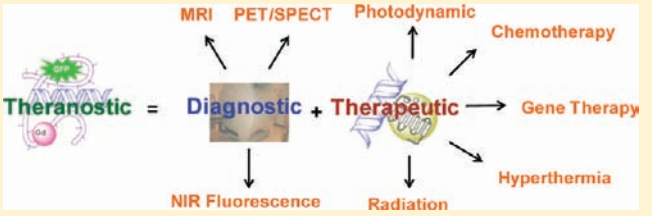
ABSTRACT: Employing theranostic nanoparticles, which combine both therapeutic and diagnostic capabilities in one dose, has promise to propel the biomedical field toward personalized medicine. This review presents an overview of different theranostic strategies developed for the diagnosis and treatment of disease, with an emphasis on cancer. Herein, therapeutic strategies such as nucleic acid delivery, chemotherapy, hyperthermia (photothermal ablation), photodynamic, and radiation therapy are combined with one or more imaging functionalities for both *in vitro* and *in vivo* studies. Different imaging probes, such as MRI contrast agents (T_1 and T_2 agents), fluorescent markers (organic dyes and inorganic quantum dots), and nuclear imaging agents (PET/SPECT agents), can be decorated onto therapeutic agents or therapeutic delivery vehicles in order to facilitate their imaging and, in so doing, gain information about the trafficking pathway, kinetics of delivery, and therapeutic efficacy; several such strategies are outlined. The creative approaches being developed for these classes of therapies and imaging modalities are discussed, and the recent developments in this field along with examples of technologies that hold promise for the future of cancer medicine are highlighted.



The term "theranostic" was coined in 2002 by Funkhouser[1] and is defined as a material that combines the modalities of therapy and diagnostic imaging. Thus, theranostics deliver therapeutic drugs and diagnostic imaging agents at the same time within the same dose. Before initiating treatment of various diseases such as cancer, it is essential to carry out diagnostic imaging to understand the cellular phenotype(s) and heterogeneity of the tumor.[2−4] In contrast to the development and use of separate materials for these two objectives, theranostics combine these features into one "package", which has the potential to overcome undesirable differences in biodistribution and selectivity that currently exist between distinct imaging and therapeutic agents. The ultimate goal of the theranostic field is to gain the ability to image and monitor the diseased tissue, delivery kinetics, and drug efficacy with the long-term hope of gaining the ability to tune the therapy and dose with heretofore unattainable control. Individualizing medicine, as opposed to adopting a 'one size fits all' approach, can move the field of nanomedicine forward toward an era of more effective and personalized treatment approaches.[5]

The most promising aspects of utilizing nanoparticles as therapeutics, diagnostics, and theranostics are their potential to localize (or be targeted) in a specific manner to the site of disease and reduce or eliminate the possible numerous untoward side effects. The nanometric size of these materials precludes them from being readily cleared through the kidneys, thereby extending circulation in the blood pool depending on their surface functionalization characteristics.[6] Also, when considering novel cancer treatments, blood vessels in many tumor types are irregular in shape, dilated, leaky, and can present fenestrations in endothelial cells. Due to the altered anatomy of tumor vessels, nanosized particles can easily extravasate from the blood pool into tumor tissues and be retained due to poor lymphatic drainage. This phenomenon of selective accumulation of nanosized particles near tumor tissues is termed the enhanced permeability and retention (or EPR) effect.[7,8] Additionally, nanoparticles have high surface area-to-volume ratios, yielding high loading capacities. Thus, nanoparticles can be loaded with therapeutic drugs and imaging agents; they may also be surface functionalized with targeting ligands and cloaking agents like poly(ethylene glycol) (PEG). Introduction of targeting ligands may help to increase the target-to-background contrast in imaging and improve the local concentration of the therapeutic at the target of interest, with the goal of reducing systemic toxicity.

In this review, we present an overview of some of the theranostic strategies developed for different types of cancer treatments, such as nucleic acid therapy, chemotherapy, hyperthermia treatment (photothermal ablation), photodynamic therapy, and radiation therapy. This review discusses syntheses and developmental studies of the novel multifunctional materials employed in this work, including linear and branched polymers, dendrimers, micelles, inorganic nanoparticles, and protein conjugates. In addition to their therapeutic uses, these materials have been functionalized with imaging agents to promote one or more diagnostic imaging techniques, such as magnetic resonance imaging, nuclear imaging (PET/SPECT/CT), and/or fluorescence imaging/optical imaging.

Nucleic acid therapy holds promise in the treatment of both acquired and inherited diseases like Alzheimer's disease, cancer, adenosine deaminase deficiency, and cystic fibrosis. In addition to traditional "gene therapy", in which a defective copy of a gene is replaced with a functional (therapeutic one), other forms of nucleic acids exist as current and potential therapeutics, such as plasmids, antisense oligonucleotides, ribozymes, DNAzymes, aptamers, and small interfering RNA (siRNA). These polynucleotides can alter gene expression at the transcriptional or post-transcriptional level and may be effective to treat cancer, cardiovascular, inflammatory, and some forms of infectious diseases. The success of polynucleotide therapeutic modalities relies on their efficient delivery to the site of disease. Nucleic acids are large, negatively charged molecules that are highly susceptible to enzymatic degradation; they are not easily internalized by cells that contain a negatively charged plasma membrane. Injection of naked nucleic acids directly to the diseased areas (such as skeletal muscles, liver, thyroid, heart muscle, urological organs, skin, and tumor) via a physical method—such as electroporation, a "gene gun", or ultrasound—can be an effective mode of delivery.[9] However, systemic injection of naked DNA is largely ineffective due to the minimal amount of intact polynucleotide reaching the final intracellular destination. Direct injection of naked DNA holds limited promise toward efficient delivery, especially to the targets that are anatomically inaccessible (e.g., solid tumors).

Over the past several decades, tremendous effort has been put forth to design and develop delivery methods to produce highly efficient and efficacious delivery vehicles. These methods involve both viral and nonviral delivery vehicles. Virus-based therapeutic delivery involves the inactivation of viral genes that cause disease and incorporation of a copy of the therapeutic gene of interest—as RNA for retroviral and lentiviral vectors or as DNA for adenoviral or adeno-associated viral vectors.[10] Viral vectors can achieve high transfection efficiency and integration of the target gene into the chromosomal DNA of the recipient cell(s). Several clinical trials[11,12] with viral vectors have raised concerns due to undesirable interference with the host genome and the potential to elicit a severe immune response. To this end, in recent years, many researchers have focused on the development of new synthetic, nonviral vehicles, which have the potential to be nontoxic and less immunostimulatory, and can be more versatile for modification and carrying different types of drug payloads. Nonviral vehicles based on synthetic polymers, dendrimers, liposomes, cell-penetrating peptides, and inorganic nanoparticles have been developed and studied in detail.[9,13,14] These types of vehicles also possess the advantageous ability to be easily modified for theranostic purposes.

To design highly efficient gene delivery vectors, identification of the rate-limiting steps involved in the path of the delivery vehicle from its site of administration to the target of interest is crucial for success. Understanding trafficking of a nucleic acid from extracellular matrix, through the cell, and into the nucleus has traditionally been done by labeling the nucleic acid with one or more fluorescent dyes and monitoring colocalization signals with a fluorescent-labeled organelle at different time points. For example, Godbey et al.[15] investigated the intracellular trafficking of poly(ethyleneimine) (PEI) and PEI-DNA complexes (polyplexes) to the nucleus with the help of confocal laser scanning microscopy. PEI and DNA were labeled with Oregon Green 488 and rhodamine, respectively, and the yellow signal resulting from colocalization of green (PEI) and red (DNA) was monitored to understand trafficking of PEI-DNA complexes. They also studied trafficking of PEI and DNA individually by monitoring green and red fluorescence signals, respectively. They investigated the PEI-DNA polyplexes after endocytosis as well, revealing that PEI enters the nucleus along with the DNA. One of the major limitations of this approach for visualization (that is, separate labeling of polymer and DNA with fluorescent dyes and monitoring colocalization signal with fluorescent spectroscopy) is inherently low spatial resolution associated with the confocal microscopy technique. Fluorescence signals from each fluorophore may overlap in spite of the polymer and DNA not actually being associated with each other; that is, this approach is unable to provide potentially valuable details, such as more precise, real-time information about association−dissociation of the polymer from the polynucleotide.[16,17]

Recent studies in which both the delivery vehicle and DNA were labeled with organic dyes have allowed the use of more sophisticated imaging techniques, such as time-lapse microscopy, fluorescence resonance energy transfer (FRET),[18,19] and fluorescence correlation spectroscopy (FCS).[20] These approaches hold promise to provide more precise information regarding polyplex trafficking and dissociation and toward development of theranostic systems. For example, Lucas et al.[17] used dual-color fluorescence fluctuation spectroscopy (FFS) to monitor complexes comprising Cy5-labeled poly(L-lysine) (PLL) and pegylated poly[2-(dimethylamino)ethyl]methacrylate-*co*-aminoethyl methacrylate (pEG-pDMAEMA-*co*-AEMA, abbreviated as pDMAEMA) and rhodamine-labeled oligonucleotide (ON). FFS possesses high spatial and temporal resolution, which permits an enhanced ability to differentiate between associated and dissociated polyplexes. The authors' use of FFS led to novel and interesting findings, such as the observation that high molecular weight pDMAEMA (1700 kDa) dissociates from ON within the cytoplasm without entering the nucleus, whereas low molecular weight PLL (30 kDa) releases ON after nuclear entry.

Despite successes such as this, there remain several limitations associated with the use of fluorescent dyes for labeling the polymeric vehicle—such as photobleaching, fast fluorescence decay, and nonuniform labeling of the polymer.[21] Further, some research has also indicated that labeling the polymer with a fluorescent label can change its physiochemical properties. For example, Remaut et al.[22] have shown with the help of fluorescence correlational spectroscopy (FCS) that diblock PEI-PEG polymers lose their ability to bind to nucleic acids when labeled with a fluorescent dye, such as Cy5. For these reasons, other labeling strategies are being widely investigated to further improve understanding of delivery vehicle trafficking.

One set of well-studied alternative labeling agents are quantum dots (QDs). Advantages of QDs over fluorescent dyes include their high extinction coefficients, strong control over optical properties, and reduced susceptibility to photobleaching.[21,23] Many QDs form FRET pairs with fluorescent organic dyes and are useful for monitoring polyplex trafficking *in vitro*. FRET is a highly sensitive technique that provides information about intracellular interactions on the nanometer scale. Upon its excitation, the emission of one fluorescent species serves to excite a second species. Given the short distance over which the emission can propagate, detection of emission from the second species serves as a strong indicator of the close proximity (that is, molecular interaction) between the two indicators. When these two indicators are attached to separate molecules, a positive FRET

signal (emission of the second indicator) is evidence of physical association of these two molecules at the time of signaling.

As an example, Ho et al.[16] demonstrated that the intracellular dissociation of polymer−pDNA complexes can be monitored via QD-FRET (Figure 1). In this study, streptavidin-functionalized, Cy5-labeled chitosan was conjugated to QD-labeled pDNA via biotin−streptavidin binding. QD-FRET analysis was performed using electron and confocal microscopy at 24, 48, and 72 h post-transfection in HEK293 cells to study unpackaging of chitosan−pDNA complexes. Their investigation indicated that at 24 h after transfection, polyplexes were localized in the perinuclear region, whereas at 72 h post-transfection, polyplexes were dissociated and DNA was located in the nucleus without any signal from chitosan (Cy5).

Commonly used techniques to visualize RNA interference (RNAi) experiments are cotransfection of siRNA with a fluorescent reporter gene (to monitor degree of reporter gene knockdown) and/or covalent end-modification of the sense strand on the siRNA to attach a fluorophore. Although above-mentioned strategies have some utility, these techniques are limited in that they are best suited for highly silenced genes and ignore moderately silenced genes, which might be of interest in some cases. Further, current transfection methods are incapable of discriminating among multiple siRNA molecules delivered simultaneously. Additionally, QDs do not photobleach and have longer fluorescence lifetimes compared to organic dyes. As an example, Bhatia and co-workers[24,25] synthesized near-infrared (NIR) QDs (emission max 655 or 705 nm) functionalized with

PEG and amino groups and attached with an siRNA (designed to knock down expression of enhanced green fluorescent protein (EGFP)) and a cell-targeting moiety (tumor-homing F3 peptide; Figure 2) via reducible disulfide (sulfo-LC-SPDP) or nonreducible (sulfo-SMCC) linkers. The F3-peptide and siRNA were attached to the surface of the QD via reducible or nonreducible linkers and their effect on cell internalization and gene knockdown was compared. The resulting molecule was transfected into cultured cells with Lipofectamine 2000, a commercially available transfection reagent, and the EGFP expression was monitored by measuring the fluorescence intensity using flow cytometry.The use of reducible versus nonreducible cross-linker for the F3 peptide did not affect the cell internalization. However, the use of reducible disulfide linker (sulfo-LC-SPDP) for siRNA showed significantly higher gene knockdown, possibly due to a change in interaction of siRNA with the RNA induced silencing complex through release of the siRNA from the particle surface.

In another example, Tan et al.[26] developed a "self-tracking" siRNA delivery vehicle based upon chitosan-coated quantum dots (green fluorescent CdSe/ZnS) as a core. The negatively charged QD was coated with positively charged chitosan via electrostatic attraction and the surface of chitosan was complexed with negatively charged siRNA against human epidermal growth factor receptor 2 (HER2) to promote delivery of the nanoparticles to breast cancer cells (SKBR3 cells) in which HER2 is upregulated; a variation of these nanoparticles was also coated with an anti-HER2 antibody (via standard EDC/NHS chemistry). Cellular uptake studies were performed and confocal microscopy on both SKBR3 and MCF-7 (HER2 under-expressed) cell lines to validate the targeting efficacy of the HER2-targeting moiety on the nanoparticles in cellular uptake and target gene knockdown (Figure 3). The QD was encapsulated to probe the delivery of the siRNA−carrier system.

Prigodich et al.[27] have developed nanoconjugates that can both detect and regulate intracellular mRNA levels via monitoring an increase in fluorescence of a "flare" that is released upon successful binding of a therapeutic oligonucleotide to its target mRNA (Figure 4a). Nanoconjugates containing gold nanoparticles were functionalized with a therapeutic antisense oligonucleotide (a chimera of DNA and a linked nucleic acid (LNA)) which binds to a specific region of an mRNA suppressing expression of survivin, a well-known gene for cancer diagnosis and treatment. An additional complementary short oligonucleotide labeled with Cy5 was conjugated onto the nanoflare that is released upon binding to the target mRNA, thereby increasing the Cy5 fluorescence intensity. The mRNA detection technique is rapid (reaches completion in 10 min) and sensitive for single-base pair mismatch recognition. These nanoflares deplete mRNA levels in sequence- and dosage-dependent manners and, consequently, hold promise toward mRNA-directed theranostics (Figure 4b).

Our group has developed a new set of theranostic polymers for the combined delivery of nucleic acids and magnetic resonance imaging (MRI) contrast agents. [28] The macromolecule structures contain a lanthanide-binding domain (diethylenetriaminepentacetic acid or DTPA) and an oligoethyleneamine (PEI-like) domain that contain secondary amines, which are protonated at physiological pH and promote binding and compaction of nucleic acids into polyplexes (Figure 5a). The flexibility in this platform is that the lanthanide-binding domain can be chelated to either gadolinium (Gd), a MRI contrast agent for sub-micrometer to millimeter scale imaging or luminescent europium (Eu) for visualization on the nanometer to micrometer scale, which can be imaged with fluorescence microscopy. These polymeric delivery vehicles integrate both therapeutic delivery and diagnostic imaging functionalities into one system. Plasmid DNA (pDNA) transfection studies performed on polyplexes formed with these delivery beacons reveal that the Gd^{3+}-containing analogues show high image contrast (compared to untransfected cells) and Eu^{3+} analogues can be imaged with fluorescent microscopy inside the cell (Figure 5b,c). These polyplexes formed with these polymer beacons showed high cell internalization efficiency and a low toxicity profile, and they hold promise to individually monitor both the nucleic acid and the polymer vehicle during the delivery process. The use of a lanthanide metal, which luminesces (f-f transition) instead of fluoresces, as opposed to other common fluorescent markers (i.e., fluorescent dyes) eliminates concerns related to photobleaching and nonuniform labeling. Also, the

long luminescence lifetime (on the order of milliseconds) characteristic of the lanthanides enables easy removal of background fluorescence via time-delayed measurements. Thus, FRET is a powerful technique for studying nanometer-scale molecular interactions. This phenomenon is called luminescence (or lanthanide-based) resonance energy transfer (LRET) and it offers several advantages over FRET.[29] Moreover, these lanthanides are known to form LRET pairs with some fluorescent dyes, such as tetramethyl rhodamine (TMR), Cy5, and some APC (allophycocyanin) dyes, which may be beneficial to monitor kinetics of polyplex association−dissociation via LRET. Current efforts are directed toward studying the effect of an increase in amine stoichiometry on transfection efficiency and toxicity and monitoring complex unpackaging via LRET with terbium- (Tb^{3+}-) containing analogues of these polymers.

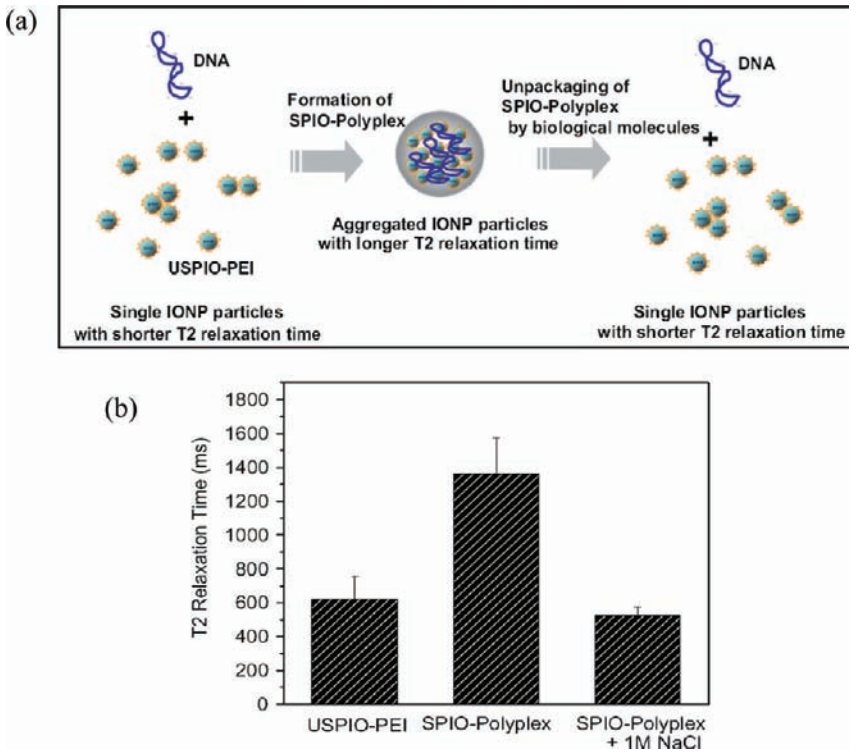

Figure 6. (a) Proposed mechanism of a "T_2 relaxation switch". (b) T_2 relaxation times upon formation of polyplexes and their subsequent dissociation upon addition of salt.
Figure adapted from Park, I.-K., Ng, C.-P., Wang, J., Chu, B., Yuan, C., Zhang, S., Pun, S. H. (2008) Determination of nanoparticle vehicle unpackaging by MR imaging of a T2 magnetic relaxation switch. *Biomaterials 29*, 724-732 with permission, Copyright Elsevier (2008).

Several interesting examples of *in vivo* administration of theranostics containing nucleic acid therapies have been reported previously; these materials are useful for the study of pharmacokinetic and biodistribution profiles of both the medicinal agent and the vehicle *in vivo*. Similar to the *in vitro* imaging discussed above, several labeling agents can be conjugated to the delivery vehicle and used for *in vivo* diagnostic imaging. Imaging agents such as NIR quantum dots (optical imaging), magnetic resonance contrast agents (MR imaging), and PET/SPECT (positron emission tomography/single photo emission computerized tomography) agents can be incorporated into the delivery system. Each of these imaging modalities has its advantages and disadvantages. For example, while MRI has good spatial resolution (10−100 μm), it is hampered by low sensitivity (micromolar quantities of paramagnetic agent must be used to see significant change in signal). Nuclear imaging techniques such as PET and SPECT imaging possess high sensitivity but are limited by low spatial resolution. Additionally, generating radionuclides in the cyclotron is expensive and exposure to ionizing radiation can be harmful in the long term.

In the case of MRI, to obtain high image contrast, significant accumulation of the contrast agents at the target site is necessary. This can be achieved by functionalizing contrast agents with suitable ligands that target various cell receptors, such as transferin receptor, folate receptor, and human/epidermal growth factor receptor 2, upregulated on the surface of various cancer cells. Both T_1 (positive) and T_2 (negative) contrast agents can be employed within theranostic materials. For *in vitro* imaging, iron oxide based nanoparticles (T_2 contrast agents) have been used and are discussed herein. Additionally, these particles can be functionalized with targeting ligands like human holo-transferin that are covalently attached to the dextran-coated monocrystalline iron oxide (Tf-MION) or cross-linked iron oxide (Tf-CFIO) and can easily be taken up by cells via receptor-mediated endocytosis.[30−32]

Park et al.[33] developed magnetic iron oxide-based nanoarchitectures that allow assessment of polyplex dissociation via tracking of changes in T_2 relaxation rates. Poly(ethyleneimine) (branched PEI, MW 10 kDa) that can bind to DNA via electrostatic interactions was covalently conjugated to ultrasmall superparamagnetic iron oxide (USPIO) to form higher-order structures (size ~100 nm). A "T_2 relaxation switch" (Figure 6a) was proposed as a tool for monitoring packaging and unpackaging of the polyplexes. When complexed with DNA, the nanoparticle carriers show longer T_2 relaxation times; conversely, upon dissociation, they reduce back to original values (Figure 6b). Increases or decreases in T_2 relaxation times upon formation or dissociation of polyplexes, respectively, can be attributed to changes in particle size, surface functional groups, and/or surface area available for water exchange from native USPIO. Salt (sodium chloride)-induced polyplex dissociation was studied via three different methods: (i) YOYO dye exclusion, (ii) turbidity measurement, and (iii) decrease in T_2 relaxation time. Plasmid-containing USPIO-PEI nanoparticles were less toxic to HeLa cells than PEI only (for 10 kDa and 25 kDa molecular weights at the same net PEI concentration) and showed higher luciferase gene expression (at N/P 15) than PEI alone.

Dubertret et al.[34] demonstrated that QDs encapsulated into phospholipid-block copolymer micelles (Figure 7) can be used as fluorescent probes for *in vitro* and *in vivo* imaging. ZnS-coated Cd−Se QDs encapsulated in the hydrophobic cavity of micelles

formed with poly(ethylene glycol)-phosphatidylethanolamine (PEG-PE) and phosphatidylcholine (PC) were functionalized with primary amines to allow covalent binding to thiol-functionalized DNA. *In vivo* studies performed in *Xenopus* embryos revealed that these QD-micelles were able to label all types of embryonic cells without any aggregation, including somites, neurons, axonal tracks, ectoderm, neural crest, and endoderm. Additionally, QDs were found to be stable against photobleaching for as long as 80 min, a time at which rhodamine green dextran dye was completely photobleached. Toxicity studies indicated no abnormalities in the embryo at typical concentration ($<5 \times 10^9$ QDs/cell)—they showed unaltered phenotype and normal health.

Medarova et al.[35] synthesized dextran-coated superparamagnetic nanoparticles (MN) covalently attached to siRNA targeting green fluorescent protein (siGFP; five per particle), an NIR-emitting dye, Cy5.5 (NIRF; three per particle), and a membrane translocation peptide, myristolyated polyarginine peptide (MPAP; four per particle) to facilitate trafficking of nanoparticles inside the cytoplasm of target cells (Figure 8a). Cellular uptake of MN-NIRF-siGFP in 9 L-glioma cells (that stably expressed green fluorescent protein (GFP)) was monitored by fluorescence microscopy. These results were compared with red fluorescent protein (RFP)-expressing 9 L-glioma cells to test the specificity of siRNA target toward GFP; target mRNA levels were compared via quantitative RT-PCR. *In vivo* studies in tumor-bearing mice bilaterally implanted with 9 L-GFP- and 9 L-RFP-expressing glioma cells showed significant mRNA knockdown in 9 L-GFP tumors compared to saline only and mismatch controls (Figure 8b). After success of these proof-of-concept studies with GFP, MN-NIRF-MPAP-siSurvivin was developed to target survivin, a member of the inhibitor of apoptosis protein (IAP) family. MN-NIRF-MPAP-siSurvivin was injected into nude mice bearing subcutaneous human colorectal carcinoma tumors (LS174T) over a

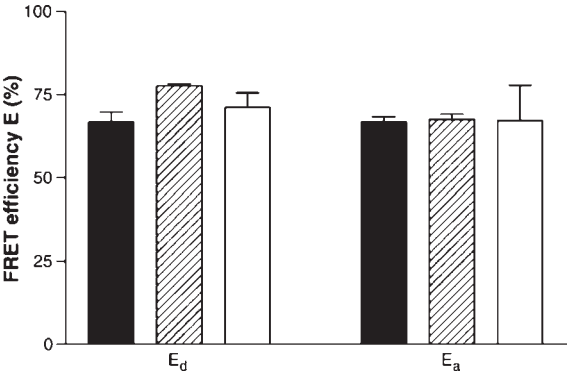

Figure 10. FRET efficiencies for donor (E_d) and acceptor (E_a) calculated based on three different measuring techniques: fluorimetry (solid bars), flow cytometry (hatched bars), and fluorescence microscopy (open bars) showed comparable results. The excitation wavelengths used for flow cytometry and fluorescence microscopy were 488 and 523 nm, respectively, and emission signals were monitored at 670 nm and above 650 nm, respectively.
Figure adapted from Schneider, S., Lenz, D., Holzer, M., Palme, K., Suess, R. (2010) Intracellular FRET analysis of lipid/DNA complexes using flow cytometry and fluorescence imaging techniques. *J. Controlled Release 145,* 289-296 with permission, Copyright Elsevier (2010).

2-week period and quantified by RT-PCR (Figure 8c)—strong reduction in survivin mRNA levels was observed. Additionally, *in vivo* studies with these particles indicated low cytotoxicity and a lack of immunostimulatory response (as monitored by aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels).

Davis and co-workers[36,37] have developed a series of linear cyclodextrin-containing polycations (CDPs) for *in vivo* delivery of nucleic acids. Their studies in mice have indicated, upon systemic injection, significant uptake (of polyplexes containing cyclodextrin polycations and siRNA against EWS-FLI1 gene to treat Ewing sarcoma) in the tumor microenvironment can be achieved due to the EPR effect; however, to maximize cellular internalization and specificity, the presence of a targeting ligand on the nanoparticles is crucial. Bartlett et al.[38] investigated the biodistribution and pharmacokinetics of polyplexes created by complexing CDP with siRNA via positron emission tomography (PET), computed tomography (CT), and bioluminescence imaging (BLI). The CDP delivery vehicles were conjugated to 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA), a chelator for [^{64}Cu], to introduce micro-PET/CT imaging functionality. *In vivo* biodistribution studies using micro-PET/CT in mice indicated that transferrin (Tf)-targeted and nontargeted nanoparticles have similar biodistribution and pharmacokinetic profiles (Figure 9). However, tissue analysis by bioluminescent imaging indicated that the targeted nanoparticles achieved greater target gene knockdown and thus had greater siRNA efficacy.

In a separate set of studies, Schneider et al.[39] studied intracellular trafficking of DNA/lipid complexes (lipoplexes) in rat smooth muscle cells (A10) via FRET. DNA and lipids were labeled with Cy3 and Cy5, respectively, and analyzed via flow cytometry, confocal microscopy, and fluorimetric techniques to calculate the donor- (E_d) and acceptor-based (E_a) efficiencies of energy transfer (Figure 10). Different optical settings (donor excitation wavelengths) were used for flow cytometry (excitation = 488 nm) and microscopy (excitation = 523 nm) to study the kinetics of lipoplex dissociation. Analysis of the efficiency of donor- and acceptor-based energy transfer studied at different time points (3, 5, 9, and 24 h) indicated that most of the DNA was released from the lipoplexes by 24 h post-transfection. These findings and techniques are crucial to understand the intracellular trafficking and mechanism of vehicle unpackaging, and their studies have highlighted the value of FRET to facilitate information acquisition with high spatial resolution inside the cell.

Several kinds of drug delivery vehicles have been developed over the years, such as polymeric micelles, block copolymers, liposomes, inorganic iron oxide nanoparticles coated with a biocompatible polymer, and quantum dot conjugates. These vehicles have been used to deliver a variety of hydrophobic/hydrophilic anticancer drugs such as paclitaxel, doxorubicin, methotrexate, and camptothecin. In addition to inclusion of these drugs, the delivery vehicles can be decorated with various imaging agents to simultaneously monitor the therapeutic delivery.

With the increasing concerns of nephrogenic system fibrosis due to gadolinium-based blood pool agents in patients with renal disease or with recent liver transplant,[40] several approaches[41,42] have been recently taken to substitute gadolinium with manganese (Mn). For example, Pan et al.[41] developed a fibrin-targeting "nanobialys"-based contrast agent and drug delivery vehicle containing a porphyrin which chelates Mn. "Nanobialys" are toroidal-shaped, nearly monodisperse reverse micellar structures formed from amphiphilic branched polyethyleneimine (PEI) in anhydrous chloroform with a core containing a porphyrin−Mn(III) complex, which is a T_1 contrast agent for MRI (Figure 11a). Amphiphilic PEI was modified by reaction of amines with hydrophobic linoleic acid (55% of primary amines were reacted) via EDC coupling. The core of the micelles was loaded with a hydrophobic (camptothecin) or hydrophilic (doxorubicin) chemotherapeutic drug, and the drug release profile was studied *in vitro* for 3 days (Figure 11c). The MR imaging of fibrin (Figure 11b) was performed with fibrin-rich clots supported on silk sutures in phosphate-buffered saline (PBS) with the help of sealed polystyrene test tubes. The MR imaging results for

(2008) Ligand-directed nanobialys as theranostic agent for drug delivery and manganese-based magnetic resonance imaging of vascular targets. *J. Am. Chem. Soc. 130,* 9186-9187. with permission from ACS.

targeted ligand-containing nanobialys (containing a fibrin-specific monoclonal antibody) were compared to nanobialys without any targeting ligand or without any metal inside as controls and demonstrated the role of the targeting agent in achieving contrast enhancement.

Shin et al.[42] developed manganese oxide-based hollow nanoparticles (HMONs) as dual (T_1 and T_2) MRI contrast and drug delivery agents. HMONs were synthesized by stabilization of manganese oxide nanoparticles with oleate, encapsulation with poly(ethylene glycol)-phospholipid, and selective removal of the manganese oxide core in acidic phthalate buffer solution (pH = 4.6) to dope it with doxorubicin (DOX). Cell culture studies indicated that these HMONs were efficiently taken up by cultured cancer cells and induced cell death. High T_1 and T_2 image contrast was obtained upon MR imaging of transfected cells as well as the brain of a mouse injected with HMONs (Figure 12).

It has been shown that, at very low concentrations, circulating iron can impart T_1 contrast to MR imaging; however, at concentrations that are commonly used for T_2-weighted imaging, T_2 contrast is the predominant effect.[43] Encapsulation of iron oxide within a hydrophobic matrix can abate the T_2 effect and, thereby, improve T_1 contrast; hence, this can enable one to develop positive contrast agents that are devoid of the gadolinium cation. Senpan et al.[43] developed vascular-targeted colloidal iron oxide nanocolloids for the detection of atherosclerotic ruptured plaques and antiangiogenic plaque therapy. These nanoparticles can be loaded with an antiangiogenic mycotoxin drug, fumagillin (Figure 13a). Colloidal iron oxide nanocolloids with phospholipids containing a partially cross-linked hydrophobic core and a low concentration of pure magnetite iron oxide particles (0.5% w/v) show high T_1 relaxivity (7 [Fe] mM^{-1} s^{-1}) compared to those with a mixed core (Fe_2O_3—Fe_3O_4 mixture,

1.3 [Fe] mM^{-1} s^{-1}) and show potential as an alternative to gadolinium-containing agents (Figure 13b).

Calcium phosphate-based delivery vehicles can be effective for the delivery of hydrophobic, insoluble drugs such as ceramide and camptothecin. Calcium phosphate nanoparticles are relatively insoluble at physiological pH (pH = 7.4) but have improved solubility in acidic pH environments (pH = 6.5). Upon endocytosis, calcium phosphate will release the drug only in acidic compartments of the cell (endosomes and lysosomes), thus reducing the off-target toxicity in systemic administration. Researchers[44,45] have used this pH-tunable solubility to develop calcium phosphate-based vehicles for controlled, pH-triggered drug delivery. Kester et al. developed colloidally stable, amine carboxylate- and poly(ethylene glycol)-functionalized calcium phosphate nanoparticles (CPNPs) for delivery of ceramide (Cer6 and Cer10) and a fluorescent dye, rhodamine-water tracer (Rh-WT), to melanoma and breast adenocarcinoma cells.[45] Upon encapsulation into CPNPs, lifetimes and quantum properties of fluorescent dyes are believed to be improved.[46,47] Nanoparticles lacking any drug within were nontoxic (Figure 14) at low concentrations, and drug encapsulation induced apoptosis in neural, melanoma, and breast adenocarcinoma cells measured by MTS assay.

Barth et al. further modified CPNP with PEG groups and one of two different antibodies targeting the gastrin (gastrin-10-PEG-CPNP) and transferrin receptor (antiCD71-Avidin-CPNP), respectively.[44] These materials were created to study the *in vivo* biodistribution of CPNPs in murine models containing pancreatic (orthotopic) and breast (subcutaneous) cancer tumors. *In vivo* imaging using NIR microscopy (indocyanine green, ICG) on athymic female mice bearing tumor xenografts indicated greater tumor accumulation of targeted nanoparticles than non-targeted ones and penetration through the blood-brain barrier (Figure 15).

Langer and co-workers[48,49] developed poly(ethylene oxide) (PEO)-modified poly(β-amino ester) (PbAE)-based materials as novel, pH-responsive, nontoxic, and biodegradable nanoparticle drug carriers. Solid unprotonated PbAEs (Figure 16a) are insoluble at physiological pH; however, the solubility increases upon protonation of the amines along the backbone. Below

pH 6.5, PbAEs release their payload of chemotherapeutic drug, such as paclitaxel. *In vivo* biodistribution of encapsulated polymeric nanoparticles was studied in nude mice via radiolabeling using ^{111}Indium oxine (Figure 16b). When tumor-bearing (human ovarian adenocarcinoma) mice were evaluated 5 h after intravenous administration, 23-fold and 8.7-fold increases in tumor accumulation (compared to an aqueous solution of paclitaxel) were observed for paclitaxel-loaded PEO-PbAE nanoparticles and PEO-poly(caprolactam) (PCL) nanoparticles, respectively.

In another approach to theranostics, magnetoplasmonic nanoparticle assemblies (MPAs) combine both the magnetic and optical properties of metal nanoparticles and can be imaged with both magnetic resonance imaging and photoacoustic imaging. The general method for synthesizing these nanoparticles is by gradual reduction of gold nanoparticles in the presence of magnetic metal particles. The field of MPAs has been primarily restricted to hyperthermia or photothermal ablation treatment in cancer therapy thus far, and there have been few examples of incorporation of anticancer drugs within these nanoparticles. Chen et al.[50] synthesized magnetoplasmonic particles with a magnetic iron oxide (Fe_3O_4) core by coprecipitation—the core was coated with a porous, water-dispersible silica layer and then functionalized with gold nanoparticles, forming corona-like structures via surface amine functionality. This corona-like morphology was studied in MPAs containing curcumin, an anticancer drug (Figure 17a), using transmission electron microscopy (TEM) (Figure 17c); the particle size was determined to be ∼400 nm and ∼600 nm for MPA-curcumin and MPA-PEG-curcumin, respectively. The T_2 relaxation time of human leukemia cells (HL-60) transfected with MPA particles loaded with curcumin was lower than that of untransfected cells, as expected. Further, results of an MTT assay to examine therapeutic efficiency revealed that, while MPA-PEG-curcumin outperforms MPA-curcumin, both are potent inducers of apoptosis in HL-60 cells (Figure 17b).

Several research groups have introduced multimodal imaging functionalities into drug delivery vehicles. For example, Xie et al.[51] adapted a novel approach of treating iron oxide nanoparticles (IONPs) with dopamine to make them moderately hydrophilic, thereby allowing them to be doped into human serum albumin (HSA) matrices in a way very similar to that used for drug loading. Using this technique, IONPs were surface functionalized with Cy5.5 (fluorescence imaging) and [^{64}Cu] (PET imaging) via NHS ester-NH_2 coupling (Figure 18a). For *in vivo* and *ex vivo* imaging, animal models were prepared by subcutaneously injecting glioblastoma cells (U87MG) into the

front flank of each mouse. Images were obtained at 1, 4, and 18 h postinjection for PET and NIRF imaging (Figure 18b) and at 18 h postinjection for MR imaging. MR imaging studies with HSA-IONPs indicated higher relaxivity (r_2) values and longer blood circulation half-life than a frequently used contrast agent, Feridex.

Liong et al.[52] synthesized mesoporous silica nanoparticles doped with superparamagnetic iron oxide nanocrystals and hydrophobic anticancer drugs, such as camptothecin (CPT) or paclitaxel (TXL), and functionalized with hydrophilic groups, like phosphonates, onto the surface to achieve high stability in aqueous solutions (Figure 19a). Incorporation of silica into theranostic nanoparticles like these can impart numerous desirable properties—silica nanoparticles are known to be endocytosed by cells, provide a mesoporous matrix capable of being doped with other inorganic metal particles (such as gold and iron oxide), and can be easily functionalized owing to silane linkers present on their surface. Additionally, a fluorescent dye, fluorescein isothiocyanate (FITC), and α-folate receptor-targeting folic acid groups were conjugated on the surface to promote uptake by tumor cells. Cellular uptake studies carried out in two types of pancreatic cancer cells, PANC-1 and BxPC3, indicated nanoparticles were internalized within 30 min of transfection. By comparison with drug-free nanoparticle controls, which were nontoxic, the toxicity of these nanoparticles was attributed to its drug payload (Figure 19b).

In order to achieve a high therapeutic concentration at the site of interest and to reduce off-target effects, several researchers have developed targeted theranostic agents to address specific receptors or proteins that are overexpressed in cancer targets, as has been mentioned above. In another example of this, Gao and co-workers[53,54] have developed targeted polymeric micellar architectures for drug delivery and magnetic resonance imaging. The core−shell morphology helps to introduce different hydrophobic functionalities (therapeutic and imaging) into the core, and the hydrophilic shell improves the stability in aqueous system and prevents aggregation. Polymeric micellar structures based on amphiphilic block copolymers maleimide-terminated poly(ethylene glycol)-*block*-poly(D,L-lactide) copolymer (MAL-PEG-PLA) and methoxy-terminated poly(ethylene glycol)-*block*-poly(D,L-lactide) copolymer (MPEG-PLA) were developed and loaded with doxorubicin (DOX) and superparamagnetic iron oxide (SPIO). Functionalization of these polymeric micelles was performed with $\alpha_v\beta_3$ integrin receptor-targeting cRGD peptide via thiol-maleimide reaction, and different extents of cRGD loading (0% vs 16%) were achieved through control of the amount of MPEG-PLA introduced into the system. Incorporation of the targeting group on polymeric micelles showed a concomitant change in cell uptake, MR image contrast (Figure 20a), and DOX-induced cytotoxicity (Figure 20b). Cellular uptake studies performed using flow cytometry and confocal laser scanning microscopy indicated that uptake of targeted particles was about 2.5 times higher than that of nontargeted analogues.

In a separate study, these polymeric micelles were modified with a lung cancer-targeting peptide (LCP) that binds specifically to $\alpha_v\beta_6$ receptors overexpressed on lung cancer cells. The specificity of LCP for $\alpha_v\beta_6$-expressing H2009 cells (lung cancer cells) was evaluated by comparative exposure to $\alpha_v\beta_6$-negative H460 cells and by using micelles containing a scrambled peptide (SP, a peptide with the same amino acid composition as LCP but scrambled sequence) in H2009 cells using [^{3}H] radioactivity measurements, confocal microscopy (Figure 21), and MRI.

The folate receptor is another surface molecule overexpressed on many cancer cells (such as lung, breast, and cervical cancer cells); consequently, numerous groups have imparted folate-receptor targeting in their theranostic nanoparticles. Santra et al.[55] developed a novel synthetic method to prepare biodegradable and

biocompatible poly(acrylic acid)-iron oxide nanoparticles (PAA-IONPs). PAA-IONPs were functionalized with NIR dyes, DiR and DiL, and an anticancer drug, Taxol, by a solvent-diffusion method, then "click" chemistry was used to introduce a folate-receptor targeting ligand. Cytotoxicity and target specificity of folate-functionalized IONP were examined in lung carcinoma cells (A549, overexpress folate receptor) and cardiomyocytes (H9c2, do not overexpress folate receptor) via a MTT assay. The results from the MTT assay indicated almost 100% survival, for both A549 and H9c2 cells, when exposed to control Taxol-free PAA-IONPs. However, upon Taxol encapsulation in these PAA-IONPs, cell survival for A549 reduced to 20% after 3 h incubation, whereas cell viability for H9c2 cells remained unchanged. These results indicate specificity of PAA-IONPs toward tumor cells that overexpress folate receptor. Drug/dye release was only observed in acidic pH or in the presence of esterase, a degradative enzyme.

In another example of targeting of the folate receptor, Kohler et al.[56] covalently functionalized superparamagnetic iron oxide (SPIO) nanoparticles with an anticancer drug, methotrexate (MTX). MTX was incorporated via a peptide linkage that is reducible under acidic pH, thereby releasing the drug into the cell upon reaching the acidic environment of the endosome/lysosome. MTX is a reduced form of folic acid that inhibits dihydrofolate reductase, thereby stopping the folic acid cycle and inducing cellular toxicity. The delivery efficacy and cytotoxicity of MTX-loaded SPIO nanoparticles vs free MTX was tested in human cervical cancer cells (HeLa) and breast cancer cells (MCF-7). The endocytosis of these particles was confirmed to be folate-receptor-mediated, as determined by use of an acidic condition (to mimic lysosomes) and TEM.

Das et al.[57] synthesized N-phosphonomethyl iminodiacetic acid (PMIDA)-functionalized ultrasmall iron oxide nanoparticles

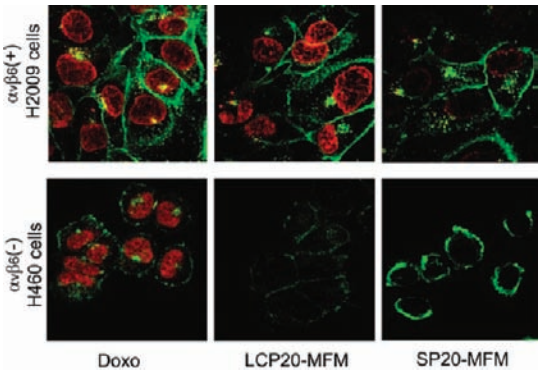

Figure 21. Evaluation of the cellular uptake of LCP-functionalized, doxorubicin (Doxo)-loaded multifunctional micelles (LCP20-MFM) in $\alpha_v\beta_6$-positive H2009 cells (top panels) and $\alpha_v\beta_6$-negative H460 cells (bottom panels) by fluorescence microscopy. Free Doxo (left panels) and MFM functionalized with a scrambled peptide (SP20-MFM, right panels) were used for comparison with LCP20-MFM (center panels). The cell membrane was stained with Alexa Fluor 350 and pseudocolored with green; Doxo fluorescence is indicated in red.

(USPIO) equipped with (i) rhodamine B isothiocyanate (RITC) for optical imaging, (ii) a chemotherapeutic drug, methotrexate (MTX), and (iii) folic acid (FA) for targeting the folic acid receptor. They initially synthesized amine-functionalized iron oxide nanoparticles via a two-step process. First, the USPIOs were synthesized by an alkali-mediated chemical coprecipitation process in the presence of PMIDA containing one phosphonic and two carboxylic groups. This process creates stable nanoparticles with high interparticle repulsion due to negatively charged carboxylic and phosphonate groups on the surface. An amine-functionalized surface was then generated by reacting the terminal carboxylic acids with diamine (EDBE) in the presence of EDC and NHS. This amine functionality was further utilized to introduce MTX, RITC, and FA onto the particle to make USPIO-PMIDA-EDBE-RITC-FA. These authors were the first to functionalize an iron oxide surface with phosphonate groups (as opposed to solely using carboxylate groups, which is more common). The benefit of using phosphonate groups—instead of or in addition to carboxylate group—is that the phosphonate bond increases thermal stability and reduces susceptibility to enzymatic degradation. These targeted USPIO-PMIDA-EDBE-RITC-FA particles showed significantly higher cell uptake and MTX-induced cytotoxicity for folate receptor-expressing cancer (HeLa) cells than in nonfolate receptor-expressing (MG-63) cells.

In a final example of iron oxide-containing theranostic nanoparticles, Kim et al.[58] have developed a facile synthetic route (Figure 22a) with good control over size to synthesize monodisperse, discrete mesoporous silica materials (smaller than 100 nm) containing a single Fe_3O_4 nanocrystal as a core ($Fe_3O_4@mSiO_2$). Fluorescent dyes, rhodamine (R) or fluorescein (F) isothiocyanate, were covalently attached to the silica surface and doxorubicin (DOX) was encapsulated within the silica matrix. Next, the surface of the rhodamine-containing nanoparticles was functionalized with PEG groups ($Fe_3O_4@mSiO_2$(R)-PEG) to minimize nonspecific interactions and lengthen the blood circulation half-life. DOX-induced cytotoxicity was studied by transfecting SK-BR-3 cells with DOX-loaded $Fe_3O_4@mSiO_2$(R)-PEG nanoparticles. *In vivo* studies were performed by subcutaneously injecting MCF-7 cells pretreated with $Fe_3O_4@mSiO_2$(R)-PEG particles into the dorsal shoulder of nude mice. The MCF-7 cells containing $Fe_3O_4@mSiO_2$(R)-PEG particles were easily detectable as dark spots on T_2-weighted MR images and elicited significant rhodamine fluorescence when examined by fluorescence imaging (Figure 22b).

Quantum dots (QDs) are semiconductor materials with cadmium−selenium (Cd−Se) or cadmium−tellurium (Cd−Te) cores. As mentioned earlier, some of the major advantages of using QDs over fluorescent dyes are high extinction coefficients, control over optical properties, and reduced susceptibility to photobleaching. In addition, many QDs are known to form FRET pairs with fluorescent dyes, which allow them to be effectively used to understand intracellular trafficking and unpackaging of particles that contain them.[14,59−61]

Bagalkot et al.[62] have developed multifunctional nanoparticles for drug delivery based upon QDs that are capable of detecting

Figure 23. and treating cancer. They have created a novel, QD-targeting aptamer−doxorubicin conjugate (QD-Apt(Dox)) (Figure 23) that effectively targets prostate cancer cells via incorporation of an RNA aptamer (A10), which binds prostate-specific membrane antigen (PSMA). QD-Apt (Dox) systems were synthesized by first conjugating amine-terminated A10 aptamer with carboxylic group-functionalized QDs via EDC coupling and NHS activation chemistry. Once the aptamer is immobilized on the QD surface, Dox was introduced and conjugated by CG-sequence intercalation within the PSMA-targeting aptamer. The release of Dox from the delivery vehicle was detected from the conjugate via bimolecular FRET (Bi-FRET, Figure 23a,b). When the QD-Apt (Dox) conjugate is intact, both the QD and Dox fluorescence are in the "OFF" state—QD fluorescence is quenched by Dox, and Dox fluorescence is simultaneously quenched due to intercalation within the A10 aptamer. However, upon the dissociation of the conjugate/complex to release drug, the fluorescence is turned "ON"; hence, this system can be used to monitor intracellular vehicle unpackaging to release its cargo. The specificity of the A10 aptamer for PSMA was tested via MTT assay and confocal microscopy by transfecting QD-aptamer (Dox) conjugates into LNCaP (PSMA+) and PC3 (PSMA-) prostate adenocarcinoma cells. Minimal cytotoxicity resulting from QD-Apt(Dox)) was observed for PC3 cells compared to LNCaP cells, whereas comparable toxicity was achieved in these two cells for free Dox. These results together indicate successful targeting of these QD-containing theranostics to PSMA via inclusion of the A10 aptamer.

In photodynamic therapy (PDT), a photosensitizer-containing drug is delivered to the tumor cell that, upon light activation, generates "killer" singlet oxygen and free radicals (reactive oxygen species (ROS)) that induce apoptosis. PDT is currently being explored as a novel cancer treatment strategy. Three important things for the success of PDT are (i) minimized systemic toxicity, (ii) adequate oxygen permeability and drug (or O_2) diffusion in the diseased region, and (iii) sufficient concentration of photosensitizer in the region of interest (must have a high singlet oxygen quantum yield). These requirements are necessary to minimize the thermal damage due to photoirradiation and to avoid unwanted toxicity to neighboring healthy cells.

Porphyrin derivatives are the most commonly used photosensitizers in PDT. When irradiated with the required wavelength, the porphyrin produces cytotoxic singlet oxygen species via reaction of excited-state porphyrin with nearby molecular oxygen. In PDT, off-target toxicity can be prevented because generating the cytotoxic species only occurs at the site of illumination, which allows the therapy to be localized. This localized accumulation of the drug can further be enhanced by conjugation with targeting moieties and/or encapsulation in nanoparticles to increase concentration at the target site. Attachment of targeting groups can help to reduce one of the major limitations associated with PDT—increased patient photosensitivity due to prolonged accumulation of the drug within the skin.

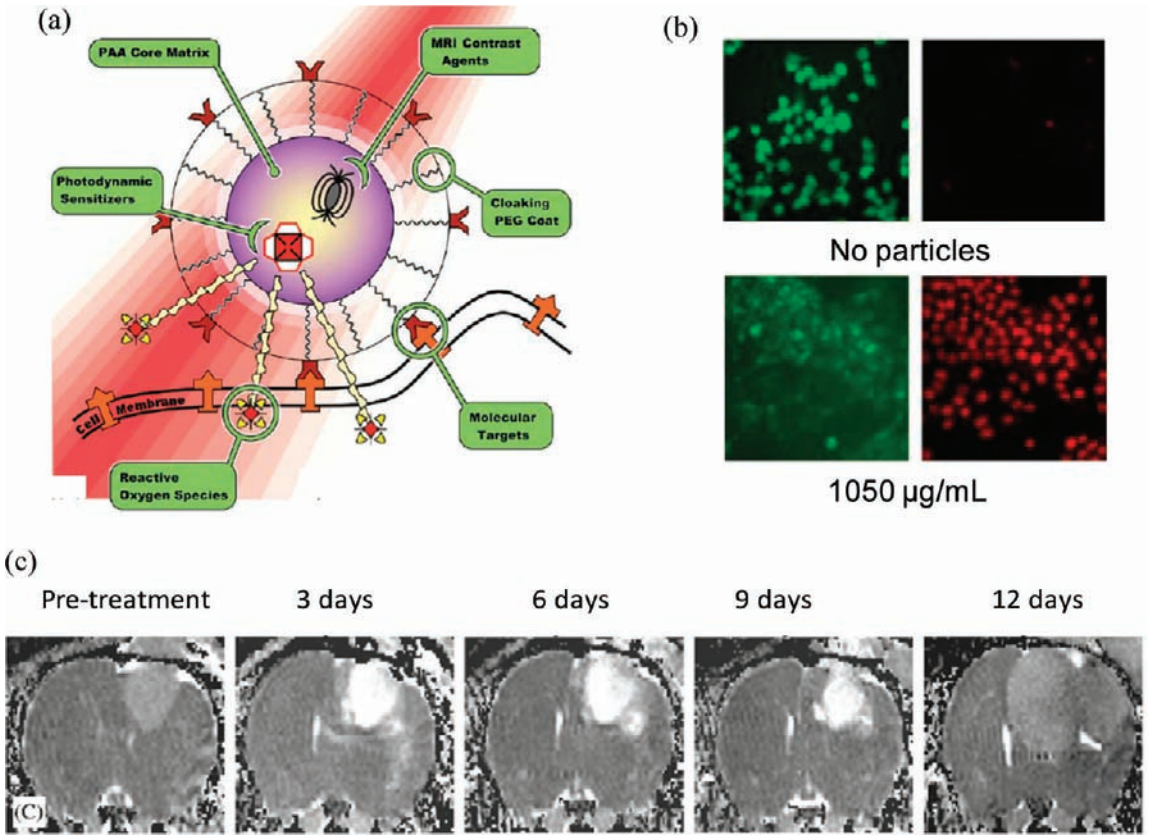

Figure 25. (a) Schematic of PAA-based multifunctional nanoparticles for photodynamic therapy. (b) *In vitro* cell kill test on 9 L glioma cells that were untreated (top) or transfected with 1050 μg/mL of PAA particles containing PHOTOFRIN (bottom). Live cells are stained with calcein acetoxymethylester (green) and dead cells with propidium iodide (red). (c) Diffusional MR imaging of rat 9 L gliosarcoma model treated with PAA nanoparticles containing PHOTOFRIN and irradiated with a laser for PDT. Treatment produced massive regional necrosis, demonstrated by large "bright" regions in the images, which resulted in shrinkage of the tumor mass. Regrowth occurred at 12 days post-treatment.

(2005) Multifunctional nanoparticle platforms for in vivo MRI enhancement and photodynamic therapy of a rat brain cancer. *J. Magn. Magn. Mater. 293*, 404-410 with permission, Copyright Elsevier (2005).

McCarthy et al.[63] developed macrophage-targeted theranostic nanoparticles (TNPs) for PDT application to cardiovascular diseases such as atherosclerosis and in-stent restenosis. Dextran-coated superparamagnetic iron oxide nanoparticles targeting the dextran receptor, SIGNR1, on macrophages were synthesized[64−68] and functionalized with a photosensitizer, 5-(4-carboxyphenyl)-10,15,20-triphenyl-2,3-dihydroxychlorin (TPC), and a fluorescent dye, Alexa Fluor 750, through covalent bonding with amine groups present on the surface of iron oxide particles. Cell uptake and light-induced phototoxicity studies carried out in a murine macrophage (RAW 264.7) cell line transfected with TNPs (0.1 mg Fe per mL) indicated only 35% cell survival after 1 h irradiation with a 646 nm laser. No toxicity was observed for TNPs without any photosensitizer loaded. TNPs (0.2 mg Fe per mL) caused as high as 100% cell death (Figure 24) after irradiation with a 646 nm laser for 1 h in human macrophage (U937) cells.

Kopelman et al.[69] have developed an extracellular PDT drug for imaging and treatment of brain tumors. This agent incorporates a photosensitizer, PHOTOFRIN (a complex mixture of porphyrin oligomers), into a polyacrylamide (PAA) core along with MRI contrast agents; it is further functionalized with PEG groups and the RGD targeting peptide on the surface of these nanoparticles (Figure 25a). Some of the major advantages of encapsulating PHOTOFRIN within a nanoparticle are that it (i) reduces the direct exposure of the drug to the physiological milieu, (ii) reduces cutaneous photosensitivity post-treatment, and (iii) significantly reduces the wait time (from 24 to 1 h) between intravenous injection of the drug and subsequent laser irradiation. The value of including a targeting ligand was demonstrated when RGD peptide-bearing nanoparticles showed higher accumulation in $\alpha_v\beta_3$-expressing cancer cells (MDA-435) than $\alpha_v\beta_3$-negative MCF-7 cells. *In vivo* pharmacokinetic behavior, studied in rats bearing 9 L gliosarcoma by diffusional MRI, indicated a 50-fold increase in circulation half-life of nanoparticles after PEGylation and a significant increase in the diffusion coefficient of the water surrounding tumor cells, indicating a decrease in rate of tumor growth and shrinkage of tumor mass (Figure 25b). The efficiency of PHOTOFRIN to generate killer singlet oxygen species and cause tumor cell death was also measured using a chemical test employing anthracene-9,10-dipropionic acid, disodium salt (ADPA)—in the presence of singlet oxygen species, the fluorescence of ADPA decays with time. Induction of cell death was also assessed by fluorescence microscopy on 9 L gliomas transfected with PAA nanoparticles containing PHOTOFRIN in varying amounts (Figure 25c). Overall, the nanoparticles were able to effectively kill brain tumors engrafted inside rats within 5 min of light exposure.

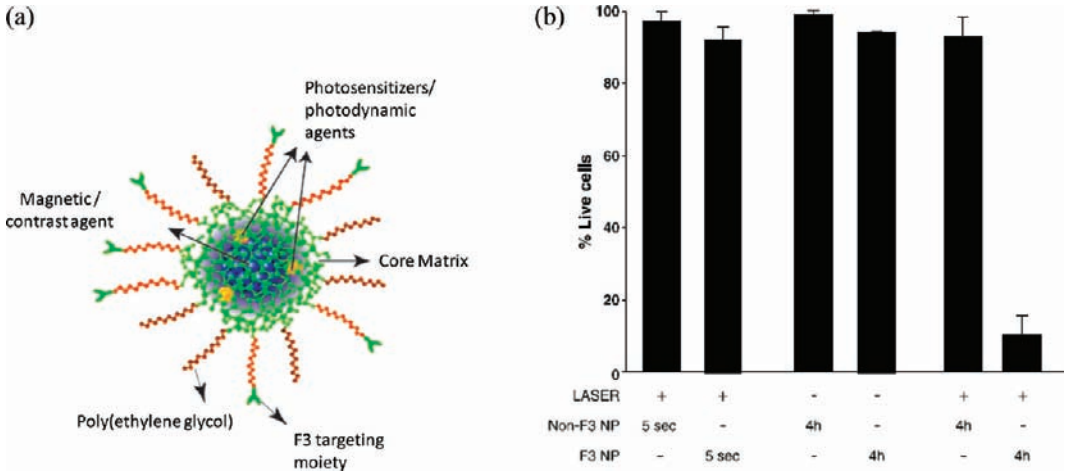

Figure 26. (a) Schematic of targeted PAA nanoparticles for PDT and diffusional MR imaging. (b) Cell viability studies performed on MDA-43 cells with PHOTOFRIN- and iron oxide-encapsulated nanoparticles lacking ("Non-F3 NP") or containing ("F3 NP") the F3 targeting ligand. Only the combination of F3-containing nanoparticles incubated for 4 h and laser irradiation significantly reduced the percentage of live cells.

L., Woolliscroft, M. J., Sugai, J. V., Johnson, T. D., Philbert, M. A., Kopelman, R., Rehemtulla, A., and Ross, B. D. (2006) Vascular targeted nanoparticles for imaging and treatment of brain tumors. *Clin. Cancer Res. 12*, 6677-6686.

Studies have shown that PDT can be promising for treatment of malignant brain tumors, for which more than 80% of the tumor growth recurs after therapy. Being a localized therapy, PDT has the potential to be very beneficial in this scenario.[70−74] A dose-dependent increase in survival rate of glioblastoma patients has also been shown, further suggesting that the future of this therapy is bright.

Reddy et al.[75] have synthesized PHOTOFRIN- and superparamagnetic iron oxide-encapsulated uniform poly(acrylamide) (PAA) nanoparticles (~40 nm) decorated with PEG groups and a vascular homing and cell-penetrating F3 peptide on the surface which targets brain cancer cells (Figure 26a). Laser irradiation (630 nm) for 5 min induced up to 90% cell death 4 h after transfection (Figure 26b). *In vivo* administration to 9 L glioma-bearing rats revealed that inclusion of PEG and targeting groups onto the surface increased the tumor half-life (from 39 to 123 min) and T_2-weighted image contrast compared to nontargeted analogues.

Another approach to introduce theranostic functionalities into a nanosystem is to covalently attach a palladium (Pd)-porphyrin chelate to mesoporous silica nanoparticles (MSNs) which are readily taken up by cells. Some of the important properties of MSNs are large surface area (~1000 m^2/g), uniform pore size (~3 nm), particle size (in the range ~70−100 nm), ease of functionalization, large payload capacity, high cellular uptake, and low cytotoxicity. Because of these properties, MSNs have several advantages over normal silica nanoparticles and, thus, are used in a wide array of applications, including chemical catalysis, drug delivery, controlled release of therapeutics, and cell labeling. Pd-porphyrin has a long phosphorescence lifetime and has been used for *in vivo* oxygen sensing and imaging.[76,77] Cheng et al.[78] synthesized (Figure 27a,b) phosphorescent Pd-meso-tetra (4-carboxyphenyl) porphyrin (PdTPP) covalently embedded in MSNs (MSN-PdTPP) as theranostic agents for the imaging and treatment of breast cancer. The energy required for phosphorescence imaging is only 10^{-4}−10^{-5} times that required for conventional PDT. Also, the concentration of singlet oxygen species generated during oxygen sensing/imaging is much lower compared to that during conventional PDT and, thus, by changing the energy of photoirradiation, the functionalities of MSN-PdTPP can be "switched" between a phosphorescence probe for oxygen sensing/imaging (diagnostics) and a photosensitizer for PDT (therapy). Breast cancer cells (MDA-MB-231) transfected with 25 μg MSN-PdTPP for 2 h at 37 °C, followed by photoirradiation (532 nm wavelength with energy 1.2 J/cm^2), showed a significant change in cell morphology and large extent of cell death indicated by high propidium iodide fluorescence (Figure 27c).

PDT is an FDA-approved first-line treatment for age-related macular degeneration and is routinely used for obstructive esophageal cancer and some forms of lung cancer.[79−81] One of the approaches for cancer treatment includes therapies that block or interrupt a specific cellular pathway or proteins involved in cell proliferation. One of these proteins is the K_i-67 protein (pKi-67), which is upregulated in highly proliferating cells during all active cell cycles (G1, S, and G2, as well as mitosis). Rahmanzadeh et al.[82] used a noncationic liposome-based vehicle for delivering fluorescently labeled (fluorescein isothiocyanate, FITC) antibodies, namely, TuBB-9 and MIB-1, that recognize K_i-67 protein in two different states. Twenty four hours after transfection in ovarian cancer cells (OVCAR-5), TuBB-9-FITC- and MIB-1-FITC-containing liposome particles (particle size ~180 nm) were found to be localized in the nucleolar regions (Figure 28a). Irradiation with a 488 nm laser (5 J/cm^2 laser power) resulted in a significant decrease in cell viability for cells incubated with TuBB-9-FITC-labeled liposomes, but not MIB-1-FITC-labeled liposomes (Figure 28b). As expected, no significant toxicity was observed for various controls, including liposome-treated cells that were not irradiated as well as irradiated cells treated with TuBB-9-FITC alone (without the liposomal carrier).

Hyperthermia, also called photothermal ablation, is a physical treatment for cancer involving the killing of cancer cells in the presence of heat. Hyperthermia leads to apoptotic cell death caused by heating of surrounding tissues or cells to a temperature of 42−46 °C; above 46 °C, photothermal ablation causes undesirable necrosis of the surrounding cells.[83,84] With no chemical payload to deliver, hyperthermia is less prone to toxic side effects that often accompany chemotherapeutic agents.

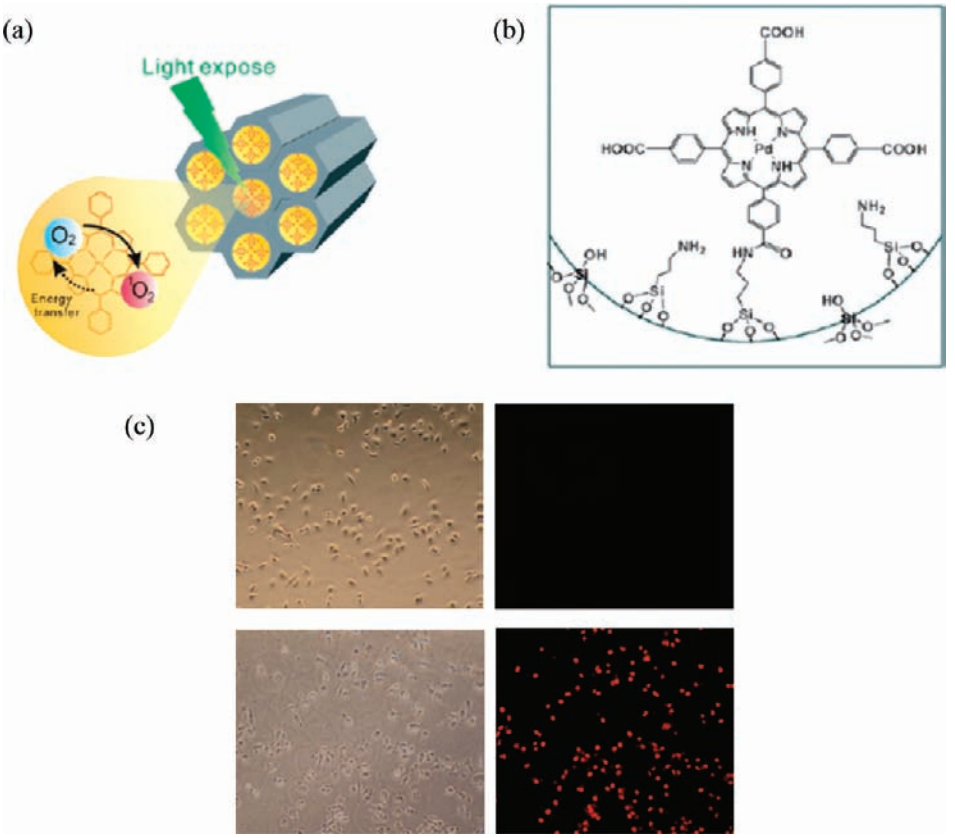

Figure 27. (a) Schematic of the mechanism of PDT with MSN-PdTPP. (b) Chemical structure of PdTPP covalently attached to MSN. (c) Propidium iodide (PI) staining of MDA-MB-231 cells treated with 25 μg of MSN-PdTPP at 37 °C for 2 h and then irradiated with a 532 nm laser. The left panels show the change in morphology of the cells before (top) and after (bottom) treatment, respectively. The right panels show red propidium iodide fluorescence (indicating dead cells) before (top) and after (bottom) treatment, respectively.

Gold nanoparticles are more commonly used for hyperthermia than other heavy metals (such as silver or cobalt) due to the unique interaction of gold with light, which results in surface plasmon resonance (SPR). In the presence of oscillating electromagnetic radiations at a particular resonance frequency, free electrons in gold undergo collective coherent oscillations (SPR oscillations) which can decay via heat emission.[85,86] Changing the size, shape, and refractive index (RI) of the material changes its SPR frequency. Ideally, this frequency is tuned in the near-infrared (NIR) region. At NIR wavelengths, the absorption of innate biological fluorochromes and water is low,[87] and thus, the light can penetrate deeper into tissues without causing damage to surrounding healthy cells.

To combine imaging and therapy in the case of gold-containing nanoparticles, architectures with iron oxide cores and gold shells have been explored widely. Gold nanoparticles with iron oxide cores, such as magnetite (Fe_2O_4) or maghemite (γ-Fe_2O_4), can be imaged using MRI. The layer of gold surrounding the magnetic iron oxide particles helps to stabilize them from *in vivo* aggregation and reduces their toxicity. The desired NIR absorption frequency for gold nanoparticles can be achieved by coating them with silica, which has a high dielectric constant and, thus, helps to lower the absorption frequency toward NIR wavelengths.[85] Iron oxide particles impart a high T_2 relaxivity (good negative contrast for MRI) and, in the presence of a magnetic field, can be localized to the site of interest. This therapeutic targeting strategy is known as magnetic field-directed hyperthermia.[88]

As an example of magnetic field-directed hyperthermia, researchers have developed human epidermal growth receptor 2 (HER2)-targeted gold nanoparticles for breast cancer treatment. Kim et al.[89] designed magnetic gold nanoshells (Mag-GNS) consisting of a magnetic iron oxide (Fe_2O_4) and silica core surrounded by a 15 nm gold shell. For breast cancer targeting, Mag-GNS functionalized with an antibody targeting HER-2/neu receptor ($Ab_{HER2/neu}$), a cell surface molecule that is overexpressed on breast cancer cells. SKBR3 breast cancer cells and lung cancer cells (H520 cells, which do not overexpress HER2/neu) were treated with $Ab_{HER2/neu}$−containing Mag-GNS for 2 h at 37 °C. Upon subsequent exposure to a femtosecond-long laser (800 nm) pulse, Mag-GNS-transfected SKBR3 cells exhibited significant cell death. T_2-weighted MR images of transfected SKBR3 cells and H520 cells showed higher image contrast for targeted particles than untransfected cells (Figure 29), with SKBR3 cells exhibiting enhanced contrast relative to H520 cells, as expected.

In a related study, Lim et al.[90] synthesized core−shell-type structures in which 9−11 nm magnetic iron oxide cores were covered with 2−3 nm hollow gold nanoshells (HGNS); the resulting materials (Fe_3O_4@Au) were surface-functionalized

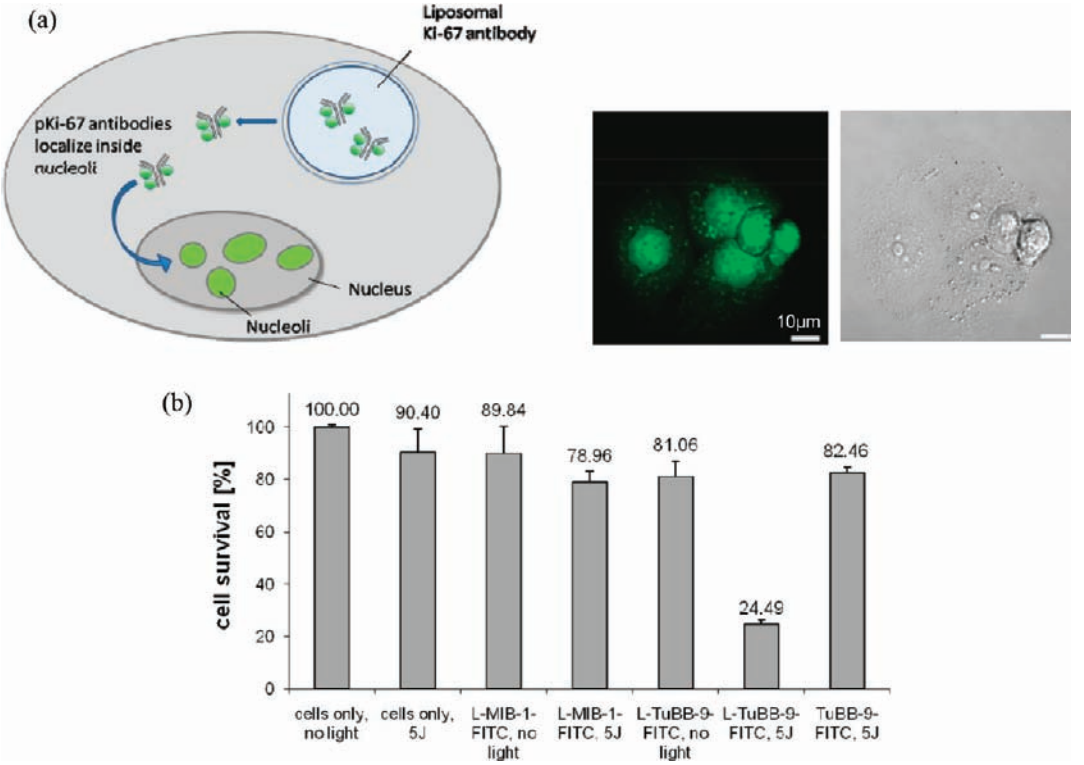

Figure 28. (a) Schematic and fluorescence micrograph of intracellular (nucleolar) localization of pKi-67-targeting liposomes. (b) MTT cell toxicity assay performed on ovarian cancer (OVCAR-5) cells incubated with TuBB-9-FITC-labeled liposomes (L-TuBB-9-FITC) indicated that more than 75% cells experienced death upon light irradiation (denoted 5J); minimal cell death was observed to upon treatment with various controls.

with anti-HER2 monoclonal antibodies (Figure 30a). The specificity of the antibody attached on the surface of HGNS (Fe_2O_3@Au) was tested in SKBR3 (HER2-positive) and MCF-7 (HER2-negative) cancer cells by further labeling these particles with tetramethyl rhodamine isothiocyanate (TRITC); TRITC fluorescence was only seen in SKBR3 cells, implicating HER2 engagement in the uptake of these nanoparticles. Photothermal therapy performed on treated SKBR3 cells with an 808 nm laser

resulted in cell death within 3 min of exposure without causing any damage to unexposed cells (Figure 30b).

Hybridization of $MnFe_2O_4$ with gold nanoparticles can help to combine MR imaging and hyperthermia treatment for cancer therapy. Recently, it has been shown that clustering of magnetic nanoparticles increases their MR properties.[91−93] Magnetic contrast agents consisting of magnetic kernels of manganese and iron oxide clusters were used to improve image contrast. Lee et al.[94] developed quadruple-layered theranostic agents (Figure 31a) for hyperthermia treatment by embedding a number of magnetic kernels in a silica layer, followed by coating with a layer of gold nanoparticles, and then finally incorporating a PEG layer and a targeting antibody, Erbitux (ERB), which binds to epidermal growth factor receptor (EGFR) that is overexpressed on certain cancer cells. T_2-weighted MR imaging of these multifunctional magnetic gold nanocomposites (MGNCs), performed on a 1.5 T magnetic scanner, indicated a dose-dependent increase in relaxivity upon increase in MGNC concentration. The specificity of the ERB antibody for EGFR-expressing tumor cells was tested via MTT assay by adding ERB- vs irrelevant antibody (IRR)-functionalized MGNCs to A431 (overexpress EGFR) and MCF7 (low EGFR expression) cells, followed by irradiation with a NIR laser (Figure 31b).

In 1957, Gilchrist and co-workers[88] first introduced the concept of magnetic fluid hyperthermia (MFH), whereby magnetic particles, in the presence of a magnetic field, produce heat by hysteresis loss and, thus, can be used for hyperthermia treatment. Comes Franchini et al.[95] employed this technique to develop (Figure 32) bovine serum albumin (BSA)- and poly(lactic-*co*-glycolic acid) (PLGA)-coated magnetic nanocarriers containing a cobalt−iron oxide (PLGA-BSA-$CoFe_2O_4$) core. In the presence of a high-frequency magnetic field (168 kHz, 21 kA/m), these particles can heat the surrounding cells up to 48 °C. At these conditions, an impressive 82% cell death is induced within 1 h of treatment. It is proposed that introducing structural anisotropy (such as via cobalt) into the iron oxide magnetic nanoparticles increases their hyperthermia efficiency and possibly also their magnetic contrast property. *In vivo* studies on the brain and liver of rats indicated that these PLGA-BSA-$CoFe_2O_4$ particles show higher image contrast compared to a commercial contrast agent, Endorem.

Radiation therapy uses high-energy radiations, such as X-rays, γ rays, and charged particles, to kill target cancer cells.[96]

Octreotide	D-Phe-Cys-Phe-D-Trp-Lys-Thr-Cys-Thr (ol)
[Tyr^3]octreotide	D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-Thr (ol)
[Tyr^3]octreotate	D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Cys-Thr

Figure 33. Structures of somatostatin analogues: octreotide, Tyr^3-octreotide and Tyr^3-octreotate
Figure adapted from de Jong, M., Breeman, W. A. P., Kwekkeboom, D. J., Valkema, R., and Krenning, E. P. (2009) Tumor imaging and therapy using radiolabeled somatostatin analogues. *Acc. Chem. Res. 42*, 873-88 with permission from ACS.

Radiation can be received externally or internally, the latter occurring via a dosage of radioactive materials which emit radiation upon their decay. This high-energy ionizing radiation causes irreversible damage to DNA, thereby inducing cell death. Another mechanism involved may be generation of free radicals, which can also cause apoptosis of the cells. If employed without any cell surface targeting groups, radiation therapy does not have any specificity toward cancer cells over normal cells. Radiation therapy can be administered as a stand-alone therapy or in combination with other types of cancer treatment, such as chemotherapy or surgical intervention.

Due to increasing concerns associated with albumin-based radiopharmaceuticals (HIV, hepatitis C), Saatchi et al.[97] developed an alternative approach based on biodegradable poly(L-lactide) (PLL) microspheres. PLL microspheres (size 0.5−2 μm) were functionalized with a microSPECT/CT contrast agent, [^{99m}Tc], and decorated with PEG via a double-emulsion solvent evaporation technique. These PEGylated PLL microspheres showed significant accumulation in the liver and the reticuloendothelial system (RES), likely due to macrophage clearance of these large microspheres. When chelated to β-emitting radionuclides such as [^{90}Y], these microspheres can be utilized for radioembolization therapy of liver tumors, uterine fibroids, meningiomas, and arteriovenous malformations, as well as local treatments of leftover and recurring disease.

Radiation therapy can also be performed by delivering radionuclide-functionalized radiopeptides to the tumor cells. Radiopeptides are attractive options in the field of cancer therapeutics because they have rapid clearance, rapid tissue penetration, target accessibility, low antigenicity, and ease of synthesis. For patients with inoperable or metastasized tumors, selective receptor-targeting radiopeptides can be a useful therapy. Radiopeptides labeled with γ- or positron-emitting radionuclides can easily be visualized with diagnostic imaging techniques, like positron emission tomography (PET), or single-photon emission computed tomography (SPECT). These radiopeptides can be labeled with γ-emitters like indium-111 [^{111}In] or [^{99m}Tc] for SPECT imaging and/or positron emitters such as gallium-68 [^{68}Ga] or fluorine-18 [^{18}F] for PET imaging. In addition, when labeled with β-emitting species (such as yttrium-90 [^{90}Y] and lutetium-177 [^{177}Lu]), they can effectively eradicate the targeted tumor cells.[98]

Last, radiopeptides that target the somatostatin receptor (which is overexpressed on the surface of a majority of neuroendocrine tumors) show promise for both imaging and therapy of tumors in which other therapies are ineffective. Somatostatin analogues containing FDA-approved DTPA-octreotide (DTPA = diethylene triamine pentaacetic acid), DOTA-octreotide (DOTA = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), DTPA-Tyr^3-octreotide/octreotate, and DOTA-Tyr^3-octreotide/octreotate have high binding affinity for the subtype 2 (sst_2) of somatostatin receptors (Figure 33).[99,100]

CONCLUSIONS

The field of theranostics remains relatively young but is developing at an incredibly fast rate. Researchers have created numerous nanoparticle-based systems that can be used for therapy, as in cases of hyperthermia or radiation therapy, and/or for delivery of chemotherapeutic drugs and diagnostic imaging agents. Several approaches include multi-imaging modalities that can facilitate tracking of nanoparticles both *in vitro* and *in vivo*. To monitor the therapy and response to therapy at a cellular level, the use of fluorescent labeling agents, such as organic fluorescent dyes or quantum dots, can permit achievement of high-resolution images delineating different organelles inside the cell. However, for *in vivo* purposes, modalities such as PET or SPECT agents and MRI contrast agents are preferred to overcome problems of background fluorescence and photobleaching.

Theranostic agents can play major roles both in early stage drug development and as clinical-stage therapeutic-containing drug candidates. *In vitro* imaging agents are important during early development, such as for modification of chemical structure and architecture to fine-tune drug properties. However, *in vivo* agents are important for advanced studies that may be promising for clinical trials. Until now, theranostics have not reached clinical trials; this field is, however, relatively young and issues related to ambiguity and/or difference between the optimum concentrations for the therapeutic and imaging agents are in the process of being resolved. For example, for systems with nuclear imaging agents, such as 2-[^{18}F]-2-deoxyglucose (FDG), and anticancer chemotherapeutics, such as doxorubicin, the dosages required for success of the individual modalities are vastly (several orders of magnitude) different. Systems with MRI agents based on gadolinium and therapeutic drugs can face similar problems because of the inherent low sensitivity of MRI. The minimum dosage required for Gd-based imaging agents, such as Magnevist, is 100 mg/kg, which is typically considerably higher than the appropriate therapeutic dose.[2] These mismatches can be overcome by exploring different combinations of diagnostic and therapeutic agents, developing new drugs that are potent at lower concentrations, and creating more advanced and sensitive imaging techniques that match the dose required for therapy and imaging. Research into theranostics that can overcome these obstacles and be suitable for important applications remains rich, and the time before theranostics begin clinical evaluation is likely to be short.

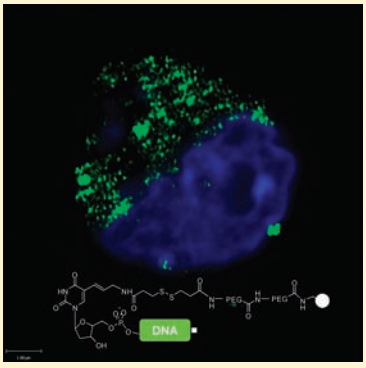
Supporting Information

ABSTRACT: A new approach for microsphere-mediated delivery of plasmid DNA has been developed and successfully evaluated. Basic molecular biology techniques were used to linearize and functionalize plasmid DNA by aminomodification, enabling efficient conjugation to carboxy-functionalized microspheres. A T cell hybridoma line was successfully transfected as determined by the efficient expression of a biologically relevant YFP fusion protein. Moreover, our data identified microsphere-mediated delivery of plasmid DNA as a noninvasive, nontoxic, and efficient gene delivery method with the potential to be applied to transfection-resistant, nondividing primary cells, including naïve T cells.



The development of an efficient carrier system for delivery of plasmid DNA (pDNA) into cells is a key technology for the progress of research in the biological sciences and medicine.[1] In the past few years, different technologies and methodologies have been developed in order to efficiently deliver nucleotides at the cellular level.[2] Examples include cell penetrating peptides,[3,4] cationic lipids,[5,6] nanodevices such as biodegradable nanoparticles[7] and nanotubes,[8] dendrimers,[9,10] polymer-mediated delivery including cationic polymers,[11] cationic amphiphiles,[12] and quantum dots,[13] in addition to more invasive techniques such as particle bombardment[14] and electroporation.[15] Even though all these approaches are currently available, there is still a need to improve transfection efficiency for specific cell lines that are difficult to transfect. We have previously reported that amino-functionalized, cross-linked polystyrene microspheres of highly defined sizes (200 nm to 2 μm) are efficient delivery agents, which can be taken up by a wide range of cell lines including adherent, suspension, primary, and stem cells.[16−18] We have achieved the effective microsphere-based delivery of siRNA[19] and proteins[20] among other biological cargos.[21−23] Recently, we reported the ability of palladium-loaded microspheres to carry out intracellular chemical reactions and their potential use to activate drugs and probes inside cells.[24] While the mechanism of uptake is not yet established, we have recently found that these microspheres are unlikely to enter cells through an endocytic pathway. The application of chemical inhibitors of endocytosis and extensive colocalization studies by microscopy and gene-expression profiling all argue against an endocytic mechanism. Instead, we have proposed an endocytosis-independent uptake mechanism that results in the uncompartmentalized, cytoplasmic localization of microspheres and their cargo.[25] The fact that these latex microspheres are easy to functionalize with high controllability over the cargo loading, in addition to showing no undesired cytotoxic effect, make them enormously attractive as a novel DNA carrier/delivery system.

Here, we describe a novel conjugation approach for microsphere-mediated delivery of pDNA inside cells resulting in expression of the encoded protein. pDNA was linearized and functionalized with 5-(3-aminoallyl)-2′′-deoxyuridine 5′′triphoshate dUTP (aminoallyl-dUTP) by an established molecular biological approach, to enable its conjugation to microspheres, which were subsequently used to transfect various cell lineages. To carry out this strategy, 200 nm polystyrene microspheres (**1**) were functionalized as described in Scheme 1 following a standard Fmoc solid-phase protocol, using Oxyma and *N*,*N*′-diisopropylcarbodiimide (DIC) as coupling reagents. The carboxy-linker (3,3′-dithiodipropionic acid), which contains a disulfide bond, enabled the efficient attachment of pDNA to microspheres to build construct (**3**) (Scheme 1). This is an efficient strategy for the delivery of the pDNA from the carrier by incorporation of cleavable bonds to enable controlled molecular release from the particle surface.The introduction of disulfide bonds into carrier molecules is an excellent approach to create an interactive delivery system that exploits the redox gradient between the extra- and intracellular compartments. Examples

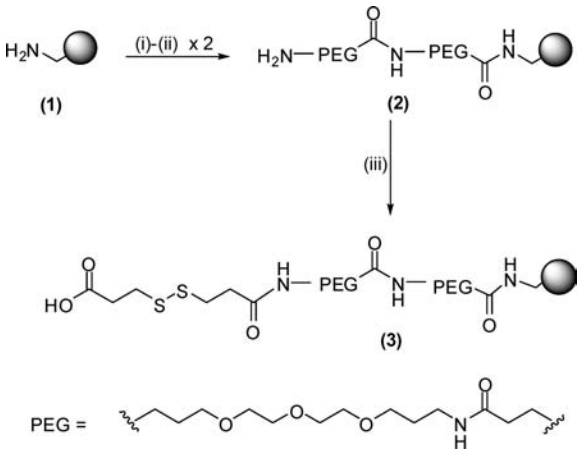
of delivery of bioactive cargos such as nucleic acid or proteins based on the introduction of disulfide bonds into carrier molecules such as chitosan or polymeric nanocapsules have been recently reported.[26,27] The efficiency of this strategy relies on the release of biological cargos from nanoparticles following cleavage of cargo−nanoparticle bonds inside biological systems. The stability associated with the disulfide bond linkage ensured that pDNA remained coupled to the microsphere during incubation in culture media. Upon cellular uptake, the nature of the disulfide bond ensured that it was cleaved within the cytosol, releasing the DNA to enable transcription and translation of the encoded protein. Additionally, microspheres were double-pegylated with a Fmoc monoprotected poly(ethylene glycol) spacer (Fmoc-PEG-OH) before being carboxyfunctionalized with a cleavable linker to give rise to microspheres (**2**) (Scheme 1).[28] There were two rationales to double-pegylate the microspheres: first, the addition of these units facilitated transport across the cell membrane by increasing bead biocompatibility, and second, the distance between the DNA and cellular vehicle was increased, which reduced the likelihood of unfavorable interactions.

The subsequent conjugation of linearized pDNA with carboxy-functionalized 200 nm polystyrene microspheres (**3**) (Scheme 1) involved the conjugation of a modified nucleotide aminoallyl-dUTP (**4**) to DNA (Scheme 2). Initially, pDNA encoding a yellow fluorescent protein (YFP)-tagged protein was linearized at a restriction endonuclease site upstream of the promoter region and amino-functionalized through the incorporation of a modified nucleotide to its 3′-end terminal. Specifically, aminoallyl-dUTP was incorporated into the pDNA by terminal deoxynucleotidyltransferase (TdT), a specialized DNA polymerase which catalyzes the addition of nucleotides to the 3′ terminus of a DNA molecule. The incorporation of an amino-reactive group onto the DNA strand enabled the conjugation of the pDNA to the carboxy-functionalized microsphere through formation of an amide bond. The aminoallyl modification enabled downstream reactions with amine-reactive compounds such as activated esters; thus, the aminoallyl-modified pDNA could be conjugated to carboxy-functionalized microspheres (**3**) in a single step as detailed in Scheme 2.

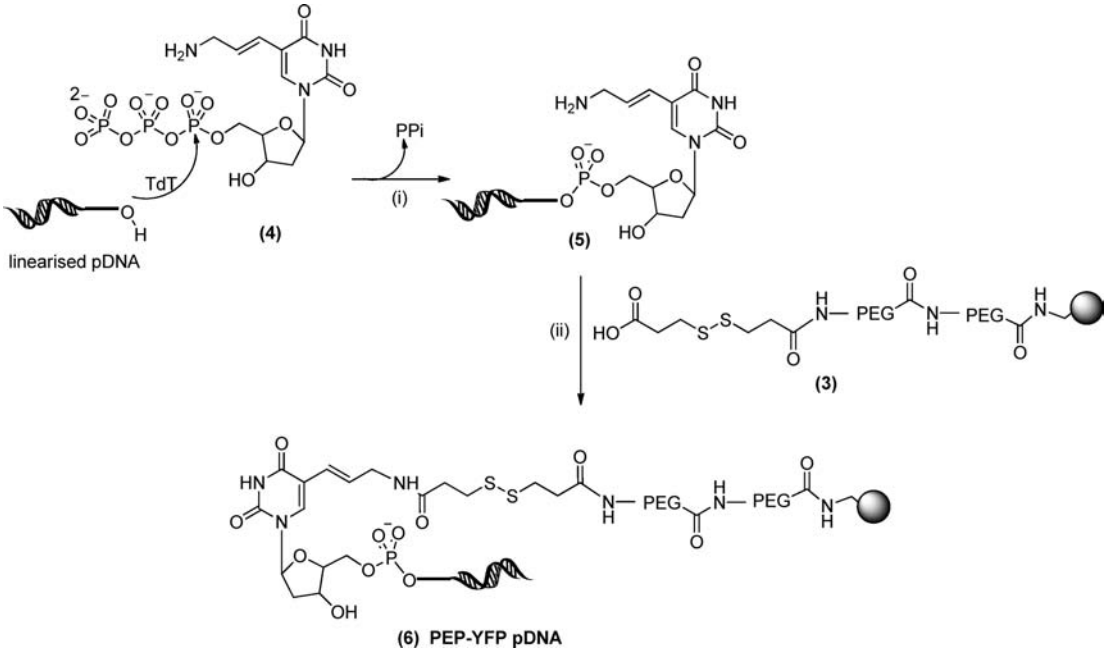
In order to validate beadfection as a novel technology for introduction and expression of DNA into transfection-resistant cell types, we selected immune cells as our model. Unlike other lineages, such as fibroblasts or endothelial cells, which are amenable to transfection by a variety of techniques, naïve T lymphocytes are small, nonproliferating, metabolically inert cells that are readily killed by most standard transfection protocols. T

Scheme 1. Microsphere Preparation for Conjugation to Linearized pDNA[a]



[a] Reagents and conditions: (i) Fmoc-PEG-OH spacer (5 equiv), Oxyma (5 equiv), DIC (5 equiv), DMF, 2 h, 60 °C; (ii) 20% piperidine in DMF, 3 × 20 min; (iii) 3,3′-Dithiodipropionic acid (5 equiv), DIC (5 equiv), DIPEA (0.1 equiv), DMF, 2 h, 60 °C.

Scheme 2. Strategy for Conjugation of DNA to Microspheres[a]



[a] Reagents and conditions: (i) TdT (20 units), 10× TdT buffer, $CoCl_2$, 37 °C, 20 min; (ii) 1. EDC, H_2O, rt, 4 h; 2. PBS pH 7.4, 18 h, rt.

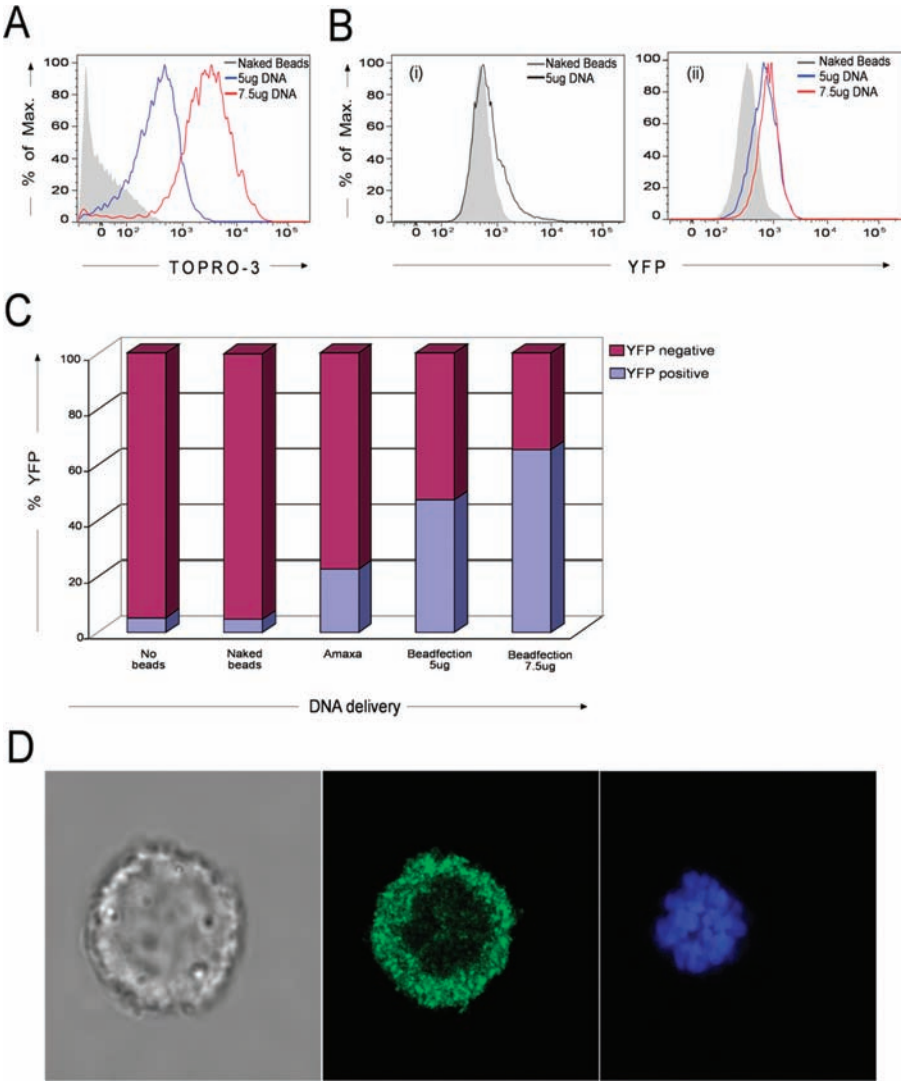


Figure 1. F5.BW hybridoma pDNA beadfection and protein expression. (A) Flow cytometric analysis of efficiency of pDNA conjugation to 200 nm microspheres by TOPRO-3 staining. (B) YFP protein expression observed 24 h after incubation: (i) Amaxa electroporation, (ii) beadfection. (C) Flow cytometric analysis of YFP expression in electroporated cells (Amaxa), pDNA-microsphere beadfected cells (Beadfection) and negative controls: untreated cells (No beads) and beads without pDNA conjugated (Naked beads). (D) Confocal microscopy image of a single T cell hybridoma (F5.BW) loaded with pDNA−microsphere conjugate **6** (DIC) expressing PEP-YFP (green). Image taken after 24 h at a 63× magnification, where nuclei are stained with DAPI.

lymphocytes can be activated *in vitro* by incubation with specific antigen or antibodies directed to the T cell receptor, whereupon they increase in cell size (from approximately 5−7 μM to ~12 μM) and enter into division. However, murine T lymphocytes, in particular, remain resistant to, and easily killed by, most standard DNA transfection methods. Development of an efficient and noninvasive system for gene delivery into nonproliferating, undifferentiating, or other transfection resistant immune cells would greatly facilitate research into the basic biology of lymphocytes that has been employed by other disciplines for many years. The ability to transfect naïve T lymphocytes remains a challenge that currently is not met by the relatively few transfection technologies available, all of which are associated with high toxicity, low efficiency, and relative lack of reproducibility.[29,30]

In order to test the beadfection protocol in T lymphocytes, we initially used an immortalized T cell hybridoma line (F5.BW). Given the relatively small size of T lymphocytes, we first evaluated the optimum size and number of microspheres that gave the most efficient delivery using fluorescein (FITC)-labeled microspheres following a previously described procedure[16] (see Supporting Information). After 24 h incubation, microspheres of 200 nm were found to be taken up most readily by the F5.BW hybridoma T cells, as the larger bead sizes were either less efficient (500 nm) or not taken up at all (900 nm) (Figure S1A-B, Supporting Information). Additionally, a linear increase in the efficacy of microsphere uptake was observed, which was proportional to the concentration of microspheres. In addition to microsphere uptake, cell viability was monitored by exclusion of a membrane-impermeable, DNA-intercalating dye, TO-PRO-3 Iodide (TO-PRO-3). Importantly, there was no change in the proportion of cells dying after incubation with the microspheres, although there was evidence of the association of smaller microspheres with dying cells (Figure S1C, Supporting Information). Analysis of the time course of microsphere uptake was carried out

(Figure S2A-B, Supporting Information), indicated that maximal uptake of 200 nm microspheres was already achieved by 4 h. Mean fluorescent intensity (MFI) was used as a measure of FITC-uptake, and these values remained unchanged following 8 h of incubation and were reduced only slightly at 24 h, which might be due to cell division and subsequent dilution of the numbers of microspheres per cell. Imaging of cells by confocal microscopy confirmed that the microspheres had entered the cell, localizing within the cytoplasm, excluding the possibility that the microspheres had simply adhered to extracellular membrane proteins (Figure S2C, Supporting Information).

To validate the use of these microsphere-based conjugates as a novel technology for DNA transfection of immune cells, we addressed whether pDNA could be delivered to F5.BW hybridoma T cells using microspheres as the transfection agent. For this purpose, pDNA encoding a lymphocyte-specific protein, proline-glutamine-serine-threonine-domain enriched phosphatase (PEP), fused at the carboxy-terminus to yellow fluorescent protein (PEP-YFP), was prepared as described in Scheme 1 and conjugated to microspheres as described in Scheme 2. To assess the efficiency of coupling of the pDNA to the microspheres, the DNA intercalator TO-PRO-3 was incubated with the microsphere suspension for 5 min after which the microspheres were washed and analyzed by flow cytometry for the presence of DNA. Figure1A shows that although the naked 200 nm microspheres stained with TO-PRO-3, covalent attachment of pDNA increased the MFI 10-fold, indicative of covalently coupled pDNA.Successful gene expression was achieved upon delivery of conjugate (**6**) (Scheme 2) to F5.BW hybridoma T cells as determined by the detection of YFP fluorescence by flow cytometry. As shown in Figure1Bii, the majority of the F5.BW hybridoma T cells expressed the PEP-YFP protein 24 h after transfection with pDNA conjugated microspheres (**6**). Coupling the microspheres with 7.5 μg of DNA rather than 5 μg provided a slight increase in transfection efficiency. As a positive control, F5.BW hybridoma T cells were transfected by the Amaxa (Lonza) electroporation method, currently the most efficient means of transfecting T lymphocytes.[31−33] Using the same relative concentration of DNA (5 μg/1 $\times$ 10^6 cells), F5.BW hybridoma T cells were Amaxa transfected and assessed by flow cytometry for YFP expression 24 h later (Figure1Bi) and 48 h later (Figure S3, Supporting Information). Notably, after 24 h beadfection led to a more uniform expression of PEP-YFP, as seen by a shift of the entire population of transfected F5.BW hybridoma T cells in Figure 1Bii. By comparison, only half as many cells were YFP^+ following Amaxa electroporation (Figure1C). However, protein expression decreased dramatically after 48 h in both the Amaxa-transfected and the beadfected cells (Figure S3). Endogenous PEP protein has previously been characterized by Western blot to reside wholly within the cytoplasm in T lymphocytes,[34] and transfected PEP was shown to localize within the cytoplasm in the nonimmune cell line HeLa.[35] Using confocal microscopy, we identified that the transcribed PEP-YFP protein similarly localized within the cytoplasm of F5.BW hybridoma T cells (Figure1D). These results show that a much higher efficiency of transfection is achieved into hybridoma T cells when the pDNA is delivered by beadfection rather than the traditional method of electroporation.

The efficient delivery of pDNA and subsequent rapid protein expression in hybridoma T cells led us to address whether naïve T lymphocytes isolated from murine lymph nodes could uptake microspheres. If so, this would identify a novel technique for the introduction of DNA into nondividing primary immune cells, which are resistant to more common transfection techniques including lipid carriers and calcium phosphate. Surprisingly, naïve $CD8^+$ T lymphocytes were as efficient in the uptake of FITC-labeled microspheres as the F5.BW hybridoma T cells (Figure S4AB), with a similar dependency on size and concentration of the microspheres. Two important considerations in the transfection of naïve T lymphocytes are whether the DNA delivery protocol leads to either cell death or cellular activation. We confirmed that neither occurred, as there was very little change in the proportion of dead cells (TO-PRO-3+, Figure S4C) and there was no expression on the cell surface of a marker of cellular activation, CD69 (Figure S4D). In contrast, the positive control for activation, which were naïve T lymphocytes stimulated with antibody to the T cell receptor (anti-CD3, Figure S4D) did show expression of CD69. Imaging of the cells by confocal microscopy confirmed that the microspheres had entered the naïve T lymphocytes and localized within the cytoplasm, as no fluorescence was observed within the nucleus (Figure S4E). These results show an efficient internalization of microspheres by naïve T lymphocytes, and consequently, they support the potential of this technology to carry out gene expression studies in this cell line and other resistant primary cells.

In conclusion, we have described a novel strategy of transfection, based on the delivery of pDNA by conjugation to microspheres. Following a simple protocol for the linearization and functionalization of the pDNA, this amino-modified DNA was successfully conjugated to 200 nm polystyrene microspheres and transfected into hybridoma T cells leading to successful expression of a biologically relevant protein fused to YFP. In addition, the microspheres were taken up by naive T lymphocytes, a primary cell which is difficult to transfect, with no associated toxicity. These data confirm the development of a novel, noninvasive, efficient, and controlled dose transfection methodology, specifically aimed at DNA delivery into transfection resistant cells that is not matched by currently available technology.

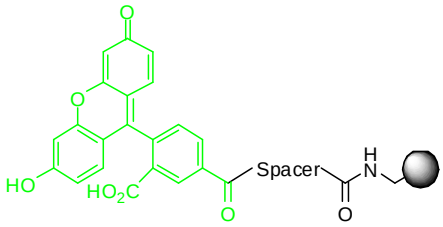
Supporting Information for

Novel Strategy for microsphere-mediated DNA transfection

Jessica G. Borger,[¥,†] Juan Manuel Cardenas-Maestre,[¥, ‡] Rose Zamoyska[*,†] and Rosario M. Sanchez-Martin[*,‡,§]

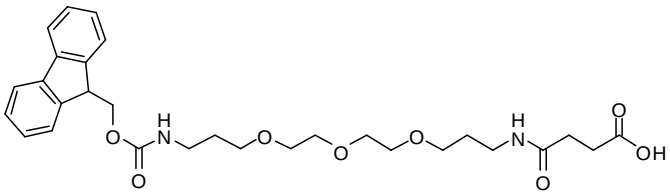
1. Preparation of Fluorescein-labeled microspheres.



Amino functionalized microspheres (1 mL; 1 equiv) were washed in DMF (3 x 1 mL) and suspended in DMF (1 mL). Separately, 5(6)-carboxyfluorescein (5 eq) was dissolved in DMF (1 mL), then oxyma (5 eq; Apollo Scientific) was added and the solution mixture mixed for 4 minutes at rt before the addition of DIC (5 eq; Sigma-Aldrich) and mixed for 8-10 minutes at rt. The solution mixture was then added to amino microspheres and suspension mixed on the Thermomixer at 1400 rpm for 2 hours at 60°C.

2. Preparation of carboxy functionalised microspheres (3)

2.1. Synthesis of Fmoc-4,7,10-trioxa-1,13-tridecanediamine succinamic acid (polyethylene glycol type spacer, Fmoc-PEG-OH)



A solution of succinic anhydride (1 g, 10 mmol, 1 eq) dissolved in acetonitrile (25 mL) was added drop wise over 1 hour under strong magnetic stirring to 4,7,10- trioxa-1,13-tridecanediamine (2.2 g, 10 mmol, 1 eq) in acetonitrile (50 mL) and stirred for a further 3 hours. The liquid phase was decanted and discarded once the waxy product had settled. The product was redissolved by the addition of an acetonitrile:H2O (1:1) solution (100 mL) and the solution was chilled to 0°C prior to a drop wise addition of 9-fluorenylmethoxycarbony-succinimide (Fmoc-OSu) (4.38 g, 13 mmol, 1.3 eq) in acetonitrile (25 mL) under vigorous magnetic stirring during which time the pH was

kept at 8/9 by addition of DIPEA. After 12 hours reaction at room temperature the solvents were removed in vacuo and the residue was dissolved in a 5% NaHCO3 aqueous solution (100 mL) and washed with EtOAc (3 x 50 mL).

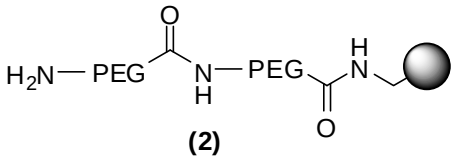
The aqueous phase was then acidified to pH 2 with 37% HCl, extracted with ethyl acetate (3 x 50 mL) and the organic phases were combined, washed with brine, dried over MgSO4 and concentrated in vacuo to afford a yellowish oil which was dissolved in hexane and purified by flash chromatography column (DCM:MeOH; 10:1) to afford the pure final compound as a sticky colorless product (3.51 g, 6.59 mmol, 65 %).

HPLC (S50D, λ=220 nm): purity 100%, retention time 8.4 minutes.

m/z (ES+) 565.5 (100%) [M+Na]+

1H NMR (500 MHz, CD3OD) δ (ppm): 1.71-1.78 (m, 4H), 2.46 (t, J = 6.54, 2H), 2.62 (t, J = 7.54, 2H), 3.26-3.34 (m, 4H), 3.49-3.65 (m, 12H), 4.20 (m, 1H), 4.38-4.44, (m, 2H), 5.30 (bs, 1H), 6.77 (bs, 1H), 7.29 (t, J = 7.41, 2H), 7.38 (t, J = 7.39, 2H), 7.59 (d, J = 7.48, 2H), 7.75 (d, J = 7.52, 2H). **13C NMR** (500 MHz, CD3OD) δ (ppm): 28.52, 29.34, 30.40, 30.98, 38.22, 38.80, 47.25, 66.40, 69.23, 69.88, 66.92, 70.02, 70.26, 70.35, 119.90, 125.02, 126.98, 127.61, 141.25, 143.95, 156.62, 172.58, 175.21.

2.2. Preparation of double PEGylated microspheres (2)

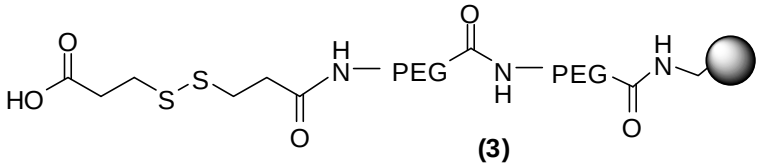


(2)

Amino functionalized microspheres **1** (1 mL; 1eq) were washed in DMF (3 x 1 mL) and suspended in DMF (1 mL). Separately, Fmoc-PEG-OH (5eq) was dissolved in DMF (1 mL), then DIC (5 eq) was added and the solution mixture mixed for 8-10 minutes at rt. The solution mixture was then added to amino microspheres and DIPEA (0.1 eq) was added. The suspension was mixed on the Thermomixer at 1400 rpm for 2 hours at 60°C. ***Fmoc deprotection*** was achieved by treating microspheres with 20% piperidine/DMF (1 mL; 3 x 20 minutes). Microspheres were obtained by centrifugation and subsequently washed with DMF (3 x 1 mL), MeOH (3 x 1 mL), deionised water (3 x 1 mL) and finally DMF (3 x 1 ml). Next, ninhydrin test was

performed to check the presence of primary amine. Then, the same protocol was repeated to give double PEGylated microspheres **2**.

2.3. Preparation of carboxy functionalised microspheres (3)



(3)

Amino functionalized microspheres **2** (1 mL; 1eq) were washed in DMF (3 x 1 mL) and suspended in DMF (1 mL). Separately, 3,3'-Dithiodipropionic acid (Sigma-Aldrich, 10 eq) was dissolved in DMF (1 mL), then DIC (5 eq) was added and the solution mixture mixed for 8-10 minutes at rt. The solution mixture was then added to amino microspheres and DIPEA (0.1 eq) was added. The suspension was mixed on the Thermomixer at 1400 rpm for 2 hours at 60°C. Microspheres were obtained by centrifugation and subsequently washed with DMF (3 x 1 mL), MeOH (3 x 1 mL), deionised water (3 x 1 mL).

3. DNA linearization and aminoallyl-dUTP incorporation

3.1. Plasmid DNA linearization

Gene sequences for PEP-YFP (J. Borger, University of Edinburgh) were encoded within the AMAXA pMax cloning vector (Lonza). Linearisation of 1µg DNA required 1U of restriction endonuclease and was incubated at 37°C overnight. Detailed protocol: A cocktail mix containing 1x digestion buffer, 1x BSA and 1U restriction enzyme/µg DNA in molecular biology grade water was prepared. pDNA (PEP-YFP) was added to the cocktail mix and incubated at 37°C for 18 hours. Digestion was stopped by inactivating the enzyme at 70°C for 10 min.

3.2. Analytical electrophoresis gel

Efficiency of restriction digest was analysed by agarose gel electrophoresis. Protocol: Agarose electrophoresis gel was performed on 1x Tris-Acetate-EDTA buffer. Samples were loaded at 0.5µg in 1x Blue juice loading dye where a 1 kb molecular weight DNA was used as ladder. Gel was visualised by UV.

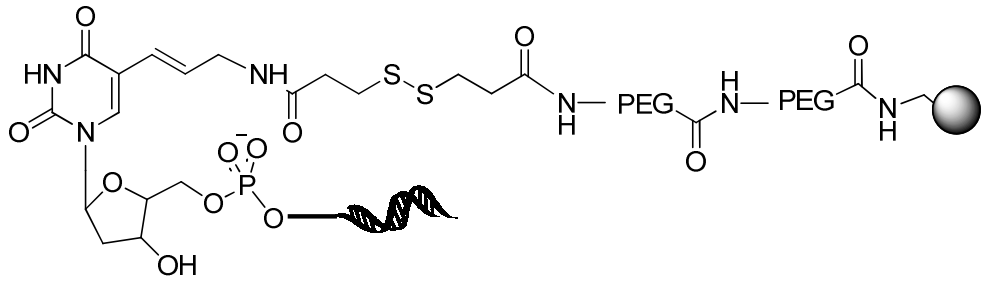
3.3. Ethanol precipitation

Linear DNA (lDNA) was ethanol precipitated and resuspended in TE buffer. Protocol: To precipitate lDNA, 1/10 volume of 3M Sodium Acetate and 3 volumes of ethanol were added to the DNA solution. DNA was precipitated at -20°C for 18 hours. The DNA was pelleted by centrifugation, ethanol aspirated to allow the DNA to air-dry and then be resuspended in TE buffer at 1µg/µl.

3.4. Aminoallyl-dUTP incorporation

Terminal deoxynucleotidyl transferase (New England BioLabs) addition of 2 mM aminoallyl-dUTP (Yorkshire Bioscience Ltd) to the 3' end of the linear DNA was performed at 37°C for 20 min, with subsequent enzyme deactivation for 10 min at 70°C. ***Detailed Protocol:*** DNA was added to a solution containing 1x TdT buffer, $CoCl_2$, 10 mM aa-dUTP and 1U TdT/µg DNA and incubated at 37°C for 20 min. The enzyme was then inactivated by heating up to 70°C for 10min. The DNA was then ethanol precipitated as described above in 3.3.

4. DNA-microspheres conjugation



(6) PEP-YFP pDNA

Carboxy functionalised microspheres **(3)** (0.1 mL; 1eq) were washed in molecular biology grade water (0.1 mL x 3 times) and suspended in 0.1 M solution of EDC in water (0.1 mL) and solution mixed for 4 hours at rt. After mixing, microspheres were collected by centrifugation and microspheres resuspended in PBS pH 7.4, then DNA solution (0.1 mL) was added and the solution mixture mixed at room temperature for 18 hours to yield microspheres-DNA conjugates **6**. After mixing, it was found quite important not to perform any washing to the lDNA-microspheres conjugates.

5. Biological Evaluation

Cell culture conditions

Cells were cultured in RPMI medium 1640 supplemented with 5% FCS, L-glutamine, 100 U/ml penicillin and streptomycin (GIBCO) and 50 µM β-mercaptoethanol. F5 hybridoma T cells were additionally incubated in 500 µg/ml G418 for selection.

Microsphere incubation

Cells were seeded in a 24 well-plate at a density of 1 x 10^6 cells per well. Once cells settled as a monolayer, microspheres at varying concentrations ($5x10^{14}$, 10^{15}, $2x10^{15}$) and varying sizes (200 nm, 500 nm, 900nm) were incubated incubated for 4, 8 and 24 hours in supplemented media without b-mercaptoethanol at 37C with 5% CO_2. Cells were harvested into PBS at each time point, washed twice and resuspended in 2% FCS/PBS. T cells were stimulated with plate-bound 5 µg/ml anti-CD3 (145-2C11, BD Pharmingen) and 2 µg/ml anti-CD28 (37.51, BD Pharmingen) for 24 hours during incubation with microspheres.

Flow cytometry

Samples were collected on a flow cytometer (LSR II, BD) and analysed using FlowJo Version 8.8.6 software (Tree Star Inc.). At least 50,000 events per sample were analyzed. T cells were stained with antibodies CD8α-PerCP (53-6.7, BD Bioscience) and CD69-Pe (H1.2F3, eBiosciences). Cell viability was determined by staining with TOP-RO-3 Iodide (Invitrogen) in PBS (1:10000).

Confocal microscopy

Cells were diluted to 10^6/ml, aliquoted onto glass multiwell slides and incubated for 20 min at 37°C to adhere to the glass. Cells were fixed in 4% paraformaldehyde (PFA) for 30 minutes. Nuclei were stained with DAPI supplemented at 1 µg/ml in Prolong Anti-fade Gold (Invitrogen) mounting media. Samples were examined on the Leica SP5 II (Leica Microsystems) with lasers exciting at 405 and 488 with the 63× objective. Data was rendered and analysed using Volocity software (Improvision).

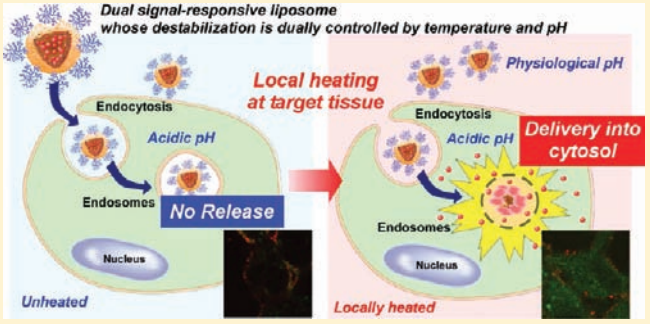
Supporting Information

ABSTRACT: For production of a new type of functional liposome whose destabilization can be triggered by a combination of a temperature signal and acidic pH signal, we prepared liposomes modified with hyperbranched poly(glycidol) derivatives having *N*-isopropylamide and carboxyl groups. HeLa cells incubated with the dual signal-responsive liposomes encapsulating a water-soluble fluorescent dye pyranine at 28 °C displayed punctate fluorescence of pyranine, indicating that the liposomes were trapped in endosome. However, after heating at 45 °C for 15 min, the same cells exhibited diffuse fluorescence of pyranine, indicating that destabilization of the liposomes in endosome with an acidic environment in combination with the brief heating caused efficient transfer of the contents into cytosol. The dual signal-responsive liposomes might have usefulness for site-specific delivery of membrane-impermeable molecules, which exhibit bioactivities in the intracellular spaces, such as siRNA and proteins.



INTRODUCTION

Recent advances in molecular biology and biotechnology have introduced highly efficient therapeutic approaches based on specific interaction to target molecules, as shown in typical examples of siRNA for specific gene silencing and protein inhibitors and antibodies of various kinds for targeted therapy. Many of their target molecules exist in intracellular spaces. Therefore, to maximize their therapeutic effects, accurate delivery of these bioactive molecules, not only to target diseased tissues, but also into their intracellular spaces where their target sites exist, are highly necessary.

Various types of nanoparticles with stimuli-sensitive properties have been produced to increase local concentration of therapeutic molecules at the target tissues. Typical examples are temperature-sensitive liposomes, which release contents in response to elevated temperature.[1−3] These temperature-sensitive liposomes encapsulating membrane-permeable anticancer drugs, such as doxorubicin, exhibited efficient tumor growth suppression upon mild heating of tumor sites.[4,5] On the other hand, intracellular delivery of bioactive molecules, which cannot permeate cellular membranes, has been attempted using liposomes having pH-sensitive properties: so-called pH-sensitive liposomes.[6,7] Liposomes are generally taken up by cells through endocytosis and are trapped in endosome, which contains a weakly acidic environment in its interior. Therefore, those with pH-sensitive properties generate abilities to release bioactive molecules and promote their transfer into cytosol.[6−9]

On the basis of the functions of these temperature-sensitive and pH-sensitive liposomes, we attempted to develop a new type of liposome having a combination of these functions, which generate a membrane-destabilizing ability under conditions of mildly acidic pH with an elevated temperature. Their ability to respond to both pH and temperature signals might be useful for targeting tissue-specific intracellular delivery of membrane-impermeable molecules, because such dual-signal-responsive liposomes can destabilize and fuse with endosomes only when entrapped in endosomes of the target tissue, which has been mildly heated (Figure 1).

Recently, we synthesized hyperbranched poly(glycidol)s (HPGs) having *N*-isopropylamide (NIPAM) and succinylate (Suc) groups, which are, respectively, temperature-sensitive and pH-sensitive groups.[10] These polymers exhibited the dual-signal-sensitive property; their characteristics changed from hydrophilic to hydrophobic in response to both pH decreasing and temperature increasing.[10] For the present study, we incorporated these polymers onto stable egg yolk phosphatidylcholine (EYPC) liposomes to produce dual-signal-responsive liposomes. The pH-responsive and temperature-responsive properties of the HPGs-modified liposomes and their performance as intracellular delivery vehicles were investigated.

EXPERIMENTAL PROCEDURES

Materials. HPG with the polymerization degree of 40, which is designated as HPG40, was kindly donated by Daicel Chemical Industries, Ltd. (Osaka, Japan). Egg yolk phosphatidylcholine (EYPC) was kindly donated by NOF Co. (Tokyo, Japan). Pyranine, decylamine, and Triton X-100 were obtained from Tokyo Chemical Industries Ltd. (Tokyo, Japan). *p*-Xylene-bis-pyridinium bromide (DPX) and LysoTracker Red DND-99 were purchased from Molecular Probes (Oregon, USA). Lissamine rhodamine B-sulfonyl phosphatidylethanolamine (Rh-PE) was purchased from Avanti Polar Lipids (Birmingham, AL, USA). 4-(4,6-Dimethoxy-1,3,5-triazin-2-yl)-4-methyl morpholinium chloride (DMT-MM), isopropylamine, and *N*-methylpyrrolidone were from Wako Pure Chemical Industries Ltd. (Osaka, Japan). Succinic anhydride was obtained from Kishida Chemical Co., Ltd. (Osaka, Japan).

Synthesis of NIPAM-Suc-HPG. NIPAM-Suc-HPGs were prepared as previously reported.[10] A typical procedure was as follows. HPG40 (5.66 g) and an excessive amount of succinic anhydride (0.24 mol) were dissolved in pyridine (60 mL) and stirred at 65 °C for 7 h under an argon atmosphere. The polymer was washed with diethyl ether and was purified using a Sephadex LH-20 column with methanol to afford Suc-HPG40. The obtained Suc-HPG40 (0.82 g) was dissolved in *N*-methylpyrrolidone (8 mL), and DMT-MM (4.0 mmol) and isopropylamine (2.9 mmol) dissolved in *N*-methylpyrrolidone (1.2 mL) was added to the solution. The mixed solution was stirred at room temperature for 24 h under an argon atmosphere in the dark, and then, decylamine (0.48 mmol) dissolved in *N*-methylpyrrolidone (1 mL) was added to the solution. The mixture was stirred at room temperature for 3 days under an argon atmosphere in the dark. To the reaction mixture, acetic acid (3 mL) was added and stirred for 1 h. The polymer was precipitated with water and washed with diethyl ether. Then, the polymer was purified using a Sephadex LH-20 column with methanol to afford $NIPAM_{35}$-Suc_{55}-HPG. Compositions of polymers were estimated using ^1H NMR. ^1H NMR spectra for Suc-HPG40 and $NIPAM_{35}$-Suc_{55}-HPG were shown in Supporting Information Figure S1 A and B, respectively. Integration of peaks for these spectra indicated that essentially no hydroxyl groups remained in Suc-HPG40 (Figure S1 A) and the molar ratio of NIPAM, Suc, and *N*-decylamide (DA) groups was 34.9/55.3/9.8 in $NIPAM_{35}$-Suc_{55}-HPG (Figure S1 B).

Turbidity Measurements. Turbidity of NIPAM-Suc-HPGs dissolved in 10 mM phosphate and 150 mM NaCl solution (pH 5.0−7.4, 5 mg/mL) was measured at 700 nm using a Jasco model V-560 spectrophotometer equipped with a Peltier-type thermostatic cell holder coupled with an ETC-505T controller. The heating rate of the sample was 1.0 °C min^{-1}. The cloud points were taken as the initial break points in the resulting transmittance versus temperature curves.

Preparation of Liposomes. To a dry, thin membrane of EYPC (7 mg) and polymer (7 mg) was added 500 μL of aqueous 35 mM pyranine, 50 mM DPX, and 50 mM phosphate solution (pH 7.4), and the mixture was sonicated for 10 min using a bath-type sonicator. The liposome suspension was further hydrated by freezing and thawing repeatedly, and was extruded through a polycarbonate membrane with a pore size of 100 nm. The liposome suspension was dialyzed against 10 mM phosphate and 140 mM NaCl buffer (pH 7.4) at 4 °C for 2 days. Then,

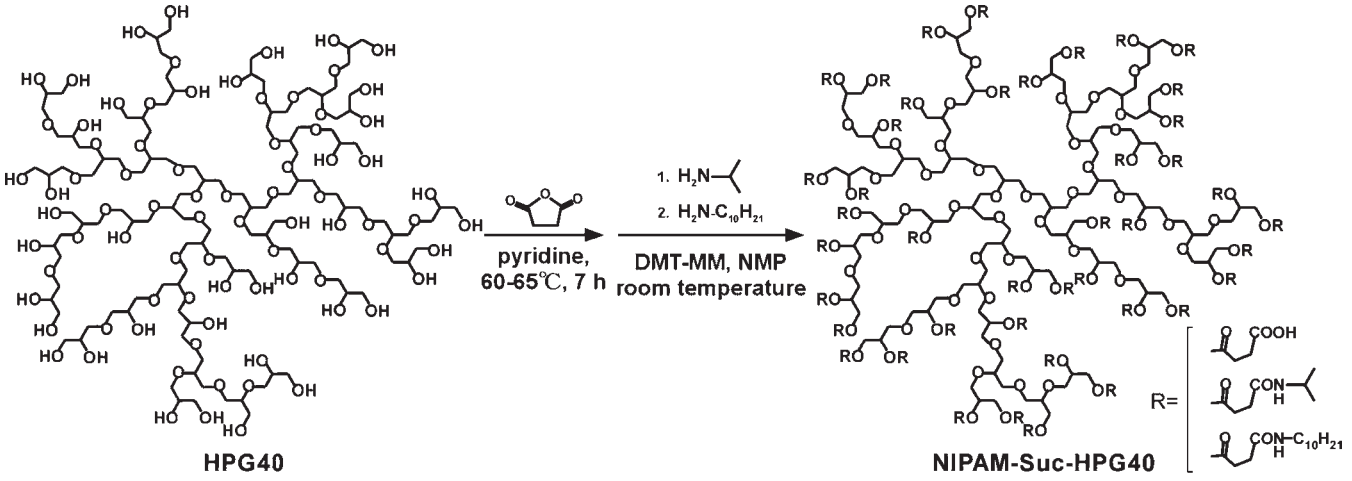

Figure 2. Preparation of NIPAM-Suc-HPG. DMT-MM and NMP represent 4-(4,6-dimethoxy-1,3,5-triazin-2-yl)-4-methyl morpholinium chloride and *N*-methylpyrrolidone, respectively.

liposome was ultracentrifuged twice at 55 000 rpm for 2 h to remove free pyranine and free polymer from the pyranine-loaded liposomes.

Pyranine Release from Liposomes. Release of pyranine from liposomes was measured as previously reported.[8,11] Pyranine fluorescence was quenched by DPX inside of the liposomes, but it exhibits intense fluorescence when released from the liposome. Polymer-modified liposomes encapsulating pyranine and DPX were suspended in 10 mM phosphate and 140 mM NaCl buffer of varying pHs (lipid concentration: 2.0×10^{-5} M) at varying temperatures, and fluorescence intensity at 512 nm of the suspension was followed with excitation at 416 nm using a spectrofluorometer (Jasco FP-6200). The percent release of pyranine from liposomes was defined as

$$release(\%) = (F_t - F_i)/(F_f - F_i) \times 100$$

where F_i and F_t mean the initial and intermediary fluorescence intensities of the liposome suspension, respectively. F_f is the fluorescence intensity of the liposome suspension after addition of Triton X-100 (final concentration: 0.1%).

Intracellular Distribution of Liposomes. The pyranine-loaded liposomes containing Rh-PE were prepared as described above except that DPX was not included in the pyranine solution and Rh-PE (0.1 mol %) was included as a liposome component. HeLa cells (2×10^5 cells) cultured in DMEM supplemented with 10% FBS and antibiotics for 2 days were washed with phosphate-buffered saline (PBS), and then incubated in DMEM without serum (500 μL). The pyranine-loaded liposomes (0.6 mM, 500 μL) were added gently to the cells and incubated for 4 h at 28 °C. After the incubation, the cells were washed with PBS three times and heated at 45 °C for 15 min. Confocal laser scanning microscopic (CLSM) analysis of these cells was performed using LSM 5 EXCITER (Carl Zeiss Co. Ltd.). The cells without the 15 min heating at 45 °C were also observed using CLSM (λ_{ex} = 485 nm). For inhibition of endosomal acidification, cells were preincubated with 100 μM chloroquine for 30 min before the incubation with liposomes.

RESULTS AND DISCUSSION

Preparation of Polymers for Liposome Modification. Hyperbranched poly(glycidol)s having NIPAM and Suc groups and decyl chains, which are anchors for their fixation onto liposomes, were prepared as presented in Figure 2 using HPG with the number average polymerization degree of 40 as previously reported.[10] The pH-sensitive and temperature-sensitive properties of the HPGs having NIPAM and Suc groups (NIPAM-Suc-HPGs) are dependent on their compositions.[10] Therefore, HPG-based polymers of five kinds having varying ratios of NIPAM and Suc groups were prepared for modification of liposomes (Table 1). We introduced decyl groups to about 10 unit % of the chain terminals of the polymers as anchors for their incorporation to liposomes. In addition, NIPAM-Suc-HPG having the NIPAM/Suc ratio of 64/36 without decyl groups, which is designated as $NIPAM_{64}$-Suc_{36}-HPG_{cont}, was synthesized as a control without anchors.

Table 1. Characterization of NIPAM-Suc-HPGs[a]

	molar ratio[b]		
polymer	NIPAM	Sue	DA
$NIPAM_0$-Suc_{89}-HPG	0	88.9	11.1
$NIPAM_{35}$-Suc_{55}-HPG	34.9	55.3	9.8
$NIPAM_{56}$-Suc_{33}-HPG	56.4	32.9	10.7
$NIPAM_{64}$-Suc_{27}-HPG	63.5	26.6	9.9
$NIPAM_{72}$-Suc_{17}-HPG	71.9	17.3	10.8
$NIPAM_{64}$-Suc_{36}-HPG_{cont}	63.8	36.2	0

[a] Suc-HPG40 was obtained by reacting HPG40 completely with excess succinic anhydride. And then NIPAM and DA groups were incorporated to Suc-HPG40 by condensation of a part of Suc groups with isopropylamine and decylamine. [b] Molar ratios of NIPAM, Suc, and DA groups in the polymers were evaluated based on ^{1}H NMR (see Supporting Information).

First, we examined pH-sensitive and temperature-sensitive properties of the NIPAM-Suc-HPGs by the detection of phase separation of their aqueous solutions (Figure 3). Figure 3A,B shows the optical transmittance of the $NIPAM_{65}$-Suc_{35}-HPG_{cont} and $NIPAM_{56}$-Suc_{33}-HPG solutions, respectively, at various pH values as a function of temperature. The solutions of these polymers were transparent at neutral pH in the experimental temperature region, indicating that their chains were highly hydrated irrespective of temperature at neutral pH. However,

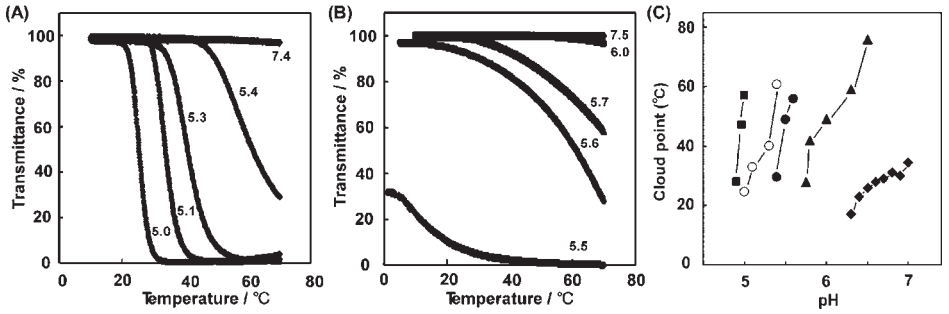

Figure 3. Temperature and pH-sensitive phase transition of NIPAM-Suc-HPGs. Temperature dependence of transmittance for solutions of $NIPAM_{64}$-Suc_{36}-HPG_{cont} (A) and $NIPAM_{56}$-Suc_{33}-HPG (B) at various pHs. (C) Cloud points of $NIPAM_{64}$-Suc_{36}-HPG_{cont} (open circles), $NIPAM_{35}$-Suc_{55}-HPG (squares), $NIPAM_{56}$-Suc_{33}-HPG (closed circles), $NIPAM_{64}$-Suc_{27}-HPG (triangles), and $NIPAM_{72}$-Suc_{17}-HPG (diamonds) as a function of pH.

these polymer solutions exhibited a temperature-dependent decrease in transmittance at pH 5−6, indicating that these polymers changed their characteristic from hydrophilic to hydrophobic depending on temperature in the weakly acidic pH region. These polymers showed the water-solubility change under similar temperature and pH regions, probably because these polymers have similar ratios of NIPAM units to succinylate units, which contribute, respectively, to temperature and pH sensitivities. Additionally, it is readily apparent that $NIPAM_{56}$-Suc_{33}-HPG changed its water-solubility with temperature gradually in broad temperature regions at weakly acidic pH compared to $NIPAM_{65}$-Suc_{35}-HPG_{cont}. For $NIPAM_{56}$-Suc_{33}-HPG, hydrophobic decyl chains connected to the polymer backbone might make its conformation more compact. Then, the polymer chains taking on a compact conformation would be unable to interact mutually as efficiently as $NIPAM_{65}$-Suc_{35}-HPG_{cont} taking on an expanded conformation, resulting in the transition in the broad temperature region for the anchor-carrying polymer.

We defined the cloud point of the polymer solution as the temperature at which the transmittance became 50%. Figure 3C shows cloud points of NIPAM-Suc-HPGs with various NIPAM/Suc ratios as a function of pH. Generally, the polymers exhibited cloud points between 20 and 60 °C. However, the pH region in which these polymers showed the cloud point tends to increase concomitantly with increase of the NIPAM/Suc ratio, indicating that their pH-sensitive and temperature-sensitive properties are controllable by adjusting their NIPAM/Suc ratio.

Dual Signal-Responsive Behaviors of Polymer-Modified Liposomes. To investigate production of dual signal-responsive liposomes, we examined the effect of modification of stable EYPC liposomes with the NIPAM-Suc-HPGs. On the basis of the result of Figure 3, we chose three kinds of HPG-based polymers with different NIPAM/Suc unit ratios, $NIPAM_{56}$-Suc_{33}-HPG, and $NIPAM_{72}$-Suc_{17}-HPG, as well as NIPAM-free $NIPAM_0$-Suc_{90}-HPG, to elucidate how the NIPAM/Suc unit ratio of the polymer affects pH- and temperature-sensitive properties of their modified liposomes. The liposomes were prepared by dispersing a mixture of egg yolk phosphatidylcholine (EYPC) and polymer in a phosphate solution containing water-soluble fluorescent dye pyranine and its quencher DPX and subsequent extrusion through a polycarbonate membrane with a pore size of 100 nm. The liposomes were purified by dialysis and subsequent ultracentrifugation. Their content release behaviors were investigated by following the fluorescence of pyranine, which become highly fluorescent when released from the liposome.[11,12] We confirmed that pyranine release from the unmodified EYPC was very low and that it was affected only slightly by pH and temperature under experimental conditions (see Figure S2). However, the liposomes modified with these polymers exhibited pyranine release depending on the ambient pH and temperature (Figure 4). The liposomes modified with $NIPAM_0$-Suc_{90}-HPG showed significant pH-responsive content release, which was significantly promoted below pH 5.5 and which achieved complete release at pH 4.5 (Figure 4A,D). However, these liposomes exhibited fundamentally equivalent pH-dependent release behavior irrespective of ambient temperature, indicating that they are responsive only to ambient pH.

On the other hand, the liposomes modified with $NIPAM_{56}$-Suc_{33}-HPG exhibited significant pH-responsive contents release at 37 and 45 °C, but they only slightly release the contents at 10 °C (Figure 4B,E). This fact indicates that these liposomes have sensitivity to both pH and temperature. Consequently, their function can be dually controlled by ambient pH and temperature. The $NIPAM_{72}$-Suc_{17}-HPG-modified liposomes showed the temperature-dependent enhancement of content release even at neutral pH, although they exhibited pH-dependent enhancement of content release below pH 6.0 to some degree (Figure 4C,F). Apparently, modification with the polymer having a high content of NIPAM moieties abolished pH-responsive properties of the liposomes and provided rather temperature-responsive properties to the liposomes.

Because the $NIPAM_{56}$-Suc_{33}-HPG-modified liposomes exhibited excellent response to both temperature and pH, we further examined the temperature-dependent enhancement of contents release at neutral pH and at pH 5.5, which respectively corresponds to the extracellular pH and the endosome pH.[13] As Figure 5 depicts, contents released from the liposomes were suppressed effectively, even at 50 °C under neutral pH condition, indicating that the liposomes retained pyranine at that pH. Similarly, under a weakly acidic condition, the liposomes retained contents less than 25 °C, but at greater than 30 °C, the liposomes enhanced the content release. On the basis of the result of Figure 2C, the $NIPAM_{56}$-Suc_{33}-HPG might change its character from hydrophilic to hydrophobic around 30 °C at pH 5.5. Therefore, the dehydrated polymer chains attached to the liposome surface might interact strongly with the liposome membrane and induce perturbation of the liposome membrane.

Control of Cytoplasmic Delivery by Dual Signal-Responsive Liposomes. We examined intracellular delivery mediated by the dual signal-responsive $NIPAM_{56}$-Suc_{33}-HPG-modified liposomes. The liposome membrane was labeled with Rh-PE to detect the location of liposomes in the cell. Plain EYPC

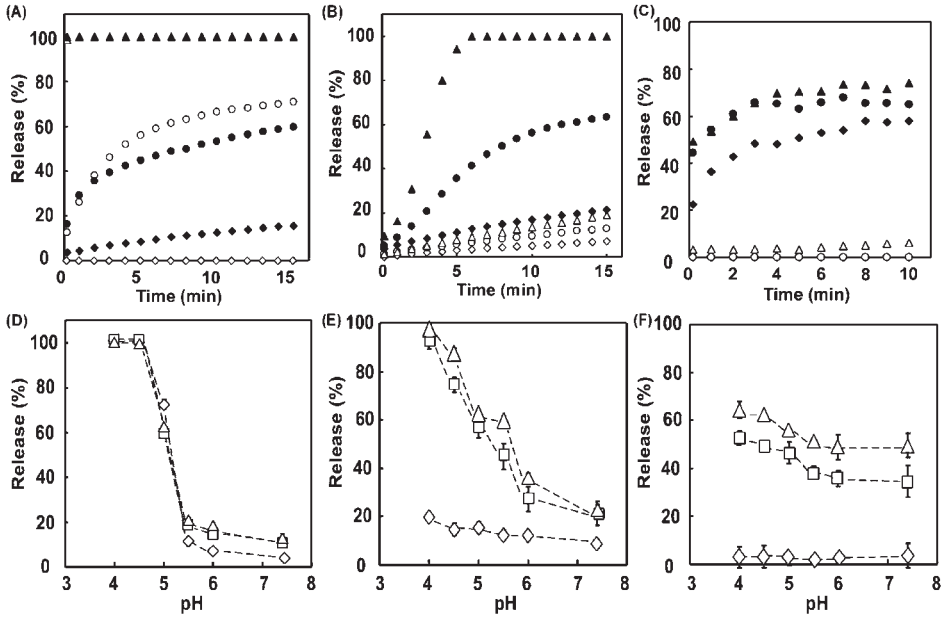

Figure 4. Typical profiles of pyranine release from liposomes modified with NIPAM$_0$-Suc$_{90}$-HPG (A), NIPAM$_{56}$-Suc$_{33}$-HPG (B), and NIPAM$_{72}$-Suc$_{17}$-HPG (C) at pH 7.4 (diamonds), pH 5.0 (circles), and pH 4.0 (triangles) at 10 °C (open symbols) or 45 °C (closed symbols). pH-Dependence of pyranine release from liposomes modified with NIPAM$_0$-Suc$_{90}$-HPG (D), NIPAM$_{56}$-Suc$_{33}$-HPG (E), and NIPAM$_{72}$-Suc$_{17}$-HPG (F). Percent release after 15 min incubation at 10 °C (diamonds), 37 °C (squares), or 45 °C (triangles) was shown.

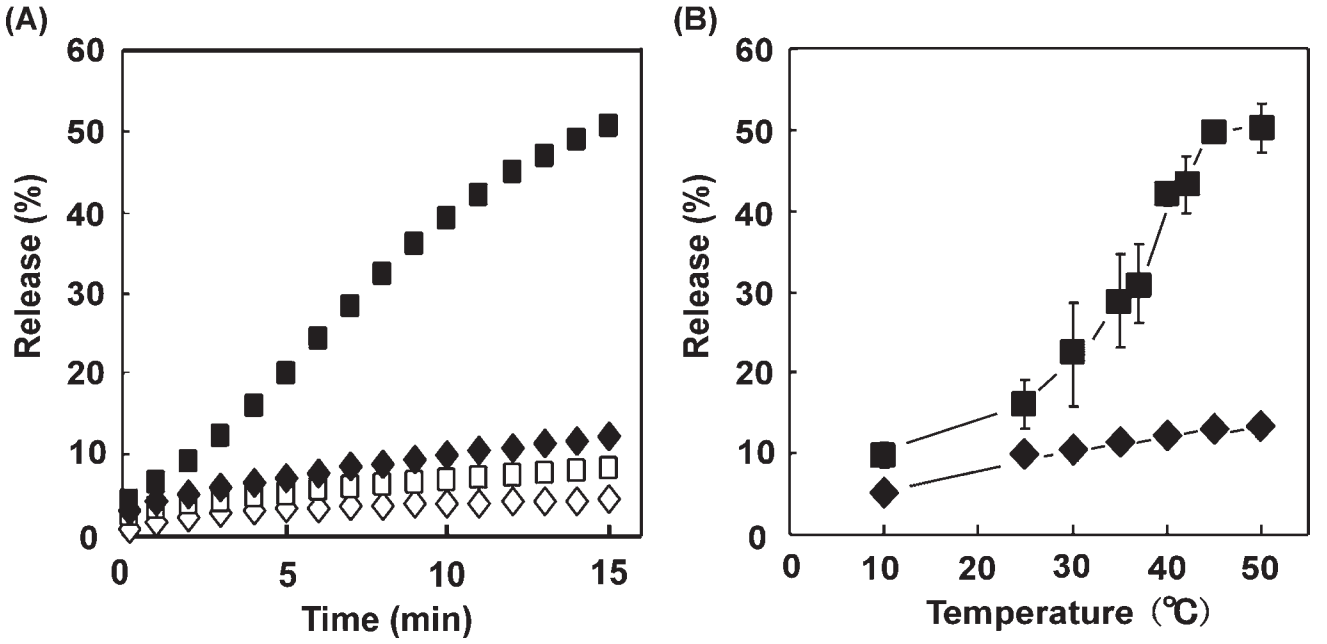

Figure 5. (A) Typical profiles of pyranine release from NIPAM$_{56}$-Suc$_{33}$-HPG-modified liposomes at pH 7.4 (diamonds) and pH 5.5 (squares) at 10 °C (open symbols) or 45 °C (closed symbols). (B) Temperature dependence of pyranine release at pH 7.4 (diamonds) and pH 5.5 (squares). Percent release after 10 min incubation was shown.

liposomes labeled with Rh-PE and loaded with pyranine were also examined as a control. These liposomes were incubated with HeLa cells for 4 h at 28 °C, where the NIPAM$_{56}$-Suc$_{33}$-HPG-modified liposomes were stable, even at weakly acidic pH (Figure 5B), then washed with PBS three times to remove free liposomes. The cells were additionally incubated in the culture medium at 28 or 45 °C for 15 min and observed using CLSM (Figure 6). As presented in Figure 6A, cells treated with the plain liposome at 28 °C displayed punctate fluorescence of Rh-PE and pyranine in the peripheral region of the cells at the same locations, suggesting that the liposomes retaining pyranine were trapped in early endosomes, which exist near the cellular surface. Because the cells were treated with the liposomes at 28 °C, the cellular activity might have been reduced. Consequently, internalization of the liposomes into the cells was limited largely to that taking place within the cellular membrane periphery. When

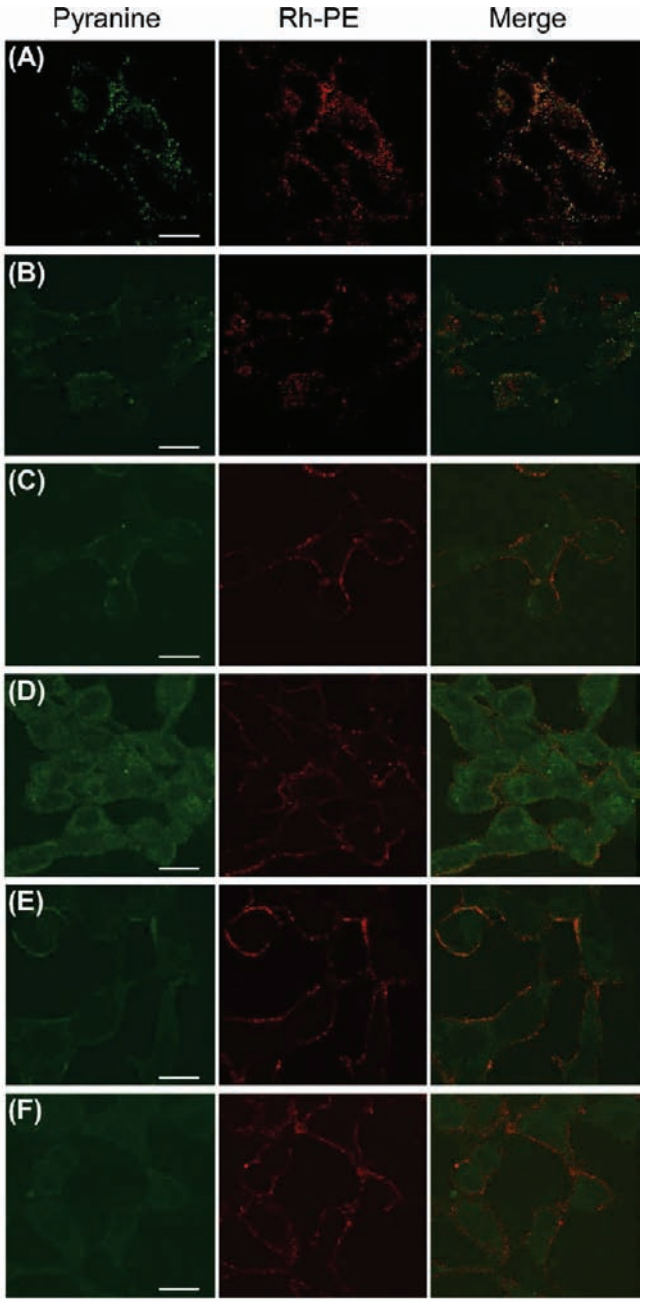

Figure 6. CLSM images of HeLa cells treated with pyranine-loaded plain (A,B) and $NIPAM_{56}$-Suc_{33}-HPG-modified (C−F) liposomes labeled with Rh-PE in the absence (A−D) or presence (E,F) of 100 μM chloroquine. Cells (2×10^5 cells) were incubated in the serum-free medium containing liposomes (0.3 mM) for 4 h at 28 °C and washed with phosphate-buffered saline three times. Then, the cells were additionally incubated at 28 °C (A,C,E) or 45 °C (B,D,F) for 15 min and were observed with CLSM. Bars represent 20 μm.

the cells were heated to 45 °C, the cells displayed the same fluorescence, indicating that the heat application did not affect the location of pyranine molecules in the cells (Figure 6B).

Similarly, cells treated with the dual signal-responsive $NIPAM_{56}$-Suc_{33}-HPG-modified liposomes at 28 °C mainly showed fluorescence around the cell surface (Figure 6C). However, when heated at 45 °C, the cells displayed the entirely different fluorescence of pyranine, which diffused in the cytosol, although Rh-PE fluorescence remained located around the cellular membrane. This fact indicates that pyranine molecules were released from liposomes and were introduced into cytosol upon heat application, although the liposomes were still in endosomes near the cellular membrane (Figure 6D). On the basis of Figure 5B, $NIPAM_{56}$-Suc_{33}-HPG chains attached onto the liposome surface strongly destabilize lipid membranes under a weakly acidic environment at temperatures higher than 35 °C. Therefore, it is likely that the polymer chains can cause significant destabilization of both the liposome and endosome membranes, enabling pyranine molecules to enter into the cytosol. Compared to the plain liposomes, the $NIPAM_{56}$-Suc_{33}-HPG-modified liposomes seemed to exhibit a tendency to remain in the peripheral region of the cellular membrane. The highly hydrated polymer chains covering the liposome surface may affect cellular processes, such as endocytosis, although the reason is unclear.

We also examined intracellular delivery mediated by the dual signal-responsive liposomes in the presence of chloroquine, which inhibits acidification of endosome.[14] As Figure 6F shows, cellular diffuse pyranine fluorescence was suppressed in the presence of chloroquine, indicating that a weakly acidic environment is required for temperature-induced triggering of liposome destabilization. These results demonstrate that destabilization of the dual signal-responsive liposomes can be triggered by mild heat application only for those trapped in weakly acidic compartments.

To confirm superiority of the dual signal-responsive liposomes, we further examined intracellular delivery using pH-sensitive but temperature-insensitive $NIPAM_0$-Suc_{90}-HPG-modified liposomes (Figure 4D) via the same incubation procedures. HeLa cells treated with the $NIPAM_0$-Suc_{90}-HPG-modified liposomes encapsulating pyranine exhibited mainly punctate fluorescence of pyranine around the periphery of cellular membrane irrespective of the temperature of the 15 min incubation (Supporting Information Figure S3). Because the cells were incubated with the liposomes for 4 h at 28 °C, which is much lower than the physiological temperature, reduced cellular activity might suppress the efficient lowering of pH in endosome. Considering that destabilization of $NIPAM_0$-Suc_{90}-HPG-modified liposomes was induced below pH 5.0 (Figure 4D), the liposomes trapped in endosome might not be efficiently destabilized, resulting in the limited extent of pyranine transfer into cytosol. This result suggests another merit of the dual signal-responsive liposomes, whose destabilization is efficiently induced through the synergy of protonated carboxyl groups and dehydrated NIPAM groups on the polymer chains.

CONCLUSION

We developed a new type of functional liposome whose destabilization can be dually controlled by pH and temperature using pH-sensitive and temperature-sensitive NIPAM-Suc-HPGs. The dual signal-responsive liposomes destabilized only when mildly heated under mildly acidic conditions. Therefore, only the liposomes taken up by cells and trapped in acidic compartments can be destabilized by mild heating. These liposomes destabilized in acidic endosome caused the transfer of contents into cytosol. To date, temperature-sensitive liposomes of various types have been developed. Their functions are focused only on temperature-induced control of drug release. Therefore, these liposomes may not be useful for delivery of membrane-impermeable molecules, such as siRNA and proteins, whose active sites exist in the intracellular space, because a large

fraction of the contents may be released from the liposomes in the extracellular space of the heated area. In contrast, the dual signal-responsive liposomes could release the contents only when trapped in the endosome of the cells in the heated area. Therefore, the dual signal-responsive liposomes might solve such problems of conventional temperature-sensitive liposomes and increase the efficacy and reliability of therapies based on these bioactive molecules. Attempts to adjust the temperature region in which the liposomes show response and to achieve sharp and drastic response upon signal applications are currently underway.

Supporting Information

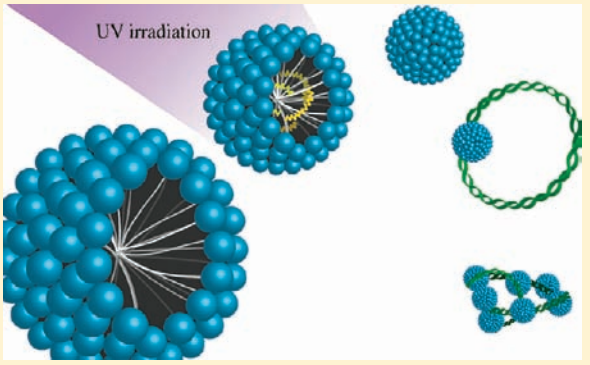
ABSTRACT: Cationic surfactants easily interact with plasmid DNA to form small lipoplexes. However, their detergent behavior and associated biological toxicity limit their use as gene delivery vectors. We have incorporated a diacetylene motif in the hydrophobic chain of cationic surfactants. By using UV irradiation, the small cationic micelles (9 nm) obtained with diacetylenic detergents were photopolymerized into 40 nm spheres. Electrostatic interactions with plasmid DNA led to the formation of 45 nm lipoplexes at N/P = 5 ratio. *In vitro* transfection of the pCMV-Luciferase plasmid resulted in gene expression (>10^{10} RLU/mg protein) at the same ratio, comparable with the commercially available JetSi-ENDO gene delivery system. This new and versatile class of molecules could lead to a new generation of *in vivo* gene delivery vectors.



INTRODUCTION

Surfactants are a compound family, which show very interesting properties. Their amphiphilic nature allows them to self-organize and form various attractive supramolecular structures like micelles, liposomes, nanotubes,[1] fibers,[2] or more complex assemblies.[3−5] These cationic constructions have received a lot of attention, partly due to their use as synthetic supramolecular vectors for gene delivery.[6−8] Ordered cationic liposomes or micelles or cationic detergents spontaneously form lipoplexes with DNA, due to electrostatic interactions between the cationic head groups of detergents and the negatively charged phosphate groups of nucleic acids.[9−11] Among the large number of cationic amphiphiles, which induce effective gene transfer, amine- and ammonium-based detergents are still the most studied.[6,7] However, these organized structures have a very dynamic nature. Monomers constantly exchange between solution and self-assemblies, inducing instability and toxicity. Thus, it has been suggested that cross-linking, using amphiphiles bearing polymerizable groups, could improve the stability of these labile systems.[12,13] Core cross-linked micelles and shell cross-linked micelles are usually obtained from copolymers and show some interesting properties in drug delivery.[14,15] However, only a few studies describe the use of diacetylene micelles.

Diacetylene surfactants receive a lot of attention due to their polymerization properties upon exposition to ultraviolet radiations.[16] This leads to the formation of more rigid structures and could also provide some new supramolecular nanoconstructs.[17] The potential application range from biosensors,[18,19] nonlinear optical devices[20] through to drug delivery.[21,22] It has been shown that diacetylene formulations[23] or polymerized liposomes[24] can deliver genes, but to the author's knowledge, few studies have been conducted on micelles.

In this paper, we describe the synthesis and the characterization of two new photopolymerized cationic micelles as synthetic DNA vectors. These new ammonium-based structures were obtained from the commercially available 10,12-pentacosadiyonic acid (PCDA) and could easily be photopolymerized. We demonstrate that these self-assemblies form lipoplexes in the presence of pCMV-Luc plasmid and can efficiently mediate gene transfer. By comparing behaviors of polymerized and nonpolymerized DNA lipoplexes, we show that polymerization significantly improves transfection and reduces toxicity.

EXPERIMENTAL PROCEDURES

Synthesis of Pentacosa-10,12-diyn-1-ol (2). To a stirred suspension of lithium aluminum hydride (0.91 g, 20.02 mmol) in THF (100 mL), a solution of 10,12-pentacosadiynoic acid (5.00 g, 13.34 mmol) in THF (50 mL) was added at 0 °C under Ar atmosphere. The resulting mixture was stirred for 90 min at RT. The reaction was quenched by adding 1 N HCl solution (25 mL) and the mixture concentrated to dryness under reduced pressure. The aqueous layer was extracted with EtOAc (2 × 30 mL), and the combined organic layers washed with 1 N HCl (20 mL), dried over anhydrous Na_2SO_4, filtered, and evaporated under vacuum to afford **2** as a white solid (4.40 g, 91% yield).

Synthesis of Pentacosa-10,12-diynyl-4-methylbenzenesulfonate (3). To a stirred solution of pentacosa-10,12-diyn-1-ol (4.40 g, 12.20 mmol) in CH_2Cl_2 (60 mL) were successively added *p*-toluenesulfonyl chloride (3.49 g, 18.30 mmol),

triethylamine (2.55 mL, 18.30 mmol), and catalytic amounts of DMAP. The resulting solution was stirred overnight at RT. A saturated solution of $NaHCO_3$ (25 mL) was added and the aqueous layer was extracted with CH_2Cl_2 (2 × 15 mL). The organic phases were combined, washed with a saturated solution of NaCl (15 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was submitted to silica-gel chromatography to afford compound **3** as a white solid (5.58 g, 89% yield).

Synthesis of *N*,*N*-Diethyl-pentacosa-10,12-diyn-1-amine (4). To a stirred solution of pentacosa-10,12-diynyl-4-methylbenzenesulfonate (7.14 g, 13.86 mmol) and Na_2CO_3 (7.35 g, 69.3 mmol) in CH_3CN (150 mL) was added diethylamine (5.07 g, 69.3 mmol). The solution was stirred at 70 °C for 24 h. The solvent was removed under reduced pressure and the residue was poured into a saturated solution of $NaHCO_3$ (60 mL). The aqueous layer was extracted with CH_2Cl_2 (4 × 25 mL), and the organic layers were combined, washed with a saturated solution of NaCl (15 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by silica-gel chromatography (eluting with EtOAc/cyclohexane 5:95) to yield compound **4** as a colorless oil (3.54 g, 79% yield).

Synthesis of 4-(2-Aminoethyl)-1,7-bis(*tert*-butoxycarbonyl)-1,4,7-triazaheptane (6). To a stirred solution of tris(2-aminoethyl)-amine (1.47 g, 10.05 mmol) in THF (40 mL) at 0 °C was slowly added BocON (4.95 g, 20.11 mmol) in THF (50 mL). The solution was stirred overnight at RT. The solvent was removed under reduced pressure and the residue was poured into EtOAc (50 mL). The organic layer was washed with NaOH 1 M (2 × 10 mL). The aqueous layer was diluted into a saturated solution of NaCl (20 mL) and was extracted with EtOAc (3 × 10 mL). The organic layers were combined, dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was purified by silica-gel chromatography (eluting with CH_2Cl_2/methanol 5:1) to yield compound **6** as a pale yellow oil (1.57 g, 45% yield).

Synthesis of Di-*tert*-butyl (((2-(tetracosa-10,12-diynamido)-ethyl)azanediyl)bis(ethane-2,1-diyl))dicarbamate (7). To a stirred solution of 10,12-pentacosadiynoic acid (1.00 g, 2.90 mmol) and *N*-hydroxysuccinimide (0.50 g, 4.33 mmol) in CH_2Cl_2 (20 mL) were added successively 1-ethyl-3-(3-dimethylamino-propyl) carbodiimide (0.83 g, 4.33 mmol) and *N*,*N*-diisopropylethylamine (757 μL, 4.33 mmol). The solution was stirred overnight at RT. The solvent was removed under reduced pressure and the residue was poured into EtOAc (20 mL). The organic layer was washed with H_2O (2 × 10 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. The white solid was solubilized into THF (50 mL) with Et_3N (606 μL, 4.33 mmol) and 4-(2-aminoethyl)-1,7-bis(*tert*-butoxycarbonyl)-1,4,7-triazaheptane **4** (1.08 g, 2.90 mmol), and the solution was stirred overnight at RT. The solvent was removed under reduced pressure, and the residue was purified by silica-gel chromatography (eluting with EtOAc) to yield compound **7** as a white solid (1.57 g, 85% yield).

Synthesis of *N*-(2-(Bis(2-aminoethyl)amino)ethyl)tetracosa-10,12-diynamide (8). To a stirred solution of **7** (0.2 g, 0.28 mmol)) in CH_2Cl_2 (5 mL) was added trifluoroacetic acid (327 μL, 4.27 mmol). The solution was stirred 4 h at RT. The solvent was removed under reduced pressure and the residue was poured into EtOAc (10 mL). The organic layer was washed with NaOH 1 M (1 × 10 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure to yield compound **8** as a white solid (0.14 g, quantitative).

Polymerization. For the photopolymerization steps, quartz cuvettes containing 3 mL of micelles solution were placed into a Cross-Linker Bio-Link 254 from Fischer Bioblock. Photopolymerization was achieved at 254 nm and 48 W.

Photopolymerization was followed by UV−visible spectroscopy on a Varian Cary 100 Bio UV−visible spectrophotometer.

CMC Measurements. Surface tensions were measured by using the du Nouy ring, as follows. First, 15 mL of solution was prepared by diluting stock solutions of micelles. The solution were then transferred to the tensiometer vessel and was allowed to equilibrate at 25 °C for 5 min.

Dynamic Light Scattering (DLS). The hydrodynamic radii were determined *via* DLS measurements using a Malvern nano ZS apparatus with the following specifications: sampling time = 90 s; refractive index of medium, 0.1 M acetate buffer = 1.340; phosphate buffer = 1.340; refractive index of particles (RI) = 1.43; medium viscosity = 1.0140 cP; temperature = 25 °C. Data were analyzed using multimodal number distribution software included with the instrument. ζ potentials were measured with the same apparatus and with the following specifications: 20 measurements per sample; dielectric constant = 80; temperature = 25 °C; beam mode F(Ka) = 1.5 (Smoluchowski model).

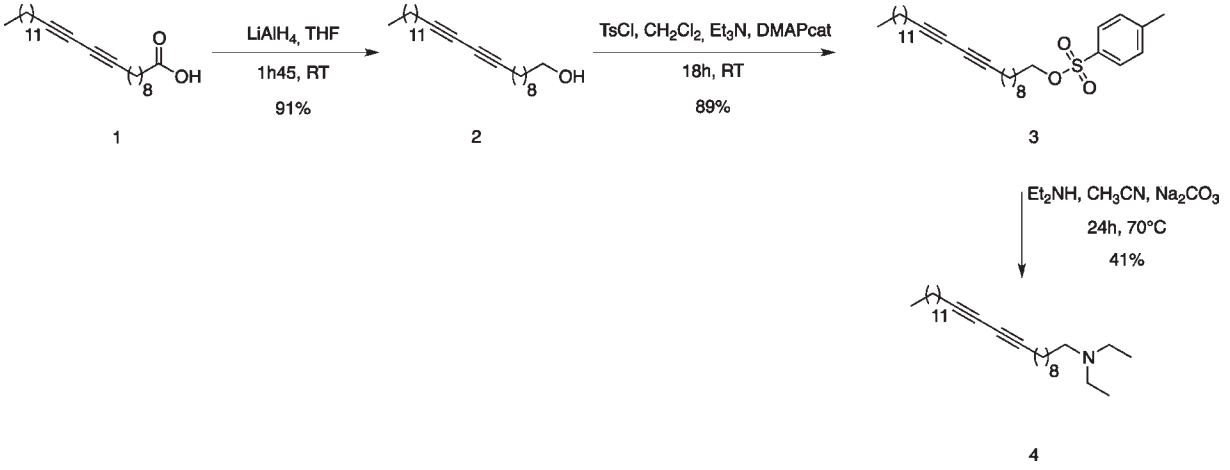
Transmission Electron Microscopy (TEM). Images were taken with a TEM Phillips CM12 apparatus, onto 300 mesh copper grids (Ted Pella, 822-F, Formvar removed). Ten microliters of sample was allowed to adsorb for 1 min onto grids. Grids were wicked from one side, and placed for 30 s on a 50 μL drop of 2% uranyl acetate, wicked again, and air-dried before imaging.

Agarose Gel Electrophoresis. Twenty microliters of water containing 5% glucose or 150 mM NaCl, 0.4 μg pCMV-Luc, and increasing amount of polymerized and nonpolymerized cationic micelles were subjected (30 min of complexation time) to electrophoresis in a 1% agarose gel containing 1 mM EDTA, 40 mM Tris acetate buffer, and 0.5 μg/mL ethidium bromide for 90 min at 100 V. DNA was visualized with an UV transilluminator at 254 nm.

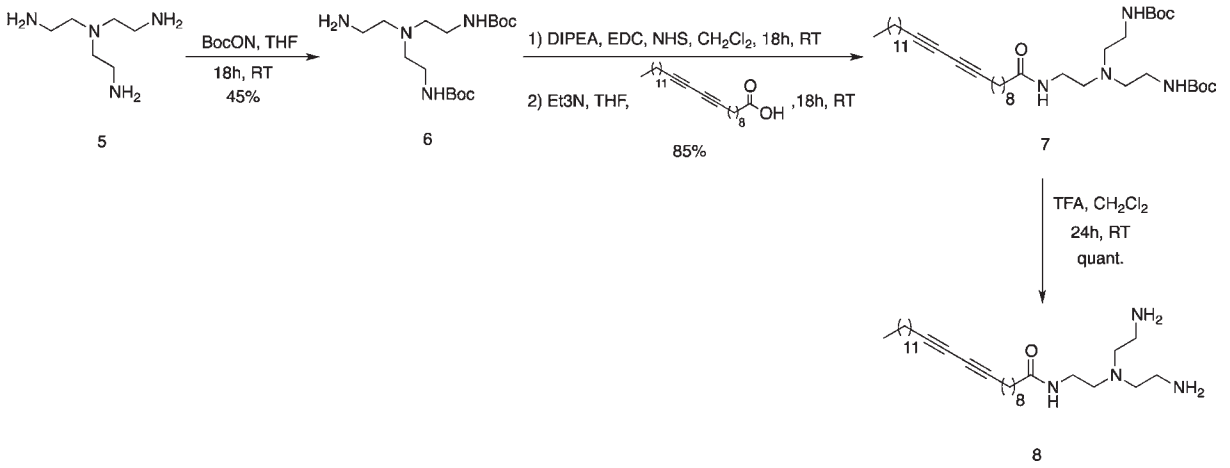
Cell Culture. HeLa cells were grown in Eagle's MEM supplemented with 10% FBS, L-glutamine (2 mM), penicillin (100 units/mL), and streptomycin (100 μg/mL). Cells were maintained at 37 °C in a 5% CO_2 humidified atmosphere and all experiments were done in triplicates. The day before experiment, cells were seeded in 24-multiwell plates at 5 × 10^4 cells/well in fresh complete medium (1 mL).

Lipoplex Formation for pCMV-Luc Delivery. The procedure is for a 24-multiwell plate experiment. Typically, an aqueous solution of polymerized and nonpolymerized micelles of compound **4** and **8**: $\mathbf{M_4P_{1h}}$, **M$_4$NP**, $\mathbf{M_8P_{1h}}$, and **M$_8$NP** (volume depending on N/P ratio), was diluted up to 50 μL in water containing 5% glucose or 150 mM NaCl. The solution was homogenized by vortexing and left for 10 min. Separately, an aqueous solution of pCMV-Luc (corresponding to 2 μg of pCMV-Luc) was diluted up to 50 μL in water containing 5% glucose or 150 mM NaCl. The solution was then homogenized and left for 10 min, after which the M_4P_{1h}, M_4NP, M_8P_{1h}, or M_8NP solution was added to the pCMV-Luc solution, and vigorously mixed (15 s). Finally, lipoplexes were incubated for 30 min at RT and added in each well by diluting with serum free cell culture medium (1 mL). Four hours later, serum (0.1 mL/well) was added. The gene expression profiles were analyzed 24 h after addition of lipoplexes. Transfection assays were also performed in the presence

Scheme 1. Synthesis of Amphiphile 4



Scheme 2. Synthesis of Amphiphile 8



of serum: after incubation, lipoplexes were added in each well by diluting with complete cell culture medium (10% serum, 1 mL).

Quantification of the Luciferase Gene Expression. Luciferase gene expression was determined 24 h after delivery with a commercial kit, using manufacturer's protocol (Luciferase Assay System, Promega, Charbonnières, France). The luminescence was measured from 10 μL of lysate during 1 s with a luminometer (Centro LB960 XS; Berthold, Thoiry, France). Luciferase activity is expressed as the mean of light units integrated over 10 s (RLU) and normalized per mg of cell protein by using the BCA assay (Pierce, Brebières, France). The errors bars represent standard deviation derived from triplicate experiments. JetPEI and JetSi-ENDO are transfection reagents (Polyplus-Transfection, Illkirch, France), used according to manufacturer's instructions.

RESULTS

Design and Synthesis. The two new ammonium-based amphiphiles were easily obtained from the commercially available acid **1**. The synthesis of compound **4**, as depicted in Scheme 1, was prepared in three steps as previously reported.[3]

BOC protection of the two terminal amines of tris(2-aminoethyl)amine affords compound **6**, which is easily coupled to the starting acid **1** as described in Scheme 2. Treatment of **7** with an excess of TFA provides a high yield of compound **8**.

Micelle Characterization. Measurements of the surface tension of M_4NP and M_8NP solutions allowed us to access the critical micellar concentrations (CMC) of nonpolymerized solutions. Curves are presented in the Supporting Information. M_4NP and M_8NP solutions have CMC values of 12 μmol/L (0.0049 mg/mL) and 21 μmol/L, (0.011 mg/mL), respectively. Following polymerization, CMC could not be detected anymore. The self-assembly of amphiphiles **4** and **8** into micelles was then assessed by DLS. Experiments with compound **4** at 600 μM (0.25 mg/mL) in various buffer solutions showed the importance of pH and medium composition. In 0.1 M phosphate buffer (pH = 7.4), we observed no micellar structures but 400 nm aggregates were observed, while in 0.1 M acetate buffer (pH = 5), amphiphile **4** led to the formation of nonpolymerized micelles (M_4NP) of 9 nm diameter (see Supporting Information). Similarly, nonpolymerized micelles of compound **8** (M_8) at 500 μM (0.25 mg/mL) were only observed in 0.1 M acetate buffer. Micelle formation and size were confirmed by transmission electron microscopy

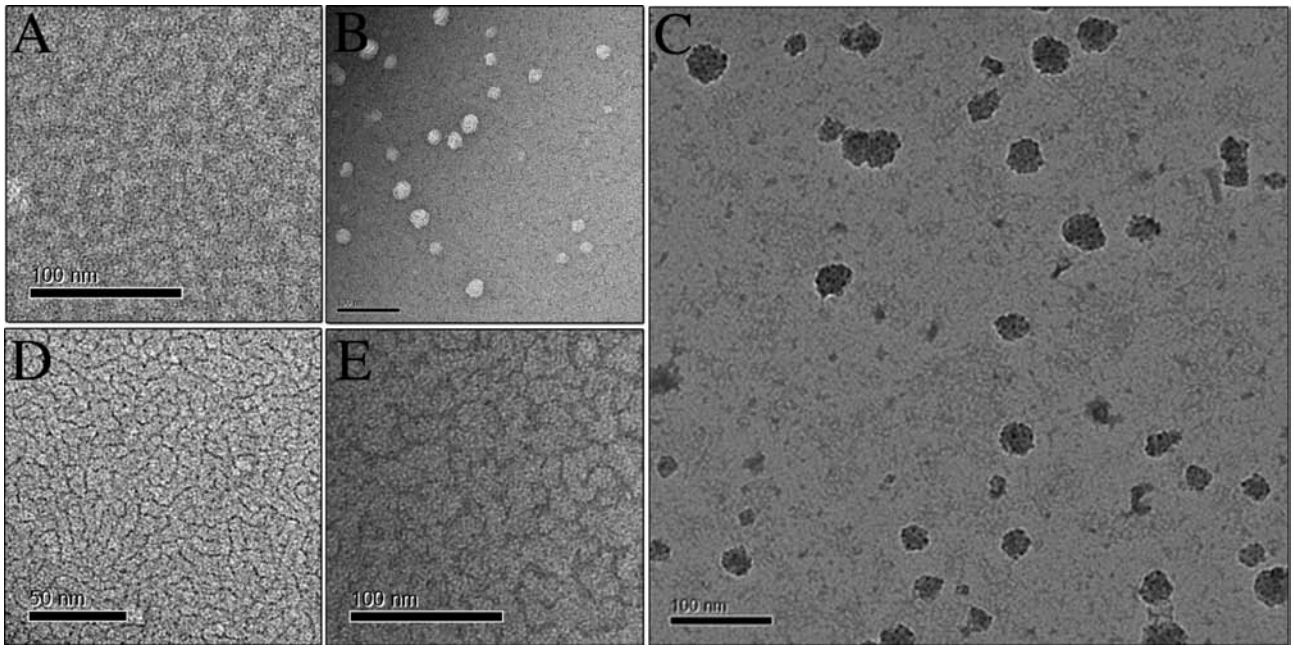


Figure 1. TEM images of M_4 and M_8 (C = 600 μM and 500 μM, respectively) in 0.1 M acetate buffer. A, M_4NP; B, M_4P_{1h}; C, M_4P_{1h} diluted to 60 μM in phosphate buffer; D, M_8NP; E, M_8P_{1h}. Scale bars: 100 nm (A, B, C, and E) and 50 nm (D).

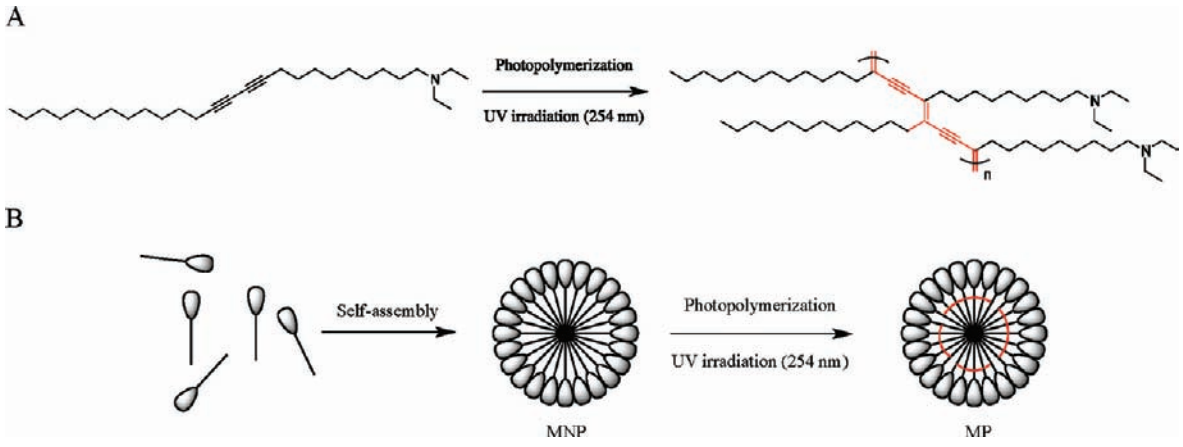

Figure 2. (A) Amphiphile **4** and corresponding polymer formula. (B) Schematic process of polymerization. Polar head groups are shown as gray balls, amphiphile chains by straight gray lines, and polymeric chains by curved red lines. (MNP: nonpolymerized micelles. MP: polymerized micelles.)

(TEM) experiments, as shown in Figure 1A,D, where elongated and tubular structures are visible.

Micelle Polymerization. Diacetylene polymerization (Figure 2) was initiated by 254 nm ultraviolet irradiation. This process was followed over time by DLS and TEM experiments. As shown in Supporting Information, the sizes of the assemblies of compound **4** increase over polymerization time. Beyond one hour, photopolymerization deeply affects the size of the structures: after four hours, objects present a 40 nm diameter, which increases up to 250 nm after 7 h. TEM only detected large aggregates. However, up to one hour of polymerization, assemblies kept the same diameter (9 nm) and still could be considered to be micelles (M_4P_{1h}). These small and spherical structures were also observed by TEM (Figure 1B), and as depicted in the Figure 1E, the same results were obtained with micelles of compound **8** polymerized for 1 h (M_8P_{1h}). The dilution of M_4P_{1h} micelles to 60 μM in phosphate buffer (Figure 1C) did not destroy their structure, and this demonstrates their resistance to dilution and pH changes, and consequently the effectiveness of the polymerization.

The polymerization process was followed every ten minutes for up to 90 min by UV−visible spectroscopy (spectra available in Supporting Information) in order to analyze the propagation process. In both cases, ene-yne bond elongation was shown by a characteristic absorption band between 250 and 300 nm. Its intensity increases over polymerization time and stabilizes at 20 min (Figure 3) showing an optimal propagation level into micelles. These analyses enabled us to choose the optimal condition taking into account self-assembly and micelle reticulation. For the rest of the study, photopolymerization time was one hour.

DNA Lipoplexes Characterization. Electrostatic interactions between plasmid DNA and nonpolymerized or polymerized micelles

were imaged by agarose gel electrophoresis of lipoplexes, which were made with increasing N/P (vector amine per DNA phosphate) ratios (Figure 4). The DNA was detected using ethidium bromide orange fluorescence.

M_4NP lipoplexes in isotonic 150 mM NaCl showed full DNA condensation at N/P 10 and the corresponding polymerized lipoplexes at N/P 2. This notable improvement was also observed for M_4 lipoplexes in iso-osmotic 5% glucose solutions in water. Thus, full DNA condensation was not observed with nonpolymerized lipoplexes in the range studied; however, it was observed at N/P 10 and above, for the polymerized lipoplexes.

A similar trend was observed for M_8 lipoplexes. DNA condensation occurred at N/P 2 in isotonic 150 mM NaCl and for N/P 3 in iso-osmotic 5% glucose solutions in water with nonpolymerized lipoplexes. A slight improvement was observed with polymerized lipoplexes.

It is interesting to note that lipoplexes formulated in 5% glucose solutions even these most compacted forms at high N/P ratio remain accessible to ethidium bromide.

Lipoplexes prepared in 5% glucose were further characterized by DLS. Size measurements on M_4P_{1h} lipoplexes (Figure 5A) showed that their diameter decreased when the N/P ratio was increased. The same behavior was observed for M_8P_{1h} lipoplexes, except at N/P 20. Both formulations showed an average diameter of 45 nm at N/P 5, which was confirmed by TEM experiments (Figure 6A,C). Zeta (ζ) potential measurements made on the above lipoplexes showed increasing positive surface charges with N/P ratio (Figures 5B). When prepared in 150 mM NaCl, lipoplexes at N/P 5 became micrometric structures made of aggregated spheres (see Supporting Information).

Transfection of Cells in Culture. pCMV-Luc gene delivery experiments were conducted with M_4 and M_8 lipoplexes on HeLa cells, prepared either in 5% glucose (Figure 7A) or 150 mM NaCl solutions (see Supporting Information).

Final monomer concentrations in wells were calculated as described in Table 1. Final plasmid concentration was fixed to 2 μg/mL.

In each case, the polymerized micelles exhibited higher transfection efficiency and lower toxicity than the nonpolymerized micelles.

N/P 5 was the optimal ratio for both M_4P_{1h} and M_8P_{1h}, and they have the same level of luciferase expression, between 10^{10} and 10^{11} RLU/mg of protein. This level is 1 order of magnitude lower than the JetPEI system, which is considered a "gold standard"

in nonviral gene delivery; it is comparable to another commercially available gene delivery lipidic system, JetSi-ENDO, which is known for its high efficiency/toxicity ratio. However, M_4P_{1h} were found to be quite toxic, compared to M_8P_{1h} in optimal conditions. Transfection efficiencies were reduced by 1 to 3 orders of magnitude in the presence of 10% serum (see Figure 8), revealing deleterious interactions between the complexes and serum proteins. Thus, further developments (e.g., PEGylation and/or targeting ligands) will be necessary for effective *in vivo* gene delivery.

DISCUSSION

The application of polydiacetylene polymeric structures for gene delivery has never been studied. In a previous study, we have shown that amphiphiles formed by coupling diynic lipophilic tails and various polar headgroups spontaneously self-assembled into micelles in aqueous solution. In particular, coupling anionic, neutral, or cationic polar headgroups to 10,12-pentacosadiynoic acid led to amphiphiles with programmed pH-dependent self-assembly properties.[25] On the other hand, when we varied the length of the hydrophobic chain length containing a neutral polar headgroup, we found that, while 12 carbon chain was too short to enable the formation of micelles, 18 and 25 carbon chains led to stable micelles with CMC of 0.091 mg/mL and 0.082 mg/mL, respectively (unpublished results). Since it appears to form robust micelles and is readily available, we decided to use 10,12-pentacosadiynoic acid (C_{25}) as a lipophilic tail for this study. Cationic monomers were easily synthetized from PCDA and, as expected, self-assembled into micelles in a simple and spontaneous process. It is interesting to note that pH and medium composition are important parameters for micelle formation.

The photopolymerization state requires a perfectly calibrated process to ensure the size reproducibility of the polymerized micelle. Elongation creates covalent cross-linking between monomers into micelles to provide a three-dimensional network and more rigid assemblies as shown in Figure 1B. However, DLS experiments showed that, beyond one hour, polymerization provides larger aggregates than the initial micelles. This fact has already been observed in micelle polymerization[26] and in this study could be explained by geometric constraints imposed by the ene-yne backbone. It is well-known that photopolymerization of diacetylene groups occurs only in a highly ordered state.[16] In our case, the propagation of ene-yne bonds strongly alters the initial morphology, resulting in larger structures with lower radii of curvature.

Micelle structures were observed by DLS and TEM over one hour of polymerization, and UV spectrophotometric analysis showed a good level of elongation. One hour of polymerization

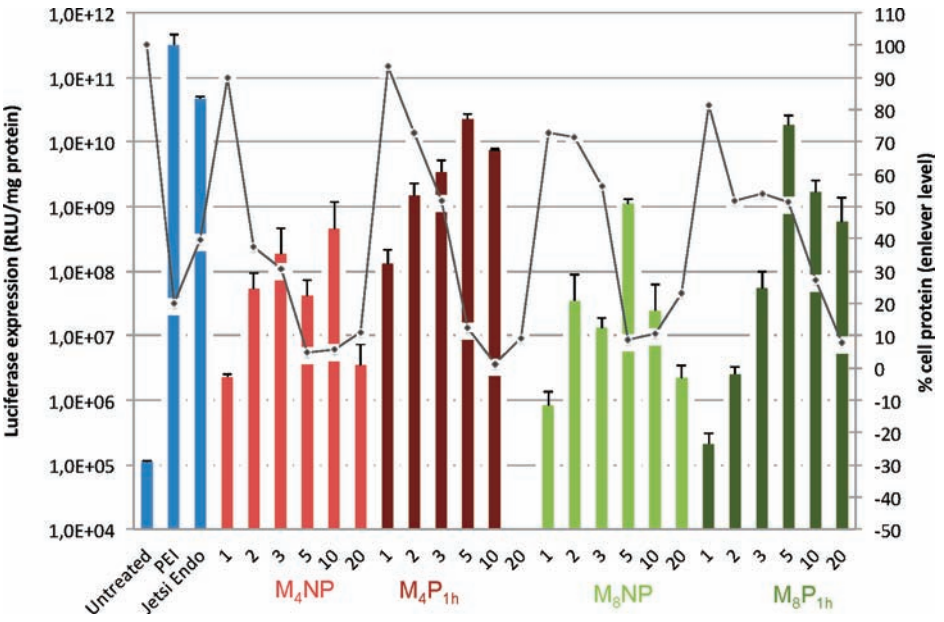

Figure 7. Gene delivery experiments of pCMV-Luc at various N/P (lipoplexes prepared in 5% glucose solution), without serum. Luciferase expression (bars) and percentage of total cellular proteins (line and circles) are given for negative control (untreated), positive control (JetPEI and JetSi-ENDO), M_4NP (light red), M_4P_{1h} (dark red), M_8NP (light green), and M_8P_{1h} (dark green). Means and sd of separate triplicates are given.

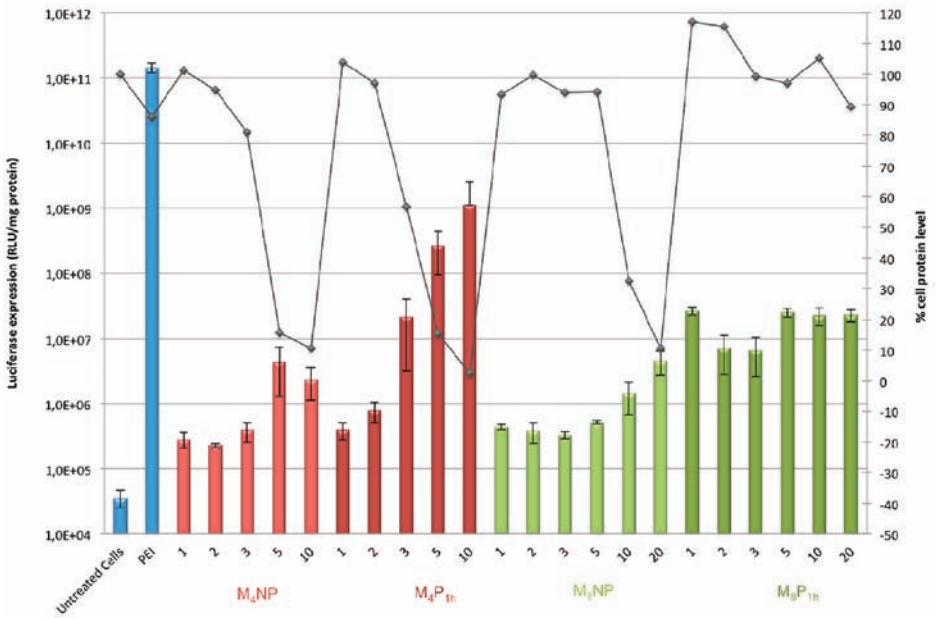

Figure 8. Gene delivery experiments of pCMV-Luc at various N/P (lipoplexes prepared in 5% glucose solution), with serum. Luciferase expression (bars) and percentage of total cellular proteins (line and circles) are given for negative control (untreated), positive control (JetPEI), M_4NP (light red), M_4P_{1h} (dark red), M_8NP (light green), and M_8P_{1h} (dark green). Means and sd of separate triplicates are given.

seemed to be the best compromise to retain the original structure, while having enough cross-linking to "freeze" the micelles. Diluting the micelles below their CMC in phosphate buffer (pH = 7) proved the efficiency of polymerization. Indeed, polymerized micelles were still observed after switching to neutral conditions, whereas nonpolymerized micelles were disrupted.

Agarose gel electrophoresis experiments showed the different behaviors of polymerized and nonpolymerized lipoplexes. Using either M_4 or M_8 complexes, the polymerized lipoplexes show full DNA condensation at lower N/P ratio than nonpolymerized lipoplexes. In polymerized micelles, the exchange of monomers between the micelle and its surroundings was strongly inhibited, and led to better DNA condensation and lipoplex stability. In isotonic 150 mM NaCl for N/P 20, no fluorescence due to the ethidium bromide staining was observed, reflecting very good DNA compaction into the lipoplexes. It has to be noted that polymerized micelles have their own green fluorescence, due to ene-yne bonds, which is absent in nonpolymerized micelles.

Lipoplexes were observed by DLS experiments in iso-osmotic 5% glucose solutions in water. A previous study showed that lipoplexes containing a single pCMV-Luc plasmid molecule have a size of about 25 nm.[27] In our case, size measurements, confirmed by TEM experiments, showed very small structures of about 40 nm, containing probably two to four plasmid molecules. This would allow further development of the lipoplexes for in vivo gene delivery because the size range should permit good tissue distribution.

In vitro transfection results showed that gene transfection potency is improved by photopolymerization, and as observed for agarose gel electrophoresis experiments, the best results are obtained for N/P 5, especially for M_8, which is considerably less toxic than M_4. This is expected since, at any given N/P ratio, the triamine M_8 concentration is only one-third of the monoamine M_4 concentration. At the optimal N/P ratio in 5% glucose solution, M_4P_{1h} and M_8P_{1h} transfection efficiencies are comparable, in serum-free serum conditions, to that of JetSi-ENDO, a cationic lipid transfection reagent. Synthesis of new amphiphilic molecules designed to be more effective for *in vivo* use, with poly(ethylene glycol) groups and targeting ligands, for example, should improve the robustness of our system.

In summary, we have prepared new cationic polydiacetylene micelles, with a reasonable *in vitro* gene transfection efficiency, and shown that photopolymerization significantly improves their transfection potency. These micelles are small, and their modular structure could lead to further developments. The use of functionalizable polar headgroups, for example, could allow addition of targeting ligands and/or poly(ethylene glycol). Alkyne polar headgroup could also lead to postfunctionalization by click-chemistry.

Table of Contents

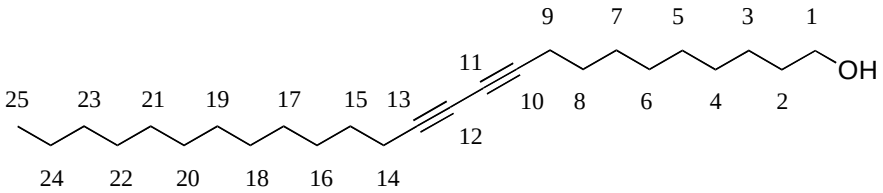
A. Materials and methods

General remarks

Unless stated otherwise, all starting materials and reagents were obtained from commercial suppliers and used without further purification. All solvents were of dry grade and purchased from Aldrich. All compounds were characterized using standard analytical and spectroscopic techniques. ^{1}H and ^{13}C spectra were obtained on a Brucker Advance III instrument (BBFO+ probe). Mass spectrometry was performed on a MS Bruker (Ion Trap, HCT Ultra, ESI) and a MS Agilent (QTof 6520, ESI) spectrometer. Unless otherwise indicated, the polarity/scan type used for ESI-MS was positive. NMR chemical shifts are reported in δ units (ppm) relative to tetramethylsilane and converted to the TMS scale using the residual proton of $CDCl_3$ (7.26 ppm for ^{1}H NMR, and 76.91 for ^{13}C NMR). Data are reported as follows: multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, br = broad), coupling constants, integration and assignment. Merck Silica Gel 60 F_{254} plates were used for analytical thin layer chromatography. TLC analysis was facilitated by the use of the following stains in addition to UV light (254 nm) with fluorescent-indicating silica-gel plates: vanillin/EtOH, $KMnO_4/H_2O$, or Ninhydrin/EtOH. Merck Silica gel 60 (particle: 40-63 μm) was employed for column chromatography. UV/vis. absorption spectra were recorded with a Varian Cary 100 bio spectrophotometer. The extinction coefficients (ε, $M^{-1}cm^{-1}$) are given as the average value obtained from three independent measurements at different concentrations (error value ± 5%). Melting points were measured in a Stuart Scientific SMP2 melting point apparatus 2 and are uncorrected.

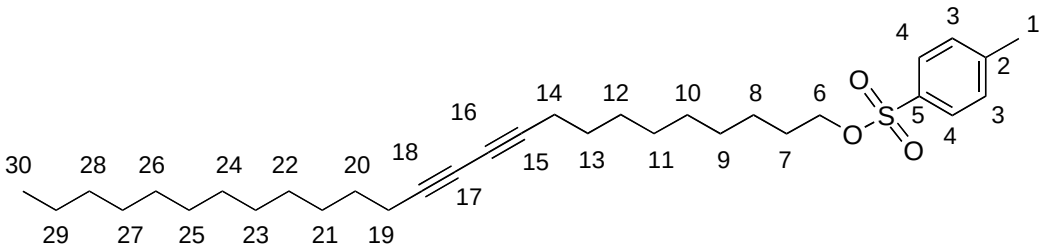
B. Product characterization

Pentacosa-10,12-diyn-1-ol (2)



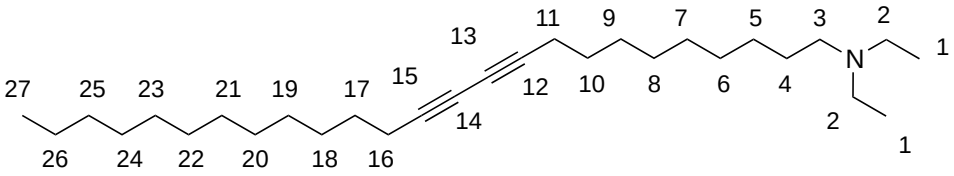
R_f = 0.32 (MeOH/CH_3Cl: 2/100); ^1H NMR (400 MHz, $CDCl_3$) δ 3.63 (t, J = 6.6 Hz, 2H, H_1), 2.24 (t, J = 7.0 Hz, 4H, $H_{9, 14}$), 1.58-1.25 (m, 34H, $H_{2-8, 15-24}$), 0.88 (t, J = 6.8 Hz, 3H, H_{25}); ^{13}C NMR (75 MHz, $CDCl_3$) δ 77.7 (1C, C_{10}), 77.6 (1C, C_{13}), 65.4 (2C, $C_{11,12}$), 63.2 (1C, C_1), 32.9 (1C, C_2), 32.1 (1C, C_{16}), 29.9-28.5 (13C, $C_{4-8,15,17-23}$), 25.9 (1C, C_3), 22.8 (1C, C_{24}), 19.4 (2C, $C_{9,14}$), 14.3 (1C, C_{25}); MS m/z (relative intensity) 360 $[M]^+$ (3.8); mp 62 ± 1 °C. UV/vis ($CHCl_3$): λ_{max} (log ε) = 244 (2.72) nm.

Pentacosa-10,12-diynyl-4-methylbenzenesulfonate (3)



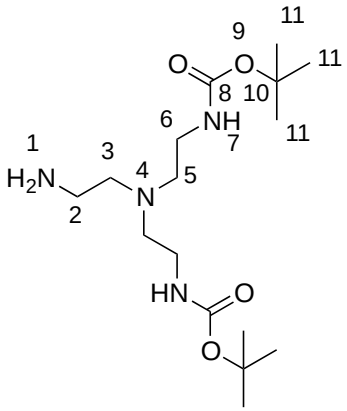
R_f = 0.68 (EtOAc/cyclohexane: 2/8); ^1H NMR (400 MHz, $CDCl_3$) **δ** 7.79 (dd, J_1 = 6.4 Hz, J_2 = 2.0 Hz, 2H, H_4), 7.34 (dd, J_1 = 8.4 Hz, J_2 = 0.8 Hz, 2H, H_3), 4.02 (t, J = 6.6 Hz, 2H, H_6), 2.45 (s, 3H, H_1), 2.23 (t, J = 7.2 Hz, 4H, $H_{14,19}$), 1.64 (m, 34H, $H_{5-13,20-29}$), 0.88 (t, J = 7.0 Hz, 3H, H_{30}); ^{13}C NMR (75 MHz, $CDCl_3$) δ 144.7 (1C, C_2), 133.47 (1C, C_5), 129.9 (2C, C_3), 128.0 (2C, C_2), 77.8 (1C, C_{15}), 77.6 (1C, C_{18}), 70.8 (1C, C_6), 65.5 (1C, C_{16}), 65.4 (1C, C_{17}), 32.1 (1C, C_{21}), 31.3 (1C, C_7), 29.9-28.4 (13C, $C_{9-13,20,,22-28}$), 25.4 (1C, C_8), 22.8 (1C, C_{29}), 21.8 (1C, C_1), 19.4 (2C, $C_{14,19}$), 14.3 (1C, C_{30}); MS m/z (relative intensity) 537 $[M+Na]^+$ (100); mp 56 ± 1 °C. UV/vis ($CHCl_3$): λ_{max} (log ε) = 241 (2.90) nm.

N,N-Diethyl-pentacosa-10,12-diyn-1-amine (4)



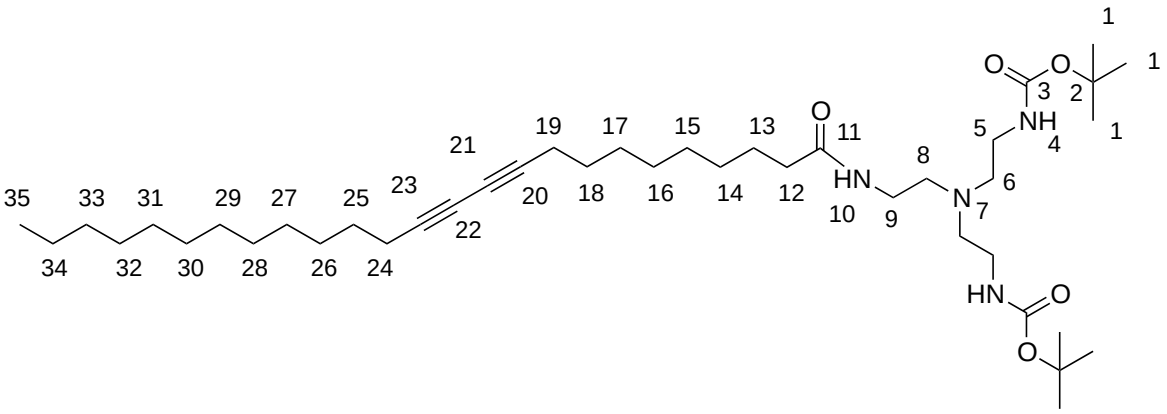
^{1}H NMR (400 MHz, $CDCl_3$) δ 2.51 (q, J = 7.5 Hz, 4H, H_2), 2.39 (t, J = 7.8 Hz, 2H, H_3), 2.23 (t, J = 7.0 Hz, 4H, $H_{11,16}$), 1.52-1.25 (m, 34H, $H_{4\text{-}10,17\text{-}26}$), 1.01 (t, J = 7.1 Hz, 6H, H_1), 0.88 (t, J = 6.9 Hz, 3H, H_{27}); ^{13}C NMR (75 MHz, $CDCl_3$) δ 77.5 (2C, $C_{12,15}$), 65.4 (2C, $C_{13,14}$), 53.1 (1C, C_3), 46.9 (2C, C_2), 31.9 (1C, C_{18}), 29.7-27.0 (15C, $C_{4\text{-}10,17,19\text{-}25}$), 22.7 (1C, C_{26}), 19.2 (2C, $C_{11,16}$), 14.1 (1C, C_{27}), 11.7 (2C, C_1); MS m/z (relative intensity) 416 $[M+H]^+$ (100). UV/vis ($CHCl_3$): λ_{max} (log ε) = 243 (2.43) nm.

4-(2-Aminoethyl)-1,7-bis(tert-butoxycarbonyl)-1,4,7-triazaheptane (6)



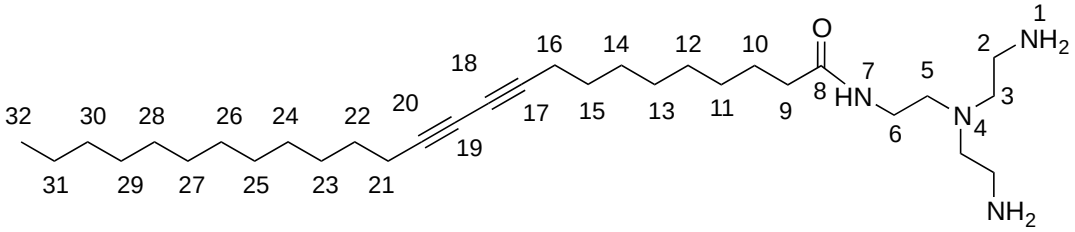
^{1}H NMR (400 MHz, $CDCl_3$) δ 3.16 (m, 4H, H_6), 2.72 (t, J = 5.8 Hz, 2H, H_2), 2.54 (t, J = 6.0 Hz, 4H, H_5), 2.49 (t, J = 6.0 Hz, 2H, H_3), 1.43 (s, 18H, H_{11}); ^{13}C NMR (75 MHz, $CDCl_3$) δ 156.3 (2C, C_8), 79.3 (2C, C_{10}), 57.1 (1C, C_3), 54.4 (2C, C_5), 40.0 (2C, C_6), 38.8 (1C, C_2), 28.6 (6C, C_{11}); MS m/z (relative intensity) 347 $[M+H]^+$ (100).

di-*tert*-butyl (((2-(tetracosa-10,12-diynamido)ethyl)azanediyl)bis(ethane-2,1-diyl))dicarbamate (7)



^{1}H NMR (400 MHz, $CDCl_3$) δ 6.81 (br s, 1H, H_{10}), 5.06 (br s, 2H, H_4), 3.27 (q, J = 5.3 Hz, 2H, H_{12}), 3.14 (q, J = 4.6 Hz, 4H, H_5), 2.55 (t, J = 5.6 Hz, 2H, H_8), 2.50 (t, J = 5.4 Hz, 4H, H_6), 2.25-2.21 (m, 6H, $H_{19,24,9}$), 1.44 (s, 18H, H_1), 1.39-1.23 (m, 32H, $H_{13\text{-}18,25\text{-}34}$), 0.87 (t, 6.8 Hz, 3H, H_{35}); ^{13}C NMR (75 MHz, $CDCl_3$) δ 173.8 (1C, C_{11}), 156.6 (2C, C_3), 79.5 (2C, C_2), 77.7 (2C, $C_{20,23}$), 65.4 (2C, $C_{21,22}$), 55.1 (2C, C_6), 54.2 (1C, C_8), 39.1 (1C, C_5), 37.5 (1C, C_9), 36.5 (1C, C_{12}), 32.0 (1C, C_{26}), 29.7-28.5 (12C, $C_{14\text{-}18,25,27\text{-}33}$), 28.6 (6C, C_1), 25.9 (1C, C_{13}), 22.8 (1C, C_{34}), 19.3 (2C, $C_{19,24}$), 14.2 (1C,C_{35}); MS m/z (relative intensity) 704 $[M+H]^+$ (100).

***N*-(2-(bis(2-aminoethyl)amino)ethyl)tetracosa-10,12-diynamide (8)**



^{1}H NMR (400 MHz, $CDCl_3$) δ 7.06 (br s, 1H, H_7), 3.31 (q, J= 5.2 Hz, 2H, H_9), 2.79 (t, J = 5.8 Hz, 4H, H_2), 2.60 (t, J = 6.0 Hz, 2H, H_5), 2.56 (t, J = 5.8 Hz, 4H, H_3), 2.24 (t, J = 7.0 Hz, 4H, $H_{16,21}$), 2.16 (t, J = 7.6 Hz, 2H, H_6), 2.06 (br s, 4H, H_1), 1.62-1.22 (m, 32H, $H_{10\text{-}15,22\text{-}31}$), 0.88 (t, 7.0 Hz, 3H, H_{32}); ^{13}C NMR (75 MHz, $CDCl_3$) δ 77.8 (2C, $C_{17,20}$), 65.4 (2C, $C_{18,19}$), 56.8 (2C, C_3), 53.5 (1C, C_5), 39.7 (2C, C_2), 36.8 (1C, C_6), 32.1 (1C, C_{23}), 29.8-28.5 (15C, $C_{9,11\text{-}15,22,24\text{-}31}$), 26.0 (1C, C_{10}), 22.8 (1C, C_{31}), 19.3 (2C, $_{C16,21}$), 14.3 (1C, C_{32}) ; HRMS m/z (relative intensity) 503.5 $[M+H]^+$ (100).

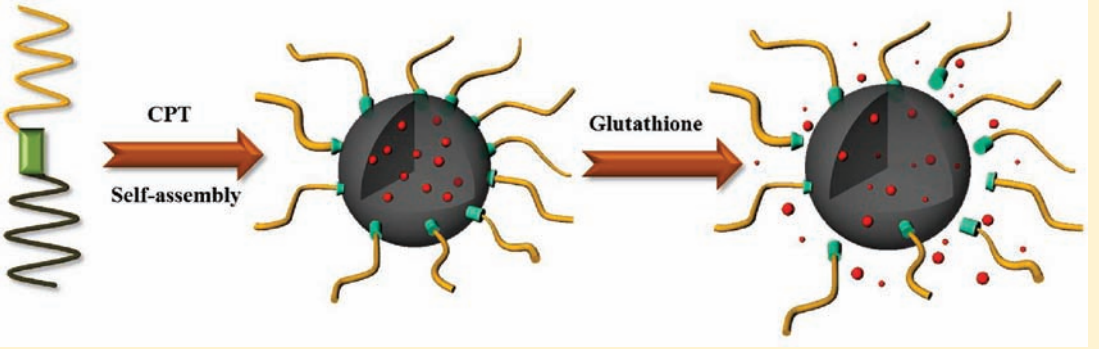
Supporting Information

ABSTRACT:



Poly(ethylene glycol)-*b*-poly(γ-benzyl L-glutamate)s bearing the disulfide bond (PEG-SS-PBLGs), which is specifically cleavable in intracellular compartments, were prepared via a facile synthetic route as a potential carrier of camptothecin (CPT). Diblock copolymers with different lengths of PBLG were synthesized by ring-opening polymerization of benzyl glutamate *N*-carboxy anhydride in the presence of a PEG macroinitiator (PEG-SS-NH_2). Owing to their amphiphilic nature, the copolymers formed spherical micelles in an aqueous condition, and their particle sizes (20−125 nm in diameter) were dependent on the block length of PBLG. Critical micelle concentrations of the copolymers were in the range 0.005−0.065 mg/mL, which decreased as the block length of PBLG increased. CPT, chosen as a model anticancer drug, was effectively encapsulated up to 12 wt % into the hydrophobic core of the micelles by the solvent casting method. It was demonstrated by the *in vitro* optical imaging technique that the fluorescence signal of doxorubicin, quenched in the PEG-SS-PBLG micelles, was highly recovered in the presence of glutathione (GSH), a tripeptide reducing disulfide bonds in the cytoplasm. The micelles released CPT completely within 20 h under 10 mM GSH, whereas only 40% of CPT was released from the micelles in the absence of GSH. From the *in vitro* cytotoxicity test, it was found that CPT-loaded PEG-SS-PBLG micelles showed higher toxicity to SCC7 cancer cells than CPT-loaded PEG-*b*-PBLG micelles without the disulfide bond. Microscopic observation demonstrated that the disulfide-containing micelle could effectively deliver the drug into nuclei of SCC7 cells. These results suggest that PEG-SS-PBLG diblock copolymer is a promising carrier for intracellular delivery of CPT.

INTRODUCTION

Self-assembled polymeric micelles, composed of amphiphilic block copolymers, have received attention as anticancer drug carriers because they can circulate in blood for long periods of time, followed by selective accumulation into tumor tissue via the enhanced permeation and retention (EPR) effect.[1−5] However, delivery of the drug into the intracellular compartments of the cancer cell is often insufficient due to the slow release of the drug from micelles.[6,7] For example, aliphatic polyester-based micelles, extensively studied as drug carriers, have shown sustained drug release over a period of days to weeks,[6−8] although dumping the drug into the intracellular compartments of the cell in tumor tissue can enhance therapeutic efficacy. In this regard, it is necessary to develop polymeric micelles that exhibit the rapid release of the drug, triggered by intracellular stimuli such as mildly acidic pH,[9] reductive agents,[10] and enzymes.[11] After reaching the tumor sites

via the EPR effect, such micelles can be internalized into tumor cells by endocytosis, followed by exposure to intracellular stimuli causing burst release of the drug.

Numerous polymers have been developed as biomaterials that are sensitive to various stimuli such as ultraviolet,[12] ultrasound,[13] pH,[14−16] and temperature.[17,18] In recent years, reduction-sensitive polymers have been extensively investigated for intracellular drug delivery, since they can rapidly release payloads under reductive environments that are similar to the intracellular compartments. Glutathione (GSH), a thiol-containing tripeptide capable of reducing disulfide bonds, is abundant in the cytoplasm of the cell (1−10 mM), whereas it is rarely present in blood plasma (~2 μM).[19,20] This unique feature of GSH has encouraged development of disulfide-bearing carriers for intracellular delivery of siRNA,[21] DNA,[22,23] and low molecular weight drugs.[10,24−29] However, syntheses of disulfide-bearing polymers are often complex and, in most cases, require thiol-exchange reactions to introduce disulfide bonds at the backbones or the side groups of polymeric carriers. A principal disadvantage of this method is the unstable nature of free thiols, which are readily oxidized even under ambient conditions, thus forming dimers instead of the desired product.[23]

In the present study, we developed reduction-sensitive and biodegradable amphiphiles for the intracellular delivery of camptothecin (CPT), an anticancer drug (Figure 1). Amphiphilic diblock copolymers, composed of poly(ethylene glycol) (PEG) and poly(γ-benzyl L-glutamate) (PBLG), were prepared with a facile synthetic method, i.e., ring-opening polymerization of benzyl glutamate *N*-carboxy anhydride (NCA) in the presence of a poly(ethylene glycol) macroinitiator (PEG-SS-NH_2). Three different diblock copolymers (PEG-SS-PBLGs) were obtained by varying the feed ratio of the macroinitiator to benzyl glutamate NCA. The physicochemical characteristics of PEG-SS-PBLGs were determined using ^{1}H NMR, dynamic light scattering (DLS), transmission electron microscopy (TEM), and fluorescence spectroscopy. The reduction sensitivity of the micelle was evaluated using an optical imaging technique in which the fluorescence signal of doxorubicin, quenched in the micelle, was monitored in the presence of different concentrations of GSH. In addition, the *in vitro* release behavior of CPT from micelles was measured in the presence and absence of GSH. The cytotoxicities of CPT-loaded micelles were tested by exposing them to the SCC7 cancer cells.

EXPERIMENTAL PROCEDURES

Materials. α-Methoxy-ω-amino PEG (mPEG-NH_2, M_n = 2000 g/mol) and mPEG-nitrophenyl carbonate (M_n = 2000 g/mol) were purchased from Laysan Bio Inc. (Arab, AL, USA). Doxorubicin· hydrochloride (DOX·HCl), CPT, benzyl glutamate, and triphosgene were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Cystamine·dihydrochloride was obtained from Tokyo Chemical Industries (Tokyo, Japan). The water used in the experiments was prepared by an AquaMax-Ultra water purification system (Younglin Co., Anyang, Korea). All other chemicals were of analytical grade and used without further purification.

Synthesis of Benzyl Glutamate NCA. Benzyl glutamate NCA was synthesized by the Fuchs-Farthing method using triphosgene.[30] In brief, benzyl glutamate (2 g, 8.4 mmol) was suspended at 50 °C in THF. After triphosgene (1 g, 2.95 mmol) was slowly added to the solution, the reaction mixture was stirred for 3 h. The clear solution obtained was poured into *n*-hexane, cooled to −20 °C, and held overnight. After the precipitate was filtered, it was washed with *n*-hexane and dried at room temperature under vacuum.

Synthesis of PEG-SS-NH_2. Triethylamine (2.8 mL, 20 mmol) and cystamine·dihydrochloride (2.25 g, 10 mmol) were dissolved at 0 °C in DMSO. mPEG-nitrophenyl carbonate (4 g, 2 mmol) in DMSO was slowly added over 15 min under nitrogen atmosphere. The reaction mixture was stirred at room temperature for 24 h. Thereafter, the solution was purified with a dialysis membrane (MWCO = 1000 Da, Spectrum Laboratories, Inc., CA, USA) against distilled water for two days, followed by lyophilization.

Synthesis of Disulfide-Bearing Diblock Copolymers. PEG-SS-PBLG diblock copolymers were synthesized via ring-opening polymerization of benzyl glutamate NCA in the presence of a cleavable macroinitiator (PEG-SS-NH_2). Benzyl glutamate NCA (0.6 g, 2.3 mmol) was added to the PEG-SS-NH_2 (0.5 g, 0.23 mmol) solution in DMF under a nitrogen atmosphere and stirred for 24 h at 35 °C. The product was precipitated in diethyl ether, filtered, and dried at room temperature under vacuum. The PEG-*b*-PBLG diblock copolymer without the disulfide bond was prepared via an identical method and used as a control. The diblock copolymers, synthesized in this study, were coded depending on the degree of polymerization (DP) of the benzyl glutamate hydrophobic block. For example, PEG-SS-$PBLG_4$ indicates the diblock copolymer in which the DP of the hydrophobic block was 4.

Characterization. The chemical structures of the polymers were characterized using ^{1}H NMR (JNM-AL300, JEOL, Tokyo, Japan) operating at 300 MHz, for which the samples were dissolved in $CDCl_3$. The sizes of the micelles were determined at 25 °C using a FPAR-1000 fiberoptics particle analyzer (Otsuka Electronics, Osaka, Japan). The morphology of the particles was observed using a TEM (JEM-2100F, JEOL, Tokyo, Japan), operated at an accelerating voltage of 200 keV.

The critical micelle concentrations (CMCs) of the copolymers were evaluated using fluorescence spectroscopy in the presence of pyrene molecules.[31] In brief, a pyrene solution (12×10^{-7} M) was prepared in distilled water, which was then mixed with the

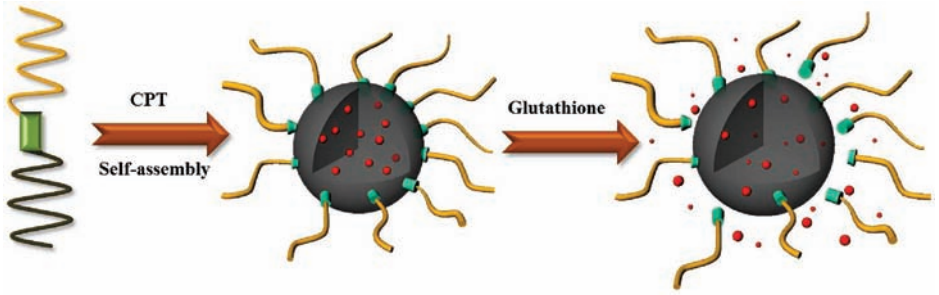

Figure 2. Schematic illustration of GSH-sensitive release of the drug from PEG-SS-PBLG micelles.

block copolymer solution to obtain a polymer concentration ranging from 1.0×10^{-4} to 1 mg/mL. The final concentration of pyrene in each sample was fixed at 6.0×10^{-7} M. The fluorescence spectra were recorded using an ISS K2 multifrequency phase and modulation fluorometer (ISS, Champaign, IL, USA). The excitation (λ_{ex}) and emission (λ_{em}) wavelengths were 336 and 390 nm, respectively.

Reduction Sensitivity of Micelles. The sensitivity of micelles to the reductive environment was estimated by exposing DOX-loaded micelles to different concentrations of GSH. DOX, which was chosen as a model fluorescence drug, was encapsulated into micelles by the solvent casting method as previously described.[32] The loading content of DOX was 6.7%, which was determined using a UV−vis spectrophotometer at 485 nm. After the DOX-loaded micelles were dispersed at various glutathione concentrations (0, 0.5, 1, 5, 10, and 20 mM), they were transferred into 96-well flat-bottomed plates and incubated for 1 h at 37 °C. The fluorescence image of DOX was obtained using a Kodak Image Station 4000MM equipped with a 12 bit CCD camera (New Haven, CT, USA).

Preparation of CPT-Loaded Polymeric Micelles. CPT-loaded micelles were prepared by the solvent casting method.[32] In brief, the PEG-SS-PBLG diblock copolymer was dissolved in a chloroform/methanol (1v:1v) mixture. CPT in chloroform and triethylamine (1v:1v) was added and stirred for 3 h. Then, the solvent was completely removed using a rotary evaporator to form a thin film. PBS (pH 7.4) was added and the solution was stirred for an additional 1 h, followed by filtration through a 0.45 μm filter to remove unloaded CPT. The solution was dialyzed against distilled water (MWCO = 1000 Da) for one day and lyophilized to obtain the CPT-loaded polymeric micelles (CPT-SS-PM). The same method was applied to the control sample to prepare CPT-loaded micelles (CPT-PM). The loading efficiency and content of CPT in polymeric micelles were determined using a UV−vis spectrophotometer (Optizen 3220UV, Mecasys Co., Ltd., Daejeon, Korea) at 370 nm.

***In Vitro* Release Behavior of CPT from Micelles.** CPT-loaded micelles (1 mg/mL) were dispersed in a PBS (pH 7.4), and the solutions were transferred to cellulose membrane tubes (MWCO = 1000 Da). The dialysis tubes were then immersed in PBS (pH 7.4) with or without GSH (10 mM). Each sample was gently shaken in a 37 °C water bath at 100 rpm. The medium was refreshed at predetermined time intervals, and the CPT concentration was determined using UV−vis spectroscopy at 370 nm.

Cytotoxicity and Intracellular Drug Release Tests. SCC7 (squamous carcinoma) cell lines, obtained from the American Type Culture Collection (Rockville, MD, USA), were cultured in RPMI 1640 medium (Gibco, Grand Island, NY, USA) containing 10% (v/v) fetal bovine serum and 1% (w/v) penicillin−streptomycin at 37 °C in a humidified 5% CO_2/95% air atmosphere. The cells were seeded at a density of 1×10^4 cells/well in 96-well flat-bottomed plates. After one day of growth, the cells were washed twice with a PBS (pH 7.4) and incubated for 12 h with various concentrations of samples. The cells were then washed twice with PBS to remove any remaining drug, and fresh culture medium was added. Twenty microliter aliquots of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide solution (5 mg/mL in PBS) were added to each well, and the cells were incubated for an additional 4 h at 37 °C. Subsequently, the medium was removed and the cells were dissolved in DMSO. The absorbance at 570 nm was measured using a microplate reader (VERSAmax, Molecular Devices Corp., Sunnyvale, CA, USA).

To observe the intracellular drug release from the micelle, the cells were incubated with DOX-loaded micelles (DOX-SS-PM and DOX-PM) for 12 h. The cells were then washed twice with PBS (pH 7.4) and fixed with 4% formaldehyde solution. For nuclear staining, the cells were incubated with 4,6-diamino-2-phenylinodole (DAPI) for 10 min at room temperature, followed by washing with PBS (pH 7.4). The intracellular localization of DOX-SS-PM and DOX-PM was observed using IX81-ZDC focus drift compensating microscope (Olympus, Tokyo, Japan).

RESULTS AND DISCUSSION

In an attempt to develop reduction-sensitive micelles, the disulfide bond was introduced between hydrophilic PEG and hydrophobic PBLG, as shown in Figure 1. Since the disulfide bond is specifically cleavable by GSH, which is abundant in the cell cytoplasm, the resulting micelles may have potential as carriers for selective delivery of the drug into the intracellular level (Figure 2). In particular, such micelles would be useful for the delivery of anticancer drugs because the intracellular concentrations of GSH in cancer cells are much greater than in normal cells .[19,20]

Synthesis and Characterization of PEG-SS-PBLG Diblock Copolymers. For facile synthesis of the disulfide-bearing diblock copolymer, PEG-SS-NH_2 was first prepared as the macroinitiator by reacting mPEG-nitrophenyl carbonate with cystamine. The ^{1}H NMR spectrum for PEG-SS-NH_2 indicated that the characteristic peaks of cystamine appeared at 1.8 ppm and 2.80−2.97 ppm (Figure 3). Alternatively, no peaks for the phenyl group were observed, suggesting complete removal of the nitrophenyl group at the chain end of mPEG. In the next step, PEG-SS-PBLG diblock copolymers were readily synthesized by ring-opening polymerization of benzyl glutamate NCA in the presence of PEG-SS-NH_2. Figure 3 shows the ^{1}H NMR spectrum of PEG-SS-$PBLG_9$ as the representative diblock copolymer, exhibiting

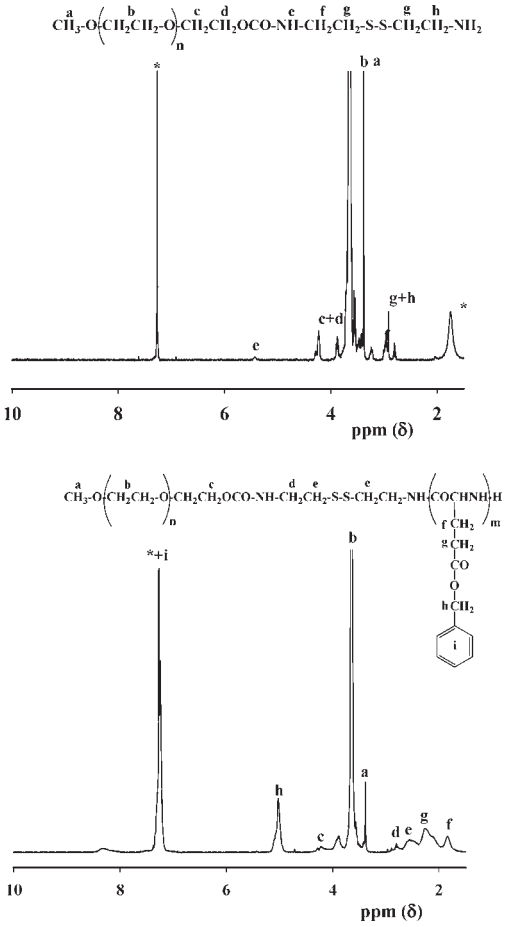

Figure 3. ^{1}H NMR spectra of PEG-SS-NH_2 and PEG-SS-$PBLG_9$.

the characteristic peaks of PEG and PBLG. The degree of polymerization of the PBLG block could be calculated based on the integration ratio of the proton peak appearing from the benzylic methylene of PBLG at 5.02 ppm and that from PEG at 3.60 ppm. As shown in Table 1, the molecular weights of the diblock copolymers were precisely controlled by varying the feed ratio of benzyl glutamate NCA to PEG-SS-NH_2. In general, the block length of PBLG in the copolymer increased as the feed ratio of benzyl glutamate NCA increased. It should be noted that, when the feed ratio was greater than 15, the resulting copolymer was barely soluble in water due to high hydrophobicity.

Owing to their amphiphilicity, PEG-SS-PBLG copolymers can form nanosized particles in aqueous environments. The size distribution and morphologies of PEG-SS-PBLG nanoparticles are shown in Figure 4. As expected, all the copolymers formed nanoparticles with unimodal size distributions. TEM images indicated that the nanoparticles were spherical in shape. The mean diameters of nanoparticles were in the range 20−127 nm, depending on the PBLG block length of the copolymer. The copolymer with the longer PBLG block formed larger nanoparticles, indicating that the size of the hydrophobic inner core is proportional to the PBLG length of the copolymer. The mean diameter of the nanoparticles did not significantly changed over the course of a week, implying high stability of the nanoparticles in an aqueous environment (data not shown).

CMCs of the copolymers were determined using pyrene as a fluorescent probe.[31] For all copolymers, the intensity ratios

(I_{338}/I_{334}) of the pyrene excitation spectra increased as the copolymer concentrations increased (see Supporting Information Figure S1). Since the increase in the intensity ratio indicates the aggregation of pyrene into the hydrophobic reservoirs of the copolymers, CMCs can be determined from the crossover point at low concentration ranges.[33] As summarized in Table 1, the CMCs of the PEG-SS-PBLG copolymers were in the range 0.005−0.065 mg/mL, which was less than those of some polymeric amphiphiles[34,35] and low molecular weight surfactants (e.g., 1.0 mg/mL for deoxycholic acid). Of the copolymers tested, PEG-SS-$PBLG_{13}$ demonstrated the lowest CMC values, indicating that the self-assembly of copolymers could be readily facilitated by longer PBLG.

For further experiments including the drug release and cytotoxicity tests, PEG-SS-$PBLG_9$ was chosen as the representative bioreducible block copolymer and PEG-*b*-$PBLG_9$ without the disulfide bond was used as the control to observe the effect of the disulfide bond as the linkage of the block copolymer. In fact, the micellar structure of PEG-SS-$PBLG_9$ was significantly affected by GSH inducing cleavage of the disulfide bond (see Supporting Information Figure S2). The PEG-SS-$PBLG_9$ in the buffer solution was readily precipitated in the presence of 10 mM GSH, implying formation of large aggregates. The precipitation might occur due to the cleavage of disulfide linkages, leading to disintegration of the micellar structure and formation of large aggregates by hydrophobic interaction between PBLG blocks detached from the micelles. On the other hand, no precipitates were observed in the control solution containing PEG-*b*-$PBLG_9$ and 10 mM GSH, suggesting high stability of the control polymer in the reductive environment.

Drug Release Pattern. In this study, CPT was chosen as a model anticancer drug because its applications have been limited by poor solubility in water, structural instability, and high toxicity to normal cells. In order to surmount these drawbacks of CPT, it is needed to develop a carrier that can increase the water solubility of CPT, preserve its chemical structure, and deliver it to the intracellular level of the cancer cell. Obviously, PEG-SS-PBLG diblock copolymers may have potential as the carrier of CPT, owing to their ability to form bioreducible nanoparticles that can imbibe hydrophobic drugs.

Table 2 shows the characteristics of CPT-loaded nanoparticles, prepared by the solvent casting method. In this experiment, PEG-SS-$PBLG_9$ copolymer was used to prepare bioreducible micelles, whereas PEG-*b*-$PBLG_9$ without disulfide bonds was used as the control. Three CPT-loaded PEG-SS-PBLG micelles (CPT-SS-PMs) were obtained by varying the feed amount of CPT. An increase in the feed amount of CPT decreased its loading efficiency. However, regardless of the feed amount of

[a] Determined using UV−visible spectrophotometer. [b] Determined using the particle analyzer.

CPT, its loading efficiencies were always greater than 60%, implying that CPT was effectively encapsulated into the micelles by the solvent casting method. The particle sizes of CPT-SS-PMs (77−120 nm) were higher than that of the bare PEG-SS-PBLG$_9$ micelle (51 nm), and the micellar size increased as the drug loading content increased. The loading efficiency and loading content of CPT for the PEG-*b*-PBLG$_9$ copolymer were comparable to those for the PEG-SS-PBLG$_9$ copolymer, suggesting that the disulfide bond did not affect the loading pattern of CPT.

The release behavior of CPT from the micelles was evaluated in the presence and absence of GSH (Figure 5). In this experiment, CPT10-SS-PM and CPT10-PM were used for investigation because they possessed similar amounts of CPT, as summarized in Table 2. In the absence of GSH, CPT10-SS-PM released 26% of CPT in the initial 3 h, after which its release rate decreased remarkably. In particular, after 10 h, no significant release of CPT occurred for the remaining period of time tested. On the other hand, in the presence of 10 mM GSH mimicking the intracellular environment, CPT was rapidly released from CPT10-SS-PM, resulting in complete release within 20 h. This might be due to the cleavage of the disulfide bond in the PEG-SS-PBLG copolymer, causing the disintegration of the micellar structure. It is of interest to note that the release behavior of CPT from CPT10-PM was not affected by GSH. Specifically, the release pattern of CPT from CPT10-PM was identical to that from CPT10-SS-PM in the absence of GSH. These results suggest that the disulfide bond in the copolymer was responsible for the rapid release of CPT, triggered by GSH.

The reduction sensitivity of micelles was investigated using DOX-loaded PEG-SS-PBLG$_9$ (DOX-SS-PM) and PEG-*b*-PBLG$_9$ (DOX-PM) in the presence of GSH as the reducing agent. Since DOX,

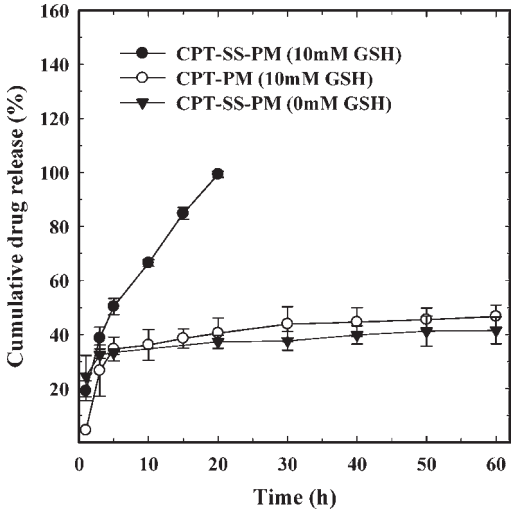

Figure 5. *In vitro* release behavior of CPT from PEG-SS-PBLG$_9$ in the absence and presence of GSH. The CPT-loaded PEG-*b*-PBLG$_9$ micelle (CPT-PM) was used as the control. The error bars in the graph represent standard deviations (n = 3).

an anticancer drug, is a hydrophobic fluorescent substance, it can be readily encapsulated into micelles in the quenched state.[9,36] Therefore, the release of DOX from micelles generates a fluorescent signal, and its intensity can be measured to estimate the concentration of DOX released. In this study, we aimed to evaluate the reduction sensitivity of micelles by observing the fluorescence images of DOX in micelles using the optical imaging technique. Figure 6 shows the fluorescence image of DOX as a function of the GSH concentration after a 1 h incubation of the DOX-loaded micelles in a PBS (pH 7.4) solution. In the absence of GSH, no significant fluorescence signals were observed for both DOX-PM and DOX-SS-PM, suggesting that most of the DOX existed in quenched states at the hydrophobic cores of the micelles. The fluorescent intensity of DOX-PM slightly increased as the GSH concentration increased, which might be due to the amphiphilic character of GSH that can weaken micellar integrity. Interestingly, DOX-SS-PM showed strong fluorescent signals at concentrations greater than 1 mM GSH, suggesting the rapid release of DOX from the micelles. These results imply that PEG-SS-PBLG micelles were highly susceptible to GSH, which is in good agreement with the release pattern of CPT in Figure 5.

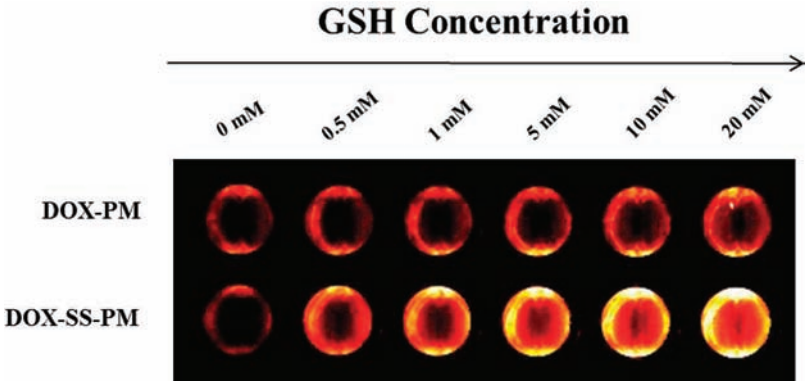

Figure 6. Fluorescent images of DOX-PM and DOX-SS-PM under different concentrations of GSH.

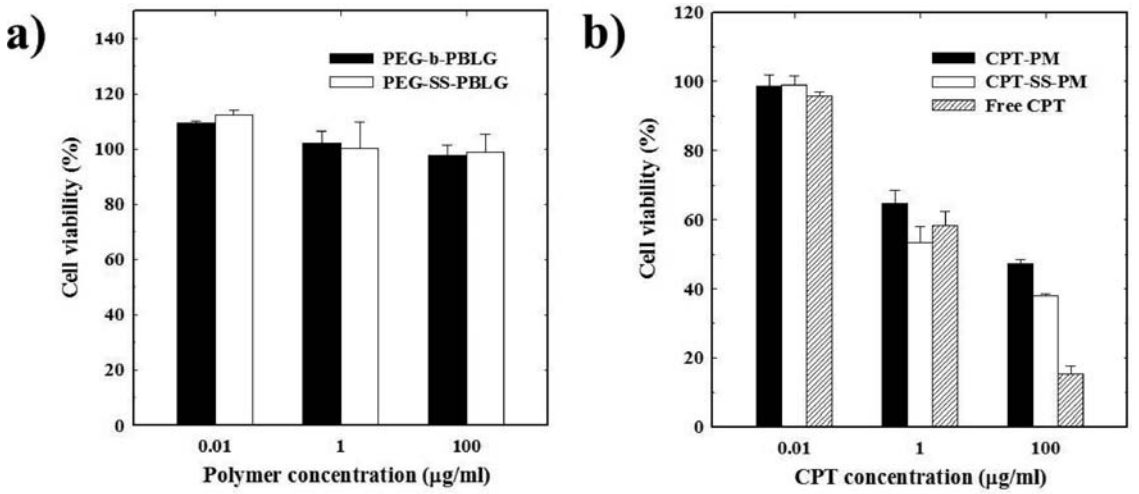

Figure 7. *In vitro* cytotoxicity of (a) bare micelles and (b) CPT-loaded micelles. The error bars in the graph represent standard deviations (n = 3).

***In Vitro* Cell Cytotoxicity and Cellular Uptake.** Figure 7 shows the cytotoxic effects of micelles with and without CPT on SCC7 cells, as evaluated using the MTT assay. Owing to their biocompatibilities, PEG-SS-PBLG$_9$ and PEG-*b*-PBLG$_9$ did not exhibit cytotoxicity to SCC7 cells. In particular, most cells were viable up to 100 μg/mL of PEG-SS-PBLG$_9$, indicating that the disulfide bond in the micelle was not harmful to the cells. Alternatively, due to the presence of the anticancer drug, both CPT10-SS-PM and CPT10-PM showed dose-dependent cytotoxicity to SCC7 cancer cells. It is important to note that the cytotoxicity of CPT-SS-PM to SCC7 cells was significantly greater than that of CPT-PM, which may be due to the rapid release of CPT from bioreducible micelles by cleavage of the disulfide bond in an intracellular environment (Figure 2).

To verify intracellular drug release, the DOX-loaded samples were monitored using the fluorescence microscope after they were treated with the SCC7 cancer cells. Since DOX interacts with DNA by specific intercalation, the fluorescence signal can be detected at the nucleus when the micelles release DOX. The results showed that, after a 12 h incubation of DOX-SS-PMs, strong fluorescence was observed at the nucleus of the cell, resulting from the rapid release of DOX from the micelles (Figure 8). On the contrary, for the reduction-insensitive control (DOX-PM), fluorescent signal was partially observed at the cytoplasm of the cell.

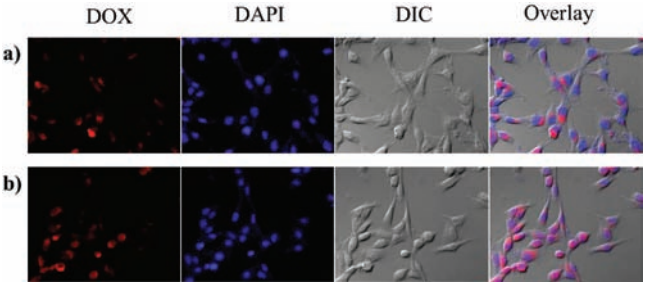

Figure 8. Fluorescent microscopic image of SCC7 cells incubated with (a) DOX-PM and (b) DOX-SS-PM. Each sample (50 μg/mL in PBS) was incubated with SCC7 tumor cells in a serum free medium for 12 h.

Therefore, it could be concluded that the DOX-SS-PMs, sensitive to GSH at the intracellular level, could effectively deliver the drug for enhanced therapeutic effect.

CONCLUSION

A series of PEG-SS-PBLG diblock copolymers, cleavable in intracellular environments, were synthesized as potential carriers of CPT for cancer therapy. The copolymers formed stable micelles in an aqueous solution and encapsulated CPT in hydrophobic

dx.doi.org/10.1021/bc2000963 |*Bioconjugate Chem.* 2011, 22, 1924–1931

inner cores with the high loading efficiency. The resulting bioreducible micelles could release CPT in the presence of GSH to mimic the reductive environment. As a consequence, CPT-loaded micelles exhibited high toxicity to SCC7 cancer cells. These results indicate that PEG-SS-PBLG block copolymers have promising potential as carriers of CPT for its selective delivery to the intracellular level of the cancer cells.

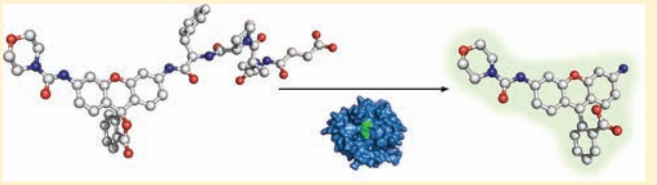
Supporting Information

ABSTRACT: Commonly used fluorogenic substrate analogues for the detection of protease activity contain two enzyme-cleavable bonds conjugated to the fluorophore. Enzymatic cleavage follows a two-step reaction with a monoamide intermediate. This intermediate shows fluorescence at the same wavelength as the final product complicating the kinetic analysis of fluorescence-based assays. Fluorogenic substrate analogues for α-chymotrypsin with one cleavable peptide bond have been prepared from morpholinecarbonyl-Rhodamine 110 (MC-Rh110). A comparison of their kinetic properties with the corresponding $(peptide)_2$-Rh110 derivatives revealed that these frequently used double-substituted substrate analogues yield only apparent K_m and k_{cat} values that are quite different from the kinetic parameters obtained from the monosubstituted MC-Rh110 based substrate analogues. Although both the monoamide intermediate and MC-Rh110 are monosubstituted Rhodamine 110 derivatives, they show different spectroscopic properties. The data from the spectroscopic analysis clearly show that these properties are directly related to the electron structure of the fluorophore and not to the previously proposed equilibrium between the lactone form and the open ionic form of the fluorophore. This knowledge about the determinants of the spectroscopic properties of monosubstituted Rhodamine 110 introduces a way for a more systematic development of new fluorogenic protease substrate analogues.



INTRODUCTION

Proteases and peptidases (EC 3.4) are enzymes that catalyze the hydrolysis of peptide bonds. They constitute approximately 2% of the human genome and are involved in many physiological processes such as cell-cycle progression, tissue remodeling, coagulation, wound healing, cell proliferation, and cell death, as well as the immune response.[1] Their involvement in these biological processes makes proteases very important drug targets. Furthermore, proteases are important biocatalysts for a wide range of industrial applications. Understanding the enzymatic mechanism and the factors determining their substrate specificity is therefore of crucial importance for the characterization of their medical relevance as well as for obtaining optimized biocatalysts.

To assay enzyme activity and substrate specificity, fluorogenic probes are commonly used.[2−4] The chemical modification of a fluorophore with one or two enzyme-cleavable bonds alters its photophysical properties and results in a nonfluorescent derivative. The fluorescence is recovered upon enzymatic cleavage. Peptide-based substrate analogues can further be designed based on photoinduced electron transfer[5] or fluorescence resonance energy transfer.[6,7] Fluorescence is often chosen as a detectable signal as it provides high sensitivity *in vitro*. Moreover, fluorescent probes also find widespread application in living cells and tissues where they provide high spatial and temporal resolution.

The choice of fluorophore is critical for the design of a good enzyme substrate analogue, and favorable fluorescent molecules have to meet several requirements: (i) high brightness to obtain high sensitivity, (ii) fluorescence excitation above 450 nm to reduce photodamage in biological molecules and to avoid interference with autofluorescence of biological samples, and (iii) no interference with the enzymatic reaction so that the kinetic parameters remain unaltered.[8] Although frequently used, Coumarin-based substrate analogues have a low brightness and are excited below 450 nm. Common fluorophores which possess the aforementioned properties and are often used for introducing an enzyme-cleavable bond are fluorescein, resorufin, and 7-hydroxy-9*H*-(1,3-dichloro-9,9-dimethylacridin-2-one) (DDAO) for esterases, phosphoesterases, and glycosidases. Fluorophores used for proteases are Rhodamine 110 and cresyl violet. The latter, however, yields only substrate analogues with insufficient stability to autohydrolysis in aqueous solutions.[9] Except for resorufin and DDAO, these substrate analogues contain two sites for conjugating the enzyme-cleavable group.[10−12] Using the double-substituted pro-fluorescent derivatives for kinetic measurements complicates a

quantitative analysis, since full fluorescence manifestation requires the cleavage of two bonds involving an intermediate with a different fluorescence intensity.

The difficulty of quantifying the kinetic constants of such a two-step reaction has been addressed in several studies, and solutions have been proposed to obtain the kinetic constants.[13,14] These approaches, however, always require the detection of the intermediate concentration, which is often not possible in a fluorescence measurement due to the overlap of the excitation and emission spectra of the intermediate and the final product. Other assays to determine the intermediate concentration such as HPLC might not be considered feasible especially in high-throughput assays or measurements in cellular systems. As a consequence, efforts are being made to synthesize monosubstituted substrate analogues, and a number of examples exist utilizing Rhodamine 110 (Rh110).

The most obvious solution might be to attach only one peptide to the Rh110 core. Although this yields a stable molecule, the applicability of such a monoamide Rh110 derivative is limited by its fluorescence, which is approximately still 10% relative to Rh110.[15] Hence, it is desirable to develop Rh110-based substrate analogues that have no intrinsic fluorescence while possessing only one enzyme cleavable bond. This has been achieved by modifying one of the amino groups with a nonhydrolyzable blocking group while attaching a peptide to the second amino group. Initially designed to increase cell permeability, a range of different blocking groups have been investigated, but they mostly yield dye molecules with a relative fluorescence intensity of only 5−15% compared to Rh110.[16−18] The best blocking group known to date, which preserves much of the high fluorescence of Rh110, introduces a urea functionality into Rh110.[19] Originally designed by Wang et al.,[20] morpholinecarbonyl-Rh110 (MC-Rh110) is a promising candidate for developing sensitive monoamide substrate analogues.

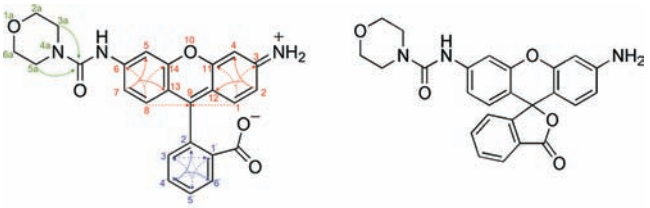
Although Rh110 has been used for many years to synthesize substrate analogues for proteases, the properties of the monosubstituted derivatives have never been investigated systematically. Double-substitution of Rh110 yields a nonfluorescent lactone. Consequently, it has been proposed in several reports that the fluorescence of monosubstituted Rh110 is determined by an equilibrium between a nonfluorescent monosubstituted lactone form and an open zwitterionic fluorescent form of the molecule. It was further suggested that the electron withdrawing character of the substituent influences this equilibrium and therefore the fluorescence intensity of the respective derivative.[18,20]

Using α-chymotrypsin as the model system, we determined the enzyme kinetic parameters for different MC-Rh110 based substrate analogues and compared them with conventional bisamide Rh110 substrate analogues. Furthermore, we performed a systematic analysis of the photophysical properties of MC-Rh110 and monoamide Rh110 in order to understand why different substituents on one of the amino-groups of Rh110 yield derivatives with different fluorescence intensity.

EXPERIMENTAL PROCEDURES

Synthetic Approaches. Unless stated otherwise, reagents were obtained from Sigma-Aldrich or Acros. The substrate analogues were purified on a Waters 996 HPLC with a Waters 600 controller. Reversed-phase C18 columns (Alltech Previal or Phenomenex Luna, both 15 cm long with 2.1 mm diameter and 5 μm particle size) were used. MPLC chromatography was performed using a Büchi Sepacore Flash apparatus. Mass spectra were run using Thermo Finnigan LCQ Advantage apparatus (ESI). NMR spectra were acquired on commercial instruments (Bruker Avance 300 MHz, Bruker AMX 400 MHz or Bruker Avance II+ 600 MHz with TXI probe or TCI CryoProbe) and chemical shifts (δ) are reported in parts per million (ppm) referenced to tetramethylsilane (^{1}H) or the internal (NMR) solvent signals (^{13}C). Rhodamine 110 (99% pure, laser grade, Acros) was used for the synthesis of the substrate analogues.

Chart 1



(suc-AlaAlaProPhe)$_2$-Rh110; (sucAAFP)$_2$-Rh110. The synthesis of (sucAAPF)$_2$-Rh110 was performed as described in the Supporting Information of De Cremer et al.[21] and verified by ESI and NMR spectrometry.

MC-Rh110. The synthesis of MC-Rh110 was based on the method described in the patent application by Diwu et al.[22] Since the described purification procedure using a silica gel column did not yield pure product, the dye was purified with MPLC using a mixture of EtOAc/$CHCl_3$/MeOH (50:47.5:2.5). Yield: 25%. MS (ESI+): 444 (MH^+). ^{1}H NMR (600 MHz, $CDCl_3$): δ (ppm) 7.99 (d, J = 7.9 Hz, 1H; H-6′), 7.65 (t, J = 7.5 Hz, 1H; H-5′), 7.59 (t, J = 7.5 Hz, 1H; H-4′), 7.50 (s, 1H; H-5), 7.15 (d, J = 7.6 Hz, 1H; H-3′), 6.83 (d, J = 6.8 Hz, 1H; H-7), 6.63 (d, J = 8.6 Hz, 1H; H-8), 6.53 (d, J = 8.3 Hz, 1H; H-1), 6.51 (s, 2H; H-4), 6.34 (d, J = 6.8 Hz, 1H; H-2), 3.90 (s_b, 2H; NH_2), 3.74 (t, J = 4.7 Hz, 4H; H-2a, 6a), 3.49 (t, J = 4.7 Hz, 4H; H-3a, 5a). ^{13}C NMR (125 MHz, $CDCl_3$): δ (ppm) 169.8 (C; COO), 154.7 (C; CO), 153.4 (C; C-6), 152.8 (C; C-11), 152.1 (C; C-14), 149.0 (C; C-3), 141.0 (C; C-2′), 135.1 (CH; C-4′), 129.7 (CH; C-1), 129.2 (CH; C-8), 128.5 (CH; C-5′), 126.9 (C; C-1′), 125.0 (CH; C-6′), 124.2 (CH; C-3′), 115.2 (CH; C-7), 113.6 (C; C-13), 111.7 (CH; C-2), 108.6 (C; C-12), 107.6 (CH; C-5), 101.6 (CH; C-4), 84.1 (C; C-9), 66.6 (CH_2; C-2a, 6a), 44.4 (CH_2; C-3a, 5a).

^{1}H NMR (600 MHz, D_2O + 5% DMSO-d_6): δ (ppm) 8.02 (d, J = 7.3 Hz, 1H; H-6′), 7.89 (s, 1H; H-5), 7.78 (t, J = 7.3 Hz, 1H; H-5′), 7.75 (t, J = 7.3 Hz, 1H; H-4′), 7.45 (d, J = 8.6 Hz, 1H; H-8), 7.44 (d, J = 8.6 Hz, 1H; H-1), 7.40 (d, J = 7.3 Hz, 1H, H-3′), 7.36 (d, J = 8.6 Hz, 1H; H-7), 7.00 (d, J = 10.6 Hz, 1H; H-2), 6.95 (s, 1H; H-4), 3.82 (t, J = 4.6 Hz, 4H; H-2a, 6a), 3.82 (t, J = 4.6 Hz, 4H; 3a, 5a). Carbon signals as derived from HSQC and HMBC NMR measurements (D_2O + 5% DMSO-d_6): δ (ppm) 164 (COO^-), 160.8 (C-3), 160 (C-14), 159.8 (C-11), 156 (CO), 155.1 (C-6), 147.6 (C-9), 137.8 (C-1′), 133 (C-1), 131.3 (C-2′), 130.4 (C-8), 130.2 (C-4′) 129.9 (C-5′), 129.6 (C-3′), 128.9 (C-6′), 118.7 (C-2), 118.1 (C-7), 116(C-13), 116.1 (C-12), 105.4 (C-5), 97.4 (C-4), 66.1 (C-2a, 6a), 44.3 (C-3a, 5a). (See Chart 1 for atom numbering and molecular structure in different solutions.)

suc-AlaAlaProPhe-Rh110-MC; sucAAPF-Rh110-MC. TBTU (*N,N,N′,N′*-tetramthyl-*o*-(benzotriazol-1-yl)uranium tetrafluoroborate) was obtained from Novabiochem and Boc-(L)-AlaAlaPro-OH from Bachem. A mixture of TBTU (215 mg, 0.7 mmol) and DIPEA (350 μL, 2 mmol) was dissolved in 1 mL of dry DMF and added to Boc-L-Phe-OH (180 mg, 0.7 mmol) dissolved in 2 mL of dry CH_2Cl_2 under Ar. MC-Rh110 (50 mg, 0.1 mmol) was dissolved in 1 mL dry CH_2Cl_2 and slowly added to the reaction. After 17 h of stirring, the solvents were evaporated and the crude mixture was directly purified by HPLC using an acetonitrile/water gradient (12−100% ACN). Yield: 40% (30 mg, 0.04 mmol) Boc-Phe-Rh110-MC. MS (ESI+): 692 (MH^+).

Deprotection of Phe was achieved by slow addition of 50/50 (v/v) TFA/CH_2Cl_2 (3 mL) to Boc-Phe-Rh110-MC (30 mg, 0.04 mmol) in CH_2Cl_2 (1.5 mL). After 3 h, the reaction was stopped and concentrated under vacuum. MS (ESI+): 592 (MH^+).

TBTU (32 mg, 0.1 mmol) and DIPEA (40 μL, 0.2 mmol) were dissolved in 1 mL of dry DMF and added to a solution of Boc-(L)-AlaAlaPro-OH (35 mg, 0.1 mmol in 3 mL dry THF), kept at 0 °C under Ar. The reaction mixture was stirred for 10 min after which it was left to warm to room temperature. The Phe-Rh110-MC was dissolved in 1 mL of dry THF and added to the above mixture. After stirring the reaction mixture at 37 °C for 12 h, the solvents were evaporated and the mixture was purified by HPLC (45% ACN in water; isocratic). Yield: 52% (21 mg, 0.02 mmol) Boc-AlaAlaProPhe-Rh110-MC. MS (ESI+): 931 (MH^+).

The Boc group was removed as described above and the deprotected product was succinylated in 4 mL THF using triethylamine (25 μL, 0.2 mmol) and succinic anhydride (10 mg, 0.1 mmol) at 37 °C for 10 h. The mixture was purified by HPLC (35% ACN in water; isocratic). Yield: 67% (14 mg, 0.015 mmol). MS (ESI+): 931 (MH^+), 953 (MNa^+). ^{1}H NMR (300 MHz, DMSO): δ (ppm) 9.98 (d, J = 5.4 Hz, 2H), 8.86 (s, 2H), 8.09−8.00 (m, 8H), 7.86 (dd, J = 1.7 Hz, J = 4.9 Hz, 2H), 7.80 (t, J = 7.3 Hz, 2H), 7.73 (t, J = 7.3 Hz, 2H), 7.68 (d, J = 1.9 Hz, 2H), 7.30−7.14 (m, 20H), 6.74 (d, J = 8.7 Hz, 2H), 6.66 (d, J = 8.7 Hz, 2H), 4.58 (dd, J = 1.7 Hz, J = 4.9 Hz, 2H), 4.51 (t, J = 7.0 Hz, 2H), 4.28−4.21 (m, 4H), 3.62 (d, J = 1.9 Hz, 2H), 7.30−7.14 (m, 20H), 6.74 (d, J = 8.7 Hz, 2H), 3.15 (dd, J = 4.7 Hz, J = 14.7 Hz, 2H), 2.93 (dd, J = 9.4 Hz, J = 13.7 Hz, 2H), 2.40−2.31 (m, 8H), 1.99−1.92 (m, 2H), 1.81−1.76 (m, 4H), 1.68−1.63 (m, 2H), 1.19−1.14 (m, 14H).

(suc-Phe)$_2$-Rh110; (suc-F)$_2$-Rh110. (Boc-Phe)$_2$-Rh110 was obtained as the product of the first step of the synthesis of (suc-AAPF)$_2$-Rh110. It was deprotected and succinylated as described above. After purification by HPLC (37% ACN in water; isocratic), the desired (suc-F)$_2$-Rh110 was obtained. MS (ESI+): 826 (MH^+). ^{1}H NMR (600 MHz, DMSO): δ (ppm) 10.39 (s, 2H), 8.38 (d, J = 7.9 Hz, 2H), 8.02 (d, J = 7.5 Hz, 1H), 7.88 (2s, 2H), 7.79 (t, J = 7.5 Hz, 1H), 7.72 (t, J = 7.5 Hz, 1H), 7.28−7.21 (m, 10H), 7.20−7.18 (m, 2H), 6.73 (d, J = 8.7 Hz, 2H), 4.62 (s, 2H), 3.07 (d, J = 9.4 Hz, 2H), 2.87 (t, J = 9.7 Hz, 2H), 2.38−2.24 (m, 8H). ^{13}C NMR (125 MHz, DMSO): δ (ppm) 173.8 (C), 171.3 (C), 170.8 (C), 168.5 (C), 150.6 (C), 140.8 (C), 137.4 (C), 135.4 (CH), 130.0 (CH), 128.9 (CH), 128.2 (CH), 127.9 (CH), 126.2 (CH), 125.6 (C), 124.7 (CH), 123.7 (CH), 115.5 (CH), 113.1 (C), 106.4 (CH), 81.6 (C), 54.8 (CH), 37.3 (CH_2), 30.0 (CH_2), 29.7 (CH_2).

suc-Phe-Rh110-MC; suc-F-Rh110-MC. Boc-Phe-Rh110-MC was obtained as the product of the first step of the synthesis of suc-AAPF-Rh110-MC. Deprotection and succinylation was performed as described above. The purified product was eluted from HPLC using 35% ACN in water (isocratic). MS (ESI+): 692 (MH^+). ^{1}H NMR (400 MHz, DMSO): δ (ppm) 10.51 (s, 1H), 8.78 (s, 1H), 8.39 (d, J = 6.5 Hz, 2H), 7.94 (d, J = 7.8 Hz, 1H), 7.90 (s, 1H), 7.72 (t, J = 7.3 Hz, 1H), 7.65 (t, J = 7.3 Hz, 1H), 7.59 (S, 1H), 7.38−7.35 (m, 1H), 7.21−7.17 (m, 5H), 7.12−7.09 (m 2H), 6.64 (S_{br}, 2H), 6.60 (t, J = 8.3 Hz, 4H), 4.50−4.48 (m, 1H), 3.54 (t, J = 4.3 Hz, 5H), 3.37 (t, J = 4.8 Hz, 5H), 3.07 (dd, J = 4.0 Hz, J = 13.7 Hz, 2H), 2.80 (dd, J = 9.8 Hz, J = 13.4 Hz, 2H), 2.6 (s, 1H), 2.26−2.01 (m, 5H).

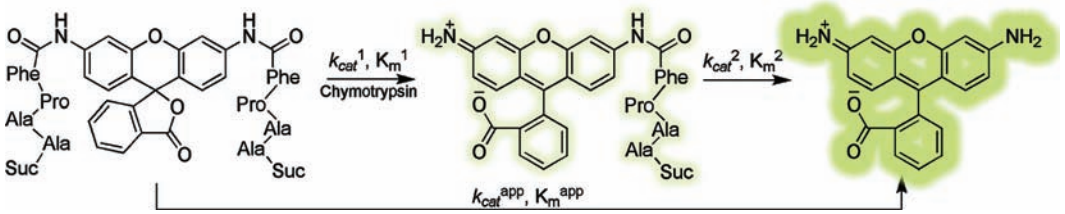
Boc-Phe-Rh110; Boc-F-Rh110. During the synthesis of (Boc-Phe)$_2$-Rh110, monosubstituted Boc-F-Rh110 was obtained as a side product after silica chromatography. It was further purified by HPLC using an ACN/water gradient (10−100% ACN). MS (ESI+): 579 (MH^+). NMR: ^{1}H NMR (600 MHz, $CDCl_3$): δ (ppm) 7.99 (d, J = 7.5 Hz, 1H), 7.68−7.56 (m, 3H), 7.30 (d, J = 6.8 Hz, 1H), 7.29−7.21 (m, 3H), 7,14 (d, J = 6.8 Hz, 1H), 6.79 (s_b, 1H), 6.65 (d, J = 8.3 Hz, 1H), 6.55−6.51 (m, 2H), 6.34 (d, J = 7.9 Hz, 1H), 5.10 (s, 1H), 4.44 (s, 1H), 3.90 (s, 2H), 3.15 (s, 2H), 1.42 (s, 9H). ^{13}C NMR (125 MHz, $CDCl_3$): δ (ppm) 177.6 (C), 169.8 (C), 153.4 (C), 152.6 (C), 152.0 (C), 149.0 (C), 139.2 (C), 135.0 (CH), 129.7 (CH), 129.4 (CH), 129.3 (CH), 129.1 (CH), 128.7 (CH), 127.4 (CH), 127.0 (C), 125.1 (CH), 124.1 (CH), 115.2 (CH), 111.8 (CH), 108.6 (C), 108.0 (CH), 101.6 (CH), 100.1 (C), 83.5 (C), 56.8 (CH), 38.1 (CH_2), 28.4 (CH_3).

Boc-AlaAlaProPhe-Rh110; Boc-AAPF-Rh110. For the synthesis of this compound, the coupling of Boc-AlaAlaPro-OH to Phe-Rh110 was not possible, as the peptide might also react with the second amino group of Rh110. Instead, the 4 amino-acid-long peptide Boc-AlaAlaProPhe-OH was coupled to Rh110 directly. In the first step, the peptide Boc-AlaAlaProPhe-OH was synthesized. Boc-AlaAlaPro-OH (200 mg, 0.6 mmol) was dissolved in 10 mL of anhydrous THF at 0 °C. To this solution, a mixture of TBTU (180 mg, 0.6 mmol) and DIPEA (130 μL, 0.7 mmol), dissolved in 2 mL dry DMF, was added. After 10 min, the cooling bath was removed and the reaction mixture was allowed to warm to room temperature. Phe-OMe (160 mg, 0.7 mmol), dissolved in 4 mL dry DMF, was added slowly to the above mixture. After 20 h of stirring, the solvents were evaporated and the crude mixture was purified on a silica gel column using CH_2Cl_2/MeOH (9:1) as the eluent. Removal of the methyl group was carried out in CH_2Cl_2 and 0.3 M NaOH. After that, the reaction was neutralized by HCl and again purified on a silica gel column using CH_2Cl_2/MeOH (9:1) as the eluent. Yield: 83% (250 mg, 0.5 mmol). MS (ESI+): 527 (MNa^+).

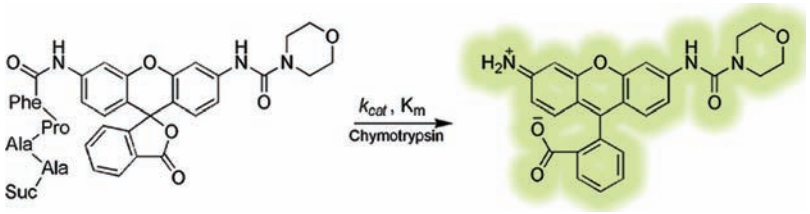
Boc-AlaAlaProPhe-OH (53 mg, 0.1 mmol), TBTU (41 mg, 0.1 mmol) and DIPEA (75 μL, 0.4 mmol) were dissolved in 2 mL of dry DMF. To this mixture, Rhodamine 110 chloride (22 mg, 0.06 mmol in 1 mL dry DMF) was added and the solution was stirred overnight at 37 °C. The resulting mixture was evaporated and purified by HPLC (40% ACN in water; isocratic). The yield was only 2% (1.2 mg). MS (ESI+): 818 (MH^+). This low yield was expected, as it has been shown before that the coupling of the complete 4 amino-acid-long peptide is much less efficient than the sequential coupling of amino acids in a multistep reaction.[18]

Kinetic Measurements. Chymotrypsin (α-Chymotrypsin from bovine pancreas; Fluka) was dissolved in PBS (10 mM phosphate pH 7.4, 138 mM NaCl, 2.7 mM KCl; Sigma). Substrates were prepared as stock solutions in DMSO. Reactions were started by adding 190 μL of chymotrypsin in PBS to 10 μL of a substrate solution in the cuvette. The final enzyme

Scheme 1. Two-Step Enzymatic Hydrolysis of the Fluorogenic Substrate Analogue (suc-AAPF)$_2$-Rh110 into the Fluorescent Product Rhodamine 110 Showing the Production of the Less Fluorescent Intermediate



Scheme 2. One-Step Enzymatic Hydrolysis of the Fluorogenic Substrate Analogue (suc-AAPF)-Rh110-MC into the Fluorescent Product MC-Rh110



concentration was 3 nM for (suc-AAPF)$_2$-Rh110 and suc-AAPF-Rh110-MC or 900 nM for (suc-F)$_2$-Rh110 and suc-F-Rh110-MC. The substrate concentrations varied between 0.4 and 50 μM. Product formation was followed by recording fluorescence (λ_{ex} = 488 nm; λ_{em} = 520 nm) with a Photon Technology International fluorescence spectrometer. The emission intensity was converted into product concentrations using calibration curves of Rh110 or MC-Rh110, respectively. K_m, k_{cat}, and k_{cat}/K_m values were obtained by least-squares fitting of the data to the Michaelis−Menten equation using *Origin* (see Supporting Information).

Determination of the Absorption and Emission Spectra. Rhodamine 110 chloride (Bioreagent, Sigma) was used to study the photophysical properties. Absorption measurements were performed with a Lambda 40 UV/vis spectrometer (Perkin-Elmer). For the fluorescence measurements, a Photon Technology International fluorescence spectrometer was used.

Fluorescence Lifetime Measurements. Excited-state lifetimes were determined using time-correlated single photon counting (TCSPC). The instrument response function (IRF) was recorded using a LUDOX scattering solution and its fwhm amounted to ~40 ps. The fluorescence decay curves were analyzed by being fitted to a convolution of the IRF with a decay function for a δ-pulse using a TRFA Global Analysis Program based on a Marquard-Levenberg least-squares fitting. The quality of the fit was judged according the criteria published by Boens et al.[23]

Determination of the Quantum Yield. Quantum yield measurements were performed with an integrating sphere using a Fluorolog 3 fluorescence spectrometer (Horiba Jobin Yvon). The procedure as well as the calculations are described in the work of de Mello.[24] The measurements of the fluorophore solutions (absorption between 0.07 and 0.15) were performed in triplicate.

RESULTS AND DISCUSSION

For the enzyme activity measurements, the following substrate analogues were synthesized: (suc-AAPF)$_2$-Rh110, suc-AAPF-Rh110-MC, (suc-F)$_2$-Rh110, and suc-F-Rh110-MC. These molecules were nonfluorescent and stable in aqueous solution. No autohydrolysis could be detected. The bis-amide substrate analogues (suc-AAPF)$_2$-Rh110 and (suc-F)$_2$-Rh110 are hydrolyzed by the enzyme following the two-step reaction shown in Scheme 1. The hydrolysis of the monoamide substrate analogues suc-AAPF-Rh110-MC and suc-F-Rh110-MC follows the reaction of Scheme 2.

Enzymatic activity was measured over a range of substrate concentrations (at least 12 data points) in order to determine the kinetic constants. At least one reaction in each series was followed to completion. In this way, the final product concentration could be determined, which corresponds directly to the initial substrate concentration. This approach yields an accurate value of the substrate concentration even if the respective compound contains noncleavable components such as molecules with D-amino acids that have not been completely removed during purification.

The results (Table 1) clearly show that the activity of α-chymotrypsin is higher for the substrate analogues containing the AAPF sequence instead of phenylalanine only. It has been observed before that the activity of α-chymotrypsin increases with increasing length of the peptide.[25] More interesting are, however, the differences between the peptide-Rh110-MC and the bis-amide Rh110 substrate analogues. For both the 4 amino-acid-long and the 1 amino-acid-long peptides, the k_{cat} values for the peptide-Rh110-MC based substrate analogue are higher than for the (peptide)$_2$-Rh110 substrate analogue. This is expected when considering that the cleavage of the bis-amide substrate analogue (Scheme 1) involves the less fluorescent intermediate. When using the fluorescence of the product as the calibration, the actual number of cleaved bonds is underestimated due to the presence of the intermediate leading to a lower measured reaction velocity and k_{cat}^{app} value. The lower K_m^{app} values for the (peptide)$_2$-Rh110 substrate analogues can potentially result from a higher effective molarity of the cleavable

dx.doi.org/10.1021/bc2001038 |*Bioconjugate Chem.* 2011, 22, 1932–1938

bonds or rebinding of the intermediate after hydrolysis of the first bond. Although we cannot exclude that the MC-moiety influences the binding of the substrate analogues to the enzyme, it appears likely that the kinetic parameters obtained from the hydrolysis of the monoamide peptide-Rh110-MC substrate analogue represent the true kinetic constants related to peptide-bond cleavage. The result that the determined k_{cat}^{app} and K_m^{app} values for the double-substituted substrate analogue do not resemble the real kinetic constants is further supported by the observation that the two cleavage steps are characterized by different kinetic constants as has been shown for other fluorogenic substrate analogues before.[13]

Making several assumptions, we have also made an attempt to calculate the individual kinetic constants of the two-step hydrolysis reaction (see Supporting Information). While the calculated k_{cat}/K_m values for the individual reaction steps have a large error, they are clearly different from each other and from the apparent values. This further emphasizes the problem associated with obtaining kinetic constants for double-substituted substrate analogues. In summary, these results show that the apparent K_m^{app} and k_{cat}^{app} values determined for the double-substituted Rh110 substrate analogues are not the true rate constants characterizing the enzymatic reaction. Clearly, there is no accurate way to determine these from an assay purely based on fluorescence. Monosubstituted substrate analogues such as peptide-Rh110-MC are required for an accurate determination of K_m and k_{cat}.

In order to obtain a more detailed picture of the molecular mechanism determining the fluorescence of MC-Rh110, we also synthesized the monosubstituted peptide-Rh110 derivatives. We expected that a comparison of MC-Rh110 with Boc-F-Rh110 and Boc-AAPF-Rh110 as well as with Rh110 would give insight into the properties determining the high fluorescence intensity of MC-Rh110. The Boc-protected analogues were used instead of the succinylated peptides, because they are easier to obtain in high purity, which is essential for spectroscopic measurements. The Boc-group is not expected to affect the structural and photophysical properties as it has been shown before that only the amino acid closest to the fluorophore determines its properties.[26] The latter is confirmed by our measurements that show similar photophysical properties for Boc-F-Rh110 and Boc-AAPF-Rh110 (see Supporting Information).

For both MC-Rh110 and Boc-F-Rh110, we have observed that their solutions in chloroform do not absorb visible light. This suggests their presence in the nonfluorescent lactone form, which is confirmed by NMR spectra. The ^{1}H signals for protons 1, 2, 7, and 8 of the xanthene moiety are shielded, and the carbon ^{13}C signal at 84 ppm corresponds to carbon 9 (see Supporting Information). Combining the ^{13}C and DEPT spectra indicates that the number of carbons is compatible with the presence of a single molecular species. When these molecules are dissolved in water, however, they absorb in the blue region with a maximum absorption coefficient of 24 600 and 52 000 M^{-1} cm^{-1} for Boc-F-Rh110 and MC-Rh110, respectively. NMR measurements of MC-Rh110 in D_2O/DMSO (5%) confirm the formation of the open zwitterionic form and do not indicate the presence of more than one species. The carbon signals of the benzene ring and C-2, 3 of the xanthene moiety show very similar ppm values as for unsubstituted Rh110 (see Supporting Information).[27] X-ray diffraction analysis of MC-Rh110 single-crystals, obtained from the slow evaporation of a methanol solution, also revealed the open ionic conformation. Methanol as a medium corresponds to a polar environment just as in an aqueous solution. In conclusion, we suggest that the previously proposed conformational equilibrium of monosubstituted Rh110 molecules is completely shifted to the lactone form in a nonpolar solution. In contrast, all molecules adopt the open ionic form in a water solution. This result is further supported by the photophysical properties of Boc-F-Rh110 and MC-Rh110 that obviously suggest a different reason for the decrease in fluorescence intensity from Rh110 to MC-Rh110 and Boc-F-Rh110.

The data presented in Figure 1 and Table 2 show that the attachment of a substituent to one of the amino groups of Rh110 leads to a blue shift of the absorption maximum, a red shift of the emission maximum, an increased bandwidth, and vibrational progression in the absorption and emission spectra. This is accompanied by a decrease of the fluorescence quantum yield. This effect is more pronounced for Boc-F-Rh110 than for MC-Rh110. These results can be rationalized by considering the

resonance forms of the dyes. For Rh110, two equivalent and isoenergetic resonance forms exist with the positive charge on the left and right amino groups, respectively. For MC-Rh110, the attachment of an electron withdrawing amide moiety to one of the amino groups destabilizes the resonance form with the positive charge on the corresponding amino group. For Boc-F-Rh110, this resonance form is even more destabilized as the electron withdrawing character of the carbonyl is no longer attenuated by the electron donating morpholino moiety. As both resonance forms are no longer iso-energetic, there is an alternation of single and double bonds in the xanthenium cation leading to a blue shift of the absorption. Furthermore, the alternation of single and double bonds increases upon excitation which leads to increased electron phonon coupling and hence increased vibrational progression. The asymmetry furthermore leads to a dipole moment along the long axis of the molecule that is different in the excited state and the ground state. This difference in dipole moment leads to an increased Stokes shift and hence a red shift of the fluorescence. Furthermore, the increased asymmetry of the π-cloud results in a reduced transition dipole moment between the S_0 and S_1 states that is reflected in the fluorescent rate constant. The molar extinction coefficient at the maximum shows an even stronger decrease resulting from the combination of an increased electron phonon coupling and a decreased transition dipole moment. Finally, the increased electron phonon coupling also leads to an increase of the nonradiative decay rate from 7.5×10^6 s^{-1} in Rh110 over 1.1×10^8 s^{-1} in MC-Rh110 and 2.5×10^8 s^{-1} in Boc-F-Rh110. Finally, it should be noted that the fluorescence lifetimes measured at both maxima of Boc-F-Rh110 are the same, indicating that they must be attributed to the same emitting species. Overall, our results clearly suggest that the differences in fluorescence intensity do not originate from the proposed equilibrium between a lactone form and a zwitterionic form but result from differences in the electron structure of the monosubstituted Rh110 derivatives.

The absence of this equilibrium is important information for single molecule experiments, where it is essential that the fluorophore population studied is homogeneous. Thus, the chemical properties of MC-Rh110 in principle make it an ideal fluorophore for preparing substrate analogues with 1:1 stoichiometry for the analysis of enzyme kinetics at the single molecule level. However, not only the chemical properties ensure that each generated product molecule can be detected individually as a fluorescent signal.[21,28] MC-Rh110 further shows sufficient brightness to be detected at the single molecule level. It is therefore our next goal to investigate if suc-AAPF-Rh110-MC and $(suc\text{-}AAPF)_2$-Rh110 also yield different kinetic parameters in single molecule experiments where the intermediate is probably not detected due to its low brightness.

In conclusion, we have synthesized a series of fluorogenic substrate analogues for α-chymotrypsin. We have shown that only substrate analogues with one cleavable bond give access to the real kinetic constants of the enzymatic reaction. The origin of the relatively high fluorescence of the morpholine-carbonyl monosubstituted Rh110 was established. We anticipate that the fluorescence of monosubstituted fluorescein derivatives is determined by the same mechanism and that in aqueous solution xanthene dyes in general adopt an open ionic form. This information is vital for the development of the next generation of monosubstituted fluorogenic substrate analogues, e.g., with improved solubility or cell permeability, which might ultimately allow the study of single enzyme molecules in living systems.

Determination of the kinetic parameters of the different substrate analogues

The enzymatic reaction of the "good" substrates $(suc\text{-}AAPF)_2$-Rh110 and suc-AAPF-Rh110-MC has been measured at 12 different concentrations between 400 nM and 25 µM using 3 nM α-chymotrypsin. For the substrates containing only Phe ($(suc\text{-}F)_2$-Rh110 and suc-F-Rh110-MC) a much higher enzyme concentration (900 nM) was required to obtain a measureable substrate conversion.

Product emission was measured every second and converted into the product concentration using calibration curves of Rh110 or MC-Rh110, respectively. The reaction velocity corresponding to the initial slope was obtained from linear regression to the first 100 – 150 data points measured. Before fitting the data to the Michaelis-Menten equation, the reaction velocity was converted into "enzymatic activity" by dividing the reaction velocity by the enzyme concentration. In this way K_m and k_{cat} could be obtained directly from least squares fitting to the Michaelis-Menten equation (Figure S1). The fit performed with Origin directly provided the standard deviations of the fitted parameters.

A)

Equation	y = P1*x/(P2 + x)

Calculation of the individual kinetic constants of the two-step hydrolysis reaction

The appearance of a shoulder in the emission spectrum during the catalytic reaction together with the hydrolytic stability of the intermediate analogues Boc-AlaAlaProPhe-Rh110 and Boc-Phe-Rh110 clearly suggests the accumulation of a stable mono-amide intermediate, which can only be hydrolysed to the final product by the enzyme. Assuming Michaelis-Menten kinetics for the individual steps, the two-step reaction needs to be described by the following scheme:

$$E + S \underset{k_{-1}}{\overset{k_1}{\Leftrightarrow}} ES \overset{k_2}{\rightarrow} E + I + R$$

$$E + I \underset{k_{-1}^{'}}{\overset{k_1^{'}}{\Leftrightarrow}} EI \overset{k_2^{'}}{\rightarrow} E + P + R\,,$$

where S signifies substrate, I intermediate, P final product, E enzyme and R liberated peptide.

Assuming that no autohydrolysis of the substrate or intermediate takes place and that the reaction of the enzyme with either substrate or intermediate are independent, S and I can be seen as competitive inhibitors. For this case velocity equations for two-substrate kinetics are valid to describe the overall reaction:[1]

$$\frac{dS}{dt} = -\frac{k_2 \cdot E \cdot S}{K_m \cdot H + S}$$

$$\frac{dI}{dt} = -\frac{k_2^{'} \cdot E \cdot I}{K_m^{'} \cdot H_1 + I} - \frac{dS}{dt}$$

$$\frac{dP}{dt} = \frac{k_2^{'} \cdot E \cdot I}{K_m^{'} \cdot H_1 + I}$$

$$H = \frac{K_m^{'} + I}{K_m^{'}}$$

$$H = \frac{K_m + S}{K_m}\ .$$

This system of differential equations cannot be solved analytically so that only a numerical fit of the measured data is possible. When using these equations to fit the data obtained from the fluorescence measurements it needs to be considered that the fluorescence intensity of the intermediate is 10% of the Rh110 intensity. As a result, the fluorescent signal originates from two components: $signal = cf(Rh110) \cdot 0.1 \cdot I + cf(Rh110) \cdot P$ with $cf(Rh110)$ being the experimentally determined calibration factor for Rh110. Therefore, when converting the measured fluorescence signal into "product concentration" using *cf*(Rh110) the following correction needs to be made before fitting is possible. The overall concentration c of molecules contributing to the fluorescence signal corresponds to $c = signal / cf(Rh110) = 0.1 \cdot I + P$.

Using the above differential equations we have performed a numerical fit of several kinetic measurements using a 10 µM solution of $(suc\text{-}AAPF)_2$-Rh110 (Figure S2). To do so, we first calculated concentration changes starting from a 10 µM solution in time intervals of 0.25 s. We then performed least squares fitting of the measured to the calculated data set allowing the four parameters K_M, k_2, $K_M^{'}$ and $k_2^{'}$ to vary.

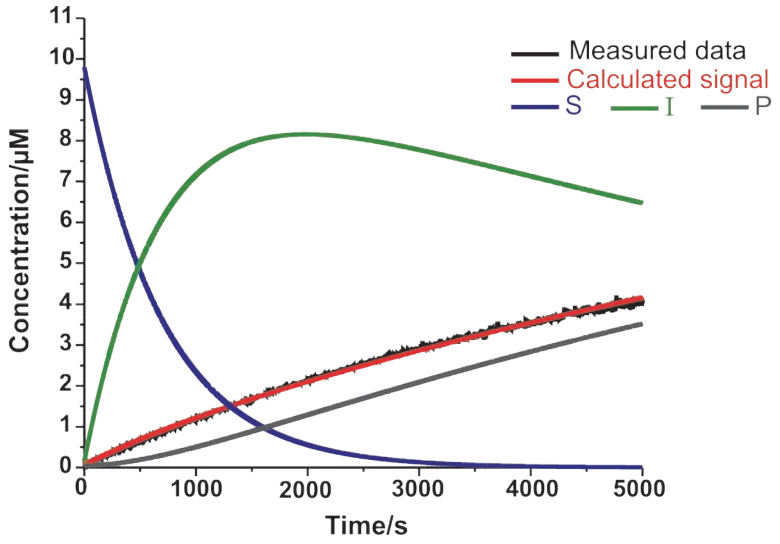

Figure S2. Measured and calculated kinetic data of the enzymatic hydrolysis of 10µM $(sucAAPF)_2$-Rh110. The numerical fit is also shown in the diagram (red line).

The fitting is not accurate due to the large number of variables and good fits can be obtained for a number of combinations of fit variables. Although variations in the individual parameters have been obtained (and k_{cat} and K_M can not be determined accurately) it was observed that the values obtained for k_2/K_m and k_2'/K_M' (i.e. k_{cat}/K_M) are obtained reproducibly and yield approximately $50 \cdot 10^4$ $M^{-1}s^{-1}$ and $4 \cdot 10^4$ $M^{-1}s^{-1}$, respectively. We would like to note here that good fits can only be obtained if $K_M \neq K_M'$ and $k_2 \neq k_2'$ clearly indicating that the rate constants for the two reaction steps need to be different.

Although the fits need to be seen critically due to their large error and the assumptions made initially, the result is still important information since it clearly shows that the two reaction steps are characterized by different kinetic constants and that the approximation of such a two step hydrolysis reaction with apparent k_{cat} and K_M values does not yield the true kinetic constants. It should further be noted that the first reaction step seems to proceed faster. The most likely explanation might be the higher effective molarity of cleavable bonds in the bis-amide substrate compared to the mono-amide intermediate.

Overall, having performed this fitting procedure with our data, it needs to be concluded that accurate fits are only possible if the intermediate concentration is known as it has been the case in the initial study by Hofmann & Sernetz.[1] This is an important result clearly showing that fluorescence experiments are not suited to obtain the rate constants for the individual steps and that the apparent rate constants obtained from fluorescence measurements do not represent the true values.

Comparison of the fluorescence properties of Boc-AlaAlaProPhe-Rh110 and Boc-Phe-Rh110

As described previously, the synthesis of Boc-AlaAlaProPhe-Rh110 is more difficult than the synthesis of Boc-Phe-Rh110. It was therefore preferable to perform the spectroscopic measurements with Boc-Phe-Rh110. To verify that the longer peptide in Boc-AlaAlaProPhe-Rh110 does not influence the fluorescence properties we have compared the absorption and emission spectra (Figure S3) as well as the fluorescence lifetimes of these two molecules. Both the absorption and emission spectra are almost identical. Further, the fluorescence decay curves, measured at the wavelengths 520, 530 and 563 nm, all fitted a monoexponential decay with a time constant of 2.8 ns for both Boc-AlaAlaProPhe-Rh110 and Boc-Phe-Rh110. These data clearly show that the length of the peptide doesn't influence the fluorescence properties and that only the first amino acid next to Rh110 defines these properties.

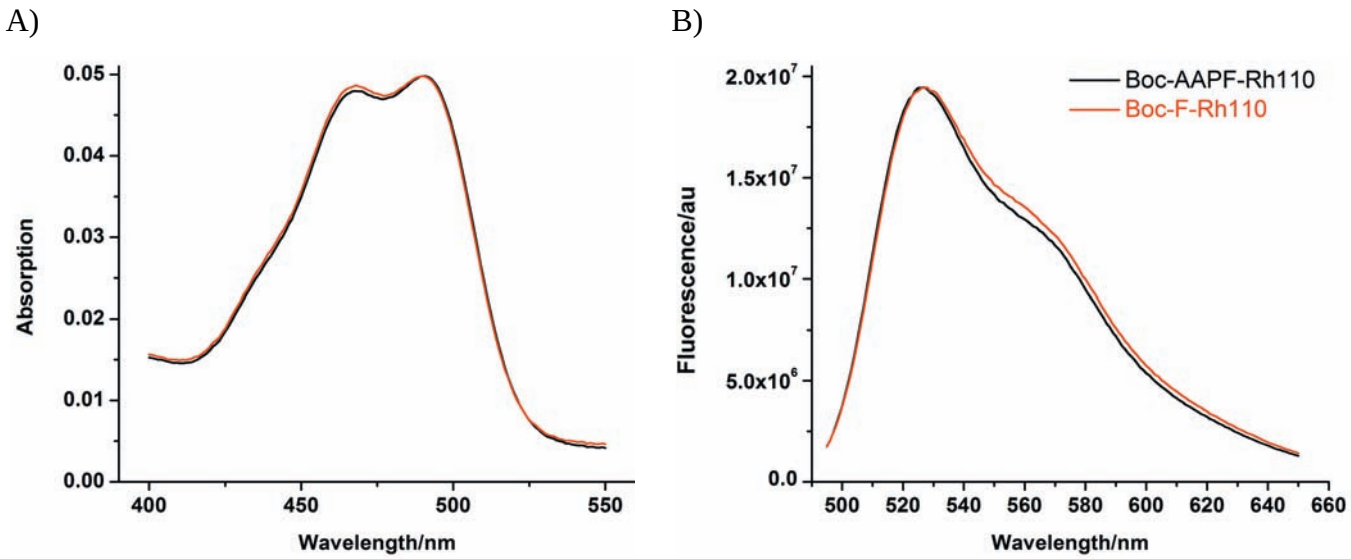

Figure S3. A) Absorption and B) emission spectra of a 2 μM solution of Boc-AlaAlaProPhe-Rh110 and Boc-Phe-Rh110 in PBS.

Crystals of MC-Rh110

Slow evaporation of methanol from a solution of MC-Rh110 resulted in small single-crystals. X-ray diffraction analysis did not yield enough resolution for publishing small molecule data but it clearly revealed the open ionic conformation presented in Figure S4.

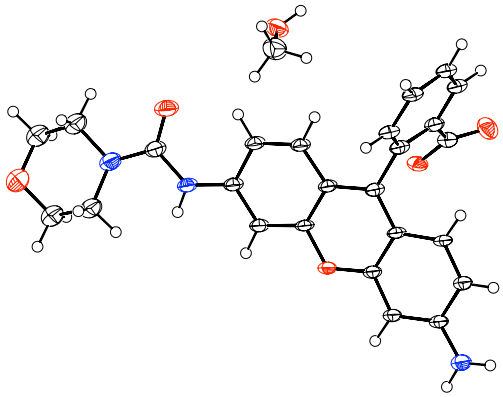

Figure S4. Crystal structure of MC-Rh110.

NMR measurements

Through NMR analysis a difference in molecular conformation of mono-substituted Rh110 was observed depending on the solvent used (apolar chloroform and polar water solution). Good spectra were obtained in $CDCl_3$ solution. Due to the low solubility of these compounds in H_2O, however, only a poor resolution ^{13}C NMR spectrum was achieved. The more sensitive two-dimensional HSQC and HMBC measurements performed for MC-Rh110 in D_2O + 5% DMSO-d_6 allowed the assignment of all carbon signals (Figure S8). The signals of the NMR spectra were assigned according to the generally accepted atom numbering of Rh110 as shown in Chart 1 of the article.

Rhodamine 110 chloride is known to be present in the open ionic form only, showing a signal for C-9 of the xanthene moiety at 158 ppm in $CDCl_3$. For both mono-substituted Rh110 derivatives BocF-Rh110

and MC-Rh110, however, a strong shielding of C-9 is observed placing the C-9 signal at 84 ppm, suggesting a lactone conformation, whereas no signal at 158 ppm is found of the open form. For Rh110 C3/6 give a signal at 156 ppm while substitution of the amine next to C-6 leads to a shift of C-3 to 149 ppm, which corresponds to the presence of an uncharged amine group (Figure S5, S6A). Combination of the ^{13}C and DEPT spectra suggests that for both BocF-Rh110 and MC-Rh110 the number of quaternary, tertiary and secondary carbons is compatible with the presence of a single conformation.

In a D_2O + 5% DMSO-d_6 solution of MC-Rh110, however, no carbon signal was observed at 84 ppm while a signal for C-9 is detected at 148 ppm and the signal for C-3 is deshielded to 161 ppm. This suggests the presence of the open ionic form in polar solutions (Figure S6). Also here the number of signals corresponds to the existence of only one conformation. In addition, ^1H NMR spectra show a stronger shielding for the protons of the xanthene moiety in chloroform solution than in water solution (Figure S7), which is expected assuming the presence of an amine group in chloroform and an ammonium group in water.

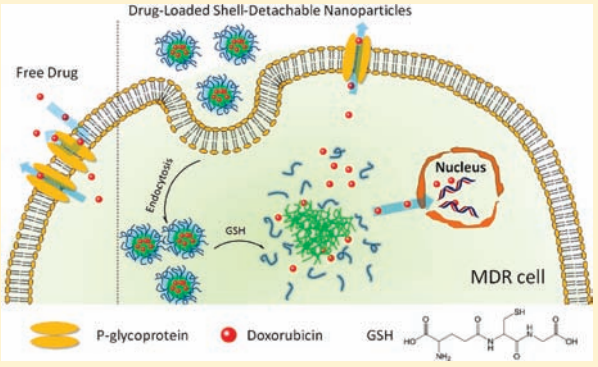
[†]Department of Polymer Science and Engineering, University of Science and Technology of China, Hefei, Anhui 230026, P.R. China

ABSTRACT: Multidrug resistance (MDR) is a major impediment to the success of cancer chemotherapy. The intracellular accumulation of drug and the intracellular release of drug molecules from the carrier could be the most important barriers for nanoscale carriers in overcoming MDR. We demonstrated that the redox-responsive micellar nanodrug carrier assembled from the single disulfide bond-bridged block polymer of poly(ε-caprolactone) and poly(ethyl ethylene phosphate) (PCL-*SS*-PEEP) achieved more drug accumulation and retention in MDR cancer cells. Such drug carrier rapidly released the incorporated doxorubicin (DOX) in response to the intracellular reductive environment. It therefore significantly enhanced the cytotoxicity of DOX to MDR cancer cells. It was demonstrated that nanoparticular drug carrier with either poly(ethylene glycol) or poly(ethyl ethylene phosphate) (PEEP) shell increased the influx but decreased the efflux of DOX by the multidrug resistant MCF-7/ADR breast cancer cells, in comparison with the direct incubation of MCF-7/ADR cells with DOX, which led to high cellular retention of DOX. Nevertheless, nanoparticles bearing PEEP shell exhibited higher affinity to the cancer cells. The shell detachment of the PCL-*SS*-PEEP nanoparticles caused by the reduction of intracellular glutathione significantly accelerated the drug release in MCF-7/ADR cells, demonstrated by the flow cytometric analyses, which was beneficial to the entry of DOX into the nuclei of MCF-7/ADR cells. It therefore enhanced the efficiency in overcoming MDR of cancer cells, which renders the redox-responsive nanoparticles promising in cancer therapy.



INTRODUCTION

Multidrug resistance (MDR) is a major impediment to the success of cancer chemotherapy.[1−3] Although cancer cells can acquire MDR through several molecular mechanisms, P-glycoprotein (P-gp) is the best known and is an important membrane transporter involved in MDR, being overexpressed in the plasma membrane of MDR tumor cells and capable of effluxing various anticancer drugs (e.g., doxorubicin and paclitaxel) out of the cells.[4−6] Nanoscale vehicles as drug carriers have shown the ability to target tumors and improve the anticancer efficacy of drugs, owing to their unique physical and biological properties,[7,8] and may provide opportunities for overcoming MDR.[9−14] Many nanobased drug delivery systems have been used for the inhibition of drug efflux mediated by P-gp.[15−21] Recently, it has been demonstrated that nanoparticles showing responsibility to intracellular stimulus are capable of delivering chemotherapeutic drugs to overcome MDR. Bae's group has carried out intensive studies on folic acid-conjugated polymer micelles, which are sensitive to early endosomal pH.[22−24] It has been suggested that MDR cancer cells may have limited capacity to defend themselves against cytotoxic chemicals.[23] In this sense, realizing a sufficiently high intracellular level of cytotoxic chemicals using an optimized delivery system might represent a novel tactic in overcoming the MDR of cancer cells, while the intracellular accumulation of drug and the intracellular release of drug molecules from the carrier could be the most important barriers for nanoscale carriers in overcoming MDR.

Nanoparticles based on diblock copolymer with a single disulfide bond in each polymer chain can be used as the intelligent drug carriers for promoted intracellular drug release.[25,26] In this study, we report that redox-responsive micellar nanoparticles based on disulfide-bridged PCL-*SS*-PEEP block polymer as a drug carrier can significantly overcome the two barriers in overcoming the MDR of cancer cells, thus reversing the multidrug resistance of cancer cells. On one hand, nanoparticles bearing a poly(ethyl ethylene phosphate) (PEEP) shell exhibit a high affinity to cells and are more efficiently internalized by cells, which help the drug escape from the pump-off by P-gp

and lead to high levels of cellular drug accumulation. On the other hand, it is known that MDR in cancer cells is often associated with an elevation in the concentration of reductive glutathione (GSH).[27] Such shell-detachable nanoparticles are sensitive to the intracellular glutathione of MDR cancer cells, resulting in significantly enhanced intracellular drug release and rapid accumulation of free drug in MDR cancer cells (Figure 1).

MATERIALS AND METHODS

Syntheses of Block Copolymers. The block copolymers were synthesized as previously reported.[26,28] Briefly, block copolymer of poly(ε-caprolactone) and poly(ethylene glycol) (PCL-*b*-PEG) was synthesized by ring-opening polymerization of ε-caprolactone (Acros, USA) in bulk at 120 °C with polyethylene glycol monomethyl ether (PEG, MW 5000, Sigma-Aldrich, USA) as the initiator and stannous octoate as the catalyst, which was purified by precipitating its solution into ether.[29] The average molecular weights were 4900 and 5000 for PCL block and PEG block, respectively.

Block copolymer of poly(ε-caprolactone) and poly(ethyl ethylene phosphate) (PCL-*b*-PEEP) was synthesized by ring-opening polymerization of ethyl ethylene phosphate using poly(ε-caprolactone) as the initiator and stannous octoate as the catalyst at 30 °C in tetrahydrofuran.[28] The resultant polymer was purified by precipitation into ethyl ether/methanol (9/1, v/v). The average molecular weights of PCL and PEEP were 4650 and 4860, respectively.

Disulfide-bridged diblock copolymer of poly(ε-caprolactone) and poly(ethyl ethylene phosphate) (PCL-*SS*-PEEP) was synthesized through a coupling reaction between the thiol end group functionalized poly(ε-caprolactone) (PCL-SH) with the pyridyldisulfide groups at the end of poly(ethyl ethylene phosphate). The mixture was allowed to react for 24 h, concentrated, and precipitated into diethyl ether/methanol (10:1 v/v) three times. The precipitate was dried in vacuum, dialyzed against water at 4 °C for 3 days, and freeze−dried to obtain the product. The average molecular weights of PCL and PEEP were 3650 and 3480, respectively.[26]

The molecular weights of the polymers above were all calculated based on ^{1}H NMR analyses.

Preparation and Characterization of DOX-Loaded Nanoparticles. Doxorubicin hydrochloride (1 mg, DOX, Hisun Pharmaceutical Co., China) and block copolymer (10 mg) were dissolved in DMSO (1 mL), and then triethylamine (5 μL) was added. The mixture was stirred for 2 h at room temperature. Thereafter, the solution was added dropwise to ultrapurified water (5 mL) with stirring and transferred into Spectrum/Por dialysis membrane (M_w cutoff = 14 000 Da, Spectrum Laboratories Inc., CA, USA). It was dialyzed against water for 24 h at 4 °C. After ultrafiltration at 3000 *g* for 10 min using Amicon Ultra-4 centrifugal filter (M_w cutoff = 10 000 Da, Millipore, USA), the solution was resuspended to desired concentrations. The DOX concentration and drug loading contents were determined by HPLC analyses as previously reported.[26] Particle size and zeta potential of nanoparticles were characterized on a Malvern Zetasizer Nano ZS90 with a He−Ne laser (633 nm) and 90° collecting optics.

Cell Culture. The human breast adenocarcinoma (MCF-7) cell line was obtained from the American Type Culture Collection (ATCC, MD, USA), and the P-gp overexpressing human breast carcinoma cell line (DOX resistant MCF-7 cell line, MCF-7/ADR) was kindly provided by Prof. Tao Zhu of University of Science and Technology of China. The cells were cultured in RPMI 1640 medium, supplemented with 10% fetal bovine serum and L-glutamine (2 mM) at 37 °C using a humidified 5% CO_2 incubator. MCF-7/ADR cells were maintained with free DOX at 5 μg mL^{-1}.

Determination of Intracellular Accumulation or Retention of Doxorubicin. MCF-7 or MCF-7/ADR cells were seeded in 24-well plates at a density of 7×10^4 cells/well and incubated overnight. The cells were washed with Earle's Balanced Salt Solution (EBSS, Invitrogen Life Science Technologies) and treated with free DOX or DOX-loaded nanoparticles in EBSS with equivalent DOX at a concentration of 5 μg mL^{-1}. Cells were incubated at 37 °C for 0.5, 1, 2, 3, or 4 h, washed twice with ice-cold phosphate-buffered saline (PBS, 0.01 M, pH 7.4), and lysed in PBS containing 1% Triton X-100 at 37 °C for 30 min with three freeze−thaw cycles. DOX concentrations in cell lysates were measured by HPLC analyses as previously reported[26] and normalized to the total cellular protein content of the cells, which was measured with the BCA (bicinchoninic acid) Protein Assay (Pierce, IL, USA).

To determine the intracellular retention of DOX, MCF-7/ADR cells were cultured with either free DOX or DOX-loaded nanoparticles for 4 h, washed with PBS, and then incubated with EBSS at 37 °C for additional 0.5, 1, 2, 3, or 4 h. Cells were lysed and the DOX concentrations in cell lysates were measured as described above.

DOX Release from DOX-loaded PCL-*SS*-PEEP Nanoparticles Caused by the Reductive Condition. DOX-loaded PCL-*SS*-PEEP nanoparticles were incubated in PBS with or without DL-dithiothreitol (DTT, 10 mM). The fluorescence emission spectra of DOX-loaded PCL-*SS*-PEEP nanoparticles were recorded after different time intervals with excitation wavelength at 479 nm using a Shimadzu RF-5301PC spectrofluorophotometer.

To determine the drug release of DOX from DOX-loaded nanoparticles, the nanoparticles were suspended in PBS at 1 mg mL^{-1} in the dialysis membrane tubing (M_w cutoff = 14 000, Spectrum/Por), and immersed in PBS (15 mL) containing 0 mM or 10 mM GSH in a shaking water bath at 37 °C.

At predetermined time points, the external buffer was collected and it was replaced with equal volume of PBS containing 0 mM or 10 mM GSH. The collected release medium was freeze−dried and dissolved in acetonitrile−water (50:50, v/v) and the concentration of DOX was analyzed by HPLC analyses.

Flow Cytometric Analyses of MCF-7/ADR Cells Following Incubation with Free DOX or DOX-Loaded Nanoparticles. MCF-7/ADR cells were seeded in 24-well plates at 1×10^5 cells per well in 500 μL of complete RPMI 1640 medium containing 10% fetal bovine serum, and incubated at 37 °C in 5% CO_2 humidified atmosphere for 24 h. The medium was replaced with fresh medium containing either free DOX or DOX-loaded nanoparticles with equivalent DOX at a concentration of 5 μg mL^{-1}, and the cells were further incubated for various lengths of time. Cells were washed with PBS twice and harvested, then suspended in PBS (200 μL) for analyses using FACSCalibur flow cytometer. Cells with PBS treatment were used as the control. The data was analyzed using *WinMDI 2.9* software.

Confocal Laser Microscopic Observation of MCF-7/ADR Cells Following Incubation with Free DOX or DOX-Loaded Nanoparticles. MCF-7/ADR cells were seeded onto 12 mm coverslips in 24-well plates with 5×10^4 cells per well and allowed to grow until 60% confluence. Cells were washed twice with PBS, and then incubated with free DOX or DOX-loaded nanoparticles (with equivalent DOX at a concentration of 5 μg mL^{-1}) in a complete RPMI 1640 medium for 24 or 48 h at 37 °C. Cells were washed twice with ice-cold PBS and fixed with fresh 4% paraformaldehyde for 15 min at room temperature. The cells were counterstained with DAPI for cell nucleus and Alexa Fluor 488 phalloidin (Invitrogen Life Science Technologies) for cell membrane following the manufacturer's instructions. The coverslips were mounted on the glass microscope slides with a drop of antifade mounting media (Sigma-Aldrich Co., USA) to reduce fluorescence photobleaching. The intracellular localization of DOX nanoparticles was visualized under a laser scanning confocal microscope (LSCM; LSM 700 Meta, Carl Zeiss Inc., Thornwood, NY).

Cell Growth Inhibition Assay. MCF-7/ADR cells were seeded in 96-well plates at 5×10^3 cells per well in complete RPMI 1640 medium (100 μL), and incubated at 37 °C in 5% CO_2 humidified atmosphere for 24 h. The culture medium was then replaced with freshly prepared culture medium (100 μL) containing either free DOX or DOX-loaded nanoparticles at different concentration (from 1×10^{-3} to 1×10^2 μg mL^{-1}). The cells were further incubated for 24, 48, or 72 h, and MTT (25 μL, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, Sigma-Aldrich Co., USA) stock solution (5 mg mL^{-1} in PBS) was added to each well to achieve a final concentration of 1 mg mL^{-1}, with the exception of the wells as blank, to which PBS (25 μL) was added. After incubation for another 2 h, extraction buffer (100 μL, 20% SDS in 50% DMF, pH 4.7, prepared at 37 °C) was added to the wells and incubated for another 4 h at 37 °C. The absorbance was measured at 570 nm using a Bio-Rad 680 microplate reader. The cell viability was normalized to that of MCF-7/ADR cells cultured in the complete culture medium. The half maximal inhibitory concentrations (IC_{50}) values were calculated based on the percentage of treatment over control.

RESULTS AND DISCUSSION

Preparation of Polymers and Nanoparticles. PCL-*SS*-PEEP is a disulfide-bridged diblock copolymer of poly(ε-caprolactone) and PEEP, which was prepared as previously reported.[26] The chemical structure is shown in Figure 1. It self-assembled into micellar nanoparticles in aqueous solution, encapsulating doxorubicin (DOX, in unsalted form) in the core with an average diameter of around 92 nm. We also made micellar nanoparticles of block copolymers poly(ε-caprolactone)-*b*-poly(ethyl ethylene phosphate) (PCL-*b*-PEEP) and poly(ε-caprolactone)-*b*-poly(ethylene glycol) (PCL-*b*-PEG) with similar particle size and size distributions for comparison, and encapsulated DOX into their hydrophobic cores at comparable drug loading contents (~6% w/w). Information about the nanoparticles is summarized in Table 1.

Table 1. Characterization of Doxorubicin-Loaded Nanoparticles

polymer	diameter [nm]	PDI[a]	zeta potential [mv]	DLC (%)[b]
PCL-*SS*-PEEP	91.7 ± 2.60	0.112	−30.6	6.53
PCL-*b*-PEEP	80.2 ± 2.27	0.105	−34.5	6.14
PCL-*b*-PEG	94.2 ± 0.93	0.135	−7.2	5.26

[a] Polydispersity index determined by dynamic light scattering. [b] Loading content of doxorubicin (w/w).

Intracellular Accumulation and Retention of DOX. We first incubated doxorubicin hydrochloride (free DOX) or DOX-loaded nanoparticles with either wild-type MCF-7 or DOX-resistant MCF-7/ADR breast cancer cells at drug doses of 5 μg mL^{-1}. The drug resistance of MCF-7/ADR cells was demonstrated by the overexpression of P-gp encoding the MDR1 gene and the reversal of DOX accumulation in the cells in the presence of verapamil hydrochloride, an inhibitor of P-gp (data not shown). At different time intervals, the intracellular DOX accumulation was quantitatively determined by analyzing the concentration of DOX in the cell lysate with high liquid performance chromatographic analyses, normalized to the total cellular protein content of the cells. Owing to the efflux of DOX by the P-gp of MCF-7/ADR cells, it was not surprising that intracellular accumulation of DOX in MCF-7/ADR cells was significantly lower than that in MCF-7 cells when the cells were incubated with free DOX (Figure 2A). However, the differences in cellular DOX levels between MCF-7 and MCF-7/ADR cells were much less prominent when the cells were incubated with DOX-loaded nanoparticles (Figure 2B−D), indicating that nanoparticles might not be the substrate of P-gp; thus, the DOX-loaded nanoparticles could be retained in the MDR cells after internalization.

On the other hand, although the use of poly(ethylene glycol) (PEG) as the shell material of nanoparticles has been the preferred strategy to help nanoparticles escape from protein opsonization and macrophage uptake in the reticuloendothelial system.[30,31] PEG also exhibits low affinity to cell membranes, behaving as an unexpected barrier to accessing the targeted cells.[32] As shown in Figure 2B, the cellular DOX level in MCF-7/ADR cells reached ~0.96 μg per mg protein when the cells were incubated with DOX-loaded PCL-*b*-PEG nanoparticles for 4 h, a value that was about 3.9 times higher when compared with treatment with free DOX. However, more DOX accumulated in MCF-7/ADR cells when the cells were incubated with DOX-loaded PCL-*SS*-PEEP or DOX-loaded PCL-*b*-PEEP nanoparticles, with the cellular DOX level in MCF-7/ADR cells reaching ~1.65 μg per mg protein after 4 h incubation, indicating that nanoparticles with PEEP shells showed greater affinity for

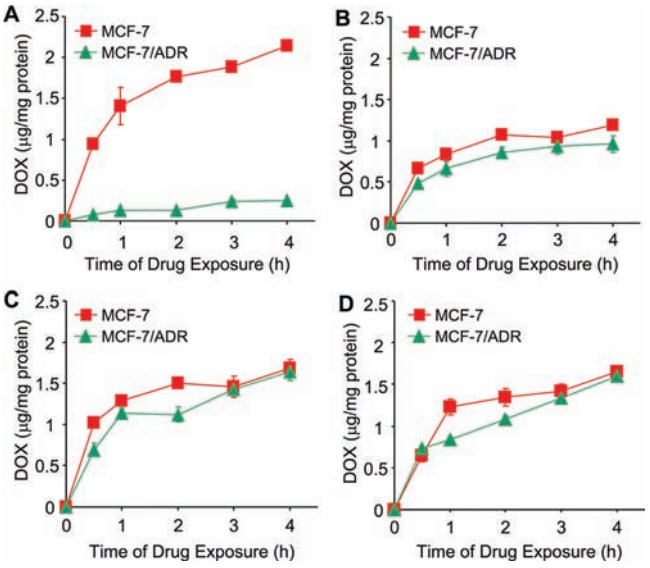

Figure 2. Doxorubicin (DOX) accumulation in wild-type MCF-7 and drug-resistant MCF-7/ADR breast cancer cells after incubation with free DOX (A), DOX-loaded PCL-*b*-PEG (B), DOX-loaded PCL-*b*-PEEP (C), and DOX-loaded PCL-*SS*-PEEP (D) nanoparticles.

cells. At the same time, it must be mentioned that no significant difference in the cellular DOX level was observed between treatments with DOX-loaded PCL-*SS*-PEEP and DOX-loaded PCL-*b*-PEEP nanoparticles (Figure 2C,D).

We next determined how DOX was retained in MCF-7/ADR cells with the delivery of different nanoparticles. MCF-7/ADR cells were incubated with either free DOX or DOX-loaded nanoparticles for 4 h, and subsequently washed with PBS to remove uninternalized free DOX or DOX-loaded nanoparticles. The cells were further incubated in fresh cell culture medium for different periods of time. It is noteworthy that we maintained the initial doses of DOX at 5 μg mL^{-1} in treatments with DOX-loaded nanoparticles but intentionally increased the initial concentration of DOX to 40 μg mL^{-1} in the free DOX treatment, to increase the initial cellular DOX level. As shown in Figure 3, as a result of drug efflux by P-gp, a fast decline in the cellular DOX level was observed in MCF-7/ADR cells preincubated with free DOX. Only 15% DOX was retained in the cells after 4 h incubation in the free DOX treatment. In contrast, the amount and rate of efflux of DOX were significantly lower when the cells were preincubated with DOX-loaded nanoparticles, and the cells retained about 50−62% DOX after 4 h incubation. These results demonstrated that encapsulation of DOX in the nanoparticles protected DOX against the pump-off by P-gp, and thus the nanoparticles increased the cellular retention of DOX in MCF-7/ADR cells.

DOX Release from DOX-Loaded PCL-*SS*-PEEP Nanoparticles Caused by the Reductive Condition. We thus demonstrated that more DOX can be accumulated and retained in MDR cells when delivered with nanoparticles, and that nanoparticles with a PEEP shell have a greater affinity for MDR cancer cells. We then focused on PCL-*SS*-PEEP nanoparticles in comparison with PCL-*b*-PEEP nanoparticles and studied intracellular DOX release in response to the endogenous reductive stimulus. The intracellular concentration of GSH is about 2−10 mM, and is often elevated in MDR cancer cells,[27] being significantly higher than the level outside the cells (ca. 2 μM).[33,34] Therefore, it is possible that PCL-*SS*-PEEP nanoparticles are subjected to rapid reductive degradation in MDR cancer cells.

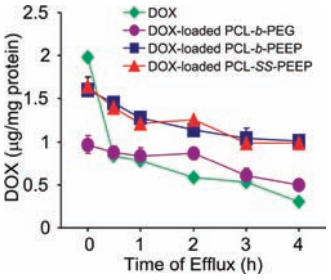

Figure 3. Retention of doxorubicin (DOX) in MCF-7/ADR cells after preincubation with free DOX (DOX), DOX-loaded PCL-*b*-PEG, DOX-loaded PCL-*b*-PEEP, and DOX-loaded PCL-*SS*-PEEP nanoparticles for 4 h. The concentration of DOX in the free DOX preincubation was 40 μg mL^{-1}, while it was 5 μg mL^{-1} for DOX-loaded nanoparticles.

We demonstrated that the detachment of the shell from the nanoparticles caused by the reductive condition accelerated drug release. The effect of PEEP shell detachment on DOX release from DOX-loaded PCL-*SS*-PEEP nanoparticles was directly observed by measuring the fluorescence spectrum of DOX in solution via treatment with 10 mM of DL-dithiothreitol (DTT). The DOX fluorescence of DTT-treated DOX-loaded PCL-*SS*-PEEP nanoparticles was remarkably enhanced (Figure 4A) whereas, in contrast, the fluorescence spectra of those without DTT treatment remained unchanged (inset in Figure 4A). It has been reported that incorporation of DOX in the hydrophobic core of micelles decreases the fluorescent intensity of DOX when compared with free DOX at the same concentration due to the self-quenching effect.[35] Therefore, the enhanced fluorescence should be due to the rapid release of drug from the nanoparticles. *In vitro* drug release was further quantitatively studied by incubating DOX-loaded PCL-*SS*-PEEP nanoparticles in GSH-containing medium. The results shown in Figure 4B revealed a slow and sustained release of 40% DOX from the nanoparticles over 4 d in the absence of GSH, probably due to the hydrophobic interactions between DOX and the PCL core. However, in the presence of 10 mM of GSH, much faster release of almost all the DOX was observed under otherwise identical conditions. These results demonstrated that cleavage of disulfide bridge linkages accelerated the rapid and complete release of the drug. It can be assumed that, in response to stimulation by GSH, the disulfide bridge linkages of PCL-SS-PEEP are reduced and broken, which destabilizes the micellar nanoparticles and results in accelerated DOX release. On the other hand, the release of DOX from DOX/PCL-*b*-PEEP nanoparticles was not affected by the addition of GSH to the release medium (Figure 4C).

Rapid Intracellular Release Caused by the Cellular Reductive Condition. To demonstrate our assumption that DOX-loaded PCL-*SS*-PEEP nanoparticles can release the drug more rapidly in response to the intracellular reduction condition in MDR cancer cells and in turn overcome drug resistance, we incubated free DOX or DOX-loaded nanoparticles with MCF-7/ADR cells, and analyzed the cells using flow cytometry at different time intervals. As shown in Figure 5A, low mean fluorescence intensity was observed when the cells were incubated with free DOX at all time intervals due to its poor cellular retention in MCF-7/ADR cells. On the contrary, higher cellular retention of DOX in MCF-7/ADR cells led to enhanced fluorescence of cells with preincubation of DOX-loaded

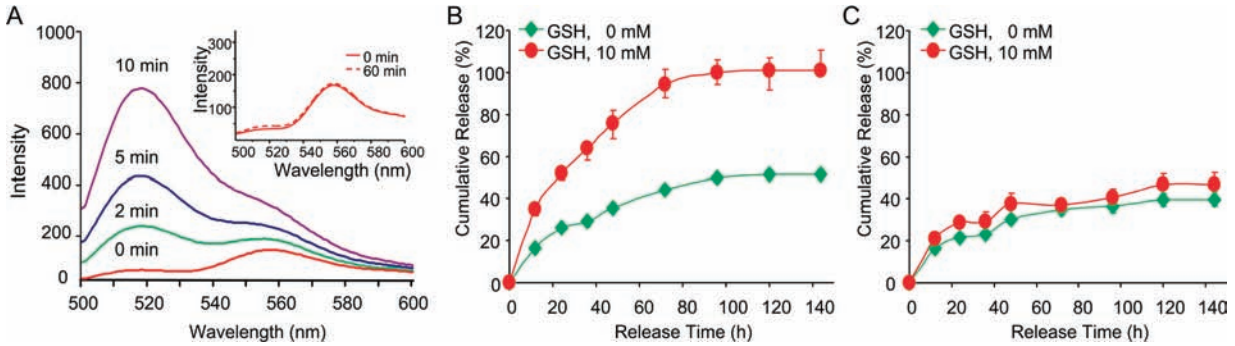

Figure 4. (A) Fluorescence spectra of DOX-loaded PCL-*SS*-PEEP nanoparticles with or without (inset) treatment of DTT for various lengths of time in PBS solution. (B) *In vitro* release of DOX from DOX-loaded PCL-*SS*-PEEP nanoparticles in PBS (pH 7.4) at 37 °C with or without GSH treatment. (C) *In vitro* release of DOX from DOX-loaded PCL-*b*-PEEP nanoparticles in PBS (pH 7.4) at 37 °C with or without GSH treatment.

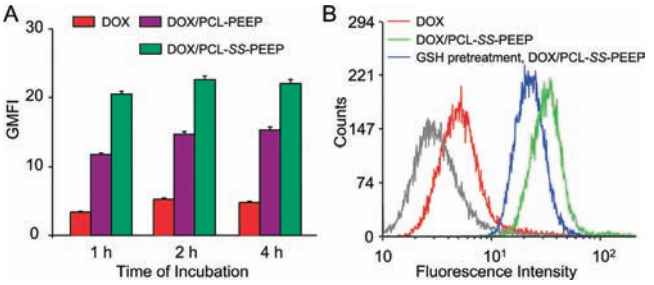

Figure 5. (A) Mean fluorescence intensity (GMFI) of MCF-7/ADR cells after incubation with free DOX, DOX-loaded PCL-*b*-PEEP (DOX/PCL-*b*-PEEP), or DOX-loaded PCL-*SS*-PEEP (DOX/PCL-*SS*-PEEP) nanoparticles for various lengths of times at a dose of 5 μg mL^{-1}. (B) Flow cytometric analyses of MCF-7/ADR cells after incubation with free DOX (DOX) or DOX-loaded PCL-*SS*-PEEP (DOX/PCL-*SS*-PEEP) nanoparticles with or without preincubation of GSH. The dose of DOX was 5 μg mL^{-1} in cell culture.

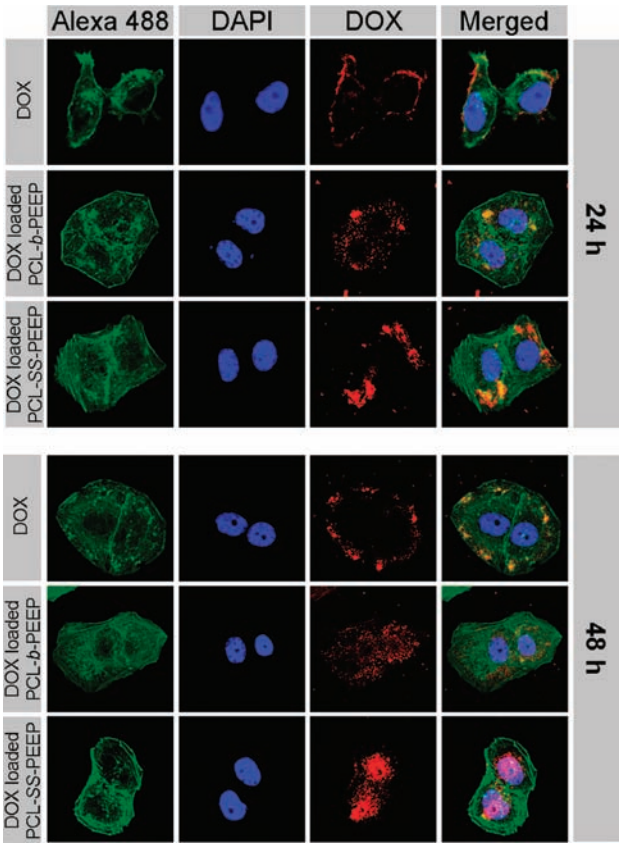

Figure 6. Confocal laser microscopic observation of MCF-7/ADR cells after incubation with free doxorubicin (DOX) or DOX-loaded nanoparticles for 24 or 48 h. The dose of DOX was 5 μg mL^{-1} in cell culture.

nanoparticles. However, although the cellular accumulation of DOX in MCF-7/ADR cells was similar between treatments with DOX-loaded PCL-*SS*-PEEP or DOX-loaded PCL-*b*-PEEP nanoparticles (Figure 2C,D), the fluorescence intensity of cells treated with DOX-loaded PCL-*SS*-PEEP was significantly higher than that in cells treated with DOX-loaded PCL-*b*-PEEP at all tested time intervals. Such enhancements should be due to the enhanced intracellular release of DOX following the cleavage of disulfide-bridges of PCL-*SS*-PEEP in MCF-7/ADR cells. As mentioned above, it was demonstrated that DOX released from the nanoparticles recovered its fluorescence, which was self-quenched in the hydrophobic PCL core of the nanoparticles. To further confirm that DOX-loaded PCL-*SS*-PEEP is effective in accelerated drug release under reductive conditions, we mixed DOX-loaded PCL-*SS*-PEEP or DOX-loaded PCL-*b*-PEEP nanoparticles with medium containing 20 mM GSH for 4 h, and then incubated this medium with MCF-7/ADR cells for 1 h. We observed a significant decline in cell fluorescence intensity with DOX-loaded PCL-*SS*-PEEP (Figure 5B) but not with DOX-loaded PCL-*b*-PEEP nanoparticles when compared with direct incubation of DOX-loaded nanoparticles that did not receive preincubation with GSH. The extracellular treatment of DOX-loaded nanoparticles with GSH led to partial extracellular release of DOX from PCL-*SS*-PEEP nanoparticles but not from PCL-*b*-PEEP nanoparticles. Nevertheless, the extracellular DOX could not be effectively retained in MCF-7/ADR cells due to the pump-off effect mediated by P-gp, resulting in the decline in cell fluorescence intensity.

Confocal Observations. We then examined whether the rapid intracellular release of DOX from DOX-loaded PCL-*SS*-PEEP nanoparticles would be beneficial to the entry of DOX into the nuclei of MCF-7/ADR cells, given that the interaction of DOX with DNA by intercalation in the nucleus is one of the major modes of action of DOX.[36,37] MCF-7/ADR cells were then incubated with free DOX, or DOX-loaded nanoparticles, and the cells were observed with confocal laser microscopy after 24 or 48 h incubation. As shown in Figure 6, DOX was mainly

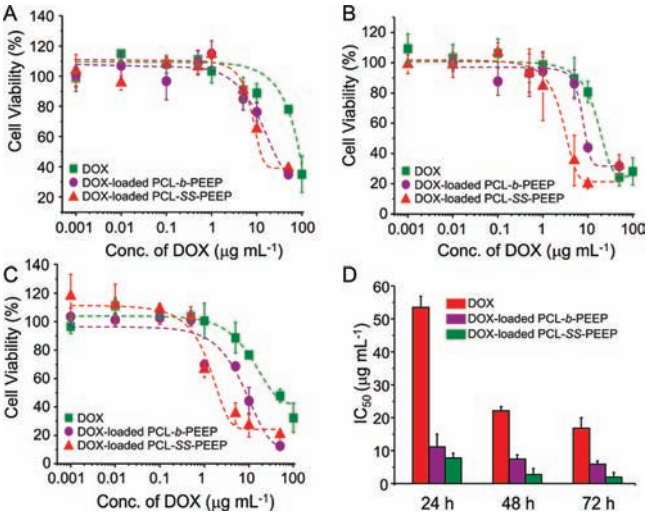

Figure 7. Viability of MCF-7/ADR cells after treatment with free DOX or DOX-loaded nanoparticles for 24 h (A), 48 h (B), and 72 h (C). (D) The half-maximal inhibitory concentration (IC_{50}) of DOX to MCF-7/ADR cells measured by MTT assay (n = 3).

located in the perimembrane region when MCF-7/ADR cells were cultured with free DOX at 5 μg mL^{-1} for 24 and 48 h, due to the action of P-gp. When DOX was incorporated into the nanoparticles, fluorescence signals were observed in the cells. Close scrutiny of the images revealed that the fluorescence signal from cells treated with DOX-loaded PCL-*SS*-PEEP was more dispersed when compared with cells treated with DOX-loaded PCL-*b*-PEEP nanoparticles, which displayed dotted red fluorescence signals. This difference indicated that shell shedding by DOX-loaded PCL-*SS*-PEEP nanoparticles might have taken place in the cells, accompanied by the rapid release of incorporated DOX. As a result, DOX was distributed mostly in the nuclei after 48 h when the cells were incubated with DOX-loaded PCL-*SS*-PEEP nanoparticles. On the contrary, only minimal amounts of fluorescence were detected in the nuclei of MCF-7/ADR cells after 48 h culture with DOX-loaded PCL-*b*-PEEP nanoparticles. Moreover, DOX signals were barely visible in cell nuclei when the cells were incubated with free DOX at the same dose.

Cytotoxicity to MCF-7/ADR Cells. The above results demonstrated that shell-detachable DOX-loaded PCL-*SS*-PEEP nanoparticles can enhance drug retention in MDR cells and more rapidly release the incorporated drug intracellularly. Therefore, delivery of DOX with PCL-*SS*-PEEP nanoparticles can rapidly increase the concentration of free drug in MCF-7/ADR cells, and is expected to improve its cytotoxicity and overcome the MDR of cancer cells efficiently. We then incubated free DOX, DOX-loaded PCL-*b*-PEEP, or DOX-loaded PCL-*SS*-PEEP nanoparticles at the equivalent DOX doses with MCF-7/ADR cells for 24 h, 48, or 72 h, and determined the half-maximal inhibitory concentration of DOX (IC_{50}) by MTT assay. The cytotoxicity to MCF-7/ADR in response to the doses of DOX was given in Figure 7A–C. As shown in Figure 7D, a significant decrease in the IC_{50} of DOX-loaded PCL-*b*-PEEP was observed when compared with free DOX treatment, owing to the accumulation effect of DOX. More importantly, the enhanced intracellular release of DOX from shell-detachable PCL-*SS*-PEEP nanoparticles significantly improved its cytotoxicity. The IC_{50} decreased to ~12% of that of free DOX and ~32% of DOX-loaded PCL-*b*-PEEP nanoparticles after 72 h incubation, demonstrating the potential of shell-detachable nanoparticles for overcoming multidrug resistance.

CONCLUSION

We have demonstrated that the rapid increase of the free drug concentration in MDR cancer cells via the delivery of shell-detachable nanoparticles is a novel strategy for overcoming the MDR of cancer cells. Our example of a nanoparticle based on disulfide-bridged diblock copolymer PCL-*SS*-PEEP exhibited high cell affinity, allowing enhanced drug accumulation and retention in MDR cells and rapid intracellular release of the incorporated cargo in response to the intracellular reductive environment. It therefore significantly enhanced the cytotoxicity of DOX to MDR cancer cells, and is therefore promising for overcoming multidrug resistance in cancer therapy.

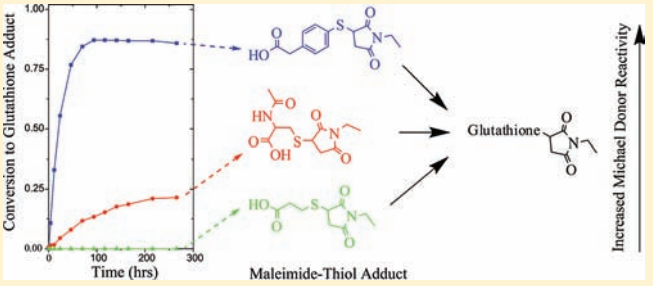
Supporting Information

ABSTRACT: Addition chemistries are widely used in preparing biological conjugates, and in particular, maleimide−thiol adducts have been widely employed. Here, we show that the resulting succinimide thioether formed by the Michael-type addition of thiols to *N*-ethylmaleimide (NEM), generally accepted as stable, undergoes retro and exchange reactions in the presence of other thiol compounds at physiological pH and temperature, offering a novel strategy for controlled release. Model studies (^{1}H NMR, HPLC) of NEM conjugated to 4-mercaptophenylacetic acid (MPA), *N*-acetylcysteine, or 3-mercaptopropionic acid (MP) incubated with glutathione showed half-lives of conversion from 20 to 80 h, with extents of conversion from 20% to 90% for MPA and *N*-acetylcysteine conjugates. After ring-opening, the resultant succinimide thioether did not show retro and exchange reactions. The kinetics of the retro reactions and extent of exchange can be modulated by the Michael donor's reactivity; therefore, the degradation of maleimide−thiol adducts could be tuned for controlled release of drugs or degradation of materials at time scales different than those currently possible via disulfide-mediated release. Such approaches may find a new niche for controlled release in reducing environments relevant in chemotherapy and subcellular trafficking.



INTRODUCTION

Controlled release of drugs has been a key area of research in the field of polymeric biomaterials, owing to the need to sustain release in order to expand the therapeutic window and efficacy of known drugs. Many chemical degradation approaches have been used to control materials-based drug delivery including chemical hydrolysis,[1] enzymatic degradation,[2] and disulfide exchange.[3] The rate of nonspecific chemical hydrolysis depends mainly on aqueous pH and temperature, as well as on the hydrophobicity of the environment around the hydrolytically labile group. Enzymatic degradation, in contrast, occurs specifically at enzyme-recognized peptide sequences, although rates of degradation are dependent on the local enzyme concentration, activity, and accessibility to the substrate. Disulfide exchange is sensitive to reducing environments and has found use in drug delivery systems due to the weak reducing capacity of blood (ca. 2−20 μM glutathione) compared with that of reductive cellular compartments or highly reductive and hypoxic tumor tissues (ca. 0.5−10 mM glutathione).[4−9] Disulfide bonds have relatively short half-lives (<1 h) in highly reductive environments, while maintaining a degree of stability in circulation.[5,8] Although control of the cleavage kinetics is possible with variations in reducing agent concentration, only limited control of kinetics has been achieved by varying the disulfide's neighboring chemical substituents (half-lives ranging from 8 to 45 min).[8]

In contrast to disulfide-based drug conjugation and polymer network formation strategies, thiol-based Michael-type addition reactions have emerged as a widely employed strategy for covalent conjugation of proteins, peptides, and drugs (to various polymers and other molecules) by the reaction of free cysteine or thiols with acrylamides, acrylates, vinyl sulfones, and maleimides.[10] Maleimides have been commonly employed due to their specificity to thiols, fast aqueous reaction kinetics, lack of byproducts, and the stability of the thioether addition product.[11] Maleimides have thus been utilized in homobifunctional cross-linkers,[12] heterobifunctional cross-linkers,[13] fluorescent labels,[14,15] as well as in PEGylation reagents[16] and cross-linking of hydrogels.[17]

While the wide use of maleimide−thiol conjugation reactions have been motivated by the product stability, there have been limited reports indicating that select succinimide thioethers can undergo retro reactions at high temperatures (>300 °C)[18] and in some aqueous environments,[19−23] although the mechanisms and exact solution conditions for these retro reactions were not elucidated in great detail. Such reports are very limited, however, despite the fact that the reversibility of adducts of thiols with α,β-unsaturated carbonyls such as ethacrynic acid and 4-hydroxyalkenals has been long reported.[24−27] We have thus recently explored the

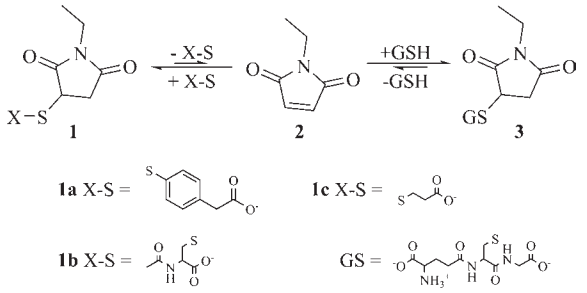
Scheme 1. Proposed Exchange of Synthesized Maleimide Thiol Adducts (1) with Glutathione in Aqueous Solutions



reversibility of maleimide−thiol conjugation reactions as a potential controlled degradation mechanism, which may have similar and complementary applications to the disulfide-mediated release of drugs in reducing environments. Scheme 1 illustrates the likely mechanism for the covalent bond transfer from the initial succinimide thioether compound (**1**) to a stable glutathione conjugate (**3**) in the presence of excess reductant. We have found that the rate and extent of this exchange, which is governed by the rate of the retro-addition, can be modulated by increasing or decreasing the Michael donor's reactivity.

EXPERIMENTAL PROCEDURES

Chemicals and General Methods. *N*-Ethylmaleimide (**2**), 4-mercaptophenylacetic acid (MPA), *N*-acetyl-L-cysteine (AcCys), 3-mercaptopropionic acid (MP), and glycine were purchased from Sigma-Aldrich (St. Louis, MO) and used without further purification. All other reagents including glutathione (GSH) and oxidized glutathione (GSSG) were purchased from Fisher Scientific (Pittsburgh, PA). Crude reactions were purified via reverse-phase chromatography on a Delta600 HPLC (Waters, Milford, MA) equipped with analytical (3.5 μm particle size, 4.6 × 75 mm) and preparative (5 μm particle size, 19 × 150 mm) Waters Symmetry300 C18 columns. Analytical linear gradients from 0% to 75% of solvent B were run over 20 min at 1 mL/min, where solvent A is 0.1% trifluoroacetic acid (TFA) in water and solvent B is 0.1% TFA in acetonitrile. Preparative-scale experiments utilized similar elution profiles determined from the analytical experiments, although with flow rates of 5 mL/min. Peaks were collected and analyzed via ESI-MS and ^{1}H NMR. ^{1}H NMR spectra were acquired under standard quantitative conditions at ambient temperature on a Bruker DRX-400 NMR spectrometer (Billerica, MA). The spectra of all purified compounds were recorded in either deuterated methanol or deuterium oxide.

Synthesis of Succinimide Thioether Compounds. Methanol-soluble mercapto-acids, MPA and MP (conjugates **1a** and **1c**), were dissolved at a concentration of 100 mg/mL in methanol and reacted with molar equivalents of **2**. A catalytic amount of triethylamine (0.01×) was added to the reaction mixture. The reaction was stirred for 30 min at room temperature. The crude product was diluted to 20 mL with solvent A and purified using RP-HPLC. Water-soluble thiol compounds AcCys and GSH (conjugates **1b** and **3**) were dissolved at a concentration of 50 mg/mL in deionized water. A molar equivalent of **2** was dissolved in MeOH (75 mg/mL) and added to the thiol solution. The unbuffered MeOH/aqueous solution had a final pH of ~4, retarding the maleimide−thiol addition reaction; therefore, the solution was stirred overnight at room temperature. The crude product was diluted to 5 mL with solvent A and purified using RP-HPLC. Purified fractions were collected and freeze−dried, with approximately 90% yield for all reactions. **1a** (Supporting Information Figure S1) ^{1}H NMR (MeOD): δ 0.96 (t, 3H), 2.63−2.69 (dd, 1H), 3.17−3.24 (dd, 1H), 3.39 (q, 2H), 3.61 (s, 2H), 4.13−4.17 (dd, 1H), 7.29 (d, 2H), 7.48 (d, 2H). ESI-MS: 338.1 $(M\text{-}1H+2Na)^+$, 338.0 calc'd ($C_{14}H_{14}NO_4SNa_2^+$). **1b** (Figure S2) ^{1}H NMR (MeOD): δ 1.16 (t, 3H), 2.03 (d, 3H), 2.42−2.55 (m, 1H), 2.93−2.99 (m, 0.5H), 3.15−3.28 (m, 2H), 3.52−3.58 (m, 2.5H), 3.96−4.00 (dd, 1H), 4.67−4.75 (m, 1H). ESI-MS: 289.1 $(M+H)^+$, 289.1 calc'd ($C_{11}H_{17}N_2O_5S^+$). **1c** (Figure S3) ^{1}H NMR (MeOD): δ 1.14 (t, 3H), 2.44−2.2.50 (dd, 1H), 2.69 (t, 2H), 2.91−2.99 (m, 1H), 3.09−3.23 (m, 2H), 3.53 (q, 2H), 3.91−3.94 (dd, 1H). ESI-MS: 276.0 $(M\text{-}1H+2Na)^+$, 276.0 9 calc'd ($C_9H_{12}NO_4SNa_2^+$). **3** (Figure S4) ^{1}H NMR (D_2O): δ 1.03 (t, 3H), 2.14 (m, 2H), 2.49 (m, 2H), 2.56−2.64 (m, 1H), 2.91−2.97 (dd, 0.5H), 3.06−3.28 (m, 2.5H), 3.45 (q, 2H), 3.89 (t, 1H), 3.93 (s, 2H), 3.94−4.00 (td, 1H), 4.60 (dt, 1H). ESI-MS: 455.2 $(M+Na)^+$, 455.1 calc'd ($C_{16}H_{24}N_4O_8SNa^+$).

NMR Analysis of MPA-NEM Retro Reactions. ^{1}H NMR spectroscopy with W5 water suppression[28] was used to monitor retro reactions of maleimide conjugates (Scheme 1). Samples of MPA were dissolved at a concentration of 3 mg/mL in 0.2 M phosphate buffer pH 7.4 with 10% D_2O. High buffer concentrations were needed (relative to those employed in the HPLC experiments below) in order to maintain a constant pH throughout the experiment, owing to the high concentration of MPA necessary for NMR investigation. After addition of compounds, the pH was adjusted to 7.4 if necessary. A molar equivalent of **2** was added to each NMR tube and the spectrum was recorded. Some samples were ring-opened by incubation at pH 8.0 @ 37 °C until ring-opening was complete (~5 days). Molar equivalents of GSH or glycine were added to ring-opened and non-ring-opened samples. Samples were incubated at 37 °C and spectra were recorded at time zero and at 24 hr.

HPLC Evaluation of Reaction Kinetics. Synthesized conjugates (**1**) were dissolved at a concentration of 0.1 mM in 50 mM phosphate buffers (pH 7.4) containing 10 mM GSH (and 5.0 mM, 0.5 mM, and 0.05 mM for GSSG). Lower buffer concentrations were employed to permit quantitative detection by HPLC, and these lower concentrations were sufficient to maintain a constant pH throughout the experiment. The kinetics of succinimide ring-opening were measured by monitoring reactions incubated without reductant. The pH values of all samples were verified and adjusted to 7.4 if needed before incubation at 37 °C. 150 μL samples were collected periodically and added to 150 μL of 0.5% formic acid solution to reduce the pH and quench the retro and ring-opening reactions. Samples were stored at −20 °C until analyzed. RP-HPLC injections were carried out under the above-defined conditions and areas of peaks were integrated to calculate conversion curves. The identities of the compounds present in each peak were determined using LC-MS or MS.

RESULTS AND DISCUSSION

NMR Analysis of MPA-NEM Retro Reactions. Our first experiments sought to validate that retro Michael-type additions were in fact a significant reaction route for select succinimide

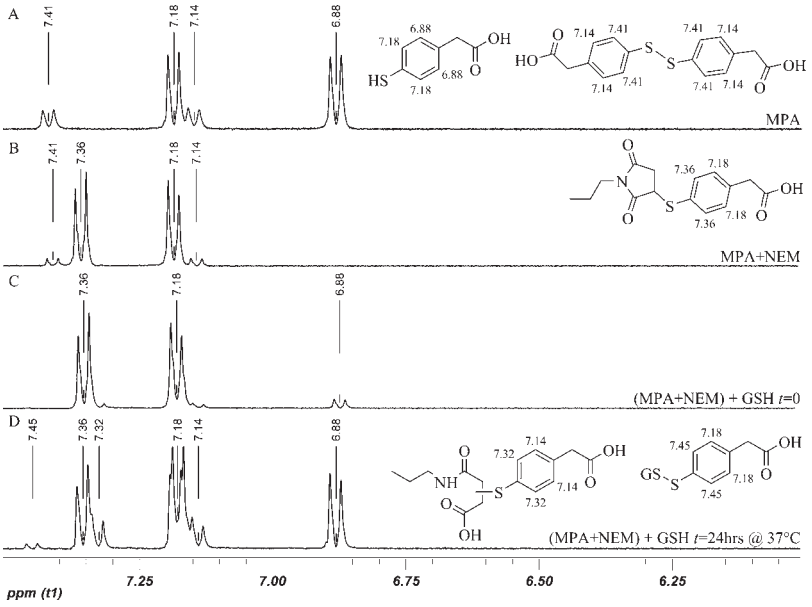


Figure 1. ^{1}H NMR of aromatic protons of (A) MPA, (B) after addition of NEM to MPA, (C) immediately after addition of GSH to (NEM+MPA) and (D) after incubation of (C) @ 37 °C for 24hrs. Evident in (D) are free MPA and small amounts of ring-opened **1a** (7.14, 7.32 ppm) and GS-MPA mixed disulfide (7.45, 7.18 ppm).

thioethers under reducing conditions. These experiments involved ^{1}H NMR analysis of the reaction of 4-mercaptophenylacetic acid (MPA) with *N*-ethylmaleimide (NEM, **2**) to yield (**1a**), with subsequent incubation with glutathione (GSH). The formation of the Michael-type adduct and its degradation via retro reactions were easily observed in the NMR experiment. Figure 1A shows the ^{1}H NMR spectrum for MPA in solution; this spectrum presents chemical shifts centered at 6.88 and 7.18 ppm, which result from the reduced MPA, as well as minor contributions from the oxidized form centered at 7.14 and 7.41 ppm. The chemical shifts of the thiophenyl aromatic protons are sensitive to the identity of the thiol substituents and thus provided a facile means to follow the addition and retro reactions (Figure 1B,C). A molar equivalent of **2** was added to the solution of MPA; upon addition of **2**, the aromatic protons shift downfield (to peaks centered at 7.18 and 7.36 ppm), indicating the production of the conjugate **1a** (Figure 1B). The resonances resulting from the small fraction of oxidized MPA (centered at 7.14 and 7.41 ppm) remained unchanged. A molar equivalent of GSH was added, resulting in immediate reduction of the unreacted MPA, indicated by a shift in the aromatic protons from 7.14 and 7.41 ppm (oxidized) to 6.88 and 7.18 ppm (Figure 1C). No other changes in the spectrum for conjugate **1a** were immediately apparent. After 24 h of incubation at 37 °C, however, MPA was liberated from **1a** as indicated by the increase in intensity of the MPA aromatic protons (centered at 6.88 and 7.18 ppm, Figure 1D). Under these conditions, a minor amount of ring-opening of the **1a** also occurred (resonances centered at 7.14 and 7.32 ppm), but the low intensity of these resonances indicates this occurs at a significantly slower rate than the retro reaction. Hydrolysis of the succinimide ring could occur on either carbonyl with respect to the thioether; however, the thiophenyl protons of either species were not distinct. Hydrolysis of the succinimide ring before incubation with GSH in these NMR experiments hindered the retro reaction as no exchange was observed over seven days incubation (data not shown). Furthermore, incubation of conjugate **1a** in the absence of reducing agents or in the presence of other nucleophiles such as glycine yielded only the ring-opened substituent (data not shown), clearly indicating that the equilibrium lies toward the Michael adduct and that formation of detectable quantities of free MPA only occurred when exogenous thiols were added to the reaction. Therefore, select succinimide thioethers should be sensitive to variations in reducing environments near physiological conditions.

HPLC Evaluation of Reactions Kinetics. We next sought to determine the selectivity of these retro and thiol-exchange reactions, as well as to obtain a quantitative measure of the time scales of these reactions, at biologically relevant concentrations of reductant. Such analysis required the quantification of small quantities of multiple compounds; HPLC and LC-MS were thus used to permit both quantification and identification. Various addition products were synthesized by reacting **2** with MPA (**1a**), *N*-acetylcysteine (**1b**), and 3-mercaptopropionic acid (**1c**). These thio-acids, which exhibit different thiol pK_a values (6.6,[29] 9.5,[30] 10.3,[31] respectively), were selected to determine how the rate of exchange may vary with the pK_a of the thio-acid. 0.1 mM of **1** was incubated in 10 mM GSH or 5.0 mM, 0.5 mM, and 0.05 mM GSSG (see below) in phosphate buffer at pH 7.4 and 37 °C; succinimide ring-opening hydrolysis rates were determined from solutions of **1** in buffer without addition of GSH. Rates of formation of the product **3** (Scheme 1), under these various conditions, were determined by monitoring changes of peak area in the HPLC experiment; the identity of the chemical species present in each fraction was confirmed by LC-MS (data not shown).

Figure 2 shows a typical set of traces obtained upon incubation of **1a** with excess GSSG, showing the location of all peaks and expanded regions highlighting relevant peaks. Arrows indicate the direction of peak growth or recession with increasing time. At time zero, a single peak was observed for compound **1a**. Over time, the peak for **1a** decreased in intensity, while peaks for compounds **3**, GS-MPA mixed disulfide, and $\mathbf{1a_{RO}}$ (ring-opened **1a**)

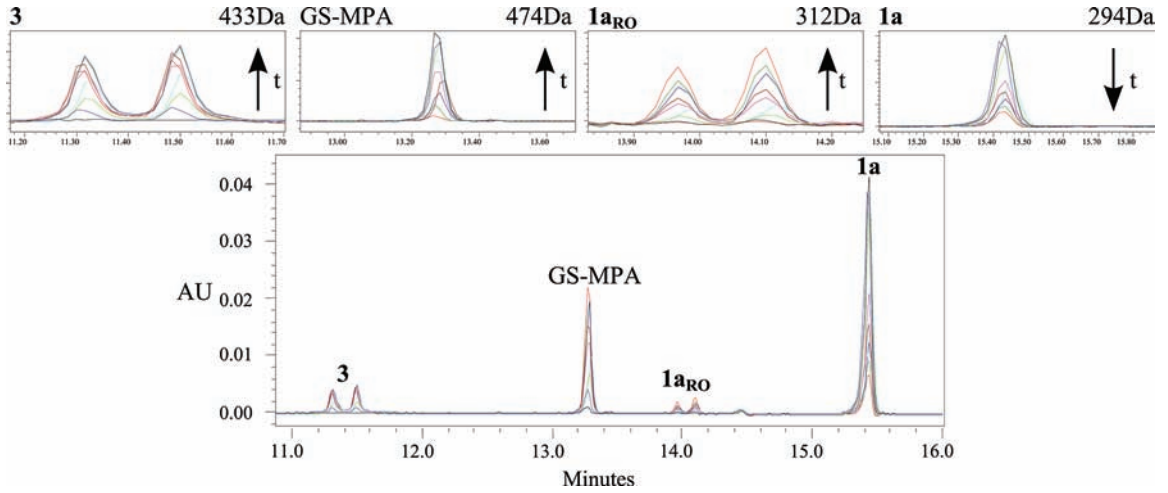

Figure 2. HPLC traces of degradation of **1a** in 50 mM phosphate buffer with 0.5 mM GSSG pH 7.4 @ 37 °C over a period of 6 days; masses obtained from LC-MS experiments are displayed for $(M+H)^+$. The peak area for **1a** decreases with time as peak areas for **3**, GS-MPA (mixed disulfide), and $\mathbf{1a_{RO}}$ increase with time, indicating the occurrence of the retro Michael-type reaction. Arrows indicate the direction of peak area growth or decline with time. Peak 3 consists of two equal peaks representing two diastereomers, while the two peaks of $\mathbf{1a_{RO}}$ evolve from ring-opening on either side of the succinimide with respect to the thioether.

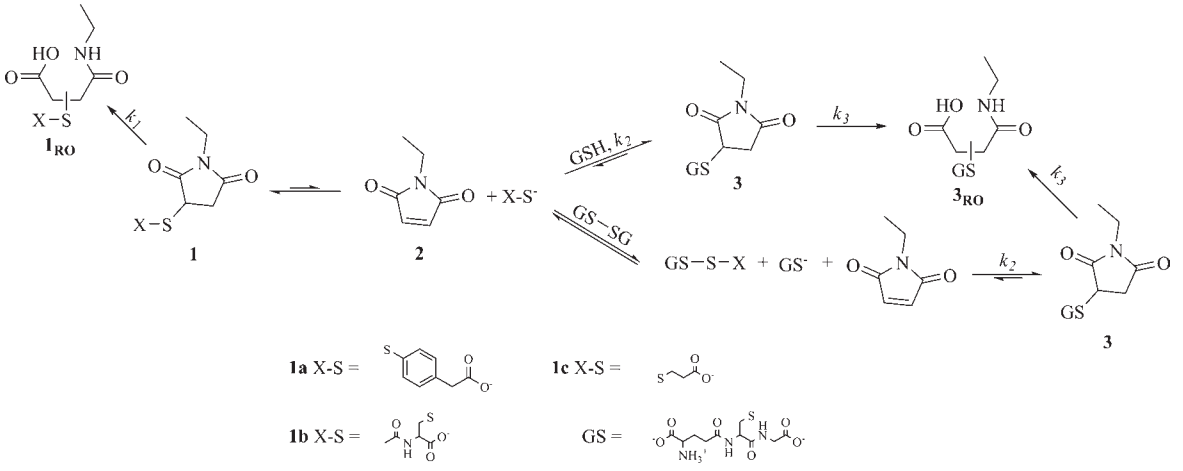
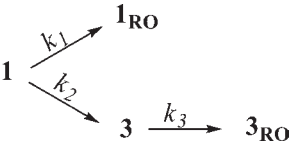
Scheme 2. Complete Reaction Cycle of 1 in Solution with Oxidized or Reduced Thiols



all increased in intensity. The loss of **1** occurred concomitantly with the generation of **3**. Peaks for **3** and **1aRO** are split into two equal peaks. Peak **3** is split as a result of the two diastereomers formed from the Michael addition of GSH to **2**[32] (verified by the equivalence of masses determined from LC-MS of the two different peaks), while **1aRO** is split depending on the side of succinimide ring-opening in relation to the thioether (also verified by the equivalence of masses determined from LC-MS of the two different peaks). Scheme 2 illustrates the likely reaction cycle for an initial conjugate **1** in the presence of excess thiols, showing ring-opening of conjugates, as well as the exchange with GSH or GSSG. Either GSH or GSSG causes exchange, with 5.0 mM GSSG yielding identical results as 10 mM GSH (Supporting Information, Figure S5). This observation suggests that the formation of **2** is the rate-limiting step in the overall reaction to **3** and is significantly slower than the disulfide exchange of the free thio-acid with excess GSSG; therefore, the oxidation state of GSH does not significantly impact the rate of formation of **3**.

Scheme 3. Simplified Reaction Cycle and Kinetics Constants for the Reaction of 1



Throughout these experiments, no measurable amount of **2** was detected, confirming the widely known fact that the equilibrium greatly favors the succinimide thioether under the experimental conditions. Thus, by neglecting the kinetics of formation of **2** (and the thiol-exchange of GSSG to yield GSH as our above experiments validate), Scheme 2 can be simplified to the combination of a consecutive and parallel reactions (Scheme 3). Thus, pseudo first-order rate constants, k_1 and k_3, can be defined for the ring-opening of **1** and **3**, and k_2 can be defined as the pseudo first-order rate

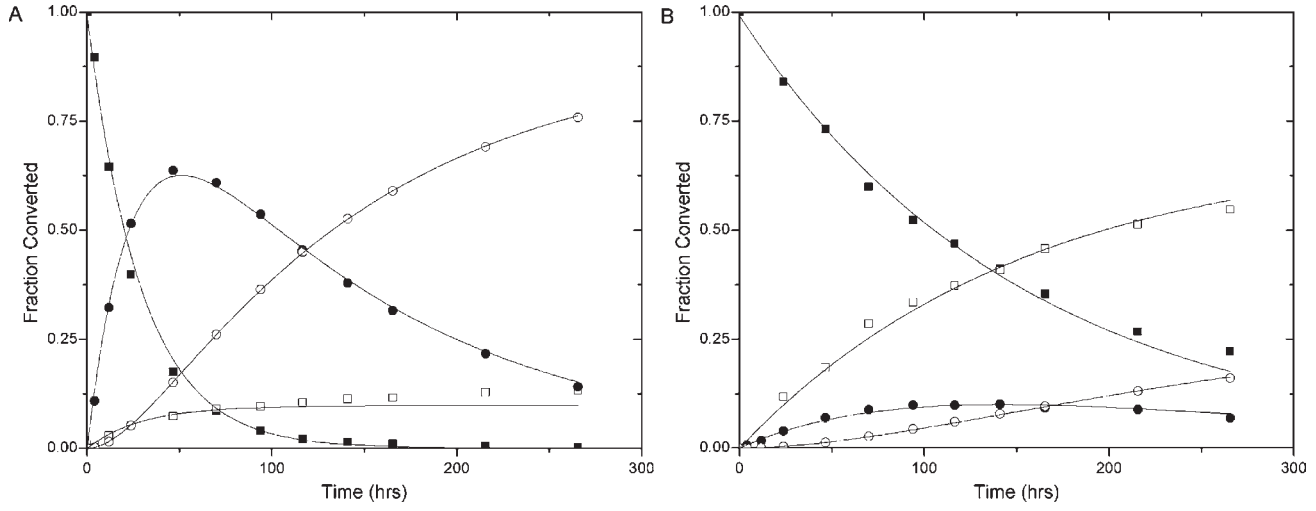


Figure 3. Relative HPLC measured concentrations for **1a** (panel A) and **1b** (panel B) over time, with constructed curves using derived rate constants and eqs 5−8 for (■) **1** (a or b), (□) $\mathbf{1}_{RO}$, (●) **3**, and (○) $\mathbf{3}_{RO}$.

constant for the retro and exchange reaction of **1** (to yield **3**) in the presence of a large excess of a thiol compound (10 mM GSH or 5 mM GSSG). Using the simplified Scheme 3, reaction rate equations (eqs 1−4)

$$\frac{d[\mathbf{1}]}{dt} = -k_1[\mathbf{1}] - k_2[\mathbf{1}] \quad (1)$$

$$\frac{d[\mathbf{1}_{RO}]}{dt} = k_1[\mathbf{1}] \quad (2)$$

$$\frac{d[\mathbf{3}]}{dt} = k_2[\mathbf{1}] - k_3[\mathbf{3}] \quad (3)$$

$$\frac{d[\mathbf{3}_{RO}]}{dt} = k_3[\mathbf{3}] \quad (4)$$

can be defined and converted to integrated rate laws (eqs 5−8)

$$[\mathbf{1}] = [\mathbf{1}]_0 e^{-(k_1 + k_2)t} \quad (5)$$

$$[\mathbf{1}_{RO}] = \frac{k_1[\mathbf{1}]_0}{k_1 + k_2}\left(1 - e^{-(k_1 + k_2)t}\right) \quad (6)$$

$$[\mathbf{3}] = \frac{k_2[\mathbf{1}]_0}{k_3 - k_2 - k_1}\left(e^{-(k_1 + k_2)t} - e^{-k_3 t}\right) \quad (7)$$

$$[\mathbf{3}_{RO}] = \frac{k_3 k_2[\mathbf{1}]_0}{k_3 - k_2 - k_1}\left(\frac{e^{-(k_1 + k_2)t} - 1}{-k_1 - k_2} + \frac{e^{-k_3 t} - 1}{k_3}\right) \quad (8)$$

Fractional concentrations of **1**, $\mathbf{1}_{RO}$, **3**, and $\mathbf{3}_{RO}$ measured by HPLC (relative to the initial concentration) were plotted as a function of time for **1a** (Figure 3A) and **1b** (Figure 3B). Equation 7 was employed to fit to the data for **3** (converted from **1a** and **1b** ($R^2 > 0.98$)), yielding k_1, k_2, and k_3 with values shown in Table 1, with their corresponding half-lives. Standard deviations for all values were calculated from the standard error from the fit.

Curves to plot the fractional concentrations of the other compounds as a function of time were constructed, as shown in Figure 3, by input of the appropriate rate constants into eqs 5−8. As clearly illustrated in the figure, the fits show exceptional agreement with collected data for all compounds. **1c** did not exhibit measurable retro and exchange reactions under these experimental conditions; therefore, only k_3 was determined. The fractional concentrations of **1** and $\mathbf{1}_{RO}$ as a function of time decreased and increased, respectively, as exponential decay functions with respect to k_1 and k_2, as shown in Figure 3. The dependence of the fractional concentrations of **3** and $\mathbf{3}_{RO}$ as a function of time were more complex, owing to the consecutive reaction mechanism, as shown by an initial increase and subsequent decrease in the fractional concentration of **3**; the fractional concentration of $\mathbf{3}_{RO}$ increased over time with a delayed onset. The extent of formation of $\mathbf{1}_{RO}$ and $\mathbf{3}_{RO}$ was directly related to the relative reaction rates of k_1 and k_2. In the reactions of **1a**, $k_2 > k_1$; therefore, the major product at equilibrium is $\mathbf{3}_{RO}$. Conversely, for **1b** $k_1 > k_2$; therefore, $\mathbf{1}_{RO}$ is the major product. Retro and exchange rates for **1a** were an order of magnitude greater than those for **1b**, with rate constants of 0.0371 ± 0.0038 versus 0.00207 ± 0.0002 h^{-1} and respective half-lives of 19 ± 2 versus 337 ± 27 h, while half-lives for ring-opening reactions of compounds **1** were the same order of magnitude (ca. 10^2) for all compounds. In comparison, half-lives for the glutathione-mediated cleavage of disulfide bonds under similar conditions range from 8 to 45 min (with pseudo first-order rate constants of 5 to 0.9 h^{-1}),[8] indicating that the use of maleimide−thiol adducts rather than disulfides may have advantages for producing more stable, yet degradable

Table 1. Pseudo-First-Order Rate Constants and Respective Half-Lives for Retro and Ring-Opening Reactions[a]

	retro reaction		ring-opening	
conjugate	k_2 (h^{-1})	half-life (h)	k_1 or k_3 (h^{-1})	half-life (h)
1a	0.0371 ± 0.0038	19 ± 2	0.0033 ± 0.0002 (k_1)	211 ± 15
1b	0.00207 ± 0.0002	337 ± 27	0.0044 ± 0.0003 (k_1)	157 ± 12
1c	n/a	n/a	0.0032 ± 0.0002 (k_1)	215 ± 11
3	--	--	0.0076 ± 0.0007 (k_3)	92 ± 2

[a] Standard deviations for all values were calculated from the standard error from fit.

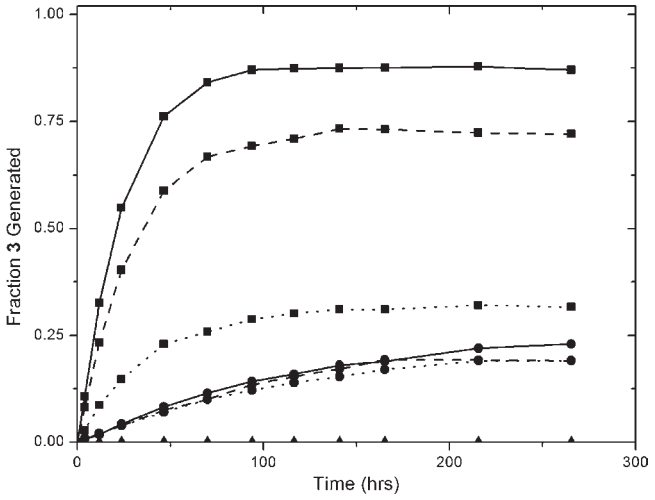

Figure 4. Fraction of **3** generated from (■) **1a**, (●) **1b**, and (▲) **1c** (at the baseline) in the presence of (—) 10 mM, (--) 1.0 mM, and (· ·) 0.1 mM GSH.

bioconjugates. Indeed, *in vivo* blood circulation stability has been shown to be as little as 4 h for disulfide-based immunotoxin-antibody conjugates, with circulation stability directly dependent on the kinetics of reduction by glutathione.[7,33,34] Accordingly, the decreased rate of exchange of the maleimide—thiol adduct with glutathione would increase compound circulation stability while maintaining cleavage sensitivity in highly reducing environments.

The release data from HPLC experiments illustrate the extent of turnover of the initial succinimide thioether under various reducing conditions, which is relevant to the use of these strategies for the liberation of drug conjugates or materials degradation. Thus, using these treatments, variations in the overall generation of **3** as a function of time (for different compounds and reductant concentrations) are presented in Figure 4 (calculations from obtained data are shown in the Supporting Information, Figures S6—S8). **1a** supported the greatest rate of conversion of the initial adduct, with conversion of nearly 85% after 70 h, followed by **1b** with much slower kinetics and substantially lower conversion, and then by **1c**, for which no measurable conversion was observed. The rate of exchange of the initial adduct is clearly impacted by the thiol pK_a, with higher pK_a decreasing the rate (Figure 4); the use of a Michael donor with sufficiently high pK_a (~10.3) can eliminate any impact of the retro reaction, as illustrated by the lack of conversion of **1c**.

Two other observations recommending the use of these strategies for tailoring the degradation of succinimide thioethers are indicated from these data. Importantly, the data in Figure 4 illustrate that the rate of thiol exchange varies with the concentration of reductant. **1a** showed the greatest dependence on reductant concentration with the total production of **3** ranging from 30% to 90% under these conditions. In contrast, conversion of **1b** showed little dependence, and that of **1c** showed no dependence, on reductant concentration; Michael donors can thus be selected for application on the basis of desired sensitivity to reductant. Additionally, the conversion to **3** can be impacted by the inactivation of **1** by ring-opening of certain adducts. The minimum half-lives for the retro reaction were approximately 19 h for **1a** and 337 h for **1b**, while those for inactivation of **1** by ring-opening were approximately 200 h. Thus, the inactivation by ring-opening became significant and limited the overall conversion to **3** for conjugates **1b** and **1c** (evidenced by the reduction in turnover of these compounds at later time points), which could be used to tailor initial release and long-term stability for specific conjugates.

The manipulation of the Michael-type addition has very limited precedent in literature, and there are no previous reports to our knowledge that seek to selectively utilize the retro reaction for a specific use. In studies by Lewis et al., in which a bis-maleimide was used to conjugate a chelating agent to a monoclonal antibody, it was determined that the resulting adduct was cleaved to some extent when exposed to fresh human serum.[19] Later, Alley et al. described mass spectrometry experiments that illustrated that an antibody—drug conjugate linked by maleimide—thiol chemistries had exchanged with rat serum albumin in vivo to yield albumin—drug adduct.[20] Concurrently, Lin et al. described studies indicating that maleimide—cysteine adducts disappeared in cells while similar iodoacetate adducts were stable.[21] The commonality in these reports stems from the use of the resulting succinimide thioether in environments containing reduced or oxidized thiol species, and although the mechanism underlying these previous observations was not discussed or determined, the reaction mechanism could proceed as suggested in Scheme 1, as supported by our experiments. More recently, Baker and co-workers have described the bromination of maleimides for reversible conjugation of thiols as a bioconjugate technique.[35—37] The process of bromination and subsequent elimination of HBr by the addition of a protected cysteine was found to be more rapid than the addition to maleimides. This bromomaleimide conjugate was found to be reversible by adding reducing agents such as GSH[36] or TCEP[37] with complete conversion within 4 h for incubation with excess GSH. In contrast, 70 h was required for 85% conversion of **2a**, indicating that the reduced reactivity of maleimides compared with bromomaleimides correlates with the rate of the retro reaction.

■ CONCLUSIONS

We have confirmed that succinimide thioethers undergo reversible addition in solutions and that exchange with nearby free thiols or disulfides can be manipulated under relevant physiological conditions. Reverse reactions of these kinds have not been reported for other Michael-type addition products such as thiol—acrylate conjugates, most likely due to the reduced Michael acceptor reactivity of acrylates compared to maleimides.[11] Glycine, substituted for GSH in control experiments, did not induce the reverse reaction under these conditions, although it has been shown that maleimides can be Michael acceptors for amine donors;[38,39] these observations suggest that the retro reaction may not be substantially affected by amine-bearing compounds present in vivo. Our data also indicate that ring-opening of the succinimide before the addition of GSH stabilizes the conjugate and will inhibit the liberation of free thio-acid and conversion to **3**. Hence, purposely ring-opening a succinimide thioether will stabilize bioconjugates for in vivo or in vitro assays if retro reactions are not desired, and ring-opening that would occur in vivo could be employed to dictate a lifetime over which a conjugated drug may be cleaved by GSH.

Importantly, thiophenyl conjugates were also sensitive to the reducing environment, with only approximately 30% converted at low reductant concentration within three days, versus 90% at high reductant concentration, potentially allowing for targeted

release/delivery. The slower 2w?>relative to disulfide-mediated release (e.g., half-lives >20 h for succinimide thioethers compared to minutes for disulfide-mediated release) may also allow for longer-term delivery of drugs in reducing environments. We note that the exchange and retro reactions kinetics discussed here were modulated by altering the thiol serving as the Michael donor; in many bioconjugates such alteration of the thiol reactivity would not be possible, particularly given that alkylthiols (i.e., cysteine) of natural proteins and peptides are common Michael donors in bioconjugation reactions. In cases in which Michael donor reactivity on proteins/peptides would be desirable, post-translational modification of natural proteins or peptides or non-natural amino acid incorporation could be employed for the addition of suitable thiols.[40] Other possibilities not investigated here rely on modulating the maleimide stability and reactivity as has been accomplished by addition of cyclohexyl or benzyl moieties to the nitrogen group to reduce the susceptibility of the maleimide ring to hydrolysis prior to addition reactions.[41] Albeit there are many different possibilities for tailoring retro reactions for use as delivery mechanisms, our observations expressed here could be exploited for both systemic and local administration of bioconjugated drugs or for imparting degradation sites in polymeric backbones or cross-linked biomaterials. Studies to test these potential opportunities are underway.

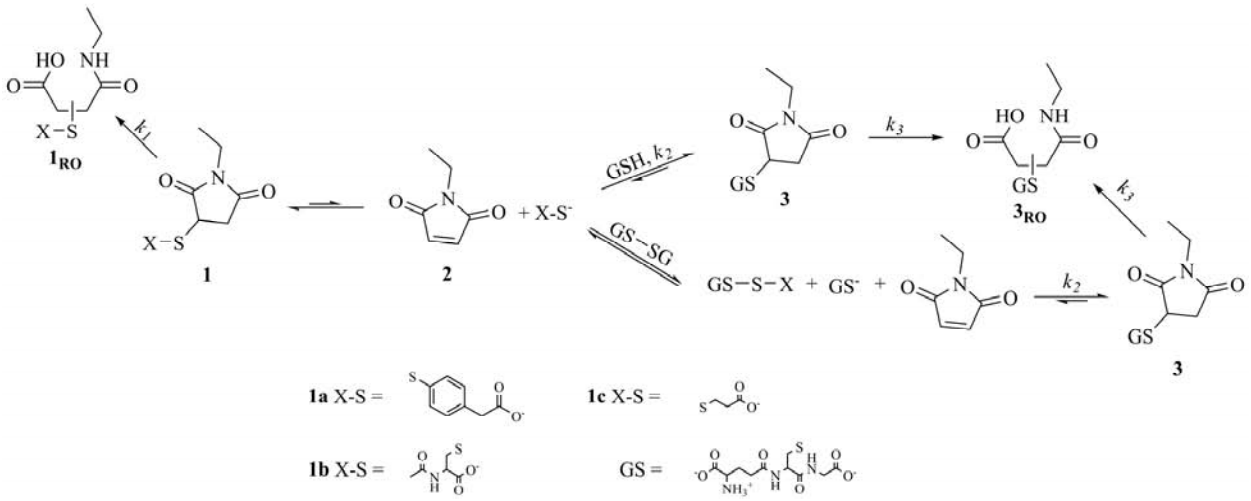
Analysis of formation of 3, monitored by HPLC



Scheme S1. Proposed exchange of the maleimide thiol adducts (**1**) with reduced (GSH) and oxidized glutathione (GSSG) and their ring opened byproducts ($\mathbf{1_{RO}}$ and $\mathbf{3_{RO}}$).

As discussed in the body of the manuscript it was found that the formation of **3** (Scheme S1) was independent of the oxidation state of glutathione, therefore a common kinetic parameter $\boldsymbol{k_2}$ was derived. Figure S5 displays the kinetic fit curves for solutions **1a** incubated with 10mM GSH and 5mm GSSG. The data points for each reading of 1a either in GSH or GSSG are similar, furthermore, fitting kinetic curves as described in the body of the manuscript to each trace yield a statistically indifferent $\boldsymbol{k_2}$.

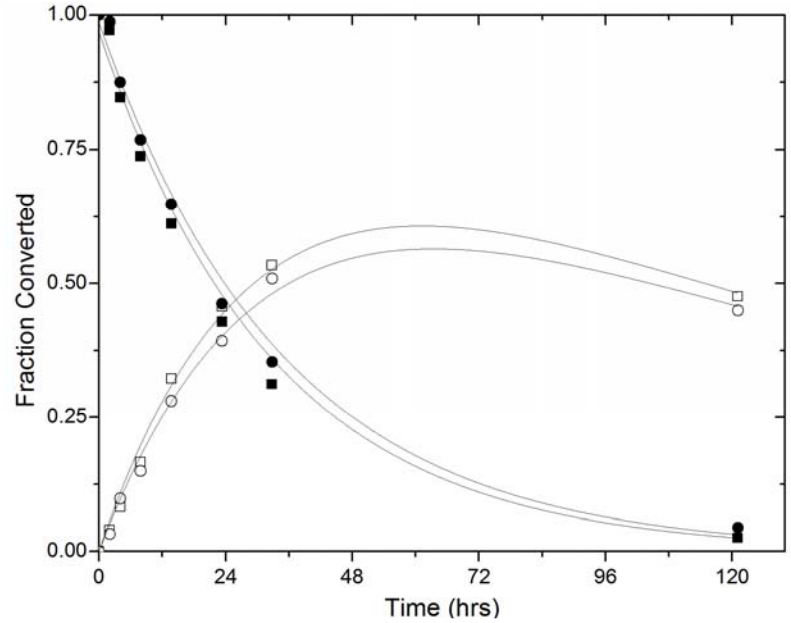


Figure S5. Relative HPLC measured concentrations for **1a** (solid) and **3** (open) in the presence of 10mM GSH (squares) and 5mM GSSG (circles) over time, with constructed curves using derived

rate constants and equations 5-8. Kinetic parameters statistically indifferent (2 sample t-test, p = 0.58, indicating no statistical evidence of a difference).

We demonstrated in the body of the manuscript our ability to predict the formation of all compounds in the reaction scheme. We present here the analysis of the total theoretical amount of **3** produced, obtained from data indicating the concentrations of relevant compounds in a select set of experiments (from **1a**). The value of this additional analysis is that it is based on confirmed measurements of the amounts of compounds of this specific set of reactions; such an analysis was not possible for all compounds studied. The procedure is as follows:

The amount of **1** converted to **3** was captured by the appearance of chromatic peak for **3** (Figure 2); monitoring the kinetics of this formation, however, was complicated by the fact that **3** ring-opens to form $\mathbf{3_{RO}}$, and that $\mathbf{3_{RO}}$ does not bind to the column and thus cannot be quantified. Therefore, a maximum, level plateau for the formation of **3** was not observed, and the data for monitoring the formation of **3** instead looked as presented in Figure S6. The loss of **3** (i.e., the amount of $\mathbf{3_{RO}}$ formed over a given time period) was estimated based on the ring opening kinetics observed when a solution of 0.1mM of **3** was incubated in buffer lacking any reductant (Figure S7). The pseudo first order rate constant, $\boldsymbol{k_3}$, for the ring-opening of **3** was determined to be 0.0076±0.0007 hr^{-1}. Computationally, the total concentration of $\mathbf{3_{RO}}$ ($[\mathbf{3_{RO}}]$) present at given time points throughout the experiment could be calculated by integrating the rate of ring-opening for **3** over time:

$$[\mathbf{3_{RO}}]\Big|_{t_1}^{t_2} = \int_{t_1}^{t_2} \boldsymbol{r} \cdot \boldsymbol{dt}$$

Where $\boldsymbol{r}$ is first order rate law equation:

$$\boldsymbol{r} = \frac{-\boldsymbol{d}[\mathbf{3}]}{\boldsymbol{dt}} = \boldsymbol{k}_3[\mathbf{3}]$$

The concentration of **3** ($[\mathbf{3}]$) over a short range of time can also be estimated by a line fit between two data points (e.g., between any given $\boldsymbol{t_1}$ and $\boldsymbol{t_2}$ data points in Figure S6) where the y-values are the integrated peak area of **3** determined from HPLC evaluation of the retro reaction, $\boldsymbol{m}$ is the slope and $\boldsymbol{b}$ is the y-intercept:

$$[\mathbf{3}] = \boldsymbol{mt} + \boldsymbol{b}$$

Overall, yielding a final equation for the amount of $\mathbf{3_{RO}}$ as:

$$[\mathbf{3_{RO}}]\Big|_{t_1}^{t_2} = \boldsymbol{k}_3 \cdot \int_{t_1}^{t_2} (\boldsymbol{mt} + \boldsymbol{b})\boldsymbol{dt}$$

Accordingly, the amount of $\mathbf{3_{RO}}$ was presented in the main manuscript as Figure 3A and 3B for compounds **1a** and **1b**. Furthermore, the summation of calculated $[\mathbf{3_{RO}}]$ values with the measured amount of **3** present at $\boldsymbol{t_n}$ yields the constructed conversion curve of **3** (total compound **1** converted **3**) presented in Figure 4 in the main manuscript.

The accuracy of estimating the total amount of converted **3** (via measurement of **3** and calculation of $\mathbf{3_{RO}}$) present as a function of time in the absence of ring opening was verified in a second set of experiments. In these experiments the amount of **3** formed from **1a** was determined on the basis of the known concentration **1a** (which is stoichiometrically equivalent to **3** in the absence of any ring opening, Scheme 1), and on the basis of conversion of **1a** to the ring-opened substituent $\mathbf{1a_{RO}}$ (which would reduce the concentration of **1a** in the reaction without conversion to **3**). Compound $\mathbf{1a_{RO}}$ bound to the HPLC column and could be quantified. Thus, the amount of **1a** and $\mathbf{1a_{RO}}$ were measured, and the amount of **3** anticipated was estimated on the basis of these measurements. This amount of **3** (determined based on these emipirical measurements) was compared to the amount of **3** estimated via the theoretical treatments above.

Because conversion of compound **1a** occurs both due to the formation **3**, and due to the ring-opening of **1a** to form $\mathbf{1a_{RO}}$, the total amount of compound **1a** converted to **3** at any point in time, t, would be:

$$[\mathbf{3}] = [\mathbf{1a}]_0 - [\mathbf{1a}]_t - [\mathbf{1a_{RO}}]_t$$

Where $[\mathbf{1a}]_0$ is the initial concentration of **1a** employed in the experiment, and $[\mathbf{1a}]_t$ and $[\mathbf{1a_{RO}}]_t$ are the measured concentrations of **1a** and $\mathbf{1a_{RO}}$ determined in the HPLC measurements at time t. Molar concentrations for **1a** and $\mathbf{1a_{RO}}$ were calculated from HPLC peak areas based on the extinction coefficients for **1a** and $\mathbf{1a_{RO}}$, which were experimentally determined from solutions of known concentration.

The measured (on the basis of the measured conversion of **1a**) and estimated (on the basis of the theoretical description above) values for the amount of **3** present as a function of time were in nearly perfect agreement (Figure S8), therefore it was assumed the above method for estimating the concentrations of conjugate **3** could be used for experiments for compounds **1b** and **1c** (whose ring-opened compounds were not possible to measure in the HPLC experiment).

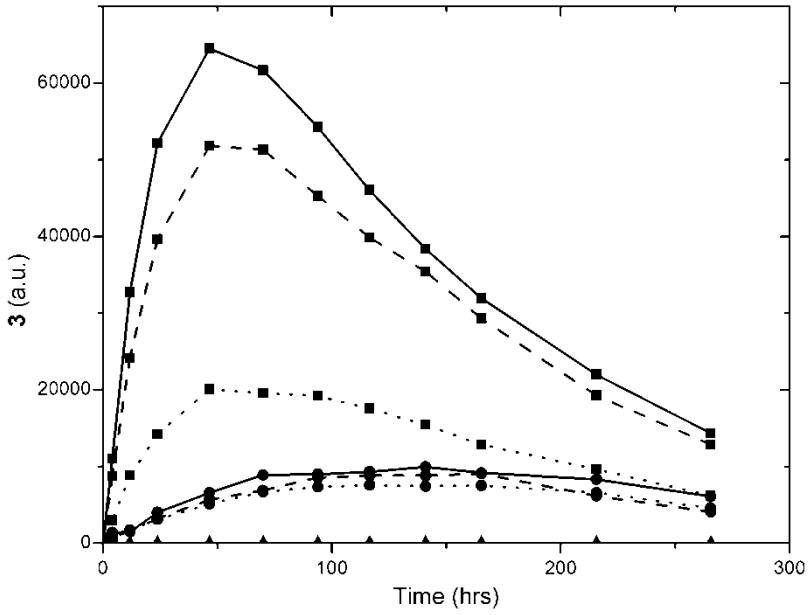

Figure S6. GS-NEM (3) formed from (■) **1a** (●) **1b** (▲) **1c** in the presence of (–) 5mM (--) 0.5mM (··) 0.05mM GSSG.

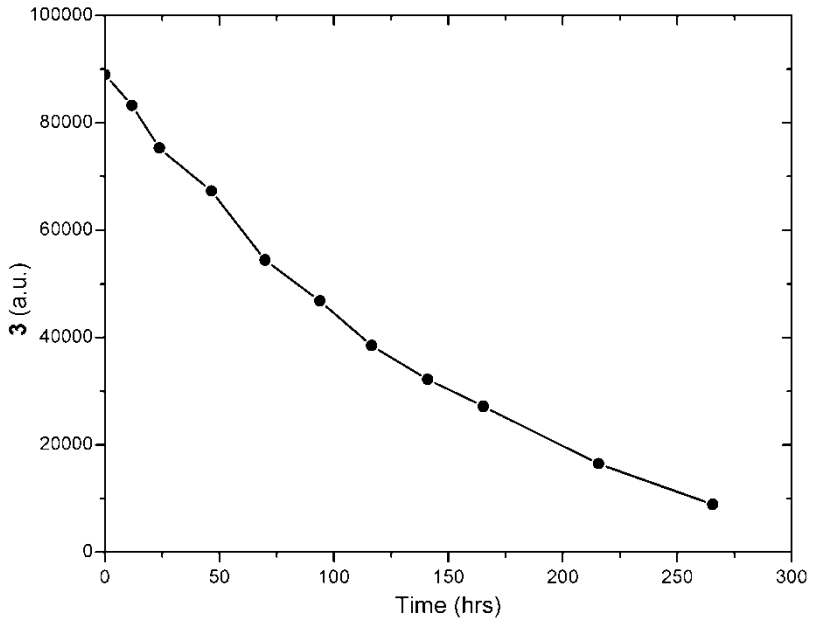

Figure S7. The concentration of **3** plotted as a function of time in the absence of added reductant. The reduction in the concentration of **3** over time is a result of ring opening, and thus this decrease indicates the rate of the ring opening.

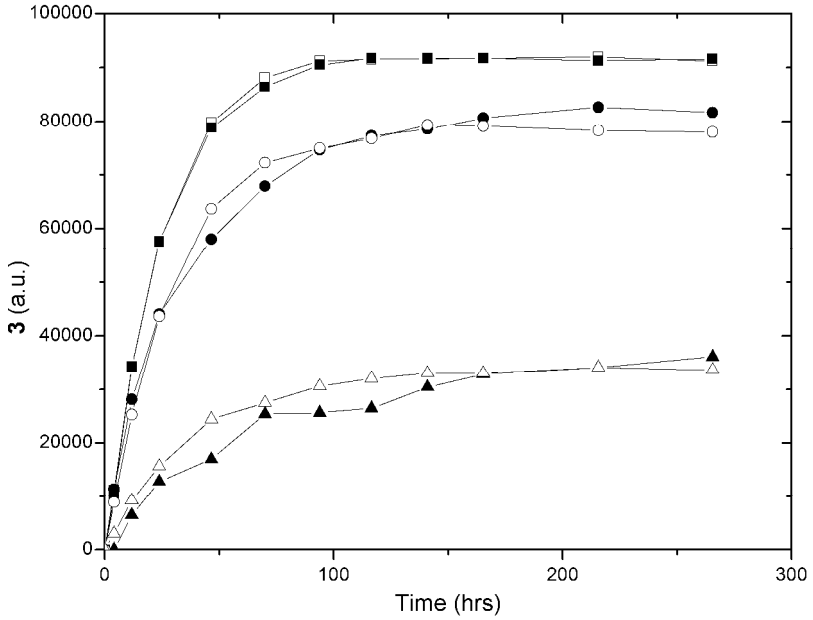

Figure S8. Comparison of measured (solid marks) and calculated (open marks) concentrations of **3** obtained from the retro addition and thiol exchange of **1a** (■) 5.0mM GSSG (●) 0.5mM GSSG (▲) 0.05mM GSSG. Trend lines are shown to aid in visualization.

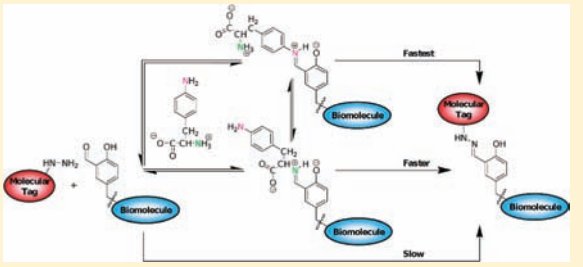
4-Aminophenylalanine as a Biocompatible Nucleophilic Catalyst for Hydrazone Ligations at Low Temperature and Neutral pH

Adam R. Blanden, Kamalika Mukherjee, Ozlem Dilek, Maura Loew, and Susan L. Bane*

Department of Chemistry, Binghamton University, P.O. Box 6000, Binghamton, New York 13902, United States

Supporting Information

ABSTRACT: Hydrazone formation and similar reactions are highly versatile and specific, but their application to biological systems has been limited by their characteristically slow reaction kinetics at neutral pH. Catalysis of these reactions through imine formation with aromatic amines such as aniline has broadened the applicability of these reactions to biomolecular labeling. High concentrations of the catalyst are necessary, which may be incompatible with the native structure of certain proteins. In this study, we investigated the utility of 4-aminophenylalanine (4a-Phe) as a catalyst for these reactions. We find that 4a-Phe is nearly as effective as aniline in catalyzing hydrazone formation between the reactive amino acid 3-formyltyrosine (3f-Tyr) and hydrazine-containing fluorophores, both free in solution and incorporated into the protein tubulin. The catalyst 4a-Phe maintains ~70% of the catalytic efficacy of aniline and is less detrimental to the native structure of tubulin. Examination of the temperature dependence of imine formation between 3f-Tyr and 4a-Phe shows an increase in imine concentration accompanying a decrease in temperature, confirming the exothermic nature of the equilibrium reaction. Interestingly, decreasing the temperature of the 4a-Phe-catalyzed hydrazone reaction between 3f-Tyr and the fluorophore 7-hydrazinyl-4-methylcoumarin *increases* the overall rate of the reaction. This result indicates that the temperature dependence of the catalyst−aldehyde equilibrium is greater than the temperature dependence of the rate constant for hydrazone formation from this intermediate, and that the rate of hydrazone formation a direct function of the concentration of the intermediate imine. These results provide a platform for conducting nucleophilic catalysis under conditions that are more compatible with biomolecular targets than previously demonstrated, thereby expanding the utility of hydrazone ligations in biological systems.



INTRODUCTION

Site-specific chemical modification of biomolecules relies on reactions of functional groups with reactivities that are orthogonal to endogenous moieties.[1] Ideally, such reactions occur rapidly under conditions that retain the native structure of the target; however, in practice most labeling systems fail to meet all criteria. Condensation reactions of aldehydes and ketones with nucleophiles such as hydrazines, hydrazides and hydroxylamines possess many attractive properties for ligations in biological systems.[2−4] They occur readily in aqueous solutions without major side reactions, and form covalent bonds with varying degrees of reversibility, tunable by the nature of the reactants. The usefulness of this class of reactions has been limited by its characteristic pH-sensitive kinetics—the rate of the condensation reaction is typically greatest near the pK_a of the nucleophile,[5] dropping off sharply at higher and lower pH.[6] Because of this kinetic profile, biomolecules that require neutral pH to maintain structural and functional integrity are not amenable to direct ligation reactions with the less basic members of this group.

Our laboratory has developed a hydrazine-tag aldehyde target-based labeling system that employs reaction of a protein containing 3-formyl-L-tyrosine (3f-Tyr), a synthetic tyrosine derivative, with a hydrazine-containing probe.[7] In this manifestation, the unnatural amino acid is appended to α-tubulin by a highly specific enzymatic reaction. Use of an aromatic hydrazine rather than a commercially available hydrazide as the nucleophile partially alleviated the problem of slow reaction at neutral pH owing to the greater basicity of the aromatic hydrazine. The aromatic hydrazine, a coumarin derivative synthesized in our lab, has an additional desirable feature, which is a red shift in its absorption and emission spectra accompanied by an increase in quantum yield upon hydrazone formation.

A wider variety of probes would increase the number of applications available for the labeled protein. However, our selection of probes has been limited precisely because our protein of interest, α,β-tubulin, is highly temperature and pH sensitive.[8−11] The commercial hydrazide-containing probes react too slowly at neutral pH and the protein is not stable at lower pH. Nucleophilic catalysis of these reactions using amines such as aniline and aniline derivatives (e.g., *p*-anisidine), which form a reactive imine intermediate with the target carbonyl, provides a potential solution to this problem. Aniline has been shown to be effective in aqueous buffered systems as well as with biomolecules and biomolecular conjugates.[3,12−15] However, it was not known at

ACS Publications © 2011 American Chemical Society

the outset of this investigation whether aniline catalysis would be amenable for use with fragile biomolecular targets such as tubulin. Millimolar concentrations of aniline are necessary to produce an appreciable amount of imine intermediate, as the equilibrium constant for imine formation is quite small (<10 M^{-1} for bisaryl imines).[16]

In this study, we explore the use of 4-aminophenylalanine (4a-Phe), a commercially available aromatic amine derivative of phenylalanine (Phe), as a catalyst for hydrazone ligations in aqueous buffer at neutral pH. We reasoned that the more hydrophilic zwitterionic molecule would be less likely to denature a protein but would retain the catalytic efficacy of aniline. Native but not denatured tubulin will assemble into microtubules, so the effect of the catalyst is assessed as the ability of the protein to form microtubules in the presence of the additive. The catalytic efficacies of aniline and 4a-Phe are compared with the protein and using a model system containing 3f-Tyr and 7-hydrazinyl-4-methylcoumarin (coumarin hydrazine, CH).

We also explore the effect of temperature on the catalytic reaction. Since bisaryl imine formation is exothermic,[17] the concentration of imine in solution can be increased by decreasing temperature. It was hoped that the increase in imine concentration would have a greater effect on the overall rate than the expected decrease in the rate of imine formation at the lower temperature. Finally, the ability of 4a-Phe to catalyze hydrazone formation with different fluorescent dyes is measured with both the model compound 3f-Tyr and 3f-Tyr-labeled tubulin. We find that 4a-Phe effectively catalyzes hydrazone formation between the unnatural amino acid and a variety of hydrazine-containing substrates, and that the labeling reaction is in fact enhanced at low temperature.

EXPERIMENTAL PROCEDURES

Reagents. Texas red hydrazide (TxRed, 90% single isomer) and 7-diethylaminocoumarin-3-carboxylic acid, hydrazide (DCCH) were purchased from Molecular Probes (Eugene, OR). CH and 3f-Tyr were synthesized as described previously.[7] The probe naphthalene-2-ylhydrazine (naphthalene hydrazine, NH) was synthesized as detailed in Supporting Information. Stock solutions of TxRed, DCCH, and NH were made in DMSO and stored at −20 °C. Stocks of CH were made fresh in PME buffer (100 mM PIPES, 1 mM $MgSO_4$, and 2 mM EGTA at pH 6.90) and discarded after 24 h. A stock solution of 3f-Tyr was made in PME and stored at 4 °C. Concentrations of TxRed, DCCH, and CH were determined spectrophotometrically using extinction coefficients of 109 000 M^{-1} cm^{-1} at 588 nm (TxRed, DMSO), 46 000 M^{-1} cm^{-1} at 420 nm (DCCH, DMSO), and 19 000 M^{-1} cm^{-1} at 346 nm (CH, PME).[7] The concentration of NH was determined by mass. The source of 4-amino-DL-phenylalanine hydrate (4a-Phe) was Sigma-Aldrich (>97% pure). All other chemicals were purchased from Sigma-Aldrich and were reagent grade or better. All experiments were performed in PME buffer unless otherwise noted. The reactions presented in this paper were conducted in PME at pH 6.9 for compatibility with tubulin. Many of these experiments were also performed in 0.1 M phosphate buffer at pH 7.0, and no difference in the results obtained with the two buffer systems was observed.

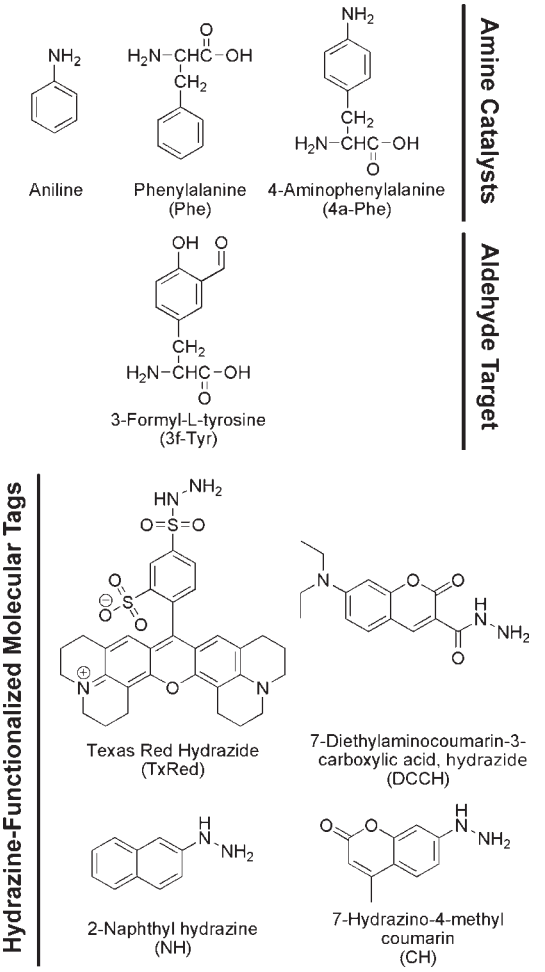
Spectral Characteristics and Kinetics of 3f-Tyr Imine Formation. Imine formation was monitored by absorption difference spectroscopy. Dual chambered cuvettes were loaded with identical volumes of 800 μM 3f-Tyr and 20 mM of aniline, Phe, or 4a-Phe. The cuvette was then placed in an HP 8453 UV−vis spectrophotometer equipped with a multicell thermostatted cuvette holder and equilibrated to 25 °C. After blanking, the solutions mixed rapidly by inversion, halving the concentration and doubling the path-length of each solution. Absorption difference spectra were collected at 30 s intervals. Steady state was reached in less than one hour, so the difference spectra of the equilibrated imine solution was also monitored at steady state. There was no change in the difference spectrum after steady state was achieved. The absorbance maximum at steady state (aniline: 440 nm, Phe: 405 nm, 4a-Phe: 415 nm) was then plotted as a function of time according to the following equation for a reversible pseudo first-order reaction approaching equilibrium:

$$-\ln(\Delta A_{eq} - \Delta A_t) = k_{obs}t$$

where ΔA_{eq} is the absorption difference at equilibrium, ΔA_t is the absorption difference at time t, and k_{obs} is the observed rate constant for approach to equilibrium, which is the sum of the forward and reverse rate constants. Values for k_{obs} were obtained from a linear fit done in *SigmaPlot 10.0* (Systat Software Inc., San Jose, CA).

Relative Initial Rates of Formation. For measurement of 3f-Tyr-4a-Phe imine formation kinetics, 800 μM 3f-Tyr and 20 mM 4a-Phe were loaded into either side of a dual-chambered cuvette as described above. The reaction vessels were equilibrated at 0 °C,

Chart 1. Structures of the Catalysts, Targets, and Probes



25 °C, or 37 °C before mixing and maintained those temperatures throughout the course of the reaction. Imine formation was monitored by the change in the absorption difference spectrum at 415 nm as a function of time. Reactions were compared based on initial rates, which were calculated for each reaction as the slope of the linear portion of the absorption vs time plot. The initial rate of each reaction was compared to its initial rate at 25 °C to yield a unitless relative initial rate.

Kinetics of Hydrazone Formation. Apparent pseudo first-order rate constants in the presence and absence the catalysts were determined by absorption difference spectroscopy in a CH and 3f-Tyr test system. Identical volumes of 800 μM 3f-Tyr and 80 μM CH were loaded into separate chambers of a dual chamber cuvette with or without 10 mM of aniline, Phe, or 4a-Phe in both chambers. (Note that including the catalyst in both chambers allows the concentration of catalyst to be constant throughout the experiment.) The solutions were allowed to equilibrate before the 3f-Tyr and hydrazine were mixed. The spectrophotometer was blanked, the solutions mixed, and reactions monitored as above at 400 nm. The resulting kinetic trace was then fit as a single pseudo first-order reaction according to the equation

$$\Delta A(t) = \Delta A_{\text{final}}(1 - e^{-k't})$$

where $\Delta A(t)$ is the absorption difference at time t, ΔA_{final} is the absorption difference at completion, and k' is the apparent pseudo first-order rate constant. These data are treated as an irreversible reaction because the hydrazones are not observed to dissociate under harsher reaction conditions (*vide infra*). Fitting was accomplished using *SigmaPlot 10.0*. For the reaction of TxRed, NH, and DCCH with 3f-Tyr, only 4a-Phe was used as a catalyst, and the wavelengths monitored were 610 nm (TxRed), 370 nm (NH), and 460 nm (DCCH); 4% DMSO was included in both chambers to solublize the probes and their hydrazones. The concentration of fluorophore was 40 μM after mixing in experiments with CH, TxRed, and NH. The concentration of DCCH was reduced to produce a final concentration of 20 μM due to low solubility of the hydrazone product from this reaction. Corroborating fluorescence experiments were conducted as previously described.[7]

Temperature-dependent rate constants were determined in the same manner, except the reactions were equilibrated at 0 °C or 37 °C in the thermostatted multicell holder prior to mixing and held at that temperature throughout the reaction and CH was the only probe used.

Temperature-Dependent Imine Formation. A mixture of 400 μM 3f-Tyr and 10 mM 4a-Phe in a 1 cm path length cuvette was placed in the thermostatted multicell holder, equilibrated to 25 °C, and allowed to react until equilibrium was achieved. The sample was then blanked, the temperature decreased to 0 °C, allowed to react until equilibrium, and a difference spectrum taken. The temperature was raised back to 25 °C, raised up to 37 °C, and finally cooled back to 25 °C, with a spectrum taken after the reactions reached equilibrium at every temperature. The criterion for equilibrium was no change in the difference spectrum for 2 min.

Tubulin Purification. Tubulin was isolated from bovine brains by two cycles of temperature-dependent polymerization and depolymerization followed by phosphocellulose ion-exchange chromatography.[18] The protein containing fractions were then pooled, drop-frozen, and stored in liquid nitrogen until use. Prior to use, frozen aliquots were gently thawed and desalted into PME buffer by the method of Penefsky.[19] The concentration was determined spectrophotometrically using an extinction coefficient of 114 000 M^{-1} cm^{-1} at 280 nm, which was calculated from sequence data as previously described with modification to account for the two bound guanosine nucleotides per tubulin dimer.[20] A detailed procedure can be found in Supporting Information.

Effect of Catalyst on Microtubule Formation. Tubulin (10 μM) was incubated with varying concentrations of the catalyst for 4 h at room temperature in PME. The samples were then equilibrated to 37 °C in 1 cm path length cuvettes in the UV−vis spectrophotometer in a thermostatted multicell holder and baselines taken. Polymerization was initiated by addition of 10% v/v DMSO and 1 mM GTP. Polymerization activity was monitored as apparent absorption increase at 400 nm, taking the plateau value to be polymerization extent. The plateau values were graphed on a semilog plot versus amine concentration and the IC_{50} value extracted from a nonlinear sigmoidal fit done in *SigmaPlot 10.0*.[21]

Preparation of 3f-Tyr Hybridized Tubulin. Tubulin was hybridized with 3f-Tyr using recombinant human tubulin−tyrosine ligase fused to glutathione transferase (GST-TTL) as previously described with minor modification.[7] Purified tubulin (40−80 μM) in PME buffer was treated with carboxypeptidase A (Sigma) for 30 min at 37 °C to remove the C-terminal tyrosine from α-tubulin. The reaction was stopped by addition of 20 mM DTT. Tubulin was equilibrated into TTL buffer (25 mM MES, 150 mM KCl, 27 μM $MgCl_2$, 2.5 mM ATP, 1 mM DTT, and 1.5% v/v glycerol at pH 6.8) by rapid gel filtration using Sephadex G-50. The protein was incubated with 1 mM 3f-Tyr and 0.45 mg mL^{-1} GST-TTL for 30 min at 37 °C. Excess ligand was removed by rapid gel filtration in Sephadex G-50 into PME buffer, and the concentration of tubulin determined spectrophotometrically as above, subtracting the absorbance due to the 0.45 mg mL^{-1} GST-TTL ($\varepsilon_{280\ \text{nm}}$ = 100 000 M^{-1} cm^{-1}, MW = 71 078). The extinction coefficient was calculated using the same method used for tubulin, and is detailed in Supporting Information.

Fluorescent Labeling of α-Tubulin. Tubulin hybridized with 3f-Tyr (40 μM) was incubated with 400 μM hydrazine-containing probe (CH, NH, DCCH, or TxRed) in the presence or absence of 10 mM 4a-Phe, along with an unmodified tubulin control. In the NH, DCCH, and TxRed reactions, 4% DMSO was also included. Reactions were allowed to progress for 15 and 60 min at either RT or 0 °C, and then immediately subjected to reducing SDS-PAGE without boiling. The gels were imaged under long-wavelength UV light. The same gels were then stained with Coomassie Brilliant Blue and imaged again under white light.

RESULTS AND DISCUSSION

The application of hydrazone ligations to biological systems has been limited by the slow kinetics of such reactions at neutral pH.[23] Rate enhancement of similar reactions by nucleophilic catalysis was first detailed by Jencks, who noted that certain amines were more effective catalysts of semicarbazone formation than predicted by a general acid catalysis mechanism and who then detailed the nucleophilic catalysis mechanism.[22,24] The recent application of this principle to biological systems by Dawson and co-workers has led to a plethora of new hydrazone and oxime ligations.[3,12−15,25−27] The work presented here

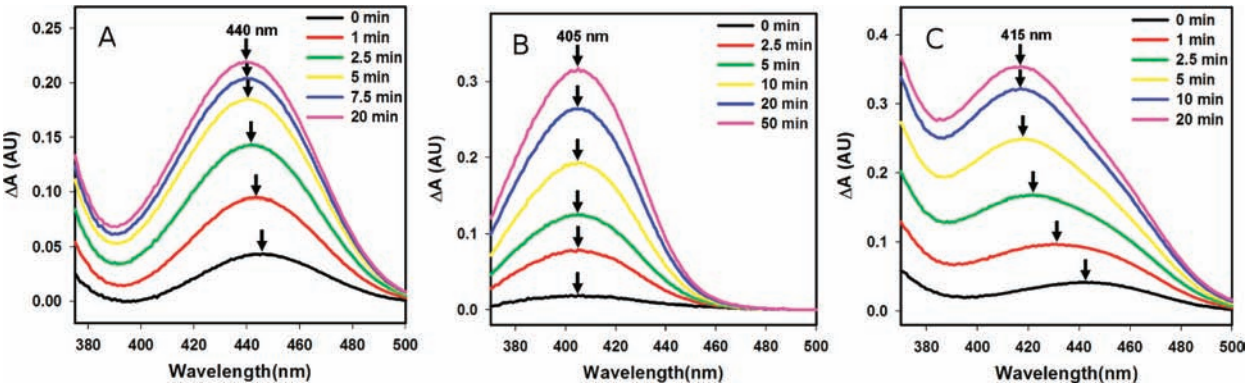


Figure 1. Time-dependent absorption difference spectra for aniline (A), Phe (B), or 4a-Phe (C) reacting with 3f-Tyr at 25 °C in PME buffer, pH 6.9. The concentration of 3f-Tyr was 400 μM and the concentrations of aniline, Phe, or 4a-Phe were 10 mM. Arrows indicate the wavelength at the maximum of the absorption difference spectrum at each time point. The peaks at $t = 0$ are due to the reaction that occurred during the seconds it took to mix the samples.

represents a continued expansion of nucleophilic catalysis in biological systems through the application of a catalyst that is more biocompatible than aniline.

Reactive Imine Formation. The catalyst 4a-Phe possesses two potential nucleophiles for imine formation: the aromatic amine of the side chain and the aliphatic α-amine. Therefore, the unmodified amino acid Phe was evaluated in parallel with aniline and 4a-Phe. Kinetics of imine formation between the three catalysts (aniline, Phe, and 4a-Phe) and the model compound 3f-Tyr were followed by absorption difference spectroscopy in aqueous buffer at neutral pH. All three catalysts formed imines with 3f-Tyr with distinct absorption difference characteristics (Figure 1, Table 1). The aniline imine peak (aromatic amine) in the absorption difference spectrum is significantly red-shifted from that of the Phe imine peak (α-amine) at equilibrium, presumably because of extended conjugation in the bisaryl product. The shape of the absorption difference spectrum of the Phe–3f-Tyr reaction is consistent throughout the reaction, indicating that a single product is formed. In the aniline–3f-Tyr reaction, the peak shape changes slightly during the reaction. The absorption maximum shifts slightly to the blue over the course of the reaction, which may be attributed to a small amount of imine formation between the α-amine and the aldehyde side chain of 3f-Tyr. The maximum of absorption difference spectrum of the 4a-Phe reaction shifts substantially during the course of the reaction, from the 445 nm (aromatic amino imine) region toward the 405 nm (α-amino imine) region. Taken together, these results indicate that imines with the *o*-hydroxybenzaldehyde moiety of 3f-Tyr form at both amino groups in 4a-Phe, and that the aromatic amino imine forms more quickly.

The relative rates at which each reaction approaches equilibrium were assessed by analyzing the data of absorbance change as a function of time as described under Experimental Procedures. The observed rate constants to equilibrium for each system are reported in Table 1. The wavelength of the absorption maximum at equilibrium was used in the calculation, since the goal was to assess equilibration rate of the entire system, which includes both α- and aromatic amines. Overall, it is observed that aniline approaches its equilibrium the fastest, Phe the slowest, and 4a-Phe at an intermediate rate.

Catalytic Efficacy and Protein Stability. The search for a more biocompatible catalyst was spurred by our interest in site-specific fluorescent labeling of the protein tubulin. When tubulin was exposed to 100 mM aniline, the concentration used in most studies currently aimed at adapting the catalysis to biomolecules; it was completely denatured and inactivated in less that 1 h (data not shown). We therefore investigated the effects of aniline, 4a-Phe, and Phe on the native structure of tubulin through polymerization activity assays. Native tubulin can be induced to assemble into microtubules, and denaturants inhibit this activity. Aniline is about 3-fold more damaging to tubulin's ability to polymerize than 4a-Phe; interestingly, unmodified Phe did not appear to affect the assembly process at equivalent concentrations (Table 2). The results suggest that the aminopropanoic acid moiety of Phe is compatible with the protein, and inclusion of this moiety in 4a-Phe protects the protein from the detrimental effects of aniline. On the basis of these results, the concentration of catalyst for subsequent experiments was fixed at 10 mM.

Table 1. Observed Rate to Equilibrium for Imine Formation with 3f-Tyr

amine	$k_{obs} \times 10^{-3}$ (s^{-1})[a]	λ_{max} (nm)[b]
Aniline	5.3 ± 0.2	445–440
4a-Phe	3.7 ± 0.1	443–415
Phe	1.4 ± 0.1	405

[a] Rate constant for equilibration of 400 μM 3f-Tyr and 10 mM of each substance at 25 °C in PME at pH 6.9, determined as described under Experimental Procedures. [b] Range of maximum wavelength of the absorption difference spectrum over the course of the reaction and monitored by absorption difference spectroscopy.

The relative catalytic efficacies of the molecules were evaluated by measuring the reaction rate of hydrazone formation between 3f-Tyr and CH as a function of catalyst. The reactants were selected because of their relevance to our tubulin labeling application, appropriate water solubilities of both the components and their resulting hydrazones, and reasonable uncatalyzed reaction kinetics for comparison.[7] Reactions were monitored by absorption difference spectroscopy as detailed in Experimental Procedures. A representative experiment is shown in Figure 2. An isosbestic point in the spectra is observed, which indicates that a single transformation is measured by the technique (i.e, hydrazine to hydrazone). Although the imine between the catalyst and 3f-Tyr absorbs in this region of the spectrum, its absorbance does not contribute to the observed difference spectrum. The 3f-Tyr/4aPhe

solution was allowed to equilibrate before the hydrazone reaction was initiated; thus, absorption due to the initial imine is eliminated by blanking the sample. The large excess of 3f-Tyr relative to CH ensures that the fractional change in imine concentration over the course of the reaction is small.

To further demonstrate that the absorption difference spectra are proportional to hydrazone formation, the reaction kinetics was monitored by fluorescence under the same experimental conditions. We have shown previously that the reaction between CH and 3f-Tyr produces a hydrazone with distinct absorption and emission properties, and that the fluorescence of the hydrazone can be observed without interference by unreacted hydrazine.[7] Figure 2C shows the kinetic trace of the fluorescence emission increase overlaid with absorption difference spectra data. The concurrence of the two data sets points to the fluorescence and absorbance signals corresponding to the same process, hydrazone formation. Calculated pseudo first-order rate constants for each signal are within experimental error of one another. In harmony with previous studies, all three catalysts increased the observed pseudo first-order rate constant for the formation of the 3f-Tyr-CH hydrazone (Table 2).[22] Aniline catalyzed the reaction most effectively (~19-fold), Phe the least effectively (~2-fold), and 4a-Phe was at an intermediate effectiveness (~13-fold). These data support the notion that the aromatic imine is the more reactive intermediate, and when both aromatic and α-amino groups are present, they may compete with each other, the net result of which is a decrease in the overall reaction rate (Scheme 1). However, this is counterbalanced by the increased concentrations of 4a-Phe that can be used because of its compatibility with the protein.

Table 2. Effect of Catalyst on the Native State of Tubulin and the Relative Efficacy of the Catalyst

catalyst	IC_{50} (mM)[a]	k (10^{-4}) (s^{-1})[b]
uncatalyzed	-	3.5 ± 0.2
aniline	28 ± 3	66 ± 0.8
4a-Phe	88 ± 13	45 ± 0.4
Phe	>100	5.5 ± 0.08

[a] IC_{50} for tubulin polymerization activity. Tubulin (10 μM) was incubated with varying concentrations of the catalyst in PME (pH 6.9) for 4 h at 25 °C and then polymerized at 37 °C. [b] Pseudo first-order rate constant for the reaction of 40 μM CH with 400 μM 3f-Tyr in the presence of 10 mM catalyst at 25 °C in PME (pH 6.9). Note the increased IC_{50} for 4a-Phe relative to aniline while still maintaining the majority of the rate enhancement for the reaction, indicating its utility as a biocompatible catalyst.

Alternative Tags. We also investigated the generalizability of 4a-Phe catalysis to varying classes of hydrazine-containing molecules using the model reaction. This was accomplished by calculating apparent pseudo first-order rate constants for reactions between 3f-Tyr and NH, DCCH, and TxRed (Table 3). The catalysis was effective for all three molecules, yielding rate enhancements of 9-, 130-, and 3-fold, respectively. Note that the rate of hydrazone formation with the more reactive aromatic hydrazines (CH and NH) is less affected by the catalyst than that of the less reactive hydrazide (DCCH). It is unclear why catalysis was less effective in the TxRed reaction. It may be that the increased sterics of the imine intermediate counteracts the greater reactivity of the iminium ion compared to the aromatic aldehyde.

Temperature Dependence of 4a-Phe and 3f-Tyr Reactions. A solution variable that frequently affects the stability of biological molecules is temperature. Proteins and nucleic acid polymers tend to be more stable at lower temperatures; the native conformation of tubulin is particularly sensitive to variations in temperature.[8,9] According to equilibrium thermodynamic parameters measured for related *o*-hydroxyl aldehyde-amine systems, imine formation is exothermic.[17] Therefore, a decrease in temperature would be expected to increase the concentration of imine in solution, which may then increase the overall efficacy of the catalyst.

Absorption difference spectroscopy was used to assess the effect of temperature on the relative equilibrium concentration of imine in a solution of the model compounds 3f-Tyr and 4a-Phe (Figure 3). The solution of the two components was equilibrated to room temperature (25 °C), and the spectrophotometer was blanked. The temperature was decreased to 0 °C, and absorption spectra were collected until no change in the spectrum was observed. A positive band was observed in the absorption difference spectrum that peaks near 440 nm, which is indicative of an increase in the concentration of the aromatic amino imine. This process was fully reversed when the temperature of the solution was restored to 25 °C. Subsequent warming of the solution to 25 °C caused a decrease in absorbance in the 440 nm region, which is consistent with dissociation of aromatic amino imine. This process was also fully reversed when cooled to 25 °C. Therefore, the imine concentration in the solution can be reversibly increased or decreased by lowering or raising the solution temperature.

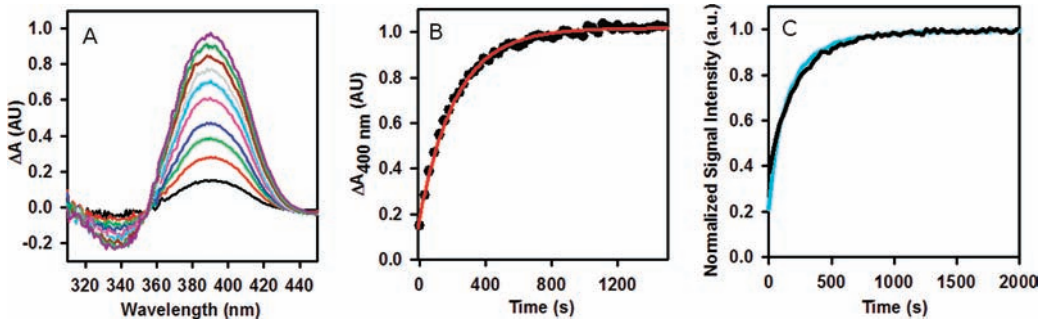

Figure 2. (A) Absorption difference spectra for the reaction of CH (40 μM) with 3f-Tyr (400 μM) at 25 °C in PME buffer, pH 6.9 in the presence of 4a-Phe (10 mM). (B) Absorption difference of the reaction shown in panel A at 400 nm as a function of time. Solid line: data fit as a single pseudo first-order reaction. (C) Kinetics of hydrazone formation catalyzed by 10 mM 4a-Phe monitored by absorption difference spectroscopy (black) and fluorescence spectroscopy (cyan). The signal data were normalized to arbitrary units to more clearly show the overlap of the kinetic traces.

Scheme 1. Proposed Reaction Pathway for 4a-Phe Catalyzed Hydrazine-Ligations with *o*-Hydroxyl Aromatic Aldehydes Attached to Biomolecules

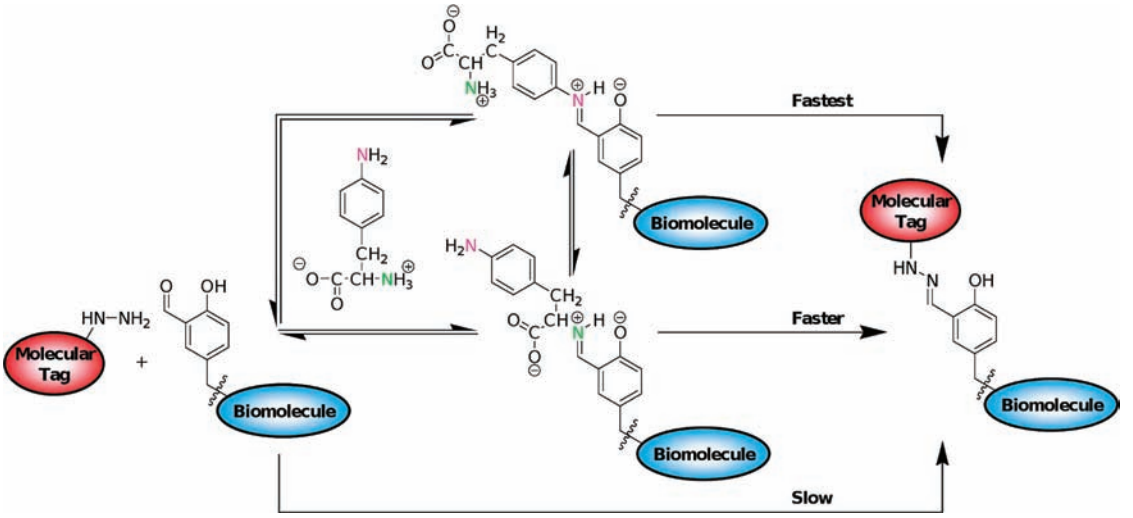

Table 3. Apparent Pseudo First-Order Rate Constants for Hydrazone Formation Between 3f-Tyr and Hydrazine-Containing Probes Catalyzed by 4a-Phe[a]

molecular tag	k_{uncat} (10^{-4}) (s^{-1})[b]	k_{cat} (10^{-4}) (s^{-1})[c]
NH	5.2 ± 0.3	45.2 ± 0.4
DCCH	0.11 ± 0.01	14.2 ± 0.04
TxRed	0.60 ± 0.12	1.8 ± 0.1

[a] Apparent pseudo first-order rate constants for the reaction of hydrazines with 3f-Tyr in the absence and presence of 4a-Phe. Experiments were performed with 400 μM 3f-Tyr with 40 μM molecular tag (20 μM in the case of DCCH) in the presence or absence of 10 mM 4a-Phe at 25 °C in PME (pH 6.9). [b] Absence of 4a-Phe. [c] Presence of 4a-Phe.

The temperature dependence of the kinetics of imine formation was assessed by measuring initial rates at the three temperatures. Table 4 compares the initial rates as a ratio of the initial rate of imine formation at 25 °C. At 0 °C, the initial rate of imine formation is about half of its value at room temperature, and at 37 °C, the initial rate is about 1-1/2 times faster.

The net effect of temperature on the catalytic ability of 4a-Phe was assessed empirically using a 3f-Tyr and CH test system. The rate of hydrazone formation was measured at the three selected temperatures in the absence or presence of 4a-Phe catalyst (Table 5). At 25 °C, 4a-Phe increased the observed rate constant by ~13-fold. At 0 °C, 4a-Phe caused a 28-fold increase in the apparent rate constant for hydrazone formation, more than double the rate enhancement observed at 25 °C (13-fold). Although there was a slight increase in observed rate constant when the temperature was increased to 37 °C (~10%), there was virtually no change in rate enhancement from 25 °C, which remained steady at 13-fold. The effect of temperature on the catalyzed reaction indicates that the effectiveness of 4a-Phe catalysis is governed by a mixture of thermodynamic and kinetic factors. We hypothesize that the thermodynamic favorability for imine formation at 0 °C is responsible for a marked increase in catalytic effectiveness by increasing intermediate imine concentration, which Cordes and Jencks determined to be a controlling factor governing the rate of imine-catalyzed semicarbazone formation.[22] It appears that

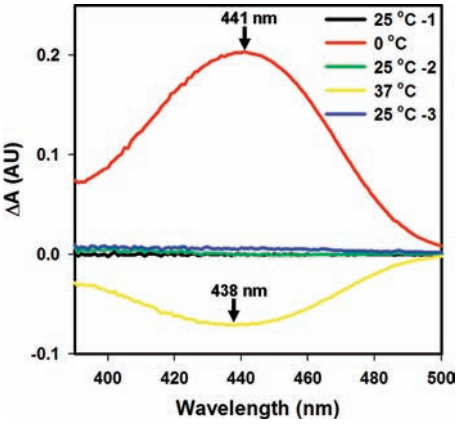

Figure 3. Effect of temperature on the absorption difference spectrum of 4a-Phe plus 3f-Tyr. A solution of 10 mM 4a-Phe and 400 μM 3f-Tyr in PME buffer (pH 6.9) was mixed at 25 °C and equilibrated until no change in the absorption spectrum was observed. The instrument was then referenced to this solution (black curve). Without removing the cuvette from the instrument, the temperature was decreased to 0 °C and the spectrum was monitored until no further change in the absorption spectrum was observed, at which point a spectrum was taken (red curve). The process of temperature change and equilibration was repeated on the same sample, which was not removed from the instrument. Green curve: After equilibration of 0 °C solution to 25 °C. Yellow curve: After equilibration of 25 °C solution to 37 °C. Blue curve: After equilibration of 37 °C solution to 25 °C. The fully reversible increase in the 440 nm region at 0 °C and decrease at 37 °C indicates aromatic amino imine concentration increases at 0 °C and decreases at 37 °C relative to the concentration at room temperature (25 °C).

kinetic favorability at 37 °C overcomes the thermodynamic disfavorability, possibly by regenerating the consumed imine intermediate more quickly. Although it is unclear how generalizable this effect is to molecules other than the *o*-hydroxyl aromatic aldehyde used in our system, it may be predicted by the energetic nature of the formation of the intermediate imine—if imine formation is sufficiently exothermic, decreasing the temperature will thermodynamically favor imine formation, thereby

Table 4. Relative Initial Rate of 4a-Phe/3f-Tyr Imine Formation at Various Temperatures[a]

temperature	$k_{i,\ app}/k_{i,\ app,\ RT}$
0 °C	0.4 ± 0.1
25 °C	1.0 ± 0.1
37 °C	1.6 ± 0.1

[a] Initial rates of formation imine at varying temperatures were determined as described under Experimental Procedures. A 400 μM solution of 3f-Tyr was reacted with 10 mM 4a-Phe at 0, 25, and 37 °C. Data are presented as the initial rate at 0, 25, or 37 °C divided by the initial rate at room temperature (25 °C).

Table 5. Effect of Temperature and 4a-Phe Catalyst on the Rate of CH/3f-Tyr Hydrazone Formation[a]

temperature	k_{uncat} (10^{-4}) (s^{-1})[b]	k_{cat} (10^{-4}) (s^{-1})[c]
0 °C	3.32 ± 0.04	94.4 ± 2.8
25 °C	3.52 ± 0.20	44.8 ± 0.4
37 °C	3.92 ± 0.08	51.6 ± 0.4

[a] Apparent pseudo first-order rate constants for the reaction of 400 μM 3f-Tyr with 40 μM CH in the absence or presence of 10 mM 4a-Phe at 0, 25, and 37 °C in PME (pH 6.9). [b] Absence of 4a-Phe. [c] Presence of 4a-Phe.

increasing imine concentration. If the rate constant of the subsequent transimination reaction has a smaller temperature dependence than the equilibrium constant for imine formation, as appears to be the case for the probes studied here (Figure 4, Table 5), then lowering the temperature of the reaction to increase its overall rate may be a general feature of these catalyzed reaction.

Application in Protein Labeling. To assess the applicability of 4a-Phe catalysis to protein labeling, we hybridized 3f-Tyr to α-tubulin as described previously[5] and allowed it to react with hydrazine-containing molecular tags. Identical reactions were performed in the presence and absence of catalyst at both 25 °C and at 0 °C. The protein was then subjected to SDS-PAGE (Figure 4) and visualized under long-wavelength UV light. It is clear that the catalysis effectively enhanced the labeling of the protein in most cases at both room temperature and 0 °C. The difference in the fluorescence intensities of the products in the catalyzed and uncatalyzed reactions are particularly evident at low temperature and short time points, consistent with the results in the model system. It should be noted that, although in this study the amino acid derivative 3f-Tyr is enzymatically appended to tubulin, the amino acid derivative suitable for incorporation into other proteins using unnatural amino acid mutagenesis (unpublished results) or via synthetic peptides. Therefore, the 4a-Phe-catalyzed hydrazone ligation reaction could be broadly applicable to protein labeling.

Hydrazone-containing conjugates have been criticized for biomolecular labeling because the reaction is an equilibrium process. It is feared that the reaction may not go to completion and that the reversibility renders the product too unstable. Equilibrium constants that have been measured for aromatic aldehyde—semicarbazide reactions in aqueous solution for aromatic semicarbazone formation in aqueous solution, which are analogous to the reactions presented here, are on the order of 10^5-10^6 M^{-1}.[28] Kalia and Raines argue that oximes are preferred over hydrazone linkages because of their superior resistance to hydrolysis.

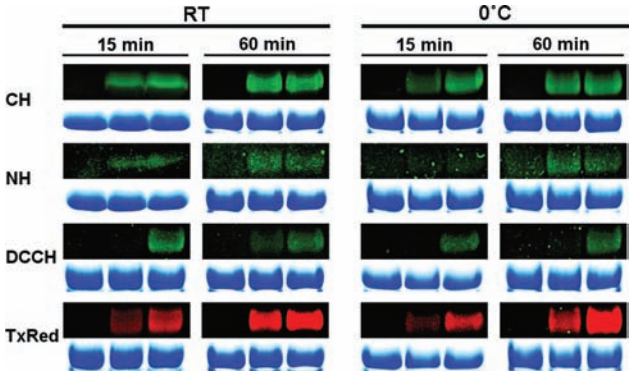

Figure 4. SDS-PAGE of α-tubulin labeled with hydrazine-containing fluorophores, visualized under long-wavelength UV light (top) and stained with Coomassie blue (bottom). Samples of tubulin (40 μM) in PME buffer were incubated with fluorophore (400 μM) for the specified time and temperature in the presence or absence of 10 mM 4a-Phe and immediately run on a gel. Each panel is from left to right: (1) Unmodified α-tubulin (control), (2) 3f-Tyr-α-tubulin, (3) 3f-Tyr-α-tubulin +4a-Phe. Note the increased fluorescence signal in most of the bands for the catalyzed reactions compared to the corresponding uncatalyzed reactions.

Their quantitative kinetic analyses show that the hydrolytic stability of hydrazone linkages is significantly affected by the structure of the hydrazone and pH at which the hydrolysis reaction is carried out. First-order rate constants of hydrazone hydrolysis decrease by 2—3 orders of magnitude from pD 5 to pD 9 in D_2O. These experiments illustrate what is generally known: hydrazone stability is dependent on structures of both reactants and pH of the medium.[29] The most pertinent question is whether a particular hydrazone is sufficiently stable for the biological application.

We have empirical observations to support our assertion that some hydrazones are well-suited for protein labeling. Tubulin labeled with this system does not observably lose the fluorophore in neutral pH buffer under conditions that retain the native structure of the protein. The hydrazone bond remains intact during SDS-PAGE (Figure 4). Moreover, SDS-PAGE gels of tubulin labeled with CH or TxRed do not noticeably lose fluorescence even after 2 weeks of storage in standard destaining solution (containing methanol, acetic acid, and water). The results suggest that the tubulin—fluorophore conjugates are stable under a variety of experimental conditions. Although the hydrazones are thermodynamically reversible, we believe that the 3f-Tyr-linked hydrazones remain intact because the products are kinetically trapped. Such behavior has been observed in hydrazone-containing dynamic covalent chemistry libraries.[30]

CONCLUSION

We conclude that 4a-Phe is a biocompatible catalyst for hydrazone ligations in aqueous buffer at neutral pH with catalytic efficacy about 70% of aniline but superior compatibility with proteins. We have applied the catalysis to a site-specific bioorthogonal labeling method for conjugating molecular labels to the C-terminus of α-tubulin under conditions that preserves the activity of the fragile protein. Importantly, we demonstrate that the reactions can be effectively conducted at 0 °C, successfully increasing the extent of labeling under conditions and time periods that are suitable for routine use with biomolecules.

SUPPORTING MATERIAL

Synthesis and Spectral Characterization of 2-Napthylhydrazine and Corresponding Hydrazone

Materials

Dry methanol, acetonitrile and THF were purchased from Acros Chimica and Aldrich and dried in our lab. Other solvents and reagents were also obtained from Acros or Aldrich and were used as received (regent grade or better). Deuterated solvents were obtained from Cambridge Isotope Laboratories. Non-deuterated solvents were degassed with argon before use.

General Procedures

^{1}H, ^{13}C spectra were recorded on instruments operating at a frequency of 360 MHz. ^{1}H NMR spectra were referenced to $CDCl_3$ (7.26 ppm). ^{13}C NMR spectra were referenced to the $CDCl_3$ (77.00 ppm). Chemical shift multiplicities are reported as s= singlet, d = doublet, t = triplet, q = quartet and m = multiplet. Flash column chromatography was performed using Baker silica gel 60-200 mesh or 200-400 mesh. Absorption spectra of all compounds were obtained by using a Hewlett-Packard 8453 diode array absorption spectrophotometer. Fluorescence emission spectra for were measured using Spex FluoroMax-3 spectrofluorometer. Reactions were monitored by thin layer chromatography using TLC plastic sheets, silica gel 60 $F_{254.}$

Fluorescence Quantum Yield Determination

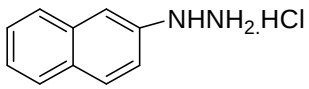
The relative fluorescence quantum yields (ϕ_F) were determined in dilute solutions with an absorbance below 0.1 at the excitation wavelength. Quinine sulfate in 0.1 M H_2SO_4 (λex = 347 nm) was used as a standard, which has a quantum yield of 0.57.[1] Solvents were dried before use. The slit width was 2 nm for both excitation and emission. The relative quantum yields were

obtained by calculating the area under corrected emission spectrum of the sample and comparing these areas with the area under corrected emission spectrum of standard solution of quinine sulfate. Correction for the refractive index was also applied. All spectra were recorded at 23 °C. All the fluorescence integrals were calculated using SigmaPlot 10.0. The relative quantum efficiencies of fluorescence were obtained with the following equation:

$$\phi_F^{sample} = \phi_F^{standard} \times (F^{sample} - F^{solvent})/(F^{standard} - F^{solvent}) \times (\eta^{sample}/\eta^{standard}) \times (A^{standard}/A^{sample})$$

where F denotes fluorescence integral with respect to wavelength, A denotes the absorbance at the excitation wavelength, and η denotes the refractive index of the solvent.

2-Naphthylhydrazine hydrochloride (1)

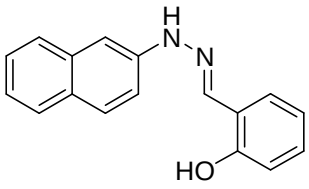


1

The procedure is modified from Portoghese et. al.[2] A stirred slurry of 2-naphthylamine (2 g, 0.01 mol) in concentrated hydrochloric acid (30 mL) was treated dropwise at -5 °C with sodium nitrite (0.89 g, 0.01 mol) in cold water (3 mL), care being taken not to allow the temperature to rise above 0 °C. After the addition of sodium nitrite, the diazotization reaction was continued for 1 hr. The solution was quickly filtered and the filtrate was poured in a thin stream into a solution of stannous chloride dihydrate (14 g, 0.05 mol) in cold hydrochloric acid (60 mL). After 1 hr, the reaction mixture was filtered and washed with water (20 mL), followed with alcohol (30 mL) and finally with ether (100 mL). The crude product was dried in the desiccator and stored under

nitrogen in the dark (1.1 g, 57%)); ^{1}H NMR (360 MHz, DMSO-d_6) δ 7.92 (d, 1H, ArH), 7.40 (t, 1H, ArH), 7.25 (t,1H, ArH), 7.20 (s, 1H, ArH), 7.15 (d, 1H, ArH), 3.85 (bs, 1H, NH); ^{13}C NMR (360 MHz, DMSO-d_6) δ 143.4, 133.6, 128.8, 127.6, 126.8, 126.5, 123.5, 117.1, 107.9.

(E/Z)-2-((2-(Naphthalen-2-yl)hydrazono)methyl)phenol (2)



2

2-Naphthylhydrazine (1.42 g, 9 mmol) was dissolved in 5 mL of 95% ethanol. Salicylaldehyde (1.1 g, 9 mmol) was also dissolved in 5 mL of ethanol and added to the previous mixture. The solution was stirred for 1 hr at room temperature (a precipitate formed) and then cooled to -15 °C. The yellow-orange solid was collected by vacuum filtration and washed with ice cold ethanol. The product was recrystallized twice from ethanol to give pure product **2** (1.1 g, 47 %). R_f = 0.56 (CH_2Cl_2); ^{1}H NMR (360 MHz, DMSO-d_6) δ 10.62 (s, 1H, OH), 8.25 (s, 1H, CH), 7.79-7.73(m, 4H, ArH), 7.63 (d, 1H, ArH), 7.16-7.41 (m, 4H, ArH), 6.85-6.92 (m, 2H, ArH); ^{13}C NMR (360 MHz, DMSO-d_6) δ 171.8, 158.6, 153.6, 150.6, 145.3, 144.9, 143.9, 143.5, 143.1, 142.4, 142, 138.4, 136.5, 132.6, 131.9, 131.4, 120.6.

Table S1. Spectral Characteristics of 1 and 2.

Compound	Solvent	λ_{abs} max (nm)	λ_{em} max(nm)	ϕ_{rel}
1	MeOH	330	383	0.021
	DMSO	338	407	0.140
	Dioxane	345	391	0.059
2	MeOH	360	444	0.065
	DMSO	359	440	0.054
	Dioxane	355	461	0.048

The compounds show a significant red-shift upon hydrazone formation, indicating increased fluorophore conjugation through the pi system (Table S1).

Sequence of GST-TTL Fusion Protein

The sequence of our GST-TTL fusion protein was predicted from the sequence of the expression plasmid pReceiver05x (Genecopoeia, Maryland) using the Translate Tool hosted by the Swiss Institute for Bioinformatics (SIB) (http://ca.expasy.org/tools/dna.html). Molecular weight of this protein was then predicted from the predicted protein sequence using the Compute pI/Mw Tool hosted by the SIB (http://ca.expasy.org/tools/pi_tool.html) and confirmed by reducing SDS-PAGE (Data not shown). The results are shown in figure S1.

Tubulin and GST-TTL Extinction Coefficients

Tubulin and GST-TTL extinction coefficients at 280 nm were calculated as described previously with minor modifications.[3] The number of the major amino-acid contributors to protein

absorbance at 280 nm (tryptophan, tyrosine, and cysteine) were determined from protein sequence data, multiplied by absorption coefficients for those residues at 280 nm, and summed according to the following equation:

$$\varepsilon(M^{-1}cm^{-1}) = (5{,}500\ M^{-1}cm^{-1})(n_{Trp}) + (1{,}490\ M^{-1}cm^{-1})(n_{Tyr}) + (125\ M^{-1}cm^{-1})(n_{Cys})$$

Where n_{Trp}, n_{Tyr}, and n_{Cys} are the number of tryptophan, tyrosine, and cysteine residues in a protein, and the corresponding coefficients are the average absorption coefficients for those residues in when in a protein. This equation assumes each cysteine represents one half a cystine. In the case of tubulin, a fourth term must be added to account for the absorbance of the two bound guanine nucleotides per dimer, yielding the following equation:

$$\varepsilon(M^{-1}cm^{-1}) = (5{,}500\ M^{-1}cm^{-1})(n_{Trp}) + (1{,}490\ M^{-1}cm^{-1})(n_{Tyr}) + (125\ M^{-1}cm^{-1})(n_{Cys}) + (7{,}760\ M^{-1}cm^{-1})(n_{GTP/GDP})$$

Where $n_{GTP/GDP}$ is the number of bound guanosine nucleotides (two in the case of a tubulin dimer) and its corresponding coefficient is the extinction coefficient for GTP/GDP in aqueous buffer at pH 6.9 as determined in our lab. The tubulin sequences used for bovine brain tubulin dimers were α_I and β_{II} as obtained from Swiss-Prot (P81947 and Q6B856 respectively). The sequence used for GST-TTL is reported in figure S1.

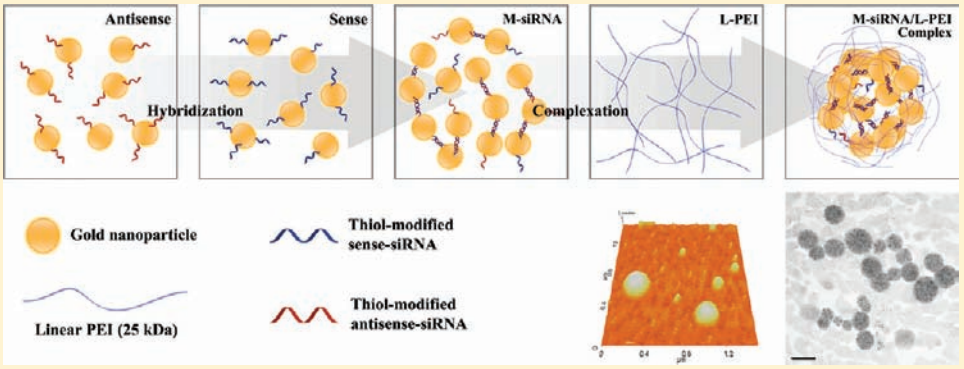
ABSTRACT:



In this study, siRNAs terminated with thiol groups were multimerized and cross-linked using ~5 nm gold nanoparticles (AuNPs) via Au−S chemisorption that can be intracellularly reduced. AuNPs immobilized with single-stranded antisense siRNA were assembled with those with single-stranded sense siRNA via complementary hybridization or assembled with those with single-stranded dimeric sense siRNA. The multimerized siRNA cross-linked by AuNPs showed increased charge density and enhanced enzymatic stability, and exhibited good complexation behaviors with a polycationic carrier, linear polyethylenimine (L-PEI). The resultant multi-siRNA/AuNPs/L-PEI polyelectrolyte complexes exhibited far greater gene silencing efficiencies of green fluorescent protein (GFP) and vascular endothelial growth factor (VEGF) compared to naked siRNA complexes. They could also be visualized by micro-CT imaging. The results suggest that AuNP-mediated multimerization of siRNAs could be a rational approach to achieve both gene silencing and imaging at a target tissue simultaneously.

INTRODUCTION

Gold nanoparticles (AuNPs) have received significant attention as nanotemplates for biomolecular conjugates because of their excellent biocompatibility, controllable morphology and size dispersity, and easy surface functionalization via well-defined Au-thiol linkages.[1−4]

For diagnostic applications, AuNPs were functionalized with oligonucleotides for ultrasensitive detection of a target nucleic acid sequence via their unique surface plasmon optical properties generated upon hybridization.[5−7] For therapeutic applications, AuNPs were conjugated with therapeutic genes such as antisense oligodeoxynucleiotides (ODNs) and small interfering RNAs (siRNAs) for efficient cellular uptake and gene inhibition.[4−11]

More recently, siRNAs have been extensively utilized for gene silencing due to their extraordinary ability to specifically and efficiently block the gene expression of a target mRNA through an RNA interference mechanism. siRNAs hold great promise as a new class of therapeutic nucleic acid drugs for treating numerous diseases including cancer and other diseases from genetic disorders to viral infections.[12−16] Clinical applications of siRNAs have been limited mostly by the lack of efficient and biocompatible delivery carriers.[17,18] Since siRNA molecules have a low charge density with high stiffness as compared to plasmid DNA, they have to condense with an excess amount of cationic polymers and lipids to form stable nanocomplexes for facile endocytic cellular uptake.[19] Highly positively charged polymers such as branched polyethylenimine (bPEI) have been popular to stably complex siRNA, but their cytotoxicity remains a serious problem. Recently, multimeric siRNAs cross-linked via intracellularly cleavable disulfide linkages were proposed to increase the charge density of siRNA.[19,20] The reducibly multimerized siRNA was synthesized by forming covalent bonds between two or more siRNA monomers via bifunctional disulfide-containing cross-linkers (e.g., dithio-bis-maleimidoethane (DTME)). It was demonstrated that the one-dimensionally aligned siRNA molecules could significantly enhance electrostatic interactions with low-molecular-weight polycationic carriers that exhibit low cytotoxicity, generating stable and compact polyelectrolyte nanocomplexes. The multimeric siRNA showed greatly enhanced gene silencing efficiencies *in vitro* and *in vivo* as compared to naked

siRNA, when complexed with linear PEI (L-PEI) at the same polymer nitrogen to siRNA phosphate (N/P) ratio.

Here, we demonstrate a facile synthetic route to multimeric siRNA species that are cross-linked by AuNPs via Au-thiol linkages. Thiolated single-stranded sense and antisense siRNA were separately anchored onto the surface of AuNPs, and they were subsequently annealed to produce multimeric siRNA cross-linked by AuNPs. In addition, single-stranded antisense siRNA/AuNPs were hybridized with a single-stranded sense dimeric and reducible siRNA as a spacing linker to control the distance between AuNPs. The resultant multi-siRNA/AuNPs are expected to regenerate naked siRNA species within cells by reductive cleavage of Au-thiol linkages. The multimeric siRNA/AuNPs were characterized in terms of their size, morphology, resistance to enzymes, and reducibility to glutathione, and condensed with L-PEI to form polyelectrolyte complexes for cellular uptake, gene silencing, and micro-CT imaging.

EXPERIMENTAL PROCEDURES

Materials. Tetrachlorohydrogenaurate ($HAuCl_4$), sodium citrate, sodium borohydride ($NaBH_4$), phosphine (4,4′-(phenylphosphinidene)bis-benzenesulfonic acid dipotassium salt), Triton X-100, and XTT based *in vitro* cytotoxicity assay kit were purchased from Sigma-Aldrich (St. Louis, MO). Linear polyethylenimine (L-PEI, M_w: 25 kDa) was purchased from Polysciences (Warrington, PA). All the chemicals were of analytical reagent grade. Dulbecco's modified eagle medium (DMEM), Roswell Park Memorial Institute (RPMI) 1640 medium, phosphate buffered saline (PBS), and fetal bovine serum (FBS) were purchased from Gibco-Invitrogen (Grand Island, NY). Enhanced green fluorescent protein (GFP) siRNA (sense strand: 5′-AACUUCAGGGUCAGCUUGC$(dT)_5$-3′; antisense strand: 5′-GCAAGCUGACCCUGAAGUU$(dT)_5$-3′), vascular endothelial growth factor (VEGF) siRNA (sense: 5′-GGAGUACCCUGAUGAGAUC$(dT)_5$-3′; antisense: 5′-GAUCUCAUCAGGGUACUCC$(dT)_5$-3′), alkanethiol-modified siRNA (the 3′-end of both the sense and antisense strands modified with thiol groups), and fluorescein-labeled single-stranded siRNA were provided from Bioneer Co. (Daejeon, Korea). RNase ONE ribonuclease was purchased from Promega Corporation (Madison, WI).

Synthesis of Phosphine-Capped Gold Nanoparticles (AUNPs). Citrate-stabilized AuNPs (5 nm in diameter) were prepared by direct reduction of Au (III) ions using citric acid.[21] Following the synthesis, the AuNPs were capped with phosphine and concentrated by precipitation and resuspension as described previously. [3] The resulting AuNPs were treated with 0.1% diethylpyrocarbonate (DEPC) followed by autoclaving at 121 °C for 20 min to yield sterile and RNase-free gold colloids.[5] The concentration of AuNPs was calculated using an extinction coefficient of 1×10^7 M^{-1} cm^{-1} at 520 nm.

AuNP-Mediated Assembly of Multimerized siRNA (M-siRNA). Phosphine-capped AuNPs were separately functionalized with single-stranded sense or antisense siRNA, according to the method described previously.[22] Either the sense or antisense-stranded thiol-modified siRNA (3.05 mol of siRNA relative to a mole of AuNPs) was added into a stirred solution of phosphine-capped AuNPs (500 nM). To promote the place-exchange reaction of siRNA at the polar defect site of the AuNPs, they were resuspended in 0.5 × TBE (45 mM Tris-base, 45 mM boric acid, 1 mM EDTA, pH 8.0)/100 mM NaCl buffer solution. The solution was further incubated for 40 h at room temperature. Unreacted siRNA was removed by centrifugation for 30 min at 50 000 × *g*. The resulting siRNA-functionalized AuNPs (obtained as red precipitates) were purified by successive dispersion/centrifugation in 0.3 M NaCl solution. In order to determine the number of siRNAs anchored onto the surface of a single AuNP, fluorescein-labeled siRNA was used for the preparation of siRNA-functionalized AuNPs.[23] The resultant siRNA-functionalized AuNPs were treated with 12 mM 2-mercaptoethanol in 0.1 M PBS solution (pH 7.4). After 12 h of incubation with gentle shaking, the solution containing the displaced siRNA was separated by centrifugation. The fluorescence in the supernatant was then analyzed using a LSM-AMINCO 8100 fluorophotometer (LSM instruments Inc., USA) with an excitation wavelength at 488 nm and an emission wavelength at 520 nm. The concentration of AuNPs in each sample was also quantified by measuring the absorbance at 520 nm using the NanoDrop ND-1000 spectrophotometer (Thermo Fisher Scientific, USA). The average number of siRNAs attached on each AuNP was calculated by dividing the amount of attached siRNA with the amount of AuNPs. M-siRNA was synthesized by annealing the sense siRNA-functionalized AuNPs with an equimolar amount of the antisense siRNA-functionalized AuNPs in 0.1 M phosphate-buffered saline (PBS) solution (pH 7.4) for 12 h at room temperature. M-siRNA having a longer spacing between AuNPs (M-siRNA-D) was also synthesized by hybridizing the antisense siRNA-functionalized AuNPs with a dimerized sense siRNA at the same molar concentration. The dimerized sense siRNA was prepared according to the previously reported procedure.[24] Briefly, 3′-end thiol-modified single-stranded sense siRNA (GFP; 5′-AACUUCAGGGUCAGCUUGC$(dT)_2$-3′) was reacted with dithio-bis-maleimidoethane, a homobifunctional thiol-reactive cross-linker, to prepare a single-stranded sense-dimer.

Physicochemical Characterization of M-siRNA. The size, shape, and spatial arrangement of AuNPs cross-linked in the M-siRNA and M-siRNA-D were investigated by transmission electron microscopy (TEM). Thirty microliters of the solution was deposited onto a 300 mesh Formvar/carbon-coated copper grid, air-dried, and then observed by a field-emission transmission electron microscope (FE-TEM, Philips TECNAI F20). The average center-to-center distance of AuNPs in the multimerized siRNA was determined by measuring more than 50 multi-siRNA/AuNPs clusters in the TEM image. UV−visible spectra of phosphine-capped AuNPs, siRNA-functionalized AuNPs, and M-siRNA were recorded from 450 to 650 nm using a Nano Drop ND-1000 spectrophotometer.

Glutathione-Responsive Release of siRNA from M-siRNA. Since the glutathione (GSH) concentration in the cytoplasm (1−10 mM) is substantially higher than in extracellular environments (2 μM in plasma), it was expected that M-siRNA would have an ability to selectively deliver siRNA into the cytoplasm.[29] Thus, to determine whether the cross-linked siRNA molecules were released from the M-siRNA in a reducible intracellular environment, the release of siRNA was examined at varying glutathione concentrations. In brief, M-siRNA (containing 1 μg equiv siRNA) was incubated in 0.1 M PBS solution (pH 7.4) containing 0, 100, 200, or 300 μM GSH at 37 °C. After incubation for 1 h, the released siRNA was separated from the AuNPs by centrifugation. Aliquots of the supernatant were diluted 2-fold with deionized water, and then analyzed by agarose gel electrophoresis for 10 min at 100 V in TAE buffer solution (40 mM Tris-HCl, 1% (v/v) acetic acid, 1 mM EDTA). After staining with ethidium bromide, the gel was imaged under UV illumination.

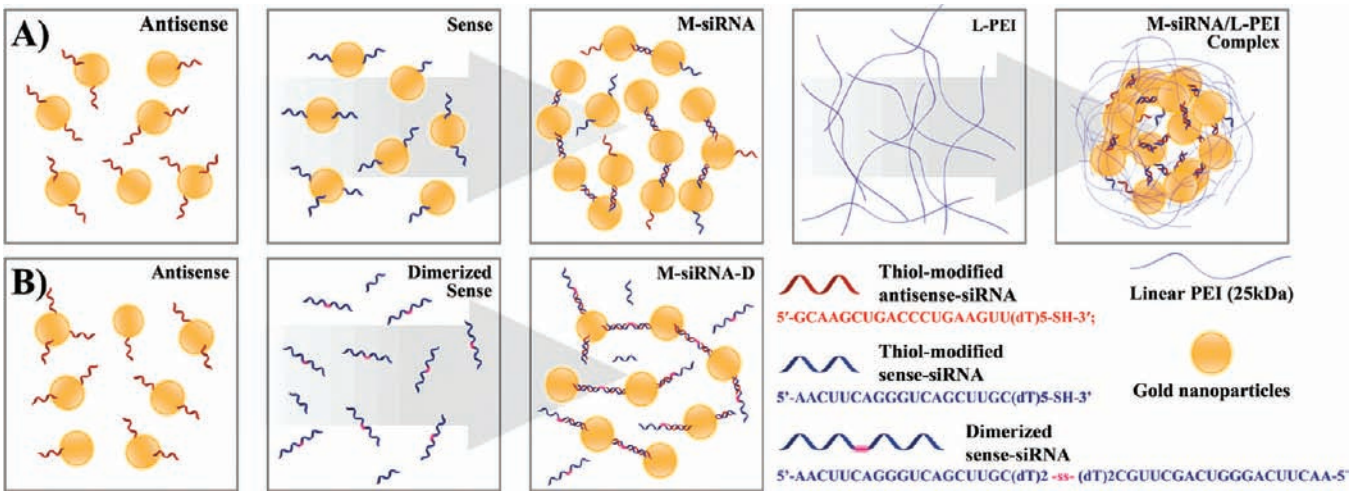

Figure 1. Schematic illustration of the formation of (A) AuNP-mediated multimerized siRNA (M-siRNA), collapsed complexes with L-PEI, and (B) another type of multimerized siRNA having a longer spacing between AuNPs (M-siRNA-D). The sequences of thiol-modified single-stranded siRNAs are 5′-AACUUCAGGGUCAGCUUGC$(dT)_5$-SH-3′ (sense) and 5′-GCAAGCUGACCCUGAAGUU$(dT)_5$-SH-3′ (antisense). The sequence of dimerized sense siRNA is 5′-AACUUCAGGGUCAGCUUGC$(dT)_2$-ss-$(dT)_2$CGUUCGACUGGGACUUCAA-5′.

Protective Effect of M-siRNA against Enzymatic Degradation. To evaluate the stability of siRNA against nuclease attack, M-siRNA and naked siRNA were treated with RNase ONE ribonuclease, which cleaves phosphodiester linkages between neighboring ribonucleotides. Two micrograms of siRNA or M-siRNA were incubated with 10 U RNase in 100 μL of the reaction buffer solution (10 mM Tris−HCl (pH 7.5), 5 mM EDTA, and 200 mM sodium acetate). In order to examine the effect of GSH on the enzymatic stability of M-siRNA, the samples were also simultaneously treated with 100 μM GSH. After incubation for 30 min at room temperature, the residual siRNA was detached from the surface of the AuNPs by treatment with 12 mM 2-mercaptoethanol in 0.1 M PBS solution (pH 7.4). Following centrifugation, the supernatant solution containing the detached siRNA was loaded on a 2% agarose gel. The remaining siRNA fraction was visualized by staining with ethidium bromide and analyzed using *Image J* software (NIH Image).

Preparation and Characterization of M-siRNA/L-PEI Polyelectrolyte Complexes. To form polyelectrolyte complexes, M-siRNA or monomeric siRNA (2 μg) dispersed in RNase-free water was mixed with L-PEI at various N/P ratios ranging from 1 to 10 in 0.1 M PBS solution (pH 7.4), and then incubated for 10 min at room temperature. The size, morphology, and internal structure of the polyelectrolyte complexes were examined using atomic force microscopy (AFM; PSIA XE-100, Park Systems, Korea) and TEM. In the AFM experiments, 100 μL of the sample solution was deposited onto a clean mica surface and images were obtained in a noncontact mode. The zeta potential values of the complexes were also measured using a dynamic light scattering instrument (Zeta-Plus, Brookhaven, NY) equipped with a He−Ne laser at a wavelength of 632 nm. The intensity-weighted particle size distribution data were collected at a scattering angle of 90° at physiological temperature, 37 °C. The zeta potential values of the complexes were measured in 0.1 M PBS solution (pH 7.4) in triplicate at 37 °C.

Evaluation of Gene Silencing Effect of M-siRNA/L-PEI Polyelectrolyte Complexes. A GFP-expressing human melanoma cell line (MDA-MB-435) was provided from Samyang Corp. (Daejeon, South Korea). The human prostate carcinoma cell line (PC-3 cells) was provided form the Korea Cell Line Bank (Seoul, South Korea). GFP-expressing MDA-MB-435 cells were seeded in a 24-well plate at a density of 2×10^5 cells per well and grown in RPMI medium supplemented with 10% (v/v) fetal bovine serum (FBS) for 24 h at 37 °C. The cells were then incubated with serum-deficient or 10% FBS-supplemented medium containing polyelectrolyte M-siRNA complexes formulated with L-PEI at N/P ratios ranging from 1 to 10. After 5 h of incubation, the culture medium was replaced with fresh medium containing 10% FBS, and further incubated for 48 h. As a control experiment, the cells were treated with only L-PEI at an equivalent concentration or monomeric siRNA/L-PEI complexes prepared at an N/P ratio of 10. To quantify the extent of GFP expression, the treated cells were washed with the PBS solution three times, and then lysed with 0.1% Triton X-100 solution in the PBS solution. After centrifugation at 4 °C, the GFP concentration in the supernatant was analyzed using a LSM-AMINCO 8100 fluorophotometer with an excitation wavelength at 488 nm and an emission wavelength at 509 nm. Relative GFP expression levels were calculated based on the GFP expression of untreated cells, which was set at 100%. To evaluate the VEGF gene silencing effect, PC-3 cells were transfected with the M-siRNA/L-PEI complexes at varying concentrations and then harvested. Total RNA was isolated using a Trizol reagent according to the manufacturer's protocol. Semiquantitative reverse transcriptase polymerase chain reaction (RT-PCR) was performed to measure the cellular VEGF mRNA levels according to our previous report.[25]

In Vitro Cytotoxicity Assay. The cytotoxicity of M-siRNA/L-PEI polyelectrolyte complexes was examined using an XTT-based *in vitro* cytotoxicity assay kit. Briefly, GFP-expressing MDA-MB-435 cells were seeded in a 48-well plate at a density of 2×10^4 cells per well, and then cultivated in RPMI medium supplemented with 10% (v/v) FBS for 24 h at 37 °C. The cells were then incubated with the M-siRNA/L-PEI complexes (siRNA concentration: 2 μg/mL), which were prepared at varying N/P ratios (N/P ratios ranging from 2 to 12), or naked siRNA (2 μg/mL) as a control. After incubation for 10 h, the cells were washed with the PBS solution, and then treated with a XTT

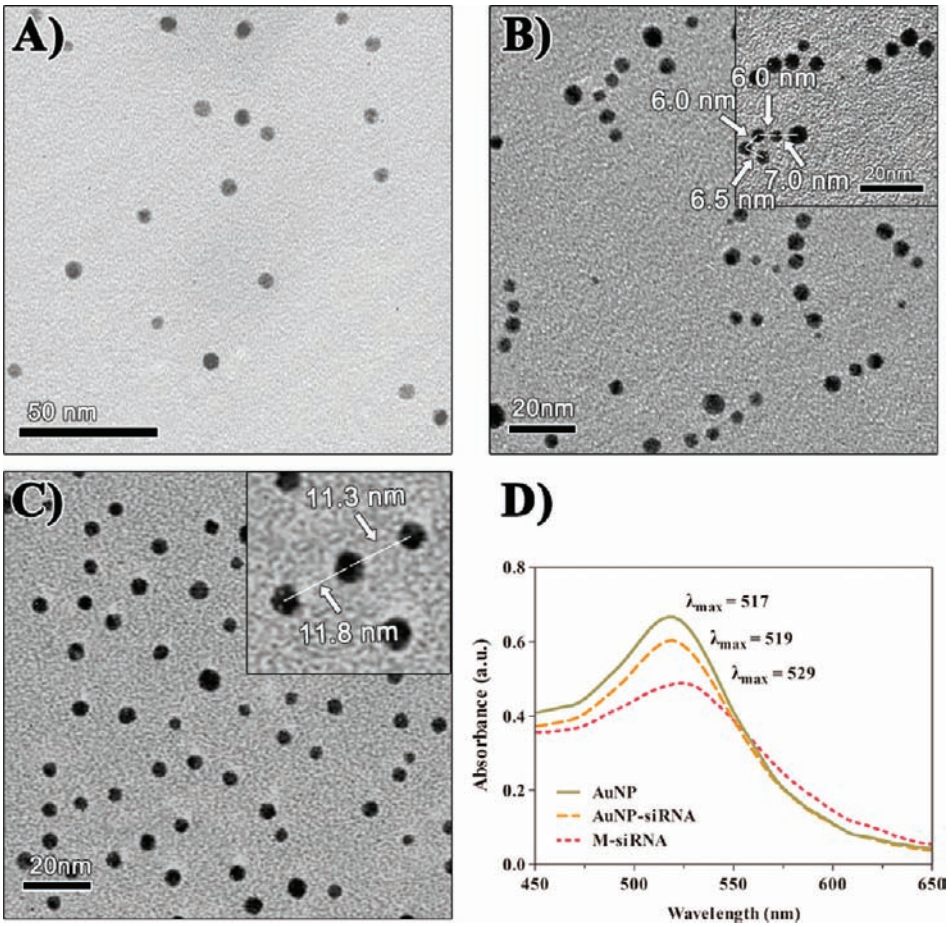

Figure 2. (A) TEM images of phosphine-capped AuNPs, (B) M-siRNA, and (C) M-siRNA-D. (D) UV−visible absorption spectra of phosphine-capped AuNPs (solid line), siRNA-AuNPs conjugates (dash), and M-siRNAs (dot).

reagent for 2 h. Cell viability was determined by measuring the absorbance at 450 nm using a Bio-Rad microplate reader, and then normalized with respect to the control population.

Micro-CT Imaging Procedures. GFP-expressing MDA-MB-435 cells were seeded in a 100 mm culture dish at a density of 1×10^6 cells per dish, and further grown for 24 h at 37 °C. The cells were then treated with the serum-deficient medium containing M-siRNA/L-PEI or monomeric siRNA/L-PEI polyelectrolyte complexes. Treatment was carefully carried out by adding the formulated complexes to the cells in a dropwise manner. After 5 h of incubation, the cells were washed three times with PBS solution, and detached using a trypsin−EDTA solution. The harvested cells were fixed with 1% formaldehyde in PBS solution. The cells were embedded in a 2% low-melting agarose gel, and then visualized through micro-CT imaging (Inveon Micro-CT, Siemens, USA).

RESULTS AND DISCUSSION

Synthesis of Phosphine-Capped AuNPs. Multimeric siRNA cross-linked by AuNPs (or AuNPs cross-linked by siRNA) was fabricated by complementary hybridization between sense and antisense single-stranded siRNA separately immobilized onto the surface of AuNPs via a Au-thiol linkage (Figure 1). In order to attain multimeric siRNA/AuNPs constructs with desired shape and morphological characters, the number of immobilized single-stranded sense or antisense siRNA molecules and their spatial distribution on the surface of negatively charged phosphine-capped AuNPs are highly important. When AuNPs were immobilized with two or more single-stranded sense or antisense siRNA molecules, they would produce linear, branched, or gel-like multimeric siRNA species by complementary hybridization, respectively. Since the number of siRNA molecules and their spatial orientation on the surface of AuNPs would primarily dictate the assembly pattern of AuNPs, the size of AuNPs is most critical in controlling the extent of siRNA immobilization. Depending on the surface area, curvature, and surface charge density of AuNPs, thiolated single-stranded sense or antisense siRNA could be bound on the surface to varying extents. To immobilize roughly two siRNA molecules on the surface, 5 nm AuNPs were prepared.[21] The size of the phosphine-capped AuNPs was 5.0 ± 1.8 nm as assessed through TEM image (Figure 2A). The UV−visible spectra showed a characteristic absorption peak near 520 nm (λ_{max} = 514 nm; data was not shown).

Multimerized siRNA Construct Formation. AuNPs were functionalized with single-stranded sense or antisense siRNAs terminated with a thiol group at their 3′ end. The thiolated 3′ end of siRNAs had an extended $(dT)_5$ overhang that could serve as a steric spacer to enhance the Au−S chemisorption of thiolated siRNA on the surface by reducing the tendency of Au-purine base interactions.[23,26−28] Because of the stiff nature of siRNA, the anchored siRNAs might be oriented perpendicularly onto the

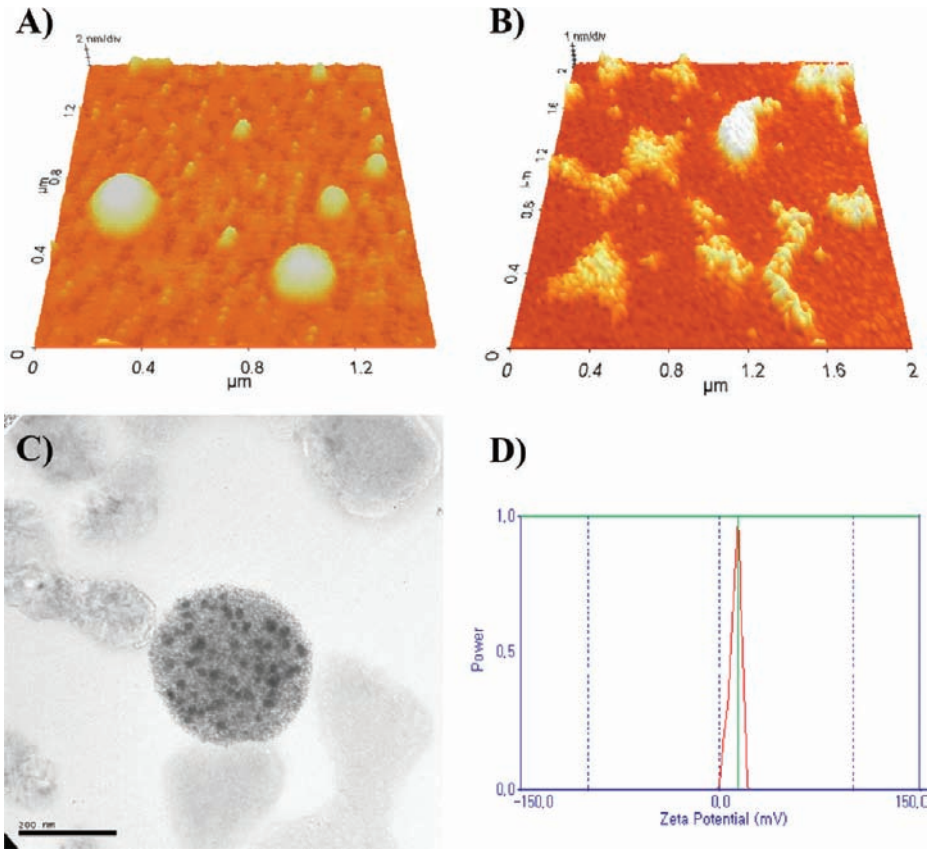

Figure 4. AFM and TEM images of M-siRNA/L-PEI complexes. (A) M-siRNA/L-PEI nanocomplex and (B) naked siRNA/L-PEI complex. (C) TEM image of M-siRNA/L-PEI nanocomplex. (D) Surface zeta potential of M-siRNA/L-PEI complex. N/P ratio of 10 was used in all measurements.

surface with a fully stretched structure, allowing for maximum hybridization with its complementary counterparts. The average number of siRNA onto the surface of an AuNP was controlled to be ~2 by adjusting a feed molar ratio of single-stranded siRNA to AuNPs at 3.05. The surface immobilization of siRNA on the Au surface was evidenced by observing a slight red shift of surface plasmon peak from 517 to 519 nm (Figure 2D). When the two separately prepared AuNPs immobilized with single-stranded sense and antisense siRNA were mixed, AuNPs were cross-linked by complementary hybridization, and they were consequently 1-D aligned with an average center-to-center distance of 6.5 ± 0.7 nm between the adjacent AuNPs (Figure 2B). The spacing

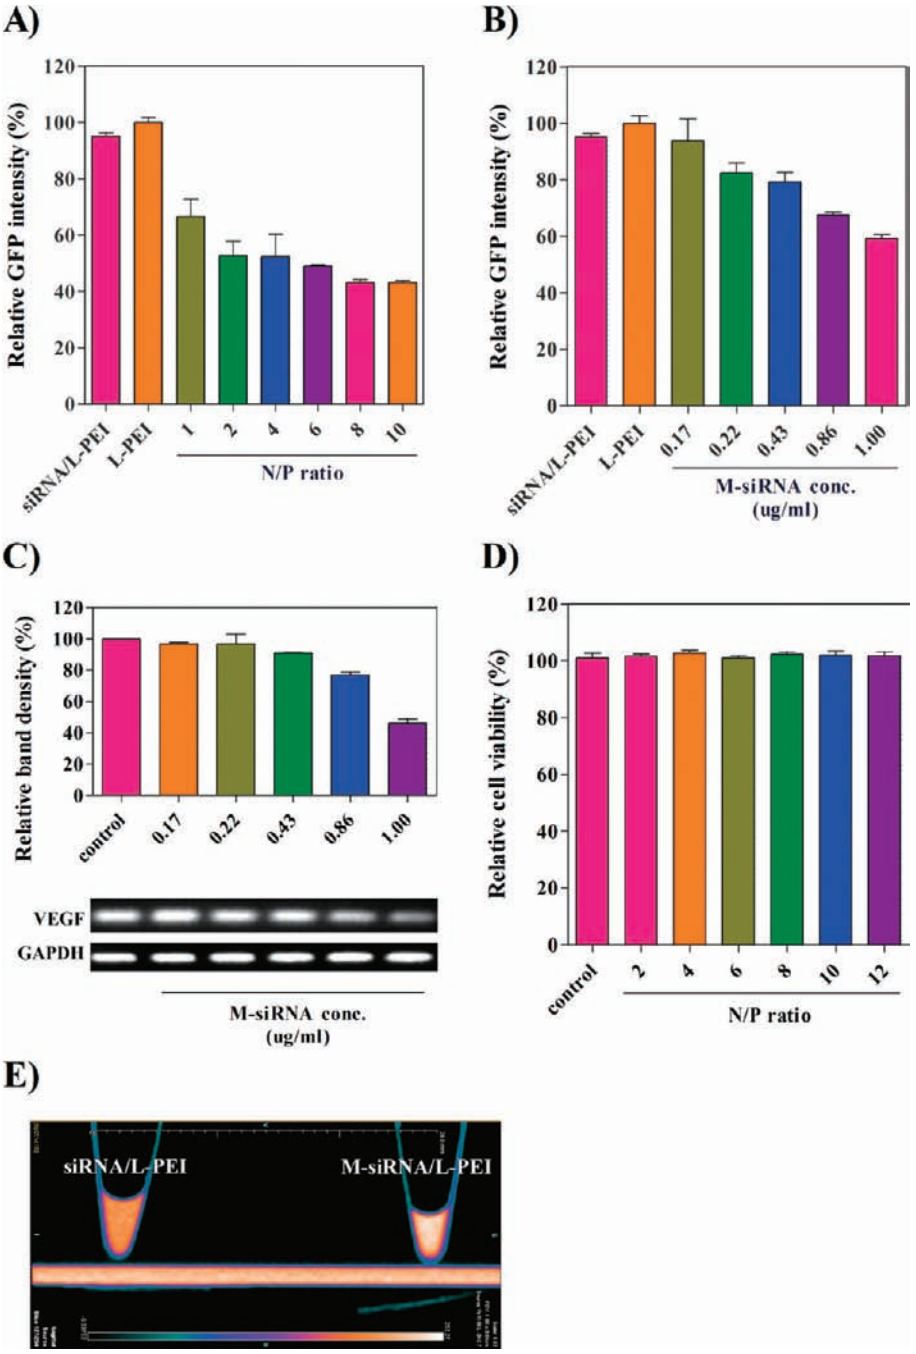

Figure 5. (A) Suppression of GFP gene expression by the M-siRNA/L-PEI complex at various N/P ratios (N/P ratio: 1−10) or the siRNA/L-PEI complex (N/P ratio: 10) under serum-deficient conditions. (B) GFP express level of MDA-MB-435 cells transfected with siRNA/L-PEI complexes, L-PEI, and M-siRNA/L-PEI complex as a function of siRNA concentration in serum-containing medium (N/P ratio: 10). (C)RT-PCR analysis (lower panel) and corresponding densitometric analysis (upper panel) of VEGF mRNA level in PC3 cells transfected with M-siRNA/L-PEI and complex (N/P ratio: 10) as a function of siRNA concentration. (D) Cytotoxicity of M-siRNA/L-PEI complexes at N/P ratios ranging from 2 to 12. (E) Micro CT imaging of agarose-embedded MDA-MB-435 cells transfected with siRNA/L-PEI (left) and M-siRNA/L-PEI (right) complexes, each complex was prepared at an N/P ratio of 10.

distance between the two neighboring AuNPs is well-matched with a calculated length of an siRNA duplex structure. The surface plasmon peak of 5 nm AuNPs was also significantly red-shifted to 529 nm after hybridization (Figure 2D), resulting from the spatial 1-D alignment of AuNPs. To further prove that the observed 1-D assembled M-siRNA was indeed formed by complementary hybridization, AuNPs immobilized with single-stranded antisense siRNA were hybridized with dimerized single-stranded sense siRNA to double the spacing distance between the AuNPs. As shown in Figure 1B, the center-to-center distance between the two adjacent AuNPs was 11.1 ± 0.2 nm, consistent with the calculated length of a dimeric siRNA structure (Figure 2C), proving that AuNPs were cross-linked by complementary hybridization between two sense and antisense siRNAs immobilized onto the surface of two separate AuNPs.

Glutathione-Triggered Regeneration of Monomeric siRNA from M-siRNA. M-siRNA was incubated with glutathione (GSH, final concentration: 0−300 μM) to verify the intracellular regeneration of naked siRNAs. The formation of monomeric siRNA was examined by agarose gel electrophoresis. The thiol-Au linkages could be reduced by intracellular reductive molecules such as GSH.[29,30] As shown in Figure 3A, the complete release of monomeric siRNA can be observed at elevated GSH concentrations. This result shows that the AuNPs-mediated multimerized siRNA (M-siRNA) could be reductively disassembled to form monomeric siRNAs within cells.

Stability of M-siRNA against Enzymatic Degradation. To evaluate the stability of M-siRNA against enzymatic degradation, the fabricated M-siRNAs were mixed with 10 units of RNase with or without 100 μM GSH. As shown in Figure 3B and C, M-siRNA survived 82.2 ± 1.4% of siRNA units even after treating with 10 units of nuclease (band 2 in Figure 3B), while naked siRNA was almost completely degraded in 30 min (band 1 in Figure 3B). In the presence of GSH (100 μM) and 10 units of nuclease, 35.6 ± 2.1% of siRNA units in the M-siRNA remained intact due to the GSH-triggered detachment of siRNA.

Polyelectrolyte Complex Formation with L-PEI. Since multimeric M-siRNA structures cross-linked by AuNPs have increased charge density as compared to monomeric siRNA, they could more readily form nanosized polyelectrolyte complexes with oppositely charged cationic polymers. Previously, we demonstrated that multimeric siRNA cross-linked by reducible disulfide linkages produced far more stable and compact polyelectrolyte complexes with cationic polymers compared to monomeric siRNA, resulting in promoted cellular uptake and enhanced gene silencing efficiency.[14,15] This was caused by enhanced electrostatic interactions between multimeric siRNA and cationic polymers. M-siRNA polyelectrolyte nanocomplexes were prepared using L-PEI (M_w 25 kDa). In the atomic force microscopy (AFM) images, the resulting M-siRNA/L-PEI polyelectrolyte complexes exhibited a compact and spherical morphology at the N/P ratio of 10 (average diameter: 289 ± 31 nm) (Figure 4A). On the other hand, monomeric siRNA/L-PEI complexes showed loosely packed aggregates at the same N/P ratio (Figure 4B). TEM image also showed that the M-siRNA/L-PEI complexes contained numerous embedded AuNPs within the complex particle (Figure 4C; average diameter of 319 ± 36.24 nm). The formation of nanosized M-siRNA polyelectrolyte complexes could be attributed mainly to ionic interactions of L-PEI with cross-linked siRNA units and, more importantly, highly anionic phosphine-capped AuNPs .[31−33] The resulting complexes had a zeta potential value of +13.2 ± 3.4 mV (Figure 4D).[34]

Gene Silencing. The gene silencing effect of M-siRNA/L-PEI nanocomplexes was examined at various N/P ratios using GFP-expressing MDA-MB-435 cells (siRNA concentration: 1 μg/mL) under serum-deficient conditions. As shown in Figure 5A, M-siRNA/L-PEI complexes exhibited enhanced GFP gene silencing efficiency down to 46.9 ± 0.9% at an N/P ratio 10. The dose-dependent silencing efficiency of M-siRNA/L-PEI complexes was further investigated at an optimal N/P ratio (N/P ratio: 10) in the media containing 10% serum. M-siRNA/L-PEI complexes showed the gradual decrease in GFP expression in a dose-dependent manner (Figure 5B), while naked siRNA/L-PEI complexes only showed slight gene inhibition under the same conditions. The gene silencing efficiency of M-siRNA/L-PEI complexes was further evaluated via semiquantitative RT-PCR using siVEGF (VEGF-silencing siRNA), one of the most widely studied antiangiogenic siRNA for cancer therapy. As shown in Figure 5C, when siRNA concentration was increased from 0.17 to 1.0 μg/mL, the relative band intensity of VEGF gradually decreased. The gene expression levels were quantified by a densitometric analysis. As shown in Figure 5C, when the siRNA concentration was increased from 0.17 μg/to 1.0 μg/mL, the relative band intensity of VEGF decreased proportionally from 99.5 ± 6.3% to 47.8 ± 5.8% in a dose-dependent manner. It seems that the enhanced gene inhibition effect of the M-siRNA/L-PEI complexes might result from the enhanced cellular uptake.

Cytotoxicity. We also examined the cytotoxicity of the M-siRNA/L-PEI complexes as a function of N/P ratio using monomeric siRNA/L-PEI complexes (at the N/P ratio of 10) as a control. As shown in Figure 5D, the M-siRNA/L-PEI complexes displayed no significant cytotoxic effects against MDA-MB-435 cells. This could be attributed to the use of relatively lower N/P ratio for M-siRNA complexation relative to that for monomeric siRNA complexation that normally requires the N/P ratio of 40 for gene silencing.

CT-Imaging. To visualize cellular uptake, MDA-MB-435 cells were transfected with M-siRNA/L-PEI or naked siRNA/L-PEI complexes (N/P ratio 10) under serum-deficient conditions, the transfected cells were imaged using micro-CT. AuNPs have been widely studied as CT contrast agents for detection of various tissues, because Au atoms have a high electron density, resulting in strong X-ray absorption.[35] The CT value for M-siRNA/L-PEI treated cells (129.6 HU) was more than 4-fold greater than that for monomeric siRNA/L-PEI treated cells (15.8 HU) (Figure 5E). These results clearly demonstrate the intracellular uptake of M-siRNA/L-PEI complexes.

■ CONCLUSIONS

We demonstrated that the formation of 1-D assembled and multimerized siRNA could be achieved via complementary hybridization between single-stranded sense and antisense siRNA immobilized AuNPs. The multimerized siRNA significantly improved the enzymatic stability of siRNA and exhibited superior complex forming ability with cationic polymers due to its substantially increased charge density. These results suggest the possibility that the AuNP-mediated siRNA multimerization could be used for efficient gene silencing.

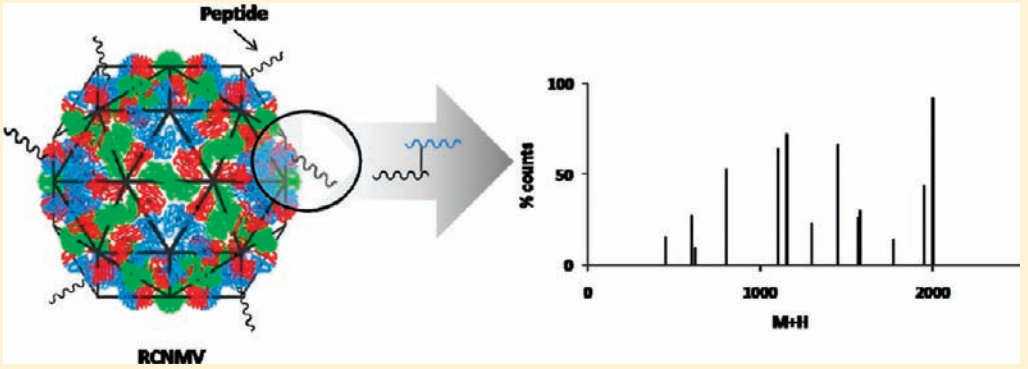
ABSTRACT:



Plant virus nanoparticle (PVN) formulations constructed from *Red clover necrotic mosaic virus* by drug infusion and targeting peptide conjugation can be employed as drug delivery tools. In this investigation, we studied the cross-linked structures formed by application of sulfosuccinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (sSMCC) and succinimidyl-[(*N*-maleimido-propionamido)-hexaethylene glycol] ester (SMPEG) as heterobifunctional linkers in the bioconjugation process. The plant virus formulations using several targeting peptides cross-linked to the plant virus capsid were characterized by LC/MS^E analysis, which produced at least 69% sequence coverage using trypsin and chymotrypsin digestion. The results showed evidence for several types of modification located in three domains of the capsid protein. Extensive linker modifications on lysines or cysteines were detected in all the domains, including both intended peptide−capsid cross-links and unintended intracapsid cross-links. Surprisingly, the most extensive peptide modification was observed in the R domain, which is thought to be quite inaccessible to peptides and cross-linking reagents in solution, since it is on the interior of the virus. These results show that heterobifunctional linkers may not be the most efficient method for attachment of peptides to plant virus capsids. As an alternative conjugation strategy, maleimide peptides were used to conjugate with the virus in a one-step reaction. Analysis by LC/MS^E showed that these one-step maleimide coupling reactions were more specific, such as modifications of C154 and to a lesser extent C267, and provide a means for achieving more effective PVN formulations.

INTRODUCTION

Red clover necrotic mosaic virus (RCNMV) is a soil-borne plant virus that has a robust and stable capsomere, which is common for the members of family *Tombusviridae*. The capsid is a $T = 3$ icosahedron composed of 180 subunits of a 37 kDa capsid protein (CP) in one of three conformations.[1] RCNMV has two nonhomologous RNAs, 3.9 kb polycisronic RNA-1 encoding the 37-kDa CP, RNA polymerase, and related protein,[2,3] and 1.5 kb monocistronic RNA-2 encoding for movement protein (MP).[4] The packaging of RNA into CPs is mediated by the trans-activator sequence located on RNA-2.[5] Gold nanoparticles attached to RNA-2 have been shown to promote self-assembly of the capsid leading to internalization of the nanoparticle in the presence of RNA-1 and CP.[6] Upon depletion of divalent ions, such as Ca^{2+} and Mg^{2+}, the virus has been observed to exist in an open-pore state.[7] There are 60 pores located at the threefold axes of the icosahedral structure. The pores have a diameter of 1.3 nm, which is sufficient for the RNA genome to diffuse out in the cytosol of plant cells. We have previously shown that preparation of the open-pore state permits drug infusion. Specifically, we have shown that ~900 doxorubicin molecules can be infused into the interior of the virus.[8] Attachment of targeting peptides to the infused virus would then make the plant virus nanoparticles (PVN) an ideal vector for targeted drug delivery.

There are three domains in the capsid protein subunits of RCNMV, RNA-interacting (R), shell (S), and protruding (P)

domains (Figure 1). The R domain consists of a series of arginines and lysines, which function to bind the RNA on the interior of the assembled capsid due to their positive charge at pH 7 and below.[7] Due to the disorder in the structure, 47 residues of the R domain, which are located adjacent to the N-terminus, are not shown in the RCNMV model. The S domain is essentially the lower part of Figure 1 (colored in blue) and P domain starts at residue 205 and is the protrusion above the S domain (colored in cyan).

This study of plant viruses follows earlier work using gold nanoparticles designed to target cells.[9−11] A certain number of the targeting peptides and bioconjugation methods are the same as those used in this study, except that bovine serum albumin (BSA) was used for conjugation rather than the capsid peptide of RCNMV. One impetus to use a plant virus as a biological nanoparticle is the greater colloidal stability of an organic composition relative to gold.[12−14] A second reason is the ability to control the precise location of targeting peptides due to the defined structure of the capsid. However, the latter advantage must be established by a characterization method, and the present study represents a first step in this direction.

Our objective is to develop an RCNMV-based nanoparticle as a drug delivery tool for cancer therapy. This paper is focused on discussing conjugation efficiency of such a formulation. Our starting point was to attach targeting peptides to the capsid using sulfosuccinimidyl 4-[*N*-maleimidomethyl]cyclohexane-1-carboxylate (sSMCC), which is used widely as a protein conjugation reagent. The reactive groups of this heterobifunctional linker consist of an *N*-hydroxysuccinimide (NHS) ester on one end, which can react with primary amines (usually lysines), and maleimide on the other that can react with thiolate groups (usually cysteines) via a Michael addition as shown in Figure 2.

Liquid chromatography−mass spectrometry (LC/MS) analysis has been proven as an effective and important technique in protein identification and characterization.[15] Ultra Performance (UP) LC/MS^E methodology was used in this study. Unlike conventional data-dependent acquisition (DDA) MS/MS, MS^E is a data-independent acquisition (DIA) approach, which gives an unbiased characterization of proteins with better sequence coverage.[16] During LC/MS^E analysis, the low collision energy scan provides information for precursor ion mass and intensity, while the elevated collision energy scan provides fragment ion data, whose correspondence to a certain precursor ion at a certain retention time is almost guaranteed by well-resolved peaks from UPLC.[17,18] Thus, it is an ideal tool for capsid protein characterization.

MATERIALS AND METHODS

Sequencing grade-modified trypsin was purchased from Promega (Madison, WI, www.promega.com). Acetonitrile (HPLC grade) and formic acid (ACS reagent grade) were from Sigma/Aldrich/Fluka (www.sigmaaldrich.com). Water was distilled and purified using a High-Q 103S water purification system (www.high-q.com). Unless noted, other reagents were purchased from Fisher or Sigma. Peptides used in the conjugation reactions with the virus are listed in Table 1.

PVN Formulation. A molar ratio of 1:2000 of purified and dialyzed RCNMV (5 mg/mL) and sSMCC cross-linker (0.5 mg/mL)

[a] All the peptides were synthesized and characterized by GenScript. [b] Receptor-mediated endocytosis and nuclear localization sequences derived from human adenovirus fiber protein.[44] [c] ADH peptide containing the HAV tripeptide can be recognized by N-cadherin, the upregulation of which is a sign of tumor progression.[45]

(Pierce) was mixed in 50 mM phosphate buffer, pH 7.2, at room temperature for 30 min. The yield of cross-linkers and peptides was studied to ascertain that the ratio of 1:2000 is optimized. While this ratio may seem relatively large, we note that RCNMV has 180 copies of CP, and each CP has 16 lysines, so that 1 equiv of RCNMV contains a total of 2880 lysines. Of course, not all of the lysines are reactive and there is an excess of unreacted sSMCC. Excess cross-linkers were removed by buffer exchange using the same phosphate buffer and a NAP-25 desalting column (GE Healthcare). For maleimide peptide conjugation, the above step was omitted. The second step for conjugating peptides was carried out by adding peptide (0.5−1 mg/mL) to the above solution and incubating under the same conditions overnight. The sample was subjected to buffer exchange using the same phosphate buffer and a G-25 size exclusion column to remove excess peptide. Quantification of RCNMV was determined by UV spectroscopy with an extinction coefficient of 6.46 ml•mg^{-1}•cm^{-1} at 260 nm (1 mg/mL, 1 cm path length).[19] Bicinchoninic acid (BCA) protein assay kit (Thermo scientific) was also used for protein quantitation. PVN samples studied include RCNMV, RCNMV-linker (-SMCC or -SMPEG), RCNMV-SMCC-Peptide (-GSGS, CD46, ADH304, and RME) and RCNMV-maleimide peptide.

Digestion. Samples were prepared and analyzed on a 4−12% bis-tris gel (NuPAGE, invitrogen) to separate any cross-linked RCNMV capsid protein and other byproducts. Bands of interest were excised and washed with 50 mM ammonium bicarbonate (pH 8.0) acetonitrile (1:1, v/v). Reduction with 10 mM tris(2-carboxyethyl) phosphine at 37 °C and alkylation with 27.5 mM iodoacetamide at room temperature were conducted for 30 min. After dehydration, each gel band was incubated with either trypsin (Promega) or chymotrypsin (Promega) overnight using an enzyme-to-protein ratio of 1:50 in 50 mM ammoniuim bicarbonate (pH 8.0). After digestion, the peptides were extracted with 50% acetonitrile/0.1% formic acid, and reduced to a volume of 30 μL. All the samples were filtered prior to LC/MS^E analysis.

Mass Spectrometry. Mass spectrometric analysis was performed with a Waters nanoACQUITY ultraperformance liquid chromatograph coupled a Q-Tof Premier mass spectrometer equipped with a Nanolockspray ion source. An injection of 8 μL of each sample was loaded onto a Waters Symmetry C18 trapping cartridge (300 μm i.d. × 1 cm length) at a flow rate of 10 μL/min, and then peptides were separated by gradient elution using a 75 μm i.d. × 25 cm column packed with BEH C18 matrix, 1.7 μm particle size (Waters), at a flow rate of 0.300 μL/min. Mobile phase A (99.9% water and 0.1% formic acid) and B (99.9% acetonitrile and 0.1% formic acid) were employed to elute peptides over a 60 min linear gradient of 2−40% B. Glu-fibrinopeptide (Sigma) at a concentration of 200 fmol/μL (m/z 785.8426) was infused via the Nanolockspray ion source at a flow rate of 600 nL/min and sampled every 30 s as the external mass calibrant. For MS^E acquisitions, alternate scans (m/z 50−1990) of 4 V for low-energy (MS channel) and 15 to 30 V for high-energy (MS^E channel) were set for data collection every 2 s. Raw data were processed by Proteinlynx Global Server v 2.4 (PLGS2.4, Waters), and the resulting files were searched against a database containing the RCNMV, trypsin, chymotrypsin, and human keratin sequences using the ion accounting algorithm ($IDENTITY^E$). Searching parameters of precursor and product ion tolerance (default setting), minimum number of product ion matches per peptide (3), minimum number of peptide matches (1), maximum number of missed cleavage sites (2), and a false discovery rate (4%) were used. Fragment ions of cross-linked peptides were analyzed by MS3D,[20] which is a web portal providing analysis of mass spectrometry data for a variety of cross-link peptides. The annotation of identified fragment ions was performed as previously described.[21] Virus peptides and conjugating peptides were defined as the α and β chain, respectively. Reported precursor and product ion masses are charge-state reduced and analyzed for isotopomers using PLGS, with intensities corresponding to the integration of ESI chromatographic peak areas. It has been shown that, with the ion detection algorithm, the given signal (intensity) is reproducible and quantitatively related to the concentration of peptide/protein.[17,18] Therefore, our quantification of conjugation yield is primarily based on comparing the intensities of precursor ions from intact and modified samples.

RESULTS

Protein Sequence Coverage of Native RCNMV. To ascertain the conjugation sites, acceptable protein sequence coverage of RCNMV is required. As shown in Figure 3, LC/MS^E analysis is able to achieve 48.1% and 33.6% amino acid sequence coverage using tryptic and chymotryptic digestion, respectively, resulting in total sequence coverage of 69.9% (usually between 58% and 69%). Other enzymes like pepsin and GluC were also tried, but no additional coverage was obtained. The lysines covered include those at positions K33, K38, K45, K102, K153, K176, K219, and K331, where we have used the standard one letter code K for lysine. For elucidating conjugation sites, we considered specific cases where the linker, inter-, and intramolecular cross-linking modifications were detected.

Evidence for Linker Modifications at K102/K103. Modifications of both nonhydrolyzed and hydrolyzed SMCC or SMPEG were detected at K102/K103 for the peptide (101)LKKLTLR(107). Given that the peptides with hydrolyzed and nonhydrolyzed linkers tend to have similar ionization efficiencies, precursor ion intensities of those peptides indicate that about half of the sSMCC and SMPEG linkers were hydrolyzed (Table 2). For the sSMCC sample, product ion data indicated both K102 (modified b_2 ion LK, unmodified y_5 KLTLR) and K103 (modified y_5 ion KLTLR) were modified at a relative ratio of 1:2 for both the hydrolyzed and nonhydrolyzed forms (Supporting Information Figure S1). For the SMPEG-labeled sample, modifications (in this case, we are referring to both hydrolyzed and nonhydrolyzed forms) were detected primarily

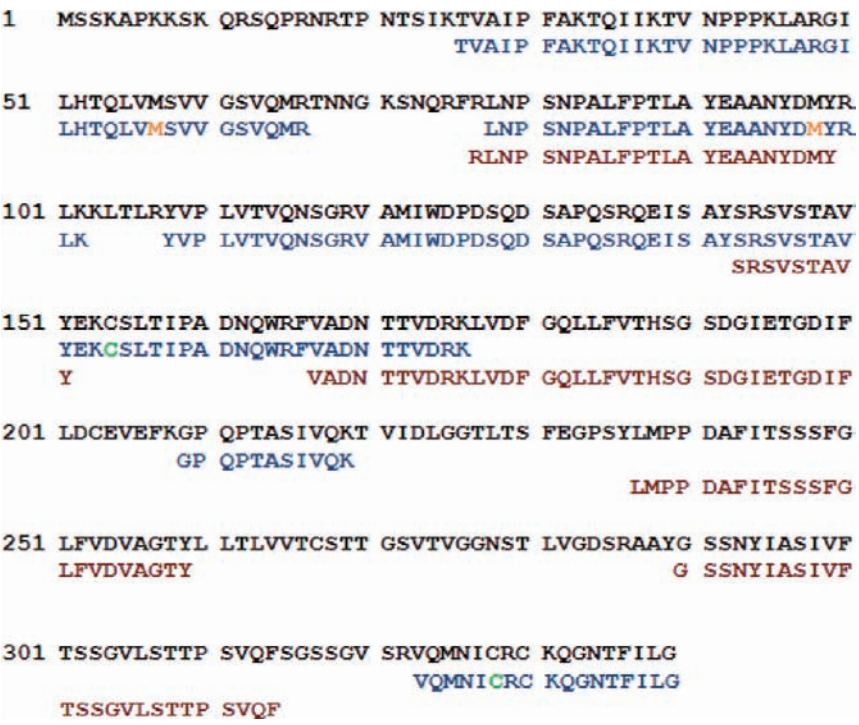

Figure 3. Coverage maps for native RCNMV. Sequence coverage for the tryptic (48.1%) and chymotryptic (33.6%) are colored in blue and purple, respectively. Oxidized methionine and alkylated cysteine are colored in orange and green, respectively.

Table 2. Intensities and Monoisotopic Masses of Precursor Ions for the Linker-Modified Capsid Peptide(101)LKKLTLR(107)

	SMCC		SMPEG	
precursor ion	intensity	$[M+H]^+$ cal/obs	intensity	$[M+H]^+$ cal/obs
nonhydrolyzed	4.27×10^4	1090.70/1090.70	1.17×10^4	1357.83/1357.64
hydrolyzed	3.92×10^4	1108.71/1108.71	1.05×10^4	1375.84/1375.84

at K103, indicating that K103 is more accessible to SMPEG than K102. These data together with the lack of identifying a conjugated peptide at K102 and K103 suggest that these residues are accessible and reactive to small molecules such as the sSMCC and SMPEG linkers, but not large molecules such as peptides.

Evidence for Intraprotein Cross-Linking at K153/C154. SSMCC is quite reactive, and it is therefore essential to determine the extent of side reactions in nanoparticle formulations where this reagent is used. For example, intramolecular cross-linking is possible when a lysine and a cysteine are sufficiently close to one another on the capsid surface. Identification of heterobifunctional cross-linker structural modifications at adjacent KC residues can be difficult because there are several possible fates for the bound sSMCC. As shown in Figure 4, the NHS-ester of sSMCC can amidate lysine (case 1) and the maleimidyl moiety can react with cysteine via a Michael addition (case 3). In either case, sSMCC can be hydrolyzed, as shown in cases 2 and 4, respectively. However, given the rapid hydrolysis rate of the ester, case 3 is not likely for the overnight incubations used in the method described here. Cysteines can also react with an NHS-ester and form a thioester bond (case 3), but since the bond is labile and susceptible to hydrolysis, this reaction is not considered important in our final preparation.[22] The final possibility is a cross-link between K and C on the same capsid protein (case 5).

All possibilities (Figure 4) can be divided into two groups according to their masses: cases 1 and 5 contain a nonhydrolyzed modification and cases 2 and 4 contain a hydrolyzed modification. Each type within the same group can be distinguished by examining the product ion spectrum generated from each precursor ion. Data from the sSMCC sample showed both modifications for the capsid peptide (145)SVSTAVYEKCSLTIPADNQWR(165). The hydrolyzed SMCC modification was assigned to cysteine because the y_{12} ion with the modification C(SMCC−OH)SLTIPADNQWR was present at a high abundance (~25%) relative to the other product ions (Supporting Information Figure S2). For the nonhydrolyzed SMCC modification, however, there was not a strong preference for case 1 or case 5 because no labeled b_9 ion or unlabeled y_{12} ion was detected, except for the occasional detection of some neutral losses that were close in mass to these ions. These results suggest that the sSMCC linker modifies either K153 or cross-links C154 and K153.

The analysis of the RCNMV sample conjugated with the SMPEG linker led to further insight regarding the possibility of cross-linking with a longer linker. In the SMPEG sample, only the hydrolyzed modification was found, and the labeled peptide

(152)EKCSLTIPADNQW(164) from the chymotryptically digested sample confirmed that the hydrolyzed linker on lysine (modified b_2) was present for the K153/C154 pair as opposed to an intraprotein cross-link between K153 and C154. This result supports the formation of an intraprotein cross-link at these residues by sSMCC. For SMPEG, the longer linker is statistically less likely to modify adjacent residues when one considers it as a freely jointed chain model.[23] The end-to-end length is equal to $\ell\sqrt{N}$ where ℓ is the PEG monomer spacing (the hypothetical bonds) and $N = 6$ for PEG6 (which is the SMPEG linker used in this study). This distance is significantly greater than the distance between the K153 amine nitrogen and the C154 sulfhydryl as estimated from the structure in the VIPER database (RCN7). These considerations agree with the lack of observed b_9 or y_{12} ions derived from the capsid peptide (145)SVSTAVYEKCSLTIPADNQWR(165) in the product ion spectra. The reason for the observed high hydrolysis yield of SMPEG can be found from studies performed in aqueous solution where it was shown that the high hydrophilicity of the PEG chain relative to the cyclohexane spacer in sSMCC[24] leads to near-complete hydrolysis of SMPEG. Intensities and scores of related precursor ions are shown in Table 3. Since the precursor ion of capsid peptide (145)SVSTAVYEKCSLTIPADNQWR(165) does not exist in the RCNMV sample, we have to use the other precursor ions (145)SVSTAVYEK(153) and (154)CSLTIPADNQWR(165) to quantify the modification. By comparing their intact precursor ion intensities for RCNMV and modified RCNMV samples, it can be estimated that about 30% of K153 and >90% of C154 are modified with sSMCC linker, while 75% of each residue was modified with the SMPEG linker.

Evidence for Intraprotein Cross-Linking at C330/K331. The adjacent amino acids C330 and K331 in the capsid peptide (330)CKQGNTFILG(339) displayed many of the features discussed above for K153/C154 residue pair. Peptide

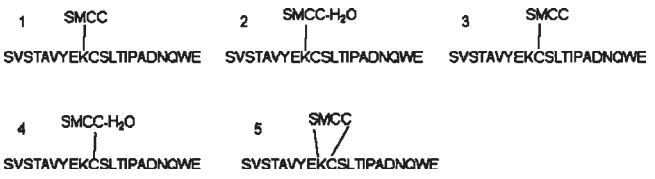

Figure 4. Schematic representation of five possible products for sSMCC conjugation of the peptide fragment (145)SVSTAVYEKCSLTIPADNQWR(165).

intensities of the unmodified peptides (330)CKQGNTFILG(339) and (332)QGNTFILG(339) (Table 3) from RCNMV and modified RCNMV samples were used to estimate the percentage of modification by sSMCC and SMPEG. The disappearance of the capsid peptide (330)CKQGNTFILG(339) in both samples suggested extensive modification. While peptide (332)QGNTFILG(339) can be generated from the capsid containing a modified C330 or unmodified CK, it is difficult to determine the accurate percentage of modification. In the sSMCC modified sample, at least 50% of K153 and C154 were modified. Similar to the K153/C154 residues, the SMPEG modification was observed only as the hydrolyzed form. Due to the lack of product ion formation for this region of the peptide, this modification can be on either K331 or C330. The increased intensity of (332)QGNTFILG(309) compared to the RCNMV sample indicated a significant amount of C330-modified sequence.

Overall, the stoichiometry of peptide conjugation of these two KC pairs is low (data not shown), partly due to severe cross-linking of these residues by sSMCC and hydrolysis of SMPEG. This is especially the case for K153/C154, since C154 is readily accessible to direct peptide conjugation (in the maleimide case shown below) but becomes protected if first exposed to the cross-linking reagents. While C330 is not accessible in the first place, the cross-linkers precluded the peptide conjugation step by modifying K331.

Extensive Modification of the R Domain Sites K33, K38, and K45. The R-domain contains a K-rich region from residues 26 to 48 with the sequence (26)TVAIPFAKTQIIKTVNPPPKLAR(48). Since trypsin cannot cleave at a modified lysine position, any identified peptides would be expected to contain one modified lysine in the middle of the peptide with an unmodified K or R at the N-terminus. For the K-rich sequence, there are three possible peptides, TVAIPFAKTQIIK, TQIIKTVNPPPK, or TVNPPPKLAR. Figure 5 shows the MS^E product ion spectra of the unmodified, sSMCC-modified, and sSMCC-GSGS peptide-modified peptide (26)TVAIPFAKTQIIK(38) at K33 obtained from the conjugated RCNMV sample. All three of the K-rich capsid peptides had similar fragmentation patterns with the most abundant ion being y_{13} (the precursor ion) at m/z 1429.88, 1648.97, and 2115.11, followed by y_9 and y_{11} ions, and then b_3 and b_4. By comparing intensities of intact precursor ions ((26)TVAIPFAK(33) and (26)TVAIPFAKTQIIK(38)) of native RCNMV to those of the conjugated sample (Table 4), it can be concluded that about 20% of K33 was modified with sSMCC, and 2/3 of those modifications also had an attached

GSGS peptide. Another sample containing the K33 modification with a peptide is RCNMV conjugated with the CD46 peptide. The precursor ion TVAIPFAK(~LSTSFC)TQIIK was identified manually with a calculated/observed m/z 2305.25/2305.26 (Supporting Information Figure S3). Representative product ions for the GSGS and CD46 conjugated peptides are listed in Table 5.

The modification of K38 in the sequence (34)TQIIKTVNPPPK(45) was even more extensive than K33. Several peptide sequences were conjugated at K38. In the CD46 sample, the precursor ion of peptide (TQIIK(~LSTSFC)TVNPPPK) was detected at the calculated/observed m/z 2211.17/2211.16 with an abundance that far exceeded the other fragment ions (Figure 6A) indicating that the collision energy settings used in the acquisition were not high enough to induce extensive fragmentation and generate highly abundant product ions. However, inspection of the product ions generated revealed

[a] All intensities have been normalized to the value of the corresponding precursor ion.

additional evidence for labeling at this position (Figure 6B). Fragment ions $y_{9\alpha}y_{6\beta}$ and $y_{10\alpha}y_{6\beta}$ (which contains the full LSTSFC peptide modification) were detected, as well as the $y_{12\alpha}y_{2\beta}$ and $y_{12\alpha}y_{1\beta}$ ions (which contain the intact capsid peptide). In addition, an extensive set of fragment ions from both the C- and N-terminus were observed, such as unmodified b_2-b_4 and y_2-y_7 ions for the capsid peptide (α chain). The virus sample conjugated with the ADH304 peptide TQIIK(~AHAVDINGNQVC)TVNPPPK showed a similar modification and fragmentation pattern to the CD46 labeled peptide, but was detected at a much lower intensity (Supporting Information Figure S5) at the calculated/observed m/z 2793.47/2793.48. The K38 residue was also modified with the GSGS peptide and was detected as TQIIK(~GSGSGC)TVNPPPK at the calculated/observed m/z 2021.06/2021.04. (Supporting Information Figure S4) Table 6 lists product ion intensities and monoisotopic masses for peptide conjugates of (34)TQIIKTVNPPP(44).

For the CD46 labeled sample, K45 was also found to be modified to some extent, as in the capsid peptide sequence (39)TVNPPPKLAR(48). The peptide TVNPPPK(~LSTSFC)LAR was the most abundant ion at the calculated/observed m/z 1968.02/1968.03. The fragmentation pattern of this particular cross-linked peptide (Figure 7) generated a series of moderately abundant y_α ions containing an uncleaved β peptide (i.e., viral peptide fragments containing the intact LSTSFC peptide) covered with moderately high intensity and a series of doubly fragmented product ions with both peptides cleaved, including $y_{8\alpha}y_{1\beta\text{-}4\beta}$, $y_{7\alpha}y_{1\beta\text{-}5\beta}$, $y_{6\alpha}y_{1\beta\text{-}4\beta}$; however, single peptide ions such as y_ω, b_ω and y_β were less numerous with diminished intensity.

On the basis of these data, K33, K38, and K45 are unequivocally modified. Among them, K38 had the greatest range of

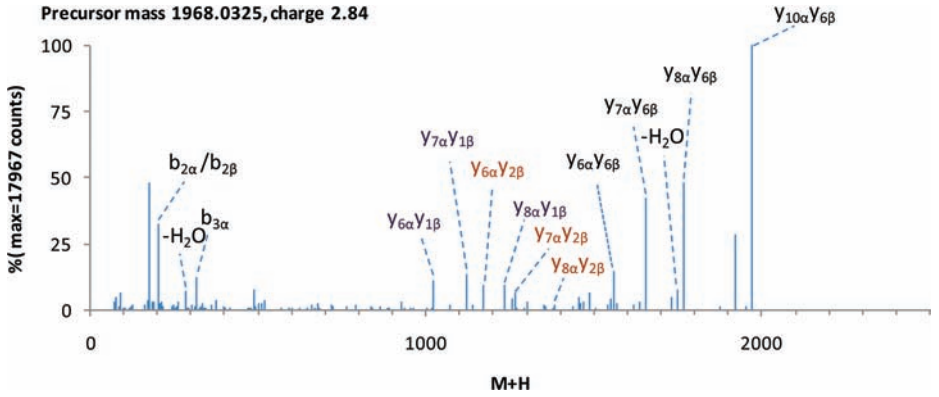

Figure 7. Portion of the MS^E product ion spectrum pertinent to conjugate peptide identification of TVNPPPK(~LSTSFC)LAR from the CD46 sample. Doubly fragmented product ions $y_{8\alpha}y_{1\beta\text{-}4\beta}$, $y_{7\alpha}y_{1\beta\text{-}5\beta}$, and $y_{6\alpha}y_{1\beta\text{-}4\beta}$ were detected, but only those with higher intensities are labeled.

conjugation including the GSGS, CD46, and ADH304 peptides, followed by K33, which was conjugated to the GSGS and CD46 peptides, while K45 was only conjugated to the CD46 peptide.

Indirect Evidence of Modification for K208 and K219. Examination of the coordinates of RCNMV in the VIPER database revealed that K208 and K219 are the two surface lysines in the P domain that appear most likely to be modified. However, it proved difficult to detect a modified lysine in this region because of poor sequence coverage. Aside from K208 and K219, there is no other Lys or Arg for tryptic digestion in the capsid sequence ranging from K176 to R286. Moreover, chymotrypsin lacks cleavage sites between residues 201 and 236. Given that trypsin only cleaves unmodified Lys residues, the capsid peptide (209)GPQPTASIVQK(219) can be observed only when both lysines are unmodified. If either lysine was modified, the abundance of this peptide would be reduced. Therefore, it was possible to infer that modification occurs in this region based on the relative intensities of (209)GPQPTASIVQK(219) in the modified and unmodified samples. Table 7 lists the intensities of the capsid peptide fragment ions detected for various conjugation samples. The coverage of fragment ions was sufficient for all of the samples that it was possible to detect the decrease in intensity that would be expected in a modified capsid peptide, which indicate that K208 and K219 must be modified to a significant extent. Table 7 also lists the intensities for (137)QEISAYSR(144), a reference capsid peptide that does not contain K or C residues. For each labeling reaction analyzed, the reference capsid peptide did not elicit a significant reduction in intensity for the sSMCC or peptide-conjugated samples compared to the intact RCNMV sample.

Evidence for Cysteine Labeling by Maleimide Peptide Modification. Given the cross-linking, aggregation, and hydrolysis issues of the sSMCC linker that were observed at the capsid sites discussed above, we turned to an alternative strategy for peptide labeling of the PVN. The characterization of cross-conjugated samples here correlated with modest targeting in samples studied using *in vitro* cell culture (data not shown). On the basis of these results, we adopted a different strategy using a maleimide-labeled ADH304 peptide which permitted the PVN-peptide conjugation reaction at Cys residues to be performed in a single step. Out of the five cysteines (154,203,267,328,330) in RCNMV, three (154,328,330) were contained in peptides identified from the unmodified RCNMV sample. Following conjugation with maleimide-modified ADH304, only C154 was detected as being labeled with the MS data appearing in Figure 8. The most abundant ion was the precursor ion at the calculated/observed m/z 2819.35/2819.37, which is consistent with the behavior of other cross-linked peptides observed using the LC/MS^E mode of acquisition. A series of y-ions for the virus peptide (α chain) were generated, including $y_{1\alpha}$ to $y_{5\alpha}$, $y_{8\alpha}$, $y_{10\alpha}$ and $y_{11\alpha}$. All b-ions of the ADH304 peptide (β chain) were produced except $b_{8\beta}$. Doubly fragmented ions were also detected as indicated in Figure 8C. Those ions that contain both one cleaved and one intact peptide, the $y_{12\alpha}y_{1\beta}$, $b_{4\alpha}y_{12\beta}$, and $y_{12\alpha}y_{2\beta}$ ions, had relatively high intensities, but also observed are ions containing cleavage events in both the capsid and ADH304 peptides with most of these ions having a single Cys or Lys residue (Lys preferred) attached to the linker, such as $b_{5\alpha}y_{1\beta}$, $b_{7\alpha}y_{1\beta}$, $b_{1\alpha}y_{11\beta}$, $b_{4\alpha}y_{1\beta}$. These data indicate that the fragmentation for this peptide cross-link is similar to that of a normal single peptide, which is expected due to the linker connecting the nitrogen side chain of the C-terminal Lys residue of the ADH304 peptide to the sulfhydryl side chain of the N-terminal Cys residue of the virus peptide. Thus, it is less likely that product ions containing both α and β peptides will be observed, particularly those with both incomplete peptide fragments. By comparing the intensity of the unmodified and modified RCNMV sample, we estimated that the percentage of ADH304 peptide conjugation is around 50%.

Overall Stability of the PVN Formulation. Modified PVN samples are prone to aggregation after more than two weeks of refrigeration at 4 °C. Figure 9 shows two distinct bands in the gel electrophoresis of the aged sample. The upper band has the same molar mass as the original virus capsid protein. The other

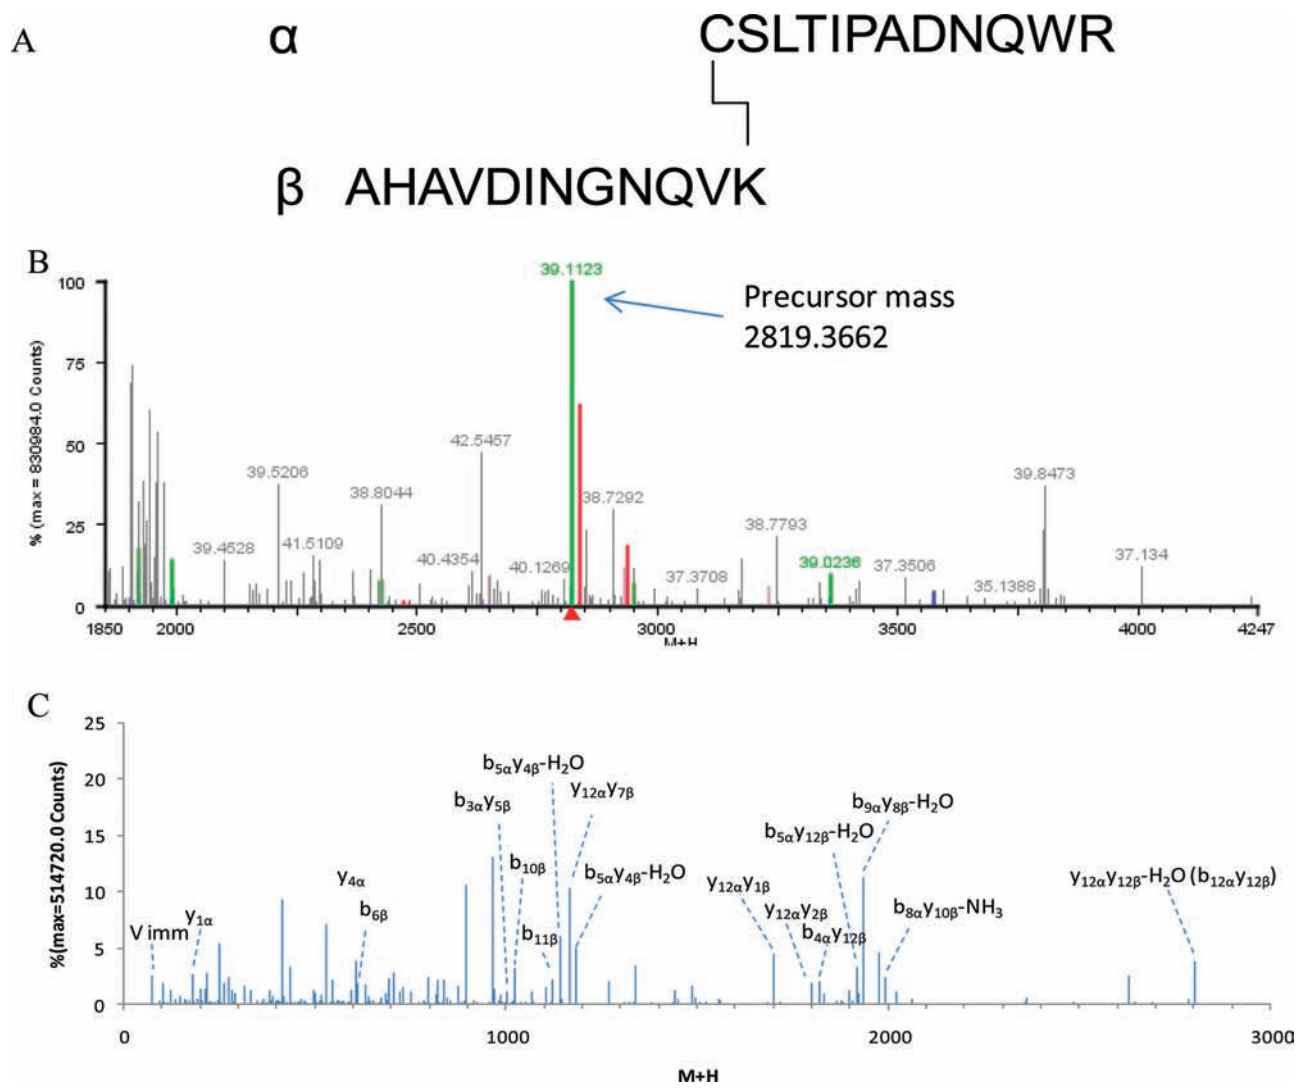

Figure 8. Detection of conjugated peptide C(ADH peptide)SLTIPADNQWR from the one-step labeling reaction of RCNMV with the maleimide-ADH304 peptide. band of lower molar mass may be the product of an autodigestion of the capsid protein. While this phenomenon is observed to some extent in native RCNMV, it appears that the conjugation of linkers and peptides accelerates the process. The coverage map on the upper and lower bands are found to be similar: both of them have coverage at the C-terminus and no coverage at the N-terminus (data not shown), indicating that the degradation probably starts from N-terminus. The capsid protein modification resulting from the maleimide ADH304 peptide

was observed in samples from the lower bands but not the upper bands.

DISCUSSION

The construction of plant virus nanoparticles for targeted drug delivery is a novel strategy, which has been described in a few reports. *Cowpea mosaic virus* (CPMV) has been conjugated with

a folic acid-PEG by Cu(I) catalyzed azide−alkyne cycloaddition (click chemistry[25]). Specific recognition of the resulting nanoparticle by tumor cells bearing the folate receptor was observed.[26] Doxorubicin loaded, folic acid conjugated *Hibiscus chlorotic ringspot virus* (HCRSV) nanoparticle was shown to increase the uptake and cytotoxicity of doxotubicin in ovarian cancer cells.[27] In addition, modification of antitumorgenesis peptide on the viral cage of *Cowpea chlorotic mottle virus* (CCMV) has been investigated and verified.[28] We have recently reported a similar strategy in RCNMV, where doxorubicin-loaded capsids[6] were functionalized with various targeting peptides using sSMCC.[26] The present study was motivated by the need for better process control during scale-up of the procedure for *in vivo* testing. Mass spectrometry analysis has been used to study virus−peptide conjugation using sSMCC and a variety of peptides. During the course of this work, it was realized that the complexity of the surface chemistry was hampering reproducibility and colloidal stability of the formulation. A simpler approach using a maleimide-modified peptide was employed and compared to bioconjugation using sSMCC.

The bioconjugation of peptides to a plant viral capsid is a key step in the development of a cell targeting technology. In our initial design for conjugation, we identified two surface lysines (K208 and K219) and one surface cysteine (C267) in the P-domain that were most accessible for bioconjugation. The data show that these sites are among the most difficult to detect by mass spectrometry due to poor sequence coverage in that region of the P-domain. Ironically, the R-domain (M1-L46) on the interior of the capsid is the region where modification by sSMCC and peptide conjugation was most easily detected by MS analysis. It was somewhat surprising that modification was so extensive in the R-domain. However, it is logical that the sheer number of lysines in the R-domain could influence the distribution of targeting peptides if they are accessible to some extent. For example, accessibility could arise from penetration of the capsid by relatively hydrophobic peptides. Alternatively, it is possible that capsid proteins may have alternative conformations that expose the R-domain. Conjugation in the S-domain (A47-E204) and P-domain (V205-G339) was also detected. However, in these regions the two cysteine−lysine pairs (K153/C154 and C330/K331) led to significant cross-linking or hydrolysis, and little conjugation of peptide. Residues K208 and K219 were observed indirectly using relative peptide intensities in conjugated and unconjugated samples. These sites did indeed show significant linker or peptide conjugation. On the basis of these MS results, we reasoned that a maleimide peptide coupling strategy would be superior to sSMCC and SMPEG cross conjugation. Indeed, coupling of a peptide to C154 was observed. Below, we discuss the relative efficiencies of the various sites and the issues of hydrolysis and cross-linking that were observed for the sSMCC and SMPEG linkers and finally conclude with a discussion of a maleimide peptide labeling strategy, which was ultimately used for both *in vitro* and *in vivo* studies.

Peptide Coupling Efficiencies. In this report, the effectiveness of sSMCC and SMPEG cross conjugation of RCNMV to the peptides CD46, GSGS, and ADH304 was explored by mass spectrometry analysis. The peptides were chosen as practical examples used in cell targeting experiments.[29] These peptides provided information on length and sequence-specific effects. Comparison of GSGS, CD46, and ADH304 peptides suggests that bioconjugation efficiency decreases as peptide length increases. One possible reason for this is a lower probability of approaching the conjugation site on the capsid surface due to steric hindrance. However, it must also be considered that the fragmentation for the larger $\alpha\beta$ peptide ions from the cross-linked peptide conjugate is less efficient, resulting in lower MS detection efficiency (see Supporting Information Figures S4−S6 for examples).

Most importantly, the MS results reveal aspects of capsid dynamics that are not evident from inspection of the structure. Peptide conjugation was mostly confined in the R domain, which is an inside region of the virus capsid according to the cryo-EM structure.[7] However, the R-domain may be accessible to the conjugating peptide because of a conformational change in the capsid that occurs under the labeling reaction conditions. Native RCNMV is most stable at pH 6.0, but while at pH 7.2 or even 8.0 during infusion, according to the observation of related viruses, it may swell and cause the disordered R domain to protrude out of the virion and become solvent exposed.[6,30,31] Results from MS analysis on degraded products also verify this hypothesis in that the N-terminus (R domain) is most likely responsible for degradation. In addition, the infusion step, as well as conjugation of linker/peptide on other sites, may also promote conformational changes and expose the R domain.

Unfavorable Side Reactions Observed Using sSMCC and SMPEG Linkers. sSMCC has been used as a cross-linker in various systems involving proteins/peptides,[32−34] especially in the field of nanotechnology where modification of nanoparticles such as quantum dots, virus, or virus particles are involved.[28,35−38] For example, sSMCC has been used to link bisphosphonate to synthetic salmon calcitonin, which is a 32 amino acid hormone with two lysines.[39] The reactions were monitored by MALDI-TOF analysis, and products with diverse numbers of SMCC/BP conjugates were observed.[39] Indeed, sSMCC has been effective in most cases, exemplified by bovine serum albumin, which contains numerous reactive lysines.[40,41] However, the application of sSMCC must be used with caution. It has been found that sSMCC destabilizes silica nanoparticles and causes aggregation.[42] There are several reports of both inter- and intra-cross-links by sSMCC in bioconjugation studies.[36,37] Our results also showed a significant degree of intercapsid cross-linking for RCNMV indicated by the gel shown in Figure 10 and the possibility of intracapsid cross-linking at position K153/C154 and C330/K331 based on LC/MS^E analysis, as discussed above.

Hydrolysis is also a problem for both the NHS ester and maleimide groups, which becomes overwhelming in the case of the SMPEG linkers. Since both NHS ester and maleimide groups on sSMCC can be hydrolyzed by hydroxide ions, it is very important to conduct the reaction at well-defined pH values to obtain the highest reaction efficiency. The nucleophilicity of lysine and cysteine is also quite pH-dependent, so there is a competition between the desired reactions of lysine and cysteine and the undesired hydrolysis reactions. For example, the ester is a very reactive group and may be hydrolyzed prior to reaction with lysines, which then may result in modification on cysteines. In the second hour-long incubation step, the maleimide may also be hydrolyzed. All of these factors can lead to the decrease of peptide conjugation efficiency. sSMCC is used instead of the uncharged variant SMCC because of the higher solubility conferred by a charged moiety. However, protocols call for the use of dimethylsulfoxide (DMSO) even when sSMCC is used. This fact underscores the issue of solubility of the reactant and possible lowered solubility of the bioconjugation product.

Finally, there was a significant amount of aggregation in the samples prepared using sSMCC that may have arisen from the bioconjugation chemistry. One cannot exclude the possibility that peptide modification itself reduces the colloidal stability of the plant virus, RCNMV. Of course, interprotein cross-linking is possible, which also reduces colloidal stability. These complexities led to consideration of an alternative strategy using a single site conjugation of a maleimide peptide.

Use of a Maleimide-Labeled ADH Peptide. A maleimide peptide was used to test whether a single-step conjugation to cysteine residues would result in a greater efficiency with fewer side reactions. Since a one-step reaction eliminates all the complex possibilities brought by the linker and with fewer virus reaction sites (five cysteines vs sixteen lysines), MS identification became much more straightforward. The results showed one out of three identified cysteines (C154) as being modified with the maleimide peptide. Although C267 appears to be quite solvent accessible based on the RCNMV structure, there is no direct evidence for coupling at this amino acid due to lack of capsid sequence coverage. However, we can infer that this amino acid is accessible based on analysis of the cysteines with spin labels. Electron paramagnetic resonance (EPR) analysis demonstrated the existence of the spin label on one cysteine residue of the virus, while MS showed negative results on the three covered cysteines of the RCNMV-spin labeled sample (data not shown). We deduce that the label has to be on one of two cysteines (C203 and C267) not covered by peptides obtained from the tryptic and chymotryptic digests. Since C267 is the more exposed cysteine, it is probably the one modified with the spin label, and there is reason to believe that the maleimide peptide may react with C267 as well.

Mass Spectrometry Assignments. Because of the specific nature of the peptide conjugation in RCNMV, and the difficulties associated with efficient fragmentation of large molecules using CID, the automated approach to MS data analysis was not always able to identify cross-links. As a result, we manually inspected product ion spectra especially in cases of peptide conjugation where a precursor ion was detected with sufficient abundance. Because the PLGS/ion accounting searching, described in the methods section, is only available for analysis of un-cross-linked peptides that contain modifications, the conjugated peptide to the virus must be treated as a fixed mass modification, and thus its fragmentation cannot be interpreted. In addition, the probability of identifying the conjugated peptide is reduced due to the preferred fragmentation of the peptide at residues distal to the cross-linked residues. Even in several cases where the cross-linked capsid peptide is identified due to its preferred fragmentation over that of the conjugated peptide, additional data acquisition using alternative CID energies will need to be developed to more confidently identify these peptide—peptide cross-links. As an alternative, we used MS3D to initially process the cross-link-peptide data and search for product ions, which was followed by manual inspection.

Automated software assignment can also fail when there is more than one modifiable residue in a capsid peptide. For instance, in the R domain where a capsid peptide contains two lysines, the software occasionally assigns a modification to the last K in the sequence, which is not possible if the peptide were generated by tryptic digestion (unless the lysine was the C-terminal residue of the protein). For example, in RCNMV samples conjugated with the GSGS peptide, capsid peptide (26)TVAIPFAKTQIIK(38) was found modified by sSMCC and the sSMCC-GSGS peptide. Software assigned the sSMCC modification on K33 and sSMCC-GSGS peptide modification on K38. The reason for the assignment was probably the presence of y_6 ion (K*TQIIK) containing the sSMCC modification and the b_8 ion (TVAIPFAK) without GSGS peptide modification. During CID, the peptide modification can be lost due to cleavage to produce an ion whose mass may match a b or y ion within the error tolerance used during automated database searching. This phenomenon is most frequently observed for modifications between capsid peptides and sSMCC. Thus, manual analysis of product ion spectra is necessary in these cases.

CONCLUSION

We have systematically investigated the conjugation of the capsid protein of RCNMV in formulations used as plant virus nanoparticles (PVNs). In these formulations, the capsid is sometimes infused with a chemotherapeutic cargo. Our focus here has been the chemical attachment of targeting peptides for *in vitro* and *in vivo* cell targeting applications. We have shown, by direct observation, that sSMCC, as a heterobifunctional linker, leads to attachment of peptides at several sites: K33, K38, and K45. Using the mass spectral data, we deduced that there is attachment at K208 and K219, although unfortunately we lack capsid sequence coverage to permit direct detection. However, there are significant disadvantages for the application of sSMCC as a heterobifunctional linker, which include intracapsid and intercapsid cross-linking and attachment of sSMCC to sites that peptides cannot access. The net effect of this unfavorable attachment is poor colloidal stability and unpredictable formulation conditions that depend strongly on the degree of hydrolysis of the sSMCC during the actual formulation. Since these factors are difficult to precisely control, sSMCC cannot be used for formulations of PVNs intended for clinical applications.

The present study also shows that a maleimide-peptide approach provides relatively efficient coupling and relatively high colloidal stability. Other than C154, the maleimide-peptide may also be attached at C267. However, this attachment could not be confirmed by mass spectrometry analysis due to the lack of capsid peptide coverage in the vicinity of C267. On the other hand, a parallel investigation using nitroxide spin-labeled RCNMV strongly suggests that C267 can be labeled. As a consequence of the present study, formulations of the maleimide-labeled ADH peptide were used for successful *in vivo* studies that will be discussed elsewhere.[43] As a result, the use of data-independent LC/MS^E has been established as a key method for the characterization of PVN formulations and will be valuable in future work using other formulations.

UPLC data and MS^E chromatograms

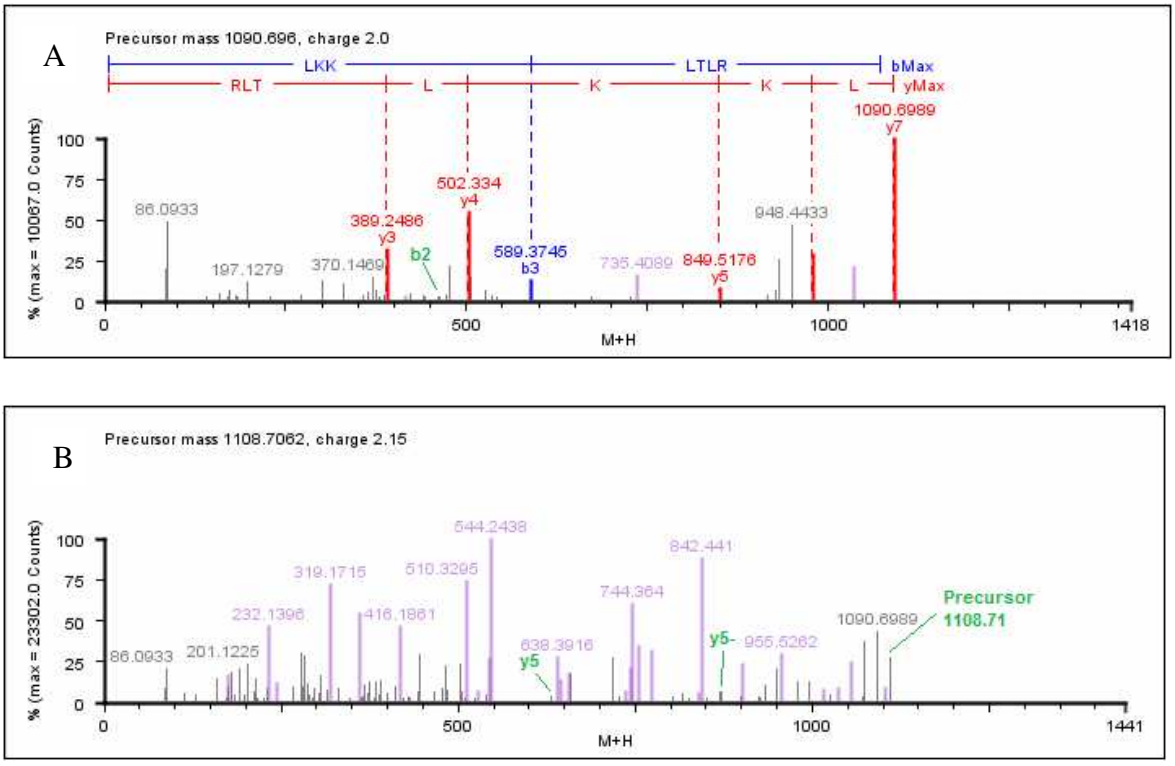

Figure S1. LC/MS^E analysis of SMCC labeling of RCNMV. (A) MS^E product ion spectrum of (101)LKK(SMCC)LTLR(107) with the b_2 ion containing the modification indicated in green. (B) MS^E product ion spectrum of (101)LKK(SMCC-OH)LTLR(107) with the y_5 ion without modification (lower mass value) and the y_5 ion with modification (higher mass value) indicated in green.

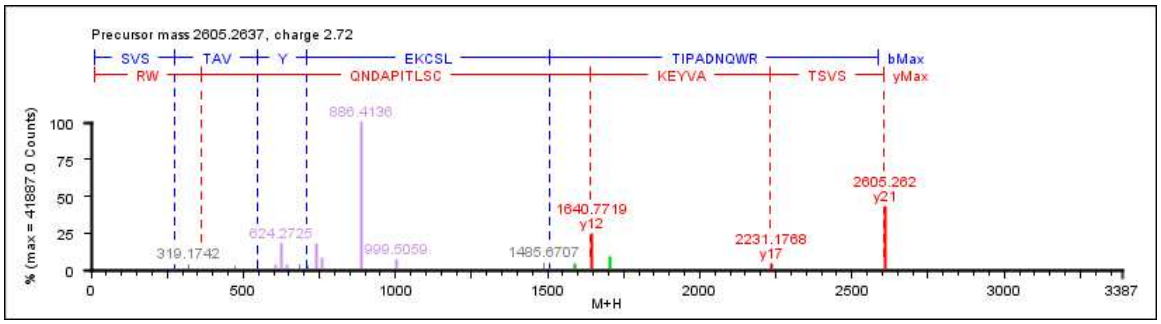

Figure S2. MS^E product ion spectrum of (145)SVSTAVYEKC(SMCCOH)SLTIPADNQWR(165) generated from the sSMCC conjugated RCNMV sample.

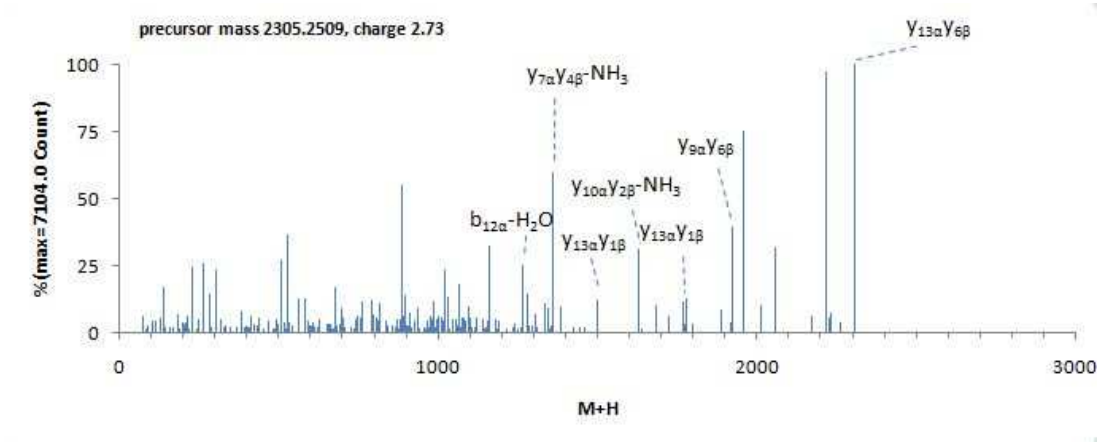

Figure S3. MS^E product ion spectrum of TVAIPFAK(~LSTSFC)TQIIK generated from the RCNMV conjugated with the CD46 peptide. The most abundant ion $[M+H]^+$ at *m/z* 2305.25 corresponds to the intact peptide conjugate. Representative crosslinked peptide product ions are shown. Although not labeled, single peptide ions $y_{1\alpha}$, $y_{5\alpha}$, and $b_{7\alpha}$ were dectected for the capsid protein.

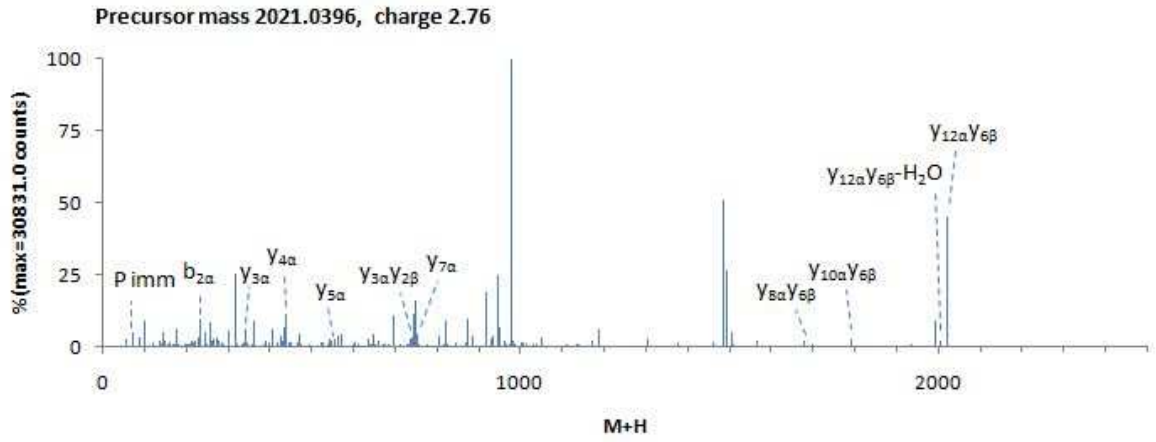

Figure S4. MS^E product ion spectrum of (26)TVAIPFAK(~GSGSC)TQIIK(38) generated from the RCNMV conjugated with the GSGS peptide. The most abundant ion $[M+H]^+$ at *m/z* 2021.04 corresponds to the intact peptide conjugate. Representative crosslinked peptide product ions and single peptide product ions are shown. Although not completely labeled, all b and y ions for the capside peptide (α chain) were detected except y_1, y_6, and b_4; all b ions for GSGS peptide (β chain) were detected.

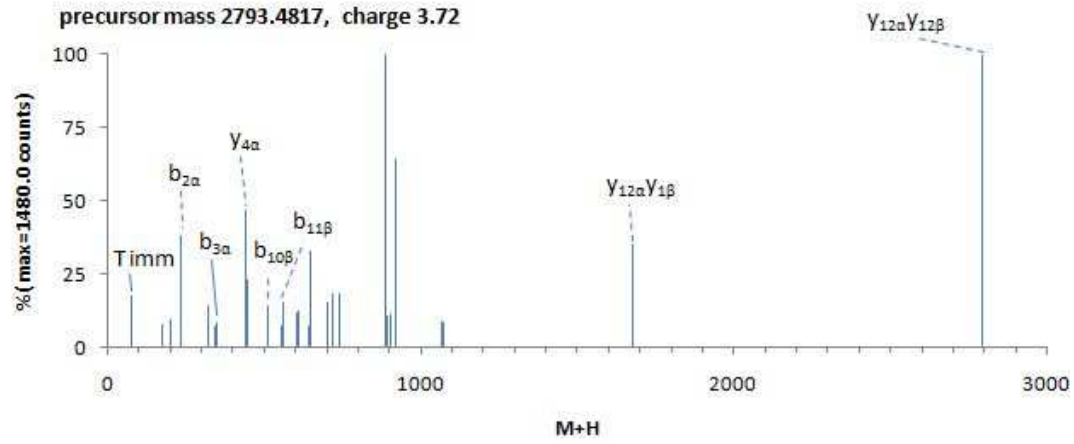

Figure S5. MS^E product ion spectrum of (34)TVAIPFAK(~AHAVDINGNQVC)TQIIK(45) generated from the RCNMV conjugated with the ADH304 peptide. The most abundant ion $[M+H]^+$ at *m/z* 2793.48 corresponds to the intact peptide conjugate. Representative crosslinked peptide product ions and single peptide product ions are shown. Although not labeled, product ions b_1, b_2, y_1, y_3-y_5 for capsid (α chain) were detected, and b_{10} and b_{11} ions for the ADH peptide (β chain) were detected.

Use of various proteases for digestion of RCNMV to extend peptide sequence coverage

In order to dectect capsid peptide sequencesnot covered by trypsin and chymotrypsin digestion, other enzymes were used. Pepsin has a primary digestion site at F, W, Y, E, and I residues, but further digestion can be random. Digestion was performed in 10 mM HCl, and after certain time, the reaction was quenched by adding 7uL of 100mM sodium phosphate buffer (pH~8.0) to increase the pH above 7. Then the sample

was frozen at -20℃ until further processing could be performed. Urea (8 M) or heating in

a boiling water bath (5 min) was used to unfold/denature the protein. The method was applied on bovine serum albumin (BSA) as a reference. Ratios of pepsin and RCNMV from 1:5 to 1:500 (wt: wt) were investigated.

The results of the pepsin digestion using a 1:100 ratio of pepsin:RCNMV (wt:wt) are shown in Figure 5. For the first few minutes, the virus was digested very quickly, but appeared to be arrested within 5 min as indicated by the large protein/peptide pieces that were left undigested. The reason for this result cannot be self-digestion or inactivation of the protease since pepsin was able to be detected in the control sample (Lane P). To attempt to circumvent this problem, additional pepsin was added at time points 15, 30 and 45 min after the initiation of the reaction to ensure that active pepsin was present in the solution during the course of the digestion. This approach promoted further digestion, but incomplete RCNMV digestion was still evident.

LC/MS^{E} analysis of RCNMV digested by pepsin did not provide reproducible results. Some samples had higher coverage but questionable peptide identications. By examining the masses of these peptides, we found that the majority of them are below 1000 Da which were difficult to identify due to the low number of product ions. This agrees with the SDS-PAGE results, in that pepsin seemed to digest only the solvent accessible part of the virus, but was not able further access the virus. In contrast, trypsin

(Lane Try) was able to more completely digest the virus except for the 6-10 kDa segments were no cleavage sites were available. In an attempt to obtain sequence information regarding this 6-10 kDa segment, in-gel digestion of this region was performed using pepsin but the small peptides generated precluded peptide detection.

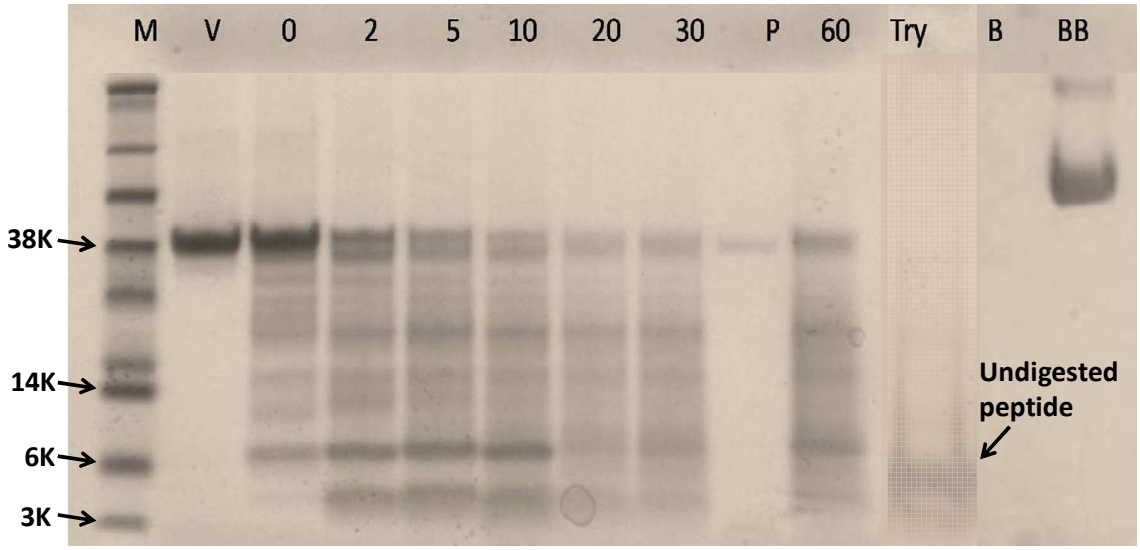

Figure S5. Combined SDS-PAGE analysis of RCNMV digestion using pepsin. For digestion, a ratio of 1:100 (pepsin:virus, wt:wt) was used. M=marker, V=virus, P=pepsin, Try= Trypsin digestion overnight, B=BSA, BB=BSA blank, and numbers=#minutes of digestion . Proteins were stained with coomassie blue.

GluC hydrolyzes proteins at glutamic acids and aspartic acids (much slower) in ammonium bicarbonate aspartic acids buffer at pH 4.0 or phosphate buffer at pH 7.8. GluC was explored as a possible avenue to increase capsid sequence coverage because there are several D and E residues in the region 176-286 where trypsin does not give adequate coverage. Unfortunately, GluC digestion did not meet our expectations. As indicated by SDS-PAGE analysis in Figure S6, GluC did not digest the capsid protein significantly in either buffer despite digesting overnight and using a 1:20 ratio of GluC:virus (wt:wt).In addition, no useful data were obtained by LC/MS^{E} analysis.

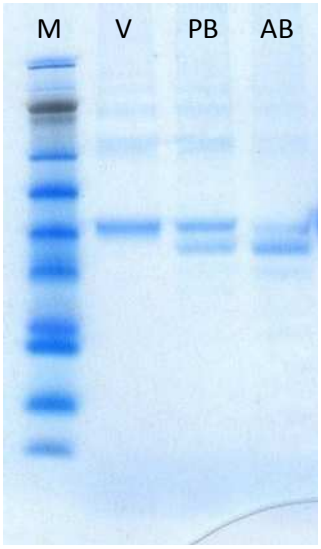

Figure S6. SDS-PAGE analysis of RCNMV digestion using GluC. For digestion, a ratio of 1:20 (GluC:virus, wt:wt) was used. M=marker, V=virus, PB=phosphate buffer, and AB= ammonium bicarbonate buffer. . Proteins were stained with coosmassie blue.

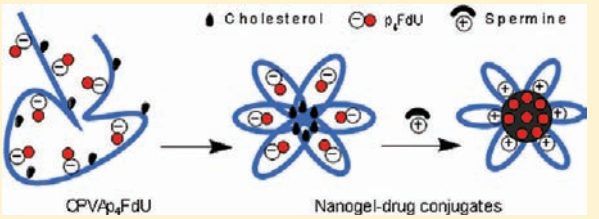
Supporting Information

ABSTRACT: Inherent or therapy-induced drug resistance is a major clinical setback in cancer treatment. The extensive usage of cytotoxic nucleobases and nucleoside analogues in chemotherapy also results in the development of specific mechanisms of drug resistance, such as nucleoside transport or activation deficiencies. These drugs are prodrugs; and being converted into the active mono-, di-, and triphosphates inside cancer cells following administration, they affect nucleic acid synthesis, nucleotide metabolism, or sensitivity to apoptosis. Previously, we actively promoted the idea that the nanodelivery of active nucleotide species, e.g., 5′-triphosphates of nucleoside analogues, can enhance drug efficacy and reduce nonspecific toxicity. In this study, we report the development of a novel type of drug nanoformulations, polymeric conjugates of nucleoside analogues, which are capable of the efficient transport and sustained release of phosphorylated drugs. These drug conjugates have been synthesized, starting from cholesterol-modified mucoadhesive polyvinyl alcohol or biodegradable dextrin, by covalent attachment of nucleoside analogues through a tetraphosphate linker. Association of cholesterol moieties in aqueous media resulted in intramolecular polymer folding and the formation of small nanogel particles containing 0.5 mmol/g of a 5′-phosphorylated nucleoside analogue, e.g., 5-fluoro-2′-deoxyuridine (floxuridine, FdU), an active metabolite of anticancer drug 5-fluorouracyl (5-FU). The polymeric conjugates demonstrated rapid enzymatic release of floxuridine 5′-phosphate and much slower drug release under hydrolytic conditions (pH 1.0−7.4). Among the panel of cancer cell lines, all studied polymeric FdU-conjugates demonstrated an up to 50× increased cytotoxicity in human prostate cancer PC-3, breast cancer MCF-7, and MDA-MB-231 cells, and more than 100× higher efficacy against cytarabine-resistant human T-lymphoma (CEM/araC/8) and gemcitabine-resistant follicular lymphoma (RL7/G) cells as compared to free drugs. In the initial *in vivo* screening, both PC-3 and RL7/G subcutaneous tumor xenograft models showed enhanced sensitivity to sustained drug release from polymeric FdU-conjugate after peritumoral injections and significant tumor growth inhibition. All these data demonstrate a remarkable clinical potential of novel polymeric conjugates of phosphorylated nucleoside analogues, especially as new therapeutic agents against drug-resistant tumors.



INTRODUCTION

Despite several decades of research and drug development, progress in the clinical struggle against cancer has been only moderate. Development of resistance by cancer cells to chemotherapeutic agents has currently become a major clinical problem, limiting the effectiveness of the treatment of hematological malignancies as well as solid tumors. Multiple studies have helped to identify many mechanisms of drug resistance, but in general terms, they can all be reduced to the prevention of a drug from entering cells, deactivation of drug molecules, or the enhanced resistance of cancer cells to apoptosis. The first group includes deficiencies in membrane nucleoside transporters or the overexpression of ATP-dependent drug efflux transporters like P-glycoprotein (MRP, BCRP) and other membrane proteins (MRP) responsible for drug efflux. In the second group, the drug metabolism/degradation and reduced levels of enzymatic drug activation should be mentioned. In the third group, the induction of antiapoptotic mechanisms, as well as the suppression of pro-apoptotic pathways, plays important roles in drug resistance.[1]

Cytotoxic nucleoside analogues belong to the important class of anticancer drugs, which are currently used as the first line of treatment of hematological malignancies and certain solid tumors.[2] These drugs act as antimetabolites by interfering with nucleic acid synthesis and enzymes of the nucleotide metabolism. The clinical efficacy of these drugs depends on higher metabolic activity and drug activation in rapidly proliferating cancer cells compared to normal cells. Activation of therapeutic nucleoside analogues occurs through the *de novo* synthesis of 5′-mono-, di-, and triphosphate derivatives, which interfere with the cellular pool of natural nucleosides. Nucleoside analogues require participation of specialized nucleoside transporter proteins such as hENT1, hENT2, or hCNT1 in order to accumulate in the cells. The integral drug uptake depends on the proper balance of the nucleoside transporters and drug efflux proteins presented on

cellular membrane. Therefore, the drug accumulation is substantially reduced when the expression of such nucleoside transporters is deficient,[3,4] or the activity of drug efflux transporter proteins is elevated.[5,6] After entering cells, nucleoside analogues undergo phosphorylation into 5′-monophosphates with deoxycytidine kinase (dCK) or thymidine kinase (TK), a rate-limiting step in the intracellular activation of nucleosides, and are subsequently converted into active 5′-diphosphates and 5′-triphosphates by other nucleoside kinases.[3] The efficacy of nucleoside analogues may further be limited by additional factors such as metabolic deamination and intracellular dephosphorylation.[7,8]

In order to increase tumor accumulation of nucleoside analogues, various prodrug and drug delivery approaches have been developed, for example, the application of lipophilic nucleoside derivatives with an enhanced cellular membrane affinity. Many prodrugs with degradable lipophilic masking groups demonstrate the enhanced cell membrane permeability.[9] Early phase clinical trials have shown some improvements in the treatment of hematological malignancies, but these prodrugs were not effective in the treatment of solid tumors.[10] Moreover, lipophilic prodrugs have a reduced half-life in circulation due to the fast accumulation in liver. Various nanocarriers such as liposomes, biodegradable nanoparticles, polymeric micelles, and nanocapsules have been extensively for tumor delivery of chemotherapeutic drugs.[11] Many of these nanocarriers demonstrated advanced features, but have also shown serious shortcomings limiting their clinical usefulness. For example, liposomal formulations were unable to achieve effective drug concentration inside tumors because many anticancer drugs (cytarabine, 5-FU, etc.) diffused rapidly through the liposome bilayer.[12]

Recently, we introduced an alternative tumor treatment strategy using formulation and nanodelivery of activated drugs, nucleoside 5′-triphosphates, encapsulated in cationic nanogels.[17] Previously, several laboratories have attempted to achieve *in vivo* delivery of bioactive 5′-triphosphates of nucleoside analogue through encapsulation in liposomes,[13,14] nanoparticles,[15] or red blood cells.[16] Evidently, the success of this strategy depends on the advantages of nanoformulations in drug protection in biological milieu, controlled drug release, and the specific tumor targeting. Nanogel carriers have dramatically improved the delivery of activated phosphorylated nucleoside analogues into cancer cells and tumor growth inhibition effect.[18,19] However, the noncovalent nature of the encapsulation of anionic 5′-triphosphates in cationic nanogels was the reason for relatively fast drug release kinetics. Here, we report synthesis of novel types of drug-loaded nanogels, containing a polymer network with covalently linked phosphorylated nucleoside analogues, which are capable of sustained drug release and structurally different from the previously studied polymeric nanogels. Covalent drug attachment is an important factor in the controlled drug release, because it allows using specific chemistries. Various hydrolytically or enzymatically sensitive linkers, such as peptides, carboxylates, and so forth, have been previously evaluated with polymeric drug delivery systems.[20−22] In this study, drug conjugates were synthesized by the attachment of nucleoside analogues through a biodegradable tetraphosphate linker starting from amphiphilic polymers such as cholesterol-modified polyvinyl alcohol (PVA) or dextrin (DEX). The linker has strong advantage over other linkers, because the polymeric drug conjugates are able to release nucleoside analogues in active phosphorylated form in the result of its hydrolytic or enzymatic degradation,

eventually showing an enhanced tumor growth inhibition efficacy against normal and drug-resistant cancer cells. These drug-containing polymer conjugates can form stable nanogels with a small hydrodynamic diameter after ultrasonication in aqueous media as demonstrated in Figure 1. Selection of biodegradable or mucoadhesive biocompatible polymers for preparation of polymeric conjugates might also reduce toxicity of chemotherapy and open potentials for oral administration of these nanoformulations.

MATERIALS AND METHODS

Materials. Most reagents, solvents, and polymers were purchased from Sigma Aldrich (St. Louis, MO) and Alfa Aesar (Wardhill, MA) with the highest available purity and used without purification unless otherwise stated. Thymidine, 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) and snake venom phosphodiesterase 1, type VI, from Carotalus adamanteus were purchased from Sigma (St. Louis, MO). Nucleoside analogues: 5-fluoro-2′-deoxyuridine (Floxuridine, FdU) was from SynQuest Laboratories (Alachua, FL), 2,2′-difluorocytidine (dFdC, Gemcitabine) was from Beta Pharma, Inc. (Branford, CT), and arabinosylcytosine (araC, Cytarabine) was from 3B Medical Systems, Inc. (Libertyville, IL). Centrifuge filter devices (MWCO 5000 Da) were purchased from Millipore (Bedford, MA).

All NMR spectra were recorded using a 500 MHz Varian NMR spectrometer. All chemical shift values are given in parts per million (ppm) and are referenced to a signal from $(CH_3)_4Si$ (0 ppm) for ^1H, DMSO-d_6 (39.7 ppm) for ^{13}C, and 85% phosphoric acid (0 ppm) for ^{31}P spectra at 25 °C. Hydrodynamic diameter, polydispersity, and zeta potential of nanogels and polymeric conjugates were measured using a dynamic light scattering instrument, the Zetasizer Nano-ZS90 (Malvern Instruments, Southborough, MA) at 25 °C. Monodisperse polystyrene dispersions were used as standards. UV absorbance of samples was measured by Biophotometer (Eppendorf, Hamburg, Germany). IR spectra were recorded using a Nicolet IR-200 FT-IR spectrometer (Thermo Scientific, Waltham, MA).

Cells. Human breast carcinoma MCF-7, human hepatocellular carcinoma HepG2, and human prostate adenocarcinoma PC-3 cells were obtained from ATCC (Rockville, MD). These cells were maintained in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 1% L-glutamine, and 2% penicillin−streptomycin at 37 °C in a humidified atmosphere containing 5% CO_2. Human breast carcinoma MDA-MB-231 cell line was a gift from Dr. R. Singh (UNMC). These cells were maintained in DMEM/Nutrient mixture F-12 (DMEM/F12) with similar supplements and serum as above. Gemcitabine-resistant human follicular lymphoma RL7/G cell line, which is characterized by a reduced level of dCK enzyme,[23] was a gift from Dr. F. Bontemps (De Duve Institute, Bruxelles, Belgium). They were grown in the presence of 2 μM gemcitabine. Nucleoside

[a] Particle size (d_h), polydispersity index (PDI), and zeta potential (ζ) were measured in 1% solutions in water after 2 h sonication. The results are average values ± SD of three measurements.

transport-deficient cytarabine-resistant human leukemic lymphoblast CEM/araC/8 cell line[24] was obtained from Dr. C. Galmarini (UFR Lyon-Sud, Oullins, France). The cells were grown in the presence of 0.5 μM cytarabine (araC). Both drug-resistant cell lines were grown in RPMI medium supplemented with 10% fetal bovine serum (FBS), 1% L-glutamine, and 2% penicillin−streptomycin at 37 °C in a humidified atmosphere containing 5% CO_2.

Synthesis of Cholesterol Conjugates. PVA was grafted with cholesterol moieties according to the procedures described below. Briefly, 2.1 g of PVA (M_w 13 kDa) was dried over phosphorus pentoxide *in vacuo* and dissolved in 50 mL of anhydrous DMSO at 70 °C. Triethylamine (0.8 mmol) was added to the cooled solution (25 °C) followed by 0.3 g (0.68 mmol) of cholesteryl chloroformate, and the final solution was stirred overnight at 25 °C. The reaction mixture was concentrated *in vacuo* and dialyzed (MWCO 3.5 kDa) against 20% aqueous ethanol three times for 24 h. The product (CPVA) was isolated after concentration *in vacuo* and freeze−drying with a yield of 80%. In another method, 2.1 g of PVA (M_w 13 kDa) was dissolved in 50 mL of anhydrous *N*-methyl pyrrolidone at 70 °C, then 0.3 g (0.68 mmol) of cholesteryl chloroformate was added, and the mixture was stirred for 4 h at 70 °C. The substituted CPVA was precipitated in diethyl ether (0.5 L) and dried *in vacuo*; the light yellow precipitate was obtained at a yield of 70%. ^{1}H NMR: 0.63 (s, 18H), 0.83 (m, 36H), 0.88 (m, 18H), 0.92 (s, 18H), 1.11−1.95 (m, 764H), 3.84−3.90 (m, 295H), 4.31 (brs, OH), 4.40 (s, 12H), 5.25 (s, 6H). Following the same protocol for PVA (M_w 31 kDa), we obtained CPVA with a yield of 85%. ^{1}H NMR: 0.65 (s, 18H), 0.83−0.85 (dd, J = 5.0, 1.6 Hz, 36H), 0.89 (d, J = 4.8 Hz, 18H), 0.94 (s, 18H), 1.07−1.98 (m, 1582H), 3.84 (m, 704H), 4.35 (12H and OH), 5.28 (s, 6H). IR: 3264, 2897, 1642, 1409, 1323, 1082, 915, 829.

The dextrin−cholesterol nanogel (CDex) was synthesized as follows. The water-soluble fraction of dextrin (M_w 9 kDa) was isolated by dialysis in a SpectraPor membrane tube (MWCO 2 kDa) followed by centrifugation. The supernatant was freeze−dried and used for nanogel synthesis. 1.0 g of the purified dextrin was dried over phosphorus pentoxide *in vacuo* and dissolved in 15 mL of anhydrous DMSO at 70 °C. After 0.3 g (0.68 mmol) of cholesteryl chloroformate was added, the reaction mixture was stirred for 24 h at 25 °C, concentrated *in vacuo*, and dialyzed (MWCO 3.5 kDa) against 20% aqueous ethanol three times for 24 h. The product (CDex) was isolated after concentration *in vacuo* and freeze−drying with a yield of 76%. ^{1}H NMR: 0.65 (s, 18H), 0.83−0.85 (dd, J = 5.0, 1.6 Hz, 36H), 0.89−1.51 (m, 211H), 3.24−3.64 (m, 333H), 4.28−5.10 (m, 122H), 5.23 (s, 6H), 5.37−5.62 (m, 55H).

Synthesis of Phosphorylating Reagent, CNEtOP(O)Im$_2$. The intermediate product CNEtOP(O)Cl_2 was synthesized by dissolving 18.6 mL (30.6 g, 0.2 mol) phosphorus (V) oxychloride and 20.6 mL (14.84 g, 0.147 mol) triethylamine in 40 mL anhydrous tetrahydrofuran (THF) at 0 °C. It was treated with 10 mL (10.45 g, 0.147 mol) 2-cyanoethanol in 5 mL THF while stirring at 0 °C. Stirring was continued for 30 min until white precipitate formed. The precipitate was carefully filtered with exclusion of moisture, and the resulting solution was concentrated *in vacuo* and distilled under argon. The product, CNEtOP(O)Cl_2, was recovered by distillation at 90 °C/1 mm with a yield of 60%.

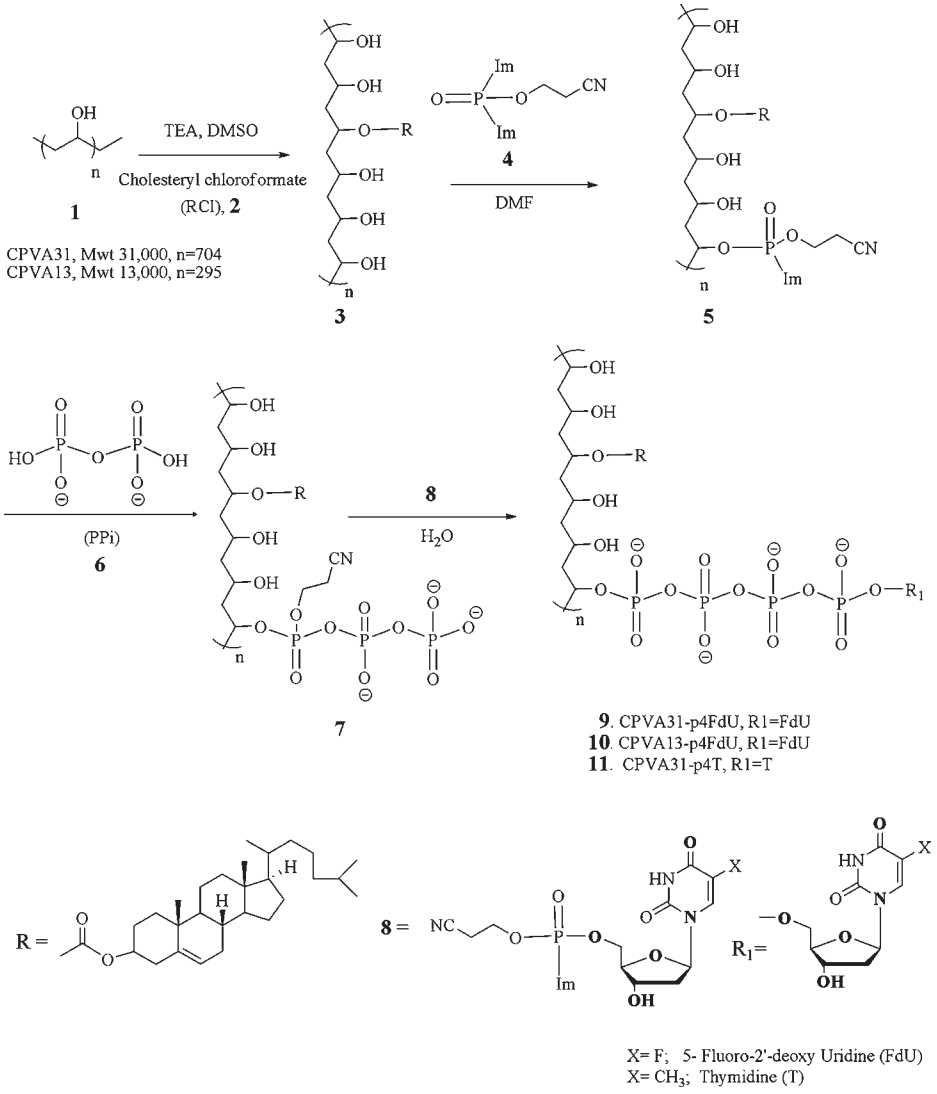
The product, CNEtOP(O)Im_2, was synthesized by mixing 2.69 g (0.015 mol) CNEtOP(O)Cl_2 and 5.25 g (0.037 mol) *N*-trimethylsilyl-imidazole in 40 mL cold anhydrous toluene. The solutions were then incubated for 2 h at room temperature, concentrated *in vacuo* to a half-volume and placed in a freezer for 2 h at −20 °C. The precipitate of CNEtOP(O)Im_2 was recovered after centrifugation with a yield of 70%.[25]

Preparation of Polymeric Drug Conjugates. A solution of 3.3 g of dried cholesterol−polymer conjugates in 33 mL DMF was treated with a 2 M solution of CNEtOP(O)Im_2 in anhydrous DMF (2 mL) for 30 min at 25 °C. Then, a 1 M solution of tetra-*n*-butylammonium salt of pyrophosphate (PPi-TBA) in anhydrous DMF (4 mL) was added, and the reaction mixture was incubated for 1 h at 25 °C. In a separate flask, floxuridine (FdU, 490 mg, 2 mmol) was treated with a 2 M solution of CNEtOP(O)Im_2 in anhydrous DMF (1 mL) and allowed to stand for 20 min at 25 °C. Both solutions were then mixed and stirred for 40 min at 25 °C. The reaction mixture was treated with 1 mL of methanol and left overnight at 4 °C. Insoluble material was removed by filtration; the nanogel conjugate was purified three times over 24 h by dialysis (MWCO 3500 Da) against 20% aqueous ethanol, concentrated *in vacuo*, and precipitated as a sodium perchlorate in acetone. FdU content in the nanogel conjugate was measured by UV absorbance (ε_{260} = 7570). Drug loading: CPVA31, 0.51 μmol/mg; CPVA13, 0.50 μmol/mg; and CDex9, 0.44 μmol/mg.

Particle Size and Zeta-Potential Measurements. The hydrodynamic diameter and polydispersity of nanogels and polymeric conjugates were measured by dynamic light scattering (DLS) using a Zetasizer Nano-ZS90 with a 15 mV solid state laser operated at a wavelength of 635 nm. In brief, dry samples were resuspended in filtered deionized water, and then sonicated for 1 h at 4 °C to form a uniform dispersion of nanoparticles and centrifuged for 4 min at 10 000 × g. The size distribution in samples was characterized by polydispersity index. Zeta-potential was calculated based on electrophoretic mobility measurements performed with an electrical field strength of 15−18 V cm^{-1} at 25 °C using the instrument software. The data reported in Table 1 represent an average of three measurements.

Enzymatic Hydrolysis. Enzymatic stability and drug release from polymeric conjugates was assayed in 50 μL reaction mixtures containing: 100 mM Tris-HCl (pH 8.75), 2 mM $MgCl_2$, 0.5 mg of snake venom phosphodiesterase (VPDE), and 0.5 mg nanogel sample (FdU, 0.25 μmol). The reaction mixture was incubated at 37 °C and, at appropriate times, 5 μL aliquots were taken out and quenched with 1.5 μL of 1 M HCl. Nucleotide content was analyzed by ion-pair HPLC using an Ascentis C18 column (10 μm, 15 cm × 4.6 mm) at a flow rate of 1 mL/min. The elution was performed with buffer A: 40 mM KH_2PO_4, 0.2%

Scheme 1. Synthetic Steps in the Preparation of CPVA Conjugates



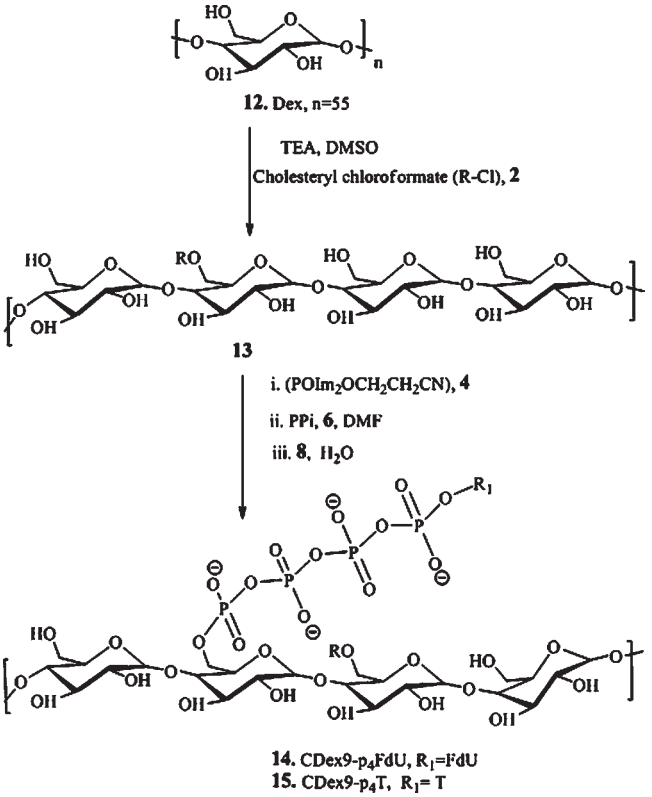
tetrabutylammonium hydroxide, pH 7.0, and buffer B: 30% acetonitrile, 40 mM KH_2PO_4, 0.2% tetrabutylammonium hydroxide, pH 7.0, in a linear gradient mode (100% B in 20 min).

***In Vitro* Drug Release.** *In vitro* drug release was investigated under different pH values. In short, 18 mg of CPVA31-p_4FdU or CDex9-p_4FdU conjugates was dissolved in 20 mL of PBS solution at pH 7.4, 4.0, and 1.0. These solutions were incubated at 37 °C and 0.5 mL aliquots were taken out every 24 h. The released nucleotides were separated from the rest of the polymeric conjugates by centrifugation at 7500 rpm for 25 min using an Amicon Ultra 0.5 centrifuge filter device (MWCO 3000 Da). The pH of the filtrate was adjusted to 7.4 and UV absorbance was measured at 260 nm.

Cytotoxicity Studies. Cytotoxicity of the polymeric conjugates was analyzed in different cancer cell lines by a standard MTT assay. Briefly, MCF-7, PC-3, HepG2, and MDA-MB-231 cells were seeded at a density of 10 000 cells/200 μL growth medium/well in flat-bottom 96-well plates; the corresponding suspensions of RL7/G and CEM/araC/8 cells were placed in round-bottom 96-well plates. Cells were allowed to grow overnight and appropriate amounts of drug, nanogels, or polymeric conjugates were added. Samples were incubated in full medium for 72 h at 37 °C, and the metabolic activity of each sample was determined by adding 20 μL of a 5 mg/mL of MTT stock solution in sterile PBS buffer to each well. The samples were then incubated for 2 h at 37 °C, the medium and the MTT dye were washed out by PBS, and 100 μL of extraction buffer (20% w/v SDS in DMF/water, 1:1, pH 4.7) was added to each well. Samples were incubated for 24 h at 37 °C. Optical absorbance was measured at 560 nm using a model 680 microplate reader (BioRad, Hercules, CA) and cytotoxicity was expressed as a percentage of survived cells relative to nontreated control cells. All samples were analyzed by an average of eight measurements (means ± SEM). These data were plotted versus drug/nanogel concentrations and converted into IC_{50} values (concentration of the 50% cell survival).

***In Vivo* Tumor Growth Inhibition Assay.** These experiments were performed using female nu/nu mice (RL7/G cells) or male nu/nu mice (PC-3 cells), aged 6−8 weeks (Charles River Laboratories, Wilmington, MA). Animal studies were carried out according to the Principles of Animal Care outlined by the National Institutes of Health, and protocols were approved by the Institutional Animal

Scheme 2. Synthesis of CDex-Conjugates (Compounds 1−11; see Scheme [1])



Care and Use Committee at the University of Nebraska Medical Center. The animals were randomly divided into groups of five per cage and maintained under sterile conditions and 12 h light/dark cycle in a temperature-controlled environment. All manipulations with animals were performed in a sterile laminar hood using sterile solutions. PC-3 and RL7/G cell suspensions of 5×10^6 cells/400 μL of medium containing 20% Matrigel (Becton-Dickinson, San Diego, CA) were injected subcutaneously in the right flank areas of mice. After tumors could be palpitated, the treatment solutions of CPVA31-p$_4$FdU were injected peritumorally (2×100 μL) twice a week at a dose of 12 mg FdU/kg. Tumor volume was measured by digital calipers and calculated based on the equation: $TV = L/2 \times W^2$, where L and W are length and width of tumor (mm).

RESULTS AND DISCUSSION

Synthesis of Nanogel Conjugates. Cholesterol is a well-known hydrophobic moiety used in many drug delivery applications in order to enhance the interactions of modified macromolecules or nanocarriers with the cellular membrane.[26,27] In our design of polymeric conjugates, we have exploited polymer modification with cholesterol for several reasons: (i) to render hydrophilic polymers soluble in organic solvents, (ii) to compel the modified polymers to form compact nanogels, and (iii) to increase membranotropic properties and ease transport of hydrophilic drug molecules across the cellular membrane. In aqueous solutions, at ultrasonication cholesterol-modified polymers form "flower-type" micelles with internally aggregated cholesterol moieties with the least association numbers 4−6.[28] We synthesized the cholesterol-modified polyvinyl alcohol (CPVA) containing six hydrophobic moieties per polymer chain by reaction of the corresponding PVA, M_w 13 and 31 kDa, with cholesterol chloroformate in dry DMSO in the presence of triethylamine at room temperature. The cholesterol-modified PVA polymers were isolated with a yield of 80−85%. In an alternative method, PVA was modified in *N*-methyl pyrrolidone at 70 °C, yielding the corresponding cholesterol-modified polymer at 70−75% as a white solid after precipitation in diethyl ether.[29] The cholesterol-modified PVA polymers were designated as CPVA13 and CPVA31 (Scheme 1). Similarly, as shown in Scheme 2, we synthesized a cholesterol-modified dextrin (CDex) with a high yield starting from dextrin (M_w 9 kDa). Four cholesterol moieties were attached to the smaller dextrin molecule. The flexibility of charged polymer chains was restricted by hydrophobic cholesterol groups aggregated in the core of nanogels. The nanogels bearing negatively charged phosphate groups formed even smaller spherical compacted particles following the addition of positively charged spermine molecules (Figure 1).

^{1}H NMR spectra showed that the cholesterol modification was nearly quantitative and amounted for six moieties per polymer chain in CPVA13 and CPVA31 and four per polymer chain in CDex9. Similarly, the formation of micelles in aqueous solutions by these polymers was also demonstrated by ^{1}H NMR spectroscopy. Figures S1 and S2 represent the spectra of CPVA13 and CDex9 in (a) D_2O and (b) DMSO-d_6, respectively (see Supporting Information). As shown in the spectra, proton signals of the cholesterol moiety (δ = 0.6−2.4 ppm) appeared in DMSO-d_6 (b), but completely disappeared or wide broadening of signals was observed in D_2O (a). This indicates the restricted molecular motion of cholesterol moieties upon self-aggregation. Our results confirmed the formation of a rigid core of hydrophobic cholesterol moieties and a relatively mobile shell consisting of hydrophilic PVA or Dex molecules in aqueous medium. The degree of cholesterol substitution (DS) was evaluated by calculating the ratio between the integrals of the protons in terminal CH_3-groups of cholesterol and methylene protons in CPVA or the protons of sugar monomers in CDex.

The hydroxyl functional groups in the cholesterol-modified polymers have been used as sites for the conjugation of the active phosphorylated nucleoside analogue, floxuridine (FdU), resulting in the formation of polymeric conjugates as anticancer drug carriers (Schemes 1 and 2). The 5′-hydroxyl group of the nucleoside analogue was chemically attached via a biodegradable tetraphosphate linker to nanogels using a 2-cyanoethyl-bis(imidazolyl)phosphate, CNEtOP(O)Im$_2$, as a phosphorylating reagent. As shown in Schemes 1 and 2, the polymers were phosphorylated with CNEtOP(O)Im$_2$ in DMF and then reacted efficiently with inorganic pyrophosphate in the form of tetra-*n*-butylammonium salt PPi-TBA(**6**) in order to form the polymeric triphosphate **7**. Separately, the 5′-hydroxyl group of the nucleoside was phosphorylated by CNEtOP(O)Im$_2$, and the activated 5′-phosphorylated nucleoside **8** was reacted in the next step with the polymeric triphosphate **7**.

In our preliminary experiments, we found that a similar phosphorylating agent, methyl-bis(imidazolyl)phosphate, MeOPOIm$_2$, reacted efficiently with the primary hydroxyl groups of nucleosides in the formation of activated 5′-monophosphates, but compared with CNEtOP(O)Im$_2$, this reaction was much slower. The relative efficacy of phosphorylation using these two reagents was compared based on the yields of nucleoside 5′-monophosphate analyzed by ion-pair HPLC. During the first hour of reaction, CNEtOP(O)Im$_2$ yielded 80% of monophosphate compared with only 10% when MeOPOIm$_2$ was used.

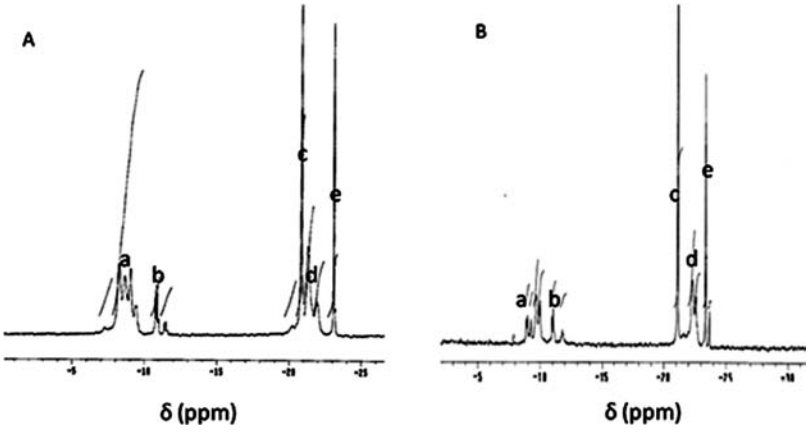


Figure 2. ^{31}P NMR spectrum of polymeric conjugates, CPVA31-p 4FdU (A) and CDex9-p4FdU (B) (phosphorus signals a−e are described in the text).

The electron donor effect of the methoxy group makes the phosphorus atom less electrophilic, which resulted in longer reaction times, especially with secondary hydroxyl groups. However, both phosphorylating agents formed the same final activated 5′-monophosphorylated nucleoside in our synthesis. Next, the activated imidazolyl-phosphate moiety in **8** readily reacted with polymer-triphosphate **7** and converted into nucleoside 5′-tetraphosphate anchored to CPVA, (**9**−**11**) or CDex (**14**, **15**). Initially, we used thymidine (T) as a model drug in this study. Polymeric conjugates were purified by extensive dialysis to remove all reactants. CPVA- and CDex-conjugated 5′-tetraphosphates of FdU were designated as CPVA13-p_4FdU, CPVA31-p_4FdU, CDex9-p_4FdU, and CDex9-p_4T and their properties are shown in Table 1. The amount of nucleoside attached to the polymer was determined by UV absorbance. We observed a high degree of nucleoside loading in nanogels, which was equal to 0.4−0.5 μmol/mg.

Covalent conjugation of the nucleoside to nanogels via a tetraphosphate linker was further verified by ^{31}P NMR and IR spectroscopy. ^{31}P NMR spectra confirmed the formation of tetraphosphate structures along with trace amounts of a triphosphate and polyphosphates such as a pentaphosphate (Figure 2). According to published chemical shifts,[30,31] upper field region of ^{31}P NMR spectra at −20 to −25 ppm corresponds to β- and γ-phosphates (peaks *c*, *d*, and *e*), while signals between −8 and −12 ppm correspond to terminal α- and δ-phosphates (peaks *a* and *b*). IR spectra of CPVA-p_4FdU have allowed us to observe conjugation of the FdU nucleoside to the CPVA nanogel (Supporting Information Figure S3). As is clearly shown in the spectra, the peak at 899 cm^{-1} corresponding to P-OR stretch, the peak at 1234 cm^{-1} corresponding to P═O stretch of phosphate, and the peak at 1708 cm^{-1} corresponding to C═O stretch of amide are clearly increased in the CPVA-p_4FdU products, while peaks at 1311−1417 cm^{-1} corresponding to O−H bonding of CPVA were reduced, confirming the formation of a polyphosphate linker between CPVA and FdU.

Particle Size and Zeta-Potential. Compact nanogel conjugates could be successfully formed as the result of self-organization of CPVA/CDex-p_4FdU molecules during ultrasonication in aqueous solutions. When sufficient energy was applied, the cholesterol moieties formed compact intramolecular clusters surrounded by a hydrophilic polymeric shell containing the embedded negatively charged drug molecules. The particle size, homogeneity, and morphology of CPVA/CDex-p_4FdU structures were measured by dynamic light scattering (DLS) and transmission electron microscopy (TEM). A single sharp peak in DLS profiles with a hydrodynamic diameter in the range of 12−45 nm implied the presence of a single population of small particles with a relatively low polydispersity index of 0.30−0.59 (Table 1). The high negative zeta-potential of CPVA/CDex-p_4FdU confirmed the presence of phosphates in the surface layer of polymeric conjugates. TEM pictures showed the spherical particle morphology with hydrodynamic diameters in the range 38−58 nm (Figure 3). We have also studied the change in particle size after neutralization of the negative charge in polymeric conjugates with the polyamine spermine (Figure 1). The addition of positively charged spermine at physiological conditions resulted in a 2−3-fold reduction in hydrodynamic and TEM-observed diameters and the change in morphology of particles, e.g., the appearance of a thicker electron-dense exterior layer surrounding these compacted polymeric conjugates.[32]

Enzymatic Hydrolysis. The formation of natural nucleoside 5′-phosphate bonds between nucleoside and nanogel backbone was further confirmed using enzymatic hydrolysis by snake venom phosphodiesterase I (VPDE). VPDE was able to catalyze the hydrolysis of esterified nucleoside 5′-phosphates into a nucleoside 5′-phosphate and also the cleavage of nucleoside 5′-phosphate from oligonucleotides with a free 3′-end.[33,34] This property of VPDE allows us to investigate the enzymatic stability of nanogel-bound nucleoside phosphates. Nanogels CPVA-p_4FdU and CDex-p_4FdU were incubated with VPDE at 37 °C and then analyzed by ion-pair HPLC (Figure 4). We observed the gradual disappearance of the initial wide peak with the elution time of 25−34 min (*a*) and the formation of a sharp peak at the elution time of ca. 5 min (*b*), which corresponded to control nucleoside 5′-phosphates (TMP or FdUMP). Structure of the released nucleoside products was further confirmed by comparison of UV spectra with initial nucleoside analogues. Our data demonstrated a nearly quantitative enzymatic release of nucleotide 5′-phosphate from polymeric conjugates within 12 to 24 h.

***In Vitro* Drug Release.** The *in vitro* release of FdU was monitored at 37 °C at different pH values (1.0, 4.0, and 7.4) in order to assess the stability of nanogel conjugates in the environments in the stomach, endosomal vesicles, and blood, respectively. Each nanogel, CPVA-p_4FdU or CDEX-p_4FdU, was placed into the appropriate buffer solution and incubated at 37 °C. Serial aliquots were removed at the appropriate times during hydrolysis, and the cleaved nucleoside/nucleotide was separated by ultrafiltration and quantified by UV absorbance.

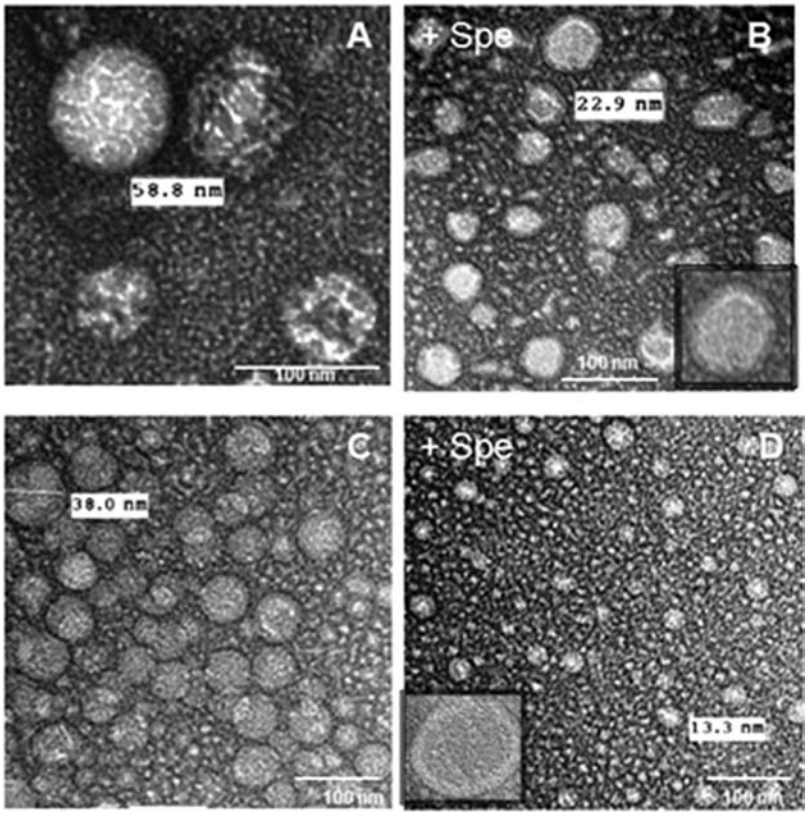

Figure 3. Transmission electron microscopy (TEM) images of nanogels formed from polymer conjugates: (A) CPVA31-p4FdU, (B) its spermine complex (Spe), (C) CDex9-p4FdU, and (D) its spermine complex. Samples were stained with vanadate.

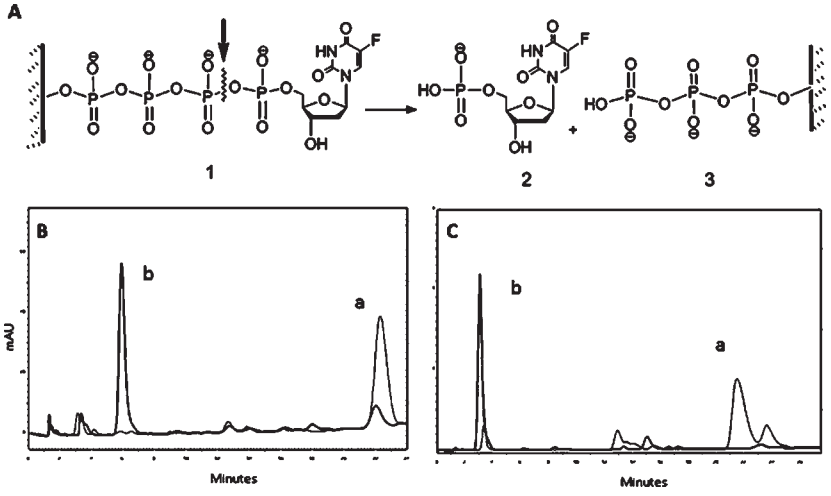

Figure 4. Enzymatic hydrolysis of polymeric conjugates by snake venom phosphodiesterase I (VPDE). (A) The enzyme hydrolyzes the P−O bond at α-phosphate group in nanogel conjugate resulting in nucleoside 5′-phosphate (2). (B) Ion-pair HPLC profiles of initial (a) and hydrolyzed (b) CPVA31-p4FdU. (C) Ion-pair HPLC profiles of initial (a) and hydrolyzed (b) CDex9-p4T after 24 h incubation with 0.01 units of VPDE enzyme.

The release profiles at different pH values are shown in Figure 5. In general, polymeric conjugates displayed linear first-order reaction kinetics of hydrolysis with slower drug release at pH 7.4 and pH 4.0 than at pH 1.0. At pH 4.0 and 7.4, drug release was 1−2% per day, while at pH 1.0 drug release reached 4% per day. These results are consistent with the pH-dependent degradation behavior of other dinucleoside polyphosphates, such as diadenosine-P**1**,P**3**-triphosphate and P**1**,P**4**-tetraphosphate.[35] However, CPVA/CDex-p_4FdU conjugates showed much slower drug release compared to diadenosine-P**1**,P**4**-tetraphosphate (25 days vs 3 days). The pH-dependent hydrolysis can be facilitated by a hydronium ion through the nucleophilic attack of protonated phosphate groups at lower pH, which results in an $S_N(P)$-type substitution, and then the formation of a penta-coordinated

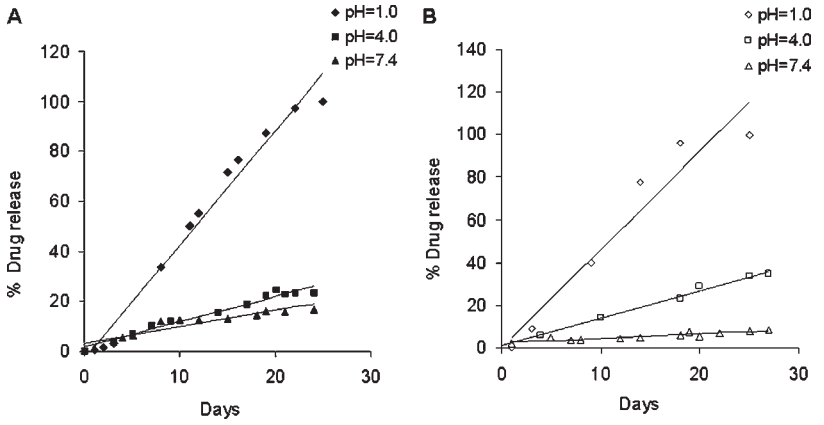

Figure 5. In vitro drug release from polymeric conjugates CPVA31-p4FdU (A) and CDex9-p4FdU (B) at different pH in buffered saline.

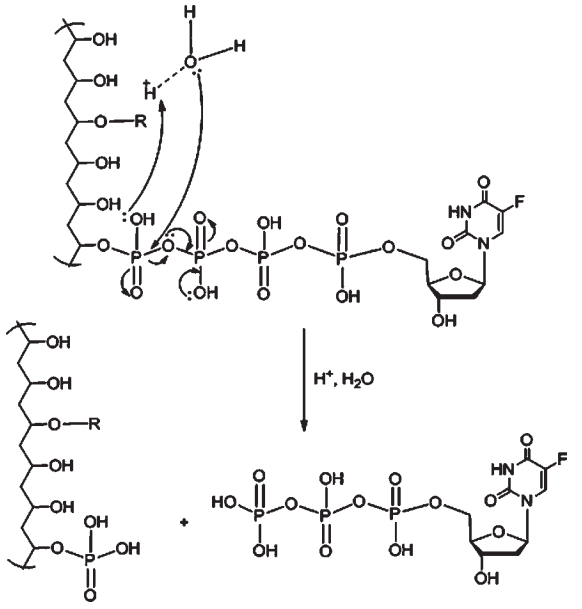
Scheme 3. Mechanism of Acidic Hydrolysis of Polymeric Conjugates and Release of Phosphorylated Nucleosides (R = cholesterol)



phosphorus transition state and nucleoside 5′-phosphates as final products (Scheme 3). Highly hydrated polymer coils surrounding the tetraphosphate linkers evidently create a steric hindrance and significantly slow down the process.

Evidently, the release of phosphorylated nucleosides in cancer cells would provide a strong therapeutic advantage to these polymeric conjugates, because the drug component does not have to pass through the phosphorylation step, which is known to be a rate-limiting step in biological activation of nucleoside analogues.[36] Our data show that this type of polymeric conjugates is capable of the sustained drug release during the extended period of time and can serve as active drug depot, significantly enhancing therapeutic effect against cancer cells. Peritumoral injections or systemic administration of polymeric conjugates would result in only minimal initial drug burst, a shortcoming of many drug delivery systems at systemic administration. Additionally, accumulation of nanocarriers from blood circulation through the enhanced permeability and retention (EPR) effect in leaking tumor neovasculature can potentially enhance the tumor growth inhibitory effect. Polymeric conjugates can also be considered as potential oral therapeutic formulations due to the observed slow drug release at low pH in the digestive tract (*in vivo* experiments are underway). We have also demonstrated that enzymatic hydrolysis of polymeric conjugates is at least 20−25 times faster than hydrolytic hydrolysis. Therefore, these polymeric conjugates, which have a slow, sustained drug release in tumor tissue and other organs in normal conditions *in vivo*, might be quickly activated by enzymatic activities present in the cytosol or subcellular compartments of proliferating cancer cells.[37] The most common type of hydrolytic enzymes in mammalian cells are cytosolic phosphodiesterases and nucleotide phosphatases, which can release active 5′-nucleotides from the polymeric conjugates.[38]

Cytotoxicity Assay. Drug resistance to nucleoside analogues is known to be an important clinical problem in the treatment of cancer. Therapeutic effects can be achieved with nucleoside analogues as a single agent or in combination with other drugs only at the increasingly higher dosage. Here, we have studied the cytotoxicity of several polymeric conjugates of activated analogues of 5-fluorouracyl as a model drug in various cancer cell lines including ones that are resistant to nucleoside analogues. The cytotoxicity of polymeric floxuridine conjugates CPVA13-p_4FdU, CPVA31-p_4FdU, and CDEX9-p_4FdU was determined in human prostate adenocarcinoma PC-3, breast carcinoma MCF-7 and MDA-MB-231, hepatic carcinoma HepG2, gemcitabine-resistant follicular lymphoma RL7/G, and cytarabine-resistant T-lymphoma CEM/araC/8 cells using a thiazolyl blue (MTT) dye reduction assay.[39] As shown in Figure 6 and Table 2, nanoconjugates showed considerably enhanced cytotoxicity and lower IC_{50} values (drug concentration resulting in 50% cell death) compared to free floxuridine in all of these cell lines. The enhancement factor (EF), which is equal to IC_{50}(drug)/IC_{50}(conjugate), was used as a measure of the increase in cytotoxicity of polymeric conjugates compared to free drug. Nanogels without conjugated drug demonstrated no cytotoxicity (IC_{50} > 10 mg/mL). All of these polymeric conjugates showed a higher EF in drug resistant cell lines, CEM/araC/8 and RL7/G, compared to other tumor cells. Specifically, CPVA13-p_4FdU and CDex9-p_4FdU exhibited an EF of 100 and 85 in CEM/araC/8 cells, while the EF showed by other cells was normally in the lower range of 3.5−50.

***In Vivo* Tumor Growth Inhibition.** The therapeutic efficacy of polymeric conjugates was evaluated in subcutaneous (s.c.) human prostate adenocarcinoma PC-3 and gemcitabine-resistant

follicular lymphoma RL7/G tumor xenograft mouse models. These tumors were established by s.c. injection of tumor cells in the lower flank areas of athymic nu−nu mice. After the observation of the initial tumors, animals were randomly separated into control and treatment groups ($n = 5-6$). Median tumor volume was measured by digital calipers twice a week simultaneously with peritumoral injections of polymeric conjugates with a dose of 80 mg/kg, which is equivalent to 10 mg FdU/kg. This way of administration allowed

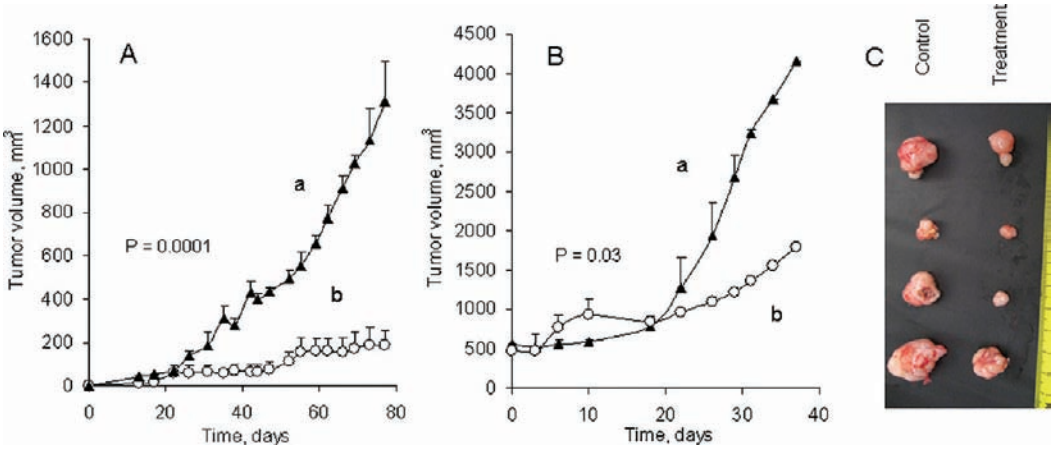

Figure 7. Tumor growth inhibition in mice with subcutaneous human prostate carcinoma PC-3 (A) and gemcitabine-resistant follicular lymphoma RL7/G (B) tumors following the peritumoral injections of the polymeric conjugate CPVA31-p4FdU (dose 80 mg/kg or 10 mg FdU/kg). The data were statistically significant with $P < 0.05$ between (a) control and (b) treatment groups. (C) Tumor photographs in the end of the experiment B taken from control and treatment groups.

a subcutaneous storage of the viscous polymer—drug conjugate and the sustained release of activated drug into the tumor. We observed a strong 6.5-fold tumor growth inhibition in human prostate carcinoma PC-3 model that confirms the high therapeutic potential of polymeric conjugates (Figure 7A). Although the observed 2-fold growth inhibition was lower in drug-resistant human follicular lymphoma RL7/G tumors compared to PC-3 tumors, the effect of the CPVA31-p_4FdU conjugate was statistically significant ($P < 0.05$) (Figure 7B). The significance of the experimental data was determined by a two-tailed Student's *t*-test. No significant weight loss or acute toxicity of polymeric conjugates was observed during the entire period of treatment. Tumors removed from experimental animals at the end of the experiments were clearly smaller than tumors in the control group (Figure 7C).

CONCLUSIONS

We have developed a novel type of covalently bound polymeric phosphorylated nucleoside analogues, polymeric conjugates, for a sustained delivery of the activated anticancer drugs into tumors. These carriers combine attractive properties of biocompatible polymers with an enhanced cytotoxic efficacy of activated nucleoside analogues and form compact drug-loaded polymeric nanoparticles. *In vitro* evaluation against various cancer cell lines, including drug-resistant cancer cells, demonstrated that the activated floxuridine conjugate has 50—100 times stronger cytotoxicity compared to free nucleoside analogue. Furthermore, the observed sustained drug release was a potential cause of the increased tumor growth inhibition following the peritumoral administration of polymeric conjugates in subcutaneous tumor xenograft models. This class of anticancer drug formulations also has features, which makes them a very promising vehicle for oral administration of activated phosphorylated nucleoside analogues.

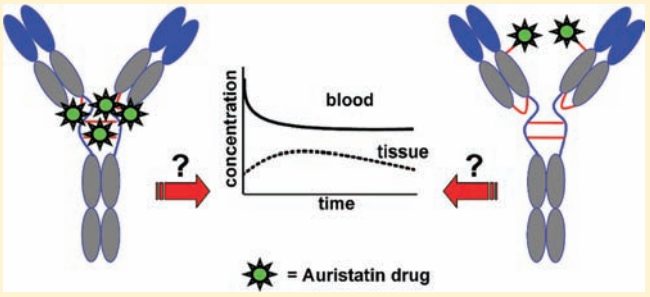
ABSTRACT: Antibody–drug conjugates (ADCs) are designed to combine the exquisite specificity of antibodies to target tumor antigens with the cytotoxic potency of chemotherapeutic drugs. In addition to the general chemical stability of the linker, a thorough understanding of the relationship between ADC composition and biological disposition is necessary to ensure that the therapeutic window is not compromised by altered pharmacokinetics (PK), tissue distribution, and/or potential organ toxicity. The six-transmembrane epithelial antigen of prostate 1 (STEAP1) is being pursued as a tumor antigen target. To assess the role of ADC composition in PK, we evaluated plasma and tissue PK profiles in rats, following a single dose, of a humanized anti-STEAP1 IgG1 antibody, a thio-anti-STEAP1 (ThioMab) variant, and two corresponding thioether-linked monomethylauristatin E (MMAE) drug conjugates modified through interchain disulfide cysteine residues (ADC) and engineered cysteines (TDC), respectively. Plasma PK of total antibody measured by enzyme-linked immunosorbent assay (ELISA) revealed ~45% faster clearance for the ADC relative to the parent antibody, but no apparent difference in clearance between the TDC and unconjugated parent ThioMab. Total antibody clearances of the two unconjugated antibodies were similar, suggesting minimal effects on PK from cysteine mutation. An ELISA specific for MMAE-conjugated antibody indicated that the ADC cleared more rapidly than the TDC, but total antibody ELISA showed comparable clearance for the two drug conjugates. Furthermore, consistent with relative drug load, the ADC had a greater magnitude of drug deconjugation than the TDC in terms of free plasma MMAE levels. Antibody conjugation had a noticeable, albeit minor, impact on tissue distribution with a general trend toward increased hepatic uptake and reduced levels in other highly vascularized organs. Liver uptakes of ADC and TDC at 5 days postinjection were 2-fold and 1.3-fold higher, respectively, relative to the unmodified antibodies. Taken together, these results indicate that the degree of overall structural modification in anti-STEAP1-MMAE conjugates has a corresponding level of impact on both PK and tissue distribution.



INTRODUCTION

Prostate cancer represents one-quarter of newly diagnosed cancer cases in men and is surpassed only by lung cancer in the number of male deaths.[1] Despite significant efforts toward improving the diagnosis[2,3] and treatment[4−7] of prostate tumors, there are few therapeutic options for metastatic prostate cancer, and developing effective treatments remains a critical priority. Antibody-based therapies are currently being developed against specific antigens that are expressed in prostate tumors. One such molecular target is the six-transmembrane epithelial antigen of the prostate 1 (STEAP1),[8] a cell-surface antigen that is overexpressed in the majority of human epithelial prostate cancers, but with restricted expression in normal tissues.[8−10] Although the normal functional role for STEAP1 is not fully understood, its restricted expression makes it an ideal antigen for antibody-mediated therapy.

The development of antibody–drug conjugates (ADCs) is a particularly promising therapeutic approach that combines the antigen targeting specificity of monoclonal antibodies with the cytotoxic potency of chemotherapeutic drugs.[11−20] Conjugation of cytotoxic drugs to antibodies can be achieved either through lysine side-chain amines or through cysteine sulfhydryl groups that are typically activated by reduction of interchain disulfide bonds. As such, a humanized IgG1 anti-STEAP1 conventional

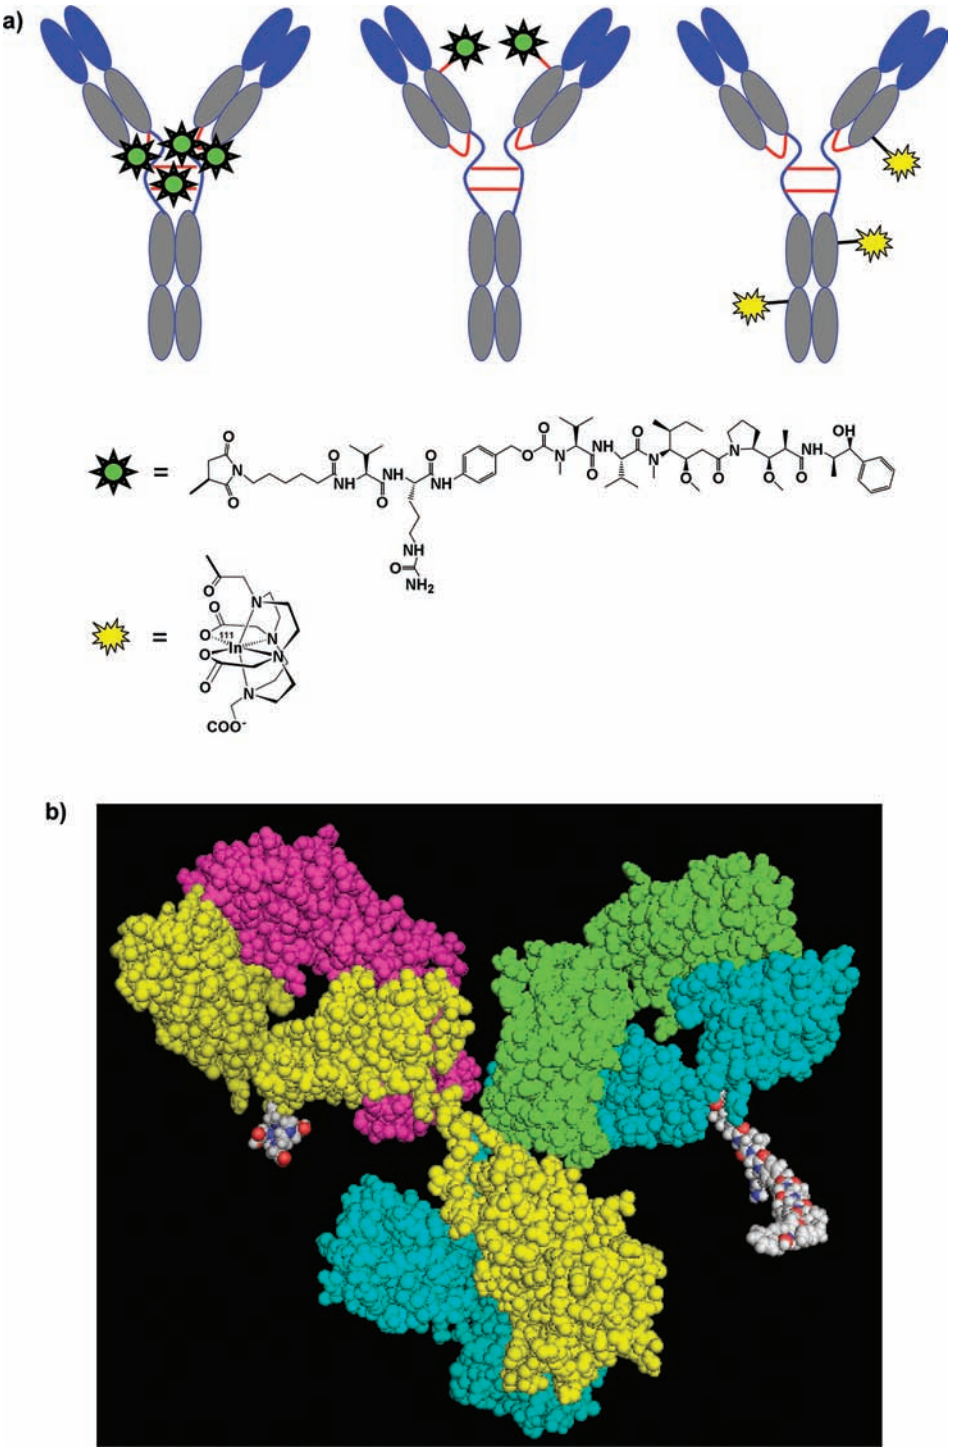

Figure 1. (a) Conceptual depiction of sites of anti-STEAP1 modification. The auristatin linker-drug, MC-vc-PAB-MMAE (green), was conjugated randomly through thioether bonds to cysteine thiols at the hinge region (left) or site-specifically to exactly two engineered thiols (center), while the radiometal chelate, DOTA (yellow), was randomly conjugated to lysine residues through amide bonds (right). (b) A space-filling three-dimensional model of an IgG1 (PDB code: 1igy) conjugated to a single molecule each of DOTA (left) and MC-vc-PAB-MMAE (right) is shown to depict the relative molecular sizes of the antibody, linker-drug, and chelate. Both MMAE and DOTA (without In^{3+}) were energy-minimized separately using the MM2 force field within *CambridgeSoft Chem3D Pro* version 7.0.0, exported as a PDB file, and merged with the IgG in the PyMOL Molecular Graphics System.[49] DOTA and MMAE are conjugated to LYS115 and CYS114 (mutated from ALA114 in 1igy), respectively. Carbons, oxygens, and nitrogens in DOTA and MMAE are colored white, blue, and red, respectively. Heavy chains bearing DOTA and MMAE are colored in yellow and blue, respectively.

antibody can be conjugated through cysteine residues to a potent antimitotic auristatin drug, monomethyl auristatin E (MMAE) via a protease-labile linker, maleimidocaproyl-valine-citrulline-*p*-aminobenzyloxycarbonyl (MC-vc-PAB, abbreviated as -vc-henceforth).[21−23] The peptidic vc-MMAE linker is designed to be stable in plasma, and has much improved stability in systemic

dx.doi.org/10.1021/bc200212a |*Bioconjugate Chem.* 2011, 22, 1994–2004

circulation compared to earlier chemically labile linkers such as hydrazone.[22] Drug conjugation in the presence of four sets of interchain disulfide bonds gives rise to a heterogeneous ADC mixture that can be described in terms of a drug to antibody ratio (DAR) distribution and an average DAR. For instance, the anti-STEAP1 ADC with an average DAR of 4 (illustrated in Figure 1) is just one possible molecular species of a mixture that may be composed of zero to eight drugs per antibody covalently attached via the -vc- linker. This heterogeneity may ultimately lead to different PK, efficacy, and toxicity properties of each fraction; for example, fractions with higher DAR have, in some cases, been reported to clear more rapidly and contributed to more severe toxicity.[24] Other reports have demonstrated, however, similar efficacy, tolerability, and PK between preparations having heterogeneous (0−8) and homogeneous (4) DAR.[25]

Recently, to control the heterogeneity of ADCs and to explore a novel strategy for potentially increasing the therapeutic window, a novel thio-anti-STEAP1 drug conjugate (TDC) was developed with site-specific conjugation through two engineered reactive thiols using ThioMab antibody technology.[15] The molecular structures in Figure 1a illustrate two ADC variants that differ in how the drug is covalently attached to anti-STEAP1. The linker-drug (vc-MMAE) is conjugated to the antibody through a thioether bond between the linker maleimide moiety and (i) a cysteine thiol that normally forms the interchain disulfide bond at the hinge region in the anti-STEAP1 ADC (Figure 1a left) or (ii) a site-specific, engineered thiol in the anti-STEAP1 TDC (Figure 1a center). The relative sizes of the antibody and MMAE are depicted in Figure 1b. Note that the theoretical drug load for the anti-STEAP1 ADC is a heterogeneous distribution of 0, 2, 4, 6, and 8 DAR, while the TDC is homogeneous with a DAR of 2. Anti-STEAP1 ADCs, including TDCs, have exhibited antitumor activity in explant and xenograft models and are being investigated for the treatment of prostate cancer.[26]

The present study investigates the potential impact of MMAE drug conjugation on antibody pharmacokinetics (PK) and tissue distribution of ADCs prepared through interchain thiol residues in a monoclonal antibody (mAb) or through site-specific, engineered cysteines in a ThioMab.[15] The anti-STEAP1 antibody and corresponding ADCs do not cross react with rat STEAP1; therefore, this species is suitable for evaluation of antigen-independent PK, biodistribution, and toxicity. In this context, the PK of four different molecular entities and biodistributions of their radiolabeled (via indium-111-DOTA, Figure 1) counterparts were compared following a single intravenous dose in rats. The rationale for selection of test molecules was to determine the potential effects of varying the site of drug conjugation and/or the DAR characteristics relative to unconjugated antibodies. Furthermore, we compared the PK profiles measured by both gamma counting and total antibody ELISA in order to bridge radiometric data from both terminal tissue distribution harvests and nonradioactive PK studies.

EXPERIMENTAL PROCEDURES

Antibody/ThioMab Production and MMAE Conjugation. The anti-STEAP1 antibody and anti-STEAP1-vc-MMAE conjugate (ADC) were prepared as previously described.[22] Briefly, the maleimido drug derivative was incubated with reduced mAbs for 1 h at 4 °C, followed by quenching with excess cysteine. Methods for construction and production of the thio-anti-STEAP1 (ThioMab) variant were reported previously.[15] Briefly, a cysteine residue was engineered at Ala114 position of the anti-STEAP1 heavy chain to produce its ThioMab variant from which the thio-anti-STEAP1-vc-MMAE conjugate (TDC) was produced. The DAR for each immunoconjugate was determined by hydrophobic interaction chromatography analysis as described earlier.[15]

DOTA Conjugation and Characterization. Proteins were conjugated to 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) for indium-111 (^{111}In) complexation by random modification of lysine residues (Figure 1a right). Aliquots containing 2−6 mg of the fully human antibodies anti-STEAP1, thio-anti-STEAP1, and the corresponding vc-MMAE conjugates were exchanged from formulation buffer into aqueous 50 mM sodium borate, pH 8.5 using illustra NAP5 columns (GE Healthcare Life Sciences, Piscataway, NJ). A quantity of 5 mol equiv of the *N*-hydroxysuccinimidyl ester of DOTA in 0.68−1.66 μL of dimethylformamide was added to the 600 μL borate-buffered protein solutions. Reaction mixtures were gently agitated (300 rpm) for 1 h at 37 °C on a Thermomixer (Eppendorf North America, Hauppauge, NY). Reaction was terminated by promptly applying the mixtures to NAP5 columns pre-equilibrated in aqueous 0.3 M ammonium acetate buffer, pH 7.0. The resulting purified DOTA-mAb conjugates were stored at 4 °C. The binding specificity and affinity to STEAP1 for all four antibody variants were characterized by total antibody ELISA (see below).

Determination of the average number of covalently attached chelates for each DOTA conjugate by radiometric assay was performed by modification of previously reported procedures.[27,28] An aliquot of 10 μL of each mAb-DOTA conjugate (2−4 mg/mL in 0.3 M ammonium acetate pH 7.0) was added to 10 μL of a standardized $InCl_3$ solution (323 μM, 3.23 nmol, containing >150 000 cpm/μL of ^{111}InCl). The reaction was incubated at 37 °C for 3 h, after which 5 μL of 50 mM EDTA and 75 μL of 0.3 M ammonium acetate pH 7 were added, followed by further incubation for 5 min at 25 °C. The entire mixture was loaded onto a NAP5 column pre-equilibrated in PBS and allowed to settle, followed by an additional 400 μL of PBS. The radiolabeled antibody fraction was eluted separately with an additional 500 μL of PBS. The radioactivity in the eluent and remaining on the NAP5 column was measured using a 1480 WIZARD Gamma Counter (Wallac, Turku, Finland) in the energy window for the 245 keV photon peak of ^{111}In and with automatic background and decay correction. The number of chelates per antibody molecule was calculated from the ratio of counts in the eluted product to the total number of counts using the method of Meares and co-workers.[27]

The number of chelates per antibody was also estimated by LC-MS. Prior to analysis, all protein samples (100 μL, 0.25−0.5 mg/mL) were deglycosylated overnight at 37 °C using 2 μL peptide *N*-glycosidase (PNGase F, Prozyme). Anti-STEAP1 ADC samples were also further subjected to a reduction step using 10 μL of 200 mM dithiothreitol (DTT). Samples were injected onto a Pepswift Monolithic PS-DVB column (0.5 × 5 mm, ID 500 μm, Dionex) using an HTS PAL autosampler (LEAP Technologies) with a cooling stack set at 4 °C. The column temperature was maintained at 70 °C using a column heater (Keystone Scientific). The LC separation was conducted using an Express LC-100 liquid chromatography system (Eksigent Technologies, Dublin, CA) at a flow rate of 15 μL/min. Mobile phase A was water with 0.1% formic acid, and mobile phase B was acetonitrile with 0.1% formic acid. The gradient condition was maintained at 2% B for 4 min, ramped to 40% B in 8 min, kept at 40% B for 3 min, increased to 100% B in 1.5 min,

retained at 100% B for 1 min, returned back to 2% B in 0.8 min, and finally equilibrated for 0.7 min before the next injection (for a total run time of 15 min). For the first 6 min, the LC flow was diverted to waste. The eluate was then directed to a Q-STAR XL quadrupole time-of-flight (TOF) mass spectrometer (AB Sciex, Foster City, CA) operated with a turbo ionspray source maintained at 200 °C in the positive ion mode. The declustering potential (DP) and focusing potential (FP) were optimized at 100 and 300 V, respectively. Data analysis was performed using the *Analyst QS 1.1* software and a Bayesian Protein Reconstruct algorithm for mass spectral deconvolution (AB Sciex, Foster City, CA).

Radiochemistry. A 2 μL (820 μCi; 30.3 MBq) aliquot of ^{111}InCl (MDS Nordion, Ottawa, ON) was added to a 20 μL aliquot of each ammonium acetate-buffered DOTA−protein conjugate. Reaction mixtures were gently agitated (300 rpm) for 1 h at 37 °C on a Thermomixer. A 5 μL aliquot of 50 mM aqueous EDTA challenge solution was added, followed by an additional 73 μL aliquot of aqueous 0.3 M ammonium acetate buffer, pH 7.0. Each radiolabeled protein was purified using NAP5 columns pre-equilibrated in PBS. Purity of each radioimmunoconjugate was assessed by size-exclusion radiometric high-performance liquid chromatography (HPLC) (isocratic, PBS, 0.5 mL/min) on an Agilent 1100 series HPLC system operated through *ChemStation* software and equipped with a Biosep-SEC-S 3000 column (Phenomenex) and a raytest Ramona 90 radioactive flow monitor.

Pharmacokinetic Studies. All experimental animal studies were conducted according to protocols that were reviewed and approved by the Institutional Animal Care and Use Committees (IACUC) of Genentech Laboratory Animal Research (LAR). Male Sprague−Dawley rats ranging from 8 to 10 weeks old and weighing approximately 250−300 g at the initiation of the study were randomly assigned to 4 groups (n = 4 per group), and administered an intravenous bolus (5 mg/kg) of test article. Blood samples were collected from each animal via the femoral vein for up to 28 days and used to derive plasma for total and conjugated antibody concentration determination using an ELISA and the concentration of free MMAE released in vivo from anti-STEAP1 conjugates in plasma using LC-MS/MS detection (see below). Plasma concentration−time data were used to estimate relevant PK parameters using *WinNonlin* software (v 5.2.1 Pharsight Corporation, Mountain View, CA). To better compare the profile between radiometry and ELISA data, radiometric (In-111) blood PK data (see below) were normalized to the same dose level.

Tissue Distribution. Juvenile male Sprague−Dawley rats (Harlan) with weight range of 75−100 g received a single bolus intravenous injection of ^{111}In-labeled conjugates. Dosing solutions were prepared by mixing the ^{111}In-DOTA-labeled test articles with the corresponding non-DOTA-conjugated molecules to achieve a total protein dose of 10 mg/kg and radioactive dose of approximately 400 μCi/kg (14.8 MBq/kg) in no more than 200 μL of PBS. A 500 μL aliquot of whole blood was terminally collected at 1 h, 1 day, 2 days, 5 days, and 7 days in lithium heparinized tubes via cardiac puncture under inhaled isoflurane anesthesia. The following tissues were subsequently harvested: lungs, liver, kidneys, heart, spleen, right femur, gastrocnemius muscle, stomach, small intestine, and large intestine. All tissues were rinsed with PBS, blot-dried, weighed, frozen on dry ice, and stored at −70 °C. Blood, tissues, and 5 μL aliquots of dosing solution standards were counted for radioactivity using a 1480 WIZARD Gamma Counter in the energy window for the 245-keV photon peak of ^{111}In and with automatic background and decay correction. Average counts per minute (cpm) were converted to percentage of injected dose per gram of tissue (%ID/g) and plotted with standard deviations. Statistical significance was determined by one-way ANOVA followed by Tukey's post-test in *GraphPad Prism* v 5.04.

Total Antibody ELISA. Nunc MaxiSorp 384-well plates (Nalge Nunc International, Rochester, NY) were coated with either anti-idiotypic antibody 5093 (Genentech, South San Francisco, CA) or donkey antihuman Fc (Jackson ImmunoResearch Laboratories, Inc., West Grove, PA) and incubated overnight at 4 °C. The plates were washed 3 times with 0.05% Tween-20 in PBS buffer (pH 7.4). Diluted standards plasma samples were added to the wells and incubated on a shaker for 2 h at room temperature. The plates were washed 6 times and a detection antibody, either goat antihuman IgG antibody conjugated to horseradish peroxidase (Bethyl Laboratories, Montgomery, TX) or goat antihuman Fc conjugated to horseradish peroxidase (Jackson ImmunoResearch Laboratories, Inc., West Grove, PA), was added to the wells and incubated on a shaker for 1 h at room temperature. The plates were washed 6 times and developed using TMB peroxidase substrate (Moss Inc., Pasadena, Maryland). Both assay ranges were 0.164−40 ng/mL with a minimum dilution of 1:100 (limit of detection = 16.4 ng/mL). TDC assays were characterized as having acceptable (80-120%) DAR analyte recovery (data not shown). For ADC assays, DAR reagents were not available to characterize analyte recovery at the time of the original study sample analysis. However, data reported from the assay herein were confirmed using a more recent assay where DAR recovery was characterized and found to be acceptable) 80−120%; data not shown).

Conjugated Antibody ELISA. Nunc MaxiSorp 384-well plates were coated with anti-MMAE antibody (Seattle Genetics Inc., Bothell, WA) and incubated overnight at 4 °C. The plates were washed 3 times with 0.05% Tween-20 in PBS buffer (pH 7.4). Diluted standards and the ADC or TDC plasma samples were added to the wells and incubated for 2 h at room temperature. The plates were washed 6 times and a detection antibody, either goat antihuman IgG antibody conjugated to horseradish peroxidase (Bethyl Laboratories, Montgomery, TX) or goat antihuman Fc conjugated to horseradish peroxidase (Jackson ImmunoResearch Laboratories, Inc., West Grove, PA), was added on a shaker for 1 h at room temperature. All plates were developed using TMB peroxidase substrate. The ADC assay range was 0.0655-16 ng/mL with a minimum dilution of 1:100 (limit of detection = 6.6 ng/mL). The TDC range was 0.164−40 ng/mL with a minimum dilution of 1:100 (limit of detection = 16.4 ng/mL). TDC and ADC assays were characterized for DAR analyte recovery as described for the total antibody ELISA.

Free MMAE Assay. The concentration of free MMAE in plasma was determined by liquid chromatography tandem mass spectrometry (LC-MS/MS). Briefly, plasma samples were protein precipitated with 100 μL of 80/20 acetonitrile/water containing 2 nM monomethylauristatin F (MMAF) as an internal standard, and analyzed for MMAE by TurboIon Spray using an API 3000 mass spectrometer (Applied Biosystems, Foster City, CA). The HPLC system used for analysis was a Shimadzu HPLC LC-10Avp system (Shimadzu Scientific Instruments, Columbia, MD), equipped with a Short Hot Pocket column heater (Keystone Scientific, Inc., Bellefonte, PA) and analytical column (Phenomenex Synergi MAX-RP 80A, C12, 4 μm, 2.0 × 50 mm)

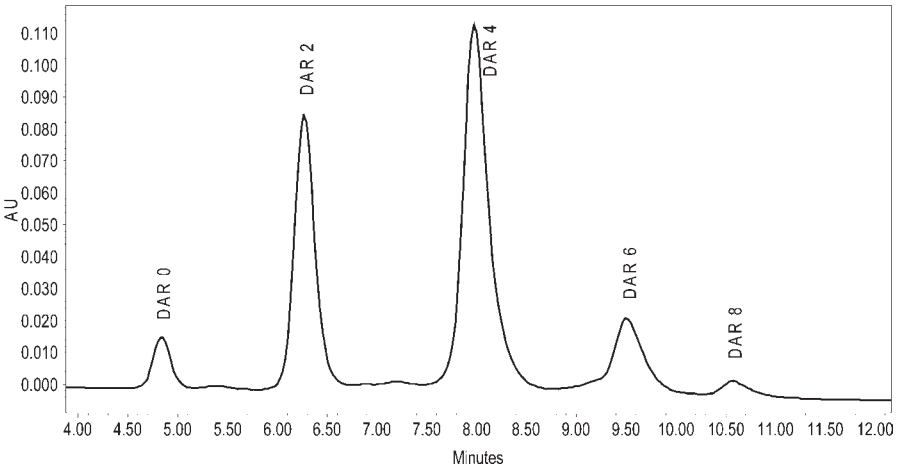

Figure 2. Representative hydrophobic interaction chromatography (HIC) of anti-STEAP1 ADC with average drug-to-antibody ratio (DAR) of approximately 3.5. The peak assignments are consistent with the conjugation of the linker−drug being primarily limited to the interchain cysteines of the antibody and leading to a DAR distribution of mainly 0, 2, 4, 6, or 8.

Table 1. Summary of Analytical Data Obtained during Characterization, DOTA Conjugation, and ^{111}In Radiolabeling of Anti-STEAP1 (mAb), Thio-anti-STEAP1 (ThioMab), and the Two Corresponding MMAE Conjugates (ADC and TDC)

test material	# MMAE (HIC)[a]	# DOTA (radiometric)[b]	# DOTA (MS)[c]	ELISA recovery (%)[d]	^{111}In labeling yield (%)[e]	^{111}In labeling purity (%)[f]
mAb	N/A	2.20 ± 0.148	2.6	73	82	98
ADC	3.1	1.50 ± 0.0787*	1.7	73	61	97
ThioMab	N/A	2.47 ± 0.273	3.2	80	84	98
TDC	1.7	1.67 ± 0.139*	2.3	82	78	99

[a] HIC: hydrophobic interaction chromatography. [b] Performed in triplicate. [c] Estimated from differences between mass spectrometry (MS) peaks before and after DOTA conjugation. [d] Measured by ELISA after DOTA conjugation to verify immunoreactivity. [e] Radiolabeling performed using ∼30 MBq ^{111}InCl and ∼40 mg DOTA-mAb in 0.3 M ammonium acetate pH 7 at 37 °C for 1 h. [f] Derived by integration of size exclusion radiochromatogram. * $P <$ 0.05 vs mAb by unpaired *t* test.

at 50 °C. Multiple reaction monitoring scan mode was used for quantitation. For MMAE quantitation, transition 732.7/170.3 was monitored for MMAF (internal standard) and 718.7/152.2 for MMAE. The LC-MS/MS assay had a lower limit of quantitation of 0.018 ng/mL (0.025 nM) with linearity demonstrable up to 18 ng/mL (25 nM) using a sample volume of 0.025 mL.

RESULTS

Antibody/ThioMab Production and MMAE Conjugation. The presence of a heterogeneous mixture of DAR species was demonstrated by hydrophobic interaction chromatography (HIC) as shown in a representative chromatogram for the anti-STEAP1 ADC (Figure 2). The calculated average DARs for the ADC and TDC used in PK and tissue distribution studies were 3.1 and 1.7 per mAb, respectively (Table 1).

DOTA Conjugation and Characterization. All four DOTA conjugates retained antigen binding, measured as percent recovery in a STEAP1-specific ELISA (Table 1). Radiometric measurement of the average number of DOTA chelates attached per antibody molecule gave values ranging from 1.5 to 1.7 for the drug conjugates and from 2.2 to 2.5 for the non-drug-conjugated molecules (Table 1). These values were in rough agreement with estimates based on shifts of mass peaks before and after DOTA conjugation, which showed a range of 1.7−2.3 for the drug conjugates and 2.6−3.2 for the non-drug-conjugated molecules (Table 1; see also Supporting Information).

Radiochemistry. Slightly lower radiochemical yields (Table 1) were obtained for the ADC (61%) and TDC (78%) than for the corresponding non-drug-conjugated antibody and ThioMab (82% and 84%, respectively). Size-exclusion HPLC demonstrated radiochemically pure (≥97%) products (Table 1) with no evidence of unconjugated ^{111}In (see Supporting Information).

Pharmacokinetic Studies. The anti-STEAP1 total antibody ELISA quantifies the antibody moiety irrespective of drug conjugation status, as the assay format is designed to capture both unconjugated antibody and ADC variants. The anti-STEAP1 conventional mAb and ThioMab showed similar PK profiles (Figure 3a), indicating that cysteine mutations had little impact on antibody clearance. Indeed, the clearances of the conventional mAb and ThioMab at rates of 7.27 ± 1.71 and 9.65 ± 2.33 mL/day/kg, respectively, were comparable (Table 2). The two drug conjugates had similar clearances, with 10.5 ± 1.42 and 9.56 ± 2.53 mL/day/kg for the ADC and TDC, respectively. The ADC total antibody cleared approximately 45% more rapidly than the corresponding unconjugated mAb at rates of 10.5 ± 1.42 and 7.27 ± 1.71 mL/day/kg ($P < 0.05$), respectively. In contrast, the TDC had a similar clearance compared with the ThioMab at rates of 9.56 ± 2.53 and 9.65 ± 2.33 mL/day/kg, respectively. This reflects the differential impact on the overall clearance of the antibody depending on site and degree of conjugation.

The anti-STEAP1 conjugate ELISA format is designed to measure any anti-STEAP1 antibody conjugated with one or more MMAE drugs. This assay is not sensitive to incremental

changes in drug load, but can estimate the overall complete drug loss from the ADC or TDC as unconjugated mAb is not measured. The anti-STEAP1 ADC and TDC showed markedly different conjugate PK profiles (Figure 4a). A summary of the PK parameters for both anti-STEAP1 total antibody and conjugate in plasma is presented in Table 2. The anti-STEAP1 ADC cleared 3 times as fast in terms of conjugated antibody relative to total antibody (33.6 ± 4.27 and 10.5 ± 1.42 mL/day/kg, respectively). However, it is difficult to distinguish whether biotransformation of ADC is dominated by MMAE release (deconjugation) versus proteolytic degradation of the antibody itself (total antibody clearance). In contrast, the TDC showed only 1.3 times faster clearance in terms of conjugated antibody compared to total antibody clearance (12.5 ± 2.41 and 9.56 ± 2.53 mL/day/kg, respectively). The clearance of the anti-STEAP1 ADC in terms of conjugated antibody was almost three times faster than that of the TDC (33.6 ± 4.27 and 12.5 ± 2.41 mL/day/kg, respectively). Overall, the volume of distribution (V_1) for all groups approximated to plasma volume in rats (31 mL/kg for a 250 g rat[29]), ranging from 39.4 ± 0.704 to 47.3 ± 8.82 mL/kg.

Plasma concentration−time profiles of free MMAE, measured by LC-MS/MS, following administration of the two MMAE-conjugated

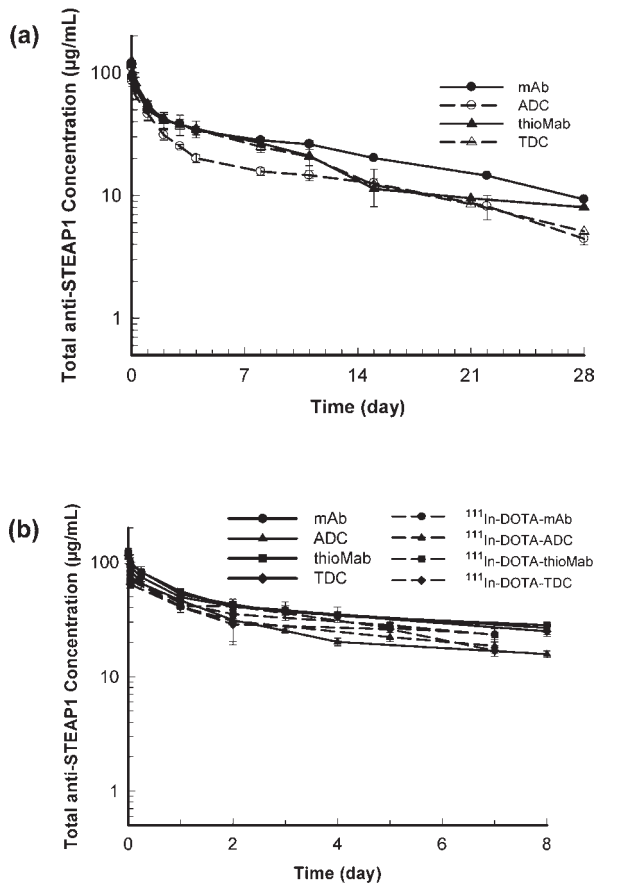

Figure 3. Mean total antibody concentrations in plasma of anti-STEAP1, thio anti-STEAP1, and the two corresponding MMAE drug conjugates in male rats following intravenous administration at 5 mg/kg. Error bars are standard deviations. Data from (a) ELISA-derived PK (solid lines) only and (b) both PK and radiometric tissue distribution (dotted lines) are included. Data for ^{111}In-labeled molecules in (b) was dose normalized to 5 mg/kg for comparison with ELISA-derived data.

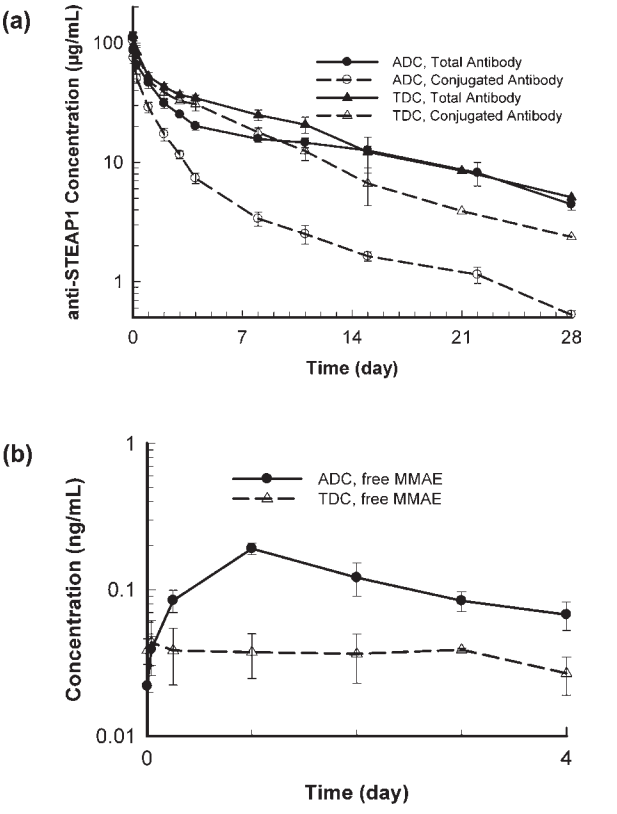

Figure 4. (a) Mean total and conjugated antibody concentrations (by ELISA) in plasma of anti-STEAP1 ADC and TDC in male rats following intravenous administration at 5 mg/kg. (b) Mean free MMAE concentrations (by LC-MS/MS) in plasma following administration of anti-STEAP1 ADC and TDC in male rats. Error bars in both (a) and (b) are standard deviations.

Table 2. Summary of Total Anti-STEAP1 Antibody Pharmacokinetics in Plasma of Anti-STEAP1 (mAb), Thio-anti-STEAP1 (ThioMab), and the Two Corresponding MMAE Drug Conjugates (ADC and TDC) in Male Rats (n =4)

test material	dose (mg/kg)	analyte	CL[a] (mL/day/kg)	V_1 (mL/kg)
mAb	5	total antibody	7.27 ± 1.71	41.4 ± 2.31
ADC	5	total antibody	10.5 ± 1.42*	44.8 ± 6.00
		conjugated antibody	33.6 ± 4.27*	47.3 ± 8.82
ThioMab	5	total antibody	9.65 ± 2.33	39.4 ± 0.704
TDC	5	total antibody	9.56 ± 2.53	42.9 ± 2.04*
		conjugated antibody	12.5 ± 2.41*	42.2 ± 1.79*

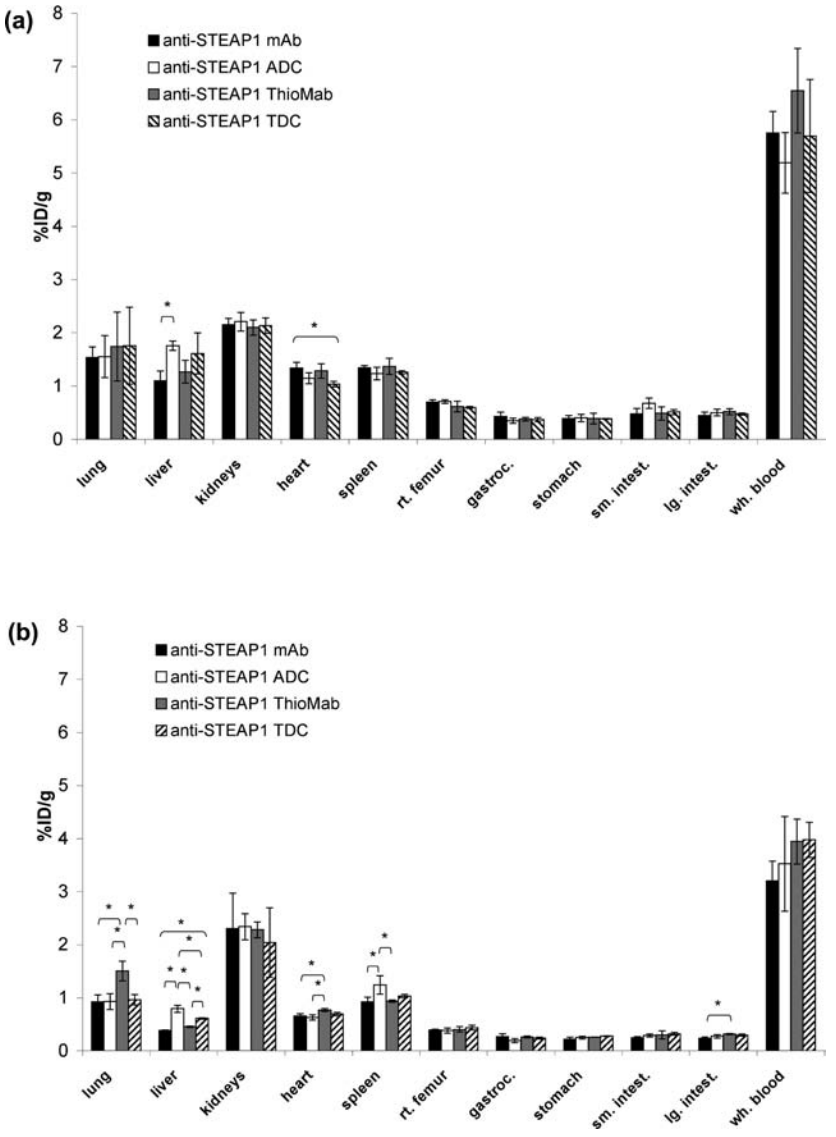

Figure 5. Tissue distribution of ^{111}In-DOTA-labeled anti-Steap1 (black), thio-anti-Steap1 (gray), and the corresponding MMAE conjugates (white and striped, respectively) in rats at (a) 24 h and (b) 120 h after intravenous injection. Data are presented as percentage of injected dose per gram of tissue (mean %ID/g ± SD for 3 rats per group). Statistically significant differences are indicated by brackets (*P < 0.05).

anti-STEAP1 antibodies are presented in Figure 4b. Although observed free MMAE concentrations were generally very low (~0.2 ng/mL or less) and detected only up to day 4 postdose for both conjugated antibodies, the anti-STEAP1 ADC showed a higher concentration of plasma MMAE at time points ranging from 6 h through 4 days. The observed free MMAE exposure measured by both C_{max} and AUC was approximately four times higher for the ADC than for the TDC (C_{max}: 0.19 ± 0.02 vs 0.04 ± 0.02 ng/mL; AUC: 0.45 ± 0.05 vs 0.14 ± 0.03 ng/mL days, respectively). These differences seem to exceed the roughly 2-fold expected difference based on DAR; however, it is difficult to distinguish between deconjugation versus total antibody catabolism in explaining greater drug loss from the ADC relative to the TDC.

Tissue Distribution. Radiometrically derived (dose-normalized) and ELISA-derived total antibody PK data were largely comparable (Figure 3b), indicating similar blood exposures of all four test articles. At 24 h postinjection, significantly (P < 0.05) higher hepatic uptake of ^{111}In was observed for anti-STEAP1 ADC (1.76 ± 0.0878) than for unconjugated anti-STEAP1 (1.10 ± 0.183%ID/g) (Figure 5a). Conversely, anti-STEAP1 TDC demonstrated lower cardiac uptake of ^{111}In at 24 h (1.04 ± 0.0497%ID/g) than unconjugated anti-STEAP1 (1.34 ± 0.108%ID/g).

At 120 h postinjection, elevated hepatic uptake of ^{111}In for anti-STEAP1 ADC relative to unconjugated anti-STEAP1 was maintained (0.791 ± 0.0648 vs 0.386 ± 0.00617%ID/g) with a similar but less pronounced trend for anti-STEAP1 TDC and its corresponding unconjugated ThioMab (0.610 ± 0.0155 vs 0.454 ± 0.0157%ID/g) (Figure 5b). Significantly (P < 0.05) higher uptake for anti-STEAP1 ADC (1.24 ± 0.173) relative to anti-STEAP1 (0.925 ± 0.0888) was also observed at 5 d in spleen. Meanwhile, thio-anti-STEAP1 uptake in both heart (0.768 ± 0.0252%ID/g) and lungs (1.50 ± 0.188%ID/g) was higher than for all other variants, which ranged from 0.628 ± 0.0476 to 0.691 ± 0.0323%ID/g in heart and from 0.923 ± 0.131%ID/g to 0.962 ± 0.0975%ID/g in lungs. Similar trends

were observed in additional tissue distribution data at 1, 48, and 168 h postinjection (see Supporting Information).

DISCUSSION

Considerable effort has been applied to understanding the PK,[30,31] tissue distribution,[20] metabolism,[32−34] and pharmacologic effects[19,35,36] of ADCs. Still, the inherent heterogeneity of these complex macromolecular entities remains a prominent challenge in understanding their properties in vivo during nonclinical development. For example, conjugation through interchain disulfides leads to ADCs with DAR ranging from 0 to 8, with each fraction potentially exhibiting a unique efficacy, PK, and toxicity profile. In addition, the existing analytical methods available for antibodies and small molecule drugs have inherent technical limitations for complex ADCs. For example, the performance of ELISA is sensitive to the heterogeneity of the analytes, and susceptible to variation in recovery of each DAR fraction.[31] Assays used in this study demonstrated 80-120% DAR analyte recovery (data not shown); however, it is not known if these analytes are structurally identical to DAR species formed in vivo.

The recent introduction of ThioMabs presents an opportunity to control the drug load and site of attachment of drug molecules, thereby limiting heterogeneity by conjugation through genetically engineered cysteine sites[15] and potentially improving the overall PK characteristics. In this context, the current single-dose study encompasses the evaluation of an anti-STEAP1 antibody, the corresponding ThioMab variant possessing engineered cysteines, and two corresponding thioether-linked MMAE conjugates (ADC and TDC, respectively) to assess the impact of conjugation site and drug load on PK and tissue distribution.

Plasma PK of anti-STEAP1 total antibody was measured by both ELISA and radiometric detection. Anti-STEAP1 total antibody clearances of the two unconjugated antibodies were similar, suggesting minimal impact on PK due to cysteine mutation (Figure 3). The PK profile comparison between unconjugated and conjugated variants reflects the impact of drug conjugation on PK and disposition of the antibodies. An increase in total antibody clearance of approximately 45% was observed for the anti-STEAP1 ADC, while no change in clearance was observed for the TDC, relative to their non-drug-conjugated counterparts. The exact magnitude of the increased clearance of the ADC may be somewhat affected by the inherent technical limitations of ELISA for mixture analysis; however, the trend is clearly apparent. Indeed, this trend toward faster plasma clearance of immunoconjugates relative to unconjugated antibodies (Figure 3a) is consistent with previous studies.[24] This suggests that controlled conjugation with lower DAR and without structural disruption of disulfide bonds (i.e., TDC) leads to minimal alteration in antibody PK behaviors. However, generalizations to other ADC platforms[37] should not be assumed, and the relationship between conjugation method and biological disposition must be independently established. In addition, a very good overall agreement existed between ELISA- and radiometrically derived PK, indicating that DOTA conjugation had no dramatic effect on disposition kinetics (Figure 3b).

The enzyme labile, peptidic vc-MMAE linker is designed to be stable in plasma, and has greatly improved stability in systemic circulation and a superior safety profile compared to chemically labile linkers such as hydrazone.[22] However, ADCs in blood may release some MMAE (i.e., deconjugate), resulting in changes in the DAR distribution of the drug-loaded species and the unconjugated antibody. To gain further mechanistic insights into ADC disposition and deconjugation, the plasma PK of conjugated antibody was measured by ELISA. The conjugate antibody assay format is designed to capture any antibody with at least one conjugated drug, such that the clearance encompasses both complete deconjugation and antibody clearance. Its comparison with total antibody clearance sheds light on the relative contribution of each process. The anti-STEAP1 ADC (average DAR = 3.1) showed a marked (approximately 3-fold) difference between conjugated antibody clearance and total antibody clearance. A similar trend between clearance rates of total antibody and conjugate for other immunoconjugates has been previously reported.[38] In contrast, deconjugation had much less impact (roughly 1.3-fold) on the overall clearance in TDC (Table 2 and Figure 4a).

Deconjugation from anti-STEAP1 ADC and TDC involves release of small molecules that may ultimately result in cytotoxic free MMAE in circulation. Very low levels of free MMAE (below 1 ng/mL) were detected for either ADC or TDC (Figure 4b). This, in part, reflects the stability of the linker and relatively limited deconjugation of MMAE from conjugated antibody; it is also likely that the result of the rapid distribution and clearance rates of MMAE in relation to its production. Alternatively, there may be additional drug catabolites other than free MMAE (e.g., Cys-MC-vc-PAB-MMAE) that are not detected by the MMAE-specific free drug assay. Although the absolute MMAE concentrations in plasma are very low, a correlation may exist between stability and MMAE levels in plasma. In this case, greater than 3-fold (based on AUC) higher free MMAE plasma levels were observed compared to the TDC. However, the higher initial drug load (roughly 2-fold) in the ADC likely contributes to the higher level of MMAE observed in plasma. Nevertheless, one plausible explanation for these observations is that conjugation through a precise number (two) of engineered cysteines induced fewer disturbances in the overall antibody structure relative to the unmodified antibody and a correspondingly more stable molecule.

Since most ADC targets are selected for their low and restricted expression in normal tissues, exploitation of the rat as a nonbinding species provides an initial assessment of antigen-independent disposition of ADCs. Overall, tissue distribution trends were similar for all four radiolabeled antibody platforms at all time points and were consistent with the expected behavior for a typical nonbinding humanized antibody in rats (Figure 5, see also Supporting Information). Concentrations in blood and in all tissues decreased over time, with the exception of kidneys, where nearly constant uptake values were sustained. This is likely due to the continual clearance of low molecular weight ^{111}In-labeled metabolites (e.g., ^{111}In-DOTA-lysine) being generated in liver and in other sites of IgG catabolism.[39] Elevated hepatic uptake for anti-STEAP1 ADC and TDC relative to the non-drug-conjugated proteins may be rationalized by higher hydrophobicities of the drug conjugates, resulting in greater reticuloendothelial system clearance. Blood-corrected uptake for liver and other tissues may be calculated from the %ID/g values reported herein based on reported fractional vascular volumes in rodents; however, this correction would affect antibodies and drug conjugates to the same extent due to similar blood exposures.[40,41]

Robust characterization of all four derivatives was necessary in order to ensure that observed differences, if any, in biological disposition were indeed due to drug conjugation, as opposed to inconsistencies in radiolabeling (Table 1). The lower observed

radiochemical yields for the ADC and TDC than for the corresponding non-drug-conjugated molecules may reflect the influence of MMAE in sterically blocking lysine residues for DOTA conjugation. Although approximately 80−90 lysine residues are present in a typical IgG1,[42] it is likely that many of these may not be solvent-accessible, especially following conjugation of MMAE. Even though slightly higher incorporation of DOTA was obtained for the non-MMAE-conjugated molecules, the effects should be minor given that much larger changes in isoelectric point (i.e., pI) would be necessary to invoke a difference in tissue distribution or PK.[42] Furthermore, the ADC and TDC herein were, in fact, modified on average by approximately one fewer molecule of DOTA than the respective non-MMAE-conjugated counterparts as measured by both radiometric assay and mass spectrometry (Table 1). If the differences in hepatic uptake (Figure 5), for instance, were due to DOTA conjugation, then the trend observed herein would be inconsistent with a previous report that overconjugation with DOTA causes increased hepatic accumulation.[43] It is therefore more likely that the conjugation of hydrophobic drug moieties, not the slightly lower DOTA conjugation yield, is responsible for the increased hepatic uptake of anti-STEAP1-MMAE conjugates relative to the mAb and ThioMab. Additionally, a STEAP1-specific ELISA confirmed that the immunoreactivities of the four variants were largely retained following DOTA conjugation (Table 1).

The choice of ^{111}In-DOTA as a probe was influenced by a desire to increase the likelihood of detecting any differences in tissue-specific uptake among the four tested platforms. Antibodies labeled with metal radionuclides via DOTA or other polyaminopolycarboxylate chelators tend to accumulate in antigen-expressing tissues following receptor-mediated endocytosis due to the residualizing properties of this charged, highly polar probe.[44] The exploitation of DOTA as a carrier for ^{111}In, a medium-energy gamma emitting radionuclide with a 2.7 day decay half-life,[45] and other metallic radionuclides is well-documented.[46−48]

Conjugation with a small molecule drug through specific sites on mAbs can potentially alter mAb hydrophobicity, charge, polarity, and PK.[42] ADCs with higher drug loads possess higher intrinsic potency; however, they may also exhibit faster blood clearance in terms of total antibody.[24] However, it should be emphasized that each antibody and drug platform should be considered on a case-by-case basis; for instance, a lysine-modified trastuzumab-maytansinoid ADC (DAR 3.3) showed similar PK compared with the analogous TDC (DAR 1.8) modified through engineered cysteines.[37] In addition, the increased release of free drug or toxic intermediates into systemic circulation or nontarget organs could potentially shrink the therapeutic window. The ability to define the DAR combined with the knowledge of PK and distribution will afford us new opportunities in optimizing ADCs.

In conclusion, an anti-STEAP1 antibody, a ThioMab variant possessing engineered cysteines, and two corresponding thioether-linked MMAE conjugates were studied in order to assess the impact of drug conjugation methodology on PK and tissue distribution. MMAE conjugation through native cysteine thiols comprising interchain disulfide bonds (average DAR 3.1) resulted in an accelerated clearance of total antibody, while conjugation through engineered cysteine thiols (average DAR 1.7) led to only a marginal difference in clearance. In addition, an ELISA assay specific for MMAE-conjugated antibody indicated that the ADC had faster clearance than the TDC, which is due in part to a greater magnitude of drug deconjugation from the ADC. Although very low in both cases, free MMAE measured in plasma was higher for the ADC relative to the TDC. Overall, modification by either method had a noticeable, albeit minor, impact on tissue distribution with a general trend toward increased hepatic uptake and reduced levels in other highly vascular organs. Taken together, these results indicate that the degree of overall structural modification of the antibody in an ADC has a corresponding level of impact on the PK behavior and stability in vivo. Accordingly, in addition to understanding the general chemical stability of the linker, it is important to consider the degree of structural modification of ADCs, the DAR distributions, and the sites of modifications to gain insight into the potential impacts on PK behavior and distribution.

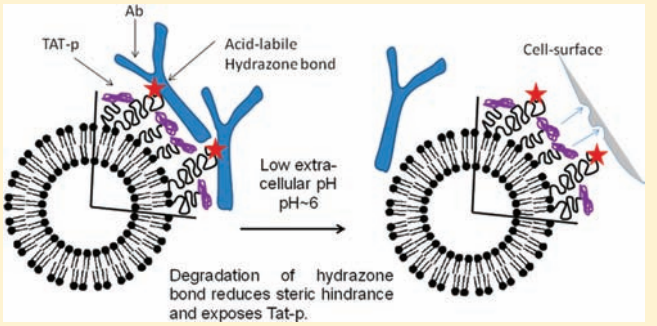
Development of the Novel PEG-PE-Based Polymer for the Reversible Attachment of Specific Ligands to Liposomes: Synthesis and in Vitro Characterization

Swati Biswas, Namita S. Dodwadkar, Rupa R. Sawant, and Vladimir P. Torchilin*

Center for Pharmaceutical Biotechnology and Nanomedicine, 360 Huntington Avenue, 312 Mugar Hall, Northeastern University, Boston, Massachusetts 02115, United States

ABSTRACT: Surface grafting of liposomes with the wide variety of ligands including antibodies and other proteins is a promising approach for targeted delivery of therapeutics. In this paper, we describe a simple method of synthesizing a hydrazine-functionalized poly(ethylene glycol)-phosphatidylethanolamine (PEG-PE)-based amphiphilic polymer which can conjugate a variety of ligands via a reversible, pH-cleavable bond. In this method, the targeting ligand is attached to the distal end of the PEG chain, which facilitates its easy access to the targeted site of interaction. The reversible attachment of targeting ligands is useful especially in multifunctional liposomal systems, whereafter successfully performing the function of targeting to the specific site, the bulky ligands, such as proteins or antibodies, are cleaved off in response to an environmental stimulus to expose some other functionalities such as ligands for intracellular penetration or organelle-specific targeting. To investigate the applicability of the protocol, the model ligands monoclonal antinucleosome antibody 2C5 and antimyosin antibody 2G4, and glycoproteins concanavalin A (Con-A) and avidin were conjugated to the synthesized polymer and incorporated into liposomes. In vitro assays including biochemical, enzyme-linked immunosorbent, fluorescence microscopy, and flow cytometry were used to confirm three key characteristics of the modified and/or liposome-attached proteins: successful conjugation of the targeting ligands to the polymer, preservation of specific activity of the ligands after the conjugation and liposome attachment, and the facile pH-sensitive ligand detachment. Monoclonal antibody 2C5 and 2G4, immobilized on the liposome surface, retained their binding affinity to corresponding antigens as confirmed by ELISA. The Con A-bearing liposomes showed significantly higher agglutination in the presence of its substrate mannan compared to plain liposomes (PL) and avidin-functionalized liposomes bound specifically with biotin−agarose. The study on the pH-dependence showed that almost 80% of the hydrazone bond was cleaved after rather brief preincubation of the immunoliposomes at pH 5 for 0.5 to 1 h. Fluorescence microscopy and flow cytometry analysis of cancer cells (HeLa and MCF-7) treated with cancer cell-specific targeting ligand mAb 2C5-bearing liposomes showed enhanced cellular binding. Studies at low pH clearly confirmed the easy cleavability of the targeting ligand from the liposomes resulting in significantly less or virtually no cellular association.



INTRODUCTION

Liposomes have served as an efficient drug delivery system for enhanced efficacy and decreased systemic toxicity of various biologically active molecules.[1,2] However, one of the major disadvantages of liposomal drug delivery systems (DDS) is that circulating liposomes are rapidly cleared when uptaken by cells of the reticuloendothelial system (RES) in the liver and spleen. To engineer liposomes capable of delivering therapeutic cargo to sites other than the RES, long-circulating polymer-coated (PEGylated) liposomes have been developed.[1,2] The modification of nanocarriers by conjugating PEG on the surface reduces many undesirable side effects triggered in vivo by various biological recognition mechanisms.[3] This property of prolonged systemic circulation also results in passive targeting of liposomes even in the areas with a compromised vasculature such as infarcts and tumors by the enhanced permeability and retention (EPR) effect.[4−9] Active targeting of liposomes to specific disease sites, such as tumors and infarcts, could be achieved by surface modification of the liposomes with various ligands, such as tumor-specific molecules including cancer cell-specific antinucleosome antibody (mAb 2C5), proteins (transferrin), peptides (RGD), and small molecules such as receptor ligands (folate) for anticancer therapy and antimyosin mAb (2G4) for the therapy of the myocardial infarction.[10−16] Thus, pharmaceutical nanocarriers can be endowed with the properties of both active and passive targeting.[17,18]

In the case of active targeting of PEGylated liposomes, the targeting moiety should be attached "above" the protective polymer

layer by coupling it to the distal end of a PEG chain to provide accessibility of the ligand to the target organ or tissue.[9,17,19] Liposomes can also be endowed with other functionalities such as enhanced intracellular penetration by surface attachment of cell-penetrating peptides (CPPs), as well as enhanced intracellular organelle recognition after cellular internalization by addition of specific ligands that target subcellular organelles such as mitochondria, lysozomes, or nuclei.[20,21]

Therefore, it is important to optimize such multifunctional nanocarriers by proper combination of several of the properties including longevity in the circulation, targetability, intracellular penetration, and organelle recognition to improve its efficacy.[22] Another approach to prepare "smart" multifunctional liposomes is to introduce the property of stimuli-sensitivity.[23,24] In our earlier study, we came up with a novel stimuli-sensitive multifunctional nanocarrier, a PEGylated TAT-p-modified pH-sensitive liposome.[23,24] The PEG chains which provide the longevity in systemic circulation for accumulation in a tumor or infarcted tissue by passive targeting were cleaved off at lowered pH environment of hypoxic areas to expose the previously hidden nonspecific cell penetrating function, such as TAT-p.

In our present study, we demonstrated a simplified synthesis of hydrazine-functionalized PEG-PE-based amphiphilic polymer, which could conjugate variety of ligands via the reversible, pH-cleavable bond. Although the concept of end-group-hydrazine-functionalized PEG−lipid conjugate has been reported,[25] in our study, we report a novel scheme of the modification of PEG-PE via only two facile reaction steps to prepare hydrazine-functionalized PEG-PE. The ligand−polymer conjugate was easily incorporated into the liposomes via its PE fragment. The targeting ligands were attached to the distal end of the PEG-chain to have sufficient freedom for various cellular interactions. Introducing a pH-sensitive linkage between bulky targeting ligand and liposome in the multifunctional liposomal system could be especially useful for drug delivery into tumors or infarcted regions with the lowered pH. After the successful target accumulation, lowered pH in such areas could cleave off the targeting ligands (and possible PEG) and expose other previously hidden (shielded) nonspecific functionalities. The model ligands used to confirm the applicability of our protocol were mAbs 2C5 and 2G4 and proteins Con-A and avidin. In this paper, we confirm that the suggested method of using stimuli-sensitive polymer for the ligand attachment can be successfully applied for the ligand conjugation, preservation of its specific activity, and further pH-dependent cleavage of these ligands attached to the liposomal surface.

EXPERIMENTAL PROCEDURES

Materials. 1,2-Distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[methoxy(polyethylene glycol)-2000] (PEG_{2K}-PE), 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B Sulfonyl)(ammonium salt, Rh-PE), L-α-phosphatidylcholine (egg, chicken), and 1,2-distearoyl-*sn*-glycero-3-phophoethanolamine-*N*-[amino(polyethylene glycol)2000](ammonium salt) (DSPE-PEG_{2K}-Amine) were purchased from Avanti Polar Lipids Inc. (Alabaster, AL) and used without further purification. Cholesterol, chloroform-*d*, triethylamine, Con-A, avidin, α-methyl mannopyranoside, 5,5′-dithio-bis (2-nitrobenzoic acid) (DTNB), *N*-acetyl-L-cystein were purchased from Sigma (St. Louis, MO). Sephadex G 25 superfine medium was from GE Healthcare Biosciences Corp. (Piscataway, NJ, USA). 2-Iminothiolane-HCl (Traut's reagent), 4-(4-*N*-maleimidophanyl)butyric acid hydrazide−HCl (MPBH), fluorescein isothiocyanate (FITC-NHS), biotin-agarose, 2,4,6-trinitrobenzene sulfonic acid (TNBSA), 5% w/v solution in methanol, were purchased from Pierce (Rockford, IL). Paraformaldehyde was purchased from Electron Microscopy Sciences (Hatfield, PA). Fluoromount-G was from Southern Biotech (Birmingham, AL). The mAb 2C5 was produced in ascites via the i.p. injection of 1.5×10^6 hybridoma cells into pristane-primed 4-week-old BALB/c male mice. The production and purification of the mAb 2C5 were carried out by Harlan Bioproducts (Indianapolis, IL) using the cells from our laboratory. Cardiac myosin-specific mAb 2G4 of the immunoglobulin IgG class available in our laboratory was collected and purified from murine ascites according to the standard ammonium sulfate precipitation method.[15,26]

Cell Culture. Human cervical carcinoma (HeLa) cells and breast cancer cell line (MCF-7) were purchased from ATCC (Manassas, VA). Dulbecco's modified Eagle's media (DMEM), fetal bovine serum (FBS), and penicillin−streptomycin solution were from CellGro (Kansas City, MO). Cells were grown in DMEM supplemented with 10% FBS, 100 IU/mL of penicillin, streptomycin, and 250 ng/mL amphotericin-B at 37 °C and 5% CO_2.

Methods. *Synthesis, Purification, and Characterization of Synthesized Polymers. 1,2-Distearoyl-sn-glycero-3-phophoethanolamine-N-[thio(polyethylene glycol)2000](ammonium salt) (DSPE-PEG-$_{2K}$-SH).* 6.2 mg (45.05 μM) of Traut's reagent dissolved in 50 μL of methanol were added into the chloroform solution (25 mg/mL) of DSPE-PEG-$_{2K}$-amine (25 mg, 8.95 μM) at room temperature (RT). The reaction mixture was stirred at RT for 2 h. Chloroform was evaporated completely, the residue dissolved in PBS and dialyzed using a cellulose ester membrane (MWCO. 1 kDa, Spectrum Medical Industries, Houston, TX) overnight. The dialysate was freeze−dried, weighed, dissolved in chloroform at 5 mg/mL, and stored at −80 °C. The quantification of sulfhydryl groups was performed by DTNB assay using *N*-acetyl cysteine for the preparation of the standard SH calibration curve.[27] The yield of the reaction was calculated to be 60%. The freeze−dried product (5 mg) was dissolved in deuterated (*d*)-chloroform (1 mL) and analyzed by ^{1}H NMR using Varian 500 mHz.

1,2-Distearoyl-sn-glycero-3-phophoethanolamine-N-[hydrazido(polyethylene glycol)2000](ammonium salt) (DSPE-PEG-$_{2K}$-CONHNH$_2$). MPBH (13.1 mg, 36.9 μM) dissolved in PBS was added into the solution of DSPE-PEG-$_{2K}$-SH (17.7 mg, 6.2 μM) in PBS (pH 7.4). The reaction mixture was stirred at RT for 4 h and put for dialysis using cellulose ester bag (MWCO 2 kDa) against water overnight before freeze−drying. The hydrazide content of the freeze−dried product was determined by the TNBSA assay following the manufacturer's protocol and using the MPBH for the preparation of a standard calibration curve.[28] The freeze−dried fluffy solid was dissolved in chloroform at 10 mg/mL and stored at −80 °C. The solid product (5−10 mg) was dissolved in *d*-chloroform (1 mL) and characterized by ^{1}H NMR using Varian 500 mHz spectroscopy. The conjugates were not chromatographically isolated after the coupling steps. All polymers were purified by dialysis after the conjugation.

Liposome Preparation. *Activation of Antibodies (mAb 2C5, mAb 2G4) and proteins (Concanavalin A, Avidin).* Antibodies (mAbs 2C5, 2G4) and glycoproteins Con-A and avidin were aldehyde-activated using freshly prepared Na periodate. 100 μL of Na periodate (0.1 M) in water was added to 1.0 mL of the antibody or protein solution (10 mg/mL) in the dark and stirred for 10 min. The reaction was quenched by the addition of sodium sulfite at a 2× molar excess over the periodate added. The

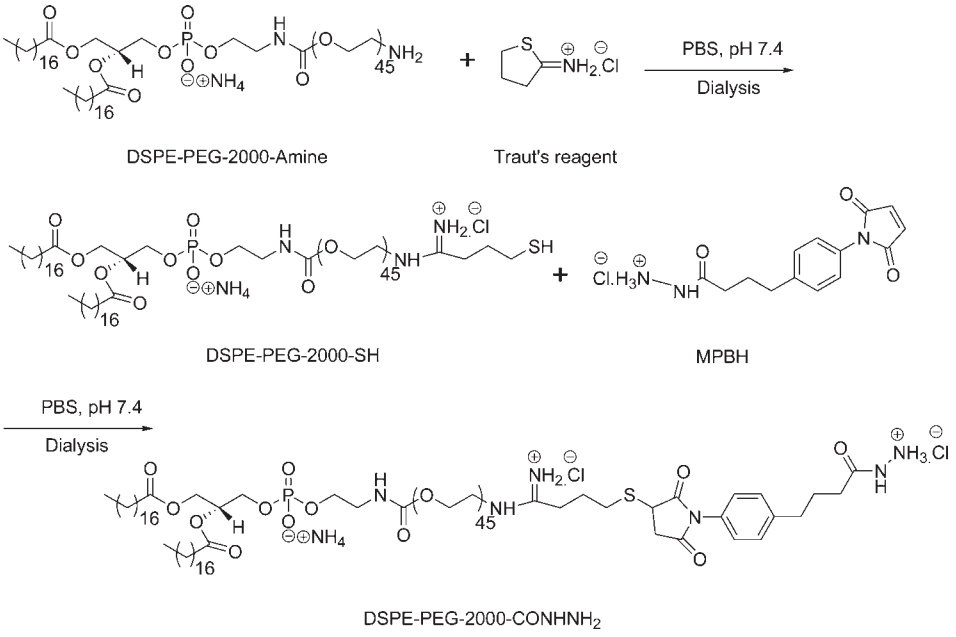

Figure 1. Synthesis of the novel polymer, DSPE-PEG-$_{2K}$-CONHNH$_2$.

aldehyde-activated antibodies or proteins were purified by gel filtration using a desalting spin column (Pierce) and used immediately.

Plain Liposomes (PL). Liposomes were prepared by the lipid film hydration technique. Briefly, a dry lipid film was prepared by rotary evaporation of a chloroform solution of all the ingredients including eggPC/cholesterol or eggPC/cholesterol/Rh-PE (in molar ratios of 65/30 or 64.5/30/0.5 with 5 mol % of DOPE-PEG-$_{2K}$) followed by the freeze−drying (Labconco, Freeze-dry system, Freezone) for at least 4 h to remove the traces of the solvent. The dry lipid film was hydrated in PBS, pH 7.4, at lipid concentration of 4 mg/mL. The hydrated mixture was vortexed vigorously for 5 min to form multilamelar vesicles and then extruded through the 200-nm-pore-sized polycarbonate membrane filters (Avanti Polar Lipids) 20 times to yield liposomes with uniform particle sizes of 150−200 nm mean diameter.

Antibody/Protein-Grafted Liposomes. Antibodies or proteins containing reactive aldehyde groups were incubated with DSPE-PEG-$_{2K}$-CONHNH$_2$ in PBS (pH 7.4) overnight at 0 °C to produce polymer−lipid conjugate-modified products. The freshly prepared loose micelles of antibody/protein conjugates (5 mol % of the total liposomal lipid) were incubated with preformed PL overnight at pH 7.4 for the transfer of the micelle components to liposomes via the postinsertion technique. The antibody or protein-grafted liposomes, 2C5-Hz-PEG-$_{2K}$-DSPE-modified liposomes (2C5-L), and 2G4-Hz-PEG-$_{2K}$-DSPE-modified liposomes (2G4-L), as well as avidin-Hz-PEG-$_{2K}$-DSPE-modified liposomes (avidin-L) and concanavalin-A-Hz-PEG-$_{2K}$-DSPE-modified liposomes (Con-A--L) were separated from unbound antibody/protein by extensive dialysis using cellulose ester membranes (MWCO 300 KDa) against PBS, pH 7.4, at 4 °C overnight.

Characterization of Liposomes. Zeta plus dynamic light scattering equipment (Brookhaven Instruments, Holtsville, NY) was used to determine the liposome size and size distribution. The zeta potentials of formulations were measured by zeta phase analysis light scattering (PALS) with an ultrasensitive zeta potential analyzer instrument (Brookhaven Instruments, Holtsville, NY). The liposome suspension was diluted as needed with water or a 1 M KCl solution to measure the particle size or zeta potential, respectively.

Determination of Immunoreactivity 2C5-L or 2G4-L by ELISA. An indirect ELISA (using an enzyme-tagged secondary Ab) was performed to assay the ability of the immunoliposomes to recognize the target antigens. ELISA microplates were coated with 50 μL of 10 μg/mL nucleosomes for testing 2C5-L, or with 50 μL of 10 μg/mL cardiac myosin for testing 2G4-L overnight at 4 °C. The plates were rinsed with the TBST buffer (Tris-buffered saline supplemented with 0.05% w/v Tween-20) and coated with 10% FBS in Tris-buffered saline. To the antigen-coated plates, 50 μL of 2C5-L or 2G4-L was added at antibody concentration of 10 μg/mL and incubated for 1 h at room temperature. Then, the plates were washed with TBST and coated with 50 μL/well horseradish peroxidase−antimouse IgG conjugate (ICN) at 1:5000 dilution. The conjugate was removed after 1 h incubation at room temperature, and the plates were again washed and incubated with enhanced Kblue TMB peroxidase substrate (Neogen Corporation, Lexington, KY) for 15 min. The microplates were read at dual wavelengths of 620 nm and at 492 nm using a Labsystems Multiskan MCC/340 microplate reader installed with GENESIS-LITE Windows-based microplate software.

Interaction of Avidin-L with Biotin. To examine the binding of Rh-PE-labeled avidin-L with biotin, two columns were prepared with the same quantity of biotin−agarose. The column was washed with PBS. Rh-labeled PL and avidin-L of same fluorescence intensity were passed through the column and first PBS and then avidin-denaturing guanidine-HCl buffer, pH 1.5, were used as eluents. The eluent was collected in 1 mL fractions. The fluorescent intensity of each fraction was measured using a multidetection microplate reader (Bio-Tek, Winooski, VT) at the 540/625 nm excitation/emission wavelengths. The degree of retention of the corresponding preparation on the column indicative of the preservation of the functional activity of the avidin to interact with biotin was estimated by following the decrease in the rhodamine fluorescence in the eluent.

dx.doi.org/10.1021/bc2002133 |*Bioconjugate Chem.* 2011, 22, 2005–2013

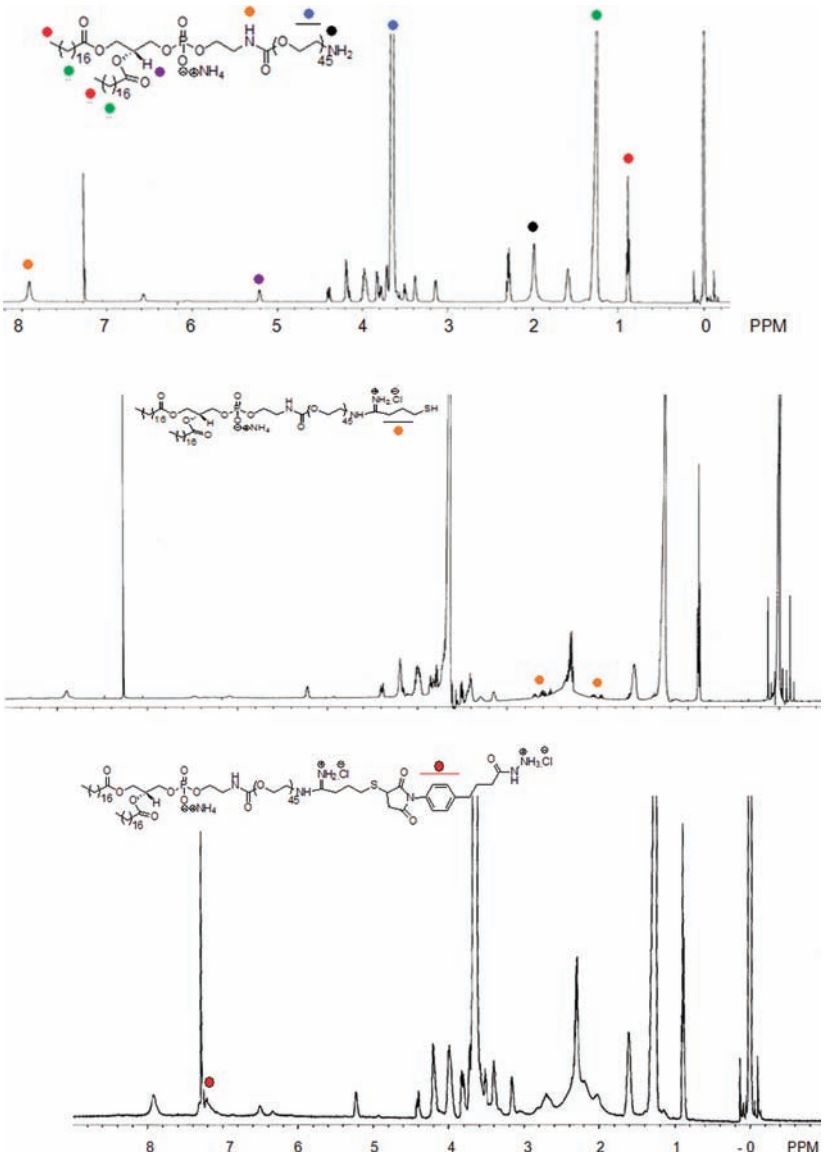

Figure 2. ^{1}H NMR spectra of DSPE-PEG-$_{2K}$-NH2, DSPE-PEG-$_{2K}$-SH, and DSPE-PEG-$_{2K}$-CONHNH$_2$.

Aggregation Assay for Con-A-L. The carbohydrate binding activity and specificity of the Con-A in Con-A-L was examined using an aggregation assay. The substrate for Con-A, mannan, was dissolved in PBS, pH 7.4, at different concentrations, and 100 μL aliquots of the solution were added to a 25 μL suspension of Con-A-L and PL in 96-well plates. The plates were shaken, incubated for 20 min at room temperature, and transferred to a Labsystems Multiskan MCC/340 microplate reader to be read at OD450 nm. Con-A in the presence of mannan aggregates, and the increase in the turbidity of the system is indicative of the preservation of Con-A's functional activity after the conjugation and immobilization on the liposome surface. The experiment was also performed in the presence of 100 μM of the competitive inhibitor, α-methyl mannopyranoside.

Labeling of Antibody (2C5) with Carboxyfluorescein (CF). A 50 μL aliquot of 2 mM 5-CF succinimidyl ester (Molecular Probes) in DMSO was added to 2 mL of a 12 μM solution of 2C5 in 50 mM TBS, pH 9.0. The mixture was incubated overnight at 4 °C, and free CF was removed by the dialysis against TBS.

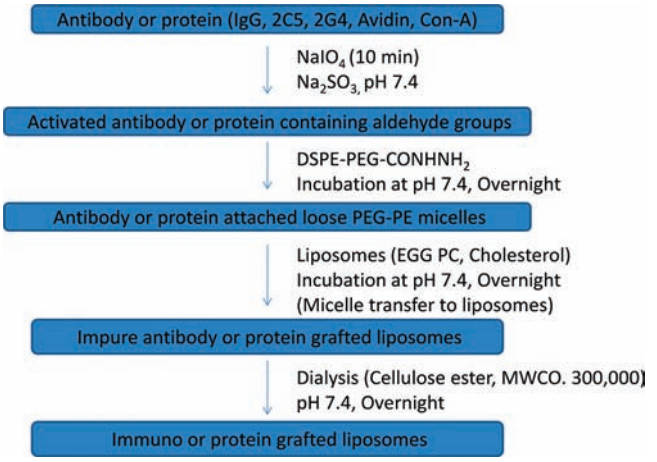
The CF-labeled antibody was used to prepare 2C5-liposomes (CF-2C5-L) following above procedure. The pH of 200 μL of CF-2C5-L (1.2 μg of lipid/mL) in PBS, pH 7.4, was lowered to pH 5 by the addition of HCl (0.1 N). The mixture was incubated at the room temperature for 1 h and dialyzed against PBS using a 300 KDa MWCO cellulose ester membrane. Fluorescence intensity of the same amount of lipids in immunoliposomes was measured at pH 7.4. Both the solutions after dialysis at pH 7.4 and pH 5 were measured using a multidetection microplate reader (Bio-Tek, Winooski, VT) at 485/528 nm excitation/emission wavelengths.

Cell Experiments. Interaction of 2C5-L with cancer cells in vitro and pH-dependent cleavability of mAb 2C5. After the initial passage in tissue culture flasks, HeLa cells were grown on coverslips placed in 6-well tissue culture plates. After the cells reached 60−70% confluence, the plates were washed with PBS and incubated with 1% BSA in DMEM for 1 h at 37 °C, 5% CO_2. Rh-PE (Lissamine-rhodamine B-phosphatidyl ethanolamine)-labeled 2C5-L and Rh-PE-labeled PL, preincubated at pH 7.4 or pH 5 for 1 h, were added to a final lipid concentration of 0.1 mg/mL and

dx.doi.org/10.1021/bc2002133 |*Bioconjugate Chem.* 2011, 22, 2005–2013

incubated for 90 min at 37 °C, 5% CO_2. After the incubation, the cells were washed with PBS and the coverslips were mounted cell-side down on glass slides with fluorescence-free glycerol-based mounting medium (Fluoromount-G; Southern Biotechnology Associates) and studied with a Nikon Eclipse E400 microscope under the bright light or under the epifluorescence with a rhodamine filter.

Scheme 1. Schematic Representation of the Preparation of Antibody- or Protein-Grafted Liposomes Using DSPE-PEG-$_{2K}$-CONHNH$_2$ Polymer



FACS Analysis. Approximately 200 000 HeLa and MCF-7 cells were seeded in 6-well tissue culture plates. After the cells reached 60−70% confluence, the plates were washed with PBS and incubated with 1% BSA in DMEM for 1 h. The immunoliposomes were preincubated for 1 h at pH 7.4 or pH 5 and treated with formulations at lipid concentration of 0.1 mg/mL for 90 min. The cells were centrifuged and washed with ice-cold PBS at least 3 times before analysis using a BD FACS Caliber flow cytometer. The cells were gated using forward versus side-scatter to exclude debris and dead cells before analysis of 10 000 cell counts. The data were analyzed with *BD Cell Quest Pro* Software.

Statistical Analysis. The data were tested for statistical significance using the paired Student's *t* test using *GraphPad Prism 4* (GraphPad Software, Inc.; San Diego, CA). Any *p* value less than 0.05 was considered statistically significant.

RESULTS AND DISCUSSION

Synthesis and Characterization of 1,2-Distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[thio(polyethylene glycol)-2000](ammonium salt) (DSPE-PEG-$_{2K}$-SH) and 1,2-Distearoyl-*sn*-glycero-3-phophoethanolamine-*N*-[hydrazido(polyethylene glycol)2000](ammonium salt) (DSPE-PEG-$_{2K}$-CONHNH$_2$). terminal hydrazine group-containing polymer DSPE-PEG-$_{2K}$-CONHNH$_2$ was synthesized following the scheme presented in the Figure 1. The starting polymer containing amine group was transformed into a thiol-modified polymer by the reaction using the Traut's reagent. The reaction yield was 60% by the DTNB assay. The next reaction with the cross-linking agent MPBH yielded 89% of DSPE-PEG-$_{2K}$-CONHNH2 calculated from the TNBSA assay.

The polymers were characterized by ^{1}H NMR in *d*-chloroform using Varian 500 MHz spectrophotometer (see the data in the Figure 2).

^{1}H NMR of DSPE-PEG-$_{2K}$-SH: δ 0.87−0.89 (t, 6H, (−CH_2-CH_3)$_2$), 1.25 (s, H from long chains of PE), 1.59−1.65 (m, 5H), 1.95−2.05 (m), 2.27−2.35 (m), 2.51−2.70 (m, −CH_2CH_2-CH_2SH), 3.14−4.4 (m), 5.2−5.24 (m, 1H), 7.89 (bs, 1H, −N*H*CO).

Liposome Preparation and Characterization. Sizes of all types of liposomes prepared according to the general Scheme 1 (PL, 2C5-L, 2G4-L, Con-A-L, avidin-L) determined by the dynamic light scattering ranged between 150 and 200 nm (Figure 3). In all cases of the subsequent modification via the postinsertion technique, the incorporation of the added ligands into the liposomes was quantitative, since HPLC revealed no micelles of the free polymer-modified ligand in the system. To estimate the quantity of the protein bound to liposomes, the 2C5-L was used labeled with CF. Protein concentration per microgram of lipid was measured by the associated fluorescence at the excitation wavelength of 490 nm and emission wavelength of 520 nm. From the fluorescence data, approximately 150−200 protein molecules of antibody were bound to the surface of a single 200 nm liposome. The calculations were based on the fact that, while preparing the liposomes, the molar ratio of DSPE-PEG-$_{2K}$-CONHNH$_2$ per antibody was 32/1 and that number of phospholipid molecules per 200 nm liposomes was estimated to be 25×10^4.[29]

Activity of mAbs 2C5 and 2G4 in 2C5-L and 2G4-L by ELISA. To investigate whether various targeting ligands could be successfully attached to the liposomal surface by this reversible pH-sensitive hydrazone bond without losing their specific activity, the ELISA assay was performed to determine the interaction of 2C5-L and 2G4-L with specific antigens for the liposome-attached antibodies, nucleosomes, and cardiac myosin, respectively. Figure 4 represents the data of the direct binding assay of various preparations of liposomes with the corresponding antigens. The 2C5-L and 2G4-L bind to the monolayers of their corresponding antigens with the same efficiency as native free antibodies. Control IgG2a isotype-matching mAb UPC10 was attached onto the liposome surface following the same protocol. All controls—PL, IgG-bearing liposomes (IgG-L), and native IgG—demonstrated only a background binding to the antigens. These results indicate that the hydrazone bond used to attach the antibody was quite stable under the conditions used, and the antibodies' specific activity toward their antigens were completely preserved after covalent coupling to the distal tips of the PEG chains of liposomes via the hydrazone bonds.

Binding of Avidin-L with Biotin−Agarose. To further confirm the preservation of the specific properties of proteins attached to liposomes using the suggested scheme, Rh-PE-labeled PL and avidin-L were passed through the biotin−agarose

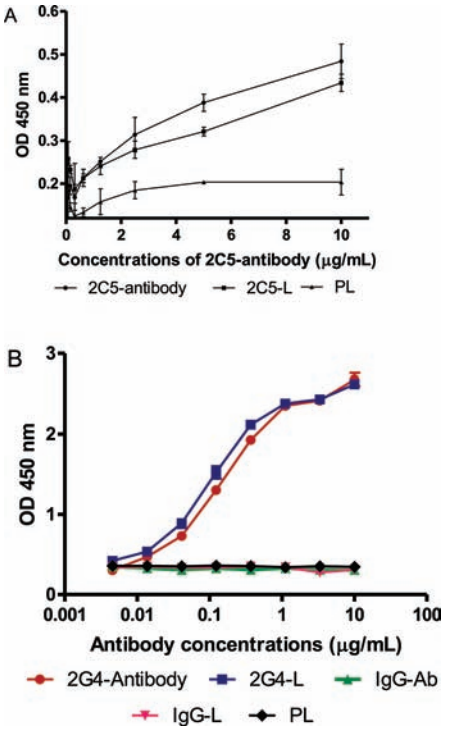

Figure 4. ELISA result for immunoliposomes. (A) Binding of 2C5-L to the monolayer of the antigen (nucleohistone) in comparison to the native mAb 2C5. (B) Binding of the 2G4-L to the monolayer of the antigen (porcine cardiac myosin) in comparison to the native mAb 2G4. The results show that the activity of the mAbs toward their antigens was retained after the conjugation on to the surface of liposomes.

column (Figure 5). The results showed the free passage of PL through the column (the fluorescence increase in initial fractions of the eluent at 540/625 excitation/emission wavelength) and complete retention of avidin-L on the column. In other words, the avidin in avidin-L was capable of strong binding with biotin. However, the treatment of the column with bound avidin-L with avidin-denaturing buffer, pH 5, released the major part of the fluorescence from the column via two possible mechanisms. First, the buffer denatured the avidin protein, which compromised the binding of avidin with the biotin−agarose and resulted in the release of Rh-labeled liposomes. Second, the lowered pH of this buffer could also degrade the hydrazone bond between avidin and liposomes and also cause the liposome release (fluorescence increase in the eluent). The result demonstrated that the avidin was successfully attached to the distal end of the polymer on the liposome surface and the specific activity of the protein was completely retained after the conjugation.

Agglutination of Con-A-L. One more test was done with Con-A-L and was based on the agglutination analysis of Con-A-L in the presence of ConA's polyvalent substrate mannan.[30,31] Figure 6 shows the turbidity changes measured by the increase in absorbance at OD450 nm in the suspensions of Con-A-L compared to PL in the presence of mannan. However, in the presence of the Con-A-specific low-molecular-weight competitive monovalent substrate, α-methyl mannopyranoside (100 μM), the turbidity rise was significantly inhibited. These data also show that, similar to avidin-L, the Con-A immobilized on the surface of liposome via the DSPE-PEG-$_{2K}$-CONHNH$_2$ polymer preserved its functional binding activity and carbohydrate specificity.

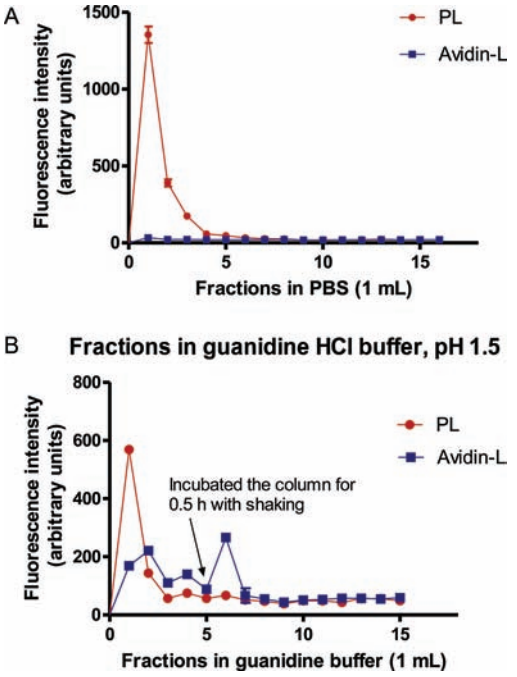

Figure 5. Binding of the Rh-PE-labeled avidin-L on biotin−agarose column compared to that of the Rh-PE-labeled PL. (A) Fluorescence intensity of the eluent collected in 1 mL fractions using PBS, pH 7.4, as mobile phase. Strong interaction of the liposome surface-attached avidin with biotin resulted in the complete retention of avidin-L in the column compared to PL. (B) Fluorescence intensity of eluent (avidin-denaturing buffer guanidine-HCl, pH 1.5) collected in 1 mL fraction. Slow release of avidin-L from the column is observed as the denaturation of the avidin progresses. The incubation of the column in denaturing buffer at room temperature resulted in an abrupt increase of the fluorescence in the eluent.

In Vitro Assay with CF-Labeled mAb 2C5 (pH-Dependent Degradation). To investigate the reversibility of the ligand attachment to the liposome surface via a pH-sensitive degradable bond at lowered pH values (mimicking to a certain extent intratumoral and/or intracellular environment), the in vitro degradation study of the ligand-modified liposomes at pH 5 was performed (Figure 7A). CF-labeled mAb 2C5 was conjugated at the distal end of the DSPE-PEG-$_{2K}$-CONHNH$_2$ and incorporated into liposomes (CF-2C5-L). The incubation of this liposome preparation at pH 5 degraded the hydrazone bond in the linker polymer and removed the labeled mAb 2C5 from the liposome, which resulted in marked decrease in cell-associated Rh-PE fluorescence. The result indicated that almost 80% of the hydrazone bond broke upon incubation of the preparation at pH 5, resulting in removing the surface-attached mAb. Dialysis, when continued at pH 5, provoked even more degradation to around 90%. This study proved the reversibility of the hydrazone bond between mAbs (or any other ligands) and liposomes, which is beneficial for the removal of the ligands attached via the proposed polymer linker from the liposome surface when it could become desirable at certain condition (for example, inside tumors or inside cells when other liposome-attached functionalities are required to become deshielded).

Fluorescence Microscopy and FACS Analysis: Interaction of 2C5-L with Cancer Cells in Vitro. Rhodamine-labeled 2C5-L were incubated with cervical cancer cells (HeLa) (Figure 7B). To enhance the cancer cell binding (eventual tumor accumulation),

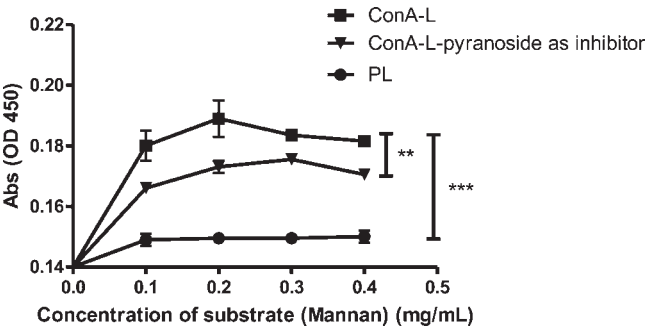

Figure 6. Agglutination analysis of Con-A-L in the presence of mannan and α-methyl mannopyranoside. The turbidity (agglutination) increases significantly with increasing concentration of mannan at OD 450 compared to PL (***$p < 0.001$, $n = 5$). In the presence of conA-specific competitive monovalent substrate α-methyl mannopyranoside (100 μM), a significant inhibition of the Con-A-L aggregation by the mannan was observed (**$p < 0.05$, $n = 5$). Results indicated the successful conjugation of Con-A onto the surface of liposome with full preservation of its specific activity.

the mAb 2C5 was used, which recognizes the surface of numerous tumor, but not normal cells via the tumor cell surface-bound nucleosomes.[15,32,33] Because mAb 2C5 binds to a broad variety of cancer cells, it may serve as a specific ligand for the delivery of drugs and drug carriers into tumors. The fluorescence microscopy result clearly demonstrated the successful recognition of HeLa cells by 2C5-L, which resulted in enhanced rhodamine fluorescence signal from the cell surface.

However, the preincubation of the 2C5-L at pH 5 resulted in loss of the antibody from the liposome surface, therefore preventing the liposome-to-cell association. PL did not show any cell association being kept at both pH values. The comparison of panels a and c in Figure 7B clearly indicates the successful conjugation of the targeting moiety (mAb 2C5) on the liposome surface, which resulted in more cellular association compared to PL. At the same time, the comparison of panels a and b shows that the action of the lowered pH eliminates the recognition phenomena (i.e., detach the antibody from the liposome because of linker degradation).

To further confirm the successful conjugation, the preservation of the functional specificity of the antibody as well as the cleavability of the hydrazone bond at lowered pH, flow cytometry-based experiments were performed with two cancer cell lines (HeLa and MCF-7) (Figure 8). FACS analysis confirmed the result obtained using the fluorescence microscopy and clearly demonstrated that the protocol used resulted in the successful conjugation of the antibody to liposomes and significantly better cellular association of 2C5-L compared to PL in both cell lines. And again, the pH-dependent linker degradation and antibody dissociation from the liposomal surface at lower pH (pH 5) was confirmed resulting in less cellular association compared to pH 7.4 in both cell lines.

Introducing a pH-sensitive linkage between a bulky targeting ligand and the liposome could be useful, for example, for drug delivery into tumors when decreased intratumoral pH after successful target accumulation could cleave off the targeting ligands and expose other functionalities such as ligands for enhanced cell penetration and intracellular trafficking to the organelles of interests.

In conclusion, an easy and simple method for synthesizing hydrazine-functionalized poly(ethylene glycol)-phosphatidyl

dx.doi.org/10.1021/bc2002133 |*Bioconjugate Chem.* 2011, 22, 2005–2013

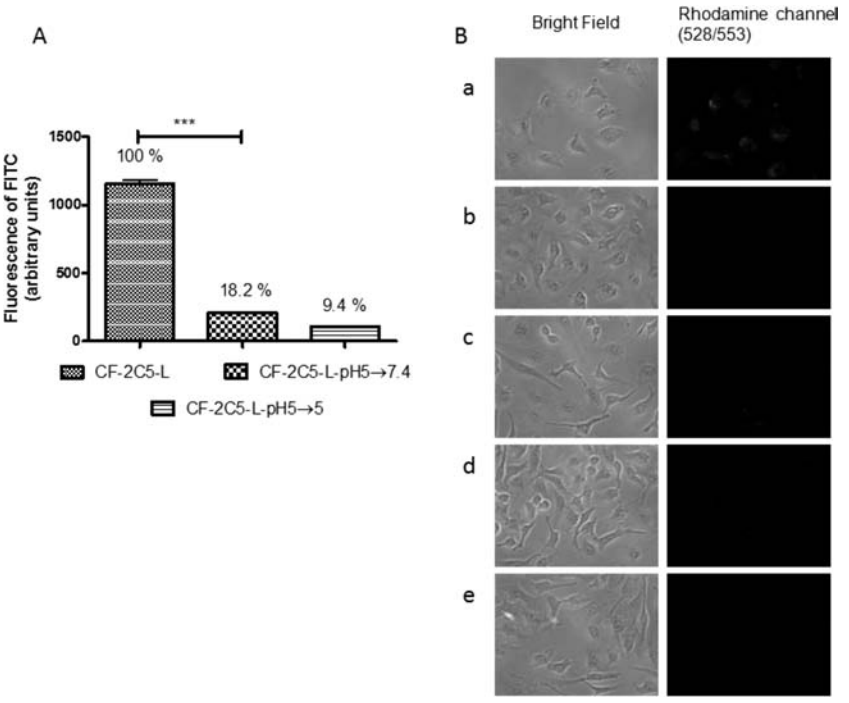

Figure 7. (A) Cleavability of CF-labeled mAb 2C5 from the liposome surface at low pH. The CF-2C5-L were preincubated at pH 5 for 1 h at room temperature and dialyzed (MWCO 300 000) against PBS at pH 7.4 and pH 5. The result clearly shows significantly (***$p < 0.001$, $n = 3$) less fluorescence after dialysis due to the hydrolysis of the hydrazone bond (around 80% and 90% fluorescence loss after the dialysis at pH 7.4 and 5, respectively) between mAb and liposome and release of free mAbs. (B) Effect of preincubation (at pH 5) of Rh-PE labeled 2C5-L on cellular association compared to 2C5-L at pH 7.4. Preincubation cleaved the antibody from the surface, thereby causing loss of the targeting potency of the liposomes, which resulted in virtually no cellular association: (a,b) 2C5-L, preincubated at pH 7.4 and 5, respectively; (c,d) PL, preincubated at pH 7.4 and 5; (e) untreated cells. Pictures of bright field and rhodamine channels are shown simultaneously for each treatment.

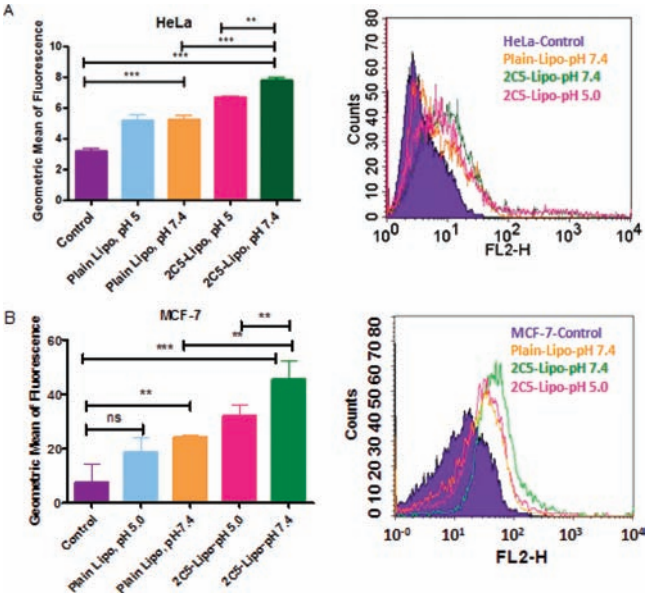

Figure 8. Flow cytometry analysis of Rh-PE-labeled 2C5-L and PL at different pH in (A) HeLa and (B) MCF-7 cell lines. The 2C5-L and PL were preincubated at pH 5 and pH 7.4 for 1 h before the incubation with the cells for 1 h. The result shows less targeting and less cellular uptake of 2C5-L after the preincubation at pH 5 than after the preincubation at pH 7.4 in both cell lines because of detachment of cell targeting antibody from the surface of the liposomes (***$p < 0.001$, **$p < 0.05$, $n = 3$).

ethanolamine polymer was developed. The polymer can readily conjugate various targeting ligands to pharmaceutical nanocarriers, such as liposomes, easily via a pH-responsive reversible hydrazone bond. Proteins avidin, Con-A, and monoclonal antibodies 2C5 and 2G4 were successfully immobilized on the liposome surface via the pH-responsive hydrazone bond. Various in vitro assays confirmed that the targeting ligands retain their specific functional activity. At the same time, the exposure of the ligand-bearing liposomes to a lowered pH results in the degradation of the hydrazone bond and detachment of the ligand.

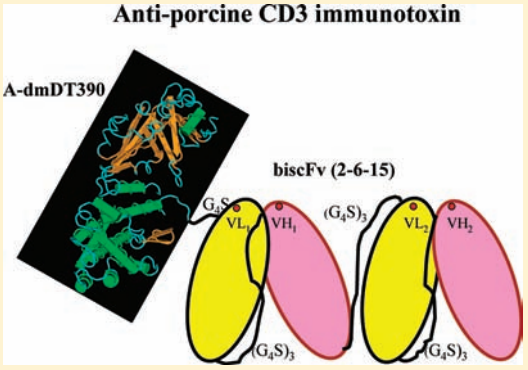
ABSTRACT: Anti-CD3 immunotoxins, which induce profound but transient T-cell depletion in vivo by inhibiting eukaryotic protein synthesis in CD3+ cells, are effective reagents in large animal models of transplantation tolerance and autoimmune disease therapy. A diphtheria toxin based antiporcine CD3 recombinant immunotoxin was constructed by fusing the truncated diphtheria toxin DT390 with two identical tandem single chain variable fragments (scFv) derived from the antiporcine CD3 monoclonal antibody 898H2−6−15. The recombinant immunotoxin was expressed in a diphtheria-toxin resistant yeast *Pichia pastoris* strain under the control of the alcohol oxidase promoter. The secreted recombinant immunotoxin was purified sequentially with hydrophobic interaction chromatography (Butyl 650 M) followed by strong anion exchange (Poros 50 HQ). The purified antiporcine CD3 immunotoxin was tested in vivo in four animals; peripheral blood CD3+ T-cell numbers were reduced by 80% and lymph node T-cells decreased from 74% CD3+ cells pretreatment to 24% CD3+ cells remaining in the lymph node following 4 days of immunotoxin treatment. No clinical toxicity was observed in any of the experimental swine. We anticipate that this conjugate will provide an important tool for in vivo depletion of T-cells in swine transplantation models.



INTRODUCTION

Previous work has demonstrated that chemically conjugated antiporcine CD3 immunotoxin is a very effective T-cell depletion reagent in pigs,[1] and this reagent has played a role in the maintenance of long-term hematopoietic stem cell transplants in the absence of graft versus host disease.[2−4] The chemically conjugated immunotoxin was created by cross-linking the monoclonal antibody to a diphtheria toxin (DT) binding site mutant, CRM9, such that the binding site of the immunotoxin was dictated by the antibody moiety.[5] However, several problems were associated with the chemical conjugate including linkage heterogeneity, low yield, and strict limitations in dosage due to nonspecific neurological toxicity in pigs.[1,6]

Recombinant antihuman and antimonkey CD3 T-cell immunotoxins have been developed.[7,8] These immunotoxins contain a diphtheria toxin protein sequence that is truncated at amino acid residue 390. The antibody moiety is placed C-terminal to the truncated toxin DT390 to prevent any interference with the translocation of biologically active diphtheria toxin A chain.[9,10] However, it was found that when the scFv of an antihuman CD3 monoclonal antibody UCHT1 was fused to the C-terminus of DT390, its binding activity was dramatically reduced by a factor of 10. Adding a second scFv moiety separated with a $(G_4S)3$ linker resulted in a 10-fold increase in binding activity compared to a monovalent fusion immunotoxin. This fusion immunotoxin, designated A-dmDT390biscFv(UCHT1), displayed an increase in potency by 10- to 30-fold as compared with the corresponding chemically conjugated immunotoxin and depleted 2.4 logs of T-cells in the lymph node compartment of transgenic mice expressing human CD3ε.[11] The clinical trial for this immunotoxin in five patients with cutaneous T-cell lymphoma has shown promising results.[12]

In this paper, we present the development of the antiporcine CD3 recombinant immunotoxin, A-dmDT390biscFv(2−6−15). The VL (variable light chain) and VH (variable heavy chain) of the antiporcine CD3 monoclonal antibody 898H2−6−15[13] were cloned by PCR, and the resulting sequence was used to synthesize codon-optimized antiporcine CD3 scFv (2−6−15) DNA sequence suitable for the *Pichia pastoris* expression. The biscFv format antiporcine CD3 recombinant immunotoxin was expressed in a diphtheria-toxin resistant yeast *Pichia pastoris* strain and purified in a two-step chromatography protocol. The *in vivo* porcine CD3 T-cell depletion profile for this immunotoxin was assessed.

EXPERIMENTAL PROCEDURES

Cloning the VL and VH of the Antiporcine CD3 Monoclonal Antibody 898H2−6−15. To construct the antiporcine CD3 recombinant immunotoxin, the scFv DNA sequence of hybridoma 898H2−6−15 was obtained by RT-PCR. RNA was isolated from the antiporcine CD3 hybridoma cell line 898H2−6−15 developed and characterized in our lab[13] with the RNeasy kit (Invitrogen). cDNA was generated from DNase (Invitrogen) treated RNA using oligo dT primer and the Superscript III kit (Invitrogen). Preliminary VH sequence was isolated using a commercially available Mouse Ig Primer Set (EMD BioSciences), specifically primers MuIgVH5′-A and MuIgGVH3′-2. Gene-specific primers were designed and used for generating cDNA (2−6−15 Hr-1) and for 5′ rapid amplification of cDNA ends (RACE) PCR (2−6−15 Hr-3, 2−6−15 Hr-4) (5′ RACE Kit, Invitrogen). The sequence of the 3′ end was determined by 3′ RACE (Invitrogen) using gene-specific primers 2−6−15 Hf-3 for generating cDNA, as well as 2−6−15 Hf-2 and 2−6−15 Hf-1 for PCR. To circumvent the expression of aberrant light chain by hybridoma 898H2−6−15, saturating levels of a primer specific for the aberrant chain (Ab Vk 5′) along with the VL primers UMIgVK 5′ and MK-3Seq 3′ were used to amplify light chains.[14] As previously, 5′ sequence was determined by 5′ RACE using cDNA generated with gene-specific primers 2−6−15 Lr-1; 5′ RACE PCR was performed with 2−6−15 Lr-2 and 2−6−15 Lr-3 (5′ RACE Kit, Invitrogen). The sequence of the 3′ end was determined by generating cDNA with gene-specific primer 2−6−15 Lf-3 and 3′ RACE PCR with 2−6−15 Lf-2 and 2−6−15 Lf-1 (3′ RACE Kit, Invitrogen). All of the PCR primers used to amplify the VL and VH are listed in Table 1. The VL and VH DNA and derived amino acid sequences are shown in Figure 1 (VL GenBank accession: JF918977; VH GenBank accession: JF918978). The borders of 898H2−6−15 VL and VH were determined according to Kabat et al (1987).[18]

Plasmid Construction. Codon optimization is necessary to express DT390-based immunotoxins in *Pichia pastoris*.[8] We used the optimized DT390 nucleotide sequence described by

Figure 1. Antiporcine CD3 monoclonal antibody 898H2−6−15 variable light (VL) and variable heavy (VH) domain DNA and derived amino acid sequence.

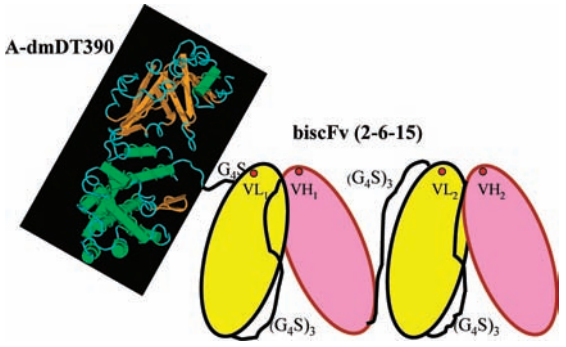

Figure 2. Schematic description of the antiporcine CD3 recombinant immunotoxin A-dmDT390biscFv(2−6−15). The putative antigen binding sites are shown as red spots.

Woo et al. (2002) for the DT390 domain in the new antiporcine CD3 immunotoxin. The DT390 has been modified to include an NH_2 terminal alanine (A) and double mutations (dm) to prevent glycosylation in the eukaryotic expression system, *Pichia pastoris*.[8,15] The antiporcine CD3 immunotoxin A-dmDT390biscFv (2−6−15) was constructed using the scFv derived from the antiporcine CD3 monoclonal antibody 898H2−6−15 following the strategy used to construct A-dm-DT390biscFv (UCHT1) in *Pichia pastoris*[8] except for the addition of an extra G_4S linker between A-dm-DT390 and biscFv (2−6−15) (Figure 2). The codon-optimized scFv (2−6−15) DNA was synthesized using the *Pichia pastoris* preferred codons.[16] Ten primers were designed for both the VL and the VH of the 2−6−15 scFv (Table 2). The primer length was limited to under 70 bases with a 21 base overlap between neighboring primers. Ten picomoles of the first and the last primers and 2 pmol of the rest of the primers were used in each PCR reaction (Pfu Turbo polymerase, Aglient, dNTP mixture at 2.5 mM each). The PCR program was 95 °C for 5 min, 25 cycles of 95 °C for 30 s, 55 °C for

30 s, 72 °C for 1 min, and then extension for another 10 min. Amplification products were analyzed by electrophoresis in 1% agarose gels and purified using QIAquik Gel Extraction Kit (Qiagen). *Bam*HI digested VL PCR fragment was ligated to *Bgl*II digested VH fragment using T4 ligase for 6 h. The first scFv (2−6−15), amplified with primers 15L1a (carrying *Nco*I site) and 15 H10a (carrying *Bam*HI site), was cloned into pET27b. The second scFv (2−6−15), amplified with 15L1b (carrying *Bgl*II site) and 15H10b (carrying stop codon and *Eco*RI site), was cloned into pET17b. After sequence confirmation, the first and second scFv

(2−6−15) were subcloned into pwPICZα-DT390 (*Nco*I-*Bam*HI/*Bgl*II-stop codon-*Eco*RI).[8]

Protein Expression and Purification in *Pichia pastoris*. The linearized antiporcine CD3 immunotoxin construct, A-dmDT390-biscFv (2−6−15) in pwPICZα, was transformed into a diphtheria-toxin resistant yeast *Pichia pastoris* strain mutEF2JC307−8(2)[17] and the transformants were selected on YPD plates containing zeocin (100 μg/mL). Six colonies were randomly picked and cultivated in small tubes containing 5 mL YPD (1% yeast extract, 2% peptone, and 2% dextrose) at 30 °C at 250 rpm for 24 h as growth phase I, then in YPG (1% yeast extract, 2% peptone, 1% glycerol) at 30 °C at 250 rpm for another 24 h as growth phase II. The cultures were induced with methanol in 2 mL BMMYC (1% yeast extract, 2% peptone, 100 mM potassium phosphate, pH 7.0, 1.34% yeast nitrogen base without amino acids, 4×10^{-5} % biotin, 0.5% methanol, and 1% casamino acids) for 48 h at 25 °C at 225 rpm. Antifoam 0.02% (Emerald Performance Materials, cat # KFO673) was added in all of the growth and induction medium. 1 mM PMSF (Phenylmethanesulfonyl fluoride, Sigma) was added with methanol to inhibit the protein degradation during the induction phase. The culture supernatants were analyzed on SDS-PAGE under nonreducing condition. One clone (ZW130) was selected and cultivated to purify A-dmDT390-biscFv (2−6−15). Sodium sulfate (Fisher Scientific) was added to 1 L of culture supernatant to a final concentration of 200 mM. The sample was loaded onto 50 mL Butyl 650 M (Tosoh) in a 5 cm × 20 cm XK50 column (GE healthcare cat #18−1000−71). The bound A-dmDT390-biscFv (2−6−15) was eluted with TGE buffer (5% glycerol, 20 mM Tris HCl, pH 8.0, 1 mM EDTA, pH 8.0). Pooled fractions (Figure 3A, elution fraction #2 to #8, 50 mL per fraction) containing A-dmDT390-biscFv (2−6−15) were diluted 6-fold with TE (20 mM Tris-HCl pH 8.0, 1 mM EDTA pH 8.0) buffer and loaded directly onto 10 mL of Poros 50HQ (Applied Biosystems) in a 1.6 cm × 20 cm XK16 column (GE healthcare, cat #18−8773−01). The bound A-dm-DT390-biscFv (2−6−15) was eluted with 150 mM sodium borate in TGE buffer and 200 mM sodium borate +50 mM NaCl in TGE buffer. The immunotoxin containing elution fractions were mixed, concentrated down with Centricon Plus-70 (30 kDa cutoff, Millipore), dialyzed against PBS pH 7.4 + 5% glycerol, filter sterilized, and stored at 80 °C.

HPLC Analysis. A-dm-DT390biscFv (2−6−15) final protein product was analyzed with Shimadzu HPLC system using Superdex 200 size-exclusion column, 10/300 GL (GE healthcare, cat # 17−5175−01). The sample volume was 100 μL using 100 μL loop. The flow rate was 0.35 mL/min. The running time was 120 min and the running buffer was 90 mM $NaSO_4$, 10 mM $NaPO_4$, pH 8.0, 1 mM EDTA.

Porcine CD3 Depletion Study in vivo. Four miniature swine, aged two months, were brought to our AAALAC accredited animal facility and were allowed to acclimate to their new surroundings for one week. Three days prior to the start of treatment, they were bled for baseline blood values: complete blood counts, serum chemistry values, and flow cytometry analysis of CD3+ T-cell populations. They were then injected through a 23 g butterfly catheter, through a peripheral vessel, with an intravenous (IV) bolus of undiluted A-dmDT390biscFv (2−6−15) at a dose of 50 μg/kg, twice daily for 4 days. Prior to each day's injections, morning blood samples were taken to monitor the aforementioned blood values. Each day's values were then compared to the pretreatment values. The animals were also injected with 4 mg/kg diphenhydramine IV bolus immediately prior to immunotoxin infusion to prevent any unexpected anaphylactic reactions, of which none were observed. To ensure that the full volume of immunotoxin was administered to the animals, each dose was flushed with 10 mL of phosphate buffered saline (pH between 6.5 and 7.5). The animals were closely monitored for signs of change in clinical condition such as lethargy and significant weight loss and no signs of toxicity were seen in any animal. The animals were bled again on days 7 and 14 following the start of injections to monitor their T-cell recovery and any possible toxicity.

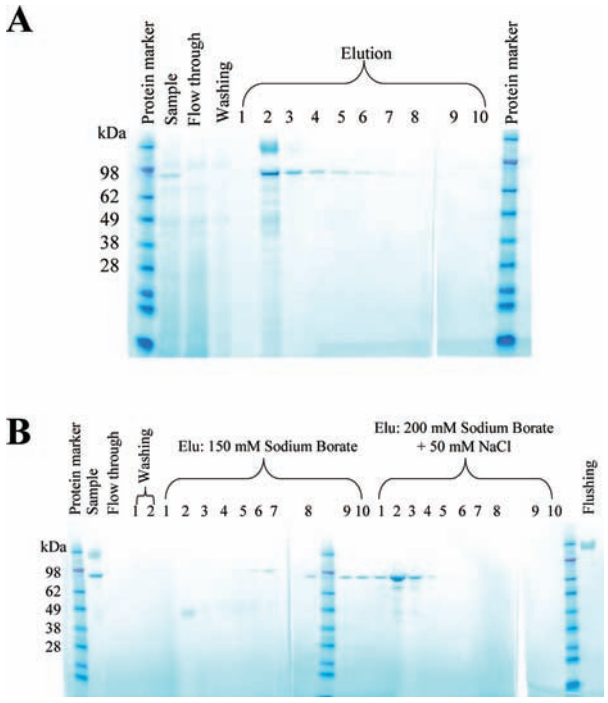

Figure 3. Two-step purification of the antiporcine CD3 immunotoxin A-dmDT390biscFv (2−6−15). (A) Capturing step with hydrophobic interaction resin Butyl 650 M. (B) Second step purification with strong anion exchange resin Poros 50HQ.

The percentage of CD3+ T-cells in the peripheral blood was determined by flow cytometry of heparinized whole blood samples after staining with FITC conjugated swine specific CD3 antibody (898H2−6−15, mouse IgGaK)[13] using BD FACS lysing solution whole blood staining procedure according to the manufacturer (BD Biosciences, San Jose, CA). The absolute T-cell count each day was calculated by multiplying the percentage of CD3+ cells in the peripheral blood by the white blood cell count. All experiments were approved by the Massachusetts General Hospital Institutional Animal Care and Use Committee.

RESULTS AND DISCUSSION

Plasmid Construction for the Antiporcine CD3 Recombinant Immunotoxin. The VL and VH DNA sequence and the deduced amino acid sequences of antiporcine CD3 mAb 898H2−6−15 are shown in Figure 1. According to Sreekrishna 1993,[16] we synthesized the codon-optimized scFv (2−6−15) and cloned it into the truncated diphtheria toxin DT390 containing yeast *Pichia pastoris* expression vector pwPICZα-A-dmDT390 between NcoI and *Eco*RI to replace the biscFv (UCHT1) portion.[8] Initially, we utilized the single chain foldback diabody format as in the

antimonkey CD3 immunotoxin construct,[7] but treatment with this recombinant immunotoxin did not result in depletion of porcine CD3+ T-cells in vivo (data not shown). We speculate that this could be because the single chain foldback diabody format is not suitable for binding the porcine CD3 epitope. Even though both 898H2−6−15 and FN18 recognize CD3 epsilon, it is likely that they bind different conformational CD3 epitopes. The traditional biscFv format, which was used in the antihuman CD3 recombinant immunotoxin (Figure 2),[8] was constructed. The bivalent immunotoxin is a multidomain protein containing the catalytic and translocation domains of DT and two VL and two VH of the antiporcine CD3 mAb 898H2−6−15. The VL and VH are joined by a 15 amino acid $(G_4S)_3$ linker (L) in the order of VL-L-VH-L-VL-L-VH.

Expression and Purification of the Antiporcine CD3 Recombinant Immunotoxin. The antiporcine CD3 recombinant immunotoxin A-dmDT390biscFv (2−6−15) was expressed using shaker flasks by scaling up from small tube expression as described in the Experimental Procedures. The scaled-up expression level is about 20 mg/L. The secreted antiporcine CD3 immunotoxin in the supernatant was captured directly by hydrophobic interaction chromatography resin Butyl 650 M (Figure 3A). For second-step purification, a strong anion exchange resin Poros 50 HQ was used. Sodium chloride alone did not work well for eluting the immunotoxin, as the glycosylated yeast host protein was coeluted with the immunotoxin.[19] Sodium borate was chosen, as it would separate the immunotoxin from the glycosylated yeast host protein and the aggregates. However, the maximal solubility for sodium borate is restricted to 200 mM, a concentration which is not strong enough to elute the majority of the immunotoxin. To overcome this problem, we added 50 mM NaCl to the 200 mM sodium borate elution buffer to increase the salt concentration. The majority of the immunotoxin was eluted with 200 mM sodium borate and 50 mM NaCl (Figure 3B). As shown in Figure 4, after two step purification we obtained the pure 95 kDa antiporcine CD3 recombinant immunotoxin. The purity reached around 95%. The final purification yield was ~13 mg per liter of the original harvested supernatant. As shown in Figure 4A, A-dmDT390biscFv (2−6−15) showed a second weak band migrating around 70 kDa. Western blots identified it as a breakdown product.

Porcine CD3 T-cell Depletion in Vivo Using the Antiporcine CD3 Recombinant Immunotoxin. The CD3 T-cell depletion function of this recombinant immunotoxin was assessed in four MGH miniature swine, aged two months. Results are shown in Figure 5. This recombinant immunotoxin was given through IV bolus at a dose of 50 μg/kg, twice daily for four days. Complete blood counts, serum chemistry values, and CD3+ T-cell numbers were measured. The immunotoxin treatment decreased the number of CD3+ T-cells in the peripheral blood to approximately 20% of the pretreatment level (Figure 5A). There was no significant effect on the number of peripheral B cells (Figure 5B). The percent CD3+ T-cells in the lymph node decreased from 74% pretreatment to 24% following 4 days of

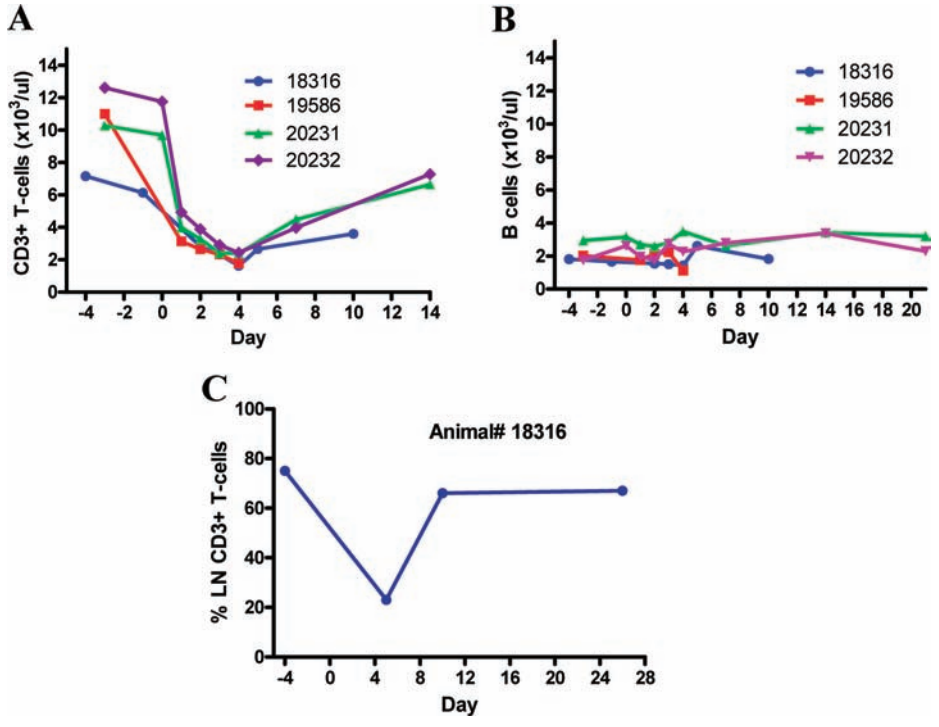

Figure 5. Porcine CD3 T-cell depletion profile in vivo for four animals using antiporcine CD3 immunotoxin, A-dmDT390biscFv (2−6−15). (A) Absolute number of CD3+ T-cells in the peripheral blood. (B) Absolute number of B cells in the peripheral blood. (C) Lymph node percent CD3+ T-cells.

immunotoxin treatment reversing the ratio of T:B cells in the lymph node (Figure 5C).

Clinically, no toxicities were observed in any of the treated animals. No anaphylactic reactions were observed. Kidney toxicity was not observed and renal values (blood urea nitrogen and creatinine) remained within normal limits. Two animals 18316 and 19586 developed mild increases of liver enzymes from baseline preimmunotoxin. Lactate dehydrogenase levels for animal 18316 increased from 1166 u/L to 1960u/L and for animal 19586 from 1722 u/L to 2017 u/L. Alkaline phosphatase levels for animal 18316 increased from 102 u/L to 204 u/L. No changes were observed in any of the other animals. Despite slight increases from baseline lactate dehydrogenase and alkaline phosphatase levels, these enzymes remained well within the normal limits in swine (575−3200 u/L for lactate dehydrogenase and 92−295 u/L for alkaline phosphatase). The transaminase remained normal and histopathology was unremarkable. In summary, we did not observe any side effect after the imunotoxin treatment. At the dose tested, the antiporcine CD3 recombinant immunotoxin did not deplete CD3 T-cells as well as its counterpart antihuman or antimonkey CD3 recombinant immunotoxins.[7,12] The dose used in swine was at least two times higher than the dose of its counterpart antihuman or antimonkey CD3 recombinant immunotoxins.[7,12] It is possible that miniature swine are more tolerant to the recombinant immunotoxin thereby allowing even further increased dosing for improved depletion effect. Given the absence of any signs of toxicity, we speculate that it is possible to increase the current daily dose or extend the administration days. A dosing study will need to be done to find the maximal safe dose and best dosing strategy for improved depletion. Since the half-life of recombinant antihuman CD3 immunotoxin is only 40 min,[12] it may not be necessary to spread 8 doses over 4 days. It is also possible that increasing the affinity of the scFv (2−6−15) similar to the affinity maturation approach used for the antimonkey CD3 recombinant immunotoxin may improve depletion function. Affinity maturation of the scFv (2−6−15) by yeast display[20] is currently in progress to isolate a higher affinity scFv (2−6−15) for improved porcine T-cell depletion in vivo.

Although CD3+ T-cell depletion following antiporcine CD3 recombinant immunotoxin treatment was not complete, in combination with other treatments, this reagent may provide sufficient T-cell depletion for certain applications.

Compared with the corresponding chemical conjugate antiporcine CD3 immunotoxin (pCD3-CRM9), this recombinant antiporcine CD3 immunotoxin [A-dmDT390biscFv(2−6−15)] has the following advantages: (1) high production level suitable for scale-up; (2) high purity and linkage homogeneity; (3) no neurological toxicity. In contrast, the chemical conjugate antiporcine CD3 immunotoxin caused significant dose-dependent neurotoxicity.[6] These finding suggest that the mutated DT binding domain of the chemical conjugate antiporcine CD3 immunotoxin can still bind to the porcine DT receptor. The recombinant antiporcine CD3 immunotoxin does not contain the DT binding domain (Figure 2). As expected, we did not observe any neurotoxicity in any of the animals treated with recombinant antiporcine CD3 immunotoxin. A-dmDT390biscFv (2−6−15) is a unique recombinant protein reagent that can be utilized in experimental porcine models of transplantation tolerance, autoimmune disease therapy, and T-cell leukemia treatment, as well as graft versus host disease studies.

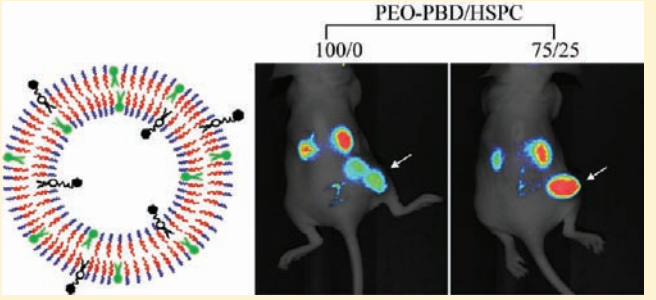
Supporting Information

ABSTRACT: Block copolymer-based vesicles have recently garnered a great deal of interest as nanoplatforms for drug delivery and molecular imaging applications due to their unique structural properties. These nanovesicles have been shown to direct their cargo to disease sites either through enhanced permeability and retention or even more efficiently via active targeting. Here, we show that the efficacy of nanovesicle targeting can be significantly improved when prepared from polymer−lipid blends compared with block copolymer alone. Polymer−lipid hybrid nanovesicles were produced from the aqueous coassembly of the diblock copolymer, poly(ethylene oxide)-*block*-polybutadiene (PEO-PBD), and the phospholipid, hydrogenated soy phosphatidylcholine (HSPC). The PEG-based vesicles, 117 nm in diameter, were functionalized with either folic acid or anti-HER2/neu affibodies as targeting ligands to confer specificity for cancer cells. Our results revealed that nanovesicles prepared from polymer−lipid blends led to significant improvement in cell binding compared to nanovesicles prepared from block copolymer alone in both *in vitro* cell studies and murine tumor models. Therefore, it is envisioned that nanovesicles composed of polymer−lipid blends may constitute a preferred embodiment for targeted drug delivery and molecular imaging applications.



INTRODUCTION

For traditional drug delivery systems, only a small fraction of the therapeutic agents reach the disease site. Targeted drug delivery seeks to improve the accumulation of these agents in the tissues of interest while reducing their relative concentration in off-target sites. If successful, this would lead to a significant improvement in treatment efficacy, while reducing drug toxicity and/or dose. Accordingly, the use of nanoparticulate systems to facilitate the targeted delivery of therapeutic agents has been extensively explored in recent years.[1−10] Drug delivery nanoplatforms have included dendrimers, polymers, liposomes, micelles, emulsions, and silica nanoparticles. Beyond their enhanced targeting capabilities and ability to carry high drug payloads, nanoparticle-based drug delivery systems have also been shown to provide protection of some drugs against degradation and have enabled the efficient delivery of substances with poor inherent solubility or low membrane permeability.[2]

Among the many nanoparticulate systems that have been reported, hollow nanometer-sized vesicles are particularly attractive due to the increased functionality imparted by their amphiphilic structure. Specifically, hydrophilic compounds can be loaded into the aqueous lumen of the nanovesicles, the hydrophobic domain serves as a natural carrier environment for hydrophobic drugs, and the exterior surface can be functionalized with molecularly specific targeting ligands.

Polymer-based nanovesicles (i.e., polymersomes), prepared from high molecular weight diblock copolymers, have a thick hydrophobic domain, typically ∼6−10 nm.[11] This is significantly larger than the hydrophobic domain of most liposomes, which are typically ∼3 nm in thickness. Compared to liposomes, polymersomes possess several beneficial properties, including increased mechanical robustness and the ability to carry large quantities of hydrophobic and hydrophilic molecules.[11,12] The vast majority of polymersomes are formed from diblock copolymers with poly(ethylene glycol) (PEG) as the hydrophilic block. This creates a relatively inert, brush-like outer shell, which imparts "stealth"-like characteristics to the nanovesicles and allows them to effectively avoid the reticuloendothelial system, resulting in longer circulation times. Further, polymersomes can be finely tuned through polymer selection to yield vesicles with diverse functionality, i.e., biodegradability, biocompatibility, permeability, elasticity, and so forth.[13−15] As a result of all these characteristics, polymersomes have garnered a great deal of

interest as nanoplatforms for a range of biomedical applications, including drug delivery, in vivo imaging, and cell mimicry.[13,16−18] For example, it has recently been shown that both hydrophobic paclitaxel and hydrophilic doxorubicin can be coloaded into polymersomes to effectively treat tumors,[13] porphyrins have been loaded into the hydrophobic domain of polymersomes creating highly fluorescent imaging agents,[19,20] and gadolinium-labeled dendrimers have been encapsulated within the lumen of polymersomes to create highly efficient magnetic resonance imaging (MRI) contrast agents.[16,17] When administered intravenously, polymeric vesicles generally maintain a long circulation time within the body and will nonspecifically accumulate within tumors due to enhanced permeability and retention (EPR). Although EPR can allow for a sufficient quantity of polymersomes to accumulate within tumors for effective treatment and/or imaging, it is generally desirable to develop actively targeted nanoplatforms to minimize nonspecific toxicity and/or enhance the efficiency of therapy.[21] Targeting, however, can often be compromised by the brush-like PEG coatings on the vesicle surface. Specifically, despite the benefits of pegylation in reducing polymer uptake by the reticuloendothelial system, it has been shown that the presence of PEG on vesicle surfaces can inhibit ligand-mediated targeting of the vesicle, due to steric effects.[22,23] Therefore, we hypothesized that the efficiency of polymersome targeting could be improved by diluting the surface density of PEG by integrating phospholipids into the membrane bilayer.

Recently, phospholipid−block copolymer hybrid nanoparticles have been reported and have drawn much attention.[17,24,25] The main components of these hybrid nanoparticles are the hollow polymeric scaffold with the incorporated phospholipid. Such hollow vesicles possess the structural stability and mechanical strength of polymer membranes and the biocompatibility and biofunctionality of phospholipid membranes. Owing to their unique structural properties, lipid−polymer hybrid vesicles may constitute a preferred nanoplatform for targeted drug delivery and molecular imaging applications. For example, Kanger and coworkers have prepared biofunctionalized lipid−polymer hybrid nanocontainers with controlled permeability for triggered delivery of drugs or imaging agents.[13,26]

In this study, we show that polymer-based nanovesicles prepared from polymer−lipid blends, as opposed to block copolymer alone, exhibit a significant improvement in tumor cancer cell binding. Specifically, lipid−polymer hybrid vesicles were produced from the aqueous coassembly of the diblock copolymer, poly(ethylene oxide)-*block*-polybutadiene, and the phospholipid, hydrogenated soy phosphatidylcholine (HSPC). The vesicles were functionalized with either folic acid or HER2/neu-targeted affibodies as targeting ligands to confer specificity for cancer cells. HER2-affibodies comprise a new class of high-affinity ligands based on a protein scaffold derived from the IgG-binding domains of staphylococcal protein A.[27] These small (6.5 kDa) robust molecules have been shown to exhibit remarkable specificity and affinity (pm range) for the HER2/neu receptor. The key features of the developed nanomaterials include nanometer-sized vesicles formed from self-assembly of amphiphilic diblock copolymers and phospholipids, brush-like PEG outer shell and tumor-targeting ligands conjugated onto hybrid nanovesicles, which serve to localize the therapeutic agent to the site of interest. Here, the design, assembly, characterization, and tumor-cell targeting of the polymer−lipid hybrid vesicles are discussed.

EXPERIMENTAL PROCEDURES

Materials. Poly(ethylene oxide)-*block*-polybutadiene copolymer (denoted PEO-PBD) was purchased from Polymer Source (Dorval, Quebec, Canada). Average molecular weights of the poly(ethylene oxide) and poly(butadiene) block were 600 and 1200, respectively. Hydrogenated soy phosphatidylcholine (HSPC), 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(Lissamine rhodamine B sulfonyl) (Rhod-PE), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[poly(ethylene glycol)2000-*N*′-carboxyfluorescein] (DSPE-PEG2K-CF), 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[amino(polyethylene glycol)-2000] (DSPE-PEG2000-Amine), and 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[folate(polyethylene glycol)-2000] (DSPE-PEG2000-Folate) were obtained from Avanti Polar Lipids (Alabaster, AL). ADIBO-dPEG4-NHS was synthesized in the lab (see Supporting Information). All other chemical were used as received. All buffer solutions were prepared with ultrapure grade water.

Preparation of Giant Vesicles. Giant vesicles were prepared by hydration of dry polymer/lipid films. Stock solutions of PEO-PBD and HSPC in chloroform were mixed in the following molar ratios: PEO-PBD/HSPC (100:0), PEO-PBD/HSPC (90:10), and PEO-PBD/HSPC (75:25). The total amount of PEO-PBD for each of the vesicle compositions was 1 mg. In all cases, a small amount of the fluorescent label, Rhod-PE, was also added for vesicle visualization. The solvent was removed using a direct stream of nitrogen prior to vacuum desiccation for a minimum of 4 h. Giant (micrometer-sized) vesicles were formed by adding 2 mL sucrose (285 mM) solution to dried film and incubating in a 65 °C water bath for more than 24 h.

Preparation of Nanometer-Sized Vesicles. Stock solutions of PEO-PBD and HSPC in chloroform were mixed in the following molar ratios: PEO-PBD/HSPC (100:0), PEO-PBD/HSPC (90:10), and PEO-PBD/HSPC (75:25). The total amount of PEO-PBD for each of the vesicle compositions was 1 mg. For folate-receptor targeting, DSPE-PEG2000-Folate (10 μL, 1 mg/mL in chloroform) was added to the PEO-PBD/HSPC mixture. Rhod-PE (2.5 μL, 1 mg/mL in chloroform) was also added as a fluorescent indicator for fluorescence microscopy images. For flow cytometric study, DSPE-PEG2K-CF (2.5 μL, 1 mg/mL in chloroform) instead of Rhod-PE was used for vesicle preparation. For Her2/neu-receptor targeting, DSPE-PEG2000-Amine (10 μL, 1 mg/mL in chloroform) was added to the PEO-PBD/HSPC mixture. The solvent was removed using a direct stream of nitrogen prior to vacuum desiccation for a minimum of 4 h. Vesicles were formed by adding an aqueous solution (0.1 M PBS, pH 7.4) to the dried film and incubating in a 65 °C water bath for 0.5 h and then sonicating for another 1 h at the same temperature. Samples were subjected to 10 freeze−thaw−vortex cycles in liquid nitrogen and warm H_2O (65 °C), followed by extrusion 21 times through two stacked 100 nm Nuclepore polycarbonate filters using a stainless steel extruder (Avanti Polar Lipids).

Micropipet Aspiration. The micropipet aspiration experiment was performed as described previously.[20,28] Briefly, micropipets made of borosilicate glass tubing (Friedrich and Dimmock, Milville, NJ) were prepared using a needle/pipet puller (model 720, David Kopf Instruments, Tujunga, CA) and microforged using a glass bead to give the tip a smooth and flat edge. Pipettes were filled with 290 mOsm PBS and mounted on a micromanipulator, and the pipet was connected via tubing to a manometer. A negative pressure, produced through the manometer using a

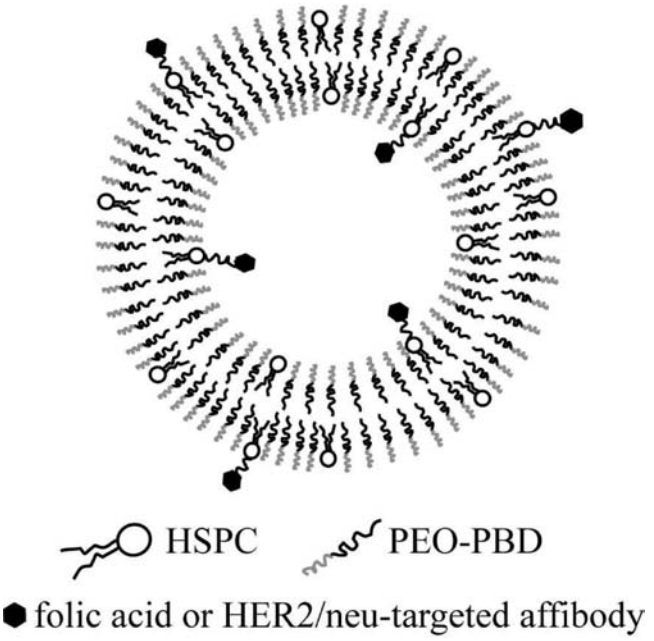

Figure 1. Schematic diagram of folate receptor or HER2/neu receptor-targeted, polymer−lipid hybrid vesicles. Nanovesicles were formed through the coassembly of the diblock copolymer PEO-PBD and the phospholipid HSPC. Folate receptor targeting was achieved by doping the vesicles with low percentage of PEG2000-DSPE-Folic acid. HER2/neu receptor targeting was achieved by conjugation of HER2/neu targeted affibodies to the vesicle surface via copper free click conjugation.

syringe, was created in the pipet to pick up a giant vesicle. The pressure applied to the vesicle was increased in stepwise increments (4 cm H_2O), and from this suction pressure (ΔP), the membrane tension (T) for a fluid membrane can be calculated from LaPlace's Law.[29] The length of the vesicle extension into the pipet in response to suction pressure was used to calculate the resulting vesicle area strain, $\alpha \equiv \Delta A/A_0$. The area elastic modulus was then measured by plotting α vs T in the high-tension regime ($T > 0.5$ dyn/cm) and calculating the slope of this tension−strain curve. Experiments were imaged using DIC optics with a 40× objective and a Cohu black-and-white CCD camera (Cohu, Inc., San Diego, CA). *ImageJ* software was used to measure membrane extensions and vesicle diameters.

Cloning and Expression of HER2-Affibody and Copper Free Click Conjugation. See Supporting Information.

Lipid Contents in Lipid−Polymer Hybrid Nanovesicles. Lipid−polymer hybrid nanovesicles, i.e., 10 mol % HSPC/90 mol % PEO-PBD and 25 mol % HSPC/75 mol % PEO-PBD, were lyophilized either before or after extrusion and purification. In these studies, samples were prepared in pure water. The residual solid was weighed and resuspended in pure water. Phospholipid content was determined by measuring the total content of phosphorus in the sample.[30] The polymer weight was calculated as the dry weight minus the lipid weight. The molar ratio of lipid to polymer was then calculated based on their respective molecular weights.

Quantification the Targeting Ligand Number on Vesicle Surface. The content of folate in the samples was determined by quantitative UV spectrophotometric analysis using the molar extinction coefficient value of 15 760 M^{-1} cm^{-1} at λ = 358 nm. Background absorbance measurements were determined using

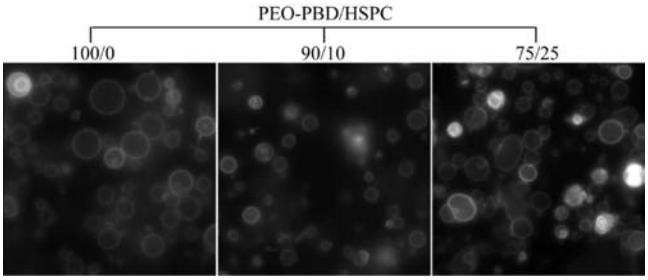

Figure 2. Fluorescent images of giant vesicles composed of PEO-PBD and HSPC at three different molar ratios. Vesicles composed of 100% PEO-PBD, 90% PEO-PBD/10% HSPC, or 75% PEO-PBD/25% HSPC were doped with a low amount (<1 mol %) of the fluorescent phospholipid Rhod-PE. Notably, it was observed that Rhod-PE was incorporated into all of the vesicles in each sample.

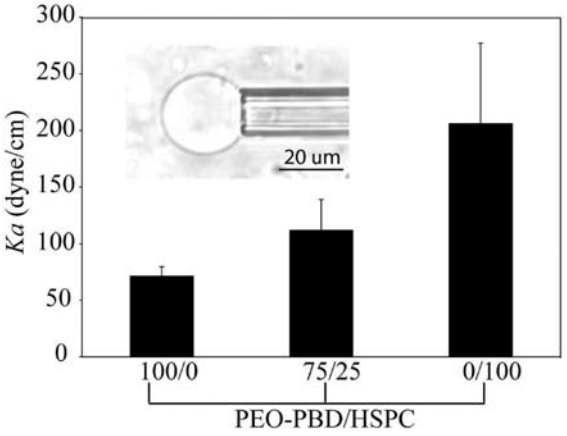

Figure 3. Elastic moduli of vesicles composed of PEO-PBD and HSPC at three different molar ratios. Micropipet aspiration was used to measure area elastic modulus (K_a) of giant vesicle formulations with different compositions of PEO-PBD and HSPC. Inset: Image of a giant polymerlipid hybrid vesicle (75 mol % PEO-PBD/25 mol % HSPC) during aspiration procedure.

analogous samples with no folate. To calculate the number of folate per vesicle, the number of vesicles in the purified sample was calculated based on the amount of polymer and phospholipid in each vesicle. For this calculation, the average diameter of each vesicle formulation was measured via dynamic light scattering. Further, the average area occupied by single polymer molecules in the bilayer was previously determined to be ~1 nm.[14] The average area occupied by single phospholipid molecules in the bilayer was previously determined to be ~0.65 nm,[31] and the thickness of the polymersome bilayer was considered to be ~6 nm based on previous study.[12] A similar approach was used to quantify the content of Rhod-PE in each vesicle. The molar extinction coefficient value used for Rhod was 93 000 M^{-1} cm^{-1} at λ = 568 nm.

Once the Rhod content per vesicle was established, it was possible to quantify the number of conjugated HER2−affibody per vesicle based on the ratio of absorbance of conjugated fluorescent-HER2 affibody relative to incorporated Rhod-PE. Notably, each HER2−affibody is labeled with a single near-infrared dye, Hilyte Fluor 750. The content of Hilyte Fluor 750 was determined by spectrophotometric analysis using the molar extinction coefficient value of 275 000 M^{-1} cm^{-1} at λ = 753 nm.

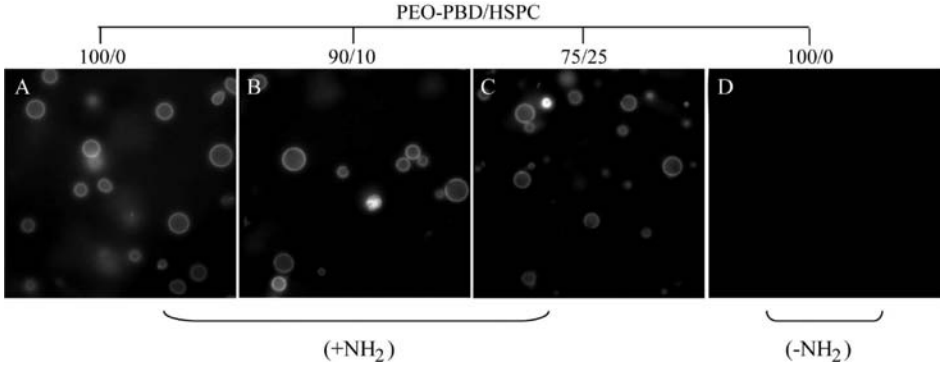

Figure 4. Fluorescent images of giant lipid−polymer vesicles following surface modification with a fluorescent dye. Vesicles prepared with (A) 100% PEO-PBD, (B) 90% PEO-PBD/10% HSPC, or (C) 75% PEO-PBD/25% HSPC were doped with low amount (<1%) of DSPE-PEG2K-NH2 and were subsequently labeled with NHS-ATTO740. (D) For comparison, 100% PEO-PBD vesicles were also prepared in the absence of DSPE-PEG2K-NH2 for NHS-ATTO740 surface conjugation.

Cell Culture. KB cells (human nasopharyngeal epidermoid carcinoma cells) were purchased from the America Type Tissue Collection (ATCC) and cultured in RPMI 1640 folic acid free media with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin at 37 °C in a humidified atmosphere containing 5% CO_2. T6−17 cells that were engineered to stably express the Her2/neu receptor (T6−17) were kindly provided by Mark Greene, MD/PhD (University of Pennsylvania). T6−17 cells were cultured and maintained in Dulbecco's modified Eagle's medium (DMEM), supplemented with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin at 37 °C and 5% CO_2.

Cell Viability via MTT Assay. NIH 3T3 cells were seeded in 96-well plates at a density of 10 000 cells per well. After incubation overnight (37 °C, 5% CO_2), the medium in each well was aspirated off and loaded with 100 μL of fresh medium containing nanovesicles with four different formulations including 100 mol % PEO-PBD, 10 mol % HSPC/90 mol % PEO-PBD, 25 mol % HSPC/75 mol % PEO-PBD, and 100 mol % HSPC. For PEO-based vesicles, the final polymer (PEO-PBD) concentration in the cultured media was 10 μM. For pure HSPC vesicles, the final HSPC concentration in the cultured media was also 10 μM. After incubation for 24 h, the nanoparticle containing medium in each well was aspirated off and replaced with 100 μL of medium and 10 μL of MTT reagent. The cells were incubated for 2 to 4 h, then 100 μL detergent reagent was added and left at room temperature in the dark for 2 h. The absorbance at 570 nm was measured using a microplate reader. Analogous viability studies were also conducted with the nanoparticle formulation consisting of 25 mol % HSPC/75 mol % PEO-PBD at PEO-PBD concentrations of 0, 5, 10, 50, 100, and 200 μM.

Fluorescence Microscopy. Cells plated in 8 glass well plates were washed once with PBS and then incubated in 200 μL of RPMI (for KB cells) or DMEM (for T6−17) containing vesicles for 2 h. For competitive inhibition experiments, cells were treated with the same vesicles but in the presence of 1 mM free targeting ligands in the media. The final PEO-PBD concentration in the cultured media was 5 μM for all imaging experiments. Prior to acquisition of fluorescence images, cells were washed with PBS three times. All microscopy images were acquired with an Olympus IX81 motorized inverted fluorescence microscope equipped with a back-illuminated EMCCD camera (Andor), an X-cite 120 excitation source (EXFO), and Sutter excitation and emission filter wheels. Images of the Rhod-PE were acquired using the filter set HQ545/30, HQ610/75, Q570LP. Images of FITC fluorescence were acquired using the filter set HQ480/40, HQ535/50, Q505LP. All filter sets were purchased from Chroma.

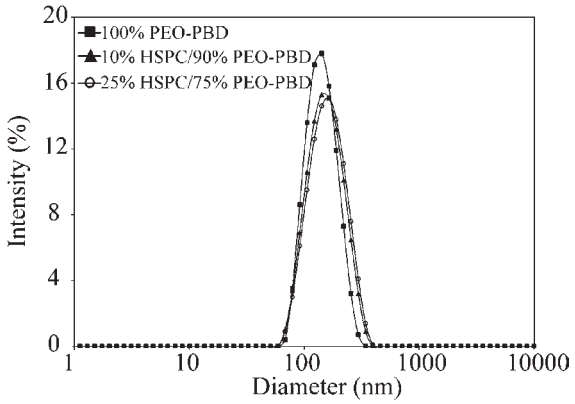

Figure 5. Intensity-weighted size distribution of three different vesicle formulations as measured by dynamic light scattering (DLS).

Flow Cytometric Analysis. Cells were dissociated from culture flasks using PBS-based enzyme free dissociation buffer and transferred to sterile 96-well plates at a final concentration of 50 000 cells per well. Targeted vesicles were added to the wells for 2 h at 37 °C. The final polymer (PEO-PBD) concentration in the cultured media was 5 μM for all flow cytometric experiments. For competitive inhibition experiments, cells were treated with the same vesicles but in the presence of 1 mM free targeting ligands in the media. Cells were transferred to 1.5 mL centrifuge tubes and washed in triplicate by pelleting cells at 1000 RCF for 3 min and then resuspending in PBS. Cells were resuspended in 250 μL of PBS and seeded in a 96-well plate (50 000 cells per well) and analyzed using a Guava Easycyte Plus system (Guava Technologies, Hayward, CA). Flow cytometry data were analyzed using *FlowJo* software (TreeStar Inc., San Francisco, CA).

***In Vivo* Imaging.** Approximately 6-week-old female Fox Chase SCID mice (Charles River Laboratory, Charles River, MS) were maintained in accordance with the Institutional Animal Care and Use Committee of the University of Pennsylvania. Mice were anesthetized via isoflurane and T6−17 cells were injected subcutaneously into the back right flank (2×10^6 cells in 0.2 mL PBS). Tumors were grown to an approximate size of 100 mm^3.

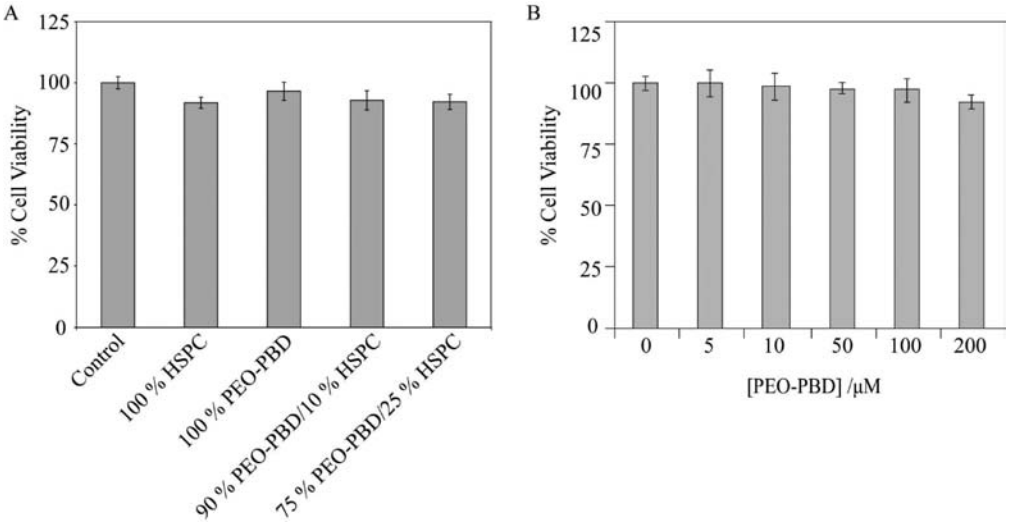

Figure 6. (A) Cell viability of NIH 3T3 cells incubated with nanovesicles with different lipid/polymer compositions. (B) Cell viability of NIH 3T3 cells incubated with 75% PEO-PBD/25%HSPC nanovesicles at different polymer concentrations. Viability was measured and normalized to cells grown in the absence of any particles based on an MTT assay.

Near-infrared (NIR) HER2-targeted nanovesicles were injected retro-orbitally (100 μM PEO-PBD in 0.2 mL PBS). Postcontrast images were collected 24 h postinjection. Fluorescent images were acquired using a Pearl NIR imaging system. Region of interest (ROI) analysis was performed using Pearl imaging software. Mean fluorescence of the tumor was measured after background subtraction.

Instrumentation. Dynamic light scattering (DLS) measurements were performed on a Zetasizer Nano from Malvern Instruments. The scattering angle was held constant at 90 °F. Fluorescence spectra measurements were acquired on a SPEX FluoroMax-3 spectrofluorometer (Horiba Jobin Yvon).

RESULTS AND DISCUSSION

Evidence of Forming Polymer−lipid Blends in Giant Vesicles. PEO-PBD are a class of synthetic amphiphilic diblock copolymers in which hydrophobic PBD is linked to hydrophilic PEG. When dispersed in aqueous medium, PEO-PBD with appropriate hydrophilic volume fractions can self-assemble to form polymeric vesicles.[11] As shown in Figure S1, the PEO-PBD selected for this study, PEO(600)-*b*-PBD(1200) (PEO-PBD), was capable of forming giant vesicles utilizing a classical swelling technique. Similarly, lipid−polymer hybrid nanovesicles could be formed from the aqueous coassembly of PEO-PBD and the phospholipid, hydrogenated soy phosphatidylcholine (HSPC). A schematic of a targeted lipid−polymer hybrid vesicle functionalized with either folic acid or HER2/neu-targeted affibodies as targeting ligands to confer specificity for cancer cells is shown in Figure 1. The ability to integrate phospholipids into the membrane of polymer-based vesicles was confirmed by preparing micrometer-sized lipid−polymer hybrid vesicles with a low molar percentage (0.5%) of fluorescent phospholipid 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(lissamine rhodamine B sulfonyl) (Rhod-PE). As shown in Figure 2, incorporation of Rhod-PE into the vesicle membrane was evident at the resolution of the optical microscope, for vesicles doped with 0, 10, or 25 mol % HSPC. The phospholipid-based fluorescent probe within polymer−lipid hybrid giant vesicles did not exhibit any obvious amphiphile phase segregation on optically resolvable length scales. However, the possibility of forming nanoscale lipid domains below the length scale of optical resolution cannot be ruled out.[12,25,32]

Table 1. Vesicle Diameters and Number of Targeting Agents per Vesicle

vesicle composition	diameter (nm)	folate/ vesicle	HER2/ vesicle
100 mol % PEO-PBD	105	310	24
90 mol %PEO-PBD/10 mol % HSPC	112	261	22
75 mol %PEO-PBD/25 mol % HSPC	117	193	21

Membrane Elasticity. To provide evidence that HSPC was successfully incorporated into the vesicle bilyaer, the elastic modulus (K_a) for three types of vesicles, 100 mol % PEO-PBD, 25 mol % HSPC/75 mol % PEO-PBD, and 100 mol % HSPC, were obtained via micropipet aspiration. The K_a is a common mechanical parameter of vesicle membranes that measures the in-plane mechanical elasticity of the membrane, and reflects the interfacial tension of the membrane interface.[11] Because the interfacial tension is a function of the chemical composition of the membrane, subtle changes in membrane lipid/polymer composition can be detected through changes in the membrane area elastic modulus.[33,34] As shown in Figure 3, polymersomes made from pure PEO-PBD were more elastic, as illustrated by their significantly lower elastic modulus (K_a = 72 dyn/cm) than pure HSPC liposomes (K_a = 206 dyn/cm). When PEO-PBD and HSPC were blended at a molar ratio 75:25, the resulting vesicles exhibited an intermediate elastic modulus (K_a = 112 dyn/cm) between the K_a values of the pure lipid and pure polymer vesicles. This intermediate elastic modulus provides further support that the vesicles were indeed a blend of the polymer and lipid.

Surface Chemistry of Hybrid Polymer−Lipid Vesicles. To provide evidence that the outer surface of pure polymer and polymer−lipid hybrid nanovesicles (10% and 25% HSPC) could be modified with various functional molecules, a small percentage

of amine-terminated phospholipid, DSPE-PEG2K-NH_2, was first doped into membrane during fabrication. The surface amines were then labeled with the amine reactive dye ATTO740 (ATTO740-NHS ester) and visualized by fluorescence microscopy. Figure 4 shows the fluorescence images obtained for giant vesicles prepared from 100 mol % PEO-PBD, 10 mol % HSPC/90 mol % PEO-PBD, and 25 mol % HSPC/75 mol % PEO-PBD after conjugation of ATTO740. In all cases, conjugation of the ATTO740 into the vesicles membrane was evident. To ensure that the ATTO dye was specifically bound to the vesicle surface, the nanovesicles were also prepared in the absence of DSPE-PEG2K- NH_2, and then incubated with ATTO740-NHS ester. In contrast to the aminated nanovesicles, these control vesicles did not exhibit a fluorescent signal, suggesting that the bound ATTO dyes were conjugated through a surface chemical reaction and not from nonspecific absorption. This result indicates that biologically active molecules could be conjugated through the reactive groups on the hybrid polymer–lipid vesicle surface.

Nanometer-Sized Vesicles Using Polymer–Lipid Blends. Following the formation of micrometer-sized vesicles, the vesicle size was reduced to the ~100-nm-size range by subjecting the sample to multiple freeze–thaw cycles and extrusion through a 100 nm polycarbonate filter. Dynamic light scattering (DLS) presented in Figure 5 revealed that hybrid vesicles with 10 and 25 mol % HSPC had mean diameters of 112 and 117 nm, respectively, while pure PEO-PBD vesicles had a mean diameter of 105 nm. To confirm that the lipid-to-polymer molar ratio was unaffected by the extrusion and purification process, the lipid content in samples containing nano- or giant hybrid vesicles was determined by measuring the phosphorus content. The polymer content was calculated by subtracting the measured lipid weight from the total dry weight of the sample (see Experimental Procedures section for details). These measurements indicated that HSPC was incorporated into the hybrid membrane at the predetermined molar ratios and that there was no significant loss of HSPC during processing. To evaluate the ability to store lipid–polymer hybrid nanovesicles, the hydrodynamic diameter of the vesicles was measured by DLS for 10 days following suspension in PBS buffer (0.1 mM phosphate, pH 7.4). It was found that vesicles prepared with 10 and 25 mol % HSPC did not exhibit any significant change in hydrodynamic diameter over this time frame.

Viability. Prior to evaluating hybrid nanovesicles for targeting living cells or tissues, their cytotoxicity was examined in a MTT cell proliferation assay (MTT = 3-(4,5-dimethylthiazol-2-yl)2,5-diphenyl-tetrazoilum bromide). Specifically, four different vesicle samples, 100% HSPC, 100% PEO-PBD, 90% PEO-PBD/10% HSPC, and 75% PEO-PBD/25% HSPC, were incubated with NIH 3T3 fibroblasts for 24 h. Each vesicle was tested in triplicate. Cell viabilities were normalized to a control cell sample that was not incubated with any vesicles. As shown in Figure 6A, none of the vesicle formulations had any significant effect on the proliferation of NIH 3T3 cells at a PEO-PBD concentration of 10 μM. The average cell viability of NIH 3T3 remained unaffected for PEO-PBD concentrations up to 100 μM for the 75% PEO-PBD/25% HSPC vesicles and only a very slight loss in viability (<8%) was observed at 200 μM PEO-PBD (Figure 6B).

Targeting Efficiency of Lipid–Polymer Hybrid Vesicles *in Vitro*. To demonstrate the feasibility of utilizing hybrid lipid–polymer vesicles to target tumor cells, we developed two different types of polymer–lipid vesicles, one targeting the folate receptor and one targeting the HER2/neu-receptor. In the first approach, the small molecule folic acid (folate) was used for tumor targeting since folate specifically binds to folate receptors, which

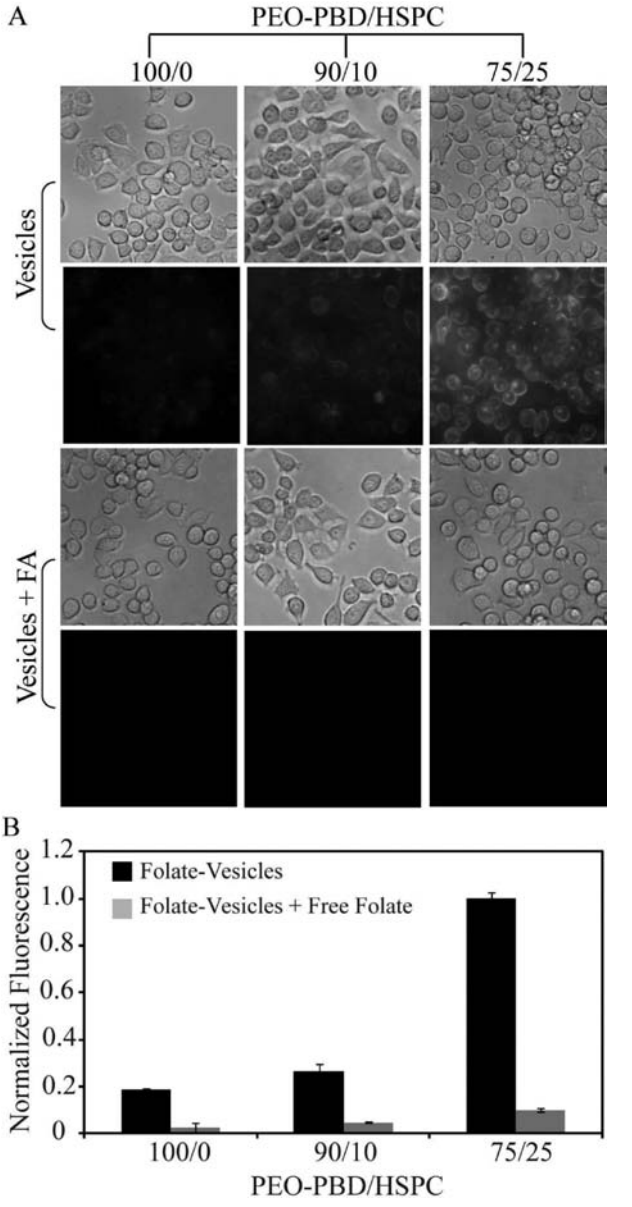

Figure 7. In cellulo analysis of folate receptor-targeted nanovesicles prepared with different lipid/polymer compositions. (A) Microscopy images of KB cells that have been incubated with various folate receptor-targeted vesicles prepared with PEO-PBD/HSPC at three different molar ratios. The top two rows show phase contrast and fluorescence images, respectively, collected in the absence of free folic acid in the media. The bottom two rows show images collected in the presence of 1 mM free folic acid in the media. All vesicles were incubated with KB cells for 2 h before images were acquired. Folate receptor targeting was achieved by doping the vesicles with low percentage of PEG2000-DSPE-Folic acid. All vesicles were also doped with a small amount of Rhod-PE. (B) Flow cytometric analysis of KB cells following incubation with folate receptor-targeted vesicles prepared with PEO-PBD/HSPC at three different molar ratios. Normalized mean fluorescent intensities are shown ± SD (n = 3). To confirm that cell binding was mediated through the folate receptor, competitive inhibition studies were performed by incubating KB cells with folate-targeted vesicles in the presence of excess free folic acid.

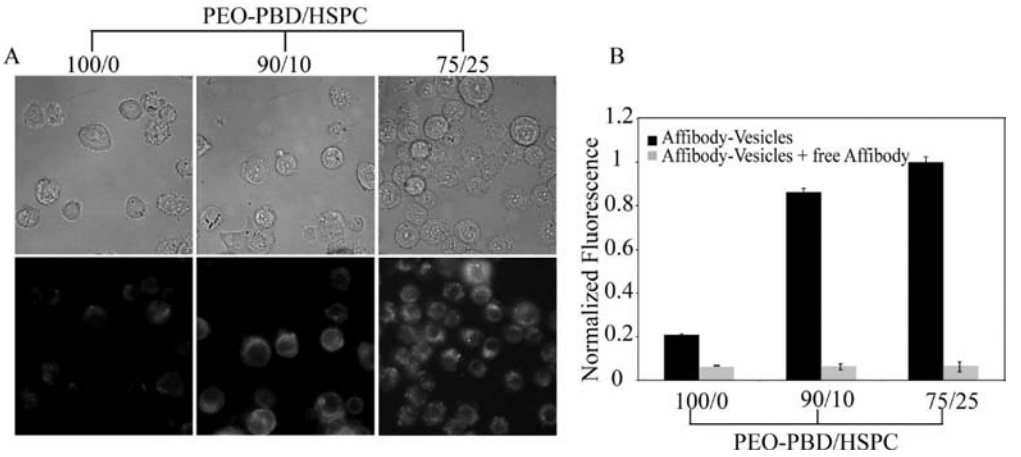

Figure 8. In cellulo analysis of Her2/neu receptor-targeted nanovesicles prepared with different lipid−polymer compositions. (A) Microscopy images of T6−17 cells that have been incubated with HER2/neu receptor-targeted vesicles prepared with PEO-PBD/HSPC at three different molar ratios. The top row shows phase contrast images, and the bottom row shows fluorescent images of the same cells. (B) Flow cytometric analysis of T6−17 cells following incubation with HER2/neu receptor-targeted vesicles prepared with PEO-PBD/HSPC at three different molar ratios. Normalized mean fluorescent intensities are shown ± SD (n = 3). To confirm that cell binding was mediated through the HER2/neu receptor, competitive inhibition studies were performed by incubating T6−17 cells with HER2/neu-targeted vesicles in the presence of excess free HER2/neu affibody.

are frequently overexpressed on tumor cancer cells. KB cells were used in this study as a model cell line to evaluate the targeting capabilities of folic acid-labeled nanovesicles since they are known to overexpress the folate receptor. Vesicles were prepared with 1,2-distearoyl-*sn*-glycero-3-phosphoethanolamine-*N*-[folate-(polyethylene glycol)-2000] (PEG2000-DSPE-Folate) and Rhod-PE at a fixed molar ratio of folic acid/Rhod per polymer. A summary of the number of targeting ligands on each vesicle is provided in Table 1. After a 2 h incubation with KB cells, fluorescent images were acquired. A bright fluorescent signal could be observed for KB cells incubated with polymer−lipid hybrid vesicles, especially PEO-PBD vesicles doped with 25% HSPC, as seen in Figure 7A. In contrast, very little fluorescence was observed from cells incubated with vesicles that did not contain HSPC. To verify that uptake of the vesicles was mediated through the folate receptor, competitive inhibition studies were performed by incubating the folate receptor-targeted vesicles with KB cells in the presence of excess free folic acid. Under these conditions, fluorescence was significantly reduced; confirming that cellular binding of the polymer−lipid hybrid vesicles was specifically mediated by the folate receptor. Analogous findings were also obtained via flow cytometry (Figure 7B). A clear shift in the mean cellular fluorescence was observed between cells incubated with folate-targeted lipid−polymer hybrid vesicles compared with cells incubated with folate-targeted vesicles that did not contain HSPC.

To confirm that the difference in targeting efficiency between pure polymer vesicles and lipid−polymer hybrid vesicles did not result from the differing number of targeting ligands on each vesicle, we further prepared 100 mol % PEO-PBD, 10 mol % HSPC/90 mol % PEO-PBD, and 25 mol % HSPC/75 mol % PEO-PBD vesicles with an equal number (n = 310) of folate ligands and fluorescent lipids on their surface. As can be seen in Supporting Information Figure S2, even at equal ligand densities, the lipid-doped nanovesicles exhibited a significantly higher degree of cell labeling than non-lipid-doped nanovesicles.

To evaluate whether polymer−lipid hybrid vesicles that had targeting agents conjugated to their outer surface also exhibited

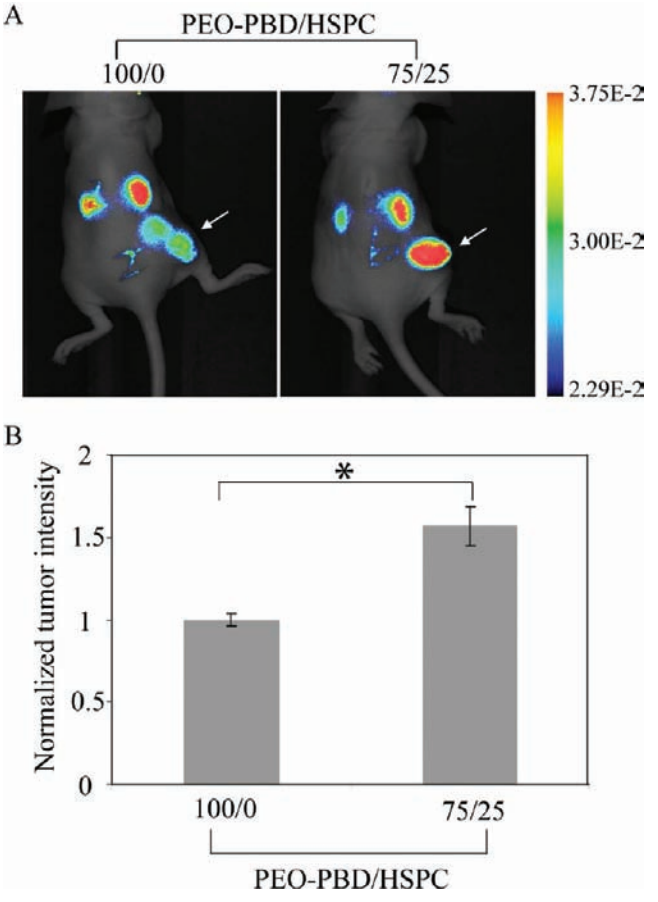

Figure 9. *In vivo* analysis of HER2/neu receptor-targeted nanovesicles prepared with different lipid/polymer compositions. (A) Fluorescence images of T6−17 tumor-bearing mice 24 h postinjection of NIR HER2/neu receptor-targeted vesicles prepared with PEO-PBD/HSPC at two different molar ratios. Tumors are indicated by white arrows. (B) Quantitative analysis of fluorescent images.

improved cellular binding, preformed vesicles were coupled to HER2/neu targeted affibodies via click conjugation.[35] After incubating the HER2-targeted nanovesicles with HER2/neu-positive T6−17 cells for 2 h, fluorescent images were acquired. As shown in Figure 8A, the HER2/neu-targeted nanovesicles composed of 25%HSPC/75%PEO-PBD exhibited a significantly higher degree of cell labeling than nanovesicles composed of 100%PEO-PBD. This was further supported by flow cytometric analysis (Figure 8B). Competitive inhibition studies using a molar excess of free HER2/neu affibody confirmed that the binding was specific for the HER2/neu receptor.

Targeting Efficiency of Lipid−Polymer Hybrid Vesicles *in Vivo*. To examine whether the incorporation of phospholipids into polymeric vessicles could be used to improve the targeting of HER2/neu-positive tumors in living subjects, near-infrared (NIR) fluorescent images of mice with T6−17 cell xenografts were acquired 24 h after retro-orbital injection of HER2-targeted lipid−polymer hybrid vesicles or HER2-targeted pure polymeric vesicles. As shown in Figure 9A, the HER2/neu-targeted nanovesicles composed of 25%HSPC/75%PEO-PBD exhibited a significantly higher signal in the tumor compared with nanovesicles composed of 100%PEO-PBD. Notably, some fluorescent signal was also observed in the kidney for both samples. Quantitative analysis of the NIR images revealed that HER2/neu-targeted nanovesicles composed of lipid−polymer blends exhibited more than a 1.5-fold improvement in tumor uptake compared with images from nanovesicles composed of 100% PEO-PBD (Figure 9B).

CONCLUSION

In summary, we have demonstrated that incorporation of HSPC into PEO-PBD-based nanovesicles can lead to a significant improvement in the efficiency of cell surface receptor targeting. It is hypothesized that incorporation of phospholipids into the vesicle bilayer diluted the density of the PEG-brush on the vesicle surface and as a result reduced the steric effect that PEG exerted on the targeting ligand. This is consistent with previous reports, which have also indicated that PEG-coatings can inhibit ligand-mediated targeting of the vesicle.[22,23] It is envisioned that the use of phospholipids can be extended to any polymer-based vesicles as a means to improve binding. Therefore, we believe that polymer−lipid hybrid vesicles constitute a promising nanoplatform for a broad variety of research areas, ranging from targeted drug delivery to molecular imaging.

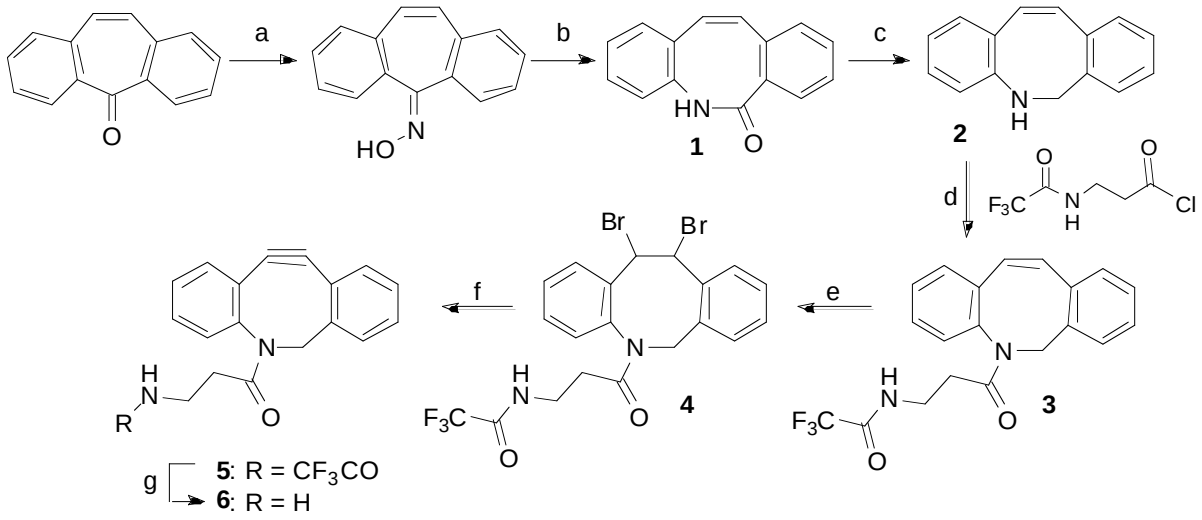
Supplementary Materials and Methods.

Synthesis.

Scheme S1.[a] Synthesis of ADIBO-C3-amine.



[a]*Reagents and conditions:* (a) $NH_2OH.HCl$, pyridine, 60%; (b) PPA, 125 °C, 73%; (c) $LiAlH_4$, ether, 58%; (d) pyridine, CH_2Cl_2, 71%; (e) pyridinium tribromide, 78%; (f) *t*-BuOK, THF, 88%; (g) K_2CO_3, aq MeOH, 58%.

5,6-Dihydrodibenzo[b,f]azocine (2). A solution of dibenzosuberenone (25 g, 121 mmol) and hydroxylamine hydrochloride (6.81 mL, 164 mmol) in pyridine (70 mL) was refluxed for 20 h. The reaction mixture was concentrated and poured into 5% aqueous hydrochloric acid (with crushed ice), stirred for 20 min, filtered, and dried in the air to provide 28.1 g of crude dibenzosuberenone oxime, as a white precipitate. Dibenzosuberenone oxime (16 g, 72.3 mmol) was added to 250 mL polyphosphoric acid at 125 °C, the reaction mixture was stirred for 60 min at this temperature, poured onto crushed ice (~700 mL), stirred for another 30 min, and filtered. The filter cake was washed with water, and dried under vacuum to provide crude dibenzo[*b,f*]azocin-6(5H)-one 1 (11.6 g, 52.4 mmol, 73%) as a grey powder.

A suspension of 1 (7.4 g, 33.4 mmol) and lithium aluminum hydride (2.494 ml, 66.9 mmol) in anhydrous ether (200 mL) was refluxed for 15 h. The reaction mixture was quenched by water, filtered, and the filter cake was washed with ether. The filter cake was dispersed in ether (100 mL), stirred for 10 min, and filtered. The combined organic layers were dried over $MgSO_4$, solvent was removed under vacuum, and the product purified by chromatography (hexanes:ethyl acetate 2:1) to provide 4.04 g (19.49 mmol, 58%) of 5,6-dihydrodibenzo[b,f]azocine (2). ^{1}H: 7.27-7.23 (m, 1 H), 7.2-7.1 (m, 3 H), 6.96-6.9 (m, 1 H), 6.9-6.8 (m, 1 H), 6.65-6.55 (m, 1 H), 6.54-6.48 (m, 1 H), 6.40 (d, *J* = 8 Hz, 1 H), 6.38-6.29 (m, 1 H), 4.51 (d, *J* = 6.8 Hz, 2 H), 4.2 (br s, 1 H); ^{13}C: 147.3, 139.3, 138.3, 134.9, 132.7, 130.3, 129.0, 128.1, 127.8, 127.6, 127.5, 121.8, 118.1, 117.9, 49.6. HRMS (ESI+) calcd for $C_{15}H_{14}N$ $[M+H]^+$ 208.1126, found 208.1120.

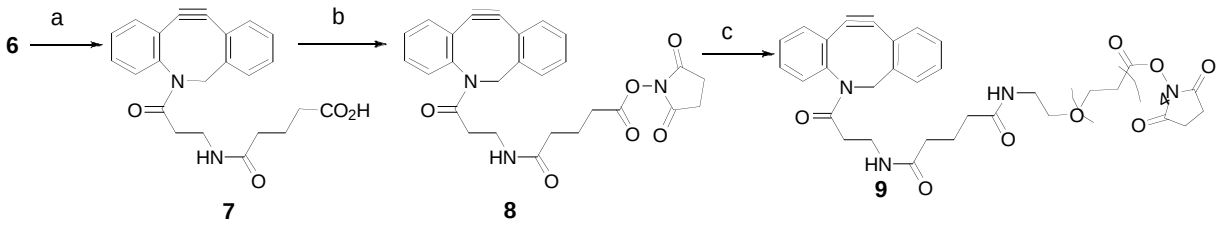
N-(6-(dibenzo[b,f]azocin-5(6H)-yl)-3-oxopropyl)trifluoroacetamide (3). 3-(trifluoroacetamido) propanoyl chloride (0.92 g, 4.52 mmol) was added to a solution of 2 (0.75 g, 3.62 mmol) and pyridine (0.859 g, 10.86 mmol) in CH_2Cl_2 (ca. 10 ml) at rt, and stirred for 30 min. The reaction mixture was diluted with CH_2Cl_2 (ca. 20 mL), washed with water (2x30 mL), dried over anhydrous $MgSO_4$ and the solvent was removed under reduced pressure. The residue was purified by chromatography (hexanes:ethyl acetate 2:3) to provide 958 mg (2.56 mmol, 71%) of 3 as yellowish oil.

N-(3-Trifluoroacetamidopropanoyl)-5,6-dihydro-11,12-didehydrodibenzo[b,f]azocine (5). Pyridine hydrobromide perbromide (0.948 g, 2.97 mmol) was added to a solution of 3 (958 mg, 2.56 mmol) in CH_2Cl_2 (4 ml) at rt, and the reaction mixture was stirred overnight. The reaction mixture was diluted with CH_2Cl_2 (20 mL), washed with 5% aqueous hydrochloric acid (20 mL), dried over $MgSO_4$, and solvent removed under vacuum. The residue was passed through a short pad of silica gel (CH_2Cl_2) to give 1.1 g of crude *N*-(3-trifluoroacetamidopropanoyl)-5,6,11,12-tetrahydro-11,12-dibromodibenzo[*b,f*]azocine (4) as an oil. Solution of crude 4 (1.1 g, 2.08

mmol) in THF (5 mL) was added to a solution of potassium t-butoxide (584 mg, 5.21 mmol) in THF (10 ml) at r.t., the reaction mixture was stirred for 1 h, diluted with ethyl acetate (20 mL), washed with 5% aqueous hydrochloric acid, brine, dried over $MgSO_4$, and the solvent was removed under reduced pressure. The crude product was purified by chromatography (hexanes:ethyl acetate, 2:1 to 1:1) to afford 685 mg (1.83 mmol, 88%) of 5 as brown oil.

N-(3-Aminopropionyl)-5,6-dihydro-11,12-didehydrodibenzo[b,f]azocine (ADIBO-C3-amine, 6). Solution of K_2CO_3 (2 g, 14.47 mmol) in 15 mL of water was added to a solution of N-(3-Trifluoroacetamidopropanoyl)-5,6-dihydro-11,12-didehydrodibenzo[b,f]azocine (5, 2.95 g, 7.12 mmol) in MeOH (30 mL) at rt and stirred overnight. Solvents were removed under reduced pressure, the residue was redissolved in CH_2Cl_2:ethyl acetate (1:4), washed with brine and water. The organic layer was dried over anhydrous Na_2SO_4, and concentrated in vacuum. The crude product was purified by chromatography (CH_2Cl_2:MeOH 10:1 to 10:4) to provide 1.14 g (4.11 mmol, 58%) of 6 as slightly yellow oil. ^{1}H NMR (500 MHz): 7.68 (d, *J* = 7.5 Hz, 1 H), 7.45-7.33 (m, 5 H), 7.29 (t, *J* = 7.5 Hz, 1 H), 7.25 (t, *J* = 7 Hz, 1 H), 5.15 (d, *J* = 14 Hz, 1 H), 3.16 (d, *J* = 14 Hz, 1 H), 2.82-2.67 (m, 2H), 2.45-2.35 (m, 1 H), 2.01-1.92 (m, 1 H), 1.6-1.4 (br s, 2 H); ^{13}C: 172.14, 151.48, 148.01, 132.12, 129.08, 128.29, 128.21, 127.99, 127.63, 127.01, 125.43, 122.85, 122.57, 114.97, 107.66, 55.25, 38.25, 38.15; HRMS (ESI+) calcd for $C_{18}H_{17}N_2O$ $[M+H]^+$ 277.1341, found 277.1339.

Scheme S2.[a] Synthesis of ADIBO-PEG_4-NHS Ester.



[a]*Reagents and conditions:* (a) Glutaric anhydride, $CHCl_3$, 59%; (b) *N*-hydroxysuccinamide, EDC, CH_2Cl_2; (c) 1) Amino-dPEG®4-acid, DIEA, CH_2Cl_2; 2) *N*-hydroxysuccinamide, EDC, CH_2Cl_2, 41%.

5-((3-(5,6-dihydro-11,12-didehydrodibenzo[b,f]azocin-5(6H)-yl)-3-oxopropyl)amino)-5-oxopentanoic acid (7). Glutaric anhydride (323 mg, 2.83 mmol) was added to solution of amine 6 (870 mg, 3.14 mmol) at r.t. in chloroform (20 ml) and the reaction mixture was stirred for 4 h at r.t. Solvent was removed in vacuum and the residue purified by chromatography (silica gel, CH_2Cl_2:MeOH 20:1) to provide carboxylic acid 7 (650 mg, 1.67 mmol, 59 %) as white waxy solid.

5-((3-(5,6-dihydro-11,12-didehydrodibenzo[b,f]azocin-5(6H)-yl)-3-oxopropyl)amino)-5-oxopentanoic acid N-hydroxysuccinamide ester (8). A solution of 7 (225 mg, 0.578 mmol), NHS (86 mg, 0.751 mmol), and EDC (150 mg, 0.780 mmol) in CH_2Cl_2 (ca. 2 mL) was stirred over overnight. The reaction mixture was diluted with CH_2Cl_2, washed with pH 6 buffer, dried over MgSO4 and concentrated. The residue was purified by chromatography on silica gel (CH_2Cl_2:MeOH 25:1) to provide 160 mg (0.32 mmol, 56 %) on NHS ester 8 as colorless oil.

ADIBO-PEG$_4$-NHS Ester (9). A solution of ADIBO-NHS ester (750 g, 1.538 mmol), amine-dPEG$_4$-acid (469 mg, 1.769 mmol), and DIEA (239 mg, 1.846 mmol) in CH_2Cl_2 (6 ml) was stirred for 1 h at r.t. EDC (442 mg, 2.308 mmol) was added to the reaction mixture followed by NHS (230 mg, 2 mmol). The reaction mixture was stirred for 3 h at r.t., diluted with CH_2Cl_2 (10 mL), washed with 5% aq. HCl, and dried over anhydrous $MgSO_4$. Solvent was removed in vacuum and the residue purified by chromatography (silica gel, CH_2Cl_2:iPrOH 20:1 to 10:1) to provide 460 g (0.626 mmol, 41 %) of ADIBO-PEG$_4$-NHS ester 9 as yellow-to-slightly orange oil. ^{1}H NMR (500 MHz): 7.67 (d, 1 H), 7.41-6.90 (m, 7H); 6.58 (br, NH), 5.18 (d, 1H), 3.76-3.41 (m,

21H), 2.84 (s, 4H), 2.68 (t, 2H), 2.45 (t, 2H), 2.31 (m, 4H), 2.08 (p, 2H); HRMS (ESI+) calcd for $C_{38}H_{47}N_4O_{11}$ $[M+H]^+$ 735.3241, found 735.3236.

Cloning and Expression of HER2-Affibody. The HER2-Affibody was cloned and expressed as previously reported.[1] Briefly, hybridized HER2-Affibody oligonucleotides were directly ligated with gel-purified *Nde*I-*Xho*I double digested pTXB1 vector (New England Biolabs, Inc) via the CloneEZ kit (Genscript). The pTXB1-HER2-Affibody vector was transformed in Rosetta™ 2(DE3)pLysS Competent Cells (Novagen). Bacterial cultures were grown to $OD_{600\ nm}$ = 0.6, and IPTG was added at a final concentration of 0.5 mM to induce T7 RNA polymerase-based expression. The cultures were allowed to express for 2 hours at 37 °C and were then pelleted by centrifugation at 10,000x g. Bacterial cell pellets were lysed by pulse sonication and HER2-Affibody complexes were isolated by centrifugation at 15,000x g. HER2-Affibodies were purified via affinity purification with a chitin bead column. HER2-Affibodies were eluted from the chitin bead column following an overnight incubation in 50 mM MESNA. Elutions were concentrated using an Ultracell 3,000 (Millipore, Billerica, MA) and then used for expressed protein ligation.

Expressed Protein Ligation. Expressed protein ligation was carried about between the thioester containing HER2-Affibody and an azido-fluorescent peptide (AzFP) with an N-terminal cysteine. The sequence of the AzFP was NH_2-CDPEK(5-FAM)DSG-D(Azi)-$CONH_2$. The K(5-FAM) represents a lysine with a fluorescein covalently attached to its ε-amino group and the D(Azi) represents a glycine with a azido group attached to its side-arm. The AzFP (0.1 mM) was incubated with approximately 0.01 mM HER2-Affibody. The EPL reaction was mixed overnight at room temperature. The EPL product and excess AzFPs were separated on a Superdex 30 chromatography column. A detailed experimental has been reported previously.[1]

Aza-Dibenzocyclooctene (ADIBO) Modification of Nanovesicles. Surface amines on nanovesicles were reacted with the amine-reactive ADIBO-dPEG$_4$-NHS, diluted 10 times from stock in dimethyl sulfoxide (DMSO), in 0.1 M sodium phosphate buffer, pH 9. The linker was added at 100 times molar excess to the nanovesicles. All nanovesicle solutions were mixed for overnight at room temperature. Nanovesicles were purified via superdex 200 chromatography columns (GE Healthcare, Piscataway, NJ).

Copper free click conjugation. Surface amines on nanovesicles were reacted with the amine-reactive ADIBO-dPEG4-NHS, diluted 10 times from stock in dimethyl sulfoxide (DMSO), in 0.1 M sodium phosphate buffer, pH 9. The linker was added at 100 times molar excess to the nanovesicles. All nanovesicle solutions were mixed for overnight at room temperature. Nanovesicles were purified via superdex 200 chromatography columns (GE Healthcare, Piscataway, NJ). ADIBO-modified nanovesicles were mixed with 30 μM of HER2-AzFP ligand in a pH neutral buffer. Reactions were mixed overnight at room temperature and then purified on Superdex 200 columns equilibrated with PBS.

HER2/neu-targeted near infrared (NIR) nanovesicles. To prepare HER2/neu-targeted nanovesicles for in vivo tumor imaging, expressed protein ligation was carried out between the thioester containing HER2-Affibody and an azido-NIR peptide (AzNIRP) with an N-terminal cysteine. Here, HiLyte Fluor™ 750 was used as NIR dye. HER2-AzNIRP was conjugated onto the surface of nanovesicles using similar procedures as those for the HER2-AzFP conjugation, as described above.

Supplementary Figures.

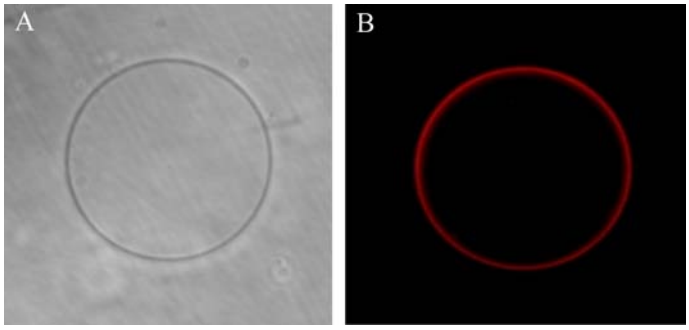


Figure S1. Microscopy images of giant vesicles composed of pure diblock copolymer PEO-PBD. The vesicles were fluorescently labeled by incorporating the phospholipid Rhod-PE into the membrane bilayer: (A) phase contrast image and (b) fluorescence image. Fluorescence is seen in an individual giant vesicle. The diameter of the vesicle is approximately 50 μm.

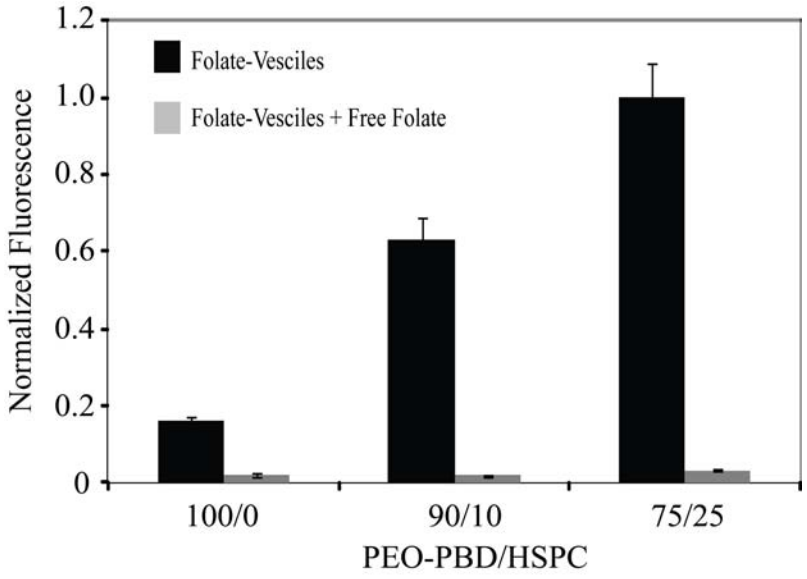

Figure S2. Flow cytometric analysis of KB cells following incubation with folate receptor-targeted vesicles prepared with PEO-PBD/HSPC at three different molar ratios. Normalized mean fluorescent intensities are shown ± S.D (n=3). Vesicles prepared with PEO-PBD/HSPC at

three different molar ratios have same number of folate ligands and fluorescent lipids (n=310) on their surface.

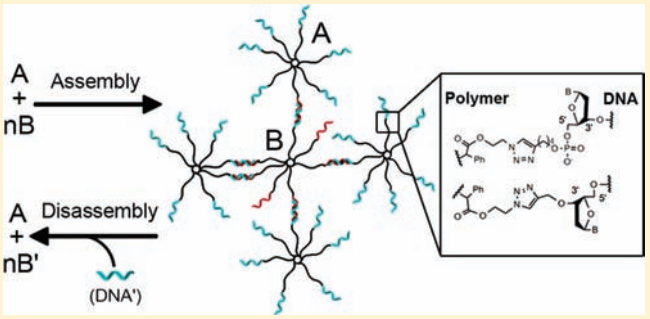
Supporting Information

ABSTRACT: Polymer biomolecule hybrids represent a powerful class of highly customizable nanomaterials. Here, we report star-polymer conjugates with DNA using a "ligandless" Cu(I) promoted azide−alkyne cycloaddition click reaction. The multivalency of the star-polymer architecture allows for the concomitant conjugation of other molecules along with the DNA, and the conjugation method provides control over the DNA orientation. The star-polymer DNA nanoparticles are shown to assemble into higher-order nanoassemblies through hybridization. Further, we show that the DNA strands can be utilized in controlled disassembly of the nanostructures.



INTRODUCTION

The marriage of synthetic polymers with naturally occurring macromolecules has led to offspring that display complex biomacromolecular architectures thereby revolutionizing the field of bioconjugations.[1−6] Bioconjugates can be obtained from copolymers produced through atom transfer radical polymerization (ATRP), as well as other controlled radical polymerization (CRP) procedures, such as reversible addition−fragmentation chain transfer (RAFT) and nitroxide-mediated polymerization (NMP).[7−12] One of the key features of these CRP procedures is the ability to produce copolymers with well-defined polymer architectures, including linear, brush, and star-shaped molecules, with a high content of functional chain ends.[6,13−18] The polymer chain ends have recently been used in further conjugations to install biotin for avidin binding,[19−21] carbohydrate conjugates for lectin binding,[22,23] or direct protein−polymer hybrids.[4,24−36] A tetrafunctional RAFT initiator used in a "core-first" method of star synthesis yielded a tetrafunctional maleimide star polymer that was conjugated to lysozyme, generating a multiprotein star polymer hybrid. In another example, *tert*-butyl acrylate was polymerized from a tetra-functional ATRP initiator and its bromo-chain ends were substituted by reaction with sodium azide to produce azide-terminated star polymers that were conjugated to a peptide.[24] The ease of obtaining multivalent functional polymeric architectures by CRP techniques has enriched the field of bioconjugates and has the potential to lead to further novel materials.

Polymer−oligonucleotide hybrids, a relatively new class of biomacromolecules, are bioconjugates of significant promise. Maynard et al.[37] conjugated siRNA to a thiolated chain of a poly(oligo(ethylene oxide)methacrylate) prepared using RAFT. The disulfide linkage formed in this conjugate was labile under reducing conditions. A more robustly linked polymer−DNA hybrid was prepared from polymers synthesized using ATRP.[38] DNA synthesized on beads was directly coupled to a phosphoramidite-terminated polystyrene that has, in previous research, been used as an amphiphilic DNA block copolymer to encapsulate nanoparticles.[39] Reaction of maleimide chain ends yielded thioester-conjugated DNA aptamers. The aptamers, or single-stranded DNA sequences that bind small-molecules, retained *in vitro* functionality in binding to their target peptide. Proposed applications for these polymer−oligonucleotide (DNA or RNA) hybrids have mainly been therapeutic stabilization and delivery of detection agents. However, DNA can provide other functional and structural properties, *in vitro*, and *in vivo*,[40−42] that can be applied advantageously to polymer hybrids. Polymer−DNA conjugates would thus provide nanoscale macromolecules that could be controlled using sequence-specific hybridization and other functional properties of DNA that are highly tunable (Scheme 1).

DNA self-assembly and nanotechnology are well-developed fields and DNA can be used to create three-dimensional materials such as nanoscale objects,[43−45] macroscopic crystals,[46−48] and DNA-based gels.[49] DNA self-assemblies and origami[50] are now moving from static to dynamic systems.[51,52] However, although those designs are based solely or largely on DNA, ready access to large (nanoscale) three-dimensional objects and their manipulation, remains challenging. Large colloidal metal-based nanoparticles can be improved in their utility with a functional coating of DNA.[53−60] Although nanoparticle−DNA hybrids and nanoscale

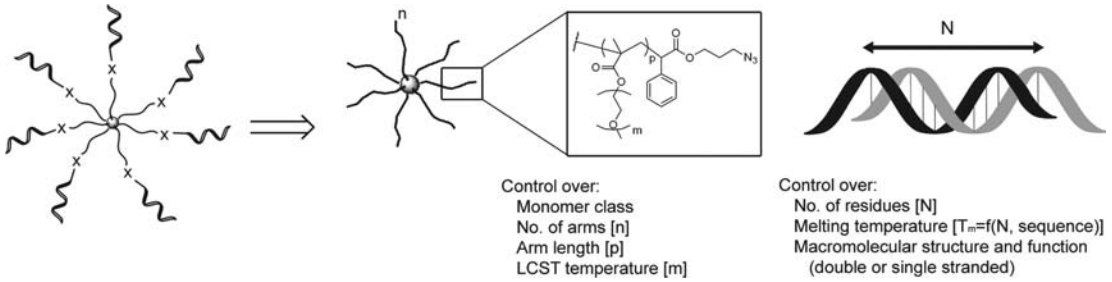
Scheme 1. Strategy for Star Polymer−DNA Hybrids by Direct Conjugation[a]



[a] These nanostructures would have high tunable control over design parameters. The star polymer−DNA conjugate would combine useful characteristics of each material into one molecule.

objects are both easily prepared and are useful, the DNA coating is nonspecific and the ability to custom tailor the coat and core is limited. A polymer nanoparticle would provide a highly customizable core material when used with DNA, including the possibility of concomitant molecules along with the DNA coat through the use of an appropriate conjugation methodology.

One of the most convenient conjugation strategies is the copper-catalyzed azide−alkyne cycloaddition (CuAAC) reaction.[61,62] This highly efficient reaction has risen to preeminence among the various "click" reactions[63] because the reacting azide and alkyne groups do not cross react with biologically abundant functional groups. The CuAAC reaction thus enables robust bio-orthogonal conjugations in aqueous media.[64,65] This click reaction has been extensively applied to the synthesis of polymers[66,67] and protein−polymer hybrids.[1,4,9,68] Besides the use with polymers and biomolecules, particularly proteins, click chemistry has been useful with synthetic and biochemically obtained DNA. DNA can be obtained with a high density of alkyne groups, and alkyne-modified DNA has been used with CuAAC for a wide variety of applications.[54,69−72] Although CuAAC has seen widespread use in both polymer chemistry and DNA supramolecular chemistry, the convergence of polymeric material and DNA through click conjugations is limited.[67,73−75]

We show that, by using CuAAC, ATRP based multivalent star polymers can be readily conjugated to functionalized DNA. Because click chemistry is used, simultaneous conjugation of these multivalent polymer cores with DNA, as well as other molecules, yields multicomponent-armed hybrids. We show that a polymer core armed with DNA provides a novel nanoscale material that can be designed quite simply, such that the DNA arms of the star can be used to engender function. While DNA can provide numerous useful functions, as a simple proof of principle for star-DNA hybrids, we demonstrate the use of hybridization properties of DNA to control the size of the star polymer nanoparticles. The self-assembly of star-DNA particles can be controlled and displacement with cDNA can reverse the assemblies. This preliminary study expands the scope of polymer−DNA hybrids by demonstrating how loading of DNA onto a multivalent architecture can provide control over self-assembly of polymer nanoparticles.

RESULTS AND DISCUSSION

Click Conjugations of DNA and Concomitant Molecules onto Star Polymers. Multiarm star polymers with peripheral functional azide-terminated arms were prepared by the macroinitiator "arm first" method. The macroinitiator was prepared using 3-azidopropyl 2-bromophenylacetate as an ATRP initiator for polymerization of $OEO_{300}MA$ (oligo(ethylene oxide) methacrylate with M_n = 300) targeting a degree of polymerization DP = 49. The macroinitiator was then copolymerized with ethylene glycol diacrylate (EGDA) under dilute conditions. The star polymers were analyzed using multiangle laser light scattering (MALLS) and determined to have M_n = 122 100, corresponding to average 7 arms per star. These star polymers with azide-terminated arms were conjugated with several different DNA strands that bore a reactive alkyne using click chemistry.

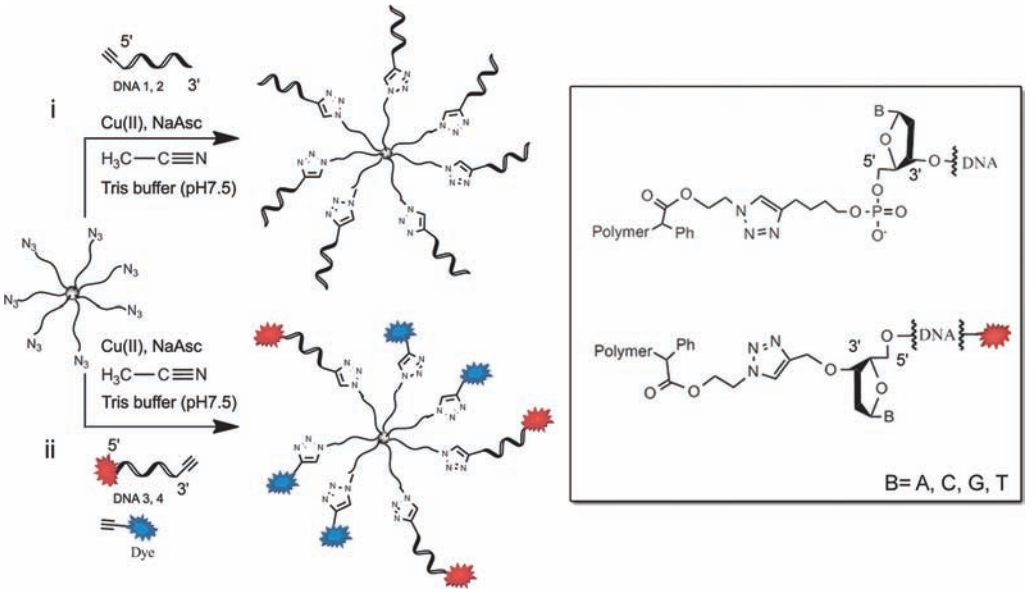
Table 1. DNA Sequences Used in This Study

		terminus	
name	sequence	5′-	3′-
DNA1	5′-cgc aag aag agc aaa cgc	Dy547	*O*-propargyl
DNA2	5′-gcg ttt gct ctt ctt gcg	Dy547	*O*-propargyl
DNA3	5′-ggc cga cgt gct tcg gct cgt	phosphohexynyl	OH
DNA4	5′-aat taa cga gcc gaa gca cgt	phosphohexynyl	OH
DNA5	5′-acg agc cga agc acg tcg gcc	OH	OH

Synthetic sequences of DNA with an alkyne, either at the 5′- or 3′-terminus, were obtained using commercially available reagents and protocols recommended by the manufacturer. For these studies, several DNA sequences were prepared with either a 5′-phosphohexynyl or 3′-*O*-propargyl group. In addition, some of the DNA strands included a terminal fluorescent dye that was incorporated during solid-phase synthesis using a commercially available phosphoramidite. A summary of the sequences used in this study is presented in Table 1.

Using recently optimized conditions to minimize DNA degradation and oxidation,[76] 3′-*O*-propargyl DNA strands (DNA1or DNA2) were initially clicked to the star polymer. Under these conditions, solutions of DNA and star-polymer in TRIS buffer (pH 7.5) with sodium ascorbate and acetonitrile (ACN) as a minor cosolvent (2%) were purged with argon gas, followed by addition of a $Cu_2SO_4 \cdot 5H_2O$ solution. The use of ACN helps stabilize Cu(I) and prevents DNA degradation due to oxidative damage under aqueous conditions, allowing successful conjugation of DNA (Scheme 2i). This "ligandless" method, using ACN, is in keeping with the philosophy of "click"-chemistry, which simplifies purification, as no additional triazole or other ligand molecules are used in the click conjugation. Following the click reaction, the

Scheme 2. Star Polymer Conjugation to DNA or DNA and Other Functional Molecules Using Click Chemistry[a]



[a] The inset depicts the structure at the click linkages. The conjugations were performed using azide functionalized star polymers and 5′-alkyne (i) and 3′-alkyne [2] modifiers on the DNA, respectively. The 3′-alkyne modifiers allow for 5′-end modification of the DNA with useful probes.

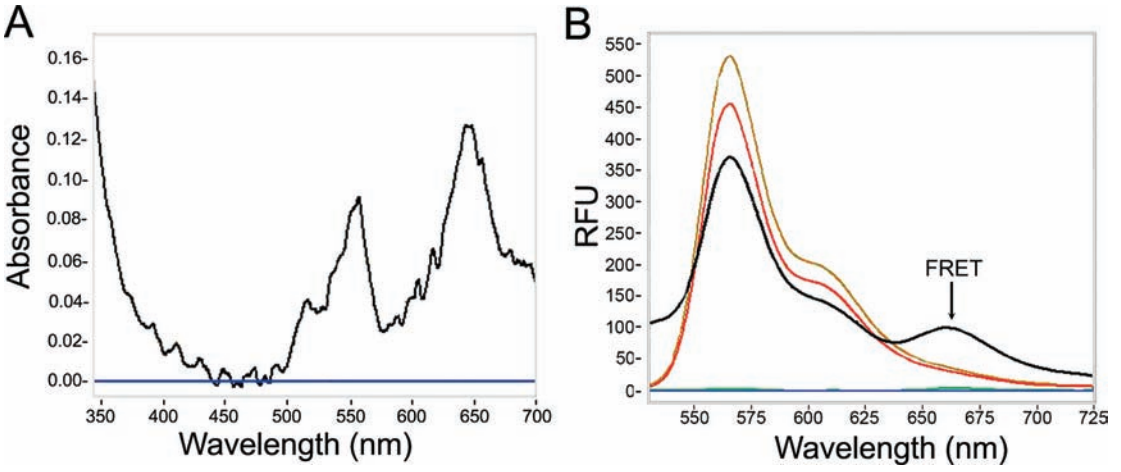


Figure 1. Click conjugation permits concomitant loading of molecules along with DNA onto a star polymer. (A) Absorption spectrum of Star/DNA1/Cy3 conjugate. (B) Fluorescence emission spectra showing FRET between fluorophores conjugated to the star polymer. All emission spectra were taken with an excitation wavelength at 470 nm. The emission spectra of Cy5 (green; on baseline), Cy3 (yellow), and a 1:1 Dy547:Cy5 solution (red) show no FRET between the fluorophores. Once DNA1 (carrying a Dy547 label) and Cy5 were conjugated to the star polymer, the emission spectrum of the conjugate (black) was a result of FRET in the fluorophore pair confirming that the two were attached to the same star polymer.

star−DNA conjugates were purified by filtration through a 10 kDa molecular mass cutoff nanosep filter that removes the solvent and ACN as well as unreacted DNA. The conjugation was verified using IR spectroscopy (Supporting Information Figure 1). Complete disappearance of the azide peak at 2200 cm^{-1} suggests that the star-polymers were essentially quantitatively conjugated to the DNA1 and DNA2.

Because star-polymers include multiple arms, we sought to demonstrate that click chemistry can be used to incorporate multiple groups onto these arms in a one-step process. Thus, DNA1, that included a 3′-*O*-propargyl group and 5′-flourescent dye, along with a second fluorescent dye bearing an alkyne were both used for the click reaction with the star polymer (Scheme 2ii). The two dyes—Dylight547 (Dy547; a Cyanine3(Cy3) equivalent) on the DNA and Cyanine5 (Cy5)—clicked on the star-polymer have known overlapping emission and absorbance regions, respectively, such that, when they are close enough, after excitation of the Dy547, the observed emission is from Cy5 due to Förster resonance energy transfer (FRET). Following the click reaction and purification of the stars to remove unreacted dyes and DNA, we could observe the absorbance peaks of both dyes (Figure 1A). As the Dy547 dye was at the 5′-terminus of the DNA and the click conjugation was at the 3′-terminus, the presence of the Dy547 absorbance peak indicated that the DNA strand remained intact. Furthermore, we were able to observe FRET emission of the multiconjugate star-DNA1-Cy5 (Figure 1B).

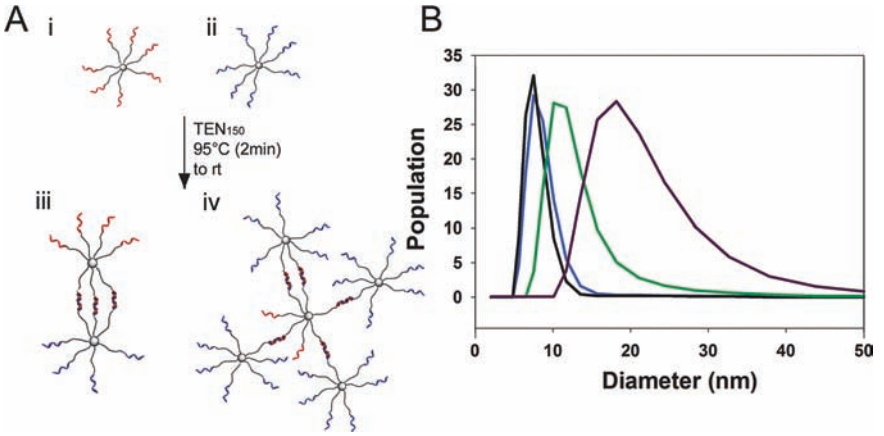

Figure 2. Controlled DNA self-assembly of star polymers. (A) Scheme for DNA directed self-assembly of star polymers. (B) DLS scans of star polymers click conjugated to DNA1 (black-Ai) and DNA 2 (blue-Aii). DNA directed hybridization of these two stars yield larger assemblies shown in a 1:1 star−DNA1/star−DNA2 ratio (green-Aiii) and in a 1:10 star−DNA1/star−DNA2 ratio (purple-Aiv) at 1 nM concentrations.

At the sample dilutions at which the fluorescence was measured, even if the statistically highly improbable reaction outcome produced star-polymer conjugates wherein some stars were only DNA-conjugated while other stars were only dye-conjugated, such a solution would not FRET. Solutions with only one dye or even both dyes in solution together do not result in the FRET emission peak. Thus, the emission due to FRET in the click-conjugate star-polymer solution strongly indicates that both DNA (with dye) and the dye molecule were click-conjugated concomitantly onto the same stars. This shows the power of the click chemistry approach to conjugate DNA as well as other molecules directly onto star-polymers together, taking advantage of the multivalency that the arms provide.

DNA-Directed Assembly of Soft Nanoparticle Hybrids. The ability to conjugate DNA by click chemistry onto star-polymers is significant as the functional properties of DNA can be harnessed. While there is a vast array of function that can be derived from DNA, we sought to demonstrate this quite simply by using the hybridization properties of DNA. Using star−DNA conjugates, star−DNA1 and star−DNA2, that include cDNA sequences, we obtained supra-molecular star−DNA architectures. DNA directed assembly was accomplished by heating solutions of mixtures of the two star−DNA conjugates (at 1 nM) at 95 °C in aqueous buffered salt solution and cooling to room temperature to anneal the DNA strands (Figure 2). We then tested for controlled hybridization behavior by altering the ratios of the star−DNA conjugates. Hybridization assembly of the nanoparticles was studied by dynamic light scattering (DLS). As expected, a relationship was found between hybridization ratio and size of the final self-assembled supramolecular architecture. Both star−DNA1 and star−DNA2 averaged approximately 4 nm. The resulting size of the 1:1 star−DNA1/star−DNA2 hybrid, Figure 2Aiii, was found to be approximately 9 nm, while a particle size of approximately 20 nm (purple) was observed in the 1:10 star−DNA1/star−DNA hybrid, Figure 2Aiv, system. No residual free stars were observed in the DLS traces thereby demonstrating the fidelity of cDNA hybridization.

These results indicate that self-assembled nanoscale structures can be readily created by using simple cDNA strands conjugated onto star polymers. By simply controlling the ratios of the star−DNA hybrids, one can control the size of the resulting particles. Star polymers provide a powerful tool for obtaining these large assemblies due to the controlled multivalent architecture unavailable to linear DNA systems. Through controlled hybridization, these stars can be used as templates for the design of more advanced DNA architectures. Additionally, nanoparticles with DNA of other functions can be designed and obtained.

Reversible Self-Assembly of Soft Nanoparticles using DNA Strand Invasion. The ability to controllably assemble star−DNA conjugate particles can be expanded by gaining control over the reverse disassembly process. The ability to control DNA self-assembly using strand invasion techniques has enabled DNA computation.[77−80] In this scheme, if one of the hybridized strands in a duplex includes a small, single-stranded overhang or "toehold", the duplex can be invaded by a cDNA strand that includes the toehold region under ambient conditions. This is typically done in linear DNA systems, and we extended this technique to the star−DNA hybrids. DNA3 and DNA4, that include partially complementary regions, were conjugated to star polymers, respectively. Additionally, the use of the 5′-phosphohexynyl-terminated DNA, rather than the 3′-*O*-propargyl DNA, demonstrated how readily the orientation of the conjugated DNA strand can be selected, thereby increasing the informational content loading. These DNA strands were designed such that, upon hybridization assembly of the star-DNA hybrids, a short unhybridized "toehold" region would remain available for an invading strand. DNA5, which is fully complementary to DNA3, can bind to the star−DNA3 conjugate displacing star−DNA4, in effect, disassembling the particles. This invasion takes place at room temperature and thus allows for detection using DLS.

Star−DNA3 and Star−DNA4 were hybridized (10 nM) at a 1:1 ratio at 95 °C in aqueous buffer (Figure 3; black and red bars). The resulting complex had a mean diameter of 70 nm by DLS (Figure 3B; green bar). This assembly of hybridized star−DNA3 to star−DNA4 at 10 nM concentrations is large, likely due to the flexibility of the nonbinding region that allows for a larger number of star−DNA to bind to one another. In contrast, the star−DNA1/star−DNA2 complexes that were hybridized at 1 nM concentration and where the strands were completely complementary with no flexible single-stranded region after hybridization formed smaller assemblies.

To evaluate control over the assembly, single-stranded DNA5 was used to disassemble the supramolecular structure.

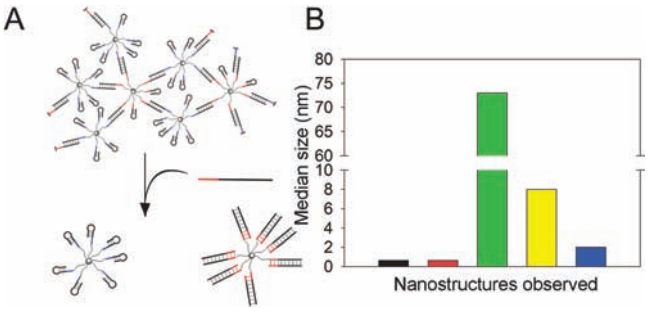

Figure 3. DNA controlled reversal of star polymer−DNA nanoassemblies. (A) Scheme for room-temperature disassembly of nanostructures using an invading DNA strand. (B) Mean area plots of DLS scans indicate a large nanoassembly (green bars) formed using a 1:1 ratio of smaller particles of star−DNA3 (black) and star−DNA4 (red) at 10 nM concentration can be subsequently gradually disassembled by an invading cDNA strand. The smaller assemblies, depicted in yellow and blue bars, are obtained at 1:100 star polymer/invading DNA and 1:300 star polymer/invading DNA ratios, respectively.

DNA5 was added in 100-fold excess over star−DNA3 to the star−DNA3/star−DNA4 hybrid complex to reduce the supramolecular assemblies from the 70 nm mean size to a hybrid of approximately 10 nm (yellow bar). The excess of invading DNA5 strand was to ensure adequate invasion of the crowded macromolecular complex at ambient temperature. When additional DNA5 was added, up to a 300-fold excess over star-DNA3 (1:300), the system reduced further in size to a mean of 2 nm (blue bar), close to that of the star−DNA complexes prior to assembly. Thus, the resulting particle corresponded to a totally disassembled star−DNA complex. The slightly larger mean size of the final complex can be attributed to the fact that this star−DNA complex is hybridized to DNA5. The phosphate backbone of the DNA caused the arms of the star to extend further due to charge repulsion, while in the parent nonhybridized stars, the single-stranded DNA collapsed into the star arms. Overall, these experiments demonstrate that assembled star−DNA hybrids can be selectively invaded. This can lead to star−DNA-based detection systems where not only the presence but also the concentration of an invading strand or other stimulus that DNA is sensitive to can be assayed.

CONCLUSIONS

This paper reports successful DNA−polymer conjugation to multifunctional star macromolecules using copper-catalyzed azide−alkyne cycloaddition. The application of click chemistry to the growing field of DNA−polymer hybrids represents a breakthrough because of the orthogonal control and high yields of this reaction. It is also useful because of ready availability of well-designed azide-terminated polymers, synthesized via CRP methodology.[81] DNA-based computing and self-assembly currently relies on either linear DNA with a toehold region[80,82] or hybrid macromolecules with an uncontrolled number of DNA arms formed by addition of DNA to nanoparticle templates.[83−85] This report demonstrates how DNA-based assembly, as well as polymeric systems, can be synergistically expanded in star polymer−DNA hybrids. We have developed a procedure that allows for preparation of star copolymers with a controllable number of azide-terminated arms per star. These peripheral functionalized stars can be clicked to alkyne DNA producing hybrids with a known number of DNA strands per star, as well as loading arms with DNA and other cargo simultaneously. The control over loading and size distribution is essential for the design and control over self-assembling nanoarchitectures.

EXPERIMENTAL SECTION

Star Polymer and DNA Synthesis. These were synthesized by standard methods. Details are included in Supporting Information.

Click Conjugation of 3′-*O*-Propargyl DNA and Cy5-Alkyne to Azide Star-Polymers. Stock solutions of $CuSO_4$, sodium ascorbate, and Tris-HCl (pH 7.5) buffer were degassed by bubbling argon through the solutions for 15 min prior to adding DNA. A reaction with 2 μM oligonucleotide in 500 mM Tris (pH = 7.5), 30 mg/mL of star polymer in THF (20 μL THF), 20 mM $CuSO_4$, and 40 mM sodium ascorbate in 3:1 water/ACN. The reaction was run for 2 h with shaking and purified with 10 K nanosep filter (Millipore). The reaction was confirmed by disappearance of the azide stretch at 2260 cm^{-1}on IR (Supporting Information Figure 1).

In the case of 3′-*O*-propargyl DNA-Dy547 and concomitant Cy5-alkyne conjugation to a single star polymer, 1.8 μM oligonucleotide and 0.2 μM Cy5-alkyne were introduced into the reaction mixture and the procedure as described above was followed. The resulting purified multivalent conjugate was analyzed using UV−vis spectroscopy (NanoDrop 1000) and emission spectroscopy (NanoDrop 3300). FRET controls were done using 100 nM Cy3 (Dy547 equivalent), 100 nM Cy5 solutions.

Hybridization Assembly of Star−DNA Conjugates. DNA-directed self-assembly of star polymers was achieved by heating solutions of 3 mg/mL (1 nM DNA) star−DNA polymer conjugates to 95 °C for 2 min in 100 mM Tris, 1 mM EDTA, and 150 mM NaCl (TEN_{150} buffer) and cooling to room temperature over 10 min. Following the hybridization cycles, star polymer assembly size was measured using dynamic light scattering (DLS) on a Zetasizer Nano spectrophotometer (Malvern Instruments Ltd.).

Controlled Disassembly of Star−DNA Nanoassemblies. Strand invasion studies were carried out at a concentration of 10 nM star−DNA. After star−DNA3 and star−DNA4 hybridization, DNA5 was added to a final concentration of 1 μM and 3 μM for a 100- and 300-fold excess over star−DNA3, respectively. Remeasurement of solutions following addition of the invading DNA5 strand was carried out after 30 s of incubation at room temperature.

Direct DNA Conjugation of Star Polymers for Controlled Reversible Assemblies

Saadyah Averick, Eduardo Paredes, Wenwen Li, Krzysztof Matyjaszewski, and Subha Das

Chemicals and General Experimental

Commercially available compounds were used without further purification unless otherwise noted. $CuBr_2$ (98%), *N,N,N',N'',N''*-pentamethyldiethylenetriamine (PMDETA, 98%) were purchased from Aldrich. CuBr (98%, Acros) was purified by stirring in acetic acid, filtered, washed with 2-propanol and then dried under vacuum. Oligo(ethylene oxide) monomethyl ether methacrylate (average molecular weight ~300, OEOMA) and ethylene glycol diacrylate (EGDA, 90%) were purchased from Aldrich and purified by passing through a column filled with basic alumina to remove the inhibitor and/or antioxidant. Phosphoramidites with labile PAC protecting groups and appropriate reagents for solid phase synthesis of DNA were purchased from ChemGenes or Glen Research and the CPG columns for standard DNA synthesis were purchased from Biosearch. The 5'-phosphohexynyl modifier and Dylight 547 phosphoramidites were purchased from Glen Research. CPG columns for 3'-*O*-propargyl DNA were purchased from ChemGenes. Copper sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$) was purchased from Sigma Aldrich. HPLC grade acetonitrile (ACN) was purchased from Fisher. Sodium ascorbate was purchased from Alfa Aesar. Other solvents and reagents not otherwise specified were purchased from Fisher.

Molecular weight and polydispersity were measured by GPC (Polymer Standards Services-PSS) columns (guard, 10^5, 10^3, and 10^2 Å), with THF eluent at 35 °C, flow rate 1.00 mL/min, and differential refractive index (RI) detector (Waters, 2410).

Toluene was used as the internal standard to correct for any fluctuation of the THF flow rate. The apparent molecular weights and polydispersity were determined with a calibration based on linear polystyrene standards using WinGPC 6.0 software from PSS. The detectors employed to measure the absolute molecular weights ($M_{w,MALLS}$) were a triple detector system containing RI detector (Wyatt Technology, Optilab REX), viscometer detector (Wyatt Technology, ViscoStar) and a multi-angle laser light scattering (MALLS) detector (Wyatt Technology, DAWN EOS) with the light wavelength at 690 nm. Absolute molecular weights were determined using ASTRA software from Wyatt Technology. DNAs were synthesized as described below. Infrared spectra (IR) were obtained on a JASCO FTIR 6300 instrument. UV-vis spectra were obtained on a NanoDrop 1000 spectrophotometer. Emission spectra were obtained on a NanoDrop 3300.

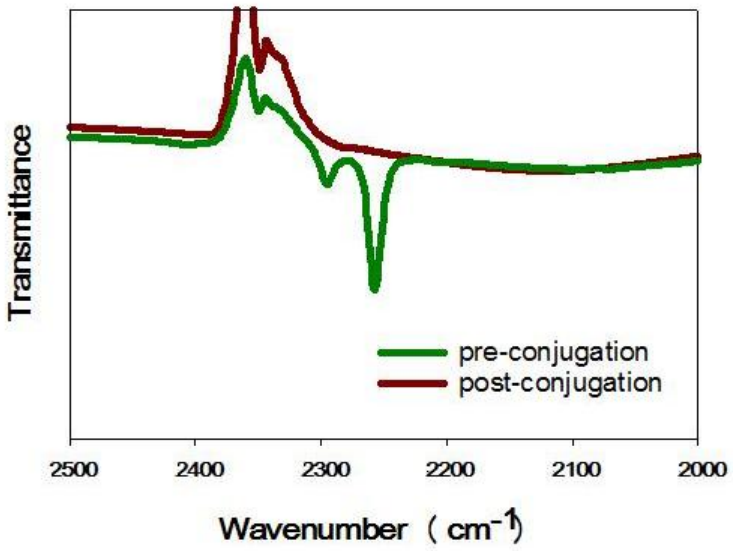
DNA synthesis

Solid phase oligonucleotide synthesis was performed on a MerMade 4 instrument (Bioautomation). Synthesis of the oligonucleotides was conducted on commercially available solid support columns and performed with standard commercially available phosphoramidites as directed by the manufacturer. Cleavage off the solid support and base deprotection of the oligonucleotides was performed by using ammonium hydroxide at 65°C for 2 h and standard protocols for PAC protected amidites as recommended by the manufacturer. Desalting and purification was conducted using a C18 columns (Waters) using protocols recommended by the manufacturer, with elution of the full length desired DNAs with ACN and water.

Star polymers synthesis and characterization

The azido group containing macroinitiator (N_3-POEOMA-Br MI) was obtained through ATRP of OEOMA from 3-azidopropyl 2-bromophenylacetate according to the procedure previously published[1] Number average molecular weight of linear N_3-POEOMA-Br MI M_n=14,700, average degree of polymerization, DP= 49.

The star polymer was prepared via arm-first method[2] The ratio of reagents $[N_3\text{-POEOMA-Br}]_0/[EGDA]_0/[CuBr]_0/[CuBr_2]_0/[PMDETA]_0$ was 1/10/0.9/0.1/1. A clean and dry Schlenk flask was charged with N_3-POEOMA-Br (0.31 g, 0.026 mmol initiating sites), EGDA (0.044 mL, 0.26 mmol), $CuBr_2$ (0.0006 g, 0.002 mmol), PMDETA (0.006 mL, 0.026 mmol) and 1.0 mL of DMF. The flask was degassed by five freeze-pump-thaw cycles, during the final cycle the flask was filled with nitrogen, and CuBr (3.6 mg, 0.025 mmol) was quickly added to the frozen mixture. The flask was sealed with a glass stopper and then evacuated and backfilled with nitrogen five times before it was immersed in an oil bath at 60 °C. Samples were withdrawn at timed intervals to measure polymer molecular weight by GPC. The reaction was stopped after 18 h via exposing the catalyst complex to air and dilution with THF. The solution was filtered through a column filled with neutral alumina to remove the copper complex, and then precipitated in diethyl ether to remove the unincorporated MIs. Apparent number average molecular weight of the purified star polymer is 43,000, and the absolute molecular weight of obtained star polymer determined by GPC MALLS is 122,100. The average arm number per star was calculated to be ~7, each arm has one azide group.



Supporting Figure 1. IR spectra of starpolymers before (green) and after (red) click reaction with alkyne DNA.

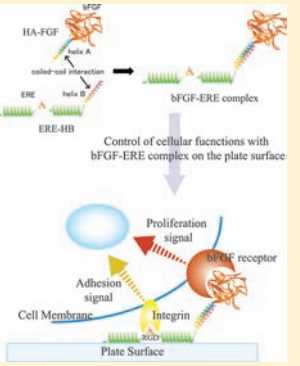
Construction of a bFGF-Tethered Extracellular Matrix Using a Coiled-Coil Helical Interaction

Eiry Kobatake,* Ryota Takahashi, and Masayasu Mie

Department of Biological Information, Graduate School of Bioscience and Biotechnology, Tokyo Institute of Technology B-28 4259, Nagatsuta, Midori-ku, Yokohama, 226-8501, Japan

Supporting Information

ABSTRACT: A novel method for construction of biomaterials for tissue engineering was developed. Noncovalent associations between extracellular matrix (ECM) and growth factors were achieved by engineering recombinant versions of both proteins that included helical peptides that could form a coiled-coil structure. The helix A peptide, which is capable of forming a coiled-coil helical structure, was fused with a matrix protein that contains a cell-adhesive RGD sequence. The helix B peptide, which is also capable of forming a coiled-coil helical structure, was fused with basic fibroblast growth factor (bFGF). Each protein retained its original activity of promoting cell adhesion and cell proliferation, respectively. These recombinant proteins associated noncovalently through coiled-coil helix formation between helix A and helix B. The resulting complex combined the functions of both proteins, and this method of joining proteins with different functionalities could be used to develop biomaterials for tissue engineering.



INTRODUCTION

Scaffolds with signaling molecules where cells can adhere, proliferate, and differentiate efficiently are essential for tissue engineering. Biomaterials providing such an environment for cells play an important role in most tissue engineering applications. In designing materials to allow specific cellular responses, recent strategies for tissue engineering applications have focused on the design of biomimetic materials. These biomaterials, which mimic functions of the extracellular matrix (ECM), are able to interact with surrounding tissues through specific molecular recognition motifs.[1,2] The incorporation of soluble signaling molecules such as growth factors and cell-binding properties into scaffold materials is one strategy to achieve biomolecular recognition of materials by cells.[3−6] In designing these strategies, supplementary steps for chemical or physical modification of the biomaterials are required. To avoid such troublesome processes, we previously constructed a fusion protein by genetic engineering, designated ERE-EGF, which is easy to immobilize onto hydrophobic surfaces and which also enhances cell adhesion and cell proliferation.[7,8]

Most signaling molecules are recognized and bound to their receptors on cell surfaces. After transducing signals into cells, they are internalized by endocytosis and digested. When the signaling molecule is immobilized on a scaffold by covalent bonding, some problems such as decreased recognition efficiency by the receptor, loss of activity, or malignant transformation caused by continuous signaling should be considered. One approach to overcome these problems is to utilize noncovalent bonding between the signaling molecule and the scaffold. Some experimental approaches include tethering of a growth factor to its substrate by engineering noncovalent bonding interactions between them. Boucher et al. utilized a coiled-coil interaction of E and K coils to immobilize epidermal growth factor (EGF) on a silicone surface.[9] A polyhistidine tag has been fused with EGF in order to immobilize EGF on a Ni^{2+}-bearing substrate.[10] Some growth factors have domains that bind to the ECM. Utilizing a similar approach, the collagen-binding domain from fibronectin has been introduced into growth factor proteins.[11−13] These fusion proteins had higher cell-growth activity when added to collagen than did soluble forms of the same proteins when they were added to cells on a collagen matrix. This method is effective for tissue engineering, which requires collagen as an ECM; however, other binding domains are needed to apply this method to other noncollagen ECM surfaces.

In order to immobilize signaling molecules to various types of ECM through noncovalent bonding interactions, the present study investigated proteins engineered to form coiled-coil dimers. Specifically, one peptide capable of forming a coiled-coil structure was fused with a growth factor protein, and another peptide with similar properties was fused with an ECM protein. A typical and well-studied coiled-coil dimer in nature is the leucine zipper of the yeast transcription factor GCN4.[14] However, this protein is a homodimer, and there is no interhelical ionic interaction. Another well-studied coiled-coil structure is the heterodimer of the Fos/Jun leucine zipper.[15] Unfavorable interhelical electrostatic interactions destabilize the homodimer form, thereby

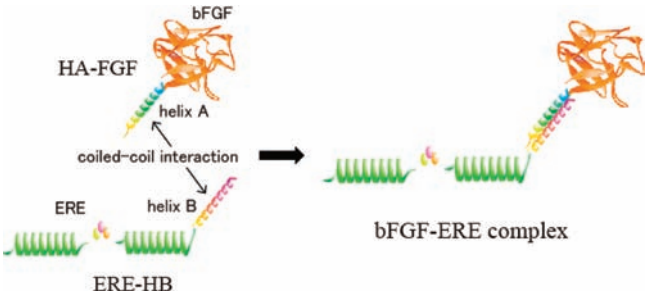

Figure 1. Design concept for the bFGF-ERE complex with a coiled-coil structure. Fusion proteins with helix A-bFGF (HA-FGF) and ERE-helix B (ERE-HB) were constructed, and they were noncovalently associated due to coiled-coil formation between the helix A and helix B moieties.

favoring heterodimer formation. On the basis of these studies, O'Shea et al. designed two peptides, designated ACID-p1 (helix A) and BASE-p1(helix B), which associate preferentially to form a stable, parallel, coiled-coil heterodimer with a leucine zipper and with favorable electrostatic interactions.[16]

In this study, the ERE protein, which has been described elsewhere,[7] was used as the ECM. In ERE, an RGD sequence found in the cell adhesion region was inserted between two other sequences, thus mimicking the ECM. Both of these peptide sequences contain 12 repeats of the polypeptide sequence Ala-Pro-Gly-Val-Gly-Val (APGVGV) designated as E. These kinds of sequence motif called elastin like polypeptides (ELPs) are found in elastin, which provides strength and flexibility in the ECM. ELPs have been paid attention as biomaterials for tissue repair.[17−19] On the other hand, basic fibroblast growth factor (bFGF) was used as a model signaling molecule since it has a wide variety of activities such as cell proliferation and differentiation. Helix A and helix B were fused at the N-terminus of bFGF and at the C-terminus of ERE, and the resulting proteins were designated as HA-FGF and ERE-HB, respectively. The structure of the complex formed between HA-FGF and ERE-HB through coiled-coil interactions is shown schematically in Figure 1. HA-FGF was immobilized via coiled-coil helix formation on a cell-culture plate whose surface was coated with ERE-HB, and the cell behavior on the surface was investigated.

EXPERIMENTAL PROCEDURES

Materials. Plasmid pBluescriptSKII (-) was obtained from Toyobo. Plasmid pET32c and *E. coli* Bl21 (DE3) were purchased from Novagen. *E. coli* KRX was obtained from Promega. Synthesized DNA fragments were purchased from Texas Genomics Japan. Synthesized oligopeptides were purchased form Sigma-genosis. Restriction enzymes and ligase were purchased from Toyobo and Takara Bio. All other chemicals were of analytical grade.

Construction of Plasmids. A pBS-FGF plasmid encoding a mouse bFGF gene was constructed previously. The DNA fragment encoding helix A was inserted at the 5′-end of the bFGF sequence of pBS-FGF. The helix A-bFGF fusion gene was inserted into pET32-c for expression, and the resulting plasmid was designated as pET-HA-FGF. A pBS-ERE plasmid encoding the ERE sequence was created as described elsewhere.[20] This plasmid has 12 repeats of APGVGV (E12) and RGD, as well as another E12 (the ERE sequence). The DNA fragment encoding (GGGS)4 as a linker peptide was inserted at the 3′-end of the ERE sequence of pBS-ERE. The DNA fragment encoding helix B was inserted into the pET32c expression vector (pET32c-helix B). The fusion gene of ERE and (GGGS)4 was inserted at the 5′-end of helix B of the pET32c-helix B. The resulting plasmid was designated as pET-ERE-HB. The DNA sequences of HA-FGF and ERE-HB with their translated sequences are shown in Supporting Information (Figure S1).

Protein Expression and Purification. *E. coli* KRX cells were transformed with plasmids and then were grown at 37 °C in an LB medium supplemented with ampicillin, to an OD_{660} = 0.6. After induction of protein expression with lamnose (0.1%) and isopropylthio-β-D-galactoside (1 mM), cells were cultured at 30 °C for another 4 h. Cells were harvested by centrifugation at 4 °C and then washed with PBS. After centrifugation, the cell pellet was resuspended in Bug Buster Reagent (Novagen) with benzonate nuclease (Novagen) and disrupted by gentle rotation. After centrifugation, the supernatant was applied to a TALON metal affinity resin (Clontech). After washing, the bound proteins were obtained by digesting with enterokinase (Novagen) for 16 h at room temperature. The enterokinase was removed by applying the digest onto EKapture agarose (Novagen).

Cell Proliferation Activity by Soluble HelixA-bFGF Fusion Protein. To investigate the growth factor activity of helixA-bFGF (HA-FGF), human umbilical vein endothelial cells (HUVEC) were utilized. The HUVEC cell line was purchased from Kurabo and maintained at 37 °C under 5% CO_2 in HuMedia EG-2 supplemented with 2% FBS, 10 ng/mL human EGF, 1 mg/mL hydrocortisone, 50 mg/mL gentamicin, 50 ng/mL amphotericin B, 5 ng/mL human bFGF, and 10 mg/mL heparin. HUVECs were seeded on a 96-well plate (coaster3595) at 2×10^3 cells/well, and HA-bFGF or bFGF was added to the HuMedia EG-2 without hFGF-b. The cells were incubated at 37 °C in a humidified atmosphere of 95% air and 5% CO_2. The culture medium was changed every 2 days. The day on which proteins were added was defined as day 0. The cell growth was observed every day under microscopy, and the numbers of cells on days 1, 3, 5, and 7 were estimated, using the Cell Counting Kit (CCK-8) (DOJINDO). The activity was evaluated at 450 nm as described in the CCK-8 kit.

Cell Adhesive Activity. Cell adhesion assays were performed in a 96-well plate (costor3361). The surfaces of the wells were coated with 10 nM of ERE-helix protein (ERE-HB). A fibronectin-coated surface was used as a positive control. BSA-coated and noncoated surfaces were used as negative controls. After incubation for 3 h at 37 °C, each well was washed with PBS, and then the wells were blocked with a 0.1% BSA solution for 2 h at 37 °C. HUVECs, prepared in a HuMedia-EG2 medium at 10^4 cells/well, were seeded in each plate. After 4 h of incubation at 37 °C, wells were washed with HuMedia-EG2. The remaining number of adhesive cells on the plate was examined using a CCK-8 kit.

Protein Binding Through a Coiled-Coil Structure. The surface of the wells of a 96-well plate (coster3361) was coated with 100 nM of ERE-HB and incubated for 3 h at 37 °C. After blocking with 0.1% BSA, various concentrations (10 nM, 100 nM, and 1 μM) of HA-FGF (100 μL) were added and the plates were incubated for 3 h at 37 °C. A solution of 100 μL of 1/5000 diluted rabbit anti-bFGF antibody (SIGMA) was reacted for 40 min at 30 °C. Finally, peroxidase-labeled antirabbit IgG antibody was reacted for 40 min at 30 °C. After thorough washing with PBS-T, HRP substrate (KPL) was added and the reaction was stopped after 2 min by adding 1 N HCl, then absorbance at 450 nm was measured using a microplate reader.

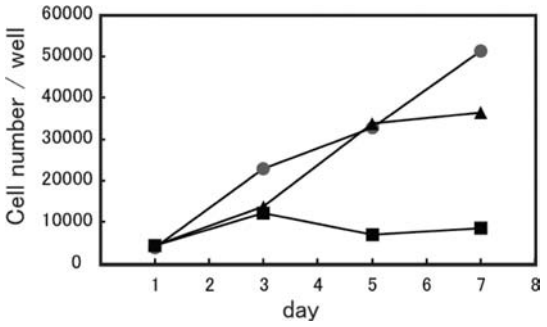

Figure 2. Cell growth with the soluble forms of the proteins. The cell growth activities of cultures with HA-FGF (▲), with bFGF (●), and without bFGF (■) were investigated by adding each protein to the HUVEC culture medium.

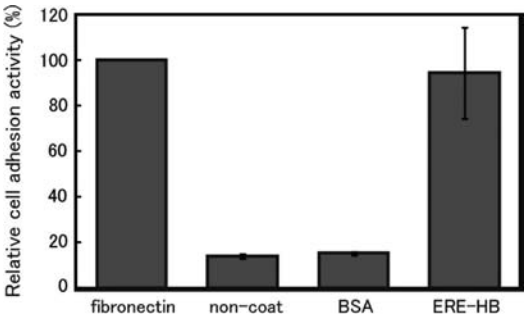

Figure 3. Cell adhesion activity of ERE-HB. Each protein was coated on a 96-well plate surface and HUVECs were then seeded. After 4 h of incubation at 37 °C, each well was washed and the remaining numbers of cells were determined. The positive control was fibronectin and samples were represented as the ratio of the number of cells attached to fibronectin-coated wells.

Growth Factor Activity of Adsorbed bFGF. The surface of wells of a 96-well plate was modified with HA-FGF by attaching a coiled-coil structure with ERE-HB as described in the previous section. HUVECs suspended in HuMedia-EG2 without bFGF at 2.0×10^3 cells/well were seeded on the plate. The culture medium was changed every 2 days. The numbers of cells on each day were counted using the CCK-8 kit. The growth kinetics of the remaining attached cells were followed for 5 days.

■ RESULTS AND DISCUSSION

Expression and Purification of Proteins. *E. coli* KRX was used as the host strain for the expression of the HA-bFGF and the ERE-HB thioredoxin fusion proteins. In our previous work, bFGF with a His-tag at the N-terminus was expressed in an insoluble fraction, and it had no bFGF activity even after refolding. Therefore, HA-bFGF was expressed as a fusion with thioredoxin at its N-terminus. LaVallie et al. reported that the fusion to thioredoxin increases the solubility of heterologous proteins synthesized in the *E. coli* cytoplasm, and that thioredoxin fusion proteins usually accumulate to high levels.[21] Also, in the case of expression of ERE-HB, thioredoxin was chosen as a fusion partner because the ERE-HB contains hydrophobic domains.[20] These fusion proteins with an attached helical peptide region were expressed at high levels in both the soluble and insoluble fractions. The proteins in the soluble fraction could be purified in a single step using a TALON metal affinity gel followed by the digestion with enterokinase to remove the His-tag and thioredoxin moieties. The expected sizes from their amino acid sequences of the HA-FGF and ERE-HB proteins after digestion with enterokinase are 21.1 kDa and 19.5 kDa, respectively. The estimated molecular weights of the proteins from SDS-PAGE (SI Figure S2) were a little larger than the expected sizes, but acidic protein[10] and elastin-like polypeptide[22] sometimes appeared larger than the calculated molecular weight in SDS-PAGE. Since the proteins bound to columns specifically and they were digested with enterokinase, we used them as objective proteins for the next experiments.

Growth Factor Activity of the Free Form of bFGF. Growth factor activities of HA-FGF and bFGF were investigated by adding 20 nM of each protein to the HUVEC culture medium. HUVECs are known to require the addition of bFGF as an essential factor for proliferation in low serum culture conditions. The growth curves of HUVEC with HA-FGF or bFGF are shown in Figure 2. HUVECs grew well in the presence of bFGF or HA-FGF, while the same cells did not grow at all without bFGF. Increased cell numbers were observed in culture with HA-FGF as well as bFGF. These results indicate that HA-FGF retained the cell growth activity of bFGF even after fusion with helix A.

Cell Adhesion Activity of ERE-HB. The HUVECs were seeded on ERE-HB-coated, fibronectin-coated, BSA-coated, and noncoated cell culture plates (Figure 3). After 4 h of incubation, the numbers of cells were counted in each plate. Cells were attached to the wells and spread on the fibronectin-coated plate, which was the positive control. However, cell attachment to the wells was barely observed on a BSA-coated plate or a noncoated plate (negative controls). In contrast, cells attached readily to the ERE-HB-coated plate (prepared with a coating concentration of 10 nM ERE-HB) as well as to a fibronectin-coated plate. Indeed, cells do not generally adhere to noncoated and BSA-coated plates, so the observed enhancement of cell adhesion to the ERE-HB-coated plates indicated that the ERE-HB protein itself must have adhered to the plate. The ERE protein adsorption to the plate surface was thus assumed but not examined further, given that this has already been reported elsewhere.[20] Because of the strong hydrophobicity of the repeated APGVGV sequence, the ERE adsorbed well onto a hydrophobic plate surface via hydrophobic bonding interactions. Even in this adsorbed state on the solid-phase surface, relatively hydrophilic regions of ERE-HB, such as the RGD sequence and the helix B sequence that was fused with an extremely hydrophilic sequence, retain their structure. The cell attachment on the ERE-HB-coated plate, according to our previous work,[20] should be attributed to the RGD sequence in ERE-HB.

Binding of HA-FGF Through Coiled-Coil Structure Formation with ERE-HB. Various concentrations of the HA-FGF were bound to the 96-well plate whose surface was coated with 100 nM of ERE-HB. The amounts of HA-FGF on the surface were indicated using an anti-bFGF antibody (rabbit) and HRP-labeled antirabbit IgG. As shown in Figure 4A, the amounts of HA-FGF bound on the surface increased in a concentration-dependent manner. However, the possibility of nonspecific adsorption of HA-FGF should be considered. To confirm the specific binding between HA-FGF and ERE-HB, ERE and bFGF without the attached helix domains were used for control experiments. In these experiments, 100 nM HA-FGF or bFGF was reacted with the surface coated with ERE-HB or ERE. The FGF moiety was detected as described above using an anti-FGF antibody, and the result is shown in Figure 4B. Among the four combinations

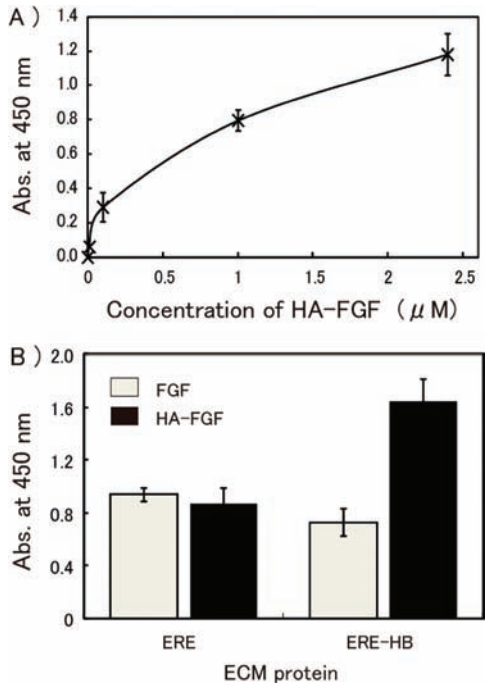

Figure 4. Binding of HA-FGF to ERE-HB with a coiled-coil structure on the solid-phase surface. (a) Various concentrations of HA-FGF were reacted with ERE-HB adsorbed on the 96-well plate surface, and the amounts of bound HA-FGF were determined using anti-bFGF antibody (rabbit) with an HRP-labeled antirabbit IgG secondary antibody. (b) The HA-FGF or bFGF was added to the surface coated with ERE-HB or ERE, and the amounts of immobilized bFGF moiety on each well were determined using an anti-bFGF antibody (rabbit) with an HRP-labeled antirabbit IgG secondary antibody.

tested, only the combination of HA-FGF and ERE-HB showed increased binding of bFGF. This indicates that the binding of HA-FGF to ERE-HB was specific. The FGF binding levels detected using the other three combinations were similar, and they should be considered background signals due to nonspecific adsorption.

In order to verify that the binding between HA-FGF and ERE-HB was due to the formation of a coiled-coil structure between helix A and helix B fused with their respective proteins, competitive inhibition of the binding of HA-FGF in the presence of helix A or helix B peptide was performed. A 100 nM HA-FGF solution was mixed with various concentrations (1 nM to 10 μM) of helix A or helix B, and the mixture was reacted with the ERE-HB-coated plate surface. The amounts of HA-FGF bound to the surface were determined as described above. The absorbance based on the bFGF surface signal was plotted against the concentration of helix A or helix B (Figure 5). The binding of bFGF was inhibited by addition of either helix A or helix B peptide in a concentration-dependent manner. These results indicated that the binding between HA-FGF and ERE-HB was due to formation of a coiled-coil structure between helix A and helix B from each protein.

bFGF Activity on the Plate Surface. HUVECs were seeded on the plate whose surface was modified with HA-FGF through coated-ERE-HB, and their growth curves were measured (Figure 6). On the ERE-HB-coated plate without HA-FGF, which was used as a negative control, clear cell growth was not observed (data not shown). As a control experiment, 100 nM

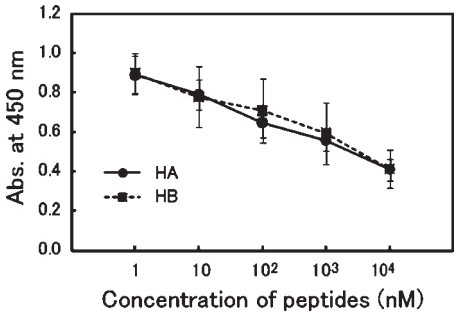

Figure 5. Competitive inhibition of binding of HA-FGF to ERE-HB using helixA and helix B peptides. The HA-FGF solution was mixed with various concentrations of helix A or helix B peptide, and the mixture was reacted to the ERE-HB-coated plate surface. The amounts of HA-FGF bound on the surface were determined using anti-bFGF antibody (rabbit) with an HRP-labeled antirabbit IgG secondary antibody.

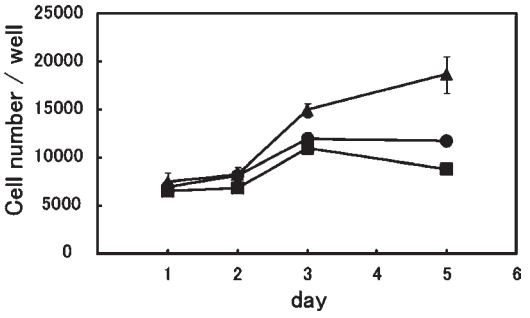

Figure 6. Cell growth with immobilized HA-bFGF. HUVECs were seeded on the plate whose surface was modified with HA-FGF through coated-ERE-HB (▲). bFGF without helix A peptide (●) or only buffer (■) was added to the culture medium at day 0 as a control experiment.

b-FGF without the attached helical peptide was added to the culture medium for seeding HUVECs. In this case, the growth curve was almost the same as that seen in the experiment without bFGF. A little growth was observed at 3 days of culture, but no cell growth was observed after that. Since the culture medium was exchanged at 2 days, bFGF that did not bind to ERE-HB should have been washed out. On the other hand, significant cell growth was observed when HA-FGF was immobilized on the ERE-HB-coated surface. The cells still grew well at 5 days of culture. These results suggest that the FGF moiety in the HA-FGF remained active even after immobilization on the plate surface, presumably through forming a coiled-coil structure with the ERE-HB. The effect of bFGF was sustained for a longer time period because the bFGF was retained in the matrix due to noncovalent bonding.

■ CONCLUSION

In this study, a novel method for construction of biomaterials for tissue engineering was developed. A designed extracellular matrix (ERE) and bFGF were combined with a noncovalent bonding by formation of coiled-coil structure. The resulting complex showed good cell adhesive and proliferation activities.

One advantage of this technique is that the growth factor or a matrix can be changed depending on the kind of target cell being studied. Preliminary experiments using a system that connected helix B with epidermal growth factor (EGF) yielded similar

dx.doi.org/10.1021/bc200249u |*Bioconjugate Chem.* 2011, 22, 2038–2042

encouraging results. In addition, we are beginning to apply this technique to construct an *in vitro* nerve system.

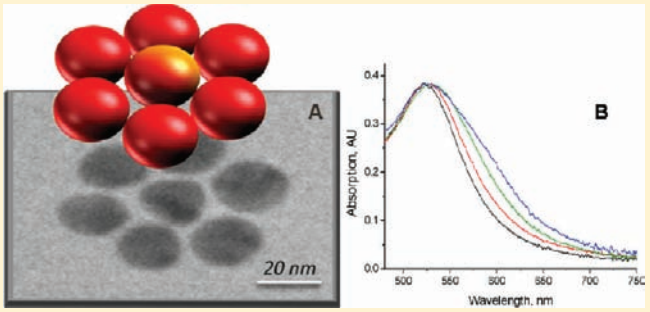
G4-DNA-Coated Gold Nanoparticles: Synthesis and Assembly

Irit Lubitz and Alexander Kotlyar*

Department of Biochemistry, George S. Wise Faculty of Life Sciences and The Center of Nanoscience and Nanotechnology, Tel Aviv University, Ramat Aviv 69978, Israel

ABSTRACT: Here, we describe the preparation of stable 15 nm gold nanoparticles (Au-NPs) coated with parallel-stranded G-quadruplexes (G4-DNA), comprising phosphorothioate residues on both sides of the DNA. Phosphorothioate residues located on the surface of the coated particles can anchor them to noncoated ones. Their incubation with more than 20-fold excess of 15 nm citrate-stabilized Au-NPs leads to the formation of flower-shaped structures comprising a central noncoated particle and five to six G-quadruplex-coated ones at the periphery, as revealed by TEM imaging analysis. The absorption band of the structures is shifted toward long wavelengths compared to individual particles not connected to each other. We show a strong dependence of plasmon coupling strength on the length of the DNA connecting Au-NPs.



INTRODUCTION

Nanoparticle−DNA conjugates[1,2] are widely used in nanoassembly,[3,4] bionanotechnologies,[5−7] and nanoelectronics.[8,9] In a classical approach, thiol-containing DNA oligonucleotides are used to stabilize the Au-NPs. Covalent interaction between the thiol attached to the end of the DNA and noble metal atoms results in coating of the particle with DNA. These particles are stable and can bind particles coated with complementary sequences via hybridization. This reaction guided by DNA−DNA bimolecular recognition leads to the formation of various multiparticle structures.[2,10,11] We have recently reported the synthesis of stable conjugates between silver nanoparticles and four-stranded G-quadruplexes.[12] The conjugates were formed during incubation of silver particles with G-quadruplexes, containing phosphorothioate anchor residues at both ends of the DNA, at near-equimolar concentrations. In the conjugates, each pair of particles was connected by a G-quadruplex. Increasing the DNA-to-particle ratio in the incubation from 1 to 3−5 resulted in the formation of aggregates that fall out of solution.

Here, we report that incubation of 15 nm gold nanoparticles (Au-NPs) with more than 15-fold molar excess of the G-quadruplexes, comprising phosphorothioate residues at both ends of the DNA, unexpectedly yields stable nonaggregated DNA-coated Au-NPs. Phosphorothioate residues located on their surface can, however, anchor them to citrate-stabilized Au-NPs. Incubation of a 30-fold excess of the latter particles with former ones leads to the formation of flower-shaped structures in which a central citrate-stabilized Au-NP is surrounded by several (5−6) DNA-coated ones. Interparticle interactions in the structure lead to a shift of the surface plasmon absorption resonance, which strongly depends on the length of the DNA molecules connecting Au-NPs in the structure.

EXPERIMENTAL PROCEDURES

Unless otherwise stated, reagents were obtained from Sigma-Aldrich (USA) and were used without further purification.

DNA Samples. The deoxyoligonucleotides, $a_5G_5a_5$, $a_5G_{10}a_5$, $a_5G_{20}a_5$, were purchased from Alpha DNA (Montreal, Canada). The four-stranded G-quadruplexes composed of 5, 10, and 20 tetrad were prepared as described in our recent work.[12]

Synthesis of NPs. *15 nm Gold Nanoparticles.* Au-NPs with a diameter of 15 nm were prepared by the reduction of $HAuCl_4$ with sodium citrate essentially as described.[13] 100 mL of 1 mM $HAuCl_4$ solution was heated in a 250 mL round-bottom flask to boiling on the hot plate under reflux. Then, 10 mL of a 38.8 mM sodium citrate solution was added quickly under vigorously stirring. The solution turns deep red in approximately 5 min after the addition of citrate. The solution was refluxed with stirring for an additional 15 min. The mixture was cooled down to room temperature and centrifuged at 10 000 rpm for 20 min at 20 °C in a Sorval SS-34 Rotor. A clear supernatant was carefully discarded, and the pellet was suspended in 4−5 mL of residual supernatant. The resulting nanoparticles were screened for their size and uniformity by TEM, revealing an average diameter of 15 ± 2 nm. The UV−vis spectra showed a characteristic absorption peak at 520 nm. Concentration of the particles was calculated using an extinction coefficient (ε) of 4.2×10^8 M^{-1} cm^{-1} at 520 nm.[14]

60 nm Gold Nanoparticles. Au-NPs with a diameter of 60 nm were also prepared by the reduction of $HAuCl_4$ with sodium citrate.[13] 50 mL of 0.01% $HAuCl_4$ solution were heated in a 250 mL round-bottom flack to boiling on a hot plate under reflux.

Then, 260 μL of 1% sodium citrate solution was added quickly under vigorously stirring. The solution turns purple in approximately 5 min after the addition of sodium citrate. The mixture was refluxed with stirring for additional 10 min and cooled down to room temperature. The particles were centrifuged at 4500 rpm for 5 min at 20 °C on a table Eppendorf centrifuge (model 5424). A clear supernatant was carefully discarded, and the pellet was suspended in 2 mL of residual supernatant. The resulting nanoparticles were screened for their size and uniformity by TEM, revealing an average diameter of 60 ± 5 nm. The UV−vis spectra showed a characteristic absorption peak at 536 nm. Concentration of the particles was calculated using an extinction coefficient (ε) of 5.3×10^{10} M^{-1} cm^{-1} at 536 nm.[15]

Gel Electrophoresis. The DNA-NP samples were loaded onto 1.5% agarose gel 7 × 7 cm^2 and electrophoresed at 4 °C at 130 V for 30 min. Tris-Acetate-EDTA (TAE) buffer, containing 40 mM Tris-Acetate and 1 mM EDTA, in addition to being used to prepare the agarose, also served as the running buffer.

TEM Measurement. A 5 μL aliquot of a sample solution in 20 mM TAE (pH 8.8) was dropped onto a carbon-coated copper grid (400 mesh). The grids (before depositing) were negatively glow-discharged using an Emitech K100X glow discharger. After incubation for 5 min at ambient temperature, the excess solution was removed by blotting with filter paper. TEM imaging was performed on a TEM JEM model 1200 EX instrument operated at an accelerating voltage of 120 kV.

Absorption Spectroscopy. Absorption spectra were recorded with a Jasco V-630 spectrophotometer (Japan).

RESULTS

Here, we used a four-stranded G-quadruplex DNA containing a central fragment flanked by phosphorothioated adenine residues on either side to coat Au-NPs. The parallel-stranded tetramolecular G-quadruplexes were prepared using oligonucleotides containing 5, 10, or 20 central G-base fragment flanked by two runs of 5 phosphorothioated adenines on either side as described in our recent publication.[12] Stable G-guadruplexes coated particles were obtained by gradually increasing NaCL concentration in a mixture of citrate-stabilized Au-NPs with 15-fold molar excess of the 10 tetrad quadruplexes as follows. The 15 nm particles (absorption is approximately equal to 30 at 520 nm) prepared as shown in the Experimental Procedures section were incubated at 42 °C with G-quadruplexes in the presence of 25 mM NaCL for 1 h. Then, the salt concentration in the incubation was increased to 100 mM, and then one hour later to 200 mM. The sample was incubated for another hour at 42 °C. No precipitate was formed during the incubation; the sample remained clear and red. In contrast, the incubation at DNA to particle ratios lying in the range from 2 to 5 leads to spontaneous aggregation of the particles and their precipitation out of the solution. These aggregates did not enter the gel (see Figure 1, lanes 1 and 2) in contrast to the particles obtained during the incubation at high (15 or higher) DNA to Au-NP ratios. The latter particles move as a relatively narrow single band in the gel (see Figure 1, lanes 3 and 4). We thus suggest that at high DNA concentrations (DNA to NP ratios) complete surface coverage is achieved before the particles collide and stick together (see schematic drawing in Scheme. 1). Due to steric reasons, the reactive phosphorothioate residues on the surface of a fully coated particle cannot bind to the metal core of another coated particle. No noticeable changes in the absorption spectrum were

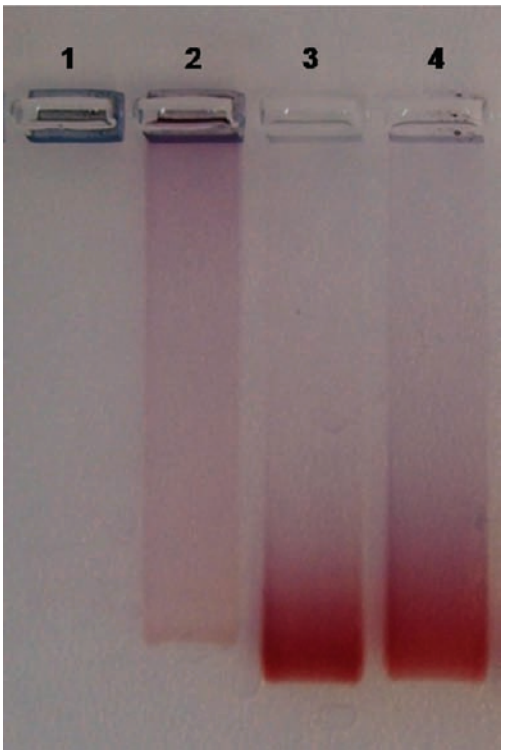

Figure 1. Electrophoresis of G-quadruplex-coated Au-NPs. 15 nm citrate-stabilized Au-NPs (absorption at 520 nm is equal to 30) were incubated with 2 μM (lane 1), 5 (lane 2), 15 (lane 3), and 20 μM (lane 4) 10 tetrad G-quadruplexes functionalized with phosphorothioated adenine residues at either side of the DNA molecule in the presence of 25 mM NaCL for 1 h at 42 °C. Then, the salt concentration was increased to 100 mM and one hour later to 200 mM. The samples were incubated for another hour at 42 °C and loaded onto a 1.5% agarose gel and electrophoresed at 130 V for 30 min at 4 °C.

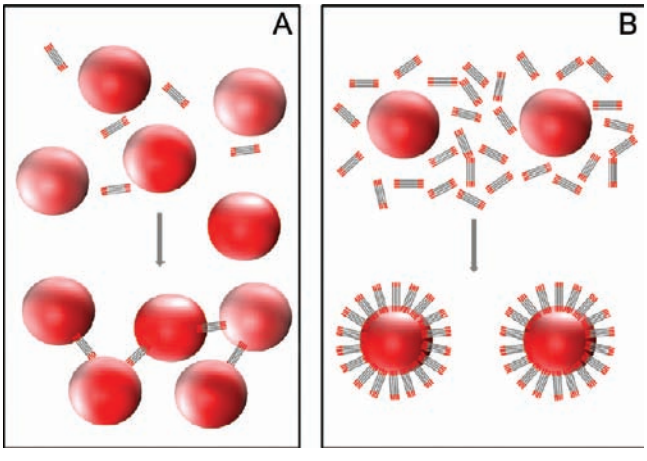
Scheme 1. Schematic Drawing of Au-NPs (Red Spheres) Interaction with G-Quadruplexes (Four Closely Spaced Black Parallel Lines) Functionalized with Phosphorothioate Residues (Short Red Fragments at Each Sides of Each Black Line)[a]



[a] (A) At near-stoichiometric concentrations, interaction of Au-NPs with the DNA molecules results in the formation of long nanoparticle chains. In the chain, the particles are connected by G-quadruplex molecules. (B) At high DNA concentrations (DNA to NP ratios), a complete surface coverage is achieved before the particles collide and stick together.

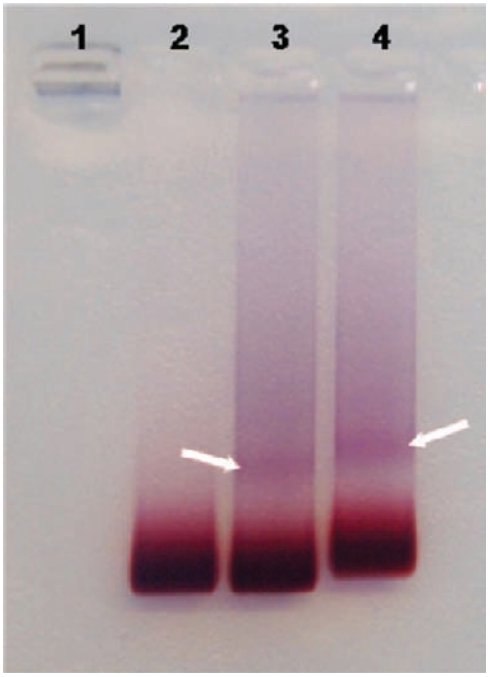


Figure 2. Electrophoretic purification of NP-flowers. Citrate-stabilized Au-NPs (lane 1) coated with 5 tetrad G-quadruplexes (lane 2) and products of 2 h incubation of citrate-stabilized Au-NPs with 30-fold excess of 5 (lane 3) and 10 tetrad (lane 4) coated Au-NPs in 50 mM Na-Pi buffer (pH = 7.4) at 42 °C. 20 μL aliquots of each sample were loaded onto a 1.5% agarose gel and electrophoresed at 130 V for 30 min at 4 °C.

observed during incubation of the particles for 14 h at 42 °C in the presence of 0.2 M NaCL. These particles can be chromatographed in contrast to citrate-stabilized ones, which precipitate in columns. High stability enabled us to use size-exclusion chromatography to purify the particles from nonbound DNA and from a minor fraction of multiparticle structures formed during the incubation. The size exclusion chromatography also enabled us to prepare particles with narrow size distribution. The particles were eluted from Sepharose CL-6B column (16 × 350 mm) in 10 mM Na-Pi (pH 7.4) in two peaks (data not presented). The first peak was eluted close to the void volume of the column and contained violet-colored multiparticle complexes. The second peak was eluted approximately 10 mL after the first one and contained individual red Au-NPs. The latter peak was collected and the particles were concentrated by centrifugation at 10 000 rpm for 20 min on a table centrifuge. The morphology of the particles was elucidated by TEM. As seen in Figure 3A, the particles are uniform and spherical with diameters of 15 ± 0.5 nm.

Despite their inability to interact with each other, the G-quadruplex-coated particles can efficiently bind to citrate-stabilized ones. Incubation of these two types of particles at near-equal concentrations yielded large multiparticle aggregates which do not enter the electrophoretic gel (data not shown). Incubation of 30-fold excess of the quadruplex-coated particles with citrate-stabilized ones, however, resulted in the formation of uniform structures that move as a narrow violet band through the gel (see Figure 2, lanes 3 and 4). The slice corresponding to the band was cut out of the gel with a razor blade. After electroelution into a dialysis bag, the sample was subjected to TEM analysis. As seen in the TEM image (see Figure 3B), the structures comprise a central particle and 5−6 ones in the periphery. They resemble

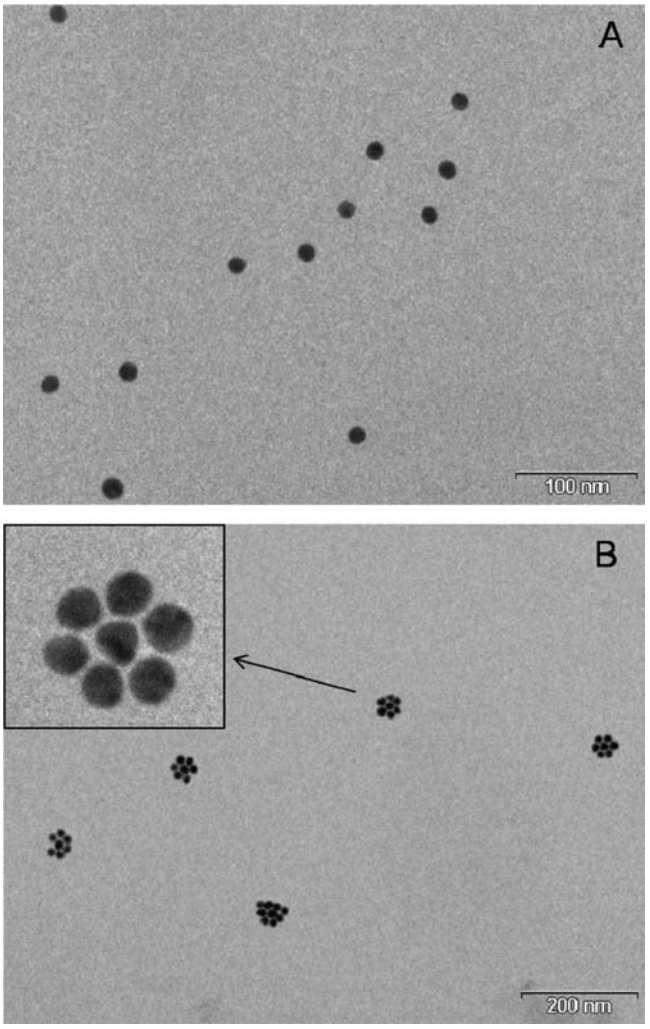

Figure 3. TEM images of (A) 15 nm G-quadruplex coated particles and (B) NP-flowers. The particles were prepared by incubation of 2 μM citrate-stabilized Au-NPs with 20 μM 10 tetrad G-quadruplexes functionalized with phosphorothioated adenine residues as shown in Figure 1. NP-flowers were prepared by incubation of citrate-stabilized Au-NPs with 30-fold excess of Au-NPs coated with 10 tetrad G-quadruplexes as shown in Figure 2. The slice corresponding to a violet band (see Figure 2, lane 4) was cut out of the gel with a razor blade, electroeluted into a dialysis bag, deposited on 400 mesh copper carbon grids, and visualized by TEM. The insert is an enlarged image of one of the flowers.

blue wildflowers, so we will refer to them as "NP-flowers" throughout the work. We have shown that the absorption spectrum of NP-flowers is red-shifted with respect to that of Au-NPs not connected to each other (compare blue and black curves in Figure 4). The red-shifted absorption is due to dipolar electromagnetic coupling between the plasmons of closely spaced nanoparticles in the flower. To investigate the dependence of the coupling strength on the distance between particles, we prepared Au-NPs coated with 5, 10, and 20 tetrad G-quadruplexes functionalized with phosphorothioated residues at both ends as described above (see Scheme 1). We have shown that the stability and the reactivity of Au-NPs are independent of the length of G-quadruplex molecules. To prepare NP-flowers, 15 nm citrate-stabilized Au-NPs were incubated with 30-fold excess of the 5, 10, or 20 tetrad quadruplex-coated 15 nm

Au-NPs. The products were separated by the electrophoresis. As clearly seen in Figure 2 (lanes 3−4), incubation of particles coated with 5 or 10 tetrad G-quadruplexes results in the appearance of a violet band corresponding to NP-flowers. We have shown by TEM (data not presented) that the average number of particles is independent of the length of DNA and is approximately equal to 6. The length of G-quadruplex molecules has, however, a noticeable effect on the shape of the absorption spectrum of the flowers. As seen in Figure 4, the spectrum of NP-flowers made of 20 tetrad G-quadruplexes is similar to that of Au-NPs not connected to each other (compare red and black curves). The spectrum of the 10 tetrad-based NP-flowers is, however, noticeably red-shifted compared to that of individual Au-NPs (compare green and black curves in Figure 4). The shift is even more pronounced for the 5 tetrad-based structures (blue curve in Figure 4). These results are in line with the dependence of plasmon coupling strength on the distance between metal particles (for review, see refs 16−18).

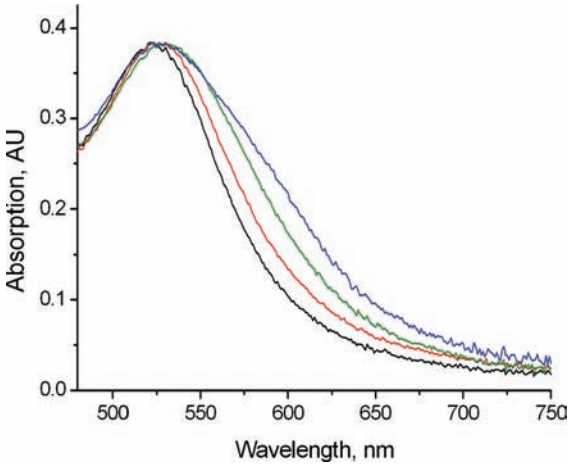

Figure 4. Absorption spectra of NP-flowers. 15 nm Au-NPs (black curve) and 20 (red curve), 10 (green curve), and 5 (blue curve) tetrad-based NP-flowers. The particles and the flowers were prepared as shown in Figures 1 and 2, respectively. The samples were electroeluted from the gel and measured.

We have also synthesized NP-flowers composed of a big (60 nm) central Au-NP particle and smaller (15 nm) peripheral ones. These flowers were prepared by incubation of a 30-fold molar excess of the 10 tetrad quadruplex-coated 15 nm Au-NPs with citrate-stabilized 60 nm ones using the experimental strategy described above. The reaction mixture was electrophoresed, the area of the gel corresponding to the blue band (see Figure 5A) was cut out of the gel, and the structures were electroeluted and analyzed by TEM. As can be clearly seen in the TEM image (see Figure 5B), the structures are composed of many peripheral particles surrounding a bigger central one. Some of peripheral particles are seen as dark spots on top of a central one. Image analysis of more than hundred individual structures revealed that the average number of particles in these NP-flowers is equal to 10 ± 5. As expected, the absorption plasmon band of the flowers is broader and red-shifted compared to that of the particles not connected to each other (compare red curve with blue and black ones in Figure 5C).

DISCUSSION

We have demonstrated that incubation of Au-NPs with a strong excess of G-quadruplexes, comprising phosphorothioate residues, yields stable nanoparticles. These particles do not aggregate even at relatively high (0.2 M) salt concentrations and can be purified and analyzed by electrophoresis and chromatography. Reactive phosphorothioate residues situated on the particle surface covalently bind to gold and silver atoms and can covalently attach the particles to metal electrodes, and other noncoated or weakly coated metal particles. This property can be used for covering metal surfaces and metal electrodes with densely packed particles. The particles can also be used to anchor long DNA molecules to metal surfaces. The method of nanoparticle coating described here is not limited to gold nanoparticles. We produce a similar coating protocol for coating silver particles as well as quantum nanodots.

These particles can be assembled into NP-flowers. We have shown that addition of a small amount (less than 10%) of citrate

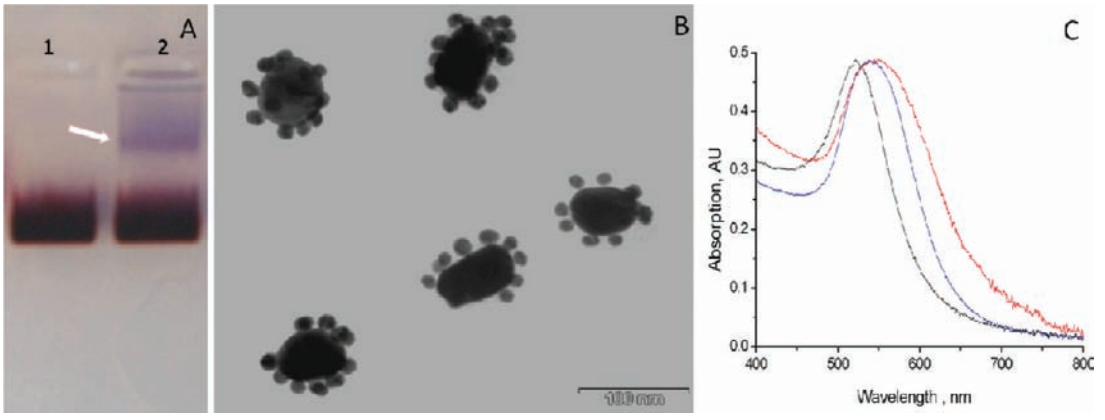

Figure 5. Preparation and properties of big NP-flowers: (A) Electrophoretic separation of NP-flowers from individual Au-NPs. 15 nm Au-NPs coated with 10 tetrad G-quadruplexes (lane 1) and products of 60 nm citrate-stabilized Au-NPs incubation with 30-fold excess of 15 nm Au-NPs coated with 10 tetrad G-quadruplexes (lane 2) in 50 mM Na-Pi buffer (pH = 7.4) for 2 h at 42 °C. 20 μL aliquots of each sample were loaded onto a 1.5% agarose gel and electrophoresed at 130 V for 30 min at 4 °C. (B) TEM image of the flowers. A slice corresponding to the violet band (A, lane 2) was cut out of the gel, and the structures were electroeluted, deposited on 400 mesh copper carbon grids, and visualized by TEM. (C) Absorption spectra of 15 nm Au-NPs coated with 10 tetrad G-quadruplexes (black curve), 60 nm citrate-stabilized Au-NPs (blue curve), and NP-flowers (red curve) electroeluted from the gel (see panel A, lane 2).

Au-NPs to G-quadruplex-coated particles results in the formation of NP-flowers. In the flower, the central citrate Au-NP is surrounded by several quadruplex-coated ones (see Figures 3B and 5B). The flowers composed of identical 15 nm particles are seen in the TEM image (see Figure 3) as planar 2D structures. We have analyzed hundreds of TEM images, but no structures containing additional particles on top of a central one have been found. In contrast, the "flowers" composed of 60 and 15 nm Au-NPs contain many smaller particles on top of a central bigger one (see Figure 5B). We can speculate that a planar arrangement is thermodynamically most favorable due to the repulsion of negatively charged peripheral particles in the NP-flower. We also cannot exclude the possibility that the preference of planar arrangement is governed by interaction of the NP-flower with the surface and that in aqueous solutions the flowers are shaped differently. Further theoretical and experimental studies are needed to address this issue.

We have demonstrated that the absorption spectrum of NP-flowers is red-shifted with respect to that of Au-NPs not connected to each other (see Figures 4 and 5C). The red shift is due to a strong dipolar electromagnetic coupling between the plasmons of closely spaced nanoparticles in the NP-flower. It is well-known that the coupling strength and extent of the coupling-induced red shift increases with decreasing interparticle distance within an individual structure.[19,20] Indeed, we have shown that the degree of the red shift strongly depends on the length of the G4-DNA linker connecting Au-NPs in the flower. G4-DNA structures are much more stable and rigid compared to canonical ds DNA. Even short G-quadruplexes composed of 5−10 tetrads are stable at room temperature in contrast to corresponding double-helical DNA molecules that dissociate into single strands. This enabled us to bring the particles very close together and to investigate plasmon coupling in NP-flowers.

The shift is very pronounced for NP-flowers composed of the particles coated with 5 tetrad G-quadruplexes, and is negligible for those composed of 20 tetrad G-quadruplex-coated ones (see Figure 4). This suggests that the strength of coupling in the flower drops with increasing interparticle separation distance from 1.6 (the length of the 5 tetrad G-quadruplex)[21] to 6.4 nm.

The shift in the plasmon absorption of the NP-flowers from 520 nm (absorption maximum of Au-NPs) to the direction of the biological window along with high stability of the structures make them potentially useful for laser photothermal diagnostics and therapy.

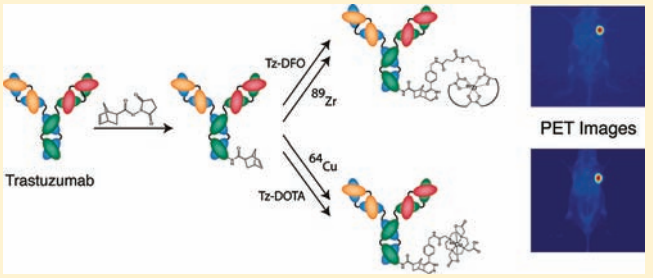
Supporting Information

ABSTRACT: A modular system for the construction of radiometalated antibodies was developed based on the bioorthogonal cycloaddition reaction between 3-(4-benzylamino)-1,2,4,5-tetrazine and the strained dienophile norbornene. The well-characterized, HER2-specific antibody trastuzumab and the positron emitting radioisotopes ^{64}Cu and ^{89}Zr were employed as a model system. The antibody was first covalently coupled to norbornene, and this stock of norbornene-modified antibody was then reacted with tetrazines bearing the chelators 1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetraacetic acid (DOTA) or desferrioxamine (DFO) and subsequently radiometalated with ^{64}Cu and ^{89}Zr, respectively. The modification strategy is simple and robust, and the resultant radiometalated constructs were obtained in high specific activity (2.7−5.3 mCi/mg). For a given initial stoichiometric ratio of norbornene to antibody, the ^{64}Cu-DOTA- and ^{89}Zr-DFO-based probes were shown to be nearly identical in terms of stability, the number of chelates per antibody, and immunoreactivity (>93% in all cases). *In vivo* PET imaging and acute biodistribution experiments revealed significant, specific uptake of the ^{64}Cu- and ^{89}Zr-trastuzumab bioconjugates in HER2-positive BT-474 xenografts, with little background uptake in HER2-negative MDA-MB-468 xenografts or other tissues. This modular system—one in which the divergent point is a single covalently modified antibody stock that can be reacted selectively with various chelators—will allow for both greater versatility and more facile cross-comparisons in the development of antibody-based radiopharmaceuticals.



INTRODUCTION

Over the past two decades, radiopharmaceuticals based on antibodies have assumed an increasingly prominent role in both diagnostic and therapeutic nuclear medicine. This trend is particularly evident in the field of positron emission tomography (PET), in which a wide variety of effective antibody-based radiotracers have been developed against an array of cancer biomarkers.[1−3] Indeed, while some promising imaging agents have been labeled with long-lived nonmetallic radionuclides such as ^{124}I, the majority of antibody-based PET bioconjugates have employed positron-emitting radiometals, including ^{64}Cu, ^{86}Y, and, most recently, ^{89}Zr.[4−8] In these systems, radiometals offer significant advantages over their nonmetallic cousins, most notably decay characteristics that result in high image quality, radioactive half-lives that complement the biological half-lives of the antibody vectors, and enhanced control and ease of radiolabeling through the use of chelating moieties.

Despite their benefits, however, these chelating moieties are the source of a somewhat confounding issue in the study of radiometalated antibodies. Put simply, different radiometals require different chelators. For example, the small, hard ^{89}Zr^{4+} cation shows very high affinity for the multiple oxygen donors of the chelator desferrioxamine (DFO), while the larger and softer ^{64}Cu^{2+} cation exhibits higher thermodynamic and kinetic stability when bound to chelators bearing nitrogen donors in addition to oxygens, for example, 1,4,7,10-tetraazacyclo-dodecane-1,4,7,10-tetraacetic acid (DOTA) and 1,4,8,11-tetraazabicyclo[6.6.2]hexadecane-4,11-diyl)diacetic acid (CB-TE2A).[6,9] Further, different chelators often require dramatically different synthetic strategies for antibody couplings.[10] In an isolated case of one antibody and one radiometal, these facts do not present a problem. However, they do create a significant obstacle to the versatility of radiometalated bioconjugates. To wit, given a particular monoclonal antibody, the development of a ^{64}Cu-CB-TE2A-mAb conjugate for PET, a ^{89}Zr-DFO-mAb conjugate for PET, and a ^{225}Ac-DOTA-mAb conjugate for therapy would require three different routes

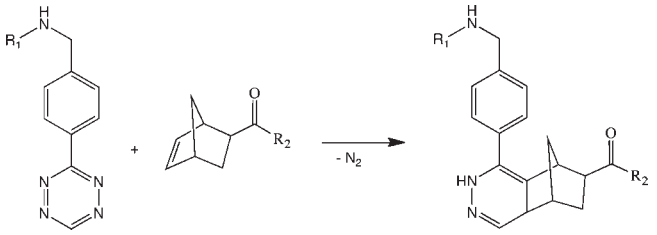

Figure 1. Tetrazine−norbornene ligation.

for antibody modification. Not only would this require additional time to develop and optimize each pathway, but the disparate routes would also mandate differing reaction conditions for each antibody, opening the door for differences in immunoreactivity and chelator/antibody ratio and ultimately making meaningful comparisons among the various radiopharmaceuticals more difficult. Consequently, a modular system—one in which the divergent point is a single covalently modified antibody stock that can be reacted selectively with various chelators—would resolve these issues and allow for more versatility and cross-comparisons in the development of antibody-based radiopharmaceuticals.

The chemical requirements of such a modular system—selectivity, biocompatibility, bioorthogonality—make it an almost perfect application for the use of click chemistry. Coined by K. Barry Sharpless, the term "click chemistry" broadly defines a group of chemical reactions by which two molecular components can be joined via a selective, rapid, clean, bioorthogonal, and biocompatible ligation.[11−13] By far, the most popular example of click chemistry is the Cu(I)-catalyzed [3 + 2] Huisgen cycloaddition between an azide and alkyne.[14] This reaction has already been widely employed in the development of radiotracers, particularly ^{18}F-based PET probes.[15−18] The application of this technology to radiometal-based probes has lagged behind, however, most likely due to concerns over metal contamination by the catalyst itself, though "clickable" chelators based on both the Cu(I)-catalyzed reaction and other Cu(I)-free systems have become more common in the literature in recent years.[19−22] Very recently, another promising "click" variant has come to light: the inverse electron demand Diels−Alder reaction between a tetrazine moiety and a strained alkene dienophile (Figure 1).[23−25] Like other click reactions, the ligation is selective, fast, biocompatible, and bioorthogonal, and unlike many Diels−Alder reactions, the coupling is irreversible, forming stable pyridazine products after the retro-Diels−Alder release of dinitrogen from the reaction intermediate. A number of different tetrazine-strained alkene pairs have been explored for the reaction, though the combination of 3-(4-benzylamino)-1,2,4,5-tetrazine (Tz) and either norbornene- or trans-cyclooctene-derivatives seems well-suited for biological applications. To date, the ligation has been employed in a variety of settings: the modification of oligonucleotides;[26] fluorescence imaging with small molecules, antibodies, and nanoparticles;[23,24,27,28] SPECT imaging with antibodies;[29] and ^{18}F-PET imaging with peptides.[30,31] However, to the best of the authors' knowledge, no application of this technology to positron-emitting radiometals has yet been made.

Herein, we report the development of a modular strategy for the construction of radiolabeled antibodies using the tetrazine-norbornene click reaction. The synthetic pathway involves three simple steps: (1) creation of a common stock of norbornene-modified antibody via peptide coupling; (2) ligation of a chelator-modified tetrazine moiety to the norbornene-modified antibody; and (3) radiolabeling of the resultant construct (Figure 2). For this proof of concept investigation, we have chosen the positron-emitting radiometals ^{64}Cu and ^{89}Zr, the chelators DOTA and DFO, and the antibody trastuzumab. ^{64}Cu and ^{89}Zr are the two most common radionuclides employed in antibody-based PET bioconjugates, and DOTA and DFO, respectively, are the most common chelators employed with these two metals.[6,9,10,32−34]

The antibody at hand, trastuzumab (Herceptin, Genentech), is an extremely well-characterized antibody specific to the human epidermal growth factor receptor 2 (HER2, also known as ERBB2). Overexpression of HER2 has been shown to be associated with augmented metastatic potential, increased tumor aggression, and poor prognosis for disease-free survival for patients with a variety of malignancies, most notably breast, ovarian, and colorectal cancer.[35−38] Trastuzumab alone has been employed as a therapeutic agent, and conjugates of both the antibody and its derivative fragments have been synthesized bearing a wide variety of radionuclides—including ^{64}Cu, ^{86}Y, ^{111}In, ^{124}I, ^{99m}Tc, and ^{89}Zr—for PET and SPECT imaging of HER2 expression.[39−47] It is our hope that this modular methodology will aid in both the expansion of the comparative study of antibodies labeled with different radionuclides and the development of novel antibody-based radiopharmaceuticals. Since more and more antibodies and dienophiles are being developed, this modular approach will likely lead to the rapid development of many novel imaging agents.[28] Importantly, while we have used positron-emitting radionuclides in this study due to our laboratory's area of expertise, this modular system need not be applied only to PET radiometals but rather can be used across the spectrum of metallic radionuclides, encompassing those employed for SPECT and radiotherapy as well.

EXPERIMENTAL PROCEDURES

Materials. All chemicals, unless otherwise noted, were acquired from Sigma-Aldrich (St. Louis, MO) and were used as received without further purification. All water employed was ultrapure (>18.2 MΩ cm^{-1} at 25 °C, Milli-Q, Millipore, Billerica, MA), and was passed through a 10 cm column of Chelex resin (Bio-Rad Laboratories, Hercules, CA) before use. DMSO was of molecular biology grade (>99.9%: Sigma, D8418), and all other solvents were of the highest grade commercially available. 1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetraacetic acid mono-*N*-hydroxysuccinimidylester (DOTA-NHS) was purchased from Macrocyclics Inc. (Dallas, TX). *N*-Succinyldesferrioxamine B was prepared according to published procedures.[48] All instruments were calibrated and maintained in accordance with standard quality-control procedures.[49] UV−vis measurements were taken on a Cary 100 Bio UV−vis spectrophotometer. NMR spectroscopy was performed on a Bruker 500 MHz NMR with *Topsin 2.1* software for spectrum analysis. HPLC was performed using a Shimadzu HPLC equipped with a C-18 reversed-phase column (Phenomenex Luna analytical 4.6 × 250 mm or Semi-Prep 21.2 × 100 mm, 5 μm, 1.0 or 6.0 mL/min), 2 LC-10AT pumps, a SPD-M10AVP photodiode array detector, and a gradient of 0:100 MeCN/H_2O (both with 0.1% TFA) to 100:0 MeCN/H_2O over 15 min].

^{64}Cu was purchased from Washington University, St. Louis, where it was produced on the Washington University School of Medicine Cyclotron (model CS-15, Cyclotron Corp.) by the ^{64}Ni(p,n)^{64}Cu reaction and purified as previously described to

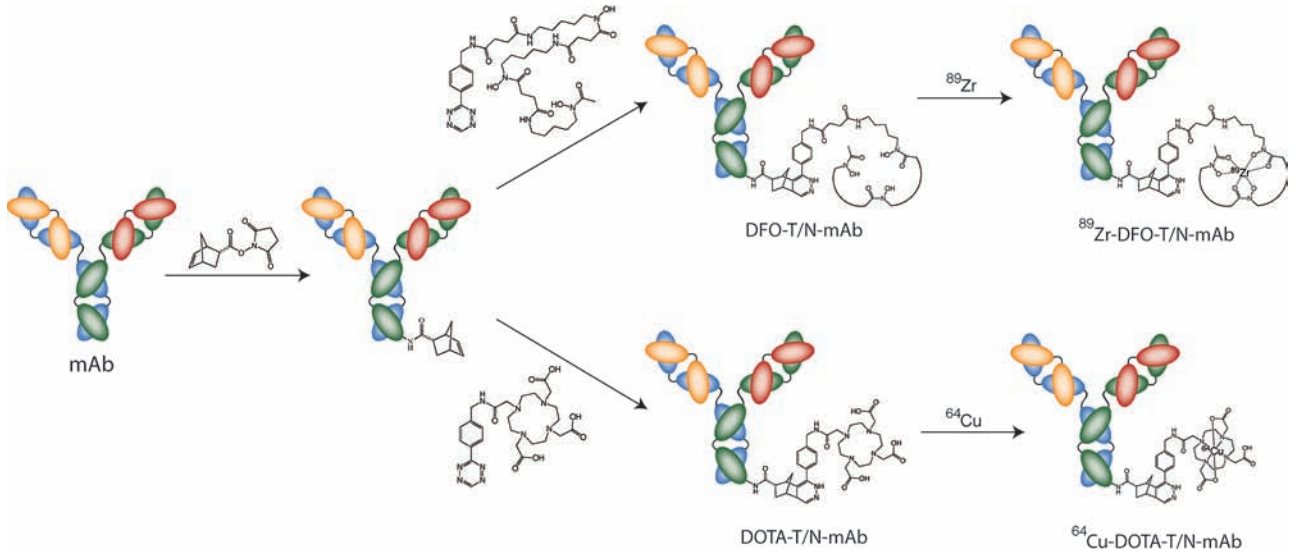

Figure 2. Schematic of a modular strategy for the construction of ^{89}Zr- and ^{64}Cu-modified antibody bioconjugates using the tetrazine-norbornene ligation.

yield [^{64}Cu]$CuCl_2$ with an effective specific activity of 200−400 mCi/μg (7.4−14.8 GBq/μg).[50] ^{89}Zr was produced at Memorial Sloan-Kettering Cancer Center on an EBCO TR19/9 variable-beam energy cyclotron (Ebco Industries Inc., British Columbia, Canada) via the ^{89}Y(p,n)^{89}Zr reaction and purified in accordance with previously reported methods to yield ^{89}Zr with a specific activity of 5.28−13.43 mCi/μg (195−497 MBq/μg).[51] All buffers used for ^{64}Cu and ^{89}Zr labeling were passed through Chelex resin before use. Activity measurements were made using a Capintec CRC-15R Dose Calibrator (Capintec, Ramsey, NJ). For accurate quantification of activities, experimental samples were counted for 1 min on a calibrated Perkin-Elmer (Waltham, MA) Automatic Wizard^2 Gamma Counter. Both ^{64}Cu and ^{89}Zr labeling reactions were monitored using silica-gel impregnated glass-fiber instant thin layer chromatography paper (Pall Corp., East Hills, NY) and analyzed on a Bioscan AR-2000 radio-TLC plate reader using Winscan Radio-TLC software (Bioscan Inc., Washington, DC). Human breast cancer cell lines BT-474 and MDA-MB-468 were obtained from the American Type Culture Collection (ATCC, Manassas, VA) and were grown by serial passage.

Synthesis of 3-(4-Benzylamino)-1,2,4,5-tetrazine (Tz). The protocol from Deveraj et al. was employed for the synthesis with slight modifications.[24] 4-(Aminomethyl)-benzonitrile hydrochloride (0.84 g, 0.005 mol) formamidine acetate (2.08 g, 0.02 mol), and elemental sulfur (0.16 g, 0.005 mol) were added to a dry, 50 mL round-bottom flask. Anhydrous hydrazine (2 mL) was then added to the flask, and the resultant orange reaction mixture was stirred for 20 h. After the allotted time, 1% $HCl_{(aq)}$ (50 mL) was slowly added to the reaction mixture, and the resultant solution was stirred for 10 min and subsequently filtered through a medium glass frit. The remaining orange solution was cooled in an ice bath to 0 °C, and a solution of 1.7 g of $NaNO_2$ in 15 mL of water was then added dropwise to the reaction mixture. While still cooled in an ice bath, acetic acid (50 mL) was added slowly, and the reaction mixture immediately turned bright pink. After allowing this solution to warm to room temperature over the course of 3 h, the solvent was evaporated at 50 °C and 20 Torr on a rotary evaporator. The resultant red crude solids were dissolved in 250 mL of water with 0.1% TFA. The aqueous solution was adsorbed onto a C_{18} column (Waters C_{18} Sep-Pak, Waters Corp., Milford, MA), washed with copious amounts of water, and eluted with acetonitrile. This bright pink, organic solution was evaporated to dryness, and the red crude was purified by flash chromatography (CombiFlash automated chromatography system, Teledyne Isco Inc., Lincoln, NE) using a gradient of 100% $CHCl_3$ (0.01% TFA) from 0 to 4 min followed by 0:100 MeOH (0.01%TFA)/$CHCl_3$ (0.01% TFA) to 30:70 (0.01%TFA)/HCl_3 (0.01% TFA) over 16 min. After the removal of solvent, the pure product was obtained in 35% yield (0.33 g, 0.0018 mol). ^{1}H NMR (500 MHz, D_2O), δ, ppm: 10.46 (s, 1H), 8.54 (d, 2H), 7.77 (d, 1H), 4.41 (s, 2H). ESI-MS: 188.1 $[M+H]^+$. HPLC t_R = 7.1 min.

Synthesis of N^1-(5-(4-((4-(1,2,4,5-Tetrazin-3-yl)benzyl)amino)-4-oxobutanamido)pentyl)-N^1-hydroxy-N^4-(5-(*N*-hydroxy-4-((5-(*N*-hydroxyacetamido)pentyl)amino)-4-oxobutanamido)pentyl)succinamide (Tz-DFO). 3-(4-Benzylamino)-1,2,4,5-tetrazine (8 mg, 0.045 mmol) was dissolved in DMSO (3 mL), and diisopropylethylamine (16 μL, 0.09 mmol) was added to this solution. After 15 min of stirring at RT, the pink DMSO solution was added to a second, premixed solution of *N*-succinyldesferrioxamine B (60 mg, 0.09 mmol) and benzotriazole-1-yl-oxy-tris-(dimethylamino)-phosphonium hexafluorophosphate (BOP, 53 mg, 0.12 mmol) in DMSO (3 mL). The combined reaction was stirred overnight and subsequently purified via C_{18} cartridge (Waters C_{18} Sep-Pak, Waters Corp., Milford, MA) and semipreparative reverse-phase HPLC. The purified product was obtained in 50% yield (molecular weight = 852.9, 19 mg, 0.023 mmol). ^{1}H NMR (500 MHz, DMSO-d_6), δ, ppm: 10.59 (s, 1H), 9.64 (s, 1H), 9.59 (s, 1H), 8.49 (m, 1H), 8.44 (d, 2H), 7.9−7.7 (m, 3H), 7.51 (d, 2H), 4.44 (d, 2H), 3.5−3.5 (m, 6H), 3.05−2.95 (m, 6H), 2.55 (t, 4H), 2.45−2.35 (m, 4H), 2.25 (t, 4H), 1.97 (s, 3H), 1.52−1.48 (m, 6H), 1.40−1.36 (m, 6H), 1.23−1.20 (m, 6H). ESI-MS: 831.5 $[M+H]^+$, 853.6 $[M+Na]^+$. HPLC t_R = 10.2 min.

Synthesis of 2,2′,2″-(10-(2-((4-(1,2,4,5-Tetrazin-3-yl)benzyl)amino)-2-oxoethyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic acid (Tz-DOTA). 3-(4-Benzylamino)-1,2,4,5-tetrazine (20 mg, 0.12 mmol) was dissolved in PBS (5 mL, pH 8.5), and diisopropylethylamine (40 μL, 0.24 mmol) was added

to this solution. This solution was then added to solid DOTA-NHS (50 mg, 0.065 mmol), and the resultant solution was stirred overnight at room temperature. The reaction was subsequently purified via C_{18} cartridge (Waters C_{18} Sep-Pak, Waters Corp., Milford, MA) and semipreparative reverse-phase HPLC. The purified product was obtained in 62% yield (molecular weight = 573.6, 23 mg, 0.04 mmol). ^{1}H NMR (500 MHz, DMSO-d_6), δ, ppm: 10.61 (s, 1H), 9.11 (br s, 1H), 8.50 (d, 2H), 7.62 (d, 2H), 4.50 (s, 2H), 4.42−4.38 (m, 4H), 3.65 (br s, 4H), 10.61 (s, 1H), 3.65−3.55 (m, 8H), 3.18−3.14 (m, 8H). ESI-MS: 574.5 $[M+H]^+$, 596.1 $[M+Na]^+$, 612.2 $[M+K]^+$. HPLC t_R = 8.1 min.

Antibody Modification. A protocol similar to that published by Devaraj et al. was employed for antibody modification.[24] 5-Norbornene-2-carboxylic acid (40 mg, 0.29 mmol) was incubated with 1.3 equiv of disuccinimidyl carbonate (100 mg, 0.39 mmol) and 1 equiv of pyridine (23 mg, 0.29 mmol) in dry acetonitrile (3 mL) for 2 h at room temperature. After 2 h, the solvent was removed via rotary evaporation, and the crude norbornene-succinimidyl ester product was recovered. Trastuzumab (purchased commercially as Herceptin, Genentech, San Francisco, CA) was purified using centrifugal filter units with a 30 000 molecular weight cutoff (Amicon Ultra 4 Centrifugal Filtration Units, Millipore Corp., Billerica, MA) and phosphate buffered saline (PBS, pH 7.4) to remove $\alpha-\alpha$-trehalose dihydrate, L-histidine, and polysorbate 20 additives. After purification, the antibody was taken up in PBS pH 8.0. Subsequently, 300 μL of antibody solution (150−250 μM) were combined with 100 μL PBS pH 8.0 and 1.5, 3, or 5 equiv of the crude norbornene-NHS ester in 10 μL of either DMF or DMSO. The reaction was incubated at room temperature for 2 h, followed by centrifugal filtration to purify the resultant antibody conjugate.

To perform the chelator ligation, 100 μL antibody solution (75−150 μM, PBS pH 7.4) was combined with 200 μL buffer (PBS pH 7.4) and a 10-fold molar excess of either Tz-DOTA or Tz-DFO in 10 μL DMSO (molar excess calculated based on initial norbornene reaction stoichiometry). The reaction was incubated at RT for 5 h and subsequently purified using centrifugal filtration to yield the completed DOTA- and DFO-modified antibodies. The final bioconjugates were stored in PBS pH 7.4 at 4 °C.

Labeling of DOTA-T/N-trastuzumab with ^{64}Cu. DOTA-T/N-trastuzumab (0.2−0.3 mg) was added to 200 μL labeling buffer (50 mM NH_4OAc, pH 5.5, though 50 mM NaOAc, pH 5.5 also is sufficient). $[^{64}Cu]CuCl_2$ (29.6−37 MBq, 800−1000 μCi) in approximately 1−3 μL 0.1 M HCl were then added to the antibody solution, and the resultant solution was incubated at room temperature for 1 h. After 1 h, the reaction progress was assayed using ITLC with an eluent of 50 mM EDTA, pH 5. The resultant ^{64}Cu-DOTA-T/N-trastuzumab was purified using either size-exclusion chromatography (Sephadex G-25 M, PD-10 column, 30 kDa, GE Healthcare; dead volume = 2.5 mL, eluted with 200 mL fractions of PBS, pH 7.4) or centrifugal column filtration. The radiochemical purity of the final radiolabeled bioconjugate was assayed by radio-TLC and was found to be >99% in all preparations. In the ITLC experiments, ^{64}Cu-DOTA-T/N-trastuzumab remains at the baseline, while $^{64}Cu^{2+}$ ions and $[^{64}Cu]$Cu-EDTA elute with the solvent front.

Labeling of DFO-T/N-trastuzumab with ^{89}Zr. DFO-T/N-trastuzumab (0.2−0.3 mg) was added to 200 μL buffer (PBS, pH 7.5). $[^{89}Zr]$Zr-oxalate (29.6−37 MBq, 800−1000 μCi) in 1.0 M oxalic acid was adjusted to pH 7.2−8.5 with 1.0 M Na_2CO_3. After evolution of CO_2(g) stops, the ^{89}Zr solution was added to the antibody solution, and the resultant mixture was incubated at room temperature for 1 h. After 1 h, the reaction progress was assayed using ITLC with an eluent of 50 mM EDTA, pH 5. The resultant ^{89}Zr-DFO-T/N-trastuzumab was purified using either size-exclusion chromatography (Sephadex G-25 M, PD-10 column, 30 kDa, GE Healthcare; dead volume = 2.5 mL, eluted with 200 mL fractions of PBS, pH 7.4) or centrifugal column filtration. The radiochemical purity of the final radiolabeled bioconjugate was assayed by radio-TLC and was found to be >99% in all preparations. In the ITLC experiments, ^{89}Zr-DFO-T/N-trastuzumab remains at the baseline, while $^{89}Zr^{4+}$ ions and $[^{89}Zr]$-EDTA elute with the solvent front.

Chelate Number. The number of accessible DFO and DOTA chelates conjugated to the antibodies was measured by radiometric isotopic dilution assays following methods similar to those described by Anderson et al. and Holland et al.[34,42,52,53] All experiments were performed in triplicate.

Immunoreactivity. The immunoreactivity of the ^{64}Cu-DOTA- and ^{89}Zr-DFO-T/N-trastuzumab bioconjugates was determined using specific radioactive cellular-binding assays following procedures derived from Lindmo et al.[54,55] To this end, BT-474 cells were suspended in microcentrifuge tubes at concentrations of 5.0, 4.0, 3.0, 2.5, 2.0, 1.5, and 1.0 × 10^6 cells/mL in 500 μL PBS (pH 7.4). Aliquots of either ^{64}Cu-DOTA- or ^{89}Zr-DFO-T/N-trastuzumab (50 μL of a stock solution of 10 μCi in 10 mL of 1% bovine serum albumin in PBS pH 7.4) were added to each tube (n = 4; final volume: 550 μL), and the samples were incubated on a mixer for 60 min at room temperature. The treated cells were then pelleted via centrifugation (3000 rpm for 5 min), resuspended, and washed twice with cold PBS before removing the supernatant and counting the activity associated with the cell pellet. The activity data were background-corrected and compared with the total number of counts in appropriate control samples. Immunoreactive fractions were determined by linear regression analysis of a plot of (total/bound) activity against (1/[normalized cell concentration]). No weighting was applied to the data, and data were obtained in triplicate.

Stability Measurements. The stability of the ^{64}Cu-DOTA- and ^{89}Zr-DFO-T/N-trastuzumab bioconjugates with respect to radiochemical purity and loss of radioactivity from the antibody was investigated *in vitro* by incubation of the antibodies in human serum for 48 h (^{64}Cu) or 7 d (^{89}Zr) at room temperature and 37 °C. The radiochemical purity of the antibodies was determined via radio-TLC with an eluent of 50 mM EDTA pH 5.0 (*vide supra*).

Cell Culture. Human breast cancer cell lines BT474 and MDA-MB-468 were obtained from the American Tissue Culture Collection (HTB-20 and HTB-132, respectively, ATCC, Bethesda, MD) and maintained in a 1:1 mixture of Dulbecco's Modified Eagle medium: F-12 medium, supplemented with 10% heat-inactivated fetal calf serum (Omega Scientific, Tarzana, Ca), 2.0 mM glutamine, nonessential amino acids, and 100 units/mL penicillin, and 100 units/mL streptomycin in a 37 °C environment containing 5% CO_2. Cell lines were harvested and passaged weekly using a formulation of 0.25% trypsin/0.53 mM EDTA in Hank's Buffered Salt Solution without calcium and magnesium.

Xenograft Models. All experiments were performed under an Institutional Animal Care and Use Committee-approved protocol, and the experiments followed institutional guidelines for the proper and humane use of animals in research. Six- to eight-week-old Athymic nu/nu female mice (NCRNU-M) were obtained from Taconic Farms Incorporated (Hudson, NY). Animals were

housed in ventilated cages, were given food and water *ad libitum*, and were allowed to acclimatize for approximately 1 week prior to treatment. Prior to tumor inoculation, mice were subcutaneously implanted with 0.72 mg 60 day release 17β-estradiol pellets (SE-121, Innovative Research of America, Sarasota, Florida) using a 10 gauge trocar. After several days, BT474 tumors were induced on the right shoulder by a subcutaneous injection of 3.0×10^6 cells in a 100 μL cell suspension of a 1:1 mixture of fresh media/BD Matrigel (BD Biosciences, Bedford, Ma). MDA-MB-468 tumors were induced on the left shoulder by a subcutaneous injection of 2.0×10^6 cells in the same manner (the number of cells injected was varied as described to compensate for cell growth rates and thus provide approximately the same tumor size at the time of radiopharmaceutical injection).

Acute Biodistribution. Acute *in vivo* biodistribution studies were performed in order to evaluate the uptake of the ^{64}Cu-DOTA- and ^{89}Zr-DFO-conjugated antibodies in mice bearing bilateral, subcutaneous BT-474 and MDA-MB-468 tumors (100−150 mm^3, 4 weeks postinoculation). Mice were randomized before the study and were warmed gently with a heat lamp for 5 min before administration of ^{64}Cu-DOTA-T/N-trastuzumab (0.74−1.11 MBq [20−30 μCi] in 200 μL 0.9% sterile saline) or ^{89}Zr-DFO-T/N-trastuzumab (0.56−0.74 MBq [15−20 μCi] in 200 μL 0.9% sterile saline) via intravenous tail vein injection (t = 0). Animals (n = 4 per group) were euthanized by CO_2(g) asphyxiation at 6, 12, 24, 36, 48, and 72 h (^{64}Cu) or 6, 24, 48, 72, 96, and 120 h (^{89}Zr). After asphyxiation, 13 organs (including both tumors) were removed, rinsed in water, dried in air for 5 min, weighed, and counted in a gamma counter calibrated for either ^{64}Cu or ^{89}Zr. Counts were converted into activity using a calibration curve generated from known standards. Count data were background- and decay-corrected to the time of injection, and the percent injected dose per gram (%ID/g) for each tissue sample was calculated by normalization to the total activity injected.

Small-Animal PET Imaging. PET imaging experiments were conducted on either a microPET Focus 120 (^{89}Zr) or a microPET R4 (^{64}Cu) rodent scanner (Concorde Microsystems).[56] Mice bearing bilateral, subcutaneous BT-474 (right shoulder) and MDA-MB-468 (left shoulder) tumors (100−150 mm^3, 4 weeks postinoculation) were administered ^{64}Cu-DOTA-T/N-trastuzumab (11.1−12.9 MBq [300−345 μCi] in 200 μL 0.9% sterile saline) or ^{89}Zr-DFO-T/N-trastuzumab (10.7−11.8 MBq [290−320 μCi] in 200 μL 0.9% sterile saline) via intravenous tail vein injection (t = 0). Approximately 5 min prior to the acquisition of PET images, mice were anesthetized by inhalation of 2% isoflurane (Baxter Healthcare, Deerfield, IL)/oxygen gas mixture and placed on the scanner bed; anesthesia was maintained using 1% isoflurane/gas mixture. PET data for each mouse were recorded via static scans at various time points between 6 and 120 h. A minimum of 20 million coincident events were recorded for each scan, which lasted between 10 and 45 min. An energy window of 350−700 keV and a coincidence timing window of 6 ns were used. Data were sorted into 2D histograms by Fourier rebinning, and transverse images were reconstructed by filtered back-projection (FBP) into a 128 × 128 × 63 (0.72 × 0.72 × 1.3 mm^3) matrix. The image data were normalized to correct for nonuniformity of response of the PET, dead-time count losses, positron branching ratio, and physical decay to the time of injection, but no attenuation, scatter, or partial-volume averaging correction was applied. The counting rates in the reconstructed images were converted to activity concentrations (percentage injected dose [%ID] per gram of tissue) by use of a system calibration factor derived from the imaging of a mouse-sized water-equivalent phantom containing ^{64}Cu or ^{89}Zr. Images were analyzed using *ASIPro VM* software (Concorde Microsystems).

Labeling Norbornene-Trastuzumab with [^{64}Cu]-Tz-DOTA. Tz-DOTA (5 μL of 1 mM solution in DMSO) was added to labeling buffer (50 mM NH_4OAc, pH 5.5), and [^{64}Cu]$CuCl_2$ (40.7−55.5 MBq [1100−1500 μCi]) in 0.1 M HCl were added to the reaction mixture. The resultant solution was incubated for 1 h at 85 °C, followed by purification via C_{18} cartridge (Waters C_{18} Sep-Pak, Waters Corp., Milford, MA) and radiochemical purity analysis via analytical HPLC (t_R = 10 min). The purified, radiolabeled [^{64}Cu]-Tz-DOTA was then added to a solution of norbornene-modified trastuzumab (0.4 mg, initial reaction stoichiometry of 5:1 norbornene/mAb) in PBS pH 7.4. The reaction mixture was allowed to incubate at 37 °C for 3 h. After 3 h, the progress of the reaction was assayed with radio-TLC using an eluent of 50 mm EDTA pH 5.0, and the radiolabeled antibody was purified with centrifugal filtration using centrifugal filter units with a 30 000 molecular weight cutoff (Amicon Ultra 4 Centrifugal Filtration Units, Millipore Corp., Billerica, MA) and phosphate buffered saline (PBS, pH 7.4). The radiochemical purity of the final radiolabeled bioconjugate was assayed again by radio-TLC and was found to be >99% in all preparations. In the radio-TLC experiments, ^{64}Cu-DOTA-T/N-trastuzumab remains at the baseline, while $^{64}Cu^{2+}$ ions, [^{64}Cu]Cu-Tz-DOTA, and [^{64}Cu]Cu-EDTA elute with the solvent front.

Statistical Analysis. Data were analyzed by the unpaired, two-tailed Student's t test. Differences at the 95% confidence level ($P < 0.05$) were considered to be statistically significant.

RESULTS AND DISCUSSION

Chemical Synthesis. 3-(4-Benzylamino)-1,2,4,5-tetrazine (Tz) was successfully synthesized through the reaction of 4-(aminomethyl)-benzonitrile hydrochloride, formamidine acetate, and elemental sulfur to form a dihydrotetrazine intermediate ((4-(1,2-dihydro-1,2,4,5-tetrazin-3-yl)phenyl)methanamine), followed by oxidation with $NaNO_2$ to form the aromatic tetrazine product. A method similar to that published by Devaraj et al. was employed; however, a number of small changes—for example, the use of 1% $HCl_{(aq)}$ rather than acetic acid in an intermediate step—were made and were found to considerably raise yields from the reported 20% to 35−40%. The product was characterized via UV−vis, ^{1}H NMR, ^{13}C NMR, and ESI-MS, and all data match that described in the original synthetic report.[24] Given the particularly promising nature of this cycloaddition reaction, the optimization of this synthesis was an important task. Tz was chosen as the particular tetrazine-based moiety for this line of experimentation due to its convenient, primary-amine coupling handle and its balance of reactivity and stability. To be sure, other tetrazine-based molecules with possible conjugation sites exist, but water instability (dimethyl 1,2,4,5-tetrazine-3,6-dicarboxylate), poor reactivity (1,2,4,5-tetrazine-3,6-diamine or 3,6-bis-(4-aminophenyl)-1,2,4,5-tetrazine), or instability (6-(6-(pyridin-2-yl)-1,2-dihydro-1,2,4,5-tetrazin-3-yl)pyridin-3-amine) render them unsuitable to the development of a modular system such as this.[29,57−59] Tz-DOTA and Tz-DFO (Scheme 1) were synthesized from Tz via simple peptide coupling reactions using the commercially available mono-NHS-ester of DOTA or *N*-succinyldesferrioxamine B and benzotriazole-1-yl-oxy-tris-(dimethylamino)-phosphonium hexafluorophosphate (BOP), respectively.

Scheme 1. Synthetic Route to Tz-DOTA and Tz-DFO

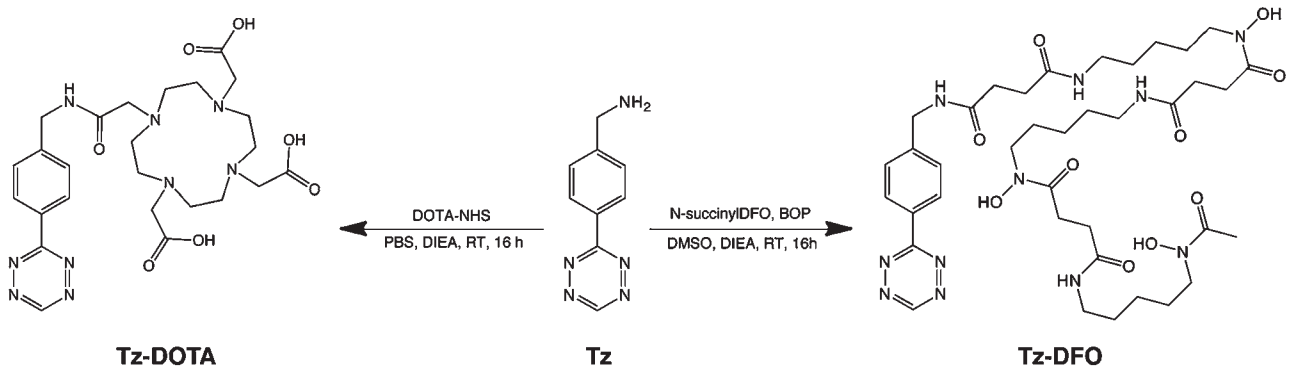

Table 1. Chemical and Biological Characterization Data for ^{64}Cu-DOTA-T/N- and ^{89}Zr-DFO-T/N-trastuzumab Bioconjugates

radionuclide	chelator	initial Nor/mAb reaction stoichiometry	chelates/mAb[a]	specific activity (mCi/mg)	immunoreactive fraction[b]	stability[c]
^{64}Cu	DOTA	1.5	1.0 ± 0.2	3.2 ± 0.4	0.96 ± 0.05	>98%

[a] $n = 3$ for all experiments presented. [b] Determined prior to *in vivo* experimentation. [c] Calculated for incubation in human serum at 37 °C for 48 h (Cu) or 7 d (Zr).

Upon synthesis, both molecules were purified via reversed-phase HPLC and fully characterized by UV−vis, ^{1}H NMR, ^{13}C NMR, and ESI-MS. Importantly, Tz-DOTA exhibits high water solubility, but Tz-DFO does not. Consequently, DMSO was used as the stock solvent and delivery vehicle for both Tz-DOTA and Tz-DFO throughout the investigation in order to ensure that the antibodies in different branches of the modular pathway were exposed to exactly the same reaction conditions. Indeed, given the ease of synthesis of both Tz-DOTA and Tz-DFO, it is easy to envision the creation of a complete library of tetrazine-modified chelators—ranging from Tz-AmBaSar to Tz-HBED to Tz-DTPA—in order to maximize the utility and versatility of this modular construction strategy.

Antibody Modification, Radiolabeling, and Characterization. The radiolabeled trastuzumab bioconjugates were constructed via a modular three-step procedure (Figure 2). A common stock of norbornene-modified mAb was first produced via the room-temperature aqueous coupling of an NHS-ester of 5-norbornene-2-carboxylic acid with the exposed lysines of trastuzumab. After purification, the resultant norbornene-modified antibodies were then incubated for 5 h at room temperature with a 10-fold excess (based on norbornene loading) of the appropriate tetrazine-modified chelator—Tz-DOTA for ^{64}Cu or Tz-DFO for ^{89}Zr—and purified via centrifugal filtration or size exclusion chromatography. The bioconjugates were radiometalated with ^{64}Cu or ^{89}Zr at room temperature under either acidic (pH 5.5) or basic (pH 7.2−8.5) conditions, respectively. The crude radiochemical yields varied according to the initial norbornene loading of the antibody; however, after purification via centrifugal filtration, the ^{64}Cu-DOTA- or ^{89}Zr-DFO-T/N-trastuzumab conjugates were isolated with RCP >99% ($n = 3$ for each construct). The modification and radiolabeling strategy is simple, robust, and relatively rapid, and no antibody aggregation or precipitation issues were observed. Unlike other methods for the modification of mAbs with DOTA or DFO, overnight incubations, wide swings in buffer pH, and temperatures over room temperature are not required.[60−64] Importantly, we also observed that the tetrazine-norbornene ligation and subsequent radiolabeling proceeded almost identically whether performed the day of norbornene modification of the antibody or four weeks later (and likely after much longer periods of time, provided the antibody is stored at 4 °C). The radiolabeling of the DOTA- and DFO-modified trastuzumab conjugates is likewise robust, with the reaction providing similar yields with freshly prepared or four-week-old mAbs.

A number of chemical and *in vitro* tests were performed in order to characterize the chelator-modified and radiolabeled antibody constructs. Three different initial reaction stoichiometries of norbornene:mAb—1.5:1, 3:1, and 5:1—were employed to investigate the effect of different chelator loadings on the performance of the antibody. After the ligation of the variably norbornene-loaded antibodies with either Tz-DOTA or Tz-DFO, radiometric isotopic dilution experiments were performed in order to determine the number of accessible chelates on each antibody. The results, shown in Table 1, clearly illustrate that increasing initial loadings of norbonene result in higher numbers of chelates per antibody. Given the quantitative nature of the tetrazine/norbornene ligation and the proximity of the number of chelates per antibody to the initial modification stoichiometry in each case, calculating the loading of norbornenes per antibody was deemed unnecessary. The combined yield of the modification and ligation reactions is relatively consistent across all three

stoichiometries (~40−60%), and the results are generally consistent with antibody ligations using tetrazine/dienophile pairs reported by Devaraj et al., Haun et al., and Rossin et al.[23,28,29] Just as importantly, the number of chelates per antibody is, within error, identical for both the DOTA-T/N-trastuzumab and DFO-T/N-trastuzumab conjugates, a critical facet for such a modular system. Not surprisingly, the varying chelate numbers also played a role in the specific activities obtained for each antibody. All of the antibody conjugates were labeled in high specific activity (>2.0 mCi/mg). Interestingly, the specific activities of both the ^{64}Cu-DOTA-T/N-trastuzumab and ^{89}Zr-DFO-T/N-trastuzumab conjugates only roughly correlate with the number of chelates per antibody: those for ^{64}Cu-DOTA-T/N-trastuzumab range from 3.2 ± 0.4 mCi/mg to 5.3 ± 0.5 mCi/mg, though the specific activities for bioconjugates with initial nor/mAb ratios of 1.5:1 and 3:1 are within error of each other. Similarly, the specific activities of the ^{89}Zr-DFO-T/N-trastuzumab conjugates range from 2.7 ± 0.2 mCi/mg to 4.3 ± 0.4 mCi/mg, but again, the specific activities of the two conjugates with fewer DFO/mAb are statistically identical. Given the different specific activities of the original radiometals, comparisons between the specific activities of the two types of construct have little merit; however, the specific activities obtained in this investigation are consistent with those reported for other ^{64}Cu-DOTA-based and ^{89}Zr-DFO-based antibody bioconjugates in the literature.[6,10,34,42,45]

The immunoreactive fractions of the ^{64}Cu-DOTA- and ^{89}Zr-DFO-conjugates were determined via specific *in vitro* cellular association assays using the HER2/*neu* positive BT-474 breast cancer cell line.[54] Regardless of the number of chelates per antibody, all six conjugates exhibited immunoreactive fractions greater than 0.93 (n = 3 for each radiolabeled antibody). Blocking experiments performed with the addition of a vast excess (>500-fold) of unlabeled trastuzumab showed virtually no radioactive antibody binding and thus demonstrated the specificity of the ^{64}Cu-DOTA- and ^{89}Zr-DFO-T/N-trastuzumab. To assay the stability of radiolabeled bioconjugates, the ^{64}Cu-DOTA- and ^{89}Zr-DFO-T/N-trastuzumab formulations were incubated in human serum for 48 h and 7 d, respectively. Radio-TLC with an eluent of 50 mM EDTA (pH 5.0) illustrated that both sets of conjugates were >96% stable after the incubation period in all cases (Table 1).

Acute Biodistribution Studies. Acute biodistribution experiments and small animal PET imaging were performed in order to assay the *in vivo* efficacy of the ^{64}Cu and ^{89}Zr-bioconjugates. For all *in vivo* investigations, the trastuzumab bioconjugates with an initial nor/mAb stoichiometry of 5:1 were chosen, though similar results would be expected for all three ratios given the uniformly high immunoreactivity, stability, and specific activity observed in all of the constructs. In the biodistrubution experiment, nude mice bearing bilateral BT-474 (HER2-positive) and MDA-MB-468 (HER2-negative) were injected via tail vein with either ^{64}Cu-DOTA-T/N-trastuzumab (0.74−1.11 MBq [20−30 μCi] in 200 μL 0.9% sterile saline, specific activity: 5.1 mCi/mg) or ^{89}Zr-DFO-T/N-trastuzumab (0.56−0.74 MBq [15−20 μCi] in 200 μL 0.9% sterile saline, specific activity: 4.7 mCi/mg). Animals (n = 4 for each time point) were euthanized by CO_2(g) asphyxiation at 6, 12, 24, 36, 48, and 72 h (^{64}Cu) or 6, 24, 48, 72, 96, and 120 h (^{89}Zr). The organs (including tumors) of each animal were harvested and weighed, the amount of activity in each was counted on a gamma counter, and the %ID/g for each organ was calculated.

kidney	5.5 ± 0.9	4.9 ± 1.0	2.9 ± 1.6	4.0 ± 0.4	4.5 ± 0.4
muscle	0.6 ± 0.2	0.7 ± 0.4	0.6 ± 0.3	1.0 ± 0.2	0.8 ± 0.1
bone	3.1 ± 2.7	1.4 ± 0.1	3.6 ± 0.4	1.1 ± 0.2	2.6 ± 1.1

In the ^{64}Cu-DOTA-T/N-trastuzumab biodistribution experiment (Table 2), high specific uptake is observed in the HER2-positive BT-474 tumor, with the %ID/g increasing from 10.4 ± 4.6 at 6 h to 55.1 ± 2.3 at 72 h (tumor/muscle ratios of 17.3 ± 7.1 and 68.8 ± 8.0, respectively). By comparison, far lower levels of ^{64}Cu-DOTA-T/N-trastuzumab uptake were seen in the HER2-negative MDA-MB-468 tumors. As expected, over the course of the experiment a concomitant decrease in the %ID/g in the blood (from 19.2 ± 5.2 at 6 h to 11.8 ± 1.3 at 72 h) also occurred. The organs with the highest background uptake were the lungs, liver, and spleen, though the uptake in these organs was at its highest point at 6 h, and by 72 h, the tumor/organ ratios for each of these organs were 5.8 ± 0.3, 6.8 ± 0.8, and 8.0 ± 1.6, respectively (see Supporting Information for complete table of tumor/organ ratios). Low levels of uptake were observed in the heart, stomach, small intestine, large intestine, kidney, muscle, and bone. Taken together, these results plainly indicate that ^{64}Cu-DOTA-T/N-trastuzumab is an effective imaging agent for the delineation of the HER2-positive BT-474 xenografts. Perhaps just as importantly, these results are consistent with those previously reported for ^{64}Cu-DOTA-T/N-trastuzumab conjugates, though the literature investigation used HER2-positive and HER2-negative non-small cell lung cancer cell lines.[65] Interestingly, far lower background liver uptake was observed in our study, and while comparisons between different tumor models systems may bear some risks, this discrepancy suggests a lower rate of ^{64}Cu decomplexation in our system.

Similarly positive results were observed in the ^{89}Zr-DFO-T/N-trastuzumab biodistribution experiments (Table 3). Initially very high blood activity levels decreased over the course of the experiment, from 42.2 ± 8.8%ID/g at 6 h to 18.2 ± 3.3%ID/g at 120 h. More importantly, high specific uptake was observed in the HER2-positive BT474 tumors, peaking at over 75%ID/g at 72 h postinjection (tumor to muscle ratio: 34.1 ± 12.7). In contrast, the uptake in the HER2-negative MDA-MB-468 tumors was significantly lower, starting at 11.2 ± 5.80%ID/g at 6 h and peaking at 120 h at 17.6 ± 3.9%ID/g. Highest background uptake was observed in the lungs, liver, spleen, and kidney, with uptake values ranging from 7 to 17%ID/g and typically decreasing over the course of the experiment. Maximum tumor to organ

kidney	15.9 ± 5.4	13.3 ± 1.2	7.0 ± 1.3	11.6 ± 2.6	10.2 ± 0.3	8.7 ± 2.9
muscle	2.2 ± 0.6	2.3 ± 0.2	1.6 ± 0.5	2.2 ± 0.4	2.2 ± 0.2	2.5 ± 0.2
bone	12.1 ± 0.8	13.2 ± 2.4	14.6 ± 3.8	15.2 ± 1.9	14.7 ± 3.1	15.1 ± 1.5

ratios for the lungs, liver, spleen, and kidney were 6.2 ± 2.6 (72 h), 5.6 ± 1.3 (96 h), 6.6 ± 3.2 (120 h), 9.8 ± 3.4 (72 h), respectively (see Supporting Information for complete table of complete tumor/organ ratios). As in the case of ^{64}Cu-DOTA-T/N-trastuzumab, after the earliest time points, only low levels of uptake were detected in the stomach, small intestine, large intestine, and muscle. Interestingly, distinct bone uptake is also observed, with %ID/g values ranging from 12.1 ± 0.8 at 6 h to 15.2 ± 1.9 at 72 h. This is certainly not a surprise, for residual bone uptake of ^{89}Zr has been reported on a number of occasions, and a recently publication by Abou et al. has shown that bone uptake is the *in vivo* fate of a number of species of ^{89}Zr, including [^{89}Zr]Zr-oxalate, [^{89}Zr]Zr-chloride, [^{89}Zr]Zr-citrate.[34,42,66] While a full discussion of the metabolic fate of ^{89}Zr-DFO-T/N-trastuzumab or ^{89}Zr-DFO is, of course, out of the scope of this work, it is interesting to note that the bone uptake does not increase dramatically over the course of the experiment, suggesting that the majority of ^{89}Zr deposition in the bone occurs very soon after injection.

Overall, these results are generally consistent with those previously reported for ^{89}Zr-trastuzumab bioconjugates by Munnink et al. and Holland et al.[42,43] No other data have been published on the uptake of ^{89}Zr-trastuzumab in HER2-negative MDA-MB-468 tumors; however, the uptake value obtained at 24 h in this study (13.4 ± 4.1%ID/g) is remarkably similar to the value obtained at the same time point in the blocking experiment (200 μg additional unlabeled trastuzumab) performed by Holland et al. with BT-474 cells: 13.5 ± 4.8%ID/g. While this latter experiment is not, of course, directly comparable, it does help establish a baseline for the nonspecific tumor uptake of radiolabeled antibody.

Overall, two key differences are evident upon comparing the biodistribution data obtained with ^{89}Zr-DFO-T/N-trastuzumab and ^{64}Cu-DOTA-T/N-trastuzumab. The first, increased bone uptake in the ^{89}Zr-DFO-T/N-trastuzumab experiment, is easily explained: free $^{89}Zr^{4+}$ is a bone-seeking radiometal, while free $^{64}Cu^{2+}$ has not been shown to accumulate in bone. Second, the HER2-specific tumor uptake and background signal (including initial blood levels) are higher in the ^{89}Zr-DFO-T/N-trastuzumab biodistribution than at the corresponding time points in the ^{64}Cu-DOTA-T/N-trastuzumab experiment. For example, at 6 h, the blood levels for ^{89}Zr-DFO-T/N-trastuzumab are 42.2 ± 8.8%ID/g, while they are 19.2 ± 5.2%ID/g for ^{64}Cu-DOTA-T/N-trastuzumab. Later, at 48 h, the uptake in the HER2-positive BT-474 tumor for ^{89}Zr-DFO-T/N-trastuzumab is 72.2 ± 7.9%ID/g, while for ^{64}Cu-DOTA-T/N-trastuzumab, it is 44.0 ± 7.7%ID/g. Moreover, at 48 h, the liver uptake of ^{89}Zr-DFO-T/N-trastuzumab stands at 12.8 ± 2.7%ID/g, while it is 6.4 ± 0.2%ID/g for ^{64}Cu-DOTA-T/N-trastuzumab at the same time point. It is possible that these variations in background uptake result from differences in the metabolism of the ^{89}Zr-DFO- and ^{64}Cu-DOTA-modified antibodies. The increase in HER2-specific uptake of the ^{89}Zr-DFO-T/N-trastuzumab is somewhat more puzzling, though these data are consistent with that obtained in other investigations of ^{64}Cu- and ^{89}Zr-trastuzumab.[42,65] In the case of small peptides, it has been previously reported that the identity of the radiometal may play a role in the uptake of otherwise identical radiopharmaceuticals;[67] however, given the vast size of antibodies, it is far less likely that the identity of the radiometal would exert as strong an influence in this case. Experiments are currently underway to further elucidate the origins of the differences between the pharmacodynamics of two conjugates.

Despite these differences, the biodistribution data plainly illustrate that both radiolabeled constructs are selectively and significantly taken up in the HER2-positive tumors. In addition, and perhaps more important in light of the goals of the investigation, the overall trends observed in uptake and tumor/organ ratio are strikingly similar in the two experiments.

Small Animal PET Imaging. Small animal PET imaging experiments were performed in order to further evaluate the *in vivo* behavior of the two radiometalated bioconjugates. In each case, nude mice (n = 5 for each construct) bearing bilateral BT-474 (HER2-positive) and MDA-MB-468 (HER2-negative) xenografts were injected via tail vein with either ^{64}Cu-DOTA-T/N-trastuzumab (11.1−12.9 MBq [300−345 μCi]) or ^{89}Zr-DFO-T/N-trastuzumab (10.7−11.8 MBq [290−320 μCi]). The animals were subsequently imaged periodically from injection (t = 0 h) to 48 h (^{64}Cu) or 120 h (^{89}Zr). The results clearly indicate that both constructs are taken up significantly and selectively in the HER2-positive BT-474 tumors (shown in Figures 3 and 4). In the case of ^{64}Cu-DOTA-T/N-trastuzumab, high blood pool activity and some background uptake are evident at the early time points, but over the course of the experiment, the

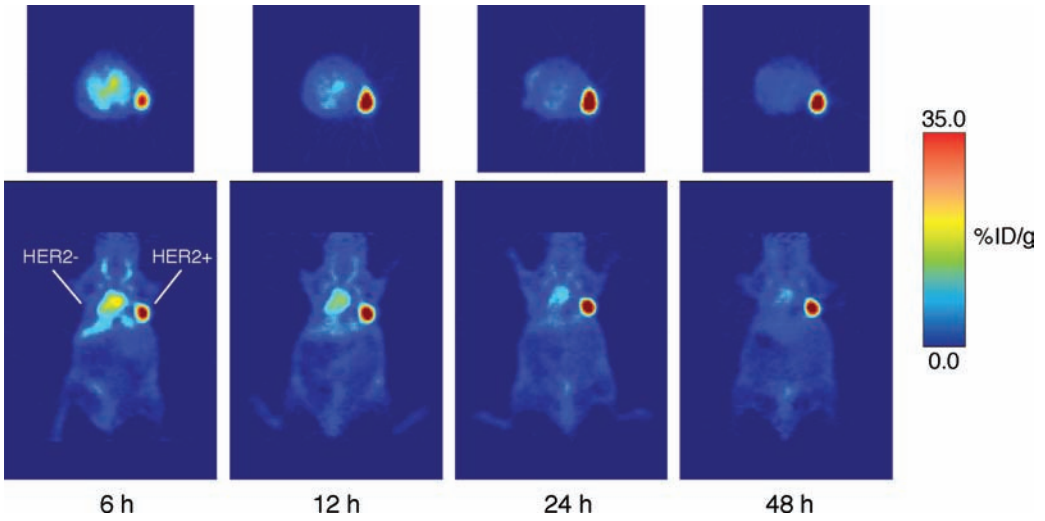

Figure 3. PET images of ^{64}Cu-DOTA-T/N-trastuzumab (11.1−12.9 MBq [300−345 μCi] in 200 μL 0.9% sterile saline) in mice bearing bilateral BT-474 (HER2-positive, right shoulder) and MDA-MB-468 (HER2-negative, left shoulder) tumors between 6 and 48 h postinjection. The transverse (top) and coronal (bottom) planar images intersect the center of the tumors.

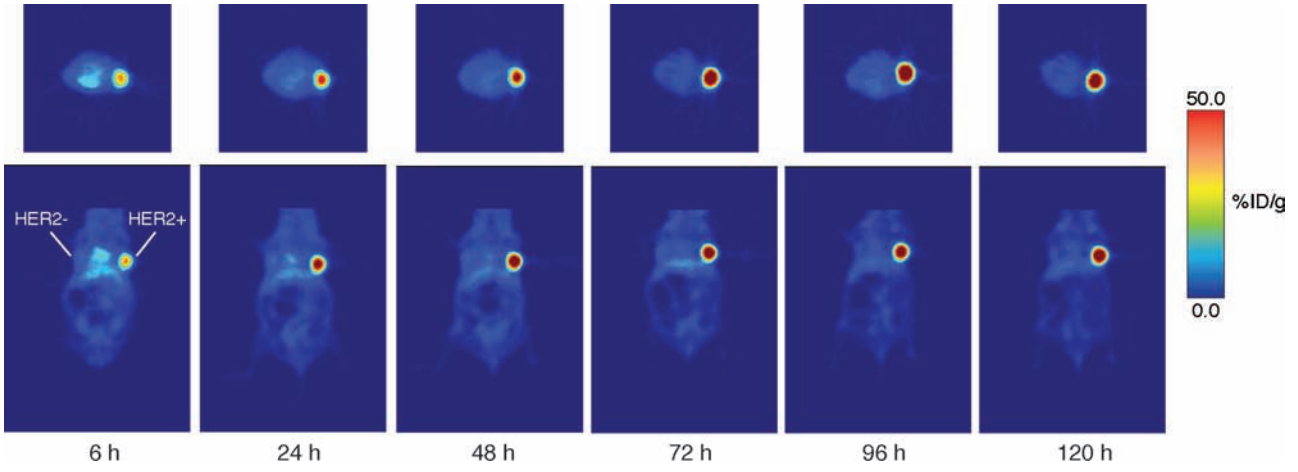

Figure 4. PET images of ^{89}Zr-DFO-T/N-trastuzumab (10.7−11.8 MBq [290−320 μCi] in 200 μL 0.9% sterile saline) in mice bearing bilateral BT-474 (HER2-positive, right shoulder) and MDA-MB-468 (HER2-negative, left shoulder) tumors between 6 and 120 h postinjection. The transverse (top) and coronal (bottom) planar images intersect the center of the tumors.

signal in the BT-474 tumor increases significantly to a point at which it is easily the most intense feature in the PET image. Similarly, for ^{89}Zr-DFO-T/N-trastuzumab, some blood pool activity is evident at the earliest time point, but the tumor uptake increases steadily in the subsequent time points along with a concomitant decrease in any background activity. The images produced by the two conjugates are very similar, a result that is consistent with the sum of the data collected in this investigation. In each case, very little background uptake is evident in either the HER2-negative MDA-MB-468 tumor or other organs. The only significant differences, as in the biodistribution experiments, are enhanced tumor and background uptake in the ^{89}Zr-DFO-T/N-trastuzumab images compared to those from ^{64}Cu-DOTA-T/N-trastuzumab and slight bone uptake of the former construct. The bone uptake is not evident in the images displayed in Figure 5 but can be spotted (though faint) in a maximum intensity projection (see Supporting Information). Just as important as the imaging similarities between the two constructs in this study, the images obtained here are consistent with those reported for other ^{89}Zr- and ^{64}Cu-trastuzumab radioagents in the literature.

Radiolabeling Trastuzumab with a Two-Step Ligation Strategy. The modular strategy described to this point comprises three simple steps: norbornene modification, tetrazine-chelator ligation, and radiometalation. However, the versatility of the tetrazine-norbornene ligation makes an alternate route possible as well: a two-step procedure in which a norbornene-modified antibody is reacted with a radiometalated, chelator-modified tetrazine (Figure 5). Indeed, similar ligations of dienophiles with radiolabeled tetrazines have already been employed with success with ^{18}F and ^{111}In, though in these cases, a transcyclooctene dienophile was employed rather than a norbornene.[29−31] To demonstrate the feasibility of such a strategy with PET radiometals, Tz-DOTA (5 nmol) was radiolabeled with ^{64}Cu (1.1−1.5 mCi) in 50 mM NH_4OAc pH 5.5 via incubation at 85 °C for 1 h (n = 3 trials). After the 1 h incubation, the labeling reaction was purified via radio-HPLC, and the product was obtained in an uncorrected

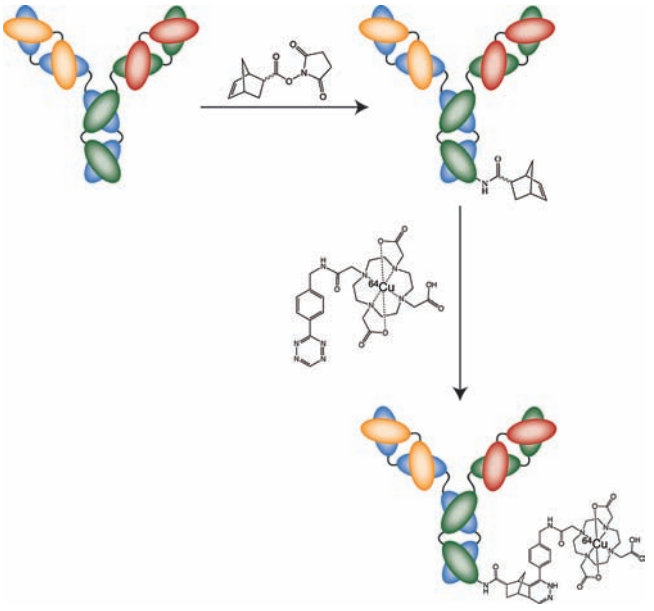

Figure 5. Schematic of the two-step radiolabeling strategy based on the ligation of norbornene-modified antibody and ^{64}Cu-labeled Tz-DOTA.

radiochemical yield of 80 ± 3% with greater than 99% radiochemical purity and a specific activity of 160 ± 5 mCi/μmol. Subsequently, this ^{64}Cu-Tz-DOTA was incubated with norbornene-modified trastuzumab (0.4 mg, 1.3 nmol, initial norbornene/mAb stoichiometry of 5:1) in PBS pH 7.4 (200 μL) at 37 °C. The progress of the reaction was monitored with radio-TLC, and after 3 h, the reaction was gauged to have reached completion. After purification via centrifugal filtration, the completed ^{64}Cu-DOTA-T/N-trastuzumab conjugate was isolated in ~75% radiochemical yield and in >99% radiochemical purity with a specific activity of 1.0 ± 0.4 mCi/mg. Granted, this specific activity is somewhat lower than that obtained with the three-step method; however, further optimization, though outside of the scope of the work at hand, could no doubt raise this specific activity to levels on par with that achieved with the three-step strategy.

Ultimately, it is our belief that the three-step method is preferable as a modular strategy for radiolabeling antibodies. This method holds the key advantage of only involving a single and relatively rapid radiochemical step, thereby minimizing the amount of radiochemistry needed for the creation of the bioconjugates while simultaneously maximizing specific activities. However, it is clear from the work currently in the literature —particularly that of Devaraj et al. and Rossin et al.—that the two-step method holds significant potential as a strategy for pretargeted antibody or peptide imaging.[23,24,27−29,31] In this application, a dienophile-modified biomolecule is first injected into a tumor-bearing animal and is permitted time to achieve its optimal biodistribution. Subsequently, a fluorophore- or radionuclide-modified tetrazine moiety is injected into the same animal and, due to the bioorthogonal nature of the tetrazine-dienophile ligation, could selectively react with the dienophile-modified biomolecule, resulting in specific localization of the marker. Indeed, both the optical and nuclear pretargeting strategies have shown very promising results. It is important to note, though, that the pretargeting systems described in the literature employ more reactive, less stable trans-cyclooctene dienophiles instead of the more stable, less reactive norbornene dienophile used in this study. Experiments are currently underway toward the creation of a pretargeting system for positron-emitting radiometals employing more reactive dienophiles.

CONCLUSION

In summary, herein we report the development of a modular system for the radiometalation of antibodies using the inverse electron demand Diels−Alder cycloaddition between tetrazine and norbornene. The strategy involves three facile, rapid, and biocompatible steps: modification of an antibody with norbornene, ligation of a chelator-modified tetrazine, and radiometalation. In this proof of concept investigation, the methodology was employed to create bioconjugates of the HER2-specific antibody trastuzumab bearing the positron-emitting radiometals ^{64}Cu and ^{89}Zr in high radiochemical purity and specific activity. For a given initial loading of norbornene, the DOTA- and DFO-modified constructs were shown to have identical numbers of chelates per antibody, and all of the radiolabeled ^{64}Cu-DOTA- and ^{89}Zr-DFO-bioconjugates displayed high serum stability and immunoreactivity. Finally, both radiolabeled bioconjugates were used in *in vivo* biodistribution and PET imaging studies with mice bearing HER2-positive (BT-474) and HER2-negative (MDA-MB-468) breast cancer xenografts. Both antibody constructs were shown to have significant and specific uptake in the HER2-positive tumor with low uptake in the HER2-negative tumor and other tissues.

This strategy does not necessarily offer a significant improvement in facility compared to popular DOTA-NHS or DFO-NCS antibody modification protocols; more importantly, however, it creates a modular platform in which a common, covalently modified antibody can be modified with a wide variety of chelators and radiometals. Given that different radiometals often require different chelators—and thus the use and optimization of different modification pathways—this methodology could no doubt aid in the rapid and robust construction of diverse radiopharmaceuticals from a single antibody stock. Further, this modular system could facilitate the creation of meaningful comparisons between bioconjugates labeled with different radiometals: as we have shown, because the chelator-modified antibodies are synthesized using identical ligation conditions, the immunoreactivity and chelator/antibody ratios of the resultant bioconjugates are likewise nearly identical regardless of the identity of the tetrazine−chelator pair.

Ultimately, therefore, this modular methodology has the potential not only to significantly aid in the synthesis and development of new radiometalated bioconjugates for PET, SPECT, and radiotherapy, but also to advance cross-pollination and constructive comparisons between radiopharmaceuticals employing diverse metallic radionuclides.

Supporting Information

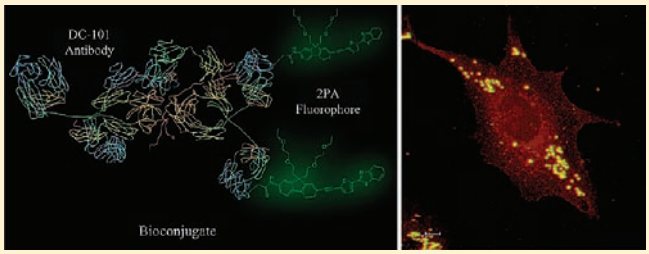
ABSTRACT: We report the synthesis and characterization of two amine reactive fluorescent dyes with efficient two-photon absorption (2PA) properties and high fluorescence quantum yields. Bioconjugation of these dyes with the DC-101 antibody proved to be useful for selectively imaging the vascular endothelial growth factor receptor 2 (VEGFR-2) in cells expressing this receptor *in vitro* and in "whole" mounted excised tumors (*ex vivo*) by two-photon fluorescence microscopy (2PFM). The penetration depths reached within the tumors by 2PFM was over 800 μm. In addition, the concentration of dye required for incubation of these bioconjugates was in the picomolar domain, the probes possessed very good photostability, and the 2PFM setup did not require any additional means of increasing the collection efficiencies of fluorescent photons to achieve the relatively deep tissue imaging that was realized, due, in large part, to the favorable photophysical properties of the new probes.



INTRODUCTION

The development of methodologies and materials to image cancer tumors is an area of increasing interest in the chemical and biomedical communities. The conjugation of fluorescent dyes with antibodies and peptides, used as targeting vectors, is a common strategy to selectively image tumors. In the interest of following tumor growth and drug efficacy, researchers have targeted the vasculature rather than the tumor itself to determine tumor size, morphology, and characteristics by different technologies (immunohistochemistry, fluorescence microscopy, photoacoustic microscopy, etc).[1−5]

Angiogenesis is the process of forming new blood vessels to support tissue growth. This fundamental physiological process promotes embryonic development, tissue repair, and fertility, although it also promotes chronic inflammation, tumor growth, and tumor metastasis.[6] Tumors, in particular, rely on angiogenesis for their continued growth. It has been demonstrated that solid tumors will not grow larger than 2−3 mm in diameter in the absence of new blood vessels and require angiogenesis to form metastases.[7] Vascular endothelial growth factor (VEGF) is a protein that stimulates vascular endothelial cell growth, survival, and proliferation. Thus, VEGF facilitates survival of existing vessels, contributes to vascular abnormalities that may impede effective delivery of antitumor compounds, and stimulates new vessel growth.[8−10]

The VEGF family consists of five members (VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor), which show different affinities for one of the three VEGF tyrosine kinase receptors (VEGFR-1, VEGFR-2, and VEGFR-3). VEGFR-1 and VEGFR-2 are expressed in vascular endothelial cells. Moreover, there is evidence that VEGFR-2 is the major mediator of VEGF-driven responses in endothelial cells and it has been considered to be crucial in angiogenic processes.[10]

In 2005, Backer and co-workers reported the use of a boronated polyamidoamine dendrimer able to target vasculature by means of a VEGF-containing bioconjugate that directed the dendrimer to a specific receptor (VEGFR). The incorporation of a near-infrared (NIR) dye (Cy5) was employed to track the bioconjugate. The targeting of tumor vasculature endothelial cells, rather than the tumor itself, was achieved, since endothelial cells in tumor neurovasculature express a significantly greater number of VEGFR-2 when compared to quiescent endothelial cells.[11] More recent work has demonstrated the use of VEGF bioconjugates containing

NIR fluorescent dyes to study the possible expression of VEGFRs in bladder inflammation.[12]

The use of two-photon absorption (2PA) fluorophores offers several advantages over their one-photon NIR counterparts. In the nonlinear absorption process, the fluorescence emission is proportional to the square of the intensity of the incident light, providing the system with numerous intrinsic advantages, e.g., deeper penetration, more confined excitation areas, less scattering, and minimal photodamage outside of the focal volume.[13]

The scientific community has access to a wealth of efficient 1PA fluorescent dyes with emissions that range from the UV to the IR and that are commercially available. However, there is a need to develop new dyes with high fluorescence quantum yields and 2PA cross sections that meet the high photostability demands that two-photon fluorescence microscopy (2PFM) imposes for repeated three-dimensional (3D) imaging. We previously described a strategy to create 2PA amine reactive probes that can be conjugated to proteins or antibodies.[14,15] In this work, we introduce the synthesis and characterization of two new fluorescent amine reactive dyes based on a fluorenyl core. The fluorophore design was based on a small series of efficient 2PA dyes that were recently reported.[16] The architecture of the fluorophores involved a fluorenyl core flanked by a triple bond−thiophene bridge (π) that led to an electron withdrawing group on one side (A). On the other, the fluorenyl core was tethered to the anti-VEGFR-2 that served as a donor (D). This resulted in systems that have a D−π−A dipolar structure.

These probes were used to prepare VEGFR-2 antibody bioconjugates (anti-VEGFR-2) that selectively bound to the VEGFR-2 in vascular endothelial cells that overexpress this specific receptor in *in vitro* experiments. Furthermore, the conjugation of these new 2PA dyes to the VEGFR-2 antibody was used to image tumor vasculature of whole-mounted excised tumors by 2PFM (Figure 1). *In vitro*, and, more significantly, *ex vivo*, thick tumor 2PFM imaging was accomplished, revealing the 3D tumor microvasculature morphology.

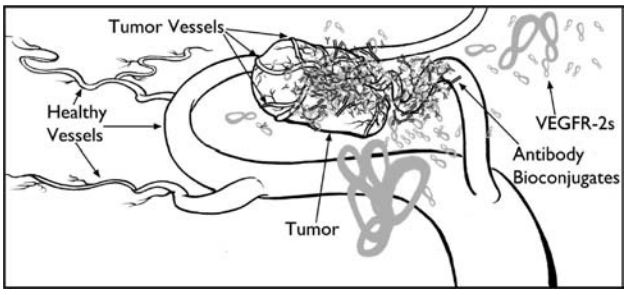

Figure 1. Depiction of a VEGFR-2 expressing tumor. Tumor cells induce the formation of new vasculature by expressing a higher concentration of VEGFR-2 which enables tumor growth. After they are treated with a 2PA fluorescent antibody bioconjugate, the tumor vessels can be imaged by 2PFM.

EXPERIMENTAL SECTION

Materials and Methods. Key intermediates **1**, **2**, and **7** were prepared as described in the literature.[15,16] All reactions were carried out under N_2. Microwave-assisted procedures were carried out in a CEM Discover unit microwave in 10 mL closed vessels; temperature, pressure, and power were programmed at a maximum value (as indicated), depending on the reaction. All other reagents and solvents were used as received from commercial suppliers. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Varian NMR spectrometer at 500 and 125 MHz, respectively. Mass analyses (APCI, atmospheric pressure chemical ionization) were performed at University of Florida. The analyses were carried out on a Finnigan LCQ—Quadrupole Ion Trap (Thermo Finnigan). Monoclonal antihuman VEGFR-2/KDR-Fluorescein isothiocyanate bioconjugate was obtained from R&D Systems and was used as a positive control without further treatment.

Synthetic Procedures and Characterization. *Synthesis of 2-(5-(9,9-Bis(2-(2-ethoxyethoxy)ethyl)-7-nitro-9H-fluoren-2-yl)thiophen-2-yl)benzothiazole (**3**).* In a 10 mL vessel, under nitrogen, 9,9-bis(2-(2-ethoxyethoxy)ethyl)-2-iodo-7-nitro-9H-fluorene (**1**; 200 mg, 0.335 mmol), 2-(5-(tributylstannyl)thiophen-2-yl)benzothiazole (**2**; 207 mg, 0.408 mmol), and $Pd(PPh_3)_2Cl_2$ (6 mg, 0.008 mmol) were dissolved in toluene (2 mL). The mixture was heated in the microwave for 25 min, at 130 °C, 150 psi, and 150 W, filtered through a Celite plug, and purified by column chromatography using as a solvent a mixture of hexane/ethyl acetate (2:1) to yield 216 mg (98%) of a light orange solid. mp 75.7−76.5 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.26−8.34 (m, 2H, Ph-H), 8.06 (d, J = 8.06 Hz, 1H, Ph-H), 7.89 (d, J = 8.06 Hz, 1H, Ph-H), 7.73−7.84 (m, 4H, Ph-H), 7.69 (d, J = 3.93 Hz, 1H, Thy-H), 7.49−7.52 (m, 1H, Ph-H), 7.48 (d, J = 3.93 Hz, 1H, Thy-H), 7.38−7.42 (m, 1H, Ph-H), 3.34−3.40 (m, 4H, CH_2), 3.27−3.31 (m, 4H, CH_2), 3.15−3.22 (m, 4H, CH_2), 2.79−2.93 (m, 4H, CH_2), 2.45−2.56 (m, 4H, CH_2), 1.10 (t, J = 6.98 Hz, 6H, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ 161.1, 153.9, 152.1, 151.2, 147.7, 147.5, 146.3, 138.6, 137.0, 135.0, 134.8, 129.7, 126.8, 126.0, 125.6, 124.8, 123.9, 123.2, 122.2, 121.7, 121.0, 120.2, 119.3, 70.4, 69.8, 67.1, 66.8, 52.5, 39.6, 15.2. MS (APCI) m/z calcd $[M + H]^+$ 659.2244, found 659.2256.

*Synthesis of 7-(5-(Benzothiazol-2-yl)thiophen-2-yl)-9,9-bis(2-(2-ethoxyethoxy)ethyl)-9H-fluoren-2-amine (**4**).* In a 10 mL vessel, under nitrogen were dissolved 2-(5-(9,9-bis(2-(2-ethoxyethoxy)ethyl)-7-nitro-9H-fluoren-2-yl)thiophen-2-yl)-benzothiazole (**3**; 300 mg, 0.45 mmol) and 10% Pd/C (30 mg) in a 1:1 mixture of THF/EtOH (4 mL). $NH_2NH_2{\cdot}2H_2O$ (300 mg, 6.0 mmol) was added to the mixture dropwise at room temperature, and then the solution was heated in the microwave to 110 °C, 100 W, and 100 psi for 30 min. The mixture was filtered though a silica plug with ethyl acetate, and after the solvent was removed under reduced pressure, the material was purified by column chromatography using as a solvent ethyl acetate to yield 280 mg (97%) of a dark yellow solid. mp 120.8−121.4 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.04 (d, J = 7.88 Hz, 1H, Ph-H), 7.86 (d, J = 7.88 Hz, 1H, Ph-H), 7.59−7.67 (m, 3H, Ph-H, Thy-H), 7.55 (d, J = 7.69 Hz, 1H, Ph-H), 7.45−7.50 (m, 2H, Ph-H), 7.34−7.40 (m, 2H, Ph-H, Thy-H), 6.75 (d, J = 7.99 Hz, 1H, Ph-H), 6.68 (dd, J = 7.99 Hz, J = 1.92 Hz, 1H, Ph-H), 3.38−3.44 (m, 4H, CH_2), 3.33−3.37 (m, 4H, CH_2), 3.21−3.26 (m, 4H, CH_2), 2.77−2.86 (m, 4H, CH_2), 2.31−2.46 (m, 4H, CH_2), 1.13 (t, J = 7.05 Hz, 6H, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ 161.3, 153.8, 151.1, 149.0, 148.8, 146.7, 141.6, 135.3, 134.6, 130.8, 130.7, 129.6, 129.6, 125.4, 125.1, 123.3, 122.8, 121.46, 121.1, 120.1, 119.0, 114.5, 109.8, 70.1, 69.7, 67.0, 66.6, 50.9, 39.9, 15.1. MS (APCI) m/z calcd $[M + H]^+$ 629.2502, found 629.2508.

Synthesis of 2-(5-(9,9-Bis(2-(2-ethoxyethoxy)ethyl)-7-isothiocyanato-9H-fluoren-2-yl)thiophen-2-yl)benzothiazole

*(**5**)*. In a two-neck round-bottom flask and under nitrogen, a solution of 7-(5-(benzothiazol-2-yl)thiophen-2-yl)-9,9-bis(2-(2-ethoxyethoxy)ethyl)-9*H*-fluoren-2-amine (**4**; 250 mg, 0.398 mmol) in chloroform (2 mL) was combined with an aqueous solution of $CaCO_3$ (103 mg, 1.03 mmol) in an ice bath. Thiophosgene (0.042 mL, 0.44 mmol) was added to the vial dropwise while stirring the mixture, and the reaction proceeded for 4 h. After completion, a 10% HCl solution was added until the gas formation ceased. The mixture was poured into water, extracted with methylene chloride, dried over magnesium sulfate, and purified by column chromatography using as a solvent a mixture of hexane/ethyl acetate (2:1) to yield 200 mg (74%) of a light orange solid. mp 103.2−104.0 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.04 (d, J = 8.10 Hz, 1H, Ph-H), 7.86 (d, J = 8.10 Hz, 1H, Ph-H), 7.70−7.73 (m, 1H, Ph-H), 7.61−7.68 (m, 4H, Ph-H, Thy-H), 7.46−7.50 (m, 1H, Ph-H), 7.41 (d, 1H, J = 4.10 Hz, Thy-H), 7.34−7.39 (m, 1H, Ph-H), 7.32 (d, J = 1.68 Hz, 1H, Ph-H), 7.21 (dd, J = 7.97 Hz, J = 1.68 Hz, 1H, Ph-H), 3.36−3.42 (m, 4H, CH_2), 3.30−3.35 (m, 4H, CH_2), 3.18−3.23 (m, 4H, CH_2), 2.78−2.91 (m, 4H, CH_2), 2.38−2.47 (m, 4H, CH_2), 1.12 (t, J = 7.11 Hz, 6H, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ 161.0, 153.7, 151.1, 150.3, 148.0, 139.6, 139.0, 136.2, 135.4, 134.7, 133.1, 130.2, 129.6, 129.5, 124.2, 122.9, 121.5, 121.4, 121.1, 120.92, 120.85, 120.7, 120.6, 120.4, 70.1, 69.6, 66.9, 66.6, 51.8, 39.6, 15.1. MS (APCI) m/z calcd $[M + H]^+$ 671.2066, found 671.2068. UV−vis (DMSO) λ_{max} 397 nm.

*Synthesis of 1-(7-(5-(Benzothiazol-2-yl)thiophen-2-yl)-9,9-bis(2-(2-ethoxyethoxy)ethyl)-9H-fluoren-2-yl)-3-butylthiourea (**6**)*. In a small vial under nitrogen, a mixture of 2-(5-(9,9-bis(2-(2-ethoxyethoxy)ethyl)-7-isothiocyanato-9*H*-fluoren-2-yl)thiophen-2-yl)benzothiazole (**5**; 56 mg, 0.083 mmol) and *n*-butylamine (0.074 mL, 1.0 mmol) at room temperature was stirred for 1 h. The remaining *n*-butylamine was removed under vacuum, and the residue was purified by column chromatography with hexane/ethyl acetate (1:1) to yield 50 mg (80%) of a bright yellow solid. mp 67.0−68.0 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.04 (d, J = 8.13 Hz, 1H, Ph-H), 7.84−7.94 (m, 2H, Ph-H, N−H), 7.67−7.73 (m, 4H, Ph-H), 7.66 (d, J = 4.01, 1H, Thy-H), 7.47−7.52 (m, 1H, Ph-H), 7.42 (d, 1H, J = 4.01 Hz, Thy-H), 7.35−7.40 (m, 1H, Ph-H), 7.32 (d, J = 1.46 Hz, 1H, Ph-H), 7.21 (d, J = 7.74 Hz, 1H, Ph-H), 6.34−6.39 (m, 1H, N−H), 3.62−3.69 (m, 2H, CH_2), 3.32−3.41 (m, 4H, CH_2), 3.24−3.30 (m, 4H, CH_2), 3.12−3.21 (m, 4H, CH_2), 2.78−2.98 (m, 4H, CH_2), 2.36−2.44 (m, 4H, CH_2), 1.57−1.65 (m, 2H, CH_2), 1.35−1.43 (m, 2H, CH_2), 1.10 (t, J = 6.96 Hz, 6H, CH_3), 0.95 (t, J = 7.55 Hz, 3H, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ 180.6, 161.1, 153.72, 153.71 150.1, 148.1, 140.1, 138.3, 136.1, 134.68, 134.67, 132.8, 129.5, 123.8, 122.9, 121.5, 121.4, 120.63, 120.61, 120.60, 120.48, 120.47, 120.0, 70.0, 69.6, 67.1, 66.5, 51.9, 39.6, 31.0, 20.2, 15.1, 15.0, 13.9. MS (APCI) m/z calcd $[M + H]^+$ 744.2958, found 744.2952. UV−vis (DMSO) λ_{max} 400 nm.

*Preparation of Bioconjugate **B1***. A mixture containing 1000 μL of monoclonal DC-101 antibody (4 mg/mL) and 1000 μL of $NaHCO_3$ (1 M) was combined with a fresh solution of isothiocyanate **5** in DMSO in a 1:6 molar protein/dye proportion and incubated for 1 h in the dark at room temperature. A mixture containing 100 μL of polyclonal VEGFR-2 antibody (1 mg/mL) and 100 μL of $NaHCO_3$ (1 M) was combined with a fresh solution of isothiocyanate **5** in DMSO in a 1:10 molar protein/dye proportion and incubated for 2 h in the dark at room temperature. The biconjugate was purified by using disposable PD-10 desalting columns from GE equilibrated and eluted with PBS buffer 7.4. Fractions containing the bioconjugate were identified using a spectrophotometer by monitoring bands at 280 and 400 nm. The degree of labeling was determined to be 3.

*Synthesis of 2-(5-((9,9-Bis(2-(2-ethoxyethoxy)ethyl)-7-nitro-9H-fluoren-2-yl)ethynyl)thiophen-2-yl)benzothiazole (**8**)*. In a 10 mL vessel, under nitrogen, 9,9-bis(2-(2-ethoxyethoxy)ethyl)-2-iodo-7-nitro-9H-fluorene (**1**; 413 mg, 0.725 mmol), 2-(5-ethynylthiophen-2-yl)benzothiazole (**7**; 175 mg, 0.725 mmol), $Pd(PPh_3)_2Cl_2$ (21 mg, 0.03 mmol), and CuI (5.7 mg, 0.03 mmol) were dissolved in a 1:4 mixture of Et_3N/toluene (3 mL). The mixture was heated in the microwave for 1 h, at 130 °C, 150 psi, and 150 W, filtered through a Celite plug, and purified by column chromatography using as a solvent a mixture of hexane/ethyl acetate (2:1) to yield 505 mg (74%) of a light orange solid. mp 105.0−106.5 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.33 (d, J = 2.00 Hz, 1H, Ph-H), 8.26 (dd, J = 8.36 Hz, J = 2.00 Hz, 1H, Ph-H), 8.02 (d, J = 7.95 Hz, 1H, Ph-H), 7.85 (d, J = 7.95 Hz, 1H, Ph-H), 7.73−7.79 (m, 2H, Ph-H, Thy-H), 7.66−7.68 (m, 1H, Ph-H), 7.54−7.60 (m, 2H, Ph-H, Thy-H), 7.46−7.50 (m, 1H, Ph-H), 7.36−7.40 (m, 1H, Ph-H), 7.31 (d, J = 3.92 Hz, 1H, Thy-H), 3.35−7.42 (m, 4H, CH_2), 3.27−3.31 (m, 4H, CH_2), 3.15−3.21 (m, 4H, CH_2), 2.80−2.93 (m, 4H, CH_2), 2.43−2.54 (m, 4H, CH_2), 1.12 (t, J = 6.85 Hz, 6H, CH_3). ^{13}C NMR (125 MHz, $CDCl_3$) δ 160.5, 153.8, 151.1, 147.5, 146.0, 138.8, 138.6, 134.9, 133.3, 133.1, 128.6, 128.5, 126.9, 126.7, 126.6, 123.4, 123.3, 121.7, 121.4, 119.2, 119.1, 96.0, 84.2, 70.3, 69.7, 66.9, 66.7, 52.3, 39.4, 15.2. Preparation of Bioconjugate **B2**. A mixture containing 1000 μL of monoclonal DC-101 antibody (4 mg/mL) and 1000 μL of $NaHCO_3$ (1 M) was combined with a fresh solution of isothiocyanate **10** in DMSO in a 1:6 molar protein/dye proportion and incubated for 1 h in the dark at room temperature. The bioconjugate was purified by using disposable PD-10 desalting columns from GE equilibrated and eluted with PBS buffer 7.4. Fractions containing the bioconjugate were identified using a spectrophotometer by monitoring bands at 280 and 391 nm. The degree of labeling was determined to be 3.

Preparation of IgG Containing Bioconjugate. A mixture containing 190 μL of IgG antibody (21.16 mg/mL) in 890 μL of PBS buffer pH = 7.4 and 1000 μL of $NaHCO_3$ (1 M) was combined with a fresh solution of isothiocyanate **10** in DMSO in a 1:6 molar protein/dye proportion and incubated for 1 h in the dark at room temperature. The bioconjugate was purified by using disposable PD-10 desalting columns from GE equilibrated and eluted with PBS buffer 7.4. Fractions containing the bioconjugate were identified using a spectrophotometer by monitoring bands at 280 and 391 nm. The degree of labeling was determined to be 3.

Measurements. Spectra of amine reactive probes and model compounds were acquired in DMSO solutions with concentrations on the order of 10^{-6} M at room temperature using 1 cm quartz cuvettes. Absorption spectra were recorded with an Agilent 8453 UV−visible spectrophotometer. Steady-state fluorescence spectra were measured with a PTI Quanta-master spectrofluorimeter in the photon counting regime of the PMT using an L-format configuration. The fluorescence spectra were corrected for the spectral dependence of the PMT. Fluorescence quantum yields were determined relative to 9,10-diphenylanthracene in cyclohexane. Absorption spectra of bioconjugates **B1** and **B2** were measured in PBS buffer using 1 mm quartz cuvettes.

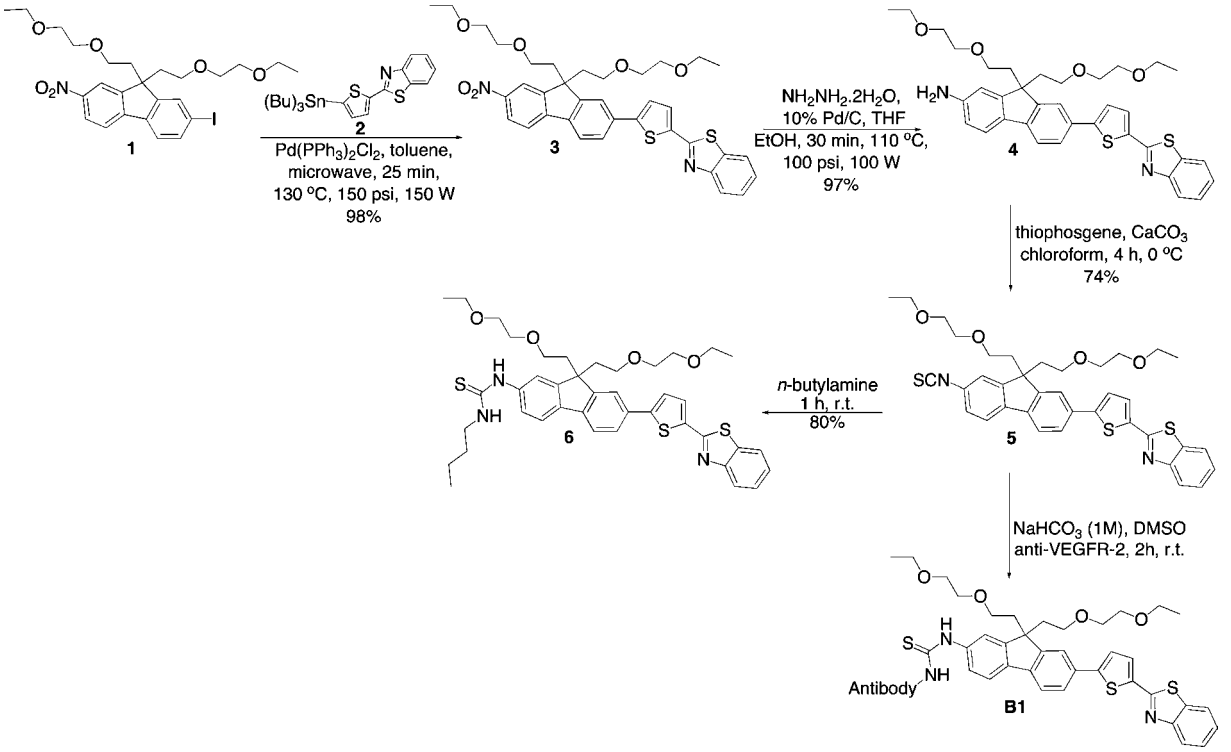
Two-photon absorption spectra were measured by the two-photon fluorescence (2PF) method relative to Rhodamine B in methanol,[17] using solutions with concentrations of approximately 10^{-4} M in spectroscopic grade DMSO following a previously reported methodology.[16]

Cell Culture and Incubation. PAE (porcine aortic endothelial) and PAE/KDR (commercially available porcine aortic endothelial expressing 2 × 10^5 VEGFR-2 per cell) were cultured in F-12 nutrient mixture (Ham's medium, Invitrogen) containing 10% fetal bovine serum (FBS) (Atlanta Biologicals) and 1% penicillin/streptomycin, at 37 °C, under a 5% CO_2 environment. Cells were cultured on no. 1 round 12 mm coverslips that were previously treated with poly-D-lysine. The treated coverslips were placed in 24-well plates, and 60,000 cells/well were seeded and incubated at the same conditions as indicated above until 75−85% confluency was reached on the coverslips. Cells were then fixed with a 3.7% solution of paraformaldehyde in pH = 7.4 PBS buffer for 10 min. The fixing agent was extracted and washed (2×) with PBS. To reduce autofluorescence, a fresh solution of $NaBH_4$ (1 mg/mL) in pH = 8 PBS buffer was used to treat the fixed cells (2x). Subsequently, cells were permeabilized with a 0.1% saponin solution in PBS containing 5% BSA. After permeabilization, PAE-KDR cells were incubated for 1 h at room temperature in a solution containing 0.4 μM solution of bioconjugate **B2** and the monoclonal antihuman VEGFR−2/KDR−fluorescein isothiocyanate bioconjugate (25 μg/mL) in culture media. PAE (negative control) and PAE-KDR cells were incubated for 2 h in a 0.4 μM solution of bioconjugate **B2** in PBS. The dye solutions were extracted by succion, and the coverslipped cells were washed abundantly with PBS (4×). The coverslipped cells were then washed with buffer PBS (2×) and mounted on microscope slides using Prolong Gold (Invitrogen) as a mounting media.

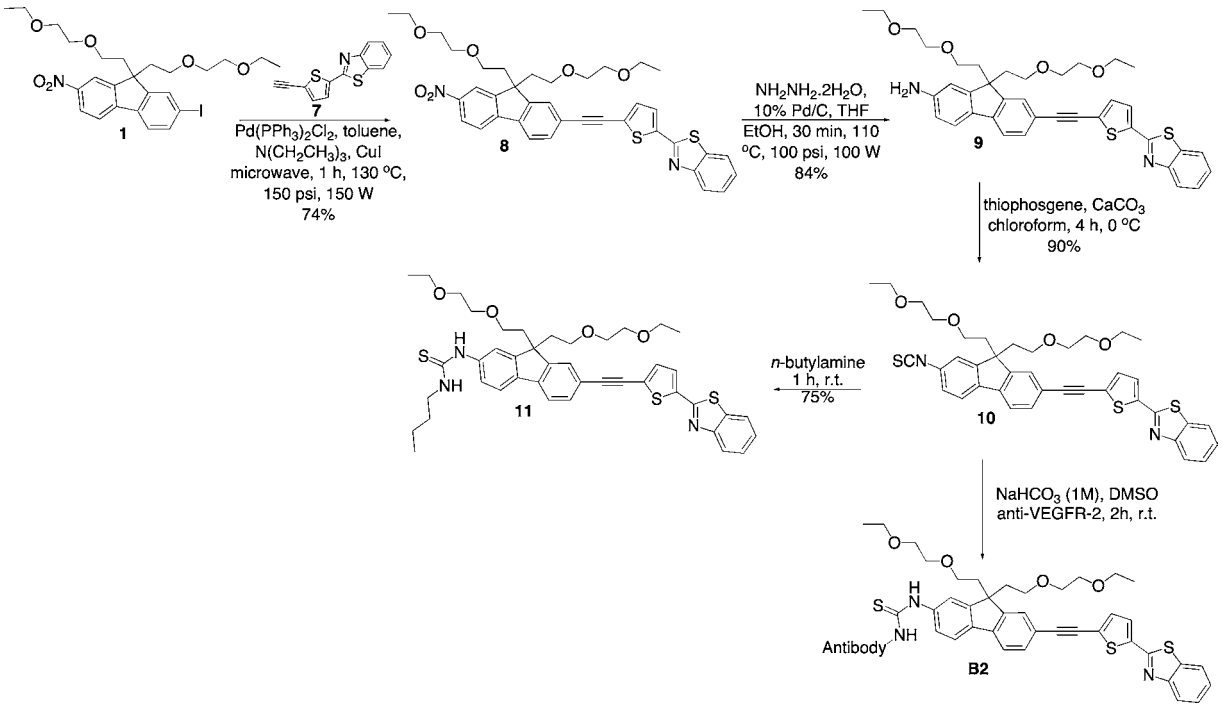
Tissue Immunofluorescence Staining. For the imaging of tumor endothelial cells, 10 μm thick sections were prepared from OCT-embedded frozen blocks. Tumor sections were incubated with rat antimouse CD31 antibody (BD Bioscience, San Diego, CA) and then Alexa Fluor 594-conjugated antirat Ig (Invitrogen).

Mouse Models and Tumor Excision. Lewis lung carcinoma cells were purchased from ATCC (Manassas, VA) and cultured in DMEM (Invitrogen) supplemented with 10% FBS. Experiments involving mice were done in accordance with

Scheme 1. Synthesis of B1



Scheme 2. Synthesis of B2



protocols approved by the Sanford-Burnham Medical Research Institutional Animal Care and Use Committee. Seven-week-old male C57BL/6 mice were purchased from Harlan Laboratories (Indianapolis, IN) and acclimated for 1 week upon delivery. Each mouse was injected subcutaneously into the right flank with 3×10^6 of Lewis lung carcinoma cells suspended in 0.1 mL of PBS. DC-101 antibody or mouse control IgG conjugated with 2PA probe (bioconjugate **B2**) was injected at a dose of 13.4 nmol (600 μg as a protein) per mouse via the tail vein 10 days after the inoculation of tumor cells. Two hours after the injection of the bioconjugate probe, mice were perfused with PBS and then 10% neutral-buffered formalin via the left ventricle under deep anesthesia with isoflurane. Tumors were excised and fixed with 10% neutral-buffered formalin for 18 h at 4 °C. After fixation, tumors were rinsed twice with PBS and cut into two pieces at the center of the tumors; one was used for

3D two-photon fluorescence imaging, and the other was embedded in OCT compound (Sakura Finetek, Torrance, CA) for immunohistochemistry analysis.

One-Photon Fluorescence Imaging. *Cell Imaging.* One-photon confocal fluorescence microscopy was performed on a Leica SP5 II equipped with a spectral scanner. Micrographs of the fixed cells were taken under the following conditions: excitation of **B2** was done at 405 nm, excitation of the FITC anti-VEGFR-2 conjuagte was done at 476 nm; and fluorescence collection of both channels was done by setting the spectral window range from 490 to 620 nm. A water immersion, 63×, 1.3 N. A. objective was used for cell imaging.

Tissue Sections. One-photon fluorescence microscopy images were recorded on an Olympus IX-81 DSU microscope equipped with a Hamamatsu EM-CCD C9100 digital camera. One-photon fluorescence images were taken using a custom-made filter cube (Ex:377/50; DM:409; Em:525/40) for bioconjugates **B2**, a FITC filter cube (Ex:477/50; DM:507; Em:536/40) for FITC anti-VEGFR-2, and a TexRed filter cube (Ex:477/50; DM:507; Em:536/40) for the Alexa Fluor 594-CD31 antibody bioconjugate.

Two-Photon Fluorescence Imaging. Two-photon fluorescence microscopy (2PFM) imaging was performed on a modified Olympus Fluoview FV300 laser scanning microscopy system equipped with a broadband, tunable Coherent Mira Ti:sapphire laser (200 fs pulse width, 76 MHz repetition rate), pumped by a 10 W Coherent Verdi frequency doubled Nd:YAG laser. The Ti:sapphire laser, tuned and mode locked to 700 nm (for cell imaging) or to 820 nm (for "whole" tumor for imaging), was used as the two-photon excitation source. Two-photon induced fluorescence was collected by a 60× (UPLANSAPO, N.A. = 1.35 Olympus) or, for *ex vivo* tumor imaging, with a 10× (UPlanFl, N. A. = 0.30) microscope objective. A high transmittance (>95%) short-pass filter (cutoff 685 nm, Semrock) was placed in front of the PMT detector within the FV300 scanhead in order to filter off background radiation from the laser source (700 or 820 nm). The optical nonlinearity (quadratic dependence) for two-photon excitation was verified with dye **11**-doped poly(methyl methacrylate) films (see Figure S4 in the Supporting Information). The average laser power used for excitation of the tumors from mice injected with **B2** was 22 and 90 mW for all the control samples.

RESULTS AND DISCUSSION

Synthesis of New Fluorescent Probes and Preparation of Bioconjugates. The synthesis of the 2PA amine reactive probes **5** and **10** was achieved in short reaction times and high yields by using microwave-assisted synthesis, as illustrated in Schemes 1 and 2, respectively. Briefly, fluorene derivative **1** was coupled to intermediates **2** and **7** by either Stille or Sonogashira coupling to yield nitro derivatives **3** and **8**, respectively. These nitro derivatives were reduced to the corresponding amine intermediates **4** and **9**.[18] Transformation of these amines into the corresponding isothiocyanates **5** and **10** was performed by a previously reported method. [14,15,19]

In order to better understand the scope and properties of these probes, conjugation with *n*-butylamine was performed to generate model compounds **6** and **11**, which have optical properties closely resembling those of the bioconjugates. Once obtained, amine reactive probes and models were structurally and photophysically characterized.

The amine-reactive probes, isothiocyanates **5** and **10**, were conjugated to anti-VEGFR-2 for 2 h at room temperature in a 10:1 molar ration of dye/protein. Purification was achieved by using a commercially available, Sephadex packed, GPC column. The antibody of choice for this conjugation was DC-101, mainly because the epitiope for this antibody is extracellular. In these studies, where mice were going to be injected with the antibody conjugate, it was clear that the location of the antigenic determinant had to be on the surface of the endothelial cells of the tumor vessels in order to maximize the labeling efficiency of the bioconjuagte. Furthermore, DC-101 (Bevacizumab) has been FDA approved for the treatment of nonsmall cell lung cancer, colon cancer, and breast cancer and is currently being studied for the treatment of ovarian, prostate, renal, pancreatic, and liver cancers.

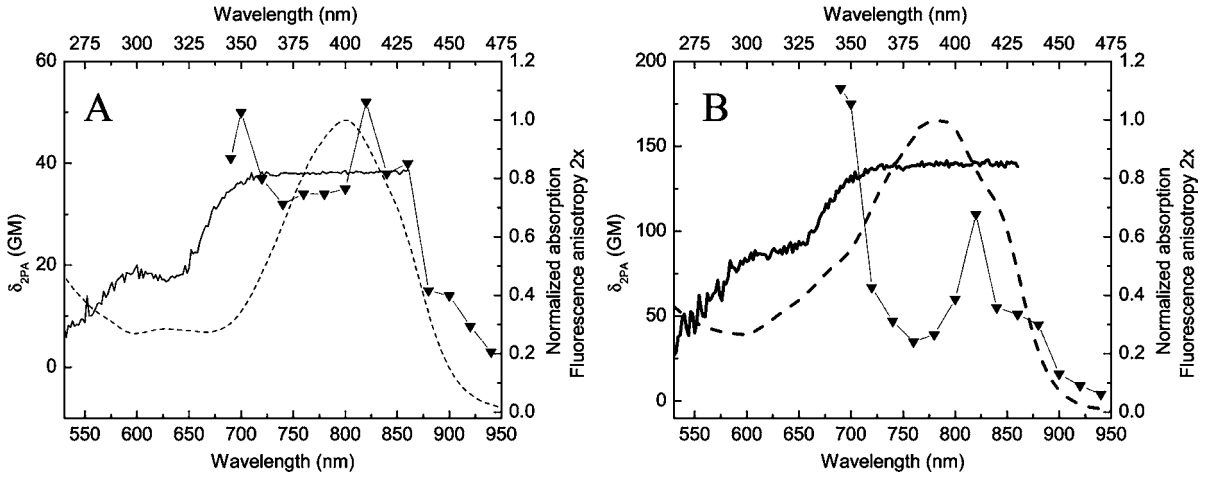

Figure 3. Normalized absorption (dash lines), two-photon absorption cross section (symbols and lines), and anisotropy (2×, solid lines) of model compounds **6** (A) and **11** (B).

Photophysical Properties. Photophysical characterization was performed for amine-reactive probes **5** and **10** and model compounds **6** and **11** (Figure 2). Table 1 reveals that there are intense absorption maxima for amine-reactive probes and model compounds located between 390 and 400 nm, whereas there was a red shift in the emission maxima when the dyes were conjugated to *n*-butylamine due to the dipolar nature of the model adducts. In addition, a larger Stokes shift was observed for the more conjugated model compound **11**.

In our previous studies, we observed that the presence of isothiocyanate groups in the fluorene system plays an important role by quenching the fluorescence of the dye, possibly by inducing intersystem crossing and allowing the molecule to relax by nonradiative pathways, but the fluorescence seems to be restored (switched on) upon conjugation.[14,15] Interestingly, in the case of these new dyes, this effect was not observed. For probe **5**, the quantum yield increased upon conjugation to the amine, as was observed previously for a similar molecule. However, for probe **10**, there was a significant decrease in the fluorescence quantum yield after conjugation with *n*-butylamine (Table 1). This important result suggests that luminescent properties cannot be predicted on the basis of only the similarities between structures.

In 2PFM applications where the upconverted fluorescence of the probe is directly interrogated, the efficiency of the probe depends on basically three parameters, namely the two-photon absorption cross section, the fluorescence quantum yield, and the quantum yield of photodecomposition. The first two parameters are of utmost importance and reflect the probability that the probe has to absorb two photons at a specific wavelength and the ratio of photons the molecule emits by means of fluorescence in relation to the photons it has absorbed, respectively. Combined, the two-photon absorption cross section and the fluorescence quantum yield constitute a parameter referred to as the action cross section, which is the product of these values ($\delta\Phi$). The parameter that is frequently overlooked is the photodecomposition quantum yield (η), which is a good indicator of how quickly a fluorofore photobleaches per photons absorbed. The figure of merit, F_M, is the action cross section normalized by the photodecomposition quantum yield ($F_M = \delta\Phi/\eta$) and is a more comprehensive parameter for evaluating the overall effiency of a fluorescent probe. In the particular case of compounds **6** and **11** (Table 1), the effiencies were quite favorable when compared to fluorescein ($F_M = 6 \times 10^6$ GM).

The lifetimes for these series of compounds were also measured in DMSO at concentrations of approximately 10^{-6} M, as shown in Table 1. A difference of 1.2 ns was found between the fluorescence lifetime of models **6** and **11**. Even though they have similar fluorescence maxima, with this difference in lifetime, it may be possible to distinguish between bioconjugates containing these dyes and different antibodies or vectors by fluorescence lifetime imaging microscopy (FLIM).

Anisotropy values of samples were measured under one-photon excitation in poly-THF at concentrations of approximately 10^{-6} M, while two-photon absorption (2PA) cross sections of model compounds were determined by the fluorescence method using DMSO solutions in concentrations of ca. 10^{-5} M. Rhodamine B in methanol was employed as a standard[17] (Figure 3). Both compounds have a significant 2PA cross section value within the measured range (700–940 nm). Anisotropy spectra exhibited a constant value at the wavelength where the maximum of linear absorption was located, corresponding to the first electronic transition $S_0 \rightarrow S_1$ (one-photon allowed); in this region, there is a decrease in the 2PA cross section value. The anisotropy began to decrease below 350 nm, reaching a minimum at around 325 nm leading to a second "plateau"; this may correspond to a higher electronic transition $S_0 \rightarrow S_n$, a two-photon allowed transition, resulting in a high 2PA cross section at this excitation wavelength.

A maximum in the 2PA spectra within the frame of the main linear absorption band was observed at around 820 nm for both model compounds. This transition correlated nicely to that responsible for the shoulder located at around 425 nm in the linear absorption spectrum. These dyes can be excited by 2PA at wavelengths as long as 850–900 nm, with the fluorescence emission ranging from 400 to 800 nm. These probes have great versatility because they can be efficiently excited over a range of wavelengths and their emission is in the visible to NIR range, required for deep tissue imaging.

After bioconjugation of the isothiocyanates with the selected antibody and purification by gel permeation chromatography, fractions containing the bioconjugates were analyzed by UV–vis spectrometry. Figure 4 shows the absorption spectra of isothiocyanate **10** (red) and biconjugate **B2** (green). The concentration of the protein in the bioconjugate was

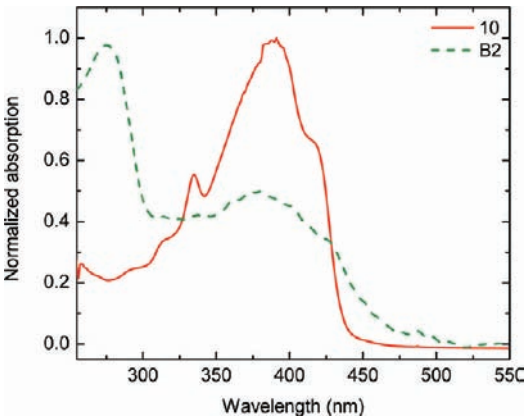

Figure 4. Normalized absorption of isothiocyanate **10** (red, solid line) and bioconjugate **B2** (green, dashed line).

determined to be ca. 50 μM, and the degree of labeling (DOL) was found to be 3. The concentration of the dye in the purified solution was estimated to be ca. 0.4 μM by using the extinction coefficient of the model compound. Preparation of bioconjugates following this method was performed more than once to evaluate the reproducibility of the method; repeated preparation of **B1** and **B2** generated these same results consistently.

Cell Imaging. To study the scope of the new bioconjugates, probes **B1** and **B2** were incubated with porcine aortic endothelial (PAE-KDR) cells that express VEGFR-2, as it is known that this receptor is found in higher concentrations when angiogenesis is occurring.[10] Preliminary studies demonstrated that fluorescence images obtained with **B2** were superior to those obtained with **B1** (not shown). Thus, bioconjugate **B2** was used for the subsequent experiments. PAE-KDR cells were coincubated with a commercially available fluorescent bioconjugate containing fluorescein isothiocyanate and a monoclonal VEGFR-2 antibody (DC101), as a positive control, and our DC101 bioconjugate **B2**. After 1 h of

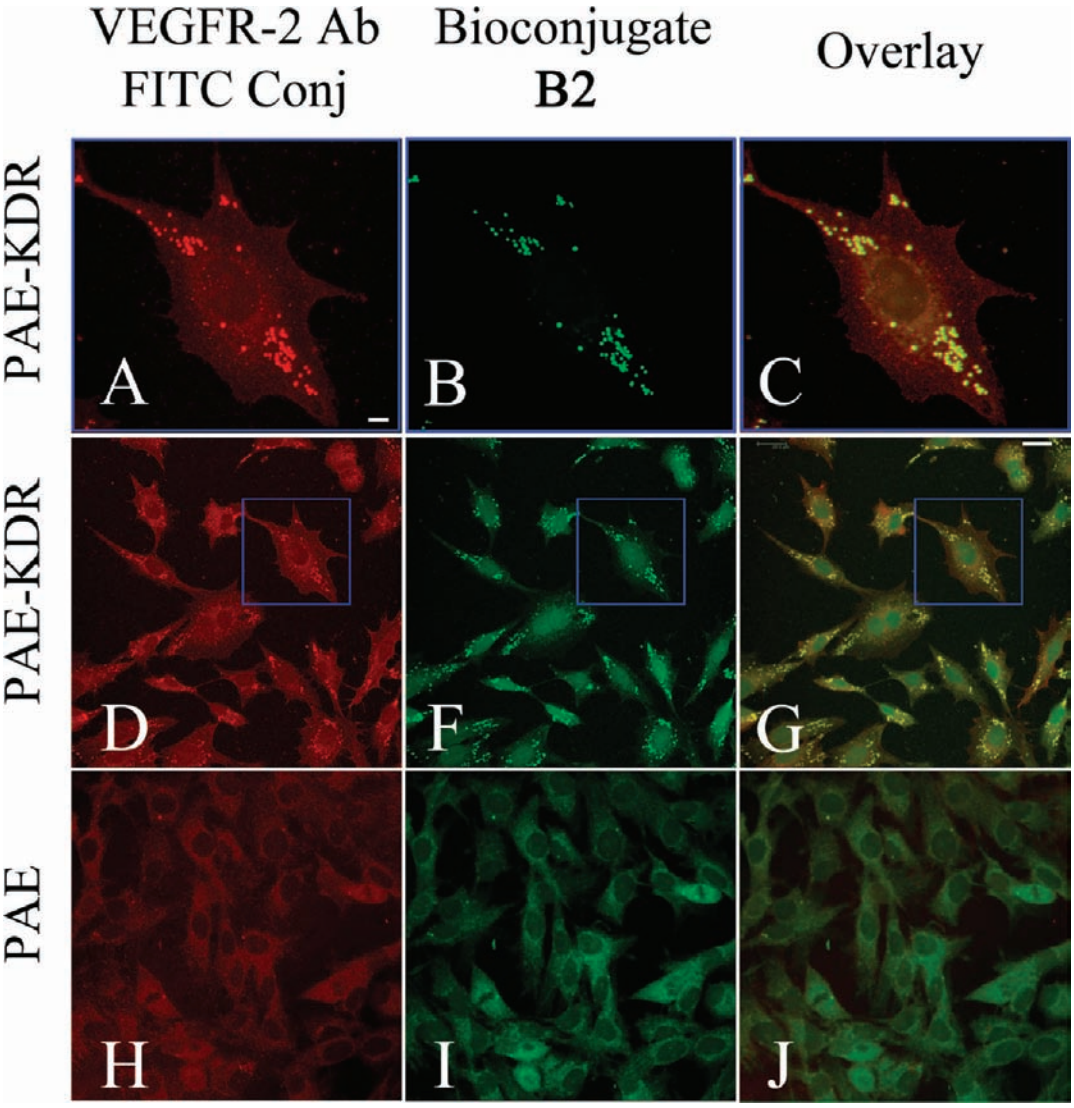

Figure 5. One-photon confocal micrographs of PAE-KDR and PAE cells. Cells were incubated with VEGFR-2 antibody-FITC conjugate (red) and DC101 bioconjugate (**B2**, green). Parts A, B, and C show the magnification of the area enclosed by the blue box in parts D, F, and G. Colocalization corroborates the VEGFR-2 selectivity (C and G) of **B2**. Fluorescence in negative control PAE cells (H and I) is much lower in intensity and less specific than that in PAE-KDR (A–G). Scale bars: 5 μm in A and 20 μm in part G.

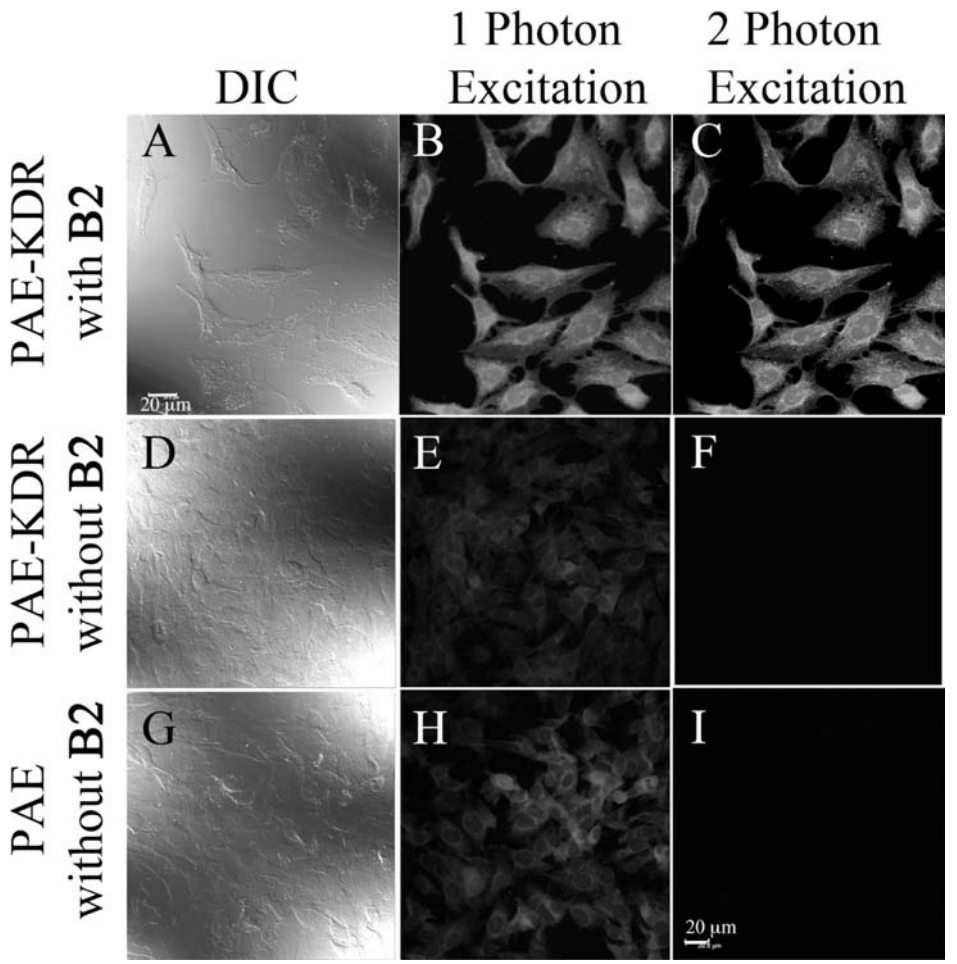

Figure 6. One- and two-photon fluorescence micrographs of PAE-KDR (porcine aortic endothelial cells expressing VEGFR-2) incubated with bioconjugate **B2** (15 μM, 45 min, A–C) and PAE-KDR; PAE cells without **B2** incubation (D–I) . A, D, and G are DIC images; B, E, and H are X–Y projections of one-photon confocal fluorescence (excitation, 405 nm; emission, spectral scanner window 480–620 nm). C, F, and I are X–Y projections along the Z-axis of two-photon fluorescence micrgraphs (excitation, 810 nm; emission, spectral scanner window 480–620 nm). The 20 μm scale bar in part A applies for parts B and C. The 20 μm scale bar in part I applies for D–I.

incubation, epifluorescence micrographs of the incubated cells revealed a high degree of colocalization between the two probes (Figures 5A–G). Figure 5C shows very good coloacalization of the commercial FITC antibody and bioconjugate **B2**. To examine the selectivity of bioconjugate **B2** toward the VEGFR-2, porcine aortic endothelial (PAE) cells that do not overexpress the receptor were used as a negative control. There is more evident autofluorescence in panel F; these are separate images. In panel B the field of view was reduced as a result of digitally zooming in that particular area; subsequently, the histograms of each micrograph are significantly different. This was particularly evident after no-neighbor deconvolution was performed on each micrograph. Micrographs of PAE cells showed little to no specific fluorescence when incubated with B2 (Figure 5I) or the VEGFR-2 antibody FITC conjugate (Figure 5H).

In the interest of comparing the difference resulting from exciting by one- versus two-photon absorption, PAE-KDR cells that had been previously incubated with **B2** were imaged by exciting at 405 and 810 nm, respectively. Collection of the one-photon fluorescence was confocal, as it was passed through a 120 μm pinhole (Figure 6 B). On the other hand, the upconverted fluorescence on the 2PFM was collected keeping the microscope pinhole completely open (Figure 6C). Fluorescence appeared to be much more localized in the 2PFM (Figure 6C) than in its one-photon counterpart. This is likely due to the fact that in the confocal image a significant proportion of the fluorescence being collected is autofluorescence, since the molecule is being excited at 405 nm. One the other hand, in 2PFM autofluorescence is not as much of a concern with excitation at 815 nm; that is, most of what is collected is fluorescence from bioconjuagte **B2**.

Whole Tumor *Ex Vivo* Imaging. Microscopy of biological specimens deep within the tissue is severely limited by scattering of visible light. However, many relevant physiological events occur within the tissue of living organisms. Imaging features deeper within tissue at micrometer resolutions has been possible by 2PFM because scattering decreases with increasing wavelengths. Within biological tissue only unscattered (ballistic) photons are effective in exciting molecules by the absorption of two-photons.[20,21] Efficient 2PA fluorophores with high two-photon absorption cross sections at near IR wavelengths have been previously reported.[16,22] Thus, 2PFM benefits from the use of near IR light that is less likely to be scattered in tissue. The maximum imaging penetration depth within biological tissue (z_{max}) has been estimated to be linearly dependent on the scattering length for excitation light in tissue, $l_s^{(ex)}$, but logarithmically dependent on the collection efficiency

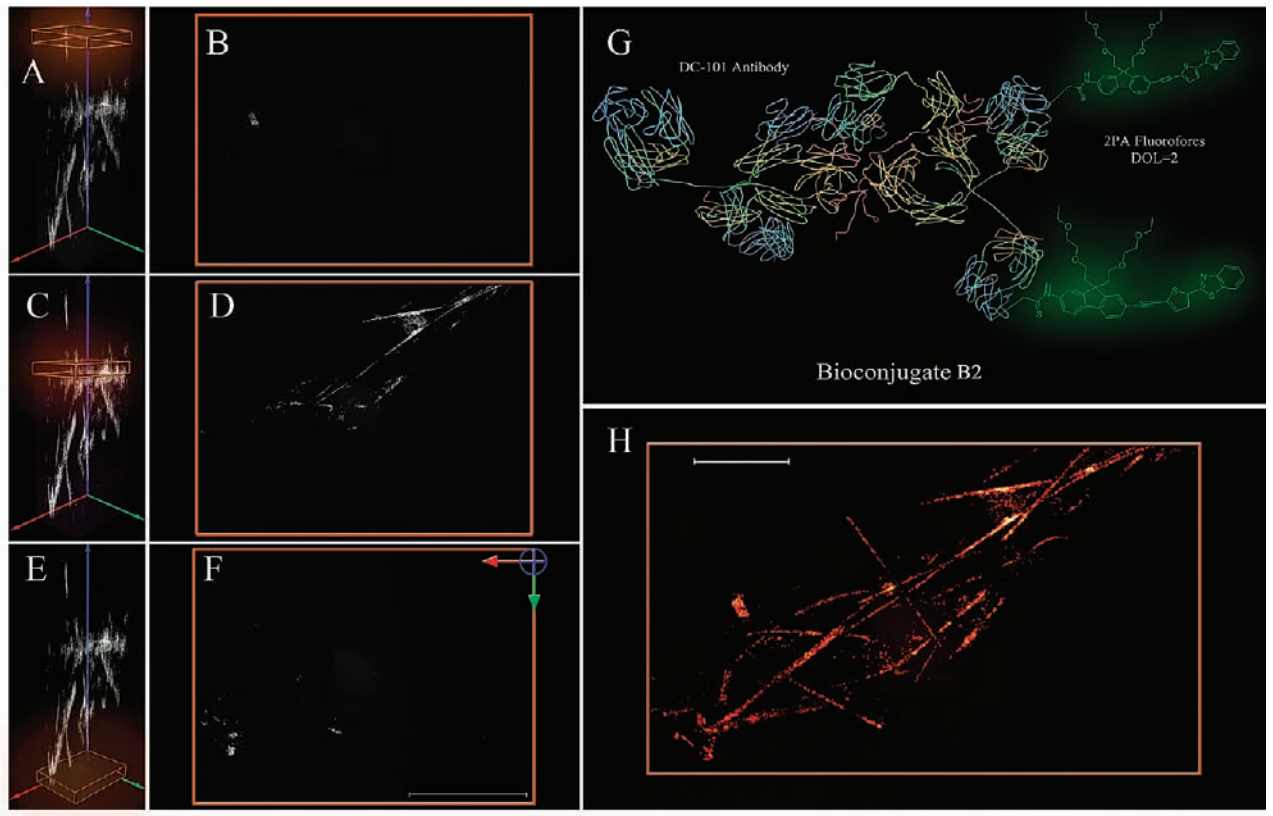

Figure 7. Whole mount tumor 2PFM micrographs of excised Lewis lung carcinoma excised tumors. Each mouse was tail vein injected with 400 μg of DC-101 bioconjugate **B2** (cartoon in G). Orange boxes (A, C, E) or squares (B, D, F) show 40 μm optical sections along the *Z*-axis. Parts B, D, and F are *X*−*Y* (red-green axes) plane projections along the *Z*-axis (blue) of optical sections centered at 740, 540, and 40 μm, respectively; parts A, C, and E show the relative position of the corresponding optical section in the *Z*-axis. The projection of the *X*−*Y* planes along the *Z*-axis (H) shows an image of chaotically intertwined vessels within the tumor. Micrographs were collected at 820 μm, 10×. Tissue penetration exceeded 830 μm. Scale bars: F, 20 μm; H, 10 μm.

of the system (fraction of fluorescent photons detected) and on the two-photon action cross section ($\delta\Phi$)[21,23] Limitations in most Ti:sapphire laser sources (1 W, 100 fs, 80 MHz, 680−1000 nm) restrict what can be done with these sources to increase imaging depth. These new, more efficient probes aim to increase the two-photon action cross section of the probe to enable imaging at greater depths in tissue.

Most efforts in improving the image quality and penetration depth of 2PFM have been oriented toward increasing the collection efficiencies of the emitted fluorescence photon,[24] microscope objective,[21] or repetition rates of the excitation source.[25] Herein, the focus has been to optimize the two-photon action cross section of fluorophores **6** and **11** in order to maximize the 2PFM imaging penetration within tumor tissue.[16] The optimal dye (**10**) was conjugated to the DC-101 antibody to facilitate observation of the formation of new vessels that overexpress VEGFR-2 receptor deep within the tumor.

A solid tumor is comprised of cancer cells and host stromal cells alike.[26,27] Neoplastic and host cells rely on blood vasculature to supply themselves with nutrients and get rid of toxins. All of these cells are exposed to hypoxic and acidic microenvironment that induces the production of positive or negative regulators of angiogenesis. In the past 20 years, more than 20 angiogenic stimulators have been discovered, with VEGF being one of the most important factors. Vascular function is key in determining the tumor microenvironment. Vasculature in healthy tissue is very well structured; in contrast, tumor vessels have very poor morphology and are conformed by immature cells in a meshlike architecture that confers a leaky property to the vessel. Because of its deep penetration, 2PFM offers an excellent means of monitoring tumor microenvironment, angiogenesis regulation, and normalization of tumor vasculature by antiangiogenic agents.[28,29]

The initial efficiency and selectivity of bioconjugate **B2** was evaluated in C57BL/6 male mice. Lewis lung carcinoma cells (3×10^6 cell/site) were implanted subcutaneously into the mice flanks. Eleven days postransplantation the tumor diameter had reached approximately 10 mm, and the mice were tail vein injected with 400 μg of the DC-101 bioconjugate **B2**. After 2 h the mice were perfused with PBS and sacrificed by formalin injection to the heart. Tumors were excised and fixed, and half was kept "whole" for tumor *ex vivo* microscopy and the other half for immunofluorescent histological experiments. The "whole" tumors were mounted on a glass coverslip and immobilized for imaging. 2PFM was conducted using both low (10×) and high (60×, oil immersion) N.A. objectives. The upconverted fluorescence was filtered prior to reaching the PMT (long pass 690 nm).

The whole tumor *ex vivo* 2PFM imaging experiments showed excellent results, allowing the visualization of vasculature over 800 μm deep in the tumor tissue (Figure 7). In Figure 7, the orange boxes (A−F) show layers corresponding to optical sections along the *Z*-axis (blue). The optical plane *X*−*Y* sections (*X*-axis in red, *Y*-axis in green) (Figure 7B, D, and F) at 738, 533, and 82 μm, respectively, show the fluorescence

dx.doi.org/10.1021/bc200299z | *Bioconjugate Chem.* 2011, 22, 2060−2071

contribution of these optical layers along the *Z*-axis. Fluorescence from two-photon excitation of the probe was recorded up 830 μm into the tumor. The relative position of these planes along the *Z*-axis can be seen in the micrographs shown in Figure 7A, C, and E, where the corresponding optical plane (orange square) is shown in the respective projection of the *X*−*Z* plane along the *Y*-axis. Projection of the *X*−*Y* planes along the *Z*-axis by the reconstruction of all of the optical planes (H) shows an image of chaotically intertwined vessels within the tumor where VEFGR-2 was overexpressed. The micrographs reveal how sensitive the 2PA phenomenon is to movements in the objective along the *Z*-axis and illustrates how useful this dye can be to reveal the formation of vasculature by 2PFM. Furthermore, the penetration that was achieved through a medium with such a wide distribution of refractive indices illustrates the potential of these efficient 2PA probes in monitoring the formation and development of vasculature in tumors by 2PFM imaging.

The selectivity of probe **B2** toward the tumor is evidenced by the excellent contrast observed in the micrographs in Figure 7; that is, there was very little nonspecific fluorescence within the tumors, mainly attributable to autofluorescence. The bioconjugate was also specific to tumors. This observation was verified by the 2PFM images of key organs of the mice that had been injected with **B2** (Supporting Information Figure S1). The organs and glands observed were kidneys, liver, heart, brain, lung, and spleen. Primarily only autofluorescence from native structures within each organ (e.g., elastin in muscle and actin in the heart) or residual dye that was being excreted (kidney) was observed.

Tissue sections (400 μm thick) of the tumors of the mice that had been injected with **B2** were costained with an Alexa Fluor 594-CD31 antibody to confirm, by fluorescence colocalization, that probe **B2** was, indeed, targeting vasculature (Figure 8). The tissue section was fixed and permeabilized for incubation with the Alexa Fluor 594-CD31 conjugate for 1 h at room temperature. Figure 8B shows the epifluorescence (1PA) corresponding to the sites where the DC-101 bioconjugate **B2** had accumulated 2 h following the tail vein injection. The vasculature was imaged by fluorescence of the Alexa Fluor 594 dye (Figure 8C). The overlay of micrographs B and C is shown in Figure 8D, where a high degree of colocalization can be observed for many vessels. As expected, not all vessels colocalized, presumably because some expressed higher levels of the VEGFR-2 than others.

The selectivity of the **B2** conjugate to the VEGFR-2 was also investigated by making an IgG conjugate with isothiocyanate **10**, which was injected in the same dose and conditions in control mice. Model compound **11** was also injected into different control mice under the same conditions to demonstrate the specificity of the monoclonal antibody **B2**. Only nonspecific fluorescence was observed from imaging these tumors by 2PFM (Supporting Information Figure S2).

CONCLUSIONS

We developed and synthesized new two-photon absorbing fluorescent amine reactive probes and bioconjugates. Photophysical characterization was performed for amine reactive probes, model compounds, and bioconjugates. The new probes demonstrated a number of desirable characteristics and optical properties, including high photostability and target selectivity. Successful imaging by one- and two-photon excitation with the bioconjugate **B2** in cells was performed, demonstrating that the new bioconjugates selectively bind VEGFR-2 in cell culture, tissue sections, and whole tumors. The DC-101 bioconjugate **B2** is a powerful new probe for selectively imaging the vascular endothelial growth factor receptor 2 (VEGFR-2) in cells expressing this receptor *in vitro* and in "whole" mounted excised tumors (*ex vivo*) by two-photon fluorescence microscopy (2PFM) imaging. This selectivity imparted excellent contrast in 2PFM micrographs that captured tumor vasculature features up to 800 μm within the tumor, despite the refractive index heterogeneity that is characteristic of this type of tissue. These images were recorded without having to increase the collection efficiency of fluorescent photons, without additional artifacts, and with a relatively low numerical aperture objective, fully exploiting the working distance of this objective. Since the tumors were "whole" mounted without prior treatment, the conditions are close to those of the *in vivo* environment. Hence, the new bioconjugate should be a candidate to continue with *in vivo* imaging of tumor models, through, e.g., a dorsal skinfold chamber where the first layers of tissue are significantly easier to access.

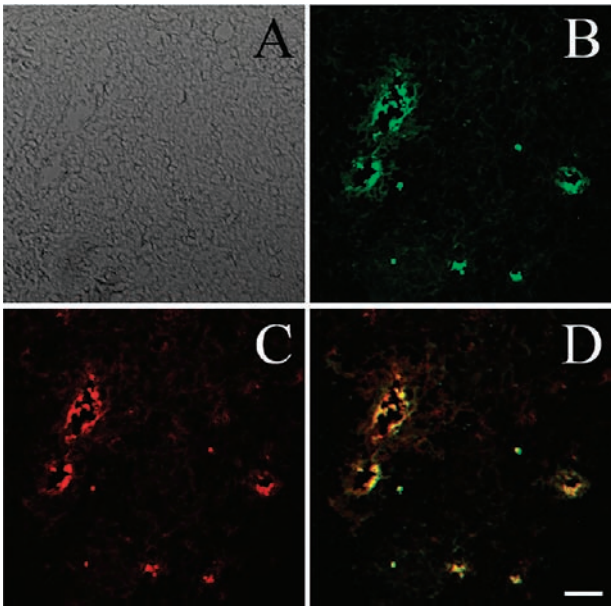

Figure 8. Micrographs of tissue sections (400 um thick) of tumors excised from a mouse injected with **B2**. The bright field image is shown in part A, and one-photon epifluorescence micrographs are shown parts B and C. An overlay of DC-101 bioconjugate **B2** (B) and Alexa Fluor 594-CD31 antibody conjugate (C) is shown in part D; colocalization confirms that probe **B2** targeted vasculature.

ASSOCIATED CONTENT

Supporting Information

^{1}H NMR and ^{13}C NMR data. Two-photon fluorescence micrographs of excised whole mount organs and glands of the mice that had been injected with bioconjuagte **B2** (negative control) and 2PFM of other negative controls are shown. A picture of the scanning process while taking a 2PFM micrograph is shown as is verification of the quadratic dependence of the microscope system for two-photon excitation, and a spectral scan vs solution emission spectrum of model probe **11**. This material is available free of charge via the Internet at http://pubs.acs.org.

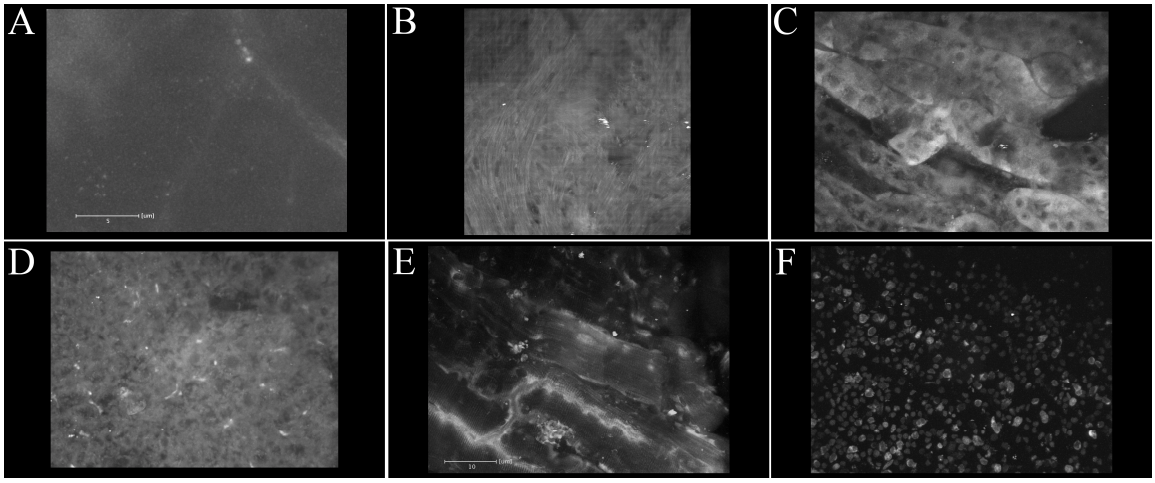

Figure S1. Two-photon fluorescence micrographs of excised whole mount organs and glands of the mice that had been injected with bioconjuagte **B2** (negative control)**.** Images were obtained from the Z-axis projection all X-Y plane optical sections of the organs**. A** brain; **B** heart; **C** kidney; **D** liver; **E** muscle; an **F** spleen. Micrographs were collected at 820 μm, 60 x. In these images mainly autofluorescence from native structures within each organ (elastin in muscle **E** and actin in the heart **B**, for example) or residual dye that was being excreted (kidney, **C**) was observed because very little to no conjugate resided in these organs (background was very modest). No vasculature formation was evidenced.

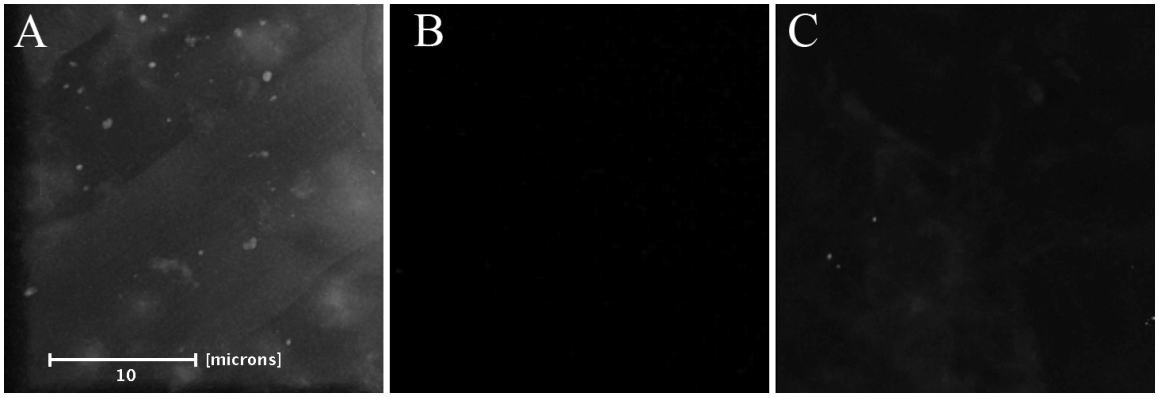

Figure S2. Whole mount tumor 2PFM micrographs of excised Lewis Lung Carcinoma excised tumors. Mice were tail vein injected 400 μg of IgG bioconjugate (**A** and **B**) or model dye **21** (**C**). Non specific fluorescence in **A** can be attributed to autofluorescence of the tissue and residual unbound dye.

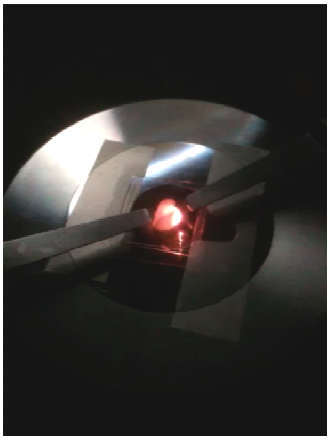

Figure S3. "Whole"-tumor mounted on microscope stage while being scanned by 810 nm, 200 fs excitation to excite the 2PA bioconjugate. In this inverted setup the tumor was immobilized between two cover slips and scanned layer by layer from below. Upconverted (two-photon induced) epifluorescence was collected either by a 10 or a 60x objective. 3-D reconstruction of the images was done in Amira 5.3 (Figure 7).

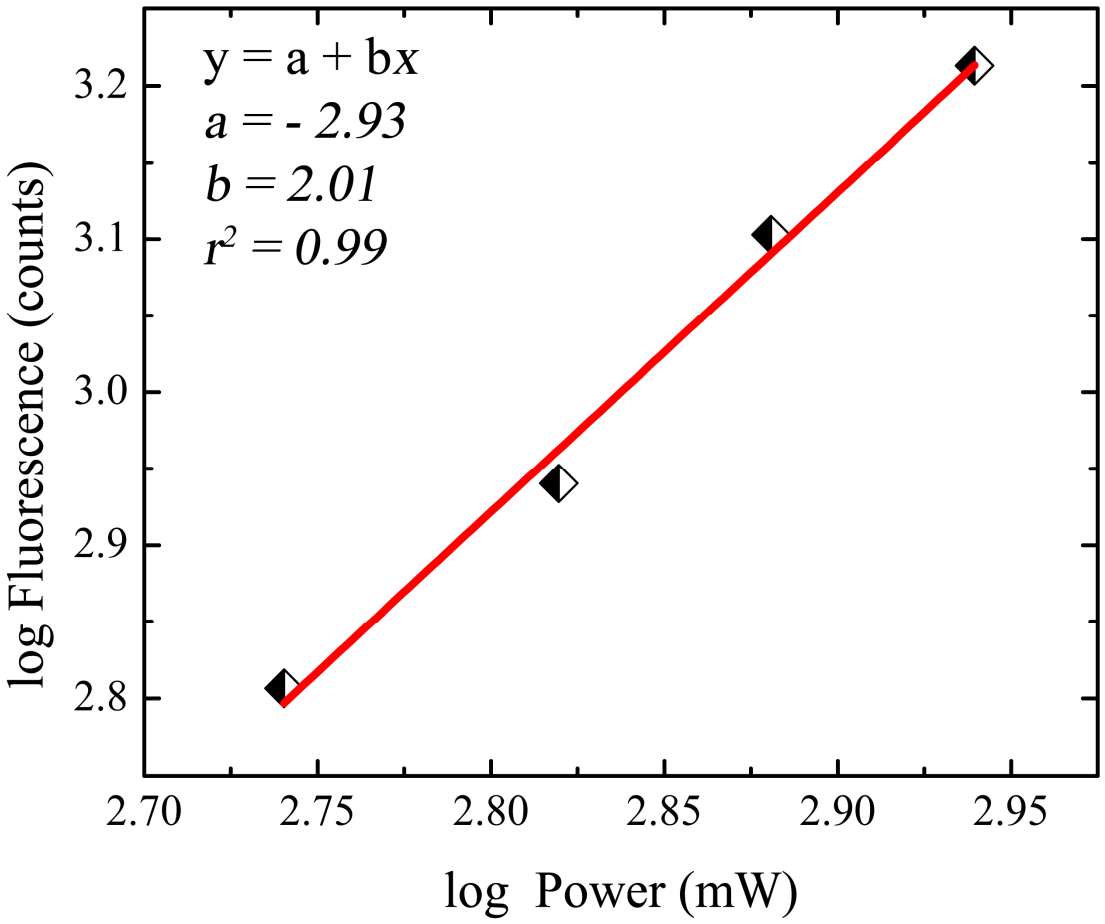

Figure S4. Quadratic dependence of the collected mean fluorescence on the average excitation. A solution of **11** in PMMA was excited at 815 nm at different powers.

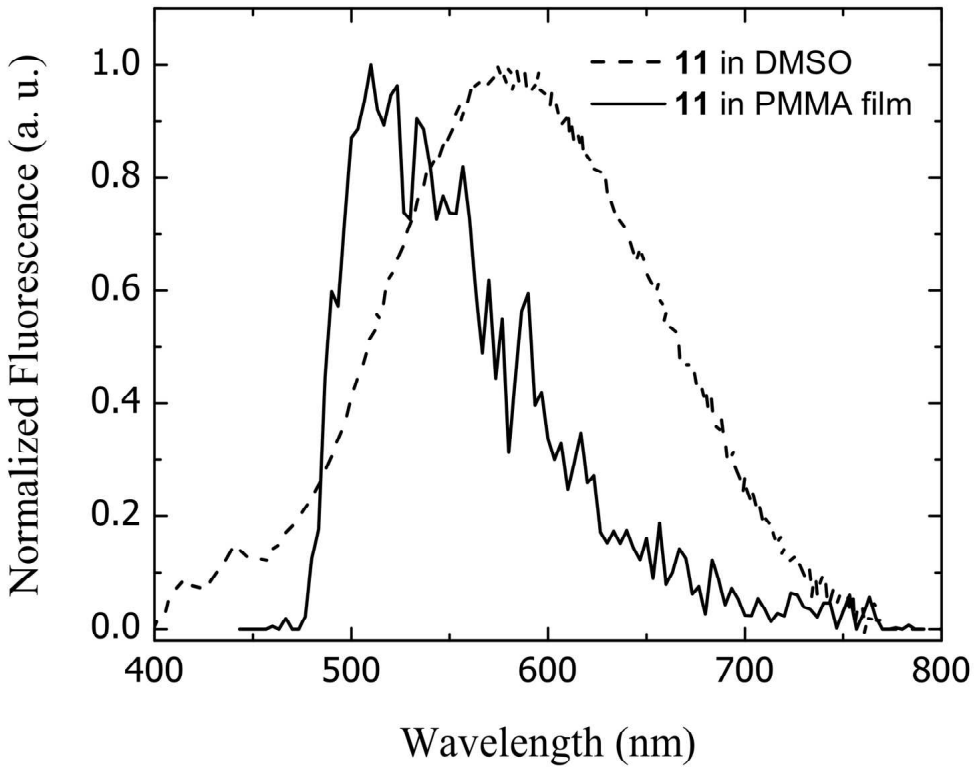

Figure S5. Emission spectra of bioconjugate **11** in DMSO (dashed line) and in a PMMA polymer film. The spectrum in DMSO solution was taken in a PTI spectrofluorimeter. The spectrum of **11** in the polymer film was taken on a Leica SP5 II equipped with a spectral scanner by taking a spectral scan of the region of interest (slit width 5 nm, step size 3 nm).

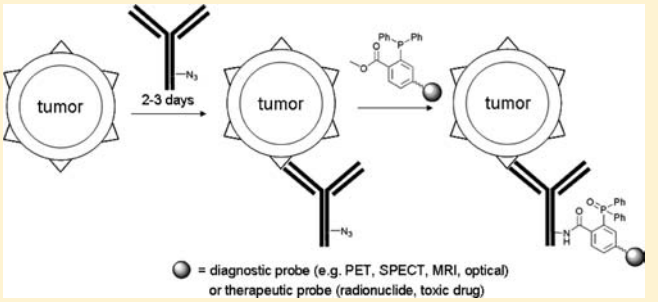
Supporting Information

ABSTRACT: The application of intact monoclonal antibodies (mAbs) as targeting agents in nuclear imaging and radioimmunotherapy is hampered by the slow pharmacokinetics of these molecules. Pretargeting with mAbs could be beneficial to reduce the radiation burden to the patient, while using the excellent targeting capacity of the mAbs. In this study, we evaluated the applicability of the Staudinger ligation as pretargeting strategy using an antibody−azide conjugate as tumor-targeting molecule in combination with a small phosphine-containing imaging/therapeutic probe. Up to 8 triazide molecules were attached to the antibody without seriously affecting its immunoreactivity, pharmacokinetics, and tumor uptake in tumor bearing nude mice. In addition, two ^{89}Zr- and $^{67/68}$Ga-labeled desferrioxamine (DFO)-phosphines, a ^{177}Lu-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA)-phosphine and a ^{123}I-cubyl phosphine probe were synthesized and characterized for their pharmacokinetic behavior in nude mice. With respect to the phosphine probes, blood levels at 30 min after injection were <5% injected dose per gram tissue, indicating rapid blood clearance. *In vitro* Staudinger ligation of 3.33 μM antibody−azide conjugate with 1 equiv of radiolabeled phosphine, relative to the azide, in aqueous solution resulted in 20−25% efficiency after 2 h. The presence of 37% human serum resulted in a reduced ligation efficiency (reduction max. 30% at 2 h), while the phosphines were still >80% intact. No *in vivo* Staudinger ligation was observed in a mouse model after injection of 500 μg antibody−azide, followed by 68 μg DFO-phosphine at t = 2 h, and evaluation in blood at t = 7 h. To explain negative results in mice, Staudinger ligation was performed *in vitro* in mouse serum. Under these conditions, a side product with the phosphine was formed and ligation efficiency was severely reduced. It is concluded that *in vivo* application of the Staudinger ligation in a pretargeting approach in mice is not feasible, since this ligation reaction is not bioorthogonal and efficient enough. Slow reaction kinetics will also severely restrict the applicability of Staudinger ligation in humans.



INTRODUCTION

Discovery of molecular targets on, e.g., cancer cells, has boosted the development of targeting agents. mAbs especially are gaining momentum for use in diagnosis and disease-selective therapy. At present, 5 mAbs have been approved by the FDA for diagnosis and 28 mAbs for therapy, either in naked form or conjugated to a toxic drug or radionuclide. Most of the approved therapeutic mAbs are intact immunoglobulins, and the majority are used for systemic treatment of cancer. In addition, hundreds of new mAbs are under development worldwide. Since intact mAbs have slow kinetics, it takes 3−6 days before optimal tumor-to-normal tissue ratios are obtained. When intact mAbs are used for nuclear imaging, imaging on the day of injection and at low radiation burden is virtually impossible, because low tumor uptake may be masked by high blood-pool activity. Furthermore, when mAbs are used for delivery of toxic agents like in radioimmunotherapy, highly radiosensitive bone marrow will be exposed continuously to a large fraction of the injected radioactivity resulting in dose-limiting myelosuppression. Clearly, achieving high tumor-to-blood ratios within a short time period after injection would provide benefit for both imaging and therapeutic applications. Strategies to prevent excessive exposure of normal tissues to toxin−mAb or radionuclide−mAb conjugates include the use of antibody fragments,[1] cleavable linkers,[2,3] local delivery,[4] antibody-directed enzyme prodrugs (ADEPT),[5] and pretargeting.[6−11] Several pretargeting approaches are under investigation: (strept)avidin−biotin,[12−14] hapten/antibody,[15] and DNA/DNA interactions.[16,17] All these pretargeting strategies

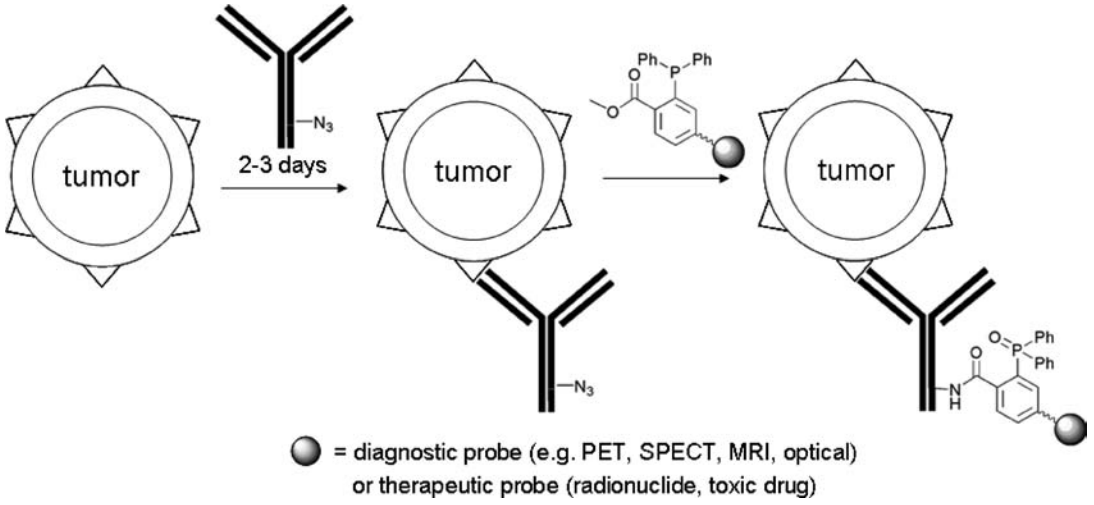
Scheme 1. Schematic Presentation of a mAb-Based Pretargeting Strategy Using the Staudinger Ligation



are based on biological interactions and suffer from several disadvantages, like the endogenous nature of the pretargeting ligand, the immunogenicity of the recognizing moiety, the large size of the recognizing moiety preventing fast imaging and effective therapy, and the weak binding of the interacting molecules. Using a covalent, nonbiological recognition system in a pretargeting approach could circumvent most of these drawbacks.

In the present study, we evaluated the possibility to use the Staudinger ligation[18−23] as the strategy for covalent conjugation in a pretargeting approach. The Staudinger ligation is a bioorthogonal reaction between a phosphine and an azide resulting in a covalent adduct with N_2 and methanol as byproducts. Next to the Staudinger ligation, other bioorthogonal reactions,[24−26] that might be applied in biological systems, are the ring-strain promoted azide−alkyne cycloaddition[27−30] and tetrazine ligation,[31−34] as published during the course of our studies.

To utilize the Staudinger ligation in a pretargeting strategy, a mAb needs to be functionalized with an azide handle. This azide handle should be relatively small and not alter the targeting properties of the mAb. The pretargeted mAb−azide will accumulate in target tissue by binding to a disease-specific antigen, while unbound mAb−azide will be cleared from the blood via the liver and spleen. Next, a small phosphine-containing diagnostic or therapeutic probe can be injected, which reacts covalently with the azide handle on the mAb (Scheme 1).

In this paper, we report on the coupling of triazide **1a** (Figure 1) to the anti-CD44v6 chimeric mAb (cmAb) U36 and the determination of the optimal triazide-to-mAb molar ratio for *in vivo* tumor targeting. To get a variety of imaging and therapeutic possibilities, DOTA and DFO-based phosphine derivatives were synthesized. DOTA can be used for labeling with Gd (MRI), ^{177}Lu (SPECT/therapeutic), ^{111}In (SPECT), ^{90}Y (therapeutic), and $^{67/68}$Ga (SPECT/PET) whereas DFO can be used for labeling with ^{89}Zr (PET), $^{67/68}$Ga, and ^{90}Nb (PET). In addition, an iodine-cubyl-phosphine was developed, which can be labeled with different PET, SPECT, or therapeutic iodine radionuclides. ^{89}Zr- and $^{67/68}$Ga-DFO-phosphines **2** and **3**, ^{177}Lu-DOTA-phosphine **4**, and ^{123}I-cubyl-phosphine **5** were prepared (Figure 1) and evaluated for their *in vitro* and *in vivo* ligation characteristics.

EXPERIMENTAL PROCEDURES

General Methods and Materials. The characteristics of the head and neck squamous cell carcinoma (HNSCC) cell lines HNX-OE and 11B, as well as the selection, production, and characterization of cmAb U36, have been described before.[35] cmAb U36 binds to the v6 region of CD44 (CD44v6), and is capable of selective tumor targeting of HNSCC as demonstrated in clinical trials.[36] ^{131}I (66.4 GBq/mL in 0.1 M NaOH) was obtained from Perkin-Elmer. The syntheses of triazide **1a** and phosphines **2**−**5** are described in the Supporting Information. Dialysis after reaction of triazide **1a** with cmAb U36 was performed with a Slide-a-Lyzer cassette from Pierce Biotechnology (cutoff 20 kDa) against PBS. mAb concentrations were measured by using the bicinchoninic acid (BCA) assay (Pierce) (UV-meter: Anthos 2001; data-analysis: Microwin) according to the suppliers instructions using naked cmAb U36 as a standard protein. HPLC analysis of antibody modification, ^{131}I-radiolabeled cmAb U36, antibody-Staudinger product stability, and *in vivo* Staudinger ligation were performed using a Jasco HPLC system equipped with a Superdex 200 10/30 GL size exclusion column (GE Healthcare Life sciences) using a mixture of 0.05 M sodium phosphate, 0.15 M sodium chloride (pH 6.8), and 0.01 M NaN_3 as the eluent at a flow rate of 0.5 mL/min. The radioactivity of the eluate was monitored using an inline NaI(Tl) radiodetector (Raytest Sockett). The ratios of triazide/cmAb U36 and phosphine/cmAb U36-triazide represent an average number of triazides or phosphines per mAb molecule, assuming Poisson distribution as generally observed in these types of mAb modifications.[37] Instant thin layer chromatography (iTLC) analysis of radiolabeled antibodies was carried out on silica impregnated glass fiber sheets (Pall Corp., East Hills, NY) using 20 mM citrate buffer (pH 5.0) as the mobile phase. Purification and isolation of ^{131}I-labeled cmAb U36-triazide conjugates and of cmAb U36-Staudinger product were performed with PD10 columns (GE Healthcare Life Sciences, NJ, USA). Gel electrophoresis was performed on a Phastgel system (Pharmacia Biotech, Amersham Biosciences) using preformed 7.5% SDS-PAGE gels under nonreducing conditions, followed by phosphor imager analysis (B&L-Isogen Service Laboratory). *In vitro* binding characteristics of the ^{131}I-cmAb U36-triazide conjugates were determined in an immunoreactivity assay essentially as described by Lindmo et al.,[38] using a serial dilution

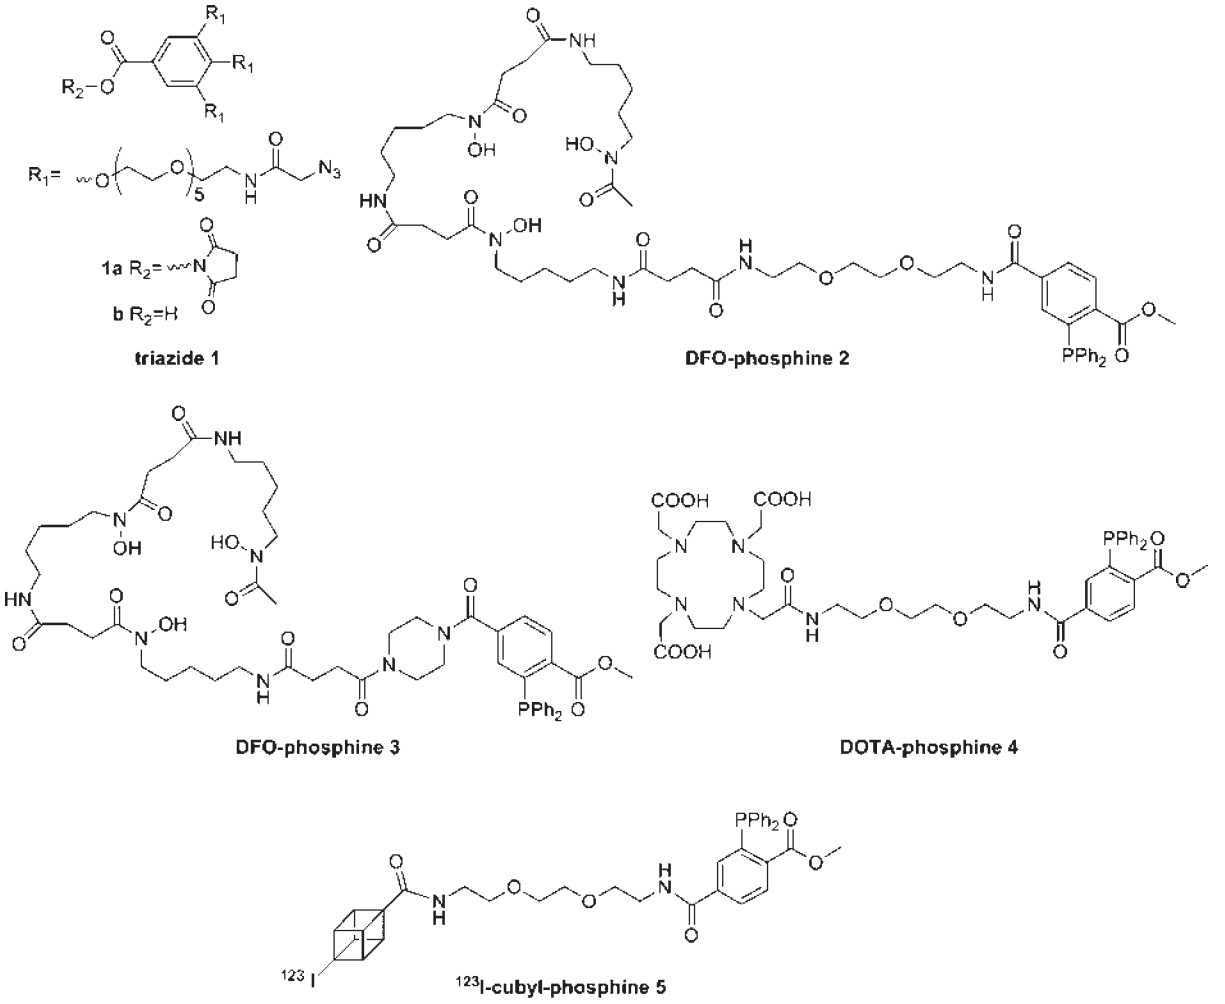


Figure 1. Selected pretargeting components for the Staudinger ligation as used in this study: triazide **1** for coupling to a mAb; DFO-phosphines **2** and **3** (for radiolabeling with ^{89}Zr and $^{67/68}$Ga), DOTA-phosphine **4** (for radiolabeling with ^{177}Lu), and ^{123}I-cubyl phosphine **5** as phosphine probes.

of 0.2% glutaraldehyde-fixed 11B cells and a fixed amount of ^{131}I-labeled cmAb U36-triazide conjugate (95 ng). After overnight incubation at 4 °C, the cell suspension was centrifuged and the specific binding calculated as the ratio of cell-bound radioactivity to the total amount of applied radioactivity. This was corrected for nonspecific binding, as determined with a 500-fold excess of non-radioactive U36-triazide. All binding assays were performed in triplicate. Single isotope counting was performed with a γ-well counter (Wallac LKB-CompuGamma 1282; Pharmacia) for ^{89}Zr, ^{67}Ga, ^{68}Ga, ^{123}I, ^{131}I, and ^{177}Lu.

cmAb U36 Modification with Triazide 1a and ^{131}I-Radiolabeling. cmAb U36 (4 mg; 11.53 mg/mL) was mixed with PBS (600 μL) and 1 M carbonate buffer pH 9.6 (30 μL) after which triazide **1a** (10, 15, 20, or 40 equiv) in DMF (20 μL) was added and incubated for 30 min at room temperature. The cmAb U36-triazide products were purified by dialysis until all unconjugated triazide was removed (assessed by HPLC-monitoring at 260 nm). After dialysis, the concentration of the cmAb U36-triazide product was determined by BCA assay. The average number of triazide molecules attached per mAb molecule was determined by HPLC using the UV absorption of triazide **1b** at 260 nm of the crude conjugation mixture. Next to the conjugation reaction, a mock reaction was performed without cmAb U36 resulting in fully hydrolyzed triazide **1b**. The difference in area corresponds to the amount of triazide **1** that was attached to cmAb U36 (see Supporting Information). ^{131}I-labeling of cmAb U36-triazide conjugates was done according to Tijink et al.[39] and is described in the Supporting Information. Radiochemical purity was determined by iTLC analysis, mAb integrity by HPLC and SDS-PAGE analysis followed by phosphor imaging, and immunoreactivity by a cell-binding assay.

Radiosynthesis of Phosphine Probes. Radiolabeling yield and percentage of oxidation were determined by HPLC analysis. The radiolabeling of the synthesized phosphine probes required extra precautions, because of the sensitivity of the phosphine for oxidation to phosphine oxide. Therefore, an appropriate antioxidant was used that did not affect the chelation itself. The preparation of ^{89}Zr- and $^{67/68}$Ga-DFO-phosphines **2** and **3**, ^{177}Lu-DOTA-phosphine **4**, and ^{123}I-cubyl-phosphine **5** are described in the Supporting Information.

Biodistribution of ^{131}I-cmAb U36-triazide Conjugates and Radiolabeled Phosphines 2−5. Radiolabeled cmAb U36-triazide conjugates were injected in nude mice bearing subcutaneously implanted xenografts of the tumor line HNX-OE, while radiolabeled phosphines were injected in tumor-free nude mice. Female mice (athymic nu/nu, 21−31 g; Harlan CPB), were 8−10 weeks old at the time of the experiment. All animal

experiments were performed according to National Institute of Health principles of laboratory animal care and Dutch national law ("Wet op de proefdieren". Stb 1985, 336). Five groups of four mice were injected via the retroorbital plexus with 185 kBq ^{131}I-cmAb U36-triazide conjugate (100 μg in 100 μL), in which the triazide was coupled to the cmAb at different molar ratios (triazide-to-mAb molar ratio 0, 4, 6, 8, and 15). The mean tumor size at start of the experiment was 104 ± 58 mm^3. Blood samples were taken at 5, 24, and 48 h post injection (p.i.). At 72 h p.i., the mice were anesthetized, bled, killed, and dissected. Blood, tumor, skin, tongue, sternum, heart, lung, liver, spleen, kidney, bladder, muscle, thighbone, colon (content), ileum (content), stomach (content), and thyroid were weighed and the amount of radioactivity in each tissue was assessed in a γ-well counter. Radioactivity uptake was calculated as the percentage of the injected dose per gram of tissue (%ID/g).

Six groups of four mice were injected intravenously (i.v.) via the tail vein with 0.4 MBq ^{89}Zr-DFO-phosphine **2** (1.52 μg, 1.3 nmol), 1.1 MBq ^{68}Ga-DFO-phosphine **2** (1.52 μg, 1.3 nmol), 0.4 MBq ^{89}Zr-DFO-phosphine **3** (1.52 μg, 1.4 nmol), 1.1 MBq ^{68}Ga-DFO-phosphine **3** (1.52 μg, 1.4 nmol), 0.4 MBq ^{177}Lu-DOTA phosphine **4** (1.50 μg, 1.7 nmol), or 0.8 MBq ^{123}I-cubyl-phosphine **5** (1.00 μg, 1.3 nmol). After 5, 10, 15, 30, 45, 60, and 90 min blood samples were taken and after 120 min, the mice were anesthetized, bled, killed, and dissected as described above.

***In Vitro* Staudinger Ligation.** Staudinger ligation efficiency was assessed by SDS-PAGE analysis of the reaction mixture followed by phosphor imager analysis. Equivalents of phosphine added for ligation were related to the reacting counterpart, the azide functionality. All Staudinger ligation experiments were performed with a cmAb U36-triazide conjugate containing on average 8 triazide **1** molecules (and thus 24 azide functionalities) and is further designated "cmAb U36-triazide". Standard reactions were performed with 1.67 nmol (0.25 mg, 40 nmol azide functionalities) cmAb U36-triazide and 1 equiv of phosphine (40 nmol, 44 μg) in 0.5 mL (6 v/v% ethanol) PBS at 37 °C for 2 h. The following characteristics were examined: (a) the *in vitro* stability of the phosphine probes **2** and **4** expressed as the chemical half-life; (b) the reactivity of phosphines **2** and **4** with cmAb U36-triazide in PBS; (c) the influence of the temperature on Staudinger ligation efficiency; and (d) the influence of the composition of the reaction medium on Staudinger ligation efficiency. The *in vitro* stability of the phosphine probes was examined by incubating 90 nmol/mL ^{89}Zr- or ^{67}Ga-DFO-phosphine **2** (10 MBq/mL) or ^{177}Lu-DOTA-phosphine **4** (7 MBq/mL) in PBS and in 10% or 37% freshly prepared human serum at 37 °C with 6 v/v% ethanol. At different time points (30, 75, and 120 min), aliquots were taken. Serum proteins were precipitated by the addition of a 2-fold excess (v/v) of acetonitrile, and after centrifugation, the supernatant was analyzed by radio-HPLC. The data obtained at 30, 75, and 120 min were plotted on a semi logarithmic scale, whereafter extrapolation to 50% decomposition gave the chemical half-life.

***In Vitro* Stability of cmAb U36-Staudinger Products.** For evaluation of the *in vitro* stability of the cmAb U36-Staudinger ligation products, samples containing 40 μg of the PD10 purified cmAb U36-Staudinger product, resulting from a reaction of cmAb U36-triazide with ^{89}Zr/^{67}Ga-DFO-phosphine **2** or ^{177}Lu-DOTA-phosphine **4**, were added to freshly prepared human serum, mouse serum or 0.9% NaCl (1:4 v/v dilution; sodium azide added to 0.02%) (n = 2). The samples were incubated at 37 °C in a CO_2-enriched atmosphere (5% CO_2). After 2, 24, and 48 h incubation, aliquots were taken and analyzed by radio-HPLC. Fractions of 0.5 mL were assessed for radioactivity in a γ-counter and used for determination of the recovery of the HPLC column.

***In Vivo* Staudinger Ligation.** Tumor-free nude mice were used for evaluation of *in vivo* Staudinger ligation in blood. By doing so, quantitative information about the ligation efficiency *in vivo* can easily be obtained. Three mice were injected with 500 μg cmAb U36-triazide (0.2 mL) via the retroorbital plexus followed by 68 μg ^{67}Ga-DFO-phosphine **2** two hours later via the tail vein. As control, three mice were injected only with 68 μg ^{67}Ga-DFO-phosphine **2**. At 5, 10, 15, 30, 60, and 90 min after injection of the phosphine probe, blood samples were taken; and after 5 h, the mice were anesthetized, bled, killed, and dissected as described above. Blood samples of 5 h p.i. of the phosphine were also analyzed by HPLC. To this end, the serum was separated from the blood by centrifugation and diluted to 25% serum with saline. HPLC-fractions of 0.5 mL were assessed for radioactivity in a γ-counter to determine whether *in vivo* Staudinger ligation had occurred.

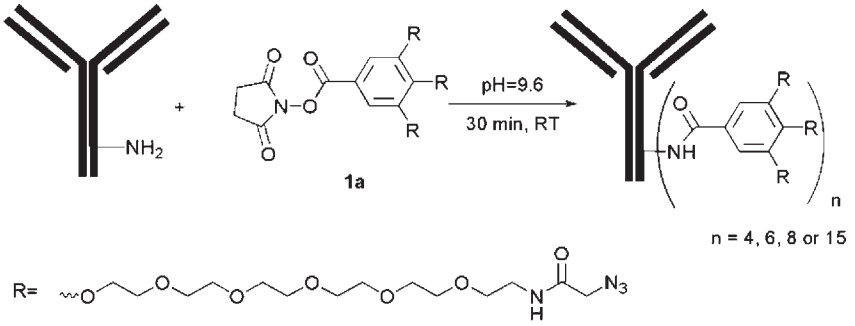
Statistical Analysis. All values are given as mean ± SD. Statistical analysis was performed on pharmacokinetics, tissue uptake, and tumor-to-blood ratios between different groups of mice with the Student's t-test (SPSS) for paired data. Two-sided significance levels were calculated and $p < 0.05$ was considered statistically significant.

RESULTS

Synthesis of ^{131}I-cmAb-Triazide Conjugates and Their Biodistribution. cmAb U36 was reacted with 10, 15, 20, or 40 equiv of triazide **1a** in order to determine the maximum loading of triazide to cmAb U36 without affecting its integrity, immunoreactivity, and *in vivo* targeting behavior (Scheme 2). The average number of triazide molecules attached to the antibody was determined by UV-HPLC and appeared to be 4, 6, 8, and 15, respectively, which means that, within the applied stoichiometry, the efficiency of modification was 37−42%. Subsequent radiolabeling of these conjugates with ^{131}I resulted in overall radiolabeling yields of >70% after purification. As a control, cmAb U36 without any triazide groups was also radiolabeled. The radiochemical purity of all 5 products was >99%, and there was a gradual decrease of the immunoreactivity upon increase of the substitution ratio from 91% (^{131}I-cmAb U36 without triazide) to 87%, 85%, 79%, and 46% for cmAb U36 containing, respectively, 4, 6, 8, and 15 triazide molecules. SDS-PAGE analysis (Figure 2) showed an increased percentage of apparent high molecular weight product at higher substitution ratio (20% for cmAb U36−15 triazide), while also a change in the apparent molecular weight of the monomeric cmAb U36 (normally ∼150 kDa) was observed.

For assessment of the optimal triazide-to-mAb molar ratio for *in vivo* tumor targeting, five groups of four mice were injected with ^{131}I-cmAb U36-triazide conjugate with, respectively, 0, 4, 6, 8, and 15 triazide molecules attached. At 5, 24, 48, and 72 h p.i., blood samples were drawn to determine the pharmacokinetics. The blood clearance of the different ^{131}I-labeled cmAb U36-triazide conjugates did not show distinctive differences (p > 0.05), albeit the conjugate with the highest triazide-to-cmAb U36 molar ratio (cmAb U36−15 triazide) tended to exhibit a faster blood clearance (Figure 3). At 72 h p.i. the %ID/g in tumor, blood, normal tissue, and gastrointestinal contents was

Scheme 2. Modification Reaction of cmAb U36 with Triazide 1a Resulting in cmAb U36-Triazide Conjugates with, Respectively, 0, 4, 6, 8, and 15 Triazide 1 Molecules Attached



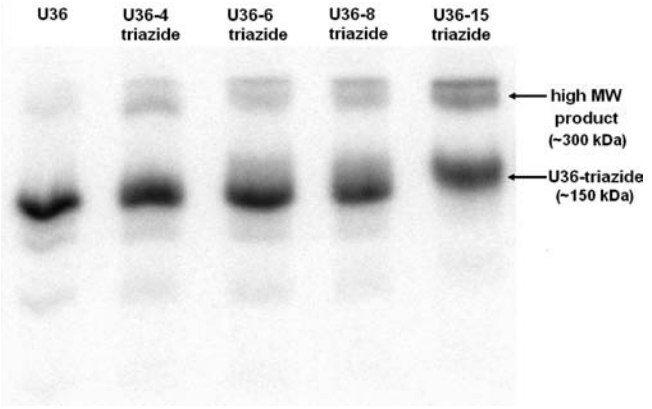


Figure 2. SDS-PAGE analysis of ^{131}I-cmAb U36-triazide conjugates with, respectively, 0, 4, 6, 8, and 15 triazide **1** molecules attached.

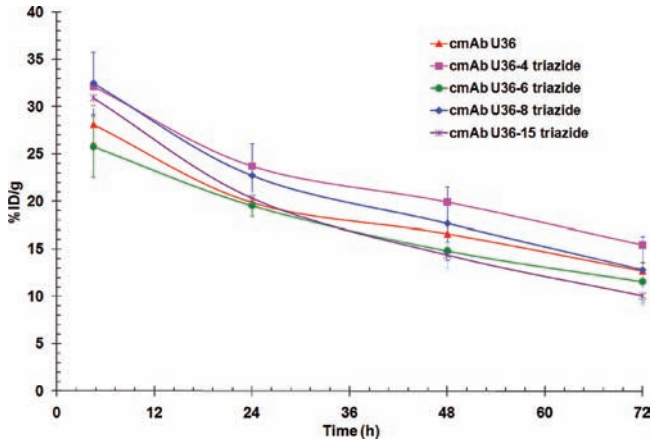

Figure 3. Pharmacokinetics of ^{131}I-cmAb U36-triazide conjugates containing, respectively, 0, 4, 6, 8, or 15 triazide **1** molecules in nude mice bearing HNX-OE tumors.

determined and depicted in Figure 4 for a selected panel of tissues. The tumor uptake of unconjugated ^{131}I-labeled cmAb U36 was 23.0 ± 3.5%ID/g, and was at the same level when 4 triazide groups were attached (23.1 ± 3.4%ID/g). However, tumor uptake tended to decrease at higher triazide-to-cmAb U36 molar ratio. A tumor uptake of 16.4 ± 3.7 and 18.7 ± 6.3%ID/g, respectively, was observed when 6 or 8 triazide groups were attached to cmAb U36. Tumor uptake of conjugates containing 15 triazide groups was 10.5 ± 1.9%ID/g, which is significantly lower than for all the other four conjugates ($p < 0.05$). No distinctive increased uptake in any of the normal organs was observed at higher triazide-to-cmAb U36 molar ratios. The ^{131}I-cmAb U36 conjugate with 15 triazide groups showed a significantly lower (1.05 ± 0.20) tumor-to-blood ratio than the other ^{131}I-cmAb U36-triazide conjugates (1.49 ± 0.24 to 1.81 ± 0.19) ($p < 0.05$). This parameter also indicates worse tumor targeting when too many triazide groups are attached to the mAb. The cmAb U36-triazide conjugate with 8 triazide groups was used in subsequent *in vitro* Staudinger ligation experiments and will be designated "cmAb U36-triazide" hereafter.

Biodistribution of Phosphine Probes. The pharmacokinetics and biodistribution of ^{89}Zr- and ^{68}Ga-DFO-phosphines **2** and **3**, ^{177}Lu-DOTA phosphine **4**, and ^{123}I-cubyl-phosphine **5** were examined in tumor-free nude mice. All six probes showed fast blood clearance, and after 30 min, less than 5%ID/g was still present in the blood (Figure 5). The phosphines are mainly excreted via the gastrointestinal and urinary tract with elevated uptake in liver (8.1 ± 1.8%ID/g) and spleen (3.2 ± 1.3%ID/g) for ^{177}Lu-DOTA phosphine **4**, and in kidney for ^{89}Zr-DFO-phosphine **2** (4.1 ± 0.6%ID/g), ^{89}Zr-DFO-phosphine **3** (2.0 ± 0.2%ID/g), and ^{177}Lu-DOTA-phosphine **4** (1.4 ± 0.2% ID/g) at 2 h p.i (Figure 6). The blood kinetics of ^{68}Ga-DFO-phosphine **2** and ^{68}Ga-DFO-phosphine **3** were comparable, while there was a difference between ^{89}Zr-DFO-phosphine **2** and ^{89}Zr-DFO-phosphine **3**, the latter clearing faster. ^{177}Lu-DOTA-phosphine **4** showed comparable blood kinetics to ^{89}Zr-DFO-phosphine **3**. ^{123}I-cubyl-phosphine **5** cleared significantly faster than the other probes and therefore this probe was not further evaluated in Staudinger ligation experiments.

Because the labeling of DFO-phosphine **3** resulted in a higher percentage of oxidation of the phosphine, it was decided to select DFO-phosphine **2** for Staudinger ligation experiments. For evaluation of the effect of the chelate on ligation efficiency, DOTA-phosphine **4** was also included.

***In Vitro* Staudinger Ligation in PBS.** The chemical half-life of ^{89}Zr- and ^{67}Ga-DFO-phosphines **2** and ^{177}Lu-DOTA-phosphine **4** in PBS in the absence of cmAb U36-triazide was examined at 37 °C. All three phosphines were only slowly oxidized in PBS with a chemical half-life of about 10 h. Staudinger ligation efficiency was investigated using cmAb U36-triazide in combination with each of the phosphine probes in aqueous solution. No significant difference in reactivity was observed for the three phosphines; Staudinger ligation efficiency was always between 20% and 25% after 2 h at 37 °C. The kinetics of

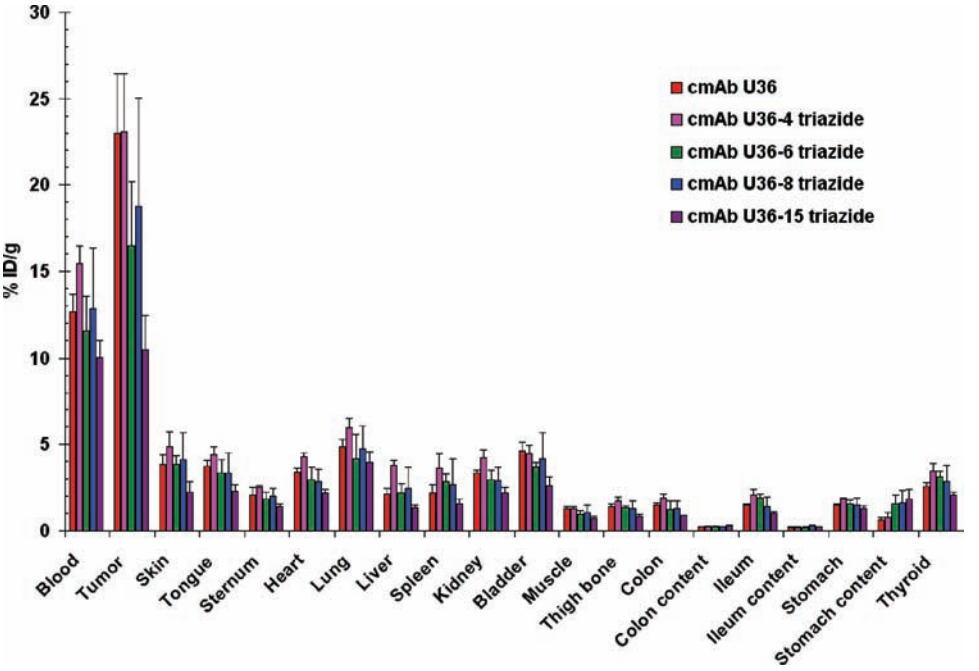

Figure 4. Biodistribution of ^{131}I-cmAb U36-triazide conjugates with, respectively, 0, 4, 6, 8, or 15 equiv of triazide **1** attached in nude mice bearing HNX-OE tumors at 72 h after injection.

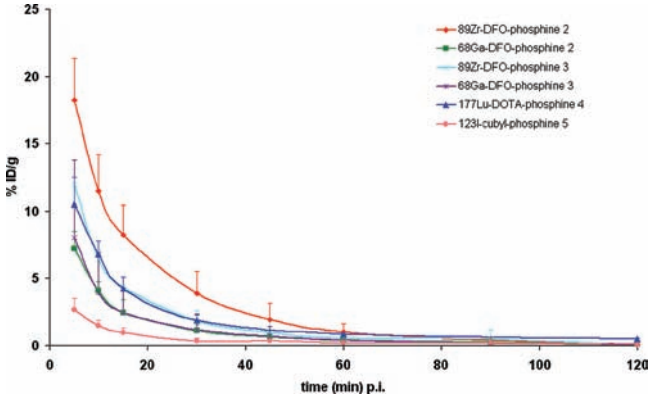

Figure 5. Pharmacokinetics of ^{89}Zr- and ^{68}Ga-DFO-phosphines **2**, ^{89}Zr- and ^{68}Ga-DFO-phosphine **3**, ^{177}Lu-DOTA phosphine **4**, and ^{123}I-cubylphosphine **5** in tumor-free nude mice.

the Staudinger ligation were determined with ^{67}Ga-DFO-phosphine **2** under standard conditions for shorter and longer periods. After 10 min, about 5% Staudinger ligation efficiency was observed, which increased to 32% after 5 h. Temperature dependency of the Staudinger ligation was examined with ^{177}Lu-DOTA phosphine **4** after 2 h incubation at 4 °C, room temperature, and 37 °C (standard temperature). The Staudinger ligation efficiency was found to be strongly temperature dependent, being 5% at 4 °C, 8% at room temperature, and 20% at 37 °C. Interestingly, when the reaction mixture contained 0.04% sodium dodecyl sulfate (SDS), the ligation efficiency was nearly twice as high (40−45% after 2 h at 37 °C).[24]

Once formed, the Staudinger products (^{89}Zr- and ^{67}Ga-DFO-Staudinger-cmAb U36 and ^{177}Lu-DOTA-Staudinger-cmAb U36) remained more than 93% intact upon 48 h incubation at 37 °C under the applied conditions (0.9% NaCl or 80% mouse or human serum). The ^{67}Ga-DFO-Staudinger cmAb-U36 product was the least stable in mouse serum (93% intact after 48 h incubation), while in human serum and 0.9% NaCl, the product was over 96% intact after 48 h incubation. The other two Staudinger ligation products were very stable in all three media for 48 h (>98% intact).

***In Vitro* Staudinger Ligation in Human Serum.** In the absence of cmAb U36-triazide, all three phosphine probes remained >90% intact in 10% human serum and >80% intact in 37% human serum after 2 h at 37 °C. Staudinger ligation took place in the presence of 10% and 37% human serum; however, the kinetics of all probes were slowed down with 30% compared with the reaction in PBS and with 50% for ^{89}Zr-DFO phosphine **2** in 37% human serum.

***In Vivo* Staudinger Ligation.** *In vivo* Staudinger ligation in blood of tumor-free mice was studied via the sequential administration of cmAb U36-triazide and ^{67}Ga-DFO-phosphine **2**. Blood kinetics and biodistribution of ^{67}Ga were not significantly different for mice which received cmAb U36-triazide plus phosphine in comparison with mice which did not receive cmAb U36-triazide, e.g., the blood levels at 5 h p.i. of the phosphine were 0.20 ± 0.04 vs 0.14 ± 0.05%ID/g. HPLC analysis of these blood samples did not reveal evidence for the presence of the cmAb U36-Staudinger product (Figure 7).

***In Vitro* Staudinger Ligation in Serum of Different Animal Species.** To explain the absence of Staudinger product formation in mice, *in vitro* Staudinger ligations experiments were performed in mouse serum and in serum of a panel of other animal species. ^{67}Ga-DFO-phosphine **2** was reacted with cmAb U36-triazide in 50% pig, goat, rabbit, human, and mouse serum for 2 h at 37 °C. In 50% mouse serum, Staudinger ligation was virtually absent (~95% reduction), and a side product was observed (Figure 8). The other sera did allow Staudinger ligation, although not as efficient as in PBS. Staudinger ligation in 50% human and goat

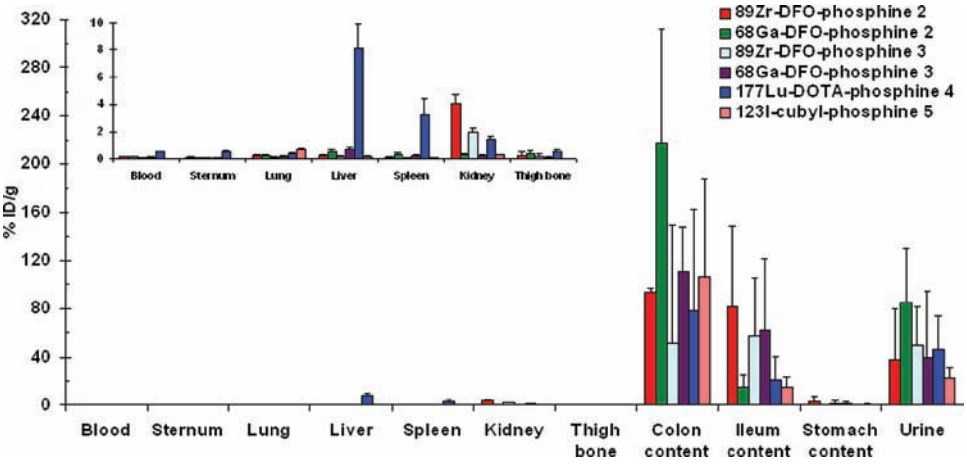

Figure 6. Biodistribution of ^{89}Zr-DFO-phosphine **2** (red bars), ^{68}Ga-DFO-phosphine **2** (green bars), ^{89}Zr-DFO-phosphine **3** (light blue bars), ^{68}Ga-DFO-phosphine **3** (purple bars), ^{177}Lu-DOTA-phosphine **4** (blue bars), and ^{123}I-cubyl-phosphine **5** (light salmon bars) in nude mice at 2 h after injection for a larger selection of tissues and a smaller selection of tissues (inset).

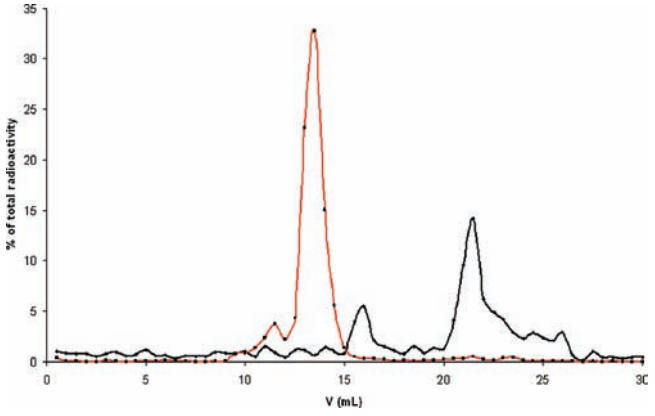

Figure 7. Representative HPLC diagram of mouse blood taken 5 h p.i. of the phosphine of a mouse that received cmAb U36-triazide and ^{67}Ga-DFO-phosphine **2** (black line). As a reference, the HPLC diagram of the *in vitro* prepared Staudinger product of this reaction is depicted (red line).

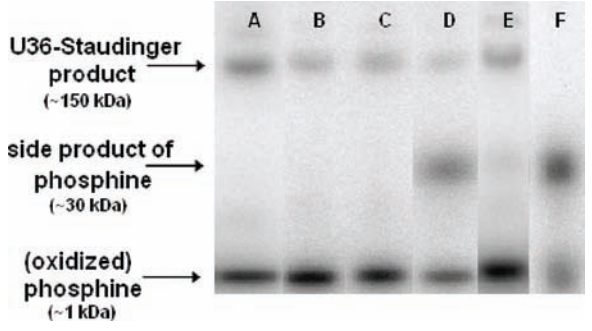

Figure 8. SDS-PAGE analysis of a Staudinger ligation reaction of cmAb U36-triazide with 1 equivalent of ^{67}Ga-DFO-phosphine **2** in the presence of 50% serum of different sources after 2 h at 37 °C: (A) PBS, no serum, (B) pig serum, (C) goat serum, (D) rabbit serum, (E) human serum, (F) mouse serum.

serum gave 30% reduction of ligation efficiency compared to PBS. Ligation efficiency in 50% pig and rabbit serum was, respectively, 50% and 75% reduced compared to PBS (Figure 8), the latter also showing the extra band on SDS-PAGE. Reduced ligation efficiency and the extra band were also observed when Staudinger ligation was performed in rat serum. Decreasing the percentage of mouse serum resulted in an increase in Staudinger ligation up to 4% efficiency in the presence of 37% mouse serum and 8% efficiency in 10% mouse serum. Reduced Staudinger ligation efficiency in mice was also observed when ^{177}Lu-DOTA-phosphine **4** instead of ^{67}Ga-DFO-phoshine **2** was used. In search for an explanation for the extra band on SDS-PAGE and the reduced Staudinger ligation efficiency in mouse serum, Staudinger ligation was also performed in the presence of mouse serum albumin. The ligation, however, was as efficient as in PBS. Dialysis of mouse serum before use (4.5 and 20 kDa cutoff) did not improve the low ligation efficiency and still gave the prominent extra band on SDS-PAGE. Finally, upon oxidation of the phosphine in advance, followed by incubation in mouse serum, no side product was observed by SDS-PAGE analysis.

DISCUSSION

The Staudinger ligation has until now been applied in the field of chemical biology and organic chemistry, but not in the field of radiochemistry nor in a pretargeting approach with mAbs. The Staudinger ligation is a bioorthogonal reaction, which implies that phosphine and azide react with each other and not with other bioavailable molecules in the body. Therefore, we investigated the applicability of this bioorthogonal reaction in a pretargeting concept with antibodies for tumor diagnosis and therapy. In the present paper, we developed the synthesis of mAb−azide conjugates and radiolabeled phosphines and evaluated their *in vivo* pharmacokinetic behavior as well as their *in vitro* and *in vivo* reactivity in Staudinger ligation.

cmAb U36 was chosen as the model mAb, because this mAb has shown high and selective tumor uptake in cancer patients. Moreover, cmAb U36 internalizes just to a limited extent, and this is expected to be a favorable characteristic for pretargeting. On the basis of the work of Bertozzi,[23] the amide containing azide **1a** was designed having a trivalent azide branch to increase the number of azides that are attached per lysine.[19,24] cmAb U36 was reacted with different amounts of triazide **1a** and subsequently radiolabeled with ^{131}I to evaluate the *in vivo* behavior. Since the

applied radiolabeling method does not impair the immunoreactivity and *in vivo* pharmacokinetic behavior of cmAb U36,[40] any change is caused by the number of triazide **1** groups that are attached to cmAb U36. A series of conjugates with, on average, 4, 6, 8, and 15 equiv of triazide **1** attached to cmAb U36 was produced (Scheme 2). The *in vitro* and *in vivo* evaluation revealed that up to 8 triazide **1** groups (24 azide functionalities) could be attached to cmAb U36 without substantially affecting the immunoreactivity, pharmacokinetics, tumor uptake, and tumor-to-blood ratio. These characteristics became clearly impaired, however, when 15 triazide **1** groups were coupled per mAb molecule, a phenomenon also observed earlier in the development of ^{186}Re-MAG3-labeled conjugates.[37]

Several radiolabeled phosphine probes were synthesized, differing in radioisotope, chelate, and linker. The major radiochemical challenge was the protection of the phosphine moiety against oxidation to phosphine oxide (see Supporting Information for experimental details). In the radiolabeling of DFO-phosphine **2** and **3** with ^{89}Zr, radiolytically formed oxidative species in the ^{89}Zr stock solution and in the reaction mixture needed to be scavenged. Sodium sulfite proved to be an excellent antioxidant. In this way, 45 μg/12 MBq/mL ^{89}Zr-DFO-phosphine **2** and **3** could be prepared with less than 10% oxidation caused by radiolabeling. Because ^{67}Ga was purified over a chromafix column just prior to use, the addition of an antioxidant was found to be unnecessary during the preparation of ^{67}Ga-DFO-phosphine **2**. However, for the *in vivo* experiment with a high dose ^{68}Ga-DFO-phosphine **2** and **3**, addition of an antioxidant to the reaction mixture appeared necessary. In this case, not sodium sulfite but a stannous sulfate containing gentisic acid solution proved adequate. A concentration of 270 μg/314 MBq/mL ^{68}Ga-DFO-phosphine **2** with 8% oxidation or ^{68}Ga-DFO-phosphine **3** with 13% oxidation could be prepared. Since addition of antioxidants like gentisic acid or ascorbic acid did not inhibit oxidation, the preparation of ^{177}Lu-DOTA phosphine **4** was restricted to the use of fresh ^{177}Lu and execution of the labeling at pH 8. In this way, oxidation caused by radiolabeling was limited to 15% and 91 μg/25 MBq/mL ^{177}Lu-DOTA-phosphine **4** could be prepared. ^{123}I-cubyl-phosphine **5** had to be synthesized from ^{123}I-cubyl carboxylic acid and linker−phosphine because direct labeling of a Br-analogue of **5** resulted in completely oxidized phosphine. Following this procedure, 95 μg/72 MBq/mL ^{123}I-cubyl-phosphine **5** could be prepared with less than 10% oxidation.

In vivo evaluation of the six radiolabeled phosphine probes revealed that blood clearance was very fast with a half-life time of less than 15 min. This means that the reaction of the phosphine probes with pretargeted mAb−triazide conjugate should be very fast for making Staudinger ligation an efficient option for *in vivo* pretargeting strategies.

The stability of ^{89}Zr- and ^{67}Ga-DFO-phosphine **2** and ^{177}Lu-DOTA-phosphine **4** in PBS was satisfactory, since the chemical half-life was about 10 h at 37 °C. However, their reactivity with cmAb U36-triazide was rather slow, taking the observed fast pharmacokinetics into account: after 2 h, Staudinger ligation efficiency was 20−25% at 37 °C, which means that per cmAb U36 molecule on average 5 to 6 out of 24 azide **1** groups have reacted. The presence of human serum did not affect the stability of the three probes, but their reactivity was reduced compared to PBS.

Although the circulation time of the probes was less than the reaction time *in vitro*, we speculated that it may still be enough to achieve conjugation *in vivo*. Therefore, we attempted to demonstrate *in vivo* Staudinger ligation in a pretargeting approach in tumor-free mice. HPLC analysis of the mouse blood revealed that the activity still present in the blood was not from cmAb U36-Staudinger product (Figure 7). To explain the complete absence of *in vivo* Staudinger ligation, we performed *in vitro* Staudinger ligation in mouse serum as well as in serum of other animal species. In the presence of mouse serum, the Staudinger ligation efficiency was severely reduced. SDS-PAGE analysis revealed that Staudinger ligation efficiency was primarily hampered by the formation of a side product. This side product was only formed when the phosphine was intact and not oxidized in advance. Identification of this side product was without success, and the molecular basis for the formation of this product is still not known. Apparently, larger molecules in mouse serum are involved, since in dialyzed mouse serum, the extra band on SDS-PAGE was still formed with concomitant reduction of Staudinger ligation efficiency. Tests in serum of other animals revealed that reduced Staudinger ligation efficiency and the formation of the extra band was not limited to mouse serum.

These results seem to be in contrast with those of the group of Bertozzi who reported on successful *in vivo* Staudinger ligation in mice.[20] In this study, azide groups were introduced on target cells by daily injection of the unnatural sugar peracetylated *N*-α-azidoacetylmannosamine (Ac_4ManNAz, 300 mg/kg) to mice for 7 days resulting in a total dose of about 52 mg azide per mouse (122 μmol), which is ∼3000 times more than we used in our research. Staudinger ligation in the splenocytes was confirmed by administration of 16 μmol phosphine-FLAG (∼300 times more than used here) 24 h after the last injection of Ac_4ManNAz. In this *in vivo* model system, in which pretargeting is not disease selective, the side reaction of the phosphine as we observed in mouse serum might be less dominant due to the very large amounts of azide and phosphine-FLAG used and the fact that intraperitoneal injections were applied. Therefore, in our opinion the results obtained in this way can not be directly translated to pretargeting approaches with mAbs.

Apart from not being bioorthogonal in rodents, chemical possibilities to increase the Staudinger ligation efficiency seem to be rather limited, and we have strong scientific doubts whether the Staudinger ligation can be made more efficient. Its kinetics are a function of subtle folding/defolding of the azide functionality at the mAb molecule and the accessibility and reactivity of the phosphorus atom within the triphenylphosphine methyl ester moiety. The mAb−triazide conjugate used was the best in the series of mono- to nonavalent azide, whereas removal of the amide next to the azide resulted in a 2-fold decrease of the efficiency (unpublished results). Variation around the phosphorus atom is very limited, since the triphenyl moiety is necessary for Staudinger ligation and to protect against oxidation of the phosphorus atom. And finally, introduction of an SDS moiety either in the triazide handle or in the phosphine probe is not expected to lead to a major breakthrough, because the observed increase in the presence of SDS in the reaction medium was only 2-fold. Therefore, we conclude that the Staudinger ligation is not the method of choice for pretargeting approaches in humans. We foresee that this also holds for the very recently reported so-called traceless Staudinger ligation.[41] This approach makes use of diphenylphosphines which are even more prone to oxidation than the triphenylphosphines used here for *in vivo* pretargeting. Possibly, the tetrazine ligation[34] is, because the reaction kinetics of this bioorthogonal reaction are reported to be at least 1000× faster than the Staudinger ligation.

General methods and materials

All starting reagents and solvents were obtained from commercial sources and used without further purification unless otherwise stated. N-succinyl desferrioxamine (N-suc-DFO) **15**[1], t-butyl-2-(2-(2-aminoethoxy)ethoxy)ethylcarbamate (**19**)[2] and 4-iodocubane carboxylic acid[3] have been prepared according to literature procedures. Compounds **6**, **8**, **9**, **10, 18**, **26** and **27** have been prepared and isolated in slightly modified procedures as compared to those described, avoiding large excesses of hexa-ethylene glycol for the preparation of **8,** avoiding higher temperatures wth NaN_3 in the synthesis of **9** and improving the yield in the preparation of **18**. Analytical data of **6**, **8**, **9**, **10**, **18**, **26** and **27** are in line with those reported. Water was distilled and deionized (18 $m\Omega cm^{-1}$) by means of a milli-Q water filtration system (Millipore, USA). The labeling buffers for ^{177}Lu labeling of DOTA-phosphine **4** were treated with Chelex-100 resin (BioRad Laboratories, USA) overnight.

^{1}H, ^{13}C, ^{19}F and ^{31}P nuclear magnetic resonance (NMR) spectra were recorded on a Bruker AC, a Bruker Avance 250 MHz, a Bruker MSL 400 MHz, a Bruker 500 MHz spectrometer, a Varian Mercury Vx 400 MHz or a Varian Gemini 300 MHz spectrometer, where spectra were recorded at a temperature of 25 °C. Chemical shifts (δ) are given in ppm, internally referenced to residual solvent resonances (^{1}H: δ = 7.29 ppm, ^{13}C: δ = 77.0 ppm). ATR-FT-IR characterizations were done on a PerkinElmer Spectrum One machine. Mass spectrometry on isolated compounds was done using a Voyager DE-PRO MALDI-TOF-MS spectrometer (Perceptive Biosystems, USA), usually applying positive and reflector mode conditions and using α-cyano hydroxy cinnamic acid (CHCA) as matrix material. LC-MS/PDA analysis on prepared materials was carried out using a LC-10AD (Shimadzu, Japan) in combination with a Surveyor LCQ Fleet MS-spectrometer and a Surveyor PDA-plus detector (Thermo Fisher Scientific Inc., USA), and applying an Alltech Alltima HP C18 3µ column (Grace Alltech, USA). High resolution mass spectra (HRMS, ESI) were recorded on a micrOTOF-Q spectrometer (Capillary voltage: -4500V; collision energy: 5eV).

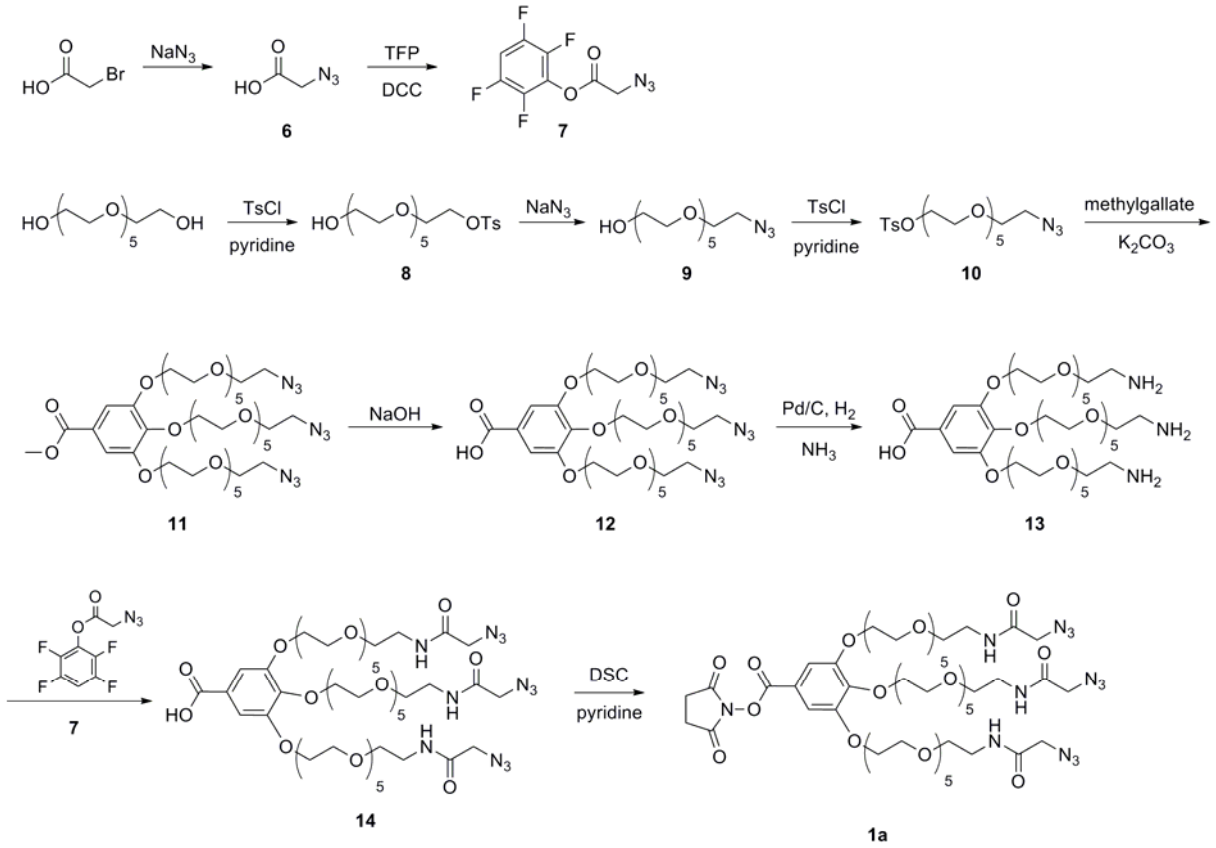
Column chromatography was performed with Baker 7024–02 silica gel (40 mm, 60 L) or Screening Devices 60Å silica gel or Merck standardized aluminum oxide 90. Thin-layer chromatography (TLC) was performed on Merck TLC-plates on aluminium sheets (Silica gel 60 F_{254} or neutral aluminium oxide 60 F_{254}) Compounds on the TLC plates were visualised by UV light. Preparative reversed phase (RP) chromatography was done on a Biotage SP1 flash purification system (Biotage AB, Sweden) using a SiliCycle C18 RP column (SiliCycle Inc., Canada) and applying linear gradients of MeCN in water.

HPLC analysis of the synthesis of phosphine **2** and **3** was done with a Chromspher 5 C18, 250x4.6 mm column (Varian) or a X-Terra MS C18 5 μm 3.9x150 mm column (Waters), using MeCN and 10 mM phosphate buffer (pH 6.0) as the eluent. The radioactivity of the eluate was monitored using an inline NaI radiodetector (Raytest Sockett). Sep-pak cartridges (Waters) were used to purify compound **16**, **22**, **24** and **30**.

^{177}Lu (9.25 GBq/mL in 0.05 M HCl) was obtained from Perkin-Elmer, ^{89}Zr (1 GBq/mL in 1 M oxalic acid) from IBA molecular, ^{67}Ga-citrate (74 MBq/mL) from Covidien, ^{68}Ga from a ^{68}Ge/^{68}Ga generator from Eckert & Ziegler Isotope Products, and ^{123}I (50 GBq/mL in 0.01M NaOH) from Cyclotron BV.

HPLC analysis of radiolabeled phosphines **2**, **3** and **4** was done with a Chromspher 5 C18, 250x4.6 mm column (Varian) or a X-Terra MS C18 5 μm 3.9x150 mm column (Waters), using MeCN and 10 mM phosphate buffer (pH 6.0) as the eluent for $^{67/68}$Ga-DFO-phosphine **2** and **3** and ^{177}Lu-DOTA-phosphine **4**, and MeCN and 50 mM phosphate buffer (pH 3.25) for ^{89}Zr-DFO-phosphine **2** and **3**. HPLC analysis of ^{123}I-cubyl-phopshine **5** was done with a Chromasil 100 C18 column (Phenomenex) using EtOH and water or MeCN, water and diisopropylamine as eluent. The radioactivity of the eluate was monitored using an inline NaI(Tl) radiodetector (Raytest Sockett). Light C18 sep-pak cartridges (Waters) were used to isolate ^{89}Zr-DFO-phosphine **2** and **3** from the labeling mixture. Single isotope counting was performed with a γ-well counter (Wallac LKB-CompuGamma 1282; Pharmacia) for ^{89}Zr, ^{67}Ga, ^{68}Ga, ^{123}I and ^{177}Lu.

Synthesis of azide **1a**



Scheme S1 Synthesis of azide **1a**

2-Azidoacetic acid (6)[4]

Bromo acetic acid (6.3 g; 45 mmol) was dissolved in dimethyl sulfoxide (DMSO) (15 mL) and NaN_3 was added in portions (3.6 g, 55 mmol) under stirring and cooling with an ice bath. After 10 min, the resulting gel was broken-up by adding DMSO (15 mL) and by vigorous stirring. The mixture was stirred overnight at room temperature (RT), then 1 M NaOH was added to increase the pH (>10), and the mixture was again stirred overnight. Water (300 mL) was added, the reaction mixture was acidified to pH<2 with 1 M HCl and was then extracted with diethyl ether (150 mL) (ethyl acetate is also possible[4], but we have observed that in time acid **6** gives transesterification in this solvent). The combined ether layer was washed with 1 M HCl (75 mL) and dried with Na_2SO_4. Addition of toluene and removal of the diethyl ether resulted in 26.7 g (87%) of a 15% (w/w) solution of **6** in toluene. A sample of the ether solution was evaporated down for analysis. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 10.7 (bs, 1H, COO<u>H</u>), 4.0 (s, 2H, C<u>H</u>$_2$N$_3$) ppm; ^{13}C-NMR ($CDCl_3$): δ = 174.4, 50.0 ppm.

2,3,5,6-Tetrafluorophenyl 2-azidoacetate (7)

A toluene solution of **6** (0.97 g of solute, 9.6 mmol), 2,3,5,6-tetrafluorophenol (TFP) (1.84 g, 11.1 mmol) in $CHCl_3$ (3 mL), and pyridinium p-toluene sulfonic acid (0.24 g; 0.96 mmol) were stirred at RT in a water bath. A solution of N,N'-dicyclohexylcarbodiimide (DCC) (2.34 g, 11.4 mmol) in $CHCl_3$ (3 mL) was added dropwise and the reaction mixture was stirred overnight under a N_2 atmosphere. The solvent was removed, MeCN (25 mL) was added and the resulting white suspension was stirred overnight at 4 °C. After filtration, solvent evaporation and silica column chromatography with a $CHCl_3$/heptane gradient, 1.6 g (67%) of pure product **7** was obtained. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.09–7.03 (m, 1H, Ph-H), 4.28 (s, 2H, CH_2N_3) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 164.5, 146.0 (d, ***J*** (FC) = 252 Hz), 140.4 (d, ***J*** (FC) = 234 Hz), 129.1, 103.9 (t, ***J*** (FC) = 22.8 Hz), 49.7 ppm; ^{19}F-NMR (375 MHz, $CDCl_3$): δ = -138.3, -152.7 ppm; ATR-FT-IR: ν = 2109 1797, 1645, 1523 cm^{-1}.

2-(2-(2-(2-(2-(2-Hydroxyethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethyl p-tosylate (8)[5,6]

Tosyl chloride (18.0 g, 94.5 mmol) was added in portions to a stirred and ice-cooled solution of hexaethylene glycol (25.4 g, 90.0 mmol) in dry pyridine (35 mL). The mixture was stirred overnight under an argon atmosphere at 4 °C, then crushed ice and 10 M HCl (45 mL) were added, and the mixture was extracted with $CHCl_3$ (200 mL). The combined organic layer was washed with water (75 mL), dried with Na_2SO_4 and concentrated in vacuo to yield an oil containing mono- and difunctionalized hexaethylene glycol. Purification was performed on a silica column using a $CHCl_3$/MeOH gradient resulting in an oil. Yield: 16.5 g (42 %). ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.79 (d, 2H, ***J*** = 8.7 Hz, Ph-H), 7.36 (d, 2H, ***J*** = 8.7 Hz, Ph-H), 4.18 (t, 2H, ***J*** = 4.7 Hz, CH_2OTs), 3.72–3.53 (m, 22H, OCH_2), 2.89 (bs, 1H, OH), 2.43 (s, 3H, Ph-CH_3) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 144.6, 132.8, 129.7, 127.8, 72.3, 70.5-70.1, 69.1, 68.5, 61.5, 21.4 ppm.

2-(2-(2-(2-(2-(2-Hydroxyethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethyl azide (9)[5,6]

The tosylate **8** (16.5 g, 37.8 mmol), NaN_3 (3.5 g, 53.8 mmol) and dry DMSO (20 mL) were stirred at RT under an argon atmosphere for 3 days. Water (50 mL) and a few mL of a saturated $NaHCO_3$ solution were added to the reaction mixture and the aqueous solution was extracted with $CHCl_3$ (100 mL). The combined organic layer was washed with water (50 mL), dried with Na_2SO_4 and concentrated in vacuo to yield 11.1 g of oily product (95%). ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 3.72–3.53 (m, 22H, OCH_2), 3.39 (t, 2H, ***J*** = 4.9 Hz, CH_2N_3), 2.78 (bs,

1H, O<u>H</u>) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 72.4, 70.5-69.9, 61.6, 50.6 ppm; ATR-FT-IR: ν = 2101 cm^{-1}.

2-(2-(2-(2-(2-(2-Azido ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethyl p-tosylate (10)[5,6]

Tosyl chloride (5.5g, 28.8 mmol) was added in portions to a stirred and ice-cooled solution of **9** (7.5 g; 24.4 mmol) in dry pyridine (10 mL). The mixture was stirred overnight under an argon atmosphere at 4 °C, then iced water (100 mL) was added and the mixture was stirred for 5-10 min. A 10 M HCl solution (10 mL) was added, and the aqueous solution was extracted with $CHCl_3$ (100 mL). The combined organic layer was washed with acidic water (1 M HCl, 75 mL), dried with Na_2SO_4 and concentrated in vacuo to give **10** (10.4 g, 92%) as a clear yellowish oil. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.80 (d, 2H, ***J*** = 8.7 Hz, Ph-<u>H</u>), 7.36 (t, 2H, ***J*** = 8.7 Hz, Ph-<u>H</u>), 4.16 (t, 2H, ***J*** = 4.7 Hz, C<u>H</u>$_2$OTs), 3.70–3.56 (m, 20H, OC<u>H</u>$_2$), 3.38 (t, 2H, ***J*** = 5.0 Hz, C<u>H</u>$_2$N$_3$), 2.43 (s, 3H, Ph-C<u>H</u>$_3$) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 144.6, 132.8, 129.7, 127.8, 70.5-70.3, 69.8, 69.1, 68.5, 50.5, 21.5 ppm.

Methyl-3,4,5-tris[2-(2-(2-(2-(2-(2-azidoethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy]-benzoate (11)

The tosylate **10** (10.4 g, 22.5 mmol), methyl gallate (1.24 g, 6.75 mmol), K_2CO_3 (9.2 g, 67 mmol), tetrabutyl ammonium bromide (70 mg) and dimethyl formamide (DMF) (67 mL) were heated overnight under argon atmosphere at 65 °C. The product was isolated by pouring the resulting suspension into a citric acid solution (1 M, 200 mL) and extracting the aqueous solution with several portions of $CHCl_3$ (300 mL). The combined organic layer was concentrated in vacuo and co-evaporated with toluene to give 9.6 g of a crude brown oil. Silica column chromatography with a dimethoxyethane/heptane gradient afforded **11** in quantitative yield (7.0 g). The product contained a small amount of alcohol **9** that was formed due to hydrolysis of the tosylate **10**. This contaminant was not removed from the mixture after this step, but after the next. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.31 (s, 2H, Ph-<u>H</u>), 4.24–4.16 (m, 6H, PhOC<u>H</u>$_2$), 3.88 (s, 3H, COOC<u>H</u>$_3$), 3.85 (t, 4H, ***J*** = 4.9 Hz, PhOCH$_2$C<u>H</u>$_2$), 3.79 (t, 2H, ***J*** = 4.9 Hz, PhOCH$_2$C<u>H</u>$_2$), 3.74–3.60 (m, 54H, C<u>H</u>$_2$O), 3.38 (t, 6H, ***J*** = 5.2 Hz, C<u>H</u>$_2$N$_3$) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 166.4, 152.1, 142.4, 124.8, 108.9, 72.2, 70.6-70.3, 69.8, 69.4, 68.7, 52.0, 50.5 ppm.

3,4,5-Tris[2-(2-(2-(2-(2-(2-azidoethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy]-benzoic acid (12)

The methyl ester **11** (2.1 g, 2.0 mmol) and NaOH (120 mg, 3.0 mmol) were stirred overnight at RT in a 8/1 MeOH/H_2O (10 mL) solution. MeOH was evaporated, the solution acidified with 1 M HCl (5 mL) and the product was extracted in $CHCl_3$ (25 mL). Drying with Na_2SO_4 and concentration in vacuo of the solution yielded 1.8 g of crude product that was purified over an alumina column (to remove the contaminant **9**), by applying an eluent mixture of $CHCl_3$/MeOH/H_2O 6/3/1. The fractions containing the product were pooled and concentrated. The oily residue was dissolved in $CHCl_3$ and the resulting solution was washed with a 1 M HCl solution (10 mL). Evaporation of the $CHCl_3$ yielded the product **12** as an oil (1.9 g, 91%). ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.39 (s, 2H, Ph-H), 4.27–4.17 (m, 6H, PhOCH_2), 3.86 (t, 4H, ***J*** = 5.0 Hz, PhOCH_2CH_2), 3.79 (t, 2H, ***J*** = 5.1 Hz, PhOCH_2CH_2), 3.75–3.60 (m, 54H, CH_2O), 3.38 (t, 6H, ***J*** = 5.1 Hz, C$H_2$$N_3$) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 169.5, 152.0, 142.6, 124.7, 109.2, 72.2, 70.5, 70.4-70.3, 69.7, 69.4, 68.6, 50.4 ppm; ATR-FT-IR: ν = 2100, 1713, 1586 cm^{-1}. MALDI-TOF-MS: $[M+Na]^+$ = 1060.3.

3,4,5-Tris[2-(2-(2-(2-(2-(2-aminoethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy]-benzoic acid (13)

A solution of the acid **12** (200 mg) in dioxane (5 mL) and 28% ammonia in water (2 mL) was placed under an N_2 atmosphere. Pd/C (10%, ca. 20 mg) was added and the mixture was then shaken under a H_2 pressure of 50 psi until FT-IR analysis showed the absence of azide groups. The Pd/C was filtered off and the filtrate was concentrated to produce **13** as an oil (100 % yield). This was used in the next synthetic step without further purification. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.36 (s, 2H, Ph-H), 4.3 (bs, 6H, NH_2), 4.25 (t, 4H, ***J*** = 5.0 Hz, PhOCH_2), 4.19 (t, 2H, ***J*** = 5.1 Hz, PhOCH_2), 3.85 (t, 4H, ***J*** = 5.0 Hz, PhOCH_2CH_2), 3.79 (t, 2H, ***J*** = 5.1 Hz, PhOCH_2CH_2), 3.75–3.60 (m, 54H, CH_2O), 2.99 (t, 4H, ***J*** = 5.2 Hz, C$H_2$$NH_2$), 2.95 (t, 2H, ***J*** = 5.2 Hz, C$H_2$$NH_2$) ppm.

3,4,5-Tris[2-(2-(2-(2-(2-(2-(2-azidoacetamido)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy]-benzoic acid (14)

The activated ester **7** (200 mg, 0.80 mmol) was added to a solution of **13** (185 mg, 0.19 mmol) and diisopropylethylamine (DIPEA) (250 mg) in $CHCl_3$ (3 mL). The reaction mixture was stirred overnight at RT and was then washed with 1 M HCl (2 mL). The solvent was evaporated and the residue was purified by RP-chromatography applying a SiliCycle C18 RP

column. The oily product **14** was isolated in 95% yield. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.35 (s, 2H, Ph-H), 7.00 (bs, 2H, NH), 6.95 (bs, 1H, NH), 4.27–4.17 (m, 6H, $PhOCH_2$), 3.95 (s, 6H, CH_2N_3), 3.85 (t, 4H, ***J*** = 5.0 Hz, $PhOCH_2CH_2$), 3.79 (t, 2H, ***J*** = 5.1 Hz, $PhOCH_2CH_2$), 3.75–3.60 (m, 54H, CH_2O), 3.45 (t, 6H, ***J*** = 5.1 Hz, CH_2NH) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 168.4, 167.1, 167.0, 152.1, 142.7, 124.7, 109.5, 72.3, 70.7, 70.5-70.3, 70.1, 69.6, 69.4, 68.8, 52.4, 39.1 ppm; ATR-FT-IR: ν = 2102, 1678 cm^{-1}; LC-MS: $[M+H]^+$ = 1209.3, $[M+2H]^{2+}$ = 605.50.

Succinimidyl 3,4,5-tris[2-(2-(2-(2-(2-(2-azidoacetamido)-ethoxy)-ethoxy)-ethoxy)-ethoxy)-ethoxy] benzoate (1a)

The acid **14** (250 mg; 0.21 mmol) and N,N'-disuccinimidyl carbonate (DSC) (75 mg; 0.29 mmol) were dissolved in MeCN (4 mL) and few drops of pyridine. After overnight stirring, a second portion of DSC (35 mg; 0.14 mmol) was added, and the mixture was stirred for 2 h more. At completion of the reaction, as confirmed by ^{1}H-NMR analysis, the solvent was evaporated and $CHCl_3$ (10 mL) was added. The organic solution was washed with an ice-cold aqueous solution of diluted HCl and NaCl (10 mL), dried with Na_2SO_4 and concentrated to give a turbid oil. Dissolution in 1/1 $CHCl_3$/diethyl ether, filtration and concentration of the filtrate in vacuo gave a quantitative amount of product **1a**. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 7.39 (s, 2H, Ph-H), 6.94 (bs, 3H, NH), 4.26 (t, 2H, ***J*** = 5.0 Hz, $PhOCH_2$), 4.20 (t, 4H, ***J*** = 4.9 Hz, $PhOCH_2$), 3.96 (s, 6H, CH_2N_3), 3.86 (t, 4H, ***J*** = 4.9 Hz, $PhOCH_2CH_2$), 3.79 (t, 2H, ***J*** = 4.8 Hz, $PhOCH_2CH_2$), 3.73–3.67 (m, 6H, CH_2O), 3.67–3.55 (m, 42H, CH_2O), 3.59 (t, 6H, ***J*** = 4.9 Hz, CH_2O), 3.48 (q, 6H, ***J*** = 5.3 Hz, CH_2NH), 2.91 (bs, 4H, CH_2CO) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 169.2, 166.9, 161.2, 152.4, 144.2, 119.3, 109.9, 72.4, 70.6, 70.5-70.3, 70.1, 69.4, 69.3, 68.9, 52.3, 39.1, 25.5 ppm; ATR-FT-IR: ν = 2103, 1738 cm^{-1}; MALDI-TOF-MS: $[M+Na]^+$ = 1328.6.

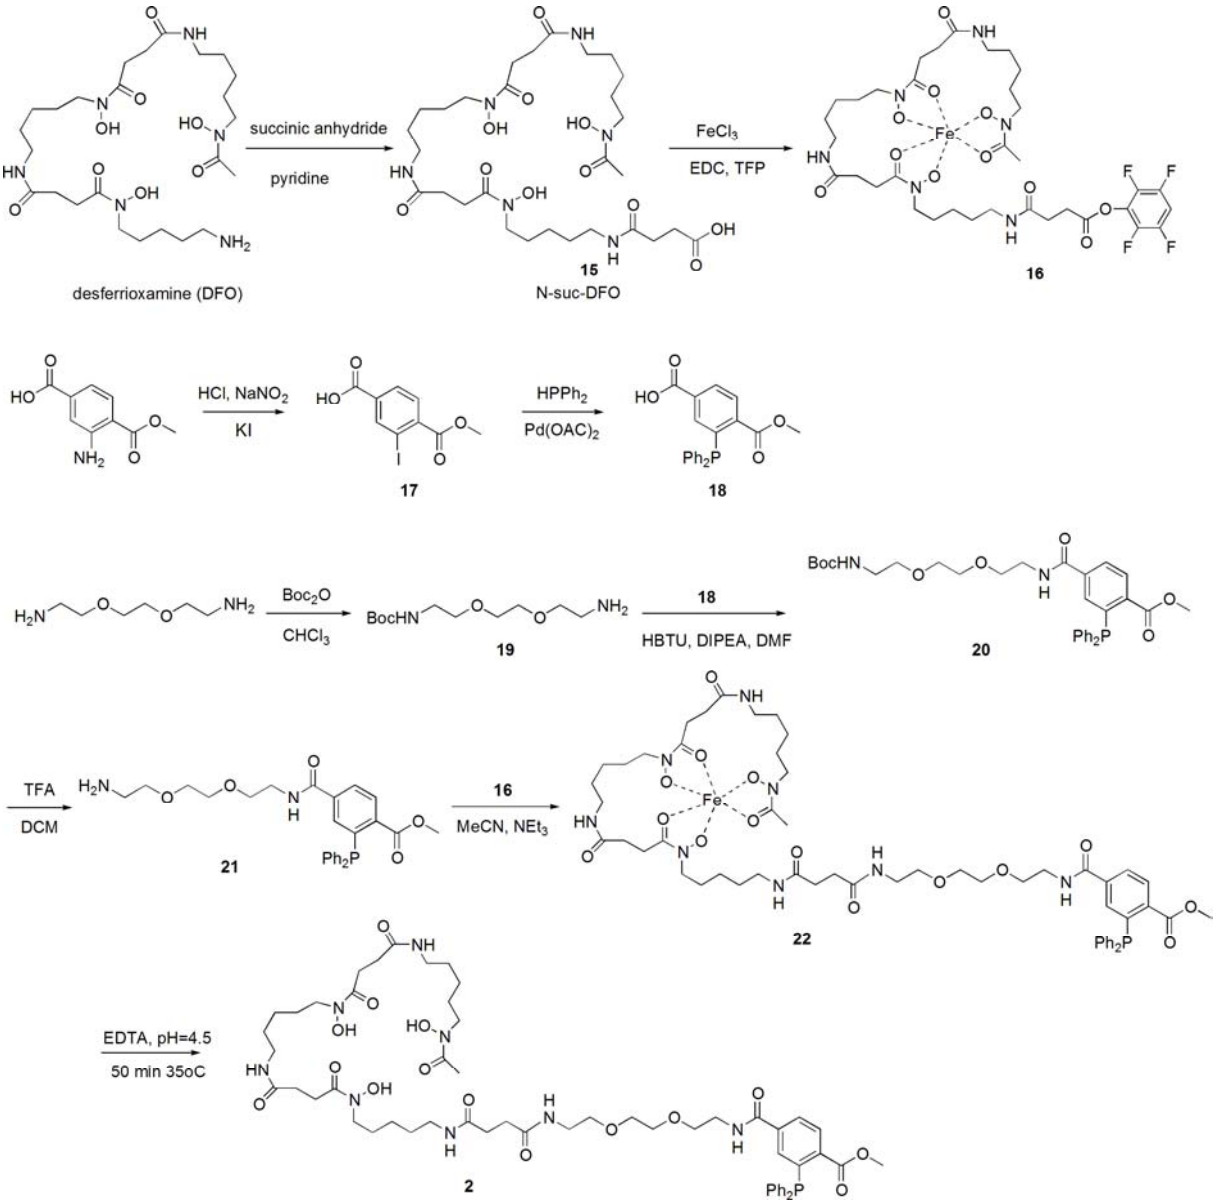
cmAb U36 modification with triazide **1a**

cmAb U36 (MW ~ 150 kDa, 4 mg, 27 nmol) was reacted with 10, 15, 20 and 40 equivalents (270, 405, 540 and 1080 nmol) of triazide **1a** (dissolved in DMF, max. 20 μL) in 1 mL total volume for 30 minutes. In parallel a mock reaction was performed with triazide **1a** without cmAb U36 resulting in fully hydrolyzed triazide **1b**. For determination of the average number of triazide **1** molecules attached per mAb molecule, the crude reaction mixtures were injected on HPLC equipped with a Superdex^{TM} 200 10/30 GL size exclusion column (GE healthcare Life sciences) using a mixture of 0.05 M sodium phosphate, 0.15 M sodium chloride (pH 6.8) and 0.01 M NaN_3 as the eluent at a flow rate of 0.5 mL/min. The retention times of the cmAb U36 was 25.6 min, of the hydrolyzed azide **1b** 40.1 min and of NHS 42.6 min. In the mock reaction the area of the hydrolyzed triazide **1b** at 40.1 min corresponded to the amount of triazide used in the reaction. In the modification reaction the area of the hydrolyzed triazide **1b** at 40.1 min corresponded to the amount of triazide that had not reacted. The percentage of triazide that had reacted, was be calculated for the difference of the hydrolyzed triazide between mock reaction and modification reaction.

^{131}I-labeling of cmAb U36-triazide compounds.

In short: 20 mL β-scintillation vials were coated with 25 μg iodogen (Pierce, Rockford, IL, USA) in dichloromethane, dried under a stream of N_2 gas, resulting in a thin coating of iodogen at the bottom surface of the vial. The vials were stored under N_2 atmosphere. To a iodogen-coated glass vial, successively 50 μL 0.5 M NaH_2PO_4 (pH 7.4), 450-X-Y μL 0.1 M Na_2HPO_4 (pH 6.8), X μL U36 and Y μL ^{131}I solution were added. After gentle shaking for 5 min, 0.1 mL ascorbic acid (25 mg/mL, pH 5) was added to reduce the iodogen, the SCl bonds and to protect cmAb U36 against radiation damage. After an additional 5 min, the reaction mixture was transferred to a syringe connected to a filter (0.22 μm Acrodisc, Gelman Sciences, Ann Arbor, MI, USA) followed by 0.4 mL 0.1 M Na_2HPO_4 (pH 6.8), used for an additional rinsing of the vial. This combined solution was filtered and purified on a PD10 column with 0.9% NaCl/ascorbic acid (5 mg/mL, pH 5) as eluent.

Synthesis of DFO-phosphine **2**



Scheme S2 Synthesis of DFO-phosphine **2**

TFP-N-suc-DFO-Fe ester (16)[1]

A stock solution of $FeCl_3$ (80 µL of 400 mg/mL in 0.5 M HCl, 32 mg, 0.20 mmol) was added dropwise to a solution of ***N*-suc-DFO** **15** (120 mg, 0.18 mmol) in 0.1 M Na_2CO_3 (2.64 mL) and 0.9 % NaCl (2.31 mL) while shaking. After 10 min 0.9 % NaCl (5 mL), MeCN (1.8 mL) and TFP solution (0.20 mL of 2 g/mL in MeCN, 0.40 g, 1.73 mmol) were added. Subsequently a first portion of 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) (0.50 g, 2.61 mmol) was added and incubated for 15 min, followed by a second portion of EDC (0.50 g, 2.61 mmol) and again incubated for 15 min. The resulting dark red solution was trapped on 2 double C18 sep-pak cartridges. The double sep-pak cartridges were washed with

60 mL H_2O each and subsequently eluted with 2 times 1.5 mL MeCN. Yield: 81% (estimated with HPLC at 430 nm).

1-Methyl-2-iodo-terephthalate (17)[7]

Hydrochloric acid (37%, 200 mL) was cooled on an ice bath, and 1-methyl-2-amino terephthalate was added. A solution of $NaNO_2$ (7.20 g; 0.104 mol) in 40 mL of H_2O was added dropwise, resulting in the evolution of a small amount of orange gas. The mixture was stirred for 30 min at 20°C and then filtered through a glass filter. The filtrate was subsequently added to a solution of potassium iodide (172 g; 1.04 mol) in H_2O (280 mL). The dark red solution was stirred for 1 h and then diluted with dichloromethane (DCM) (2 L) and washed with sat. Na_2SO_3 (2 times 400 mL), H_2O (800 mL), and sat. NaCl (400 mL). The combined aqueous layer was back extracted with DCM (500 mL). The combined organic layer was dried over Na_2SO_4 and concentrated in vacuo. The crude product was dissolved in hot MeOH (60 mL) and H_2O (20 mL) was added. Cooling to 4 °C and subsequent filtration afforded **17** as a bright yellow solid (18.92 g; 62%), mp=165-166°C. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 11.4 (br.s, 1H, O<u>H</u>), 8.69 (d, 1H, ***J*** = 1.6 Hz, Ph-<u>H</u> (H6)), 8.11 (dd, 1H, ***J*** = 1.6 Hz, J = 8.0 Hz, Ph-<u>H</u> (H4)), 7.83 (dd, 1H, ***J*** = 1.6 Hz, ***J*** = 8.0 Hz, Ph-<u>H</u> (H3)), 3.97 (s, 3H, C<u>H</u>$_3$) ppm; ^{13}C-NMR (400 MHz, $CDCl_3$): δ = 169.9, 166.5, 142.6, 140.1, 132.5, 130.5, 129.4, 93.4, 52.9 ppm; FT-IR (ATR): ν = 2957, 2845, 2646, 2535, 1737, 1693, 1552, 1480, 1417, 1248, 742 cm^{-1}.

1-Methyl-2-diphenylphosphino-terephthalate (18)[7]

To a flame dried flask was added MeCN (30 mL), NEt_3 (5.32 g; 52.3 mmol), compound **17** (3.06 g; 10.0 mmol) and palladium acetate (42 mg; 0.2 mmol). The mixture was degassed in vacuo. While stirring under an atmosphere of argon, diphenylphosphine (2.16 g; 11.6 mmol) was added to the flask via a syringe. The resulting solution was heated at 80°C for 3 d, and then allowed to cool to RT and concentrated in vacuo. The residue was dissolved in DCM (175 mL), washed with H_2O (175 mL), and 1 M hydrochloric acid (2 times 50 mL), and concentrated in vacuo. The crude product was dissolved in hot MeOH (100 mL) and cooled to 4°C. Filtration afforded the phosphine product as a golden yellow solid (2.87 g; 78%), mp=206°C. ^{1}H-NMR (400 MHz, $CDCl_3$): δ = 10.8 (br.s, 1H, O<u>H</u>), 8.07–8.00 (m, 2H, <u>H4 and H6</u>), 7.67 (d, ***J*** = 4.0 Hz, 1H, <u>H3</u>), 7.37-7.25 (m, 10H, Ph-<u>H</u>), 3.75 (s, 3H, C<u>H</u>$_3$) ppm; ^{13}C-NMR (100 MHz, $CDCl_3$): δ = 170.6, 166.7, 141.5 (d, ***J*** (PC) = 29.5 Hz), 138.9 (d, J (PC) =

19.1 Hz), 136.9 (d, ***J*** (PC) = 10.0 Hz), 135.6, 133.8 (d, ***J*** (PC) = 10.0 Hz), 131.9, 130.6, 129.7, 129.0, 128.7 (d, ***J*** (PC) = 7.1 Hz), 52.4 ppm; ^{31}P-NMR (80 MHz, $CDCl_3$): δ = -4.04 ppm; FT-IR (ATR): ν 2952, 2846, 2536, 1726, 1686, 1434, 1262, 1244, 1106, 1057, 743 cm^{-1}.

Phosphine 21

2-(1H-Benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU) (1.04 g; 2.74 mmol) was dissolved in dry (DMF) (12 mL) and DIPEA (0.96 mL; 5.48 mmol) and phosphine **18** (1.0 g; 2.74 mmol) were added. The mixture was stirred under argon at RT for 10 min, after which a solution of **19** (0.75 g; 3.0 mmol) in DMF (2.5 mL) was added. The mixture was stirred for 2 h and subsequently diluted with diethyl ether (165 mL), and washed with saturated $NaHCO_3$ (3 times 110 mL) and 0.1 M HCl (110 mL). The organic layer was dried with Na_2SO_4 and concentrated in vacuo to yield phosphine **20** as a yellow foam. This yellow foam was dissolved in DCM (7.5 mL) and trifluoroacetic acid (TFA) (7.5 mL) and stirred for 2 h at RT. The mixture was concentrated in vacuo and redissolved in DCM (37 mL). This organic solution was washed with saturated Na_2CO_3 (75 mL) and the aqueous layer was back extracted with DCM (20 mL). The combined organic solution was dried with Na_2SO_4 and concentrated in vacuo to yield a yellow oil. This crude product was purified by silica column chromatography using a gradient of $CHCl_3$/MeOH/NEt_3 of 100/1/0.1 to 10/1/0.1. Yield: 1.17 g (86 % over two steps). ^{1}H-NMR (200 MHz, $CDCl_3$): δ = 8.00 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 1.6 Hz, Ph-H), 7.78 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 3.6 Hz, Ph-H), 7.05–7.34 (m, 11H, Ph-H), 3.66 (s, 3H, CO_2CH_3), 3.41–3.52 (m, 10H, CH_2), 2.79 (t, 2H, ***J*** = 5 Hz, CH_2NH_2) ppm; ^{31}P-NMR (101 MHz, $CDCl_3$): δ = -3.7 ppm; HRMS (ESI): m/z = 495.2022 [M^+], calc. for $C_{27}H_{32}N_2O_5P$ = 495.2043.

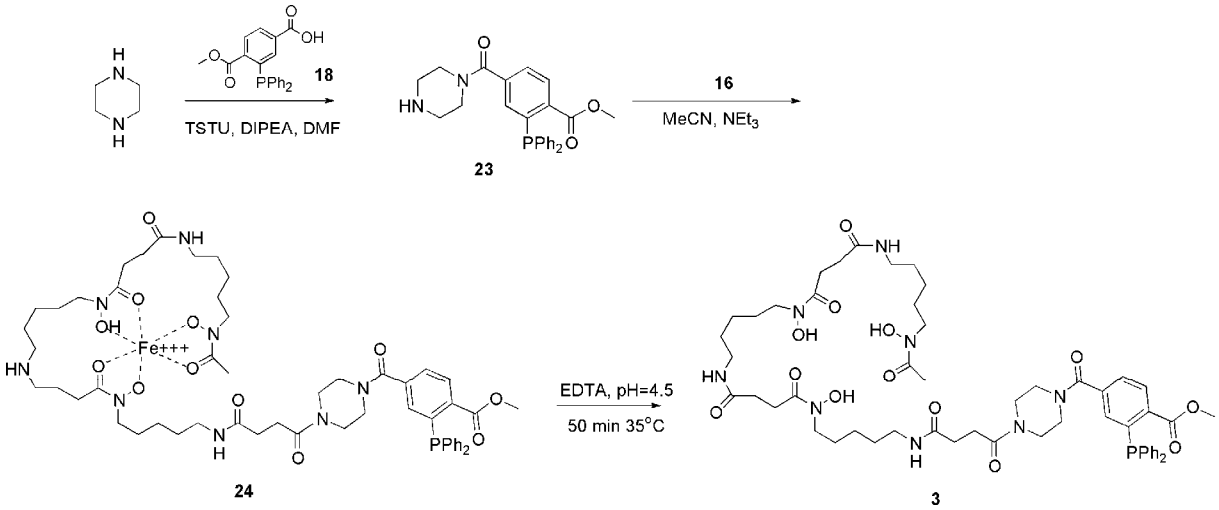
Fe-DFO-phosphine 22

To a solution of TFP-***N***-suc-DFO-Fe ester **16** (103 mg, 0.12 mmol) in MeCN (4 mL) were added 3 eq. of NEt_3 (51 µL, 0.36 mmol) and 1 eq. of phosphine **21** (60 mg, 0.12 mmol) in MeCN (3 mL). The resulting solution was stirred overnight at RT, subsequently concentrated in vacuo and dissolved in 10% MeCN in H_2O and trapped on 2 sep-pak cartridges (C18). The sep-pak cartridges were washed with 60 mL H_2O and eluted with 5 mL MeCN. Yield: quantitative.

DFO-phosphine 2

To a solution of Fe-DFO-phosphine **22** (142 mg; 0.12 mmol) in MeCN (8 mL) was added ethylenediaminetetraacetic acid (EDTA) (75 mL of 25 mg/mL), H_2SO_4 solution (18.75 mL of pH=4.5) and MeCN (17 mL). The solution was heated at 35°C for 50 min. A white precipitate was formed during Fe^{3+} removal. This white precipitate was separated from the aqueous phase by centrifugation and washed with H_2SO_4 solution (pH=4.5, 20 mL) and H_2O (20 mL), followed by lyophilization. Yield: quantitative. Purity: >95 % according to HPLC. ^{1}H-NMR (500.23 MHz, DMSO): δ = 9.62 (s, 3H), 8.62 (dd, 1H, ***J*** = 5.5Hz, J= 5.5Hz), 8.01 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 1.5 Hz), 7.90 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 1.5 Hz), 7.86 (dd, 1H, ***J*** = 5.5 Hz, ***J*** = 5.5 Hz), 7.79–7.77 (m, 3H), 7.57–7.54 (m, 1H), 7.44–7.36 (m, 7H), 7.22–7.18 (m, 4H), 3.65 (s, 3H), 3.43–3.39 (m, 12H), 3.37–3.33 (m, 4H), 3.16–3.14 (m, 2H), 3.00–2.98 (m, 6H), 2.59–2.56 (m, 4H), 2.28–2.25 (m, 8H), 1.96 (s, 3H), 1.51–1.47 (m, 6H), 1.39–1.35 (m, 6H), 1.22–1.20 (m, 6H) ppm; ^{13}C-NMR (125.78 MHz, DMSO): δ = 172.0, 171.5, 171.3, 171.1, 170.1, 166.3, 165.3, 139.8 (d, ***J*** (PC) = 28.9 Hz), 137.2, 137.0 (d, ***J*** (PC) = 12.6 Hz), 136.3 (d, ***J*** (PC) = 20.1 Hz), 133.5 (d, ***J*** (PC) = 21.4 Hz), 133.2, 130.1, 129.0, 128.7 (d, ***J*** (PC) = 7.5 Hz), 126.8, 69.5, 69.1, 68.7, 52.1, 47.0, 46.7, 38.4, 30.7, 29.9, 28.8, 27.6, 26.0, 23.5, 20.4 ppm; ^{31}P-NMR (161.97 MHz, $CDCl_3$): δ = -5.3 ppm; HRMS (ESI): m/z = 1137.5580 [M^+], calc. for $C_{56}H_{82}N_8O_{15}P$ = 1137.5632.

Synthesis of DFO-phosphine **3**



Scheme S3 Synthesis of DFO-phosphine **3**

Piperazine-phosphine 23

TSTU (110 mg, 0.37 mmol) was dissolved in dry DMF (1.15 mL) and DIPEA (96 µl, 0.55 mmol) and phosphine **18** (99 mg, 0.27 mmol) were added. The mixture was stirred under argon at RT for 10 minutes, and then a solution of piperazine (86 mg, 1 mmol) in 1.5 mL dry DMF was added. The mixture was stirred for 2 h, subsequently diluted with diethyl ether (20 mL) and washed with saturated $NaHCO_3$ (3 times 20 mL) and 0.1 M HCl (20 mL). To the aqueous layer was added ammonium hydroxide in water resulting in a basic layer, which was extracted with diethyl ether (25 mL). The combined organic layers were dried with Na_2SO_4 and concentrated in vacuo to yield the crude product. The crude product was purified with column chromatography with $CHCl_3$/MeOH/NEt_3 50/1/0.01 resulting in a slightly yellow solid. Yield: 73 mg (63 %). ^{1}H-NMR (500.23 MHz, $CDCl_3$): δ = 8.10 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 3.5 Hz, Ph-H); 7.54 (dd, 1H, ***J*** = 2.0 Hz, ***J*** = 8.0 Hz, Ph-H), 7.37–7.31 (m, 6H, Ph-H), 7.28–7.24 (m, 4H, Ph-H), 6.89–6.88 (m, 1H, Ph-H), 3.75 (s, 3H, CH_3), 3.65 (s, 2H, CH_2), 3.11 (s, 2H, CH_2), 2.85 (s, 2H, CH_2), 2.52 (s, 2H, CH_2) ppm; ^{13}C-NMR (125.8 MHz, $CDCl_3$) δ = 169.0, 166.6, 140.9 (d, ***J*** (PC) = 29.6 Hz), 138.4, 137.1 (d, ***J*** (PC) = 11.1 Hz), 135.4 (d, ***J*** (PC) = 19.2 Hz), 133.8 (d, ***J*** (PC) = 21.0 Hz), 132.4, 131.2 (d, ***J*** (PC) = 2.4 Hz), 129.0, 128.7 (d, ***J*** (PC) = 7.2 Hz), 127.6, 52.3, 48.1, 45.8, 45.4, 42.6 ppm; ^{31}P-NMR (101.25 MHz, $CDCl_3$): δ = -4.1 ppm; HRMS (ESI): m/z = 433.1687 [M^+], calc. for $C_{25}H_{26}N_2O_3P$ = 433. 1676.

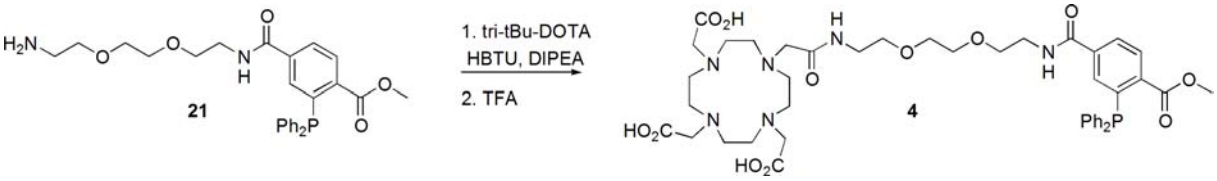
Fe-DFO-piperazine-phosphine 24

To a solution of TFP-***N***-suc-DFO-Fe ester (**16**) (107 mg, 127 µmol) in 4.3 mL MeCN was added 3 eq. NEt_3 (53.3 µL, 0.38 mmol) and 1 eq. piperazine-phosphine **23** (54.7 mg, 127 µmol) in 1 mL MeCN. The resulting solution was stirred overnight at RT, subsequently concentrated in vacuo and diluted to 10% MeCN in water by the addition of 48 mL water and trapped on 2 sep-pak cartridges (C18). The sep-pak cartridges were washed with 60 mL water and eluted with 5 mL MeCN. Yield: quantitative

DFO-phosphine 3

To a solution of Fe-DFO-piperazine-phosphine **24** in MeCN (127 µmol, 12.4 mL) were added 73.8 mL EDTA (25 mg/mL), 18.45 mL H_2SO_4 buffer (pH=4.5) and 12.4 mL MeCN. The solution was heated at 35 °C for 50 minutes. The solution was extracted with DCM (3 times 120 mL) and dried with Na_2SO_4 and concentrated in vacuo and finally lyophilized. Yield: 103 mg (76%). Purity: >95 % according to HPLC. ^{1}H-NMR (500.23 MHz, $CDCl_3$): δ = 9.65 (s, 1H), 9.61 (s, 2H), 8.03 (dd, 1H, ***J*** = 7.7 Hz, ***J*** = 4.0 Hz), 7.86–7.77 (m, 3H), 7.63–7.56 (m, 2H), 7.43–7.37 (m, 5H), 7.25–7.20 (m, 4H), 6.91–6.82 (m, 1H), 3.65 (s, 3H), 3.46–2.99 (m, 22H), 2.57–2.50 (m, 4H), 2.28–2.25 (m, 6H), 1.96 (s, 3H), 1.50–1.48 (m, 6H), 1.39–1.36 (m, 6H), 1.22–1.19 (m, 6H) ppm; ^{13}C-NMR (125.78 MHz, DMSO): δ = 172.0, 171.3, 171.1, 170.2, 170.1, 167.9, 166.2, 139.9 (d, J (PC) = 29.2 Hz), 138.6, 136.9 (d, J (PC) = 11.6 Hz), 135.0 (d, J (PC) = 19.2 Hz), 133.5 (d, J (PC) = 20.9 Hz), 131.8, 130.6, 129.1, 128.8 (d, J (PC) = 7.2 Hz), 127.7, 52.1, 47.1, 47.1, 46.8, 38.4, 30.5, 30.3, 29.9, 28.8, 27.8, 27.6, 26.0, 23.5, 20.4 ppm; ^{31}P NMR (101 MHz, $CDCl_3$): δ = -5.4 ppm; HRMS (ESI): m/z = 1075.5218 [M^+], calc. for $C_{54}H_{76}N_8O_{13}P$ = 1075.5264.

Synthesis of DOTA-phosphine **4**



Scheme S4 Synthesis of DOTA-phosphine **4**

DOTA-phosphine 4

HBTU (1.32 g, 3.49 mmol) was dissolved in dry DMF (15 mL) and DIPEA (0.90 g; 6.98 mmol) and the DOTA tris(t-Bu) ester building block (2.00 g, 3.49 mmol) were added. The mixture was stirred under argon at RT for 10 min, and a solution of amine **21** (1.90 g, 3.84 mmol) in DMF (5 mL) was added. The mixture was stirred for 2 h, concentrated, redissolved in CH_2Cl_2 (100 mL), and subsequently washed with a saturated $NaHCO_3$ solution (3 times 50 mL), water, and 1 M NaOH (50 mL). The organic layer was dried with Na_2SO_4 and concentrated in vacuo. The crude product was purified by column chromatography on silica, by eluting with $CHCl_3$ and then with 5% (v/v) MeOH in $CHCl_3$. The purified tris-***tert***-butyl ester protected product was dissolved in CH_2Cl_2 (7 mL) and TFA (5 mL), and stirred at RT for 1 h. The mixture was concentrated, and again dissolved in CH_2Cl_2 (7 mL) and TFA (5 mL), and stirred for an additional 2 h. The mixture was concentrated and coevaporated (2x) with $CHCl_3$ (10 mL) and then concentrated in vacuo. The product was dissolved in water (30 mL) and lyophilized to yield **4** as a fluffy, yellow powder (1.16 g, 96%). ^{1}H-NMR (MeOD): δ = 8.04 (dd, 1H, ***J*** = 3.7 Hz, ***J*** = 8.1 Hz, Ph-H), 7.79 (dd, 1H, ***J***=1.7 Hz, ***J*** = 8.1 Hz, Ph-H), 7.45 (dd, 1H, ***J*** = 3.7 Hz, ***J*** = 1.7 Hz, Ph-H), 7.4–7.2 (m, 10H, Ph-H), 4.05–3.70 (br.m, 8H, CH_2), 3.68 (s, 3H, CH_3), 3.60–3.10 (br m, 28H, CH_2) ppm; ^{13}C-NMR (100 MHz, DMSO): 171.6, 168.6, 166.3, 165.6, 165.3, 158.2 (q, ***J*** (FC) = 43.7 Hz, TFA), 139.7 (d, ***J*** (PC) = 37.2 Hz), 137.1, 137.0 (d, ***J*** (PC) = 25.5 Hz), 136.3 (d, ***J*** (PC) = 27.0 Hz), 133.4 (d, ***J*** (PC) = 27.7 Hz), 131.3 (d, ***J*** (PC) = 13.1 Hz), 130.0, 128.8 (d, ***J*** (PC) = 23.3 Hz), 128.6, 126.7, 116.6 (q, ***J*** (FC) = 392.1 Hz, TFA), 69.5, 68.6, 54.7, 539, 52.6, 52.1, 50.5, 48.4, 48.0, 40.5–38.5 (m, DMSO-***d6*** + 2x CH_2NHCO). ^{31}P-NMR (MeOD): δ = 33.82 (oxidized phosphine, ca. 5%), -3.91 (phosphine 4, ca. 95%), -15.19 (t, HPO_2F_2, ***J*** = 953 Hz) ppm; ATR-FT-IR: ν = 3287, 3074, 2872, 2546, 1718, 1651, 1547, 1435, 1292, 1189, 1130, 745, 720, 698 $cm^{-1;}$ MALDI-TOF: m/z $[M + H]^+$ 881.4 Da.

Radiolabeling of DFO-phosphines **2** and **3** with ^{89}Zr and $^{67/68}$Ga

Radiosynthesis of ^{89}Zr-DFO-phosphine **2** and **3**:

The radiolabeling of DFO with ^{89}Zr was done according to Verel ***et al***.[1] with minor adjustments. In short: Radiolabeling of DFO-phosphine **2** for ***in vitro*** experiments: To ^{89}Zr in 1 M oxalic acid (500 µL, max. 500 MBq) a Na_2SO_3 solution was added (100 µL of 50 mg/mL in H_2O) and incubated for at least 2 h. Next, to 10-50 MBq of the Na_2SO_3 containing ^{89}Zr solution, adjusted to 200 µL 1 M oxalic acid, were added 0.9% NaCl (262-300 µL) and 2 M Na_2CO_3 (90 µL) and reacted for 10 min. Hereafter 0.5 M HEPES (1.2 mL of pH 7.2-7.4), DFO-phosphine (500 µg), EtOH (318 µL) and 0.9% NaCl (90 µL) were added (total volume 2.2 mL) and the reaction mixture was shaken for 30 min at RT. The radiolabeling yield was always >93% and the percentage of oxidation caused by radiolabeling was <10% (n>10). The reaction mixture was used as such for ***in vitro*** Staudinger ligation experiments.

Radiolabeling for ***in vivo*** experiments: the same conditions as for the ***in vitro*** experiments were applied using 26.7 MBq ^{89}Zr and 100 µg DFO-phosphine **2** or **3**. ^{89}Zr-DFO-phosphine **2** was prepared with 7% oxidation and ^{89}Zr-DFO-phosphine **3** with 8% oxidation caused by radiolabeling. The reaction mixture was diluted with a Na_2SO_3-solution (0.5 mL of 1 mg/mL in 0.9% NaCl) and the product was trapped on a light C18 sep-pak to remove chemical reagents like oxalic acid. The light C18 sep-pak was washed with the Na_2SO_3 solution (2 mL) and eluted with fractions of 100 µL of a 80/20 EtOH/Na_2SO_3 solution. The products eluted in fractions 2 and 3 with 81% overall yield. 100 µL (12 MBq, 48.9 µg DFO-phosphine **2** or 11.7 MBq, 49.0 µg DFO-phosphine **3**) of this solution was diluted with EtOH and 25 mg/mL hydroxypropyl-β-cyclodextrin in 0.04% tween-20, to solubilize the product without causing unacceptable oxidation of the phosphine. 50 µL of this solution was injected per mouse and contained 0.4 MBq/1.52 µg (1.3 nmol) ^{89}Zr-DFO-phosphine **2** (total: 15% oxidation of the

phosphine) or 0.4 MBq/1.52 μg (1 4 nmol) ^{89}Zr-DFO-phosphine **3** (total: 20 % oxidation of the phosphine) and 10% EtOH

Radiosynthesis of $^{67/68}$Ga-DFO-phosphine **2** and **3**:

Radiolabeling of DFO-phosphine **2** for ***in vitro*** experiments: ^{67}Ga-citrate was converted to $^{67}GaCl_4^-$ via a chromafix procedure[8]. ^{67}Ga in H_2O (35 μL, 10-70 MBq) was incubated with 3 M ammonium acetate buffer of pH 7 (100 μL) for 5 min. Hereafter, 0.25 M ammonium acetate buffer of pH 5.5 (100 μL), DFO-phosphine **2** (100 μg), EtOH (30 μL) and 0.9% NaCl (20 μL)) were added and reacted for 3 min. Radiolabeling yield was always >95% and the percentage of oxidation caused by radiolabeling was always <10% (n>10). The reaction mixture was used as such for ***in vitro*** Staudinger ligation experiments.

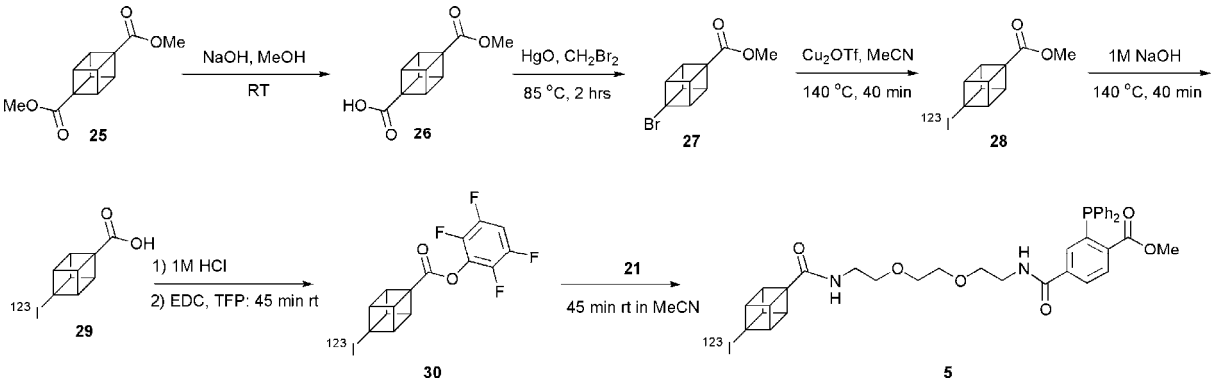
Radiolabeling for ***in vivo*** experiments on the kinetics of radiolabeled phosphine probes: ^{68}Ga was eluted from a ^{68}Ge/^{68}Ga generator according to the manufacturer protocol with ultra pure 0.1 M HCl solution (3.5 mL) and purified according to the method of Vosjan[8]. ^{68}Ga (70 μL, 116-120 MBq) was incubated with 3M ammonium acetate of pH 7 (100 μL) for 5 min. Then an anti-oxidant solution (25 μL of 100 mg/mL gentisic acid pH 3.4 + $SnSO_4$ (6 mg/mL)) was added and the mixture was left for 10-15 min. Subsequently, 0.25 M ammonium acetate of pH 8.5 (75 μL), DFO-phosphine **2** or **3** (100 μg), EtOH (60 μL) and 0.9% NaCl (40 μL) were added and reacted for 5 min (final pH 5.4). After dilution with 0.9% NaCl and EtOH, to a final concentration of 10% EtOH, 50 μL of this solution were injected per mouse and contained 1.1 MBq/1.52 μg (1.3 nmol) ^{68}Ga-DFO-phosphine **2** (7% oxidation of the phosphine, 98% labeling efficiency) or 1.1 MBq/1.52 μg (1.4 nmol) ^{68}Ga-DFO-phosphine **3** (13% oxidation of the phosphine, 98 % labeling efficiency).

Radiolabeling for ***in vivo*** Staudinger ligation experiments: ^{67}Ga in H_2O (140 µL, 56 MBq) was incubated with 0.5 M ammonium acetate buffer of pH 6.7 (800 µL) for 5 min. Hereafter DFO-phosphine **2** (520 µg), EtOH (120 µL) and 0.9% NaCl (80 µL)) were added and reacted for 3 min. 150 µL of this solution was injected per mouse and contained 7.4 MBq/68 µg (60 nmol) ^{67}Ga-DFO-phosphine **2** (9% oxidation of the phosphine, 100% labeling efficiency) and 10% EtOH.

Radiolabeling of DOTA-phosphine **4** with ^{177}Lu

To ^{177}Lu (10-50 MBq) in 0.05 M HCl (10 µL) were added 0.25 M ammonium acetate of pH 8.5 (140 µL) and DOTA-phosphine **4** (100 µg). The reaction mixture was incubated for 10 min at 45 °C. Radiolabeling yield was always >90% and the percentage of oxidation caused by radiolabeling was always <15% (n>10). For ***in vitro*** experiments the reaction mixture was used as such. Radiolabeling for ***in vivo*** experiment: to ^{177}Lu (16.9 MBq) in 0.05 M HCl (15 µL) were added 0.2 M ammonium acetate of pH 8.5 (660 µL) and DOTA-phosphine **3** (62 µg). The reaction was incubated for 10 min at 45°C. After dilution with 0.9% NaCl and EtOH, to a final concentration of 10% EtOH, 50 µL of this solution was injected per mouse and contained 0.4 MBq/1.50 µg (1.7 nmol) ^{177}Lu-DOTA-phosphine **4** (18% oxidation of the phosphine, 98% labeling efficiency).

(Radio)synthesis of I-cubyl-phosphine **5**



Scheme S5 Synthesis of ^{123}I-cubyl-phosphine **5**

4-(methoxycarbonyl)-1-cubanecarboxylic acid (26)[9]

To a solution of 1,4-bis(methoxycarbonyl)cubane **25** (2.25 g, 10.2 mmol) in THF (70 mL) was added dropwise a solution of 2.5 M sodium hydroxide in MeOH (4 mL, 10 mmol). After stirring overnight at RT the solvents were removed in vacuo without heating, after which H_2O (25 mL) was added. The aqueous layer was washed with $CHCl_3$ (3x25 mL) to remove unreacted starting materials, after which it was acidified with concentrated HCl to pH 3. The aqueous layer was extracted with $CHCl_3$ (3x25 mL). The combined organic layer was dried with $MgSO_4$ and concentrated in vacuo to give a white solid. Yield: 2 g (95%). Aanalytical data were according to literature[9].

Methyl-4-bromo-1-cubane carboxylate (27)[10]

To a suspension of **26** (1.64 g, 7.9 mmol) and HgO (2.5 g, 11.5 mmol) in CH_2Br_2 (47 mL) was added dropwise Br_2 (0.77 mL, 14.9 mmol) in CH_2Br_2 (5 mL). Subsequently the suspension was stirred for 2 h at 85°C, cooled down to RTand filtered to remove $HgBr_2$. The resulting solution was concentrated in vacuo and the solid was dissolved in hexane (40 mL) and washed with H_2O (3x20 mL). The organic layer was concentrated in vacuo and purified

by column chromatography with hexane:ethyl acetate 4:1 and crystallized from hexane resulting in a white solid. Yield: 1.16 g (61%). Analytical data were according to literature[10].

I-cubyl-phosphine (5) (cold reference compound)

HBTU (69 mg, 0.18 mmol) was dissolved in dry DMF (1 mL) and DIPEA (63 µL; 0.36 mol) and phosphine **21** (100 mg; 0.2 mmol) were added. The mixture was stirred under argon at RTfor 10 min, after which a solution of 4-iodocubane carboxylic acid[3] (50 mg; 0.18 mmol) in DMF (1 mL) was added. The resulting solution was stirred overnight at RT, followed by the addition of diethyl ether (20 mL). The organic layer was washed with saturated $NaHCO_3$ solution (3 x 15 mL) and 0.1 M HCl (15 mL) and dried over Na_2SO_4 and concentrated in vacuo. The crude product was purified by silica column chromatography using a gradient from 100% $CHCl_3$ to $CHCl_3$/MeOH/NEt_3 (10/1.5/0.1). Yield: 95 mg (70%). ^{1}H-NMR (250.13 MHz, $CDCl_3$): δ = 8.16 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 3.7 Hz, Ph-H), 7.89 (dd, 1H, ***J*** = 8.0 Hz, ***J*** = 1.6 Hz, Ph-H), 7.61–7.37 (m, 11H, Ph-H), 6.62 (s, 1H, NH), 6.21 (s, 1H**,** NH), 4.40–4.26 (m, 8H, CH_2CH_2NH), 3.72 (s, 3H, OCH_3), 3.72–3.44 (m, 10H, cubyl-H, CH_2O) ppm; ^{13}C-NMR (125.8 MHz, $CDCl_3$): δ = 171.1, 166.5, 166.3, 137.3, 136.5 (d, ***J*** (PC) = 17.9 Hz), 133.9, 133.8, 132.9, 131.8 (d, ***J*** (PC) = 10.4 Hz), 130.9 (d, ***J*** (PC) = 2.5 Hz), 129.3, 128.7 (d, ***J*** (PC) = 7.8 Hz), 128.5 (d, ***J*** (PC) = 13.0 Hz), 127.2, 70.2, 70.1, 69.8, 69.5, 57.9, 54.6, 52.4, 50.1, 39.8, 38.9, 36.2 ppm; ^{31}P-NMR (101.25 MHz, $CDCl_3$): δ = -4.1 ppm; HRMS (ESI): m/z = 751.1396 [M^+], calc. for $C_{36}H_{37}IN_2O_6P$ = 751.1428.

^{123}I-cubyl-phosphine (5)

To [^{123}I]-iodide in 0.01 N NaOH (~ 100 µL) was added 0.1 M H_2SO_4 (1 mL). The radioiodide was trapped on a platinum column under nitrogen atmosphere[11], washed with H_2O (5 mL), MeCN (5 mL) under nitrogen atmosphere and finally dried with nitrogen. ^{123}I was eluted with

MeCN and hydrogen gas resulting in > 90% recovery of the activity in less than 0.3 mL MeCN. Methyl-4-bromo-1-cubane carboxylate **27** (1.6 mg, 6.6 μmol) was reacted under anhydrous conditions with Cu_2OTf (10 μL of 1 mg/mL in MeCN), 1,4-dimethylpiperazine (10 μL of 10 mg/mL in MeCN) and ^{123}I in 100 μL total volume of MeCN at 140 °C in a closed vessel for 30 min. The reaction was allowed to cool down to RT, diluted with 45/55/0.2 MeCN/H_2O/diisopropylamine (DIPA) (0.5 mL), and purified by HPLC (flow 1 mL/min, eluent: 45/55/0.2 MeCN/H_2O/DIPA) resulting in methyl-4-^{123}Iodo-1-cubane carboxylate **28** in HPLC eluent in 65% yield. The collected product was hydrolyzed quantitatively by the addition of 1M NaOH (20 μL) and heating at 140 °C for 40 min in a closed vessel resulting in 4-^{123}Iodo-1-cubane carboxylic acid **29**. Hereafter, EDC (84.2 mg; 0.44 mmol) and TFP (300 μL of 200 mg/mL in MeCN) were added to the solution and reacted for 45 min at RT. The reaction mixture was diluted to 10 % EtOH with H_2O and trapped on a light C18 Sep-pak cartridge. The Sep-pak cartridge was washed with H_2O (15 mL) in order to remove excess TFP and EDC and eluted with MeCN resulting in TFP-ester **30** in 94% isolated yield. The purified TFP-ester **23** was reacted with phosphine **21** (1.2 mg; 2.4 μmol) in the presence of 3 equivalents diisopropylethylamine (DIPEA) for 30 min at RT resulting in ^{123}I-cubyl-phosphine **5**. ^{123}I-cubyl-phosphine **5** was diluted with 55/45/0.2 EtOH/H_2O/DIPA (0.5 mL) and purified with preparative HPLC (flow 1 mL/min, eluent: 55/45/0.2 EtOH/H_2O/DIPA) and collected in a stock solution of cold I-cubyl-phosphine **5** in EtOH (0.438 mg in 4.06 mL EtOH). Prior to injection the stock solution was diluted with 0.9% NaCl to arrive at a final concentration of 10% EtOH. 100 μL of this solution was injected and contained 0.77 MBq ^{123}I-cubyl-phosphine **5** (1 μg; 1.34 nmol) (5% oxidation of the phosphine).

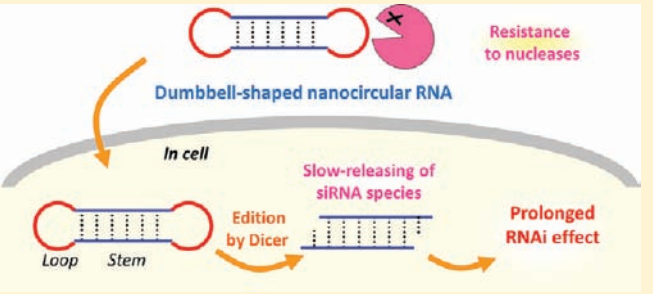
Supporting Information

ABSTRACT: RNA interference (RNAi) is one of the most promising new approaches for disease therapy. The design of a dumbbell-shaped nanocircular RNA allows it to act as a short interfering RNA (siRNA) precursor. To optimize the design, we studied the relationship between the nanostructure and RNAi activity by synthesizing various RNA dumbbells. An RNA dumbbell with a 23-bp stem and 9-nt loops was the most potent. Sequence analysis by mass spectrometry showed that Dicer could edit RNA dumbbells to siRNA species. The reaction offered the slow release of siRNA species, which conferred prolonged RNAi activity. Introduction of DNA into the loop position significantly stabilized the dumbbell in biological fluid without any loss of RNAi activity. In-depth pharmacological evaluation was performed by introducing dumbbells into HeLa cells that stably express the target luciferase gene. The dumbbells provided a rapid silencing effect and retained this effect for a longer time even at a lower concentration than that at which standard siRNA completely lost RNAi activity. We conclude that an RNA dumbbell with DNA loops is the most promising design for in vivo applications for RNA medicine.



INTRODUCTION

RNA interference (RNAi) is a potent and highly specific gene-silencing phenomenon that was first reported for the nematode *Caenorhabditis elegans* by Fire and Mello in 1998.[1] They discovered that genes could be silenced by introducing double-stranded RNAs (dsRNAs) complementary to the mRNA sequences.[1] Since then, RNAi has been shown to be an evolutionarily well-conserved process that plays an important role in host defense and regulation of gene expression.[2] The RNAi pathway is initiated by the enzyme Dicer, an endoribonuclease in the RNase III family, which cleaves long dsRNA into short dsRNA fragments called short interfering RNA (siRNA). siRNA is a dsRNA molecule of about 20−23 nucleotides (nt) in length with 2-nt 3′ overhangs on either end. In the pathway, after being incorporated into a protein complex known as the RNA-induced silencing complex (RISC), the siRNA strand subsequently guides the RISC to the complementary mRNA molecule, where they cleave and destroy the cognate RNA.[3]

Much effort has been dedicated to the application of siRNAs as therapeutic agents, since they were shown to be effective in mammalian cells.[4−7] A wide variety of chemical modifications has been proposed to improve the stability of siRNAs in serum. For example, modification of the phosphate backbone with phosphorothioates or boranophosphates and modification of the ribose moiety with 2′-*O*-methyl, 2′-fluoro, or 4′-thio groups has been examined.[8−13] These chemical modifications can increase the stability of siRNAs, although they often decrease RNAi activity. There is also concern that unnatural RNA derivatives might be toxic in the body. A method to stabilize nontoxic natural RNA strands should be useful for applying RNAi technology in the development of therapeutic agents.

RNA molecules that can induce RNAi, but with different strand lengths or shapes than those of normally used canonical siRNA, have been reported recently.[14−21] Increasing the length of an siRNA duplex makes it a substrate for Dicer and has been found to increase its potency.[14] Changing the shape may also influence the RNAi activity; for example, the efficacy of an asymmetric dsRNA duplex, which was named asymmetric interfering RNA (aiRNA) and which comprises a 19-nt guide strand and 15-nt passenger strand, was reported.[16] In this report, aiRNA

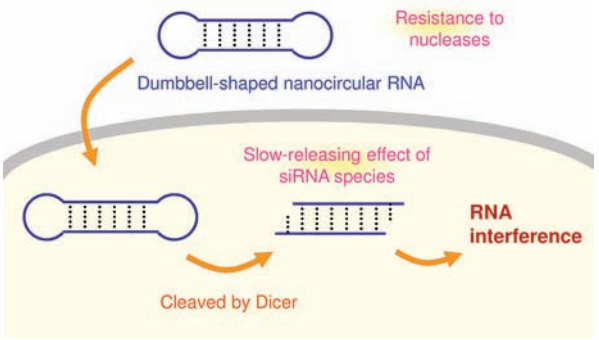

Figure 1. Proposed mechanism of the RNAi effect induced by a dumbbell-shaped nanocircular RNA.

was as efficient as conventional siRNA in silencing the target genes and was less prone to causing unwanted off-target effects.[16] Recently, we altered the structure of the siRNA molecule and produced dumbbell-shaped nanocircular RNAs that withstand enzymatic degradation and have a prolonged RNAi effect despite their natural RNA strand (Figure 1).[20] On the basis of the understanding that nucleases typically start by chewing at the loose ends of RNA,[22] we created circularized siRNA by designing a molecule that assembles into a stable dumbbell shape with a base-paired central stem connected by two loops at both ends. Closing off the ends limits the enzymatic activity of the exonuclease and confers greater stability of the RNA.[20]

Encouraged by these initial findings, we have been pursuing strategies to further increase the effectiveness of RNA dumbbells for RNAi. An important issue remaining is that of optimizing the loop structure of the RNA dumbbells. The mechanism shown in Figure 1 indicates that the loop can be cleaved by Dicer and is not necessary for the RNAi effect. However, in a previous study, we found that the single-stranded RNA loop is a weaker point than the stem in terms of stability because the loops can be cleaved by nucleases.[23,24] In addition, the loop and its related structure are also important for controlling the editing position by Dicer. To develop a more effective dumbbell structure, our current work focuses on modifying the loop sequences and structures. Here, we report on our systematic studies on the effect of changing the loop sequences and structures on RNAi activity. We also analyzed the dicing reaction of Dicer on an RNA dumbbell by comparing the reaction with RNAs of the related structure and by identifying the sequences using mass spectrometry (MS). We also synthesized RNA dumbbells that have loops containing deoxynucleotides or hexaethylene glycol linker to increase the biological stability. We confirmed their improved stability in both serum and cell lysates, and we found that they are good candidates for further study for clinical purposes.

EXPERIMENTAL PROCEDURES

RNA Synthesis and Purification Methods. RNA oligonucleotides were synthesized on a Gene World H-8-SE DNA synthesizer (Gene World, Tokyo, Japan) using 2′-*O*-TBDMS or 2′-*O*-TOM protected β-cyanoethyl phosphoramidites (Glen Research, Sterling, VA). 5′-Phosphorylation was performed on the synthesizer using Chemical Phosphorylation Reagent (Glen Research). Spacer Phosphoramidite 18 (Glen Research) or Spacer 18 Amidite (Biosearch Technologies, Novato, CA) was used as the hexaethylene glycol linker. Deprotection was performed according to the procedure provided by the supplier. Deprotected oligonucleotides were purified by 15% denaturing polyacrylamide gel electrophoresis (PAGE) and isolated by the "crush-and-soak" method.[25] Desalted RNAs were precipitated with sodium acetate (pH 5.2) and 2-propanol. siRNA-1 targeted 849−869 nucleotides,[26] and uGL3 targeted 153−173 nucleotides in the coding region of GL3 luciferase relative to the first nucleotide of the start codon.[4] All siRNA sequences were characterized by matrix-assisted laser desorption ionization - time-of-flight (MALDI-TOF) MS (RIKEN Brain Scientific Institute (BSI) Research Resources Center, Japan).

Enzymatic Synthesis of RNA Dumbbells using T4 RNA Ligase. The final composition of the reaction mixture was as follows: 2 μM 5′-phosphorylated-dsRNA, 0.05−0.4 units/μL T4 RNA ligase (Takara Bio, Otsu, Japan), 25% PEG 6000, 0.006% bovine serum albumin (BSA), 50 mM Tris-HCl (pH 7.5), 10 mM $MgCl_2$, 10 mM DTT, and 1 mM ATP. After the 5′-phosphorylated RNAs were annealed, PEG 6000, BSA, and T4 RNA ligase were added to the concentrations described above, and the reaction mixture was incubated at room temperature overnight. After extraction with chloroform, the RNA was precipitated by the addition of sodium acetate (pH 5.2) and 2-propanol. The ligated products were purified by preparative (1 mm thick) denaturing PAGE (10% polyacrylamide, 25% formamide, 7 M urea in 1× TBE). The bands were visualized by UV shadowing, and crushed and extracted with 0.2 M NaCl and 10 mM ethylenediaminetetraacetic acid (EDTA, pH 8.0). The eluate was desalted using a Sep-Pak cartridge (Waters, Milford, MA). The RNA dumbbells were precipitated with sodium acetate (pH 5.2) and 2-propanol.

Measurements of RNAi Activity of RNA Dumbbells by Dual-Luciferase Assay. All RNAs used were annealed at 5 μM concentrations in annealing buffer (100 mM potassium acetate, 30 mM HEPES-KOH at pH 7.4, 2 mM magnesium acetate) by heating at 90 °C for 3 min and then cooled slowly to room temperature. The solutions were incubated further at 4 °C overnight.

NIH/3T3 cells (RIKEN Cell Bank, Japan) were grown at 37 °C under 5% CO_2 in Dulbecco's modified Eagle's medium (DMEM; Invitrogen, Carlsbad, CA) supplemented with 10% fetal calf serum (FCS; Israel Beit Haemek, Israel). Cells were passaged regularly to maintain exponential growth. One day before transfection, cells were plated in 96-well plates (1.6×10^4 cells/100 μL per well). Cotransfection of the reporter plasmids and RNAs was performed using GeneSilencer (Genlantis, San Diego, CA) as described by the manufacturer for adherent cell lines. Just before cotransfection, the culture medium was replaced with 56 μL of DMEM without FCS, and 0.2 μg of pGL3-Control (Promega, Madison, WI), 0.2 μg of pRL-TK (Promega), and 2.5 pmol of RNA formulated into liposomes (44 μL) were added to each well. Four hours after the transfection, 100 μL of 20% FCS in DMEM was added to each well. Luciferase expression was monitored with the Dual-Luciferase Reporter Assay System (Promega) on a Wallac ARVO SX (PerkinElmer, Waltham, MA).

Atomic Force Microscopy (AFM) Imaging and Computer Modeling of the RNA Dumbbell Db-23. A drop of the RNA sample (200 pM in 10 mM Tris-HCl, pH 7.2, 12.5 mM $MgCl_2$, and 1 mM EDTA) was spotted on the mica, which was cleaved freshly and pretreated with 3 μL of 1 mM $NiCl_2$. After 30 s, the unbound RNA was removed by rinsing with Milli-Q water (Millipore, Billerica, MA). The sample was dried in a silica gel desiccator for one day, and AFM images were obtained under ambient conditions using a Nanoscope IIIa (Veeco Instruments Inc., Plainview, NY) in tapping mode with an SSS-NCH tip (NanoWorld AG, Neuchâtel, Switzerland). The three-dimensional

structure of Db-23 was energy-minimized using AMBER* in the *MacroModel* program.

Dicer Cleavage Reaction of RNAs with Various Structures. Annealed RNAs (2.5 μM) were incubated with 0.1 units/μL ColdShock-DICER (TmCspB and fragment of h-Dicer; cold shock protein from Thermotoga maritime (TmCspB) is added in this product to increase the dsRNA digestion efficiency; Takara Bio) in 20 mM Tris-HCl (pH 8.5), 150 mM NaCl, and 2.5 mM $MgCl_2$ at 37 °C. After 1, 6, and 18 h, aliquots (4.5 μL) were taken from the mixture, the reaction was stopped by mixing with 1.5 μL of 0.5 M EDTA (pH 8.0), and the samples were frozen. The samples were analyzed by 15% nondenaturing PAGE. siRNA Ladder Marker (Takara Bio) was used as the size marker for dsRNA. The total amount of RNA loaded was adjusted according to stem length to obtain uniform intensity for the bands. The gels were stained with SYBR Green I (Lonza, Rockland, ME), and visualized by scanning on a BioRad Molecular Imager FX (BioRad, Hercules, CA).

MALDI-TOF MS Analysis of the Products Produced by Dicer from the RNA Dumbbell Db-23. Db-23 (2.5 μM, 1250 pmol) was incubated with 0.1 units/μL ColdShock-DICER in 20 mM Tris-HCl (pH 8.5), 150 mM NaCl, and 2.5 mM $MgCl_2$ at 37 °C for 16 h. RNA was recovered from the reaction mixture by alcohol precipitation using sodium acetate (pH 5.2) and 2-propanol after phenol–chloroform extraction. Two-thirds of the precipitated RNA was purified by 15% nondenaturing PAGE. Each band was visualized by UV shadowing, excised, and extracted with 10 mM EDTA, pH 8.0 (0.5 mL × 2). The eluate was lyophilized, and the RNA was alcohol-precipitated using sodium acetate (pH 5.2) and 2-propanol. The MALDI-TOF MS spectra were measured on Microflex MALDI-TOF MS spectrometer (Bruker Daltonics, Billerica, MA) at RIKEN BSI Research Resources Center (positive mode, reflector mode, 3-hydroxypicolinic acid as the matrix).

Stability of Loop-Modified RNA Dumbbells in Bovine Serum. RNA (5 μM) was annealed in annealing buffer. Bovine serum (Invitrogen) was added to a final volume of 80% and the sample was incubated at 37 °C. After 0.5, 1, and 2 h, aliquots (5 μL) were taken from the mixture, mixed with 5 μL of 0.5 M EDTA (pH 8.0), and frozen. The samples were analyzed by 15% nondenaturing PAGE. siRNA Ladder Marker (Takara Bio) was used as the size marker for dsRNA. The gel was stained with SYBR Green I (Lonza) and visualized by scanning on a BioRad Molecular Imager FX.

Stability of Loop-Modified RNA Dumbbells in the Cell Lysate. HL60 cells (RIKEN Cell Bank) were grown at 37 °C in 5% CO_2 in RPMI 1640 medium (Invitrogen) supplemented with 10% FCS (Israel Beit Haemek) for three days to 100% confluency in a 75-mL flask. Cells were separated by centrifugation at 1000 × *g* for 2 min. Pelleted cells were resuspended in 1 mL of RPMI 1640 medium with 10% FCS and transferred to a 1.5 mL tube. After centrifugation at 1000 × *g* for 2 min, the supernatant was removed and the pellet was suspended in 400 μL of lysis buffer [10 mM sodium phosphate (pH 7.5), 10 mM $MgCl_2$, 150 mM NaCl, 1 mM DTT, 1% NP-40, and 0.2 mg/mL phenylmethylsulfonyl fluoride] and kept at −20 °C for 30 min.[27] After thawing, the cells were centrifuged at 14 000 × *g* for 15 min at 4 °C. The supernatant was separated, and its protein concentration was quantified by the Bradford method using BSA as a standard. The protein concentration was 16.8 mg/mL.

RNA (2.5 μM) was incubated with the cell lysate at a protein concentration of 10 mg/mL at 37 °C. After 0.5, 1, 2, and 4 h, aliquots (2 μL) were taken from the mixture, mixed with 5 μL of 0.5 M EDTA (pH 8.0), and frozen. They were analyzed by 15% nondenaturing PAGE. siRNA Ladder Marker (Takara Bio) was used as the size marker for dsRNA. The gel was stained with SYBR Green I (Lonza) and visualized by scanning on a BioRad Molecular Imager FX.

Time and Dose Dependency of RNA Dumbbells of the RNAi Effect. A multifunctional envelope-type nanodevice (MEND) was used as the model of a lipid nanoparticle; MEND was prepared as described previously.[28] Briefly, a lipid film comprising 1,2-dioleoyl-3-trimethylammonium propane (DOTAP)/dioleoylphosphatidyl ethanolamine (DOPE)/cholesterol (DOTAP, DOPE, and cholesterol were purchased from Avanti Polar Lipids, Inc., Alabaster, AL) was hydrated with 1 mL of 10 mM HEPES buffer (pH 7.4) and then incubated for 10 min at room temperature. The hydrated lipid film was sonicated using a probe-type sonicator to form small unilamellar vesicles (SUVs). RNA was complexed with stearyl octa-arginine (Kurabo Industries Ltd., Osaka, Japan) in 10 mM HEPES buffer (pH 7.4) at a nitrogen/phosphate ratio of 1.1. The RNA complex was then mixed with the SUV at a ratio of 1:2 (v/v) to coat the RNA complex with the lipid membrane. The average diameter and the ζ-potential of the prepared MEND were determined using a Zetasizer Nano ZS ZEN3600 (Malvern Instruments, Worcestershire, UK).

HeLa cells stably expressing luciferase (HeLa-Luc) were cultured in DMEM supplemented with 10% fetal bovine serum (FBS), penicillin (100 U/mL), streptomycin (100 μg/mL), and G418 (0.4 mg/mL) at 37 °C in an atmosphere of 5% CO_2 and 95% humidity. To examine the silencing effect of MEND, 4×10^4 HeLa-Luc cells were seeded in a 24-well dish one day before transfection. The MEND was suspended at the RNA concentration indicated in 0.25 mL of Opti-MEM (Invitrogen) without serum and added to the HeLa-Luc cells, and the mixture was incubated for 3 h at 37 °C. Next, 1 mL of DMEM supplemented with 10% FBS, penicillin (100 U/mL), streptomycin (100 μg/mL), and G418 (0.4 mg/mL) was added, and the mixture was incubated for 21 or 45 h. For further observation, the HeLa-Luc cells treated with MEND were collected and reseeded every two days as described above. The cells were washed and lysed with reporter lysis buffer (Promega). Luciferase activity in the cell lysate was measured using a luminometer (Luminescencer-PSN; ATTO, Tokyo, Japan) and luciferase assay reagent (Promega). The protein concentration was measured using a BCA Protein Assay Kit (Thermo Fisher Scientific, Waltham, MA). Luciferase activity was expressed as relative light units per mg of protein. The silencing effect was calculated as a percentage using the following equation:

$$\textit{Silencing effect}(\%) = [1 - (\mathrm{TEanti} - \mathrm{Luc}/\mathrm{TEnon})] \times 100$$

where TEanti-Luc and TEnon represent luciferase activity after transfection with MEND with and without antiluciferase RNA, respectively.

For statistical evaluation, comparisons between multiple treatments were made using one-way analysis of variance followed by the Bonferroni test. A *P*-value of <0.05 was considered significant.

RESULTS

Design and Synthesis of RNA Dumbbells to Optimize the Loop Sequences and the Stem Length. We reported recently on the synthesis of dumbbell-shaped nanocircular RNAs and their superior RNAi effect (Figure 1).[20] RNA dumbbells comprise a double-stranded stem region that contains an antisense sequence to the target mRNA and two loops at both ends of the stem. In the previous report, we used 9-nt sequences (UUCAAGAGA) as the loops, which are commonly used as the hairpin loop in the

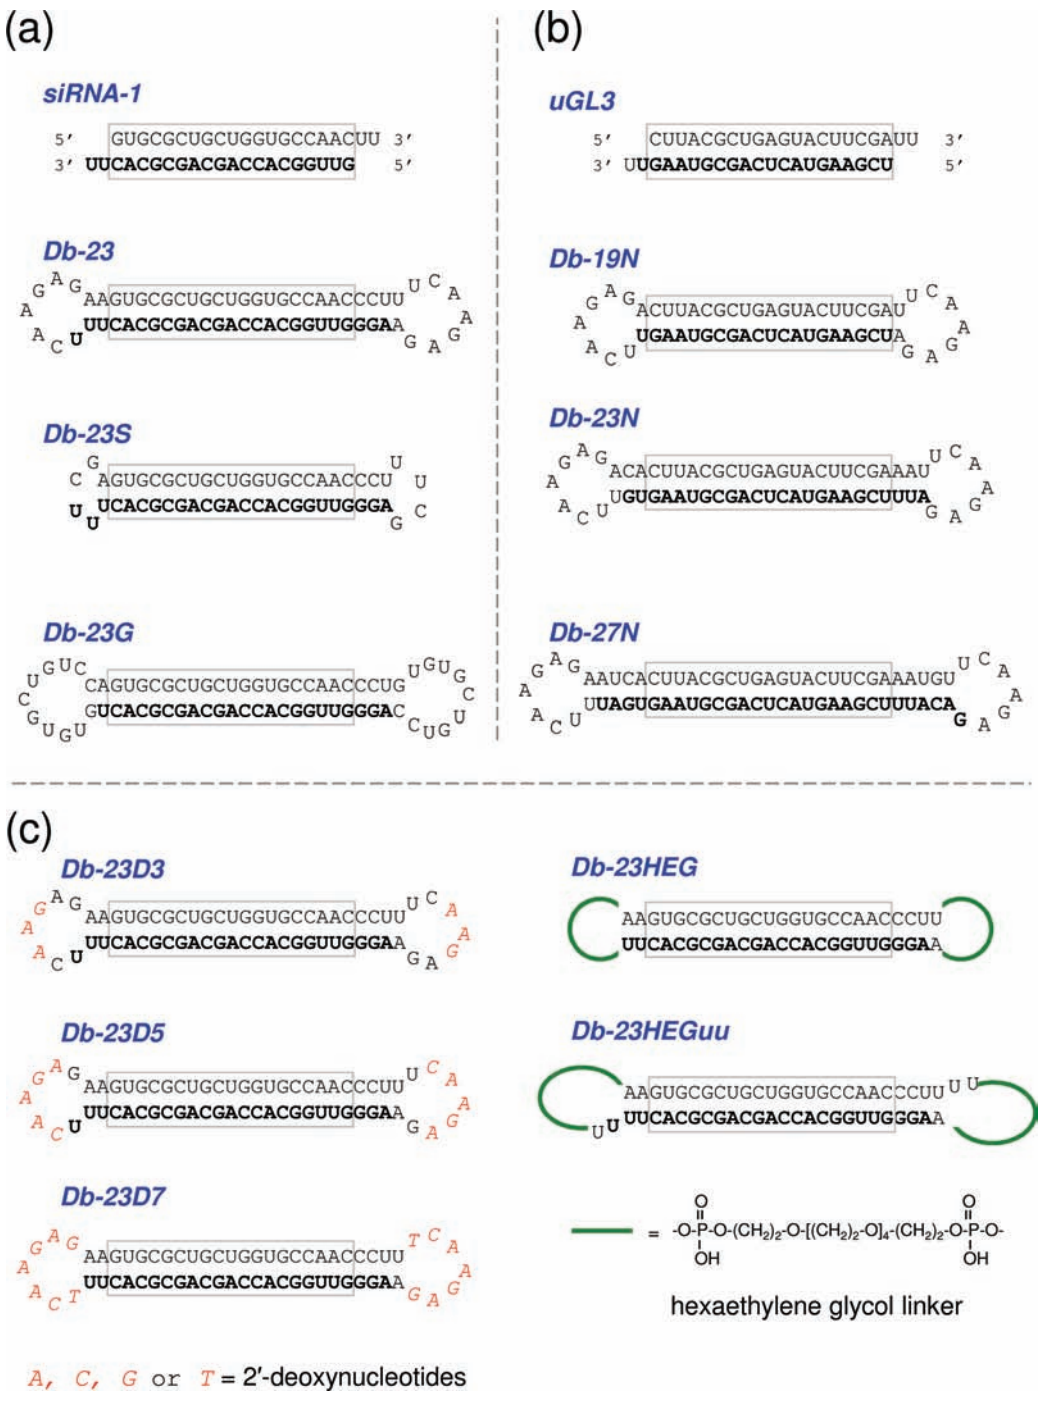

Figure 2. Sequences and structures of RNAs used in this study. Complementary sequences to the target mRNA are shown in bold. The stem regions of siRNA (19-bp) and the same sequences in the dumbbells are shown in the boxes. (a) RNA dumbbells with different loop sequences. siRNA sequences targeting GL3 luciferase corresponded to the coding regions 849−869. (b) RNA dumbbells with different stem lengths that target the coding regions 153−173 of GL3 luciferase. (c) RNA dumbbells with chemically modified loops by deoxyribonucleotides (red italic letters) or hexa(ethylene glycol) linker (green lines). They target the coding regions 849−869 of GL3 luciferase.

expression system of an RNA molecule.[29] We optimized the stem length of the dumbbells from 15 bp to 27 bp, and the RNA dumbbell with a 23 bp stem (Db-23) was found to have the best RNAi activity.[20] In this paper, we describe further studies on the structure−activity relationship of this RNA dumbbell.

First, to understand the influence of the loop sequences on their RNAi effect, two more RNA sequences in the loops were tested (Figure 2a). One of the RNA dumbbells, named Db-23S, has shorter 4-nt loops (UUCG).[30] The other, named Db-23G, has longer 11-nt loops (GUGUGCUGUCC)[26,31] compared with Db-23, which has 9-nt loops. These two other sequences were also adopted from the known sequences used in the expression system of shRNA. These RNA dumbbells were synthesized using the same method as that used to produce

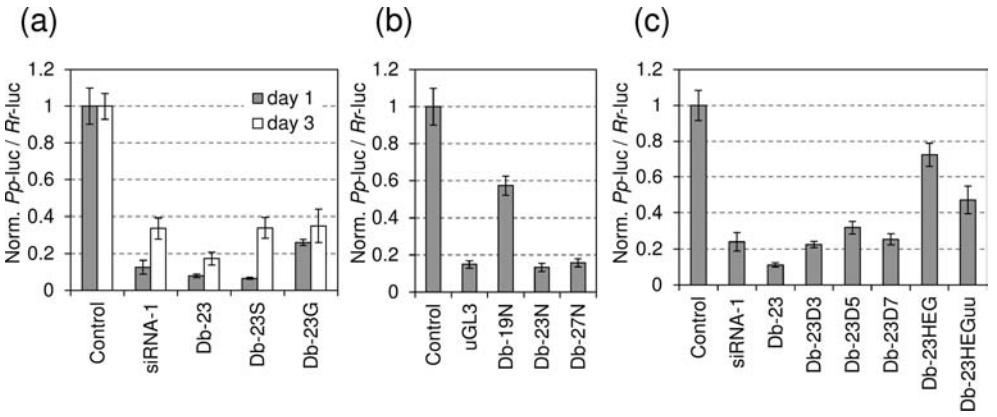

Figure 3. RNAi with RNA dumbbells. NIH/3T3 cells were cotransfected with RNA (at 25 nM) and the vectors. The expression of the two luciferase genes was measured after 24 h (day 1; gray bars) or three days (day 3, white bars). The ratios of the target to control luciferase were normalized to a control (no RNA). The plotted data are the means ± SD of four independent experiments. (a) RNAi by RNA dumbbells with different loop sequences (Figure 1a). (b) RNAi by RNA dumbbells with different stem lengths (Figure 1b). (c) RNAi by RNA dumbbells with loop-modified dumbbells (Figure 1c).

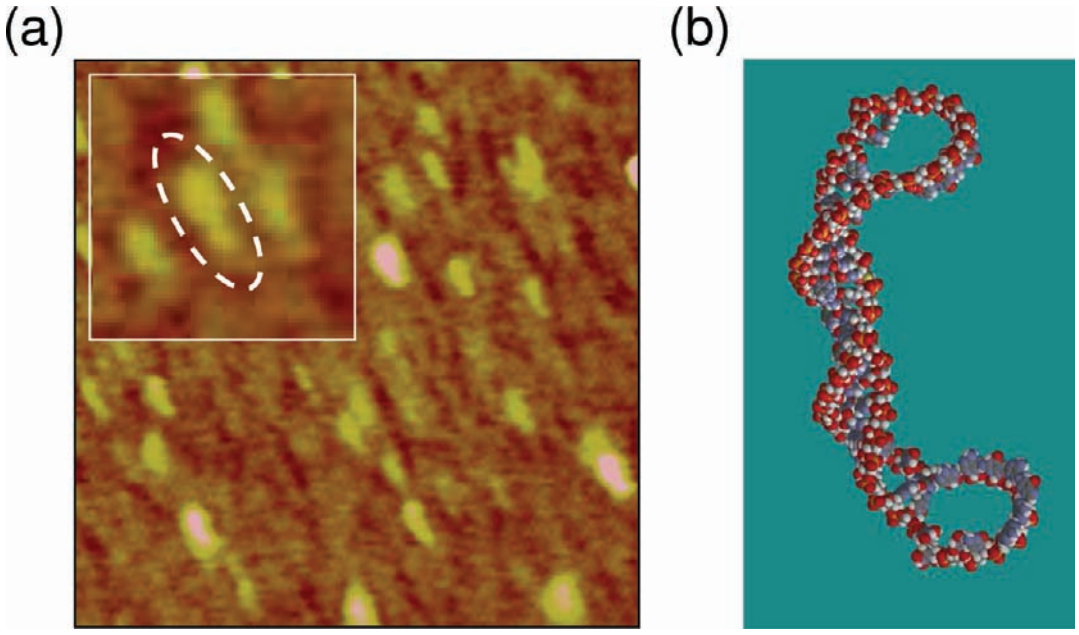

Figure 4. Three-dimensional structure of the RNA dumbbell Db-23. (a) AFM showing Db-23. The panel shows the area of 400 nm × 400 nm. The magnified image (60 nm × 60 nm) is shown in the inset. (b) Computer modeling by *MacroModel* software showing three-dimensional structure of Db-23.

Db-23. That is, the dumbbells were split in the loops and each strand was chemically synthesized (Supporting Information Figure S1). Nicks were ligated using T4 RNA ligase, and the RNA dumbbells produced were purified by denaturing PAGE.

We measured their RNAi activity by cotransfecting RNA and two distinct luciferase vectors using transfection reagent into NIH/3T3 cells, a mouse embryonic fibroblast cell line.[4]

As shown in Figure 3a, Db-23S and Db-23 showed similar interference activity 24 h after transfection, although Db-23G showed weaker activity. However, Db-23 showed better activity than Db-23S over the longer term, at three days after transfection. We selected the 9-nt loop sequences for further experiments.

Next, to determine whether the method can be generalized to other RNA dumbbells, we synthesized RNA dumbbells that target the other region of GL3 firefly luciferase mRNA. As shown in Figure 2b, these targeted sequences other than those shown in Figure 2a. The three differed in their stem lengths, and we confirmed the optimum length of the stem once again. As shown in Figure 3b, Db-23N showed better RNAi activity than Db-19N and comparable activity with Db-27N. We also synthesized two dumbbells with a 21-bp stem in these two distinct sequences (Supporting Information Figure S2a). We found better RNAi activity in dumbbells with a 23-bp stem than in those with a 21-bp stem (Figure S2b). We conclude that a 23-bp stem, not a 27-bp stem, is optimum when the 9-nt sequence UUCAAGAGA is used as the loops because the stem should be in a minimum length to avoid undesired effect such as interferon response.[32]

Three-Dimensional Structure of RNA Dumbbells. The structure of RNA dumbbells might be an important determinant

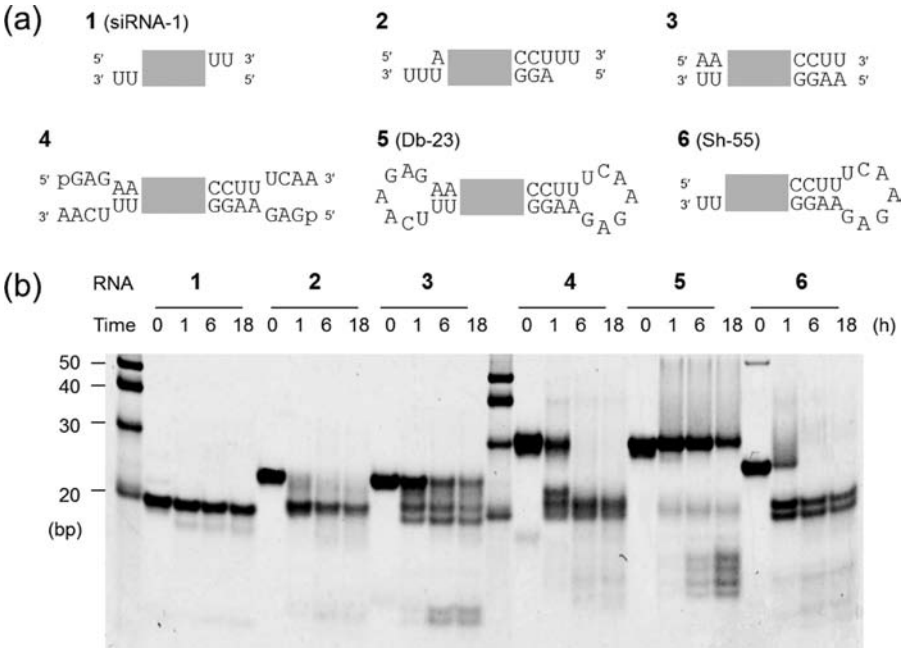

Figure 5. Processing of RNAs with the Dicer enzyme. (a) Structure of substrate RNAs used in this study. All substrate RNAs (**1** to **6**) contain an identical double-stranded 19-bp sequence, which is shown as a gray box in the structure. The sequences are 5′r(GUGCGCUGCUGGUGCCAACUU)3′ (upper) and 3′r(CACGCGACGACCACGGUUG)5′ (lower). The structural feature of RNAs are described as follows: (**1**) 21-nt dsRNA with 2-nt overhangs (siRNA-1), (**2**) 25-nt dsRNA with 2-nt overhangs, (**3**) 25-nt dsRNA with blunt ends (BL-23), (**4**) 32-nt dsRNA with frayed ends, a precursor of Db-23 (L-23) (ref [20]), (**5**) RNA dumbbell with a stem and two loops (Db-23), and (**6**) hairpin-shaped 55-nt ssRNA with 2-nt overhang (Sh-55). (b) Nondenaturing PAGE analysis of the digestion reaction of RNAs (**1** to **6**) with Dicer, visualized with SYBR Green I staining.

of the biological properties such as stability, intracellular distribution, and RNAi effect. We observed the structure of Db-23 directly using AFM; the results are shown in Figure 4a. The three-dimensional structural model of Db-23, which was optimized by *MacroModel* software, is shown for comparison in Figure 4b. In the AFM images,[33,34] the shape of Db-23 was observed as a rod. The observed height of Db-23 was 1.0 ± 0.55 nm, which is similar to the value in previous reports of RNA molecular images. Because the radius of the AFM tip was 2 nm, the estimated molecular length for Db-23 was 15.2 ± 3.6 nm, which is similar to the value of 11.2 nm that was calculated from the model structure. In addition, both ends of the RNA molecule in the AFM image protruded slightly, reflecting the looped structures of the molecules.

Dicer Processing of an RNA Dumbbell and Its Related RNAs. In our previous report, we showed that Db-23 is cleaved by Dicer and produces dsRNA of about 20-bp.[20] However, when compared with its nicked counterpart, the processing of Db-23 was slow. In this report, we examined in detail the cleavage reaction of Db-23 by Dicer with regard to the structure−activity relationship (Figure 5). In our previous study, we confirmed the production of 20-bp dsRNA only by PAGE.[20] In this paper, we directly analyzed the RNA sequences produced by Dicer by measuring their mass by MALDI-TOF MS (Figure 6).

As shown in Figure 5a, we compared the cleavage reaction of Db-23 (**5**) to that of several dsRNAs with various terminal structures, such as 21-nt dsRNA with 2-nt overhangs (**1**, siRNA-1), 25-nt dsRNA with 2-nt overhangs (**2**), 25-nt dsRNA with blunt ends (**3**), 32-nt dsRNA with frayed ends like an open dumbbell (**4**), or 55-nt hairpin-shaped ssRNA with a 2-nt overhang named Sh-55 (**6**). RNAs were treated with recombinant Dicer enzyme for up to 18 h, and the reaction mixtures were analyzed by PAGE at each time. All RNAs were digested to about 20 bp of dsRNAs, though RNA products shorter than 20 bp were more abundant when Db-23 was digested. However, the speed of digestion differed according to the structure. Dicer clearly preferred structures with an overhang over the blunt end because dsRNA (**2**) disappeared more rapidly than did dsRNA (**3**) (Figure 5b).[15,35] Although one side of the loop in Sh-55 (**6**) did not disturb the reaction, formation of dumbbell structure (**5**) by two loops greatly interfered with the activity (Figure 5b). After 18 h, 35% of Db-23 remained, although other RNAs disappeared completely. These experiments show that the design of a dumbbell structure characterized by the lack of an end should delay its cleavage by Dicer.

Next, we used MALDI-TOF MS to analyze the sequences of the digest produced from Db-23 by Dicer.[36] As a reference experiment, we analyzed the dicing reaction of Sh-55, which lacks one of the two loops of Db-23. As expected given the known action of Dicer,[37,38] four major peaks were found in the spectrum (Supporting Information Figure S3); these peaks were identified as two 21-nt and two 22-nt RNAs produced when Sh-55 was cleaved by Dicer. Next, the digest of the RNA dumbbell (Db-23) was analyzed. We purified the mixture of RNAs using nondenaturing PAGE to separate RNAs of about 20 bp (Figure 5b, Figure S4, lane 4). As shown in Figure 6a, the band gave a complex spectrum, suggesting the existence of multiple cleavage sites. However, these bands contained RNA strands of m/z 6600 to 7400, which correspond to sequences of 21- to 23-nt RNA. Several peaks were identified in its sequences (Figure 6b). These results show that cleavage occurred in the stem portion or in the middle of the loop portion. Although the identified sequences should have complementary sequences, the complexity of the spectrum prevented us from confirming this. Still, with this experiment, we confirmed that Dicer transformed the RNA dumbbell into 21- to

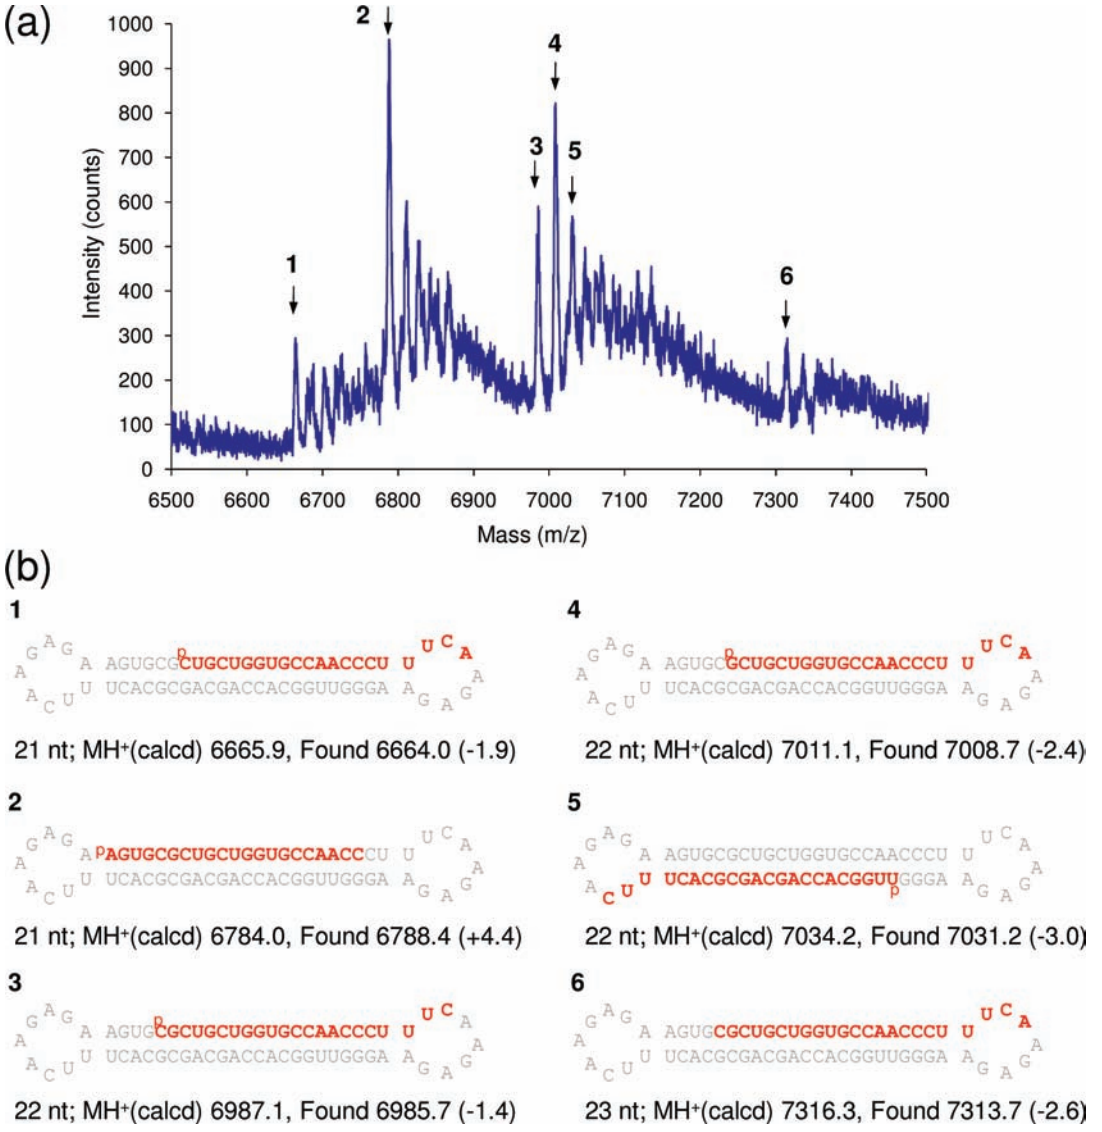

Figure 6. MALDI-TOF MS analysis of digestion products of Db-23 by Dicer. A band corresponding to about 20 bp in length in nondenaturing PAGE was excised, and RNAs were extracted from the gel and analyzed (Figure S4). (a) Mass spectrum of the digestion products. Peaks of the identified sequences are indicated by arrows and numbers **1** to **6**. (b) RNA sequences identified as peaks **1** to **6** in the spectrum shown in (a). 23-nt RNAs, which can be regarded as components of the siRNA species.

Synthesis of Loop-Modified RNA Dumbbells. An RNA dumbbell is stabilized against degradation in serum because of its termini-free structure.[20] However, we observed a nicking reaction in the single-stranded loop region as the first reaction when RNA dumbbell Db-23 was incubated in serum.[23,24] We decided to reinforce the loop moiety by introducing some modifications that are thought to be nontoxic. As shown in Figure 2c, ribonucleotides in the loop were replaced with their cognate 2′-deoxynucleotides, which comprise DNA, or with a hexaethylene glycol linker, which has been used to form folds and hairpins to bridge sections of oligonucleotides.[39−43] Deoxynucleotides are used in siRNAs, especially in the overhang regions, in the hope that this will make the siRNA resistant to nucleases.[4,44] In this study, we varied the number of 2′-deoxynucleotides introduced as three (Db-23D3), five (Db-23D5), or seven (Db-23D7) per one loop, to determine the optimum for substitution. These loop-modified RNA dumbbells were synthesized by ligating two chemically synthesized RNA strands using T4 RNA ligase (Figure S1g−k). To construct them, we preferred to make nicks in the single-stranded loop region if possible, because T4 RNA ligase works more efficiently on a single strand than on a double strand.[45] Ribonucleotide was then used as a nucleotide at the 3′-end (acceptor), because the ligation reaction is slowed with 2′-deoxynucleotide as an acceptor.[45] Ligation reactions to make these dumbbells proceeded well (Figure S5), although ligation in the double-stranded stem required more enzyme units, as expected.[45] After ligation, the dumbbells were purified by denaturing PAGE and used in further experiments.

The RNAi activity of these loop-modified RNA dumbbells was measured by a dual-luciferase assay 24 h after transfection in NIH/3T3 cells (Figure 3c). Substitution of ribonucleotides with 2′-deoxynucleotides in the loops (Db-23D3, Db-23D5, and

dx.doi.org/10.1021/bc2003154 |*Bioconjugate Chem.* 2011, 22, 2082–2092

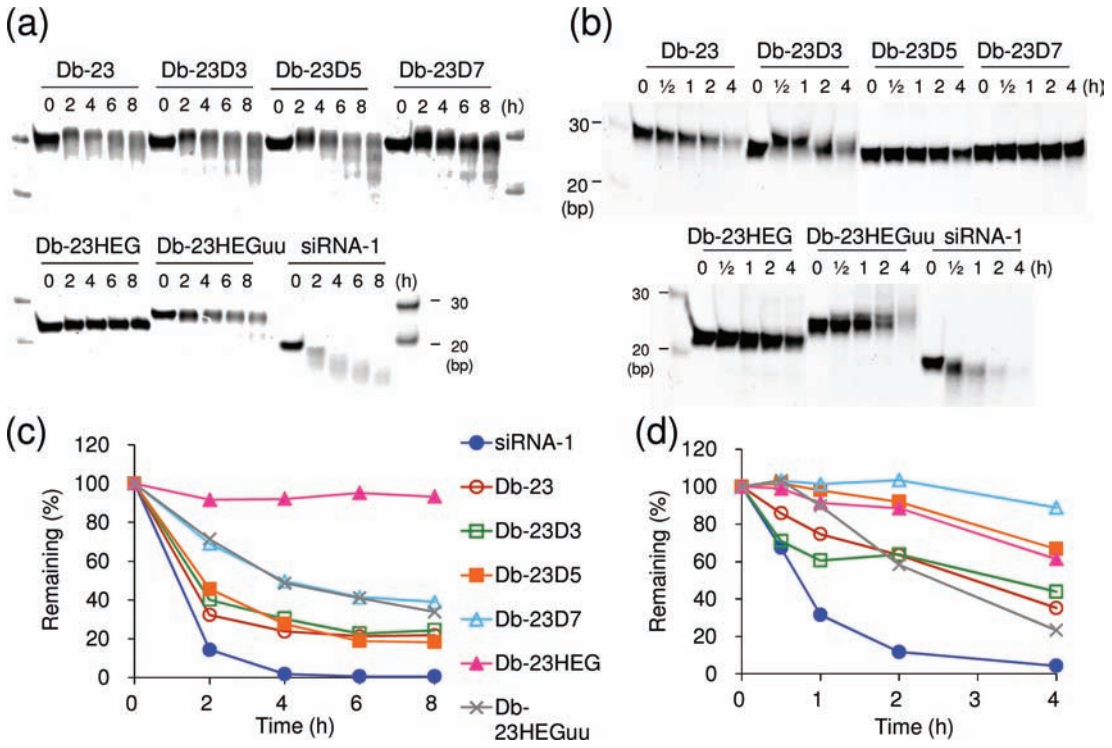

Figure 7. Stability of loop-modified RNA dumbbells. Nondenaturing PAGE analysis of digestion reaction with bovine serum (a) and with cell lysate of HL60 cell line (b). Remaining RNA sequences in the gel shown in (a) and (b) were quantified in (c) and (d), respectively.

Db-23D7) slightly decreased the activity compared with that of Db-23. In the substitutions with hexa(ethylene glycol) (Db-23HEG and Db-23HEGuu), the RNAi activity decreased more, compared with that of DNA-modified dumbbells. We concluded that dumbbells containing deoxynucleotides in the loops could be promising candidates in terms of retaining RNAi activity and adding biostability at the same time.

Stability of Loop-Modified Dumbbells in Serum and Cell Lysates. In clinical applications of RNAi, RNAs are injected into venous blood and must survive until reaching the target cells or organ.[46] Therefore, the biological stability of the RNA dumbbell is very important. To examine whether loop-modified RNA dumbbells become more stable in biological fluids, we incubated these modified dumbbells in bovine serum at 37 °C. As shown in Figure 7a, the reaction was analyzed by PAGE for up to 8 h, and the band intensity of undegraded RNA was quantified and plotted. We observed a stabilization effect of deoxynucleotides introduced into the loops, notably on Db-23D7 (Figure 7a,c). Db-23HEG, which has a hexa(ethylene glycol) linker and no unpaired nucleotide in the loop, was the most stable and almost no substantial degradation was detected in this reaction condition. The stability of Db-23HEGuu was clearly lower than that of Db-23HEG because of the presence of two uridine residues in the loops of Db-23HEGuu.

Increasing the stability of RNAs in living cells would extend the effective period of RNAi. To evaluate this ability, we examined the stability of RNA dumbbells in cell lysates.[27] Cell lysates were prepared from HL60 cells, a human promyelocytic leukemia cell line. Similar to the results in serum, RNA dumbbells were stabilized by introducing deoxynucleotides into the loops (Figure 7b,d). Interestingly, unlike in serum, Db-23D7 was more stable than Db-23HEG in cell lysates. These experiments confirmed that replacement of ribonucleotides with deoxynucleotides or hexa(ethylene glycol) in the loops confers significant biostability to RNA dumbbells.

Time and Dose Dependency of RNA Dumbbells in the RNAi Effect. Ideally, in clinical applications, a small dose of RNA should cause RNAi for a long time.[5] To investigate the ability of RNA dumbbells more thoroughly, the time and dose dependency of their RNAi were measured. RNA dumbbells Db-23, Db-23D3, Db-23D5, and Db-23D7 were introduced into HeLa cells stably expressing a firefly luciferase (HeLa-Luc), using the MEND method, in which RNA is complexed with a polycation followed by encapsulation by a lipid envelope.[28] The complexed RNA dumbbells were about 50 nm in diameter and had a −10 mV ζ-potential, values that are similar to those of the siRNA complex (siRNA-1: 53 nm and −14 mV). The observed diameter and ζ-potential of MENDs encapsulating the RNAs were 70−100 nm and 30−50 mV. To evaluate their silencing effect for up to eight days (192 h), the luciferase activity of the HeLa-Luc cells was measured with repeated passage after treatment with MENDs at a dose of 0.04 μM RNA. As shown in Figure 8a, the silencing effect of siRNA-1 reached a peak 48 h after the treatment. By contrast, RNA dumbbells retained their peak for longer, from 24 to 72 h. Introduction of 2′-deoxynucleotides into the loops (Db-23D3, Db-23D5, or Db-23D7) did not significantly change their RNAi activity, which was similar to that of Db-23. The silencing effect lasted longer for RNA dumbbells than for siRNA-1 (Figure 8a). Next, the dose dependency of the silencing effect was measured 24 and 144 h after the treatment (Figure 8b,c). At 24 h, RNA dumbbells exhibited a greater silencing effect than siRNA-1 at lower doses (Figure 8b). The differences in the silencing effect between RNA dumbbells and siRNA-1 expanded with longer incubation to 144 h after the treatment (Figure 8c). At lower doses, siRNA-1 did not show activity, but RNA dumbbells retained a significant effect. At both

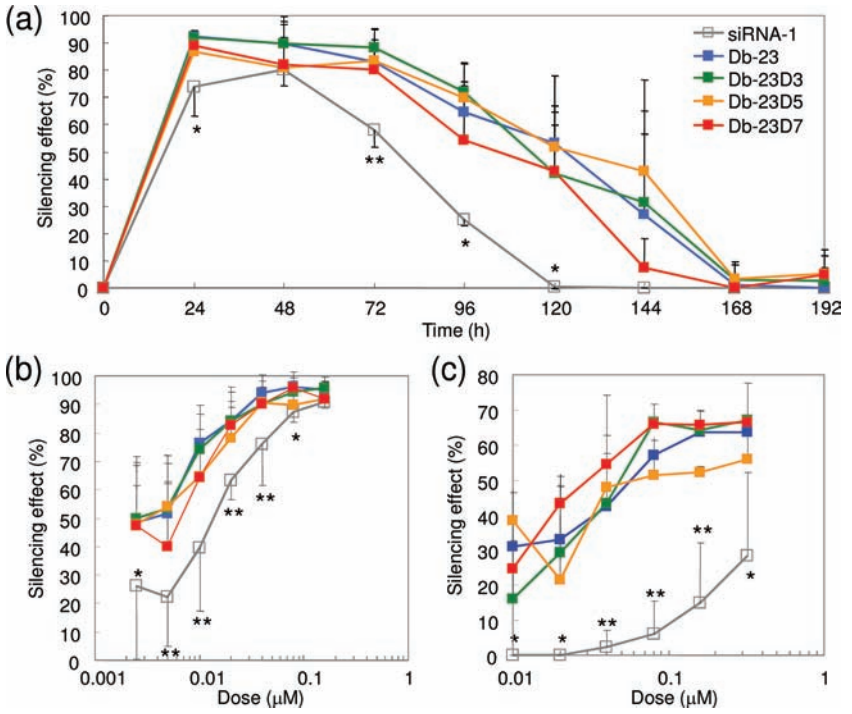

Figure 8. Time and dose dependency of RNA dumbbells of the RNAi effect. HeLa cells stably expressing luciferase were transfected with an MEND encapsulating siRNA-1 or an RNA dumbbell. Error bars were displayed in only one direction to prevent overlapping. (a) Time course of the silencing effect treated with MENDs at a dose of 0.04 μM of RNA. (b,c) Dose−response curves of MENDs at 24 h (b) and 144 h (c). The silencing effect is expressed as the mean ± SD (n = 3) $^{*}P < 0.05$, $^{**}P < 0.01$, RNA dumbbells vs siRNA-1.

times (24 and 144 h after treatment), the activity did not differ among the four kinds of RNA dumbbells. We should note that the silencing effect of Db-23D7 at 0.04 μM was 55% in Figure 8c but only 10% in Figure 8a at 144 h. The disagreement might be explained by the fact that the experimental errors became larger at later time points in Figure 8a, or simply because the two experiments were conducted independently. This discrepancy did not change the conclusion we obtained from the experiments shown in Figure 8. That is, the RNA dumbbells were stabilized in biological fluid by introduction of deoxynucleotides into the loops without any loss of RNA activity. These results show that RNA dumbbells can exert their silencing activity in mammalian cultured cells for longer than their canonical siRNA counterpart in a statistically significant way, presumably because RNA dumbbells retain their sequences longer after being delivered into the cytosol.

DISCUSSION

We optimized their loop sequences and stem length of RNA dumbbells (Figures 2 and 3). Our results suggest that the stem of 23 bp in length and 9-nt loop sequence UUCAAGAGA maximized the RNAi effect. With this design, an RNA dumbbell can be recognized by Dicer and produce siRNA species. Sequence analysis by MALDI-TOF MS confirmed the production of 21- to 23-nt RNAs that produced siRNA species after digestion with Dicer. dsRNAs are known to activate the innate immune response when introduced into cells.[47] In particular, siRNAs lacking dinucleotide 3′-overhangs activate the interferon system in cells because the overhang is a characteristic of endogenous Dicer products.[48] Considering this observation, we performed a preliminary experiment to test the ability to cause the interferon response by measuring the mRNA levels of interferon response-related genes (*OAS1* and *STAT1*) by quantitative real-time PCR after introducing RNA dumbbells into HeLa cells or HeLa S3 cells (Supporting Information Figure S6).[32,47] Various RNA dumbbells such as an all-RNA dumbbell (Db-23), dumbbells with DNA loops (Db-23D5 and Db-23D7), and dumbbells with an HEG loop (Db-23HEG and Db-23HEGuu) were examined and compared with standard siRNA (siRNA-1) or dsRNAs (BL-23 and L-23). In this experiment, we did not see any significant upregulation by the dumbbells; the mRNA levels of *OAS1* and *STAT1* were within 1.5-fold of those of mock-transfected cells (Figure S6). We concluded that dumbbell RNA does not cause a significant interferon response as does standard siRNA.

As shown in Figure 8c, RNA dumbbells caused a much more potent RNAi effect even at a lower concentration and for a longer time. Because RNAs are administered by injection through a vein in clinical applications, improving their stability in biological fluids will be valuable for delivering the RNAi effect within the target organ. Substituting ribonucleotide residues with 2′-deoxynucleotides in the loop position of the dumbbell significantly stabilizes it without the loss of RNAi activity (Figures 7 and 8). We conclude that an RNA dumbbell with DNA loops is the most promising design for in vivo applications.

The loop in the dumbbell can be modified to add various functions without affecting RNAi activity because the loop would be cleaved by Dicer and natural dsRNA as siRNA species is released eventually. For example, introduction of RNA or DNA aptamer, or even peptide, could confer membrane permeability or targetability in addition to biological stability. Interestingly, a nanoring such as a hexagon was constructed by assembling the RNA dumbbell through the interaction of a kissing loop.[49] The various nanostructures could be designed using RNA dumbbells

as an assembly unit, which might provide multiple functions. We plan to design and synthesize such highly functional dumbbells in the future.

In conclusion, we designed various RNA dumbbells to determine the optimum structure. A native RNA dumbbell with a 23 bp stem and 9-nt loops (UUCAAGAGA) had the most effective RNAi effect. Introduction of deoxynucleotides into the loops significantly stabilized the dumbbells in serum and cell lysates without loss of RNAi activity. The optimized RNA dumbbells showed longer silencing activity compared with the authentic siRNA counterpart.

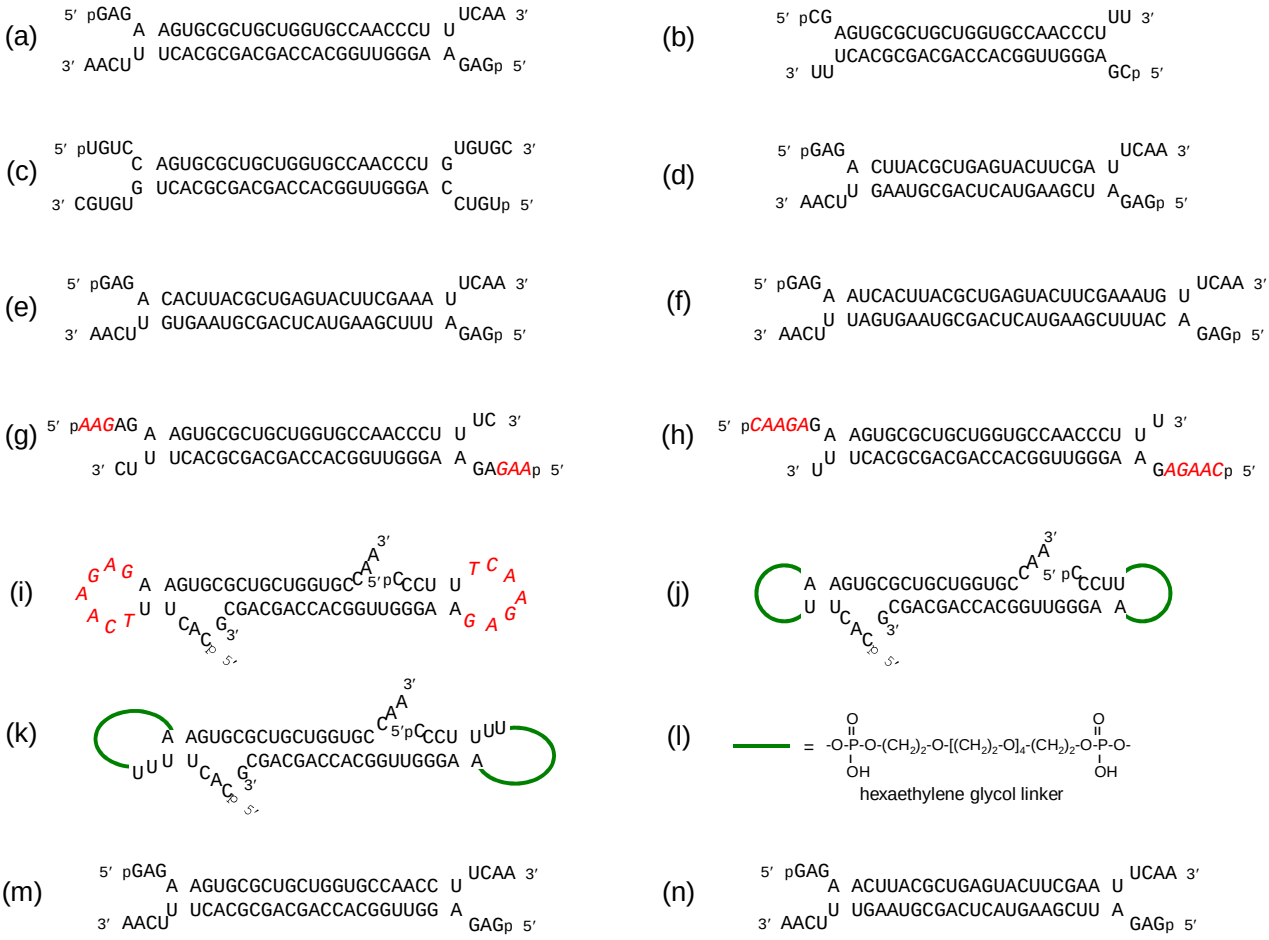

Figure S1. Chemically synthesized RNA sequences to be converted to a dumbbell by ligation reaction. They are ligated with T4 RNA ligase either at the single-stranded ends or at the nicks in the stem. All RNA oligos are 5′ phosphorylated (Letter p on 5′ -end means it is phosphorylated). Nucleobases written in red italic letters are replaced by deoxyribonucleotides (g, h and i). Green lines inserted into RNA sequences represent hexaethyleneglycol linker (l). The resulting RNA dumbbells are as follows: (a) Db-23, (b) Db-23S, (c) Db-23G, (d) Db-19N, (e) Db-23N, (f) Db-27N, (g) Db-23D3, (h) Db-23D5, (i) Db-23D7, (j) Db-23HEG, (k) Db-23HEGuu, (m) Db-21, (n) Db-21N.

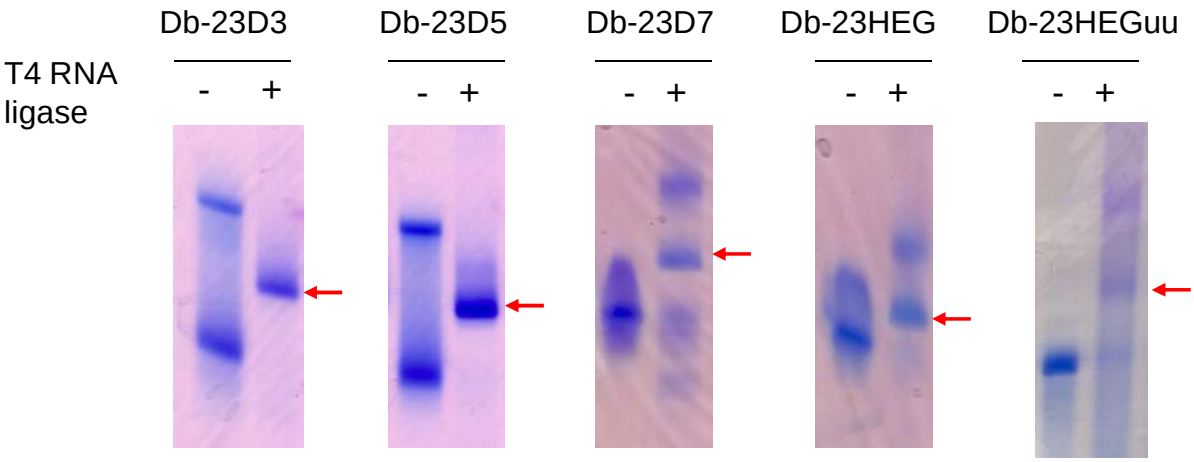

Figure S5. PAGE Analysis of ligation reactions to form loop-modified RNA dumbbells. Two chemically synthesized RNAs were annealed and ligated with T4 RNA ligase. Reaction mixture was analyzed by 10% denaturing PAGE (7 M urea, 25% formamide) and the gel was visualized by Stains-All staining. Red arrows point the ligated products (dumbbells).

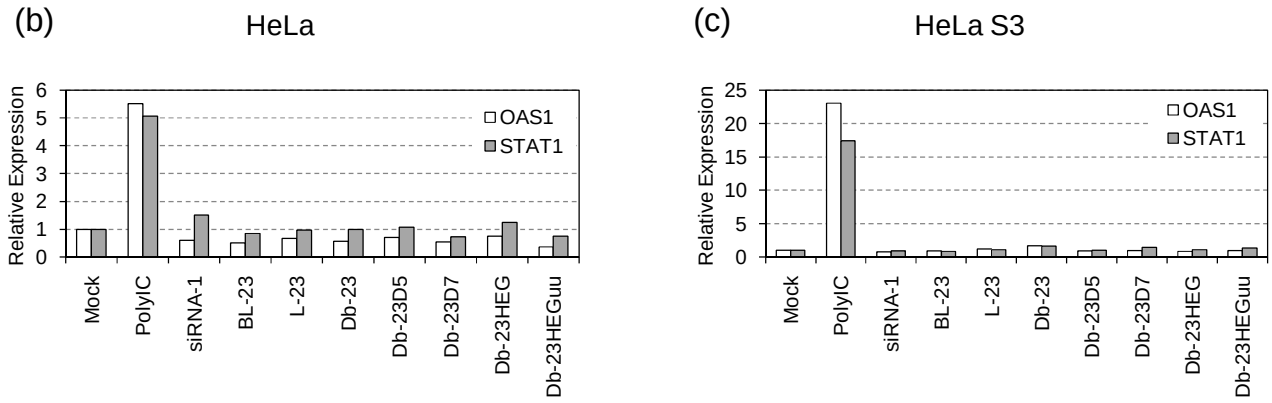

Figure S6. Quantitative real-time PCR analysis of OAS1 and STAT1 levels in mammalian cultured cells after RNA transfection. (a) Sequences and structures used in this study. (b)(c) HeLa cells (b) or HeLa S3 cells (c) were transfected with various RNAs at a concentration of 100 nM. OAS1, STAT1 and β–actin mRNA levels were measured 48 h after the transfection. Data are shown as ratios, target gene/β–actin and normalized to a mock transfected control (Mock). Polyinosinic-polycytidylic acid (PolyIC) was transfected to the cells at 0.21 μg/mL concentration.

Experimental details

Quantitative real-time PCR analysis of OAS1 and STAT1 levels in mammalian cultured cells after RNA transfection (interferon response assay)

All RNAs used were annealed at 5 μM concentrations in annealing buffer (100 mM potassium acetate, 30 mM HEPES-KOH at pH 7.4, 2 mM magnesium acetate) by heating at 90 °C for 3 min, then cooled slowly to room temperature. The solutions were further incubated at 4 °C overnight.

HeLa cells (RIKEN Cell Bank, Japan) were grown at 37 °C under 5% CO_2 in MEM (Sigma, MO) supplemented with 10% fetal calf serum (FCS; Israel Beit Haemek, Israel). HeLa S3 cells (RIKEN Cell Bank) were grown at 37 °C under 5% CO_2 in S-MEM (Invitrogen) supplemented with 10% fetal bovine serum (FBS). Cells were regularly passaged to maintain exponential growth. One day before transfection at 50 - 70% confluency, cells were plated in 48-well plates (2.5×10^4 cells/250 μL per well). Transfection of RNAs at 100 nM or polyIC (42 ng per well; Takara Bio, Japan) was carried out with GeneSilencer (Genlantis, CA) as described by the manufacturer. Just before transfection, the culture medium was replaced with 149 μL of medium without serum, and 20 pmol of RNA , 42 ng polyIC formulated into liposomes (51 μL) were added to each well. Four hours after the transfection, 200 μL of 20% serum in medium was added to each well. Two days after the transfection, cells were harvested and total RNA was extracted using RNeasy Mini Kit with DNase I treatment (Qiagen, CA). cDNA was produced using 75 ng of total RNA using PrimeScript RT reagent kit (Takara bio) and random hexamers in a 10 μL reaction according to the manufacturer's instructions. Expression of Stat1 and Oas1 was determined using real-time PCR at RIKEN BSI Research Resources Center (Japan) on Applied Biosystems 7900HT (Applied Biosystems, CA) by SYBR Green method. β-actin expression was used for normalization of the real-time PCR data. PCR reactions were run in duplicate and the data from these were confirmed to differ by < 0.5 threshold cycle. Sequences used for the primers were: STAT1, 5′-d(GCTGGCACCAGAACGAATGA) -3′ and 5′-d(TACCAAACCAGGCTGGCACA) -3′ ; OAS1, 5′-d(AGGTAGCTCCTACCCTGTGTGTGTG) -3′ and 5′-d(GAAGACAACCAGGTCAGCGTCA) -3′; β-actin, 5′-d(TGGCACCCAGCACAATGAA) -3′ and 5′-d(CTAAGTCATAGTCCGCCTAGAAGCA) -3′.

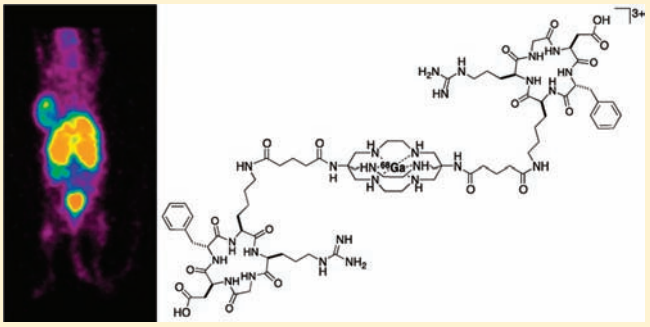
Supporting Information

ABSTRACT: Tumor-targeting peptides radiolabeled with positron-emitting ^{68}Ga are promising candidates as new noninvasive diagnostic agents for positron emission tomography (PET). The targeting peptides are tethered to a chelator that forms a stable coordination complex with Ga^{3+} that is inert to dissociation of Ga^{3+} *in vivo*. Metal complexes of macrobicyclic hexaamine "sarcophagine" (sar = 3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane) ligands exhibit remarkable stability as a result of the encapsulating nature of the cage amine ligand. A Ga^{3+} sarcophagine complex, $[Ga\text{-}(1\text{-}NH_3\text{-}8\text{-}NH_2\text{-sar})]^{4+}$, has been characterized using X-ray crystallography, demonstrating that Ga^{3+} is coordinated to six nitrogen atoms in a distorted octahedral complex. A bifunctional derivative of $(NH_2)_2$sar, possessing two aliphatic linkers with carboxylic acid functional groups has been attached to two cyclic-RGD peptides that target the $\alpha_v\beta_3$ integrin receptor that is overexpressed in some types of tumor tissue. This dimeric species can be radiolabeled with $^{68}Ga^{3+}$ in >98% radiochemical yield and $^{68}Ga^{3+}$ does not dissociate from the ligand in the presence of transferrin, an endogenous protein with high affinity for Ga^{3+}. Biodistribution and micro-PET imaging studies in tumor-bearing mice indicate that the tracer accumulates specifically in tumors with high integrin expression. The high tumor uptake is coupled with low nonspecific uptake and clearance predominantly through the kidneys resulting in high-quality PET images in animal models.



INTRODUCTION

Diagnostic imaging using positron emission tomography (PET) can provide clinicians with valuable information to guide and assess treatment regimes. PET relies on administering a tracer containing a positron-emitting isotope to a patient and then subsequently detecting the emitted radiation as the tracer passes through the body or accumulates within tissues as a function of biological processes. The radiolabeled glucose analogue FDG (^{18}F-fluoro-2-deoxy-D-glucose) is routinely used to probe glucose metabolism central to many cellular functions, but personalized and disease-specific diagnosis requires radiotracers that are designed to selectively target molecular characteristics of cells involved in the pathological process. ^{18}F is produced in a cyclotron and requires transport to imaging centers without an onsite facility. There are, therefore, potential advantages in using radiotracers that can be synthesized from generator-produced radioisotopes. Recently, the positron-emitting isotope, ^{68}Ga, has become available commercially by way of a ^{68}Ge/^{68}Ga generator.[1] The parent nuclide, ^{68}Ge, possesses a half-life of 271 days, and so ^{68}Ge/^{68}Ga generators can produce sufficient quantities of ^{68}Ga for up to one year. This generator system provides a relatively inexpensive and reliable source of a positron-emitting radionuclide without the need for a cyclotron. The favorable decay properties of ^{68}Ga (positron-emission, E_{max} 1.9 keV, 90%) coupled to a half-life of 68 min mean that the radionuclide is attractive for imaging applications based on peptide-targeted systems.[2,3]

Radioisotopes of gallium are already in use in nuclear medicine, for example, γ-emitting ^{67}Ga in the form of ^{67}Ga-citrate is used for single photon emission computed tomography scanning of lymphoma.[4] A ^{68}Ga complex bound to a peptide that targets neuroendocrine tumors is currently in clinical trials.[5] Peptide-targeted gallium containing imaging agents rely on a bifunctional ligand that complexes the gallium radioisotope into a coordination complex and also possesses a functional group to attach the targeting peptide to the gallium complex. It is important that the resulting Ga^{3+} complex is stable *in vivo*, as dissociation of $^{67/68}Ga^{3+}$ from the ligand can result in unwanted accumulation of activity in bone as well as prolonged circulation in the blood resulting in high background activity and inferior image quality.[6,7]

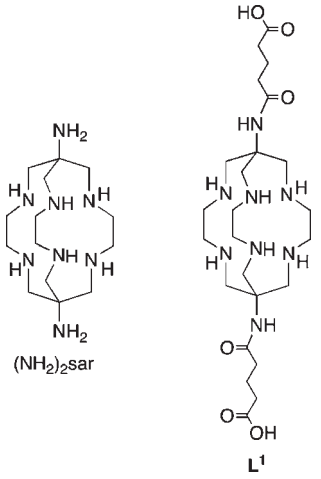

Figure 1. Structures of $(NH_2)_2$sar and $\mathbf{L^1}$.

Acyclic and cyclic bifunctional chelators have been investigated to coordinate $^{68}Ga^{3+}$ as well as the γ-emitting isotope $^{67}Ga^{3+}$. Currently, the most frequently employed cyclic chelators for attachment to targeting peptides are the macrocycles DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid)[5,8−15] and NOTA (1,4,7-triazacyclononane-1,4,7-triacetic acid).[16−21] Tracers incorporating NOTA bind Ga^{3+} rapidly under mild conditions, and the gallium complexes exhibit a high degree of stability. However, ligands based on a DOTA framework require heating for prolonged periods of time to bind Ga^{3+}, and the resulting complexes are only moderately stable in the presence of competing ligands, such as transferrin.[6] More recently, a bifunctional linear chelator with an N_4O_2 binding mode[22] and a bifunctional tris-hydroxy(pyridinone) chelator[23] have demonstrated promising properties for gallium radiopharmaceutical application, including fast and quantitative radiolabeling at room temperature, high complex stability, and a favorable biodistribution profile that included a renal clearance pathway.

An alternative macrocyclic ligand framework to the triaza and tetraazamacrocycles is the macrobicyclic hexaamine ligand, 1,8-diamino-3,6,10,13,16,19-hexaazabicyclo[6.6.6]icosane, commonly referred to as "diaminosarcophagine" ($(NH_2)_2$sar) (Figure 1).[24,25] Metal complexes of $(NH_2)_2$sar exhibit high stability and are kinetically inert, largely due to the encapsulating nature of the cage-like ligand.[26,27] Metal complexes of $(NH_2)_2$sar and functionalized derivatives have been attached to biomolecules,[28,29] and a few bifunctional derivatives have been synthesized, primarily designed as ligands for ^{64}Cu-based radiopharmaceuticals.[30−41] Metal complexes of this class of ligand have been investigated extensively but there are no reports of Ga^{3+} complexes. To our knowledge, this is the first report of using a sarcophagine ligand to coordinate positron-emitting ^{68}Ga. A derivative of $(NH_2)_2$sar with two pendent acyl groups ($\mathbf{L^1}$) each containing a carboxylic acid functional group has been conjugated to two targeting peptides bearing an arginine-glycine-aspartate (RGD) motif. Cyclic peptides with the sequence cyclic-(RGDxK) (where x = DPhe(f) or DTyr(y)) bind with high affinity and specificity to the $\alpha_v\beta_3$ integrin receptor that is overexpressed in activated endothelial cells of cancer neovasculature and some types of tumors.[18−20,42−54] Visualization of $\alpha_v\beta_3$ integrin receptors by diagnostic imaging is of interest in characterizing tumor angiogenesis. In this work, two cyclic-(RGDfK) peptides have been attached to a single cage amine ligand, $\mathbf{L^1}$, to give a dimeric targeting molecule $\mathbf{L^1}(RGDfK)_2$, which has been radiolabeled with $^{68}Ga^{3+}$. The dimeric construct has the possibility of benefiting from superior binding to target cells due to a bivalent effect where a single radiolabeled tracer binds to two receptors on a single cell. Diagnostic tracers possessing two or more peptide groups have demonstrated increased tumor uptake relative to their monomeric analogues and, as a result, superior PET image quality.[49,51] The *in vivo* behavior of this new dimeric cyclic-RGD gallium-68 radiotracer has been investigated in tumor-bearing mice.

EXPERIMENTAL SECTION

Instrumentation. ESMS spectra were recorded in the positive ion mode on an Agilent 6510 Q-TOF LC/MS mass spectrometer coupled to an Agilent 1100 LC system (Agilent, Palo Alto, CA). Data were acquired and reference mass corrected via a dual-spray electrospray ionization source, using the factory-defined calibration procedure. Each scan or data point on the total ion chromatogram is an average of 9652 transients, producing 1.02 scans s^{-1}. Spectra were created by averaging the scans across each peak. Mass spectrometer conditions: fragmentor, 200−300 V; drying gas flow, 7 L/min; nebulizer, 30 psi; drying gas temp, 325 °C; V_{cap}, 4000 V; skimmer, 65 V; OCT R_fV, 750 V; scan range acquired, 150−3000 m/z.

HPLC-MS traces were recorded using an Agilent Poroshell 300SB-C18 column (5 μm, 2.1 × 75 mm) coupled to the Agilent 6510 Q-TOF LC/MS mass spectrometer described above. Aliquots (1−10 μL) of each sample were injected onto the column using the Agilent 1100 LC system, with a flow rate of 0.25 mL/min and a gradient mobile phase, which started with 100% 0.1% formic acid in water at 5 min to 100% 0.1% formic acid in acetonitrile at 25 min. Data acquisition parameters are the same as those described above for mass spectra.

Semipreparative HPLC purifications were performed using an Agilent 1200 series HPLC system. Solvent gradients and column specifications are described below. An automated Agilent 1200 fraction collector collected 2.5 mL fractions and fraction collection was time-based. Each fraction was analyzed using MS and analytical HPLC. Reverse-phase HPLC method 1 employed an Eclipse XDB-C18 5 μm 9.5 × 250 mm column with a flow rate of 3 mL min^{-1}. The gradient mobile phase started with 100% solvent A (0.1% trifluoroacetate in water) at 5 min to 100% solvent B (0.1% formic acid in acetonitrile) at 75 min. Reverse-phase HPLC method 2 employed an Eclipse XDB-C18 5 μm 9.5 × 250 mm column with a flow rate of 3 mL min^{-1}. The gradient mobile phase started with 100% solvent A at 5 min and increased at a rate of 1% B min^{-1} until all components had eluted. The 1850 MBq $^{68}Ge/^{68}Ga$ generator used in this study was obtained from IDB Holland BV, The Netherlands. Radio-TLC analyses were performed using a Raytest Rita-Star TLC scanner using Merck TLC silica gel 60F254 plates.

Radio-HPLC analyses were performed using a Shimadzu HPLC consisting of a SCL-10AVP system controller, a SIL-10ADVP autoinjector, a LC-10 ATVP solvent delivery unit, a FCV-10AL control valve, a DGU-14A degasser, and a SPD-10AVP UV detector. This was coupled to a radiation detector consisting of an Ortec model 276 Photomultiplier Base with Preamplifier, an Ortec 925-SCINT ACE mate Preamplifier, Amplifier, BIAS supply and SCA and a Bicron 1 M 11/2 Photomultiplier Tube. The reverse-phase radio-HPLC method utilized a Machery-Nagel Nucleosil 5 C18-AB 250 × 4 mm column, with a flow

rate of 1 mL min^{-1}. The gradient mobile phase started with 100% solvent A to 80% solvent B at 12 min, with 100% A from 12 to 15 min. The size exclusion radio-HPLC method employed a Waters Biosuite 125 5 μm HR SEC, 300 × 7.8 mm column with a flow rate of 1 mL min^{-1} of 0.1 M phosphate buffer (pH 7) for a data acquisition time of 20 min.

Micro-PET scanning and well-counter instrumentation is described below.

NMR spectra of $[Ga((NH_2)_2sar)](NO_3)_3$, $\mathbf{L^1}$ and $[Ga\mathbf{L^1}](NO_3)_3$ were acquired in D_2O on a Varian FT-NMR 500 spectrometer. ^1H NMR spectra were acquired at 500 MHz, and ^{13}C NMR spectra were acquired at 125.7 MHz. ^1H NMR and ^{13}C NMR spectral shifts were referenced to acetone (δ = 2.22 ppm, δ = 30.89 ppm, respectively). ^1H NMR spectra of $\mathbf{L^1}(RGDfK)_2$ and $[Ga(\mathbf{L^1}(RGDfK)_2)](C_2F_3O_2)_3$ were acquired at 25 °C on a Bruker 600 MHz Avance II spectrometer with a TCI cryoprobe. NMR solutions typically contained ~1 mg/mL peptide in 90% H_2O/10% D_2O without buffer, pH 2−4. TOCSY spectra were acquired over 6292 Hz with 2048 complex data points in F2, 512 increments in F1, and 16 scans per increment. For all experiments in 90%H_2O/10%D_2O, water suppression was achieved using presaturation. Spectra were processed using *TOPSPIN* v 1.3 (Bruker, Germany) software. The *t*1 dimensions of all TOCSY spectra were zero-filled to 2048 real data points with QSINE bell window functions applied in both dimensions followed by Fourier transformation and fifth-order polynomial baseline correction.

Materials and Synthesis. *Synthesis of $[Ga((NH_2)_2sar)]^{3+}$.* To a mixture of $(NH_2)_2$sar (14 mg, 0.003 mmol) dissolved in acetonitrile (2 mL) was added $Ga(NO_3)_3 \cdot xH_2O$ (9 mg) dissolved in methanol (2 mL) resulting in the immediate precipitation of a white solid. The solid was collected by filtration and washed with methanol. The solid was recrystallized from a water/ethanol mixture to give colorless needle-like crystals. A further recrystallization from water/acetone in the presence of HNO_3 (conc., 3 drops) gave colorless block-shaped crystals suitable for X-ray crystallography. MS: $[Ga(C_{14}H_{32}N_8)]^+$ 381.20 (experimental), 381.20 (calculated).

Crystal data: $[Ga((NH_2)_2sar)](NO_3)_3$ $Ga_2C_{28}H_{70}N_{24}O_{24}$, M = 1266.52, T = 130 (2) K, λ = 1.54184, monoclinic, space group $P21/n$, a = 10.3267 (3), b = 13.5498 (5), c =17.1407 (4) Å, β = 93.660(2)°, V = 2393.52 (13) Å^3, Z = 2, D_c = 1.757 mg M^{-3}, μ(Cu−Kα) 2.372, F(000) = 1320, crystal size 0.1930 × 0.1080 × 0.0360 mm^3. 9405 reflections measured, 4323 independent reflections (R_{int} = 0.043), the final R was 0.0328 [$I > 2\sigma(I)$] and $wR(F^2)$ was 0.0866.

The compounds $\mathbf{L^1}$ and $(t\text{-Boc})_5(Succ)_2\mathbf{L^1}$ were synthesized as previously reported.[33]

$[Ga\mathbf{L^1}](NO_3)_3$: A solution of ethanol (100 mL) containing $Ga(NO_3)_3 \cdot xH_2O$ (100 mg), $\mathbf{L^1} \cdot xHCF_3SO_3$ (150 mg) and sodium acetate (0.1 M) was heated at reflux overnight. Concentrated hydrochloric acid (5 mL) was added and the solution was applied to a DOWEX 50Wx2 cation exhange column (H^+ form, 10 × 5 cm). The column was washed with 1 M HCl solution (500 mL) and then eluted with 4 M HCl (350 mL) and the eluent was evaporated to dryness under reduced pressure at 45 °C to give a colorless residue. Yield: $[Ga\mathbf{L^1}](Cl)_3 \cdot xHCl$: 160 mg. The colorless residue was dissolved in deionized water (~5 mL) and several drops of nitric acid were added and the solution left to crystallize overnight. Colorless crystals were collected by filtration. MS: $[GaC_{24}H_{44}N_8O_6]^+$ 609.27 (experimental), 609.27 (calculated). ^1H NMR: δ 1.87, m, 4H, βCH_2 (with respect to COOH); 2.29, t, ^3J = 7.3 Hz, 4H, glutarate CH_2; 2.42, t, ^3J = 7.2 Hz, 4H glutarate CH_2; 2.96, d, ^3J = 9.5 Hz, 6H, cage CH_2; 3.43, d, ^3J = 13.4 Hz, 6H, cage CH_2; 3.61, d, ^3J = 9.5 Hz, 6H, cage CH_2; 3.91, d, ^3J = 13.4 Hz, 6H, cage CH_2. ^{13}C NMR: δ 23.1, 35.7, 37.7 (glutarate CH_2), 49.8, 52.4, 57.8 (cage), 178.8, 180.7 (CO).

$\mathbf{L^1}(RGDfK)_2$: Cyclic-(RGDfK) peptide was synthesized by solution cyclization of the linear protected peptide, H-Asp-(OtBu)-D-Phe-Lys(Boc)-Arg(Pbf)-Gly-OH, followed by deprotection using trifluoroacetic acid in the presence of triisopropylsilane and water followed by purification using semipreparative HPLC.[55] Cyclic-(RGDfK) peptide (3 mg) and $(t\text{-Boc})_5(Succ)_2\mathbf{L^1}$ (5 mg) were dissolved in dimethylformamide (400 μL) and diisopropylethylamine (3 μL) was added. This solution was stirred at ambient temperature for 2 h. Acetonitrile/water (50%/50%) (4 mL) was added and the solution applied to a C18 semipreparative HPLC column and separated using HPLC method 2. Fractions containing pure material were combined, frozen and lyophilized. $(t\text{-Boc})_5\mathbf{L^1}(RGDfK)_2$ (1 mg) eluted at 43 min. MS: $[C_{103}H_{166}N_{26}O_{28}]^{2+}$ 1108.12 (experimental), 1108.12 (calculated). Analytical HPLC: 14.24 min (0% to 100% B in 25 min). $(t\text{-Boc})_5\mathbf{L^1}(RGDfK)_2$ was dissolved in trifluoroacetic acid (1−2 mL) and stirred for ~2 h. The trifluoroacetic acid was evaporated under a stream of N_2 gas. Acetonitrile (1 mL) and water (1 mL) were added to redissolve the residue, and the solution frozen and lyophilized. The dried material was redissolved and purified using a C18 semipreparative HPLC column using HPLC method 2. $\mathbf{L^1}(RGDfK)_2$: MS $[C_{78}H_{126}N_{26}O_{18}]^{2+}$: 857.49 (experimental), 857.49 (calculated). Analytical HPLC: 11.84 min (0% to 60% B in 25 min).

$[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$: An ethanol solution containing $\mathbf{L^1}(RGDfK)_2$ (~50 μg) and gallium nitrate (10 μg) with sodium acetate (0.1 M) was heated at 65 °C for one hour. Similarly, two reaction solutions containing the same components were incubated at room temperature and 35 °C for one hour. The mixture was diluted with deionized water and LCMS was acquired of an aliquot. A sample of $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ for NMR analysis was synthesized in a similar manner and was subsequently isolated using HPLC method 2.

Radiochemical Synthesis. $^{68}GaCl_3$: ^{68}Ga was eluted from the generator where ^{68}Ge was attached to a tin dioxide column using 6 mL of 0.4 M HCl. The method for purifying $^{68}GaCl_3$ was adapted from a previously reported procedure.[56] A solution of $^{68}GaCl_3$ was eluted from the $^{68}Ge/^{68}Ga$ generator with aqueous HCl (5 mL, 0.4 M) and $^{68}GaCl_3$ was trapped on a cation exchange column (BioRad AG 50W × 4, 200−400 mesh). The cation exchange column was washed with a solution of 0.15 M HCl in acetone/water (80%/20%) (1 mL) and $^{68}GaCl_3$ was eluted with a solution of 0.05 M HCl in acetone/water (97.5%/2.5%) (0.4 mL).

$[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$: An aliquot (0.05 M HCl in acetone/water (97.5%/2.5%), 200 μL) containing $^{68}GaCl_3$ (6−12 mCi) was added to $\mathbf{L^1}(RGDfK)_2$ (~50 μg) dissolved in a sodium acetate/ethanol solution (0.1 M, 2 mL). The mixture was heated at 85 °C for 30−35 min, at which point the solvent had evaporated. The remaining residue was dissolved in aqueous sodium chloride (0.9%, 2 mL). TLC analysis (0.1 M sodium citrate mobile phase): $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ R_f < 0.1, 98.8%; $^{68}Ga^{3+}$ R_f > 0.8, 1.2%. Radio-HPLC analysis: Scintillation detector 9.68 min, 100%, UV−vis detector, 9.67 min.

Stability Studies. Stability studies using $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$: Radiolabeled $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$, synthesized as described above, was dissolved in phosphate buffer (800 μL, 1 M, pH 7.4) containing 6 mg of apo-transferrin. This solution was incubated

at 37 °C for 120 min. Aliquots were subjected to HPLC analysis using a size exclusion column after 0 and 120 min. UV−vis detector: apo-transferrin, 7.97 min. 0 min: TLC analysis: $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ $R_f < 0.1$, 98.9%; $^{68}Ga^{3+}$ $R_f > 0.8$, 1.1%. Scintillation detector $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$, 13.19 min, 100%. 120 min: TLC analysis: $R_f < 0.1$, 97.7%; $^{68}Ga^{3+}$ $R_f > 0.8$, 2.3%. Scintillation detector: 13.41 min, 88.62%; 14.49 min, 11.38%.

Tumor Cell Line. Mouse mammary epithelial cell line, 66cl4β3, was a gift from Dr N. Pouliot (Peter MacCallum Cancer Centre, Melbourne, Australia). The cells have been genetically engineered to express high levels of integrin $\alpha_v\beta_3$.[57] The human squamous cell carcinoma line A431 was purchased at ATCC. Cells were maintained at 37 °C in a 5% CO_2 incubator and cultured in α-MEM medium supplemented with either 5% (66cl4β3 cells) or 10% (A431 cells) fetal calf serum.

In Vitro Studies. Cells (2.5×10^5 cells/well) were plated in 12-well plates and incubated overnight. Prior to addition of activity, the cells were washed three times with PBS and incubated at 37 °C for 15 min with 1 mL of uptake buffer (125 mM NaCl, 4.8 mM KCl, 1.3 mM $CaCl_2$, 1.2 mM $MgSO_4$, 25 mM HEPES, 1.2 mM KH_2PO_4, 5.6 mM glucose, pH adjusted to 7.4 with NaOH). The uptake buffer was then replaced by 0.5 mL uptake buffer containing 0.62 MBq/mL of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ and incubated at 37 °C for 30 min. Cells were washed three times with ice−cold PBS and solubilized in 0.5 mL sodium borate solution (10 mM) containing 1% sodium dodecyl sulfate. The lysates were transferred to tubes for well counting and ^{68}Ga disintegrations at 511 Kev ±15% were quantified in a well counter (187-950-A100 MCA; Biomedex Medical Systems) attached to a multichannel analyzer interfaced with *Atomlabs 950* software. For experiments at 4 °C, cells were placed on ice 15 min prior to addition of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ and during the course of the incubation period. Uptake medium containing $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ was also cooled to 4 °C prior to addition to cells. All experiments were performed in quadruplicate and normalized to protein content (BCA method, Pierce). Results were expressed as the percentage of the added radioactive dose per mg of protein (%AR/mg).

Tumor Implantation and PET Imaging. Tumor xenografts were established in the shoulder of 6−8 week old anaesthetized (inhalation of 2.5% isoflurane [Abbott Laboratories] in 50% O_2 in air) Balb/c mice by injecting 10^5 66cl4β3 cells subcutaneously in 100 μL 1:1 PBS/Matrigel (BD Biosciences). When tumor volumes reached approximately 200 mm^3, a size at which partial volume effects are modest on the micro-PET system used for imaging, mice were injected with 15−22 MBq $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ in 100 μL saline via lateral tail vein. Two hours after tracer injection, animals ($n = 5$) were anaesthetized as above and scanned for 10 min on a Mosaic small animal PET scanner (Philips Medical Systems, Ohio, USA; resolution 2.7 mm at the center of the FOV). An energy window of 450−700 keV and a 6 ns coincidence-timing window were used. Data were acquired in 3D mode and corrected for isotope decay and random disintegrations. Images were reconstructed with the 3D RAMLA algorithm and tracer uptake measured using the region of interest (ROI) software on the Mosaic workstation. Briefly, ROIs were drawn around tumors as well as background regions chosen to represent the mediastinal blood pool excluding regions of tracer accumulation such as kidneys and bladder. Tumor-to-background ratios were calculated by dividing the maximum pixel intensity within the tumor ROI by the average pixel intensity within the background ROI.

Biodistribution Studies. After 0.5, 1, 1.5, and 2 h, animals ($n = 3$ for each time point) were sacrificed and tumor and tissues were removed and weighted before analysis of retained radioactivity. Disintegrations at 511 Kev ±15% were quantified in a well counter (187−950-A100 MCA; Biomedex Medical Systems) attached to a multichannel analyzer interfaced with *Atomlabs 950* software. For blocking studies, animals ($n = 3$) were coinjected with 0.2 mg of cyclic-(RGDfK) peptide and sacrificed at 2 h and subjected to the same tumor and tissue analysis as described above. Linear regression models were used to estimate mean differences in uptake between blocked and unblocked animals, and the Wald test was used to obtain p-values for these differences.

RESULTS AND DISCUSSION

Synthesis of $\mathbf{L^1}(RGDfK)_2$. The bifunctional ligand $\mathbf{L^1}$ possesses two carboxylate groups and can be derivatized to give a sarcophagine−peptide dimeric species containing two biologically active peptide groups. The first dimeric construct of $\mathbf{L^1}$ a cage amine ligand tethered to two bombesin targeting peptides was reported recently, as well the characterization of the $^{64}Cu^{2+}$ complex.[58] A similar synthetic strategy was applied here to prepare a derivative with two cyclic-RGD peptide motifs linked to a single cage amine ligand, $\mathbf{L^1}(RGDfK)_2$. In the first step of the synthesis, the secondary amine groups of $\mathbf{L^1}$ were protected with *N-tert*-butoxycarbonyl (*t*-Boc) to give a derivative with five *N-tert*-butoxycarbonyl groups, $(t\text{-Boc})_5\mathbf{L^1}$ (Scheme 1). This protection step ensures selectivity in the peptide coupling reaction preventing any potential coupling between the secondary amine atoms of one cage amine ligand with the activated ester of another cage amine ligand. The reaction of $(t\text{-Boc})_5\mathbf{L^1}$ with *N*-hydroxysuccinimide in the presence of diisopropylethylamine allowed isolation of the activated N-succinimidyl ester, $(t\text{-Boc})_5(Succ)_2\mathbf{L^1}$. This activated ester was then reacted with cyclic-(RGDfK), the activated ester reacting with the amine side chain of lysine. Deprotection followed by purification by HPLC allowed isolation of $\mathbf{L^1}(RGDfK)_2$ (Scheme 1).

In at least one experiment of this type, the coupling reaction between $(t\text{-Boc})_5(Succ)_2\mathbf{L^1}$ and cyclic-(RGDfK) did not go to completion allowing the isolation of a product where only one of the activated esters had coupled to the peptide. Purification by HPLC enables the isolation of a compound where one peptide had formed an amide with the carboxylate functional group on one end of the ligand, but the second carboxylate functional group remained as an unreacted activated N-succinimidyl ester, $(t\text{-Boc})_5(Succ)\mathbf{L^1}(RGDfK)$. This species with a single activated ester remaining can be used to form heterodimeric sarcophagine derivatives as illustrated by the synthesis of $\mathbf{L^1}(RGDfK)(Lys^3$-bombesin1−14) (see Supporting Information). Lys^3-bombesin-(1−14) is a 14 amino acid peptide that binds to gastrin-releasing receptors that are overexpressed in certain cancers and radiolabeled derivatives have been used to image tumors. The isolation of this elegant heterodimeric cage amine ligand highlights the exciting possibilities for multimeric constructs synthesized from $\mathbf{L^1}$ as dual function radiotracers.

Synthesis of $[Ga(NH_2)_2sar)]^{3+}$, $[GaL^1]^{3+}$, and $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$. Sarcophagine ligands offer a flexible macrobicyclic cage amine framework with six secondary amine donors capable of encapsulating metal ions in a six coordinate environment with geometries varying between octahedral and trigonal prismatic.[59−61] Many metal complexes of sarcophagine and its derivatives have been structurally characterized by X-ray crystallography, but this is the

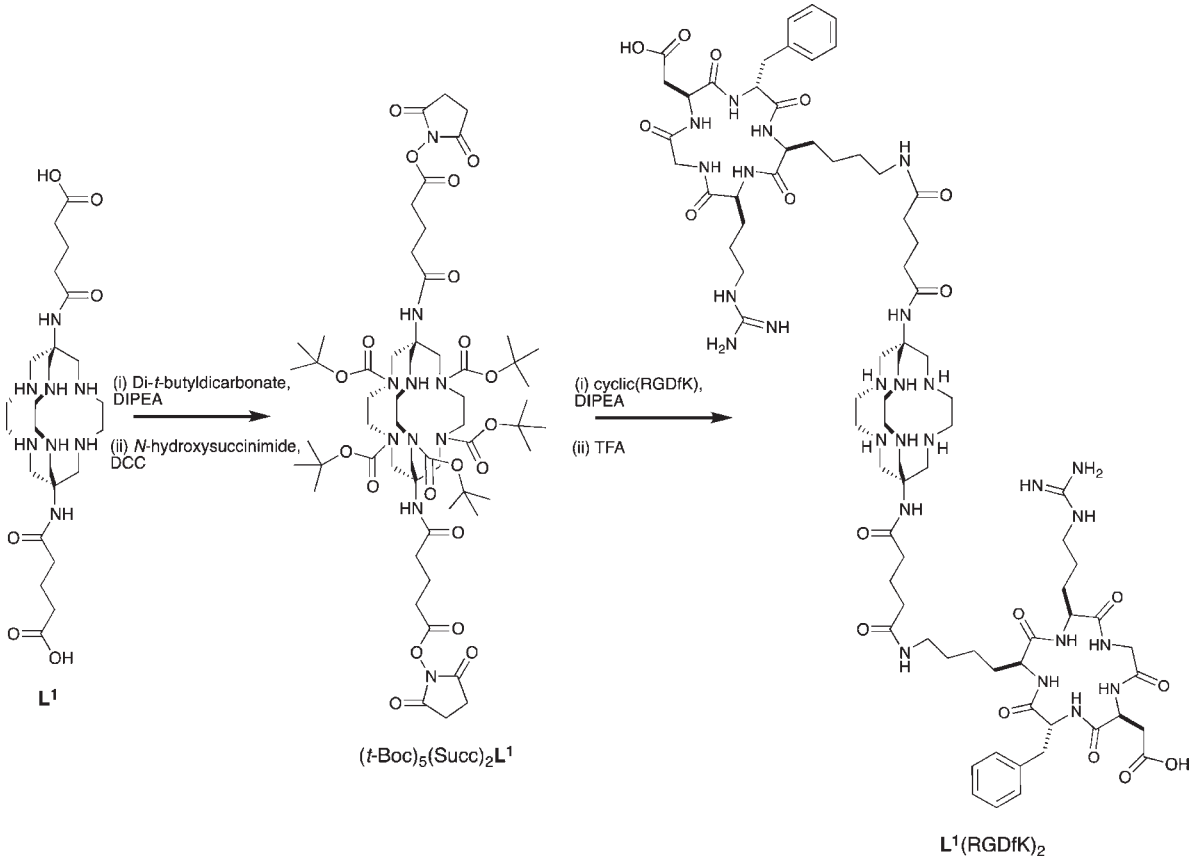

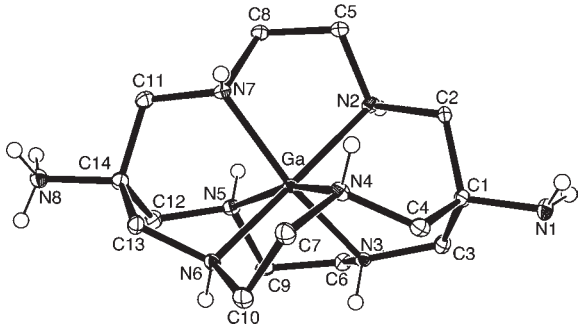

Figure 2. ORTEP representation of the cation present in $[Ga\text{-}(1\text{-}NH_3\text{-}8\text{-}NH_2\text{-}sar)](NO_3)_4$. Ellipsoids are shown at the 40% probability level. Hydrogen atoms attached to carbon are omitted for clarity.

first report of the molecular structure of a gallium sarcophagine complex. The gallium complex of $(NH_2)_2$sar was prepared by addition of $Ga(NO_3)_3$ to a solution of the ligand in acetonitrile at room temperature. Crystals of $[Ga((NH_2)(NH_3)sar)]^{4+}$ suitable for structural studies were grown from an aqueous solution after the addition HNO_3 (Figure 2). The gallium is six coordinate with a distorted octahedral geometry with trigonal distortions with both enantiomers present in the unit cell. The Ga−N bond lengths range 2.068(2)−2.114(2) Å. The encapsulating ligand adopts a relatively rare *lel*$_2$*ob* conformation where the terms *lel* and *ob* refer to either parallel or oblique orientations of the C−C bond of the five-membered chelate ring with respect to the C_3 axis.[30,60,61] The nitrate anions have several close contacts to NH residues of the cage amine ligand to form an intricate hydrogen bonding array within the lattice.[61]

Efforts to form Ga^{3+} complexes of L^1 and $L^1(RGDfK)_2$ using nonradioactive naturally abundant gallium sources focused on conditions designed to be relevant to radiolabeling with $^{68}Ga^{3+}$ that is obtained from a $^{68}Ge/^{68}Ga$ generator that is normally eluted with hydrochloric acid. The coordination of Ga^{3+} to the diacylated ligand L^1 was monitored by ^1H NMR and ESMS revealing

dx.doi.org/10.1021/bc200319q |*Bioconjugate Chem.* 2011, 22, 2093–2103

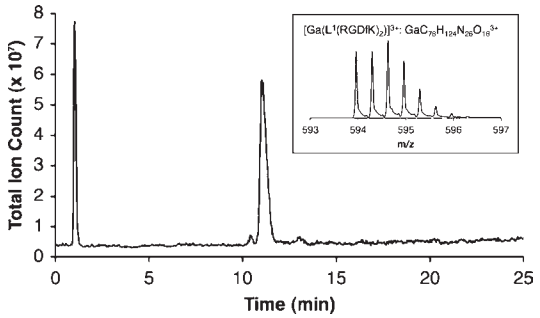

Figure 3. HPLC-MS chromatogram of $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$, R_t = 11.01 min (R_t = 1.01 min) corresponds to sodium acetate). Inset: ESMS of peak at R_t = 11.01 min = $[^{nat}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$.

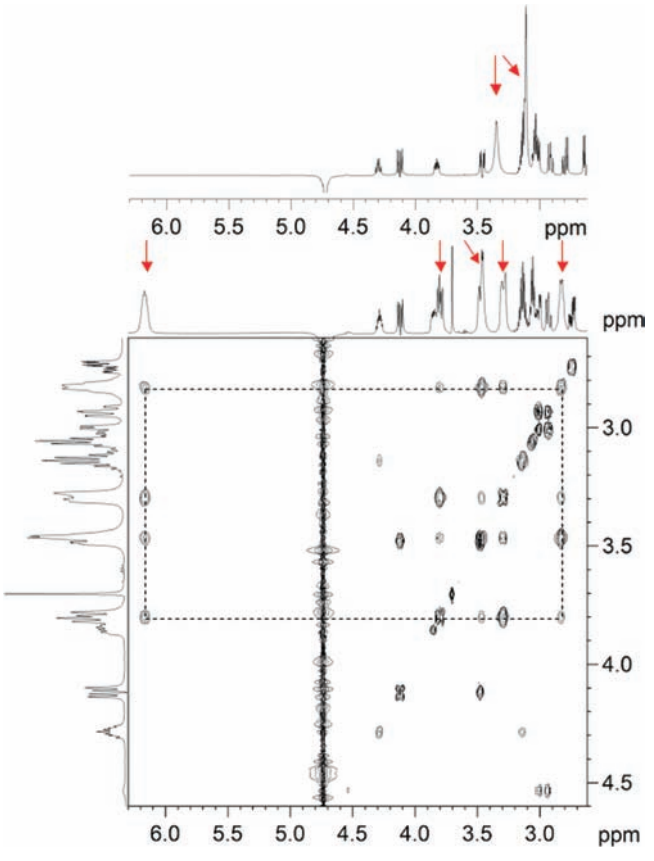

Figure 4. Top: ^{1}H 1D NMR spectrum of $\mathbf{L^1}(RGDfK)_2$ in H_2O/D_2O. Bottom: ^{1}H TOCSY spectrum of $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ in H_2O/D_2O with ^{1}H 1D projections. Arrows indicate sarcophagine group proton signals.

that $[Ga\mathbf{L^1}]^{3+}$ forms quantitatively in ethanolic mixtures of sodium acetate (0.1 M). A ^{1}H NMR spectrum of $[Ga\mathbf{L^1}]^{3+}$ indicates that the metal ion is coordinated to the secondary amine nitrogen atoms of the sarcophagine ligand due to the appearance of four geminally coupled diastereotopic methylene signals of the sarcophagine ligand framework. The ESMS has a signal at m/z = 609.27 with the expected isotope pattern corresponding to the monocationic complex originating from deprotonation of the two carboxylic acids, of $[Ga\mathbf{L^1}\text{-}2H^+]^+$.

The gallium complex of $\mathbf{L^1}(RGDfK)_2$ can be prepared in ethanol containing sodium acetate (0.1 M) by heating at 65 °C for 30 min. The complex, $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$, was characterized

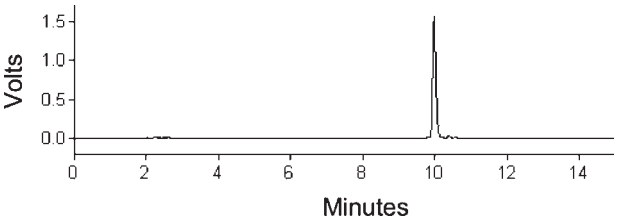

Figure 5. HPLC chromatogram of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ (detection of radioactivity).

by HPLC-MS with a single peak in the chromatogram with a signal in the ESMS at m/z = 594.63 with the expected isotope pattern corresponding to tricationic $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ (Figure 3). The stability of the attached RGDfK peptide under these reaction conditions was confirmed by analysis by HPLC. Complexation at a lower temperature (35 °C) resulted in lower yields of $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$.

The coordination of Ga^{3+} within the encapsulating cage amine ligand rather than to the donor atoms of the cyclic-(RGDfK) peptide was confirmed by ^{1}H NMR spectroscopy. The ^{1}H NMR spectrum of $\mathbf{L^1}(RGDfK)_2$ in H_2O/D_2O (90%/10%) has two broad resonances between 3.0 and 3.5 ppm, each integrating to twelve protons (Figure 4, top, red arrows) due to the methylene groups of the sarcophagine framework. Resonances that could be attributed to the secondary amine atoms of the cage framework are not observed as a result of the rate of proton exchange relative to the NMR time scale under these conditions (H_2O, pH 3−5). A consequence of coordination and encapsulation of Ga^{3+} by the cage amine ligand is that the methylene protons become diastereotopic as observed in the ^{1}H NMR spectrum of $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$, confirming that the metal ion resides within the cage framework (Figure 4). Unlike the "free" ligand, it is possible to observe a resonance attributable to protons from the secondary amine groups of the cage in $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ and the TOCSY spectrum shows that methylene cage protons and protons of the secondary amine groups are all coupled to each other (Figure 4).

$\mathbf{L^1}(RGDfK)_2$ Can Be Radolabeled with $^{68}Ga^{3+}$ to Give $[Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ in High Radiochemical Purity. Solutions containing $^{68}GaCl_3$ were eluted from the $^{68}Ge/^{68}Ga$ generator using aqueous HCl solutions—in this case, 0.4 M HCl solution (5 mL).[56] Postelution preconcentration and purification results in solutions of $^{68}GaCl_3$ containing lower concentrations of HCl, lower concentrations of "other" metal ions including Zn^{2+} (decay product), $^{68}Ge^{4+}$ (break-through from generator), Fe^{3+} and Ti^{4+} (generator matrix), and smaller volumes of solution. The postelution purification method employed here yielded solutions of $^{68}GaCl_3$ (15−25 mCi) in 400 μL 0.05 M HCl in ~97.5% acetone/2.5% water.

Addition of this preconcentrated $^{68}GaCl_3$ solution to $\mathbf{L^1}$-$(RGDfK)_2$ (50 μg) in a solution of ethanol containing sodium acetate (0.1 M, 1 mL) and heating the mixture at 85 °C for 30 min resulted in the formation of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ in high radiochemical yield. During the heating period, the solvent evaporated and the residue was dissolved in saline for *in vivo* experiments. The radiochemical purity was greater than 98% with $\mathbf{L^1}(RGDfK)_2$ binding Ga^{3+} quantitatively to form a single radiolabeled product (Figure 5), as monitored by radio-TLC and radio-HPLC. The composition of the radiolabeled compound was confirmed by HPLC with coelution of the radiolabeled product with "cold" $[Ga((\mathbf{L^1}(RGDfK)_2)]^{3+}$ (detected at λ_{220}). This also confirmed that the conjugated peptide was stable under the radiolabeling conditions. Performing the radiolabeling at room

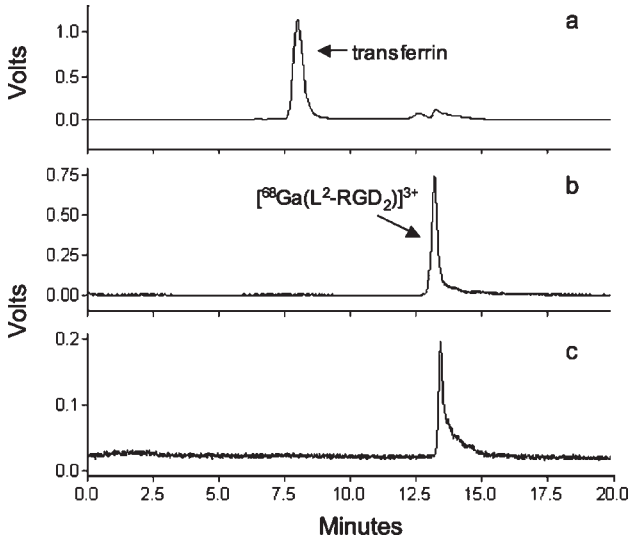

Figure 6. Size exclusion chromatography of (a) apo-transferrin protein (λ_{220}); (b) $[Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ (with a radiation detector); (c) solution of $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ incubated with apo-transferrin for 120 min (with a radiation detector).

temperature results in a lower radiochemical yield (30% after incubation for 30 min). The radiolabeling conditions described give a single radioactive product in high radiochemical yield allowing for minimal postprocessing of labeled species prior to *in vivo* administration.

$[Ga(L^1(RGDfK)_2)]^{3+}$ is Stable in the Presence of Transferrin. The endogenous protein transferrin is an iron transporter with two Fe^{3+} binding sites that is abundant in human serum (2.5 mg/mL, of which about 30% is occupied with Fe^{3+}). Transferrin binds Fe^{3+} with high affinity ($\log \beta_1 = 22.8$, $\log \beta_2 = 44.3$) but also displays high affinity for Ga^{3+} ($\log \beta_1 = 20.3$, $\log \beta_2 = 39.6$), which has a similar ionic radius to Fe^{3+}.[62] One of the major challenges in the design of any gallium radiopharmaceutical is to impart sufficient kinetic stability to the Ga^{3+} complex so that it can withstand competition in the presence of high serum levels of transferrin. The kinetic stability of $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ was assessed by a challenge experiment with apo-transferrin (iron-free transferrin). A sample of $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ was incubated at pH 7.0 at 40 °C for 2 h in the presence of apo-transferrin (7 mg/mL), and the mixture was analyzed by size exclusion chromatography. Under the size exclusion chromatographic conditions employed here, apo-transferrin elutes at 7.97 min (detected at λ_{220}) and $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ elutes at 13.19 min (detected using a radiation detector) (Figure 6). After incubation with apo-transferrin for 2 h, >88% of the radioactive activity is associated with a species with a retention time of 13.41 min and the remaining activity, 11%, is associated with a species with a retention time of 14.49 min (Figure 6). Additionally, analysis by radio-TLC of the incubated sample indicated that only *ca.* 2.0% of ^{68}Ga activity could be attributed to ^{68}Ga not bound to peptide or protein. These data indicate the presence of a ^{68}Ga-bound peptide species, and importantly, there is no transfer of $^{68}Ga^{3+}$ to apo-transferrin indicating that the $^{68}Ga^{3+}$ sarcophagine complex is kinetically stable in the presence of apo-transferrin.

***In Vitro* Characterization of Cell Uptake of $[^{68}Ga(L^1(RGDfK)_2)]^{3+}$.** *In vitro* uptake of $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ was compared in 66cl4β3 cells that have been engineered to express high levels of integrin $\alpha_v\beta_3$[57] and A431 human squamous cell carcinoma cells that do not express $\alpha_v\beta_3$.[63] Radioactivity counted

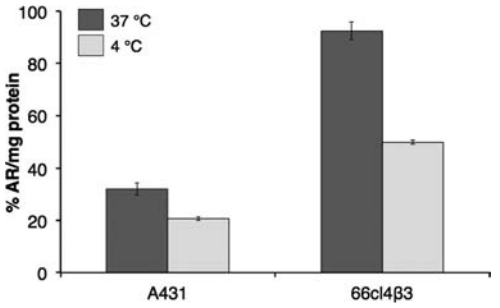

Figure 7. *In vitro* uptake of $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ in $\alpha_v\beta_3$-positive 66cl4β3 cells vs $\alpha_v\beta_3$-negative A431 cells. Cells were incubated either at 37 or 4 °C for 30 min with 0.6 MBq $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$. Results are expressed as percentage of added radioactivity per mg of protein (%AR/mg protein) and represent mean ± standard error of four experiments.

in cells incubated at 37 °C represents cell surface-bound and internalized ^{68}Ga activity, whereas radioactivity counted in cells incubated at 4 °C largely represents only cell surface-bound activity. Activity for 66cl4β3 cells measured 92.5 ± 3.4 of % added radioactivity/mg protein (%AR/mg) at 37 °C, and 49.8 ± 0.9%AR/mg at 4 °C, indicating that over 40%AR/mg is internalized after 30 min incubation at 37 °C (Figure 7). This contrasts the observations for the negative control A431 experiments, where radioactivity measured 32.0 ± 2.3%AR/mg at 37 °C and 20.7 ± 0.7 at 4 °C, indicating that only ~10%AR/mg is internalized after 30 min incubation at 37 °C.

These *in vitro* results demonstrate that $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ exhibits both significantly increased cell-surface binding and internalization in an $\alpha_v\beta_3$-positive cell line compared to an $\alpha_v\beta_3$-negative cell line, suggesting retention of activity toward $\alpha_v\beta_3$ receptors.[64] Nonetheless, in-depth biological characterization of this class of tracers is the focus of ongoing work.

Biodistribution and Tumor Uptake $[^{68}Ga(L^1(RGDfK)_2)]^{3+}$. Mice bearing subcutaneous 66cl4β3 tumors that express high levels of integrin $\alpha_v\beta_3$ were sacrificed 0.5, 1, 1.5, and 2 h after injection of 15−22 MBq $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ in the tail vein. Primary tumor, blood, muscle, kidney, and liver were recovered, and the radioactivity in these tissues was measured by well counting (Figure 8). In the tumor, the percentage of injected dose per gram of tissue (%ID/g) reached an average value of 4.80 ± 1.38 at 0.5 h postinjection (PI) rising to 6.83 ± 0.47 at 1.5 h PI and remaining at 6.30 ± 0.45 at 2 h PI. Radioactivity cleared rapidly from the blood, reaching a peak of 1.23 ± 0.33%ID/g at 0.5 h PI that decreased to 0.25 ± 0.03%ID/g at 2 h PI. Muscle activity was low over the time course of the experiment (<1%ID/g at all time points). High levels of activity were observed in the kidney, with the highest activity seen at 1 h PI (40.23 ± 11.26% ID/g) decreasing by half by 2 h PI (19.96 ± 0.88%ID/g). Liver uptake was moderate, with activity measuring between 6 and 9% ID/g at all observed time points. Tumor/blood ratios gradually increased over the course of the experiment, consistent with rapid blood clearance and high tumor retention, increasing from 4.46 ± 2.06 at 0.5 h PI to 26.37 ± 5.38 at 2 h PI.

The high tumor uptake together with the low retention in nontarget organs observed soon after the tracer injection (from 1.5 h) makes $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ eminently suitable for PET imaging using short-lived isotopes such as ^{68}Ga. These results also indicate that $[^{68}Ga(\mathbf{L}^1(RGDfK)_2)]^{3+}$ is predominantly eliminated through the kidneys and that the hepato-biliary clearance route contributes minimally to excretion of ^{68}Ga activity. Clearance

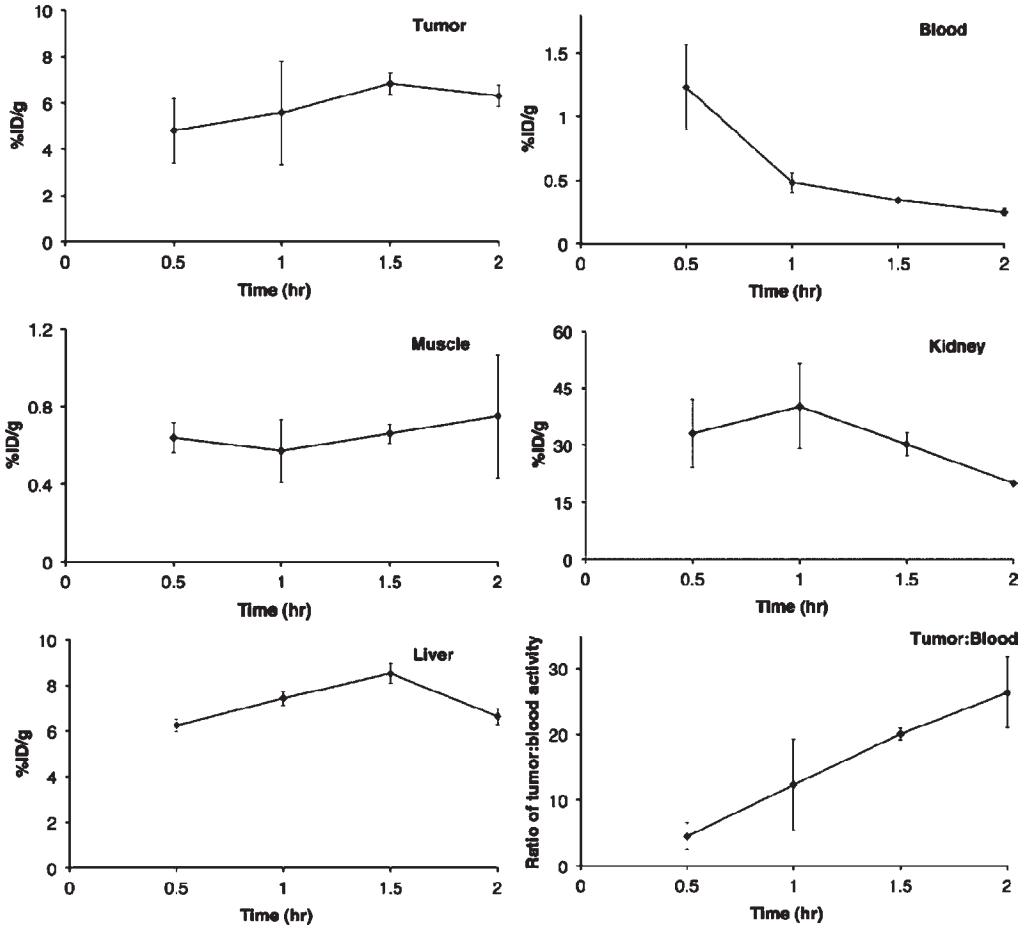

Figure 8. Time-dependent biodistribution of ^{68}Ga radioactivity in Balb/c mice bearing 66cl4β3 tumors administered with $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$. Results are expressed as percentage of injected dose per gram of tissue (%ID/g) and represent the mean ± SD from four separate experiments, each comprising three mice.

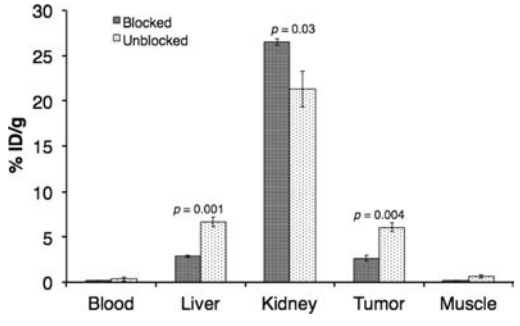

Figure 9. Biodistribution of ^{68}Ga activity in Balb/c mice bearing 66cl4β3 tumors 2 h postinjection with $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ cyclic-(RGDfK) peptide ("blocked") or with $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ ("unblocked"). Data presented are the mean ± standard error values of 3 mice, and p values were calculated using a Wald test of differences between means.

predominantly through the kidneys is favorable for diagnostic imaging purposes often leading to rapid clearance of activity in nontarget organs and tissue, resulting in low background levels for PET images.

To investigate the specificity of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ for $\alpha_v\beta_3$ integrin receptor, a "blocking" experiment was performed by coinjecting cyclic-(RGDfK) with $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ (Figure 9). The specific blocking of $\alpha_v\beta_3$ resulted in a decrease of 56% of activity in the tumor at 2 h PI (6.07 ± 0.49%ID/g for a standard injection vs 2.64 ± 0.34%ID/g for a blocking experiment, p = 0.004), confirming that the peptide targeting group is indeed targeting receptors that bind the cyclic-(RGDfK) motif. Similarly, coinjection of cyclic-(RGDfK) resulted in a decrease of over half the measured activity in the liver at 2 h PI (6.66 ± 0.52%ID/g for a standard injection vs 2.87 ± 0.13%ID/g for a blocking experiment, p = 0.001), indicating that liver uptake of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ is most likely receptor-mediated. Taken together, these results clearly indicate that the tumor retention of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ is selective and receptor-mediated.

$[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ PET Imaging. Micro-PET scans of Balb/c mice bearing 66cl4β3 tumors were acquired at 2 h PI as ratios for tumor/kidney and tumor/blood were highest at 2 h PI (0.32 ± 0.01 and 26.37 ± 5.38, respectively). A representative micro-PET scan is included in Figure 10. In all scans, tumors could be easily delineated from normal tissue, with an average tumor/background intensity ratio of 2.68 ± 0.16. Consistent with biodistribution data, the kidneys and liver of each animal could also be delineated, along with the bladder. Notably, micro-PET scans indicate that skeletal uptake is low, which is consistent with the kinetic stability of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ *in vivo*.

SUMMARY

The encapsulating yet flexible sarcophagine ligands form kinetically and thermodynamically stable metal complexes with fast complexation kinetics, and have been demonstrated to be of particular interest in the development of copper radiopharmaceuticals.[33−35,37−39]

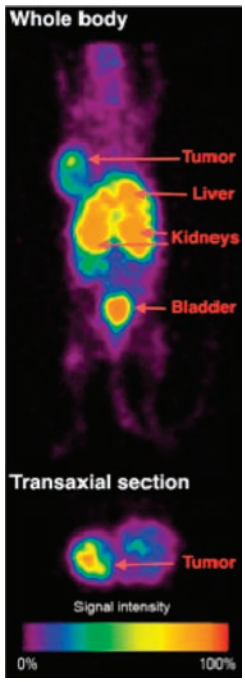

Figure 10. Micro-PET scan of a Balb/c mouse with selective uptake of $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ in 66cl4β3 tumor. PET images were obtained 2 h post injection of 15−22 MBq $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$.

This work shows that bifunctional sarcophagine ligand systems also have the potential to be utilized as chelating agents for peptide targeted gallium radiopharmaceuticals that make use of the commercially available $^{68}Ge/^{68}Ga$ generator. A Ga^{3+} complex of a sarcophagine ligand has been structurally characterized by X-ray crystallography showing that the metal ion resides within the cavity of the cage amine ligand coordinated to six nitrogen atoms in a distorted octahedral environment. A macrobicyclic cage amine bifunctional chelator based on the sarcophagine ($\mathbf{L^1}$) framework has been conjugated to two cyclic-(RGDfK) peptides to give a dimeric bioconjugate with the potential for bivalent interactions with $\alpha_v\beta_3$ integrin receptors that are overexpressed on the cell surface of certain tumors. This new conjugate, $\mathbf{L^1}(RGDfK)_2$, binds Ga^{3+}, and the complex has been characterized by NMR spectroscopy and HPLC-mass spectrometry. It is possible to synthesize the radioactive analogue with positron emitting $^{68}Ga^{3+}$ in high radiochemical yields, and the resulting complex is kinetically stable with $^{68}Ga^{3+}$ remaining in the cage amine ligand when challenged with apo-transferrin. Biodistribution studies and micro-PET imaging in mice reveal high selective tumor uptake and clearance predominantly through the kidneys, and this is important for producing images with low background coupled to high tumor uptake. Furthermore, micro-PET images are consistent with the high stability of the $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ complex during the imaging period demonstrating that $[^{68}Ga(\mathbf{L^1}(RGDfK)_2)]^{3+}$ is suitable for *in vivo* imaging of $\alpha_v\beta_3$ integrin receptors and has the potential to provide noninvasive diagnosis of tumors as well as monitoring of antiangiogenic or anti-$\alpha_v\beta_3$ targeted therapies.

Synthesis of L^1(RGDfK)(Lys^3-bombesin(1-14))

(***t***-Boc)$_5$(Succ)$\mathbf{L^1}$(RGDfK): cyclic-(RGDfK) peptide (3 mg) and (***t***-Boc)$_5$(Succ)$_2$-$\mathbf{L^1}$ (5 mg) were dissolved in dimethylformamide (400 μL) and diisopropylethylamine (3μL) was added. This solution was stirred at ambient temperature for 2 hours. Acetonitrile/water (50%/50%) (4 mL) was added and the solution applied to a C18 semi-preparative HPLC column and separated using an Eclipse XDB-C18 5 μm 9.5 x 250 mm column with a flow rate of 3 mL min^{-1}. The gradient mobile phase started with 100% solvent A (0.1% trifluoroacetate in water) at 5 min to 100% solvent B (0.1% formic acid in acetonitrile) at 75 min. Fractions containing pure material were combined, frozen and lyophilised. (***t***-Boc)$_5\mathbf{L^1}$(RGDfK)$_2$ (1 mg) eluted at 43 min. (***t***-Boc)$_5$(Succ)$\mathbf{L^1}$(RGDfK) (2 mg) eluted at 49 min. MS: $[C_{80}H_{130}N_{18}O_{24}]^{2+}$ 863.48 (experimental) 863.48 (calculated); Analytical HPLC: 16.73 and 16.84 min (0 to 100% B in 25 min).

Lys^3-bombesin(1-14) (3 mg) and (***t***-Boc)$_5$(Succ)$\mathbf{L^1}$(RGDfK) (2 mg) were dissolved in dimethylformamide (400 μL) and diisopropylethylamine (3 μL) was added. This solution was stirred at ambient temperature for 5 – 10 mins. Acetonitrile/water (50%/50%) (4 mL) was added and the solution applied to a C18 semi-preparative HPLC column and separated using an Eclipse XDB-C18 5 μm 9.5 x 250 mm column with a flow rate of 3 mL min^{-1}. The gradient mobile phase started with 100% solvent A (0.1% trifluoroacetate in water) at 5 min to 100% solvent B (0.1% formic acid in acetonitrile) at 75 min. The fraction containing (***t***-Boc)$_5\mathbf{L^1}$(RGDfK)(Lys^3-bombesin(1-14)) eluted at 43 min. This was frozen and lyophilised. MS: $[C_{147}H_{236}N_{39}O_{39}S]^{3+}$ 1068.25 (experimental) 1068.24 (calculated); Analytical HPLC: 14.13 min (0 to 100% B in 25 min).

(***t***-Boc)$_5\mathbf{L^1}$(RGDfK)(Lys^3-bombesin(1-14)) was dissolved in trifluoroacetic acid (1 – 2 mL) and stirred for ~ 2 hours. The trifluroacetic acid was evaporated under a stream of N_2 gas. Acetonitrile (1 mL) and water (1 mL) were added to redissolve the residue, and the solution frozen and lyophilised. The dried material was redissolved and purified using a C18 semi-preparative HPLC column using an Eclipse XDB-C18 5 μm 9.5 x 250 mm column with a flow rate of 3 mL min^{-1}. The gradient mobile phase started with 100% solvent A (0.1% trifluoroacetate in water) at 5 min and increased at a rate of 1% B min^{-1} until all components had eluted. MS: $[C_{122}H_{195}N_{39}O_{29}S]^{2+}$: 1351.74 (experimental), 1351.74 (calculated); Analytical HPLC: 14.43 min (0 to 60% B in 25 min).

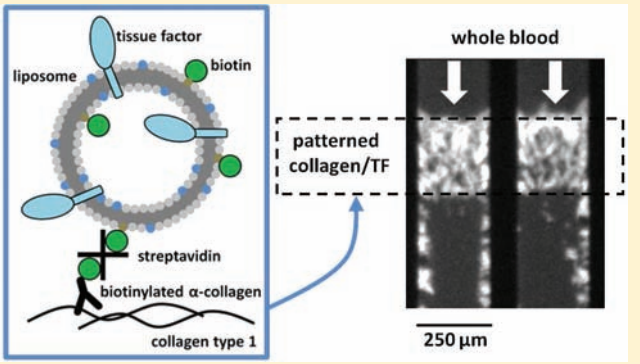
Relipidated Tissue Factor Linked to Collagen Surfaces Potentiates Platelet Adhesion and Fibrin Formation in a Microfluidic Model of Vessel Injury

Thomas V. Colace, Jannielle Jobson, and Scott L. Diamond*

Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States

ABSTRACT: Microfluidic devices allow for the controlled perfusion of human or mouse blood over defined prothrombotic surfaces at venous and arterial shear rates. To mimic in vivo injuries such a plaque rupture, the need exists to link lipidated tissue factor (TF) to surface-bound collagen fibers. Recombinant TF was relipidated in liposomes of phosphatidylserine/phosphatidylcholine/biotin-linked phosphatidylethanolamine (20:79:1 PS/PC/bPE molar ratio). Collagen was patterned in a 250-μm-wide stripe and labeled with biotinylated anticollagen antibody which was then bound with streptavidin, allowing the subsequent capture of the TF liposomes. To verify and detect the TF liposome−collagen assembly, individual molecular complexes of TF-factor VIIa on collagen were visualized using the proximity ligation assay (PLA) to produce discretely localized fluorescent events that were strictly dependent on the presence of factor VIIa and primary antibodies against TF or factor VIIa. Perfusion for 450 s (wall shear rate, 200 s^{-1}) of corn trypsin inhibitor (CTI, a factor XIIa inhibitor) treated whole blood over the stripe of TF-collagen enhanced platelet adhesion by 30 ± 8% ($p < 0.001$) and produced measurable fibrin (>50-fold increase) as compared to surfaces lacking TF. PS/PC/bPE liposomes lacking TF resulted in no enhancement of platelet deposition. Essentially no fibrin was formed during perfusion over collagen surfaces or collagen surfaces with liposomes lacking TF despite the robust platelet deposition, indicating a lack of kinetically significant platelet-borne tissue factor in healthy donor blood. This study demonstrates a reliable approach to link functionally active TF to collagen for microfluidic thrombosis studies.



INTRODUCTION

Tissue factor (TF) in the vessel wall is exposed during injury or atherosclerotic plaque rupture and binds circulating factor VIIa. As a cofactor in this complex, TF dramatically enhances the catalytic activity of factor VIIa toward factor X and factor IX. Generation of factor Xa results in formation of the prothrombinase complex (Xa/Va) to generate thrombin. Thrombin, a potent activator of platelets, is necessary for the production of clot stabilizing fibrin.

The incorporation of TF into growing thrombi has been suggested to occur through a variety of mechanisms. While the presence of TF in platelets and other nonactivated blood cells in healthy blood has been an ongoing debate,[1−3] several studies have shown the localization of TF-bearing microparticles to sites of injury via the P-selectin/PSGL1 interaction,[4] and its synthesis by a variety of extracellular matrix cells in normal and atherosclerotic vessels.[5] For decades, various TF preparations have been used as a clinical laboratory reagent in the study of prothrombin times, but TF has rarely been deployed in microfluidic injury models. For microfluidic thrombosis models, it is critical to present both collagen to platelets as well as lipidated TF to the plasma. By simultaneously activating and capturing platelets with surface-bound collagen along with triggering of the coagulation protease cascade with surface-bound TF, the central biology of thrombosis and hemostasis is recreated. In contrast, addition of exogenous TF into blood absolutely fails to recreate the dynamical aspects of thrombosis reliant on the surface presentation of TF to flowing blood.

The activity of tissue factor relies on its insertion into a phospholipid membrane containing approximately 20% negatively charged phosphatidylserine.[6] Reliable techniques using readily available reagents have been developed to "relipidate" TF into phospholipid vesicles or membranes.[7] In vitro flow studies which include these designs are rare, however, and mainly focus on the dynamics of thrombin or fibrin production.[8] In traditional microfluidic studies, the roles of platelet adhesion and coagulation are commonly separated through the use of heparin or Phe-Pro-Arg-chloromethylketone (PPACK, an irreversible thrombin inhibitor) or through the perfusion of platelet-free plasma over a previously formed platelet surface.[9,10] When studied in vivo in the mouse laser injury model, however, platelet deposition and thrombin production occur simultaneously.[11] These models

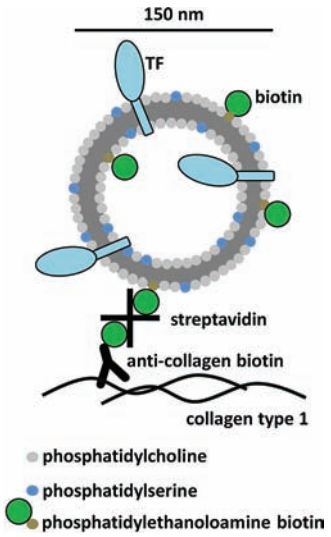

Figure 1. Tissue factor was relipidated in liposomes consisting of a molar ratio of 79:20:1 phosphatidylcholine to phosphatidylserine to biotinylated phosphatidylethanolamine in a lipid to TF ratio of 10 000:1. Dynamic light scattering indicated that the average vesicle radius was approximately 74.4 ± 28.0 nm. The liposomes were physically linked to collagen type 1 surface treated with a goat polyclonal antibody conjugated to biotin through a streptavidin linker.

have been helpful in defining a role for thrombin in platelet adhesion and fibrin generation in platelet plug stabilization; however, they lack characterization and control of the local hemodynamic conditions.[12]

In this study, we describe a method for generating reproducible surfaces of collagen and active tissue factor for use in microfluidic analyses of platelet function. We have modified the TF-bearing liposomes described by Smith et al.[7] to include a biotinylated lipid which we use to bind the vesicles to a collagen surface via a biotinylated anticollagen antibody and streptavidin (Figure 1). We have verified that these thrombogenic surfaces are functionally active leading to enhanced platelet deposition and measurable fibrin formation. Furthermore, we have characterized the surface through the use of the proximity ligation assay (PLA), a dual antibody immunodetection technique capable of visualizing individual molecule complexes based on molecular-scale proximity.

MATERIALS AND METHODS

Materials. Lipids, L-α-phosphatidylcholine (PC), L-α-phosphatidylserine (PS), and biotinylated phosphatidylethanolamine (bPE) were from Avanti Polar Lipids (Alabaster, AL, USA). Recombinant human tissue factor was from Haematologic Technologies Inc. (Essex Junction, VT, USA). Bio-Beads SM-2 (BioRad Laboratories, Hercules, CA, USA) were cleaned in methanol and stored under HEPES Buffered Saline (HBS, 20 mM HEPES, 150 mM NaCl, pH 7.4 [NaOH]) at 4 °C. The detergent, Triton X-100, was from Fisher Scientific (Fair Lawn, NJ, USA) Duolink proximity ligation assay (PLA) amplification and detection reagents were from O-Link Bioscience through distributor Axxora (San Diego, CA, USA). The primary monoclonal PLA antibody against tissue factor was from Haematologic Technologies and polyclonal primary against factor VIIa was from Abcam (Cambridge, MA, USA), as well as the biotinylated goat polyclonal anti collagen type 1 antibody. Streptavidin was from Sigma (St. Louis, MO, USA). Acid-insoluble collagen type 1 from equine tendon was from Chronolog Corp. (Havertown, PA, USA) and acid-soluble human collagen type 1 was from Advanced Biomatrix (San Diego, CA, USA). Poly(dimethylsiloxane), PDMS, for the microfluidic devices (Sylgard 184) was from Ellsworth Adhesives (Germantown, WI, USA) and Sigmacote used for hydrophobic treatment of glass slides was from Sigma. Finally, the anticoagulants corn trypsin inhibitor (CTI) and Pro-Arg-chloromethylketone (PPACK) were from Haematologic Technologies, and platelet labeling anti-CD41 antibody was from AbDSerotec (Raleigh, NC, USA). The fibrin-specific fluorescent monoclonal antibody was a generous gift from the Mortimer Poncz lab at the Children's Hospital of Philadelphia.

Blood Collection and Preparation. Blood was collected via venipuncture from healthy donors who were self-reported as free of medication for at least 10 days into CTI (40 μg/mL) for microfluidic assays or PPACK (100 μM) for TF detection assays. All volunteers provided informed consent in accordance with IRB approval and the Declaration of Helsinki. Whole blood was treated with Alexafluor 647-conjugated anti CD-41 monoclonal antibody for platelet detection in microfluidic assays 5 min prior to perfusion. PFP was generated for TF/VIIa complex detection assays by centrifugation of whole blood at 1000 *g* for 10 min. All blood samples were used within 1 h of the draw.

Preparation of Biotinylated TF Liposomes. Relipidation of recombinant tissue factor into liposomes was performed according to a previously described technique.[7] Briefly, PC, PS, and b-PE stored in chloroform were dried under vacuum in a 79:20:1 molar ratio, respectively. The dried film was resuspended in 1 mL of 4 mM Triton X-100 in HBS and allowed to hydrate for 30 min. Recombinant tissue factor was added and incubated for 10 min (10 000:1 lipid to TF). To this, 50 mg of Bio-Bead slurry was added and was gently agitated for 90 min, and then, 350 mg more of Bio-Bead slurry was added and gently agitated for the same amount of time. The beads were allowed to settle, and the supernatant was collected. The hydrodynamic radius of the resulting liposomes was determined by dynamic light scattering (Protein Solutions DynaPro, Wyatt Technology, Santa Barbara, CA, USA) to be 74.4 ± 28.0 nm.

Preparation of Collagen−Liposome Surfaces for Detection. Acid-soluble collagen was first neutralized to a pH of 7.4 with 1 M NaOH and then incubated on Sigmacote-treated glass slides for 2.5 h (300 μg/mL). The collagen surfaces were rinsed in HBS and treated with goat polyclonal anticollagen biotin (10 μg/mL) for 10 min and rinsed again. The droplet area was then treated with streptavidin (10 μg/mL) for another 10 min before rinsing. Ten microliters of the relipidated tissue factor liposome solution was added to the surface and allowed to rest for 1 h. A representation of the liposomes/collagen surface is presented in Figure 1. The relipidated tissue factor surfaces were finally treated with PFP (100 μM PPACK) for 30 min in order to generate TF/VII complexes.[13] When these surfaces were prepared for microfluidic assays, the steps were performed in a microfluidic patterning device which consisted of a single channel 250 μm wide as described in ref 14. Acid-insoluble collagen was used for these studies, as it better supports platelet adhesion. The final result was a strip of protein rather than a droplet. These surfaces were not treated with plasma, as they would be introduced to whole blood in the flow experiment.

Detection of TF/VIIa Complexes. Single tissue factor/factor VIIa complexes were detected on our thrombogenic surfaces

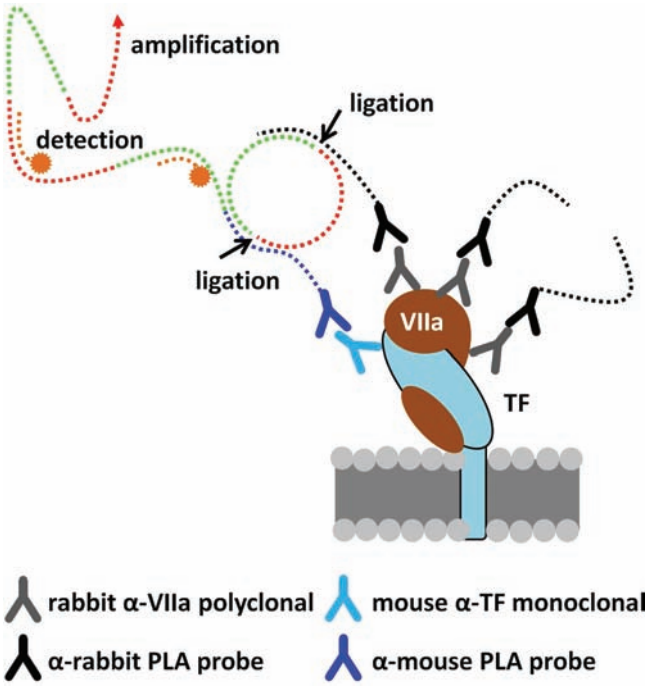

Figure 2. The Duolink proximity ligation assay is capable of detecting single molecule complexes. Primary antibodies directed against the components of the complex act to localize two "PLA probes", which are species-specific antibodies conjugated to short oligonucleotides. When the probes are brought together, they form a closed loop when complementary oligonucleotides are added. This loop is enzymatically ligated, which provides a template for rolling circle amplification. Small fluorescently labeled oligonucleotides hybridize with the amplified product producing a detection signal.

using the Duolink PLA.[15] Briefly, a mouse monoclonal antibody to tissue factor and a rabbit polyclonal antibody to factor VIIa were selected as primary antibodies. The binding of these antibodies to the TF/VIIa complex served as a localization site for two species-specific antibodies conjugated to short oligonucleotides (PLA probes). When the probes are in close proximity (i.e., bound to their antigens, which are bound to a protein complex), they may hybridize with two other oligonucleotides in solution, forming a loop. This loop is then ligated to create a closed circle which is an active site for rolling circle DNA amplification. Finally, fluorescently labeled oligonucleotides hybridize with the replication product to produce a detection signal. Figure 2 is an illustration of this technique.

Microfluidic Platelet Adhesion Model. Two sets of microchannels were designed in PDMS according to a previously described technique.[14,16] First, a patterning device consisting of a single channel 250 μm wide and 5 cm long was used to generate strips of thrombotic protein (collagen and tissue factor) according to the procedure above. This device was then removed and a flow device placed over the protein strip with perpendicular 250 μm channels resulting in a platelet/protein interaction zone measuring 250 × 250 μm^2 in each channel. The channels were blocked with 0.5% bovine serum albumin in HBS for 30 min prior to perfusion with whole blood. Blood was perfused through the channels at a wall shear rate of 200 s^{-1} via syringe pump (Harvard Apparatus PHD 2000, Holliston, MA, USA) and the interaction zone monitored via fluorescence microscopy (IX81, Olympus America Inc., Center Valley, PA, USA) in 15 s intervals.

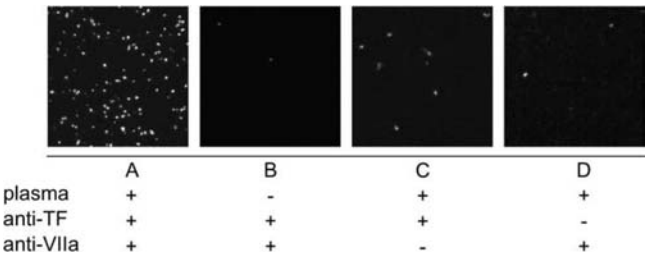

Figure 3. The PLA signal appears as 1 μm fluorescent dots (A). We have demonstrated that, in the absence of complexes (no factor VII from plasma [B]) or of either primary antibody (VIIa [C] or TF [D]), detection does not occur.

Images were captured using a CCD camera (ORCA-ER, Hamamatsu, Bridgewater, NJ, USA) illuminated with a mercury lamp (100 W, 620 nm Ex/700 nm Ex). Fluorescent intensity was evaluated using the freely available *ImageJ* software (NIH).

RESULTS

Detection of Single TF/VIIa Complexes. Tissue factor VIIa complexes were generated on a polymerized human collagen type 1 surface by linking relipidated tissue factor liposomes with 1% biotinylated-PE to a biotinylated anti-collagen antibody via streptavidin. We chose to use soluble collagen for this application as it creates a more uniform layer with less background fluorescence than fibrillar collagen surfaces. All surfaces were blocked in solutions of 0.5% BSA for 30 min prior to detection. The primary antibodies were used at a final concentration of 1 μg/mL and were incubated in open droplet reactions for 1 h at 37 °C. Following this, the PLA reaction was run according to the manufacturer's instructions.

The amplification product was observed as an approximately 1-μm-sized fluorescent dot (Figure 3) that was at least 3-fold brighter than the background. In order to confirm that we were detecting the desired complexes and not nonspecific antibody binding, two sets of controls were run. First, samples with linked tissue factor liposomes were either treated or untreated with plasma (±factor VIIa). Each sample was treated with both primary and secondary antibodies as well as all Duolink amplification and detection reagents. The images presented are representative of several 20× fields of view (Figure 3a,b). Identical samples with linked TF liposomes were incubated with human plasma and were treated with just the TF primary antibody or just the factor VIIa primary antibody (Figure 3c,d). These samples were treated according the unmodified Duolink procedure. The results demonstrate that the complete TF/VIIa complex must be present and that it must be treated with both primary antibodies for detection by PLA. Fluorescent staining observed under the negative control conditions is believed to be the result of nonspecific binding of the secondary PLA probes.

Effect of TF Liposomes under Flow Conditions. Fibrillar collagen surfaces with linked tissue factor liposomes were generated in a microfluidic model of thrombosis, as well as surfaces with liposomes lacking tissue factor. Whole blood anticoagulated with CTI (40 μg/mL), to inhibit the contact activation pathway, was perfused over the surfaces at an inlet wall shear rate of 200 s^{-1}. The experiment was performed in multichannel microfluidic device that allowed for 8 separate (but equal) adhesion events to be monitored simultaneously.[16] The data represented in Figure 4 are the fluorescent intensities of the surfaces captured in 15 s

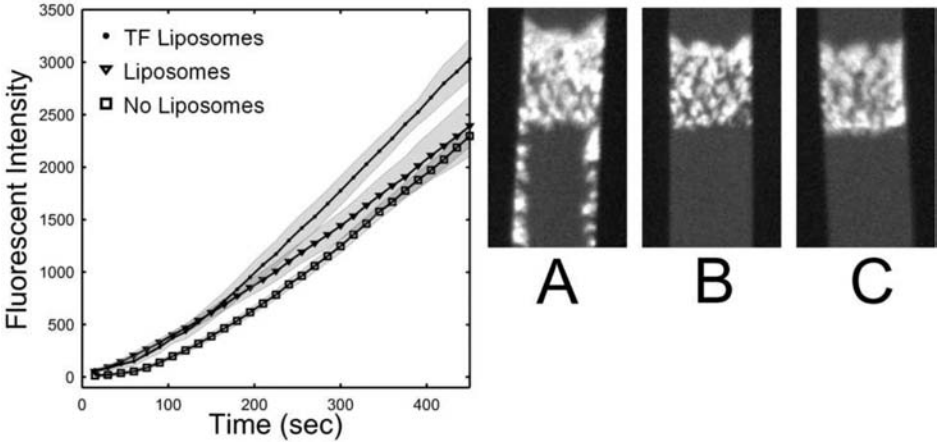

Figure 4. Tissue factor liposomes linked to collagen increased platelet deposition in a microfluidic injury model 30 ± 8.0% as compared to a similar surface with liposomes lacking TF or a control collagen surface. Whole blood was perfused over these surfaces at 200 s^{-1} in the presence of CTI (40 μg/mL). Each condition was performed in 8 separate channels and monitored simultaneously. The data represent the mass of platelets adhering at the collagen patch (in arbitrary units) and are presented ± STD. Representative images of platelet adhesion at 450 s are presented for each case ([A] TF liposomes, [B] liposomes, [C] control surface). Flow is from top to bottom. Platelet accumulation for the TF surface appears brighter, denser, and protrudes upstream. Platelets also adhere downstream of the main platelet mass when TF is present on the liposome/collagen surface, possibly as a result of fibrin deposition.

intervals over a 450 s period. The intensity represents the average mass of platelets aggregating on the surface. A significant increase (30 ± 8%, $p < .0001$) was observed in platelet deposition when the surface contained TF positive liposomes after 450 s of perfusion. Platelets also adhered downstream from the collagen patch, possibly on fibrin deposits (Figure 4a). Platelet adhesion to the liposome surface lacking tissue factor was undistinguishable from a control sample untreated with antibody, streptavidin, or liposomes after 450 s.

In a parallel experiment, unlabeled platelets in whole blood (40 μg/mL CTI) were perfused over a collagen surface treated with TF positive or negative liposomes in the presence of a fluorescently labeled fibrin-specific antibody (3 μg/mL). The data reveal that liposomes containing tissue factor are required for fibrin formation in the platelet mass during the 450 s perfusion. Detectable fibrin appears between 15 and 30 s into the TF liposome perfusion. Figure 5a shows the deposition of fibrin downstream from the collagen strip. When PS-PC-bPE liposomes lacking TF were attached to collagen, there was no increase in platelet deposition and no production of fibrin, consistent with the fact that PSPC liposomes do not trigger thrombin production in CTI-treated plasma.[17]

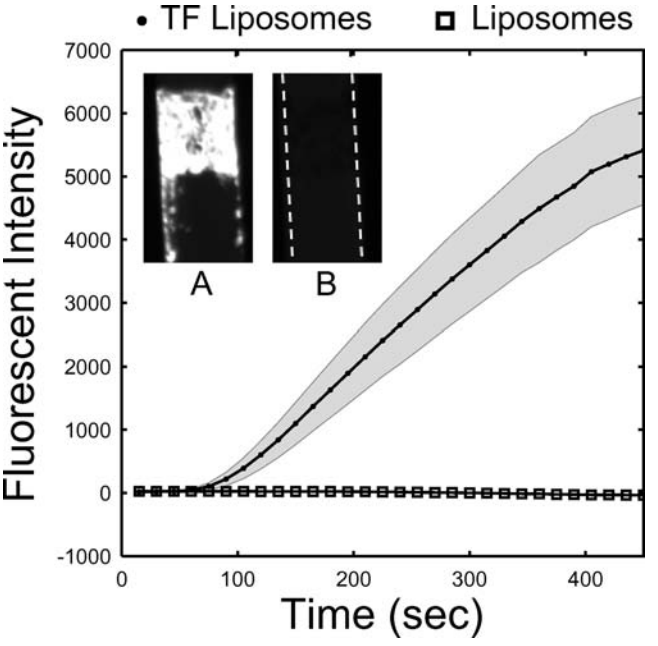

Figure 5. Whole blood treated with CTI (40 μg/mL) was perfused over a TF liposome/collagen surface or liposome/collagen surface at 200 s^{-1} in the presence of a fluorescently labeled fibrin specific monoclonal antibody. Each condition was performed and monitored simultaneously in 8 separate channels. Fluorescent intensity (in arbitrary units) of the fibrin mass accruing in the platelet mass is presented ± STD. The inset illustrates the two conditions after 450 s of perfusion (flow is from top to bottom). No fibrin deposition appears with the TF negative liposomes (B), while massive deposition appears for the positive liposomes (A). Fibrin deposition is detected downstream of the main thrombus as well.

DISCUSSION

Utilizing the tight binding between biotin and streptavidin, we have created a thrombogenic surface that consists of relipidated TF liposomes linked to an immobilized collagen surface. This construct produces a physiologically relevant hemostatic response which includes platelet activation, platelet adhesion, and coagulation, as is observed in vivo. The advantage of our ex vivo system, however, is that it allows for robust and reproducible control of hemodynamics, surface composition, and blood pharmacology. Furthermore, it represents a higher throughput and lower cost approach than animal models.

The results presented as part of this work were intended to verify the new TF liposome/collagen injury model against previous findings. Prior work in our lab conducted by Okorie et al., who spotted TF liposomes onto collagen features, demonstrated a 25% increase in platelet adhesion when the highest concentration of printed liposomes was used (25 molecules/μm^2).[18] In the new model, we observe a similar response (30% increase ± 8%) and capture the robust increase in fibrin formation reported in that study, as well. While we estimate a slightly lower TF concentration on our surface (see below) [0.1 to 1 molecules/μm^2], we may

explain the increased potency by the physical linking of liposomes to the collagen surface. The observation that platelet adhesion does not increase on liposome surfaces containing TF until ~200 s is supported by other groups who observed lag times in thrombin generation of >60 s,[19,20] as well as the lag time observed in fibrin generation in Figure 5. We also suggest that thrombin generation during primary adhesion has a less noticeable effect due to strong GPVI signaling generated by fibrillar collagen at early times.

In addition to platelet adhesion, the kinetics of fibrin deposition in our assay also compare well to other experimental models. In the mouse laser injury model, for example, measurable fibrin appears at 10−15 s after insult.[21] In these studies, the clotting response is triggered by activation of the endothelium and is driven by the exposure of tissue factor, not the subendothelium. Platelet adhesion is strongly dependent on PAR4 activation.[22] Therefore, a more relevant model may be the $FeCl_3$ injury, in which collagen and thrombin signaling play important roles regarding time to thrombus initiation and likelihood of vessel occlusion.[23−25] In these studies, FcγRII$^{-/-}$ or PAR4$^{-/-}$ mice, which lack collagen or thrombin signaling, respectively, have some protection from full vessel occlusion. Factor XIIa is not inhibited in the mouse models, whereas CTI is used in our in vitro perfusion studies with human blood.

We have demonstrated that our findings with the new TF/collagen assay compare well to other ex vivo and in vivo work. We have also used PLA to detect TF/factor VIIa complexes. However, quantifying fM to pM levels of surface TF is complex and is a drawback to other models as well.[8] With reasonable assumptions, we can provide an estimate of the [TF] range. Extensive characterization of tissue factor liposomes has been previously performed.[7] Using the relipidation technique described above, 80−90% of TF is recovered in liposomes, and approximately 50% of this TF is accessible. In our assay, these values predict that 5 molecules of TF per liposome are available (10 000:1 lipid to TF ratio). If we consider the results from PLA to represent a lower bound on the number of surface captured liposomes (PLA is known to have significantly less than 100% detection), we estimate 0.02 liposomes/μm^2. This value corresponds to 0.1 to 1 molecules TF/μm^2 for 100% or 10% PLA detection efficiency, respectively. These estimates compare well to our own prior work and relipidated TF patches created by other groups (0.3 molecules TF/μm^2).[26] Furthermore, we estimate that the random packing limit for spheres in 2 dimensions sets an upper bound of approximately 10^2 TF molecules/μm^2.

In vivo models of thrombosis have demonstrated the importance of coagulation in response to vessel injury. Using TF liposomes linked to a collagen surface, we have demonstrated an ex vivo system that is sensitive to both the coagulation and platelet aggregation components of the hemostatic mechanism.

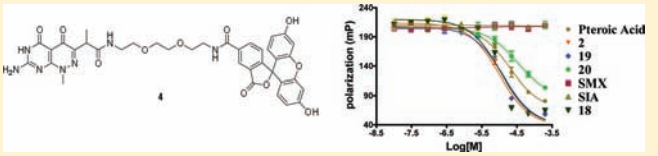
Supporting Information

ABSTRACT: Dihydropteroate synthase (DHPS) is the classical target of the sulfonamide class of antimicrobial agents, whose use has been limited by widespread resistance and pharmacological side effects. We have initiated a structure-based drug design approach for the development of novel DHPS inhibitors that bind to the highly conserved and structured pterin subsite rather than to the adjacent *p*-aminobenzoic acid binding pocket that is targeted by the sulfonamide class of antibiotics. To facilitate these studies, a robust pterin site-specific fluorescence polarization (FP) assay has been developed and is discussed herein. These studies include the design, synthesis, and characterization of two fluorescent probes, and the development and validation of a rapid DHPS FP assay. This assay has excellent DMSO tolerance and is highly reproducible as evidenced by a high Z′ factor. This assay offers significant advantages over traditional radiometric or phosphate release assays against this target, and is suitable for site-specific high-throughput and fragment-based screening studies.



INTRODUCTION

There is a clear need to develop novel antimicrobial agents due to the widespread emergence of drug resistance.[1,2] Sulfonamides have been used as synthetic antibiotics since the 1930s to treat a wide variety of Gram-positive, Gram-negative, and protozoal infections, but their use has been greatly compromised by the emergence of resistance and the poor tolerance of certain patient populations.[2−7] Sulfonamides target the enzyme dihydropteroate synthase (DHPS) encoded by the *fol*P gene and function as competitive inhibitors of one of the DHPS substrates, *p*-amino benzoic acid (*p*ABA).[8] DHPS possesses a classic $(\beta/\alpha)_8$ TIM barrel structure, and the *p*ABA binding site is at the edge of the barrel and comprises loop regions where the mutations that confer sulfonamide resistance are found.[9,10] In contrast, the other substrate of DHPS dihydropterin pyrophosphate (DHPP) binds in a deep, structured pocket within the DHPS β-barrel. This pocket has a high degree of conservation between species, and no resistance mutations have been reported in or adjacent to the pterin binding site. Thus, we believe that the pterin binding site is an attractive alternative target for the design of novel antimicrobial agents.

Currently, the principal screening methods for DHPS are either radiometric or use coupled colorimetric phosphate release assays.[11−13] Although these assays do offer some advantages, they also suffer from a number of practical issues which pertain to their use for site-specific high-throughput screening: The instability and limited availability of the DHPP pterin substrate, the undesirable use of radioactive materials, the need for coincubation with pyrophosphatase and spectrometric interference in the colorimetric assays, and the lack of site specific inhibition information suitable for identifying the selective pterin-binding site inhibitors. In this paper, we report the design, development, and validation of a rapid, sensitive, and site-specific DHPS fluorescence polarization (FP) assay.[14]

A typical FP probe consists of a tracer derived from a high-affinity ligand, a spacing linker and a fluorophore. Previously, we reported structural studies of several small pterin-based inhibitors of DHPS,[15,16] and the two most potent inhibitors **1** and **2** were selected as candidate tracers to develop the FP probes (Figure 1a). The cocrystal structure of DHPS bound to compound **2** was used as a guide to determine the optimal linker length between the tracer and the fluorophore. The carboxylate group of **2** points away from the pterin binding site and was judged to be a suitable linking position. From visual inspection, the distance from the solvent-exposed surface to the carboxylate group was estimated to be approximately the length of two ethylene glycols (or aminoethanol). On the basis of this, three molecular probes with spacer lengths of 1, 2, and 3 ethylene glycols (or aminoethanol) were modeled into the cavity using Schrodinger Glide and our previously validated docking approach (see Supporting Information, Figure S1).[17] From these studies, both the amide-linked two and three glycol/aminoethanol-long probes were shown to bind well. The three-unit spacer would be

expected to improve solubility, and 2,2′-(ethane-1,2- diylbis-(oxy))diethanamine was therefore selected as the linker to offset the poor aqueous solubility of the pterin analogues that has previously been encountered.[18] Thus, **4** was chosen for synthesis and, using an analogues approach, probe **3** was also designed and selected for synthesis from **1** using a similar-sized linker (Figure 1b).

EXPERIMENTAL SECTION

Probe Synthesis. Methanol, trifluoroacetic acid (TFA), dichloromethane, triethylamine (TEA), acetone, *N*,*N*-dimethylformamide (DMF), tetrahydrofuran (THF), formic acid, and *tert*-butyl 2-(2-(2-aminoethoxy)ethoxy) ethylcarbamate **6** were purchased from Sigma-Aldrich (St. Louis, MO). 2,5-Dioxopyrrolidin-1-yl 3′,6′-dihydroxy-3-oxo-3*H*-spiro[isobenzofuran-1,9′-xanthene]-5-carboxylate **9** was purchased from OChem, Inc. (Des Plains, IL). *O*-(Benzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (HBTU) was purchased from AK Scientific, Inc. (Union City, CA). Compounds **2** and **5** were prepared as previously reported.[16,19] The reactions were monitored by thin-layer chromatography (TLC) on precoated Merck 60 F254 silica gel plates and visualized by UV detection. The identity of final compounds was determined on a Waters Acquity UPLC MS C18 (H_2O + Formic → ACN + Formic) 5 min gradient, PDA (215−400 nm), ELSD, Acquity SQD ESI Positive MS. High-resolution mass spectra were determined on Waters Acquity UPLC C18 (H_2O → ACN gradient over 4 min) Xevo G2 Q-TOF ESI Negative, resolution mode, compound internally weighted to leucine enkephalin lock solution, calculated error of <3 ppm. The purity of final compounds was determined by UPLC/UV/ELSD/MS (see Supporting Information for UPLC/UV/ELSD/MS method). Both compounds **3** and **4** showed ELSD purity at 96% (see Supporting Information Figures S3 and S4). Melting points were obtained on an OptiMelt Automated Melting Point System (Lambda Photometrics, UK) and were uncorrected. All ^{1}H and ^{13}C spectra were recorded on a Bruker ULTRASHIELD 400 plus or Bruker 800/US^2. The chemical shift values are expressed in ppm (parts per million) relative to tetramethylsilane as internal standard; coupling constants (*J*) are reported in hertz (Hz).

tert-Butyl (2-(2-(2-((2-Amino-5-nitroso-6-oxo-1,6-dihydropyrimidin-4-yl)amino)ethoxy)ethoxy)ethyl)carbamate ***7***. A mixture of **5** (0.175 g, 0.938 mmol) and *tert*-butyl 2-(2-(2-aminoethoxy)ethoxy) ethylcarbamate **6** (0.233 g, 0.938 mmol) in methanol was heated at reflux for 20 h. After cooling, the reaction mixture was filtered. To the filtrate was added 2.5 g silica gel, and the solvent of filtrate was removed under reduced pressure to afford a dry plug, which was loaded on a silica gel column and eluted with chloroform/methanol (20:1). Fractions containing the product were pooled and evaporated to afford **7** as a brick red solid (0.21 g, 58%): R_f 0.4 ($CHCl_3$/CH_3OH = 5:1); mp 166−168 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.36 (s, 9H), 3.07 (q, J = 5.9 Hz, 2H), 3.40 (t, J = 6.1 Hz, 2H), 3.55 (t, J = 4.5 Hz, 8H), 6.78 (t, J = 5.6 Hz, 1H), 7.08 (s, 1H), 8.19 (s, 1H), 10.96 (s, 1H), 12.49 (s, 1H); ^{13}C NMR (101 MHz, DMSO-d_6) δ 28.19 (s), 39.49, 68.17, 69.19, 69.44, 69.60, 77.53, 140.60, 152.21, 155.54, 156.37, 161.46; MS$^+$ 387.31.

2-Amino-6-((2-(2-(2-aminoethoxy)ethoxy)ethyl)amino)-5-nitrosopyrimidin-4(3H)-one ***8***. A solution of **7** (0.1 g, 0.259 mmol) in TFA/CH_2Cl_2 (v/v = 1:1, 6 mL) was stirred at room temperature for 1 h. The solvent was removed under reduced pressure. Any remaining TFA was removed by repeated coevaporation with methanol, ether, and acetone to give **8** as trifluoroacetic acid salt, a dark red solid (0.10 g, 97%): mp 200−204 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 3.01−3.04 (m, 2H), 3.57−3.66 (m, 10H), 7.12 (s, 1H), 7.87 (s, 2H), 8.29 (s, 1H), 10.98 (s, 1H), 12.59 (s, 1H); ^{13}C NMR (101 MHz, DMSO-d_6) δ 38.72, 66.73, 67.94, 69.59, 140.23, 152.44, 156.50, 158.57 (q, J = 128 Hz), 161.16; MS$^+$ 287.26.

N-(2-(2-(2-((2-Amino-5-nitroso-6-oxo-1,6-dihydropyrimidin-4-yl)amino)ethoxy)ethoxy)ethyl)-3,6-dihydroxy-3′-oxo-3′H,10H-spiro[anthracene-9,1′-isobenzofuran]-5′-carboxamide ***3***. TEA (46.7 μL, 0.337 mmol) and 5-carboxyfluorescein *N*-hydroxysuccinimide ester **9** (0.044 g, 0.094 mmol) were added to a solution of **8** (0.03 g, 0.075 mmol) in acetone (4 mL). The reaction was stirred at room temperature for 4 h before being concentrated in vacuo. The crude residue purified by preparative HPLC using a Gemini 5 μ C18 110A AXIA column (50 × 30.00 mm, 5 μm) and a gradient of 20−85% MeOH+4%THF/10 mM ammonium bicabonate over 10 min period with the retention time of the product being 4.8 min. The respective fractions were pooled and concentrated to afford **3** as an orange solid (0.036 g, 75%): ^{1}H

NMR (400 MHz, DMSO-d_6) δ 3.47−3.59 (m, 12H), 6.42 (dd, J = 8.9, 2.2 Hz, 2H), 6.49 (d, J = 2.1 Hz, 2H), 6.62 (d, J = 8.9 Hz, 2H), 7.29 (d, J = 8.0 Hz, 1H), 8.12 (d, J = 8.0 Hz, 1H), 8.46 (d, J = 1.2 Hz, 1H), 8.88 (t, J = 5.5 Hz, 1H), 12.48 (s, 1H); ^{13}C NMR (201 MHz, DMSO) δ 68.33, 68.86, 69.62 (d, J = 11.6 Hz), 102.41, 109.85, 116.15, 125.35, 126.14, 129.57, 131.80, 135.51, 140.72, 152.61, 153.74, 158.36, 163.96, 165.25, 166.20, 166.61, 168.41; HRMS m/z [M-H]$^-$ calcd for $C_{31}H_{27}N_6O_{10}$: 643.5835, found: 643.1771.

tert-Butyl 2-(2-(2-(2-(7-amino-1-methyl-4,5-dioxo-1,4,5,6-tetrahydropyridazino[3,4-d]pyrimidin-3-yl)propanamido)ethoxy)-ethoxy)ethylcarbamate ***10***. To a solution of **2** (0.1 g, 0.377 mmol) and HBTU (0.157 g, 0.415 mmol) in DMF (5 mL), *tert*-butyl 2-(2-(2-aminoethoxy)ethoxy)ethylcarbamate **6** (0.112 g, 0.452 mmol) was added. The reaction mixture was stirred at room temperature for 3 h, diluted with water, and extracted with dichloromethane twice. The organic layer was dried with sodium sulfate; the solvent was evaporated to give a white solid at room temperature. The residue was washed with anhydrous ether and filtered to give **10** as a white solid (0.155 g, 83%): R_f = 0.35 ($CHCl_3$/CH_3OH = 5:1); mp 230 °C (dec); ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.22−1.24 (d, J = 7.2 Hz, 3H), 1.36 (s, 9H), 3.03−3.08 (m, 2H), 3.13−3.20 (m, 2H), 3.35−3.37 (m, 4H), 3.48 (s, 4H), 3.74 (s, 3H), 3.85−3.91 (q, J = 7.2 Hz, 1H), 6.76 (t, J = 5.5 Hz, 1H), 7.83 (t, J = 5.6 Hz, 1H), 7.95 (bs, 2H), 10.84 (bs, 1 H); ^{13}C NMR (101 MHz, DMSO-d_6) δ 14.61, 28.19, 30.73, 35.74, 38.69, 41.00, 69.06 (d, J = 13.1 Hz), 69.48 (d, J = 13.6 Hz), 77.51, 155.54, 157.36, 162.25, 167.10, 171.95. 2-(7-Amino-1-methyl-4,5-dioxo-1,4,5,6-tetrahydropyridazino-[3,4-d]pyrimidin-3-yl)-N-(2-(2-(2-aminoethoxy)ethoxy)ethyl)-propanamide ***11***. Compound **10** (0.3 g, 0.6 mmol) was added to a solution of TFA/Cl_2Cl_2 (1:1 v/v). The reaction mixture was stirred at room temperature for 30 m. The solvent was removed under reduced pressure. Any remaining TFA was removed by repeated coevaporation with diethyl ether to afford **11** as trifluoroacetic acid salt as a white solid (0.246 g, 80%): mp 160 °C (dec); ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.25−1.27 (d, J = 7.2 Hz, 3H), 1.36 (s, 9H), 3.00−3.03 (m, 2H), 3.09−3.27 (m, 2H), 3.39−3.43 (m, 4H), 3.53−3.60 (m, 2H), 3.64−3.72 (m, 2H), 3.78 (s, 3H), 3.93 (q, J = 7.2 Hz, 1H), 7.81 (t, J = 5.3 Hz, 1H); ^{13}C NMR (101 MHz, DMSO-d_6) δ 14.35, 41.19, 66.68, 68.91, 69.70, 100.69, 153.59, 155.46, 157.26, 158.11, 158.41, 160.19, 167.59, 171.70; MS$^+$ 396.26.

N-(2-(2-(2-(2-(7-Amino-1-methyl-4,5-dioxo-1,4,5,6-tetrahydro-pyridazino[3,4-d]pyrimidin-3-yl)propanamido)ethoxy)ethoxy)-ethyl)-3′,6′-dihydroxy-3-oxo-3H-spiro[isobenzofuran-1,9′-xanthene]-5-carboxamide ***4***. A solution of **11** (0.050 g, 0.098 mmol), 2,5-dioxopyrrolidin-1-yl 3′,6′-dihydroxy-3-oxo-3*H*-spiro-[isobenzofuran-1,9′-xanthene]-5-carboxylate **9** (0.058 g, 0.123 mmol), and TEA (61.2 μL, 0.442 mmol) in DMF (4 mL) was stirred at room temperature for 4 h. The crude product was purified by preparative HPLC using a Gemini 5 μ C18 110A AXIA column (50 × 30.00 mm, 5 μm) and a gradient of 20−85% MeOH + 4% THF/10 mM ammonium bicarbonate over 10 min period. The retention time of the product was 4.8 min. The respective fractions were pooled and concentrated to afford the title compound **4** as an orange solid (0.050 g, 68%): ^{1}H NMR (400 MHz, DMSO-d_6) δ 1.21−1.23 (d, J = 8 Hz, 3H), 3.38−3.62 (m, 12H), 3.73 (s, 3H), 3.86−3.91 (q, J = 8 Hz, 1H), 6.46−6.49 (m, 2H), 6.56−6.62 (m, 4H), 7.33 (d, J = 8.0 Hz, 1H), 7.85 (t, J = 5.6 Hz, 1H), 8.16 (d, J = 8.0 Hz, 1H), 8.48 (bs, 1H), 8.89 (t, J = 5.2 Hz, 1H); ^{13}C NMR (201 MHz, DMSO) δ 14.52, 38.77, 40.93, 68.71, 69.03, 69.55, 100.72, 102.38, 109.86, 115.38, 124.71, 125.75, 129.46, 135.70, 153.29, 153.79, 156.64, 157.57, 161.36, 165.08, 167.28, 168.16, 171.96; HRMS m/z [M-H]$^-$ calcd for $C_{37}H_{34}N_7O_{11}$: 752.7100, found: 752.2316.

Protein Preparation. *Bacillus anthracis* DHPS (*Ba*DHPS) was prepared as described previously.[16]

Probe Characterization—Isothermal Titration Calorimetry (ITC). The purified *Ba*DHPS protein was dialyzed against 50 mM HEPES, 5 mM $MgCl_2$, pH 7.6. ITC titrations were performed with an Auto-iTC200 Isothermal Titration Calorimeter (MicroCal) in 40 mM HEPES, 4 mM $MgCl_2$ at pH 7.6 and 25 °C over 19 2 μL injections each of 500 μM ligand into 20 μM *Ba*DHPS. Data were analyzed using *MicroCal Origin 7.0* software using a one-site binding model.

Probe Characterization—Fluorescence Polarization. The titration experiment was performed in triplicate with 6 nM of compounds **3** and **4** and 2-fold increasing concentrations of *Ba*DHPS (0.009 to 150 μM) in a 96-well plate with a final volume of 100 μL in 1× PBS buffer. Data were fit to a Langmuir isotherm

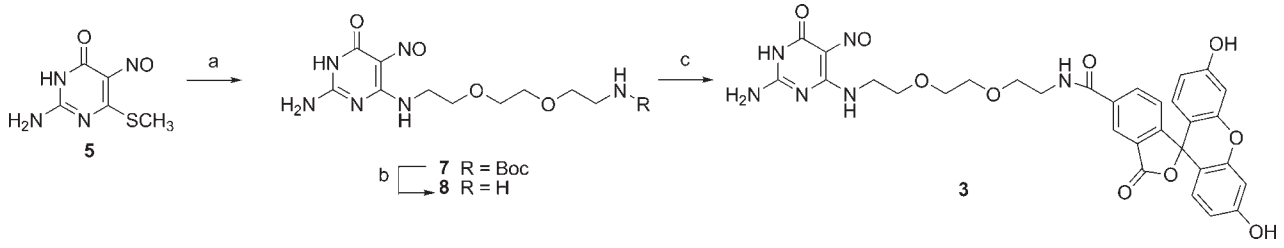
$$\mathrm{FP} = \mathrm{FP}^0 + \Delta\mathrm{FP} \cdot \left(\frac{1}{1 + K_D/[\mathrm{DHPS}]}\right)$$

To confirm pterin-pocket binding of **4**, inhibitor **2** was titrated (10 nM to 400 μM) against 6 nM of **4** and 6 μM of *Ba*DHPS in 1× PBS buffer to a final volume of 100 μL in a black polystyrene 96-well plate (Costar, Corning Inc.). The data were fit to the equation derived from the definition of dissociation constant with the approximation of a negligible concentration of fluorescent probe described in the Supporting Information.[20,21] All FP measurements were performed on a 2103 EnVision multilable reader (Perkin-Elmer) with excitation and emission wavelength filters of 450 ± 8 nm and 535 ± 40 nm, respectively.

High-Throughput Fluorescence Polarization Assay. In developing the FP assay for high-throughput screening purposes, we followed the NIH NCGC guidelines (http://www.ncgc.nih.gov/guidance/section5.html#practical-fluor-polar). FP measurements were performed as described previously, but using PMT sensitivity set to low and 100 readings per well. Assays were performed in flat-bottom, black polystyrene 384-well plates (3821 Costar, Corning Inc.) in 40 mM HEPES, 4 mM $MgCl_2$ at pH 7.6. The final assay volume was 20 μL/well. All measurements were performed in triplicate except for Z' determination assays in which 12 replicates were used in each group. The typical final DMSO concentration in tests was 2% except for DMSO tolerance experiments in which varied DMSO concentrations were used as indicated.

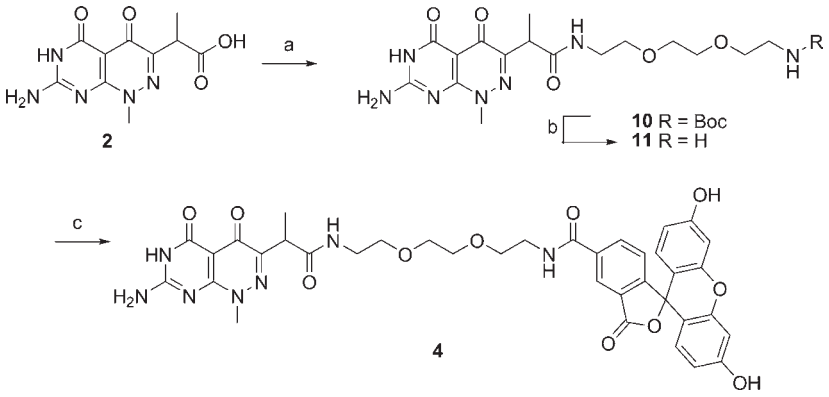
To optimize the assay, equilibrium binding experiments of **4** to *Ba*DHPS were performed under the following conditions: each individual well in a 384-well assay plate contained 2.7 μM **4** and increasing concentrations (from 0 to 16 μM) of *Ba*DHPS protein in assay buffer. The plate was mixed on a slow-moving shaker for the indicated times at 25 °C and the polarization signals were measured at room temperature. To test the signal stability, the FP of a plate containing samples was measured at different times over a period of 18 h. The assay equilibration time was determined by monitoring the FP signal at several time intervals as indicated. Between each reading, the plate was covered with a black lid to prevent photobleaching. For tracer specificity experiments, each individual well contained 2.7 μM **4** and 8 μM of *Ba*DHPS and DMSO; for competition experiments, each

Scheme 1. Synthesis of FP Probe 3[a]



[a] Reagents and conditions: (a) *tert*-butyl (2-(2-(2-aminoethoxy)ethoxy)ethyl)carbamate **6**, CH_3OH, reflux, 20 h, 58%; (b) TFA, 97%; (c) 5-carboxyfluorescein *N*-succinimidyl ester **9**, DMF, TEA, 75%.

Scheme 2. Synthesis of Probe 4[a]



[a] Reagents and conditions: (a) *tert*-butyl (2-(2-(2-aminoethoxy)ethoxy)ethyl)carbamate **6**, HBTU, DMF, rt, 3 h, 83%; (b) TFA, 80%; (c) 5-carboxyfluorescein *N*-succinimidyl ester **9**, DMF, TEA, 68%.

individual well contained 2.7 μM **4**, 8 μM of *Ba*DHPS, 100 μM of **2** and DMSO; each control well contained 2.7 μM **4** and DMSO. The experiments were performed under conditions similar to those described above and the FP data were measured in triplicate. This experiment was repeated two more times on different days. To determine the effect of DMSO on the assay, DMSO tolerance experiments were performed under the above conditions with 2.7 μM **4**, 8 μM of *Ba*DHPS, and varying concentration of DMSO from 0.02% to10% (v/v). To determine the assay robustness, Z′-factor statistic experiments were implemented in triplicate in which 2 groups of samples, the high signal group and low signal group, were involved. The high signal group represents samples with protein and tracer. The low signal group represents samples with protein, tracer, and ligand **2** at 100 μM. This experiment was repeated two more times on different days. The Z′ factor is calculated using the equation $Z' = 1 - (3\sigma^+ + 3\sigma^-)/(\text{Mean}^+ - \text{Mean}^-)$, where σ^+ is the standard deviation of high signal group; σ^- is the standard deviation of low signal group; Mean^+ is the mean of high signal group; and Mean^- is the mean of low signal group. All experimental data were analyzed using *Microsoft Excel* (Microsoft Corporation, Redmond, WA) and *Prism 4.0* (Graphpad Software Inc., San Diego, CA).

Assay Validation—Competitive Displacement of 4 by Known DHPS Inhibitors. Competitive displacement studies were performed with DHPS inhibitors **2**, **18**, **19**, **20**, pteroic acid, SMX, and SIA. Stocks of these inhibitors were prepared in DMSO at 10 mM and serially diluted in assay buffer. FP assay was performed under following conditions: Corning black 384-well plate contained 2.7 μM probe **4**, 8 μM *Ba*DHPS protein, and each tested inhibitor at varying concentrations to a final volume of 20 μL. The plate was shaken for 25 min at room temperature and the FP values were recorded. The measured FP values (mP) were plotted against the $\log_{10}$ values of competitor concentration. Herein, the displacement data were empirically fit. In order to calculate accurate K_D values for hit compounds out of the HTS, where the approximation of a negligible concentration of fluorescent probe does not hold true due to experimental conditions, the exact analytical approach described by Wagner et al.[20,21] can be applied.

RESULTS AND DISCUSSION

The synthesis of FP probe **3** was achieved from 5-nitroso-6-methylpyrimidine **5**, [19] which was conjugated with *tert*-butyl 2-(2-(2-aminoethoxy)ethoxy)ethylcarbamate **6** in refluxing methanol to give **7**. [22] The Boc-protected **7** was converted to free terminal amine **8** by treatment with TFA. Coupling of **8** with 5-carboxyfluorescein *N*-succinimidyl ester **9** in the presence of TEA in DMF afforded the desired probe **3** in good yields. [23]

FP probe **4** was synthesized from **2**. Coupling of **2** with **6** in the presence of HBTU in DMF provided amide **10**, which then was treated with TFA to afford the free amine **11**. Coupling of **11** with **9** in the presence of TEA in DMF afforded the second FP probe **4** in good yields.

Prior to establishing the FP assay, the equilibrium dissociation binding constants (K_D) of the two probes were measured using two independent methods, isothermal titration calorimetry (ITC) and FP. Using ITC, the K_D values were found to be

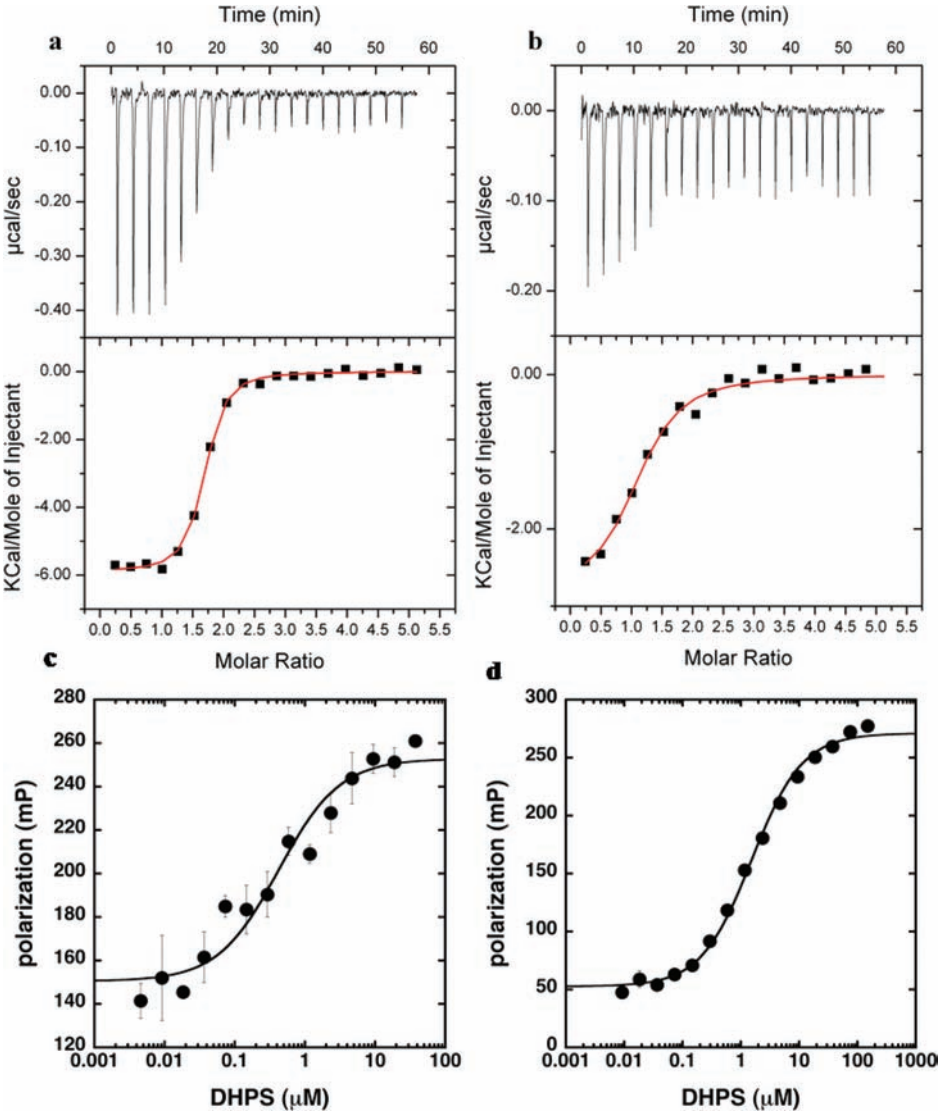


Figure 2. Measuring direct binding of compounds **3** and **4** to *Bacillus anthracis* DHPS (*Ba*DHPS). (a) ITC titration of 500 μM of **3** into a 20 μM *Ba*DHPS solution. Binding site $N = 1.59 \pm 0.0108$; ΔH is -5.9 ± 0.059 kcal/mol; ΔS is 0.0982 kcal/mol; K_D is 0.34 ± 0.043 μM. (b) ITC titration of 500 μM of **4** into a 20 μM *Ba*DHPS solution. Binding site $N = 1.09 \pm 0.0464$; ΔH is -2.8 ± 0.159 kcal/mol; ΔS is 0.16 kcal/mol; K_D is 2.7 ± 0.64 μM. (c) Direct binding of **3** to *Ba*DHPS by FP (average of 3 independent experiments). Error bars represent standard error of the mean; K_D is 0.37 μM $\pm$ 0.1 . (d) Direct binding of **4** to *Ba*DHPS by FP (average of 3 independent experiments). Error bars represent standard error of the mean; K_D is 1.5 ± 0.1 μM.

0.34 ± 0.043 μM for compound **3** and 2.7 ± 0.64 μM for compound **4** (Figure 2a,b). Using FP,[24,25] the K_D values were found to be in excellent agreement, 0.37 ± 0.1 μM for compound **3** and 1.5 ± 0.1 μM for compound **4** (Figure 2c,d). The affinities of both probes were found to be weaker than their corresponding parent inhibitors ($K_D = 0.124 \pm 0.017$ μM for **2** using ITC). This was anticipated and is likely due to some loss of receptor binding interactions from the introduction of the linker groups and the bulky fluorescein fluorophore. Comparison of the two probes showed that **3** has an apparently higher binding affinity than **4** to *Ba*DHPS, but the ITC and the FP data for **3** both showed that binding was not at a 1:1 ratio, whereas this was the case for **4** which has better FP signal. Further analysis by incubating **3** in 1% BSA showed that the FP absorbance of **3** was significantly reduced, which indicated that **3** is a nonspecific protein binder. Consequently, **3** was dropped from further study and **4** was selected to develop the DHPS FP binding assays.

Finally, to confirm pterin-binding pocket binding, we monitored the displacement of **4** by its parent compound **2** at low probe concentrations using an FP competition experiment. The binding signal of **4** disappeared within a narrow concentration range of **2** (Figure 3), and curve fitting (see Supporting Information) generated a K_D value for **2** of 0.24 ± 0.07 μM, which agrees well with the value obtained by ITC (0.124 ± 0.017 μM). It has already been confirmed by X-crystallography that **2** binds *Ba*DHPS at the pterin-binding site,[16] and this experiment therefore confirms that the FP probe **4** is a competitive binder with respect to **2** and binds at the pterin-binding pocket in *Ba*DHPS as expected.

To develop the high-throughput FP screening assay, it was necessary to determine the optimum protein concentration for competitive binding. Thus, **4** at its K_D (we chose the ITC value of 2.7 μM) was titrated with varying concentrations of *Ba*DHPS (Figure 4) and the FP signal monitored. In the absence of

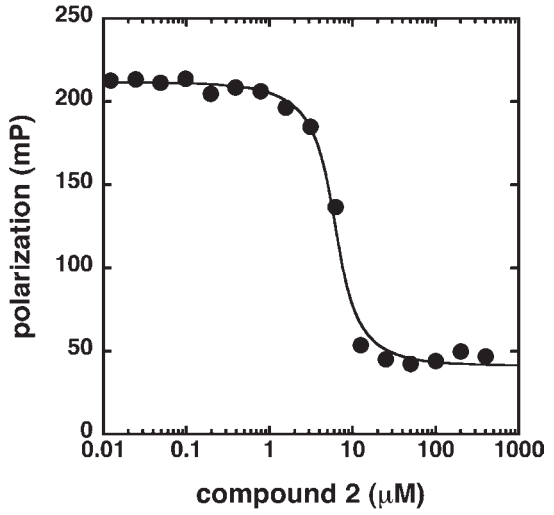

Figure 3. FP competition titration of nonfluorescent compound **2** (10 nM to 400 uM) against compound **4** (6 nM), and **6** μM *Ba*DHPS (average of 3 independent experiments). $K_D = 0.24 \pm 0.07$ μM.

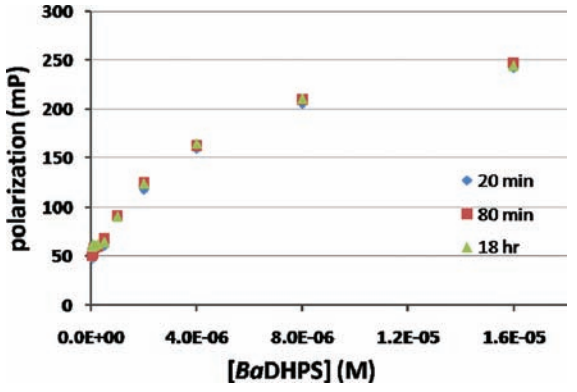

Figure 4. Titration of **4** (2.7 μM) with *Ba*DHPS monitored by FP. Increasing concentrations of *Ba*DHPS (0−16 μM) was incubated with **4** at 25 °C and the response measured at 20 min, 80 min, and 18 h.

protein, a low polarization value of 50 mP was observed, but with increasing concentrations of *Ba*DHPS protein, the FP signal progressively increased until it reached saturation. This revealed an assay window of up to 200 ΔmP which is a robust signal window for a FP assay. By examining the response curve (Figure 4), DHPS at 8 μM was selected for further assay development because this concentration yields an acceptable assay window of ΔmP ∼150 mP. This experiment was also used to evaluate the stability of the FP signal, which becomes an important parameter in the high-throughput screening of large number of compounds over long periods of time.[26] To this end, the probe was incubated with *Ba*DHPS for a period of 18 h within which the FP signal of the plate was read several times. The binding curves showed that the FP signal is very stable with little noticeable difference. In addition, incubation of the probe with protein reached signal saturation in a very short time (∼20 min), which is an added advantage (Figure 4).

DMSO is routinely used to dissolve or dilute compounds for screening assays; therefore, the effect of various DMSO concentrations on the FP signal was studied. Specifically, **4** was incubated with *Ba*DHPS in the presence of varying DMSO concentrations

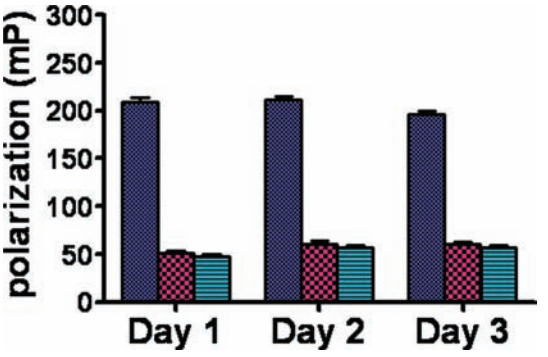

Figure 5. Tracer specificity test. blue bars: 2.7 μM of **4** with 8 μM of *Ba*DHPS in buffer; red bars: 2.7 μM of **4**, 8 μM of *Ba*DHPS, and 100 μM of **2** in buffer; green bars: 2.7 μM of **4** only in buffer.

up to 10% and the variation in FP signal was monitored (see Supporting Information Figure S2). This experiment showed that the FP binding assay tolerated DMSO well, up to a concentration of 10%, with less than 10% reduction of the FP signal, which remained stable for 18 h (higher DMSO concentrations were not tested because the DMSO concentration will not exceed 10% in a typical assay).

To evaluate the performance of the DHPS FP binding assay, the Z′ value was calculated for the assay carried out in a 384 well plate format.[27] In general, Z′ values between 0.5 and 1.0 are considered acceptable. Here, the Z′ values for the *Ba*DHPS FP binding assay obtained from three independent experiments were 0.87, 0.87, and 0.86, respectively (see Supporting Information Figure S3), and these values showed that the assay is highly reproducible. Furthermore, the FP assay with **4** was also tested against *Staphylococcus aureus* DHPS (*Sa*DHPS) using similar assay conditions, and this also performed remarkably well with a Z′ value at 0.84. This confirms that the assay is suitable for future high-throughput screening against multiple DHPS enzymes.

Finally, competitive displacement assays were performed with various known DHPS inhibitors to test the robustness of the developed FP assay and to validate its utility for detecting specific inhibitors that target the pterin-binding pocket. In an initial competition binding experiment in which *Ba*DHPS, probe **4**, and its parent inhibitor **2** were coincubated under high-throughput assay optimized conditions, the binding signal of **4** was completely abolished by an excess of **2** and the FP signal was almost identical to that for probe **4** in the absence of protein. The results were stable over a three-day period (Figure 5) and are consistent with the titration experiment shown in Figure 3. Seven inhibitors were then tested: **2**, **18** (an analogue of **2**), and **19** are DHPS inhibitors that are known to target the pterin-binding pocket,[16] sulfamethoxazole (SMX) and sulfanilamide (SIA) are two sulfonamides that bind the *p*ABA binding pocket, and **20** and pteroic acid are two DHPS inhibitors that engage both the pterin- and *p*ABA-binding sites simultaneously. The competition experiment (Figure 6) showed that all the compounds known to bind the pterin-binding site on DHPS (**2**, **18**, **19**, **20**, and pteroic acid) are able to compete off the FP probe **4** and are identified as hits in the current assay. However, SMX and SIA, which bind to the *p*ABA subsite, are not able to compete off the FP probe **4** and thus would not be identified as hits since the assay described herein specifically identifies compounds that bind to the pterin subsite.

In summary, two pterin-based fluorophores **3** and **4** were designed, synthesized, and evaluated as probes for the development

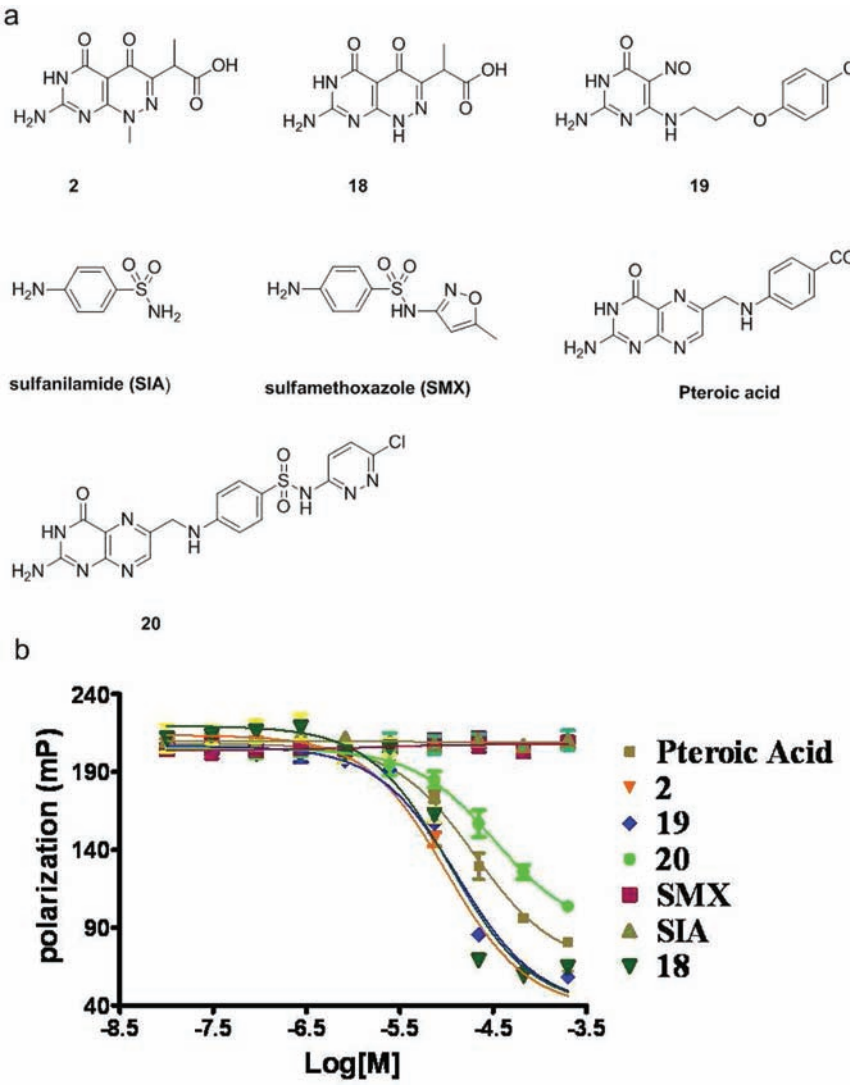

Figure 6. (a) Structure of small molecule inhibitors evaluated in FP competition experiment. (b) Competitive displacement of **4** from *Ba*DHPS by various DHPS inhibitors.

of a FP assay for screening against *Ba*DHPS and *Sa*DHPS. The FP assay described herein, in which **4** is used as probe, is rapid, accurate, robust, and reproducible as evidenced by an excellent Z′ factor. Furthermore, it has great tolerance with respect to the typical concentrations of DMSO used in small molecule screening and is suitable for identifying DHPS inhibitors that bind to the pterin subsite in a high-throughput format. Finally, **4** can be further used to subsequently derive K_D values for the pterin pocket inhibitors identified in the high-throughput FP assay.

SUPPORTING INFORMATION

Kd fit equation for competition experiments:

The following equation derived from the definition of dissociation constant with the approximation of a negligible concentration of fluorescent probe:

$$FP = FP^{0} + \Delta FP \bullet \left\{ \frac{-\left[K_{comp} \bullet ([comp] - [DHPS]) + 2 \bullet [DHPS] + K_{D}\right] + \sqrt{\left[K_{comp} \bullet ([comp] - [DHPS]) + 2 \bullet [DHPS] + K_{D}\right]^{2} + 4 \bullet [DHPS] \bullet \left[K_{comp} \bullet ([DHPS] - [comp]) + K_{comp} \bullet K_{D} - [DHPS] - K_{D}\right]}}{2 \bullet \left[K_{comp} \bullet ([DHPS] - [comp]) + K_{comp} \bullet K_{D} - [DHPS] - K_{D}\right]} \right\}$$

where K_D is the dissociation constant between the probe and DHPS, K_{comp} is the ratio between dissociation constant between the K_D and the K_d of the competitor.

Method for HPLC/UV/ELSD/MS

LC-MS chromasolv grade methanol and ammonium bicarbonate were obtained from Sigma-Aldrich (St. Louis, MO). Milli-Q water as an ultrapure laboratory grade water was used in aqueous mobile phase.

Chromatographic separation was performed on an Acquity UPLC BEH C18 1.7 μm, 2.1 x 50 mm column (Waters Corporation, Milford, MA) using an Acquity ultra performance liquid chromatography system. Data were acquired using Masslynx v. 4.1 and analyzed using the Openlynx software suite. This was coupled to an Acquity photodiode array detector, which acquired UV data from 210-400 nm. The flow was then split, with half directed to an evaporative light scattering detector (ELSD) and half to an SQ mass spectrometer. The total flow rate was 0.7 mL/min. The sample injection volume was 2 μL. The UPLC column was maintained at 50 °C and the gradient program started at 90% A (10 mM ammonium bicarbonate in MilliQ H_2O), changed to 70% A over 0.2 min, to 95 % B (100% methanol) over 1.4 minutes, held for 0.35 minutes, then to 90% A over 0.05 minutes. The mass spectrometer was operated in positive-ion mode with electrospray ionization. The conditions were as follows: capillary voltage 3.4 kV, cone voltage 30 V, source temperature 130 °C, desolvation temperature 400 °C, desolvation gas 800 L/hr, cone gas 100 L/hr. A full scan range from m/z = 110-1000 in 0.2 s was used to acquire MS data. The ELSD-drift tube temperature was set at 52 °C.

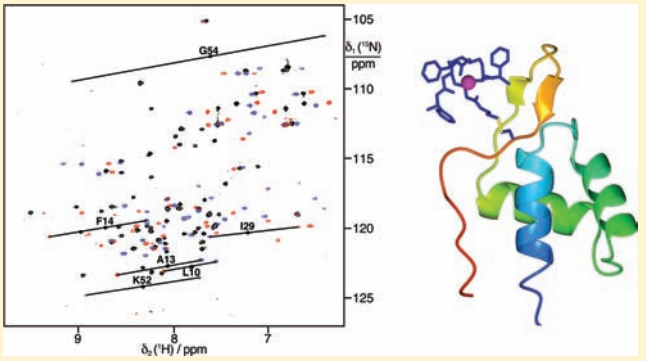
Supporting Information

ABSTRACT: Structural studies of proteins and protein−ligand complexes by nuclear magnetic resonance (NMR) spectroscopy can be greatly enhanced by site-specific attachment of lanthanide ions to create paramagnetic centers. In particular, pseudocontact shifts (PCS) generated by paramagnetic lanthanides contain important and unique long-range structure information. Here, we present a high-affinity lanthanide binding tag that can be attached to single cysteine residues of proteins. The new tag has many advantageous features that are not available in this combination from previously published tags: (i) it binds lanthanide ions very tightly, minimizing the generation of nonspecific effects, (ii) it produces PCSs with high reliability as its bulkiness prevents complete motional averaging of PCSs, (iii) it can be attached to single cysteine residues, alleviating the need of detailed prior knowledge of the 3D structure of the target protein, and (iv) it does not display conformational exchange phenomena that would increase the number of signals in the NMR spectrum. The performance of the tag is demonstrated with the N-terminal domain of the *E. coli* arginine repressor and the A28C mutant of human ubiquitin.



INTRODUCTION

Site-specific attachment of paramagnetic lanthanide ions to proteins produces large effects in NMR spectra that contain valuable long-range structural information.[1,2] Among the paramagnetic effects, pseudocontact shifts (PCS) stand out for their ease of measurement (as the difference in chemical shifts observed for samples labeled with, respectively, a paramagnetic or a diamagnetic lanthanide ion) and high information content (as PCSs can be observed for nuclear spins beyond 40 Å from the metal ion).

The PCS, $\Delta\delta^{PCS}$ (in ppm), of a nuclear spin can be described by[3]

$$\Delta\delta^{PCS} = \frac{1}{12\pi r^3}\left[\Delta\chi_{ax}(3\cos^2\theta - 1) + \frac{3}{2}\Delta\chi_{rh}\sin^2\theta\cos 2\varphi\right] \quad (1)$$

where $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$ denote, respectively, the axial and rhombic components of the magnetic susceptibility anisotropy ($\Delta\chi$) tensor and r, and θ and φ are the polar coordinates of the nuclear spin with respect to the principal axes of the $\Delta\chi$ tensor. The limited number of parameters in eq 1 and the long-range nature of lanthanide-induced PCSs makes them powerful tools for structure determinations of protein−protein[4,5] and protein−ligand complexes (for recent reviews, see refs 6 and 7). In practice, eight parameters suffice to fit $\Delta\chi$ tensors to the 3D structure of a protein (x, y, z coordinates of the metal ion, three Euler angles to relate the orientation of the $\Delta\chi$ tensor to the frame of the protein atom coordinates, and the $\Delta\chi_{ax}$ and $\Delta\chi_{rh}$ parameters). Lanthanides are uniquely suited for PCS measurements, as different lanthanides produce different magnitudes of $\Delta\chi$ tensors while their chemical properties are very similar. This avoids chemical shift changes due to chemical differences among different paramagnetic and diamagnetic (La^{3+}, Y^{3+}, Lu^{3+}) ions.

A lanthanide ion can generate large PCSs only if it is site-specifically attached to the target protein in a rigid manner. If the tether between the lanthanide and the protein is flexible, the $\Delta\chi$ tensor associated with the lanthanide changes its orientation relative to the protein and the resulting averaging over positive and negative PCS values greatly reduces the magnitude of

 © 2011 American Chemical Society

observable PCSs. Therefore, no PCS may be observed if the tether allows substantial reorientation of the lanthanide ion with respect to the protein.

The problem of rigid lanthanide attachment can be addressed in different ways. Lanthanide chelates with two arms for attachment to two cysteine residues have been shown to minimize residual motion of the lanthanide relative to the protein.[8−10] A related strategy combines an N-terminal fusion with a lanthanide binding peptide (LBP) with a disulfide bond between the LBP and the target protein.[5,11] Engineering an LBP into the turn between two strands of a β-sheet similarly immobilizes lanthanides.[12] Another strategy coordinates the lanthanide by groups from two different sites of the protein. One group may be a small lanthanide binding tag attached to a cysteine residue, while the other group can be a carboxyl group of the protein.[13,14] Small tag molecules can also be attached to two cysteines with the aim of coordinating a single lanthanide between the two tags.[15,16] Finally, a lanthanide binding site can be engineered into the target protein by introducing amino acids with negatively charged side chains.[17] All these strategies rely on prior knowledge of the 3D structure of the target protein, at least at the site of modification.

To harness the power of PCSs for 3D structure determinations, however, it is necessary to use lanthanide tags that can be site-specifically attached without detailed knowledge of the 3D structure of the target protein. In this situation, tags with single attachment points have an advantage even if they may only incompletely immobilize the lanthanide ion. For example, LBPs with single cysteine residues have been shown to deliver large PCSs following attachment to the target protein via a disulfide bond.[18,19] The bulkiness of the tag restricts the amplitude of motion relative to the protein by steric constraints, preventing excessive averaging of the PCSs. Similarly, tags based on lanthanide complexes derived from cyclen (1,4,7,10-tetraazacyclododecane) can deliver PCSs of useful magnitudes, while providing exceptionally small dissociation constants of the lanthanide from the tag and robustness against extreme conditions of pH, temperature, and denaturants.[8,20] As a drawback, synthesis of cyclen tags can be expensive and arduous to prepare, and conformational equilibria can result in multiple sets of NMR signals.[20]

Lanthanide complexes of DOTA derivatives display two fundamental conformational equilibria.[21] The first affects the chirality of the cyclen ring. The second equilibrium affects the chirality of metal coordination by the acetate groups. Both equilibria are coupled. It has been shown that the equilibria can be pushed toward a single conformation of the lanthanide complex by incorporating chiral centers in the cyclene ring and its pendants[22] or, more simply, by turning the acetate groups of DOTA into amides with chiral amines.[23]

In the following, we present a new cyclen tag with three chiral amide groups and one nonchiral pendant for attachment to a cysteine residue of the target protein. We show that the three chiral amide pendants are sufficient to maintain a single enantiomeric conformation, as evidenced by a single set of peaks in the protein NMR spectrum, and that, even at 45 °C, the tag is free of complications arising from slow conformational exchange phenomena that have been reported for a different chiral DOTA tag.[20]

EXPERIMENTAL PROCEDURES

Tag Synthesis—(*S*)-2-Bromo-*N*-(1-phenylethyl)acetamide (1). Bromoacetyl bromide (12.7 g, 63 mmol) was added dropwise via syringe to a solution of (*S*)-1-phenylethanamine (15.3 g, 126 mmol) in DCM (200 mL) at 0 °C under nitrogen. Stirring was continued for a further 2 h at room temperature. The solution was washed with 2 N HCl (100 mL) followed by saturated brine (100 mL), then dried ($MgSO_4$), and solvent removed under reduced pressure to afford **1** (12.7 g, 83%) as a white solid. ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.40−7.25 (m, 5H), 6.79 (br s, 1H), 5.12 (apparent p, J = 7.0 Hz, 1H), 3.95−3.82 (m, 2H), 1.55 (d, J = 6.9 Hz, 3H). ^{13}C NMR (101 MHz, $CDCl_3$) δ 164.7, 142.5, 128.9, 127.7, 126.2, 49.7, 29.4, 21.7. LRMS (ESI) m/z 244 (7%, $[M[^{81}Br]H]^+$), 242 (7, $[M[^{79}Br]H]^+$), 138 (10), 136 (9), 105 (100).

2,2′,2″-(1,4,7,10-Tetraazacyclododecane-1,4,7-triyl)tris-(*N*-((*S*)-1-phenylethyl)acetamide) (2). A solution of **1** (18.4 g, 76 mmol) in chloroform (500 mL) was added dropwise to a stirred mixture of cyclen (4.37 g, 25 mmol) and DIPEA (35 mL, 200 mmol) in chloroform (500 mL) under a nitrogen atmosphere at room temperature. The mixture was stirred for a further 24 h, then washed with water, and the organic phase dried over $MgSO_4$. After removal of the solvent, the residue was purified by flash chromatography (gradient from 90:10:1 to 80:20:2 EtOAc/MeOH/NH_3) to afford the product (10.2 g, 61%) as a thick, light yellow oil. ^{1}H NMR (400 MHz, DMSO) δ 8.36 (d, J = 8.0 Hz, 2H), 8.26 (d, J = 7.8 Hz, 1H), 7.33−7.26 (m, 12H), 7.25−7.16 (m, 3H), 4.98−4.85 (m, 3H), 3.15−3.00 (m, 6H), 2.73−2.43 (m, 16H), 1.41−1.30 (m, 9H). ^{13}C NMR (101 MHz, DMSO) δ 169.7(2), 169.6(8), 144.7, 144.4, 128.2, 128.2, 126.6, 126.5, 126.0, 126.0, 57.7, 55.9, 52.7, 52.3, 50.9, 47.7, 47.6, 46.4, 22.5, 22.4. LRMS (ESI) m/z 656 (85%, $[M+H]^+$), 329 (100, $[M+2H]^{2+}$).

2-Chloro-*N*-(2-(pyridin-2-yldisulfanyl)ethyl)acetamide (3). To a stirred solution of 2-(pyridin-2-yldisulfanyl)ethanamine hydrochloride (3.00 g, 13.5 mmol) and chloroacetic acid (1.28 g, 14 mmol) in 1:10 dichloromethane/acetonitrile (50 mL) was added DIPEA (7.0 mL, 400 mmol) and BOP (6.63 g, 15 mmol). The reaction mixture was stirred overnight at room temperature under nitrogen. Upon completion of the reaction, the solvent was removed under reduced pressure and the resulting crude product was dissolved in saturated $NaHCO_3$ solution (150 mL) and washed with ether (3 × 100 mL). The combined organic layers were washed with saturated brine, dried ($MgSO_4$), and the solvent removed under reduced pressure. Flash chromatography (30:70 ethyl acetate/petroleum spirit) afforded **2** (2.80 g, 79%) as a slightly yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.56 (ddd, J = 4.9, 1.8, 0.9 Hz, 1H), 8.26 (br s, 1H), 7.60 (ddd, J = 8.0, 7.4, 1.8 Hz, 1H), 7.47 (dt, J = 8.1, 1.0 Hz, 1H), 7.14 (ddd, J = 7.4, 4.9, 1.1 Hz, 1H), 4.09 (s, 2H), 3.67−3.56 (m, 2H), 2.97−2.87 (m, 2H). ^{13}C NMR (101 MHz, $CDCl_3$) δ 166.3, 159.1, 150.2, 137.0, 121.5, 121.4, 42.9, 38.9, 37.6. LRMS (ESI) m/z 265 (40%, $[M[^{37}Cl]H]^+$), 263 (100, $[M[^{37}Cl]H]^+$).

2,2′,2″-(10-(2-Oxo-2-(2-(pyridin-2-yldisulfanyl)ethylamino)-ethyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)tris(*N*-((*S*)-1-phenylethyl)acetamide) (C1). A mixture containing **3** (1.40 g, 2.1 mmol), **2** (1.00 g, 3.8 mmol), and DIPEA (610 μL, 3.8 mmol) in acetonitrile (50 mL) was stirred at room temperature for 48 h. The resultant white precipitate was filtered and dried to afford C1 (0.65 g, 35%) as a white solid. Evaporation of the filtrate and purification of the residue by flash chromatography (90:10:1 DCM/MeOH/NH_3) afforded a further crop of the product (0.78 g, 41%). ^{1}H NMR (400 MHz, DMSO) δ 8.46−8.42 (m, 1H), 8.28 (t, J = 5.8 Hz, 1H), 8.19 (d, J = 8.1 Hz, 1H), 8.15 (d, J = 8.1 Hz, 2H), 7.83−7.76 (m, 1H), 7.73 (dt, J = 8.1, 1.0 Hz, 1H), 7.33−7.25 (m, 12H), 7.24−7.16 (m, 4H), 5.00−4.86 (m, 3H),

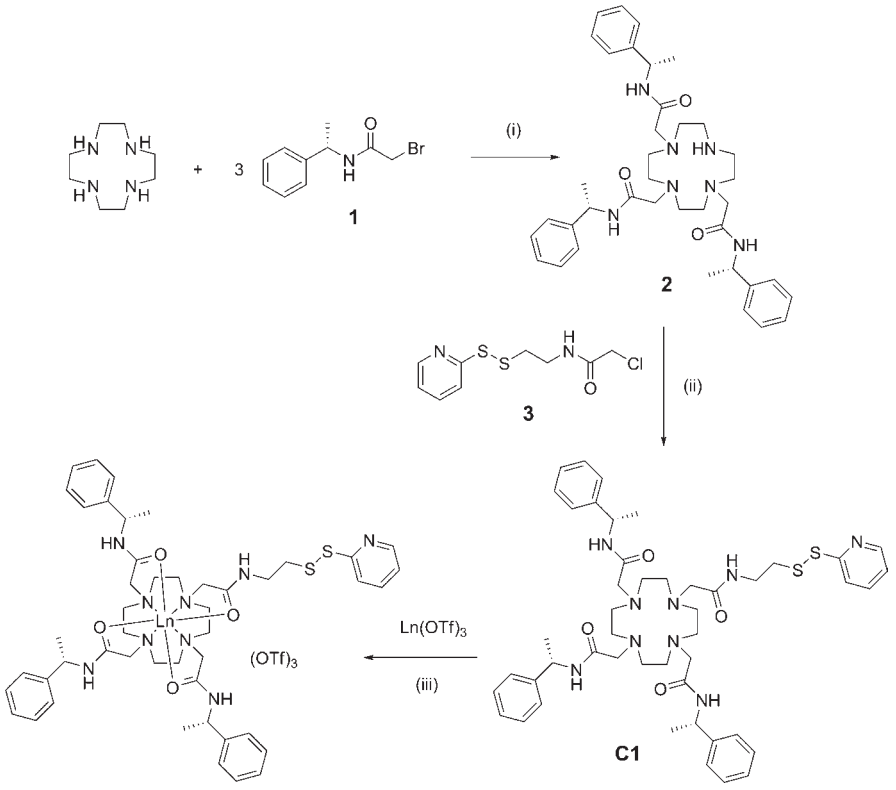

Figure 1. Synthesis of C1 tag and lanthanide complexes. Conditions: (i) DIPEA, chloroform, RT, O/N; (ii) DIPEA, acetonitrile, RT, 2 d; (iii) acetonitrile, reflux, O/N.

3.41−3.32 (m, 2H), 3.07−2.96 (m, 6H), 2.93−2.83 (m, 4H), 2.75−2.42 (m, 16H), 1.43−1.28 (m, J = 8.8, 7.1 Hz, 9H). ^{13}C NMR (101 MHz, DMSO) δ 170.6, 169.4, 169.4, 159.1, 149.6, 144.4, 144.3, 137.7, 128.2, 126.6, 126.0, 126.0, 121.2, 119.3, 58.1, 57.9, 57.6, 53.6, 53.3, 52.9, 47.6, 37.6, 37.4, 22.2, 22.1. HRMS (ESI): m/z: calcd for$[M+H]^+$ $C_{47}H_{64}N_9O_4S_2$: 882.4517, found: 882.4555.

Formation of Metal Complexes. As binding of lanthanides to DOTA-type cyclen derivatives is extremely slow and requires heating, we did not attempt to exchange the metal ion from tagged protein samples. To produce protein samples with different lanthanides, the C1 tag was prepared with different paramagnetic and diamagnetic ions (Tb^{3+}, Tm^{3+}, Yb^{3+}, Y^{3+}) by heating the tag in acetonitrile with a molar equivalent of the respective metal triflate salts overnight at 80 °C, followed by freeze−drying to afford off-white powders. Stock solutions of the C1−lanthanide complexes were prepared in water with concentrations of up to 20 mM.

Tagging Reaction. Uniformly ^{15}N/^{13}C-labeled samples of the N-terminal domain of the *E. coli* arginine repressor (ArgN) were produced on M9 minimum medium as described.[24] A 0.2 mM solution of ArgN in NMR buffer (20 mM MES, pH 6.6) was reduced by 5 equiv of DTT and subsequently washed with NMR buffer using a Millipore ultrafilter with a molecular weight cutoff of 3 kDa. The solution was added to a 3-fold excess of tag in NMR buffer to yield a total volume of 0.5 mL and the mixture was incubated at room temperature for 5 h. The reaction mixture was washed again with NMR buffer and concentrated to a final volume of 0.5 mL.

Uniformly ^{15}N-labeled samples of the mutant A28C of human ubiquitin were prepared as described.[15] DTT reduction of the thiol was as above for ArgN followed by passage over a PD10 column equilibrated with degassed NMR buffer (50 mM HEPES pH 7.5). A 15-fold excess of tag was added from a 20 mM stock solution in water to an approximately 50 μM solution of the protein and left for 3 h at room temperature and then overnight at 3 °C. Excess tag was removed by passage over a PD10 column and the sample concentrated using a Millipore ultrafilter to a final protein concentration of about 70 μM.

NMR Spectra. NMR spectra were recorded at 25 °C on 600 MHz NMR spectrometers equipped with cryogenic probes (Bruker Avance and Varian INOVA in the case of ArgN and ubiquitin(A28C), respectively). ^{15}N-HSQC, 3D HNCA, and HN(CO)CA spectra were recorded from differently tagged ArgN. ^{15}N-fast-HSQC spectra were recorded from differently tagged ubiquitin(A28C), and a 3D NOESY−^{15}N-HSQC spectrum was recorded from the ubiquitin(A28C)−C1-Y^{3+} complex. Resonance assignments of paramagnetic NMR spectra were supported by the program *Numbat*[25] to fit $\Delta\chi$ tensors to a set of unambiguously assigned PCSs and predict the PCSs of unassigned paramagnetic cross-peaks in several rounds of $\Delta\chi$ tensor fitting and resonance assignments.

Fitting of $\Delta\chi$ Tensors. $\Delta\chi$ tensors were fitted to the first conformer of the NMR structure of ArgN (PDB accession code 1AOY[24]) following a previously described protocol.[26,27] Briefly, the structure of ArgN with the C1 tag was modeled using the enantiomeric mirror image of the crystal coordinates of the DOTA-tetraamide Gd^{3+} complex with 1-phenylethyl amine (DOTAMPh, CSD accession code EQOZUF[28]). One of the 1-phenylethyl groups of the DOTAMPh molecule was changed to a 2-thioethyl group, which was connected via a disulfide bond to the sulfur of Cys68 of ArgN. 4×10^6 different conformations

were generated by randomly changing the χ_1 and χ_2 angles of Cys68 and the dihedral angles of the disulfide bond and ethylene tether, using dihedral angles of 60°, −60°, and 180° for the C−C bonds and dihedral angles of −90° or 90° for the S−S bond, with an uncertainty range of ±10°. Conformations producing steric clashes with the protein were excluded. The remaining 2287 conformers were used to fit $\Delta\chi$ tensors to the experimental PCSs. The final $\Delta\chi$ tensor was taken to be the one obtained with the conformation producing the best least-squares fit to the experimentally observed PCS data. As a measure of the precision of the $\Delta\chi$-tensors and metal positions, the fits to each of the 2287 model conformers were repeated 100 times, omitting 20% of the data from each metal ion in a Monte Carlo protocol.[25]

Fitting of $\Delta\chi$ tensors to the ubiquitin mutant A28C followed the same protocol as for ArgN. The fits used the first conformer of the NMR structure (PDB accession code 1D3Z[29]). 2897 conformers were obtained that were free of steric clashes between tag and protein.

RESULTS

Synthesis of the C1 Tag and Its Lanthanide Complexes. Figure 1 shows the synthetic route used to prepare the "conjugation ready" C1 tag from 1,4,7,10-tetraazacyclododecane (cyclen). This involved the sequential attachment of the three chiral amide groups and one nonchiral pendant via reaction with α-haloacetamide derivatives of (*S*)-1-phenylethanamine and 2-(pyridin-2-yldisulfanyl)ethanamine, respectively. Although chromatography was required at both stages to remove impurities, the synthesis avoided the need for protection groups and afforded the tag in good overall yield. The lanthanide complexes of C1 were readily prepared by refluxing 1:1 mixtures of the ligand and metal triflate salts, $Ln(OTf)_3$ (Ln = Dy^{3+}, Tb^{3+}, Tm^{3+}, Yb^{3+}, Y^{3+}), in acetonitrile overnight.

Tagging Reaction and Protein NMR Assignments. The C1 tag was attached to ArgN by adding the protein to a 3-fold excess of tag rather than adding tag to protein, to avoid the possibility of disulfide-bond formation between different protein molecules which could arise from disulfide exchange. The reaction reproducibly delivered tagged ArgN with greater than 95% yield. Samples were produced with tags loaded with different lanthanides (Dy^{3+}, Tb^{3+}, Tm^{3+}, Yb^{3+}) or a diamagnetic metal (Y^{3+}).

The C1 tag was attached to the ubiquitin mutant A28C using a similar protocol or a large excess of tag as described in the Experimental Procedures. Reaction yields increased with the duration of incubation (from hours to days) with the C1 tag. An overnight reaction at 3 °C (i.e., conditions suitable for less stable proteins) yielded 80−90% of tagged ubiquitin. Even the use of a large excess of tag produced no evidence for disulfide mediated protein dimerization.

The backbone NMR resonances of paramagnetic and diamagnetic ArgN-C1 complexes were assigned using 3D HNCA and HN(CO)CA spectra. The resonance assignments obtained are compiled in Supporting Information Table S1. Chemical shift changes in ArgN and ubiquitin(A28C) tagged with diamagnetic Y^{3+} tags were limited to amides in the vicinity of the cysteine residue, indicating that the tags did not significantly alter the protein structures. The resonance assignments of the diamagnetic ubiquitin(A28C)−C1−Y^{3+} complex were established by a 3D NOESY−^{15}N-HSQC spectrum. For either protein, resonance assignments of the paramagnetic samples were aided by the fact that the PCSs produced by different lanthanides

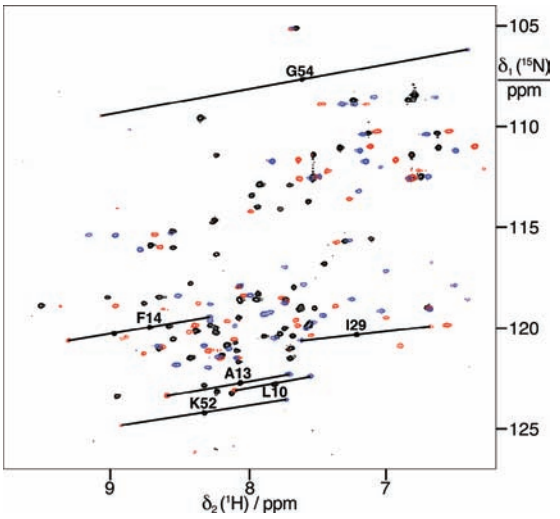

Figure 2. Superimposition of ^{15}N-HSQC spectra of 0.2 mM solutions of uniformly ^{13}C/^{15}N-labeled N-terminal domain of the *E. coli* arginine repressor ligated at Cys68 with the C1 tag loaded with Y^{3+} (black peaks), Tb^{3+} (red), or Tm^{3+} (blue). All spectra were recorded at 25 °C on a 600 MHz NMR spectrometer in a 20 mM MES buffer, pH 6.6. Selected diamagnetic cross-peaks are labeled with their resonance assignments and connected by lines with their paramagnetic partners.

displaced the cross-peaks along almost straight lines. Supporting Information Table S2 shows the experimentally determined PCSs of ubiquitin(A28C).

PCS Measurements and $\Delta\chi$ Tensors. Pronounced PCSs were observed in the complexes of ArgN and ubiquitin(A28C) tagged with C1 containing Dy^{3+}, Tb^{3+}, Tm^{3+}, or Yb^{3+}. All samples produced high-quality NMR spectra (Figure 2 and Supporting Information Figure S2). There was no evidence for conformational heterogeneity of the tag or slow conformational exchange, neither in the C1−Yb^{3+} tag alone (Figure S1) nor in the ubiquitin(A28C) mutant tagged with C1−Yb^{3+} and measured with high signal-to-noise ratio (Figure S3). No minor conformational species appeared at 45 °C (Figures S1 and S3).

$\Delta\chi$ tensors were fitted to the experimental PCSs using the first conformer of the NMR structure of ArgN[24] with the covalent structure of the tags crafted onto it via a disulfide bond linkage to Cys68. Table 1 shows the parameters of the fitted $\Delta\chi$ tensors. The tensors were sufficiently large to generate PCSs of up to 0.13 ppm at the site most remote from Cys68 (the amide proton of Asp39 in the C1(Tb)-tagged protein which is 32 Å from the site of the metal ion).

Fits of the $\Delta\chi$ tensors to the NMR structure of ubiquitin[29] produced smaller tensors than in the case of ArgN (Supporting Information Table S3), suggesting that the exposure of Cys28 on the surface of the protein permits a greater amplitude of motion for the tag (Figure S4; the calculated solvent accessibility of Cys68 of ArgN is about 7% and is 22% for Cys28 of ubiquitin(A28C)). As in the case of ArgN, however, the C1 tag produced significantly larger $\Delta\chi$ tensors than a previously used NTA derivative (N^{α},N^{α}-bis(carboxymethyl)-L-cysteine) that is a much smaller molecule with a shorter linker.[15]

Back-calculated and experimental PCSs correlated closely for ArgN and ubiquitin (Figure 3). Remarkably, the correlation was better for ubiquitin than for ArgN despite the greater conformational freedom of the C1 tag on the surface of ubiquitin, indicating that tag mobility is a lesser impediment to good fits of PCS data than structure quality.

Table 1. $\Delta\chi$ Tensors of Different Metal Ions Bound to ArgN-C1[a]

metal ion	$\Delta\chi_{ax}$ /10^{-32} m^3	$\Delta\chi_{rh}$ /10^{-32} m^3	Q^b	tensor axis	coordinates of tensor axes

				z	−0.320	0.883	0.344

[a] The tensors are listed in their unique tensor representation (UTR)[25] as obtained by fitting of the PCSs of Table S1 to ArgN (PDB ID 1AOY model 1)[24] simultaneously using the PCSs induced by Dy^{3+}, Tb^{3+}, Tm^{3+}, and Yb^{3+} and a common metal position. The fits used PCSs of amide protons in structurally well-defined regions of the protein (residues 8−20, 26−37, 43−52). The covalent structure of the tag was taken into account as described in the main text. The orientations of the tensor axes are given as unit vectors with respect to the origin (0, 0, 0). Uncertainty ranges (shown in brackets) were obtained by a Monte Carlo error analysis that randomly omitted 20% of the PCSs (100 trials for each of 2287 modeled tag conformations). The coordinates of the common metal position in the best fit using 100% of the PCSs were (13.705, 11.580, 0.445). A small fraction (9%) of the best solutions in the Monte Carlo trials positioned the metal in a group about 4 Å from this position. These solutions were omitted from the error analysis. In the remaining solutions, the metal was displaced by <1.9 Å. [b] Q-factor calculated as root-mean-square deviation between measured and predicted PCSs divided by the root-mean-square of the measured PCSs. The Q-factor of the simultaneous four-metal fit is 0.16.

DISCUSSION

Our results indicate that the C1 tag reliably produces PCSs following attachment to single cysteine residues. This is an important advantage over DPA tags[13,14,27] or IDA and NTA tags[15,16] that often generate vanishingly small PCSs if the metal ion is not coordinated by an additional carboxyl group from the protein, as mobility of the tether to the protein invariably reduces the magnitude of the PCSs observed in the protein. The reliability with which the C1 tag generates PCSs can be attributed to its bulkiness, which limits the amplitude of reorientational motions of the DOTA moiety relative to the protein. For comparison, no PCSs could be generated with lanthanides in the ubiquitin (A28C) mutant tagged with the much smaller 4MDPA tag[27] (data not shown), despite there being only a single rotatable bond in the linker between the lanthanide and the disulfide bond. Reliable generation of PCSs in the absence of structural information is an essential prerequisite before the power of PCS data can be harnessed for 3D structure determinations of proteins.

Generation of sizable PCSs in the target protein is greatly aided by an intrinsically large $\Delta\chi$ tensor of the lanthanide tag. Remarkably large paramagnetic shifts have been reported for the Yb^{3+} complex of the symmetrical parent compound of the C1 tag, DOTAMPh, which has 1-phenylethylacetamide pendants attached to all four nitrogens of the cyclen ring.[23] As the cyclen protons are separated from the lanthanide by only a few bonds, it is unclear, however, which fraction of the paramagnetic shifts in DOTAMPh must be attributed to contact shifts rather than PCSs. In a protein tagged with C1, however, contact shifts can be neglected for protons that are sufficiently far from the metal to yield observable NMR signals. Remarkably, the $\Delta\chi_{ax}$ value of 13 × 10^{-32} m^3 determined for the ArgN-C1(Yb^{3+}) complex (Table 1) is almost two times greater than any that has been reported for Yb^{3+} complexes of calbindin D_{9k},[30] CLaNP-5.2,[8,9] lanthanide binding peptides,[19] or DPA tags.[13,19,27] Correspondingly large residual dipolar couplings (RDC) could be observed on an 800 MHz NMR spectrometer, with $^1D_{HN}$ RDCs of up to 20.3 Hz measured for ArgN-C1(Tm^{3+}) at 25 °C. Maximal $^1D_{HN}$ RDC values greater than 20 Hz are hallmarks of the best lanthanide tags currently available.[8,20,31,32] Under the conditions of our RDC measurements, a maximal $^1D_{HN}$ value of about 20 Hz would be predicted for the $\Delta\chi_{ax}$ value of 37 × 10^{-32} m^3 associated with ArgN-C1(Tm^{3+}) (Table 1). This close agreement between predicted and experimental maximal RDC values would suggest that the tag has little conformational freedom. Large uncertainty ranges, however, were associated with the $\Delta\chi$ tensor determinations, which may be attributed to the fairly long distance of the metal from the protein surface (8 Å from the sulfur of the cysteine residue; Figure 4) and similar directions of the principal tensor axes of the different metals (Table 1).

In contrast to the situation encountered with RDCs, where the average of different alignment tensors can be represented by a single average tensor, an ensemble of different $\Delta\chi$ tensors from different metal positions cannot be approximated well by a single average tensor, at least not close to the metal ion, since PCSs are distance-dependent. At greater distances from the paramagnetic center, however, the approximation by an average $\Delta\chi$ tensor is much better, as different tag conformations have a smaller relative influence on the distance between nuclear spins and paramagnetic center. Therefore, even if mobility of the tag leads to a reduced average $\Delta\chi$ tensor, this tensor still yields useful structural restraints at greater distances from the metal ion, as long as it fits the experimentally observed PCSs in those regions of the protein. The large intrinsic $\Delta\chi$ tensor associated with the C1 tag thus makes it a useful tool for protein structure analysis even in the presence of substantial averaging as observed for the ubiquitin A28C mutant. Notably, PCSs could be measured for almost all peaks of ubiquitin (Supporting Information Figure S2) and even using all PCSs from residues 2−72 produced a better fit of back-calculated versus experimental PCSs for ubiquitin than for ArgN for which only a NMR structure determined by NOEs and J couplings is available (Figure 3).

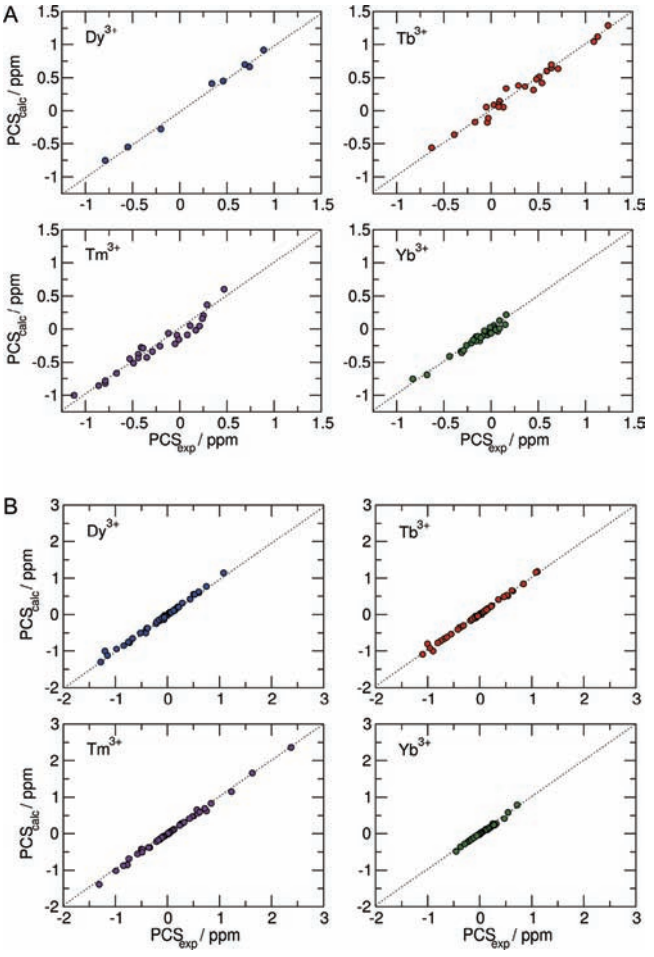

Figure 3. Correlations between back-calculated and experimental pseudocontact shifts of (A) the N-terminal domain of the *E. coli* arginine repressor and (B) ubiquitin obtained by the fits of Table 1 and Supporting Information Table S3, respectively.

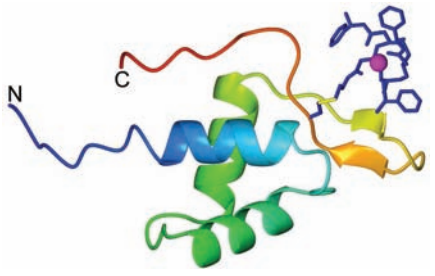

Figure 4. Model of the N-terminal domain of the *E. coli* arginine repressor with a C1-lanthanide complex bound to Cys68. The model represents the best fit of the PCSs to the first conformer of the NMR structures (PDB ID 1AOY[24]). The structure of the tag was derived from the crystal coordinates of a DOTA-tetraamide Gd^{3+} complex as described in the main text. The lanthanide ion is represented by a magenta sphere. The disulfide bond of the linker is highlighted in yellow. The N- and C-termini are labeled. The side chain of Cys68 and the tag are shown in a heavy atom representation.

$\Delta\chi$ tensor fits easily generate large uncertainty ranges for metal tags on protein surfaces, as the metal position must be determined along with five other tensor parameters (Euler angles and axial and rhombic components). For example, an unrealistically large distance of the metal from the protein can often be quite readily compensated for by a correspondingly larger tensor. To avoid such artifacts, we used a fitting procedure that explicitly restricts metal coordinates to positions that are compatible with the covalent structure of the tag and its steric requirements. Unless the tag is completely immobilized, however, the particular tag conformation producing the best fit must not be taken too literally, as the fitting does not consider the different rotamers of the linker moiety that may lead to the average metal position found.

The C1 tag carries the same ethylene thio linker as the previously published cyclen tags DOTA-M8[20] and CLaNP-5.1.[8] In the case of the DOTA-M8 tag, 15−20% of the tag was observed to assume a second conformation at 25 °C, which was tentatively attributed to cis−trans isomerization of the amide bond of the tether. This percentage rose to 50% at 50 °C.[20] In contrast, no second conformational species was reported for the CLaNP-5.1 tag[8] and we found no evidence for slow conformational exchange in the C1 tag either, not even at 45 °C (Supporting Information Figures S1 and S3). The C1 tag is thus suitable for measurements at elevated temperatures.

For the CLaNP-5.1 tag, data have been reported only for a single metal ion (Yb^{3+}) and protein site,[8] making comparisons difficult. We would expect the C1 tag to be less prone to PCS averaging because of its greater bulkiness. Compared to the even bulkier lanthanide binding peptides,[18,19] the C1 tag, like most DOTA-type tags, binds lanthanide ions much more tightly, is more resistant to unfolding under nonphysiological conditions, and is easier to use, as it is synthesized with an activated disulfide bond. The high lanthanide affinity of DOTA-type tags (dissociation constants of 100 pM have been reported for lanthanide complexes of cyclen with *N*-acetamide pendants, DOTAM[33]) is a decisive advantage for experiments with metalloproteins, where a kinetically less inert metal binding tag could lead to equilibration between the metals of the protein and the tag, for studies of compounds that display high natural affinities for lanthanides, such as DNA and RNA, and for EPR experiments with Gd^{3+} that depend on the absence of unbound Gd^{3+} ions.[34]

The parent compound of the C1 tag, DOTAMPh, forms a square antiprismatic complex[23] that completely encases the lanthanide ions except for a single coordination site for a water molecule.[35] The poor accessibility of the lanthanide is an advantage in interaction studies, where more solvent-exposed metal ions could produce misleading results by direct interactions between the metal and the interaction partner. The C1 tag thus carries great promise for lead compound development by fragment-based drug design, where PCSs observed for weakly binding fragments can be used to define their binding site, orientation, and structure.[36,37]

Using different lanthanides in the same protein-tag construct generates $\Delta\chi$ tensors of different magnitude, but the orientations of the principal axes of the tensors usually vary little.[13,30,38] It is a distinct possibility that a tag produced with opposite chirality (using (*R*)-1-phenylethanamine instead of (*S*)-1-phenylethanamine) may generate different tensor orientations relative to the protein. PCS data measured with both enantiomeric tags could thus deliver two independent sets of restraints to position nuclear spins relative to the protein.

In conclusion, the new lanthanide tag presented here displays an attractive combination of properties, including reliable generation of PCSs, conformational homogeneity, and tight lanthanide binding. We anticipate that it will become an important tool

for assessing the structure of biological macromolecules by NMR spectroscopy.

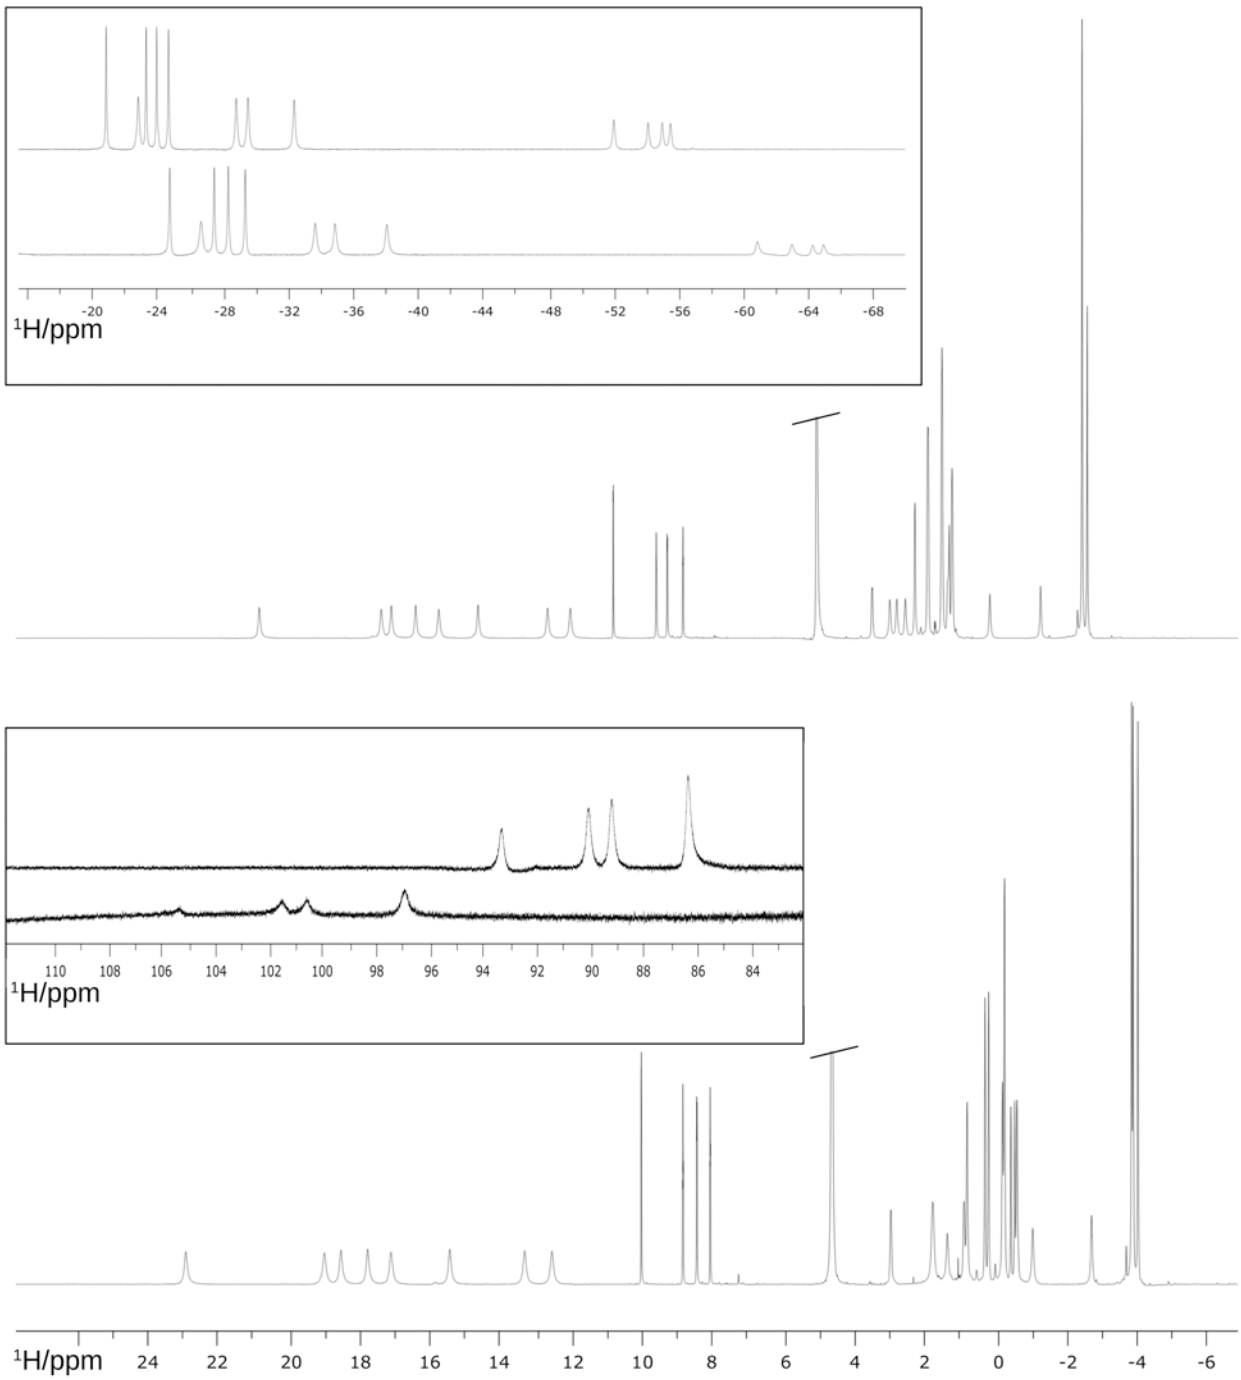

Figure S1. One-dimensional ^{1}H NMR spectra of the C1-Yb^{3+} complex in D_2O at 25 ^{o}C (lower traces) and 45 ^{o}C (upper traces), recorded on a 600 MHz Varian INOVA NMR spectrometer. The panels contain all the NMR signals observed. The signals with the largest paramagnetic shifts (inserts) come in groups of four inequivalent protons as expected for the symmetry of the cyclen ring in a single conformation. The absence of minor peaks attests to the purity of the compound and the absence of minor conformational species. The signals cluster closely at the chemical shifts detected for the parent compound $[Yb(DOTAMPh)]^{3+}$ at 17 ^{o}C (Dickins et al., 2003), namely 101.3, 17.8, 14.5 and -35.3 ppm for the signals of the cyclen ring, and -29.1 and -65.8 ppm for the methylene protons of the amide pendants. The signal intensities at extreme chemical shifts are weaker due to very large offset effects.

Table S1. Chemical shifts of $^{13}C/^{15}N$-labeled ArgN tagged with C1 with different metal ions in 20 mM MES, pH 6.6 at 25 ºC.

(Paramagnetic peaks of the ArgN-C1-Dy^{3+} sample were measured in a ^{15}N-HSQC spectrum.)

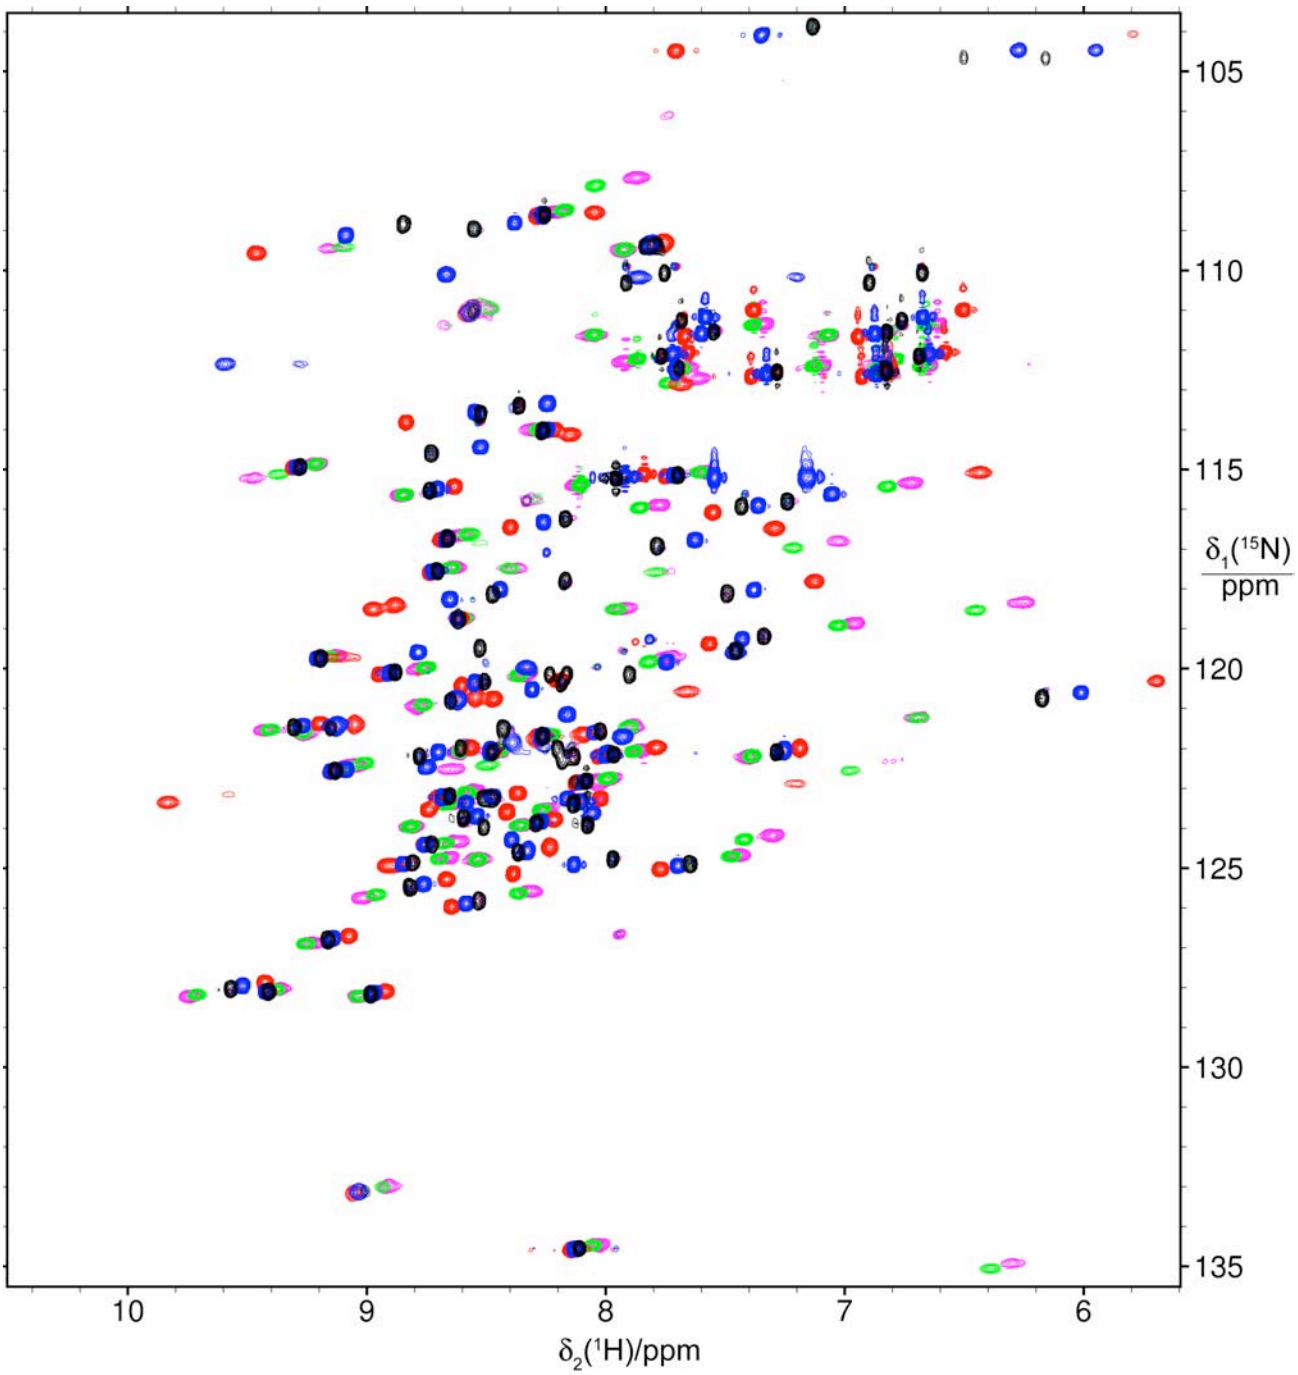

Figure S2. Superimposition of ^{15}N-HSQC spectra of about 70 μM solutions of the uniformly ^{15}N-labeled ubiquitin A28C mutant, ligated at Cys28 with the C1 tag loaded with Y^{3+} (black peaks), Yb^{3+} (blue), Tb^{3+} (green), Tm^{3+} (red), or Dy^{3+} (magenta). Judging by the intensities of the main peaks, the tagging yields varied between 80% and 100%. All spectra were recorded at pH 7.5 and 25 ^{o}C on a Varian INOVA 600 MHz NMR spectrometer.

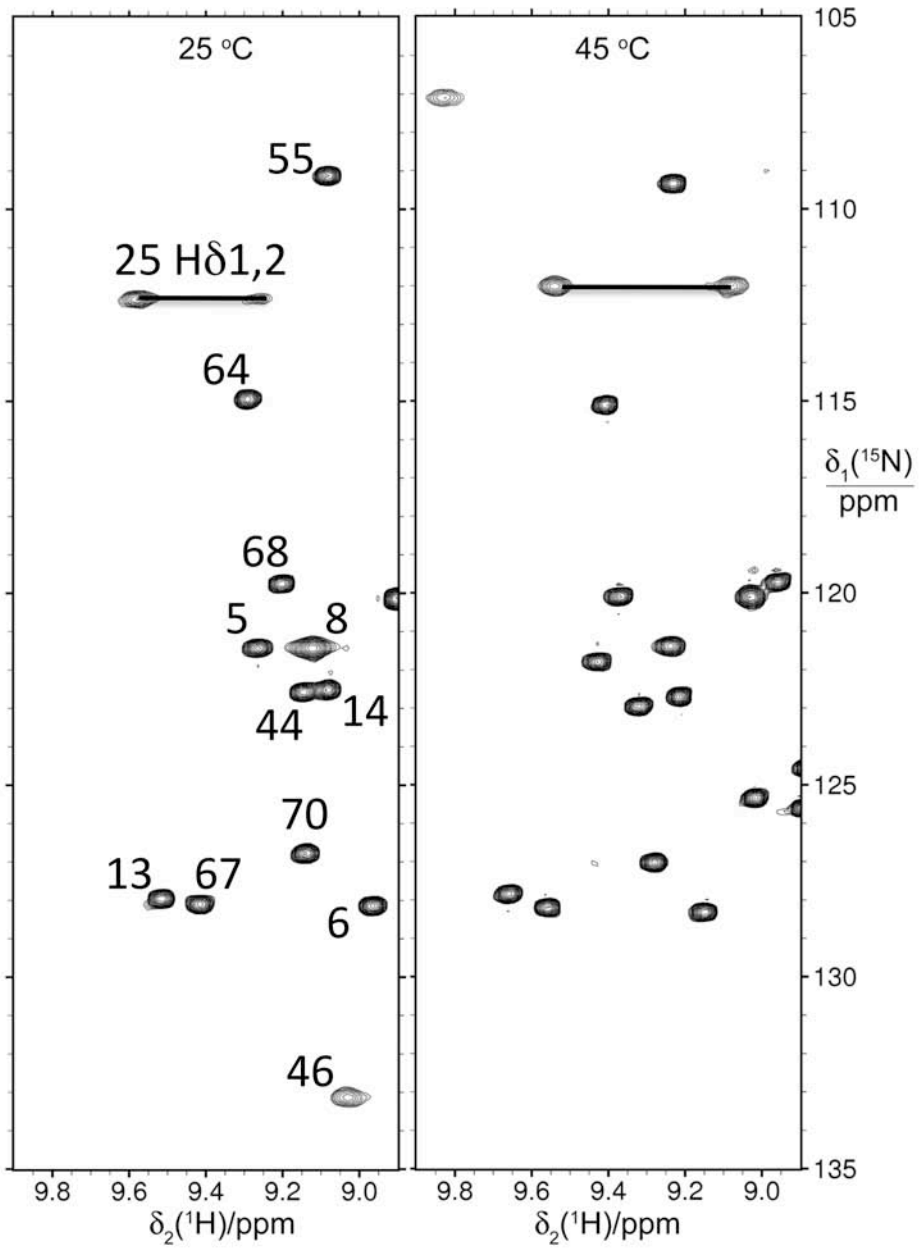

Figure S3. High-field spectral regions from ^{15}N-HSQC spectra of about 70 μM solutions of the uniformly ^{15}N-labeled ubiquitin A28C mutant, ligated at Cys28 with the C1 tag loaded with Yb^{3+} at pH 7.5 and two different temperatures. The signal-to-noise ratio for most peaks is better than 100:1. The lowest contour level was plotted at the height of the top noise peaks. No additional weak cross-peaks appear at either temperature, i.e. there is no evidence for slow conformational exchange phenomena of the C1 tag. The peaks in the left panel are labelled with the sequence number of the backbone amide protons. The side chain resonances of Asn25 are connected by a line.

Table S2. Pseudocontact shifts measured for backbone amide protons of ubiquitin(A28C) tagged with C1 and loaded with different lanthanides.[a]

[a] Data measured of about 70 μM solutions in (50 mM HEPES buffer) at pH 7.5 at 25 °C. The PCSs were determined as the chemical shift observed with paramagnetic lanthanides minus the corresponding chemical shift observed with ubiquitin(A28C)-C1 loaded with Y^{3+}. NA: not assigned; NO: not observed.

Table S3. $\Delta\chi$ tensors of different metal ions bound to the C1 tag on Cys28 of the ubiquitin mutant A28C.[a]

Metal ion	$\Delta\chi_{ax}$ /10^{-32} m^3	$\Delta\chi_{rh}$ /10^{-32} m^3	Q^b	Tensor axis	Coordinates of tensor axes

				z	0.236	0.609	0.757

[a] The tensors are listed in their unique tensor representation (UTR; Schmitz et al. 2008) as obtained by fitting of the PCSs of the structurally ordered residues 2-72 in Table S2 to the first conformer of the NMR structure of ubiquitin (PDB ID 1D3Z; Cornilescu et al. 1998) simultaneously using the PCSs induced by Dy^{3+}, Tb^{3+}, Tm^{3+} and Yb^{3+} and a common metal position. The covalent structure of the tag was taken into account as described in the main text. The orientations of the tensor axes are given as unit vectors with respect to the origin (0, 0, 0). Uncertainty ranges (shown in brackets) display the most extreme values identified among the family of fits obtained by a Monte Carlo error analysis that randomly omitted 20% of the PCSs. The coordinates of the common metal position in the best fit were (61.868, -91.284, -8.631). Relative to this position, the metal was displaced by up to 1.3 Å, when 20% of the PCSs were left off in the Monte Carlo error analysis.

[b] Q-factor calculated as root-mean-square deviation between measured and predicted PCSs divided by the root-mean-square of the measured PCSs. The *Q*-factor of the simultaneous four-metal fit is 0.07.

Figure S4. Model of the C1 tag bound to Cys28 in the ubiquitin mutant A28C. The model represents the best fit of the PCSs to the first conformer of the NMR structure (PDB ID 1D3Z (Cornilescu et al. 1998). The structure of the tag was derived from the mirror image of the crystal coordinates of the Gd^{3+} complex with 2,2',2'',2'''-(1,4,7,10-tetraazacyclododecane-1,4,7,10-tetrayl)*tetrakis*(*N*-((*R*)-1-phenylethyl)acetamide) (DOTAMPh, CSD accession code EQOZUF; Parker2003), as described in the main text. The lanthanide ion is represented by a magenta sphere. The disulfide bond of the linker is highlighted in yellow. The side chain of Cys28 and the tag are shown in a heavy atom representation.

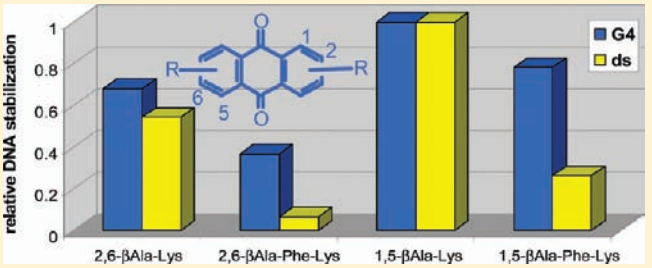
Tuning G-Quadruplex vs Double-Stranded DNA Recognition in Regioisomeric Lysyl-Peptidyl-Anthraquinone Conjugates

Giuseppe Zagotto, Antonio Ricci, Elena Vasquez, Andrea Sandoli, Silvia Benedetti, Manlio Palumbo, and Claudia Sissi*

Department of Pharmaceutical Sciences, University of Padova, Via Marzolo 5, 35131 Padova, Italy

Supporting Information

ABSTRACT: Anthraquinone is a versatile scaffold to provide effective DNA binders. This planar system can be easily conjugated to protonable side chains: the nature of the lateral groups and their positions around the tricyclic moiety largely affect the DNA recognition process in terms of binding affinity and mode, as well as sequence and structure of the target nucleic acid. Starting from an anthracenedione system symmetrically functionalized with N-terminal lysyl residues, we incremented the length of side chains by introducing a Gly, Ala, or Phe spacer, characterized by different flexibility, lipophilicity, and bulkiness. Moreover, 2,6, 2,7, 1,8, and 1,5 regioisomers were examined to yield a small bis(lysyl-peptidyl) anthracenedione library. By merging spectroscopic, enzymatic, and cellular results, we showed that the proper combination of a basic aminoacid (Lys) with a more hydrophobic residue (Phe) can provide selective G-quadruplex recognition, in particular when side chains are located at positions 2,6 or 2,7. In fact, while these derivatives effectively bind G-quadruplex structures, they behave at the same time as rather poor double-stranded DNA intercalators. As a result, the Lys-Phe substituted anthraquinones are poorly cytotoxic but still able to promote a senescence mechanism in cancer cells. This combination of chemical and biological properties foresees potentially valuable applications in anticancer medicinal chemistry.



INTRODUCTION

Telomeres are specialized nucleoprotein structures localized at the end of chromosomes. They protect genomic information from degradation, fusion, and recombination and allow the DNA damage response machinery to discriminate between double-strand breaks and natural chromosome ends.[1] Telomeric DNA comprises several kilobases of tandem repeats of a G-rich DNA sequence (TTAGGG in humans) and are characterized by a single-stranded 3′ end (ca. 150−200 nucleotides). However, its length is progressively reduced in somatic cells due to the "end replication" problem.[2] When telomeres reach a critical length, cells enter a replicative senescence state and division no longer occurs.[3] On the contrary, over 80% of cancer cells maintain telomere integrity due to an up-regulation of a reverse transcriptase called telomerase.[4] This enzyme catalyzes the synthesis of telomeric DNA repeats, stabilizing telomeres length and contributing to cellular immortalization and oncogenesis.[5]

Due to its involvement in cell immortalization, telomerase represents a promising anticancer target.[6] Various strategies have been devised to directly target the enzyme or associated proteins. An alternative approach comprises derivatives directed toward the 3′ single-stranded end of telomeric DNA.[7] In this case, small molecules are used to induce nucleic acid folding into a noncanonical structure called the G-quadruplex, which is inaccessible to the RNA template component of telomerase.[8]

In the past decades, a large number of small molecules have been reported to efficiently bind G-quadruplex DNA and to inhibit telomerase.[9−11] Most of them are based on a polycyclic aromatic core that stacks by $\pi-\pi$ interactions over the terminal planar G-tetrads of a quadruplex. In addition, cationic side chains can interact with the negatively charged phosphate backbones in G-quadruplexes.

Properly substituted anthraquinones were early identified as potential effective G-quadruplex binders.[12−14] In particular, the substitution pattern with protonable side chains was shown to play a major role in driving selectivity toward double-stranded or G-quadruplex structures. In previous studies, we reported the modulation of G-quadruplex recognition by anthracenedione derivatives symmetrically disubstituted at 2,6 or 2,7 positions with one or two aminoacidic residues.[15,16] We showed the importance of the size of the planar surface, which was affected by reversal of the direction of the amide linkage connecting the anthracenedione to the side chains. Additionally, a significant role of ionic interactions was confirmed, since N-terminal protonable

aminoacids (Lys, Arg) largely incremented G-quadruplex binding. Clearly, charged interactions simultaneously promote binding to double-stranded DNA too. However, taking into account the different geometries of the two DNA structures, it should be possible to optimize the relative position of the charged groups with reference to the aromatic core to preferentially drive the ligand toward one DNA fold.

Here, we synthesized and analyzed a small library of disubstituted peptidyl anthraquinones characterized by a lysyl N-terminal residue. We modulated its distance from the planar moiety by introducing mono- and dipeptidyl spacers, characterized by increasing steric hindrance and hydrophobicity (Gly, Ala, Phe). Additionally, the relative position of the two protonable groups was varied by considering the 2,6, 2,7, 1,8, and 1,5 regioisomers. These structural features should allow identifying the peptidyl anthraquinone requirements that grant selectivity for G-quadruplex vs duplex DNA by establishing distinct patterns of hydrogen bonding, hydrophobic, and charge interactions. In particular, preferential binding to G-quadruplex folded telomeric DNA would likely produce telomerase inhibition and cancer cell death without greatly affecting somatic cells.

EXPERIMENTAL PROCEDURES

Synthesis. All water- or air-sensitive reactions were carried out in oven-dried glassware under a nitrogen atmosphere with dry solvents, unless otherwise noted. All commercial reagents were purchased from Sigma-Aldrich and were used without further purification. The solvents were purchased from Fluka, WMC, and Carlo Erba; they were anhydrified as follows: *N*,*N*-Dimethylformamide (DMF) was distilled under reduced pressure over BaO; diisopropylethylamine (DIPEA) and piperidine were distilled over CaH_2. ^1H NMR spectra were recorded on a Bruker Avance AMX 300 spectrometer. Chemical shifts (δ) are expressed in parts per million relative to tetramethylsilane (ppm), and the following abbreviations were used for the multiplicities: s = singlet, d = doublet, dd = doublet doublets, t = triplet, dt = doublet triplets, tt = triplet triplets, q = quartet, m = multiplet, bm = broad multiplet, and bs = broad singlet. Mass spectrometric data were obtained using a Mariner API-TOF (Perseptive Biosystems Inc., Framingham, MA 01701, USA). Purities ($\geq$95%) of all tested compounds were established by HPLC using a Varian Pro Star equipped with an UV−vis detector (BioRad) and a Phenomenex C18 (4.6 × 250 mm, 5 μm) column. The mobile phase results from combination of (A) H_2O/TFA (99:1) and (B) MeOH/TFA (99:1). A gradient from 5% to 60% of solution B over 20 min followed by 5 min at the latter percentage was used; the flow rate was set at 1.0 mL/min. The signals were detected with a UV−vis detector at 254 nm. Within the experimental part, AQ stands for anthraquinone; in particular, AA-AQ stands for amino acid substituted anthraquinone.

General Procedure for the Synthesis of the Acyl Chloride Derivative of an Amino Acid. $SOCl_2$ (1 mol) was added to a solution of the desired Fmoc-amino acid (100 mmol) in 50 mL of DCM and heated at reflux under N_2 atmosphere for 4 h. The solvent was then removed by distillation and the crude white solid dried under high vacuum.

General Procedure for Peptide Coupling via Acyl Chloride. The acyl chloride derivative of the desired Fmoc-amino acid (100 mmol) was added to a solution of the required diaminoanthraquinone (25 mmol) in 15 mL of DMF. The solution thus obtained was stirred at RT under N_2 atmosphere for 3 h before pouring it into cold Et_2O (250 mL). The resulting precipitate was collected by centrifugation, washed with HCl 0.1 M (3 × 50 mL), isopropanol (20 mL), and Et_2O (50 mL), and dried under vacuum.

General Deprotection Procedure of the Fmoc Group. A solution of the desired AA-AQ derivative (10 mmol) in piperidine/DMF 10% (1 mL) was stirred at RT for 20 min and then poured into cold Et_2O (20 mL). The resulting precipitate was collected by centrifugation, washed with Et_2O (3 × 20 mL), MeOH (1 × 20 mL), and Et_2O (2 × 30 mL), and finally dried under vacuum.

General Procedure for Peptide Coupling via TBTU, HOBt, and DIPEA. A solution of the desired Fmoc-amino acid (40 mmol) in anhydrous DMF (5 mL) was introduced in a round-bottomed flask containing TBTU (42 mmol), HOBt (42 mmol), and DIPEA (128 mmol); the resulting solution was stirred for 15 min at RT under N_2 atmosphere. A solution of the desired AA-AQ (10 mmol) in anhydrous DMF (5 mL) was added and the mixture stirred at RT for 4 h under N_2 atmosphere. The mixture was poured in Et_2O (50 mL), and the resulting precipitate was collected by centrifugation, washed with Et_2O (3 × 50 mL), MeOH (2 × 10 mL), and Et_2O (50 mL), and finally dried under vacuum.

General Deprotection Procedure of the Boc Group. A solution of the desired Boc-AA-AQ (10 mmol) in TFA/H_2O 95% (5 mL) was stirred at RT for 20 min and then poured into Et_2O (30 mL). The resulting precipitate was collected by centrifugation, washed with Et_2O (3 × 30 mL), and dried under vacuum.

Synthetic Oligonucleotides. The labeled human telomeric sequence l-Tel23 5′-Dabcyl-AGGGTTAGGGTTAGGGTTAGGGT-FAM 3′ was synthesized and purified by ATDBIO (Southampton, UK). All other oligonucleotides were provided by Eurogentec (Belgium) (Tel22, AGGGTTAGGGTTAGGGTTAGGG; dsUP, 5′-FAM- GTGAGATACCGACAGAAG; dsDOWN CTTCTGTCGGTATCTCAC-Dabcyl 3′; 1GGG, TACAGATAGTTAGGGTTAGACTTA; 2GGG, TACAGATAGTTAGGGTTAGGGTTA; TS AATCCGTCGAGCAGAGTT; ACX: GTGCCCTTACCCTTACCCTTACCCTAA; TSNT: AATCCGTCGAGCAGAGTTAAAAGGCCGAGAAGCGAT; NT: ATCGCTTCTCGGCCTTTT; Tup:TGAGGATCCGCCTGGACAGCATGG-3′; Tdown: GTCGAATTCTCGGCGAGAAGCAGG).

Calf thymus DNA (ctDNA) was purchased from Sigma Aldrich (USA) and used with no further purification.

Fluorescence Melting Assay. Fluorescence melting curves were determined in a Roche LightCycler (λ_{ecc} 488 nm, λ_{em} 520 nm) in a total reaction volume of 20 μL containing 0.25 μM of l-Tel23 and increasing ligands concentrations in LiP buffer (10 mM LiOH, 50 mM KCl, pH 7.4 with H_3PO_4). In a typical experiment, the oligonucleotide was first denatured by heating to 95° at a rate of 0.1 °C s^{-1}, maintained at 95 °C for 5 min, and then annealed by cooling to 30 °C at a rate of 0.1 °C s^{-1}. Then, samples were maintained at 30° for 5 min before being slowly heated to 95 °C (1 °C/min) and annealed at a rate of 1 °C/min. When double-stranded DNA was used, dsUP and dsDOWN were mixed at equimolar concentrations, heated to 95 °C for 5 min, and then cooled to room temperature overnight before use. Recordings were taken during both the annealing and melting steps.

T_m values were determined from the first derivatives of the melting profiles using the Roche *LightCycler* software. Each curve

was repeated at least three times and errors were ±0.4 °C. ΔT_m were calculated by subtracting the T_m value recorded in the presence of the ligand from the corresponding value in the absence of ligand.

Circular Dichroism Measurements. Circular dichroism spectra from 220 to 450 nm were recorded using 10 mm path length cells on a Jasco J 810 spectropolarimeter equipped with a NESLAB temperature controller and interfaced to a PC 100 in 10 mM Tris-HCl, 50 mM KCl pH 7.4. Before data acquisition, Tel22 solutions (4 μM) were heated at 95 °C for 5 min and left to cool overnight at room temperature. The reported spectrum of each sample represents the average of 3 scans recorded with 1 nm step resolution. Observed ellipticities were converted to mean residue ellipticity $[\theta] = \text{deg} \times \text{cm}^2 \times \text{d mol}^{-1}$ (Mol. Ellip.).

Electromobility Shift Assay. End-labeled single-stranded oligonucleotides were obtained by incubating the oligonucleotides with T4 polynucleotide Kinase and [γ-^{32}P] ATP for 30 min at 37 °C. The enzyme was then removed by extraction with phenol/chloroform/isoamylic alcohol (25:24:1). A mixture of purified labeled and unlabeled oligonucleotides (total final concentration 10 μM) was heated to 95 °C for 5 min in 10 mM Tris, 1 mM EDTA, 100 mM KCl, pH 8.0 buffer and allowed to cool overnight at room temperature. The folding of the starting material was monitored by native 16% polyacrylamide gel electrophoresis in 0.5× TBE (44.5 mM Tris base, 44.5 mM boric

acid and 1 mM Na_2EDTA) added of KCl (100 mM in buffer and 20 mM in gels).

Resolved bands on dried gels were visualized and quantified on a PhosphorImager (Amersham).

***Taq* Polymerase Assay.** Compounds were assayed with *Taq* polymerase reaction by using pBR322 (2.5 ng) as DNA template and appropriate primer sequences (T_{up} and T_{down}, 0.5 μM each) to amplify the 964−1064 plasmid sequence by PCR. The reaction was carried out in a Perkin-Elmer thermocycler performing 25 cycles of 30 s at 94 °C, 30 s at 65 °C, and 30 s at 72 °C. The reaction products were resolved on a 2% agarose gel in 1× TBE (89 mM Tris base, 89 mM boric acid, and 2 mM Na_2EDTA) and stained by ethidium bromide.

Telomerase Activity Assay (TRAP Assay). Telomerase activity was assayed using a modified telomere repeat amplification protocol (TRAP) assay. As a source of telomerase, the total cell lysates derived from human melanoma cell line HeLa were used. Protein concentration of the lysates was assayed using Bio-Rad protein assay kit using BSA as standard. A 50 μL TRAP reaction mix (50 μM of dNTPs, 0.2 μg of primer TS, 0.1 μg of return primer ACX, 500 ng of protein extract, 2 U *Taq* polymerase) was prepared in the presence/absence of increasing drug concentration in 20 mM Tris-HCl, pH 8.3, 68 mM KCl, 1.5 mM $MgCl_2$, 1 mM EGTA, 0.05% v/v Tween-20. An internal control template (0.01 mmol TSNT) with its return primer (1 ng NT) were added to the reaction mixture. Then, the telomerase elongation step has been performed (30 min at 30 °C) followed by a PCR amplification step (30 cycles of 30 s at 37 °C and 30 s at 58 °C). Telomerase products were resolved by 10% polyacrylamide gel electrophoresis in TBE 0.5× and visualized by staining with Sybr Green I.

MTT Assays. HeLa (human hepitelial) cell line was maintained in DMEM medium supplemented with 10% heat-inactivated fetal calf serum, 50 U/mL of penicillin G, and 50 μg/mL of streptomycin, at 37 °C in humidified atmosphere and 5% of CO_2.

To evaluate toxic profiles of the potential antitelomerase compounds, MTT assays were performed as described: cells were plated in 96 well plates at 10 000 cells/well, and cultured overnight. Afterward, compounds were added in triplicate and plates were incubated in the presence of the drug for 72 h. At the end of this period, MTT was added to a final concentration of 0.8 mg/mL, and two additional hours of incubation were performed. After that, medium was aspirated carefully and 150 μL of DMSO were added per well. Soluble formazan salts were homogenized by manual pipetting and absorbance at 540 nm was read. Curves consisted of 8 serial dilutions in triplicate in each case, and results were analyzed as sigmoidal dose−response curves.

Cell Senescence Assay. HeLa cells were plated in 6-well plates at 10 000 cells/well and cultured overnight. Afterward, compounds were added in triplicate (2.5 μM and 0.5 μM for C-16 and D-16, respectively) and plates were incubated in the presence of the drug for 240 h. Every 72 h, the medium was changed and new drug was added. At the end of the treatment, medium was removed and cells were washed once with 1 mL of PBS and fixed with 1 mL of 2% formaldehyde, 0.2% glutaraldehyde in PBS for 15 min at room temperature. After another washing step with PBS, cells were stained with 1 mL of 37.2 mM citric acid/sodium phosphate (pH 6.0), 140 mM NaCl, 1.8 mM $MgCl_2$, 5 mM $K_3Fe(CN)_6$, 5 mM $K_4Fe(CN)_6$ $3H_2O$, and 1 mg/mL X-gal in dimethylformamide. Plates were incubated overnight at 37 °C and then photographed with a light microscope.

RESULTS

Chemistry. Starting materials for the synthesis of all derivatives were the appropriate diamino-substituted anthraquinones (AQ). While 2,6-diamino and 1,5-diamino AQ are commercially available, the 2,7-diamino and 1,8-diamino AQ were obtained via reduction of the corresponding dinitro derivatives.[17] In particular, the 2,7-dinitro AQ scaffold was obtained through a one-pot nitration−oxidation of commercial anthrone, as previously described.[16] The common synthetic route for all the disubstituted AQs is summarized in Scheme 1. Due to the low reactivity of the aryl amino groups, the first aminoacidic coupling (AA1) was efficiently carried out using the appropriate acyl chloride derivative (AA-Cl). These substrates were prepared treating the selected AA (Fmoc-glycine or Fmoc-β-alanine) with an excess of thionyl chloride in CH_2Cl_2 (Scheme 2). A first Fmoc deprotection of the amino groups, followed by salification with trifluoroacetic acid (TFA) led to the first group of compounds (**A-2**, **B-2**, **C-2**, **D-2**, and **E-2**). The salification step was performed to favor the solubility of the anthraquinone derivatives in water.

These compounds were used as starting blocks to synthesize several derivatives which can be divided into 5 related families: **A** and **B** where a glycine or a β-alanine was the AA_1 at positions 2 and 6, respectively; **C**, **D**, and **E** which correspond to the 2,7, 1,5, and 1,8 regioisomers of compound **B**.

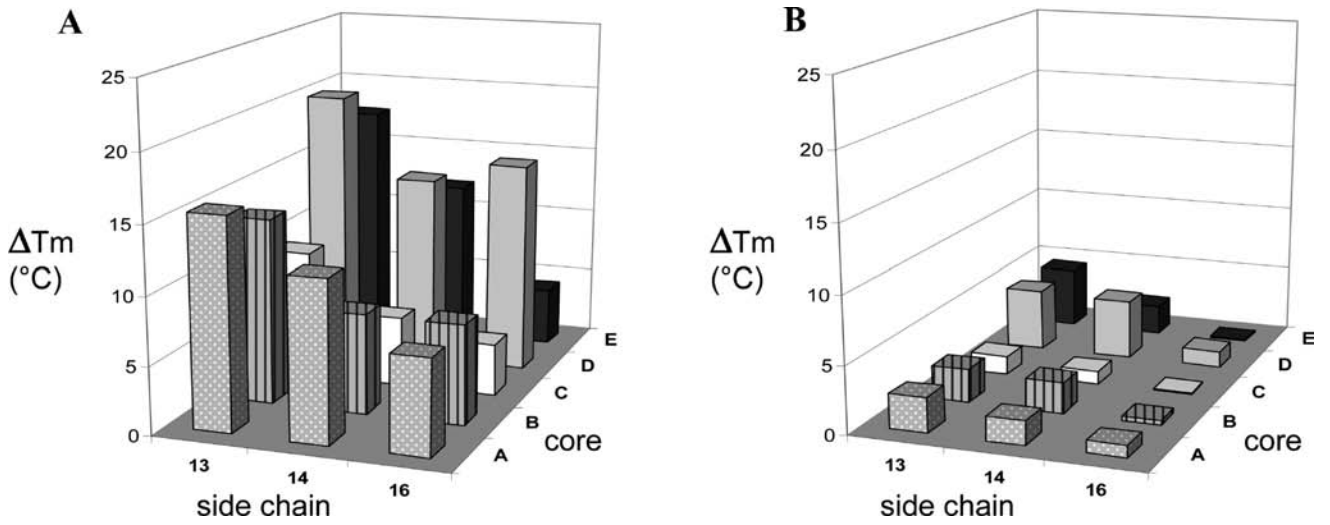

Figure 1. Variation of the melting temperature (ΔT_m) of a G-quadruplex folded telomeric sequence (A, 0.25 μM) or double-stranded DNA (B, 0.25 μM) upon addition of 1 μM selected anthraquinones in 50 mM KCl. Errors were ±0.4 °C.

The novel derivatives were prepared by standard peptide coupling of the free amino AA_1-AQ and the desired Fmoc- or Boc-protected AA_2 derivatives using TBTU, HOBt, and DIPEA as coupling reagents (Scheme 2). In the first case, basic deprotection led to the free amino derivatives, which were coupled with a third amino acid or salified with TFA to afford more water-soluble derivatives. In the case of the Boc-protected compounds, the acidic condition used to remove the Boc protective group directly led the desired trifluoroacetic salts derivatives. The side chains composition of the synthesized anthraquinones is reported in Table 1.

Fluorescence Melting Assays. All test derivatives were evaluated for their ability to bind and stabilize G-quadruplex structures by fluorescence melting measurements.

We used an oligonucleotide corresponding to the human telomeric sequence labeled at the 5′-end with a quencher (dabcyl) and at the 3′-end with a fluorophore (fluorescein). When the oligonucleotide folds into an intramolecular G-quadruplex, these groups are in close proximity, and as a consequence, the fluorescence is quenched. When DNA melts, the strands fall far apart and a large increase in fluorescence occurs. This system allows us to easily monitor DNA folding/unfolding processes upon temperature variation.[18,19] Drug binding to DNA affects nucleic acid stability, hence its melting temperature (T_m). Since a correlation exists between the observed T_m shift (ΔT_m) and the DNA binding affinity of structurally related binders, this allows us to build a relative G-quadruplex affinity ranking order.[20] Thus, the melting profile of the oligonucleotide (T_m in the absence of ligand 57.2 °C) was recorded in the presence of increasing anthracenedione concentration (0−20 μM, Supporting Information). The ΔT_m values determined for all derivatives at 1 μM concentration are included in Table 3. The behavior of the test ligands toward telomeric G-quadruplex is generally conserved among the 5 tested families (Figure 1A). In particular, it emerged that the introduction of an amino acid between AA_1 and the charged residue sensibly reduces the G-quadruplex stabilizing efficiency. This effect is more significant when shifting from Gly or Ala to become maximal with Phe. This suggests that the flexibility and bulkiness of the linker is relevant for G-quadruplex interaction, likely favoring the proper localization of the positive charge on the polyanionic target.

Fluorescence melting analysis was used also to evaluate the preference of the new derivatives for G-quadruplex structure vs duplex DNA arrangement by using a random double-stranded sequence (5′-GTGAGATACCGACAGAAG, T_m 52.8 °C). The ΔT_m value determined for all derivatives at 1 μM concentration are included in Table 3 and plotted in Figure 1B. All tested compounds stabilize double-stranded DNA to a considerably lesser extent than G-quadruplex. Interestingly, dsDNA recognition is more prominent for derivatives of the **D** and **E** families that bear substituents at positions 1,5 or 1,8. Comparison of melting data on different DNA folding underlines that for derivatives containing the Phe-Lys dipeptide (compounds with side chain -**16**) relevant thermal stabilization occurs only with the G-quadruplex structure, which suggests remarkable selectivity in the drug−DNA recognition process.

For a direct comparison of the ligand-mediated DNA stabilization on the two tested folds, melting profiles of the telomeric sequence were recorded in the presence of variable amounts of its complementary strand (Figure 2).[21] The results confirmed that the Phe-Lys containing analogues are the most selective for G-quadruplex structures. Indeed, they are the only derivatives able to increment the melting temperature of the quadruplex form when the double-stranded arrangement is highly favored (presence of an excess of complementary C-rich strand).

Circular Dichroism. The peculiar signature of the CD spectrum of the G-quadruplex folded telomeric sequence Tel22 is well-characterized. In potassium-containing buffer, it shows a positive band at 295 nm with a shoulder at 260 nm, which corresponds to a mixed type (antiparallel and parallel) strand arrangement.[22] Tel22 dichroic response was extensively modified in the presence of increasing concentrations of our ligands, thus confirming that they are effective binders (Figure 3). In particular, CD titrations confirmed a strong binding affinity for all tested compounds to G-quadruplex: saturation occurred at comparable drug/DNA ratio and indicated the binding of two anthraquinones per G-quadruplex unit (Figure 3C). In analogy to most of the known G-quadruplex interacting agents, this supports the stacking of one ligand on both terminal tetrads of the G-quadruplex.

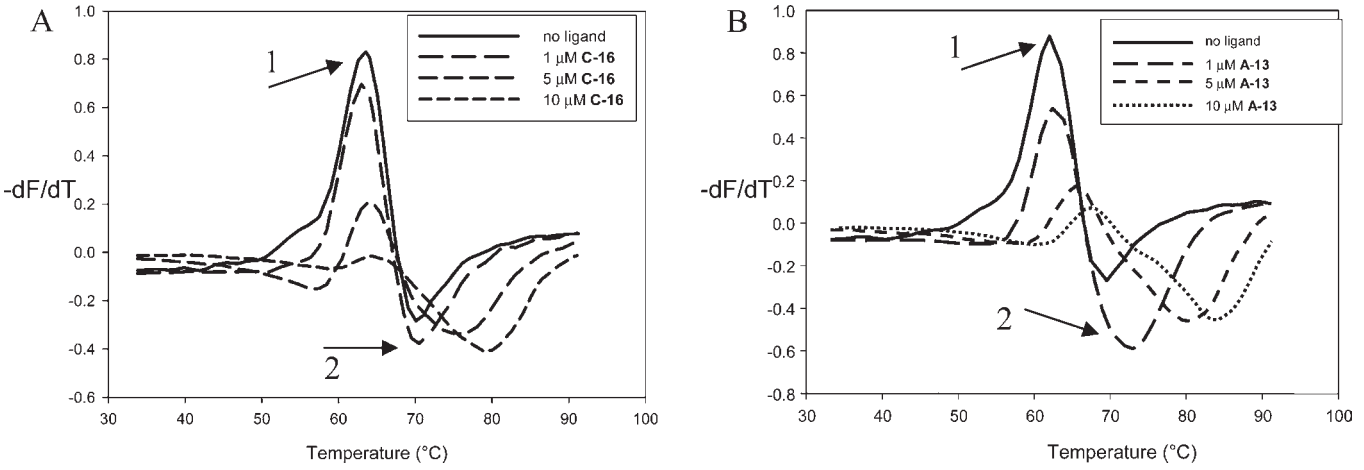

Figure 2. First derivatives of the melting profiles of a G-quadruplex folded telomeric sequence (0.25 μM) recorded in the presence of an excess (20-fold) of its complementary strand in 50 mM KCl. Arrows 1 and 2 indicate the shifts of the duplex and quadruplex melting transitions, respectively. Panels A and B refer to addition of **C-16** and **A-13**, respectively.

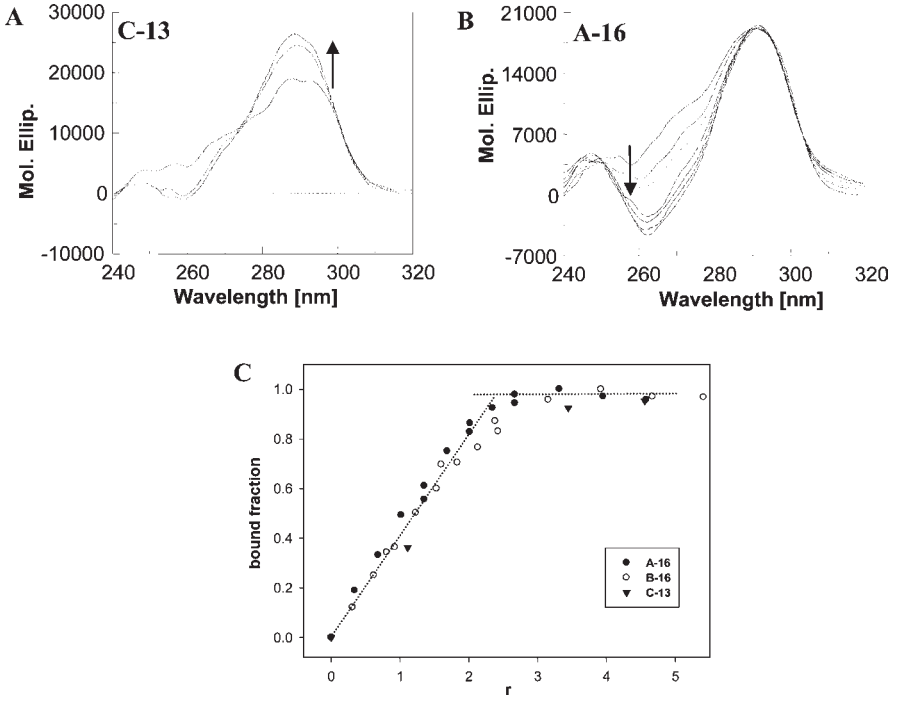

Figure 3. Circular dichroism spectra of Tel22 (4 μM) recorded in the presence/absence of anthraquinone derivatives in 10 mM Tris, 50 mM KCl, pH 7.4, 25 °C. Arrows indicate the changes induced by increasing concentrations of **C-13** (A) and **A-16** (B). The variation of the fraction of bound Tel22 upon increasing ligand/DNA ratio (r) determined by CD titrations is described in panel C.

Generally, an increment in the positive band at 295 nm is observed suggesting a stabilization of the antiparallel components of the G-quadruplex nucleic acid structure. Interestingly, the Phe-Lys substituted derivatives (compounds with side chain −**16**) induced the most notable variations at 260 nm. Since the tested derivatives showed comparable absorption spectra and, additionally, no significant induced CD in the drug absorption range, we are confident in assigning the observed differences primarily to slightly different binding modes.

When similar measurements were performed using a double-stranded DNA (we used calf thymus DNA, ctDNA, due to its similarity to the human nucleic acid composition) as the target, we still found odd behaviors for derivatives containing the Phe-Lys sequence (Figure 4B). In general (see, for example, the series -**13**, Figure 4A), an increment of the DNA dichroic intensity at 275 nm occurred which sustains intercalation into the double helix. On the contrary, all Phe-Lys containing derivatives showed a reduction in the DNA band intensities at both 275 and 245 nm (Figure 4B). Although this confirms a DNA−ligand interaction, it suggests that intercalation is probably not the principal binding mechanism. Generally, DNA intercalation of anthraquinone derivatives disubstituted at positions 1,5, 2,6, and 2,7 occurs by a threading mechanism with the planar system being oriented more or less perpendicularly to the base pair longest dimension

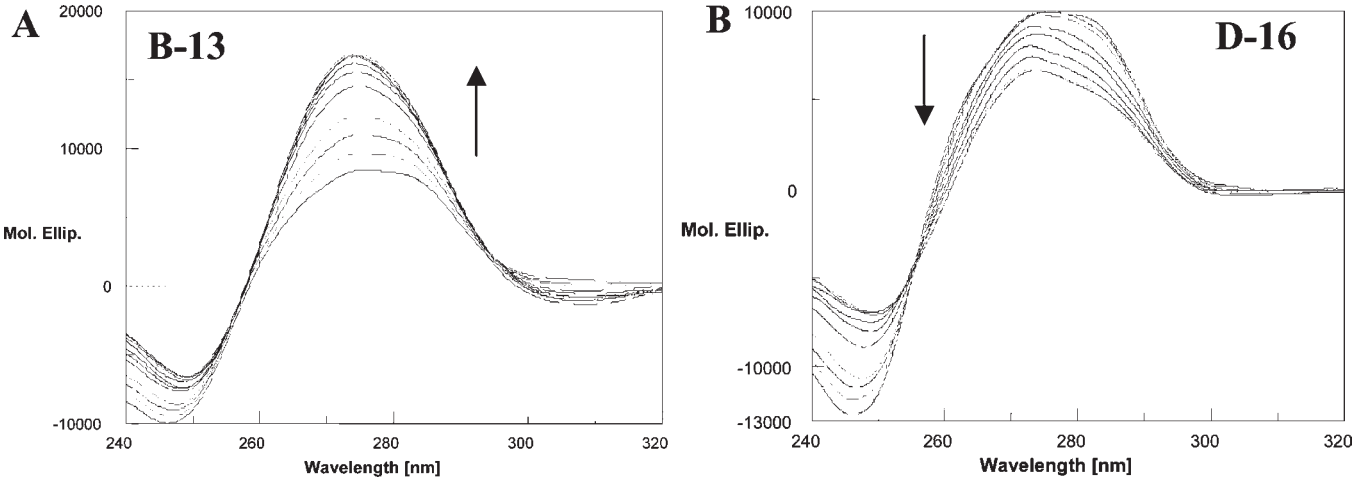

Figure 4. Circular dichroism spectra of ctDNA (88 μM) recorded in the presence of increasing concentrations of anthraquinone derivatives in 10 mM Tris, 50 mM KCl, pH 7.4, 25 °C.

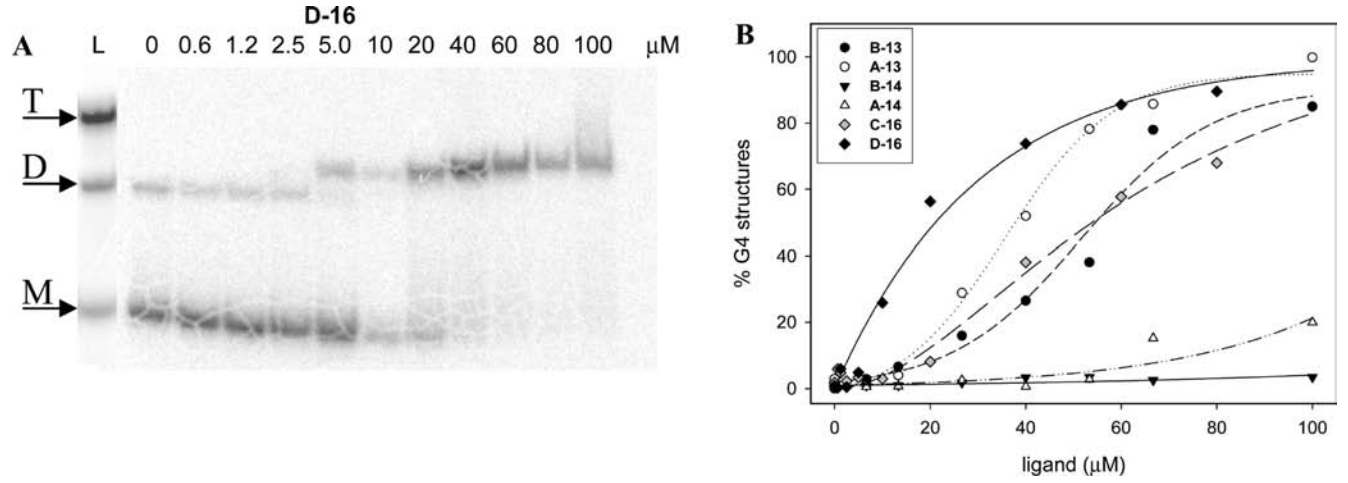

Figure 5. Induction of G-quadruplex structure by selected ligands in 10 mM Tris, 50 mM KCl, pH 7.4, 25 °C. Panel A: variation of the electrophoretic mobility of the unfolded oligonucleotide 2GGG (10 μM) upon addition of **D-16** due to its conversion into a dimeric G-quadruplex. A marker (L) for the monomeric (M), dimeric (D), or tetrameric (T) form is included. Panel B: plot of % of G-quadruplex forms promoted by increasing ligands concentrations.

and one side chain located in each DNA groove.[23] We can infer that the presence of the bulky Phe residue prevents threading of the side chains between the base pairs. As a result, an external binding mode promoted by the presence of highly charged residues in the side chains can be favored. This is particularly true for **B-16**, since it converts dsDNA into an insoluble compact form also at low ligand/DNA ratio.

Electromobility Shift Assay. Electromobility shift assays were performed to evaluate the ability of tested molecules to induce G-quadruplex folding of the human telomeric sequence (Figure 5).

In these experiments, we used an oligonucleotide which contains two repeats of the human telomeric sequence TTAGGG (2GGG). This sequence can form intermolecular (dimeric or tetrameric) G-quadruplex structures that migrate more slowly than the nonstructured single-stranded DNA (Figure 5A). None of our tested derivatives promoted the formation of tetrameric G-quadruplexes. However, some of them were able to promote induction of a dimeric G-quadruplex arrangement of the 2GGG sequence depending upon side chain composition.

Negligible conversion of oligomer 2GGG to an intermolecular G-quadruplex structure was observed when an amino acid is interposed between the AA_1 and the N-terminal Lys residue (compare compounds -**13** with homologues -**14**; Figure 5B). Interestingly, the presence of a Phe (compounds with side chain -**16**) that was observed to comparably reduce the thermal stability of the DNA—ligand complex, allows retention of effective G-quadruplex induction, the most successful being derivative **D-16** with side chains located at positions 1,5. These data further support a peculiar behavior associated to the presence of a Phe residue in the side chains.

Enzymatic Inhibition and Cell Toxicity Assays. To assess possible interference of test drugs with enzymatic processes involving DNA, we examined the effects of peptidyl anthraquinones upon DNA amplification and elongation mediated by *Taq* polymerase and telomerase, respectively. In addition, we determined the cytotoxic activity of our compounds by MTT assay on HeLa human cancer cells. The results are summarized in Table 2.

E-16	4.3	0.1

[a] DNA concentration was 0.25 μM, experimental error ±0.4°C.

For all active derivatives, inhibition of telomerase-mediated DNA elongation occurred generally at lower concentrations in comparison to DNA amplification. From these data, selective telomerase inhibition by our ligands cannot be firmly established from the present results, since competition between telomerase elongation and *Taq* polymerase amplification can occur.[24] In any event, the observed modulation of telomerase elongation is well-related to G-quadruplex binding thermodynamics as shown by the almost linear dependence of IC_{50} for telomerase inhibition from $\Delta T_m/T_m$, where T_m is the melting temperature in the presence of saturating amounts of the drug (Figure 6).[15] On the contrary, the G-quadruplex affinity data are poorly related to cell cytotoxicity.

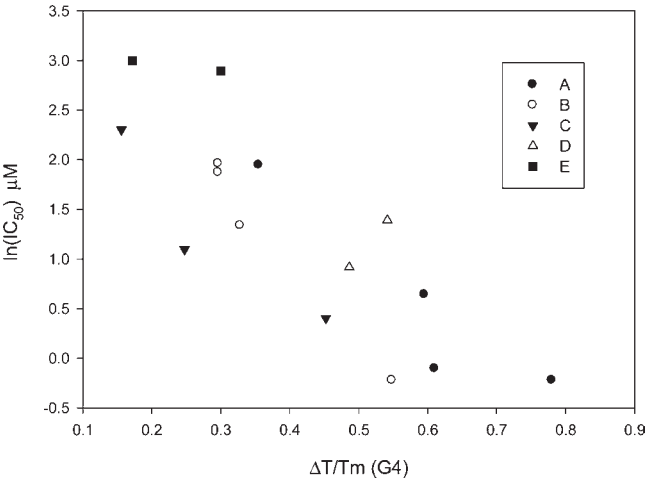

Figure 6. Correlation between Telomerase elongation inhibition (IC50) and thermal stabilization ($\Delta T_m/T_m$) of telomeric G-quadruplex measured for all tested derivatives.

In turn, *Taq* inhibition correlates with double-stranded DNA stabilization and, to a lesser extent, to cell cytotoxicity. In this case, the most active compounds are 1,5 and 1,8 derivatives that, indeed, were confirmed to be the most efficient DNA intercalators. We can infer that a short-term drug exposure causes an interference with processing of the nucleic acid that ultimately is translated into a cytotoxic signal.

Accordingly, poor dsDNA binders like **B-16** and **C-16** are poorly cytotoxic. Interestingly, however, both latter anthraquinones stimulated β-galactosidase activity in HeLa cells treated for 240 h at subcytotoxic concentrations without appreciably affecting cell growth (Figure 7), which is consistent with an induction of delayed senescence. However, when the more cytotoxic 1,5 regioisomer (**D-16**) was used in the same conditions, senescence induction was clearly coupled to a significant drop in cell growth. These results further emphasize the peculiar behavior of the Phe containing derivatives also at a cellular level.

DISCUSSION

The DNA binding properties of 9,10-anthracenedione derivatives have been extensively studied in the past,[25] highlighting that the nature of the side chains as well as their relative position are critical factors to address their DNA binding mode.[12,14] Conceivably, the presence of positively charged groups in the side chains greatly favors the binding process although generally regardless of the sequence/structure they bind to. However, provided that different DNA arrangements locate phosphate groups at different relative distances, in principle, charged interactions could be used for selective recognition if the binders' chains are appropriately positioned with reference to the macromolecule. Here, we showed for all test derivatives that increasing the distance of the lysyl residue from the anthracenedione ring system invariantly decreases G-quadruplex affinity. This is probably due to the fact that the positive charges are, on average, located more

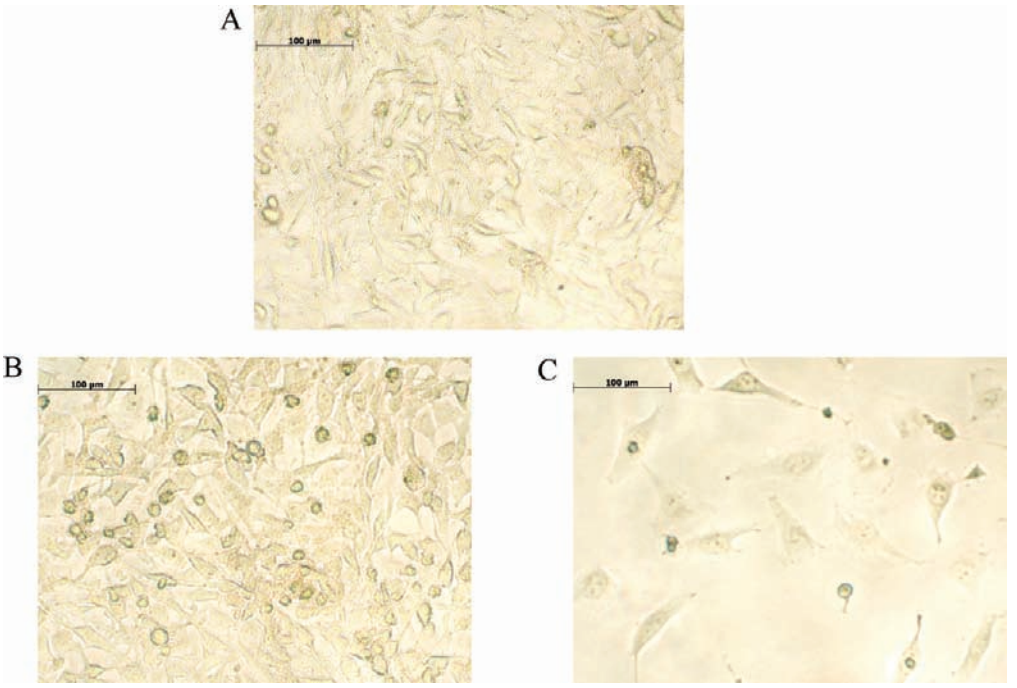

Figure 7. β-Galactosidase activity of HeLa cell when untreated (A) or treated with **C-16** (B) or **D-16** (C) for 144 h.

distant from the anionic sites of DNA. Hence, compounds having longer side chains with clear additional flexibility (possibly rendered less effective by the rigid peptide bonds) cannot get closer to the target counterions than the starting congeners. Apparently, introduction of the bulky Phe residue is even more detrimental than the presence of a glycine or alanine linker. However, Phe-containing derivatives turn out to be selective for G-quadruplex because, unlike other congeners, they hardly bind to double-stranded DNA, yet they are still able to stack on top of the terminal tetrads without requiring significant DNA distortion.

Shifting side chains from position 2,6 or 2,7 (families **A**, **B**, and **C**) to 1,5 (family **D**) or, to a lesser extent, to 1,8 (family **E**) helps increasing G-quadruplex stabilization, but at the same time, it promotes effective binding to dsDNA. Interestingly, this behavior is distinct from the one we reported for anthracene derivatives of the bisanthrene family.[26] In fact, among those anthracene derivatives, the shift of the side chains from 2,6 to 1,5 positions slightly incremented G-quadruplex recognition but remarkably disfavored double-stranded DNA binding. This suggests that the presence of the carbonyl groups causes different orientations of the anthracenedione vs anthracene ring when bound to G-quadruplex DNA.

As far as the biochemical and biological results, we found pronounced cell growth inhibition when the double-stranded DNA recognition process is efficient. On the other hand, the onset of senescence in cancer cells is particularly evident with the more telomerase-sensitive derivatives, which produce selective G-quadruplex stabilization. In conclusion, although we did not succeed in effectively improving G-quadruplex binding, we were able to remarkably uncouple quadruplex vs duplex affinity, which gives useful hints for future design of compounds exhibiting selectivity and efficient tetraplex-inducing properties at the same time.

Experimental Part.

Synthesis and characterization of compounds **A/B/C-1,2,3,4,7,8 A-5,6,13,15** and their precursor were described by us in a previous paper.[1]

Fmoc-glycine-Cl (3)

Obtained from **(1)** according to the general procedure for the synthesis of the acyl chloride of an aminoacid. Yield: 88%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 7.96 (d, 2H, J=7.2 Hz), 7.68 (d, 2H, J=7.2 Hz), 7.72 (t, 1H, J=6.1 Hz) 7.49 (t, 2H, J=7.2 Hz), 7.40 (t, 2H, J=7.2 Hz), 4.37 (d, 2H, J=6.4 Hz), 4.30 (t, 1H, J=6.4 Hz), 3.37 (d, 2H, J=6.1 Hz).

Fmoc-β-alanine-Cl (4)

Obtained from **(2)** according to the general procedure for the synthesis of the acyl chloride of an aminoacid. Yield: 85%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 7.89 (d, 2H, J=7.4 Hz), 7.68 (d, 2H, J=7.2 Hz), 7.41 (t, 2H, J=7.4 Hz), 7.32 (t, 2H; J=7.2 Hz), 4.28 (d, 2H, J=6.1 Hz), 4.2 (t, 1H, J=6.1 Hz), 3.20-3.17 (m, 2H), 2.37 (t, 2H, J=7.0 Hz).

1,5-[Fmoc-β-Alanine-amidyl]-anthracen-9,10-dione (D-1).

Obtained from 1,5-diaminoanthraquinone according to the general procedure for coupling ***via*** acyl chloride. Yield: 84%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.78 (s, 2H), 8.44 (d, 2H, J=2.2 Hz), 8.19 (d, 2H, J=8.6 Hz), 8.04 (dd, 2H, J=2.2 Hz, J=8.6 Hz), 7.88 (dd, 4H, J=0.9, J=7.4 Hz), 7.70 (dd, 4H, J=0.9 Hz, J= 7.4 Hz), 7.56 (t, 2H, J=5.7 Hz), 7.36 (td, 4H, J=0.9 Hz, J= 7.4 Hz), 7.25 (td, 4H, J=0.9 Hz, J=7.4 Hz), 4.82 (d, 4H, J=5.7 Hz), 4.23 (bt, 2H), 3.39 (m, 4H), 2.60 (t, 4H, J=6.6 Hz). **HRMS** (ESI) ***m/z*** for $C_{52}H_{42}N_2O_8$: ($[M+H^+]^+$) calcd 823.3014, found 823.3032; ($[M+2H^+]^{2+}$) calcd 412.1543, found 412.1578.

1,8-[Fmoc-β-Alanine-amidyl]-anthracen-9,10-dione (E-1).

Obtained from 1,8-diaminoanthraquinone according to the general procedure for coupling ***via*** acyl chloride. Yield: 85%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.82 (s, 2H), 8.47 (d, 2H, J=2.3 Hz), 8.16 (d, 2H, J=8.8 Hz), 8.06 (dd, 2H, J=2.3 Hz, J=8.8 Hz), 7.81 (dd, 4H, J=1.0, J=7.4 Hz), 7.68 (dd, 4H, J=1.0 Hz, J= 7.4 Hz), 7.53 (t, 2H, J=5.7 Hz), 7.40 (td, 4H, J=1.0 Hz, J= 7.4 Hz), 7.29 (td, 4H, J=0.9 Hz, J=7.4 Hz), 4.78 (d, 4H, J=5.7 Hz), 4.18 (bt, 2H), 3.32 (m, 4H), 2.62 (t, 4H, J=6.6 Hz). **HRMS** (ESI) ***m/z*** for $C_{52}H_{42}N_2O_8$: ($[M+H^+]^+$) calcd 823.3014, found 823.3033; ($[M+2H^+]^{2+}$) calcd 412.1543, found 412.1569.

1,5-[β-Alanine-amidyl]-anthracen-9,10-dione (D-2)

Obtained from **C-1** according to the general procedure for deprotection of the Fmoc group. Yield: 88%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.80 (s, 2H), 8.49 (d, 2H, J=2.3 Hz), 8.23 (d, 2H, J=8.5 Hz), 7.89 (dd, 2H, J=2.3 Hz, J=8.6 Hz), 6.46 (bs, 4H), 3.36-3.25 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{22}H_{22}N_2O_4$: ($[M+H^+]^+$) calcd 381.1557, found 381.1575; ($[M+2H^+]^{2+}$) calcd 191.0815, found 191.0840.

1,8-[β-Alanine-amidyl]-anthracen-9,10-dione (E-2)

Obtained from **D-1** according to the general procedure for deprotection of the Fmoc group. Yield: 87%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.76 (s, 2H), 8.49 (d, 2H, J=2.3 Hz), 8.23 (d, 2H, J=8.5 Hz), 7.89 (dd, 2H, J=2.3 Hz, J=8.6 Hz), 6.46 (bs, 4H), 3.36-3.25 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{22}H_{22}N_2O_4$: ($[M+H^+]^+$) calcd 381.1557, found 381.1569; ($[M+2H^+]^{2+}$) calcd 191.0815, found 191.0838.

1,5-[Alanine-β-Alanine-amidyl]-anthracen-9,10-dione (D-4)

Obtained from **D-3** according to the general procedure for deprotection of the Fmoc group. Yield: 89%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.69 (s, 2H), 8.45 (d, 2H, J=1.9 Hz), 8.12 (d, 2H, J=8.5 Hz), 8.02 (dd, 2H, J=8.5 Hz, J=1.9 Hz), 4.05-3.93 (m, 2H), 3.46-3.35 (m, 4H), 2.59 (t, 4H, J=6.1 Hz), 1.27 (d, 6H, J=7.4 Hz). **HRMS** (ESI) ***m/z*** for $C_{26}H_{30}N_6O_6$: ($[M+H^+]^+$) calcd 523.2300, found 523.2313; ($[M+2H^+]^{2+}$) calcd 262.1186, found 262.1196.

1,8-[Alanine-β-Alanine-amidyl]-anthracen-9,10-dione (E-4)

Obtained from **E-3** according to the general procedure for deprotection of the Fmoc group. Yield: 91%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.73 (s, 2H), 8.45 (d, 2H, J=1.9 Hz), 8.12 (d, 2H, J=8.5 Hz), 8.02 (dd, 2H, J=8.5 Hz, J=1.9 Hz), 4.05-3.93 (m, 2H), 3.46-3.35 (m, 4H), 2.59 (t, 4H, J=6.1 Hz), 1.27 (d, 6H, J=7.4 Hz). **HRMS** (ESI) ***m/z*** for $C_{26}H_{30}N_6O_6$: ($[M+H^+]^+$) calcd 523.2300, found 523.2317; ($[M+2H^+]^{2+}$) calcd 262.1186, found 262.1199.

2,6-[Glycine-β-Alanine-amidyl]-anthracen-9,10-dione (B-6)

Obtained from **A-5** according to the general procedure for deprotection of the Fmoc group. Yield: 91%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.63 (s, 2H), 8.48 (d, 2H, J=1.7 Hz), 8.11 (d, 2H, J=8.6 Hz), 8.03 (dd, 2H, J=8.6 Hz, J=1.7 Hz), 3.54 (s, 4H, J=6.1 Hz), 3.39 (t, 4H, J=6.4 Hz), 2.62 (t, 4H, J=6.4 Hz). **HRMS** (ESI) ***m/z*** for $C_{24}H_{26}N_6O_6$: ($[M+H^+]^+$) calcd 495.1987, found 495.1992; ($[M+2H^+]^{2+}$) calcd 248.1030, found 248.1031.

1,5-[Phenylalanine-β-Alanine-amidyl]-anthracen-9,10-dione (D-8)

Obtained from **D-7** according to the general procedure for deprotection of the Fmoc group. Yield: 87%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.76 (s, 2H), 8.42 (d, 2H, J=1.9 Hz), 8.10 (d, 2H, J=8.5 Hz), 8.03 (dd, 2H, J=8.5 Hz, J=1.9 Hz), 7.24-7.11 (m, 10H), 4.2 (td, 2H, J=3.4 Hz, J=10.3 Hz), 3.42 (m, 4H), 2.96 (dd, 2H, J=4.2 Hz, J=13.3 Hz), 2.79 (dd, 2H, J=10.3 Hz, J=13.3 Hz). **HRMS** (ESI)

m/z for $C_{38}H_{38}N_6O_6$: ($[M+H^+]^+$) calcd 675.2926, found 675.2942; ($[M+2H^+]^{2+}$) calcd 338.1499, found 338.1509.

1,8-[Phenylalanine-β-Alanine-amidyl]-anthracen-9,10-dione (E-8)

Obtained from **E-7** according to the general procedure for deprotection of the Fmoc group. Yield: 88%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.78 (s, 2H), 8.42 (d, 2H, J=1.9 Hz), 8.10 (d, 2H, J=8.5 Hz), 8.03 (dd, 2H, J=8.5 Hz, J=1.9 Hz), 7.24-7.11 (m, 10H), 4.2 (td, 2H, J=3.4 Hz, J=10.3 Hz), 3.42 (m, 4H), 2.96 (dd, 2H, J=4.2 Hz, J=13.3 Hz), 2.79 (dd, 2H, J=10.3 Hz, J=13.3 Hz). **HRMS** (ESI) ***m/z*** for $C_{38}H_{38}N_6O_6$: ($[M+H^+]^+$) calcd 675.2926, found 675.2945; ($[M+2H^+]^{2+}$) calcd 338.1499, found 338.1512.

1,5-[Fmoc-Alanine-β-Alanine-amidyl]-anthracen-9,10-dione (D-3)

Obtained from **D-2** according to the general procedure for coupling ***via*** TBTU. Yield: 88%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.78 (s, 2H), 8.45 (d, 2H, J=1.9 Hz), 8.10 (d, 2H, J=8.5 Hz), 8.02 (dd, 2H, J=8.5 Hz, J=1.9 Hz), 7.83 (d, 4H, J=7.3 Hz), 7.49 (d, 4H, J=7.3 Hz), 7.39 (t, 4H, J=7.3 Hz), 7.37 (t, 4H, J=7.3 Hz), 4.19 (d, 4H, J=5.4 Hz), 4.14 (t, 2H, J=5.4 Hz), 4.05-3.91 (m, 2H), 3.43-3.31 (m, 4H), 2.59 (t, 4H, J=6.1 Hz), 1.27 (d, 6H, J=7.4 Hz). **HRMS** (ESI) ***m/z***: for $C_{55}H_{48}N_6O_{10}$: ($[M+H^+]^+$) calcd 953.3505, found 953.3531.

1,8-[Fmoc-Alanine-β-Alanine-amidyl]-anthracen-9,10-dione (E-3)

Obtained from **E-2** according to the general procedure for coupling ***via*** TBTU. Yield: 86%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.76 (s, 2H), 8.45 (d, 2H, J=1.9 Hz), 8.10 (d, 2H, J=8.5 Hz), 8.02 (dd, 2H, J=8.5 Hz, J=1.9 Hz), 7.83 (d, 4H, J=7.3 Hz), 7.49 (d, 4H, J=7.3 Hz), 7.39 (t, 4H, J=7.3 Hz), 7.37 (t, 4H, J=7.3 Hz), 4.19 (d, 4H, J=5.4 Hz), 4.14 (t, 2H, J=5.4 Hz), 4.05-3.91 (m, 2H), 3.43-3.31 (m, 4H), 2.59 (t, 4H, J=6.1 Hz), 1.27 (d, 6H, J=7.4 Hz). **HRMS** (ESI) ***m/z***: for $C_{55}H_{48}N_6O_{10}$: ($[M+H^+]^+$) calcd 953.3505, found 953.3531.

2,6-[Fmoc-Glycine-β-Alanine-amidyl]-anthracen-9,10-dione (B-5)

Obtained from 2,6-[β-Alanine-amidyl]-anthracen-9,10-dione according to the general procedure for coupling ***via*** TBTU. Yield: 87%. ^{1}H-NMR (d_6-DMSO; 300 MHz): δ 10.63 (s, 2H), 8.46 (d, 2H, J=1.9 Hz), 8.1 (d, 2H, J=8.6 Hz), 8.04 (dd, 2H, J=8.6 Hz, J=1.9 Hz), 7.97 (t, 2H, J=6.1 Hz), 7.86 (d, 4H, J=7.2 Hz), 7.68 (d, 4H, J=8.0 Hz), 7.53 (t, 2H, J=6.1 Hz), 7.39 (t, 4H, J=8.0, J=7.2 Hz), 7.30 (t, 4H, J=8.0 Hz, J=7.2 Hz), 4.25 (d, 4H, J=7.1 Hz), 4.19 (t, 2H, J=7.1 Hz), 3.58 (d, 4H, J=6.1 Hz), 3.39 (m, 2H), 2.65 (t, 4H, J=6.4 Hz). **HRMS** (ESI) ***m/z***: for $C_{53}H_{44}N_6O_{10}$: ($[M+H^+]^+$) calcd 925.3192, found 925.3201.

1,5-[Lysine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (D-13)

Obtained from **D-9** according to the general procedure for for the deprotection of the Boc group. Yield: 94%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.70 (s, 2H), 8.50 (d, 2H, J=2.1 Hz), 8.17 (d, 2H, J=8.8 Hz), 8.03 (dd, 2H, J=8.8 Hz, J=2.1 Hz), 3.85 (m, 2H), 3.41 (q, 4H, J=6.6 Hz), 2.79 (t, 4H, J=7.5 Hz), 2.66 (t, 4H, J=6.6 Hz), 1.78 (m, 4H), 1.54 (m, 4H), 1.42 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{32}H_{44}N_8O_6$: ($[M+H^+]^+$) calcd 637.3457, found 637.3486; calcd ($[M+2H^+]^{2+}$) 319.1765, found 319.1804.

1,8-[Lysine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (E-13)

Obtained from **E-9** according to the general procedure for the deprotection of the Boc group. Yield: 92%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.73 (s, 2H), 8.50 (d, 2H, J=2.1 Hz), 8.17 (d, 2H, J=8.8 Hz), 8.03 (dd, 2H, J=8.8 Hz, J=2.1 Hz), 3.85 (m, 2H), 3.41 (q, 4H, J=6.6 Hz), 2.79 (t, 4H, J=7.5 Hz), 2.66 (t, 4H, J=6.6 Hz), 1.78 (m, 4H), 1.54 (m, 4H), 1.42 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{32}H_{44}N_8O_6$: ($[M+H^+]^+$) calcd 637.3457, found 637.3492; calcd ($[M+2H^+]^{2+}$) 319.1765, found 319.1793.

2,6-[Lysine-Alanine-Glycine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (A-14)

Obtained from **B-14** according to the general procedure for the deprotection of the Boc group. Yield: 92%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.53 (s, 2H), 8.55 (d, 2H, J=7.5 Hz), 8.48 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.1 Hz), 8.05 (dd, 2H, J=8.1 Hz, J=2.0 Hz), 4.27-4.36 (m, 2H), 3.75 (t, 2H, J=6.1 Hz), 3.72 (d, 4H, J=5.4 Hz), 2.76 (t, 2H, J=7.5 Hz), 1.63-1.71 (m, 4H), 1.48-1.58 (m,

4H), 1.3-1.4 (m, 4H), 1.23 (d, 6H, J=7.5 Hz). **HRMS** (ESI) ***m/z*** for $C_{36}H_{50}N_{10}O_8$: ($[M+H^+]^+$) calcd 751.3886, found 751.3897; ($[M+2H^+]^{2+}$) calcd 376.1979, found 376.1991.

2,6-[Lysine-Alanine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (B-14)

Obtained from **A-14** according to the general procedure for the deprotection of the Boc group. Yield: 92%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.54 (s, 2H), 8.55 (d, 2H, J=7.5 Hz), 8.48 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.1 Hz), 8.05 (dd, 2H, J=8.1 Hz, J=2.0 Hz), 4.27-4.36 (m, 2H), 3.75 (t, 2H, J=6.1 Hz), 3.42-3.52 (m, 2H), 2.76 (t, 2H, J=7.5 Hz), 2.59 (t, 4H, J=6.1 Hz), 1.63-1.71 (m, 4H), 1.48-1.58 (m, 4H), 1.3-1.4 (m, 4H), 1.23 (d, 6H, J=7.5 Hz). **HRMS** (ESI) ***m/z*** for $C_{38}H_{54}N_{10}O_8$: ($[M+H^+]^+$) calcd 779.4199, found 779.4221; ($[M+2H^+]^{2+}$) calcd 390.2136, found 390.2147.

2,7-[Lysine-Alanine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (C-14)

Obtained from **C-14** according to the general procedure for the deprotection of the Boc group. Yield: 92%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.03 (s, 2H), 8.55 (d, 2H, J=7.5 Hz), 8.48 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.1 Hz), 8.05 (dd, 2H, J=8.1 Hz, J=2.0 Hz), 4.27-4.36 (m, 2H), 3.75 (t, 2H, J=6.1 Hz), 3.42-3.52 (m, 2H), 2.76 (t, 2H, J=7.5 Hz), 2.59 (t, 4H, J=6.1 Hz), 1.63-1.71 (m, 4H), 1.48-1.58 (m, 4H), 1.3-1.4 (m, 4H), 1.23 (d, 6H, J=7.5 Hz). **HRMS** (ESI) ***m/z*** for $C_{38}H_{54}N_{10}O_8$: ($[M+H^+]^+$) calcd 779.4199, found 779.4217; ($[M+2H^+]^{2+}$) calcd 390.2136, found 390.2150.

1,5-[Lysine-Alanine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (D-14)

Obtained from **D-14** according to the general procedure for the deprotection of the Boc group. Yield: 91%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.03 (s, 2H), 8.55 (d, 2H, J=7.5 Hz), 8.48 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.1 Hz), 8.05 (dd, 2H, J=8.1 Hz, J=2.0 Hz), 4.27-4.36 (m, 2H), 3.75 (t, 2H, J=6.1 Hz), 3.42-3.52 (m, 2H), 2.76 (t, 2H, J=7.5 Hz), 2.59 (t, 4H, J=6.1 Hz), 1.63-1.71 (m, 4H), 1.48-1.58 (m, 4H), 1.3-1.4 (m, 4H), 1.23 (d, 6H, J=7.5 Hz). **HRMS** (ESI) ***m/z*** for $C_{38}H_{54}N_{10}O_8$: ($[M+H^+]^+$) calcd 779.4199, found 779.4223; ($[M+2H^+]^{2+}$) calcd 390.2136, found 390.2147.

1,8-[Lysine-Alanine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (E-14)

Obtained from **E-14** according to the general procedure for the deprotection of the Boc group. Yield: 92%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.03 (s, 2H), 8.55 (d, 2H, J=7.5 Hz), 8.48 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.1 Hz), 8.05 (dd, 2H, J=8.1 Hz, J=2.0 Hz), 4.27-4.36 (m, 2H), 3.75 (t, 2H, J=6.1 Hz), 3.42-3.52 (m, 2H), 2.76 (t, 2H, J=7.5 Hz), 2.59 (t, 4H, J=6.1 Hz), 1.63-1.71 (m, 4H), 1.48-1.58 (m, 4H), 1.3-1.4 (m, 4H), 1.23 (d, 6H, J=7.5 Hz). **HRMS** (ESI) ***m/z*** for $C_{38}H_{54}N_{10}O_8$: ($[M+H^+]^+$) calcd 779.4199, found 779.4226; ($[M+2H^+]^{2+}$) calcd 390.2136, found 390.2147.

2,6-[Lysine-Glycine-Glycine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (A-15)

Obtained from **B-18** according to the general procedure for the deprotection of the Boc group. Yield: 91%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.63 (s, 2H), 8.66 (t, 2H, J=5.4 Hz), 8.49 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.8 Hz), 8.06 (dd, 2H, J=8.8 Hz, J=2.0 Hz), 3.8 (m, 6H), 3.3 (d, 4H, J=5.4

Hz), 2.76 (t, 4H, J=7.5 Hz), 1.70 (m, 4H), 1.52 (m, 4H), 1.39 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{34}H_{46}N_{10}O_8$: ($[M+H^+]^+$) calcd 723.3573, found 723.3590; ($[M+2H^+]^{2+}$) calcd 362.1823, found 362.1850.

2,6-[Lysine-Glycine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (B-15)

Obtained from **A-18** according to the general procedure for the deprotection of the Boc group. Yield: 90%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.66 (s, 2H), 8.66 (t, 2H, J=5.4 Hz), 8.49 (d, 2H, J=2.0 Hz), 8.17 (d, 2H, J=8.8 Hz), 8.06 (dd, 2H, J=8.8 Hz, J=2.0 Hz), 3.8 (m, 6H), 3.4 (q, 4H, J=6.8 Hz), 2.76 (t, 4H, J=7.5 Hz), 2.60 (t, 4H, J=6.8 Hz), 1.70 (m, 4H), 1.52 (m, 4H), 1.39 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{36}H_{50}N_{10}O_8$: ($[M+H^+]^+$) calcd 751.3886, found 751.3892; ($[M+2H^+]^{2+}$) calcd 376.1979, found 376.1993.

2,6-[Lysine-Phenylalanine-Glycine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (A-16)

Obtained from **B-22** according to the general procedure for the deprotection of the Boc group. Yield: 91%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.64 (s, 2H), 8.61 (d, 2H, J=7.5 Hz), 8.5 (d, 2H, J=2.0 Hz), 8.31 (t, 2H, J=5.4 Hz), 8.18 (d, 2H, J=8.1 Hz), 8.06 (dd, 4H, J=8.1 Hz, J=2.0 Hz), 7.12-7.2 (m, 8H), 7.2-7.28 (m, 2H), 4.49-4.57 (m, 2H), 3.72 (d, 4H, J=5.4 Hz), 3.7 (t, 2H), 2.97 (dd, 2H, J= 5.4 Hz, J=13.6 Hz), 2.83 (dd, 2H, J=8.8 Hz, J=13.6 Hz), 2.72 (t, 4H, J=7.5 Hz), 1.70 (m, 4H), 1.52 (m, 4H), 1.33 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{48}H_{58}N_{10}O_8$: ($[M+H^+]^+$) calcd 903.4512, found 903.4539; ($[M+2H^+]^{2+}$) calcd 452.2292, found 452.2306.

2,6-[Lysine-Phenylalanine-β-Alanine-amidyl]-anthracen-9,10-dione tetra-trifluoroacetate (B-16)

Obtained from **A-22** according to the general procedure for the deprotection of the Boc group. Yield: 91%. **^{1}H-NMR** (d_6-DMSO; 300 MHz): δ 10.64 (s, 2H), 8.61 (d, 2H, J=7.5 Hz), 8.5 (d, 2H, J=2.0 Hz), 8.31 (t, 2H, J=5.4 Hz), 8.18 (d, 2H, J=8.1 Hz), 8.06 (dd, 4H, J=8.1 Hz, J=2.0 Hz), 7.12-7.2 (m, 8H), 7.2-7.28 (m, 2H), 4.49-4.57 (m, 2H), 3.69-3.76 (t, 2H), 3.41-3.52 (m, 2H), 2.97 (dd, 2H, J= 5.4 Hz, J=13.6 Hz), 2.83 (dd, 2H, J=8.8 Hz, J=13.6 Hz), 2.72 (t, 4H, J=7.51 Hz), 2.55 (t, 4H, J=5.4 Hz), 1.70 (m, 4H), 1.52 (m, 4H), 1.33 (m, 4H). **HRMS** (ESI) ***m/z*** for $C_{50}H_{62}N_{10}O_8$: ($[M+H^+]^+$) calcd 931.4285, found 931.4288; ($[M+2H^+]^{2+}$) calcd 466.2449, found 466.2457.

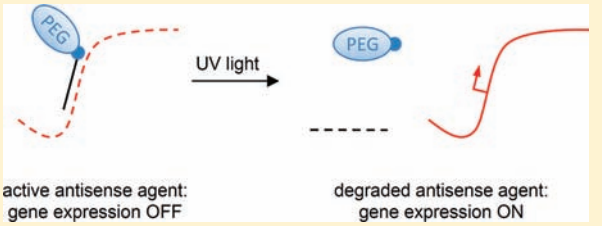
Stabilization and Photochemical Regulation of Antisense Agents through PEGylation

Jeane M. Govan, Andrew L. McIver, and Alexander Deiters*

Department of Chemistry, North Carolina State University, Campus Box 8204, Raleigh, North Carolina 27695, United States

Supporting Information

ABSTRACT: Oligonucleotides are effective tools for the regulation of gene expression in cell culture and model organisms, most importantly through antisense mechanisms. Due to the inherent instability of DNA antisense agents, various modifications have been introduced to increase the efficacy of oligonucleotides, including phosphorothioate DNA, locked nucleic acids, peptide nucleic acids, and others. Here, we present antisense agent stabilization through conjugation of a poly(ethylene glycol) (PEG) group to a DNA oligonucleotide. By employing a photocleavable linker between the PEG group and the antisense agent, we were able to achieve light-induced deactivation of antisense activity. The bioconjugated PEG group provides stability to the DNA antisense agent without affecting its native function of silencing gene expression via RNase H-catalyzed mRNA degradation. Once irradiated with UV light of 365 nm, the PEG group is cleaved from the antisense agent leaving the DNA unprotected and open for degradation by endogenous nucleases, thereby restoring gene expression. By using a photocleavable PEG group (PhotoPEG), antisense activity can be regulated with high spatial and temporal resolution, paving the way for precise regulation of gene expression in biological systems.



INTRODUCTION

Antisense oligonucleotides are extensively used in cell and developmental biology to inhibit gene expression. Site-specific hybridization of antisense agents to target mRNAs suppresses translation, either by degradation of the mRNA though an RNase H-dependent mechanism or by steric blocking of the ribosome.[1−3] Intracellularly, nonmodified DNAs are quickly degraded, mainly by 3′ exonucleases,[4] limiting the applicability of non-modified DNA as antisense agents. For the past two decades, modifications have been made to oligonucleotides to improve the pharmacokinetics and physicochemical properties. Various modifications to the phosphate backbone and the ribose have been developed to improve the stability and half-life of oligomers, including 3′-3′ inverted thymidines,[5] phosphorothioate linkages,[6] locked nucleic acids (LNA),[7] and 2′-*O*-methyl groups.[8]

PEGylation, the covalent attachment of a poly(ethylene glycol) polymer, enhances the pharmacokinetic properties of both oligonucleotides[9] and proteins[10−12] by shielding them from nucleases and proteases thus increasing their stability. Studies have also shown that PEGylation enhances the absorption, bioavailability, and biodistribution of biological macromolecules while reducing toxicity and immunological effects.[9] In addition, PEGylated triplex forming oligonucleotides and siRNAs have shown to be more efficiently taken up by cells and have displayed improved stability.[13,14]

We hypothesized that the combination of oligonucleotide PEGylation in conjunction with a light-cleavable linker group would enable photochemical control over antisense agent stability and activity. Light represents an ideal external control element for the study of gene expression and protein function with high spatial and temporal resolution.[15−18] Light-removable protecting groups ("caging groups") have been applied to the light-regulation of DNA function through the inhibition of the oligonucleotide's ability to undergo Watson−Crick base-pairing until the groups are removed through light irradiation.[19−31] Here, we propose that a PhotoPEGylated antisense agent will inhibit gene expression (Scheme 1A) until irradiation with nondamaging UV light removes the PEG group, leading to intracellular degradation of the oligonucleotide and subsequent activation of gene expression (Scheme 1B). Advantages of this approach compared to existing methods of photochemical regulation of antisense function are that (a) it can be easily applied to standard, commercially available DNA, (b) it stabilizes the DNA under physiological conditions, and (c) it enables the light-deactivation of antisense function and thus activation of gene expression.

EXPERIMENTAL PROCEDURES

Synthesis and Purification of PEGylated Oligonucleotides. A 3′ amino-modified phosphodiester DNA oligonucleotide (10 μM, Integrated DNA Technologies) was 5′ radiolabeled with ^{32}P-λ ATP (MP Biomedicals) using T4 polynucleotide kinase (New England Biolabs). The 5′ ^{32}P-DNA-NH$_2$ (2 μM) was reacted with *N*-hydrosuccinimide (NHS) ester PEG (200 μM, Laysan Bio, Inc.) in phosphate saline buffer (PBS, pH 8.0) and incubated for 4 h at 30 °C. Due to incomplete PEGylation, the

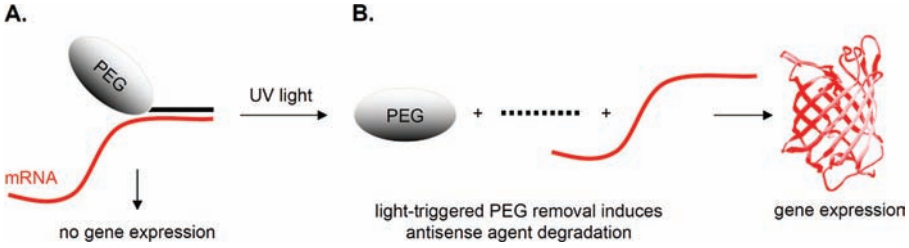
Scheme 1. Photoregulation of Antisense Activity with Light-Removable PEG Groups[a]



[a] (A) A PEGylated antisense agent binds to the mRNA target sequence, which recruits RNase H to the mRNA/DNA duplex leading to the degradation of the mRNA and thus gene silencing. (B) A PhotoPEG antisense agent is cleaved upon UV irradiation, leaving the DNA-based antisense agent susceptible to degradation by exonucleases, thereby allowing the translation of the mRNA and gene expression.

PEGylated DNA was gel purified, electro-eluted, and concentrated using a Millipore centricon (3000 Da molecular weight cutoff). The PEGylated DNA was quantified using a standard curve on a 20% denaturing PAGE gel, through scanning on a Typhoon FLA 7000 and measuring the band intensities using *ImageQuantTL*.

Melting Temperature Measurements. The melting temperature (T_m) of each PEGylated DNA/RNA duplex was measured using a Cary 100 Bio UV/vis spectrometer with a temperature controller (Varian). The PEGylated DNA antisense agent and RNA substrate (0.5 μM) were incubated in buffer (0.15 M NaCl, 0.05 M NaH_2PO_4, pH 7.2). The samples were heated to 100 °C for 2 min, and then cooled to 20 °C at a rate of 2 °C/min, held at 20 °C for 5 min, and then heated to 100 °C at a rate of 2 °C/min. Absorbance was recorded at 260 nm every 1 °C. The T_m was determined by the maximum of the first derivative of the absorbance vs temperature plot. Standard deviations were calculated from three independent experiments.

RNase H Assay. The RNase H assay was performed as described by Tang et al.[32] with the following modifications: PEGylated DNA (10 nM) and RNase H buffer were equilibrated, followed by the addition of radiolabeled RNA (^{32}P-γ ATP, 1 μM). The mixture was incubated at 37 °C for 20 min, and RNase H (New England Biolabs, 1 U) was added, followed by an additional incubation for 1 h at 37 °C. Samples were analyzed on a 10% denaturing PAGE gel and scanned on a Typhoon FLA 7000.

Photochemical Regulation of Antisense Activity in Mammalian Cells. HEK 293T cells were passaged into a poly-L-Lys coated 96-well plate, grown to 70% confluency, and transfected with pEGFP-N1 (Clontech, 150 ng), pDsRed-monomer (Clontech, 150 ng), and antisense agents (25 pmol) using X-tremeGENE (Roche). pEGFP-N1 encodes enhanced green fluorescent protein (EGFP) and served as the transfection control. pDsRed-monomer encodes a red fluorescent protein (DsRed) and was the targeted gene in this study. After 4 h, media was removed, the cells were irradiated on a transilluminator (365 nm, 25 W), and DMEM media was added. Following a 48 h incubation at 37 °C, 5% CO_2, the media was removed and the cells were imaged on a Jenco inverted microscope. The cells were lysed and the fluorescence was measured on a plate reader (EGFP 485/507 ex/em, DsRed 557/585 BioTek Synergy 4 Microplate Reader).

Spatial Control of Gene Expression in Mammalian Cells. NIH 3T3 cells were passaged into a black 96-well plate and grown to 75% confluency, followed by transfection with pEGFP-N1 (150 ng), pDsRed-monomer (150 ng), and antisense agent (25 pmol) using X-tremeGENE. After 4 h, the media was removed and half of the well was covered with an aluminum foil mask. The cells were irradiated for 2 min on a transilluminator (365 nm, 25 W) and DMEM media was added. Following a 48 h incubation, the media was removed and the cells were imaged on a Zeiss Axio Observer inverted microscope (5× magnification, filter sets 43 HE DsRed and 38 HE eGFP).

RESULTS AND DISCUSSION

First, the PEGylated DNA was synthesized through the acylation of 3′ amino-modified oligonucleotides with *N*-hydroxysuccinimide-activated poly(ethylene glycol)s of 5 kDa, 20 kDa, or 40 kDa (Scheme 2A). A DNA sequence targeting the DsRed gene was selected for subsequent cell-based reporter assays.[27,33] The PEGylated antisense agents were purified through gel electro-elution (Scheme 2C). In order to validate that the PEG group will stabilize the nonmodified DNA against nucleases, the 3′ PEGylated oligonucleotides were incubated in DMEM growth media (10% FBS). Upon conjugation of the 5 kDa PEG group to the deoxyoligonucleotide, the stability increased from 4 to 24 h. The 20 kDa PEG and the 40 kDa PEGylated oligonucleotides displayed similar trends with stabilizing DNA for a minimum of 24 h. The stability of the PEGylated oligonucleotides was also tested in the presence of exonuclease I, by measuring oligonucleotide integrity over time. A 15-, 30-, and 60-fold increased stability was found for DNA PEGylated with 5, 20, and 40 kDa PEG reagents, respectively. Thus, increasing the size of the bioconjugated PEG from 5 kDa to 40 kDa increases the stability of the oligonucleotide in both DMEM media and in the presence of an exonuclease (Supporting Information, Figures S1 and S2).

Melt curves of the PEGylated antisense agents were measured in the presence of target mRNA (5′ GCAGGAGGCCUCCUCCGAGAACGUCAUCACCGAGUUCAUCAAGGU 3′) to ensure that the PEG groups do not affect DNA/RNA hybridization. The non-PEGylated antisense agent had a T_m of 69 °C (Table 1). The conjugation of the 5 kDa PEG to the DNA phosphodiester oligonucleotide did not interfer with DNA/RNA hybridization as the T_m slightly decreased by 6 °C when compared to the non-PEGylated DNA. With an increasing PEG size to 20 kDa and 40 kDa, the T_m decreased by 13 and 19 °C, respectively, but hybridization was still detected (see Supporting Information, Figure S3). Therefore, all PEGylated deoxyoligonucleotides undergo DNA/RNA hybridization and thus have potential to function as antisense agents in live cells. The attachment of a smaller PEG group (5 kDa) had a less pronounced effect on melting point depression than larger PEG groups (20 kDa or 40 kDa).

Since the PEG groups do not affect DNA/RNA hybridization, the activity of the PEGylated DsRed antisense agents was

[a] Standard deviations were derived from T_m measurements conducted in triplicate.

determined in cell culture. Human embryonic kidney (HEK) 293T cells were co-transfected with pEGFP-N1, pDsRed-monomer, and the PEGylated antisense agents. The PEGylated antisense agents target the DsRed mRNA, while the enhanced green fluorescent protein (EGFP) served as a transfection control; therefore, DsRed fluorescence was normalized to EGFP fluorescence. The nonmodified antisense agent (AA) showed no knockdown of DsRed expression (Figure 1A), presumably due to a rapid intracellular degradation of the deoxyoligonucleotide (as discussed above). As a positive control, a hairpin loop-protected DsRed antisense agent that has previously been shown to successfully inhibit DsRed expression was used.[27,33] This hairpin-protected antisense agent (AA-HP) produced a 74% inhibition of DsRed expression (Figure 1B). Gratifyingly, all PEGylated antisense agents (AA-5K, -20K, and -40K) achieved similar levels of DsRed suppression (58−68%). Since the knockdown is not statistically different ($p \geq 0.15$), it can be concluded that even small PEG groups of 5−20K are sufficient for the protection of small deoxyoligonucleotides. Thus, the ability of nonmodified, PEGylated DNA to act as a translational-silencing antisense agent in tissue culture was demonstrated for the first time.

Antisense agents can inhibit gene function via two pathways: (a) the antisense agent can sterically block the translation of the mRNA or (b) the mRNA:DNA duplex can recruit RNase H to bind to the duplex and degrade the mRNA.[2] In order to determine by which mechanism the PEGylated antisense agent inhibits gene expression, an RNase H assay was performed. The DsRed mRNA target in the absence of antisense DNA was not affected by the addition of RNase H (Figure 2, Lanes 1−2). Nonmodified DsRed AA was incubated with its complementary mRNA sequence in the presence and absence of RNase H. As expected, only upon addition of RNase H was the mRNA

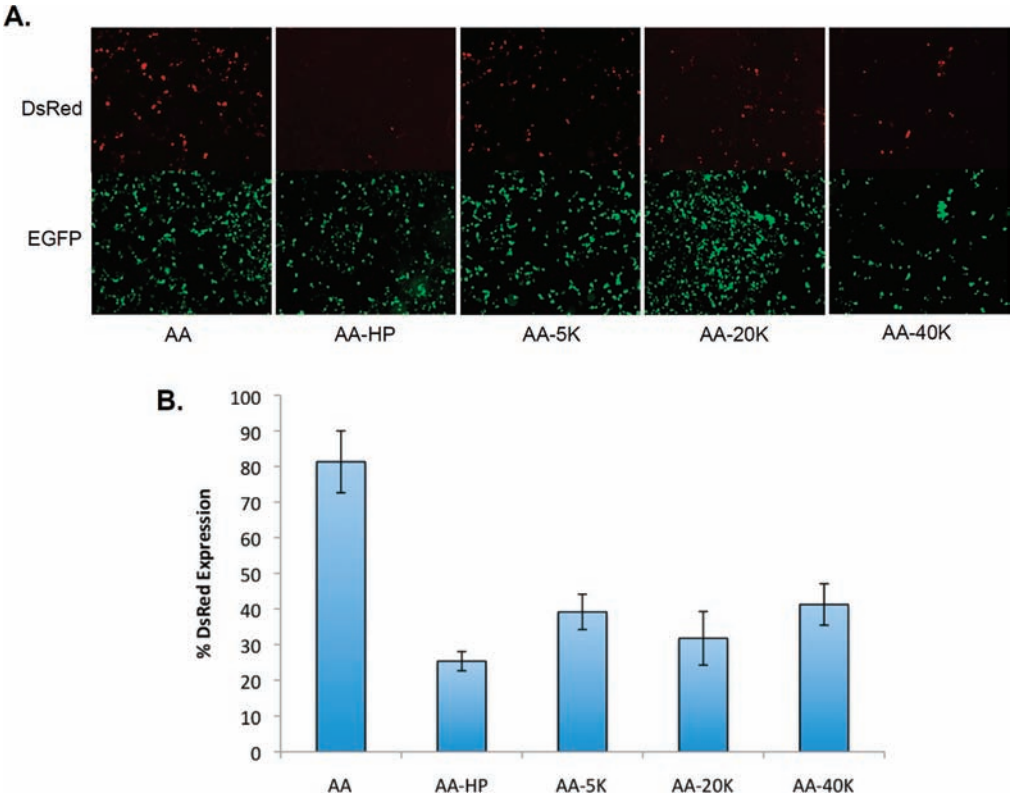

Figure 1. Inhibition of DsRed expression by PEGylated antisense agents. HEK 293T cells were transfected with pEGFP-N1, pDsRed-Monomer, and antisense agent. (A) After a 48 h incubation, the media was removed and the cells were imaged. The DsRed channel is shown above the EGFP channel. (B) Cells were subsequently lysed and the fluorescence was measured on a BioTek plate reader. DsRed (557/585 nm) fluorescence was normalized to EGFP (485/507 nm) fluorescence. Error bars represent standard deviatons from three independent experiments. AA: nonmodified antisense agent. AA-HP: hairpin-protected antisense agent. AA-5K: 5 kDa PEGylated antisense agent. AA-20 kDa: 20 kDa PEGylated antisense agent. AA-40: 40 kDa PEGylated antisense agent.

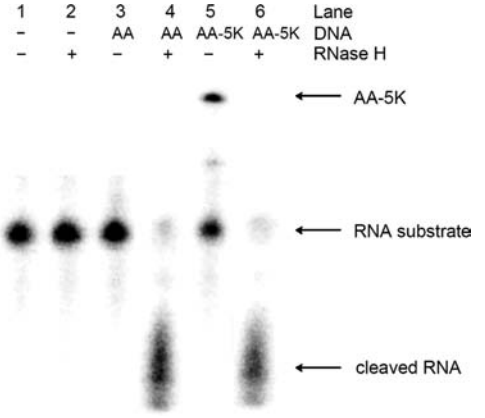

Figure 2. PEGylated antisense agent induces RNA degradation through an RNase H mediated mechanism. AA and AA-5K PEG were incubated with a radiolabeled RNA substrate and RNase H for 1 h at 37 °C. Samples were analyzed on a 10% denaturing gel and imaged with a Typhoon FLA 7000. AA: nonmodified antisense agent. AA-5K: 5 kDa PEGylated antisense agent.

degraded (Figure 2, Lanes 3−4). The same result was obtained for the PEGylated AA-5K DNA and RNase H (Figure 2, Lanes 5−6), indicating that the presence of the PEG group has no effect on the recruitment of RNase H. Thus, the PEGylated antisense oligonucleotide most likely inhibits gene expression intracellularly through RNase H-mediated degradation of mRNA.

On the basis of the results presented above, PEGylated oligonucleotides are active and stable antisense agents in cell culture, while the non-PEGylated DNA is quickly degraded. Thus, we hypothesized that we can photochemically inactivate an antisense agent by inserting a light-cleavable linker between the PEG group and the DNA (Scheme 2B). In order to test this hypothesis, we used a previously synthesized 5 kDa PhotoPEG reagent[34] and additionally synthesized a 20 kDa PhotoPEG group. The DsRed antisense DNA was PEGylated with the PhotoPEG group as shown in Scheme 2B.

The photoactivation of gene expression was conducted by transfection of the 5 kDa and 20 kDa PhotoPEGylated antisense agents with pEGFP-N1 and pDsRed-monomer into HEK 293T cells. The cells were irradiated for 2 min using a transilluminator (365 nm, 25 W), followed by incubation for 48 h. As in the previous cellular experiments, EGFP was used as a transfection control and DsRed fluorescence was normalized to EGFP fluorescence. The 5 kDa PhotoPEG antisense agent (AA-5K PhotoPEG) reduced DsRed expression by 52% (similar to earlier results shown in Figure 1), and after irradiation, DsRed expression was fully restored—comparable to the no antisense agent control (Figure 3A,B). The 20 kDa PhotoPEG antisense agent (AA-20K PhotoPEG) almost completely inhibited DsRed expression (80% inhibition), while after irradiation, fully restored DsRed expression was observed as well. Gene silencing with the

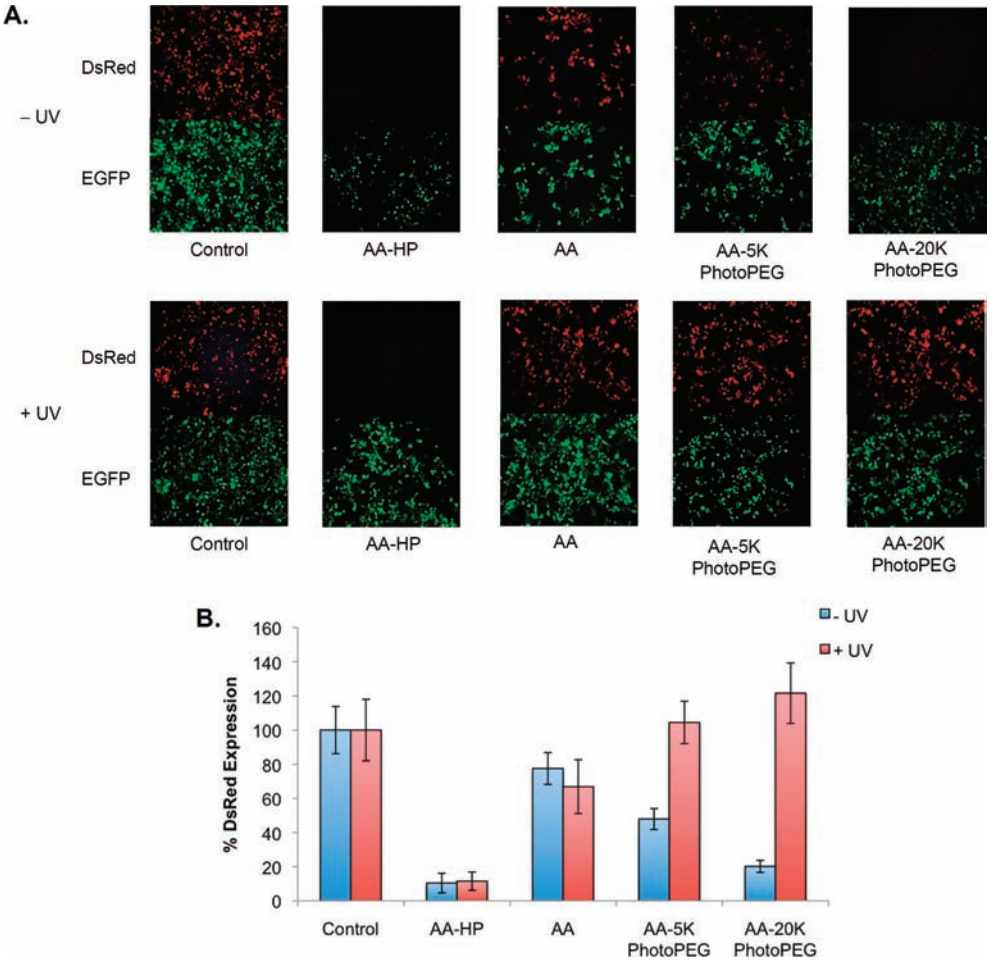

Figure 3. Light activation of gene expression using a PhotoPEGylated antisense agent. HEK 293T cells were transfected with pEGFP-N1, pDsRed-Monomer, and antisense agent. Cell were irradiated for 2 min (25 W, 365 nm) or kept in the dark. (A) Cells were imaged after 48 h. The DsRed channel is shown above the EGFP channel. (B) Cells were then lysed, and the fluorescence was measured on a BioTek plate reader. DsRed (557/585 nm) fluorescence was normalized to EGFP (485/507 nm) fluorescence. Error bars represent standard deviations from three independent experiments. AA-HP: hairpin-protected antisense agent. AA: nonmodified antisense agent. AA-5K PhotoPEG: 5 kDa photocleavable PEGylated antisense agent. AA-20K PhotoPEG: 20 kDa photocleavable PEGylated antisense agent.

AA-20K PhotoPEG reagent was more pronounced than what was previously observed for the simple PEG reagent without the light-cleavable linker (Figure 1). However, based on our cellular stability assays (see Supporting Information), the AA-20K PEG was more stable than the AA-5K PEG toward enzymatic degradation. This demonstrates the excellent switching from virtually complete inhibition of gene expression before irradiation to fully restored gene expression after irradiation. For the first time, nonmodified, standard DNA was conjugated with a photocleavable PEG group and used in the photochemical activation of gene expression.

Having successfully achieved light-activation of gene expression with an excellent off/on ratio by using the PhotoPEGylated antisense agent, we next investigated the possibility of spatial control over DsRed expression in mammalian cells. In a 96-well plate, the AA-20K PhotoPEG was cotransfected into NIH 3T3 cells with pEGFP-N1 and pDsRed-monomer. Only one-half of a well was then irradiated for 2 min (365 nm, 25 W), followed by incubation for 48 h. Consistent with earlier observations, the nonmodified antisense agent (AA) exhibited no inhibition of DsRed expression (Figure 4); conversely, the hairpin-protected antisense agent (AA-HP) completely inhibited DsRed expression. Cells transfected with the 20 kDa PhotoPEG antisense agent were only irradiated on the left half of the well and DsRed expression is only observed within the irradiated area. In the nonirradiated area, the right side of the micrograph, no DsRed expression is visible due to an intact PEGylated DsRed antisense agent. Thus, a high level of spatial control over gene activation was achieved.

In summary, PhotoPEG antisense agents were developed that enable precise activation of gene expression through UV irradiation. Traditionally, antisense agents are stabilized by various backbone and sugar modifications for applications in tissue culture and whole organisms. These modifications are often synthetically challenging and, moreover, prevent RNase H-catalyzed mRNA degradation. If RNase H cleavage of mRNA is desired, mixed modified/nonmodified deoxyoligonucleotides need to be synthesized. We discovered that simple PEGylation stabilizes nonmodified DNA intracellularly with minimal to no effect on antisense activity, DNA/RNA hybridization, and RNase H-catalyzed mRNA degradation, thus providing efficient and readily synthesized antisense agents. The application of a light-cleavable PhotoPEG linker inserted between the PEG polymer and the

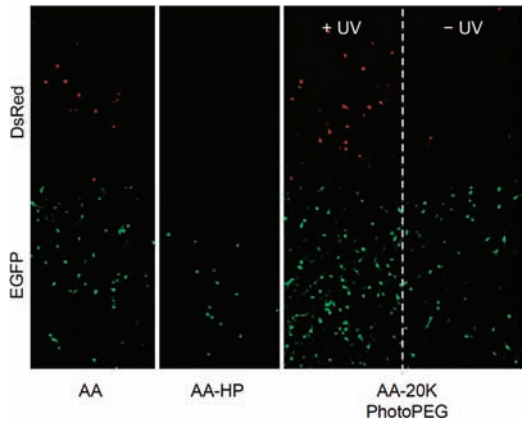

Figure 4. Spatial activation of gene expression using a PhotoPEGylated antisense agent. NIH 3T3 cells were transfected with pEGFP-N1, pDsRed-Monomer, and AA-20K PhotoPEG. Only one-half side of the well was irradiated for 2 min (25 W, 365 nm) and the cells were imaged after 48 h. The DsRed channel is shown above the EGFP channel. AA: nonmodified antisense agent. oligonucleotide enabled sequence-specific gene silencing until cells were briefly irradiated with UV light of 365 nm, inducing PEG cleavage and subsequent rapid, intracellular degradation of the antisense oligonucleotide. Degradation of the antisense agent then in turn activates the expression of the previously silenced gene of interest. Moreover, in addition to temporal control over gene expression, the developed methodology introduced a simple means for spatial control over gene activation through locally restricted irradiation of a monolayer of mammalian cells. This approach (light-*activation* of gene expression) is complementary to classical antisense caging methodologies (light-*deactivation* of gene expression). Due to the straightforward design of the reagents, only requiring standard deoxyoligonucleotides, the developed methodology can be readily applied in any chemical biology, cell biology, and molecular biology lab.

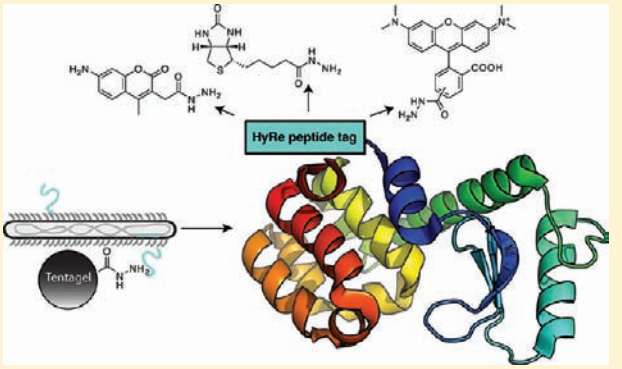
ABSTRACT: New site-specific protein labeling (SSPL) reactions for targeting-specific, short peptides could be useful for the real-time detection of proteins inside of living cells. One SSPL approach matches bioorthogonal reagents with complementary peptides. Here, hydrazide reactive peptides were selected from phage-displayed libraries using reaction-based selections. Selection conditions included washes of varying pH and treatment with $NaCNBH_3$ in order to specifically select reactive carbonyl-containing peptides. Selected peptides were fused to T4 lysozyme or synthesized on filter paper for colorimetric assays of the peptide−hydrazide interaction. A peptide−lysozyme protein fusion demonstrated specific, covalent labeling by the hydrazide reactive (HyRe) peptides in crude bacterial cell lysates, sufficient for the specific detection of an overexpressed protein fusion. Chemical synthesis of a short HyRe tag variant and subsequent reaction with two structurally distinct hydrazide probes produced covalent adducts observable by MALDI-TOF MS and MS/MS. Rather than isolating reactive carbonyl-containing peptides, we observed reaction with the N-terminal His of HyRe tag **114**, amino acid sequence HKSNHSSKNRE, which attacks the hydrazide carbonyl at neutral pH. However, at the pH used during selection wash steps (<6.0), an alternative imine-containing product is formed that can be reduced with sodium cyanoborohydride. MSMS further reveals that this low pH product forms an adduct on Ser6. Further optimization of the novel bimolecular reaction described here could provide a useful tool for *in vivo* protein labeling and bioconjugate synthesis. The reported selection and screening methods could be widely applicable to the identification of peptides capable of other site-specific protein labeling reactions with bioorthogonal reagents.



INTRODUCTION

Site-specific protein labeling (SSPL) provides a powerful tool for the *in vivo* tracking of protein localization, dynamics, and concentration.[1,2] SSPL enables visualization of specific proteins through conjugation to an appropriately functionalized probe. Genetically encoded fluorescent protein fusions provide a facile route to site-specific protein labeling[3] and are the current standard in labeling technology;[4] however, the large size and limitation to a fluorescent signal has stimulated a search for smaller and chemically flexible labeling strategies. One route, enzymatic labeling of genetically encoded peptide substrates, is useful in forming fluorescent conjugates *in vivo*, and has been reviewed recently.[5,6] Another powerful approach harnesses unique peptide sequences capable of forming covalent bonds with chemical probes. The latter approach does not require additional enzymes or reagents. Here, for example, we describe the selection, screening, and characterization of hydrazide reactive peptides (Figure 1).

Nonenzymatic SSPL reactions have revolutionized protein purification and visualization. For example, short polyhistidine peptides ("His-tags") selectively coordinate nickel (Ni^{2+}), or cobalt (Co^{2+}) chelated to a solid support. A genetically encoded His_6-tag enabled purification of dihydrofolate reductase from crude, *E. coli* cell lysate under both native and denaturing conditions.[7] Used by innumerable laboratories for protein purification, His-tags can also enable protein visualization via binding to a fluorescent, zinc-conjugated small molecule (HisZiFiT).[8] Another stand-alone, probe-reactive peptide, uses the tetracysteine motif (amino acid sequence CCXXCC) to selectively react with fluorogenic bisarsenical probes *in vitro* and *in vivo*.[9−11] Other short peptides are capable of being modified with fluorescent probes and include labeling of tetraserine motifs by bisboronic acids,[12] polyaspartic acids by zinc fluorophores,[13] and lanthanide binding peptides with lanthanide ions.[14,15]

Discovery of new SSPL peptide−probe pairs requires both a modestly reactive small molecule and a unique, complementary peptide. The small molecule must be stable to physiological conditions, yet reactive upon peptide binding. The partnering reactive peptide is ideally short enough to minimize misfolding and mislocalization of the fused protein, yet sufficiently long to ensure unique representation in the proteome. Suited for the identification of such complementary peptides, phage display enables the rapid sifting of vast libraries to identify peptides with affinity for essentially any target, including proteins,[16,17] small

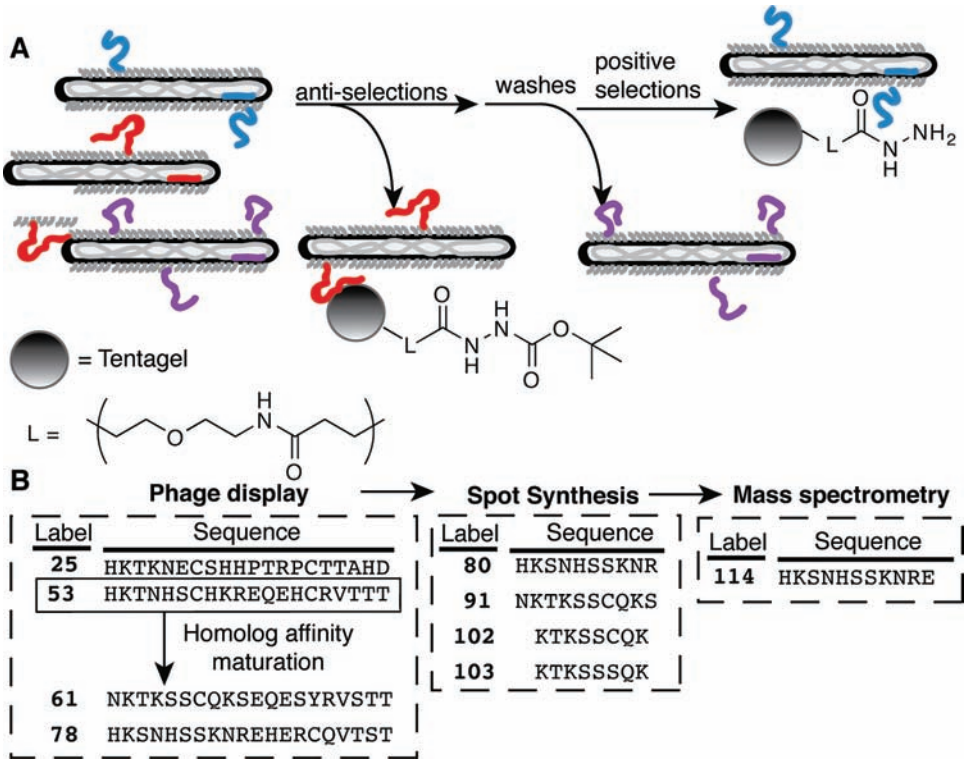

Figure 1. (A) Selections for hydrazide binding peptides included antiselections with Boc-protected hydrazide resin to remove nonspecific peptides (e.g., the red peptide), positive selections with hydrazide-derivatized resin to capture hydrazide interacting peptides (e.g., the blue peptide), and extensive wash steps to remove nonbinding peptides (e.g., the purple peptide). (B) Sequences of peptides discussed in the text from selections of phage-displayed peptide libraries, spot synthesis, and chemical synthesis followed by mass spectrometry analysis.

molecules,[1] and inorganic materials.[18] The filamentous bacteriophage used in phage display links the encoding DNA sequence to the displayed peptide, providing easy routes to both amplify and identify the selected peptides.[19,20]

Two examples illustrate the utility of phage display to identify either noncovalent or covalent SSPL peptide−probe pairs. First, conventional affinity-based phage display identified tightly binding peptides that modulate the fluorescence of Texas red.[21] After many rounds of optimization, a 38-residue peptide tethered via an intramolecular dimerization domain was developed that noncovalently bound a calcium-sensitive Texas red derivative with a K_D of 80 pM.[22] Second, reaction-based phage display targeted a diketone to isolate the 20-mer peptide rpf1368, which forms enaminones with various diketone-containing probes.[23] The reported peptides from the initial rounds of selection for both of these examples proved functional yet inefficient. Further optimization of the peptides through appending additional libraries to previously selected sequences and performing more stringent selections ultimately yielded tighter-binding or more reactive peptides.[22,23]

Other functionalities could be amenable to the discovery of bioorthogonal peptide−probe pairs using either affinity or reaction-based phage display. Side-chain modifying electrophiles, such as iodoacetamide and *N*-hydroxy succinamide are exceptional modifying agents for cysteine and lysine, respectively. These functionalities are insensitive to 3D sequence space, and can modify exposed side chains. Therefore, these reagents are restricted to use with purified proteins. Considering the nucleophilic nature of biopolymers, nucleophilic probes should be vastly more discriminating toward specific amino acid sequences. Thus, we focused on a nucleophilic functionality with known bioorthogonality toward proteins. Hydrazides do not react with unmodified biopolymers, but are used to label and isolate oxidized molecules with reactive carbonyls.[24] Reactive carbonyl-containing proteins, for example, can be purified from biological samples using biotin hydrazide and surface-bound avidin for mass spectrometry identification.[25,26]

Reactive carbonyls can also be introduced into protein sequences through enzymatic labeling of peptide substrates. Ligation of a ketone-containing probe to an acceptor peptide with biotin ligase generates a reactive carbonyl for modification with hydrazide probes.[27] Similarly, formylglycine-generating enzyme modifies cysteine in the sequence LCTPSR to generate a reactive carbonyl for subsequent hydrazide labeling.[28] These peptides are easily incorporated as fusions to proteins of interest for labeling with either hydrazide- or aminooxy-derivatized compounds, after treatment with the appropriate enzyme.[28,29] Unnatural amino acid incorporation can also introduce ketone-based amino acids.[30,31]

We sought to simplify protein labeling with hydrazide probes by identifying peptides with affinity for hydrazide, thus eliminating the need for the coexpression of a modifying enzyme. Hydrazides can interact with polypeptides in four different mechanisms (Figure 2). First, hydrazides would form hydrazones with reactive carbonyls present in oxidized peptides. A large number of spontaneous reactions introduce reactive carbonyls into protein sequences including conjugation to oxidized lipids and oxidation of susceptible amino acids (such as the side chains of arginine, histidine, lysine, or proline); both reactions occur during some age- and disease-related stresses.[32,33] In addition, peptides from a phage-displayed library could act as substrates for

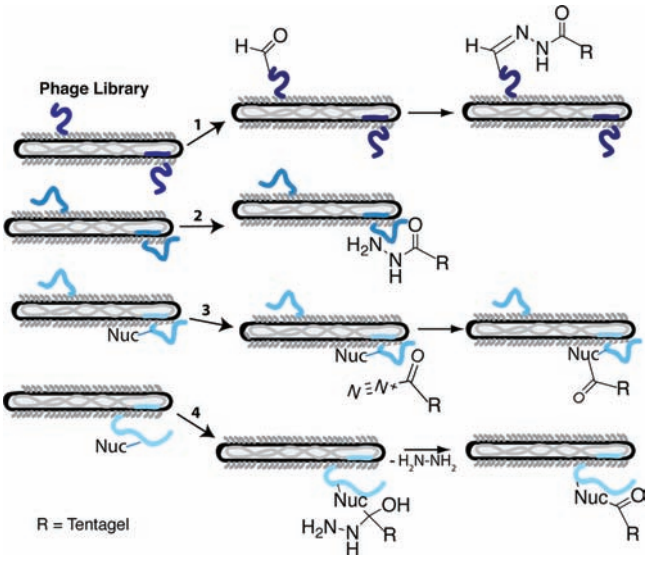

Figure 2. Potential mechanisms for the selection of hydrazide interacting peptides from phage-displayed libraries include oxidation of susceptible peptides (**1**) for capture with hydrazide-derivatized Tentagel via hydrazone bond formation. Additionally, phage-displayed peptides could form high-affinity noncovalent interactions with the hydrazide functionality (**2**). Alternatively, the hydrazide functional group could be oxidized and attacked by a peptide nucleophile liberating nitrogen gas (**3**). Lastly, a nucleophile from the displayed peptide could attack the carbonyl of the hydrazide functional group, displacing hydrazine (**4**).

carbonyl-forming enzymes such as the formylglycine-generating enzyme, described above.[34] Therefore, peptides susceptible to either enzymatic or atmospheric oxidation would react with hydrazide-based capture agents.

Alternatively, peptides could noncovalently bind to the probe, as was discovered for the Texas red binding peptides. However, the small size of the hydrazide group might preclude high-affinity binding. Contrary to peptide oxidation, the hydrazide functional group could be selectively oxidized, thereby presenting an electrophile for attack by a peptide nucleophile before displacement of nitrogen. The enzyme tyrosinase oxidizes acylhydrazide to an acyl diazene, to liberate nitrogen; and has been used as a chemical deprotection strategy.[35] In the fourth mechanism, a peptide nucleophile could attack the hydrazide carbonyl, exhibiting similar reactivity as cysteine proteases such as cathepsin K inhibition by acylhydrazide inhibitors. In this example, the active site cysteine attacks the carbonyl of the acylhydrazide resulting in a stabilized tetrahedral intermediate.[36]

Thus, reaction-based phage selections for peptides interacting with the hydrazide functional group could explore a number of different reaction possibilities to expand the palette of bioorthogonal peptide−probe pairs (Figure 1). After five rounds of selection and DNA sequencing of the selected phage to determine trends of the peptide interactions with the hydrazide functionality, one sequence was chosen for further affinity maturation by homologue shotgun scanning. The selected peptides were screened for interaction with hydrazide probes through fusion to T4 lysozyme. After homologue affinity maturation, the interaction of selected peptides with biotin hydrazide was compared through peptide spot synthesis and screening. The most promising short peptides identified by spot synthesis were chemically resynthesized, treated with hydrazide-containing probes, and analyzed by mass spectrometry. Given the reactivity of hydrazides with ketones and aldehydes, we expected to isolate oxidation-susceptible peptides. Instead, the isolated 20-mer peptides are nucleophilic toward certain hydrazide derivatives.

EXPERIMENTAL PROCEDURES

Selections for Hydrazide Binding Peptides. To remove background-binding peptides, an antiselection was performed by incubating a previously described, phage-displayed peptide library[37] with Boc-hydrazide Tentagel for 1 h at room temperature in a peptide reaction vessel. The unbound phage were next subjected to a positive selection through incubation with a new aliquot of deprotected, hydrazide Tentagel for 20−60 min with decreasing concentrations of resin in each round. The hydrazide-bound phage were washed three to six times with increasing volumes of PBS (from 10 to 50 mL) and times (from 2 to 20 min) for each subsequent round. Additional wash steps to enhance the stringency of selections included two washes with HCl (0.1 M, 1.5 mL) in rounds 1 and 2, and three to six washes of HCl (0.1 M, 50 mL) in rounds 4 and 5. The phage−resin mixture was then rebuffered with a wash of PBS (50 mL, 10 min) before being resuspended in PBS (1.5 mL) for storage and propagation. Half of the phage−Tentagel suspension was incubated with 10 mL of XL-1 blue *E. coli* (OD_{600} = 0.5−1.0) for 20 min with shaking at 37 °C. A small aliquot of the infected cells was titered on LB-carbenicillin-agar plates, and the remaining culture was transferred to 2YT (250 mL) supplemented with M13-KO7 helper phage before overnight incubation at 37 °C with shaking. Individual colonies from the titer plate were sequenced following PCR using M13 primers (Supporting Information).

Bacterial Subcloning and Overexpression of HyRe−Lysozyme Fusion. The selected peptides were subcloned into a plasmid encoding each peptide fused through a GGGSG linker to the N-terminus of T4 lysozyme (Supporting Information). Correctly ligated plasmids were transformed into heat shock competent BL21(DE3) *E. coli*. An overnight 37 °C culture (10 mL LB, 40 μg/mL kanamycin) was added to 1 L of LB media supplemented with kanamycin (40 μg/mL), and grown for an additional ∼2.5 h at 37 °C to an OD_{600} of 0.6. The addition of IPTG (1 mM) induced protein expression at 30 °C for 4 h. Following centrifugation and sonication, the crude supernatant was purified using cation exchange chromatography. Protein fusions were eluted with a gradient to 1 M NaCl and fractions containing the protein fusion were then combined and concentrated. Gel permeation chromatography further purified fusion proteins to >95% homogeneity (Figure S2 A in Supporting Information).

Biotin Hydrazide and Rhodamine B Hydrazide Binding Assay to HyRe 53-T4 Lysozyme Fusion. Following purification, the HyRe peptide **53**-T4 lysozyme fusion, the proteolyzed peptide **53**-T4 lysozyme fusion, or wild-type T4 lysozyme was treated with either biotin hydrazide (1 mM in PBS for 1 h at room temperature) or an equivalent volume of buffer (negative controls) before the addition of SDS loading dye (20% volume). The solution was then incubated at 95 °C for 3 min to denature the proteins. The denatured protein samples were added to two 15% SDS-page gels before electrophoresis at a voltage of 130 V for 90 min. One protein gel was Coomassie-stained, and the other gel was transferred to a nitrocellulose membrane via electrophoresis in transfer buffer (25 mM Tris base, 192 mM glycine, 20% methanol, 0.02% SDS, pH 8.3) at 100 V for 100 min. This

nitrocellulose membrane was blocked with 1.0% Tween 20 in PBS overnight at 4 °C. Biotinylation was assessed by incubating the membrane with SAV-AP at room temperature for 1 h. This membrane was washed five times with PT before visualization by treatment with 4-chloro-1-naphthol and 3,3′-diaminobenzidine, tetrahydrochloride (Pierce) before image capture. Binding to a hydrazine fluorophore was visualized by adding rhodamine B hydrazide (final concentration 1 mM) was added to crude lysates for 1 h at room temperature, before SDS-PAGE and electrophoretic transfer to nitrocellulose as before. The blot was then visualized using a GE Typhoon scanner (532 nm laser, 580 bp 30 filter, 400 PMT voltage).

Spot Synthesis and Assay of HyRe Peptide Variants. Peptides were synthesized as C-terminal adducts to filter paper, and deprotected as outlined in ref 47. A background-binding assay was completed by incubating the sheets of spot-synthesized peptides with SAV-HRP, before visualization with BCIP/NBT. The AP substrates, BCIP (135 mM in DMF) and NBT (61 mM in 70% DMF), were added to AP buffer (100 mM Tris, 100 mM NaCl, 2 mM $MgCl_2$, 0.05% Tween-20, pH 9.5) to a final concentration of 445 μM and 403 μM, respectively. This buffer was added to the spot-synthesized peptide cellulose sheets, and incubated for 5 min. After washing five times, images of the sheets were captured by digital photography under white light illumination. Peptides specifically binding to biotin hydrazide were then assayed by incubating biotin hydrazide (0.17 mM) in PBS for 2 h. The sheet was then washed five times (50 mL, 2 min each), before readdition of SAV-HRP, revisualization with BCIP/NBT, and reimaging.

HyRe Peptide Synthesis and Reaction with Hydrazide Derivatives. Peptides **103** and **114** were synthesized on a 0.2 mmol scale using standard solid-phase peptide synthesis with Fmoc-protected amino acids (Aroz technologies) on Rink amide resin (Novabiochem). The synthesized peptides were cleaved, purified, and characterized, using standard conditions (Figures S7 in Supporting Information). The purified peptides were resuspended in water before dilution into PBS to a 1 mM final concentration. The hydrazides dissolved in DMSO were then added to each peptide (1 mM final concentration), and incubated at room temperature for 1−3 h before desalting with C_{18} peptide desalting Zip-Tips (Varian; Palo Alto, CA) and characterized by MALDI-TOF MS.

RESULTS

Selections of Hydrazide Ligands from a Phage Library. The naïve, M13 phage-displayed peptide library included ∼2.5×10^{10} unique sequences fused to the major coat protein, P8. This collection of peptide sequences included 22 different configurations of disulfide-constrained peptide libraries and one linear peptide library, ranging in length from 8- to 20-mers[37,38] (Table S1 in Supporting Information).

Molecular display selections can sometimes fail due to deleterious amplification of "background binding" peptides; such peptides are selected for binding to either the solid support or blocking agents employed during selection, and do not specifically bind to the target. Background binding peptides are removed from the phage library through antiselections using similar selection conditions without the target. Thus, before each round of selection, an antiselection with Boc-hydrazide Tentagel removed peptides with an affinity for Tentagel. The antiselected phage library was added to a second aliquot of deprotected hydrazide Tentagel, and used to select phage-displayed peptides with affinity for hydrazide (Figure 1A). This water-miscible solid support enables stringent wash steps to remove nonspecific binding peptides during positive selections. Up to half a liter of different wash buffers was applied to 20 mg of resin during each round of selection. Additionally, in an effort to ensure capture of oxidized peptides, the phage library was subjected to treatment with sodium cyanoborohydride ($NaCNBH_3$), and washes of varying pH. The reactive carbonyl-hydrazide reaction is reversible at low pH,[39] which in round 1 provided a route to selectively elute bound phage from the Tentagel. Sodium cyanoborohydride will reduce hydrazones, [40] permanently linking the selected phage to the Tentagel. After five rounds of increasingly stringent selection conditions (including shorter reaction times, lower concentration of target resin, and increasing numbers of longer washes), the amino acid sequences of 74 phage-displayed, hydrazide interacting peptides were determined by DNA sequencing to yield 58 distinct sequences (Table S2 in Supporting Information).

In round 1, 4.4×10^7 phage were isolated, but more stringent conditions in round 2 reduced the phage titers to 6.6×10^5 plaque forming units, and 2.2×10^6 phage colonies in round 3. The titers then equilibrated to 1×10^7 for the final two rounds of selection. More importantly, 30% of the first round of selection was identified as empty phagemid by sequencing, whereas 0% of the selectants in rounds 2−5 were empty phagemid. The reduced presence of empty phagemid in the selected pool demonstrates a successful selection for functional phage-displayed peptides.

The success of molecular display selections can be gauged by sequence homology and other trends in the sequences of selectants.[41] In selections for binding to hydrazide Tentagel, hydrophilic amino acid side chains were enriched during selections, and hydrophobic amino acid side chains were almost entirely absent from the selected sequences. Furthermore, the sequences from selection rounds 3−5 were entirely derived from 2 of the 23 peptide scaffolds, $X_7CX_4CX_7$ and $X_6CX_7CX_5$ (where X represents any of the 20 naturally occurring amino acids). Several peptides appeared in multiple rounds of selection, including peptide **25**, identified in selection rounds 2 through 5, and peptide **53**, which accounted for ∼30% of the isolated sequences from the final 2 rounds of selection.

Next, peptides with potentially higher affinity for hydrazide were selected using homologue shotgun scanning. This method applies a protein-based, medicinal chemistry approach with a library composed of either the wild-type or closely homologous amino acid.[42,43] This library strategy focuses peptide diversity space, and selects for subtle side chain substitutions that can collectively contribute large effects to binding affinity. Additionally, conserved residues during these selections can indicate functionally important side chains.

Chosen for its high frequency among the initial selectants, peptide **53** formed the basis for a homologue shotgun-scanning library. Unlike previous homologue shotgun-scanning libraries, each amino acid position encoding His, Arg, or Lys was substituted with a library codon encoding His, Lys, Arg, Asn, Ser, Pro, or Gln. These additional amino acid residues were included for their observed importance in hydrazide binding from the initial library selectants. Reaction-based selections analogous to those described above isolated an additional 23 hydrazide interacting peptides (Table S2 in Supporting Information). Peptide **61** was identified in homologue shotgun scanning rounds 2 through 4, and peptide **78** dominated round 4,

accounting for 60% of the selectants. Additionally, valine at position 17 and glutamic acid at positions 11 and 13 were highly conserved, suggesting the importance of those residues for hydrazide binding (Figure S1C in Supporting Information).

Notably, highly enriched peptides, **61** and **78**, include only one cysteine residue. Thus, the intramolecular disulfide bonds engineered into the naïve libraries appeared unnecessary for hydrazide binding. This result contrasts with previous studies in which intramolecular disulfide bonds in peptides selected from phage-displayed peptide libraries contribute critical stability to peptide structure for target binding.[44,45] This observation presented the opportunity, explored below, to eliminate cysteine residues in chemically synthesized versions of the selected peptides.

Typically, screens examining the functionality of individual phage-displayed selectants quantify the relative binding abilities of selectants from a library. Conventional screens for hydrazide binding with phage-displayed peptides proved problematic due to cross-reactivity between biotin hydrazide and contaminants remaining in the phage solutions, likely oxidized proteins. Two screening approaches explored the capabilities of the selected hydrazide interacting peptides. First, the gene for peptide **53** was fused to a test protein T4 lysozyme for colorimetric assays. Second, peptides and peptide variants from both the original selections and the homologue shotgun scanning selections were spot-synthesized on filter paper.

Hydrazide Binding to Peptide-T4 Lysozyme Fusions. To test the reaction specificity of the selected peptides, the frequently selected peptide **53** was subcloned into an expression plasmid (pET-28c, Invitrogen) as an N-terminal fusion to the enzyme T4 lysozyme. The purified fusion protein was then treated with biotin hydrazide (1 mM) for two hours at room temperature in aqueous buffer (PBS at pH 7.2). SDS-PAGE and subsequent binding assay of the lysozyme fusions, either treated or untreated with biotin hydrazide, demonstrated that fusion to peptide **53** conferred biotin−hydrazide binding ability (Figure 3, lanes 1−2). Sustained affinity during the denaturing conditions required for SDS-PAGE (95 °C in SDS) can provide evidence for covalent labeling of peptide−probe interactions (e.g., the bis-arsenical tetracysteine peptide reaction).[10] Therefore, additional mass spectrometry-based experiments were performed to identify the covalent adducts formed by hydrazide reactive (HyRe) peptide **53** and its variants reacting with hydrazide derivatives.

As might be expected for fusions to a well-folded protein separated by a glycine linker (amino acid sequence of GGGSG), the peptide lysozyme fusions are susceptible to proteolysis (Figure 3, lanes 1−2). HyRe peptide **53** is completely removed from the N-terminus of lysozyme by endogenous protease activity (Figure 3, lanes 3−4), as confirmed by MALDI-TOF mass spectrometry (Figure S2 C in the Supporting Information). Proteolytic removal of the HyRe tag prevents reaction with biotin hydrazide (Figure 3B, lane 3), and no signal is observed in the biotin-binding assay. Comparable results are observed for the negative control, treatment of wild-type lysozyme with biotin hydrazide (Figure 3B, lanes 5−6). Selective proteolysis from the N-terminus of lysozyme demonstrates that biotin hydrazide reacts site-specifically with the HyRe tag and not with the other amino acids of lysozyme.

Additionally, rhodamine B hydrazide reacts exclusively with the **53**−lysozyme fusion protein in crude *E. coli* lysate (Figure 3D). Following SDS-PAGE and electrophoretic transfer to nitrocellulose of the crude lysate reaction mixture, the fluorescent probe labels only the fusion protein. Taken together, the experiments with lysozyme fusion show that two different hydrazide derivatives selectively label HyRe peptide **53**. Therefore, further characterization of the interaction between HyRe peptide tags and hydrazide-containing probes focused on a covalent reaction.

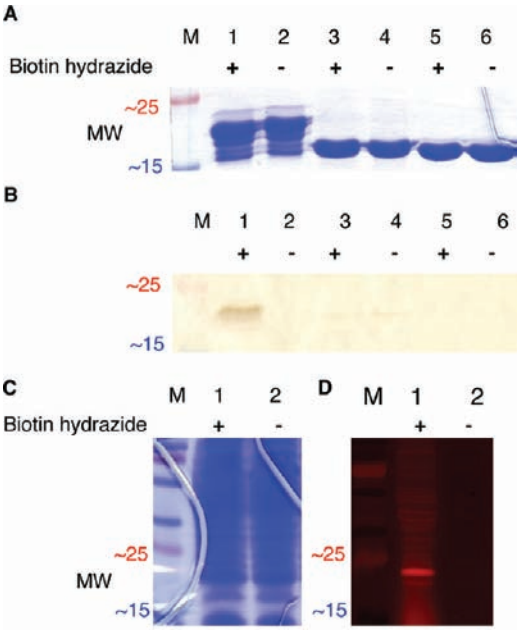

Figure 3. (A) SDS-PAGE of the purified **53**−lysozyme fusion protein (22.3 kDa in lanes 1−2), the fully proteolyzed **53**−lysozyme fusion protein (19.2 kDa in lanes 3−4), and wild-type lysozyme (18.6 kDa in lanes 5−6). Each sample was either treated (+) or untreated (-) with biotin hydrazide (1 mM) for 1 h at room temperature before electrophoresis. (B) Western blot analysis for biotin hydrazide labeling the purified **53**−lysozyme fusion protein. The protein gel and Western blot, excerpted for clarity here, are shown in full in Figure S2 in Supporting Information. (C) SDS-PAGE of the **53**−lysozyme fusion protein in crude *E. coli* lysates, either treated (+) or untreated (-) with 1 mM rhodamine B hydrazide before separation by SDS-PAGE. (D) The protein lysate shown in (C) was then transferred electrophoretically to nitrocellulose, and imaged by fluorescence scanning. "M" indicates molecular weight standards.

Spot Synthesis of Hydrazide-Interacting Peptides. Peptides **61**, **78**, and **53** and variants of all three were chemically resynthesized using spot synthesis. In this technique, each peptide is covalently attached as a C-terminal fusion to spatially segregated positions on a cellulose membrane.[46,47] Spot synthesis allows for the simultaneous fabrication and screening of hundreds of different peptides in a format free from biological contaminants such as post-translational modifications by enzymes (e.g., formylglycine-generating enzyme)[34] or reactive carbonyl-containing metabolites (e.g., pyridoxal phosphate).[48,49] The synthesized analogs of peptides **61** and **78** included sequential 10-mers and single-site alanine substitutions. Scanning sequential 10-residue peptides could identify smaller active sequence of the HyRe tag. The spot-synthesized variants of peptide **53** included all 1, 2, 3, and 4 contiguous amino acid deletions. Additionally, the homologue shotgun scanning results suggested substitution of serine for cysteine in the HyRe peptide tags. Three different spot synthesis cellulose sheets containing over 350 different variants were synthesized and screened for

binding to biotin hydrazide (Figures S3−S5 in Supporting Information).

Following deprotection of the spot-synthesized peptides, the relative binding affinity for biotin hydrazide was assayed by treatment with streptavidin conjugated to alkaline phosphatase (SAV-AP) and developed through addition of the AP substrates 5-bromo-4-chloro-3-indolyl phosphate (BCIP) and nitrotetrazolium blue (NBT). The levels of SAV-AP activity in each spot can provide an estimate of the efficiency of each peptide in the reaction with biotin hydrazide. However, many factors can influence the signal intensity at individual spots including peptide synthesis failure and purity.[50] Additionally, identical sequences in different locations on the filter paper produced slightly variant levels of reactivity with hydrazide (see HyRe tag **53** in Figure 4). Thus, the qualitative analysis of spot synthesis reported here focuses on trends and requirements for hydrazide−peptide reactivity.

Testing all possible contiguous 10-mers from both HyRe tags **61** (peptides 80−90) and **78** (peptides 91−101) revealed the importance of the N-terminal amino acids for reactivity with biotin hydrazide (Figure S6 in Supporting Information). The 10-residues at the N-terminus of peptide **78**, labeled peptide **80**, resulted in the highest overall signal intensity for reaction with biotin hydrazide on spot synthesis sheet 1, a result confirmed through duplicated synthesis and screens (Figure 4). However, peptide **80** also exhibited high background signal in the SAV-AP assay. This independent assay for background included all steps except treatment with biotin hydrazide, and measures peptide interaction with SAV-AP or the ability of the peptides to dephosphorylate BCIP.

The spot synthesis screens guided the synthesis of HyRe tags with both reactivity toward biotin hydrazide and reduced background binding. For example, HyRe peptide **91**, the N-terminal 10 residues of HyRe tag **61**, reacted efficiently with biotin hydrazide, but also had high background binding to SAV-AP. Further minimization via spot synthesis and screening identified HyRe peptide **102**, an 8-mer peptide derived from HyRe tag **61**, which resulted in the highest specific reactivity with biotin hydrazide relative to background levels. HyRe tag **102** includes one cysteine residue; therefore, the Cys7Ser substitution, peptide **103**, was also spot-synthesized. This cysteine-free 8-mer peptide produced a signal equivalent to peptide **102**, and also exhibited little background in the SAV-AP assay (Figure 4). Thus, as observed by homologue shotgun scanning, cysteine residues from the original selected HyRe tags can be omitted in homologue variants of peptide **53** without drastically reducing reactivity with biotin hydrazide.

Single-point alanine substitutions of every residue in HyRe **61** and **78** had little effect on the qualitative reactivity of HyRe peptides with biotin hydrazide. Given the relative insensitivity for single-point alanine substitutions, we next examined contributions made by each type of amino acid side chain to HyRe tag function by substituting all occurrences of each amino acid with alanine (Figure 4). For example, peptide **104** substituted all four threonines of peptide **53** with alanine. Subsequent reaction with biotin hydrazide and assay of the ten spot-synthesized peptides demonstrated the critical importance of arginine, histidine, and lysine side chains. Conversely, HyRe peptide **110** substituted Ala in place of both Glu residues, and resulted in increased background binding to SAV-AP. The importance of glutamic acid in position 11 also correlates to the conserved glutamic acids observed in homologue affinity selections (Figure S1 in Supporting Information). The spot-synthesis results guided the choice of peptides for large-scale synthesis.

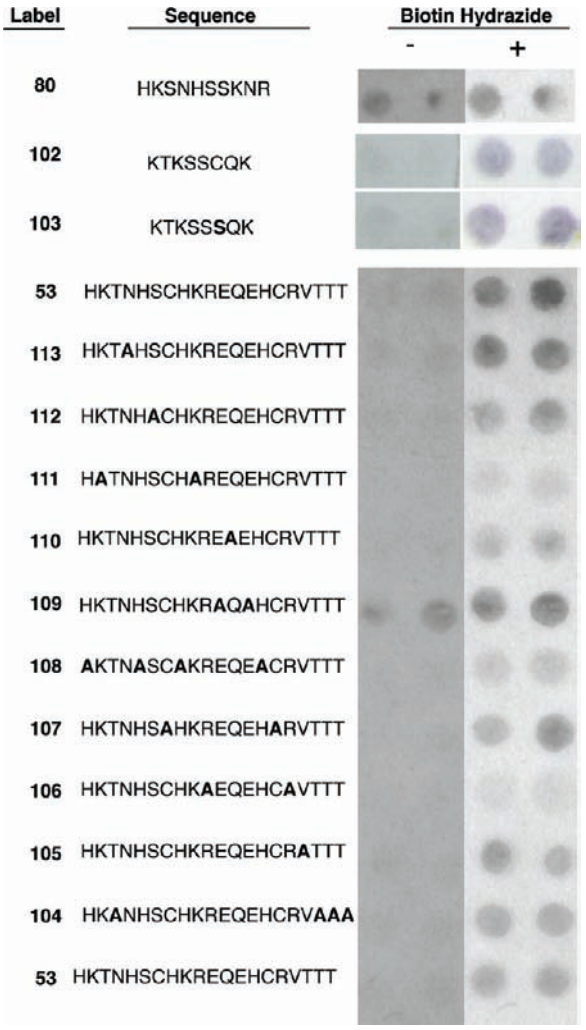

Figure 4. Variants of selectant peptides were spot-synthesized and either treated (+) or untreated (-) with biotin hydrazide before binding to SAV-AP and visualization through addition of the AP substrate. The N-terminal 10-mer from peptide **78** produces a nonspecific signal in the SAV-AP assay. An 8-mer from peptide **61** produces a specific signal for biotin hydrazide, as does the Cys7Ser substituted 8-mer, **103**. Each type of amino acid in peptide **53** was substituted with alanine to identify key side chain functionalities required for the interaction with biotin hydrazide, while the other residues of peptide **53** remained unchanged. Bold letters indicate substitutions in the selected peptides.

Synthesis and Mass Spectrometry Analysis of HyRe Peptides. Two peptides identified initially from phage selections with hydrazide Tentagel and then minimized by screening spot-synthesized peptides were chosen for additional analysis: peptide **114**, the N-terminal 11-residues from peptide **78** including the specificity determining Glu11, and peptide **103**, residues 2 through 9 with the Cys7Ser substitution of HyRe peptide **61**. After conventional solid-phase peptide synthesis, HPLC purification, and MALDI-TOF MS confirmation (Figure S7 in the Supporting Information), the synthesized HyRe peptides were treated with 12 different hydrazide-containing small molecules (structures shown in Figure S8) at equimolar concentrations (1 mM) in PBS, pH 7.2. The reactions were monitored by

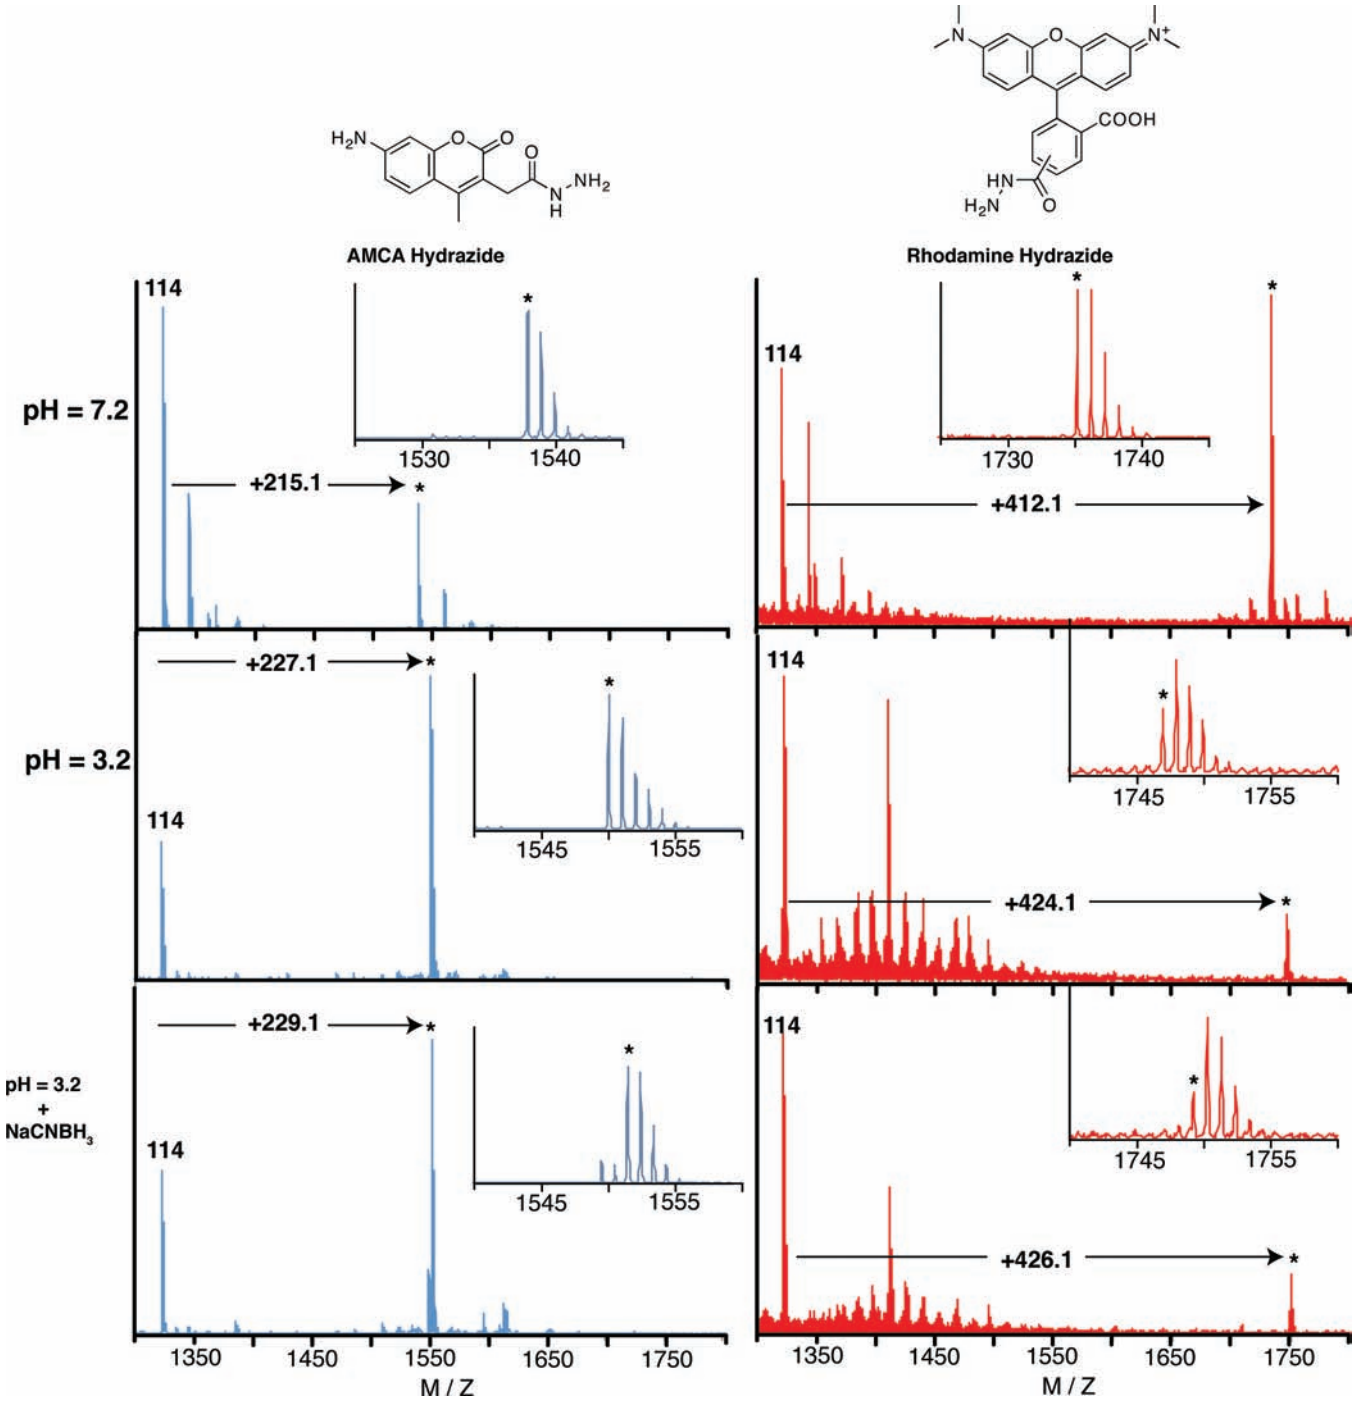

Figure 5. Treatment of peptide **114** with two hydrazide-containing probes. Treatment with AMCA hydrazide at pH 7.2 produces a species with an additional mass of 215 mass units. However, treatment at pH 3.2 produces an adduct with an additional 227 mass units, which can be reduced with $NaCNBH_3$. Treatment of **114** with rhodamine B hydrazide produces similar species at both pH 7.2 and 3.2, as well as upon reduction. The peaks marked with an asterisk (*) are the new adducts observed upon treatment with the hydrazide-containing probes.

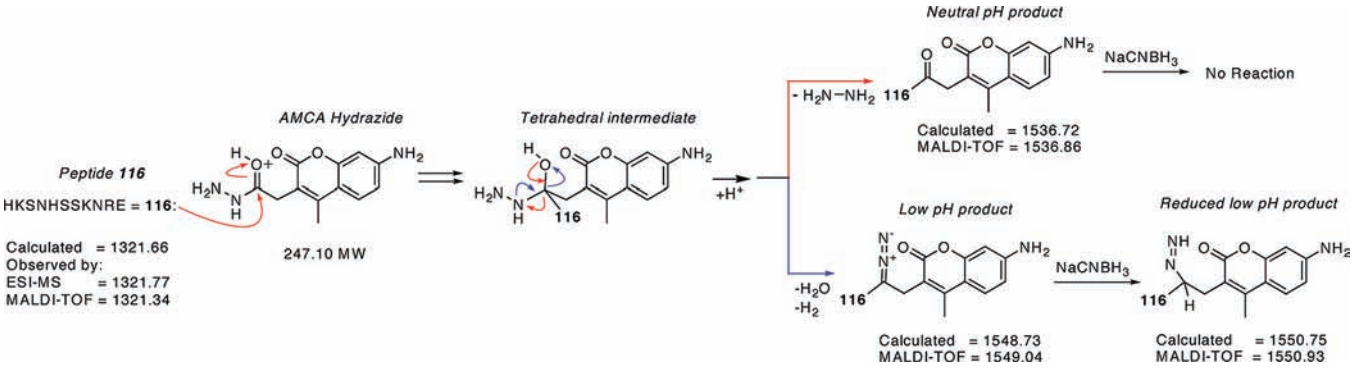
MALDI-TOF mass spectrometry (Figure 5). Interestingly, only AMCA hydrazide (aminomethylcoumarin acetate hydrazide) and rhodamine B hydrazide produced new mass adducts with either peptide.

At pH 7.2, both HyRe peptides reacted with AMCA hydrazide to produce adducts with identical additional mass. The discussion here focuses on peptide **114**, though similar results were observed for reactions of AMCA hydrazide with HyRe peptide **103** (Figures S7 in Supporting Information). Treatment of HyRe peptide **114** with AMCA hydrazide, followed by analysis with MALDI-TOF mass spectrometry, identified a new compound with an additional mass of 215 amu (Figure 5). Similarly, treatment of peptide **114** with rhodamine B hydrazide produced a new compound with an additional mass of 412. Both probes yield products with masses 32 amu less than the sums of the peptides and probes. The observation of new probe-specific

Scheme 1. Proposed Mechanism for the Reaction between HyRe Tag 114 and AMCA Hydrazide[a]



[a] At pH = 7.2, loss of hydrazine justifies the observed loss of 32 mass units. At acidic pH (3.2 to 6.0), the loss of 20 mass units most likely results from a dehydration plus additional oxidation, to yield a product capable of reduction by $NaCNBH_3$.

higher-molecular-weight adducts is evidence for a single, covalent bond-forming reaction between the selected peptide and hydrazide reagents. Furthermore, the difference in mass provides insight into the reaction mechanism.

MSMS analysis of the neutral pH peptide **114**-AMCA hydrazide reaction reveals that the modification was restricted to daughter ions containing His1 and was absent from fragments lacking this residue. For example, a modified b-ion of the first residue (m/z = 481.2) was observed, while the y″-ion corresponding to residues 2−11 (lacking His1) possessed zero modifications (m/z = 1185.6). Additionally, both modified and unmodified b ions are observed for every residue, while no modified y″ ions were observed. Therefore, the modification resides on the N-terminal histidine. This bond between AMCA hydrazide and the peptide is labile to MSMS conditions as some unmodified ions are observed in the mass spectrum. This result was also observed in the analysis of the reaction product between **114** and rhodamine B hydrazide.

Addition of the hydrazide derivatives to HyRe peptide **114** followed by loss of hydrazine (32 amu) could account for the observed mass of the product (Scheme 1). In this proposed mechanism, the imidazole of the N-terminal His attacks the hydrazide carbonyl. Subsequent collapse of the tetrahedral intermediate displaces hydrazine. Additionally, since the leaving group hydrazine has not been directly observed, oxidation of the hydrazine, prior to displacement, could contribute to the mechanism.

Notably, the HyRe peptide−hydrazide reaction takes place under mild conditions. The reaction occurs in aqueous buffer, at room temperature and physiological pH. No transition metal ions, organic solvents, and other proteins or cofactors are required. A peak corresponding to the adduct can be observed in the MALDI-TOF mass spectrum essentially immediately after the peptide and AMCA hydrazide are mixed, desalted, and applied to the mass spectrometer.

The reaction product could not be detected by reverse-phase HPLC or pH-neutral, ion-exchange chromatography. The reaction produces sufficient product for detection by fluorescence (peptide **53** fused to lysozyme in Figure 3), spot synthesis assays (Figure 4), and MS (peptide **114** in Figure 5). However, insufficient product is obtained for spectroscopic analysis, including HPLC detection. The MS analysis benefits from concentration by the desalting Zip-Tips for sample preparation. Furthermore, the Zip-Tips appear to enrich for the product of the reaction with hydrazide, as the very hydrophilic HyRe peptide **114** is incompletely retained by C_{18} Zip-Tips (data not shown). However, after modification with either of the hydrophobic hydrazide fluorophores, the peptides could be preferentially retained on the Zip-Tips. Alternatively, the covalent products from the hydrazide reaction could be initiated by the MS conditions; however, MS is typically used to characterize covalent bonding. Despite these caveats, the interaction between the HyRe peptides and hydrazide derivatives is sufficiently strong for various previously described assays.

The sensitivity of using MALDI-TOF mass spectrometry provided a method to investigate the basis for the selection of these peptides from the phage-displayed peptide libraries. As described above, the selections featured both washes with pH 5 buffer and the addition of $NaCNBH_3$ in an attempt to select reactive carbonyl containing peptides. However, the electrophilic modification of the N-terminal His complicates interpretation of the selection conditions. Specifically, the imidazole side chain should be largely protonated at pH values <6, thus preventing modification on this side chain at low pH.

MS screening of conditions between pH 3 and 11 identified a new product formed at low pH values. For pH values ≤6, a different product resulted from the treatment of peptide 114 with AMCA and rhodamine B hydrazide. AMCA hydrazide added 227 and rhodamine B hydrazide added 424 amu (Figure 5). Both modifications result from the loss of 20 amu following addition of the probe to the peptide. Such conjugates could result from a condensation (−18 amu) accompanied by an additional oxidation (−2 amu). Additionally, these products from the low pH reaction, unlike the analogous neutral pH products, are reducible upon addition of $NaCNBH_3$, producing new adducts with +2 additional atomic mass units (Figure 5 and Scheme 1).

MSMS of the products from the low pH reaction of peptide **114** with AMCA hydrazide reveals that the fluorescent probe covalently attaches to a different amino acid, than was observed for neutral pH (Figure 6). MSMS analysis of the products from the AMCA hydrazide reaction demonstrates modification of the Ser6 side chain. Thus, the modification has switched residues from His1 at neutral pH to Ser6 at pH 5. This observation suggests a different mechanism for the selection of HyRe peptides from the phage-displayed peptide libraries. Consistent with the observed $NaCNBH_3$ reduction, a diazo compound or other imine-containing isomer could be formed.

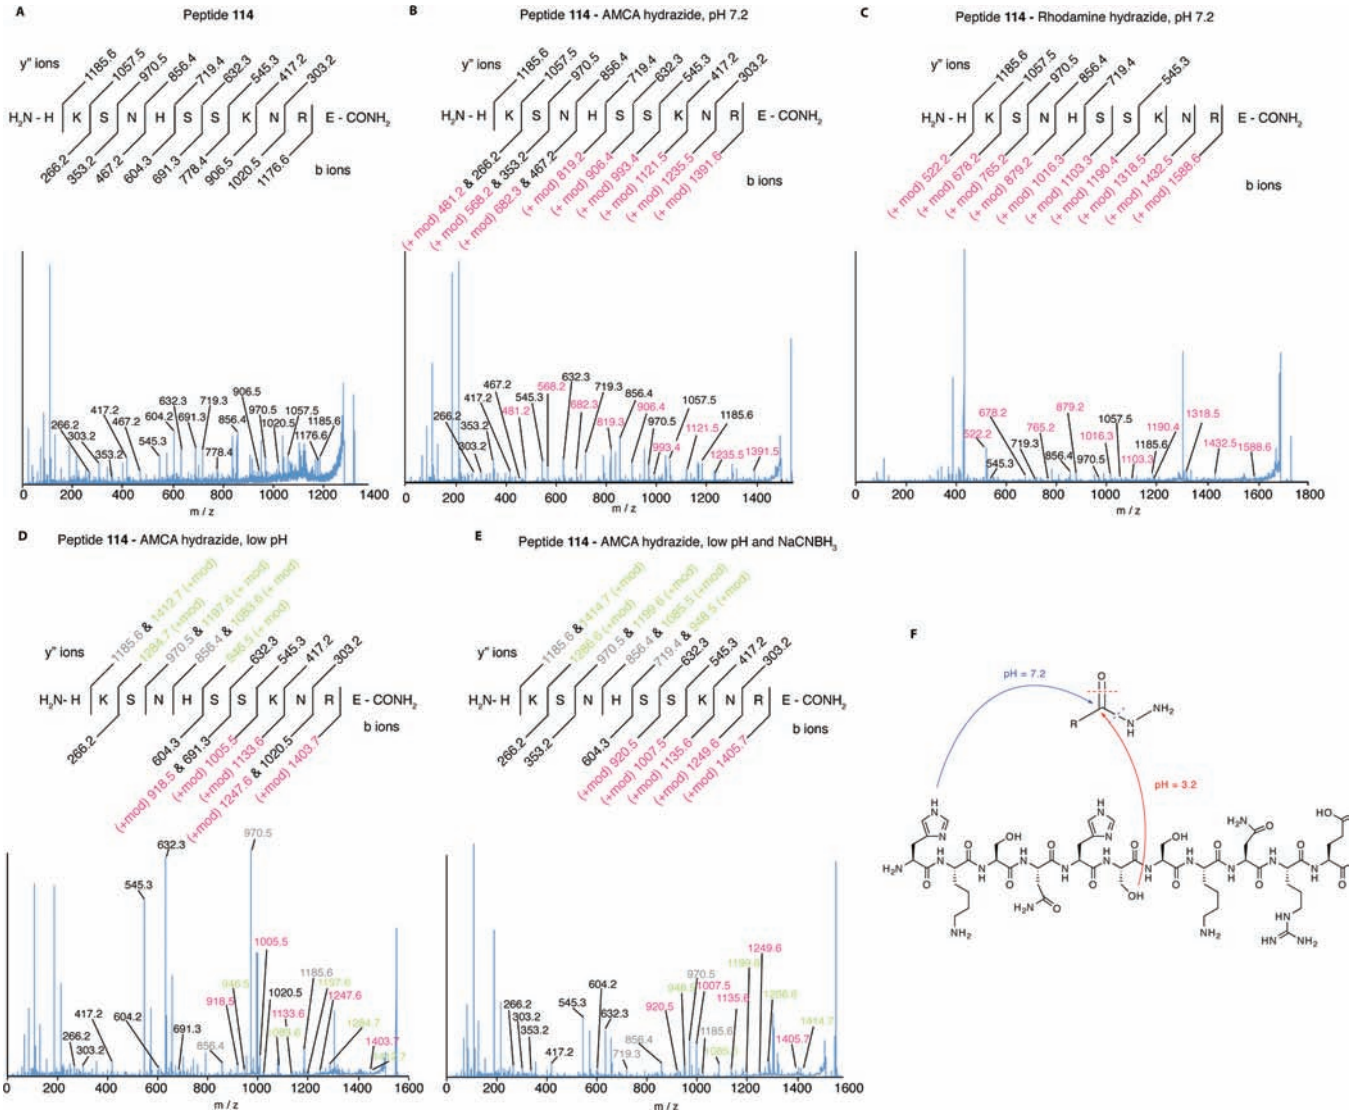


Figure 6. MSMS of products from the reaction of peptide **114** with AMCA and rhodamine B hydrazides. (A) MSMS of unmodified peptide 114 reveals all expected b and y″ ions. (B,C) MSMS of both the AMCA- and rhodamine-modified peptides reveals an unmodified set of y″ ions and a complete set of modified b ions indicating the covalent modification (+mod) occurs on the side chain of the N-terminal histidine. (D) MSMS of the reaction product at low pH and (E) following reduction with $NaCNBH_3$ product indicates that the covalent modification occurs on Ser6. The MSMS chromatogram of peptide **114** modified with rhodamine B hydrazide at low pH was dominated by rhodamine cleavage adducts (data not shown). (F) Schematic diagram for the observed covalent modifications.

In conclusion, as shown by the results in Figures 3−6 the selected peptides can react with hydrazide derivatives at a range of different pH values and with sufficient efficiency for detection by MS, spot synthesis, and fluorescence blot assays.

DISCUSSION

The identification of short, stand-alone peptides capable of directing SSPL reactions remains a major challenge in modern chemical biology. The HyRe peptides offer an important step toward the goal of short peptides composed of naturally occurring amino acids that can react with hydrazide-based probes without requiring additional enzymes or reagents. The short sequence length of the peptides identified here and the availability of hydrazide-containing chemical probes suggest that HyRe tags could be used in a large number of applications with minimal perturbation, if the sequences are further optimized. As demonstrated here, HyRe peptide tags are capable of selectively detecting fusions in crude cell lysates on Western blots (Figure 3).

Selection and screens required careful planning to minimize false positives. To avoid the selection of streptavidin-binding peptides, streptavidin was omitted from the selection protocols. Thus, no sequences commonly associated with streptavidin binding were observed (e.g., HPQ-based sequences).[41] Thus, any background binding in the spot synthesis results reflects nonspecific interactions with SAV-AP or other components of the binding assay. Furthermore, the spot synthesis results clearly demonstrate the importance of 20-mer peptides for high-specificity interactions between HyRe peptides and hydrazide derivatives. Shorter peptides were more likely to result in higher background assay levels.

Though the HyRe peptides react with different hydrazide bearing probes, the results reaffirm the adage, "you get what you

screen [and select] for."[51] The selection conditions targeted hydrazide-derivatized Tentagel, which includes a linker between the PEG and the surface-exposed hydrazides. The resultant HyRe peptides also required an additional carbonyl at the γ-carbon of the hydrazide, found in both AMCA and rhodamine B hydrazide, for the covalent reaction observed by MS. Thus, the selection conditions isolated peptides requiring a functionality analogous to the linker of the targeted Tentagel. Interestingly, amide linkers have been found to participate in other examples of reaction discovery.[52,53] Though designed to specifically capture reactive carbonyl-containing peptides, the selection conditions described here identified peptides that react with hydrazide derivatives at neutral and low pH values, and subsequently with $NaCNBH_3$.

Contrary to expectations, the selected peptides provide a nucleophile to react with the carbonyl of the hydrazide functionality. The HyRe tag-hydrazide reactivity reported here is analogous to acylhydrazide inhibitors of cathepsin K, in which an active site nucleophilic thiol forms a reversible covalent bond with the acylhydrazide carbonyl. Though the covalent bond in this example could be observed by X-ray crystallography, the lability of the resultant adduct prevented product isolation by both dialysis and HPLC. Similarly, the efficiency of the hydrazide reaction by our selected peptides was insufficient for detection by HPLC.

In conclusion, this report demonstrates the reactivity of HyRe peptides composed of naturally occurring amino acids, which were selected from two generations of combinatorial libraries. As fusions to filter paper and lysozyme, the HyRe peptides react with both biotin hydrazide and rhodamine B hydrazide, respectively, to provide detectable adducts. Such reactions can provide an immediately usable method for labeling a single protein in complex mixtures, such as the cell lysate in Figure 3D. In the future, the reaction of the HyRe tags with hydrazide derivatives could provide a powerful new tool for bioconjugate synthesis and *in vivo* protein labeling.

Additional Experimental procedures

All reagents were purchased from Sigma Aldrich (Milwaukee, WI), and used without further purification. M13 phage display libraries were re-propagated using KO7 helper phage from New England Biolabs (Ipswich, MA). Boc-hydrazide Tentagel and nitrotetrazolium blue (NBT; a substrate for AP) were purchased from Acros Organics (Geel, Belgium). AMCA hydrazide, streptavidin conjugated to alkaline phosphatase, high-sensitivity streptavidin conjugated to horseradish peroxidase, and chloronapthol and diaminobenzidine (CN/DAB) (AP substrate) were purchased from Pierce (Piscataway, NJ). The gene for T4 lysozyme (mutant C54T and C97A) was a gift from Prof. Bryan Matthews (University Oregon). DNA sequencing was performed by GeneWiz (South Plainfield, NJ).

Primers used in this study:

LysPetR2 5'-ATAGCCCTCGAGCTATTACGGTAGATTTTTATACGCGTC-3'

Degenerate bases in Homolog**53** are named in accordance with IUBMB conventions.

Construction of the homolog shotgun scanning library

The homolog shotgun scanning library of HyRe tag 53 was generated using Homolog**53** oligonucleotide targeting the pM1165a phagemid[1] for site-directed mutagenesis using previously reported protocols.[2]

Selections with homolog shotgun scanning library

The phage-displayed peptide library was incubated with Boc-hydrazide Tentagel (50 mg in 10 mL PBS) for 1 h at room temperature in a peptide reaction vessel. The filtrate was transferred to a new vessel, and incubated with hydrazide Tentagel for 20 to 60 min with decreasing concentrations of deprotected resin for each round of selection. The resin was washed six times with PBS (50 mL for 6 min). Additional washes included pH = 5.6 PBS (50 mL for 20 min) and HCl (0.1 M, 50 mL for 10 min). The phage-resin mixture was then pH-buffered with a final PBS wash (50 mL, 10 min), and were re-propagated and titered, as previously described.[2]

HyRe peptide fusions to T4 lysozyme

PCR with primers LibPetR and LibPetF amplified the genes encoding the peptides from the selected phage and incorporated an NcoI site at the 5'-terminus of the amplicon. The gene for T4 lysozyme with mutations C54A and C97T was amplified using primers LysPetF1 and LysPetR2, which incorporates a stop codon and an XhoI site at the 3'-terminus of the amplicon. The primers LibPetR and LysPetF both include complementary regions for gene synthesis by overlap extension PCR. The pET-28c(+) plasmid (Novagen) and the purified gene synthesis product were digested with the restriction enzymes NcoI and XhoI (New England Biolabs). The digested products were mixed and ligated using T4 DNA ligase (New England Biolabs) by incubation in ATP-supplemented buffer at 16 °C for 16 hours. The crude ligation product was transformed into

heat shock competent XL-1 *E. coli* cells, and plated onto Luria Broth (LB) agar plates supplemented with kanamycin (40 μg/mL) for overnight incubation at 37 °C. The DNA sequences of the resultant colonies were confirmed using T7 primers.

Synthesis of Rhodamine B hydrazide

Rhodamine B hydrazide was synthesized by adding tert-Butyl carbazat to NHS rhodamine B (Pierce), deprotecting with 50:50 TFA:DCM, and purifying by reverse phase HPLC.

Synthesis of HyRe peptides

The peptides **114** and **104** were synthesized on 0.2 mmol scale using standard solid-phase peptide synthesis with Fmoc-protected amino acids (Aroz technologies) on Rink amide resin (Novabiochem). The synthesized peptides with a carboxamide C-terminus were deprotected and cleaved from the resin using a mixture of 9.5 mL trifluoroacetic acid, 0.25 mL triisopropylsilane, and 0.25 mL of H_2O at room temperature for 4 h under N_2. The cleavage mixture was filtered from the resin, and precipitated in ice-cold diethyl ether for 20 min. The precipitate was next centrifuged at 3 krpm for 20 min at 4 °C, before being re-suspended in deionized H_2O. The peptides were purified by reverse-phase HPLC with a C_{18} column using a gradient from 100% solvent A (99.9% H_2O / 0.1%TFA) to 50% solvent B (95% acetonitrile / 4.9%H_2O / 0.1%TFA) over 40 min. Fractions containing the purified peptides were combined and concentrated using rotary evaporation, followed by vacuum centrifugation. Purified peptides were subjected to analytical HPLC and MALDI-TOF to verify purity (>80%), and confirm identity, respectively (**Supporting Figs. 7-8**).

MALDI-TOF sample preparation and analysis

After the peptides (1 mM) were treated with Aminomethylcoumarin acetate hydrazide (AMCA-hydrazide) (1 mM) in PBS for 2.5 h, the reaction mixtures were applied to a C_{18} Ziptip (Varian), washed with 0.1% TFA in deionized water, and eluted with a saturated solution of α-Cyano-4-hydroxycinnamic acid (CHCA) in 25% aqueous acetonitrile containing 0.1 % TFA. The eluates were deposited on a stainless steel target. An ABI SciEx TOF/TOF 5800 (Applied Biosystems) system with a reflectron using standard configurations and parameters was used to obtain the MALDI-TOF mass spectra. The averaged spectra were exported to Excel for analysis.

*The column “sib” indicates the number of siblings or identical sequences identified in the same round.

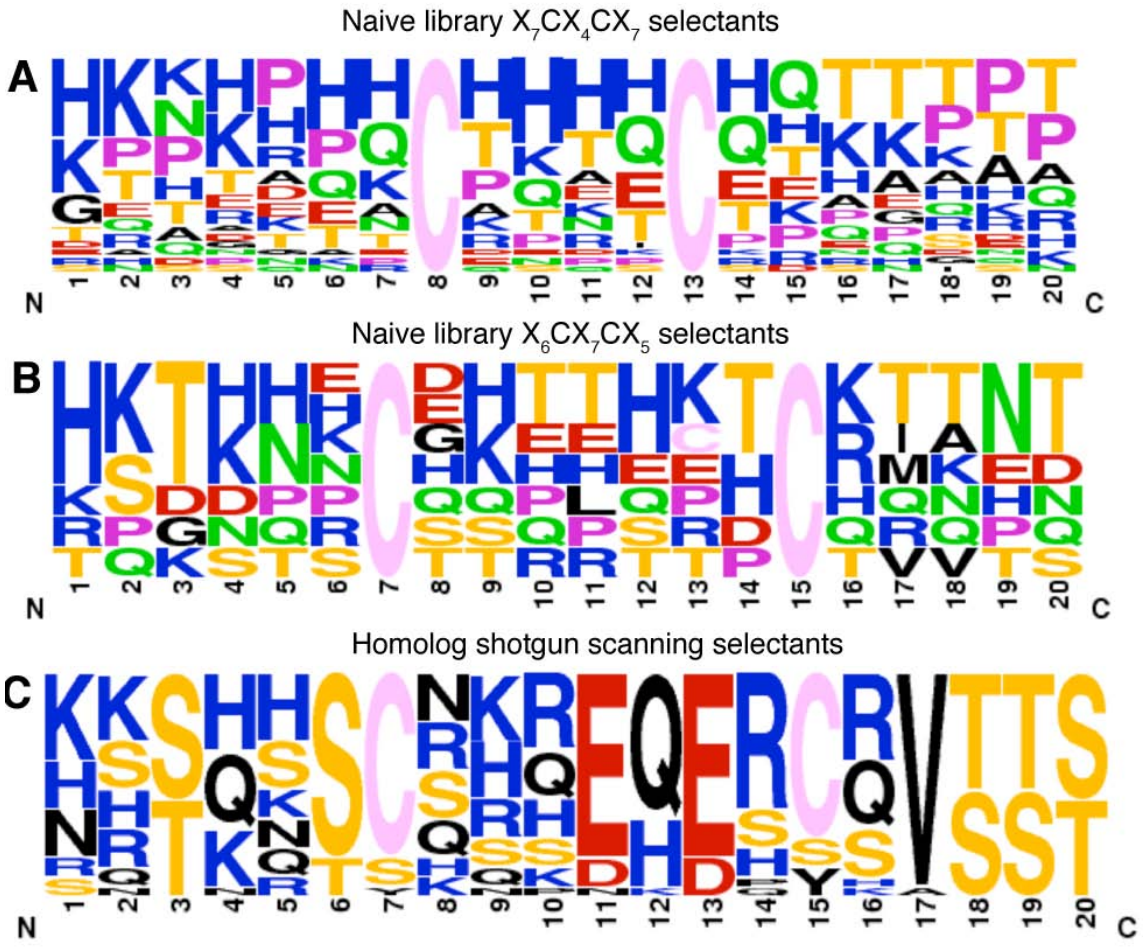

Figure S1. Sequence analysis of selectants from the naïve (A and B) and homolog shotgun scanning (C) libraries (weblogo.berkeley.edu).

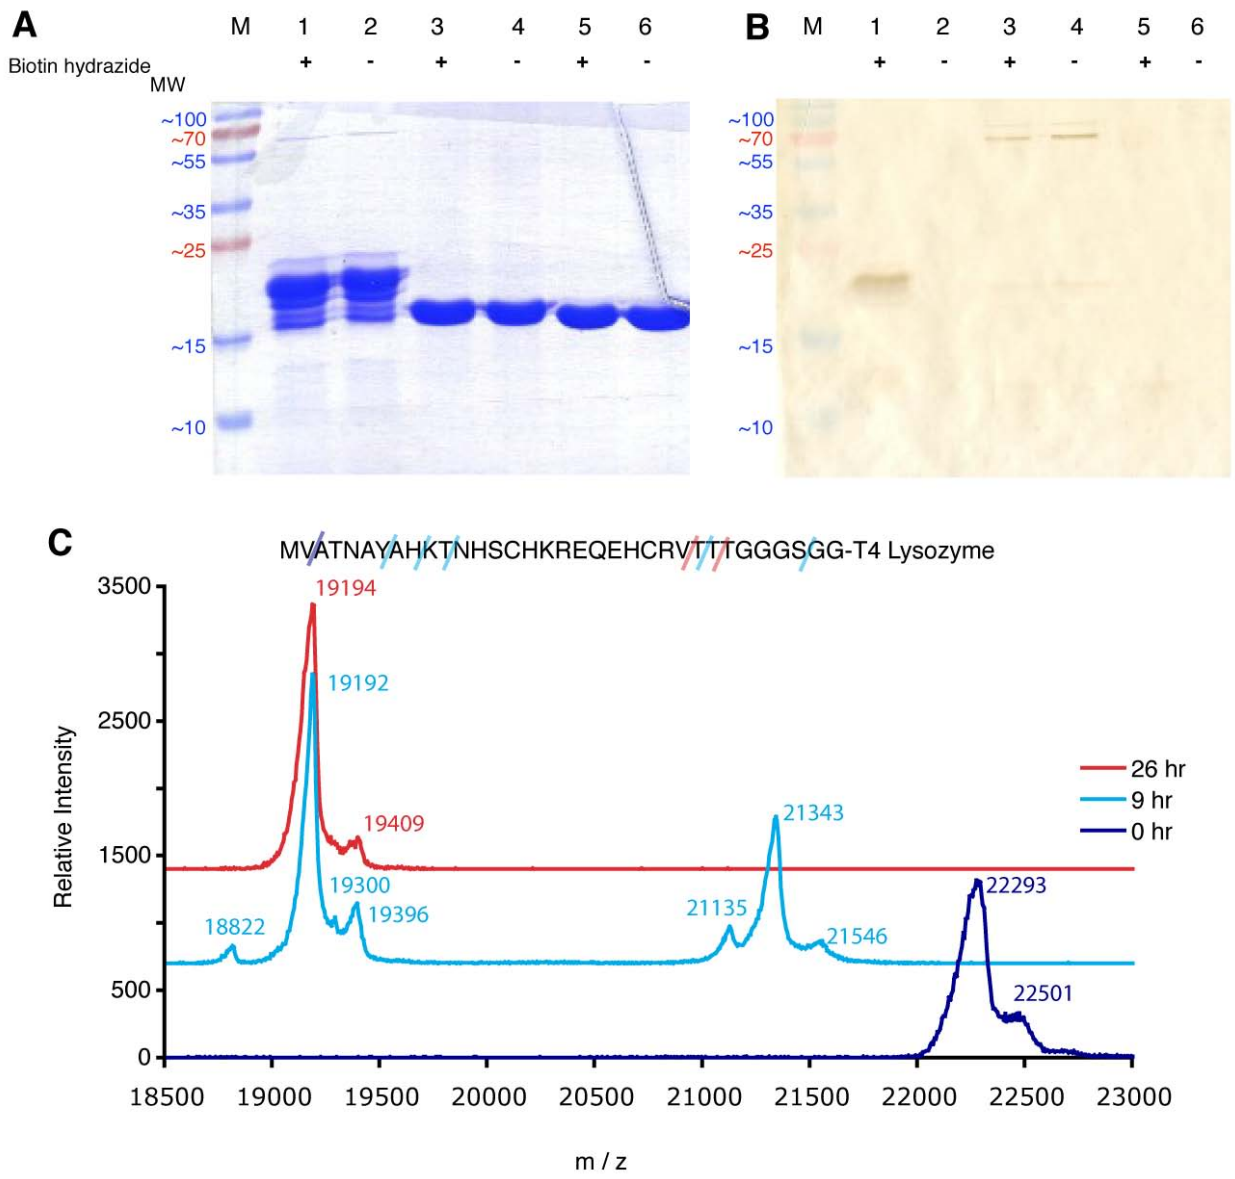

Figure S2. (A and B) The full SDS-PAGE and Western blot of the HyRe **53**-T4 lysozyme fusion excerpted in Figure 3. (C) MALDI-TOF of **53**-T4 lysozyme fusion incubated at room temperature for the indicated times. The MALDI-TOF results indicate that the HyRe tag is specifically cleaved from the fusion. These results also account for the partially proteolyzed fusion proteins after purification apparent in lanes 1 and 2 of the protein gel shown in (A).

Figure S3. Spot synthesis examining variants of peptides **53**, **61**, and **78**. A) After treatment with biotin hydrazide the sheet was developed by exposure to SAV-AP, followed by washing and then addition of AP substrates. B) The synthesized peptide sequences include all single, double, triple, and quadruple contiguous amino acid deletions of HyRe peptide **53** (A2-F12). Variants of HyRe tags **61** and **78** include single alanine substitutions (G3-H10; and I12-K6) and all contiguous 10-mers (H12-I10; and K8-L6). The 10-mers for both peptides **61** and **78** are analyzed and compared in Supporting Figure S4.

Figure S4. Spot synthesis peptide sheet 2. A) Both before and after treatment with biotin hydrazide (indicated with a – or +), the sheet was developed by exposure to SAV-AP, followed by washing and then addition of AP substrates. B) The synthesized peptide sequences include contiguous 9, 8, 7, and 6-mers; single alanine substitutions, single, double and triple amino acid deletions of peptide **80** and **91**. Peptide variants of **80** reveal background binding or no activity. Some of the **91** variants reveal specificity for binding to biotin hydrazide, especially the 8-mer **102** (F10). Additionally, the contiguous 10-mers of original selectants **25**, **53**, **49**, **46** and **50** were also synthesized and screened (H13-M2). Scored through sequences were incorrectly synthesized.

Figure S5. Spot synthesis peptide sheet 3. A) Both before and after treatment with biotin hydrazide the sheet was developed by exposure to SAV-AP, followed by washing and then addition of AP substrates. B) The synthesized peptide sequences include full-length 20-mers from the original phage selections and were synthesized in duplicate (A1-B12). Each type of amino acid was substituted with alanine in HyRe peptides **53** and **46,** and synthesized in duplicate (C1-F12). The most interesting short peptides from spot synthesis peptide sheets 1 and 2 were re-synthesized in duplicate to determine background binding (G1-J12). Cysteine was substituted for alanine in the short 10-mers (I1-J12). The contiguous 10-mer variants from original selectants **51** and **52** were also tested (K1-L12).

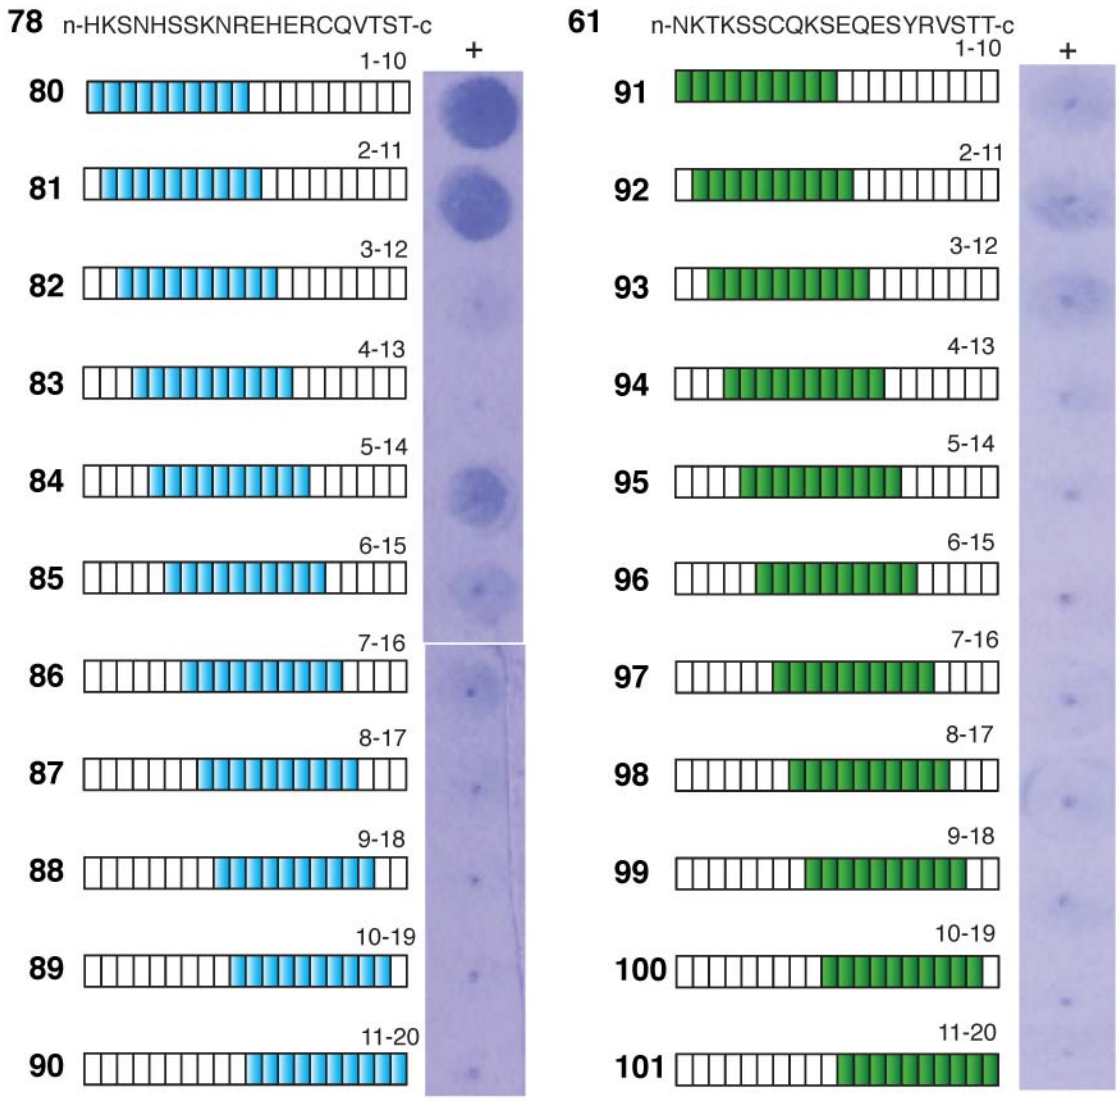

Figure S6. Analysis of contiguous 10-mer peptides **61** and **78** derived from HyRe peptide **53**. As shown by spot synthesis, the N-terminus of both peptides contributes critical residues to the peptide reactivity with biotin hydrazide at pH 7.

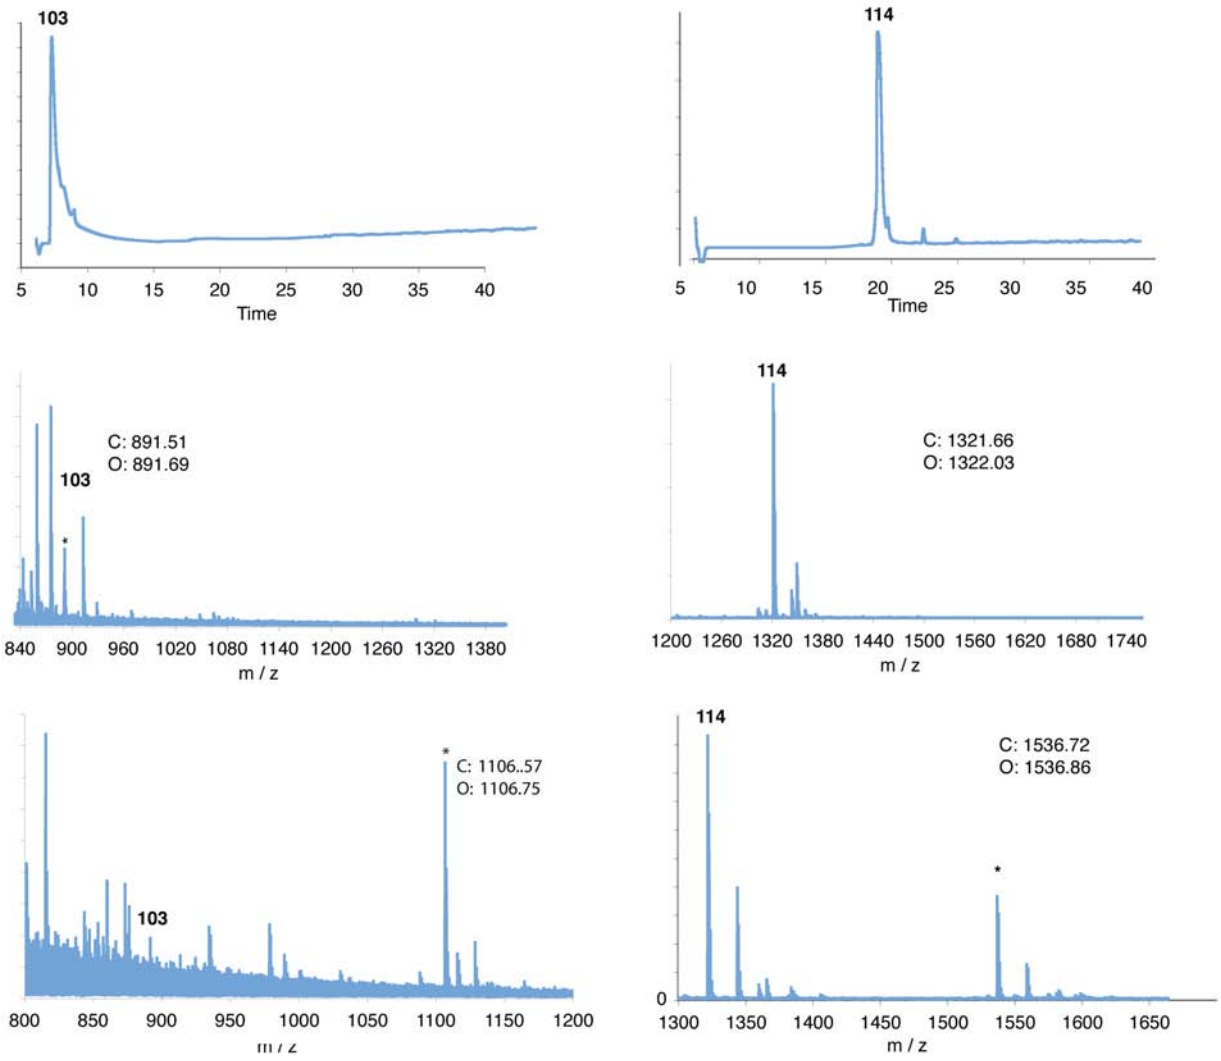

Figure S7. Analytical HPLC and MALDI-TOF MS analysis of synthesized and purified HyRe peptide **114** variants. The chromatograms (top) were monitored at 210 nm. MALDI-TOF MS analysis of purified HyRe tag variants (middle). MALDI-TOF MS analysis of the two peptides treated with AMCA hydrazide, revealing the +215 amu products (bottom). "C:" and "O:" indicate the calculated and observed (*) molecular weights, respectively.

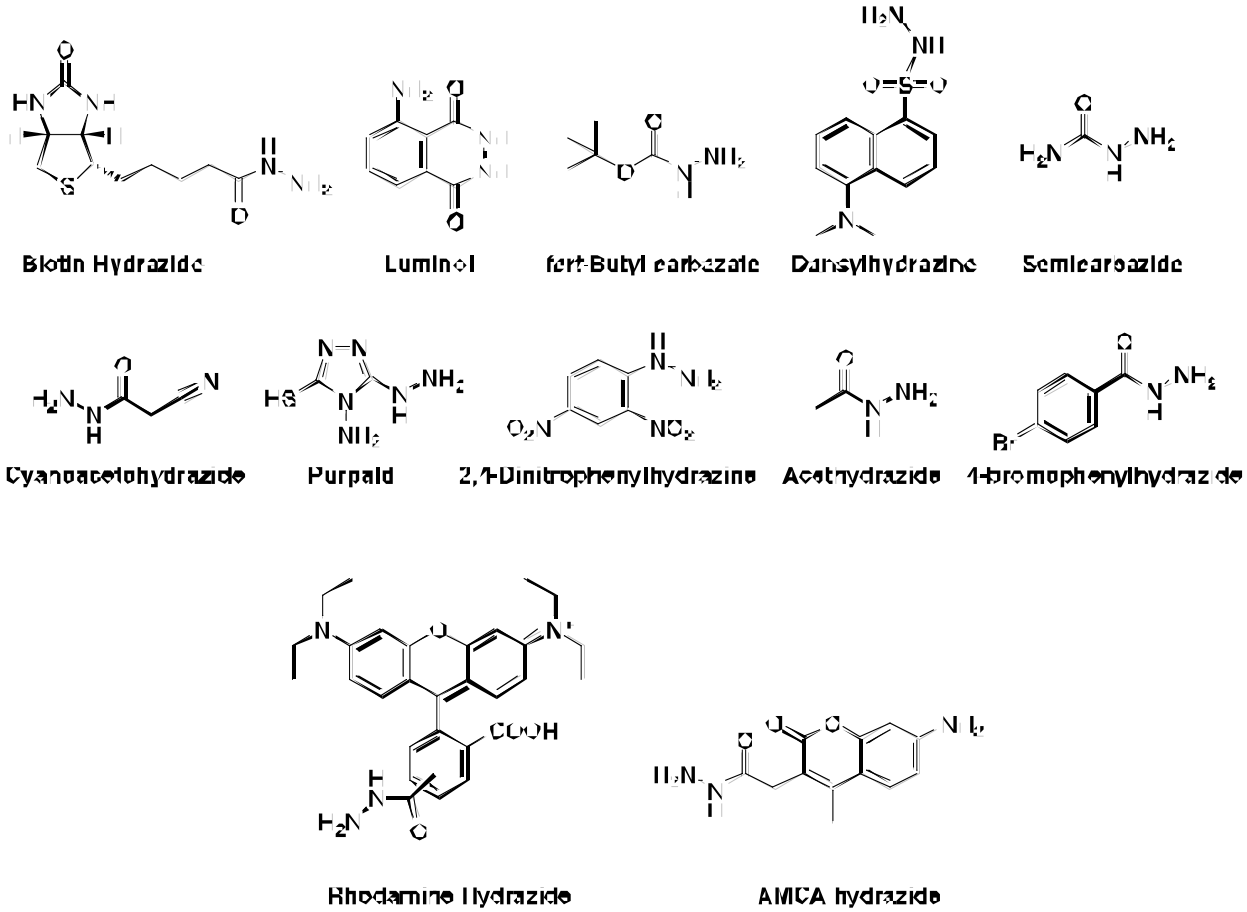

Figure S8. 12 unique hydrazides and hydrazine derivatives used to determine the generality of the reaction with peptide **114**. Only rhodamine B hydrazide and AMCA hydrazide produce the a covalent adduct upon reaction with the peptide at pH 7.

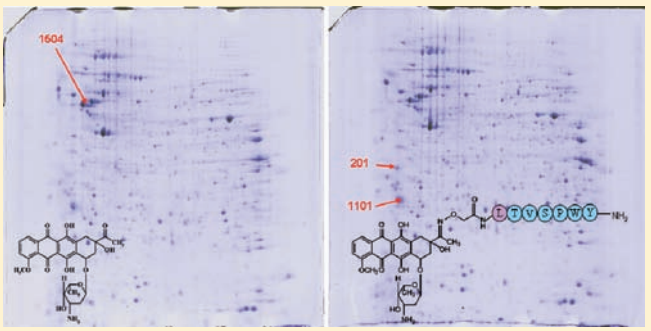
Supporting Information

ABSTRACT: Daunomycin (Dau) is a DNA-binding antineoplastic agent in the treatment of various types of cancer, such as osteosarcomas and acute myeloid leukemia. One approach to improve its selectivity and to decrease the side effects is the conjugation of Dau with oligopeptide carriers, which might alter the drug uptake and intracellular fate. Here, we report on the synthesis, characterization, and *in vitro* biological properties of a novel conjugate in which Dau is attached, via an oxime bond, to one of the cancer specific small peptides (LTVSPWY) selected from a random phage peptide library. The *in vitro* cytostatic effect and cellular uptake of Dau═Aoa-LTVSPWY-NH_2 conjugate were studied on various human cancer cell lines expressing different levels of ErbB2 receptor which could be targeted by the peptide. We found that the new daunomycin–peptide conjugate is highly cytostatic and could be taken up efficiently by the human cancer cells studied. However, the conjugate was less effective than the free drug itself. RP-HPLC data indicate that the conjugate is stable at least for 24 h in the pH 2.5–7.0 range of buffers, as well as in cell culture medium. The conjugate in the presence of rat liver lysosomal homogenate, as indicated by LC-MS analysis, could be degraded. The smallest, Dau-containing metabolite (Dau═Aoa-Leu-OH) identified and prepared expresses DNA-binding ability. In order to get insight on the potential mechanism of action, we compared the protein expression profile of HL-60 human leukemia cells after treatment with the free and peptide conjugated daunomycin. Proteomic analysis suggests that the expression of several proteins has been altered. This includes three proteins, whose expression was lower (tubulin β chain) or markedly higher (proliferating cell nuclear antigen and protein kinase C inhibitor protein 1) after administration of cells with Dau-conjugate vs free drug.



INTRODUCTION

Anthracyclines (e.g., daunomycin, doxorubicin, epirubicin, idarubicin) are antineoplastic agents widely used in the treatment of various types of cancer, such as osteosarcomas and acute myeloid leukemia.[1]

Daunomycin (Dau) is one of the anthracycline-type antitumor agents able to inhibit the division of the cells by intercalating to DNA or/and by inhibiting the topoisomerase-II.[2] Clinical application of Dau is limited by side effects such as nausea, vomiting, and lack of appetite, but the most severe side effect is cardiotoxicity.[3] The intrinsic or acquired resistance of tumor cells to daunomycin also reduces the response to the treatment.[4]

To investigate the effect of anthracyclines at the molecular level, a few proteomic studies were carried out. In these publications two types of studies are reported. In communications belonging to the first group, proteomics are used to identify proteins involved in the development of multidrug resistance.[5−7] Other authors studying the effects of anthracycline drugs (adriamycin, epirubicin, or daunomycin) on various tumor cells compared the protein expression profiles of treated and untreated cells. In these papers proteins were determined

with altered expression due to the treatment with free drug. The authors observed these changes mainly in the expression level of cytoskeletal proteins and proteins involved in protein biosynthesis, metabolic pathways, and apoptosis.[8−12] In both types of studies various treatment schedules (time, concentration) and proteomic methods were used. It is important to note that—according to our knowledge—no studies were reported so far on changes of the protein expression profile after treatment of anthracycline−carrier conjugates in comparison with that of free drug treatment.

It has been shown that conjugation of anthracycline drug to different types of carrier (e.g., oligo- and polypeptides,[13,14] proteins,[15] polysaccharides,[16] polymers,[17,18] and dextran[19]) could improve the selectivity and decrease the side effects by utilizing different cellular uptake mechanism(s).

Daunomycin has four functional groups suitable for covalent conjugation (Figure 1). According to the literature data, the most frequently used site for conjugation is the primary amino group of the carbohydrate moiety even though the free amino group is critical for binding to DNA.[20] If this amino group is used for conjugation, the drug has to be released from the conjugate in order to generate the free amino function. Modification of anthracyclines is also possible on the 13-oxo group using different hydrazide[21−24] and *O*-alkyl-hydroxylamine[23,25] derivatives. The replacement of the methyl ether group on C-4 provides another option for conjugation. This strategy has recently been employed for the coupling of daunomycin to triplex forming oligonucleotides.[26]

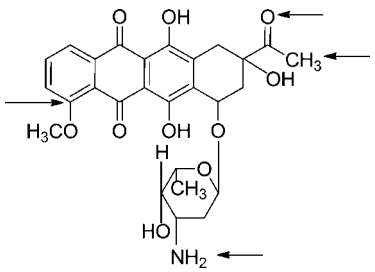

Figure 1. Structure of daunomycin. Four functions suitable for covalent conjugation are indicated by arrows.

Peptide conjugates of daunomycin were synthesized for various purposes: to reduce its side effects;[23] to circumvent the multidrug resistance;[27,28] and to increase the selectivity or target the molecule to a specific part of the body.[21,29−31]

It was found that the nature of the chemical bond between daunomycin and the peptide could markedly influence the chemical and biological properties of the conjugate and, thus, the efficacy of the drug. We described earlier that conjugates containing an oxime bond between daunomycin and the oligopeptide were chemically stable and also effective on HL-60 human leukemia and HepG2 human hepatoma cell lines.[32] On the basis of the observations in the present study, an oxime bond was utilized for the attachment of daunomycin to the targeting peptide.

Here, we describe the synthesis, chemical characterization, *in vitro* stability, cytotoxicity, cytostatic effect, and cellular uptake profile of a new conjugate in which daunomycin is conjugated to a tumor specific peptide via an oxime bond.

Tumor targeting peptides are often selected for their binding to cell surface proteins involved in biological functions such as cell surface receptors, growth factor receptors, and cell adhesion molecules. Members of the ErbB receptor tyrosine kinase family are central regulators of normal and tumor cell functions.[33] This family has four members: the epidermal growth factor receptor (EGFR), ErbB-2, ErbB-3, and ErbB-4.[34] ErbB-2 is a tumor-associated receptor responsible for tumor cell survival, proliferation, and metastases in many human cancers.[35−37] This tyrosine kinase-linked transmembrane protein is overexpressed in 30−50% of primary breast cancers.[38]

Using random phage peptide libraries, Shadidi and coworkers aimed to identify peptides that specifically or preferentially bind to breast cancer cells. The selected peptides did not bind to normal mammary epithelial cells but showed preferential binding and internalization into breast cancer cell lines.[39] One of the cancer-specific oligopeptides, peptide LTVSPWY, was identified as an ErbB-2-binding peptide. It was also shown that its GFP-fusion derivative was specifically internalized by SK-BR-3 human breast cancer cells.[35,40] This peptide was also chemically coupled to antisense oligonucleotides.[39,41]

Here we report on our findings related to the preparation and analysis of the relevant functional properties (e.g., *in vitro* cytotoxicity, cytostatic effect, cellular uptake) of the new Dau−peptide conjugate on cancer cells with different expression levels of ErbB-2. For these studies, cell lines with normal expression (e.g., MCF-7) or with overexpression of ErbB-2 (e.g., SK-BR-3)[42] were selected. In addition we have included HepG2 cells, which express the ErbB-2 receptor to some extent,[43] as well as HL-60 cells highly sensitive to daunomycin treatment. Data presented in this paper might also be useful to identify proteins with altered expression due to the treatment with Dau-conjugate and could be considered as future potential targets for rational design in cancer chemotherapy.

MATERIALS AND METHODS

Materials. Daunomycin hydrochloride was a gift from the Institute of Drug Research Institute (IVAX, Budapest, Hungary). The amino acid derivatives were obtained from Reanal (Budapest, Hungary) and IRIS Biotech (Marktredwitz, Germany). Rink-Amide MBHA resin (0.65 mmol/g) was purchased from Novabiochem (Darmstadt, Germany). Scavengers (thioanisole, ethanedithiol [EDT], phenol), coupling agents (*N*,*N*′-diisopropylcarbodiimide [DIC], 1-hydroxybenzotriazole [HOBt]), and cleavage reagents (piperidine, 1,8-diazabicyclo[5.4.0]undec-7-ene [DBU], trifluoroacetic acid [TFA]) were Fluka (Buchs, Switzerland) products. Acetonitrile [ACN], acetone, and *N*-methylpyrrolidone [NMP] were from Merck (Darmstadt, Germany). Dimethylformamide [DMF], dichloromethane [DCM], diethyl ether, NH_4OAc, and EtOAc were purchased from Reanal (Budapest, Hungary). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide [MTT], RPMI-1640 medium, and fetal calf serum [FCS] were obtained from Sigma-Aldrich (Budapest, Hungary). HPMI buffer (HEPES buffered medium RPMI-1640 containing D-glucose, $NaHCO_3$, NaCl, HEPES, KCl, $MgCl_2$, $CaCl_2$, $Na_2HPO_4{\cdot}2H_2O$) and lysis buffer (0.15 M NaCl, 5 mM EDTA, 1% Triton-X100, 10 mM Tris-HCl pH = 7.4, 5 mM DTT, and protease inhibitor used according to the recommendation of the manufacturer) were prepared in our laboratory using ingredients purchased from Sigma-Aldrich (Budapest, Hungary). Rehydration buffer (7 M urea, 2 M thiourea, 4% CHAPS, 40 mM Tris, 2% servalyt) and equilibration buffer (6 M urea, 2% SDS, 30% glycerol, 2.5

dx.doi.org/10.1021/bc2004236|*Bioconjugate Chem.* 2011, 22, 2154−2165

mM Tris-HCl) were also prepared in our laboratory. IPG strips (pH 3−10 NL, 17 cm) were purchased from Bio-Rad Laboratories (Hercules, CA). Trichloroacetic acid (TCA) was obtained from Roth (Karlsruhe, Germany). The BCA assay kit was a Pierce product (Rockford, USA).

Synthesis of Dau═Aoa-Leu-OH and Dau═Aoa-LTVSPWY-NH_2 Conjugates. *Synthesis of Dau═Aoa-Leu-OH.* H-Leu-OH (0.1 mmol) was dissolved in 1.5 mL of 2 M K_2CO_3. This solution was diluted with 1.5 mL of DMF, and an equivalent amount of Boc-Aoa-OPcp (0.1 mmol) in 1.5 mL of DMF was added. The reaction proceeded at room temperature (RT) for 24 h. DMF was removed, and the remaining material was washed with diethyl ether and dissolved in water. The pH of the solution was adjusted to 2.0 with 1 M HCl. The compound was extracted with EtOAc, and the organic phase was dried over $MgSO_4$. The EtOAc was removed, and the oily compound was dried in a desiccator for 1 day. The Boc group was cleaved with TFA containing 5% distilled water at RT for 1 h. After the removal of the cleavage mixture, 2 mL of 0.2 M NH_4OAc was added. The daunomycin hydrochloride (1.5 equiv) was added to this solution. The coupling reaction was carried out at RT overnight. For semipreparative RP-HPLC purification, 2 mL of A eluent (water containing 0.1% TFA) was added to the reaction mixture and the solution was injected. The target compound was characterized by analytical RP-HPLC (as described below; R_t = 33.8 min) and ESI-MS (Bruker Esquire 3000+; M_{mo}[calcd] = 713.4; M_{mo}[exptl] = 714.4).

For the RP-HPLC analysis a laboratory-assembled Knauer HPLC system (Bad Homburg, Germany) was used with a Phenomenex Luna C18 column (250 mm × 4.6 mm, 5 μm particle size, 100 Å pore size) (Torrance, CA). The gradient elution system consisted of 0.1% TFA in water (eluent A) and 0.1% TFA in acetonitrile/water = 80/20 (v/v) (eluent B). First, the eluent B content was 0% for 5 min; then it was varied from 0 to 90% in 50 min at a flow rate of 1 mL/min at room temperature. The sample (20 μL) was injected, and peaks were detected at λ = 214 nm.

Synthesis of NH_2-O-CH_2-CO-LTVSPWY-NH_2. Peptide LTVSPWY was prepared manually by solid phase synthesis on Rink-Amide MBHA resin (0.65 mmol/g) using the Fmoc/^{t}Bu strategy. The following side chain protected amino acid derivatives were used: Tyr(^{t}Bu), Trp(Boc), Ser(^{t}Bu), Thr(^{t}Bu). The protocol of the synthesis was as follows: (i) Fmoc deprotection with piperidine/DBU/DMF (2:2:96 v/v) solution (4 times, 2 + 2 + 5 + 10 min); (ii) washing with DMF (5 × 1 min); (iii) coupling 3 equiv of Fmoc-amino acid derivative−DIC-HOBt dissolved in NMP (60 min); (iv) washing with DMF (5 × 1 min); (v) ninhydrin or isatin test. Boc-aminooxy-acetic acid was also coupled on the solid phase to the free *N*-terminal amino group of Leu using a DIC/HOBt coupling agent. The coupling time was 60 min. The peptide derivative was cleaved from the resin with a TFA/H_2O/thioanisol/EDT/phenol (10 mL/0.5 mL/0.5 mL/0.25 mL/0.75 g) mixture (2 h, RT). After the resin was filtered off, the peptide derivative was precipitated with cold diethyl ether and centrifuged. The pellet was solubilized in 0.1% TFA (aqueous solution), freeze-dried, and characterized by analytical RP-HPLC (as described below; R_t = 24.4 min) and ESI-MS (Bruker Esquire 3000+; M_{mo}[calcd] = 936.9; M_{mo}[exptl] = 936.6).

Conjugation of Daunomycin to NH_2-O-CH_2-CO-LTVSPWY-NH_2. Equal amounts of Dau hydrochloride and aminooxyacetyl peptide (NH_2-O-CH_2-CO-LTVSPWY-NH_2) were dissolved in a mixture of 0.2 M NaOAc/AcOH buffer (pH 5.0) and DMSO (85:15 v/v%). The reaction mixture was stirred at room temperature, and the reaction was monitored by analytical RP-HPLC using an Eurospher-100, C18 column (250 mm × 4 mm, 5 μm particle size, 300 Å) (Knauer, Bad Homburg, Germany), and an appropriate gradient (10% eluent B for 5 min, then 10−80% eluent B in 50 min; eluent A (0.1% TFA in water) and eluent B (0.1% TFA in acetonitrile/water = 80/20 (v/v)). The flow rate was 1 mL/min. The sample (20 μL) was injected, and peaks were detected at λ = 214 nm. The Dau═Aoa-LTVSPWY-NH_2 conjugate was formed in one day.

The crude product was purified by semipreparative RP-HPLC using a C18 Phenomenex Jupiter column (250 mm × 10 mm) packed with 10 μm silica (300 Å pore size) (Torrance, CA, USA) using the above-mentioned eluents and a linear gradient. The sample (6 mg in 2 mL of eluent A) was injected into the column at a flow rate of 4 mL/min. The purified conjugate was dissolved in 0.1% TFA (aqueous solution), freeze-dried, and characterized by analytical RP-HPLC (as described above; R_t = 33.7 min), ESI-MS (Bruker Esquire 3000+; M_{mo}[calcd] = 1446.5; M_{mo}[exptl] = 1446.0), and amino acid analysis after hydrolysis with 6 M HCl for 24 h at 110 °C (measured [calcd]: T 1.17 [1]; S 1.17 [1]; P 1.02 [1]; V 0.92 [1]; L 0.89 [1]; Y 0.84 [1]).

Stability/Degradation of Dau═Aoa-LTVSPWY-NH_2 Conjugate. For the stability studies, the conjugate was dissolved in 0.1 M sodium citrate/citric acid buffer (pH 2.5, 5.0, or 7.0) or in 10% FCS containing DMEM cell culture medium and incubated at 37 °C. Aliquots were taken from the solution after 3 and 24 h and analyzed in a analytical RP-HPLC system under the conditions described above for the analysis of the conjugate.

The degradation of the Dau═Aoa-LTVSPWY-NH_2 conjugate was determined in the presence of rat liver lysosomal homogenate prepared as previously described.[44] The protein concentration of the lysosomal fraction was determined by Pierce BCA protein assay (bicinchoninic acid) according to the manufacturer's protocol (Thermo Fisher Scientific, Rockford, IL, USA). Briefly, 100 μg of lysosomal homogenate was added to 100 μg of bioconjugate dissolved in 1 mL of 0.2 M sodium acetate buffer, pH 5.0 (bioconjugate/lysosomal homogenate ratio = 1:1, w/w). The reaction mixture was incubated at 37 °C, and aliquots of 50 μL were taken at 5 min and 2, 4, 6, 8, and 24 h. The reaction was terminated by adding 5 μL of acetic acid, and the composition of the mixture was determined by liquid chromatography in combination with mass spectrometry (LC-MS). A control experiment was performed with a conjugate solution in 0.2 M sodium acetate buffer (pH 5.0), which was incubated at 37 °C for 24 h and analyzed by LC-MS as previously described.[44]

Absorption and Emission Spectra of Dau═Aoa-Leu-OH and Dau═Aoa-LTVSPWY-NH_2 Conjugates. Ground-state absorption spectra were recorded with 1 nm steps and 2 nm bandwidth using a Cary 4E (Varian, Mulgrave, Australia) spectrophotometer. Spectra of Dau and its derivatives were recorded at 10 μM concentration in Tris buffer (pH 7.4) containing 20 mM Tris-HCl and 50 mM NaCl.

Corrected steady-state emission spectra of the compounds were obtained using a Fluorolog-3 (Yvon Jobin, France) spectrofluorimeter. The excitation wavelength was λ = 488 nm, and the emission was detected between 495 and 800 nm. The excitation wavelength was chosen because the laser of the BD-

LSR II flow cytometer used for cellular uptake studies operates at this excitation wavelength. The same content of the compound solution was used in the absorption studies.

DNA-Binding of Dau═Aoa-Leu-OH and Dau═Aoa-LTVSPWY-NH_2 Conjugates. The ratio of the integrated fluorescence intensity of daunomycin derivatives in the absence of DNA (I_0) and in the presence of DNA (I) was used to calculate the amount of bound compound according to the following equation:

$$c_{free} = c_t(I/I_0 - P)/(1 - P)$$

where c_t is the known added amount of compound and P is the ratio of the observed quantum yield of fluorescence of the totally bound compound to that of the free one; c_{bound} was then obtained by difference.[45] The ratio $P = I_\infty/I_0$ was obtained from the initial value of I and the plateau value of I at the highest DNA concentration.

Apparent binding constants were determined by the neighbor exclusion model[46] using the equation

$$\frac{r}{c_{free}} = K(1 - nr)\left[\frac{1 - nr}{1 - r(n - 1)}\right]^{n-1}$$

where r is the number of moles of bound compound per mole of DNA base pair, K is the intrinsic binding constant, and n is the exclusion parameter in base pairs. DNA concentration was calculated on the basis of the measured optical density at 260 nm.

Cells. HL-60 human leukemia cells (ATCC: CCL-240) and HepG2 human hepatoma cells (ATCC: HB-8065) were cultured in RPMI-1640 medium supplemented with 10% FCS (fetal calf serum, Sigma Ltd.), 2 mM L-glutamine, and 160 μg/mL gentamycin.[47] SK-BR-3 human breast cancer cells (ATCC: HTB-30) and MCF-7 human breast adenocarcinoma cells (ATCC: HTB-22) were maintained in DMEM (Sigma Ltd., St. Louis, MO) medium containing 10% FCS, L-glutamine (2 mM), gentamycin (160 μg/mL), 1 mM pyruvate, and nonessential amino acids (Sigma Ltd.). Cell cultures were maintained at 37 °C in a humidified atmosphere with 5% CO_2.

***In Vitro* Cytostatic and Cytotoxic Effect.** The *in vitro* cytostatic and cytotoxic effect of the compounds was evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide-assay (MTT-assay).[48] For the experiment, 5×10^3 cells per well were plated on 96-well plates. After 24 h incubation at 37 °C, cells were treated for 3 h with the conjugate and control compounds dissolved in serum-free medium. The compounds were tested in the $(2.6 \times 10^{-4})-10^2$ μM concentration range. Cells treated with serum-free medium for 3 h were used as negative control. To determine the cytostatic effect, cells were washed twice with serum-free medium and cultured for a further 72 h in serum containing medium. To characterize the cytotoxicity of the compounds, MTT-assay was carried out directly after the 3-, 24-, 48-, or 72-h treatment: MTT solution was added to each well (final concentration: 367 μg/mL). After 3.5 h of incubation, purple crystals were formed by mitochondrial dehydrogenase enzyme of living cells. Cells were centrifuged for 5 min at 863 g, and the supernatant was removed. Crystals were dissolved in DMSO, and the optical density (OD) of the samples was measured at λ = 540 and 620 nm using an ELISA Reader (Labsystems MS reader, Finland). OD_{620} was subtracted from OD_{540}. The percent of cytostasis or cytotoxicty was calculated using the following equation:

$$\text{cytotoxicity \% or cytostasis \%} = [1 - (OD_{treated}/OD_{control})] \times 100$$

where $OD_{treated}$ and $OD_{control}$ correspond to the optical densities of treated and control cells, respectively. Cytostasis % or cytotoxicty % was plotted as a function of concentration, fitted to a sigmoidal curve, and based on this curve, the half maximal inhibitory concentration (IC_{50}) value was determined. IC_{50} represents the concentration of a drug that is required for 50% inhibition *in vitro* and expressed as micromolar units.

Cellular Uptake. To study the cellular uptake of the compounds, 10^5 cells per well were plated on a 24-well plate. After 24 h of incubation at 37 °C, cells were treated for 1.5 h with the compounds dissolved in serum-free medium in the 0.8−100 μM concentration range. Cells treated with serum-free medium for 1.5 h were used as negative control. After treatment and incubation, cells were washed with HPMI and treated with trypsin for 10 min. The effect of trypsin was stopped by the addition of HPMI supplemented with 10% FCS, and then the cells were transferred from the plate to FACS-tubes. After washing, cells were resuspended in HPMI, and the ratio of daunomycin-positive cells was determined by flow cytometry (BD LSR II, BD Bioscience, San Jose, CA, USA). Data were analyzed with the FACSDiVa software.

Two-Dimensional (2D) Gel Electrophoresis. In order to prepare cell lysates, 5×10^5 HL-60 cells per well were plated on 6-well plates. After 24 h of incubation at 37 °C, cells were removed from the plate and treated for 24 h with the conjugate (c = 9 μM) or daunomycin (c = 0.024 μM). These concentrations were chosen on the basis of *in vitro* cytotoxicity data. Cells treated with cell culture medium for the same period of time were used as control. After incubation, cells were washed with PBS and centrifuged at 220*g* for 5 min, and the supernatant was discarded. A volume of 40 μL lysis buffer was added per 10^6 cells, and samples were incubated for 30 min on ice and centrifuged for 20 min at 16000*g*. The protein content of the supernatant was determined spectrophotometrically by BCA assay according to the manufacturer's instructions using bovine serum albumin as a standard.

To remove salts and contaminants, proteins were precipitated by five volumes of ice-cold acetone at −28 °C for 3 h. Samples were centrifuged at 16000*g* for 20 min. The supernatant was discarded, and the pellet was dried with nitrogen gas and resuspended in rehydration buffer. After sonication for 10 min, samples were placed into a rehydration tray, and passive rehydration of 17 cm nonlinear IPG strips (pH 3−10) was carried out overnight. Approximately 0.5 mg of total protein was loaded on each gel. A Bio-Rad Protean IEF cell instrument was used for the isoelectric focusing. The steps of the isoelectric focusing were as follows: (i) 0−150 V in 3 min, (ii) 150 V for 30 min, (iii) 150−300 V in 15 min, (iv) 300 V for 30 min, (v) 300−3500 V in 150 min, (vi) 3500 V for 10 h. After isoelectric focusing, samples were equilibrated first in equilibration buffer I (containing DTT) for 20 min and then in equilibration buffer II (containing iodoacetamide) for 20 min. After washing, the IPG strips were placed on a 12% SDS gel and overlaid with 0.5% agarose. Gel electrophoresis was performed using a Bio-Rad PROTEAN II ix cell. The current was set to 25 mA/gel until the samples ran from the strip to the gel, and then 40 mA/gel was applied. After the run, gels were prefixed for 1 h with 12% TCA and stained with Coomassie Brillant Blue G-250-containing staining solution overnight. Gels

dx.doi.org/10.1021/bc2004236|*Bioconjugate Chem.* 2011, 22, 2154−2165

were destained with 25% methanol in Milli-Q water and scanned with a GS-800 calibrated densitometer (Bio-Rad) using QuantityOne software. From each sample two replicate gels were prepared and analyzed.

2D-Gel Image Analysis. On the gel images, spots were matched and the quantity of the proteins was compared with PDQuest 8 software (Bio-Rad). The computer analysis allowed automatic detection with manual corrections and quantification of protein spots, as well as matching between control gels and gels from treated samples. The significance of differences between protein spots was evaluated by Student's *t*-test, and $p < 0.05$ was considered as significant.

In-Gel Tryptic Digestion. Spots with significant quantitative differences were manually excised and transferred to siliconized tubes. Gel pieces were washed once with Milli-Q water for 15 min and then an acetonitrile–Milli-Q (3:2 v/v) solvent mixture was added. After 30 min, the acetonitrile–Milli-Q solvent mixture was removed, and the gel pieces were dried using a SpeedVac (Eppendorf). Gel pieces were rehydrated with 20 mM ammonium bicarbonate buffer (pH 8.0) for 15 min. This buffer was changed to an acetonitrile–Milli-Q (3:2) solvent mixture, and gels were incubated for 30 min. The steps after SpeedVac centrifugation were repeated until the gel pieces were transparent. After the last incubation with an acetonitrile–Milli-Q (3:2) solvent mixture, gels were dried in a SpeedVac (Eppendorf). To the dry gel pieces, 50 μL of 20 mM ammonium bicarbonate containing 12.5 ng/μL of sequencing grade modified trypsin solution (Promega, Madison, WI) was added. The samples were incubated at 4 °C for 45 min, and then the trypsin containing solution was changed to 20 mM ammonium bicarbonate buffer (pH 8.0) and incubated at 37 °C for at least 12 h. The tryptic peptides were extracted from the gel with a mixture of acetonitrile–0.1% TFA in Milli-Q (3:2, v/v).

Identification of Proteins. Tryptic peptide mixtures were analyzed by reversed-phase liquid chromatography nanospray tandem mass spectrometry (LC-MS/MS) using an LTQ-Orbitrap mass spectrometer (Thermo Fisher) and an Eksigent nano-HPLC. The characteristics of the reversed-phase LC column were 5 μm, 200 Å pore size C18 resin in a 75 μm i.d. × 10 cm long piece of fused silica capillary (Hypersil Gold C18, New Objective). After injecting the sample, the column was washed with 90% eluent A (0.1% formic acid, aqueous solution) and 10% eluent B (0.1% formic acid in acetonitrile) for 5 min. Peptides were eluted using a linear gradient of 10–50% eluent B in 25 min and then 50–80% eluent B in 5 min, at a 300 nL/min flow rate.

The LTQ-Orbitrap mass spectrometer was operated in a data dependent mode in which each full MS scan (30 000 resolving power) was followed by five MS/MS scans, where the five most abundant molecular ions were dynamically selected and fragmented by collision-induced dissociation (CID) using a normalized collision energy of 35% in the LTQ ion trap. Dynamic exclusion was allowed. Tandem mass spectra were searched against the SwissProt protein database using Mascot (Matrix Science) with the following parameters: "Trypsin" cleavage with one missed cleavage, cysteine alkylation by iodoacetamide as a constant modification, and methionine oxidation as a variable modification.

RESULTS

Synthesis and Chemical Characteristics of Dau=Aoa-Leu-OH and Dau=Aoa-LTVSPWY-NH_2 Conjugates. For the synthesis of Dau=Aoa-Leu-OH, the amino acid H-Leu-OH was reacted with the *N*-protected aminooxy-acetic acid active ester (Boc-Aoa-OPcp), followed by the removal of the *N*-terminal Boc protecting group of the amino acid derivative. The oxime bond formation between the free primary amino group of H-Aoa-Leu-OH and the C^{13} oxo function of Dau was achieved in solution with acceptable overall yield (55%). The crude product was purified by RP-HPLC, and the conjugate was characterized by analytical RP-HPLC (R_t = 33.8 min) and mass spectrometry (Bruker Esquire 3000+; M_{mo}[calcd] = 713.4; M_{mo}[exptl] = 714.4).

The strategy used for the preparation of daunomycin conjugate with peptide LTVSPWY is outlined in Figure 2.

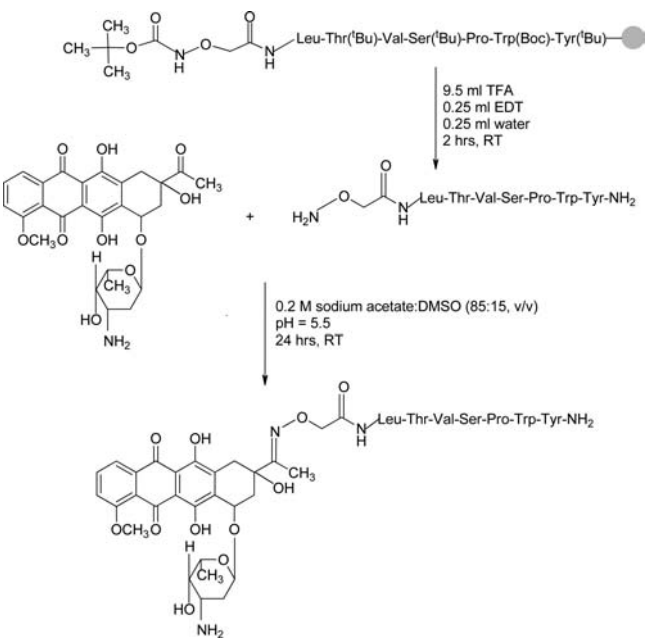

Figure 2. Outline of the synthesis of the Dau=Aoa-LTVSPWY-NH_2 conjugate.

First, the oligopeptide LTVSPWY was synthesized on solid phase using the Fmoc/^{t}Bu strategy and Rink-Amide MBHA resin to obtain the peptide amide. Boc-aminooxy-acetic acid was coupled on solid phase to the free *N*-terminal amino group of Leu using the DIC/HOBt based active ester strategy. The protected peptide derivative was cleaved from the resin, resulting in NH_2-O-CH_2-CO-LTVSPWY-NH_2 (Aoa-LTVSPWY-NH_2), which was used for the conjugation with daunomycin in solution using a buffer (pH 5.0) and DMSO (85:15 v/v) mixture. The product obtained in 24 h was purified by RP-HPLC and characterized by analytical RP-HPLC (R_t = 33.7 min), ESI-MS (Bruker Esquire 3000+; M_{mo}[calcd] = 1446.5; M_{mo}[exptl] = 1446.0), and amino acid analysis (measured [calcd]: T 1.17 [1]; S 1.17 [1]; P 1.02 [1]; V 0.92 [1]; L 0.89 [1]; Y 0.84 [1]). The analytical RP-HPLC chromatogram of the purified conjugate is shown in the Supporting Information (Figure S1).

Absorption and Emission Properties of Dau=Aoa-Leu-OH and Dau=Aoa-LTVSPWY-NH_2 Conjugates. First, the absorption spectra of the conjugates (Dau=Aoa-Leu-OH and Dau=Aoa-LTVSPWY-NH_2) and Dau were recorded at pH 7.4, and the shapes of these spectra were found to be similar. The corrected steady-state emission spectra of the compounds were obtained using a λ = 488 nm excitation

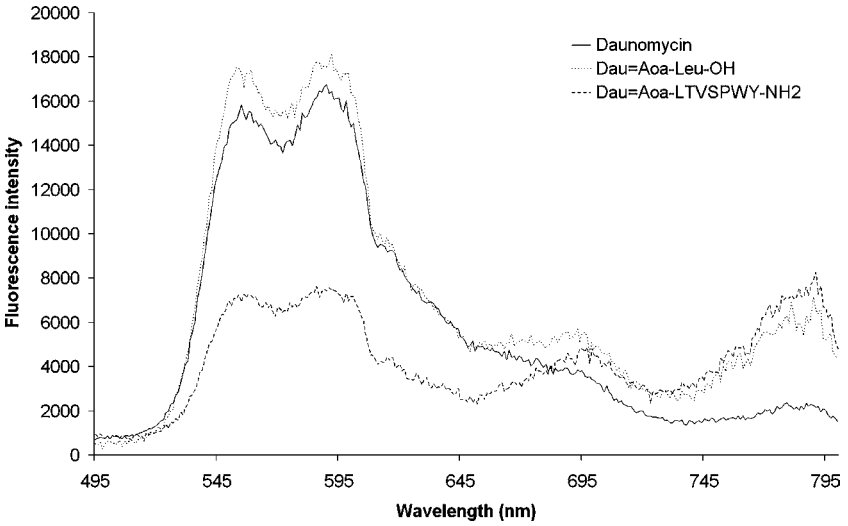

Figure 3. Emission spectra of Dau═Aoa-LTVSPWY-NH_2 and Dau═Aoa-Leu-OH conjugates as well as daunomycin using λ = 488 nm excitation and recorded at 10 μM concentration in Tris buffer (pH 7.4) containing 20 mM Tris-HCl and 50 mM NaCl.

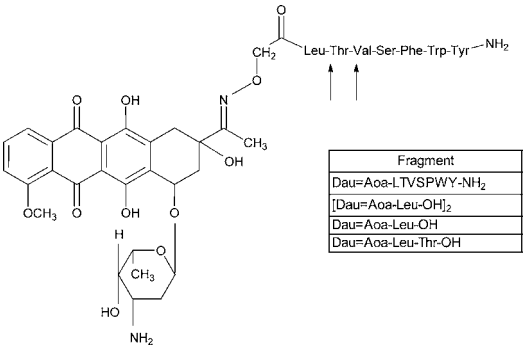
wavelength under identical conditions. The emission spectra recorded between λ = 495 and 800 nm for daunomycin, Dau═Aoa-Leu-OH, and Dau═Aoa-LTVSPWY-NH_2 are shown in Figure 3. The comparative analysis of the shape of the curves indicates a high level of similarities. In each spectrum, two maximum points were identified (λ = 555 and 595 nm). The fluorescence intensity of the conjugate Dau═Aoa-LTVSPWY-NH_2 was lower compared to those of the other two compounds. One possible explanation of this phenomenon is the presence of the aromatic amino acids (Trp and Tyr) in the sequence of the peptide. Alston and co-workers studied the influence of peptide sequence and conformation on the fluorescence of tryptophan containing peptides and proteins. Large differences in the emission spectra of the peptides were detected, suggesting that the amino acid sequence influences the fluorescence intensity either directly through quenching by the side chains or, more likely, indirectly through an effect on the conformational ensembles of the peptides.[49]

Stability/Degradation of Dau═Aoa-LTVSPWY-NH_2 Conjugate. The stability of the conjugate under acidic and neutral conditions (aqueous buffer solutions; pH 2.5, 5.0, and 7.0) was determined for a period of 3−24 h by analytical RP-HPLC. The recorded chromatograms are shown in the Supporting Information (Figures S2−S4). It was found that, at all investigated pH values, the chromatogram of the Dau═Aoa-LTVSPWY-NH_2 conjugate did not markedly change even after 24 h. These results indicate that the conjugate is stable in the pH range studied at room temperature at least for 24 h. Furthermore, the stability of this compound was determined in 10% serum containing DMEM cell culture medium (pH 7.3). Similarly, aliquots were taken from the solution after 3 and 24 h and analyzed by RP-HPLC. The chromatograms (S5) clearly show that even after 24 h the Dau═Aoa-LTVSPWY-NH_2 conjugate is stable under the circumstances applied in the *in vitro* experiments.

Considering a potential pathway for compounds entering the cells, the degradation of the Dau═Aoa-LTVSPWY-NH_2 conjugate in the presence of rat lysosome homogenate was also investigated.

The stability/degradation of Dau═Aoa-LTVSPWY-NH_2 was determined up to 24 h, and the cleavage products were identified by LC-MS as shown in Figure 4 and the Supporting Information (Figure S6).



Fragment	$Mw_{calc.}$	$Mw_{exp.}$
Dau=Aoa-LTVSPWY-NH_2	1446.58	1446.40
$[Dau=Aoa-Leu-OH]_2$	1427.48	1427.30
Dau=Aoa-Leu-OH	713.74	713.90
Dau=Aoa-Leu-Thr-OH	814.84	815.00

Figure 4. Cleavage sites (black arrows) and the corresponding fragments identified by LC-MS after incubation of the Dau═Aoa-LTVSPWY-NH_2 conjugate in the presence of rat liver lysosomal homogenate.

After 5 min of incubation with the rat liver lysosomal homogenate, the cleavage of the -Thr-Val- peptide bond was detected by mass spectrometry (the Dau═Aoa-Leu-Thr-OH fragment was observed in the mass spectrum at m/z 816.0 (1+)). After 2 h, one more proteolytic fragment, Dau═Aoa-Leu-OH, was detected at m/z 714.9 (1+), indicating the cleavage of the -Leu-Thr- peptide bond. However, no cleavage of the oxime bond between Dau and aminooxy-acetyl-Leu was observed. After 6, 8, and 24 h, only the Dau═Aoa-Leu-OH proteolytic fragment could be detected. The formation of a noncovalent dimer of Dau═Aoa-Leu-OH was also determined by mass spectrometry (m/z 1428.3 (1+)). The LC-MS analysis of a conjugate solution incubated for 24 h at 37 °C in the absence of the lysosomal homogenate did not lead to the identification of any degradation product; only the intact conjugate was detected at m/z 1447.8 (1+) (Supporting Information, Figure S6). In conclusion, the conjugate was chemically stable under the conditions studied and specifically cleaved by the lysosomal enzymes, with the smallest drug containing metabolite being Dau═Aoa-Leu-OH.

Table 1. Cytotoxicity Expressed as IC_{50} ± SD Values (in μM) of Dau═Aoa-LTVSPWY-NH_2 Conjugate and Free Daunomycin as a Function of Time on HL-60 Cells

	time (h)			
compd	3	24	48	72
Dau	8.03 ± 3.25	0.02 ± 0.01	0.001 ± 0.000	$<2.56 \times 10^{-4}$
Dau═Aoa-LTVSPWY-NH_2	>100	10.21 ± 0.27	2.75 ± 1.04	2.02 ± 0.94

DNA-Binding Ability of Dau═Aoa-Leu-OH and Dau═Aoa-LTVSPWY-NH_2 Conjugates. The apparent binding constant (K), proportional to the DNA-binding ability of the compounds, was determined by using the neighbor exclusion model[46] for conjugate Dau═Aoa-LTVSPWY-NH_2, for conjugate Dau═Aoa-Leu-OH (considered as the smallest drug containing metabolite of Dau═Aoa-LTVSPWY-NH_2), and for free daunomycin as a control. We found that all the compounds were able to bind to DNA. However, the binding efficacies were different. The following order could be established: K ($\times 10^5$) (M^{-1}) = 11.70 for Dau > K ($\times 10^5$) (M^{-1}) = 3.23 for Dau═Aoa-Leu-OH > K ($\times 10^5$) (M^{-1}) = 2.75 for Dau═Aoa-LTVSPWY-NH_2. These data indicate that the interaction between Dau and DNA is more pronounced than the interaction with the conjugates. It is interesting to note that no marked difference was observed in the DNA-binding capacity between Dau═Aoa-LTVSPWY-NH_2 with seven amino acid residues in the chain and Dau═Aoa-Leu-OH possessing only a single amino acid attached to daunomycin. This means that not only the intact conjugate, Dau═Aoa-LTVSPWY-NH_2 but also its degradation product can efficiently bind to the DNA.

***In Vitro* Cytostatic Effect of the Dau═Aoa-LTVSPWY-NH_2 Conjugate.** The *in vitro* cytostatic effect of the Dau═Aoa-LTVSPWY-NH_2 conjugate and free daunomycin was determined and expressed as IC_{50} values on four human cancer cell lines: HL-60 human leukemia, HepG2 human hepatoma, MCF-7 human breast adenocarcinoma, and SK-BR-3 human breast cancer cell lines. We found that the conjugate and also the free daunomycin exerted the highest cytostatic effect on HL-60 cells. Concerning the *in vitro* cytostatic effect of the conjugate, the following order could be established: HL-60 (IC_{50} = 0.53 ± 0.12 μM) > HepG2 (IC_{50} = 3.07 ± 0.02 μM) > MCF-7 (IC_{50} = 7.42 ± 0.49 μM) > SK-BR-3 (IC_{50} = 37.90 ± 2.83 μM). These data clearly indicate that the conjugate was less effective on SK-BR-3 cells, while on HepG2 and MCF-7 cells it had a higher cytostatic effect. We expected a higher cytostatic effect on SK-BR-3 cells, because the ErbB-2 receptor is overexpressed on these cells,[42] while MCF-7 has a normal ErbB-2 expression level. The comparison of the cytostatic effect of free daunomycin results in a slightly different order: HL-60 (IC_{50} = 0.05 ± 0.03 μM) > MCF-7 (IC_{50} = 0.18 ± 0.09 μM) > HepG2 (IC_{50} = 0.66 ± 0.21 μM) > SK-BR-3 (IC_{50} = 3.64 ± 0.52 μM). However, the IC_{50} values for MCF-7 and HepG2 differ only marginally. In the case of HepG2, the IC_{50} value of the conjugate was 4.5 times higher than that of daunomycin. The ratio between the IC_{50} for the conjugate per IC_{50} for the free drug was 10.6, 41.2, and 10.4 in the cases of the HL-60, MCF-7, and SK-BR-3 cells, respectively, indicating that on MCF-7 cells the relative effectivity of this conjugate was not as high as it was on HL-60, SK-BR-3, and HepG2 cells.

Cellular Uptake of Dau═Aoa-LTVSPWY-NH_2 Conjugate. Cellular uptake of compounds (Dau═Aoa-LTVSPWY-NH_2 conjugate and Dau) was studied by flow cytometry, and the percentage of daunomycin positive cells was determined. Data are shown in Figure 5. We observed concentration dependent cellular uptake in the cases of SK-BR-3, HepG2, and MCF-7 cells but not in the case of HL-60 cells. The percentage of the daunomycin-positive cells was almost 100% after treating HL-60 cells with any concentration of the conjugate. Daunomycin was taken up the most efficiently by HL-60 and MCF-7 cells at a concentration of 0.8 μM (data not shown), while cellular uptake of the conjugate was observed only at 20 μM concentration for MCF-7 cells, and also at this concentration, the ratio of daunomycin-positive cells was only 20.5%. Cellular uptake of the conjugate was higher in the case of HepG2 and SK-BR-3 cells compared to that of MCF-7.

Optimization of Treatment Conditions for Proteomic Studies. On the basis of *in vitro* cytostasis and cellular uptake data obtained after the treatment with the Dau═Aoa-LTVSPWY-NH_2 conjugate, HL-60 cells were selected for further studies. We were interested in determining the alterations in the protein expression profile of treated HL-60 cells by proteomic methods. Therefore, first the optimal

treatment conditions (time and concentration) had to be established. For this purpose, the *in vitro* cytotoxicity of Dau=Aoa-LTVSPWY-NH_2 and daunomycin was determined on HL-60 human leukemia cells after 3, 24, 48, and 72 h of treatment. The calculated IC_{50} values of the compounds are shown in Table 1. After 3 h, the conjugate was not cytotoxic in the concentration range applied [(2.6×10^{-4})–10^2 μM]. The IC_{50} values of the Dau=Aoa-LTVSPWY-NH_2 conjugate decreased with time to IC_{50} = 10.21 ± 0.27 μM (24 h) and IC_{50} = 2.75 ± 1.04 μM (48 h). In the case of treatment with daunomycin for 72 h, the cells died almost completely; therefore, this treatment time could not be used to compare the effects of daunomycin

and the conjugate. In the case of 24 and 48 h treatment times, both daunomycin and the conjugate had a cytotoxic effect on HL-60 cells; however, the free daunomycin was more cytotoxic.

On the basis of these data the following conditions were selected for the proteomic studies: c = 9 μM for Dau=Aoa-LTVSPWY-NH_2 conjugate, c = 0.024 μM for daunomycin, and 24 h treatment time.

Protein Expression Profile of Treated and Nontreated HL-60 Cells. After optimizing the treatment conditions, HL-60 human leukemia cells were treated for 24 h with Dau=Aoa-LTVSPWY-NH_2 conjugate or with daunomycin. Proteins were isolated from treated as well as from nontreated control cells and separated by two-dimensional gel electrophoresis. Gel patterns after staining were compared using the PDQuest software. Comparisons of representative gels are shown in Figures 6–8. The spots with higher optical density are denoted with an arrow and are shown only on the gel where higher expression is observed. In the sample from cells treated with daunomycin, four differently expressed proteins could be observed compared to the nontreated control cells (Figure 6, Table 2). Two proteins (tubulin β chain and Ran-specific GTPase-activating protein) showed higher (7.26-fold and 2.09-fold, respectively) and two proteins (proliferating cell nuclear antigen and β-actin) showed lower (0.12-fold and 0.14-fold, respectively) expression levels in daunomycin-treated samples compared to nontreated sample.

In the case of a Dau=Aoa-LTVSPWY-NH_2-treated sample, eight significantly different spots were identified (Figure 7, Table 3) in comparison with the nontreated control sample. Two spots could be indicative of a higher (2.29-fold and 2.21-fold) level of protein expression. These are Ran-specific GTPase-activating protein, which is involved in the regulation of cell cycle, and an actin-binding protein, Plastin-2, respectively. However, the expression of six proteins decreased

Table 4. Identified Proteins with Different Expressions in the Daunomycin-Treated or Dau=Aoa-LTVSPWY-NH_2 Treated Samples[a]

[a]Spot number is for the identification of the spots on the gel. Average levels of the proteins in different samples are calculated by PDQuest 8.0 software. Fold change is the ratio of the average protein expression level in the conjugate and daunomycin-treated samples. M_r is the theoretical molecular weight, while p*I* is the theoretical isoelectric point of the identified protein.

after the treatment with the conjugate. The expression level of a heat-shock protein and two proteins involved in signaling decreased compared to the nontreated control cells.

The intensity of two additional spots corresponding to proteins involved in metabolic pathways (D-3-phosphoglycerate dehydrogenase and fructose-bisphosphate aldolase A) was weaker. This observation might suggest that the expression of these proteins could occur also at a lower level, but the drop is less marked (by 0.49-fold and 0.47-fold, respectively). It is important to point out that increased expression of the Ran-specific GTPase-activating protein was observed in both daunomycin- and Dau=Aoa-LTVSPWY-NH_2 conjugate-administered cells at a similar level (2.09-fold in Dau-treated and 2.29-fold in conjugate-treated samples, respectively).

Protein expression profiles of cells treated with daunomycin or with conjugate were also compared. The results are summarized in Figure 8 and Table 4. Three significantly different protein spots were detected. These changes suggest that one protein, the tubulin β chain, was expressed at a lower level (by 0.20-fold) in Dau=Aoa-LTVSPWY-NH_2 conjugate-treated cells. In contrast, the administration of HL-60 cells with the conjugated drug for 24 h resulted in markedly higher expression of two proteins: the proliferating cell nuclear antigen (by 12.63-fold) and the 14−3−3 protein γ (by 11.50-fold) compared to that of free daunomycin-treated cells.

DISCUSSION

Here, we report on the synthesis, characterization, and *in vitro* cytostatic effect of a new oxime bond containing the daunomycin conjugate Dau=Aoa-LTVSPWY-NH_2. The stability of this compound was investigated under different conditions, and it was found that even after 24 h the Dau=Aoa-LTVSPWY-NH_2 conjugate was not degraded either in 10% serum containing medium or in sodium acetate/acetic acid buffers in the pH range studied (pH 2.5−7.0). The conjugate in the presence of rat liver lysosomal homogenate was cleaved enzymatically, resulting in Dau=Aoa-Leu-OH as the smallest drug containing metabolite of the conjugate. This metabolite, as well as the Dau=Aoa-LTVSPWY-NH_2 conjugate, could bind efficiently to DNA; therefore, DNA synthesis might be inhibited by this compound in the cells.

The *in vitro* cytostatic and cytotoxic effect and cellular uptake of the conjugate indicated that the cellular uptake mechanism could be different in the case of the studied cell lines. The cellular uptake of the Dau=Aoa-LTVSPWY-NH_2 conjugate was limited in the case of MCF-7 cells, which express ErbB-2 in normal or low levels.[42] In contrast, SK-BR-3 cells, which are ErbB-2 overexpressing cells, could take up the conjugate more effectively. The IC_{50} value of Dau=Aoa-LTVSPWY-NH_2 on SK-BR-3 cells was higher compared to other investigated cell lines. Interestingly, free daunomycin was not as effective on this cell line as on the others (in this case the IC_{50} value of the conjugate was only 10.4 times higher than that of free daunomycin). This finding, e.g. the cells with the highest amount of targeted receptors showed the lowest cytostatic effect, needs to be studied further. Experiments are in progress to analyze the uptake mechanism. Efficient cellular uptake and a remarkable *in vitro* cytostatic effect of the Dau=Aoa-LTVSPWY-NH_2 conjugate were observed on HepG2 cells, which moderately express the ErbB-2 receptor.[43] The difference in the cellular uptake properties and the *in vitro* cytostatic effect of the Dau=Aoa-LTVSPWY-NH_2 conjugate on different cell lines could be explained by different cellular uptake mechanisms and/or the different intracellular fates of the compound. Also, the mode of action might be different for the Dau-conjugate compared to Dau itself. The conjugate had the highest cytostatic effect on HL-60 cells and the cellular uptake was also the most effective in the case of this cell line. On HL-60 cells, Trinks and co-workers could not detect ErbB receptors by Western blot analysis, while mRNA expression was observed.[50] These data suggest that in the case of HL-60 cells the conjugate could be taken up efficiently by one or more different mechanisms.

For a better understanding of the effect of the Dau=Aoa-LTVSPWY-NH_2 conjugate on HL-60 cells, we have initiated a comparative analysis of the protein expression profile of treated and nontreated cells and also of conjugate vs free daunomycin treated cells. We observed that the expression level of several proteins altered due to the treatment with the conjugate or with the free drug (Dau) in comparison with proteins from untreated cells. Most interestingly, three proteins were identified, whose expression was lower (tubulin β chain) or markedly higher (proliferating cell nuclear antigen and protein kinase C inhibitor protein 1) after administration of HL-60 cells with Dau−peptide conjugate vs free drug. The results of proteomic analysis performed and described in this paper could be adaptable for systematic analysis of the mechanism of action of bioconjugates with preferential properties vs the properties of the covalently attached free cargo (e.g., drug). On the basis of findings summarized in this paper, further studies are in progress to identify the potential role of proteins, whose expression level was dependent on the compounds (free vs conjugated drug) used for treatment and could be considered as relevant for target validation.

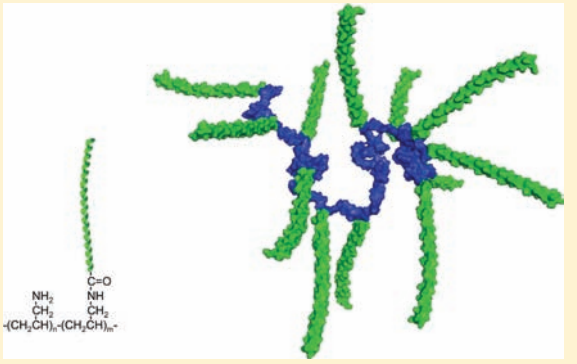
Conjugation of Type I Antifreeze Protein to Polyallylamine Increases Thermal Hysteresis Activity

Özge Can[†] and Nolan B. Holland*

Department of Chemical & Biomedical Engineering, Cleveland State University, 2121 Euclid Avenue, Cleveland, Ohio 44115, United States

ABSTRACT: Antifreeze proteins (AFPs) are ice binding proteins found in some plants, insects, and Antarctic fish allowing them to survive at subzero temperatures by inhibiting ice crystal growth. The interaction of AFPs with ice crystals results in a difference between the freezing and melting temperatures, termed thermal hysteresis, which is the most common measure of AFP activity. Creating antifreeze protein constructs that reduce the concentration of protein needed to observe thermal hysteresis activities would be beneficial for diverse applications including cold storage of cells or tissues, ice slurries used in refrigeration systems, and food storage. We demonstrate that conjugating multiple type I AFPs to a polyallylamine chain increases thermal hysteresis activity compared to the original protein. The reaction product is approximately twice as active when compared to the same concentration of free proteins, yielding 0.5 °C thermal hysteresis activity at 0.3 mM protein concentration. More impressively, the amount of protein required to achieve a thermal hysteresis of 0.3 °C is about 100 times lower when conjugated to the polymer (3 μM) compared to free protein (300 μM). Ice crystal morphologies observed in the presence of the reaction product are comparable to those of the protein used in the conjugation reaction.



INTRODUCTION

Antifreeze proteins (AFPs) help organisms to survive at subzero temperatures or at temperatures lower than the freezing point of their body fluids by inhibiting ice crystal growth. Interest in this phenomenon has given rise to many studies in order to gain more information as to how they prevent the ice crystal growth.[1] It is generally accepted that AFPs bind to specific planes of the ice surface, which stops subsequent crystal growth at temperatures below the colligative melting point. This interaction of AFPs with ice crystals results in thermal hysteresis, which is the difference between the freezing and melting temperatures. AFPs also prevent the redistribution of the water between ice crystals and the solution referred to as ice recrystallization.[2] These properties have use in potential applications such as cold storage of cells or tissues, ice slurries used for refrigeration systems, and food storage.[3−8] To minimize the amount of protein needed for a given application, antifreeze proteins with thermal hysteresis activity at low concentrations are desirable.

Among AFPs, there is a considerable variance in thermal hysteresis activity, even among proteins with similar structures. The most extensively characterized type I fish AFP is the winter flounder HPLC6 protein, which has three repeats of 11 amino acid residues.[9,10] A longer type I AFP is AFP9 from winter flounder, which has four repeat sequences.[11] This longer protein is more active than its shorter isoform, illustrating the general effect of increased size on the thermal hysteresis activity. More recently, a much larger type I AFP was discovered in American plaice with a molecular weight of approximately 17 kDa. This protein is five times larger than the AFP9 and exhibited significant thermal hysteresis activity even at low concentrations.[12,13]

Differences in thermal hysteresis activity have also been observed in other types of AFPs. For example, the activity of β-helical insect AFPs is affected by the addition or deletion of coils from the structure of the protein. It has been shown that enhanced activity in longer insect AFPs results from the larger ice surface binding area of the proteins, as long as the repeating sequences continue to match the ice crystal lattice structure.[14,15]

For the globular type III antifreeze proteins, a different mechanism for increased activity has been reported. Miura et al. observed enhanced activity in a natural protein consisting of two type III AFP domains connected by a nine residue linker.[16] They compared the activity of this protein with its single domain counterpart and reported that the two-domain protein is more active than the single domain protein. This enhancement is most pronounced at low concentrations, yielding thermal hysteresis activities as much as 6 times greater than the monomer. This effect was explained by the assumption that the average distance between the two domains of the protein adsorbed on the surface is smaller than that of the adsorbed monomers. Hence, in order to saturate the ice surface and stop the ice growth, a smaller amount of dimer would be needed as compared to the monomer.

A more detailed investigation of the increased activity of the type III dimers showed that a recombinant two-domain type III AFP from Antarctic eel pout is twice as active as its monomer.[17] However, when they inactivated one of the domains, its activity was reduced to only 1.2 times greater than that of the monomer.

When two monomers were linked through a disulfide bond such that two domains could not bind to the ice surface simultaneously, the dimer was again only 1.2 times as active as its monomer, indicating that the two domains need to be both active and able to simultaneously bind to the ice surface to achieve maximum activity.

Expanding on this principle, thermal hysteresis activity of type III was further increased by adding domains by tandem repetition to create three and four domain proteins.[18] However, diminishing return above three domains was observed. On the basis of the reported flexibility of the linker,[19,20] this likely is the result of limited freedom of the domains in the multimer, particularly the central domains that are confined at both termini.

To overcome the limited mobility of tandem repeats, we present here a different strategy for increasing the number of domains per molecule. Type I AFPs are conjugated to a polymer chain through their carboxy-terminal end. This results in multiple binding domains per chain, while still retaining individual domain mobility. Type I AFP, as opposed to a more active AFP, was chosen for two reasons. First of all, it consists of a single α helix with no disulfide bonds or post-translational modification, so large quantities of active protein (~100 mg/L of culture) can be expressed in *E. coli* and purified using relatively simple procedures.[21] Second, it could be modified to remove acidic residues that would compete with the carboxy-terminus in the conjugation reaction. The goal of the work is to reduce the amount of protein necessary to observe significant thermal hysteresis activity, so the low overall thermal hysteresis of the Type I AFP is not a primary issue.

MATERIALS AND METHODS

Synthesis and Cloning of the Genes for the Proteins. *E. coli* strain BL21*(DE3) (Invitrogen) was used as the cloning and the expression host strain using the pET20b vector (Novagen). The procedure for obtaining the gene for producing the type I AFP genes was previously described by Solomon and Appels.[21] We used a slightly modified version of their technique to obtain the sequence for rAFP (Table 1). Briefly, four primers were used, two of which included the major portion of the sequence that was extended using the two other shorter primers according to the overlap extension technique. It is noteworthy that rAFP was designed based on 11 amino acid repeat sequences found in the native winter flounder proteins, but differs in that the repeat sequences have less variability than the native proteins and it contains five 11 residue repeats instead of the three or four repeats naturally found.

In order to conjugate this protein to a polyallylamine (PAA) specifically through its carboxy terminus, we produced a variant of the protein with the two aspartic acid residues replaced by asparagines, which have a similar side group size but without the carboxylic acid group (Table 1). This modified protein, rAFP-N, was prepared with the same procedure to create the gene for producing rAFP except using a slightly modified forward extension primer to replace the aspartic acid residues with asparagines.

PCR amplifications were carried out using a thermal cycler (Thermo Electron Corp.) in a 50 μL reaction containing 0.01 μM template primers, 1.25 μM short primers, nuclease free water, and PCR master mix (Promega). Purified DNA and the pET20b expression vector were each 10-fold over digested with NdeI and *Bam*HI restriction endonucleases. Digestion products were prepared for ligation by purification with agarose gel electrophoresis.

Table 1. Amino Acid Sequence and Thermal Hysteresis Activity of Reported AFP Constructs

protein	sequence/structure	activity at 0.3 mM (°C)
rAFP	MD TASDAAAAAAL (TAANAAAAAAL)$_4$ TAR	0.28
rAFP-N	MN TASNAAAAAAL (TAANAAAAAAL)$_4$ TAR	0.23
rAFP-N/PAA	Polyallylamine-*graft*-rAFP-N	0.50

Quick Ligase Buffer (New England Biolabs) was used in 5 min ligation reaction including approximately 50 ng of the vector DNA and a 10-fold molar excess of the insert DNA followed by plating. After overnight growth, colonies were selected and plasmid DNA was purified using a miniprep kit (Qiagen). DNA sequencing (Cleveland State University Genomics Laboratory) was used to verify that the gene was ligated into the plasmid properly.

Protein Expression and Purification. Overnight cultures of transformed bacteria in 5 mL of ampicillin containing LB medium was used to inoculate 1 L cultures having 100 mg ampicillin. Samples were induced with isopropyl-β-D-thiogalactopyranoside (IPTG) (Thermo Fisher Scientific) after cultures reached an optical density of 0.6 at 600 nm. Induced samples were shaken in an incubator at 37 °C for 6 h.

Samples were purified (>95% as measured by polyacrylamide gel electrophoresis and reverse-phase HPLC) using ethanolic extraction according to the protocol reported by Solomon and Appels.[21] The purified protein was dialyzed against 100 mM ammonium bicarbonate using 1000 Da cutoff membrane followed by lyophilization.

Molecular weights of the proteins were determined by mass spectrometry as 5108.6 and 5105.6 Da for rAFP and rAFP-N, respectively. These results were in accordance with the weights calculated from the primary sequences. Concentration of a master solution was determined by amino acid analysis (University of Oklahoma Molecular Biology Proteomics Facility).

Conjugation Reactions. In a round-bottom flask, 5 μL polyallylamine (Sigma-Aldrich) (M_w ~17 000, 20 wt % in water) was mixed with 24 μL EDC (1-Ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride) (Sigma-Aldrich) and 10.9 μL sulfo-NHS (*n*-hydroxysulfosuccinimide) (Sigma-Aldrich) in 300 μL 0.4% acetic acid, 30 mM ammonium bicarbonate.[22] Approximately 13 times molar excess of the rAFP-N (0.3 mM) was added to the reaction mixture, which was stirred for 2 h at room temperature. Unreacted impurities were removed by dialysis using 3500 MW cutoff Spectra/Por dialysis membrane.

Size Exclusion HPLC. A 500 μL aliquot of the reaction mixture was loaded on the 20 mL bioscale size exclusion column (Bio-Rad Laboratories) filled with Toyopearl HW-55F resin (Tosoh). Reaction buffer solution was pumped through the column in the down-flow mode at a flow rate of 1 mL/min. UV absorbance at 230 and 280 nm were used to monitor the eluted sample.

Thermal Hysteresis Experiments. The concentration dependence of the thermal hysteresis activity of the AFPs was measured as the difference between the melting and the freezing temperatures of protein solutions. The melting and freezing points were measured as previously described using a homebuilt nanoliter osmometer attached to an optical microscope (Olympus).[23] Briefly, a single drop of protein solution was suspended in oil.

The droplet was flash frozen at around −30 °C and, upon increasing the temperature to the melting point, was thawed slowly until a single ice crystal was obtained. The temperature was subsequently decreased (0.01 °C/min) until reaching the freezing temperature, where rapid crystal growth was observed.

RESULTS

We successfully expressed and purified two different recombinant type I antifreeze proteins, rAFP and rAFP-N (Table 1), as verified by DNA sequencing of the gene, mass spectrometry, and amino acid analysis. The rAFP protein was first designed and expressed by Solomon and Appels,[21] based on the HPLC6 winter flounder type I AFP. It consists of initial HPLC6 residues, including the first 11-residue repeat sequence, followed by four of the terminal HPLC6 11-residue repeats. The five 11-residue repeats is greater than the three commonly found in nature. The rAFP-N protein is the same as rAFP except that mutations were introduced to substitute the two aspartic acid residues with asparagine residues. This eliminates the acidic side groups that could compete with the protein carboxy terminus in the conjugation reaction with the amine groups of the polyallylamine.

The conjugation reaction product of rAFP-N (5.1 kD) with PAA (17 kD) was passed through a size exclusion chromatography column (Figure 1) and fractionated to determine which peaks contained active antifreeze protein, as determined by thermal hysteresis measurements and ice crystal morphologies. The 280 nm absorbance is attributed to the PAA, whereas both the protein and PAA absorb at 230 nm. The first (high molecular weight) peak contains active antifreeze protein and corresponds to the reaction product. The second peak also exhibits activity, and is attributed to unreacted protein. None of the other peaks contained active protein.

All three protein constructs (rAFP, rAFP-N, and rAFP-N/PAA) exhibit thermal hysteresis activity (Figure 2). Although rAFP and rAFP-N have comparable activities up to 0.2 mM, the activity for rAFP-N was lower than that for rAFP at higher concentrations. We speculate that the lower thermal hysteresis activity of rAFP-N may be the result of reduced solubility since the charged aspartic acid residues were removed to facilitate the specific conjugation reactions, but it could also be caused by structural differences induced by the point mutations. When compared to reported thermal hysteresis values of its shorter isoform HPLC-6,[24] rAFP is more active at all concentrations measured, i.e., up to 2 mM.

The activity of the rAFP-N/PAA is measured using the reaction mixture, which includes both the rAFP-N conjugated to the PAA and any unreacted protein. For comparison to the unconjugated protein, the thermal hysteresis is plotted against the protein domain concentration, which includes both protein domains conjugated to the polymer and free unreacted domains. This domain concentration is based on the known amount of protein added in the reaction. At concentrations below 0.3 mM of rAFP-N, the rAFP-N/PAA reaction product is at least twice as active compared to rAFP or rAFP-N. It would have been preferable to compare the conjugation product purified from unreacted protein by chromatography. However, quantification of the protein domain concentration in the fractionated samples was not successful. We attempted using NMR, but the signal from the acetic acid in the sample buffer, which was necessary to solubilize the product, overwhelmed the NMR spectra of the sample. Amino acid analysis of the product also did not produce reliable results presumably because of the interference of the polymer backbone.

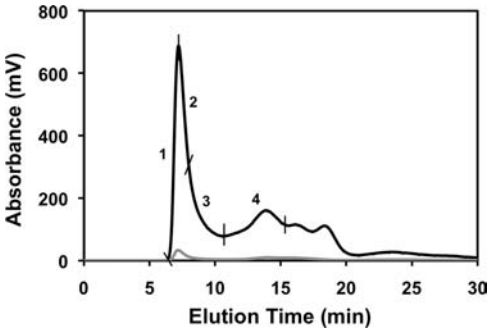

Figure 1. Size exclusion chromatograph of the conjugation reaction mixture. The sample was fractionated at several intervals to identify the peaks that contained active antifreeze proteins. The sample is detected by UV absorbance (black line: 230 nm, gray line: 280 nm).

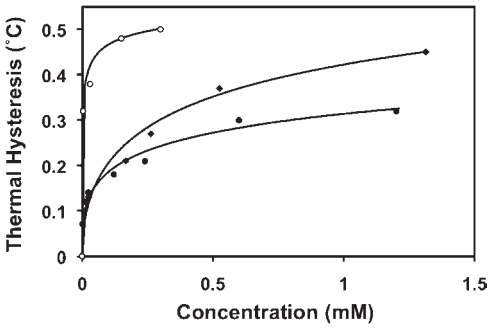

Figure 2. Concentration dependence of thermal hysteresis. Thermal hysteresis measurements of the pure proteins, rAFP (diamonds) and rAFP-N (solid circles), and the reaction product, rAFP-N/PAA (open circles), were measured at a cooling rate of 0.01 °C/min. The concentrations for rAFP-N/PAA indicate the molar concentration of the rAFP-N protein molecules used in the reaction mixture.

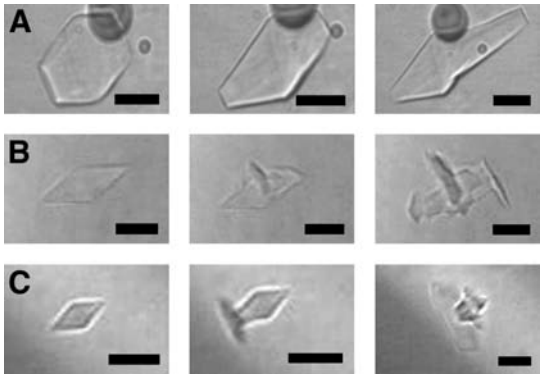

Figure 3. Ice crystal morphologies in the presence of antifreeze protein constructs: A, rAFP (530 μM); B, rAFP-N (600 μM); C, rAFP-N/PAA (32 μM of rAFP-N). For all samples, the *c*-axis is parallel to the paper plane. Scale bars are 10 μm.

Ice crystal morphologies were observed in the presence of the AFP. At all concentrations, the ice crystal morphologies in the presence of rAFP were similar, with ice crystals between 10 and 15 μm at low concentrations and slightly larger at 0.53 mM (Figure 3A). Truncated bipyramidal ice crystals are initially

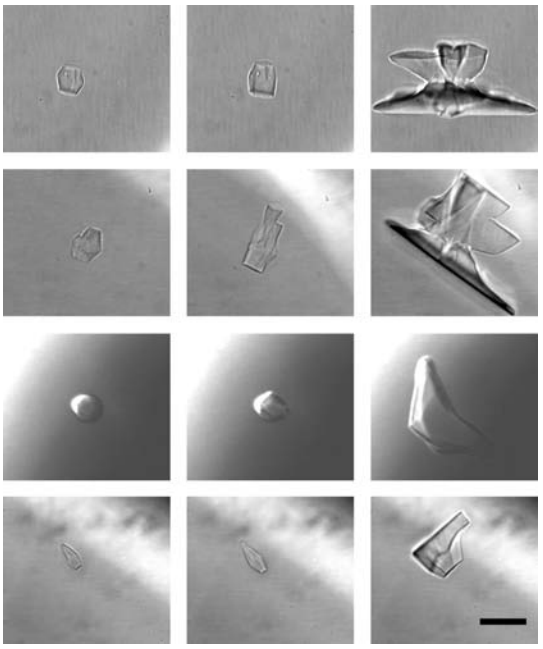

Figure 4. Ice crystal morphologies in the presence of the HPLC purified rAFP-N/PAA. The *c*-axis is parallel to the paper plane except for the third row, in which it is perpendicular to the paper plane. From left to right: Initial single ice crystal, ice crystal just before and after the burst point, respectively. First row is the left arm of the first peak in Figure 1, while the remaining rows represent the top-right of the first peak, bottom-right of the first peak, and the second peak in Figure 1, respectively. No ice crystal morphology change was detected for the remainder of the peaks. Scale bar is 10 μm.

formed, followed by more complete bipyramid formation over time. Similar hexagonal bipyramidal ice crystal morphologies have been reported in the presence of the shorter isoform of rAFP.[25] At the burst point, the ice crystals fail at the bipyramid tip growing in the direction of the *c*-axis. The rAFP-N also produced bipyramidal structures, which were frequently truncated at lower concentrations. Surprisingly, the rAFP-N burst point morphology was substantially different than rAFP. Ice crystals failed at the edge and center of the crystal with ice crystal growth always along the *a*-axis (Figure 3B). Ice crystal morphologies of the rAFP-N/PAA reaction product revealed similar behavior as rAFP-N except that much smaller ice crystals were obtained at all concentrations (Figure 3C). Again, failure occurred at the tip and at the center of the ice crystal growing along the *a*-axis, similar to rAFP-N.

The first and second peaks of the rAFP-N/PAA reaction product purified by size exclusion chromatography (Figure 1) were fractionated and ice crystal morphologies were observed (Figure 4). The concentration for these samples is unknown due to the inability to quantify the conjugated protein adequately. Thermal hysteresis activities of the samples from first row to the fourth row are 0.25, 0.28, 0.20, and 0.11 °C, respectively. No ice crystal morphology change was detected for the remainder of the peaks indicating that the first two peaks constitute the majority of the reacted and unreacted protein.

DISCUSSION

Activity of antifreeze proteins is primarily measured through the concentration-dependent thermal hysteresis, which is the difference between the melting and freezing points of ice crystals in AFP solutions. Thermal hysteresis results from the noncolligative depression of the freezing point through AFP interaction with the ice crystal surface. Several factors have been reported to affect the thermal hysteresis activity of a given protein, including the size of the protein (steric effect), the surface area and lattice matching of the ice binding face (affinity), and the ability of the multiple protein domains to bind with the ice surface simultaneously (avidity).[14,15,17,20] The widely accepted mechanism for thermal hysteresis is described by a model based on the Kelvin effect.[26] Once proteins bind to the ice surface, the spacing between the adsorbed protein molecules determines the level of thermal hysteresis activity. This model relies on the pinning of the ice crystal by the proteins leading to curvature of the growing ice surface between the protein molecules resulting in an increased energy barrier for the addition of water molecules. This can stop the growth of the ice crystal, effectively lowering the freezing point. Since the growth of the ice crystals has been observed to be completely stopped, the proteins must be irreversibly adsorbed to the ice.

Irreversible adsorption conflicts with the observed concentration dependence of thermal hysteresis, which suggests that there is an equilibrium process occurring. To reconcile these observations, Kristiansen and Zachariassen[27] presented a convincing model with a two-step process: protein equilibrium (reversible) binding occurs at the colligative freezing temperature as the ice begins to form, but as the crystals mature, the proteins become trapped in the surface (irreversible) to result in thermal hysteresis. The concentration dependence of thermal hysteresis is a result of different protein concentrations present at the interface due to the reversible binding step.

On the basis of the above model, for a given antifreeze protein that binds to a specific plane of the ice surface, increasing the concentration at the interface during the reversible adsorption step will tend to increase the thermal hysteresis. Adsorption/desorption equilibrium should therefore be considered when designing an antifreeze protein molecule. The most common approach used to increase surface concentrations has been to increase the affinity of protein binding to the ice, by increasing the area of the protein binding face for helical AFPs.[11,12] The increase in affinity reduces the rate of desorption leading to an increased equilibrium protein concentration at the surface. Increasing the affinity is to some extent limited in that the quality of lattice matching diminishes with the addition of helical repeats.

Increased avidity also can result in increased thermal hysteresis, particularly at low protein concentrations, as has been reported with the naturally occurring two-domain type III AFP.[20] Using a modified Langmuir adsorption model, we illustrated that this can be explained by an increased surface concentration during reversible adsorption.[28] This insight inspired the design of the high-avidity AFP construct produced by the conjugation of multiple AFPs to a polymer chain (Figure 5). The high avidity results in an increased concentration of the surface-bound proteins and activity of the product. Hence, a smaller concentration of protein is required to obtain the same activity compared to free AFP.

The proposed mechanism of action is for the increase in activity of the rAFP-N/PAA is the increased avidity. During the reversible step of the AFP interaction with ice crystals, multiple proteins attached to a single polymer chain can adsorb to the ice surface. Even if there was a relatively weak interaction of

Figure 5. Schematic representations of rAFP-N/PAA reaction product. The rAFP-N models were created by extending the length of winter flounder AFP (PDB ID 1WFA[37]) while maintaining the α-helical structure, using *DeepView/Swiss-PdbViewer* software program.[38] PAA (17 kDa) was produced using *PyMOL* version 0.99.

the individual proteins, resulting in significant probability of exchange of the molecules, desorption of one or more of the protein molecules would not be enough to disengage the whole construct from the surface. All proteins would need to desorb simultaneously, leading to near-zero probability of complete desorption. This will lead to high surface coverage even at low solution concentrations. It is noteworthy that, using a similar approach, the conjugation of hydrophobic side chains to polymers has been used to produce stable adsorbed layers on hydrophobic surfaces.[29]

As expected, in the reaction product containing the AFP conjugated to the PAA we observed an increase in thermal hysteresis compared to equivalent concentrations of pure protein, particularly at low concentrations. We expect that using reaction mixture containing both the conjugate and unreacted protein underestimates the actual thermal hysteresis values of conjugation product with no free AFP. The degree of this underestimation may be relatively small in light of the reported conferring of full activity to a defective AFP by the addition of a small fraction of an active AFP.[30] Even with the potential underestimation of the effectiveness, it is impressive that the conjugated product was able to achieve a thermal hysteresis of 0.3 °C with about 1% of the total protein concentration needed for the free AFP (3 μM of the protein domain compared to 300 μM, respectively). This drastically lowers the total amount of protein necessary to achieve the same activity.

If the high avidity of the rAFP-N/PAA leads to high surface coverage particularly at low concentrations, one may question why a greater increase in thermal hysteresis is not observed. Although there is significant thermal hysteresis activity improvement within the concentration range studied, these values fall below the thermal hysteresis values reported for the hyperactive type I AFP.[13] A likely answer is that the distribution of the protein along the polymer both in distance and in frequency may not be optimal for maximizing surface coverage. This could lead to incorrect alignment of the protein molecules on the ice lattice. The reaction product obtained in this study has multiple protein molecules attached to a polyamine carrying multiple ice binding sites. It is likely that misalignment of the ice binding faces during the reversible exchange is more pronounced for this bigger molecule compared to individual protein molecules and hence there might be a limit to the number of protein molecules on the polymer chain that can simultaneously align with the ice surface. By changing the ratio of protein to polymer, an optimal number of proteins for the maximizing thermal hysteresis activity could be obtained. If greater thermal hysteresis is desired, another approach could be to use more active antifreeze proteins such as insect antifreeze proteins.

Different types of AFPs produce different ice crystal morphologies, which is attributed to their structural differences.[31] For example, type I AFPs bind to the bipyramidal (201) plane of ice.[26] Molecular modeling studies revealed that the main source of this interaction was the steric compatibility between the ice plane and the AFP.[32] Type III AFPs comparably bind to the prism (100) plane of the ice crystal.[33] Similarly, steric contributions and hydrophobic interactions were found to play an important role in ice binding of these AFPs by using molecular dynamics simulations, ice docking, and energy minimization studies.[26,34−36] The ice crystal morphology observed for both rAFP-N and the conjugation product rAFP-N/PAA is initially a truncated bipyramid that may grow with time to form a more complete bipyramid, more often at higher concentrations. The similar behavior suggests that the conjugation does not alter the manner in which the proteins bind to the ice surface. It is unknown why the morphology of the ice crystal growth is different between the rAFP and the rAFP-N. The conversion of the two aspartic acids to asparagines are outside of the binding region of the protein and are not expected to alter the simple α-helical fold of the protein. For some unknown reason, the loss of the charged residues leads to the greater prevalence of truncated bipyramidal crystals, as well as burst growth along the *a*-axis instead of the *c*-axis.

Creating superior AFP constructs that have thermal hysteresis activity at low concentrations would make it more feasible economically to use them as additives for cryopreservation and refrigeration systems. We have successfully demonstrated a potential route toward this goal. Through the use of higher-activity AFP domains, such as insect AFPs, and optimizing the density of conjugation, even greater improvements in activity might be obtained.

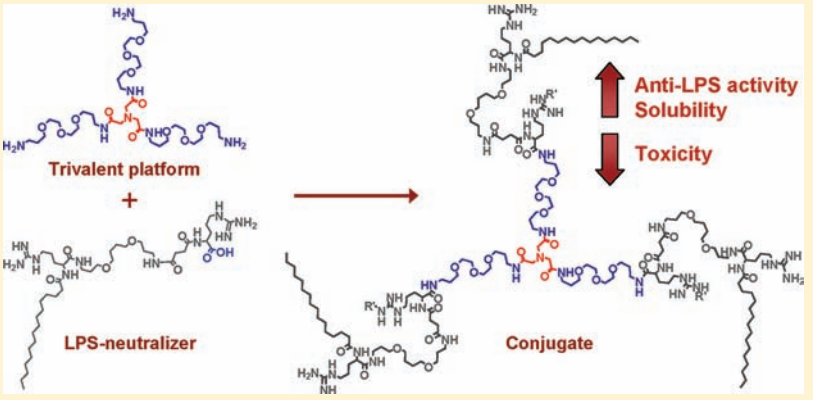
Supporting Information

ABSTRACT:



PEGylated multivalent structures are a new class of platform for biological applications due to their biocompatibility properties. Here, we present the synthesis of a trivalent structure **1** based on poly(ethylene glycol) units (PEG) as potential synthetic multifunctional carrier molecule. To evaluate whether this PEGylated platform could be useful for the conjugation of bioactive compounds, a well-known lipopolysaccharide (LPS) inhibitor **2**, developed in our laboratory, was selected to be conjugated to **1**. The LPS-neutralizing activity of the resulted conjugates and precursors was established using the chromogenic *Limulus* amebocyte lysate (LAL) assay. The trivalent structure **1** did not show LPS-binding activity, nonconjugate LPS inhibitor **2** showed high LPS-neutralizing activity, and the trivalent conjugate **4** displayed increased LPS-neutralizing activity and a reduced toxicity profile. These results prove the efficacy of this trivalent platform as a multivalent ligand scaffold for biological applications.

INTRODUCTION

The conjugation of bioactive compounds to oligo- and polymeric materials constitutes a useful strategy of outstanding interest in the field of medicinal chemistry.[1,2] These materials can be used either as carrier systems for drug delivery or as bioactive multivalent platforms for the presentation of several copies of a pharmacological agent with a specific topology. Overall, these systems should enable the administration of much lower doses of the drug with higher efficiency, thereby minimizing unwanted side effects. Additionally, for substances with poor water solubility, these systems afford the possibility to increase this property and hence the effectiveness of the drug.

Dendrimer structures have emerged as a new class of biopolymers with structural properties[3−5] and biological applications of interest.[6−10] These compounds are highly branched polymers with a well-defined chemical composition and structure. In this regard, PEGylated dendrimers, in which a multifunctional dendritic core is attached to polyethylene glycol (PEG) chains, are a subclass of dendrimers that maintain the special features of the dendrimers and amplify the properties of PEG.[11,12] PEG is a highly flexible, water-soluble, nontoxic, and non-immunogenic polymer. Drug or protein conjugation to PEG increases its solubility in water, protects against degrading enzymes, and prevents immunogenicity, preserving the original biological functions of the conjugated bioactive molecules.[13] In addition, the presence of PEG reduces kidney ultrafiltration, improves bioavailability,

The potent LPS-neutralizing agent **2** and the amphipathic monomer **3** are also shown. (i) TFA-DCM (1:1); (ii) TFA-H_2O-TIS (95:2.5:2.5); (iii) PyBOP, HOBt, DIEA.

increasing drug half-life, and, in general, facilitates its administration.[14,15] In fact, various PEGylated dendrimers have been described and showed lower toxicity, fewer hemolytic properties, long blood circulation times, low organ accumulation, and high accumulation in tumor tissue.[16−18]

Nevertheless, the synthesis of highly branched dendritic structures is often tedious and challenging and involves considerable synthetic effort, generally resulting in low yields of final dendrimers.[19] Simple, easy-to-synthesize multivalent platforms (i.e., generation 0 dendrimers) that are able to maintain some of these unique dendrimer properties are the optimal scaffolds to construct new multivalent ligands. Multivalence is a phenomenon whereby multiple, simultaneous, energetically coupled target/ligand interactions enhance the overall activity and selectivity compared to the corresponding monomeric interaction.

Here, we describe the synthesis of a very promising class of trivalent PEG-based platform **1**, which consists of three copies of monodisperse PEG units attached to nitrilotriacetic acid (NTA) as trivalent ligand scaffold (Figure 1). In addition to the conjugation of multiple copies of bioactive compounds, such platforms may also increase water solubility and reduce toxicity of the conjugated molecules caused by the presence of PEG moieties.

To evaluate whether this PEGylated platform could be useful in the conjugation of bioactive compounds, a LPS inhibitor developed in our laboratory, compound **2**,[20] was selected to be conjugated to **1** (Figure 1). LPS is a bacterial endotoxin present in the outer leaflet of Gram-negative bacteria that plays a major role in Gram-negative sepsis.[21] Sepsis is a serious systemic response to infection that represents the foremost cause of death in intensive care units (ICUs),[22] accounting for 750 000 hospitalizations in the U.S. annually.[23,24] To date, only one example of dendrimers with LPS-neutralizing activity has been reported.[25,26] In these studies, David and co-workers examined a variety of amine-terminated poly(amidoamine) (PAMAM) dendrimers.[27] The authors derivatized the surface amines of these dendrimers with lipopolyamines and obtained a multibranched dendritic structure that neutralized LPS-induced inflammatory responses *in vitro* and afforded protection against endotoxic shock in a murine model.[26] No reports concerning other types of dendritic-like multivalent structures have been found in the literature.

The selected LPS-inhibitor, compound **2**, was successfully conjugated to the trivalent platform **1**, thereby rendering a new construct **4** with an improved endotoxin-neutralizing activity and toxicity profile, confirming the utility of this new PEGylated platform as a multivalent scaffold.

EXPERIMENTAL PROCEDURES

General Materials and Methods. All chemicals and solvents were purchased from Calbiochem-Novabiochem AG, Iris Biotech GmbH, Fluka Chemika, Albatross Chem, GL Biochem, Sigma-Aldrich, Panreac, KaliChemie, Merck KGaA, or Scharlau and

were used as received without further purification. Distilled and deionized water was used for the preparation and rinsing of all solutions. Endotoxin-free water, LPS from *E. coli* 055:B5 and Polymyxin B were purchased from Sigma. The LAL reagent and the chromogenic substrate were obtained from Cambrex. Analytical RP-HPLC was performed using an Alliance 2695 Waters chromatography system with a RP Symmetry column and a Waters 996 photodiode array detector, using different linear gradients (see SI). Semipreparative HPLC was carried out on a Waters chromatography system equipped with a Waters 2487 dual absorbance detector and ESI-MS Waters Micromass ZQ), performed on a Symmetry column with linear gradients of B, MeCN (with 0.1% TFA), in A, H_2O (with 0.1% TFA), at a flow rate of 20 mL/min, using different linear gradients (see SI). Flash RP-LC was performed on a Combi Flash system from Isco Teledyne using RediSep C_{18} cartridges (4 g) with linear gradients of B, MeCN (with 0.1% TFA), in A, H_2O (with 0.1% TFA), at a flow rate of 20 mL/min (see SI for elution conditions). HPLC-MS was performed on Waters Alliance 2695 chromatography system equipped with Waters 995 photodiode array detector and ESI-MS Waters Micromass ZQ), on a Symmetry column with linear gradients of B, MeCN (with 0.1% FA), in A, H_2O (with 0.1% FA), at a flow rate of 20 mL/min (see SI for elution conditions). Mass spectra were recorded on a Voyager MALDI-TOF spectrometer using either ACH or SA matrices dissolved in H_2O/MeCN/FA (1:1:0.1). ^{1}H NMR spectra were recorded on a Varian Mercury 400 spectrometer at 400 MHz in DO_2. Peptide solid-phase synthesis was carried out following standard methods[28] described in Supporting Information section.

Synthesis of (TOTA)$_3$NTA (1). NTA (12.0 mg, 0.063 mmol), was preactivated for 15 min with DIC (29.4 μL, 0.19 mmol) and HOBt (28.3 mg, 0.19 mmol) in 10 mL of DCM−DMF (7:3). Then, Boc-TOTA (73.6 mg, 0.23 mmol) and TEA (52.74 μL, 0.38 mmol) dissolved in 10 mL of DCM−DMF (7:3) were added to the preactivated NTA. The reaction was stirred for 48 h under N_2 atmosphere at room and checked by RP-HPLC (conditions A). The solvent mixture was evaporated under vacuum, and the residue was dissolved in DCM; washed with saturated $NaHCO_3$ and brine; dried over $MgSO_4$ and evaporated to dryness under vacuum to obtain **1a** as yellow oil (76.2 mg, 95% yield, 67% purity). The crude mixture **1a** was purified using a flash chromatography system with a RP C_{18} column (condition G in SI) to afford **1a** (83% of recovery yield). **1a**: RP-HPLC (t_R = 23.1 min, purity 97%, condition A in SI); MALDI-TOF (m/z calcd. for $C_{51}H_{99}N_7O_{18}$ 1097.74, found 1098.6 [M+H]+). ^{1}H NMR (400 MHz, D_2O): δ ppm 1.43 (s, 27H), 1.71−1.84 (m, 12H), 3.21 (m, 6H), 3.26 (bs, 6H), 3.36 (dd, J = 6.8, 12.4 Hz, 6H), 3.53 (t, J = 6.02, 6.02 Hz, 12H), 3.56−3.66 (m, 24H), 5.12 (bs, 3H), 7.73 (bs, 3H). ^{13}C NMR (400 MHz, MeOD): δ ppm 28.37, 29.15, 29.60, 37.23, 38.34, 50.49, 59.79, 69.34, 69.37, 70.08, 70.42, 76.68, 77.00, 77.32, 77.32, 156.06, 170.33. Then, compound **1a** was treated with 15 mL of TFA−DCM (1:1) for 30 min. TFA was removed by evaporation to dryness yielding **1** (41.1 mg, 96% yield). **1**: RP-HPLC (t_R = 8.1 min, purity 88%, condition A in SI), MALDI-TOF (m/z calcd. for $C_{36}H_{75}N_7O_{12}$ 797.55, found 798.6 $[M+H]^+$).

Synthesis of 2a. Fmoc-6-aminohexanoic acid (1 equiv) and DIEA (10 equiv) were sequentially added to 2-chlorotrityl chloride resin (300 mg, 1.00 mmol/g) and the resin was stirred for 1 h. The incorporation was followed by a 10 min capping step with MeOH (240 μL). After Fmoc removal, Fmoc-Arg(Pbf)−OH (4 equiv) was incorporated into the resin using 2 × 45 min consecutive coupling treatments with HATU (4 equiv) in DMF as coupling reagent in the presence of DIEA (8 equiv). Next, the Fmoc group was removed and Fmoc-protected N1-(Fmoc)-1,12-diamino-4,9-dioxadodecan-succinamic acid (4 equiv) was coupled overnight using HOAt (4 equiv), PyBOP (4 equiv), and DIEA (12 equiv). Then, the Fmoc group was removed and Fmoc-Arg(Pbf)-OH was incorporated using the conditions explained above. Finally, palmitic acid (5 equiv) was added overnight with HOAt (5 equiv), PyBOP (5 equiv), and DIEA (15 equiv). The compound was then cleaved using TFA−DCM (1:99) (5 × 0.5 min). Solvents were evaporated and the residue was dissolved in H_2O−MeCN (1:1) and lyophilized to afford **2a** (139.1 mg, 32% yield). The crude product was purified by semipreparative RP-HPLC (condition F in SI) to yield **2a** with optimal purity. **2a** RP-HPLC (t_R = 14.9 min, purity 97%, condition D in SI), ES+MS (m/z calcd. for $C_{74}H_{125}N_{11}O_{15}S_2$ 1471.9, found 738 [M+H]+/2).

Synthesis of 2. The synthesis of **2** has been described elsewhere.[20] Fmoc-6-aminohexanoic acid (4 equiv) was coupled to Rink Amide MBHA resin with DIC (4 equiv) and HOAt (4 equiv) in DMF for 6 h. Subsequent steps in solid phase were carried out as explained for the synthesis of **2a**. Finally, the cleavage of the compound from the solid support and deprotection of side-chain groups was carried out with TFA−H_2O−TIS (95:2.5:2.5) for 2 h. TFA was then removed by evaporation with nitrogen and the crude compound was precipitated with cold anhydrous TBME, dissolved in H_2O−MeCN (1:1) and lyophilized. Then, it was purified by semipreparative RP-HPLC (condition E in SI) to yield the desired **2** with excellent purity. **2** RP-HPLC (t_R = 10.4 min, purity 98%, condition C in SI), MALDI-TOF (m/z calcd. for $C_{48}H_{94}N_{12}O_8$ 966.73, found 967.81 $[M+H]^+$).

Synthesis of 3. Fmoc-Arg(Pbf)-OH (1 equiv) in DCM and DIEA (10 equiv) were sequentially added to CTC resin (218 mg, 1.00 mmol/g), and the resin was stirred for 1 h. At the end of the coupling, a treatment with MeOH (175 μL) for 10 min was carried out to cap the free chloride groups of the resin. The Fmoc group was removed and palmitic acid (5 equiv) was added overnight with HOAt (5 equiv), PyBOP (5 equiv), and DIEA (15 equiv) as coupling reagents. Cleavage of the final compound from the resin was afforded by mild acidic treatments with TFA−DCM (1:99; 5 × 0.5 min). The solvents were evaporated, the compound dissolved in H_2O−MeCN (1:1), and lyophilized to obtain **3a** (102.7 mg, 71% yield), which was used without purification. **3a** HPLC (t_R = 16.8 min, purity 95%, condition D in SI). Then, **3a** was treated with TFA−H_2O−TIS (95:2.5:2.5) for 1 h. TFA was evaporated and the residue was dissolved in MeOH, precipitated with cold TBME, dissolved in H_2O−MeCN (1:1), and lyophilized to obtain 4.2 mg of **3** with 86% of yield. **3** RP-HPLC (t_R = 19.5 min, purity 89%, condition B in SI), MALDI-TOF (m/z calcd. for $C_{22}H_{44}N_4O_3$ 412.34, found 413.01 $[M+H]^+$).

Synthesis of Compound (2-TOTA)$_3$NTA (4). Compound **2a** (20.0 mg, 0.0136 mmol) dissolved in 10 mL of DCM−DMF (7:3) was preactivated for 15 min by adding PyBOP (7.1 mg, 0.0136 mmol) and HOBt (2.0 mg, 0.0136). Then, **1** (3.30 mg, 0.0041) and DIEA (4.6 μL, 0.0272 mmol) dissolved in 10 mL of DCM−DMF (7:3) were added. The mixture was stirred under N_2 atmosphere at room temperature for 72 h; the reaction was controlled by RP-HPLC (condition B in SI). The solvent was evaporated under vacuum and the residue dissolved in DCM; washed with saturated $NaHCO_3$, 10% HCl, and brine; dried over $MgSO_4$; and evaporated to dryness. The crude product was dissolved in MeOH and precipitated with cold TBME to obtain **4a** (18.8 mg, 70% yield). **4a**: RP-HPLC (t_R = 26.3 min, purity

80%, condition B in SI); MALDI-TOF (m/z calcd. for $C_{258}H_{444}N_{40}O_{54}S_6$ 5162.91, found 5180.02 $[M+18]^+$). Then, **4a** (18.8 mg) was treated with TFA−H_2O−TIS (95:2.5:2.5) for 3 h and TFA was evaporated. The residue was dissolved in MeOH and precipitated with cold TBME. After centrifugation−decantation, the compound was dissolved in H_2O−MeCN (1:1) and lyophilized to afford **4** as a white solid (6.1 mg, 86% yield). **4**: RP-HPLC (t_R = 17.2 min, purity 83%, condition B in SI); MALDI-TOF (m/z calcd. for $C_{180}H_{348}N_{40}O_{36}$ 3648.94, found 3649.93 $[M+H]^+$).

Synthesis of (3-TOTA)$_3$NTA (5). **3a** (20.0 mg, 0.030 mmol) was preactivated for 15 min with PyBOP (15.7 mg, 0.030 mmol) and HOBt (4.5 mg, 0.030 mmol) in 10 mL of DCM−DMF (7:3). Compound **1** (7.26 mg, 0.0091 mmol) and DIEA (10.2 μL, 0.060 mmol) were dissolved in 10 mL of DCM−DMF (7:3) and after stirring for 10 min were added to the preactivated compound **3a**. The mixture reaction was stirred under N_2 atmosphere at room temperature for 72 h and controlled by RP-HPLC (condition B). Then, the solvent was evaporated under vacuum and the residue was dissolved in DCM; washed with saturated $NaHCO_3$, 10% HCl, and brine; dried over $MgSO_4$; filtered; and evaporated to dryness to obtain **5a**. This compound was dissolved in MeOH and precipitated by the slow addition of cold MeCN (20.2 mg, 81% yield). **5a**: RP-HPLC (t_R = 26.6 min, purity 84%, condition B in SI); MALDI-TOF (m/z calcd. for $C_{141}H_{249}N_{19}O_{27}S_3$ 2738.79, found 2762.01 $[M+Na]^+$). The protected **5a** (20.2 mg, 0.0073 mmol) was treated with TFA, as previously explained for compound **4**. Workup yielded **5** as a white solid (8.6 mg, 88% yield). **5** RP-HPLC (t_R = 14.9 min, purity 92%, condition B in SI); MALDI-TOF (m/z calcd. for $C_{102}H_{201}N_{19}O_{18}$ 1981.8, found 1981.78 $[M+H]^+$).

LPS Neutralizing Activity. All solutions used in the LPS-neutralizing activity assay were tested to ensure they were endotoxin-free, and the material was sterilized by heating for 3 h at 180 °C. LPS-neutralizing activity was measured using the chromogenic *Limulus* Amebocyte Lysate (LAL) test, following the manufacturer's instructions (Cambrex). The LAL reagent contains a clottable protein that is activated in the presence of non-neutralized LPS, being an extremely sensitive indicator of the presence of endotoxin. When activated, this enzyme catalyzes the release of *p*-nitroaniline (pNA) from the colorless chromogenic substrate Ac-Ile-Glu-Ala-Arg-pNA. The released pNA can be measured photometrically at 405 nm. Compounds were initially dissolved in sterile phosphate buffered saline, PBS (137 mM NaCl, 2.7 mM KCl, 4.3 mM Na_2HPO_4, 1.4 mM KH_2PO_4, pH 7.0) at a concentration of 100 μM and preincubated with LPS (100 pg/mL in sterile, endotoxin-free water) in a 96-well microplate for 60 min at 37 °C. Polymyxin B (10 μg/mL in sterile PBS) was used as a positive control. The colorimetric reaction was started by adding 12.5 μL of LAL reagent (reconstituted by adding 1.4 mL of LAL reagent water) for an incubation period of 10 min at 37 °C. After this time, non-neutralized LPS was detected by the addition of 25 μL of the chromogenic substrate (reconstituted with 6.5 mL of LAL reagent water) for 5 to 8 min at 37 °C. Acetic acid (25% v/v final concentration) was added to stop the reaction, and the absorbance was monitored at 405 nm in a Multiskan Ascent microplate plate reader (ThermoLabsystems). At this concentration, compounds that showed an LPS neutralization above 75% were tested to determine their IC_{50} (the concentration required to neutralize 50% of LPS *in vitro*). IC_{50} values were determined by a serial dilution assay using 100 pg/mL of LPS and a range of compound concentrations (50 to 0.001 μM). All assays were run in triplicate, and the curves were automatically adjusted by nonlinear regression using *Prism 4* (GraphPad) software.

Cell Culture. Mouse macrophages (RAW 264.7) were obtained from ATCC (American Type Culture Collection, USA). The cells were grown in Dulbecco's Modified Eagle's Medium (DMEM, Gibco BRI) supplemented with 10% fetal bovine serum (FBS−Gibco BRI) and 1% L-glutamine. The cultures were incubated at 37 °C in a humidified atmosphere of 5% CO_2−95% air. Subcultures of macrophages were prepared every 2−3 days by scraping cells into fresh medium.

MTT Cell Viability Assays. Cell viability was evaluated by a MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide) assay. RAW 264.7 cells were seeded in sterile 96-well microtiter plates at a seeding density of 6×10^4 cells/mL in DMEM supplemented with 10% FBS and allowed to settle for 24 h. Compounds were added at a 10 μM concentration to the plates and the cells were further incubated for 24 h. After removal of the medium, the precipitated formazan crystals were dissolved in optical grade DMSO (100 μL), and the plates were read at 570 nm using a Wallac 1420 Workstation.

RESULTS AND DISCUSSION

Design of Drug Conjugates with LPS-Neutralizing Activity. The trivalent PEGylated platform (compound **1**, Figure 1) was obtained by convergent synthesis from the condensation of a commercially available propylene glycol (TOTA) and a trifunctional core (NTA). This and other types of polycarboxylic acids have been used *in vivo* as chelating agents for metals and their complexes as contrast agents for magnetic resonance imaging (MRI).[29,30] Since their physiological removal was confirmed in studies,[31] they have been considered excellent cores for the design of further biological applications.

As a first step and in order to evaluate whether our trivalent platform would be useful for the conjugation of biologically active compounds, we conjugated **2** to the trivalent structure **1** (Figure 1). In an ongoing research program currently underway in our laboratory, compound **2** has recently been reported to show high LPS-neutralizing activity.[20] This compound displays unique chemical features for optimal LPS binding: two Arg residues conveniently separated by a PEG linker and a fatty acid linked at the *N*-terminus. In fact, the cationic residues interact with the negative phosphate groups of lipid A[32] which is the endotoxic moiety of the LPS,[33,34] while the palmitic acid promotes hydrophobic interactions with the lipophilic part of the endotoxin[35] and confers amphipathicity to the whole molecule, a prerequisite for LPS neutralization.[36] Moreover, the presence of a PEG spacer is of interest in terms of improved water solubility and pharmacokinetic profiles.[14] In addition, the palmitoyl Arg monomer **3** was included in the design to further evaluate the relevance of the topology of positive charges in terms of LPS interaction (Figure 1).

Synthesis of Trivalent PEGylated Platforms. The synthesis of the trivalent platform **1** was achieved after conjugation of conveniently monoprotected TOTA into the NTA core (see Scheme 1 in Supporting Information). From diverse reaction conditions evaluated, the use of DIC in the presence of HOBt and TEA in DMF−DCM (7:3) for 48 h gave the best results. To ensure an optimal yield, an excess of base was required to avoid amine proton capture. The use of Fmoc as the protecting group of TOTA was precluded in this design because of partial Fmoc elimination during the coupling reaction. Hence, Boc-TOTA was

coupled to NTA under the conditions described above to yield the Boc-protected compound **1a** (95% yield, 67% purity). The protected compound was then purified using an automated flash chromatography system with a reverse-phase C_{18} column under acid conditions. It is essential to purify the compound while it is being protected to separate it efficiently from other byproduct. Finally, the Boc group was removed by treatment with TFA 50% in DCM for 30 min to obtain **1**.

Conjugation of Bioactive Compounds to the Trivalent Platform. To achieve proper conjugation, the carboxamide group of compound **2** was replaced by a free carboxylic acid and Arg side chains were kept protected with the Pbf group (see Scheme 2 in Supporting Information). The synthesis of **2** has been reported in detail elsewhere.[20] CTC resin was used as solid support in order to obtain the free carboxylic acid compound **2** required for amide bond conjugation. After the addition of Fmoc-6-aminohexanoic acid (Fmoc-Ahx-OH) using DIEA as a base, Fmoc-Arg(Pbf)-OH was coupled with two consecutive treatments with the reactive aminium salt HATU.[37] Next, N1-(Fmoc)-1, 12-diamino-4,9-dioxadodecan-succinamic acid was coupled overnight using PyBOP instead of HATU to prevent *N*-terminus guanidylation.[38] After the second Arg coupling, palmitic acid was added overnight. The compound was finally cleaved from the solid support with mild acid treatments to yield **2a**. In turn, **3a** was easily obtained on solid phase after incorporation of Fmoc-Arg(Pbf)-OH into CTC, and subsequent Fmoc removal and palmitic acid coupling.

Thus, **2a** and **3a** were conjugated to **1** with the coupling reagent PyBOP in the presence of HOBt and DIEA under anhydrous conditions (Figure 1). The reactions were monitored by HPLC (see Supporting Information). The conjugation HPLC traces of **2a** with **1** showed that the conjugated compound **4a** polarity did not diminish drastically compared with its precursor **2a**, even though **4a** contained three palmitoyl residues and six protected side chain arginines (Arg(Pbf)). The same effect was observed for the conjugate **5a** (data not shown). This behavior illustrates how PEG-containing platforms are useful molecules to solubilize hydrophobic compounds. After completion of the conjugation, a series of workup methods were evaluated, and we found that simple extraction and precipitation procedures were useful to obtain the protected conjugates with optimal purities, thus avoiding tedious and both compound and time-consuming RP-HPLC purifications. Finally, the protected conjugates were treated with TFA to yield the desired conjugates **4** and **5** with purities higher than 80% without any purification steps.

LPS-Neutralizing Activity. The LPS-neutralizing activity of the conjugated constructs **4** and **5** was assayed using the chromogenic *Limulus* amebocyte lysate (LAL) assay.[39] The activity of these compounds was compared against the activity of unconjugated **2** and **3** to study the effect of the conjugation. Finally, trivalent platform **1** was also included to determine whether this structure displayed on its own anti-LPS activity. All compounds were tested at 100 μM, and the assay was performed as described in the Experimental Procedures. The anti-LPS peptide polymyxin B (PMB)[40] was used as a positive control in this assay (Figure 2).

The trivalent structure **1** did not display LPS-binding activity. This result correlates well with other studies that describe how, although necessary, the presence of positive charges is not enough for effective LPS binding and neutralization.[35] Moreover, the inability of this platform to neutralize LPS is relevant, since it ensures that these structures will not interfere with the biological activity of bioactive conjugated molecules and will only act as

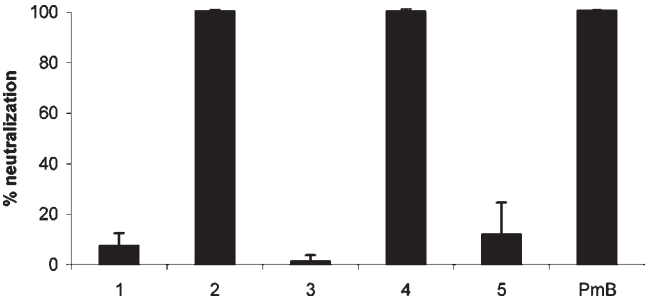

Figure 2. Inhibitory activity of the compounds was determined using the chromogenic LAL assay. PMB was included as a positive control. Compounds were tested at a 100 μM concentration in the presence of 100 pg/mL of LPS. The LPS-binding assay was performed in three independent assays as described in the Experimental Procedures. Data are represented with ± standard deviation (SD).

Table 1. LPS Neutralization Activity (IC_{50}) and Cell Viability of Compounds 2 and 4

compound	IC_{50} (μM)[a]	% of cell viability[b]
2	18 ± 1	109 ± 18
4	9 ± 1	110 ± 14

[a] Inhibition of the compounds was determined using the chromogenic LAL assay. The inhibitory activity is represented as IC_{50}. Standard deviations (SD) are also included. The assay was performed as described in the Experimental Procedures. [b] Cell viability was evaluated using RAW 264.7 cells, after 24 h of incubation in the presence of 10 μM concentration of compounds by MTT assay. The assay is described in the Experimental Procedures.

multivalent scaffolds. At the evaluated concentration, **2** showed high LPS-neutralizing activity, which is consistent with published data.[20] In contrast, monomeric compound **3** was inactive, thereby suggesting that two positively charged residues were required to interact with lipid A, regardless of amphipathicity. Finally, conjugates **4** and **5** showed interesting behaviors. Construct **4** retained the neutralizing activity of inhibitor **2** and totally neutralized LPS at 100 μM. In contrast, compound **5** had poor activity, even though three copies of the acyl-Arg monomer were exposed to LPS. Hence, as previously observed with other LPS-binders, even though these compounds are usually cationic their LPS neutralizing properties lie on the appropriate geometrical distribution of the positive charges on the binder chemical structure rather than on their number.[35,41] To further analyze the effect of conjugation and multivalency, compounds **2** and **4** were subjected to serial dilutions, and their IC_{50} values (i.e., the concentration required to neutralize 50% of LPS *in vitro*) were calculated (Table 1).

The experimental IC_{50} values obtained revealed that the conjugation of **2** to the PEGylated trivalent structure involved a twofold enhancement of its LPS-neutralizing activity. Such improvement correlates with the presence of three equal copies of bioactive compound **2** in construct **4**, suggesting an almost full exposure of **2** in the multivalent construct.

The trivalent structures proposed herein are cationic in nature, and it is known that some amphipathic cationic compounds could present basal toxicity associated to cell membrane activity.[42,43] Thus, we examined the toxicity, if any, of these conjugates in cells. In order to choose an appropriate cell model, we selected RAW 264.7 murine macrophages. These cells are a powerful model to

study LPS-induced cell signaling as well as the efficacy of LPS inhibitors, given that they are critical members of the innate immune system and play a major role in the pathogenesis of sepsis.[21] In fact, the inhibition of inflammatory mediators such as tumor necrosis factor-α (TNF-α) from LPS-challenged macrophages[44] is usually measured to determine the efficacy of LPS-neutralizers.[33,45] However, cationic dendrimers have recently been described to induce apoptosis in this cell model.[46] Thus, in a first attempt to determine whether these multivalent platforms are viable agents for future *in vitro* and *in vivo* studies, the cytotoxicity of compounds **2** and **4** was evaluated using MTT assays. These compounds were tested at a concentration close to their IC_{50} values, or 10 μM. At this concentration, both compounds were nontoxic (Table 1). It has already been reported that these cells can tolerate **2** at 10 μM, although it becomes moderately toxic at higher concentrations.[20] Interestingly, **4** was devoid of any toxic effect even though it contained three copies of **2**. These findings are consistent and support the notion that both PEGylation and the conjugation of molecules to cationic dendrimers is a viable strategy to reduce or even remove their intrinsic toxicity while maintaining the bioactive properties of the drug.[16]

CONCLUSIONS

Here, we have presented the synthesis of a novel trivalent PEGylated structure. This platform was obtained by convergent synthesis from the condensation of a commercially available propylene glycol (TOTA) and NTA as the multifunctional core. The value of this PEGylated platform for the conjugation of bioactive compounds was assayed with compound **2,** a previously described LPS-neutralizer. As a proof of concept, compound **2** was conjugated to the trivalent structure **1** to render construct **4**. The conjugated compound displayed improved LPS-neutralizing activity and a reduced toxicity profile over the parent compound, thus proving the efficacy of this platform as a multivalent ligand scaffold for biological applications.

Peptide solid-phase synthesis method

Solid phase syntesis was carried out manually using the Fmoc strategy in polypropylene syringes fitted with polyethylene porous disks. Solvents and soluble reagents were removed by suction. Washings between deprotection and couplings steps were carried out with DMF and DCM using 10 mL of solvent/g of resin each time. When syntheses were performed on 2-chlorotrityl chloride resin (CTC); DCM was previously treated with basic alumina. The Fmoc group was removed by treatment with piperidine–DMF (1:4, v/v). All synthesis process was performed at 25 ºC. Couplings were monitored using standard colorimetric tests for solid-phase synthesis.[28]

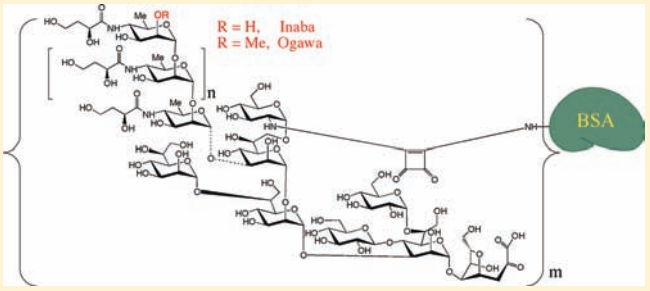
ABSTRACT: Bacterial O-SP—core antigens can be conjugated to proteins in the same, simple way as synthetic, linker-equipped carbohydrates by applying squaric acid chemistry. Introduction of spacers (linkers) to either O-SP—core antigens or protein carriers, which is involved in commonly applied protocols, is not required. The newly developed method described here consists of preparation of a squaric acid monoester derivative of O-SP—core antigen, utilizing the amino group inherent in the core, and reaction of the monoester with the carrier protein. The intermediate monoester can be easily purified; its conjugation can be monitored by SELDI-TOF mass spectrometry and, thus, readily controlled, since the conjugation can be terminated when the desired carbohydrate—protein ratio is reached. Here, we describe production of conjugates containing the O-SP—core antigen of *Vibrio cholerae* O1, the major cause of cholera, a severe dehydrating diarrheal disease of humans. The resultant products are recognized by convalescent phase sera from patients recovering from cholera in Bangladesh, and anti-O-SP-core-protein responses correlate with plasma antilipopolysaccharide and vibriocidal responses, which are the primary markers of protection from cholera. The results suggest that such conjugates have potential as vaccines for cholera and other bacterial diseases.



INTRODUCTION

Lipopolysaccharides (LPS) are carbohydrate polymers characteristic of Gram-negative bacteria. They consist of Lipid A, the toxic part through which the LPS is anchored into the bacterial cell wall, the intermediate core oligosaccharide, and the O-specific polysaccharide (O-antigen, O-SP), which extends into the bacterial environment, and is a virulence factor and the major protective antigen of *V. cholerae* and many other bacterial pathogens.[1−3] Because of their toxicity, complete LPS molecules are normally not used as components of vaccines, especially parenteral vaccines, although oral whole-organism killed vaccines contain a large component of LPS. Lipopolysaccharides can be detoxified in many ways, one of which is mild hydrolysis with dilute acetic acid, which separates the O-SP—core antigen from the Lipid A. Many methods for conjugation of carbohydrates, synthetic or bacterial, to proteins are available,[4−6] but most of them rely on significant chemical modification of the carbohydrate antigen to make it amenable to conjugation. Such approaches have the potential disadvantage that many epitopes in the antigen important for eliciting protective immunity may be changed by the treatment. This problem can be overcome by using for conjugation a functional group intrinsic to the polysaccharide, such as a carboxyl group in acidic polysaccharides or the free amino group in glucosamine that is present in the O-SP—core. A number of groups have produced conjugate vaccines targeting the O-SP of *Vibrio cholerae*, a Gram-negative bacterium and the cause of cholera, a severe dehydrating diarrheal illness of humans with epidemic potential.[7] Globally, almost all cholera is caused by organisms of two serotypes (Inaba and Ogawa) of the *V. cholerae* O1 serogroup. Protection against cholera is serogroup specific, and the vibriocidal response and anti-LPS antibodies are currently among the best markers of protection against cholera.[8] The vibriocidal response itself is largely directed against *V. cholerae* LPS.[9,10]

The first to attempt conjugation of an acid-detoxified *V. cholerae* LPS to proteins utilizing the amino group in the core were Gupta and co-workers.[11] They derivatized the O-SP—core antigen of *V. cholerae* O1 (serotype Inaba, Figure 1), as well as the carrier protein, with *N*-succinimidyl 3-(2-pyridyldithio) propionate, and effected single-point attachment between the two molecular

species. A similar approach, but using different chemistry, was taken by Mulard and co-workers[12] in their more recent, very carefully executed work. When the latter authors[12] revisited the approach by Gupta,[11] which involved derivatization of both carrier and antigen, they argued that introduction of linker was necessary to overcome the decreased reactivity of the amino group in the glucosamine, due to steric hindrance.

The squaric acid chemistry of conjugation of two amine species discovered by Tietze[13] has been shown to be a useful means for preparation of neoglycoconjugates from synthetic oligosaccharides.[14] The method is quite efficient,[6] but reservations have been expressed concerning its potential utility in conjugate vaccine development.[15] For instance, in limited animal studies, oligosaccharides linked to proteins via squaric acid chemistry induced lower antioligosaccharide antibody responses compared to responses induced by an oligosaccharide−protein conjugate linked via adipic acid chemistry, although both vaccines induced very prominent antioligosaccharide responses.[16] We have previously developed prototype cholera vaccines using short synthetic oligosaccharides involving the terminal sugar of *V. cholerae* O1 O-SP and squaric acid chemistry, and found these constructs to be immunogenic and protective in the standard cholera animal model,[17] calling into question the assumption that conjugation by squaric acid chemistry may not be of utility. We have examined a number of variables that affect the rate of conjugation by the squaric acid method.[18] On the basis of our more recent detailed study,[19] we have revised the original protocol and have now applied it to the full bacterial O-SP−core antigens of *V. cholerae* O1 Ogawa and Inaba, not just small oligosaccharide fragments, and a model protein BSA directly, without prior introduction of a linker to either O-SP−core antigen or protein carrier. Here, we report that such conjugation is not only possible, but equally simple as with synthetic, linker-equipped oligosaccharides and, as with synthetic oligosaccharides,[14] can be done with a very small amount of material. The method in the present form[19] is simple to perform, gives reproducible results, allows preparation of carbohydrate−protein constructs in a predictable way, and appears to be superior to protocols developed earlier.

EXPERIMENTAL PROCEDURES

General. V Vials equipped with Spin Vanes (Wheaton Science) were used as reaction vessels. Conjugation of carbohydrates was monitored by the BioRad Protein Chip SELDI system using NP-20 chip arrays. 3,5-Dimethoxy-4-hydroxycinnamic acid (sinapinic acid) was used as matrix. ^{13}C NMR spectra (150 MHz) of O-SP−core antigens were taken at ambient temperature for solutions in D_2O with a Bruker Avance 600 spectrometer equipped with a cryoprobe. Assignments of NMR signals could be confidently made by comparison with spectra of synthetic[20] α-glycosides of hexasaccharide fragments of the respective O-SPs, since spectra of the O-SP−core and the hexasaccharides showed close similarity of chemical shifts of equivalent carbon atoms of the internal residues and of the terminal upstream[21] residues. Bovine serum albumin (BSA) was purchased from Sigma (cat. no. A-4503), and used as supplied. Squaric acid dimethyl ester was purchased from Aldrich Chemical Co. and recrystallized from MeOH.

Isolation of the Lipopolysaccharides of *Vibrio cholerae* O1, Serotypes Inaba and Ogawa, and Preparation of the O-SP−core Antigens. LPS was obtained from *V. cholerae* O1, Ogawa (strain X-25049) or Inaba (strain 19479), by hot phenol/water extraction[22] followed by enzymatic treatment (DNase, RNase and protease), and ultracentrifugation (100 000 × *g* for 3 h). The pellet containing LPS was dialyzed against distilled water and freeze−dried. The LPS (10 mg/mL in 1% (v/v) aqueous acetic acid) was heated at 105 °C for 3 h.[23] Each hydrolysate was separated into chloroform-soluble and water-soluble fractions by thorough mixing with an equal volume of chloroform, followed by low-speed centrifugation. The water-soluble fraction containing the degraded polysaccharide moiety was separated, washed three or more times with chloroform, and then freeze−dried. The degraded polysaccharide was further fractionated by size exclusion chromatography (Sephacryl S-200) using water as eluant, giving two major peaks. The first peak corresponding to the O-SP−core[23,24] was isolated and freeze−dried. The crude O-SP−core products were further purified by ultrafiltration using centrifugal filter devices (3K Amicon Ultra, Millipore)

and dialyzed against 10 mM aqueous ammonium carbonate (centrifugation at 4 °C, 14 000 × *g*, 8 times, ~35 min each time) to remove the low molecular mass material. The retentate was lyophilized to afford the O-SP—core antigens as white solids.

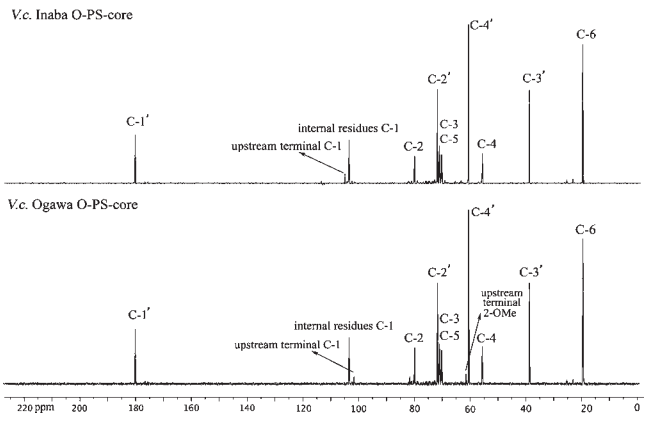

Figure 2. ^{13}C NMR spectra of the crude O-SP—core antigens of *V. cholerae*, serotype Inaba and Ogawa in D_2O.

The ^{13}C NMR spectra are in Figure 2. The SELDI-TOF mass spectral analysis indicated that the average molecular mass of the Inaba and Ogawa O-SP—core antigens were ~5100 and 5900 Da, respectively.

Preparation of Squarate Derivatives of the O-SP—core Antigens. 3,4-Dimethoxy-3-cyclobutene-1,2-dione (~0.5 mg) was added to a solution of O-SP—core antigen (0.80 mg and 0.92 mg for Inaba and Ogawa, respectively) in pH 7 phosphate buffer (0.05 M, 50 μL) contained in a 1 mL V-shaped reaction vessel, and the mixture was gently stirred at room temperature for 48 h. The resulting solution was transferred into an Amicon Ultra (0.5 mL, 3K cutoff) centrifuge tube and dialyzed against pure water (centrifugation at 4 °C, 14 000 × *g*, 8 times, ~35 min each time). The retentate was lyophilized to afford the O-SP—core squarate monomethyl ester as white solid [0.75 mg (94%) and 0.86 mg (93%)] for Inaba and Ogawa, respectively.

Conjugation of the O-SP—core Antigens to BSA. *Conjugation of the Inaba O-SP—core Antigen.* BSA (0.9 mg) and the methyl squarate derivative of the Inaba O-SP—core antigen described above (0.75 mg) were weighed into a 1 mL V-shaped reaction vessel and 60 μL of 0.5 M pH 9 borate buffer was added (to form ~2.5 mM solution with respect to the antigen; antigen/carrier = 10.8:1). A clear

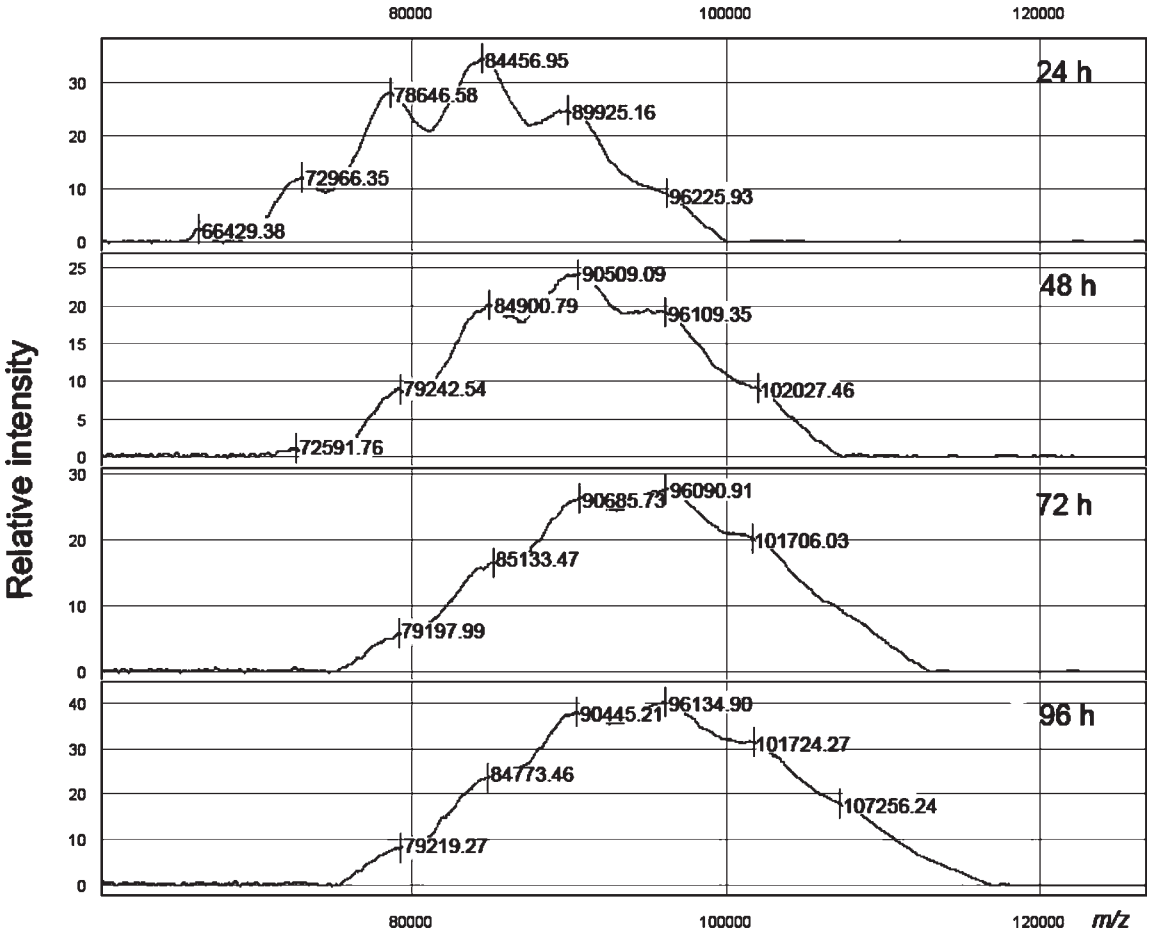

Figure 4. Monitoring of the conjugation of Ogawa O-SP−core antigens to BSA.

solution was formed. The mixture was stirred at room temperature and the reaction was monitored by SELDI-TOF MS at 24, 48, 72, 96, and 240 h (Figure 3), when the reaction was terminated by addition of 300 μL of pH 7 phosphate buffer. The solution was transferred into an Amicon Ultra (0.5 mL, 30 K cutoff) centrifuge tube and dialyzed (centrifugation at 4 °C, 10 000 × *g*, 8 times, 12 min) against 10 mM aqueous ammonium carbonate. After lyophilization, 0.80 mg (73%, based on BSA) of conjugate was obtained as a white solid. On the basis of the average MW of the hapten, the ratio hapten/BSA was 2.8:1 (conjugation efficiency, 26%).

Conjugation of the Ogawa O-SP−core Antigen. The protocol described above was followed with 0.86 mg of the methyl squarate derivative of the Ogawa antigen described above, 0.45 mg of BSA (antigen/carrier = 21.5: 1) and 30 μL of pH 9 borate buffer (~4.9 mM solution with respect to hapten). Monitoring of the progress of the conjugation is shown in Figure 4. After freeze−drying, 0.54 mg (84%, based on BSA) of conjugate was obtained as a white solid. On the basis of the average MW of the hapten, the ratio hapten/BSA was 4.8:1 (conjugation efficiency, 23%).

Evaluation of Immunoreactivity of Conjugates. *Assessing Lipopolysaccharide (LPS), O-SP−core-BSA, and BSA-Specific Antibody Responses in Plasma of Patients with Cholera, as Well as Vibriocidal Responses.* Acute and convalescent phase blood was obtained through fully Institutional Review Board-approved protocols from twenty individuals with *V. cholerae* O1 stool-culture-confirmed cholera (Ogawa = 10; Inaba = 10) admitted to the hospital of the International Centre for Diarrheal Diseases Research, in Dhaka Bangladesh (ICDDR, B). For this study, we used blood samples obtained on days 2 and 7 after onset of illness for antigen-specific and vibriocidal assays. We measured the vibriocidal antibody titer and antigen-specific IgG antibody responses using the homologous serotype of *V. cholerae* O1 LPS, or O-SP−core-BSA, Ogawa or Inaba.

We quantified anti-LPS, O-SP−core-BSA, and BSA IgG responses in plasma using standard enzyme-linked immunosorbent assay (ELISA) protocols.[25,26] To assess anti-LPS IgG responses, we coated ELISA plates with the homologous serotype of *V. cholerae* O1 LPS (2.5 μg/mL)[27] in PBS. To assess anti-O-SP−core-BSA or anti-BSA IgG responses, we coated ELISA plates with O-SP−core/BSA (1 μg/mL) or BSA (5 μg/mL) in carbonate buffer pH 9.6, respectively. To each well, we added 100 μL/well of plasma (diluted 1:50 in 0.1% BSA in phosphate-buffered saline−Tween) and detected the presence of antigen-specific antibodies using horseradish peroxidase-conjugated anti-human IgG antibody. After 1.5 h incubation at 37 °C, we developed the plates with a 0.55 mg/mL solution of 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid (ABTS; Sigma) with 0.03% H_2O_2 (Sigma), and determined the optical density at 405 nm with a Vmax microplate kinetic reader (Molecular Devices Corp. Sunnyvale, CA). Plates were read for 5 min at 14 s intervals, and the maximum slope for an optical density change of 0.2 U was reported as millioptical density units per minute (mOD/min). We normalized ELISA units by calculating the ratio of the optical density of the test sample to that of a standard of pooled convalescent-phase plasma from patients

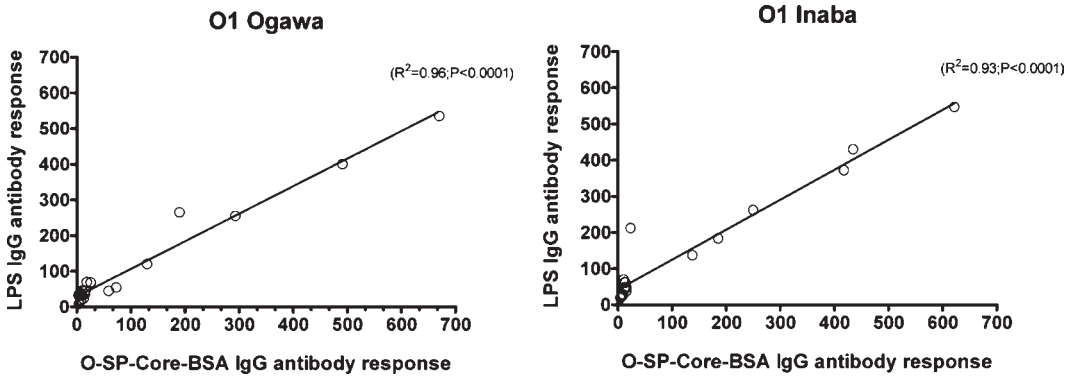

Figure 5. Correlation between anti-*V. cholerae* O1 LPS IgG antibody responses and corresponding O-SP−core-BSA IgG antibody responses. Lines designate the linear correlations between the responses. Antibody responses were assessed for 10 patients with Ogawa (left panel) and 10 with Inaba (right panel) during the acute and convalescent phases of infection.

recovered from cholera. We assessed vibriocidal responses as previously described, using guinea pig complement and the homologous serotype of *V. cholerae* O1 Ogawa (X-25049) or Inaba (19479) as the target organism.[25] The vibriocidal titer was defined as the reciprocal of the highest serum dilution resulting in >50% reduction of the optical density associated with *V. cholerae* growth compared to that of the positive control wells without plasma.[26] We compared the magnitude of acute to convalescent phase responses, and tested for significance using Wilcoxon Signed Rank test, and used linear regression for correlation analysis between vibriocidal antibody and antigen-specific antibody responses. All reported P values were two-tailed, with a cutoff of $P < 0.05$ considered a threshold for statistical significance.

■ RESULTS AND DISCUSSION

Conjugations were performed with O-SP−core antigens of *Vibrio cholerae* O1, serotypes Inaba and Ogawa, and the increasing molecular mass of the conjugate was monitored as described.[28] The structures of O-SPs of the two strains are very similar; they consist of a chain of (1→2)-α-linked moieties of 4-amino-4,6-dideoxy-α-D-mannopyranose (perosamine), the amino groups of which are acylated with 3-deoxy-L-*glycero*-tetronic acid. The O-SPs of the two strains differ in that the terminal, upstream perosamine moiety in the Ogawa strain carries a methoxy group at C-2 (Figure 1). The ^{13}C NMR spectra (Figure 2) of the antigens, where the signals of the O-SPs largely predominate, show all structurally significant peaks present in the spectra of the related, synthetic hexasaccharides.[20]

To ascertain whether simple, direct conjugation of O-PS−core antigens is feasible, the antigens were treated with an excess of squaric acid dimethyl ester at pH 7 for 2 days, when the product was isolated by dialysis followed by freeze−drying. The material thus obtained showed only moderate UV absorption at the wavelength characteristic of squaric acid, but successful formation of the corresponding monomethyl ester manifested itself when the material was treated with BSA at pH 9 resulting in smooth conjugate formation (Figures 3 and 4).

Knowing that the reaction rate of conjugation decreases with the size of oligosaccharides, and considering the actual reaction rates for a disaccharide, tetrasaccharide, and hexasaccharide,[19] the conjugation was carried out at initial Inaba O-SP−core/BSA ratio 1:1.2 (w/w), which corresponded to an approximate molar Inaba O-SP−core/BSA ratio of 10.8/1. The conjugation was performed at an O-SP−core concentration of ∼2.5 mM. When the conjugation process was terminated after 10 d, SELDI analysis of the purified conjugate after freeze−drying showed that the average molecular mass of the conjugate obtained was 81 000 Da (molar ratio O-SP−core/BSA = ∼2.8). The conjugate still contained some (∼5%) of the unchanged BSA (shown also in Figure 3, 240 h).

To ensure that no BSA used at the onset of the conjugation would be left unconjugated, the reaction of the Ogawa O-SP−core antigen was set up at a higher initial O-SP−core/BSA ratio [∼2:1 (w/w), which corresponded to an approximate initial molar Ogawa O-SP−core/BSA ratio of 21.5:1]. As shown in Figure 4, only a negligible amount of unchanged BSA was present in the conjugation mixture after 24 h of the reaction time. After 96 h, when the conjugation was terminated, the conjugate was isolated, and MS analysis by SELDI showed the average molecular mass of the conjugate obtained to be ∼95 000 Da (molar ratio O-SP−core/BSA = ∼4.8).

To assess the immunoreactivity of the conjugates and their potential use as cholera vaccines, we measured anti-O-SP−core-BSA antibody levels in the blood of patients with cholera in Bangladesh, and compared these responses to anti-LPS and vibriocidal responses, the latter two being among the primary predictors of protection against cholera.[8,29−31] There was excellent correlation of the immunoreactivity of the O-SP−core-BSA conjugates and the homologous anti-LPS responses in convalescent phase blood of humans recovering from cholera in Bangladesh (Ogawa, $R^2 = 0.96$, $P < 0.001$; Inaba, $R^2 = 0.93$, $P < 0.001$; Figure 5). There was also significant and antigen-specific increases in anti-O-SP−core-BSA responses in convalescent compared to acute phase blood for both the Ogawa and Inaba constructs ($P < 0.05$; Figure 6). Responses correlated with the vibriocidal response for Ogawa, and less well for Inaba (Ogawa, $R^2 = 0.74$, $P < 0.001$; Inaba, $R^2 = 0.2$, $P < 0.04$; Figure 7); importantly these correlation curves mirrored those of the LPS IgG to vibriocidal relationship.

As pointed out above, previous researchers have proposed that conjugate vaccines using squaric acid chemistry may not permit the development of maximal immune responses targeting sugar moieties. Here, we show that O-SP−core-protein conjugates produced by this simplified protocol are recognized by convalescent phase sera from patients recovering from cholera in Bangladesh, and anti-O-SP-core-protein responses correlate with plasma anti-LPS and vibriocidal responses. These results suggest that such conjugates might have utility as vaccines, although this can only be addressed by direct immunization studies and immunologic analysis. Currently available cholera vaccines use

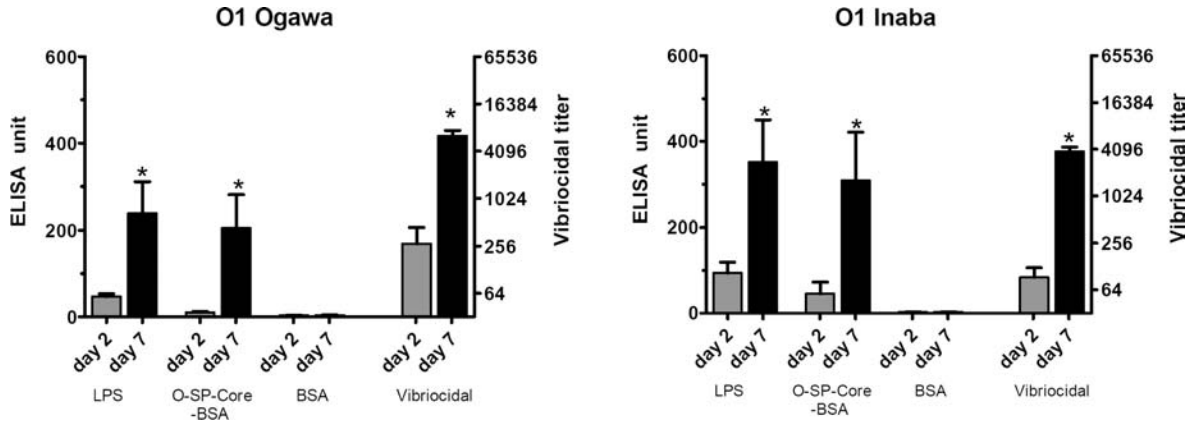

Figure 6. Mean normalized antigen-specific IgG and vibriocidal antibody responses in plasma (with standard errors of the means [SEM]). Plasma IgG and vibriocidal responses are shown on the left and right (log 2) axes, respectively. An asterisk denotes a statistically significant difference ($P < 0.05$) from the baseline (day 2) titer.

the oral route of immunization with killed whole cell preparations, require repetitive dosing, and provide protection that lasts for 6 to 36 months.[32] Infection with natural cholera results in protection that lasts for years or decades.[33−35] Development of inexpensive and simple-to-produce cholera vaccines that provide durable protective immunity would be significant. Whether a conjugate vaccine administered parenterally, transcutaneously, singly, or as a booster would fulfill these parameters is currently unclear and will be the objective of our future investigations.

CONCLUSIONS

We have shown that, when a sufficiently powerful method of conjugation is applied, coupling of bacterial O-SP−core antigens to proteins is a simple, high yielding process, and derivatization aimed at introducing linkers to either O-SP−core antigens or carrier proteins prior to conjugation is not necessary. This could eliminate lengthy and often costly operations involved in industrial conjugate production. Squaric acid chemistry of conjugation of amine-containing substances[13,19] is a useful tool for conjugation of carbohydrate antigens, synthetic or bacterial, to amine containing carriers. As can be expected from reaction rates determined for various oligosaccharides by this method,[19] high molecular mass substances, such as the fragments of LPS used in this work, conjugate at a proportionally diminished, but acceptable, rate and efficiency. Conjugation of O-SP−core antigens to protein carriers by this method utilizes the free amino group that is inherent in the LPS core and, thus, yields neoglycoconjugates with single-point attachment of ligands to carriers. From this point of view, the method is analogous to those involving chemical attachment of spacers to the synthons involved prior to conjugation.[11,12] Compared to the latter approaches, the conjugation described herein is much simpler and less laborious, and affords conjugates in higher yields with comparable overall conjugation efficiency. It produces conjugates that are fully and specifically recognized by immune responses in humans recovering from infection. Such features are particularly attractive for development of conjugate vaccines such as cholera, targeting infections of the world's most impoverished.

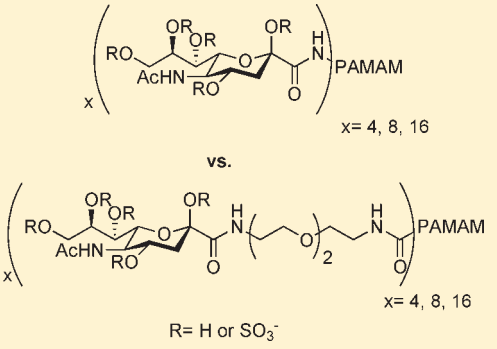
Supporting Information

ABSTRACT: A study was undertaken to evaluate the feasibility of synthesizing six sialic acid-PAMAM glycodendrimers using unprotected sialic acid in as few as 1−4 steps using two different reaction pathways, and to assess the sulfated derivatives for anti-HIV activity. The syntheses were accomplished through either the direct attachment of the sialic acid carboxyl group to amine-terminated PAMAM (a divergent-like approach) using BOP coupling, or by first reacting sialic acid with a polar bifunctional spacer molecule, attaching the sugar-linker to carboxy-terminated PAMAM (a convergent-like approach), and again using BOP-mediated coupling reactions. It was hypothesized that the latter approach would be the most successful method, as any steric congestion between the sialic acid and the PAMAM would be minimized using an intervening polar linker. However, the divergent-like synthesis proved to be the superior method, resulting in 11.4%, 14%, and 28% of the fully substituted generations 0, 1, and 2 sialic acid-PAMAM conjugates, respectively, as compared to 6.4% of only the generation −0.5 sialic acid-linker-PAMAM conjugate for the convergent-like method. Upon sulfation of the four glycodendrimers, binding capabilities to the recombinant HIV protein, gp120, were assessed using an ELISA assay. Compounds that showed promising binding characteristics were then further assessed for inhibition of HIV-1 infection using a well-characterized luciferase reporter gene neutralization assay. The generation 2 sulfated sialic acid-PAMAM glycodendrimer, **sulfo-6**, bearing 16 sialic acids with 11 sulfate groups incorporated at 4.03% sulfur content by weight, was found to inhibit all four HIV-1 strains tested in the low micromolar range.



INTRODUCTION

By the close of 2009, there were an estimated 33.3 million people worldwide infected with HIV. This included 2.6 million newly infected, and 1.8 million deaths.[1] This is a 3-fold increase compared to 1990.[2] HAART (highly active antiretroviral therapy) slows the progression of HIV to AIDS, and lengthens and improves the quality of life for those infected. There are now 4 million people worldwide on HAART, with 73% of those in Africa. However, three times as many people need treatment in resource-limited nations that are not receiving it.[3,4]

In addition to millions still needing HAART treatment, the utility of antiretroviral drugs is further limited by viral resistance and toxicity issues.[5,6] Moreover, there still exists no safe, effective vaccine or prophylactic drug approved for preventing the acquisition of HIV. The introduction of potent and cost-effective therapies able to not only treat HIV, but also prevent the transmission of the virus is of the utmost importance. This is particularly critical in regions of the world such as sub-Saharan Africa, where 67% of the world's HIV infected individuals reside.[2,7] Here, an estimated 80% of people infected are not aware of their own HIV status, and 90% of individuals do not know their partner's status.[3]

Sulfated polysaccharides have long been recognized as having potent anti-HIV activity. Several naturally occurring sulfated polysaccharides, such as heparin sulfate (HS) and dextran sulfate (DS), inhibit the binding of HIV to CD4 positive cells *in vitro* in the μg/mL or μM range (Figure 1).[8−10] The inhibition of HIV by polyanionic polysaccharides has been actively studied. There are regions in the HIV surface glycoprotein gp120 containing multiple basic amino acids, namely, the principle neutralizing domain (V3 loop, amino acids 303−338), the C-terminal region (amino acids 495−516), and a conserved region involved in chemokine coreceptor binding (discontinuous amino acids in regions 117−123, 207, 419−444).[11−14] These regions have been shown to interact with polyanions such as HS and DS, which prevent binding to complementary antibodies.[13,15] Surface plasmon resonance (SPR) studies revealed strong polyanion-gp120 binding with immobilized HS and monomeric gp120, yielding an affinity constant of 220 nM. These studies also determined that an average of 4.4 gp120 molecules bind each

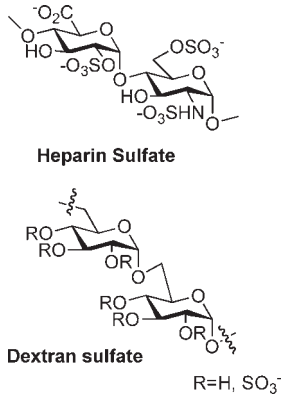

Figure 1. Structures of polyanionic polysaccharides possessing anti-HIV activity.

chain of heparin, indicating that higher avidity binding would be possible in a multivalent sense.[15−17] Mechanistically, it has been proposed that HIV binds to cell surfaces electrostatically between the polybasic V3 loop and host cell surface heparan sulfate proteoglycans (HSPG).[18] Another group suggested that a sequential process occurs, whereby first HSPG binds through a high-affinity, selective interaction with the V3 loop on gp120, followed by a second, lower-affinity interaction between such polyanions and the conserved chemokine coreceptor region.[15] It has also been noted that the binding between gp120 and polyanions occurs without disrupting the gp120-CD4 interaction, further strengthening the argument that the polybasic regions of gp120 bind to the chemokine coreceptors.[11,15,18]

HS and DS, while having strong affinity to the basic regions of gp120, are also anticoagulants, making it difficult to achieve therapeutic anti-HIV levels of the drugs without compromising blood clotting time.[19] Additionally, in phase I/II clinical trials, DS was found to be poorly absorbed orally, and when given intravenously, resulted in toxic side effects such as reversible thrombocytopenia and alopecia and did not yield a therapeutic effect based on HIV marker levels such as p24.[20,21] However, a later study of DS found good oral absorption of DS into the bloodstream indicating that DS has therapeutic potential and merits further study.[22]

A wide variety of other polysaccharides isolated from native sources, and either naturally or synthetically sulfated, have been found to have *in vitro* anti-HIV activity. Included are polysaccharides isolated from bacteria such as *E. coli* K5, marine plants such as algae, marine invertebrate animals such as tunicates and sponges, and land plants such as lichen.[23] These sulfated homo- and heteropolysaccharides contain numerous simple monosaccharide building blocks such as glucuronic acid, *N*-acetylglucosamine, galactose, mannuronic acid, and L-fucose, to name a few. Most of these polysaccharides have anti-HIV activities in the μg/mL range, all suffer from polydispersity of structure, and some have toxicity issues similar to DS and HS.[23]

Sulfated polysaccharides, while potent *in vitro* inhibitors of HIV, have not yet proven to be effective drug candidates for HIV due to their inherent polydispersity, as well as toxicity issues. We hypothesize that, if several shorter chains of the sulfated sugars are anchored to a carrier molecule, anti-HIV activity can be maintained, while toxicity and polydispersity of structure can be decreased or eliminated. A carrier molecule that can be utilized in this fashion is a dendrimer.

Dendrimers are a unique class of multivalent polymers, first reported by Tomalia and co-workers in 1985.[24] They are globular in shape and consist of a wide variety of architectures, with diverse sizes and chemical composition. Dendrimers are built in series with varying numbers of branches, which gives rise to a group of related molecules known as generations (G). With each branching reaction comes an increase in the number of branches, and subsequently, the next highest generation. Dendrimers can be synthesized in one of two ways, either divergently or convergently. Divergent synthesis involves building the dendrimer from the core outward, while a convergent strategy entails first building blocks of the molecule separately, then attaching them to a minimal core structure in the final step. Dendrimers have been used in many medical applications ranging from drug delivery to uses as immunodiagnostic reagents, MRI contrast reagents, gene delivery vectors, immunostimulation agents/adjuvants, or drug delivery vehicles.[25−30] Dendrimer research is important due to the diversity of structures that can be devised and their utility in numerous biological applications. It is important to understand the toxicity, solubility, and other properties of dendrimers, to ensure that they can be safely used in the development of new therapeutics. PAMAM (poly(amido amine))-based dendrimers have been well-evaluated both *in vitro* and *in vivo*. In the *in vivo* studies in mice and rats, it has been found that PAMAM is cytotoxic in a size-dependent fashion, with larger generations being more toxic.[31] Other properties affecting toxicity are charge (anionic PAMAM is less toxic than cationic) and surface modification with other groups, such as PEG (polyethylene glycol) or sugars.[32] PEGylation/glycosylation of PAMAM yields dendrimers with much lower toxicity profiles.[31]

When dendrimers are glycosylated, they are known as glycodendrimers, a class of compounds first reported by Roy in 1993.[33] Glycodendrimers built on a variety of dendrimer scaffolds such as PAMAM have found numerous uses in medicine due to the multivalent effect. Monovalent carbohydrates typically have weak millimolar binding constants in protein−carbohydrate recognition.[34] However, binding affinities achieved by the multivalent effect are orders of magnitude improved over a one molecule−one receptor binding event.[35,36] In nature, the multivalent effect is observed in many interactions, for example, in the viral infection by influenza where the viral trimeric hemagglutinin protein recognizes multiple copies of the carbohydrate sialic acid on the host cell.[37] A variety of sialic acid glycodendrimers were formulated as multivalent inhibitors of the binding between hemagglutinin and the host cell. The degree of inhibition achieved by these glycodendrimers was 32−50 000-fold higher than from monovalent sialic acid.[37] Glycodendrimers, therefore, present an alluring prospect for other medical applications because they increase the valency of a biologically active carbohydrate and improve the binding constants between the carbohydrate and the target protein.[38,39]

Scientists have begun to explore glycodendrimers as anti-HIV agents. Many of these are glycosphingolipid (GSL) mimics, as it is known that GSLs can be utilized by HIV-1 as alternate host cell receptors in the infection process.[40] The first account by Schengrund reported the synthesis of sulfated galactosyl ceramide (SGalCer)-coated polypropyleneimine (PPI) dendrimers, directed at preventing infection in CD4-negative cells.[41,42] In their studies, they determined that gp120 bound to their glycodendrimers in the nM range, as compared to the known polysaccharide HIV inhibitor DS, which bound in the pM range. Cytotoxicity of the glycodendrimers at up to 3 mg/mL was not

observed. Since this initial report, there have been a few more examples of potential anti-HIV glycodendrimers. Two other GalCer-based dendrimers were reported by Castillon and co-workers and Blanzat, Turrin, and co-workers.[43,44] One had a polyglycerol (PG) dendrimer core, and had lower activity than the Schengrund glycodendrimers.[42,43] The other GalCer glycodendrimers were based on a phosphonic acid core, and determined to have sub-μM IC_{50}s in a cell-based HIV assay (IC_{50} is the concentration that reduces HIV infection by 50%). However, these suffered from high cytotoxicities.[44,45] Another report was of a polylysine-sulfated cellobiose system.[46,47] This glycodendrimer was found to have an EC_{50} (effective concentration for 50% effect) of 3.2 μg/mL, comparable to the NRTI (nucleoside reverse transcriptase inhibitor) ddC (2′-3′-dideoxycytidine), and was also determined to have low cytotoxicity. Additionally, a mannose-based PG glycodendrimer was reported that targeted the dendritic cell lectin DC-SIGN.[48] The IC_{50} activity of this glycodendrimer was μM, similar to the others. Finally, Schengrund and co-workers recently reported two types of glycodendrimers based on the PPI core, terminating in either of the glycosphingolipid derived sugar headgroups, 3′-sialyllactose (GM_3) or globotriose (Gb_3).[40] The GM_3 and Gb_3 glycodendrimers were assessed for anti-HIV-1 activity in T-cells and primary peripheral blood mononuclear cells (PMBCs), and yielded IC_{50} values ranging from 0.1 to 7.4 μg/mL.[40]

While the above results are encouraging, the search for easy to make, cost-effective, and potent new anti-HIV therapeutics remains a significant goal for the scientific/medical community in light of the high rate of infection continuing to this day, the longer life spans of infected individuals, and the therapeutic failures occurring due to drug toxicity and resistance. All of these factors contribute to fewer therapeutic strategies available to a patient the longer they have been infected. Additionally, if new anti-HIV therapeutics can be designed in such a way that they are simple and cost-effective to produce, it will be easier to implement therapy in resource-limited regions of the world, where the bulk of HIV infections are occurring.

Along these lines, we endeavored to create an initial trial set of 6 compounds based on the commercially available dendrimer core, PAMAM (G = −0.5, 0, 0.5, 1, 1.5, and 2), and the unprotected sugar, sialic acid (**10**, Scheme 2). This could be accomplished by one of two pathways, a one-step divergent-like pathway (Scheme 4), whereby sialic acid was directly coupled to PAMAM, or a four-step convergent-like approach, where an intermediary linker (**8**, Scheme 1) was first reacted with sialic acid, then the sugar−linker conjugate coupled to PAMAM Scheme 3). The first approach was anticipated to be the most difficult as the sialic acid carboxyl group is sterically congested and might not be accessible enough to the also sterically crowded multiple reaction centers in PAMAM. These potential pitfalls led us to develop the second pathway, where a long linear hydrophilic linker was first attached to sialic acid, followed by reaction of the sugar−linker to PAMAM. This was thought to be the best approach, as the steric consequences suffered by both reaction partners would be greatly minimized in the presence of the hydrophilic linker. Whichever pathway produced the desired glycodendrimer conjugates with the best yields would then be utilized in further syntheses.

As for the individual sugar and dendrimer choices, there were many factors to consider. PAMAM was chosen primarily because of its availability and also because there was an abundance of data available on the cellular toxicities of PAMAM-based molecules

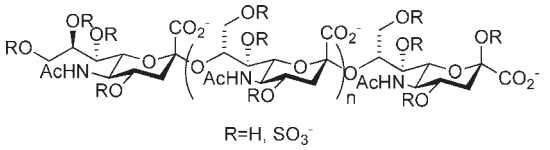

Figure 2. Sulfated colominic acid.

(*vide supra*). Sialic acid was chosen for a few key reasons as well. First, it contains a carboxyl group attached to the anomeric carbon, making it easy to append it to either an amino-bearing linker or to an amino-terminated PAMAM using standard solution-phase peptide coupling methodologies, all without having the sugar protected. Second, some preliminary anti-HIV data have been reported for a sialic acid-based polysaccharide, colominic acid, in the sulfated form. Colominic acid is an α-2→8-linked polymer of sialic acid (Figure 2). Yang and co-workers found EC_{50} values as low as 0.06 μg/mL for the larger molecular weight, more highly sulfated derivatives of colominic acid (MW ranging from 8 to 16 kDa, sulfation 8−12%) in MT-4 and C8166 cell lines infected with HIV in the presence of these molecules.[19] Their assay control, DS, yielded EC_{50} values of 0.5 and 2.51 μg/mL in the same cell lines, respectively. Finally, by using the base sugar from a polymer with known anti-HIV activity, we would be able to quickly ascertain if utilizing PAMAM as a scaffold for the multivalent presentation of sulfated sugars to the target protein, gp120, was as/more effective in binding to gp120/inhibiting HIV infection than the known sulfated linear polysaccharide standard, DS.

Once synthesized, all of the sulfated sialic acid-PAMAM glycodendrimers could be assessed for anti-HIV-1 activity by two separate, yet complementary assays. The first assay, a fast ELISA (enzyme-linked immunosorbent assay) developed in our lab, could be used to screen for the presence of gp120 binding. If activity was found, a second, more sensitive luciferase reporter gene assay could then be utilized to determine how well the sulfoglycodendrimers were able to inhibit HIV-1 infection of TZM-bl cells.

EXPERIMENTAL PROCEDURES

General Materials and Methods. All nuclear magnetic resonance (NMR) spectroscopy was performed on a Bruker Avance III 500 MHz NMR spectrometer with either D_2O or $CDCl_3$ solvents purchased from Acros. To simplify the analysis of the ^1H NMR spectra for compounds **1**−**6**, the integrations were normalized for 1/4 of total protons, the equivalent of 1 branch of the full glycodendrimer. For ^{13}C analysis, 3-(trimethylsilyl) tetradeutero sodium propionate (TSP) from Wilmad was used as a zero point reference, and all spectra were proton decoupled. MALDI mass spectral analysis was conducted on a Kratos/Shimadzu Axima-CFR MALDI-TOF (University of the Pacific) and a Bruker Reflex III MALDI-TOF (The Ohio State University). High-resolution ESI mass spectral analysis was conducted on an IonSpec Fourier transform mass spectrometer (University of Arizona). Flash chromatography was performed using flash silica gel (32−63 μM) from Dynamic Adsorbents Inc. Dialysis purification was performed using Spectra/por Biotech Cellulose Ester dialysis membrane from Spectrum Laboratories Inc. Reverse-phase high-pressure liquid chromatography (RP-HPLC) was conducted on a Hewlett-Packard TI-series 1050 using a Grace Prevail C-18 5 μ 250 × 10 mm column. Fast-paced liquid chromatography (FPLC) was performed with a Pharmacia pump P-500 with a LC Controller LCC-500 Plus.

The column used in conjunction with the FPLC was a Bio-Gel P-10 2.5 cm × 120 cm column.

The reagents used came from a variety of sources and were used without further purification: All poly(amidoamine) (PAMAM) dendrimers were purchased from Aldrich. Benzotriazol-1-yloxytris-(dimethylamino)phosphonium hexafluorophosphate (BOP) was from Nova Biochem. *N,N*-Diethylisopropyl amine (DIPEA) was purchased from Alfa Aesar. Trifluoroacetic acid (TFA), triethylamine (TEA), ammonium bicarbonate, and *N,N*-dimethylformamide (DMF) were from EMD. Di-*tert*-butyl dicarbonate ($(Boc)_2O$) was purchased from Acros. 1,8-Diaminotriethyleneglycol was obtained from Huntsman. *N*-Acetylneuraminic acid (sialic acid) was purchased from Nacalai Tesque. 500 kDa dextran sulfate was purchased from Sigma-Aldrich.

Note on Characterization. All labels on protons in the ^1H NMR data correspond to assignments given on the spectra. The spectra can be found in the Supporting Information section.

Nomenclature Note. All glycodendrimers are named as follows: The number of end points, tetramer, octamer, or 16-mer, followed by glyco-. If a linker is present between PAMAM and sialic acid, the abbreviation DATEG (1,8-diaminotriethyleneglycol) appears. The name terminates in PAMAM dendrimer.

{2-[2-(2-Amino-ethoxy)-ethoxy]-ethyl}-carbamic Acid *tert*-Butyl Ester (8). 1,8-Diaminotriethyleneglycol **7** (5.0 g, 33.8 mmol) was weighed into a flame-dried 500 mL round-bottomed flask. Methanol (135 mL) was added, followed by TEA (340 mg, 3.4 mmol), then $(Boc)_2O$ (7.38 g, 33.8 mmol). The reaction was heated to 35 °C and stirred overnight. The solvents were evaporated under reduced pressure and the crude residue was purified by flash chromatography using 1:1 methanol/chloroform, giving **8** as a viscous golden oil (4.25 g, 17.1 mmol, 51% yield). ^1H NMR (D_2O): δ 1.41 (s, 9H, H_T), 2.79 (t, 2H, J = 5.4 Hz, H_S), 3.25 (t, 2H, J = 5.4 Hz, H_P), 3.57 (q, 4H, J = 5.0 Hz, 9.7 Hz, H_Q), 3.66 (s, 4H, H_R). ^{13}C NMR (D_2O, TSP internal std): δ 30.4, 42.6, 72.1, 72.2, 74.9, 161.

***N*-Acetylneuraminic Acid {2-[2-(2-Amino-ethoxy)-ethoxy]-ethyl}-amide (11).** Sialic acid (**10**, 100 mg, 0.32 mmol) was weighed into a flame-dried 25 mL round-bottomed flask, dissolved into DMF (2 mL) and placed under nitrogen. BOP (210 mg, 0.48 mmol) was added to the solution as a solid. In a separate flask, the linker **8** (87 mg, 0.35 mmol) was dissolved in DMF (1 mL). DIPEA (170 mg, 1.28 mmol) was then added. This mixture was next added to the sialic acid solution. The reaction was heated to 35 °C and stirred for 24 h. The solvent was evaporated under reduced pressure. The crude was dissolved in 1:2 dichloromethane/TFA (12 mL) and stirred for 2 h before the solvents were evaporated under reduced pressure. The crude material was purified with RP-HPLC using a gradient of deionized water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid giving **11**, as a gummy white solid (155 mg, 0.35 mmol, 88% yield). ^1H NMR (D_2O): δ 1.67 (t, 1H, J = 12.2 Hz, H_B), 2.03 (s, 3H, H_C), 2.31 (dd, 1H, J = 4.7 Hz, 13 Hz, H_A), 3.19 (t, 3H, J = 4.8 Hz, H_P), 3.43 (m, 2H, H_S), 3.55−3.73 (M, 11H, $H_{G,H,J,Q,R}$), 3.82 (dd, 1H, J = 2.6 Hz, 11.9 Hz, H_E), 3.89 (t, 1H, J = 10.3 Hz, H_I), 4.05 (m, 2H, $H_{D,F}$). ^{13}C NMR (D_2O, TSP internal std): δ 22.3, 39.0, 39.3, 39.8, 52.4, 63.4, 66.6, 67.0, 68.4, 68.9, 69.7, 69.8, 70.4, 70.7, 96.0, 173, 175. High-resolution electrospray mass spectrometry (HR-ESI+: $[M + H]^+$ ($C_{17}H_{34}N_3O_{10}$) calcd m/z = 440.2239. Found m/z = 440.2238.

General Procedure for the Synthesis of Glyco-DATEG-PAMAM Dendrimers. PAMAM G = −0.5, 0.5, and 1.5 (1 equiv) were transferred to a 10 mL round-bottomed flask, G = −0.5 as a solid, and 0.5 and 1.5 as a 20% wt solution in methanol. The methanol was evaporated from G = 0.5 and 1.5 *in vacuo*. Next, DIPEA (2.5 equiv/arm) was added, and flushed with nitrogen. DIPEA (2.5 equiv/arm) was added, followed by BOP (1.2 equiv/arm). The sugar linker **11** (1.1 equiv/arm) was placed into a second 10 mL round-bottomed flask and dissolved in DMF (1 mL). The two solutions were mixed together, heated to 35 °C, and stirred under nitrogen for 1, 7, and 14 days, respectively. The solvents were evaporated under reduced pressure and the crude product was dialyzed with 500 MWCO tubing in a 1 L flask against nanopure water. The water was changed once every hour for four hours, and allowed to stir overnight at 4 °C . The remaining crude material was then lyophilized. The dialyzed crude material was then purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid. Fractions containing the product were collected, grouped, and further purified using a 2.5 × 120 cm Bio-Gel P-10 in 0.03 M ammonium bicarbonate. A 6.4% yield of only compound **1** was achieved by this method.

General Procedure for the Synthesis of GlycoPAMAM Dendrimers. Sialic acid (**10**, 1.1 equiv/arm) was weighed into a flame-dried 10 mL round-bottomed flask, flushed with nitrogen, then dissolved into DMF (4 mL). BOP (1.5 equiv/arm) was then added as a solid. PAMAM G = 0, 1, or 2 (20% wt in methanol) (1 equiv) was next weighed into a separate 10 mL round-bottomed flask and the methanol was evaporated under reduced pressure. DMF (1.5−2.0 mL) and DIPEA (2.5 equiv/arm) were added to the flask with PAMAM. The PAMAM solution was then added to the sialic acid solution, heated to 35 °C, and the reaction was stirred for 1, 7, or 14 days, respectively, under nitrogen. The crude reaction product was dialyzed with 500 MWCO tubing against nanopure water. The water was changed once an hour for four hours, then left stirring overnight at 4 °C. The crude material was then purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid providing compounds **2**, **4**, and **6** in 11.4%, 14%, and 28% yields, respectively.

General Sulfation Procedure. Nonselective sulfation of the glycodendrimers was carried out according to the procedure of Kunou et al.[49] Briefly, the glycodendrimers were sulfated under a nitrogen atmosphere at 0 °C, using a 3:1 ratio of SO_3−pyridine complex to hydroxyl groups per sugar unit. 10 mg of each glycodendrimer and the appropriate mass of SO_3−pyrindine complex were each dissolved in 1.25 mL of dry DMF under N_2. The sulfating solution was added dropwise into the glycodendrimer solutions and the reaction mixtures were stirred for 1 h at 0 °C under N_2. The reactions were terminated by the addition of 0.5 mL ice−cold water and the pH values of the reaction mixtures were adjusted to above 9 with 2 M NaOH. The reaction mixtures were next added dropwise to 50 mL of ice−cold acetone and left to precipitate at −20 °C for 24 h. The precipitates were collected by centrifugation, then decantation of the acetone. The precipitates were dissolved in small volumes of water and purified via dialysis (either 500 or 1000 MWCO tubing was used, Spectra/Por) against purified DI water at 4 °C. The sulfated glycodendrimers were then obtained as fine white solids by lypohilization. Finally, the sulfated glycodendrimers were evaluated by Columbia Analytics in Tucson, AZ, to determine the % sulfur for each. From this information, the approximate number of sulfate groups incorporated into each glycodendrimer was determined. For **sulfo-1**, **2**, **4**, and **6**, the %S

incorporated into each glycodendrimer was 11.22%, 15.32%, 2.02%, and 4.03%, respectively.

General procedure for the competitive ELISA with biotinylated recombinant gp120. A competitive ELISA was developed to determine the inhibitive binding properties of the sulfated glycodendrimers against the HIV-1 monoclonal antibody peroxidase-labeled murine mAb1101-P gp120 HIV-1 (Immunodiagnostics), to biotin-labeled rgp120 HIV-1 IIIB (b-rgp120, Immunodiagnostics). Dextran sulfate (500 kDa) was used as a positive assay control, and buffer was used as a negative assay control. Competition between the b-rgp120 and the mAb was evidenced by a decrease in the overall absorbance at 450 nm. To run the assay, a 1:5000 dilution of b-rgp120 was prepared in PBS and 100 μL of this dilution was transferred to the wells of Reacti-Bind NeutrAvidin-coated strip plates (Thermo Scientific). The plates were incubated for 1 h at 25 °C while shaking at medium speed in a Jitterbug Plate Incubator Shaker (Boekel). The plates were washed three times with PBS containing 0.05% (v/v) Tween 20. 200 μL of PBS containing 1% (w/v) BSA was added to each well to block nonspecific binding sites and the plates were incubated for 1 h at 25 °C while shaking at medium speed. While blocking, a 1:1000 dilution of the mAb 1101-P, and 0.2−400 μg/mL dilutions of the sulfated glycodendrimers were prepared in PBS-Tween 20 containing 0.1% (w/v) BSA. The plates were washed three times, and then the wells were treated in duplicate with 50 μL of the sulfated glycodendrimer dilutions plus 50 μL of the mAb1101-P dilution and incubated for 1 h at 25 °C while shaking at medium speed. The plates were washed three times. The wells were treated with 100 μL of SureBlue peroxidase substrate (KPL) and the kinetic reaction absorbances were read for 10 min at 655 nm on a BioRad model 550 plate reader. The kinetic reaction was stopped by the addition of 100 μL of 1 M HCl to each well. The end point absorbances were read at 450 nm. The duplicate end point readings were averaged and plotted against the log of the concentration (g/L) in a nonlinear regression analysis using GraphPad *Prism 4* software. From this, IC_{50} (inhibitory concentration to achieve 50% of the effect, in this case 50% less binding between b-rgp120 and the mAb) values in μg/mL and R^2 values were determined. A minimum of two assays were completed for each glycodendrimer or standard.

HIV Neutralization Luciferase Reporter Gene Assay. Inhibition of HIV infectivity by the sulfated glycodendrimers was assessed in a formally optimized, validated, and GCLP (good clinical laboratory practice)-compliant infectivity reduction assay according to the method of Montefiori *et al.* and conducted at Duke University in the GCLP-certified Primate Central Immunology Laboratory.[50,51] The solid glycodendrimer samples and dextran sulfate were prepared for analysis as follows: They were first dissolved in PBS and sterile-filtered to give 1 mg/mL concentrations. The 1 mg/mL stock solutions were serially diluted 1:3 in concentrations ranging from 50 to 0.02 μg/mL. The HIV-1 strains utilized in the assay included Q23.17 (Clade A), MN.3 (Clade B), MW965.26 (Clade C), and TV1.21 (Clade C). The cells assayed for infection were TZM-bl cells expressing CXCR4, and engineered to express the human cell receptors CD4 and CCR5, in addition to the enzymes, firefly luciferase and *Escherichia coli* β-galactosidase. An additional positive control, HIVIG-C, a purified IgG pooled from HIV^+ donors from South Africa, was prepared from a stock 12.5 mg/mL solution and used in the assays in 1:3 dilutions ranging from 625 to 0.29 μg/mL.

RESULTS AND DISCUSSION

The purpose of this work was to examine the ease of synthesizing glycodendrimers of various generations using both convergent-like and divergent-like synthetic strategies, and to perform some preliminary assessments for potential HIV-1 activity. With the sole exception of the preparation of compound **8**, no protecting group chemistry was used in this study. Because protecting group strategies require two additional steps per group, and result in lower overall yields, eliminating these steps saves time, and precludes the need for numerous purification steps. To achieve this, a synthetic route was devised where the reactions were conducted in a polar solvent to ease solubility issues, the reagents would not target the unprotected hydroxyls, and the chemistry utilized was efficient enough to allow for the desired conversion to the fully substituted products could be readily achieved. Whichever strategy proved superior would then allow for the creation of a variety of glycodendrimers of various sizes and sugar compositions more quickly. To test the convergent-like strategy for the synthesis of dendrimers, sialic acid was coupled to a hydrophilic linker, **8**, which was then attached to PAMAM, both utilizing amide linkages. As linker **8** was amine terminated, the half generations of carboxylic acid-terminated PAMAM ($G = -0.5$, 0.5, and 1.5) were employed in these cases. For the divergent-like strategy, the carboxyl group of sialic acid was coupled directly to the terminal amine of PAMAM $G = 0$, 1, and 2.

Glycodendrimer Synthesis. Generations −0.5, 0.5, and 1.5 were coupled to the sugar−linker complex through a convergent synthetic method. To achieve this, the linker (1,8-diaminotriethyleneglycol, **7**) was singly protected with di-*tert*-butyldicarbonate ($(Boc)_2O$). As both ends of the linker are chemically equivalent, this reaction afforded three products: unreacted starting material (**7**), the monoprotected linker (**8**), and the diprotected linker (**9**). Monoprotected linker (**8**) was isolated by normal phase flash chromatography using 1:1 chloroform and methanol, giving the desired product (**8**) in a 51% yield (Scheme 1).

The monoprotected linker (**8**) was next coupled to sialic acid (**10**) using benzotriazol-1-yloxytris(dimethylamino)phosphonium hexafluorophosphate (BOP) coupling conditions. After overnight reaction at 35 °C, the Boc protecting group was removed in 1:2 dichloromethane/trifluoroacetic acid (TFA) (Scheme 2).

Compound **11** was purified by reverse-phase high-pressure liquid chromatography (RP-HPLC), giving the desired product in 88% overall yield for two steps. Next, the sugar−linker (**11**) was attached to PAMAM generations −0.5, 0.5, or 1.5 via an amide coupling using BOP and DIPEA (*N*,*N*-diisopropylethylamine) in DMF at 35 °C, under nitrogen for 1, 7, or 14 days, respectively, producing glycodendrimers **1** and **3** (Scheme 3).[52] Glycodendrimer **5**, unfortunately, was not isolated.

To make compounds **2**, **4**, and **6** using a divergent-like approach, sialic acid (**10**) was mixed with the appropriate PAMAM and allowed to react using BOP coupling conditions at 35 °C under nitrogen gas for 1, 7, or 14 days. This produced glycodendrimers **2**, **4**, and **6** (Scheme 4).

Glycodendrimer Characterization. One of the primary goals of the research presented herein was to develop an efficient synthetic strategy to evaluate convergent and divergent-like synthetic methods to determine which method was simpler/more efficient for the synthesis of sialic acid-coupled glycodendrimers as that could serve as effective and potent anti-HIV-1 agents. An additional goal involved the minimization/elimination of the polydispersity inherent to the

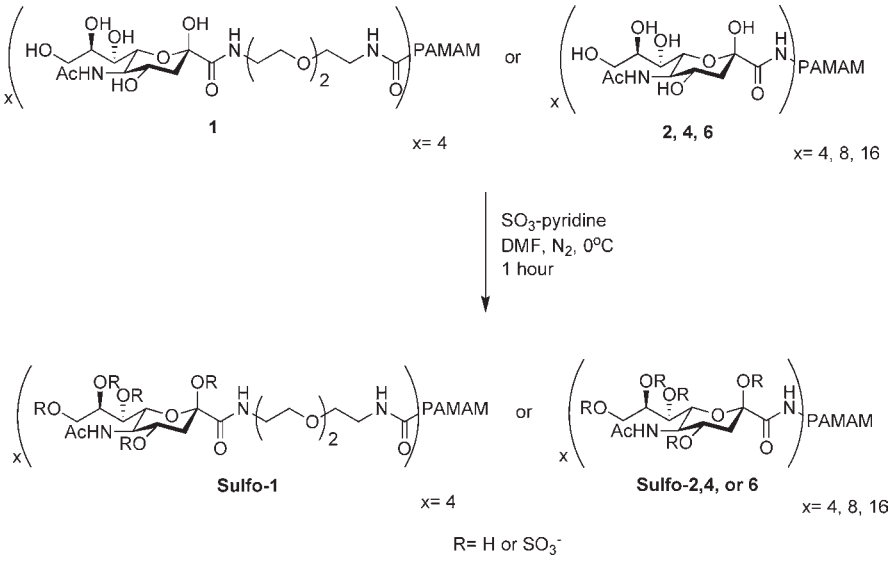
polysaccharides known to have anti-HIV activity. If successful, this would result in structurally well-defined glycodendrimers, and allow for a greater understanding of which features are the most critical for anti-HIV-1 activity. This was viewed as an important aspect of the study as many of the previous reports yielded incompletely substituted glycodendrimers (*vide supra*).[40,41,43,46,47] In the current study, the divergent-like approach consisted of only a single step between sialic acid and the appropriate amine-terminated PAMAM via a BOP coupling (Scheme 4). This synthesis was anticipated to be difficult, as the carboxyl group on sialic acid is sterically hindered. That, along with a large, bulky dendrimer, and the simultaneous occurrence of multiple reactions in the coupling step, was expected to present a great synthetic challenge and result in understandably low yields. The convergent-like synthesis, on the other hand, was expected to be much more facile as an intermediary polar primary amine-terminated linker was first attached to sialic acid in a 1:1 reaction, which was then coupled to carboxy-terminated PAMAM dendrimers (Scheme 3). This strategy was expected to be advantageous, as the steric issues between sialic acid and PAMAM would be minimized by the presence of a long polar spacer molecule. It was thus anticipated that the coupling between the sialic acid-linker (**11**) and various PAMAM cores would result in greater yields than the divergent-like approach.

It was therefore a surprise to find that the divergent-like synthetic method, where sialic acid was directly coupled to PAMAM, produced the desired fully substituted products in higher yields than the convergent-like approach. For the divergent-like reactions, compounds **2**, **4**, and **6** were all isolated and completely characterized via ^{1}H NMR, ^{13}C NMR, and MALDI-MS in modest yields of 11.4%, 14%, and 28%, respectively. The yields were likely low due to the steric issues previously mentioned.

For the convergent-like method, however, the addition of the diaminotriethylene glycol linker was expected to aid the reactions by reducing steric hindrance, yet resulted in minimal/no product isolation. Compound **1** was only isolated/characterized in 6.4% yield. For compound **3**, the impurity of the sample and the low quantities produced precluded the ability to obtain confirmatory ^{1}H or ^{13}C data; only MALDI MS analysis was possible. The calculated molecular weight for **3** is 4462 Da; however, MALDI MS showed small peaks for (M+H) m/z = 4467, (M−H_2O)

dx.doi.org/10.1021/bc200331v |*Bioconjugate Chem.* 2011, 22, 2186–2197

Scheme 5. Nonselective Sulfation of Glycodendrimer Products



m/z = 4448, and (M−2H_2O) m/z = 4428, along with impurity peaks (M-compd **11**-H_2O) m/z = 4027 and (M-2 compd **11**) m/z = 3619. Compound **3** has more than 180 carbon atoms, so it is likely there are at least two ^{13}C atoms adding weight beyond the calculated molecular mass. Compound **5** was neither isolated nor confirmed, even after multiple attempts at synthesizing and purifying this molecule. We hypothesize that the linker may have been too conformationally flexible, allowing the linker to fold back on itself and participate in intramolecular hydrogen bonding with the polar face of the sialic acid. It is believed that this would result in reduced/absent reactivity of the sugar−linker to PAMAM.

These results clearly indicate that, for our system, the divergent-like synthesis was the superior method as fully substituted sialic acid glycodendrimers resulted. Yield improvements for the divergent-like approach are currently being sought in the laboratory through substitution of the solvent and/or coupling reagent. It is thought that a better combination can be found for this system that will behave more favorably with the polarity/solubility issues of the reactants, and result in improved yields, all while maintaining the ability to use unprotected sugars.

Assessment of anti-HIV Activity. The second major goal of the work presented herein involved the evaluation of sulfated derivatives of the glycodendrimers for possible anti-HIV activity. Once all of the glycodendrimers (**1**, **2**, **4**, and **6**) were successfully isolated and characterized, they were sulfated and purified according to the method of Kunou et al. (Scheme 5).[49] As this method is not selective as to the location or number of sulfates incorporated on the sugar hydroxyl groups, and the molecules had been completely characterized after their initial synthesis, further NMR and mass spectral analysis was not conducted. Instead, elemental analysis for % sulfur (%S) was completed. Using the %S for each glycodendrimer, the average number of sulfate groups incorporated into each glycodendrimer was calculated. The %S for sulfated compounds **sulfo-1**, **2**, **4**, and **6** were 11.22%, 15.32%, 2.02%, and 4.03%, respectively, which translated to an average number of sulfate groups incorporated of 10, 13, 2−3, and 11, respectively. The nonregiospecific sulfation method was utilized, rather than a more selective method, as these require additional protection/deprotection steps to incorporate the sulfate group on a specific hydroxyl group. As this was a preliminary study to elucidate a synthetic path that would yield glycodendrimers with anti-HIV-1 activity in the fewest possible steps, it was decided that achieving a completely monomolecular compound at this stage of the project in terms of both the number of sugars and sulfate groups incorporated was of lesser importance than achieving a fully substituted glycodendrimer product. This will, however, continue to be a goal in future work.

To evaluate whether or not the sulfated glycodendrimers had the capability of binding to the target HIV-1 protein, gp120, a simple in-house competitive binding ELISA assay was developed. This assay was utilized as an initial screen to quickly assess whether or not the sulfated glycodendrimers had the ability to bind to b-rgp120 (biotinylated recombinant gp120) and thereby inhibit the binding between b-rgp120 and an HRP (horseradish peroxidase)-labeled monoclonal antibody specific to the V3 loop of gp120. Briefly, b-rgp120 was incubated with NeutrAvidin-coated plates. NeutrAvidin is a proprietary biotin-binding protein capable of binding with high avidity to biotin-containing molecules and adhering them more/less permanently to the surface of the plate. This was done to ensure that gp120, with a high carbohydrate composition (∼50% by weight), did not wash off of the plate. After blocking the open sites with bovine serum albumin (BSA), the competitive binding step was initiated where both the HRP-labeled monoclonal antibody specific to the V3-loop of gp120 and either the serially diluted sulfated glycodendrimer or assay controls were incubated with the anchored gp120. After the prescribed incubation period and rinsing, the HRP substrate was added, and the reaction was monitored for 10 min at 655 nm, to observe linearity of the kinetics. The reaction was then stopped with the addition of HCl and the plate read again at 450 nm to ascertain the end point absorbances.

All of the sulfated glycodendrimers (**sulfo-1**, **2**, **4**, **6**) were initially evaluated by the ELISA. Each compound was assayed in duplicate wells a minimum of two times, and all results were compared to the positive assay control, 500 kDa dextran sulfate (Figure 1), containing 17% sulfur (2.3 sulfates/sugar).[53] Dextran

Table 1. Summary of Pertinent Structural and HIV Assay Data for Sulfated Glycodendrimers and Positive Assay Controls, Dextran Sulfate, and Antibody HIVIG-C

compound	approxx MW (g/mol)	% sulfur	avg # sulfates	ELISA IC_{50}[d]	Q23.17 (Clade A) IC_{50}[e]	MN.3 (Clade B) IC_{50}[e]	MW965.26 (Clade C) IC_{50}[e]	TV1.21 (Clade C) IC_{50}[e]
Sulfo-1	2821	11.22	10 (2.5/sugar)	>71 μM	NA[a]	NA[a]	NA[a]	NA[a]

Dextran Sulfate	500 000	17	2.3/sugar	1.6 nM	8.2 nM	4.4 nM	2.8 nM	2.6 nM
HIVIG-C	150 000	NA[a]	NA[a]	NA[a]	98.7 nM	35.3 nM	8.7 nM	0.34 μM

[a] NA = Not applicable/no assay was conducted. [b] Reduction in the absorbance at 450 nm by **Sulfo-6** was only observed at the highest compound concentrations tested and did not reach the cutoff level of a 50% reduction in absorbance at 450 nm. [c] Reduction in the luciferase signal by **Sulfo-4** was only observed at the highest compound concentrations tested and did not reach the 50% neutralization cutoff. [d] Values are the sample concentration (μM) at which the absorbance at 450 nm was reduced by 50% compared to the control wells (no test sample). Sample concentrations ranged from 0.1 to 200 μg/mL in the assay wells. [e] Values are the sample concentration (μM) at which relative luminescence units (RLUs) were reduced 50% compared to virus control wells (no test sample). Sample concentrations ranged from 0.02 to 50 μg/mL for the sulfoglycodendrimers and DS, and 0.29−625 μg/mL for HIVIG-C.

sulfate consistently results in an average IC_{50} (inhibitory concentration for a 50% reduction in gp120 binding) of 1.6 nM with an R^2 value of 0.99 for the nonlinear regression fit for dose−response analysis (Table 1). **Sulfo-1**, **2**, and **4** did not fit nonlinear regression dose−response curves, evidenced by low R^2 values (data not shown). For **Sulfo-6**, higher concentrations of this molecule led to a noticeable decline in the absorbance at 450 nm, indicating that some binding to gp120 was achieved; however, a 50% inhibition of antibody binding to b-rgp120 was not achieved. It was hypothesized that lack of quantitative results by the ELISA may have had more to do with the lower sensitivity limits of the ELISA, rather than whether or not the compounds actually had anti-HIV activity, and we are in the process of optimizing the ELISA assay to improve its sensitivity. The decision was therefore made to evaluate the two higher-order sulfated glycodendrimers (**sulfo-4** and **6**) directly for anti-HIV activity using the luciferase reporter gene assay because it is a more sensitive assay. **Sulfo-1** and **sulfo-2** were not evaluated further, because we had recently determined that other sulfated glycodendrimers of similar size did not yield anti-HIV-1 activity in the luciferase assay (data not shown).

The luciferase reporter gene assay used in this analysis was first developed by Shaw and co-workers, then further optimized and validated by Montefiori and colleagues.[50,51,54] This assay evaluates a single round of infection of a modified TZM-bl cell line, derived from HeLa. TZM-bl cells express the HIV-1 coreceptor, CXCR4, and have been engineered to express coreceptor CCR5 and receptor CD4, in addition to the integrated reporter genes for firefly luciferase and the β-galactosidase gene from *Escherichia coli*. The pseudoviruses utilized (Q23.17 (Clade A), MN.3 (Clade B), MW965.26 (Clade C), and TV1.21 (Clade C)) are infectious, but are not able to replicate to yield viable virions and are thus limited to one round of infection. Upon infection of the TZM-bl cells, the *tat* gene carried by the pseudovirus is expressed and the resultant Tat protein trans-activates the luciferase reporter gene. Development of the assay involves quantifying the luminescence resulting from the enzyme activity of luciferase, which is directly proportional to the number of infection events by the pseudoviruses. Addition of an agent with anti-HIV activity results in a decrease in the luminescence signal. Both **sulfo-4** and **6** were analyzed in the TZM-bl luciferase reporter gene assay, in addition to the positive control, dextran sulfate. The IC_{50} values (Table 1) are the sample concentration at which the relative luminescence units were reduced by 50% compared to virus control wells (no test sample). HIV inhibitory activity was detected for **Sulfo-6**, with IC_{50} values for all viruses tested in the low micromolar range. Reduction in luciferase signal by **Sulfo-4** was only observed at the highest compound concentrations tested and did not reach the 50% neutralization cutoff. The positive controls, dextran sulfate and HIVIG-C, were both potent inhibitors as expected, yielding nM inhibition in all four HIV-1 strains, except TV1.21 for HIVIG-C, which was μM.

As with all *in vitro* assays, the results obtained are constrained by the system used. Experiments in other laboratories have shown that HIV neutralization assays in the TZM-bl cell system may be less sensitive than assays in other cells, such as T cell lines and PHA-stimulated PBMCs,[40] and that viruses produced in 293T cells are more sensitive to neutralizing antibodies than the same virus produced in PBMCs.[55] We have also observed that an assay based on the T cell line A3R5 can be 10- to 100-fold more sensitive in the detection of neutralizing antibodies than the TZM-bl assay, but only for viruses with a tier 2 (less-sensitive) neutralization phenotype (unpublished data).[56] The viruses assayed here for inhibition by **sulfo-4** and **sulfo-6** are all tier 1 (more neutralization sensitive) and are equally sensitive to neutralizing antibodies when assayed in TZM-bl and A3R5 cells. However, it is possible that neutralization by sulfated polysaccharides may behave differently in these two assay systems than neutralization by antibodies, and the results here may underestimate the potential of these two compounds to inhibit HIV in an optimal *in vitro* assay. Like Louder *et al.*, we have also found that a virus produced in 293T cells is more sensitive to neutralization by antibodies than the same virus grown in activated human PBMCs. The viruses used herein were pseudoviruses produced in 293T cells. In humans, the infecting HIV would likely have been produced by lymphoid or monocytoid cells. If HIV inhibition by sulfated polysaccharides follows the trend observed with neutralization by antibodies, the results here may overestimate the inhibition of HIV by **sulfo-4** and **sulfo-6** in an infected individual. Clearly, further studies are needed to understand the true utility of these and similar compounds in protection from HIV infection *in vivo*, but the results presented

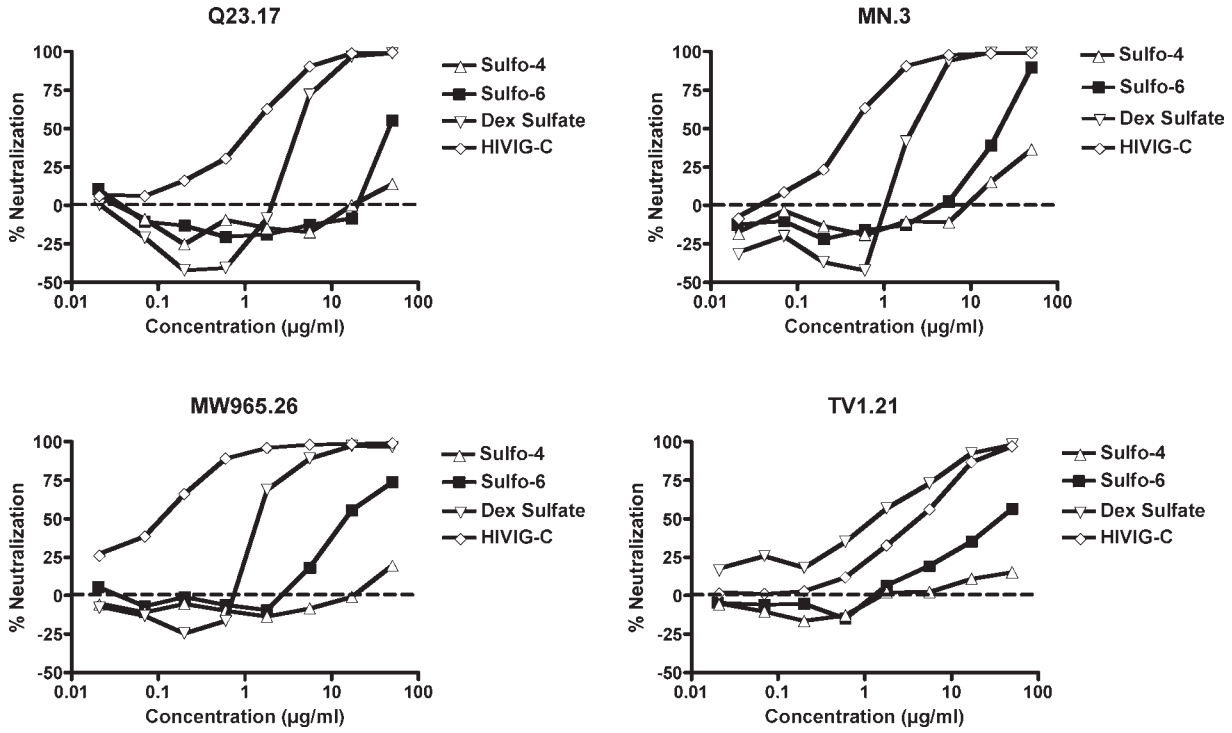

Figure 3. HIV-1 luciferase reporter gene assay results for % neutralization of four different HIV-1 strains (Q23.17, MN.3, MW965.26, and TV1.21) in TZM-bl cells by glycodendrimers **sulfo-4** and **sulfo-6** with positive controls, dextran sulfate and HIVIG-C.

here provide encouragement for continuing to evaluate this strategy (Figure 3).

The combined data from both the ELISA and luciferase reporter gene assay suggest a few conclusions regarding the potential of these molecules as anti-HIV molecules. First, the assays were found to be complementary to one another: the luciferase assay confirmed the anti-HIV activity of **sulfo-6** that was suggested by the ELISA result. This supports our strategy for screening glycodendrimer compounds: the ELISA serves as a simple screen for whether or not a sulfated glycodendrimer has the ability to bind the target gp120 protein, while the luciferase assay measures how well the sulfated glycodendrimers prevent the infection of the TZM-bl cells. Second, the activity of **sulfo-6** is superior to that of **sulfo-4**. **Sulfo-4** contains 2.02% sulfur, 8 sugar residues and a MW of approximately 4000 Da. It cannot be determined from the data gathered whether the poor activity observed for **sulfo-4** was due to the small size, the low % sulfur, or as a result of both factors. Further study of these effects is required. Therefore, all future sulfoglycodendrimers envisioned will need to be equal/larger than **sulfo-6**, and have a minimum of 4% sulfur (by wt). It is hypothesized that, as the sulfoglycodendrimers increase in size/sulfur content, both assays will be better able to quantitate the HIV-1 activity, as the sulfoglycodendrimers will be more adept at binding to gp120 multivalently, and potentially serve as effective anti-HIV-1 agents. This is supported by a report by Subramaniam and co-workers, where it was reported that the native trimeric spike of gp120 has a width of 15 nm.[57] Compared with the known diameters of unsubstituted PAMAM $G = 1$ and 2, which are 1.9 and 2.6 nm, respectively, it can be theorized that the glycodendrimers reported herein can interact with/bind to at least one gp120 monomer apiece.[58] It is also supported by reports in the literature illustrating a variety of (glyco)dendrimer-based molecules with anti-HIV activity (μM—nM), with molecular weights ranging from 12 400 to 24 581 Da.[41,43,47,59] As we have now reported a sulfoglycodendrimer (**sulfo-6**) with a MW of 8777 Da and 4.03% sulfur with μM activity across all HIV-1 strains evaluated, we are satisfied that the ELISA/luciferase assay combination will provide adequate sensitivity for future molecules evaluated, as these will all be larger in size and contain a minimum of 4% sulfate (by wt). Finally, in taking the sialic acid monosaccharide, presenting it multivalently on PAMAM, and sulfating it, we were able to observe modest μM activity (IC_{50} values ranging from 1.6 to 5.1 μM). These values compared well to the EC_{50} value of 0.4 μM for an 8000 Da sulfated colominic acid derivative containing 6% sulfur, as reported by Yang et al.[19] This indicates that the strategy of taking smaller pieces of a polysaccharide of known anti-HIV properties and presenting them in a multivalent sense on a dendrimer scaffold can yield structurally well-defined sulfoglycodendrimers with good anti-HIV activity. This approach may also result in derivatives with reduced or absent toxicity issues as compared to the sulfated polydisperse polysaccharides from which they are derived. This latter issue will be addressed in future studies.

CONCLUSIONS

In summary, an initial series of 6 sulfoglycodendrimers were sought, synthesized by either a divergent-like or convergent-like approach, as potential anti-HIV agents. The syntheses were planned with the fewest steps possible and no sugar protecting group chemistry, to find the fastest and most facile way to make sulfoglycodendrimers in the best yields possible. While it was initially believed that the four-step convergent-like approach would be the best reaction sequence, as the steric issues of both sialic acid and PAMAM were minimized through the addition of an intermediary hydrophilic linker, only **1** was produced, and in poor yield. This contrasts with the one-step divergent-like pathway, which at the outset was not expected to work well, given that

both the sialic acid and PAMAM structures were sterically congested. Surprisingly, this path led to the production of all three desired glycodendrimers, **2**, **4**, and **6**, in modest yields, and all in one step. Glycodendrimers **1**, **2**, **4**, and **6** were all fully substituted with respect to the number of sugars attached to the reactive groups terminating the various generations of PAMAM, thereby eliminating the polydispersity of structure found in the parent polysaccharide colominic acid. While the chemical sulfation process was not regioselective, it was viewed to be of lesser importance at the current time than finding the appropriate synthetic method and determining the general minimum structural requirements necessary for these molecules to have anti-HIV-1 activity. This was achieved in **sulfo-6**. The synthesis of a completely monomolecular product in terms of the number of both sugars and sulfates incorporated remains a future goal.

In addition to finding an appropriate synthesis for the glycodendrimers, a simple binding screen and well-characterized confirmatory functional assay were utilized to rapidly determine their potential anti-HIV activity. Upon evaluation of the sulfoglycodendrimers, **sulfo-1**, **2**, **4**, and **6**, the in-house ELISA screening assay suggested that only **sulfo-6** bound to b-rgp120. This was confirmed using the more sensitive luciferase reporter gene neutralization assay, which detected μM activity for **sulfo-6**. Thus, we have shown that a simple monosaccharide building block derived from a known anti-HIV sulfated polysaccharide can yield molecules possessing anti-HIV-1 activity when appended to a multivalent scaffold, even though they are smaller in size than the parent polysaccharide.

■ ACKNOWLEDGMENT

The authors are indebted to Dr. David Montefiori from Duke University for providing the expertise and resources for acquiring the HIV luciferase reporter gene assay results (supported by NIH contract AI30034). We would additionally like to thank Drs. Shiu-Lok Hu and Yun Li at Washington State University for the extensive conversations, guidance, and initial HIV luciferase reporter gene assay results (with partial support provided by NIH P51 grant RR000166). The authors would finally like to thank Careena Cary for running the sulfation reactions, and Drs. Andreas Franz from the University of the Pacific and Dr. Arpad Somogyi from the University of Arizona, for their assistance with the mass spectral analysis. Financial support for this work from NIH-AREA (1R15AI068444-01), Research Corporation Cottrell College Science Award (CC6610), and an NSF-MRI grant to fund the 500 MHz NMR (CHE MRI-0922676) are gratefully acknowledged.

Supporting Information

Experimental Procedures:

Tetrameric glyco-DATEG-PAMAM dendrimer (**1)**: PAMAM G = -0.5 (24 mg, 0.055 mmol) was weighed into a flame-dried 10 mL round-bottomed flask and dissolved in DMF (1 mL), and flushed with nitrogen. DIPEA (71 mg, 0.55 mmol) was added, followed by BOP (120 mg, 0.27 mmol). The sugar linker **11** (100 mg, 0.23 mmol) was placed into a second 10 mL round-bottomed flask and dissolved in DMF (1 mL). The two solutions were mixed together, heated to 35˚C, and stirred under nitrogen for 24 hours. The solvents were evaporated under reduced pressure and the crude product was dialyzed with 500 MWCO tubing in a 1L flask against nanopure D.I. water. The water was changed once every hour for four hours, and allowed to stir overnight at 4˚C. The remaining crude material was then lyophilized. The dialyzed crude material was then purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid. Fractions containing the product were collected, grouped, and purified through size exclusion chromatography with 0.03 M ammonium bicarbonate as the mobile phase. This provided compound **1**, as a fluffy white solid (3 mg, 0.0017 mmol, 6.4% yield). ^{1}H NMR (D_2O): δ 1.73 (m, 1H, H_B), 2.09 (s, 3H, H_C), 2.36 (dd, 1H, *J*= 5.0Hz, 16.4Hz, H_A), 2.49 (t, 2H, J=7.2Hz, H_M), 2.68 (s, 1H, H_K), 2.87 (t, 2H, *J*=7.1Hz, H_L), 3.43 (t, 3H, J=5.4Hz, H_P), 3.49 (m, 3H, H_S), 3.67 (m, 17H, $H_{G,J,Q,R}$), 3.78 (m, 1H, H_H), 3.88 (dd, 1H, *J*=2.6Hz, 11.8Hz, H_E), 3.95 (t, 1H, *J*=9.7Hz, H_I), 4.11 (m, 2H, $H_{D,F}$). ^{13}C NMR (D_2O, TSP internal): δ 24.9, 35.2, 41.6, 41.7, 42.4, 51.90, 51.92, 54.9, 66.0, 69.5, 71.0, 71.4, 71.6, 71.6, 72.2, 72.3, 72.9, 73.2, 98.3, 98.3, 98.4, 175.6, 177.6, 177.7. MALDI-TOF: $[M + Na]^+$ ($C_{82}H_{148}N_{14}O_{44}Na$) calcd m/z = 2055.9671, Found m/z = 2058.4.

Tetrameric glycoPAMAM dendrimer (**2)**: Sialic acid (cmpd **10**, 200 mg, 0.66 mmol) was weighed into a flame-dried 10 mL round-bottomed flask, flushed with nitrogen, then dissolved into DMF (4 mL). BOP (400 mg, 0.9 mmol) was then added as a solid. PAMAM G=0 (20% by wt. in methanol) (75 mg, 0.15 mmol) was next weighed into a separate 10 mL round-bottomed flask and the methanol was evaporated under reduced pressure. DMF (1.5 mL) and DIPEA (190 mg, 1.5 mmol) were added to the flask with PAMAM. The PAMAM solution was then added to the sialic acid solution, heated to 35˚C, and the reaction was stirred for four days under nitrogen. The crude reaction product was dialyzed with 500 MWCO tubing against nanopure water. The

water was changed once an hour for three hours then left stirring overnight at 4˚C. The crude material was then purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid providing compound **2**, as a fluffy white solid (29.4 mg, 0.017 mmol, 11.4% yield). ^{1}H NMR (D_2O): δ 1.69 (t, 1H, *J*=12.3Hz, H_B), 2.08 (s, 3H, H_C), 2.34 (dd, 1H, *J*=4.9Hz,13Hz, H_A) , 2.76 (m, 2H, H_M), 3.40 (m, 7H, $H_{K,L,N,O}$), 3.61 (d, 1H, *J*=9.3Hz, H_G), 3.66 (dd, 1H, *J*=6.3Hz, 11.8Hz, H_J), 3.77 (m, 1H, H_H), 3.87 (dd, 1H, *J*= 2.4Hz, 11.8Hz, H_E), 3.94 (t, 1H, *J*=10.3Hz, H_I), 4.09 (m, 2H, $H_{D,F}$). ^{13}C NMR (D_2O, TSP internal std): δ 25.1, 32.7, 41.56, 41.6, 42.7, 51.6, 52.5, 55.2, 66.2, 69.7, 71.3, 73.2, 73.5, 98.6, 118.2, 120.5, 165.8, 166.1, 175.6, 175.9, 177.9. MALDI-TOF: $[M + Na]^+$ ($C_{66}H_{116}N_{14}O_{36}Na$) calcd m/z = 1703.7574, Found m/z =1703.8.

Octameric glyco-DATEG-PAMAM dendrimer (**3**): Sugar linker **11** (53 mg, 0.12 mmol) was weighed into a flame-dried 10 mL round-bottomed flask, flushed with nitrogen, then dissolved into DMF (1 mL). BOP (58 mg, 0.13 mmol) was added as a solid. PAMAM G=0.5 (20% by wt. in methanol) (16 mg, 0.013 mmol) was weighed into a separate 10 mL round-bottomed flask and the methanol was removed *in vacuo*. Next, DMF (1 mL), then DIPEA (34 mg, 0.26 mmol), were added to the PAMAM. The PAMAM mixture was added to the sugar linker. The reaction was heated to 35˚C for seven days. The solvents were evaporated *in vacuo* and the crude was freeze-dried. The crude was dialyzed with 500 MWCO tubing against nanopure water. The water was changed every hour for four hours, then stirred overnight at 4˚C. The crude material was next purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid. This was followed by size exclusion chromatography in 0.03 M ammonium bicarbonate buffer. ^{1}H and ^{13}C NMR showed the PAMAM was not fully substituted. For compound **3**, the calculated molecular weight for $C_{182}H_{328}N_{34}O_{92}$ $[M+H]^+$ was 4462.2031. MALDI MS showed small peaks for $[M+H]^+$ m/z=4467.033, $[M-H_2O]$ m/z=4447.926, and $[M-2H_2O]$ m/z=4428.818, but also found was [M-cmpd **11**-H_2O] m/z=4027.557. While MALDI MS shows evidence that **3** was synthesized, it was not present in a large enough quantity to get clear ^{1}H or ^{13}C data.

Octameric glycoPAMAM dendrimer (**4)**: Sialic acid (**10,** 190 mg, 0.62 mmol) was weighed into a flame-dried 10 mL round-bottomed flask, flushed with nitrogen, then dissolved in DMF (4 mL). BOP (310 mg, 0.7 mmol) was added as a solid. PAMAM G=1 (20% by wt. in methanol)

(100 mg, 0.07 mmol) was weighed into a separate 10 mL round-bottomed flask and the methanol was evaporated off under reduced pressure. DMF (2 mL) and DIPEA (180 mg, 1.4 mmol) were added to the PAMAM. The two solutions were mixed and the reaction was stirred under nitrogen for seven days. The solvents were then evaporated *in vacuo* and the crude was freeze-dried. The crude solid was next dialyzed with 500 MWCO tubing against nanopure D.I. water. The water was changed every hour for four hours then stirred overnight at 4˚C. The crude material was next purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid. This was followed by size exclusion chromatography using Biogel P-10 gel in 0.03 M ammonium bicarbonate buffer producing compound **4**, as a fluffy white solid (28 mg, 0.0101 mmol, 14% yield). ^{1}H NMR (D_2O): δ 1.68 (t, 2H, *J*=12.3Hz, H_B), 2.07 (s, 6H, H_C), 2.33 (dd, 2H, *J*= 5.0Hz, 13.1Hz, H_A), 2.43 (m, 6H, H_M), 2.63 (m, 1H, H_K), 2.83 (m, 6H, H_L), 3.33 (m, 12H, $H_{N,O}$), 3.60 (d, 2H, *J*=9.6Hz, H_G), 3.66 (dd, 2H, *J*=6.2Hz, 11.8Hz, H_J), 3.77 (m, 2H, H_H), 3.86 (dd, 2H, *J*=2.4Hz, 11.8Hz, H_E), 3.93 (t, 2H, *J*=10.2Hz, H_I), 4.07 (m, 4H, $H_{D,F}$). ^{13}C NMR (D_2O, TSP internal std.): δ 25.0, 35.3, 35.5, 39.6, 41.3, 41.7, 42.5, 51.8, 52.8, 54.0, 55.0, 66.0, 69.5, 69.54, 71.1, 72.9, 73.2, 98.4, 175.7, 177.6, 177.9. MALDI-TOF: $[M + H]^+$ ($C_{150}H_{264}N_{34}O_{76}$) calcd m/z = 3757.7837, Found m/z =3759.3.

16-mer glyco-DATEG-PAMAM dendrimer (**5)**: Sugar linker **11** (75 mg, 0.17 mmol) was weighed into a flame-dried 10 mL round-bottomed flask, flushed with nitrogen, then dissolved into DMF (1 mL). BOP (93 mg, 0.21 mmol) was added as a solid. PAMAM G=1.5 (20% by wt. in methanol) (25 mg, 0.0085 mmol) was weighed into a separate round-bottomed flask and the methanol was evaporated off *in vacuo*. Next, DMF (1 mL), then DIPEA (44 mg, 0.34 mmol) were added to PAMAM. The PAMAM mixture was added to the sugar-linker. The reaction was heated to 35˚C and run for 14 days. The solvents were then evaporated *in vacuo*, and the crude was freeze-dried. The crude solid was next dialyzed with 500 MWCO tubing against nanopure water. The water was changed every hour for four hours, then stirred overnight at 4˚C. The crude material was then purified using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid. This was followed by size exclusion chromatography using Biogel P-10 gel in 0.03 M ammonium bicarbonate buffer. ^{1}H NMR showed that no fractions contained the fully substituted product. Compound **5** was not isolated. No clear ^{1}H NMR was collected that indicated the presence of compound **5**, therefore, no samples were sent out for MALDI-MS analysis.

16-mer glycoPAMAM dendrimer (**6)**: Sialic acid (**10**, 46 mg, 0.15 mmol) was weighed into a flame-dried 10 mL round-bottomed flask, flushed with nitrogen, then dissolved in DMF (1 mL). BOP (84 mg, 0.19 mmol) was added as a solid. PAMAM G=2 (20% by wt. in methanol) (25 mg, 0.0077 mmol) was weighed into a separate round-bottomed flask and the methanol was evaporated under reduced pressure. DMF (1 mL) and DIPEA (40 mg, 0.31 mmol) were added to the PAMAM. The two solutions were mixed, heated to 35˚C, and reaction was stirred under nitrogen for 14 days. The solvents were then evaporated under reduced pressure and the crude sample was freeze-dried. The crude solid was then dialyzed with 500 MWCO tubing. The water was changed once an hour for four hours, then stirred overnight at 4˚C. Initial purification was conducted using RP-HPLC with a linear gradient between water/0.1% trifluoroacetic acid and acetonitrile/0.1% trifluoroacetic acid. This was followed by size exclusion chromatography using Biogel P-10 gel in 0.03 M ammonium bicarbonate buffer providing compound **6**, as a fluffy white solid (17 mg, 0.00215 mmol, 28% yield). ^{1}H NMR (D_2O): δ 1.70 (m, 4H, H_B), 2.10 (s, 12H, H_C), 2.35 (dd, 4H, *J*=4.9Hz, 13.1Hz, H_A), 2.46 (m, 14H, H_M), 2.68 (m, 1H, H_K), 2.86 (m, 14H, H_L), 3.36 (m, 24H, $H_{N,O}$), 3.63 (d, 4H, *J*=9.5 Hz, H_G), 3.69 (dd, 4H, *J*= 6.2 Hz, 11.8Hz, H_J), 3.79 (m, 4H, H_H), 3.89 (dd, 4H, *J*= 2.4 Hz, 11.8Hz, H_E), 3.96 (t, 4H, *J*=10.2 Hz, H_I), 4.10 (d, 8H, *J*=10.8 Hz, $H_{D,F}$). ^{13}C NMR (D_2O, TSP internal std): δ 25.0, 35.5, 39.6, 41.3, 41.7, 51.9, 54.1, 55.0, 66.0, 69.45, 69.5, 71.1, 73.0, 73.3, 98.32, 98.34, 98.36, 98.38, 175.7, 177.7, 177.9, 166.6 MALDI-TOF: $[M + Na]^+$ ($C_{318}H_{560}N_{74}O_{156}Na$) calcd m/z = 7934.8056, Found m/z =7937.166.

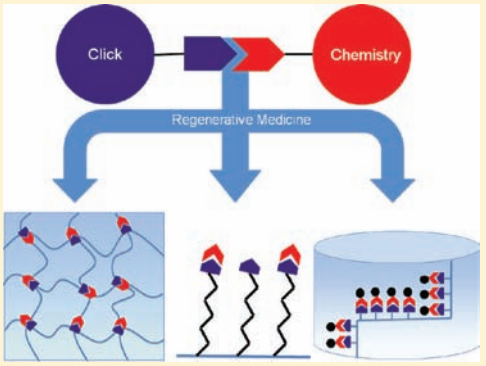
Regenerative Biomaterials that "Click": Simple, Aqueous-Based Protocols for Hydrogel Synthesis, Surface Immobilization, and 3D Patterning

Chelsea M. Nimmo[†,‡] and Molly S. Shoichet*[,†,‡,§,∥]

[†]The Donnelly Centre for Cellular and Biomolecular Research, [‡]Department of Chemistry, [§]Department of Chemical Engineering and Applied Chemistry, and [∥]Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, Ontario, Canada

ABSTRACT: The click chemistry era has generated a library of versatile "spring-loaded" reactions that offer high yields, regio- and stereospecificity, and outstanding functional group tolerance. These powerful transformations are particularly advantageous for the design of sophisticated biomaterials that require high levels of precision and control, namely, materials that promote tissue regeneration such as hydrogels, 2D functionalized substrates, and 3D biomimetic scaffolds. In this review, the synthesis and application of regenerative biomaterials via click chemistry are summarized. Particular emphasis is placed on the copper(I)-catalyzed alkyne−azide cycloaddition, Diels−Alder cycloadditions, and thiol−click coupling.



INTRODUCTION

In the simplest terms, tissue engineering has been defined as the delivery of biomolecules, cells, and supporting structures to the body to promote self-healing.[1] To accomplish this, biocompatible materials are required to serve as either structural supports for tissue regeneration or delivery vehicles for cell and drug transplantation. Biomaterials can also represent investigative tools to elucidate mechanisms vital to regeneration. Common materials employed within regenerative medicine strategies include both two-dimensional (2D) substrates and three-dimensional (3D) biomaterials. 2D substrates are most often used as exploratory tools to study the presentation of specific bioactive factors on cell fate. 3D biomaterials are similarly exploited, but can also be manipulated to serve as a space filling agent, a delivery vehicle, or a tissue engineering scaffold.[2] These strategies require well-defined structural materials and surfaces that impose sophisticated function in order to advance the field of regenerative medicine. This has created a trend toward the convergence of synthetic organic techniques within regenerative biomaterials.

The exponential growth of click chemistry research within the past decade has greatly facilitated the development of chemoselective chemistries applicable within regenerative medicine. In 2001, Sharpless and co-workers introduced the term "click chemistry" to define a set of nearly perfect reactions that resemble natural biochemical ligations.[3] These "spring-loaded" reactions are orthogonal, regioselective, and highly efficient. Moreover, click reactions can be performed in aqueous solutions at room or physiological temperature, and display outstanding functional group tolerance, making them compelling reactions within the bioengineering toolkit for polymer synthesis and bioconjugation.[4]

Given that there has been a number of outstanding reviews written on polymer synthesis via click chemistry for biomedical applications,[4−7] this review will focus on the emerging trend of click chemistry within the field of regenerative medicine. A prime example is click cross-linked hydrogels. Click reactions have also gained popularity as bioconjugation techniques for decorating 2D cell substrates, and as elegant patterning chemistries for immobilizing bioactive factors within 3D scaffolds (Figure 1). The review begins with a brief overview of three common click reactions employed within regenerative biomaterials, and further highlights their use in tissue engineering and regenerative medicine.

COMMON CLICK REACTIONS IN REGENERATIVE BIOMATERIALS

The term click chemistry often refers to the common copper(I)-catalyzed alkyne−azide cycloaddition (CuAAC) (Scheme 1A). This reaction is very similar to the classic Huisgen cycloaddition[8] where an organic azide reacts with an alkyne to form a triazole ring. Through the addition of a Cu(I) catalyst, Meldal[9] and Sharpless[10] demonstrated that the Huisgen cycloaddition reaction can proceed at low temperatures with high rates, efficiency, and regiospecificity. Moreover, near-perfect conversion is obtainable in both aqueous and organic

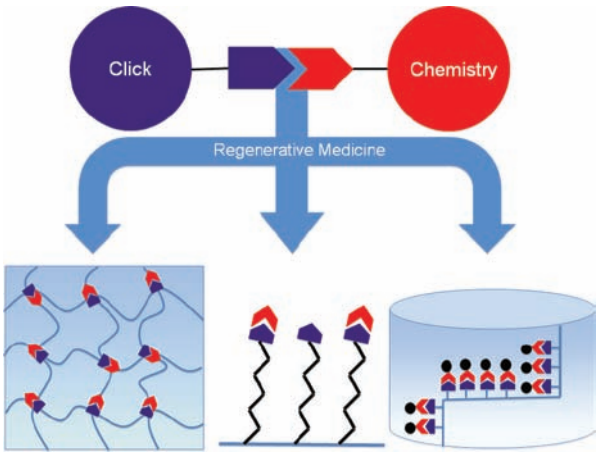

Figure 1. Schematic representation of click chemistry applied to regenerative biomaterials. Click chemistry has been employed as a cross-linking chemistry for hydrogel synthesis, and as bioconjugation techniques for decorating 2D cell culture.

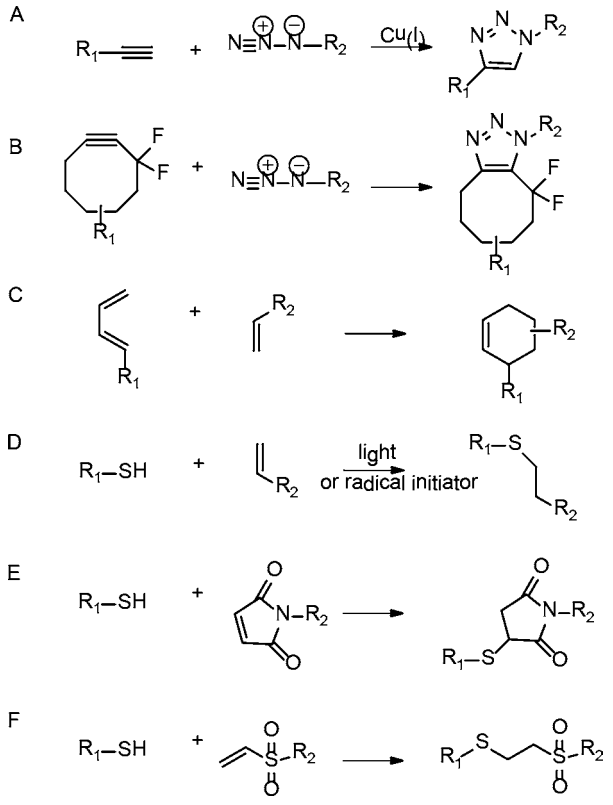
Scheme 1. Common Click Reactions for Regenerative Biomatenals[a]



[a](A) Copper(I)-catalyzed alkyne–azide cycloaddition (CuAAC), (B) azide–alkyne coupling (SPAAC), (C) Diels–Alder (DA) cycloaddition, (D) Radical- mediated thiol–ene coupling, (E) Thiol-Michael addition between maleimides, and (F) between thiols and vinyl sulfones.

solvents. CuAAC has proved to be particularly advantageous within biomedical applications considering that the starting materials, azides and terminal alkynes, are remarkably stable within biological systems, enabling facile introduction of these reactive groups into a wide range of biomolecules. Moreover, alkynes and azides are not found in nature, thereby limiting side products from forming.

However, the term click chemistry is not limited to the CuAAC reaction, but embodies a synthetic philosophy of many reactions with distinct mechanisms and conditions. A comparison of click chemistries for regenerative biomaterials is summarized in Table 1. According to Sharpless, a reaction can achieve click status if it consists of readily available orthogonal reactants that combine under mild conditions to produce a single stereospecific product, with little or no isolation.[3] Within the past decade, there has been increasing investigation into reactions that meet this definition, yet do not require a metal catalyst.[11] The Bertozzi lab has developed a reaction of azides with cyclooctyne derivatives[12] referred to as strain-promoted azide–alkyne coupling (SPAAC) (Scheme 1B). These cyclooctyne derivatives greatly increase reactivity of azide–alkyne cycloadditions in the absence of copper, particularly when difluorinated.[13] Baskin et al. exploited this phenomenon to conjugate fluorophores to biological molecules by incorporating a *gem*-difluoro group next to a strained alkyne.[14] Reported reaction rates were 30–60 times faster compared to those with nonfluorinated cyclooctynes.

Another click cycloaddition is exemplified by the Diels–Alder (DA) reaction; a highly selective [4 + 2] cycloaddition between an electron-rich diene and an electron-poor dienophile (Scheme 1C). This reaction was first reported by Otto Diels and Kurt Alder in 1928,[15] making the DA cylocaddition the oldest known click reaction. DA chemistries offer high yields and minimal sides reactions, and require very little energy. Contrary to other click reactions, which commonly result in carbon–heteroatom bonds, carbon–carbon bonds are formed in DA cycloadditions. These bonds are thermally reversible at elevated temperatures. Water has been shown to accelerate DA reactions,[16,17] making the DA reaction particularly desirable for biomedical applications.

Beyond cycloadditions, other highly efficient reactions, such as nucleophilic substitutions, radical additions, and Michael additions, are also considered click reactions. In particular, thiol-click chemistries have recently gained merit within the field of regenerative biomaterials. Schlaad and co-workers were the first to identify the radical-mediated thiol–ene reaction as a click reaction.[80] In the mechanism, a radical abstracts a hydrogel from the thiol to form an active thiyl radical, allowing for an addition reaction between the thiyl radical and the carbon–carbon double bond or "ene". While both heat and light can be used to generate radicals to initiate the thiol–ene mechanism (Scheme 1D), photoinitiation of the radical addition reaction between thiols and alkenes allows for spatial and temporal control. Using light, the reaction can be easily manipulated by controlling the light intensity, the dose, or the duration.[79] This thiol-click reaction has found specific applications for biofunctionalization and surface modification.[18]

Thiol-Michael addition reactions represent another principle variation among the thiol–click chemistries applicable to regenerative biomaterials (Scheme 1E, F). The Michael addition of thiols to electron-deficient "enes" has been investigated since at least the 1940s,[81] and to this day, it continues to be a versatile tool within the field of bioconjugate chemistry. Thiol–click Michael additions typically involve α,β-unsaturated carbonyl compounds, and depend upon the nucleophilicity of the thiol component.[79] Thiol–maleimide click coupling (Scheme 1E) is a particularly relevant example for this review, as it is frequently exploited for protein conjugation.[71,72,75,76] The vinyl sulfone–thiol click reaction (Scheme 1F) has served as an important cross-linking mechanism for the synthesis of enzyme-degradable hydrogels.[44]

Table 1. Comparison of Common Click Reactions for Regenerative Biomaterials

click reaction	pH	reaction time	reactivity	specific advantages	specific disadvantages	biomaterial application
CuAAC	3–12	<1 h	increases at lower pH, or increased Cu(I)	azides/alkynes not found in nature	unstable and toxic copper catalyst required	hydrogel synthesis,[21−29] 2D protein immobilization[57−62]
SPAAC	7.4	<1 h	Increases with difluorination of cyclooctyne	no copper requirement	difficult synthesis of difluorinated cyclooctynes	PEG hydrogel synthesis[30,31]
DA	5.5–6.5	<8 h	accelerated by water	no catalyst required	longer reaction time	HA hydrogel synthesis,[42] 2D protein immobilization[63,64]
Thiol–ene	6–8	<2 h	radical-mediated	spatial/temporal control	cross-reactivity with thiols, photoinitiator often required	hydrogel synthesis,[48,49] 2D protein immobilization,[65,66] hydrogel patterning[30,31,74]
Thiol–Michael	6–8	<1 h	Depends on the nucleophilicity of the thiol component	facile introduction of proteins	cross-reactivity with thiols	hydrogel synthesis,[43,44,46,47] hydrogel patterning[71,72,75,76]

CLICK CROSS-LINKED HYDROGELS FOR TISSUE ENGINEERING AND DRUG DELIVERY

Hydrogels are water-swollen, cross-linked polymer networks capable of imitating the mechanical and architectural nature of the cellular microenvironement of soft tissue.[19] Due to their high water content, hydrogels permit facile transport of oxygen, nutrients, soluble factors, and waste. Moreover, many hydrogels are biocompatible, biodegradable, and can be synthesized and processed under relatively mild conditions. Accordingly, hydrogels represent an optimal platform for many regenerative medicine strategies. Often, hydrogel matrices are used to provide a blank canvas in which biomolecules are immobilized, thereby providing a defined chemical environment to guide cell fate. Synthetic poly(ethylene glycol) (PEG) and naturally derived agarose are two common examples of such hydrogels.[73,75]

The mechanical characteristics of hydrogels are dictated by the number of cross-links formed between the polymer chains via covalent bonds or noncovalent interactions. In the past, popular hydrogel cross-linking methodologies have included radical polymerization and high-energy irradiation.[20] The majority of these reactions require cytotoxic cross-linking agents or initiators, which can reduce biocompatibility of the material. Within the past decade, click chemistry has emerged as a viable alternative for both chemically cross-linked hydrogels and their biofunctionalization. While copper is also known to be cytotoxic, the strained reactions described above overcome this deficit of CuAAC chemistry.

Alkyne–Azide Click Cross-Linked Hydrogels. Ossipov et al. were the first to recognize the CuAAC reaction as an efficient chemoselective cross-linking method for hydrogel synthesis.[21] Poly(vinyl alcohol) (PVA) was functionalized with either acetylene or azide groups, and cross-linked by mixing their aqueous solutions together with copper sulfate ($CuSO_4$) and sodium ascorbate as the cycloaddition catalyst. In another example, alkyne-modified PVA was cross-linked with bifunctional PEG-diazide cross-linkers. Hydrogels prepared with polyfunctional PVA formed higher-modulus gels with reduced swelling compared to those synthesized with the bifunctional PEG cross-linker.

Hawker and co-workers[22] applied the CuAAC click cross-linking reaction to the synthesis of pure PEG hydrogels. In their approach, diacetylene- and tetraazide-functionalized PEG were reacted in a 2:1 ratio at room temperature under aqueous conditions in the presence of $CuSO_4$ and sodium ascorbate. By manipulating both the polymer and catalyst concentration, they were able to tune the cross-linking efficiency. Following hydrogel formation, both acetylene and azide functionalized chromophores were swollen into the hydrogel to visualize any unreacted azide/acetylene functional groups. This revealed less than 0.2% unreacted functional groups, confirming the efficient nature of the CuAAC reaction. The degree of swelling and stress/extension properties of the hydrogels were also examined by varying the length of the diacetylene PEG chain.

To illustrate the utility of the CuAAC cross-linked PEG hydrogels as tissue engineering and drug delivery scaffolds, various researchers have incorporated peptides and degradable linkers within their click cross-linked networks. In particular, inclusion of the fibronectin tripeptide sequence, arginine-glycine-aspartate (RGD), has been shown to be an essential additive in almost all "blank slate" hydrogel formulations for tissue culture. RGD is a prime cell adhesion site that is

recognized by many integrin receptors;[23] therefore, incorporation of this peptide facilitates cell-matrix interactions. Liu et al. synthesized diazide-functionalized RGD peptides to cross-link tetraacetylene PEG under aqueous conditions with $CuSO_4$ and sodium ascorbate.[24] By varying the temperature, catalyst, and precursor concentrations, the gelation time was altered from 2 to 30 min. An increase in temperature or $CuSO_4$ resulted in a decreased gelation time. The storage modulus was also tailored by changing the azide linker length. These RGD peptide hydrogels were tested for fibroblast delivery to promote tissue repair. By increasing the concentration of RGD peptide, fibroblast adhesion and proliferation also increased.

In a similar approach, van Dijk et al. incorporated a protease-sensitive peptide within a CuAAC cross-linked PEG hydrogel (Figure 2).[25] Alkyne-functionalized star-shaped PEG molecules (either 4- or 8-armed with a MW of 10 and 20 kDa, respectively) were cross-linked with the protease-sensitive bis-azido peptide in aqueous solution in the presence of $CuSO_4$ and sodium ascorbate. Incubation of the hydrogels in trypsin leads to complete degradation of hydrogels after 40−80 h, depending on the cross-link density.

The CuAAC reaction has also been employed as a cross-linking method for natural polymers. While hydrogels formed from synthetic materials, such as PEG, offer a blank canvas permissive to cell function, materials native to the extracellular matrix (ECM) can promote cell function.[19] A prime example of a native material commonly employed in regenerative strategies is hyaluronic acid (HA)—a ubiquitous nonsulfated glycosaminoglycan, which impacts embryonic development, tissue organization, wound healing, and angiogenesis.[26] Crescenzi et al. used the CuAAC click reaction to cross-link HA.[27] Hyaluronic acid (HA) was modified with either azide or alkyne groups and cross-linked in water with Cu(I) at room temperature. Their hydrogel revealed intriguing characteristics for both drug release and tissue engineering applications. As a model for drug delivery, benzidamine and doxorubicin were encapsulated within the click hydrogels, which displayed release profiles ranging from hours to several weeks, depending on the cross-link density. To confirm the possibility that these hydrogels could serve as tissue engineering scaffolds, yeast cells were imbedded within the hydrogels, following removal of the copper catalyst through dialysis. Cells exhibited 80% proliferating activity after 24 h in culture. In a follow-up study, the influence of the dialkyne structure on the properties of these HA click cross-linked hydrogels was examined.[28] HA azido-derivatives cross-linked with shorter dialkynes experienced weaker storage moduli, corresponding to predicted cross-linking densities as determined by ^{1}H NMR.

Gao and co-workers also employed the CuAAC reaction to cross-link natural biopolymers.[29] Both HA and chondroitin sulfate (CS) were modified to contain azide functionalities, and cross-linked with gelatin that had been modified with an alkyne functionality. They argue that this triple copolymer system better mimics the natural components of ECM by incorporating proteoglycans, such as CS, and denatured collagen products, such as gelatin, to promote cell surface adhesion. Aqueous solutions of the polymers were combined and catalyzed by Cu(I) to form a hydrogel with the time to gelation varying as a function of catalyst concentration. Chondrocytes were cultured *in vitro* to assess the cytotoxicity of the click hydrogels. After 3 days in culture, a confluent layer of cells had formed, confirming the benefit of this click cross-linked hydrogel for chondrocyte adhesion and proliferation.

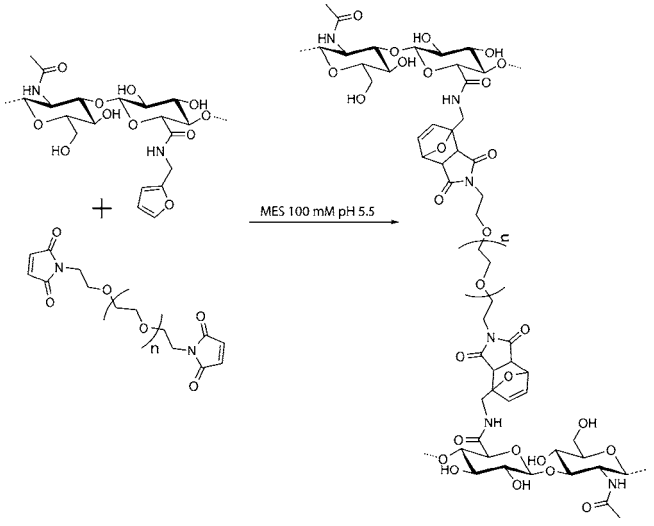
Anseth and co-workers have gone beyond traditional CuAAC cross-linking chemistry and synthesized PEG hydrogels via SPAAC, to bestow copper-free, physiological conditions within their networks.[30] In their approach, a four-arm PEG tetra-azide was reacted with difunctionalized difluorinated cyclooctyne polypeptide sequence, to incorporate enzymatically degradable cross-linker sequences throughout the material. Gelation occurred in less than 5 min, and both rheological and ^{1}H NMR data support the ideality of the network, similar to previous click-based networks.[22] This click strategy tolerates cell encapsulation with high viabilities (>90% at 24 h). As an extension of this study, De Forest et al. enabled control over cross-link density and shear moduli of these SPAAC cross-linked PEG hydrogels.[31] By altering either the azide to cyclooctyne ratio or the molecular weight of PEG, hydrogels were synthesized with tunable moduli ranging 1000−6000 Pa. These SPAAC cross-linked PEG hydrogels have also served as patterning platforms for the immobilization of biological functionalities using thiol−ene click photocoupling[30,31] (see Click Patterning of 3D Scaffolds section).

A drawback of CuAAC cross-linking is the lack of temporal and spatial control due to the generation of the catalytic Cu(I) species.[32] Spatial and temporal control of network formation is paramount in many tissue engineering applications. To overcome

this, Adzima et al. sought to catalyze the CuAAC cross-linking reaction via the photochemical reduction of Cu(II) to Cu(I).[32] Generating Cu(I) photochemically is analogous to the initiation of a radical or carbocation species in traditional photopolymerization processes, resulting in total spatial and temporal control of the CuAAC reaction. The authors developed this photoinducible azide–alkyne cycloaddtion (pCuAAC) reaction to synthesize hydrogels by irradiating multifunctional alkyne and azide functionalized PEG monomers in the presence of $CuSO_4$ and Irgacure 2959 photoinitiator. To extend this system to biological systems, the authors suggest modifications to mimic reverse-ATRP polymerizations that require significantly lower copper levels.[33]

Diels–Alder Click Cross-linked Hydrogels. Although the DA click reaction has long served as an exceptional cross-linking method for the synthesis of complex polymer networks,[34−37] the preparation of cross-linked hydrogels via DA chemistry remains largely unexplored. A few DA hydrogels have been synthesized with synthetic polymers;[38−41] however, these studies have mainly examined the effect of temperature on both gelation time and retro-DA reaction. Recently, Shoichet and co-workers reported a DA cross-linked hydrogel with a specific tissue engineering application in mind.[42] Furan-modified HA was synthesized and cross-linked via dimaleimide-PEG to form a stable hydrogel by mixing the two aqueous solutions at room temperature (Scheme 2). By controlling the furan to maleimide molar ratio, the mechanical and degradation properties of the DA hydrogels could be altered. The reported shear modulus of the hydrogels ranged from 275 to 680 Pa, similar to that of central nervous system tissue. After 14 days of culture *in vitro*, endothelial cells displayed high levels of cell survival (>98%), and appeared to interact with the HA matrix. The minimal swelling, complete degradation, and cell-interactive properties of these DA hydrogels make them promising materials for soft tissue engineering.

Scheme 2. Formation of Diels-Alder Hyaluronic Acid Click Hydrogels[42]



Thiol–Click Cross-Linked Hydrogels. Qiu et al. were the first to harness the thiol-Michael click reaction for hydrogel formation.[43] PEG-based copolymers containing multiple thiol functionalities were cross-linked via divinylsulfone-PEG in neutral phosphate buffer. This system proved to be bioorthogonal, as protein additives did not interfere with the click cross-linking reaction; however, these proteins did not contain any exposed thiols that could interfere with the reaction. A thiol-click cross-linked hydrogel may be inappropriate for protein delivery if any free thiol groups are present on the proteins. Notwithstanding this limitation, when proteins were incorporated into these gels, their release was sustained for 2–4 weeks.

Hubbell and co-workers took advantage of this Michael-type addition click reaction to synthesize hydrogels with characteristics similar to that of native ECM.[44] Their approach was to incorporate integrin-binding sites for cell adhesion and enzyme-degradable sites into the matrix such that cell-secreted matrix metalloproteinases (MMPs) would enable cell migration into and remodeling of the biomimetic ECM.[45] To achieve this, they cross-linked bis-cysteine MMP substrate peptides with vinyl sulfone-functionalized multiarm PEG. The resulting click hydrogel networks displayed a defined molecular architecture, and allowed for invasion by primary human fibroblasts. Cellular invasion was shown to be dependent on the proteolytic activity of the incorporated peptide. The hydrogels were also employed as a drug delivery vehicle for the recombinant human bone morphogenetic protein (BMP2) to rat cranium defects. Correlating with their work *in vitro*, bone regeneration *in vivo* depended on the enzymatic sensitivity of the incorporated substrate.

Chawla et al. recently developed a 3D cell culture platform for mesenchymal stem cells (MSCs) by cross-linking a saccharide-peptide copolymer via Michael-type conjugation addition between cysteine (Cys) and vinyl sulfone (VS).[46] By altering the pH of the cross-linking reaction, or the VS to Cys ratio, they were able to tune both the degradation and mechanical properties of the gel. Hydrogels that were cross-linked with an equimolar ratio of VS to Cys maintained their mechanically stability for longer than 21 days *in vitro*, similar to dextran hydrogels cross-linked by Michael addition.[47] These hydrogels also exhibited a rapid gelation time, suggesting utility for in situ surgical procedures, and displayed a microporous network when visualized under environmental scanning electron microscopy. Cell encapsulation was facilitated by the cross-linking reaction occurring in culture medium. MSCs remained viable after 14 days (>90%) in culture.

The radical-mediated thiol–ene click reaction has also been employed as a hydrogel cross-linking method. Anseth and co-workers developed a platform for hydrogel synthesis by a step-growth reaction mechanism via thiol and norbornene functionalities.[48] Not always achievable with simple Michael addition, thiol–ene photopolymerization offers spatial and temporal control of network formation. Hydrogels were synthesized by mixing norbornene-functionalized PEG with either chymotrypsin- or MMP-degradable linkers in a 1:1 stoichiometric ratio in PBS. The networks maintained high cell viability following encapsulation (>95% following 24 h). Anderson et al. utilized these thiol–ene photopolymerized PEG hydrogels to examine MSC behavior in response to network properties.[49] Both MMP cleavable peptide linkers and nondegradable PEG-dithiol linkers were incorporated into the hydrogel to monitor how MSC degradation of the matrix affects their differentiation behavior. Their findings suggest that directed chondrogenic and adipogenic differentiation of MSCs are facilitated by increased cell-mediated hydrogel degradation.

CLICK IMMOBILIZATION OF PEPTIDES ON 2D SURFACES

Well-defined chemically modified substrates, such as self-assembled monolayers (SAMs), serve as investigative tools to explore fundamental interactions applicable to regenerative strategies. Surface functionalization is particularly advantageous when engineering substrates for cell culture to harness control over cell-matrix interactions. Many have employed this strategy to immobilize ECM-derived biomolecules for ultimate characterization of their effects on cell adhesion.[50−53] Popular immobilization strategies in the past have been based on adsorption or covalent modification of a protein's functional group(s) to a chemically activated surface.[54,55] These methods can result in side reactions and are difficult to characterize both physically and in terms of cellular response. Accordingly, there has been a paradigm shift in the existing approaches for surface functionalization from unspecific and nonselective reactions toward highly specific orthogonal reactions that ensure bioactivity and facilitate characterization of engineered surfaces.[56]

CuAAC Click Immobilization. CuAAC is chemoselective against common functionalities in biomolecules, and thus, stable reactive species can be introduced within biomolecules with ease. Accordingly, CuAAC serves as an effective click reaction to chemoselectively immobilize peptides to otherwise bioinert SAMs. Becker and co-workers developed a universal technology for surface conjugation of any biomolecule containing accessible azide groups.[57] SAMs were subjected to oxidation by UV exposure, creating a monotonically increasing carboxyl density gradient. A bifunctional propargyl-functionalized linker was then attached to the carboxylic moieties of the gradient to yield an alkyne gradient, making it susceptible to modification with any azido-derivatized species via CuAAC chemistry. The authors tested their methodology by conjugating the RGD tripeptide sequence in a density gradient ranging from 0 to 140 pmol cm^{-2}. Smooth muscle cells cultured on the RGD gradient surfaces revealed enhanced cell attachment with increased RGD concentration. Alkyne-modified KGRGDS has also been successfully coupled by CuAAC chemistry to self-assembled polymeric micelles with azide-functional groups, thereby yielding RGD-functionalized polymeric nanoparticles that specifically bind to corneal epithelial cells.[58]

Becker and co-workers later exploited their CuAAC technology to couple osteogenic growth peptide (OGP) to SAMs in order to explore the effects of OGP density on preosteoblast cell adhesion, morphology, and proliferation.[59] OGP has been recognized as a promising agent for bone tissue engineering applications because it stimulates tissue regeneration of bone defects.[60] To create the peptide gradient, the carboxylic acid functionalities on the SAM layer were reacted with the amine terminal of a bifunctional amine-poly(ethylene oxide)-alkyne linker, resulting in an alkyne gradient. Azide-terminated OGP peptides were then conjugated to the alkyne gradient by immersing substrates in a solution of $CuSO_4$, sodium ascorbate, and peptide for 24 h at 40 °C. Preosteoblast cells were cultured on the OGP functionalized gradient surfaces in serum-free conditions for 7 days. Cell adhesion was highest at low OGP peptide concentrations. At day 3, cells experienced faster doubling rates compared to cells cultured on control surfaces, but this effect subsided by day 7. This is indicative of the natural transition made by osteoblasts from proliferative to maturation phases. Gene expression experiments also verified this phenomena with a 10-fold increase in collagen I expression between days 3 and 7, coinciding with the initial stages of bone mineralization.

Hudalla and Murphy fabricated SAMs expressing a variation of the adhesive RGD peptide, RGDSP, as a means to study stem cell adhesion.[50] This was achieved via CuAAC. SAMs were first prepared by immersing a gold substrate in an ethanolic solution of 80 mol % tri(ethylene glycol) alkanethiolate ($HS\text{-}EG_3$) and 20 mol % azide-terminated hexa(ethylene glycol) alkanethiolate ($HS\text{-}EG_6\text{-}N_3$). The resulting mixed SAMs contained approximately 10% $HS\text{-}EG_6\text{-}N_3$ and 90% $HS\text{-}EG_3$ (Figure 3A); however, this result could be

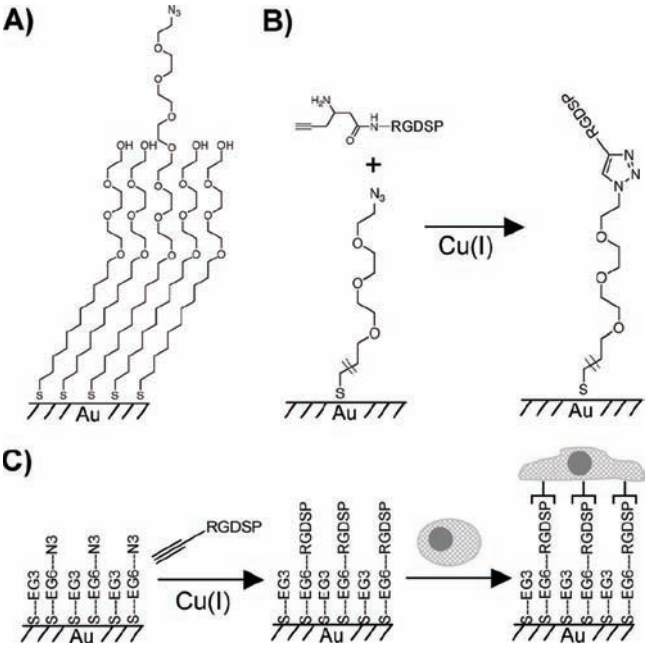


Figure 3. CuAAC click immobilization of peptides to SAM substrates to study stem cell adhesion.[50] (A) Mixed SAMs bearing azide groups; (B) reaction between azide-functionalized SAMs with acetylene-bearing RGDSP; (C) the surface density of RGDSP immobilized via CuAAC affects mesenchymal stem cell adhesion and spreading. (Copyright American Chemical Society, reproduced with permission[50].)

tailored by varying the ratio of $HS\text{-}EG_6\text{-}N_3$ and $HS\text{-}EG_3$. The SAMs were classified as bioinert, as they displayed minimal nonspecific protein adsorption. Acetylene-bearing RGDSP (Hex-RGDSP) was then conjugated to the SAMs via $HS\text{-}EG_6\text{-}N_3$ in the presence of a Cu(I) catalyst (Figure 3B). The CuAAC reaction efficiency illustrated near-quantitative conjugation upon the addition of a tertiary amine, which has been a proven method utilized by others to enhance CuAAC efficiency by binding the Cu(I) catalyst.[61] MSCs were cultured on top of the RGDSP-presenting SAMs. RDGSP surface density and intermolecular spacing regulated MSC morphology and attachment (Figure 3C).

In a followup study, Hudalla and Murphy demonstrated that CuAAC conjugation of biomolecules to SAM substrates can be conducted in parallel with other chemistries, namely, carbodiimide condensation.[62] Incorporation of carboxylate-terminated hexaethylene glycol alkanethiolate ($HS\text{-}EG_6\text{-}COOH$) with the original mixed SAM allowed for conjugation of two distinct peptides, RGDSP and TYRSRKY, a

proteoglycan-binding peptide. These experiments revealed that these distinct extracellular factors work synergistically to regulate MSC adhesion on 2D substrates. They also demonstrated that soluble biomolecules, such as heparin, can disrupt specific cell-material interactions, and in turn direct MSC adhesion.

Diels–Alder Click Immobilization. Yousaf and Mrksich were the first to exploit the DA reaction for protein immobilization on 2D surfaces.[63] In their approach, SAMs were modified with a hydroquinonequinone group, which upon oxidation provides a quinone, enabling a cycloaddition between the quinone and a cyclopentadiene (cp). To demonstrate this DA approach, they immobilized a biotin-cp conjugate, and tested the affinity of the immobilized biotin for streptavidin. This work demonstrated that the DA click reaction is an attractive bioconjugation technique for a wide variety of applications, which could be extended to regenerative therapies. The authors also state that this method would allow for controlled, sequential immobilization of several biomolecules.

Sun et al. demonstrated the use of sequential click reactions for protein immobilization on solid surfaces.[64] First, the DA click reaction was used to immobilize a heterobifunctional PEG linker carrying alkyne and cyclodiene terminal groups onto an N-(E-maleimidocaproyl)-functionalized glass slide. This resulted in an exposed alkyne-terminated PEGylated surface, vulnerable to conjugation with azide-containing biomolecules via CuAAC click chemistry. Again, biotin was chosen as a model protein for immobilization. Biotin-PEG-azide was added to a glass vial containing the alkyne-PEGylated glass slide, $CuSO_4$, and a tertiary amine ligand. The reaction was left at 4 °C for 12 h. Biotinylated glass slides were then immersed in a solution of dilute FITC-conjugated streptavidin at 4 °C for 2 h. Confocal fluorescence images verified the fidelity of the click protein immobilization. This technique is applicable to a wide range of functionally complex biomolecules for the design of biomimetic surfaces.

Thiol–Ene Click Immobilization. Waldmann and co-workers reported the use of the thiol–ene reaction to photochemically pattern proteins and other biomolecules onto solid surfaces.[65] Polyamidoamine dendrimers, containing an aminocaproic acid spacer, were covalently attached to a silicon oxide wafer surface. Cystamine was then conjugated to the spacer, which upon disulfide reduction, exposed free thiols on the surface. A solution of terminal-olefin-functionalized biomolecules were spread onto the surfaces, and covered with a photomask. Following irradiation at 365–405 nm, a covalently attached pattern of thioethers was obtained. As a test application, biotin was photochemically patterned onto a thiolated wafer, and subsequently incubated in a solution of Cy5-labeled streptavidin to render a fluorescent pattern surface. Immobilization was shown to be dependent on irradiation time and concentration of immobilized peptide. They further exemplified the broad applicability of their patterning method by immobilizing alkaline phosphatase, Ras, and phosphopeptide, all of which retained their bioactivity and binding affinities.

In an extension of this work, Waldmann and co-workers demonstrated fast, oriented covalent immobilization of proteins directly from lysates, eliminating any additional protein chemical modifications.[66] The authors took advantage of the fact that, in cells, many proteins are post-translationally S-farnesylated at a C-terminal "CAAX-box" by protein farnesyltransferase (FTase).[67] By genetically coding for the CAAX tag, the authors enabled farnesylation *in vitro* or *in vivo* with FTase, creating a facile method for "ene" incorporation into a protein of interest. Once farnesylated, these proteins were immobilized via the thiol–ene photochemical click reaction to surface-exposed thiols.

■ CLICK PATTERNING OF 3D SCAFFOLDS

Throughout the past decade, several scaffolds have emerged aiming to mimic the cellular microenvironment and ultimately control cell fate and guide tissue regeneration. These scaffolds can be fine-tuned to study a specific parameter of the microenvironment. Notably, the effect of peptide presentation on the cell has been examined by spatially immobilizing proteins and adhesion peptides in 3D patterns within scaffolds. Growth factors localized in 3D scaffolds remain bioactive[68−70] and have been shown to orient axonal growth,[71,72] guide cellular migration,[73] and cause morphological changes.[30] The stringent spatial resolution and controlled biochemical heterogeneity required for 3D patterning make simple bioorthogonal chemistries paramount. The use of click reactions for 3D patterning of scaffolds allows significant spatial control when combined with multiphoton processing.[75,76] Additionally, many of these hydrogel scaffolds are click cross-linked, and sequentially click patterned.[30,31,74]
