY1-BAP)-SA conjugates were subjected to thrombin cleavage. After the heteroconjugation reaction of CY1-BAP and SAs, thrombin was added to the solutions at a final concentration of 20 U/mL. The solutions were analyzed in the same manner by SDS-PAGE and native-PAGE analyses.

Immobilization of BAP-SA Conjugates to a Biotin-Coated Plate. To standardize the experimental conditions, the BAP enzymatic activities of the BAP-SA conjugates were first measured in the solution state. After the heteroconjugation reaction, 10 μL of each BAP-SA conjugate sample was taken and added to 990 μL of 1 mM *p*-nitrophenylphosphate (*p*-NPP)/1 M Tris-HCl (pH 8.0) in a UV quotes cell. The absorbance increase derived from the generated *p*-nitrophenol (*p*-NP) at 410 nm was monitored for 3 min at 25 °C. One unit of BAP enzymatic activity was defined as an activity that catalyzes the dephosphorization reaction of 1 μmol of *p*-NPP in 1 min, and the *p*-NP absorbance coefficient of 16 900 M^{-1} cm^{-1} was employed to calculate the unit value. All the sample solutions were then diluted using 10 mM Tris-HCl (pH 8.0) to a concentration of 0.5 unit/mL and 125 mM of NaCl was added. To immobilize the BAP-SA conjugates, 100 μL of each BAP-SA conjugate solution was added to a well of biotin-coated plates (Pierce Biotin Coated Clear 8-Well Strip Plates) preliminarily washed with TBS three times and then incubated at 25 °C for 30 min. The wells were washed with TBS three times to remove unbounded proteins. Lastly, BAP enzymatic activities were measured in each well by adding 200 μL of 1 mM *p*-NPP/1 M Tris-HCl (pH 8.0) to each well and the increase in the absorbance at 410 nm was monitored for 10 min at 37 °C.

RESULTS AND DISCUSSION

Homoconjugation Reaction of SA. Prior to heteroconjugation, SAs were treated with HRP in the absence of BAP and the reactivity of SAs against HRP treatment was evaluated. The results of SDS-PAGE analyses of HRP-treated SA samples are shown in Figure 1. The band representing monomeric

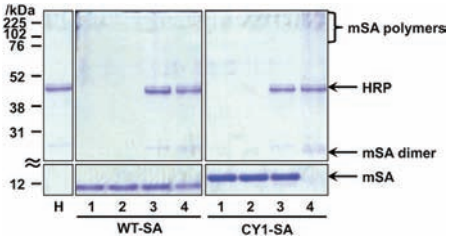

Figure 1. SDS-PAGE analyses of HRP-treated SAs. Lane H: HRP; Lane 1: SA; Lane 2: SA with the addition of H_2O_2; Lane 3: SA with the addition of HRP; Lane 4: SA with the addition of HRP and H_2O_2.

WT-SA at ~12 kDa remained after HRP treatment (Lane 4 for WT-SA), with a slight decrease in intensity. Additionally, a new band corresponding to the mSA dimer, close to a band arising from a contaminating protein in the HRP sample (<32 kDa), can be observed, yet the intensity is very weak. These results suggest that the intrinsic tyrosine residues of SA can be partly recognized by HRP. In contrast, the band of monomeric CY1-SA completely disappeared after HRP treatment and new bands corresponding to the mSA dimer and polymers emerged (Lane 4 for CY1-SA). This observation indicates that the tyrosine residues in the appended Y-tag were efficiently recognized by HRP and polymerized, since dityrosine, a coupling product of tyrosyl radicals, can be reactivated by HRP and form branched

cross-linkage. Figure 2 shows the molecular image of a subunit of SA showing its intrinsic tyrosine residues as CPK models. As

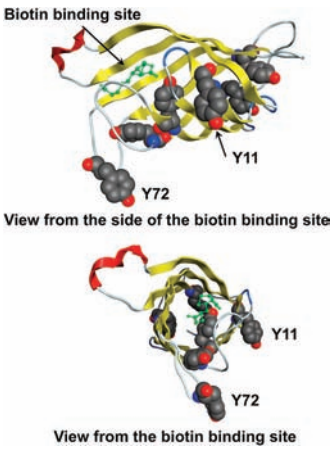

Figure 2. Molecular images of a subunit of WT-SA showing its intrinsic tyrosine residues as CPK models (PDB ID: 1MK5). The numbering of the amino acids began from the initiation codon of the methionine.

seen in Figure 2, Y11 and Y72 of SA are exposed on the surface of the protein. In particular, Y72 is located on a loop and is likely to be relatively flexible. We hypothesized that these two tyrosine residues are responsible for the homoconjugation of WT-SA upon HRP treatment and evaluated the reactivities of these two tyrosine residues by introducing the mutations Y11F and Y72F to WT-SA (see Supporting Information). The formation of dityrosine, one of the products of the tyrosine coupling reaction, was monitored by measuring the fluorescence intensity at 400 nm. The Y72F mutation significantly reduced the formation of the dityrosine upon HRP treatment, whereas the Y11F mutation had negligible effect. Therefore, Y72 is likely to be the primary tyrosine residue that is recognized by HRP and facilitates homoconjugation of WT-SA. This result also shows that, to be recognized by HRP, a tyrosine residue must not only be exposed on the protein surface but also needs to be in a flexible region, as the Y11 of WT-SA appears to be not recognized by HRP. The crystallographic data of five amino acid residues at the C-terminus of SA were not obtained (PDB ID: 1MK5), indicating high flexibility of the C-terminal region. Thus, the introduction of a flexible tyrosine residue as a Y-tag at the flexible SA C-terminus drastically increased the reactivity against HRP treatment, suggesting that the cross-linking of CY1-SA predominantly occurred through the Y-tag. The results obtained here demonstrate that the peroxidase-catalyzed tyrosine-coupling reaction is generally applicable to recombinant Y-tagged proteins.

Heteroconjugation Reaction of BAP and SA. BAP and SA were treated with HRP for the heteroconjugation reaction. The results of the SDS-PAGE and native-PAGE analyses of BAP-SA conjugation samples are shown in Figure 3. When WT-BAP and WT-SA were treated with HRP, both proteins exhibited virtually no reactivity, resulting in the presence of no new bands, and no observed change around 52 and 12 kDa, corresponding to mBAP and mSA, respectively (Figure 3A, Lane 1 for WT-BAP). The presence of a cross-linked WT-SA species was observed in the fluorescence image of the native-PAGE; however, this band was extremely weak.

In the case of either BAP or SA possessing a Y-tag, the heteroconjugation reaction between BAP and SA occurred only

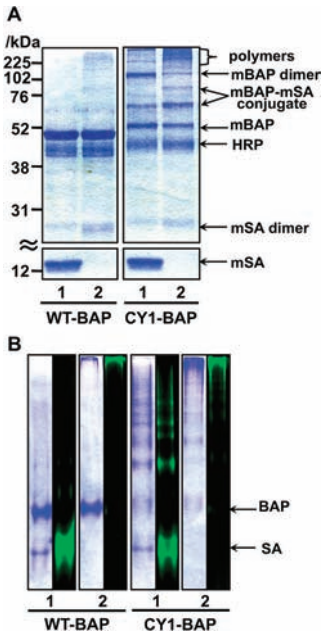

Figure 3. SDS-PAGE (A) and native-PAGE (B) analyses of the heteroconjugation reaction of BAP and SA. Lane 1: BAP with the addition of WT-SA, HRP, and H_2O_2; Lane 2: BAP with the addition of CY1-SA, HRP, and H_2O_2. In the native-PAGE analysis, SA was visualized by biotin-4-fluorescein (right of each picture).

when the Y-tag was appended to BAP. In the SDS-PAGE analysis, new bands emerged at ~60 kDa and above the mBAP dimer bands (around 102 kDa) with a ladder distribution (Figure 3A, Lane 1 for CY1-BAP). The new band at ~60 kDa corresponds to the mBAP-mSA conjugate based on the molecular weight, and the higher molecular weight bands are presumably conjugates in which mSA is attached to mBAP oligomers and polymers. In the native-PAGE analysis, most of the bands of the conjugates exhibited fluorescence from biotin-4-fluorescein indicating the presence of SA (Figure 3B, Lane 1 for CY1-BAP). This result shows that, when CY1-BAPs are cross-linked with each other, WT-SA was partly involved in protein conjugation. In contrast, WT-BAP was not cross-linked with CY1-SA even though CY1-SA was highly self-cross-linked in the same solution. These results can be explained as follows. As explained earlier, WT-SA has two largely exposed intrinsic tyrosine residues, Y11 and Y72, and Y72 can be recognized by HRP. However, although Y72 of WT-SA can be recognized by HRP and also the radical exchange reaction from the Y-tag of CY1-BAP can help to activate the exposed tyrosine residues of WT-SA, a large portion of WT-SA remained unreacted. Therefore, the heteroconjugation efficiency between CY1-BAP and WT-SA was not high. On the other hand, WT-BAP possesses no intrinsic tyrosine residues that are fully exposed on the surface of BAP, resulting in no heteroconjugation reaction between CY1-SA.

In the case of the heteroconjugation reaction of CY1-BAP and CY1-SA, in the SDS-PAGE analyses, the mSA band completely disappeared and multiple bands corresponding to BAP-SA conjugates emerged (Figure 3A, Lane 2 for CY1-BAP). The emergence of a new band at ~80 kDa corresponds to the mBAP-$(mSA)_2$ conjugate. The mBAP-$(mSA)_2$ conjugate was considered to be a form of a branched conjugate cross-linked through the Y-tag of each protein or a form where one Y72 of an mSA dimer, which is formed by intramolecular cross-linking

dx.doi.org/10.1021/bc200420v | Bioconjugate Chem. 2011, 22, 2332–2338

via the Y-tags, is involved in the cross-coupling with the Y-tag of mBAP. It is interesting that such conjugates were not observed in the case of the heteroconjugation reaction between CY1-BAP and WT-SA. In the solution of CY1-BAP and WT-SA, the homoconjugation reaction of WT-SA through its exposed tyrosine residue Y72 may compete with the heteroconjugation reaction with CY1-BAP. Thus, the cross-linking of WT-SAs was not observed and no further reaction of such species with CY1-BAP was observed. As a result, it can be assumed that the mBAP-$(mSA)_2$ conjugate was solely observed in the co-cross-linking of CY1-BAP and CY1-SA. In the native-PAGE analysis of the (CY1-BAP)-(CY1-SA) conjugate, the molecular weight of the conjugates dramatically increased when compared with the (CY1-BAP)-(WT-SA) conjugate, indicating efficient conjugation between BAP and SA through the Y-tag (Figure 3B, lane 2 for CY1-BAP). No precipitate was observed in the solution after the heteroconjugation reaction of CY1-BAP and CY1-SA, despite the extremely high molecular weight of the (CY1-BAP)-(CY1-SA) conjugate that barely enters the running gel of the native-PAGE.

Thrombin Treatment of CY1-BAP-SA Conjugates. To evaluate the cross-linking morphologies of the BAP-SA conjugate, the Y-tag of CY1-BAP was cleaved by thrombin treatment. Ideally, the efficiency of the heteroconjugation reaction is equivalent to the efficiency of the homoconjugation reaction of BAP and SA. Assuming that CY1-BAP and SA consistently cross-link with each other, the Y-tag cleavage from CY1-BAP after the heteroconjugation reaction should yield a substantial amount of free SA. The results of the SDS-PAGE and native-PAGE analyses of (CY1-BAP)-SA conjugate samples after thrombin treatment are shown in Figure 4. The conjugate

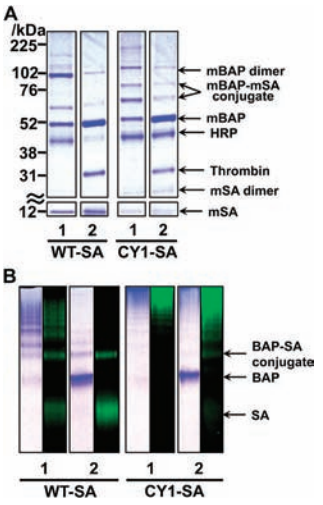

Figure 4. SDS-PAGE (A) and native-PAGE (B) analyses of thrombin-treated CY1-BAP-SA conjugates. Lane 1: SA with the addition of CY1-BAP, HRP, and H_2O_2; Lane 2: thrombin was added to the samples of lane 1 and incubated for 12 h at 37 °C. In the native-PAGE analysis, SA was visualized by biotin-4-fluorescein (right of each picture).

of WT-SA and CY1-SA was almost completely digested by thrombin, and resulted in the presence of SA monomers and BAP monomers in the SDS- and native-PAGE analyses (Lane 2 for WT-SA). The results indicate that the (CY1-BAP)-(WT-SA) conjugate was cross-linked site-specifically through the Y-tag of CY1-BAP. In the case of the (CY1-BAP)-(CY1-SA) conjugate, thrombin treatment should also digest the conjugates to yield BAP monomers. However, from the result of the native-PAGE analysis, it is clear that most of the CY1-SA remained in the highly cross-linked form even after thrombin treatment (Figure 4B, lane 2 for CY1-SA). The molecular weight of the (CY1-BAP)-(CY1-SA) conjugate decreased upon thrombin treatment; therefore, CY1-BAP and CY1-SA are clearly conjugated to each other. However, it is clear that the majority of CY1-SA has self-conjugated. SA is a tetramer protein, and hence, CY1-SA possesses four flexible Y-tags in a molecule, indicating the high probability of intramolecular cross-linking of the Y-tag upon HRP treatment. Additionally, the intrinsic tyrosine residues of SA contribute to the homoconjugation of CY1-SA. In addition, the molar concentration of SA was much higher than that of BAP in the reaction mixture (0.2 mg/mL of each protein). For these reasons, CY1-SA was found to be highly self-cross-linked, even in the presence of the reactive CY1-BAP protein.

Immobilization of BAP-SA Conjugates to a Biotin-Coated Plate. The protein functions of both BAP and SA were examined by immobilizing BAP-SA conjugates onto biotin-coated plates. In this study, the resultant BAP-SA conjugates were conjugates of BAP and SA in the ratio of *n* to *m*. As a result, when the BAP-SA conjugate was cast onto the biotin-coated plates, if one SA binds to one biotin, multiple numbers of BAP will be immobilized. After immobilization of the BAP-SA conjugate on the biotin-coated plates, the BAP enzymatic activities were measured and the results are shown in Figure 5. Enzymatic activity of BAP was detected on the

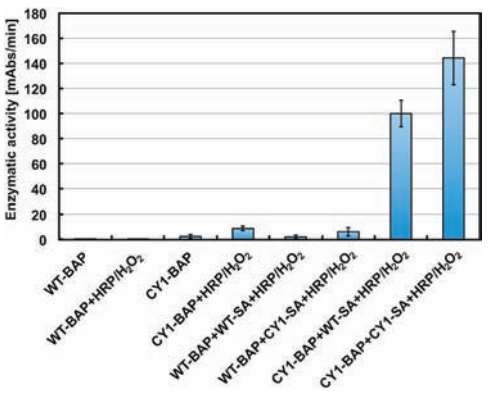

Figure 5. Enzymatic activity of BAP-SA conjugates on a biotin-coated plate.

biotin-coated plates; therefore, both BAP and SA retained their functions after the heteroconjugation reactions. BAP-SA conjugates prepared from CY1-BAP exhibited higher enzymatic activity than the others. This is because of the successful heteroconjugation of CY1-BAP with SA (Figure 3). When both SA and BAP possess the Y-tag, the tyrosine coupling efficiency was much higher than the other conditions examined, and hence, the (CY1-BAP)-(CY1-SA) conjugate showed the highest enzymatic activity on the biotin-coated plates. In addition, the (CY1-BAP)-(WT-SA) conjugate showed considerably higher enzymatic activity despite the absence of the Y-tag on SA. Under the reaction conditions for the CY1-BAP/WT-SA conjugation, CY1-BAP occasionally cross-linked with WT-SA and also self-cross-linked to yield CY1-BAP oligomers and polymers. Therefore, the conjugation ratio of BAP and SA in (CY1-BAP)-(WT-SA) conjugates is ideal for exhibiting high BAP enzymatic activity on the biotin-coated plates, to which

dx.doi.org/10.1021/bc200420v | *Bioconjugate Chem.* 2011, 22, 2332–2338

polymeric CY1-BAP with a small fraction of conjugated WT-SA was captured. However, since the heteroconjugation efficiency between CY1-BAP and WT-SA was not high, the overall enzymatic activity of the (CY1-BAP)-(WT-SA) conjugate was not as high as that of the (CY1-BAP)-(CY1-SA) conjugate.

The ratio of BAP and SA appears to be important in achieving high BAP enzymatic activity on the plates. Thus, (CY1-BAP)-(CY1-SA) conjugates were prepared by differing the ratio of SA/BAP. Here, the BAP concentration was fixed at 0.2 mg/mL and evaluated in the same manner. The results are shown in Figure 6. We expected that the (CY1-BAP)-(CY1-SA) conjugate prepared at a low ratio of SA/BAP should exhibit high enzymatic activity of BAP on the biotin-coated plate, because a large number of CY1-BAP could be attached to a small number of SA molecules. Contrary to our expectation, as the ratio of SA/BAP decreased, the conjugates exhibited lower enzymatic activity. Additionally, at SA/BAP ratios over 1/1, there was no significant difference in the BAP enzymatic activity on the biotin-coated plate. This can be explained as follows. As we discussed earlier, the CY1-SA preferentially self-cross-linked even in the presence of CY1-BAP. Therefore, in the solutions of the (CY1-BAP)-(CY1-SA) conjugate prepared at low ratios of SA/BAP, a large amount of CY1-BAP was not cross-linked with SA and most of the CY1-SA was self-cross-linked intramolecularly because of the low concentration used. As the ratio of SA/BAP increased, the efficiency of the co-cross-linking between BAP and SA increased, resulting in the immobilization of more BAP molecules on the biotin-coated plate. However, at the same time, the amount of SA conjugates, which were not co-cross-linked with BAP, also increased. Those SA conjugates would cover the surface of the biotin-coated plate, resulting in the immobilization of fewer BAP proteins on the plate. With these two processes taking place, the BAP enzymatic activity on the surface saturated at the SA/BAP ratio over 1/1. The results indicate that, to obtain high BAP enzymatic activity on the biotin-coated plate, at least equivalent amounts of SA against BAP are required.

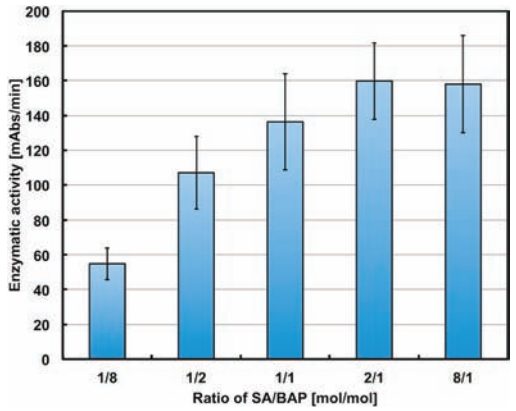

Figure 6. Enzymatic activity of (CY1-BAP)-(CY1-SA) conjugates prepared at various ratios of SA/BAP. The CY1-BAP concentration was fixed at 0.2 mg/mL (approximately 4 μM of mBAP). The ratio of SA/BAP was calculated from molar amounts of monomeric SA and BAP.

CONCLUSION

In this report, we demonstrated the heteroconjugation of BAP and SA by the HRP-catalyzed tyrosine cross-linking reaction. WT-SA exhibited very low reactivity against HRP treatment: the main reaction site of WT-SA upon HRP treatment was Y72. However, introduction of a Y-tag drastically increased the reactivity of SA against HRP treatment, which resulted in the homoconjugation of CY1-SA. The BAP-SA conjugate was efficiently obtained by HRP treatment when Y-tags were introduced to both SA and BAP. CY1-BAP and WT-SA were also cross-linked; however, WT-BAP did not cross-link with CY1-SA because of the presence of the exposed tyrosine residues on SA and the absence of exposed tyrosine residues on the surface of BAP. Thrombin treatment of the BAP-SA conjugate revealed that the (CY1-BAP)-(WT-SA) conjugate had site-specifically cross-linked with each other through the Y-tag of CY1-BAP. Thrombin treatment of the (CY1-BAP)-(CY1-SA) conjugate yielded BAP monomers, but most of the CY1-SA remained in high molecular weight forms, suggesting that CY1-SA was highly self-cross-linked even in the presence of CY1-BAP. The BAP-SA conjugate prepared from CY1-BAP and CY1-SA showed the highest enzymatic activity when immobilized on a biotin-coated plate because of the higher heteroconjugation efficiency.

CONTENTS

1. Measurement of fluorescence emission from dityrosine.

To evaluate of which intrinsic tyrosine residues are responsible for homoconjugation of WT-SA upon HRP treatment, the formation of dityrosine was monitored by measuring the fluorescence emission from dityrosine at ~400 nm with an excitation light of ~320 nm. The suspected intrinsic tyrosine residues of WT-SA, Y11 and Y72, were substituted by phenylalanine (in single letter form: F). We prepared three types of WT-SA mutants, WT-SA(Y11F), WT-SA(Y72F), and WT-SA(Y11F/Y72F) by the site-directed mutagenesis technique using KOD-Plus-Mutagenesis Kit (TOYOBO Co., Ltd., Osaka, Japan). The fluorescence from dityrosine of WT-SA, WT-SA mutants, and CY1-SA was measured using a fluorescence spectrophotometer (PerkinElmer LS55) before and after the 3 min HRP treatment. The HRP treatment condition was same as the homoconjugation reaction of SAs in the manuscript except that the reaction was conducted with a volume of 400 µL. The fluorescence spectra from 360 to 600 nm were obtained with an excitation wavelength of 315 nm and a sharp cut-off filter set at 350 nm. The excitation spectra were measured from 280 to 350 nm while monitoring the fluorescent intensity at 400 nm with a sharp cut-off filter at 390 nm. Also, the increase in the fluorescence intensity at 420 nm (excitation light of 315 nm with a sharp cut-off filter at 350 nm) was measured by using time-driven measurement mode. The reaction condition was same as mentioned above, but the reaction was conducted in a quarts cell (cell volume of 400 µL) for fluorescence measurement. After H_2O_2 was pipetted to the reaction mixture in a quarts cell all at once, the measurement was immediately started and monitored for 3 min. The results are shown in **Figure S1**.

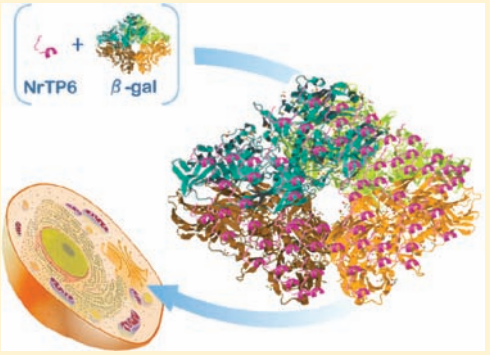
ABSTRACT: Nucleolar targeting peptides (NrTPs), a recently developed family of cell-penetrating peptides, have been shown to be very efficient in entering cells and accumulating in their nucleoli. In this work, we have used conjugates of NrTP6 (YKQSHKKGGKKGSG) covalently linked to β-galactosidase in order to demonstrate the capacity of NrTP for intracellular delivery of large molecules. NrTP6/β-galactosidase conjugates, prepared by maleimide-based chemistry, were stable and enzymatically active on the standard 4-methylumbelliferyl β-D-galactopyranoside substrate. Their translocation into HeLa cells, monitored by β-galactosidase activity as a readout of the uptake, showed efficient cellular entry and thus demonstrated the potential of NrTPs for intracellular delivery of large-size cargos with preservation of biological activity.



INTRODUCTION

Cell-penetrating peptides (CPPs) are short cationic sequences that, without disrupting membranes, can enter cells and carry over various types of cargo molecules.[1−3] Interest in these peptides started two decades ago with the observation that the HIV-1 accessory protein Tat is able to translocate into cells.[1] Since that time, CPPs have been shown capable of transporting biologically active cargos to the cell interior, both *in vivo* and *in vitro*.[4−6] Additionally, considerable effort has been invested in understanding the ability of CPPs to internalize various cargos [e.g., proteins, nucleic acids, fluorophores, radiolabels, magnetic resonance imaging (MRI) contrast agents, quantum dots, and so forth[7−10]], with the aim of developing CPPs into molecular tools with potential applications in basic research, diagnostics, or therapeutics. Relevant examples are pep-1 (Chariot), currently used as a commercial transfection reagent,[6,11,12] and KAI-9803, a selective δ-protein kinase C inhibitor conjugated to Tat that reduces injury associated with ischemia and reperfusion in animal models, presently undergoing phase IIb clinical trials.[13]

In principle, for any cargo intended to be ferried into a cell, a conjugate with a CPP can be envisaged. For instance, CPPs conjugated to either nucleic acids or proteins have been successfully used for transfection or antibody delivery.[14−16] Their eventual application in the therapeutic delivery of different drugs remains a challenging yet promising area of CPP research.[4,7,13] Studies of Tat-mediated protein translocation opened the way to CPP-facilitated delivery of proteins of different types and sizes, among which GFP (30 kDa), IgG (120−150 kDa), or β-galactosidase (465 kDa) have already been successfully tested.[2,4−7] β-Galactosidase (β-gal), in particular, is a frequent [2,6] and convenient cargo for CPP-mediated protein delivery, given its large size and its well-characterized enzymatic activity, for which different assays are available.[17−19] As to the conjugation of CPPs to the cargo of interest, whether a protein, a nucleic acid, or a nanoparticle, a number of approaches involving chemical conjugation, simple electrostatic interaction, or molecular fusion have been described.[2,4,6,20−22]

Nucleolar targeting peptides (NrTPs) were first described in 2008 as the result of structural minimization of the sequence of crotamine,[23] a 42-residue toxin that is one of the main components of the venom of the South American rattlesnake (*Crotalus durissus terrificus*).[24] The representative NrTP1 sequence (YKQCHKKGGKKGSG)[23] has been shown to possess remarkable translocating properties, namely, fast internalization (<15 min) and preferential nucleolar localization. For the purpose of this study, the original Cys at position 4 of NrTP1 has been mutated to Ser, and an extra Cys added to the C-terminal to facilitate conjugation. The resulting analogue, NrTP6 (YKQSHKKGGKKGSG), shows no detriment in CPP properties in the free form (unpublished), and we hereby demonstrate its ability to translocate large biomolecules into cells with full preservation of activity, a necessary condition

for NrTP-mediated delivery of therapeutically relevant cargos into cells and tissues. Our positive results offer obvious opportunities for NrTP application, given that the nucleolus has a key role in ribosome biogenesis and the control of the cell cycle and, more recently, has been reported to take part in the control of stress and viral infection.[25−27]

EXPERIMENTAL PROCEDURES

Chemicals. Fmoc-protected amino acids, 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and Fmoc-Rink-amide (MBHA) resin were obtained from Iris Biotech GmbH (Marktredwitz, Germany). HPLC-grade acetonitrile, and peptide synthesis-grade *N*,*N*-dimethylformamide (DMF), dichloromethane (DCM), *N*,*N*-diisopropylethylamine (DIEA), and trifluoroacetic acid (TFA) were from Carlo Erba-SDS (Peypin, France). 4-Methylumbelliferyl *β*-D-galactopyranoside (MUG), Triton X-100, *β*-galactosidase (EC 3.2.1.23) from *Escherichia coli* (grade VI), and 3-maleimidobenzoic acid *N*-hydroxysuccinimide ester (MBS) were obtained from Sigma (Madrid, Spain). DMEM, trypsin 0.05%, phosphate buffer saline (PBS), fetal bovine serum (FBS), penicillin, and streptomycin were from Invitrogen (Spain). All other chemicals were from Aldrich (Madrid, Spain)

Peptide Synthesis. The NrTP6 (YKQSHKKGGKKGSG) sequence was synthesized with an extra Cys residue at either the C- (i.e., NrTP6-C) or the N-terminus (C-NrTP6). Solid-phase peptide synthesis was done by Fmoc-based chemistry on Fmoc-Rink-amide (MBHA) resin (0.1 mmol) in a model 433 peptide synthesizer (Applied Biosystems, Foster City, CA) running FastMoc protocols. Couplings used 8-fold molar excess of both Fmoc L-amino acid and HBTU, and 16-fold molar excess of DIEA. Side chain protecting groups were *tert*-butyl (Ser, Tyr), *tert*-butyloxycarbonyl (Lys), and trityl (Cys, Gln, His). After chain assembly, full deprotection and cleavage of the N-deblocked resin were carried out with trifluoroacetic acid (TFA)-water-ethanedithiol-triisopropylsilane (94:2.5:2.5:1 v/v, 90 min, rt). Finally, peptides were precipitated by addition of chilled diethyl ether, taken up in H_2O, and lyophilized. Analytical reversed-phase HPLC was performed on a Luna C_{18} column (4.6 mm × 50 mm, 3 μm, Phenomenex). Linear gradients of solvent B (0.036% TFA in acetonitrile) into A (0.045% TFA in H_2O) were used for elution at a flow rate of 1 mL/min, with UV detection at 220 nm. Preparative HPLC runs were performed on a Luna C_{18} column (21.2 mm × 250 mm, 10 μm; Phenomenex), using linear gradients of solvent B (0.1% in acetonitrile) into A (0.1% TFA in H_2O), as required, with a flow rate of 25 mL/min. Matrix-assisted time-of-flight mass spectra were recorded in the reflector mode in a Voyager DE-STR workstation (Applied Biosystems, Foster City, CA) using α-hydroxycinnamic acid as matrix. Fractions of adequate HPLC homogeneity and with the expected mass were combined, lyophilized, and used in the cell uptake experiments.

Conjugation. The protocol for conjugation of NrTP6 to *β*-gal was adapted from Leteef et al.[28] Briefly, 1 mg of *β*-gal was dissolved in 2.1 mL of cold PBS and 4 mg of MBS were dissolved in 400 μL of DMF (1 μM and 32 mM *β*-gal and MBS concentrations, respectively). 160 μL of the MBS solution was then added to the *β*-gal solution under constant stirring and allowed to react for 30 min at 4 °C, to convert the protein Lys residues into maleimide units. The reaction mixture was then loaded to a Sephadex G-25 PD-10 desalting column (GE Healthcare) pre-equilibrated with 50 mM phosphate buffer, pH 6. 1 mL fractions were collected at 4 °C, and the three with highest absorbance at 290 nm were pooled and mixed with 1 mg (0.6 mmol) of either NrTP6-C or C-NrTP6, to assess the effect of the conjugation position on cargo internalization and preservation of bioactivity. The pH was adjusted to 7.5, and the mixture was incubated for 3 h and then dialyzed against 6 changes (30 min each) of 10 mM phosphate buffer pH 7.4, at 4 °C. The total protein concentration in the conjugates was determined by the Bradford method.[29] Conjugates with 100-fold lower concentrations of MBS (0.32 mM instead of 32 mM) were prepared likewise.

***β*-Gal Enzyme Assay.** The colorless 4-methylumbelliferyl-*β*-D-galactopyranoside (MUG) substrate is hydrolyzed by *β*-gal into 4-methylumbelliferone (4-MU), whose formation was monitored by its bright blue fluorescence (λ_{exc} = 360 nm, λ_{exc} = 440 nm, pH 7.4). Briefly, MUG was dissolved at 0.5 mM concentration in PBS containing 5 mM $MgCl_2$ and the enzyme reaction was started with the addition of either free *β*-gal (0−6 μg/mL) or conjugate (0−10 μg/mL), following a procedure adapted from previous reports.[6,30] The kinetics of 4-MU production was monitored by fluorescence intensity measurements, for 90 min, on a TECAN Infinite 200 Multimode microplate reader (Männedorf, Switzerland).

Uptake of NrTP6-C/*β*-gal (or C-NrTP6) Conjugate. Having established the activity of the NrTP6/*β*-gal conjugates in cell-free conditions, their internalization by human adenocarcinoma epithelial (HeLa) cells (gently supplied by Dr. Xavier Mayol, Cancer Cell Line Repository, Municipal Institute of Medical Research, Barcelona) was next studied. Cells were cultured in Dulbecco's Modified Eagle's Medium (DMEM), supplemented with 10% (v/v) of heat inactivated fetal bovine serum (FBS), 10 U/mL penicillin, and 100 μg/mL streptomycin, at 37 °C in a 5% CO_2 atmosphere. Cells were used for internalization experiments when they reached ca. 80% confluence. Experiments were performed either in Petri dishes (35 mm × 10 mm) or in 4-well plates. Briefly, conjugate (0−12 μg/mL) was incubated with cells for 60 min at 37 °C and 5% CO_2 atmosphere. Trypsin was added after incubation to detach cells and hydrolyze extracellular nonincorporated (membrane and nonmembrane bound) conjugate. Next, cells were harvested, centrifuged twice at 500 *g* for 5 min (with an intervening PBS wash), and permeabilized with 0.1% (v/v) Triton X-100 for 15 min at 25 °C. A last centrifugation step was done also at 500 *g* for 5 min and supernatant was assayed for enzymatic activity by fluorescence spectroscopy accordingly with the procedure described above. For these samples, 4-MU end point concentrations were also precisely quantified by UV absorbance after stopping the reaction by alkalinization with 50 mM NaOH to pH 9. UV absorbance measurements (ε_{360} = 1.9 × 10^4 M^{-1} cm^{-1}) were also done on a TECAN Infinite 200 Multimode microplate reader. The efficiency of internalization was studied either with a fixed cell density (2 × 10^5 cells/mL) at different conjugate concentrations or, alternatively, with a fixed amount of conjugate (7 μg/mL) and variable cell densities, in the (2−12) × 10^5 cells/mL range. Cell viability was controlled throughout the 60 min incubation both by the trypan blue exclusion assay and by differential interference contrast microscopy (DIC) in a Leica TSC-SP2 microscope (Wetzlar, Germany). Controls using nonconjugated enzyme and peptide, either combined or separately, were also performed. Moreover, an extensive study of *β*-gal residual activity was done, testing the enzyme in the 0−170 μg/mL concentration range.

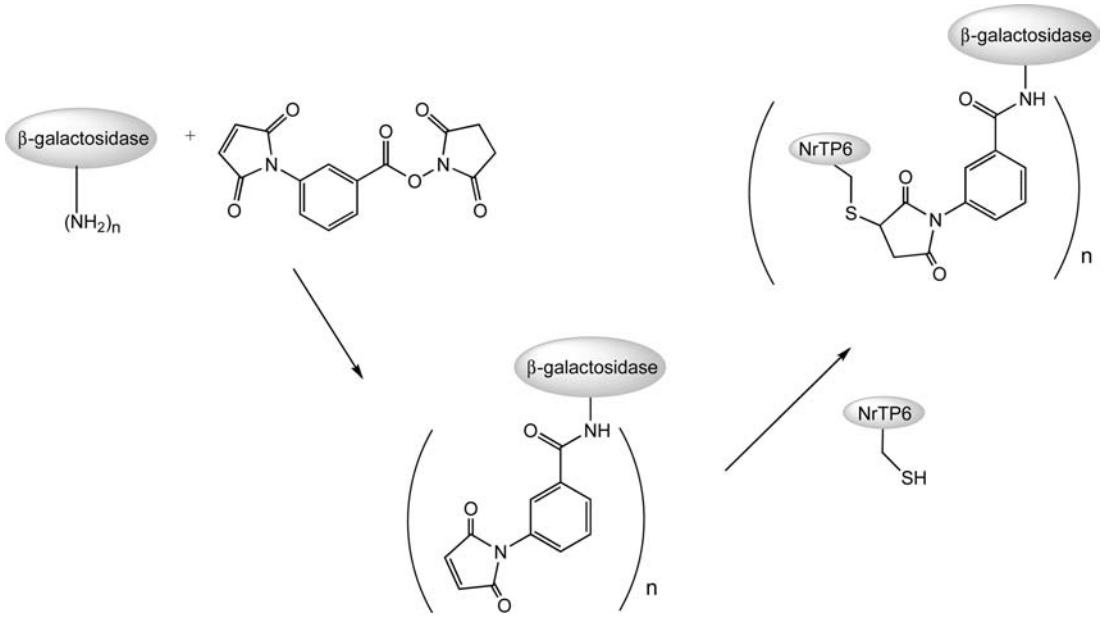

Figure 1. Maleimide-mediated conjugation of NrTP6-C and C-NrTP6 to *β*-galactosidase. The Cys residue was either on the C- or on the N-terminus of the peptide (NrTP6-C or C-NrTP6, respectively).

RESULTS AND DISCUSSION

Chemical conjugation, either protein (or peptide)-protein[13,16,28] or protein (or peptide)-nucleic acid,[20,31,32] is a well-established procedure for covalent attachment of two molecules. Figure 1 illustrates the conjugation between NrTP6 and *β*-gal, the latter chosen as a model to test CPP-mediated uptake of large cargos.[1,2,6] *β*-Gal activity was used as a readout of the uptake, with the fair assumption that activity and internalization are directly related. *β*-Gal is a large homotetramer, with 1023 amino acid residues per subunit, often used as a reporter of product transcription. The enzyme catalyzes the hydrolysis of lactose and other *β*-D-galactosides into monosaccharides. Although very specific for the galactose moiety, it is rather promiscuous regarding the rest of the substrate, which has allowed the development of different colorimetric assays for measuring activity.[33] For our study, we chose as probe 4-methylumbelliferyl-*β*-D-galactoside (MUG), hydrolyzed by *β*-gal to fluorescent 4-methylumbelliferone (4-MU).[6,30] *β*-Gal activity was measured by means of progression curves of fluorescent product formation (Figure 2). The enzymatic assay was conducted under substrate excess conditions, ensuring quasi-steady-state enzyme activity. In this way, initial rates can be assumed as V_{max} and, hence, k_{cat} is defined by the slope of the v_0 vs conjugate concentration variation (Figure 2). Fluorescence data were normalized by dividing by the fluorescence intensity of a 1 μg/mL solution of free *β*-gal after 90 min. Prior to cell uptake experiments, the enzymatic activity of various NrTP6/*β*-gal conjugates was confirmed (Figure 3A), a linear relationship being found between v_0 and conjugate concentration up to 2.5 μg/mL. The enzymatic activity was also compared with that of free *β*-gal at different stages of the protocol to ensure that no loss of activity was occurring. Results revealed a linear relationship between enzymatic activity and concentration from 0 to 5 μg/mL of free *β*-gal, with a k_{cat} of 26.3×10^{-3} μg^{-1} mL min^{-1} and r^2 = 0.995.

Next, HeLa cells were incubated with the conjugate and activity was measured in the cell-free extract upon addition of

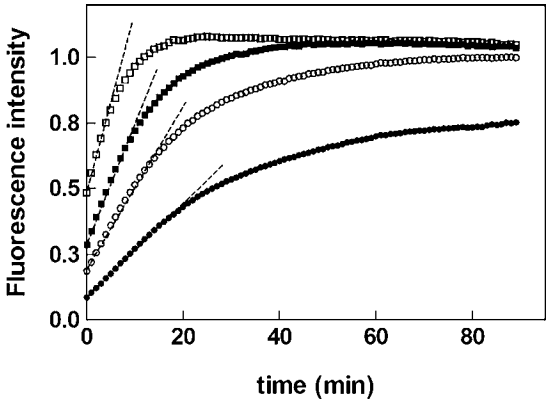

Figure 2. Time-course of *β*-galactosidase enzymatic activity. Fluorescence intensity, proportional to the 4-MU product concentration, was recorded at 440 nm (excitation at 360 nm) over 90 min after addition of enzyme to MUG substrate. The above kinetic curves correspond to 0.5 μg/mL (●), 1 μg/mL (○), 1.5 μg/mL (■), and 2.5 μg/mL (□) free *β*-gal concentrations, respectively. Fluorescence intensity values were normalized to the intensity for 1 μg/mL of *β*-gal at 90 min. Initial rates, v_0, were determined from the initial slope of the curves. The same procedure was used for *β*-gal conjugate samples (alone or after cell incubation).

MUG. Figure 3B shows a clear dependence of product formation on conjugate concentration, hence supporting the efficient delivery of NrTP6-conjugated *β*-gal into HeLa cells. Incubation with nonconjugated *β*-gal (Figure 3B) resulted in no product formation, in further support of the inability of *β*-gal to enter cells unless conjugated to an efficient CPP. The fact that the tetrameric form of *β*-gal is required for enzymatic activity clearly demonstrates that the conjugate not only enters cells, but does so while preserving its proper folding and oligomerization, i.e., with minimal interference, if any, from NrTP on the cargo structure. A control experiment with a mixture of nonconjugated NrTP6 and *β*-gal gave negative results that ruled out the possibility of NrTP6 electrostatic binding to *β*-gal, forming conjugates with translocating activity.

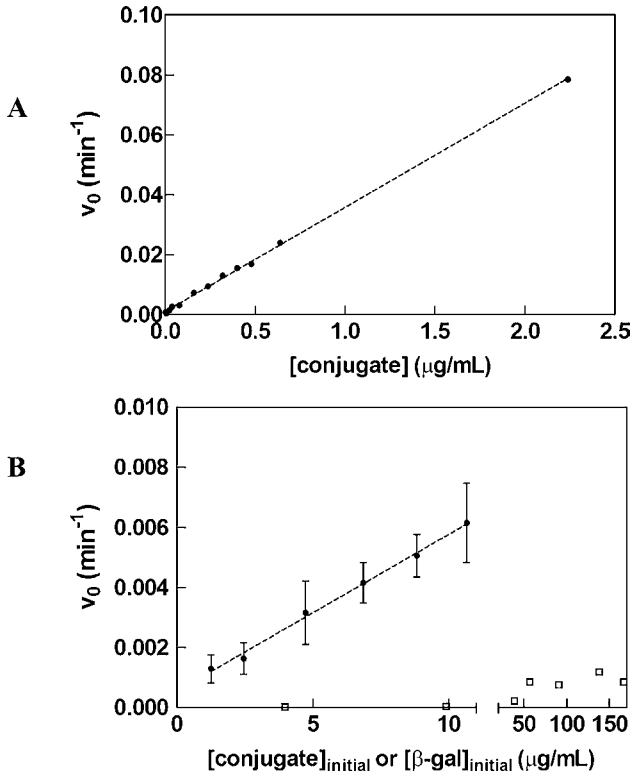

Figure 3. Enzymatic activity of the NrTP6-C/β-gal conjugate. (A) Standard activity in the absence of cells. (B) Activities of conjugate (circles) and β-gal (open squares) incubated with a cell-free extract (initially 2×10^5 HeLa cells/mL) for 60 min. Initial rates, v_0, were determined as indicated in Figure 2. k_{cat} values of 34.7×10^{-3} and 0.52×10^{-3} μg^{-1}.mL.min^{-1}, for conjugate alone and for the cell-free extract, respectively, were obtained. Results are from duplicates of a representative experiment.

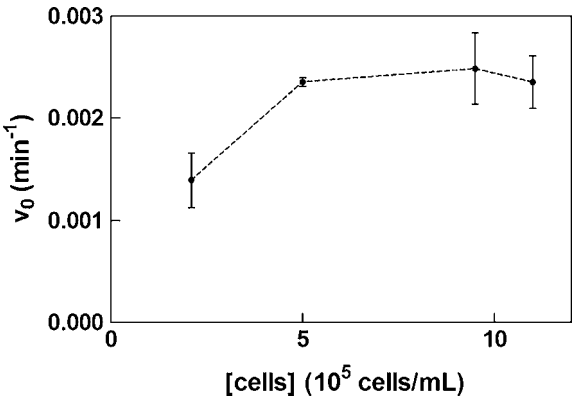

Figure 4. Effect of cell number on the enzymatic activity of the NrTP6-C/β-gal conjugate. Conjugate (7 μg/mL) was incubated with various cell densities for 60 min, at 37 °C. Initial rates, v_0, were determined as indicated in Figure 2. Results are from duplicates of a representative experiment.

The apparent decrease in the k_{cat} of β-gal from 34.7×10^{-3} to 0.52×10^{-3} μg^{-1} mL min^{-1} upon HeLa cell internalization (Figure 3 B) may be explained by several factors: The first, and possibly most relevant, is the fact that not all the conjugate is internalized. This is supported by Figure 4, where the fraction of internalized conjugate is shown to increase until a threshold level is reached. Another important factor for the apparent lower activity of the conjugate in the cell-free extract is competition for β-gal between MUG and endogenous substrates, mainly membrane components such as ganglioside GM1, lactosylceramides, glycoproteins, and keratin sulfate.[34,35] On the other hand, no significant competition for MUG appears to exist between endogenous and conjugated β-gal, as observed by the nonsignificant amounts of 4-MU detected in control experiments using nonconjugated NrTP (data not shown). In the above scenarios, CPP-to-cell ratio, rather than absolute CPP concentration, would appear to be influential in the uptake (or delivery) capacity of NrTP6, with the possibility of improving the delivery by increasing the volume of incubating peptide.[36]

Assuming no change in the intrinsic activity of NrTP6-delivered β-gal upon entering the cell, given that the apparent decrease in activity is essentially due to the equilibrium between the conjugate inside and outside the cell, the fraction of conjugate that penetrates the cell can be calculated from the above k_{cat} data to be 1.51%. Even if that value is underestimated, it is within the range reported for the uptake of other conjugates (0.07% to 5%).[37−39] Cargo size, even if CPP-mediated, is known to affect the efficiency of translocation, as observed, e.g., for the best-studied Tat.[40] Indeed, the highest reported uptake efficiency (5%) corresponds to a oligodeoxynucleotide−doxorubicin conjugate,[37] much smaller than the present NrTP6/β-gal conjugates (6.5 kDa vs 465 kDa). Our results reveal an intracellular conjugate concentration in the 3−57 μg/mL range, depending on the initial conjugate concentration and assuming a volume of 2.6 pL for a HeLa cell.[41] Assuming 116 NrTP6 copies bound to each β-gal tetramer (one per Lys residue), and from the respective molecular weights of β-gal and NrTP6 (465 and 1.6 kDa), it follows that approximately 72% and 28% of conjugate weight correspond to β-gal and NrTP, respectively. From this, the concentration of internalized β-gal can be estimated to be in the 2−41 μg/mL range. This rather high local concentration, entirely due to CPP-mediated internalization, clearly envisages relevant results with other more application-driven cargos.

Additional aspects explored in the present study included cell viability, as well as the influence of the position (N- or C-terminal) and extent of conjugation upon NrTP6/β-gal uptake. With regard to cell viability, both trypan blue exclusion and DIC live imaging after 60 min incubation with either type of conjugate (NrTP6-C or C-NrTP6-derived) revealed over 98% viability and no detectable signs of morphological changes or cellular stress over that period. Further comparison between both types of conjugates also showed similar uptake levels, either in cell-free assays (Figure 5) or upon incubation with HeLa cells (Figure 6), suggesting that positioning of the Cys residue at either the N- and C-terminal end has similar impact on both the conjugation and translocation efficiencies. Finally, results in Figure 6 also show that no significant differences exist between conjugates made with amounts of the bifunctional MBS reagent differing by a factor of 100.

The experimental results of the present report offer a necessary proof-of-concept for the intracellular delivery of large molecules mediated by NrTPs. It is worth noting that, two decades after introduction of the CPP concept, studies on delivery of drugs and other cargos by the most extensively studied CPPs (e.g., Tat, Ant, pep-1, and oligo-arginines) are still ongoing and, for the more recently discovered CPPs, insights on their translocation abilities and the underlying mechanisms are still scarce. In this regard, the present results are a valuable contribution to establishing the role of NrTPs as

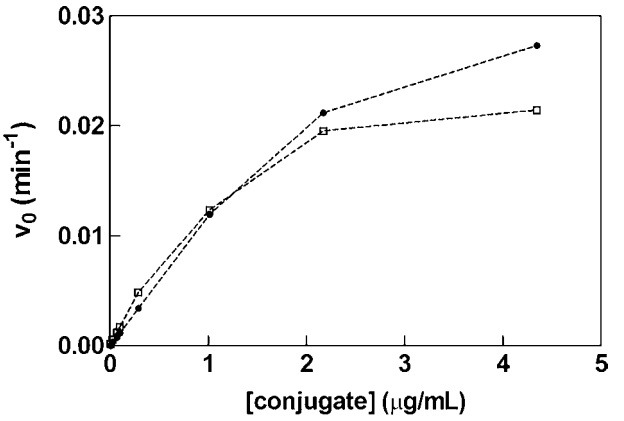

Figure 5. Effect of N- vs C-terminal conjugation on enzymatic activity. NrTP6-C (open squares) and C-NrTP6 (circles) derived β-gal conjugates assayed in the absence of cell extract. Initial rates, v_0, were determined as indicated in Figure 2.

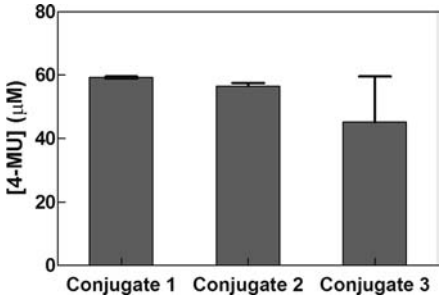

Figure 6. Effect of conjugation position and NrTP6/β-gal density on uptake efficiency. Conjugates **1**−**3** are, respectively, NrTP6-C/β-gal, C-NrTP6/β-gal, and NrTP6-C/β-gal prepared with 100-fold less MBS. [4-MU] was determined spectrophotometrically ($\varepsilon_{360\ nm}$ = 1.9 × 10^4 M^{-1} cm^{-1} at pH 9), after incubation with HeLa cells for 60 min, at 37 °C, and 90 min reaction in the cell-free extract, stopped with NaOH 50 mM. Results are duplicates from a representative experience. Scale bars represent the range of variation.

useful biotools. β-Gal is a rather large protein (size estimated as 17.4 × 13.0 × 7.5 nm^3 from Protein Data Bank (entry 1DP0) data, using the UCSF Chimera software, http://plato.cgl.ucsf.edu/chimera/), far exceeding the thickness of cell membranes. The fact that it is also well above the size of many therapeutically relevant cargos (e.g., antibodies are ∼150 kDa), in conjunction with the preferential nucleolar localization of NrTPs, allows to envisage promising applications for NrTPs in areas such as immunotherapy or cell cycle regulation.

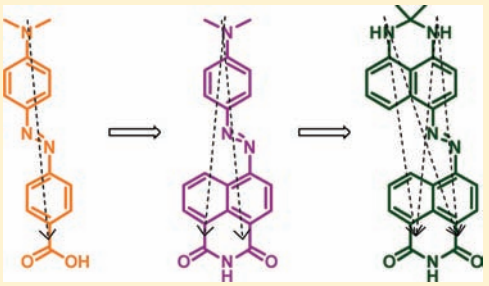
Multi-Path Quenchers: Efficient Quenching of Common Fluorophores

Pete Crisalli and Eric T. Kool*

Department of Chemistry, Stanford University, Stanford, California 94305-5080, United States

Supporting Information

ABSTRACT: Fluorescence quenching groups are widely employed in biological detection, sensing, and imaging. To date, a relatively small number of such groups are in common use. Perhaps the most commonly used quencher, dabcyl, has limited efficiency with a broad range of fluorophores. Here, we describe a molecular approach to improve the efficiency of quenchers by increasing their electronic complexity. Multi-Path Quenchers (MPQ) are designed to have multiple donor or acceptor groups in their structure, allowing for a multiplicity of conjugation pathways of varied length. This has the effect of broadening the absorption spectrum, which in turn can increase quenching efficiency and versatility. Six such MPQ derivatives are synthesized and tested for quenching efficiency in a DNA hybridization context. Duplexes placing quenchers and fluorophores within contact distance or beyond this distance are used to measure quenching via contact or FRET mechanisms. Results show that several of the quenchers are considerably more efficient than dabcyl at quenching a wider range of common fluorophores, and two quench fluorescein and TAMRA as well as or better than a Black Hole Quencher.



INTRODUCTION

Fluorescence quenchers are employed in a wide variety of fluorometric assays, particularly for detection of nucleic acids, reporting on enzymatic activity, and detecting other molecules of interest with turn-on responses.[1−11] However, for optimal performance, delicate matching of fluorophore and quencher is often needed, imposing limits on molecular designs and complicating applications.[12−14] For example, in order to cover the emission spectrum from violet to near-infrared, multiple different quenchers are needed, which can be an obstacle in assays designed to detect multiple analytes in one sample.[14,15] 4-(Dimethylamino)-azobenzene-4′-carboxylic acid (Dabcyl), perhaps the most commonly used fluorescence quencher, is generally limited to quenching of fluorophores that emit in the violet to green region of the visible spectrum (approximately 390 to 520 nm).[11,16] To cover fluorophores that emit further to the red, a variety of other quenchers have been developed, such as the Black Hole Quenchers (BHQ)[16] and QSY quenchers;[17] however, coverage of a broad spectrum still requires the use of multiple quenchers. In the BHQ series, for example, a total of four different compounds are necessary to provide for quenching of all commonly used wavelengths in fluorescence assays.[13] QSY quenchers are even more limited in quenching ability as a result of their narrow absorbance spectra.[12,14] Recently, some nonfluorescent cyanine-based quenchers have been reported that do have broadened spectral properties and provide for efficient quenching in caspase assays.[8] However, these quenchers display strong spectral overlap only with near-IR emitting fluorophores and may not quench other fluorophores as effectively.

Most commonly, quenching of fluorophores occurs by one of two mechanisms: contact quenching and FRET quenching.[12−14,18,19] In contact quenching, the fluorophore and quencher are in sufficiently close proximity to allow for direct electronic interaction of the excited state of the fluorophore with the quencher molecule.[18−21] Consequently, absorbed light at the excitation wavelength will primarily be nonradiatively transferred as heat to the surrounding environment, with only a limited amount of energy released as fluorescence. When the distance between the fluorophore and the quencher is increased, generally to the range 20−100 Å, the alternative mechanism of FRET quenching is observed.[12,14,18] In this mechanism, quenching efficiency is dependent upon the orientation of the fluorophore and quencher, the distance between them, and the overlap of the emission spectrum of the fluorophore and the absorption spectrum of the quencher.[12,14] To take advantage of these mechanisms, it is desirable to design quenchers with broadened absorbance spectra to allow for a greater range of fluorophore emissions that can be quenched by the FRET mechanism, while maintaining strong contact quenching.[12,14]

To address this issue, we have designed a novel set of quenchers that have multiple electronic conjugation pathways. By altering the existing scaffolds of common quenchers to increase the number of electron donor and acceptor groups, a series of Multi-Path Quenchers (MPQs) has been designed that provides for broader absorbance properties, in turn allowing for fluorescence quenching of a considerably wider range of fluorophores for each given quencher (Figure 1). Five new quenchers based on modifications to the dabcyl structure as well as one based upon modification of a Black Hole Quencher scaffold have been prepared and tested in a DNA context for

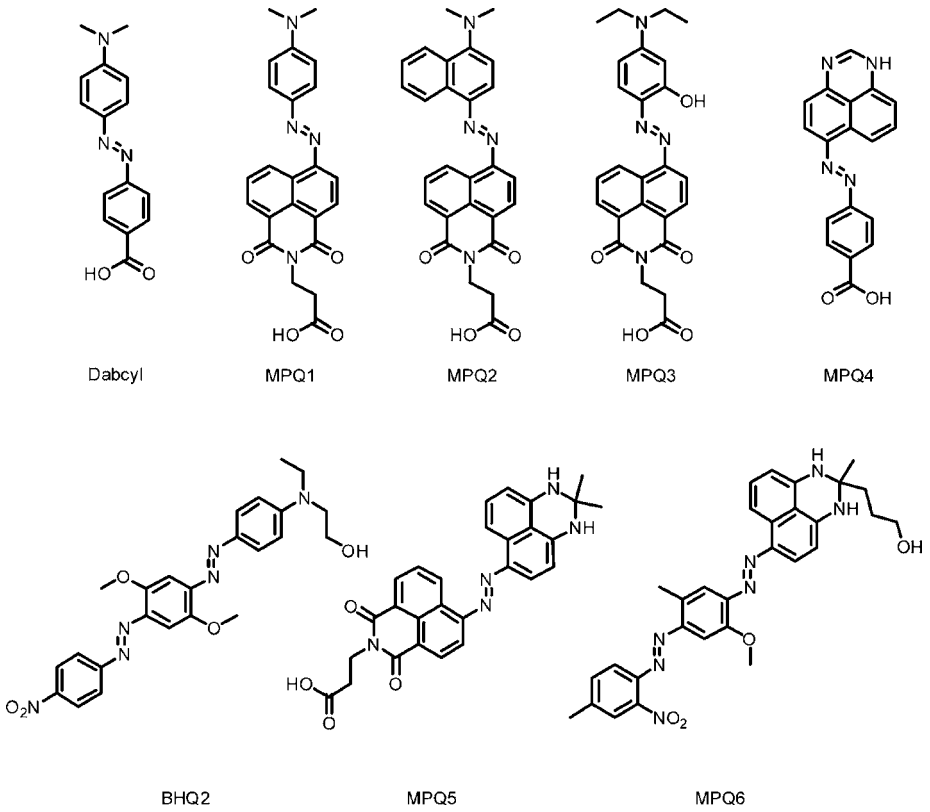

Figure 1. Structures of Multi-Path Quenchers (MPQs) and commercially available quenchers used in this study.

quenching efficiency, for comparison with previous studies.[3] We find that this strategy yields broadened absorption spectra and enhances efficiency over a wider range of wavelengths as compared with a common quencher such as dabcyl.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Chemicals were purchased from Sigma-Aldrich and used without further purification. Solvents were purchased from Acros Organics and used as received. UltraMild DNA phosphoramidites and solid supports were purchased from Glen Research. BHQ2 phosphoramidite and 3′-Quasar 670 CPG were purchased from Biosearch Technologies. AlexaFluor 350 succinimidyl ester was purchased from Invitrogen. 5′-Fluorophore-modified oligonucleotides were purchased from Biosearch Technologies (FAM, TAMRA, Quasar 670) or Stanford University Protein and Nucleic Acid Facility (Cy3) and purified by HPLC.

Instrumentation. ^{1}H and ^{13}C NMR spectra were recorded on a Varian 400 MHz NMR or a Varian 500 MHz NMR spectrometer and internally referenced to the residual solvent signal; J values are reported in Hz. Oligonucleotides sequences were synthesized on an ABI 394 DNA synthesizer using UltraMild reagents and phosphoramidites. ESI-MS analysis was performed by the Stanford University Mass Spectroscopy Facility. Analytical and semipreparative high-performance liquid chromatography was performed on a LC-CAD Shimadzu liquid chromatograph, equipped with a SPD-M10A VD diode array detector and a SCL 10A VP system controller using reverse-phase C18 columns (Grace ProSphere C18−300 10 μ). DNA concentrations were determined on a Cary 100 Bio UV−vis spectrophotometer at 90 °C. Fluorescence measurements were performed on a Fluorolog 3 Jobin Yvon fluorophotospectrometer equipped with an external temperature controller. Oligonucleotide masses were determined by the Stanford University Protein and Nucleic Acid Facility using a Perspective Voyager-DE RP Biospectrometry MALDI-TOF mass-spectrometry instrument using a 3-hydroxypicolinic acid/diammonium hydrogen citrate matrix.

Synthetic Procedures. *Methyl 3-(6-Amino-1,3-dioxo-1H-benzo[de]isoquinolin-2(3H)-yl)propanoate (1).* 0.196 g (0.81 mmol) of 4-nitronaphthalic anhydride[23,24] and 0.107 g (1.5 eq, 1.21 mmol) of β-alanine were refluxed in 4 mL ethanol for 3 h. The resulting orange suspension was cooled to room temperature, diluted with water, and filtered to provide 0.185 g (73%) of the nitro intermediate. The intermediate was suspended in 3 mL methanol, and 0.7 mL concentrated HCl and 0.569 g (5.1 equiv, 3 mmol) tin(II) chloride dihydrate was added and the solution was heated to reflux for 2 h. Cooling to room temperature and dilution with water followed by filtration provided 0.125 g (71%) of a bright yellow−brown solid. ^{1}H NMR (DMSO-d_6, 400 MHz): 8.61 (1H, d, J = 8.4), 8.41 (1H, d, J = 7.6), 8.18 (1H, d, J = 8.4), 7.64 (1H, dd, J = 7.6), 7.46 (2H, brs, N*H*), 6.83 (1H, d, J = 8.4), 4.24 (2H, t, J = 7.2), 3.57 (3H, s), 2.61 (2H, t, J = 7.2). ^{13}C NMR (DMSO-d_6, 100 MHz): 32.3, 35.3, 51.5, 107.3, 108.2, 119.3, 121.6, 124.0, 129.4, 129.7, 131.0, 134.0, 152.8, 162.7, 163.7, 171.4. ESI MS: M + H$^+$ = 299.58 (Calc 299.10).

General Procedure for MPQ Methyl Ester Synthesis.[25] 1.5 mL concentrated H_2SO_4 was cooled to 0 °C in an ice−water bath. 0.249 g (1.05 equiv, 3.6 mmol) sodium nitrite was slowly added. The viscous suspension was heated to 65 °C until complete dissolution occurred, and then cooled to 0 °C. 1.02 g (3.04 mmol) of **1** was added in portions over 30 min. Two milliliters acetic acid was added to aid in solubility. After stirring at room temperature for 3 h, a solution of 3.4 mmol coupling partner in 0.65 mL acetic acid was added dropwise at 0 °C. The

dx.doi.org/10.1021/bc200424r | *Bioconjugate Chem.* 2011, 22, 2345−2354

resulting suspension was stirred for 1 h, then diluted with saturated sodium acetate and stirred at 0−10 °C for 3 h. The resulting solution was filtered, washed with warm water, and crystallized in ethanol to afford the azo dye methyl ester **2**.

*MPQ1 Methyl Ester (**2a**).* (50% yield) ^{1}H NMR ($CDCl_3$, 400 MHz): 9.25 (1H, d, J = 7.2), 8.63−8.67 (2H, m), 8.04 (2H, d, J = 7.6), 7.96 (1H, d, J = 8.4), 7.83 (1H, dd, J = 7.2), 6.80 (2H, d, J = 7.6), 4.52 (2H, t, J = 7.4), 3.71 (3H, s), 3.17 (6H, s), 2.80 (2H, t, J = 7.4). ^{13}C NMR ($CDCl_3$, 100 MHz): 32.7, 36.2, 40.4, 51.9, 111.6, 112.3, 121.8, 122.3, 126.5, 126.8, 131.0, 131.6, 132.1, 144.7, 152.2, 153.5, 164.0, 164.4, 171.9. ESI MS: M + H$^+$ = 431.42 (Calc 431.17).

*MPQ2 Methyl Ester (**2b**).* (62% yield) ^{1}H NMR ($CDCl_3$, 400 MHz): 9.34 (1H, d, J = 8.8), 9.11 (1H, d, J = 8.0), 8.67−8.70 (2H, m), 8.22 (1H, d, J = 8.4), 8.10−8.14 (2H, m), 7.89 (1H, dd, J = 8.0), 7.69 (1H, dd, J = 8.0), 7.59 (1H, dd, J = 7.6), 7.11 (1H, d, J = 8.4), 4.54 (2H, t, J = 7.4), 3.71 (3H, s), 3.11 (6H, s), 2.81 (2H, t, J = 7.4). ^{13}C NMR ($CDCl_3$, 100 MHz): 32.7, 36.3, 44.8, 52.0, 112.8, 112.9, 114.0, 122.6, 123.8, 125.0, 125.6, 127.2. 127.6, 131.0, 131.7, 132.0, 143.3, 152.0, 156.4, 163.9, 164.3, 167.7, 171.9. ESI MS: M + H$^+$ = 481.92 (Calc 481.19).

*MPQ3 Methyl Ester (**2c**).* (52% yield) ^{1}H NMR ($CDCl_3$, 400 MHz): 8.59−8.63 (3H, m), 8.09 (1H, d, J = 8.4), 7.78 (1H, dd, J = 7.8), 7.38 (1H, d, J = 9.6), 6.53 (1H, dd, J = 9.6, 2.6), 5.97 (1H, d, J = 2.6), 4.50 (2H, t, J = 7.4), 3.70 (3H, s), 3.51 (4H, q, J = 7.2), 2.78 (2H, t, J = 7.4), 1.30 (6H, t, J = 7.2). ^{13}C NMR ($CDCl_3$, 100 MHz): 13.1, 32.7, 36.2, 45.6, 51.9, 98.1, 110.8, 111.6, 122.7, 126.9, 128.6, 131.6, 132.6, 154.9, 163.8, 171.9. ESI MS: M + H$^+$ = 475.42 (Calc 475.20).

*MPQ5 Methyl Ester (**2d**).* (20% yield) ^{1}H NMR ($CDCl_3$, 400 MHz): 9.34 (1H, d, J = 8.4), 8.66−8.68 (2H, m), 8.40 (d, 1H, J = 8.4), 8.19 (d, 1H, J = 8.4), 8.09 (d, 1H, J = 8.0), 7.84 (dd, 1H, J = 7.6), 7.50 (dd, 1H, J = 7.6), 6.62 (d, 1H, J = 7.2), 6.55 (d, 1H, J = 8.4), 4.53 (t, 2H, J = 7.2), 3.71 (s, 3H), 2.81 (t, 2H, J = 7.2), 1.61 (s, 6H). ^{13}C NMR: (spectrum could not be obtained due to poor solubility). ESI MS: M + H$^+$ = 508.42 (Calc 508.20).

General Procedure for Methyl Ester Hydrolysis. 500 mg MPQ methyl ester was dissolved in anhydrous THF (at a concentration of 0.085 M). To this solution, 2.02 equiv potassium trimethylsilanolate was added, and the resulting solution stirred overnight at room temperature, at which point TLC indicated consumption of starting material. The solvent was removed *in vacuo* and the resulting solid dissolved in a minimal amount of water. Hydrochloric acid (1 M) was added to precipitate the free carboxylic acid, which was filtered, washed with water, and dried. The product **3** was used for DNA conjugation without further purification. All free acids were found to be poorly soluble in common deuterated solvents.

*MPQ1 (**3a**).* (80% yield) ^{1}H NMR ($CDCl_3$, 500 MHz): 9.26−9.35 (1H, m), 8.64−8.96 (2H, m), 7.96−8.05 (3H, m), 7.84−7.91 (1H, m), 6.80 (2H, d, J = 9.0), 4.54 (2H, t, J = 7.0), 3.18 (s, 6H), 2.87 (2H, t, J = 7.0). NMR indicates some degradation to naphthalic anhydride during prolonged storage. ^{13}C NMR: (spectrum could not be obtained due to poor solubility). ESI MS: M + H$^+$ = 417.33 (Calc 417.16).

*MPQ2 (**3b**).* (36% yield) ^{1}H NMR ($CDCl_3$, 500 MHz): 9.45 (1H, d, J = 8.5), 9.12 (1H, d, J = 7.5), 8.71−8.75 (2H, m), 8.24 (1H, d, J = 8.0), 8.14−8.18 (2H, m), 7.96 (1H, dd, J = 8.0), 7.73 (1H, dd, J = 7.0, 1.5), 7.63 (1H, dd, J = 7.0, 1.5), 7.14 (1H, dd, J = 8.5), 4.59 (2H, t, J = 7.0), 3.17 (6H, s), 2.91 (2H, t, J = 7.0). ^{13}C NMR: (spectrum could not be obtained due to poor solubility). NMR and ESI-MS indicate that this compound degrades to the naphthalic anhydride during prolonged storage. ESI MS: M + H$^+$ = 467.50 (Calc 467.17).

*MPQ3 (**3c**).* (80% yield) ^{1}H NMR ($CDCl_3$, 500 MHz): 8.62−8.66 (3H, m), 8.12 (1H, dd, J = 8.5, 2.5), 7.80 (1H, dd, J = 7.0), 7.41 (1H, d, J = 9.5), 6.55 (1H, dd, J = 9.5, 2.5), 5.99 (1H, d, J = 2.5), 4.51 (2H, t, J = 7), 3.52 (4H, q, J = 7), 2.79 (2H, t, J = 7), 1.31 (6H, t, J = 7). ^{13}C NMR (spectrum could not be obtained due to poor solubility). ESI MS: M + H$^+$ = 461.33 (Calc 461.18).

*MPQ5 (**3d**).* (87% yield) ^{1}H and ^{13}C NMR data could not be obtained as a result of very poor solubility in common NMR solvents. ESI MS: M + H$^+$ = 494.42 (Calc 494.18).

*MPQ4 (**3e**).* A solution of 0.270 g (1.05 equiv, 3.90 mmol) $NaNO_2$ in 2 mL H_2O was added dropwise to a mixture of 0.510 g (1.0 equiv, 3.72 mmol) 4-aminobenzoic acid in 12 mL 1 M HCl at 0 °C. After 30 min, a solution of 0.657 g (1.05 equiv, 3.90 mmol) of 1-H-perimidine in 9 mL 1 M HCl was added, and the resulting suspension stirred at 0 °C for 2 h. The suspension was diluted with a solution of 2.15 g NaOAc in 15 mL H_2O, stirred at room temperature for 2 h, then filtered and washed with warm water to give a dark purple solid. Crystallization from ethanol afforded 0.916 g (78%). A complex ^{1}H NMR spectrum results from tautomerization in the perimidine scaffold (see Supporting Information). ^{13}C NMR data could not be obtained as a result of poor solubility in common NMR solvents. ESI MS: M + H$^+$ = 317.25 (Calc 317.10).

*3-(2-Methyl-2,3-dihydro-1H-perimidin-2-yl)propan-1-ol (**4**).* 6.19 g (39 mmol) 1,8-diaminonaphthalene was added to a solution of 4.35 mL (1.1 equiv, 43 mmol) 5-hydroxy-2-pentanone and 0.089 g (0.01 equiv, 0.4 mmol) *p*-toluenesulfonic acid monohydrate in 15 mL ethanol. The solution was stirred at 60 °C for 90 min, whereupon the solution had solidified. The resulting solid was cooled to room temperature, filtered, washed with ethanol, and crystallized from aqueous ethanol to yield a pale gray solid (4.11 g, 43%). ^{1}H (DMSO-d_6, 400 MHz): 7.07 (2H, dd, J = 7.8), 6.83 (2H, d, J = 8.4), 6.34 (2H, d, J = 7.2), 6.29 (2H, brs, N*H*), 4.37 (1H, t, O*H*), 3.30 (2H, m), 1.53−1.62 (4H, m), 1.29 (3H, s). ^{13}C NMR (DMSO-d_6, 100 MHz): 26.5, 27.1, 36.9, 61.2, 65.5, 103.6, 111.5, 114.0, 127.0, 134.2, 141.8. ESI MS: M + H$^+$ = 243.50 (Calc 243.15).

*MPQ6 (**5**).* 0.291 g (1.20 mmol) of **4** was dissolved in a solution of 20 mL 1:1 THF/acetone stirred at 0 °C. 0.600 g (1.2 equiv, 1.44 mmol) Fast Corinth V was added in portions to give a dark blue solution, which was stirred at 0 °C for 1 h. The reaction was diluted with water and extracted 3 times with CH_2Cl_2. The combined organic extracts were washed once with water, once with brine, dried ($MgSO_4$), filtered, and the solvent removed *in vacuo*. Column chromatography (5% MeOH in CH_2Cl_2 containing 0.5% Et_3N) afforded 0.094 g (14%) of a dark purple solid. ^{1}H NMR ($CDCl_3$, 400 MHz): 8.19 (1H, d, J = 8.0), 7.84 (1H, d, J = 8.8), 7.66−7.69 (3H, m), 7.40−7.47 (3H, m), 6.53−6.56 (2H, m), 4.02 (3H, s), 3.66 (2H, t, J = 6.0), 2.74 (3H, s), 2.50 (3H, s), 1.88−1.92 (2H, m), 1.75−1.80 (2H, m), 1.52 (3H, s). ^{13}C NMR ($CDCl_3$, 100 MHz): 17.0, 21.3, 27.2, 27.6, 29.8, 38.6, 56.3, 62.7, 99.0, 112.8, 119.2, 124.4, 133.6, 141.3, 143.6, 147.4. ESI MS: M + H$^+$ = 554.42 (Calc 554.25).

*MPQ6 Phosphoramidite (**6**).* 0.164 g (0.296 mmol) MPQ6 was dissolved in 2.5 mL anhydrous acetonitrile, 0.15 mL (3 equiv, 0.861 mmol) *N,N*-diisopropylethylamine was added and

the solution was stirred at room temperature under argon. 0.10 mL (1.5 equiv, 0.448 mmol) 2-cyanoethyl *N,N*-diisopropylchlorophosphoramidite was added and the resulting solution was stirred at room temperature under argon for 2 h. The solution was concentrated and purified by column chromatography (2:3 EtOAc/Hexanes → 2:1 EtOAc/Hexanes, containing 0.5% Et_3N) to yield 0.036 g product (13%). ^{31}P NMR displayed two peaks at 148.61 ppm and 148.55 ppm, and the product was used for DNA synthesis without further characterization.

DNA Conjugation. TAMRA-, Fluorescein-, and Quasar 670-conjugated DNA sequences were synthesized using their respective 3′ CPGs, cleaved, and purified by HPLC using a gradient elution of 0.05 M TEAA and acetonitrile. AlexaFluor 350 succinimidyl ester and ATTO 590 succinimidyl ester were reacted with 3′-amino modified DNA. Cy3-modified DNA was synthesized using Cy3 Phosphoramidite (Glen Research) with 5′ to 3′ synthesis. Quencher-labeled oligonucleotides were synthesized with a 5′-amino-modifier **5** appended to the 5′-terminus. The monomethoxy-trityl protecting group was removed on the synthesizer using alternating 10 s cycles of deprotection reagent (3% trichloroacetic acid in DCM) and DCM washes for 3 min. The solid support was added to a suspension containing 35 mM quencher-COOH, 35 mM 1-hydroxy-7-azabenzotriazole (HOAt), 35 mM 2-(7-Aza-1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HATU), and 150 mM diisopropylethylamine (DIPEA) in 750 μL anhydrous DMF. Solutions were shaken at room temperature and protected from light for 16 h, then rinsed with 4 × 500 μL DMF and 4 × 500 μL AcCN. The labeled DNA was cleaved from the solid support using UltraMild conditions (0.05 M K_2CO_3 in MeOH) at room temperature for 4 h, filtered to remove CPG, diluted with water, and purified by reverse-phase HPLC.

Fluorescence Experiments. A solution of 30 nM of fluorescently labeled 20mer was created in a total volume of

800 μL hybridization buffer (10 mM $MgCl_2$, 70 mM Tris·borate, pH 7.55) at 37 °C. The fluorescence of the solution was taken in triplicate (using published excitation and emission values with excitation and emission slits of 2 and 5 nm, respectively) and averaged. A concentrated solution of quencher labeled DNA was added to bring the final volume to 150 nM. The oligonucleotides were allowed to hybridize until the fluorescence emission remained constant, then the fluorescence spectrum was taken in triplicate and averaged. Quenching efficiency was calculated at the emission maxima by dividing the quenched fluorescence by the initial fluorescence, multiplying by 100, then subtracting from 100.[14] All experiments were performed in triplicate and averaged.

RESULTS

Quencher Design. The new quencher structures are given in Figure 1. These were designed with the standard diazo dye framework analogous to the common dabcyl quencher, but with larger conjugated multifunctional donors or acceptors. The purpose of the design was to provide multiple conjugated pathways from donor to acceptor groups, thus potentially broadening the absorption spectra of the dyes. The first five (MPQ1–5) were built on the standard azobenzene framework, while the sixth (MPQ6) was designed as a multipathway variant of the bis-azobenzene framework common to BHQ quenchers.

Synthesis. As shown in Scheme 1, reaction of β-alanine with 4-nitronaphthalic anhydride and subsequent reduction of the nitro group easily afforded **1** which could be diazotized to allow for formation of MPQs by reaction with a variety of anilines. Similar derivatives of these compounds were reported earlier for use as disperse dyes, and the properties of the compounds synthesized are consistent with those previously reported.[25,26] Hydrolysis of the methyl ester afforded a carboxylic acid moiety that could easily be attached to amino-modified DNA by HATU/HOAt coupling. DNA synthesis utilized UltraMild protecting groups to avoid hydrolysis of the naphthalimide core under regular ammonia or ammonia/methylamine cleavage/deprotection. MPQ6 was prepared by the addition of dihydroperimidine **4** to Fast Corinth V salt in a cold solution of 1:1 THF/atone, and readily converted to a phosphoramidite for DNA coupling, again with UltraMild conditions. DNA sequences were selected to maintain consistency with previous oligonucleotide-based experiments for comparing fluorescence quenchers.[14] For comparison with the new quenchers, we prepared analogous DNA conjugates of dabcyl and of BHQ2, possibly the two most widely used quenchers. BHQ2 was selected instead of BHQ1 based upon the better performance of BHQ2 against a variety of fluorophores in previous studies.[14] For testing the quenchers, we prepared DNA conjugates of common fluorescent dyes with varied emission properties, emitting from the blue to the far red (442 to 662 nm).

Spectral Properties. Absorption data for the six MPQs conjugated to DNAs are given in Figure 2 and Table 1. The data reveal that, as designed, the MPQ dyes have considerably broadened absorbance spectra compared to their parent quencher molecules (dabcyl and BHQ). Save for MPQ3, all other quenchers containing the naphthalimide core show significantly increased $\Delta\lambda_{1/2\ max}$ values when compared to dabcyl, validating the design strategy. This is particularly the case for MPQ2 and MPQ5, whose $\Delta\lambda_{1/2\ max}$ values are considerably greater and even further red-shifted than the other dyes.

For the naphthalimide derivatives, where the electron acceptor has been altered to incorporate a second conjugation pathway, we noted some differences in spectral properties

between the 20mer and 15mer quencher−oligonucleotide conjugates. As anticipated, the parent quencher dabcyl shows negligible change in spectral properties, maintaining an absorbance maxima of 472 nm and a $\Delta\lambda_{1/2\ max}$ of 115 nm in both sequences. Both MPQ1 and MPQ3, however, display slight red-shifts upon moving from the 20mer oligonucleotide to a different 15mer sequence context. MPQ2, in contrast, shows a considerable blue shift and significant broadening on going from the 20mer to the 15mer DNA.

Altering the electron donating group also provides for some interesting and broadened spectral properties. As seen with MPQ4, a considerable red shift is observed in the absorbance maximum, while an almost 35 nm increase in $\Delta\lambda_{1/2\ max}$ is observed compared to dabcyl. Much like MPQ1−3, this quencher also shows a change when moved from the 20mer to a 15mer, with the $\Delta\lambda_{1/2\ max}$ increasing and the absorbance maximum again shifting to the red.

MPQ5 and MPQ6, incorporating the dihydroperimidine moiety, displayed the most distinct spectral properties. Whereas all other quenchers possess a single broadened absorbance maximum, MPQ5 and MPQ6 display two maxima. MPQ5, like the other quenchers, exhibits a slightly altered absorbance spectrum as the sequence of the oligonucleotide changes, while MPQ6, like BHQ2, maintains approximately the same spectrum on the two DNAs. For these last two quenchers, the formation of a red-shifted absorbance maximum comes with a moderate cost to the extinction coefficient. When compared to MPQ1, MPQ5 clearly displays a lower extinction coefficient at the λ_{max}, both on DNA and in ethanol (see Supporting Information). Comparison of BHQ2 and MPQ6 yields the same result, indicating that the addition of the new conjugation pathway may reduce the extinction coefficient of each individual peak.

The most obvious benefit of the added conjugation is observed in a comparison of MPQ6 with its parent BHQ1. While BHQ1 displays an absorption maximum at 534 nm and generally quenches fluorophores that emit in the range from 480 to 580 nm,[16] MPQ6 displays considerably broadened properties. MPQ6 shares one conjugation pathway with BHQ1, giving rise to an absorbance maximum at 537 nm, but the alternative conjugation pathway inherent to the dihydroperimidine scaffold adds an absorption at 656 nm as well, extending the range of quenching available to the dye greatly (vide infra). Thus, MPQ6 has a $\Delta\lambda_{1/2\ max}$ ranging from 465 to 735 nm (270 nm total), considerably greater than BHQ2 (146 nm) and in fact greater than the quenching ranges of BHQ1 and BHQ2 combined.

Fluorescence experiments confirmed that these quenchers are completely nonemissive, as excitation of solutions containing the DNA-labeled quenchers at 100 nM concentration showed no measurable emission above that of buffer (see Supporting Information). Extinction coefficients were determined at the absorbance maximum of each compound in ethanol and can be found in the Supporting Information; note that they differ slightly from the absorbance maxima found when the quenchers are placed on DNA in Figure 2 and Table 1.

Quenching Efficiency. Quenching efficiency was determined by the use of DNA hybridization as a means of controlling fluorophore−quencher distance (Figure 3).[14] As

such, fluorophores were attached to the 3′ end of the sequence 5′-CCG-TAT-TAT-ATG-TTT-AAA-AA-3′ and quenchers were attached to the 5′ end of complementary 15mer or 20mer sequences. Use of a 20mer context (placing dye and quencher immediately adjacent to one another at the duplex terminus) allowed for analysis of contact quenching. The selected 15mer sequence had been previously reported to allow for examination of FRET quenching,[14] but the observation of ground state complex formation between quencher-labeled 15mers and fluorophore containing 20mers indicates a strong degree of contact quenching as well, consistent with other quencher studies and indicating a mixed mechanism of quenching for the sequences shown in Figure 3b (see Supporting Information).[27] To allow for analysis of quenching entirely by FRET, 5′ fluorophore labeled sequenches were used (see Figure 3c), separating the quencher and fluorophore by 15 bp of duplex structure. Contact quenching data would be most relevant for molecular applications where dye and quencher are in very close proximity, whereas FRET data may be most predictive of applications in which the two are held at some distance. Since FRET efficiency depends on spectral overlap, one expects that FRET quenching performance would be more strongly dependent on absorption characteristics than contact quenching, providing a better means of examining the newly created quenchers.

Quenching efficiencies were measured as fraction (percent) loss of emission intensity upon hybridization to the fluorophore of interest, as displayed in Table 2 (contact quenching), Table 3 (mixed mechanism quenching), and Table 4 (FRET quenching). We also compared the fluorescence ratios (fluorescence in the unquenched state divided by fluorescence in the quenched state) of the quenchers against each fluorophore (Figure 3), which better illustrates the differences among the dyes, and which is often the most important factor in a fluorometric assay.

Contact and Mixed Mechanism Quenching. As anticipated, quenching of AlexaFluor 350 (λ_{em} = 442 nm) is poor for the MPQ series (Figure 3a), with dabcyl having a greater quenching efficiency (75.7% contact, 70.4% FRET) than those prepared and tested. This is consistent with the fact that dabcyl is the most blue-shifted quencher of those assayed and has the greatest spectral overlap with AlexaFluor 350. However, the quenchers of the MPQ series (particularly MPQ3) nearly equal dabcyl in contact quenching of this dye. BHQ2 is slightly superior to either of these quenchers in performance with this blue coumarin fluorophore.

The data show enhanced performance of the red-shifted MPQ quenchers as the emission wavelength of the fluorophore increases. For fluorescein (λ_{em} = 517 nm, Figure 4b), it is readily observed that MPQ3 is as efficient as even BHQ2 in contact quenching, while four of the novel quenchers (MPQ1, MPQ2, MPQ3, and MPQ6) all display superior quenching abilities in a mixed mechanism context. At the emission of Cy3 (λ_{em} = 563 nm), only MPQ5 performs less efficiently than dabcyl in terms of contact quenching, with all others displaying superior performance to the common quencher. These results begin to show the red-shifted properties of the new quenchers created, as the parent dabcyl is no longer able to efficiently quench Cy3 emission, while the new dyes display considerably better quenching properties. Moreover, MPQ6 is particularly intriguing, as it is equals (contact quenching) or even surpasses (mixed mechanism quenching) BHQ2 in quenching of Cy3 emission.

As emission shifts further red to TAMRA (λ_{em} = 580 nm), all MPQ quenchers display markedly greater quenching efficiency than dabcyl (Figure 4d). We note that TAMRA (unique among the fluorophores tested here, as it is poorly quenched in general[14]) is relatively poorly quenched by all quenchers including dabcyl and BHQ2, an effect observed previously. Moreover, MPQ4 is as good at contact quenching of TAMRA

dx.doi.org/10.1021/bc200424r | Bioconjugate Chem. 2011, 22, 2345–2354

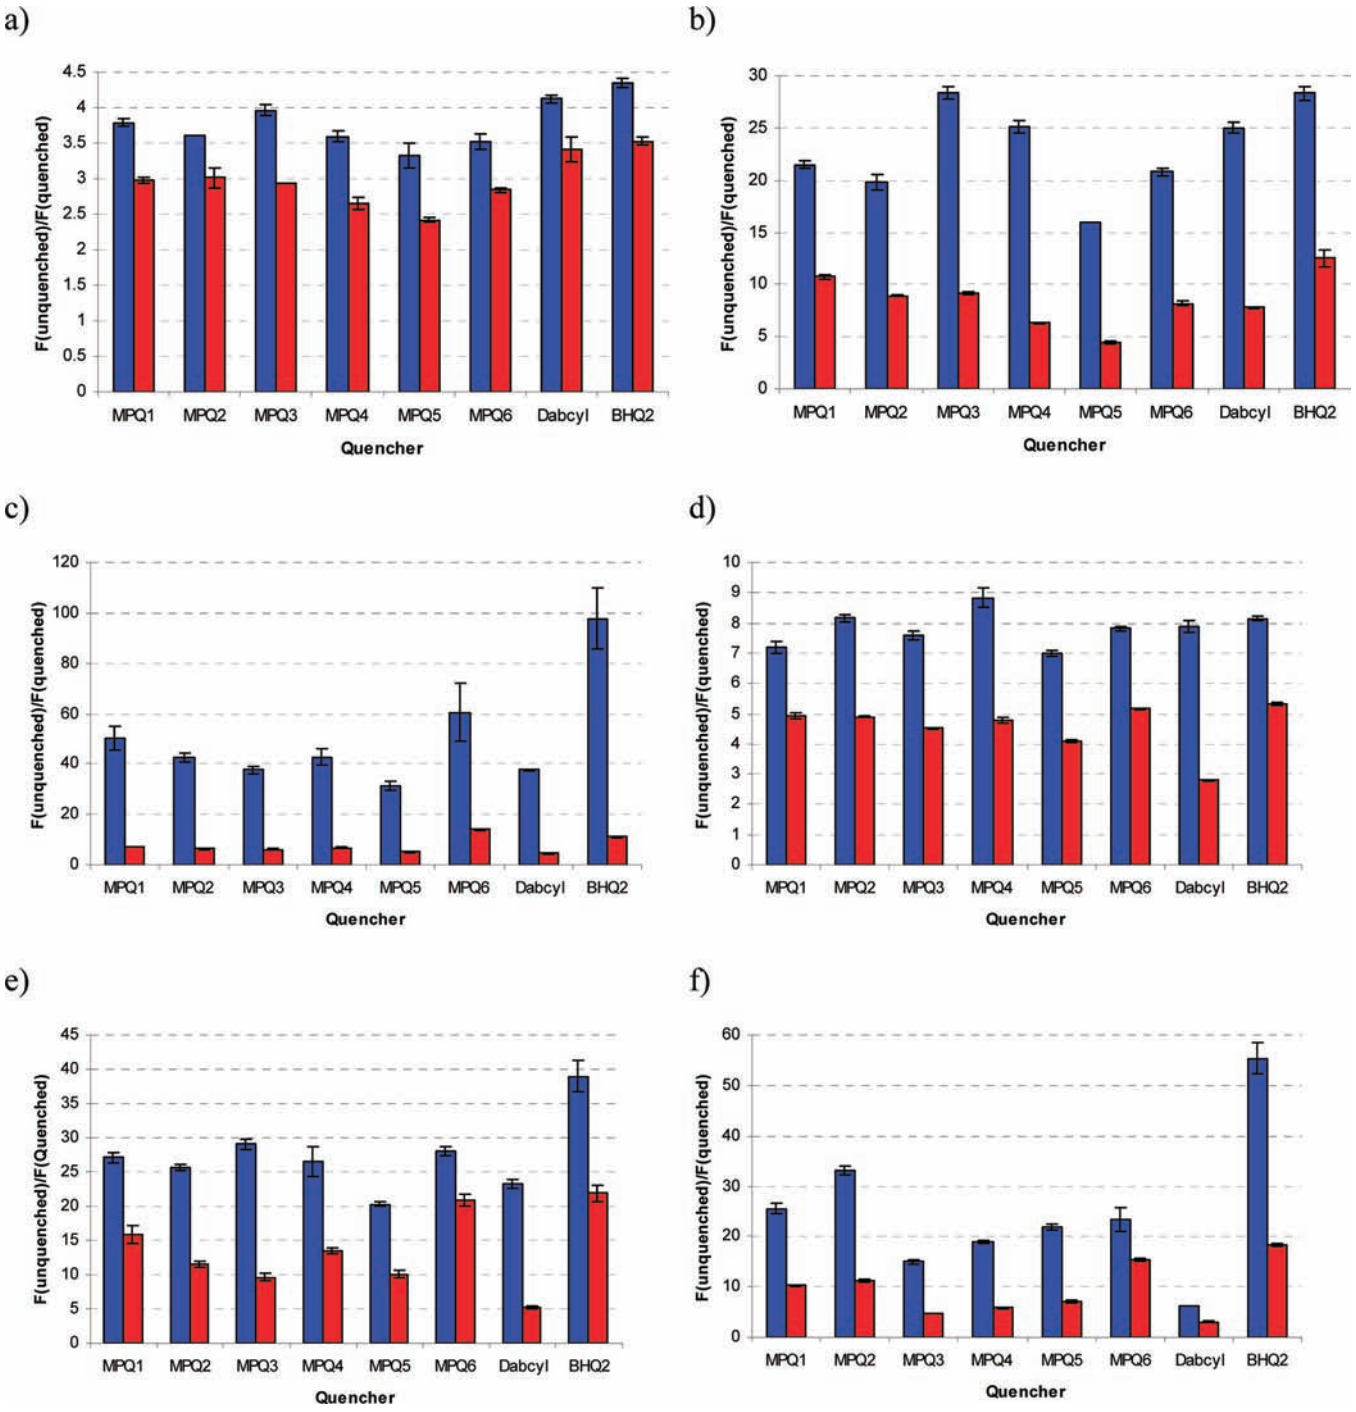

Figure 4. Fluorescence quenching ratios for contact (blue) and mixed mechanism (red) quenching with (a) AlexaFluor 350, (b) Fluorescein, (c) Cy 3, (d) TAMRA, (e) ATTO 590, and (f) Quasar 670.

as even BHQ2, while all but MPQ3 and MPQ5 are approximately as efficient in mixed mechanism quenching as BHQ2. Again, MPQ6 offers promising results, as it displays comparable quenching properties to BHQ2. At the emission of Atto 590 (λ_{em} = 624 nm), all quenchers still perform markedly better than the parent dabcyl (Figure 4e), with MPQ5 again serving as the single exception. Although not operating by an entirely FRET mechanism, the advantages of the red-shifted absorbance properties become clearer as the relatively small five-base increase in length between quencher and fluorophore greatly affects the quenching ability of dabcyl with considerably smaller effect on the ability of the MPQs to quench the emission of Atto 590. Quasar 670 (a Cy5 variant, λ_{em} = 662 nm) was the furthest-red emitting fluorophore tested. At this wavelength, the limits of certain MPQs begin to become evident, although contact quenching overall remains highly efficient (up to 97%; see Tables 2 and 3 and Figure 4f).

FRET Quenching. To properly assess quenching based entirely on a FRET mechanism, hybridization of 5′-quencher labeled sequenches to 5′-fluorophore labeled sequences was carried out (Figure 3c).[27] As a result of the poor spectral overlap of all new quenchers with the emission of the short-

wavelength AlexaFluor 350 (λ_{em} = 442 nm), FRET quenching of this fluorophore was not examined. Similarly, with the poor quenching efficiency of MPQ5, particularly in mixed mechanism quenching studies (Table 2) and the low extinction coefficient of this compound relative to the others synthesized, the quencher was not used in FRET quenching studies.

FRET quenching studies were complicated by the inherent nucleobase quenching by the 3′-dG on the quencher-containing strand. To account for this, an oligonucleotide sequence lacking a 5′ quencher was synthesized and served as a control for quenching due only to the 3′-dG (Table 4). Although such quenching was negligible for fluorescein, Atto 590, and Quasar 670, the 3′-dG was found to strongly quench both Cy3 and TAMRA emission (Table 4). Quenching of TAMRA by guanosine is well-known and unsurprising,[28,29] but quenching of Cy3 in this context was unexpected, as previous studies had indicated an activation of Cy3 fluorescence by guanine.[14,28]

In general terms, the FRET results (Table 4) confirm the expanded quenching properties of the new dyes, with all new quenchers performing better than dabcyl for all fluorophores tested. MPQ1 and MPQ2 were even capable of quenching Atto 590 to a moderate degree, while the parent dabcyl showed, as expected, negligible quenching of the red-emitting dye, indicating the ability to red-shift the absorbance properties and quenching abilities. MPQ6 again provides superior results, as it was able to quench all fluorophores as well as or even better than BHQ2 in an entirely FRET context. Whereas BHQ1 (the parent compound of MPQ6) is a poor FRET quencher of red-emitting fluorophores such as Quasar 670 and Atto 590 as a result of negligible spectral overlap,[27] incorporation of the dihydroperimidine subunit in MPQ6 gives rise to a greatly broadened absorbance spectrum and results in a compound with FRET quenching efficiency better than BHQ2, as in the case of Quasar 670.

DISCUSSION

Overall, the data show that several MPQ dyes outperform their parent dye (dabcyl) in performance in a contact quenching format with all of the fluorophores tested except the most blue-shifted fluorophore (Alexa 350). As for quenching by the FRET mechanism, which is most relevant to the present electronic design concept, all of the MPQ quenchers perform better than dabcyl with all of the fluorophores. This confirms that broadening of the absorbance spectrum of the quencher can confer superior performance. While most of the new dyes do not exceed the quenching ability of the advanced BHQ2 compound, a number of MPQ quenchers equal this quencher's performance with specific fluorescent labels, and thus could be considered as serious alternatives to this molecule.

The chief intent of the molecular design of MPQs was to broaden the efficient quenching range of the parent quenchers. The data show that this approach is successful: several of the MPQs give >95% contact quenching and excellent FRET quenching of fluorophores as far to the blue as fluorescein and as far red as Quasar 670, while the parent dabcyl compound quenches none of the five fluorophores significantly in the FRET mode and only one better than 95% in the contact mode. Thus, we conclude that incorporation of the naphthalimide core does result in the desired increase in generality and a greater range of fluorescence quenching beyond that of dabcyl. Moreover, incorporation of the dihydroperimidine moiety into the BHQ1 scaffold affords a new quencher (MPQ6) that also displays quenching efficiency over a wide wavelength range.

All five quenchers derived from the dabcyl structure (MPQs 1−5) display significantly enhanced quenching of all fluorophores emitting beyond fluorescein, in both contact and FRET quenching. As such, they should be considered as excellent alternatives to dabcyl in any assay that relies on quenching of a fluorophore emitting above approximately 520 nm and even as far as 624 nm, as shown by the ability of MPQ1 and MPQ2 to effectively quench the emission of Atto 590 in the FRET mode. MPQ3 appears to be an excellent quencher specifically for fluorescein, as it performed better than other quenchers for this fluorophore in both contact and FRET quenching. Further, MPQ6 uniquely serves as a competitive alternative to BHQ2 for both contact and FRET quenching of all fluorophores used in this study, particularly those emitting between approximately 560 and 670 nm. As the FRET quenching of this compound is approximately equal to or greater than BHQ2 for Fluorescein, Cy3, TAMRA, Atto 590, and Quasar 670, it may have its greatest utility in FRET-based fluorescence assays.

To our knowledge, the only previous similar approach in quencher design (i.e., taking advantage of increased electronic complexity) employed an azulene dimer, but was limited to quenching only in the near-IR region with limited efficiency.[30] An alternative design utilizing an azaphthalocyanine structure displayed a broadened absorbance spectrum, but has only been fully assayed to date in quenching of FAM and Cy5.[27] Experiments further displayed the ability of the azophthalocyanine dye to quench a larger set of fluorophores (ranging in emission from 517 nm to 703 nm), but only in a contact quenching setting, without exploration of FRET quenching of the expanded set of fluorophores.[31] The use of the perimidine scaffold has been shown before to proffer a red-shift to fluorescent dyes,[32] but the current work is the first case of the use of perimidine for altering the properties of fluorescence quenchers.

One interesting aspect of the spectral properties of some the new Multi-Path Quenchers is their environmental sensitivity. MPQs 1−5 undergo moderate to significant changes upon a change in nearly DNA sequence. For all but MPQ4, this is likely the result of the incorporation of the naphthalimide core, which is well-known to be environmentally sensitive itself.[22,33] In addition, the 4-aminonaphthalimide core has been employed in DNA sensors due to its inherent environmental sensitivity, providing a further explanation for the changes observed here.[34] As use of the 4-aminonaphthalimide core has shown environmental dependence in different DNA settings, it is likely that such is the same explanation for the derived quenchers, but a further exploration is necessary to allow for an accurate conclusion of the mechanism creating the different absorbance spectra for MPQs 1−5. It seems possible, however, that one might in the future take advantage of this property in the design of "smart quenchers", where the environment of the quencher could be part of the design, either blue-shifting or red-shifting the absorbance spectrum in response to structure or changes in environment. Further investigation is needed to explore this possibility.

Table S1: MALDI-TOF calculated and observed masses of DNA sequences used.
*An insufficient amount of labelled DNA was prepared to obtain an analytical HPLC

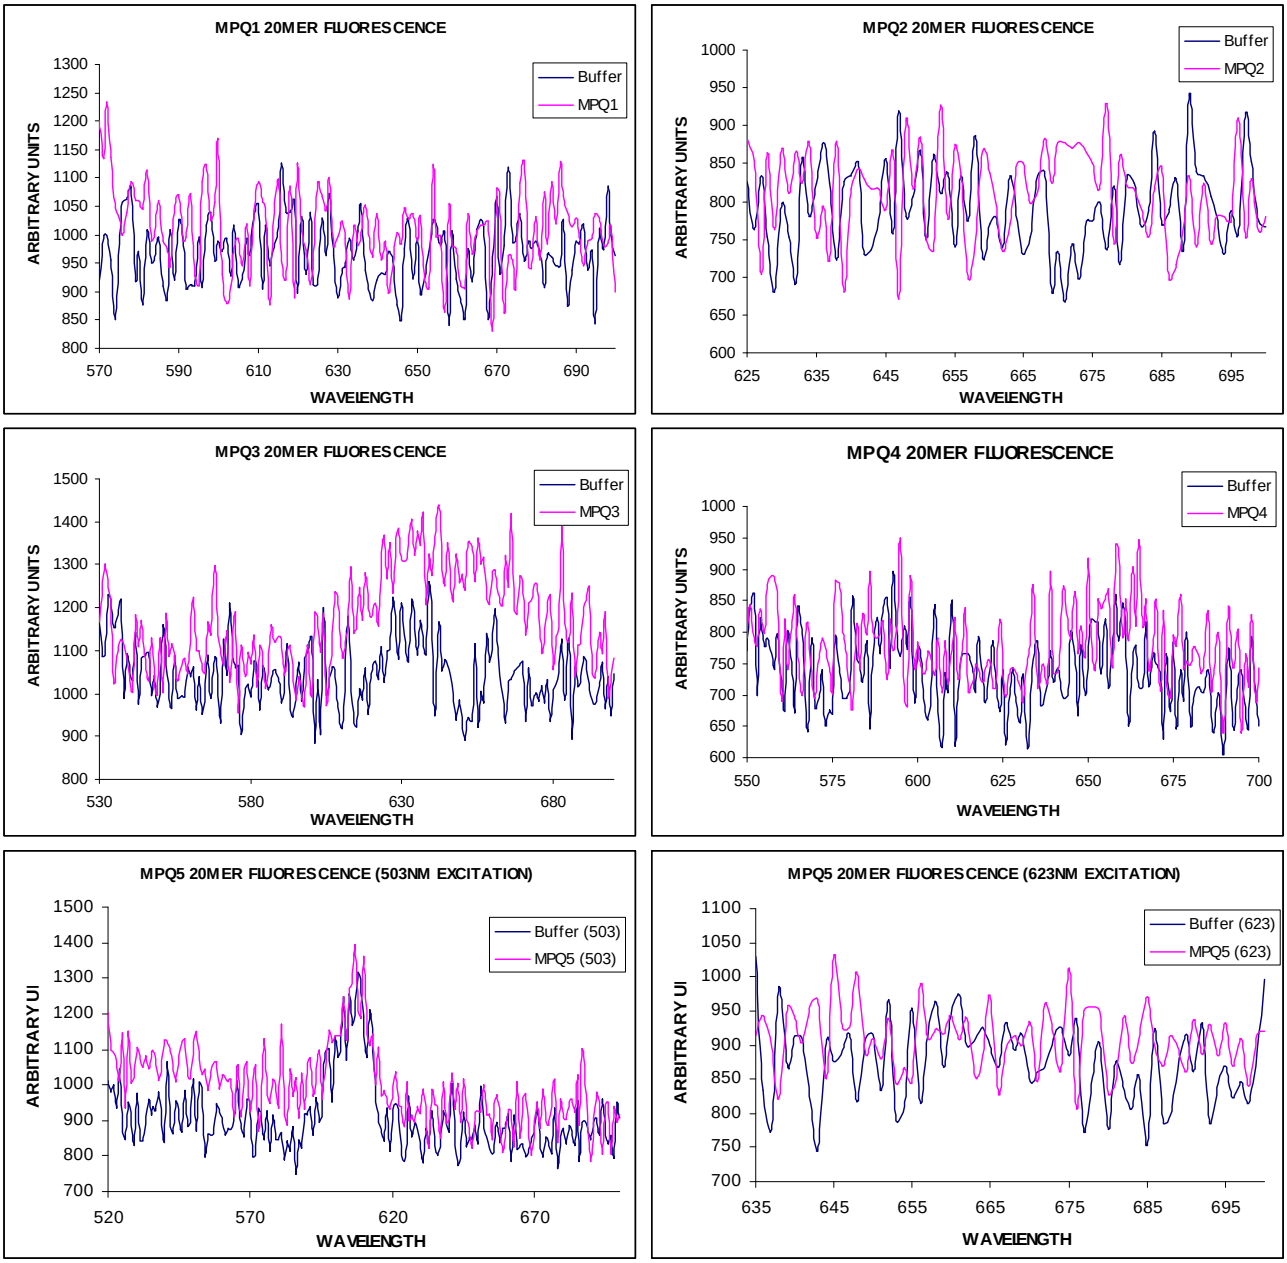

Figure S1: Fluorescence spectra of quencher 20mers (---) compared to buffer alone (---). Samples (100nM) were excited at the λ_{max} values indicated in Table XXXX.

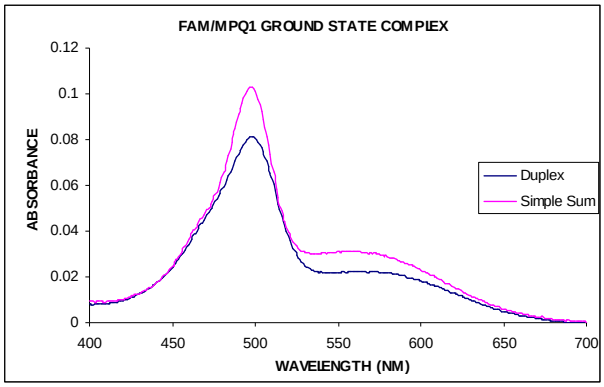
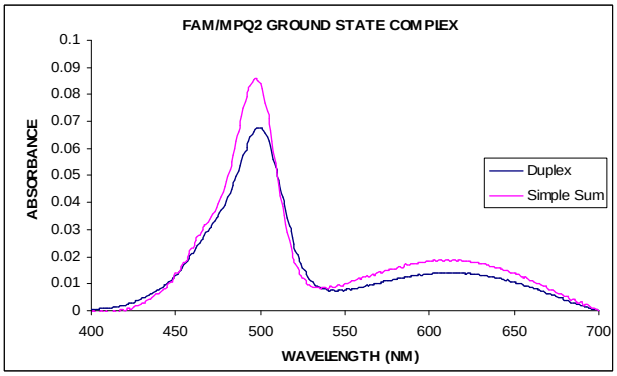
Quencher	λ_{max}	ε_{max}	ε_{260}
MPQ1	512	36400	25100
MPQ2	516	19200	10300
MPQ3	517	50800	15000
MPQ4	522	22600	10800
MPQ5	617	8700	18200
MPQ6	620	28700	N.D.*

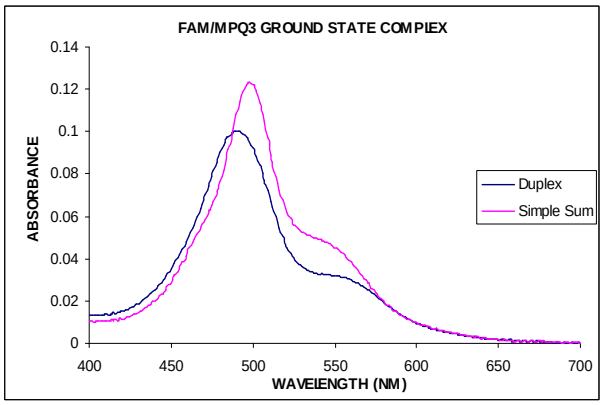
Table S2: Absorbance maxima and extinction coefficients (in L M^{-1} cm^{-1}) for multiple pathway quenchers in ethanol. ε_{260} values are provided for quenchers in 9:1 PBS:DMF

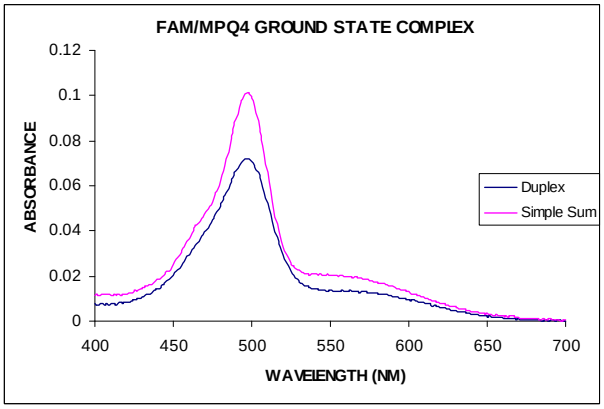
* Value could not be determined as a result of aggregation. A value of 8000 L M^{-1} cm^{-1} was used in DNA concentration calculations (the value of BHQ1 at 260 nm).

Figure S2: Ground state complex formation between MPQ 20mers and 3'-Fluorescein 20mer. Duplexes were formed by annealing a solution 1 μM of each strand in hybridization buffer at 70 °C for 5 minutes then allowing to cool to room temperature over 30 minutes. The simple sum was created by adding solutions containing only 1 μM of either quencher or fluorophore labelled strand.









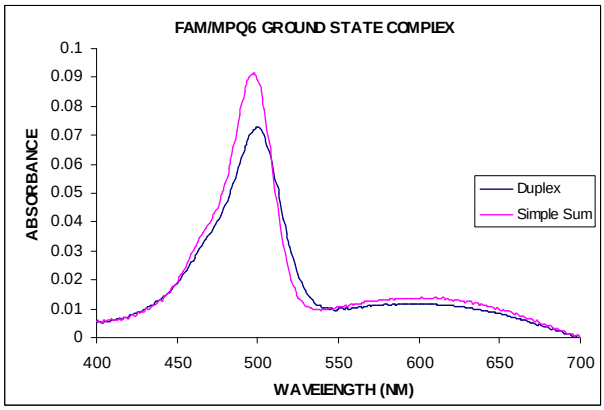


Figure S2: Ground state complex formation between 5'-Dabcyl or 5'-BHQ2 15mers and 3' Fluorophore labelled 20mers. Duplexes were formed by annealing a solution 1 μM of each strand in hybridization buffer at 70 °C for 5 minutes then allowing to cool to room temperature over 30 minutes. The simple sum was created by adding solutions containing only 1 μM of either quencher or fluorophore labelled strand.

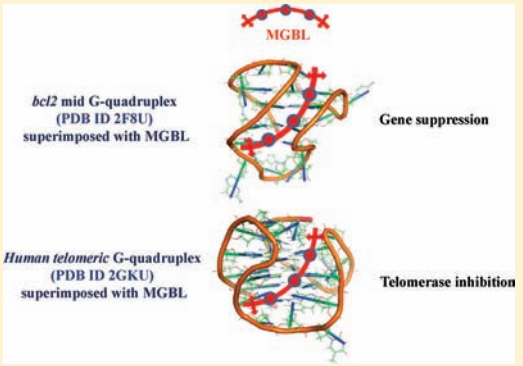
Interaction of G-Quadruplexes with Nonintercalating Duplex-DNA Minor Groove Binding Ligands

Akash K. Jain[‡] and Santanu Bhattacharya*[,‡,†]

[‡]Department of Organic Chemistry, Indian Institute of Science, Bangalore 560 012, India

[†]Chemical Biology Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore 560 012, India

ABSTRACT: The enzyme telomerase synthesizes the G-rich DNA strands of the telomere and its activity is often associated with cancer. The telomerase may be therefore responsible for the ability of a cancer cell to escape apoptosis. The G-rich DNA sequences often adopt tetra-stranded structure, known as the G-quadruplex DNA (G4-DNA). The stabilization of the telomeric DNA into the G4-DNA structures by small molecules has been the focus of many researchers for the design and development of new anticancer agents. The compounds which stabilize the G-quadruplex in the telomere inhibit the telomerase activity. Besides telomeres, the G4-DNA forming sequences are present in the genomic regions of biological significance including the transcriptional regulatory and promoter regions of several oncogenes. Inducing a G-quadruplex structure within the G-rich promoter sequences is a potential way of achieving selective gene regulation. Several G-quadruplex stabilizing ligands are known. Minor groove binding ligands (MGBLs) interact with the double-helical DNA through the minor grooves sequence-specifically and interfere with several DNA associated processes. These MGBLs when suitably modified switch their preference sometimes from the duplex DNA to G4-DNA and stabilize the G4-DNA as well. Herein, we focus on the recent advances in understanding the G-quadruplex structures, particularly made by the human telomeric ends, and review the results of various investigations of the interaction of designed organic ligands with the G-quadruplex DNA while highlighting the importance of MGBL-G-quadruplex interactions.



INTRODUCTION

At the ends of the chromosomes, i.e., the telomeres, DNA does not consist of a complex protein-coding sequence. Instead, these are made of a simple sequence such as TTGGGG in the ciliate *Tetrahymena*[1] or TTAGGG in humans,[2] which are repeated a few hundred times in humans and fewer times in ciliates. The bulk of telomeric DNA adopts a double-helical conformation keeping the GT-rich sequence paired with its CA-rich complement. However, the 3′-end of such DNA protrudes as a single-stranded overhang in all the eukaryotes studied.[2−5] This DNA sequence binds to specific proteins, which cap the chromosome ends either directly or by inducing a particular DNA structure.[5]

DNA in the cell nucleus is copied and transcribed by enzymes such as DNA and RNA polymerases. DNA synthesis is catalyzed by DNA polymerase, an enzyme which has crucial role in the DNA replication. A DNA polymerase elongates the new DNA strand from 5′ to 3′ direction, by adding a free nucleotide onto the growing 3′-end of the new strand. It never begins the synthesis of a new chain, and therefore, it needs a primer to add the first nucleotide at the 3′-OH group of the primer. The first two bases of the primer are always the RNA bases, while other bases may be either DNA or RNA. Primers are synthesized by an enzyme, primase. Conversion of the duplex DNA into a single-stranded DNA, with the help of an enzyme, called helicase, facilitates the replication of each strand. Complete replication of the overhanging end of the chromosome cannot be accomplished by conventional DNA polymerases.[4] In almost all eukaryotes, the chromosomal end-replication problem is solved by the enzyme telomerase, a ribonucleoprotein.[5] A portion of the RNA subunit of telomerase provides the nucleic acid template that the DNA cannot provide for itself.[6,7] The enzyme telomerase is upregulated in nearly 80−90% of the cancer cells, leading to an abnormal growth of cells.[7] Telomerase inhibition therefore comprises a key strategy for the development of anticancer agents. This is because studies so far have shown that the telomerase inhibitors can stop the proliferation of the cancer cells or cause apoptosis of the cancer cells, while they have no effect on most of the normal cells.[8]

The telomere cap is composed of telomerase (having the components *hTERT*, *hTERC*, *Hsp90*, *Tp1*, and so forth), telomere-associated proteins (like *TRF1*, *TRF2*, Tankyrase, *TIN2*, *POT1*, Dykserin, and so forth), and telomeric DNA repair proteins (for instance, *MRE11*, *RAD50*, *KU70*, *XRCC5*/*KU80*, and *H2AX*, etc.). This machinery maintains the length of

the telomere.[9] A G-quadruplex selective ligand triggers the folding of the G-rich repeats of DNA into a G4-DNA structure. In turn, this inhibits the binding of telomerase and its associated proteins with telomere, thereby stopping the telomere elongation process.[9] Since G4-DNAs do not serve as substrates for the telomerase, these structures have been the focus of much research in medicinal and biological chemistry as attractive targets for the anticancer drug design.[7,9,10] All G4-DNAs contain a basic repeating and stacking motif, the G-quartet structure, which is formed by four guanine bases and held in a plane by the Hoogsteen mode of hydrogen bonds (Figure 1A).[7−11] DNA is a potential target for several

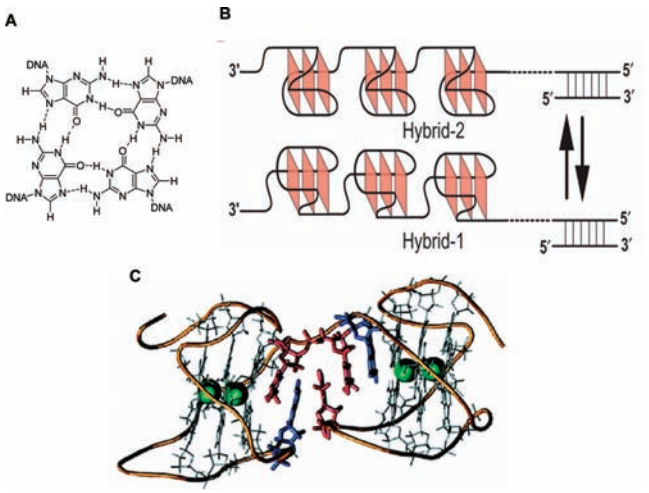

Figure 1. (A) Structure of a G-quartet is shown, in which the hydrogen bonding patterns are also indicated. (B) Schematic model of the DNA secondary structure in human telomeres. The hybrid-type telomeric G-quadruplex structures can be readily folded and stacked end to end to form compact-stacking structures for multimers in the elongated telomeric DNA. anticancer drugs and there are many possible mechanisms of action.[12] G-quadruplex interactive compounds inhibit telomerase by stabilizing the single-stranded 3′-telomere ends as G4-DNA.[7,11]

Besides telomeres, the G4-DNA forming sequences occur in biologically relevant regions of the genome including the immunoglobulin switch regions,[13] the transcriptional regulatory regions of a number of genes such as the insulin gene,[14] and also the promoter regions of several oncogenes such as *c-kit*, *c-myc*, *c-myb*, *K-RAS*, *bcl-2*, and many others.[15−18] Formation of G-quadruplex structures from these G-rich promoter sequences induced by a small molecular ligand provides a means of achieving selective gene regulation and thereby target a protein, the product of gene expression. This has been demonstrated for the *c-myc* oncogene at the nuclease hypersensitivity element (NHE) III_1 which is responsible for up to 90% of *c-myc* transcription.[15,19]

Topology of these G-quadruplex structures depends on the DNA sequence, number of telomeric repeats, oligodeoxynucleotide (ODN) concentration, and an appropriate stabilizing cation.[20] A 27-mer G4-DNA forming sequence in *c-myc* forms a dynamic mixture of four intramolecular quadruplexes which differ in their loop arrangements.[15,19] Similarly, a 22-mer G4-DNA forming sequence, *c-kit87up*, in the promoter region of *c-kit* forms a unique intramolecular quadruplex in K^+ solution.[21] Presently, much of the research effort involving G-quadruplex DNA is directed toward the study of G4-DNA formed by human telomeric repeats $d[T_2AG_3]_n$, particularly a 21-mer sequence $d[T_2AG_3]_3G_3$ and a 22-mer $d[AG_3(T_2AG_3)_3]$. Altering the TTAGGG to TTAGAG in any one of the repeats of T_2AG_3 converts an intramolecular to an intermolecular G-quadruplex with varying degrees of parallel and antiparallel-stranded character, depending on the length of the incubation time, the concentration of the ion present in solution (Li^+, Na^+, or K^+), and the exact DNA sequence.[22] A human telomeric DNA repeat sequence can form two related types of the G4-DNA structures, known as hybrid-1 or hybrid-2 structures (Figure 1B), depending on the flanking segments, out of which the hybrid-2 type is predicted to be the major structural component in the human telomeric DNA.[23−26] These solution structures are different from the K^+-stabilized crystal structure of the G4-DNA derived from 22-mer sequence $d(AG_3[T_2AG_3]_3)$.[26] Other possible G4-DNA conformations adopted by short human telomeric sequences and quadruplex-forming sequences in other genes were already reviewed.[27] Recently, a dimeric structure for the eight-repeat human telomeric sequence containing 2-folded quadruplex units was reported on the basis of high-resolution G4-DNA structure obtained for the four-repeat sequence (Figure 1C).[28] Different topologies of the G4-DNA (in telomeric and genomic regions) having some unusual intermediates as shown by NMR experiments were reviewed recently.[29]

Drug−DNA complex formation may be divided into two broad areas via (i) covalent and (ii) noncovalent interactions.[30] Covalent interactions are generally irreversible. DNA alkylating agents like nitrogen mustards fall under this category. Also *cis*-platin cross-links to DNA, specifically through the N-7 atom of purines of DNA base pairs impeding their hydrogen bond forming capacity with cDNA bases. Such compounds inhibit transcription, translation, and replication of DNA and have long been used as anticancer drugs.[30−32]

Intercalative and nonintercalative drugs represent the major classes of noncovalently interacting compounds.[33] Intercalators generally insert between the layers of nucleic acid base pairs and disrupt the shape of the double-helix significantly, thereby preventing replication and transcription often by untwisting the DNA.[30,31,33] Nonintercalative molecules interact with the duplex DNA through its major and minor grooves. These grooves differ in their electrostatic potential, hydrogen bonding characteristics, steric requirements, hydrophobicity, hydration, and microenvironmental polarity.[30,31,33−39] Most of the DNA binding proteins associate through the major groove of the duplex DNA, while small molecular mass ligands bind via both the major and minor grooves of DNA.[33] DNA minor groove binding ligands (MGBLs) are generally "crescent-shaped" molecules which recognize the minor grooves in a sequence-specific manner. Oligopeptides (netropsin, distamycin-A),[34,40] benzimidazoles (Hoechst 33258, Hoechst 33342),[37] DAPI,[33] berenil,[33] bis-quaternary cations (SN 6999, SN 7167, SN 18071),[31] cyanine dyes (DTDC, DODC),[31] and so forth are some of the well-known MGBLs of low molecular mass. These molecules typically recognize 3−5 base pairs, and some of their analogues including dimers recognize even longer stretches of DNA.[34−42]

MGBLs bind with the non *B*-DNA and multistranded DNA structures too. There are reports on the studies of the complexes of MGBLs involving *ps*-DNA[31] and triplex[31,43] and G-quadruplex DNA.[44] Herein, we provide an overview of the nature of interaction of G-quadruplex DNA with low molecular mass organic ligands with a special emphasis on MGBLs. Since G-quadruplexes are involved in several important cellular functions, the studies of these complexes should be useful in the design and discovery of some effective chemotherapeutic agents.

G-QUADRUPLEXES AND ORGANIC LIGANDS

G-quadruplex DNA structures have affinity for small, positively charged organic ligands. G4-DNAs have several sites of interaction with an organic ligand, mainly through the G-tetrads and the grooves. G-quadruplex stabilizing molecules (particularly the end-stacking ones) often have the following features, e.g., a central symmetrical and a planar core, an extended delocalized π-electron system, tertiary amines which become positively charged due to the protonation under physiological conditions of pH, and the side chains that are able to form hydrogen bonds with the DNA bases and with the phosphate backbone of the loops.[45] Many end-stacking ligands fit this description, although this is not always a general rule. Thus, the compounds that bind with the G4-DNA grooves may have entirely different molecular features. In 1997, a crystal structure of G4-DNA formed by hexanucleotide TG_4T in Na^+ solution was elucidated. This showed several distinct structural features different from that of the duplex DNA.[46] This includes notably the possession of four quasi-equivalent grooves along with a pronounced channel of negative electrostatic potential running through the center of the planes of the G-quartets, allowing the metal ions to be coordinated between the planes in a bipyramidal antiprismatic manner. Structural properties of the G4-DNA grooves vary according to molecularity and type (strand orientation) of the G-quadruplex.[47] Four-stranded intermolecular G4-DNA has four identical grooves that are of about the same size as the minor groove of *B*-DNA.[48] In contrast to the parallel-stranded G-quadruplexes, the four grooves in an antiparallel quadruplex are not identical, e.g., fold-over monomeric G4-DNAs with diagonal loops have one wide groove, two medium-sized grooves, and one narrow groove.[49] Taking these features into account, many compounds were synthesized to target the G4-DNA formed by the human telomeric DNA sequence.[50] Structures of some small organic cation-G4-DNA complexes have been recently reviewed[27] and are supposed to be helpful in finding out new structure-based leads for the design of anticancer drugs. The intramolecular G4-DNA made by the sequence $d[AG_3(T_2AG_3)_3]$ has seven major binding sites available for a drug, made up of two G-tetrads for end-stacking (parallel-loop and diagonal-loop), one wide groove, two medium-sized grooves, one narrow groove, and top parallel loop binding sites (Figure 2). Thus, the geometries and functional groups of the G-quadruplexes are different from that of the duplex DNA. A drug can bind to multiple sites suggested by its skeleton and functional groups present in it. Thus, although 3,6-bis(1-methyl-4-vinylpyridinium iodine) carbazole (BMVC, **1**) exerts a strong interaction with all the sites, its binding with the end-stacked G-quartets is the most favorable.[51]

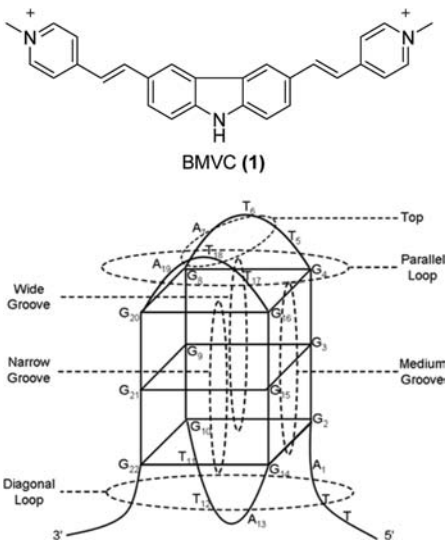

Figure 2. Molecular structure of 3,6-Bis(1-methyl-4-vinylpyridinium iodine) carbazole (BMVC, top) and a sketch of the G4-DNA structure made by human 22-mer telomeric DNA showing its binding sites for a drug (bottom). Figure adapted from ref 51, with permission of the American Chemical Society.

G-QUADRUPLEXES IN NON-TELOMERIC REGIONS

As mentioned earlier, G4-DNA forming motifs have been identified and characterized in functional regions (e.g., promoters and enhancers) of many oncogenes such as *c-kit*, *c-myc*, *c-myb*, *K-RAS*, *bcl-2*, and other cell growth-related genes.[13−21,29,52] Most of these G4-DNA motifs in the gene promoter regions have physical chemical properties and structural characteristics that might make them interact strongly with putative drugs.[18] Further, they have such diverse structures that a high degree of selectivity might be possible.[18,21,29] The initial report on genome-wide analyses highlighting multiple regulatory roles of G4-DNA structure appeared in 2006,[53] followed by a number of recent reports.[17,54−56] G4-DNA formation in genes may affect the cellular function in different possible ways. G4-DNA formation in the insulin-linked polymorphic region upstream of the insulin gene enhanced its transcription, where single/double mutations that disrupted the G4-DNA structure afforded reduced promoter activity.[14] On the other hand, G4-DNA also acts as a "silencer element" for certain oncogenes.[15,18,57] Several proteins from different organisms that interact with the G4-DNA have been reported.[58−60] They play an important role in transcription of certain genes and can be classified by function into five major groups. These are those that (i) increase the stability of G4-DNA, (ii) destabilize G4-DNA in a noncatalytic way, (iii) unwind catalytically G4-DNA in an ATP-dependent fashion, (iv) promote the formation of G4-DNA, or (v) specifically cleave DNA at or adjacent to a quadruplex forming domain. G4-DNA structures in the promoter regions have generally been targeted by end-stacking ligands, which have been already reviewed.[18]

GROOVE BINDING LIGANDS FOR G-QUADRUPLEX DNA

As discussed above, the bulk of the research concerning the G4-DNA binding ligands has focused heavily on the ligands having aromatic rings that could potentially stack on the terminal G4-planes on both ends of the G4-DNA. Other potential binding

dx.doi.org/10.1021/bc200268a | *Bioconjugate Chem.* 2011, 22, 2355−2368

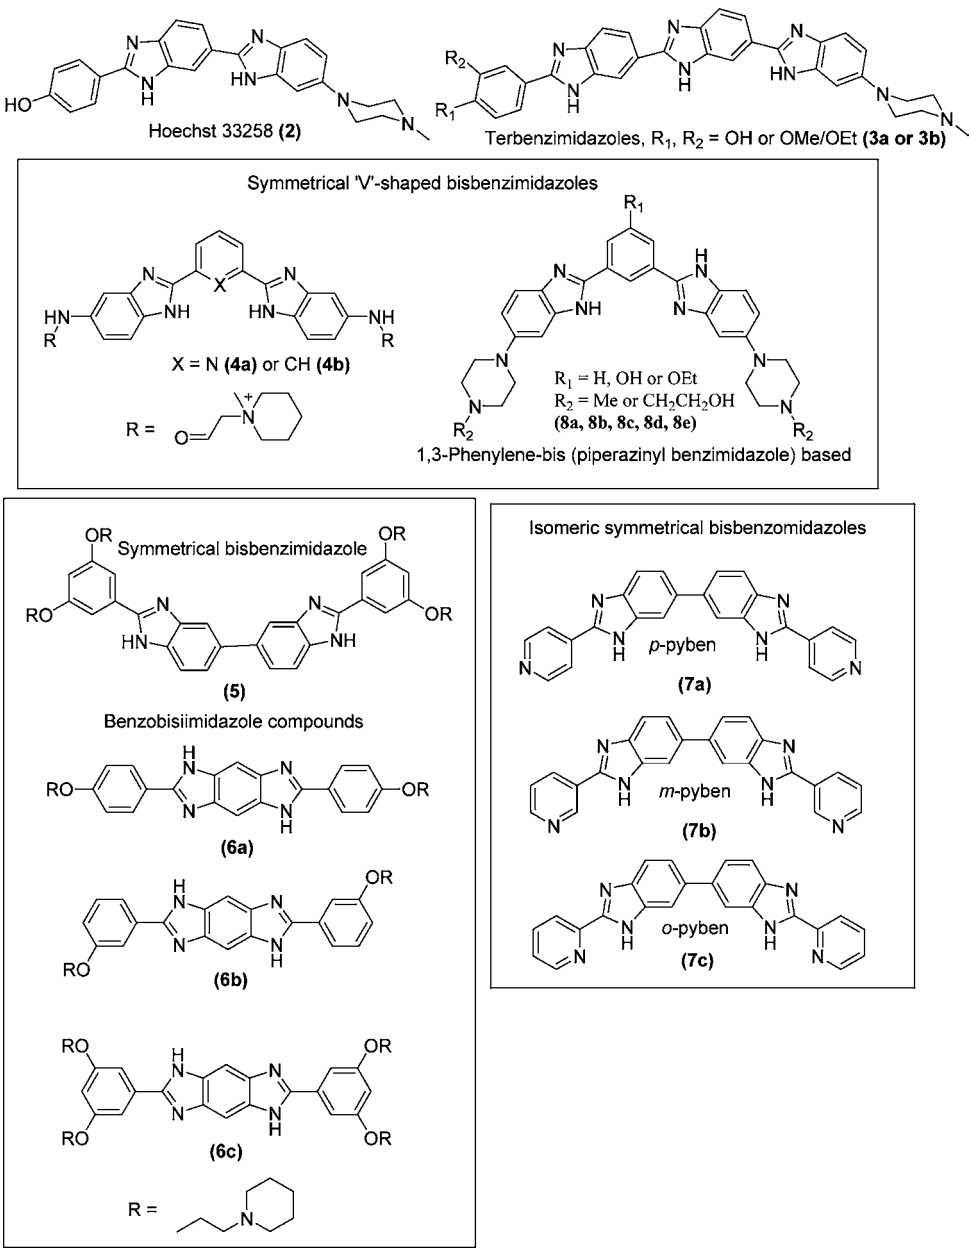

Figure 3. Molecular structures of benzimidazole-based ligands: Hoechst 33258, terbenzimidazoles, 'V'-shaped bisbenzimidazoles,[67] benzobisimidazoles,[68] symmetrical isomeric bisbenzimidazoles used to study tunable binding with the duplex DNA in presence of metal ion,[63] symmetrical 'V'-shaped bisbenzimidazoles based on 1,3-phenylene-bis(piperazinyl benzimidazole) [R_1 = H, R_2 = CH_2CH_2OH;[69] R_1 = OH or OEt, R_2 = Me or CH_2CH_2OH],[70] benzobisimidazoles,[68] symmetrical isomeric bisbenzimidazoles used to study tunable binding with the duplex DNA in presence of metal ion.[63]

sites include the four grooves of the G4-DNA. The width, depth, and accessibility of these four grooves depend on the strand alignment and the topologies of the connecting loops. The structural differences between the duplex and the G4-DNA grooves offer an alternative yet important strategy for the design and synthesis of new ligands for differentiation between the two nucleic acid structures. The grooves are protected by the double-chain-reversal loops, but edgewise and diagonal loops do not have such restrictions. The G4-plane is made by the Watson–Crick base pairing scheme, and the major groove edges of guanines and minor groove edges are still available for further recognition. It was shown that an adenine can align with the minor groove edge of a G4-plane guanine, to form a sheared G.A noncanonical pair, leading to the creation of a A(G.G.G.G) pentad.[61] The structure-based design of ligands and their consequent synthesis to achieve significant binding with individual grooves of defined G4-DNAs is still an ongoing challenge in the field. Since the dimensions of the G4-DNA grooves differ with the type of the G4-DNA, donor–acceptor patterns of the H-bonding sites also vary.[62] Thus, successful implementation of the groove binding is an important strategy to selectively target a particular G4-DNA structure.

FEATURES OF THE GROOVE BINDING LIGANDS

Benzimidazole Based Scaffolds. The benzimidazole moiety is structurally related to the purine bases and is found in several biologically relevant natural compounds. Bisbenzimidazole-based Hoechst 33258 generally binds with 4–5

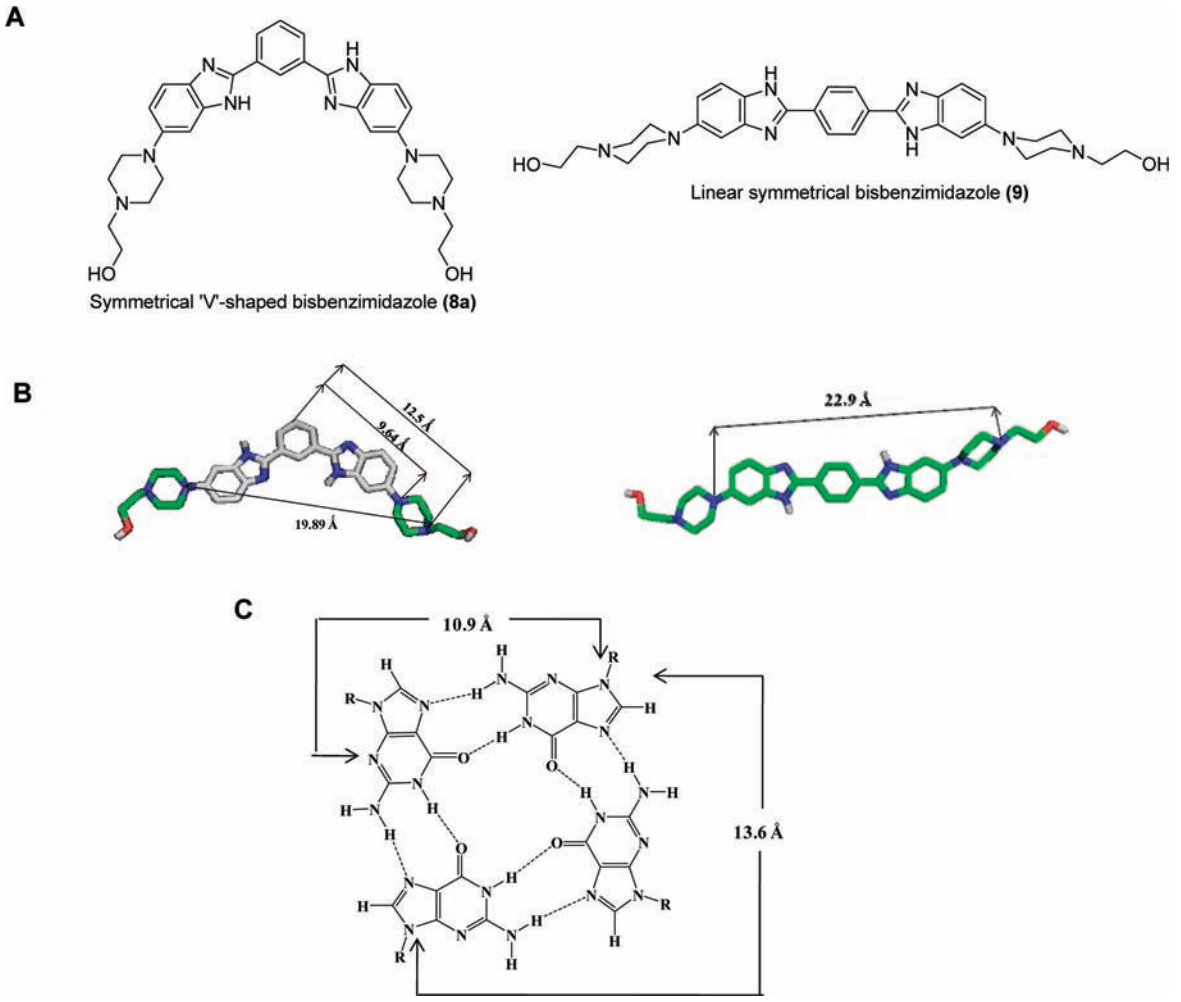

Figure 4. (A) Chemical structures of symmetrical 'V'-shaped bisbenzimidazole (**8a**) and its linear isomer (**9**).[69] (B) Optimized structures at the B3LYP/6-31G* level of theory of **8a** and **9** (adapted from the ref 69, with permission of the American Chemical Society). (C) Structures of the G-tetrad along with interatomic distances.

contiguous AT base pairs of the duplex DNA (**2**, Figure 3). In contrast, the terbenzimidazoles bind with extended sequences of DNA (**3**, Figure 3).[37−39] Other benzimidazole derivatives were also studied to modulate their binding affinity toward duplex and other higher-order DNA structures.[30,31,37,43] Interestingly, three symmetrical isomeric bisbenzimidazole compounds show very different binding affinity toward AT-rich duplex DNA (Figure 3).[63] Hoechst 33258 binds with the G4-DNA formed by the DNA sequence derived from human *c-myc* promoter region, d($G_4AG_3TG_4AG_3TG_4A_2G_2TG_4$). Using UV, fluorescence spectroscopic, and SPR techniques, a binding constant of the order of 10^6 M^{-1} was estimated.[64] Anisotropy measurements and higher lifetime obtained from time-resolved decay experiments reveal that Hoechst 33258 bound to G4-DNA is rotationally restricted in a less polar environment than in the bulk buffered medium. As Hoechst 33258 is known to bind specifically to A−T-rich regions of the duplex DNA, the likelihood of Hoechst 33258 interacting with the AAGGT loop of the G4-DNA was proposed.[64] Later on, the binding was examined by NMR data too.[65] Upon addition of Hoechst 33258 to the solution of a G4-DNA made from a 24-mer sequence d[$TGAG_3TG_4$ $AG_3TG_4A_2G_2$] (pu24), the imino protons of the top G4-plane's residues are found to be most perturbed (shifted toward upfield and broadened).[65] This is an observation which is consistent with the stacking of these ligands on the top G-tetrad. Further, imino proton of G13, which is involved in the terminal G-quartet formation, is greatly broadened, suggesting multiple stacking configurations of Hoechst 33258 over G13. Recently, Hoechst 33258 was shown to stabilize the G4-DNA, a sequence derived from the human telomeric repeats in solution having Na^+ ions, but not K^+.[66] However, in the molecular crowding conditions mimicked by the addition of polyethylene glycol (PEG), it lost its G-quadruplex binding affinity and consequent telomerase inhibition activity.[66] The negative effect of the molecular crowding could be attributed to the reduced affinity between the ligands and the G4-DNA, possibly as a consequence of decreased water activity and enhanced viscosity of the medium.

Two symmetrical V-shaped bisbenzimidazole derivatives were prepared and one of them was shown to induce the G4-DNA formation and stabilize it.[67] The benzimidazole constructs that are more effective have pyridine as the central aromatic core and substitutions on benzimidazoles at 3- and 6-positions (**4a**), making a planar and relatively nonflexible conformation because of the intramolecular H-bonding between the imidazole hydrogen and the nitrogen of pyridine. This compound (**4a**) also showed effective nuclease resistance activity.[67] Other molecules having benzene as the central ring

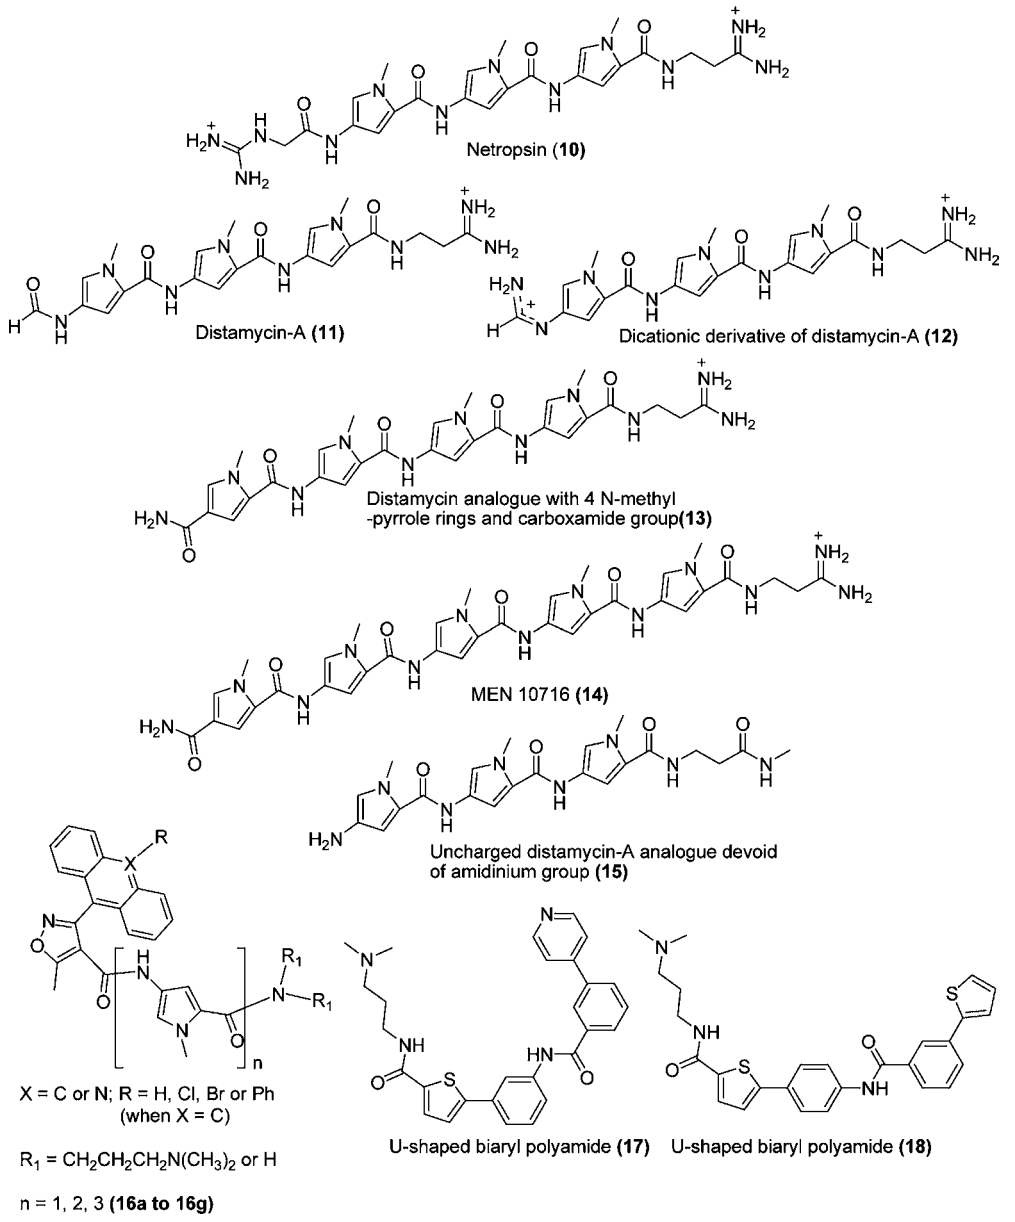

Figure 5. Chemical structures of netropsin, distamycin-A, and carbamoyl analogues of distamycin having 4 and 5 *N*-methyl-pyrrole rings and dicationic derivative[76] of distamycin-A (distamycin-A analogue having 5 rings is called MEN 10716),[82] uncharged distamycin-A analogue devoid of amidinium group,[83] anthracenylioxazole lexitropsin conjugates,[84] and planar U-shaped byaryl polyamides.[85]

and substitutions at 1- and 2-positions, however, show much less affinity toward the G4-DNA. Recently, a symmetrical, linear bisbenzimidazole (**5**) and some benzobisimidazole compounds (**6a**–**6c**, Figure 3) were tested against the duplex and the G4-DNA.[68] Linear bisbenzimidazole (**5**) was found to bind with the double-helical DNA, while the benzobisimidazole compounds were found to stabilize the G4-DNA preferentially over the duplex DNA. Side chains have an important role in the G-quadruplex binding and telomerase inhibition. These benzobisimidazole derivatives have a conjugated aromatic surface, which probably aids their binding with a G-quadruplex DNA via π–π stacking.[68]

The shape of a G-quadruplex ligand has an important role toward the affinity and stabilization of the G4-DNA. G4-DNA interactions with two isomeric bisbenzimidazole-based compounds with different shapes ('V'-shaped, angular vs linear; Figure 3) were investigated.[69] While the linear isomer (**9**) shows little affinity for the monomolecular G4-DNA structure generated in the presence of Na^+, the 'V'-shaped angular isomer (**8a**, R_1 = H, R_2 = CH_2CH_2OH), expected to cover three guanines of the G-quartet, induces a significant structural change of the intramolecular G4-DNA, above a threshold concentration. The structural change was evident from the pronounced changes observed both in the CD spectra and from the electrophoretic experiments using the G4-DNA. Notably, this V-shaped isomer also induces the G4-DNA formation without any added cation. The ligand-G4-DNA complexes were also investigated by computational methods, which provide additional information on the structure–activity relationships (Figure 4). Dimensions of the angular isomer match with those of the G-quartet, and it should cover three guanines of the G-quartet. The linear isomer, which should cover two guanines of the G-quartet, caused less structural change and provided little stabilization to the G4-DNA. In agreement with these

observations, TRAP assay results with the telomerase extracted from A549 cells show that the angular isomer is a significantly more effective inhibitor of the telomerase activity.[69]

A series of symmetrical 'V'-shaped bisbenzimidazoles based on 1,3-phenylene-bis (piperazinyl benzimidazole) compounds was synthesized (**8b**−**8d**, Figure 3). These compounds induce G4-DNA formation even without any added cation with the ODN sequence $d(T_2G_4)_4$ relevant to *Tetrahymena*.[70] Binding affinity of these molecules toward the G-quadruplex increases upon introduction of an electron-donating ethoxy group on the central phenyl ring. The dimensions of these compounds match with those of the G-tetrad plane as per calculations, suggesting that end-stacking as the possible mode of the G-quadruplex stabilization. Appearance of an induced circular dichoric (ICD) signal at a higher drug: DNA ratio, however, indicates the groove binding as well.[70]

Oligopeptides and Related Lexitropsins. Some reports are available regarding the interaction of netropsin (Nt, **10**), distamycin-A (Dist-A, **11**), and their other oligopeptide analogues with the G4-DNA (Figure 5). This class of molecules acts as the minor-groove binders (MGB) for the duplex DNA.[34,35,42] Binding properties of these *N*-methyl pyrrole containing cresent-shaped oligopeptides with the duplex DNA depend on the number of pyrrole rings and the presence or absence of a leading amide (in Dist-A).[34] Longer analogues (beyond four/five consecutive rings) tend to lose their selectivity toward certain AT-rich DNA sequences. This is because the curvature of such long ligands often fails to match with the pitch of the DNA double-helix, disrupting the H-bonding and van der Waals interactions necessary for the specific sequence recognition.[31,34,36] Dist-A and Nt were also investigated with the three G-quadruplexes characterized by different groove widths: $[d(TG_4T)]_4$ (Q1), $[d(G_4T_4G_4)]_2$ (Q2), and $d(G_4T_2G_4TGTG_4T_2G_4)$ (Q3) using homonuclear NMR.[71] Below 2:1 ligand/G-quadruplex stoichiometry, Dist-A, in a dimeric form, binds with each groove of the tetraplex to form short-lived complexes on an NMR time scale. At higher drug/DNA ratios, a second Dist-A dimer specifically binds with the tetraplex, to give a 4:1 complex, in slow exchange with the 2:1 complex. Nt was found to be in a fast chemical exchange with all three kinds of G-quadruplexes, whereas Dist-A interacted tightly with Q1 and, to a less extent, with Q2. Both molecules possess higher affinity toward the duplex DNA than the G4-DNA. Two opposite models were proposed for the Dist-A complexed, parallel G4-DNA containing ODNs of different sequences in K^+ buffers. The first one suggests that Dist-A molecules bind as dimers in the two opposite grooves of the G4-DNA $[d(TG_4T)]_4$;[72,73] while the second one suggests that two Dist-A molecules stack on the terminal G-tetrad planes of the G4-DNAs made up of each of $[d(TAG_3T_2A)]_4$, $[d(TAG_4T_2)]_4$, and $[d(TAG_5T)]_4$ on the basis of NMR studies.[74] Below 2:1 ligand−tetraplex stoichiometry, Dist-A, in a dimeric form, binds to each groove of the tetraplex to form short-lived complexes on the NMR time scale. Therefore, only one set of signals for the four strands was observed. The fast exchange behavior of the lower complex (2:1 Dist-A-G4-DNA) could be changed only to an intermediate regime by decreasing the temperature of the system. As the temperature was reduced from 300 to 280 K, there was a general broadening of the resonances, with peaks belonging to Dist-A broadening more than the other peaks, probably due to the slower reorientation of the Dist-A dimer. At higher drug/DNA ratios, a second Dist-A dimer specifically binds with the G4-DNA, to give a 4:1 complex, in slow exchange with the 2:1 complex, as evidenced from the appearance of separate proton resonances for the two species. This behavior may be explained assuming that the binding of the second drug pair is more favorable than the binding of the first one.[72] Nt is involved in fast exchange on the NMR time scale with its binding sites on the tetraplex.[72]

A new modified oligonucleotide, namely, $d(TGG^{Me}GGT)$, having G^{Me} (8-methyl-2′-deoxyguanosine), able to fold into a quadruplex, was used to study its interactions with Dist-A.[73] Thus, the 8-methyl group of the four dG^{Me} of the quadruplex $[d(TGG^{Me}GGT)]_4$ faces right into the very central region of the grooves, pointing outward from the G4-DNAs. As a result, if Dist-A interacts with the groove of the G-quadruplex, the presence of these bulky groups in the very central region of the four grooves should prevent (or at least should limit) the insertion of Dist-A molecules. Consequently, the formation of a stable complex would be impeded. In the case of $[d(TG_4T)]_4$, Dist-A displayed a high affinity toward the G4-DNA as evidenced from the appearance of a new set of signals during the NMR titration. Furthermore, Dist-A caused a loss of the original fourfold symmetry of the free G4-DNA. During the entire titration process of the G-quadruplex $[d(TGG^{Me}GGT)]_4$, the four strands remain magnetically equivalent and only a general change in the chemical shift resonances are observed. Thus, the presence of the methyl groups in the central region of the grooves does affect the binding of Dist-A to the quadruplex, and hence, Dist-A interacts with the grooves of the quadruplex. The affinity between Dist-A and $[d(TG_4T)]_4$ is enhanced (∼10-fold) when the ratio of Dist-A and the quadruplex is increased.[73]

Dist-A was reported to stack on the terminal G4-planes having the flanking bases of the G4-DNA.[74] This allowed detection of 2:1, 4:1, and 8:1 Dist-A/G4-DNA complexes. Dist-A also inhibits the interaction of BLM helicase (an enzyme which unwinds the G4-DNA) with the G4-DNA. Dist-A inhibited binding of the G-quadruplex by nucleoilin (Nuc)-RGG_9. However, Dist-A exerts no effect on the interaction of G4-DNA with either a full-length murine nucleolin (Nucleolin) or a recombinant nucleolin possessing amino acid residues 281−709 that is devoid of the acidic N-terminus (Nuc-1,2,3,4-RGG_9) or recombinant nucleolin having only four RBD domains (RNA binding domains, Nuc-1,2,3,4).[74] These results show that Dist-A may be used to probe the interactions of G4-DNAs with certain proteins. These also indicate that at least two independent modes of protein−G4-DNA interactions may be studied by the sensitivity to Dist-A.

In another report, interactions of Dist-A, tel01, and DTC with the G4-DNA were studied using ESI-MS.[75] When two different ligand−G4-DNA complexes were subjected to a mass spectral analysis, distinct fragmentation patterns were observed. Tel01-G4-DNA complexes underwent a facile loss of the drug and produced single-strand ODN, while Dist-A-G4-DNA complexes produced single-strand ODN ions bound with the Dist-A. DTC-G4-DNA complexes had similar fragmentation patterns.[75] Thus, it may be concluded that DTC and Dist-A bind with $[d(T_2G_5T)]_4$ through the grooves. Different binding behavior observed with such drug molecules suggests that a sequence-dependent interaction prevails in the G4-DNA recognition events.

Recently, Nt and a dicationic derivative of Dist-A (**12**, Figure 5) were studied with $[d(TG_4T)]_4$ G4-DNA using NMR titrations and isothermal titration calorimetry (ITC).[76] Dicationic derivatives form 2:1 complex with the G4-DNA.

Interactions in both cases (Nt and the dicationic Dist-A) are entropically driven with a small favorable enthalpic contribution. The stoichiometry and thermodynamic properties of interactions of Dist-A/its analogues with G4-DNA are affected by the presence of different cations in solution. Dist-A and its two carbamoyl derivatives (**13**, **14**; having 4 and 5 *N*-methyl-pyrrole rings, respectively, Figure 5) were reported to behave differently from the target $[d(TG_4T)]_4$ and $d[AG_3(T_2AG_3)_3]$ G4-DNAs in K^+ and Na^+ solutions.[77] Out of these carbamoyl derivatives, one having 5 *N*-methyl-pyrrole rings (**14**) is also called MEN 10716. Dist-A and its 4 *N*-methyl-pyrrole derivative bind with the parallel quadruplex structure $[d(TG_4T)]_4$ in 1:1 stoichiometry in solution containing Na^+.[78] Dist-A and the 4 *N*-methyl-pyrrole derivative bind with the investigated G4-DNA in both solution conditions; conversely, the 5 *N*-methyl-pyrrole derivative seems to have a lower G4-DNA affinity in any case as evidenced from the ITC and ^1H NMR studies.[77] The 4 *N*-methyl-pyrrole derivative, however, showed a 10-fold higher G4-DNA affinity than the duplex DNA.[78]

A number of amide-linked oligo *N*-methyl-pyrroles based on Dist-A molecules, having 2 to 6 pyrrole rings and substitutions at different positions (2,4-substitution vs 2,5-substitution), were also synthesized. These interact with a human intramolecular G4-DNA $d[G_3(T_2AG_3)_3]$.[79] Several of these molecules show an enhanced ratio of binding constants toward the G4-DNA vs the duplex DNA compared to that of Dist-A itself or its analogue with a 2,5-disubstituted pyrrole system. The G-quadruplex binding affinity increases with the number of *N*-methyl-pyrrole units of this class of ligands, suggesting that such an interaction is consistent with a mixed groove/G-quartet stacking mode of binding. A qualitative molecular model of a six-repeat pyrrole polyamide molecule docked onto the crystal structure of a human 22-mer G-quadruplex structure is shown (Figure 6),

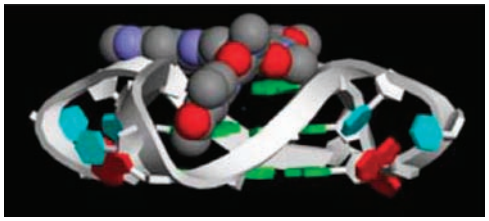

Figure 6. Qualitative molecular model of a six-repeat pyrrole polyamide molecule docked onto the crystal structure of the human 22-mer G-quadruplex structure. Figure adapted from the ref 79, with permission of the Royal Society of Chemistry.

where the two repeats of the polyamides located in a G4-DNA groove and the others stack on a terminal G-quartet surface.[79]

Oligoamides having up to 3 *N*-methyl-pyrrole (Py) or -imidazole (Im) units were shown to have less effect on the G-quadruplex stability than other known end-stacking G4-DNA ligands like Tel 01, porphyrin, DAPER, PIPER, and so forth.[80,81] In contrast, oligoamides having 4 or more rings induce stabilization of the G-quadruplexes.

Dist-A derivative MEN 10716 (**14**, Figure 5) inhibits the human telomerase enzyme in a dose-dependent manner.[82] Exposure of human melanoma *JR8* cell extracts and *U2-OS* human steogenic sarcoma cell line extracts to MEN 10716 induced a dose-dependent inhibition of the telomerase activity, with an IC_{50} value of 24 ± 3 mM. A chronic exposure of the *H460* nonsmall cell lung cancer cells to the above drug (100 mM every other day for 50 days) induced a consistent inhibition (>85%) of the telomerase activity.[82] Inhibition of the telomerase by Dist-A and its 2,5-disubstituted derivative was also determined using a modified PCR based TRAP assay.[79] These two compounds were examined in this experiment up to a concentration of 100 μM, and concomitant controls were carried out to ensure that there was no interference with the correct functioning of *Taq* polymerase at these concentrations. Dist-A exhibited a $^{tel}EC_{50}$ value of ~25 μM, whereas its 2,5-disubstituted derivative showed no telomerase inhibitory activity even at 100 μM. However, both compounds show significant PCR inhibition, suggesting that the positive result obtained in the TRAP assay is not necessarily due to the telomerase inhibition and other mechanisms are possible.[79] Dist-A also inhibits protein interactions with the G4-DNA. The utility of Dist-A as a probe of the G4-DNA−protein interactions was thus demonstrated and two separate modes of the protein−G4-DNA interactions, which may be analyzed by the sensitivity to Dist-A, were proposed.[74]

An uncharged Dist-A analogue, where the major change in its structure involved the replacement of the amidinium group by an uncharged *N*-methyl amide moiety (**15**, Figure 5), was used to probe the importance of the unique Coulombic interactions in the Dist-A/$[d(TG_4T)]_4$ complex formation.[83] Removal of the positively charged terminal group results in an exceptional ligand−G4-DNA complex formation in which the grooves as well as the 3′-end of the telomeric DNA are occupied. Furthermore, a lack of charge in the ligand molecule does not affect the relative orientation of two molecules of the analogue forming a dimer. The positively charged amidinium moiety of the Dist-A interacts with the phosphate groups of the G-quadruplex, providing a favorable (although small) enthalpic contribution, while the analogue, where the amidinium group is replaced by the uncharged *N*-methyl amide moiety, cannot interact with electrostatic complementarity.[83] The binding affinity of the uncharged analogue with the G4-DNA as

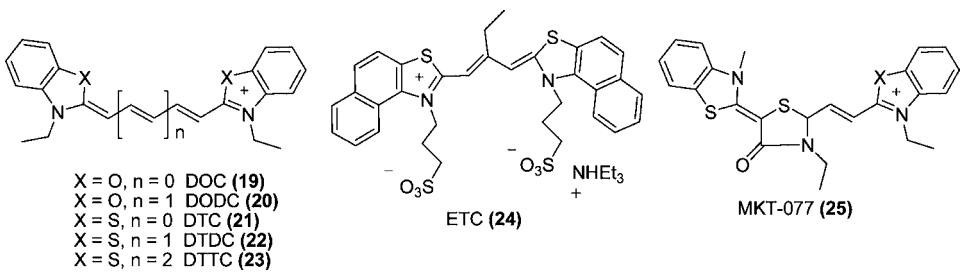

Figure 7. Chemical structures of common carbocyanine dyes (**19**−**23**), dyes ETC (**24**), and MKT-077 (**25**) synthesized based on cyanine dyes.

measured from ITC is 9×10^5 M^{-1} at 25 °C. However, no comparison of binding affinity with Dist-A was given.

Some anthracenyl isoxazole lexitropsin conjugates (**16**, **17**; Figure 5) were developed recently. Plausible binding modes of these compounds after energy minimization have suggested that one of them binds with the G4-DNA via intercalation, by displacing a guanine. Other compounds bind via a stacking mode with the G-tetrad.[84] G4-DNA formed by the sequence d[5′-CATGGTGGT$_3$(G_3TTA)$_4$CCAC-3′] quench the fluorescence of ligands suggesting a $\pi-\pi$ stacking interaction of the ligand with the G-tetrad. Some planar U-shaped biaryl polyamides (**17**, **18**) possessing high selectivity toward the G-quadruplex over the duplex DNA were also developed.[85] Compound **17** shows high selectivity for the human telomeric G4-DNA, while compound **18** is selective for two *c-kit* G4-DNAs.

Cyanine Based Ligands. Carbocyanine dyes (**19**−**23**, Figure 7) represent another class of MGBLs which are often studied with the G4-DNA. These compounds form complexes with the minor grooves of the duplex DNA, and show pronounced exciton splitting in their ICD spectra.[30,86] Stacked species are important for the recognition of G4-DNA. Studies with the duplex DNAs demonstrate that ligands that bind DNA as stacked dimers have enhanced binding affinity/selectivity over similar ligands which bind as monomers.[86] Similar stacking in the G4-DNA grooves seems to be a favorable way to selectively recognize different G4-DNA structures. Such a mode of interaction probably optimizes through an induced fit component, between the stacked ligands and the G-bases of the G-quadruplexes. On the basis of different spectroscopic studies, 3,3′-diethyloxa-dicarbocyanine (**20**, DODC) was shown to bind with the grooves of a dimeric hairpin G-DNA.[87] DODC−G4-DNA interaction resulted in some unique spectral signatures, e.g., a new absorbance peak (534 nm), an ICD signal (534−626 nm), a quenching of the fluorescence intensity of the ligand on excitation with the visible light, and a strong energy transfer from DNA.[87] In the electrophoresis experiments, only the G4-DNA bound to DODC were detectable above the background. However, neither the duplex DNA bound to DODC nor the free G4-DNA was observable. G4-DNA was detectable even in the presence of a high concentration of the duplex DNA. This demonstrates the ability to detect a small amount of dimeric hairpin quadruplex in the presence of a large amount of the duplex DNA. The concentration ratio was limited by the capacity of the gel.[87] Satellite hole spectroscopy studies also supported the groove-binding model for DODC with the G4-DNA.[88]

A different study using competition dialysis assay suggests that DODC has a preference for the triplex DNA compared to the G4-DNA. Although no structural information is available on this molecule in the DNA-bound form, it is possible that due to the geometric features, DODC could be binding to a G-quadruplex groove rather than stacking on a G-quartet. If this is indeed true, then its affinity should be highly sensitive to the groove dimensions, which vary along with the type of the G4-DNA.[62] Electrospray ionization mass spectrometric patterns also support the diethylthiocarbocyanine iodide (**21**, DTC) binding with the G4-DNA grooves.[75,89,90] Dissociation patterns of the DTC/G4-DNA complexes resemble those of Dist-A. Therefore, it is predicted that DTC interacts with the parallel G4-DNA [d(T_2G_5T)$_4$] through groove-binding.[75] Tel01 was found to interact via end-stacking with the G4-planes of the G4-DNA.[75] However, binding to G4-DNA and telomerase inhibition by only DTC among all the carbocyanines tested appears to be a result which is ambiguous.[90]

SPR studies indicate that Dist-A binds very weakly to the telomeric DNA sequence attached on a support.[72] The binding of Dist-A is likely to be seen in the experimental methods such as NMR, which employs high concentrations of the ligand.[72] Screening experiments with other MGB polyamides also did not reveal any significant G4-DNA interactions. These results are contrary to other reports, where Dist-A and its analogues have been studied with the G4-DNA using NMR and ESI-MS.[71−73,75] DODC was shown to have higher affinity toward the G-quadruplex grooves via stacking, as suggested by the negative ICD spectra, and is presented as a more promising G4-DNA groove-binding model system.[91] Dist-A did not show any induced signal. A new fluorescence-based study of the G4-DNA ligands was reported using DODC and DTDC as reporter molecules along with other G-quadruplex ligands.[92] *N*-Methyl mesoporphyrin IX (NMM), DODC, and DTDC (**22**) allow the monitoring of several structural features of G4-DNA, as these molecules detect G4-DNA structure specifically. These three molecules were used as reporter molecules to screen six G4-DNA ligands. The fluorescence intensity of the reporter increases when it binds to the G4-DNA. Addition of ligands can either enhance or diminish the fluorescence due to the reporter molecule. DODC and DTDC also exhibit ICD upon binding to the most of the G4-DNAs indicating groove binding. NMM competes with DODC and DTDC in binding with d($G_2T_2G_2TGTG_2T_2G_2$). NMM also competes with DODC in binding with d(T_2AG_3)$_4$.[92] Recently, binding of a novel cyanine dye 3,3′-di(3-sulfopropyl)-4,5,4′,5′-dibenzo-9-ethylthiacarbocyanine triethylammonium salt (ETC, **24**, Figure 7) was studied with unimolecular human telomeric G-quadruplex, owing to its common properties with the G4-DNA ligands.[93] ETC also has specific interactions with an intramolecular telomeric G4-DNA via end stacking.[94] ETC stacks on one specific end of the hybrid, some selective parallel and antiparallel G-quadruplexes, or on both ends of the normal parallel G4-DNA. Nearby loop structures also play an important role in the binding. Some specific lateral or unusual propeller loops "snatch" part of ETC molecule and facilitate stacking on the end G-quartet, while the diagonal or special lateral snap-back loops block the access of ETC molecule to the G4-DNA frame.

Several *in vitro* G4-DNA related biological activities of MGBLs were also reported. G-quadruplex ligands, e.g., TMPyP4, NMM, coraylene, Dist-A, DODC, and DTC, along with perylene diimides (PDI) were investigated as inhibitors of the G-quadruplex and the duplex DNA helicase activities of the T-antigen (T-ag).[95] G-quadruplex helicase activity was found to be strong and similar to that of duplex DNA helicase activity of the T-ag. Analysis of the SV40 genome demonstrates the presence of sequences that may form intramolecular G-quadruplexes, which are presumed to be natural substrates for the G4-DNA helicase activity involving the T-ag. Dist-A, which does not inhibit the G-quadruplex unwinding activity of bloom syndrome homologue (BLM) gene, was found to be a weak inhibitor of the G4-DNA unwinding activity of the T-ag. DODC weakly inhibits the G′2 (bimolecular G-quadruplex) unwinding activity of the T-ag. A number of other G4-DNA ligands including Hoechst 33258 and DTC were found to be, however, not as effective inhibitors of the G4-DNA unwinding activity of the T-ag. PDIs were found to be potent and selective inhibitors of the T-ag associated G4-DNA helicase activity.[95] The effect of DODC on telomerase activity was also explored.

It reduced telomerase activity in pheochromocytoma PC-12 cells in a dose-dependent manner (10−100 mM) after 12 h of treatment.[96]

In another study, DODC inhibited telomerase in nasopharyngeal carcinoma NPC-Tax (a control NPC cell line), but not in NPC-TW01 cells, when studied with the extracts from cells, which were treated with 0.7 mM of DODC for 1−3 days. On direct addition of DODC to the study media, inhibition was observed at 10 mM for the NPC-Tax and 500 mM for the NPC-TW01 nasopharyngeal carcinoma cells, respectively.[97] DODC itself was able to induce apoptotic cell death, although it did not reduce the telomerase activity in the NPC-TW01 cells. Instead, DODC induced the cell apoptosis via a mitochondrion-mediated mechanism. DODC inhibited the uptake of another mitochondrial probe 3,3′-dihexyloxacarbocyanine iodide. By proteomic comparative analysis, it was apparent that DODC induced the increase of prohibition level in the mitochondria, indicating an occurrence of the mitochondrial perturbation. Moreover, DODC increases the levels of p53 and an 18 kDa truncated Bax on mitochondria, which in turn potentiates the release of cytochrome *c* for the activation of caspases.[97] In a different study, at the tested concentrations, DODC had little effects on the hydrolysis of the substrates under question in presence of either K^+ or Li^+ ions, or on the stability of the $d[T_{24}(G_3TTA)_3G_3]$ G4-DNA and on the electrophoretic mobilities of either $d[T_{24}(G_3T_2A)_3G_3]$ or $d[T_{24}GTGTGAGTG_2AG_2TGTGAG_2T]$.[98] DODC did neither inhibit the exonuclease hydrolysis nor the telomerase activity.[97] It also destabilized the G4-DNA under experimental conditions. The synergistic effects between low-dose arsenic trioxide and DODC on the apoptosis of HT1080 cells were also investigated.[99] Results reveal that low-dose arsenic could block cell cycle arrest at the G2/M phase and induce apoptosis, whereas DODC could block cell cycle arrest at the G0/G1 phase but does not induce apoptosis. However, cells pretreated with DODC showed greater sensitivity to arsenic than untreated cells. DODC alone could induce the hairpin G-quadruplex formation and inhibit the telomerase activity in a dose-dependent manner. It has been predicted that DODC can synergistically enhance the apoptosis induced by arsenic, suggesting that increased cell senescence in response to arsenic is induced by an altered telomere state rather than by a loss of telomerase.[99] Rhodacyanine dye MKT-077 (**25**, Figure 7) has also been reported to have telomerase inhibition activity.[100] Due to its structural similarity with DODC, an interaction with the G4-DNA may be possible for the activity.[62]

The binding mode of DODC with the G4-DNA is a matter of considerable interest. One can imagine four possible modes of noncovalent association: (a) intercalation between the G-quartets, (b) binding through the grooves, (c) interaction with the thymine loops, and (d) outside binding. The possibility of outside binding can be easily eliminated on the basis of the fluorescence collisional quenching data and the ICD spectra. On the basis of the ICD spectra obtained for DODC complexed with two different G-quadruplexes $[d(G_4T_4G_4)]_2$ and $[d(G_3T_4G_3)]_2$, which have similar loops, binding only to the loops is overruled. Furthermore, the dye does not bind specifically to the unimolecular hairpin Watson−Crick duplex containing a T_4 loop. Thus, groove binding and intercalation remain as the two plausible modes of specific binding.[87] On the basis of preliminary NMR data, DODC is suggested to bind within the loops of the G4-DNA.[92] CD and fluorescence competition studies with these ligands also suggest binding with the loops of the G4-DNA. Atomic resolution data are, however, needed to unambiguously determine the structures of the G4-DNA-cyanine dye complexes.[92] However, for the cyanine dye−duplex DNA complexes, the appearance of ICD spectra is due to the groove binding. Other classical MGBLs (berenil, DAPI, SN-18071, etc.) have still not been examined for their interaction with the G4-DNAs.

CONCLUDING REMARKS AND PERSPECTIVES

Telomeres, *r*DNA, and promoter regions have been identified as potential targets, and there are over 350 000 predicted sequences in the genome that can fold into G-quadruplex structures, raising the daunting task of determining selective targets for these drugs.[17,101] G-quadruplex ligands acting on both telomeric and nontelomeric quadruplexes have significant biological importance and quite a few of them are in clinical trials.[18,29,102,103] Few examples include G4-DNA binding ligands, RHPS4,[104] telomestatin,[105] derivative of telomestatin HXDV,[106] BRACO-19,[107] porphyrin TMPyP4,[15] quarfloxin (CX-3543),[108] 307A,[109] triazines,[110] and so forth. Quarfloxacin was originally developed to bind to the c-myc promoter. Instead, it appears to bind ribosomal quadruplexes, interfering with the binding of the protein nucleolin, which normally binds to the G-quadruplex structures, leading to cell death in cancerous cells. Quarfloxin is in the phase II clinical trials for the treatment of carcinoid/neuroendocrine tumors.[108,111] However, it is still a long way off to get G4-DNA binding ligands as successful anticancer agents.

As discussed earlier, the ligands which bind to the G-quadruplex grooves also exert stabilizing effects. The grooves of the G4-DNA structures have different characteristics than the grooves of the duplex DNA, and thus, the ligands that bind only with the grooves of the G4-quadruplex selectively should be able to recognize DNA in a structure-specific manner with high affinity. DNA minor groove binding ligands are known to be able to distinguish the variable groove widths engendered by a specific sequence.[112] G4-DNA structures give many variations within the generic theme of a G-quadruplex forming motif. Therefore, ligand design and development in the future would necessitate dealing with more complex issues of structural variations. Thus, this should not be limited to duplex versus G4-DNA distinction only. Availability of alternating groove widths in the G-quadruplexes in this regard may provide a platform toward selective targeting of specific topological and conformational forms of the G4-DNA. Ligands capable of spanning two or more grooves in the G-quadruplex may be able to distinguish one form from another based upon the appropriate groove dimensions and their specific orientations. Furthermore, "designed" MGBLs should be capable of selective targeting as well. To find new quadruplex groove binding agents, the molecular nature of the G-quadruplex grooves must therefore be considered judiciously. Interestingly, all known grooves of the G-quadruplex structures that have been characterized are chemically and conformationally quite different from the minor grooves of the duplex DNA. Thus, the recognition of the grooves of these nucleic acid structures is supposed to give a higher degree of selectivity over other types of DNA structural motifs, which may not be possible in the case of most of the existing end-stacking G-quadruplex ligands. Therefore, to understand the structural and conformational requirements for the recognition of the grooves of G4-DNA,

many of the existing MGBLs should be chemically modified logically.

Toward the success of the G-quadruplex binding ligands at the genetic level, the hypothesis proposed by Huppert is relevant,[111] in that the fusion of the G4-DNA recognition molecules with systems that bind to specific sequences of the duplex DNA are feasible. Tethering MGBLs that are able to recognize six or more contiguous DNA base pairs (e.g., terbenzimidazoles)[37−39,43] or longer "designed" Py/Im polyamides[33−36,39] might provide an increase in the specificity and binding affinity depending on the nature, length, and/or flexibility of the linkers used.

Some of the MGBLs discussed so far bind with the non-natural or model G-quadruplexes like $[d(TG_4T)]_4$ and also those made from the modified nucleotides.[71−78] These MGBLs may not be of much use in developing a drug. However, MGBLs that bind with the natural G-quadruplexes may be of significant medicinal importance. These include cyanine dyes,[81−88] oligopeptide-based on distamycin analogues, in particular, the longer oligopeptides,[69−73] and certain benzimidazoles.[64−70] Longer oligopeptides lose helical phase matching with the grooves of the duplex-DNA and thus prefer to bind with the non *B*-DNA structures. Carbon skeleton of benzimidazoles,[69,70] oligopeptides,[85] and cyanine dyes may be suitably crafted to make them G-quadruplex DNA-specific. Thus, MKT-077, a compound structurally similar to DODC, is already being used in clinical trials as an anticancer agent.[113] It shows selective cytotoxity toward cancer cells,[114] which may be due to its ability to localize specifically on the mitochondria of the cancer cells.[113] Examples of G-quadruplex binding MGBLs discussed in this review should therefore serve as a useful source for the design of a whole new class of highly selective groove-binding ligands with attractive biological properties.

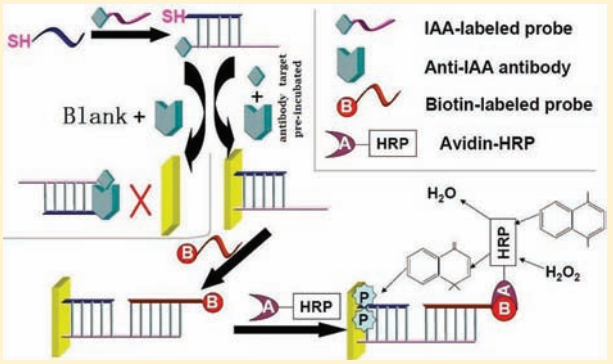
Supporting Information

ABSTRACT: Identification and quantification of small organic molecules capable of binding to a protein of interest with reasonable affinity and specificity is a central problem. Via developing DNA-encoded recognizing probe, we validate a proof-of-principle for constructing of small target-to-DNA conversion that screens the small molecule–protein interaction. Successful identification of β-indole acetic acid, abscisic acid, or 2,4-dichlorophenoxyacetic acid/corresponding antibody binding implies its fascinating potential for interrogating small molecule/protein interaction.



The identification and quantification of small organic molecules capable of binding to a protein of interest with reasonable affinity and specificity is a central problem in chemistry, biology, and medicine. Although spectroscopic and chromatographic measurements for the exploration of small-molecule/protein interaction and detection of small molecules have achieved impressive results,[1−5] these traditional techniques generally require expensive instrument, specific signal reporters, or cumbersome assay procedures. Thus, the development of a universal protocol for the convenient, cost-effective, sensitive, and selective detection of small molecules remains a compelling need. Considering the enormous capabilities[6−11] of oligonucleotides in site-specific labeling, sequence-specific biobarcoding, versatile amplification, and isolation, the DNA-encoded oligonucleotide probe has emerged as an appealing tool for the construction and screening of large chemical libraries.[12] However, for the existing aptameric screening systems, the ability of aptamer probes to convert the probes/target molecule binding into a measurable signal is highly dependent on their conformational change originating from the formation of the target binding pockets.[5,13−17] Moreover, aptamers are the greatly appreciated binding molecules against the corresponding targets. To meet the requirements of many technological applications, it would be desirable to introduce a universal signaling scheme for detecting some organic ligands with low molecular weight (e.g., oligonucleotides and non-nucleic acid biomolecules).[18] Inspired by the biological behavior change (for example, susceptibility to enzymatic cleavage[6,19] or polymerization[20]) of original or modified oligonucleotide probes upon binding to specific target molecules, utilizing microgravimetric quartz-crystal-microbalance, we proposed a novel signaling scheme for investigating the interaction of small molecule with specific protein. This screening scheme is based on the design of a target molecule-linked DNA hybrid that is responsible for the transduction of common immunoreaction into the specific oligonucleotide detection. The present "signal-on" microgravimetric biosensor can not only screen the small target molecule, but also provide quantitative analysis with desirable analytical features (e.g., low detection limit, high sensitivity, and selectivity, as well as a wide dynamic range and cost-effectiveness).

Phytohormone screening is considerably significant to agriculture, horticulture, and other related fields. Considering the pressing needs for the precise and sensitive measurements, β-indole acetic acid (IAA), a small plant hormone molecule regulating the plant growth was used as the model target molecule for testing proposed analytical technique. It is well-known that the characteristics of sensing platform are highly dependent on the signaling format. Namely, the "signal-on" reporting mechanism is superior to the "signal-off" one in terms of the detection sensitivity and working range. Although the sandwich immunoassay format is promising for sensitively detecting the target antigen, small molecules cannot simultaneously interact with two antibodies, precluding their inter-

rogation by "signal-on" two-site immunoassay including the powerful "immuno-PCR" amplification technique.[21] In the present communication, the change in the self-assembly behavior of thiolated small molecule-tethered DNA hybrid, which is closely related with the presence of target analyte in sample, was employed to translate the interaction of antibody with small molecules into microgravimetric sigal. The DNA sequences involved in the encoding oligonucleotide-based sensing are detailed in Table 1. The screening principle of

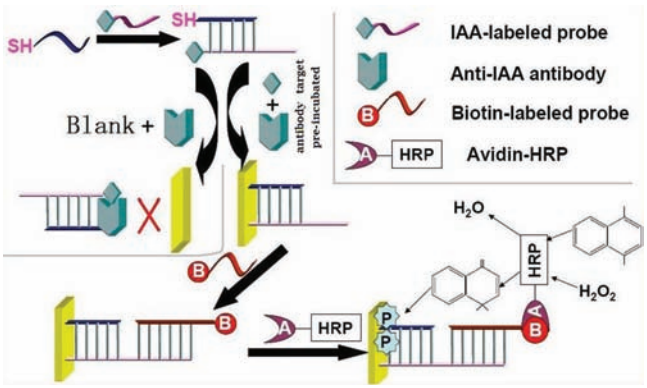
Table 1. Oligonucleotides Designed in This Study[a]

Oligonucleotide name	Sequence (5'-3')
Assembling probe	GGCAGGATCGGACAGC-SH
Steric hindrance-related probe (recognition probe being attached to IAA)	NH_2-GCTGTCCGATCCTGCCACTCTGACGAGCT ACTGACC
Signaling probe	Biotin-TTTGGTCAGTAGCTCGTCAG

[a]The assembling probe is modified with thiol group at the 3′ end to self-assemble onto the surface of quartz-crystal-microbalance (QCM). The steric hindrance-related probe is functionalized with amino groups at the 5′ end in order to prepare recognition probes by being covalently attached to IAA molecule containing a COOH moiety; the signaling probe is biotinylated at the 5′ end to capture the avidin-HRP conjugate. Because two underlined segments are complementary to each other as the shaded parts behave, the three sequences are designed to form the sandwich hybrid complex via hybridization reaction.

the microgravimetric assay platform that converts the presence of target small molecules into the appearance of DNA probes (defined as small target-to-DNA conversion), as well as the signaling procedure, is illustrated in Scheme 1. The proposed

Scheme 1. Schematic Diagram of the Amplified Detection of IAA



scheme is essentially a competitive assay between the labeled and free small molecule, which compete for binding the antibody protein. When adding target molecule sample, the free IAA can bind to the anti-IAA antibody protein by preincubating in a solution, inhibiting the formation of antibody/IAA-labeled probe (also called recognition probe)/assembling probe complex in the subsequence step. Namely, the IAA attached to recognition probe/assembling probe hybrid cannot interact with antibody because the binding site of antibody is occupied by free IAA. In this case, the thiol of assembling probe can randomly run into the quartz-crystal-microbalance (QCM) surface, resulting in the s-Au bond. Thus, the recognition probe is easily captured on the surface. It is well-known that the rigid DNA duplex is easier to immobilize onto the gold substrate in a spatially ordered manner than a flexible single-stranded DNA molecule. Naturally, during this step, not only is the intrinsic self-assembly behavior of the thiolated probe maintained, but hybridization of this probe with the recognition probe can also improve the capability to self-assembly on the QCM surface. Subsequently, the biotin-labeled probe can be immobilized on the resulting surface of QCM (also used as an electrode when performing the electrochemical measurements to characterize the sensing interfaces at different stages of target detection) via specific hybridization to the fragment close to the 3′ end. As a result, the avidin-HRP is capable of being adsorbed onto the resultant QCM via the biotin−avidin bridge. In the presence of H_2O_2, the HRP-biocatalyzed oxidation of 4-chloro-1-naphthol occurs and the precipitation of the insoluble product is produced on the support surfaces, generating an enhanced mass or electrochemical signal (this process is called the signal amplification step, only involved during evaluation of the features of the proposed microgravimetric sensing platform). In contrast, in the absence of IAA in the sample, the assembling probe/recognition probe conjugate can interact with antibody protein, forming the triplex. Because the thiol group is designed to be in close proximity to the terminal IAA of recognition probe, binding of the recognition probe to the antibody protein, a large biomolecule, can cause steric hindrance serving as the barrier to the self-assembly of a thoil-labeled assembling probe/recognition probe hybrid. As a result, encoding DNA is not adsorbed onto the QCM surface. This is capable of inhibiting the subsequent transducing reaction and amplification process. In this case, no signal is observed. Apparently, via encoding the information on the IAA/antibody interaction and decoding the appearance of DNA recognition probe, a versatile amplification route for exploring small molecule/protein interaction in a "signal-on" manner is developed. The developed small target-to-DNA conversion scheme is described in detail in the text; the characterization of the resulting microgravimetric transducer is represented; the screening ability is validated and primary application is evaluated to afford convincing evidence for the reliability and practicality of the proposed fluorescence assay.

The rationality of the proposed design for screening the small molecule/protein interaction is validated by the impedance data. As shown in Figure 1, even if the biomolecules confined on the electrode surfaces are different from each other, each attachment of the molecules involved can consistently induce a considerable increase in the electrochemical impedance, indicating the expected attachment and bioactivity of surface-confined biomolecules. Considering the intrinsic feature of biomolecules and binding affinity at different stages, it is reasonable that a different change in impedance is observed. For example, compared with the difference between lines a and b, line c does not exhibit a significant increase. This should be attributed to the fact that the signaling probe has no large moiety (e.g., HRP) and is immobilized via hybridizing to the surface-confined recognition probe rather than self-assembling directly onto the electrode surface as the thiolated probe/recognition probe hybrid does. Moreover, due to the shorter base sequence, the amount of its negative charge is smaller than the overall value of assembling probe/recognition probe conjugate, generating the comparatively weak electrostatic repulsion between dissolved ferricyanide and resultant electrode. In contrast, substantial increase in impedance is observed for line e compared with all other lines. This is

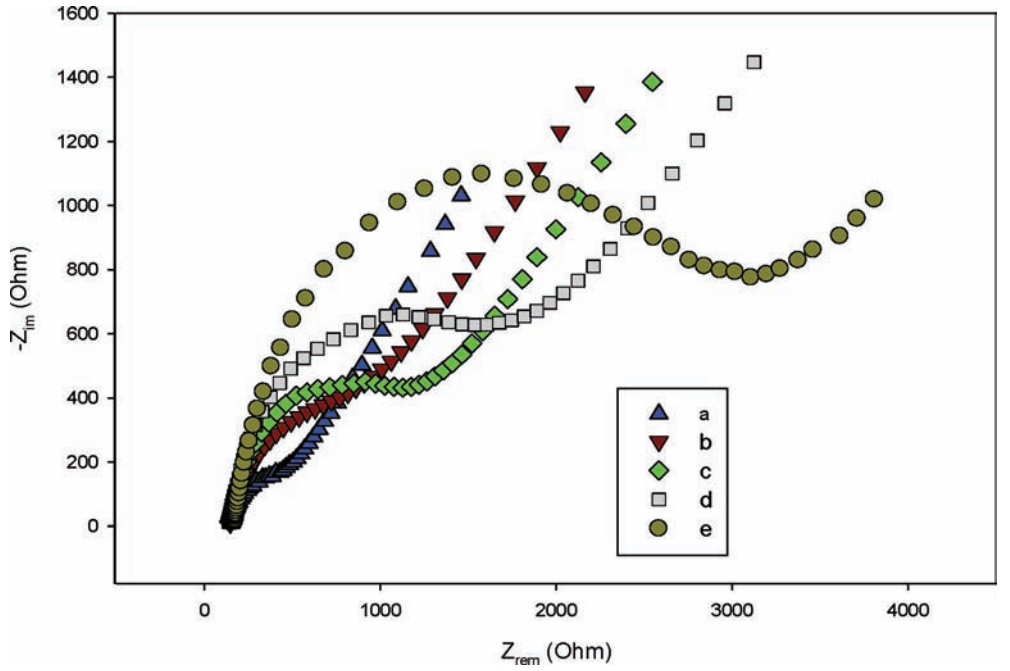


Figure 1. Nyquist diagram of Faradic impedance measurements collected for the same QCM with different modified surfaces corresponding to the following: (a) the bare QCM; (b) the self-assembly of the mixture of tube 1 and tube 2 onto the QCM (see the experimental section for the details); (c) hybridization of the surface b with signaling probe; (d) exposure of interface c to HRP-avidin; (e) the same as interface d but with the biocatalyzed deposition in the presence of 1×10^{-3} M 4-chloro-1-naphthol and 1.5×10^{-4} M H_2O_2. The IAA concentration of 20 μM is involved in this section.

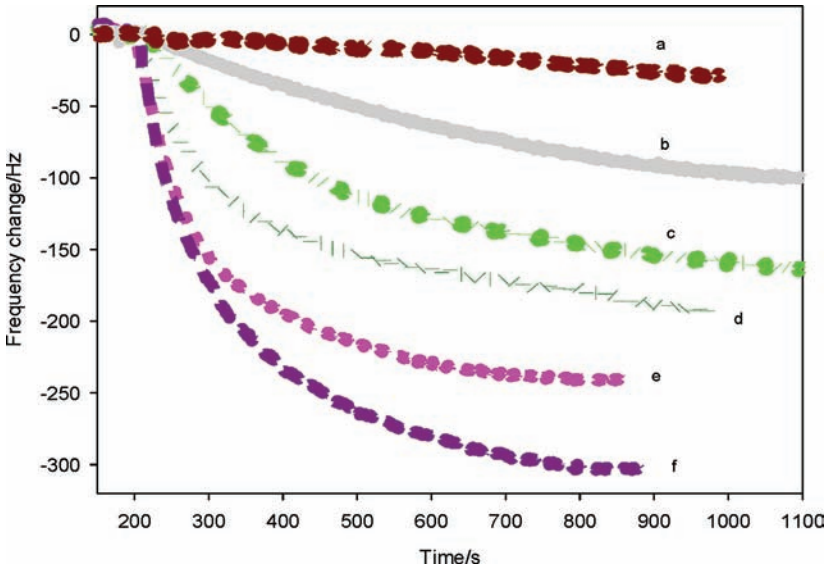

Figure 2. Capability of microgravimetric quartz-crystal-microbalance transducer. The lines indicate typical characteristics of frequency responses in the absence (a,b) and presence of 0.2 μM IAA (c), 0.4 μM IAA (d), 2 μM IAA (e), and 20 μM IAA (f) under given conditions. Note that line a corresponding to the blank sample has no HRP-avidin compared with line b.

because the biocatalyzed precipitation of the insoluble product can directly electrically insulate the electrode surface. As an effective technique to probe the interface properties of functionalized electrodes, the measured data by impedance spectroscopy provide the strong evidence that the proposed screening strategy can efficiently work.

To confirm the feasibility of the DNA encoding-based sensing scheme, the interactions between the IAA at the different concentrations and the constant concentration of antibody protein are monitored in a real-time manner. The measured data are shown in Figure 2. The frequency change directly reflects the amount of biocatalyzed insoluble precipitation by avidin-HRP, which is associated with the content of surface-confined assembling probe/recognition probe hybrid that is highly dependent on the number of target in solution. Thus, the frequency shift is employed to evaluate the small molecule/protein interaction. The experimental data clearly shows that the presence of IAA can rapidly induce the frequency shift especially in the first period of time (e.g., line c), and the higher concentration of IAA results in the larger

dx.doi.org/10.1021/bc200086c | *Bioconjugate Chem.* 2011, 22, 2369–2376

frequency change (e.g., line e), indicating a success in screening the interaction of small molecules with protein. Assuming there is a dynamic equilibration between IAA/antibody complex and free IAA and antibody, increasing the concentration of IAA in the sample can promote the formation of antibody/IAA complex. Naturally, this decreases the amount of antibody that can bind to the IAA-labeled assembling probe/recognition probe hybrid. Consequently, more recognition probes can be immobilized onto the substrate surfaces, finally generating a larger frequency shift. Although the blank sample produces a slight frequency shift (line b), it can be easily distinguished from target samples even at the low concentration (line c). The unwanted frequency change should be attributed to the nonspecific adsorption avidin-HRP onto the QCM surface and/or other factors. Frequency shift upon the blank is expected to be alleviated (see the following section for the further discussion). Taking into account the observation that frequency shift corresponding to target samples especially at the high concentration (e.g., line f) tends to stabilize after 800 s, this incubation time is selected in the subsequent experiments (this data-processing method is called the steady-state measurement) though the blank sample (line b) can make the crystal frequency further rise after this response point.

To exactly evaluate the utility of the small target-to-DNA conversion-based sensing protocol for the quantification of small molecule, the IAA at various concentrations were detected under identical conditions and a dose−response curve was constructed. The results are described in Figure 3.

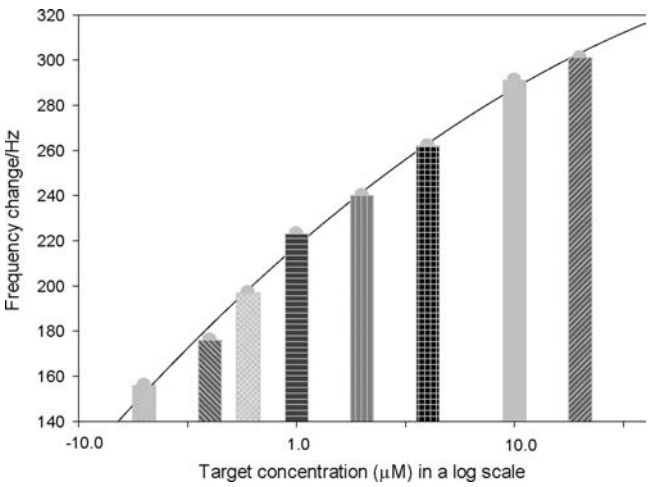

Figure 3. Calibration curve describing the relationship between the frequency responses and the concentration of IAA under given conditions. The curves are expressed as the frequency decreases against the logarithm of IAA concentration. The regression equation is $Y = 217.6 + 83.57X - 13.71X^2$ with a correlation coefficient of 0.9947, where Y represents the difference between recorded frequency values after and before injecting biocatalytic deposition solution, while X is the logarithm of IAA concentration, respectively. The largest relative standard deviation of three measurements performed for samples is not more than 7.5%. The detection limit is 0.1 μM, which is defined as three times the standard deviation corresponding to the blank sample measurement.

The detection limit is 0.1 μM, indicating a value improved by 9 times to 2 orders of magnitude compared with the previously reported biosensors on the basis of both optical[22] and electrochemical[23] measurements for the detection of the same target molecule. The dynamic response range for IAA is observed to be from 0.1 to 20 μM, suggesting a substantially improved screening capability. The more detailed comparison with two or more other literature works in terms of other assay features is shown in Table S1 of Supprting Information. It is noteworthy that those measurements were carried out under randomly given conditions. The further improved analytical characteristics are expected to be achieved after optimizing the parameters influencing the response signal.

The assay selectivity against several other molecules is depicted in Supporting Information Figure S1. The frequency shift corresponding to nontarget molecules is less than 8.0% assuming that the IAA-triggered signal (the difference between the frequencies of blank and IAA) is 100%. The recovery results provide the immediate evidence that the newly developed piezoelectric transducer shows good quality in accuracy and stability (shown in Supporting Information Table S2).

To validate the universality of the proposed screening strategy, utilizing the same DNA probes, the interactions of the other two small molecules, abscisic acid (ABA) and 2,4-dichlorophenoxyacetic acid (2,4-D), with their respective antibodies were investigated according to the procedure similar to that for IAA assay. The results are shown in Figure 4. Regardless of target species, the frequency change of QCM increases with increasing target concentration (Figure 4A and B). The rise of the frequency shift originates from the fact that more and more assembling probe/recognition probe hybrids are freed. Taking into account the competition between free targets and labeled targets for antibodies, this reflects that the increasing number of target molecules interact with the antibody proteins. The measured results also indicate that the different concentrations of target species in samples can be detected via the developed strategy. Namely, quantification of ABA and 2,4-D can be implemented via the DNA-encoded signal conversion strategy. Strikingly, although no substantial difference (not more than 5%) between the frequency changes at high concentration (e.g., 20 μM) of IAA (Figure 3), ABA (Figure 4A), and 2,4-D (Figure 4B) is observed, the low concentration of ABA or 2,4-D more easily induces the frequency change of QCM. ABA (Figure 4A Inset) and 2,4-D (Figure 4B Inset) at concentration of 0.4 μM can cause the signal intensities of 38% and 35%, respectively, while IAA at the same concentration only leads to the signal intensity of 24% (Figure 4C). From this, one can infer that more desirable analytical characteristics could be achieved when the DNA-encoded signal conversion strategy is employed to detect ABA and 2,4-D. These experimental results, as well as comparative data, validate to a great extent the universality and intriguing assay capability of the developed screening strategy.

In the present work, a successful "signal-on" sensing strategy possessing the desirable signal amplification capability is proposed for screening the interaction of anti-IAA antibody with IAA and quantitative detection of IAA. Along this line, a proof of concept is for the first time presented for other small molecules of interest including chemical and biological species via utilizing steric hindrance-mediated behavior change (e.g., self-assembly and intermolecular binding) of DNA oligonucleotides. Oligonucleotides serve as the information-encoded molecules during the small target-to-DNA conversion. Decoding the oligonucleotides involved can unambiguously screen the small target/protein interaction. This not only achieves a "signal-on" response mechanism, but also circumvents the drawbacks usually encountered by the conventional small molecule assays, facilitating the design of a sensing

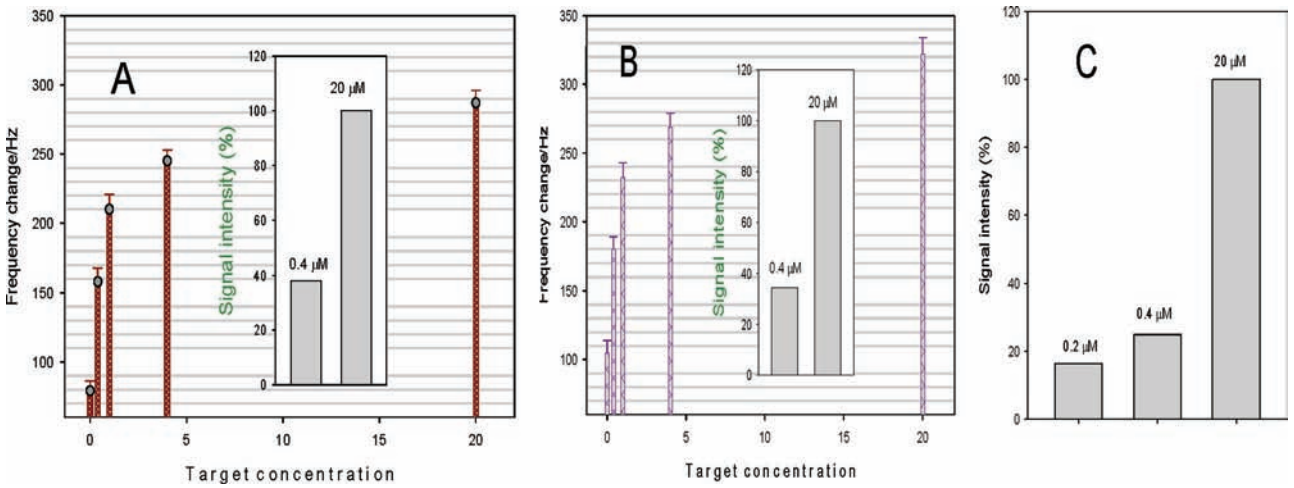

Figure 4. DNA-encoded signal conversion for screening the interaction between ABA (A), 2,4-D (B), and their respective antibody protein. The signaling procedure similar to that for IAA assay was employed. The error bars represent standard deviations of three measurements performed for each sample. To evaluate the capability of the sensing strategy to investigate the different small molecules, the largest frequency shift induced by the highest concentration of targets was assigned as 100%. On the basis of this assumption, the frequency changes corresponding to the low concentration of targets were accurately calculated. Utilizing this method, the data obtained from the ABA, 2,4-D, and IAA assays are depicted in A Inset, B Inset, and C, respectively. The data in C are estimated from Figure 3.

scheme and a screening procedure. For example, a considerable amount of immunosensing systems for the detection of small molecules rely usually on anti-immune complex antibodies. Not only are those antibodies difficult to produce, but the systems also exhibit high cross-reactivity with the unliganded primary antibody.[24] Additionally, aptamer probes are attracting increasing attention from analysts and biochemists, and substantial research efforts have been focused on devising aptameric systems to obtain the information on a wide variety of target species including small molecules. However, even if the sandwich-type assay is not considered that requires each target analyte to be simultaneously bound by two antibodies, the oligonucleotides responsible for recognizing small molecules must have the unique features so that the structure-switching upon the addition of analytes is ensured to occur[5,25−27] or the binding activity can be maintained even after being split into two half-sites.[17,28] In contrast, because the oligonucleotides used in the proposed signaling protocol are the common strands, the encoding DNAs require nothing about the base sequence or second structure. This indicates a general and desired tool holding the appreciated potential for targeting applications. As an attractive sensing strategy for transducing the small molecule/protein interaction into a detectable signal, the small target-to-DNA conversion scheme exhibits other several distinct advantages as listed below.

Because the small molecule/protein interaction is independent of the oligonucleotide sequences as indicated in Scheme 1, the assay systems for different targets could be cost-effectively designed by sharing the DNA probes except for substituting other species for IAA when preparing the recognition probes. The detection of ABA and 2,4-D has preliminarily proven this intrinsic advantage. Moreover, oligonucleotide is suitable for the construction of various recognition probes for specific targets due to its outstanding features, such as huge diversity of unique sequences, sufficient biostability, easy synthesis, and modification. Additionally, different DNA sequences can be used to prepare recognition probes for recognizing target molecules in a one-to-one manner. In this case, employing other measurement techniques, for example, fluorescence spectroscopy, simultaneous detection of different small molecules is expected to be readily achieved after designing a proper signaling scheme (e.g., labeling DNA probes with different fluorescent dyes as described in the following section).

Moreover, after converting the interaction of small molecules with proteins into the emergence of DNA sequences, extracting the information on small molecules can be accomplished via screening the DNA sequences. This signaling strategy represents an appealing avenue for screening the small molecules through various preexisting toolkits available for DNA manipulation. Besides the methods to manipulate DNAs, this makes the seeming impossible measurement techniques for small molecule assays, as well as signal amplification methods, possible. For example, microgravimetric transducer for the detection of molecules with small molecular weight could not be achieved unless anti-immune complex antibodies were devised.[29] However, the detection of IAA based on microgravimetric measurement can be achieved via the developed sensing scheme even without any anti-immune complex antibodies, demonstrating the promising signaling strategy for small molecules of interest. Note that other techniques (e.g., electrochemical and fluorescent measurements) are also capable of executing such a small target-to-DNA conversion and could possibly offer other advantages (for example, assay convenience and high sensitivity). For example, compared with the microgravimetric transducer that only records the frequency change during the signal amplification step, the electrochemical measurement can obtain the overall signal intensity value corresponding to several steps (difference between line a and line e of Figure 1 in which each of the impedance changes from line b to line e are closely associated with the content of IAA in the sample). In this case, the signal-to-noise ratio can increase from 3.6 to 7.0. This intrinsic, attractive feature endows the current sensing scheme with additional advantages, making it a potentially robust tool suitable for screening small molecules.

Polymerase chain reaction (PCR) and rolling circle amplification (RCA) activated by DNA polymerase can dramatically replicate the linear and circularized oligonucleotide strands under specific conditions, respectively, affording

powerful tools for the sensitive immuoassay. Immuno-PCR[30−33] and immuno-RCA[34,35] based immunosensing systems exhibited impressive assay performances (allowing detection of protein analytes with zeptomole[36] or subzeptomole[35] sensitivity), indicating a dominant direction for developing ultrasensitive immunoassays. However, both amplification techniques require cumbersome antibody−DNA conjugation processes to convert the antigen−antibody immunoreaction events into DNA strand detection. To circumvent the aforementioned limitations, although aptamer sequences able to directly recognize their target proteins with high affinity and specificity have recently been used to implement the binding event conversion,[37−39] the formation of sandwich structure is yet the prerequisite for designing the detection schemes. The small target-to-DNA conversion strategy described in the present work facilitates the applications of DNA-based signal amplification biotechnologies (e.g., PCR and RCA) in the small molecule recognition.

Additionally, the small target-to-DNA conversion is based on the change of self-assembly behavior of thiolated assembling probe/recognition probe hybrid due to the increase in steric hindrance between terminal thiol group and the QCM surface upon the IAA/antibody interaction. However, the increase in steric hindrance could essentially inhibit the binding of recognition probe-labeled small species to specific receptors (for instance, interaction between recognition probe-labeled biotin and avidin or enzyme-conjugated avidin), offering the excellent opportunity to develop a variety of optical or electrochemical signaling schemes for sensitively investigating the small molecule/protein interaction. As a conceptual model system for screening the interaction between small molecules and proteins in a homogeneous manner, the small target-to-DNA conversion-based fluorescent assay scheme is described in Supporting Information Scheme S1. Small molecules in sample can compete with the recognition probe-labeled ones for antibody protein, freeing the DNA hybrid. This promotes the binding of biotin conjugated to assembling probe to the QD surface-confined avidin, generating the FRET from QDs to fluorescent dyes. In the absence of target, antibody protein may easily bind to the recognition probe-conjugated small molecule, leading to the increase of steric hindrance that prohibits the interaction between surface-confined avidin and biotin of assembling probe. In this case, the distance between fluorescent dye and QD is great. Thus, FRET does not occur and no optical signal is observed. If encoding DNA sequences modified with different fluorescent dyes are involved in this system, the simultaneous detection of different small molecules could be implemented.

Nevertheless, addition efforts should be made to further improve the analytical capability of the proposed system. As shown in Figure 2, the blank sample can make the crystal frequency continuously decrease even if slowly. The failure to suppress the blank-induced frequency change could be attributed to two possible causes. First, the HRP−avidin conjugates could be adsorbed onto the QCM surface presumably via replacing the preadsorbed glycin molecules rather than the specific avidin/biotin binding reaction. Second, the small amount of assembling probe/recognition probe hybrid could not bind to the antibody protein event in the absence of target under given conditions. This results in the unwanted immobilization of assembling probe/recognition probe hybrid that, in turn, causes the adsorption of HRP−avidin conjugates during the subsequent assay step. Regardless of the anchoring nature, residual HRP−avidin conjugates can slowly catalyze the oxidation of 4-chloro-1-naphthol in the presence of H_2O_2, generating a continuous decrease of crystal frequency. Presumably, the former should be cured via optimizing the incubation time for the interaction between HRP−avidin and biotin of the signaling probe on the QCM surface or via substituting other stronger blockers for glycin molecules, and the latter should be capable of being inhibited via increasing the concentration of antibody protein involved. Another efficient method to suppress the effect of the blank frequency change on the sensing performance is to pursue the maximum reaction rate-based data. Namely, the optimal time response dot (OPD), which is defined as the datum point corresponding to the maximum slope in the real-time measurement curve, is employed for quantitative detection of target molecule. To confirm the rationality of this alternative, the frequency values corresponding to the 250 s response dot, at which the frequency value in line b approaches that in line a, are used to characterize the sensing platform. The calculated data show that the signal-to-noise ration is increased from 3.6 to 15.5, exhibiting superior properties over the steady-state measurement technique. Clearly, it is natural that the screening capability of the small target-to-DNA conversion-based microgravimetric transducer can be further improved if additional efforts are made along the aforementioned directions.

Additionally, the essential requirement for the DNA-encoded signal conversion is that the binding of labeled small molecules to antibody proteins can successfully proceed. Presumably, attachment of oligonucleotides, especially double-stranded oligonucleotides, to the small molecules, could more or less inhibit the immunoreaction between small molecules and antibodies, compromising the capability to transfer the recognition event into the detectable signal. Thus, although three small molecules (IAA, ABA, and 2,4-D) were sensitively detected, the developed signaling strategy could not possibly be applied to analyze any small molecules.

In summary, DNA oligonucleotides are used to mediate the transition of interaction between IAA and specific antibody into the detectable signal, elegantly developing a microgravimetric biosensor for the small molecule detection. Utilizing the transducer, not only can the efficient investigation of IAA/antibody interaction and sensitive quantification of IAA be accomplished compared with the conventional assays, but also the analytical capability is expected to be further improved. More importantly, via encoding and decoding with the aid of the DNA probes, a novel small target-to-DNA conversion concept is represented, paving the way to develop the various sensing platforms for the expansion of IAA detection methods to other small targets and analytes. It seems plausible that the success in developing DNA-encoded microgravimetric transducer for IAA assay provides the proof-of-principle evidence that validates the DNA strand-encoded small molecule/protein recognition process and promotes the application of versatile oligonucleotide-based signaling schemes and relative signal amplification biotechnologies in basic and applied research besides in the genomics.

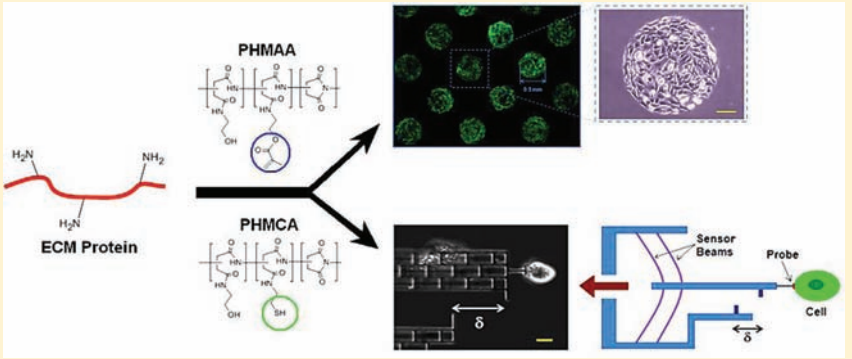
Supporting Information



ABSTRACT: Materials used in various biological applications are often modified with proteins to regulate biomolecular and cellular adhesion. Conventional strategies of protein conjugation accompany monovalent bifunctional protein linkers, which present several limitations in molecular synthesis and protein conjugation. Herein, we present a new strategy of preparing multivalent polyaspartamide linkers in a simple top-down manner, and also demonstrate that the resulting polymer linkers allow us to readily conjugate proteins to both organic and inorganic materials. The top-down synthesis of polyaspartamide linkers was performed by partially opening succinimidyl ring moieties of polysuccinimide (PSI) with the controlled number of nucleophiles reactive to photo-cross-linked hydrogel or gold-coated inorganic materials: (1) Poly(2-hydroxyethyl-*co*-2-methacryloxyethyl aspartamide) (PHMAA) presenting methacrylate was used to micropattern fibronectin or collagen on a hydrogel in order to regulate cell adhesion and growth area on a micrometer scale. (2) Poly(2-hydroxyethyl-*co*-2-mercaptoethyl aspartamide) (PHMCA) presenting thiol functional groups was used to link fibronectin to a gold-coated silicon microelectromechanical probe designed to measure cell traction force. Overall, these multivalent polyaspartamide protein linkers will greatly assist efforts to analyze and regulate the cellular adhesion to and phenotypic activities of a wide array of substrates and devices.

A variety of organic and inorganic materials are widely used in the assembly of in vitro cell culture platforms, biomedical implants, and biomicroelectromechanical systems (bio-MEMS) devices.[1−5] These materials are usually chemically linked with a series of proteins, such as fibronectin, collagen, and antibodies, in order to control cellular adhesion to the materials.[6,7] The number and spacing of these proteins act as insoluble signals to regulate cellular phenotypes.[8−10] Various forms of bifunctional linkers are increasingly used for stable protein conjugation.[11−14] These linkers largely contain two monovalent functional groups: one reactive to a protein and the other reactive to a material. These linkers require multiple modification and purification steps during molecular synthesis and protein conjugation to target substrates, thus necessitating extensive labor. In addition, the number of monovalent linkers should increase in tandem with the amount of protein conjugated to the materials due to their monovalency, which raises concerns over increased cytotoxicity and inadvertent changes in material properties.

To resolve these challenges encountered with the use of monovalent linkers, this study presents a simple top-down synthetic strategy to prepare a polyaspartamide linker with controlled multivalencies of reactive groups to both proteins and materials. In addition, this study demonstrates that the polymeric linkers allow us to conjugate cell adhesion proteins with a single step. Polysuccinimide (PSI) with the average

molecular weight of 22 000 g mol^{-1} was synthesized by acid-catalyzed polycondensation of aspartic acid and used as a starting molecule (Scheme 1 (**I**) and Figure S1a in Supporting Information).[15] PSI consists of a series of succinimidyl units which allow ring-opening nucleophilic addition.[16,17] In this study, we partially opened the succinimidyl rings of PSI with a controlled amount of amine-based nucleophiles that are reactive to a target material, in order to create a polyaspartamide linker in a top-down manner. The protein of interest, which also contains amine groups, would be conjugated to the intact succinimidyl groups of polyaspartamide in the same fashion as the amine-based nucleophilic substituents. This synthetic strategy allows the linker to present a variety of functional groups needed for conjugation to specific

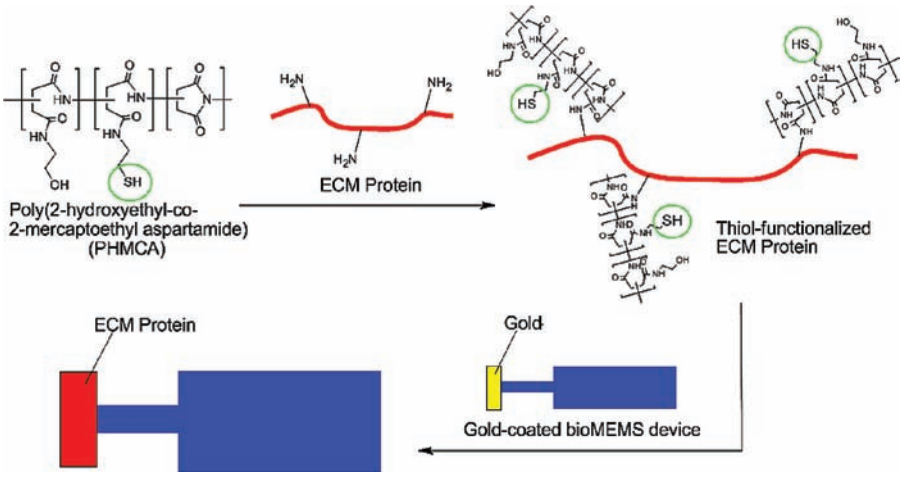
Scheme 2. Synthesis of PHMCA and Its Reaction with Fibronetin (Fn) to Form Fn-PHMCA[a]



[a]Chemically reactive thiol groups are marked with green circles. Fn-PHMCA was used to conjugate Fn to gold-coated bio-MEMS device.

materials simply by using nucleophiles containing different functional groups. Here, we demonstrate the function and versatility of this polyaspartaminde linker with two applications: (1) protein conjugation to a hydrogel using a polyaspartamide linker containing methacrylic groups, and (2) protein conjugation to a gold-coated bio-MEMS device using a polyaspartamide linker containing thiol groups.

First, we synthesized a polyaspartamide linker that can conjugate cell adhesion proteins to a hydrogel that is conventionally used for in vitro cell culture. For this purpose, designated amounts of ethanolamine and 2-aminoethyl methacrylate were added sequentially to PSI to prepare poly(2-hydroxyethyl-co-2-methacryloxyethyl aspartamide) (PHMAA) (Scheme 1 (**II**) and Figure S1b in Supporting Information). The addition of 2-aminoethyl methacrylate to PSI presented the linker with methacrylic groups needed for radical polymerization. The ethanolamine allowed us to control the number of unreacted succinimidyl groups independent of the number of methacrylic groups, and also to render the linker water-soluble by presenting hydroxyl groups.

These hydroxyl groups were not reactive toward unreacted succinimidyl groups of the PHMAA, as confirmed with minimal changes in the peak integrals corresponding to unreacted succinimidyl groups in the ^{1}H NMR spectrum (Figure S1b in Supporting Information). Separately, PSI was mixed with ethylene glycol to further determine whether hydroxyl groups are reactive toward succinimidyl groups. The ^{1}H NMR spectrum of the resulting product was identical to that of original PSI (Figure S1d in Supporting Information), without showing any changes in peaks corresponding to unreacted succnimidyl groups. On the other hand, PSI mixed with ethylenediamine resulted in immediate polymeric precipitation.

The ability of PHMAA to copolymerize with gel-forming monomers was evaluated by examining whether the PHMAA can cross-link acrylamide monomers to form a hydrogel and to further control hydrogel properties. PHMAA was able to cross-link acrylamide to form a hydrogel via in situ free radical polymerization (Figure S2 in Supporting Information). Furthermore, the PHMAA could increase the elastic modulus and resistance to fracture of the hydrogel with the degree of methacrylic substitution (DS_{MA}), the percentage of succinimidyl groups conjugated with methacrylic groups (Figure 1a). We suggest that mechanical properties of the hydrogel should be further tuned by increasing concentrations of acrylamide and PHMAA. In addition, mechanical properties of hydrogels were not significantly changed during incubation in neutral media, which addresses the lack of significant hydrolysis of unreacted succinimidyl units of PHMAA.

PHMAA was then reacted with fibronectin (Fn), a cell adhesion protein, to prepare Fn reactive to a hydrogel (Fn-PHMAA) (Scheme 1, **III**). The DS_{MA} of PHMAA used to conjugate Fn was kept constant at 10%. The reaction between PHMAA and Fn was confirmed by monitoring the decrease of free amine groups quantified with TNBS (trinitrobenzenesulfonic acid) assay (Table S1 and Figure S3 in Supporting Information).[18] Increasing the amount of Fn while keeping PHMAA constant led to a more rapid decrease of amine groups in the TNBS assay. Furthermore, ^{1}H NMR analysis of PHMAA reacted with varying amounts of glycine, as a model amino acid, showed that the degree of substitution of glycine (DS_{Gly}), analyzed with peak integral ratio of the reacted glycine to the total succinimidyl groups, could be varied from 3.6% to 11.9%. These results show that the multivalency of unreacted succinimidyl groups in PHMAA facilitated reactions with multiple amine groups in protein.

The resulting Fn-PHMAA was used to control the size and spacing of cell adhesion domains on a polyacrylamide hydrogel, combined with a microcontact printing technique (Figure S4 in Supporting Information).[19] Briefly, a circular array of Fn-PHMAA was placed on a glass surface using a microcontact stamp onto which the Fn-PHMAA was physically adsorbed. Both the diameter and spacing of the circles were kept constant at 500 μm. The subsequent in situ cross-linking reaction between acrylamide and *N*,*N*,*N*′,*N*′-methylene bisacrylamide on top of the micropatterened Fn-PHMAA resulted in a polyacrylamide hydrogel which presented circular arrays of fibronectin with regular size and spacing on its surface, as confirmed with immunofluorescent labeling (Figure 1b). The fibronectin mass per circular pattern, determined from a colorimetric immunoassay, was kept constant at 5 μg cm^{-2}. In contrast, the same polyacrylamide hydrogel fabrication on top of pure Fn without PHMAA, a negative control, resulted in limited conjugation of Fn to the surface.

The circular patterns of Fn on the polyacrylamide hydrogel were recognized by cells plated on the gel. Fibroblasts seeded on the hydrogel surface with circularly patterned Fn-PHMAA

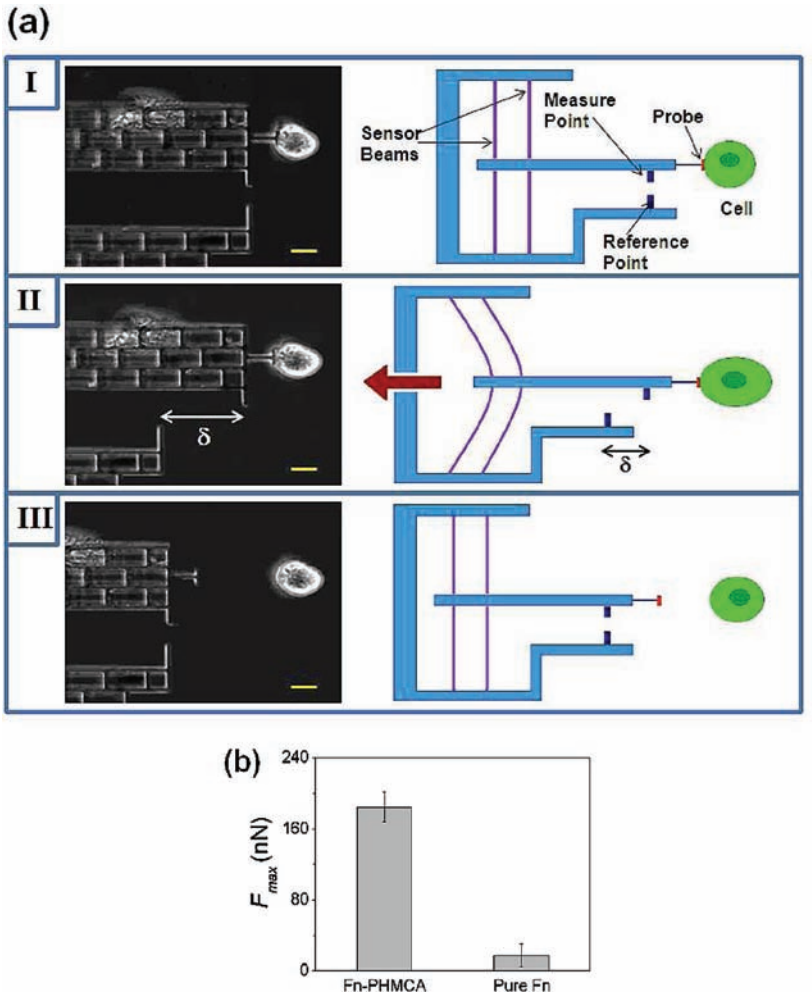

Figure 2. (a) Schematic description of measurement of cell force response using a bio-MEMS device. First, the probe conjugated with Fn is placed in contact with cell (**I**). After incubation, the device is moved away from the cell laterally (red arrow) at a constant rate (**II**). The probe is connected to sensor beams. Due to the cell's adhesion to the probe, it is displaced from the original position, as indicated by the difference between the measurement point and reference point. The probe is continuously pulled until it is finally detached from the cell (**III**). (Scale bar: 15 μm.) (b) The maximum applied force (F_{max}) was significantly larger when the probe was conjugated with Fn-PHMCA than with pure Fn.

adhered exclusively on the patterned area (Figure 1b-**I**). Furthermore, the cells adhered to the circular pattern proliferated over time, while remaining confined to the patterned area (Figure 1c and Figure S5 in Supporting Information). In contrast, the hydrogel patterned with pure Fn displayed limited cell adhesion (Figure 1b-**II**).

The same results were also observed when type I collagen and human airway smooth muscle cells (haSMCs) were used instead of Fn and fibroblasts (Figure S6 in Supporting Information). For this study, collagen linked with PHMAA (DS_{MA} = 10%) was used to pattern the polyacrylamide hydrogel surface with a circular array of collagen at a density of 10 μg cm^{-2}, following the same procedure as described in SI Figure S4. haSMCs exclusively adhered and proliferated within this circularly patterned hydrogel area. This result verifies that PHMAA can chemically link a variety of cell adhesion proteins to the hydrogel and control spatial organization of a wide array of anchorage-dependent cells.

Next, we synthesized a polyaspartamide linker modified with a controlled number of thiol groups for its use in protein conjugation to gold-coated inorganic substrates (Scheme 2). Gold has been extensively used in biosensors such as bio-MEMS and surface plasmon resonance (SPR), due to its inertness, robust structural integrity, and excellent conductivity.[20,21] These gold-coated devices are commonly modified with cell adhesion proteins or antibodies using a thiol-substituted bifunctional monovalent linker, which is typically synthesized via multiple substitution and purification steps. Here, we synthesized poly(2-hydroxyethyl-2-mercaptoethyl aspartamide) (PHMCA) with the controlled number of thiol groups. The same synthetic procedure to create PHMAA in Scheme 1 was used, except that cysteamine was used as a nucleophile to present thiol groups (Scheme 2 and Figure S1c in Supporting Information). The number of thiol groups in PHMCA, which are available to react with gold, was determined to be 10 per molecules, according to a colorimetric assay using Ellman's reagent.[22] The percentage of cysteamine that side-reacted to form thioester linkages was 24% (see Supporting Information). PHMCA was then mixed with Fn to prepare the Fn-PHMCA, and the reaction between PHMCA and Fn was confirmed with TNBS assay, as conducted for Fn-PHMAA (data not shown).

The resulting Fn-PHMCA was used to chemically modify the surface of the gold-coated probe of a bio-MEMS device which is designed to measure force exerted by cells under local uniaxial stretching.[23,24] The bio-MEMS device is made from a single crystal silicon wafer, and the surface of its probe was

dx.doi.org/10.1021/bc200339s | *Bioconjugate Chem.* 2011, 22, 2377–2382

coated with gold to prevent nonspecific interaction with cells (Figure S7 in Supporting Information). Then, the probe was immersed in a solution of Fn-PHMCA to chemically link Fn to the probe (Scheme 2). Separately, another device was also immersed in a solution of pure Fn as a negative control.

The probe modified with Fn-PHMCA or pure Fn was allowed to contact a fibroblast to form specific bonds between Fn and cellular integrins. The device was then pulled from the cell at a rate of 1 μm s^{-1}, and its maximum stretching force (F_{max}) before the cell detachment from the probe was calculated by the equation $F_{max} = k\delta$, where k is the spring constant of the sensor beams to which the probe is attached, and δ is the displacement of the probe from its original position (Figure 2a). The probe coated by the pure Fn was readily detached from the cell with only a small displacement (average $\delta \approx 6$ μm, $F_{max} \approx 20$ nN), indicating poor linkage between Fn and the probe. In contrast, the cell contacted by a Fn-PHMCA modified probe exerted a significant force resulting in an average δ of 55 μm ($F_{max} \approx 185$ nN) (Figure 2b). Furthermore, the F_{max} values were minimally changed during repeated use of the same probe, demonstrating that the chemical linkage of Fn-PHMCA to the gold-coated probe was well retained.

In summary, this study presents a novel strategy of synthesizing versatile polyaspartamide linkers that allow convenient conjugation of proteins to a variety of materials. The synthetic strategy of introducing functional groups by nucleophilic addition to PSI in a top-down manner allowed us to independently control the number of units reactive to proteins and those to materials in a highly efficient manner. In addition, these linkers allow a convenient one-step conjugation of various proteins to organic and inorganic materials. However, the chemical reaction between the linker and protein may cause a small portion of proteins to be denatured, the extent of which should be more carefully examined in future studies. These mutivalent linkers therefore present several attributes superior to conventional monovalent linkers. Furthermore, we expect that the versatility of the polyaspatamide linkers, due to their synthetic strategy of presenting functional groups in a simple top-down manner, will make it possible to further utilize a wide array of conjugation chemistries necessary for tailormade materials.

Supporting Information

ABSTRACT: Tissue macrophages play a critical role both in normal physiology and in disease states. However, because of a lack of specific imaging agents, we continue to have a poor understanding of their absolute numbers, flux rates, and functional states in different tissues. Here, we describe a new macrophage specific positron emission tomography imaging agent, labeled with zirconium-89 (^{89}Zr), that was based on a cross-linked, short chain dextran nanoparticle (13 nm). Following systemic administration, the particle demonstrated a vascular half-life of 3.9 h and was found to be located primarily in tissue resident macrophages rather than other white blood cells. Subsequent imaging of the probe using a xenograft mouse model of cancer allowed for quantitation of tumor-associated macrophage numbers, which are of major interest in emerging molecular targeting strategies. It is likely that the material described, which allows the visualization of macrophage biology in vivo, will likewise be useful for a multitude of human applications.

INTRODUCTION

Macrophages are white blood cells that are produced by the differentiation of monocytes after their entry into tissues. While their primary role is to phagocytose pathogens and cellular debris, in response to tissue insults they can also act to stimulate the recruitment of lymphocytes and other immune cells. However, despite their known importance and widespread distribution throughout the body, little quantitative information exists regarding their total mass, relative numbers at different sites, distribution profiles across different diseases, or their mobilization and flux rates under both disease and normal physiologic conditions. Early landmark papers[1] used macrophage specific antibodies (F4/80 in mice) to estimate macrophage numbers under resting conditions or have attempted macrophage quantitation using other molecular markers (e.g., Mac-3,[2] CD68,[3] or PG-M1[4]).

In previous work, our laboratory developed dextran-coated nanomaterials that, upon systemic administration, were readily engulfed by mononuclear phagocytic cells. They could thus be used as imaging probes for examining the function of these cells in humans.[5,6] Importantly, we now not only have shown that dextran-coated iron oxide nanoparticles have high macrophage avidity but also have used them for magnetic resonance imaging (MRI)[5,6] and optical[7] as well as positron emission tomography (PET) imaging.[8,9] While these multimodal nanoparticles were originally developed for MRI, using MRI to quantify exact nanoparticle numbers in vivo in different organs is often complicated, particularly in bone marrow and lung tissue. Radiolabeled nanomaterials have only recently been synthesized but have already shown potentially interesting clinical applications.[8−13] In general, it is possible to administer radiolabeled nanomaterials at much lower concentrations than their magnetic (and fluorescent) counterparts. Furthermore, their pharmacokinetics can also be titrated by size and surface

optimization and can be matched with PET isotopes with the appropriate decay rate (e.g., ^{18}F, ^{64}Cu, ^{68}Ga, and ^{89}Zr).

Given the absence of optimized macrophage specific nanoparticulate imaging agents, our goal was to systematically develop such materials through an iterative synthesis and screening procedure.[14] Here, we describe the characteristics and in vivo behavior of one lead compound identified from an initial larger screen. This nanoparticle is composed of several short (10 kDa) dextran strands cross-linked into a 13 nm diameter nanoparticle. Because our aim is to ultimately use these materials clinically, we avoided the use of longer chain length linear dextrans as synthetic building blocks, because of their associated hypersensitivities.[15] Rather, given their long clinical history,[16] we chose to incorporate shorter dextrans into the nanoparticles. We subsequently showed that the described preparation is readily labeled with ^{89}Zr ($t_{1/2}$ = 78.4 h; β^+ = 22.3%) via desferrioxamine and can be used with PET to quantitate macrophages in vivo. Finally, in view of the recent interest regarding the role of tumor-associated macrophages (TAMs) in cancer,[17,18] we validated the agent by quantitating tumoral macrophages in a mouse model of cancer.

RESULTS

Nanoparticle Characterization. Cross-linked dextran nanoparticles (DNPs) were synthesized and aminiated following a modified literature procedure that uses epichlorohydrin as a cross-linking agent.[14] Following workup, dialysis for several days provided highly pure DNPs. The size of the particles could then be reproducibly controlled as a function of the duration of the cross-linking reaction. Varying the duration of the reaction allowed synthesis of three preparations (mean diameters of 5, 6, and 13 nm), as measured by dynamic laser light scattering (DLS). The size distribution by volume data for these preparations is presented in Figure 1B and Figure SI.1 of the Supporting Information. The dextran concentration of these three preparations was determined by employing a sugar-reducing quantitative colorimetric method in the presence of phenol and sulfuric acid.[19] The amine concentrations relative to the dextran concentration were 1.09, 0.93, and 1.17 μmol/mg of dextran, respectively, for the three different DNPs.[20] Characterization of the 13 nm DNPs by matrix-assisted laser desorption ionization (MALDI) mass spectrometry demonstrated a mean molecular mass of 80 kDa for these particles. Dextran's weight contribution to the particles was determined to be 53, 54, and 43% for the 5, 6, and 13 nm DNPs, respectively. The mean number of amine groups per 13 nm DNP particle was measured to be 40.

Particle size and morphology were further verified by transmission electron microscopy (TEM). TEM images (Figure 1) not only demonstrated the nanoparticles' spherical shape and homogeneous appearance but also showed mean (narrow) diameters and overall sizes consistent with the DLS measurements. In negative controls, no globular-shaped nanoparticles were observed.

Modification of the particle surface for in vivo use was based on the relative modification of amines. The particles were first labeled with one or two fluorochromes [VT-680 (Perkin-Elmer)] per nanoparticle to allow intravital microscopy, flow-assisted cytometry, and immunofluorescence histology. Second, ~20% of amines were capped with the zirconium chelator desferrioxamine, an FDA-approved drug. Finally, to investigate the effects of pharmacokinetic modulation, all remaining amines were either left free or capped by reaction with an

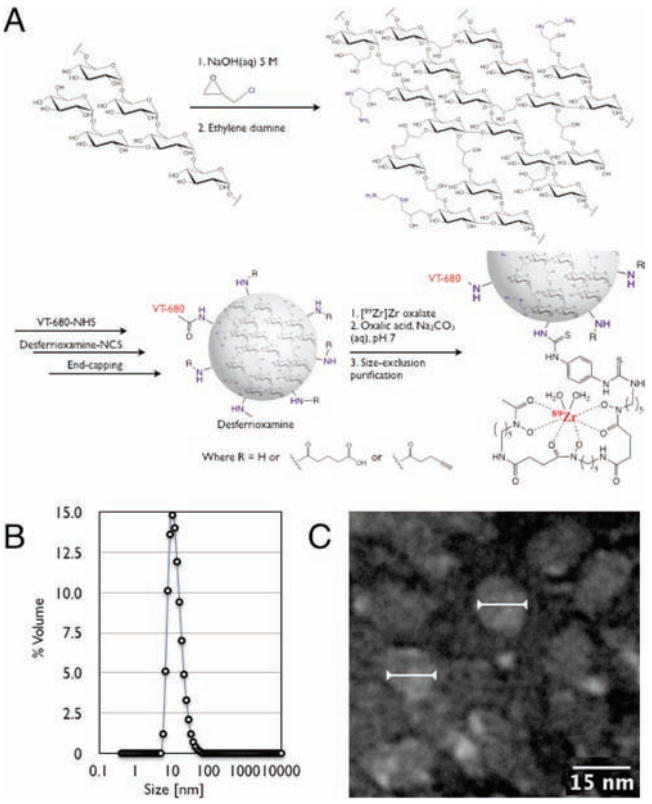

Figure 1. (A) General synthesis and radiolabeling of dextran nanoparticles (DNPs). (B) Dynamic laser light scattering data for the 13 nm DNP preparation. (C) Transmission electron microscopy image of several individual DNPs measuring 13 nm in diameter on average (arrows).

excess amount of succinic anhydride or pentynoyl-NHS ester. Following each modification step, DNPs were purified either by size exclusion chromatography or by size exclusion membrane filtration. As expected, when DNP-NH_2 was fully capped with succinic anhydride, a dramatic shift in ζ potential was observed from 30.0 to -30.1 ± 1.0, indicating a change in the surface charge from positive to negative.

The desferrioxamine-conjugated DNPs were labeled with [^{89}Zr]Zr oxalate in quantitative yield within 1 h, following a previously described procedure.[21] Within 25 min at 25 °C, the radiochemical yield of DNPs with ^{89}Zr was higher than 99.5%. The trace amount of free ^{89}Zr ions was then removed by centrifugal membrane filtration. The radiochemical purity was 100%, and no remaining free ^{89}Zr ions were detected on the high-performance liquid chromatography (HPLC) chromatogram after purification. The ^{89}Zr-labeled DNPs did not show any sign of degradation, determined by ITLC, at 36 °C in phosphate-buffered saline (PBS), for up to 5 days. While ^{18}F is the most common PET tracer used in the clinical setting, the longer-lived ^{89}Zr was chosen for this work in anticipation that nanoparticles would require longer circulation times for uptake into macrophages.

In Vivo Testing. To understand the effects of size and capping on pharmacokinetics, we performed blood half-life measurements. For the pentynoyl-capped 5, 6, and 13 nm DNPs (Figure 2A), the blood half-life data fit a two-phase exponential decay model, with values of 0.2, 0.9, and 6.1 h, respectively. The 5 and 6 nm preparations showed considerable renal excretion and much lower levels of macrophage

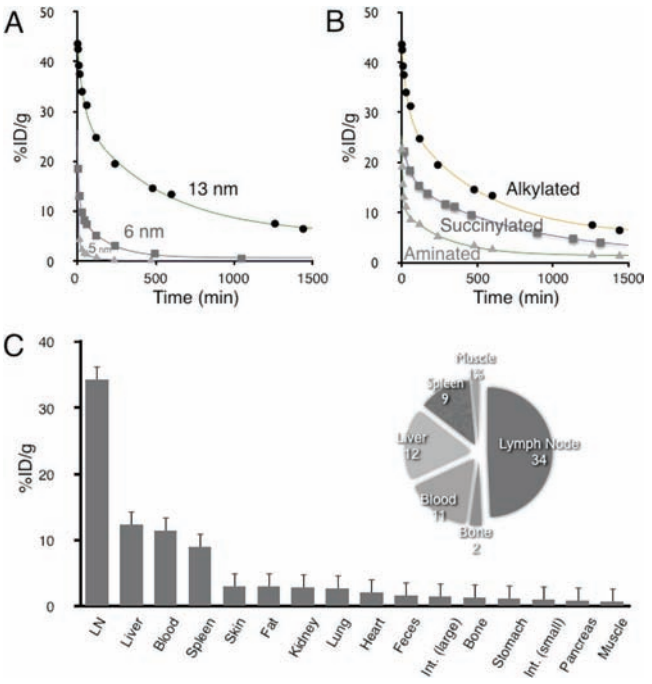

Figure 2. Pharmacokinetics of different DNPs. (A) Effect of size on blood half-life. (B) Effect of surface modification on blood half-life. (C) Biodistribution plotted as tissue concentration 24 h after intravenous administration of succinylated 13 nm DNPs. The inset shows the distribution in major organs.

accumulation, and thus, subsequent efforts focused solely on the 13 nm DNPs. To further determine the effects of surface modification on blood half-life, we compared desferrioxamine-labeled DNP with free amines, succinic anhydride, or pentynoyl-NHS ester capping (Figure 2B). The two-phase blood half-lives were 1.3 h for the aminated, 3.9 h for the succinylated, and 6.1 h for the pentynoylated preparations. These results demonstrate that blood half-life can be modulated on the basis of particle size as well as surface modification chemistry. Reasoning that the succinylated 13 nm DNP had ideal pharmacokinetics for ^{89}Zr, we chose it for biodistribution experiments. Figure 2C summarizes the organ distribution 24 h after injection of 100 μCi showing primary accumulation in lymph nodes [34 ± 16% of the injected dose/g of tissue (% IDGT)], liver (12 ± 2% IDGT), blood [11 ± 1% IDGT, located primarily in circulating leukocytes (see below)], and spleen (9 ± 1% IDGT), with much lower levels of accumulation in most other tissues, including bone, kidneys, and intestines. If we adjust for excretion (19.2 ± 0.8% of the injected dose over 24 h) and the body mass of the main organs, the overall activity of the succinylated 13 nm DNP was 22 ± 3% in liver, 19 ± 2% in circulating cells, and 2 ± 0.1% in spleen, with the remainder distributed in other organs.

In Vivo Imaging. We next performed PET-CT imaging using the same ^{89}Zr-labeled DNP described above in a cancer mouse model. We used a syngeneic colon carcinoma (CT26) mouse model because it had been used extensively for investigations of tumor infiltrating host cells,[22] vaccines,[23] and other studies.[24,25] Figure 3 shows representative images from different mice bearing the xenografts. The extent of tumoral uptake was surprisingly high (20 ± 5% IDGT), surpassing concentrations of other reticuloendothelial system RES organs in some animals. To determine whether tumoral accumulation was due to cellular uptake or extraversion and interstitial accumulation, we performed extensive correlative histology and flow cytometry studies.

Harvested tumors were sliced into ~1 mm sections and imaged by autoradiography to juxtapose sections to Mac-3 (a macrophage specific stain) histological stain. Overall, there was good agreement between "hot spots" and Mac3 positivity through the sections (Figure 4). Histology showed distinct uptake of fluorescent DNPs in Mac3 positive cells and a general lack of uptake in Mac3 negative cells (Figure 4).

To further investigate the pharmacokinetics and cellular uptake of the DNP, we performed confocal intravital microscopy studies. H2B-RFP-expressing HT1080 tumor cells were implanted in dorsal skinfold window chambers, and after the tumors had grown for 8 days, animals received CLIO-FITC, a commonly used macrophage imaging agent.[6] The following day, fluorescent DNP nanoparticles were administered systemically, and animals were imaged over time. Figure 5A shows representative imaging 3 h postinjection demonstrating DNP (red) primarily in the vasculature with little cellular uptake or even interstitial accumulation. Tumor cells (blue) and tumor-associated macrophages (TAMs, green) were clearly identified. Twenty-four hours postinjection, most of the DNPs had localized exclusively to TAMs with little compound remaining in the vasculature or tumor cells. The Pearson's colocalization

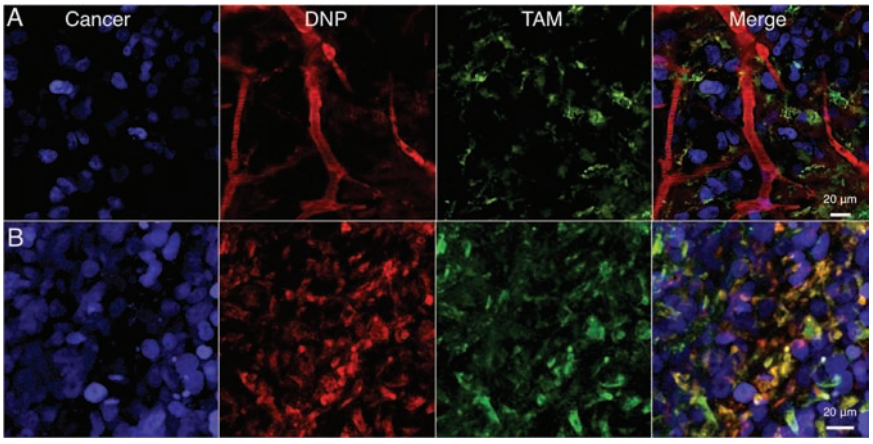

Figure 5. Microscopy of the distribution of DNPs in the tumor microenvironment in a live mouse (A) 3 h after injection and (B) 24 h after injection. Initially, the DNP is primarily seen in the vasculature, whereas it is almost exclusively colocalized (yellow) with TAMs after 24 h.

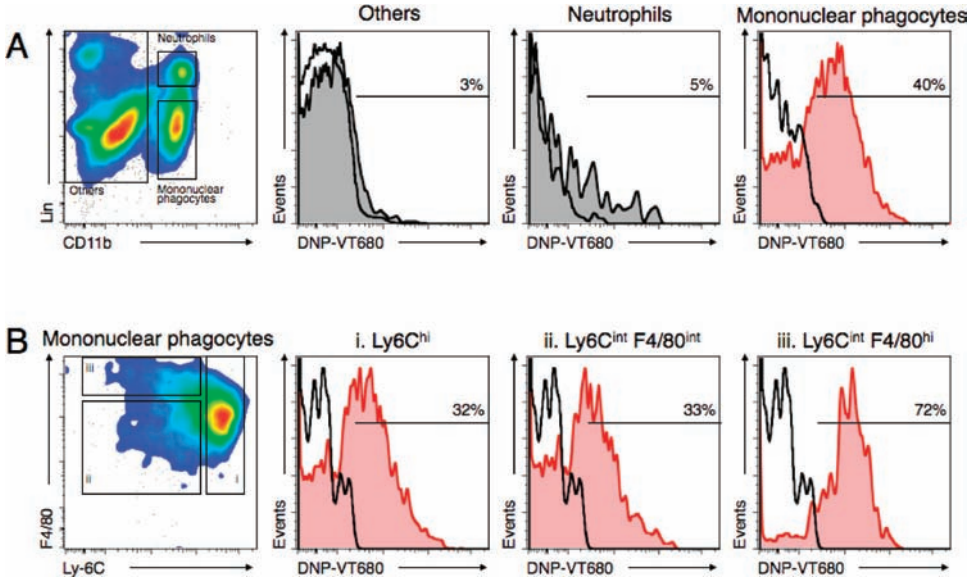

Figure 6. (A) Flow cytometric identification of mononuclear phagocytes ($CD11b^+$ Lin^{low}), neutrophils [$CD11b^+$ Lin^{high} ($Ly\text{-}6G^+$)], and other cells ($CD11b^-$) in the tumor stroma (left). The three histograms at the right show the percent of each population with detectable DNP-680 particles. Nearly all fluorescent DNP (DNP-680) is associated with mononuclear phagocytes. (B) Flow cytometric identification of mononuclear phagocyte subsets. $CD11b^+$ Lin^{low} cells were further divided into $Ly6C^{hi}$ (i) and $Ly6C^{int}$ $F4/80^{int}$ (ii) monocyte-like cells and $Ly\text{-}6C^{int}$ $F4/80^{hi}$ macrophages (left). The three histograms at the right show the percent of each population with detectable DNP-680 particles. DNP is associated with both monocyte subsets ($Ly6C^{hi}$ and $Ly6C^{lo}$) as well as with macrophages ($F4/80^{hi}$).

coefficient between DNP (red) and TAM (green) was 0.82 ± 0.07 (n = 5).

To augment the results of the IVM imaging, we performed flow cytometry on harvested tissues 24 h after administration of fluorescently labeled DNP. Presented in Figure 6, these data indicate that 40% of TAMs were positive for DNPs while only 5% of neutrophils and 3% of other lymphocytes were positive for DNPs. Figure SI.3 of the Supporting Information includes FACS data analysis of the uptake of DNPs in liver and kidney tissues. Here, 35 and 40% of macrophages are positive for DNP in the liver and kidney, respectively, and 7 and 9% of all other lymphocytes in these organs are positive for DNP. Together, these data and the IVM indicate strong specificity of DNPs for macrophages.

DISCUSSION

We have synthesized a 13 nm nanoparticle comprised of short, cross-linked dextrans that were modified with desferrioxamine to chelate ^{89}Zr for imaging of macrophages by PET. The nanoparticle was stable and biocompatible and accumulated specifically in tissue resident macrophages upon systemic administration. We show that cellular accumulation is complete within 24 h of administration (vascular $t_{1/2}$ of 3.9 h), showing faster kinetics compared to those of larger dextran nanoparticles in clinical use (vascular $t_{1/2}$ of ~24−48 h).[6] We did not observe any adverse effects at the doses used, and this is consistent with observations from dextran preparations in clinical use.[26] It should be pointed out that the PET dose was <5% of the MR comparable dose of iron oxide nanoparticles[9] and could be further reduced with higher specific activity. Imaging and corroborative experiments in xenograft tumor models showed extensive accumulation in TAMs, and this should be particularly useful for prognostication of cancers[27,28] or therapy assessment.[29,30]

Previously used dextran nanoparticles were primarily designed to have magnetic iron oxide cores and were naturally larger (20−200 nm). To determine the ideal size of dextran nanoparticles for PET applications, we initially performed a size optimization study leading up to the current preparation. Specifically, we synthesized analogous dextran nanoparticles 5, 6, and 13 nm in diameter [chosen from a larger size range (2−30 nm) study performed previously] and determined their pharmacokinetics, renal clearance rates, and macrophage uptake in vivo. Perhaps as expected, the 5 nm nanoparticle showed considerable renal clearance whereas the 13 nm nanoparticle had the highest level of macrophage uptake and was thus chosen for subsequent experiments. Prior to this study, we also compared the biological behavior of linear and cross-linked dextrans and found the latter to be better tolerated. While the current preparation indeed shows ideal imaging characteristics and clean macrophage uptake, on the basis of the intravital microscopy and flow cytometry result, we anticipate a few changes for future clinical preparations. For one, we would anticipate using a ^{68}Ga tracer to minimize radiation exposure and perhaps modulate the anticipated longer human blood half-life through modification of residual amines with alternative capping agents.[14]

A number of prior studies have used alternative PET agents for imaging macrophages, including ^{18}FDG,[31,32] ligands for the peripheral benzodiazepine receptor ligands (e.g., PK11195),[33,34] or magneto-optical nanoparticles.[8,9] Although commonly used, FDG is not macrophage specific as many nonphagocytic cells will also internalize glucose, particularly cancer, neuronal, and muscle cells as well as other leukocytes.[35,36] Peripheral benzodiazepine receptor ligands have been primarily used for neuroinflammation studies, and few validation studies of peripheral macrophages are available. The receptor is now known to be the translocator protein (TSPO), an 18 kDa protein that has many functions and is found in diverse tissues, including heart, liver, adrenal, testis, brain, and lymphatic tissue, in addition to leukocytes and macrophages.[37] Therefore, any imaging agent targeting this receptor would not be specific for macrophages.

We anticipate that the developed macrophage selective imaging agents will be useful for a number of applications in which quantitation of macrophages and inflammation levels are important. One of the most obvious applications is in cancer therapy where inflammation has been associated with inverse prognosis[27] and where antimacrophage strategies are now being employed to enhance therapeutic effects.[30] Another application is quantitation of inflammation in atherosclerosis and myocardial infarction in patients undergoing statin treatments. Macrophage imaging could be used as a surrogate of lesion activity. Finally, there are numerous other medical applications where foci of infection or inflammation require localization (e.g., neuroinflammation, Crohn's disease, and arthritis) or quantitation (e.g., macrophage activity in fat tissue of obese patients). We hope that the described material and future clinical derivatives fulfill the requirements of specificity and may be uniquely suited for clinical imaging.

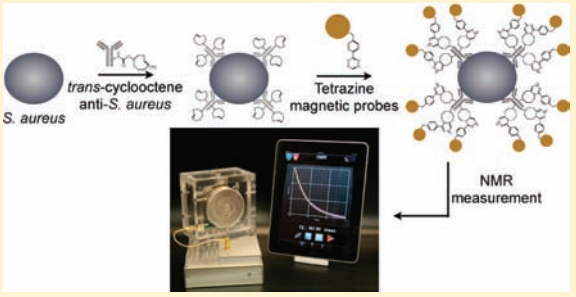
ABSTRACT: The development of faster and more sensitive detection methods capable of identifying specific bacterial species and strains has remained a longstanding clinical challenge. Thus to date, the diagnosis of bacterial infections continues to rely on the performance of time-consuming microbiological cultures. Here, we demonstrate the use of bioorthogonal chemistry for magnetically labeling specific pathogens to enable their subsequent detection by nuclear magnetic resonance. Antibodies against a bacterial target of interest were first modified with *trans*-cyclooctene and then coupled to tetrazine-modified magnetic nanoprobes, directly on the bacteria. This labeling method was verified by surface plasmon resonance as well as by highly specific detection of *Staphylococcus aureus* using a miniaturized diagnostic magnetic resonance system. Compared to other copper-free bioorthogonal chemistries, the cycloaddition reaction reported here displayed faster kinetics and yielded higher labeling efficiency. Considering the short assay times and the portability of the necessary instrumentation, it is feasible that this approach could be adapted for clinical use in resource-limited settings.



Faster assays, combined with detection of multiple bacterial species and strains, would not only improve global health but effectively lower healthcare costs.[1,2] Examples of these detection methods include fluorescence imaging using sugar molecules (e.g. maltohexaose and trehalose) for highly specific labeling of targeted bacteria,[3,4] and colorimetric assay based on enzyme−gold nanoparticle system.[5] In an effort to develop a simple diagnostic test that could be routinely used for the detection of bacterial pathogens in resource-limited clinical settings, we extended a bioorthogonal binding method to the identification of bacterial pathogens. The method is based on a two-step strategy in which antibodies are first modified to bind specific targets and are then coupled to multiple magnetic probes. Signals from these probes can subsequently be detected by nuclear magnetic resonance (NMR). Furthermore, in cases where target concentrations are low, this method has the added advantage of being able to amplify target signals.[6,7] A major challenge to developing diagnostic tests for bacteria has been achieving accurate detection of target pathogens from complex specimens, which may contain multiple bacterial strains. We have now overcome this hurdle by employing the cycloaddition bioorthogonal reaction of *trans*-cyclooctene (TCO)-modified antibodies to robustly and efficiently label bacteria with tetrazine (Tz)-modified magnetic nanoprobes (MNPs).[8] The labeled pathogens were then detected using a newly developed diagnostic magnetic resonance (DMR) system. Here, the clinical potential of this method is demonstrated by the accurate and rapid (<30 min) detection of *Staphylococcus aureus* (*S. aureus*) in human sputa.

It is often the case that the use of large affinity ligands results in low conjugation efficiency to nanoprobes and thus ineffective binding of the conjugates to targeted cells.[6] As a result, each new preparation of immunoconjugates for cellular labeling requires an optimization process to maximize its binding to targeted samples. As an alternative strategy, the use of bioorthogonal covalent reactions has become of increasing interest as a novel platform for biological labeling. Such reactions not only are highly selective toward their binding partners, but also have fast reactivity in biological solutions and at ambient temperatures.[9−11] The approach is also modular and generalizable. Namely, a vast array of affinity ligands for cellular targeting can be prepared using bioorthogonal components, and generic probes can be used for labeling.[12] Tz/TCO cycloaddition in particular has demonstrated great potential: it is catalyst-free, shows good stability in biological media, displays much faster reaction kinetics compared to other bioorthogonal reactions, and is capable of significantly amplifying probe-loading onto targets.[13,14] Indeed, recently, this reaction was successfully adapted to the molecular profiling of cancer cells[6,7,15] as well as to *in vivo* imaging.[16]

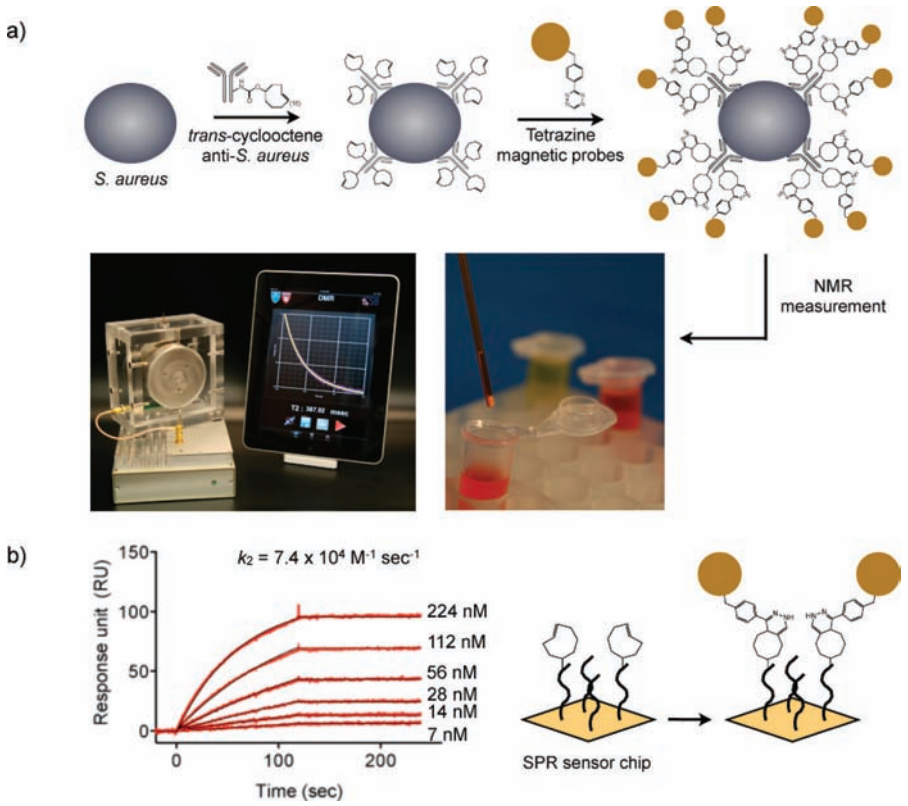

Figure 1. (a) Schematic of the two-step magnetic labeling method involving the cycloaddition of *trans*-cyclooctene (TCO) to tetrazine (Tz). *Staphylococcus aureus* (*S. aureus*) cells were first targeted with TCO-modified antibodies and then coupled to Tz-modified magnetic nanoprobes. Given that each antibody is bound by ~15 TCO molecules, multiple probes can be attached to each marker. The labeled cells were subsequently loaded into a disposable tube for detection using a diagnostic magnetic resonance device. (b) Surface plasmon resonance (SPR) measurements (left) and a schematic of the binding kinetics between Tz-modified probes and surface-immobilized TCO (right). The fast second-order rate constant (k_2 = 7.4 × 10^4 M^{-1} s^{-1}), determined by flowing the probes at different concentrations, is largely due to the multivalent binding of Tz-MNPs.

The cycloaddition reaction of Tz and TCO offers a modular platform for effectively coupling magnetic probes to the surface of a particular target using a generalized labeling strategy. Figure 1a describes the developed two-step approach for bacterial detection based on the Tz/TCO reaction. We initially coupled amine-reactive Tz to the amine groups present on the MNPs; MNPs were composed of an iron oxide core and a dextran coating.[17] Likewise, affinity ligands were modified with amine-reactive TCO. Samples were first incubated with TCO-conjugated antibodies to specifically target the bacteria before coupling with Tz-modified MNPs (Tz-MNPs). This labeling method rendered the bacteria superparamagnetic, and thus enhanced the transverse relaxation of the samples, as determined by NMR. After loading the samples into disposable tubes, their relaxation rates (R_2) were measured using a miniaturized DMR system.[18]

The binding kinetics of the probes to TCO molecules were characterized using surface plasmon resonance (SPR).[19] To determine the association constant of the Tz-modified probes to TCO, sequentially increasing concentrations of Tz-MNPs were flowed over the SPR sensor surface, which was functionalized with TCO molecules. With a measured second-order rate constant of $k_2 \approx 7.4 \times 10^4$ M^{-1} s^{-1} at room temperature, the reaction of Tz-MNPs with TCO proved fast and highly stable under the continuous flow stream of the SPR (Figure 1b). The capacity of the MNPs for multivalent binding and the fast kinetics of Tz/TCO thus indicated its suitability for rapid magnetic labeling of targeted bacteria.

S. aureus was selected as the specific target for pathogen detection, for which a highly selective antibody against the bacteria (anti-SA) was used as the affinity ligand. The antibodies were subsequently modified with TCO; an average of ~15 TCO molecules were conjugated to each antibody, as determined by matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry (SI Figure S1). Each MNP was functionalized with approximately ~8 fluorescent moieties and ~56 Tz molecules, as measured by the SPDP assay.[20] The bacteria were first tagged with TCO-anti-SA before being sequentially coupled to Tz-MNPs. Fluorescence microscopy (Figure 2a) showed that bacterial labeling using the bioorthogonal approach was both efficient and consistent. In contrast, control samples showed only punctate traces of green fluorescence, thus confirming the minimal nonspecific binding of the Tz-probes (Figure 2b).

The specificity of the Tz/TCO labeling method was further investigated by applying the assay to other relevant pathogens. About 10^5 CFU of the target bacteria (*S. aureus*), an acid-fast species (*Mycobacterium smegmatis*), as well as Gram-negative (*Haemophilus influenzae, Escherichia coli, Pseudomonas aeruginosa*), and Gram-positive bacteria (*Streptococcus pneumoniae*) were each mixed with TCO-anti-SA and then incubated with Tz-MNPs in a 300 μL volume. Each sample was then concentrated by centrifugation and transferred to the sample chamber of the DMR device for analysis (~10^4 CFU in 2 μL volume). The measured ΔR_2 value for each sample was then converted to cellular relaxivity Δr_2 (ΔR_2 divided by cell

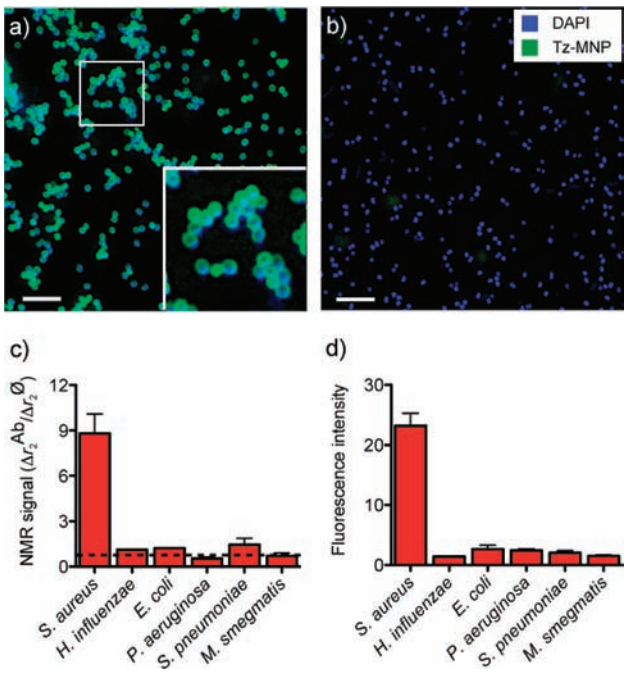

Figure 2. Selective bacterial labeling using bioorthogonal chemistry. (a) DAPI stained *S. aureus* (blue) were targeted with TCO-anti-SA and labeled with fluorescent Tz-modified probes (green). Labeling of the bacterial membrane can be clearly seen in the enlarged inset image (bottom right; higher magnification of boxed region). Scale bar, 5 μm. (b) Minimal fluorescence from the probes was observed on the control nontargeted bacterial samples. (c) Detection of *S. aureus* using the diagnostic magnetic resonance (DMR) device (~10^4 CFU in 2 μL volume). A panel of bacterial strains was incubated first with TCO-antibodies (specific for *S. aureus*) and then with Tz-MNPs, before undergoing measurement with DMR. The displayed nuclear magnetic resonance (NMR) signals were determined by calculating the ratio of cellular relaxivities between the targeted (Δr_2^{Ab}) and control ($\Delta r_2^{\varnothing}$) samples. Bioorthogonal labeling yielded accurate and elevated NMR signals for the targeted *S. aureus*, but not for other bacteria. (d) Fluorescence measurements of the bacterial samples, as determined by flow cytometry. The mean fluorescence intensity was normalized by calculating the ratio between each bacterial sample and the nontargeted control. *S. aureus* showed considerably higher normalized fluorescence intensity than other bacteria. Overall, the fluorescence measurements obtained by flow cytometry showed an excellent correlation with measurements obtained by DMR.

concentration), a value which is proportional to the number of MNPs per bacterium.[21] For *S. aureus*, the Δr_2 was ~9-fold higher than the background, whereas the Δr_2 for other pathogens showed a small or no increase over the baseline (Figure 2c). Corresponding fluorescence measurements by flow cytometry also correlated well with the DMR results (Figure 2d), thus demonstrating the reliable dual-labeling capability of the method for both optical and magnetic detection. Since the DMR device requires only small sample volumes (~2 μL), it could be useful as a complementary diagnostic technique in cases where only scant samples are available.

We next evaluated the efficacy of this bioorthogonal labeling method using clinically relevant samples (Figure 3). Expectorated samples were prepared by spiking *S. aureus* (~10^5 CFU) into human sputa (1 mL volume). Reagents for three different bioorthogonal groups were synthesized to compare their labeling efficiency in clinical samples, namely, Tz/TCO, Tz-norbornene (Tz/Norb), and dibenzylcyclooctyne-azide

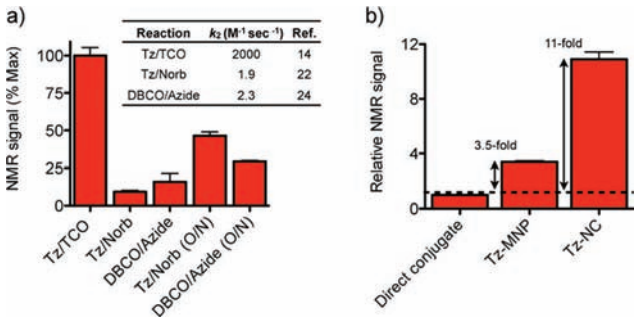

Figure 3. Comparison of the effectiveness of different bioorthogonal labeling strategies. (a) After liquefying human sputa containing *S. aureus* (~10^5 in 1 mL sputa), the bacteria were targeted and labeled using three different reactions. The inset table summarizes previously reported k_2 second-order rate constants for the different bioorthogonal chemistries. The Tz/TCO system was more effective in labeling bacteria than either of the alternative catalyst-free bioorthogonal chemistries, even with overnight (O/N) incubation (8 h). (b) The two-step labeling approach proved better at labeling bacteria than direct immunoconjugation. By using materials with higher magnetization (nanocrystals/NC versus magnetic nanoprobes/MNP), the NMR signal and detection sensitivity could be enhanced further.

(DBCO/Azide). For the Tz/Norb method, antibodies were tagged with norbornene and Tz-MNPs were used as the binding probes;[22,23] for the strain-promoted DBCO/Azide method, azide-modified antibodies and DBCO-MNPs were used (SI Figure S2).[24] Following sputum liquefaction, all samples were labeled with antibodies conjugated to the above-listed small molecules and their corresponding probes. The labeled samples were then divided for subsequent bacterial counts and DMR measurement. At the optimal probe concentration (50 μg/mL) and incubation time (15 min), the Tz/TCO labeling method yielded considerably higher DMR signals, outperforming Tz/Norb and DBCO/Azide methods even after longer overnight (O/N) incubation times (8 h) (Figure 3a). This result is consistent with previous reports which have shown that the Tz/TCO system has kinetics that are several orders of magnitude faster than other bioorthogonal reactions (Figure 3a inset).[14,22,24]

The modular Tz/TCO approach provided a facile method for enhancing the specificity and sensitivity of bacterial detection. In addition, by enabling the attachment of multiple MNPs per target, the Tz/TCO system resulted in a far higher DMR signal (>350%) to that of direct antibody–MNP conjugates (Figure 3b). The detection threshold for *S. aureus*, using the Tz/TCO MNPs was determined to be ~200 CFU with cutoff ΔR_2 value of 5% (SI Figure S3). The detection sensitivity can be further enhanced by increasing the r_2 relaxivity of the magnetic particles, which is achieved by using materials with strong magnetization and by increasing the size of the magnetic nanocrystals. Indeed, by replacing the MNPs with doped iron oxide nanocrystals (NCs) with higher transverse relaxivity (r_2 = 380 mM^{-1} s^{-1}, SI Figure S4),[25] the DMR sensitivity could be further improved (>300%). While the cross-linked iron oxide MNPs (transverse relaxivity r_2 = 70 mM^{-1} s^{-1}) are sufficient for initial labeling and detection experiments, the highly magnetic NCs would be useful for detection of pathogens in scant samples. The Tz/TCO method could also be extended to antibodies against other target pathogens for labeling and detection (SI Figure S5). Since DMR detection requires small volumes of samples, a parent

dx.doi.org/10.1021/bc200490r | *Bioconjugate Chem.* 2011, 22, 2390–2394

specimen can be divided into smaller aliquots, and each sample can be profiled for different pathogens via modular Tz/TCO approach. Such a capacity would be particularly useful in cases of infection where specific bacterial species are suspected or need to be ruled out in complex biological samples. The recent outbreak of enterohemorrhagic *Escherichia coli* (EHEC) strain O104:H4 exemplifies such needs. We are currently investigating this approach for the detection of *Mycobacterium tuberculosis* in clinical sputum samples.

In summary, we have developed a magnetic labeling assay capable of rapid pathogen detection using bioorthogonal conjugation chemistry. The cycloaddition between TCO-labeled *S. aureus* and Tz-modified MNPs enables specific bacteria to be labeled and subsequently detected. The magnetic labeling approach is efficient, chemoselective for the targeted pathogen (determined by the antibody used), and applicable to sputum samples. By using this magnetic labeling technique together with the miniaturized detection device (DMR), the strategy could serve as a promising diagnostic platform for pathogen detection within a point-of-care clinical setting.

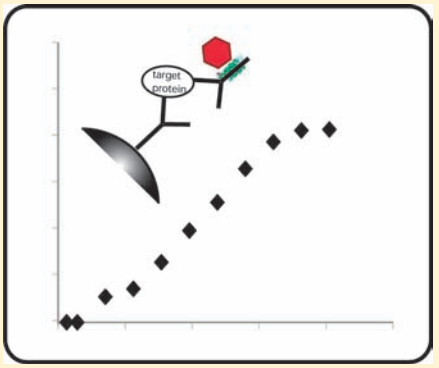
Covalent Immunoglobulin Labeling through a Photoactivable Synthetic Z Domain

Anna Konrad,[†] Amelie Eriksson Karlström,[‡] and Sophia Hober*,[†]

[†]Division of Proteomics, AlbaNova University Center, [‡]Division of Molecular Biotechnology, School of Biotechnology, Royal Institute of Technology (KTH), SE-106 91 Stockholm, Sweden

ABSTRACT: Traditionally, labeling of antibodies has been performed by covalent conjugation to amine or carboxyl groups. These methods are efficient but suffer from nonspecificity, since all free and available amine/carboxyl groups have the possibility to react. This drawback may lead to uncontrolled levels and locations of the labeling. Hence, the labeled molecules might behave differently and, possibly, the binding site of the antibody will also be affected. In this project, we have developed a highly stringent method for labeling of antibodies by utilizing an immunoglobulin-binding domain from protein A, the Z domain. Domain Z has been synthesized with an amino acid analogue, benzoylphenylalanine, capable of forming covalent attachment to other amino acids upon UV-exposure. This feature has been used for directed labeling of immunoglobulins and subsequent use of these in different assays.



INTRODUCTION

Immunoglobulins, or antibodies, are a group of molecules that are extensively used as affinity reagents in many applications in research, clinical diagnostics, and therapy. With the ability to bind their ligands with high affinity and in a selective manner, they are of great importance, and are, by far, the most commonly used affinity reagents.[1] As when employing any affinity reagent, the method used for detection needs to be considered. The antibodies' excellent capacities to bind their ligands need to be combined with high selectivity in order to be of great use. As a consequence, techniques for labeling of antibodies necessarily need to be of high quality. To make detection of the antibody and its binding events possible, a reporter group is normally attached to the antibody. Methods most commonly used when conjugating reporter groups to the antibody are based on the exploration of amine or carboxyl groups in the protein for coupling.[2] Another application that ordinarily takes advantage of the surface-exposed functional groups in the protein is the immobilization to a solid support. When applying amine- or carboxyl-based chemistry, normally a high degree of labeling or immobilization is obtained, but unfortunately, the binding site might be compromised, since the control of level and location of the labeling/coupling is limited. This means that optimization of the protocol is needed for every antibody and every conjugation/immobilization. Hence, a method for labeling, where specific and controlled conjugation can be achieved, would be a great advantage. To obtain specific conjugation, molecules that have a natural, specific, and defined binding to antibodies could be employed. Moreover, to be able to conjugate the antibodies in a complex environment, with other proteins in the conjugation mixture, is desirable due to stabilizing molecules often being added to the antibody mixture for stabilizing purposes.

Several Ig-binding molecules have been reported in literature.[3−5] Among these, staphylococcal protein A (SpA), binding to VH and Fc, is one of the best characterized. Staphylococcal protein A is frequently used in many different applications, such as affinity chromatography, where its ability to bind antibodies is utilized. The protein is used both for purification of IgG molecules[6] and as affinity tag for protein purification.[7] The five homologous domains, EDABC, that constitute protein A, each consists of approximately 58 aa, and share the Ig-binding feature.[8] NMR analysis of the structure of the B domain shows a three-helix bundle with the helices ordered in an antiparallel fashion. The domains of protein A exhibit binding to both the Fc and Fab regions of immunoglobulins. By X-ray crystallography, the structure of the B domain in complex with the Fc region of IgG has been solved, and it revealed an interaction that mostly involved amino acids of hydrophobic character.[9] Binding seems to occur in the interface between CH_2 and CH_3 of IgG, where 11 residues from helix 1 and helix 2 of the B domain are suggested to participate.[9,10] Also, the structure of the interaction between protein A and the Fab region has been solved. The crystal structure of the D domain binding the Fab region of human IgM disclosed the involvement of 11 residues of helices 2 and 3 from the D domain and an interaction of a polar character with the variable heavy chain.[11] By altering two positions in the B-domain of protein A, an engineered variant called the Z

domain has been made. In the N-terminal of the Z domain, an alanine residue was replaced by valine. A glycine-to-alanine substitution was made for the removal of a hydroxylamine cleavage site,[12] which also resulted in loss of binding to the Fab region.[11,13] The Z domain is small (6.7 kDa), easy to produce, and has a stable three-dimensional structure and also the capacity to refold.[14] It was previously proven to be suitable for chemical peptide synthesis, thereby making the introduction of synthetic active groups possible, extending the usability of the domain.[15]

Benzoylphenylalanine (BPA) is a synthetic amino acid that can be incorporated in a peptide during synthesis. Benzophenone (BP), which is part of BPA, is a photoreactive group that forms covalent bonds to other amino acids upon UV-exposure. BPA is considered to be efficient, stable, and also easy to handle,[16] and it is primarily used when mapping protein−ligand interactions. When mapping interactions, the strategy is to produce variants of a protein with BPA incorporated at different positions, and then allow the protein to bind its interaction partner.[17] When subjecting the complex to UV light, BPA forms a diradical, which renders the generation of a covalent bond between the protein and its interaction partner possible.

The utilization of an antibody-binding protein domain with an incorporated photoreactive group for attachment to antibodies has previously been reported by Jung et al. By using a modified C2 domain from streptococcal Protein G and covalently attaching BP at positions 21 and 29 via two incorporated cysteines, a photoreactive procedure could be used for modification of the antibodies. It was demonstrated that this approach could be used for directed antibody immobilization onto a surface. The strategy included recombinant production of the domain and by site-directed mutagenesis two cysteines were incorporated. The cysteines were labeled by maleimide chemistry for attachment of the photoreactive group, BP, into the domain.[18]

In this study, we report the development of a stringent and effective method for specific covalent labeling of immunoglobulins. By the use of a synthetic Z domain with the photoreactive probe BPA incorporated in the amino acid sequence, covalent conjugation to the antibody has been achieved. In this report, SPPS has been used as a means for production, and in this manner, we are able to incorporate the BPA as an unnatural amino acid specifically in the peptide backbone. Thereby, production and modification could be made in a single manufacturing process. Moreover, a detection-handle, biotin, could be incorporated in a specific position into the protein. By combining the inherent affinity of the Z domain and the Fc-fragment with the ability of BPA to create a covalent bond, specifically labeled antibodies were successfully achieved, characterized, and tested in different platforms.

MATERIAL AND METHODS

General. In this study, recombinantly produced Zwt was used as a reference.[12] The protein domain was randomly biotinylated resulting in an average of four biotin moieties/domain, as measured by MALDI-MS (data not shown).

Several antibodies used were kind gifts; FITC-BSA-specific antibody (human IgG1 and mouse IgG2a, BioInvent International AB) and antibody specific for His_6-ABP (polyclonal, Atlas Antibodies AB).

Production of Peptides. The two variants ZF5BPA (Z5BPA) and ZH18BPA (Z18BPA) were produced by solid-phase peptide synthesis using Fmoc/*t*Bu protection strategy. The syntheses were performed on a 433 A Peptide synthesizer (Applied Biosystems) using an acid-labile Fmoc-amide resin (substitution 0.67 mmol g^{-1}, Applied Biosystems). Cleavage of the Fmoc group was performed using 20% (v/v) piperidine in NMP. The coupling reactions were performed with a 10-fold molar excess of amino acid activated with 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) and 1-hydroxybenzotriazole (HOBt) (both from Iris Biotech GmbH) and DIEA in NMP. Apart from the amino acids underlined in Table 1, single couplings were carried out. Unreacted amino groups were capped with acetic anhydride. Standard side-chain protecting groups were used except in position 58, where Fmoc-Lys(Mtt)-OH (NovaBiochem) was introduced. The photactivable probe Fmoc-BPA-OH (Peptech Corporation) was incorporated in position 5 in Z5BPA and in position 18 in Z18BPA.

Incorporation of biotin in Z5BPA and Z18BPA was performed with the peptides still bound to the resin. The peptide-resin was treated with TFA/TIS/DCM (1:5:94) for the removal of the 4-methyltrityl (Mtt) group protecting the ε-amine of Lys58. Biotin was coupled with 5 equiv of D-biotin (Sigma), activated with HBTU/HOBt/DIEA in NMP for 2 × 1 h, with the reactions monitored using Kaiser test.[19]

The removal of protecting groups and release from the resin were achieved by treatment with TFA/TIS/H_2O (95:2.5:2.5) for 2 h at room temperature. The peptides were extracted in H_2O/*tert*-butyl methyl ether (1:1) and lyophilized.

HPLC and MS. The products from the syntheses of Z5BPA and Z18BPA were analyzed and purified by RP-HPLC, using a Silica-C18 column with 3.5 μm particle size and 4.6 × 150 mm length (Agilent Technologies). A flow rate of 0.9 mL min^{-1} and a gradient of solvent B (0.1% TFA/CH_3CN, vol/vol) in solvent A (0.1% TFA/H_2O, vol/vol) were used. Fractions obtained from RP-HPLC were analyzed by MS, and the correct products were pooled and lyophilized. The protein concentration of the samples was determined by amino acid analysis (Aminosyraanalyscentralen).

Mass spectrometry was used to verify that correct products were obtained. The products from the syntheses of Z5BPA and Z18BPA were analyzed by ESI-MS, performed on a Q-TOF II (Waters Corporation, Micromass MS Technologies). For Z5BPA-bio and Z18BPA-bio, the fractions collected in RP-HPLC were analyzed using a MALDI-MS Biflex IV (BRUKER Daltonics). As reference and for external calibration myoglobin, carbonic anhydrase II (CA II) and insulin (all obtained from Sigma-Aldrich) were used.

General Procedure for Photoconjugation. 100 nM antibodies and 1 μM Z5BPA-bio or Z18BPA-bio in PBS were incubated in 20 °C for 1 h. Cross-linking was achieved by exposure to light, 365 nm (Spectronics Corporation) for

45 min, or 1 h on ice. For the analysis of conjugated antibodies by Biacore and Western Blot, Fc and Fab fragments as well as full-length IgG were used. 1.3 μM of the antibody/antibody fragment was mixed with 26 μM Z5BPA-biotin in PBST and incubated at room temperature for 1 h. The antibody solutions were exposed to light at 365 nm for 2 h on ice.

For buffer exchange spin concentrators with a 10 kDa cutoff (Vivaspin, Sartorius Stedim Biotech) were used, centrifugation at 15 000 rcf for 10 min. Buffers used were 0.2 M HAc (VWR), pH 3.2, for lowering the pH and PBST for restoring the pH to 7. The protein content was analyzed by measuring absorbance at 280 nm (280 nm, ε = 210 00 M^{-1} cm^{-1}).

Luminex. *Bead Coupling.* Proteins and antibodies were coupled to beads according to the manufacturer's recommendation (COOH Microspheres, Luminex Corporation). 1.6 μg antibody to FITC-BSA was used for coupling to approximately 5×10^5 beads. Protein FITC-BSA (BioInvent International AB) and His_6-ABP (Atlas Antibodies AB) were coupled using 2 μg for approximately 2.5×10^5 beads and 10 μg for 1×10^6 beads, respectively. Coupled beads were kept at 4 °C in a storage buffer (Blocking Reagent for ELISA, Roche Applied Science).

Analysis of Photoconjugated Antibodies. Antibodies subjected to photoconjugation were diluted with PBST to a concentration of 100 nM. Filter plates (0.45 μm MSHVN45 MultiScreen HTS, Millipore) were used for incubation of 45 μL diluted antibody with 5 μL bead solution (200 beads/μL) at 23 °C with mixing for 1 h. Washing with 3 × 50 μL PBST was performed before PhycoLink Streptavidin-R-Phycoerythrin (2.2 μg mL^{-1}) (Prozyme) was supplied. After incubation (23 °C for 20 min) and washing (3 × 50 μL PBST), the fluorescence was measured with Luminex Lx200. When performing the sandwich assay, the first incubation with beads was made with target protein at 23 °C for 1 h; thereafter, a wash step (3 × 50 μL PBST) was introduced, followed by the procedure described above.

SPR-Analysis. Analysis of the binding kinetics of Z5BPA and Z18BPA to different IgG molecules was performed by the use of SPR technology (BIAcore 2000 instrument, Biacore). Antibodies and human serum albumin (HSA) were immobilized onto a CM5 sensor chip resulting in approximately 2000 response units (RU) for the antibodies, and 700 RU for HSA. A flow rate of 30 μL min^{-1} at 25 °C was used during the analysis. HBS-EP (HEPES 100 mM, NaCl 1.5 M, EDTA 34 mM (Merck) and 0.05% (v/v) surfactant p20 (VWR)) was used as a running buffer, and for regeneration of surfaces 10 mM HCl. The proteins were analyzed in concentrations ranging from 1.6 nM to 203.5 nM for Z5BPA-bio, 11.9 nM to 1560 nM for Z18BPA-bio, and 5.0 nM to 635 nM for Zwt. All samples were run in duplicate. The software *BIAevaluation 3.2* (BIAcore AB) was employed to determine the dissociation constants based on the Langmuir 1:1 model.

The antigen His_6-ABP was immobilized onto a CM5 sensor chip resulting in 280 response units (RU). Polyclonal rabbit IgG targeting the HisABP-construct was subjected to the photolabeling procedure either with photoreactive Z5BPA-biotin or without the reagent, both performed in duplicate. The samples were diluted to a concentration of 100 nM and flown over the Biacore surface with the antigen for analysis of the ability of the antibody to bind the antigen. The resulting Biacore curves were referenced against a blank chip surface. To obtain K_D values for the photolabeled and unlabeled antibodies, *GraphPad Prism* was used for nonlinear regression analysis of binding data from the Biacore. The curve fits were calculated from an average curve of duplicate samples, conjugated and unconjugated antibodies, respectively, flown over the chip surface.

Western Blot. Protein or antibodies (2−3 μg) were separated on SDS-PAGE gradient gels (NuPAGE 4−12% Bis-Tris SDS-PAGE, NuPAGE 3−8% Tris-Acetate (Invitrogen) or Criterion 10−20% Tris-HCl (Bio-Rad) under reducing conditions, followed by transfer to PVDF membranes (Invitrogen or Bio-Rad) according to the manufacturer's recommendations. Membranes were soaked in methanol and blocked (0.5% casein in 1×PBST vol/vol) for 1 h at 20 °C. To directly detect biotinylated proteins, the membrane was incubated with peroxidase-conjugated streptavidin (diluted 1:70 000, DakoCytomation). For detection of specific proteins, the membranes were first incubated with antibodies (of rabbit, goat species, respectively) specific for HisABP or human albumin for 1 h, followed by washing (1×PBST). Detection was made possible by either peroxidase-conjugated streptavidin (diluted 1:5000, DakoCytomation) or peroxidase-conjugated IgG directed to goat antibodies (diluted 1:100 000, Sigma-Aldrich). Detection was carried out with Immobilion Western Chemiluminescent HRP substrate (Millipore) according to the manufacturer.

RESULTS

Design and Synthesis of Z-Variants. The procedure of labeling and covalent attachment of reporter groups to antibodies is traditionally done through the chemistry of amine or carboxyl groups in the antibody. This is an efficient method, but since the labeling occurs randomly, many different groups in the protein have the possibility to react and the conjugated group might influence the binding of the antibody to its antigen. Hence, an optimization of the labeling conditions is a necessity for every antibody, and therefore, an alternative method for specific and directed labeling would be beneficial for many applications. Directed labeling would also be beneficial for antibodies in complex environment, where other proteins surround the antibody. Here, we report a novel method that enables a specific labeling of antibodies where a photoactivable probe together with a specific binding event is utilized to achieve covalent and specific attachment to immunoglobulins. To achieve a specific and reliable covalent labeling, the IgG-binding domain Z was utilized.

After studying the structural data available on Protein A (domain B) and its interaction surface with IgG, the positions Phe5 and His18 were chosen to be exchanged for BPA. Phenylalanine 5 is positioned in the N-terminal part of the domain, close to the first helix, and it is also claimed to participate in the binding between the B-domain and IgG (Deisenhofer 1981). The other position, histidine 18, is the last amino acid in the first helix, and it is not suggested to be part of the binding to IgG, but is situated in close proximity to the binding surface. Hence, two variants of the Z domain were produced, Z5BPA and Z18BPA. To achieve specific incorporation of the photoreactive probe, the two molecules were produced using solid-phase peptide synthesis. In Table 1, the sequences of the synthesized molecules are shown, where underlined amino acids were coupled twice during synthesis to ensure a high yield of the product. In both Z5BPA and Z18BPA, a D2E substitution was made to avoid aspartimide formation during synthesis. This substitution had previously been shown not to interfere with the structural or functional behavior of the Z domain.[15]

The synthesis products, Z5BPA and Z18BPA, were purified using RP-HPLC, and the purified correct products were verified using MS (data not shown). To enable easy and flexible detection and to be able to analyze the efficiency of the conjugation, the two variants were specifically biotinylated in at the C-terminus of the protein domain. This was made by applying an orthogonal strategy, through the incorporation of a lysine protected with a 4-methyltrityl (Mtt) group in the last position in the sequence of the domains. Also, these protein products were successfully purified to homogeneity and analyzed by MS (Figure 1a and b).

Analysis of the Binding Characteristics of the Z-Variants. The ability of the Z domain to refold after synthesis has been shown previously,[15] and therefore, retained binding to IgG was expected. However, with the introduction of BPA in different positions in the proximity of, or in the binding surface, there is a potential risk of influencing the ability to bind IgG. Therefore, an analysis of the binding kinetics of the two Z variants using surface plasmon resonance (SPR) was made. The ability of the two novel Z variants to bind to different IgG molecules was analyzed and compared to the parental Z domain. The analysis revealed an affinity of Z5BPA-bio/to IgG complex comparable to the parental Z/IgG. However, a considerably lower affinity was detected when analyzing the binding of Z18BPA-bio to IgG (Table 2).

Evaluation of Covalent Coupling of Z-Variants to Immunoglobulins. For the evaluation of covalent coupling of the two modified Z domains to IgG, two approaches were employed. In the first approach, polyclonal rabbit IgG was coupled to Luminex beads and then incubated with the synthetic Z domains, followed by light-induced activation of the covalent coupling (Figure 2A, setup 1). Thereafter, the beads were washed with a low-pH buffer in order to break all noncovalent interactions. By comparing the biotinylation of beads washed with low pH, with beads washed with neutral buffer, we were able to show that Z5BPA-bio could be covalently attached to IgG. Different concentration of the participating molecules and also different times for the UV light activation was used, and it was concluded that the most effective ratio between IgG and Z was 1:10 (IgG:Z). Moreover, the time for illumination of the reaction vessel was set to 1 h. Also, data show that the variant Z18BPA-bio was not covalently linked to IgG by this treatment (Figure 2B). To ensure that this behavior was not concentration-dependent, a higher concentration of Z18BPA-bio was used (1:500, IgG:Z), but still no covalent coupling was obtained (data not shown).

The successful conjugation of Z5BPA-bio to IgG was further confirmed in the second approach, where cross-linking was performed in solution and the photoconjugated antibodies were evaluated in the Luminex system. In this experiment, Z5BPA-bio and IgG were incubated in solution and subjected to UV light for cross-linking. To remove excess unbound Z molecules, a spin filter column (10 kDa cutoff) was used. This also allows for buffer exchange and lowering of pH, which enable release of noncovalently bound Z molecules from IgG. Hence, the bound and cross-linked Z domains will stay attached to the IgG molecules, while noncovalently bound Z domains will be released and washed away. In order to investigate the efficiency of covalent coupling of the bound Z5BPA-bio to the antibody, a sample of the photoconjugated antibodies was taken out before lowering the pH. Also, as negative control recombinantly produced and biotinylated Z was used. For evaluation of the covalent conjugation, antigens were linked to Luminex beads

and subsequently incubated with corresponding IgG molecules from the conjugation experiment (Figure 2A, setup 2). In the negative control, biotinylated Z, the signal diminishes when

Table 2. K_D values for Z5BPA-bio, Zwt, and Z18BPA-bio Binding to Human IgG1 and Mouse IgG2a

	Z5BPA-bio	Z18BPA-bio	Zwt
Human IgG1	10 nM	60 μM	20 nM
Mouse IgG2a	650 nM	-	550 nM
Rabbit IgG poly	30 nM	-	60 nM

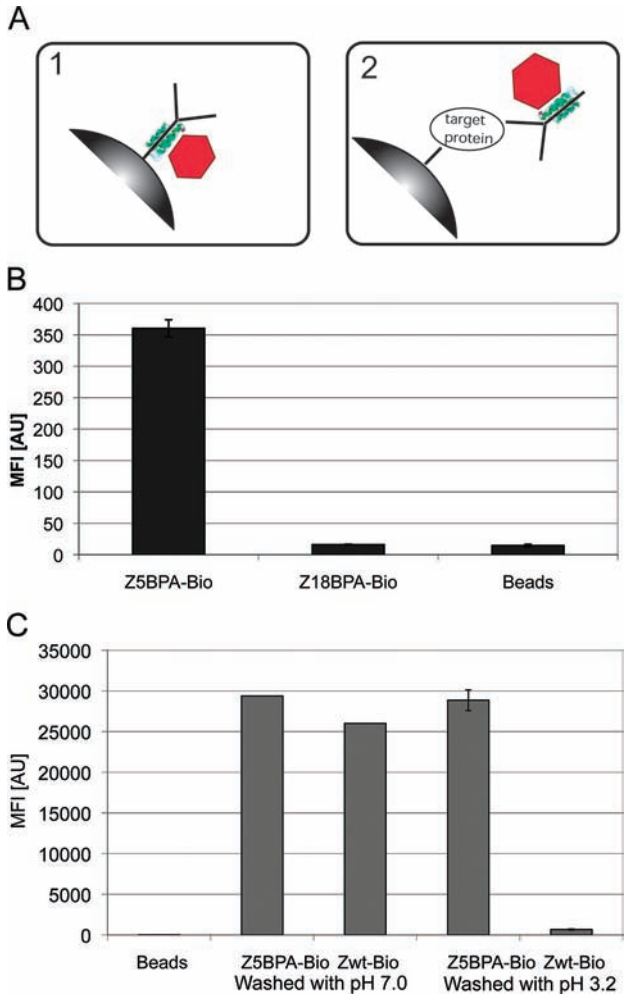

Figure 2. Covalent conjugation of the Z-variants was evaluated by using the Luminex platform. (A) The two different strategies used for analysis of covalent coupling are shown. In strategy 1, the antibodies were covalently coupled to Luminex beads. Thereafter, the beads were incubated together with the different Z variants and illuminated with UV-light. After washing, the biotinylation was detected by fluorescently labeled streptavidin. In strategy 2, the IgG and Z-variants were mixed and illuminated in solution. After illumination, the protein mixtures were washed, with a buffer with pH 3.2 or 7.0. To enable this, spin concentrators were used. After further washing and increasing the pH to neutral, the antibody solution was mixed with Luminex beads with already covalently attached antigens. Also, here the biotinylation was detected by fluorescently labeled streptavidin. (B) The cross-linking of Z5BPA-bio and Z18BPA-bio to polyclonal rabbit IgG. As negative control, uncoupled beads were used. Strategy 1 in (A) was used. Mean value of two different experiments is shown.

lowering the pH; hence. the noncovalent interaction between Z and IgG is possible to break with low pH (Figure 2C). Moreover, Z5BPA-bio is efficiently linked to the IgG molecules since the IgG molecules after treatment with low pH still give a strong signal. Also, the ability to bind the antigen indicates that the paratope of the antibody is intact. Evaluation of the conjugation efficacy was made by comparing the achieved signal before and after treatment with low pH. Therefore, the conclusion that more than 80% of the bound Z-molecules were efficiently cross-linked to the immunoglobulins could be drawn (Figure 2C).

Specificity of Labeling. Since many manufactured antibodies are stabilized by the addition of other proteins, commonly albumin, it is important to be able to perform the conjugation in complex solutions. To investigate the selectivity of the labeling, a solution containing eight times more HSA than specific monoclonal antibodies was prepared. The efficiency of the conjugation was analyzed and compared with conjugation without HSA (assay number 1 in Figure 3A). The efficiency of the labeling is not affected by the presence of HSA (Figure 3B). To assess any unwanted biotinylation of HSA, a Western blot experiment was performed. In the first experiment, all biotinylated proteins were detected (Figure 3C, left panel), and in the second setup, the present HSA molecules were detected (Figure 3C, right panel). This experiment indicates that no covalent coupling of the biotinylated Z-domains to HSA has occurred. However, since the migration of HSA in SDS-PAGE is rather similar to the heavy chain of IgG in complex with the Z domain, another experiment was performed. This time, the biotinylation was assessed using Luminex analysis. An HSA-binding protein was covalently attached to Luminex beads. Thereafter, the UV-exposed IgG-Z5BPA-bio or HSA-Z5BPA-bio mixture was mixed with the beads. Now, HSA or IgG is able to bind to the beads, by using either the covalent coupled protein's inherent ability to bind HSA or the conjugated antibody's ability to bind to the antigen. Thereafter, biotinylation was assessed through fluorescently labeled streptavidin. By utilizing the ability of the antibodies to selectively bind to the antigen-conjugated beads (assay number 1 in Figure 3A), high signals from the antigen binding IgG-molecules could be detected. Since similar signal intensity was detected both before and after washing with low pH, we could conclude that the conjugation of Z5BPA-bio to the antibodies was very effective. Furthermore, the conclusion that no biotinylation of HSA was obtained could be drawn since no signal was detected from the HSA-binding beads mixed with fluorescently labeled streptavidin (assay number 2 in Figure 3A). However, the ability of HSA to bind to the beads was confirmed by HSA-recognizing antibodies conjugated with biotin (setup 3 in Figure 3A,D). These results also show that the covalent attachment of Z to IgG is specific since no biotinylation of HSA could be detected.

To investigate the influence of labeling on the antigen binding capacity of the antibody an SPR-analysis of conjugated and unconjugated antibodies, binding was performed. As can be seen in Figure 4A–C, conjugated and unconjugated antibodies show the same affinity to its antigen, which confirms that the antigen-binding site is preserved after complete conjugation (Figure 4). The similar K_D values obtained for conjugated and unconjugated, 6.0 nM and 6.4 nM, respectively, clearly show that the antigen site of the antibody remains unaffected after being subjected to the conjugation process (Figure 4B,C).

To further show the specificity of the conjugation, Z5BPA-biotin was allowed to react with full-length antibodies, Fc fragments, and Fab fragments. The obtained conjugations were analyzed by Western blot. Figure 5 shows that conjugation occurs at the Fc part of the antibody, since no biotinylation could be detected on the Fab fragments. However, biotinylation

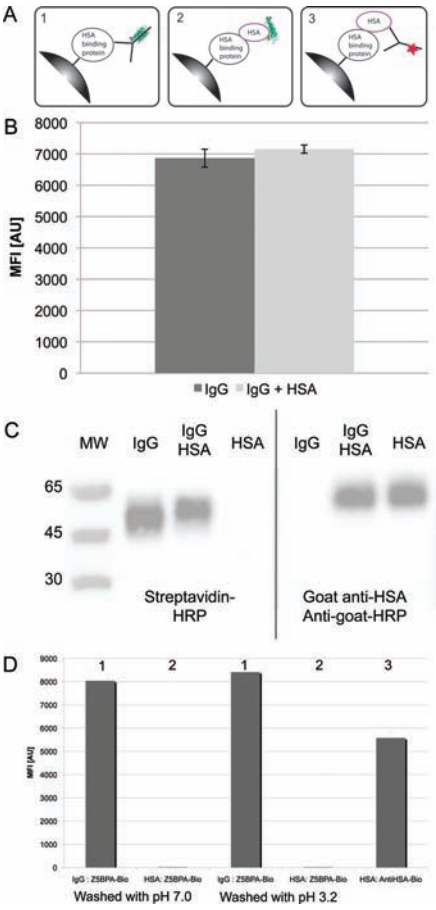

Figure 3. Degree of covalently linked Z5BPA-bio domain in a complex sample was analyzed. Samples of antibodies to be photoconjugated with Z5BPA-biotin were supplemented with 800 nM HSA (Albumina Kabi). (A) Three different strategies used for analysis of covalent coupling are shown. An HSA-binding protein was covalently attached to the Luminex beads. These beads could be used in three different ways. According to strategy 1, the attached protein is used as an antigen, since the labeled antibody is directed to this protein. In strategy 2, the protein is used to bind to HSA. In these two experiments, streptavidin-R-phycoerythrin is used to detect any biotinylation. In strategy 3, antibodies with biotin are used to detect the bound HSA. (B) Degree of cross-linking was analyzed both with and without HSA in the sample. Covalent linking of Z5BPA-bio was unaffected by the HSA present in the sample. Setup according to strategy 1 in Figure (A) was used. (C) To assess if Z5BPA-bio was able to covalently bind to the HSA molecule, a Western blot was performed. In the left panel, the amount of covalently linked Z5BPA-bio in three different samples was analyzed using streptavidin-HPR. No attachment to the HSA molecule could be detected. In the right panel, the presence of HSA in the samples was analyzed by using goat antibodies targeting HSA, visualized with HRP-conjugated antigoat antibodies. (D) To confirm the conclusion from the previous experiment, a Luminex experiment was made where both the amount of biotinylated IgG molecules and HSA molecules were analyzed using strategy 1 in (A). The number of biotinylated IgG molecules was shown to be high, both after and before treatment with low pH. This indicates a high degree of covalent coupling by Z5BPA-bio. The amount of biotinylated HSA-molecules was analyzed using strategy 2 in (A). No biotinylation could be detected before or after treatment with low pH. To ensure the presence of HSA, a third strategy was used (number 3 in (A)); hence, detecting HSA with an HSA-binding antibody and thereby the presence of HSA was confirmed.

was detected on both the full-length antibodies and the Fc fragments (Figure 4D).

Use of Conjugated Antibodies. The photoconjugated antibodies were used in a sandwich assay setup where capture antibodies were coupled to beads and incubated with target protein in various concentrations (Figure 5A). After thorough washing, target-specific photoconjugated antibodies were added. The beads were washed, and the fluorescence from streptavidin-R-phycoerythrin was detected by using the Luminex platform. Analyses using both human monoclonal antibodies and mouse monoclonal antibodies recognizing FITC-BSA were successfully performed, and the antigen could be detected down to a concentration of 0.1 ng/mL within a concentration window spanning 4 orders of magnitude (Figure 5).

Also, the conjugated antibodies were used for detection in a Western blot assay. By conjugation of the antibodies with Z5BPA-bio, the protein targeted by the antibodies could be detected by streptavidin-HRP. In Figure 5C, two Western blot membranes are shown. On the rightmost membrane, proteins are detected with covalently conjugated antibodies, and on the left membranes, as a negative control, the same antibodies were used, but in the conjugation step, Z-Bio, lacking the BPA group, was used. The molecular weights of the protein bands detected are as expected; hence, the system works both in a sandwich setup with the antigen in solution and in detection of proteins bound to a membrane.

DISCUSSION

To be able to covalently attach the Z domain to immunoglobulins, the structural information on the binding site was thoroughly studied. Two amino acids in close proximity to the binding surface were exchanged for the photoactivable probe, BPA. Both suggested Z variants were successfully synthesized with high yield and the C-terminal biotinylation was efficiently and specifically made through an orthogonal protection strategy (Figure 1). The interaction between IgG and the two synthesized Z variants was analyzed revealing a retained affinity for the Z5BPA-bio molecule, while Z18BPA-bio showed very low affinity (~100 μM, Table 2). For the Z5BPA-bio molecule, both the on- and off-rates are in the same range as for the parental Z domain (data not shown). The retained affinity of the Z5BPA-bio variant could be explained by steric similarity of phenylalanine and BPA making the inherent structure of Z intact. The addition of the extra benzoyl group seems to fit well between the two molecules upon binding. On the other hand, replacement of histidine 18 for BPA is deleterious and destroys the interaction with IgG. This could be due to the change of charge in the position of amino acid 18. Also, the larger side chain of the unnatural amino acid could sterically inhibit the ability to bind IgG. This photoactivable molecule has previously been used to covalently label antibodies through incorporation in an antibody binding molecule from protein G,[18] but a different strategy for production of the binding domain was used. In this publication, they have recombinantly produced the IgG-binding domain and after purification covalently attached a BPA-group via a cysteine. Moreover, the area of application in the referred study was to covalently attach the antibodies onto a solid support in an oriented way. In this project, we have focused on labeling of the antibodies for detection purposes.

A very important characteristic of a molecule used for selective labeling is the efficiency of the covalent linking. Hence, a thorough characterization of this was performed. Different IgG molecules were used for this analysis, and in

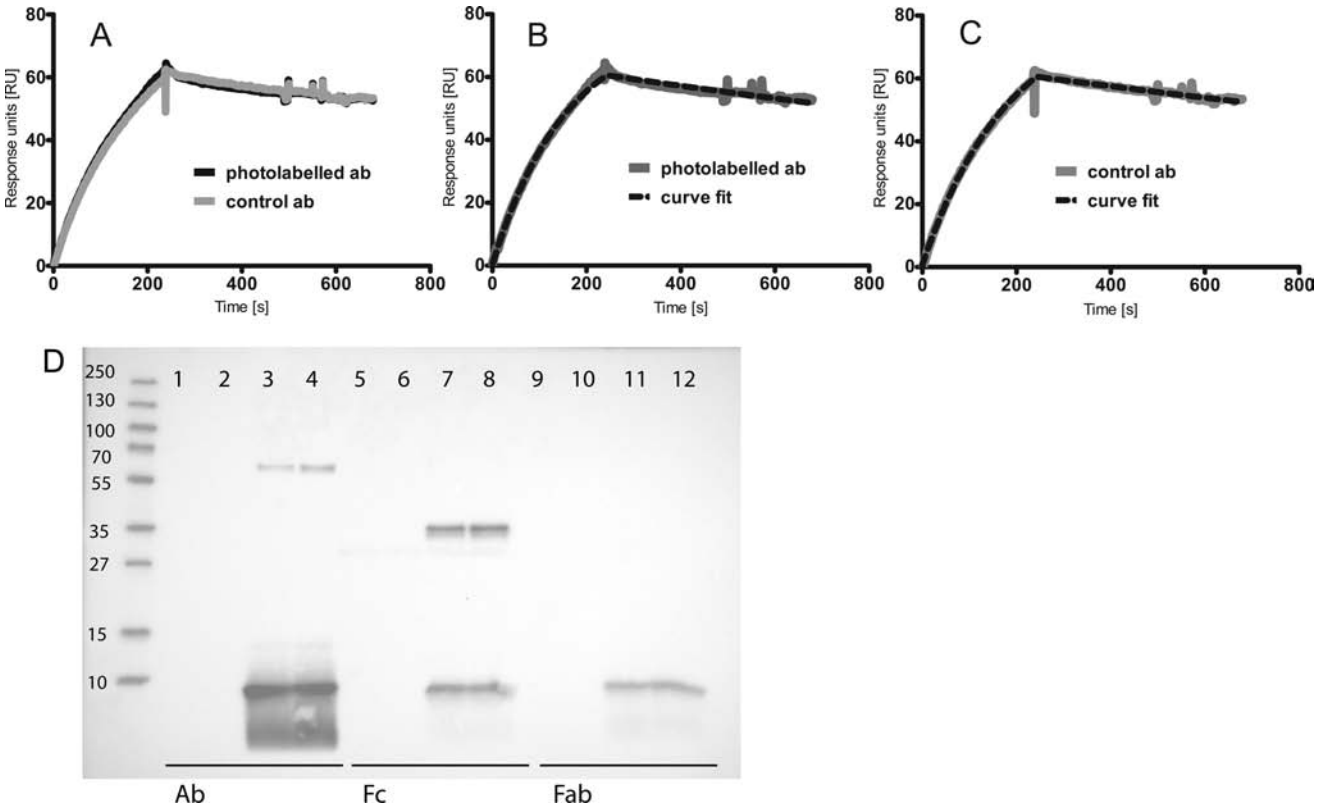

Figure 4. Investigation into the performance of an antibody was made by analyzing the affinity constant for antigen binding before and after conjugation. Moreover, specificity of the conjugation was assessed by Western blot analysis. (A) SPR analysis of antibodies targeting their antigen was performed, before and after conjugation. Antigen was immobilized on the chip and the antibodies were flowed over the surface. Average of duplicate samples is shown. Nonlinear regression analysis were made of the binding curve of (B) photolabeled antibodies giving a K_D value of 6.0 nM and (C) control antibodies giving a K_D value of 6.4 nM. Hence, the labeling procedure does not influence the performance of the antibody. (D) Western Blot analysis of duplicate samples of conjugated and unconjugated full-length antibodies (lanes 1−4), Fc fragments (lanes 5−8), and Fab fragments (lanes 9−12). Z5BPA conjugates specifically to the Fc part of the antibodies.

the experiment, the amount of covalently attached Z-domains were compared with the amount of Z-domains able to bind to the IgG molecules. All immunoglobulins with affinity for Z were successfully covalently labeled, with an efficiency of more than 80% when the ratio 1:10 (IgG:Z) was used (Figure 2).

When using the coupling strategy in complex solution, we could conclude that no unwanted covalent labeling could be detected, despite high concentration of both HSA and Z5BPA-bio (Figure 3). This is of utmost importance and shows that the benzophenone (BP) group needs to be in very close proximity to create a covalent link, thereby ensuring specific and directed covalent attachment. Hence, specific and stable interaction as well as UV light of correct wavelength is needed. The necessity of UV light makes this photoactivable probe convenient and easy to handle since no light protection is needed during the synthesis, purification, or other experimental steps where no conjugation is desired. Moreover, if a covalent bond not is created, the probe relaxes to the ground state after excitation and thereby the uncoupled Z molecules are possible to use in a next round of labeling (data not shown).

To assess the functionality of the covalently linked antibodies, three different methods were used. A sandwich assay was successfully designed by taking advantage of capturing antibodies covalently linked to Luminex beads. The prepared beads were incubated with different concentrations of antigen (Figure 5A). Hence detection could be made by streptavidin using conjugated antibodies from both mouse and human. Also, an ordinary Western blot was made showing that here also the conjugated antibodies successfully detect the anticipated proteins on the membrane. These data show that the covalent linkage between IgG and Z5BPA-bio is stable and usable in different well-known assays. When performing the sandwich assay, antigen concentrations down to 0.1 ng/mL could be detected. The conjugated antibodies in this study could possibly have one or two biotin on each antibody since only one biotin is incorporated in each Z domain. Hence, by introducing more than one biotin or even by directly introducing a number of fluorescent probes in the Z domain the detection level will likely be improved. The comparison of the ability of conjugated and unconjugated antibodies to bind their antigen by SPR analysis shows that the procedure allows the antibody to retain its binding to the antigen and that the covalently attached photoreactive Z5BPA-biotin does not influence the reactivity of the antibody (Figure 4). The specificity of the labeling is further demonstrated by the Western blot experiment where biotin is detected only if the antibody or antibody fragment is covalently conjugated. The data clearly show that conjugation is achieved on the full-length antibody and also on Fc fragment. However, no conjugation could be detected on the Fab fragment (Figure 4D).

Here, we have presented a stringent and effective method for labeling of antibodies by utilizing an IgG-binding protein domain, Z. By introducing a photoactivable group in the

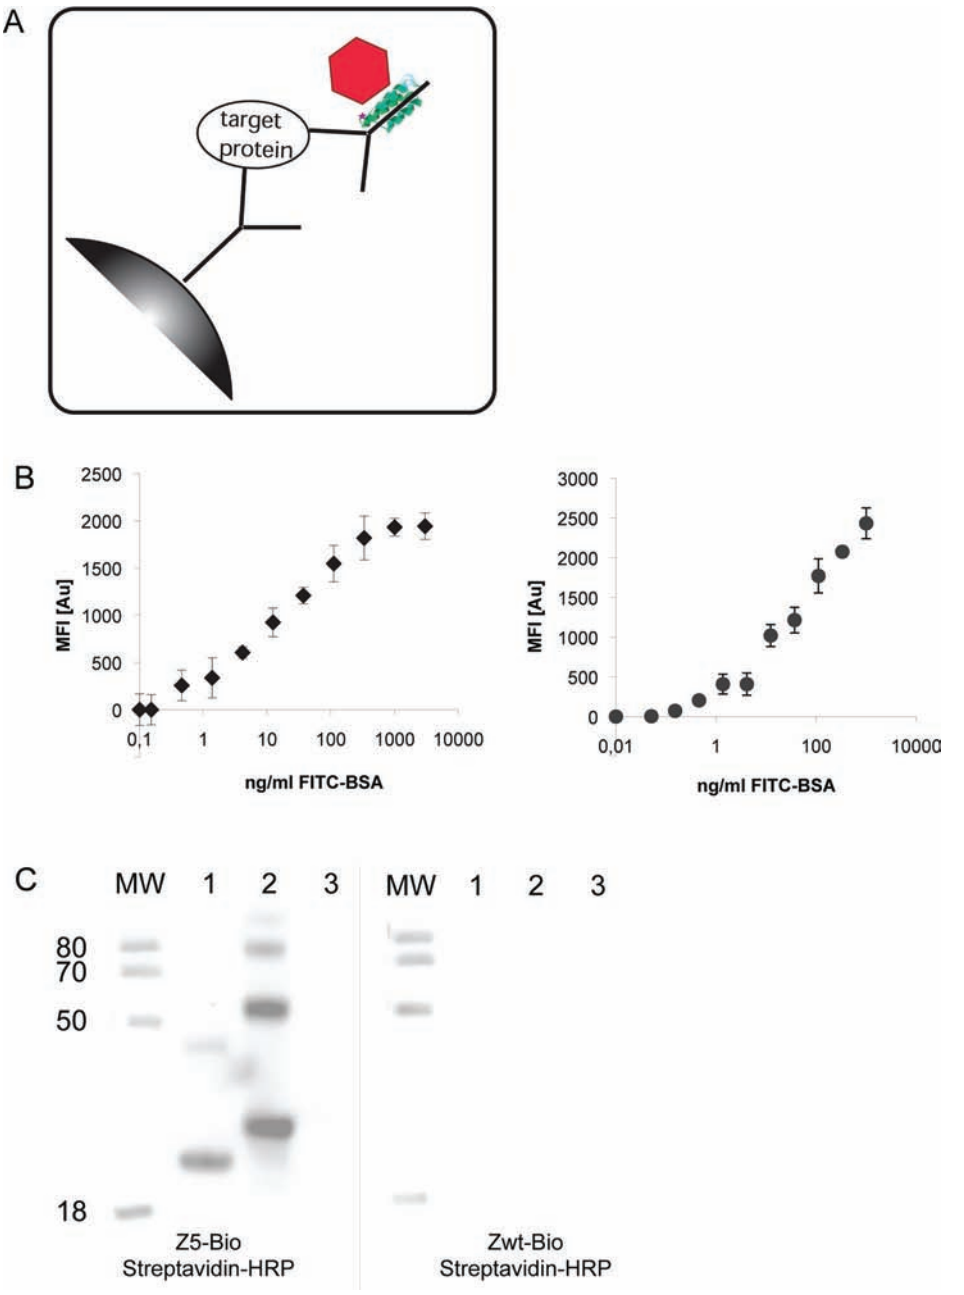

Figure 5. Covalently cross-linked antibodies were used in two common assays. (A) Sandwich analysis where the capturing antibodies were attached to Luminex beads. (B) Incubation of beads with different concentrations of antigen and subsequent washing. The amount of captured antigen was analyzed by using detection antibodies covalently linked to Z5BPA-bio in combination with streptavidin-R-phycoerythrin. The diagram to the left shows human monoclonal IgG1 targeting FITC-BSA, and in the right diagram, mouse monoclonal IgG2a is used; the mean values of three experiments are shown. (C) Covalently cross-linked antibodies were used in a Western blot analysis. In the left panel, detection was made by using an antibody covalently linked to Z5BPA-bio, and in the right panel, the same antibody but with Zwt-bio was used as control. Protein samples on the gel are as follows: MW, a molecular weight marker; lane 1, His6ABP (19 kDa); lane 2, His6ABP-PrEST (25.5 kDa).

protein scaffold during synthesis, a covalent linkage between IgG and the synthesized protein domain can be created with very high efficacy. This linkage has been shown to be efficiently formed and stable under different conditions. Here, we have been using biotin as the reporting group, but a large variety of different groups could be introduced in the protein domain to tailor-make the antibodies for a certain purpose. The new approach for labeling of antibodies presented here is both flexible and reliable and would be suitable for a wide range of applications where antibodies are used in the capture or detection step.

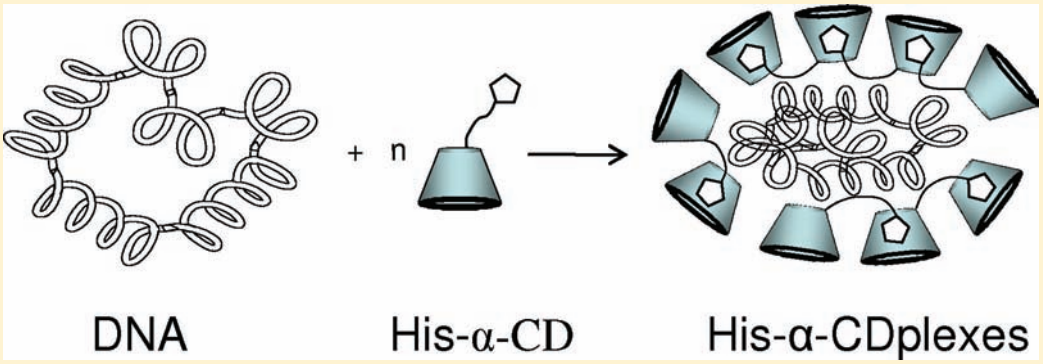
Supporting Information



ABSTRACT: α-Cyclodextrin was transformed in a cationic unit after *per* substitution with histidine (His-α-CD) and lysine (Lys-α-CD) molecules on the primary face. His-α-CD and Lys-α-CD were used to form electrostatic complexes (CDplexes) with a plasmid DNA encoding luciferase gene, and the ability of CDplexes to transfect mammalian cells was examined using HEK293-T7 cells. The luciferase activity in cells transfected with His-α-CDplexes was 8-fold higher than that obtained Lys-α-CDplexes. When the transfection was carried out in the presence of chloroquine, the luciferase activity with His-α-CDplexes and Lys-α-CDplexes increased 6 and 25 times, respectively. The lower enhancement with His-α-CDplexes confirmed that histidine induced a proton sponge effect inside endosomes upon imidazole protonation, favoring DNA delivery in the cytosol. At the same time, we found that the condensation of DNA with His-α-CD was unexpectedly stronger than that obtained with the lysyl-α-CD counterpart. Moreover, it was as strong as that observed with high molecular weight polylysine. NMR (ROESY and DOSY) investigations in the absence of DNA showed that an inclusion complex is formed between the imidazole ring of histidine and the hydrophobic cavity of CD but no His-α-CD polymers can be formed by intermolecular interactions. These results suggest that intermolecular interactions between imidazole and His-α-CD cavity could be involved to form supramolecular assemblies in the presence of a DNA scaffold leading to DNA condensation into low diameter particles.

INTRODUCTION

Cyclodextrins are natural biocompatible cyclic oligosaccharides composed of 6, 7, or 8 D(+)-glucose units linked by α-1,4-linkages and named α-, β-, or γ-cyclodextrin, respectively. Recently, various cyclodextrin-based gene delivery systems have been developed.[1] For instance, cyclodextrin can be transformed in a cationic unit after *per* substitution with small cationic molecules. These derivatives can condense a plasmid DNA (pDNA) to form CDplexes that can be used for the transfection of mammalian cells. For example, α- and β-cyclodextrins have been *per* substituted with oligoethylenimine repeat units (from 1 to 14).[2,3] The transfection efficiency of HEK293 and COS-7 cells increased as the length of the oligoethylenimine moiety increased from diethylenetriamine to pentaethylenehexamine residues. β-Cyclodextrin was used also as a scaffold to prepare a homogeneous sevenfold symmetric polyaminothiourea amphiphiles for gene transfer.[4−6] Cationic cyclodextrins have been derivatived in cationic polyrotaxanes either with a poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) triblock copolymer, a PEI-b-PEG-b-PEI copolymer or α,ω-dimethacrylate poly(ethylene glycol).[7−9] For certain CD derivatives, the transfection efficiency was comparable to that obtained with JetPEI, the gold standard cationic polymer. One of the major barriers for gene transfer is

the endosome escape allowing the delivery of the plasmid DNA in the cytosol. For this purpose, histidine can be used. The imidazole ring of histidine is a weak base that has the ability to acquire a cationic charge when the pH of the environment drops below 6. As has been demonstrated for poly(histidine), this phenomenon can induce membrane fusion and/or membrane permeation in an acidic medium.[10,11] Moreover, the accumulation of protonated histidine residues inside acidic vesicles can induce a proton sponge effect, which increases their osmolarity and their swelling. The proof of concept has been shown with polylysine partially substituted with histidine residues that has caused a tremendous increase by 3−4.5 orders of magnitude of the transfection efficiency of DNA/polylysine polyplexes.[12] Then, several histidine-rich polymers and peptides as well as lipids with imidazole polar heads have been reported to be efficient carriers to deliver nucleic acids including DNA and RNA *in vitro* and *in vivo*.[13] More remarkable, histidylated carriers are often weakly cytotoxic, making them promising chemical vectors for nucleic acid delivery.

Here, we have used α-CD as a scaffold to prepare histidylated CD as DNA carrier. α-CD was chosen because of its lower propensity to form an inclusion complex with cholesterol than β-CD.[14−16] Indeed, β-CD has been shown to extract cholesterol from cell membranes. We have synthesized the hexakis(6-deoxy-6-histidinyl)cyclomaltohexaose (His-α-CD) (**2**) (Scheme 1). This derivative had six α-amino groups usable for pDNA interaction and six imidazole rings for acid-mediated membrane destabilization after CDplex uptake by the cells into endosomes. The polyamino α-CD counterparts, the hexakis(6-deoxy-6-amino)cyclomaltohexaose (NH_2-α-CD) (**1**) and the hexakis(6-deoxy-6-lysinyl)cyclomaltohexaose (Lys-α-CD) (**3**), were also synthesized (Scheme 1). The former had six amino groups as His-α-CD and the latter twelve. The capacity of these cationic α-CD derivatives to condense pDNA was determined and the transfection efficiency of CDplexes was evaluated in HEK293-T7 cells using the luciferase gene as read-out. Unexpectedly, a strong condensation of pDNA by His-α-CD was evidenced. Furthermore, we showed by NMR investigations the involvement of an inclusion complex between the imidazole ring of histidine and the hydrophobic cavity of CD. These results suggest that supramolecular assemblies of His-α-CD in the presence of a DNA scaffold could occur during the formation of His-α-CDplexes.

EXPERIMENTAL PROCEDURES

All reagents were purchased from Sigma (St. Quentin Fallavier, France) unless otherwise stated.

The synthesis of hexakis(6-deoxy-6-iodo)cyclomaltohexaose has been adapted from ref 17, and hexakis(6-deoxy-6-azido)cyclomaltohexaose from ref 3 and hexakis(6-deoxy-6-amino)cyclomaltohexaose from ref 18. The detailed experimental protocols and the characterizations are reported in the Supporting Information (S1).

Hexakis(6-deoxy-6-histidinyl)cyclomaltohexaose (His-α-CD). Boc_2-His-OSu (0.59 g, 1.30 mmol) was added to a stirring solution of hexakis(6-deoxy-6-amino)-cyclomaltohexaose (0.20 g, 0.207 mmol) in DMSO (5 mL),

dx.doi.org/10.1021/bc200167p | *Bioconjugate Chem.* 2011, 22, 2404−2414

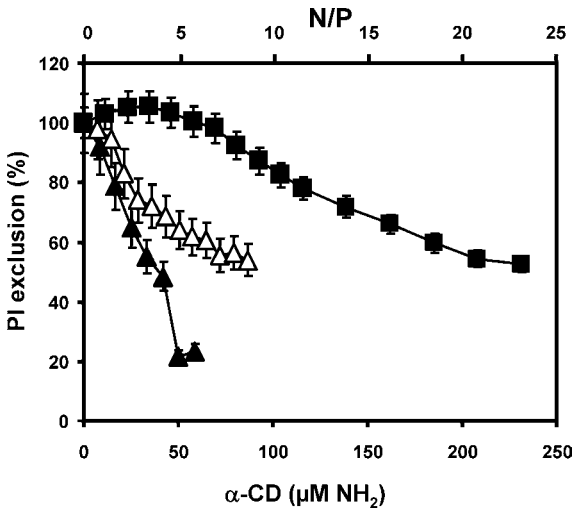

Figure 1. Interaction of polyamino-α-CD derivatives with DNA. Aliquots of solution containing polyamino-α-CD derivatives were sequentially added to pDNA (2.5 μg) in 650 μL of 10 mM Hepes buffer, pH 7.4, in the presence of ethidium bromide (2 μM). The fluorescence intensity was measured (λ_{ex} = 530 nm; λ_{em} = 580 nm) after each addition of samples, and the fraction of dye exclusion was calculated from the fluorescence intensity measured in the absence and in the presence of polyamino-α-CD derivatives. N/P corresponds to the ratio between the number of positive charges of polyamino-α-CD derivatives and that of the negative charges of the pDNA phosphate. His-α-CD (▲); Lys-α-CD (△); NH_2-α-CD (■).

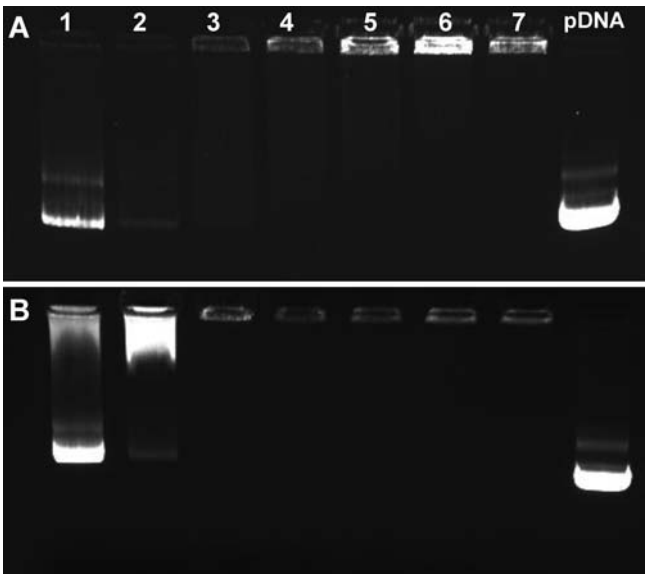

Figure 2. Agarose gel electrophoresis shift assay of pDNA in the presence of various quantities of His-α-CD (A) and Lys-α-CD (B). Lanes 1, 2, 3, 4, 5, 6, 7, and 8 correspond to pDNA/CD weight ratios (μg/μg) of 1/0.5, 1/1, 1/2, 1/3, 1/4, 1/6, and 1/8, respectively. pDNA line correspond to migration of pDNA in the absence of any polyamino α-CD derivatives. Electrophoresis was conducted for 1 h under 80 V/cm through a 0.6% agarose gel containing ethidium bromide (1 μg/mL) in 95 mM Tris, 89 mM boric acid, and 2.5 mM EDTA (pH 8.6). An ultraviolet lightbox was used to visualize ethidium bromide-stained DNA in gels.

and the reaction was carried out at room temperature for 24 h. Then, 2 mL of trifluoroacetic acid (TFA) was added and the medium was stirred for 12 h. After removal of TFA under reduced pressure, the product was recovered by precipitation in ethyl acetate (AcOEt) with 71% yield (0.45 g). ^{1}H NMR (D_2O, 300 MHz): δ ppm 7.7 (H10), 6.9 (H9), 4.5 (H1), 4.0 (H7), 3.8 (H3), 3.6 (H5), 3.5 (H6), 3.3 (H2), 3.0 (H8), 2.8 (H4). ^{13}C NMR (D_2O, 100 MHz): δ ppm 171.7 (C═O, amide), 163.3 (q, C═O, TFA), 136.8 (C-10 arom. imidazole), 132.9 (C quat. arom. imidazole), 116.7 (C-9 arom. imidazole), 117.0 (CF_3, TFA), 101.9 (C-1), 82.6 (C-4), 72.8, 72.1, 69.7 (C-2, C-3, C-5), 53.8 (C-7; $CHNH_3$), 39.6 (C-6), 30.2 (C-8). For $C_{72}H_{108}N_{24}O_{30}$, MS (MALDI-TOF/TOF): 1795.8 uma $[M + Li]^+$, 1827.8 uma $[M + K]^+$.

Hexakis(6-deoxy-6-lysinyl)cyclomaltohexaose (Lys-α-CD). *N*,*N*-diBoc-lysine (0.432 g, 1.24 mmol) was dissolved in dry DMF (10 mL). 1-Hydroxybenzotriazole (HOBt) (0.176 g, 1.30 mmol) was added, and the solution was cooled to 0 °C in an ice bath. *N*,*N*′-Dicyclohexylcarbodiimide (DCC) (0.261 g, 1.27 mmol) was then added, and the temperature was maintained at 0 °C for a further 60 min. The reaction mixture was then allowed to warm to room temperature during which time dicyclohexylurea precipitated out. After stirring for a further 60 min at room temperature, a suspension of hexakis(6-deoxy-6-amino)cyclomaltohexaose (0.200 g, 0.207 mmol) and methyl morpholine (0.14 mL) in dry DMF (5 mL) was added to the reaction medium and the solution was stirred at room temperature for 24 h. The dicyclohexylurea precipitate was filtered off, and the filtrate was concentrated under reduced pressure at 50 °C as oil. Then, saturated $NaHCO_3$ (100 mL) was added to the oil to give a suspension which was stirred for 1 h and filtered. The precipitate was washed with H_2O and dried under high vacuum. The crude product underwent subsequent Boc deprotection in a MeOH/TFA (10:2; v/v) solution at room temperature, and the solvent was evaporated and replaced by AcOEt (5 mL). The precipitate was filtered and the expected product was recovered in 65% yield (0.418 g). ^{1}H NMR (D_2O, 500 MHz): δ ppm 4.95 (d, 6 H), 3.40−4.08 (m, 36 H), 3.31 (m, 6 H), 3.02 (m, 12 H), 1.96 (m, 12 H), 1.74 (m, 12 H), 1.49 (m, 12 H). ^{13}C NMR (D_2O, 125 MHz): δ ppm 170.1 (C═O, amide), 162.6−163.4 (C═O, TFA), 113.1−120.1 (CF_3), 102.1 (C-1), 82.9 (C-4), 72.7, 72.3 (C-2, C3), 70.0 (C-5), 53.3 (C-7; $CHNH_3$), 39.5 (C-6), 39.2 (C-11; CH_2NH_3), 30.9, 26.6, 21.8 (C-8, C-9, C-10; CH_2). For $C_{72}H_{138}N_{18}O_{30}$ (M_w = 1735), MS (MALDI-TOF/TOF): 1736.0 uma $[M + H^+]$.

Polymers. PLK_6 and PLK_{190}—poly(L-lysine) with degree of polymerization of 6 and 190, respectively—were purchased from Sigma Aldrich and Bachem (Bubendorf, Switzerland), respectively. $K_{20}H_{20}$ was a poly(L-lysine) with degree of polymerization of 20 (NeoMPS SA, Strasbourg, France) in which all the ε-amino functions of the lysyl residues were substituted with histidine residues as described.[19]

Cells and Cell Culture. Human embryonic kidney 293T7 cells were grown at 37 °C in a humidified atmosphere containing 5% CO_2 in MEM medium containing 10% heat inactivated fetal bovine serum (PAA Laboratories, Les Mureaux, France), 2 mM L-glutamine (Fischer Bioblock, Illkirch, France), 100 U/mL penicillin (Fischer Bioblock), 100 U/mL streptomycin (Fischer Bioblock), and Geneticin (400 μg/mL).[20] Cells were mycoplasma-free as evidenced by MycoAlert Mycoplasma Detection Kit (Lonza, Levallois Perret, France).

Plasmids. pTG11033 (pCMV-Luc; 9514 bp) (kindly given by Transgene S.A., Strasbourg, France) was a plasmid DNA encoding the *firefly* luciferase gene under the control of the

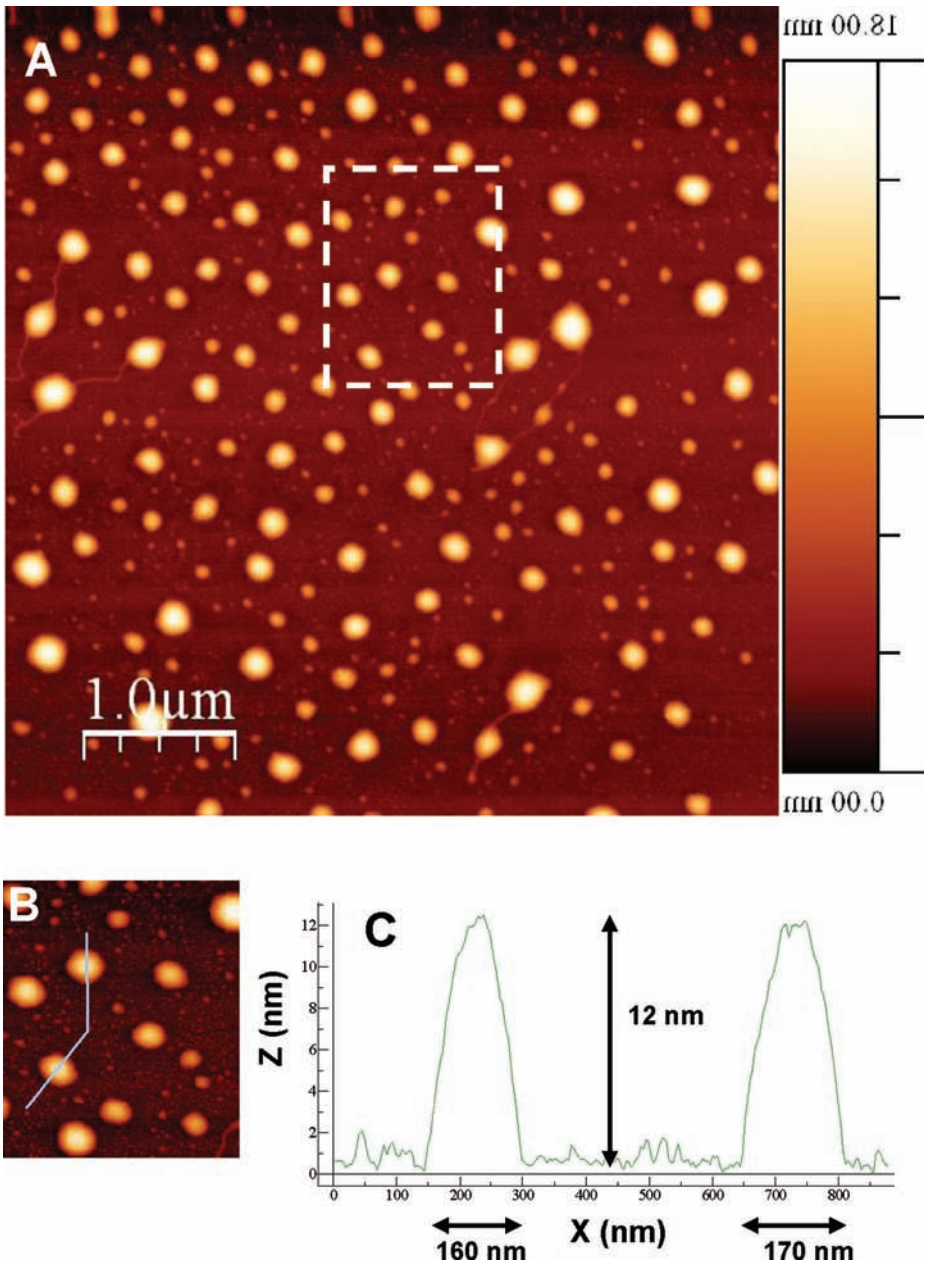

Figure 3. AFM morphology of His-α-CD/pDNA complexes (N/P of 4.2). (A) 2D topography: tapping mode in air; scan size: 5 μm, scan rate: 0.603 Hz, I. Gain: 0.4, P. Gain: 0.5, Amp. (C) AFM profile of His-α-CD/pDNA complexes along the line in image in (B) where Z is the height and X the diameter.

human cytomegalovirus promoter. Supercoiled plasmid DNA was isolated by a standard alkaline lysis method, and purification was carried out with the QIAGEN Mega Kit (QIAGEN, Courtaboeuf, France).

Dye Exclusion Experiments. Aliquots of solution containing cationic derivatives were sequentially added to pDNA (2.5 μg) in 650 μL of 10 mM Hepes buffer, pH 7.4, in the presence of ethidium bromide (2 μM). The fluorescence intensity was measured (λ_{ex} = 530 nm; λ_{em} = 580 nm) after each addition of samples and the fraction of dye exclusion was calculated from the fluorescence intensity measured in the absence and in the presence of cationic derivatives.

Measurements of Size and ζ Potentials. CDplexes were prepared by adding 40 μg of His-α-CD or Lys-α-CD in 60 μL of 10 mM Hepes buffer, pH 7.4, to 10 μg pDNA in 140 μL of 10 mM Hepes buffer, pH 7.4. The solution was mixed by up−down pipetting, vortexed for 4 s, and allowed to stand for 30 min at 20 °C. Then, CDplexes were diluted to 1.4 mL in 10 mM Hepes buffer, pH 7.4. Their size and their ζ potential were measured with ZetaSizer 3000 (Malvern Instruments, Orsay, France). The size was measured by quasi-elastic laser light scattering (QELS) with a sample refractive index of 1.59 and a viscosity of 0.89. The system was calibrated with the 200 ± 5 nm polystyrene polymers (Duke Scientific Corps, Palo Alto, CA). The diameter of CDplexes was calculated in the automatic mode. Their ζ potential was measured by electrophoretic mobility. The following parameters were set up: viscosity, 0.891 cP; dielectric constant, 79; temperature, 25 °C;

dx.doi.org/10.1021/bc200167p | *Bioconjugate Chem.* 2011, 22, 2404−2414

F(Ka), 1.50 (Smoluchowsky); maximum voltage of the current, 15 V. The system was calibrated with DTS 5050 standard from Malvern. Measurements were done ten times with the zero-field correction. The ζ potential was calculated with the Smoluchowsky approximation.

Atomic Force Microscopy. Two microliter aliquots of His-α-CD/pDNA complexes at a mass ratio of 4:1 prepared in 10 mM hepes buffer were adsorbed for 5 min on freshly cleaved muscovite mica. The surface was rinsed thoroughly with ultrapure water and dried for 2 h under vacuum-drying. AFM imaging was performed in tapping mode with Tap300A1-G tip (Budget Sensors, Combo, US) at a scanning speed of 0.603 Hz with an AFM Veeco Dimension 3100 (Veeco, Santa Barbara, CA) using high frequency (300 kHz) and Tap300Al-G silicon probe with tip radius <10 nm (Budget Sensors). Images were treated using the *WSxM 5.0* software.[21]

Transfections. Two days prior to transfection, cells were seeded at 1×10^5 cells per 2 cm^2 in culture medium (1 mL) in a 24-well plate. At the time of the experiment, cell cultures were 80% confluent. CDplexes were prepared by adding 30 μg of His-α-CD or Lys-α-CD in 45 μL of 10 mM Hepes buffer, pH 7.4, to 7.5 μg pDNA in 105 μL of 10 mM Hepes buffer, pH 7.4. The solution was mixed by up−down pipetting, vortexed for 4 s, and allowed to stand for 30 min at 20 °C. It was adjusted to 1.5 mL with culture medium supplemented with 10% FBS before transfection. The medium was removed, the CDplex solution (0.5 mL, 2.5 μg pDNA) was added in each well, and cells were incubated for 4 h at 37 °C. Then, the medium was removed, and cells were cultured 48 h at 37 °C in complete culture medium. Luciferase activity was measured using a Lumat LB9507 luminometer (Lumat LB9507, Berthold, Wildbach, Germany), and the luciferase activity (Relative Light units, RLU) was normalized to RLU per milligram extracted protein.[22]

NMR Experiments. NMR experiments were carried out in D_2O using an Avance 300 MHz Bruker instrument, except for the rotating frame Overhauser effect spectroscopy (ROESY) and heteronuclear 2D experiments which were realized using an Avance 600 MHz Bruker instrument. The temperature calibration of the 300 MHz spectrometer was performed with a sample of 100% CH_3OH in the temperature range between 298 and 313 K.

For the diffusion-ordered spectroscopy (DOSY) experiments, the maximum field gradient strength was calibrated using a homemade Plexiglas phantom (8 mm ±0.01 length and a width equal to the inner diameter of the NMR tube) inserted in a H_2O-filled NMR tube and using the pulse program *calibgp*.[23] Some "negative" projection images of the phantom as a function of applied field gradient strength is given (Supporting Information Figure S2). The linear plot of the obtained gradient strengths against the gradient strength setting (GPZ1) used gave a maximum field gradient strength equal to 56.8 G/cm. The accuracy of the calibrations was checked by measuring the self-diffusion coefficient of a mixture H_2O/D_2O (10%/90% in moles) at 25 °C.[24] The DOSY experiments were carried out using the stegp1s pulse sequence with a linear gradient of 16 steps between 2% and 95%. Before each diffusion experiment, the proton relaxation times were determined in order to correctly set the D1 parameter of the DOSY sequence, and the length of the gradient δ and the diffusion time Δ were optimized for each analyzed product.

RESULTS AND DISCUSSION

Synthesis of α-CD Derivatives. Hexakis(6-deoxy-6-amino)cyclomaltohexaose was synthesized according to previous reported procedures. Then, the coupling between protected amino acid and hexakis(6-deoxy-6-amino)-cyclomaltohexaose were conducted following two synthetic pathways in order to reach a good yield of each product (Scheme 1). Deprotection of the amine functions of the grafted amino groups were then performed to obtain the expected products. ^{1}H NMR (SI Figures S3 and S4) and ^{13}C NMR (SI Figure S5 and S6) spectra show that His-α-CD and Lys-α-CD were synthesized with good purity. MS (MALDI-TOF/TOF) spectrum of the histidinylated conjugate show peaks at 1795.8 and 1827.8 uma (respectively, Li^+ and K^+ adducts) confirming the presence of α-CD substituted by 6 histidyl residues (SI Figures S7). MS (MALDI-TOF/TOF) spectrum of the lysylate conjugate indicated a molecular weight of 1736 uma corresponding to α-CD substituted with 6 lysyl residues (SI Figures S8). Undersubstitution of the CD was detected by mass spectroscopy as witnessed by the presence of a peak at 1608.9 uma, which corresponds to modified cyclodextrin with one glucopyranose unit having an hydroxyl function at the 6 position (SI Figure S8). This compound was found to form a complex with HOBt-TFA salt, demonstrated by a peak at 1880.1 uma, at a concentration not detectable by NMR.

Interaction of Polyamino α-CD Derivatives with DNA. The ability of each polyamino α-CD to condense a plasmid DNA was evaluated by fluorescence dye exclusion using ethidium bromide. This nonfluorescent molecule becomes fluorescent once intercalated between the base pairs of the plasmid DNA. Conversely, the fluorescence intensity drops due to dye exclusion when DNA condensation occurs in the presence of polycationic molecules. As shown in Figure 1, the dye exclusion depended on the polyamino α-CD types. The fluorescence intensity decreased rapidly when the amount of His-α-CD increased, indicating a strong condensation of the plasmid DNA. The maximum of the dye exclusion reached 80% in the presence of 7.5 μg (4.2 nmol) His-α-CD corresponding to a N/P charge ratio of 4.2. N/P was the charge ratio between the number of positive charges of the polyamino α-CD derivatives and the negative charges of the pDNA phosphate. All the pDNA phosphate functions are negatively charged and the 12 amino groups of Lys-α-CD are positively charged at pH 7.4. On the basis of our previous results on histidylated polylysine, we have hypothesized that His-α-CD contained 8 positive charges at pH 7.4. We have indeed reported that the protonation of the imidazole groups in histidylated polylysine occurs at a 1.1 pH unit higher (6.9) than that of histidine, meaning that 2 of the 6 imidazole rings are protonated at pH 7.4.[25] Surprisingly, no significant dye exclusion and no DNA condensation were observed in the presence of NH_2-α-CD. The fluorescence intensity decreased much more in the presence of Lys-α-CD than in the presence of NH_2-α-CD. The maximum of the dye exclusion reached 50% in the presence of 17 μg (120 nmol) Lys-α-CD at N/P of 15. While Lys-α-CD contained more positive charges than His-α-CD, DNA condensation with Lys-α-CD was lower than with His-α-CD. The formation of DNA complexes with the polyamino α-CD derivatives was monitored by agarose gel electrophoresis (Figure 2). The gel retardation experiments indicated that no migration of 1 μg pDNA was observed from 1 μg His-α-CD and 2 μg Lys-α-CD. Compared to pDNA/Lys-α-CD, the lower

level of BET staining of pDNA with His-α-CD from a 1/1 weight ratio evidenced a better DNA condensation that was in line with dye exclusion experiments. In these weight ratios, the migration of pDNA was observed with α-CD-NH_2 confirming the absence of pDNA condensation (not shown).

Physicochemical Parameters of DNA/Polyamino α-CD Derivatives Complexes (CDplexes). The size and the ζ potential of CDplexes were measured at their optimal DNA/CD ratio. Dynamic light scattering measurements of His-α-CDplexes at N/P of 4.2 indicated that their diameter was close to 225 ± 45 nm with a polydispersity index (PDI) of 0.31 indicative of a relative homogeneity of the size distribution. These CDplexes were slightly positive (ζ potential = 7 ± 5 mV). In contrast, the size of Lys-α-CDplexes at same N/P was close to 640 ± 90 nm (PDI of 0.64) and the ζ potential was −1 ± 3 mV. This result confirmed the higher DNA condensation capacity of His-α-CD. The lower DNA condensation capacity of Lys-α-CD formed larger and less homogeneous CDplexes. His-α-CDplexes were cast on mica and observed by AFM. All the pDNA was complexed with His-α-CD and formed globular particles (Figure 3A,B). On the basis of the AFM profiles, His-α-CDplexes demonstrated the average diameter and height of 170 and 12 nm, respectively (Figure 3C). Compared to DLS, the CDplexes dimension was slightly smaller with AFM because AFM provides measurement of a single particle, while DLS gives the mean value for the non-monodispersed solution of particles.[26]

Transfection Efficiency. The ability of these CDplexes to transfect mammalian cells was examined using HEK293-T7 cells and pCMVLuc, a plasmid encoding the luciferase gene. The cells were incubated for 4 h with CDplexes containing 2.5 μg pDNA. Figure 4 shows that the luciferase activity in cells

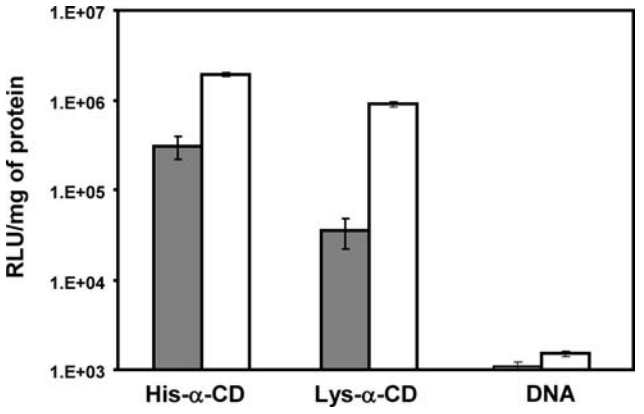

Figure 4. Transfection of HEK293-T7 cells with CDplexes. Cells were transfected with pCMVLuc (2.5 μg) free or complexed with His-α-CD or Lys-α-CD at N/P of 5.3 and 8.5, respectively. Transfection was carried out in the absence (gray bars) or the presence (white bars) of 100 μM chloroquine. The luciferase activity expressed as relative light units per mg protein (RLU/mg of protein) was measured upon 48 h of culture. The values shown are averages of three independent experiments.

transfected with His-α-CDplexes (3×10^5 RLU/mg of protein) was 8-fold higher than that obtained Lys-α-CDplexes. When the transfection was carried out in the presence of chloroquine—a lysosomotropic reagent that favors destabilization of acid vesicles [27]—the luciferase activity of His-α-CDplexes and Lys-α-CDplexes increased 6 and 25 times, respectively. The enhancement was lower with His-α-CD compared to Lys-α-CD, because His-α-CD contains acid-protonable imidazole groups that induce a proton sponge effect inside endosomes which favors the delivery of pDNA into the cytosol in the absence of chloroquine. Here, the protonation behavior of the imidazole groups in His-α-CDplexes is expected to be as in polyplexes made with histidylated polylysine (His-pLK). We have indeed reported that the ζ potential of His-pLK polyplexes increased 8 times when the pH decreased from 7.5 to 5.0 indicating that the protonation of the imidazole groups in His-pLK occurs in polyplexes.[25] The transfection efficiency of His-α-CD was about 3 orders of magnitude lower than that of lPEI (6×10^8 RLU/mg proteins), the gold standard cationic polymer. Nevertheless, the transfection efficiency of His-α-CD was as high as that of HeLa and H9c2 cells with pDNA complexed with a β-cyclodextrin substituted with seven tetraethylenpentamine residues.[28] It was close to the transfection of HEK293 cells with pCMV-Luc complexed with a *per* ethylenimine α-CD (2×10^6 RLU/mg of protein) that contained also protonable amines.[2] Of note, DNA complexed with *per* oligoethylenimine α-CD became very efficient (1×10^9 RLU/mg proteins) when the number of ethylenimine repeat units reached 4.[8]

Comparative DNA Condensation Capacity of His-α-CD and Poly(L-lysines). The unexpected DNA condensation capacity of His-α-CD prompted us to compare this ability with that of other cationic polymers such as poly(L-lysine) by using fluorescence dye exclusion. Surprisingly, DNA condensation with His-α-CD (8 NH_2 functions per CD molecule) was close to that observed with PLK_{190} (190 NH_2 functions per polymer molecule) (Figure 5). The maximum of the dye exclusion

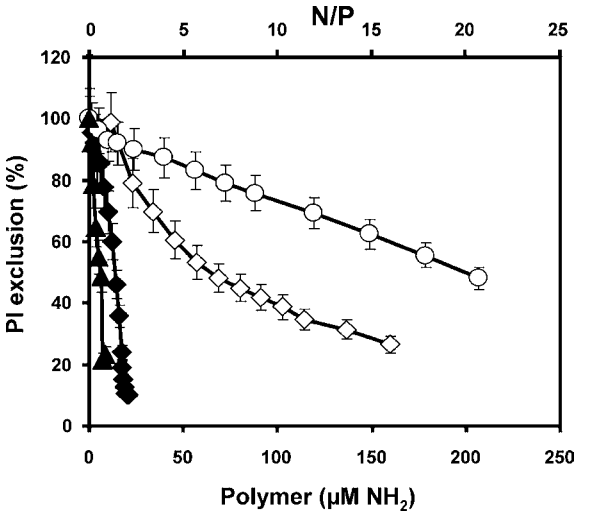

Figure 5. Interaction of polymers with DNA. Aliquots of solution containing polymers were sequentially added to pDNA (2.5 μg) in 650 μL of 10 mM Hepes buffer, pH 7.4, in the presence of ethidium bromide (2 μM). The fluorescence intensity was measured (λ_{ex} = 530 nm; λ_{em} = 580 nm) after each addition of sample and the fraction of dye exclusion was calculated from the fluorescence intensity measured in the absence and in the presence of polymers. N/P corresponds to the ratio between the number of positive charges of polymers and that of the negative charges of the pDNA phosphate. His-α-CD (▲); PLK_{190} (◆); PLK_6 (◇); $K_{20}H_{20}$ (○).

reached 90% in the presence of 0.11 μM (i.e., 21 μM NH_2) PLK_{190} at N/P of 2. The DNA condensation capacity of His-α-CD was higher than with PLK_6 containing 6 NH_2 functions per

dx.doi.org/10.1021/bc200167p | Bioconjugate Chem. 2011, 22, 2404–2414

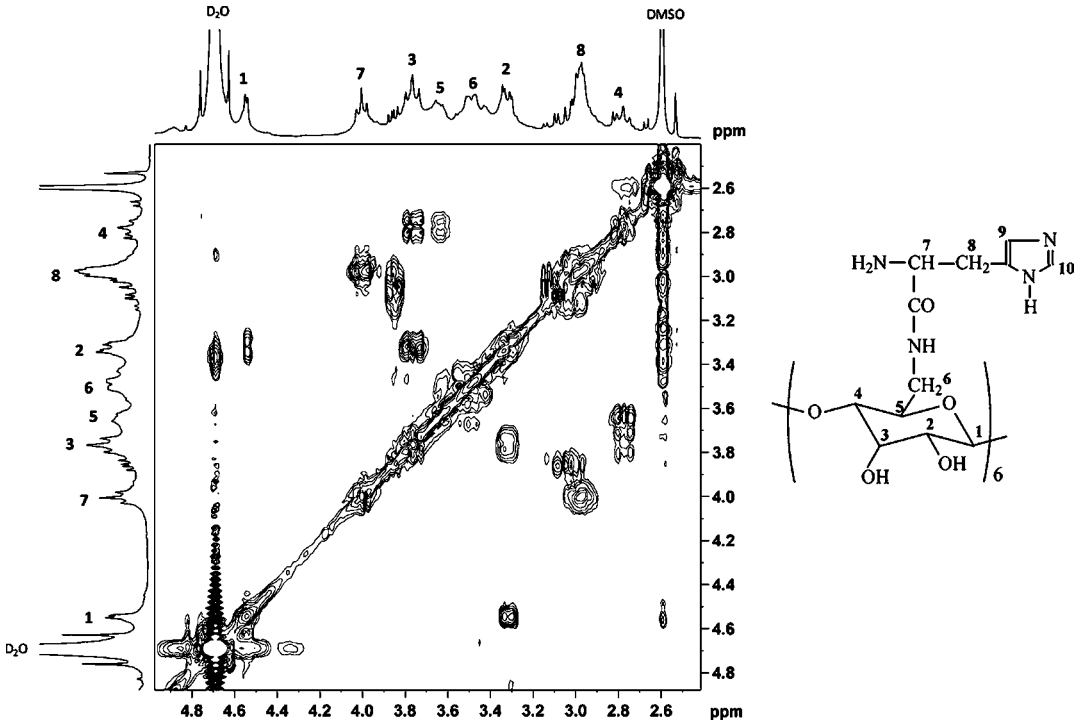

Figure 6. COSY NMR experiment of His-α-CD.

polymer molecule (Figure 5). Surprisingly, the DNA condensation was much higher with His-α-CD than with $K_{20}H_{20}$ (Figure 5). This latter polymer was a poly(L-lysine) of 20 lysyl residues that were substituted with a histidine residue linked on their ε-amino group. On the basis of the number of positive charges, one would be expected that DNA condensation will be stronger with $K_{20}H_{20}$ than with His-α-CD. Note that the DNA condensation with $K_{20}H_{20}$ was also lower than with PLK_6. Therefore, the DNA condensation capacity of His-α-CD did not involve only interaction of the positive charges of the α-CD derivative with the phosphate groups of the nucleic acid, but suggested the formation of a supramolecular structure allowing cooperative interaction with DNA involving CD and histidine. Indeed, it is known that the imidazole group can form an inclusion complex with the hydrophobic cavity of cyclodextrin.[29] Binding constants of imidazole to α-cyclodextrin are approximately 6 times higher than those for β-cyclodextrin as measured by microcalorimetric technique. Therefore, we have examined by NMR investigation the possible formation of supramolecular structures from His-α-CD molecules which could explain the strong interaction with pDNA.

Characterization of Supramolecular Association by NMR. *CD Derivatives ROESY NMR Experiments.* First, 1D and 2D NMR of His-α-CD were performed to confirm the structure of the product. On the basis of the ^{1}H NMR spectra of the initial reactants and on the correlation spectroscopy (COSY) NMR spectrum, all the peaks of the His-α-CD ^{1}H spectrum were assigned (Figure 6). It was observed that integration of the peak at 7.75 ppm of the proton borne by the carbon between the two nitrogen atoms decreased with time until complete exchange with deuterium. This fact was also observed for each imidazole derivative. The heteronuclear single quantum correlation (HSQC) experiment of His-α-CD was used to identify each carbon of the product (SI Figure S9).

To examine the possible formation of supramolecular structures from His-α-CD molecules, a 2D ROESY NMR experiment was carried out to determine which protons were close to each other in space even if they were not bonded. The spectrum in Figure 7 shows that the CD proton H5, which is located inside the CD cavity, is correlated to the proton H9 of the imidazole group *via* an intense negative cross-peak, whereas there is no cross-peak between the proton H5 and the proton H10 belonging to the imidazole group. In the same way, we observe a negative cross-peak between the protons H3 and H10 and no correlation between H3 and H9. This result demonstrates that an inclusion complex occurs through the CD primary side. Discrimination between intra- (Figure 8b) and intermolecular (Figure 8c) interaction between the CD cavity and the imidazole moieties requires more investigation. When the same experiments were performed with Lys-α-CD, the 2D ROESY NMR spectrum showed no negative cross-peak between the proton H5 of the CD and the methylene groups of the lysine (peaks 8, 9, and 10), indicating the absence of inclusion between lysyl residue and the hydrophobic cavity of CD (SI Figure S10, Figure 9).

CD Derivatives DOSY NMR Experiments. Diffusion-ordered spectroscopy (DOSY) experiments were attempted to determine whether His-α-CD allowed supramolecular assemblies or not. DOSY NMR which is based on a pulse-field gradient spin−echo NMR experiment, in which components experience diffusion, provides relevant information for the study of mixtures or for the structure characterization of polymers (see Supporting Information).[30,31] On the basis of the scheme in Figure 8c, His-α-CD supramolecular species would be dimers or higher molecular weight species. Thus, a decrease of the diffusion coefficients would be correlated to the increase of the molecular weight of the molecules. First, the diffusion coefficients of D_2O, L-histidine, and α-CD in an equimolar mixture of α-CD and L-histidine were, respectively, found equal

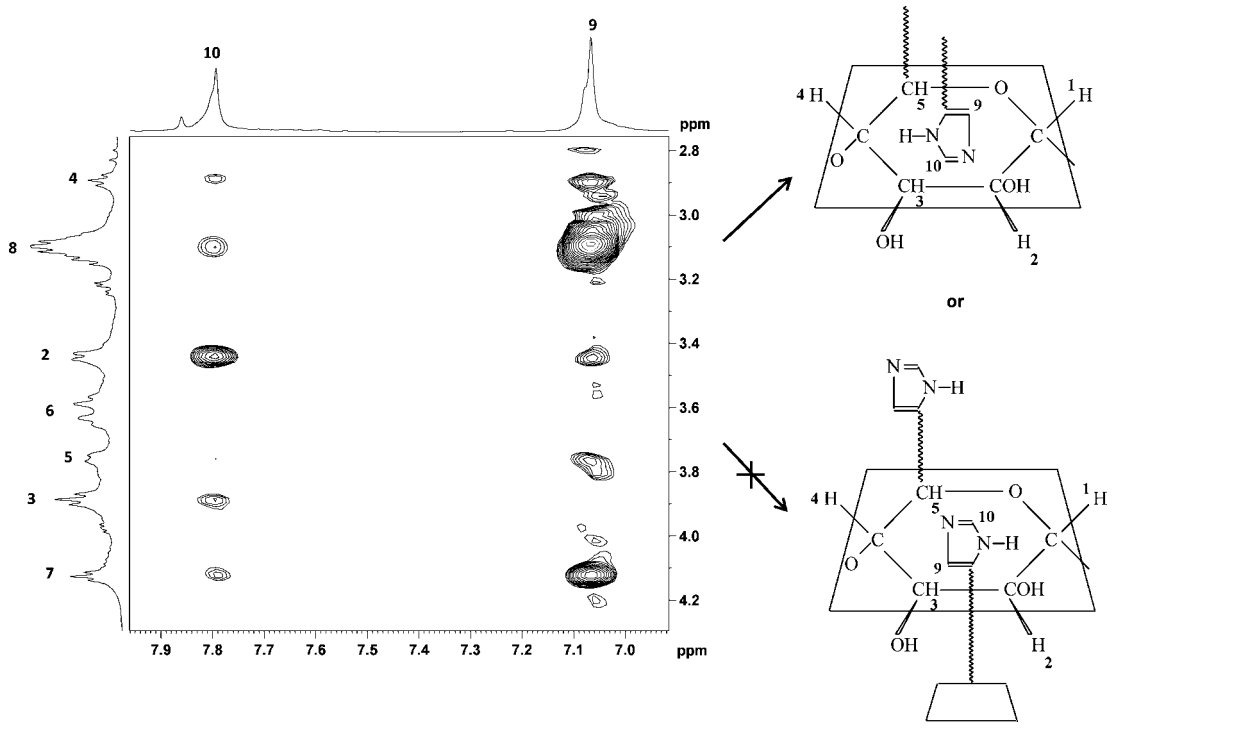

Figure 7. Zoomed ROESY NMR experiment of His-α-CD in D_2O.

to 1.86×10^{-9} $m^2.s^{-1}$, 5.92×10^{-10} $m^2.s^{-1}$, and 2.82×10^{-10} $m^2.s^{-1}$ (SI Figures S11 and S12; Table 1). Then, the diffusion coefficient of α-CD alone (2.78×10^{-10} $m^2.s^{-1}$) or in an equimolar mixture with methyl-L-histidine (2.83×10^{-10} $m^2.s^{-1}$) were determined (Table 1). The DOSY treatment of His-α-CD alone gave a diffusion coefficient of 1.93×10^{-10} $m^2.s^{-1}$ from the peak at ~7.0 ppm or 2.21×10^{-10} $m^2.s^{-1}$ taking into account the broad peak located between 2.8 ppm and 4.3 ppm (protons from the CD and histidine group) (SI Figure S13; Table 1). These close values confirm that the imidazole group was linked to α-cyclodextrin. The DOSY treatment of Lys-α-CD gave 1.85×10^{-10} $m^2.s^{-1}$ from the anomeric peak, 1.83×10^{-10} $m^2.s^{-1}$ from the broad peak between 4.2 and 3.1 ppm, 1.75×10^{-10} $m^2.s^{-1}$ from the peak at 2.9 ppm, 1.87×10^{-10} $m^2.s^{-1}$ from the peak at 1.9 ppm, 1.78×10^{-10} $m^2.s^{-1}$ from the peak at 1.6 ppm, and 1.86×10^{-10} $m^2.s^{-1}$ from the peak at 1.35 ppm (SI Figure S14). These values were very close, giving an average diffusion coefficient of 1.83×10^{-10} $m^2.s^{-1}$ (Table 1).

Overall, these experiments show that the diffusion rates of the solvent molecules are almost the same whatever the considered DOSY and corresponds to the highest values compared to the investigated molecules. When α-CD is substituted with α-amino acids, the diffusion coefficient is lower than the initial α-CD in agreement with its higher hydrodynamic volume. The comparison of the two grafted α-CD (having a similar molar mass) shows that the diffusion coefficient of His-α-CD is slightly higher than that of Lys-α-CD, explained by the higher hydrodynamic volume of the protonated Lys-α-CD compared to that of His-α-CD. The diffusion coefficient measurements of His-α-CD were confirmed by increasing the attenuation, i.e., the values of Δ and δ (run 5, Table 1). The signal-to-noise ratio decrease was compensated by a higher number of scans (run 6, Table 1), and no variation of the diffusion coefficient was noticed (runs 4, 5 and 6, Table 1). Taking in account the ROESY experiment showing the interaction between the imidazole ring and the hydrophobic cavity of the α-CD, and the diffusion values, it appears that only intramolecular interactions occur between His-α-CD molecules under NMR conditions. Compared with transfection experiments, NMR experiments with His-α-CD were performed at a much higher CD concentration (~100 times higher), and no large diffusive species was detected, suggesting that the supramolecular association of His-α-CD was not favored under any NMR conditions, i.e., without plasmid added to the CD derivatives. During His-α-CDplex formation, interaction between amino groups of His-α-CD and DNA phosphate moieties might provide a scaffold for a template association of His-α-CD via inclusion complexes between CD and the histidine moieties (Figure 8c). This effect can be compared to the spontaneous polymerization by disulfide bond when sulfhydryl cross-linking peptides or polymers were bound to pDNA leading to stable DNA condensates.[32−34]

Table 1. DOSY NMR Experiments: Determination of the Diffusion Coefficients (D) of Different Samples[a]

		D ($m^2.s^{-1}$)		
run	signal used for the D determination	peak at 7 ppm	H_1	CD broad
1	α-CD		2.78×10^{-10}	2.70×10^{-10}
2	mixture (1/1) α-CD/histidine	5.92×10^{-10}	2.82×10^{-10}	
3	mixture (1/1) α-CD/Me-Lhistidine	5.32×10^{-10}	2.83×10^{-10}	
4	His-α-CD	1.93×10^{-10}		2.21×10^{-10}
5	His-α-CD	2.00×10^{-10}		2.11×10^{-10}
6	His-α-CD	2.05×10^{-10}		2.10×10^{-10}
7	Lys-α-CD		1.85×10^{-10}	1.83×10^{-10}

[a] $M_{\alpha CD}$ = 972 g/mol; $M_{histidine}$ = 155 g/mol; $M_{Me\text{-}Lhistidine}$ = 169 g/mol; $M_{His\text{-}\alpha\text{-}CD}$ = 1789 g/mol; $M_{Lys\text{-}\alpha\text{-}CD}$ = 1735 g/mol. Runs 1,2,34: Δ = 200 ms and δ = 4.5 ms; runs 5 and 6: Δ = 300 ms and δ = 6 ms. Note that no calculation was conducted from the peak at 7.7 ppm because it disappeared with time, and from the anomeric CD proton which overlapped with the solvent peak for His-α-CD.

CONCLUSION

In the present work, we demonstrated that His-α-CD can condense a plasmid DNA allowing the formation of CDplexes that transfect cells. At the same time, we found that the DNA condensation capacity of His-α-CD is unexpectedly higher than that obtained with the lysyl-α-CD counterpart. NMR studies demonstrated that the formation of an inclusion complex between histidine and the hydrophobic cavity of CD occurs and only intramolecular interaction occurs between His-α-CD molecules in the absence of DNA. These results suggest that intermolecular interactions between imidazole and His-α-CD cavity can take place to form supramolecular assemblies in the presence of a DNA scaffold increasing the DNA condensation.

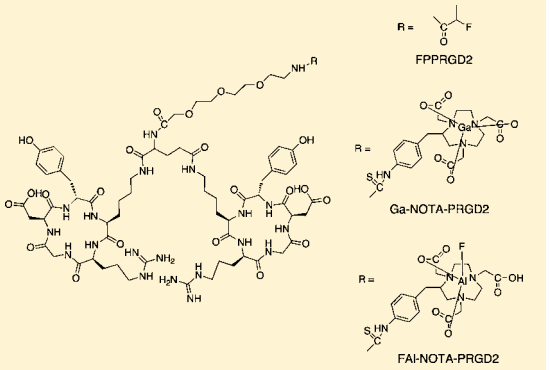
ABSTRACT: [^{18}F]FPPRGD2, an F-18 labeled dimeric cyclic RGDyK peptide, has favorable properties for PET imaging of angiogenesis by targeting the $\alpha_v\beta_3$ integrin receptor. This radiotracer has been approved by the FDA for use in clinical trials. However, the time-consuming multiple-step synthetic procedure required for its preparation may hinder the widespread usage of this tracer. The recent development of a method using an F-18 fluoride-aluminum complex to radiolabel peptides provides a strategy for simplifying the labeling procedure. On the other hand, the easy-to-prepare [^{68}Ga]-labeled NOTA-RGD derivatives have also been reported to have promising properties for imaging $\alpha_v\beta_3$ integrin receptors. The purpose of this study was to prepare [^{18}F]FPPRDG2, [^{18}F]FAl-NOTA-PRGD2, and [^{68}Ga]Ga-NOTA-PRGD2 and to compare their pharmacokinetics and tumor imaging properties using small animal PET. All three compounds showed rapid and high tracer uptake in U87MG tumors with high target-to-background ratios. The uptake in the liver, kidneys, and muscle were similar for all three tracers, and they all showed predominant renal clearance. In conclusion, [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2 have imaging properties and pharmacokinetics comparable to those of [^{18}F]FPPRGD2. Considering their ease of preparation and good imaging qualities, [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]NOTA-PRGD2 are promising alternatives to [^{18}F]FPPRGD2 for PET imaging of tumor $\alpha_v\beta_3$ integrin expression.



INTRODUCTION

Tumor angiogenesis is the process of new blood vessel formation necessary for tumor growth and metastasis,[1] and the integrin $\alpha_v\beta_3$ receptor plays an important role in promoting, sustaining, and regulating the angiogenesis.[2,3] In recent years, major efforts and progress have been made in the development of radiolabeled Arg-Gly-Asp (RGD) containing peptides to image tumor angiogenesis by targeting integrin $\alpha_v\beta_3$ receptors in various types of tumors.[4,5] It is widely accepted that imaging tumor angiogenesis can be used not only for early detection of cancers, but also for monitoring treatment outcomes.[4,6−9] Cyclic RGD peptides with various modifications have been labeled with ^{99m}Tc[10] and ^{111}In[11] for SPECT imaging and labeled with ^{18}F,[12] ^{64}Cu,[13] ^{68}Ga,[14,15] and ^{89}Zr[16] for PET imaging. The peptide modifications have included dimerization and polymerization of up to 8 cyclic RGD peptide units to increase binding affinity, and the attachment of polar functional groups—such as sugar and poly(ethylene glycol) (PEG)—to increase renal excretion.[17,18] [^{18}F]FPPRGD2, an F-18 labeled dimeric cyclic RGDyK peptide with mini-PEGylation, has favorable properties for PET imaging of tumor angiogenesis, and it has been approved by the FDA for use in clinical trials[18,19]

F-18 is the most widely used positron emitting radioisotope for PET imaging, and its physical properties are ideally suited for RGD peptide-based PET imaging probes. The majority of methods used in labeling RGD peptides with ^{18}F use a prosthetic group, such as *N*-succinimidyl 4-[^{18}F]fluorobenzoate ([^{18}F]SFB)[20] or 4-nitrophenyl 2-[^{18}F]fluoropropionate ([^{18}F]-NPFP),[7] and the time-consuming multiple-step synthetic procedure required for preparation may hinder the widespread use of these ^{18}F-labeled RGD tracers. The preparation of [^{18}F]FPPRGD2 also faces these challenges. Efforts have been made with some success to simplify the labeling procedure by direct labeling of RGD peptides with a preattached functional group with a proper leaving group for fluoride displacement.[21] On the other hand, labeling radioactive metal ions through a preattached chelator on RGD peptides has been blessed with a much simpler procedure. One advantage of using coordination chemistry is that only very small amounts of chelators are required to reach high labeling yield, which allows the radiotracer to be prepared without the need of HPLC

purification, while maintaining reasonable specific activity levels. The easy preparations of ^{68}Ga-labeled NOTA-RGD derivatives are examples that have been reported to have promising properties for tumor imaging.[14,15,22]

Application of chelation chemistry has led to recent discovery and development of ^{18}F fluoride−aluminum complexes to radiolabel peptides that provide a strategy to simplify the labeling procedure.[23,24] The goal of this study was to prepare [^{18}F]FPPRDG2, [^{18}F]FAl-NOTA-PRGD2, and [^{68}Ga]Ga-NOTA-PRGD2 from the same pegylated dimeric RGD peptide PEG3-E[c(RGDyK)]$_2$ (denoted as PRGD2) and to compare their pharmacokinetics and imaging properties in a U87MG glioblastoma xenograft model using microPET.

MATERIALS AND METHODS

The p-SCN-Bn-NOTA was purchased from Macrocyclics (Dallas, TX) and PRGD2 was obtained from Peptides International (Louisville, KY). All of the other chemicals were purchased from Sigma-Aldrich. A Waters 600 high-performance liquid chromatography (HPLC) system with a Waters 996 photodiode array detector (PDA) using a preparative C_{18} HPLC column (PROTO 300 C_{18} 5 μm, 250 × 20 mm, Higgins Analytical, Inc.) was used for peptide purification. A Varian BOND ELUT C_{18} column (100 mg) was used for solid-phase extraction. Another Waters 600 HPLC pump with a Waters 996 PDA and an online radioactivity detector (Beckman) using a semiprep C_{18} HPLC column (Vydac C_{18} peptide and protein 5 μm, 250 × 10 mm, Grace Davison) was used for purification of radiolabeled compounds. A Perkin-Elmer 200 series HPLC pump with a Waters 2487 UV detector and a Bioscan Flow-Count detector using an analytical C_{18} HPLC column (Vydac C_{18} peptide and protein 5 μm, 250 × 4.6 mm, Grace Davison) was used for analysis or purification of labeled compounds. Mass spectra were obtained with a Waters LC-MS system (Waters, Milford, MA) that included an Acquity UPLC system coupled to a Waters Q-Tof Premier high-resolution mass spectrometer. The ^{68}Ge/^{68}Ga generator was purchased from Ithemba Laboratories (South Africa) and ^{18}F-fluoride was obtained from the NIH cyclotron facility.

Preparation of NOTA-PRGD2. NOTA-PRGD2 was synthesized following our previously reported procedure with modifications.[15] Briefly, 7.0 mg (15.5 μmol) of *p*-SCN-Bn-NOTA in 50 μL of dimethyl sulfoxide (DMSO) was added to a 4 mL glass vial containing 21.0 mg (14 μmol) of PRGD2 and 20 μL of diisopropylethylamine in 0.3 mL *N*,*N*-dimethylformamide (DMF). After 1 h, the reaction was quenched with 20 μL of acetic acid in 1 mL water. The reaction mixture was purified with a preparative HPLC running a linear gradient starting from 6% A (0.1% TFA in acetonitrile) and 94% B (0.1% TFA in water) for 5 min and increasing to 65% A at 35 min with a flow rate of 12 mL/min. The fractions containing the desired product (55%) were collected and lyophilized to give 15.0 mg of white powder. The purity of the product was >95% by analytical HPLC (t_R = 16.4 min). LC-MS: $[MH]^+$ = 1989.69 (m/z), calc: 1988.91 ($C_{87}H_{128}N_{24}O_{28}S$).

Preparation of Al-NOTA-PRGD2. To a 1 mL V-vial containing 1.1 mg of NOTA-PRGD2 in 0.2 mL of deionized water was add 0.21 mg of aluminum chloride in 20 μL 0.5 M pH 4.0 sodium acetate buffer. The vial was sealed and the mixture was heated at 105 °C for 10 min and then injected onto a preparative RP HPLC C_{18} column with a linear gradient starting from 6% A (0.1% TFA in acetonitrile) and 94% B (0.1% in water) for 5 min and increasing to 65% A at 35 min at the flow rate of 12 mL/min. A single peak at the retention time of 19.7 min was collected and analyzed with LC-MS. The peak had the $[MH]^+$ = 2013.6660 (m/z) which matched the calculated mass for Al-NOTA-PRGD2 ($C_{87}H_{125}AlN_{24}O_{28}S$: 2012.8631). The sample was lyophilized overnight to give 1.1 mg of white powder (99%). The purity of the product was >97% by analytical HPLC (Dionex, 4.6 × 150 mm) with a retention time of 15.5 min with a baseline separation from the NOTA-PRGD2 (16.4 min).

Preparation of FAl-NOTA-PRGD2. To a 1 mL V-vial containing 0.2 mL of deionized water were added 10 μL of 2 mM aluminum chloride in 0.1 M pH 4.0 sodium acetate buffer and 7 μL of 3.0 mM sodium fluoride in 0.1 M pH 4.0 sodium acetate buffer. The mixture was heated at 100 °C for 10 min, and 5 μL of 2.5 mM NOTA-PRGD2 in 0.1 M pH 4.0 sodium acetate buffer was added to the reaction mixture, which was then heated at 100 °C for another 10 min. The solution was cooled and injected onto an analytical RP C_{18} column (Vydac C_{18}) running a linear gradient starting from 5% A (0.1% TFA in acetonitrile) and 95% B (0.1% TFA in water) for 2 min and increasing to 65% A at 32 min at 1 mL/min. The peaks at 15.5 min and 15.7 were collected as a single fraction. The LC-MS analysis showed two mass components in this fraction with $[MH]^+$ = 2013.67 (m/z) corresponding to the mass of Al-NOTA-PRGD2 (R_t = 15.5 min) and $[MH]^+$ = 2033.65 (m/z) corresponding to FAl-NOTA-PRGD2 (calculated for $C_{87}H_{126}AlFN_{24}O_{28}S$: 2032.87).

Preparation of Ga-NOTA-PRGD2. To a 1 mL V-vial containing 2.6 mg of NOTA-PRGD2 in 0.3 mL of deionized water was add 0.5 mg of gallium chloride in 0.1 mL of 0.1 M pH 4.0 sodium acetate buffer. The mixture was heated at 80 °C for 10 min and then injected onto a preparative RP HPLC C_{18} column running the same gradient as described above. A single peak at the retention time of 19.5 min was collected and lyophilized overnight to give 2.6 mg of white powder (99%). LC-MS: $[MH]^+$ = 2056.0730 (m/z) corresponding to Ga-NOTA-PRGD2 (calculated for $C_{87}H_{125}GaN_{24}O_{28}S$: 2054.8072).

Preparation of 4-Nitrophenyl 2-[^{18}F]-fluoropropionate. The 4-nitrophenyl [^{18}F]-2-fluoropropionate was prepared on a GE TRACERLab FXN according to a published procedure[19] with some modifications. For a typical run, [^{18}F]fluoride was trapped on an ^{18}F Separation Cartridge (CHROMAFIX, 30-PS-HCO_3) from a source vial containing the aqueous [^{18}F]fluoride (3.7 GBq, 0.2 mL) by pulling the vacuum line. The activity was eluted to a glassy-carbon reaction vessel with 1 mL 90% acetonitrile containing 15.0 mg of K222 and 3.5 mg of potassium carbonate. The liquid in the reaction vessel was removed with vacuum to produce anhydrous [^{18}F]fluoride. After cooling, 5 mg of ethyl 2-bromopropionate in 0.5 mL of acetonitrile was added to the reaction vessel and heated at 100 °C for 10 min to form ethyl 2-[^{18}F]-fluoropropionate. At the end the of the reaction, 125 μL of 0.2 N potassium hydroxide in 375 μL of acetonitrile was added to the reaction vessel, which was then heated at 100 °C for another 10 min to produce the potassium salt of 2-[^{18}F]fluoropropionic acid. The solution was diluted with 1 mL of acetonitrile and the liquid was removed with vacuum, and 20 mg of bis-4-nitropenyl carbonate in 1 mL of acetonitrile was added to react with potassium 2-[^{18}F]fluoropropionate to form 4-nitrophenyl 2-[^{18}F]fluoropropionate at 100 °C for 10 min. After cooling, the reaction mixture was diluted with 1 mL of 25% acetonitrile/water with 5% acetic acid and loaded onto a

semiprep Phenomenex Luna C_{18} column running at 5 mL/min with 40% acetonitrile/water containing 0.1% TFA as the mobile phase. The product was collected at the retention time of 21 min into a flask containing 30 mL of water with 0.1% acetic acid. The solution containing the desired product was passed through a Waters Sep-Pak Plus C_{18} cartridge and the activity trapped on the cartridge was washed with 1 mL of water.

Preparation of [^{18}F]FPPRGD2. The activity trapped on the C_{18} cartridge as described above was eluted manually with 1 mL of methylene chloride into a 1 mL polypropylene tube and the water layer on top of the methylene chloride was removed by using a syringe. The methylene chloride in the tube was evaporated under argon flow at room temperature, and 1 mg of PRGD2 in 0.1 mL of DMSO containing 20 μL of diisopropylethylamine was added to the tube and heated at 80 °C for 10 min. At the end of the reaction, the reaction mixture was cooled and diluted with 0.7 mL of water containing 25 μL of acetic acid and loaded onto a semiprep HPLC column (Vydac C_{18}) running a linear gradient starting from 5% A (0.1% TFA in acetonitrile) and 95% B (0.1% TFA in water) for 2 min and increasing to 65% A at 32 min at 5 mL/min. The desired product was collected at a retention time of 14 min and diluted with 10 mL water and trapped on a Varian Bond Elut C_{18} column (100 mg). The radioactivity trapped on the C_{18} column was eluted with 0.3 mL of 1 mM HCl−ethanol solution, and the ethanol was removed with argon flow, and the final product was then dissolved in PBS.

[^{18}F]FAl-NOTA-PRGD2. Three microliters of 2 mM aluminum chloride in 0.2 M pH 4 sodium acetate buffer was added to a 1 mL V-vial containing 0.1 mL of aqueous [^{18}F]fluoride (0.37 GBq), which was then heated at 100 °C for 10 min to form the aluminum−fluoride complex. The vial was cooled, 6 μL of 2 mM NOTA-PRGD2 in 0.2 M pH 4 sodium acetate buffer was added, and then the vial was heated at 100 °C for another 10 min. At the end of the reaction, the mixture was injected onto an analytical HPLC column (Vydac C_{18}) running a linear gradient starting from 5% A (0.1% TFA in acetonitrile) and 95% B (0.1% TFA in water) for 2 min and increasing to 65% A at 32 min at 1 mL/min. The radioactive peak containing the desired product was collected at a retention time of 16 min and diluted with 15 mL of water and trapped on a Varian Bond Elut C_{18} column (100 mg). The radioactivity trapped on the C_{18} column was eluted with 0.3 mL of 80% ethanol/water with 2% acetic acid, the ethanol solution was evaporated with argon flow, and the final product was then dissolved in PBS. A separate procedure was performed without HPLC purification and the reaction mixture was directly loaded onto the C_{18} cartridge.

[^{68}Ga]Ga-NOTA-PRGD2. The fresh ^{68}Ga activity was eluted from the ^{68}Ge/^{68}Ga generator with 0.6 M HCl at 0.5 mL per fraction into the 1.5 mL polypropylene tubes. The fraction containing the most radioactivity (~0.15 GBq) was added to 0.45 mL of 1 M HEPES buffer and 15 μg of NOTA-PRGD2 in 5 μL of 0.2 M pH 4 sodium acetate buffer. The mixture was heated at 80 °C for 10 min. At the end of the reaction, the activity was loaded onto an analytical HPLC column (Vydac C_{18}) running a linear gradient starting from 5% A (0.1% TFA in acetonitrile) and 95% B (0.1% TFA in water) for 2 min and increasing to 65% A at 32 min at 1 mL/min. The desired product was collected at 16 min, diluted with 15 mL of water, and trapped onto a 100 mg Varian Bond Elut C18 column. The radioactivity trapped on the C_{18} column was eluted with 0.3 mL of 80% ethanol/water with 2% acetic acid, the ethanol solution was removed with argon flow, and the final product was redissolved in PBS. A separate procedure was performed without HPLC purification, and the reaction mixture was directly loaded onto the C_{18} cartridge. The reactions were done at room temperature and at 80 °C. The crude mixture and purified product were also analyzed with analytical HPLC for their radiochemical purities.

Cell Binding Assay. The $\alpha_v\beta_3$ receptor binding assay was performed to determine binding affinities of E[c(RGDyK)]$_2$ analogues. Briefly, U87MG cell line was cultured in DMEM medium (GIBCO) containing 10% (v/v) fetal bovine serum (GIBCO) supplemented with penicillin (100 μg/mL), streptomycin (100 μg/mL), nonessential amino acids (100 μM), and sodium pyruvate (1 mM) at 37 °C with 5% CO_2. When grown up to 80% confluence, cells were scraped off and suspended with binding buffer [25 mM 2-amino-2-(hydroxymethyl)-1,3-propanediol, hydrochloride (Tris-HCl), pH 7.4, 150 mM NaCl, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$ and 1 mM $MnCl_2$, 0.1% bovine serum albumin (BSA)] at a final concentration of 2×10^6 cells/mL. In a 96-well plate, 1×10^5 U87 MG cells/well were incubated with ^{125}I-Echistatin (0.74 kBq/well, PerkinElmer, Inc.) in binding buffer in the presence of different concentrations of E[c(RGDyK)]$_2$ analogues at room temperature for 1 h. After incubation, the plate was washed three times with phosphate buffered saline (PBS) containing 0.1% BSA, and the radioactivity was measured by γ-counting. The EC_{50} values were calculated by nonlinear regression analysis using the *GraphPad Prism* computer-fitting program (GraphPad Software, Inc., San Diego, CA). Each data point is a result of the average of triplicate wells.

Preparation of Animal Tumor Models. All animal studies were conducted in accordance with the principles and procedures outlined in the Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care and Use Committee of the Clinical Center, NIH. The human glioblastoma cell line U87MG was grown in DMEM medium supplemented with 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin (Invitrogen), and in a humidified atmosphere containing 5% CO_2 at 37 °C. The cells were harvested by trypsinization with trypsin/EDTA. The U87MG tumor model was developed in 5 to 6-week-old female athymic nude mice (Harlan Laboratories) by injection of 5×10^6 cells in their right shoulders. Tumor growth was monitored using caliper measurements of perpendicular axes of the tumor. The mice underwent small-animal PET studies when the tumor volume reached 100−300 mm^3 (3−4 weeks after inoculation).

MicroPET Imaging and Analysis. PET scans and image analysis were performed using an Inveon microPET scanner (Siemens Medical Solutions). About 3.7 MBq of ^{18}F or ^{68}Ga labeled tracer was administered via tail vein injection under isoflurane anesthesia. For blocking study, about 300 μg of unlabeled dimeric RGD peptide E[c(RGDyK)]$_2$ was injected 30 min before the [^{18}F]FAl-NOTA-PRGD2. Five-minute static PET images were acquired at 30 min, 1 h, and 2 h postinjection (n = 3−5 per group). The images were reconstructed using a two-dimensional ordered-subset expectation maximum (2D OSEM) algorithm, and no correction was applied for attenuation or scatter. For each scan, regions of interest (ROIs) were drawn using vendor software (*ASI Pro* 5.2.4.0) on decay-corrected whole-body coronal images. The radioactivity concentrations (accumulation) within the tumors, muscle, liver, and kidneys were obtained from mean pixel values within the

multiple ROI volume and then converted to MBq per milliliter. These values were then divided by the administered activity to obtain (assuming a tissue density of 1 g/mL) an image-ROI-derived percent injected dose per gram (%ID/g).

Biodistribution Study of [^{18}F]FAl-NOTA-PRGD2. Immediately after PET imaging, the tumor-bearing mice with or without blocking dose were sacrificed and dissected. Blood, tumor, major organs, and tissues were collected and wet-weighed. The radioactivity in the wet whole tissue was measured with a γ-counter (Perkin- Elmer). The results were expressed as percentage of injected dose per gram of tissue (% ID/g). Values were expressed as mean ± SD (n = 4 per group).

In Vitro Stability of [^{18}F]FAl-NOTA-PRGD2. About 5.6 MBq of [^{18}F]FAl-NOTA-PRGD2 in 50 μL of PBS was added to 400 μL of mouse serum and incubated at 37 °C. About 60 μL of this serum sample was taken out at 1, 30, 60, and 120 min and put into a plastic tube. An equal volume of acetonitrile was added to each tube and centrifuged at 6000 rpm for 8 min. The supernatant was separated from the pellet, and both the supernatant and pellet were measured for their radioactivity. The supernatant was diluted with 300 μL of PBS and injected on to an analytical HPLC. The tube was measured for its radioactivity before and after HPLC injection. The radioactivity coming out of HPLC column was also collected and measured.

RESULTS

Chemistry. The structures of PEGylated dimeric RGD peptides are shown in Figure 1. The 2-fluoropropanoyl labeled PRGD2 is designated as FPPRGD2. *S*-2-(4-Isothiocyanatobenzyl)-1,4,7-triazacyclononane-1,4,7-triacetic acid is designated as p-SCN-Bn-NOTA. The p-SCN-Bn-NOTA labeled PRGD2 is designated as NOTA-PRGD2. The aluminum NOTA-PRGD2 complex is designated as Al-NOTA-PRGD2, and the aluminum fluoride complex of NOTA-PRGD2 is designated as FAl-NOTA-PRGD2. Gallium NOTA-PRGD2 complex is designated as Ga-NOTA-PRGD2.

NOTA-PRGD2, Al-NOTA-PRGD2, and Ga-NOTA-PRGD2 were prepared at mg scale that can be lyophilized and weighed for further use. The yield of Al-NOTA-PRGD2 and Ga-NOTA-PRGD2 was almost quantitative. Chemical purities of these compounds were >97% determined by analytical HPLC analysis. FAl-NOTA-PRGD2 was prepared in small-scale

reaction, collected from HPLC and used directly as the reference compound. The identities of nonradioactive compounds were determined by LC-MS, which observed m/z ions that matched their calculated molecular weights. Preparation of FAl-NOTA-PRGD2 yielded a mixture of FAl-NOTA-PRGD2 and Al-NOTA-PRGD2 that were not separable by HPLC.

In order to confirm that adding metal NOTA complex to the PRGD2 does not affect the binding affinity of the peptides to integrin receptors, we performed competitive cell binding assays with ^{125}I-echistatin as the radioligand in integrin $\alpha_v\beta_3$ positive U87MG cells. Results of the cell-binding assays were plotted and fitted to sigmoid curves for the displacement of ^{125}I-echistatin from U87MG cells (Figure 2A). The IC_{50} values are listed in Figure 2B. The results indicated that the adding metal NOTA complex to PRGD2 had up to 2-fold increase on the binding affinity of the peptides compared to that of FPPRGD2.

Radiochemisty. The radiolabeling of the three compounds is summarized in Table 1. The radiochemical yield for 4-nitrophenyl 2-[^{18}F]fluoropropionate prepared from Tracer FX-FN system was around 20−25%, and the yield for coupling of 4-nitrophenyl 2-[^{18}F]fluoropropionate with PRGD2 was over 75%. The overall yield was 10−15% (uncorrected) with a total synthesis time of around 3 h and the measured specific activity was 114 ± 72 GBq/μmol (EOB). The labeling efficiency for [^{18}F]FAL-NOTA-PRGD2 varied between 5% and 25%, depending on the reaction volumes. When the reaction volume was between 50 and 100 μL, the yield was consistently between 20% and 25% (uncorrected). The total synthesis time was about 40 min with HPLC purification and about 25 min without HPLC purification. The radiochemical purity was over 97%. The radiochemical yield for [^{68}Ga]Ga-NOTA-PRGD was about 70% (uncorrected) with HPLC in a total synthesis time of 30 min.

Table 1. Comparison of Reaction Condition and Yield of [^{18}F]FAl-NOTA-PRGD2, [^{18}F]FPPRDG2, and [^{68}Ga]Ga-NOTA-PRGD2

tracer name	total time (min)	HPLC	reaction temperature	labeling yield (n = 5)
[^{18}F] FPPRDG2	180	yes	80 °C	10−15%
[^{68}Ga]NOTA-PRGD2	30	yes	80 °C	75%
	15	no	RT	40%
[^{18}F]FAl-NOTA-PRGD2	40	yes	100 °C	5−25%
	25	no	100 °C	5−25%

Purification of Radiolabeled Products by Solid-Phase Extraction. To further simplify the labeling procedure, the solid-phase extraction method was used to prepare both [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2. The tracer could be prepared in about 15 min. Without the HPLC purification, the specific activity was determined by the amount of peptide used, assuming the complete recovery of peptide and the amount of radioactivity used. In our preparation of these two tracers, 12 nmol of PRDGD2 was used to make [^{18}F]FAl-NOTA-PRGD2, and 8 nmol of peptide was used to make [^{68}Ga]Ga-NOTA-PRGD2. In this study, ^{18}F activity was limited to 0.37−1.5 GBq, and ^{68}Ga activity limited to 0.15−0.20 GBq . For a 37 MBq of product, at the end of synthesis the specific activity was 6.14 GBq/μmol for [^{18}F]FAl-NOTA-PRGD2 and 9.25 GBq/μmol for [^{68}Ga]Ga-NOTA-PRGD2. For a 0.37 GBq of product, the specific activities were 30.71 GBq/μmol and 46.25 GBq/μmol, respectively, for [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2. For [^{68}Ga]Ga-NOTA-PRGD2, when only solid-phase extraction was used the radiochemical yield was 40% at room temperature and reached over 90% at 80 °C. The radiochemical purity was also >97% for room temperature reaction with a slight decrease of radiochemical purity (95%) at 80 °C.

***in Vitro* Stability of the Radiotracers.** Both [^{68}Ga]Ga-NOTA-PRGD2 and [^{18}F]FAl-NOTA-PRGD2 were stable in PBS at room temperature. After 4 h, the radiochemical purities were >95% with HPLC analysis. We also tested the stability of [^{18}F]FAl-NOTA-PRGD2 in mouse serum up to 2 h at 37 °C. After treating the serum samples with acetonitrile and centrifugation, 85% of radioactivity was in solution. The recovery of radioactivity from HPLC was >96% without any detectable F-18 fluoride. The parent compound at 1, 30, 60, and 120 min constituted 96.8%, 96.6%, 95.1%, and 95.0% of recovered radioactivity, respectively.

MicroPET Imaging. After radiolabeling, we applied the three imaging probes to *in vivo* PET imaging with U87MG tumor bearing mice. The representative decay-corrected coronal images at different time points after injection of the radiotracers are shown in Figures 3−5. The U87MG tumors were clearly visualized with good tumor-to-background contrast with all of the tracers as early as 30 min postinjection (p.i.). The quantitative tracer uptake of tumors and major organs is summarized in Table 2, expressed as % ID/g. At 60 min p.i., the tumor uptake of [^{18}F]FPPRGD2 was 2.56 ± 0.48% ID/g (n = 5), which was consistent with a previous report.[18] As for [^{68}Ga]Ga-NOTA-PRGD, the tumor uptake was 2.98 ± 0.53% ID/g (n = 3). The tumor uptake of [^{18}F]FAl-NOTA-PRGD2 was 3.92 ± 0.18%ID/g (n = 4), which was significantly higher than that of the other two tracers (p < 0.05). Besides tumor

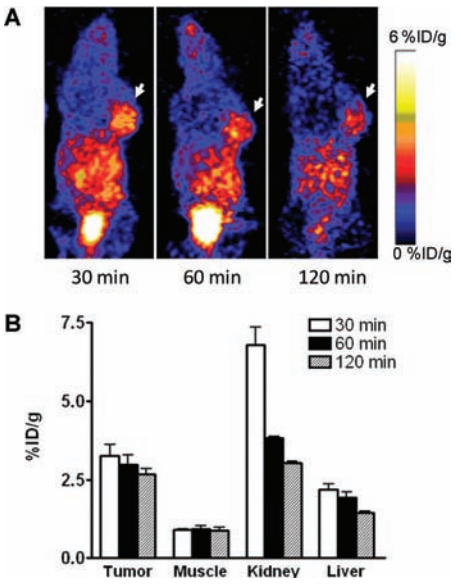

Figure 4. *In vivo* PET imaging of U87MG xenografted mice by [^{68}Ga]Ga-NOTA-PRGD2. (A) Decay-corrected whole-body coronal microPET images of U87MG tumor-bearing mice at 30, 60, and 120 min after injection of 3.7 MBq of [^{68}Ga]Ga-NOTA-PRGD2. Tumors are indicated by arrows. (B) Quantification of [^{68}Ga]Ga-NOTA-PRGD2 in U87MG tumor, liver, kidneys, and muscle. ROIs are shown as mean %ID/g ± SD.

uptake, all tracers showed relatively high kidney accumulation, especially at the early time point (30 min p.i.), then dropped significantly afterward, indicating rapid renal clearance. All three tracers showed relatively low liver uptake. Compared with the other two tracers, [^{18}F]FPPRGD2 showed faster clearance from tumors. We believe this may be a consequence of the lower binding affinity of FPPRGD2 as determined by vitro cell binding affinity study.

Biodistribution Studies. In order to further confirm the PET imaging quantification, the biodistribution of [^{18}F]FAl-NOTA-PRGD2 with and without blocking dose was evaluated in U87MG tumor-bearing athymic nude mice immediately after PET imaging (Figure 6). Consistent with PET imaging data, the tumor uptake measured by direct tissue sampling and gamma-counting was 1.45 ± 0.47%ID/g at the 2 h time point. The tracer accumulations in the kidneys and liver were 4.88 ± 0.82 and 1.47 ± 0.50%ID/g, respectively, at 2 h p.i. In the blocking experiment, U87MG tumor showed significantly decreased accumulation of [^{18}F]FAl-NOTA-PRGD2 with an uptake value of 0.15 ± 0.04%ID/g ($p < 0.001$).

DISCUSSION

Labeling peptides and proteins with ^{18}F is usually achieved using prosthetic groups. The required multistep procedure for preparation of the prosthetic group, its purification, subsequent protein coupling step, and final purification results in relatively low overall radiochemical yield. In addition, multistep syntheses are more difficult to automate.[25] F-18 click chemistry has been used in several studies to label peptides.[26] However, it requires the preparation of azide or alkyne functional group modified peptides and two radiochemical synthesis steps, and in some cases, it involves volatile [^{18}F]-azide synthon. Alternatively, several groups including our lab have developed direct labeling methods of peptides with ^{18}F.[21,27,28]

We have applied [^{18}F]FPPRDG2 to monitor the treatment effect of various anticancer drugs longitudinally on mouse tumor models.[7−9] The routine preparation of [^{18}F]FPPRDG2, which is a 3 h procedure, is quite challenging. Currently, there is no commercially available automated synthesizer that is capable of producing [^{18}F]FPPRDG2 without major modifications. McBride and Laverman et al.[23,24,29] reported the method of using the [^{18}F]fluoride-aluminum-NOTA complex for labeling peptides. Although the radiolabeling conditions required heating, the inherent thermal stability of RGD peptides suggested that they would be good substrates for this radiolabeling method. The precursor for making [^{18}F]-

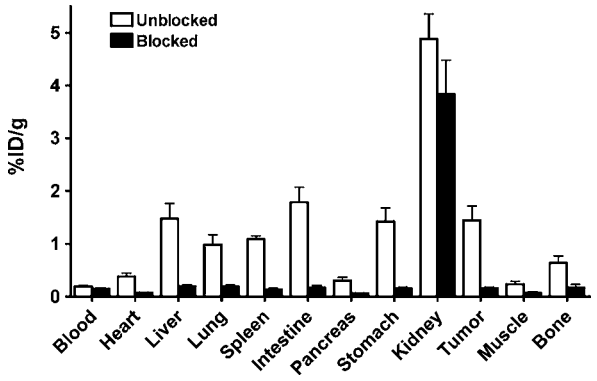

Figure 6. *Ex vivo* biodistribution of [^{18}F]FAl-NOTA-PRGD2 (3.7 MBq per mouse) in U87MG tumor bearing nude mice at 2 h time points after microPET scans with or without unlabeled RGD peptide as blocking agent. Columns, mean %ID/g (n = 4 per group); bars, SD.

FPPRDG2 was chosen as building block for direct comparison studies.

The dimeric PRGD2 peptide was selected for this comparison study for three major reasons. Dimeric PRGD2 showed higher affinity for $\alpha_v\beta_3$ integrin receptor than its monomeric counterpart. PEGylation improved the properties by reducing the renal retention of this class of compounds. Finally, the terminal amine of the PEG moiety served as an attachment point of the radiolabel.[18] Attachment of an NOTA functional group to this terminal amine of PRGD2 provided a chelate that can be effectively utilized for both [^{18}F]fluoride-aluminum and ^{68}Ga. In this study, we successfully prepared [^{18}F]FAl-NOTA-PRGD2 and compared its imaging quality with that of [^{18}F]FPPRDG2 and [^{68}Ga]Ga-NOTA-PRGD2 as an integrin $\alpha_v\beta_3$ imaging agent in U87MG mouse tumor model. The results were very encouraging, and further studies are needed to determine if [^{18}F]FAl-NOTA-PRGD2 is suitable for clinical use.

We applied HPLC columns to purify labeled NOTA complexes. The [^{18}F]FAl-NOTA-PRGD2 was eluted as a single radioactive peak. It overlapped with Al-NOTA-PRGD2 complex and had a baseline separation from NOTA-PRGD2. It has been reported that, when NOTA was used as the chelator, two interchangeable radioactive peaks were formed.[29] This was explained as the formation of two isomers of the complex. However, in our preparation only a single radioactive peak was observed. Since [^{18}F]FAl-NOTA-PRGD2 was not separated from Al-NOTA-PRGD2 in our case, the specific activity was determined by the amount of aluminum chloride used. Our labeling yield was lower than reported by Laverman et al.,[29] but the amount of peptide used in our reaction was also less. In order to allow radiolabeling without HPLC purification, we limited the use of peptide to a 2:1 ratio with aluminum chloride. Although others have used a QMA column to purify and concentrate ^{18}F-fluoride,[23] in our hands aqueous ^{18}F activity was used directly from the target, and the QMA treatment did not change the labeling yield. Generator-produced ^{68}Ga with its 68 min half-life is an attractive alternative for institutions without a cyclotron. In this study, the same peptide was used for labeling Ga-68 for a direct comparison. Labeling yield for forming Ga-68 complex was higher than for forming F-18 FAl complex, and the amount of peptide needed was also less.

When the solid-phase extraction was used for the preparation of both [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2, the tracer could be prepared in about 15 to 25 min. Compared with that of [^{18}F]FPPRDG2, this procedure is tremendously time-saving. Moreover, with a scale-up preparation for a 0.37 GBq of product, the specific activity went up to 30.7 GBq/μmol and 46.2 GBq/μmol, respectively, for [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2. These specific activity levels should meet the requirement for clinical studies. For Ga-68 labeling, specific activity can be further increased by using less peptide. Another important aspect of using solid-phase extraction is that the standard kit can be formulated and distributed. This is especially important for multiple-center studies, since the amount of peptide used can be predetermined precisely.

After applying the tracers to *in vivo* PET imaging, we found that FPPRGD2 showed tumor uptake and major organ distribution that were similar to those in one of our previous studies.[18] However, the tumor uptake of [^{68}Ga]Ga-NOTA-PRGD2 was somewhat lower than that in another study.[22] The reason for this is unclear, and we will investigate the *in vivo* behavior of this tracer further for potential clinical translation. Another issue is that both [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2 showed longer tumor retention than that of [^{18}F]-FPPRDG2 in U87MG tumors. Although we do not have a definitive explanation for this, we cannot exclude the possibility of transchelation of the metal ions within the tumor region.

CONCLUSION

Both [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2 can be prepared with or without HPLC purification in a much simpler fashion than [^{18}F]FPPRGD2. Moreover, these two new radiotracers have imaging properties and pharmacokinetics that are comparable to, or superior than, those of [^{18}F]FPPRGD2. Considering the ease of preparation and imaging quality, [^{18}F]FAl-NOTA-PRGD2 and [^{68}Ga]Ga-NOTA-PRGD2 are promising alternatives to [^{18}F]FPPRGD2 for PET imaging of tumor $\alpha_v\beta_3$.

Engineering Cell Surfaces via Liposome Fusion

Debjit Dutta,[†] Abigail Pulsipher,[†] Wei Luo,[†] Hugo Mak,[‡] and Muhammad N. Yousaf*[,†]

[†]Department of Chemistry and the Carolina Center for Genome Science, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27599-3290, United States

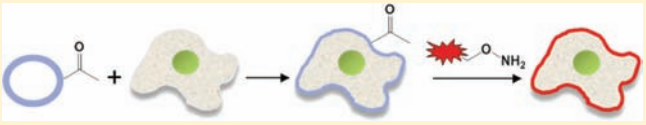
ABSTRACT: In this study, we have rewired cell surfaces with ketone and oxyamine molecules based on liposome fusion for applications in cell-surface engineering. Lipid vesicles, functionalized with ketone and oxyamine molecules, display complementary chemistry and undergo recognition, docking, and subsequent fusion upon covalent oxime bond formation. Liposome fusion was characterized by several techniques including matrix-assisted laser-desorption/ionization mass spectrometry (MALDI-MS), light scattering, fluorescence resonance energy transfer (FRET), and transmission electron microscopy (TEM). When cultured with cells, ketone- and oxyamine-containing liposomes undergo spontaneous membrane fusion to present the respective molecules from cell surfaces. Ketone-functionalized cell surfaces serve as sites for chemoselective ligation with oxyamine-conjugated molecules. We tailored and fluorescently labeled cell surfaces with an oxyamine-conjugated rhodamine dye. As an application of this cell-surface engineering strategy, ketone- and oxyamine-functionalized cells were patterned on oxyamine- and ketone-presenting surfaces, respectively. Cells adhered, spread, and proliferated in the patterned regions via interfacial oxime linkage. The number of ketone molecules on the cell surface was also quantified by flow cytometry.



INTRODUCTION

Membrane fusion processes are ubiquitous in biology and span multicellular communication, extracellular signaling, reconstruction of damaged organelles, and integration of cells into complex tissues and organs.[1] As a result, there has been much interest in developing model systems to mimic biological membranes to investigate the mechanisms of fusion and for use in various biotechnological applications. For example, cells secrete and display proteins and lipids during vesicle trafficking events that either diffuse into the ECM or become components of the cell membrane after fusion.[2] Naturally, lipid vesicles provide an ideal platform for such studies and have been widely used to examine various membrane-related processes, including fusion.[3−5] In order for fusion to occur, the membranes must be brought into close proximity, followed by bilayer destabilization.[6] Fusion of such lipid vesicles or liposomes can be initiated by using divalent cations, polycations,[7] positively charged amino acids,[8] and membrane-disrupting peptides.[9,10] Historically, synthetic chemical agents have also been employed to fuse vesicle membranes[11−14] through nonspecific interactions. However, recent exciting efforts to improve selectivity and control over vesicle fusion have been achieved through the use of small, synthetic molecular recognition pairs.[15,16] Since vesicle fusion is a natural process and has been shown to influence the construction of cells into multicellular organisms, much research has focused on using liposomes to deliver cargo, reagents, nanomaterials, and therapeutic agents to cells. To our knowledge, there have been very few reports of employing liposome fusion to cell membranes as a method to deliver small chemical functional groups in order to tailor the cell membrane for subsequent bio-orthogonal and chemoselective ligation reactions.[17] This platform would find wide use in studying fundamental cell behavior and provide a range of new tools for tissue engineering and biomedical applications.

Cell-surface receptors that decorate the cell membrane influence a number of biological processes, such as cell adhesion, differentiation, intercellular communication, and tissue formation.[18] As such, methods that selectively engineer the cell surface by introducing chemoselective functional groups will have a significant role in directing and influencing many biological processes for applications in cell-based therapies, drug delivery, and tissue engineering.[19−23] Previous cell-surface modification strategies involve the introduction of chemoselective functional groups through metabolic and genetic engineering approaches.[24−26] However, such strategies may perturb cellular processes by altering cellular physiology.[27]

In this study, we present a method to tether chemoselective ketone and oxyamine groups from cell surfaces by liposome delivery toward the goal of rewiring the cell surface. Alkyl ketone and oxyamine molecules spontaneously insert into lipid vesicles upon synthesis. When mixed, chemical recognition occurs, producing stable oxime bonds under physiological conditions. The reaction is also bio-orthogonal and, thus, does not interfere with any other chemical moieties in its cellular surroundings.[28−31] The synthetic ketone and oxyamine molecules fused on the cell membrane serve as cell-surface receptors, providing tools for the attachment of other functional materials, biomolecules, and probes on the cell

Scheme 1. List of Liposomes, Molecules, and Cells Used in This Study[a]

[a](1) Keto-LUV; (2) oxy-LUV; (3) keto-NBD-PE LUV; (4) oxy-rhod-PE LUV; (5) ketone-functionalized liposomes; (6) oxyamine-functionalized liposomes; (7) fluorescein-ketone; (8) rhod-oxyamine; (9) ketone-functionalized fbs; and (10) oxyamine-functionalized fbs.

surface. Liposome fusion was characterized by matrix-assisted laser-desorption/ionization mass spectrometry (MALDI-MS), dynamic light scattering (DLS), fluorescence resonance energy transfer (FRET), transmission electron microscopy (TEM), fluorescence-activated cell sorting (FACS), and fluorescence microscopy analyses.

MATERIALS AND METHODS

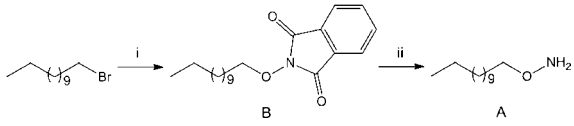
All chemical reagents were of analytical grade and used without further purification. Lipids egg palmitoyl-oleoyl phosphatidylcholine (POPC), egg 1-palmitoyl-2-oleoyl-phosphatidylglycerol (POPG), 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP), egg 1,2-diphytanoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl) (ammonium salt) (NBD-PE), and egg 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (ammonium salt) (Rhod-PE) were purchased from Avanti Polar Lipids (Alabaster, AL). Antibodies and fluorescent dyes were obtained from Invitrogen (Carlsbad, CA). FITC-labeled beads were purchased from Spherotech, Inc. (Forest Lake, IL) and all other chemicals were obtained from Sigma-Aldrich or Fisher. Swiss 3T3 albino mouse fibroblasts (fbs) were obtained from the Tissue Culture Facility at the University of North Carolina (UNC).

Transmission electron microscopy (TEM) images were acquired using a TF30He Polara G2 (FEI company) electron cryomicroscope, operating at 300 keV. Images were recorded using a Tietz single port model 415 4k × 4k CCD camera with a 15 μm pixel size. Fluorescence resonance energy transfer measurements (FRET) were performed using a SPEX Fluorolog-3 Research T-format Spectrofluorometer with an excitation wavelength of 471 nm. Dynamic light scattering was performed using a Nikomp model 200-laser particle sizer with a 5 mW HeNe laser at an excitation wavelength of 632.8 nm and using a Wyatt DynoPro plate reader. Flow cytometry was performed using a Dako CyAn ADP (Beckman-Coulter, Brea, CA), and the data was analyzed with *Summit 4.3* software. Phase contrast and fluorescent imaging was performed and processed using a Nikon TE2000-E inverted microscope and *Metamorph* software, respectively.

Syntheses. Tetra(ethylene glycol)-terminated alkanethiol (EG_4) was synthesized as previously reported.[32] Fluorescein-ketone (**7**; Scheme 1) was synthesized as previously reported.[33] The syntheses of *O*-dodceyloxyamine (**A**; Scheme 2) and rhod-oxyamine (**8**) are described below.

*2-(Dodecyloxy)isoindoline-1,3-dione (**B**).* To a solution of *N*-hydroxyphthalimide (1.96 g, 12.04 mmol, 1.5 equiv) and sodium bicarbonate (10.11 g, 12.04 mmol, 1.5 equiv) in DMF (20 mL) at 80 °C was added 1-bromododecane (1.93 mL, 8.02 mmol). The mixture was refluxed and stirred for 12 h. The reaction was diluted with DCM and washed with H_2O (6 × 50 mL), 1 M $NaHCO_3$ (3 × 50 mL), and H_2O (2 × 50 mL), dried over $MgSO_4$, and concentrated to afford a white solid, **B** (2.66 g, 87%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.91 (m, 3H), 1.28 (bm, 16H), 1.47−1.49 (m, J = 9.2 Hz, 2H), 1.77−1.83 (m, J = 22.0 Hz, 2H), 4.20−4.23 (t, J = 13.6 Hz, 2H), 7.28−7.30, 7.75−7.77 (dm, J = 4.8, Hz, J = 5.6 Hz, 2H, 2H). (ESI) (m/z) [M + H$^+$]: 332.28.

Scheme 2. Synthesis of *O*-Dodecyloxyamine (A)[a]



[a]Reagents and conditions. (i) *N*-hydroxyphthalimide (1.5 equiv), $NaHCO_3$ (1.5 equiv), DMF, reflux, 80 °C, 12 h; 87%; and (ii) hydrazine (6 equiv), dry DCM, N_2, 12 h; 74%.

*O-Dodecyloxyamine (**A**).* To a solution of **B** (2.65 g, 8.00 mmol) in dry DCM (30 mL) under inert atmosphere (Ar) was slowly added hydrazine (1.53 mL, 48.00 mmol, 6 equiv). Upon addition, a white precipitate immediately formed. The mixture was stirred for 12 h. The reaction was diluted with DCM and washed with H_2O (6 × 50 mL), dried over $MgSO_4$, and concentrated to afford a pale yellow oil, **A** (1.18 g, 74%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.88−0.91 (t, J = 13.6 Hz, 3H), 1.28 (s, 18H), 1.57−1.60 (m, J = 14.0 Hz, 2H), 3.65−3.69 (t, J = 13.2 Hz, 2H). (ESI) (m/z) [M + H$^+$]: 201.22.

*(N-(4-(tert-Butoxycarbonylamino)butyl)sulfamoyl)-2-(6-(diethylamino)-3-(diethyliminio)-3H-xanthen-9-yl)-benzenesulfonate (**C**).* To a solution of rhodamine lissamine (0.880 g, 1.53 mmol) in chloroform ($CHCl_3$, 30 mL) at room temperature (RT) was added N-BOC-1,4-diaminobutane (0.431 g, 2.29 mmol, 1.5 equiv) and TEA (0.305 mL, 2.29, 1.5 equiv). The mixture was stirred for 8 h and then extracted with H_2O (6 × 25 mL). The organic layers were concentrated to afford a dark purple solid **C**. ^{1}H NMR was taken in $CDCl_3$ to confirm **C** (1.045 g, 95%). TLC conditions for entire synthesis: $CHCl_3$/MeOH (7.5:2.5). ^{1}H NMR (400 MHz, MeOD) δ 1.09−1.07 (t, J = 8.1 Hz, 6H), 1.36−1.33 (m, J = 12.3, 15H), 1.66−1.64 (m, J = 8.6 Hz, 4H), 3.47−3.44 (m, J = 12.1, 6H), 4.20−4.18 (q, J = 7.8 Hz, 4H), 5.66 (s, 1H), 5.77 (d, 1H), 6.01 (d, 1H), 6.34−6.30 (m, J = 16.1 Hz, 2H), 7.21 (d, 1H), 7.29 (d, 1H), 7.98 (d, 1H), 8.04 (d, 1H). (ESI) (m/z) [M + H$^+$]: 716.31.

*5-(N-(4-Aminobutyl)sulfamoyl)-2-(6-(diethylamino)-3-(diethyliminio)-3H-xanthen-9-yl)benzenesulfonate (**D**).* To **C** (0.600 g, 0.837 mmol) was added a solution of TFA, H_2O, and triisopropylsilane (TIPS) in a ratio of 95:2.5:2.5 (10 mL). The mixture was stirred at RT under N_2 for 3 h and was then extracted with $CHCl_3$ and H_2O (4 × 25 mL). The organic layers were dried and concentrated to afford a purple solid, **D** (0.45 g, 85%). ^{1}H NMR (400 MHz, MeOD) δ 1.11−1.09 (t, J = 8.7, 6H), 1.33−1.31 (m, J = 7.4 Hz, 6H), 1.70−1.67 (m, 4H, J = 12.5, 4H), 2.63−2.62 (m, J = 4.6 Hz, 2H), 3.51−3.49 (m, J = 8.7 Hz, 6H), 4.20−4.18 (q, J = 7.8 Hz, 4H), 5.64 (s, 1H), 5.71 (d, 1H; Ar−H), 6.02 (d, 1H), 6.32−6.30 (m, J = 8.3 Hz, 2H), 7.24 (d, 1H), 7.30 (d, 1H), 7.98 (d, 1H), 8.04 (d, 1H). (ESI) (m/z) [M + H$^+$]: 628.27.

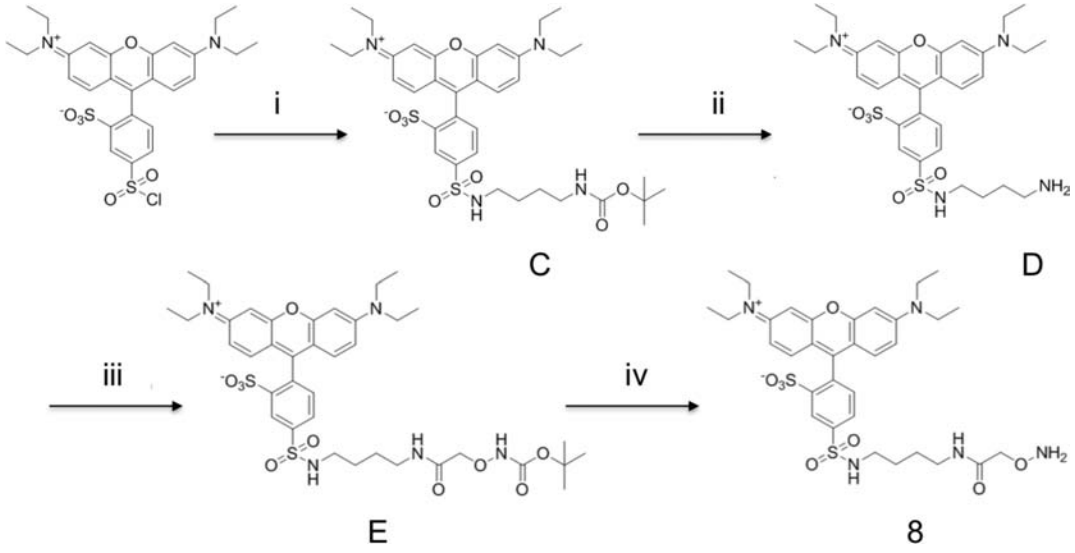
Scheme 3. Synthesis of Rhod-Oxyamine (8)[a]



[a]Reagents and conditions. (i) N-BOC-1,4-diaminobutane (1.5 equiv), TEA (1.5 equiv), $CHCl_3$, N_2, 25 °C, 8 h; 95%, (ii) triisopropylsilane (TIPS)/H_2O/TFA (2.5:2.5:95), N_2, 25 °C, 3 h; 85%, (iii) *N*-hydroxysuccinimide (NHS, 2 equiv), *N,N′*-dicyclohexylcarbodiimide (DCC, 2 equiv), aminooxy acetic acid (2 equiv), TEA (excess), DMF, N_2, 25 °C, 4 h; 60%, and (iv) TIPS/H_2O/TFA (2.5:2.5:95), N_2, 25 °C, 3 h; 81%.

*2-(6-(Diethylamino)-3-(diethyliminio)-3H-xanthen-9-yl)-5-(N-(2,2-dimethyl-4,8-dioxo-3,6-dioxa-5,9-diazatridecan-13-yl)sulfamoyl)benzenesulfonate (**E**).* To a solution containing *N,N′*-dicyclohexylcarbodiimide (DCC, 0.394 g, 1.91 mmol, 2 equiv), *N*-hydroxysuccinimide (NHS, 0.220 g, 1.91 mmol 2 equiv), and aminooxy acetic acid (0.356 g, 1.91 mmol, 2 equiv) in DMF was stirred under N_2 for 0.5 h. **D** (0.43 g, 0.684 mmol) was then added in DMF (20 mL), followed by TEA (excess). The mixture was strirred for 4 h and then concentrated. Flash chromatography was performed using $CHCl_3$/MeOH (8:2) to elute, **E**. The product was concentrated to afford a purple solid **E** (0.32 g, 60%). ^{1}H NMR (400 MHz, MeOD) δ 1.10−1.08 (t, J = 8.8, 6H), 1.39−1.36 (m, J = 12.3 Hz, 15H), 1.65−1.63 (m, J = 7.9, 4H), 3.08−3.06 (m, J = 8.0, 2H), 3.48−3.46 (m, J = 8.3, 6H), 4.17−4.15 (q, J = 7.7, 4H), 4.38 (s, 2H), 5.61 (s, 1H), 5.73 (d, 1H), 6.02 (d, 1H), 6.31−6.30 (m, J = 4.4, 2H), 7.24 (d, 1H), 7.32 (d, 1H), 7.96 (d, 1H), 8.09 (d, 1H). (ESI) (m/z) [M + H$^+$]: 801.31.

*5-(N-(4-(2-(aminooxy)acetamido)butyl)sulfamoyl)-2-(6-(diethylamino)-3-(diethyliminio)-3H-xanthen-9-yl)-benzenesulfonate (rhod-oxyamine, **8**; Scheme 3).* To **E** (0.30 g, 0.374 mmol) was added a solution of TFA, H_2O, and triisopropylsilane (TIPS) in a ratio of 95:2.5:2.5 (10 mL). The mixture was stirred at RT under N_2 for 3 h and was then extracted with $CHCl_3$ and H_2O (4 × 25 mL). The organic layers were dried and concentrated to afford a purple solid, and flash chromatography was performed using $CHCl_3$/MeOH (8:2) to elute **8** (0.21 g, 81%). ^{1}H NMR (400 MHz, $CDCl_3$) δ 1.12−1.00 (t, J = 8.2, 6H), 1.42−1.40 (m, J = 7.9, 6H), 1.62−1.60 (m, J = 7.7, 4H), 3.07−3.05 (m, J = 8.0, 2H), 3.45−3.42 (m, J = 12.4, 6H), 4.11−4.09 (q, J = 8.4, 4H), 4.24 (s, 2H), 5.64 (s, 1H), 5.75 (d, 1H), 6.02 (d, 1H), 6.29−6.27 (m, J = 4; 2H), 7.28 (d, 1H), 7.31 (d, 1H), 7.92 (d, 1H), 8.05 (d, 1H). (ESI) (m/z) [M + H$^+$]: 701.28.

Formation of Lipid Vesicles. *Liposome Fusion Studies.* Dodecanone (55 μL, 10 mM in $CHCl_3$ at 5 mol %) was dissolved with egg palmitoyl-oleoyl phosphatidylcholine (POPC) (430 μL, 10 mg/mL in $CHCl_3$, at 95 mol %) and *O*-dodecyloxyamine (60 μL, 10 mM in $CHCl_3$ at 5 mol %) was mixed with POPC (410 μL, 10 mg/mL in $CHCl_3$ at 75 mol %), and egg 1-palmitoyl-2-oleoyl-phosphatidylglycerol (POPG) (92 μL, 10 mg/mL in $CHCl_3$ at 20 mol %). Both lipid sample mixtures were then concentrated under high vacuum for 4 h. The dried lipid samples were reconstituted and brought to a final volume of 3 mL in PBS buffer, pH 7.4. The contents of the vial were warmed to 50 °C and sonicated for 20 min, in a tip sonicator, until the solution became clear and large unilamellar vesicles (LUVs) containing ketone (keto-LUV, **1**; Scheme 1) or oxyamine (oxy-LUV, **2**) groups were formed.

FRET Fusion Studies. NBD-PE and rhod-PE were added to two separate vials at 2 mol %. The dried lipid samples were then reconstituted in 2.43 mL of PBS buffer, pH 7.4. The contents of the vial were warmed to 50 °C and sonicated for 20 min, in a tip sonicator, until the solution became clear, and LUVs containing ketone (keto-NBD-PE LUVs, **3**) or oxyamine (oxy-rhod-PE LUVs, **4**) groups were formed.

Liposome Fusion to Cells. To generate ketone- and oxyamine-containing liposomes for cell fusion studies, dodecanone (55 μL, 10 mM solution in $CHCl_3$ at 5 mol %) and *O*-dododecyloxyamine (60 μL, 10 mM solution in $CHCl_3$ at 5 mol %) were dissolved with egg-POPC (424 μL, 10 mg/mL in $CHCl_3$ at 93 mol %) and 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP, 10 μL, 10 mg/mL in $CHCl_3$ at 2 mol %) in chloroform followed by concentration under high vacuum for 4 h. The dried lipid samples were then reconstituted and brought to a final volume of 3 mL in PBS buffer, pH 7.4. The contents of the vial were warmed to 50 °C and sonicated for 20 min, in a tip sonicator, until the solution became clear, and LUVs containing ketone (**5**) or oxyamine (**6**) groups were formed.

Matrix-Assisted Laser-Desorption/Ionization Mass Spectrometry (MALDI-MS). Preparation of Gold-Coated MALDI Sample Plates. Gold-coated MALDI sample plates (123 × 81 mm) (Applied Biosystems, Foster City, CA) were prepared by electron-beam deposition (Thermionics Laboratory Inc., Hayward, CA) of titanium (5 nm) and then gold (12 nm). In order to form self-assembled monolayers (SAM) of

alkanethiolates on the plates, the slides were immersed in a 1 mM solution of aminooxyundecanethiol in EtOH for approximately 1 min, rinsed with EtOH and dried, and then backfilled with a 1 mM solution of mercaptoundecanol in EtOH for 1 h. Once removed from solution, the surfaces were rinsed with EtOH and dried before use.

Liposome Preparation. Keto-LUVs (**1**) were generated as previously described and were then delivered and allowed to react with the oxyamine-terminated MALDI sample plate (90 min). The plates were then washed with water (3 × 3 mL) and EtOH (2 × 3 mL) and dried before use.

MALDI Analyses. MS analyses were carried out using an AB SCIEX TOF/TOF 5800 System (Applied Biosystems, Foster City, CA).

Dynamic Light Scattering (DLS). Keto- (**1**) and oxy- (**2**) LUVs were generated as previously described and tested by DLS for monodispersity and uniformity. Light scattering experiments were performed using a Nikomp model 200 laser particle sizer with a 5 mW helium−neon laser at an exciting wavelength of 632.8 nm. Standard deviation determinations were made using Gaussian analysis. A Wyatt DynoPro dynamic scattering plate reader was used to collect the light scattering data.

FRET Analyses. Keto- (**3**) and oxy- (**4**) LUVs containing NBD-PE and rhod-PE, respectively, were generated as previously described and tested by FRET. All fluorescence measurements were performed in a SPEX Fluorolog-3 Research T-format Spectrofluorometer. NBD fluorescence was measured at 471 nm (excitation) and 531 nm (emission), maintaining narrow excitation slits to reduce light scattering interference. To obtain FRET measurements, the NBD dye was excited at 471 nm, and the emission was scanned through 600 nm, and the emission signal for rhod-PE was observed at 578 nm. Fluorescence was followed immediately after mixing oxy-rhod-PE LUV (**4**, 3 mM in PBS, 100 μL) with keto-NBD-PE LUV (**3**, 3 mM in PBS, 100 μL) for approximately 2 h at 2 min intervals. The total lipid concentrations were adjusted to 0.2 mM, and the two LUV populations had a 1:1 molar ratio. A constant flow of water was passed through the cuvette holder for temperature control. The temperature was maintained at 25 °C.

TEM Analyses. Keto- (**1**) and oxy- (**2**) LUVs were made as previously described (0.2 mM in PBS, pH 7.4). The two vesicle solutions (1:1) were mixed at room temperature for 30 min. Four microliter aliquots of vesicles suspended in buffer applied to standard lacey carbon EM grids were prepared according to published methods. The specimens were blotted from behind and then submerged into aurenyl acetate solution for staining. The hydrated specimens were then placed in a TF30He Polara G2 (FEI company) electron cryomicroscope operating at 300 keV. Images were recorded using a Tietz single port model 415 4k × 4k CCD camera with a 15 μm pixel size on the chip. Pixel sizes at the specimen level were used to calculate accurate dimensions for the specimen.

Cell Adhesion Patterning. Self-assembled monolayers (SAMs) presenting aldehyde or oxyamine and tetra(ethylene glycol) (EG_4) groups were patterned using microfluidic oxidation and microfluidic lithography, respectively.[34,35] EG_4 has been shown to passivate substrates against cell and protein adsorption.[36] Therefore, the ratio of EG_4 and aldehyde or oxyamine groups was 90:10 to ensure that fibroblasts (fbs) were only adhering to the patterned surface regions that presented 10% oxyamine or aldehyde groups, driven via oxime conjugation. Fbs were separately cultured with keto- (**5**) or oxy- (**6**) LUVs as previously described and were then seeded ($\sim 10^2$ cells/mL, 2 h) to the patterned oxyamine or aldehyde surfaces, respectively. Media that 10% calf bovine serum (CBS) and 1% penicillin/streptomycin was then added, and the substrates were incubated at 37 °C in 5% CO_2 for 4 d. Cells cultured with liposomes, not containing the key functional groups, did not attach to the patterned surfaces. Substrates were then stained and imaged by fluorescence microscopy. Exposure times of 400 and 1200 ms were used to image nuclei and actin, respectively.

Fibroblast (Fb) Culture. Swiss 3T3 albino mouse fbs and Rat2 fbs were cultured in Dulbecco's Modified Eagle Medium (Gibco) containing 10% calf bovine serum (CBS) and 1% penicillin/streptomycin at 37 °C in 5% CO_2.

Delivery of Functionalized Liposomes to Cells. Cells were seeded onto a tissue culture plate and allowed to grow for 48 h at 37 °C in 5% CO_2 in CBS media.

Cell-Surface Engineering. Two cell-surface engineering methods were employed to fluorescently label fbs. In this first method, a solution of oxy-LUVs (**6**, 3 mM) was incubated with a ketone-functionalized fluorescein (**7**, 0.15 mM, 1 equiv, 2 h), forming fluorescently labeled liposomes. The liposomes were then added to fbs in culture for 2 h. After fusion, the cells were washed with PBS (3 × 2 mL), trypsinized (1 mL, 5 min, 37 °C, 5% CO_2), diluted with CBS-containing media ($\sim 10^2$/mL), and seeded to a glass substrate (1 × 1 cm^2, 2 h). The cells were then imaged under a fluorescence microscope with an exposure time of 1/1200 s. In the second method, a solution of keto-LUVs (**5**, 200 μL, 0.6 mM) was added to fbs in culture for 2 h, resulting in membrane fusion and subsequent display of ketones from the cell surface (**9**). Rhod-oxyamine (**8**, 100 μL, 0.7 mM in H_2O) was then added the cells for 2 h. After oxime formation, the fbs were washed with PBS (3 × 2 mL), trypsinized (1 mL, 5 min, 37 °C, 5% CO_2), diluted with CBS-containing media ($\sim 10^2$/mL), and seeded to a glass substrate (1 × 1 cm^2, 2 h). The cells were then imaged under a fluorescence microscope with an exposure time of 1/1200 s.

Flow Cytometry. Liposomes with varying oxyamine mol % (i.e., 0%, 1%, 5%, and 10%) were generated and cultured with separate populations of fbs (**6**, 3 mM, 4 h), resulting in membrane fusion and subsequent display of oxyamine groups from cell surfaces (**10**). Ketone-functionalized fluorescein (**7**, 0.15 mM 2 h) was then reacted with the fbs, generating fluorescently labeled cells. The control cells (i.e., not displaying oxyamine groups) were incubated with ketone−fluorescein for 2 h each, under the same conditions. The cells were then washed with PBS (3 × 5 mL), trypsinized (1 mL, 5 min, 37 °C, 5% CO_2), centrifuged (5 min, 1000 rpm), resuspended in RPM I (without phenol red), centrifuged (5 min, 1000 rpm), and resuspended in RPMI ($\sim 10^7$ cells/2 mL). Fluorescence-assisted cell sorting analyses (FACS) of the control and fbs with 1%, 5%, and 10% oxyamine were then performed (2 × 10^3 cells). Fluorescence measurements were calibrated using RCP-5-30 beads ($\sim 10^7$ beads/mL, 2 × 10^3 beads counted, Spherotech, Inc., Lake Forest, IL) of known fluorescein equivalent molecule density.[37] The RCP-5-30 beads contain a mixture of several similar size particles with different fluorescence intensities and a blank. Every particle contains a mixture of fluorophores that allows excitation at any wavelength from 365 to 650 nm. As a result, the RCP-30-5 beads have a twofold purpose: (1) calibrate the different channels in the flow cytometer being used and (2) cross-calibrate the relative number of fluorophores with cells or particles stained with known number

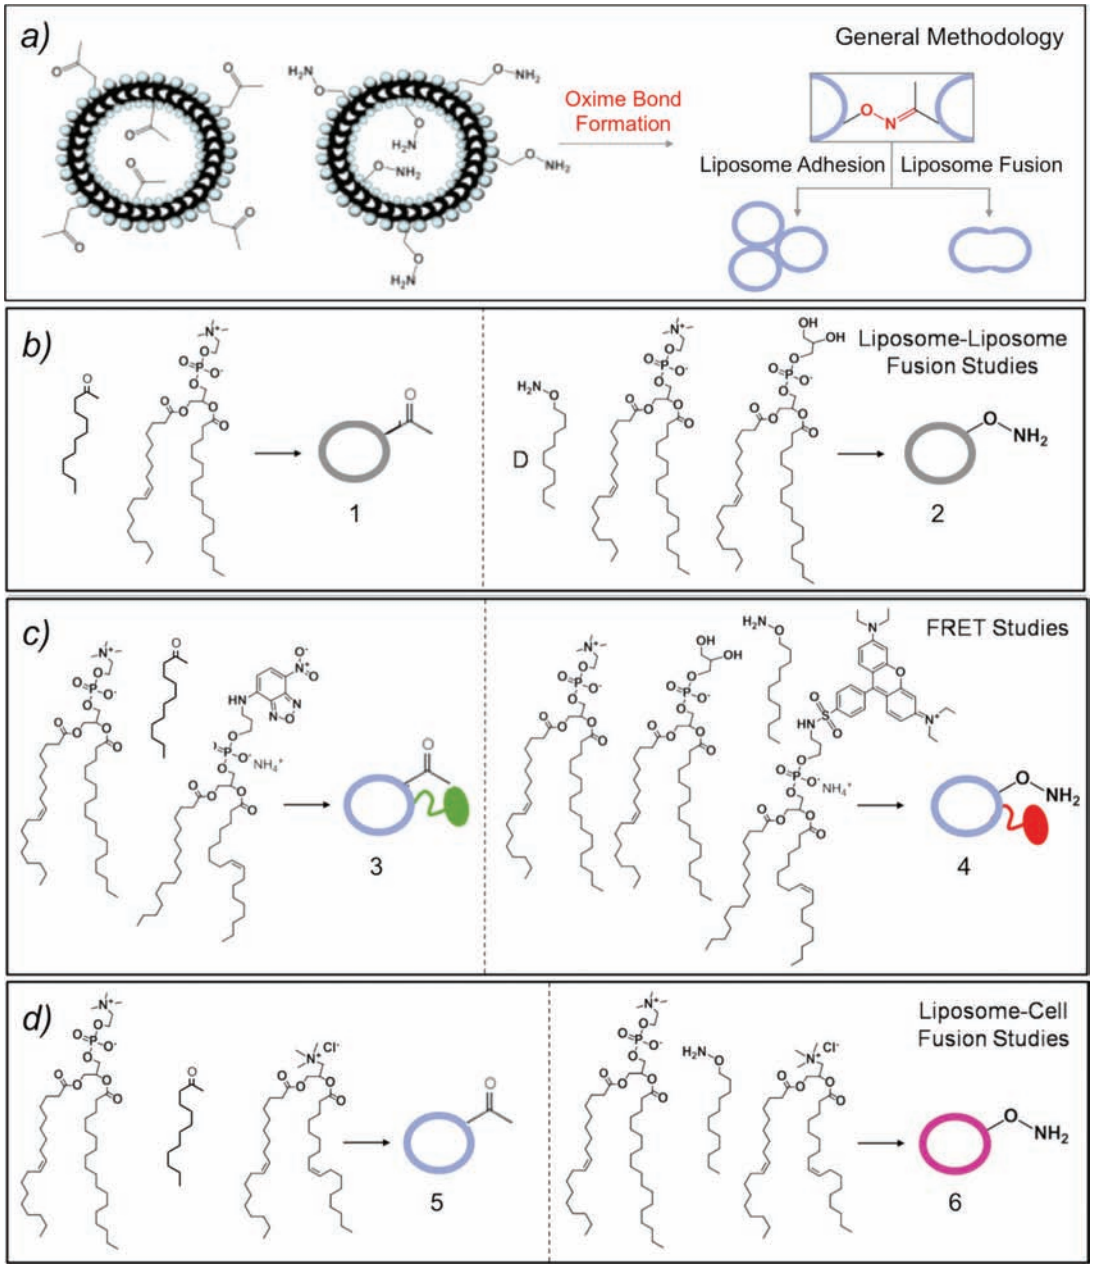


Figure 1. General schematic and corresponding lipid components for the formation of fused and adhered liposomes based on chemoselective oxime conjugation. (a) When mixed, ketone- and oxyamine-tethered liposomes react chemoselectively to form an interfacial, covalent oxime linkage, resulting in liposome docking and adhesion. Docked liposomes either fuse or form multiadherent structures. (b) Dodecanone molecules were incorporated into neutral, POPC at a ratio of 5:95 to form keto-LUVs (**1**), while *O*-dodecyloxyamine molecules were incorporated into POPC and negatively charged, POPG at a ratio of 5:75:20 to form oxy-LUVs (**2**). These liposomes were used for liposome−liposome fusion studies. (c) Dodecanone molecules were incorporated into POPC and fluorescence donor, NBD-PE at a ratio of 5:93:2 to form keto-NBD-PE LUVs (**3**). *O*-Dodecyloxyamine molecules were incorporated into POPC, POPG, and fluorescence acceptor, rhod-PE at a ratio of 5:73:20:2 to form oxy-rhod-PE LUVs (**4**). These liposomes were used for FRET studies. (d) Dodecanone molecules were incorporated into POPC and positively charged, DOTAP at a ratio of 5:97:2 to form ketone-presenting liposomes (**5**). *O*-Dodecyloxyamine molecules were incorporated into POPC and DOTAP at a ratio of 5:93:2 to form oxyamine-presenting liposomes (**6**). These liposomes were used for cell-liposome fusion studies.

of spectral matching fluorophores, such as FITC, to estimate the number of fluorophores on stained cells. No background is required to be subtracted because the different fluorophores are calibrated to the different flow cytometer channels. The raw data obtained in Figure 5b was cross-calibrated to the calibration curve that is generated with the RCP-30-5 beads to obtain the values seen in Figure 5c. The approximations of FITC molecules per cell in Figure 5c were determined by cross calibrating the 0% (control), 1%, 5%, and 10% oxyamine-containing liposomes to the standard curve (blank and 5 fluorophores) generated using the manufacturer's Excel spreadsheet and instructions (Spherotech, Inc., Lake Forest, IL). After generating a standard calibration curve with the RCP-30-5 beads, the mean fluorescence intensities obtained from the FITC channel were cross-calibrated with the curve using the manufacturer's spreadsheet to produce an approximation of the number of molecules per cell. The number of counted beads in each sample were the same.

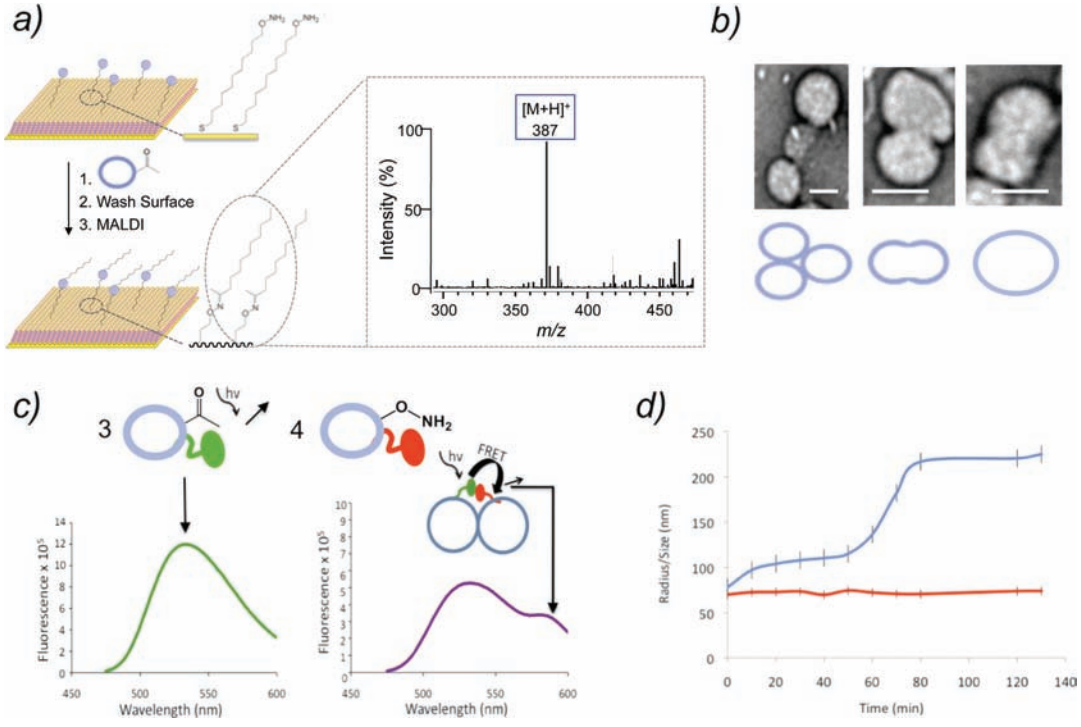

Figure 2. Characterization of the formation of fused and adhered liposomes based on chemoselective oxime conjugation. (a) Mass spectrometry (MS) data representing the oxime ligation of keto-LUVs to self-assembled monolayers (SAMs) of oxyamine-terminated alkanethiol on a gold surface is displayed. Matrix-assisted laser desorption/ionization (MALDI) was performed after keto-LUVs were delivered to the surface, and a mass of 387 units was detected, confirming oxime conjugation. (b) Structural analyses using transmission electron microscopy (TEM), representing the adhesion and fusion of keto- (**1**) and oxy- (**2**) LUVs over time. The following images are shown from left to right: multiadherent liposomes that are not fused; partially fused liposomes; and a single, large liposome after complete fusion. The scale bars represent 60 nm. (c) Fluorescence resonance energy transfer (FRET) analysis of liposome adhesion and fusion was monitored over 2 h. Fluorescence emission of keto-NBD-PE/PC LUVs (**3**), excited at 460 nm, was observed by scanning 475−600 nm (green trace). Fluorescence emission of keto-NBD-PE/PC LUVs (**3**) mixed with oxy-rhod-PE/PC/POPG LUVs (**4**) is represented (purple trace). A new FRET emission peak is observed at 578 nm showing mixed liposome adhesion. (d) Dynamic light scattering (DLS) was performed upon mixing liposomes (**1** and **2**) to monitor vesicle size change as a function of time. Increases in vesicle size were observed due to aggregation, adhesion, or fusion (blue trace). Liposome saturation was reached ~80 min after mixing. Without the presence of ketone and oxyamine functional groups, the LUV size remains constant (red trace).

Fluorescent intensities based on number of cells counted were compared to the standard bead and control cells lacking fluorescent molecule conjugation and approximate numbers of fluorescent compound bound to the surface was calculated. Flow cytometry was carried out using a Dako CyAn ADP (Beckman-Coulter, Brea, CA), and data was analyzed with *Summit 4.3* software.

■ RESULTS AND DISCUSSION

In previous studies, we demonstrated how chemoselective oxime chemistry can be used to present biospecific ligands from supported, model fluid lipid bilayer membranes for protein receptor recognition.[38] We also showed that the resultant oxime bond is extremely stable under physiological conditions.[33−35] In this report, we employ a similar oxime ligation strategy to generate a number of large unilamellar vesicles (LUVs) that present ketone or oxyamine functional groups. We first initiated liposome−liposome fusion events through molecular recognition and subsequent oxime bond formation and characterized the fusion using fluorescence resonance energy transfer (FRET), matrix-assisted laser-desorption/ionization mass spectrometry (MADLI-MS), dynamic light scattering (DLS), and transmission electron microscopy (TEM). Next, liposomes containing ketone and oxyamine groups were cultured with 3T3 Swiss albino fibroblasts, resulting in membrane fusion and display of oxyamines and ketones from the cell surface for further fluorescent probe conjugation. For the liposome−liposome fusion events studied by MALDI-MS (Figure 2a), DLS (Figure 2d), and TEM (Figure 2b), dodecanone and dodecyloxyamine molecules were incorporated, separately, into neutral, egg palmitoyl-oleoyl phosphatidylcholine (POPC) at a ratio of 5:95 to form keto-LUVs (**1**) and oxy-LUVs (**2**), respectively (Figure 1a,b). When observing liposome fusion via FRET analyses (Figure 2c), dodecanone molecules were mixed with POPC and fluorescence donor, egg 1,2-diphytanoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl) (NBD-PE) at a ratio of 5:93:2 to form keto-NBD-PE-LUVs (**3**), while dodecyloxyamine molecules were incorporated into POPC, negatively charged, egg 1-palmitoyl-2-oleoyl-phosphatidylglycerol (POPG), and fluorescence acceptor, egg 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (rhod-PE) at a ratio of 5:73:20:2 to form oxy-rhod-PE-LUVs (**4**). Finally, liposomes that contained dodecanone, POPC, and cationic lipid, 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) (5:93:2, **5**) and liposomes that composed of dodecyloxyamine, POPC, and DOTAP (5:93:2, **6**) were generated to investigate liposome-cell fusion processes (Figure 1d). Cationic lipid, DOTAP, was incorporated to induce membrane fusion due to the electrostatic interactions with the negatively charged cell surface.[39,40]

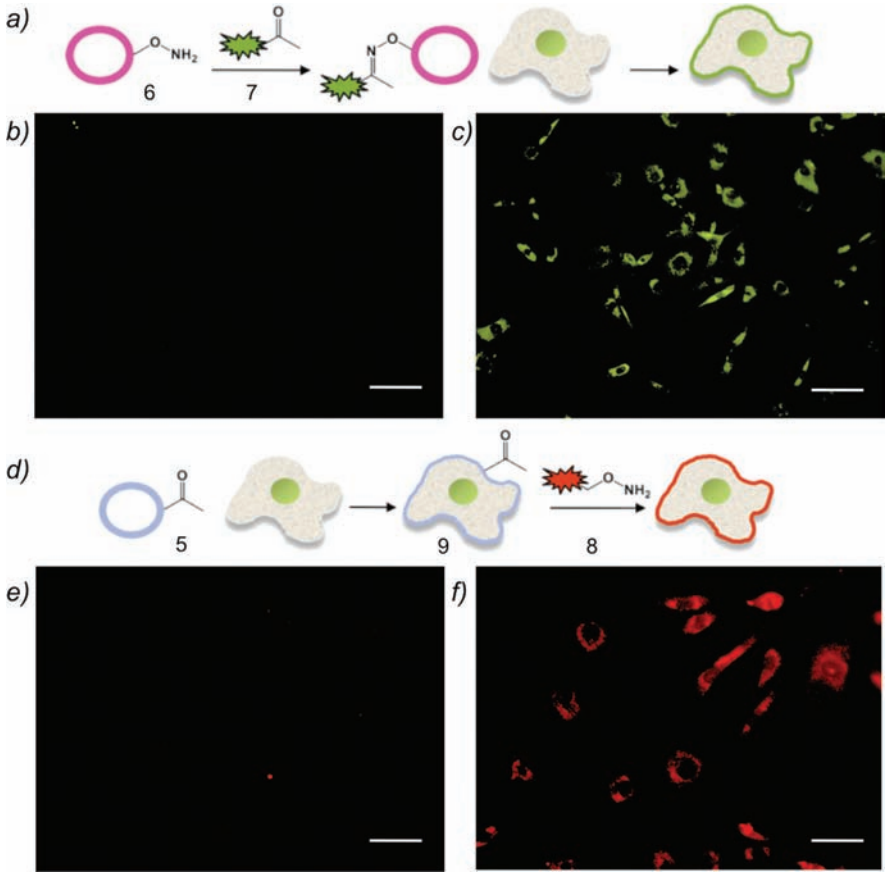

Figure 3. (Top) Schematic describing the delivery and subsequent fusion of fluorescent liposomes to cell surfaces with corresponding brightfield and fluorescent images. (a) Oxy-LUVs (**6**, 3 mM) were reacted with fluorescein−ketone (**7**, 0.15 mM, 2 h) to generate green fluorescent liposomes. The fluorescent liposomes were then added to fbs in culture, resulting in the fluorescent labeling of cells after liposome fusion to the cell membrane. Micrographs show (b) control cells where liposomes not containing oxyamine groups were incubated with fluorescein−ketone and added to fbs in culture for 2 h and (c) green fluorescently labeled cells after oxyamine-functionalized liposomes were incubated with fluorescein−ketone and delivered to fbs (2 h). (Bottom) General schematic and images for cell-surface tailoring using liposome fusion and chemoselective oxime chemistry. (d) Keto-LUVs (**5**, 3 mM) were added and fused with the cells to display these groups from the cell surface (**9**). Addition of rhod-oxyamine (**8**, 0.7 mM in H_2O, 2 min) resulted in chemoselective oxime formation and red fluorescent labeling of the cells. Images display (e) control fbs where liposomes not displaying ketones were fused to the membrane (2 h) and rhod-oxyamine was added and no fluorescence was observed, and (f) fluorescently labeled cells after ketone-functionalized liposomes were fused to fbs (2 h) and cells were incubated with rhod-oxyamine. Scale bars for b,c,d,e represent 50 and 30 μm, respectively.

Fusion Methodology and DLS Analyses. Our general fusion methodology is described in Figure 1a. Two liposome populations (**1** and **2**, **3** and **4**, or **5** and **6**) were mixed, resulting in liposome docking, adhesion, and finally fusion due to the formation of stable, interfacial oxime bonds. Depending on the application, liposomes fuse to each other, forming larger liposomal structures (Figure 2b) or to cell surfaces and then be further conjugated with the corresponding oxime component. DLS was performed upon mixing liposomes **1** and **2** over 2 h to monitor vesicle size change as a function of time. Increases in vesicle size were observed due to aggregation, adhesion, or fusion (blue trace, Figure 2d). Liposome saturation was reached ~80 min after mixing. We believe that, in some cases, liposomes **1** and **2** associate with each other through oxime chemistry and initiate docking/adhesion until enough liposomes have clustered to induce a sharp growth in size. We initially varied the ketone and oxyamine concentrations and found through our cell-surface engineering experiments and FACS analyses that higher ketone and oxyamine concentrations led to increases of these functional groups on the cell surface. However, increasing the concentration of functional groups led to faster fusion events but did not necessarily increase the liposome size after liposome−liposome fusion. We are studying the detailed relationship among the kinetics of liposome fusion, liposome size, and concentration of functional groups in the liposome. In control reactions, LUVs not presenting ketones were reacted with LUVs containing oxyamines (**1**) (red trace, Figure 2d). Likewise, LUVs containing ketone groups (**2**) were mixed with LUVs that did not display oxyamines. For both of these control experiments, no size change was observed over time. This result strongly supports that liposome adhesion and fusion are driven by chemoselective oxime bond formation between the ketone- and oxyamine-alkanes.

TEM. Structural insight into the formation of different adhered and fused liposomes was observed through TEM (Figure 2b).[41] Vesicles of different sizes and shapes result after 2 h of liposome mixing (keto-LUV, **1**, and oxy-LUV, **2**). The liposome size gradually increases with time and is consistent with the data collected from other sizing experiments (e.g., DLS). Upon reaction, the following three structures were observed: multiadherent liposomes that were not fused,

dx.doi.org/10.1021/bc200236m | *Bioconjugate Chem.* 2011, 22, 2423−2433

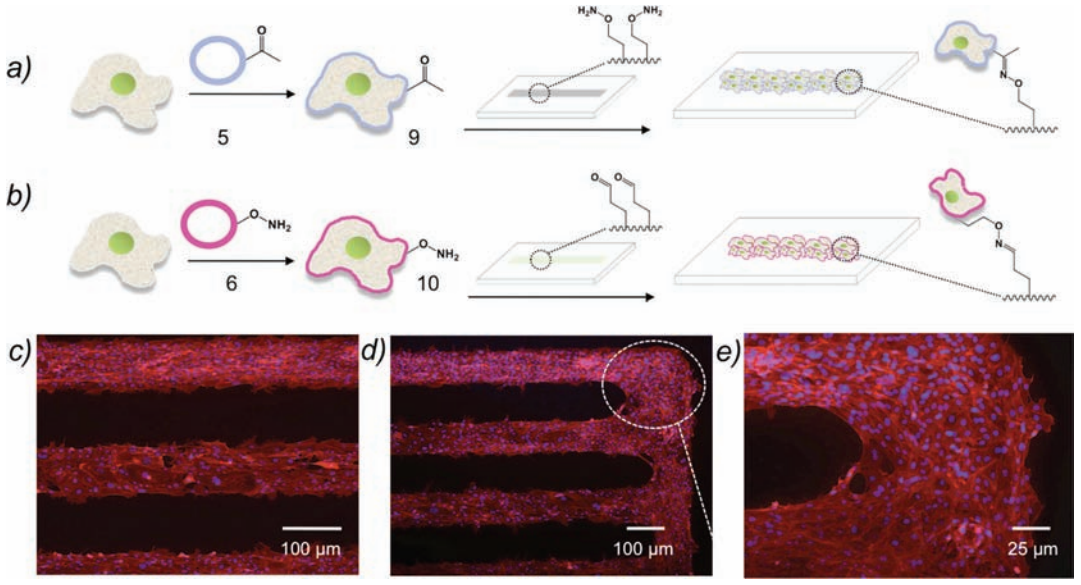

Figure 4. Schematics and fluorescent micrographs of rewired cells adhered to patterned self-assembled monolayers (SAMs) of alkanethiolates on gold substrates. (a,b) Keto- (**5**) and oxy-LUVs (**6**, 3 mM, 4 h) were cultured with separate fb populations, producing ketone- and oxyamine-presenting fbs (**9** and **10**, respectively). These cells were then seeded (~10^2 per mL, 2 h) to patterned, oxyamine- and aldehyde-terminated SAMs (10%), respectively, and allowed to adhere through stable oxime conjugation. The unpatterned surface regions present tetra(ethylene glycol), which resists cell and protein adsorption. The cells then grew and proliferated only filling out the oxyamine- and aldehyde-tethered surface regions, respectively. (c) Fluorescent micrograph of patterned ketone-fbs (**9**), adhered to an oxyamine-terminated SAM is shown. (d,e) Fluorescent micrographs of patterned oxyamine-fbs (**10**), adhered to an aldehyde-terminated SAM are demonstrated. Cells were stained with DAPI (blue, nucleus) and phalloidin (red, actin).

partially fused liposomes, and completely fused, large uni- and multilamellar liposomes (Figure 2b).

FRET. Figure 2c shows a liposome fusion assay involving FRET characterization. A lipid-bound FRET pair, NBD-PE (donor) and rhod-PE (acceptor), were incorporated at 2 mol % concentration during liposome generation to produce keto-NBD-PE LUVs (**3**) and oxy-rhod-PE LUVs (**4**), respectively. Hypothetically, fusion of these vesicles should result in a gradual decrease in the donor emission peak and an increase in acceptor emission peak[40] due to the close proximity of these dyes. As shown, vesicle mixing resulted in this FRET fusion signature. Fusion was observed immediately upon mixing **3** and **4**, slowing within 2 h to a stable population, which is similar to earlier sizing results. An emission peak was not observed for the acceptor rhodamine dye when performing control experiments that tested the energy transfer with an LUV that did not contain oxyamines. Similar results were observed when LUVs that did not contain ketones or oxyamines were mixed. This data further supports that liposome aggregation and fusion are based on chemoselective oxime bond formation.

MALDI-MS. Oxime conjugation, after keto-LUV (**1**) fusion, was confirmed by MALDI-MS analysis. Self-assembled monolayers (SAMs) of aminooxyundecanethiol were formed on a gold-coated, sample plate. A solution containing keto-LUVs (**1**) was then allowed to fuse and react with the surface for 90 min, followed by MALDI-MS examination. A mass of 387 units was detected, confirming successful oxime conjugation, resulting from liposome fusion on the surface (Figure 2a).

Cell-Surface Labeling. Chemical approaches to engineer cell surfaces have emerged as powerful tools for a variety of biomedical and biotechnological applications, including tissue engineering, drug delivery, and cell-based therapies.[24] Several metabolic and genetic approaches to display small molecular recognition pairs at cell surfaces for further covalent modification have been achieved through Click chemistry[42] and Staudinger ligation.[20] However, such strategies may alter cellular physiology and interfere with normal biochemical pathways.[28] In this report, we use oxime chemistry to tailor and fluorescently label cell surfaces via a novel liposome fusion strategy. As mentioned, cationic lipid, DOTAP, was incorporated within keto- and oxy-LUVs to initiate electrostatic destabilization and subsequent fusion to the cell membrane.[39] As such, the minimum DOTAP concentration required to facilitate liposome–cell fusion was determined to be 2% through fluorescence labeling optimization. Keto-LUVs were generated using DOTAP and POPC concentrations that ranged from 0.5% to 5% and 90% to 94.5%, respectively, while maintaining a 5% ketone concentration. These liposomes were incubated with fibroblasts (fbs) for 4 h, conjugated with an oxyamine-tethered rhodamine (rhod-oxyamine, **8**) (0.7 mM, 2 h), and the cell fluorescence intensities were then compared. From 2% to 5% DOTAP, the intensities were almost identical, indicating that 2% DOTAP is sufficient to initiate fusion. The liposomes for liposome–cell fusion events were approximately ~60 nm in diameter, similar to those used for the liposome–liposome fusion characterization.

Given this optimized lipid ratio (POPC/ketone or oxyamine/DOTAP at 93:5:2), two cell-surface engineering methods were employed to fluorescently label fbs. Similar to our optimization experiments, a solution of keto-LUVs (**5**, 200 μL, 0.6 mM) was added to fbs in culture for 2 h, resulting in membrane fusion and subsequent display of ketones from the cell surface (**9**) (Figure 3d). Rhod-oxyamine (**8**, 100 μL, 0.7 mM in H_2O) was then added the cells for 2 h. After oxime formation, the fbs were washed with PBS, trypsinized, diluted with CBS-containing media (~10^2/mL), seeded to a glass substrate, and imaged under a fluorescent microscope. As

dx.doi.org/10.1021/bc200236m | *Bioconjugate Chem.* 2011, 22, 2423–2433

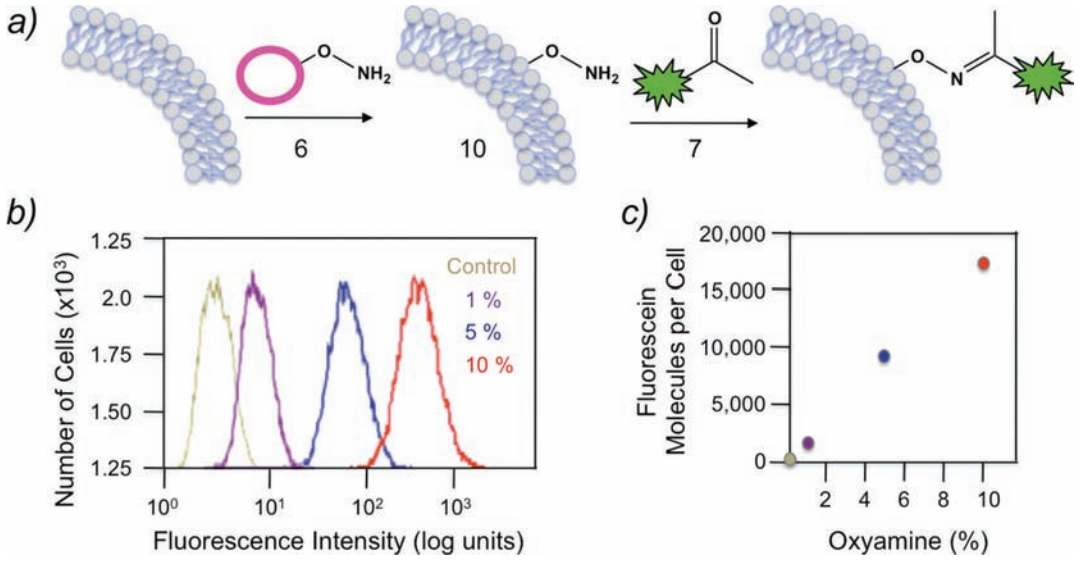

Figure 5. Cell surface molecule quantification using flow cytometry. (a) Oxy-LUVs (**6**, 3 mM) were added to fbs in culture (4 h), resulting in membrane fusion and subsequent display of oxyamine groups from cell surfaces (**10**). Ketone-functionalized fluorescein (**7**, 0.15 mM, 2 h) was then reacted with the fbs, generating fluorescently labeled cells. (b) Liposomes with varying oxyamine mol % (0%, 1%, 5%, and 10%) were generated and cultured with separate populations of fbs. After reacting with ketone−fluorescein, the cell populations were washed with PBS, trypsinized, centrifuged, resuspended in RPMI media, and tested using FACS analyses. As shown, the fluorescence intensity increased with increasing oxyamine concentration. (c) The number of molecules present at the cell surface with respect to oxyamine concentration was quantified using flow cytometry. A bead with a known FITC molecule density was employed as a standard comparison to calculate the number of oxyamines after oxy-LUVs (**6**) with 0%, 1%, 5%, and 10% oxyamine was cultured with cells. As the oxyamine concentration increased, the molecules per cell increased linearly (0%, 128; 1%, 1600; 5%, 9800; and 10%, 17 400). Twenty thousand cells were counted for each sampling.

observed in Figure 3f, the conjugation of rhod-oxyamine with ketone-presenting fbs resulted in the red fluorescence labeling of cells. When the control fbs (i.e., no ketone groups present) were reacted with rhod-oxyamine (**8**) and then imaged, no fluorescence was observed (Figure 3e). Demonstrating the flexibility of this liposome-based surface labeling strategy, we modified fb surfaces to present a ketone-functionalized fluorescein dye (**7**) after oxy-LUV-ketone-fluorescein conjugation and subsequent membrane fusion (Figure 3a). A solution of oxy-LUVs (**6**, 3 mM) was incubated with a ketone-functionalized fluorescein (**7**, 0.15 mM, 1 equiv, 2 h), generating fluorescently labeled liposomes. The liposomes were then added to fbs in culture for 2 h. After fusion, the cells were washed with PBS, trypsinized, diluted with CBS-containing media (~10^2/mL), seeded to a glass substrate, and imaged under a fluorescent microscope. Figure 3c presents green fluorescently labeled fbs after fusion with fluorescein-functionalized LUVs. Through fluorescent and confocal imaging, it appears that, after membrane fusion and/or endocytosis of cultured liposomes, fluorescence is also observed in several membrane organelles. This is an advantage of the system in that ketone or oxyamine groups are present at the cell surface and also decorate various internal membranes. It may be possible to label internal organelles with oxyamine chemistry for future targeting studies and applications. We assume that these lipids and fluorophores are packaged and trafficked to and from the cell surface and internal compartments. However, enough functional groups are present on the cell surface to provide handles for further oxime chemistry conjugation to tailor cell surfaces. When liposomes not containing oxyamine groups were incubated with fluorescein−ketone and added to fbs in culture for 2 h, no fluorescence was observed (Figure 3b). Thus, our control images indicated that reaction and labeling does not occur without the proper oxime recognition pair (Figure 3b and e). Furthermore, under these conditions, we observed no changes in cell behavior upon liposome fusion to cells, which is a very important feature for future *in vivo* applications. Thus, by combining liposome fusion and oxime chemistry, we were able to tailor the cell surface with either ketone groups or oxyamine groups, which may act as chemoselective cell-surface receptors for a range of small molecules, ligands, biomolecules, and nanoparticles.

Cell Patterning: Rewiring Adhesion. The ability to pattern and adhere cells to different materials, such as thin metal films, polymer scaffolds, and nanoparticles, with a simple and straightforward chemoselective and bio-orthogonal approach would be beneficial for cell biology, tissue engineering, and biotechnology. Thus, we employed liposome fusion-based toward cell-surface engineering to modify and rewire cell surface to adhere to patterned 2D substrates, directed through stable oxime bond conjugation. Figure 4a,b illustrates the strategy to rewire cell surfaces for the goal of cell adhesion to self-assembled monolayers (SAMs) of alkanethiolates on gold substrates. Employing microfluidic oxidation[34] and lithography,[35] aldehyde and oxyamine SAMs, respectively, were patterned at a ratio of 10%. The remaining 90% of the surface was backfilled with tetra(ethylene glycol) alkanethiol, which is known to pacify biomaterials against nonspecific protein adsorption and cell adhesion.[36] Meanwhile, fbs were cultured separately with keto- (**5**) and oxy-LUVs (**6**, 3 mM, 4 h), resulting in membrane fusion and subsequent display of ketones (**9**) and oxyamines (**10**) from cell surfaces. The resulting ketone- and oxyamine-presenting fbs were then seeded (~10^2 cells/mL, 2 h) to the patterned oxyamine and aldehyde substrates, respectively, and allowed to react and form stable oxime linkages in the patterned regions. The cells were cultured for 4 d on these substrates, growing and proliferating in the patterned regions. The results of patterned keto-fbs on

dx.doi.org/10.1021/bc200236m | *Bioconjugate Chem.* 2011, 22, 2423−2433

oxyamine SAMs are shown in Figure 4c; patterned oxy-fbs on aldehyde SAMs are displayed in Figure 4d,e. Furthermore, unmodified cells did not attach to the surface. Thus, this strategy allows for a bottom-up, bio-orthogonal synthetic approach to rewire how cells adhere to materials and does not require metabolic or genetic cell manipulations.

Flow Cytometry. Flow cytometry was performed to further verify the ability of tailoring small molecules to cell surfaces through covalent oxime bond formation. This method also enables the quantification of ketone and oxyamine molecules that are present at the cell surface after liposome delivery and subsequent membrane fusion. Liposomes that incorporated varying oxyamine concentrations of (i.e., 0, 1, 5, and 10 mol %) were generated (**6**, 3 mM), cultured with separate fb populations for 4 h, resulting in membrane fusion and oxyamine display (**10**, Figure 5a). A ketone-modified fluorescein dye (**7**, 0.15 mM, 2 h) was then conjugated to the cell surfaces in each population, producing green fluorescently labeled fbs. The FACS analyses results are demonstrated in Figure 5b. Twenty thousand cells were counted for all samples. As shown, the fluorescence intensity increases with increasing number of oxyamine molecules present for fluorescein conjugation. Additionally, the control cell population that was fused with unmodified liposomes and reacted with ketone–fluorescein (**7**) demonstrated the lowest intensity. Furthermore, a bead with known FITC molecule density was calibrated and used as a standard comparison to quantify the number of oxyamine molecules present at the cell surface after fusion.[37] Figure 5c displays the correlation between oxyamine mol % and oxyamine molecules per cell counted by FACS analyses. The calculated molecules per cell for the control fbs and oxyamine-presenting fbs that were fused with 1%, 5%, and 10% oxyamine were approximately 128, 1300, 9800, and 17 400, respectively. A linear trend was observed; as the molecule concentration increased, the fluorescence intensity and number of molecules at the cell surface increased. Thus, the density of molecules that decorate cell surfaces can be controlled and quantified using this liposome fusion-based methodology for cell-surface engineering.

CONCLUSION

In summary, we developed a chemoselective synthetic cell receptor system based on a liposome delivery and fusion strategy. Ketone and oxyamine groups were introduced to a liposomal system and chemoselective vesicle fusion was achieved using molecular recognition and interfacial oxime bond formation. Subsequent delivery of the decorated liposomes to cells lead to fusion and modification of a cell surface by bio-orthogonal reactive groups that serve as synthetic chemoselective cell receptors. Ketone and oxyamine modified cells were patterned on solid surfaces, displaying oxyamine and ketone groups, respectively. Thus, rewiring cell adhesion was achieved using chemoselective oxime bond formation and without using any cell adhesive ligands, such as Arg-Gly-Asp (RGD) and fibronectin. Since no biomolecules are used with this strategy, no long-term stability and degradation issues in complex cell culture media or *in vivo* will affect cell targeting or cell assembly. This methodology may have diverse applications in biomedical technologies including tissue engineering and regenerative medicine. Cells displaying ketone and oxyamine groups can react chemoselectively to form three-dimensional (3D) and tissue-like structures as directed through *in situ* oxime bond formation.[43] This method can be extended to generate 3D cell coculture systems and study cell–cell interactions. The ketone- and oxyamine-functionalized liposomes may have extensive applications in drug delivery and diagnostic applications, in which the interior of the liposome contains cargo while the exterior surface can be simultaneously functionalized with the tracking agent.

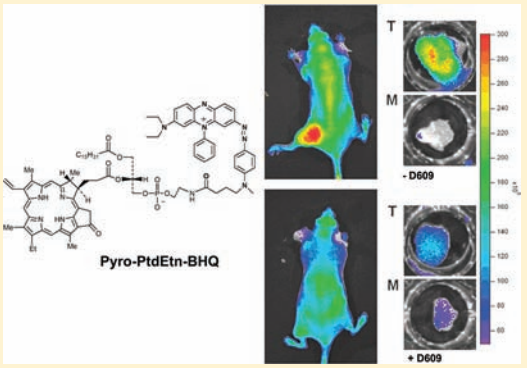
In Vivo Detection of Phospholipase C by Enzyme-Activated Near-Infrared Probes

Theresa M. Mawn, Anatoliy V. Popov, Nancy J. Beardsley, Klara Stefflova,[†] Matthew Milkevitch,[‡] Gang Zheng,[§] and E. James Delikatny*

Department of Radiology, University of Pennsylvania, Philadelphia, Pennsylvania 19104, United States

ABSTRACT: In this article, the characterization of the first near-infrared (NIR) phospholipase-activated molecular beacon is reported, and its utility for *in vivo* cancer imaging is demonstrated. The probe consists of three elements: a phospholipid (PL) backbone to which the NIR fluorophore, pyropheophorbide *a* (Pyro), and the NIR Black Hole Quencher 3 (BHQ) were conjugated. Because of the close proximity of BHQ to Pyro, the Pyro-PtdEtn-BHQ probe is self-quenched until enzyme hydrolysis releases the fluorophore. The Pyro-PtdEtn-BHQ probe is highly specific to one isoform of phospholipase C, phosphatidylcholine-specific phospholipase C (PC-PLC), responsible for catabolizing phosphatidylcholine directly to phosphocholine. Incubation of Pyro-PtdEtn-BHQ *in vitro* with PC-PLC demonstrated a 150-fold increase in fluorescence that could be inhibited by the specific PC-PLC inhibitor tricyclodecan-9-yl xanthogenate (D609) with an IC_{50} of 34 ± 8 μM. Since elevations in phosphocholine have been consistently observed by magnetic resonance spectroscopy in a wide array of cancer cells and solid tumors, we assessed the utility of Pyro-PtdEtn-BHQ as a probe for targeted tumor imaging. Injection of Pyro-PtdEtn-BHQ into mice bearing DU145 human prostate tumor xenografts followed by *in vivo* NIR imaging resulted in a 4-fold increase in tumor radiance over background and a 2 fold increase in the tumor/muscle ratio. Tumor fluorescence enhancement was inhibited with the administration of D609. The ability to image PC-PLC activity *in vivo* provides a unique and sensitive method of monitoring one of the critical phospholipase signaling pathways activated in cancer, as well as the phospholipase activities that are altered in response to cancer treatment.



INTRODUCTION

Molecular imaging techniques offer the potential ability to detect cancer at a curable stage, to monitor and adjust patient treatments, and to improve the efficiency of cancer drug development.[1] Direct monitoring of a molecular target allows detailed elucidation of key metabolic pathways and specific cellular processes that become deregulated in cancer.[2−6] Lipids play an important role in the regulation of cellular responses and communication,[7] so it is not surprising that the lipid metabolic profile has been found to be altered in a variety of cancers. The development of probes for imaging lipid metabolism has been relatively unexplored but holds great promise for resolving and monitoring specific molecular targets for anticancer therapy.

Magnetic resonance spectroscopy (MRS) has been used extensively to study the biochemistry and physiology of cancer cells and solid tumors by observing changes in the lipid metabolites of phosphatidylcholine (PtdCho). Over the past two decades, ^{1}H- and ^{31}P-MRS have consistently revealed the presence of increased levels of phosphocholine (PC) in breast,[8−14] prostate,[13,15−18] and brain[8,13,16,19−21] cancer cells and solid tumors. Elevated levels of PC, in particular, have been correlated with the degree of malignancy,[22−24] and it has been shown that PC levels decrease in response to chemotherapeutic treatment.[25] Although elevations in PC have been attributed to up-regulation of choline transport and choline kinase activity,[22,25] there is also evidence that increased PtdCho catabolism may also play a role.[14,26,27] Phosphatidylcholine-specific phospholipase C (PC-PLC) hydrolyzes PtdCho to PC and diacylglycerol and has been implicated in contributing to the irregular choline metabolism in cancer.[26,28,29] It is of growing importance to resolve the source of PC as a potential marker for the malignant phenotype[10,30] and for assessing tumor response to therapy.[31,32]

In a previous paper, we reported the synthesis of a series of self-quenched near-infrared (NIR) fluorescent probes sensitive to the actions of phospholipases.[33] This follows from our studies in which the enzymatic activation of a protease-sensitive probe resulted in the separation of a fluorophore from a dark quencher leading to increased fluorescence.[34,35] In this article, we focus on one probe, Pyro-PtdEtn-BHQ (1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphoethanolamine-BHQ-3), which is highly specific to PC-PLC, in order to directly examine the contribution of the catabolic pathway to increased levels of PC. The NIR fluorophore, pyropheophorbide *a* (Pyro; λ_{ex} = 410, 665 nm; λ_{em} = 670, 725 nm), is attached to the *sn*-2

position, and the NIR Black Hole Quencher 3 (BHQ, absorbance range: 620−730 nm) is conjugated to the headgroup. The close proximity of the quencher to the fluorophore results in fluorescence quenching. Upon enzymatic cleavage by PC-PLC, the fluorescent moiety is separated from the phospholipid, and fluorescence is restored. Results from a positive control, a fluorescent unquenched lipid analogue, Pyro-PtdEtn (1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphoethanolamine), are also reported.

It is demonstrated that Pyro-PtdEtn-BHQ exhibits a marked specificity for PC-PLC and that it can be activated in cultured DU145 human prostate tumor cells and tumor xenografts. Moreover, fluorescence can be attenuated using tricyclodecan-9-yl xanthogenate (D609), a specific inhibitor to PC-PLC, both in solution and *in vivo*. These data indicate that the catabolic pathway of PC formation via PC-PLC may be an important contributor to the alterations in choline metabolism seen in cancer progression and development.

MATERIALS AND METHODS

Synthesis of Pyro-PtdEtn-BHQ and Pyro-PtdEtn. The detailed synthesis and characterization of a series of phospholipase-sensitive fluorophores has been published elsewhere.[33] Pyropheophorbide *a* (λ_{abs} = 665 nm, λ_{em} = 725 nm) was prepared from *Spirulina Pacifica* algae (Cyanotech Corporation, Kailua-Kona, HI, USA) according to a previously published procedure.[36] *N-tert*-butoxycarbonyl-1-palmitoyl-*sn*-glycero-3-phosphoethanolamine (Lyso-PtdEtn-N-Boc, Avanti Polar Lipids, Inc., Alabaster, AL) was acylated with Pyro in the presence of *N*-(3-dimethylaminopropyl)-N′-ethyl carbodiimide hydrochloride (EDC), and 4-dimethylaminopyridine (DMAP). N-Boc deprotection with trifluoroacetic acid resulted in the permanently fluorescent phospholipid analogue, Pyro-PtdEtn, at 30% yield (50 mg). Further N-acylation of Pyro-PtdEtn with BHQ succinimidyl ester hexafluorophosphate (BHQ-3-$SU^+PF_6^-$, λ_{abs} = 620−730 nm, Biosearch Technologies, Novato, CA) in the presence of triethylamine (Et_3N) in CH_2Cl_2 gave rise to Pyro-PtdEtn-BHQ at 15% yield (20 mg).

Phospholipases. Phospholipases were obtained from Sigma (St. Louis, MO), dissolved in Tris buffer (50 mM Tris-HCl, pH 7.4) and stored in aliquots at −20 °C. Mammalian phospholipase isoforms were used whenever available: $sPLA_2$ (type IB, porcine pancreas and bovine pancreas), otherwise bacterial isoforms were employed: PC-PLC (*Bacillus cereus*), PI-PLC (*B. cereus*), SMase (*B. cereus*), and PC-PLD (*Streptomyces chromofuscus*).

Lipid Dispersions. Pyro-PtdEtn-BHQ or Pyro-PtdEtn (ε = 110,000 M^{-1} cm^{-1} at 410 nm) was combined with PtdCho (chicken egg, Avanti Polar Lipids, Inc., Alabaster, AL) in chloroform and dried under a stream of nitrogen. Lipid films were rehydrated with buffer (50 mM Tris-HCL, pH 7.4), and small unilamellar vesicles were formed by sonication until an optically clear dispersion was obtained. For TLC and MALDI-TOF experiments, a concentration of 200 μM Pyro-PtdEtn-BHQ was used at a mole fraction of 0.05 in egg PtdCho. For kinetic experiments, a concentration of 1 μM Pyro-PtdEtn-BHQ was used at mole fractions of 0.002−0.04 in egg PtdCho.

TLC Assay. Aliquots (200 μL) of the sonicated Pyro-PtdEtn-BHQ/egg-PtdCho (MF 0.05) lipid dispersion were incubated at 37 °C with 1 U of enzyme: PC-PLC, PI-PLC, SMase, PC-PLD, type IA $sPLA_2$, or type IB $sPLA_2$. After 24 h, a sample from each aliquot was separated on an UV Silica Gel TLC plate using the solvent chloroform/methanol (100:15). Fluorescent bands due to cleavage were detected using a 385 nm UV lamp. The *Rf* of each band was compared to a control Pyro-PtdEtn-BHQ/lipid dispersion that had not been exposed to enzyme.

HPLC and MALDI-TOF Mass Spectrometry. Products of the Pyro-PtdEtn-BHQ-phospholipase cleavage experiments were separated using reverse-phase HPLC. The HPLC system consisted of a Waters 600 controller with a quaternary pump equipped with a Waters 2996 diode array detector (Waters Corp, Milford, CT) and a Zorbax 300SB-C3 column (4.6 × 150 mm, Agilent Corp, Santa Clara, CA). The flow rate of the mobile phase was 1.5 mL/min. The mobile phase composition was (A) acetonitrile, (B) 0.1 M triethylamine + acetic acid, pH 7, and (C) methanol. Solvent composition began with 80% solvent A and 20% solvent B, which was increased to 90% A and 10% B over 10 min. Conditions were then changed to 90% A and 10% C for 10 min followed by 90% C and 10% A over 60 min. The identity of isolated fragments was subsequently confirmed with MALDI-TOF MS using an Applied Biosystems Voyager DE Mass Spectrometer with positive mode ionization. The matrix consisted of α-cyano-4-hydroxycinnamic acid or 2-(4-hydroxyphenylazo)benzoic acid.

Confocal Microscopy Studies. Cells (1×10^5 cells/mL) were grown on Nunc chambered culture slides for 24 h and incubated for 1 h at 37 °C with 10 μL of 5 μM Pyro PL or Pyro-PtdEtn-BHQ in saline or saline as a control. The cells were rinsed, mounted, and observed via confocal microscopy on a Zeiss LSM 510 META confocal microscope with λ_{ex} = 633 nm and λ_{em} = 665−718 nm. The intensity density was quantified from each image using ImageJ software and normalized to the area occupied by cells.

Kinetics Analysis by Fluorescence Spectroscopy. A Molecular Devices SpectraMax M5 microplate reader was used to measure the fluorescence from 100 μL samples containing 1 μM substrate dispersed in egg-PtdCho vesicles in buffer (50 mM Tris-HCl, pH 7.4). Following enzyme addition, the initial rate measured in relative fluorescence units per minute (RFU/min) was determined using SoftMax Pro Software (Molecular Devices, Sunnyvale, CA) with λ_{ex} = 410 nm and λ_{em} = 675 nm.

Cell Culture. The human prostate carcinoma cell line, DU145, was maintained in MEM Eagle culture medium supplemented with 10% (v/v) fetal calf serum, 2 mM L-glutamine, and 1% penicillin/streptomycin and buffered with 20 mM sodium bicarbonate. Cultures were grown in 150 cm^2 filter cap tissue culture flasks using standard culture conditions of 37 °C and 5% CO_2 in air.

***In Vivo* NIR Fluorescence Imaging.** DU145 cells (5×10^6) were injected subcutaneously above the left hind legs of 4−6 week old athymic nude mice (NCI, Fort Dietrich, MD). Tumors were grown for 4−6 weeks until they reached a volume of 200−400 mm^3. Mice were fed low-fluorescent pellets (Labdiet 5 V02, Animal Specialties and Provisions, LLC, PA) for 1−3 days prior to imaging. Mice were anesthetized with 100 μL of ketamine (50 mg/mL) /acepromazine (5 mg/mL). Prescan visible and fluorescent images were taken with a Xenogen IVIS system using Cy5.5 fluorescence filters (λ_{ex} = 615−667 nm, λ_{em} = 695−770 nm), and an exposure time of 1 s. Following the prescan image, the mice were injected i.v. with 80 nmol Pyro-PtdEtn or Pyro-PtdEtn-BHQ solubilized in 50 mM Tris-HCl, pH 7.4, and 0.1% Tween-80 (200 μL/mouse). In inhibition experiments, D609 (Sigma-Aldrich, St. Louis, MO) was administered intraperitoneally at a dose of 50 μg/g body weight 30 min prior to and 30, 60, and 120 min post-injection

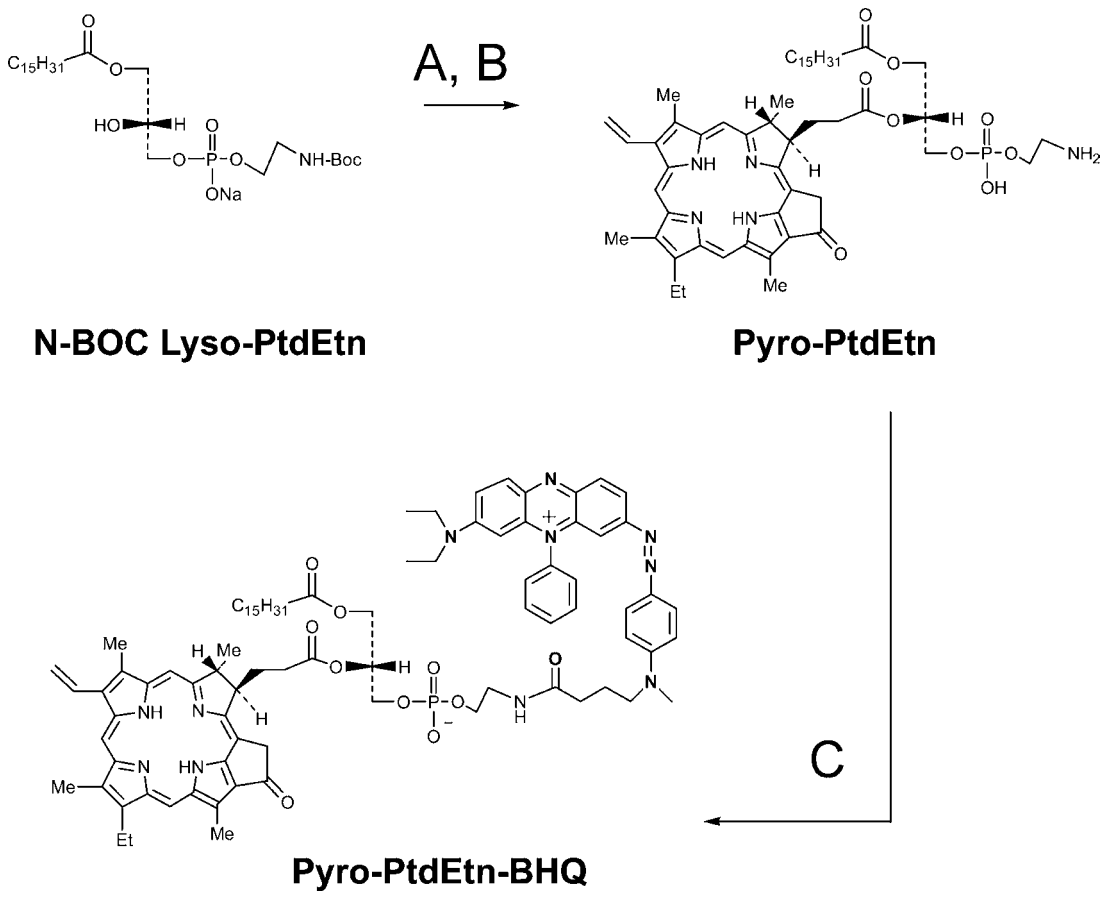

Figure 1. Synthesis of Pyro-PtdEtn and Pyro-PtdEtn-BHQ. (A) Pyro, EDC, DMAP, and CH_2Cl_2, at 25 °C, 72 h, argon (Ar); (B) TFA and CH_2Cl_2, at 0 °C, 4 h, Ar; (C) BHQ-3-$SU^+PF_6^-$, Et_3N, and CH_2Cl_2, at 25 °C, 12 h, Ar.

of Pyro-PtdEtn-BHQ.[37,38] Images were acquired every few minutes for the first 1.5 h, followed by every hour up to 6 h, and then again between 24 and 30 h. Background fluorescence was subtracted from all images. A region of interest was drawn around both the tumor and the contralateral muscle, and the average radiance was measured (photons/s/cm^2/sr). The tumor/muscle average radiance ratios were calculated at each time point.

Amplex Red Assay of PC-PLC Activity in Extracts of Tumor Xenografts. DU145 tumors were excised from euthanized mice and weighed (~90 mg). Tumors were sliced, minced, and transferred to 15 mL centrifuge tubes in 7 mL of cold PBS (without Ca^{2+} or Mg^{2+}). Samples were centrifuged at 7000 rpm for 8 min. PBS was removed, and pellets were lysed at 4 °C for 30 min with 0.5 mL of lysis buffer (50 mM Tris-HCl at pH 7.4, 1% Triton X-100, 1 Complete Mini protease inhibitor tablet, 1 mM EGTA, 2 mM EDTA, and 150 mM NaCl). The lysed suspensions were homogenized for 5 min and centrifuged at 13,500 rpm for 10 min, and the supernatant fraction was collected and stored at −80 °C. PC-PLC activity was determined by adding the thawed supernatant fraction to a reaction mixture containing 0.4 mM Amplex Red, 1 unit/mL horseradish peroxidase, 4 unit/mL alkaline phosphatase, 0.1 unit/mL choline oxidase, and 0.5 mM PtdCho in 1× Reaction Buffer (50 mM Tris-HCl, pH 7.4, 0.14 M NaCl, 10 mM dimethylglutarate, and 2 mM $CaCl_2$).[39] PC released from PtdCho by PC-PLC is converted to choline by alkaline phosphatase, which is further oxidized to form H_2O_2. In the presence of horseradish peroxidase, the H_2O_2 reacts with Amplex Red to generate the fluorophore, resorufin, which was detected using λ_{ex} = 560 nm and λ_{em} = 590 nm on the SpectraMax M5 plate reader.

Statistical Analysis. All data are presented as the mean ± SD. Statistical analysis of *in vivo* tumor/muscle average radiance was conducted using a Student's *t*-test. The test performed was two-tailed when testing Pyro-PtdEtn against Pyro-PtdEtn-BHQ (±D609) and one-tailed when testing Pyro-PtdEtn-BHQ against Pyro-PtdEtn-BHQ + D609. A p value ≤0.05 was considered to be significant.

RESULTS

Synthesis and Spectral Characteristics of Pyro-PtdEtn and Pyro-PtdEtn-BHQ. The synthesis of Pyro-PtdEtn and Pyro-PtdEtn-BHQ is presented in Figure 1. The close proximity of BHQ to Pyro, as well as the strong BHQ absorbance over the Pyro emission wavelength region, results in efficient contact and FRET quenching of this construct.

Specificity and Sensitivity. To determine probe specificity, Pyro-PtdEtn-BHQ was incubated for 24 h with a range of phospholipases: PC-PLC, phosphatidylinositol-specific PLC (PI-PLC), sphingomyelinase (SMase), phosphatidylcholine-specific phospholipase D (PC-PLD), type IA secretory phospholipase A_2 ($sPLA_2$), type IB $sPLA_2$ (porcine), and type IB $sPLA_2$ (bovine). TLC analysis showed that Pyro-PtdEtn-BHQ could be cleaved by PC-PLC, and to a lesser extent, SMase and PC-PLD (Figure 2) with the fluorescent Pyro moiety appearing under UV light as a red spot with a retention factor (Rf) of 0.9 (Columns 2 and 4). The sample

dx.doi.org/10.1021/bc200242v | *Bioconjugate Chem.* 2011, 22, 2434–2443

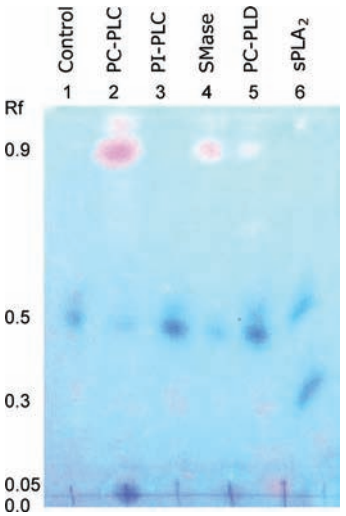

Figure 2. Specificity determined by TLC. Pyro-PtdEtn-BHQ/egg-PtdCho lipid dispersions were incubated with enzymes for 24 h and the products separated on a TLC plate using chloroform/methanol (100:15): 1, Control (no enzyme); 2, PC-PLC; 3, PI-PLC; 4, SMase; 5, PC-PLD; and 6, sPLA2 (IB, porcine). BHQ moieties were visible as blue spots, while fluorescent Pyro moieties were observed as red spots under UV excitation (385 nm). No enzyme activity was observed by PI-PLC, whereas sPLA2 (porcine type IB) cleavage showed 2 nonfluorescent spots. The observed cleaved products confirmed by HPLC followed by MALDI-TOF are as follows: *Rf* = 0.9, 1- acyl-2-pyropheophorbide glycerol (lanes 2, 4, and 5); *Rf* = 0.5, Pyro-PtdEtn-BHQ; *Rf* = 0.3, Lyso-Pyro- PtdEtn-BHQ (lane 6); *Rf* = 0.05 (red), 1-acyl-2-pyropheophorbide-3-phosphate (lane 5); *Rf* = 0.0 (blue), phospho-BHQ-3 (lanes 2, 4, and 5).

exposed to PC-PLD (Column 5) resulted in two fluorescent products, at *Rf* 0.9 and 0.05, while the uncleaved Pyro-PtdEtn-BHQ and the cleaved nonfluorescent product, phospho-BHQ-3, were visible as dark spots at *Rf* 0.5 and 0.0, respectively. No activity was observed with PI-PLC (Column 3). Type IB (porcine) $sPLA_2$ released one nonfluorescent product at *Rf* 0.3 (Column 6), whereas no cleavage was seen using either type IA $sPLA_2$ or type IB $sPLA_2$ (bovine).

To confirm these assignments, the TLC samples were analyzed by HPLC with UV−visible detection and MALDI-TOF MS (Figure 3). Figure 3A shows the HPLC chromatogram of Pyro-PtdEtn-BHQ, showing two closely separated peaks at retention times (RT) of 56.4 and 57.9 min. MALDI-TOF MS confirmed that the high RT peak corresponded to free Pyro-PtdEtn-BHQ (Table 1, calculated molecular weight (MW), 1497.8 Da; found, 1497.7 *m*/*z*), whereas the low RT peak (Figure 3D; found, 1498.2 *m*/*z*) also displayed a series of low MW ions from 500−800 *m*/*z* and may correspond to lipids from vesicle-encapsulated Pyro-PtdEtn-BHQ. Upon treatment with PC-PLC, we observed two cleavage products (Figure 3B). The corresponding UV−visible spectra (Figure 3C) showed that the first product (RT = 21.0 min) exhibited the absorbance spectrum of Pyro, whereas the second (RT = 53.4 min) exhibited the spectrum of BHQ. MALDI-TOF MS further validated that Pyro-PtdEtn-BHQ was cleaved by PC-PLC into two products that had MWs consistent with 1-palmitoyl-2-pyropheophorbide glycerol (calculated, 846.5 Da; found, 846.2 *m*/*z*) and phosphoethanolamine-BHQ-3 (calculated, 669.3 Da; found, 669.7 *m*/*z*), as shown in Figure 3E and F, respectively, and in Table 1. Incubation with SMase resulted in the same cleavage products (Table 1). MALDI-TOF MS also confirmed the existence of the two fluorescent products detected by HPLC in the sample treated with PC-PLD, the expected 1-palmitoyl-2-pyropheophorbide-*sn*-glycero-3-phosphate and 1-palmitoyl-2-pyropheophorbide glycerol, the same product released

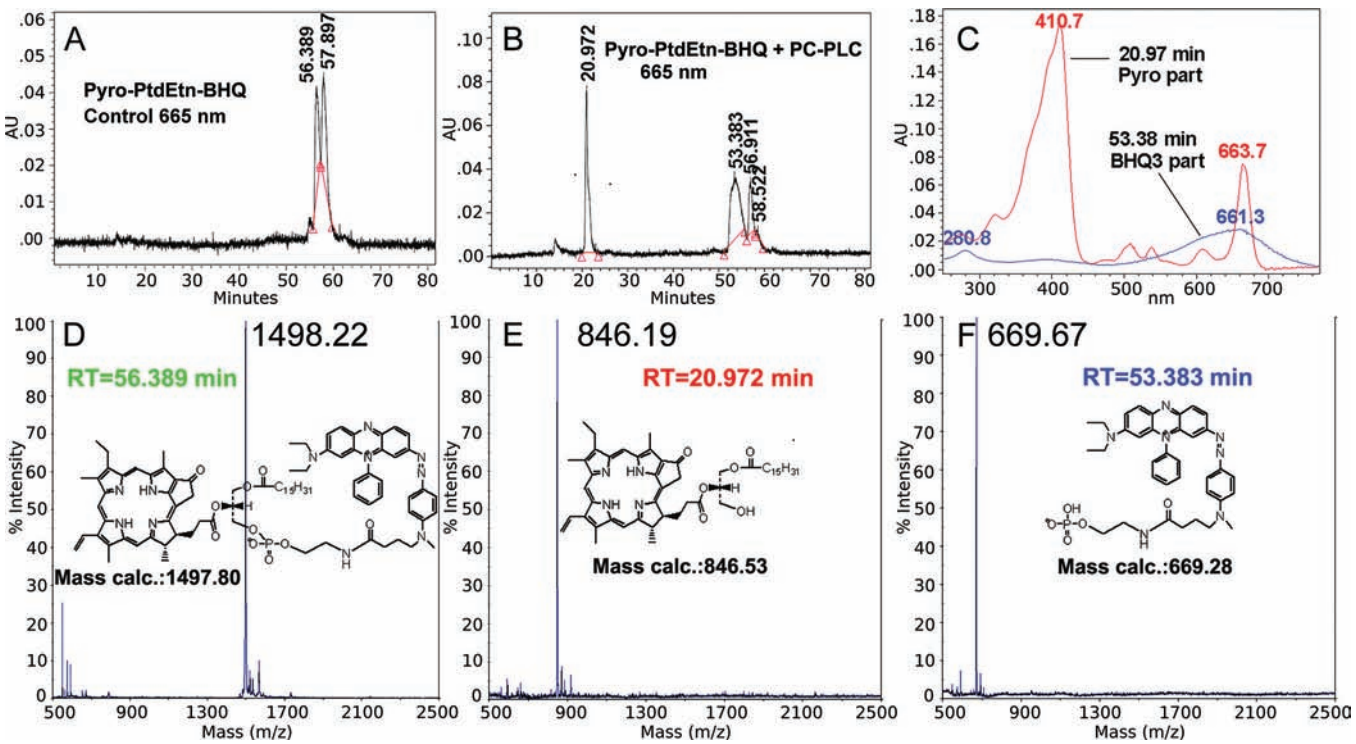

Figure 3. Validation of PC-PLC activation of Pyro-PtdEtn-BHQ. HPLC chromatogram of (A) Pyro-PtdEtn-BHQ and (B) cleavage products of Pyro-PtdEtn-BHQ from the actions of PC-PLC; (C) corresponding UV spectra of cleaved products; MALDI-TOF mass spectra and chemical structures of (D) Pyro-PtdEtn-BHQ and PC-PLC derived products: (E) 1-palmitoyl-2-pyropheophorbide glycerol and (F) phospho-BHQ-3.

			257.3

by PC-PLC (Table 1), suggesting a cross-reactivity or a PC-PLC impurity. We found the nonfluorescent product released by $sPLA_2$ (type IB, porcine) to be the result of phospholipase A_1 activity having a molecular weight consistent with 2-pyropheophorbide-*sn*-glycero-3-BHQ-3 (Table 1), presumably also due to the lack of enzyme specificity or enzyme impurity.

Although PC-PLC, SMase, and PLD all demonstrated the ability to hydrolyze Pyro-PtdEtn-BHQ after incubation for 24 h, observation of these reactions by fluorescence spectroscopy revealed that the kinetics of these reactions were very different (Figure 4A).

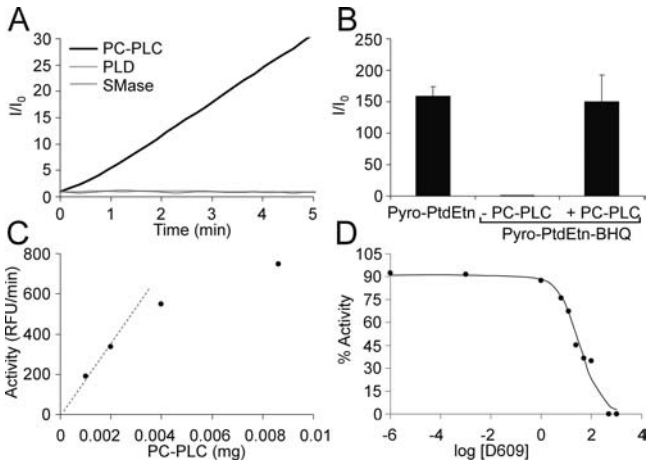

Figure 4. Characterization of Pyro-PtdEtn-BHQ kinetics. (A) Time-dependent increase in fluorescence of 1 μM Pyro-PtdEtn-BHQ incubated with 10 U each of PC-PLC, PLD, or SMase; (B) fold increase in fluorescence of 1 μM Pyro-PtdEtn-BHQ before and after complete activation by PC-PLC, as compared to that of Pyro-PtdEtn at equal concentrations (error bars represent s.d., n = 3); (C) dependence of fluorescence release from Pyro-PtdEtn-BHQ on PC-PLC concentration; (D) inhibition of PC-PLC activity toward 1 μM Pyro-PtdEtn-BHQ by D609 (IC_{50} = 34 ± 8 μM).

The addition of PC-PLC (10 U) to 1 μM Pyro-PtdEtn-BHQ dispersed in egg-PtdCho vesicles (MF 0.02) led to a 30-fold increase in fluorescence within 5 min. In contrast, the fluorescence released by PC-PLD and SMase was negligible even after 1 h, indicating a remarkable sensitivity of Pyro-PtdEtn-BHQ for PC-PLC. As shown in Figure 4B, the complete hydrolysis of Pyro-PtdEtn-BHQ by PC-PLC *in vitro* resulted in a ~150-fold fluorescence increase, equaling the fluorescence of Pyro-PtdEtn at equal concentrations.

We determined the dependence of activity on enzyme concentration by adding increasing amounts of PC-PLC to 1 μM Pyro-PtdEtn-BHQ in egg-PtdCho dispersions (MF 0.003). The activity of PC-PLC with Pyro-PtdEtn-BHQ (Figure 4C) increased with enzyme and was linear up to 0.002 mg (0.5 U) of enzyme.

The rate of Pyro-PtdEtn-BHQ hydrolysis could be inhibited by D609, a specific PC-PLC inhibitor.[40] Activity was measured as a function of D609 concentration after the addition of 0.5 U PC-PLC (Figure 4D). Complete inhibition was achieved with 500 μM D609 and an IC_{50} of 34 ± 8 μM was determined.

Probe Uptake in Cancer Cells. To confirm the cellular uptake of Pyro-PtdEtn-BHQ, confocal fluorescence microscopy studies were performed on DU145 human prostate cancer cells incubated with Pyro-PtdEtn, Pyro-PtdEtn-BHQ, or PBS as a control (Figure 5). Pyro-PtdEtn-treated DU145 cells exhibited

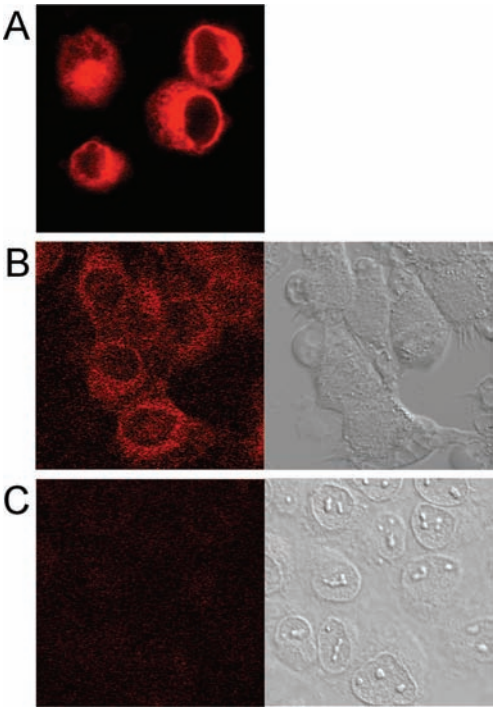

Figure 5. Confocal microscopy studies. Fluorescence (Left) and bright field (Right) micrographs of DU145 cells incubated for 1 h with (A) 5 μM Pyro-PtdEtn, (B) 5 μM Pyro-PtdEtn-BHQ, or (C) PBS as a control.

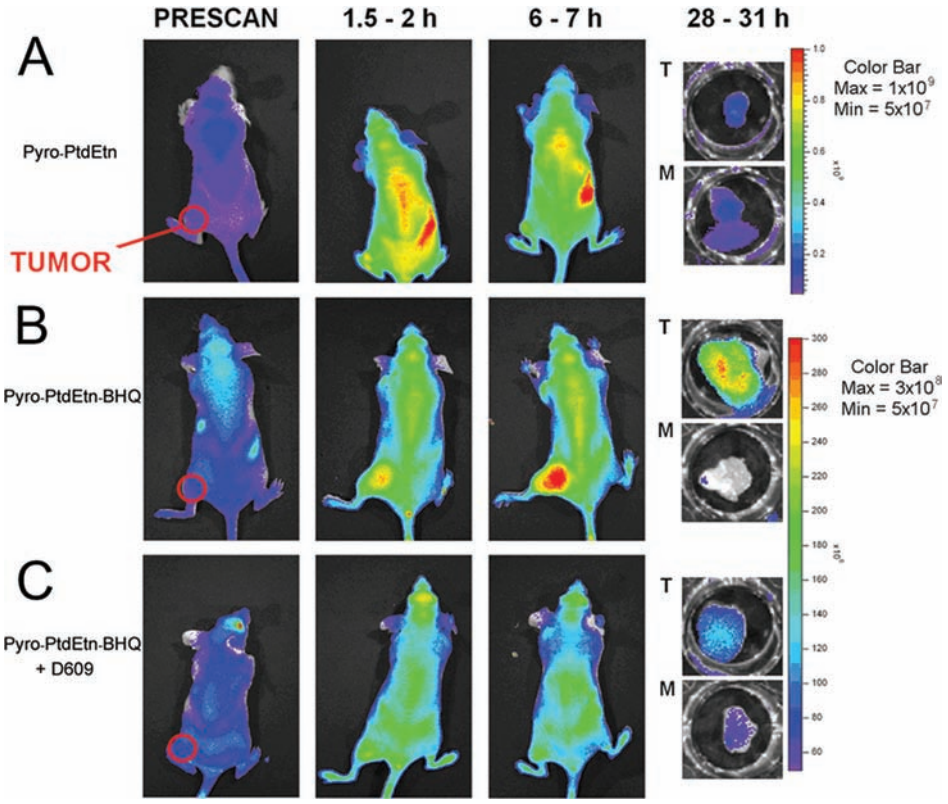

Figure 6. *In vivo* imaging of Pyro-PtdEtn, Pyro-PtdEtn-BHQ, and Pyro-PtdEtn-BHQ + D609 treatment. Nude mice bearing DU145 tumors on the left hind flank received 80 nmol i.v. of (A) Pyro-PtdEtn or (B and C) Pyro-PtdEtn-BHQ dispersed in 0.1 μM Tween-80. Mice in (C) received additional D609 injections (50 μg/g body weight, i.p.) at −30, 30, 60, and 120 min postinjection of Pyro-PtdEtn-BHQ. Images are shown at prescan, 1.5−2 h, and 6−7 h. The tumor (T) and muscle (M) tissues from each mouse were excised at 28−31 h.

a strong predominantly cytoplasmic fluorescent signal (Figure 5A). DU145 cells incubated with Pyro-PtdEtn-BHQ exhibited perinuclear and punctate cytoplasmic fluorescence that was approximately 8-fold less intense, due to differential cell uptake, incomplete intracellular activation, or quenching by BHQ (Figure 5B). Fluorescence in cells incubated with Pyro-PtdEtn-BHQ was approximately 10-fold more intense than DU145 cells incubated only with PBS (Figure 5C).

***In Vivo* Imaging of PC-PLC Activity.** We evaluated the efficacy of Pyro-PtdEtn-BHQ as a potential fluorescent imaging agent for detecting PC-PLC activity *in vivo*. Nude mice bearing DU145 human prostate tumor xenografts were injected with either Pyro-PtdEtn-BHQ or Pyro-PtdEtn as a positive control. Fluorescence images were acquired over the first 6 h and continued the next day between 24 and 30 h. Pyro-PtdEtn exhibited fast circulation throughout the body, accumulating primarily in the stomach, liver, and intestines (Figure 6A). By 6 h, the substrate was clearing through the digestive tract. By 28 h, very little radiance remained in the tumor or the contralateral muscle, as seen in the excised tissues in Figure 6 (T, tumor; M, muscle). Injection of Pyro-PtdEtn-BHQ, however, led to a gradual increase in tumor radiance within 1.5 h (Figure 6B) that was greatly increased at 6 h. At 30 h, we could still observe a high level of radiance in the excised tissue relative to the contralateral muscle tissue. Note that the Pyro-PtdEtn radiance detected *in vivo* is ∼3-fold higher than that of the cleaved Pyro-PtdEtn-BHQ radiance, which suggests that complete hydrolysis of Pyro-PtdEtn-BHQ is not being achieved.

In order to validate that the increase in tumor radiance after Pyro-PtdEtn-BHQ injection was due to PC-PLC activation, mice were injected with the PC-PLC inhibitor D609. As expected, D609 treatment inhibited *in vivo* activation of Pyro-PtdEtn-BHQ, resulting in reduced tumor radiance (Figure 6C). At 31 h, the excised tumor tissue exhibited half as much radiance as that found without D609 treatment.

Representative time dependence of the tumor and contralateral muscle radiance measurements for Pyro-PtdEtn, Pyro-PtdEtn-BHQ, and Pyro-PtdEtn-BHQ + D609 are shown in Figure 7. Administration of Pyro-PtdEtn led to a sharp increase in tumor and muscle radiance, reaching a maximum tumor radiance of ∼10-fold over baseline at 30 min, followed by an immediate drop as the probe begins to clear, and return to prescan level by 24 h post-injection (Figure 7A). In contrast, Pyro-PtdEtn-BHQ tumor radiance gradually increased ∼4-fold over baseline during the first 4 h and was maintained continually up to 24 h before beginning to clear from the tumor (Figure 7B). From 2−24 h, the tumor radiance increased to about 2.5-fold greater than that in the contralateral muscle and was significantly greater at 24 h ($p < 0.05$). Pre- and post-treatment with D609 caused an overall attenuation of tumor radiance as soon as 2 h after injection and continued to suppress probe activation until clearance at 28 h (Figure 7C). The average of the tumor/muscle radiance ratios for each condition are presented in Figure 7D. Here a 2-fold increase in tumor/muscle ratio was observed by 24 h in mice treated with Pyro-PtdEtn-BHQ. D609 treatment significantly inhibited the activation of Pyro-PtdEtn-BHQ at the 24 h time point ($p < 0.05$), decreasing the tumor/muscle ratio back to baseline.

At the end of the experiment (28−31 h post-injection), the organs were excised and imaged on the IVIS-100 in 24 well

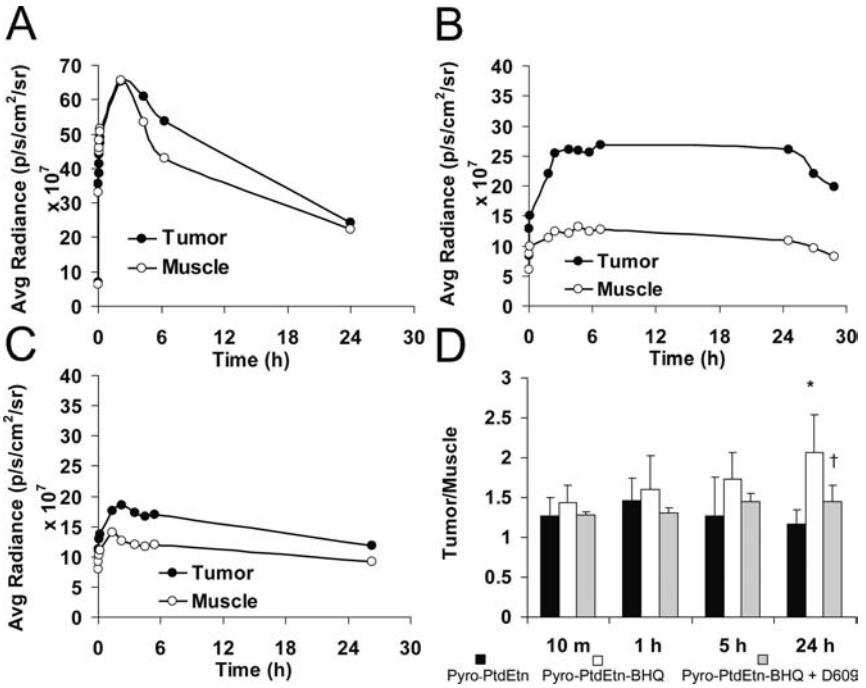

Figure 7. Representative time courses of measured tumor and muscle average radiances. The average radiance from the tumor and muscle tissue and was quantified in mice injected with (A) Pyro-PtdEtn, (B) Pyro-PtdEtn-BHQ, and (C) Pyro-PtdEtn-BHQ + D609. (D) Tumor/muscle average radiance. The average tumor radiance was normalized to muscle for Pyro-PtdEtn (n = 5), Pyro- PtdEtn-BHQ (n = 5), and Pyro-PtdEtn-BHQ + D609 treatment (n = 3). Error bars represent SD. * Significantly (p = 0.011) different from Pyro-PtdEtn. † Significantly (p = 0.024) different from Pyro- PtdEtn-BHQ without D609 treatment.

plates (Table 2). These data show major residual fluorescence in the stomach, intestine, and liver and indicate that these probes are excreted via the bile, liver, and stool as would be expected for a lipid soluble probe.

Validation of PC-PLC Activity in Extracts of DU145 Tumor Xenografts. To validate the presence of PC-PLC activity in DU145 tumor xenografts, the Amplex Red PC-PLC Assay Kit (Invitrogen, Eugene, OR) was used in excised tumor extracts. PC-PLC activity was shown to increase linearly as a function of total supernatant protein (Figure 8A) as detected by increases in resorufin fluorescence (Figure 8A). This activity was shown to decrease as a function of D609 concentration (Figure 8B).

■ DISCUSSION

In this article, we report a direct, sensitive, and feasible method for detecting PC-PLC activity employing a self-quenched phospholipid analogue that restores NIR fluorescence upon enzymatic hydrolysis. A high specificity was found for PC-PLC in solution studies, and enzyme activity was detected in cultured DU145 human prostate cells and *in vivo* using a DU145 tumor xenograft mouse model.

Although activatable fluorescent probes to detect phospholipase activity *in vitro* have been previously reported,[41−47] Pyro-PtdEtn-BHQ is unique in that it contains the NIR fluorochrome, pyropheophorbide *a*, which allows for increased photon penetration through biological tissue in a spectral region where tissue autofluorescence is markedly reduced.[48] This modification means that *in vivo* NIR optical detection of phospholipase activity has been made possible. Pyropheophorbide was chosen as the fluorophore for these studies because when conjugated, it is both neutral and hydrophobic, two properties necessary for the lipid-based probe to be incorporated into membranes. However, pyropheophorbide *a* is also a known photosensitizer, with a high singlet oxygen quantum yield, opening the possibility that this and other related probes could be used for photodynamic therapy to treat tumors *in vivo*.

This article shows that Pyro-PtdEtn-BHQ is highly specific to PC-PLC, when compared to several other phospholipase isoforms. As a phospholipid analogue, Pyro-PtdEtn-BHQ was also shown to be a substrate for PC-PLD and SMase, although with much less activity. Thus, it is possible that increases in activity could arise from activation by other enzymes, at a much slower rate. The inhibition studies with D609 would indicate that that is probably not the case. However, it is known that enzyme specificity and affinity for phospholipase-sensitive probes can be adjusted by altering the hydrophobicity and the length of the intervening fatty acyl chain at the *sn*-2 position.[33,49−51] We are currently in the process of synthesizing and testing a range of phospholipase probes of varying enzyme specificities and NIR fluorochromes, which will allow for multispectral detection of several phospholipases simultaneously.[33] This proposed molecular imaging strategy will lead to the development of probes specific to other important phospholipases and allow us to test these hypotheses in detail.

In this study, some bacterial isoforms of phospholipases were used for *in vitro* testing. This is due to the commercial unavailability of mammalian isoforms of these enzymes. A controversy also exists in the literature as to the origin of PC-PLC activity in mammals, as a mammalian isoform of this protein has never been cloned. However, isoforms have been isolated from mammalian sources.[52,53] There is also substantial evidence that the mammalian PC-PLC has functional similarity to the bacterial isoform. PC-PLC activity, as measured by D609-sensitive PC release from PtdCho, has been demonstrated in

Table 2. Fluorescence Intensity Observed in Excised Organs[a]

probe	organ/ adrenal glands	kidney	liver	spleen	heart	intestine	lung	muscle	stomach	tumor	pancreas

[a]Data are expressed as photon flux (photons/s). The numbers of animals for each condition are in parentheses. Organs were removed from mice 28−31 h after injection of the probe and imaged in 24-well plates using the IVIS-100 system. The data show that residual fluorescence remains predominantly in the liver, intestine, and stomach, indicating excretion via the liver and stool.

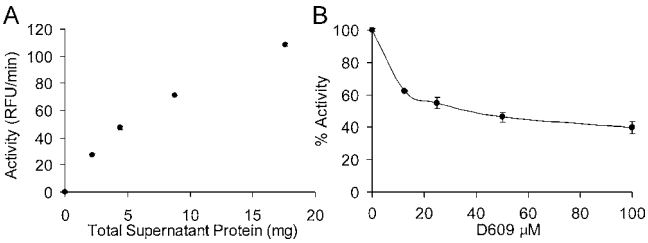

Figure 8. PC-PLC activity measured by Amplex Red. (A) Activity measured in relative fluorescence units per minute (RFU/min) as a function of protein (mg) from extracts of DU145 tumor xenografts. (B) Inhibition of PC-PLC activity in supernatants by D609.

cytoplasmic extracts of NIH-3T3 cells.[26] Polyclonal antibodies against *B. cereus* PC-PLC have been used to detect the translocation of a cross-reactive mammalian PC-PLC from the cytosol in control cells to the plasma membrane in oncogene-transformed cells.[26] An increased plasma membrane PC-PLC expression has also been shown to accompany tumor progression in ovarian cancer cell lines.[54] This PC-PLC activity could be measured with the Amplex Red assay and was sensitive to the action of D609. Our imaging results are consistent with these studies in that Pyro-PtdEtn-BHQ detected the presence of a D609-sensitive PC-PLC activity in DU145 tumors, which could be confirmed in extracts with the Amplex Red assay. We hope that the development of this probe will allow further investigation into the origins of PC-PLC activity and aid in the resolution of this controversy.

One of the added benefits of using enzyme-activated fluorescent imaging probes is the advantage of inherent signal amplification.[55,56] Our solution studies demonstrate an increase in fluorescence up to 150-fold greater than background. *In vivo*, although affected by the absorbance and scattering effects of biological tissue, an ∼4-fold increase in radiance was observed and a 2-fold increase in tumor to muscle fluorescence ratio. This signal increase over the background compares well with other recently reported enzyme-activated NIR probes used for imaging tumors *in vivo*, such as a cathepsin-sensitive probe[56] and a caspase 1 selective probe,[57] which display 3−4-fold and 1.7-fold tumor increases, respectively. These results establish Pyro-PtdEtn-BHQ as an excellent candidate for molecular imaging.

The *in vivo* results described in this work indicate that PC-PLC may be an important molecular marker for cancer. The additional coregistration of images obtained using phospholipase-activated NIR fluorescent probes with choline metabolite levels obtained from *in vivo* MRS could critically impact the field of cancer detection by offering a sensitive and specific method of examining the lipid catabolic pathways linked to the malignant phenotype.

ABSTRACT: The therapeutic efficacies of radiolabeled biotin, pretargeted by monoclonal antibody (mAb)−streptavidin fusion protein CC49 scFvSA, were compared to those of radiolabeled mAb CC49, using the three radiolanthanides in an animal model of human colon cancer. The purpose of the present study was to compare antibody pretargeting to conventional radioimmunotherapy using ^{149}Pm, ^{166}Ho, or ^{177}Lu. Nude mice bearing LS174T colon tumors were injected sequentially with CC49 scFvSA, the blood clearing agent biotin-GalNAc$_{16}$, and ^{149}Pm-, ^{166}Ho-, or ^{177}Lu-DOTA-biotin. Tumor-bearing mice were alternatively administered ^{149}Pm-, ^{166}Ho-, or ^{177}Lu-MeO-DOTA-CC49. Therapy with pretargeted ^{149}Pm-,^{166}Ho-, and ^{177}Lu-DOTA-biotin increased the median time of progression to a 1 g tumor to 50, 41, and 50 days post-treatment, respectively. Therapy with ^{149}Pm-,^{166}Ho-, and ^{177}Lu-MeO-DOTA-CC49 increased the median time to progression to 53, 24, and 67 days post-treatment, respectively. In contrast, saline controls showed a median time to progression of 13 days postinjection. Treatment with pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-biotin or ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-CC49 increased tumor doubling time to 18−36 days, compared to 3 days for saline controls. Among treated mice, 23% survived >84 days post-therapy, and 11% survived 6 months, but controls survived <29 days. Long-term survivors showed tumor growth inhibition or partial regression, extensive necrosis in residual masses, and no evidence of nontarget tissue toxicity at necropsy. Both pretargeted and conventional RIT demonstrated considerable efficacy in an extremely aggressive animal model of cancer. Our results identified ^{177}Lu as an optimal radiolanthanide for future evaluation of these agents in toxicity and multiple-dose therapy studies.

INTRODUCTION

Radiolabeled monoclonal antibodies have been used extensively for radioimmunotherapy (RIT), most notably treatment of non-Hodgkin's lymphoma.[1] However, RIT is generally unsuccessful in solid tumor therapy due to insufficient tumor uptake without bone marrow toxicity. In addition, high tumor-to-background ratios generally cause radiolabeled mAbs to exhibit relatively poor imaging contrast.

The mAb CC49 is a pancarcinoma antibody[2] that targets the tumor-associated glycoprotein-72 (TAG-72).[3] Immunohistochemical studies demonstrated that its first-generation mAb, B72.3, binds to the majority of human epithelial malignancies,[4−9] including 82% of colon carcinomas,[10] while being essentially nonreactive with most normal human tissues.[11] The mAb CC49 has the same range of immunoreactivity as B72.3.[2,11] However, CC49 has a 6.4-fold higher binding affinity for TAG-72 than B72.3,[2] enabling it to react with a greater number of malignant cell types.[11]

Compared to B72.3, ^{131}I-labeled CC49 showed greater tumor xenograft targeting[12] and improved therapeutic efficacy[13] in nude mouse models. Clinical RIT trials of ^{131}I-CC49 demonstrated high tumor uptake, but did not produce any substantial responses.[14−16] Therefore, a single-chain (scFv) construct of CC49 was developed and shown to have promise for tumor therapy in tumor-bearing mouse models.[17] Additional improvements in RIT will likely require novel approaches, such as the use of different radionuclides, new antibody constructs, and novel delivery platforms.

First, the development of new therapeutic radionuclides, such as radiolanthanides, should be explored. The decay characteristics of three radiolanthanides for tumor therapy are compared to traditionally used ^{131}I and ^{90}Y in Table 1. All of these radiolanthanides have γ emissions suitable for tracking RIT

agents in living systems and estimating absorbed radiation doses to normal and malignant tissues. The radiolanthanides ^{149}Pm, ^{166}Ho, and ^{177}Lu have a range of half-lives and β^- energies for therapy. An advantage to using these radiolanthanides is that their chemistries are quite similar. DOTA, a macrocyclic chelating agent, complexes many radiometals, including lanthanides, with extremely high thermodynamic, kinetic, and *in vivo* stability.[18] DOTA can be used for stable attachment of ^{149}Pm, ^{166}Ho, or ^{177}Lu to RIT constructs.

Antibody pretargeting is a RIT approach in which an antibody conjugate or fusion protein is attached to an artificial "receptor". Such an agent is administered first and allowed to accumulate in tumors. Then, radionuclide therapy is given in the form of a small molecule that binds rapidly with high affinity to the mAb-receptor construct prelocalized to tumor cells. This process can cause immediate accumulation of therapeutic radiation in tumors, allowing for considerable improvements in tumor-to-background ratios, tumor absorbed dose, therapeutic efficacy, and normal organ toxicity.

Strategies for pretargeting include mAb/hapten,[19−25] biotin/avidin or streptavidin,[26−39] and oligonucleotide/antisense oligonucleotide analogue[40−43] approaches. The high-affinity binding of biotin to streptavidin ($\sim 10^{13}$ M^{-1}) makes this system especially attractive for pretargeted RIT. Both mAb−biotin and mAb−streptavidin conjugates have been investigated for pretargeting of radiolabeled streptavidin and biotin, respectively. However, radiolabeled streptavidin has been shown to result in high kidney uptake and high liver uptake resulting from cross-linking of circulating biotinylated mAb, compromising tumor targeting.[36] Clearance of biotinylated mAb with cold streptavidin or avidin have only slightly increased tumor-to-blood ratios.[44,45] Furthermore, radiolabeled streptavidin diffuses slowly into tumors over a 24 h period.[38] Thus, radiolabeled streptavidin can show considerable retardation in its tumor penetration. Pharmacokinetic modeling studies[46] indicated that a protocol involving radiolabeled biotin and mAb−streptavidin conjugates produces the highest tumor-to-blood ratio and residence time of radioactivity in tumors. Small, hydrophilic, and rapidly diffusible pretargeting agents undergoing rapid renal elimination, with minimal uptake in normal tissues, are ideal.[47]

A chemical streptavidin conjugate[48] of CC49 was labeled *ex vivo* with ^{111}In-DTPA-biocytin. This conjugate showed very similar tumor uptake and biodistribution as ^{111}In-DTPA-CC49. These studies suggested that streptavidin-CC49 constructs have potential for pretargeting applications.

As opposed to a whole antibody chemical conjugate, the use of a fusion protein based on the murine CC49 scFv construct and streptavidin (CC49 scFvSA)[49,50] was evaluated. CC49 scFvSA forms a 176 kDa tetramer with high immunoreactivity and high biotin binding efficiency and stability.[49,51] Evidence of *in vivo* stability of the fusion protein was suggested by specific tumor uptake, as well as intended uptake in the liver following administration of a synthetic clearing agent.[49] The biodistribution of CC49 scFvSA-pretargeted ^{111}In-DOTA-biotin in nude mice bearing LS174T human colon cancer xenografts demonstrated very similar tumor uptake as a chemical conjugate, but with an increase in tumor-to-blood ratio.[52]

CC49 scFvSA has also been used to pretarget ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin to LS174T colorectal tumors in nude mice.[35] Maximum tumor uptakes of ^{149}Pm (22.9% ID/g), ^{166}Ho (30.2% ID/g), and ^{177}Lu (35.4% ID/g) were achieved at 1 to 4 h postinjection. Extremely rapid blood clearance was accompanied by urinary excretion of 59−66% ID within 1 h. In LS174T-bearing nude mice, the biodistributions of CC49 scFvSA-pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin were very similar. Most normal tissue uptakes were nearly identical for all three radiometals at all time points. Thus, this pretargeting system provided a highly uniform delivery platform for the evaluation of new therapeutic lanthanide radionuclides.

However, the three radiolanthanides showed some significant differences in maximum LS174T xenograft uptake and washout of radioactivity from the tumor with time. Areas under the time−activity curves showed that ^{177}Lu had the highest tumor-to-blood ratio, an indication that it might provide the best "therapeutic index" for pretargeted RIT. Yet, preliminary dosimetry estimates suggested that washout reduced the mouse tumor absorbed dose from ^{177}Lu by 4- to 5-fold, compared to ^{149}Pm and ^{166}Ho. Therefore, differences in tumor uptake and retention, physical half-lives, and β^- particle path lengths may play important roles in determining the effectiveness of pretargeted RIT with these radiolanthanides. In the present studies, the therapeutic efficacies of radiolabeled biotin, pretargeted by CC49 scFvSA, were compared to those of intact radiolabeled mAb CC49, using the three radiolanthanides, ^{149}Pm, ^{166}Ho, and ^{177}Lu, in nude mice bearing human colon cancer xenografts.

EXPERIMENTAL PROCEDURES

General. $^{149}PmCl_3$ (50 mCi in 25−50 μL of 0.05 M HCl), $^{166}HoCl_3$ (80 mCi in 50−80 μL of 0.05 M HCl), and $^{177}LuCl_3$ (25 mCi in 10−20 μL of 0.05 M HCl) were obtained from the University of Missouri (MU) Research Reactor (MURR; Columbia, MO). The mAb−streptavidin fusion protein CC49 scFvSA,[51] clearing agent biotin−$GalNAc_{16}$,[51] and DOTA−biotin were obtained from NeoRx Corporation (Seattle, WA). Methoxy-DOTA (MeO−DOTA)[53] was provided by the DOW Chemical Company (Freeport, TX). CC49 was produced from the hybridoma cell line provided by Dr. Jeffrey Schlom at the National Cancer Institute (Bethesda, MD). Reversed-phase thin-layer chromatography (TLC) was performed on Whatman (Clifton, NJ) $MKC_{18}F$ plates. The TLC plates were developed in 10% (w/v) ammonium acetate/methanol (1:1). Radio-TLC detection was accomplished using a Bioscan (Washington, DC) AR-2000 imaging scanner. The purity of the conventional radioimmunoconjugates was confirmed by gel filtration HPLC (GF-HPLC), using a Waters Delta 600 (Waters, Milford, MA) chromatograph equipped with a manual Rheodyne injector, a Waters 2487 dual-wavelength UV detector, a Packard 500TR Flow Scintillation Analyzer (Packard, Downers Grove, IL) with a LQ flow cell for ^{149}Pm, ^{166}Ho, and ^{177}Lu, a Waters busSAT/

IN analog−digital interface, and the Waters *Millennium 32* software package. A Superose 12 HR 10/30 (Amersham Pharmacia, Torrance, CA) column (300 × 10 mm), an isocratic mobile phase of 100 mM NaH_2PO_4/0.05% NaN_3, pH 6.8, and a flow rate of 0.50 mL/min were used. All solutions were prepared using ultrapure water (18 MΩ-cm resistivity). All other reagents were purchased Fischer Scientific (Pittsburgh, PA). Outbred female nu/nu mice (4−6 weeks of age) were obtained from Harlan Sprague−Dawley (Indianapolis, IN). Tumors were measured using Vernier calipers (Scienceware, D-2922/B/KWB).

Cell Line. The LS174T cell line was obtained from the American Type Culture Collection (Manassas, VA). Immediately prior to implantation into nude mice, the cells were tested for mycoplasma and screened for a panel of 13 murine pathogens by PCR. All test results were negative, and all sentinel mice in the facility housing the nude mice tested negative for these pathogens during the course of the studies.

Radiolabeling of Pretargeting RIT Conjugates. The labeling procedure used was previously described by Lewis et al.[35] Briefly, to 32.0 mCi of ^{149}Pm, 10.0 mCi of ^{166}Ho, or 25.0 mCi of ^{177}Lu in 80 μL of 0.20 M ammonium acetate, pH 5.0, containing approximately 1 mg/mL of gentisic acid, was added 32 μg of DOTA−biotin, 10 μg of DOTA−biotin, and 25 μg of DOTA−biotin, respectively. The reaction mixtures were incubated at 80 °C for 1 h, after which 1 mM DTPA, pH 6.0, was added. The reaction mixtures were incubated at room temperature for 10 min, after which radiochemical purity was assessed by reversed-phase radio-TLC. Typical labeling efficiencies were 99−100%.

Radiolabeling of Conventional RIT Conjugates. A modified method previously described by Mohsin et al. was used to label MeO-DOTA-CC49.[53] MeO−DOTA has been shown to bind ^{149}Pm, ^{166}Ho, and ^{177}Lu with high kinetic stability, as demonstrated by an *in vitro* hydroxyapatite assay.[53] An initial specific activity of 5 μCi/μg was used for ^{149}Pm-, ^{166}Ho-, and ^{177}Lu labeling reactions. In the labeling reactions, 320−365 μL of 1.0 M ammonium acetate, pH 4.5, was added to 6.5 mCi of $^{149}PmCl_3$ in 24.0 μL of 0.05 M HCl, 3.0 mCi of $^{166}HoCl_3$ in 2.0 μL of 0.05 M HCl, or 7.0 mCi of $^{177}LuCl_3$ in 3.0 μL of 0.05 M HCl, followed by 1.04−1.42 mg of MeO-DOTA-CC49 in 320−370 μL of 0.25 M ammonium acetate, pH 7.0. The reaction mixture was incubated at 43 °C for 1 h, and DTPA, pH 6.0, was added to a final concentration of 1 mM. The reaction mixture was allowed to stand for 15 min at room temperature and then purified using a Bio-Spin 6 column (Bio-Rad, Hercules, CA) equilibrated with 10 mM Na_2HPO_4/150 mM NaCl. Labeling efficiencies ranged from 65% to 80%. The specific activity was adjusted to 1 μCi/μg after purification, by dilution with unmodified CC49. Radiochemical purity was determined after purification by GF-HPLC.

Therapy Studies. All therapy studies were conducted in compliance with the guidelines established by the Animal Care and Use Committee of the University of Missouri-Columbia Animal Care Quality Assurance Office. Female athymic nude mice (20−25 g) were implanted subcutaneously (s.c.) in the hind flank with 2 × 10^6 LS174T human colon cancer cell suspensions (0.15 mL) in Hank's Balanced Salt Solution. The tumor xenografts grew to100−400 mg by day 15. All mice were fed a biotin-deficient diet (Purina Biotin Deficient Diet 5836, Purina Mills, Richmond, IN) for 6 days prior to radiopharmaceutical administration and up to 7 days postinjection.

For pretargeted RIT, groups of 8−10 mice were given a single injection of CC49 scFvSA (600 μg, 3.4 nmol), i.v. via the tail vein (t = 0). After 20−24 h, the synthetic clearing agent, biotin-$GalNAc_{16}$ (100 μg, 12.5 nmol), was given i.v. via the tail vein. Four hours after the clearing agent was administered, the mice received a tail vein injection of ^{149}Pm-, ^{166}Ho-, or ^{177}Lu-DOTA-biotin, at doses of 1.25 mCi/1.25 μg, 1.0 mCi/1.0 μg, and 1.5 mCi/1.5 μg, respectively. For conventional RIT, groups of 8−10 mice were given a single tail vein injection of ^{149}Pm-, ^{166}Ho-, or ^{177}Lu-MeO-DOTA-CC49, at doses of 250 μCi/250 μg, 200 μCi/200 μg, and 300 μCi/300 μg, respectively. Tumor growth was assessed by taking three-dimensional measurements of tumor volume using Vernier calipers. Tumor volume was calculated using the formula: V = (length × width × depth) × $\pi/6$.

Tumor Dosimetry. Mouse xenograft absorbed doses were calculated as described previously[54] using a modification of the method of Hui et al.[55] The model of Hui et al. is based on the dimensions and masses of organs in a nude mouse of approximately 25 g body weight. All organs were modeled as ellipsoids, with the exception of bone and bone marrow. Whole femur was selected to represent the bone and bone marrow, which were modeled as concentric cylinders. Radioactivity was assumed to be uniformly distributed within each of the organs, the carcass, and the tumor. Self-organ tumor absorbed radiation energy was determined as the amount of absorbed energy remaining in the tumor per radioactive decay. Cross-organ tumor absorbed radiation energy was determined using the approximation that the energy of β^- particles that escaped the source organ was deposited in adjacent organs.[55] The ratios of energy deposited in the tumor from adjacent organs were assumed to be approximately proportional to the ratios of the surface areas that overlapped with the tumor. To better simulate the geometry of a flank xenograft, it was assumed that the tumor was a sphere, with half the volume in contact with the remainder of body and half, covered with 0.5 mm of skin, protruding above the surface.

The Monte Carlo radiation transport code MCNP-4C[56] was used to obtain absorbed fractions for monoenergetic β^- particles. MCNP-4C was run in photon electron mode, in order to track both β^- particles and Bremsstrahlung radiation produced by the particles. For each monoenergetic β energy, 10^4 histories were run on a standard desktop personal computer, resulting in absorbed energy uncertainties on the order of 1%. When the absorbed fractions are averaged over the 25 to 50 energy bins representing a β spectrum, the final uncertainties are smaller than 1%. Standard energy cutoffs (0.001 MeV) and weight cutoffs for both β^- particles and photons were used. To calculate absorbed fractions for the polyenergetic β^- spectra of ^{149}Pm, ^{166}Ho, and ^{177}Lu, absorbed fractions were first determined at 51 energies from 0.025 to 2.5 MeV. β spectra were then calculated using the NUCDECAY code[57] and these monoenergetic responses were numerically integrated over the respective radiolanthanide spectra. An S-value was calculated for an average tumor weight of 200 mg, assuming radioactivity to be uniformly distributed within a sphere of unit density. This approach assumes that tumors of similar size in different animals have similar uptake characteristics, and the resulting absorbed dose is an average of that absorbed by each tumor.

Statistical Analysis. Response to therapy was assessed based on the number of days required for tumor volume to reach 1 g, using one-way analysis of variance (ANOVA) using

statistical software *SPSS 12.0.1* (Chicago, IL). The survival fraction of each treatment group was evaluated by Kaplan–Meier density analysis using *SPSS 12.0.1*, with a confidence interval of 95% ($p < 0.05$).

RESULTS AND DISCUSSION

An optimized pretargeting protocol,[49] based on the use of CC49 scFvSA, was employed for these studies. Injection of 600 μg (3.4 nmol) of CC49 scFvSA was sufficient to saturate tumors, as previously shown by the biodistribution of ^{125}I-labeled fusion protein.[49] After maximum tumor uptake at approximately 24 h, a molar excess of 100 μg (12.5 nmol) of the synthetic clearing agent biotin-GalNAc$_{16}$ was administered. This dose allowed for maximum clearance of circulating fusion protein to the liver for metabolic degradation, while having no effect on tumor retention.[51] After a sufficient time for clearance (4 h later), radiolanthanide-labeled DOTA–biotin was injected. DOTA–biotin was labeled to the same specific activity with all three radiometals, so different amounts of DOTA–biotin were administered using ^{149}Pm, ^{166}Ho, and ^{177}Lu. However, in each case the dose of fusion protein was in molar excess, allowing efficient binding of differing amounts of radiolabeled DOTA–biotin.

In the case of intact CC49,[53] we found that radiolanthanide labeling of the antibody at 5 μCi/μg, followed by dilution to 1 μCi/μg, gave superior radiolabeling and biodistribution results. Therefore, all CC49 doses were prepared according to this procedure.[53] While the amounts of radiolabeled CC49 administered differed among the three lanthanides, for each radiometal the tumor targeting would occur under conditions of antigen excess, allowing efficient uptake of the radiolabeled mAb.

The present studies compared directly, versus saline controls, the therapeutic efficacies of ^{149}Pm, ^{166}Ho, and ^{177}Lu for both pretargeted and conventional RIT in the same animal model of cancer. Initial single-dose therapy studies of CC49 scFvSA-pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin (Figure 1), as well as ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA-CC49 (Figure 2), were performed in nude mice bearing LS174T human colon carcinoma xenografts. Animals were injected with radiopharmaceuticals or control vehicle on day 15 of tumor growth. After CC49 scFvSA pretargeting, mice were injected with 1.25 mCi of ^{149}Pm-DOTA-biotin, 1.0 mCi of ^{166}Ho-DOTA-biotin, or 1.5 mCi of ^{177}Lu-DOTA-biotin. For conventional RIT, mice received 0.25 mCi of ^{149}Pm-MeO-DOTA-CC49, 0.2 mCi of ^{166}Ho-MeO-DOTA-CC49, or 0.3 mCi of ^{177}Lu-MeO-DOTA-CC49.

Because these studies were not taken to toxicity, the relative injected doses of each of the radiopharmaceuticals had to be estimated from previously obtained biodistribution data.[35,53] A major consideration was blood uptake, which would result in whole body irradiation and potential toxicity. A second consideration was tumor uptake, taking into account the half-life of the radionuclide and the maximum time of tumor localization. Due to its slow blood clearance, these factors were especially important for the intact antibody. For example, ^{166}Ho has a half-life of 26.9 h and a maximum tumor uptake at 96 h, meaning that most radioactive decays will occur in the blood and result in whole body irradiation. Thus, blood-to-tumor ratios were used to estimate injected doses of radiolanthanide-labeled CC49. Using 0.2 mCi of ^{166}Ho-, 0.25 mCi of ^{149}Pm-, and 0.3 mCi of ^{177}Lu-MeO-DOTA-CC49, the area under the curve (AUC) blood-to-tumor ratios[53] were each approximately

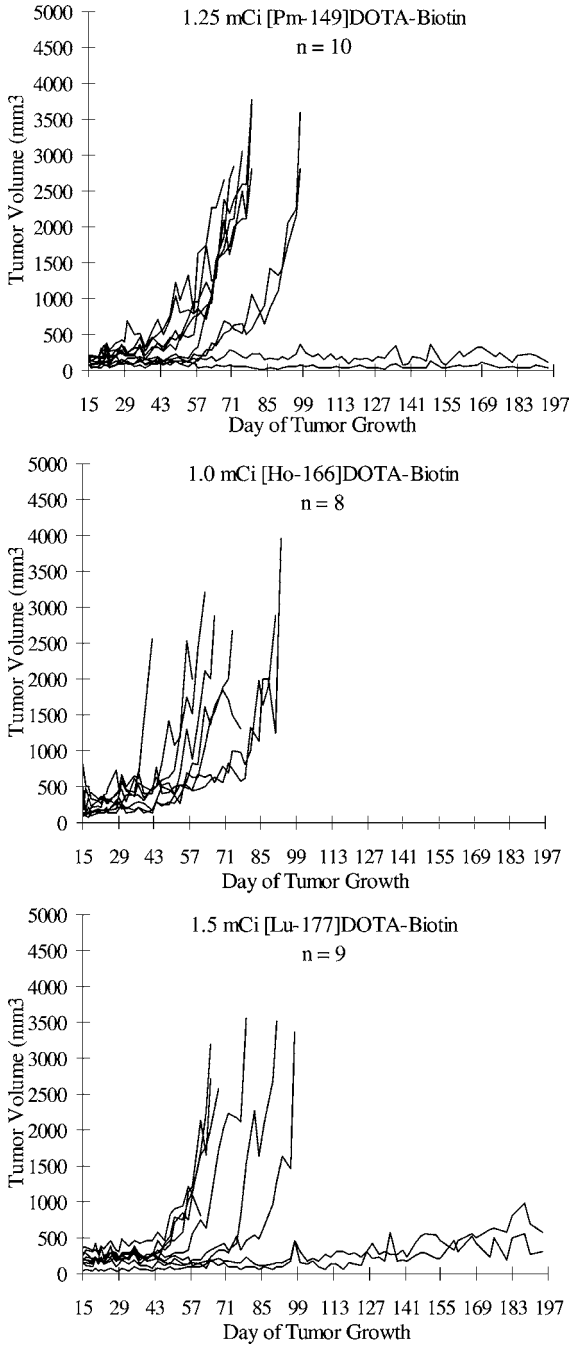

Figure 1. Tumor growth curves for LS174T-bearing nude mice treated with CC49 scFvSA-pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin.

0.1. The respective doses of ^{166}Ho-, ^{149}Pm-, and ^{177}Lu-DOTA-biotin were five times higher than those administered using the intact antibody, based on approximate whole body clearance of the pretargeting protocol. In the conventional and pretargeted RIT studies, no animals showed any signs of overt systemic toxicity, such as weight loss >20%, lethargy, or diarrhea.

We previously determined that the most statistically relevant end point criterion in this model is time to progression to a tumor burden of 1 g.[58] Figures 3 and 4 show the Kaplan–Meier plot of time to progression to a 1 g tumor for pretargeted and conventional RIT groups, respectively. Therapy with pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin increased the median time to progression to 50 ± 10, 41 ± 5, and 50 ± 10

dx.doi.org/10.1021/bc200258x | *Bioconjugate Chem.* 2011, 22, 2444–2452

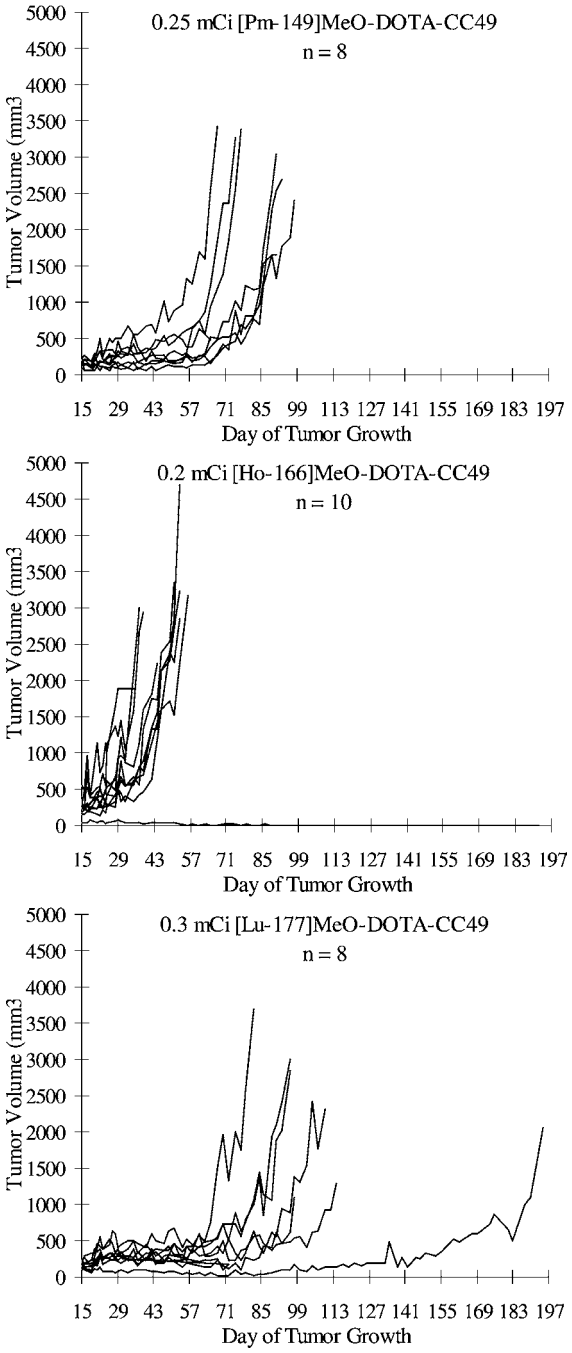

Figure 2. Tumor growth curves for LS174T-bearing nude mice treated with ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA-CC49.

days post-treatment, respectively. Therapy with ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA-CC49 increased the median time to progression to 53 ± 7, 24 ± 2, and 67 ± 9 days post-treatment, respectively. In contrast, saline controls showed a median time to progression of 13 ± 1 days postinjection and a mean tumor volume doubling time of only 3 days. Treatment with pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-biotin increased the average tumor volume doubling time to 27, 38, and 36 days, respectively. Therapy with ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-CC49 increased mean tumor volume doubling time to 18, 10, and 36 days, respectively.

The mean times to progression to a 1 g tumor were lowest for ^{166}Ho pretargeted and conventional RIT, compared to the

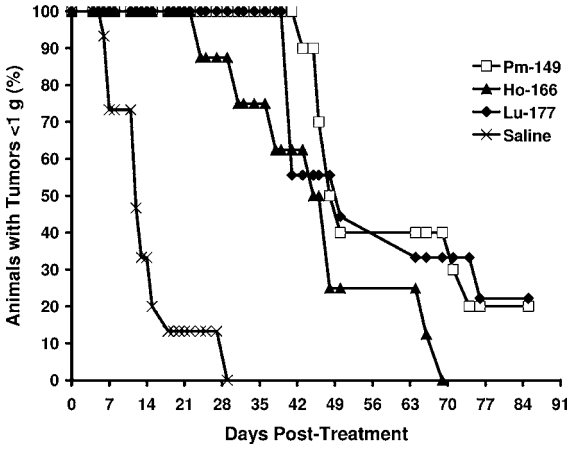

Figure 3. Time to progression to a tumor burden of 1 g in LS174T-bearing nude mice (n = 8−10 per group) treated with CC49 scFvSA-pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin, compared to saline controls.

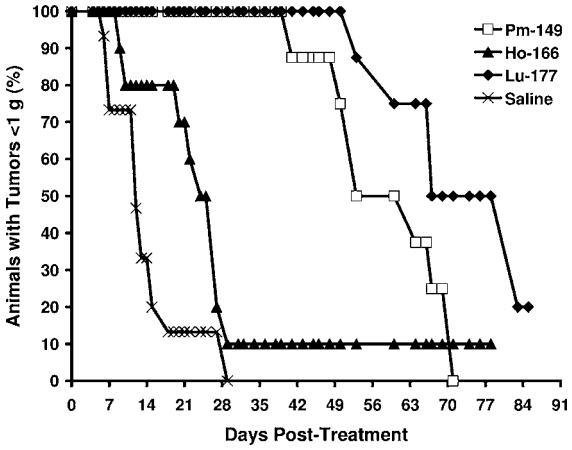

Figure 4. Time to progression to a tumor burden of 1 g in LS174T-bearing nude mice (n = 8−10 per group) treated with ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA-CC49, compared to saline controls.

other two radiolanthanides. For conventional RIT, a possible explanation for this result could be that it takes 96 h to reach maximum tumor uptake, and the half-life of ^{166}Ho is only 26.9 h. Most of the ^{166}Ho decay would then occur in the blood and not at the tumor site. In the case of pretargeting, maximum tumor uptake occurs within 4 h.[35] However, the 1.76 and 1.84 MeV β^- particles of ^{166}Ho have a maximum range of approximately 9 mm in soft tissue, meaning that proportionally less radiative energy, compared to ^{149}Pm and ^{177}Lu, would be deposited in the LS174T xenograft.

For pretargeted RIT using ^{149}Pm and ^{177}Lu, the mean times to progression to a tumor burden of 1 g were statistically identical. However, a significant difference was observed between ^{149}Pm and ^{177}Lu in the case of conventional RIT, with ^{177}Lu-MeO-DOTA-CC49 showing superior tumor growth inhibition. With these two radiolanthanides, both pretargeted and conventional RIT effected highly durable therapeutic responses in an extremely aggressive animal model of human colon cancer. Because ^{177}Lu and ^{149}Pm were statistically equivalent for pretargeting, but ^{177}Lu was superior for conventional RIT, ^{177}Lu was selected as an optimal radiolanthanide for future evaluation of both delivery platforms in toxicity and multiple-dose therapy studies.

dx.doi.org/10.1021/bc200258x | Bioconjugate Chem. 2011, 22, 2444−2452

Among mice treated with CC49 scFvSA-pretargeted ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-DOTA-biotin and ^{149}Pm-, ^{166}Ho-, and ^{177}Lu-MeO-DOTA-CC49, 23% survived >84 days post-therapy, and 11% survived 6 months, at which time the studies were terminated. All saline controls had to be sacrificed within 29 days of injection, with a median survival of only 18 days postinjection, demonstrating the highly aggressive nature of the LS174T model. Median survival in both the pretargeted ^{149}Pm and ^{177}Lu treatment groups was 82 days post-therapy, while in the conventional ^{149}Pm and ^{177}Lu RIT groups, median survival was 89 and 98 days, respectively. A summary of the therapy results is given in Table 2.

Table 2. Summary of Therapy Results

radiopharmaceutical	median survival (days)	survival at 84 days (%)	survival at 6 months (%)
^{149}Pm-DOTA-biotin	82	40	20
^{166}Ho-DOTA-biotin	70	25	0
^{177}Lu-DOTA-biotin	82	40	20
^{149}Pm-CC49	89	50	0
^{166}Ho-CC49	53	10[a]	10[a]
^{177}Lu-CC49	98	75	12.5

[a]Represents one animal with a 38 mg tumor that survived 6 months.

Some of the best previously reported outcomes of any therapeutic interventions in nude mice bearing established (>100 mg) LS174T xenografts have been a 63.2 day mean survival[59] following administration of ^{90}Y-labeled anti-CEA mAb ZCE025 and bone marrow transplantation and a 95.5 day median survival[60] after multiple bolus injections of ^{131}I-CC49, both of which were optimized treatment regimens. A more direct comparison of the CC49scFvSA pretargeting system can be found in an evaluation of the intraperitoneal model of LS174T colon cancer. Buchsbaum et al.[51] used the same CC49scFvSA protocol, injected intraperitoneally, to obtain very similar biodistributions of ^{177}Lu, compared to our intravenous administration of ^{149}Pm, ^{166}Ho, and ^{177}Lu in the flank xenograft model.[35] In pretargeted ^{177}Lu therapy studies, Buchsbaum and co-workers achieved 57 and 60 day median survivals, following single injections of 600 or 800 μCi, respectively. These results were superior to those obtained with ^{90}Y. The ^{177}Lu doses they used were also considerably lower than the dose employed in our experiments, and death was used as the end point for their studies. In contrast, we injected 1.5 mCi of pretargeted ^{177}Lu-DOTA-biotin and measured time to progression to a 1 g tumor, as frequent ulcerations complicated further evaluation of the flank xenograft model. Regardless of these differences, the results of our initial single-dose therapy studies of pretargeted and conventional RIT with radiolanthanides compare favorably with the best results in the literature. In addition to studies in tumor-bearing mice, a CC49scFvSA/^{90}Y-DOTA-biotin pretargeting protocol has also been evaluated in patients with metastatic colon cancer, demonstrating the potential clinical utility of pretargeting with this fusion protein.[61]

All 6-month survivors showed no macroscopic or microscopic evidence of nontarget tissue toxicity at necropsy. These animals experienced tumor growth inhibition, partial regression, and, in one instance, complete regression. However, the mouse microscopically free of disease after 6 months initially had a 38 mg tumor treated with ^{166}Ho-MeO-DOTA-CC49, which was an anomalous outcome. Histopathology of the residual masses from all other 6-month survivors (Figure 5) revealed extensive

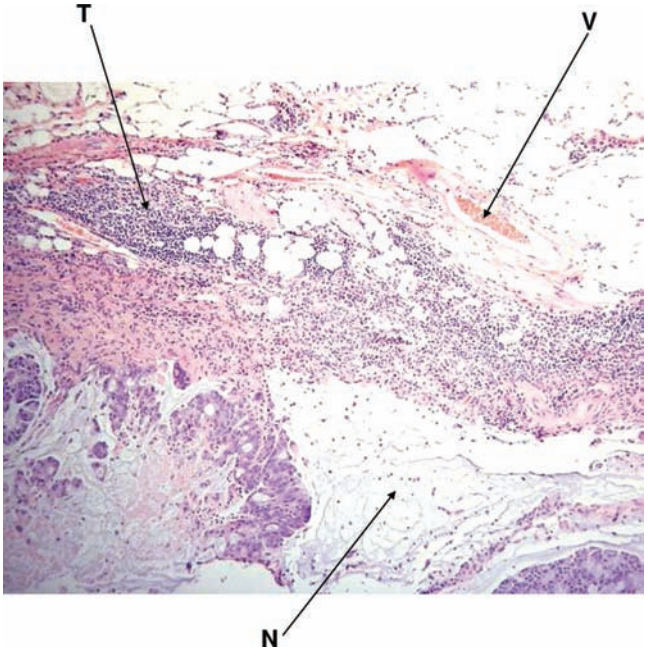

Figure 5. Hematoxylin- and eosin-stained section of the residual mass of a mouse 6 months after treatment with 1.5 mCi of CC49 scFvSA-pretargeted ^{177}Lu-DOTA-biotin, showing extensive necrosis (N), viable tumor tissue (T), and blood vessels (V).

(80−90%) tumor necrosis, with multifocal areas of pyogranulomatous inflammatory infiltrates. Conversely, 10−20% of each mass also consisted of viable and, with one exception, well-vascularized tumor cells exhibiting mitotic rates of 8−10 or 10−12 per 400 power field. However, these long-term survivors all had complete tumor growth inhibition or partial regression at 6 months post-therapy, suggesting that, in spite of the relatively high mitotic rates, the tumor cell-loss factor substantially outweighed the degree of proliferation.

■ CONCLUSIONS

These studies provide impetus to investigate why these experimental therapies demonstrate such considerable efficacy and how they can be improved further in an adjuvant setting. All animals with residual malignancy remained healthy with stable disease or in partial remission for a period corresponding to at least 25% of their life expectancy. This remarkable finding raises the possibility that radiolanthanide agents for pretargeted and conventional RIT may one day allow colorectal cancer patients to experience relatively normal longevity and quality of life. The future implementation of optimized radiolanthanide treatment regimens, such as multiple-dose therapy, has the potential to be even more efficacious for cancer treatment.

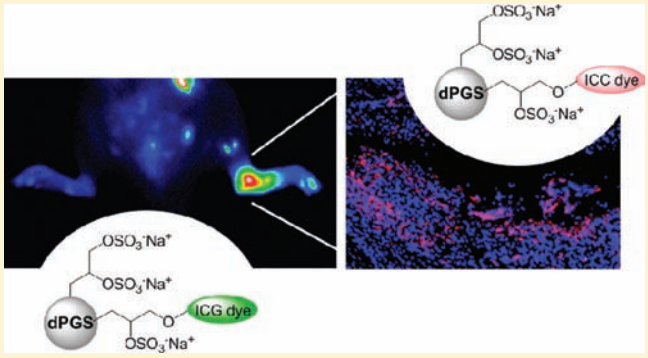
Supporting Information

ABSTRACT: We present a highly selective approach for the targeting of inflammation with a multivalent polymeric probe. Dendritic polyglycerol was employed to synthesize a polyanionic macromolecular conjugate with a near-infrared fluorescent dye related to Indocyanine Green (ICG). On the basis of the dense assembly of sulfate groups which were generated from the polyol core, the resulting polyglycerol sulfate (molecular weight 12 kD with ~70 sulfate groups) targets factors of inflammation (IC_{50} of 3−6 nM for inhibition of L-selectin binding) and is specifically transported into inflammatory cells. The *in vivo* accumulation studied by near-IR fluorescence imaging in an animal model of rheumatoid arthritis demonstrated fast and selective uptake which enabled the differentiation of diseased joints (score 1−3) with a 3.5-fold higher fluorescence level and a signal maximum at 60 min post injection. Localization in tissues using fluorescence histology showed that the conjugates are deposited in the inflammatory infiltrate in the synovial membrane, whereas nonsulfated control was not detected in association with disease. Hence, this type of polymeric imaging probe is an alternative to current bioconjugates and provides future options for targeted imaging and drug delivery.



INTRODUCTION

Macromolecular conjugates are ideal entities for the delivery of drugs or diagnostics to diseased organs, tissues, and cells, as they can be effectively optimized for uptake, binding, release, and tolerability. Today, novel targeted macromolecules encompass mostly proteins and antibodies, which are recombinantly produced and either operate directly as therapeutics or are employed as carrier molecules for the delivery of conjugated effector molecules. A fundamental challenge with targeting molecules of biological origin is their inability in multipathway inhibition often leading to insufficient efficacy in the complex *in vivo* situation of disease treatment.[1]

An alternative to biological targeting molecules is provided by fully synthetic nanosized polymeric entities, which are accessible by comparably simple and economical chemical procedures. Many approaches using nanoparticles, dendrimers, and self-assembling systems as carriers for therapeutic drugs and diagnostic effectors are currently being followed.[2] Particularly, dendritic macromolecular polymers offer interesting applications for drug delivery and targeting. The multifunctional surface of dendritic structures is ideal to modify the physiological properties of the macromolecule by changing the surface properties, e.g., through conjugation with targeting structures or the assembly of charged moieties.[3,4] Most recently, we demonstrated that polyanionic, dendritic polyglycerol sulfates (dPGS) exert strong binding affinity to cellular targets involved in the inflammatory process, such as L- and P-selectins, which are bound with nanomolar affinity as demonstrated by a concentration-dependent SPR assay *in vitro*.[5,6] By inhibiting leucocyte infiltration *in vivo*, the substance exhibited efficient anti-inflammatory efficacy in a mouse dermatitis model.[5] Furthermore, dPGS binding to selectins was shown to increase with molecular weight and number of sulfate groups.[6] Polyanionic analogues employing polyglycerol sulfonates, carboxylates, or phosphates exert only weak binding to selectins (around μM), thereby revealing the particular specificity of dPGS.[7]

The underlying rationale of our studies described herein encompasses, on one hand, the evaluation of dPGS as carrier molecule for the targeting of diagnostic molecules to sites of

inflammation and, on the other hand, to gain information on the *in vivo* distribution of such polymers. Thus, our aim was to generate a novel type of imaging probe involving near-IR dyes of the kind of Indocyanine Green (ICG). By visualizing the interaction of the polyanionic macromolecular conjugate within inflammatory processes, a novel molecular targeting mechanism is translated from the *in vitro* biological behavior to the performance as *in vivo* contrasting probe.

EXPERIMENTAL SECTION

Materials. All chemicals used were reagent grade, used as received, and purchased from Acros Organics (Belgium) or Sigma-Aldrich (Germany) unless stated otherwise. 11-Bromo-1-undecanol (>97%) was purchased from Fluka (Germany), and 4-(2-carboxyethyl)-phenylboronic acid from Alfa Aesar (Germany). Dendritic polyglycerol (dPG, compound **1**) with a molecular weight of 6000 g/mol and a PDI < 1.6 was synthesized according to literature via an anionic multi-branching ring-opening polymerization of glycidol and pentaerythritol as starter.[8,9] The ICC propargyl dye **5** was synthesized as published,[10] and is commercially available through IRIS Biotech, Germany. Dialysis was performed with regenerated cellulose tubings (MWCO 2000) purchased from Carl Roth. Reversed phase chromatographic purification was performed using RP-18 Redisep flash columns (ISCO CombiFlash Rf system). ^{1}H NMR and ^{13}C NMR spectra were recorded at 25 °C at concentrations of 100 g·L^{-1} on a JEOL ECX 400 spectrometer, operating at 400 and 101 MHz, respectively. NMR chemical shifts δ are reported in ppm and the deuterated solvent peak was used for calibration. Mass spectra were obtained from an ESI-Time-of-Flight LC/M mass spectrometer 6210 (Agilent Technologies) operating at a flow rate of 10 μL/min. Combustional analysis to determine degrees of sulfation was performed on a Vario EL III elemental analyzer. IC_{50} values were determined by SPR as published.[5]

Synthesis of Conjugates. *11-Azidoundecyl-polyglycerol (**2**).* dPG **1** (0.83 mmol, 5 g) was dissolved in dry DMF (40 mL) and statistically deprotonated with sodium hydride (60% in mineral oil, 2.08 mmol, 83 mg, 2.5 equiv) at 80 °C under Ar atmosphere for 30 min. 11-Azido-1-undecanyl-tosylate[11] (1.5 mmol, 0.54 g, 1.8 equiv) was added to the mixture and the reaction was kept for further 24 h at 80 °C. Subsequently, the solvent was removed under reduced pressure, the residue redissolved in aqua dest. (50 mL), and repeatedly extracted with DCM (3 × 50 mL). The aqueous phase was concentrated and further purified by dialysis in MeOH for 48 h, while the solvent was replaced three times. After concentration under reduced pressure and drying in high vacuum, 4.6 g (88%) of the title compound was obtained as a slightly yellow, viscous oil.

^{1}H (400 MHz, MeOH-d_4) δ 4.03−3.40 (m, dPG-backbone); 1.70−1.50 (m, alkyl-C$\underline{H}_2$CH$_2$O, alkyl-C$\underline{H}_2$CH$_2$N$_3$); 1.47−1.26 (m, 7×CH$_2$-alkyl). ^{13}C (101 MHz, MeOH-d_4) δ 81.5, 81.3, 79.7, 73.9, 72.8, 72.4, 72.2, 70.9, 70.6, 64.4, 63.0, 62.7 (PG-backbone), 52.4 (CH$_2$N$_3$), 31.7, 31.0, 30.6, 30.3, 29.9, 29.0, 28.6, 27.8, 27.0 (alkyl CH$_2$). IR (KBr) ν/cm^{-1} 3365 (s), 2927 (m), 2871 (m), 2071 (vs), 1122 (s), 1098 (s), 977 (m), 822 (m). Elemental analysis: calcd. C 49.065, H 8.250, N 0.680; found C 47.37, H 8.632, N 0.528.

*11-Azidoundecyl-polyglycerolsulfate (**3**).* Azidoundecyl-dPG **2** (0.63 mmol, 4.0 g) was dissolved in dry DMF (25 mL) and a solution of sulfurtrioxide pyridine complex (0.05 mol, 8.0 g, 80 equiv) in dry DMF (50 mL) was slowly added to the solution via a dropping funnel at 60 °C under Ar atmosphere and stirred for 5 h. Then, the reaction mixture was allowed to cool to room temperature and to react for further 24 h. The reaction was quenched by the addition of aqueous NaOH (1 M) until pH 8 was reached. The solvent was removed under reduced pressure and the crude product was dialyzed against water for 24 h while the solvent was replaced 3 times. After concentration under reduced pressure and drying in high vacuum, 8.1 g (92%) of the title compound was obtained as colorless solid. ^{1}H (400 MHz, D$_2$O) δ 4.58−4.17 (m, CH$_2$−OSO$_3$Na) 4.16−3.55 (m, dPG-backbone); 1.83−1.62 (m, alkyl-C$\underline{H}_2$CH$_2$O, alkyl-C$\underline{H}_2$CH$_2$N$_3$); 1.57−1.31 (m, 7×CH$_2$-alkyl). ^{13}C (101 MHz, D$_2$O) δ 79.1, 78.0, 76.6, 71.0, 70.3, 69.1, 68.4, 67.7 (PG-backbone), 52.1 (CH$_2$N$_3$), 29.5, 29.4, 29.3, 29.2, 29.0, 28.9, 29.8, 26.8, 26.1 (CH$_2$-alkyl). IR (KBr) ν/cm^{-1} 3481 (m), 2929 (m), 2871 (m), 2099 (m), 1653 (s), 1472 (m), 1255 (s), 1074 (s), 1048 (s), 939 (m), 779 (m). Elemental analysis: calcd. C 21.94, H 3.14, N 0.29, S 17.37; found C 19.48, H 3.204, N 0.238, S 17.20.

Meso-4-(2-carboxyethyl)phenyl NIR Dye from IR-820. A mixture of IR-820 (0.59 mmol, 0.5 g) and 4-(2-carboxyethyl)-phenylboronic acid (1.06 mmol, 0.21 g) in water (15 mL) was heated to 90 °C for 48 h in the presence of Pd(PPh$_3$)$_4$ (0.09 mol, 0.1 g). The reaction mixture was poured into diethyl ether and the resulting precipitate isolated by centrifugation. Purification was achieved by RP-18 chromatography (Combi-Flash) using water/methanol as eluent. Evaporation of methanol followed by lyophilization afforded 0.2 g (37%) of the product as green amorphous solid. ^{1}H (400 MHz, DMSO-d_6) δ 1.41 (s, 12H), 1.66−1.86 (m, 10H), 1.98 (t, 2H), 2.65−2.81(m, 8H), 3.10 (t, 2H), 4.24 (t, 4H), 6.28 (d, 2H), 7.23 (dd, 4H), 7.45 (t, 2H), 7.56 (dd, 4H), 7.71 (d, 2H), 8.01 (dd, 4H), 8.09 (d, 2H). MS (ESI-TOF) m/z calcd for $C_{55}H_{59}N_2NaO_8S_2$ $[M]^+$ 962.3611, found 962.3591; calcd $[M+Na]^+$ 985.3508, found 985.3491; calcd $[M-H+2Na]^+$ 1007.3328, found 1007.3308.

*Meso-propargyl NIR Dye (**4**).* To as solution of meso-4-(2-carboxyethyl)phenyl heptamethine dye (0.1 mmol, 100 mg) and 2-(1*H*-7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyl uronium hexafluorophosphate (HATU; 0.18 mmol, 67 mg) in dry DMF (3 mL) was added diisopropylethylamine (0.2 mmol, 35 μL). After 30 min stirring at room temperature, a mixture of propargylamine (0.16 mmol, 10 μL) and diisopropylethylamine (0.3 mmol, 50 μL) was added and the reaction stirred at room temperature for 20 h. The product was precipitated with diethyl ether and isolated by centrifugation. Purification was achieved by RP-18 chromatography (CombiFlash) using water/methanol as eluent. Lyophilization afforded 55 mg (53%) of the product as green amorphous solid. ^{1}H (400 MHz, DMSO-d_6) δ 1.41 (s, 12H), 1.65−1.78 (m, 10H), 1.96 (t, 2H), 2.65−2.85 (m, 8H), 3.15 (t, 2H), 4.15−4.35 (m, 6H), 3.30 (t, 1H), 6.30 (d, 2H), 7.25 (dd, 4H), 7.45 (t, 2H), 7.58 (dd, 4H), 7.72 (d, 2H), 8.05 (dd, 4H), 8.10 (d, 2H). MS (ESI-TOF) m/z calcd for $C_{58}H_{61}N_3NaO_7S_2$ $[M]^+$ 999.2406, found 999.3692; calcd $[M+Na]^+$ 1022.2298, found 1022.3827; calcd $[M+K]^+$ 1038.3384, found 1038.3559.

*Polyglycerol Sulfate−NIR Dye Conjugate (**6**).* 11-Azidoundecanyl-polyglycerolsulfate **3** (7.0 μmol, 100 mg) and propargyl dye **4** (21 μmol, 21 mg) were dissolved in a 1:1 mixture of PBS/ethanol (1.2 mL). To this solution was added $CuSO_4 \cdot 5H_2O$ (3.0 μmol, 100 μL of a stock solution of 7.8 mg in 1 mL PBS), sodium ascorbate (6.0 mmol, 100 μL of a stock solution of 12.4 mg in 1 mL PBS) and another 200 μL of ethanol. The mixture was allowed to react at 40 °C for 72 h.

dx.doi.org/10.1021/bc2002727 | *Bioconjugate Chem.* 2011, 22, 2453−2460

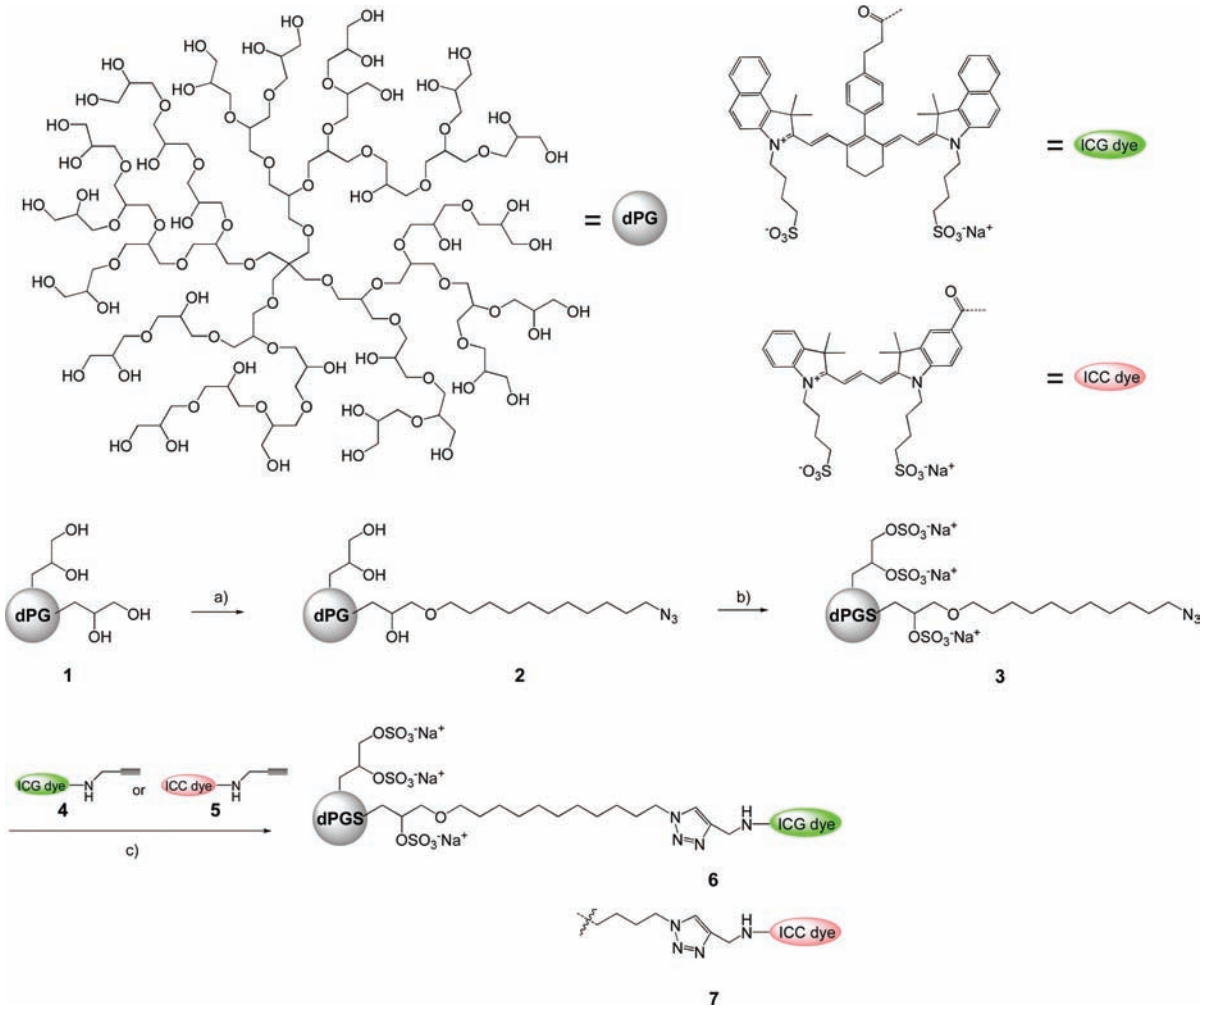

Figure 1. Chemical structures of conjugates and synthetic pathway: (a) NaH, 11-azido-1-undecanyltosylate, DMF, 80 °C, 24 h; (b) SO_3-pyridine, DMF, 60 °C, 5 h; (c) $CuSO_4$, Na-ascorbate, PBS/ethanol, 40 °C, 72 h.

After evaporation of ethanol, the residue was stirred in methanol/ethanol 1:1 and the supernatant decanted after precipitating the nonsoluble product by centrifugation. Finally, the product was isolated by RP-18 chromatography (Combi-Flash) eluting as first fraction with water as eluent. Lyophilization afforded 165 mg (77%) of **6** as green solid. ^{1}H (400 MHz, D_2O/DMSO-d_6 1:1) δ 8.40−6.20 (m, dye aromatic and polymethine groups, triazol group); 4.55−4.25 (m, CH_2−OSO_3Na); 4.20−3.60 (m, dPG-backbone); 2.20−1.80 (m, dye methylene groups); 1.65−1.20 (m, alkyl-$C\underline{H}_2CH_2O$, alkyl-$C\underline{H}_2CH_2N_3$, CH_2-alkyl linker, dye methyl groups). Elemental analysis: calcd. C 25.04, H 3.35, N 0.55, S 16.66; found C 22.41, H 2.412, N 0.539, S 17.93.

*Polyglycerol Sulfate−ICC Dye Conjugate (**7**).* 11-Azidoundecanyl-polyglycerolsulfate **3** (7.0 μmol, 100 mg) and propargyl ICC dye **5** (21 μmol, 15 mg) were reacted in a 1:1 mixture of PBS/ethanol (1.2 mL) and the product isolated as described for compound **6**. Lyophilization afforded 180 mg (85%) of **7** as red solid.

Photophysical Characterization. Absorption spectra were recorded on a Lambda 950 spectrophotometer (Perkin-Elmer), fluorescence spectra were measured with a JASCO FP-6500 spectrofluorometer (150 W xenon lamp, R928 Hamamatsu photomultiplier). Fluorescence quantum yields are calculated relative to the standard dye ICG in DMSO, which has a value of 13%.[12] Dye-to-polymer ratio was estimated from the UV−vis spectrum of a 5 μM conjugate solution prepared with the initial assumption of a dye-to-polymer molar ratio of 1 and a molecular weight of 13 000 g/mol.

Cell Culture. The epithelial human lung cancer cell line A549 was routinely propagated as follows: DMEM medium, with 10% fetal calf serum, 2% glutamine, and penicillin/streptomycin (all from PAN Biotech) added. Cells were seeded into medium at 1×10^5 cells/mL, cultured at 37 °C with 5% CO_2, and split 1:5 two times a week. Peripheral blood mononuclear cells (PBMC) were prepared from peripheral blood of different healthy donors by a sequence of differential centrifugation on Ficoll-Hypaque, adherence to polystyrene culture flasks for 2 h, and subsequent washing with RPMI containing 10% fetal calf serum (both from PAN Biotech) to remove nonadherent cells. The cells were stimulated with 100 ng/mL lipopolysaccharide (LPS; Sigma) for 24 h to prime proinflammatory processes.[13]

In Vivo Fluorescence Imaging. *Animal Model.* Animals in this study were maintained in accordance with the Guide for the Care and Use of Laboratory Animals published by the U.S. National Institute of Health (NIH publication no. 85−23, revised 1996). All experiments were approved by the local animal welfare committee. For arthritis studies, we used female Lewis rats with a body weight of (150 ± 10) g on arrival

dx.doi.org/10.1021/bc2002727 | *Bioconjugate Chem.* 2011, 22, 2453−2460

(Charles River) fed a normal diet. Collagen-induced arthritis (CIA) was induced as described before.[14−16] After fluorescence imaging, the animals were killed in deep anesthesia by intravenous injection of T61 ad us. vet. (Intervet) at a dose of 2 mL/animal.

Clinical Scoring. Clinical symptoms of the ankle joints after induction of arthritis are disposed in scores from 0 to 3. The ankle joints were scored in the following way: 0 − no clinical symptoms, 1 − low grade swelling, 2 − middle grade swelling and reddening, and 3 − high grade swelling, reddening, and mobility reduction.

Administration of Conjugates. The imaging probe **6** was dissolved in sterile PBS (PAN Biotech, Berlin, Germany) and administered i.v. via the tail vein at a dose of 4 mg/kg (corresponding to 0.15 μmol dye per kg). Animals included for later histology additionally received ICC conjugate **7** at a dose of 1 mg/kg.

Imaging Device and Image Processing. A camera-based fluorescence imaging system (Camera: EMCCD-Camera, IXON BV887, Andor) was used for imaging of animals. As excitation source, a light emitting diode (LED) array with λ_{max} of 750 nm illuminating an area of 20 cm × 20 cm and a short pass filter (λ = 750 nm, LCLL 750) were used. The following parameters were adjusted: exposure time, 100 ms; EM gain, 3000; delay, 18.8 ms; shift time, 0.9 ns/line; preamplifier, 4.6; detector temperature, −65 °C; binning, 2 pixel by 2 pixel; film, kinetic series with 3000 frames, kinetic cycle time, 200 ms, 1 accumulation; images, accumulation series with 100 frames, accumulation cycle time 200 ms. Two long pass filters ($\lambda_{50\%}$ = 800 nm, 5 OD, 800 LP, 800 ALP) were applied to suppress excitation light. The images were analyzed as published.[16] Briefly, regions of interest (ROI) were set and illumination intensities corrected for background. Images are normalized to the mean intensity from an ROI placed over the reference standard. Mean and 90th percentile values are determined in ROI for the right and left ankles, the area of the whiskers, and the eye.[16]

Cytochemistry. In the present study, cells were seeded at 5 × 10^4 cells/mL in a 24-well culture plate on glass coverslips (Sigma), and cultured for 24 h at 37 °C. Thereafter, cells were cultured with medium containing 10^{-6} M **6**, **7**, and 10^{-5} M polyglycerol-ICC (nonsulfated control)[17] for different times at 37 °C. Afterward, cells were fixed with cold acetone, rinsed, and covered with 4,6-diamidino-2-phenylindole (DAPI, Abcam, Cabridge, UK) for nuclear counterstain. Image acquisition was performed using a Leica DMRB microscope (Leica, Solms, Germany). Images were taken with a digital camera (Spot 32, Diagnostic Instruments).

Histochemistry. Histochemical staining was performed on paraffin sections (10 μm) of tissue of liver fixed with formalin or cryosections (5 μm) of tibiotarsal articulations. Tissues were removed 3 h post injection (p.i.) of dPGS-ICC or polyglycerol-ICC from control animals or rats with CIA. Tissue sections were deparaffinated and fixed with acetone. Non-decalcified tissues of tibiotarsal articulation were shock-frozen using liquid nitrogen. Microtome sections were removed from the block with cellotape and then transferred to slides, dried overnight, and fixed with acetone for 30 s.[18] DAPI was used for nuclear counterstain. Image acquisition was performed using a Leica DMRB microscope (Leica). Images were taken with a digital camera (Spot 32, Diagnostic Instruments).

RESULTS AND DISCUSSION

Synthesis of Polyglycerol Sulfate Conjugates with Cyanine Dyes. The synthetic path involves the derivatization of dendritic polyglycerol (dPG) with a reactive linker in a fashion in which approximately only one dye molecule on average is conjugated to the polymer. Dye conjugation via "Click" chemistry after sulfation of the majority of hydroxyl groups leads to the desired near-IR imaging conjugate. The synthesis is illustrated in Figure 1. The synthesis of dPG (compound **1** in Figure 1) was achieved by a one-step anionic multibranching ring-opening polymerization of glycidol started on the initiator pentaerythritol. After purification by dialysis, a highly viscous oil was obtained with a typical PDI of 1.4−1.6 and a number average molecular weight M_n of approximately 6000 g/mol.[8,9] Before the sulfation reaction to the desired polyglycerol sulfate, a small proportion of the hydroxyl groups was modified by reaction with 11-azidoundecanyl-1-tosylate forming an ether linkage between polymer and aliphatic chain. The appearance of the azide functionality in **2** was supported by IR (characteristic band at 2100 cm^{-1}). According to ^{1}H NMR signal integration (see Supporting Information), 60% of polymer carried a linker moiety on average. Subsequently, the material was sulfated with SO_3·pyridine complex[5,19] giving the azidoundecanyl-modified sulfated polyglycerol **3** in high yield. Elementary analysis revealed a high degree of sulfation of 92% (75 of theoretically 80 hydroxyl functions converted for M_n 6000 g/mol); thus, the M_n of the sulfated species is approximately 12 000 g/mol. Conjugation for near-infrared imaging in the spectral range of Indocyanine Green (ICG) was accomplished with the novel propargyl derivative **4**. We prepared this fluorescence label from the commercial dye IR-820 referring to a recently published procedure by Achilefu et al. who applied the Suzuki method of aryl-halide substitution to the central chloro function in the IR-820 structure.[20] In our approach, we used 4-(2-carboxyethyl)phenylboronic acid as reaction component, thereby introducing a carboxyethyl linker symmetrically into the chromophore. Amidation with propargylamine under standard conditions led to the desired derivative **4** for conjugation to the polyglycerolsulfate **3**. Coupling of **4** was achieved by copper-mediated 1,3-dipolar cycloaddition ("Click"-conjugation) between the azide group at the polymer and the propargyl residue at the dye. The resulting conjugate **6** was characterized by ^{1}H NMR and by photooptical methods. The conjugation reaction yielded a dye-to-polymer ratio of approximately 0.66 estimated from the absorption spectra (see below). We included furthermore a VIS fluorophore into our studies and synthesized an analogous conjugate (**7**) employing the indocarbocyanine (ICC) propargyl moiety **5** already published in other studies.[7,10] The influence of dye conjugation on target binding was determined by SPR (Biacore)[5,6] yielding inhibition (IC_{50}) values for L-selectin similar to nonconjugated dPGS of identical sulfation but without linker modification (conjugate **6**, IC_{50} 3 nM; conjugate **7**, IC_{50} 6 nM; nonconjugated dPGS, 4 nM). Hence, dye conjugation does not hamper target affinity of the resulting conjugate.

Photophysical Properties. In order to characterize the conjugate **6** with respect to its optical properties, we were interested in the dye-to-polymer ratio and in the resulting fluorescence quantum yield. The data for conjugate **6** in comparison with the free dye are summarized in Table 1. First, absorption measurements were conducted in phosphate-

Table 1. Photophysical Properties of Free Dye and Polyglycerolsulfate Conjugate 6

compound	solvent[a]	absorption max. (nm)[b]	fluorescence max. (nm)	FQ[c]
free dye	DMSO	806	836	0.052
	DMSO/PBS (1:1)	800	823	0.097

	PBS	730, 792, 886	817	0.006
	serum	738, 806, 886	818	0.018
7	PBS	518, 553, –	568	n.d.
	serum	526, 559, –	572	n.d.

[a]Data for free dye in PBS and conjugate **6** in DMSO are not determined due to insolubility, and no reasonable spectra were obtainable. [b]Spectral data for **6** and **7** from left to right: dimer band, monomer band, J-band. [c]Fluorescence quantum yield relative to ICG in DMSO (0.13).[12]

buffered saline and in serum as most relevant physiological media. The spectra depicted in Figure 2 illustrate that the conjugate exhibits a pronounced tendency to form aggregates. For comparison, the theoretically optimal absorbance profile of the fluorophore is obtained by measuring the free dye in DMSO. Unfortunately, **6** is not soluble in DMSO or methanol due to the extremely high anionic charge, so we had to exclude this solvent. In PBS, strong aggregation is apparent from the collapsing extinction of the absorbance maximum of **6** at 792 nm and growth of the dimer shoulder at 730 nm, together with sign of a J-band at 886 nm. Also, the fluorescence yield is rather low at 0.6% (excitation 720 nm). This behavior has been studied intensively for protein and antibody conjugates with lipophilic fluorescent labels, mainly dyes of cyanine type.[21,22] In serum as the more physiologically relevant medium, we obtained a slightly restored main absorption band, accompanied by an increased fluorescence quantum yield of 1.8%. Despite insolubility in DMSO, a mixture of PBS/DMSO of 1:1 gave a similar spectrum and a quantum yield of 2.7%. Compared to other covalent conjugates of the ICG chromophore type[21,23] and also unmodified ICG in nanoformulations,[24] however, this level appears sufficient for further biological studies.

For the free dye, a very high extinction coefficient in DMSO was measured at 195 000 M^{-1} cm^{-1} representing the theoretically optimal condition to determine optical properties due to the absence of aggregation phenomena. Assuming an extinction coefficient of 150 000 M^{-1} cm^{-1} from the spectral shape in serum or PBS/DMSO (Figure 2) to estimate the dye-to-polymer ratio in **6**, a concentration of 3.3 μM, which corresponds to a dye loading of 66%, can be calculated. This is in approximate agreement with the maximal achievable loading based on 60% linker attachment (see above). The difficulty in accurately determining the ratio between a carrier unit and a dye is similar to observations with antibody conjugates with rather lipophilic heptamethine dyes, such as ICG.[21] In fact, as discussed by Villaraza et al., the clear analysis of dye loading as well as supposedly successfully achieved separation of covalently attached dye from aggregated nonattached impurities is difficult, as in size exclusion chromatography (SEC) both specimens may elute similarly. Furthermore, our polymer carriers do not exhibit UV absorption, thus lacking a method to quantify the polymer concentration by spectrophotometry.

Cellular Uptake. On the *in vitro* level, we have already demonstrated the ability of polyglycerol sulfates to inhibit L- and P-selectin binding with high specificity over other anionic groups, such as sulfonate and carboxylate.[7] Applying conjugates **6** and **7**, both of which exhibit high binding to L-selectin with conjugated fluorophore (see above) allows the translation to the cellular level. We found that the polymer clearly localizes within tumor cells, as well as in activated mononuclear cells, as shown in cell culture and tissue specimens.

Figure 3A illustrates that the NIR conjugate **6** appears comparably in A549 cells when setting up a microscope with excitation and detection technique capable of exciting and imaging the near-IR fluorophore permitting direct visualization of **6**. Compound **7**, employing ICC dye[7,10] with typical fluorescence properties fitting the Cy3-filter (550 nm/580 nm), allows the same subcellular localization with a sharper image

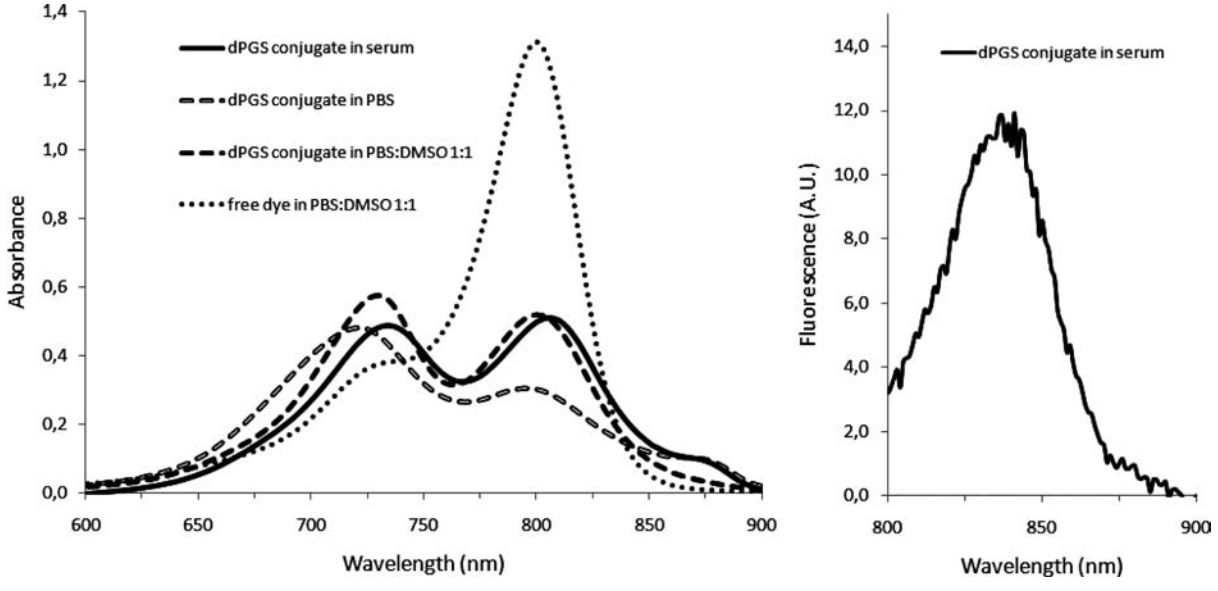

Figure 2. Absorbance spectra of conjugate **6** in different solvents compared to free dye in PBS/DMSO 1:1. Fluorescence emission spectrum of **6** in serum (excitation: 760 nm).

impression (Figure 3B). As expected, no cellular signals after incubation with polyglycerol-ICC as control could be detected (Figure 3C). Due to the absence of technical routine solutions for microscopic imaging in the near-IR, we continued to employ compound **7** as standard probe for microscopic studies, hereby assured that **6** and **7** exhibit identical cellular uptake behavior as proven by the above-described bridging comparison. Accordingly, uptake of conjugate **7** could be demonstrated *in vitro* in human peripheral blood mononuclear cells stimulated with LPS to induce for inflammatory processes (Figure 3D). Moreover, intracellular localization after targeting to macrophages in the living organism was proven by studying liver tissue 3 h post i.v. injection of conjugate **7** into rats. As shown in Figure 3E, enrichment in rat liver macrophages (Kupffer cells) with a certain level of fluorescence signals also detectable in activated endothelial cells and hepatocytes can be followed *ex vivo* by fluorescence microscopy of liver tissue specimens.

In Vivo Imaging. Conjugate **6** was employed as imaging probe for *in vivo* studies using the well-established arthritis rat model in which joint inflammation is induced by the injection of bovine type II collagen.[15,16] After i.v. administration of the probe (dose: 4 mg/kg of polymer corresponding to 0.2 μmol/kg fluorophore), fluorescence images were generated up to 24 h post injection. Images from a time series of a control and two CIA animals are shown in Figure 4. The false colors allow easy identification of the diseased joints. As is typical in the disease progression of this animal model, a certain number of joints remains either unaffected or at a low disease score. In the fluorescence imaging setting, we were able to differentiate dye probe uptake depending on the acuteness of the inflammation within the same animal. In Figure 4, the middle row impressively shows that the absence of clinical signs (score 0) does not lead to pronounced fluorescence enhancement.

For further quantification, images were analyzed by applying appropriate regions of interest (ROIs) to the area of ankle joints, eyes, and a fluorescent reference cube. Accordingly, a total of 10 joints in control rats and 20 joints in arthritic animals were evaluated. The fluorescence intensity from the eyes is helpful as a basic signal indicating the pharmacokinetic behavior of the injected probe in the blood compartment.

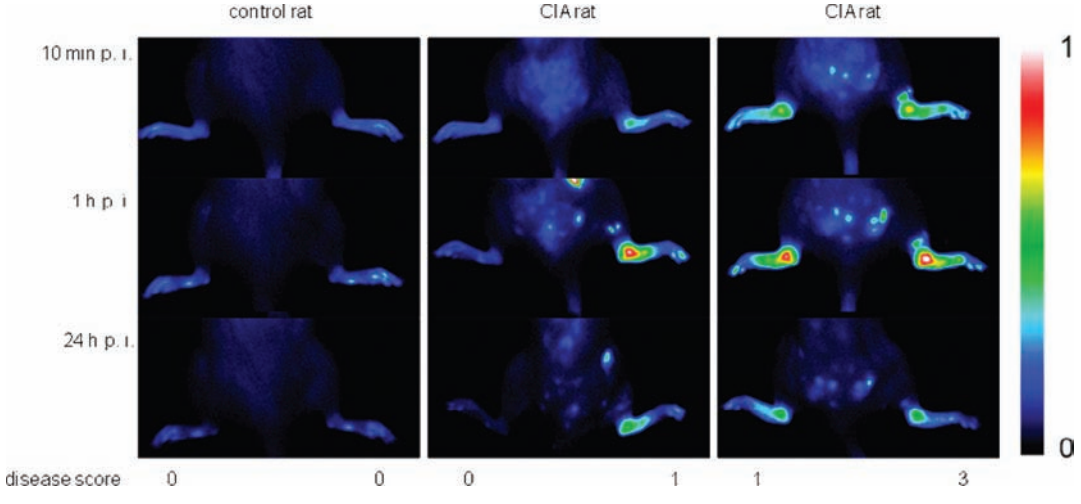

Figure 4. Comparison of fluorescence images in false colors (normalized to a fluorescence reference cube) of a control rat and rats with collagen-induced rheumatoid arthritis (different clinical scores are indicated) after 10 min, 1 h, and 24 h post injection of **6** (4 mg/kg b.w.). One representative example of at least $n = 5$.

Figure 5 illustrates the resulting average signal kinetics of joints of healthy animals, and joints of treated animals, grouped into

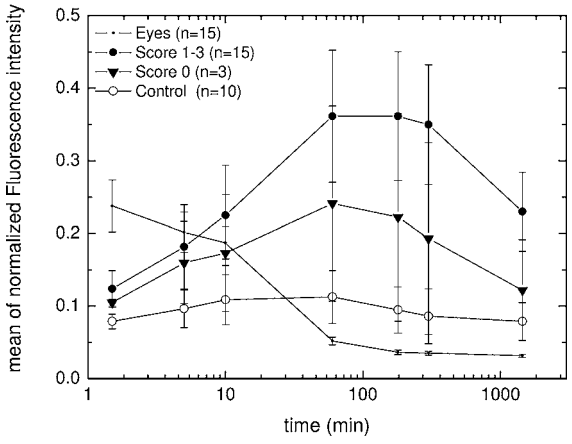

Figure 5. Temporal behavior of means of normalized fluorescence intensity derived from 90th percentiles of ROIs covering the ankle joints and the opened eye of the rats post injection of conjugate **6**. The error bars indicate the single standard deviation derived from the number of measured values *n* (individual joints as independent events).

score 0 and scores 1−3, as well as in the eye. The results show that conjugate **6** generates an almost 3.5-fold signal increase in the affected joint (score 1−3) at the time of maximal intensity at 60 min. Interestingly, for joints of the treated group with no clinical signs (score 0) a 2-fold signal enhancement in comparison to the healthy group can still be calculated (n = 3). Data of fluorescence intensity of ICG derived from ROIs over ankle joints at defined time intervals of each animal group were analyzed employing the Mann−Whitney test for independent samples. At 10 min after bolus injection, the significance of fluorescence intensity values between controls and diseased joints (score 1−3) was calculated (MedCalc, vers. 11.1.0.0) and the two tailored probability yielding $p < 0.0001$. The significance is even more pronounced at later time points, as can be seen from the difference of means in Figure 5. These findings indicate that the molecular targeting of the polyanionic macromolecule is effectively directed to early signs of the disease before clinical manifestation can be evidenced. In fact, the targeting of early signs in joint inflammation, involving the formation of autoantibodies activating macrophages, the release of proinflammatory cytokines, the activation of endothelial cells, and finally the infiltration of inflammatory cells in the articulation,[25] remains a challenge in diagnosis and treatment before clinical manifestation (edema, destruction of cartilage, and bone) occurs.[26]

The fluorescence signal measured over the eye, as a rough estimate for the change of dye concentration in the blood, reaches almost its minimal level at the time of maximal signal in the joints. This allows an explanation of the high and early contrast in the images. Typically, macromolecular targeting for diagnostic imaging purposes might be hampered by long-circulating probe fractions and resulting high signal background, so that the required target-to-blood signal ratios are not sufficiently developed. By employing the eye fluorescence as a provisional solution to monitor blood kinetics, a roughly estimated blood half-life is shorter than 1 h, fast enough for reasonable contrast enhancement.

Histological Examination of Tissues. To enable a postmortem histological recovery of the dPGS conjugate and confirm the *in vivo* imaging data, we analyzed tissues of the tibiotarsal articulation by fluorescence microscopy using the 550 nm channel (Cy3) to excite the ICC dye (Figure 6). No

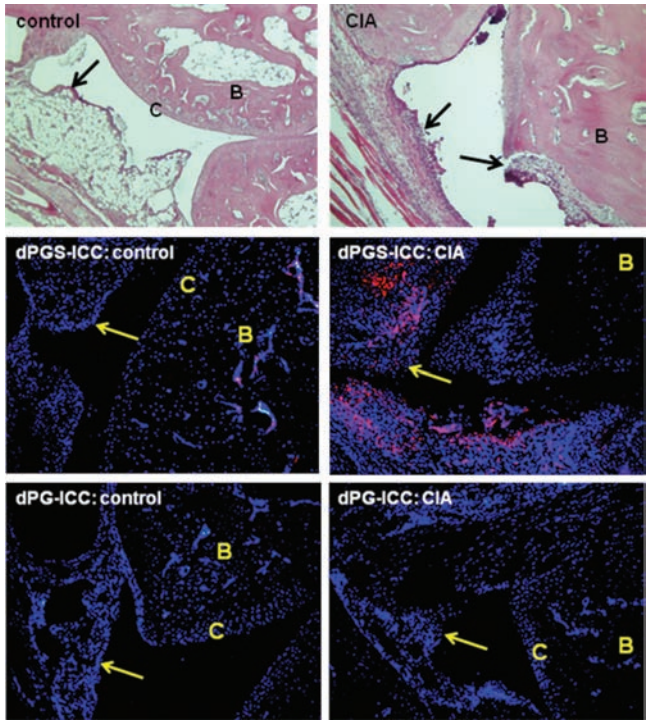

Figure 6. Conventional and fluorescence histology of tissues from tibiotarsal articulation of rats with collagen-induced rheumatoid arthritis (CIA) or healthy controls 3 hs post i.v. injection of dPGS-ICC (**7**) or nonsulfated PG-ICC.[17] Arrowhead: synovial membrane. B: bone. C: cartilage. Nuclear staining with DAPI (blue), compounds in red.

fluorescence signals were detectable in the articulations of healthy animals 3 h post i.v. administration of **7**. In the tissues of rats with CIA, conjugate **7** was enriched in the inflammatory infiltrate in the synovial membrane. The treatment of both control and CIA rats with nonsulfated polyglycerol−ICC conjugate[17] as control did not lead to uptake into the cells of the synovial membrane, thus further supporting the specific targeting behavior of dPGS observed with the near-IR fluorescent version **6** as *in vivo* imaging probe.

■ CONCLUSION

We have demonstrated that dendritic polyglycerol sulfate (dPGS) acts as a novel type of synthetic nanocarrier suited for inflammation-specific molecular imaging. The polymer was readily synthesized by a polymerization and sulfation procedure and conjugated with either a near-infrared dye or a VIS dye to facilitate *in vitro* and *in vivo* detection in disease models. Both conjugates behave similarly regarding its cellular uptake into epithelial cells and macrophages. The specific intracellular localization is yet to be further elucidated with respect to the mechanism involved. Our ongoing work involves studies on uptake possibly via transporter proteins and scavenger receptors into inflammatory cells, as well as the impact of the type of anionic group on cellular interaction.[7] Translation into the diagnostic application was accomplished by *in vivo*

dx.doi.org/10.1021/bc2002727 | *Bioconjugate Chem.* 2011, 22, 2453−2460

fluorescence imaging in a rat arthritis model, demonstrating fast and selective targeting of tissue inflammation and permitting the differentiation of early onset of disease progression. We conclude that dendritic macromolecules provide interesting opportunities beyond the usually employed drug delivery systems with nanoparticles and other high molecular weight systems based on passive targeting. Here, we utilized highly dense anionic charge to impart specific interaction with factors of inflammation, ultimately generating carrier systems for targeted diagnostics and therapeutics.

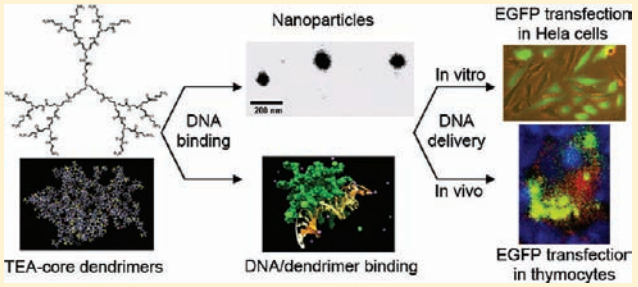
ABSTRACT: With the aim of developing dendrimer nanovectors with a precisely controlled architecture and flexible structure for DNA transfection, we designed PAMAM dendrimers bearing a triethanolamine (TEA) core, with branching units pointing away from the center to create void spaces, reduce steric congestion, and increase water accessibility for the benefit of DNA delivery. These dendrimers are shown to form stable nanoparticles with DNA, promote cell uptake mainly via macropinocytosis, and act as effective nanovectors for DNA transfection in vitro on epithelial and fibroblast cells and, most importantly, in vivo in the mouse thymus, an exceedingly challenging organ for immune gene therapy. Collectively, these results validate our rational design approach of structurally flexible dendrimers with a chemically defined structure as effective nanovectors for gene delivery, and demonstrate the potential of these dendrimers in intrathymus gene delivery for future applications in immune gene therapy.



INTRODUCTION

DNA-based gene therapy and the recently developed small interfering RNA (siRNA)-based gene silencing show great promise as therapeutic approaches for treating and controlling inherited as well as acquired diseases. The main obstacle to successful gene therapy is the lack of safe and effective vectors for nucleic acid delivery. To date, the most efficient vectors are viral; however, these do have fatal drawbacks relating to immunogenicity and toxicity, in addition to practical problems concerning large-scale production and quality control. Therefore, developing safe and efficient nonviral vectors for nucleic acid delivery is urgently needed and of paramount importance for gene therapy.[1−4] Nonviral vectors are noninfectious and elicit only weak immune responses; thus, repeated injections can be used for the treatment of chronic diseases. Other important advantages include their convenient preparation and use, as well as their reasonable manufacturing cost. Their major disadvantage relates to a lower transfection efficiency compared to viral vectors. Therefore, improving the tranfection efficiency of nonviral vectors constitutes the ultimate aim and challenge.

Nonviral vectors are usually divided into two main classes—cationic lipids and polymers.[5] In both cases, the positive charges of the vectors interact with anionic nucleic acids and form stable complexes that protect the nucleic acid from

degradation and promote cell uptake. Among the nonviral vectors, cationic dendrimers, characterized by a unique nanoscale spherical architecture, regular dendritic branching, and radial symmetry, are a special family of polymeric vectors.[6−8] The most extensively studied dendrimers for nucleic acid delivery are poly(amidoamine) (PAMAM) dendrimers,[9−13] which bear primary amines at the dendrimer surface and tertiary amines at the branching units inside.[14,15] Positively charged at physiological pH, these primary amines yield a high charge density at the dendrimer surface, which is responsible for ionic condensation with nucleic acids and binding to the cell surface. After entering the cells through endocytosis, the dendrimer delivery complexes are entrapped in endosomes where they are reported to release DNA into the cytosol via a "proton sponge" effect.[16,17] The released DNA molecules are eventually trapped in the nucleus where transcription can occur.

Paradoxically, DNA transfection with partially degraded and structurally fractured PAMAM dendrimers is 2 orders of magnitude higher than that of nondegraded ones.[13] This could be ascribed to the fact that partially degraded dendrimers are endowed with a more flexible and open structure compared to their intact counterparts, and are thus more accessible for interaction with DNA via both electrostatic interactions and mutual accommodation in space. In addition, the open and flexible structure allows water molecules to pervade the nanovector interior more easily, consequently increasing the availability of the inner tertiary amines for protonation. This, in turn, may result in an enhanced buffering capacity via a proton sponge effect, ultimately leading to more efficient DNA release and hence a better transfection efficiency.

Partially degraded and fractured PAMAM dendrimers are obtained either by thermal degradation or by alkaline hydrolysis of the intact dendrimers. However, these processes cannot offer precise control over structure. In addition, dendrimer synthesis is a time-consuming and painstaking process involving stepwise construction as well as tedious workup for separation and purification. Therefore, deliberately degrading a laboriously synthesized perfect dendrimer is neither satisfactory nor economical, and results in a waste of both manpower and energy. With this in mind, we wished to investigate whether rationally designed genuine (i.e., nondegraded) PAMAM dendrimers with flexible structures might behave similarly to their partially degraded rigid counterparts, thus enabling their use as efficient nanovectors for nucleic acid delivery.

We therefore conceived and synthesized structurally flexible PAMAM dendrimers starting with triethanolamine (TEA) as the dendrimer core (Figure 1A).[18−21] Our rationale for molecular design of structurally flexible dendrimers is rather straightforward: with TEA as the dendrimer core, the branching units start at a distance of 10 successive bonds away from the central amine, whereas the prototype NH_3-core PAMAM dendrimers branch out immediately at the central nitrogen of the NH_3 core.[14] Consequently, TEA-core dendrimers feature an extended core and are expected to be less congested in space, with their branching units and terminal end groups being less densely packed than those of NH_3-core dendrimers. We have previously reported these dendrimers for their efficient interaction with RNA molecules[18,19] and their effective delivery of small interfering RNA molecules.[20−23] However, their structural flexibility and their DNA delivery ability have not been investigated yet. Here, we report that these dendrimers have indeed flexible structure and are also effective nanovectors for DNA transfection in vitro and in vivo in the mouse thymus. It is worth mentioning here that the thymus is an attractive organ for immune gene therapy, as it is the primary site of production of functional T lymphocytes playing a crucial role in adaptive immune responses.[24] Owing to the potential use of an intrathymic gene transfer strategy for immune modulation, it is of primary importance to develop nanocarriers for effective DNA transduction in thymus.[25] Historically, gene transfer in the thymus has been a challenge with respect to efficiency and safety. Intrathymic transfection using viral[26−28] or nonviral[28] vectors or electroporation[29] was previously reported to be either inefficient or technically demanding. The results reported here provide the first experimental evidence that the structurally flexible PAPAM dendrimers are effective nanocarriers for DNA delivery and gene transfer in mouse thymus, which may introduce new perspectives to immune gene therapy via intrathymic dendrimer-mediated DNA delivery.

EXPERIMENTAL PROCEDURES

General. Plasmid DNA containing the luciferase gene was a gift from Prof. Barbara Demeneix (CNRS, Paris, France). EGFP plasmid pEGFP-N1 was purchased from Clontech (Clontech laboratories, Inc. CA, USA). Poly(lysine), ethidium bromide, endocytosis inhibitors (cytochalasin D, genistein, and chlorpromazine), paraformaldehyde, and bovine serum albumin (BSA) were supplied by Sigma (Sigma−Aldrich, Lyon, France). YOYO-1 iodide, endocytosis markers (Alexa-Fluor 647-labeled dextran, transferrin, and cholera toxin B), Alexa-Fluor 647-labeled Phalloidin, DAPI, and Hoechst 34580 were purchased from Invitrogen (Invitrogen Ltd., Paisley, UK). HeLa and $LMTK^-$ cells were grown in MEM with Earle's salt (Eurobio, Paris, France) and supplemented with 10% fetal bovine serum (FBS, Perbio, France), 2 mM Glutamax (Eurobio), 100 units/mL penicillin (Eurobio), and 100 μg/mL streptomycin (Eurobio). Cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere.

NMR DOSY Experiments. DOSY experiments were performed at 300 K on a Bruker Avance spectrometer operating at 500 MHz for the ^{1}H Larmor frequency with a 5 mm triple-resonance inverse Bruker cryoprobe optimized for ^{1}H detection and equipped with an actively shielded *z*-gradient coil. D_2O solutions were prepared at 1 mg mL^{-1} by weighing the proper amount of dendrimer sample directly into the NMR sample tube and adding 0.6 mL of deuterated solvent. Note that the D_2O viscosity was taken as 1.05 cP. The NMR pulse sequence was based on a simulated echo and incorporated bipolar gradients and a longitudinal eddy current delay.[30] Typically, the diffusion time was kept constant at 700 ms and bipolar sine gradient pulses between 0.8 and 2.3 ms were employed. The gradient pulse recovery time and the longitudinal eddy current delay were set to 0.25 and 25 ms, respectively. To determine the weight average molecular weight of the dendrimers, the following procedure was followed. Because the lower generation TEA-core PAMAM dendrimers ($\mathbf{G_1}$−$\mathbf{G_3}$) have well-defined and fully characterized molecular weights, they were selected and used as references in order to obtain the corresponding scaling law (and hence the calibration curve) between the self-diffusion coefficients and the molecular weight of TEA-core dendrimers:

$$D = 5.958 \times 10^{-9} M_w^{-0.468} \quad (1)$$

By using eq 1, the molecular weight of all the TEA-core PAMAM dendrimers (G_1–G_7), including those used to build the calibration curve (G_1–G_3), were subsequently estimated (Figure 1B) from their self-diffusion coefficients D, and the

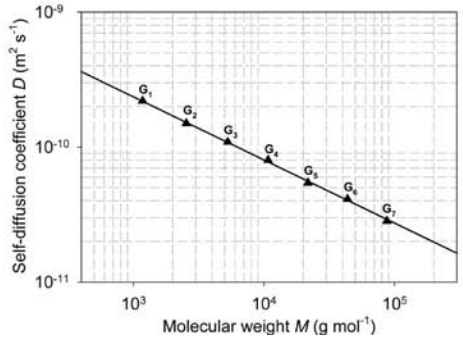

Figure 1. (A) TEA-core PAMAM dendrimer (G_2 was drawn for clarity). (B) General information of the synthesized TEA-core PAMAM dendrimers together with their self-diffusion coefficient D and hydrodynamic radius R_h obtained from DOSY NMR experiments. (C) DOSY-derived self-diffusion coefficient D as a function of the calculated molecular weight M for TEA-core PAMAM dendrimers G_1–G_7 (triangles). The best-fit was obtained as described in the Experimental Section.

results agreed very well (roughly ±5%) with those obtained previously by MS and GPC (Figure 1B).

Potentiometric pH Titration of Dendrimer. The G_5, G_6, or G_7 dendrimer was diluted to a concentration of primary amine of 1.25 mM. pH titration was carried out with 50 mM HCl using a Mettler Toledo 320-S pH meter.

Molecular Modeling. All MD simulations were performed using the *sander* and *pmemd* modules of the AMBER 9 suite of programs,[31] and the new version of the Dreiding force field recently developed by the Goddard group and specifically optimized for dendrimers in water solutions.[32,33] The free energy of binding between the dendrimers and the DNA was calculated according to a previously validated approach[34,35] based on the Molecular Mechanics–Poisson–Boltzmann methodology.[36] Calculations were carried out in parallel on 128 processors of IBM/BCX calculation cluster of the CINECA supercomputer facility, Bologna, Italy. The mesoscopic simulations were carried out with the DPD modulus of *Materials Studio* (v 4.4, Accelrys Inc., USA), according to a multiscale procedure developed by our group.[35]

Preparation of the Plasmid DNA/Dendrimer Complexes. The dendrimers were diluted to an appropriate concentration in 20 mM Tris-HCl buffer (pH 7.6) and 150 mM NaCl, with all solutions stored at 4 °C. The plasmid DNA was diluted to 20 ng/μL in 150 mM NaCl solution. Both solutions were mixed at various N/P (= [total end amines in dendrimer]/[phosphates in DNA]) and incubated at 37 °C for 30 min. The final concentration of plasmid DNA was adjusted to 10 ng/μL.

Gel Retardation Assays of the DNA/Dendrimer Complexes. Each complex (4 μL) containing 250 ng plasmid DNA and the corresponding dendrimer was kept at 37 °C in buffer solution for 30 min before loading on a 0.7% agarose gel in standard TAE buffer for electrophoresis. The DNA bands were stained by ethidium bromide and then detected by a Herolab EASY CCD camera (type 429K) (Herolab, Wiesloch, Germany).

Stability of DNA/Dendrimer Complex Against DNase. An aliquot of 1.8 μg of DNA and the indicated amounts of dendrimers was kept at 37 °C for 30 min. Then, the complexes were incubated in the presence of 1 unit DNase/μg DNA for 0, 5, 10, 20, 30, 45, 60, 75, and 90 min at 37 °C, and aliquots (4 μL) of the corresponding solution containing 200 ng of DNA were withdrawn, added to 0.44 μL 10% SDS solution on the ice, and then subjected to electrophoresis in 1.2% agarose gel in standard TAE buffer. The DNA bands were stained as described above.

Transmission Electron Microscope (TEM) Imaging. Studies were performed with a JEM-1230 electron transmission microscope. Ten microliters of a solution of plasmid DNA (5 ng/μL) were mixed with 10 μL of a solution of dendrimer in 50 mM Tris-HCl buffer (pH 7.4). After equilibration (30 min), 4 μL of this mixture were dropped on a standard carbon-coated copper TEM grid, and then allowed to evaporate (1 h at 30 °C, ambient pressure). The grid was then stained with uranyl acetate (2% in 50% alcoholic solution) for 3 min. Imaging was performed immediately after air–drying for 20 min.

Dynamic Light Scattering Measurement. The plasmid DNA solution was mixed with indicated amount of dendrimer solution at different N/P ratios. The final concentration of the plasmid DNA was 50 ng/μL. After incubating at 37 °C for 30 min, dynamic light scattering (DLS) measurements were performed using Zetasizer Nano-ZS (Malvern, Ltd., Malvern, UK) with a He–Ne ion laser of 633 nm.

dx.doi.org/10.1021/bc200275g | *Bioconjugate Chem.* 2011, 22, 2461–2473

Uptake of DNA/Dendrimer Complexes in HeLa Cells. To evaluate cellular uptake and subsequent intracellular routing of complexes, pCMVLuc was used and labeled with YOYO-1. Briefly, 20 μg of pCMVLuc was mixed with 5 μL of YOYO-1 (80 μM) and incubated at room temperature for 10 min in the dark. One day before use, HeLa cells were seeded at a density of 5×10^4 cells/chamber in 8-well glass chamber slides (Labtek, Nunc, USA). Preparation of the plasmid DNA/dendrimer complexes was performed as described before. Then, the complex containing YOYO-1-labeled plasmid DNA was added to the cells in Opti-MEM transfection medium.

Confocal Microscopy. After incubation for 1.5 h at 37 °C, the cells were washed with PBS and staining with Hoechst 34580. Zeiss LSM 510 Meta laser scanning confocal microscope equipped with inverted Zeiss Axiovert 200 M stand (Carl Zeiss GmbH, Jena, Germany) was used for visualization. Images were acquired using LSM 510 software (Carl Zeiss GmbH, Jena, Germany). For cell uptake in the presence of endocytosis markers, the Alexa-Fluor 647-labeled markers were added during the final 15 min incubation of DNA/dendrimer nanaoparticles prior to nuclear staining with Hoechst. For observation of actin rearrangement, after incubation for 15 min at 37 °C with DNA/dendrimer nanaoparticles, cells were fixed in 4% paraformaldehyde, permeabilized with 0.1% Triton, incubated with 1% bovine serum albumin (BSA), and stained with Alexa-Fluor 647 phalloidin to label actin fibers, then with DAPI to label the nuclei.

Flow Cytometry. The uptake mechanism of the DNA/dendrimer nanoparticles was examined by means of specific inhibitors of different endocytotic pathways. For inhibition experiments, the cells were seeded at a density of 5×10^5 cells in 3.5 cm dishes (Nunc, USA) one day before, then they were incubated with one of following inhibitors: cytochalasin D (to inhibit macropinocytosis), genistein (to inhibit caveolae-mediated endocytosis), or chlorpromazine (to inhibit clathrin-mediated endocytosis) for 1 h in completed medium before the DNA/dendrimer complexes were added. Inhibitors were used at concentrations in which they were not cytotoxic for HeLa cells. After incubation for 15 min at 37 °C with YOYO-1-labeled DNA/dendrimer complex, the cell uptake efficiency was measured using flow cytometry analysis (Beckman Coulter Epics Elite, Beckman Inc., Miami, FL). Each assay was performed in triplicate.

Luciferase Transfection in HeLa Cells. Transfection experiments were carried out using the protocol described previously.[37] Briefly, 24 h before transfection, 5×10^4 HeLa cells were seeded in 24-well tissue culture plates. The desired amount of dendrimer reagent or jetPEI (2 μL per μg of DNA) (Polyplus-Transfetion, Illkirch, France) and 1 μg of pCMVLuc were diluted separately in 50 μL of 150 mM NaCl solution. After 10 min, the transfection reagent solution was added to the DNA solution. The solution was homogenized and left 30 min. Before transfection, cells were incubated with 1 mL of MEM without serum. Then, 100 μL aliquots of pCMVLuc/dendrimer complex solution were added per well and the plates were incubated at 37 °C. After 4 h of incubation, 100 μL aliquots of FBS were added per well and the plates were further incubated at 37 °C for 24 h. Each experiment was done in triplicate.

Luciferase gene expression was measured using a commercial kit (Promega, France). After removing the complete medium, three washings with 1 mL of PBS solution were made. Then, 100 μL aliquots of 1× lysis buffer were added per well, and the plate was incubated at room temperature for 30 min. The lysates were collected and centrifuged at 14 000 *g* for 5 min. The luciferase assay was assessed with 5 μL of lysate after injection of 100 μL of luciferin solution. The luminescence (RLU) was monitored with an integration over 10 s with a luminometer (Berthold, France). Results are expressed as light units integrated over 10 s (RLU), per mg of cell protein using the BCA assay (Pierce, France).

EGFP Transfection in HeLa Cells. In vitro transfection efficiency was evaluated on HeLa cell line using a plasmid containing a reporter gene enhanced green fluorescence protein (EGFP). Cells were seeded into a 24-well plates at a density of 1×10^5 cells per well in 500 μL of complete medium 24 h prior to transfection. After the DNA/dendrimer complexes containing 1 μg of DNA were incubated with cells at 37 °C for 4 h, 50 μL FBS was added. After 48 h, cells were washed in PBS and immediately visualized by using an inverted fluorescence microscope Olympus IX70 equipped with an AxioCam HR digital camera from Carl Zeiss. Images were acquired using *AxioVision* software (Olympus Corp., NY, USA). For quantification, the cells were washed twice with PBS and collected. The fluorescent intensity of positive cells was measured with the flow cytometer (Beckman Coulter Epics Elite, Beckman Inc., Miami, FL).

Effect of Bafilomycin A1. The transfection experiments involving bafilomycin A1 were performed as described above except that the HeLa cells were preincubated with 200 nM bafilomycin A1 at 37 °C for 1 h.

EGFP Transfection in LMTK$^-$ Fibroblasts. Twenty-four hours before transfection, 1×10^4 LMTK$^-$ cells were seeded in 96-well tissue culture plates. The desired amount of dendrimers $\mathbf{G_5}-\mathbf{G_7}$ and DNA plasmid pEGFP-N1 (Clontech) were diluted separately in 50 μL of MEM media. Dendrimers were added to DNA and the solution was homogenized and left for 30 min. Then, 100 μL of pEGFP-N1/dendrimer complex solution was added per well and the plate was incubated at 37 °C. After 4 h, 10 μL of FBS was added per well and the plate was left for 48 h at 37 °C. Cells were visualized under fluorescence microscopy for the observation of EGFP positive cells and transfection efficiency was quantified by *Image-J* software. Cell viability was determined by MTT assay. Each experiment was carried out in triplicate.

EGFP Transfection in Mouse Thymus. C57/BL6 Wild Type (WT) mice (Charles River) were bred and maintained under specific-pathogen-free conditions. All experiments were done in agreement with the French and European ethical rules (authorization number: 13−27). Thymic in vivo gene transfer was performed at 5−6 weeks of age. Animals were anesthetized by intraperitoneal injection with a mixture of ketamine (100 mg/kg body weight; Imalgene 500; Rhone-Merieux) and xylazine (10 mg/kg body weight; Rompun 2%; Centravet). A 20 μL formulation containing 10 μg of pEGFP-N1 or pEGFP/dendrimer complexes prepared in 0.9% NaCl was slowly injected with an insulin syringe in each thymic lobe. Untreated mice were taken as negative control. Animals were kept warm until recovery. After 48 h, mice were sacrificed, and thymi were removed from anaesthetized animals and washed in PBS (1×), then analyzed for EGFP expression by confocal microscopy and flow cytometry.

Western Blot. Proteins were extracted by using the Nuclear Protein Extraction Kit (Panomics). Protein concentrations were measured using the Pierce BCA protein assay. Protein samples were run on SDS polyacrylamide gel (Invitrogen) and transferred to nitrocellulose membranes (BioRad). Incubation with the GFP antibody (1:1000, Roche) was performed

overnight at 4 °C. Mouse polyclonal anti-β-actin was used as loading control (Santa Cruz Biotechnology). Proteins were visualized using horseradish peroxidase-conjugated secondary antibody (1:1000; Amersham Pharmacia Biotech) and the enhanced chemiluminescence (ECL) detection system (Pierce).

Immunofluorescence. To identify the distribution and EGFP cell expression, 12 μm thymic sections were prepared by cryosectioning after embedding the organs in OCT (Sakura Finetech) and mounted on glass slides. Sliced samples were kept in a humidified chamber and were not allowed to dry during staining. Sections were fixed with 4% paraformaldehyde (Sigma Aldrich) in phosphate buffer for 1 h. Frozen sections were stained with anti-CD3 hybridomas (OKT3) (kindly provided by Dr. B. Malissen, CIML, Marseille, France). Alexa 546 goat anti-mouse IgG was used as secondary antibody. As negative control, untreated thymi were used in all experiments. Tissues were counterstained with 4′,6′-diamidino-2-phenylindole (DAPI) at 1 mg/mL and mounted with Mowiol fluorescent mounting medium (Calbiochem). Fluorescent images were acquired by a Zeiss LSM 510 confocal microscope with a 515−525 nm bandpass filter set to view EGFP, a 560 nm long-pass filter set to view Alexa-546, and a 420 nm long-pass filter set to view DAPI. All images were exposed using the same exposure time under the same magnification.

Flow Cytometry. Mice thymi were minced in FACS buffer (PBS 1×, 3% FCS, 0.02 sodium azide) to obtain thymocytes. Cell suspension was filtered through 200 μm nylon mesh and centrifuged at 1500 rpm for 5 min. Precipitated cells were resuspended in FACS buffer. One to two million thymocytes were first incubated with the 2.4G2 hybridoma supernatant to block nonspecific binding of labeled antibodies. Then, cells were stained with a mixture of PE-labeled CD4 and APC-labeled CD8 mAbs (BD Pharmingen). Viable and EGFP positive cells were examined using a FACScalibur flow cytometer and data analyzed with *FlowJo* software (Tree Star, Inc.).

Statistical Analysis. Statistical analysis was performed by a one-way ANOVA test followed by Fisher's protected least significant difference (PLSD) test (Statview 512, Brain Power Inc., Calabases, CA). $p \leq 0.05$ was considered significant (*); $p \leq 0.01$ (**); $p \leq 0.001$ (***).

RESULTS AND DISCUSSION

DOSY NMR Study of TEA-Core Dendrimers. The TEA-core PAMAM dendrimers of generation 1 to 7 ($\mathbf{G_1}$−$\mathbf{G_7}$) were synthesized and characterized in terms of structure and molecular weight as previously described (Figure 1).[18−22] In this work, we further studied their behavior in solution and their sizes and molecular weights using diffusion ordered NMR spectroscopy (DOSY).[38,39] DOSY is based on the pulsed gradient spin echo (PGSE) experiment,[40] which labels the spatial position of the nuclear spins using pulsed magnetic field gradients and allows us to infer the molecular self-diffusion coefficient from their translational displacement over a given time period. Specifically, DOSY[38] allows the self-diffusion coefficient D to be measured, which in turn is related at infinite dilution to the molecular size through the well-known Stokes−Einstein equation

$$D = \frac{kT}{6\pi\eta R_h} \quad (1)$$

where k is Boltzmann's constant, T is the absolute temperature, η is the solvent viscosity, and R_h is the hydrodynamic radius of the molecule (spherical approximation). In addition, DOSY data can be used to estimate the weight average molecular weight of macromolecules,[39] because calibration curves can be established to correlate the self-diffusion coefficient to the molecular weight of macromolecules under specific experimental conditions for a given set of compounds.

The self-diffusion coefficients D obtained for TEA-core dendrimers in D_2O solutions are reported in Figure 1B, together with the corresponding hydrodynamic radius R_h estimated for $\mathbf{G_1}$−$\mathbf{G_7}$ by using eq 1. As can be seen, the higher the dendrimer generation, the smaller the self-diffusion coefficient and the greater the hydrodynamic radius (Figure 1B). This is in line with the molecular construction of PAMAM dendrimers, higher-generation dendrimers displaying a greater weight and a larger size.

The hydrodynamic radii of TEA-core dendrimers as obtained by DOSY experiments were also compared to those reported in the literature for the NH_3-core dendrimers (Table S1 in Supporting Information).[41] Although both types of dendrimers exhibit similar chemical composition and molecular weights, these data showed that TEA-core dendrimers systematically had larger hydrodynamic radii—hence, larger molecular size—than the corresponding NH_3-core dendrimers.[39] Moreover, the difference in size between these two series of dendrimers increased significantly with increasing dendrimer generation, a clear indication that the TEA-core dendrimers assume a more extended conformation in solution. This can be explained by the larger core of the TEA-core dendrimers and by the branching units not directly connected to the focal point of the core, as opposed to NH_3-core dendrimers that exhibit highly compact structures due to the most closely and densely packed branching units. In other words, the molecular structure of TEA-core dendrimers in solution is much less compact than that of NH_3-core dendrimers, which in turn suggests that the former may comparatively possess higher structural flexibility.

We further studied the evolution of the measured self-diffusion coefficients as a function of their molecular weights for TEA-core PAMAM dendrimers. On a double-logarithmic $D = f(M_w)$ plot, all data are perfectly aligned (Figure 1C). Using the corresponding scaling law for TEA-core dendrimers (see Experimental section), we could estimate the molecular weights for dendrimers ($\mathbf{G_1}$−$\mathbf{G_7}$) from their corresponding self-diffusion coefficients D (Figure 1B). The molecular weights obtained in this way for the TEA-core dendrimers parallel the results previously determined by MS and are even closer to the calculated values than the GPC-derived values (Figure 1B).[19,20] This further confirms the quality of the TEA-core dendrimers synthesized in this work.

TEA-Core Dendrimers Have Flexible Structures Favoring Interaction with DNA. We next studied the structural flexibility of the TEA-core dendrimers and their complexes with DNA molecules by computer modeling using atomistic molecular dynamics (MD) and mesoscale simulation techniques. Due to the large size of dendrimers of generation 7 that would lead to extensive calculation and data processing, we performed MD simulations on isolated TEA-core dendrimers of generations 4, 5, and 6 ($\mathbf{G_4}$, $\mathbf{G_5}$, and $\mathbf{G_6}$), NH_3-core dendrimers of generations 4, 5, and 6 ($\mathbf{G_4}'$, $\mathbf{G_5}'$, and $\mathbf{G_6}'$) and their respective complexes with DNA. Here, we focus our comments only on the results obtained with dendrimers of generation 6.

Figure 2A,B shows two equilibrium MD snapshots of G_6 and G_6' respectively, and Figure 2C,D illustrates the superposition of different snapshots taken from their respective MD trajectories. The structural differences between these two dendrimers are blindingly obvious: while G_6 exhibits an open flexible conformation featuring void spaces within its interior (Figure 2A), G_6' is more rigid and compact, with uniformly distributed monomer units and no restricted void spaces in the entire molecule (Figure 2B). The enhanced flexibility of TEA-core dendrimers is well-testified by the wider conformational space visited by G_6 (Figure 2C) during the entire MD simulation with respect to the NH_3-core G_6' counterpart (Figure 2D). It is noted that the presence of hollow spaces in G_6 allows a significantly larger number of water molecules to penetrate into the dendrimer interior with respect to G_6'. This property makes the tertiary amine groups in the dendrimer interior more accessible to water molecules, and therefore more readily available for protonation and subsequent ammonium cation hydration in G_6. This, in turn, may lead to a higher buffering capacity, which was further confirmed by the results of potentiometric titration experiments, as the dendrimers G_5–G_7 displayed flat monotonic titration curves (see Figure 5D).

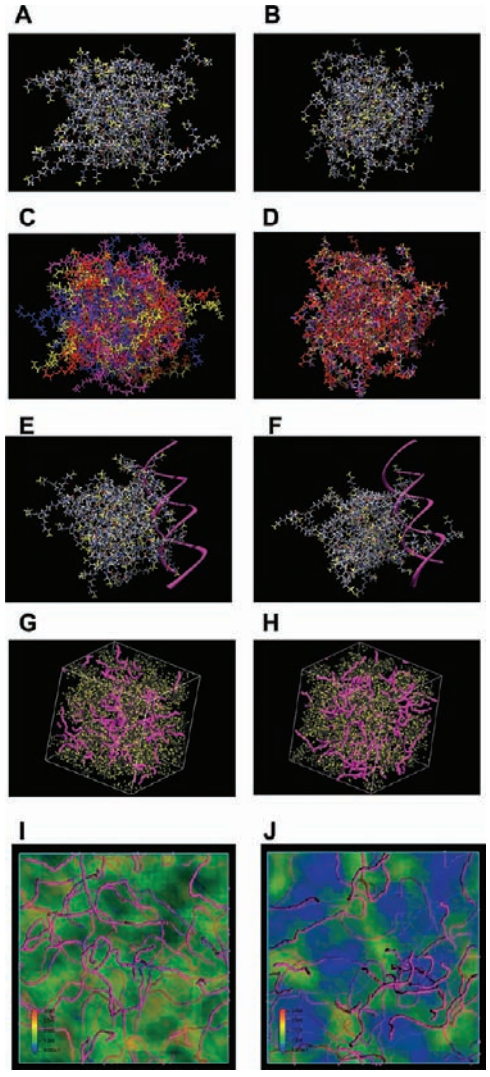

Figure 2. Equilibrium MD snapshots of (A) TEA-core dendrimer G_6 and (B) NH_3-core dendrimer G_6' (In the MD snapshots, dendrimer atoms are portrayed as colored sticks, except for the terminal units, which are portrayed as yellow sticks-and-balls. Atom color code: white, hydrogen; red, oxygen; blue, nitrogen; gray, carbon. Cl^- ions and water molecules have been omitted for clarity). Superposition of different conformations of TEA-core dendrimer G_6 (C) and NH_3-core dendrimer G_6' (D) taken as snapshot along the entire MD trajectory (The different dendrimer conformations are portrayed with different colors, while water and counterions are omitted for clarity). MD snapshots of (E) TEA-core dendrimer G_6 and (F) NH_3-core dendrimer G_6', in complex with a small fragment of double-helix DNA (Dendrimers are depicted as in panels (A) and (B), and DNA is highlighted as a magenta ribbon). Mesoscale morphologies of the self-assembled systems between TEA-core dendrimers G_6 and DNA (G), and NH_3-core G_6' and DNA (H) (The dendrimers are portrayed as gray beads except for the terminal units, which are painted in yellow. The DNA chains are represented as magenta sticks). Panels (I) and (J) highlight the different distribution of DNA and water within the self-assembled DNA/G_6 and DNA/G_6' nanoscopic systems (DNA is portrayed in magenta as in panels (G) and (H), while water is represented as colored density fields: according to the scale reported in the lower left corner of the panels, low density values are blue, while high density values are red).

Additional insightful structural information on DNA/dendrimer complexes was again obtained using atomistic molecular dynamics. The conformation of the TEA-core dendrimer G_6 is such that the outer branches can readily move toward the phosphate backbone of DNA during complex formation, and the surface amino groups can arrange themselves via "induced-fit" for optimal binding with DNA (Figure 2E). This observation is somehow reminiscent of histones undergoing an induced fit conformational change when binding to DNA to form the nucleosome. In contrast, the more rigid and compact structure of the NH_3-core dendrimer G_6' (Figure 2F) prevents this molecule from undergoing significant "induced-fit" conformational readjustment, and consequently, not all terminal amine groups are available to self-orient for optimal DNA binding.

Further evidence for the difference in structural flexibility between these two dendrimer series stem from the mesoscale simulations of their complexes with DNA molecules. A typical result of mesoscale simulation is the morphology and the structure of the matter at nanoscale level at the desired conditions of temperature and composition. Figure 2G,H compares the nanoscale morphology of the DNA/G_6 and DNA/G_6' systems, whereas Figure 2I,J highlights the different distribution of DNA and water within the self-assembled DNA/G_6 and DNA/G_6' nanoscopic systems. In the DNA/G_6 structure, the dendrimers are able to complex the DNA efficiently and homogeneously (Figure 2G,I). On the contrary, for G_6', some DNA chains are less well enwrapped in the system, and DNA bundles are still present (Figure 2H,J). The water density mapping at the mesoscale level also supports the hypothesis of a higher degree of hydration and a more uniform water molecule distribution in the DNA/G_6 system (Figure 2I) with respect to the DNA/G_6' one (Figure 2J). These results are in line with those obtained by MD, demonstrating the easy accessibility of water molecules to the interior of structurally flexible dendrimers.

TEA-Core Dendrimers Form Stable Nanoparticles with DNA and Protect DNA from Degradation. Knowledge of cationic dendrimers to self-assemble with anionic DNA via electrostatic interaction is well-established, and the formation of stable and nanoscale DNA/dendrimer complexes is a prerequisite for efficient cell uptake, intracellular delivery, and transgene expression.

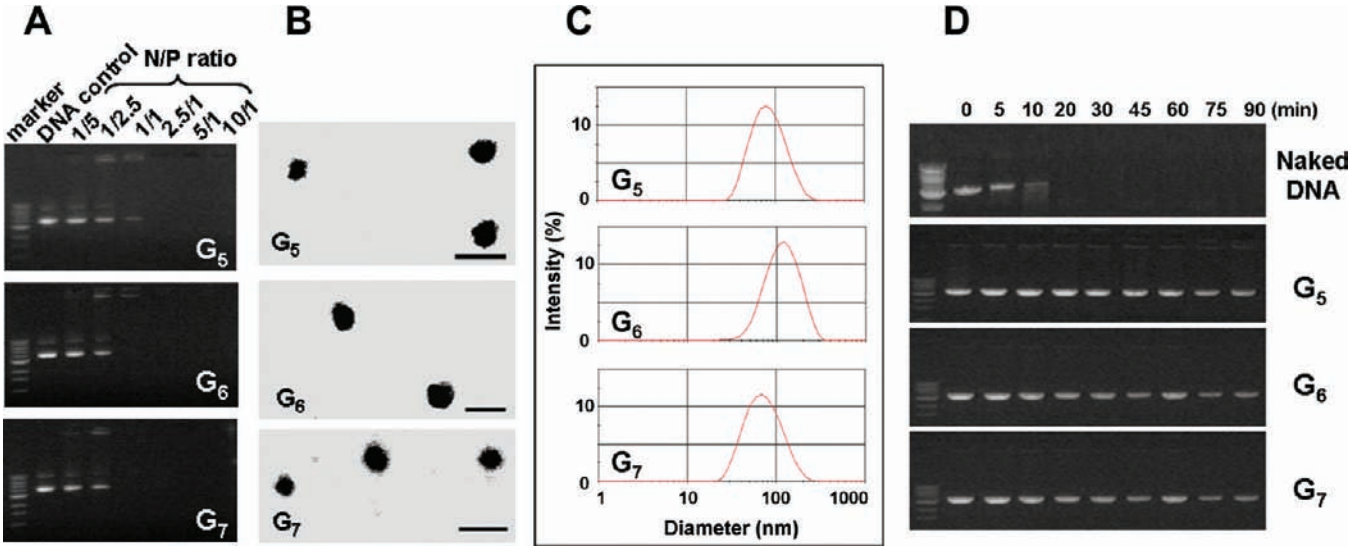

Figure 3. Formation of plasmid DNA/dendrimer complexes as revealed by agarose gel (A), transmission electron microscopy (B), dynamic light scattering (C), and the resulting complexes protect DNA from DNase degradation (D). (A) Migration of luciferase plasmid DNA (250 ng per well) in the presence of G_5−G_7 at charge ratios N/P 1/5−10/1 in 50 mM Tris-HCl buffer pH 7.4. (B) Transmission electron microscopic image of DNA/dendrimer complexes prepared in 50 mM Tris-HCl buffer pH 7.4 using 5 ng/μL plasmid DNA and G_5−G_7 at an N/P ratio of 10. Scale bars represent 200 nm. (C) Light scattering analysis of plasmid DNA/dendrimer complexes prepared using 50 ng/μL plasmid DNA and G_5−G_7 at an N/P ratio of 10. (D) Compared to the naked DNA (200 ng/well), which was degraded within 10 min in the presence of DNase, DNA complexed with G_5−G_7 at an N/P ratio of 2.5 was resistant to DNase and remained stable even after 90 min incubation.

We first studied the complex formation between plasmid DNA and TEA-core dendrimers using gel electrophoresis, a widely used technique for assessing complex formation with nucleic acids. Due to the cooperative electrostatic interactions, cationic dendrimers G_5−G_7 were able to fully condense negatively charged DNA at an N/P ratio above 2.5 (Figure 3A), totally preventing DNA from migration. This suggests the formation of positively charged and stable dendriplexes between dendrimers and plasmid DNA at an N/P ratio ≥2.5. In addition, the complex formation depended on the dendrimer generation: all DNA molecules were complexed with G_7 at N/P = 1,whereas free DNA was observed in trace and considerable amounts with G_6 and G_5, respectively (Figure 3A). This indicates that dendrimers of higher generations form more stable DNA/dendrimer complexes, presumably due to their greater cooperativity and tighter DNA binding domains.[42,43]

The size of the DNA/dendrimer complex is also critical for gene delivery. Due to their compatibility with both extracellular diffusion and endocytosis, small DNA/dendrimer nanoparticles would be an advantage for in vivo experiments. We examined the size and morphology of the DNA/dendrimer complexes using transmission electron microscopy (TEM). Compact, uniform, and nanoscale spherical particles were observed for the DNA/dendrimer complexes using dendrimers G_5−G_7 at N/P ratio of 10, with diameters around 100 nm (Figure 3B). This was further confirmed by dynamic light scattering (DLS), a technique which provides the size, size distribution, as well as surface potential (ζ-potential) of DNA/dendrimer complexes in solution. Results from DLS measurement showed that the DNA/dendrimer complexes have sizes around 100 nm using dendrimers G_5−G_7 at N/P ratios of 10 (Figure 3C). Moreover, ζ-potential measurement gave positive values around +30 mV for the DNA/dendrimer complexes. Taken together, these results demonstrate that the structurally flexible TEA-core PAMAM dendrimers readily condense plasmid DNA into compact and stable colloidal nanoparticles.

We then verified the ability of the DNA/dendrimer nanoparticles to protect DNA against enzymatic degradation. As shown in Figure 3D, naked DNA was completely digested by DNase within 10 min, whereas DNA complexed with dendrimer G_5−G_7 remained intact even after 90 min incubation with the DNase. This result demonstrates that the dendrimer nanoparticles effectively protect DNA from enzymatic degradation, which is a basic prerequisite for efficient DNA delivery.

Cell Uptake of DNA/Dendrimer Nanoparticles Mainly via Macropinocytosis. Cell uptake of DNA/dendrimer nanoparticles is one of the early events in gene delivery. We studied the internalization of DNA/dendrimer complexes in HeLa cells using live cell confocal microscopy with green fluorescent dye YOYO-1 labeled DNA. The green fluorescent DNA/G_6 nanoparticles were effectively internalized in the cells (Figure 4A), whereas no green particles could be observed in the absence of dendrimer under the same experimental conditions (data not shown). Consequently, the effective cell uptake of negatively charged DNA is unambiguously mediated by the cationic dendrimer which acts as nanocarrier.

It has been reported that several pathways can drive cell uptake of nanoparticles with sizes around 50−300 nm, such as macropinocytosis, clathrin-mediated endocytosis, and caveolae-mediated endocytosis.[44−49] We therefore used specific inhibitors and biomarkers of various endocytotic pathways to distinguish which pathway is taking DNA/dendrimer nanoparticles into cells. As illustrated in Figure 4B, cytochalasin D, a macropinocytosis inhibitor, reduced the cell uptake of DNA/G_6 in a dose-dependent manner. Genistein, an inhibitor specifically involved in caveolae-mediated endocytosis, had no notable inhibitory effect on cell uptake; whereas chlorpromazine, a specific inhibitor of clathrin-mediated endocytosis, led only to a slight uptake decrease. In addition, the YOYO-1 labeled DNA colocalized with a macropinocytosis marker dextran but not with transferrin or cholera toxin B (Figure 4C), markers of clathrin- and caveolae-mediated endocytosis, respectively.

dx.doi.org/10.1021/bc200275g | Bioconjugate Chem. 2011, 22, 2461−2473

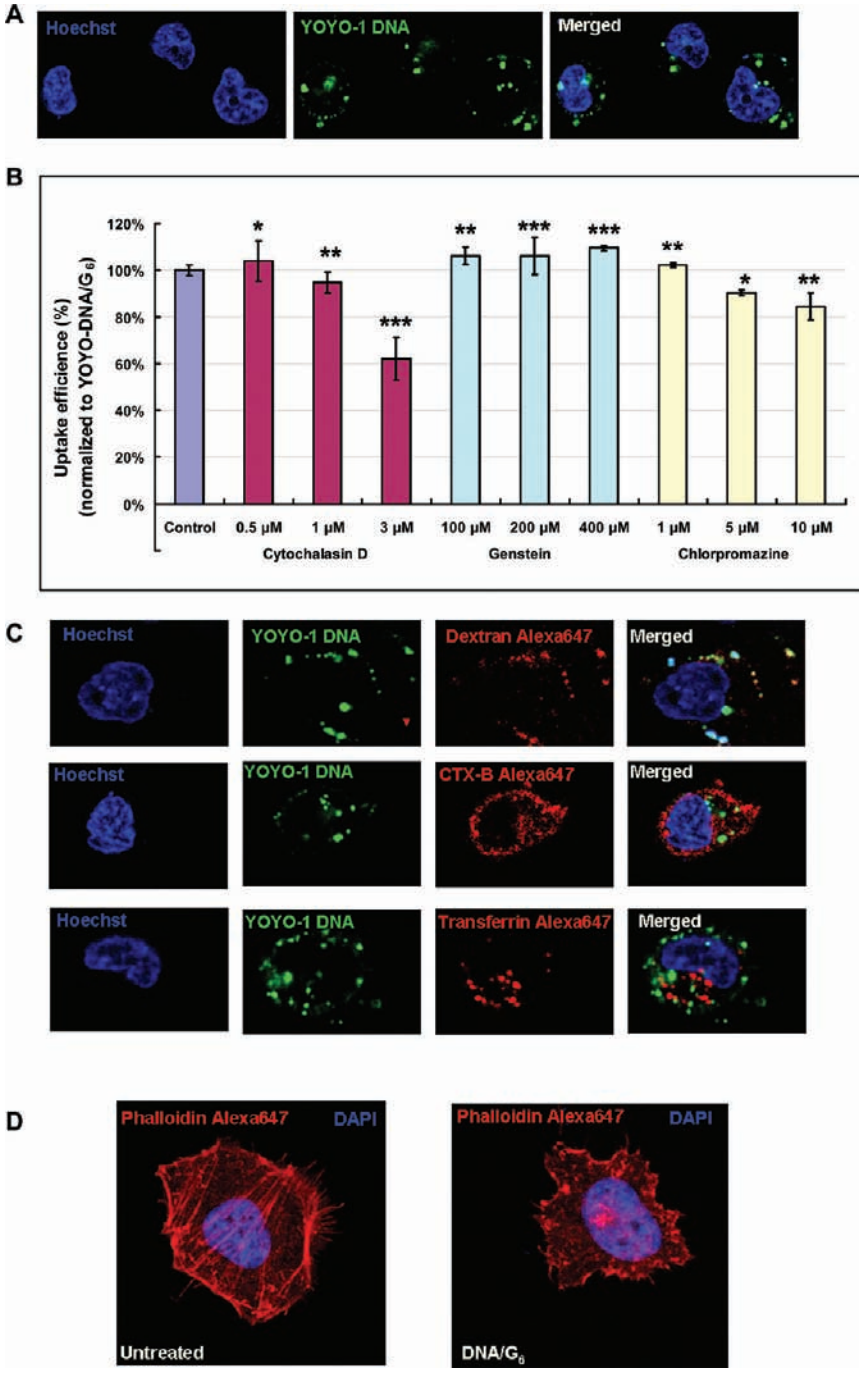

Figure 4. Uptake of YOYO-1-labeled DNA/$\mathbf{G_6}$ complexes in HeLa cells analyzed by live-cell-confocal microscopy (A), using specific inhibitors (B), and fluorescent endocytosis markers (C) of different uptake pathways and phalloidin probe for actin rearrangement (D). (A) Green channel image of the YOYO-1-labeled DNA/$\mathbf{G_6}$ nanoparticles, blue channel image of the nuclei of HeLa cells stained by Hoechst 34580, and merged image of both. (B) Effect of cytochalasin D (to inhibit macropinocytosis), genistein (to inhibit caveolae-mediated endocytosis), and chlorpromazine (to inhibit clathrin-mediated endocytosis) on the cell uptake of the YOYO-1-labeled DNA/$\mathbf{G_6}$ complexes on HeLa cells. (C) Cell uptake of YOYO-1-labeled DNA/$\mathbf{G_6}$ complexes in the presence of different endocytosis markers: dextran (marker of macropinocytosis), cholera toxin B (marker of caveolae-mediated endocytosis), and transferrin (marker of clathrin-mediated endocytosis). (D) Fluorescent labeling of actin fibers using phalloidin reveals actin depolymerization, a hallmark of macropinocytosis. *, ** and ***, differ from control ($p \leq 0.05$, $p \leq 0.01$ and $p \leq 0.001$ respectively) by Student's t test.

Furthermore, actin depolymerization, a hallmark of macropinocytosis, was observed after the application of the DNA/$\mathbf{G_6}$ particles using phalloidin marker (Figure 4D). Altogether, these results clearly demonstrate that macropinocytosis is the major uptake pathway.

Effective DNA Transfections in Vitro. For dendrimer-mediated DNA transfection in vitro, we first evaluated the luciferase gene expression in HeLa cells. Significant luciferase expression was obtained with dendrimers $\mathbf{G_5}$, $\mathbf{G_6}$, and $\mathbf{G_7}$ (Figure 5A), whereas the lower-generation dendrimers $\mathbf{G_1}$–$\mathbf{G_4}$ yielded dramatically reduced expression (data not shown). Moreover, DNA transfection was dependent on the N/P charge ratio. The most efficient gene transfection was observed with $\mathbf{G_6}$ at an N/P ratio of 10, with the efficiency being almost

dx.doi.org/10.1021/bc200275g | Bioconjugate Chem. 2011, 22, 2461–2473

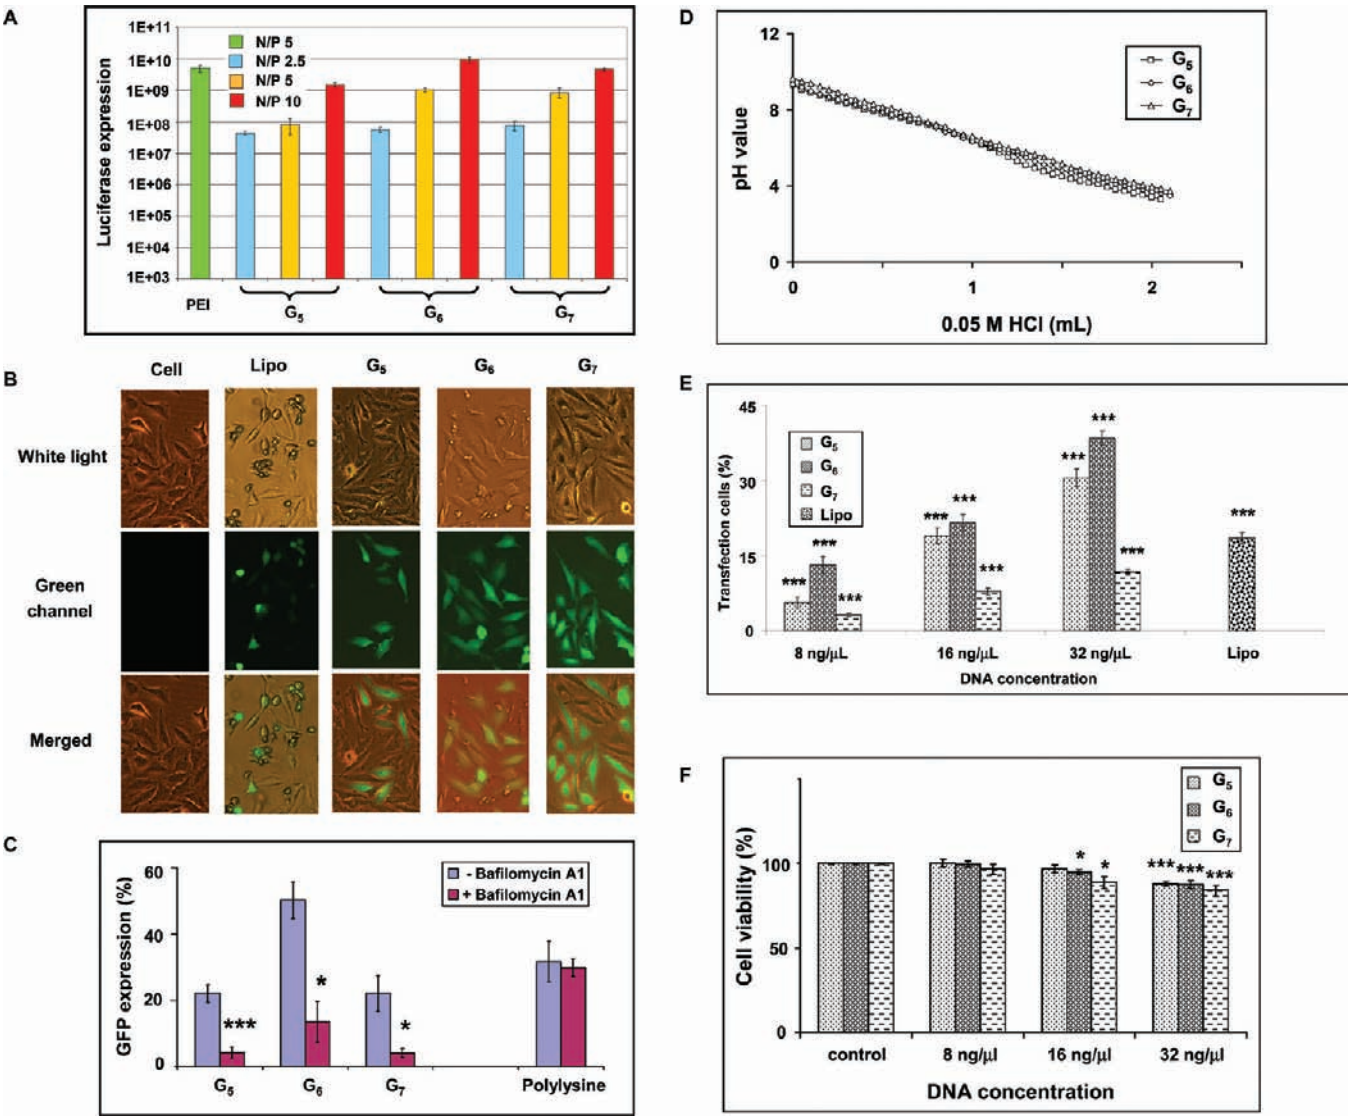

Figure 5. (A) Luciferase transfection in HeLa cells using TEA-core dendrimers G_5−G_7 as vectors (at various N/P ratios) and 1 μg of pCMVLuc plasmid. Luciferase activity was determined 24 h after transfection and expressed as RLU/mg protein of cell lysates. (B) Images of EGFP transfected HeLa cells using G_5−G_7 as vectors and 1 μg pEGFP-N1 plasmid at an N/P ratio of 10, compared to nontreatment control and cells treated with DNA/Lipofectamine complexes. 2-fold higher than that of poly(ethylene imine) (PEI), one of the most effective nonviral transfection reagents available to date.[16] It should be mentioned here that the thermally degraded fractured PAMAM dendrimers have a transfection activity similar to that of PEI.[9] We also compared the transfection efficiency of the TEA core dendrimer with the commercially available structurally rigid ethylenediamine (EDA) core dendrimer (Figure S1 in Supporting Information). Our results confirmed that TEA core dendrimer is more efficient for DNA transfection than the corresponding EDA-core dendrimer. With all the results presented here, we conclude that genuine (i.e., nondegraded), structurally flexible TEA-core dendrimers having precisely controlled structures are effective nanovectors for DNA transfection, with efficiencies similar or superior to PEI and hence to fractured PAMAM dendrimers.

In order to further assess the transfection efficacy in individual cells, we carried out assays for enhanced green fluorescent protein (EGFP) expression in HeLa cells using mock-transfected cells as negative control and Lipofectamine as a positive control (Figure 5B). Lipofectamine is one of the most commonly used lipid vectors, characterized also by its well-known cytotoxicity. Under our experimental conditions, most HeLa cells died after treatment with DNA/Lipofectamine; whereas G_5−G_7 dendrimers led to excellent EGFP expression, particularly G_6 being the most efficient vector, with a level of transfection up to 60%.

The above transfection results perfectly correlate with those previously obtained with fractured and degraded PAMAM dendrimers,[13] namely, that only higher-generation dendrimers mediate effective transfection. These higher-generation dendrimers contain larger DNA binding regions,[42,43] thus creating stronger interactions between DNA and dendrimer via

dx.doi.org/10.1021/bc200275g | Bioconjugate Chem. 2011, 22, 2461−2473

cooperative amplification. However, interactions that are too strong between DNA and dendrimer may prevent DNA release from complexes, thereby compromising transfection efficiency. This may explain why $\mathbf{G_6}$ has the best transfection efficiency compared to both the lower-generation dendrimer $\mathbf{G_5}$ and the higher-generation dendrimer $\mathbf{G_7}$.

We further examined whether the buffer-based endosomolytic activity plays an important role using bafilomycin A1. Bafilomycin A1 is a proton pump inhibitor and selectively inhibits vacuolar H^+-ATPase and prevents acidification of endosomes. Figure 5C shows a significant decrease of EGFP expression level in HeLa cells in the presence of bafilomycin A1 for dendrimer-mediated DNA delivery, suggesting that dendrimer-mediated DNA transfection was dependent on the endosomal acidification process. This is in line with the structural features of TEA-core PAMAM dendrimers, which harbor a large number of tertiary amines in the interior able to produce a robust buffer capacity and proton sponge effect for endosomal release. Additional support for this hypothesis comes from the result obtained from the pH titration experiment (Figre 5D) where indeed the dendrimers $\mathbf{G_5}$–$\mathbf{G_7}$ displayed flat titration curves, an indication of high buffer capacity. Since we had no NH_3-core PAMAM dendrimers available in our hands as a control, we then asked whether poly(lysine), which contains only primary amine groups and has been reported to be devoid of proton-sponge effect, could be used as a negative control. We therefore determined poly(lysine)-mediated EGFP expression in HeLa cells in the presence and absence of bafilomycin A1 (Figure 5C). As expected, there was no notable change of EGFP expression in the presence of bafilomycin A1, suggesting the absence of proton-sponge effect in poly(lysine)-mediated DNA transfection. These results demonstrate unambigously that the "proton-sponge" effect played an important role for our dendrimer mediated DNA transfection.

We next performed assays for EGFP expression in mouse fibroblast $LMTK^-$ cells. $LMTK^-$ fibroblasts are known to be difficult to transfect using nonviral vectors. Gratifyingly, our dendrimers $\mathbf{G_5}$–$\mathbf{G_7}$ led to effective EGFP expression (Figure 5E). The highest tranfection efficiency was achieved again using $\mathbf{G_6}$ at N/P = 10, with a transfection level of up to 40%, better than the commercial transfection reagent lipofectamine (Figure 5E). Under the serumless transfection conditions used, no significant toxicity was observed for $\mathbf{G_5}$–$\mathbf{G_7}$ (Figure 5F). The transfection efficiency was decreased in the presence of 10% serum in the transfection medium (Figure S2 in Supporting Information). This observation may limit their in vivo applications via systemic administration but much less by direct injection (vide infra).

Efficient DNA Transfection in Vivo via Intrathymic Injection. We further evaluated in vivo DNA transfection in the mouse thymus as a model. We used both $\mathbf{G_6}$ and $\mathbf{G_7}$ for the in vivo delivery of the EGFP plasmid as a proof-of-concept, since $\mathbf{G_6}$ showed the best DNA tranfection efficiency in vitro, whereas $\mathbf{G_7}$ was successfully used in siRNA delivery in various systems.[20−22] In addition, the DNA complexes with $\mathbf{G_6}$ and $\mathbf{G_7}$ were more stable and retained their size and surface potential values even at high salt concentration (Table S2 in Supporting Information). It should be mentioned that our dendrimers have reduced transfection efficiency in the presence of serum (Figure S2 in Supporting Information); we therefore sought to employ means that do not depend on blood circulation to reach the target organ. We thus chose direct intrathymic injection of DNA/dendrimer complexes.

In vivo DNA transfection experiments were carried out on C57/BL6 WT mice. Mice were first anesthetized, and a volume of 20 μL (containing 10 μg EGFP plasmid complexed with dendrimer at N/P ratio of 10) was then slowly injected into each thymic lobe. All mice survived well during and after the intervention; no signs of toxicity were observed. Strong EGFP expression in the thymi following injection of DNA/dendrimer complexes was revealed by Western blot analysis using an antibody against EGFP (Figure 6A), whereas only weak EGFP levels were detected following naked DNA injection. Therefore, the observed high expression of EGFP in mice thymi is a direct consequence of dendrimer-mediated DNA delivery.

We next examined the transfected thymi by confocal microscopy (Figure 6B). Untreated mice exhibited no EGFP signal (control in Figure 6B); mice with naked DNA injection showed a very weak EGFP signal, whereas EGFP expression mediated by $\mathbf{G_6}$ was significantly stronger (Figure 6B). In addition, costaining analysis with the CD3 thymocyte marker showed a colocalization with the green EGFP signal within these thymocytes (Figure 6B and enlarged in Figure 6C). Consequently, these results demonstrate an efficient and effective dendrimer-mediated DNA transfection in mouse thymus, specifically in thymocytes.

We further analyzed EGFP expression in the different subpopulations of thymocytes. It is known that thymocyte differentiation can be divided into three major stages defined by the expression of CD4 and CD8 markers. The most immature or double-negative stage is characterized by the lack of expression of CD4 and CD8 markers ($CD4^-CD8^-$, double-negative, DN). Double negative cells progress to a stage where there is expression of both CD4 and CD8 markers ($CD4^+CD8^+$, double-positive, DP) before lineage commitment to single-positive (SP) cells which express either CD4 (SP $CD4^+$) or CD8 (SP $CD8^+$) marker. We therefore immunophenotyped EGFP expression within the four main thymocyte subpopulations, namely, $CD4^-CD8^-$ double-negative (DN), $CD4^+CD8^+$ double-positive (DP), $CD4^+$ and $CD8^+$ single-positive (SP) (Figure 6D). We found high percentages of transfection (25.1% of DN, 1.59% of DP, 1.20% of SP $CD4^+$, and 6.96% of SP $CD8^+$ cells) in mice thymi treated with injection of DNA/dendrimer complexes. As expected, no signal was detected in untreated mice thymi, nor was any notable EGFP expression observed in mice thymi treated with naked DNA injection. This finding strongly confirms transgene expression to be a direct consequence of dendrimer-mediated DNA delivery. Finally, it is to be noted that the DN thymocytes were preferentially transfected. This is because immature DN thymocytes undergo rapid proliferation, and therefore lead to higher transfection with respect to the other three subpopulations. Additionally, notable transfection was also observed with more mature SP $CD8^+$ cells, which are considered relatively quiescent. Collectively, our results demonstrate that the structurally flexible TEA-core PAMAM dendrimers studied in this work are safe and effective nanovectors for intrathymic DNA delivery and gene expression. To our knowledge, this is the first experimental evidence that dendrimers could act as efficient nanovectors for DNA transfection in mouse thymus, opening new avenues for future applications of dendrimer-mediated gene therapy for both inherited and acquired immunodeficient diseases.

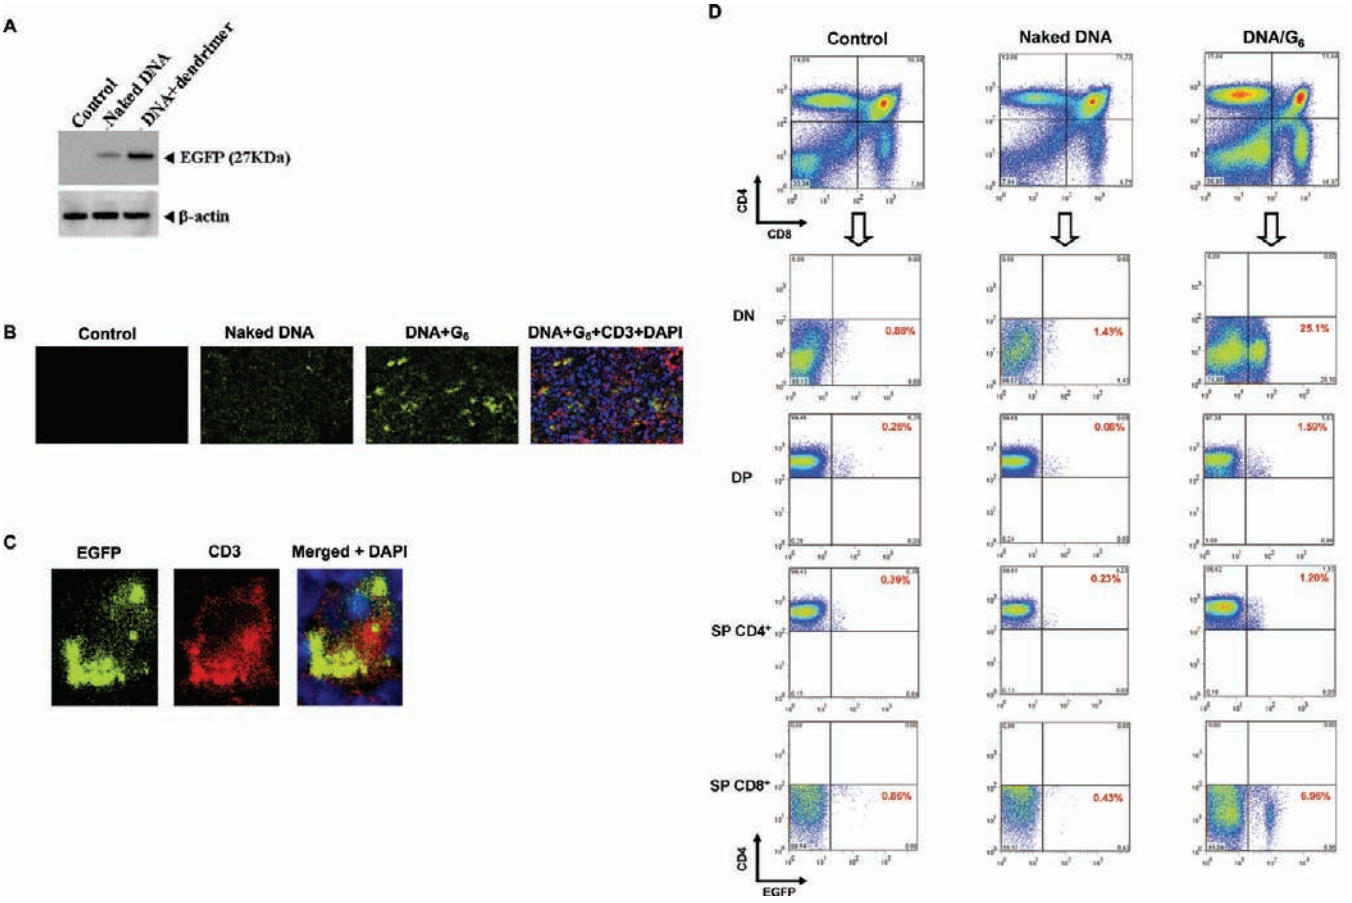

Figure 6. In vivo EGFP expression in thymi was assessed by Western blot (A), immunofluorescence (B and C) and flow cytometry (D). (A) Western blot analysis of EFGP protein expressed in mice thymi in the presence and absence of dendrimer compared to nontreated control. (B) The EGFP fluoresence was analyzed using confocal microscopy with thymi sections derived from mice that were nontreated (control), injected with naked DNA, or injected with DNA/dendrimer complexes: nuclei appear as blue (DAPI staining) and thymocytes as red (anti-CD3 antibody labeling). (C) Enlarged image showing EGFP transfected thymocytes costained with anti-CD3 antibody (red) and DAPI (blue for nuclei laebling). (D) Thymocyte profile stained with CD4 and CD8 monoclonal antibodies was analyzed by flow cytometry 48 h after injection. The percentage of each population of thymocytes is indicated within each quadrant. The different populations of thymocytes expressing EGFP protein were analyzed for thymi derived from mice that were nontreated (control), injected with naked DNA, and injected with DNA/$\mathbf{G_6}$ complexes, respectively. The percentage of EGFP transfected cells is indicated in red within the quadrant of each population. DN: $CD4^-CD8^-$ double-negative cells; DP: $CD4^+CD8^+$ double-positive cells; SP $CD4^+$: single-positive cells which express CD4 marker; SP $CD8^+$: single-positive cells which express CD8 marker.

CONCLUSION

We have developed triethanolamine (TEA) core PAMAM dendrimers as structurally flexible nanovectors for nucleic acid delivery. As shown in the present work, these dendrimers have greater structural flexibility and a more open conformation with void spaces in the interior. They self-assembled with DNA molecules into nanoparticles via an "induced fit" process, resembling histone/DNA interaction in nature. The resulting DNA/dendrimer nanoparticles could effectively protect DNA from degradation and facilitate cell entry mainly via macropinocytosis. Furthermore, due to their open and void structure, these dendrimers are well-adapted to act as 3D protons sponges per se with easier access of water molecules inside the dendrimer interior and leading to increased protonation of interior tertiary amines. This enhances the buffering capacity thus benefiting DNA endosome release. Fulfilling our expectations, these dendrimers were efficient nanovectors for gene delivery in vitro to transfection-resistant fibroblasts as well as in vivo to the mouse thymus, an extremely challenging organ for DNA transfection.

It has been previously reported that the thermally degraded fractured PAMAM dendrimers have an activity similar to PEI.[9] Our results demonstrate that genuine (i.e., nondegraded), structurally flexible dendrimers with precise structural features also are effective nanovectors for DNA transfection, with efficiencies similar or superior to PEI and hence to fractured PAMAM dendrimers. The experimental results presented here, coupled with computer-aided molecular simulations, provide evidence for the development of functional dendrimers for DNA transfection using rational design of structurally flexible dendrimers.[50−52] Compared to random thermal or alkaline degradation, a process which does not allow precise control over the structure, rational design based synthesis allows the development of dendrimer nanovectors with a defined yet flexible structure. Consequently, these dendrimers have a higher potential of becoming vectors for nucleic acid-based therapies in general.

It is important to note that these dendrimers are particularly effective in delivering and expressing a gene in the thymus. The thymus is an attractive organ for immune gene therapy, and yet,

dx.doi.org/10.1021/bc200275g | Bioconjugate Chem. 2011, 22, 2461−2473

gene transfer in the thymus is exceedingly challenging with respect to efficiency and safety. Previous work on intrathymic transfection using viral[26−28] and nonviral[28] vectors as well as electroporation[29] was either inefficient or technically demanding. We demonstrate here for the first time that the structurally flexible PAPAM dendrimers could effectively deliver DNA and reach a high level gene expression in the mouse thymus. Therefore, structurally flexible dendrimer-mediated gene transfer is a promising tool for further development of strategies aimed at immune gene therapy via intrathymic DNA delivery. In addition, as these dendrimers are also efficient nanovectors for siRNA delivery in vitro and in vivo,[20−22] they hold great potential for both in vitro (functional genomics) and in vivo (therapeutic) applications of nucleic acid delivery in general. Last but not least, structure-controlled, size-tailored dendrimers should provide useful tools for use in various applications in biotechnology such as targeted drug delivery systems and drugs based on mimicking the functions of certain natural biomacromolecules.[53]

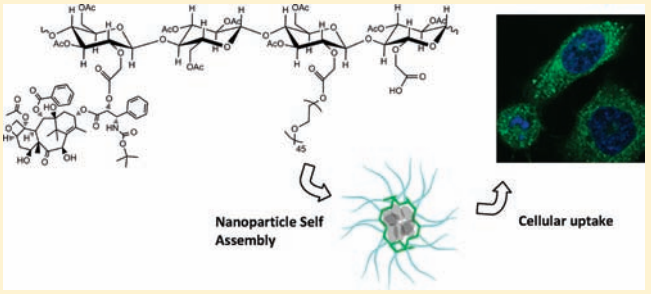
Synthetic Modification of Carboxymethylcellulose and Use Thereof to Prepare a Nanoparticle Forming Conjugate of Docetaxel for Enhanced Cytotoxicity against Cancer Cells

Mark J. Ernsting, Wei-Lun Tang, Noah MacCallum, and Shyh-Dar Li*

Drug Delivery and Formulation Group, Medicinal Chemistry Platform, Ontario Institute for Cancer Research, 101 College Street, Suite 800, Toronto, Ontario, M5G 0A3, Canada

ABSTRACT: A nanoparticle formulation of docetaxel (DTX) was designed to address the strengths and limitations of current taxane delivery systems: PEGylation, high drug conjugation efficiency (>30 wt %), a slow-release mechanism, and a well-defined and stable nanoparticle identity were identified as critical design parameters. The polymer conjugate was synthesized with carboxymethylcellulose (CMC), an established pharmaceutical excipient characterized by a high density of carboxylate groups permitting increased conjugation of a drug. CMC was chemically modified through acetylation to eliminate its gelling properties and to improve solvent solubility, enabling high yield and reproducible conjugation of DTX and poly(ethylene glycol) (PEG). The optimal conjugate formulation (Cellax) contained 37.1 ± 1.5 wt % DTX and 4.7 ± 0.8 wt % PEG, exhibited a low critical aggregation concentration of 0.6 μg/mL, and formed 118−134 nm spherical nanoparticles stable against dilution. Conjugate compositions with a DTX degree of substitution (DS) outside the 12.3−20.8 mol % range failed to form discrete nanoparticles, emphasizing the importance of hydrophobic and hydrophilic balance in molecular design. Cellax nanoparticles released DTX in serum with near zero order kinetics (100% in 3 weeks), was internalized in murine and human cancer cells, and induced significantly higher toxic effects against a panel of tumor cell lines (2- to 40-fold lower IC50 values) compared to free DTX.



INTRODUCTION

The taxanes paclitaxel (PTX) and docetaxel (DTX) are common cancer therapy agents with a broad spectrum of antitumor activity, and are currently formulated with Cremophor EL/ethanol/saline[1] and Tween80/ethanol/saline, respectively, due to their water insolubility, each of which causes hypersensitivity reactions, requiring premedication regimes.[2,3] DTX is replacing PTX in clinical applications due to enhanced action,[4] and reports on polymeric formulations of DTX are indicating that the drug can be more effectively and safely delivered.[5−7] The use of polymers to improve solubility, pharmacokinetics (PK), pharmacodynamics (PD), bioavailability, efficacy, and toxicity profiles is commonly defined as polymeric therapeutics, and is a thriving field of study.[8−10] It has been demonstrated that soluble macromolecules with molecular weights (MW) above 40 kDa circulate longer than small molecule drugs in the bloodstream due to reduced renal clearance.[11,12] Further, Matsumura and Maeda observed that tumor vasculature is highly permeable, and that high MW polymers or nanoparticles can selectively accumulate in these tissues as a result.[13] Neovascular structures in malignant tissues tend to contain gaps through which <400 nm particles can extravasate,[14,15] and furthermore, lymphatic drainage in tumors is usually absent: particles can readily enter but not exit the tumor compartment.[16−18] The enhanced permeability and retention (EPR) effect provides significant motivation to develop polymer therapeutics, and has also given rise to nanomedicine, where structures comprising liposomes,[19−21] polymeric micelles,[22−24] polymersomes,[25−27] and dendrimers[28−30] can effectively deliver drug through this passive targeting effect.[31] However, polymers and particles can be readily opsonized and cleared in the reticulo-endothelial system (RES, bone marrow, liver, and spleen), reducing the effectiveness of these delivery systems.[19,32] PEGylation of a polymer or nanoparticle can reduce interaction of opsonins with the underlying chemistry through steric hindrance and reduction of hydrophobic and electrostatic interactions, minimizing clearance of the particle in the RES.[19,33−36]

Hydrophobic drugs such as PTX can be loaded non-covalently in nanoparticle formulations. Notable within this field are the PEG-PLA micelles (Genexol, now in phase II clinical trials)[37] and NK105, a PEG-aspartic acid formulation.[23] Both formulations improve upon administration of PTX through elimination of the Cremophor-based delivery vehicle, which causes hypersensitivity issues in human patients,[19] and by enabling treatment with an increased dose to improve efficacy. In comparison to Genexol and NK105, Opaxio (also known as Xyotax and Poliglumex) is a PTX−polyglutamate conjugate.

The PK profiles of PTX (Taxol), NK105 (micelle), Genexol (micelle), and Opaxio (conjugate) have been compared, and half-lives were measured to be 13.3, 10.6, 11.4, and 120 h, respectively, in humans.[22,38] As hydrophobic drugs such as PTX and DTX rapidly partition from micelles to plasma proteins, depleting the nanoparticles of drug content,[39] conjugation of taxanes to the polymeric carrier to control release can be desirable.[40,41] The PK profiles of NK105 and Genexol were nearly identical to that of free PTX, whereas the Opaxio polymer conjugate was the only mode by which PK was substantially improved. Although the toxicity of PTX was substantially reduced with Opaxio in preclinical models, hypersensitivity is reported as one of the dose-limiting toxicities in clinical trials,[42] which might arise due to the polymer. Furthermore, Opaxio is not PEGylated, and 24 h postinjection was completely cleared from the blood circulation in mice.[43] The polyglutamate polymer chain is also hydrolytically labile, and is known to break down rapidly into lower MW fragments, leading to significant accumulation of PTX-containing identities in the kidney, heart, and lungs in addition to tumor and liver accumulation.[43] This nonspecific biodistribution may contribute to Opaxio's toxicity.

Developing a biocompatible polymer backbone with a good safety profile for drug delivery remains challenging. Polysaccharides have potential due to their known safety profiles and use as excipients in a variety of pharmaceutical products. Certain classes of polysaccharides are approved as excipients for oral, transcutaneous, and parenteral drug administration (FDA inactive ingredients database),[44] but when referenced against the synthetic polymer field, little work has been done with these biocompatible polysaccharides in the contemporary nanoparticle drug delivery field.[45−48] Cera et al. conjugated doxorubicin and daunomycin to carboxymethylcellulose (CMC) and hyaluronic acid (HA), and reported that these compounds were toxic to cells *in vitro*, but with lower potency compared to the free drug. In addition, the degree of CMC acid group substitution with doxorubicin was low (DS 9 mol %).[49] Uglea et al. conjugated benzocaine to CMC (DS >50 mol %) and oxidized CMC, and tested the effects of these polymers on s.c. sarcoma tumors in rat models, and reported moderate antitumor effect from a single i.p. injection.[50] Auzenne et al. conjugated PTX to HA (DS 10 mol %), and performed *in vitro* and *in vivo* efficacy assays.[51] Mice were implanted with ovarian carcinoma xenografts in the peritoneal cavity, and were treated with an intraperitoneal injection of 200 mg/kg PTX-HA, a treatment which effectively cured the mice and was well tolerated. Inoue et al. reported on a camptothecin analogue (DX-8591) conjugated to a carboxymethyldextran via a peptide spacer (DS 40 mol %), which demonstrated strong action against tumors in mice models and human patients.[52,53] Wang et al. conjugated PTX to heparin (20 wt %), but could only form nanostructures when coformulated with free PTX. [54] In short, polysaccharides appear to have potential as polymer therapeutics, with positive outcomes being reported for selected compositions. However, polysaccharides are generally water-soluble and are incompatible with organic solvents, limiting drug conjugation chemistry, resulting in low coupling yields for hydrophobic drugs (<20 wt %).[53,55] Low drug coupling appears to be linked with rapid drug release: the efficacy of polysaccharide conjugates may be improved through increased drug content. In addition, increasing drug content in the polymer conjugate may facilitate its assembly into stable nanoparticles that provide enhanced protection for the drug, improving PK and efficacy. In this work, we focus on using CMC as a polymer backbone for the delivery of DTX. There are several advantages to the use of CMC: (a) CMC finds widespread use in biomaterials (e.g., OP-1 putty), pharmaceutical formulation (FDA Inactive Ingredients Database), and food (FDA database of Select Committee on GRAS substances reviews); (b) CMC has been approved by FDA for parenteral use in products such as Vivitrol, Sandolog, and Sandostatin, and is known to be bioeliminable;[44] (c) there is no known biological activity compared to hyaluronan and heparin; and (d) CMC presents as an attractive candidate polymer due to a high carboxylate DS (0.8) compared to other polysaccharides (0.2−0.5), enabling the incorporation of high drug content and increased particle-forming properties. This report describes the synthesis and characterization of a nanoparticle forming PEGylated carboxymethylcellulose−DTX conjugate (Cellax), and provides in vitro evidence of an enhanced cytotoxicity against a panel of cancer cell lines.

MATERIALS AND METHODS

Sodium carboxymethylcellulose (CEKOL 30000, MW = 275K, degree of substitution (DS) = 0.82) was received from CPKelco (Atlanta, Georgia, USA), and is an FDA and EU foodgrade material. Glacial acetic acid, acetic anhydride, sulfuric acid, acetone, acetonitrile, poly(ethylene glycol) methyl ether (mPEG−OH, MW = 2000), 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide HCl (EDC HCl), *N*-hydroxysuccinimide (NHS), 4-dimethylaminopyridine (DMAP), and diethyl ether were purchased from Sigma Aldrich (Oakville, ON). DTX was purchased from LC Laboratories (Woburn, MA, USA). Slide-a-Lyzer dialysis cartridges were purchased from Pierce Biotechnology (Rockford, IL). Vivaspin 10 kDa MWCO ultracentrifugation filters were purchased from Fisher (Ottawa, ON, Canada). Cell culture materials (media and supplements) were purchased from Invitrogen (Burlington, ON, Canada). All other reagents were purchased from Sigma Aldrich (Oakville, ON).

^{1}H NMR Analysis. Samples were dissolved in deuterated chloroform ($CDCl_3$), deuterium oxide (D_2O), or *N,N*-dimethylsulfoxide (DMSO), and were analyzed on a Bruker 500 instrument. Spectra were processed using *TOPSpin* software.

HPLC, UPLC/MS, and GPC Analysis. DTX analysis was performed on an HPLC system consisting of a Waters e2696 Separation Module, 2414 RI and 2998 PDA detectors, and operated by *Empower Pro 2* software. The samples were injected onto an Agilent XDB-C18 column (1.8 μm, 4.6 × 50 mm) column with 0.35 mL/min 95/5 acetonitrile (MeCN)/water isocratic program. The method for analysis and detection of taxanes was derived from several published reports,[56−58] adapted for the instrumentation in the lab. For routine analysis, known taxane identities (docetaxel, paclitaxel, and 7-epidocetaxel) were identified by PDA detector with a selected wavelength of 274 nm. During method development, samples were analyzed by a Waters Acquity UPLC/MS system equipped with a PDA and SQ MS detector. In these analyses, samples were injected on an Acquity UPLC BEH C18 column (1.7 μm, 2.1 × 50 mm), at a flow rate of 0.4 mL/min, with a gradient program of 95/5 to 10/90 water/MeCN over 5 min. Detection of taxanes was in ES+ mode. Polymers were analyzed by a GPC system consisting of a Waters e2696 Separation Module, 2414 RI and 2998 PDA detectors, and operated by *Empower Pro 2* software. THF soluble samples were injected

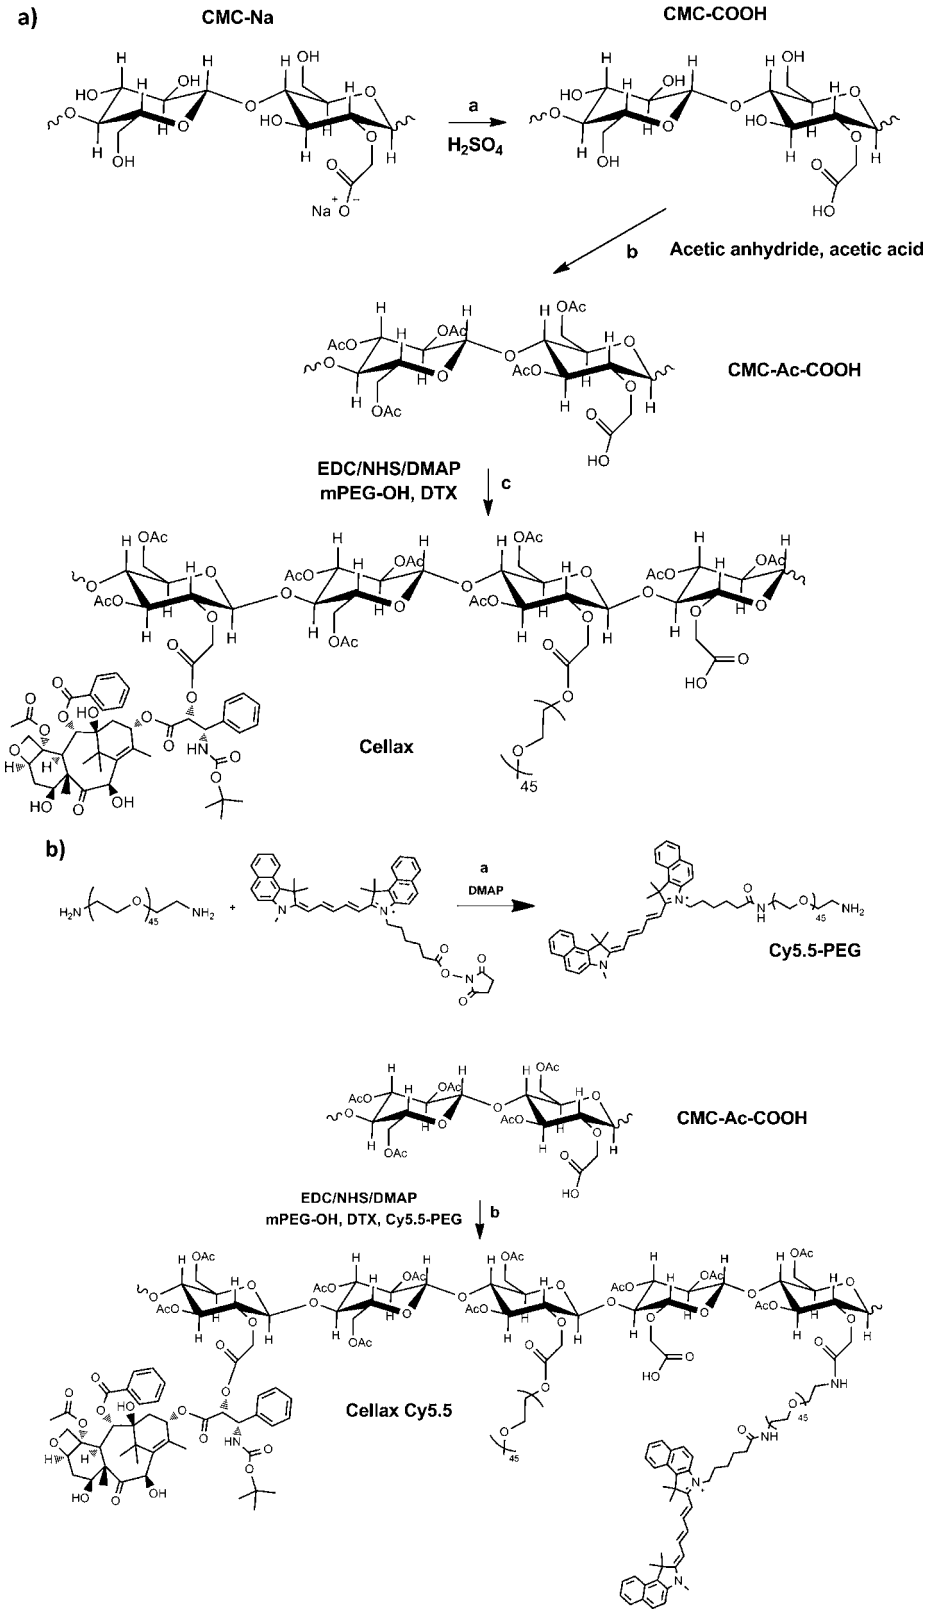

Figure 1. (a) Schematic of polymer modifications. Note that the distribution of anhydroglucose monomer substitutions is random: for ease of depiction, monomers are drawn in simplified form. onto Waters Styragel HR5E and HR 3 columns (in series) with 0.35 mL/min THF flow rate. Water-soluble samples were analyzed using a Waters Ultrahydrogel 1000 column with a 1 mL/min flow rate of water. Detection of free DTX and PEG was by PDA (274 nm) and RI, respectively.

Calculation of Stoichiometry for the CMC Polymers. The CMC-Na polymer was modified with carboxymethyl groups, and was supplied by the manufacturer with an analyzed DS value of 0.82: each galactose monomer unit contained 0.82 mol carboxylic acid and 2.18 mol hydroxyl. The molecular weight of each monomer was approximated as 162 g/mol (galactose) + (59.01 g/mol (acid group) × 0.82) = 210 g/mol. These chemical composition values were used to calculate the stoichiometry of reactions performed on CMC polymers.

Acetylation of the CMC. The method for acetylation of CMC was adapted from a method reported by Namikoshi.[59] According to Figure 1, sodium carboxymethylcellulose (CMC-Na, 10 g) was weighed into a round-bottom flask, and was suspended in 20% sulfuric acid (200 mL) with vigorous stirring at room temperature for 2 h. The slurry of CMC−COOH was washed with water until the water tested neutral, and then washed with 3 × 30 mL glacial acetic acid volumes. The CMC−COOH was transferred to a round-bottom flask placed in an ice bath, and suspended in glacial acetic acid (50 mL). Acetic anhydride (30 mL) and sulfuric acid (1.2 mL) were added to the chilled slurry, the temperature was raised to 50 °C, and the solution was vigorously stirred for 3 h, or until the solution clarified. The reaction solution was concentrated by rotary evaporation (58 °C, 58 mbar) and was precipitated in deionized water. The water was extracted by centrifuging the suspension, the pellet was resuspended in water, and the process was repeated until reaching a neutral pH. The acetylated CMC (CMC-Ac) powder was dried under vacuum overnight, dissolved in minimal acetone, and precipitated through water. The polymer was centrifuged out of solution, dried by lyophilization, and analyzed by ^{1}H NMR in DMSO.

Synthesis of Cellax. The preparation of Cellax discussed throughout this report is described here (40 mol % DTX feed, 30 mol % PEG feed), followed by related reactions producing compositions across a range of DTX feeds. 40/30 Synthesis: acetylated carboxymethylcellulose (CMC-Ac, 300 mg, 1.2 mmol acid) was weighed into a 25 mL glass vial, and dissolved in MeCN (2 mL). EDC HCl (448 mg, 2.3 mmol) was dissolved in a mixture of MeCN (12 mL) and water (0.5 mL). NHS (269 mg, 2.3 mmol) and DMAP (29 mg, 0.23 mmol) were dissolved in MeCN (1 mL). mPEG−OH (702 mg, 0.35 mmol) was dissolved in MeCN (2 mL). DTX (378 mg, 0.47 mmol) was dissolved in a mixture of MeCN (12 mL) and DMF (1 mL). The EDC HCl, NHS, and DMAP reagents were added to the CMC-Ac solution, followed by addition of the mPEG−OH and the DTX (Figure 1a). The solution was stirred overnight at room temperature with protection from light. The solvent was removed by rotary evaporation (55 °C, 5 mbar), and the product (Cellax) was dissolved in MeCN (3 mL), and precipitated through 40 mL diethyl ether. The polymer was dried, redissolved in MeCN, and the precipitation was repeated twice. The solvent was removed by vacuum, and the fine powder was twice triturated with water (25 mL) and recovered by centrifugation. The product was analyzed by GPC for uncoupled PEG and DTX, and washing was repeated if residual reagent was detected. ^{1}H NMR analysis ($CDCl_3$) was conducted to confirm the presence of DTX and PEG, and to estimate molecular composition. ^{1}H NMR ($CDCl_3$) δ, 40 mol % DTX feed: 8.12 (d, 2H, C25 and C29), 7.61 (t, 1H, C27), 7.51 (t, 2H, C26 and C28), 7.41 (m, 4H, C31, C32, C34, C35), 7.34 (m, 1H, C33), 6.23 (m, 1H, C13), 5.71 (m, 1H, C2), 5.25 (m, 1H, C4′), 5.10 (br, 1H, C10), 4.98 (d, 1H, C5), 4.32 (m, 1H, C20-A), 4.25 (m, 1H, C7), 4.19 (br, 1H, C20−B), 3.64 (s, 4H, PEG), 3.38 (s, 3H, PEG), 3.0−5.5 (m, CMC polymer), 2.57 (m, 1H, C6-A), 2.38 (3H, C22), 2.02 (m, 3H, acetyl), 1.86 (m, 4H, C6 and C18), 1.75 (br, 3H, C19), 1.34 (s, 9H, C7′, C8′, C9′), 1.29 (s, 3H, C16), 1.14 (s, 3H, C17). In related syntheses, the feed ratio of DTX was varied (10, 20, 30, 50, and 90 mol %) to generate polymer compounds with differing levels of DTX content and constant PEG content. Synthesis and purification processes were identical to the 40 mol % feed described above. Compounds were dissolved in $CDCl_3$ for ^{1}H NMR analysis, and composition was estimated by integration of selected signals.

Synthesis of CMC-Ac-PEG (control polymer). A CMC-Ac-PEG control molecule was synthesized using the same conditions as described for Cellax. CMC-Ac (100 mg, 0.38 mmol acid) was reacted with mPEG−OH (230 mg, 0.12 mmol) in the presence of EDC HCl (147 mg, 0.77 mmol), NHS (88 mg, 0.77 mmol), and DMAP (9 mg, 0.08 mmol) in MeCN (6 mL). After overnight reaction, the solvent was removed by rotary evaporation (55 °C, 5 mbar), dissolved in water (5 mL), and dialyzed against multiple exchanges of water using 20 kDa MWCO Slide-a-lyzer dialysis cartridges. The purified product was recovered by lyophilization, and analyzed by aqueous-phase GPC to verify that unreacted PEG had been entirely extracted. Analysis of chemical composition was by ^{1}H NMR in D_2O.

Synthesis of Cy5.5 Labeled Cellax. Conjugation of Cy5.5 to Cellax was adapted from Wang at al. (Figure 1b).[54] PEG Bisamine$_{2000}$ (169 mg, 0.084 mmol) was dissolved in MeCN (2 mL), to which was added DMAP (1 mg, 0.008 mmol) and Cy5.5 NHS ester (50 mg, 0.084 mmol, 0.5 mL MeCN). The solution was stirred for 4 h at room temperature and protected from light. Acetylated carboxymethylcellulose (CMC-Ac, 100 mg, 0.39 mmol acid) was weighed into a 25 mL glass vial, and dissolved in MeCN (2 mL). EDC HCl (149 mg, 0.78 mmol) was dissolved in MeCN (4 mL) and water (0.15 mL). NHS (90 mg, 0.78 mmol) and DMAP (10 mg, 0.08 mmol) were dissolved in MeCN (0.5 mL). mPEG$_{2000}$−OH (156 mg, 0.08 mmol) was dissolved in MeCN (1 mL) with mild heating. DTX (157 mg, 0.19 mmol) was dissolved in MeCN (4 mL) and DMF (0.25 mL). The EDC HCl, NHS, and DMAP reagents were added to the CMC-Ac solution, followed by addition of the Cy5.5-PEG reaction solution and the mPEG$_{2000}$−OH and the DTX. The solution was stirred overnight at room temperature with protection from light. The product (Cy5.5 Cellax) was purified by the same procedure used to purify Cellax. ^{1}H NMR analysis ($CDCl_3$) was conducted to confirm the presence of DTX and PEG.

Cellax Particle Preparation. Cellax polymer conjugate (CMC-Ac-DTX-PEG) (2 mg) was dissolved in MeCN (0.2 mL), and added dropwise to a vortexing solution of 1.8 mL normal saline in a 15 mL conical tube. Vortexing was maintained for 1 min after solution addition. The resulting Cellax particle solutions were transferred to a Slide-a-lyzer 10 000 MWCO cartridge, and dialyzed against normal saline (100 mL) for 3 h, with two exchanges of dialysate. The particles were filtered through a 25 mm Millipore PVDF filter, and transferred to a Vivaspin centrifugal filter unit (10 000 MWCO), and spun at 3000 rpm to concentrate the particles. The size of the

particles was determined by dynamic light scattering with a particle analyzer (Zetasizer Nano-ZS, Malvern Instruments Ltd., Malvern, UK). DTX content of the Cellax nanoparticles was determined by diluting the sample 20× in 90/10 saline/DMSO, measuring UV absorbance at 274 nm (Nanodrop, ThermoScientific) and calculating DTX concentration using a DTX calibration curve.

Cellax-Cy5.5 particles were prepared with 95 wt % Cellax and 5 wt % Cellax-Cy5.5: Cellax (1.9 mg) and Cellax-Cy5.5 (0.1 mg) in MeCN (10 mg/mL) were added dropwise to a vortexing solution of 1.8 mL normal saline, and were purified and characterized for particle size and DTX content.

TEM Analysis. Cellax particles were diluted 100× in deionized water, and a 2 μL aliquot of solution was pipetted onto the surface of Formvar coated copper TEM grids (TedPella, Redding, CA) and allowed to air-dry. Analysis was performed on a Hitachi HD-2000 STEM at the Centre for Nanostructure Imaging (Department of Chemistry, University of Toronto), using a high angle annular dark field detector, with an activation voltage of 200 kV and a current of 10 mA.

Determination of Critical Aggregation Concentration. The fluorescence-based method for determination of the critical aggregation concentration (CAC) was adapted from Zhang.[6,60] 1,6-Diphenyl-1,3,5-hextriene (DPH, 1.175 mg) was dissolved in MeCN (10 mL) to form a stock solution. Cellax (10 mg) was dissolved in 1 mL of the DPH stock solution to form a 10 mg/mL solution, and was serially diluted with the DPH solution to form a series of 10 concentrations of Cellax in a constant concentration of DPH. One hundred microliter aliquots of each sample were precipitated dropwise in 900 μL normal saline on a vortexer at room temperature for 1 min. Fifty microliter aliquots of each particle solution were transferred to a black 96 well microplate, and fluorescence was measured (Ex 360, Em 460) on a Chameleon plate reader. Two distinct linear curves on a fluorescence vs log concentration plot converged, and the CAC was calculated by using linear algebraic solution for intersection of curves. To demonstrate the stability of Cellax nanoparticles on dilution, particles were diluted with normal saline to form a series of dilutions above and below the CAC, were incubated at 37 °C for 12 h, and particle size was analyzed (Zetasizer).

In Vitro Release of DTX from the Cellax Nanoparticles. Cellax particles were assayed for DTX content by UV assay and were spiked with PTX as an internal standard before mixing with an equal volume of fetal bovine serum (FBS) under aseptic conditions (final DTX and PTX contents were 100 μg/mL and 5 ug/mL, respectively, in 50% FBS).[55] Samples were incubated at 37 °C, and at selected time points (1, 2, 3, 4, 7, 14, and 21 days), 1 mL volumes were taken and combined with 3 mL ethyl acetate, the samples were mixed well for 30 min, and centrifuged at 4000 rpm for 5 min to separate the layers. The ethyl acetate layer was taken off, the solvent was evaporated off, and the residue resuspended in 0.5 mL MeCN and analyzed by HPLC. DTX and PTX peaks appeared at 7.8 and 8.1 min, respectively. A calibration curve for DTX was prepared by spiking a saline/FBS solution with DTX and the PTX internal standard, followed by the same extraction protocol, and this calibration was used to calculate the DTX content in the incubated samples. A new peak appeared in the analysis of incubated samples at 8.4 min, and by LC/MS analysis was determined to be an isomer of DTX (ES+ 878 mass). The isomer was quantified in a manner similar to DTX.

In Vitro Analysis of DTX Toxicity (IC50 Analysis). EMT-6 murine mammary carcinoma cells and LL/2 murine Lewis lung cell carcinoma cells were cultured in DMEM media supplemented with 10% FBS, penicillin (100 U/mL), and streptomycin (100 μg/mL). The mouse mammary carcinoma cell line EMT-6 was a generous gift from Dr. David Stojdl at the CHEO Research Institute and Dr. Douglas Mahoney at the University of Ottawa. All other cell lines were purchased from the NCI. The MDA-MB-231, PC3, and PAN02 lines were cultured in RPMI 1640 media supplemented with 10% FBS. For plating, cells were released from the culture flask with trypsin, resuspended at a concentration of 1×10^4 cell/mL, and 100 μL of cell suspension was added to the wells of 96 well polystyrene plates. A slight modification (5×10^4 cell/mL) was made for the MDA-MB-231 analysis, as these cells were slow-growing compared to the other cell lines. The cells were maintained for 24 h in culture (37 °C, 5% CO_2, humidified) before addition of particles. DTX solutions were made up in DMSO and diluted with media to form a 100 nM stock solution with 0.1% DMSO content (0.1% DMSO was determined to be nontoxic to the cell lines). These DTX samples were 2× serially diluted with 0.1% DMSO media. Cellax particles were assayed for DTX content, and 10× serially diluted with media. Polymer control (CMC(Ac)-PEG) solutions were prepared to match the mass concentration of the Cellax dilutions. The cultures were maintained for 3 days, at which time cell viability was assayed by the XTT assay. Briefly, a 1 mg/mL solution of XTT reagent and 1.53 mg/mL solution of phenazine methylsulfate in water were prepared, and 5 μL of phenazine methylsulfate was added to each mL of XTT solution. Fifteen microliter aliquots of the XTT solution were added to each well, the culture plates were incubated for 2 h at 37 °C, and absorbance of each well at 480 nm was then read. Wells treated with media (or 0.1% DMSO media) represent 100% viable cultures, and wells containing no cells represent background signal. In a parallel experiment, the DTX solutions added to the cultures were fractionated over two days, with addition of 1/4 the dose every 12 h for 2 days. The viability data were analyzed in GraphPad *Prism*, and the IC50 for each system was calculated.

In Vitro Analysis of Cellax Particle Uptake. EMT-6, LL/2, PAN02, PC3, and MDA-MB-231 cells were adjusted to 1×10^5 cell/mL, and 1 mL of cell suspension was added to 24 well plates containing sterile glass coverslips. After 24 h of incubation, media in each well was aspirated, and replaced with media containing Cellax-Cy5.5 (0.1 mg DTX/mL). Two parallel experiments were conducted with 10% FBS or 10% heat deactivated FBS containing media. The cell cultures were incubated for 12 h, after which the media was aspirated, and cells were fixed with 500 μL of methanol for 1 min. The methanol was aspirated, the wells were washed 2× with PBS, and 500 μL of 0.5 μg/mL DAPI solution was added. After 5 min, the DAPI solution was aspirated, and the slips were rinsed twice with PBS. The coverslips were mounted on glass slides with 95% glycerol/5% PBS, and imaged on an Olympus Fluoview confocal microscope (AOMF, Toronto, ON).

RESULTS AND DISCUSSION

Nanomedicine approaches to the detergent-free delivery of taxanes include polymeric micelles (NK105[23] and Genexol[37]), protein complexes such as Abraxane,[61] and polymer conjugates such as Opaxio.[40] While micelle-based PTX formulations such as NK105 increase the dose of PTX that can be safely

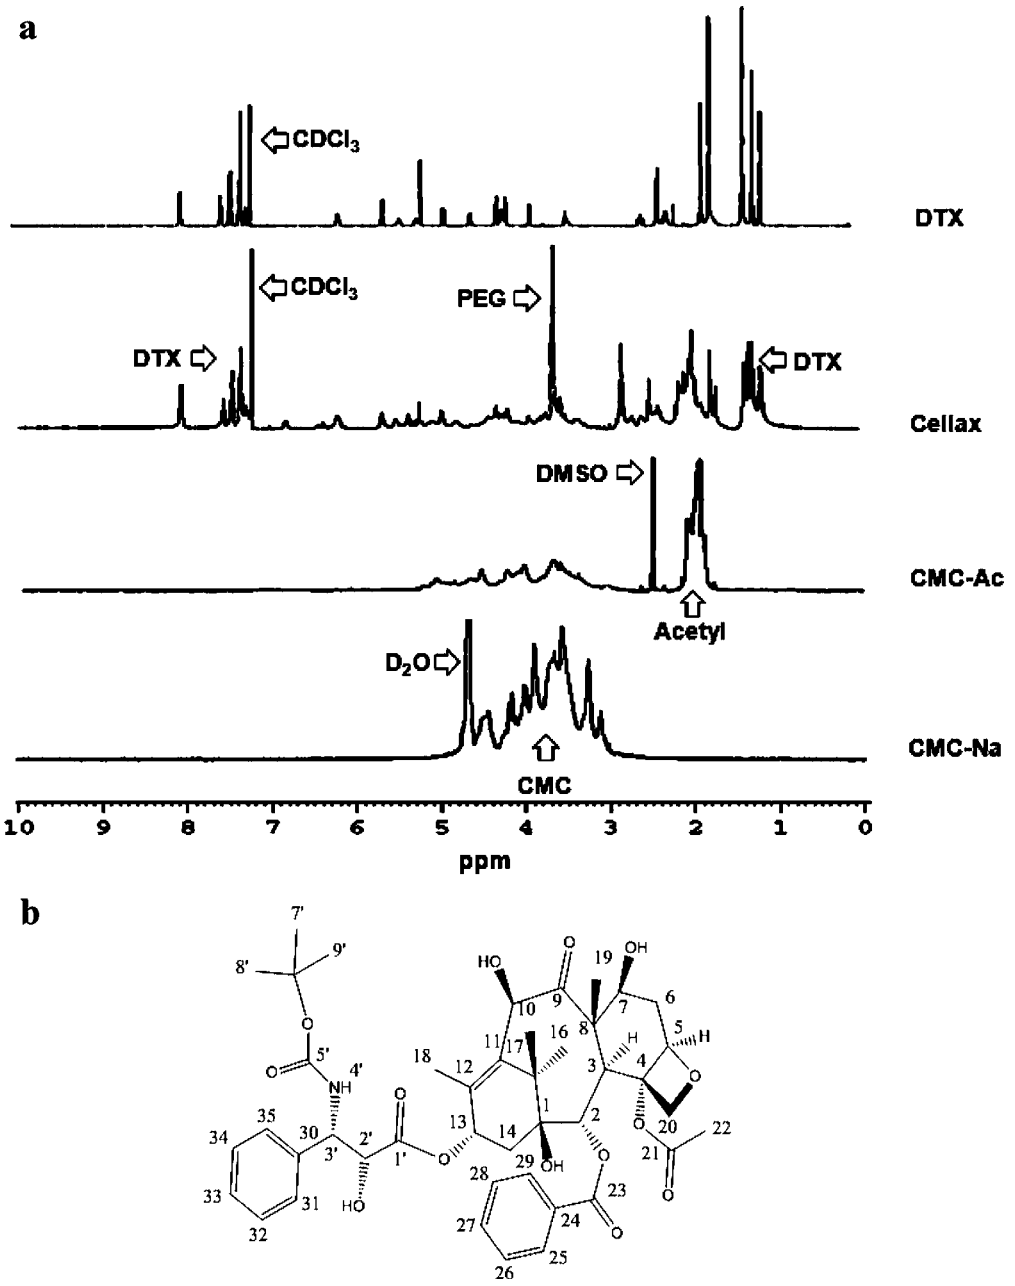

Figure 2. [1]H NMR of Cellax and Components. (a) Spectra of DTX, sodium carboxymethylcellulose (CMC-Na), acetylated CMC, and the Cellax product. (b) DTX with the carbon numbering scheme.

administered and improve antitumor efficacy and the PK profile in mouse models, the PK profile of the micelle formulated PTX in clinical trials is not improved over Taxol,[23,37] likely due to rapid plasma partitioning.[39] Similarly, Abraxane improves antitumor efficacy compared to Taxol by increasing the maximum tolerated dose, but the PK profile is not enhanced.[62] Conjugation of the drug to a polymeric carrier can control drug migration, and can enhance the PK and efficacy provided that the polymer is biocompatible and has low renal and RES clearance. Furthermore, the polymer should travel in blood in a state that enables permeation into malignant tissues by the EPR effect, exhibits a low volume of distribution, and contains a drug–polymer linker that is cleavable in tumor tissues. A clinically known example of this approach is a PTX–polyglutamic acid conjugate (Opaxio), which improves PK and has exhibited promise in phase I clinical trials.[42] However, a signal for needed improvement to the polymer therapeutic design is given by unpromising phase III clinical trial outcomes (www.celltherapeutics.com). The Opaxio polyglutamate backbone is labile, and the polymer is readily digested into low molecular weight fragments containing PTX, which widely distribute to normal organs including the kidneys, lungs, and heart:[43] if the polymer breaks down during transport to the tumor, the polymer therapeutic advantage is diminished.[43,63,64] Furthermore, Opaxio could not be detected 24 h postinjection in mice,[43] suggesting the need for improved PK, possibly via PEGylation. Prolonged blood circulation is a prerequisite for enhanced tumor uptake, the well-supported central hypothesis of the EPR effect.[32] Further, no published reports indicate that this polymer conjugate assembles into protective nanoparticles, and it is likely then that polymer amide linkages and the ester drug linkages are readily exposed to enzymatic degradation

dx.doi.org/10.1021/bc200284b | *Bioconjugate Chem.* 2011, 22, 2474–2486

during blood transport. Our objective in design of a polymer therapeutic was to prepare biocompatible cellulose-based nanoparticles to leverage the EPR effect and protect the drug from early release or alteration, to incorporate PEG to reduce RES clearance, and to release DTX in a controlled and slow release mechanism in the target tissue. CMC was selected based on its known safety profile as an excipient, and due to the reasonable stability of the backbone in human physiological conditions, ensuring maintenance of macromolecule integrity during circulation. In addition, CMC represents a viable backbone chemistry for conjugation due to its high DS (0.8). In our initial screening of known biocompatible polysaccharides, conjugation of DTX to carboxymethyl dextran (DS of 0.2) failed to yield particle forming identities, likely due to a low DS and corresponding low hydrophobic drug content. CMC presents with a minor limitation, however, as sodium CMC is water-soluble and gels in water, and is only sparingly soluble in organic solvents such as DMF or DMSO,[65] limiting synthesis options for non-water-soluble drugs. In the method development process, the sodium counterion on the carboxylic acid was exchanged with triethylamine (TEA) or tetrabutylammonium (TBA) in order to generate solvent-soluble polysaccharide as described by others.[34,66] However, the coupling efficiency of carboxylate groups to DTX and PEG esters using EDC/NHS chemistry was low (<10%), and particles formed using these materials were heterogeneous in size and prone to self-aggregation. Therefore, we first acetylated the hydroxyl groups of CMC using acetic anhydride with sulfuric acid catalysis to produce a solvent-soluble version of CMC.

Acetylation of CMC. The DS per anhydroglucose unit, as specified by the manufacturer, was 0.8 mol acid per mol anhydroglucose and, by inference, 2.2 mol hydroxyl per mol anhydroglucose. We calculated the theoretical moles of hydroxyl (converted to acetyl) groups and acid groups, and designed conjugation schemes accordingly. The reaction solution transitioned from a suspension to a clear yellow solution after 2 h of reaction, and by ^{1}H NMR analysis, conversion was quantitative and yields >90%. The resulting CMC-Ac polymer was a powdery white solid, readily soluble in DMF, THF, and MeCN, with no gelling properties. Figure 2A: ^{1}H NMR (DMSO) δ: 3.0−5.5 (m, CMC H), 2.02 (m, acetyl CH_3). ^{1}H NMR analysis confirmed the DS calculations: by integration of the ^{1}H NMR spectra, the ratio of anhydroglucose protons and acetyl protons was found to conform to prediction. Acetylation of the CMC polymer was quantitative provided that the CMC polymer was scrupulously washed in each stage of the protocol to remove residual sulfuric acid (to minimize discoloration) and residual water (inhibition of anhydride reaction).

Conjugation of DTX and PEG to CMC. CMC-Ac was soluble in DMF, but pilot DTX and PEG coupling reactions performed in DMF with EDC/NHS/DMAP did not exhibit good yields, and particles formed from these materials were unstable and nonuniform. In solvent screening, MeCN promoted higher conversions, and subsequently, all conjugation reactions were performed in MeCN. In addition, to minimize the dilution of reagents, 1.5 vol % water was added to dissolve EDC, and 3.0 vol % DMF was added to dissolve the DTX in the MeCN solvent. Purification of the polymer by dialysis was initially attempted, but as PEG, DTX, and the CMC reagents exhibit different solubility profiles, problems with precipitation and low purification efficiency occurred. Triturating finely ground Cellax product with water effectively extracted uncoupled PEG, and precipitation of MeCN solutions of Cellax through diethyl ether extracted uncoupled DTX. Complete extraction of the uncoupled PEG and DTX was confirmed by GPC analysis of the product. However, the Cellax polymer absorbed to the polystyrene columns, and GPC analysis was restricted to identification of impurities. The final product for all feed ratios was a fine white powder, readily soluble in acetonitrile, DMF, THF, and chloroform. Typical reactions yielded ~80 wt % of theoretical recovery. See Figure 2A for the NMR spectra of Na-CMC, CMC-Ac intermediate, DTX, and the final Cellax polymer, and Figure 2B for the DTX carbon numbering scheme. The relative mol % of each unit (CMC, PEG, and DTX) in the conjugate was estimated by integration of the spectra, and by back-calculation using the molecular weight of each component, mole and weight percentages were calculated. Polymer conjugates were prepared with a range of DTX mol % feeds (10, 20, 30, 40, 50, and 90 mol %). By ^{1}H NMR analysis, the peak assignments were identical in all polymer products, varying only in the integration of peaks assigned to PEG and DTX. As shown in Figure 3a, all

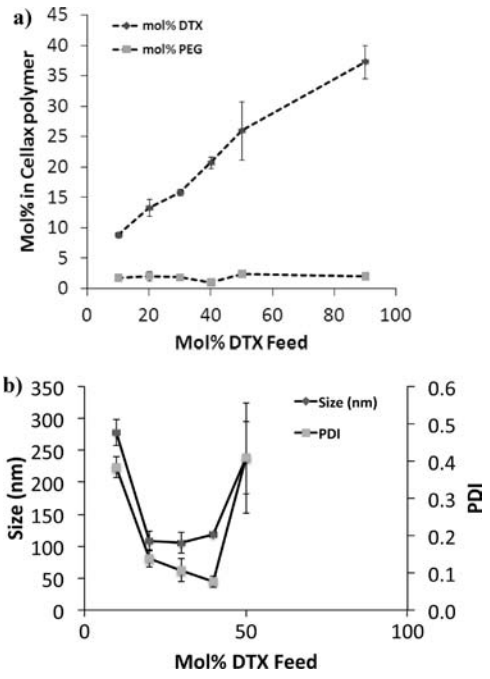

Figure 3. Optimization of Cellax formulation. (a) DTX was fed into the reactions at different ratios relative to the carboxylic acid content of the CMC(Ac) polymer, and PEG was maintained at a feed of 30 mol %. The resulting polymers were characterized for substitution with DTX and PEG. Good correlation between DTX feed and resulting Cellax composition was observed (R^2 = 0.94). (b) Cellax polymers formed nanoparticles when they contained a defined range of DTX content. Polymers with compositions outside this range formed larger less defined particles, or precipitated.

conjugates exhibited a similar DS for PEG (1.8 to 2.4 mol %, ~7% coupling conversion), and the DS for DTX varied in a linear relationship (R^2 = 0.98) with increasing molar feed. Docetaxel coupling conversion was ~50% of feed (Figure 3a). The MW of the Cellax polymer is estimated from NMR data to be 4.75 × 10^5 g/mol. The capability to perform the reaction in organic phase, the reproducible and high level of DTX coupling to the polymer, and the elimination of gelling properties confirmed the benefits of the CMC acetylation. All polymer

conjugates (10−90 mol % DTX feeds) were water-insoluble, and the formation of defined particles or disorganized precipitates depended on their specific composition. For the preferred composition (40 mol % DTX feed), the Cellax polymer contained 20.8 ± 1.6 mol % DTX (37.3 ± 1.5 wt %) and 1.1 ± 0.2 mol % PEG (4.7 ± 0.8 wt %). Polymers prepared across the 10−90 mol % feed range of composition were tested for particle forming characteristics (size and polydispersity index (PDI)): as seen in Figure 3b, polymers prepared with 20−40 mol % DTX feed (12.3−20.8 mol % DTX, 26.2−37.3 wt % DTX) yielded particles ranging 105−118 nm, with low PDI (<0.1). Outside this specific range of DTX composition, particle size exceeded 200 nm, particle PDI values were >0.3, and much of the polymer precipitated. Although PEG DS was low compared to DTX DS (1.8−2.4 mol %), increasing PEG content (either through >30 mol % feed or use of higher MW PEG5000) disrupted particle forming properties. For effective nanoparticle forming properties, the hydrophobic (DTX) and hydrophilic (PEG) elements of the Cellax macromolecule were balanced, so that when these amphiphilic structures contacted isotonic aqueous solution, they would assemble into stable nanoparticles and protect the drug cargo from direct exposure to serum enzymes.

Particle Formulation and Stability. Nanoparticles were prepared using the well-established nanoprecipitation method[67] by slow addition of a MeCN or THF solution of Cellax polymer conjugate into aqueous media (10× dilution), and desired particles were produced provided the concentration of Cellax in the organic solvent solution ranged between 10 and 25 mg/mL. It was observed that particles formed from 25 mg/mL solutions were approximately 150 nm in size, and particles formed from 10 mg/mL solutions were smaller (105−120 nm). For all subsequent work, the 10 mg/mL MeCN polymer solution and 10× dilution parameters (1 mg/mL polymer in particle solution) were set so as to provide for the smallest-sized population of nanoparticles. As described in Table 1,

Table 1. Cellax Particle Size Characteristics in Different Aqueous Systems (Zetasizer Measurements)

solution	size (nm)	PDI
PBS	134.0 ± 3.4	0.1 ± 0.08
Saline (0.9%)	118.2 ± 1.8	0.08 ± 0.02
Sucrose (10%)	128.5 ± 3.2	0.10 ± 0.04

Cellax nanoparticles could be formed in a variety of isotonic solutions with defined diameter (118−134 nm, PDI < 0.1). TEM analysis (Figure 4) of the particles in normal saline (104 ± 15 nm) supported the Zetasizer measurement (118 nm ±1.5 nm). The critical aggregation concentration (CAC), determined by the DPH assay, was 0.6 μg/mL. In comparison, hyaluronic−paclitaxel conjugates have a reported critical micelle concentration (cmc) of 7.8 μg/mL,[68] poly(glutamylglutamine-PTX) has a cmc of 25 μg/mL,[69] and PEG-polyesters typically have cmcs of the same order of magnitude (μg/mL levels) as Cellax.[70−72] Cellax particles were diluted serially to 0.5 μg/mL and examined for size stability: as dilution occurred, particle size exhibited only a minor increase when diluted to the limits of Zetasizer particle size detection, and did not disassemble (Figure 5). As Cellax was stable at the CAC, it is probable that these particles will remain stable at high dilution in biological systems. For example, in a 20 g mouse model treated at 40 mg DTX/kg, 200 μL of Cellax administered i.v. (10 mg Cellax/mL,

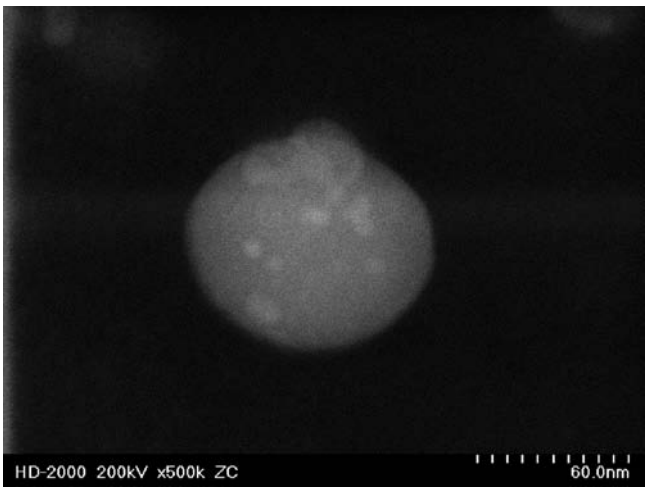

Figure 4. TEM analysis. Cellax particles were applied to Formvar coated copper grids, and analyzed by dark-field TEM (500 000× magnification). Six randomly picked particles were imaged, and the size was measured: particle diameter = 104 ± 15 nm.

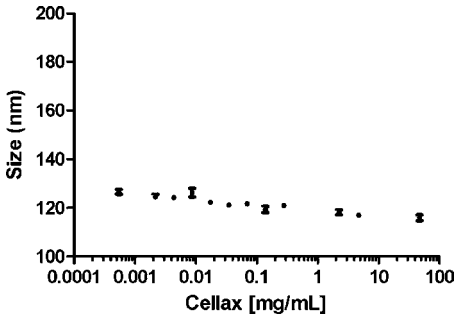

Figure 5. Dilution stability. Cellax particles were diluted from 47 mg/mL to 0.1 μg/mL (below the critical aggregation concentration and at the limits of particle size detection) and were stored for 24 h prior to analysis. Particle diameter increased slightly as the particles were diluted.

4 mg DTX/mL) would be diluted in ∼2 mL blood volume to 2 mg Cellax/mL. Considering the scenario when 90% of particles are out of circulation, the concentration of Cellax would be still well above CAC, and the DTX cargo would remain protected from serum esterases. In addition to stability against dilution, Cellax particles were stable in storage (>2 months, ongoing study) in saline, in contrast to reports on Abraxane and various PTX micelle formulations which exhibit limited stability in suspension.[73,74]

In Vitro DTX Release. The release of DTX from Cellax nanoparticles in serum was analyzed to affirm that hydrolysis of the ester bonds would occur. By LC/MS analysis, two identities with an ES^+ MS value of 808.8 m/z were detected, corresponding to DTX and a DTX isomer, 7-epidocetaxel: these peaks were analyzed to generate a total taxane release value.[57,75,76] The isomerization of Taxol (PTX) and Taxotere (DTX) in serum and the decreased activity are well-documented metabolic phenomena,[57,77,78] partly due to the unavoidable metabolism of taxanes in biological systems which supports the need to create a protective formulation for taxanes (i.e., nanoparticle encapsulated). As shown in Figure 6, the release of DTX over the course of 21 days (3.6%/day) was sustained, culminating in full release, with half of the total taxane released as active DTX. This data was contextualized

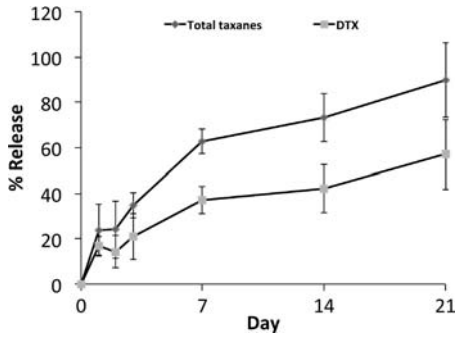

Figure 6. Release of DTX from Cellax particles in FBS containing saline (50 vol %). Particles were incubated at 37 °C in a 5% CO_2 atmosphere. At selected time points, samples were extracted and analyzed for taxanes by HPLC. Two peaks were detected: DTX and 7-epidocetaxol. Total taxanes refers to the combined release of DTX and the isomer, and indicates when full release had been reached.

with respect to published reports on taxane conjugates. For example, release of PTX from water-soluble carboxylmethyl dextran conjugates (5.5−6.5 wt % PTX) is rapid, with total release occurring within 3−4 days.[55] Release of DTX from water-soluble albumin conjugates (1.5 wt % DTX) is likewise rapid, with 40% release in 1 day.[7] Release of DTX from PEG conjugates (26 wt % DTX) is more controlled, with full release in 6 days.[6] Release of PTX from polyglutamic acid conjugates (35.8 wt % PTX) is slow and similar to Cellax, with 15−30% release recorded in 4−5 days.[43,79] It is posited that ready access of hydrolytic enzymes to the ester bonds linking the taxane to the macromolecule may drive the high rate of hydrolysis in low DS (<30 wt %) polymer conjugates. Conjugates with low drug content appear to exhibit rapid release profiles which might lead to reduced blood circulation time and efficacy. For Cellax, the high degree of substitution, the condensed state of the nanoparticle, and the addition of PEG shielding appears to effectively control the rate of hydrolysis, so that 3 weeks of sustained release were observed. Although the drug release rate

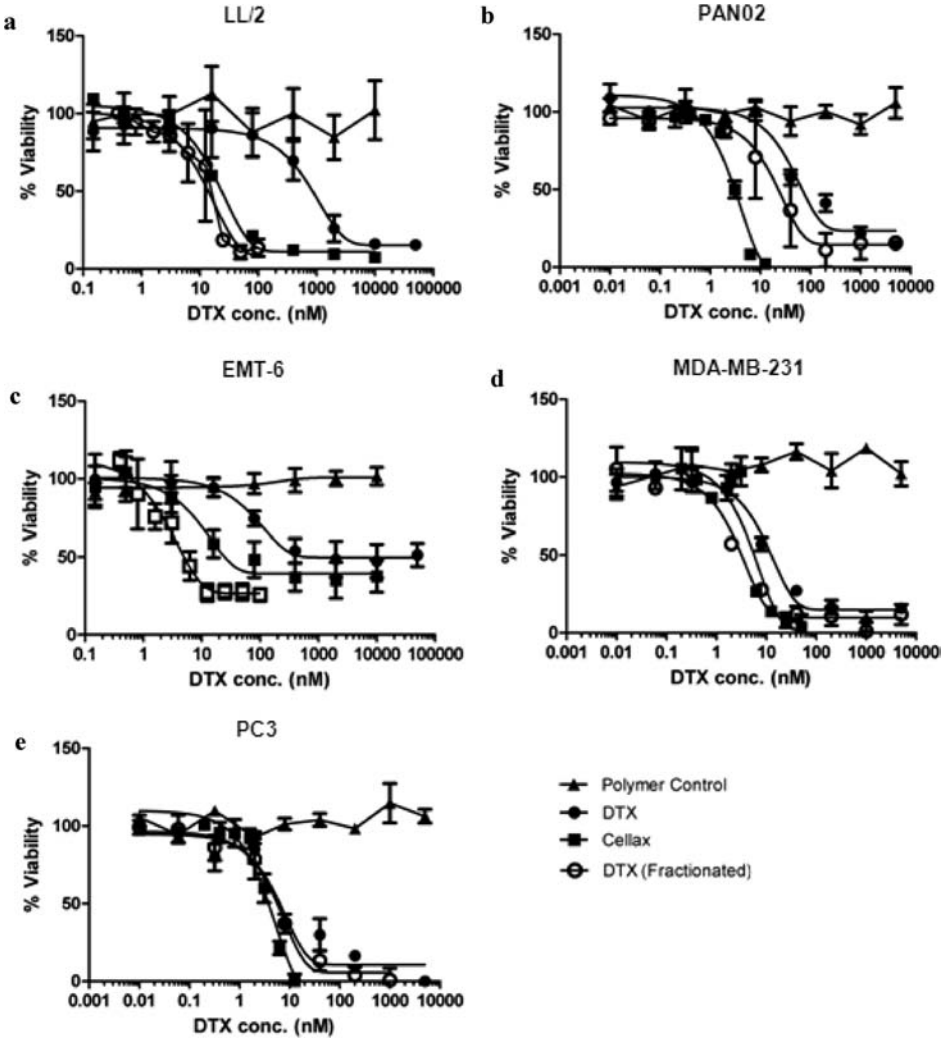

Figure 7. IC50 analysis of DTX toxicity. (a) LL/2. (b) PAN02. (c) EMT-6. (d) MDA-MB-231. (e) PC3. Cells were cultured on tissue culture polystyrene (1000 cell/well, 5000 cell/well for MDA-MB-231) for 1 day, followed by addition of media containing DTX, Cellax, or drug-free polymer controls. Polymer controls at each selected DTX concentration are matched to the Cellax sample by weight concentration (mg/mL). For fractionated treatment of free DTX, the dose was administered in four parts over two days, for a total dose matched to a bolus dose. Cultures were maintained for 3 days, until the no-treatment control wells approached confluence. Cell viability was determined by the XTT assay, with no-cell background signal being subtracted. IC50 curves were calculated in *GraphPad Pro*. Each group was $n = 9$, and error bars are ± standard deviation.

Table 2. In Vitro Cytotoxicity Analysis (IC50 Analysis)

cell line	IC50 DTX (nM) bolus dose	IC50 DTX (nM) fractionated dose	IC50 Cellax (nM)	fold increase in toxicity (Cellax vs bolus DTX)
LL/2 (murine, lung)	767 ± 10	12 ± 4	19 ± 3	40
PAN02 (murine, pancreatic)	71 ± 1	10 ± 8	3 ± 1	24
EMT-6 (murine, mammary)	80 ± 3	6 ± 3	9 ± 3	9
MD-MBA-231 (human, breast)	10 ± 4	3 ± 1	5 ± 1	2
PC3 (human, prostate)	6 ± 1	6 ± 1	3 ± 1	2

from Opaxio is well-controlled in vitro, the rapidly degradable backbone of the conjugate led to relatively short blood half-life in vivo (5.3 h)[40] and increased drug accumulation in normal tissues compared to conventional long-circulating nanoparticles.[32]

In Vitro Analysis (IC50 and uptake study). The cytotoxicity of different DTX formulations was measured by following cancer cell line viability. The concentration of control CMC(Ac)-PEG polymer in cell culture was matched to the concentrations of Cellax, and at no level were there any indications of cytotoxic effects on these cells (Figure 7). The cancer cell lines exhibited sensitivity to free DTX in conformity with published reports:[80,81] IC50 analysis confirmed an enhanced cytotoxic effect of Cellax against LL/2, PAN02, and EMT-6 lines, compared to free DTX, and a slightly superior effect against the PC3 and MDA-MB-231 lines (Table 2 and Figure 7). The Cellax treatment was 40× more toxic against LL/2, 24× more toxic against PAN02, 9× more toxic against EMT-6, and 2× more toxic against the MD-MBA-231 and PC3 lines. Increased Cellax toxicity was approximately related to the chemosensitivity of each cell line (a higher DTX IC50 correlated to a larger fold increase in toxicity when treated with Cellax). The same panel of cells exposed to fractionated matched doses of DTX over 2 days displayed IC50 values similar to the Cellax treated cells (Table 2). Cellax is a member of a small class of conjugates that are more effective than free drug *in vitro*,[82] as free drug tends to be more potent than conjugates or micelle formulations.[40,69] DTX is an anti-mitotic anti-neoplastic drug which binds to tubulin and impedes cell replication, ultimately inducing apoptosis and cell death.[83] Compared to a single bolus dose of DTX, the Cellax polymer released DTX continuously, and this sustained-release model represents a preferred dosing modality for this drug. A number of recent reports have emphasized the benefit of metronomic (fractionated) DTX exposure, as opposed to burst release. For example, De Souza et al. reported that a chitosan/laurinaldehyde/egg phosphatidylcholine/DTX gel (DTX-Po-Li_{gel}) slow-releasing DTX in the i.p. cavity exhibited significant activity against SKOV3-luc xenograft ovarian tumors compared to intermittent treatment with DTX.[84] In preclinical and clinical studies, the administration of lower and more frequent doses of chemotherapeutic has been observed to improve efficacy and reduce toxicity, with efficacy effects being attributed to increased cell death and anti-angiogenesis effects.[85,86] In this study, we confirmed a similar toxicity benefit with fractionated therapy against the chemo-insensitive cell lines (EMT-6, LL/2, and PAN02), with a smaller benefit observed for the chemosensitive PC3 and MDA-MB-231 lines. In addition to the benefits of slow release, internalization of the polymer-conjugate and enhanced release in lysosomes may further enhance the action of DTX. For example, Opaxio is reportedly internalized in the cytoplasm, and this process is understood to deliver more drug to the cell via accelerated hydrolysis of ester bonds (pH and enzyme mediated), enhancing the bioavailability of the taxane.[42] Similarly, the dendrimer conjugate of PTX developed by Khandare et al. also displayed significantly enhanced intracellular uptake leading to increased cytotoxicity compared to the free drug.[82] In our study, we found that Cy5.5-labeled Cellax nanoparticles were internalized in all five cell lines, both human and murine: the signal was punctate, suggesting uptake in vesicles, possibly through pinocytosis or phagocytosis (Figure 8). To control for the possibility that

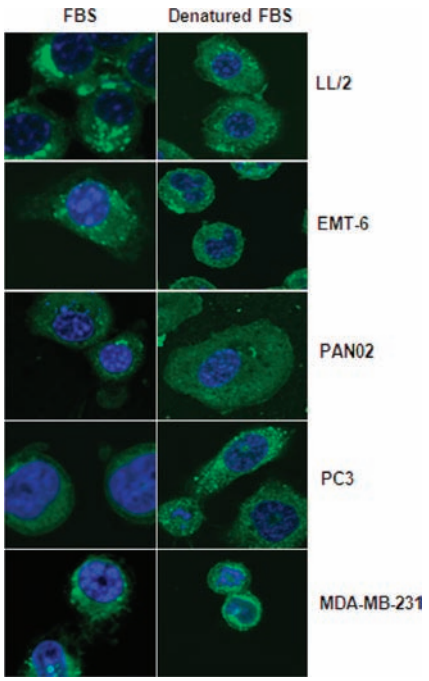

Figure 8. Cellular uptake of Cy5.5-labeled Cellax particles. Cells were cultured on glass coverslips in 12 well plates (1×10^4 cell/well), maintained for 24 h in FBS or denatured-FBS supplemented media, treated with Cellax particles (0.3 mg polymer/mL, 0.1 mg DTX/mL), and incubated for 24 h. Postincubation, cells were fixed, stained with DAPI, and visualized by confocal microscopy at 40× magnification.

Cy5.5 label was being cleaved extracellularly by FBS-sourced esterases and being internalized independent of the Cellax particle, we incubated the Cellax Cy5.5 particles in both active and heat-inactivated FBS-containing media: no difference in uptake was observed between the two groups. By NMR analysis of Cellax-Cy5.5 polymer, no significant deviations in composition compared to Cellax could be detected, but to minimize the influence of Cy5.5 chemistry on the biological behavior of Cellax particles, particles were prepared with a mixture of 95% Cellax and 5% Cellax-Cy5.5, yielding highly fluorescent particles with no alteration in physiochemical properties.

CONCLUSION

In summary, we have developed a new polymer conjugate of docetaxel with the following unique features: (A) the carboxymethylcellulose polymer backbone is biocompatible and reasonably stable with a proven safety profile, (B) the CMC was acetylated to facilitate high hydrophobic drug coupling (37 wt %) compared to other polysaccharide conjugates that have been reported, (C) the composition of the CMC polymer was optimized to form stable nanoparticles, and (D) the Cellax conjugate was PEGylated. The synthesis outcomes were low in variation with good control over composition and physical properties. Cellax released DTX at a slow and controlled rate of 3.8 wt % per day: in vitro, the cytotoxicity of Cellax was improved by 2−40-fold compared to free DTX, possibly arising due to the slow release mechanism and cellular internalization.

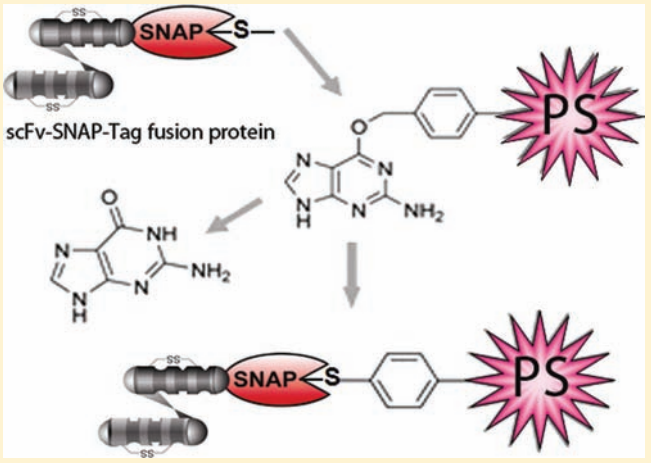
ABSTRACT: Cancer cells can be killed by photosensitizing agents that induce toxic effects when exposed to nonhazardous light, but this also causes significant damage to surrounding healthy cells. The specificity of photodynamic therapy can be increased by conjugating photosensitizing agents to antibodies and antibody fragments that bind specifically to tumor cell antigens. However, standard conjugation reactions produce heterogeneous products whose targeting specificity and spectroscopic properties can be compromised. In this study, we used an antibody fragment (scFv-425) that binds to the epidermal growth factor receptor (EGFR) as a model to investigate the use of SNAP-tag fusions as an improved conjugation strategy. The scFv-425-SNAP-tag fusion protein allowed the specific conjugation of a chlorin e6 photosensitizer modified with *O*(6)-benzylguanine, generating a homogeneous product that was delivered specifically to EGFR$^+$ cancer cells and resulted in significant, tumor cell-specific cytotoxicity. The impact of our results on the development of photodynamic therapy is discussed.



INTRODUCTION

Photodynamic therapy (PDT) is a promising and minimally invasive approach for the treatment of cancer. Following the introduction of improved photosensitizers and clinical application protocols, several FDA-approved PDT drugs have become available and others are in various stages of preclinical and clinical development.[1,2] The photosensitizing agent can exert its effect when activated by nonhazardous light directly, by becoming cytotoxic, or indirectly, by initiating the in situ production of toxic free radicals or reactive oxygen species (ROS). These processes cause damage to cells and ultimately induce cell death by apoptosis or necrosis.[3] The site of cellular damage depends on the photosensitizer type, the incubation period, and the mode of delivery.[4] In general, anionic photosensitizers localize in lysosomes, whereas cationic photosensitizers accumulate in mitochondria and cause damage there.[5]

One of the greatest challenges in PDT is the lack of specificity. Photosensitizers damage healthy tissue as well as tumor tissue after activation by light, and also can result in prolonged skin photosensitivity.[6] To increase the specificity of PDT, photosensitizers have been conjugated to tumor-specific monoclonal antibodies or single chain antibody fragments (scFv), resulting in so-called photoimmunoconjugates that deliver the photosensitizer directly to the tumor tissue, this approach is known as photoimmunotherapy (PIT).[7] Standard coupling reactions are unsuitable for the conjugation of photosensitizers and antibodies because there is no reliable way to ensure that antibody−photosensitizer conjugates are produced in the optimal stoichiometric ratio.[8,9] Furthermore, the chemical properties of the photosensitizer (e.g., hydrophobicity and the number and arrangement of charged groups) can alter the pharmacokinetic properties and biodistribution of the antibody, and may cause nonspecific binding and internalization behavior. Random conjugation can also cause the self-quenching of photosensitizer excited states, thus reducing photodynamic activity.[7] More controlled conjugation reactions are therefore required to overcome these limitations.

The epidermal growth factor receptor (EGFR, erbB1, HER1), one of four members of the ErbB family of tyrosine kinase growth factor receptors, is overexpressed in approximately 30% of epithelial cancers and has thus become an attractive target for cancer immunotherapy.[10,11] The recombinant anti-EGFR antibody fragment scFv-425 binds to EGFR expressing cancer cells and internalized upon binding.[12] We used scFv-425 as a model for the development of a new conjugation strategy to improve the specificity and efficacy of PIT. To achieve these aims, we used scfv-425 as a targeting moiety fused to the SNAP-tag to enable site-specific conjugation with the photosensitizer chlorin e6. The SNAP-tag is a 20 kDa protein tag that binds covalently to substrates containing *O*(6)-benzylguanine (BG)[13,14] and has previously been used to modify scFv fusion proteins with fluorophores for optical imaging.[12,15] Chlorin e6 was modified with BG bridged by a (PEG-24) spacer to increase the distance between the photosensitizer and the protein. The target specific toxicity was analyzed in vitro with four tumor cell lines with varying amounts of EGFR expression.

EXPERIMENTAL PROCEDURES

Cell Culture. The human epidermal carcinoma cell line A431 (ATCC no.: CRL-259), human Hodgkin lymphoma cell line L540 (DSMZ no.: ACC 72), Chinese hamster ovary cell line CHO-K1 (ATCC: CCL-6), and human embryonic kidney cell line HEK-293T cells (ATCC: CRL-11268) were cultured in RPMI-1640 medium supplemented with 2 mM L-glutamine, 10% (v/v) fetal bovine serum (FBS), and 100 U/mL penicillin–streptomycin. The human breast carcinoma cell lines MDA-MB-468 (ATCC: HTB-132) and MDA-MB-231 (ATCC: HTB-26), and human cervical carcinoma cell line SiHa (ATCC: HTB-35) were cultured in DMEM with 10% (v/v) fetal bovine serum (FBS) and 100 U/mL penicillin–streptomycin. All cells were incubated at 37 °C in a 5% CO_2 atm. All media and additives were obtained from Invitrogen, Darmstadt, Germany.

Protein Expression and Purification. The sequence for each scFv was inserted into the SfiI and NotI-digested site of eukaryotic expression vector pMS-SNAP providing an N-terminal binding ligand (scFv-425 or scFv-Ki4) and a C-terminal SNAP-tag sequence. The TGA stop codon is generated immediately after His_6 tag sequence. His_6-tagged fusion proteins were purified from cell-free supernatants on an Äkta FLPC system with a 5 mL Ni-NTA Superflow cartridge (Qiagen, Hilden, Germany) after equilibration with 4× buffer (200 mM NaH_2PO_4, 1.2 M NaCl, 40 mM imidazole, pH 8). Bound His-tagged proteins were eluted with elution buffer (50 mM NaH_2PO_4, 300 mM NaCl, 250 mM imidazole, pH 8). After elution, proteins were dialyzed at 4 °C overnight against phosphate-buffered saline (PBS) containing 1 mM dithioerythritol (Carl Roth GmBH, Karlsruhe, Germany). Ectoine cryopreservative was added to a final concentration of 50 mM, and aliquots were stored at −20 °C.

Modification of Ce6 with Benzylguanine. The carboxyl groups of Ce6 (Porphyrin Products, Logan, UT) were modified with benzylguanine by mixing 2 mg Ce6 in dimethylformamide for 30 min at room temperature with 5-fold molar excess of EDC and sulfo-NHS (Sigma-Aldrich, St. Louis, MO). The activated mixture was then mixed with a 2-fold molar excess of the benzylguanine linker BG-PEG24-NH_2 (Covalys Biosciences AG, Witterswil, Switzerland) in the dark at room temperature overnight. The modified Ce6 was purified by HPLC using a Shimadzu Prominence HPLC system and a 2.5 μm (4.6 × 50 mm) Water XBridge $OSTC_{18}$ column (Waters, Milford, MA) at a flow rate of 1 mL/min. Separations were carried out using a 20 min gradient from 0.1 M TEAA to 100% acetonitrile, monitored at 280 and 410 nm. The masses of Ce6, BG-PEG24-NH2, and BG-PEG24-Ce6 were confirmed using a Micromass QTOFII mass spectrometer with an electrospray ion source Advion Nanomate (Advion, Ithaca, NY, USA) 7 μL sample volume, 1.4 kV. Accurate masses were derived from mass spectra in the range 300–2500 m/z using the MaxEnt3 algorithm (Micromass) in the range 400–2000 Da.

Protein Labeling. The purified SNAP-tag fusion proteins were conjugated with BG-modified dyes (Covalys Biosciences AG, Witterswil, Switzerland) or BG-modified Ce6 by incubation in the dark with a 1.5–3-fold molar excess of dye for 2 h at room temperature. Residual dye was removed by gel filtration chromatography using Zeba Spin Desalting Columns, 7K MWCO (Thermo Fisher Scientific, Rockford, IL). The theoretical extinction coefficient of the proteins and the extinction coefficients of the fluorescence dyes were used to determine the coupling efficiency photometrically.

Labeled proteins were visualized after separation by SDS-PAGE with either a UV transilluminator Gel Doc XR gel documentation (Bio-Rad Laboratories, München, Germany) or a CRi Maestro imaging system (CRi, Woburn, MA, USA) using the blue and yellow filter sets.

Flow Cytometry. The binding efficiency of the labeled and unlabeled fusion proteins was determined by flow cytometry using a FACSCalibur device and *CellQuest* software (Becton & Dickinson, Heidelberg, Germany). $EGFR^+$ cell lines A431, MDA-MB468, MDA-MB-231, and SiHa were used to test the binding efficiency of scFv-425-SNAP, and $EGFR^-$ cell lines L540 and CHO-K1 were used as negative controls. The control fusion protein scFv-Ki4-SNAP recognizes the antigen CD30 and should therefore bind to L540 cells but not to the other cell lines. Approximately 4×10^5 cells were incubated in 200 μL PBS containing 0.5 μg of labeled protein for 20 min on ice. The cells were then washed twice with 1.8 mL PBS in a conventional cell washer and analyzed by flow cytometry.

Confocal Microscopy. Cells were visualized with a TCS SP5 confocal microscope (LEICA Microsystem, Wetzlar, Germany). Cells were prepared as described above for flow cytometry. Binding efficiency was determined by incubating cells with the labeled fusion proteins for 30 min on ice. Internalization was monitored by incubating cells with the labeled fusion proteins for 30 min at 37 °C.

Phototoxicity of scFv-425-SNAP-Ce6. A431, MDA-MB468, MDA-MB-231, SiHa, and CHO-K1 cells (2×10^4) cultured in 96 well plates as described above were washed twice in PBS and then treated with increasing concentrations of either Ce6, scFv-425-SNAP-Ce6, or Ki4-scFv-SNAP-Ce6 followed by incubation for 3 h at 37 °C. Control cultures were incubated with 500 μg/mL zeocin instead of the photosensitizer. Cells were washed three times with PBS, then resuspended in 100 μL of fresh phenol red free culture medium. The cells were then irradiated with visible light (VIS) plus water-filtered infrared light A (wIRA) using the Hydrosun type 505 radiator with a water-containing cuvette and an orange filter OG590, with a spectrum in the range 580–1400 nm (Hydrosun Medizintechnik GmbH, Müllheim, Germany). The irradiation experiments were performed taking into account the physical and photobiological laws described by Piazena and Kelleher.[16] The cells were placed in a water-bath and temperature was controlled during irradiation (total irradiance: 112 mW/cm^2, dose: 25 J/cm^{2}a VIS, 76 J/cm2 wIRA, exposure time: 15 min). Thereafter, cells

were incubated for a further 24 h at 37 °C in a 5% CO_2 atmosphere.

Cell viability was determined using the XTT cell proliferation kit II (Roche, Mannheim Germany), 24 h after irradiation. Cells were incubated with 2,3-bis(2-methoxy-4-nitro-5-sulphonyl)-5[(phenyl-amino)carbonyl]-2*H*-tetrazolium hydroxide reagent (1 mg/mL), and incubated for 4 h at 37 °C. Reduction of XTT to formazan by viable tumor cells was monitored colorimetrically at an absorbance wavelength of 450 nm and a reference wavelength of 630 nm using an ELISA plate reader Elisareader ELx808 (Bio-TEK, Bad Friedrichsahll, Germany).

Caspase-3/7 activity in cell lysates was determined using the Apo-ONE Caspase-3/7 assay (Promega, Mannheim, Germany) 24 h after light activation. Briefly, 100 μL of Apo-ONE reagent was added to the cells, and they were incubated for 6 h before fluorescence readings were taken with an ELISA plate reader Elisareader ELx808 (Bio-TEK, Bad Friedrichschall, Germany) using an excitation wavelength of 485 nm and an emission wavelength of 535 nm. The concentration of ROS was determined by measuring the 485/535 nm fluorescence ratio of H2DCFDA (Invitrogen, Darmstadt, Germany). Briefly, 2×10^4 cells were incubated in the presence of 50 nM Ce6 or 200 nM scFv-425-SNAP-Ce6 and 10 μM H_2DCFDA for 30 min in PBS containing 1% FCS. The cells were washed twice with warm PBS containing 2.5% FCS, cultured for 2 h in RPMI-160 medium and illuminated as described above. Fluorescence readings were taken directly after illumination. A blank probe (cells and medium) reading was used as the background and subtracted from all the sample readings.

Data Analysis. Statistical analysis and curve fitting were performed with *GraphPad Prism* software (GraphPad, San Siego, CA). Data are presented as the mean ± MES. Student's *t* test and two-way analysis of variance were used to assess the significance of independent experiments. The criterion $p < 0.05$ was used to determine statistical significance.

RESULTS

Expression, Purification, and Functional Analysis of scFv-SNAP-Tag Fusion Proteins. The coding sequences for the EGFR-specific scFv-425 antibody fragment[12] and a control fragment (scFv-Ki4)[15] that binds to a different antigen (CD30) were transferred to the pMS-SNAP bicistronic vector to generate the complete scFv-425-SNAP and scFv-Ki4-SNAP cassettes, as shown in Figure 1A. The constructs were introduced into HEK-293T cells by transfection and stably transformed cells were identified by selection on zeocin and by monitoring green fluorescent protein (GFP) activity. The fusion proteins were isolated from the culture supernatant to a final purity of ~90% by affinity chromatography (using the C-terminal His_6 tag) and the final yield was 18 mg/L of protein in the supernatant (Figure 1B).

The activity of the SNAP-tag was confirmed in each of the fusion proteins by mixing the unprocessed culture supernatant, the flowthrough fraction, and the eluate from the chromatography step with BG-modified Vista Green (Figure 1C). The binding activity of the scFv-425-SNAP protein was confirmed by flow cytometry using one target cell line expressing EGFR (A431) and one control cell line lacking this antigen but expressing CD30 (L540). Binding was detected with a secondary anti-His_5 Alexa 488 antibody. Flow cytometry data confirmed the rapid and efficient binding of scFv-425-SNAP specifically to $EGFR^+$ target cells, whereas scFv-Ki4-SNAP bound only to the $CD30^+$ L540 cells (Figure 1D).

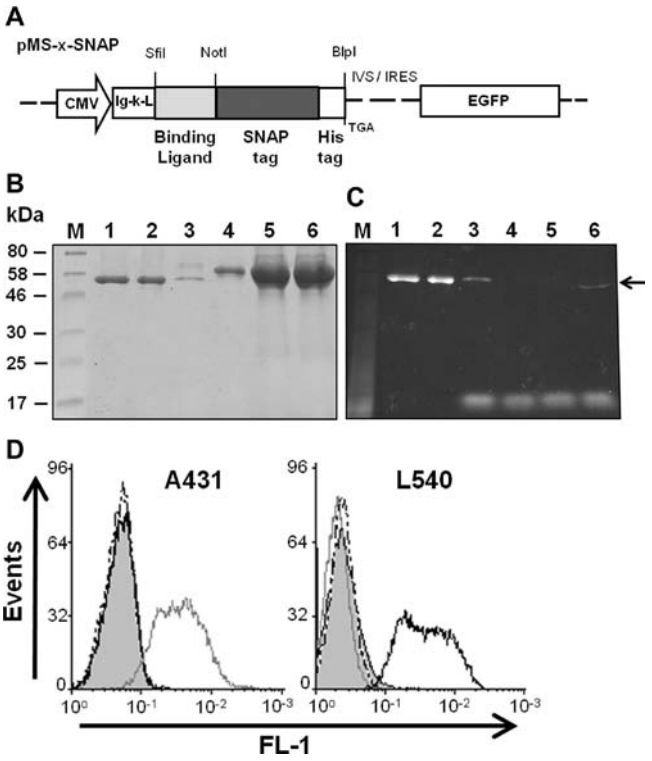

Figure 1. Construction, expression, and binding of the SNAP-tag fusion proteins. (A) Schematic diagram of the bicistronic eukaryotic expression cassettes for the recombinant SNAP-tag fusion proteins. Under the control of the cytomegalovirus (CMV) promoter, the pMS-scFv-425-SNAP vector encodes the antigen binding domain (scFv-425) joined in-frame to the SNAP-tag. The control vector is the same as described above, but the binding domain is replaced by scFv-Ki4. The fusion proteins are secreted by an immunoglobulin κ leader (Ig-κ-L) sequence, and a TGA stop codon is placed immediately after the C-terminal His_6-tag. The additionally transcribed internal ribosome entry site (IVS-IRES) mediates the cotranslational expression of enhanced fluorescent protein (EGFP). (B) Coomassie brilliant blue-stained SDS-PAGE of the purification fractions 1−4 (eluted with an imidazole concentration up to 250 nM) of scFv-425-SNAP protein and (C) corresponding BG-Vista Green-mediated in-gel UV visualization of the fusion protein (indicated by a black arrow). M, Prestained Protein Marker, Broad Range (7−175 kDa); 5, flowthrough; 6, supernatant of HEK-293T cells. (D) Flow cytometric binding analysis of scFv-425-SNAP and scFv-Ki4-SNAP control to $EGFR^+$ A431 and $EGFR^-$ L540 cells. Filled gray curves represent untreated cells. Cells were incubated with 0.5 μg/mL of the purified fusion protein scFv-425-SNAP (light gray curve) and scFv-Ki4-SNAP (black curve). Fluor 488-conjugated anti-Penta-His monoclonal antibody was used as the secondary antibody. To exclude nonspecific staining of the secondary antibody, omission of the His-tagged fusion protein served as control (dotted black curves).

Modification of the Photosensitizer Chlorin e6 with Benzylguanine. The photosensitizer chlorin e6 (Ce6) was modified successfully using *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride (EDC), the sodium salt of hydroxysulfosuccinimide (sulfo-NHS), and a BG-PEG24-NH2 linker. Ce6 carboxyl groups were modified to BG groups, and the BG-modified Ce6 was purified using HPLC (data not shown). Ce6 modification with BG was confirmed by mass spectrometry. The accurate masses of Ce6 (597.215 Da), BG-PEG24-NH2 (1398.761 Da), and BG-PEG24-Ce6 (1979.004 Da) were detected on a Micromass QTOFII mass spectrometer, which confirmed that purified BG-PEG24-Ce6 had the same

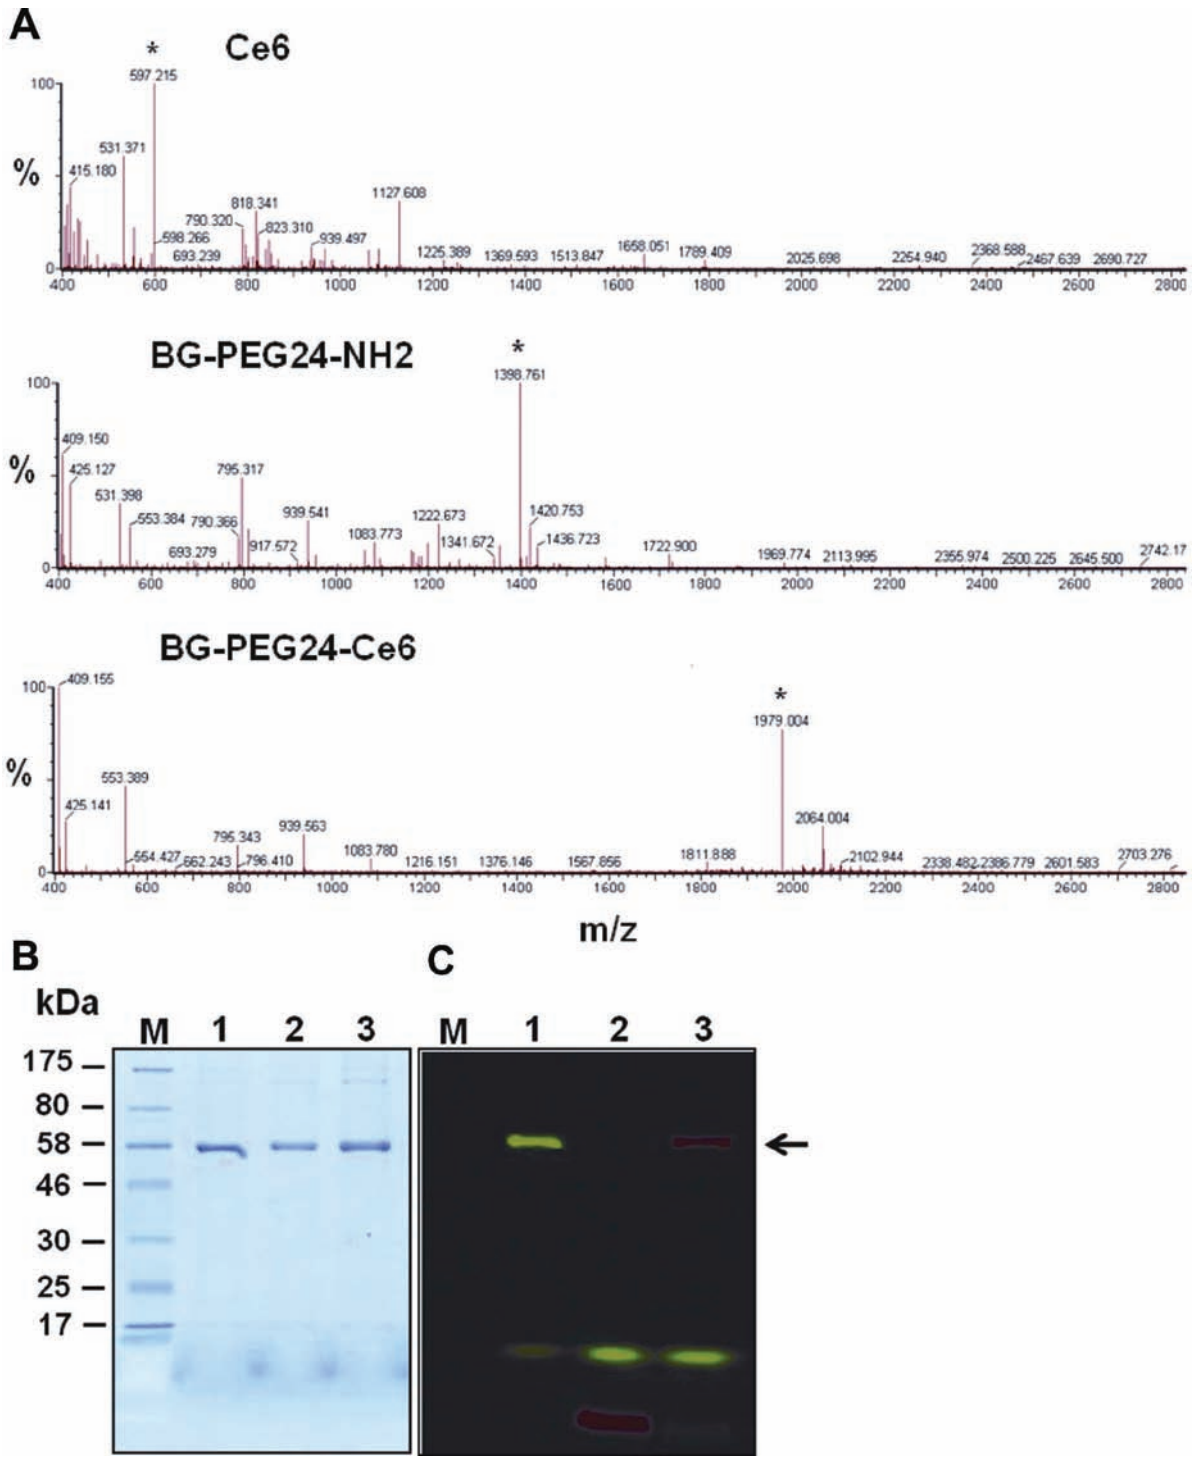

Figure 2. Analysis of Ce6 photosensitizer by mass spectrometry before and after modification with benzylguanine (BG). (A) ESI mass spectrum of Ce6, BG-PEG24-NH_2, and BG-PEG24-Ce6. The top panel represents Ce6 (597.215 Da), the middle panel represents BG-PEG24-NH_2 (1398.761 Da), and the bottom panel represents BG-PEG24-Ce6 (1979.004 Da), indicated by asterisks. The diagram presents the relative frequency (%) on the *y*-axis correlated to the mass-to-charge (m/z) ratio on the *x*-axis. (B) Coomassie brilliant blue-stained SDS-PAGE of coupling of BG-PEG24-Ce6 or BG-Vista Green to scFv-425-SNAP and (C) corresponding in-gel fluorescence visualization of the fusion proteins (indicated by a black arrow). The different dye spectra were unmixed based on their spectral patterns using CRi Maestro multispectral imaging system. M, Prestained Protein Marker, Broad Range (7−175 kDa); 1, scFv-425-SNAP incubated with a 1.5-fold molar excess of BG-Vista Green; 2, scFv-425-SNAP first blocked with bromothenylpteridine (BTP), then incubated with a 1.5-fold molar excess of BG-Ce6 for 2 h and then postincubated with a 1.5-fold molar excess of BG-VISTA Green; 3, scFv-425-SNAP first incubated with a 1.5-fold molar excess of BG-Ce6, and then incubated with a 1.5-fold molar excess of BG-Vista Green.

mass as the theoretical mass calculated for coupled Ce6 and BG-PEG24-NH2 (Figure 2A).

Protein Labeling with BG-Modified Fluorophores and Ce6. The functionality of the SNAP-tag was tested by coupling

dx.doi.org/10.1021/bc200304k | *Bioconjugate Chem.* 2011, 22, 2487−2495

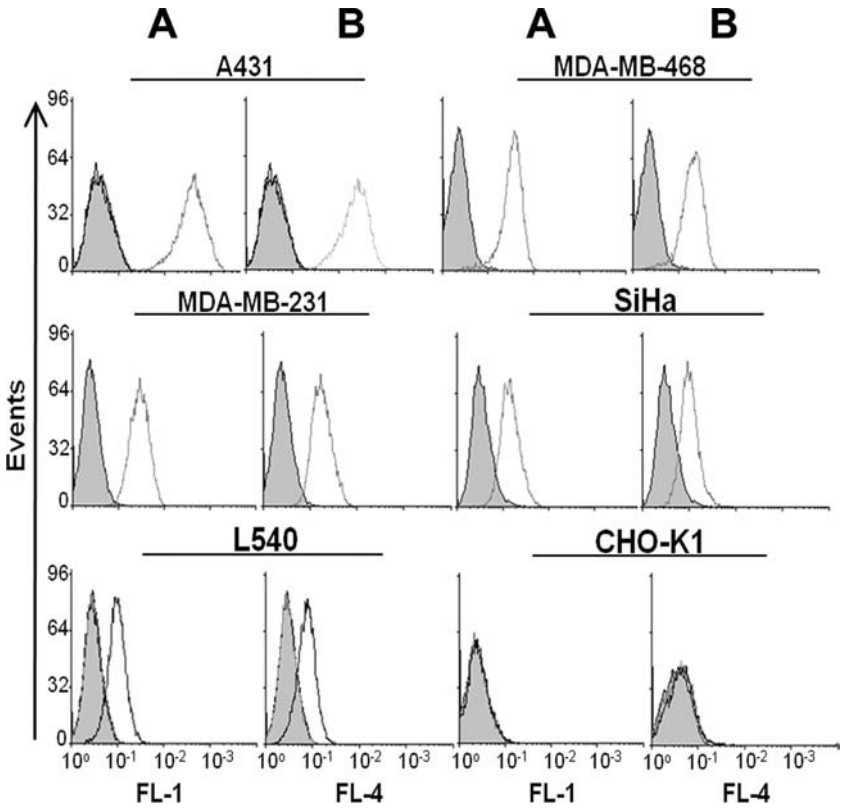

Figure 3. Binding activity of scFv-425-SNAP-Vista Green and scFv-425-SNAP-Ce6 to several EGFR$^+$ cell lines. Flow cytometry analysis was carried out after incubating 4×10^5 cells (filled gray curves) with each fusion protein for 20 min at 37 °C in PBS. Specific binding of (A) scFv-425-SNAP-Vista Green and (B) scFv-425-SNAP-Ce6 (light gray curves) to A431, MDA-MB-468, MDA-MB-231, SiHa, L540, and CHO-K1 cells were evaluated in parallel. As a control, scFv-Ki4-SNAP-Vista Green (black curves) was tested against L540 CHO-K1 and A431cells. Vista Green fluorescence (A) was analyzed in the FL-1 channel and Ce6 (B) in the FL-4 channel.

to BG-modified fluorescent dye, which revealed a labeling efficiency of 85−90% after a 2 h incubation at room temperature (data not shown). The reaction was repeated using BG-modified Ce6. The photosensitizer reacted solely with the active SNAP-tag in the fusion proteins and the reaction could be irreversibly blocked with bromothenylpteridine (BTP), as shown by postincubation with a 1.5-fold molar excess of BG-Vista Green. Analysis with the CRi Maestro imaging system showed no fluorescence associated with the previously blocked fusion protein and saturated SNAP binding to BG-Ce6 in nonblocked fusion proteins (Figure 2B, C).

Flow Cytometry and Confocal Microscopy. To determine the activity of labeled scFv-425-SNAP fusion proteins, flow cytometry analysis was carried out using proteins that had been labeled with either BG-Vista Green or BG-Ce6. All the labeled proteins showed a strong fluorescence signal on the corresponding target cell line (A431, MDA-MB-468, MDA-MB-231 and SiHa) but not on control cells (L540 and CHO-K1) after a 30 min incubation on ice (Figure 3). As expected, labeled scFv-Ki4-SNAP showed a strong fluorescence signal on L540 but not on A431 and CHO-K1 cells.

Confocal microscopy revealed strong, specific, and homogeneous membrane staining on A431, MDA-MB468, MDA-MB-231, and SiHa cells incubated with scFv-425-SNAP-Ce6 (Figure 4). The labeled fusion protein was specifically and efficiently taken up into EGFR$^+$ cell lines after a 30 min incubation at 37 °C but not at 4 °C. In contrast, no signal was detected when the EGFR$^-$ cell lines L540 and CHO-K1 were incubated with scFv-425-SNAP-Ce6 under the same conditions.

Photocytotoxicity of scFv-425-SNAP-Ce6. The cytotoxic effects of scFv-425-SNAP-Ce6 and unconjugated BG-Ce6 were evaluated using an XTT-based colorimetric cell proliferation assay with the four EGFR$^+$ cell lines and CHO-K1 as a negative controls. The viability of A431, MDA-MB-468, MDA-MB-231, and SiHa cells treated with scFv-425-SNAP-Ce6 was reduced significantly, in a concentration-dependent manner, after a 24 h incubation followed by light activation. The IC_{50} values were 48 nM (A431), 38 nM (MDA-MB-468), 200 nM (MDA-MB-231), and 218 nM (SiHa). CHO-K1 cells remained unaffected even when exposed to 800 nM of the conjugated fusion proteins, and the control construct scFv-Ki4-SNAP-Ce6 had a negligible effect in both A431 and CHO-K1 cells (Figure 5A). In contrast, unconjugated Ce6 was toxic toward all the cell lines, with IC_{50} values of 16 nM (A431), 22 nM (MDA-MB-468), 22 nM (MDA-MB-231), 26 nM (SiHa), and 18 nM (CHO-K1). These data are shown in Figure 5C.

Both the conjugated and unconjugated forms of Ce6 were toxic only after light activation, as confirmed by carrying out parallel experiments without the light activation step. No significant reduction in viability was observed in any of the cell lines (Figure 5B,D).

To determine whether scFv-425-SNAP-Ce6 selectively induced programmed cell death in target cells by triggering the apoptotic pathway, we analyzed the activity of caspase-3 and caspase-7 in A431, MDA-MB-231, MDA-MB468, SiHa, and CHO-K1 cells 24 h after light activation. Both scFv-425-SNAP-Ce6 (200 nM) and unconjugated Ce6 (50 nM) increased the levels of caspase-3 and caspase-7, whereas no

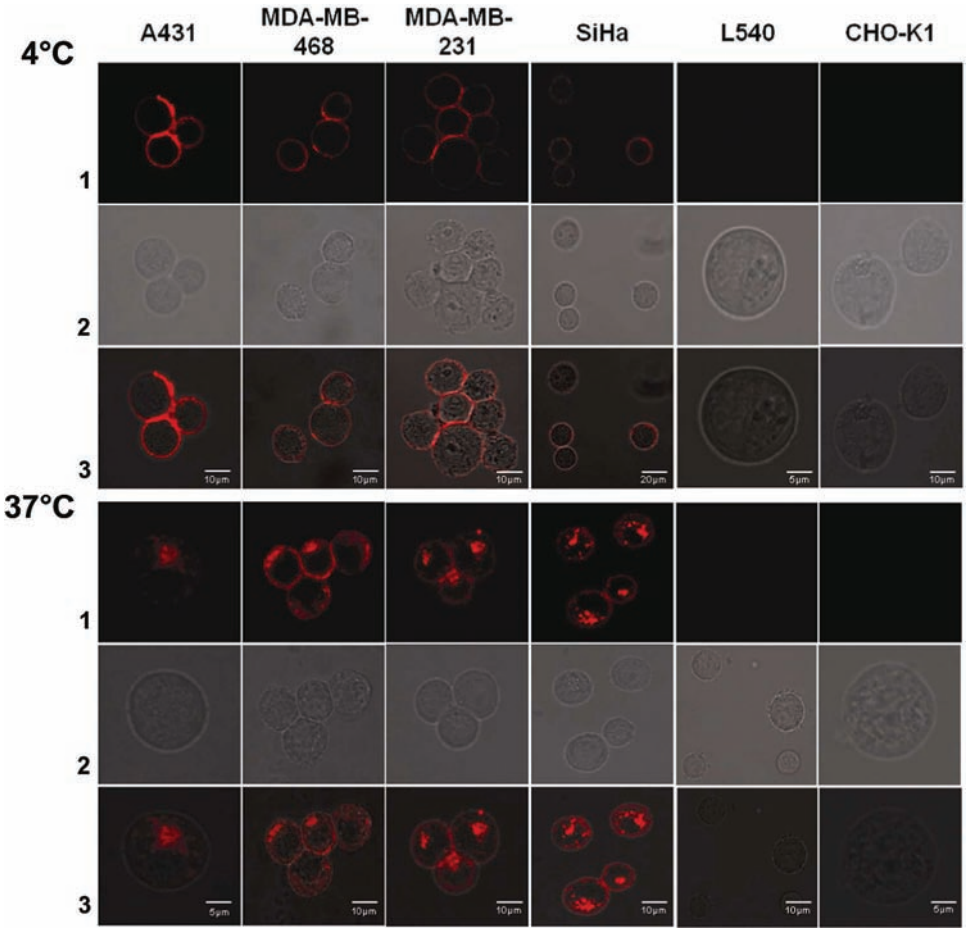

Figure 4. Binding and internalization of scFv-425-SNAP-Ce6 analyzed by confocal microscopy. Confocal images were obtained for the EGFR$^+$ cell lines A431, MDA-MB-468, MDA-MB-231, and SiHa, and for the EGFR$^-$ cell lines L540 and CHO-K1. All cells were incubated with 0.5 μg scFv-425-SNAP-Ce6 for 30 min at 4 °C (upper panel) or for 60 min at 37 °C (lower panel). (1) Ce6 fluorescence signal; (2) transmitted light; (3) overlay of fluorescence signal and transmitted light. Magnification is indicated by the white scale bars.

significant increase was observed in A431 cells treated with 200 nM scFv-Ki4-SNAP-Ce6 (Figure 5E).

The production of ROS in photoactivated A431 cells was investigated by measuring the 485/535 nm fluorescence of DCF, produced by the oxidation and deacetylation of 6-carboxy-2′,7′-dichlorodihydrofluoresceindiacetatedi(acetoxymethyl)ester (H_2DCFDA). We found that a burst of ROS synthesis follows light activation in the presence of 200 nM of the conjugated Ce6 and 50 nM of the unconjugated Ce6, but there was only a small increase in ROS levels in nonirradiated cells, barely above the background level observed in cells that were not treated with the photosensitizer (Figure 5F).

■ DISCUSSION

Photodynamic therapy (PDT) is a minimally invasive treatment that uses nontoxic photosensitizers and harmless visible light in combination with oxygen to produce cytotoxic reactive oxygen species that kill malignant cells by apoptosis and/or necrosis.[17] Many different photosensitizers have been developed, but we chose Ce6 as a model because it has been evaluated extensively in PDT studies and also has advantageous physical and chemical properties. Ce6 has an absorption maximum at 664 nm, which is a good compromise between photon efficacy and cell penetration,[18] and the presence of carboxyl groups allows further functionalization.[7]

One of the main drawbacks of PDT is the scattergun effect of activated photosensitizers, which tends to damage healthy as well as tumor cells. Targeted therapy using antibodies has revolutionized cancer treatment, and several antibodies that bind to tumor cell antigens have achieved blockbuster status. The efficacy of therapeutic antibodies can be improved by covalently linking them to additional effector molecules (e.g., radionuclides, drugs, or toxins),[19] as this achieves selective delivery and should reduce the systemic toxicity traditionally associated with small molecule drugs.[20] The same principle can be applied to photosensitizers, an approach known as photoimmunotherapy (PIT). Effector molecules are generally conjugated to antibodies using either the reduced sulfhydryl groups of cysteine residues or amino groups in lysine side chains. However, both methods yield heterogeneous products, comprising a mixture of conjugated antibodies with the effector attached at different sites and a variable number of effectors attached to each antibody resulting in a range of molar rations and very different pharmacokinetic, efficacy, and safety profiles.

Hamblett and colleagues[21] have studied the toxicity, pharmacokinetic properties, and therapeutic efficacy of heterogeneous antibody−drug conjugates by purifying three antibody fractions containing two, four, and eight conjugated molecules of monomethyl-auristatin E (MMAE). The fraction with eight MMAE groups was poorly tolerated and rapidly cleared compared to the other fractions and demonstrated the lowest

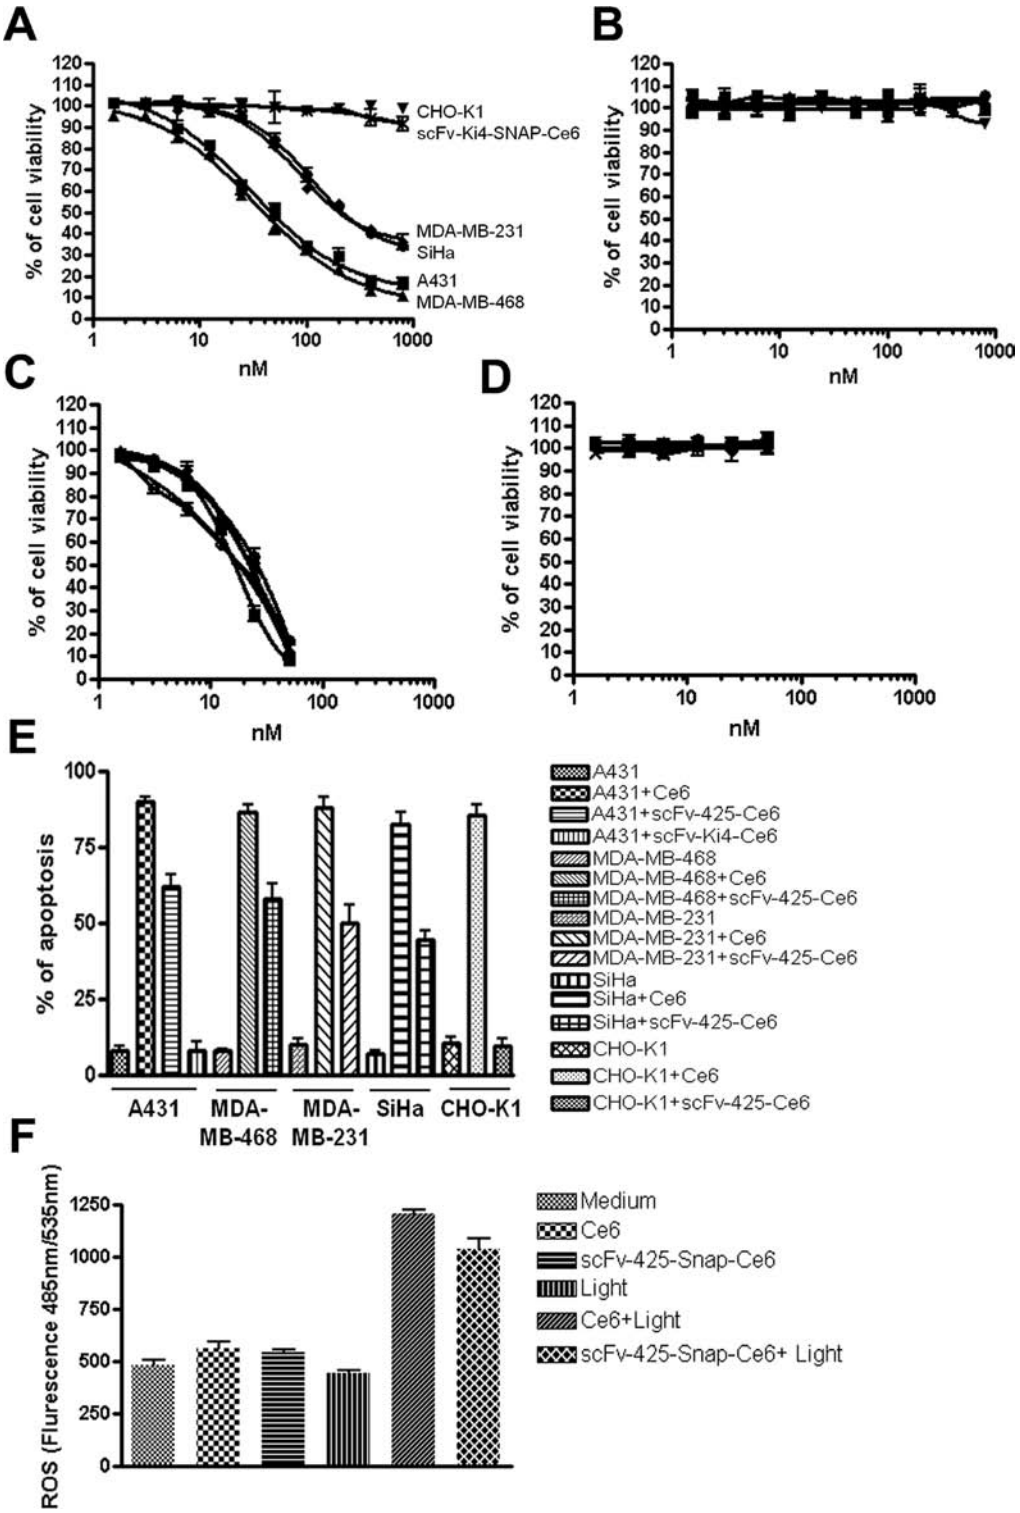

Figure 5. Evaluation of photodynamic therapeutic efficiency. Cell proliferation and apoptosis assays were carried out using the scFv-425-SNAP-Ce6. The cytotoxicity of scFv-425-Ce6 was determined against cell lines A431 (■), MDA-MB-468 (▲), MDA-MB-231 (♦), SiHa (●), and CHO-K1 (▼) using the XTT proliferation assay on (A) irradiated cells and (B) nonirradiated cells. The cytotoxicity of scFv-Ki4-SNAP-Ce6 against A431 cells (-X-) was tested as a control. The same cells were treated with different concentrations of unconjugated Ce6 and cell viability was analyzed (C) with and (D) without light activation. (E) Apoptosis was evaluated using the Apo-ONE Homogeneous Caspase-3/7 Assay, with 50 nM Ce6, 200 nM scFv-SNAP-Ce6, and 200 nM scFv-Ki4-SNAP-Ce6. (F) The generation of reactive oxygen species (ROS) due to illumination of photosensitized A431 cells was detected using the dichlorofluorescein derivative carboxy-H2DCFDA reagent.

efficacy. This suggests that the key design parameter for antibody−drug conjugates is the number of drug molecules attached to the antibody. However, even purifying antibodies that carry the same number of drug molecules still generates a complex mixture because of the many alternative attachment sites.[21] For example, there are approximately 40 lysine residues in a typical antibody, potentially resulting in more than one million different conjugated antibody species. Similarly, there

dx.doi.org/10.1021/bc200304k | *Bioconjugate Chem.* 2011, 22, 2487−2495

are between one and eight cysteine residues, typically generating approximately 100 conjugated variants. Each version of the antibody−drug conjugate typically displays a unique and unpredictable pharmacokinetic profile.[20]

To avoid the issues discussed above, we investigated the use of SNAP-tag technology to provide a unique conjugation site on the antibody, allowing the production of a homogeneous conjugate preparation. We engineered a construct in which the coding sequence of a scFv antibody that binds specifically to EGFR was genetically fused to the SNAP tag cassette, which endows the antibody with a SNAP-tag and therefore allows site-specific conjugation BG-modified substrates, in this case Ce6. This conjugation method can be applied to any antibody−photosensitizer combination as long as the antibody carries the SNAP-tag and the substrate is modified with a BG group. We therefore also prepared a control construct in which the scFv-Ki4, which binds to CD30 and is thus irrelevant for the treatment of $EGFR^+$ tumors, was also labeled with Ce6.

The conjugation reaction was successful, allowing the preparation of homogeneous samples of scFv-425-SNAP-Ce6 and scFv-Ki4-SNAP-Ce6. We then tested these preparations for their ability to kill tumor cells specifically. We found that scFv-425-SNAP-Ce6 selectively killed $EGFR^+$ cells in four human tumor-derived cell lines representing epidermal, breast, and cervical carcinomas (A431, MDA-MB-231, MDA-MB468, and SiHa) after exposure to light. The phototoxicity of scFv-425-SNAP-Ce6 was dependent on the presence of EGFR, receptor internalization and light, and toxicity was most potent in A431 and MDA-MB468 cells, which express the largest amount of the receptor [$(1-1.3) \times 10^6$ receptors/cell].[22,23] The other cells lines expressed less EGFR (1.3×10^5 receptors/cell for MDA-MB-231 and $(2 \times 10^4)-(2 \times 10^5)$ receptors/cell for SiHa),[23,24] and the toxicity of scFv-425-SNAP-Ce6 was concomitantly reduced, although not to the point where the fusion protein would be therapeutically ineffective. This means that scFv-425-SNAP-Ce6 can target a wide range of $EGFR^+$ cells, not only those with the highest expression levels. No toxicity was observed when $EGFR^-$ cells (CHO-K1) were exposed to scFv-425-SNAP-Ce6.

We have previously shown that scFv-425-SNAP accumulates directly in mouse kidneys after injection, and is subsequently detected in the bladder, indicating clearance by renal filtration. Despite the rapid clearance, the accumulation and retention of scFv-425-SNAP in tumor tissue was evidently sufficient to yield very high tumor to background ratio 10 h postinjection.[12]

In conclusion, we have demonstrated for the first time the conjugation of photosensitizers to a scFv antibody using SNAP-tag technology. This rapid and efficient method produces a homogeneous conjugate with define pharmacokinetic and therapeutic profiles. This provides proof of the principle that SNAP-tag technology can be used to produce targeted photoimmunotherapeutic agents for cancer therapy, avoiding the off-target effects that have thus far limited the development of PDT.

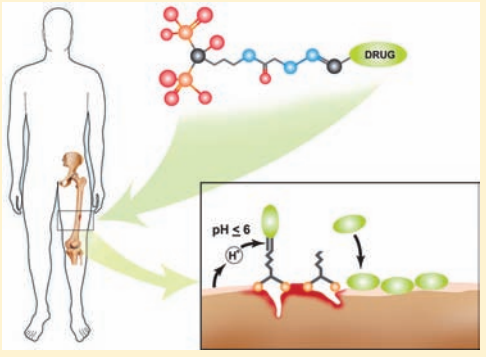
ABSTRACT: Skeletal diseases have a major impact on the worldwide population and economy. Although several therapeutic agents and treatments are available for addressing bone diseases, they are not being fully utilized because of their uptake in nontargeted sites and related side effects. Active targeting with controlled delivery is an ideal approach for treatment of such diseases. Because bisphosphonates are known to have high affinity to bone and are being widely used in treatment of osteoporosis, they are well-suited for drug targeting to bone. In this study, a targeted delivery of therapeutic agent to resorption sites and wound healing sites of bone was explored. Toward this goal, bifunctional hydrazine-bisphosphonates (HBPs), with spacers of various lengths, were synthesized and studied for their enhanced affinity to bone. Crystal growth inhibition studies showed that these HBPs have high affinity to hydroxyapatite, and HBPs with shorter spacers bind more strongly than alendronate to hydroxyapatite. The HBPs did not affect proliferation of MC3T3-E1 preosteoblasts, did not induce apoptosis, and were not cytotoxic at the concentration range tested (10^{-6}–10^{-4} M). Furthermore, drugs can be linked to the HBPs through a hydrazone linkage that is cleavable at the low pH of bone resorption and wound healing sites, leading to release of the drug. This was demonstrated using hydroxyapatite as a model material of bone and 4-nitrobenzaldehyde as a model drug. This study suggests that these HBPs could be used for targeted delivery of therapeutic agents to bone.

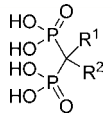


INTRODUCTION

Active targeting of therapeutic agents to bone reduces drug toxicity and improves drug bioavailability at the desired site.[1] Bone tissue is characterized by constant remodeling, whereby it continuously undergoes formation and resorption; perturbations in bone remodeling are associated with several metabolic bone diseases, such as osteoporosis.[2−4] Therefore, molecules that inhibit bone resorption or stimulate bone formation show drug activity against various skeletal disorders.[5] Although a range of therapeutic agents is available to treat skeletal disorders,[6] their clinical application is hampered by their uptake in nontargeted sites and the consequent undesired side effects.[7]

Several bisphosphonates (BPs) show antiresorptive properties and are being prescribed in the treatment of skeletal diseases.[6,8,9] BPs are stable analogues of naturally occurring pyrophosphate and have high affinity to bone and hydroxyapatite (HA).[10] Besides the two phosphonate groups, BPs have two other substituents (R^1 and R^2) on their geminal carbon. BPs with a hydroxyl or an amine group at R^1 facilitate tridentate binding to bone and HA, and show an increased affinity to these materials.[11,12] The overall nature of the R^2 substituent also contributes toward enhancing the bone-seeking ability and pharmacological properties of BPs.[10,13]

Recently, a number of drug targeting and drug delivery strategies have been reported using a range of delivery vehicles,



such as polymer scaffolds, liposomes, dendrimers, micelles, hydrogels, peptides, and antibodies.[14−21] However, drug targeting to bone sites requires molecules that have high affinity to bone. Besides BPs, other molecules, such as D-aspartic acid octapeptide,[20,21] polymalonic acid,[22] and tetracycline,[23,24] show affinity to bone. BPs have advantage over other molecules because their affinity can be tuned by changing their R^1 and R^2 substituents. Moreover, in addition to being prescribed as drugs, BPs are also being studied for drug targeting and drug delivery to bone,[25−30] including the administration of radiopharmaceuticals and imaging agents to bone for diagnostic applications.[31−35] For the purpose of drug targeting to bone, various strategies of BP-drug conjugation have been investigated by us and others.[29,35−38] Ideally, for targeted drug delivery to bone, BP-drug conjugates should have a stable linkage between the BP and drug molecule that can survive during systemic circulation of the conjugate following parenteral administration, and at the same time be labile at the

bone surface to release the drug locally. Most of the strategies mentioned above employ agents that are conjugated to BPs through stable, noncleavable linkages resulting in the administration of the complete conjugate to the treatment site.[25,29,31−33,35] Current approaches that employ cleavable linkages either are too labile to ensure delivery of the drug to the desired site[26,27] or show limited release providing inadequate availability of drug for action.[26] A strategy that involves labile conjugation to one of the phosphonate groups of BP could compromise the affinity of the corresponding BP-drug conjugate toward bone, because it is through the phosphonate groups that BPs bind to the mineral matrix.[27]

Herein, we report a novel strategy for targeted delivery of therapeutic agents to sites of low pH, such as bone resorption lacunae and areas of wound healing, through their conjugation to enhanced affinity bifunctional BPs with a pH-triggered cleavable linkage. In particular, we have synthesized seven novel hydrazine-bisphosphonates (HBPs) (**2**−**8**), which have a hydroxyl group as R^1, while R^2 contains a hydrazine functionality attached through spacers of various length and hydrophobicity (Table 1). Furthermore, experiments were performed to explore the binding affinity, cytotoxicity, drug conjugation, and pH triggered drug release of HBPs.

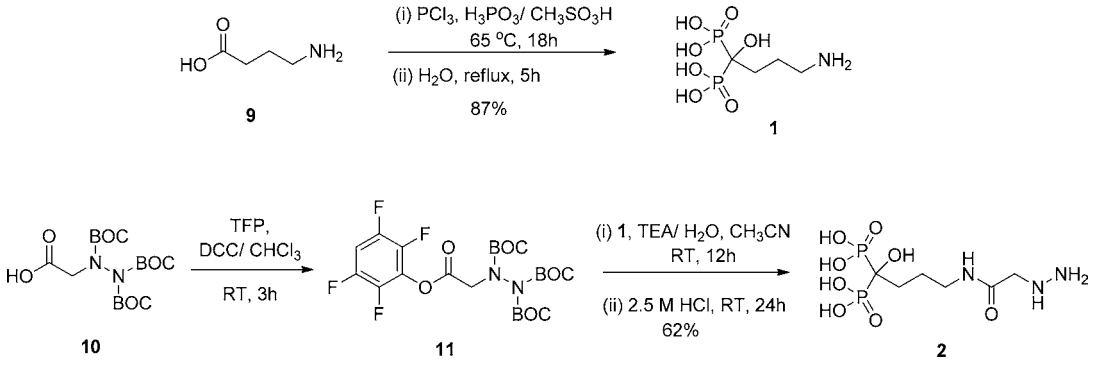
Materials. The osteoblastic cell line MC3T3-E1 was obtained from American Type Culture Collection (CRL-2593; ATCC, Rockville, MD). Alpha minimum essential medium (αMEM) and fetal bovine serum (FBS) were purchased from GIBCO-Invitrogen (Carlsbad, CA). The BCA protein assay kit was obtained from ThermoFisher Scientific (Rockford, IL). The cell proliferation reagent WST-1 was purchased from Roche (Mannheim, Germany). Ac-DEVD-AFC was obtained from Enzo Life Sciences (Plymouth Meeting, PA). 4-Aminobutanoic acid, 6-aminohexanoic acid, 8-aminooctanoic acid, glycine, glycylglycine, glycylglycylglycine, methanesulfonic acid, phosphorous acid, phosphorus trichloride, and 2,3,5,6-tetrafluorophenol (TFP) were purchased from Alfa Aesar (Ward Hill, MA). *N,N′*-Dicyclohexylcarbodiimide (DCC), triethylamine (TEA), tri-BOC-hydrazinoacetic acid (TBHA), reagent grade hydroxyapatite powder, potassium hydroxide, sodium acetate, sodium chloride, sodium hydroxide, etoposide, tris(hydroxymethyl)aminomethane hydrochloride (Tris-HCl), 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid (HEPES), 3-[(3-cholamidopropyl)dimethylamino]-1-propanesulfonate (CHAPS), ethylenediaminetetraacetic acid disodium salt dihydrate (EDTA), sodium fluoride (NaF), sodium orthovanadate, leupeptin hemisulfate salt, aprotinin bovine, phenylmethylsulfonylfluoride, DL-dithiothreitol (DTT), glycerol, and Triton X-100 were purchased from Sigma-Aldrich (St. Louis, MO). Calcium chloride, hydrochloric acid, and potassium dihydrogen phosphate were obtained from EMD Chemicals (Gibbstown, NJ). Acetonitrile, chloroform, dichloromethane, diethyl ether, dimethyl sulfoxide (DMSO), hexane, and phosphoric acid were purchased from Mallinckrodt (Hazelwood, MO). The NMR solvents deuterium oxide and deuterated chloroform were purchased from Cambridge Isotope Laboratories (Andover, MA).

Apparatus. ^{1}H NMR, ^{31}P NMR, and ^{13}C NMR spectra were obtained on a Varian INOVA 400 MHz spectrometer (Palo Alto, CA). Electrospray ionization mass spectrometry was performed on a ThermoFinnigan LCQ mass spectrometer (Waltham, MA). HA crystal growth experiments were performed using an Isotemp Refrigerated Circulator and pH meter (Fisher Scientific, Pittsburgh, PA). UV−vis spectra were obtained with an Agilent 8453 UV−visible spectrophotometer (Agilent Technologies, Santa Clara, CA). Deionized water was produced using a Milli-Q water purification system (Millipore, Bedford, MA).

Scheme 1. Synthesis of Alendronate 1 and HBP 2



dx.doi.org/10.1021/bc2003132 | Bioconjugate Chem. 2011, 22, 2496−2506

Synthesis of (4-Amino-1-hydroxybutylidene)-bisphosphonic Acid Monosodium Salt (1). (4-Amino-1-hydroxybutylidene)bisphosphonic acid monosodium salt or monosodium alendronate (**1**) was synthesized in an inert atmosphere according to a previously reported procedure from 4-aminobutanoic acid (**9**)[39,40] as outlined in Scheme 1. A 25 mL flask was fitted with an addition funnel and a reflux condenser. Ice-cold water was circulated through the condenser. The system was flushed with nitrogen; and 4-aminobutyric acid (**9**) (4.0 g, 38.7 mmol), phosphorous acid (3.18 g, 38.7 mmol), and methanesulfonic acid (16 mL) were added to the flask. The mixture was heated for 5 min at 65 °C. PCl_3 (9.0 mL, 85.3 mmol) was added over 20 min, and the mixture was stirred for 18 h at 65 °C. The solution was cooled to 25 °C and quenched into 0−5 °C water (40 mL) with vigorous stirring. The reaction flask was rinsed with an additional 16 mL of water, and the combined solution was refluxed for 5 h at 110 °C. The solution was cooled to 23 °C, and the pH was adjusted to 4−4.5 with 50% (v/v) NaOH. The resulting mixture was allowed to react for 10−12 h at 0−5 °C. The white solid obtained was filtered and washed with cold water (20 mL) and 95% ethanol (20 mL). The solid was dried under vacuum at room temperature (RT) to obtain compound **1** as a white solid in 87.1% (9.22 g) yield. ^{1}H NMR (D_2O): δ 3.02 (t, 2H), δ 2.00 (m, 4H). ^{13}C NMR (MeCN/D_2O): δ 72.9 (t), δ 39.33 (s), δ 29.94 (s), δ 21.48 (t). ^{31}P NMR (H_3PO_4/D_2O): δ 18.53. MS (MALDI-TOFMS): 272 $[M+H+Na]^+$.

Synthesis of Tri-*tert*-butyl 2-(2-oxo-2-(2,3,5,6-tetrafluorophenoxy)ethyl)hydrazine-1,1,2-tricarboxylate (11). Tri-BOC-hydrazinoacetate (**10**) (90.0 mg, 0.231 mmol) and TFP (42.1 mg, 0.254 mmol) were dissolved in 5 mL chloroform. DCC (52.3 mg, 0.254 mmol) in 5 mL chloroform was added dropwise to the reaction mixture and stirred at RT. The progress of the reaction was followed by thin layer chromatography (TLC). After complete consumption of **10** (3 h), the 1,3-dicyclohexyl urea formed in the reaction mixture was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was then suspended in an adequate amount of hexane, the remaining 1,3-dicyclohexyl urea was removed by filtration, and the filtrate was evaporated *in vacuo* to obtain crude compound **11**. The crude material was purified by column chromatography (hexane/acetone 85/15 v/v) to obtain pure compound **11** as a pale yellow liquid in 97% (120.5 mg) yield. ^{1}H NMR (CD_3CN): δ 7.25 (m, 1H), δ 3.20 (s, 2H) δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 168.01 (s), δ 154.35 (s), δ 153.75 (s), δ 150.54 (s), δ 148.70 (s), δ 147.10 (s), δ 146.40 (s), δ 102.10 (s), δ 84.22 (s), δ 83.27 (s), δ 82.21 (s), δ 54.33 (m), δ 28.20 (s).

Synthesis of (4-(2-Hydrazinylacetamido)-1-hydroxybutane-1,1-diyl)bisphosphonic Acid (2). Compound **1** (50.0 mg, 0.154 mmol) was suspended in 1 mL of deionized water, and TEA (93.2 mg, 0.923 mmol) was added to the suspension. After a few seconds of stirring at RT, the suspension became clear. The reaction was stirred at RT for 5 min. Compound **11** (124 mg, 0.231 mmol) was dissolved in 1.5 mL of acetonitrile and added to the reaction mixture. TEA (15.5 mg, 0.154 mmol) was added, and the reaction mixture was stirred at RT for 12 h. The reaction mixture was washed with diethyl ether (10 mL) and evaporated *in vacuo*. The obtained solid was treated with 2 mL of 2.5 M HCl, and the solution was stirred at RT for 24 h. The solvent was removed *in vacuo*, and the crude product was sonicated twice in ethanol at RT for 2 h and filtered to obtain a white solid of pure compound **2** in 62% (31 mg) yield. ^{1}H NMR (D_2O): δ 3.78 (s, 2H), δ 3.28 (t, 2H), δ 1.99 (m, 2H), δ 1.84 (m, 2H). ^{13}C NMR (MeCN/D_2O): δ 170.41 (s), δ 74.17 (t), δ 51.58 (s), δ 40.50 (s), δ 31.75 (s), δ 24.17 (s). ^{31}P NMR (H_3PO_4/D_2O): δ 19.08. MS (+ ESI): 322 $[M+H]^+$.

General Procedure for Synthesis of Compounds 13a−13f. Compound **12a−12f** (0.401 mmol, 1.2 equiv) was suspended in 1 mL of deionized water, and TEA (0.668 mmol, 2.0 equiv) was added to the suspension. After a few seconds of stirring at RT, the suspension became clear. The reaction was stirred at RT for 5 min. Compound **11** (0.334 mmol, 1.0 equiv) was dissolved in 1.5 mL of acetonitrile, and the solution was added to the reaction mixture. TEA (0.167 mmol, 0.5 equiv) was added, and the reaction mixture was stirred at RT for 12 h. The reaction mixture was washed with diethyl ether, and the solvent was evaporated *in vacuo* to obtain crude compound **13a−13f**. The crude product **13a−13f** was used in the next reaction without further purification.

*Compound **13a**.* Following the procedure shown for **13a−13f**, compound **13a** was obtained by amide coupling of compound **11** and glycine (**12a**) as a paste in 95% yield. ^{1}H NMR ($CDCl_3$): δ 4.10 (s, 2H), δ 3.98 (s, 2H), δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 174.56 (s), δ 168.46 (s), δ 154.46 (s), δ 153.86 (s), δ 150.65 (s) δ 84.52 (s), δ 83.16 (s), δ 82.45 (s), δ 54.93 (m), δ 45.91 (m), δ 28.22 (s).

*Compound **13b**.* Following the procedure shown for **13a−13f**, compound **13b** was obtained by amide coupling of compound **11** and 4-aminobutenoic acid (**12b**) as a paste in 97% yield. ^{1}H NMR ($CDCl_3$): δ 4.10 (s, 2H), δ 3.60 (d, 2H), δ 2.35 (m, 2H), δ 1.30 (m, 2H), δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 182.70 (s), δ 170.70 (s), δ 154.30 (s), δ 153.40 (s), δ 150.56 (s) δ 84.24 (s), δ 83.56 (s), δ 82.10 (s), δ 54.30 (m), δ 39.41 (m), δ 35.60 (m), δ 28.41 (s), δ 23.42 (m).

*Compound **13c**.* Following the procedure shown for **13a−13f**, compound **13c** was obtained by amide coupling of compound **11** and glycylglycine (**12c**) as a paste in 94% yield. ^{1}H NMR ($CDCl_3$): δ 4.02 (s, 2H), δ 3.99 (s, 2H), δ 3.80 (s, 2H), δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 174.44 (s), δ 169.24 (s), δ 168.43 (s), δ 154.34 (s), δ 153.55 (s), δ 151.20 (s), δ 85.12 (s), δ 83.66 (s), δ 83.05 (s), δ 55.15 (m), δ 45.24 (m), δ 43.31 (m), δ 28.15 (s).

*Compound **13d**.* Following the procedure shown for **13a−13f**, compound **13d** was obtained by amide coupling of compound **11** and 6-aminohexanoic acid (**12d**) as a paste in 96% yield. ^{1}H NMR ($CDCl_3$): δ 4.03 (s, 2H), δ 3.33 (d, 2H), δ 2.21 (t, 2H), δ 1.61 (m, 2H), δ 1.45 (m, 27H), δ 1.28 (m, 2H). ^{13}C NMR ($CDCl_3$): δ 178.04 (s), δ 170.20 (s), δ 154.44 (s), δ 153.34 (s), δ 151.84 (s), δ 85.11 (s), δ 83.24 (s), δ 83.48 (s), δ 54.35 (m), δ 38.92 (m), δ 34.32 (m), δ 29.15 (s), δ 28.40 (s), δ 26.37 (s), δ 24.75 (s).

*Compound **13e**.* Following the procedure shown for **13a−13f**, compound **13e** was obtained by amide coupling of compound **11** and glycylglycylglycine (**12e**) as a paste in 93% yield. ^{1}H NMR ($CDCl_3$): δ 4.01 (s, 2H), δ 3.98 (d, 2H), δ 3.91 (d, 2H), δ 3.80 (d, 2H), δ 1.42 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 174.45 (s), δ 169.75 (s), δ 169.51 (s), δ 168.01 (s), δ 154.55 (s), 151.40 (s), 151.14 (s), δ 85.40 (s), δ 85.29 (s), δ 83.51 (s), δ 55.49 (m), δ 45.30 (m), δ 43.77 (m), δ 43.34 (s), δ 28.19 (s).

*Compound **13f**.* Following the procedure shown for **13a−13f**, compound **13f** was obtained by amide coupling of compound **11** and 8-aminooctanoic acid (**12f**) as a paste in 95% yield. ^{1}H NMR ($CDCl_3$): δ 4.02 (s, 2H), δ 3.23 (m, 2H), δ 2.22 (t, 2H), δ 1.59 (m, 4H), δ 1.45 (m, 27H), δ 1.25 (m,

6H). ^{13}C NMR ($CDCl_3$): δ 178.40 (s), δ 170.05 (s), δ 154.14 (s), 151.25 (s), 151.19 (s), δ 85.17 (s), δ 85.39 (s), δ 83.89 (s), δ 38.90 (m), δ 34.00 (t), δ 30.10 (m), δ 29.12 (s), δ 29.65 (s), δ 26.58 (s), δ 24.54 (s).

General Procedure for Synthesis of Compounds 14a−14f. Compound **13a−13f** (0.386 mmol, 1.0 equiv) and TFP (0.425 mmol, 1.1 equiv) were dissolved in 15 mL chloroform. DCC (0.425 mmol, 1.1 equiv) in 10 mL chloroform was added dropwise to the reaction mixture and stirred at RT. The progress of the reaction was followed by TLC. After complete consumption of **13a−13f** (3 h), the 1,3-dicyclohexyl urea formed in the reaction mixture was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was then suspended in an adequate amount of hexane, the remaining 1,3-dicyclohexyl urea was removed by filtration, and the filtrate was evaporated *in vacuo* to obtain crude compound **14a−14f**. The crude product was purified by column chromatography (CH_2Cl_2/MeOH 90/10 v/v) to obtain the pure compound as a pale yellow liquid.

*Compound **14a***. Following the procedure shown for **14a−14f**, compound **14a** was obtained from **13a** by treatment of TFP and DCC as a sticky liquid. ^{1}H NMR ($CDCl_3$): δ 6.60 (s, 1H), δ 4.25 (s, 2H), δ 4.10 (s, 2H), δ 1.42 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 174.02 (s), δ 168.32 (s), δ 154.21 (s), δ 153.14 (s), δ 150.78 (s), δ 148.72 (d), δ 146.89 (d), δ 146.10 (s), δ 101.80 (s), δ 84.12 (s), δ 83.85 (s), δ 82.64 (s), δ 54.41 (m), δ 45.00 (m), δ 28.44 (s).

*Compound **14b***. Following the procedure shown for **14a−14f**, compound **14b** was obtained from **13b** by treatment of TFP and DCC as a sticky liquid. ^{1}H NMR ($CDCl_3$): δ 6.60 (s, 1H), δ 4.05 (s, 2H), δ 3.20 (d, 2H), δ 2.67 (m, 2H), δ 1.97 (m, 2H), δ 1.42 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 182.47 (s), δ 170.12 (s), δ 154.10 (s), δ 153.45 (s), δ 151.10 (s), δ 148.69 (d), δ 147.23 (d), δ 146.80 (s), δ 102.10 (s), δ 84.58 (s), δ 83.74 (s), δ 82.36 (s), δ 54.33 (m), δ 39.45 (m), δ 33.56 (m), δ 23.47 (s), δ 28.56 (s).

*Compound **14c***. Following the procedure shown for **14a−14f**, compound **14c** was obtained from **13c** by treatment of TFP and DCC as a sticky liquid. ^{1}H NMR ($CDCl_3$): δ 6.98 (s, 1H), δ 4.38 (s, 2H), δ 4.11 (s, 2H), δ 3.41 (s, 2H), δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 170.28 (s), δ 169.52 (s), δ 167.00 (s), δ 156.00 (s), δ 151.12 (s), δ 150.02 (s), 148.23 (d), δ 147.45 (d), δ 146.69 (s), δ 102.47 (s), δ 85.67 (s), δ 85.00 (s), δ 83.90 (s), δ 55.87 (s), δ 45.65 (s), δ 43.06 (m), δ 28.14 (s).

*Compound **14d***. Following the procedure shown for **14a−14f**, compound **14d** was obtained from **13d** by treatment of TFP and DCC as a sticky liquid. ^{1}H NMR ($CDCl_3$): δ 6.97 (s, 1H), δ 4.05 (s, 2H), δ 3.95 (s, 2H), δ 2.31 (m, 2H), δ 2.62 (m, 4H), δ 1.80 (m, 2H), δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 177.12 (s), δ 170.89 (s), δ 154.69 (s), δ 153.78 (s), δ 151.11 (s), 148.60 (d), δ 147.05 (d), δ 146.44 (s), δ 102.10 (s), δ 85.25 (s), δ 83.73 (s), δ 83.92 (s), δ 54.33 (m), δ 38.96 (m), δ 33.56 (m), δ 29.78 (s), δ 28.40 (s), δ 26.58 (s), δ 24.45 (s).

*Compound **14e***. Following the procedure shown for **14a−14f**, compound **14e** was obtained from **13e** by treatment of TFP and DCC as a sticky liquid. ^{1}H NMR ($CDCl_3$): δ 6.75 (s, 1H), δ 4.42 (d, 2H), δ 4.10 (m, 4H), δ 3.85 (d, 2H), δ 1.50 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 170.81 (s), δ 170.10 (s), δ 170.05 (s), δ 165.87 (s), δ 156.00 (s), 154.80 (s), 151.20 (s), 148.48 (d), δ 147.23 (d), δ 146.10 (s), δ 103.76 (s), δ 85.79 (s), δ 85.51 (s), δ 84.07 (s), δ 55.96 (m), δ 49.46 (s), δ 43.61 (s), δ 40.82 (s), δ 28.11 (s).

*Compound **14f***. Following the procedure shown for **14a−14f**, compound **14f** was obtained from **13f** by treatment of TFP and DCC as a sticky liquid. ^{1}H NMR ($CDCl_3$): δ 6.98 (s, 1H), δ 4.05 (s, 2H), δ 3.95 (s, 2H), δ 2.40 (s, 2H), δ 1.65 (m, 4H), δ 1.38 (m, 6H), δ 1.45 (m, 27H). ^{13}C NMR ($CDCl_3$): δ 178.58 (s), δ 170.89 (s), δ 154.45 (s), 151.69 (s), 151.51 (s), 148.72 (d), δ 147.20 (d), δ 146.40 (s), δ 102.10 (s), δ 85.93 (s), δ 85.54 (s), δ 83.12 (s), δ 38.95 (m), δ 33.50 (t), δ 30.32 (m), δ 29.45 (s), δ 29.10 (s), δ 26.70 (s), δ 25.73 (s).

General Procedure for Synthesis of Compounds 3−8. Compound **1** (0.154 mmol, 1.0 equiv) was suspended in 1 mL of deionized water, and TEA (1.077 mmol, 7.0 equiv) was added to the suspension. After a few seconds of stirring at RT, the suspension became clear. The reaction was stirred at RT for 5 min. Crude compound **14a−14f** (0.231 mmol, 1.5 equiv) was dissolved in 1.5 mL of acetonitrile and added to the reaction mixture. TEA (0.154 mmol, 1.0 equiv) was added, and the reaction mixture was stirred at RT for 12 h. The reaction mixture was washed with diethyl ether (10 mL) and evaporated *in vacuo*. The obtained solid was treated with 2 mL of 2.5 M HCl, and the solution was stirred at RT for 24 h. The solvent was removed *in vacuo*; the crude product was sonicated twice in ethanol at RT for 2 h, and filtered to obtain pure compounds **3−8**.

*Compound **3***. Following the procedure shown for **3−8**, compound **1** was coupled to compound **14a** by amide linkage, followed by an acid treatment to obtain pure compound **3** as a white solid in 55% yield. ^{1}H NMR (D_2O): δ 3.95 (s, 2H), δ 3.84 (s, 2H), δ 3.26 (t, 2H), δ 1.98 (m, 2H), δ 1.84 (m, 2H). ^{13}C NMR (MeCN/D_2O): δ 172.10 (s), δ 171.74 (s), δ 74.15 (t), δ 51.40 (s), δ 47.62 (s) δ 40.60 (s), δ 31.70 (s), δ 24.09 (s). ^{31}P NMR (H_3PO_4/D_2O): δ 19.16. MS (+ ESI): 379 $[M+H]^+$.

*Compound **4***. Following the procedure shown for **3−8**, compound **1** was coupled to compound **14b** by amide linkage, followed by an acid treatment to obtain pure compound **4** as a white solid in 63% yield. ^{1}H NMR (D_2O): δ 3.73 (s, 2H), δ 3.22 (t, 4H), δ 2.25 (t, 2H), δ 1.95 (m, 2H), δ 1.80 (m, 4H). ^{13}C NMR (MeCN/D_2O): δ 176.87 (s), δ 170.46 (s), δ 74.16 (t), δ 51.54 (s), δ 40.66 (s), δ 39.52 (s), δ 34.04 (s), δ 31.84 (s), δ 25.66 (t), δ 24.16 (s). ^{31}P NMR (H_3PO_4/D_2O): δ 19.32. MS (+ ESI): 407 $[M+H]^+$.

*Compound **5***. Following the procedure shown for **3−8**, compound **1** was coupled to compound **14c** by amide linkage, followed by an acid treatment to obtain pure compound **5** as a white solid in 56% yield. ^{1}H NMR (D_2O): δ 4.04 (s, 2H), δ 3.92 (s, 2H), δ 3.86 (s, 2H), δ 3.25 (t, 2H), δ 1.96 (m, 2H), δ 1.84 (m, 2H). ^{13}C NMR (MeCN/D_2O): δ 171.55 (s), δ 170.79 (s), δ 170.62 (s), δ 72.82 (t), δ 50.04 (s), δ 42.15 (s) δ 41.88 (s), δ 39.26 (s), δ 30.06 (s), δ 22.71 (s). ^{31}P NMR (H_3PO_4/D_2O): δ 19.08. MS (+ ESI): 436 $[M+H]^+$.

*Compound **6***. Following the procedure shown for **3−8**, compound **1** was coupled to compound **14d** by amide linkage, followed by an acid treatment to obtain pure compound **6** as a white solid in 59% yield. ^{1}H NMR (D_2O): δ 3.73 (s, 2H), δ 3.22 (q, 4H), δ 2.25 (t, 2H), δ 1.98 (m, 2H), δ 1.82 (m, 2H), δ 1.59 (t, 2H), δ 1.52 (t, 2H), δ 1.30 (m, 2H). ^{13}C NMR (MeCN/D_2O): δ 177.70 (s), δ 169.94 (s), δ 73.95 (t), δ 51.36 (s), δ 40.43 (s) δ 39.86 (s), δ 36.37 (s), δ 31.64 (s), δ 28.62 (s), δ 26.15 (s), δ 25.68 (s), δ 23.99 (s). ^{31}P NMR (H_3PO_4/D_2O): δ 19.14. MS (+ ESI): 435 $[M+H]^+$.

*Compound **7***. Following the procedure shown for **3−8**, compound **1** was coupled to compound **14e** by amide linkage,

Compound ***8***. Following the procedure shown for **3**−**8**, compound **1** was coupled to compound **14f** by amide linkage, followed by an acid treatment to obtain pure compound **8** as a white solid in 57% yield. ^{1}H NMR (D_2O): δ 4.06 (s, 2H), δ 4.0 (s, 2H), δ 3.92 (s, 2H), δ 3.86 (s, 2H), δ 3.25 (t, 2H), δ 1.98 (m, 2H), δ 1.84 (m, 2H). ^{13}C NMR (MeCN/D_2O): δ 173.19 (s), δ 172.01 (s), δ 172.17 (s), δ 171.92 (s), δ 74.15 (t), δ 51.45 (s) δ 43.73 (s), δ 43.49 (s), δ 43.15 (s), δ 40.60 (s), δ 31.67 (s), δ 24.15 (s). ^{31}P NMR (H_3PO_4/D_2O): δ 19.15. MS (+ ESI): 463 $[M+H]^+$.

Crystal Growth Inhibition Assay for Binding Affinity Study. As BPs target bone surfaces under active formation and resorption of HA,[41] a crystal growth inhibition assay was performed to measure the affinities of HBPs to HA. This method has commonly been used to examine BP binding affinity.[42,43] Kinetic experiments of HA crystal growth were performed in a nitrogen atmosphere in magnetically stirred (400 rpm) double-jacketed vessels at pH 7.4 and 37.0 ± 0.1 °C, as described in a previously reported procedure.[42,43] In brief, the reaction solution with final ionic strength of 0.15 M was prepared by mixing calcium chloride (2.0 mmol), potassium dihydrogen phosphate (2.0 mmol), and sodium chloride (132.0 mmol) followed by degassing and filtration. The titrant with final ionic strength of 0.15 M was prepared by mixing calcium chloride (2.0 mmol), potassium hydroxide (10.0 mmol), and sodium chloride (134.0 mmol) followed by degassing and filtration. The reaction was initiated by adding 5 mg seed mass of HA crystallites into 100 mL of reaction solution. The constant thermodynamic driving force for growth of HA crystals was maintained by keeping the pH constant at 7.4 with addition of titrant. The volume of titrant added was recorded as a measure of HA crystal growth. Crystal growth inhibition experiments were performed in presence of at least six different concentration of each of HBPs (**2**−**8**). For positive control, experiments were performed in presence of six different concentrations of alendronate (**1**), whereas for negative control, experiments were performed in the absence of any BP.

Cell Culture. The MC3T3-E1 cells were cultured in prewarmed αMEM medium that was supplemented with 10% FBS at 37 °C in a humidified atmosphere composed of 5% CO_2. The cells were seeded into 96-well plates at a density of 1×10^4 cells/well for *in vitro* quantification of intracellular protein and caspase activity. One day after seeding, the cultures were treated with various concentrations (1×10^{-6}, 1×10^{-5}, and 1×10^{-4} M) of HBPs. Cells without HBPs were used as a negative control, while cells treated with 10^{-6}, 10^{-5}, or 10^{-4} M of etoposide were used as positive controls. The plates were incubated again for 24, 48, and 72 h before use for further analysis. The experiments were conducted in triplicate and repeated at least three times to ascertain the reproducibility of the results.

Intracellular Protein Quantification. Intracellular protein was measured using a commercially available BCA assay kit. Briefly, the medium was removed, and the adherent cells were washed with PBS. The cultures were lysed by 10 min incubation in 50 μL of lysate buffer (20 mM Tris-HCl, pH 7.4, 150 mM NaCl, 1 mM EDTA, 10 mM NaF, 1 mM sodium orthovanadate, 5 μg/mL leupeptin, 0.14 U/mL aprotinin, 1 mM phenylmethylsulfonylfluoride, and 1% (v/v) Triton X-100), followed by 2 s of sonication. Volumes of 10 μL of the cell lysate samples and standards (solutions of known concentrations of bovine serum albumin) were added to the wells of a 96-well microtiter plate followed by addition of 200 μL of the working reagent; the well contents were mixed thoroughly by shaking the plate for 2 min. The plate was incubated at 37 °C for 30 min and then cooled to RT. The absorbance of the samples was measured at 562 nm on a plate reader. The amount of protein in the sample was calculated using a standard plot.

Cell Cytotoxicity Assay. The cytotoxicity of the HBPs was determined using a colorimetric WST-1 assay. The assay was conducted after 72 h of HBP treatment in accordance with the manufacturer's instructions. In brief, cultures in 96-well plates were incubated with 10 μL/well of cell proliferation reagent WST-1 at 37 °C for 60 min in a humidified atmosphere composed of 5% CO_2. The plate was cooled to RT, and the absorbance of the samples was measured at 450 nm on a plate reader.

Apoptosis Assay. Apoptosis was determined by measuring the intracellular caspase-3 activity. The cultures were lysed by 10 min of incubation in 50 μL of lysate buffer (20 mM Tris-HCl, pH 7.4, 150 mM NaCl, 1 mM EDTA, 10 mM NaF, 1 mM sodium orthovanadate, 5 μg/mL leupeptin, 0.14 U/mL aprotinin, 1 mM phenylmethylsulfonylfluoride, and 1% (v/v) Triton X-100), followed by 2 s of sonication. The cell lysate was treated with 50 μM Ac-DEVD-AFC in 50 mM HEPES buffer (pH 7.4, 100 mM NaCl, 0.1% CHAPS, 10 mM DTT, 1 mM EDTA, and 10% (v/v) glycerol) at RT for 60 min in the dark. The caspase-3 activity was determined by measuring the fluorescence at λ_{em} = 510 nm (λ_{ex} = 485).

Synthesis of Compound 16. Compound **2** (10.0 mg, 0.028 mmol) was suspended in 10 mL of deionized water. The reaction mixture was acidified with 10 μL of acetic acid. 4-Nitrobenzaldehyde (**15**) (8.4 mg, 0.056 mmol) was dissolved in DMSO and added to the above suspension. The reaction was stirred at RT for 48 h. The solvent was evaporated *in vacuo* to obtain crude product **16**. Compound **16** was dissolved in water and washed with ethyl acetate to remove excess reactant **15**. The water layer containing **16** was used in the next reaction without further purification.

Synthesis of Compound 19. 4-Nitrobenzoic acid (**18**) (100.0 mg, 0.598 mmol) and TFP (109.3 mg, 0.658 mmol) were dissolved in 5 mL acetone. DCC (135.8 mg, 0.658 mmol) in 5 mL acetone was added dropwise to the reaction mixture and stirred at RT. The progress of the reaction was followed by TLC. After complete consumption of **18** (3 h), the 1,3-dicyclohexyl urea formed in the reaction mixture was removed by filtration, and the filtrate was evaporated *in vacuo*. The residue was then suspended in an adequate amount of acetonitrile, the remaining 1,3-dicyclohexyl urea was removed by filtration, and the filtrate was evaporated *in vacuo* to obtain crude compound **19**. Compound **19** was used in the next reaction without further purification.

Synthesis of Compound 20. Compound **1** (60.0 mg, 0.185 mmol) was suspended in 1 mL of deionized water and TEA (111.9 mg, 1.108 mmol) was added to the suspension. After a few seconds of stirring at RT, the suspension became clear. The reaction was stirred at RT for 5 min. Crude

compound **19** (92.2 mg, 0.277 mmol) was dissolved in 1.5 mL of acetonitrile and added to the reaction mixture. TEA (18.7 mg, 0.185 mmol) was added, and the reaction mixture was stirred at RT for 12 h. The reaction mixture was washed with 10 mL diethyl ether several times, and the water layer was lyophilized to obtain a sticky solid. The reaction product was then sonicated twice in ethanol for 2 h at RT and filtered to obtain pure compound **20**. ^{1}H NMR (D_2O): δ 8.33 (d, 2H), δ 7.95 (d, 2H), δ 3.45 (t, 2H), δ 1.98 (m, 4H). ^{31}P NMR (H_3PO_4/D_2O): δ 18.23. MS (- ESI): 397 $[M-H]^-$.

***In Vitro* Studies of Drug Targeting and Drug Release.** Compound **16** is a HBP-drug conjugate, where a model drug (4-NBA) is conjugated to HBP **2** via hydrazone linkage. The conjugate was immobilized on HA surface and studied for its release at various pH solutions. In brief, compound **16** (1 mg) in water was equally distributed into three Eppendorf tubes and diluted to get 1.0 mL of total volume each. Excess of HA (50.0 mg) was added to each Eppendorf tube, and the tubes were stirred at RT for 0.5 h. After centrifugation at 1000 rpm for 5 min, the supernatant was discarded. The HA was washed twice with 1.0 mL water, followed by centrifugation, and the supernatant was discarded. A volume of 1.0 mL acetate solution (0.1 M sodium acetate, 0.05 M sodium chloride) of pH 5.0, 6.0, and 7.4 was added in three Eppendorf tubes, respectively. The Eppendorf tubes were incubated at 37 °C with continuous shaking. The suspensions were centrifuged at particular time points, and the absorbance of the supernatants was measured (λ = 265 nm, 1 cm cuvette) to calculate the amount of 4-NBA released from the immobilized conjugate.

For the control studies, the above experiment was repeated with compound **20**. Compound **20** is a BP-drug conjugate, where the model drug (4-NBA) is conjugated to alendronate via amide linkage. The conjugate was immobilized on the HA surface and studied for its release at various pH solutions. In brief, compound **20** (1 mg) in water was equally distributed into three Eppendorf tubes and diluted to get 1.0 mL of total volume each. Excess of HA (50.0 mg) was added to each Eppendorf tube, and the tubes were stirred at RT for 0.5 h. After centrifugation at 1000 rpm for 5 min, the supernatant was discarded. The HA was washed twice with 1 mL water, followed by centrifugation, and the supernatant was discarded. A volume of 1.0 mL acetate solution (0.1 M sodium acetate, 0.05 M sodium chloride) of pH 5.0, 6.0, and 7.4 was added in three Eppendorf tubes, respectively. The Eppendorf tubes were incubated at 37 °C with continuous shaking. The suspensions were centrifuged at particular time points, and the absorbance of the supernatants was measured (λ = 265 nm, 1 cm cuvette) to calculate the amount of 4-NBA released from the immobilized conjugate.

RESULTS AND DISCUSSION

BPs have high affinity toward bone and HA. After administration, BPs bind to bone surfaces where they can be internalized into osteoclasts and cause their apoptosis.[44−46] In other words, BPs control bone resorption through apoptosis of osteoclasts. However, this could be a drawback of the BP treatment because it disturbs the bone remodeling cycle. In general, bone remodeling is a lifelong process, whereby osteoblasts and osteoclasts work simultaneously for bone formation and bone resorption, respectively. Bone formation and bone resorption are interdependent processes, and therefore, osteoblastic function of bone formation also gets affected by controlling osteoclastic bone resorption. Along with controlling bone resorption, subsequent bone formation at resorption sites is crucial; this can be achieved by delivering therapeutic agents to bone resorption sites using bisphosphonates. Active drug targeting at sites of bone metastases and calcified neoplasms using polymeric carrier was reported previously. Alendronate and an antiangiogenic agent, TNP-470, were conjugated to *N*-(2-hydroxypropyl)methacrylamide (HPMA) through a cathepsin K sensitive tetrapeptide (Gly-Gly-Pro-Nle).[47,48] Because of alendronate conjugation, HPMA was found to be distributed to bone tumors and the endothelial compartments of bone metastases with a good antitumor efficacy. However, one could eliminate the polymeric carrier and make a simpler and smaller conjugate by coupling drugs directly to high affinity BPs via hydrolyzable bonds. Therefore, our overall goal is to make BPs capable of delivering drug molecules, including bone growth factors, at bone resorption sites. The first goal was to design novel BPs that demonstrate high binding affinity to HA and contain a functional group that could be used to conjugate therapeutic agents to BPs through an acid-labile linkage. Substituents (R^1 and R^2) at the germinal carbon of the BP contribute toward bone affinity; in particular, the presence of a hydroxyl at R^1 enhances bone affinity by enabling tridentate binding to HA.[10−12] In that regard, we chose 1-hydroxy-1,1-bisphosphonic acid as the basic backbone of bifunctional BPs.

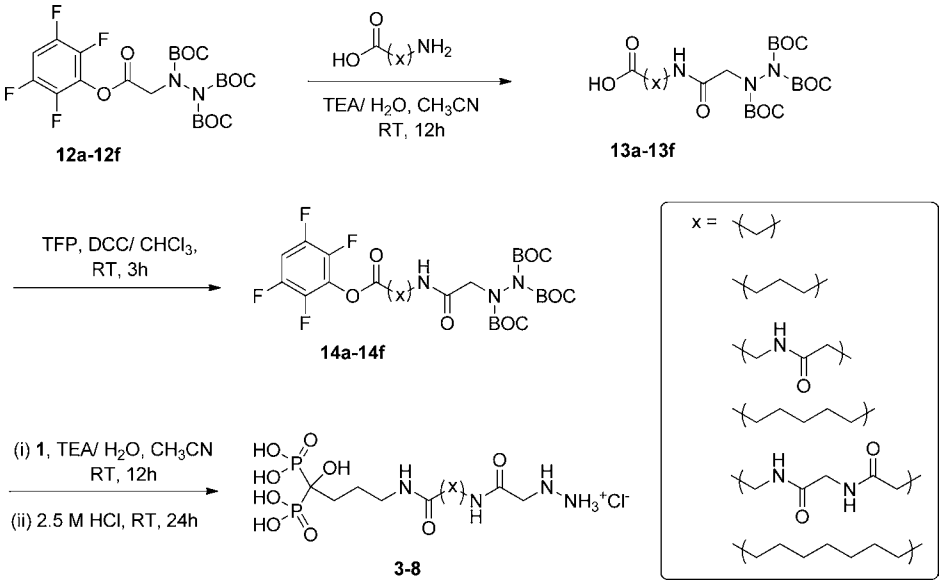
The designed 1-hydroxy-1,1-bisphosphonic acid backbone has a hydroxyl at R^1, while the R^2 substituent was used to introduce a different functional group that could be subsequently used for attachment of therapeutic agents. The attachment of a therapeutic agent to BP is possible through several reversible and irreversible linkages such as amide, ester, imine, hydrazone, ether, and thioether coupling. However for drug delivery at wound healing sites and resorption sites, where the pH is acidic,[49,50] acid-labile linkages such as those provided by hydrazones and imines are more appropriate. Imine hydrolyses rapidly at pH $\leq$ 7.0,[51] while hydrazone is stable at physiological pH. Further, the rate of hydrolysis of the hydrazone linkage increases gradually with decrease in pH from 7.4.[52,53] Therefore, the hydrazone linkage presents advantages over the imine linkage when sustained drug release is desired at the bone surface. Hence, the hydrazine functionality was introduced in 1-hydroxy-1,1-bisphosphonic acid at R^2 to obtain bifunctional HBPs.

It is important that the HBP-drug conjugate should not only be stable during systemic circulation, but should also bind to the bone surface before releasing the drug at the desired site. The attached drug may sterically affect this interaction between the BP and the bone surface. Consequently, a spacer was introduced in the synthesized HBPs between the BPs and the terminal hydrazine. HBPs with several spacers of varying length and hydrophobicity were synthesized.

A straightforward synthesis was used to create the desired HBPs (**2**−**8**). Compound **2** has the shortest spacer attaching hydrazine to 1-hydroxy-1,1-bisphosphonic acid. To synthesize HBP **2**, monosodium alendronate was prepared first in an inert atmosphere according to a previously reported procedure from 4-aminobutanoic acid by reaction with phosphorous acid and phosphorus trichloride in methanesulfonic acid and subsequent hydrolysis.[39,40] The reactive ester of TBHA (**10**) was prepared by dropwise addition of DCC in chloroform to a mixture of TBHA and TFP in chloroform at RT. This reactive ester was then coupled with monosodium alendronate in basic condition at RT to obtain BOC-protected HBP **2**. The BOC-protection

dx.doi.org/10.1021/bc2003132 | *Bioconjugate Chem.* 2011, 22, 2496−2506

Scheme 2. Synthesis of HBPs 3−8



of the hydrazine group was removed with treatment of 2.5 M HCl to obtain HBP **2**. The crude product was sonicated twice in ethanol at RT for 2 h and filtered to obtain pure HBP **2** (Scheme 1).

Using a similar strategy, six other analogues of HBP **2** (**3**−**8**) with spacers of different length and hydrophobicity were synthesized by introducing various amino acids, such as glycine (**12a**), 4-aminobutanoic acid (**9**), glycylglycine (**12c**), 6-aminohexanoic acid (**12d**), glycylglycylglycine (**12e**), and 8-aminooctanoic acid (**12f**), respectively (Scheme 2). All seven HBPs were obtained and were characterized with ^{1}H NMR, ^{31}P NMR, ^{13}C NMR, and electrospray ionization mass spectrometry.

The binding affinities of the HBPs were measured and compared with alendronate, which is a commercially available BP having high affinity to HA. BPs are known to inhibit the crystal growth of HA and target bone surfaces under active formation and resorption of HA.[41] Therefore, a crystal growth inhibition assay, which is a widely used method for determination of binding affinity of BP,[42,43] was performed to measure the affinities of HBPs to HA. During the experiments, a favorable environment for crystal growth of HA was maintained. The crystal growth of HA was measured in the presence of various concentration HBPs. The pH was maintained at 7.4 by addition of titrant, and the volume of titrant added was recorded as a measure of HA crystal growth. A range of experiments were performed in presence of various concentrations (0, 1.0×10^{-7}, 2.5×10^{-7}, 5.0×10^{-7}, 7.5×10^{-7}, and 1.0×10^{-6} M) of HBPs and alendronate. For every experiment of HA crystal growth, a plot of the volume of titrant added vs time was generated. A typical set of plots is depicted in Figure 1. The growth rate (R) at any instant can be described by

$$R = \beta \frac{dV}{dt} \quad (1)$$

where dV/dt is the rate of titrant addition, and β is a constant whose value reflects the titrant concentration with respect to the surface area of HA during crystal formation; β was considered as constant for all experiments.

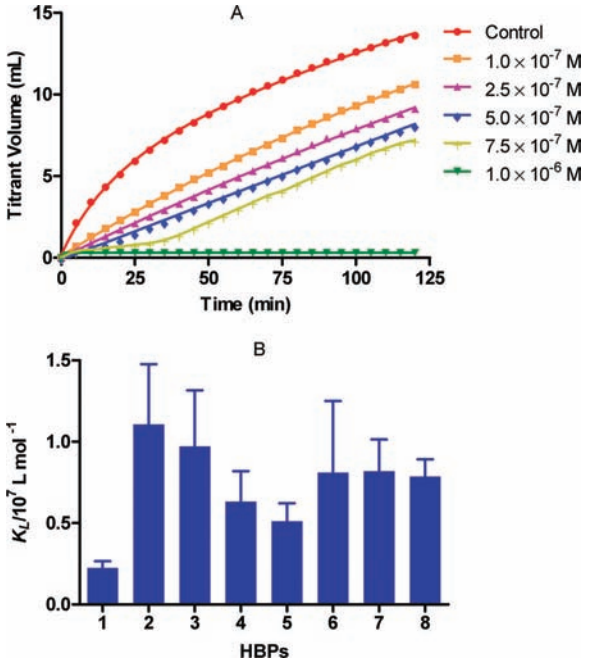


Figure 1. (A) Plot of HA crystal growth in the presence of varying concentrations of HBP **2** at pH 7.4 and 37 °C (seed mass = 5 mg). (B) Relative adsorption affinity constants (K_L) of alendronate (**1**) and HBPs **2**−**8** measured at varying concentrations of BPs ($C = 1.0 \times 10^{-7}$, 2.5×10^{-7}, 5.0×10^{-7}, and 7.5×10^{-7} M) at pH 7.4 and 37 °C. Data are the average ± one standard deviation ($n = 4$).

It can be noted from Figure 1 that the HA crystals appear to grow nonlinearly during the early stage of the experiment due to initial seeding of the HA crystals. The flat line parallel to the X-axis indicates the complete prevention of crystal growth. A pseudo-Langmuir adsorption isotherm can be used to describe the rates of HA crystal growth and can be expressed by

$$\frac{R_0}{R_0 - R_i} = 1 + \frac{1}{K_L C} \quad (2)$$

dx.doi.org/10.1021/bc2003132 | Bioconjugate Chem. 2011, 22, 2496−2506

where C is the concentration of BP added, and R_0 and R_i are the rates of HA crystal growth in the absence and presence of BP, respectively.

By rearranging eqs 1 and 2, the relative adsorption affinity constants (K_L) can be described by

$$K_L = \frac{\frac{dV_0}{dt} - \frac{dV_i}{dt}}{C\frac{dV_i}{dt}} \quad (3)$$

where dV_0/dt and dV_i/dt are the rates of titrant addition at early stage of the experiment in the absence and presence of BP, respectively.

The relative trend of binding affinities of alendronate (**1**) and HBPs (**2**–**8**) at various concentrations of BPs is shown in Figure 1. The shorter length HBPs (**2** and **3**) showed significantly higher binding affinities than alendronate ($p < 0.05$). Overall, all seven HBPs showed high binding affinities to HA, which makes them suitable for drug targeting.

Apart from its targeting ability, the ideal drug-carrier should not induce unnecessary toxic effects, especially against bone-forming cells (osteoblasts). HBPs could also have toxic affects toward other cells and tissues or affect cell differentiation, which could cause substantial morbidity.[54] The primary purpose of this study was to demonstrate the potential of HBPs for targeted delivery of the attached drugs at bone-resorption sites through *in vitro* experiments. Therefore, HBPs at various concentrations (10^{-6}–10^{-4} M) were evaluated for their possible cytotoxicity and apoptotic effect against preosteoblasts. The intracellular protein measured after 24, 48, and 72 h treatment of HBPs showed no abnormal changes in cell proliferation (Figure 2). The amount of protein in the HBP-treated cells was similar to the control over a period of 72 h. Cell viability studies were performed and metabolic activity was quantified using the commercially available WST-1 kit. MC3T3-E1 cells exposed to HBPs for 72 h showed activity similar to that of control (Figure 3). Although the metabolic activity of cells exposed to 10^{-4} M HBPs for 72 h showed 10% decrease in cell viability, the difference was not statistically significant.

Because caspases are required for cell apoptosis, the possibility of HBP-induced cell apoptosis was evaluated by measuring caspase-3 activity. Caspase-3 is a cysteine-aspartic acid protease and cleaves Ac-DEVD-AFC releasing the fluorogenic AFC, which can be quantified by fluorescence spectroscopy.[55] Apoptosis of MC3T3-E1 preosteoblasts was confirmed by treatment with 10^{-6}, 10^{-5}, or 10^{-4} M etoposide for 72 h, which resulted in 2–3-fold increase in caspase-3 activity (results not shown). As shown in Figure 4, however, HBPs did not induce apoptosis in MC3T3-E1 preosteoblasts after 72 h of exposure; all treatments resulted in statistically similar levels of caspase activity. Because HBPs showed no apoptotic and cytotoxic effects on preosteoblasts, HBPs could be utilized as a vehicle for drug delivery applications.

HBP **2** was used to demonstrate the targeted delivery of therapeutic agents to bone. In particular, in vitro drug targeting to HA and drug release from the HA surface was demonstrated using 4-NBA as a model drug. 4-NBA was conjugated with HBP **2** in DMSO/water, and then the conjugate was immobilized on HA by adding excess of HA particles to the reaction mixture at RT. HA with the attached conjugate was separated by centrifugation and washed thoroughly with water to remove unconjugated 4-NBA (Scheme 3). The triggered

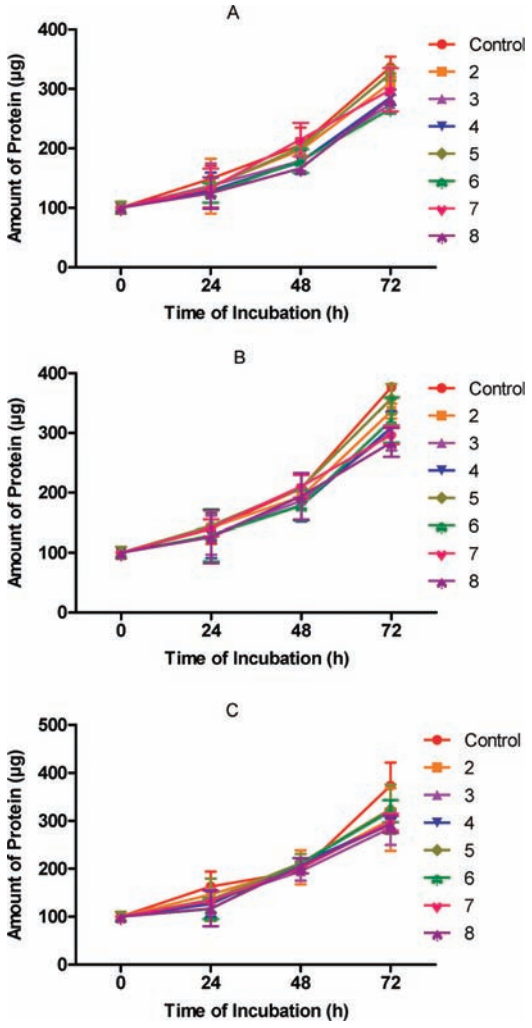

Figure 2. Intracellular protein contents showing MC3T3-E1 cell growth for 72 h after HBP treatment. Plots A, B, and C show results for exposure to HBPs at 1×10^{-6}, 1×10^{-5}, and 1×10^{-4} M, respectively. Error bars denote standard deviation.

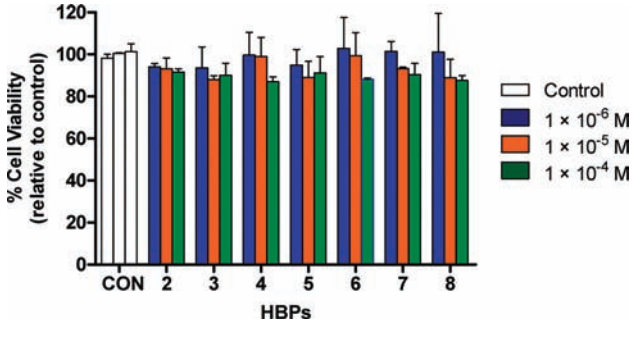

Figure 3. MC3T3-E1 cell viability measured after 72 h of incubation with no HBP (CON) and HBPs **2**–**8** at different concentrations (1×10^{-6}, 1×10^{-5}, and 1×10^{-4} M). The data are expressed as percentage of the control. The white, blue, orange, and green bars represent treatment of no HBP (control), 1×10^{-6}, 1×10^{-5}, and 1×10^{-4} M HBPs, respectively. Error bars denote standard deviations.

release of 4-NBA from the immobilized 4-NBA-HBP conjugate on HA was demonstrated at various pH as shown in Figure 5. HA with the attached conjugate was resuspended in 0.1 M sodium acetate (pH 5.0, 6.0, or 7.4) and incubated at 37 °C. The suspensions were centrifuged at particular time points, and

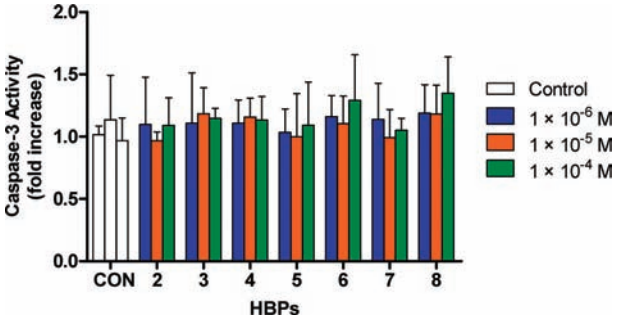

Figure 4. Apoptosis of MC3T3-E1 cells measured 72 h following addition of no HBP (CON) and HBPs **2**–**8** at three different concentrations (1×10^{-6}, 1×10^{-5}, and 1×10^{-4} M). The data are expressed as percentage of the control. The white, blue, orange, and green bars represent treatment of no HBP (control), 1×10^{-6}, 1×10^{-5}, and 1×10^{-4} M HBPs, respectively. Error bars denote standard deviations.

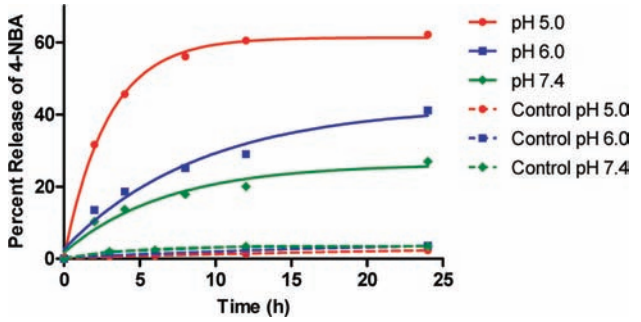

Figure 5. Percent release of 4-NBA (percentage of cleaved hydrazone bonds) from the immobilized conjugate on HA surface at 37 °C. Solid line and dotted line represent 4-NBA release from **17** and **21**, respectively.

the absorbance of the supernatants was measured at 265 nm using a UV–vis spectrophotometer to calculate the amount of released 4-NBA. It was observed that, in the first 12 h of incubation, there was approximately 60%, 30%, and 20% of 4-NBA released from the immobilized conjugate at pH 5.0, 6.0, and 7.4, respectively. Since HBPs have higher affinity for bone than does alendronate, they are expected to carry and deliver the attached drug at bone resorption sites as well as calcified bone tumors. Similar to this study, drug release at resorption sites was previously reported using a polymeric system with a spacer composed of a cathepsin K sensitive tetrapeptide (Gly-Gly-Pro-Nle).[56] Cathepsin K, which is expressed at higher level in osteoclasts, could cleave the polymer at the cathepsin K sensitive tetrapeptide and initiate drug release. However, cleavage of the polypeptide by cathepsin K could be affected by steric hindrance, which could change the rate of drug release. On the other hand, HBPs are not crowded molecules, and therefore, the rate of hydrolysis of the hydrazone and consequent drug release is expected to be affected less by steric effects.

To confirm that release of 4-NBA occurs via hydrazone cleavage rather than through desorption of the conjugate from the HA surface, 4-NBA was conjugated to alendronate (**1**) through formation of an amide bond. The conjugate was immobilized on HA surface by adding excess of HA particles, and then the particles were washed thoroughly with water to

Scheme 3. Synthesis, Immobilization of Model Drug–BP Conjugate, and Incubation at 37 °C in Acetate Solutions of Various pH[a]

remove unconjugated 4-NBA and nonspecifically adsorbed conjugate molecules. HA with the attached conjugate was treated similarly as described above, and the amount of released 4-NBA was measured by UV−vis spectroscopy (Scheme 3). From the control experiments, it was observed that there was no significant release of 4-NBA through desorption from the immobilized conjugate **21** (Figure 5).

CONCLUSION

In conclusion, we have reported the synthesis of novel, bifunctional HBPs (**2**−**8**), which show high binding affinities to HA. Through *in vitro* experiments, HBPs demonstrated no apoptotic and cytotoxic effects on MC3T3-E1, a preosteoblast cell. 4-NBA, a model drug, was bound to HA through a HBP, and its *in vitro* release at various pH was recorded. It was observed that hydrolysis of hydrazone bonds in the conjugate and subsequent release of 4-NBA was slow at physiological pH but much faster at pH lower than physiological, such as the pH in bone resorption sites and sites of wound healing.[49,50] Consequently, HBP−drug conjugates could be useful in local delivery of attached drugs to the resorptive microenvironment of bone tissue. Overall, this approach should improve the therapeutic index by boosting pharmacological efficacy and diminishing undesirable side effects.

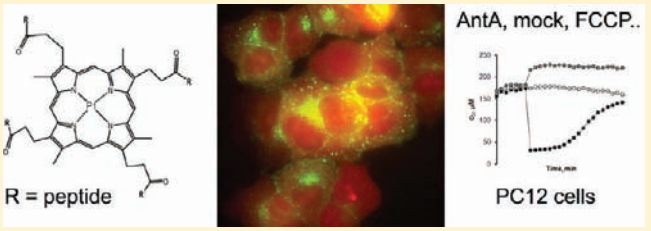
Supporting Information

ABSTRACT: A panel of phosphorescent oligoarginine conjugates of tetracarboxylic Pt(II)-coproporphyrin I dye (PtCP), monosubstituted with long peptides or tetra-substituted with short peptides and having different linkers and peripheral groups, is described. Their photophysical properties, cell loading efficiency, and mechanisms of transport into the cell were investigated and compared. The conjugates were seen to rely on endocytotic mechanisms of cell entry, which are different from that of the unconjugated oligoarginine peptide, and show diverse patterns of intracellular distribution. On the basis of this study, the tetra-substituted PtCP conjugate displaying whole cell distribution was selected for the sensing of intracellular O_2. This probe has been tested in biological experiments on a fluorescence plate reader, including the monitoring of *in situ* oxygenation of respiring cells and their responses to metabolic stimulation. Similar conjugates of the phosphorescent Pd(II)-coprorphyrin and fluorescent coproporphyrin-ketone were also synthesized and assessed for the sensing of low levels intracellular O_2 and ratiometric pH-sensing, respectively. The results produced and the structure–activity relationships determined can facilitate the rational design of new bioconjugates of porphyrin dyes tailored to specific applications.



INTRODUCTION

Targeted delivery of molecules into the cell is required for many research (probes and effectors), diagnostic (imaging agents), and therapeutic (drugs) purposes. The main strategies to achieve this include direct (passive) translocation across the plasma membrane, facilitated transport through receptor or drug-mediated endocytosis, and the use of liposomes, delivery, and targeting vectors.[1−3] To date, significant progress has been achieved with nucleic acid and protein structures,[2] whereas the delivery of small molecules such as drugs, fluorophores, and other macrocyclic structures still require a better understanding of the mechanisms of intracellular transport and structure–activity relationships.[4−7]

Tetrapyrrols represented by numerous natural (porphyrins, heme, and vitamin B_{12}) and synthetic compounds are actively used as drugs (e.g., SOD mimetics[8]), photosensitizers in tumor photodynamic therapy (PDT),[9−11] oxygen-sensitive probes,[9,12] and labels.[13] For some of these applications, targeted delivery of the tetrapyrrol into the cell, tissue, or a particular subcellular compartment is an essential requirement. Thus, in PDT, the initial focus on the improvement of photophysical properties of drug candidates and distribution between normal and malignant tissue is now shifting toward more specific delivery of sensitizer molecules to a particular location within the cells (e.g., mitochondria rather than lysosomes[11,14]).

In quenched-phosphorescence sensing of molecular oxygen (O_2), where Pt(II)- and Pd(II)-porphyrins are commonly used,[15] there is a need to have both extracellular, cell-impermeable probes for imaging tissue and vasculature,[12,16] and intracellular probes targeted to subcellular compartments, particularly the mitochondria where most of the O_2 gets consumed.[17] However, hydrophobic tetrapyrrols show poor selectivity of intracellular accumulation and distribution, limited solubility in aqueous media, and high nonspecific binding to various biomolecular and cellular structures. Cationic porphyrins often possess cyto- and genotoxicity (via interaction with the DNA), and therefore, anionic dyes such as coproporphyrin and substituted tetraphenylporphyrin derivatives are more frequently used. However, these structures have low intrinsic ability to penetrate the plasma membrane of mammalian cells.[4,18]

Aiming to improve intracellular delivery and distribution of the porphyrins, several approaches have been proposed including functionalization with hydrophobic polyethyleneglycols[19] or sugars,[20] preparation of dendrimers and nanoparticles, or conjugation with other fluorophores such as rhod-

[a]Structures of PtCP-conjugates are presented in Figure 1, and initial porphyrin dyes are shown in Supporting Information.

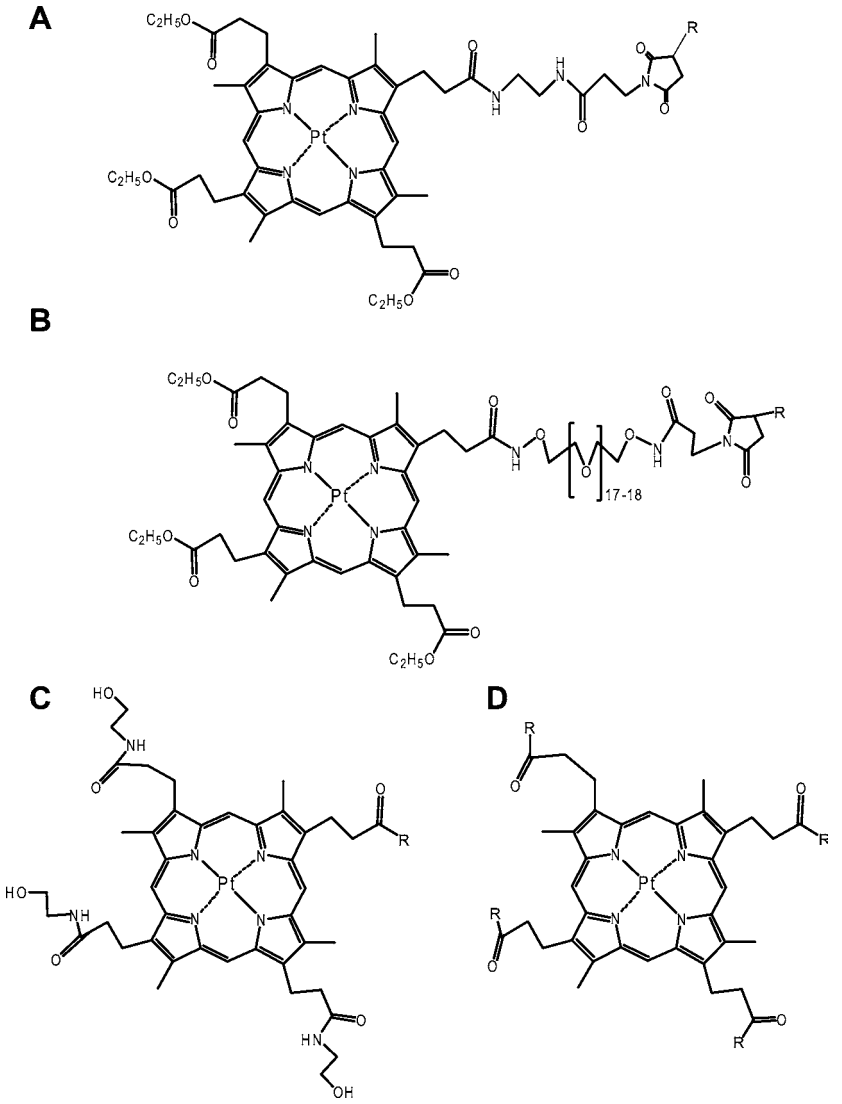

Figure 1. Structures of the PtCP conjugates. All conjugates have the same coproporphyrin core but different side groups. The position of conjugation with the peptide is designated by R. A, conjugates PEPP1 and PEPP5; B,: conjugates PEPP2 and PEPP4; C, conjugate PEPP6; and D, branched conjugates PEPP3 and T1-T5.

amine,[16,21−25] the use of escort peptide sequences (such as cyclic RGD),[26] or cell-penetrating peptides.[19,27] Thus, mono-substituted conjugates of porphyrins with Arg- and Pro-rich peptides have shown improved cell penetration, intracellular

dx.doi.org/10.1021/bc200324q | Bioconjugate Chem. 2011, 22, 2507−2518

accumulation, and retention of the key functionality in oxygen sensing applications or PDT.[28−31] However, this strategy requires a more detailed knowledge of structure−activity relationships.

Here, we describe a panel of new cell-penetrating conjugates of Pt-coproporphyrin I (PtCP) with oligoarginine peptides. Considering the cell penetrating behavior of oligoarginine peptide vectors[32] and the initial studies with monosubstituted PtCP conjugates with relatively long peptides (9−11 amino acids long),[28−31] we hypothesized that tetra-substituted (branched) PtCP conjugates with short Arg-rich peptides may also possess cell-penetrating ability. Therefore, we synthesized an extended panel of both mono- and tetra-substituted PtCP conjugates and evaluated them comparatively to establish structure−activity relationships. We demonstrate that depending on the substitution, linkers, peripheral groups, and hydrophilicity, the resulting conjugates can show different cell penetrating properties and intracellular distribution while retaining the important functional properties of the porphyrin moiety. These results provide the basis for the development of new porphyrin structures with controlled cell permeation and distribution for a range of biological applications.

EXPERIMENTAL PROCEDURES

Materials. The reactive derivatives of coproporphyrin I containing the amino (pentafluorophenyl, PFP)- and thiol-reactive (maleimido, MI) modifications (PtCPTE-MI, PtCP-$(PFP)_4$, PtCPTE-PEG_{850}-MI, PdCP$(PFP)_4$, CPK$(PFP)_4$, and PtCP$(NH\text{-}CH_2CH_2\text{-}OH)_3$-PFP) were synthesized in our lab. Their synthesis procedures and molecular structures are given in Supporting Information. Fluorescent probes MitoTracker Green, MitoTracker Red, LysoTracker Green, LysoTracker Red, and Alexa488-transferrin were from Invitrogen (USA), and phosphorescent probe MitoXpress was from Luxcel Biosciences (Cork, Ireland). Synthetic peptides (purity >85% by HPLC; structures confirmed by mass spectrometry) were from Genscript (Piscataway, NJ, USA). Luminescent cell viability kit CellTiter-Glo was from Promega (Madison, WI, USA), and $H_2NPEG_{850}NHBoc$ was from RAPP Polymere (Tubingen, Germany).

Standard cell culture 96 well plates from Sarstedt (Wexford, Ireland) were used for growing the cells and for time-resolved phosphorescence measurements. White 96 well plates from Greiner Bio-One (Frickenhausen, Germany) were used for the luminescent ATP assay. All other reagents were from Sigma-Aldrich Ltd. (Dublin, Ireland).

Preparation of Conjugates. The monosubstituted conjugates PEPP1−2, PEPP4−6 were prepared by mixing equimolar quantities (0.1−1.0 μmol scale) of the reactive porphyrin derivative and the corresponding peptide in DMSO (in the presence of triethylamine for amino-coupling), incubating for 24 h at room temperature, and purifying by RP-HPLC on a Discovery C18 column (1 × 25 cm, 5 μm, Sigma) using a gradient of CH_3CN in 0.1% TFA. The conjugate fractions were collected, vacuum-dried, reconstituted in DMSO, and stored in small aliquots at −18 °C. Typical yields were 30−90%.

The tetra-substituted conjugates PEPP3, PEPP3B, PEPP3C, and T1-T5 were prepared via amino-coupling in DMF in the presence of molar excess of triethylamine, using PtCP$(PFP)_4$ and peptide or L-Arg methyl ester at a 1:10 molar ratio, and incubating for 6−16 h at room temperature; 1−5 mg scale. Then, the mixture was diluted 1:10 with water, applied on the Discovery DSC-18 20 mL/5 g column (Supelco-Sigma), washed with MeOH/H_2O (1:1), and eluted with MeOH/H_2O/CH_3COOH (50:48:2). The conjugate fractions were vacuum-dried and reconstituted in water or DMSO. The yield was typically ∼90% with respect to the porphyrin. Purity of the conjugates was confirmed by RP-HPLC (see Supporting Information). The composition, chemical structure, and abbreviations of the conjugates are given in Table 1 and Figure 1.

Spectral Measurements. Absorption spectra were recorded on a 8453 UV−vis diode-array spectrophotometer (Agilent) and luminescence spectra on a LS50B luminescence spectrometer (PerkinElmer). Phosphorescence quantum yields were measured in PBS, containing 10% FBS (21% O_2) or with additional 5 mg/mL KH_2PO_4 and 5 mg/mL Na_2SO_3 (0% O_2) using PtCP as a reference.[33] Phosphorescence lifetimes of the conjugates were measured on a Cary Eclipse spectrometer (Varian-Agilent) using phosphorescence decay application and single-exponential fit. The pH-sensitive fluorescence of CPK and PEPP3C probes was measured at 0.25 μM concentration in a citrate−phosphate buffer system at pH 3−8 using 406 nm excitation wavelength with fluorescence emission collected at 600−700 nm. For measurement of the fluorescence of free base, the probes were dissolved in DMSO.

Cell Culture. Human colon carcinoma HCT116, rat pheochromocytoma PC12, human epithelial carcinoma HeLa, human neuroblastoma SH-SY5Y, human hepatocellular liver carcinoma HepG2, and murine embryonic fibroblasts MEF cells were from ATCC (Manassas, VA, USA). The cells were cultured in standard tissue culture flasks, collagen IV-coated 96-well microplates, 35 mm Petri dishes or collagen-poly-D-lysine-coated glass bottom dishes (MatTek, Ashland, MA), and 12-well chambers (Ibidi, Martinsried, Germany) using DMEM medium supplemented with 10% FBS (SH-SY5Y, HepG2, MEF, and HeLa cells) or McCoy 5A with 10% FBS (HCT116). PC12 cells were grown and differentiated as described previously.[29]

For the assessment of cellular uptake efficiency, cells were grown to a confluence 75−100%, incubated with 1 μM of the conjugate for 16 h, washed three times with medium, and measured on the TR-F plate reader. For the analysis by flow cytometry, cells were grown on 35 mm Petri dishes, similarly stained with conjugates, washed with PBS, trypsinized, and then analyzed.

Mechanisms of Cellular Uptake Studies. MEF and HCT116 cells were grown on glass-bottom dishes to a confluence 30−50% and incubated with the conjugates (5 μM PEPP3 or 2 μM PEPP4) for 6 h at 37 °C, then washed, and analyzed by fluorescence microscopy. Inhibitors of endocytosis were used as described previously[28] at concentrations 50 μM (EIPA, inhibits macropinocytosis), 5 mM (MBCD, inhibits lipid-raft dependent endocytosis), and 10 μg/mL (CPZ, inhibits clathrin-mediated endocytosis) with 30 min of preincubation. The influence of surface proteoglycans on cellular uptake was assessed by 1 h of preincubation and subsequent incubation with the conjugate in the presence of 50 μg/mL heparin sulfate (Sigma H6279). To see the effect of competition with unlabeled oligoarginine, cells were incubated with the probe in the presence of 10 μM GR_9 peptide. Temperature effect was studied by incubating the cells for 30 min at 4 °C and then with the conjugate for 6 h at 4 °C. ATP depletion was achieved by preincubating cells in glucose-free medium (DMEM/10% FBS/10 mM Galactose and 20 mM

HEPES, pH 7.2) for 1 h 45 min, followed by 15 min of incubation with 10 μM oligomycin, and then incubation with the conjugate for 6 h. To block the function of lysosomes, a 30 min preincubation with 0.25 μM concanamycin A was used.

In flow cytometry analysis, loaded cells were trypsinized, washed with Phenol Red-free DMEM with 10% FBS and 20 mM HEPES, pH 7.2, and measured on a Guava PCA-96 flow cytometer (Millipore, Billerica, MA, USA) under 532 nm laser and 675 nm emission filters, as recommended.[28]

Live cell microscopy was performed on a wide-field fluorescence microscope Axiovert 200 (Carl Zeiss, Goettingen, Germany) equipped with a 390 nm LED and filter cube (ex., 390/40 nm; em., 655/40 nm) for imaging of PtCP, PdCP, and CPK dyes. PEPP3B probe was imaged at decreased (2%) O_2. Staining with organelle-specific markers MitoTracker Green/Red (50 nM), LysoTracker Green/Red (100 nM), and transferrin-Alexa488 (0.5 μM) was performed for 30 min, followed by one washing.

Cell viability was assessed via total ATP levels using a CellTiter-Glo luminescent kit (Promega) and the manufacturer's protocol.

TR-F intensity and lifetime measurements were conducted on a Victor2 reader (Perkin-Elmer) as described previously[34] using D340 excitation and D642 emission filters, counting at two delay times, 30 μs (t_1) and 70 μs (t_2), gate time 100 μs, and integration time 1 s. For the PEPP3B probe, the D665 emission filter, t_1 = 400 μs and t_2 = 450 μs, gate time 1200 μs, and counting time 2 s were used. Lifetime was calculated as: $\tau = (t_2 - t_1)/\ln(F_1/F_2)$, where F_1 and F_2 correspond TR-F readings at delay times t_1 and t_2.

Conjugate uptake efficiency by dPC12, HCT116, HeLa, and MEF cells was assessed by comparing F_1 signals for the different probes and conditions.

Monitoring of Respiration and icO$_2$. Differentiated PC12 cells were stained with 2 μM PEPP3 (or PEPP3B) for 16 h in RPMI1640 supplemented with 1% HS and 100 ng/mL NGF and washed three times with the same medium then with Phenol Red-free DMEM containing 10 mM Glucose (or 10 mM Galactose instead), 1 mM Na-pyruvate, 20 mM HEPES, pH 7.2, and 100 ng/mL NGF. The cells were incubated for 2 h and then measured on a Victor2 plate reader. After baseline stabilization (~20−60 min depending on O_2), mitochondrial effectors were added to the cells (1/10 volume of 10× stock), and monitoring was resumed.

Calibration of PEPP3 phosphorescence lifetime was performed in the hypoxia chamber at 37 °C and different pO_2. Cells stained with the probe were treated with 10 μM AntA (to block respiration and local O_2 gradients) were monitored kinetically to determine steady-state τ values. These values were plotted against dissolved O_2 concentration (200 μM at 20.9% O_2, 37 °C[35]), from which, using Origin 6.0 (Microcal, USA) software, the following analytical function was obtained (r^2 = 0.9807): $[O_2] = 1551.73 - 57.55\cdot\tau + 0.5347\cdot\tau^2$.

Data Assessment. The microplate reader results are presented as the mean values with the standard deviation (error bars on the plots) obtained from at least 6 replicates. In cellular uptake experiments, the variability in each group was analyzed by one-tailed t test (significance level 0.05). The microscopy experiments were performed in triplicate. This ensures the consistency of the results.

RESULTS

Design and Synthesis of Cell-Penetrating PtCP Conjugates. Cell-penetrating ability of oligoarginine peptides and their conjugates mostly depends on the total number of Arg residues (7−9 are required for efficient transport), while their sequence and length are less important.[32] The conjugates of coproporphyrins demonstrate rather low cell-penetration for tricarboxylic PtCP and improved accumulation for the neutral derivatives (PtCPTE-CFR$_9$, PEPP1); however, the latter structures are quite hydrophobic and show a high degree of nonspecific binding and localization similar to those of lysosomes and endosomes.[29] Aiming to overcome these drawbacks, we prepared modified monosubstituted conjugates with (i) an additional hydrophilic PEG$_{850}$ moiety (PEPP2), (ii) mitochondrial targeting sequence[36] with (PEPP4), and (iii) without PEG$_{850}$ (PEPP5). In order to increase hydrophilicity and reduce nonspecific binding, three ester groups in PtCPTE were also replaced with ethanolamine (PEPP6) (Figure 1).

Four propionic acid residues allow simple tetra-substitution of the PtCP moiety. It was shown that branched oligoarginine sequences can also provide efficient intracellular delivery.[32,37] Therefore, we prepared tetra-substituted PtCP conjugates with eight (PEPP3), four (T5), and 12 (T4) Arg, and also with additional Ala (T1), Ser (T2), and Gly (T3) residues (Figure 1d).

The conjugations were performed by thiol or amino coupling using the reactive MI and PFP derivatives of PtCP, respectively, with purification by RP-HPLC[29] (Figure S1, Supporting Information). Some of the peptides were amidated at C-termini to eliminate zwitterionic structures and retain molecular charge at around +8 (except for T5, PEPP4, and PEPP5; see Table 1). The branched conjugates showed shorter retention times on the C18 column and higher hydrophilicity than the monosubstituted conjugates with a similar charge (e.g., PEPP5 and PEPP3). PEPP6 conjugate with ethanolamine modification was also quite hydrophilic (Table 1).

Photophysical Properties. All tetra-substituted conjugates displayed absorption spectra similar to those of free PtCP and its oligonucleotide conjugates.[38] For the monosubstituted conjugates, absorption maxima were slightly blue-shifted similar to those of protein conjugates,[13] which is indicative of J or H stacking interactions of the PtCP moiety [39] (Figure S2A-B, Supporting Information). Excitation and emission spectra remained unaffected for all the conjugates; however, the conjugation with peptides had a significant effect on the emission yield (Figure S2, Supporting Information). In 10% FBS (typical culturing conditions), quantum yields for the monosubstituted conjugates decreased at a higher length of the peptide (e.g., PEPP1 vs PEPP5) and the addition of the PEG spacer. For PEPP6 with three ethanolamine residues, the absorption spectra shift and internal quenching were much greater. Internal quenching, which was also high for tetra-substituted conjugates, can be largely reduced by the anionic surfactants (0.5 mM SDS), which solubilize the PtCP moiety (for PEPP3 in deoxygenated conditions, the quantum yield was 0.55; not shown). Similar interactions may occur with the conjugate inside the cells (see below). Despite the differences in quantum yields, all the PtCP conjugates displayed similar phosphorescence lifetimes: 20−23 μs in air-saturated and ~80 μs in deoxygenated media (DMEM with 10% FBS, Figure S2D, Supporting Information), i.e., similar to the other PtCP based probes.[34] The PEPP3 conjugate measured in DMEM at 0, 1,

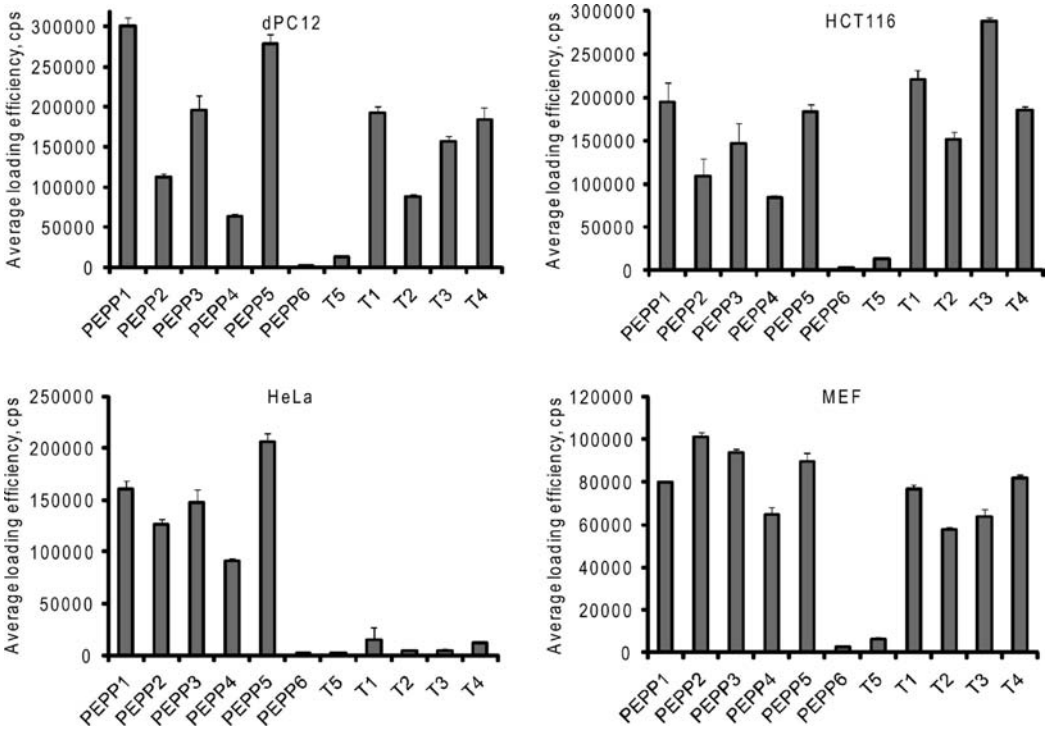

Figure 2. Uptake of conjugates by different mammalian cell lines. Cells were seeded onto collagen IV-coated 96 well plates, incubated with conjugates (1 μM) for 16 h, washed three times, and measured on a microplate reader.

10, 50, and 100% FBS showed no changes in phosphorescence emission lifetime (not shown).

Uptake of the Conjugates by Mammalian Cells. Cellular uptake of the conjugates was first analyzed in cell populations on the TR-F reader. Most of the conjugates showed efficient cell loading with MEF, HeLa, HCT116, and dPC12 cells at 1 μM and 16 h incubation (Figure 2). Linear and branched conjugates PEPP1 and PEPP3 produced high loading signals in all cell lines, whereas the PEG-modified PEPP2 showed a lower degree of loading. The more hydrophobic PEPP4 and PEPP5 with the mitochondrial targeting sequence displayed cell-specific penetration, while conjugates PEPP6 (ethanolamine-modified) and T5 (four Arg) showed poor accumulation in all cell lines tested. The tetra-substituted T1−T4 conjugates showed cell-specific loading: high for HCT116, moderate for dPC12, and poor for HeLa cells. The presence of additional amino acids in branched conjugates (Ala in T1 or Gly in T3) did not interfere with cell loading; however, the presence of Ser in T2 reduced it. As expected, the higher number of Arg in T4 did not improve loading. Therefore, we can conclude that 8−9 Arg ensure optimal cell penetration of coproporphyrin conjugates and that hydroxyl groups can decrease it (conjugates T2, PEPP6, and PEG-containing PEPP2 and PEPP4).

The above results on cell loading were verified by fluorescence microscopy and flow cytometry, which allow single cell analyses. Flow cytometry was not as sensitive as TR-F, and only highly loaded cells were detectable. For such samples, the whole population gave rather uniform fluorescent signals, and unloaded cells (scattering, but no fluorescence) were not seen. Fluorescence microscopy also confirmed the positive loading of HCT116 and MEF cells with the monosubstituted conjugates at 1 and 10 μM concentrations (Figures 3 and S3 (Supporting Information)), except for PEPP6, which was undetectable even at 10 μM and 16 h of incubation. Loading with T2 was marginally lower than that for T1, T3, or PEPP3 (Figure 4) confirming that hydroxyl groups interfere with cell penetrating ability. For T5, loading was detectable only at 10 μM, but with clear signs of toxicity and the appearance of a round cell shape.

Similar efficiency and loading patterns were observed with the other cell lines: rather weak for HeLa, moderate for PC12 and HCT116, and high for MEF, HepG2, and SH-SY5Y (data not shown). The differences can be explained by the different shape, size, membrane composition, and mechanisms of transport for these cells.

Intracellular Distribution of the Conjugates. Wide-field fluorescence microscopy imaging revealed that different conjugates show different intracellular distribution in HCT116, MEF, PC12, SH-SY5Y, and HepG2 cells (see representative data in Figures 3 and S3 (Supporting Information)). Compared to PEPP1, PEPP2 displayed a more diffused cytoplasmic distribution, while PEPP3 gave a more uniform distribution across the cell including the nucleus (Figure 4), with higher accumulation in the nucleus at 10 μM (Figures 3 and S3 (Supporting Information)). PEPP4 and PEPP5 harboring the mitochondrial targeting sequence (with or without PEG_{850} linker) displayed a better intracellular accumulation and brightness than PEPP1, but they did not localize in the mitochondria (Figure 4) and had localization similar to that of the endosomal marker transferrin (data not shown). All branched conjugates T1−T4 and PEPP3 showed very similar intracellular distribution, and the addition of Ala (T1), Gly (T3), or extra Arg (T4) had no visible effects (Figures 3, 4, and S3 (Supporting Information)). T2 with the Ser residue gave only a faint punctuated cytosolic pattern, and localization of T5 could not be assessed as the cells quickly died at high probe concentrations (not shown).

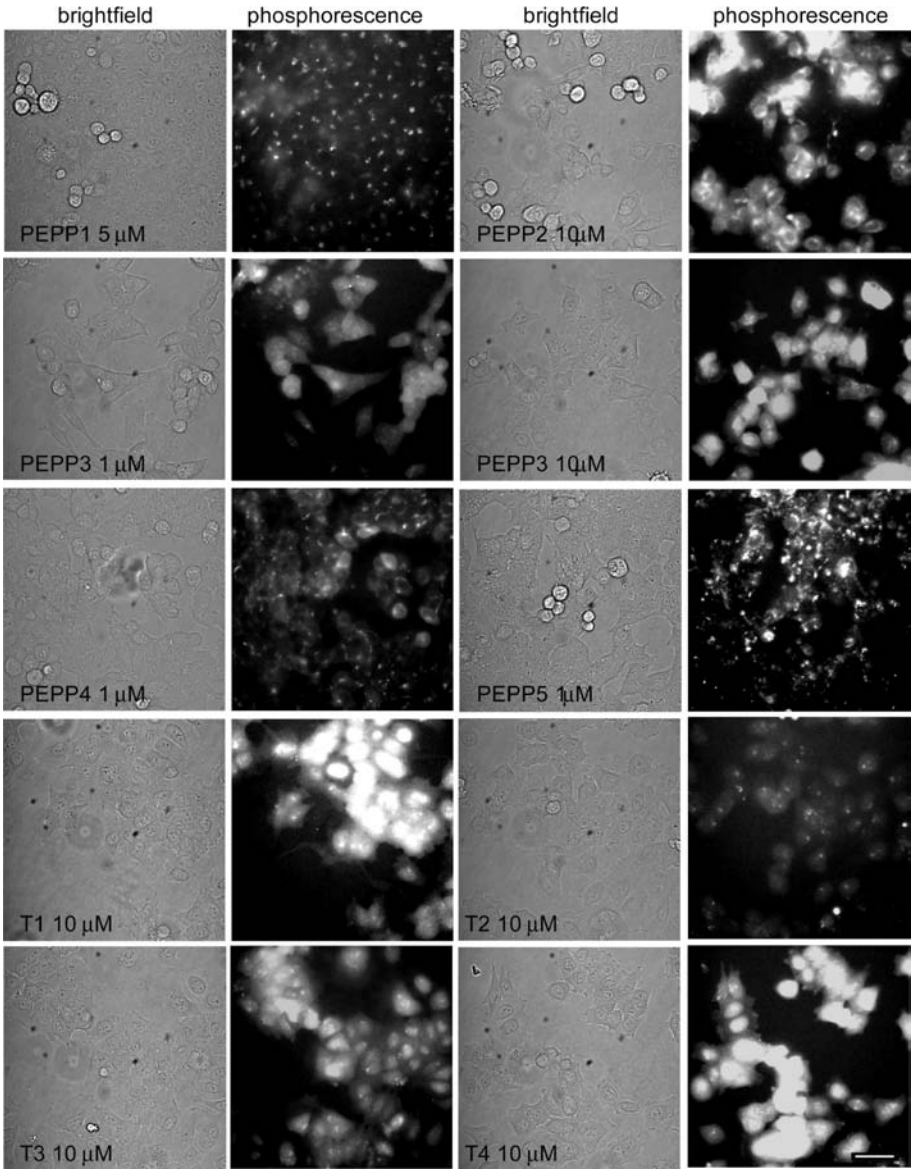

Figure 3. Fluorescence microscopy analysis of HCT116 cells stained with different PtCP conjugates. Cells were seeded onto collagen-poly-D-lysine coated glass bottom dishes at a concentration of 30,000/dish, incubated for 16−18 h with conjugates at specified concentrations, washed, and imaged. Brightfield and fluorescent (390 nm excitation/650 nm emission) images are shown. Scale bar = 50 μm.

Mechanisms of Cellular Uptake for Mono- and Tetra-Substituted Conjugates. Knowledge of the mechanisms of cellular uptake and cell entry pathways allows the regulation of transport of the cargo inside the cell. Such studies involve the inhibition of specific uptake pathways with drugs using the shortest treatment time to minimize the disruption of cellular function.[40,41] Since the flow cytometry method cannot distinguish between internalized and surface-bound probes, fluorescence microscopy which allows direct observation of the cell phenotype and the qualitative effect of inhibitors, was applied to study HCT116 and MEF cells. Two representative conjugates from each class were chosen for these experiments: PEPP3 (branched) and PEPP4 (linear). PtCP conjugates show rather slow rates of cellular uptake,[18,31,32,37,42] which were 4−6 h for PEPP3 and PEPP4 (Figure S4, Supporting Information). The unlabeled oligoarginine did not have a measurable effect on the loading of the conjugates (Figures 5 and S5 (Supporting Information)), thus indicating a different mechanism of uptake.

The main mechanisms of cell entry reported for oligoarginine, endocytosis and direct translocation,[37,40,43,44] can be assessed by analyzing the temperature and ATP dependence of the uptake. For PEPP3 and PEPP4, the loading at 4 °C was almost completely inhibited; however, weak staining of the cell surface for PEPP4 indicates that interaction with the cell membrane still occurs (Figures 5 and S5 (Supporting Information)). Uptake of PEPP3 and PEPP4 by the cells depleted in ATP (olygomycin and absence of glucose) was reduced significantly. We therefore concluded that both branched PEPP3 and linear PEPP4 rely on an endocytosis mechanism of cell entry.

Furthermore, inhibition of macropinocytosis by EIPA slightly reduced the uptake of branched conjugate PEPP3 by HCT116 and MEF cells, with the loss of nuclear localization (Figure 5). Inhibition of the clathrin-mediated pathway by CPZ reduced the uptake even more strongly, and inhibition of lipid-raft formation by MBCD had no effect. Noteworthy, 6 h of treatment with EIPA and CPZ still left a high percentage of

viable cells, whereas treatment with MBCD changed cell morphology (round shape phenotype) and caused cell detachment. Similarly, treatment with EIPA and CPZ moderately decreased the uptake of monosubstituted PEPP4, and MBCD had no visible effect (Figure.5). Since the uptake of PEPP3 was significantly affected by CPZ, we performed a competition experiment with transferrin (marker of clathrin-mediated endocytosis[41]) and observed a partial (~30%) reduction of loading of the conjugate (Figure S5, Supporting Information).

These results indicate that PEPP3 and PEPP4 utilize both macropinocytosis and clathrin-mediated uptake pathways. This means that after internalization they should remain in recycling endosomes or undergo endosomal escape followed by migration to the cytoplasm and other compartments. Endosomal escape can be inhibited by agents that disturb the function of acidic compartments.[45−47] We treated MEF cells with concanamycin A (V-ATPase inhibitor) and observed that PEPP3 lost its nuclear localization, remaining only in the cytoplasm. This drug had no effect on PEPP4 (Figure S5, Supporting Information), thus suggesting that PEPP4 stays in recycling endosomes.

Furthermore, the presence of heparin sulfate caused a partial decrease of uptake and perinuclear localization of PEPP3, whereas for PEPP4, the uptake was completely abolished with the formation of visible aggregates (Figure S5, Supporting Information). This suggests that interactions cell surface sugars are important for the monosubstituted conjugates.

Monitoring of Intracellular O_2 with the PtCP Conjugates. The PEPP3 conjugate was among the best in terms

(F) Responses to 1 μM FCCP for the cells pretreated with 10 μM OM.

of cellular uptake and distribution; therefore, we decided to test it as an O_2-sensing probe with dPC12 cells. Optimal loading was at around 2 μM producing minimal cell toxicity, high phosphorescence intensity signals, and stable lifetime values in resting cells (Figure 6a−c). To enable the determination of O_2 concentration, we calibrated PEPP3 in live nonrespiring dPC12 cells[35] by measuring its phosphorescence lifetime at different levels of atmospheric pO_2 and 37 °C. Calibration curve $O_2 = f(\tau)$ is shown in Figure 6d.

To test probe performance, the cells grown, differentiated, and loaded in standard microplates were treated with metabolic effectors: FCCP, oligomycin, and antimycin A (Figure 6e−f). Prior to stimulation, resting dPC12 cells demonstrated stable baseline signals, which reflect partial deoxygenation of the monolayer compared to the bulk medium. The addition of FCCP (mitochondrial uncoupler) induced a prominent response: a large decrease in cellular oxygen due to increased respiration (the cell layer is acting as a sink for dissolved O_2 and the medium layer as a diffusion barrier for atmospheric oxygen[35]). The response had a bell shape, decreasing at high concentration (4 μM) due to FCCP toxicity. Pretreatment of cells with 10 μM oligomycin (complex V inhibitor) decreased basal respiration (higher icO_2) and the magnitude of response (Figures 6e and S6, Supporting Information). Antimycin A (complex III inhibitor) increased icO_2 to ambient levels (Figures 6f and S6, Supporting Information). These results are in agreement with those of the other icO_2 probes.[28,29,34] They demonstrate that the PEPP3 conjugate works reliably as an icO_2 probe in the measurement of cell oxygenation and metabolic responses of cell populations producing good quality data in a simple format with high sample throughput.

Conjugates of the Other Coproporphyrin Dyes. Compared to PtCP, PdCP has a significantly longer unquenched phosphorescence lifetime (~1 ms) and therefore

dx.doi.org/10.1021/bc200324q | Bioconjugate Chem. 2011, 22, 2507−2518

is better suited for the sensing of physiological O_2 levels (0−50 μM[9]). In contrast to the phosphorescent dyes PtCP and PdCP, coproporphyrin-ketone (CPK) shows bright longwave fluorescence, structural and spectral similarity with chlorins, high photostability, and characteristic changes to pH. This makes CPK a promising candidate for use as a ratiometric pH probe[48] or a photosensitizer in PDT.[11] On the basis of PdCP and CPK dyes, we synthesized structural analogues of PEPP3 conjugate, PEPP3B and PEPP3C, respectively (Figure 7a), and investigated their properties.

PEPP3B and PEPP3C demonstrated absorption and emission spectra similar to those of unconjugated CPK and PdCP (Figure 7c−d). Thus, PEPP3B showed significantly longer lifetimes and higher sensitivity to O_2 than the PEPP3 probe, producing rather low phosphorescent signals at 21% O_2 due to strong quenching. PEPP3C exhibited bright fluorescence and pH-dependence, however, compared to those of free CPK, and spectral changes in fluorescence occurred at more acidic pH (pKa < 3), which did not match the cytosolic pH range (7.0−7.4) (Figures 7e and S7, Supporting Information). As expected, both PEPP3B and PEPP3C showed efficient uptake by HCT116 cells and intracellular distribution similar to that of PEPP3 (Figure 7b). In the case of PEPP3C, high fluorescent signals were observed (Figure 7f), suggesting its potential suitability for imaging and plate reader applications within the optimized range of working concentrations (2−10 μM, similar to PtCP-based branched conjugates). The behavior of the PEPP3B conjugate in the experiments with dPC12 cells on a microplate reader performed at 10% O_2 (Figure 7g,h) was seen to be similar to PEPP3. This conjugate produced similar signal patterns: basal respiration levels produced phosphorescence lifetimes of ∼500−600 μs, which dropped to ∼400 μs in oligomycin and antimycin treated cells and increased to ∼700 μs upon mitochondrial uncoupling with FCCP. This indicates that PEPP3B can be used for monitoring of icO_2 under hypoxia. Other conjugates of these two dyes with oligoarginine moieties can also be prepared.

DISCUSSION

A number of PtCP conjugates with long linear and short branched oligoarginine peptides, an additional mitochondria-targeting sequence, different side groups, and linkers were prepared and characterized. Testing these conjugates with several common cell lines allowed us to establish structure−activity relationships, which can aid in further rational design and application of such structures. For the monosubstituted conjugates with CFR_9 peptides, the hydrophilic PEG_{850} linker did not improve their cell loading and water solubility; however, this was achieved with tetra-substituted PtCP conjugates with the R_2-R_3 peptides. We also showed that the overall structure can affect the photophysical properties of PtCP moiety.

Analyzing the uptake of the conjugates by mammalian cells, we observed a large variation in its efficiency and subsequent intracellular distribution. The presence of hydroxyl groups (PEPP6 and T2) and the PEG_{850} linker (Figures 2−3 and S3 (Supporting Information)) slightly reduced the efficacy of cellular uptake. For the tetra-substituted conjugates, we found that a minimum 8 Arg residues is required for efficient internalization. Branched PtCP conjugates showed lower brightness (emission quantum yields) in aqueous solutions; however, TR-F signals in stained cells were comparable to the signals produced by the linear conjugates. This can be explained by the higher loading efficiency and/or elimination of internal quenching upon their internalization.

Compared to the previously reported PEPP1,[29] the new conjugates show better and more diverse intracellular distribution, ranging from endosomal to whole cell localization. The cytoplasmic accumulation was demonstrated for the linear oligoarginine conjugate with the PEG linker (PEPP2), while whole cell location with nuclear accumulation at higher concentrations was observed for branched (PEPP3, T1, T3, and T4) conjugates. Surprisingly, the targeting sequence in PEPP4 and PEPP5 did not lead to their mitochondrial accumulation. This can be explained by (i) special requirements for mitochondrial targeting of small molecules such as PtCP; (ii) limitations imposed by the endosomal cell entry (e.g., no escape from endosomes for PEPP4, Figure S5, Supporting Information); and (iii) functional inactivation of the targeting sequence within the supra-molecular structure (sterical factors).

Comparative analysis of branched (PEPP3) and linear (PEPP4) conjugates shows that both types use temperature- and ATP-dependent endocytosis mechanisms of cell entry. The latter is unaffected by MBCD and partially inhibited by EIPA and CPZ. This data points to the involvement of mixed uptake mechanisms. For the two different cell lines, MEF and HCT116, no significant differences were observed in cellular uptake, suggesting low cell-specificity. Cell penetration of the conjugates appears to be different from the unconjugated oligoarginine peptide, for which the uptake can vary in different cell lines.[2,43]

The structure−activity relationships established for the panel of PtCP conjugates can be exploited to design new cell-penetrating conjugates of porphyrin dyes with predetermined properties. This was illustrated by investigating icO_2 sensing properties of one chosen conjugate, PEPP3, and preparing its homologues from the PdCP and CPK dyes (PEPP3B and PEPP3C conjugates, respectively).

In the icO_2 sensing experiments, PEPP3 showed good analytical performance. It can be used at lower concentrations than the existing peptide-based probes,[28,29] with equal or shorter loading time (6−16 h) and without any significant effect on cell viability (Figure6). Furthermore, cell staining with PEPP3 did not interfere with the other cellular markers (LysoTracker Red, LysoTracker Green, Transferrin, MitoTracker Red, and MitoTracker Green; data not shown), thus indirectly confirming the minimal impact of the former on the function of these organelles. This probe was calibrated over physiological O_2 concentrations and tested in time-lapse respiration experiments with live cells on a TR-F reader, both under normoxic and hypoxic macro-environments. The profiles of cell oxygenation and responses to model drugs and metabolic stimulations measured with this conjugate were consistent with results obtained with the other probes.[28,34,49]

PEPP3B and PEPP3C conjugates based on the analogues of PtCP also demonstrated efficient accumulation in the cells and gave localization patterns similar to those of PEPP3. The PdCP based PEPP3B conjugate showed suitability for monitoring low O_2 under a hypoxic environment, while PEPP3C showed pH sensitivity, which was shifted toward the acidic range probably due to the multiple charges on R-residues. The latter should be kept in mind when designing the intracellular probes with pH-dependent properties. This study can also be used to develop new cell-permeable porphyrin based probes and drugs (e.g., PDT photosensitizers) targeted to different subcellular locations.

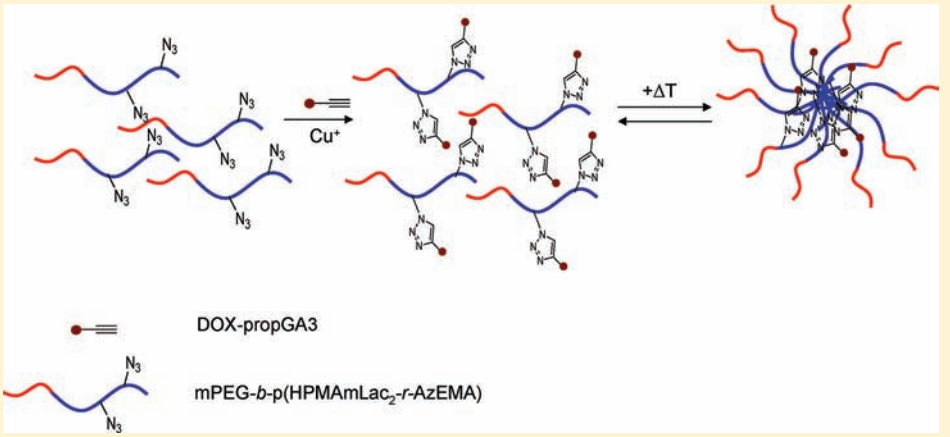
Supporting Information



ABSTRACT: Doxorubicin is an anthracycline anticancer agent that is commonly used in the treatment of a variety of cancers, but its application is associated with severe side effects. Biodegradable and thermosensitive polymeric micelles based on poly(ethylene glycol)-*b*-poly[*N*-(2-hydroxypropyl) methacrylamide-lactate] (mPEG-*b*-p(HPMAmLac$_n$)) have been studied as drug delivery systems for therapeutic and imaging agents and have shown promising *in vitro* and *in vivo* results. The purpose of this study was to investigate the covalent coupling of a doxorubicin-glucuronide prodrug (DOX-propGA3) to the core of mPEG-*b*-p(HPMAmLac$_2$) micelles. This prodrug is specifically activated by human *β*-glucuronidase, an enzyme that is overexpressed in necrotic tumor areas. To this end, an azide modified block copolymer (mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA)) was synthesized and characterized, and DOX-propGA3 was coupled to the polymer via click chemistry with a high (95%) coupling efficiency. Micelles formed by this DOX containing polymer were small (50 nm) and monodisperse and released 40% of the drug payload after 5 days incubation at 37 °C in the presence of *β*-glucuronidase, but less than 5% in the absence of the enzyme. *In vitro* cytotoxicity experiments demonstrated that DOX micelles incubated with 14C cells showed the same cytotoxicity as free DOX only in the presence of *β*-glucuronidase, indicating full conversion of the polymer-bound DOX into the parent drug. Overall, this novel system is very promising for enzymatically responsive anticancer therapy.

INTRODUCTION

Doxorubicin (or adriamycin) is an anthracycline cytotoxic anticancer agent that is commonly used in the treatment of a variety of cancers.[1] Its activity is based on the killing of rapidly dividing cells, but is not selective to cancer cells.[2] Therefore, the clinical use of doxorubicin is associated with several side effects, the most important being cardiomyopathy, which can be life-threatening, and therefore severely limits the (cumulative) dose of the drug that can be administered.[3,4] Tumor-selective and efficient drug delivery systems are under investigation that ideally mask the side effects of doxorubicin and simultaneously increase its therapeutic efficacy.[5,6] Among the developed systems, liposomal doxorubicin (Doxil/Caelyx) has been the most successful and is presently used in the clinic,[7] while

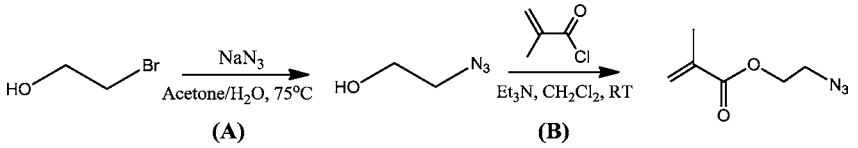
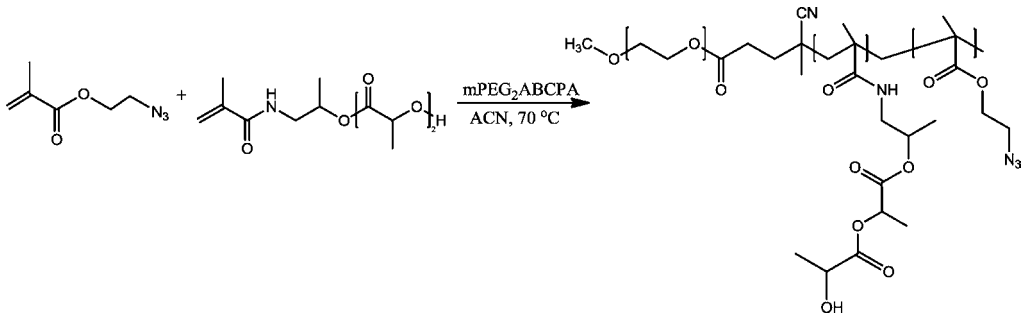


Scheme 2. Synthesis of mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) Block Copolymer with Free Radical Polymerization Using mPEG$_2$ABCPA Macroinitiator and HPMAmLac$_2$ and AzEMA as Monomers



doxorubicin formulated in polymeric micelles has been investigated in clinical trials.[8] Besides particulate carriers, important work has also been done regarding drug−polymer conjugates, where doxorubicin is attached to water-soluble polymers through enzymatically or hydrolytically sensitive linkers.[9−13]

Alternatively, the therapeutic index of chemotherapeutics can also be improved by prodrugs.[14,15] A doxorubicin-glucuronide prodrug (DOX-GA3) has been studied by Haisma et al., and very promising *in vitro* and *in vivo* results have been obtained.[16−18] This prodrug is selectively activated in tumors by β-glucuronidase, an enzyme which is released in the necrotic tumor extracellular space.[19] When DOX-GA3 was intravenously injected into OVCAR-3 tumor bearing mice, a 60-fold higher maximum tolerated dose than free doxorubicin was observed. Importantly, increased therapeutic efficacy was found which was attributed to the decreased systemic toxicity of the prodrug and the increased drug concentrations found in tumor tissue after its administration, compared to mice treated with the parent drug.[18] However, DOX-GA3 displayed poor pharmacokinetics; it was completely eliminated from systemic circulation 4 h after i.v. injection.[17] Therefore, to improve its circulation kinetics, the same group investigated the more lipophilic methylester derivative DOX-mGA3. This derivative was shown to yield DOX-GA3 after hydrolysis of the methyl ester by esterases in blood, which was subsequently converted into DOX by activation by β-glucuronidase.[17] Importantly, this prodrug demonstrated an improved circulation half-life compared to DOX-GA3,[17] which was attributed to the slow release of DOX-GA3 in blood after administration of DOX-mGA3. Therefore, a better therapeutic efficacy was expected, which has not yet been studied to date. However, as was also concluded by de Graaf et al.,[17] it is expected that the DOX-mGA3 prodrug would be more therapeutically useful if its solubility was increased, which can be achieved by the use of suitable drug delivery systems. Therefore, by loading the prodrug in a suitable nanoparticulate carrier the circulation half-life can be substantially improved.

Biodegradable and thermosensitive diblock copolymers composed of poly(ethylene glycol)-*b*-poly[*N*-(2-hydroxypropyl)-methacrylamide-lactate] (mPEG-*b*-p(HPMAmLac$_n$)) have been studied as micelle-forming building blocks for the delivery of hydrophobic agents.[20,21] mPEG-*b*-p(HPMAmLac$_n$) consists of a permanently hydrophilic (mPEG) and a thermosensitive (p(HPMAmLac$_n$)) block, and forms polymeric micelles in aqueous solutions above its critical micelle temperature (CMT).[22] The ease of loading of these micelles and their tunable biodegradability, resulting from hydrolysis of the lactic acid side chains under physiological conditions causing micelle disintegration,[23,24] as well as their size (60−80 nm, suitable for passive targeting to tumors after i.v. administration through the EPR effect[25]), render them very attractive systems for drug delivery to tumors. In recent studies, mPEG-*b*-p(HPMAmLac$_n$) micelles have been successfully used to solubilize the cytostatic drug paclitaxel, the photosensitizer Si(sol)$_2$*Pc*, vitamin K, and an MRI contrast agent.[26−28] Importantly, core-cross-linking resulted in remarkably improved circulation kinetics and consequently in substantially enhanced EPR-mediated drug targeting to tumors.[29] In a recent study, we showed that when a doxorubicin derivative was coupled to the cross-linked core of mPEG-*b*-p(HPMAmLac$_n$) micelles through a pH-sensitive hydrolytically degradable linker and the formulation was intravenously injected into tumor bearing mice, an increased antitumor effect and prolonged survival of the animals as compared to free doxorubicin (with no side effects) was observed.[30] This increased efficacy was attributed to the hypothesis that, upon injection of micelles with covalently bound DOX, a higher amount of the anticancer agent reached the tumor, compared to i.v. injection of the free drug. Active targeting of mPEG-*b*-p(HPMAmLac$_n$) polymeric micelles has also recently been demonstrated, via the conjugation of an anti-EGFR nanobody on their surface, resulting in increased cellular binding and uptake.[31]

The purpose of this study was to investigate the covalent coupling of a doxorubicin-glucuronide prodrug to the core of mPEG-*b*-p(HPMAmLac$_2$) micelles. To this end, an azide modified block copolymer (mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA)) was synthesized (Schemes 1 and 2) and a propargyl derivative of DOX-mGA3 (DOX-propGA3) was coupled to it via click chemistry (Scheme 3), a synthetic methodology that has been receiving great attention in the pharmaceutical field

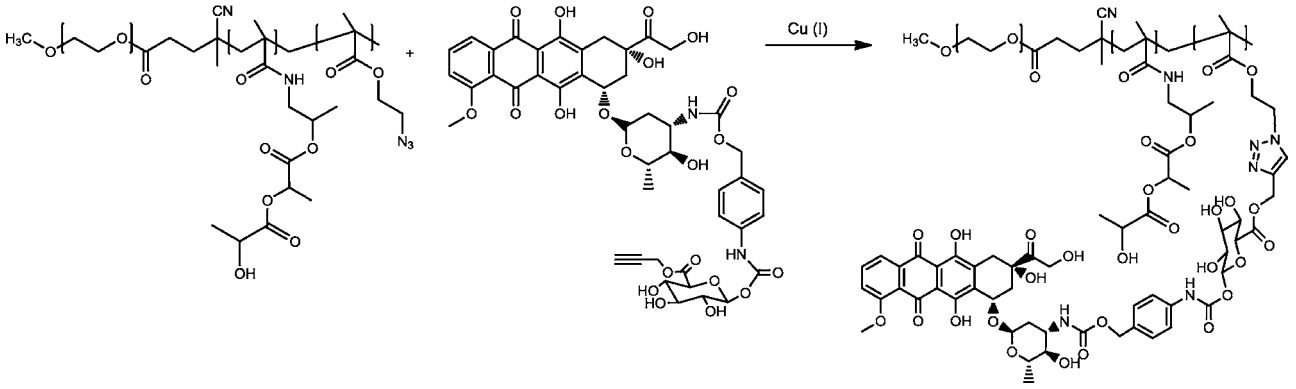
Scheme 3. Click Reaction between mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) Block Copolymer and DOX-propGA3



during the past years, due to its high efficiency and selectivity.[32−35] The obtained polymers were characterized for coupling efficiency and critical micelle concentration. It was demonstrated that DOX-propGA3 could be coupled in high yields (95%) and the polymers obtained were able to form micelles at low concentrations. Next, micelles of these block copolymers were formed, and characterized for size and release of doxorubicin in both the presence and absence of human *β*-glucoronidase. Last, the cytotoxicity of these micelles against UM-SCC-14C cells in the absence and presence of human *β*-glucoronidase was examined and compared to that of DOX-propGA3, DOX-GA3, and free DOX.

MATERIALS AND METHODS

General. Acetonitrile, dichloromethane, diethyl ether (Et_2O), and dimethylformamide (DMF) were purchased from Biosolve Ltd. (Valkenswaard, The Netherlands). HPMAmLac$_2$ was obtained from Syncom BV, Groningen, The Netherlands. The mPEG$_2$-ABCPA macroinitiator (4,4-azobis(4-cyanopentanoic acid)) was synthesized as reported previously.[21] 2-Bromoethanol, copper bromide (CuBr), copper sulfate ($CuSO_4$), hydroquinone monomethyl ether (MEHQ), methacryloyl chloride, sodium ascorbate, sodium azide, and triethylamine were purchased from Sigma-Aldrich Co. (Zwijndrecht, The Netherlands). *β*-Glucuronidace from bovine liver (type B-10, ∼10 000 units/mg solid) was purchased from Sigma-Aldrich Co. (Steinheim, Germany). ^{1}H NMR spectra were recorded using a Gemini 300 MHz spectrometer. FT-IR spectra of lyophilized samples were acquired using KBr pellets with a Bio-Rad FTS6000 (BIO-RAD, Cambridge, MA) system, by accumulating 512 scans per spectrum at a data point resolution of 2 cm^{-1}. GPC analysis was performed using a Waters 2695 controller equipped with a RI (for the detection of the polymer) and a UV (480 nm, for the detection of doxorubicin) detector. Separation was performed using a PLgel MIXED-D column (Polymer Laboratories) at 40 °C and DMF (with 10 mM LiCl) as the mobile phase, at a flow rate of 0.7 mL/min. The molecular weights of the polymers were determined using poly(ethylene glycol) standards and RI detection. DOX-propGA3 was synthesized essentially as described in ref 36 and DOX-GA3 as described in ref 37.

Synthesis of 2-Azidoethanol. Sodium azide (23.4 g, 360 mmol) and 2-bromoethanol (27.0 g, 216 mmol) were dissolved in a mixture of acetone (50 mL) and water (10 mL) and refluxed at 75 °C for 3 days. After removing acetone under vacuum, the product was 5 times extracted with 100 mL of ethyl acetate. The organic phase was dried using anhydrous $MgSO_4$ and the solvent was removed under vacuum, resulting in 10.4 g of 2-azidoethanol in the form of a slightly yellow oil (55% yield).

^{1}H NMR ($CDCl_3$) *δ* (ppm) 1.8 (O*H*, br), 3.4 (CH_2N$_3$, t), 3.8 (CH_2OH, t).

Synthesis of 2-Azidoethyl Methacrylate (AzEMA). 2-Azidoethanol (2.0 g, 23 mmol) and triethylamine (3.8 mL, 27 mmol) were dissolved in 40 mL dichloromethane and cooled in an ice bath. Next, methacryloyl chloride (2.6 g, 25 mmol) dissolved in 15 mL dichloromethane was slowly added for 20 min. The reaction was allowed to proceed for 2 h at room temperature. Next, 30 mL of a saturated $NaHCO_3$ aqueous solution was added and the mixture was stirred for 30 min in an ice bath to deactivate methacryloyl chloride. The organic phase was washed with 30 mL of a saturated NaCl solution once, dried using anhydrous $MgSO_4$, and concentrated under vacuum. The crude product was purified by flash silica gel chromatography (Acros silica gel 60 A, 0.030−0.075 mm, Geel, Belgium) with dichloromethane as an eluent, resulting in 2.59 g of 2-azidoethyl methacrylate (AzEMA) as a slightly yellow oil (73% yield). The monomer was stabilized by 400 ppm of hydroquinone monomethyl ether (MEHQ) to avoid premature polymerization and stored at −20 °C.

^{1}H NMR ($CDCl_3$) *δ* (ppm) 2.0 ($CH_2C(CH_3)CO$, s), 3.5 (CH_2N$_3$, t), 4.3 (CH_2CH$_2$N$_3$, t), 5.6 and 6.2 ($CH_2C(CH_3)CO$, t). IR ν_{max} 2106 cm^{-1} (N$_3$).

Synthesis of mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA). The synthesis of azide functionalized copolymers (mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) (2−20% of AzEMA)) was performed by free radical polymerization using HPMAmLac$_2$ and AzEMA as monomers and (mPEG$_{5000}$)$_2$-ABCPA as radical macroinitiator (ratio of monomer/initiator was 150:1), according to a previously published procedure.[22] Briefly, the starting materials were dissolved in anhydrous acetonitrile in airtight glass vials at a total concentration of 300 mg/mL. After flushing with nitrogen for at least 10 min at room temperature, the solution was heated to 70 °C and stirred for 24 h at this temperature. Next, the formed polymers were precipitated by dropwise addition of the solution to an excess of diethyl ether. The supernatant was discarded and the precipitated polymers were dissolved in water, dialyzed (membrane cutoff 12−14 kDa) against water for at least 24 h, and finally recovered by freeze−drying.

^{1}H NMR ($CDCl_3$): *δ* (ppm) 6.5 (br, CONHCH$_2$), 5.0 (br, NHCH$_2$C*H*(CH$_3$)O and COC*H*(CH$_3$)OH), 4.4 (br, COC*H*(CH$_3$)OH), 4.1 (br, OCH_2 of AzEMA), 3.6 (br, PEG methylene protons), 3.5 (br, CH_2N$_3$ of AzEMA), 3.4 (br,

dx.doi.org/10.1021/bc2003499 | *Bioconjugate Chem.* 2011, 22, 2519−2530

$NHCH_2CH(CH_3)$), 2.0–0.6 (main chain protons of the $HPMAmLac_2$ block). The mole percentage of AzEMA (f_{AzEMA}) in the synthesized block copolymers was determined using ^1H NMR analysis using eq 1 and the number average molecular weight of the thermosensitive (core-forming) block (M_n) using eq 2

$$f_{AzEMA}(\%) = \frac{I_{4.1\,ppm}/2}{I_{4.4\,ppm} + I_{4.1\,ppm}/2} \times 100 \quad (1)$$

$$M_n = [(I_{4.1\,ppm}/2)\cdot M_w(AzEMA) + I_{4.4\,ppm} \cdot M_w(HPMAmLac_2)]/(I_{3.6\,ppm}/448) \quad (2)$$

$I_{4.1ppm}$, $I_{4.4ppm}$, and $I_{3.6ppm}$ are the integrals of the protons at 4.1, 4.4, and 3.6 ppm, respectively, and 448 the number of protons per PEG_{5000} chain. To calculate the M_n of the block copolymer, the above calculated value was added to the molecular weight of mPEG (5000).

Click Reaction of $mPEG_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) Block Copolymer with DOX-propGA3. $mPEG_{5000}$-p(95%$HPMAmLac_n$-*r*-5%AzEMA) (30 mg) and DOX-propGA3 (6.6 mg, 2 equiv to azide) were dissolved in 100 μL DMF. Then, CuBr (0.1–1 equiv to DOX-propGA3) dissolved in 300 μL DMF was added. After stirring at room temperature for 24 h under nitrogen, the polymer was precipitated in an excess of diethyl ether and collected by centrifugation and drying under nitrogen.

The above-described reaction was also performed in the presence of $CuSO_4$ and sodium ascorbate to yield Cu^+ *in situ*.[38] To this end, 5 mg of $mPEG_{5000}$-*b*-p($HPMAmLac_2$-*r*-5% AzEMA) and 1.1 mg of DOX-propGA3 (2 equiv to azide) were dissolved in 90 μL DMF. Then, $CuSO_4$ (0.1–1 equiv to DOX-propGA3) and sodium ascorbate (1 equiv to $CuSO_4$) dissolved in 10 μL water were added. After stirring at room temperature for 24 h under nitrogen, the polymer was precipitated by addition of the mixture to an excess of diethyl ether and collected by centrifugation and drying under nitrogen.

DOX-propGA3 was also coupled to the polymer in a ratio of 1 mol of DOX-propGA3 per mol of polymer. Briefly, 50 mg of $mPEG_{5000}$-p($HPMAmLac_n$-*r*-AzEMA) (with 10 or 20 mol % AzEMA relative to total monomers) and 2.5 mg DOX-propGA3 (1 equiv to mole of polymer, 5% w/w) were dissolved in 900 μL DMF. Next, $CuSO_4$ (1 equiv to DOX-propGA3) and sodium ascorbate (1 equiv to DOX-propGA3) dissolved in 100 μL H_2O were added, and the mixture was stirred for 48 h under a nitrogen atmosphere. Finally, the synthesized polymers were isolated by precipitation in diethyl ether, dissolved in water, and dialyzed (membrane cutoff 12–14 kDa) against water for at least 24 h, and finally recovered by freeze–drying.

Determination of the Critical Micelle Temperature (CMT). The CMT of the different polymers was determined by the change in turbidity of an aqueous solution of each polymer with temperature using a Shimadzu UV2450 UV/vis spectrometer, essentially as described previously.[39] The polymers were dissolved in 120 mM ammonium acetate buffer (pH 5.0) at 0 °C at a concentration of 2 mg/mL. The turbidity at 650 nm was measured every 0.2 °C during heating (1 °C/min). Onsets on the *X*-axis, obtained by extrapolation of the turbidity–temperature curves during heating to turbidity zero, were considered as the CMT.

Micelle Formation by the Rapid Heating Procedure. Micelles were formed via the "rapid heating" procedure as described previously.[40] In brief, the block copolymers were dissolved in 120 mM ammonium acetate buffer (pH 5.0) at a concentration of 5 mg/mL at 0 °C. Next, the solution (1 mL) was rapidly heated to 50 °C using a water bath under vigorously shaking to form micelles.

Determination of the Critical Micelle Concentration (CMC). The CMC of the azide containing block copolymers before and after conjugation of DOX-propGA3 was determined using pyrene as a fluorescent probe.[41] Micelles of the different block copolymers were formed as described in the Materials and Methods section. The micellar dispersions were cooled to room temperature and subsequently diluted with 120 mM ammonium acetate buffer (pH 5.0) yielding different polymer concentrations ranging from 10^{-5} to 2.5 mg/mL. Next, 5 μL of pyrene dissolved in acetone (concentration 0.18 mM) was added to 0.75 mL polymer solution. The samples were incubated overnight at room temperature in the dark to allow equilibration. Prior to the measurements, the solutions were incubated at 37 °C for at least 15 min.

Fluorescence excitation spectra of pyrene were obtained using a Horiba Fluorolog fluorometer (90° angle). The excitation spectra were recorded at 37 °C from 300 to 360 nm with the emission wavelength at 390 nm. The excitation and emission band slits were 4 and 2 nm, respectively. The intensity ratio of I_{338}/I_{333} was plotted against the polymer concentration to determine the CMC.[41] The excitation spectra of pyrene incorporated in empty mPEG-p$HPMAmLac_2$ micelles and in micelles with conjugated DOX-propGA3 were identical (data not shown), demonstrating that doxorubicin did not confound the CMC measurements.

Dynamic Light Scattering. DLS measurements were performed using a Malvern CGS-3 multiangle goniometer with a JDS Uniphase 22mW He–Ne laser operating at 632 nm, an optical fiber-based detector and a digital LV/LSE-5003 correlator. Autocorrelation functions were analyzed by the cumulants method (fitting a single exponential to the correlation function to obtain the mean size and the PDI) and the CONTIN routine (fitting a multiple exponential to the correlation function to obtain the distribution of particle sizes). All measurements were performed at a 90° angle.

Release of Doxorubicin from Polymeric Micelles. Micelles were formed as described in the Materials and Methods section, using $mPEG_{5000}$-*b*-p(90%$HPMAmLac_n$-*r*-10%AzEMA) containing 1 equiv of DOX-propGA3 per mol of total polymer. The release of DOX and DOX-GA3 from the micelles and also from free DOX-propGA3 (37 °C) was followed in time by diluting the samples with PBS pH 7.4 containing 0.1% (w/v) bovine serum albumin (final free DOX-propGA3 concentration 10 μg/mL, final polymer concentration in micelles 200 μg/mL corresponding to 10 μg/mL of DOX-propGA3) followed by addition of β-glucuronidase (final enzyme concentration was 20 μg/mL) and incubation at 37 °C. As a control, samples in the same buffer were also prepared, without the addition of the enzyme. Next, samples were taken at regular time points and analyzed with gradient HPLC chromatography, using a C18 Sunfire column and potassium phosphate buffer pH 3 (20 mM) with 5% acetonitrile as eluent A (75–60% in 12 min) and 100% acetonitrile as eluent B (25–40% in 12 min). The detection was performed using fluorescence at 480 nm excitation and 560 emission. The retention time of doxorubicin was 3 min, of

DOX-GA3 6.6 min, and of DOX-propGA3 10 min. Calibration was performed by injecting different volumes (0.3−50 μL) of a doxorubicin standard to result in a range of 0.016−2.76 nmol of DOX. The injection volume of the unknowns was 50 μL, and the concentrations (μmol/mL) of DOX and DOX-GA3 were calculated by comparing the area under the curve of the peak at 3 and 6.6 min, respectively, and comparing it to the doxorubicin calibration curve.

***In Vitro* Cytotoxicity.** Human head and neck squamous carcinoma (HNSCC) cells UM-SCC-14C (abbreviated as 14C, developed by Dr. T.E. Carey, Ann Arbor, MI, USA) were seeded into 96-well plates (4×10^3 cells/well) and cultured overnight in Dulbecco's Modified Eagle's medium (DMEM, Invitrogen, Breda, The Netherlands) containing L-glutamine (2 mM), 7.5% (v/v) fetal bovine serum, penicillin (100 IU/ml), streptomycin (100 μg/mL), at 37 °C in a humidified atmosphere containing 5% CO_2. Next, the medium was replaced with 100 μL of medium with or without β-glucuronidase (20 μg/mL). Dilutions of samples of DOX, DOX-GA3, and DOX-propGA3 and of mPEG-*b*-(90%pHPMAmLac$_2$-*r*-10% AzEMA) micelles with covalently bound DOX-propGA3 were prepared in HEPES buffer 5 mM, pH 7.4, to obtain final DOX concentrations 0.02−43.8 μM. Next, the dilutions were added in quadriplicates (50 μL), followed by incubation for 72 h. The viability of the adhered cells was determined using a WST-1 assay (Cell Proliferation Reagent WST-1, Roche Diagnostics GmbH, Roche Applied Science, 68298 Mannheim, Germany).

RESULTS AND DISCUSSION

Synthesis of 2-Azidoethyl Methacrylate (AzEMA). 2-Azidoethyl methacrylate (AzEMA) was synthesized as shown in Scheme 1, using a slightly modified previously published procedure.[42] In the first step, 2-bromoethanol was reacted with sodium azide and the formed compound, 2-azidoethanol, was obtained in a yield of 55% after extraction in ethyl acetate. The structure of 2-azidoethanol was confirmed by NMR analysis that showed a shift of the methylene proton peaks of the product compared to the starting material (2-bromoethanol) from 3.9 to 3.8 and from 3.5 to 3.4 (Figure S1, Supporting Information). Next, the alcohol moiety of 2-azidoethanol was reacted with methacryloyl chloride resulting in 2-azidoethyl methacrylate (AzEMA) which was obtained in a yield of 73%. After methacrylation and purification, the 3 additional peaks at 6.2, 5.6, and 2 ppm of the protons of the methacrylate group appeared. In addition, the peak at 3.8 ppm of the methyl proton adjacent to the alcohol was shifted to 4.3 ppm, indicating connection via esterification (Figure S2, Supporting Information). Lastly, IR analysis of AzEMA showed the characteristic peak of the azide at 2106 cm^{-1} [43,44] (Figure 2A).

Synthesis of mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) Block Copolymer. mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) with various amounts of AzEMA (2−20 mol % relative to total monomers) were synthesized by free radical polymerization using HPMAmLac$_2$ and AzEMA as monomers and mPEG$_2$ABCPA as radical macroinitiator (Scheme 2), using the same procedure as reported previously.[22] The characteristics of the synthesized polymers are summarized in Table 1. The different polymers were obtained in good yields (64−77%), and had M_n values (calculated using ^{1}H NMR analysis using eq 2) ranging from 15 to 22 kDa and M_w/M_n of around 2 (GPC analysis), which is a normal molecular weight distribution for polymers synthesized with this type of free radical polymerization.[22] Importantly, ^{1}H NMR analysis of block copolymers containing AzEMA revealed a unique resonance peak at 4.1 ppm (Figure 1B, arrow) which was not observed in the ^{1}NMR spectrum of the block copolymer without AzEMA (Figure 1A), and is assigned to the methyl protons at the β position to the azide group. The peaks of the methyl protons adjacent to the azide group at 3.5 ppm could not be clearly seen due to their overlap with the PEG peak. By integrating the peak at 4.1 ppm, the mol % AzEMA in the different copolymers was calculated using eq 1 and was found to be around 50% of the feed ratio (Table 1). IR analysis also showed a peak at 2100 cm^{-1} characteristic for the azide vibration,[43,45] the intensity of which also increased with increasing AzEMA content (Figure 2).

dx.doi.org/10.1021/bc2003499 | *Bioconjugate Chem.* 2011, 22, 2519−2530

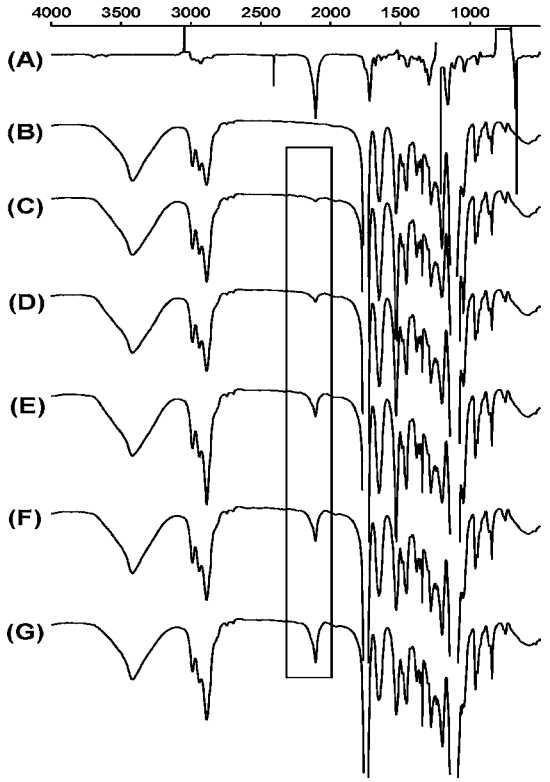

Figure 2. IR spectra of AzEMA monomer (A) and mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) block copolymers containing 0% (B), 2% (C), 5% (D), 10% (E), 15% (F), and 20% (G) AzEMA.

The critical micelle temperature of the copolymer without azide was 5.3 °C (Table 1) which is in agreement with previous publications.[22] The CMT decreased with increasing AZEMA content, indicating that the incorporation of AzEMA increased the hydrophobicity of the copolymer, as expected from the incorporation of the more hydrophobic AzEMA (C log *P* of AzEMA was 2.31, versus −0.27 for HPMAmLac$_2$, as calculated by *ChemDraw Ultra 12.0* software).

Micelles of mPEG-*b*-p(HPMAmLac$_2$-*r*-AzEMA) copolymers were formed by a rapid heating procedure[40] and the particle size was measured by DLS (Table 1). The copolymers formed small micelles with average diameters 50−60 nm and a low PDI (~0.1).

Click-Coupling of DOX-propGA3 to mPEG$_{5000}$-*b*-p-(HPMAmLac$_2$-*r*-AzEMA). The conjugation of DOX-propGA3 to the polymer was carried out, as depicted in Scheme 3, using mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) containing 5 mol % azide. CuBr as well as $CuSO_4$/sodium ascorbate were used as catalysts, and the reaction was performed for 24 h at room temperature in DMF. A ratio of 1:2 azide to alkyne was used. The reaction progress was monitored by IR (by the decrease of the azide vibration at 2100 cm^{-1}). When 0.1−1 equiv CuBr was used as a catalyst, no conjugation was observed, as evidenced from the observation that the intensity of the azide peak had not dropped (data not shown). Neither 0.1 nor 0.5 equiv of $CuSO_4$ in the presence of ascorbate was sufficient to accomplish the reaction (Figure 3B and C). The click reaction only occurred when the amount of $CuSO_4$ was increased to 1 equiv (relative to DOX-propGA3), as indicated by the complete disappearance of the azide peak (Figure 3D). This shows that, in the case of click reaction of the steric hindered doxorubicin molecule with the bulky polymer, *in situ* reduction

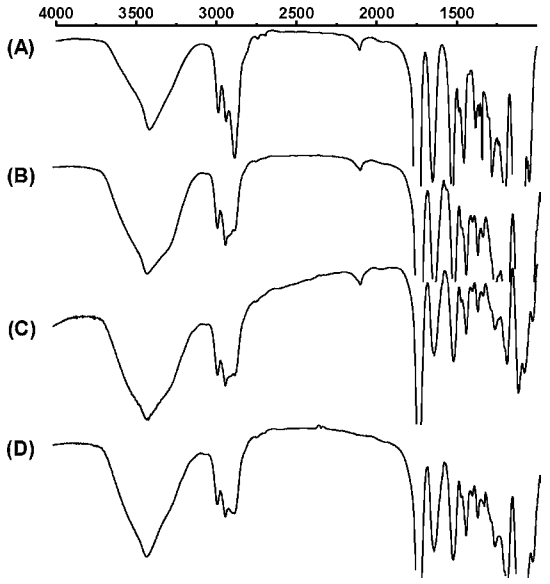

Figure 3. IR spectra of mPEG$_{5000}$-*b*-p(95%HPMAmLac$_2$-*r*-5%AzEMA) (A) and of conjugates of mPEG$_{5000}$-*b*-p(95%HPMAmLac$_2$-*r*-5% AzEMA) with DOX-propGA3 using a azide/alkyne ratio of 1:2 and 0.1 equiv (B), 0.5 equiv (C), and 1 equiv (D) of $CuSO_4$ (relative to DOX-propGA3) as a catalyst, in the presence of sodium ascorbate (1 equiv to $CuSO_4$).

of Cu^{2+} by ascorbate is required, as well as the presence of at least 1 equiv of $CuSO_4$.

The polymer−drug conjugate synthesized as described above, however, lost its thermosensitivity and was insoluble in water, most probably due to the high amount of hydrophobic DOX-propGA3 coupled, which makes it unsuitable to prepare micelles with the rapid-heating method (see Materials and Methods). Therefore, coupling reactions were carried out using diblock copolymers containing 20% and 10% AzEMA and 1 equiv of DOX-propGA3 per mol of polymer (corresponding to 5% w/w ratio of DOX-propGA3 to polymer), in the presence of 1 equiv $CuSO_4$ and ascorbate (relative to doxorubicin). IR analysis showed that the azide peak did not disappear completely, as expected from the excess of azide used (spectra not shown). The polymers obtained were freely soluble in water at 0 °C and had an CMT of ~1 °C (Table 3) which is slightly lower than the CMT of the azide polymer used for derivatization (CMT of 2−3 °C, Table 2). This decrease in CMT is probably due to the increased hydrophobicity of the polymer due to its conjugation with DOX-propGA3.

To prove convincingly that doxorubicin was covalently linked to the polymeric backbone, GPC analysis was performed using dual UV (480 nm, characteristic absorption for doxorubicin) and RI detection. The chromatograms of the polymers obtained by the conjugation using the polymer with 10% azide groups are shown in Figure 4. Figure 4A shows that mPEG$_{5000}$-*b*-p(90%HPMAmLac$_2$-*r*-10%AzEMA) eluted at 18 min (RI detection), while no signal was observed at 480 nm. On the other hand, DOX-propGA3 eluted at 22.3 min (both RI and UV (480 nm) detection) (Figure 4B). GPC analysis of the conjugate showed that the majority of DOX-propGA3 eluted at 16.6 min (UV detection, Figure 4C), which is close to the retention time of the polymer (17.8 min, Figure 4C; the slight shift in the signal peaks can be attributed to the GPC system, where the RI-detector was serially attached to the UV detector). A small peak was observed at the retention time of

Table 2. Results of Conjugation of mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) to DOX-propGA3 (1 equiv DOX per mol of polymer) Using 1:1 $CuSO_4$/Sodium Ascorbate (1 equiv to DOX-propGA3) as Catalyst

polymer used	% conjugation	CMT (°C) (before/after DOX conjugation)	CMC (mg/mL) (before/after DOX conjugation)	Z_{ave} (nm)	PDI

free DOX-propGA3 (22.3 min, Figure 4C). From the area under the curve of the free and coupled DOX-propGA3 peaks, it was calculated that the coupling efficiency was 94%

Table 3. Concentration (μM) Required for 50% of Inhibition (EC_{50}) of Viability of 14C Cells Induced by Doxorubicin, DOX-GA3, DOX-propGA3, and Micelles with Covalently Bound DOX-propGA3 after Incubation for 72 h

	EC_{50} (μM DOX)	EC_{50} (μM DOX) with β-glucuronidase
DOX	0.10 ± 0.06	0.16 ± 0.02
DOX-GA3	21.3 ± 4.8	0.19 ± 0.04
DOX-propGA3	44.8 ± 3.2	0.63 ± 0.02
DOX-propGA3 micelles	47.3 ± 6.2	0.22 ± 0.01

(Table 2), indicating almost quantitative conjugation. Similar results were obtained when the polymer containing 20% azide was used (Table 2). When a physical mixture of polymer with DOX-propGA3 was analyzed using GPC (22% w/w DOX-propGA3 to polymer), the peaks of the polymer at 18 min (RI detection) and of DOX-propGA3 at 22.3 min (UV detection) were visible, but no shift of the DOX-propGA3 UV peak was observed (Figure 4D), indicating that the conjugation observed was due to the covalent coupling of DOX-propGA3 to the polymer.

To check whether the synthesized conjugates were still able to form micelles, the rapid heating procedure was applied and the critical micelle concentration was determined using pyrene as a fluorescent probe. The CMC was determined from the plot of the intensity ratio I_{338}/I_{333} as a function of polymer concentration (Figure 5). A red shift was observed with increasing polymer concentration, indicating the partitioning of pyrene in the hydrophobic environment of the micellar core.[41,46] Azide-containing polymers had a slightly higher CMC than the polymer without azide (Table 2). This is most probably because the azide containing polymers have slightly lower molecular weights (Table 1) and the CMC is known to increase with decreasing molecular weight of the core forming block.[47,48]

Conjugates of DOX with the azide block copolymers were shown to have a slightly higher CMC than the corresponding azide copolymers without DOX (Table 2). This was unexpected, as these conjugates possessed lower CMTs than the azide polymers, indicating that the thermosensitive block became more hydrophobic upon DOX conjugation. The log*P* of DOX-mGA3, which is structurally similar to DOX-propGA3, has been measured and it was found to be 1.27 (and 0.52 for DOX),[17] which demonstrates the lipophilic nature of the prodrug. It has been shown previously that the CMC decreases when a more hydrophobic block is used.[48] Therefore, we anticipated a lower CMC for these DOX-conjugated polymers. The fact that we did not observe a lower CMC for these conjugates might be due to the detection limit of the determination method used using pyrene partition.

Micelles formed by DOX-propGA3 conjugated polymers (10% or 20% azide content) above their CMC were characterized for size and polydispersity using DLS. Small (50 nm) monodisperse micelles were formed (Table 2) and DOX containing polymers had similar size characteristics as the corresponding polymers without DOX (Table 1), showing that the coupling of DOX-propGA3 to the polymer backbone did not affect the size of the micelles formed.

Release of Doxorubicin from mPEG$_{5000}$-*b*-p(HPMAmLac$_2$-*r*-AzEMA) Micelles with Conjugated DOX-propGA3. As has been shown previously, the methyl ester derivative of DOX-GA3 (DOX-mGA3) releases DOX in two steps: First, DOX-mGA3 is converted into DOX-GA3 via cleavage of the methyl ester group (by hydrolysis at pH 7.4 or by esterase activity), and next, DOX-GA3 is enzymatically converted into DOX by β-glucuronidase.[17] The first step is necessary, because DOX-mGA3 is a not good substrate for β-glucuronidase. As DOX-propGA3 differs from DOX-mGA3 only by the presence of a propargyl group instead of a methyl group, the same behavior was anticipated. The conversion of DOX-propGA3 to DOX was studied by incubating the prodrug in PBS/0.1% BSA buffer pH 7.4 with or without β-glucuronidase (20 μg/mL) and measurement using HPLC (Figure 6A). DOX-propGA3 showed a peak in the HPLC chromatogram at 10 min, while the retention time of doxorubicin was 3 min and that of DOX-GA3 6.6 min. Upon incubation of DOX-propGA3 for 24 h at pH 7.4 (37 °C), its peak at 10 min shifted to 6.6 min (Figure 6A), which demonstrates that DOX-propGA3 was quantitatively converted to the more hydrophilic DOX-GA3 derivative by hydrolysis of the propargyl ester. On the other hand, upon incubation for 24 h at pH 7.4 (37 °C) in the presence of β-glucuronidase, the DOX-propGA3 peak completely shifted to 3 min (Figure 6A), which shows that the prodrug was converted into DOX. The amount of DOX released was calculated from the peak area and compared with the DOX content of the prodrug, and it was demonstrated that after 24 h incubation at pH 7.4 (37 °C) in the presence of enzyme the conversion was almost quantitative (90%). Therefore, it is concluded that upon incubation in buffer pH 7.4 containing β-glucuronidase, DOX-propGA3 is converted into DOX-GA3 by hydrolysis of the propargyl ester, which is then subsequently converted into DOX by β-glucuronidase activity (Scheme 4).

HPLC analysis of the micelles with conjugated DOX-propGA3 before any incubation showed no peaks corresponding with DOX-propGA3, DOX-GA3, or DOX (Figure 6B), demonstrating again that no significant amount of unreacted DOX-propGA3 remained after conjugation and purification. Upon incubation for 24 h at pH 7.4 (37 °C), a peak at 6.6 min was observed corresponding with DOX-GA3, indicating that the conjugated DOX-propGA3 was converted to free DOX-GA3, most probably due to ester hydrolysis (Scheme 4). When the incubation was performed in the presence of β-glucuronidase, this peak shifted to 3 min indicating conversion into doxorubicin

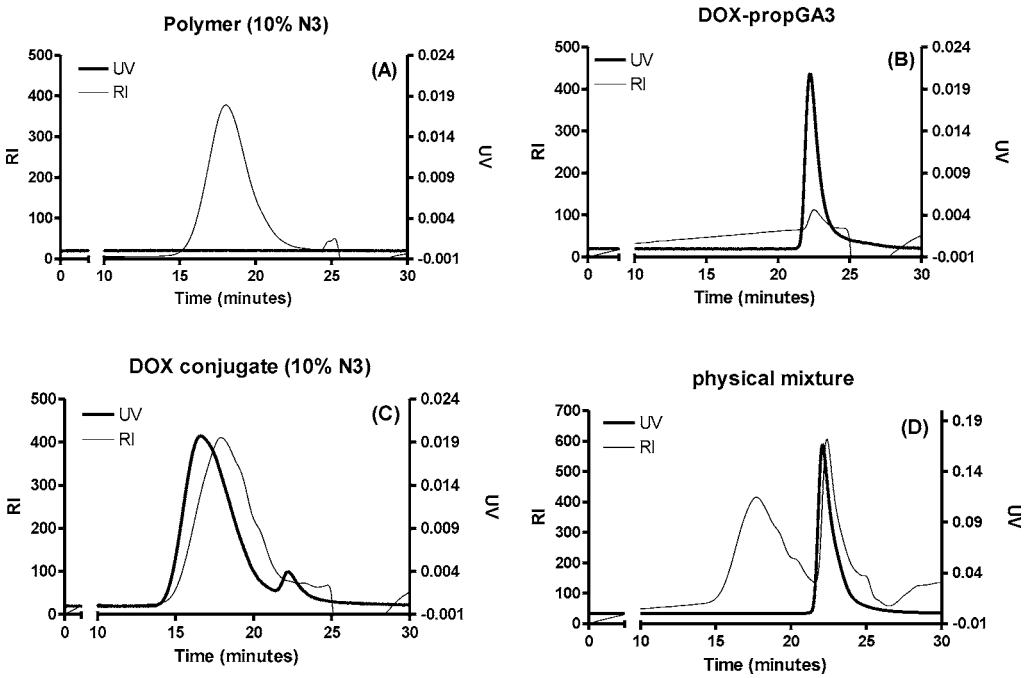

Figure 4. GPC analysis with dual RI and UV (480 nm) detection of (A) mPEG-*b*-p(90%HPMAm-*r*-10%AzEMA), (B) DOX-propGA3, (C) click conjugate of mPEG-*b*-p(90%HPMAm-*r*-10%AzEMA) with DOX-propGA3, and (D) physical mixture of mPEG-*b*-p(90%HPMAm-*r*-10%AzEMA) and DOX-propGA3.

by the enzyme (Figure 6B, Scheme 4). Determination of the amount of DOX released from the micelles demonstrated that after 5 days incubation in the presence of *β*-glucuronidase DOX was still being released from the micelles and had reached 35% of the total content, while less than 5% release was observed in the absence of *β*-glucuronidase (Figure 7A). Moreover, a 10-fold higher amount of enzyme gave no difference in release kinetics of DOX (results not shown). It has been shown in the past that the methyl ester of DOX-GA3 (DOX-mGA3) is not a good substrate for *β*-glucuronidase and that conversion into DOX only occurs after hydrolysis of the ester bond that yields DOX-GA3.[17] Consequently, since a 10-fold higher amount of enzyme did not accelerate the release, it is most likely that the conversion of polymer-bound DOX-propGA3 to DOX-GA3 via hydrolysis is the rate-limiting factor for the generation of DOX. To further clarify this, the release of DOX-GA3 from the micelles in the absence and presence of enzyme was also investigated. It was observed that in the absence of *β*-glucuronidase the area under the curve of DOX-GA3 peak (6.6 min) increased in time and reached 40% of the total content after 5 days (Figure 7B), demonstrating that DOX-GA3 was released from the micelles with no conversion to DOX. The rate of DOX-GA3 formation in

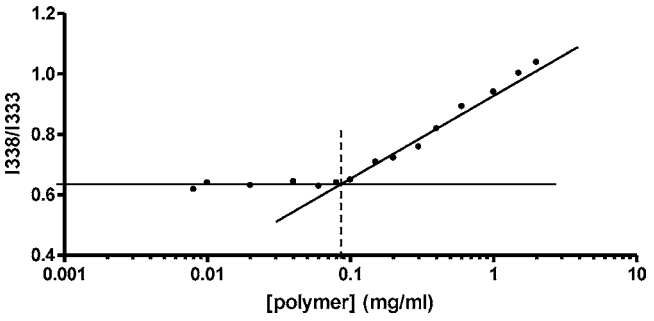

Figure 5. I_{338}/I_{333} for pyrene as a function of concentration of conjugate of DOX-propGA3 with mPEG-*b*-p(90%HPMAmLac$_2$-*r*-10% AzEMA). The CMC was calculated from the intersection of the horizontal line at low polymer concentrations with the tangent of the curve at high polymer concentrations.

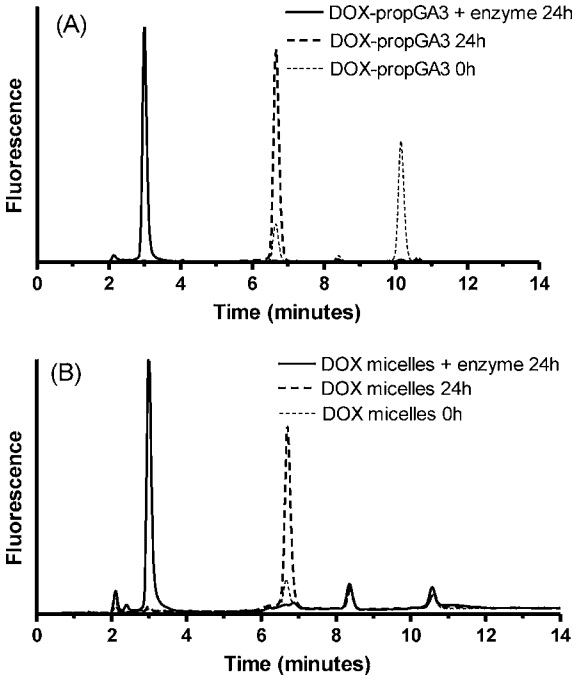

Figure 6. HPLC analysis of (A) DOX-propGA3 (10 *μ*g/mL) and of (B) micelles with covalently bound DOX-propGA3 (200 *μ*g/mL of polymer) before incubation (0 h), after 24 h incubation in a PBS/BSA 0.1% pH 7.4 buffer, and after 24 h incubation in a PBS/BSA 0.1% pH 7.4 buffer containing 20 *μ*g/mL *β*-glucuronidase. Doxorubicin had a retention time of 3 min, DOX-GA3 6.6 min, and DOX-propGA3 10 min.

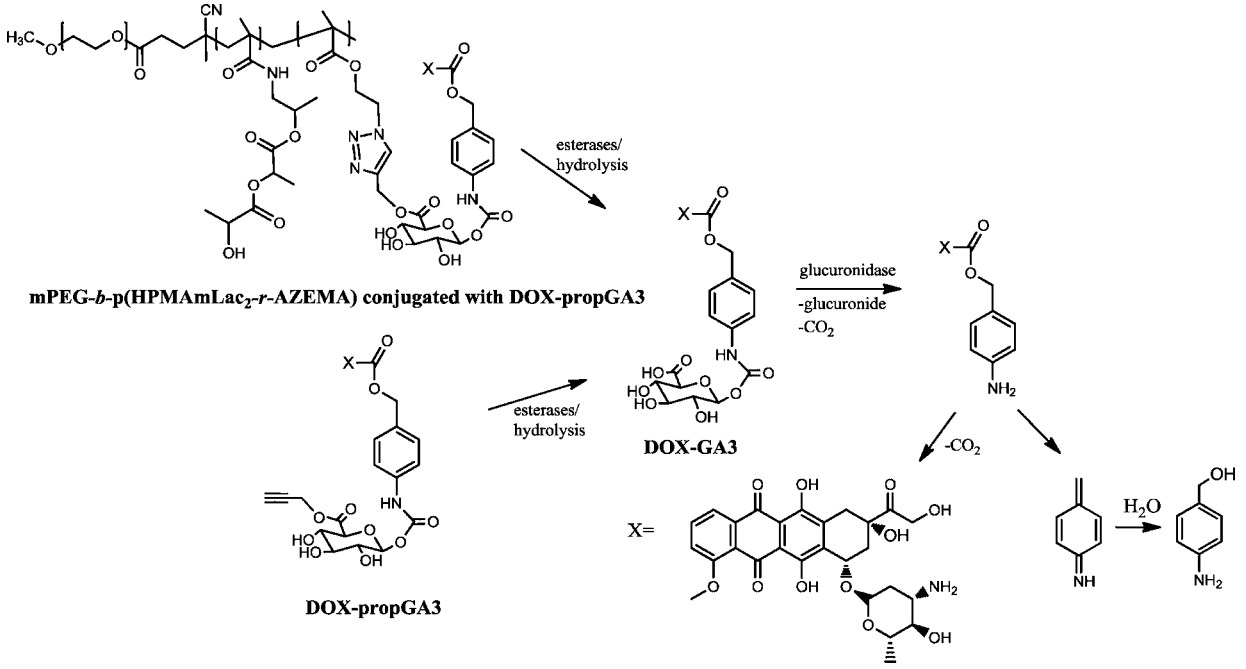
Scheme 4. Conversion of Free or Polymer-Bound DOX-propGA3 to DOX-GA3 by Chemical Hydrolysis and/or by Esterases and Subsequent Release of DOX by β-Glucuronidase



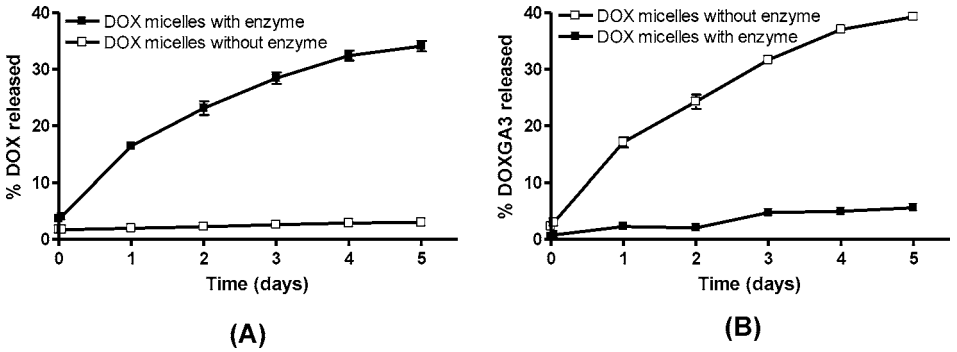


Figure 7. HPLC analysis of the release of DOX (A) and DOX-GA3 (B) from micelles (200 μg/mL polymer) with covalently bound DOX-propGA3 in the presence and absence of β-glucuronidase.

the absence of enzyme (Figure 7B) was similar to the rate of DOX formation in the presence of enzyme (Figure 7A) indicating that once DOX-GA3 was produced it was directly converted into DOX by the enzyme (also because in the presence of β-glucuronidase less than 10% DOX-GA3 was recovered). These observations confirm the hypothesis that the hydrolysis of the ester bond to convert polymer-bound DOX-propGA3 to free DOX-GA3 is the limiting factor for the DOX generation. Likely, the generation of DOX-GA3 from polymer-bound DOX-propGA3 is slower than from free DOX-propGA3 because the water activity in the hydrophobic core of the micelles is lower than in bulk, and therefore, the hydrolysis process slows down.[23] Besides, the hydrolysis of the ester bond might be slower due to the increased steric hindrance caused by its close proximity to the polymer backbone.

***In Vitro* Cytotoxicity.** The cytotoxicity of DOX, DOX-GA3, DOX-propGA3, and micelles with covalently bound DOX-propGA3 (prepared using mPEG-*b*-(90%pHPMAmLac$_2$-*r*-10%AzEMA)) against 14C cells was investigated both in the presence and in the absence of β-glucuronidase (Figure 8 and Table 3). Micelles without DOX showed no cytotoxicity (data not shown), which is in line with previous results.[27,30] As expected, DOX showed the highest cytotoxicity (EC_{50} of 0.10 μM; Table 3 and Figure 8A). In the presence of β-glucuronidase, approximately the same cytotoxicity was observed (Figure 8A; EC_{50} of 0.16 μM; Table 3), demonstrating that the enzyme did not affect the cytotoxic effect of free DOX. On the other hand, when cells were incubated with DOX-GA3 and DOX-propGA3 in the absence of enzyme, the observed cytotoxicity was about 200−300 times less compared to DOX (Table 3; EC_{50} 21.3 μM for DOX-GA3, 44.8 μM for DOX-propGA3). These results are in agreement with previous publications[17] and demonstrate that, in the culture medium, a minimum amount of DOX was formed from the prodrugs, which was also demonstrated in the previous section (Figure 7) after incubation in a pH 7.4 buffer. When DOX-GA3 and DOX-propGA3 were incubated with cells in medium containing β-glucuronidase, an increased cytotoxic effect was observed (Table 3, EC_{50} 0.19 μM for DOX-GA3, 0.63 μM for DOX-propGA3) which was in the same range as that of DOX. Similar results have been published for DOX-mGA3 and DOX-GA3.[17,18] It has been shown that DOX-mGA3 is not a good

dx.doi.org/10.1021/bc2003499 | *Bioconjugate Chem.* 2011, 22, 2519−2530

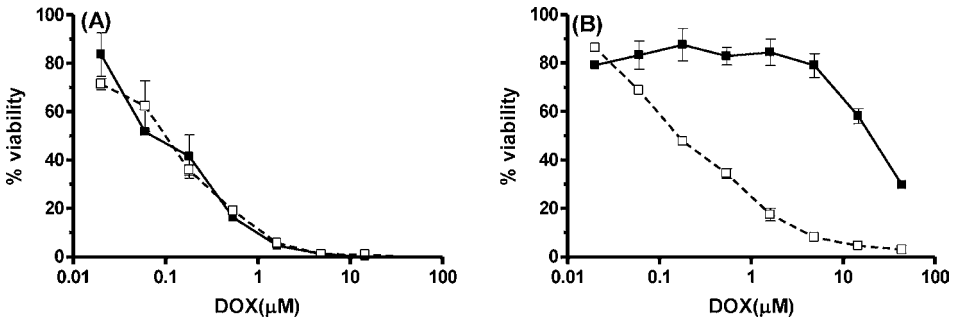

Figure 8. Viability of 14C cells in medium with (□) or without (■) β-glucuronidase (20 μg/mL), incubated for 72 h with (A) Doxorubicin and (B) mPEG-*b*-(90%pHPMAmLac$_2$-*r*-10%AzEMA) polymeric micelles with covalently bound DOX-propGA3.

substrate for β-glucuronidase and that conversion only occurs after hydrolysis of the ester bond,[17] so the same behavior is most likely also valid for DOX-propGA3. It can be assumed that, either due to chemical hydrolysis in the culture medium (as was observed in buffer; see previous section) or due to the presence of esterases, DOX-propGA3 was converted to DOX-GA3, which was then converted into DOX by β-glucuronidase.

Figure 8B shows the cytotoxicity results of 14C cells exposed to polymeric micelles with covalently bound DOX-propGA3 in the absence and presence of β-glucuronidase (Figure 8B). Without the addition of enzyme, a low cytotoxicity effect was observed (EC_{50} 47.3 μM), demonstrating again, as observed after incubation in a pH 7.4 buffer (Figure 7), that in the medium only a low amount of DOX was released. Importantly, in the presence of β-glucuronidase, the cytostatic activity became very similar to that of DOX (Figure 8B, EC_{50} 0.22 μM). This finding is rather interesting, as in the previous section it was demonstrated that the release of DOX from the micelles is incomplete even after 5 days incubation in the presence of β-glucuronidase at pH 7.4. This was attributed to the incomplete release of DOX-GA3 from the micellar core as compared to the release from free DOX-propGA3 (due to slow hydrolysis in the hydrophobic micellar core), which resulted in slow DOX release, because only DOX-GA3 is a good substrate for β-glucuronidase and not the polymer-bound drug. In previous studies, it has been demonstrated that conversion of DOX-mGA3 to DOX-GA3 is much faster in the presence of esterase than in buffer ($t_{1/2}$ was ~20 min in the presence of carboxylesterase and 10 h in buffer pH 7.4).[17] Therefore, most probably, esterases in the culture medium contributed to the complete conversion of polymer-bound DOX-propGA3 to DOX-GA3, which was then subsequently converted into DOX by the β-glucuronidase. This enzymatic conversion can occur by penetration of esterases into the core of the micelles or by cleavage of the produg form free polymer chains which are in dynamic equilibrium, a mechanism suggested for the enzymatic degradation of PEG-Oligo(ε-caprolactone) micelles by lipase.[49] As a result of both the chemical and enzymatic hydrolysis, micelles with covalently bound DOX-propGA3 released DOX-GA3 in the culture medium, which was then converted to DOX by the action of β-glucuronidase.

CONCLUSION

A novel, azide-modified block copolymer mPEG$_{5000}$-*b*-p-(HPMAmLac$_2$-*r*-AzEMA) was synthesized and a propargyl derivative of the DOX-GA3 prodrug (DOX-propGA3) was coupled to this copolymer via click chemistry with a very high (~90%) coupling efficiency. Micelles formed by this polymer were small (50 nm) and monodisperse. The glucuronide spacer of the prodrug used is known to be selectively cleaved by β-glucuronidase, an enzyme present in necrotic tumor areas. Indeed, it was shown that DOX micelles demonstrated the same cytotoxicity as free DOX when incubated with 14C cells in the presence of serum and β-glucuronidase. Therefore, improved *in vivo* antitumor efficacy is anticipated.

ABSTRACT: Optical imaging is emerging as an important tool to visualize tumors. However, there are many potential choices among the available fluorophores. Optical imaging probes that emit in the visible range can image superficial tumors with high quantum yields; however, if deeper imaging is needed then near-infrared (NIR) fluorophores are necessary. Most commercially available NIR fluorophores are cyanine based and are prone to nonspecific binding and relatively limited photostability. Silica-containing rhodamine (SiR) fluorophores represent a new class of NIR fluorophores, which permit photoactivation via H-dimer formation as well as demonstrate improved photostability. This permits higher tumor-to-background ratios (TBRs) to be achieved over longer periods of time. Here, we compared an avidin conjugated with SiR700 (Av-SiR700) to similar compounds based on cyanine dyes (Av-Cy5.5 and Av-Alexa Fluor 680) in a mouse tumor model of ovarian cancer metastasis. We found that the Av-SiR700 probe demonstrated superior quenching, enabling activation after binding-internalization to the target cell. As a result, Av-SiR700 had higher TBRs compared to Av-Cy5.5 and better biostability compared to Av-Alexa Fluor 680.

INTRODUCTION

Target-specific optical imaging probes are promising tools in the molecular imaging of cancer. Optical imaging probes offer high sensitivity, low cost, and portability, and do not entail exposure to ionizing radiation. However, optical imaging is limited by poor tissue penetration. The use of fluorophores that absorb and emit in the near-infrared (NIR) range have less absorption and scatter from tissue, permitting deeper tissue penetration than is possible with fluorophores based on visible light. Another critical feature of an optical imaging probe is that it has high tumor-to-background ratios (TBRs). One way to achieve this is to have extremely high binding affinities for the tumor and rapid excretion of the unbound compound. Another, more practical approach, is to activate the fluorescence only upon binding to the target tissue; thus, unbound conjugates yield a minimal signal while target-bound conjugates have a high signal leading to very high TBR. Optical imaging is unique in its ability to be activatable as opposed to radionuclide imaging that is "always on".[1,2] A number of quenching mechanisms have been implicated in fluorescence activation. One method is the formation of H-dimers using xanthene based fluorophores, such as rhodamine; H-dimer formation of these fluorophores leads to efficient quenching.[3]

An optical probe must also be able to withstand biodegradation after internalization since this affects the durability of the signal. Rhodamine core fluorophores generally demonstrate better photostability and biostability than cyanine-based dyes and have high fluorescence quantum yield.[4]

Thus, the optimal imaging probe is one that is highly activatable, yet photostable, and, absorbs and emits light in the NIR. While several cyanine based optical probes are commercially available, rhodamine based probes are not.

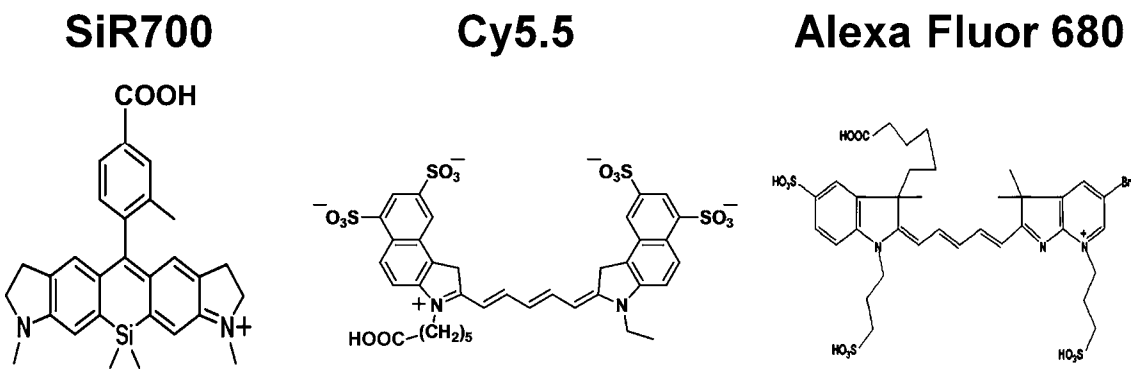

Figure 1. Chemical structures of NIR fluorophores compared in this study. SiR700 is a NIR fluorophore synthesized on a silica rhodamine core. We compared this to two commercially available NIR fluorophores synthesized using a cyanine core, Cy5.5, and Alexa Fluor 680. Carboxyl residues are modified to succinimidyl esters and used for functionalizing fluorophores.

Recently, Koide et al. described silica-containing rhodamine dyes (SiR), with excellent photophysical properties such as an emission peak at over 650 nm.[5] However, the ability of SiR dyes to quench via H-dimer formation *in vitro* and *in vivo*, while maintaining good *in vivo* photo- and biostability, has not been evaluated. Here, we compare conjugates of avidin SiR fluorophore (Av-SiR700) with two cyanine-based NIR fluorophores conjugates Av-Cy5.5 and Av-Alexa Fluor 680 (Av-Alexa680) in a mouse model of metastatic ovarian cancer during *in vivo* optical imaging.

EXPERIMENTAL PROCEDURES

Amino-Reactive NIR Fluorophores. Amino-reactive Cy5.5- and Alexa Fluor 680-succinimidyl esters were purchased from GE Healthcare (Piscataway, NJ) and Invitrogen Co. (Carlsbad, CA), respectively. The synthesis method of SiR700-succinimidyl esters has been published.[5,6] The chemical structures of all three NIR fluorophores are shown in (Figure 1).

Synthesis of Avidin-Conjugated NIR Fluorophores. Avidin (6 nmol), was purchased from Pierce Biochemical, Inc. (Milwaukee, WI), and was incubated with amino-reactive NIR fluorophores (Cy5.5 and SiR700; 60 nmol, Alexa680; 40 nmol) in 0.1 M phosphate buffer (pH 8.5) at room temperature for 15 min. Each mixture was purified with a Sephadex G25 column (PD-10; GE Healthcare, Piscataway, NJ). The protein concentration was determined by measuring the absorption at 280 nm with a UV−vis system (8453 UV−Visible Value System; Agilent Technologies, Santa Clara, CA). The concentration of NIR fluorophores was measured by absorption with the UV−vis system to confirm the number of fluorophore molecules conjugated to each avidin molecule.[7] The number of fluorophore molecules per all avidin conjugates was ~3.

H-Dimer Formation and Quenching Efficiency of Av-Cy5.5, Av-Alexa680, and SiR700 *in Vitro*. The quenching−dequenching characteristics of each avidin-conjugate were investigated by treating the conjugates with 5% SDS to disassociate any molecular interaction between fluorophores. The fluorescence signal intensity of each conjugate was measured with a fluorescence spectrometer before and after 5% SDS (Perkin-Elmer LS55, Perkin-Elmer, Shelton, CT). The absorption spectrum was measured with a UV−vis system (8453 UV−Visible Value System; Agilent Technologies).

Cell Culture. An established ovarian cancer cell line known to overexpress the β-D-galactose receptor, SHIN3, was used for *in vitro* fluorescence microscopy, flow cytometry, and *in vivo* optical imaging using a murine intraperitoneal disseminated ovarian cancer model. The cell lines were grown in RPMI 1640 medium (Gibco, Gaithersburg, MD) containing 10% fetal bovine serum (FBS) (Gibco), 0.03% L-glutamine at 37 °C, 100 units/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2.

Fluorescence Microscopy. SHIN3 cells (1×10^4) were plated on a cover glass bottom culture well and incubated for 16 h. Then, Av-Cy5.5, Av-Alexa680, or Av-SiR700 was added to the medium (3 μg/mL), and the cells were incubated for 4 h. Cells were washed three times with phosphate-buffered saline (PBS), RPMI 1640 medium was added back to all samples not imaged immediately, and fluorescence microscopy was performed immediately (T0), 24, 48, or 72 h later using an Olympus BX61 microscope (Olympus America Inc., Melville, NY) equipped with the following filters: excitation wavelength, 590 to 650 nm; emission wavelength, 665 to 740 nm. Transmitted light differential interference contrast (DIC) images were also acquired.

Flow Cytometry. Flow cytometry was performed to detect the *in vitro* stability of Av-Cy5.5, Av-Alexa680, and Av-SiR700 in SHIN3 cancer cells. SHIN3 cells (1×10^4) were plated on a 6 well culture plate and incubated for 16 h. Av-Cy5.5, Av-Alexa680, or Av-SiR700 was added to the medium (3 μg/mL), and the cells were incubated for 8 h. Next, the cells were washed three times with PBS, RPMI 1640 medium was replaced, and cells were trypsinized either immediately, 24, 48, or 72 h later. Then, flow cytometry was performed. A 635 nm red diode laser was used for excitation, and fluorescence signal from cells was collected using a 661/16 nm band-pass filter. Cells were analyzed in a FACScan cytometer (Becton Dickinson, Franklin Lakes, NJ), and all data were analyzed using CellQuest software (Becton Dickinson). *In vitro* biostability of each NIR-probe was measured as the rate of change in mean fluorescence intensity (MFI) over time from 0 to 72 h.

Animal Model of Peritoneal Metastases. All procedures were carried out in compliance with the Guide for the Care and Use of Laboratory Animal Resources (1996), National Research Council, and approved by the institutional Animal Care and Use Committee. The tumor xenografts were established by intraperitoneal injection of 4×10^6 SHIN3 cells suspended in 200 μL of PBS in female nude mice (National Cancer Institute Animal Production Facility, Frederick, MD). Experiments with tumor-bearing mice were performed at 14−17 days after injection of the cells.

dx.doi.org/10.1021/bc2003617 | *Bioconjugate Chem.* 2011, 22, 2531−2538

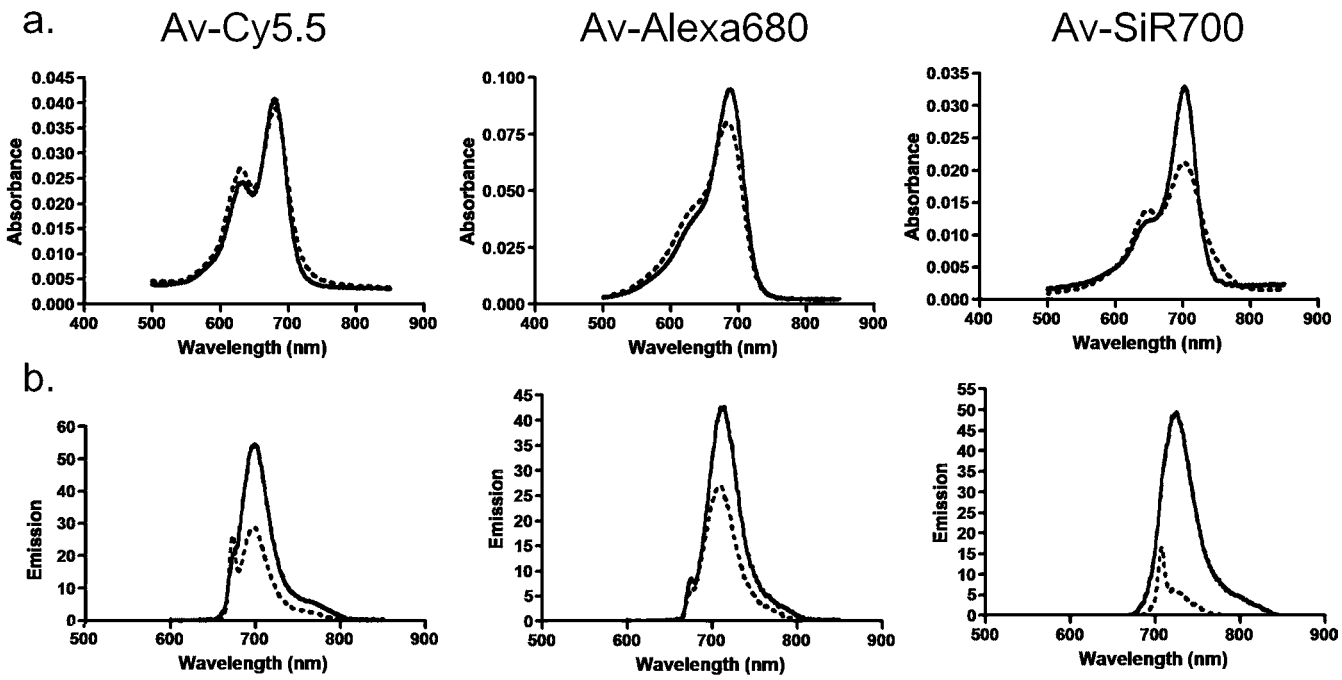

Figure 2. (a) Absorbance spectra of NIR imaging probes, consisting of a NIR fluorophore conjugated to avidin, without SDS (dashed line) and with SDS (solid line). The blue-shifted peak on the Av-Cy5.5 and Av-SiR700 curves without SDS represents H-dimer formation. Av-Alexa680 does not demonstrate H-dimer formation. Following SDS treatment, an increase in the Av-SiR700 monomer peak is characteristic of the dissociation of xanthene dimers forming excitons. (b) Emission spectra of NIR imaging probes without (dashed line) and with (solid line) SDS. Emission is increased following SDS treatment for all fluorophores; however, Av-SiR700 demonstrates the greatest increase in emission following SDS.

***In Vivo* Fluorescence Imaging.** Twenty-five micrograms each of Av-Cy5.5, Av-Alexa680, and Av-SiR700 was diluted in 300 μL of PBS and injected into the peritoneal cavities of tumor bearing mice. Then, 4, 24, or 72 h after intraperitoneal injection mice were euthanized with carbon dioxide inhalation. Immediately afterward, the abdominal cavities were exposed, and the 3 mice, each representing a different time point, were placed side by side on a nonfluorescent plate to compare fluorescence intensity for each NIR-probe over time. NIR fluorescence imaging was performed with the Pearl Imager (LI-COR Biosciences, Lincoln, NE). The instrument is a light-tight chamber equipped with a cooled charge-coupled device (CCD) camera. Illumination was provided by a 685 nm diode laser, and the peak emission band is at 720 nm. Images were acquired and processed using Pearl Cam Software v1.0 (LI-COR Biosciences).

Determination of TBRs for Each NIR Probe. NIR fluorescence images of the whole abdominal cavity were obtained as described above. The TBRs of each NIR probe were determined by placing a region of interest (ROI) over tumors labeled 4 h after injection of NIR probe and an ROI of equal size over surrounding normal abdominal tissue of the same animal. ROI total signal intensity for tumors was then compared with total signal intensity from the ROI of the surrounding tissue. Image processing was performed with Pearl Cam Software v1.0.

***Ex Vivo* Fluorescence Imaging For Quantitation.** Tumors were removed after *in vivo* imaging. Tumor explants were placed on a nonfluorescent plate, and NIR imaging was performed and processed.

Semi-Quantitative Analysis of *In Vivo* Stability of NIR-Probes. NIR fluorescence images of the tumor explants were obtained as described above. The *in vivo* stability of each NIR probe was compared using semiquantitative analysis. Briefly, ROIs were drawn around each tumor implant, and the average fluorescence intensity was used to quantify signal for each NIR probe at 4, 24, and 72 h after injection of the NIR probe. *In vivo* stability of each NIR probe over time was determined by comparing the percent decrease in the MFI relative to the MFI measured at the 4 h time point.

Statistical Analysis. Comparison of TBR between NIR probe and *in vivo* stability for each probe over time was done using one-way ANOVA with Tukey's multiple comparisons post-test. All statistical analysis was performed using GraphPad Prism, version 4.0c, for Macintosh (GraphPad Software, San Diego CA, www.graphpad.com).

RESULTS

Av-SiR700 Demonstrates H-Dimer Formation and Efficient Quenching *in Vitro*. The absorbance spectra of Av-Cy5.5, Av-Alexa680, and Av-SiR700 are displayed in Figure 2a. A blue-shifted absorbance peak representing H-dimer formation was observed for all three conjugates. The addition of SDS was used to dissociate the H-dimers. Following SDS addition, the absorption of Av-SiR700 demonstrated an increase in absorption of the monomer peak and a decrease in the blue-shifted H-dimer peak. Alternatively, Av-Cy5.5 and Av-Alexa680 demonstrated decreases in the H-dimer peak after the addition of SDS; however, there were small changes in the absorbance of the monomer peak. The amount of H-dimer formation was determined by the change in absorption of the H-dimer absorption peak relative to the monomer peak for all Av-Cy5.5, Av-Alexa680, and Av-SiR700 before and after the dissociation of H-dimers by the addition of SDS as described previously.[8] The H-dimer ratios for Av-Cy5.5, Av-Alexa680, and Av-SiR700 were 1.16, 1.29, and 2.13, respectively.

The amount of signal quenching from H-dimer formation can be appreciated by the amount of fluorescence activation

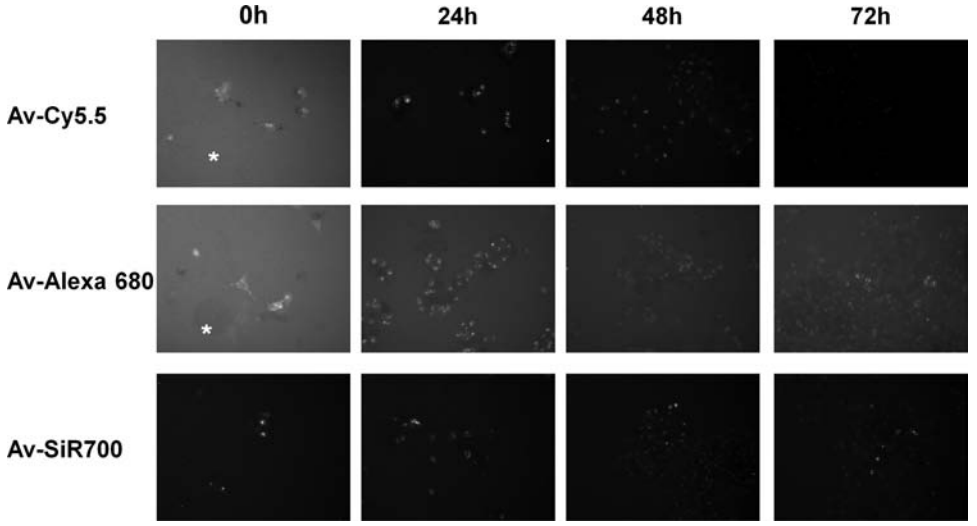

Figure 3. Serial fluorescence microscopy images of SHIN3 cells following incubation with NIR probes. SHIN3 cells were incubated with each NIR imaging probe for 4 h, and fluorescent microscopy was performed immediately (T0) and at 24, 48, and 72 h after thorough washing with PBS. At T0, SHIN3 cells could be identified after treatment with each probe, but Av-Cy5.5 and Av-Alexa680 demonstrated considerable background signal represented by fluorescence detected where there were no cells (asterisks). 24, 48, and 72 h demonstrate a gradual decrease in fluorescent signal for each NIR probe. Exposure time: Av-Cy5.5 and Av-SiR700 = 200 ms, and Av-Alexa680 = 500 ms.

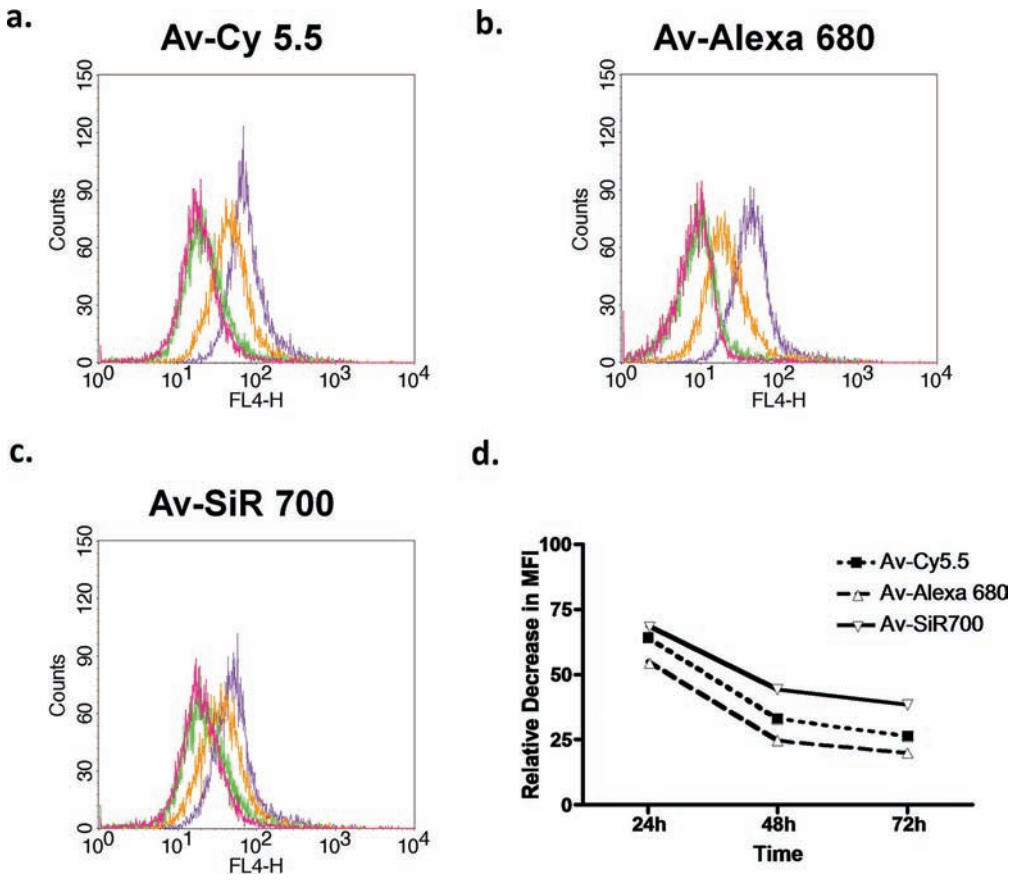

Figure 4. Flow cytometry analysis of SHIN3 cells immediately (purple), 24 h (orange), 48 h (green), and 72 h (magenta) after PBS wash and removal of (a) Av-Cy5.5, (b) Av-Alexa680, or (c) Av-SiR700, which demonstrates fluorescent signal degradation over time. Then, the amount of MFI degradation relative to T0 was compared (d). Av-SiR700 demonstrates less of a decrease in MFI from T0 than Av-Cy5.5 and Av-Alexa680 at all time points.

observed after the addition of SDS. Av-Cy5.5, Av-Alexa680, and Av-SiR700 all demonstrate an increase in fluorescence intensity after the addition of SDS (Figure 2b). The ratio of peak fluorescence intensity after SDS addition to peak fluorescence intensity before SDS addition for Av-Cy5.5, Av-Alexa680, and Av-SiR700 was 1.9, 1.58, and 8.35, respectively.

***In Vitro* Stability of NIR Probes.** *Fluorescence Microscopy.* After 4 h of incubation with 3 μg/mL of either Av-Cy5.5,

dx.doi.org/10.1021/bc2003617 | *Bioconjugate Chem.* 2011, 22, 2531–2538

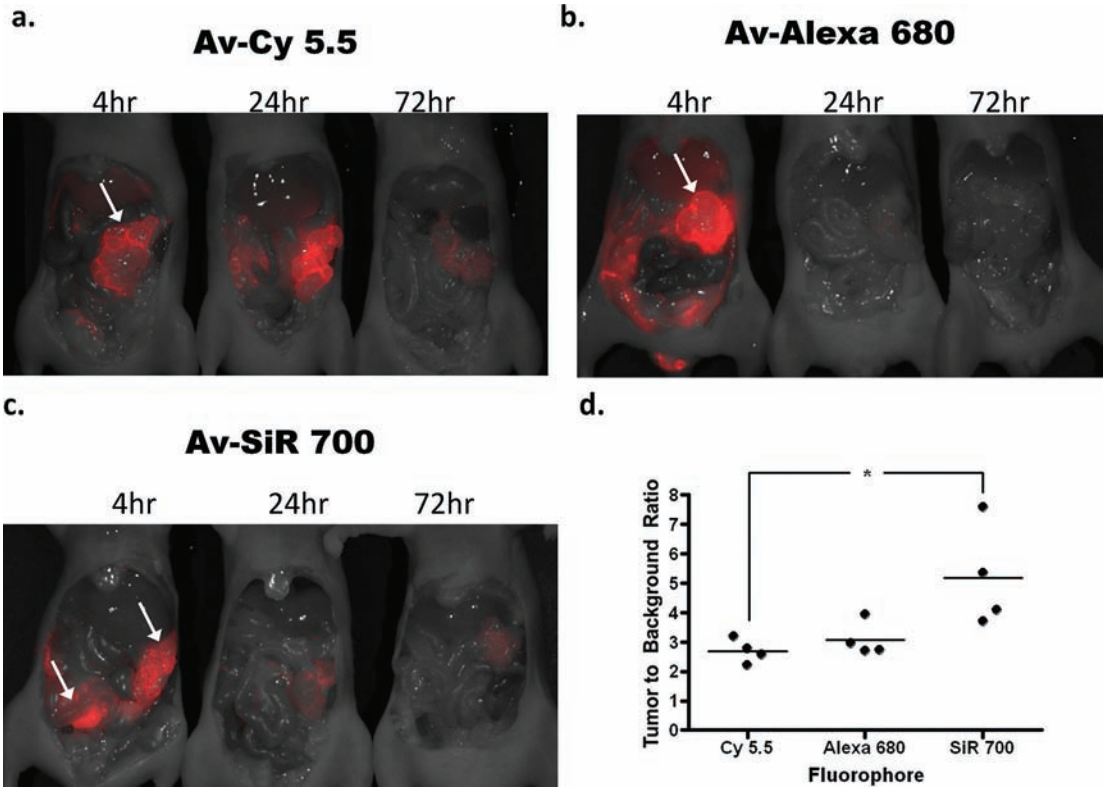

Figure 5. *In vivo* fluorescence images of tumor-bearing mice 4, 24, or 72 h after intraperitoneal injection of either (a) Av-Cy5.5, (b) Av-Alexa680, or (c) Av-SiR700. Images clearly identify SHIN3 tumors within the abdomen (arrows). Images clearly demonstrate the degradation of each NIR imaging probe over time. Interestingly, Av-Cy5.5 appears to demonstrate an increase in fluorescence intensity of the tumor from 4 to 24 h after Av-Cy5.5 injection. Whole body *in vivo* images were then used to calculate the TBR for each NIR imaging probe at 4 h after injection. ROIs were drawn around the tumors, and ROIs of the same size were drawn over the adjacent abdomen to determine the background signal. This is represented graphically (d), demonstrating that Av-SiR700 has a relatively higher TBR than Av-Alexa680 but that Av-SiR700 has a significantly greater TBR than Av-Cy5.5, ($p < 0.05$).

Av-Alexa680, or Av-SiR700, live cell imaging demonstrated intracellular uptake of each imaging probe documented by discrete intracellular punctuate signals representing probe uptake by lysosomes (Figure 3). At the initial time point (T0), images of SHIN3 cells using Av-Cy5.5 and Av-Alexa680 demonstrate high background signal due to nonspecific binding of Av-Cy5.5 and Av-Alexa680 to areas where there were no SHIN3 cells present (asterisks). Fluorescence microscopy of SHIN3 cells labeled with Av-SiR700 at T0 demonstrated specific labeling of SHIN3 cells with minimal nonspecific binding due to H-dimer formation and quenching. Serial imaging performed at 24, 48, and 72 h after washing with PBS demonstrated a progressive decrease in signal for all three NIR probes. However, Av-Cy5.5 and Av-SiR700 were brighter than Av-Alexa680 *in vitro*; therefore, live cell images were obtained at 200 ms for both Av-Cy5.5 and Av-SiR700, and images were obtained at 500 ms for Av-Alexa680.

Flow Cytometry. To evaluate the *in vitro* NIR imaging probe stability after target binding, we performed FACS on SHIN3 cells after 8 h of incubation with either Av-Cy5.5 or Av-Alexa680, or Av-SiR700. Then, we performed serial FACS analysis at 24, 48, and 72 h after the removal of each NIR imaging probe from the culture medium. The corresponding histograms are shown (Figure 4a–c). The MFI values for Av-Cy5.5, Av-Alexa680, and Av-SiR700 were used to determine the relative decrease in fluorescence signal (Figure 4d). Time course analysis was performed expressing MFI over time as a percentage of MFI at 0 h, and MFI values decreased for each NIR fluorophore by 35.8%, 44.9%, and 31%, respectively, at 24 h. At 48 h, the decrease in MFI from MFI at 0 h for Av-Cy5.5, Av-Alexa680, and Av-SiR700 was 67%, 75.3%, and 55.8%, respectively. After 72 h, the decrease in fluorescent intensity for each of the NIR probes from baseline was 73.7%, 80.1%, and 61.6%, respectively.

Assessment of NIR Probes *in Vivo*. To evaluate the *in vivo* characteristics of each NIR imaging probe, Av-Cy5.5, Av-Alexa680, or Av-SiR700 were injected into the peritoneal cavities of mice with disseminated peritoneal SHIN3 ovarian cancer implants, and side by side *in vivo* fluorescent images of the entire exposed abdomen were obtained at 4, 24, or 72 h after NIR imaging probe injection (Figure 5a–c). TBRs were determined by drawing an ROI over tumors and drawing an ROI of equal size over a nontumor-bearing area adjacent to the tumor within the abdominal cavity. The TBR for each NIR imaging probe is graphically represented (Figure 5d). The average TBRs of tumors targeted with Av-Cy5.5, Av-Alexa680, and Av-SiR700 at 4 h after the administration of each imaging probe was 2.7, 3.1, and 5.2, respectively. Av-SiR700 demonstrated the highest relative TBR of the NIR imaging probes we tested, but the TBR calculated for Av-SiR700 was only statistically significantly different compared to that of Av-Cy5.5 ($p < 0.05$).

To evaluate the *in vivo* stability of each NIR imaging probe, we removed tumors labeled with each NIR imaging probe and placed them on a nonfluorescent plate. Tumor explants for each NIR imaging probe were imaged side by side to compare

dx.doi.org/10.1021/bc2003617 | *Bioconjugate Chem.* 2011, 22, 2531–2538

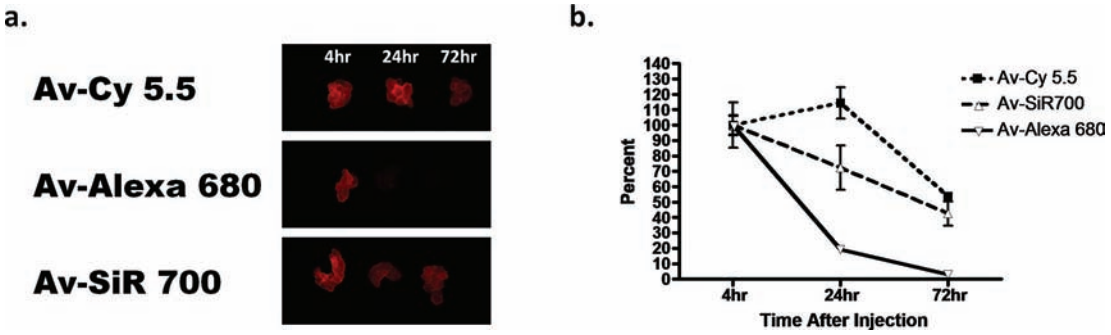

Figure 6. (a) Tumor explants following 4, 24, or 72 h after intraperitoneal injection of Av- Cy5.5, Av-Alexa680, or Av-SiR700 were used to semiquantitatively compare fluorescence intensity of each NIR imaging probe. ROIs were drawn around each tumor, and average fluorescence intensity was calculated. Then, values were calculated and graphed relative to the 4 h time point. The graph demonstrating the decrease in signal for each NIR imaging probe over time is shown (b). Av-Alexa680 demonstrates rapid decrease in fluorescence intensity with a significantly greater decrease in fluorescence intensity at 72 h than Av-Cy5.5 and Av-SiR700 with p values <0.001 and <0.01, respectively. Av-Cy5.5 demonstrates a relative increase in fluorescent intensity from 4 to 24 h but then shows a rapid decrease in fluorescence intensity. There was no significant difference in decrease in fluorescence intensity over time between Av-Cy5.5 and Av-SiR700.

Table 1. Calculated Extinction Coefficient Values of the Monomer and Dimer of Cy5.5, Alexa680, and SiR700 Conjugated with Avidin

reagents	Av-Cy5.5		Av-Alexa680		Av-SiR700	
forms	monomer	dimer	monomer	dimer	monomer	dimer
peak EC at long wavelength (nm)	250000/680	200000/680	180000/687	86000/687	100000/702	52000/702
peak EC at short wavelength (nm)	150000/629	210000/629	71000/631	110000/631	36000/647	47000/647
						(EC: cm/M)

the tumor signal at 4, 24, or 72 h after probe injection (Figure 6a). Then, an ROI was drawn around each tumor explant, and the average signal intensity was calculated and used to determine the decrease in signal over time for each NIR imaging probe. The time course showing the decrease of average intensity for each NIR imaging probe expressed as a percentage of fluorescence relative to the 4 h time point is illustrated in (Figure 6b). Change in average intensity relative to the 4 h time point at 24 h for Av-Cy5.5, Av-Alexa680, and Av-SiR700 was 114.5%, 19.3%, and 72.4%, respectively. At the 72 h time point, the decrease in average intensity for each NIR imaging probe as a percentage of the 4 h time point was 53.8%, 2.8%, and 42.6%, respectively. Av-Cy5.5 demonstrated less relative decrease in fluorescence when compared to those of Av-Alexa680 and Av-SiR700; however, the difference observed for Av-Cy5.5 was not statistically significant relative to that of Av-SiR700. Interestingly, *in vivo* average fluorescence of tumors labeled with Av-Cy5.5 demonstrated a relative increase in fluorescence between 4 and 24 h after injection. Av-Alexa680 demonstrated the lowest *in vivo* stability (compared with Av-Cy5.5 $p < 0.001$ and Av-SiR700 $p < 0.01$) at 72 h.

DISCUSSION

There are several key issues in optical probe design. The required tissue penetration of light needed for a specific clinical application is dependent on the wavelength of emitted light; NIR allows more depth of penetration than does visible light and results in lower autofluorescence. Another design parameter is the length of time that the fluorescence is required for an application, which is dependent on the biostability of the conjugate. Finally, the desired sensitivity of the agent is dependent on the TBR which can be improved by either increasing the binding affinity to the target or decreasing the background signal or both.[9−11] Advances in chemistry have led to the development of activateable optical imaging probes that have higher TBR when compared to "always on" fluorophores.[12−14] Several different mechanisms currently exist for the development of activateable optical imaging probes.

For instance, at high concentrations, xanthene derived fluorophores such as rhodamines form H-type and J-type homodimers that efficiently quench fluorescence.[15−17] H-type homodimers can also form at much lower concentrations after the fluorophore is covalently conjugated to proteins.[3] This homodimer formation induces short (H-dimer) or long (J-dimer) shifts of the fluorophore's absorbance spectra. The presence of a blue-shifted absorption peak in addition to the expected monomer absorption peak is indicative of H-dimer formation as shown in the Table 1. H-dimer absorption shifts may occur by several processes. Xanthene derived fluorophores are unique in that two identical molecules may come together to form H-homodimers with very short distances between the fluorophores. In this circumstance, the H-dimers may behave as a single quantum system that can delocalize excitation energy resulting in almost complete loss of fluorescence emission through excitation formation.[15] Once the conjugates are released from each other by changes in pH or by enzymatic processes, the fluorophores will again fluoresce. Another process by which fluorescence quenching may occur is when two fluorophores interact with each other such that they donate or accept partially excited photons from each other leading to the incoherent transfer of energy and resulting in fluorescence quenching.[16] This interaction, known as Forster resonance energy transfer (FRET), occurs at slightly larger distances up to 10 nm than H-dimer formation within 1 nm[15,16] and results in less effective quenching. Previously, activateable NIR optical imaging probes were based on cyanine core fluorophores.[18] Activateable NIR imaging probes using cyanine cores mostly

dx.doi.org/10.1021/bc2003617 | *Bioconjugate Chem.* 2011, 22, 2531−2538

utilized FRET as a means to quench fluorescence. However, with the development of SiR fluorophores, which have xanthene-based rhodamine cores, H-dimer formation readily occurs. SiR fluorophores are able to form H-dimers, as well as undergo FRET, and can be designed to utilize the photo-induced electron transfer (PeT) effect to create activatable probes.

One method of distinguishing quenching due to H-dimer formation from FRET quenching is by chemically dissociating the H-dimers and looking for a change in the absorbance characteristics.[17] The dissociation of quenched H-dimers results in a decrease in the H-dimer absorption peak and a subsequent increase in absorption of the monomer peak. However, molecules that are quenched primarily due to FRET demonstrate a minimal decrease in absorbance at the H-dimer peak; but they generally do not strongly influence the absorbance at the monomer peak. Thus, the absorbance of the monomer peak remains relatively unchanged even after dequenching, although the fluorescence signal can be activated regardless of either quenching mechanism.

In this study, SDS was used with the three agents, Av-SiR700, Av-Cy5.5, and Av-Alexa680, to detect changes in the absorbance characteristics of each imaging probe. Av-Cy5.5 initially demonstrated a blue-shifted peak in absorbance as well as the typical peak representing the monomer. However, upon addition of SDS, there was a slight increase in absorbance of the monomer peak that showed that only 32% of Cy5.5 molecules formed the H-type dimer. From this, it can be concluded that Av-Cy5.5 fluorescence quenching is mostly caused by FRET rather than the more effective H-dimer quenching. In contrast, upon addition of SDS to Av-SiR700, the decrease in the blue-shifted peak is accompanied by an increase in absorbance at the monomer peak suggesting that 80% of SiR700 molecules formed the H-type dimer resulted in the quenching of the SiR700, which is due to the formation of H-dimers, which effectively quenched fluorescence emission up to 88%.

It must be noted that different activation and quenching strategies may act independently of one another allowing the combination of multiple quenching methods. This was recently demonstrated by using H-dimer formation in combination with a pH dependent PeT quenching in the design of an activateable optical probe. This led to an optical imaging probe that demonstrated higher TBR for tumor nodules during endoscopy than an activateable probe that utilized H-dimer formation alone.[8]

Av-SiR700 demonstrated specific visualization of SHIN3 cells without nonspecific binding. However, both Av-Cy5.5 and Av-Alexa680 had nonspecific background signals observeable by fluorescence microscopy. FACS time course analysis was used to determine if Av-SiR700 was stable after endocytosis by target cells. At all time points analyzed, Av-SiR700 demonstrated less fluorophore degradation than Av-Cy5.5 and Av-Alexa680. Av-Alexa680 demonstrated the most rapid degradation of fluorescence emission of the three fluorophores tested.

The *in vivo* characteristics of Av-SiR700 were assessed by determining TBR and *in vivo* biostability by measuring degradation of fluorescence intensity over time. TBR analysis showed that Av-SiR700 demonstrated higher TBRs than either Av-Cy5.5 or Av-Alexa680. *In vivo* biostability of the fluorescence signal was determined by measuring the fluorescence intensity and graphing it as a ratio of fluorescence intensity at baseline. At 24 and 72 h after probe injection, Av-Cy5.5 had less deterioration of the fluorescence signal than either Av-Alexa680 or Av-SiR700. Av-Alexa680 had the most rapid *in vivo* degradation of fluorescence intensity. Interestingly, the tumor labeled with Av-Cy5.5 demonstrated higher fluorescence intensity at the 24 h time point than the 4 h time point. This may be explained by the nonspecific sequestration of Av-Cy5.5 in nontarget tissues with subsequent release of the imaging probe back into the circulation enabling Av-Cy5.5 continued access to the target tissue as reported with antibody-Cy5.5 conjugates in the previous study.[19] This nonspecific sequestration of Av-Cy5.5 in nontarget tissue may also be due to factors such as the probe's lipophilicity, charge, or pharmacokinetic profile.

Thus, the SiR700 demonstrates several desirable features. It is a NIR fluorophore, which utilizes a rhodamine core instead of the more typical cyanine core. Because SiR700 appears to use both H-dimer and FRET mechanisms for quenching, a more dramatic TBR could be achieved than with cyanine core fluorophores, Cy5.5, or Alexa680. Moreover, SiR700 demonstrates excellent biostability *in vivo*. Av-SiR700 was also found to have less nonspecific binding to the tissue than Av-Cy5.5, and Av-SiR700 demonstrated superior *in vivo* fluorescence stability when compared to that of Av-Alexa680. These findings suggest that SiR700, a member of a new class of NIR probes, exhibits desirable properties that could be useful for *in vivo* optical imaging.

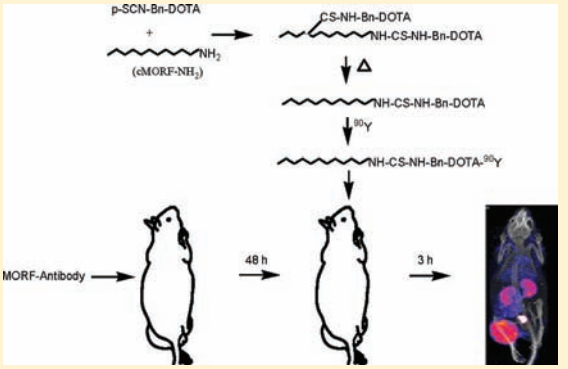
^{90}Y labeled Phosphorodiamidate Morpholino Oligomer for Pretargeting Radiotherapy

Guozheng Liu,* Shuping Dou, Yuxia Liu, Yuzhen Wang, Mary Rusckowski, and Donald J. Hnatowich

Department of Radiology, University of Massachusetts Medical School, Worcester, Massachusetts 01655, United States

ABSTRACT: While ^{188}Re has been used successfully in mice for tumor radiotherapy by MORF/cMORF pretargeting, previous radiolabeling of the amine-derivatized cMORF with ^{90}Y, a longer physical half-life nuclide, was not very successful. After developing a method involving a prepurification heating step during conjugation that increases labeling efficiency and label stability, the biodistribution of ^{90}Y-DOTA-Bn-SCN-cMORF (^{90}Y-DOTA-cMORF) was measured in normal mice and in MORF-CC49 pretargeted mice that bear LS174T tumors. Absorbed radiation doses were then estimated and compared to those estimated for ^{188}Re. The pharmacokinetics of the ^{90}Y-DOTA-cMORF in normal mice and in the pretargeted nude mice was similar to that observed previously with ^{99m}Tc- and ^{188}Re-MAG$_3$-cMORFs. While the ^{90}Y-DOTA-cMORF cleared rapidly from normal tissues, tumor clearance was very slow and tumor radioactivity accumulation was constant for at least 7 days such that the tumor/blood (T/B) ratio increased linearly from 6 to 25 over this period. Therefore, by extrapolation, normal tissue toxicities following administration of therapeutic doses of ^{90}Y may be comparable to that observed for ^{188}Re in which the T/B increased from 5 to 20. In conclusion, radiolabeling of DOTA-cMORF with ^{90}Y was improved by introducing a prepurification heating step during conjugation. The ^{90}Y-DOTA-cMORF provided a similar T/B ratio and biodistribution to that of ^{188}Re-MAG$_3$-cMORF and was retained well in the tumor pretargeted with MORF-CC49. Because of the longer physical half-life, the T/NT absorbed radiation dose ratios were improved in most organs and especially in blood.



INTRODUCTION

Pretargeting using a pair of morpholino oligomers (MORF/cMORF) has been shown to be effective in preclinical studies.[1,2] A major advantage of the MORF/cMORF pretargeting approach is the ease with which the cMORF effector can be chemically modified, for example, to change chelators or linkers for different radionuclides, without affecting the cMORF/MORF affinity critical to the pretargeting approach. Thus far, this effector has been radiolabeled with ^{99m}Tc and ^{111}In for imaging and ^{188}Re for radiotherapy.[2−4] We now report on the radiolabeling of the cMORF with ^{90}Y, the biodistribution of ^{90}Y-cMORF, and the estimated absorbed radiation dose improvements using ^{90}Y-cMORF/MORF pretargeting compared to ^{188}Re-cMORF/MORF pretargeting. Although ^{90}Y and ^{188}Re have similar average beta energies (0.935 vs 0.716 MeV, respectively), under identical conditions (i.e., tumor retention and clearance from normal tissues) the longer physical half-life of ^{90}Y (64 h) compared to ^{188}Re (17 h) will provide higher tumor to organ absorbed radiation dose ratios because a larger portion of the ^{90}Y in circulation will be cleared without depositing its energy in the normal tissues.

Previous ^{90}Y labeling using *para*-isothiocyanate benzyl DOTA (i.e., p-SCN-Bn-DOTA) as a chelator was judged to be not very successful due to low labeling efficiencies.[5] A possible explanation for these marginal results may have been identified in a subsequent ^{111}In labeling of cMORF using p-SCN-Bn-DTPA as a chelator, in which heat-sensitive side conjugation products were observed.[6] Because introduction of a heating step after conjugation reaction and before purification, after subsequent labeling, was found to greatly improve label stability in that study, a similar approach was applied in this investigation using p-SCN-Bn-DOTA.

After successful ^{90}Y labeling, the biodistribution of cMORF was measured and the absorbed radiation doses to normal organs and tumor pretargeted with MORF-CC49 were estimated and compared with those previously reported for ^{188}Re-cMORF in the identical tumor model.[3,4] The dosages and timing determined to be optimal with ^{99m}Tc-cMORF[7] and used previously with ^{188}Re-cMORF[4] were again used in this study, because the antibody is the same and the blood clearance among ^{99m}Tc, ^{188}Re, and ^{90}Y labeled cMORFs was found to be similar. For the same reason and as explained below, the relationship between tumor accumulation of ^{90}Y-cMORF and tumor size was assumed and also confirmed to be the same as that for ^{188}Re-cMORF and ^{99m}Tc-cMORF.

MATERIALS AND METHODS

The MORF (5′-TCTTCTACTTCACAACTA) and cMORF (5′-TAGTTGTGAAGTAGAAGA) were obtained from Gene-Tools

(Philomath, OR) with a primary amine attached to the 3′ equivalent terminal via a 3-carbon linker. The p-SCN-Bn-DTPA or -DOTA was from Macrocyclics (Dallas, TX). The P4 resin (Bio-Gel P-4 Gel, medium) was from Bio-Rad Laboratories (Hercules, CA). The $^{111}InCl_3$ and $^{90}YCl_3$ were from Perkin-Elmer Life Science Inc. (Boston, MA). The CC49 antibody that was produced from the CC49 hybridoma by Strategic Biosolutions (Ramona, CA) was conjugated with MORF as previously described.[7,8] All other chemicals were reagent grade and were used without purification.

The cMORF, MORF, and antibody concentrations were determined by UV spectrophotometry. All the cMORF preparations were analyzed by size exclusion HPLC. The HPLC system was equipped with a Superdex 75 HR10/30 column (optimal separation range: 3-70 kDa; Amersham Pharmacia Biotech, Piscataway, NJ) and with both UV and radioactivity in-line detectors. The eluant was 0.10 M pH 7.2 phosphate buffer at a flow rate of 0.60 mL/min. Radioactivity recovery was routinely measured and was always greater than 90%.

^{90}Y Measurements. Because ^{90}Y is a pure β emitter, accurate quantitation of radioactivity in organs can be difficult under certain circumstances.[9] In this investigation, we confirmed that radioactivity of liquid ^{90}Y samples may be accurately measured in a NaI(Tl) well detector by using standards,[9−11] provided that the volume was the same, the samples were in the same type of counting tube, and especially the radioactivity was homogeneously distributed. As such, tissue samples were digested in SOLVABLE solution (PerkinElmer, Waltham, MA) in 5 mL polystyrene tubes and the volume was adjusted to 2.5 mL before counting. The ^{90}Y radioactivity value provided by the manufacturer was considered to be accurate and was used to calibrate the NaI(Tl) well counter.

DOTA Conjugation and ^{90}Y Labeling of cMORF. In a previous study,[6] after conjugation with p-SCN-Bn-DTPA, the cMORF was radiolabeled efficiently with ^{111}In, but the radiolabel was shown to be unstable to heating. Suspecting that the conjugation procedure had produced both stable and unstable conjugates, heating the reaction mixture before purification in the conjugation process yielded a product that provided both a high radiolabeling efficiency and a stable ^{111}In label. The same approach was applied in this investigation to the conjugation of cMORF with p-SCN-Bn-DOTA. Thus, 2.5 mg of p-SCN-Bn-DOTA was dissolved in 0.25 mL of a 0.5 M Na_2CO_3−$NaHCO_3$ buffer at pH 9.8 and mixed with 2.3 mg of lyophilized 3′-amine-derivatized cMORF. After an overnight incubation at room temperature, 1 mL of 0.25 M NH_4OAc buffer at pH 5.2 was added and the conjugation solution was heated at 100 °C for about 3 h before loading onto a 1 × 50 cm open P4 column. The column was eluted with the 0.25 M NH_4OAc buffer and three peak fractions of about 0.6 mL were pooled. The radiolabeling was achieved by adding 1−3 μL of $^{90}YCl_3$ solution in 50 mM HCl to 10−30 μL of the purified DOTA-cMORF solution followed by heating at 100 °C for 10 min. All animal studies were performed with ^{90}Y-DOTA-Bn-SCN-cMORF prepared in this fashion (^{90}Y-cMORF).

In Vitro Stability of ^{90}Y-cMORF. The ^{90}Y-cMORF was tested for radiolabel stability in phosphate buffer, in saline, and in fresh mouse serum. Specifically, 60 μL of the ^{90}Y-cMORF solution was added to 250 μL of each medium before incubation either at room temperature (phosphate buffer and saline) or 37 °C (mouse serum). An aliquot was removed for HPLC analysis at different times over 48 h. In addition, the ^{90}Y-cMORF was radiolabeled at different specific activities up to 3.5 mCi/37 μg of cMORF in the final volume of 80 μL. The radiolabel stability was examined after 20 h at room temperature by HPLC for evidence of radiolysis.

Pharmacokinetics of ^{90}Y-cMORF. Optimization of a pretargeting protocol requires information on pharmacokinetics.[7,12−15] Accordingly, the in vivo behavior of the ^{90}Y labeled cMORF was again measured. Normal CD-1 mice (Charles River Laboratories, MA) in 5 groups (N = 4) each received 1 μg (45 μCi) of ^{90}Y-cMORF by a tail vein injection and were euthanized at 10 min, 0.5 h, 1 h, 3 h, or 6 h. Organs were harvested, digested, and counted as described above. The %ID and %ID/g were calculated against a standard of the injectate. All animal studies were performed with the approval of the UMMS Institutional Animal Care and Use Committee.

Subsequently, the dosage and timing parameters for pretargeting were selected following the guide lines described previously.[15] Any convenient dosage of the pretargeting antibody may be selected that does not saturate the accessible tumor antigens, and any pretargeting interval may be used that provides an acceptable antibody tumor/normal tissue ratio. Because the antibody and the mouse tumor model were the same, the antibody dosage and the pretargeting interval used in this study were identical to those previously used for ^{99m}Tc-cMORF and ^{188}Re-cMORF.[4,7] The optimal dosage of the cMORF effector is related to antibody dosage, pretargeting interval, and its own blood clearance curve. Because the blood clearance of ^{90}Y-cMORF was shown to be sufficiently similar to those of ^{99m}Tc-cMORF and ^{188}Re-cMORF, the optimal cMORF dosage determined previously was used again.

Twenty NIH Swiss Nude mice (Taconic Farms, Germantown, NY) each received 10^6 LS174T colon cancer cells in the left thigh. After 11 days, when the tumors were about 0.3 g, each mouse received via a tail vein 30 μg MORF-CC49 (MORFs per antibody = 0.68) and 48 h later 2.5 μg of ^{90}Y-MORF (50 μCi). Thus, the cMORF/MORF molar ratio was close to the optimal 3.1.[4,7] The biodistribution of the ^{90}Y-cMORF was followed for 7 days. The target thigh containing the tumor and the contralateral thigh were excised at the same anatomical position. The skin on both thighs was removed, and the tumor weight was calculated by subtracting the weight of the normal thigh from that of the tumored thigh. After the bone and as much of the muscle tissues as possible were removed, the tumor was cut into pieces of 0.3−0.4 g, digested, and the radioactivity was measured in a NaI(Tl) well counter along with other organs as described above. Because the dosages and timing in this study are assumed to be optimal based on the above discussion, the tumor accumulations of the effector may therefore be assumed to be at their MPTAs (Maximum Percent Tumor Accumulations, defined as the percent tumor accumulation under the condition when the MORFs in tumor are just saturated by the cMORF).[14,15]

Absorbed Radiation Dose Estimates. The estimated absorbed radiation doses to normal organs and to tumor by pretargeting with ^{90}Y-cMORF were compared with those by pretargeting with ^{188}Re-cMORF. The AUCs (Area Under the radioactivity−time Curve, also known as cumulated radioactivity concentration) were calculated from the best fits to the %ID/g data with decay corrections, to estimate the absorbed radiation doses for the normal organs of interest. Using the self-absorbed model [16,17] as in our previous ^{188}Re studies,[3,4] the absorbed radiation dose in Rads was calculated by the expression 2.143 × 0.935 (MeV) × AUC (μCi h/g), where 2.143 is a unit conversion factor and 0.935 MeV is the average energy of the ^{90}Y β particles.

Estimating the absorbed radiation dose to tumor is more complicated, since tumor accumulation is strongly related to tumor size[18−20] and the tumor size is an unpredictable variable among these studies. Therefore, a comparison of tumor dose for different effectors requires normalizing the tumor accumulation to a certain tumor size using its accumulation vs size relationship under optimal dosage and timing (i.e., at the MPTA). The relationship between ^{99m}Tc-cMORF accumulation and tumor size was previously measured accurately for a substantial number of animals over a range of tumor sizes.[18] Because the in vivo behavior of cMORF was found to be sufficiently independent of the radiolabels of ^{99m}Tc, ^{188}Re, and ^{90}Y, the MPTA-tumor size relationship for ^{99m}Tc-cMORF was assumed to be the same for ^{188}Re-cMORF and ^{90}Y-cMORF. This assumption was confirmed by comparing the predicted and observed tumor accumulations (see below). In the absorbed radiation dose comparison between ^{90}Y-cMORF and ^{188}Re-cMORF, a tumor size of 0.5 g was selected, since most tumors in this and our previous studies fall roughly in the range 0.25−1.0 g.

RESULTS

DOTA Conjugation and ^{90}Y Labeling of cMORF. Similar to the conjugation with p-SCN-Bn-DTPA,[6] conjugation of cMORF with p-SCN-Bn-DOTA without prepurification heating yields a conjugate that provides a high ^{111}In labeling efficiency (Figure 1A, a) but with label instability leading to partial decomposition after heating at 100 °C for 1 h (Figure 1A, b). The equivalent results with ^{90}Y are essentially identical (Figure 1A, c and d). However, if introducing a heating step after conjugation but before purification, the conjugation product can be radiolabeled with either ^{111}In or ^{90}Y at high efficiency and the label becomes stable against heating (Figure 1A, e and g, respectively). The hybridization ability of the cMORF after conjugation and radiolabeling with either ^{111}In or ^{90}Y is preserved, as shown by the shift to higher molecular weight of the labeled cMORF peaks upon the addition of its MORF complement (Figure 1A, f and h, respectively).

In Vitro Stability of ^{90}Y-cMORF. As shown in Figure 1B, b and c, after introducing the heating step into the conjugation procedure, the ^{90}Y radiolabel on cMORF is also stable in phosphate buffer, saline, and serum at least for 48 h (the small peak at 21 min in c is due to self-association of cMORF at room temperature). Figure 1 B, d−f, presents the radiochromatograms of ^{90}Y-cMORF after 20 h of incubation at room temperature in the 80 μL labeling solution at values of specific radioactivity of 63, 1430, and 3440 μCi/37 μg. The increasing decomposition products are most probably the result of radiolysis. To avoid complications due to radiolysis, samples of ^{90}Y-cMORF were used immediately after preparation.

Pharmacokinetics of ^{90}Y-cMORF. Table 1 presents the biodistributions at various times of ^{90}Y-cMORF (prepared by the modified conjugation that includes the prepurification heating) in normal mice and in tumored mice pretargeted with MORF-CC49. As shown by the data in normal mice, the

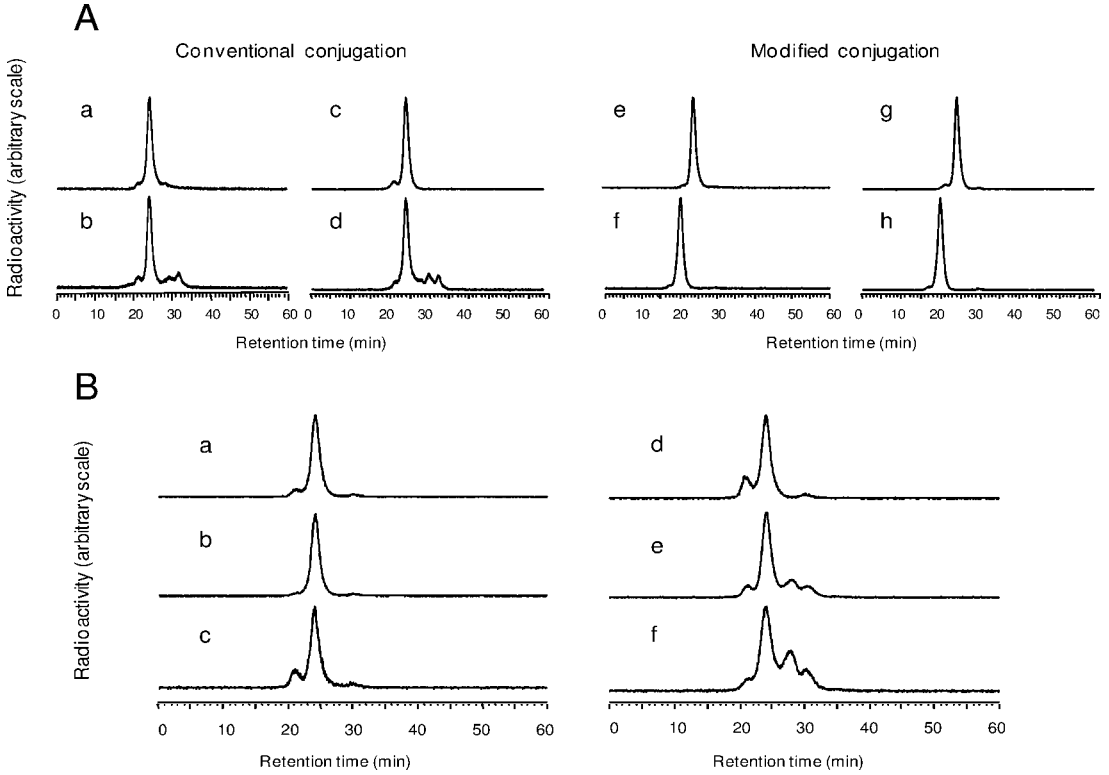

Figure 1. (A) HPLC radiochromatograms of ^{111}In and ^{90}Y labeled cMORFs after conjugating with p-SCN-Bn-DOTA without heating (i.e., conventional) and radiolabeling with mild heating (a and c, respectively) or heating at 100 °C for 1 h (b and d, respectively). Also presnted are the ^{111}In and ^{90}Y HPLC radiochromatograms of cMORF after conjugating with p-SCN-Bn-DOTA but after inclusion of the prepurification heating step during conjugation (i.e., modified) (e and g, respectively) as evidence of increased stability, and the corresponding radiochromatograms after addition of excess MORF (f and h, respectively) as evidence of preserved hybridization affinity. (B) HPLC radiochromatograms of ^{90}Y-cMORF (a) immediately before and (b) 48 h after incubation in serum at 37 °C and (c) 48 h after incubation in phosphate buffer at room temperature. Also presented are HPLC radiochromatgrams of ^{90}Y-cMORF after 20 h of incubation at room temperature in the 80 μL of labeling solution at specific radioactivities of 63, 1430, and 3440 μCi/37 μg cMORF (d−f), showing decomposition most probably due to radiolysis.

[a]Mean ± SD.

^{90}Y-cMORF clears rapidly, similar to the ^{99m}Tc-cMORF and ^{188}Re-cMORF.[21,22] The blood and normal organ clearance is essentially completed by 3 h, although with slightly higher normal tissue levels.

Because of the longer half-life of ^{90}Y compared to ^{188}Re, tumor retention and normal organ clearance could be followed for longer periods. As shown in Table 1, the tumor accumulation in %ID is fairly constant with time, while the tumor accumulation in %ID/g is decreasing due to tumor growth. As for normal organs, except in kidney, the background radioactivity is much lower than that in tumor and clears rapidly, similar to our earlier results with ^{188}Re-cMORF.[3,4] Figure 2a–h reproduces the normal organ ^{90}Y levels from 3 h to 7 days from the table. The solid lines represent the best fits for the ^{90}Y-cMORF and the dotted lines represent those to the values for ^{188}Re-cMORF in our earlier study.[4]

The tumor accumulation vs size relationship for ^{99m}Tc-cMORF determined earlier in the identical animal model[18] was MPTA (%ID/g) = 4.51 × tumor weight (g)$^{-0.66}$. This relationship was assumed to hold true also for ^{90}Y-cMORF and ^{188}Re-cMORF, because the MPTA is proportional to the area under the blood clearance curve[13−15] and, as Table 2 presents, the blood clearance of the three effectors are sufficiently similar. This assumption is supported by the results presented in Table 1. From the table, the average tumor size at 3 h was 0.46 ± 0.30 g and, based on the above relationship, the MPTA for ^{90}Y-cMORF is calculated to be 7.53 %ID/g, therefore in close agreement with the measured 7.15 ± 2.19 %ID/g in Table 1. Previously, in the case of ^{188}Re-cMORF, the tumor accumulation was 8.66 ± 1.18 %ID/g for a tumor size of 0.36 g,[3] also in close agreement with the predicted value of 8.76 %ID/g. These agreements provide confidence in the following calculations of absorbed radiation doses in tumor using normalized tumor accumulation.

Absorbed Radiation Dose Estimate. The AUCs for organs were calculated from the best fits to the biodistribution data with decay correction. The AUC for tumor was based on a predicted tumor accumulation of 7.13 %ID/g for a 0.5 g LS174T tumor obtained from on the MPTA-tumor size relationship, assuming no tumor growth during the study. Both AUCs and the calculated absorbed radiation doses are listed in Table 3. Because of the higher accumulation and longer retention, the absorbed radiation dose to tumor by ^{90}Y pretargeting is at least 5-fold higher than those for other organs. The tumor dose would be even higher in a cohort of animals with smaller tumors than 0.5 g. For comparison, historical data for ^{188}Re pretargeting are also listed but again with the AUC and absorbed radiation dose for tumor size normalized to 0.5 g and calculated assuming no growth during therapy.

Figure 3 presents the T/NT AUC ratios (i.e., the absorbed radiation dose ratios or the therapeutic indexes[23]) for ^{90}Y pretargeting and two previous ^{188}Re pretargeting studies in the same mouse model.[3,4] Although the normal tissue backgrounds are slightly higher for ^{90}Y (Figure 2), the T/NT AUC ratios are not lower but higher due to its longer half-life.

DISCUSSION

Yttrium-90 is an attractive therapeutic radionuclide that has seen use in animal and patient studies while conjugated to antitumor antibodies. Of particular interest, ^{90}Y has been the radionuclide of choice in several pretargeting studies using avidin/biotin or the bispecific antibody/hapten recognition systems.[17,24−38] In the development of tumor radiotherapy approaches by MORF/cMORF pretargeting, we have previously employed ^{188}Re as the therapeutic radionuclide.[3,4] We now consider ^{90}Y as an alternative of longer physical half-life that can potentially improve radiotherapy effectiveness. Accordingly, in this investigation a method was developed to label this nuclide to the cMORF effector and to evaluate the

properties of the ^{90}Y-cMORF in LS174T tumored NIH Swiss nude mice pretargeted with the MORF-CC49 antibody.

Although the radiolabeling of cMORF with ^{90}Y via p-SCN-Bn-DOTA was expected to present few difficulties, we observed instabilities of the ^{90}Y-cMORF, reminiscent of that observed previously when radiolabeling cMORF with ^{111}In via p-SCN-Bn-DTPA.[6] A search of the literature provided no mention of similar instabilities when these bifunctional chelators were used to label antibodies. In our earlier study of ^{111}In-cMORF, we were able to resolve the label instability by including a pre-purification heating step after conjugation. The same approach was applied in this investigation in connection with ^{90}Y-cMORF labeling and shown to be successful.

Changes in the effector or pretargeting antibody require the dosage and timing of the pretargeting protocol to be optimized. However, as we have now demonstrated, the pharmacokinetic and pretargeting behavior of cMORF is generally not influenced by the nature of the chelators and radiolabels at least among ^{99m}Tc-MAG$_3$-cMORF, ^{188}Re-MAG$_3$-cMORF, and ^{90}Y-DOTA-Bn-SCN-cMORF. Accordingly, optimization of the dosage and timing parameters for ^{90}Y pretargeting became unnecessary since the values for ^{99m}Tc had been previously determined[7] and can be used again with confidence. For the same reason, the tumor accumulation–size relationship useful for comparing potential therapeutic effects was assumed and confirmed to be the same as that for ^{99m}Tc established previously.

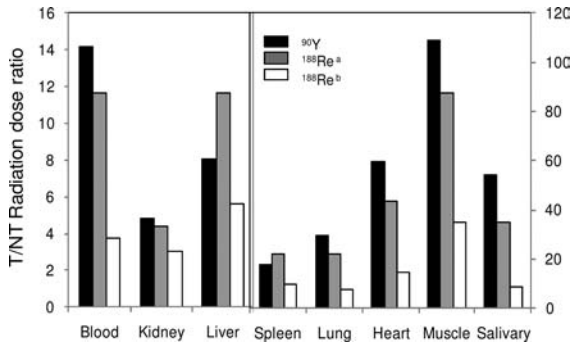

Figure 3. Histograms presenting the T/NT dose ratios (i.e., the tumor therapeutic indexes) for ^{90}Y and two previous ^{188}Re pretargeting studies in the same mouse model. (a) ref 4; (b) ref 3.

With the tracer level pretargeting data, potential therapeutic improvement of ^{90}Y as an alternative to ^{188}Re was evaluated. This evaluation was facilitated by using identical MORF and cMORF sequences, identical CC49 antibody and identical LS174T tumor model to that used previously.[7] Since the average β energies of ^{90}Y and ^{188}Re and the pharmacokinetics of the labeled cMORFs are similar, the T/NT dose ratio improvement is mainly due to the longer physical half-life.

CONCLUSION

Radiolabeling of DOTA-cMORF with ^{90}Y was improved by introducing a prepurification heating step into the conjugation process. The T/B ratio and biodistribution of ^{90}Y-DOTA-cMORF labeled in this fashion were found to be similar to that observed previously for ^{188}Re-MAG$_3$-cMORF. Nevertheless, because of the longer physical half-life of ^{90}Y, an improvement in therapeutic efficacy may be expected in future radiotherapy studies.

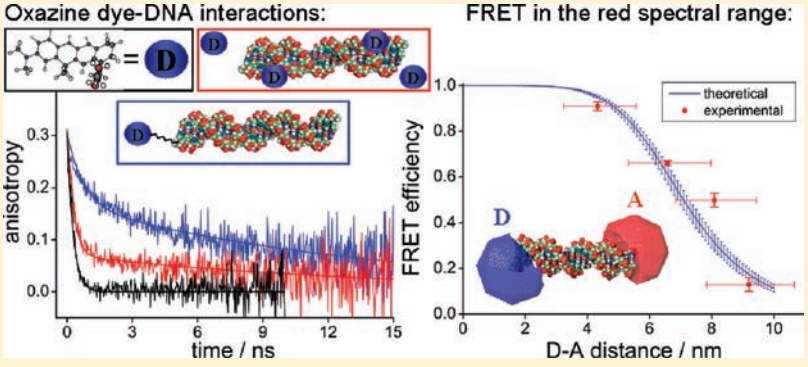
Supporting Information



ABSTRACT: In this work, the photophysical properties of two oxazine dyes (ATTO 610 and ATTO 680) covalently attached via a C6-amino linker to the 5′-end of short single-stranded as well as double-stranded DNA (ssDNA and dsDNA, respectively) of different lengths were investigated. The two oxazine dyes were chosen because of the excellent spectral overlap, the high extinction coefficients, and the high fluorescence quantum yield of ATTO 610, making them an attractive Förster resonance energy transfer (FRET) pair for bioanalytical applications in the far-red spectral range. To identify possible molecular dye−DNA interactions that cause photophysical alterations, we performed a detailed spectroscopic study, including time-resolved fluorescence anisotropy and fluorescence correlation spectroscopy measurements. As an effect of the DNA conjugation, the absorption and fluorescence maxima of both dyes were bathochromically shifted and the fluorescence decay times were increased. Moreover, the absorption of conjugated ATTO 610 was spectrally broadened, and a dual fluorescence emission was observed. Steric interactions with ssDNA as well as dsDNA were found for both dyes. The dye−DNA interactions were strengthened from ssDNA to dsDNA conjugates, pointing toward interactions with specific dsDNA domains (such as the top of the double helix). Although these interactions partially blocked the dye-linker rotation, a free (unhindered) rotational mobility of at least one dye facilitated the appropriate alignment of the transition dipole moments in doubly labeled ATTO 610/ATTO 680−dsDNA conjugates for the performance of successful FRET. Considering the high linker flexibility for the determination of the donor−acceptor distances, good accordance between theoretical and experimental FRET parameters was obtained. The considerably large Förster distance of ∼7 nm recommends the application of this FRET pair not only for the detection of binding reactions between nucleic acids in living cells but also for monitoring interactions of larger biomolecules such as proteins.

INTRODUCTION

Dye-labeled oligonucleotides have many applications in life sciences.[1−3] These range from fundamental research in molecular and cell biology (e.g., the study of intracellular RNA distribution and dynamics[4,5] or the affinity and specificity of DNA-binding proteins[6,7]) to medical research [e.g., the characterization of potential RNA therapeutic agents (antisense oligonucleotides and ribozymes) for oligonucleotide therapy[8]]. In many cases, Förster resonance energy transfer (FRET)-based oligonucleotide probes are used. The FRET technique allows the detection of binding reactions between biomolecules without separation of excess probe material[8] and is therefore especially suited for in vivo applications such as live cell imaging.[1,5,9,10] Short terminally labeled nucleic acid FRET probes are preferably applied in RNAomics (RNA research). Here, different fundamental concepts such as competitive hybridization probes, side-by-side probes, and molecular beacons that contain short DNA (double-stranded, single-stranded, and hairpin-structured by intramolecular base pairing within one DNA single strand) are applied.[3,4]

Many dyes show specific molecular interactions with DNA; e.g., intercalation, groove binding, and a stacked conformation parallel to the terminal base pair of the DNA helix were described for cyanine dyes[11−16] and rhodamine dyes.[15−17] Such dye−DNA interactions may change the photophysical properties of the dyes, e.g., fluorescence enhancement,[18,19] alterations in fluorescence anisotropy,[13,17,20,21] or fluorescence quenching.[17,22−24]

The demand for techniques that allow the visualization of RNA in living cells is increasing in RNAomics.[10] In particular, fluorescent probes that can be excited and detected in the visible red to near-infrared spectral range are very attractive for in vivo applications as their usage strongly reduces the level of photodamage of the living cells.[25,26] Further advantages are the elimination of the tissue background signal and an increase in tissue penetration depth due to the very low intrinsic absorption and fluorescence emission of the biological samples as well as reduced light scattering in this spectral range.[27−29] Moreover, rugged red diode lasers that are less expensive and more energy-efficient than gas lasers commonly applied in confocal laser scanning microscopes are available for excitation.[30−32] Thus, fluorescent probes containing red or near-infrared dyes are in demand for in vivo microscopy.[28] Cyanine and rhodamine dyes, e.g., Cy5 and TAMRA, are frequently used as FRET-based oligonucleotide probes[33,34] despite the strong dye−DNA interactions that have been revealed for those dyes (vide supra).

The FRET efficiency depends on the spectral overlap between the fluorescence emission of the donor (D) and the absorption of the acceptor (A) as an intrinsic property of the particular FRET pair and the actual distance between D and A, but also on the relative orientation of the respective transition dipoles between both dyes.[35] Consequently, a complete restricted mobility of the dyes due to strong molecular dye−DNA interactions may limit the applicability of a certain FRET pair for oligonucleotide probes.[36] In addition to dye−DNA interactions, the flexible molecular structure of cyanine dyes induces photoisomerization processes that compete with the fluorescence emission.[37−39]

Fluorescent dyes with absorption maxima between 600 and 750 nm that exhibit high extinction coefficients and decent quantum yields can be found among the ATTO dyes.[40] In contrast to the frequently used cyanine dyes, the chromophores of the ATTO dyes possess a more rigid molecular structure that is less prone to photophysical transformations such as isomerization.[40] However, until now, the photophysical properties of their bioconjugates and molecular dye−biomolecule interactions had been investigated in only a few studies.[41−47] To the best of our knowledge, only three studies have been published so far in which DNA conjugates of far-red ATTO dyes (ATTO 655, ATTO 647, and ATTO 647N) were used in FRET applications.[45−47]

In this study, two ATTO dyes were investigated with respect to their performance as a FRET pair for oligonucleotide probes. As the photophysics of the fluorescent probes provides the basis for the detection of the molecular event of interest (such as a binding interaction), the effects of the bioconjugation on the photophysical properties must be well characterized for each dye−biomolecule system on a case-to-case basis. An in-depth photophysical characterization of the oxazine derivatives ATTO 610 (D) and ATTO 680 (A) as well as of dye−DNA conjugates with different DNA lengths is presented. The two dyes were chosen because of the excellent spectral overlap, the high extinction coefficients, and the high fluorescence quantum yield of ATTO 610, making them an attractive novel FRET pair for bioanalytical applications in the far-red spectral range. Using tailor-made DNA strands, the FRET parameters and the experimental performance were determined and compared to theoretically obtained parameters. Moreover, the molecular interactions of the 5′-terminally attached dyes with ssDNA as well as dsDNA were investigated in detail using high-end fluorescence techniques such as time-resolved fluorescence anisotropy and fluorescence correlation spectroscopy.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. The carboxylated dyes ATTO 610 (A610-COOH) and ATTO 680 (A680-COOH) were purchased from ATTO-TEC GmbH (Siegen, Germany). Stock solutions of the carboxylated dyes were prepared in acetonitrile (analytical grade) at concentrations of 0.2−1 mM. Both dyes are oxazine derivatives. The structural formulas of A610-COOH[40] and A680-COOH[48] are shown in Figure 1 (left). The

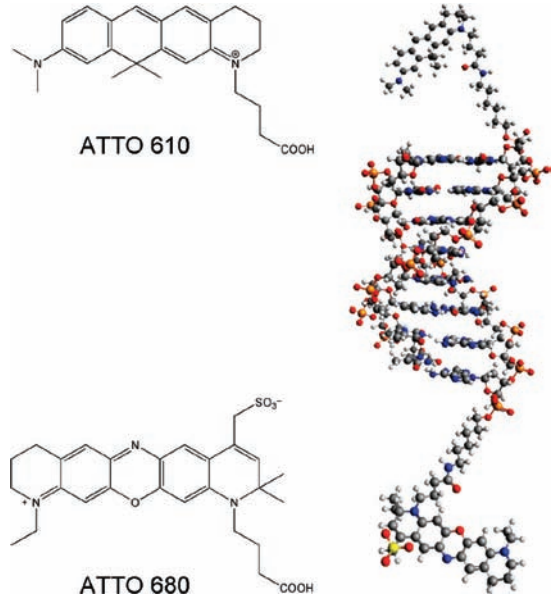

Figure 1. Structural formulas of ATTO 610 carboxylic acid (A610-COOH) and ATTO 680 carboxylic acid (A680-COOH) (left) and three-dimensional structure of the doubly labeled dye−dsDNA conjugates (right). The three-dimensional structure of the doubly labeled dye−dsDNA conjugates is shown for the 8 bp dsDNA conjugated at the opposite 5′-ends with the donor ATTO 610 (A610) and the acceptor ATTO 680 (A680) via a C6-amino linker.

molecular weights of the dyes, including counterions, are 491 g/mol for A610-COOH and 631 g/mol for A680-COOH.

A610 was conjugated via a linker of six carbon atoms (C6-amino linker) to the 5′-end of single-stranded DNA (ssDNA) of different lengths [8, 16, 20, and 24 bases (b)]. A680 was conjugated to the complementary ssDNA accordingly. The dye−ssDNA conjugates were custom-synthesized and purified (double HPLC grade) by IBA GmbH (Göttingen, Germany).[49] The sequences and molecular weights (M) of the oligonucleotides are summarized in Table 1. In addition, unlabeled complementary ssDNA was also purchased from IBA GmbH (double HPLC grade purification). The final concentration of each oligonucleotide sample was adjusted to 0.1 mM.

The spectroscopic characterization of the carboxylated dyes as well as the dye−ssDNA conjugates was conducted in doubly distilled water. For the fluorescence measurements, diluted solutions of the dyes and the dye−DNA conjugates were used (optical density at λ_{ex} < 0.1). For the investigation of FRET, double-stranded (ds) DNAs of 8, 16, 20, and 24 base pairs (bp) containing the donor (A610) on the one 5′-end and the acceptor (A680) on the opposite 5′-end were prepared by hybridization of the complementary dye−ssDNA conjugates

dx.doi.org/10.1021/bc200379y | Bioconjugate Chem. 2011, 22, 2546−2557

Table 1. Sequences and Molecular Weights (M) of the DNA Single Strands

identifier	DNA length [bases (b)]	DNA sequence (5′ → 3′)	M of the DNA (g/mol)
A610−8b ssDNA	8	AAGGCCTA	2418
A680−8b ssDNA	8	TAGGCCTT	2400
A610−16b ssDNA	16	ATCGAAGGCCTAGGTA	4926
A680−16b ssDNA	16	TACCTAGGCCTTCGAT	4830
A610−20b ssDNA	20	TATCCGAAGGCCTAGCGTAT	6113
A680−20b ssDNA	20	ATACGCTAGGCCTTCGGATA	6113
A610−24b ssDNA	24	ATATCGCGAAGGCCTAGCGGTATA	7396
A680−24b ssDNA	24	TATACCGCTAGGCCTTCGCGATAT	7300

(Figure 1, right). To obtain dsDNA conjugated with either A610 or A680, we hybridized the dye−ssDNA conjugates with the unlabeled complementary ssDNA. The dsDNA samples were studied in doubly distilled water containing 1 M NaCl (analytical grade).

Hybridization of the Dye−ssDNA Conjugates. Samples containing the two complementary DNA single strands, each at a final concentration of 0.03 mM in a 1 M NaCl solution, were prepared and placed in a polymerase chain reaction machine (Analytik Jena). Heating the samples to 363 K for 1 min abolished any intramolecular base pairing of the DNA single strands. The hybridization took place at 287 K (for the 8b DNA) and 318 K (for the 16b, 20b, and 24b DNA) for 15 h. A 1 M NaCl solution was used as the solvent to increase the melting temperature of the dsDNA (Table 2) and to shift the equilibrium in the direction of double-strand formation. In Table 2, the lengths and the melting temperatures of the dsDNA are listed. The DNA lengths were calculated using a length increment of 0.34 nm/bp, which is found in general for the B-type DNA double helix.

Table 2. Lengths and Melting Temperatures (T_m) of the DNA Double Strands

DNA length (bp)	DNA length (nm)	T_m (K) at 0.195 M monovalent cation	T_m (K) in a 1 M NaCl solution
8	2.72	297	309
16	5.44	316	328
20	6.80	325	337
24	8.16	330	342

Absorption and Fluorescence Spectroscopy. The absorption spectra were recorded in the spectral range of 230−750 nm using a Lambda 750 UV−vis spectrometer (Perkin-Elmer). The steady-state fluorescence measurements were performed using a Fluoromax-3 spectrofluorometer (Horiba Jobin Yvon) operated in the single-photon-counting mode. The time-resolved fluorescence measurements were taken using an FL920 spectrofluorometer (Edinburgh Instruments) equipped with a multichannel plate (Europhoton) and operated in a time-correlated single-photon-counting (TCSPC) mode. A SC450 supercontinuum source (Fianium) equipped with an acousto-optic tunable filter (AOTF) with a pulse width of 6 ps and 20 MHz repetition rate was used for excitation. A610 was excited (λ_{ex}) in the spectral range of 570−650 nm and A680 in the range of 615−688 nm. The fluorescence emission (λ_{em}) was recorded in the spectral range of 600−750 nm for A610 and 630−800 nm for A680. The exact excitation and emission wavelengths are given with the experimental results. The temperature was kept constant at 295 K. The single- and double-exponential fluorescence decays were analyzed according to eqs 1 and 2

$$I(t) = A \exp(-t/\tau) \quad (1)$$

$$I(t) = A_1 \exp(-t/\tau_1) + A_2 \exp(-t/\tau_2) \quad (2)$$

where I is the fluorescence intensity, A the pre-exponential factor, t the time, and τ the fluorescence decay time. The fractional contribution of component i to the total steady-state intensity (f_i) was defined according to eq 3. For the decay analysis, the commercial software package provided by Edinburgh Instruments (FAST software) was used.

$$f_i = \frac{A_i\tau_i}{\sum_{i=1}^{n} A_i\tau_i} \quad (3)$$

The fluorescence quantum yield (φ) of A610-COOH in 1 M NaCl solution was determined with a photoluminescence quantum yield measurement system (C9920, Hamamatsu Photonics). The data were analyzed with the commercial software package provided by Hamamatsu.

Fluorescence Anisotropy. Fundamental anisotropy as well as time-resolved fluorescence anisotropy was determined as described by Kupstat et al.[50] The fundamental anisotropy r_0 of the carboxylated dyes was measured at 277 K in glycerine. For the analysis of the anisotropy decays of the carboxylated dyes and the A610−dsDNA conjugates measured at a λ_{ex} of 650 nm and a λ_{em} of 675 nm, eq 4 was used

$$r(t) = r_0 \exp(-t/\theta) \quad (4)$$

where t is the time and θ the rotational correlation time. The double-exponential anisotropy decays of the dye−ssDNA and dye−dsDNA conjugates were analyzed using eq 5, which is an anisotropy model for the segmental mobility of a biopolymer-bound dye.[51]

$$r(t) = r_0\left[\alpha\exp\left(\frac{-t}{\theta_1}\right) + (1-\alpha)\exp\left(\frac{-t}{\theta_2}\right)\right] \quad (5)$$

where the parameter θ_1 refers to the rotational correlation time of the segmental motion and θ_2 refers to the rotational correlation time of the overall rotational motion of the macromolecule. The contribution of θ_1 to the overall anisotropy decay is given by the parameter α, and consequently, $(1-\alpha)$ represents the contribution of θ_2. The fundamental anisotropy that was separately determined under high-viscosity conditions (vide supra) to $r_0 = 0.3$ was fixed during the fitting of the anisotropy decays. For the dye−ssDNA conjugates, the parameter θ_2 was approximated assuming the rotational motion of a sphere

(calculated according to eq 6) and fixed during the fitting.

$$\theta = \frac{4\pi {R_h}^3 \eta}{3kT} \quad (6)$$

where R_h is the hydrodynamic radius of the dye−ssDNA conjugates in water determined from the FCS measurements (vide infra), η the solvent viscosity, k the Boltzmann constant, and T the temperature. For the evaluation of the experimental results, the rotational correlation times of the DNA double strands were calculated with HYDROPRO.[52]

Fluorescence Correlation Spectroscopy (FCS). The FCS measurements were performed on a single-molecule spectrometer system (MicroTime 200, Picoquant, and IX-71, Olympus) using a supercontinuum source with a pulse width of 6 ps and 20 MHz repetition rate (SC400-2 with AOTF, Fianium) for excitation. The power of the excitation light (λ_{ex} = 622 nm, and λ_{ex} = 630 nm) coupled to the microscope was in the range of 50−65 μW (measured without a lens). The excitation beam was focused into the sample by a microscope lens (Olympus PlanApo 100×, 1.40 oil objective). The fluorescent light was collected by the same lens and guided via a dichroic mirror, a long pass filter [RG-645 for A610 and RG-665 for A680 (Melles Griot)], a 50 μm pinhole, and a final 50:50 beam splitter onto two single-photon avalanche diodes (APDs) (Perkin-Elmer). The autocorrelation curves $G(t_{lag})$ were calculated by cross correlating photons from the two APDs using SymPhoTime version 5.1.31 (Picoquant). The dimensions of the focal volume (ω_0 and z_0) were determined using a calibration standard (ATTO 655-carboxylic acid in doubly distilled water).[53] The autocorrelation functions $G(t_{lag})$ were fitted according to eq 7

$$G(t_{lag}) = \frac{1}{N}\left(1 + \frac{t_{lag}}{t_{lat}}\right)^{-1}\left(1 + \frac{{\omega_0}^2}{{z_0}^2}\frac{t_{lag}}{t_{lat}}\right)^{-1/2} \quad (7)$$

where t_{lag} is the lag time, N the average molecule number in the focal volume, and t_{lat} the lateral diffusion time that a molecule needs to leave the focal volume.[54] Via t_{lat}, the diffusion coefficient D_{lat} can be calculated according to eq 8.

$$t_{lat} = \frac{{\omega_0}^2}{4D_{lat}} \quad (8)$$

The Stokes−Einstein equation (eq 9), where k is Boltzmann's constant, T the temperature, and η the solvent viscosity, relates D_{lat} with the hydrodynamic radius R_h of a (spherical) molecule in solution.

$$D_{lat} = \frac{kT}{6\pi\eta R_h} \quad (9)$$

Förster Resonance Energy Transfer (FRET). The Förster distance R_0 was calculated according to eq 10[55]

$$R_0 = \sqrt[6]{\frac{9\ln(10)\kappa^2\varphi_D J(\lambda)}{128\pi^5 N_A n^4}} \quad (10)$$

where κ^2 is an orientation factor for the transition dipole moments of donor (D) and acceptor (A), φ_D the quantum yield of D, $J(\lambda)$ the overlap integral, N_A Avogadro's number, and n the refractive index of the medium.

The average κ^2 is usually assumed to be $^2/_3$, which is appropriate in the case of complete rotational freedom of D and A (dynamic random averaging of the transition dipole moments of D and A).[35] Following the work of van der Meer,[56] κ^2 can be expressed in terms of the angle between the electric field of D and the absorption transition dipole moment of A (ω) and the angle between the emission transition dipole moment of D and the line connecting the centers of D and A (θ_D) according to eq 11.

$$\kappa^2 = \cos^2\omega(1 + 3\cos^2\theta_D) \quad (11)$$

Averaging over all possible ω values leads to eq 12, in which the average κ^2 can take values between $^1/_3$ and $^4/_3$ depending on θ_D (Figure 1S of the Supporting Information). An equivalent expression can be found for θ_A.

$$\overline{\kappa^2}(\theta_D) = \cos^2\theta_D + \frac{1}{3} \quad (12)$$

$J(\lambda)$ was determined as described by Kupstat et al.[50] using the fluorescence emission spectrum of A610-COOH and the absorption spectrum of A680-COOH. On the basis of R_0, the theoretical FRET efficiency (E_{theo}) can be calculated for different D−A distances (R) according to eq 13.

$$E_{theo} = \frac{{R_0}^6}{{R_0}^6 + R^6} \quad (13)$$

To take the high flexibility of the C6-amino linker into account when determining the actual R for the dye−dsDNA conjugates, we performed accessible volume (AV) simulations using FRETnps Tools.[57] The dsDNA structures were generated with the nucleic acid builder (NAB) that is part of AmberTools. The AVs of the dyes were simulated independently for each DNA end. For this simulation, the linker length was set to 1.6 nm (because of their flexibility, the C4 side chains of the dyes were considered as part of the linker), the linker diameter was set to 0.4 nm,[58] and dye diameters of 1.0 and 1.1 nm were used for A610 and A680, respectively. From the AV data, R distributions were obtained by numerical computation of the pair correlation function between the two one-particle densities. The peak maxima of the R distributions were used as the average distance between D and A in the dye−dsDNA conjugates with different DNA lengths.

The experimental FRET efficiency (E_{exp}) was determined from the fluorescence decays of D according to eq 14

$$E_{exp} = 1 - \frac{\tau_{DA}}{\tau_D} \quad (14)$$

where τ_{DA} is the fluorescence decay time of D in the presence and τ_D in the absence of A. To measure selectively D's fluorescence emission when A is present, we used an excitation wavelength (λ_{ex}) of 590 nm and an emission wavelength (λ_{em}) of 620 nm.

RESULTS

Effects of Bioconjugation on the Basic Photophysical Properties of the Dyes. The effects of DNA conjugation on the absorption and fluorescence properties of the dyes were investigated for the dye−ssDNA conjugates as well as for the singly labeled dye−dsDNA conjugates. The basic photophysical data of the free and conjugated dyes are summarized in Table 3.

The absorption spectra of the dye−ssDNA and dye−dsDNA conjugates basically comprise the absorption of the single moieties, namely, the absorption of the dye in the visible red

Table 3. Basic Photophysical Properties of the Free Dyes, the Dye−ssDNA Conjugates, and the Singly Labeled Dye−dsDNA Conjugates[a]

	absorption maximum (nm)	fluorescence excitation maximum (nm)	fluorescence emission maximum (nm)	fluorescence decay time τ (ns)
A610-COOH	616	616	634	3.3 ± 0.1
A610−ssDNA	623−629, shoulder at 650	623−625, shoulder at 650	640	4.0 ± 0.1 to 4.6 ± 0.1[b]
A610−dsDNA	629−647	625−629, shoulder at 650	636 and 665	4.2 ± 0.2
A680-COOH	680	680	697	1.7 ± 0.1
A680−ssDNA	688	688	703	2.1 ± 0.1 to 2.4 ± 0.1[b]
A680−dsDNA	688	688	702	2.4 ± 0.1

[a]The fluorescence emission and excitation spectra were measured with a λ_{ex} of 570 nm and a λ_{em} of 690 nm for A610 and a λ_{ex} of 615 nm and a λ_{em} of 730 nm for A680. The fluorescence decays were measured at a λ_{ex} of 615 nm and a λ_{em} of 635 nm for A610 and at a λ_{ex} of 688 nm and a λ_{em} of 703 nm for A680. The error of τ was determined from repeated measurements. [b]As the τ of the A610− and A680−ssDNA conjugates was slightly increased with an increase in DNA length, the range of τ is stated.

spectral range and the UV absorption band of the DNA with its maximum at ∼260 nm (Figure 2S of the Supporting Information). However, as a result of the DNA conjugation, the absorption maximum of A680 was bathochromically shifted by 8 nm compared to the absorption maximum of A680-COOH. For the A610−DNA conjugates, a larger effect was found. In addition to the 7−31 nm bathochromically shifted spectral position of the A610 absorption maximum, a significant spectral broadening compared to that of A610-COOH was found for the ssDNA- and dsDNA-conjugated dye (Figure 3S of the Supporting Information). These changes in the absorption of conjugated A610 were attributed to an additional absorption band formed at ∼650 nm that increased in intensity from ssDNA to dsDNA conjugates (for the ssDNA conjugates, this band was observed as a shoulder occurring at lower energies with regard to the regular absorption, whereas for the dsDNA conjugates, the band was distinctly increased in intensity resulting in a more red-shifted absorption maximum). This absorption band was differently pronounced for the dye−DNA conjugates with different DNA lengths (Figure 3S of the Supporting Information).

Trends similar to those found in the absorption spectra were observed in the fluorescence excitation spectra. The excitation spectra of both dyes showed the bathochromically shifted absorption upon conjugation to ssDNA and dsDNA (vide supra). As already found in the absorption spectra of conjugated A610 (vide supra), the additional band at ∼650 nm was more pronounced for the dye−dsDNA conjugates than for the dye−ssDNA conjugates (Figure 2, left, and Figure 4S of the Supporting Information). However, the band detected at ∼650 nm in the excitation spectra was less intense compared to that in the absorption spectra. Corresponding to the absorption measurements, the fluorescence emission maxima of the conjugated dyes were bathochromically shifted, as well (Table 3). However, no significant spectral broadening of the fluorescence emission was observed (Figure 2, right, and Figure 5S of the Supporting Information).

As a further consequence of DNA conjugation, the fluorescence decay times of the dyes were altered. Compared to that of A610-COOH, the decay time of the ssDNA-conjugated A610 (τ) was increased from 3.3 ± 0.1 ns to values between 4.0 ± 0.1 and 4.6 ± 0.1 ns depending on the DNA length (see Table 1S of the Supporting Information). The decay time of A680 was increased from 1.7 ± 0.1 ns for A680-COOH to values between 2.1 ± 0.1 and 2.4 ± 0.1 ns for the ssDNA-conjugated dye (see Table 1S of the Supporting Information). The fluorescence decay times of the dye−dsDNA conjugates were similar to those of the corresponding dye−ssDNA conjugates (Table 3). However, in contrast to those of the dye−ssDNA conjugates, the decay times of the dye−dsDNA conjugates showed, if any, only a minor dependence on DNA length.

In a further step, the A610−dsDNA conjugates were excited in the spectral range of the additional absorption band at a λ_{ex} of 650 nm (vide supra). An "anomalous" fluorescence emission band with a maximum λ_{em} at ∼665 nm that was not detected for A610-COOH was observed (Figure 2, right). The intensity of this emission band depended on temperature; with increasing temperature, the intensity decreased (Figure 6S of the Supporting Information, right). The same was observed in the fluorescence excitation spectra (Figure 6S of the Supporting Information, left). The corresponding fluorescence decays (λ_{ex} = 650 nm; λ_{em} = 675 nm; T = 295 K) were double-exponential containing a short component with a decay time τ_1 of 1.6 ± 0.1 ns (f_1 = 29−40%) and a long component with a τ_2 of 4.0 ± 0.2 ns (f_2 = 60−71%) (f_1 and f_2 differed slightly for the A610−dsDNA conjugates with different DNA lengths).

In a reference experiment, absorption and fluorescence spectra as well as the fluorescence decay time of A610-COOH in the presence of unlabeled 24 bp dsDNA were measured. Except for a small bathochromic shift of ∼3 nm in the absorption maximum, no further alterations in the absorption of A610-COOH were observed [no spectral broadening and no additional absorption band at 650 nm as observed for the DNA-conjugated dye (vide supra)]. The fluorescence spectra showed the regular excitation and emission bands of A610-COOH [no bathochromic shifts and no anomalous emission band at 665 nm as observed for the DNA-conjugated dye (vide supra)]. The fluorescence decay time of A610-COOH (λ_{ex} = 615 nm, and λ_{em} = 635 nm) was slightly increased from 3.3 ± 0.1 ns without DNA to 3.8 ± 0.1 ns in the presence of the dsDNA.

Interaction between Conjugated Dyes and ssDNA. To reveal molecular dye−ssDNA interactions, the mobility of the conjugated dyes was investigated using FCS and time-resolved fluorescence anisotropy measurements. Comparing the FCS curves of the free dyes and the dye−ssDNA conjugates in water, we found an increase of the lateral diffusion time t_{lat} (see Figure 3, left, for A610). The lateral diffusion time t_{lat} was increased with an increase in DNA length (see Figure 3, left, for A610). As t_{lat} was increased, the diffusion coefficient D_{lat} was decreased (according to eq 8). For both free dyes A610-COOH and A680-COOH, similar values of D_{lat} were obtained (Table 4). According to the similar molecular weight increase of the diffusing units when the dyes are conjugated to the ssDNA (see Table 1 for M values of the ssDNA), the D_{lat} values of both dyes were

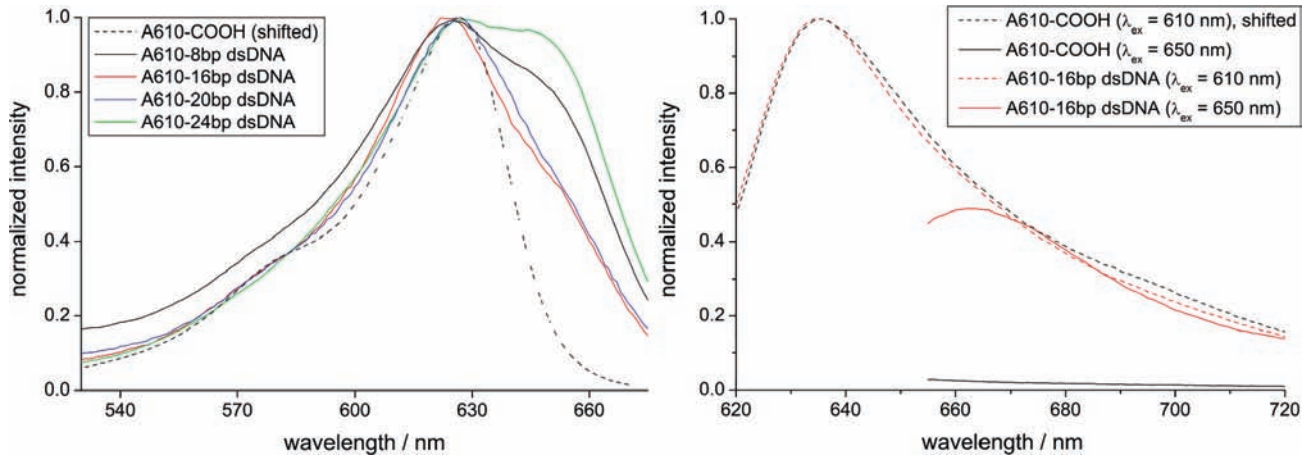

Figure 2. Fluorescence excitation (left) and emission (right) of the A610−dsDNA conjugates. The fluorescence excitation spectra were recorded at a λ_{em} of 690 nm and the emission spectra at λ_{ex} values of 610 and 650 nm. To provide a better comparison of the spectra, the A610-COOH excitation spectrum was bathochromically shifted by 11 nm and the emission spectrum (λ_{ex} = 610 nm) by 2 nm. The fluorescence emission spectra were normalized to the maximum of the regular fluorescence emission (at 634 and 636 nm, respectively).

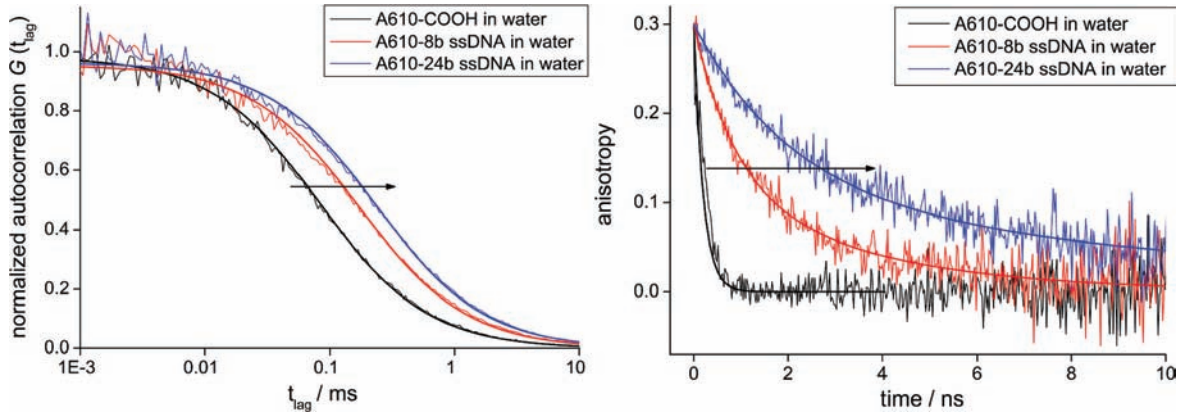

Figure 3. FCS curves (left) and time-resolved anisotropy decays (right) of the free dye A610-COOH and the A610−ssDNA conjugates. The FCS and the time-resolved anisotropy curves were measured at 295 K. For the FCS measurements, the samples were excited at a λ_{ex} of 622 nm and the emission was detected at a λ_{em} of >630 nm. The anisotropy decays were measured at a λ_{ex} of 615 nm and a λ_{em} of 635 nm.

decreased comparably with an increase in DNA length (Table 4). The hydrodynamic radii of the diffusing units (R_h) that were calculated via D_{lat} according to eq 9 are given in Table 4. As expected, an increase in R_h was found because of the ssDNA conjugation of the dyes, and a small R_h increase was observed with an increase in DNA length.

The rotational motion of the ssDNA-conjugated dyes was investigated with time-resolved fluorescence anisotropy measurements. For the free dyes in water, fast, single-exponential anisotropy decays were measured (see Figure 3, right, for A610-COOH). As expected from the comparable molecular weights of the dyes, similar rotational correlation times (θ) were determined for A610-COOH and A680-COOH (Table 5). These values are in good accordance with the rotational correlation times θ_{theo} (Table 5) that were calculated from the R_h values of the free dyes (Table 4) according to eq 6. Compared to those of the free dyes, the anisotropy decays of the ssDNA-conjugated dyes were slower (see Figure 3, right, for the ssDNA-conjugated A610). This effect was enhanced with an increase in DNA length. For the double-exponential anisotropy decays of the dye−ssDNA conjugates, the anisotropy model for the segmental mobility of a biopolymer-bound dye (eq 5) was successfully applied. In Table 5, the fit parameters provided by this

Table 4. Diffusion Coefficients (D_{lat}) and Hydrodynamic Radii (R_h) of the Free Dyes and the Dye−ssDNA Conjugates in Water at 295 K[a]

[a]The FCS measurements were performed using a λ_{ex} of 622 nm and a λ_{em} of >630 nm for A610 and a λ_{ex} of 630 nm and a λ_{em} of >640 nm for A680. The error in D_{lat} was determined from repeated measurements, and the error in R_h was calculated from the error in D_{lat}.

model [α (contribution of the fast rotational motion to the anisotropy decay), θ_1 (rotational correlation time of the fast motion), and θ_2 (rotational correlation times of the slow motion)] are summarized. θ_2 was calculated from R_h (Table 4) according to eq 6 and fixed during the fitting process. Comparable θ_2 values were obtained for the dye−ssDNA conjugates of equal DNA length because of their similar R_h values. As R_h was increased with an increase in DNA length, θ_2 was increased, as well (Table 5). The segmental motion of the dye−ssDNA

[a]The dye−ssDNA conjugates were investigated in water and the dye−dsDNA conjugates in a 1 M NaCl solution. The corresponding anisotropy decays were measured at a λ_{ex} of 615 nm and a λ_{em} of 635 nm for A610 and a λ_{ex} of 688 nm and a λ_{em} of 703 nm for A680. θ_{theo} for the free dyes was calculated from R_h (Table 4). The error in θ_{theo} was determined from the error in R_h. The segmental rotational correlation time of the dye−DNA conjugates is θ_1. The contribution of the segmental motion to the anisotropy decay is given by α, and θ_2 refers to the overall rotational motion. θ_2 for the dye−ssDNA conjugates was calculated from R_h (Table 4) and fixed during the fitting process. The error in θ_2 was determined from the error in R_h. The error in θ_1 as well as α for the dye−ssDNA conjugates was determined from the error in θ_2. For the dye−dsDNA conjugates, the errors in α, θ_1, and θ_2 result from the error in the fit.

conjugates exhibited an increased rotational correlation time θ_1 compared to those of the free dyes (Table 5). For the A610−ssDNA conjugates, θ_1 was slightly increased with an increase in DNA length, whereas for the A680−ssDNA conjugates, a consistent θ_1 of ∼1 ns was obtained regardless of the DNA length (Table 5). For both dye−ssDNA conjugates, the segmental rotation contributed mostly to the depolarization process with an α of 60−90% (except for the A610−8b ssDNA and A680−24b ssDNA conjugate).

Interaction between Conjugated Dyes and dsDNA. The dye−dsDNA interactions were investigated on the singly labeled dye−dsDNA conjugates using time-resolved fluorescence anisotropy measurements. Similar to those of the dye−ssDNA conjugates (vide supra), double-exponential anisotropy decays that could be fitted very well with the model for the segmental mobility of a biopolymer-bound dye were measured (Figure 7S of the Supporting Information, blue line, and Figure 8S of the Supporting Information, blue and red line). However, compared to that of the dye−ssDNA conjugates, the contribution of segmental rotation to the anisotropy decay of the dye−dsDNA conjugates was decreased (Table 5). For both dyes, a similar rotational correlation time for the segmental motion (θ_1) of approximately 1 ns was determined (Table 5). As the molecular weight (M) is almost equal for the A610− and A680−dsDNA conjugates of the same length, the rotational correlation times for the overall rotation of the macromolecule (θ_2) are similar for the dye−dsDNA conjugates of equal length (Table 5). Assuming the M of the dyes (see Experimental Procedures) to be significantly smaller than the M of the DNA (Table 1), we approximated theoretical values for θ_2 by calculating the rotational correlation times of the DNA double helices with HYDROPRO.[52] Three rotational correlation times were obtained for each DNA double strand in the ranges of 3−4 ns for the 8 bp dsDNA, 6−13 ns for the 16 bp dsDNA, 8−21 ns for the 20 bp dsDNA, and 10−31 ns for the 24 bp dsDNA. The experimentally determined θ_2 values (Table 5) correspond well with the theoretical values.

In a further step, the fluorescence anisotropy of the A610−dsDNA conjugates at the anomalous fluorescence emission band [λ_{ex} = 650 nm, and λ_{em} = 675 nm (vide supra)] was investigated. Compared to the anisotropy decays measured at the regular fluorescence emission (λ_{ex} = 615 nm, and λ_{em} = 635 nm), significantly delayed anisotropy decays were found (Figure 7S of the Supporting Information). This delay can be attributed to a complete loss of segmental mobility. The anisotropy decays could be fitted single-exponentially providing a single rotational correlation time for each A610−dsDNA conjugate (Table 2S of the Supporting Information), which is in the range of the predicted rotational correlation times for the corresponding DNA double strand (vide supra).

To further investigate the dye−dsDNA interactions in a reference experiment, molecular interactions between the free dyes and unlabeled dsDNA were investigated. For A680-COOH in the absence and presence of unlabeled 24 bp dsDNA (λ_{ex} = 688 nm, and λ_{em} = 703 nm), no differences in the rotational correlation times (θ = 0.4 ± 0.1 ns for both samples) and the fluorescence decay time (τ = 1.8 ± 0.1 ns for both samples) were found. In contrast, the single-exponential fluorescence anisotropy decay of A610-COOH (λ_{ex} = 615 nm, and λ_{em} = 635 nm) in the absence of DNA (θ = 0.3 ± 0.1 ns) turned into a double-exponential decay in the presence of unlabeled 24 bp dsDNA (Figure 9S of the Supporting Information, red line). In the latter case, two rotational correlation times were obtained: θ_1 = 0.3 ns (this value was fixed to the rotational correlation time of free A610-COOH during the fit) with a contribution of 77 ± 1%, and θ_2 = 14.8 ± 1.7 ns with a contribution of 23 ± 1%. The obtained θ_2 is in excellent agreement with the θ_2 determined for the A610−24 bp dsDNA conjugate (Table 5).

Förster Resonance Energy Transfer (FRET). For the A610/A680 FRET pair, an overlap integral of 1.15×10^{16} nm^4 M^{-1} cm^{-1} was determined using the area-normalized fluorescence emission spectrum of A610-COOH and the absorption spectrum of A680-COOH measured in a 1 M NaCl solution. In the case of full rotational freedom of the D and A molecules, the average κ^2 is $^2/_3$, resulting in a Förster distance (R) of 7.1 ± 0.2 nm [calculated according to eq 10 using a φ_D of 0.6 and an n of 1.343 (for a 1 M NaCl solution)[59]]. The error in R_0 results from the experimental errors in the

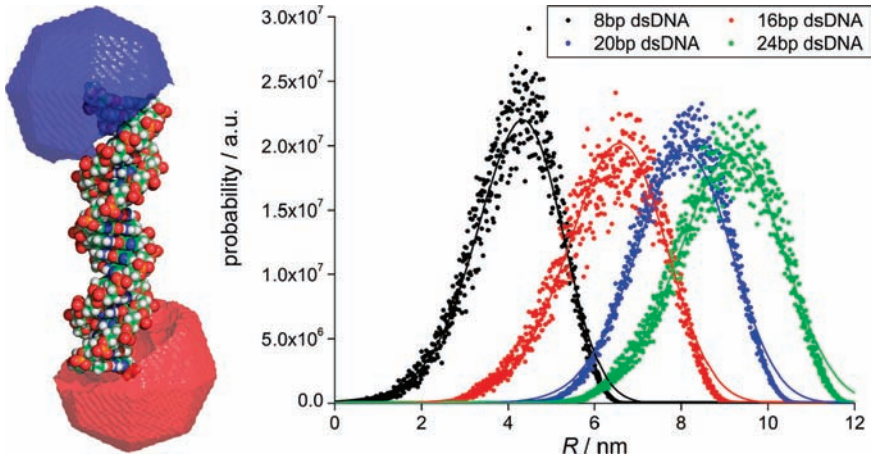

Figure 4. Accessible volumes (AV) for the dyes attached to the opposite 5′-ends of the DNA double helix (left) and D−A distance (R) distributions (right) calculated from the AV data. The accessible volumes of the dyes conjugated to the 20 bp dsDNA are colored blue for A610 and red for A680.

fluorescence quantum yield of A610 as well as in the extinction coefficient of A680. If one dye species (either the D or the A molecule) is fixed in a defined orientation and the other dye species is freely rotating, then the average values of κ^2 are found between $^1/_3$ (for a perpendicular orientation of the transition dipole moments to the line connecting the centers of D and A) and $^4/_3$ (for a parallel or antiparallel orientation of the transition dipole moments to the line connecting the centers of D and A) (according to eq 12; see also Figure 1S of the Supporting Information for a detailed analysis). In these cases, the corresponding limiting values for R_0 are 6.3 nm ($\kappa^2 = {}^1/_3$) and 8.0 nm ($\kappa^2 = {}^4/_3$). The experimental FRET efficiency was determined using the fluorescence decay time of A610 in the absence and presence of A680. For this purpose, the singly labeled A610−dsDNA and doubly labeled A610/A680−dsDNA conjugates were used. In the latter case, D and A are placed in defined proximity separated by the rigid dsDNA spacer. The volume that is accessible for the dyes because of the structural flexibility of the linker is illustrated in Figure 4 (left). The resulting D−A distance (R) distributions are shown in Figure 4 (right).

The fluorescence decays of the A610/A680−dsDNA conjugates were double-exponential (except for that of the A610/A680−24 bp dsDNA conjugate) containing a short component that depended on the length of the DNA spacer and a long component that was constant for all DNA lengths. The short component τ_{DA} ranging from 0.4 ± 0.05 to 3.7 ± 0.1 ns (Table 3S of the Supporting Information) was attributed to the fluorescence quenching of A610 due to FRET. The long component τ_2 ranging from 4.1 ± 0.1 to 4.3 ± 0.1 ns was similar to the τ determined for the A610−DNA conjugates in the absence of A (Table 3S of the Supporting Information). Consequently, τ_2 was attributed to those A610 molecules that did not participate in FRET because of an unfavorable and fixed orientation of the transition dipoles of both dyes ($\kappa^2 = 0$) as well as unpaired A610−ssDNA conjugates. The fluorescence decay of the A610/A680−24 bp dsDNA conjugates needed to be fitted single-exponentially, because τ_{DA} and τ_2 were not sufficiently differentiated to be resolved. The decay time of the A610−dsDNA conjugates (τ_D) is stated in Table 3S of the Supporting Information.

For a comparison of theoretically and experimentally obtained FRET parameters, the theoretical and the experimental FRET efficiency (E_{theo} and E_{exp}, respectively) were plotted versus the D−A distance (R) (Figure 5). E_{theo} was calculated for different R values via R_0 (for $\kappa^2 = {}^2/_3$) according to eq 13 (Figure 5, black

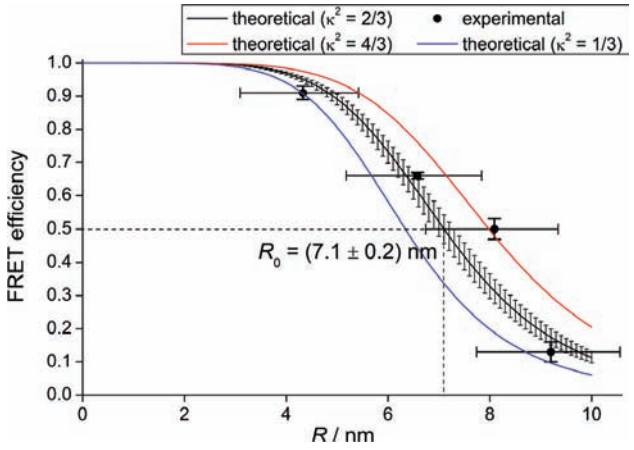

Figure 5. FRET efficiency of the A610/A680 FRET pair at different D−A distances (R). The error in E_{theo} (for $\kappa^2 = {}^2/_3$) was calculated from the error in R_0, which results from the experimental errors for the fluorescence quantum yield of A610 as well as the extinction coefficient of A680. The error in E_{exp} (vertical error bars, ΔE) was calculated from the errors in τ_{DA} and τ_D, which were determined from repeated measurements. The horizontal error bars (ΔR) indicate the distribution of E_{exp} that results from the full width at half-maximum of the R distributions (Figure 4, right). In addition, the interval of E_{theo}, which is defined by the minimal ($\kappa^2 = {}^1/_3$) and maximal ($\kappa^2 = {}^4/_3$) average κ^2 values, is shown (area between the blue line and the red line).

line). The error in E_{theo} was calculated from the error in R_0 (vide supra). E_{exp} was calculated according to eq 14 using τ_{DA} and τ_D (vide supra). The peak maxima of the R distributions (Figure 4, right) were used as the average distance between D and A, and E_{exp} was plotted versus these values (Figure 5, black dots). The error in E_{exp} was calculated from the errors in τ_{DA} and τ_D, which were determined from repeated measurements (Figure 5, ΔE, vertical error bars). The distribution of E_{exp} resulting from the full width at half-maximum of the R distributions (Figure 4, right) is indicated by the horizontal error bars (Figure 5, ΔR). In addition, E_{theo} was calculated for the minimal and maximal average κ^2 that can be achieved in the case of a complete rotational restriction of one dye species and rotational

dx.doi.org/10.1021/bc200379y | Bioconjugate Chem. 2011, 22, 2546−2557

freedom of the other (vide supra). The results are shown in Figure 5 (blue line for $\kappa^2 = {}^1/_3$ and red line for $\kappa^2 = {}^4/_3$). As one can see in Figure 5, E_{exp} fits very well in the range of the limiting E_{theo} for κ^2 values of ${}^1/_3$ and ${}^4/_3$.

DISCUSSION

As a general effect of DNA conjugation, the absorption and fluorescence maxima of both oxazine dyes were shifted to longer wavelengths and the fluorescence decay times were increased. Such changes in the basic photophysical properties upon bioconjugation have been observed previously for other dyes, including oxazine dyes.[23,37,46,60,61] For the conjugated A680, no influence of DNA length and sequence on absorption and fluorescence spectra was observed. However, the fluorescence decay times of both dyes were slightly increased with an increase in the length of the ssDNA; no such effect of chain length was seen in the case of conjugation to the dsDNA. Because of the structural flexibility of the ssDNA, small length-dependent changes in the microenvironment of the dyes may be induced, e.g., because of the rotational flexibility of the DNA−phosphate backbone or the formation of single intramolecular hydrogen bonds. Such a structural flexibility does not exist in the case of the dsDNA, and the accessible DNA microenvironment is now strictly defined (see Figure 4, left). Compared to A680, the conjugated A610 exhibited stronger alterations of its photophysics. In addition to the bathochromically shifted absorption maximum, an additional spectral broadening toward the red spectral range caused by a new absorption band was detected. The new absorption band was more intense for the dsDNA conjugates than for the ssDNA conjugates. The same was observed in the fluorescence excitation spectra, but the new band was less pronounced compared to the absorption spectra. The altered absorption points toward strong ground-state interactions between the electronic systems of A610 and DNA that require spatial proximity between them. In addition, a new red-shifted fluorescence emission band was detected upon excitation at the new absorption band. The new emission band along with the altered absorption might be an indication of a charge transfer process between the dye and DNA. Accordingly, at least two different species of A610 must be present, one species that shows the regular absorption/emission and one species causing the new absorption/emission band. The differences in the relative intensities (new to regular band) between absorption and excitation spectra may be attributed to differences in the fluorescence quantum yields of both species. In line with the results of the absorption measurements, the new emission band was much more intense for the dsDNA conjugates than for the ssDNA conjugates. The differences observed for the A610−ssDNA and −dsDNA conjugates concerning the relative intensity of the new absorption/emission band indicate that the three-dimensional DNA structure might play a role in mediating the charge transfer interaction. Although in the A610−dsDNA case the conjugates of different lengths possess the same three-dimensional DNA structure (B-type double helix), the new absorption band was differently pronounced (the same was observed for the A610−ssDNA conjugates). This suggests that the differences in the DNA sequence of the dye−DNA conjugates are responsible for the varying intensity of the new absorption band. The results of the anisotropy measurements and the AV simulations indicate that the terminal 5 bp are similar easily accessible for A610 in each DNA conjugate (vide infra). However, no clear dependence on the guanine-cytosine (GC) content (G is often involved in electron transfer processes and acts as a fluorescence quencher[41,46]) was found. To elucidate the influence of the terminal DNA sequence on the altered absorption/emission of conjugated A610, further investigations based on the systematic variation of the last base pairs are required.

To reveal steric dye−DNA interactions, we performed detailed time-resolved fluorescence anisotropy and fluorescence correlation spectroscopy (FCS) measurements. From the anisotropy and FCS results, it was concluded that the mobility of the dyes was altered because of the conjugation to ssDNA as well as to dsDNA. Comparable diffusion coefficients were determined for the A610− and A680−ssDNA conjugates of equal DNA length. Studies of the rotational mobility revealed steric interactions between dyes and DNA. The rotational motion of a dye that is covalently linked to a biomolecule can consist of several (coupled) rotational components (rotation of the dye, the linker, and the biomolecule around the different axes). In an anisotropy decay, the different rotations can only be resolved if they differ sufficiently in their corresponding rotational correlation times. The anisotropy model for the segmental mobility of a biopolymer-bound dye distinguishes between two rotational components, the fast segmental rotation of a part of the macromolecule including the dye (e.g., dye and linker) and the slow overall rotation of the whole macromolecule. This model was successfully applied in the analysis of the anisotropy decays of the dye−DNA conjugates. Because of DNA conjugation, the rotational correlation time of both dyes that is represented by the fast segmental motion (θ_1) was increased compared to that of the free dyes. This was due to the coupling of the rotational motions of the dye and C6-amino linker. For the dsDNA conjugates of both dyes as well as the A680−ssDNA conjugates, θ_1 was independent of DNA length whereas θ_1 for the A610−ssDNA conjugates was slightly increased with an increase in DNA length. In the case of the A610−ssDNA conjugates, this finding indicates a slightly hindered dye−linker rotation. The conjugated A610 might sterically interact with variable, length-dependent ssDNA structures that are formed due to the structural flexibility of the DNA single strands (e.g., by the formation of single intramolecular hydrogen bonds), resulting in a slightly delayed dye−linker rotation. On the other hand, the rigid DNA double helix provides a structurally similar microenvironment for the conjugated dyes that is independent of DNA length. Hence, the dye−linker rotation of the dsDNA conjugates of both dyes was independent of DNA length. The fast θ_1 of ∼1 ns that was determined for the segmental motion of the dye−dsDNA conjugates as well as the A680−ssDNA conjugates was consequently attributed to an unhindered dye−linker rotation. The contribution of the segmental rotation to the overall anisotropy decay (α) was decreased from the dye−ssDNA conjugates to the dye−dsDNA conjugates. For the ssDNA conjugates of both dyes, the segmental rotation dominated the anisotropy decay, whereas for the dye−dsDNA conjugates, the slow rotational motions of the whole macromolecules were dominant. These results indicate an increased level of coupling between the rotational motions of the conjugated dyes and the DNA molecules in the case of the dye−dsDNA conjugates. Such a rotational coupling of dye and DNA was also observed in a reference experiment, where the rotational mobility of free A610-COOH in the presence of unlabeled 24 bp dsDNA was investigated. In this case, two rotational correlation times were detected. One was equal to the rotational correlation time of the free dye in the absence of DNA, and the other corresponded to θ_2 for the slow

rotational motion of the dye−24 bp dsDNA conjugates. As the unlabeled DNA molecule by itself is not fluorescent under the applied excitation conditions, these results strongly point toward molecular dye−dsDNA interactions leading to an equilibrium between DNA-bound dye molecules whose fast rotation is completely hindered and unbound dye molecules that rotate freely. From these findings, we concluded that in the case of the dye−dsDNA conjugates two subpopulations of conjugated dyes exist, one that is able to perform a free fast dye−linker rotation and another subpopulation whose rotation was completely hindered because of strong molecular dye−dsDNA interactions. As the dye−DNA rotational coupling and, accordingly, the steric dye−DNA interactions were strengthened from ssDNA to dsDNA conjugates, we suppose that the dyes interact with specific domains of the DNA double helix or functional groups (e.g., hydroxyl groups) whose accessibility is promoted by the double-helix structure. For several prominent dyes, e.g., Cy3, Cy5, or tetramethylrhodamine, interactions with the major groove of the DNA double helix as well as stacked conformations on top of the dsDNA are described in the literature (for terminally attached dyes).[14−17] Such molecular interactions could lead to a hindrance of the dye rotation, resulting in a strong coupling of the dye mobility to the DNA rotation.[17,37] The AV simulations demonstrated that a region containing the terminal 5 bp of the DNA double helix is accessible for the conjugated dyes. Hence, interactions of dyes with specific dsDNA domains are sterically possible. These aspects support the assumption that molecular interactions with specific dsDNA domains are responsible for the complete rotational restriction that was observed for a fraction of dsDNA-conjugated dyes.

To shed more light upon the specific A610−dsDNA interactions causing the new absorption and anomalous fluorescence emission band (vide supra), we measured anisotropy decays using these specific excitation and emission wavelengths. In this case, the rotational mobility of the dye was completely coupled to the DNA rotation and a complete loss of the segmental mobility was observed. This result suggests that the electronic A610−DNA interactions observed in the absorption and emission spectra were accompanied by strong steric interactions between the dye and dsDNA. Although strong steric interactions were also observed between free A610-COOH and unlabeled dsDNA (vide supra), no alterations in absorption and fluorescence emission were found in this case (except for a minor bathochromic shift in the absorption maximum and a small decay time increase indicating a change in the microenvironment of the dye). This finding suggests that a specific steric dye−DNA arrangement is necessary to induce the altered absorption and dual fluorescence emission that is formed only when A610 is covalently attached to the end of the DNA double helix. Such a specific dye−DNA arrangement could be induced by hydrogen bonds between the dimethylamino group of A610 (see Figure 1, top left) and, e.g., the opposite 3′-OH end of the complementary strand of the DNA double helix. As we expect that such a dye−DNA interaction would be more and more disrupted with an increase in temperature, the influence of temperature on the intensity of the anomalous fluorescence band was investigated. In fact, the intensity of the anomalous fluorescence excitation and emission band was decreased with an increase in temperature. This result supports the assumption that specific interactions such as hydrogen bonds between a dye and DNA are responsible for the observed altered absorption and dual fluorescence emission of DNA-conjugated A610.

The results discussed above show that even structurally similar dyes (dyes of the same class) can be differently affected in their photophysics upon bioconjugation. For A610, strong alterations in the absorption and fluorescence properties were found that were not observed for A680 to the same extent. Although both dyes exhibited comparably pronounced steric interactions with the DNA in the case of the dye−dsDNA conjugates, A610 interacted with dsDNA even if it was not forced by covalent binding into the proximity of the DNA (in the case of no bioconjugation). The driving force for this interaction might be attributed to the increased hydrophobicity of A610 compared to that of A680 [which is more hydrophilic because of its sulfate group (see Figure 1, left)]. Both dyes possess nitrogen atoms that are able to form hydrogen bonds with functional groups of the DNA such as hydroxyl groups; however, the dimethylamino group of A610 is located in a more exposed position. Along with the higher hydrophobicity, this may result in a stronger dye−DNA interaction for A610 compared to A680.

For the investigation of FRET, doubly labeled dsDNA of different lengths was used in which the donor (D) A610 and the acceptor (A) A680 were attached to the opposite 5′-ends. The A610/A680−dsDNA conjugates showed a distance-dependent fluorescence quenching of A610 due to FRET. The rotational mobility of D and A influences the transition dipole orientation factor κ^2, which is an important parameter affecting the effective Förster distance and, thus, the FRET efficiency (according to eqs 10 and 13). In the anisotropy measurements of the singly labeled dsDNA conjugates, it was found that a subpopulation of the conjugated dyes was able to perform a free fast dye−linker rotation, whereas the rotational mobility of the other subpopulation was completely hindered (vide supra). As the dyes do not sterically interact, it was assumed that for the doubly labeled dsDNA conjugates all combinations of dye mobilities (D_{free}−A_{free}, D_{free}−A_{fixed}, D_{fixed}−A_{free}, and D_{fixed}−A_{fixed}) are equally probable. In the case of rotational freedom of both dye species (D_{free}−A_{free}), the average κ^2 is $^2/_3$ (according to eq 11 and averaging over the polar angle θ_D[56]). In the case of rotational freedom of one dye species (either D or A) and a complete rotational restriction of the other dye species (D_{free}−A_{fixed} and D_{fixed}−A_{free}), the minimal and maximal average κ^2 values are $^1/_3$ and $^4/_3$, respectively, depending on the angle between the transition dipole moments of the fixed dye species and the line connecting the centers between D and A (according to eq 12 and Figure 1S of the Supporting Information). Hence, assuming an average κ^2 between $^1/_3$ and $^4/_3$ is a good approximation in the majority of cases. The contribution of the fraction of doubly labeled dsDNA conjugates, in which the rotational mobility of both dyes was completely hindered (D_{fixed}−A_{fixed}), to FRET was assumed to be negligible because of unfavorable transition dipole orientations [the events, where no FRET occurs due to $\kappa^2 = 0$, can be realized in an infinite number of ways (whenever the electric field of D and the absorption transition dipole moment of A are perpendicular to each other; see eq 11)].[56] This assumption was supported by the occurrence of a second unquenched fluorescence decay time of A610 in the doubly labeled dsDNA conjugates. Consequently, the Förster distance and the resulting theoretical FRET efficiencies were calculated for both limiting cases of the average κ^2. Considering the high linker flexibility in the determination of the D−A distances, the experimental FRET efficiency calculated from the

fluorescence quenching of A610 (vide supra) was found to be exactly in the range of the theoretical FRET efficiencies for κ^2 values of $^1/_3$ and $^4/_3$. This excellent accordance strongly supports our assumption that at least one dye species (either D or A) facilitated the appropriate alignment of the transition dipoles in the doubly labeled dsDNA conjugates for FRET to be operative. A small experimental error must be taken into account for the experimental FRET efficiencies of the 20 and 24 bp dsDNA conjugates that was attributed to the inaccuracy of the resolution of two insufficiently differing fluorescence decay times (τ_{DA} was determined in the presence of τ_2), resulting in an increased E_{exp} for the 20 bp dsDNA conjugates and a slightly decreased E_{exp} for the 24 bp dsDNA conjugates.

In summary, we characterized a promising novel FRET pair for the far-red spectral range with regard to its applicability for oligonucleotide probes. In this process, we paid special attention to molecular dye−DNA interactions and the resulting alterations in the photophysics of the dyes. Our study underlines the necessity to conduct case-by-case studies for each fluorescence probe, even if the probes belong to the same class (e.g., like in our case to oxazine dyes), because of the possibility of dye-specific interactions, which may arise from small differences in the chemical structure. For the ATTO 610/ATTO 680 FRET pair, a considerably large Förster distance of approximately 7 nm was theoretically calculated and experimentally approved, recommending the application of this FRET pair not only for the detection of binding reactions between nucleic acids in living cells but also for the monitoring of interactions of larger biomolecules such as proteins.

Supporting Information

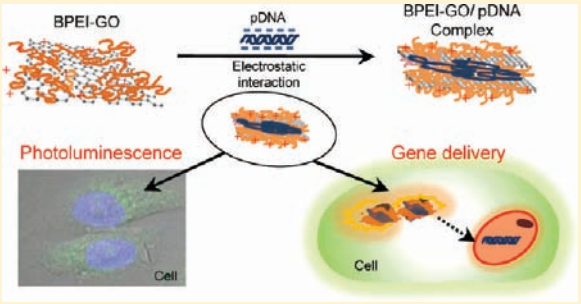
ABSTRACT: Graphene oxide (GO) has attracted an increasing amount of interest because of its potential applications in biomedical fields such as biological imaging, molecular imaging, drug/gene delivery, and cancer therapy. Moreover, GO could be fabricated by modifying its functional groups to impart specific functional or structural attributes. This study demonstrated the development of a GO-based efficient gene delivery carrier through installation of polyethylenimine, a cationic polymer, which has been widely used as a nonviral gene delivery vector. It was revealed that a hybrid gene carrier fabricated by conjugation of low-molecular weight branched polyethylenimine (BPEI) to GO increased the effective molecular weight of BPEI and consequently improved DNA binding and condensation and transfection efficiency. Furthermore, this hybrid material facilitated sensing and bioimaging because of its tunable and intrinsic electrical and optical properties. Considering the extremely high transfection efficiency comparable to that of high-molecular weight BPEI, high cell viability, and its application as a bioimaging agent, the BPEI–GO hybrid material could be extended to siRNA delivery and photothermal therapy.



INTRODUCTION

Graphene, a single-atom-thick and two-dimensional sp^2 carbon networking material, has attracted great attention because of its remarkable electronic, mechanical, and thermal properties.[1−3] Graphene has also been used in biomedical fields, including biological sensing, molecular imaging, gene/drug delivery, and cancer therapy.[4−11] In particular, graphene oxide (GO), a precursor for graphene, is endowed with several favorable properties such as electronic, sp^2 $\pi-\pi$ interaction, and fluorescence quenching ability.[12−14] Moreover, GO possesses unique features such as facile synthesis, high water dispersibility, good colloidal stability, easily tunable surface functionalization, and good biocompatibility, which are highly conducive for bioapplications.[15] All these attributes make GO more potent than carbon nanotubes considering its in vitro and in vivo biological applications. Interestingly, sp^2 $\pi-\pi$ interaction between GO and a hydrophobic drug could facilitate the loading of the drug onto the GO surface, and this could be utilized in its facile application as a drug delivery carrier.[6,8] Similarly, the utility of GO could be extended to gene delivery and biological sensing considering the quenching properties of fluorescence-labeled DNA.[7] Strong $\pi-\pi$ stacking interaction between GO and single-stranded DNA (ssDNA) facilitates the loading of ssDNA onto GO and subsequently provides protection of DNA against enzymatic degradation.[16] However, no such interaction exists between GO and double-stranded DNA (dsDNA) as DNA bases are concealed within the double helix, preventing the generation of $\pi-\pi$ stacking interaction between dsDNA and GO.[17] Therefore, it is imperative to modify the GO to achieve effective loading of plasmid DNA (pDNA) and thereby efficient gene delivery. A feasible strategy for accomplishing such DNA complexation and transfection ability of GO could involve integration of cationic vectors.

Various viral and nonviral vector-mediated delivery strategies have been employed to achieve efficient gene transfection. The use of viral vectors, despite their high efficiency, has been impaired greatly because of the associated mutagenicity or oncogenesis, several host immune responses, and high cost of production.[18] Therefore, nonviral vectors, including cationic polymers, liposomes, dendrimers, and inorganic materials, attract significant attention in spite of their low efficacy.[19−21] There is a continuous effort to modify and refine these gene delivery systems either by adopting different strategies or by installing various functional attributes in the existing systems. Among cationic polymers such as polyethylenimine (PEI), chitosan, and Polyamidoamine (PAMAM), high molecular weight branched PEI (HMW BPEI) has been used widely as a gold standard for gene delivery vehicle. HMW BPEI showed high transfection efficiency because of enhanced cellular uptake and a high level of endosomal escape.[22,23] Nevertheless, the

associated cytotoxicity of HMW BPEI severely limited its use as an effective gene carrier. Interest has now shifted toward low-molecular weight (LMW) BPEI that exhibits relatively low cytotoxicity, but very poor transfection efficacy in comparison with HMW BPEI.[24,25] Furthermore, LMW BPEI exhibited enhanced cellular uptake and transfection efficiency with low cytotoxicity when it was conjugated to inorganic materials such as gold, silica, iron oxide, and carbon materials.[26−29] We presumed that hybrid gene carrier fabricated by conjugation of LMW BPEI to GO would increase the effective molecular weight of LMW BPEI and consequently improve DNA binding and condensation and transfection efficiency.

Recently, carbon-based fluorescent nanomaterials have garnered attention because of their considerably stable emissions and lower cytotoxicity, imposing less environmental concern. The photoluminescence (PL) of carbon-based nanomaterials generally emanated from isolated polyaromatic structures.[30,31] Interestingly though, GO itself contains an isolated polyaromatic structure; the PL properties of GO have not been explored much mainly because of its low emission efficiency.[32] The carboxylic and epoxy groups of GO are known to induce nonradiative recombination of localized electron−hole pairs and thereby confer the nonemissive property of GO. However, recent reports found that such nonradiative recombination of localized electron−hole pairs could be avoided by conjugating alkylamines to both the epoxy and carboxylic groups of GO through nucleophilic reaction. Consequently, the modification of nonradiative recombinative sites transforms GO into a highly efficient emitter.[33] One intention of this study has been to enhance the efficiency of PL intensity of GO by conjugating it with BPEI, and an elaborate investigation to gain further insight into the PL properties of the BPEI−GO nanoconstruct has been conducted.

We presumed that the newly designed BPEI−GO nanoconstruct may facilitate sensing and imaging because of its tunable and intrinsic electrical and optical properties. In this study, GO was modified with LMW BPEI, and their physiological properties (colloidal stability, DNA compaction ability, and transfection efficiency) and imaging properties were investigated.

EXPERIMENTAL PROCEDURES

Materials. The graphene oxide (GO) powder was obtained from Cheap-Tubes Inc. (Brattleboro, VT). Branched polyethylenimine (BPEI; molecular masses of 1.8 and 25 kDa) was purchased from Polyscience, Inc. (Warrington, PA). Triethylamine (TEA) was obtained from Samchun Chemicals. 1-Ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride (EDC) was purchased from Sigma Chemical Co. (St. Louis, MO). *N*-Hydroxysuccinimide (NHS) was obtained from Fluka. The dialysis membrane (molecular mass cutoff of 3.5 kDa) was purchased from Spectrum Laboratories (Rancho Dominguez, CA). pDNA (pCMV-Luc) encoding luciferase was prepared from digestion and ligation using pGL3 (Promega, Madison, WI) and pcDNA3 (Invitrogen, Carlsbad, CA) vectors. Briefly, pGL3 was digested with XbaI and HindIII, and the following luc+ gene frame was purified by agarose gel electrophoresis and elution. Then, pCMV-Luc was constructed by insertion of the luc+ gene frame at the XbaI and HindIII restriction sites of pcDNA3 and amplified. pCMV-Luc was propagated in a chemically competent DH5α strain (GibcoBRL) and prepared from overnight bacterial cultures followed by alkaline lysis and column purification with a Qiagen plasmid Maxi kit (Qiagen, Valencia, CA). TOTO-3 iodide was purchased from Invitrogen (Eugene, OR), and mounting medium for fluorescence with DAPI was purchased from VECTOR (Burlingame, CA).

Synthesis of the BPEI−GO Conjugate. Prior to conjugation of BPEI to GO, the amount of carboxyl groups of GO was estimated by direct acid−base titration. To conjugate BPEI (M_w = 1.8 kDa) to the carboxyl groups of GO by EDC/NHS coupling, we dispersed the dried GOs in deionized water by sonication for 30 min, and EDC (54.3 mg, 0.4 mmol) and NHS (50.6 mg, 0.4 mmol) were added to the GO solution (0.5 mg/mL, 0.5 mg) in a vial. TEA (100 μL) was added to a BPEI solution (0.396 g) in deionized water. Subsequently, BPEI (M_w = 1.8 kDa) was added to the GO solution (1 mL, 0.5 mg/mL) and stirred for 1 day at room temperature. The resulting BPEI−GO solution was dialyzed against a 3500 Da molecular mass cutoff dialysis membrane in deionized water for 2 days to remove the unreacted BPEI.

Charaterization of GO and the BPEI−GO Conjugate. The concentration of BPEI in the BPEI−GO conjugate was determined by measuring the cuprammonium complex formed between BPEI and copper ion(II) at 630 nm using UV−vis spectrophotometry (UV 2550, Shimadzu), and the observed conjugation ratio of BPEI to GO was found to be 22, which is represented as BPEI−GO22. BPEI−GO5 and BPEI−GO8 were also synthesized by following the same procedure described above differing only in the amounts of BPEI1.8K used (0.04 g for BPEI−GO5 and 0.4 g for BPEI−GO8).

The size and morphology of GO and BPEI−GO were investigated with a tapping mode atomic force microscope (AFM, Nanoscope IIIa, Digital Instrument Inc.). A droplet of GO and BPEI−GO dispersion (~0.01 mg/mL) was cast onto a freshly prepared silicon oxide wafer (p-type), which was then dried at 80 °C. The chemical conjugation of BPEI to GO was confirmed by FT-IR spectroscopy (VERTEX70 FT-IR spectrophotometer, Bruker Optics) using a KBr pellet. The colloidal stability of GO, BPEI−GO, and the BPEI/GO mixture was checked by dispersing the samples in water, PBS, and DMEM medium containing 10% FBS for 30 min to 1 h at room temperature.

ζ Potential Measurements. The surface charge of GO, BPEI−GO, and BPEI−GO/pDNA complexes in DPBS buffer (pH 7.4) was confirmed by ζ potential measurements using a Zetasizer Nano Z (Malvern Instruments, Malvern, U.K.). BPEI−GO/DNA complexes were prepared at various N/P ratios [the ratio of concentrations of total nitrogen atoms (N) of BPEI to the phosphate groups (P) of pDNA] (2, 5, 10, and 20) by addition of the BPEI−GO suspension to the pDNA solution in DPBS buffer (pH 7.4). The final pDNA concentration was adjusted to 33 μg/mL. The mixtures were then incubated for 30 min prior to measurement of the ζ potential at room temperature.

Agarose Gel Retardation Assay. Complexes of pDNA with GO, BPEI1.8K, and BPEI−GO were prepared by addition of the sample suspension (10 μL) to the pDNA solution (10 μL) at various N/P ratios ranging from 0 to 50 in DPBS buffer and incubation for 30 min at room temperature. The complexes were then electrophoresed through a 1% (w/v) agarose gel containing ethidium bromide (EtBr, 0.5 μg/mL) in 0.5 TAE (Tris-acetate-EDTA) buffer at 100 V for 20 min. The gel was then analyzed on a UV illuminator (wiseUV WUV, DAIHAN Scientific, Seoul, Korea).

Cell Culture. A human cervical cancer cell line (HeLa) and a human prostate cancer cell line (PC-3) were cultured in a

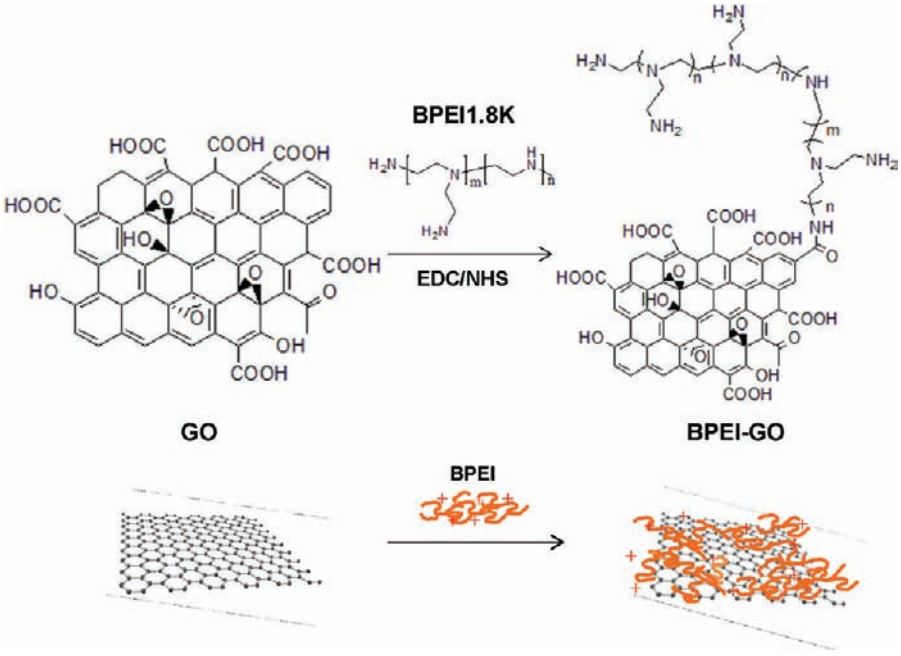

Figure 1. Synthetic scheme of BPEI−GO. BPEI (M_w = 1.8 kDa) was conjugated to the carboxyl groups of GO by EDC/NHS coupling. The dried GO was dispersed in deionized water by sonication for 30 min. EDC and NHS were added to the GO solution. TEA was added to a BPEI solution in deionized water. Subsequently, BPEI was added to the GO solution, and the mixture was stirred for 1 day at room temperature.

humidified atmosphere (5% CO_2) at 37 °C. Dulbecco's modified Eagle's medium (DMEM), Roswell Park Memorial Institute medium (RPMI-1640), penicillin/streptomycin, fetal bovine serum (FBS), and Dulbecco's phosphate-buffered saline (DPBS) were purchased from Invitrogen-Gibco (Carlsbad, CA). The luciferase assay kit and reporter lysis buffer were purchased from Promega, and the bicinchoninic acid (BCA) protein assay reagent kit was purchased from Pierce Chemical Co. (Rockford, IL). Cell viability was estimated by using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (Sigma-Aldrich).

Luciferase Reporter Gene Assay. HeLa and PC-3 cells were seeded on 24-well culture plates at an initial density of 7 × 10^4 cells/well and incubated for 24 h in 500 μL of DMEM or RPMI-1640 containing 10% FBS at 37 °C in a humidified atmosphere with 5% CO_2. Samples (10 μL) were complexed with 2 μg of pDNA (10 μL) at various N/P ratios and incubated for 30 min. The cells were incubated with the complexes (20 μL) in 250 μL of serum-free medium for 4 h and then incubated for 18 h in 500 μL of fresh medium containing 10% FBS. After the cells had been washed with DPBS, lysis buffer was then added to the well (200 μL/well) for lysis of cells. Luciferase reporter gene expression was evaluated using a microplate spectrofluorometer (VICTOR3 V Multilabel Counter, Perkin-Elmer, Wellesley, MA).

Cytotoxicity Assay. The cytotoxicity of complexes was evaluated by the MTT assay. Cells were seeded onto 96-well plates at a density of 1 × 10^4 cells/well and incubated for 24 h. pDNA (0.2 μg/μL) was complexed with the samples at various N/P ratios in DPBS buffer and incubated for 30 min. Complexes were incubated with the cells for 4 h in 100 μL of serum-free medium, followed by further incubation for 20 h in 200 μL of medium containing 10% FBS. Cell medium was replaced with 200 μL of fresh medium and 20 μL of an MTT solution (5 mg/mL) and incubated for an additional 4 h. The medium was then removed, and 150 μL of DMSO was added to the wells to dissolve the internalized purple formazan crystals. An aliquot (100 μL) was taken from each well and transferred to a fresh 96-well plate. The absorption was measured at 570 nm using a microplate spectrofluorometer. The relative percentage of the control cells (nontreated), which were not exposed to the transfection system, was used to represent 100% cell viability.

Photoluminescence Spectrum Study. The photoluminescence (PL) spectrum was recorded with a spectrofluorophotometer (RF-5301PC, SHIMADZU) to obtain the PL profile of BPEI−GO. The PL of BPEI−GO was scanned at various excitation wavelength ranging from 400 to 480 nm, and the λ_{max} excitation was found to be 480 nm. The λ_{max} excitation and λ_{max} emission of BPEI−GO were measured at 480 and 520 nm, respectively.

Confocal Fluorescence Microscopy Study. HeLa cells were seeded at a density of 1 × 10^4 cells/well in a 12-well plate over glass coverslips. Cells were incubated with BPEI−GO/pDNA complexes for a certain period of time at 37 °C. After the cellular uptake had been quenched via addition of cold DPBS, cells were washed twice with cold DPBS and fixed with 4% paraformaldehyde for 30 min at room temperature. Cells on a coverslip were mounted in Vectashield antifade mounting medium with DAPI (Vetor Laboratories), observed with a confocal laser scanning microscope (CLSM), and analyzed with Olympus Fluoview version 1.5.

■ RESULTS AND DISCUSSION

Synthesis and Characterization of BPEI−GO. To construct the GO-based gene delivery vector, LMW BPEI1.8K (M_w = 1.8 kDa) was covalently conjugated to the carboxyl group of GO using EDC/NHS chemistry (Figure 1). The amount of conjugated BPEI in BPEI−GO was analyzed by measuring the UV−vis absorbance of cuprammonium complexes of BPEI−GO at 630 nm, and the estimated conjugation ratios of BPEI to GO were found to be 5, 8, and 22 and were

dx.doi.org/10.1021/bc200397j | Bioconjugate Chem. 2011, 22, 2558−2567

denoted as BPEI−GO5, BPEI−GO8, and BPEI−GO22, respectively (Table 1). The successful conjugation of the carboxyl group of GO and amino group of BPEI was confirmed by FT-IR spectroscopy, which showed the characteristic peak of the amide bond at 1630−1695 cm^{-1}, confirming the reported value (Figure 2). The appearance of the vibration band around 1650 cm^{-1} due to the C═O stretching of the primary amide in BPEI−GO and the disappearance of the carboxylic group bands at 1733 cm^{-1} of pristine GO substantiated the formation of amide linkages. Furthermore, in the case of BPEI−GO, the absence of the band at 1050 cm^{-1} that was observed earlier in GO due to the presence of epoxide moieties clearly established the successful chemical conjugation. However, the band at 1626 cm^{-1} arising due to the C═C vibration of aromatic rings was observed in both GO and BPEI−GO and implied the preservation of the sp^2 character in BPEI−GO after the chemical conjugation.[34,35]

Table 1. Characteristics of the BPEI−GO Conjugate[a]

	reaction condition (equivalent to COOH of GO[b])			BPEI in BPEI−GO[c]		
BPEI−GO	BPEI (equiv)	EDC/NHS (equiv)	GO (mg)	mg	μmol	BPEI:GO conjugation ratio[d] (w/w)
BPEI−GO5	10	20		2.33	1.29	5
BPEI−GO8	10	200	0.5	3.94	2.18	8
BPEI−GO22	100	200		11.07	6.15	22

[a]The reaction was conducted in deionized water. [b]The amount of carboxyl groups of GO was estimated by direct acid−base titration. On the basis of the estimated carboxylic acid content, an excess molar ratio of EDC/NHS and BPEI were added to the GO for GO−BPEI synthesis. [c]The concentration of BPEI in BPEI−GO was determined by measuring the cuprammonium complex formed between PEI and copper(II) at 630 nm using UV−vis spectrophotometry. [d]Conjugation ratios were determined by calculating the weight of BPEI and GO in the BPEI−GO conjugate.

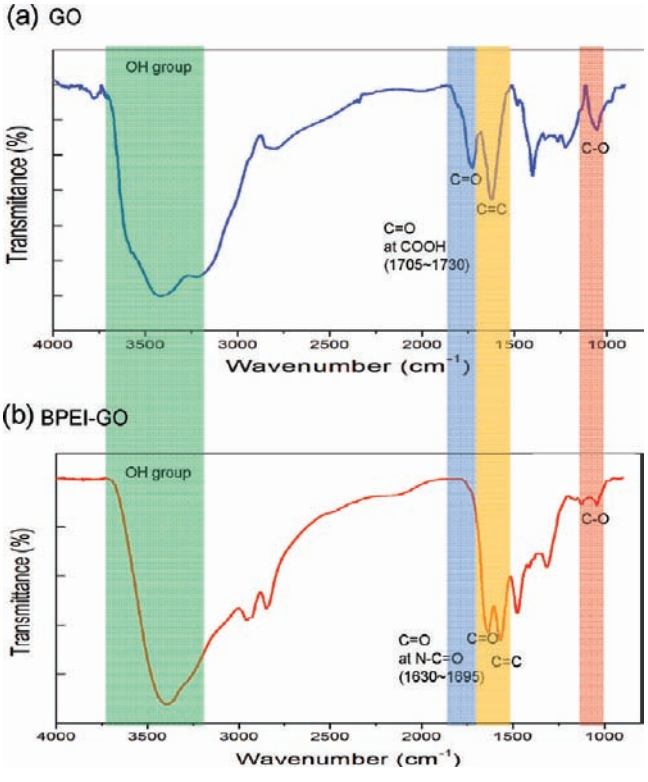

Figure 2. FT-IR spectra of GO (a) and BPEI−GO (b). Conjugation of the carboxyl group of GO and the amino group of BPEI was confirmed by FT-IR spectroscopy, which showed the characteristic peak of the amide bond at 1630−1695 cm^{-1}.

Colloidal property constitutes an important parameter in evaluating the viability of a biomaterial in a biological application. Accordingly, colloidal stability of GO, the BPEI/GO mixture, and the BPEI−GO conjugate was investigated in water, PBS, and 10% serum-containing medium (Figure 3).

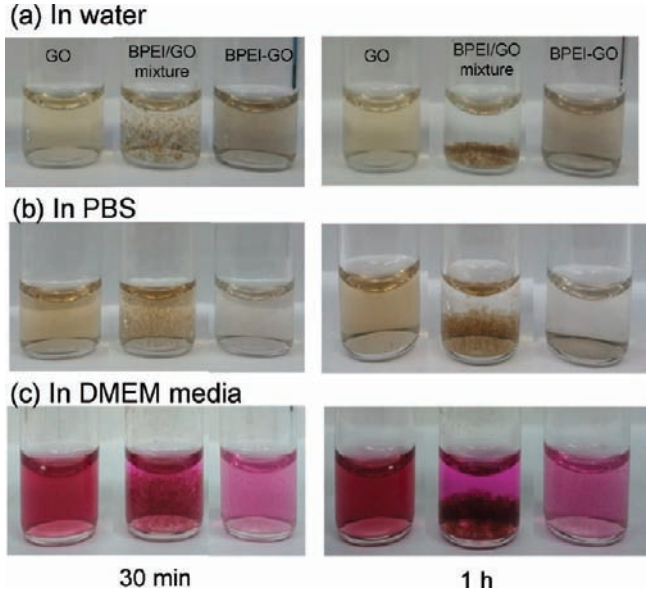

Figure 3. Colloidal stability of GO, the BPEI/GO mixture, and BPEI−GO22 in water (a), PBS (b), and DMEM medium containing 10% FBS (c).

Noticeable aggregation was observed for the BPEI/GO mixture, while no aggregation was observed for unmodified GO or the chemically modified BPEI−GO22 conjugate even after longer incubation times in all types of media under investigation. Such observations could easily be explained considering the charge repulsion phenomenon of colloids. In general, identical charges repel each other to provide colloidal stability. Therefore, negatively charged GO remains in good colloidal stability in solution because of the charge repulsion of GO particles (Figure S2 of the Supporting Information). Likewise, in the case of BPEI−GO, GO was evenly and completely coated with positively charged BPEI and showed excellent colloidal stability even under physiological conditions (10% serum-containing medium). However, colloidal stability was found to be very low for a simple BPEI/GO mixture that contained two oppositely charged molecules and allowed the charge interaction leading to aggregation. The effect of surface charges on colloidal stability was also be corroborated by ζ potential measurements as described later.

The size and morphology of GO and BPEI−GO with various degrees of conjugation was studied by AFM (Figure 4). The

dx.doi.org/10.1021/bc200397j | Bioconjugate Chem. 2011, 22, 2558−2567

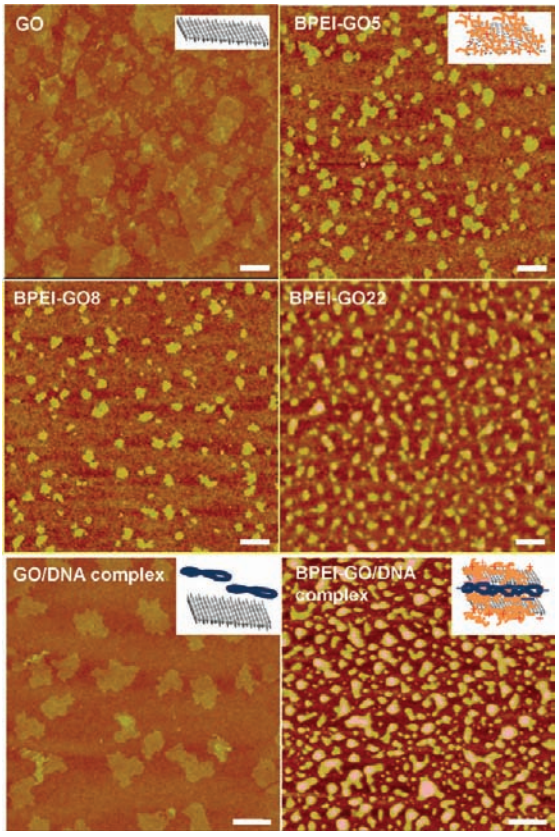

Figure 4. AFM images of GO, BPEI–GO, the GO/DNA complex, and the BPEI–GO/DNA complex. A droplet of GO and BPEI–GO dispersion was cast onto a freshly prepared silicon oxide wafer (p-type), followed by drying at 80 °C. The scale bar is 500 nm.

size of the unmodified GO was found to be 500–600 nm, and a thickness of 0.6–1.3 nm corresponds to one to two layers of GO. Interestingly, the BPEI–GO conjugate showed a reduced size of 100–200 nm and an increased thickness of 6–8 nm. However, the increase in the ratio of the degree of conjugation of BPEI to GO had little effect on the size and thickness of the BPEI–GO conjugates. Then, the effect of complexation with pDNA on the size and morphology of GO and BPEI–GO was investigated by AFM. As expected, complexation of GO with pDNA did not change the size and thickness of GO, which clearly demonstrated the absence of any significant interaction between GO and pDNA. In contrast, the size and thickness of BPEI–GO/pDNA complexes were increased to 300–400 and 16–18 nm, respectively, upon formation of the complex. The reduced size of BPEI–GO compared to that of GO could be attributed to the folding of the GO sheet. During EDC/NHS-mediated conjugation, the primary amine of BPEI not only formed an amide linkage with the carboxylic groups residing at the GO edges but also underwent a ring-opening reaction with the epoxy functionalities at the basal plane of the GO sheets.[36] It could be assumed that the free ends of the conjugated BPEI formed an amide linkage with the carboxylic groups present in the same or other GO sheet leading to the folding and cross-linking of the GO sheets, which resulted in the reduced size and increased thickness arising from the stacking of the GO sheets. The increase in the size and thickness of the BPEI–GO conjugate upon complexation with pDNA could be explained by considering the electrostatic interaction between the negatively charged pDNA and positively charged BPEI–GO conjugates. pDNA was thought to be sandwiched between two BPEI–GO stakes giving rise to the increased thickness. Such vertical stacking might lead to a multilayer structure. Similarly, complexation involving the laterally conjugated BPEI and pDNA might lead to lateral elongation and, hence, the increased size of the BPEI–GO/pDNA complex.

Formation of the Polyelectrolyte Complex and ζ Potential Measurements. It is necessary for an efficient gene carrier to interact with pDNA generally through electrostatic interaction and form a nanosized complex. As described above, unmodified GO does not interact with pDNA and, therefore, cannot form a complex with pDNA. However, GO modified with BPEI should acquire positive surface charge and is expected to interact with pDNA having a negatively charged phosphate backbone. Therefore, in this study, formation of a complex of the gene carrier with pDNA was investigated by agarose gel electrophoresis analysis. As expected, GO did not form a complex with pDNA even at higher N/P ratios of 50 because of its negative charge, while BPEI underwent complete complexation with pDNA at a low N/P ratio of 5 (Figure 5a). Although BPEI–GO5 having a lower conjugation ratio formed complexes with N/P ratios of

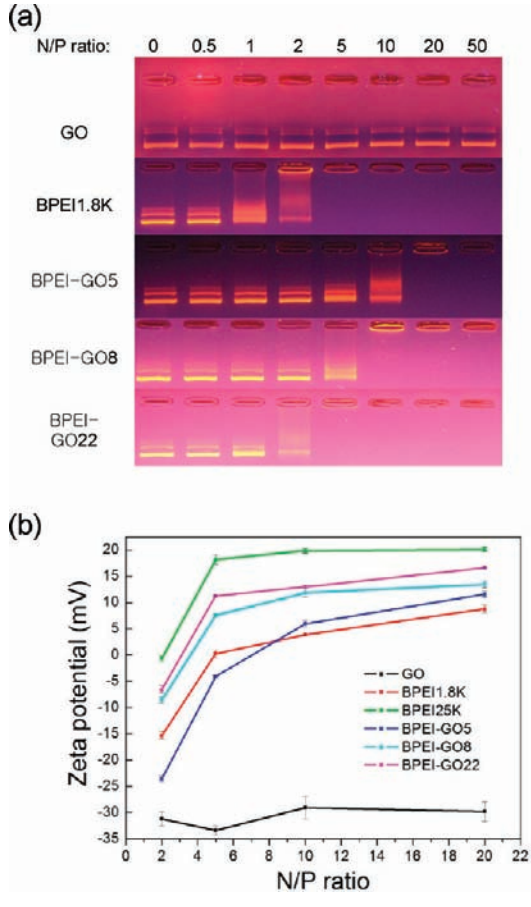

Figure 5. Agarose gel retardation study (a) and ζ potential measurements (b) of pDNA complexed with GO, BPEI1.8K, and BPEI–GO conjugates at various N/P ratios. (a) Complexes of pDNA with GO, BPEI1.8K, and BPEI–GO conjugates were electrophoresed through a 1% (w/v) agarose gel and then analyzed with a UV illuminator. (b) The final pDNA concentration for ζ potential measurement was adjusted to 33 μg/mL. The complexes were then incubated for 30 min prior to the measurement of ζ potential at room temperature.

dx.doi.org/10.1021/bc200397j | Bioconjugate Chem. 2011, 22, 2558–2567

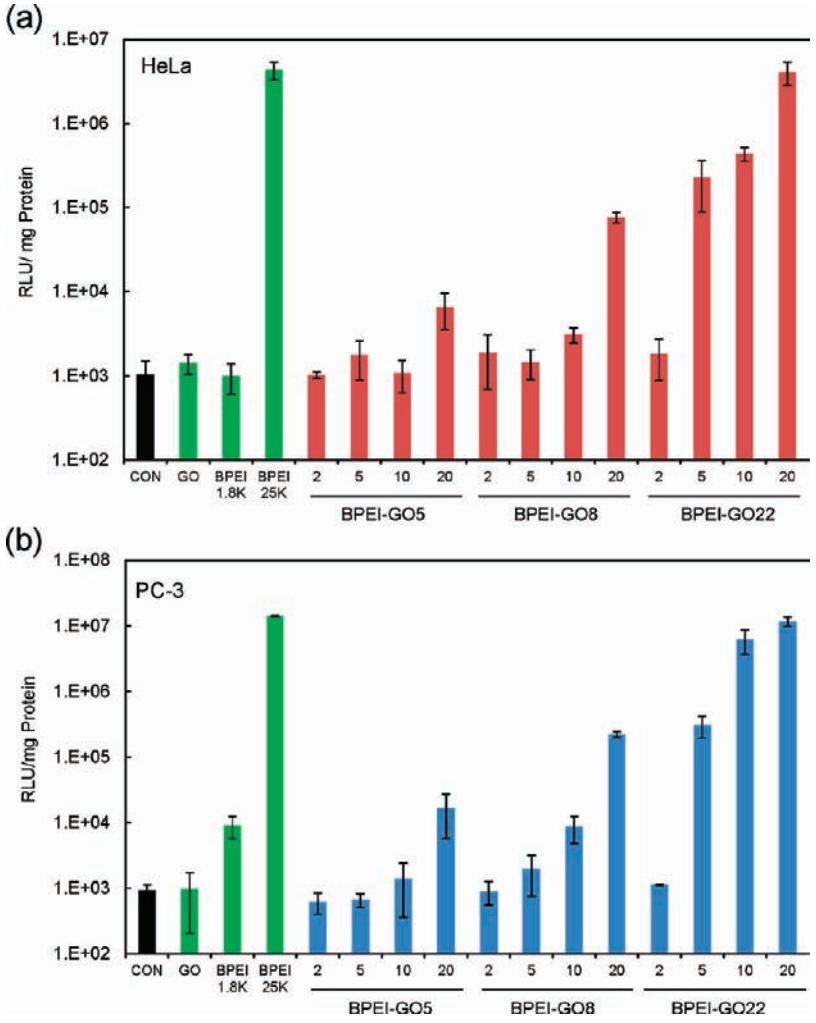

Figure 6. Transfection of GO, BPEI (1.8K and 25K), and BPEI−GO conjugates at predetermined N/P ratios in HeLa (a) and PC-3 (b) cell lines. Cells were seeded on 24-well culture plates at an initial density of 7×10^4 cells/well. The cells were incubated with the complexes in 250 μL of serum-free medium for 4 h and then incubated for 18 h in 500 μL of fresh medium containing 10% FBS. After the cells had been washed with DPBS, lysis buffer was then added in the well (200 μL/well) for lysis of cells. Luciferase reporter gene expression was evaluated using a microplate spectrofluorometer.

>10, the complexation ability of BPEI−GO5 was found to be weaker than that of unmodified BPEI, which might stem from the interfering effect of negatively charged GO through the disruption of the ionic interaction of BPEI and pDNA. The complexation ability of BPEI−GO conjugates with pDNA was enhanced with an increase in conjugation ratios because of the multivalent effect of BPEI−GO. Therefore, conjugation of positively charged BPEI to negatively charged GO ensured that BPEI−GO formed a nanosized complex with pDNA.

Along with complex formation ability, the surface charge of the nanocomplex governs the cellular uptake and transfection ability of the complex. Therefore, the surface charge of the nanocomplex was studied by ζ potential measurement (Figure 5b and Figure S2 of the Supporting Information). Over the entire range of N/P ratios, GO shows a negative ζ potential value, which clearly demonstrated its inability to form a complex with DNA. HMW BPEI25K forms a complex with pDNA at low N/P ratios and shows the highest positive value of ζ potential, while LMW BPEI1.8K has a lower ζ potential. BPEI−GO8 and BPEI−GO22 exhibited considerably higher positive ζ potentials than LMW BPEI1.8K. However, these complexes showed positive surface charges lower than that of HMW BPEI25K, and it was considered to be advantageous for BPEI−GO conjugates as the excessively high positive charge of HMW BPEI25K induced higher cytotoxicity. The positive surface charge and stable polyelectrolyte complex formation of BPEI−GO tend to interact favorably with the negatively charged cell surface, thereby facilitating efficient cellular uptake.

Gene Transfection Study. To investigate the immense potential of BPEI−GO as an efficient gene carrier, we performed the luciferase gene expression assays in HeLa and PC-3 cells. The transfection efficiency was evaluated for GO, BPEI25K, BPEI1.8K, and BPEI−GO complexes at various N/P ratios. Unmodified GO and LMW BPEI1.8K showed negligible gene transfection, but HMW BPEI25K showed stronger gene transfection ability, which is considered a gold standard in nonviral gene delivery carriers (Figure 6). Overall, the level of gene transfection was increased with an increase in the N/P ratio and conjugation ratio of BPEI to GO as shown in Figure 6. BPEI−GO22 showed considerable gene transfection even at an N/P ratio of 5. At N/P ratios of 10 and 20, transfection was comparable to that of BPEI25K in both types of cells (HeLa and PC-3). This observation of the strong gene transfection ability of BPEI−GO22 might be due to the multivalent effect of

dx.doi.org/10.1021/bc200397j | *Bioconjugate Chem.* 2011, 22, 2558−2567

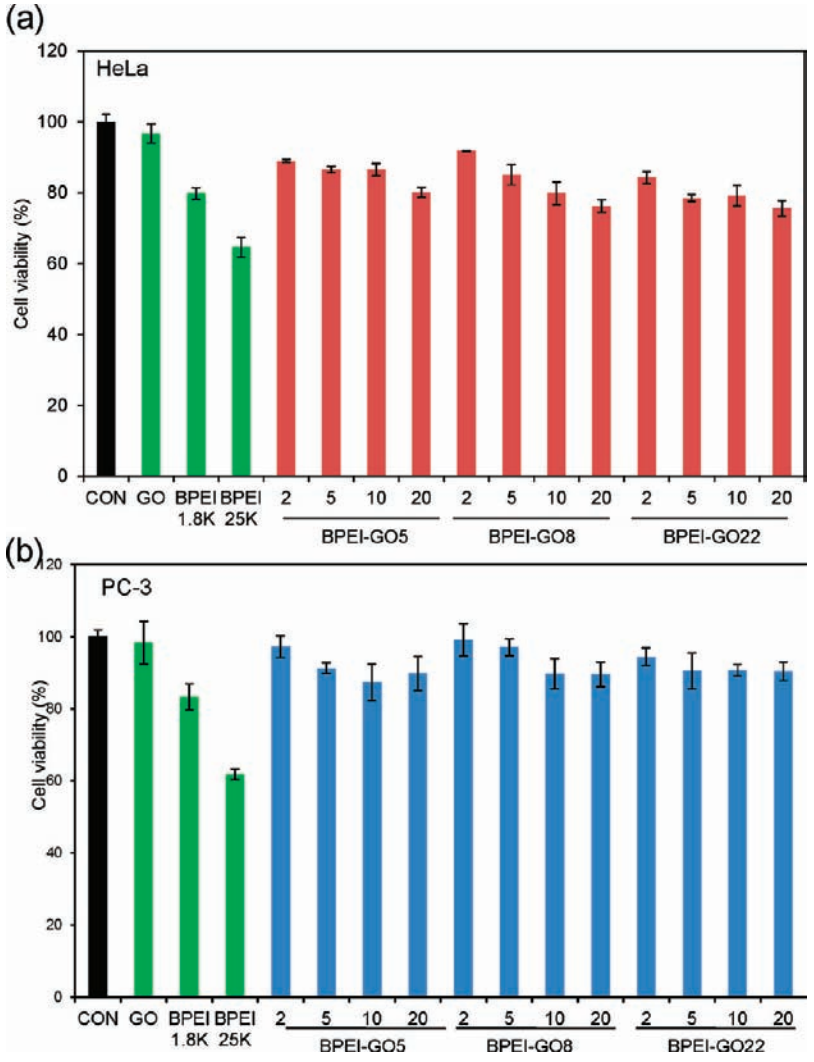

Figure 7. Cell viability profile of GO, BPEI (1.8K and 25K), and BPEI−GO conjugates at predetermined N/P ratios in HeLa (a) and PC-3 (b) cell lines. Cells were seeded onto 96-well plates at a density of 1×10^4 cells/well and incubated for 24 h. Complexes were incubated with the cells for 4 h in 100 μL of serum-free medium, followed by further incubation for 20 h in 200 μL of medium containing 10% FBS. Cell medium was replaced with 200 μL of fresh medium and 20 μL of an MTT solution (5 mg/mL) and incubated for an additional 4 h. The relative percentage of the control cells (nontreated), which were not exposed to the transfection system, was used to represent 100% cell viability.

LMW BPEI1.8K conjugated to the GO, which is favorable for formation of a stable polyelectrolyte complex with pDNA and highly positive surface charge. Though BPEI25K was considered as the gold standard in transfection, significant cytotoxicity of BPEI25K should be considered carefully before use. Therefore, the cell toxicity of all gene carriers was investigated with an MTT assay.

Cytotoxicity Assay. The cytotoxicity of GO, BPEI1.8K, BPEI25K, and BPEI−GO conjugates was studied by an MTT assay. As shown in Figure 7, GO did not show cell toxicity in HeLa cells. BPEI1.8K shows 80% cell viability; however, 40% of the cells were found to be dead in HMW BPEI25K-transfected cells. In the case of BPEI−GO, cell toxicity is increased slightly with an increase in N/P ratio, but BPEI−GO maintained >80% cell viability at all N/P ratios. Similar results were observed for PC-3 cells. Although HMW BPEI25K showed a high gene transfecion efficiency, its high cell toxicity rendered it less encouraging for practical application. However, BPEI−GO complexes demonstrated high transfection efficiency without inducing significant cytotoxicity. The low cytotoxicity of BPEI−GO can be attributed to the low cytotoxic character of LMW BPEI, which was retained in BPEI−GO even after conjugation with GO.[26−29] This implies the great potential of BPEI−GO as a nonviral gene delivery carrier with low toxicity.

Photoluminescence Study. The excellent optical property of GO makes it a very enticing agent in bioimaging and fluorescence-assisted cellular uptake tracking. In this study, we investigated the optical property of GO and BPEI−GO by UV−vis absorbance and PL spectroscopy. GO and BPEI−GO both exhibited UV−vis absorbance over a wide range of wavelengths, though the absorbance of BPEI−GO was found to be higher than that of GO (Figure 8a). The difference in absorbance could be rationalized on the basis of the accompanied surface modification during amidation and ring opening amination of epoxy moieties leading to the reduction of GO after conjugation of BPEI to GO, which is in good accordance with other reports.[37,38] The λ_{max} excitation and λ_{max} emission of BPEI-GO were found to be 480 and 520 nm, respectively (Figure 8b). Though the PL of GO and the BPEI/GO mixture was negligible, BPEI−GO displayed a significant increase in PL when excited at 480 nm; however, a further steep increase in PL intensity was observed when BPEI−GO

dx.doi.org/10.1021/bc200397j | Bioconjugate Chem. 2011, 22, 2558−2567

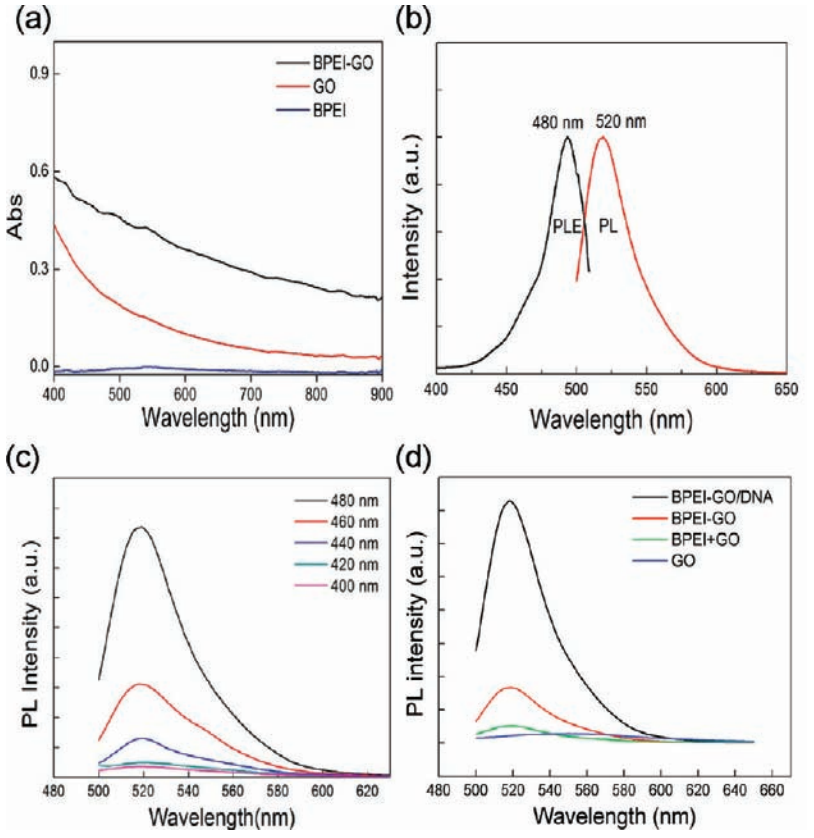

Figure 8. (a) UV−vis absorption spectrum of GO, BPEI, and BPEI−GO in water (0.01 mg/mL). (b) BPEI−GO photoluminescence excitation (PLE) spectrum with a detection wavelength of 480 nm and BPEI−GO PL spectrum excited at 480 nm. (c) BPEI−GO PL spectrum in water recorded for progressively longer excitation wavelengths from 400 to 480 nm in 20 nm increments. (d) PL spectrum of the BPEI−GO/DNA complex, BPEI−GO, the BPEI/GO mixture, and GO in water (0.01 mg/mL).

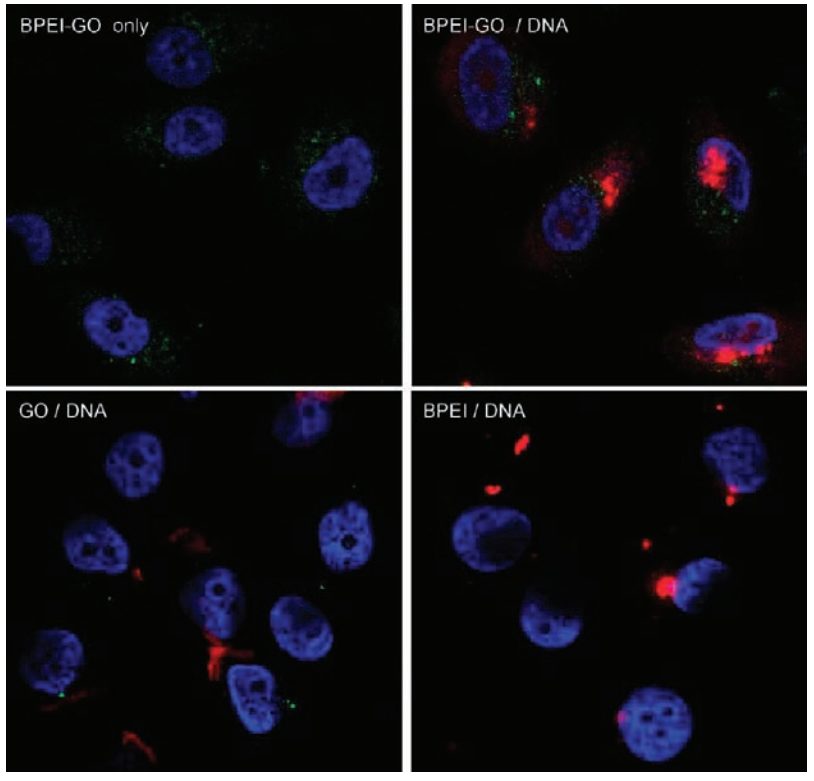

Figure 9. Confocal fluorescence microscopic images of a PC-3 cell line treated with BPEI−GO, DNA complexes with BPEI−GO, GO, and BPEI. pDNA was labeled with TOTO-3, and nuclei were stained with DAPI; a 488 nm laser was then applied to observe PL.

dx.doi.org/10.1021/bc200397j | *Bioconjugate Chem.* 2011, 22, 2558−2567

formed a complex with pDNA (Figure 8d). Both GO and BPEI−GO absorbed light over a wide range of wavelengths (Figure 8a), but GO displayed considerably low emission that could be attributed to the nonradiative emission of GO arising due to the presence of a carboxylic group and an epoxy group.[33] On the other hand, the conjugation of BPEI to GO effectively restored the conjugated aromatic clusters and suppressed the nonradiative emission of GO through nucleophilic binding of BPEI to the carboxylic group and the epoxy group of GO. At the same time, the ionic interaction between BPEI and GO adversely affected the PL; however, the combined effects gave rise to an overall increase in the PL intensity of BPEI−GO compared to that of GO. After incorporation of pDNA, BPEI preferentially formed a complex with pDNA and induced recovery of the PL intensity of BPEI−GO that was partially lost due to the ionic interaction between GO and BPEI.[39] The observed facts certainly prove the potential of BPEI-GO as a good emitter by reduction of nonradiative emission and induction of radiative emission.

Bioimaging Study. To evaluate the potential of BPEI−GO as a bioimaging reagent, we conducted the transfection studies of GO and BPEI−GO with or without pDNA complexation and tracked the movement of the complexes during the transfection using confocal microscopy (Figure 9 and Figure S3 of the Supporting Information). To visualize the movements of complexes, pDNA was labeled with TOTO-3 and nuclei were stained with DAPI, and then a 488 nm laser was applied to observe PL. No green PL was observed when GO and BPEI were employed alone, which was in accordance with a previous PL spectroscopy study. However, significant green fluorescence of BPEI−GO was observed after transfection into the cells, which confirmed the distribution of BPEI−GO in the cytosol. In addition, when the BPEI−GO/pDNA complex was transfected into cells, not only green fluorescence but also red fluorescence of pDNA was observed in cells, which demonstrated the efficacy of the developed dual-labeled complex in providing information regarding the location of BPEI−GO and pDNA. Therefore, these results clearly illustrate the potential of the BPEI−GO nanoconstruct as a bioimaging reagent.

CONCLUSION

In conclusion, to develop GO as an efficient gene carrier, it was imperative to conjugate a cationic gene carrier to GO as unlike ssDNA, dsDNA could not be loaded on GO through $\pi-\pi$ stacking interaction. Our work demonstrated the successful fabrication of GO through covalent linkage with LMW BPEI, which acted as a cationic gene carrier. It was confirmed that BPEI−GO possessed high gene delivery efficiency and exhibited high cell viability. Furthermore, the PL properties of GO were enhanced through conjugation of BPEI to GO, which advocated the immense potential of BPEI−GO as a fluorescence reagent. This highly efficient gene delivery and the excellent photoluminescence activities of the GO-based nanoconstruct will definitely merit further attention in the development of more sophisticated carrier systems that could serve both as a gene delivery vector and as a bioimaging tool. There are a few reports that demonstrated the fabrication of carbon nanotube-based nanomaterials and their enhanced efficiency in siRNA delivery[40] as well as in photothermal therapeutic applications.[41] Considering the extremely high transfection efficiency comparable to that of HMW BPEI and the high cell viability, its application could be extended to siRNA delivery, drug delivery, and photothermal therapy by installing further functional and structural attributes such as enhancing dispersibility through pegylation.

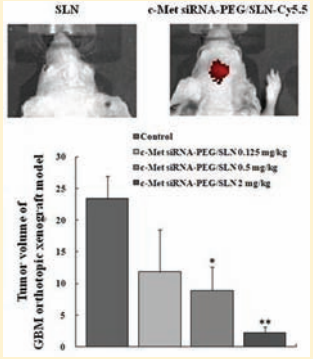
ABSTRACT: RNA interference is a powerful strategy that inhibits gene expression through specific mRNA degradation. *In vivo*, however, the application of small interfering RNAs (siRNAs) is severely limited by their instability and their poor delivery into target cells and tissues. This is especially true with glioblastomas (GBMs), the most frequent and malignant form of brain tumor, that has limited treatment options due to the largely impenetrable blood-brain barrier. Here, cationic solid lipid nanoparticles (SLN), reconstituted from natural components of protein-free low-density lipoprotein, was conjugated to PEGylated c-Met siRNA. The c-Met siRNA-PEG/SLN complex efficiently down-regulated c-Met expression level, as well as decreased cell proliferation in U-87MG *in vitro*. In orthotopic U-87MG xenograft tumor model, intravenous administration of the complex significantly inhibited c-Met expression at the tumor tissue and suppressed tumor growth without showing any systemic toxicity in mice. Use of Cy5.5 conjugated SLN revealed enhanced accumulation of the siRNA-PEG/SLN complexes specifically in the brain tumor. Our data demonstrates the feasibility of using siRNA-PEG/SLN complexes as a potential carrier of therapeutic siRNAs for the systemic treatment of GBM in the clinic.



INTRODUCTION

Glioblastoma multiforme (GBM) is a very aggressive brain tumor, and the prognosis of patients with GBMs remains poor despite multidisciplinary treatment approaches, such as surgical resection, radiotherapy, and chemotherapy. Furthermore, GBM is particularly difficult to treat because the brain is endowed with a uniquely privileged immune environment by the blood-brain barrier (BBB). To date, the BBB remains largely impenetrable by the existing oncology drugs,[1] necessitating the development of novel delivery methods for treating GBM.

Toward this end, we previously developed a novel solid lipid nanoparticle (SLN) that can serve as a good carrier of cancer cell targeting moieties.[2] In particular, the SLNs were designed to carry small interfering RNAs (siRNAs). Use of siRNAs has been long-desired, because it can specifically silence oncogenes that control proliferation, apoptosis, angiogenesis, or migration of the tumor cells.[3] However, its application in the clinic has been limited due to its poor stability in biological fluids and nonspecific cellular uptake.[4−6] We overcame these issues by conjugating the siRNAs with poly(ethylene glycol) (PEG) and by mimicking naturally occurring low-density lipoprotein complexes that are common in bodily fluids[7] using poly-ethylenimine (PEI) to form nanoscale polyelectrolyte complex micelles *in vitro*.[2] This would now allow *in vivo* systemic administration of siRNA-based therapy possible, and the question remains whether the siRNA-PEG/SLN can also be effective in crossing the BBB.

Here, we report an orthotopic human brain tumor mouse model using the siRNA-PEG/SLN delivery system to evaluate its penetration across the BBB to the tumor site. Systemic intravenous administration of the SLN successfully and specifically delivered the siRNA to the tumor and lowered the tumor cell proliferation and tumorigenicity.

MATERIALS AND METHODS

Materials. Cholesterol hydrochloride (Chol), L-α-dioleoyl phosphatidylethanolamine (DOPE), and 3β-[*N*-(*N*′,*N*′-dimethylaminoethane)-carbamoyl]-cholesterol (DC-Chol) were obtained from Avanti Polar Lipids (Alabaster, AL). Cholesteryl oleate and glyceryl trioleate were purchased from Sigma-Aldrich (St. Louis, MO). All other chemicals were of analytical reagent grade.

Synthesis of Cationic Solid Lipid Nanoparticles (SLN). Cationic solid lipid nanoparticles (SLNs) were produced by a modified emulsification-solvent evaporation method, as reported previously.[2] Briefly, cholesteryl oleate (22.5 mg), glyceryl trioleate (1.5 mg), DOPE (7 mg), Chol (5 mg), and DC-Chol (14 mg) were codissolved in 2 mL of chloroform/methanol mixture (2:1, v/v). After 10 mL of deionized water was added, the mixture was vortexed for 2 min and subsequently sonicated for 5 min using a Bronson Sonifier 450 equipped with a microtip (20 kHz, duty cycle = 35, output control = 3.5). The resulting emulsion was transferred to a round-bottom flask and then the solvent was rapidly evaporated at 60 °C at 20 mmHg using a rotary evaporator (EYELA, Japan). The produced SLNs were purified by extensive dialysis against deionized water (M_w cutoff of 100 kDa).

Formation of siRNA-PEG/SLN Complexes. An siRNA targeting human c-Met (sense; 5′-GUGCAGUAUCCUCUGA-CAGUU-(CH2)6 NH2−3′, antisense; 5′-CUG UCA GAG GAU ACU GCA CUU-3′) and a nontargeting (NT) siRNA (sense; 5′-GUUCAGCGUGUCCGGCGAGTT-(CH2)6-NH2−3′, antisense; 5′-CUCGCCGGACACGCUGCU-GAACTT-3′), both modified with 3′-hexylamine on the sense strand, were obtained from Samchunlly Inc. siRNA was conjugated with PEG through a disulfide bond as described previously.[8] SLN was incubated with siRNA-PEG conjugate at room temperature for 15 min in deionized water. To minimize interference from autofluorescence in *in vivo* imaging studies, siRNA-PEG/SLN complex was labeled with near-infrared Cy5.5. The diameter and surface zeta-potential were measured using a dynamic light scattering (DLS) instrument (Zeta-Plus, Brookhaven Instrument Co., NY) as described previously.[2] The SLN was observed by atomic force microscopy (AFM; PSIA XE-100, Park Systems, Santa Clara, CA) and transmission electron microscopy (TEM; Zeiss Omega 912, Carl Zeiss, Oberkochen, Germany).

Cell Culture and Transfection. U-87MG human GBM cells (ATCC) were grown in EMEM supplemented with 10% FBS, 2 mM L-glutamine, penicillin (100 units/mL), and streptomycin (100 μg/mL). For siRNA-PEG/SLN transfection, c-Met expressing U-87MG ells were plated on a 6-well plate at a density of 2.5×10^5 cells/well. After 24 h of incubation, the medium was replaced by fresh medium containing 0.5% FBS and 20 nM NT or 40 nM c-Met siRNA-PEG/SLN complexes were added to the cells. After 6 h incubation at 37 °C, the transfection medium was discarded and supplemented with medium containing 0.5% FBS. After an additional 24 h of incubation, the cells were harvested for Western blotting.

Western Blotting. Cell lysates were prepared from transiently transfected U-87MG cells by scraping 90% confluent 10 cm dishes into NP40 Cell Lysis Buffer (50 mM Tris, pH 7.4, 250 mM NaCl, 5 mM EDTA, 50 mM NaF, 1 mM Na_3VO_4, 1% NP40, 0.02% NaN_3) (Invitrogen Corporation, Camarillo, CA) containing protease inhibitor cocktail tablets (Roche, Laval, QC). The protein concentrations were determined using the Bradford protein assay (Bio-Rad Laboratories, Inc., Hercules, CA) according to the manufacturer's directions. Proteins were separated by SDS-PAGE, transferred onto PVDF membrane (GE Healthcare, Piscataway, NJ), and immunoblotted with primary antibodies overnight at 4 °C. A rabbit polyclonal antibody raised against a C-terminal cytoplasmic domain of human c-Met (1:200; Abcam, San Francisco, CA) was used. A mouse monoclonal antibody against β-actin (1:5000; Sigma, Saint Louis, MO) was used for the internal control. Bound antibodies were detected using horse radish peroxidase-conjugated goat antirabbit IgG (1:5000, Invitrogen) or goat antimouse IgG (1:5000, Zymed, San Francisco, CA) and were visualized via enhanced chemiluminescence (GE Healthcare).

In Vitro Proliferation Analysis. Cells were seeded at a density of 0.5×10^4 cells/well in 96-well plates and were transfected with NT or c-Met siRNA-PEG/SLN as described above. After transfection, cells were treated with 200 ng/mL of HGF for 24 h, 48 h, 72 h, or 96 h. Cell proliferation was quantified using Cell Counting Kit-8 (CCK-8) (Dojindo Molecular Technology, Gaithersburg, MD, USA), which assays cellular mitochondrial dehydrogenase activity as a measure of cell viability.

GBM Orthotopic Model and siRNA Treatment. Animal experiments were approved by the appropriate Institutional Review Boards of the Samsung Medical Center (Seoul, Korea) and conducted in accord with the "National Institute of Health Guide for the Care and Use of Laboratory Animals" (NIH publication no. 80−23, revised in 1996). For orthotopic GBM animal model, anesthetized 6-week-old male Balb/c-nu mice were secured in a rodent stereotactic frame, a hollow guide screw was implanted into a small drill hole made at 2 mm left and 1 mm anterior to the bregma, and 2×10^5 U-87MG cells in 5 μL HBSS were injected through this guide screw into the white matter at a depth of 2 mm [anterior/posterior (AP) +0.5 mm, medial/lateral (ML) +1.7 mm, dorsal/ventral (DV) −3.2 mm]. Two weeks after tumor cell implantation, mice were randomized into four groups (n = 7 for each group) and were given intravenous injection of SLN alone (control), 0.125 mg/kg, 0.5 mg/kg, or 2 mg/kg of c-Met siRNA-PEG/SLN complex intravenously three times once a week (Figure 3A). Brains were harvested and processed for paraffin embedding at six hours after the final injection.

For tumor mass volume quantification, standard H&E staining was performed in the paraffin sections and observed under optical microscope. The tumor volume was calculated by measuring the section with the largest tumor portion and applying the formula: $(\text{width})^2 \times \text{length} \times 0.5$. The c-Met expression in tumor was determined by immunohistological staining using mouse antihuman c-Met monoclonal antibody (Zymed). Peroxidase-conjugated secondary antibodies were used and visualized by incubating the slides with stable 3,3′-diaminobenzidine (DAB) for 10−20 min. The sections were rinsed with distilled water, counterstained with Gill's hematoxylin for 1 min, and mounted with Universal Mount (Research Genetics, Huntsville, AL).

In Vivo Quantification of c-Met siRNA-PEG/SLN Tumor-Tropism into the Brain. To evaluate tumor targeting of c-Met siRNA-PEG/SLN complex in U-87MG tumor-bearing mouse, siRNA-PEG/SLN complex conjugated with Cy5.5 was utilized. Three weeks after tumor cell implantation, mice were randomized into two groups (n = 3 for each group) and were given single intravenous injection of SLN alone (control) or 0.5 mg/kg c-Met siRNA-PEG/SLN-Cy5.5 complex (Figure 4A). Two days after injection, the mice were anesthetized with 2−3% isoflurane. The signal from Cy5.5 was detected in the region of the brain using a prototype Xenogen IVIS Spectrum *in vivo* imaging system (Caliper Life Science). Fluorescence intensity was analyzed as photons per second (p/s) by *Living Image 3.1* software (Caliper Life Science).

RESULTS AND DISCUSSION

Although siRNA is a promising nucleic acid drug in gene therapy, various intra- and extracellular barriers hamper therapeutic applications. Negatively charged siRNAs have extremely low cellular uptake and transfection efficiency, and undergo rapid chemical degradation when administered intravenously. To overcome the in vivo stability problem of siRNA, we report here a new delivery system for siRNAs that can readily cross the BBB for a targeted therapy of GBM. We chose to target c-Met, since its overexpression is associated with poor prognosis and invasiveness of tumors in GBM patients,[9] and we demonstrate that c-Met siRNA treatment can successfully attenuate GBM tumor growth in vivo.

Synthesis and Characterization of siRNA-PEG/SLN Complex. Our RNAi delivery system is based on the formation of SLN complex with PEGylated siRNA. PEGylated

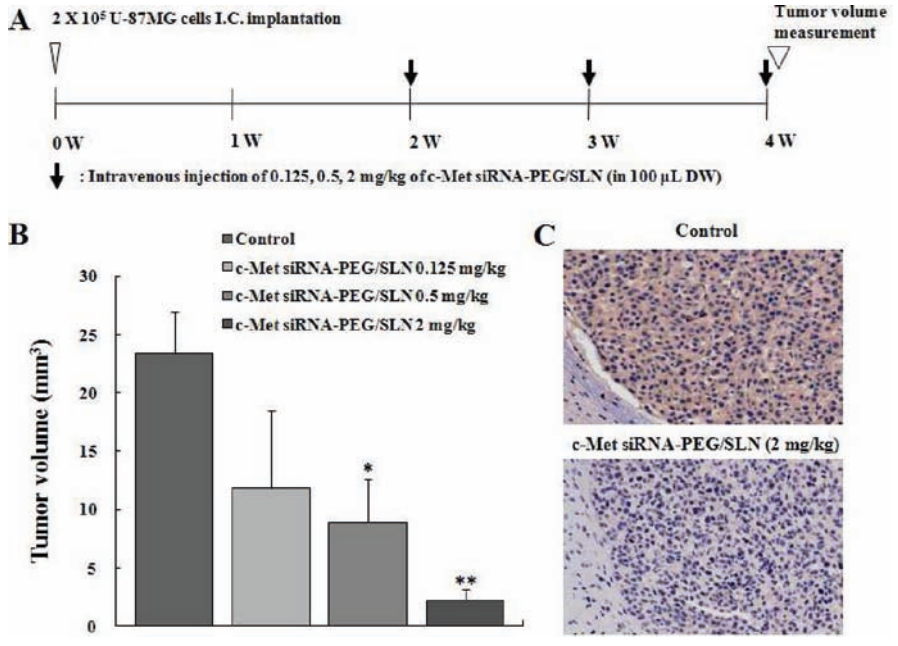

Figure 3. *In vivo* c-Met targeting in xenograft tumor. (A) The timeline for the assessment of in vivo antitumor activities of c-Met siRNA-PEG/SLN complex in an orthotopic xenograft model. (B) c-Met siRNA-PEG/SLN complex reduced U-87MG tumor volumes in a dose-dependent manner. Data are expressed as the mean ± SE. (C) Representative microphotographs of immunohistochemistry determining c-Met expression in the brains of control siRNA or c-Met siRNA treated mice. Immunopositive cells were visualized by brown DAB staining. Values are mean ± SEM $*p < 0.05$, $**p < 0.01$, vs Control.

c-Met siRNA or NT siRNA was conjugated with SLN at room temperature in deionized water. The mean diameter of SLN as measured by laser light scattering was 117.4 ± 11.7 nm (Figure 1A), and the zeta potential value of SLN was 37.3 ± 2.3 mV, indicating good stability of the complex (Figure 1B). The TEM (Figure 1C) and AFM (Figure 1D) observations confirmed the size and the spherical shape of the SLN. We demonstrated previously the ability to target the delivery of siRNA-PEG complex specifically to cancer cells in vitro.[2] Here, we show for the first time that these SLN could be utilized as nontoxic, serum-stable, and highly effective carriers for delivery of siRNA specifically to tumor site in vivo.

c-Met siRNA-PEG/SLN Complex Down-Regulates c-Met Protein and Tumor Cell Proliferation. To establish the efficacy and specificity of this targeting method, we used U-87MG glioblastoma cell lines positive for expression of c-Met. The c-Met siRNA-PEG/SLN complex exhibited profound inhibition extent of c-Met expression (32.5 ± 1.9% reduction, as compared to the no treatment control) than the NT siRNA-PEG/SLN complex (2.9 ± 3.0% reduction, as compared to the no-treatment control) ($P < 0.01$; Figure 2A). In the proliferation assay, treatment with the c-Met siRNA-PEG/SLN complex significantly reduced tumor cell proliferation in a dose dependent manner; 20 nM and 40 nM groups showed 13.1% and 23.4% tumor cell proliferation reduction, respectively, compared with NT siRNA-PEG/SLN complex group. No such reduction was observed with the NT siRNA-PEG/SLN complex compared to the control (Figure 2B). These results indicate that our c-Met siRNA-PEG/SLN complex specifically reduces proliferation of glioblastoma cells by controlling the expression of c-Met in vitro.

Antitumor Effects of c-Met siRNA-PEG/SLN Complex in a Glioma Xenograft Orthotopic Model. The antitumor effects of systemic administration of c-Met siRNA-PEG/SLN complex were evaluated by giving intravenous injection of the complex in U-87MG orthotopic models. Two weeks after tumor cell implantation, mice were randomized into four groups ($n = 7$ for each group) and were given intravenous injection of SLN alone (control), 0.125 mg/kg, 0.5 mg/kg, or 2 mg/kg of c-Met siRNA-PEG/SLN complex intravenously three times once a week (Figure 3A). The tumor volumes were determined at the day of last c-Met siRNA-PEG/SLN complex injection. Treatment with c-Met siRNA-PEG/SLN complex significantly inhibited U-87MG tumor growth in a dose-dependent manner; 0.125 mg/kg, 0.5 mg/kg, and 2 mg/kg groups showed 50%, 62%, and 91% tumor volume reduction, respectively, compared with the control group ($*P < 0.05$ and $**P < 0.01$ vs control, Figure 3B). Immunohistochemical staining of the tumor sections demonstrated that there was a down-regulation of c-Met with c-Met siRNA-PEG/SLN complex administration (Figure 3C). These results indicate that a SLN-based siRNA delivery system can overcome the current problems facing siRNA therapy. Here, we showed that GBM tumor volume reduction can be effectively achieved via RNAi-mediated down-regulation of c-Met. More importantly, we show that the SLN complex employed here allows for a systemic in vivo application of c-Met siRNAs in glioblastoma orthotopic models that can effectively control tumor growth. It should be noted that no significant difference in body weight changes was observed between mice with and without treatment of siRNA-PEG/SLN complex during the indicated experimental period (data not shown). This suggests that there was no apparent critical systemic toxicity caused by the formulations.

c-Met siRNA-PEG/SLN Complex Can Cross the Blood-Tumor Barrier and Specifically Target the Tumor Site. To investigate the in vivo BBB-permeability of the c-Met siRNA-PEG/SLN complex, we intravenously administered Cy5.5-labeled c-Met siRNA-PEG/SLN complex to mice bearing the U-87MG tumor (Figure 4A). At 48 h postinjection,

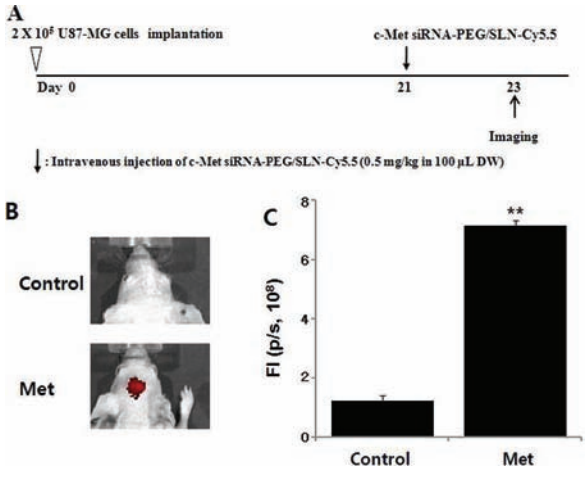

Figure 4. *In vivo* optical imaging of c-Met siRNA-PEG/SLN complex in tumor-bearing mice. (A) Detailed experimental schedules using the glioblastoma animal model are illustrated. (B) Distribution of Cy5.5-labed c-Met siRNA-PEG/SLN complex in brain bearing glioblastoma cells was visualized by *in vivo* fluorescent optical imaging. (C) Fluorescence intensity (FI) was analyzed. Values are mean ± SEM $^{**}p < 0.01$ vs Control.

Cy5.5-labeled c-Met siRNA-PEG/SLN complex showed higher fluorescence intensity in the brain compared to the no-treatment control (Figure 4 B,C). Grzelinski et al.[10] previously reported a similar delivery system of gene silencing but with local intratumor injection of siRNA/polyethlenimine complex in subcutaneous U-87MG model. Our work illustrates an improved delivery system that is effective even with systemic intravenous administration of the RNAi/nanoparticle complex in an orthotopic model. We speculate that siRNA-based therapy in orthotopic models may have been difficult to evaluate in the past due to the difficulty of delivery across the BBB. The system employed here showed that the siRNA-PEG/SLN can specifically cross the BBB to the tumor site (Figure 4) with no apparent systemic toxicity. This is highly significant since it provides proof-of-concept that in vivo diagnostics can also be a potential future application of the technology employed here. Caution should be taken by noting that the mice model used here lacks an intact immune system, so the innate immune response to RNAi will need to be addressed in future studies. Nevertheless, the tumor-tropic delivery of siRNAs across the BBB and the outstanding tumor volume reduction achieved by our system provide great promise for a clinical application in the near future.

CONCLUSIONS

Here, we present the SLN complexed with siRNAs as a viable platform for RNAi-based gene targeting, providing clinical rationale for the use of siRNAs against optimal targets of a given tumor. Specifically for GBM, we introduce SLN-complexed, c-Met-specific siRNAs as an efficient tool for attenuating tumor growth *in vitro* and *in vivo*. There was a successful tumor control via intravenous administration of the siRNA complex in the orthotopic GBM xenograft tumor model, along with specific tumor-tropic localization of the SLN per *in vivo* imaging. The model described here indicates that this approach is a highly feasible novel therapeutic option for GBM in the clinic.

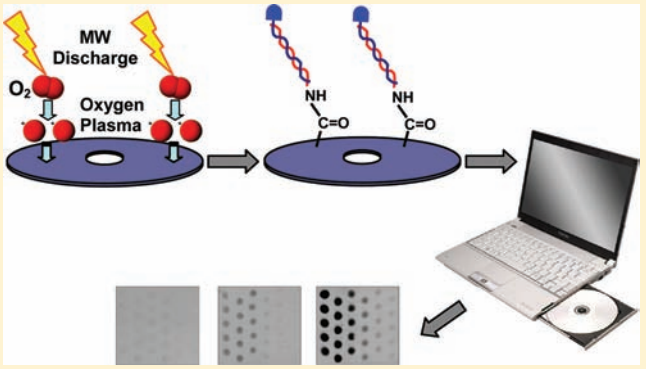
Supporting Information

ABSTRACT: A novel DNA microarrying platform based on oxygen plasma activation of polycarbonate surface of compact disks (DVD) is presented. Carboxylic acid groups are generated in few seconds on polycarbonate in an efficient, fast, and clean way. Following this surface activation strategy, amino-modified oligonucleotide probes were covalently attached, reaching an immobilization density of 2 pmol cm^{-2}. Atomic force microscopy imaging revealed the nondestructive character of this treatment when applied for short times, allowing for disk scanning in standard DVD drives. DNA assays performed on oxygen plasma treated disks resulted very efficient with maximum hybridization yield of 93% and reaching a low limit of detection (200 pM) for perfect match synthetic oligonucleotide targets when reading the disk with a standard drive as detector. The approach was also evaluated by scoring single nucleotide polymorphisms with a discrimination ratio of 12.8. As proof of concept, the oxygen plasma treated interactive polycarbonate DNA microarraying platform was applied to the detection of PCR products of *Salmonella* spp., reaching a detection limit of 2 nM that corresponds to a DNA concentration of only 1 c.f.u./mL. The results confirm the suitability of the microarray platform for analysis of biological samples with high sensitivity.



INTRODUCTION

DNA assays have been growing due to their broad applications in many fields (e.g., gene analysis, clinical diagnosis, or pathogen detection). Among the numerous assay types, oligonucleotide microarray technology allows for high-throughput, sensitive and selective DNA detection in a miniaturized format. For that, glass is the support commonly employed, but organic polymers also have high potential in microarray analysis due to their good mechanical and optical properties, mass production, and price.

Optical disks are attractive analytical supports, given the low cost of mass production and the countless surface chemistry strategies to attach probes for biosensing in different formats. Several approaches have been reported for bioanalytical applications in microarray format on optical disks.[1,2] Performances of drive as detector demonstrated that compact disk (CD) technology is very competitive. Ubiquity and the price of a disk reader provide huge advantages compared to the usual equipment, including fluorescence scanners and flow cytometers.

Electrostatic immobilization of DNA probes on positively charged surfaces, e.g., amino-silanized glass or charged-nylon membranes, is a common strategy to attach them in a random manner. However, covalent immobilization achieves probe directionality, reduces background noise, and develops a stable biomolecule layer.[3,4] Indeed, this strategy has been employed for the vast majority of commercial products because of its versatility, durability, and good functionality.[5,6]

Covalent linking of probes on optical disks requires functionalization of the surface since polycarbonate (PC), the main component of disks, lacks appropriated reactive chemical groups. A number of chemical and physical processes for covalent attachment of proteins and nucleic acid probes on PC surfaces are reported in the literature.[7−12] Most of these methods have limitations since they modify the opto-mechanical properties of the surface or use experimental setups that disable disk reading with disk drives. Also, classical chemical reactions must be carefully handled on disks as PC can be severely damaged. Our research group has developed chemical approaches, involving covalent attachment of probes on PC.[13−15] Several advantages were highlighted in DNA hybridization assays with limits of detection of 2.5 nM and scoring single nucleotide polymorphism (SNP), using covalently anchored aminated oligomers through a glutaraldehyde cross-linker.[14]

[a]The nucleotide bases for polymorphism detection are marked in bold.

However, cleaner, easy-going, and more efficient methods are demanded. Thus, Li et al.[16] reported UV/O_3 treated compact disks, allowing the immobilization of biotin, oligonucletotides, and immunoglobulins by covalent linkage. Maintaining the disk structure, DNA hybridization events were detected with a sensitivity of 25 nM by analyzing errors of the disk reading in a standard CD drive. These figures should be improved to reach the sensitivity required in real applications.

Plasma methods have attracted much attention for surface modification of polymeric materials. It is generated by applying an electric discharge to a neutral gas, developing radicals highly reactive with any species or surface they reach. Plasma treatment is a fast, effective, and clean method to create chemical moieties with minimal waste products. Plasma methods to develop chemically reactive polymeric surfaces have been reviewed by Siow et al.[17] Surface modification of polymers by plasma has been widely physico-chemically characterized, including treated PC surfaces.[18] Oxygen plasma is reported to be more effective than others gases such as air, N_2, or Ar, for the treatment of PC, introducing oxygenated groups on the surface and providing a very low treatment depth and homogeneity on a molecular scale.[19] To the best of our knowledge, studies about the ability of these treated PC surfaces to covalently link DNA probes for bioassaying have not been published yet.

In this article, we describe an oxygen plasma activated PC surface of compact disks to covalently attach aminated oligonucleotide probes, developing a novel and general microarraying platform applicable to nucleic acid based methods. The optimal working conditions to maintain disk operations and surface activity were also approached despite the delicate structure of DVD (PC substrate covered with several layers of different materials) and the hard conditions inside the plasma reactor.

This novel microarray platform, compatible with disk reading, is created and applied, as a proof of concept, to score SNPs and detect polymerase chain reaction (PCR) products, achieving good performance.

EXPERIMENTAL PROCEDURES

Chemicals. The immobilization-printing buffer (HEPES: 50 mM 2-[4-(2-hydroxyethyl)piperazin-1-yl]ethanesulfonic acid buffer, containing 40% (v/v) glycerol, pH 7.0); hybridization buffer (3 × SSC: 45 mM sodium citrate buffer and 450 mM NaCl, pH 7.0); PBS-T (10 mM sodium phosphate buffer, 150 mM NaCl, and 0.05% (v/v) Tween 20, pH 7.2); and washing solutions were filtered through a 0.22 μm pore size nitrocellulose membrane from Whatman GmbH (Dassel, Germany), before use.

Oligonucleotides were from Sigma-Aldrich (Madrid, Spain), and the sequences are shown in Table 1. Digoxigenin labeled PCR products were 151 bp long and used to detect specifically *Salmonella* spp. Ten nanometer colloidal gold labeled antidigoxigenin immunoglobulin was from Aurion (Wageningen, The Netherlands). *N*-Hydroxysuccinimide (NHS), 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide (EDC), Crystal Violet, Tween 20, formamide, and silver enhancer solutions were supplied by Sigma-Aldrich (Madrid, Spain). Note: All the chemicals should be handled following the corresponding material safety data sheets.

Surface Activation and Characterization. DVD-R disks were purchased from MPO Ibérica (Madrid, Spain). The disks were first conditioned by gentle ethanol washing, water rinsing, and dried by centrifugation. For oxygen plasma activation, disks were introduced inside a microwave plasma reactor PVA Tepla 200 Plasma System (Feldkirchen, Germany) operating at 2.45 GHz and continuous 100 W power for 30 s. Oxygen pressure inside the reactor was 120 Pa. Disks were stored under vacuum and dry conditions until probe attachment.

Surface contact angle measurements were taken on OCA20 equipment and data analyzed using SCA20 software from Dataphysics Instruments GmbH (Filderstadt, Germany). The measurements were done in quintuplicate at room conditions with a volume drop of 10 μL.

X-ray photoelectron spectra were recorded with a Sage 150 spectrophotometer from SPECS Surface Nano Analysis GmbH (Berlin, Germany). Nonmonochromatic AlKa radiation (1486.6 eV) was used as the X-ray source operating at 30 eV constant pass energy for elemental specific energy binding analysis. Vacuum in the spectrometer chamber was 9×10^{-9} hPa and the sample area analyzed 1.0 mm^2. The surface topographies were examined with a Nanoscope IIIa atomic force microscope from Digital Instruments (Santa Barbara, CA, USA), operating in tapping mode in air at room temperature.

Crystal violet dye was employed to estimate the density of carboxylic acid groups generated on oxygen plasma treated PC surfaces, as previously described.[20] Raw polycarbonate surface from standard DVDs was used as the control.

Oligonucleotide Immobilization. Amino modified oligonucleotide probes were attached to oxygen plasma DVD by carbodiimide chemistry. To this end, the oligo probe was serially dissolved (concentration ranging from 0.05 to 5 μM) in printing buffer with EDC and NHS at 20 mM. Solutions were immediately microarrayed on the oxygen plasma activated surface as 50 nL drops with a noncontact dispenser (AD1500, Biodot Inc., Irvine, CA) in a 90% humidity environment. The disk layout consisted of eight segmented areas (45° separation) each one constituted of 30 spots of ∼500 μm diameter, spaced 1 mm and distributed in 6 columns and 5 rows. In this manner,

dx.doi.org/10.1021/bc2004268 | *Bioconjugate Chem.* 2011, 22, 2573−2580

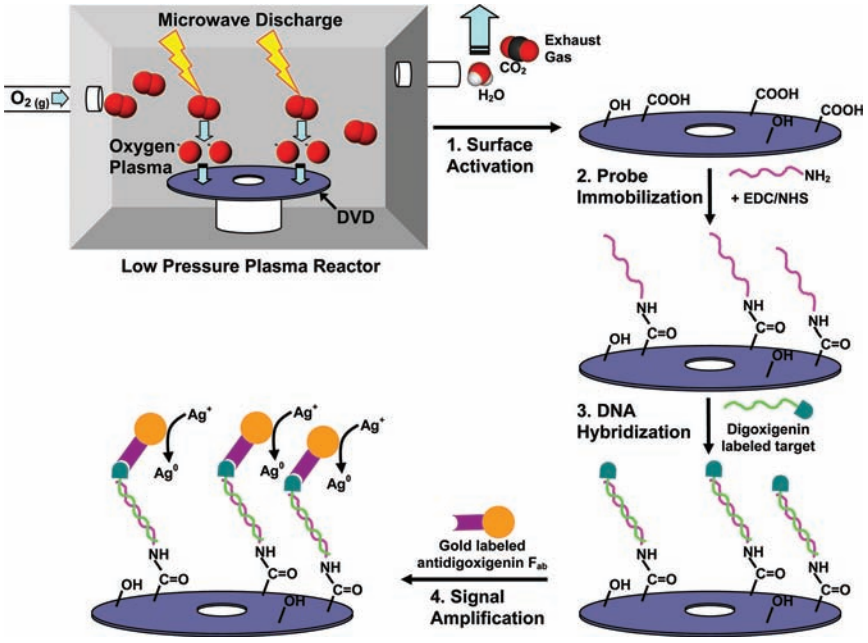

Figure 1. Scheme of oxygen plasma activation procedure of DVD PC surfaces, covalent attachment of oligonucleotides, DNA hybridization, and assay development.

eight samples can be simultaneously analyzed. The coupling reaction was carried out at 4 °C for 16 h under controlled humidity conditions. After that, the activated surface was washed with PBS-T for 1 min, rinsed with water, and dried by slight centrifugation.

DNA Hybridization Assays on DVD. For hybridization studies, both digoxigenin labeled oligomer target and PCR products were used. The latter, first, was denaturated into single DNA strands by high temperature treatment prior to their application to the disk. This method involves a 5 min incubation step at 95 °C followed by 1 min on ice. Target and PCR product solutions (100 μL) in hybridization buffer were evenly distributed on disk areas using 22 × 22 mm glass coverslips. After 1 h at 37 °C, the disk was washed with PBS-T, rinsed with deionized water, and dried by slight centrifugation. Next, 1 mL of gold labeled antidigoxigenin solution (1:100 in PBS-T) was dispensed onto the disk and covered with a 12 cm diameter dummy plastic surface. After 1 h at room temperature, the disk was washed, rinsed, and dried as before. To display the hybridization reaction, the disk was incubated with 1 mL of 1:1 (v/v) silver enhancer solution distributed as before and the reaction stopped by washing with water after 18 min at room temperature. The disk was dried as described above and read with a CD/DVD drive.

The CD/DVD drive was from LG Electronics (Englewood Cliffs, NJ, USA) and holds two lasers, 650 and 780 nm, which focus on the spiral data track of CD and DVD disks, respectively. During the disk reading, the laser hits the reaction product which modifies the optical properties of the disk surface, attenuating the signal captured by the photodiode. This signal is related with target concentration. A detailed description of the optical disk drive working as chemical detector is described elsewhere.[2] A scheme of surface activation, probe immobilization, and DNA hybridization assays is depicted in Figure 1.

Oligonucleotide Surface Density. The immobilization probe density was estimated by measuring the fluorescence of a Cy5-labeled oligonucleotide tracer (Table 1), and the hybridized target density was calculated through the fluorescence of the target-1 after hybridization with probe-1, immobilized on PC activated chips at different densities. The fluorescent intensity of the spots was determined by a homemade apparatus incorporating a charge couple device camera Retiga EXi from Qimaging Inc. (Burnaby, Canada) and light emitting diodes Toshiba TLOH157P as the fluorescence excitation source.[21]

After the corresponding immobilization and hybridization steps, the chips were washed, rinsed, and dried, the fluorescence signal of the spots was quantified, and the density of immobilized and hybridized DNA was extracted from the respective calibration curves (Figures S3 and S4, Supporting Information). For each experimental condition tested on the microarrays, 12 replicates spots of each solution were spotted on the treated polycarbonate DVD surface. The experiment was repeated three times. The immobilization and hybridization data presented are the average of these repetitions, and the error bars represent the standard deviation observed on this average. The yield of DNA hybridization was calculated as the ratio of the target to probe densities.

■ RESULTS AND DISCUSSION

Surface Characterization. Oxygen activated DVD surface was characterized by water contact angle measurements which give information about surface hydrophilicity that, in fact, is related to the presence of oxygenated functional groups. The contact angle in water decreased from 79° of raw hydrophobic PC surface to a constant value of 16° after 30 s plasma treatment (Figure 2A). The efficiency of oxygen plasma treatment was demonstrated considering that only 5 s of activation decreases the contact angle up to 30°, being in good agreement with that observed in raw polycarbonate after treatment with different plasma gases.[19,22] As is shown in Figure 2, uniformity of the oxidized surfaces was corroborated from the low dispersion of the contact angle measurements randomly taken on the disk surface.

dx.doi.org/10.1021/bc2004268 | Bioconjugate Chem. 2011, 22, 2573–2580

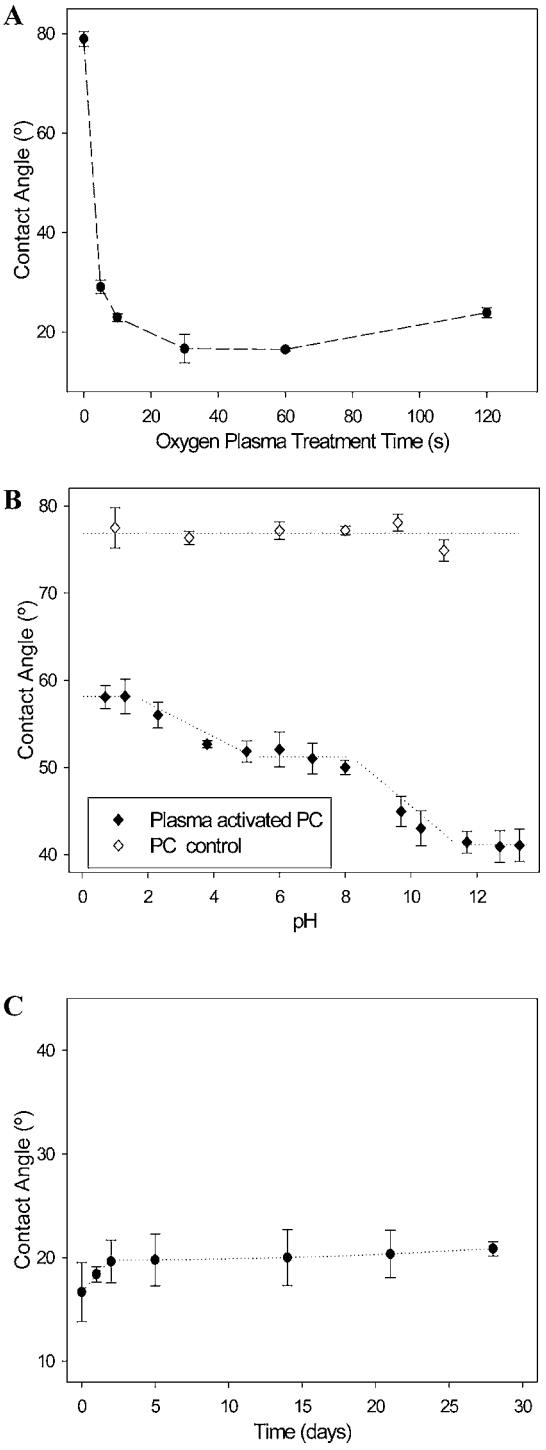

Figure 2. (A) Change of contact angle in water of DVD PC surfaces treated by oxygen plasma (100 W, 120 Pa) with the activation time. (B) Contact angle titration curves of untreated and oxygen plasma activated (100 W, 120 Pa, 30 s) DVD PC surfaces. The dotted lines are to facilitate reading only. (C) Variation of water contact angle of plasma treated DVD PC surfaces as a function of storage time in a vacuum desiccator.

Considering that the oxygen plasma treatment incorporates to the polycarbonate surface different oxygenated groups such as alcohols, carboxylic acids, and other carbonyl functions and that these groups are protonated or deprotonated depending on their pK_a and the pH of the medium, we found out their presence by means of a contact angle titration curve using buffered solutions. Thus, the contact angle was gradually decreased as the pH was raised, observing two smooth transitions from pH 1.0 to 5.0 and from 8.0 to 12.0 (Figure 2B). Contrarily, the contact angle remained constant on untreated disks within the pH range tested. This might suggest the presence of phenols and aromatic acids on the activated surface since the pK_a of benzoic acid and phenol is 4.2 and 9.9, respectively. Nevertheless, the smoothness of the titration leaps points to a mixture of several moieties and other functionalities, in different ratios, making it difficult to identify the nature of each chemical surface group. Although carboxylic acids are the only preferred groups for the subsequent covalent attachment of aminated probes, phenols would not interfere in the coupling efficiency of oligonucleotides through carbodiimide chemistry. Furthermore, phenols contribute to surface hydrophilicity, reducing the nonspecific adsorption of oligonucleotide targets and other assay reagents such as gold-labeled antidigoxigenin immunoglobulin.

The whole leap in the contact angle titration curve is about 20°, which is lower than that the obtained with other treatments.[23] However, the high density of the functional groups was determined by the crystal violet procedure. The differences in the signal obtained between activated and raw PC surfaces determine a density of ionizable groups (acids and phenols) of 1.2×10^{-9} mol cm^{-2}. This figure is higher than that reported for PC surfaces after 1 h of UV irradiation or 10 min of UV/ozone treatment (0.25 and 0.48×10^{-9} mol cm^{-2}, respectively).[24,25] Although the estimated density refers to functional ionizable groups, it can be considered that carboxylic acid moieties constitute approximately half of the total since the magnitudes of the two titration curve leaps were similar (Figure 2B). Even so, the density of carboxylic acid groups is much higher than 0.15×10^{-9} mol cm^{-2}, that is, the one calculated for close-packed ssDNA strands.[26]

The change of hydrophobicity of the treated surface was also studied by XPS. The C1s and O1s spectra of untreated and treated DVDs revealed a change in the atomic ratio O/C from 0.17 to 0.29 after oxygen plasma treatment for 30 s. Deconvolution of C1s spectra showed that new bonds of C–O are formed during the activation (Figure S1, Supporting Information). Thus, to the bands at 286.6 and 290.5 eV, due to single and quadruple bonds between C and O present in the chemical structure of PC, plasma activation adds new bands at 287.5 and 288.8 eV, corresponding to double and triple bonds, respectively.[18] This confirms the presence of new carbonyl and carboxylic groups on the treated surface. Also, a slight increase in the band height at 286.5 eV points the generation of new phenol or phenoxy functionalities. However, given the performances of the XPS technique, new spectra with higher resolution could be required to accurately corroborate these results.

Achieving an efficient functionalization of the surface is as important as keeping its physical properties in order to read the disks in a standard CD/DVD drive. AFM imaging of treated and untreated surfaces revealed that the topography of DVDs, in terms of root-mean-square roughness value (R_{rms}), does not change during the first minute of plasma treatment (Figure S2, Supporting Information). Contrarily, 5 min of activation resulted on disk imperfections (visible by naked eye) because the DVD is composed of several layers of materials whose adherence fails during prolonged plasma treatment. Nevertheless, shorter activation times produce only minimum etching

dx.doi.org/10.1021/bc2004268 | Bioconjugate Chem. 2011, 22, 2573–2580

of the surface, and PC chemical modification is the dominant process.

However, plasma treated polymer surfaces progressively lose their anchoring capacity during storage time: the aging effect. This phenomenon is detected through the increase of hydrophobicity (surface contact angle increasing). As is shown in Figure 2C, when plasma activated DVD PC surfaces were stored under vacuum and dry conditions, the water contact angle only increased from 16° to 21° after a month of storage. This means that the aging effect over the activated disks is minimum, and the surface continues being reactive for biomolecule immobilization after storage.

DNA Microarray Platform. A DVD derivatized surface with carboxylic acid moieties constitutes a potential platform to attach probes for biosensing purposes. The application of these modified surfaces by covalent immobilization of aminated oligonucleotide probes on 30 s plasma activated DVDs and further development of DNA hybridization-based assays was demonstrated for the first time.

A study to ascertain the best conditions for oligonucleotide immobilization on oxygen plasma treated PC surfaces was carried out. The pH is a paramount parameter that needs to be controlled when using carbodiimide chemistry; indeed, slightly acidic solutions (pH 5) are known to better stabilize active NHS esters, but alkaline conditions are needed to reach a good density of the nonprotonated amino group of modified oligonucleotides and for nucleophilic attack to occur at the activated surface (pK_a of conjugated acid of aliphatic amino is approximately 9.0). Thus, comparing different printing buffers, a maximum oligonucleotide immobilization density was reached at neutral medium (HEPES buffer pH 7.0).

The high hydrophilicity of the treated surfaces causes the spreading of the printed spots in a manner in which they overlapped each other. Also, this diffusion of the spotted solutions increased the evaporation speed, hindering reaction of probes with the disk surface. To control these issues, glycerol was added to the printing solution showing that 40% (v/v) was the optimal content to avoid the aforementioned problems.

Operating at the described conditions, the probe immobilization was studied over PC oxygen plasma treated surfaces at different times, using fluorescent dye marked oligonucleotide as the tracer (See Experimental Procedures).

Probe immobilization density increased with the surface treatment time, probably due to the higher carboxylic acid group density, but 1 min treatment or longer decreased the efficiency to attach oligonucleotides (Figure 3). Extended plasma treatments might also generate low molecular weight material on it, including a weak boundary layer, due to the etching of the surface.[18] This material, together with the immobilized probe, is removed from the surface after the washing step, and therefore, less amount of oligonucleotide is finally attached on the surface. However, the immobilization density increases with the concentration of oligonucleotide dispensed on the surface, reaching a plateau at concentrations between 5 and 10 μM.

An immobilization density of 2 pmol cm^{-2} was reached in the studied conditions. This density was similar to that reported by others authors working on activated plastics (5 and 10 pmol cm^{-2} for UV-Ozone activated PC and aminated PMMA, respectively)[25,27] or commercial reactive microarray glass slides (11 pmol cm^{-2}).[28] High immobilization densities do not necessarily imply an improvement in the hybridization yield, so

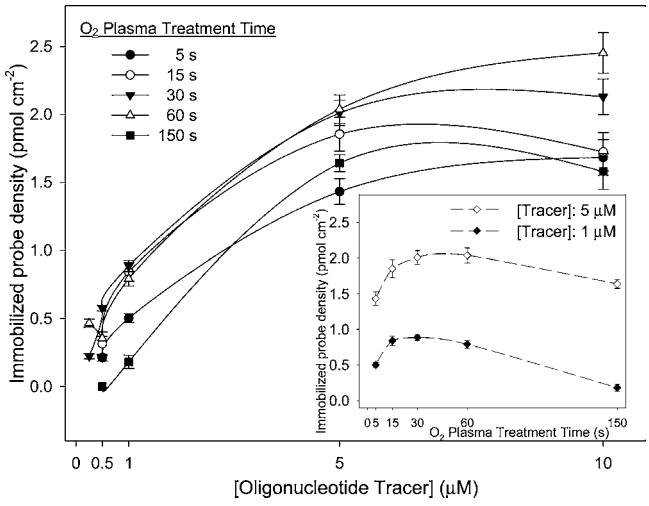

Figure 3. Oligonucleotide immobilization density on activated DVD PC surfaces by oxygen plasma (100 W, 120 Pa) at different times. Inlet, immobilized density dependence on the time of plasma activation for two concentrations of tracer. Density values were calculated from fluorescence intensity values of Cy5 labeled probes measured with a CCD camera.[21] EDC/NHS in printing buffer without probe oligonucleotide were employed as negative controls.

the obtained one is suitable to detect DNA with high sensitivity.

However, a negligible response (S/N < 3) was obtained from a nonspecific probe anchoring on a plasma treated polycarbonate surface when fluorescent labeled oligonucleotides without an amino group are used (Target 1) or when the amino modified oligonucleotides were used in the absence of EDC/NHS (negative controls). This confirmed that other reactive groups formed on the PC surface during the plasma treatment, such as epoxides or oxygen radicals, were not present in such an amount to react and produce significant nonspecific probe immobilization. Likewise, although some degree of $\pi-\pi$ or other hydrophobic interactions could be established between purine and pyrimidine bases and the aromatic moiety of the polycarbonate, no signal was observed, over nonactivated disks at the probe concentrations employed, supporting the suitability of the plasma treated surfaces for covalent attachment of aminated probes at low concentrations.

DNA Hybridization Assays. The performance of oxygen plasma activated DVDs to attach DNA probes was assessed through hybridization assays with oligonucleotides and PCR products, establishing its sensitivity and selectivity. Several considerations related with the design of the oligonucleotides sequence were taken into account before carrying out optimization studies. First, a poly T tail 10 to15 long was added at the 5′ end with the role of spacer to physically separate them from the surface, alleviating possible steric interferences.[29] Second, the length of probes and targets ranged 21 to 26 bp as a trade off between hybridization efficiency and specificity.[30]

The yield of hybridization was determined by comparison of the response obtained after the recognition event between Probe 1 and Target 1 to that achieved by the immobilization of tracer. As shown in Figure 4A, hybridized target density increased with target concentration, reaching a plateau at 200 nM for the tested probe concentrations (0.5−5 μM) and a maximum DNA target density of 0.93 pmol cm^{-2} (probe, 5 μM; target, 500 nM). This figure was similar to that achieved on other activated plastics[25,27] and corresponds to a hybrid-

dx.doi.org/10.1021/bc2004268 | Bioconjugate Chem. 2011, 22, 2573−2580

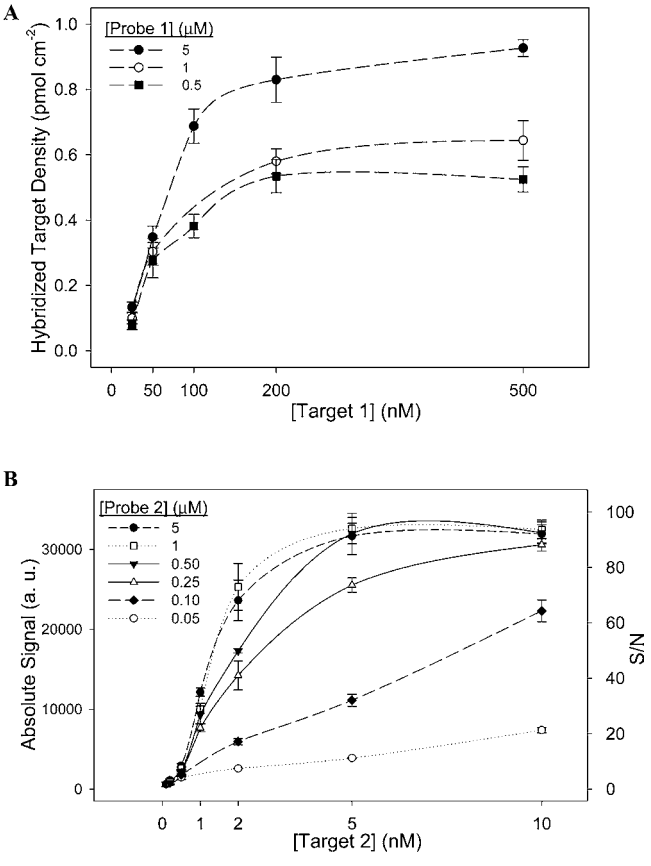

Figure 4. (A) Hybridized target density on oxygen plasma activated DVD PC surfaces (100 W, 120 Pa, 30 s), calculated from fluorescence intensity values of Cy5 labeled targets obtained with a CCD camera.[21] Hybridization buffer without target was employed as the negative control. (B) Absolute signal and S/N values (mean value ± standard deviation of 15 replicates) for DNA hybridization assays on plasma activated standard DVDs with different probe and target concentrations read with a standard DVD drive. Hybridization buffer without target was employed as the negative control.

ization yield of 46%. The efficiency is higher than that reached on other polymeric surfaces (between 6 and 18%), probably due to the superiority of this novel platform to immobilize probes at the optimal density. Indeed, it is well known that hybridization efficiency depends strongly on the amount of probe attached on the sensing surface in a manner that full hybridization is only achieved at lower probe densities because repulsive electrostatic and steric interactions are minimized.[31] Although recent approaches have reported to avoid it,[32] this "sweet spot" phenomenon has been confirmed multiple times by others authors over several DNA microarray supports.[33,34] Likewise, and in good agreement with these observations, the yield of hybridization on oxygen plasma activated PC was 93% at the lowest probe density tested (0.56 pmol cm^{-2}).

Detection of DNA target was performed on a DVD disk by using 5′-digoxigenin labeled oligonucleotides and gold labeled antidigoxigenin immunoglobulin and silver amplification to produce a solid reaction product. The hybridization assay performed with these reagents showed the highest S/N values compared to those of others using biotin labeled oligonucleotides and gold labeled streptavidin (Figure S5, Supporting Information). However, the modulation of the silver enhancement conditions is paramount to achieve an optimal contrast for detection.[35] Thus, shorter reactions do not develop enough reaction product for quantification whereas reactions that are too long increase the level and noise of the background, dropping the signal-to-noise ratio. In our case, 18 min was selected as the suitable amplification time to get the best contrast and S/R values. This time is longer than the optimal one found for assays over other PC disks, probably due to the different surface chemistry achieved with plasma treatment.[1,14] The linear dynamic range and limit of detection (LOD) related to the probe density and target concentration is shown in Figure 4B. Thus, a limit of detection of 200 pM, calculated as the concentration of target giving a signal equal to three times the standard deviation of the background signal, was reached when immobilizing the 5 μM probe. Likewise, the dynamic range for the hybridization assay can be improved by controlling the amount of immobilized probe and the reaction time of the silver enhancement step (e.g., shortening the reaction time to avoid saturation for higher target concentrations, Figure S6, Supporting Information).

At the conditions described here, the background signal was negligible (S/N < 3), saving the blocking step with BSA or ethanolamine and reducing assay time. In addition, such a background level is indicative of low nonspecific adsorption of gold-labeled antidigoxigenin immunoglobulin on this hydrophilic surface.

The relatively high yield of hybridized target achieved with our approach implies that very little amount of DNA probe is needed to obtain a detectable signal. Thus, dispensing 50 nL of 5 μM probe solution means that only 50 fmol of oligonucleotide per assay is used (considering a single spot as an individual assay), which is quite low compared to that in other protocols such as microfluidic arrays.

However, it is also important to keep the stability of the probe-coated surface with time. Thus, weekly hybridization assays demonstrated that the immobilized probes on plasma treated PC surfaces were active during, at least, two months after being printed on the disks without significant loss (12%) of the hybridization signal.

The selectivity of our approach was evaluated through hybridization assays using target oligonucleotides with mismatched bases with respect to the sequence of the immobilized probe. Negligible responses (S/N < 3) were obtained assaying 5 and 10 base-pair mismatch targets (Figure 5A) for a broad range of concentrations (from 0.1 to 500 nM). More interesting, due to its potential application in genotyping, is the ability of the sensing platform to discriminate single nucleotide polymorphisms (SNPs), predicting disease predispositions or drug responses in individuals.[36] Working with stringent conditions, such as a lower ionic strength hybridization buffer (1 × SSC) and the addition of formamide at 50% (v/v), maximum discrimination ratio of 12.8 was reached (Figure 5B), being in the range of those achieved with other approaches for oligonucleotides of similar length.[37]

Also, the potential of the new microarray disk surface for sensitive and selective detection of PCR amplified DNA products of pathogens was tested. The nucleotide sequence of the immobilized probe 2 was complementary to the central region of 151 bp amplicon specific to detect *Salmonella* spp. Although the high temperature pretreatment denatures PCR products (dsDNA) into ssDNA complementary strands, during its application on the disk, incubation time is an essential parameter to avoid amplicon reassociation and control the hybridization assay, as shown in Figure 5C. Thus, higher responses were obtained after 60 min. At the described

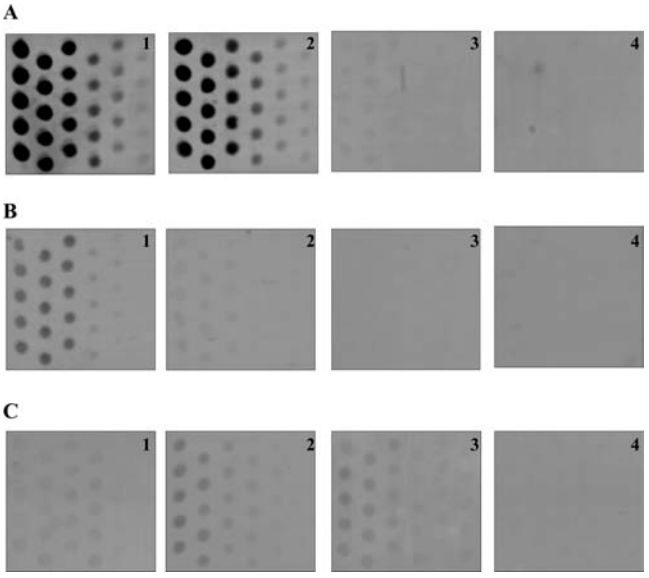

Figure 5. Optical density images of DNA hybridization assays performed on DVD-Rs and read with a standard DVD drive. Columns, from left to right, correspond to probe 2 at concentrations of 5, 1, 0.5, 0.25, 0.1, and 0.05 μM, respectively. (A) Hybridization with target at 5 nM in nonstringent conditions (3× SSC buffer without formamide). Panels 1−4 correspond to perfect match, single, 5, and 10 base mismatch oligonucleotides targets, respectively (targets 2, 3, 4, and 5, respectively). (B) Hybridization with target at 5 nM in stringent conditions (1× SSC buffer with formamide at 50% (v/v)). Panels 1−4 correspond to perfect match, single, 5, and 10 base mismatch targets, respectively (targets 2, 3, 4, and 5, respectively). (C) Panels 1−3 correspond to hybridization with *Salmonella* spp. PCR product at 2 nM for 15, 60, and 120 min, respectively. Panel 4 corresponds to hybridization with *Cronobacter* amplicon at 2 nM for 60 min used as the negative control. S/N values were 21.8, 17.0, 8.7, 5.5, 2.2, and 0.5 (panel 2) and 15.0, 11.4, 6.8, 3.8, 3.1, and 3.5 (panel 3) for 5, 1, 0.5, 0.25, 0.1, and 0.05 μM probe 2 concentration, respectively.

conditions, the new microarray was able to detect 2 nM of amplicon. This limit of detection is about 1 order of magnitude better than that reached with synthetic oligonucleotides, probably due to the lower diffusion coefficient of larger targets and the reassociation of the two amplicon strands during hybridization on the disk. However, negligible responses (S/N < 3) in the detection of negative PCR control products (*Cronobacter sakazakii*) confirmed the selectivity of our approach.

Considering the target solution volume used for hybridization assays (100 μL), and the number of spots printed per array (30), a limit of detection of 200 pM is equivalent to 700 amol of DNA molecules, which is 2 orders of magnitude lower than the reported one for DNA detection on UV/ozone treated compact disks.[16] However, differences in assay format (line array instead of spot microarray), type of disk (CD instead of DVD), and reading strategy (error reading detection instead of acquiring the attenuated analog signal) could be decisive for the differences found between the two approximations.[2,38] Indeed, at this stage, the approach presented here shows an important sensitivity enhancement on the state of the art (DNA microarrays on standard disk surfaces).[14,37] The detection limit of 2 nM of PCR product reached with our approach is equivalent to detect 150 μgL^{-1} of PCR amplified DNA. This result is very interesting because this amount of DNA comes from 1 colony-forming unit/mL. This achievement in sensitivity, together with the ultrafast and nonaggressive performance of surface modification protocol, reveal plasma treated DVDs as practical platforms for DNA microarray sensing. Moreover, the DVD disk and drive approach constitutes an analytical tool with high potential compared to other microarray detection platforms such as confocal fluorescent scanners or flow cytometers, with advantages such as low cost, portability, and high-throughput capability to analyze thousands of samples in field conditions.

CONCLUSIONS

Oxygen plasma treated DVD polycarbonate surface is a novel and superior DNA microarray support. The surface activation is fast and clean adding to the optical and mechanical properties of the disk's new capabilities, allowing scanning with standard disk drives. The treatment generates active and stable moieties on the polycarbonate surface, allowing for the covalent immobilization of amino modified probes with appropriate densities for developing sensitive DNA hybridization assays.

Mass production of functionalized disks could be carried out smartly and easily since only 30 s of treatment gives an appropriate surface density of functional moieties. At the same time, in this process, the chemical modification is independent of substrate geometry, making it possible to uniformly activate several disks during a single plasma treatment. This is a clean activation strategy because it requires tiny amounts of chemicals or solvents, avoiding the generation of classical synthesis waste byproducts, adding extra value as an environmentally friendly procedure.

However, polycarbonate could be derivatized with different functional groups by proper selection of the employed plasma gases (e.g., introduction of amines from ammonia plasma for attaching biomolecules containing carboxylic acids). Also, other immobilization strategies such as streptavidin−biotin or the use of monofunctional or bifunctional linkers are of direct and simple implementation.[39]

Detection of PCR amplified DNA products were also demonstrated, reaching high sensitivity and selectivity, with an inverse relationship between probe density and hybridization yield. The limits of detection are very low and comparable to those reported in the literature using fluorescent, enzymatic, or metal nanoparticle labels on plastic supports. The advantages shown by compact disk reading technology, such as ubiquity, low cost, portability, and high-throughput, give this approach scalability and great potential.

Influence of Minor Backbone Structural Variations in Modulating the in Vitro Gene Transfer Efficacies of α-Tocopherol Based Cationic Transfection Lipids

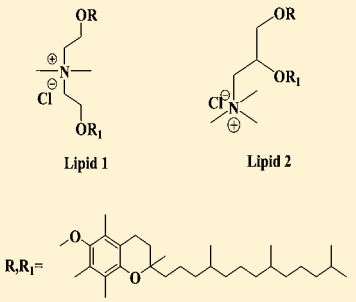
Bhavani Kedika and Srilakshmi V. Patri*

Department of Chemistry, National Institute of Technology, Warangal -506004, Andhra Pradesh, India

Supporting Information

ABSTRACT: Toward probing the influence of backbone structural variation in cationic lipid mediated gene delivery of α-tocopherol based lipids, two novel α-tocopherol based lipids **1** and **2** have been designed and synthesized. The only structural difference between the cationic amphiphiles **1** and **2** is the backbone structure, where lipid **1** has a non-glycerol backbone and lipid **2** has a glycerol backbone. The lipids **1** and **2** showed contrasting transfection efficiencies: lipid **1** showed high gene transfer efficacy in multiple cultured animals cell lines, whereas lipid **2** is transfection incompetent. In summary, the present findings demonstrate that in the case of α-tocopherol based lipids even minor structural variations like backbone can profoundly influence size, DNA binding characteristics, cellular uptake, and consequently gene delivery efficacies.

Structures of Lipids 1 and 2 containing the same hydrophobic region, same head group and linker group functionality but differ only in the backbone region.



INTRODUCTION

To develop an efficient gene therapeutic approach, design of safe and efficient gene delivery reagents is a prerequisite. Cationic liposomes are one of the more promising nonviral systems for use in gene therapy.[1−18] Since the pioneering development of glycerol backbone-based cationic transfection lipid (*N*-[1-(2,3-dioleyloxy)propyl])-*N*,*N*,*N*-trimethylammonium chloride (DOTMA) in 1987,[19] design and syntheses of a plethora of more efficient cationic transfection lipids, including our own,[20] have been reported. The number of commercially available cationic lipid-based transfection kits are the fruits of such intense global efforts in developing safe and efficient cationic lipids for use in gene therapy. The molecular structures of most of these commercially available cationic transfection lipids contain glycerol as the backbone. With a view to address how important the presence of glycerol backbone in the molecular architectures of many commercially available cationic transfection lipids is, several groups have succeeded in developing a highly efficient series of non-glycerol-based novel transfection lipids.[21−29] The in vitro transfection efficiencies of some of these new cationic lipids developed are better than the most extensively used commercially available glycerol-based cationic amphiphiles used in transfecting cells.[21−29]

In our ongoing program on designing efficient novel cationic transfection lipids, we recently demonstrated the potential of novel α-tocopherol based monocationic lipids for use in liposomal gene delivery.[20] Understanding the structural parameters of cationic amphiphiles which can influence their gene transfer properties is important for designing efficient liposomal gene delivery reagents. Investigations into the role of various molecular-level modifications in different synthetic lipids on their membrane properties and further influence their gene transfer efficiencies are reported.[30−34] To our knowledge, the importance of structure of the backbone group linking the hydrophobic tail and hydrophilic head of cationic lipid is an unexplored area in cationic lipid gene delivery. To this end, with a view to understand the effect of structural variation in backbone on the transfection efficiencies of α-tocopherol based cationic amphiphiles, we have designed and synthesized two novel α-tocopherol based cationic lipids (**1** and **2**; Chart 1), wherein lipid **1** is with nonglycerol backbone and lipid **2** is with glycerol backbone. Findings from the transfection studies and DNA binding studies demonstrate that lipid **1** is more stable and highly transfecting when compared to lipid **2**. The fluorescence microscopic experiments reveal that lipid **1** has higher uptake by the cells and greater expression of reporter gene when compared to lipid **2**. Taken together, the present findings demonstrate that even minor structural variations like backbone in α-tocopherol based cationic amphiphiles can profoundly influence DNA binding, size, cellular uptake, and consequently gene delivery efficacies of cationic liposomes.

EXPERIMENTAL SECTION

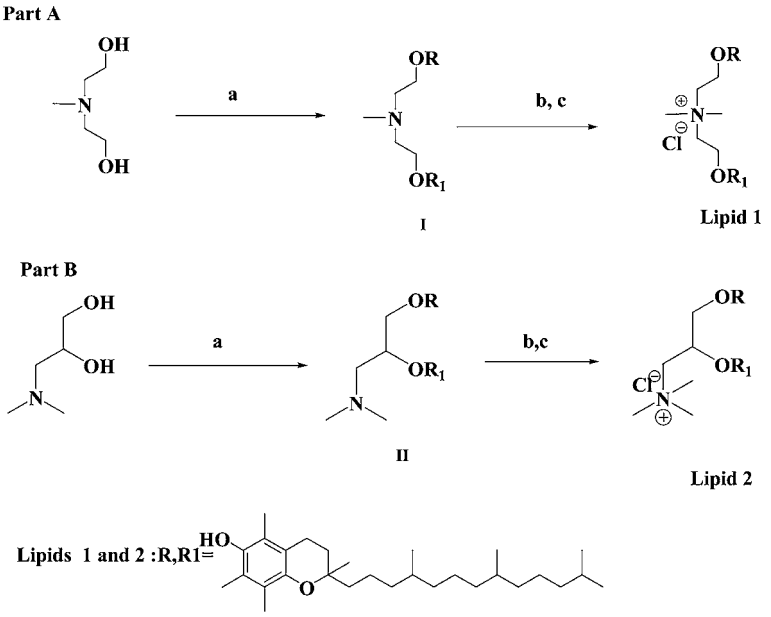
General Procedures and Reagents. Mass spectral data were acquired by using a commercial LCQ ion trap mass spectrometer (ThermoFinnigan, SanJose, CA, USA) equipped with an ESI source. ^{1}H NMR spectra were recorded on a Varian FT 300 MHz NMR spectrometer. *N*-Methyl diethanol amine and *N*,*N*-dimethyl l,2,3-propane diol were purchased from Sigma Co. *p*-CMV-SPORT-*β*-gal plasmid, *α*5GFP plasmid, and Rhodamine-PE were generous gift from IICT (Indian Institute of Chemical Technology), Hyderabad. LipofectAmine-2000 was purchased from Invitrogen Life Technologies (USA). Cell culture media, fetal bovine serum, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), poly(ethylene glycol) 8000, *o*-nitrophenyl-*β*-D-galactopyranoside were purchased from Sigma, St. Louis, USA. NP-40, antibiotics, and agarose were purchased from Hi-media, India. DOPC was purchased from Fluka (Switzerland). Unless otherwise stated, all the other reagents purchased from local commercial suppliers were of analytical grades and were used without further purification. The progress of the reaction was monitored by thin-layer chromatography using 0.25 mm silica gel plates. Column chromatography was performed with silica gel (Acme Synthetic Chemicals, India; finer than 200 and 60−120 mesh). Elemental analyses were performed by combustion procedure using Perkin-Elmer 2400 series II CHNS analyzer. Both the synthesized lipids **1** and **2** showed more than 95% purity.

Synthesis. Synthetic routes for preparing cationic lipids **1** and **2** are shown schematically in parts A and B, Scheme 1, respectively. Details of the synthetic procedures, purifications, and spectral characterizations of lipids **1** and **2**, as well as all their synthetic intermediates, shown in Scheme 1 are described below.

Synthesis of Lipid ***1*** *(Scheme 1 Part A). Synthesis of Tertiary Amine (Intermediate I Scheme 1 Part A).* A mixture of *N*-methyl diethanolamine (0.5 g, 4.19 mmol) and potassium hydroxide (∼4.0 g, 7.13 mmol) was taken in 10 mL of toluene in a two-necked round-bottomed flask fitted with a Dean−Stark apparatus. The reaction mixture is refluxed for two hours to remove the water as azeotropic mixture. To the reaction mixture, mesylated *α*-tocopherol (4.69 g, 9.22 mmol) (prepared as reported earlier[18]) is added and refluxed at 80 °C for 48 h. The solvent is evaporated and dried. The residue was taken in ethyl acetate (100 mL), washed with water (2 × 100 mL), dried over anhydrous magnesium sulfate, and filtered. The organic solvent is evaporated on a rotary evaporator. The column chromatographic purification of the resulting residue using 60−120 mesh size silica gel and eluting with 3−4% ethyl acetate (v/v) in hexane afforded 1.7 g, (42.92% yield, R_f = 0.8 in 10% ethyl acetate/hexane) of the intermediate tertiary amine.

^{1}H NMR (300 MHz, $CDCl_3$) δ ppm 0.75−0.95 [m, 24H, CH-C$\underline{H}_3$ tocopheryl], 1.55 [s, 6H, C$\underline{H}_3$-2 tocopheryl], 1.00−1.4 [m, 36H -(C$\underline{H}_2$)$_9$ tocopheryl], 1.8−1.9 [m, 4H, C$\underline{H}_2$-3 tocopheryl], 1.96−1.98 [s, 3H, N-C$\underline{H}_3$], 2.05 [s, 6H, C$\underline{H}_3$-5 tocopheryl], 2.15 [s, 6H, C$\underline{H}_3$-8 tocopheryl], 2.20 [s, 6H, C$\underline{H}_3$-7 tocopheryl], 2.55−2.6 [t, 4H, C$\underline{H}_2$-4 tocopheryl], 3.4−3.6[m,

Scheme 1. Synthesis of Lipids 1 and 2



Reagents: a) Mesylated tocopherol, KOH, Toulene, 48 h b) Methyl Iodide, K_2CO_3, rt, 3 days c) Amberlyst anion exchange resin

4H, N-C$\underline{H}_2$-CH$_2$-O-], 3.8−3.9 [m, 4H, N-CH$_2$-C$\underline{H}_2$-O-]. ESIMS: m/z 945 [M$^+$+1] for $C_{63}H_{109}NO_4^+$.

Synthesis of N,N-di[(O-α-deoxyα-tocopherol)-ethyl]-N,N-dimethylammonium chloride (lipid **1** *Scheme 1 Part A).* The intermediate tertiary amine obtained in step (a) of synthesis of lipid **1** (0.5 g, 0.52 mmol) was taken in a 25 mL round-bottomed flask and huge excess of methyl iodide (6 mL) was added to it. After stirring the reaction mixture at room temperature for 48 h, the solvent was removed on a rotary evaporator. The column chromatographic purification of the resulting residue using 60−120 mesh size silica and 2−3% (v/v) methanol in chloroform as eluent afforded the title compound as a quaternary iodide salt (0.4 g, 78.89% yield, R_f = 0.7, 10% methanol/chloroform). Finally, the pure title lipid **1** was obtained by subjecting the quaternized ammonium iodide salt to "repeated chloride ion exchange chromatography" using Amberlyst A-26 chloride anion exchange column and 60 mL of chloroform as eluent. ^{1}H NMR (300 MHz, CDCl$_3$) δ ppm 0.8−0.9 [m, 24H, CH-C$\underline{H}_3$ tocopheryl], 1.45 [s, 6H, C$\underline{H}_3$-2 tocopheryl], 1.00−1.4 [m, 36H -(C$\underline{H}_2$)$_9$ tocopheryl], 1.7−1.9 [m, 4H, C$\underline{H}_2$-3 tocopheryl], 2.05 [s, 6H, C$\underline{H}_3$-5 tocopheryl], 2.15 [s, 6H, C$\underline{H}_3$-8 tocopheryl], 2.20 [s, 6H, C$\underline{H}_3$-7 tocopheryl], 2.55−2.6 [t, 4H, C$\underline{H}_2$-4 tocopheryl], 3.7−3.8 [s, 6H, N-C$\underline{H}_3$], 4.1−4.2 [m, 4H, N-C$\underline{H}_2$-CH$_2$-O-], 4.35−4.45 [m, 4H, N-CH$_2$-C$\underline{H}_2$-O-]. ESIMS (lipid **1**): m/z 959 [M$^+$] for $C_{64}H_{112}NO_4^+$. Calculated: %N, 1.41; %C, 77.25; %H, 11.35. Observed: %N, 1.46; %C, 77.54; %H, 11.61.

Synthesis of Lipid **2** *(Scheme 1 Part B). Synthesis of Tertiary Amine (Intermediate II Scheme 1 Part B).* The intermediate tertiary amine is synthesized by taking a mixture of 3-(dimethylamino) propane-1,2-diol (0.5 g, 4.19 mmol), potassium hydroxide (∼4.0 g, 7.13 mmol), and mesylated α-tocopherol (4.69 g, 9.22 mmol) and following the same procedure as given in the synthesis of lipid **1**. The column chromatographic purification of the resulting residue using 60−120 mesh size silica gel and eluting with 4−5% ethyl acetate (v/v) in hexane afforded 2.0 g (50.50% yield R_f = 0.6, 10% ethyl acetate in hexane) of the intermediate tertiary amine. ^{1}H NMR (300 MHz, CDCl$_3$) δ ppm 0.8−0.9 [m, 24H, CH-C$\underline{H}_3$ tocopheryl], 1.55 [s, 6H, C$\underline{H}_3$-2 tocopheryl], 1.00−1.4 [m, 36H -(C$\underline{H}_2$)$_9$ tocopheryl], 1.7−1.9 [m, 4H, C$\underline{H}_2$-3 tocopheryl], 1.94−1.96 [s, 6H, N-C$\underline{H}_3$], 2.05 [s, 6H, C$\underline{H}_3$-5 tocopheryl], 2.15 [s, 6H, C$\underline{H}_3$-8 tocopheryl], 2.20 [s, 6H, C$\underline{H}_3$-7 tocopheryl], 2.55−2.6 [t, 4H, C$\underline{H}_2$-4 tocopheryl], 2.95−3.05 [m, 2H, CH$_2$-OR-CH-OR-C$\underline{H}_2$-N-(CH$_3$)$_2$], 4.0−4.1 [m, 1H, CH$_2$-OR-C$\underline{H}$-OR-CH$_2$-N-(CH$_3$)$_2$], 4.1−4.2 [m, 2H, C$\underline{H}_2$-OR-CH-OR-CH$_2$-N-(CH$_3$)$_2$]. ESIMS: m/z 944 [M$^+$] for $C_{63}H_{108}NO_4^+$.

Synthesis of N-([1-(2,3-dideoxyα-tocopherol)propyl])-N,N,N-trimethylammonium chloride (lipid **2** *Scheme 1 Part B).* The intermediate tertiary amine obtained in step a of synthesis of lipid **2** (0.5 g, 0.52 mmol) was quaternized using methyliodide. The quaternization is carried out following the procedure given in the synthesis of lipid **1** that yields the title compound as a quaternary iodide salt (0.43 g, 84.81% yield, R_f = 0.7, 10% methanol/chloroform). Finally, the pure title lipid **2** was obtained by subjecting the quaternized ammonium iodide salt to "repeated chloride ion exchange chromatography" using Amberlyst A-26 chloride ion exchange column and 60 mL of chloroform as eluent. ^{1}H NMR (300 MHz, CDCl$_3$) δ ppm 0.7−0.9 [m, 24H, CH-C$\underline{H}_3$ tocopheryl], 1.55 [m, 6H, C$\underline{H}_3$-2 tocopheryl], 1.00−1.4 [m, 36H -(C$\underline{H}_2$)$_9$ tocopheryl], 1.7−1.85 [m, 4H, C$\underline{H}_2$-3 tocopheryl], 2.05 [s, 6H, C$\underline{H}_3$-5 tocopheryl], 2.15 [s, 6H, C$\underline{H}_3$-8 tocopheryl], 2.20 [s, 6H, C$\underline{H}_3$-7 tocopheryl], 2.55−2.6 [t, 4H, C$\underline{H}_2$-4 tocopheryl], 3.8−3.9 [s, 9H, N-C$\underline{H}_3$], 4.15−4.25 [dd, 2H, CH$_2$-OR-CH-OR-C$\underline{H}_2$-N-(CH$_3$)$_3$], 4.3−4.45 [dd, 2H, C$\underline{H}_2$-OR-CH-OR-CH$_2$-N-(CH$_3$)$_3$], 4.7−4.8 [m, 1H, CH$_2$-OR-C$\underline{H}$-OR-CH$_2$-N-(CH$_3$)$_3$]. ESIMS (lipid **1**): m/z 959 [M$^+$] for $C_{64}H_{112}NO_4^+$. Calculated: %N, 1.41; %C, 77.25; %H, 11.35. Observed: %N, 1.74; %C, 77.05; %H, 11.05.

Cells and Cell Culture. B16F10, CHO, A-549, MCF-7, and HepG2 cell lines were procured from the National Centre for Cell Sciences (NCCS), Pune, India. Cells were cultured at 37 °C in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum, 50 μg/mL penicillin, 50 μg/mL streptomycin, and 20 μg/mL kanamycin in a humidified atmosphere containing 5% CO$_2$.

Preparation of Liposomes. The cationic lipid and the colipid (DOPC) in 1:2 mol ratio were dissolved in a mixture of chloroform and methanol (1:1) in a glass vial. The solvent was removed with a thin flow of moisture-free nitrogen gas and the dried lipid film was then kept under high vacuum for 8 h. One milliliter of sterile deionized water was added to the vacuum-dried lipid film and the mixture was allowed to swell overnight. Liposomes were vortexed for 1−2 min to remove any adhering lipid film and sonicated in a bath sonicator for 2−3 min at room temperature to produce multilamellar vesicles (MLV). MLVs were then sonicated in an ice bath until clarity using a Branson 450 sonifier at 100% duty cycle and 25 W output power for 1−2 min to give a clear, translucent solution. These resulting clear aqueous liposomes were used in forming lipoplexes.

Preparation of Plasmid DNA. *p*CMV-SPORT-β-gal plasmid was amplified in DH5α strain of *Escherichia coli*, isolated by the alkaline lysis procedure, and finally purified by PEG-8000 precipitation as described previously.[35] The purity of plasmid was checked by A_{260}/A_{280} ratio (around 1.9) and 1% agarose gel electrophoresis.

Transfection Biology. Cells were seeded at a density of 10 000 (for B16F10 and MCF-7) and 15 000 cells (for CHO, A-549, and HepG2) per well in a 96-well plate 18−24 h before the transfection. Then, 0.3 μg (0.91 nmol) of plasmid DNA was complexed with varying amounts of lipids in plain DMEM medium (total volume made up to 100 μL) for 30 min. The charge ratios were varied from 0.3:1 to 9:1 over these ranges of lipids. Just prior to transfection, cells plated in the 96-well plate were washed with PBS (2 × 100 μL) followed by the addition of lipoplexes. After 4 h of incubation, 100 μL of DMEM with 20% FBS was added to the cells. The medium was changed to 10% complete medium after 24 h, and the reporter gene activity was estimated after 48 h of incubation. The cells were washed twice with PBS (100 μL each) and lysed in 50 μL lysis buffer [0.25 M Tris-HCl (pH 8.0) and 0.5% NP40]. Care was taken to ensure complete lysis. The β-galactosidase activity per well was estimated by adding 50 μL of 2× substrate solution [1.33 mg/mL ONPG, 0.2 M sodium phosphate (pH 7.3), and 2 mM magnesium chloride] to the lysate in a 96-well plate. Absorbance of the product *ortho*-nitrophenol at 405 nm was converted to β-galactosidase units by using a calibration curve constructed using pure commercial β-galactosidase enzyme. Each transfection experiment was repeated 3 times on 3 different days. The transfection values reported were average values from three replicate transfection plates assayed on three different days. The values of β-galactosidase units in replicate plates assayed on the same day varied by less than 20%.

Transfection Biology in the Presence of Serum. Cells were seeded at a density of 10 000 (for B16F10 and MCF-7) and 15 000 cells (for CHO, A-549, and HepG2) per well in a 96-well plate 18−24 h before the transfection. Then, 0.3 μg (0.91 nmol) of plasmid DNA was complexed with lipids (**1** and **2**) in DMEM medium in the presence of increasing concentrations of added serum (10−50% v/v and total volume made up to 100 μL using plain DMEM medium) for 30 min. The lipid/DNA charge ratio of these lipoplexes was maintained at 9:1, at which both lipids showed their highest transfection ability in all five types of cells used for transfection (CHO, A-549, B16F10, HepG2, and MCF-7). The remaining experimental procedure and determination of β-galactosidase activity per well are similar to that reported for the in vitro transfection experiments.

Transfection Using α5GFP Plasmid. For α5GFP pDNA expression experiment, 25 000−30 000 cells per well were seeded in 24-well plates (Corning Inc., Corning, NY) for 12 h in 300 μL of growth medium such that the well became 30−50% confluent at the time of transfection. Liposomes of lipids **1** and **2** were complexed with α5GFP expressing *p*DNA (1 μg/well) at 9:1 lipid/DNA charge ratio in plain DMEM (total volume made up to 100 μL) for 30 min. The complexes were then diluted with 200 μL DMEM and added to the cells. After 4 h of incubation, DMEM was removed and cells were supplemented with complete medium. The cells were incubated for 24 h. Cells were washed with PBS (100 μL) and fixed with 3.8% paraformaldehyde in PBS at room temperature for 10 min. The green fluorescent cells expressing α5GFP were detected under an inverted fluorescence microscope (Nikon, Japan).

Cellular Uptake Studies by Inverted Fluorescence Microscopy. Cells were seeded at a density of 10 000 cells/well in a 96-well plate usually 18−24 h prior to the treatment in 200 μL of growth medium such that the well became 30−50% confluent at the time of transfection. *p*CMV-SPORT-β-gal DNA (0.3 μg of DNA diluted to 50 μL with serum-free DMEM media) was complexed with rhodamine-PE labeled cationic liposomes (diluted to 50 μL with DMEM) of lipids **1** and **2** using 9:1 lipid to DNA charge ratio. The cells were washed with PBS (1 × 200 μL), then treated with lipoplexes, and incubated at a humidified atmosphere containing 5% CO_2 at 37 °C. After 4 h of incubation, the cells were washed with PBS (3 × 200 μL) to remove the dye and fixed with 3.8% paraformaldehyde in PBS at room temperature for 10 min. The red fluorescent cells were detected under an inverted fluorescence microscope (Nikon, Japan).

Toxicity Assay. Cytotoxicity of lipids **1** and **2** was assessed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reduction assay as described earlier.[36] The cytotoxicity assay was performed in 96-well plates by maintaining the same ratio of number of cells to amount of cationic lipid, as used in the transfection experiments. MTT was added 24 h after the addition of cationic lipids to the cells followed by 3 h of incubation. Results were expressed as percentage viability = [A_{540} (treated cells) − background/A_{540} (untreated cells) − background] × 100.

DNA-Binding Assay. The DNA binding ability of cationic lipids **1**and **2** was assessed by conventional gel retardation assay on a 1% agarose gel (prestained with ethidium bromide) across the varying lipid/DNA charge ratios of 0.3:1 to 9:1. *p*CMV-SPORT-β-gal (0.30 μg) was complexed with varying amounts of cationic lipids in a total volume of 20 μL of DMEM and incubated at room temperature for 20−25 min. Four microliters of 6× loading buffer (0.25% bromophenol blue in 40% (w/v) sucrose in H_2O) was added to it, and 20 μL of the resultant solution was loaded in each well. The samples were electrophoresed at 80 V for 45 min and the DNA bands were visualized in the gel documentation unit.

DNase I Sensitivity Assay. Briefly, in a typical assay, pCMV-β-gal (0.6 μg) was complexed with varying amounts of the cationic lipids (using the indicated lipid/DNA charge ratios of 0.3:1 to 9:1) in a total volume of 20 μL in DMEM and incubated at room temperature for 30 min on a rotary shaker. Subsequently, the complexes were treated with 5 μL of DNase I (at a final concentration of 1 μg/mL) in the presence of 20 mM $MgCl_2$ in a final volume of 50 μL and incubated for 20 min at 37 °C. The reactions were then halted by adding EDTA (to a final concentration of 50 mM) and incubated at 60 °C for 10 min in a water bath. The aqueous layer was washed with 50 μL of phenol/chloroform mixture (1:1, v/v) and centrifuged at 10 000 rpm for 5 min. The aqueous supernatants were separated, loaded (15 μL) on a 1% agarose gel, and electrophoresed at 80 V for 2 h. The DNA bands were visualized with ethidium bromide staining.

Zeta Potential (ζ) and Size Measurements. The sizes and the surface charges (zeta potentials) of liposomes and lipoplexes were measured by photon correlation spectroscopy and electrophoretic mobility on a Zeta sizer $3000HS_A$ (Malvern, U.K.). The sizes were measured in Dulbecco's modified Eagle's medium (DMEM) with a sample refractive index of 1.59 and a viscosity of 0.89 cP. The system was calibrated by using the 200 nm ± 5 nm polystyrene polymer (Duke Scientific Corp., Palo Alto, CA). The diameters of liposomes and lipoplexes were calculated by using the automatic mode. The zeta potential was measured using the following parameters: viscosity, 0.89 cP; dielectric constant, 79; temperature, 25 °C; *F*(Ka), 1.50 (Smoluchowski); maximum voltage of the current, V. The system was calibrated by using DTS0050 standard from Malvern. Measurements were done 10 times with the zero-field correction. The potentials were calculated by using the Smoluchowski approximation.

RESULTS AND DISCUSSION

The present work illustrates the synthesis of lipids **1** and **2** and their physicochemical characteristics. The results of in vitro transfection experiments performed on five different types of cell lines to assess the transfection properties of lipoplexes of lipids **1** and **2** are reported. In addition, the inverted fluorescent microscope experiments in support of the results obtained in in vitro transfection studies are reported. A study of cytotoxicity in all the cell lines studied for transfection and serum compatibility of lipids **1** and **2** are also reported.

Chemistry. Toward probing the influence of the backbone structural variation in gene delivery efficacies of α-tocopherol based cationic amphiphiles, we designed and synthesized lipids **1** and **2** (Scheme 1) such that the two lipids architecturally differ only in the backbone functionality (non-glycerol and glycerol backbone). Lipid **1** was synthesized by reacting *N*-methyldiethanolamine with mesylated α-tocopherol to yield an intermediate followed by quarternization using methyl iodide and chloride ion exchange chromatography over Amberlyst anion exchange resin (Scheme 1, part A). To prepare lipid **2**, *N*,*N*-dimethyl-l,2,3-propanediol was reacted with mesylated α-tocopherol to yield tertiary amine as intermediate (Scheme 1, part B). The tertiary amine intermediate upon quarternization

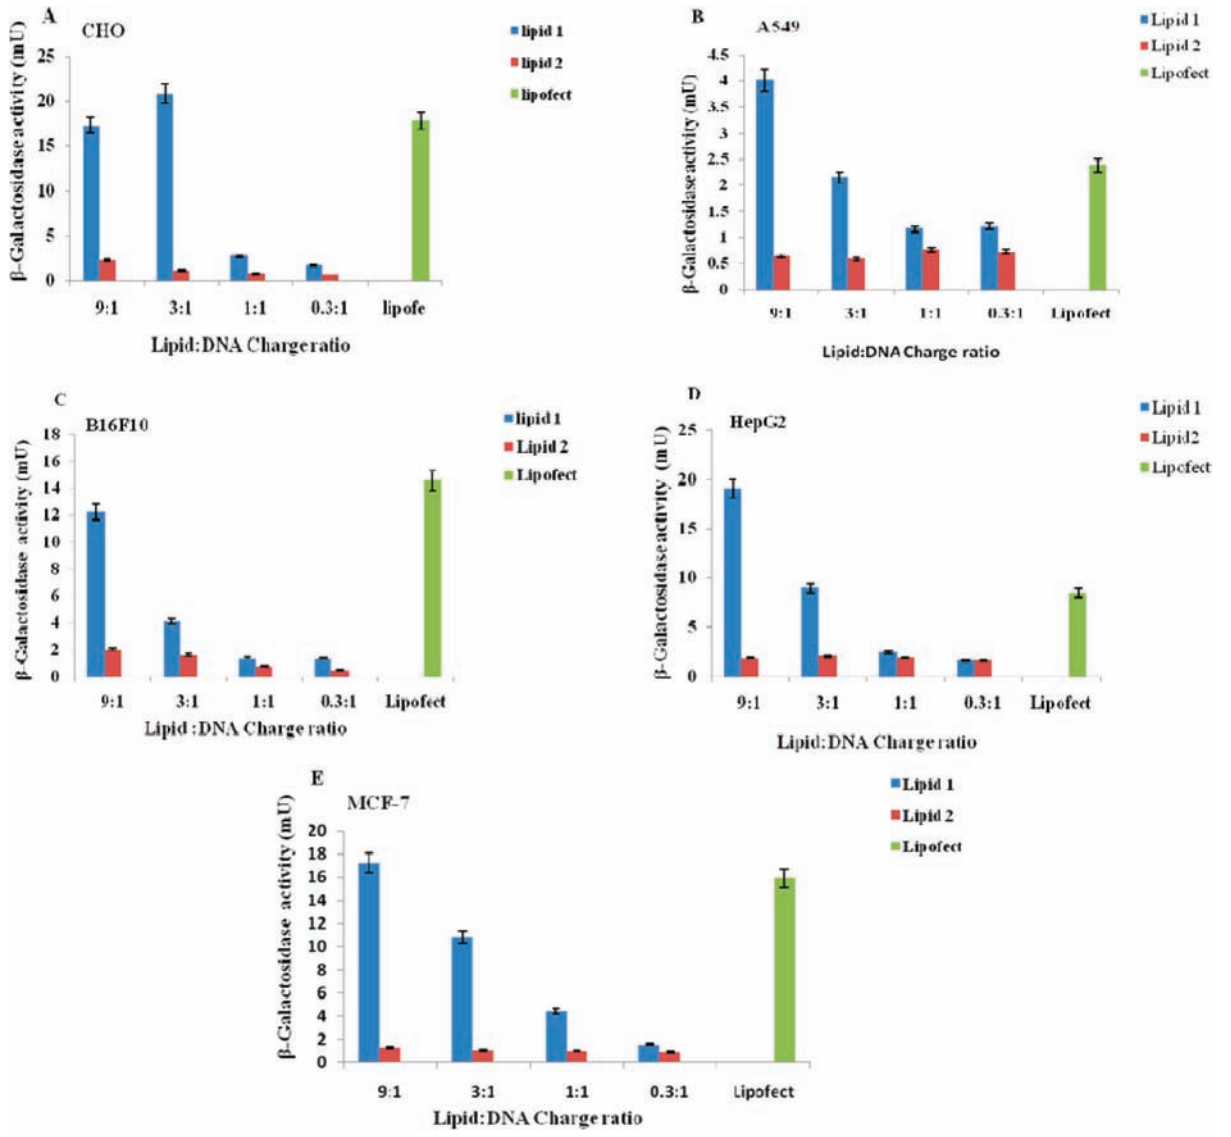

Figure 1. In vitro gene delivery efficiencies of lipids **1** and **2** in CHO (A), A549 (B), B16F10 (C), HepG2 (D), and MCF-7 (E) cell lines. Units of β-galactosidase activity were plotted against the varying lipid-to-DNA charge ratios (9:1−0.3:1). The transfection efficiencies of the lipids were compared to that of commercial formulation. Transfection experiments were performed as described in the text. Both lipids were tested on the same day, and the data presented are the average of three experiments performed on three different days.

with excess methyl iodide followed by chloride ion exchange over Amberlyst anion exchange resin afforded the target lipid **2** (Scheme 1, part B). The structures of all the intermediates (Scheme 1) and of the final target lipids **1** and **2** were confirmed by ^{1}H NMR and mass spectra. The purity of the final lipids were confirmed by elemental (C, H, N) analysis.

Transfection Biology. *In Vitro Transfection Studies.* Reporter gene expression assay was used in evaluating the in vitro gene delivery efficacies of lipids **1** and **2** in five cultured mammalian cells including A-549 (human lung carcinoma cells), B16F10 (murine melanoma cells), CHO (Chinese hamster ovary cells), HepG2 (human hepatocarcinoma), and MCF-7 (human breast adenocarcinoma cells) using *p*-CMV-SPORT-β-gal plasmid DNA as the reporter gene encoding the enzyme β-galactosidase across the lipid/DNA charge ratios of 9:1−0.3:1. Despite the presence of glycerol and nonglycerol backbone being the only structural differences between lipids **1** and **2**, only lipid **1** is competent in delivering reporter gene into all the five cell lines particularly at higher charge ratios, that is, at 3:1 and 9:1 (Figure 1, parts A−E).

Lipid **1** showed its higher gene delivery efficacies at lipid/DNA charge ratio of 9:1 in A-549, B16F10, HepG2, and MCF-7 cells (Figure 1, parts B−E, respectively) and at lipid/DNA charge ratio of 3:1 in CHO cells (Figure 1, part A). In contrast, lipid **2** turned out to be essentially incompetent in delivering genes into any of these five cells across the entire lipid/DNA charge ratios of 9:1−0.3:1 (Figure 1, parts A−E). Interestingly, lipid **1** is found to be comparable with or better than the commercially available formulation at specified lipid/DNA charge ratios in all cell lines except in B16 F10 type in which it is found to be less transfecting compared to commercial formulation. Lipid **1** is found to be one and half times better in transfecting A549 and nearly two and half times better in transfecting HepG2 type of cells compared to commercial formulation. Thus, the relative transfection profiles of lipids **1** and **2** summarized in parts A−E of Figure 1 demonstrate that the structural variation in the backbone region of α-tocopherol

dx.doi.org/10.1021/bc2004395 | *Bioconjugate Chem.* 2011, 22, 2581−2592

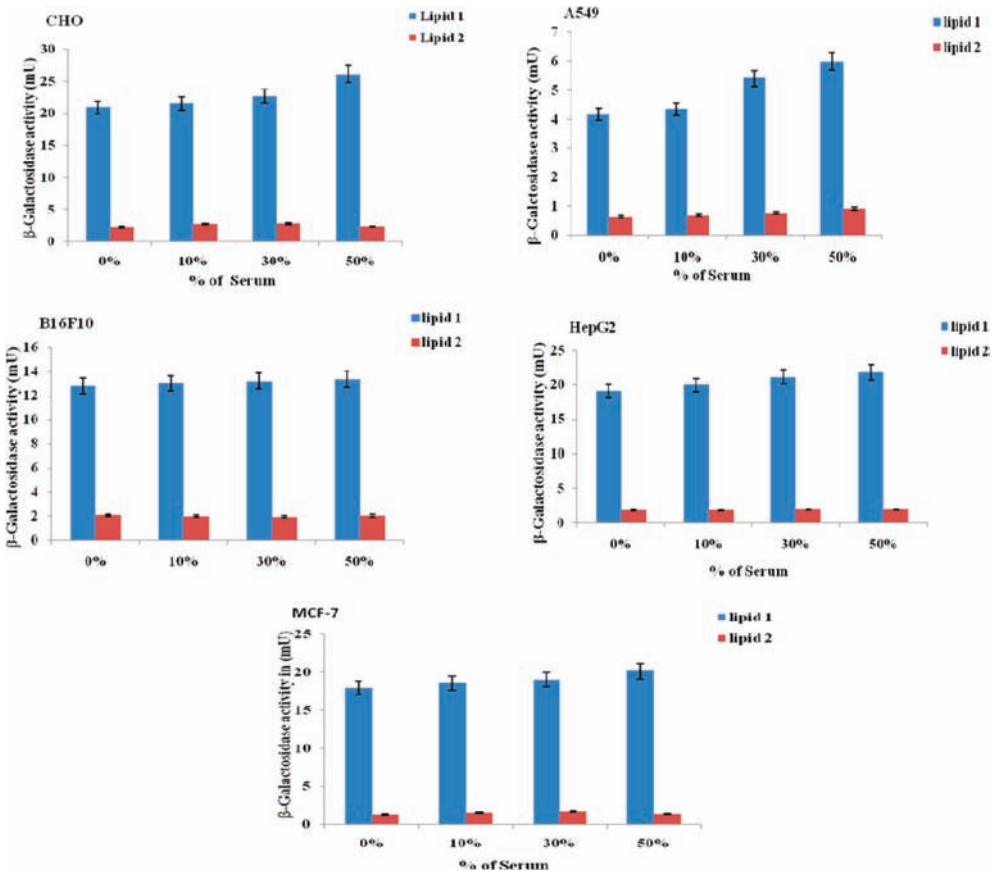

Figure 2. Transfection efficacies of the cationic lipids **1** and **2** in the presence of increasing concentrations of serum added. In vitro transfection efficiencies of lipid/DNA complexes prepared using *p*CMV-*β*-gal-SPORT reporter gene at lipid/DNA charge ratio of 9:1 were evaluated in the presence of increasing concentrations of serum added in CHO (A), A-549 (B), B16F10 (C), HepG2 (D), and MCF-7 (E) cell lines. Both the lipids were tested on the same day, and the data presented are the average of three experiments performed on three different days.

based cationic amphiphiles is a crucial parameter capable of profoundly influencing gene transfer efficacies of *α*-tocopherol based cationic amphiphiles.

Serum Compatibility. The gene transfer efficacies of cationic amphiphiles, in general, are evaluated either in complete absence of serum or in the presence of only 10% (v/v) added serum as disclosed in many prior reports.[23,29,37−41] However, the clinical success of cationic transfection lipids depends on their serum compatibility. The in vitro gene transfer efficacies of cationic amphiphiles usually get adversely affected in the presence of serum.[42−49] Such serum incompatibility of cationic transfection lipids is believed to begin via adsorption of negatively charged serum proteins onto the positively charged cationic liposome surfaces preventing their efficient interaction with cell surface and/or internalization.[50−52]

Toward probing the serum compatibility of the lipids **1** and **2**, in vitro gene transfer efficacies for the lipids **1** and **2** were evaluated across lipid/DNA charge ratio 9:1 at which both lipids showed their higher transfection ability in all five types of cell lines used for transfection (CHO, A-549, B16F10, MCF-7, and HepG2) in the presence of increasing concentrations of serum added (10−50%, v/v) (Figure 2). Interestingly, for reasons not clear at this stage of investigation, the in vitro gene transfer efficacy of lipid **1** is found to be increasing in the presence of up to 50% added serum while that of lipid **2** is found to be unaffected by concentration of serum added (Figure 2). Thus, the transfection efficiency of lipid **1** is found to be highly serum-compatible even at higher levels of added serum.

α5GFP Plasmid Transfection. The relative transfection efficacies of lipids **1** and **2** were also evaluated by the in vitro transfection studies using *α*5GFP (a plasmid DNA encoding green fluorescence protein) in representative HepG2 and A549 (Figure 3, I and II) cells using lipoplexes with 9:1 lipid/DNA charge ratio (the charge ratio where the lipid **1** shows higher transfection in both types of cell lines). After washing the cells with phosphate buffer saline, live HepG2 and A549 cells were viewed under an inverted fluorescence microscope. The numbers of fluorescently labeled cell lines are found to be more when the cells were treated with lipoplexes of lipid **1** than that of lipoplexes of lipid **2** (Figure 3).

Cellular Uptake Study. Results from in vitro transfection experiments demonstrate that lipid **1** is efficient in transfecting multiple cultured cell lines, whereas lipid **2** is incompetent in transfecting in any of these cell lines. Thus, in order to probe the role of cellular uptake behind the contrasting transfection profiles of lipids **1** and **2** the cellular uptake experiments were performed. The representative A549 and MCF-7 cell lines were treated with lipoplexes comprising *p*CMV-SPORT-*β*-gal plasmid DNA and rhodamine-PE labeled liposomes of lipids **1** and **2** with lipid/DNA charge ratio 9:1. The number of A549 and MCF-7 cell lines labeled red are found to be relatively more when treated with lipoplexes of lipid **1** against lipid **2** from the cellular uptake experiment (Figure 4). Thus, these results of cellular uptake experiments (Figures 4) support the

dx.doi.org/10.1021/bc2004395|*Bioconjugate Chem.* 2011, 22, 2581−2592

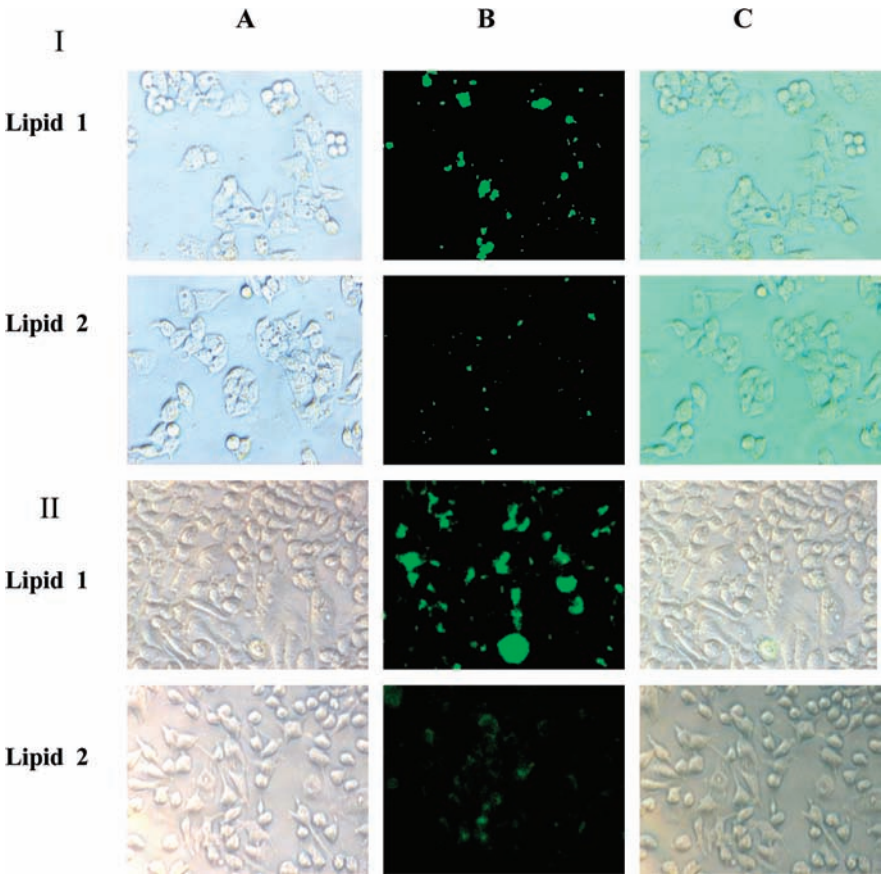

Figure 3. Inverted microscopic images of representative HepG2 (I) and A549 (II) cell lines transfected with lipoplexes of lipids (**1** and **2**) and α5GFP expressing plasmid DNA. Lipid/DNA charge ratios in all the lipoplexes were maintained at 9:1 (A) bright field images, (B) fluorescent images, and (C) overlay images. The details of inverted fluorescence microscopic experiments are described in the text.

notion that the varying transfection profiles of lipids **1** and **2** could be attributed to the cellular uptake variations of the respective lipids. This reemphasizes the supposition that the degree of cellular uptake plays an important role in contrasting transfection profiles of lipids **1** and **2**.

Lipid/DNA Binding Assay. The electrostatic binding interactions between the plasmid DNA and the cationic lipids **1** and **2** at varying lipid/DNA charge ratios were measured by conventional electrophoretic gel retardation assay and DNase I sensitivity assays (Figures 5 and 6). The corresponding electrophoretic gel patterns observed in the gel retardation assay for lipoplexes formed from lipids **1** and **2** are shown in (Figure 5). The gel patterns revealed striking contrasting DNA binding profiles of lipids **1** and **2**. Careful observation of the experimental results unveil that lipid **1** was capable of completely inhibiting electrophoretic mobility of plasmid DNA when lipoplexes were prepared at higher lipid/DNA charge ratios of 9:1 and 3:1 (Figure 5). In contrast, the lipid **2** was found to be completely inefficient in binding DNA even at this higher lipid/DNA charge ratios. At lower lipid/DNA charge ratios (1:1 and 0.3:1), the amount of free DNA associated with lipid **2** is found to be higher when compared to lipid **1** (Figure 5). The stability of lipoplexes formed by lipids **1** and **2** was further confirmed by monitoring the sensitivities of the lipoplexes upon treatment with DNase I. After the free DNA digestion by DNase I, the total DNA (both the digested and inaccessible DNA) was separated from lipid (by extracting with organic solvents) and loaded on a 1% agarose gel. Figure 6 summarizes the results of such DNase I protection experiments for lipoplexes prepared from the cationic lipids **1** and **2** across the entire lipid/DNA charge ratios of 9:1 to 0.3:1. The band intensities of inaccessible and therefore undigested DNA associated with transfection incompetent lipids **2** is found to be significantly less compared to those associated with transfection efficient lipid **1** across the lipid/DNA charge ratios of 9:1 to 0.3:1. Thus, the findings in the conventional gel mobility shift (Figure 5) and DNase I sensitivity assays (Figure 6) together are consistent with the supposition that strong lipid−DNA binding interactions in the lipoplexes perhaps play important role behind the higher transfection efficacies of lipid **1**.

The results of gel retardation assay and sensitivity of the lipoplexes upon treatment with DNase I in the presence of anionic lipid[53,54] (Supporting Information) reveal that the anionic lipid studied in this experiment can displace the ionic interaction between plasmid DNA and the cationic lipids **1** and **2**. It can be deduced from this result that the anionic molecules present in the cell can also displace the ionic interactions between plasmid DNA and the cationic lipids **1** and **2**, thereby releasing plasmid DNA into the cell cytoplasm.

Toxicity Studies. MTT-based cell viability assays were performed in all five types of cell lines used for transfection (CHO, A-549, B16F10, MCF-7, and HepG2) treating with lipoplexes of lipids **1** and **2** across the range of lipid/DNA charge ratios (9:1−0.3:1) used in the actual transfection experiments. Cell viabilities of both the lipids **1** and **2** in all five types of cell lines are found to be remarkably high (more than 85%) particularly up to the lipid/DNA charge ratios of 3:1

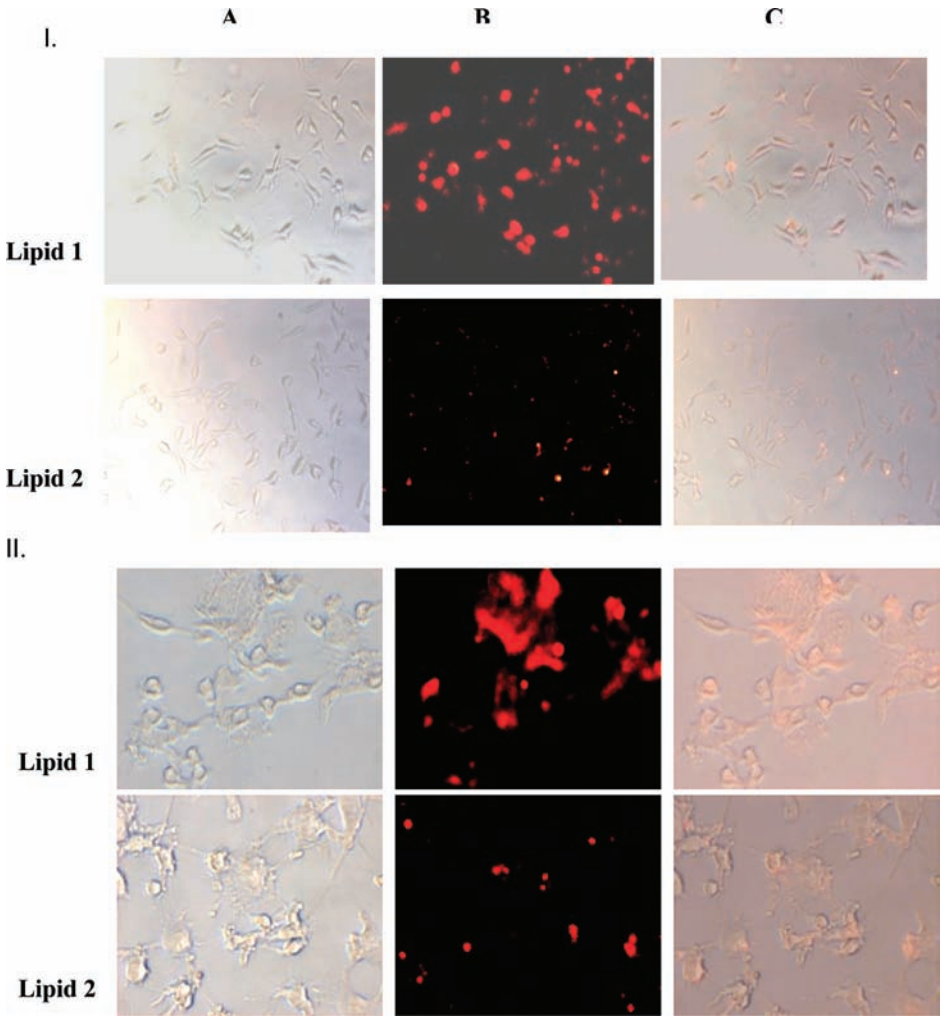

Figure 4. Cellular uptake of Rhodamine labeled lipoplexes. Inverted microscopic images of A549 (I) and MCF-7 (II) cell lines transfected with rhodamine labeled lipoplexes of lipids **1** and **2** prepared at higher in vitro transfection lipid/DNA charge ratios of 9:1 (A) bright field images, (B) fluorescent images, and (C) overlay images. The details of the experiments are described in the text.

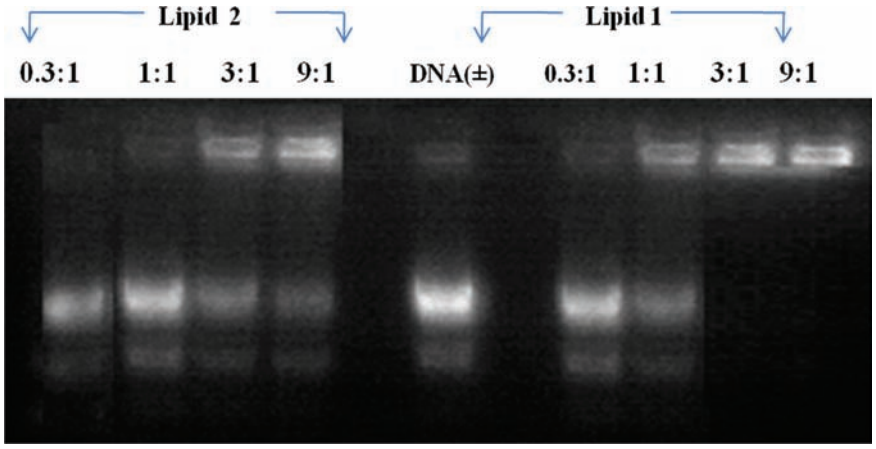

Figure 5. Electrophoretic gel patterns for lipoplex-associated DNA in gel retardation assay. The lipid/DNA charge ratios are indicated at the top of each lane. The details of the gel experiment are as described in the text.

(Figure 7). Except in CHO cell lines, in all the other cell lines the cell viabilities of both lipids **1** and **2** are found to be $\gtrsim$80% at higher charge ratio of 9:1. Thus, the contrasting in vitro gene transfer efficacies of the lipids **1** and **2** are unlikely to originate from varying cell cytotoxicities of the lipids.

Nanosizes and Global Surface Charges of the Lipoplexes. To gain insight into the liposomal physical properties, sizes, and surface potentials of the liposomes of lipids **1** and **2** (prepared in DI water) and their lipoplexes (prepared in DMEM) were measured using dynamic laser light scattering technique

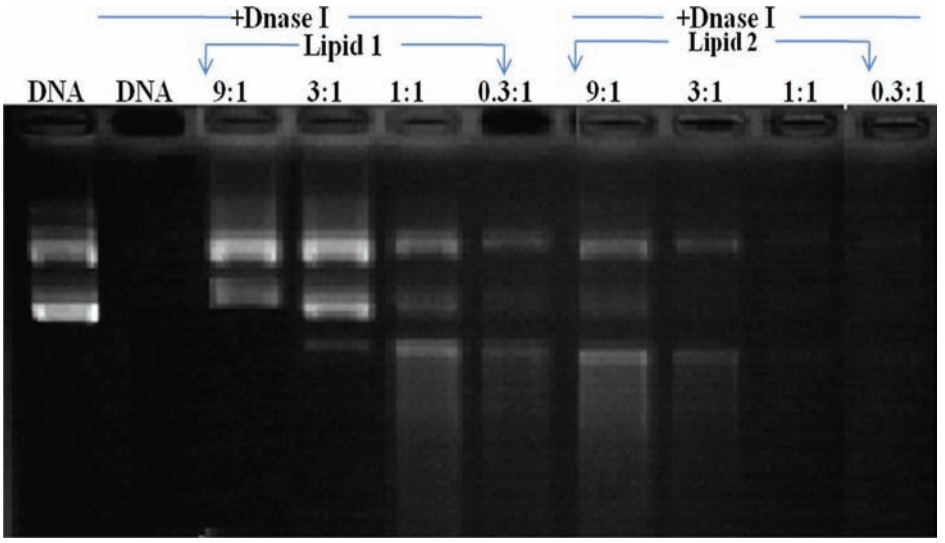

Figure 6. Electrophoretic gel patterns for lipoplex-associated DNA in DNase I sensitivity assay. The lipid/DNA charge ratios are indicated at the top of each lane. The details of the treatment are as described in the text.

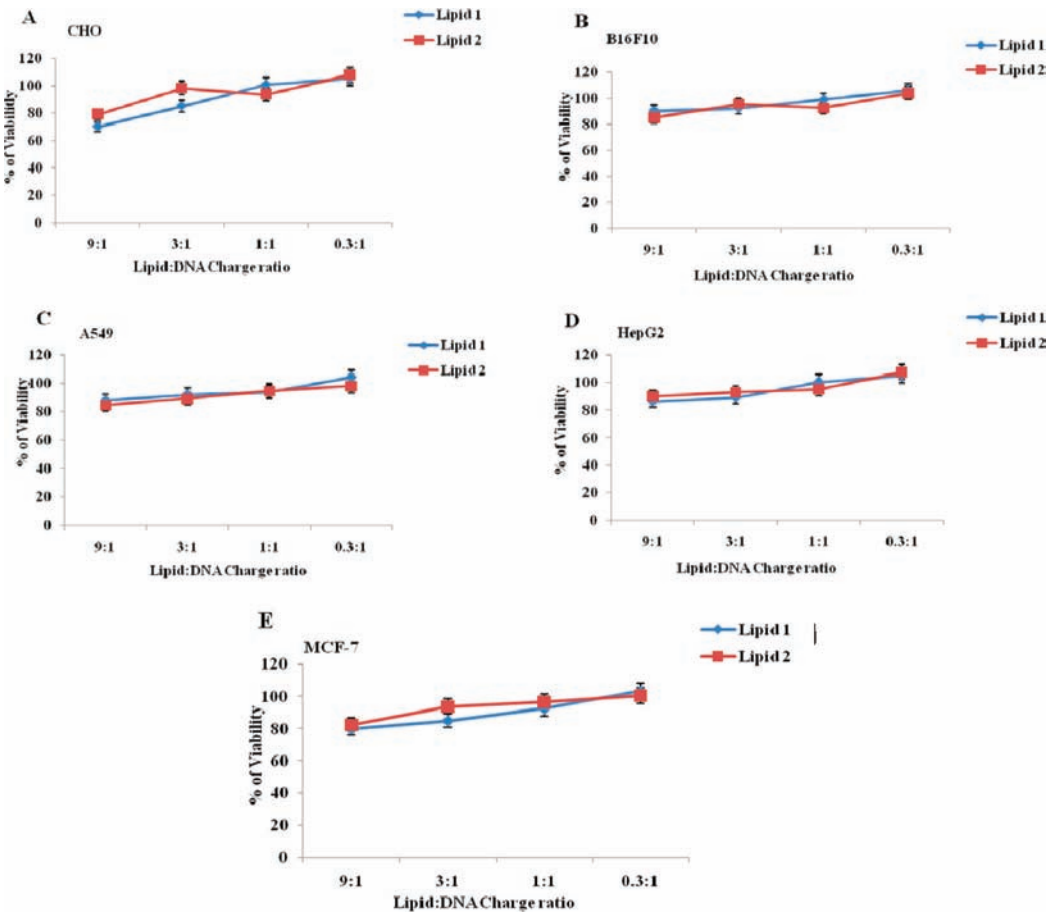

Figure 7. MTT-assay based percent cell viabilities of CHO (A), A-549 (B), B16F10 (C), HepG2 (D), and MCF-7 (E) cell lines treated with lipoplexes of lipids **1** and **2** with lipid/DNA charge ratios 9:1−0.3:1. The cell viability values shown are the average of triplicate experiments performed on same day. The details of the MTT-assay are as described in the text.

(Zetasizer 3000A, Malvern Instruments, U.K.). The sizes and surface potentials of these liposomes and lipoplexes were measured in the absence and in the presence of 10% serum.

Liposomes of lipid **1** were found to be smaller in size compared to liposomes of lipid **2** (Table 1). Lipoplexes of lipid **1** were found to increase from 350 to 800 nm in size as lipid/DNA charge ratios decreased from 9:1 to 0.3:1, whereas lipoplexes of lipid **2** showed steady increase from 600 to 750 nm (Table 1). Significant lipoplex size reduction at higher lipid/DNA charge ratios for lipid **1** can be attributed to the

			Size (nm)			
1	175.4 ± 3.5 (149.2 ± 1.0)	781.7 ± 16.7 (626.1 ± 4.5)	740.3 ± 22.2 (592.7 ± 6.8)	570.6 ± 26.0 (383.9 ± 19.1)	352.6 ± 49.7 (256.3 ± 12.6)	
2	253.2 ± 5.3 (219.1 ± 4.4)	739.2 ± 24.1 (529.2 ± 27.1)	706.6.2 ± 9.5 (512.4 ± 11.5)	640.6 ± 18.5 (420.2 ± 1.5)	686.7 ± 2.8 (497.9 ± 10.6)	
			Zeta potentials (mV)			
1	22.2 ± 3.1 (18.7 ± 3.5)	−12.5 ± 1.8 (−8.2 ± 4.9)	4.7 ± 3.2 (1.2 ± 0.8)	5.9 ± 2.1 (3.4 ± 1.4)	17.6 ± 5 (13.8 ± 3.2)	
2	9.5 ± 6.5 (7.1 ± 2.0)	−14.9 ± 1.8 (−12.8 ± 3.5)	−1.5 ± 1.6 (−5.2 ± 1.5)	5.1 ± 5.0 (1.4 ± 2.1)	8.3 ± 1.0 (6.5 ± 4.0)	

[a]Sizes and ζ potentials of liposomes and lipoplexes of lipids **1** and **2** in the absence and in the presence of 10% serum (values within parentheses) were measured by laser light scattering technique using Zetasizer 3000A (Malvern Instruments, U.K). Values shown are the averages obtained from three (size) and ten (zeta potential) measurements.

pronounced DNA condensation efficacies of lipid **1** and hence the higher transfection efficacies of lipid **1** at higher lipid/DNA charge ratios when compared to lipid **2**. Interestingly, the global surface potentials of lipoplexes of lipid **1** were found to be somewhat more positive than those for lipoplexes of lipid **2** in the lipid/DNA charge ratio range 9:1−0.3:1 (Table 1). Results of size and zeta potentials of liposomes and lipoplexes of lipids **1** and **2** in the presence of serum are as shown in the parentheses of Table 1. Significant reduction in size of liposomes and lipoplexes of lipids **1** and **2** was observed. This reduction in size of lipoplexes in the presence of serum was reported earlier.[55] The observed size reduction of lipoplexes in the presence of serum may be the result of a number of factors, including viscosity, serum protein binding, refractive index, and the partial dissociation of the lipoplexes. These observations suggest that the serum-induced decrease in size may not be the primary cause of the higher transfection efficiency of lipid **1** in the presence of serum.

CONCLUSIONS

In summary, the findings described provide the first experimental evidence for the influence of backbone structural variation in liposomal gene delivery of α-tocopherol based cationic lipids. Two α-tocopherol based cationic amphiphiles **1** and **2** were designed and synthesized containing the same hydrophobic region, same headgroup and linker group functionality, but differ only in the backbone region. In vitro findings delineated that lipid **1** showed higher gene transfer efficacies than lipid **2** in multiple cultured mammalian cells including CHO, B16F10, HepG2, MCF-7, and A549. Findings in dynamic laser light scattering studies revealed that lipid **1** significantly condenses DNA compared with lipid **2**. Inverted fluorescence microscopic studies using lipoplexes of lipids **1** and **2** containing green fluorescent protein encoding plasmid DNA and Rhodamine-labeled lipoplexes of lipids **1** and **2** respectively demonstrated significantly higher expression of GFP and higher cellular uptake with lipoplexes of lipid **1**. To conclude, the findings described demonstrate the dramatic influence of backbone structural variation in liposomal gene delivery of α-tocopherol based cationic lipids.

Supporting Information

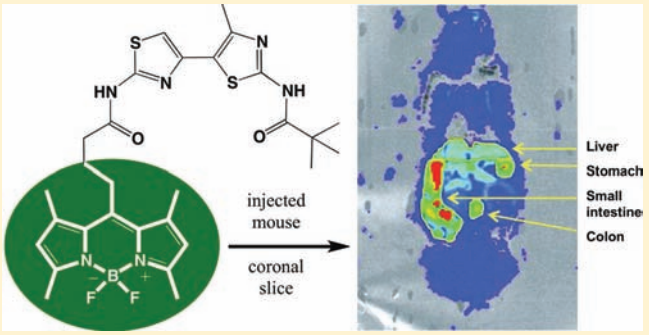
ABSTRACT: We previously reported the identification and structure–activity analysis of bithiazole-based correctors of defective cellular processing of the cystic fibrosis-causing CFTR mutant, ΔF508-CFTR. Here, we report the synthesis and uptake of a functional, fluorescently labeled bithiazole corrector. Following synthesis and functional analysis of four bithiazole–fluorophore conjugates, we found that **5**, a bithazole-based BODIPY conjugate, had low micromolar potency for correction of defective ΔF508-CFTR cellular misprocessing, with comparable efficacy to benchmark corrector corr-**4a**. Intravenous administration of **5** to mice established its stability in extrahepatic tissues for tens of minutes. By fluorescence imaging of whole-body frozen slices, fluorescent corrector **5** was visualized strongly in gastrointestinal organs, with less in lung and liver. Our results provide proof-of-concept for mapping the biodistribution of a ΔF508-CFTR corrector by fluorophore labeling and fluorescence imaging of whole-body slices.



INTRODUCTION

The genetic disease cystic fibrosis (CF) is caused by mutations in the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR) protein, a cAMP-regulated chloride channel expressed in epithelial cells in lung, pancreas, testis, intestine, and other organs.[1,2] The most common CF-causing CFTR mutation is deletion of phenylalanine at residue 508 (ΔF508), which produces a misfolded protein that is retained at the endoplasmic reticulum (ER) and rapidly degraded.[3−6] A major focus in CF research is the identification and development of compounds, termed correctors, that normalize defective ΔF508-CFTR cellular processing to promote its plasma membrane targeting.[7−10]

By high-throughput screening, we previously reported the identification of bithiazole-based ΔF508-CFTR correctors such as corr-**4a**.[11] Corr-**4a** improved ΔF508-CFTR trafficking, resulting in partial restoration of cell chloride permeability. Following structure–activity relationship (SAR) studies conducted on 148 methylbithiazole analogues revealed that the substitution of the phenyl amide at position X (**2**; Figure 1) for a pivoyl amide improved potency,[12] and the addition of a dimethylamino-substituted phenyl moiety at position Y improved water solubility while retaining corrector activity.[13]

These findings have led us to further assess the utility of functional bithiazole derivatives at positions X and Y as ΔF508-CFTR correctors. With the intent to monitor the *in vitro* and *in vivo* efficacies of these compounds, we have incorporated photostable fluorescent dyes onto the bithiazole core (**3**–**6**; Figure 1). Herein, we report the synthesis and characterization of four fluorescently labeled bithiazole-based compounds, along with their corrector activity, as a proof-of-concept demonstration of the use of fluorescent CF correctors to probe uptake. While these derivatives are not development candidates, the work here demonstrates the possibility of synthesizing a functional fluorescent corrector whose uptake can be studied using imaging methodology.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All chemicals were purchased from commercial suppliers and used without further purification unless otherwise noted. Analytical thin layer chromatography was carried out on precoated glass plates (silica gel 60 F_{254}, 250 μm thickness) and visualized with UV light at 245 nm. Flash chromatography was performed with 60 Å, 32–63 μm silica gel (Scientific Absorbents). Synthesized products were concentrated by rotary evaporation under reduced pressure. ^{1}H NMR spectra were recorded at 400 or 600 MHz at ambient temperature with DMSO-d_6, $CDCl_3$, or CD_3OD as solvent. ^{13}C NMR spectra were recorded at 100 or 150 MHz at ambient temperature with DMSO-d_6, $CDCl_3$, or CD_3OD as solvent. Chemical shifts are reported in parts per million relative to $CHCl_3$ (^{1}H, δ 7.26, ^{13}C, 77.16), DMSO-d_5 (^{1}H, δ 2.50, ^{13}C, 39.52), or CHD_2OD (^{1}H, δ 3.31, ^{13}C, 49.00). Infrared spectra were recorded on an ATI-FTIR spectrometer (Mattson Genesis II). The specifications of the LC-MS are as follows: electrospray (+) ionization, mass range 150–1500 Da, 20 V cone voltage, and Xterra MS C_{18} column (2.1 mm × 50 mm × 3.5 μm). Dye precursors 4-(4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3*a*-diaza-s-indacene-8-yl)-butyric acid (**7**)[14] and 7-hydroxycoumarin-3-carboxylic acid (**8**)[15,16] were synthesized and characterized according to literature methods. Bithiazole intermediates 1-(2-amino-4-methylthiazol-5-yl)-ethanone HCl (**9**),[17] 1-(2-amino-4-methylthiazol-5-yl)-2-bromoethanone (**10**), 1-(2-chloro-5-(dimethylaminophenyl)-thiourea (**11**), and *N*-(5-acytyl-4-methylthiazol-2-yl)pivalamide (**13**)[18] were synthesized as previously described.

***N*^{2}-(2-Chloro-5-(dimethylamino)phenyl)-4′-methyl-4,5′-bithiazole-2,2′-diamine (12).** Bromothiazole **10** (3.14 g, 11.56 mmol) and thiourea **11** (2.28 g, 9.92 mmol) were dissolved in ethanol (27 mL), and the mixture was heated to reflux for 2 h. After cooling to room temperature, the solid was collected by filtration and rinsed with cold ethanol to afford aminobithiazole **12** (3.68 g, 79%) as a pale pink solid. IR (neat) ν_{max} 3388, 3210, 3035, 1628, 1609, 1586, 1544, 1514, 1474, 1450, 1406, 1068, 1048, 879, 870, 807 cm^{-1}; ^{1}H NMR (400 MHz, DMSO-d_6) δ 2.40 (s, 3H), 3.08 (s, 6H), 7.00 (d, J = 8.8 Hz, 1H), 7.15 (s, 1H), 7.46 (d, J = 8.8 Hz, 1H), 8.24 (s, 1H), 9.47 (br s, 2H), 10.01 (s, 1H); ^{13}C NMR (150 MHz, DMSO-d_6) δ 17.05, 40.32, 101.12, 104.46, 107.57, 108.99, 114.41, 129.34, 137.41, 143.05, 143.88, 149.84, 162.79, 165.73; MS (ESI) m/z calcd. 365.05, found 366.04 $[M + H]^+$.

General Procedure for Preparation of Fluorescent Bithazole Probes 3–6 via CDI-Mediated Amide Formation. Fluorophore **7** (or **8**; 1.5 equiv) was dissolved in DMF (2.21 mL/mmol fluorophore) followed by the addition of carbonyldiimidazole (CDI; 1.5 equiv). The mixture was stirred for 30 min at room temperature, and aminobithiazole **12** (or **15**; 1 equiv) was added in one portion. The reaction was warmed to 80 °C and stirred for 48 h. After cooling to room temperature, the mixture was poured into water to precipitate the product. The solid was collected by filtration, rinsed with water, and dried under vacuum to yield **3**–**6**, each as a crude solid.

10-(4-(2-(2-Chloro-5-(dimethylamino)phenylamino)-4′-methyl-4,5′-bithiazol-2′-ylamino)-4-oxobutyl)-5,5-difluoro-1,3,7,9-tetramethyl-5*H*-dipyrrolo[1,2-*c*:1′,2′-*f*]-[1,3,2]diazaborinin-4-ium-5-uide (3). According to the general procedure for amide formation, **7** (138 mg, 0.41 mmol), DMF (0.91 mL), CDI (66 mg, 0.41 mmol), and **12** (100 mg, 0.27 mmol) gave crude solid, which was purified by flash column chromatography (1.25:1 hexane/EtOAc) to produce **3** (36 mg, 19%) as a red solid; IR (neat) ν_{max} 2916, 1686, 1600, 1581, 1535, 1513, 1431, 1017, 843 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.04 (m, 2H), 2.35 (s, 6H), 2.49 (s, 6H), 2.54 (s, 3H), 2.58 (m, 2H), 3.01 (m, 2H), 3.05 (s, 6H), 6.01 (s, 2H), 6.35 (dd, J = 2.8, 8.9 Hz, 1H), 6.62 (s, 1H), 7.20 (d, J = 8.9 Hz, 1H), 7.62 (br s, 1H), 7.88 (d, J = 2.8 Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ 14.61, 16.49, 17.28, 26.97, 27.45, 36.06, 40.92, 102.68, 102.82, 107.32, 108.77, 122.02, 122.32, 129.37, 131.54, 136.82, 140.49, 142.40, 144.62, 150.44, 154.42, 155.90, 162.92, 169.28; MS (ESI) m/z calcd. 681.21, found 682.19 $[M + H]^+$.

***N*-(2-(2-Chloro-5-(dimethylamino)phenylamino)-4′-methyl-4,5′-bithiazol-2′-yl)-7-hydroxy-2-oxo-2*H*-chromene-3-carboxamide (4).** According to the general procedure for amide formation, **8** (154 mg, 0.75 mmol), DMF (1.65 mL), CDI (121 mg, 0.75 mmol), and **12** (200 mg, 0.50 mmol) gave crude solid, which was purified by recrystallization in EtOH to yield **4** (108 mg, 20%) as an orange solid; IR (neat) ν_{max} 3276, 2208, 2164,1695, 1679, 1529, 1509, 1373, 1264, 1195, 1134, 834 cm^{-1}; ^{1}H NMR (400 MHz, DMSO-d_6) δ 3.02 (s, 6H), 6.44 (dd, J = 2.9, 8.9 Hz, 1H), 6.86 (d, J = 1.9, 1H), 6.94 (dd, J = 2.1, 8.6 Hz, 1H), 7.01 (s, 1H), 7.22 (d, J = 8.9 Hz, 1H), 7.91 (d, J = 8.7 Hz, 1H), 8.07 (d, J = 2.8 Hz, 1H), 8.96 (s, 1H), 9.63 (s, 1H), 11.33 (br s, 1H), 11.85 (s, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 17.09, 40.54, 102.02, 103.96, 104.44, 108.94, 111.26, 111.84, 114.85, 121.90, 129.41, 132.63, 137.43, 141.87, 142.91, 149.33, 149.76, 153.72, 156.66, 159.71, 161.31, 163.24, 164.63; MS (ESI) m/z calcd. 553.06, found 554.11 $[M + H]^+$.

***N*-(5-(2-Bromoacetyl)-4-methylthiazol-2-yl)pivalamide (14).** A solution of **13** (6.5 g, 27.1 mmol) in 30% HBr in AcOH (40 mL) was treated with $PryH^+Br_3^-$ (11.25 g, 35.17 mmol) and stirred at room temperature for 48 h. Water was added and the aqueous layer was extracted with CH_2Cl_2. The combined organic extracts were washed with saturated

dx.doi.org/10.1021/bc2004457 | *Bioconjugate Chem.* 2011, 22, 2593–2599

$NaHCO_3$ and brine. The organic layer was dried over sodium sulfate, filtered, and evaporated under reduced pressure. The residue was purified by flash column chromatography (20−40% EtOAc/hexane) to yield 4.23 g (49%) of the title compound **14** as a white solid; IR (neat) ν_{max} 3260, 2970, 2928, 1687, 1660, 1530, 1493, 1370, 1318, 1280, 1220, 1196, 1136, 975, 819 cm^{-1}; ^1H NMR (600 MHz, $CDCl_3$) δ 1.28 (s, 9H), 2.52 (s, 3H), 4.17 (s, 2H); ^{13}C NMR (150 MHz, $CDCl_3$) δ 17.85, 26.82, 33.58, 39.37, 121.19, 157.27, 160.69, 177.27, 184.34; MS (ESI) m/z calcd. 318.00, found 318.97 $[M + H]^+$.

***N*-(2-Amino-4′-methyl-4,5′-bithiazol-2′-yl)pivalamide (15).** To a solution of **14** (2.38 g, 7.46 mmol) in EtOH (15 mL) was added thiourea (568 mg, 7.46 mmol). The mixture was heated to reflux and stirred for 12 h. After cooling to room temperature, hexane was added to fully precipitate the product and the solid was collected by filtration and washed with cold ethanol to obtain 607 mg (27%) of **15** as a cream-colored solid; IR (neat) ν_{max} 3198, 3180, 2967, 2932, 1675, 1621, 1597, 1515, 1484, 1353, 1304, 1141, 994, 898 cm^{-1}; ^1H NMR (600 MHz, CD_3OD) δ 1.31 (s, 9H), 2.41 (s, 3H), 4.91 (br s, 2H), 6.88 (s, 1H); ^{13}C NMR (150 MHz, CD_3OD) δ 16.36, 27.20, 40.22, 106.73, 113.08, 131.93, 149.20, 159.55, 172.11, 179.12; MS (ESI) m/z calcd. 296.08, found 297.08 $[M + H]^+$.

5,5-Difluoro-1,3,7,9-tetramethyl-10-(4-(4′-methyl-2′-pivalamido-4,5′-bithiazol-2-ylamino)-4-oxobutyl)-5*H*-dipyrrolo[1,2-*c*:1′,2′-*f*][1,3,2]diazaborinin-4-ium-5-uide (5). According to the general procedure for amide formation, **7** (140 mg, 0.42 mmol), DMF (0.93 mL), CDI (68 mg, 0.42 mmol), and **15** (83 mg, 0.28 mmol) gave crude solid, which was purified by flash column chromatography (1.25:1 hexane/EtOAc) to produce **5** (94 mg, 55%) as a neon orange solid; mp 266 °C dec; IR (neat) ν_{max} 3189, 2960, 1655, 1547, 1509, 2923, 1706, 1546, 1506, 1406, 1197, 1061, 983, 834 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 1.30 (s, 9H), 2.01 (m, 2H), 2.36 (s, 6H), 2.50 (s, 6H), 2.51 (s, 3H), 2.53 (m, 2H), 2.97 (m, 2H), 6.03 (s, 2H), 6.91 (s, 1H), 8.91 (br s, 1H), 10.05 (s, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ 14.59, 16.49, 16.94, 26.94, 27.26, 27.40, 35.82, 39.24, 108.53, 121.09, 122.02, 131.59, 140.58, 142.19, 143.35, 144.80, 154.39, 155.96, 157.67, 170.02, 176.26; HRMS: Anal. $C_{29}H_{35}BF_2N_6O_2S_2$ m/z calcd. 612.2433, found 613.2405 $[M + H]^+$.

7-Hydroxy-*N*-(4′-methyl-2′-pivalamido-4,5′-bithiazol-2-yl)-2-oxo-2*H*-chromene-3-carboxamide (6). According to the general procedure for amide formation, **8** (209 mg, 1.01 mmol), DMF (2.25 mL), CDI (164 mg, 1.01 mmol), and **15** (200 mg, 0.68 mmol) gave crude solid, which was purified by recrystallization from DMF to yield **6** (56 mg, 17%) as a canary yellow solid; IR (neat) ν_{max} 3376, 2967, 2959, 1698, 1616, 1521, 1505, 1266, 1192, 1129 cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ 1.25 (s, 9H), 6.86 (d, J = 1.8 Hz, 1H), 6.93 (dd, J = 2.1, 8.6 Hz, 1H), 7.29 (s, 1H), 7.88 (d, J = 8.7, 1H), 8.94 (s, 1H), 11.32 (br s, 1H), 11.78 (s, 1H), 11.99 (s, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 16.86, 26.61, 35.75, 102.06, 108.65, 111.21, 111.88, 114.89, 119.51, 132.64, 142.30, 143.20, 149.40, 156.12, 156.42, 156.70, 160.25, 161.17, 164.72, 176.56; MS (ESI) m/z calcd. 484.09, found 485.03 $[M + H]^+$.

Short-Circuit Current Measurements. Fisher rat thyroid (FRT) epithelial cells stably expressing human ΔF508-CFTR were generated as described previously.[19] The FRT cells were cultured on Snapwell porous support for 7−9 days. Test compounds were incubated with FRT cells for 18−24 h at 37 °C prior to measurements. Standard short-circuit current measurement procedures were followed as previously described.[20] The basolateral solution contained 130 mM NaCl, 2.7 mM KCl, 1.5 mM KH_2PO_4, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$, 10 mM glucose, and 10 mM Na-HEPES (pH 7.3). In the apical bathing solution, 65 mM NaCl was replaced by Na gluconate, and $CaCl_2$ was increased to 2 mM. Solutions were bubbled with air and maintained at 37 °C. The basolateral membrane was permeabilized with 250 μg/mL amphotericin B. Hemichambers were connected to a DVC-1000 voltage clamp (World Precision Instruments Inc.) via Ag/AgCl electrodes and 1 M KCl agar bridges for recording of short-circuit current.

Cellular Uptake. FRT cells[19] were cultured on coverglasses and mounted in a perfusion chamber maintained at 37 °C. Cells were incubated with serum-free culture medium containing 10 μM **5** in culture medium. Cells were imaged over 45 min using a laser-scanning confocal microscope (Nikon C1, 100× oil objective, NA 1.49) using appropriate filter sets. Cells expressing endoplasmic reticulum-targeted green fluorescent protein (GFP) were also imaged.

***In Vivo* Metabolic Stability.** All experiments involving live animals were performed according to procedures approved by the Institution of Animal Care and Usage Committee (IACUC) at UCSF. Compound **5** (250 μg/100 μL; 10% DMSO, 10% Tween 80, 40% propylene glycol, 20% ethanol, and 20% H_2O; sterilized through a 20 μm filter prior to injection) or saline was injected intraorbitally in adult CD1 mice. Mice were sacrificed by anesthetic overdose and cervical dislocation at 10 or 30 min. Following perfusion with PBS, organs were harvested and homogenized with PBS (1 mL/g of tissue). An equal volume of cold CH_2Cl_2 was added to extract **5** from the tissue/aqueous layer. Homogenates were centrifuged for 15 min at 4000 rpm and 4 °C. The organic layer was evaporated with nitrogen to 100 μL and the residue was analyzed by TLC. TLC was carried out on precoated glass plates (silica gel 60 F_{254}, 250 μm thickness), using a solvent system of 1:1 ethyl acetate/hexane, and fluorescent images were acquired on a Kodak 4000 mm image station (Eastman Kodak Company, Rochester, NY). TLC plates were imaged with excitation and emission bandpass filters of 465 and 535 nm, respectively, with f-stop at 2.8 and an exposure time of 2 min.

In a separate experiment, **5** was administered by tail vein injection (250 μg/100 μL; 10% DMSO, 10% Tween 80, 40% propylene glycol, 20% ethanol, and 20% H_2O; sterilized through a 20 μm filter prior to injection) in adult mice. Mice were sacrificed by anesthetic overdose and cervical dislocation at 10 or 30 min. Dye-containing extracts (obtained as outlined in the preceding paragraph) were dissolved in eluent (30 μL DMSO and 120 μL 3:1 CH_3CN/H_2O with 0.5% formic acid). Reverse-phase HPLC was carried out using a C18 column (Supelco, 2.1 mm × 100 mm × 5 μm) connected to a solvent delivery system (Waters model 2690, Milford, MA). Elution conditions were as follows: 1 min at 95% CH_3CN/5% H_2O, followed by a linear gradient from 95% CH_3CN/5% H_2O to 0% CH_3CN/100% H_2O over 9 min; 3 min at 0% CH_3CN/100% H_2O; a linear gradient from 0% CH_3CN/100% H_2O to 95% CH_3CN/5% H_2O over 3 min; and a linear gradient from 95% CH_3CN/5% H_2O to 100% CH_3CN/0% H_2O over 2 min (0.2 mL/min flow rate). Mass spectra were acquired to confirm compound identity using a mass spectrometer (Alliance HT 2790 + ZQ) using positive ion detection, scanning from 150 to 850 Da.

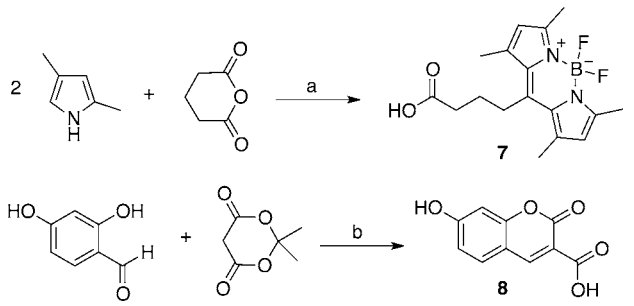
Whole-Body Slice Imaging. Optical imaging studies were performed on a reflectance optical scanner (IVIS-50, Caliper Life Sciences, Hopkinton, MA), and data acquisition and processing were performed using the *Living Image* software v

3.2. Compound **5** was formulated in 10% DMSO, 10% Tween-80, 40% propylene glycol, 20% ethanol, and 20% water (2 nmol, 150 μL). The formulated solution was sterilized through a 20 μm filter prior to injection. Male nu/nu mice (Charles Rivers, MA) that had been on a nonfluorescent diet more than 10 days were injected intravenously via tail vein with 150 μL of **5** (2 nmol) or saline. Mice were euthanized 10 min postinjection and immediately frozen and stored at −80 °C. Whole body slices at 40 μm thickness were cut using a cryotome (Hacker-Bright Sledge Microtome, Winnsboro, SC). Coronal slices through the midsection were imaged using excitation and emission bandpass filters of 468 ± 22 nm and 545 ± 30 nm, respectively. Images were collected using the same field of view with binning set at 4, f-stop at 2, and exposure time 20 s. Total photon efficiency is a measure of fluorescent photons from the specimen normalized against the excitation intensity; the resulting efficiency is expressed in units of cm^2.

RESULTS

Chemistry. Synthesis of the BODIPY dye containing a free carboxyl group (**7**) was achieved via a one-pot condensation between 2 equiv of 2,4-dimethylpyrrol and glutaric anhydride followed by the coordination of $BF_3{\cdot}OEt_2$ (Scheme 1).[14,21] The

Scheme 1. Synthesis of Fluorescent Dyes[a]



[a]Reagents: (a) i. $BF_3{\cdot}OEt_2$, CH_2Cl_2, reflux, ii. $BF_3{\cdot}OEt_2$, Et_3N; (b) piperidinium acetate, EtOH, reflux.

hydroxy-substituted coumarin-3-carboxylic acid **8** was prepared by Knoevenagel condensation of 2,4-dihydroxybenzaldehyde with Meldrum's acid directly releasing a free carboxyl group in one pot.[15] The percent yield for this one-pot transformation was 76%.

Next, two amino bithiazole intermediates (**12** and **15**) were synthesized (Scheme 2); each intermediate was designed to allow for late stage attachment of the fluorescent dye. Aminobithiazole building block **12** was synthesized by α-bromination of aminothiazole **9** in 86% yield followed by condensation with 1-(2-chloro-5-(dimethylaminophenyl)thiourea **11** in 79% yield. CDI-mediated condensation of **12** with fluorescent acids **7** and **8** provided probes **3** and **4** in modest yields (**3**, 19%, and **4**, 20%, respectively). To synthesize the aminobithiazole precursor **15**, aminothiazole **9** was first treated with CDI-activated pivalic acid to give **13** (83% yield) followed by α-bromination with 30% HBr in AcOH and pyridinium tribromide to produce **14** (49% yield). Bromination of **13** proved to be more difficult than bromination of **9**; therefore, a stronger acidic medium (HBr vs HOAc) was required. Subsequent condensation with thiourea afforded aminobithiazole intermediate **15** (27% yield). Acids **7** and **8** were then activated with CDI and subsequently

treated with **15** to obtain fluorescent compounds **5** and **6** in modest yields (**5**, 55%, and **6**, 17%, respectively).

Corrector Activity. We followed established standard short-circuit current measurement procedures[20] to determine the corrector activity of each fluorescently labeled bithiazole. Apical membrane chloride current was measured in ΔF508-CFTR expressing FRT cells after basolateral membrane permeabilization and in the presence of a transepithelial chloride gradient. Cells were incubated for 18−24 h with 10 μM test compound prior to short-circuit current assay. DMSO vehicle was used as a control. Figure 2A shows minimum apical membrane current with DMSO alone, with a small increase following addition of the cAMP-elevating agent forskolin (20 μM) and the potentiator genistein (50 μM). The increased apical membrane current was inhibited upon addition of the CFTR inhibitor $CFTR_{inh}$-172. While conjugates **3** and **4** (Figure 2A) had little corrector activity at 10 μM, conjugate **6** had moderate activity, and **5** had efficacy comparable to that of 5 μM corr-**4a**. On the basis of its corrector activity, we chose **5** for further studies.

Intracellular Uptake. To assess cellular uptake and localization of conjugate **5**, FRT cells were imaged by confocal microscopy at different times after exposure to 10 μM **5**. Figure 2B shows rapid uptake of **5** within 1 min, which remained stable for >45 min. Fluorescence was observed in an intracellular compartment consistent with a characteristic membrane pattern of the endoplasmic reticulum, which is similar to that in FRT cells expressing ER-targeting GFP (Figure 2B). While not conclusive, the high lipophilicity of **5** would account for its intracellular staining pattern, as endoplasmic reticulum membranes constitute the vast majority of cell membranes.

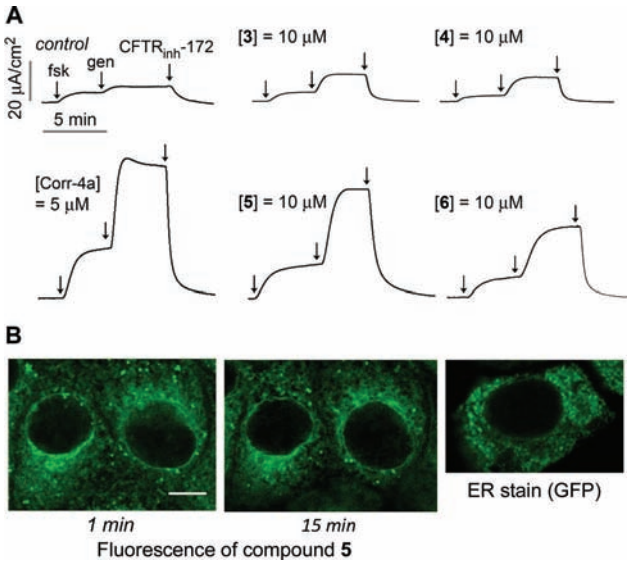

Figure 2. ΔF508-CFTR corrector activity and cellular uptake of **5**. (A) Short-circuit measurements showing apical membrane chloride current after incubation for 24 h at 37 °C with 10 μM of indicated fluorescent bithiazoles. Negative control was incubation with DMSO vehicle alone and positive control was incubation with corr-**4a** (5 μM). Forskolin (20 μM), genistein (50 μM), and $CFTR_{inh}$-172 (10 μM) were added as indicated. (B) Confocal micrographs of live FRT cells after incubation with **5** for 1 or 15 min; for comparison, ER staining shown of FRT cells expressing an ER-targeted GFP. Scale bar, 5 μm.

Metabolic Stability. To determine a suitable time point for whole-body slice imaging of the organ distribution of conjugate **5**, the metabolic stability of **5** was first assessed by fluorescence imaging of TLC plates (see Supporting Information p. S9). By 10 min, **5** was metabolized in liver, but remained largely intact in lung and kidney. By 30 min, **5** was not detected in lung or kidney, and little nonmetabolized compound was seen in liver. Extracts from the lung, liver, kidney, brain, and heart obtained at 10 and 30 min were also analyzed by LC-MS. Rapid uptake and clearance of **5** was found in the liver, lung, kidney, and heart, with no compound seen in brain. Figure 3 shows LC-MS analysis of lung extract at 10 and

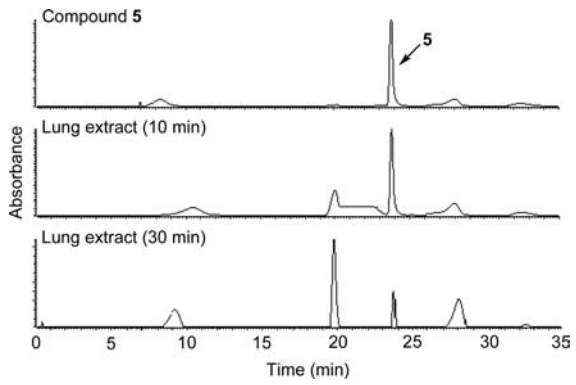

Figure 3. Qualitative LC-MS data for identification of **5** in lung extract. HPLC chromatograms (absorbance, 494 nm) of **5** (A), and lung extract at 10 min (B) and 30 min (C) post injection.

30 min after intravenous injection of **5**. While we have not analyzed the chemical basis of conjugate instability, which would be a major undertaking beyond the scope of the study focused here on a single fluorescent corrector, the detection of intact **5** supports the following imaging studies described below. Chromatograms of liver, kidney, brain, and heart are provided in the Supporting Information (p. S9–S12).

Uptake Measured in Whole-Body Slices. Fluorescence imaging of **5** was done in whole-body slices obtained at 10 min after intravenous administration, in which the above data showed that **5** was largely intact in extrahepatic organs. Coronal slices at the midsection of mice were imaged. Figure 4 shows accumulation of **5** mainly in gastrointestinal organs, including stomach, small and large intestine, and liver, with lesser fluorescence in lung. Little background signal was seen in slices from control mice.

DISCUSSION

In a recent study, we synthesized a focused library of 54 thiazole-tethered pyrazoles that allowed for incorporation of property-modulating functionality (ester, acid, and amide) on C5 of the pyrazole ring (see Figure 5).[18] These pyrazolylthiazoles retained ΔF508-CFTR corrector activity (<1 μM) and improved the experimentally determined log*P* (1.2 log units lower than corr-**4a**). That work also established that the corrector binding site of ΔF508-CFTR affords a fair degree of plasticity with regard to the aniline-moiety binding pocket; compare **16** to corr-**4a** (Figure 5). Building on that insight, we speculated that perhaps the ΔF508-CFTR corrector binding site could accommodate the fluorescent dye moieties shown in analogues **5** and **6** where the dye is attached at the 2-amino position (see Figure 1). SAR insight regarding the plasticity of the presumed amide-binding pocket of ΔF508-CFTR, while less extensive,[7] suggested that dye attachment via the 2′-amino as in analogues **3** and **4** might also retain corrector activity (see Figure 1). We did not attempt to generate conjugates with near-infrared dyes (NIR dyes; for example, a bithaizole modified with a Cy7-based dye[22]) because, while they would offer the advantages of long-wavelength fluorescence and noninvasive imaging, their large size would likely interfere with corrector activity. Positron emission tomography (PET; another noninvasive technique) using an ^{18}F-labeled CF corrector has the potential advantage of only very modestly modifying the small molecule. However, because of the higher costs and complexity, this technique was judged as inappropriate for our initial proof-of-concept work [note: we have synthesized an ^{19}F-labeled analogue of corr-**4a** (4-fluorobenzamide replacing benzamide; refer to Figure 1) that has corrector efficacy comparable to 5 μM corr-**4a**]. On the basis of this analysis, we synthesized fluorescent bithiazole analogues **3**–**6**.

BODIPY and hydroxycoumarin fluorophores were selected for conjugation with bithiazole cores **12** and **15** (see Scheme 2) because each dye is readily generated in one synthetic operation (see Scheme 1), insensitive to changes in pH, affords bright fluorescence and photostability, and has modest molecular size. Also, the preparation of each final substrate (**3**–**6**) closely parallels already developed synthetic protocols.[21]

Of the four bithiazole–fluorophore conjugates **3**–**6**, BODIPY **5** was the most efficacious corrector (see Figure 2A), having comparable corrector activity to that of corr-**4a**. We therefore selected BODIPY **5** for *in vivo* and imaging studies. The activity of **5** further supports the notion that the "analine-binding pocket" of ΔF508-CFTR affords exploitable plasticity.

Small molecular weight therapeutics are desirable in part due to their ability to permeate the cell membrane. An initial concern with the conjugation of a fluorescent dye to the core of corr-**4a** was the possibility of reduced cell plasma membrane

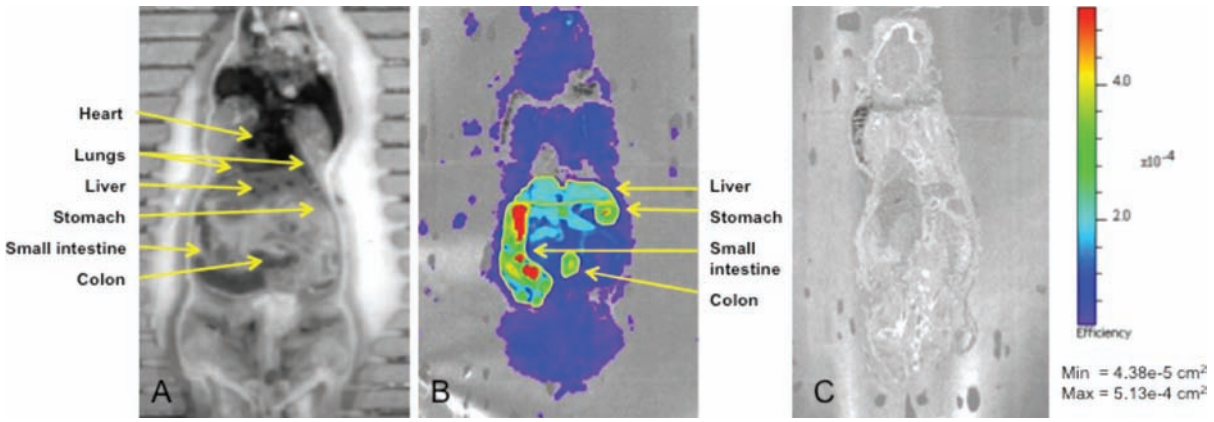

Figure 4. Fluorescence imaging of the coronal slices of mice at 10 min after injection of 2 nmol of **5** or saline. Shown are white light image (A) and fluorescence images of the coronal slice from mice injected with **5** (B) or saline (C).

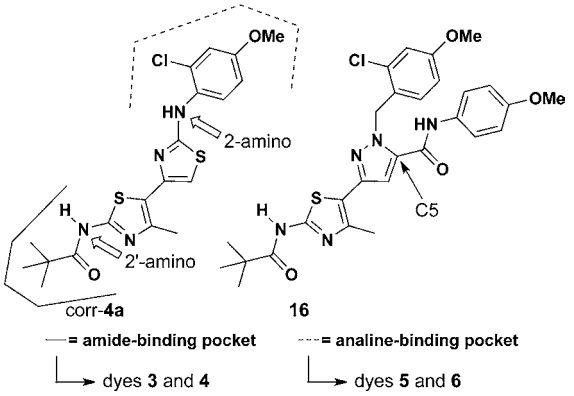

Figure 5. Presumed aniline- and amide-binding pockets of ΔF508-CFTR.

permeability. However, as seen from the rapid appearance of intracellular fluorescence in Figure 2B, conjugate **5** is highly permeable across cell membranes. The rapid uptake and probable ER distribution of **5** is likely a consequence of its lipophilicity at position Y (see Figure 1).

Metabolic stability studies showed that, in the lung, the primary organ of interest in cystic fibrosis, the main fluorescent species at 10 min after intravenous administration was the original compound, allowing unambiguous interpretation of whole-body slice fluorescence images. Unfortunately, however, conjugate **5** is rapidly metabolized by the liver, precluding analysis of its biodistribution at longer times by the methods used here. Interestingly, despite the highly lipophilic nature of the BODIPY moiety at position Y, **5** does not significantly cross the blood-brain barrier at 10 min.

Optical imaging is a sensitive tool to monitor the *in vivo* distribution of exogenous fluorescent agents in animals.[23] Here, the incorporation of BODIPY on the bithiazole core has allowed detection of fluorescence at 510 nm. Because of the limited tissue penetration of light at 510 nm, images were obtained of whole-body coronal slices at 10 min following intravenous administration of **5**. Of relevance to cystic fibrosis, **5** was largely targeted to gastrointestinal organs, where CFTR is expressed, and to lesser extent in lung.

CONCLUSION

In conclusion, our data define the early uptake in mice of a functional, fluorescently labeled bithiazole ΔF508-CFTR corrector. The BODIPY fluorophore did not appear to interfere with the corrector activity of conjugate **5**, but is likely to affect its biodistribution, as lipophilic compounds often accumulate in adipose tissues such as the stomach and intestine. Although the rapid hepatic metabolism and clearance of **5** restricted our analysis of biodistribution to early times after administration, fluorescence imaging of coronal slices has provided information about the uptake of **5**, and hence proof-of-concept for the strategy of fluorescent drug labeling and analysis of biodistribution by whole-body slice imaging.

Supporting Information

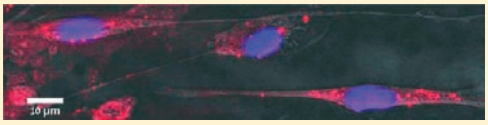
ABSTRACT: Growth factors are critical components in the tissue engineering approach. Basic fibroblast growth factor (bFGF), a representative growth factor, stimulates the cellular functions of various cells and has been used extensively for the repair and regeneration of tissues. The *in vivo* half-life time of free bFGF is short, about 3−10 min, due to rapid enzymatic degradation. Stabilization of the bFGF was accomplished by the covalent or physical conjugation of this factor to fluorescent maghemite (γ-Fe_2O_3) nanoparticles. In the present study, nasal olfactory mucosa (NOM) cells from adult rats were cultured in suspension on chitosan microcarriers (MCs) in the presence of the nonconjugated or bFGF-conjugated nanoparticles, or the free factor. The floating cells/nonconjugated, conjugated, or free bFGF/MCs aggregates were then seeded in a viscous gel. In this manuscript, we are the first to report that the stabilization of the factor by its conjugation to these nanoparticles significantly improved NOM cell-proliferation properties (migration, growth, and differentiation), compared to the same concentration, or even five times higher, of the free factor. This novel approach may significantly contribute to the advancement of the tissue engineering field.



INTRODUCTION

Tissue engineering is an emerging scientific approach to regenerate damaged and diseased tissues.[1] By applying combinations of biomaterials, cells, and bioactive molecules, regeneration of damaged or diseased tissues can be facilitated, ultimately leading to the functional replacement of these tissues.[2] Growth factors are becoming leading therapeutic candidates for tissue engineering approaches.[3] Growth factors are endogenous polypeptides, secreted by a wide range of cell types, which initiate intracellular signals to regulate cellular activities such as adhesion, proliferation, migration, and differentiation. The local delivery of growth factors to the injured tissue site is essential to trigger cellular actions, through binding, to specific receptors on the surface of the target cells, and thereby stimulate the regenerative processes.[4,5]

FGF-2, also known as bFGF, is a representative growth factor which promotes proliferation, differentiation, and numerous other cellular functions of a wide variety of cells, including mesenchymal, neuroectodermal, and endothelial cells.[6] For example, bFGF has been reported to significantly promote NOM cell proliferation and maintain its survival.[7,8] It has also shown a high therapeutic potential for the repair and regeneration of damaged tissues, including skin, blood vessel, muscle, adipose, tendon/ligament, cartilage, bone, tooth, and nerve tissue.[9] For instance, the administration of bFGF to damaged neurons stimulates neurogenesis and provides neuroprotection in different animal models of neurodegenerative diseases, e.g., Parkinson's,[10] Alzheimer's,[11,12] and Huntington's.[13]

The main disadvantage of bFGF is its short *in vivo* half-life time, about 3−10 min, due to rapid enzymatic degradation, leading to loss of biological activity and functions.[6,14] It therefore requires frequent direct injections of the factor in order to maintain its bioavailability necessary for tissue repair. However, repeated administration may lead to undesirable systematic effects and toxicity due to nonspecific distribution and accumulation of the factor throughout the body. To obtain satisfactory performance, growth factors are adsorbed onto, or encapsulated within, nanomaterials to protect their stability and biological activity in a sustained and controllable manner.[15] Recent literature concerning novel biomaterials indicates increasing interest in developing inorganic nanoparticles suitable as growth factor delivery systems mainly by controlled release, such as mesoporous silica nanoparticles,[16] quantum dots,[17] calcium phosphate,[18] and calcium sulfate nanoparticles.[19]

Magnetic iron oxide nanoparticles are particularly promising due to their high surface area to volume ratio, magnetic properties, biocompatibility, relative nontoxicity, and biodegradability. The use of iron oxide magnetic nanoparticles for various biomedical applications, e.g., hyperthermia, diagnosis, cell-labeling and sorting, DNA separation, MRI contrast agents, and drug delivery, have already been demonstrated.[20−26] The combination of magnetic and fluorescent entities may also provide new two-in-one multifunctional nanomaterials with a broad range of both potential diagnostic and therapeutic applications.[27]

For tissue engineering approaches, the use of magnetic nanoparticles is emerging as a potential target, diagnostic, and therapeutic agent. It has been reported that magnetic

nanoparticles could be coupled to cells and used to target these labeled cells by an external magnetic field at the desired site in the body.[28] The migration of the labeled cells after implantation can be detected noninvasively using MRI.[29] In addition, various proteins, growth factors, and so forth could be bound to these nanoparticles that might be delivered to the damaged tissue, where they would play a role in tissue development and repair.[30] The use of magnetite (Fe_3O_4) magnetic nanoparticles to enhance cell seeding in tissue engineering scaffolds via a magnetic field has also been reported recently.[31,32] A few studies also investigated the influence of magnetic nanoparticles in the presence and absence of a growth factor on cellular proliferation and differentiation, following long-term incubation. Very recently, Park and co-workers reported that unmodified iron oxide nanopartices in the presence of free nerve growth factor (NGF) synergistically promoted the neurite outgrowth of PC12 cells.[33] Shimizu and co-workers recently demonstrated that glutaraldehyde-activated magnetic beads of 250 nm average diameter covalently bonded to NGF or a brain-derived neurotrophic factor (BDNF) promoted the neurite outgrowth of embryonic chick dorsal root ganglia neurons. In addition, these nanoparticles coated with both NGF and BDNF promoted the neurite outgrowth of PC12h cells. However, in all the cases mentioned above, the observed biological effect was similar, or even lower, than that of the soluble-free NGF, BDNF, or both, respectively.[34]

In the present study, NOM cells were derived from the olfactory mucosa of adult rats. Olfactory mucosa is a potential source of olfactory ensheathing cells and multipotent neural stem cells, which have been used in autologous transplantation therapies for the treatment of degenerative or traumatic conditions of the central nervous system, such as Parkinson's disease or spinal cord injury.[35−37] There are several potential advantages of NOM transplants. These cells are easily obtained through simple nasal biopsies, making them attractive for autologous transplantation and thus eliminating the issue of rejection. Moreover, the neurons and the sustentacular cells within the NOM are able to renew themselves constantly during their life span.

The present article describes a method of preparing new bFGF-conjugated fluorescent maghemite (γ-Fe_2O_3) nanoparticles that induce the significant stabilization of the bFGF through its covalent or physical immobilization to the nanoparticle's surface.[38,39] The NOM cells were cultured in suspension on biodegradable, positively charged MCs in the presence of nonconjugated or bFGF-conjugated nanoparticles, or the free factor. The floating cells/nonconjugated, conjugated, or free bFGF/MCs aggregates were then seeded in a viscous gel (NVR-gel[40]). In this study, we describe the effect of the conjugation of the bFGF to fluorescent γ-Fe_2O_3 nanoparticles on the migration, growth, and differentiation of the NOM cells, compared to the nonconjugated fluorescent nanoparticles and different concentrations of the free bFGF.

MATERIALS AND METHODS

Materials. The following analytical-grade chemicals were purchased from commercial sources and used without further purification: ferrous chloride tetrahydrate, hydrochloric acid (1 M), sodium hydroxide (1 M standard solution), sodium chloride, sodium nitrite, dimethyl sulfoxide (DMSO), gelatin from porcine skin, human serum albumin (HSA), rhodamine B isothiocyanate (RITC), divinyl sulfone (DVS), triethylamine (TEA), Triton X-100, and D-glucose from Sigma (Israel); recombinant human basic fibroblast growth factor (bFGF) from PeproTech (Israel); midi MACS magnetic columns from Miltenyi Biotec GmbH (Germany); bicarbonate buffer (BB, 0.1 M, pH 8.4), phosphate-buffered saline (PBS free of Ca^{2+} and Mg^{2+}, 0.1 M, pH 7.4), Dulbecco's modified eagle medium-nutrient mixture F-12 (DMEM-F12), fetal calf serum (FCS), gentamycine, glutamine, hepes, and trypsin-EDTA solution (0.25%) from Biological-Industries (Israel); human bFGF ELISA kit Quantikine HS from Biotest (Israel); tissue culture plates and 35 cm culture plates from JET BioFiL (Israel); chitosan powder microcarriers (MCs) from Medovent GmbH (Germany). Water was purified by passing deionized water through an Elgastat Spectrum reverse osmosis system (Elga, High Wycombe, UK). NVR-gel was obtained from NVR Ltd. (Neuro-Vascular Reconstruction Laboratories, Ness Ziona, Israel).[40] This gel is composed of 0.7% cross-linked hyaluronic acid enriched with 30 mg/mL laminin (Sigma, St. Louis, MO, USA). The culture medium used in this study was composed of 90% DMEM-F12, 10% FCS, 6 g/L D-glucose, 2 nM glutamine, and 25 μg/mL gentamycine.

Synthesis of γ-Fe_2O_3 Nanoparticles Containing the Fluorescent Probe Rhodamine (R-γ-Fe_2O_3). γ-Fe_2O_3 nanoparticles were prepared by the nucleation and growth of a maghemite layer onto gelatin/iron oxide nuclei, according to the description in ref 24. R-γ-Fe_2O_3 nanoparticles of 15.0 ± 1.1 diameter were prepared by a similar procedure, substituting the gelatin for RITC-conjugated gelatin. Briefly, RITC was covalently conjugated to gelatin by adding 0.5 mL of DMSO containing 5 mg of RITC to 20 mL of aqueous gelatin in solution (1%). The pH of the aqueous solution was then raised to 9.5 by carefully adding a NaOH aqueous solution (1 N). The solution was then shaken for 1.0 h at 60 °C. The RITC-conjugated gelatin solution was then dialyzed at 60 °C against water to remove the excess of unbound RITC. The volume of the solution was then adjusted to 80 mL by adding water, after which the synthesis was continued, as described in our previous publication.[41]

Synthesis of the DVS-Derivatized R-γ-Fe_2O_3 Nanoparticles. R-γ-Fe_2O_3 nanoparticles were functionalized with activated double bonds via the interaction between the primary amine groups of the gelatin coating of the R-γ-Fe_2O_3 nanoparticles and DVS. Briefly, 12 μL of DVS were added to 1 mL of the R-γ-Fe_2O_3 nanoparticles dispersed in BB (3 mg/mL, pH 8.4). TEA was then gradually added until a pH of 10.5 was reached. The reaction mixture was then shaken at 60 °C for 18 h. The formed DVS-derivatized R-γ-Fe_2O_3 nanoparticles were then washed from excess DVS with BB using the high-gradient magnetic field (HGMF) technique.[24]

Covalent Conjugation of the bFGF to the DVS-Derivatized R-γ-Fe_2O_3 Nanoparticles. The covalent conjugation of bFGF to the R-γ-Fe_2O_3 nanoparticles was accomplished via the interaction of the amino and/or hydroxyl groups of the growth factor with the activated double bonds on the nanoparticle's surface, via the Michael addition reaction. Briefly, 125 μL of a bFGF PBS solution (0.4 mg/mL, pH 7.4) were added to 125 μL of the DVS-activated nanoparticles dispersed in BB (4 mg/mL, pH 8.4) at a [Nanoparticles]/[bFGF] weight ratio of 10. The reaction mixture was then shaken at room temperature for 18 h. Blocking of the residual double bonds was then accomplished by adding 1% glycine (w/v) and then shaking for an additional hour. The obtained R-γ-Fe_2O_3-bFGF nanoparticles were then washed from non-magnetic waste with PBS using the HGMF technique. A similar

experiment was also performed substituting the weight ratio [Nanoparticles]/[bFGF] of 10 for 50, by substituting the 125 μL of the bFGF solution for 25 μL.

HSA Coating on the R-γ-Fe_2O_3 Nanoparticles. Coating of the R-γ-Fe_2O_3 nanoparticles with HSA was accomplished by precipitation of this protein onto the surface of the fluorescent maghemite nanoparticles. Briefly, 1 mL of a HSA BB solution (10 mg/mL, pH 8.4) was added to 33 mL of the R-γ-Fe_2O_3 nanoparticles dispersed in BB (4 mg/mL, pH 8.4). The pH was then raised to 9.5 by adding carefully a NaOH aqueous solution (1 N). The reaction mixture was shaken at pH 9.5 and 60 °C for 24 h, and then cooled gradually to room temperature. The obtained HSA-coated R-γ-Fe_2O_3 nanoparticles were then washed with BB from nonmagnetic waste using the HGMF technique.

Physical Conjugation of the bFGF to the HSA-Coated R-γ-Fe_2O_3 Nanoparticles. bFGF was physically conjugated to the HSA-coated R-γ-Fe_2O_3 nanoparticles by adding 125 μL of a bFGF PBS solution (0.4 mg/mL, pH 7.4) to 125 μL of the HSA-coated R-γ-Fe_2O_3 nanoparticles dispersed in BB (4 mg/mL, pH 8.4) at a [Nanoparticles]/[bFGF] weight ratio of 10. The reaction mixture was then shaken at room temperature for 18 h. The obtained R-γ-Fe_2O_3~bFGF (~ is the symbol for the physical conjugation of bFGF to the nanoparticles) were then washed from nonmagnetic waste with PBS using the HGMF technique. A similar experiment was also performed substituting the weight ratio [Nanoparticles]/[bFGF] of 10 for 50, by substituting the 125 μL of the bFGF solution for 25 μL.

Binding Yield and Bound Concentration of the bFGF to the R-γ-Fe_2O_3 Nanoparticles. The concentration of the bFGF conjugated to the fluorescent maghemite nanoparticles was determined by measuring the unbound bFGF with an ELISA kit (Human bFGF Quantikine HS, Biotest Israel) and subtracting it from the initial concentration. The binding yield was calculated by multiplying the ratio between the concentration of the bound factor to the initial concentration by 100. The reported values are an average of at least three measurements of each sample.

bFGF Leakage Extent. The leakage of bFGF, conjugated covalently or physically to the R-γ-Fe_2O_3 nanoparticles, into PBS containing 4% HSA was evaluated using the following procedure: R-γ-Fe_2O_3-bFGF or R-γ-Fe_2O_3~bFGF nanoparticles dispersed in PBS containing 4% HSA (2 mg/mL, pH 7.4) were shaken at room temperature for 24 h. Then, the bFGF-conjugated nanoparticles were removed from the supernatant using the HGMF technique and the concentration of bFGF in the filtrate was measured by the human bFGF ELISA kit.

Characterization of the Functional Nanoparticles. Transmission electron microscopy (TEM) pictures were obtained with a FEI Tecnai C2 Biotwin electron microscope with 120 kV accelerating voltage. Samples for TEM were prepared by placing a drop of the diluted sample on a 400-mesh carbon-coated copper grid. The average size and size distribution of the dry particles were determined by measuring the diameter of more than 200 particles with image analysis software, *AnalySIS Auto* (Soft Imaging System GmbH, Germany). The hydrodynamic diameter and size distribution of the nanoparticles dispersed in the aqueous phase were measured using a submicrometer particle analyzer, model N4 Plus, Coulter Electronics, England. Magnetic measurements were performed at room temperature, by an Oxford Instrument vibrating sample magnetometer (VSM, Oxford Instruments, UK).

Surgical Procedure for the Dissection of Adult Rat NOM. The NOM cells were derived from the olfactory mucosa of Lewis inbred rats (Harlan, Israel). Adult Lewis rats (250 g) were nasally infused with 0.7% Triton X-100 to both nostrils 4 days prior to their scarification. The Triton X-100 caused moderate damage to the neuroepithelium, which enhanced the active NOM tissue reconstruction by basal round and horizontal precursor cells. Prior to the NOM dissection, cardiac perfusion of the rats was made with 60 mL of saline. All the experiments were carried out under the Animals' Care and Use Committee, which is recognized by the Israeli authorities for animal experimentation.

Cultivation of the NOM Cells in the Presence of the Nonconjugated, Conjugated, or Free bFGF. The dissected NOM tissue was fragmented, separated from its bones under a stereomicroscope, and washed several times with an ice-cold culture medium. The NOM fragments were then enzymatically dissociated with a trypsin−EDTA solution (0.25%) for 30 min, washed with a culture medium, and adapted to a 1×10^7 cells/mL culture medium in each 24-well culture plate. Round coverslips were inserted per well, and each well received 0.2 mL of 2% (w/v) chitosan MCs (4 mg) suspended in PBS. Concomitantly, each well received 10 μL (10 μg bound bFGF/well) of the R-γ-Fe_2O_3-bFGF nanoparticles dispersed in PBS (2 mg/mL, pH 7.4). The mixture containing the R-γ-Fe_2O_3-bFGF nanoparticles (0.02 mg) and the MCs (4 mg), [0.5% ($w_{nanoparticles}/w_{MCs}$)], was incubated at 37 °C for 1.0 h. Subsequently, 100 μL of the NOM cell suspension (1×10^6 cells/well) was added and incubated with the R-γ-Fe_2O_3-bFGF nanoparticles/MCs aggregates at 37 °C for an additional 1.0 h. Then, each well received 1.0 mL of culture medium and incubated for additional 5 days. 50 μL of the formed floating cells/R-γ-Fe_2O_3-bFGF nanoparticles/MCs aggregates of each well were then transferred and seeded into 1 mL of the NVR-gel in 35 mm culture dishes. Twenty-four hours after the cultivation, 1.0 mL of the culture medium was added to each culture dish and changed every 4.0 days. Similar experiments were also performed in the presence of the R-γ-Fe_2O_3, R-γ-Fe_2O_3~bFGF nanoparticles and different concentrations of the free bFGF, e.g., the same concentration as the conjugated one, 5 and 10 times higher (0.38, 1.9, and 3.8 μg/well, respectively). The cultures were examined daily under an Olympus IX70 phase contrast microscope (Japan).

The surface morphology of the cells/nanoparticles/MCs aggregates was characterized with a scanning electron microscope (SEM) model FEI Quanta 250 FEG (Oregon, USA). For this purpose, samples were fixed in 2.5% glutaraldehyde in a PBS solution for 1.0 h at room temperature and then washed three times with PBS. The fixed samples were dehydrated in series of 50%, 70%, 80%, 90%, and 100% ethanol/water solutions (v/v) for 10 min each. The residual ethanol was removed using series of 50%, 75%, and 100% (×3) Freon/ethanol solutions (v/v), for 10 min each. Finally, the samples were left for a few seconds to dry at room temperature. The dried samples were mounted on aluminum stubs and sputter-coated with gold in vacuum for 4 min before viewing.

Cellular Uptake Study. The cellular uptake and internalization of the R-γ-Fe_2O_3-bFGF nanoparticles in the NOM cells was studied by acquiring a time series of Z-stacks optical cross-sectional images of the NOM cells. At different time intervals of the cultivation, the cells were washed extensively with PBS and fixed in 4% paraformaldehyde for 15 min at room temperature. After repeated rinsing in PBS, cells in culture on cover glasses

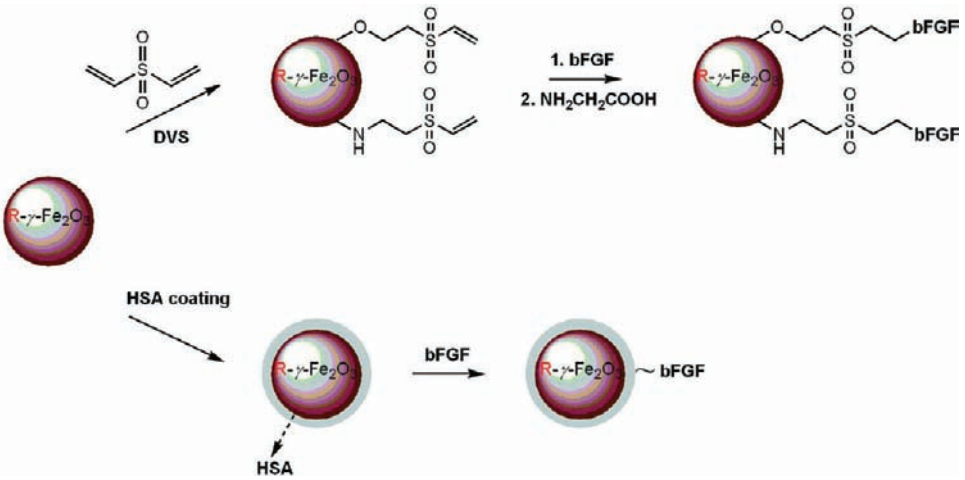

Figure 1. Scheme illustrating the covalent (A) and physical (B) conjugation of bFGF to the R-γ-Fe_2O_3 nanoparticles (− and ~ are symbols for the covalent and physical binding of the bFGF to the nanoparticles, respectively).

underwent nuclear staining and mounting with DAPI-fluoromount-G (catalog #0100−20, SouthernBiotech). The slides were then observed with a LSM 510 fluorescence confocal laser scanning microscope (Zeiss, USA) to obtain the Z-stacks of the cells. Images were captured using the microscope and processed using a computer-based programmable image analyzer *Imaris 6.15* (Zeiss, USA). Each stack focused progressively to a depth of 1.4 μm within the cell and a series of 20 stacks were obtained per cell. The stacks focused on the axial position of the fluorescent tagged nanoparticles, enabling visualization of the location of these particles within the NOM cells. Nuclei are visible in blue due to the DAPI staining (excitation at 359 nm and emission at 457 nm); red fluorescence was derived from the nanoparticles (excitation at 550 nm and emission at 573 nm). Light microscope images were obtained with a Olympus BX60F5 microscope (Eisenberg Bros., Israel).

Immunocytochemistry. Cell cultures were washed three times with PBS, fixed in 4% paraformaldehyde for 15 min at room temperature, and then washed again three times with PBS. The cells were then permeabilized with 0.1% Triton X-100 in PBS for 12 min, and then washed three times with PBS. The cells were then incubated with background buster (to avoid nonspecific staining) for 1.0 h at room temperature. After washing three times with PBS, the cells were incubated overnight at 4 °C with the appropriate primary antibodies in a PBS solution. The following primary antibodies were used: rabbit antitubulin β3, clone EP1331Y (β3Tub, neuronal marker, 1:200, catalog #NB110−576−10, Novus Biologicals); rabbit antineurofilament medium (NF, neuronal marker, 1:400, catalog #NB300−133, Novus Biologicals), mouse anti-S100B (glia marker, 1:80, catalog # DM111−05, Acris Antibodies), and mouse antinestin, clone rat-401 (neurofilament protein, neuronal precursor marker, 1:100, catalog #sc-33677, Santa Cruz Biotachnology). The cultures were subsequently washed three times with PBS and were incubated overnight at 4 °C with the appropriate dye-conjugated secondary antibodies (DyLight 649-conjugated donkey antimouse IgG, 1:200, catalog #715−495−151, Jackson ImmunoResearch; DyLight 488-conjugated donkey antirabbit IgG, 1:200, catalog #711−485−152, Jackson ImmunoResearch), and were washed again three times with PBS. Control experiments were performed similarly, but in the absence of the primary antibodies. Finally, the nuclei of the cells were stained and mounted with DAPI-fluoromount-G. All of the images were observed with a NIKON 90i microscope (Japan) and processed using the *Cell-R* software under the same conditions (exposure time and magnification). To assess the percent of the differentiated cells, we counted only the cells that were stained in both their nuclei and cytoplasm, by DAPI dye and by the specific marker antibodies. The cell % which was positively stained by a specific marker antibody was calculated relative to all the DAPI stained nuclei. The reported values are an average of measurements performed on six randomly, nonoverlapping fields of each triplicate-tested culture.

Statistical Analysis. Statistical analysis was performed by the Student's *t*-test. The results are expressed as a mean ± standard deviation (SD). $P < 0.05$ was considered to be statistically significant.

RESULTS AND DISCUSSION

Characterization of the Nonconjugated and the bFGF-Conjugated R-γ-Fe_2O_3 Nanoparticles. Uniform fluorescent γ-Fe_2O_3 nanoparticles were prepared by nucleation followed by the controlled growth of γ-Fe_2O_3 thin films onto the gelatin-RITC/iron oxide nuclei, as described in our previous publications.[41] The main advantage of these fluorescent nanoparticles is due to the fact that the fluorescent dye is covalently encapsulated within the nanoparticles and not surface bound, as in the common fluorescent nanoparticles. Thus, surface properties such as zeta potential and surface-bound ligand capacity of the nanoparticles are retained.

Figure 1 describes the general approach through which the covalent and physical immobilization of bFGF onto the surface of the R-γ-Fe_2O_3 nanoparticles have been performed. The R-γ-Fe_2O_3 nanoparticles contain gelatin within and on the surface of the nanoparticles.[41] The surface gelatin provides functional groups, e.g., primary amines and hydroxyls, through which functionalization of these nanoparticles with activated double bonds, via the Michael addition reaction, was accomplished with excess DVS. The residual activated double bonds of the DVS-derivatized R-γ-Fe_2O_3 nanoparticles were then used for covalent binding, via the Michael addition reaction of the bFGF to the surface of the R-γ-Fe_2O_3 nanoparticles. Blocking of the remaining double bonds was then performed with glycine. bFGF, besides its covalent binding to the DVS-derivatized

dx.doi.org/10.1021/bc200454k | *Bioconjugate Chem.* 2011, 22, 2600−2610

R-γ-Fe_2O_3 nanoparticles, was also physically attached to the HSA-coated R-γ-Fe_2O_3 nanoparticles. This physical conjugation is based on the fact that the albumin is a carrier protein with high affinity to various exogenous and endogenous compounds, e.g., thrombin, factor VIIa, and so forth.[42,43] Indeed, leakage of both the covalently and physically bound bFGF into PBS containing 4% HSA was not detected by the bFGF ELISA kit.

Figure 2 presents the dry (A) and hydrodynamic (B) diameters and size distributions of the R-γ-Fe_2O_3 nanoparticles

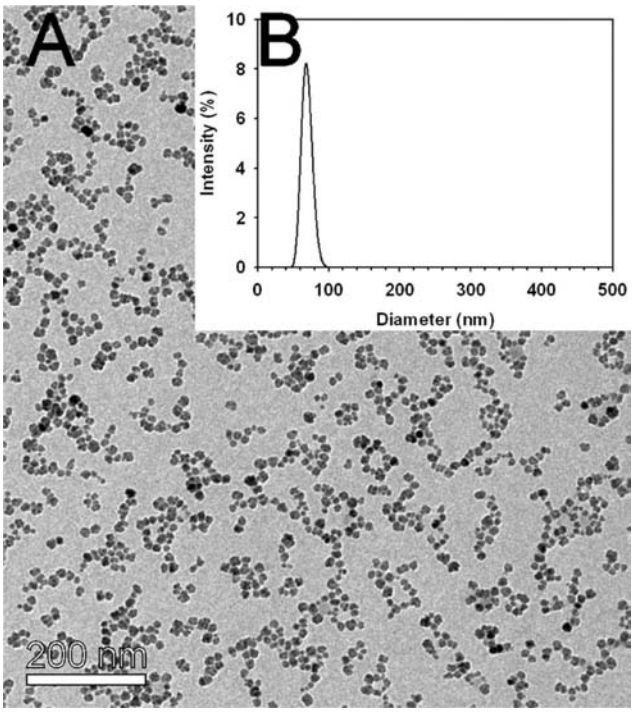

Figure 2. TEM image (A) and size histogram (B) of the R-γ-Fe_2O_3 nanoparticles.

as measured by TEM images and light scattering, respectively. The dry diameter is 15.0 ± 1.1 nm, while the hydrodynamic diameter is 70.0 ± 15 nm. The difference in the diameter measured by TEM and light scattering is due to the fact that the second method also takes into account the surface-adsorbed solvent (water) molecules. The measured dry and hydrodynamic diameters and size distributions of the bFGF-conjugated nanoparticles were slightly higher than those of the nonconjugated ones, e.g., 18.3 ± 1.4 and 22.0 ± 2.1 nm for the dry R-γ-Fe_2O_3-bFGF and R-γ-Fe_2O_3~bFGF nanoparticles, respectively, and 93.0 ± 11 and 106 ± 14 nm for the hydrodynamic R-γ-Fe_2O_3-bFGF and R-γ-Fe_2O_3~bFGF nanoparticles, respectively. Both the nonconjugated and the bFGF-conjugated nanoparticles possess a single population of narrow size distribution, as shown in Figure 2. The immobilization yield of the covalent conjugation of the bFGF to the R-γ-Fe_2O_3 nanoparticles was similar to that of the physical one for both weight ratios of [Nanoparticles]/[bFGF], 10 and 50, as demonstrated in Table 1. For example, for the weight ratio of 10, the covalent and physical immobilization yields were 95.4% and 96.9%, respectively. These high binding yield values may indicate that, in addition to the covalent binding, physical adsorption of the bFGF onto the surface of the nanoparticles may also be involved.[44] Table 1 also shows, as expected, that, for both immobilization types, by decreasing the weight ratio

Table 1. Influence of the Weight Ratio [Nanoparticles]/[bFGF] on the Conjugation Yield and the Concentration of the bFGF Conjugated to the R-γ-Fe_2O_3 Nanoparticles[a]

	conjugation yield (weight %)		[bound bFGF] [$\mu g_{(bFGF)}$/ $mg_{(nanoparticles)}$]	
[nanoparticles]/[bFGF] (w/w)	covalent	physical	covalent	physical
10	95.4	96.9	95.4	96.9
50	92.3	94.4	18.5	18.9

[a]The calculation of the conjugation yield and concentration was accomplished as described in the experimental section.

[Nanoparticles]/[bFGF] the concentration of the bFGF bound to the R-γ-Fe_2O_3 nanoparticles increases, e.g., at the weight ratios of 50 and 10, the covalently bound bFGF concentrations are 18.5 and 95.4 (μg/mg), respectively. On the basis of the above results, we chose to continue this study at [Nanoparticles]/[bFGF] weight ratio of 10.

Characterization of the Interaction Between the Chitosan MCs and the bFGF-Conjugated Nanoparticles. The fluorescence microscope image shown in Figure 3

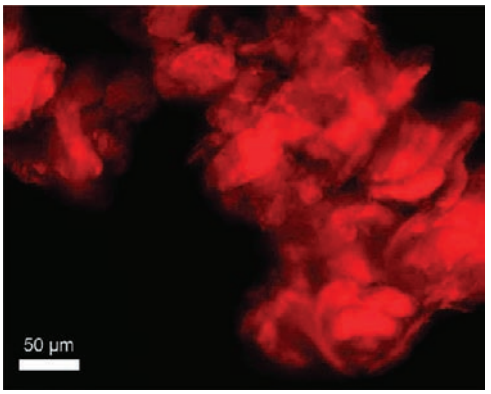

Figure 3. Fluorescence microscopy images of the chitosan MCs interacted with the R-γ-Fe_2O_3-bFGF nanoparticles. Red single staining was obtained by adding the R-γ-Fe_2O_3-bFGF nanoparticles dispersed in PBS to the MCs suspended in PBS, as described in the Materials and Methods section.

illustrates by the red staining the adherence of the R-γ-Fe_2O_3-bFGF nanoparticles to the chitosan MCs. This electrostatic interaction occurs immediately after the addition of the R-γ-Fe_2O_3-bFGF nanoparticles to the MCs suspension. It should be noted that the same behavior was also observed when substituting the R-γ-Fe_2O_3-bFGF nanoparticles for the R-γ-Fe_2O_3~bFGF nanoparticles or the nonconjugated R-γ-Fe_2O_3 nanoparticles.

Our previous study showed that the $M(H)$ curve of the R-γ-Fe_2O_3 nanoparticles has no hysteresis loop, and possesses a saturation magnetization of 55 emu/g.[45] Zero field cooled–field cooled (ZFC-FC) measurements of these nanoparticles exhibit a blocking temperature (T_B) at ca. 275 K, indicating the superparamagnetic behavior of these nanoparticles.[46] Figure 4 presents the magnetization curves at room temperature of the R-γ-Fe_2O_3-bFGF/MCs aggregates containing 0.5 (A) and 0.25 (B) % ($w_{(nanoparticles)}/w_{MCs}$) of the R-$\gamma$-$Fe_2O_3$-bFGF nanoparticles (0.02 or 0.01 mg nanoparticles/4.0 mg MCs). This figure illustrates that both $M(H)$ plots reach magnetic saturation around 2000 Oe. The saturation magnetizations of

dx.doi.org/10.1021/bc200454k | Bioconjugate Chem. 2011, 22, 2600–2610

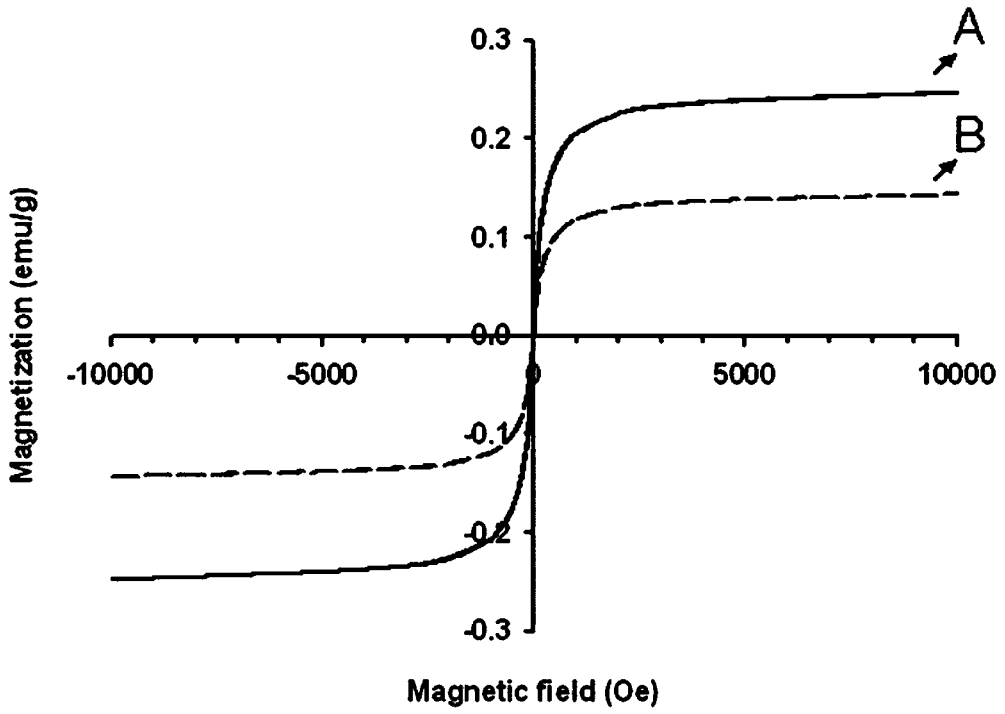

Figure 4. Magnetization curves at room temperature of the R-γ-Fe_2O_3-bFGF/MCs aggregates containing 0.5% (A) and 0.25% (B) ($w_{(nanoparticles)}/w_{MCs}$) of the R-$\gamma$-$Fe_2O_3$-bFGF nanoparticles.

the R-γ-Fe_2O_3-bFGF/MCs aggregates containing 0.5% (A) and 0.25% (B) nanoparticles are 0.26 and 0.14 emu/g, respectively. The difference in the magnetization extent of the R-γ-Fe_2O_3-bFGF/MCs aggregates is probably attributed to the different concentrations of the R-γ-Fe_2O_3-bFGF nanoparticles attached to the MCs. The higher the concentration, the higher the saturation magnetization is. A relatively simple and convenient way to remove the R-γ-Fe_2O_3-bFGF/MCs aggregates from the aqueous PBS continuous phase by a magnetic field is shown in Figure 5. Due to the binding of the R-γ-Fe_2O_3-bFGF nanoparticles to the MCs, the nanoparticles/MCs aggregates become magnetic and easily removed from the aqueous continuous phase by a simple magnet.

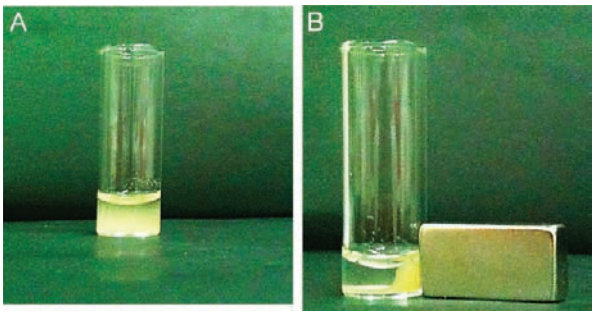

Figure 5. Magnetic MCs dispersed in PBS, before (A) and after (B) applying a magnetic field. The R-γ-Fe_2O_3-bFGF nanoparticles/MCs aggregates were prepared by addition of the R-γ-Fe_2O_3-bFGF nanoparticles to the MCs suspension in PBS, according to the Methods and Materials section.

Influence of the bFGF Conjugation on the Growth of the NOM Cells. In general, the NOM cells were grown in the first stage for a week in suspension attached to the MCs in the presence of the nonconjugated or bFGF-conjugated nanoparticles or the free factor. Subsequently, the formed floating cells/nonconjugated, conjugated, or free bFGF/MCs aggregates were transferred and seeded in the NVR-gel. The cell/MC culture method used in this study mainly served the purpose of establishing a high concentration of NOM cell cultures of long-term viability compared to other standard culture methods.[47,48] The NVR-gel, a transparent and biocompatible semisolid matrix, is composed of cross-linked hyaluronic acid containing the adhesive molecule laminin.[40] This gel has been reported to form a desirable supporting environment for cell attachment, growth, and differentiation, particularly for long-term cultivation.[40] The unique attribute of elasticity of this gel enables its use for clinical applications of tissue engineering, either by its direct implantation or by incorporation into an appropriate scaffold at the site of an injured tissue.[49]

Figure 6 demonstrates by typical phase-contrast microscope images the NOM cell migration and growth from the cells/nonconjugated or bFGF-conjugated nanoparticle/MC aggregates and from the cells/free bFGF/MCs aggregates in the NVR-gel, immediately (A) and 7.0 days after the cultivation in the NVR-gel (B–G). Figure 6A, corresponding to the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates immediately after the cultivation in the NVR-gel, reveals only MCs in the background, which means that the migration of the NOM cells to the NVR-gel had not yet occurred. Similar images were also observed when the R-γ-Fe_2O_3-bFGF nanoparticles in the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates were replaced with R-γ-Fe_2O_3~bFGF or nonconjugated R-γ-Fe_2O_3 nanoparticles. Figure 6B–D exhibit a significant difference in the amount of the migrated/proliferated NOM cells in the NVR-gel 7.0 days after cultivation. The difference in cell migration and growth depends on the type of R-γ-Fe_2O_3 derivative. The lowest amount of migrated/proliferated NOM cells in the NVR-gel was observed in the presence of the nonconjugated R-γ-Fe_2O_3 nanoparticles (Figure 6B), while a significantly higher amount of migrated/proliferated cells were observed in

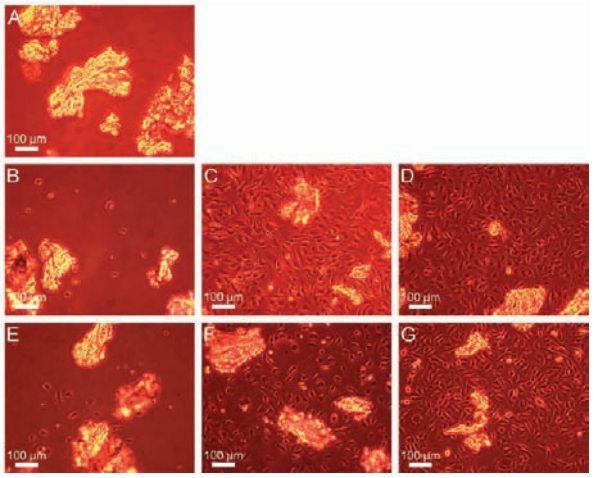

Figure 6. Phase contrast microscope images illustrating the effect of the conjugated and free bFGF on the migration and growth of the NOM cells from the cells/nonconjugated or bFGF conjugated nanoparticles/MC aggregates (A–D) and from the cells/free bFGF of different concentrations/MC aggregates (E–G) in the NVR-gel, immediately (A) and 7 days after cultivation in the NVR-gel (B–G). (A) exhibits the effect of the nonconjugated and bFGF conjugated R-γ-Fe_2O_3 nanoparticles immediately after cultivation, (B) the effect of the nonconjugated R-γ-Fe_2O_3 nanoparticles 7 days after cultivation, (C,D) the effect of the R-γ-Fe_2O_3-bFGF and R-γ-Fe_2O_3~bFGF nanoparticles 7 days after cultivation, respectively. The effect of the same concentration of the free factor as that of the conjugated bFGF, 5 and 10 times higher, 7 days after cultivation in the NVR-gel, is illustrated in images (E,F,G), respectively.

the presence of the R-γ-Fe_2O_3-bFGF (Figure 6C) or R-γ-Fe_2O_3~bFGF (Figure 6D) nanoparticles. These results indicate that the conjugation of the bFGF to the nanoparticles enhances the migration/proliferation rates of the cells in the NVR-gel. It should also be noted that both the covalently (Figure 6C) and the physically (Figure 6D) conjugated bFGF nanoparticles induced a quite similar number of migrated/proliferated cells. The effect of the bFGF conjugation to the nanoparticles on NOM cell migration/proliferation compared to that of the free factor at the same concentration, 5 and 10 times higher, is illustrated in Figure 6E,F, and G, respectively. These figures clearly show that the number of NOM cells that had migrated/proliferated in the NVR-gel was substantially higher in the presence of the conjugated bFGF (Figures 6C,D). Only in the presence of a 10× higher free bFGF concentration (Figures 6G) was the number of migrated/proliferated NOM cells similar to those of the conjugated factor. This observation may due to the fact that the conjugation of bFGF to the nanoparticles increases its stability against inhibitors and proteolytic enzymes present in the culture, and thus prolongs its activity, compared to that of the free factor. A similar stabilization effect was reported previously by us for thrombin,[38] glial cell-derived neurotrophic factor,[39] TRAIL,[50] factor VIIa,[51] and methotrexate[52] conjugated to γ-Fe_2O_3 nanoparticles. Long-term stability of thrombin, TRAIL, and methotrexate conjugated to the γ-Fe_2O_3 nanoparticles compared to the free ones was also previously demonstrated.[38,50,52]

Figure 7 illustrates by SEM images the attached (A) and the migrated/proliferated (B) NOM cells from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates to the NVR-gel, 7.0 days after cultivation in the NVR-gel. This picture presents the NOM cells that remained on the surface of the MCs (A) and those that migrated/proliferated in the NVR-gel, forming a network of bipolar cells (B).

Figure 8 illustrates by typical phase-contrast microscope images the migration/proliferation of the NOM cells from the cells/R-γ-Fe_2O_3 nanoparticles/MC aggregates (A) and from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates (B) 24.0 days after cultivation in the NVR-gel. This figure shows that, in the presence of the nonconjugated R-γ-Fe_2O_3 nanoparticles/MC aggregates (Figure 8A), a relatively small number of the NOM cells migrated/proliferated in the NVR-gel. In addition, the cells that migrated/proliferated in the NVR-gel were flat, resembled fibroblasts, and seemed not to divide intensively. Contrarily, in the presence of the R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates (Figure 8B), a massive amount of mainly tapered bipolar cells migrated/proliferated in the NVR-gel to form an interconnected network. This excessive increase in the number of the tapered bipolar cells is indicative of their intensive multiplication and differentiation.

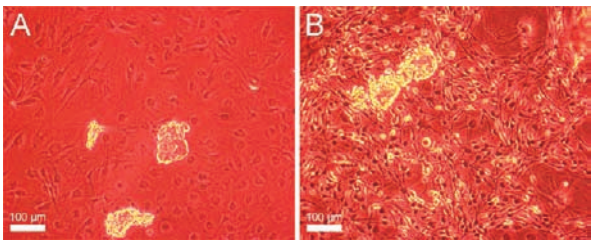

Figure 8. Phase-contrast microscopic images illustrating the migration and growth of the NOM cells from the cells/R-γ-Fe_2O_3 nanoparticles/MC aggregates (A) and from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates (B) 24 days after cultivation in the NVR-gel, as described in the Materials and Methods section.

For a quantitative determination of the effect of the free/conjugated bFGF on the kinetics of the migration/proliferation

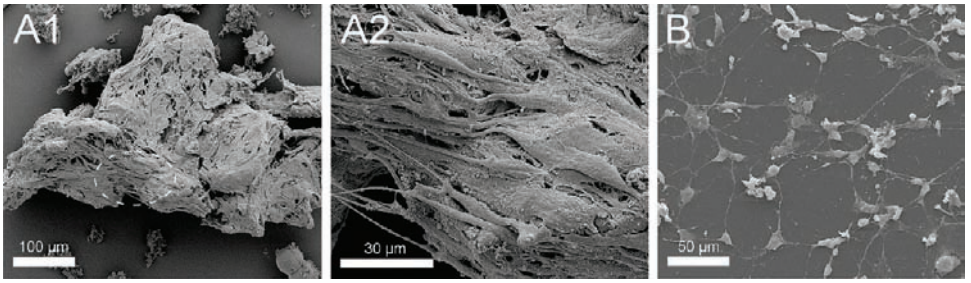

Figure 7. SEM images illustrating the attached (A1,A2) and the migrated/proliferated (B) NOM cells from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MCs aggregates to the NVR-gel, 7 days after cultivation in the NVR-gel, as described in the Methods and Materials section. A2 represent higher magnifications of the circled region shown in A1.

of the NOM cells in the NVR-gel, the total number of cells dispersed in the NVR-gel was counted, using *ImageJ* software, as shown in Figure 9. This figure presents the total number of

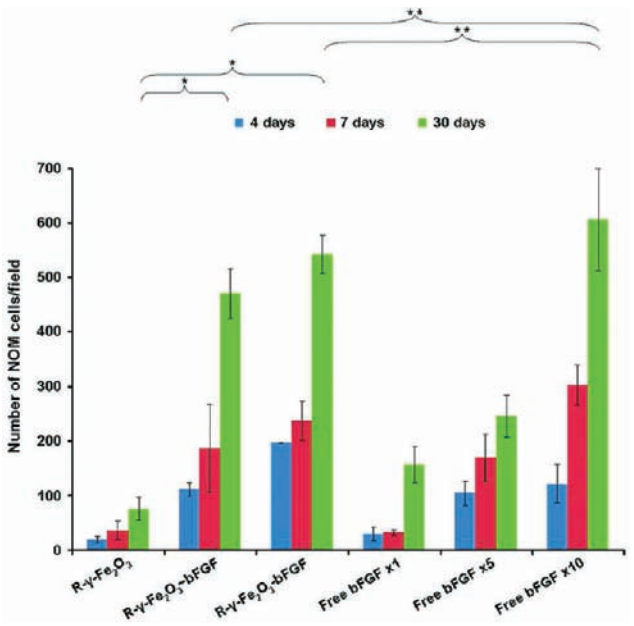

Figure 9. Quantitative analysis of the NOM cells migrated/proliferated from the cells/nonconjugated or bFGF conjugated nanoparticles/MCs aggregates and from the cells/free factor of different concentrations/MC aggregates (i.e., same concentration as the conjugated one, 5, and 10 times higher), 4, 7, and 30 days after cultivation in the NVR-gel, as described in the Materials and Methods section. The reported values are an average of measurements performed on at least three randomly nonoverlapping fields of each triplicate tested culture (* $P < 0.05$; ** $P > 0.05$).

cells migrated/proliferated from the cells/nonconjugated or bFGF-conjugated nanoparticles/MC aggregates and from the cells/free bFGF of different concentrations/MC aggregates to the NVR-gel, 4, 7, and 30 days after cultivation in the NVR-gel. This figure illustrates that the migration/proliferation rates of the NOM cells in the NVR-gel are according to the following order: R-γ-Fe_2O_3-bFGF slightly higher than the R-γ-Fe_2O_3~bFGF ($P > 0.05$), while both are significantly higher than the nonconjugated R-γ-Fe_2O_3 (*$P < 0.05$). For example, 30 days after cultivation in the NVR-gel, the number of cells counted in the presence of the R-γ-Fe_2O_3-bFGF, R-γ-Fe_2O_3~bFGF, and R-γ-Fe_2O_3 nanoparticles was 542 ± 28, 470 ± 37, and 74 ± 14, cells/field, respectively. In addition, Figure 9 also exhibits, as expected, the acceleration in the NOM cell migration/proliferation as the concentration of the free factor increases. However, the cell migration/proliferation rates in the presence of the same concentration of the free factor (free × 1) as the conjugated factor, or even 5 times higher, were lower than that observed for the conjugated factor ($P < 0.05$). Only when the concentration of the free factor was 10 times higher than that of the conjugated factor were similar cell migration/proliferation rates observed (**$P > 0.05$). For example, 30 days after cultivation in the NVR-gel, the number of cells counted in the presence of the covalently conjugated bFGF, free ×1, free ×5, and free ×10 was 542 ± 28, 157 ± 24, 245 ± 31, and 600 ± 67 cells/field, respectively.

Cellular Uptake of the bFGF-Conjugated Nanoparticles by the NOM Cells. Figure 10 demonstrates by

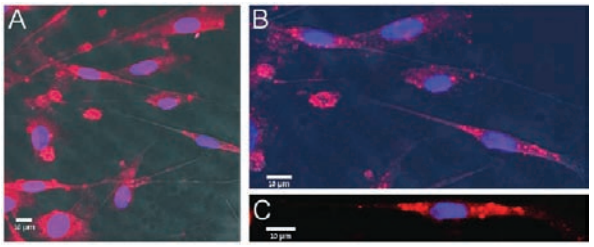

Figure 10. Fluorescence confocal microscopy images showing the cellular uptake and distribution of the R-γ-Fe_2O_3-bFGF nanoparticles in the lysosomes of the migrated/proliferated NOM cells, 7 days after cultivation in the NVR-gel, as described in the Materials and Methods section. (A,B) exhibit combined fluorescence and differential interference contrast (DIC) images; (C) exhibits a fluorescence image. Images (B) and (C) illustrate higher magnification of (A).

fluorescence confocal microscopy images the cellular internalization of the R-γ-Fe_2O_3-bFGF nanoparticles in the migrated/proliferated NOM cells, 7.0 days after cultivation in the NVR-gel. This figure reveals that these nanoparticles were efficiently internalized by endocytosis within the NOM cells, as clearly observed inside the cells as red dots. It is also seen that the nanoparticles were entrapped in the cytoplasm of the cells, mainly in the lysosomes. The internalization of the R-γ-Fe_2O_3-bFGF nanoparticles was also confirmed by Z-stacking confocal microscope images, as shown in the Supporting Information, Figure S1. This figure shows the various sections of a typical NOM cell along its *Z*-axis, and reveals that the majority of the fluorescence from the nanoparticles occurred in the middle of the cell (Figure S1g-l) compared to its top (Figure S1a-f) or bottom (Figure S1m-t), indicating that the nanoparticles are mainly internalized by the cells and not adsorbed on their surface. The bFGF-conjugated nanoparticles were internalized inside the cells, probably via receptor-mediated endocytosis.[53,54] The cellular uptake of these nanoparticles in the NOM cells was also confirmed by Prussian blue iron staining followed by counterstaining with nuclear fast red, as shown in Figure 11.[55] This figure demonstrates by light

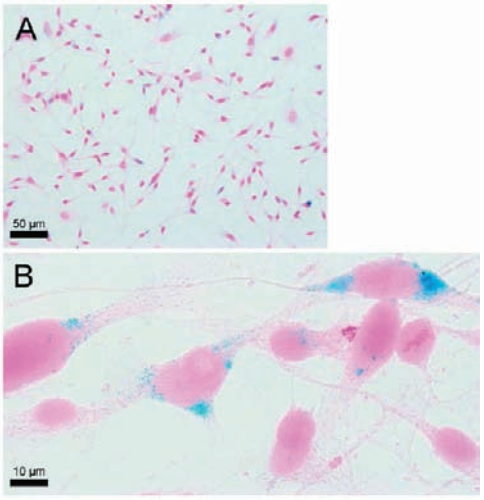

Figure 11. Light microscope images showing the Prussian blue iron staining followed by counterstaining with nuclear fast red of the migrated/proliferated NOM cells from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates to the NVR-gel, 7 days after cultivation in the NVR-gel (A). (B) represents a higher magnification of a specific region shown in (A).

microscopy images the blue granules in the cytoplasm of the cells, indicating the accumulation of the R-γ-Fe_2O_3-bFGF nanoparticles within the NOM cells, 7.0 days after cultivation in the NVR-gel.

Immunofluorescent Staining Illustrating the Effect of the Conjugation of bFGF on the Differentiation of the NOM Cells. Figure 12 illustrates by fluorescent microscopy the immunofluorescent staining images against specific cell markers of the NOM cells migrated/proliferated from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MCs aggregates (A1,A2,B1,B2) and from the cells/R-γ-Fe_2O_3 nanoparticles/MCs aggregates (C1,C2,D1,D2) to the NVR-gel, 10 days after cultivation in the NVR-gel. The same region of each tested culture was stained with two cell markers, (A:A1,A2) and (C:C1,C2), with anti-S100B and anti-NF, (B:B1,B2) and (D:D1,D2) with antinestin and anti-β3Tub. These figures clearly exhibit that the differentiation and the number of the cells (as illustrated in Figures 6 and 8) migrated/proliferated in the NVR-gel observed in the conjugated bFGF (Figure 12A,B) are significantly higher than that observed for the nonconjugated nanoparticles (Figure 12C,D). Quantitative analysis of the NOM cells grown in the bFGF-conjugated nanoparticles that were stained with anti-S100B and anti-NF (Figure 12A1,A2) revealed that 91.7 ± 3.8% of the cells were positively stained with anti-NF. From these 91.7 ± 3.8% cells, 69.8 ± 3.0% were also positively stained with anti-S100B, while the remaining cells (21.9 ± 3.1%) were not stained by this antibody. 8.3 ± 3.8% of the cells were not stained by any of these two markers. These results indicate that the major part of the cultured NOM cells in the presence of the conjugated bFGF are composed of neuronal cells and/or glia cells. In the parallel cultures (Figure 12B1,B2), which were stained with anti-β3Tub and antinestin, 98.9 ± 1.6% of the cells were positively stained with anti-β3Tub. From these 98.9 ± 1.6% cells, 59.0 ± 2.4% were also positively stained with antinestin, while the remaining cells (39.9 ± 3.9%) were not stained by this antibody. 1.1 ± 1.6% of the cells were not stained with any of these two markers. Altogether, these results demonstrate that the cultured NOM cells on MCs in the presence of the conjugated bFGF are composed mainly from neuronal and/or neuronal precursor cells. On the other hand, Figure 12C1,C2,D1,D2 shows that the number of cells and the differentiation of the NOM cells grown in the presence of the nonconjugated nanoparticles in the NVR-gel were negligible and not suitable for statistical analysis. These results are in good agreement with previous publications showing that bFGF promotes neuronal differentiation of adult and embryonic mouse olfactory epithelium and adult human olfactory epithelium.[56,57]

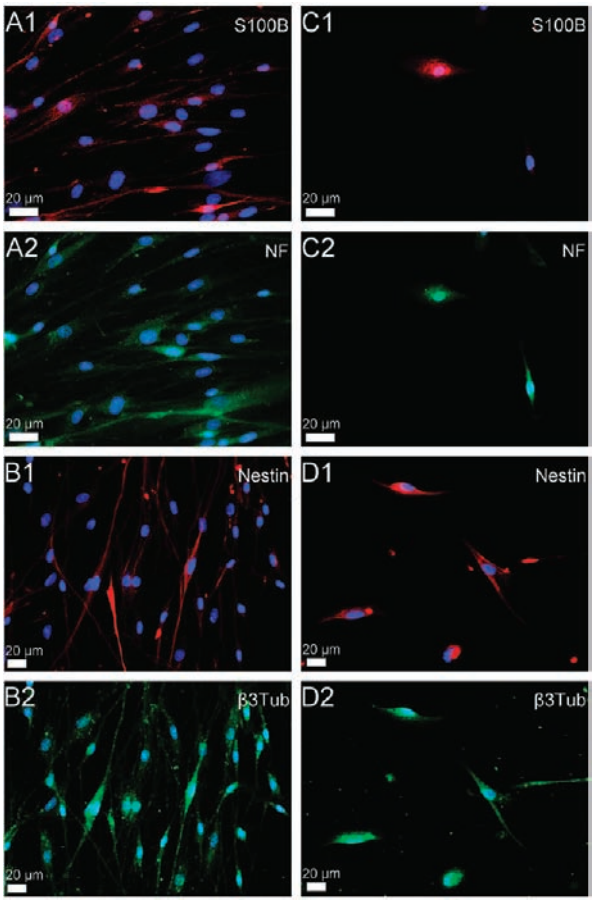

Figure 12. Fluorescence microscopy images illustrating the immunofluorescence staining of the NOM cells migrated/proliferated from the cells/R-γ-Fe_2O_3-bFGF nanoparticles/MC aggregates (A,B) and from the cells/R-γ-Fe_2O_3 nanoparticles/MC aggregates (C,D) to the NVR-gel, 10 days after cultivation in the NVR-gel. Antibodies against the following cell markers: S100B (glia marker, far red, A1,C1), NF (neuronal marker, green, A2,C2), nestin (neuronal precursor marker, far red, B1,D1), and β3Tub (neuronal marker, green, B2,D2) have been used. The nuclei of the NOM cells were dyed with DAPI (blue, A–D). The same region of each tested culture was stained with two cell markers, (A:A1,A2) and (C:C1,C2) with anti-S100B and anti-NF, (B:B1,B2) and (D:D1,D2) with antinestin and anti-β3Tub.

CONCLUSIONS

This manuscript shows that the conjugation of bFGF, either covalently or physically, to the R-γ-Fe_2O_3 nanoparticles significantly enhances the migration, growth, and differentiation of the NOM cells compared to the same concentration, or even 5 times higher, of the free bFGF. These bioactive nanoparticles may therefore be an efficient tool for growth factor delivery. In the future, we plan to extend this study for growth factors other than bFGF, e.g., NGF, VEGF, and so forth, and the use these conjugated factors for *in vivo* tissue engineering. The tissue engineering study will be accomplished, either directly or by incorporation, for the cultured cells/growth factor conjugated R-γ-Fe_2O_3 nanoparticles/MC aggregates into an appropriate scaffold at the site of an injured tissue. The effect of the migrated cells from the MCs on the repair of the examined tissue and the possibility of tracing them noninvasively by MRI will be investigated.

Supporting Information

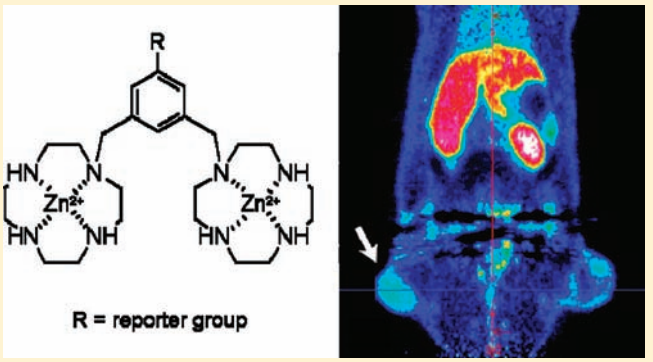
ABSTRACT: In vivo cell-death imaging is still a challenging issue. Until now, only ^{99m}Tc-labeled HYNIC-rh-annexin A5 has been extensively studied in clinical trials. In the ongoing search for an alternative imaging agent, we synthesized a series of fluorescent zinc-cyclen complexes as annexin A5 mimics and studied structural variations on the uptake behavior of cells undergoing apoptosis/necrosis. The number of cyclen chelators was varied and the spacer separating cyclen from the central scaffold was modified. Five zinc-cyclen complexes were labeled with fluorescein for flow cytometric studies and one was labeled with ^{18}F for in vivo applications. Jurkat cells were treated with staurosporine to induce apoptosis/necrosis, incubated with the fluorescein-labeled zinc complexes and analyzed them by flow cytometry. Fluorescent annexin A5 and propidium iodide were applied as reference dyes. Flow cytometry revealed greater accumulation of zinc-cyclen complexes in staurosporine treated cells. The uptake was contingent on the presence of zinc and the fluorescence intensity was dependent on the number of zinc-cyclen groups. Confocal laser scanning microscopy showed the {bis[Zn(cyclen)]}$^{4+}$ complex distributed throughout the cytosol different to annexin A5. Owing to the structural similarity of the bis-cyclen ligands with CXCR4 binding bis-cyclam derivatives the zinc-cyclen complex uptake was challenged with the meta derivative of AMD3100. Lack of uptake depletion in staurosporine treated cells ruled out measurable CXCR4 interaction. PET imaging using the ^{18}F labeled zinc-cyclen complex revealed significantly higher uptake in an irradiated Dunning R3327-AT1 prostate tumor as compared to the contralateral control tumor. PET imaging of a HelaMatu tumor model additionally showed an increased uptake after taxol treatment. It could be demonstrated that the fluorescent zinc-cyclen complexes offer potential as new agents for flow cytometry and microscopic imaging of cell death. In addition, the ^{18}F labeled analogue holds promise for in vivo applications providing informations about cell death after radiation therapy and cytostatic drug treatment.



INTRODUCTION

Evading apoptosis is one of the hallmarks of cancer. Overcoming this resistance is important for the success of therapeutic interventions. Apoptosis is accepted as one of the key readouts for early prediction of anticancer treatment response. Imaging apoptosis, therefore, will provide important information to ascertain the effectiveness of anticancer therapies.

Due to the loss of membrane asymmetry at the onset of apoptosis, phosphatidylserine (PS) becomes exposed on the extracellular cell membrane. Annexin A5 (AnxA5), a protein involved in the inhibition of blood coagulation, binds to externalized phosphatidylserine (PS) of apoptotic cells. The binding itself is driven through the formation of a ternary Ca^{2+} complex of AnxA5 with the carboxyl-phospholipid headgroup of PS.[1,2] This concerted interaction results in a considerable strong binding affinity of K_d <10^{-10} M.[3] Owing to this property, fluorescent annexin A5 was introduced as a tool for flow-cytometric detection of apoptosis[4] and is now broadly applied in cell biological research.[5,6] The in vivo imaging of apoptosis was made possible using ^{99m}Tc labeled AnxA5,[7] which was later modified to ^{99m}Tc-HYNIC-rh-annexin A5 and examined in clinical studies.[8]

On the basis of PS selectivity and binding strength of AnxA5, searches for small molecules as annexin mimics have been undertaken to further improve the property of apoptosis imaging. In reference to the role of Ca^{2+} in AnxA5, various Zn^{2+} complexes providing similar cocomplexation characteristics have been investigated as phosphate selective compounds.

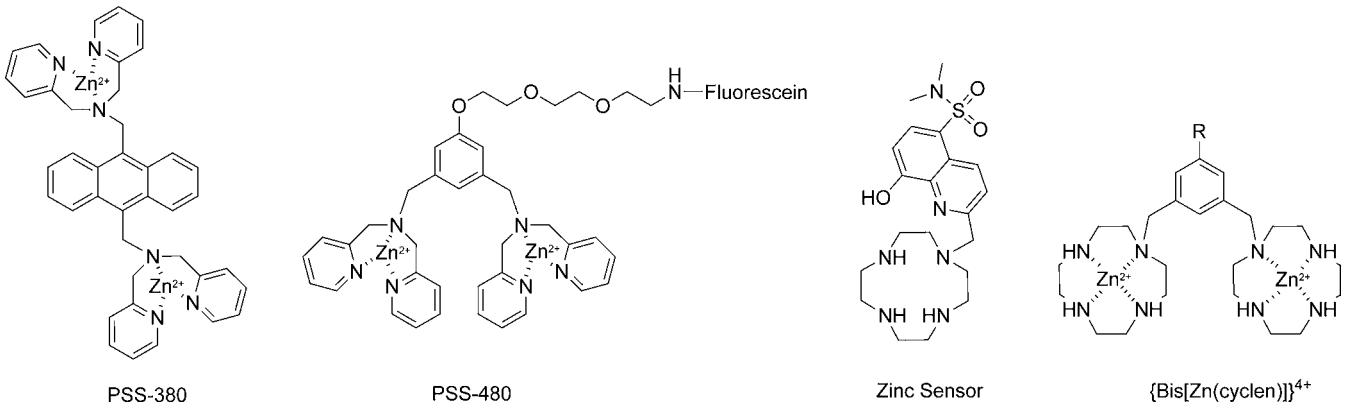

Figure 1. Chemical structures of zinc complexes used as phosphate sensors, a zinc sensor, and the general structure of bis[Zn(cyclen)]$^{4+}$, all designed for apoptosis imaging (R = reporter group).

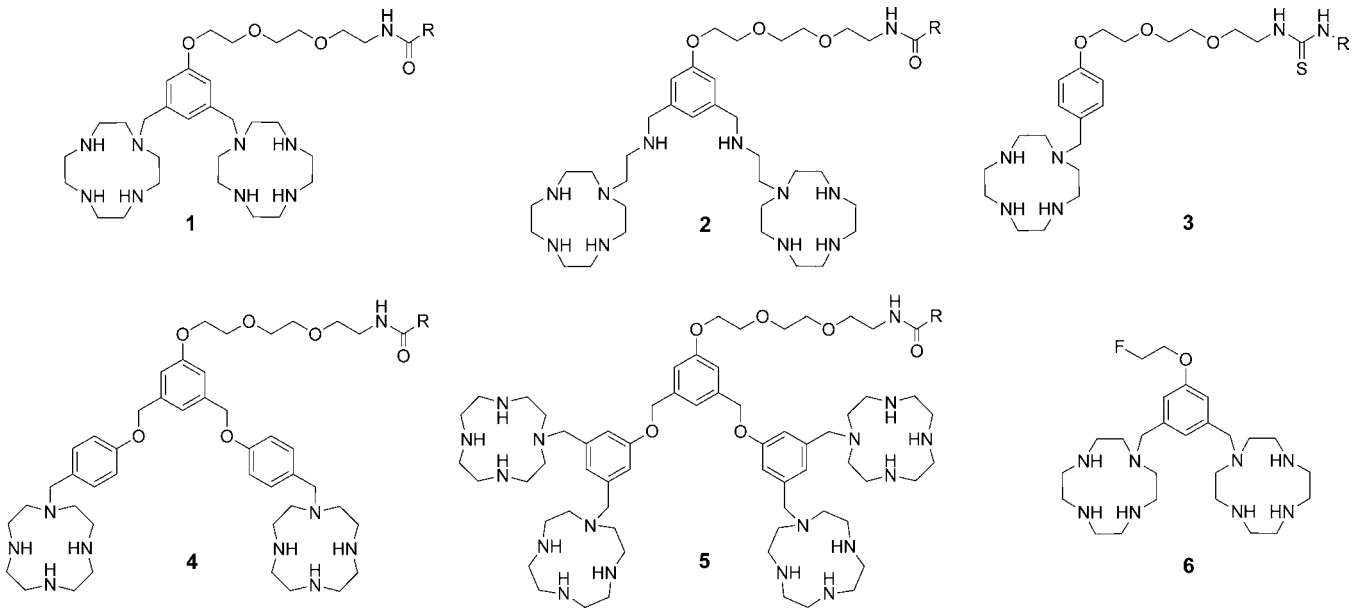

Figure 2. Chemical structures of cyclen derivatives **1**–**6** (R = fluorescein).

The bis(zinc(II)-dipicolylamine) complex PSS-380 shown in Figure1 was described to interact in this way allowing images of apoptotic cells.[9] The bifunctional complex ligand PSS-380 originated from developments of fluorescent chemosensors for phosphorylated peptides.[10,11] Several second-generation bis-(zinc(II)-dipicolylamine) complexes (Figure 1) have been synthesized and tested with artificial phospholipid vesicles[12] and apoptotic cells.[13] Cyclen-based zinc(II) probes were also suggested as microscopic imaging agents for apoptotic cells. The latest development includes the zinc sensor 8-hydroxy-5-*N*,*N*-dimethylaminosulfonylquinolin-2-ylmethyl-pendant cyclen (Figure 1) showing a complexation constant for Zn^{2+} of log K = 22.4 ± 0.1 M^{-1}. The amplified fluorescence was explained with the presence of an increased intracellular zinc concentration during apoptosis which led to complex participation of the chromophore pendant group.[14] The complex stability of the zinc sensor is much higher as compared to dipicolylamine-zinc complexes PSS-380 and PSS-480. The latter stability constants are approximately 10^7 M^{-1} and 10^4 M^{-1} for the first and second Zn^{2+} complex, respectively.[11,15,16]

Therefore, it remains to be examined whether zinc once bound to dipicolylamine stays complexed after the injection into the blood circulation. As indicated above, cyclen derivatives form more stable Zn(II) complexes providing a decent chance to survive complexed in vivo and to bind to the target site (log K[Zn(cyclen)]$^{2+}$ = 15.3 M^{-1}).[17,18] Consequently, the zinc-dipicolylamine complex structure elements were replaced with [Zn(cyclen)]$^{2+}$ to form *m*-phenylene bridged {bis[Zn(cyclen)]}$^{4+}$ derivatives (Figure 1). The ternary complex formation with externalized PS headgroups should similarly proceed as described for the zinc sensor or by the formation of multiple coordination bonds between multinuclear Zn^{2+} complexes and polyanionic compounds.[14,18]

We synthesized six cyclen derivatives, five comprising fluorescein tags and one labeled with ^{18}F (Figure 2). The fluorescent label was chosen for the investigation of structure-related effects on cell binding because of the methodological advantage of flow cytometry. Structural variations of the chelators included methylene (**1**) and 2-azabutylene spacers (**2**) separating cyclen from the central scaffold. In order to study the influence of multimerization, a series of cyclen derivatives with mono-, bis-, and tetra-cyclen structure elements (**3**–**5**) have been included. After complexation with Zn^{2+}, we evaluated these compounds on apoptotic Jurkat cells using flow

dx.doi.org/10.1021/bc200457b | *Bioconjugate Chem.* 2011, 22, 2611–2624

cytometry and confocal laser scanning microscopy (CLSM). To exclude the influence of CXCR4, cell uptake of zinc-cyclen complex $[\mathbf{Zn_2 1}]^{4+}$ was competed with a structurally related biscyclam derivative known to exhibit CXCR4 affinity. CXCR4 is a G-protein coupled chemokine receptor expressed on Jurkat cells and is physiologically involved in, e.g., the homing of metastasizing cells and the T-cell uptake of X4-HIV-1.[19] In addition, the presence of this receptor after induction of apoptosis was studied using a mouse anti-CXCR4 antibody. Furthermore, the in vivo applicability of the radiofluorinated zinc complex of **6** was demonstrated by positron emission tomography (PET) using rats bearing an irradiated Dunning prostate adenocarcinoma and mice carrying HelaMatu tumors treated with taxol.

MATERIALS AND METHODS

General. All chemicals and solvents were purchased from Sigma-Aldrich (Munich, Germany) or Merck (Darmstadt, Germany) and used without further purification. HPLC purifications were performed with Agilent 1100 Series (Agilent, Santa Clara, USA) on a Chromolith SemiPrep RP-18e column (100−10 mm, Merck, Darmstadt, Germany) using a flow of 8 mL/min and a gradient of 100% water (0.1% TFA) to 100% acetonitrile (0.1% TFA). For analytical HPLC, a Chromolith Performance RP-18e column (100−4.6 mm; Merck KGaA, Darmstadt, Germany) was used using a flow of 4 mL/min and the above-mentioned gradient. Analytical HPLC was used to prove the purity of the compounds. ESI mass spectrometry was performed with a Triple Quadrupole mass spectrometer TSQ 7000 (Thermo Fisher Scientific, Bremen, Germany). NMR spectra were measured with a Varian Mercury Plus 300, a Varian NMR System 500 (Varian, Palo Alto, USA), and a Bruker DRX 500 Avance (Bruker BioSpin, Rheinstetten, Germany).

Annexin A5 Alexa Fluor 488 was purchased from Molecular Probes (Invitrogen, Paisley, UK). Anti-hCXCR-4 (fusin) and mouse monoclonal antibody Ig_{2A} clone 12G5 were obtained from R&D Systems (Minneapolis, MN, USA). Cell experiments were conducted with the human T-lymphocyte cell line Jurkat J6, clone E6−1) which was purchased from ECACC (European Collection of Cell Culture, HPA Culture Collections, Salisbury, UK). The cells were cultivated in RPMI 1640 (PAA Laboratories GmbH, Pasching, Austria) containing 1% glutamine and 10% FBS at 37 °C in a 5% CO_2 atmosphere and maintained in log phase.

Flow cytometry was performed with a DAKO Galaxy Flow-Cytometry System (DAKO, Glostrup, Denmark) equipped with *Partec* analysis software (Münster, Germany).

Confocal laser scanning microscopy (CLSM) images were obtained with a LSM 410 microscope (Carl Zeiss Micro-Imaging GmbH, Jena, Germany) and processed with *Advanced Imaging Microscopy Release 4.2* software (Zeiss, Jena, Germany).

The following buffer systems were used for cell experiments. Annexin binding buffer (10 mM HEPES (*N*-(2-hydroxyethyl)-piperazin-*N*′-2-ethane sulfonic acid), 150 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, 1.8 mM $CaCl_2$) pH 7.4; TES buffer (5 mM TES (*N*-[tris(hydroxymethyl)methyl]-2-amino sulfonic acid), 145 mM NaCl) pH 7.4; PBS buffer (Dulbeccos's PBS without Ca and Mg, PAA Laboratories GmbH, Pasching, Austria).

Analysis and purification of radioactive compounds were conducted on a LATEK P-400 HPLC with a LATEK UV-Detektor (Eppelheim, Deutschland), λ = 220 nm, and a Bioscan radiodetector (Washington, USA). Purification of the radiofluorinated compounds was performed using a Chromolith SemiPrep RP-18e column (100−10 mm, Merck, Darmstadt, Germany) with a gradient of 100% water (0.1% TFA) to 100% acetonitrile (0.1% TFA) in 7 min and a flow of 10 mL/min.

Syntheses. *2-(2-(2-(Tritylamino)ethoxy)ethoxy)ethanol* ***7***. 2-[2-(2-Aminoethoxy)ethoxy]ethanol[20] (1.45 g, 9.72 mmol) and triethylamine (135 μL, 79 μmol, 0.1 equiv) were dissolved under nitrogen in CH_2Cl_2 (20 mL). Tritylchloride in CH_2Cl_2 (15 mL) was added dropwise at room temperature. After 16 h, the solvent was evaporated. The crude product was purified by silica gel column chromatography (EtOAc/petroleum ether = 1:1, 0.1% DIPEA). Yield 1.4 g (38%). ESI-MS: m/z = 392.3, calc. 392.3 $[M+H]^+$. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.44−7.37 (m, 6H), 7.24 (m, 6H), 7.14−7.07 (m, 3H), 3.64−3.43 (m, 10H), 2.29 (t, 2H, ^3J = 5.4 Hz) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 146.03, 128.66, 127.77, 126.24, 72.45, 71.29, 70.66, 70.36, 70.08, 61.78, 43.04 ppm.

2-(2-(2-Bromoethoxy)ethoxy)-N-tritylethylamine ***8***. K_2CO_3 (223 mg, 1.61 mmol, 1.5 equiv) and tetrabromomethane (514 mg, 1.55 mmol, 1.5 equiv) were added under nitrogen to a solution of **7** (400 mg, 1.02 mmol) in CH_2Cl_2 (10 mL). Triphenylphosphine (422 mg, 1.60 mmol, 1.5 equiv) in CH_2Cl_2 (10 mL) was added dropwise. After stirring for 18 h at room temperature, K_2CO_3 was removed by filtration and the solvent was evaporated. Silica gel column chromatography (EtOAc/petroleum ether = 1:2, 0.1% DIPEA) yielded 436 mg (94%). ESI-MS: 456.2; calc. 454.2 $[M+H]^+$. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.43−7.37 (m, 6H), 7.23−7.16 (m, 6H), 7.14−7.07 (m, 3H), 3.70 (t, 2H, ^3J = 6.4 Hz), 3.57−3.43 (m, 6H), 3.33 (t, 2H), 2.28 (t, 2H, ^3J = 5.4 Hz) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 146.09, 128.64, 127.72, 126.18, 71.28, 71.20, 70.61, 70.47, 70.05, 43.00, 30.22 ppm.

O-Alkylation of Phenolic Compounds: General Procedure. The respective phenol (1.2 equiv) and 2-(2-(2-bromoethoxy)ethoxy)-*N*-tritylethylamine **8** (1 equiv) were dissolved under nitrogen in acetonitrile. K_2CO_3 (1.5 equiv) was added and the mixture was refluxed for 20 h. After cooling to room temperature, K_2CO_3 was removed by filtration, and the crude product was purified by silica gel column chromatography.

Zn^{2+}-Complexation. The cyclen derivatives **1**−**5** were dissolved in double distilled water (200 μL/500 μg ligand) and adjusted with 0.1 M NaOH to pH 8−10. 0.1 mM $Zn(NO_3)_2$ in H_2O was added to obtain a molar Zn^{2+}/cyclen ratio of 1:1. After heating for 2 h at 50 °C, the complexes were formulated to give 0.5 mM aqueous solutions which were lyophilized for later applications.

1,3-Bis(1,4,7,10-tetraazacyclododec-1-yl-methyl-4,7,10-tri-tert-butyloxycarbonyl ester)-(5-hydroxy)-benzene ***35***. Compound **34** (400 mg, 340 μmol) was dissolved in THF. A 1 M solution of tetrabutylammoniumfluoride in THF (442 μL, 442 μmol, 1.3 equiv) was added at 0 °C. The reaction mixture was stirred for 30 min at 0 °C and 30 min at room temperature. The solvent was removed *in vacuo*; and the product was dissolved in Et_2O, washed with saturated ammonium chloride solution, and dried over $MgSO_4$. Filtration and solvent evaporation yielded **35** as a white solid. Yield 325 mg (90%). MALDI-MS: m/z = 1064.1, calc. 1063.7 $[M+H]^+$. ^1H NMR (500 MHz, DMSO-d_6, 343 K): δ = 9.09 (s, 1H), 6.60 (s, 2H), 6.55 (s, 1H), 3.66 (s, 4H), 3.54−3.47 (m, 8H), 3.35−3.30 (m, 8H), 3.28 (s, 8H), 2.58 (s, 8H), 1.41 (s, 18H), 1.37 (s, 36H) ppm. ^{13}C NMR (500 MHz, DMSO-d_6, 343 K): δ = 156.70, 154.53, 154.16, 136.49, 122.72, 115.82, 78.07, 77.79, 54.57, 53.86, 48.19, 46.46, 46.16, 27.90, 27.67 ppm.

1,3-Bis(1,4,7,10-tetraazacyclododec-1-yl-methyl-4,7,10-tri-tert-butyloxycarbonylester)-(5-(1-fluoro-2-methoxyethane))-benzene ***36***. Compound **35** (57.0 mg, 53.6 μmol) in acetonitrile was reacted with 2-fluoroethyl tosylate (23.4 mg, 107 μmol) and K_2CO_3 (22.2 mg, 161 μmol) under reflux for 18 h. The K_2CO_3 was filtrated and the solvent was evaporated *in vacuo*. Column chromatography on silica gel (cyclohexane/EtOAc = 4:1) yielded 40 mg **36** as a white solid (67%). MALDI-MS: m/z = 1110.3, calc. 1109.7 $[M+H]^+$. ^1H NMR (500 MHz, DMSO-d_6, 343 K): δ = 6.79 (s, 2H), 6.75 (s, 1H), 4.76−4.63 (m, 2H, ^3J = 47.8 Hz), 4.24−4.14 (m, 2H, ^4J = 29.0 Hz), (s, 4H), 3.54−3.48 (m, 8H), 3.37−3.32 (m, 8H), 3.29 (s, 8H), 2.58 (s, 8H), 1.41 (s, 18H), 1.36 (s, 36H) ppm. ^{13}C NMR (500 MHz, DMSO-d_6, 343 K): δ = 157.76, 154.57, 154.16, 137.44, 124.30, 114.89, 82.22, 80.89, 78.07, 77.84, 54.94, 53.95, 48.20, 46.41, 46.29, 27.86, 27.63 ppm.

1,3-Bis(1,4,7,10-tetraazacyclododec-1-yl-methyl)-(5-(1-fluoro-2-methoxyethan))-benzene ***6***. Compound **36** (40 mg, 36 μmol) was dissolved in TFA/CH_2Cl_2 = 1:1 and stirred at room temperature for 1 h. After solvent removal, the TFA salt of the product was obtained as a white solid. Yield 42 mg (100%; **6**+5TFA). ESI-MS: m/z = 255.2, calc. 255.2 $[M+2H]^{2+}$. ^1H NMR (500 MHz, DMSO-d_6): δ = 6.91 (d, 2H, ^4J = 0.9 Hz), 6.77 (s, 1H), 4.82−4.69 (m, 2H, ^3J = 47.8 Hz), 4.30−4.20 (m, 2H, ^4J = 30.0 Hz), 3.72 (s, 4H), 3.14 (s, 8H), 3.09−3.01 (m, 8H), 2.87−2.80 (m, 8H), 2.77−2.71 (m, 8H) ppm. ^{13}C NMR (500 MHz, DMSO-d_6): δ = 158.01, 136.67, 123.79, 115.05, 82.42, 81.08, 55.36, 47.30, 44.50, 42.17, 41.93 ppm.

1,3-Bis-(1,4,7,10-tetraazacyclododec-1-yl-methyl)-(5-(1-[^{18}F]fluoro-2-methoxyethane))-benzene ***^{18}F-6***. The protected precursor **36** (2.5 mg, 2.34 μmol) in 10 μL DMF was reacted with 2-[^{18}F]fluoroethyl tosylate[23] (185 MBq) in 200 μL DMF in the presence of K_2CO_3 (5 mg). The reaction mixture was stirred for 35 min at 120 °C and separated by semipreparative HPLC. The eluate was concentrated on a C18-SepPak-light cartridge and eluted with 2 mL EtOH. Evaporation of the solvent yielded 68 MBq (77% decay-corrected). Deprotection of **^{18}F-36** was performed at ambient temperature with 200 μL TFA in 50 μL acetonitrile. Owing to the HPLC purification of **^{18}F-36**, the specific activity was estimated to >50 GBq/μmol.

After evaporation, the complexation of **^{18}F-6** with Zn^{2+} was carried out in 100 μL PBS for 5 min at 70 °C containing 10 μL of an aqueous 1.5 mM $Zn(NO_3)_2$ solution. For imaging experiments, the zinc complex of **^{18}F-6** was diluted with 400 μL PBS and filtered sterile.

Cell Experiments. *Flow Cytometry.* Apoptosis was induced with 10^6 cells/mL using staurosporine (1 μM) during 4 h. The cells were washed with PBS and split into 1 mL samples containing 10^6 cells. After centrifugation, cells were taken up in 100 μL TES buffer for incubation with complex solutions or in 100 μL annexin binding buffer for annexin experiments. 1.0 μL of a 0.5 mM complex solution was added to the TES buffered cells and 1.5 μL of Alexa Fluor 488 conjugated annexin was added to the cells taken up in annexin binding buffer. After 15 min incubation in the dark, the suspensions were diluted with 300 μL TES or annexin binding buffer. Flow-cytometry measurements were performed with 100 μL cell suspension and 900 μL cold buffer. 6×10^3 cells were counted in each experiment. Where necessary, 10 μL propidium iodide solution (250 μg/mL) was added just before the measurement. Control cells were treated in the same way and measured as a comparison with each experiment.

Evidence of CXCR4. The anti-hCXCR-4 antibody was diluted with cold PBS to a concentration of 10 μg/mL. Control and apoptotic Jurkat cells (approximately 10^6) were suspended in 100 μL antibody solution and incubated for 30 min at 4 °C. The cells were washed three times with cold PBS and taken up in 100 μL PBS solution of FITC-labeled antimouse monoclonal antibody Ig_{2A}. After 30 min incubation at room temperature, the cells were washed again three times with cold PBS and finally dispersed in 400 μL PBS. 100 μL cell suspension was added to 900 μL cold PBS and measured in a flow cytometer.

Competition with meta AMD3100. 1.0 μL of a 50 mM aqueous solution of meta AMD3100, synthesized according to the literature[24] and 1.0 μL of 0.5 mM complex $[\mathbf{Zn_2 1}]^{4+}$ solution was added to 10^6 staurosporine treated Jurkat cells in cold TES buffer. The cells were incubated 15 min at room temperature in the dark. The samples were diluted with TES buffer to 400 μL. 100 μL of the suspension were added to 900 μL cold buffer and measured by flow cytometry.

Confocal Laser Scanning Microscopy (CLSM). Apoptosis induction of Jurkat cells for CLSM experiments was performed as described above. To prevent free floating under coverslips, the cells were immobilized on polylysine precoated slides. After incubation with $[\mathbf{Zn_2 1}]^{4+}$ for 15 min, the cells were transferred to the object slide and placed under the microscope. Images were taken from the midcell *z*-plane.

Animal Studies. The experiments were approved by the governmental review committee on animal care. All animal experiments were performed in compliance with the current version of the German law concerning animal protection and welfare. Animals were kept under standard laboratory conditions at the German Cancer Research Center or at Bayer Healthcare Research Facilities.

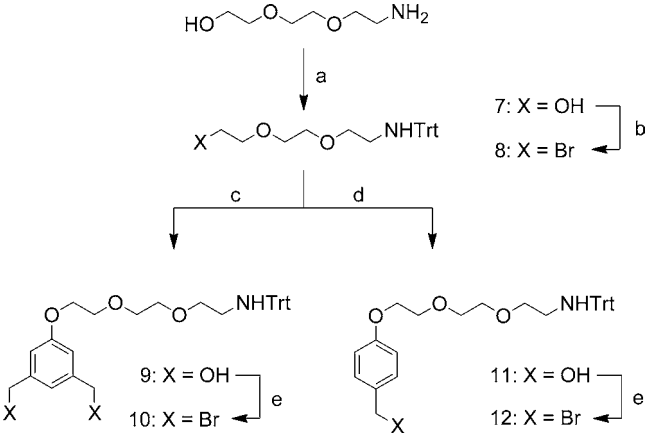
Male Copenhagen rats (approximately 180 g) were subcutaneously transplanted on both thighs with 1×10^6 Dunning adeno carcinoma R3327-AT1 cells. Fourteen days after tumor cell implantation, the left tumor was irradiated with a single dose of 50 Gy using an Artiste linear accelerator (Siemens AG, München, Germany). The right tumor served as control. One day before (day 13 after tumor cell inoculation) and six and ten days after irradiation, the rats were imaged using $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$. 15–25 MBq in 200 μL PBS was injected into the tail vein. For the PET-scan, the animals were anesthetized with sevoflurane and maintained under anesthesia during the scan (2.5% for induction and 1% for maintenance of anesthesia). PET studies were performed with the Siemens Inveon small animal PET scanner (Siemens, Knoxville, USA). A transmission scan was done for 10 min prior to tracer administration with two rotating germanium pin sources to obtain cross sections for attenuation correction. PET data were acquired for 1 h in list mode on an Inveon scanner (Siemens Erlangen Germany) using a matrix of 256 × 256 (pixel size $0.3882 \times 0.3882 \times 0.796$ mm^3). The images were reconstructed iteratively using the space alternating generalized expectation maximization method (SAGE, 16 subsets, 4 iterations) applying median root prior correction.

1.5×10^6 HelaMatu (human cervix carcinoma) tumor cells were inoculated in a volume of 100 μL (medium/matrigel) into the right shoulder of nude mice (NMRI nu/nu, female, ca. 20 g, obtained from Taconic). At day 12 after inoculation, animals were treated with taxol using 18 mg/kg i.v. or vehicle (5% cremophore, 5% ethanol). PET images were acquired using an Inveon small animal PET/CT scanner (Siemens, Knoxville, USA) at 60 min p.i. for 10 min. After the PET study, animals were sacrificed, and tumors were removed and cut into 18 μM slices (Cryostat Fa Leica CM 3050 S). Tumor slices were exposed to a phosphoimager plate (BAS-SR Imaging plate, Fuji, IP-SR 20 × 25) overnight. Analysis was performed using the BAS-5000 Imaging System (Fuji). Cleaved caspase 3 in the tumor samples was detected by immunohistochemistry (IHC) using a polycolonal antibody against cleaved caspase 3 (rabbit, Cell Signaling, # 9661-S). IHC was performed using established standard protocols.

RESULTS

Syntheses. The syntheses of the title compounds essentially followed the preparation strategy applied to obtain bis(dipicolylamine) derivatives.[12] This route offered the possibility of attaching different fluorescent dyes as well as other markers such as radiolabels in the perspective of in vivo imaging. As outlined in Scheme 1, the core structures were obtained as *N*-trityl protected 3,5-bis(bromomethyl)- (**9**) and 4-bromomethyl phenyl (**10**) derivatives.

Scheme 1. Syntheses of Bis(cyclen) Scaffolds



(a) Trityl chloride, Et_3N, CH_2Cl_2; (b) CBr_4, K_2CO_3, Ph_3P, CH_2Cl_2; (c) 3,5-Bis(hydroxymethyl)phenol, K_2CO_3, acetonitrile, reflux; (d) 4-Hydroxymethylphenol, K_2CO_3, acetonitrile, reflux; (e) CBr_4, Ph_3P, CH_2Cl_2.

Tris(Boc)cyclen (Z) was alkylated using precursors **10** and **12** yielding compounds **13** and **19**, respectively (Scheme 2). Selective cleavage of the trityl group with hexafluoroisopropa-

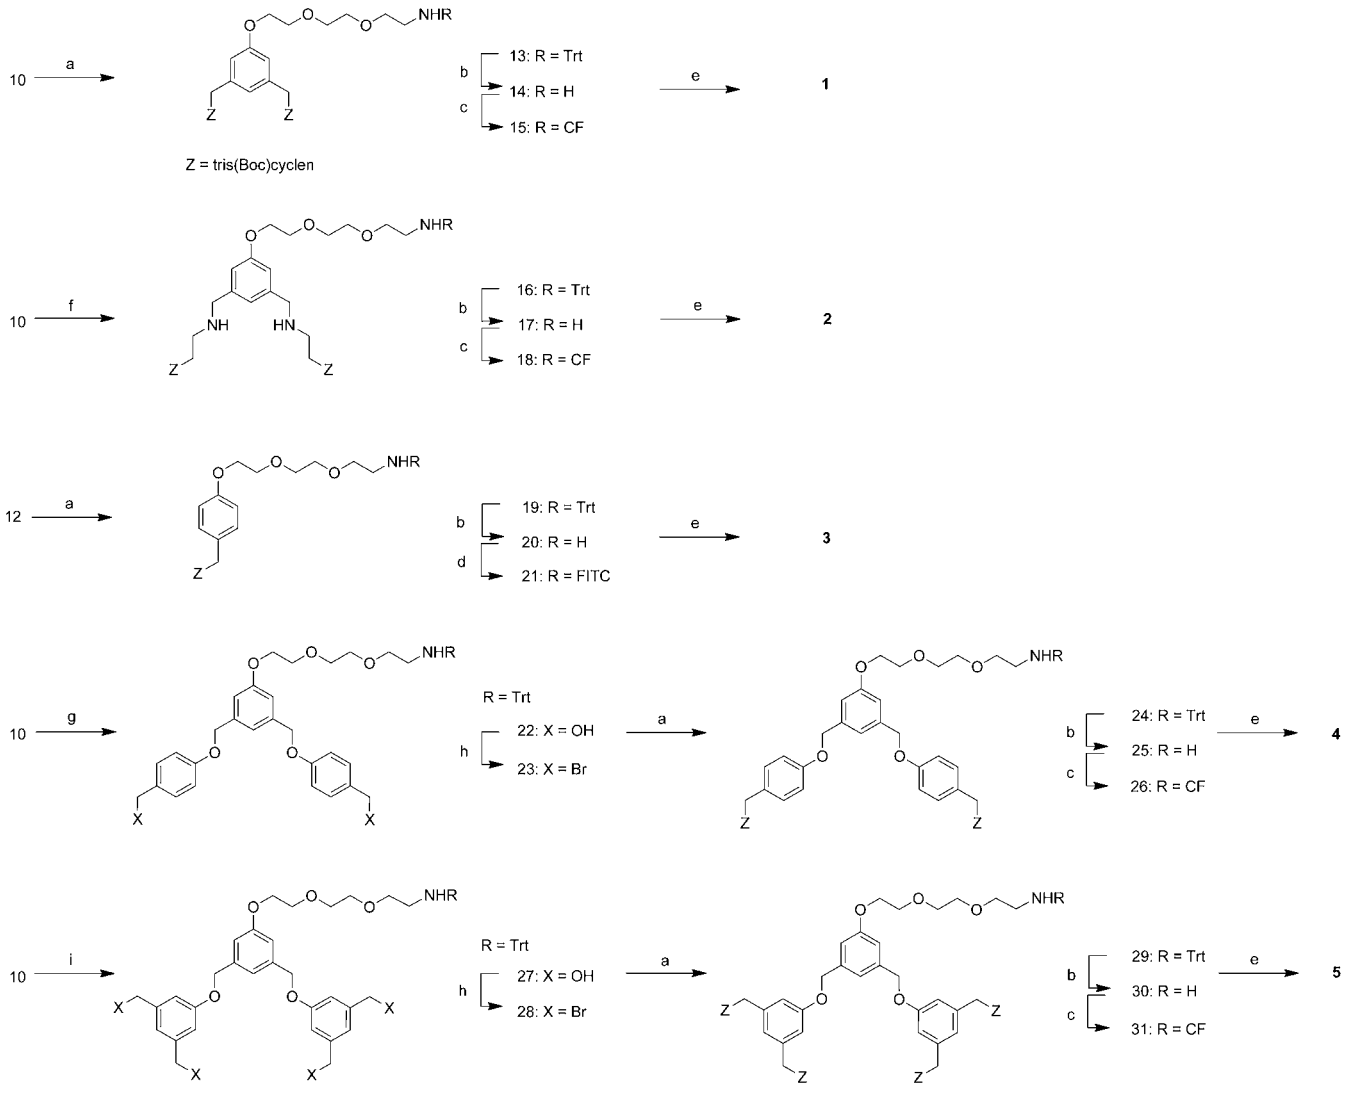
Scheme 2. Syntheses of Bis(cyclen) Ligands



(a) Tris(Boc)cyclen, K_2CO_3, KI, acetonitrile, 50 °C; (b) Hexafluoroisopropanol/1% H_2O, CH_2Cl_2; (c) CF-PFP ester, DIPEA, DMF; (d) FITC, DIPEA, DMF; (e) TFA, CH_2Cl_2; (f) Aminoethyl-tris(Boc)cyclen, K_2CO_3, acetonitrile, 50 °C; (g) 4-Hydroxymethylphenol, K_2CO_3, acetonitrile, reflux; (h) CBr_4, Ph_3P, CH_2Cl_2; (i) 3,5-Bis(hydroxymethyl)phenol, K_2CO_3, acetonitrile, reflux.

nol was followed by the introduction of fluorescent markers carboxyfluorescein pentafluorophenol ester (5(6)-CF-PFP) and fluorescein isothiocyanate (FITC). Deprotection of the cyclen amino functionalities yielded chelator **1** as well as the mono cyclen **3**. In order to introduce a pendant heteroatom into the spacer, tris(Boc)cyclen providing an aminoethyl side arm was alkylated with compound **10**. Removal of the trityl group, conjugation with 5(6)-CF-PFP, and Boc deprotection resulted in chelator **2**. The cyclen multimers **4** and **5** were obtained via elongation of the central scaffold **10** with 4-hydroxymethylphenol and 3,5-di(hydroxymethyl)phenol. Alkylation of tris(Boc)cyclen using the resulting bromo compounds **23** and **28** together with selective trityl deprotection and reaction with 5(6)-CF-PFP gave compounds **26** and **31**, respectively. Final Boc deprotection resulted in the cyclen derivatives **4** and **5** which were then complexed with Zn^{2+} for biological experiments.

The synthesis of the radiofluorination precursor **35** proceeded through alkylation of tris(Boc)cyclen with the TBDMS protected phenol **33** (Scheme 3). After silyl deprotection, compound **35** was reacted with 2-fluoroethyl tosylate and treated with TFA to cleave the Boc groups forming ligand **6**. The radiolabeled congener ^{18}**F-6** was prepared accordingly using HPLC purified 2-[^{18}F]fluoroethyl tosylate.

The final step implied the formation of the Zn^{2+} complexes. Aqueous solutions of the fluorescein-cyclen derivatives were heated at 50 °C with 1 equiv Zn^{2+}/cyclen. The resulting complexes were lyophilized and redissolved in H_2O to form 0.5 mM solutions. The HPLC purified, noncarrier added radiofluorinated bis(cyclen) **6** was transferred into the zinc complex $[\mathbf{Zn_2}(^{18}\mathbf{F\text{-}6})]^{4+}$ by adding Zn^{2+} salt and heating.

Flow Cytometry. The influence of the $\{$bis[Zn(cyclen)]$\}^{4+}$ complexes on cell size and granularity was studied with $[\mathbf{Zn_2 1}]^{4+}$ to exclude cell damaging of untreated Jurkat cells during flow cytometry. The cells were, therefore, analyzed using the flow cytometric sideward (SSC) and forward (FSC) scatter signals which allowed the detection of advanced apoptotic and secondary necrotic cells. The cells were incubated in TES buffer with $[\mathbf{Zn_2 1}]^{4+}$ at concentrations in the range 0−50 μM for up

to 72 h. As demonstrated in the Supporting Information, toxicity against vital Jurkat cells proved negligible.

Apoptosis was induced in Jurkat cells with 1 μM staurosporine for 4 h.[25] Figure 3 shows flow-cytometric density plots (upper row) obtained with Alexa Fluor 488 labeled annexin A5 (AnxA5-AF) and propidium iodide (PI). Cells with high binding of Annexin A5 were found in the rectangle Q1, indicating 4.7% of apoptotic cells for the control cell population vs 38.5% of apoptotic cells after staurosporine treatment. This value varied between 30% and 60%. Simultaneous binding of annexin A5 and propidium iodide are found in Q2, indicating cells which were in the transition of apoptosis to necrosis (late apoptosis and secondary necrosis).[26] Here, 2.5% was obtained for untreated and 19.1% for staurosporine treated cells. Cells in segment Q3 represent unchanged cells and those in Q4 are solely dyed with PI, presumably completely necrotic cells.

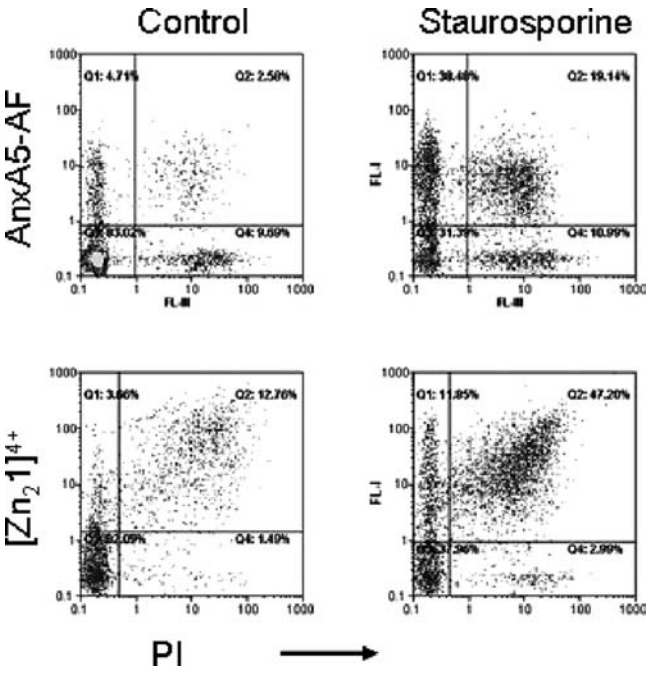

Figure 3. Flow cytometric density plots of Jurkat cells in the presence of AnxA5-AF/propidium iodide (PI) and $[\mathbf{Zn_21}]^{4+}$ (lower panel) after treatment with staurosporine (right). Untreated controls are shown on the left.

Lower row of density plots (Figure 3) illustrates flow cytometry results which were obtained with the same experimental setup as described above but in the presence of $[\mathbf{Zn_21}]^{4+}$. After staurosporine treatment, 11.9% was found in Q1 and 47.2% in Q2. The latter value indicated $[\mathbf{Zn_21}]^{4+}$-binding together with PI accumulation. The sum of Q1 and Q2 was about 60% for both AnxA5-AF and the zinc complex. It appears remarkable that after the addition of $[\mathbf{Zn_21}]^{4+}$ and PI the SSC and FSC signals of the staurosporine treated cells were shifted into the secondary necrosis fraction (arrow in SI) and that these signals can be attributed to Q2. With the exception of $[\mathbf{Zn_22}]^{4+}$, this effect was also observed using the remaining fluorescent zinc-cyclen complexes.

The insertion of a pendant ethylene amino group like in $[\mathbf{Zn_22}]^{4+}$ led to histograms almost indistinguishable between staurosporine treated and control cells. Both the $[\mathbf{Zn_22}]^{4+}$ complex-related fluorescence of treated and control cells appeared in Q1 at 38.2% and 31.9%, respectively, showing similar distribution patterns. The intensity of the green fluorescence of $[\mathbf{Zn_22}]^{4+}$ was, however, strongly reduced as compared with the fluorescence of $[\mathbf{Zn_21}]^{4+}$ in apoptotic cells.

Ligands **3**, **4**, and **5** were synthesized to study the influence of the number of $[Zn(cyclen)]^{2+}$ groups on the fluorescence of staurosporine treated cells. While complex $[\mathbf{Zn_24}]^{4+}$ showed similar results as obtained with $[\mathbf{Zn_21}]^{4+}$, the tetrameric cyclen complex $[\mathbf{Zn_45}]^{8+}$ increased the mean fluorescence intensity (MFI) of the green fluorescence signals of treated Jurkat cells by a factor of 2.3. The monomeric $[\mathbf{Zn3}]^{2+}$ produced in turn a

much smaller MFI, 2 vs 34 of $[\mathbf{Zn3}]^{2+}$ and $[\mathbf{Zn_2 1}]^{4+}$or $[\mathbf{Zn_2 4}]^{4+}$, respectively (SI).

The relevance of zinc(II) in the cyclen complexes, which as outlined in the introduction was thought to be necessary for the ternary interaction with PS, was tested by comparing the complex with the free ligand. The free cyclen derivative **4** produced an unspecific fluorescence of low intensity, whereas the complex $[\mathbf{Zn_2 4}]^{4+}$ showed strong fluorescence of staurosporine treated cells as described above (SI).

All flow cytometric results described so far were obtained in the presence of the respective zinc complexes. Removal of these dyes by two washing steps resulted in the loss of most of the intracellular dye. The reverse result was obtained by increasing the zinc-complex concentration leading to an increase of the mean fluorescence intensity of treated Jurkat cells. Loss and increase of fluorescence intensity indicates reversibility of concentration-dependent accumulation. Figure 4 shows this

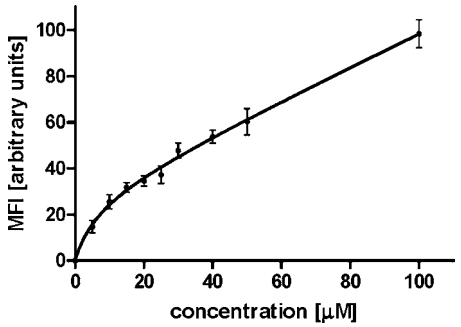

Figure 4. Mean fluorescence intensity (MFI) of staurosporine treated Jurkat cells in the presence of increasing amounts of $[\mathbf{Zn_2 1}]^{4+}$ (Data are expressed as mean ± SD; n = 3.)

dependence, which was obtained with $[\mathbf{Zn_2 1}]^{4+}$ and staurosporine treated Jurkat cells. The mean fluorescence intensity increased within the 0−100 μM range without reaching saturation.

Confocal Laser Scanning Microscopy (CLSM). Clues about the intracellular location of the $\{$bis[Zn(cyclen)]$\}^{4+}$ complexes were obtained using confocal laser scanning microscopy (CLSM). Staurosporine treated Jurkat cells were incubated with a zinc-cyclen complex and placed under the microscope. Figure 5a (and SI) exemplarily shows staurosporine treated cells which deposited $[\mathbf{Zn_2 1}]^{4+}$ throughout the cytoplasm. The membrane binding of AnxA5-AF on the other hand is obvious (Figure 5b).

Influence of the CXCR4 Receptor. The presence of CXCR4 on Jurkat cells was confirmed on control and staurosporine-treated cells using the mouse anti-CXCR4 antibody mAb12G5. Flow cytometry revealed a strong expression of ca. 80% for both cell types. The mean fluorescence intensity was comparable, which means that there is no significant difference in the exposure of CXCR4 on treated and control cells. In addition, competition with the meta derivative of AMD3100 was performed which is known to bind CXCR4 in the low nanomolar range. Even with 100-fold molar excess, no depletion of the $[\mathbf{Zn_2 1}]^{4+}$ fluorescence was observed with apoptotic cells (SI).

PET Imaging. The in vivo behavior of the $\{$bis[Zn(cyclen)]$\}^{4+}$ compounds was studied with $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$. Male Copenhagen rats bilaterally transplanted with Dunning R3327-AT1 prostate tumors were irradiated on one side with a

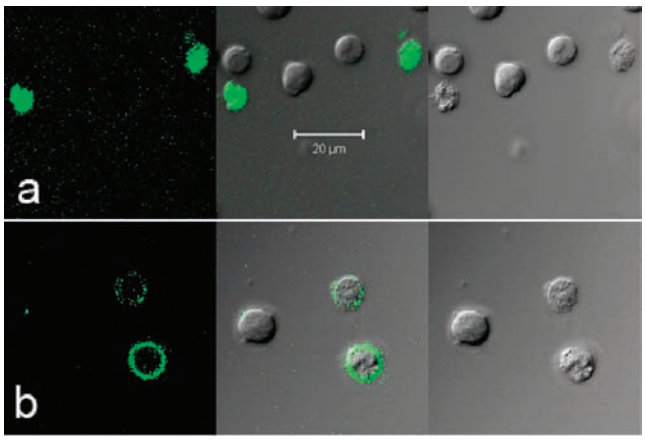

Figure 5. CLSM images (λ_{exc} 488 nm/3%; BP 505−530 nm) of staurosporine treated Jurkat cells incubated with $[\mathbf{Zn_2 1}]^{4+}$ (a) and AnxA5-AF (b). The different locations of both compounds are conclusive: cytoplasmic distribution of $[\mathbf{Zn_2 1}]^{4+}$ (a) and outer membrane accumulation of AnxA5-AF (b).

single dose of 50 Gy. The contralateral tumor served as a control. PET images were obtained one hour after intravenous injection of $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$ at day six after irradiation (Figure 6a). The irradiated tumor accumulated more radioactivity than the control which showed only faint uptake in the rim area. The time dependence of radioactivity in both tumors indicated modestly elevated initial uptake and retarded washout in the irradiated tumor (SI). With the exception of kidneys and liver, the residual abdominal background activity proved to be low.

In addition, $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$ was tested with HelaMatu tumor bearing mice 2 days after taxol treatment. PET images were acquired 60 min after injection of $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$. The treated animal shown in Figure 6b indicated higher tumor uptake as compared to the control tumor (Figure 6d). In comparison to the rat image, the background radioactivity of the mouse (liver, kidneys, intestine) appeared to be higher. In addition, bone joint activity indicated some defluorination. Quantification of tumor radioactivity in the excised tumors confirmed the stronger accumulation in treated tumors (SI). Additional autoradiography of excised tumor slices after the PET-study confirmed this finding in the treated tumors (Figure 7a versus c) and staining for cleaved caspase 3 proved the presence of apoptotic tissue after taxol treatment (Figure 7b versus d).

DISCUSSION

Among other approaches, search for the replacement of the apoptosis imaging agent [^{99m}Tc(HYNIC-rh-annexin A5)] has been focused on metal complexes which were also attractive as phosphate sensors in cell biology. Especially, zinc-cyclen complexes have been found to bind phosphate or other anionic groups.[18] Consequently, a series of mono-, di-, and tetrameric cyclen ligands have been synthesized, capable of stabilizing Zn^{2+} for in vivo applications and of functioning as carriers of fluorescent or radioactive reporter probes. The syntheses of the complex ligands summarized in Schemes 1−3 were followed by zinc complexation as the final reaction step.

Flow cytometry of Jurkat cells which are incubated with fluorescent annexin A5, like AnxA5-AF, represents an established method to determine the degree of apoptosis after contact with cytostatic agents.[4−6] The inhibitory activity of staurosporine on protein kinases of Jurkat cells is known to induce apoptosis.[25] Owing to the disposition of apoptotic cells,

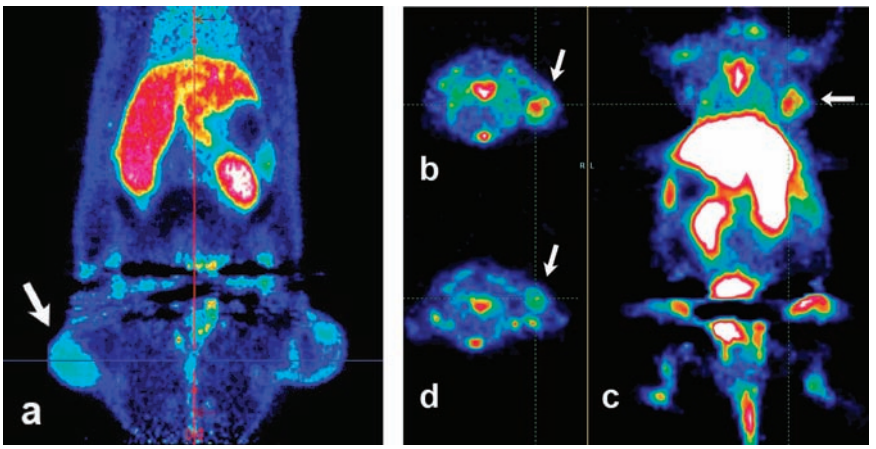

Figure 6. One hour coronal PET image of a rat with a bilaterally transplanted Dunning prostate adenocarcinoma 6 d after 50 Gy radiation therapy (a). The irradiated tumor is indicated by the arrow. One hour PET image of a mouse with HelaMatu tumors (arrows) two days after treatment with taxol (b,c) and the untreated control (d). Transaxial slices are shown in (b) and (d), and a coronal slice is shown in (c).

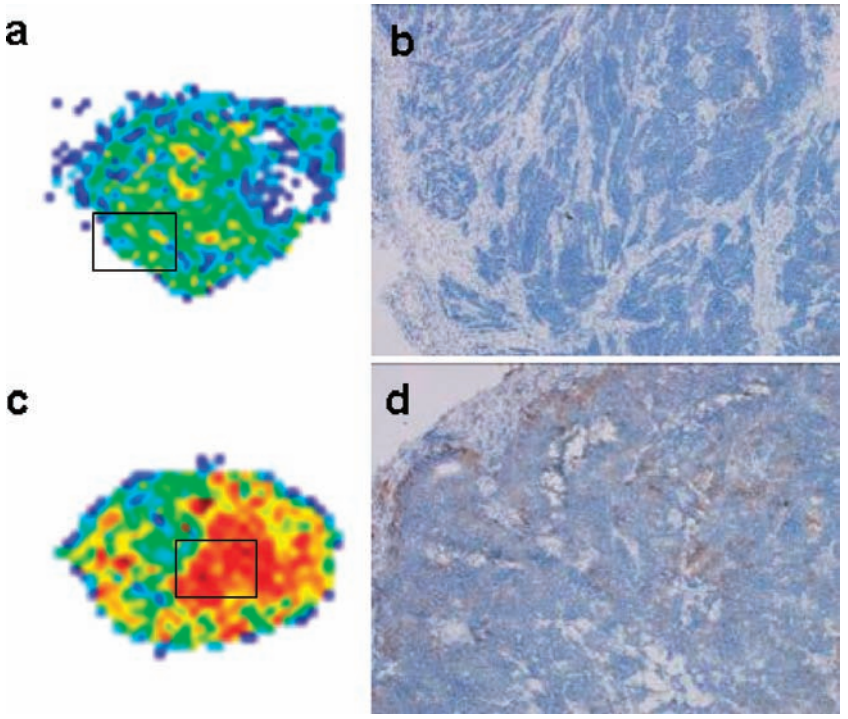

Figure 7. Autoradiography of HeLaMatu tumor slices taken from animals of the PET study (a,c) and IHC images (frames) stained for cleaved caspase 3 (b,d). Upper panel: Tumor samples from control animals. Lower panel: Tumor samples from taxol treated animals. The radioactive uptake (frames) corresponds with the presence of cleaved caspase 3 IHC.

this effect is accompanied by the formation of late apoptotic and secondary necrotic cells.[26]

As illustrated in Figure 3, most staurosporine treated cells were recorded in the Q1 rectangle where cell signals accumulate resulting from annexin A5 binding with externalized PS (see also Figure 5b). In Q2, cell signals from AnxA5-AF and PI binding are collected, which owing to PI uptake indicate leakiness of the damaged cell membrane. This area of flow-cytometric measurements (33% of Q1+Q2) represents the above-mentioned secondary necrosis state of dying cells.

Replacing AnxA5-AF with the bis(cyclen) complex $[\mathbf{Zn_2 1}]^{4+}$, most cells with green fluorescence also showed PI uptake after staurosporine treatment. Although the cell suspensions were taken from the same cell pool, $[\mathbf{Zn_2 1}]^{4+}$ stained the majority of cells in the secondary necrotic population Q2 (80% of Q1+Q2) (Figure 3; lower panel).

The larger Q2 fraction is obviously related to the common permeability of both dyes $[\mathbf{Zn_2 1}]^{4+}$ and PI. Remarkably, these Q2 signals belong to the SSC and FSC signals indicating changes of size and granularity associated with the onset of cell death (arrow in respective SSC/FSC plot, SI). The question whether intracellular accumulating $[\mathbf{Zn_2 1}]^{4+}$ is responsible for this effect can be related to the observation of Kimura et al. that $\{bis[Zn(cyclen)]\}^{4+}$ complexes are able to form ternary complexes with DNA bases like thymidine.[27] This interference is, however, only in effect if apoptosis has been triggered by staurosporine and the zinc complex is internalized. Any cell

dx.doi.org/10.1021/bc200457b | *Bioconjugate Chem.* 2011, 22, 2611–2624

damaging effects of the zinc complex on vital cells were not observed (SI).

As reviewed in the introduction, binding of the zinc complexes on apoptotic cells through the coordination of externalized PS was thought to lead to membrane binding. However, the fluorescence of $[\mathbf{Zn_21}]^{4+}$ was found exclusively in the cytosol of staurosporine affected cells. This finding and the clear membrane fluorescence of AnxA5-AF are apparent in the CLSM images shown in Figure 5. A similar intracellular distribution was reported with bis(zinc(II)-dipicolylamine) complexes.[9,12,13] Microscopic fluorescence images indicate that PSS-480 (Figure 1) stains most prominently those apoptotic Jurkat cells which are also positive with 7-amino-actinomycin, a PI like DNA intercalator, known to dye secondary necrotic cells.[13]

The assumption that zinc-cyclen derivatives can profit from multimerization was demonstrated with $[\mathbf{Zn_45}]^{8+}$. With staurosporine treated cells, this tetramer showed a more than doubled fluorescence intensity as compared to the two comparable dimeric complexes $[\mathbf{Zn_21}]^{4+}$ and $[\mathbf{Zn_24}]^{4+}$. The monocyclen complex $[\mathbf{Zn3}]^{2+}$, on the other hand, produced only signals with reduced intensity. The increase of the fluorescence intensity was obviously mediated by the additional zinc-cyclen functionalities. It may, therefore, be speculated that the uptake initially begins through binding at externalized PS which transports the resulting ternary complexes with the help of aminophospholipid translocase into the cytosol. On the other hand, concentration driven diffusion through a damaged cell membrane may also be conceivable. The absence of zinc, however, inhibits fluorescent signals in Q1 and Q2 (complex ligand **4**, SI) which also points to translocase assisted internalization.

An additional observation supporting this notion is given by the introduction of an exocyclic pendant nitrogen. Complex $[\mathbf{Zn_22}]^{4+}$ contains an extra heteroatom able to coordinate zinc and to compete with PS thereby disturbing PS related membrane penetration. The comparable green, but strongly reduced fluorescences of $[\mathbf{Zn_22}]^{4+}$ in treated as well as in control cells may be explained with unspecific binding (SI).

A saturation experiment was performed with staurosporine treated cells in order to evaluate an uptake limit. Figure 4 illustrates the increase of fluorescence with increasing concentration of $[\mathbf{Zn_21}]^{4+}$. Above 20 μM and up to 100 μM, the uptake of $[\mathbf{Zn_21}]^{4+}$ followed a straight relationship without signs of saturation. It was also evident that the removal of these complexes from the medium resulted in a strong reduction of the intracellular fluorescence. These findings indicate a rather weak intracellular interaction of $\{bis[Zn(cyclen)]\}^{4+}$ complexes.

Owing to the structural similarity of the title compounds, with several bis-cyclam derivatives potential CXCR4 interactions were scrutinized. It is known that the bis-cyclam AMD3100 and its meta derivative including the respective Cu^{2+}, Zn^{2+}, or Ni^{2+} complexes have anti-HIV activity through binding at the chemokine receptor CXCR4.[28] The expression of CXCR4 on Jurkat J6 cells is known and proven to be positive on both staurosporine treated and control cells. Consequently, CXCR4 dependent differences between treated and control cells, which were obtained with the zinc-cyclen complexes, appear to be unlikely. To further exclude the participation of CXCR4 on $[\mathbf{Zn_21}]^{4+}$ uptake, in staurosporine treated cells competition with a 100-fold molar excess of meta AMD3100 was performed. The similarity of flow-cytometry results indicated no involvement of this receptor in the $[\mathbf{Zn_21}]^{4+}$ uptake (SI).

The capacity of $\{bis[Zn(cyclen)]\}^{4+}$ complexes to transport fluorescent dyes into apoptotic and secondary necrotic cells was also investigated using a radiolabeled complex. High-dose radiation therapy was used to induce cell death which is known to force tumors mainly into necrosis. Rats with Dunning prostate adenocarcinoma transplants were, therefore, irradiated using a single gamma dose of 50 Gy. The rats were imaged with $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$ six days after treatment. As illustrated in Figure 6a, the irradiated tumor clearly showed significant uptake while the untreated control was negative. This was due to the higher initial uptake just after injection of $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$ and the delayed washout as compared with the contralateral control (SI). The radioactivity of the excretion organs, kidney and liver, was in the expected range, while the residual background activity was low.

The accumulated radioactivity in the Dunning tumor is certainly due to massive cell death after such a high radiation dose.[29] An investigation into the imaging kinetics as a response to therapy has been performed for ten days after the onset of therapy. The data indicate maximal accumulation of $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$ at day six while decrease of intensity was observed at day ten (SI). The contralateral control tumor meanwhile increased the uptake indicating cell death due to short tumor doubling time of 5.6 ± 0.4 days.[30]

A second imaging experiment using $[\mathbf{Zn_2(^{18}F\text{-}6)}]^{4+}$ was carried out with taxol treated HelaMatu tumor bearing mice. The transaxial PET images of a taxol treated animal (Figure 6b) indicated higher tumor uptake in comparison to the control (Figure 6d). Quantification of the mean tumor uptake values showed an increase by 30% in the treatment group while the tumor size decreased by 15% in comparison to the control group (SI). Autoradiograms of tumor tissue slices shown in Figure 7a,c confirmed the result of the PET study, and immunohistochemistry (Figure 7b,d) validated the presence of apoptotic tissue which corresponded with radioactivity accumulation after taxol treatment.

The perspective of having radiolabeled markers of cell death either produced by apoptosis and/or by secondary necrosis is attractive, because therapy control is one of the main areas of interest during the follow-up of cancer patients. Currently, a series of conventional investigations, including radiography, CT, sonography, and MRI, acquire this information covering the extent and morphology of tumor masses and, to some degree, alterations in tumor perfusion. In contrast, nuclear medicine has at its disposal a series of surrogate markers that are used for the assessment of the therapy response. Radiofluorinated $bis[Zn(cyclen)]^{4+}$ complexes might be more specific for the imaging of therapy response providing information about cell death in treated tumors. Further work is underway to optimize the pharmacokinetics of zinc cyclen complexes and to understand more about the uptake mechanism.

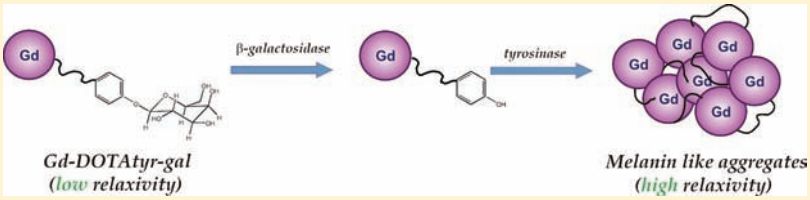
Supporting Information



ABSTRACT: The aim of this work is to design and test an MRI probe (Gd-DOTAtyr-gal) able to report on the gene expression of β-galactosidase (β-Gal) in melanoma cells. The probe consists of a Gd-DOTA reporter bearing on its surface a tyrosine-galactose-pyranose functionality that, upon the release of the sugar moiety, readily transforms, in the presence of tyrosinase, into melanin oligomeric/polymeric mixture. The formation of Gd-DOTA-containing melanin oligomers and polymers is accompanied by a marked increase of the water proton relaxation rate. The steps involving the release of the galactose-pyranose group and the formation of the melanin-like structure have been carefully investigated *in vitro* by relaxometric and UV−vis measurements. Cellular uptake studies of Gd-DOTAtyr-gal by melanoma cells have shown that the probe enters the cells, and it appears not to be confined in endosomal vesicles. Using B16−F10*LacZ* transfected cells, the fast formation of paramagnetic melanin-Gd(III)-containing species has been assessed by the measurement of increased longitudinal relaxation rates of the cellular pellets suspensions. The *in vitro* results have been confirmed in *in vivo* MRI investigations on murine melanoma tumor bearing mice. Upon direct injection of Gd-DOTAtyr-gal, a good contrast is observed after 5 h post injection in B16−F10*LacZ* tumors, but not in B16−F10 tumors lacking the β-Gal enzyme. Gd-DOTAtyr-gal in combination with tyrosinase introduces a novel approach for the detection of β-Gal expression by MRI in vivo.

INTRODUCTION

The development of reliable means to follow gene expression *in vitro* and *in vivo* has attracted great interest in recent years. Gene expression is commonly monitored by introducing a marker gene to follow the regulation of the gene of interest.[1] The bacterial *LacZ* gene is a very popular gene reporter, with applications ranging from immunosorbent assays to in situ hybridizations and evaluation of gene distributions. Indeed, *LacZ* has been used in medical trials revealing regions of tissue transfection in biopsy specimens based on hystologic staining. As such, many colorimetric stains and assays have been developed and are in routine use, including reagents such as nitrophenyl-β-D-galactopyranoside, which generates a yellow color, or 4-chloro-3-bromoindole-galactose, which gives a blue stain, and 3,4-cyclohexenoesculetin β-D-galactopyranoside, which yields a black stain, respectively.[2] The application of such methods has various drawbacks such as the need for hystological processing of the region of interest. Magnetic Resonance Imaging offers an alternative to light microscopy, allowing the investigation of intact tissues at the cellular resolution level. The first attempt to tackle the issue of MRI visualization of β-Gal gene expression was carried out by Meade and co-workers by reporting that the relaxivity of a galacto-pyranose-substituted tetraazamacrocycle coordinated to a Gd(III) ion can be specifically "switched on" by removing the sugar with β-galactosidase.[3] Unfortunately, the gain in relaxivity brought about by the activation step is relatively small (for several reasons as elucidated in a successive paper from the same author).[4]

Since Meade's seminal work, MRI detection of β-Gal expression has been under intense scrutiny with the aim of exploring amplification routes that would allow its improved implementation in *in vivo* studies.

Hanaoka et al. reported on the exploitation of the RIME (receptor-induced magnetization enhancement) by using a β-Gal-activated Gd(III) bearing agent which, upon release of the β-galactopyranoside moiety, enhances its relaxivity thanks to the binding to HSA.[5] A similar attempt to amplify the MRI response of a β-Gal responsive Gd(III) complex has been pursued by Yun-Ming Wang et al.[6]

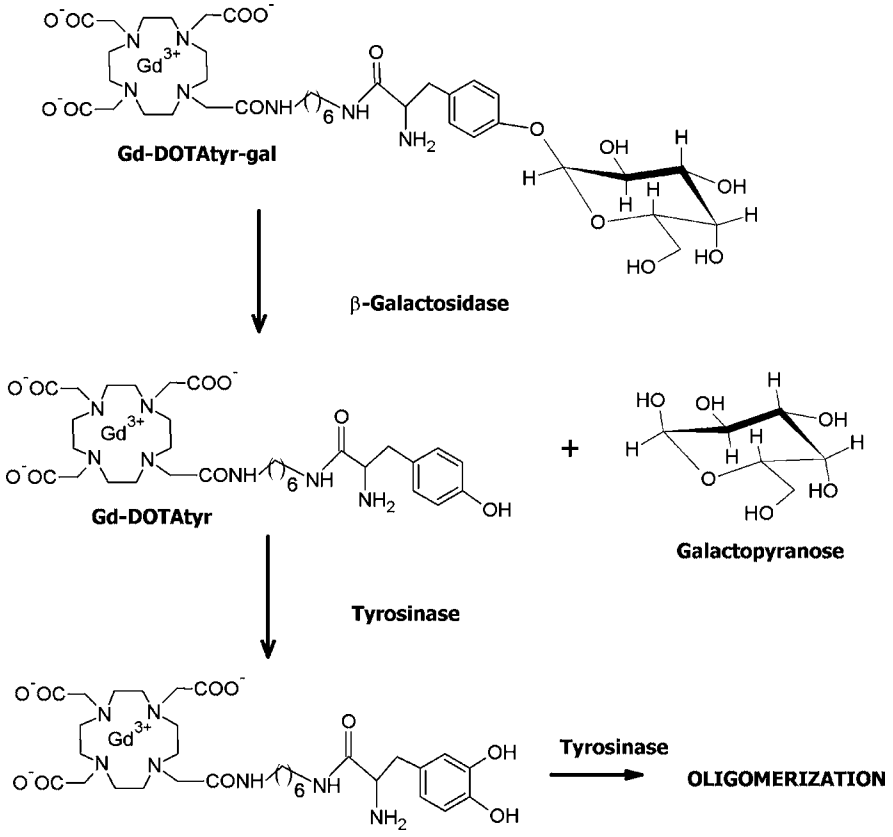
Chart 1. Schematic Representation of the Oligomerization Process Achieved upon the Action of β-Galactosidase and Tyrosinase Enzymes



These results represent an interesting proof-of-concept of the RIME approach, but its transaction to cellular and animal applications might be hampered by the fact that β-Gal is in the cytoplasm and HSA is mainly in the extracellular compartments.

As one of the key issues for a successful *in vivo* application deals with the internalization of the probe, Engelmann et al.[7] tackled the problem of penetrating the cell membrane by endowing the surface of a Gd(III) complex with a suitable cationic peptide sequence. The cell-penetrating peptide is bound to a galacto-pyranose moiety and the linkage is selectively cleaved only in β-Gal transfected cells. Thus, the cell accumulation of the MRI agent would be possible only upon β-Gal enzymatic transformation, as the unconverted metal complex could effectively efflux from the cells.

Another efficient method to accumulate a metal complex inside cells relies on the formation of oligo/polymeric structures such as those obtained by Bodganov et al.[8−11] They found that melanin-like macromolecules can form when hydroxo-functionalized Gd(III) chelates are in the presence of tyrosinase or myeloperoxidase.

In the present work, which aims at exploiting the latter route in order to amplify the MRI response at the targeted cells, the designed probe consists of a Gd-DOTA monoamide chelate bearing a tyrosine −OH functionality protected by a galactose moiety (Gd-DOTAtyr-gal). Upon cleavage of the galactose moiety (step activated by the action of β-galactosidase), the tyrosine group, in the Gd-DOTAtyr product, becomes available for the tyrosinase activated melanin polymerization. The formation of the paramagnetic melanin-like macromolecule can be assessed by MRI because the relaxivity of Gd(III)-complexes increases, in the field range 0.5−1.5 T, if they are part of macromolecular systems, as a consequence of the lengthening of their reorientational correlation time (τ_R) (Chart 1).

The β-galactosidase-responsive probe has been tested in B16−F10 and B16−F10*LacZ* murine melanoma cells. Melanoma cells have been used for the enzymatic assays, as these cells possess high tyrosinase activity as witnessed by their natural melanin pigmentation. We also demonstrated the ability of Gd-DOTAtyr-gal to visualize stably expressing *LacZ* melanoma tumors *in vivo* upon its direct intratumoral injection.

EXPERIMENTAL PROCEDURES

Materials. All reagents used for the synthesis of DOTAtyr-gal and DOTAtyr ligands were purchased from Sigma Aldrich Co. β-galactosidase (product no. G5635−5KU isolated from *Escherichia coli*) was purchased from Sigma Aldrich and used without any further purification. β-Gal Staining Kit was purchased from Invitrogen. Tyrosinase isolated from *Mushroom* was obtained from Sigma-Aldrich.

NMR spectra were recorded on JEOL Eclipse Plus400 and Bruker Avance 600 spectrometers operating at 9.4 and 14 T, respectively. ESI mass spectra were recorded on a Waters Micromass ZQ. Analytical and preparative HPLC-MS were carried out on Waters FractionLynx autopurification system equipped with Waters 2996 diode array and Waters Micromass ZQ (ESCI ionization mode) detectors. DOTAMA-$(OtBu)_3C_6NH_2$ was prepared following a reported procedure.[12]

Synthesis of Gd(III) complexes (Scheme 1 and Scheme 2). *Synthesis of N-(9-Fluorenylmethoxycarbonyl)-O-1,1(dimethyl)ethyl-tyrosine pentafluorophenyl Ester*

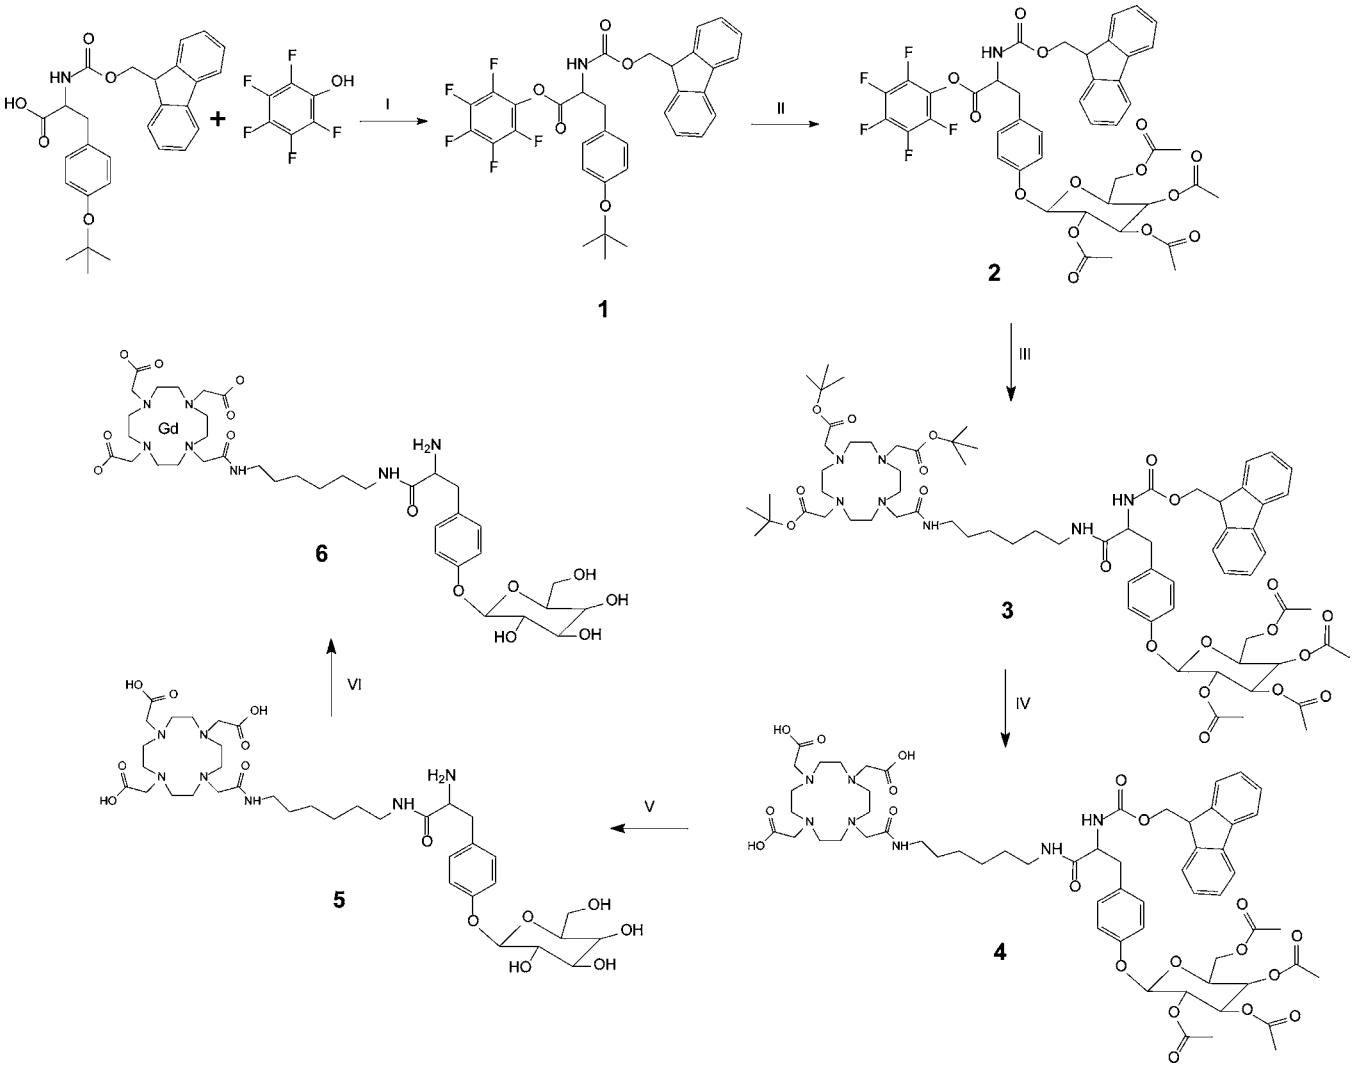
Scheme 1. Synthetic Pathway to Gd-DOTAtyr-gal[a]



[a](I) EDCI,CH_2Cl_2; (II) Acetobromogalactose, AgOTf, CH_2Cl_2 dry; (III) DOTAMA(O*t*Bu)$_3C_6NH_2$, HOBt, CH_2Cl_2; (IV) TFA,CH_2Cl_2; (V) NaOMe, MeOH; (VI) $GdCl_3$, H_2O, pH 7.

(1). A solution of Fmoc-Tyr-(tBu)OH (2 g, 4.35 mmol), pentafluorophenol (0.8 g, 4.35 mmol) and EDCI (0.834 g, 4.35 mmol) in CH_2Cl_2 (60 mL) was stirred overnight at 0 °C. The solution was transferred to a separatory funnel and washed with water (2 × 10 mL). The organic layer was dried over anhydrous Na_2SO_4, and the solvent was removed under reduced pressure to give the product as a white solid in quantitative yield. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.33 (s, 9H), 3.21 (m, 2H), 4.21 (t, 1H), 4.43 (m, 2H), 4.98 (m, 1H), 6.96 (d, 2H), 7.01 (d, 2H), 7.31 (m, 2H), 7.38 (m, 2H), 7.54 (d, 2H), 7.77 (d, 2H). ^{13}C NMR (101 MHz, $CDCl_3$): δ 28.89, 37.31, 47.19, 54.77, 67.31, 78.71, 120.11, 124.52, 125.08, 127.17, 127.87, 129.34, 129.89, 136.72, 139.74, 139.90, 141.42, 142.43, 143.78, 155.01, 155.60, 168.16.

*Synthesis of N-(9-Fluorenylmethoxycarbonyl)-O-[2,3,4,6-tetra-O-acetyl-D-galactose-1-(yl)-tyrosine Pentafluorophenyl Ester (**2**).* Compound **1** (2.0 g, 3.2 mmol), AgOTf (1.6 g, 6.4 mmol), and molecular sieves (3 Å, 2.5 g) were placed in a predried flask covered with aluminum foil. After evacuation (0.1 Torr), the flask was filled with argon and dry CH_2Cl_2 (40 mL) was used to suspend the reagents. The suspension was cooled to −10 °C and a solution of the acetyl bromogalactose (1.1 g, 2.6 mmol) in dry CH_2Cl_2 (35 mL) was added. After 120 min at −10 °C, the suspension was neutralized with DIPEA (1 mL, 5.74 mmol) followed by filtration through Celite. The filtrate was concentrated to dryness and the residue was purified by column chromatography (silica gel, CH_2Cl_2: MeOH 95:5, R_f 0.32) to yield a white solid. Yield: 70%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.98 (s, 3H), 2.00 (s, 6H), 2.10 (s, 3H), 3.21 (m, 2H), 4.00 (m, 1H), 4.11 (m, 2H), 4.21 (m, 1H), 4.44 (m, 2H), 4.98(m, 1H), 5.09 (m, 1H), 5.30 (m, 1H), 5.40 (m, 1H), 5.51 (m, 1H), 6.97 (d, 2H), 7.13 (d, 2H), 7.28 (m, 2H), 7.38 (m, 2H), 7.50 (d, 2H), 7.75 (d, 2H), 8.31 (broad, CONH, 1H). ^{13}C NMR (101 MHz, $CDCl_3$): δ 20.66, 20.78, 37.21, 47.19, 54.63, 61.42, 66.79, 67.82, 70.81, 71.68, 78.72, 89.80, 120.45, 124.55, 125.05, 127.17, 127.91, 129.39, 129.82, 136.72, 139.74, 139.90, 141.42, 142.40, 143.75, 155.01, 155.61, 168.16, 169.51, 169.92, 170.09, 170.29; $C_{44}H_{38}NO_{14}F_5$ ESI-MS (M+H$^+$) calcd 900.2, found 900.4.

*Synthesis of 1-[2-Oxo-3-aza-9[N-(9-fluorenylmethoxycarbonyl)-O-[2,3,4,6-tetra-O-acetyl-D-galactose-1-(yl)]-tyrosinylamine]nonyl]-1,4,7,10-tetraazacyclododecane-4,7,10-triacetic Acid 1,1(Dimethyl)ethyl Ester (**3**).* To a

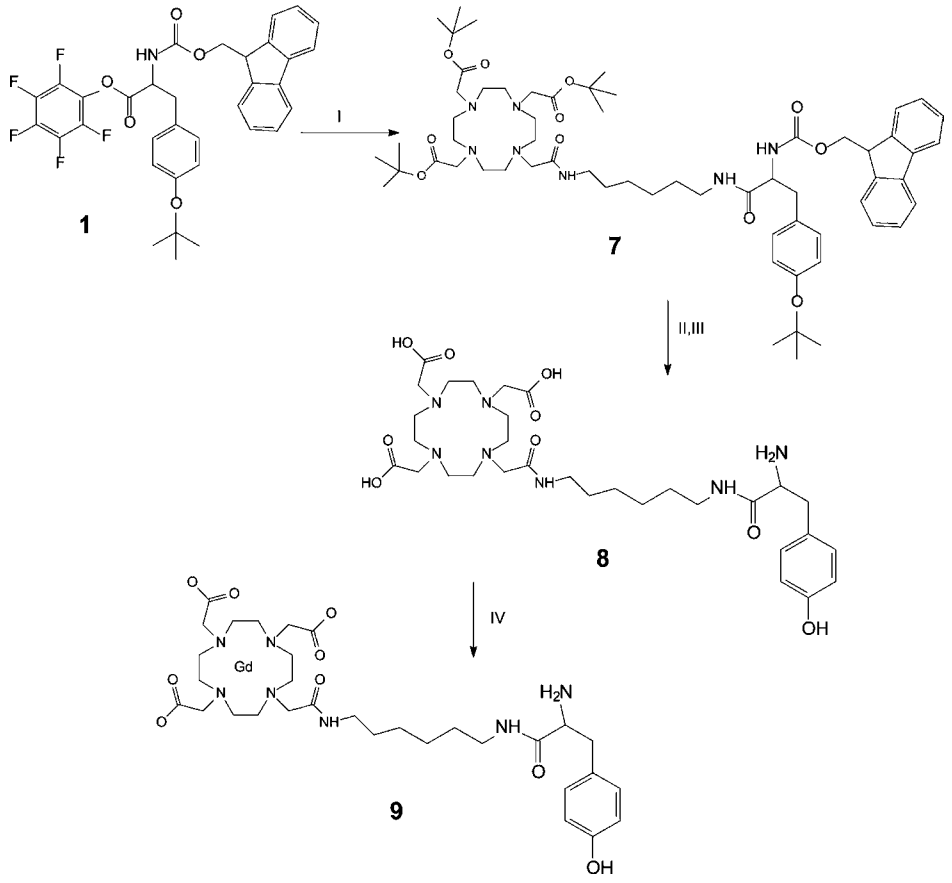
Scheme 2. Synthetic Pathway to Gd-DOTAtyr[a]



[a](I) DOTAMA(O*t*Bu)$_3$C$_6$NH$_2$, HOBt, CH_2Cl_2; (II) piperidine, CH_2Cl_2; (III) TFA,CH_2Cl_2; (IV) $GdCl_3$, H_2O, pH 7.

solution of DOTAMA(O*t*Bu)$_3$C$_6$NH$_2$ (0.75 g, 1.1 mmol) in CH_2Cl_2 (30 mL) was slowly added **2** (1.0 g, 1.1 mmol) in 30 mL of CH_2Cl_2. After 20 min, HOBt (0.042 g, 0.28 mmol) and DIPEA (0.19 mL, 1.1 mmol) were added to the reaction mixture and stirred at 0−5 °C under argon atmosphere for 3 h, then for another 16 h at room temperature. The reaction mixture was washed with 10 mL of water and dried over anhydrous Na_2SO 4. The filtrate was evaporated to dryness and the white solid was purified by column chromatography (silica gel, elution gradient: CH_2Cl_2/MeOH 95:5 → 9:1 → 8:2) to yield a white solid. Yield: 82%. ^{1}H NMR (600 MHz, $CDCl_3$): δ 1.40 (m, 2H), 1.44 (s, 27 H), 1.50 (m, 2H), 1.60 (m, 2H), 1.85 (m, 2H), 1.98 (s, 3H), 2.02 (s, 6H), 2.10 (s, 3H), 2.70−3.60 (broad, 24H), 3.71 (s, 4H), 4.02 (m, 1H), 4.16 (m, 2H), 4.22 (m, 3H), 4.45 (m, 2H), 4.79 (m, 1H), 5.08 (m, 1H), 5.32 (m, 1H), 5.41 (m, 1H), 5.51 (m, 1H), 6.97 (d, 2H), 7.12 (d, 2H), 7.28 (m, 2H), 7.37 (m, 2H), 7.42 (broad, CONH, 1H), 7.51 (d, 2H), 7.74 (d, 2H), 7.89 (broad, CONH, 1H), 8.21 (broad, CONH, 1H).^{13}C NMR (151 MHz, $CDCl_3$): δ 20.65, 20.72, 25.91, 26.00, 27.90, 28.45, 28.93, 29.66, 37.31, 38.71, 38.81, 47.21, 53.51, 54.54, 55.62, 55.74, 56.17, 54.69, 61.44, 66.72, 67.86, 70.79, 71.65, 78.86, 79.19, 81.6, 89.81, 120.11, 124.41, 125.23, 127.18, 127.82, 129.94, 130.41, 141.42, 143.74, 154.48, 155.89, 155.92, 168.18, 169.57, 169.91, 170.06, 170.31, 171.42, 172.11, 172.23, 172.45, 176, 22; $C_{72}H_{103}N_7O_{20}$ ESI-MS (M +H$^+$) calcd 1386.7, found 1386.9.

*Synthesis of 1-[2-Oxo-3-aza-9[N-(9-fluorenylmethoxycarbonyl)-O-[2,3,4,6-tetra-O-acetyl-D-galactose-1-(yl)]-tyrosinylamine]nonyl]-1,4,7,10-tetraazacyclododecane-4,7,10-triacetic Acid (**4**).* The solution of **3** (1 g, 0.72 mmol) in TFA/CH_2Cl_2 (1:1, 10 mL) was stirred at 0 °C. After 3 h stirring, the reaction mixture was evaporated and the procedure was repeated twice in order to remove all three *t*Bu moieties. Then, the product was precipitated with excess diethyl ether, isolated by centrifugation, washed thoroughly with diethyl ether, and dried in vacuo. The product was used for the next step without further purification: a pale white solid.

*Synthesis of 1-[2-Oxo-3-aza-9[O-[D-galactos-1-(yl)]-tyrosylamido]nonylaminocarbonylmethyl]-1,4,7,10-tetraazacyclododecane-4,7,10-triacetic Acid (**5**).* The solution of **4** (1.2 g, 0.99 mmol) and NaOMe (0.27 g, 4.9 mol) in methanol (26 mL) was stirred under argon atmosphere at 0 °C. After 5 h stirring, the solution was acidified to around pH 7 with Dowex cationic resin. The reaction mixture was filtered and the solvent evaporated to yield a white solid. The crude material was dissolved in water, loaded over an Amberchrom CG161 column and eluted with a water−methanol gradient (100:0 to 0:100). After solvent evaporation, product **5** was collected as a white solid (yield 65%). ^{1}H NMR (600 MHz, D_2O): δ 1.32, 1.42, 1.66 (m, 8H), 2.98−3.16 (broad, 14H), 3.33−3.82 (broad, 22H), 3.93 (m, 1H), 4.99 (m, 1H), 6.87 (d, 2H), 7.12(d, 2H) . ^{13}C NMR (151 MHz, D_2O): δ 25.54, 25.68, 27.97, 28.24, 34.54, 38.51, 38.43, 53.93, 56.05, 56.12, 56.49, 56.75, 65.55, 69.11, 69.77, 71.84, 73.36, 100.91, 117.92, 128.81, 130.91, 156.44, 169.227, 170.01, 171.96, 178.12; $C_{37}H_{61}N_7O_{14}$ ESI-MS for (M+H$^+$) calcd 828.9, found 828.7. For (M+2H^{2+}) calcd 414.9, found 414.7.

dx.doi.org/10.1021/bc200486j | *Bioconjugate Chem.* 2011, 22, 2625−2635

*Synthesis of 1-[2-Oxo-3-aza-9[N-(9-fluorenylmethoxycarbonyl)-O-1,1(dimethyl)ethyl-tyrosinylamine]nonyl]-1,4,7,10-tetraazacyclododecane-4,7,10-triacetic Acid 1,1(Dimethyl)-ethyl Ester (**7**).* To a solution of DOTAMA(O*t*Bu)$_3$$C_6NH_2$ (0.500 g, 0.74 mmol) in CH_2Cl_2 (25 mL) was slowly added **1** (0.46 g, 0.74 mmol) in 30 mL of CH_2Cl_2. After 20 min, HOBt (0.12 g, 0.75 mmol) and DIPEA (0.12 mL, 0.74 mmol) were added and the mixture was stirred for 6 h at 0−5 °C under inert atmosphere. The reaction mixture was then washed with 7 mL of water and dried over anhydrous Na_2SO_4. The filtrate was evaporated to dryness and the residue was purified by column chromatography (silica gel, CH_2Cl_2/MeOH 9:1) R_f: 0.38. Yield: 89%. ^{1}H NMR (600 MHz, $CDCl_3$): δ 1.27 (s, 9H) 1.42 (m, 2H), 1.48 (s, 27 H), 1.49 (m, 2H), 1.62 (m, 2H), 1.87 (t, 2H), 2.07−3.30, 3.40−3.50 (b, 22H), 3.54 (s, 4H), 4.23 (m, 3H), 4.40 (s, 2H), 4.45 (m, 1H), 6.97 (d, 2H), 7.12 (d, 2H), 7.28 (m, 2H), 7.37 (m, 2H), 7.43 (broad, CONH, 1H), 7.51 (d, 2H), 7.74 (d, 2H), 7.91 (broad, CONH, 1H), 8.23 (broad, CONH, 1H). ^{13}C NMR (151 MHz, $CDCl_3$): δ 25.93, 26.01, 28.02, 28.57, 28.88, 28.97, 29.67, 37.41, 38.61, 38.91, 46.67, 47.29, 53.01, 53.24, 54.59, 56.22, 56.57, 58.94, 67.31, 78.76, 120.11, 124.81, 125.13, 127.08, 127.62, 129.98, 130.31, 141.42, 143.84, 155.38, 155.83, 169.42, 172.11, 172.23, 172.45, 174.22; $C_{62}H_{93}N_7O_{11}$ ESI-MS (M+H$^+$) calcd 1112.5, found 1112.7.

*Synthesis of 1-[2-Oxo-3-aza-9[-L-tyrosinylamine]nonyl]-1,4,7,10-tetraazacyclododecane-4,7,10-triacetic Acid (**8**).* The compound 7 (0.91 g, 0.075 mmol) was dissolved in CH_2Cl_2 (25 mL) containing 10% of piperidine and stirred under inert atmosphere at 0 °C. After 3 h stirring, the solvent was evaporated. Upon the addition of diethyl ether, a white solid was obtained. The crude solid was washed with ice-cooled ether and dried. To the white solid, a solution of TFA/CH_2Cl_2 (1:1 *v*/*v*) was added in one step and stirred. After 4 h, the reaction mixture was evaporated, and the procedure was repeated twice in order to remove all three *t*Bu moieties. Then, the product was precipitated with excess diethyl ether, isolated by centrifugation, washed thoroughly with diethyl ether, and dried in vacuo. It was then dissolved in H_2O (4 mL) at pH neutralized by addition of diluted NaOH at 0 °C. The crude product was purified by preparative HPLC-ESI (+)MS by using a Waters Atlantis RPdC18 19/100 column by Method 1 using H_2O/TFA 0.1% (A) and CH_3CN/TFA 0.1% (B) as eluents (see the Supporting Information) .The pure product was obtained as a white powder (Yield 44%). HPLC: Method 2 (see the Supporting Information), retention time 8.90 min, purity 95%. ^{1}H NMR (600 MHz, D_2O): δ 1.39, 1.51, 1.60, 1.85 (m, 8H), 2.70−3.60 (broad, 21H), 3.68 (broad, 6H), 4.23 (m, 4H), 6.76 (d, 2H), 6.98 (d, 2H).^{13}C NMR (151 MHz, D_2O): δ 25.76, 25.92, 28.13, 28.32, 36.34, 38.58, 38.75, 53.82, 46.67, 48.51, 51.11, 53.54, 55.27, 116.00, 126.93, 130.97, 155.32, 168.76, 168.89, 171.24, 171.88; $C_{31}H_{51}N_7O_9$ ESI-MS for (M+H$^+$) calcd 666.4, found 666.3. For (M+2H^{2+}) calcd 333.9, found 333.7.

*Synthesis of Gd-DOTAtyr-gal (**6**) and Gd-DOTAtyr (**9**).* To the solutions of DOTAtyr-gal and DOTAtyr ligands (10 mmol) in water (250 mL), a solution containing $GdCl_3$ (9 mmol) was added. The solution was slowly neutralized to pH 7 with 2 N NaOH. When the pH was constant, the solution was desalted by Sephadex G10 column. The absence of any free Gd(III) ions was checked through the Orange Xylenol spectrophotometric test.[13] Gd-DOTAtyr-gal: $C_{37}H_{58}GdN_7O_{14}$ ESI-MS (M+H$^+$) calcd 983.14, found 983.12. HPLC: Method 2 (Supporting Information), retention time 4.89 min, purity 92%. Gd-DOTAtyr: $C_{31}H_{48}GdN_7O_9$ ESI-MS (M+H$^+$) calcd 821.3, found 821.2. HPLC: Method 3 (Supporting Information), retention time 7.60 min, purity 96%.

Relaxometric Characterization. The longitudinal water proton relaxation rate was measured at 25 °C by using a Stelar Spinmaster (Stelar, Mede, Pavia, Italy) spectrometer operating at 20 MHz, by mean of the standard inversion−recovery technique. The temperature was controlled with a Stelar VTC-91 air-flow heater equipped with a copper constantan thermocouple (uncertainty 0.1 °C). The relaxometric characterization of the field-dependent relaxometry of the paramagnetic Gd(III)-probe solutions was carried out through the acquisition of the NMRD profiles. The proton $1/T_1$ NMRD profiles were measured at 25 °C on a fast field-cycling Stelar relaxometer over a continuum of magnetic field strengths from 0.00024 to 0.47 T (corresponding to 0.01−20 MHz proton Larmor frequencies). The relaxometer operates under computer control with an absolute uncertainty in $1/T_1$ of ±1%. Additional data points in the range 20−70 MHz were obtained on the Stelar Spinmaster spectrometer. The concentration of the solutions used for the relaxometric characterization was determined according to the relaxometric method reported in the Supporting Information section.

***In Vitro* Assessment of Enzyme Activity.** To assess the effect of β-galactosidase enzyme on the r_1 value of Gd-DOTAtyr-gal solution, β-galactosidase isolated from *Escherichia coli* was used. *Escherichia coli* enzyme was reconstituted with 0.1 M sodium phosphate buffer, pH = 7.4 at 25.0 ± 0.1 °C. To assess the effect of tyrosinase enzyme on the r_1 value of Gd-DOTAtyr-gal solution, previously activated by β-galactosidase cleavage, tyrosinase isolated from *Mushroom* was used. *Mushroom* enzyme was reconstituted with 0.1 M sodium phosphate buffer, pH = 7.4 at 25.0 ± 0.1 °C.

Cell Culture. B16−F10 melanoma cells (mouse) were obtained from American Type Culture Collection (ATCC, Manassas, USA), while B16−F10*LacZ* cells were obtained from Riken BRC Cell Bank (Depositor Hamada Hirofumi, Japan). Both cell lines were grown in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum from Lonza (Lonza Sales AG, Verviers. Belgium), 100 U/mL penicillin, and 100 mg/mL streptomycin and maintained at 37 °C under 5% CO_2 conditions. After 3 days of culture, the cells were harvested with trypsine/EDTA, counted with the Trypan-blue exclusion test, and assayed for tyrosinase activity.

Cellular Tyrosinase Activity Assay. The specific activity of tyrosinase was determined by UV/vis spectrophotometry on a Hitachi U2800 spectrometer using L-DOPA as the substrate and was assayed on the basis of the method reported by Tomita et al.[14] Ca. 1 × 10^6 B16−F10 and B16−F10*LacZ* cells were washed with PBS, added to 0.5 mL of a 1 mM L-DOPA solution, sonicated to induce cell lysis, and the absorbance at 475 nm was measured over time by maintaining the temperature of the reaction mixture at 37 °C. An extinction coefficient of 3700 M^{-1} cm^{-1} was used for the quantification of the dopachrome formation.

Functional β-Galactosidase *in Vitro*. Functional expression of β-galactosidase in cells was measured by staining B16−F10*LacZ* cell by the β-Gal Staining Kit according to the manufacturer's instructions. Cells were grown in small dishes (6 cm in diameter) and fixed with 2 mL fixation solution at room temperature for 15 min. The dishes were washed twice with phosphate buffer solution, and 2 mL staining solution (1 mg/mL X-gal) was added at room temperature until the cells were

stained blue. Cells were examined on microscope (Olympus IX70 inverted).

Cell Labeling. The cells were cultured in 75 cm^2 flasks in a humidified incubator at 37 °C and at CO_2/air (5:95 v/v). 8 × 10^5 B16−F10 and B16−F10*LacZ* cells were seeded in 6 cm Petri dishes. Twenty-four hours after seeding, the incubation medium was removed. Cells were washed and incubated in a fresh DMEM medium with different concentrations (10−15−20 mM) of GdDOTAtyr-gal and GdDOTAtyr for 4 h at 37 °C in a CO_2 incubator. After this incubation time, the cells were washed three times with 5 mL ice-cold phosphate-buffered saline (PBS), detached with ethylene diamine tetraacetic acid (EDTA), and, for the T_1 measurement at 1.0 T, collected in 50 μL of PBS, transferred into glass capillaries that were centrifuged at 1500 *g* for 5 min and placed in an agar phantom.

For the electroporation experiment, (3−4) × 10^6 B16−F10*LacZ* cells were detached from the cell culture flask with a trypsin/EDTA solution and placed in an electroporation cuvette containing increasing concentrations of Gd-DOTAtyr-gal in 0.8 mL of PBS. The electroporation was performed using Gene Pulser II electroporation system (Bio-Rad Laboratories, Hercules, CA, USA), applying a single shock at 0.2 V, with 500 or 960 microF capacitance and with a time constant of about 10 ms. Cells were then left in ice for 30 min, washed three times with 10 mL ice-cold PBS, and, for the T_1 measurement at 1.0 T, collected in 50 μL of PBS and transferred into glass capillaries that were placed in an agar phantom. T_1 values were measured on an ASPECT M2 System (Israel) operating at 1 T by using a saturation recovery spin echo sequence (TE = 8.6 ms, 12 variable TR ranging from 40 to 3000 ms, NEX = 4, FOV = 1.7 × 1.7 cm^2, 1 slice, slice thickness = 1 mm).

Determination of Intracellular Gd^{3+}Concentration. At the end of incubation experiments, labeled B16−F10 and B16-*LacZ* melanoma cells were sonicated in order to destroy cellular membranes and obtain cell lysates. Then, cell homogenates were mineralized with HCl 37% (50:50) in sealed vials at 120 °C overnight and the intracellular content of Gd(III) determined according to the method reported in Supporting Informations. The protein content was determined from cell lysates by the Bradford method using bovine serum albumin as standard. One milligram of protein corresponds to 6.1 × 10^6 B16−F10*LacZ* and 6.3 × 10^6 B16−F10 cells.

Adhesion Assay. B16−F10 and B16−F10*LacZ* cells were detached using 2 mM EDTA in PBS, washed with PBS, counted to final concentration of 5 × 10^5 cells/mL and incubated with Gd-DOTAtyr-gal (15 mM) and Gd-DOTAtyr (15 mM) for 4 h at 37 °C in DMEM containing 10% FBS. The cells were then immediately seeded in 3.5 cm Petri dishes. After 30 min, 1 h, 2 h, and 3 h of incubation, the medium and the floating cells were carefully removed by aspiration, and the attached layers were washed twice with PBS. The firmly attached cells were then counted using a cell counting chamber (Burker-Turk chamber) for quantification. Cell adhesion curves were generated after counting triplicate Petri dishes.

Animal Model. 6- to 10-week-old female C57Bl6 mice (Charles River Laboratories, Calco, Italy) were inoculated subcutaneously in the left flank with 0.2 mL of a single suspension containing approximately 1 × 10^6 B16−F10*LacZ* or B16−F10 melanoma cells, respectively. Mice were constantly treated in accordance with European Community guidelines and Ethical Committee Rules of the University of Torino.

MR Images Studies *in Vivo*. To investigate whether β-galactosidase expressing cells could be noninvasively imaged, C57Bl6 mice (n = 6) bearing subcutaneously grown B16−F10 and B16−F10*LacZ* tumors were injected intratumor with 40 μL of Gd-DOTAtyr-gal solution (7.5 mM). MR images were acquired on the Aspect M2 system (Aspect Imaging, Shoam, Israel) operating at 1T equipped with a horizontal bore MRI magnet using a standard T_1 weighted multislice spin echo sequence (TR = 250 ms, TE = 7.0 ms, NEX = 10, FOV = 3.5 cm, 6 slices, slice thickness = 1 mm). Prior to MRI examination, animals were anesthetized by injecting tiletamine/zolepam (Zoletil 100), 20 mg/kg, +xylazine (Rompum), 5 mg/kg.

RESULTS AND DISCUSSION

Design and Synthesis of Gd-DOTAtyr-gal and Gd-DOTAtyr. Gd-DOTAtyr-gal was designed to detect β-galactosidase activity through the conversion into Gd-DOTAtyr that, in the presence of tyrosinase, polymerizes to form melanin-like structures that are characterized by relaxivity values higher than those of the molecular Gd-DOTAtyr-gal and Gd-DOTAtyr complexes. Therefore, Gd-DOTAtyr-gal consists of three moieties: (i) the outer galacto-pyranose unit that acts as masking group and hampers the start of the polymerization; (ii) the phenolic functionality that in the presence of tyrosinase quickly oxidizes to yield polymeric derivatives; and (iii) the Gd(III) complex that acts as the MRI reporting unit.

Gd-DOTAtyr has been synthetized in order to assess its ability to polymerize in tyrosinase containing buffer or cytosol solutions as well as in intact melanoma cells. The melanin-like polymers display a tendency to precipitate as the molecular weight increases. On one hand, this is a limitation because one can exploit only the relaxation enhancement offered by the smaller oligomers. On the other hand, the formation of a polymer implies that the transformed Gd-complexes do not leave the cell and, moreover, their final insolubilization appears as an advantage in terms of limiting the toxicity of the Gd-containing species.

Relaxometric Characterization of Gd-DOTAtyr and Gd-DOTAtyr-gal. The relaxivity of Gd-DOTAtyr and Gd-DOTAtyr-gal in water, at 20 MHz and 25 °C, is 5.8 and 7.8 mM^{-1} s^{-1}, respectively. Their relaxivity profiles in the range of frequencies 0.01−70 MHz (NMRD profiles) have been registered and reported in Figure 1. The relaxivity of Gd-DOTAgal is slightly higher than that of Gd-DOTAtyr at any magnetic field strength because of the higher molecular weight.

The NMRD profiles have been analyzed in terms of the available theory of paramagnetic relaxation, and the main relaxometric parameters have been determined. The two complexes are characterized by similar values for the electronic relaxation time (τ_{so} = 160 ps and 150 ps for Gd-DOTAtyr-gal and Gd-DOTAtyr) and water exchange lifetime (500 ns), while they differ in their reorientational correlation times that were determined to be 192 ps and 125 ps for Gd-DOTAtyr-gal and Gd-DOTAtyr, respectively.

The cleavage of the galactosyl-pyranose moiety operated by the β-galactosidase enzyme (2 μM) has been followed over time at 37 °C by measuring the change in the relaxation rate (at 20 MHz and 25 °C) of the solutions of Gd-DOTAtyr-gal upon addition of the enzyme in phosphate buffer and in serum (Figure 2).

As shown in Figure 2, the transformation of Gd-DOTAtyr-gal into Gd-DOTAtyr, witnessed by the observed decrease of relaxivity, occurs quite readily either in phosphate buffer or in serum.

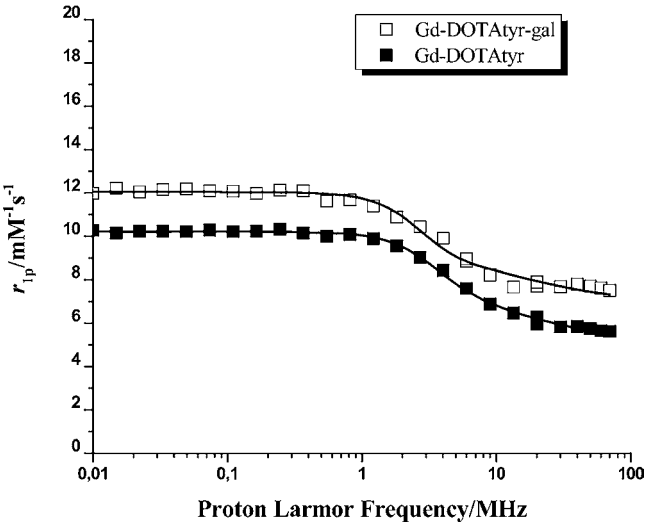


Figure 1. ^{1}H NMRD profiles of Gd-DOTAtyr-gal (□) and Gd-DOTAtyr (■) measured at 25 °C and neutral pH. The data refer to the millimolar concentration of the paramagnetic complexes.

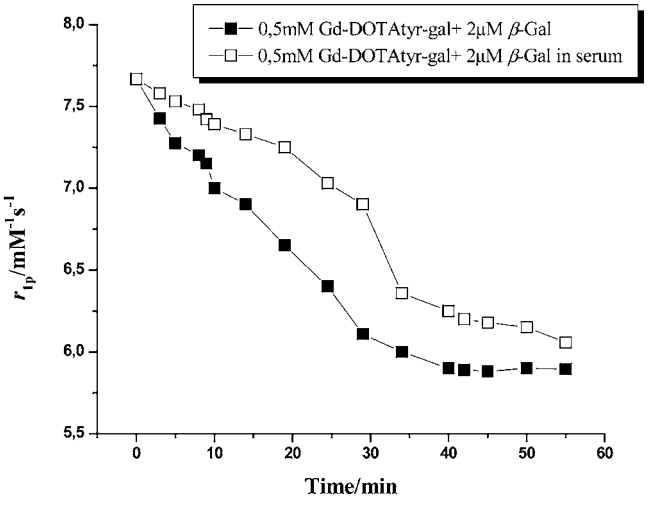

Figure 2. Variation of the relaxivity of Gd-DOTAtyr-gal as a consequence of addition of β-galactosidase enzyme in phosphate buffer (■) and in serum (□).The measurements were carried out at 20 MHz and 25 °C.

Next, the formation of melanin-like polymers from Gd-DOTAtyr in the presence of tyrosinase enzyme has been assessed by either colorimetric and relaxometric measurements. In fact, the formation of melanin-like polymers is characterized by a progressive darkening of the solution (increase of UV absorbance at 475 nm) and by the decrease of the solvent water proton relaxation time (Figure 3).

A similar experiment was also performed on a solution of Gd-DOTAtyr-gal, not activated by β-galactosidase. In this case, no darkening nor any change in the proton relaxation time was observed when the tyrosinase enzyme was added to the solution (Supporting Informations). Having established that Gd-DOTAtyr-gal transforms into Gd-DOTAtyr in the presence of β-galactosidase and Gd-DOTAtyr yields a melanin-like polymer in the presence of tyrosinase, a solution of Gd-DOTAtyr-gal (0.35 mM), β-galactosidase (2 μM), and tyrosinase (3 μM) has been prepared and the change in light absorption and proton relaxation times have been measured.

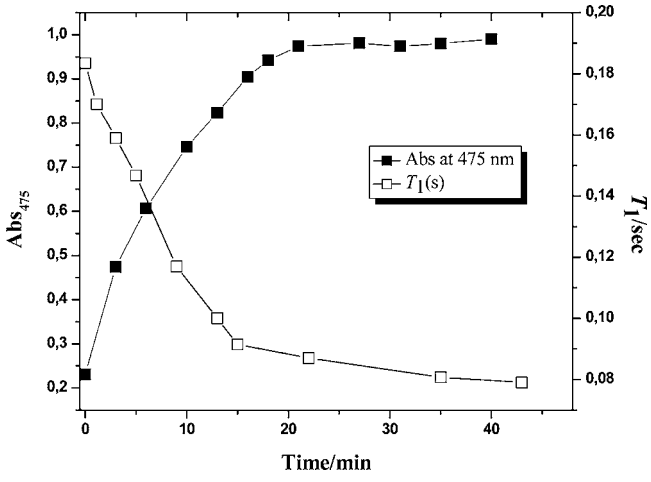

Figure 3. Plot of the spectrophotometric (■) and water proton relaxation time measurements (□) (25 °C, 20 MHz) of a Gd-DOTAtyr (0.35 mM) solution in the presence of tyrosinase enzyme (3 μM) as a function of time.

The obtained results (Supporting Informations) are very similar to those found for the Gd-DOTAtyr in the presence of tyrosinase. This finding clearly shows that the transformation of Gd-DOTAtyr-gal into Gd-DOTAtyr and then the oligomer formation take place in agreement with what was observed for the separated steps of galactose-pyranose release and melanin formation.

Relaxometric Analysis of the Activation Process. An in-depth characterization of the relaxation enhancement for Gd-DOTAtyr-gal solutions upon addition of β-galactosidase and tyrosinase was obtained through the acquisition of the NMRD profiles (Figure 4). As described above, the profile of Gd-

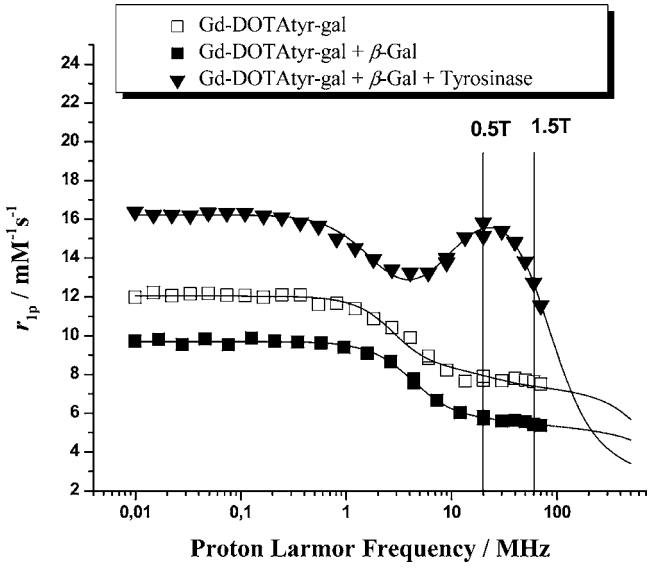

Figure 4. ^{1}H NMRD profiles of Gd-DOTAtyr-gal (□), Gd-DOTAtyr-gal after the addition of β-Gal (■), and Gd-DOTAtyr-gal after the addition of β-Gal and tyrosinase (▼) registered at 25 °C. The data refer to the millimolar concentration of the paramagnetic complexes. The higher r_{1p} values observed in the presence of the two enzymes are due to the formation of paramagnetic melanin-like macromolecules.

DOTAtyr-gal complex (open squares) has the classical shape shown by low molecular weight systems. Incubation of Gd-

dx.doi.org/10.1021/bc200486j | Bioconjugate Chem. 2011, 22, 2625–2635

DOTAtyr-gal complex with β-galactosidase at 37 °C for 40 min (red filled squares) led to a decrease of the relaxivity values along the entire range of investigated frequencies. The lower relaxivity is indicative of the formation of the lower molecular weight system (τ_R = 112 ps) achieved upon the release of the galactose moiety. The obtained profile is in fact almost superimposable with that of the Gd-DOTAtyr complex reported in Figure 1. The successive addition of tyrosinase enzyme (3 μM) to the remaining complex for 40 min leads to the formation of the oligomerized high relaxivity system (filled triangles - τ_R = 5.6 ns). Polymerization is the expected reactivity pathway for the phenolic product (obtained by the action of β-galactosidase) in the presence of tyrosinase, in agreement with the previously reported results for Gd-based tyrosinase and myeloperoxidase responsive agents.[8−11]

Investigation into the shapes of the profiles for the polymeric and monomeric Gd-containing systems reveals that there is a strong dependence of the responsiveness of the Gd-probe from the magnetic field strength at which the experiments are carried out. A marked jump in relaxivity is in fact observed in the field range 0.5−1.5 T (working fields of many clinical MR-scanners). At higher field strengths, the differences in relaxivities of the activated and inactivated systems become less marked.

Enzymatic Activity Assays in B16−F10 and B16−F10*LacZ* Melanoma Cells. In order to evaluate more closely the potential of Gd-DOTAtyr-gal for cellular applications, tests have been carried out in B16−F10 and B16−F10*LacZ* murine melanoma cells. Melanoma cells have been used for the enzymatic assays, as these cells possess high tyrosinase activity as witnessed by their natural melanin pigmentation.[15]

Cellular tyrosinase activity was assayed according to the method of Thomita et al. using L-DOPA as substrate and following the conversion of DOPA to DOPAchrome via DOPA quinone.[14,16] The increase of absorbance with time reports about the DOPAchrome formation and, in turn, on cell tyrosinase activity. Under these conditions, the enzymatic activity of one million B16−F10 and B16−F10*LacZ* cells has been estimated to be ca. 30 U and 3 U, respectively (by using an extinction coefficient for DOPAchrome at 475 nm of 3700 M^{-1} cm^{-1}). One unit of tyrosinase activity is defined as the amount of enzyme that catalyzes the trasformation of 1 μmol L-tyrosine/min. The low tyrosinase activity found for B16−F10*LacZ* fresh homogenates appears to be a frequent phenomenon already reported for other melanoma engineered cells (Figure 5)[14−16] where it has been described as one of the phenotypic variations of cellular differentiation.[18] However when 1×10^6 B16−F10*LacZ* melanoma cells were injected into C57BL/6 mouse, the mouse developed a partially or fully melanotic tumor. This phenomenon, already reported in the literature,[17−19] proved that these cells retained the capacity of producing the pigment, although this capacity appeared not to be well-expressed *in vitro*. Therefore, after being cycled in mice, the B16−F10*LacZ* cells were again assayed *in vitro* by the method of Thomita et al. using L-DOPA as substrate, and a significant resumption of tyrosinase activity was observed (Figure 5).

To assess the enzymatic activity of β-galactosidase in the cells, B16−F10*LacZ* cells were stained with β-Gal Staining Kit and examined under optical microscope as shown in Figure 6.

β-Gal Staining Kit is based on 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-Gal), a non-inducing chromogenic substrate for β-Gal. The resultant halogenated indigo is a very stable and insoluble dark blue compound (Figure 6).

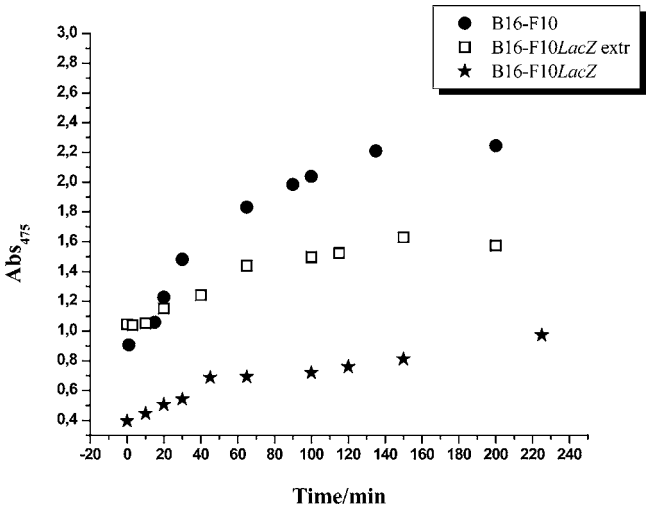

Figure 5. Absorbance at 475 nm as a function of time for B16−F10, B16−F10*LacZ*, and B16−F10*LacZ* (isolated from injected mice) cells homogenates added to a 0.5 mL of a 1 mM L-DOPA solution.

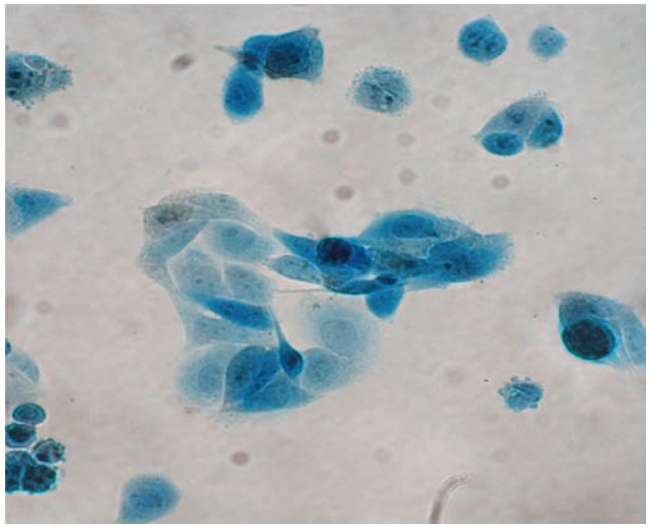

Figure 6. B16−F10*LacZ* cells were stained for β-gal activity by the β-Gal Staining Kit (1 mg/mL X-gal) before examination under the microscope.

Incubation of Gd-DOTAtyr-gal with B16−F10 and B16−F10*LacZ* Cell Homogenates. In each experiment, 8×10^6 B16F10 or a similar number of B16−F10*LacZ* cells were added to 100 μL of a 1 mM Gd-DOTAtyr-gal solution, sonicated to induce cell lysis, and the proton longitudinal relaxation rate at 20 MHz and 25 °C was measured over time while maintaining the temperature of the reaction mixture at 37 °C (Figure 7).

As shown in Figure 7, the relaxivity steadily increases to reach a "plateau" value, after 30 h of incubation. The observed behavior is consistent with the formation of a Gd-incorporated, melanin-like macromolecule. No effect is observed when Gd-DOTAtyr-gal is incubated with B16−F10 cells, lacking the β-Gal enzyme.

Uptake of Gd-DOTAtyr-gal and Gd-DOTAtyr into B16−F10 and B16−F10*LacZ* Cells. Translation of this enzyme-based approach to in vivo applications requires that a sufficient amount of Gd-responsive probe is internalized by the cells to be monitored. The uptake efficiency by melanotic B16−

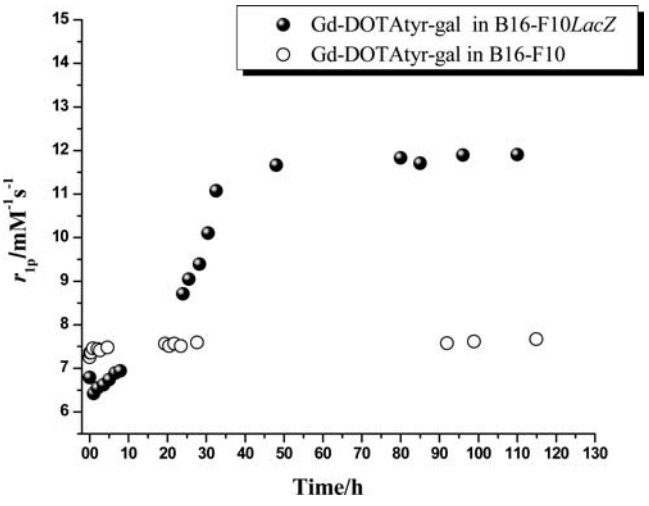

Figure 7. Variation of the relaxivity of Gd-DOTAtyr-gal over time in the presence of B16−F10*LacZ* (●) and B16−F10 (○) cell homogenates. The measurements were carried out at 20 MHz and 25 °C.

F10 and B16−F10*LacZ* cells was assessed by incubating 1 × 10^6 cells in DMEM medium in the presence of different concentrations (10−15−20 mM) of Gd-DOTAtyr-gal and Gd-DOTAtyr, for 4 h at 37 °C (Figure 8).

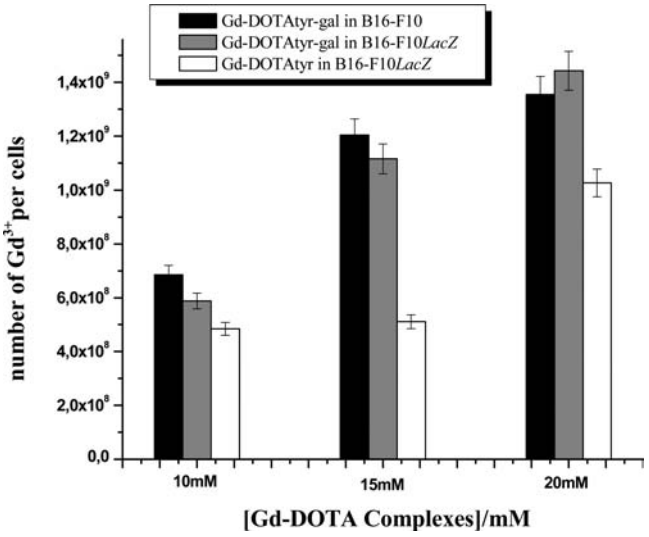

Figure 8. Number of Gd^{3+} units per cell internalized after incubation of Gd-DOTAtyr-gal in B16−F10 (black) and B16−F10*LacZ* (gray) cells and Gd-DOTAtyr in B16−F10*LacZ* cells (white) for 4 h at 37 °C.

The uptake of Gd-DOTAtyr-gal in both *β*-Gal expressing and parent melanoma cells is significantly higher than that of Gd-DOTAtyr. The higher accumulation efficiency of Gd-DOTAtyr-gal may be accounted for the specific recognition of galectin receptors, which are galactose-specific lectins particularly hyperexpressed on B16−F10 cells.[20,22] Support to the specificity of internalization of Gd-DOTAtyr-gal thanks to the recognition of galectins exposed on cell membrane surfaces has been found in measuring the perturbation of the adhesion of B16−F10 cells to fibronectin of culture dishes. It is in fact known that cell−cell and cell−ECM (extracellular matrix) adhesions are mediated not only by integrin−ligand interactions but also by lectin−saccharide interactions.[20,21]

Recently, El-Boubbou et al.[20] demonstrated that galactose-functionalized magnetic nanoparticles strongly interact with B16−F10 cells, and that this interaction is responsible for a reduction of adherent cells by more than 50%.

Upon incubation of B16−F10*LacZ* cells with 15 mM Gd-DOTAtyr-gal, we observed a progressive reduction of the amount of adherent cells increasing the incubation time if compared with control cells (Figure 9). In contrast, a very small

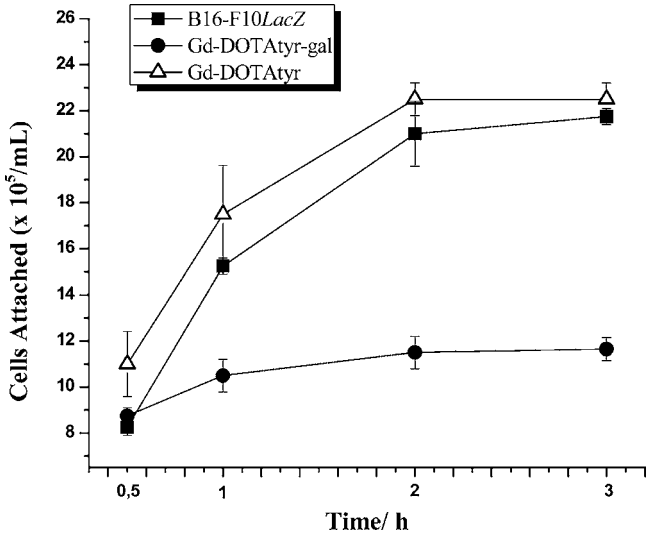

Figure 9. Adhesion of mouse melanoma B16−F10*LacZ* cells to the surface was significantly reduced by incubation with Gd-DOTAtyr-gal (●), while Gd-DOTAtyr (Δ) had no effect on cell adhesion as compared to the cells without any treatment (■).

effect was observed when cells were incubated with Gd-DOTAtyr.

In order to be activated by the cytosolic enzymes, an important issue for the activation of the probe relies on the need to avoid the endosomal compartmentalization of the internalized probe. This issue has been tackled by measuring the variation of observed relaxation rate (at 1T and 25 °C) of the internalized probe as a function of its intracellular concentration (Figure 10). It was recently demonstrated that the occurrence of a linear increase of the observed relaxation rate with the amount of internalized paramagnetic probe is a good reporter of the cytoplasmic localization of the Gd(III)-probe, while a "quenching" effect on the observed relaxation rate is observed in the case of its endosomal entrapment.[23−25] As shown in Figure 10, a linear correlation has been observed, which witnesses that Gd-DOTAtyr-gal, after being internalized by cells, is localized in the cytosol and available for the interaction with *β*-galactosidase and tyrosinase enzymes. Furthermore, in Figure 10 the relaxation rates of cells labeled via their incubation with Gd-DOTAtyr-gal for 4 h at 37 °C are compared with those obtained for cells in which the same Gd(III)-containing probe has been internalized by electroporation (that invariantly leads to a cytoplasmatic localization). The two internalization pathways show the same linear growth of observed relaxation rates as a function of the intracellular Gd(III) complex concentration, to support the view that the same cytoplasmic localization is taking place.

***In Vivo* MRI Experiments.** To assess the *in vivo* capability of the complex Gd-DOTAtyr-gal to discriminate between

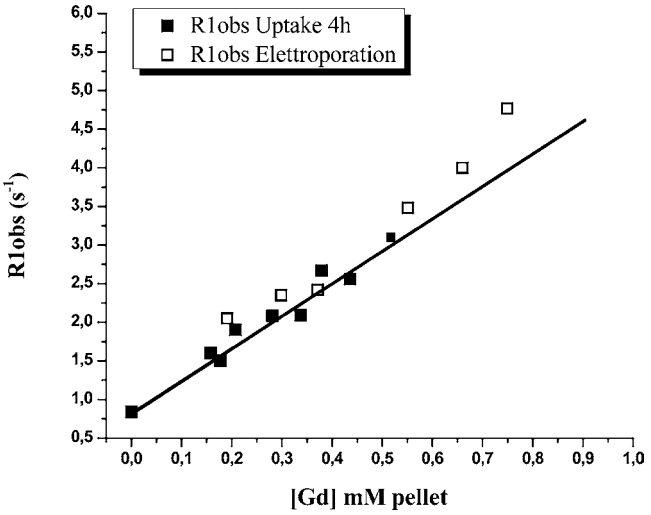

Figure 10. Observed longitudinal relaxation rates of B16−F10*LacZ* cellular pellets, measured at 1 T and 25 °C, as a function of Gd^{3+} concentration in the cellular pellets from uptake experiments (■) and electroporation experiments (□).

melanoma tumors with and without *β*-galactosidase gene expression, an MRI study was carried out on two tumor-bearing animal models, namely, (i) C57Bl6 mice grafted with the murine melanoma cell line B16−F10; (ii) C57Bl6 mice grafted with the murine melanoma cell line B16−F10*LacZ*.

The model was obtained by subcutaneous injection of 1 million of B16−F10 or B16-F10*LacZ* cells, on the right limb of six female C57Bl6J mice. At 10−12 days after implantation, a tumor mass of a 2−3 cm width is clearly detectable in each mouse at the site of injection. At this time, animals received intratumoral injections of the Gd-DOTAtyr-gal (40 *μ*L of 7.5 mM solution) and T_1 weighted multislice MR images were acquired at 1.0 T.

A strong T_1 contrast was detected in the *LacZ* expressing tumors after 4−5 h from contrast agent injection. At the same detection time, no T_1 contrast was observed in the B16−F10 tumor, which was injected with the same amount of contrast agent (Figure 11a). The observed signal enhancement of the B16−F10*LacZ* tumor was an order of magnitude higher than the one observed for B16−F10 tumor (3.5 ± 1.6) (Figure 11b). The intense enhancement clearly indicates that Gd-DOTAtyr-gal is activated by *β*-galactosidase and tyrosinase enzymes both presented in B16−F10*LacZ* tumor.

CONCLUSIONS

The *β*-galactosidase gene *LacZ* is often used as a reporter constructor in eukaryotic transfection experiments due to the proteolytic resistance of the protein product and the easily assayed enzyme activity. In this study, a new Gd(III)-based probe was designed, prepared, and enzymatically tested to be a good *β*-galactosidase substrate in melanoma B16 homogenate. Upon cleavage by *β*-galactosidase, the tyrosine residue can interact with the tyrosinase enzyme in B16−F10*LacZ* melanoma cells with subsequent formation of high-relaxivity Gd-DOTA containing oligomers.

A good relaxation enhancement effect was detected. The slow activation of the probe could be due to a relatively low turnover of the enzyme; therefore, higher loading would allow a larger amount of substrate to be converted by the enzyme, thus giving rise to a larger relaxation enhancement effect.

The ability of Gd-DOTAtyr-gal to enter B16−F10*LacZ* cells following intratumoral injection has been demonstrated.

dx.doi.org/10.1021/bc200486j | *Bioconjugate Chem.* 2011, 22, 2625−2635

Besides melanoma cells, Gd-DOTAtyr-gal would be a good gene reporter for any doubly transfected (β-Gal and Tyr) cells. Finally, the importance of working at low magnetic field strength has been shown when the determinant of the relaxation enhancement is represented by the molecular reorientational time.
