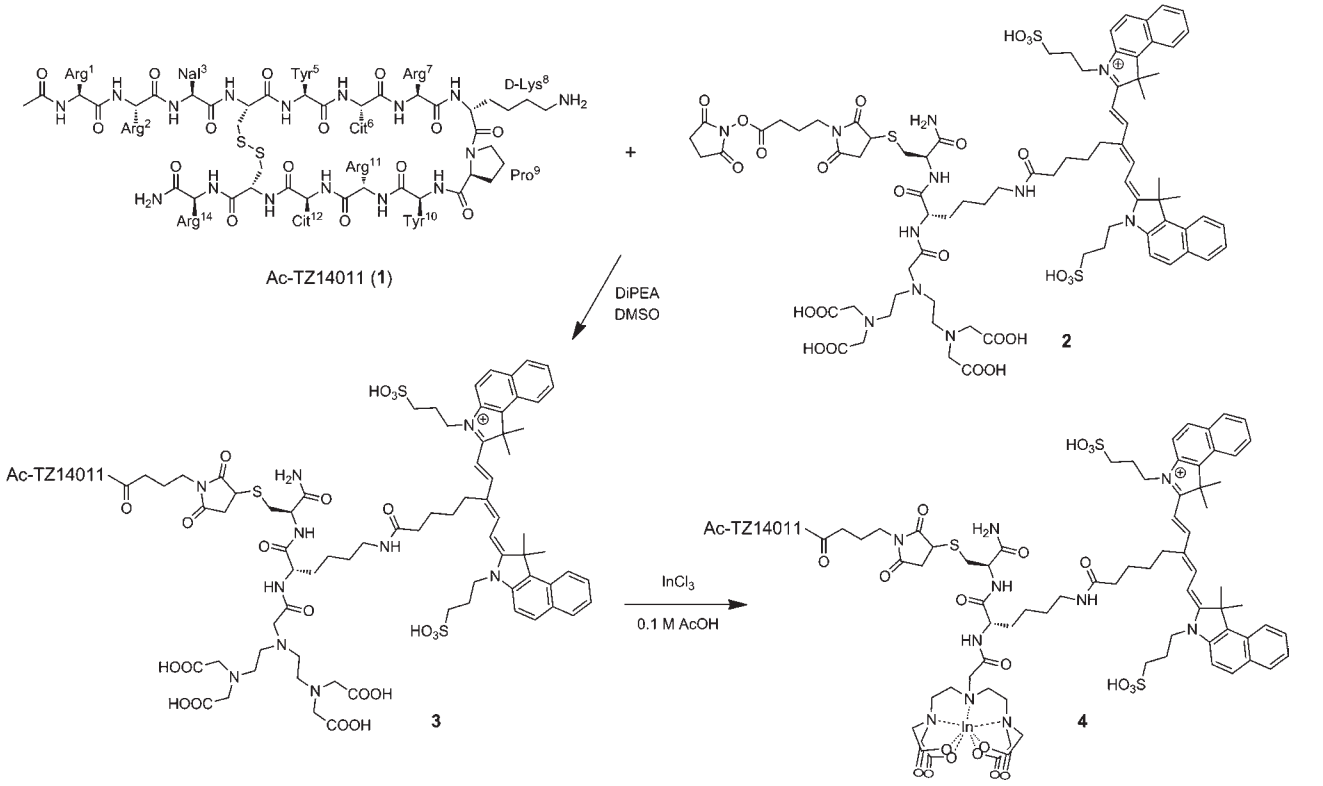
Supporting Information

ABSTRACT:

The antagonistic Ac-TZ14011 peptide, which binds to the chemokine receptor 4, has been labeled with a multifunctional single attachment point reagent that contains a DTPA chelate and a fluorescent dye with Cy5.5 spectral properties. Flow cytometry and confocal microscopy showed that the bimodal labeled peptide gave a specific receptor binding that is similar to monofunctionalized peptide derivatives. Therefore, the newly developed bimodal peptide derivative can be used in multimodal imaging applications.

The chemokine receptor 4 (CXCR4) is a G-protein-coupled membrane receptor which is present in various cell types.[1,2] Besides its expression in normal tissues, a 5.5-fold upregulation of CXCR4-expression was found in breast cancer tissue,[3] and CXCR4 upregulation is reported for at least 22 other types of cancer.[4,5] CXCR4 has also been shown to play a critical role in (breast) cancer progression and metastatic spread.[6,7] Because of its prominent role in oncology, overexpression of CXCR4 has been suggested to be of value in imaging applications.[8,9]

For molecular imaging of cancer-related biomarkers, several modalities are in use, including SPECT, PET, MRI, and fluorescence imaging.[10] Each modality has its own strengths and weaknesses, and therefore, often a combination of modalities is needed during the clinical trajectory.[11−14] Recently, we have shown the added value of multimodal imaging agents in surgical guidance.[15−17] In this application, combined pre- and intraoperative imaging is achieved, whereby surgical planning is based on the radioactive signal and optical surgical guidance is achieved via the fluorescent component. This application can be expanded to tumor targeting peptides.[13]



For an imaging agent to be detectable in multiple modalities, it needs to contain at least two different diagnostic labels. As we recently summarized, the combination of radiolabels for SPECT or PET, and fluorescent labels in particular, has potential in peptide-based molecular imaging.[13] This combination benefits from the high sensitivity of nuclear imaging and the high spatial resolution of fluorescence imaging[14] and allows the use of stoichiometric 1:1 labels.[13]

Several CXCR4 antagonistic peptides have been reported.[18,19] One of the most potent peptides, T140, is a 14 amino acid containing disulfide-bridged peptide with a rigid β-hairpin conformation.[20] Residues 2, 3, 5, and 14 of T140 are mainly responsible for CXCR4 binding, whereas the residues 7−10 in the type II′ β-turn do not have direct contacts with CXCR4 within 3.0 Å.[21] Recently, a crystal structure of CXCR4 with the horseshoe crab peptide polyphemusin analogue CVX15, which is similar to T140, confirmed that residues 2, 3, 5, and 14 form important interactions with the receptor.[22] T140 has been optimized to Ac-TZ14011 for better CXCR4 binding, higher *in vivo* stability, and easier functionalization, i.e., in Ac-TZ14011

only one amine group is present (D-Lys[8]).[23−25] The binding of dye- and chelate-labeled Ac-TZ14011 peptides to CXCR4 has already been validated *in vitro* and *in vivo*;[13,23−25] the specificity of Ac-TZ14011 for CXCR4 has been underlined by the fact that a scrambled peptide and a peptide with inversed stereocenters could not label CXCR4 expressing cells.[26] However, a multimodal derivative of this CXCR4-targeting peptide has not yet been reported.

Here, we report the conjugation of a multimodal imaging label (also referred to as multifunctional single-attachment-point, MSAP, reagent[27,28]) to Ac-TZ14011. We have performed *in vitro* validation studies to examine the influence of the MSAP label on the specificity and receptor affinity and we report initial *in vivo* experiments.

The bimodal peptide derivative was generated using the MSAP reagent (**2**), which bears a DTPA and a CyAL-5.5$_b$ fluorochrome reporter and a reactive NHS ester.[27−29] The synthesis of the MSAP reagent **2** is described in the Supporting Information. Via the active NHS ester, it was selectively coupled to the D-Lys[8] amine functionality on Ac-TZ14011 (**1**; see Scheme 1). The resulting peptide derivative Ac-TZ14011-MSAP (**3**) was purified with preparative HPLC and characterized using mass spectrometry. To study the possible influence of chelation of a metal ion in the DTPA moiety, a portion of Ac-TZ14011-MSAP (**3**) was coordinated to (nonradioactive) indium, yielding Ac-TZ14011-MSAP-In **4** (Scheme 1).

The absorption spectra of **3** and **4** were analogous and also the emission spectra were very similar (see Supporting Information Figure S1). In both cases, the absorption maximum was found at 680 nm and the emission maximum at 704 nm. Moreover, the fluorescent signal intensity was not reduced when indium was bound in the DTPA-chelate.

Table 1. Quantitative Analysis of Cellular Uptake of MDAMB231 and MDAMB231^{CXCR4+} Cells Using a CXCR4 Antibody and the Peptides 3 and 4[a]

compound	MFIR ± SD MDAMB231	MFIR ± SD MDAMB231^{CXCR4+}	ratio of MFIRs
12G5-PE antibody	1.116 ± 0.054	4.920 ± 1.46	4.4
3	10.94 ± 1.62	45.27 ± 2.19	4.1
4	18.24 ± 1.93	56.67 ± 2.84	3.1

[a] MFIR = mean fluorescence intensity ratio.

The ability of peptides **3** and **4** to discriminate between basal and CXCR4 overexpressing tumor cells was quantitatively examined with flow cytometry. As a reference "golden standard", the commercially available phycoerythrin (PE) labeled anti-CXCR4 antibody CD184, clone 12G5 (12G5-PE), was used. The 12G5-PE antibody showed that the higher CXCR4 expressing cells, MDAMB231^{CXCR4+}, had a 4.4× upregulation of CXCR4 compared to the basal cell line MDAMB231 (Table 1). This ratio of 4.4 is an intrinsic property of the two cell lines, and therefore, a peptide-based probe which can also obtain this ratio performs as well as the antibody. The ratio of the fluorescent signals found for peptide derivative **3** was 4.1, which nicely corresponds to the ratio obtained with the antibody (Figure 1 and Table 1). This indicates that this peptide is equally suited to detect CXCR4-expression levels.

The mean fluorescence intensity ratios (MFIRs) for Ac-TZ14011-MSAP (**3**) were approximately 10 times higher than

dx.doi.org/10.1021/bc2000947 |*Bioconjugate Chem.* 2011, 22, 859–864

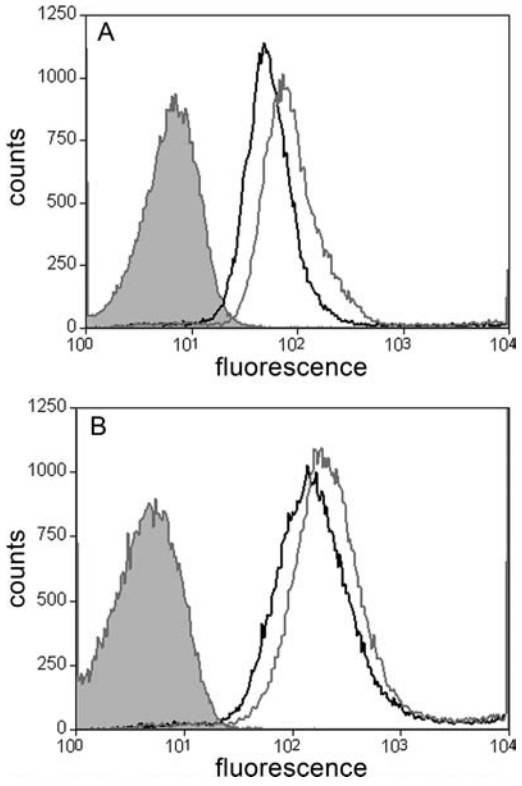

Figure 1. Flow cytometry analysis of the peptides **3** and **4** using (A) MDAMB231 cells or (B) MDAMB231^{CXCR4+} cells. Both graphs show untreated cells (trace filled with gray), 1 μM of **3** (black trace), and 1 μM of **4** (gray trace).

that of the antibody (Table 1). This difference is probably caused by the fact that the concentration used for the antibody was significantly lower than that of the peptides, 6.4 nM and 1 μM, respectively. Moreover, due to the lower autofluorescence with the flow cytometer settings used with the MSAP peptides, the voltage of the photomultiplier detector could be set higher when the MSAP peptides were measured, compared to the PE-labeled antibody.

For Ac-TZ14011-MSAP-In (**4**), the obtained uptake ratio for the MDAMB231^{CXCR4+} and MDAMB231 cells was somewhat lower, namely, 3.1 (Table 1). Since both cell types had a higher MFIR (Table 1), this is perhaps caused by an increase in nonspecific binding of **4** to the cells (Figure 1). The increased nonspecific binding most likely is a charge-related effect. The DPTA chelate in peptide **3** is mainly −2 charged (four carboxylates and two protonated nitrogen atoms), and indium-bound DTPA in **4** has a charge of −1 (four carboxylates, no protonated nitrogen atoms and In^{3+}),[30,31] increasing the hydrophobicity of the imaging label. In general, labels with increased hydrophobicity drive (nonspecific) cellular uptake.[13]

In general, conjugation of a bifunctional imaging label to a peptide reduces the receptor affinity.[13] Therefore, we have thoroughly studied the influence of our MSAP-label in peptides **3** and **4** on receptor binding and compared it to that of monofunctionalized derivatives and the parental peptide. Initially, we determined the dissociation constants (K_D) of **3** and **4** by a saturation binding assay (Figure 2A). The K_D value of **3** was used to determine the K_D values of Ac-TZ14011-DTPA (**5**), Ac-TZ14011-FITC (**6**), and Ac-TZ14011 (**1**) with competition experiments (Figure 2B,C).

Incubation of MDAMB231^{CXCR4+} cells with different concentrations of Ac-TZ14011-MSAP (**3**) yielded a binding curve that appears to exist out of two components (Figure 2A). The nonlinear component of the binding curve can be ascribed to specific receptor binding and the linear component to nonspecific cell binding. By using this binding model, it was not needed to determine the nonspecific binding directly. The K_D of Ac-TZ14011-MSAP (**3**) derived from this curve was 186.9 nM (Table 2). The indium labeled derivative Ac-TZ14011-MSAP-In (**4**) again gave somewhat higher fluorescent values (see Figure 1 and Figure 2A) and a K_D of 177.1 nM (Table 2). The similarity in the CXCR4-receptor affinities of **3** and **4** indicates that indium binding does not affect the interaction with CXCR4.

To compare the receptor affinities of **3** and **4** with the other peptide derivatives, different amounts of Ac-TZ14011 (**1**), Ac-TZ14011-DTPA (**5**), or Ac-TZ14011-FITC (**6**) were added in the presence of 250 nM of Ac-TZ14011-MSAP (**3**) (Figure 2B,C). All three peptide derivatives could compete with Ac-TZ14011-MSAP (**3**) for CXCR4 binding, confirming the specific CXCR4 binding of Ac-TZ14011-MSAP (**3**). The K_D values, obtained by fitting the inhibition curves with a competition model, of the monolabeled peptides Ac-TZ14011-DTPA (**5**) and Ac-TZ14011-FITC (**6**) were in the order of the K_D values of **3** and **4** (Table 2). These results illustrate that the bifunctional MSAP label does not hamper receptor binding more than the smaller FITC and DTPA labels. However, the unlabeled Ac-TZ14011 peptide **1** gave an approximately 20× higher receptor affinity than derivatives **3** and **4** (Table 2). Since the affinity of Ac-TZ14011-MSAP-In (**4**) remains in the nanomolar range, this decrease is not likely to be an obstruction for using **4** in molecular imaging applications.[32] The previously reported scrambled peptide TR14010 (**7**) showed no significant binding; K_D > 5000 nM (Table 2, see Supporting Information for the structure of TR14011).[26]

Molecular modeling studies showed that D-Lys^8 in T140 has no interactions with CXCR4.[21] Furthermore, the crystal structure of CVX15, which is similar to T140, with CXCR4 also showed no crucial interactions.[22] However, we found that D-Lys^8 functionalization in Ac-TZ14011 still influences binding affinity. This influence might be explained by looking at the different effects modifications of the peptide can have on (CXCR4) receptor binding. A modification on the peptide (i) can directly change a receptor interaction (e.g., a hydrogen bond), (ii) can change the 3D structure of the peptide, and/or (iii) can hinder the phamacophore to bind properly to the receptor via steric hindrance.[21] Here, the third effect is most likely to cause the drop in affinity.

A logical chemical modification to reduce the steric hindrance would be the incorporation of a larger spacer between the imaging label and the pharmacophore. Although it has been shown that incorporation of a 6-aminocaproic acid spacer does not yield a higher affinity,[24] it is possible that longer spacers will be more effective. However, this influence of the spacer still is under investigation.

Next to validating the receptor affinity of peptide **3**, also its cellular distribution needs to overlap with the locations where the G-protein-coupled receptor CXCR4 is most likely to be expressed, namely, the cell membranes.[1,2] Confocal microscopy imaging of MDAMB231^{CXCR4+} cells incubated with **3** indeed revealed clear cell membrane staining (Figure 3). The incubation

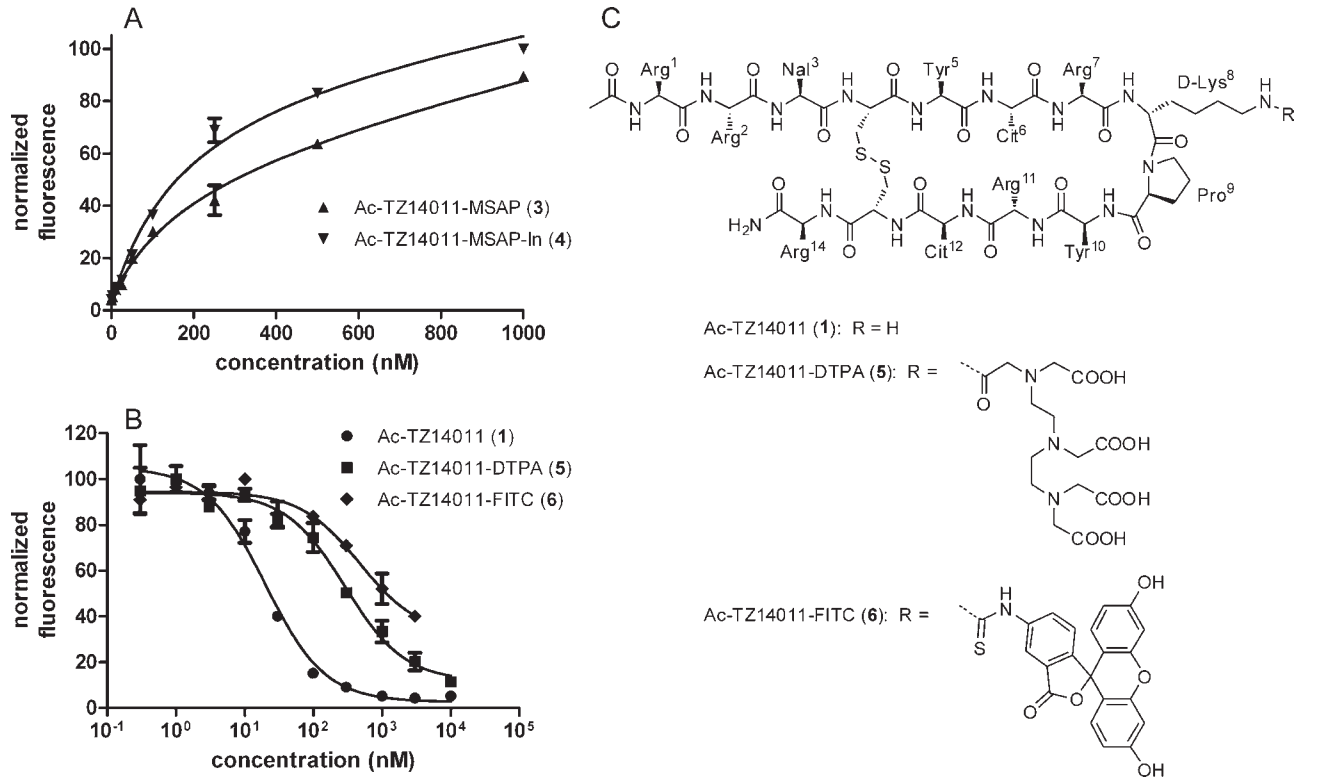

Figure 2. (A) Determination of affinity of constructs **3** and **4** with saturation binding experiments. (B) Competition experiments with three other Ac-TZ14011 peptides in the presence of 250 nM of **3**. (C) Structures of the peptides used for competition experiments.

Table 2. Dissociations Constants (K_D) of the Constructs

construct	K_D (nM)
Ac-TZ14011-unlabeled (**1**)	8.61 ± 1.42
Ac-TZ14011-MSAP (**3**)	186.9 ± 52.4
Ac-TZ14011-MSAP-In (**4**)	177.1 ± 37.2
Ac-TZ14011-DTPA (**5**)	124.4 ± 23.9
Ac-TZ14011-FITC (**6**)	203.5 ± 67.1
TR14010 (**7**)	>5000

was performed at 4 °C to minimize the initial metabolic activity. During imaging at 37 °C, minor staining in vesicular structures was detected. Vesicular internalization is common for liganded membrane receptors, and this form of signal accumulation in the cells proves the potential of using CXCR4 as a target in molecular imaging applications.

Initial *in vivo* studies were performed to evaluate the tumor targeting. Therefore, mice with CXCR4 positive "spontaneous" MIN-O tumors were used instead of the MDAMB231^{CXCR4+} cell line, because the CXCR4 expression in MDAMB231^{CXCR4+} cells decreases to basal levels *in vivo*. Mice were injected with ^{111}In-labeled Ac-TZ14011-MSAP, and after 24 h, the mice were imaged with SPECT/CT and fluorescence imaging (Figure 4). Both imaging modalities showed high tumor uptake.

For biodistribution studies, we again used mice with CXCR4 positive MIN-O tumors and mice with CXCR4 negative 4T1 tumors as negative control (both tumors had a murine background to prevent xenograph effects) (Table 3). The tumor-to-muscle ratio for the MIN-O tumor was 4.55 ± 0.68, and for the 4T1 tumor, it was 1.20 ± 0.12 ($p < 0.01$), indicating that

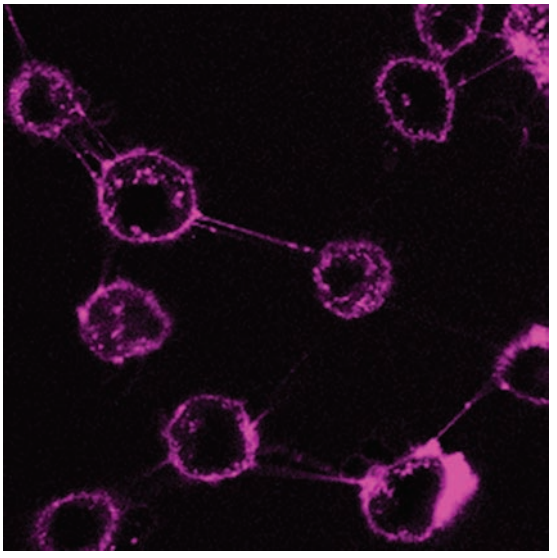

Figure 3. Confocal microscopy of Ac-TZ14011-MSAP (**3**) using MDAMB231^{CXCR4+} cells.

Ac-TZ14011-MSAP can be used to discriminate CXCR4 positive from CXCR4 negative tumors *in vivo*.

In conclusion, we report the first bifunctional CXCR4 antagonistic peptide, containing a Cy5.5-like dye and a DTPA chelate. Despite the functionalization with a relatively large MSAP label, *in vitro* the Ac-TZ14011 derivative retains its specificity and has a high CXCR4-affinity. Moreover, indium binding to the chelate does not affect the fluorescent properties. The initial *in vivo*

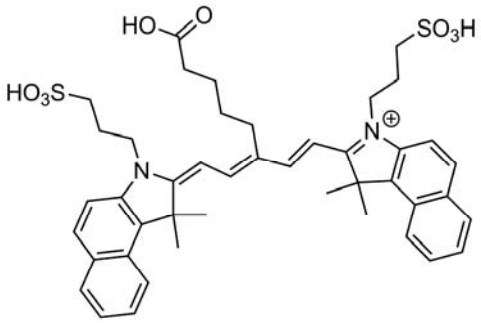
Synthetic procedures

General



All chemicals were obtained from commercial sources and used without further purification. The reactions were monitored by thin layer chromatography (TLC).

Ac-TZ14011 (1)

Ac-TZ14011 was synthesized according to described procedures.[1]

CyAL-5.5$_b$

CyAL-5.5$_b$ was synthesized according to previously described procedures.[2]

MSAP reagent (2)

The multifunctional single attachment point (MSAP) reagent (**2**) was synthesized based on previously described procedures.[3,4] Briefly, the dipeptide (Fmoc-Lys(ivDde)-Cys(Trt)-Rink resin) was obtained with Fmoc synthesis on a Rink Amide MBHA resin. After Fmoc removal using a piperidine/DMF solution (1:4), DTPA-tetra-*t*-butyl ester (cat. # B-365, Microcyclics) was attached to the N-terminus of the peptide using 2 equiv of DTPA-tetra-*t*-butyl ester, 2 equiv of PyBop and 12 equiv of DiPEA (overnight, room temperature). The ivDde group was removed using 2% hydrazine in DMF (10 mL/g resin, 3 × 3 min) and the CyAL-5.5$_b$ fluorochrome was coupled using 1.5 equiv of CyAL-5.5$_b$, 2 equiv of PyBop and 8 equiv of DiPEA in DMF (overnight, room temperature). The dipeptide was cleaved from the resin and the trityl group was removed using

TFA/H_2O/TIS/EDT (88/2/5/5) for 2 × 4 h (3 mL each time). The resulting crude product was purified by a semi-preparative HPLC with a PLRP-S column. The product was identified by MS and is denoted as DTPA-Lys(CyAL-5.5$_b$)-Cys-NH_2. MS: $[M]^+$ calculated 1404.56, found 1404.15.

A solution of the bifunctional reagent 4-maleimidobutyric acid N-hydroxysuccinimide ester (Thermo Scientific, 11.7 mg, 41.8 μmol), DTPA-Lys(CyAL-5.5$_b$)-Cys-NH_2 (14.2 mg, 10.1 μmol) and DiPEA (5 μL, 28.7 μmol) in 800 μL of anhydrous DMF was stirred for 2 h at room temperature. Reversed phase-HPLC purification was employed on a semi-preparative HPLC with a Vydac C18 column. MSAP reagent **2** was obtained as a blue powder (8.2 mg, 48%) after pooling of the appropriate fractions and lyophilization. MS: $[M]^+$ calculated 1684.6, found 1684.4.

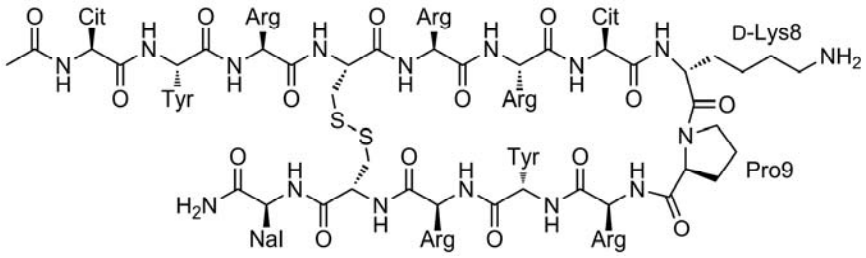
Ac-TZ14011-MSAP (3) (Scheme 1)

Ac-TZ14011 (**1**) (8.4 mg, 3.0 μmol) and the MSAP reagent (**2**) (3.4 mg, 2.0 μmol) were dissolved in 2 mL of DMSO. DiPEA (7.0 μL, 40 μmol) was added and the mixture was stirred overnight at room temperature, after which the mixture was purified by preparative HPLC using a Waters HPLC system with a UV detector operating at 230 nm and a Waters Atlantis C18 10 μm (250 × 19 mm) column. A gradient of 0.05% TFA in H_2O/CH_3CN 9:1 to 0.05% TFA in H_2O/CH_3CN 1:4 40 minutes was used. The product was obtained as a blue fluffy solid (3.9 mg, 45%) after pooling of the appropriate fractions and lyophilization. MS (MALDI-TOF): $[M+H]^+$ calculated 3676.677, found 3676.256.

Ac-TZ14011-MSAP-In (4) (Scheme 1)

A solution of **3** with a concentration of 160 μM in 0.1 M AcOH was prepared. Half of this solution was diluted (1:1 v/v) with 0.1 M of AcOH to yield a stock solution of 80 μM of **3**. The other half was added to the same amount of 160 μM of $InCl_3$ in AcOH, incubated for 30 minutes, yielding a stock solution of 80 μM of **4**.

Ac-TZ14011-DTPA (5)



Ac-TZ14011-DTPA was synthesized according to previously described procedures.[1]

Ac-TZ14011-FITC (6)

Fluorescein isothiocyanate isomer I (FITC; 2.32 mg, 5.95 μmol) in 500 μL of DMSO was added to Ac-TZ14011 (11.1 mg, 3.96 μmol) in 1 ml of 0.1 M $NaHCO_3$ and 2 ml of CH_3CN. The mixture was stirred overnight at room temperature, the solution was concentrated and the product was purified by preparative HPLC using a Waters HPLC system with a UV detector operating at 230 nm and a Waters Atlantis C18 10 μm (250 × 19 mm) column using a gradient of 0.05% TFA in H_2O/CH_3CN 9:1 to 0.05% TFA in H_2O/CH_3CN 1:4 in 40 minutes. The product was obtained as a yellow fluffy solid (4.3 mg, 35%) after pooling of the appropriate fractions and lyophilization. MS (MALDI-TOF): $[M+H]^+$ calculated 2496.118, found 2495.168.

Scrambled peptide TR14010 (7)

TR14010 was synthesized according to previously described procedures.[5]

Spectroscopy

For the recording of absorption and emission spectra 0.25 mL of stock solution of **3** or **4** was added to 1 mL of EtOH and 2.25 mL of PBS. Absorption spectroscopy was performed on a Lambda Bio 20 spectrometer (Perkin Elmer). Emission spectra were recorded using a 627 nm LED lamp (Luxeon III Star, Lambt, red, Farnell) and a VS140-VISNIR-CCD spectrometer (Horiba Jobin Yvon). Absorption and emission spectra of **3** and **4** are shown in Figure S1.

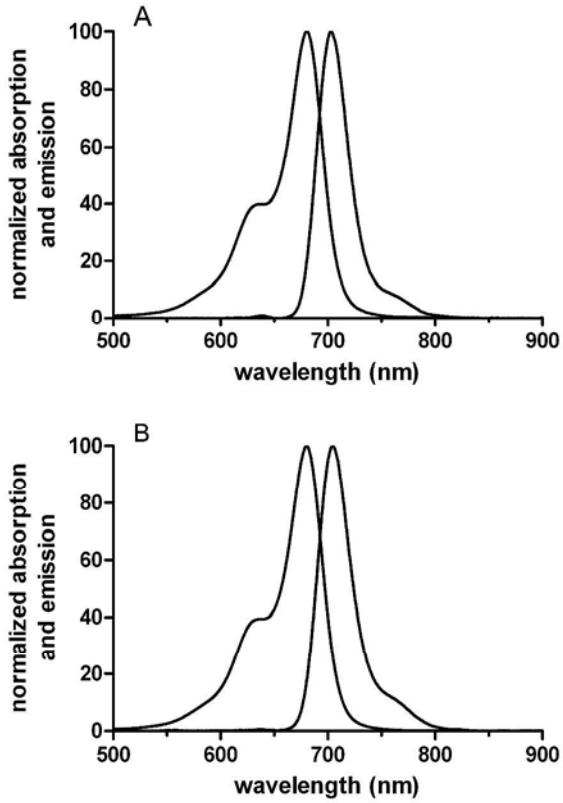


Figure S1. Absorption and emission spectra of compounds **3** (A) and **4** (B).

IN VITRO experiments

Cell culture

Human breast cancer cell lines MDAMB231 and MDAMB231^{CXCR4+} were kindly provided by Olaf van Tellingen and Ed Roos (both NKI-AvL, Amsterdam, The Netherlands), respectively. MDAMB231 cells were used as control based on their basal CXCR4 expression. MDAMB231^{CXCR4+} cells were selected by flow cytometry based on their high CXCR4-expression levels. Both cell lines were maintained in Gibco's minimum essential medium (MEM) enriched with 10% fetal bovine serum, Penicillin/Streptomycin, L-glutamine, non-essential amino acids, sodium pyruvate and MEM vitamins solution (all Life Technologies Inc.). Cells were kept under standard culture conditions.

Flow cytometry analysis of MDAMB231 and MDAMB231^{CXCR4+} cell binding (Figure 1 and Table 1)

Freshly cultured MDAMB231 or MDAMB231^{CXCR4+} cells were trypsinized, aliquoted in portions of 300 000 cells, centrifuged (1200 rpm, 5 min, 4 °C) and decanted. 6.4 nM of monoclonal phycoerythrin (PE) labeled anti-CXCR4 antibody (CD184 12G5-PE (12.5 μg/mL), BD Biosciences) or 1 μM of **3** or **4** in 50 μL of 0.1% bovine serum albumin (BSA) in phosphate buffered saline (PBS) was added to the cells. After 1 hour of incubation at 4 °C, the cells were washed (2 ×) with 300 μL of 0.1% BSA in PBS, resuspended in 300 μL of 0.1% BSA in PBS and fluorescence was measured using a CyAn ADP flow cytometer (DakoCytomation) with APC-Cy7 settings (635 nm laser and 750 nm long pass filter) for **3** and **4**. Live cells were gated on Forward Scatter, Side Scatter and Pulse Width and approximately 20 000 viable cells were analyzed. All experiments were performed in triplicate.

Determination of dissociation constants (Figure 2 and Table 2)

MDAMB231^{CXCR4+} cells were trypsinized and aliquoted in portions of 300 000 cells. For saturation binding experiments different concentrations of **3** or **4**, in a range of 0 – 1000 nM, were added. For competition experiments different concentrations (0 – 10000 nM) of Ac-TZ14011 (**1**), Ac-TZ14011-DTPA (**5**) or Ac-TZ14011-FITC (**6**) in the presence of 250 nM of **3** were added. Cells were incubated for 1 hour at 4 °C. The cells were washed (2 ×) with 300 μL of 0.1% BSA in PBS, resuspended in 300 μL of 0.1% BSA in PBS and fluorescence was measured using a CyAn ADP flow cytometer (DakoCytomation) with APC-Cy7 settings. Live cells were gated on Forward Scatter, Side Scatter and Pulse Width and approximately 20 000 viable cells were analyzed. All experiments were performed in duplicate.

The normalized geometric means were fitted with equations in the GraphPad Prism 5 software. The K_D values of **3** and **4** were calculated using the 'Binding – Saturation, One site – Total' nonlinear regression equation (Eq.1). The K_D values of Ac-TZ14011 (**1**), Ac-TZ14011-DTPA (**5**) and Ac-TZ14011-FITC (**6**) were calculated using the 'Binding – Competitive, One site – Fit K_i' nonlinear regression equation (Eq. 2 and 3).

$$y = \frac{B_{max} * x}{K_D + x} + NS * x + Background \qquad \text{(Eq. 1)}$$

y = normalized fluorescence

B_{max} = maximum specific binding in the units of the y axis

x = concentration of **3** or **4** in nM

K_D = equilibrium dissociation constant of **3** or **4** in nM

NS = slope of nonspecific binding

Background = amount of normalized fluorescence with no added compound

$$\log IC_{50} = \log(10^{\log K_D} * (1 + \frac{[\mathbf{3}]}{K_{D,\mathbf{3}}})) \qquad \text{(Eq. 2)}$$

$$y = Bottom + \frac{Top - Bottom}{1 + 10^{(x - \log IC_{50})}} \qquad \text{(Eq. 3)}$$

IC_{50} = concentration of competitor that results in binding half-way between Bottom and Top

K_D = equilibrium dissociation constant of the competitor in nM

[**3**] = concentration of **3** (250 nM)

$K_{D,\mathbf{3}}$ = dissociation constant of **3** (186.9 nM)

y = normalized fluorescence

Bottom and Top = plateaus in the units of the y axis

Confocal microscopy (Figure 3)

MDAMB231^{CXCR4+} cells were seeded onto coverslips (Ø 24mm; Karl Hecht GmbH & Co) and incubated overnight. The cells were washed with PBS and incubated with 1 μM of Ac-TZ14011-MSAP (**3**) for 1 h at 4 °C and washed again with ice cold PBS. Confocal microscopy images were taken at 37 °C on a Leica TCS-SP2-AOBS Live confocal microscope (Leica Microsystems Heidelberg GmbH).

IN VIVO experiments

IN VIVO model

For generation of the CXCR4-positive mouse tumor lesions, FVB mice (n = 3; 3-4 weeks of age) were used. Before transplantation (and imaging), mice were anaesthetized using a hypnorm (VetaPharma Ltd)/dormicum (Midazolam; Roche)/water solution (1:1:2; 5 µL/g i.p.). Via a small incision, the inguinal lymph node was excised where after a piece of preinvasive 8w-B MIN-O tissue was placed into the remaining tissue of the 4th mammary gland.[6-8] Approximately 3 weeks after transplantation, lesions were deemed suitable for further experiments. Control experiments were performed using orthotopic transplantation of 0.25×10^5 4T1 mouse tumor cells into the mammary tissue of Balb/c nude mice (n = 3; 6-8 weeks of age). Cells were cultured under standard conditions in MEM medium containing MEM vitamins, L-glutamine, non-essential amino acids, natrium pyruvate and penicillin/streptomycin solution (all BD Biosciences). Before transplantation, cells were trypsinized and washed with HBSS (BD Biosciences). Transplantation of cells was carried out under identical conditions as placement of the MIN-O segments. All animal experiments were performed in accordance with Dutch welfare regulations and approved by the local ethics committee.

Radiolabeling of Ac-TZ14011-MSAP (3)

Ac-TZ14011-MSAP (**3**) was dissolved in 0.1 M of acetic acid (50 µg / 100 µL) and $InCl_3$ (10 MBq / 50 ug of **3**; Covidien-Mallinkrodt) was added. After 30 minutes of incubation, labeling was validated with thin layer chromatography (TLC) using 74 mM of sodium citrate (pH 5) as an eluent and a VCS-201 TLC scanner (Veenstra Instruments). In all cases, labeling efficacy was >99%. Before injection, saline (1:1) was added.

Single photon emission computed tomography (SPECT)/computed tomography (CT) (Figure 4A)

24 Hours after intravenously injection of 50 µg of ^{111}In-labeled Ac-TZ14011-MSAP (10 MBq), the mice were placed in a temperature controlled (37 °C) animal holder (Equipment Veterinaire MINERVE) before performing a SPECT/CT scan on the

nanoSPECT/CT (Bioscan Inc.) The region of interest incorporating the whole body was selected, based on a (sagital) tomographic planning X-ray image followed by a helical 3D CT. After this, a sequential total body SPECT scan of the same field of view was performed. After acquisition, the data was reconstructed with HiSPECT software (Scivis GmbH). The SPECT and CT data sets were automatically co-registered. The images were analyzed using the InVivoScope post processing software (Bioscan, Inc.).

Fluorescence imaging (Figure 4B)

After SPECT/CT, the mice were sacrificed. In vivo fluorescence imaging was conducted on the IVIS 200 camera (Xenogen Corp.) using Living Imaging Acquisition and Analysis software (Xenogen Corp.). Images were acquired with standard Cy5.5 (excitation 615-665 nm and emission 695-770 nm) settings.

Biodistribution studies (Table 3)

After fluorescence imaging, tissues were excised. Tissues were weighed and the amount of radioactivity present in the tissues was counted using a Perkin Elmer 1480 Wizard 3'' automatic gamma counter (245 keV; 60 sec). Counts per minute were converted into MBq and corrected for decay. The percentage of the injected dose per gram of tissue (%ID/g) was calculated as followed: ((MBq measured in tissue/ injected dose) *100%) / weight of tissue.

Facile Synthesis of Symmetric, Monofunctional Cyanine Dyes for Imaging Applications

Lai-Qiang Ying* and Bruce P. Branchaud

Life Technologies, 29851 Willow Creek Road, Eugene, Oregon 97402, United States

Supporting Information

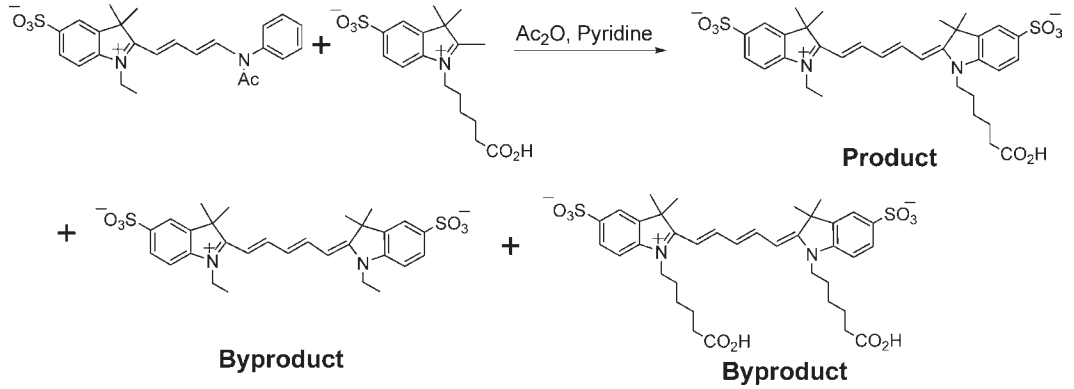
ABSTRACT: Efficient syntheses of several members of a new class of symmetric, monocarboxylate-functionalized cyanine dyes have been developed. The synthesis is a simple two-step method, typically with greater than 60% yield and easy final product purification. The new monocarboxylate-functionalized cyanine dyes exhibit excellent water solubility and similar excitation and emission properties to those of Cy5 and Alexa Fluor 647. The application of the new dyes in cellular imaging has been demonstrated through direct conjugating of the dye with an antibody, then imaging of microtubules inside cells, visualized by near-infrared fluorescence microscopy.

Fluorescent dyes are generally well-known for fluorescence labeling and detection of biomolecules, in diverse applications to studies of cells, tissues, proteins, antibodies, and nucleic acids through fluorescence microscopy, fluorescence immunoassays, and flow cytometry.[1,2] The labeling of biomolecules with fluorescent dyes is generally achieved via amine-reactive functionalities such as isothiocyanate and *N*-hydroxysuccinimide esters[3−5] or thiol-reactive iodoacetamide and maleimide groups.[6−8] Near-infrared (NIR) fluorescent dyes with absorption and emission maxima over 600 nm are particular useful for *in vivo* imaging due to the minimal autofluorescence of biological samples in the NIR range.[9] Among the NIR probes, the cyanine dyes, with large extinction coefficients and high quantum yields, are the most widely used probes for optical imaging *in vivo* and in single molecule fluorescence microscopy.[10−17] The common, commercially available cyanine dyes such as Cy3, Cy5, and Cy7 are monofunctional and asymmetric, with a single activated carboxylic acid group attached to one of the indoleninium or benzindoleninium moieties.[3,18]

Cyanine dyes are usually prepared by condensing indoleninium or benzindoleninium moieties to a polymethine chain in a stepwise synthetic strategy. That synthetic approach can result in the formation of undesired symmetric difunctionalized or unfunctionalized dyes as byproducts, and the desired monofunctional products often must be purified by HPLC, resulting in lower overall yields (Scheme 1).[3] Alternative syntheses of monofunctional symmetric heptamethine cyanine dyes have been developed via the reaction of chloro-substituted cyanine dyes with either (1) nucleophiles or (2) in Suzuki-Miyaura cross-coupling reactions.[19−22]

Many cyanine dyes exhibit low quantum yields in H_2O, and many are also not very stable.[23] Recently, a synthetic method has been reported for the preparation of monofunctional (carboxyl, azido, and alkynyl groups) pentamethine carbocyanine dyes, based on modifications of the synthetic method using malonaldehyde dianil dye precursors.[24] The compounds prepared by that method have lower quantum yields than Cy5, and they have shown florescence quenching properties when the dye is conjugated to antibodies, similar to the florescence quenching seen with Cy5.[25]

Development of new NIR probes with increased fluorescence brightness, improved photostability, and lower nonspecific binding is needed for improved imaging applications. Also, better, facile, high-yield syntheses of NIR probes would also be a significant improvement over current methods. In this report, we present a simple two-step procedure for the synthesis of monocarboxylate-functionalized cyanine dyes based on the pyridine-containing malonaldehyde dianil dye precursor. The monocarboxylate-functionalized cyanine dyes can be prepared in high yield (>60%) with excellent water solubility and display similar excitation and emission properties as Cy5 and Alexa Fluor 647. To evaluate the utility of the monocarboxylate functionalized cyanine dyes, these probes were conjugated with goat antimouse IgG, and used for cell imaging. The results of microtubule imaging inside cells demonstrate the potential applications of the monocarboxylate functionalized cyanine dyes for use as NIR probes.



The synthesis of asymmetric cyanine dyes such as Cy5 by the stepwise condensation of indoleninium or benzindoleninium moieties to a polymethine chain always produces some of the undesired symmetric dyes as byproducts (Scheme 1). This methodology leads to low yields of the desired products and difficulty in purification.

Scheme 1. Synthetic Route for Preparation of Cy5[3]

Scheme 2. Synthesis of Symmetric and Monofunctional Cyanine Dyes 5a and 5b[a]

[a] Reaction conditions: (a) NaOAc, Ac_2O, HOAc, 115 °C; (b) 6-bromohexanoic acid, KI, NMP, 115 °C; (c) 4-(bromomethyl)benzoic acid, KI, NMP, 115 °C; (d) TSTU, TEA, DMF.

In an effort to develop improved methods for the synthesis of NIR cyanine dyes suitable for bioconjugation, our synthesis of symmetric monocarboxylic acid derivatives has been developed, as shown in Scheme 2. These dyes have two identical monosulfonated indoleninium moieties **1** and are assembled from the aldol-like condensation of the indoleninium salt **1** and the iminium salt **2** in high yield (68%). The two sulfonate groups on the aromatic rings and two sulfopropyl groups on the nitrogen

fluorophore	λ_{abs} (nm)[a]	λ_{em} (nm)[a]	ε (M^{-1} cm^{-1})[b]	Φ[c]
CyP1−5 acid **4a**	638	653	220 000	0.19
CyP2−5 acid **4b**	638	653	223 000	0.18
Cy5	649	666	250 000	0.27
Alexa Fluor 647	649	664	240 000	0.28

[a] Spectra were obtained in PBS buffer, pH 7.4. [b] Extinction coefficients at 638 nm for dyes **4a** and **4b** are averaged over three sets of equivalent experiments. [c] Emission spectra were excited at 610 nm.

of the indolenine ring give all of the dyes (**3**, **4a**, **4b**, **5a**, and **5b**) excellent water solubility, which is particularly important, because the intrinsic hydrophobicity of the dye can lead to aggregation in an aqueous environment, which, in turn, can cause fluorescence quenching and a reduced quantum yield.[26] The carboxylic acid group is introduced onto the central carbon atom of the polymethine chain through alkylation of pyridine with 6-bromohexanoic acid or 4-(bromomethyl)benzoic acid. In the final step, the carboxylic acid group is converted to the succinimidyl ester using *O*-(*N*-succinimidyl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TSTU). In combination with the simple isolation of the dyes by precipitation from ethyl acetate and HPLC purification, the overall yields for the dyes **5a** and **5b** are 55% and 53%, respectively.

Both CyP1−5 acid **4a** and CyP2−5 acid **4b** display nearly identical spectroscopic profiles. Absorption and emission spectra of both CyP1−5 acid **4a** and CyP2−5 acid **4b** are shown in Figure 1. The optical properties of CyP1−5 acid **4a**, CyP2−5 acid **4b**, Cy5, and Alexa Fluor 647 are summarized in Table 1. CyP1−5 acid **4a** and CyP2−5 acid **4b** have optical features of a typical pentamethine cyanine dye with absorption and emission maxima at 638 and 653 nm, respectively. The absorption and emission maxima of both dyes are blue-shifted by 11 nm in comparison to those of Alexa Fluor 647, whereas the Stokes shifts are nearly identical to that of Alexa Fluor 647, ~15 nm. Both CyP1−5 acid **4a** and CyP2−5 acid **4b** have a brightness of roughly 40−50K (brightness measured as quantum yield × extinction coefficient) with extinction coefficients greater than 220 000 M^{-1} cm^{-1} and quantum yields of 0.18 or higher in aqueous solution. Furthermore, both CyP1−5 acid **4a** and CyP2−5 acid **4b** show excellent photostability (Figure 2).

To evaluate the fluorescence properties of fluorophore labeled antibodies, CyP1−5 succinimidyl ester **5a** and CyP2−5 succinimidyl

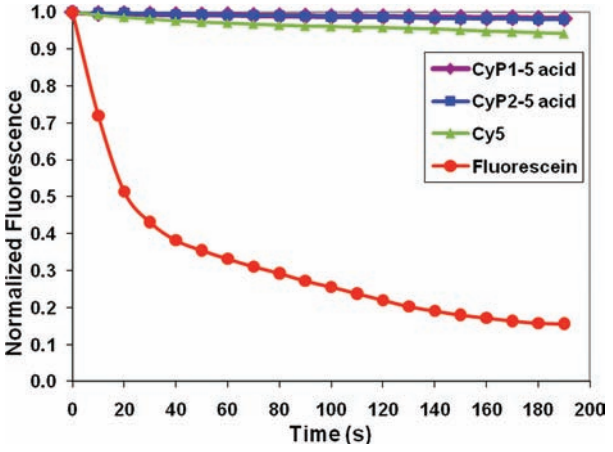

Figure 2. Photostability of CyP1−5 acid, CyP2−5 acid, Cy5, and fluorescein in PBS, pH 7.4.

ester **5b** were used to conjugate with antibody at three different molar ratios (MR = 6, 10, and 15; see Supporting Information for details). The higher fluorophore to antibody ratios are generally preferred to maximize the fluorescence signal from each antibody molecule. However, beyond some optimal fluorophore to antibody ratio, the fluorescence signal per antibody will decrease due to quenching by resonance energy transfer between fluorophores on the same protein molecule.[27] So, the parameters of optimal labeling for each dye must be developed. The fluorescence spectra of CyP1−5 succinimidyl ester **5a** and CyP2−5 succinimidyl ester **5b** labeled antibody are shown in Figure 3. As shown in Figure 3, antibodies labeled with either **5a** or **5b** fluoresce very well even at high fluorophore/protein ratios. The fluorescence properties of antibodies labeled with **5a** and **5b**, as well as Cy5, respectively, are summarized in Table 2. With increasing degree of labeling (DOL), the quantum yield of antibodies labeled with either **5a** or **5b** is consistently decreased due to fluorophore self-quenching. However, the mutual intramolecular quenching between **5a** (or **5b**) labels by the resonance energy transfer is much weaker than Cy5. For example, an antibody with ~5.5 Cy5 labels has a very low quantum yield of 0.02 due to quenching of the multiple dyes on the same antibody.[25] In contrast, fluorophores **5a** and **5b** can achieve brighter total fluorescence (TF) per antibody. The weaker quenching effect of antibodies labeled with either **5a** or **5b** is probably due to the repulsive electrostatic interactions of four sulfonate group negative charges inhibiting the

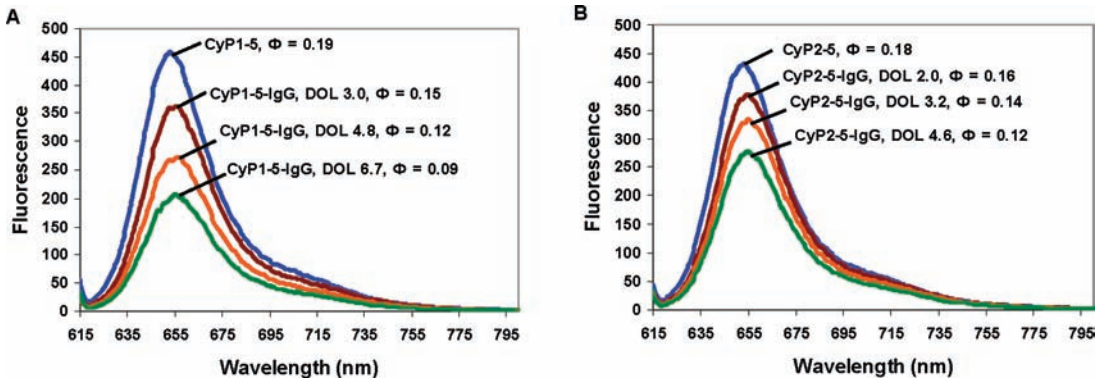

Figure 3. Emission spectra of CyP1−5 (A), and CyP2−5 (B) labeled antibody in PBS, pH 7.4.

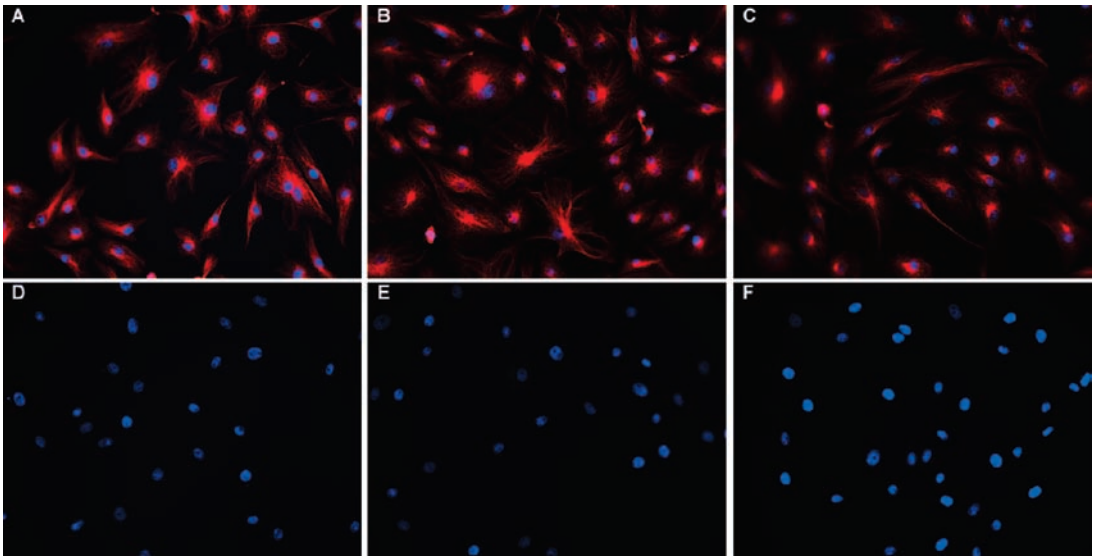

Figure 4. Fluorescene microscopy of BPAEC cells incubated fluorophore-labeled antibody. Cells incubated with **5a**-labeled antibody (A) and control (D), **5b**-labeled antibody (B) and control (E), and Alexa Fluor 647-labeled antibody (C) and control (F). Fluorescence signal from the nuclear stain, DAPI, colored in blue, NIR fluorophores colored in red.

Table 2. Fluorescence Properties of Fluorophore-Labeled Antibody

fluorophore	DOL	Φ[a]	TF (Φ × DOL)
CyP1−5 NHS **5a**	3.0	0.15	0.45
	4.8	0.12	0.58
	6.7	0.09	0.60
CyP2−5 NHS **5b**	2.0	0.16	0.32
	3.2	0.14	0.45
	4.6	0.12	0.55
Cy5	1.2	0.19	0.23
	3.0	0.09	0.27
	5.5	0.02	0.11

[a] Spectra were obtained in PBS buffer, pH 7.4.

close approach of the dyes to each other, thus minimizing the self-quenching.

To assess the performance of the fluorophore-labeled antibodies for cell imaging, the **5a**-labeled antibody (DOL 4.8) and **5b**-labeled antibody (DOL 4.6), as well as Alexa Fluor 647-labeled antibody (DOL 4.5), were chosen as secondary antibodies for imaging of tubulin on bovine pulmonary artery endothelial (BPAEC) cells. After BPAEC cells were fixed with 4% formaldehyde and permeabilized with 0.2% Triton-X, the cells were incubated with mouse antitubulin primary antibody, followed by incubating with dye-labeled (**5a**, **5b**, and Alexa Fluor 647) goat antimouse IgG secondary antibody, as well as the nuclear stain DAPI, respectively. As a control study, the cells were also directly incubated with dye-labeled (**5a**, **5b**, and Alexa Fluor 647) goat antimouse IgG secondary antibody without incubating mouse antitubulin primary antibody. The cells were monitored by fluorescence microscopy to visualize the distribution of microtubules inside cells (Figure 4). A good fluorophore should have bright fluorescence, good photostability, and low nonspecific binding. These new NIR dyes **5a** and **5b** certainly meet these criteria, showing bright fluorescence intensity similar to Alexa Fluor 647 and high specific staining for microtubules.

In conclusion, an efficient and facile methodology for synthesis of symmetric, monofunctional cyanine dyes has been developed. The obtained fluorophores exhibit bright fluorescence with extinction coefficients greater than 220 000 M^{-1} cm^{-1}

dx.doi.org/10.1021/bc2001006 |*Bioconjugate Chem.* 2011, 22, 865–869

and quantum yields of higher than 0.18, as well as good photostability. These dyes were also tested for antibody labeling and the obtained conjugates display excellent fluorescence properties. These new dyes are expected to have great potential in imaging applications.

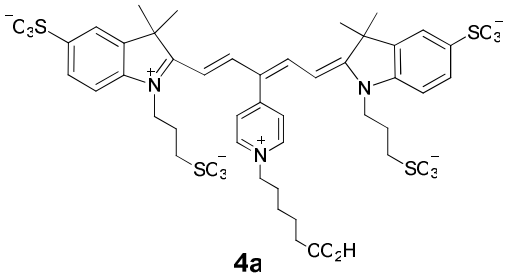
General Materials and Methods

All chemicals and solvents were purchased from Aldrich, Acros or TCI and were used without further purification. Thin layer chromatography (TLC) was performed on aluminum-backed plates with silica gel 60 with F_{254} indicator. All of the dyes for characterization were purified by high-performance liquid chromatography (HPLC) on a Waters prep LC instrument equipped with a Waters 2998 photodiode array detector. If not otherwise noted, HPLC solvent A is 25 mM triethylammonium acetate (TEAA) in water and solvent B is MeOH. All moisture- or air-sensitive reactions were carried out under a static argon atmosphere. ^{1}H NMR (400 MHz) spectra were recorded at room temperature on a Bruker ADVANCE-400 spectrometer with residual proton resonances in deuterated solvents (DMSO-d_6) as the internal standard. LC/MS spectra were obtained with a Waters micromass ZQ instrument. Absorption and emission spectra were determined using a PerkinElmer Lambda 35 UV−visible spectrophotometer and a PerkinElmer LS 55 fluorescence spectrophotometer, respectively. The molar extinction coefficient was obtained from HPLC-purified compounds using Beer's law at 0.1-1.0 μM concentration. The relative fluorescence quantum yield was determined using the model:

$\Phi_{F(X)} = (A_s/A_x)\,(F_x/F_s)\,(n_x/n_s)^2\,\Phi_{F(s)}$

where Φ_F is the fluorescence quantum yield, ***A*** is the absorbance, ***F*** is the area under the emission curve, and ***n*** is the refractive index of the solvents used in the measurement.[1] The subscripts ***s*** and ***x*** represent the standard and the unknown, respectively. Cy5 was used as a reference standard.[2]

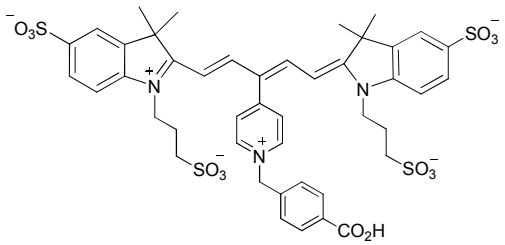
Synthesis of intermediate (3).



3

2,3,3-Trimethyl-1-(3-sulfonatopropyl)-3*H*-indoleninium-5-sulfonate (**1**) was prepared according to a literature procedures.[3] Indoleninium **1** (1.6 g, 4.2 mmol), 2-(4-pyridyl) malondialdehyde **2**

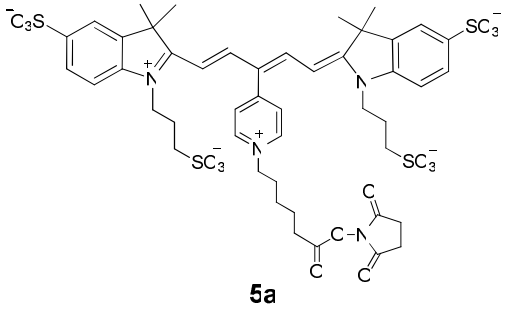
(283 mg, 1.9 mmol), and sodium acetate (1 g, 12 mmol) were dissolved in 15 mL acetic anhydride and 15 mL acetic acid. The reaction solution was heated at 115 °C for 4 h in a sealed pressure tube. The crude product was then precipitated by the addition of ethyl acetate (80 mL) and washed with additional ethyl acetate (50 mL × 2). Preparative HPLC (Phenomenex Luna C18 250 × 21.2 mm column, 20−40% buffer B over 40 min at a flow rate of 20 mL/min) was used to purify intermediate **3** (1.47 g, 68% yield) giving the blue dye as the triethylammonium salt. ^{1}H NMR (400 MHz, D_2O): δ 8.79 (d, 2H, *J* = 6.4 Hz), 8.19 (d, 2H, *J* = 14.4 Hz), 7.83 (s, 2H), 7.76 (m, 4H), 7.30 (d, 2H, *J* = 8.8 Hz), 5.70 (d, 2H, *J* = 14.0 Hz), 3.97 (t, 4H, *J* = 8.4 Hz), 3.11 (q, 18H, *J* = 7.2 Hz), 2.75 (t, 4H, *J* = 7.2 Hz), 1.98 (m, 4H), 1.69 (s, 12H), 1.19 (t, 27H, *J* = 7.2 Hz). ESI-MS $[M+H]^+$ *m*/*z* calcd. for 836.16, found 836.23.



Synthesis of CyP1-5 acid (4a).

4a

Intermediate **3** (200 mg, 0.17 mmol), 6-bromohexanoic acid (663 mg, 3.4 mmol), and potassium iodide (56 mg, 0.34 mmol) were dissolved in 10 mL NMP. The reaction solution was heated at 115 °C for 5 days in a sealed pressure tube. The crude product was then precipitated by the addition of ethyl acetate (40 mL) and washed with additional ethyl acetate (20 mL × 2). Preparative HPLC (Phenomenex Luna C18 250 × 21.2 mm column, 10−40% buffer B over 40 min at a flow rate of 20 mL/min) was used to purify CyP1-5 acid **4a** (182 mg, 90% yield) giving the blue dye as the triethylammonium salt. ^{1}H NMR (400 MHz, D_2O): δ 8.85 (d, 2H, *J* = 6.8 Hz), 8.15 (d, 2H, *J* = 14.4 Hz), 7.93 (d, 2H, *J* = 6.8 Hz), 7.80 (s, 2H), 7.72 (d, 2H, *J* = 8.4 Hz), 7.24 (d, 2H, *J* = 8.4 Hz), 5.72 (d, 2H, *J* = 14.4 Hz), 4.59 (t, 2H, *J* = 7.2 Hz), 3.97 (t, 4H, *J* = 7.6 Hz), 3.09 (q, 24H, *J* = 7.2 Hz), 2.75 (t, 4H, *J* = 6.4 Hz), 2.15 (m, 4H), 1.92 (m, 4H), 1.66 (s, 12H), 1.63 (m, 2H), 1.44 (m, 2H), 1.16 (t, 36H, *J* = 7.2 Hz). ESI-MS $[M+H]^+$ *m*/*z* calcd. for 950.23, found 950.31.

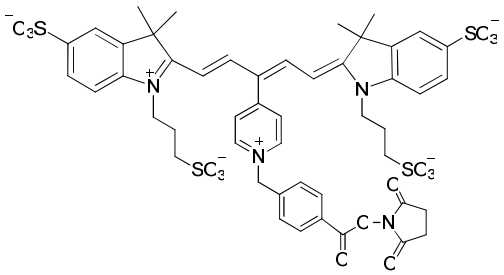


Synthesis of CyP2-5 acid (4b).

4b

Intermediate **3** (200 mg, 0.17 mmol), 4-(bromomethyl)benzoic acid (731 mg, 3.4 mmol), and potassium iodide (56 mg, 0.34 mmol) were dissolved in 10 mL NMP. The reaction solution was heated at 115 °C for 24 h in a sealed pressure tube. The crude product was then precipitated by the addition of ethyl acetate (40 mL) and washed with additional ethyl acetate (20 mL × 2). Preparative HPLC (Phenomenex Luna C18 250 × 21.2 mm column, 10−40% buffer B over 40 min at a flow rate of 20 mL/min) was used to purify CyP2-5 acid **4b** (187 mg, 91% yield) giving the blue dye as the triethylammonium salt. ^{1}H NMR (400 MHz, D_2O): δ 8.84 (m, 2H), 8.14 (dd, 2H, *J* = 4.4 Hz, 14.4 Hz), 7.95 (m, 4H), 7.81 (s, 2H), 7.74 (d, 2H, *J* = 8.8 Hz), 7.66 (d, 2H, *J* = 8.0 Hz), 7.27 (m, 2H), 5.86 (s, 2H), 5.73 (d, 2H, *J* = 14.4 Hz), 3.98 (t, 4H, *J* = 7.6 Hz), 3.10 (q, 24H, *J* = 7.2 Hz), 2.76 (t, 4H, *J* = 6.4 Hz), 1.94 (m, 4H), 1.66 (s, 12H), 1.16 (t, 36H, *J* = 7.2 Hz). ESI-MS $[M+H]^+$ *m*/*z* calcd. for 970.20, found 970.29.

Synthesis of CyP1-5 succinimidyl ester (5a).



5a

CyP1-5 acid **4a** (25 mg, 0.02 mmol), O-(*N*-succinimidyl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TSTU, 10 mg, 0.03 mmol), and Et_3N (10 μL, 0.07 mmol) were dissolved in 3 mL dry DMF. The reaction mixture was stirred at room temperature for 1 h under argon. The mixture was then precipitated by the addition of ethyl acetate (20 mL) and washed with ethyl

acetate (20 mL), acetone (20 mL), ether (20 mL), and dried under vacuum to afford CyP1-5 succinimidyl ester **5a** as a blue solid (24 mg, 90% yield). ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.99 (d, 2H, *J* = 6.8 Hz), 8.50 (d, 2H, *J* = 14.4 Hz), 7.90 (d, 2H, *J* = 6.8 Hz), 7.85 (s, 2H), 7.62 (d, 2H, *J* = 8.4 Hz), 7.39 (d, 2H, *J* = 8.4 Hz), 5.89 (d, 2H, *J* = 14.4 Hz), 4.58 (t, 2H, *J* = 7.2 Hz), 4.13 (t, 4H, *J* = 7.6 Hz), 3.09 (q, 6H, *J* = 7.2 Hz), 2.89 (s, 4H), 2.81 (t, 4H, *J* = 6.4 Hz), 2.47 (m, 4H), 2.22 (m, 2H), 1.80 (m, 4H), 1.76 (s, 12H), 1.55 (m, 2H), 1.18 (t, 9H, *J* = 7.2 Hz). ESI-MS $[M+H]^+$ *m*/*z* calcd. for 1047.25, found 1047.44.

Synthesis of CyP2-5 succinimidyl ester (5b).

5b

CyP2-5 acid **4b** (20 mg, 0.017 mmol), O-(*N*-succinimidyl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TSTU, 10 mg, 0.03 mmol), and Et_3N (10 μL, 0.07 mmol) were dissolved in 3 mL dry DMF. The reaction mixture was stirred at room temperature for 1 h under argon. The mixture was then precipitated by the addition of ethyl acetate (20 mL) and washed with ethyl acetate (20 mL), acetone (20 mL), ether (20 mL), and dried under vacuum to afford CyP2-5 succinimidyl ester **5b** as a blue solid (18 mg, 86% yield). ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.94 (d, 2H, *J* = 6.8 Hz), 8.50 (d, 2H, *J* = 14.4 Hz), 8.21 (d, 2H, *J* = 8.0 Hz), 8.13 (d, 2H, *J* = 8.0 Hz), 7.95 (s, 2H), 7.85 (s, 2H), 7.63 (dd, 2H, *J* = 1.6 Hz, 8.4 Hz), 7.39 (d, 2H, *J* = 8.4 Hz), 6.06 (s, 2H), 5.93 (d, 2H, *J* = 14.4 Hz), 4.14 (t, 4H, *J* = 7.6 Hz), 3.10 (q, 12H, *J* = 7.2 Hz), 2.89 (s, 4H), 2.73 (t, 4H, *J* = 6.4 Hz), 1.82 (m, 4H), 1.76 (s, 12H), 1.17 (t, 18H, *J* = 7.2 Hz). ESI-MS $[M+H]^+$ *m*/*z* calcd. for 1067.22, found 1067.41.

Optical Properties

Absorption spectra and extinction coefficients of the fluorophores were obtained on a PerkinElmer Lambda 35 UV−visible spectrophotometer. Extinction coefficients were measured in phosphate-buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 10 mM Na_2HPO_4, 2 mM KH_2PO_4, pH 7.4), and were averaged from three sets of parallel experiments. For each trial, 2~3 mg of the HPLC-purified dyes were weighed on a Mettler Toledo analytical balance with an error of ±0.01 mg and were dissolved in deionized water using a 10 mL volumetric flask to prepare the stock solutions. Emission spectra were collected on a PerkinElmer LS 55 fluorescence spectrophotometer. Quantum yields were measured for each dye derivative with the maximum absorption for each sample less than 0.1, using Cy5 as a standard (Φ = 0.27).[2] Photostability data were collected on a Nikon Eclipse E400 spectrofluorometer equipped with a Nikon mercury lamp. Dye photo-bleaching was observed by monitoring the fluorescence emission of absorbance-matched dye samples (absorbance ~0.03) at an excitation wavelength 630 nm for 3 min.

General Antibody Labeling Procedures

Stock solutions of the sulfoindocyanine succinimidyl esters were made in dry DMSO at 10 mg/mL concentration. Antibody was dissolved in 0.1 M $NaHCO_3$ buffer at 2 mg/mL concentration. The desired amount of dye was calculated as follows:

$$\text{mL of 10 mg/mL dye} = \frac{\text{mg protein}}{\text{Mw of protein}} \times \text{MR} \times \frac{\text{Mw of dye}}{10}$$

where MR is the molar ratio of dye to protein. For example, using 2 mg of Goat anti-mouse IgG (Mw 145,000) and a 10:1 molar ratio of dye **5a** (Mw 1,249) to protein gives:

$$\frac{2}{145{,}000} \times 10 \times \frac{1249}{10} = 0.017 \text{ mL of 10 mg/mL dye } \mathbf{5a}$$

The desired amount of dye was added to the above antibody solution and incubated at room temperature for 1 h with gentle stirring. Free dye was separated from the labeled antibody by gel permeation chromatography (Bio-Rad BioGel P-30 resin) using PBS buffer as eluent.

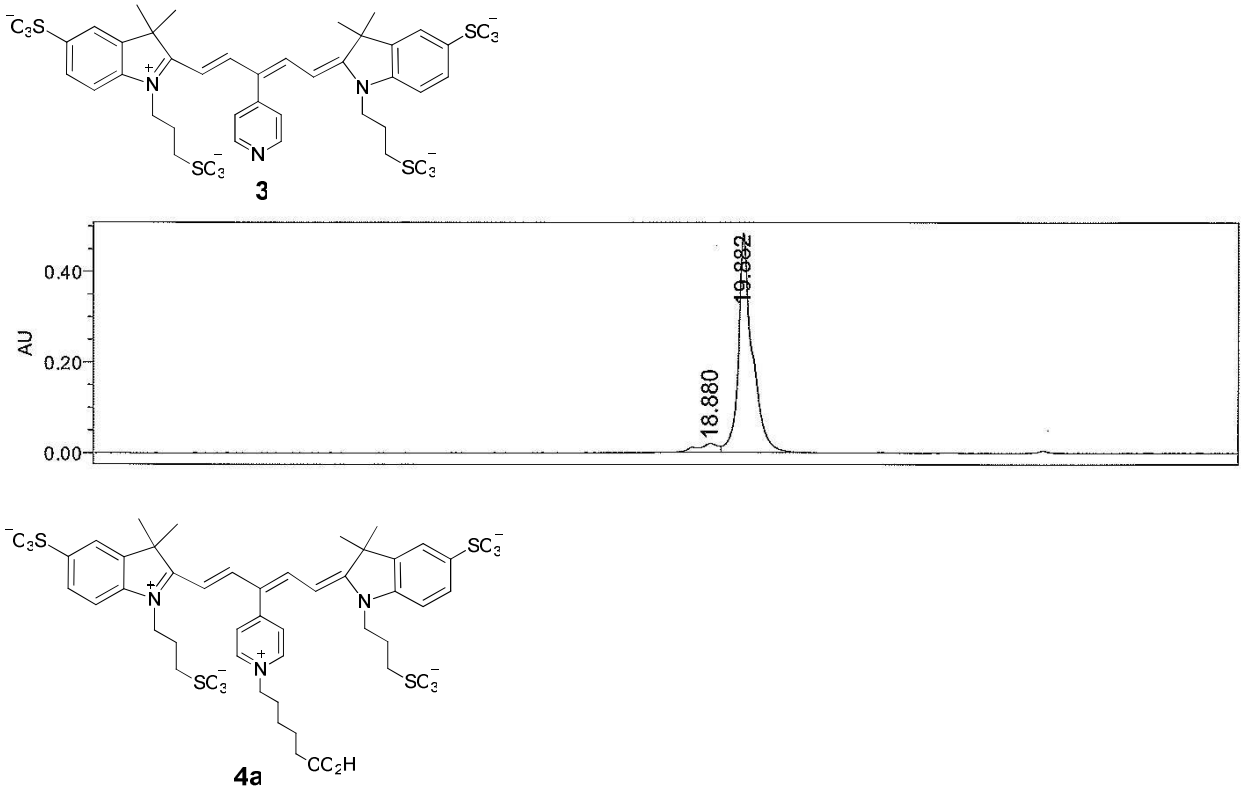
Determination of the Degree of Labeling

A simple method for estimating the degree of labeling (DOL) is determined by direct measuring the protein absorbance at 280 nm and dye absorbance at the absorption maximum. The protein concentration is calculated as follows:

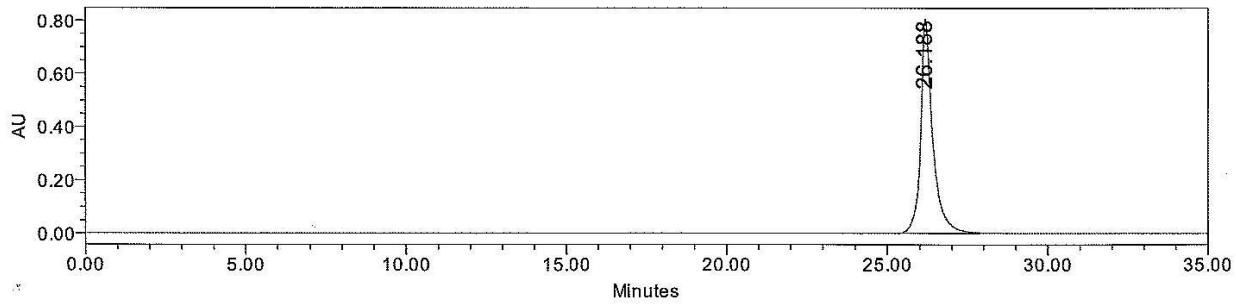
$$\text{Protein concentration (M)} = \frac{A_{280} - XA_{dye}}{\varepsilon_{protein}}$$

where the molar extinction coefficient (ε) of a typical IgG at 280 nm is 203,000 $cm^{-1}M^{-1}$. The absorbance of dyes **5a** and **5b** is measured at 638 nm, and the correction factor (X) for the dyes **5a** and **5b** is about 0.04.

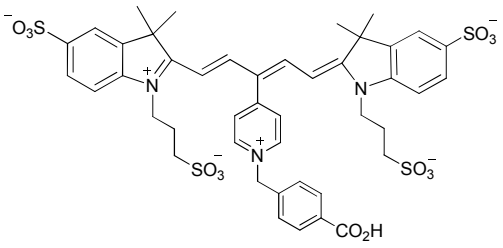
The degree of labeling (DOL) is calculated as follows:



$$\text{DOL} = \frac{A_{dye}\,\varepsilon_{protein}}{(A_{280} - XA_{dye})\,\varepsilon_{dye}}$$



Fluorescence Labeling and Cell Imaging



Bovine Pulmonary Artery Endothelial (BPAEC) cells in Dulbecco's modified eagle medium (DMEM) supplemented with 20% fetal bovine serum (FBS) were cultured on glass coverslips for 24 h to reach 50%-70% confluency. The cells were fixed with 4% formaldehyde in PBS for 15 min at 37 ºC, then washed with PBS (2X). The cells were permeabilized with 0.2% Triton-X in PBS for 5 min at room temperature, then washed with PBS (3×). The cells were blocked with blocking solution (5% normal goat serum (NGS)/0.2% BSA in PBS) for 30 min at room temperature. Then, the cells were incubated with mouse anti-tubulin primary antibody (2 μg/mL in blocking solution) at room temperature for 1 h. The cells were washed with PBS (3×), followed by incubating with dye-labeled goat anti-mouse secondary IgG antibody (10 μg/mL in blocking solution) at room temperature for 30 min. The cells were washed again with PBS (3×), and incubated with the nuclear stain 4',6-diamidino-2-phenylindole (0.2 μg/mL DAPI) in PBS for 2 min. The cells were washed with PBS (3×), eH_2O (1×), and 0.1% Tween-20 solution (1×). After the coverslips were air-dried, the coverslips were mounted in Cytoseal onto microscopy slides. Fluorescent images were captured on a Zeiss Axioskop 2 fluorescence microscope with 40× objective equipped with a Hamamatsu ORCA-ER CCD camera using excitation and

emission filters from Omega Optical. The nuclear stain DAPI was imaged using a 365 ± 5 nm band-pass filter for excitation and a 400 ± 5 nm cutoff filter for emission. The NIR fluorophore was imaged using a 610 ± 20 nm band-pass filter for excitation and a 650 ± 20 nm band-pass filter for emission. Exposure times of 100 and 200 ms, for the nuclear stain and carbocyanine dye channels, respectively, were used for image collection. All images from the carbocyanine dye channel were processed with identical leveling.

Cell Imaging and Fluorescence Intensity

Fluorescene microscopy of BPAEC cells incubated fluorophore-labeled antibody.
Cells incubated with **5a**-labeled antibody (A), **5b**-labeled antibody (B), and Alexa Fluor 647-labeled antibody (C). Imaging in the bottom is a close up view of representative cells. Fluorescence signal from the nuclear stain, DAPI, colored in blue, NIR fluorophores colored in red.

Fluorescence relative intensity of BPAEC cells labeled with **5a**-GAM IgG, **5b**-GAM IgG, and AF647-GAM IgG, respectively. The mean intensity was averaged based on five different images.

Targeted Albumin-Based Nanoparticles for Delivery of Amphipathic Drugs

Rongzuo Xu, Michael Fisher, and R. L. Juliano*

Division of Molecular Pharmaceutics, UNC Eshelman School of Pharmacy, University of North Carolina, Chapel Hill, North Carolina 27599, United States

Supporting Information

ABSTRACT: We report the preparation and physical and biological characterization of human serum albumin-based micelles of approximately 30 nm diameter for the delivery of amphipathic drugs, represented by doxorubicin. The micelles were surface conjugated with cyclic RGD peptides to guide selective delivery to cells expressing the $\alpha_v\beta_3$ integrin. Multiple poly(ethylene glycol)s (PEGs) with molecular weight of 3400 Da were used to form a hydrophilic outer layer, with the inner core formed by albumin conjugated with doxorubicin via disulfide bonds. Additional doxorubicin was physically adsorbed into this core to attain a high drug loading capacity, where each albumin was associated with about 50 doxorubicin molecules. The formed micelles were stable in serum but continuously released doxorubicin when incubated with free thiols at concentrations mimicking the intracellular environment. When incubated with human melanoma cells (M21+) that express the $\alpha_v\beta_3$ integrin, higher uptake and longer retention of doxorubicin was observed with the RGD-targeted micelles than in the case of untargeted control micelles or free doxorubicin. Consequently, the RGD-targeted micelles manifested cytotoxicity at lower doses of drug than control micelles or free drug.

INTRODUCTION

A major disadvantage of hydrophobic drugs is low water solubility and associated poor pharmacokinetic profiles, which in turn can contribute to adverse effects and low therapeutic efficacy. A variety of systems, including polymers, micelles, liposomes, nanoparticles, and microspheres, have been investigated to improve the parental delivery of hydrophobic agents. Albumin is a major blood protein, and due to its abundance, low immunogenicity, good biocompatibility, and ability to be transcytosed across vascular endothelia, it has been utilized in delivery systems for moieties such as anticancer drugs,[1,2] photosensitizers,[3] antifungal drugs, and diagnostic imaging agents.[4,5] In one approach, the albumin carrier is used as a single molecule, where the drugs are covalently conjugated to the free thiol in the cysteine-34 position[6] or to introduced free thiols.[7] This type of conjugation strategy maintains the physiochemical properties of albumin while significantly improving the tumor uptake of conjugated drugs. In this strategy, however, only one or a few therapeutic molecules are carried by each albumin molecule, leading to low delivery efficiency. Albumin can also be formulated into microspheres or nanoparticles through precipitation in organic solvent followed by cross-linking.[8−10] The formed particles can encapsulate tens to thousands of drug molecules per particle, achieving high drug-loading efficiency. However, with sizes in the range of several hundred nanometers to several micrometers, these particles are prone to uptake by reticuloendothelial system in liver and spleen. Another approach has been reported that can formulate hydrophobic drugs into albumin nanoparticles in the size range between 100 and 200 nm.[11,12] Thus, Abraxane, a paclitaxol−albumin nanoparticle with average size of 130 nm, has been extensively investigated in animal and clinical studies.[13]

Polymeric micelles with sizes of 20−100 nm provide effective carriers for delivery of hydrophobic or amphipathic compounds.[14,15] In aqueous media, amphiphilic block copolymers spontaneously assemble into micelles with a distinct core−shell structure. The hydrophilic portion of the copolymer, usually PEG with molecular weights ranging from 2 to 15 kD, forms a coronal layer; the hydrophobic portion, typically consisting of poly(propylene oxide), poly(D,L-lactic acid), poly(ε-caprolactone), poly(glutamic acid), or poly(L-aspartic acid), to name a few, forms a core that acts as a reservoir for drugs such as doxorubicin, paclitaxel, docetaxel, camptothecin, and others.[16−19] Polymeric micelles often have high drug payloads in the form of either chemically conjugated or physically entrapped drug. They typically have high stability in the circulation owing to low critical micelle concentration and long circulating lifetime due to a size above the renal filtration threshold and due to PEG's ability to evade recognition by the reticuloendothelial system (RES). These properties aid in the preferential

accumulation of micelles in tumor tissue through the enhanced permeability and retention (EPR) effect,[20−22] resulting in reduced toxicity to healthy tissues and improved antitumor efficacy. However, there remain concerns about the possible toxicities of polymeric micelles, including general cytotoxicity, hematoxicity, immunogenicity, carcinogenicity, and other aspects,[23] making high biocompatibility a prerequisite for synthetic copolymer micelles.

With these considerations in mind, we report the first example of targeted albumin-based nanoscale micelles for delivery of amphipathic drugs. We hypothesize that increasing the hydrophobicity of PEGylated albumin by addition of drug, and diminishment of primary amine groups on the protein surface, can drive the aggregation and formation of polymeric micelles. In addition, functionalization of the distal ends of the PEG chains can be used to incorporate ligands into the micelle outer layer to guide active targeting. We use doxorubicin, an anthracycline agent widely used for the treatment of leukemia, lymphoma, and solid tumors, as a model compound.[24,25] Doxorubicin is conjugated to the amine group on albumin using a bifunctional linker that provides a disulfide bond between the protein and the drug, while additional doxorubicin molecules become physically entrapped in the micelle. A cyclic RGD peptide was conjugated to the micelle PEG chains, since it is a ligand with high binding affinity to $\alpha_v\beta_3$ integrin, a membrane protein highly expressed in angiogenic endothelia and in some cancer cells.[26,27] This targeted albumin micelle delivery system is described herein with focus on its synthesis, physiochemical characterization, and uptake and pharmacological efficacy in cultured cells.

MATERIALS AND METHODS

Materials. Human serum albumin, ethylene glycol-bis-(2-aminoethylether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA), doxorubicin hydrochloride, 2-mercaptoethanol, ninhydrin, hydrindantin, and 2-methoxyethanol were purchased from Sigma-Aldrich (St. Louis, MO, USA). AlexaFluor 488 C5 maleimide was from Invitrogen (Carlsbad, CA, USA). Hydroxylamine hydrochloride, sulfosuccinimidyl 6-(3′-[2-pyridyldithio]-propionamido) hexanoate (Sulfo-LC-SPDP), and 2-iminothiolane were from Pierce (Rockford, IL, USA). Bifunctional poly(ethylene glycol) (PEG), Malhex-NH-PEG-O-C_3H_6-CONHS, was purchased from Rapp Polymere (Tubingen, German). Cyclo[RGDfK(Ac-SCH2CO)] peptide was from Peptide International (Louisville, KY, USA).

Preparation of Albumin Conjugates with Cyclic RGD PEG or 2-Mercaptoethanol PEG. Human serum albumin (30 mg, 4.44×10^{-7} mol) was reacted with AlexaFluor 488 C5 maleimide (1 mg, 1.39×10^{-6} mol) for 4 h at room temperature in phosphate saline buffer (PBS, pH 7.4) containing 1 mM EDTA. This was followed by dialysis in a MWCO 3500 cassette (Pierce, Rockford, IL) overnight at room temperature. Amine groups from lysine residues on the albumin surface were then reacted with Mal-hex-NH-PEG5000-C_3H_6-CONHS (60 mg, 1.2×10^{-5} mol) in PBS with 1 mM EDTA (pH 7.4) for 4 h. The unreacted PEG derivative was removed by dialysis in a MWCO 100 000 chamber (Havard Apparatus, Holliston, MA, USA). The PEGylated albumin (equivalent to 15 mg of albumin) was reacted with cyclo[RGDfK(Ac-SCH2CO)] (10 mg, 1.47×10^{-5} mol) in PBS with 1 mM EDTA and 50 mM hydroxylamine for 24 h at room temperature. The product, denoted as RPA, was purified by extensive dialysis in a MWCO 100 000 chamber for 24 h. MPA was prepared by conjugating PEGylated albumin (equivalent to 2 mg of albumin) with 100 μg of 2-mercaptoethanol in PBS with 1 mM EDTA for 24 h and dialysis in a MWCO 100 000 chamber overnight. The number of PEG molecules conjugated was estimated by determining the loss of surface amine groups using a ninhydrin test.

Preparation of RGD-PEG-Albumin-Doxorubicin Conjugates (RPA-DOX). RPA (equivalent to 2 mg albumin) was reacted with sulfo-LC-SPDP (0.5 mg, 9.5×10^{-7} mol) in PBS with 1 mM EDTA for 4 h at room temperature, followed by dialysis in a MWCO 100 000 chamber overnight. Doxorubicin hydrochloride (1.5 mg, 2.6×10^{-6} mol) was reacted with 2-iminothiolane (0.36 mg, 2.6×10^{-6} mol) for 2 h at PBS with 1 mM EDTA to create thiolated (-SH) doxorubicin (ESI-MS $[M+1]^+$: 647.47 (observed), 645.79 (calculated)). An excess of the resulting doxorubicin-thiol was then reacted with the product from the RPA and sulfo-LC-SPDP reaction; the final product RGD-PEG-albumin-doxorubicin conjugates (denoted as RPA-DOX) was thus prepared. RPA-DOX was further purified by dialysis in PBS with 1 mM EDTA for 24 h, and stored in a refrigerator at 4 °C. The number of doxorubicin molecules conjugated via the SPDP linker was estimated using the ninhydrin reaction. Please note that, for the sake of simplicity, here and in the sections that follow we refer to these materials as albumin−doxorubicin conjugates although it is actually a thiolated form of doxorubicin that is conjugated. Likewise, the drug that is released from the conjugate is termed doxorubicin although it is actually the thiolated form.

Preparation of 2-Mercaptoethanol-PEG-Albumin-Doxorubicin Conjugates (MPA-DOX). The preparation of MPA-DOX was exactly parallel to that of RPA-DOX except that MPA lacking RGD groups was utilized.

FPLC-QELS and Zeta Potential. Samples (100 μL) containing albumin conjugates at 0.1 to 0.5 mg protein per mL were loaded on a fast protein liquid chromatography (FPLC) system (GE Healthcare) equipped with a Superdex-200 size exclusion column and quasi-elastic light scattering (QELS) (Wyatt, Santa Barbara, CA, USA). The data were collected and analyzed using *Astra* software (Wyatt, Santa Barbara, CA, USA). The zeta potentials of the RPA-Dox and MPA-Dox were measured using a Zetasizer (Malvern Instruments, Westbury, MA).

TEM. The RPA-Dox and MPA-Dox were diluted and dropped on 200 mesh carbon-coated copper grids (Ted Pella, Redding CA) and allowed to attach for two minutes. Uranyl acetate aqueous solution (2−5%) was then added on the grid for 2 min to counterstain the nanoparticles. The TEM images were then acquired with magnification of 17 000 times using a JEOL 100CX II transmission electron microscope.

Conjugate Serum Stability. RPA-DOX and MPA-DOX containing 20 μM doxorubicin were incubated in PBS containing 10% serum, using PBS as a control. After incubation at 37 °C for 0.3, 2, 4, and 8 h, a fraction was collected and ultrafiltered at 3400 rpm for 3 min using a YM-50 filter (Millipore, Bedford, MA, USA). Both the eluted phase and the residual volume on top of the filter were collected. The volumes were measured (V_{up} denotes residual volume and V_{down} denotes volume of filtrate buffer) and the absorbance at 481 nm was determined (A_{up} denotes absorbance of residual and A_{down} denotes absorbance of filtered volume). The percentage of released doxorubicin was calculated by the equation: Percentage of released doxorubicin (%) = $[(A_{down} \times (V_{up} + V_{down})]/(A_{up} \times V_{up} + A_{down} \times V_{down}) - 6\%) \times 100$. The 6% is an estimate of the nonspecific leaking of RPA-DOX or MPA-DOX themselves. The serum stability curve was produced by plotting the percentage of released doxorubicin versus time.

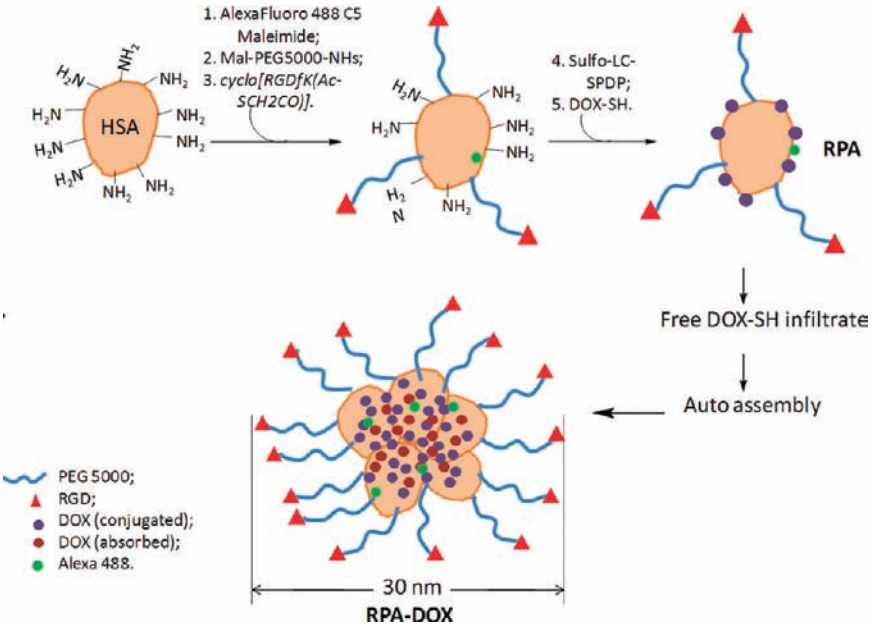

Figure 1. Preparation of RPA-Dox.

Release of Doxorubicin by Sulfhydryls. RPA-Dox and MPA-Dox containing 20 μM doxorubicin were incubated at 37 °C in PBS (pH 7.4) containing 10 mM glutathione and 100 μM cysteine, or in unmodified PBS as control. Samples were collected after 15, 120, and 240 min and 8, 24, and 48 h of incubation and ultrafiltered at 3400 rpm for 3 min using a YM-50 filter (Millipore, Bedford, MA, USA). The percentage of released doxorubicin was calculated, and the time course of doxorubicin release was then generated by plotting percent of released doxorubicin versus time.

Cell Uptake. M21+ human melanoma cells that express the $\alpha_v\beta_3$ integrin were seeded on 24 well plates at 4×10^4 cells per well and cultured overnight. The cells were either preincubated with 100 μM cyclic (RGDfV) for half an hour or directly incubated with doxorubicin, RPA-DOX, or MPA-DOX at concentrations ranging from 100 nM to 2 μM in Opti-MEM medium. After 4 h incubation, the cells were harvested by trypsinization. The fluorescence intensity at 488/575 nm of doxorubicin[28] per cell was determined using a Cyan flow cytometer (Beckman Coulter, Miami, FL).

Confocal Microscopy. M21+ cells were cultured in complete DMEM medium in a glass-bottom culture dish (MatTek, Ashland, MA) overnight. The medium was replaced with Opti-MEM medium containing 2 μM free doxorubicin, RPA-DOX, or MPA-DOX and incubated for 4 h at 37 °C. Additional samples were continued in culture in drug-free complete DMEM medium for 12 h. The doxorubicin distribution was imaged using a Zeiss confocal microscopy with a 63× objective lens and a 488 nm laser light source. The images were analyzed using Zeiss LSM software.

Cytotoxicity. M21+ cells were seeded into 96 well plates at a density of 5000 cells per well. After overnight incubation, the medium was aspirated and fresh DMEM medium containing different concentrations of free doxorubicin, RPA-Dox, or MPA-Dox was added; the concentrations of RPA-Dox and MPA-Dox are expressed in doxorubicin equivalents. The cells were continuously cultured at 37 °C and 5% CO_2 for 3 days. The cytotoxicity was then assessed by a modified MTT assay. Briefly, the medium was replaced by a mixture of 200 μL of fresh DMEM medium and 20 μL of MTT solution (5 mg/mL MTT in PBS), followed by 2 h incubation. The culture medium was then removed by aspiration. Then, 100 μL DMSO was added into each well, stirred, and absorbance at 540 nm of the cell suspension was determined using a FLUOstar Omega Microplate Reader (BMG Labtech, Offenburg, Germany). The cytotoxicity was evaluated through comparing absorbance of treated cells against the untreated controls. The results of cytotoxicity assay were used to construct dose−response curves and IC_{50} doses were determined.[29] The toxicities of RPA and MPA, without doxorubicin, were determined in a parallel assay. In a separate experiment, the toxicity of doxorubicin itself versus its thiolated derivative was also compared using the MTT assay.

RESULTS

Synthesis and Characterization. The preparation of albumin−doxorubicin micelles is outlined in Figure 1. First, human serum albumin (HSA) was labeled with the green fluorescent dye Alexa Fluor 488 at the free thiol group at Cys34. Subsequently, several Mal-PEG-NHS moieties with molecular weight of 3400 were conjugated to primary amines on the HSA surface to form PEGylated albumin. The unreacted PEG derivative was removed by dialysis in a MWCO 100 000 bag. Excess cyclo[RGDfK-($AcSCH_2CO$)] was then incubated with the PEGylated albumin in the presence of hydroxylamine to form RGD-PEG-HSA (RPA). Alternatively, 2-mercaptoethanol was used to react with PEGylated albumin to form 2-mercaptoethanol-PEG-HSA (MPA) as a control. The amount of PEG per albumin was determined using a ninhydrin test[30] to compare the primary amine density before and after the PEGylation reaction. RPA has an average of 17.5 PEGs per albumin molecule while MPA has 15.1 PEGs. Additional primary amine groups on the surface of RPA and MPA were reacted with sulfo-LC-SPDP followed by

conjugation with the thiolated doxorubicin derivative to form PEGylated albumin doxorubicin complexes termed RPA-DOX or MPA-DOX. The reaction between thiol and SPDP created a disulfide linker that can be potentially cleaved by endogenous thiols to liberate the thiolated doxorubicin.

[a] Note: the peaks were numerated and displayed at Figure 2 and Supporting Information Figure S.1.

The physical aspects of the conjugates were monitored, as summarized in Figure 2, Supporting Information Figure S.1, Figure 3, and Tables 1 and 2. Significant size and apparent molecular weight increases were observed after the addition of the PEG derivative followed by cyclic RGD or 2-mercaptoethanol. Both RPA and MPA exist primarily as monomers and trimers with narrow molecular weight distributions, indicated by low polydispersity indices. However, FPLC-QELS analysis showed that the RPA-DOX has a hydrodynamic radius of about 15 nm and molecular weight of more than 1 million Da, with a single distribution and a low polydispersity index. The RPA-DOX was visualized by transmission electromicroscopy (TEM), revealing a diameter averaging about 30 nm, which is consistent with its hydrodynamic size (Figure 3). Compared with RPA, RPA-DOX has much larger particle size as well as apparent molecular weight. Thus, the RPA-DOX must contain several albumin molecules that have coaggregated. We postulate that RPA-DOX monomers oligomerize to form nanoscale micelles. This may be due to the amphiphilicity of PEGylated RPA-DOX, where the hydrophilicity can be attributed to PEG and the hydrophobicity is from albumin that has lost a significant fraction of its primary amines, with hydrophobicity further increased by the conjugation of doxorubicin molecules. The zetasizer revealed that the formed micelles had a slightly negative surface potential (Table 2).

As determined by a ninhydrin test, RPA-DOX had approximately 24.6 chemically conjugated doxorubicins per albumin. However, the total amount of doxorubicin associated with the albumin micelle was greater, as determined by measuring absorbance at 481 nm, where doxorubicin (as well as its thiolated derivative) has an extinction coefficient of 10 410 M^{-1} cm^{-1} at 25 °C.[31] This revealed that an average of 50.6 doxorubicin molecules were associated with each albumin molecule. This suggests that extra doxorubicin molecules were physically accommodated in the hydrophobic domain of the formed micelle, probably through hydrophobic interaction and van de Waals forces. This substantially increased the drug loading of the albumin micelles (Table 2).

The driving force of micelle formation was further evaluated by synthesizing a series of RPA derivatives, where each RPA was conjugated to sulfo-LC-SPDP and then to doxorubicin derivatives at ratios from 1:5:5 to 1:30:90. The FPLC analysis (Supporting Information Figure S.2) showed that higher molecular weight complexes started to form when each RPA was conjugated to doxorubicin derivatives at a molar ratio of 1:5. However, in this condition UV absorbance showed that only a

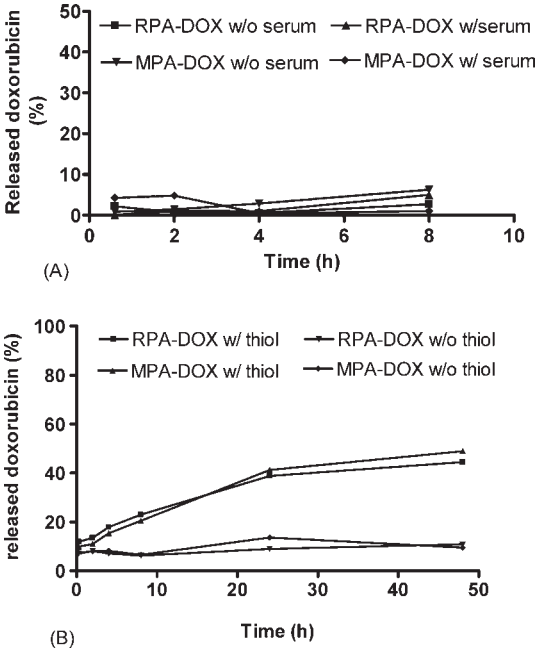

Figure 5. Doxorubicin release kinetics. (A) RPA-DOX and MPA-DOX were incubated with PBS only or PBS with 10% serum at 37 °C. (B) RPA-DOX and MPA-DOX were incubated at in PBS with thiols from 10 mM glutathione and 100 uM cysteine or PBS only at 37 °C.

part of RPA-DOX was formed into micelles with most of it staying in the same form and distribution as drug-free RPA. With the doxorubicin amount increased from 5 per RPA to 30 per RPA, additional RPA was incorporated into micelles. When doxorubicin was reacted to RPA at a molar ratio of 1:90, with excess doxorubicin derivatives, almost all RPA was formed into micelles with a single peak distribution. This result clearly shows that higher amounts of doxorubicin can function as a driving force for micelle formation. The doxorubicin conjugates on RPA were determined by observing the release of pyridine-2-thione (λ_{max} = 343 nm) from the reaction intermediate, and the final amount of doxorubicin associated with RPA was determined by the absorbance of doxorubicin at 481 nm (Supporting Information Table S.1). It shows that RPA5 and RPA30 lost significant amounts of loaded doxorubicin during dialysis while RPA90 retained approximately 44 doxorubicin molecules per RPA. This result shows that using extra amounts of doxorubicin in the formulation process can result in more doxorubicin loaded on RPA. Taken together, it suggests that formulating RPA with a high amount of doxorubicin will drive the formation of micelles that stably hold associated doxorubicin molecules.

The stability of the formed micelles was tested (Figure 4). After five weeks storage in PBS buffer with 1 mM EDTA at 4 °C, only trace amounts of doxorubicin were detected after ultrafiltration of the material. This result shows that the doxorubicin is stably held inside the micelle. The stored batch of RPA-DOX was also analyzed by FPLC-QELS. This showed that RPA-DOX kept its single peak distribution profile with a low polydispersity index and maintained its size close to freshly prepared material. This suggests that RPA-DOX does not aggregate into larger particles under this storage condition. The critical micelle concentration (CMC) was not determined. However, when diluted to concentrations lower than 0.2 μM albumin equivalent, the micelles maintained their structure when visualized by TEM. No doxorubicin leaked out into solution during ultracentrifugal filtration with a MWCO 50 kDa filter. This indicates that the albumin micelle has a similarly low CMC value to other polymeric micelles, typically on the order of 10^{-6}–10^{-7} M.

Doxorubicin Release. RPA-DOX was tested by incubation in PBS or PBS with 10% serum at 37 °C for up to 8 h (Figure 5A). Less than 5% of doxorubicin was released, suggesting that PBS or serum had little influence on the stability of RPA-DOX. RPA-DOX and MPA-DOX show similar doxorubicin release kinetics when incubated in PBS containing 10 mM L-glutathione and 100 μM cysteine, the typical free thiol concentrations of intracellular cytosol[32−34] (Figure 5B). The doxorubicin released from nanoparticles can pass through a MWCO 50 000 filter, while RPA-DOX and MPA-DOX show minimal filtration, thus allowing the liberated doxorubicin to be separated and quantified. Figure 5B shows that it took 8 h to release approximately 15% of doxorubicin from the micelle and 48 h to release 40%. Considering that the micelle would enter target cells through endocytosis, the breakdown of the albumin by

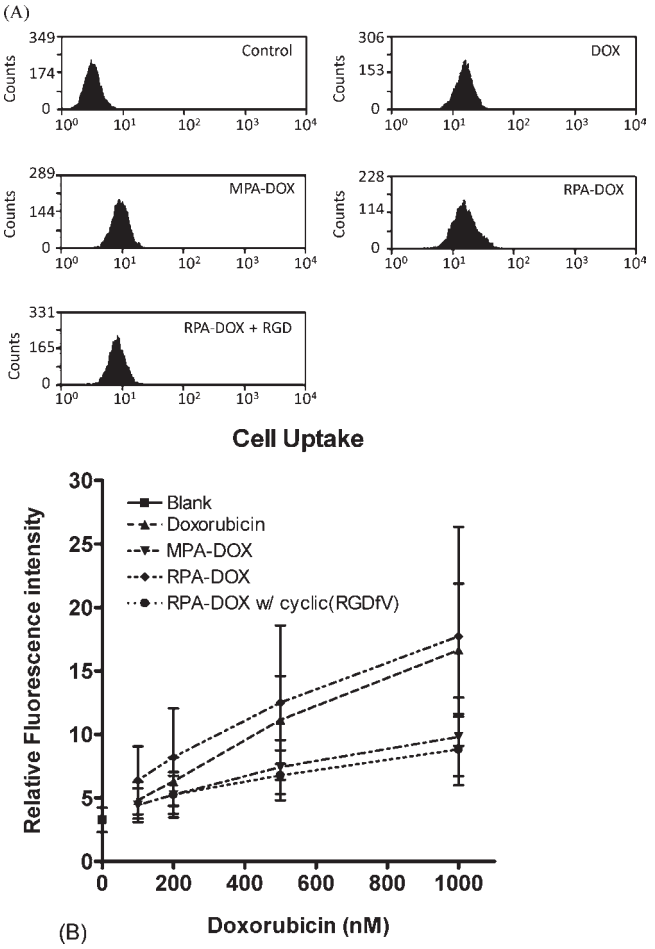

Figure 6. Cellular uptake of doxorubicin formulation. In (A), M21 cells were incubated 4 h in Opti-MEM medium containing medium only; 1 μM doxorubicin, RPA-DOX, and MPA-DOX with 1 μM doxorubicin; and RPA-DOX with 1 μM doxorubicin with preincubation of 100 μM of cyclic(RGDfV); FL2 channel of flow cytometry was set to collect doxorubicin fluorescence. (B) shows the dynamic cellular uptake of doxorubicin formulation. (mean ± SD, from about 5000 cells).

proteinases in endosomal and lysosomal compartments might be expected to accelerate the doxorubicin release. As a control, when incubated in PBS for 48 h, approximately 5% of doxorubicin was released.

Cell Uptake. The uptake of doxorubicin was examined by flow cytometry, as seen in Figure 6. The fluorescence intensity of doxorubicin was excited by 488 nm wavelength light and detected at 575 nm. The mean fluorescence intensity per cell was approximately linear with doxorubicin concentration in all cases. At concentrations ranging between 200 and 1000 nM, RPA-DOX displayed the highest doxorubicin uptake, followed by free doxorubicin and MPA-DOX. When the concentration of doxorubicin was 2 μM, free doxorubicin had the highest doxorubicin uptake, probably because it entered cells by passive diffusion, while RPA-DOX and MPA-DOX entered cells through endocytosis that could be saturated or rate limited. With cells preincubated half an hour with 100 μM cyclic(RGDfV), a ligand for $\alpha_v\beta_3$ integrin, the uptake of RPA-DOX was suppressed to a level close to MPA-DOX. This result shows that conjugation of cyclic RGD on the surface of the albumin micelles supports receptor mediated endocytosis.

The subcellular distribution of doxorubicin was imaged by confocal microscopy (Figure 7). With free doxorubicin, after 4 h incubation in Opti-MEM medium, the bulk of the fluorescence was located in the nucleus (Figure 7A). After a further 16 h culture in drug-free medium, only limited doxorubicin fluorescence was retained inside the nucleus, with the overall fluorescence significantly decreased. With RPA-DOX, after 4 h incubation most of the doxorubicin fluorescence was in cytoplasmic vesicles in the area surrounding the nucleus (Figure 7B), indicating that RPA-DOX enters the cell via a pathway different from free doxorubicin. After 16 h further culturing in drug-free medium, significant amounts of doxorubicin could be seen in the nucleus (Figure 7E), with overall fluorescence of doxorubicin remaining at a high level. This result indicates that doxorubicin delivered by RPA-DOX was retained in cells much longer than free doxorubicin and gradually infiltrated into the nucleus. The MPA-DOX showed similar subcellular distribution as RPA-DOX. However, the fluorescence intensity was much lower under the same imaging conditions, indicating that a lesser amount of doxorubicin was successfully delivered to cells by this nontargeted formulation.

Cytotoxicity. The cytotoxicity of the micelles to M21+ human melanoma cells was determined using an MTT assay and is shown in Figure 8. As shown, RPA-DOX has the highest potency, followed by free doxorubicin and then MPA-DOX. The IC_{50} doses for RPA-DOX, free doxorubicin, and MPA-DOX were calculated to be approximately 200 nM, 500 nM, and 1200 nM, respectively. The cytotoxicities of RPA and MPA were also evaluated by a similar method; after 72 h incubation with M21+ cells, neither of them caused significant toxicity. As a free drug, the thiolated form of doxorubicin that is associated with the nanoscale micelles is slightly less toxic than doxorubicin itself (see Supporting Information Figure S.3). Thus, the increased potency of RPA is not due to a greater effectiveness of the thiolated doxorubicin but rather to improved delivery. Since RPA-DOX contains both bound doxorubicin and conjugated doxorubicin, it is difficult to attribute the cytotoxic effect to one or the other of these components. Further, at present we do not know how quickly the conjugated drug is actually released within the cells. Although the data in Figure 5 suggest release over a period of hours in a reducing environment that mimics the cell interior, the actual release may be quicker due to contributions of endosomal proteases.

■ DISCUSSION

In this report, we describe targeted nanoscale micelles prepared from albumin and the amphipathic anticancer drug doxorubicin. There has been substantial interest in conjugates of antineoplastic agents with proteins, including albumin and monoclonal antibodies, and several moieties have reached clinical trials or entered the clinic.[35] However, in many cases only one or a few drug molecules are linked to the protein. In these cases, better effects are achieved with extraordinarily potent agents such as the calicheamicins rather than more conventional drugs.[36] Another approach has been to utilize micelles based on block copolymers to deliver antitumor agents.[15,37−39] This approach often has the advantage of allowing incorporation of a large number of drug molecules into micelles thus facilitating the utilization of well-known agents such as anthracyclines and taxanes. However, there are inevitably some concerns about possible toxicities of synthetic polymers.[40,41]

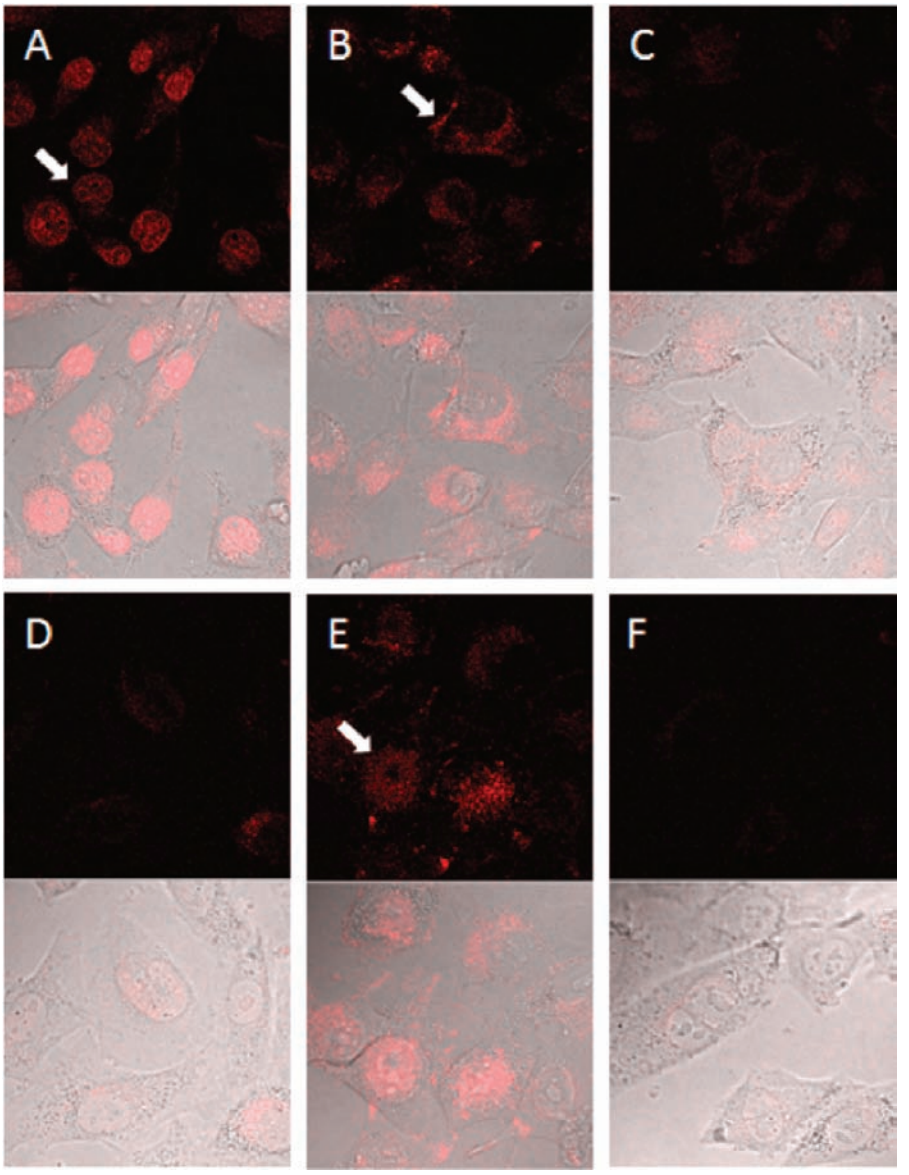

Figure 7. Confocal microscopy of doxorubicin uptake. Cells were incubated for 4 h with 2 μM doxorubicin in free form (A), RPA-DOX (B), or MPA-DOX (C), or further cultured in drug-free medium for 12 h; see (D), (E), and (F), respectively. Arrows point to the doxorubicin subcellular distributions.

The albumin-based nanoscale micelles described here may offer some advantages over other systems in that they provide a high degree of drug loading while being composed of nontoxic biocompatible materials. Our preparation process gives rise to multimeric aggregates of PEG-ylated albumin that contain about 50 doxorubicin molecules per albumin and that are relatively uniform in size with a mean diameter of about 30 nm. We describe this material as nanoscale micelles based on the fact that they are stable in aqueous suspension suggesting the presence of a hydrophilic outer region, but they noncovalently bind a substantial amount of doxorubicin suggesting a hydrophobic core. However, further work will be required to fully delineate the structure and assembly process for this material as well as the implications for pharmacological effects. Thus, at present we do not have detailed information on the structure of the RPA-DOX micelles or the placement of conjugated or bound doxorubicin moieties. Further, the relative contributions of the bound and conjugated drug to the overall pharmacological effect are not known.

The conjugation of RGD-terminated PEG to the albumin results in micelles capable of specifically targeting cells that express the $\alpha_v\beta_3$ integrin. Thus, the RGD-containing RPA-DOX is taken up more efficiently than MPA-DOX, the control conjugate. Further, the uptake of RPA-DOX by $\alpha_v\beta_3$-positive cells is almost completely blocked by the presence of excess RGD illustrating that uptake is ligand-specific. The RPA-DOX micelles displayed excellent potency versus $\alpha_v\beta_3$-positive melanoma cells with an IC_{50} 6-fold lower than that of the control conjugate. Once accumulated in cells, both the covalently linked and the noncovalently absorbed doxorubicin should be readily released from albumin carrier by a combination of reversal of disulfide bonds by intracellular thiols and by proteolytic processes in endosomes and lysosomes.

The strategy described here builds on our previous work using targeted albumin−PEG conjugates to deliver oligonucleotides.[42] However, in that case the conjugates remained as polydisperse but monomolecular entities. In the

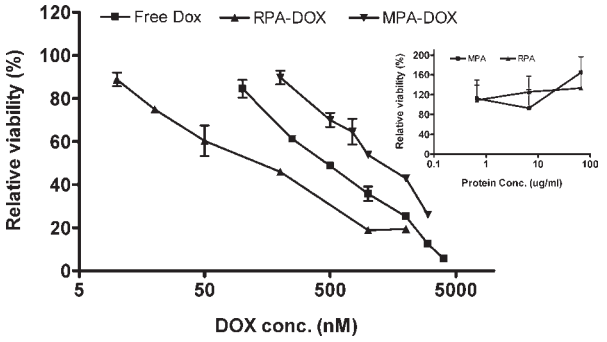

Figure 8. Cytotoxicity of RPA-DOX, MPA-DOX, and free doxorubicin on M21+ cells. The cytotoxicity of MPA and RPA equivalent to RPA-DOX and MPA-DOX containing 0.5 uM to 50 uM of doxorubicin was evaluated in a parallel assay; see inset.

present case, covalent linkage of doxorubicin to the PEG–albumin conjugates apparently drives their aggregation into nanoscale micelles. The ability of the micelles to accommodate additional noncovalently bound drug dramatically raises the drug-loading factor and may allow for very efficient delivery. However, the in vivo targeting and delivery capability of these constructs remains to be determined.

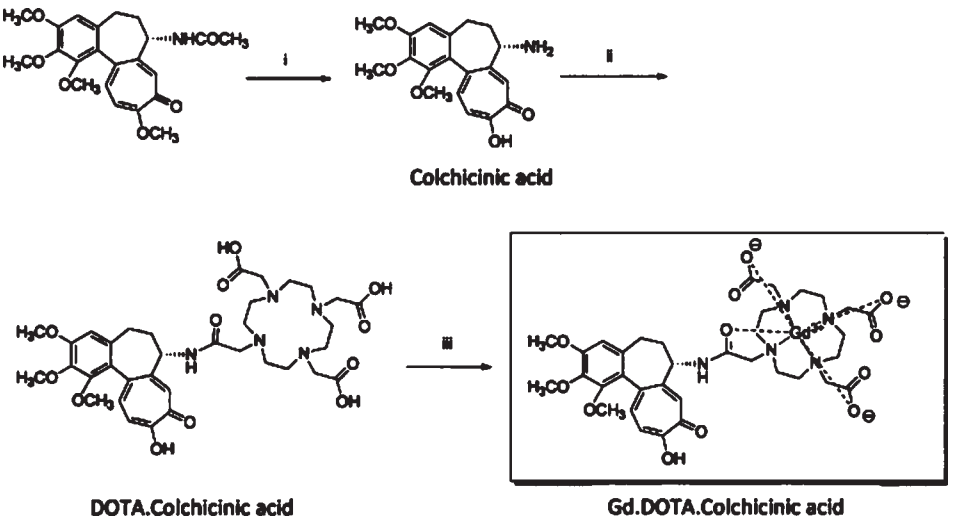
ABSTRACT: Colchicine, a known tubulin binding agent and vascular disrupting agent, causes rapid vascular shut down and central necrosis in tumors. The binding of tubulin results in tubulin destabilization, with characteristic cell shape changes and inhibition of cell division, and results in cell death. A gadolinium(III) labeled derivative of colchicine (Gd·DOTA·Colchicinic acid) was synthesized and characterized as a theranostic agent (enabling simultaneous diagnostic/real time MRI contrast imaging). *In vitro*, Gd·DOTA·Colchicinic acid was shown to initiate cell changes characteristic of tubulin-destabilization in both OVCAR-3 and IGROV-1 ovarian carcinoma cell lines *in vitro* over a period of 24 h, while maintaining the qualities of the MR imaging tracer. *In vivo*, Gd·DOTA·Colchicinic acid (200 mg/kg) was shown to induce the formation of central necrosis, which was confirmed *ex vivo* by histology, in OVCAR-3 subcutaneous tumor xenografts, while simultaneously acting as an imaging agent to promote a significant reduction in the MR relaxation time T_1 ($p < 0.05$) of tumors 24 h post-administration. Morphological changes within the tumor which corresponded with areas derived from the formation of central necrosis were also present on MR images that were not observed for the same colchicine derivate that was not complexed with gadolinium that also presented with central necrosis *ex vivo*. However, Gd·DOTA·Colchicinic acid accumulation in the liver, as shown by changes in liver T_1 ($p < 0.05$), takes place within 2 h. The implication is that Gd·DOTA·Colchicinic acid distributes to tissues, including tumors, within 2 h, but enters tumor cells to lower T_1 times and promotes cell death over a period of up to 24 h. As the biodistribution/pharmacokinetic and pharmacodynamics data provided here is similar to that of conventional colchicines derivatives, such combined data are a potentially powerful way to rapidly characterize the complete behavior of drug candidates *in vivo*.



INTRODUCTION

It is well established that tumor growth is dependent upon the generation of a functional vascular supply and that tumor vasculature differs significantly from that of vessels in normal tissues.[1−4] Normal tissues have well-ordered vessels with quiescent endothelial cells, whereas tumor vasculature is a chaotic network of tortuous, thin-walled, leaky vessels, with a high proportion of immature, proliferating endothelial cells that rely on their tubulin cytoskeleton to maintain shape.[3,4] Consequently, tumor endothelium can be targeted in therapeutic approaches to cancer that leave normal blood vessels unaffected.[5] In particular, vascular disrupting agents (VDAs) invoke the selective collapse of tumor vasculature, leading to a loss in tumor blood flow, secondary cell death, and tumor necrosis due to ischemia.[6] VDAs have largely consisted of tubulin-depolymerizing agents such as colchicine and its derivatives, and more recently, the flavonids such as 5,6-dimethylxanthenone-4-acetic acid (DMXAA). Colchicine binds to β-tubulin, inhibiting tubulin polymerization, resulting in microtubule destabilization. Destabilization of the microtubule cytoskeleton induces cell shape changes, which in the endothelial cells of tumors, results in cell detachment, exposure of the basal lamina, and vessel occlusion.[7] However, colchicine is too toxic for clinical use as it is only effective close to its maximum tolerated dose (MTD). Derivatives of colchicine have therefore been developed, the best known being disodium combretastatin A-4 3-*O*-phosphate (CA-4-P) and ZD6126, both of which induce vascular occlusion and therefore antitumor effects in a wide range of tumor models at doses that are less than one-tenth of the MTD.[8−11]

Scheme 1. Synthesis of Gd·DOTA·Colchicinic acid[a]

[a] (i) 30% H_2SO_4, 100 °C, 5 h, 20%; (ii) DOTA-NHS-ester, DCM, 40 °C, 3 eq. Et_3N, 12 h, 98%; (iii) $6H_2O \cdot GdCl_3$, H_2O, 90 °C, quantitative.

The impact of VDAs on tumor tissue has been demonstrated histologically in numerous tumor models, revealing central necrosis within 24 h of a single injection with a characteristic thin rim of viable tumor cells at the periphery.[9,12] The rim is thought to be a consequence of these cells receiving nutrients/oxygen from nontumor vessels in adjacent normal tissue allowing these tumor regions to regrow. Therefore, VDA treatment is not expected to cause tumor shrinkage or significant growth delay as a single therapy. Accordingly, in the absence of tumor shrinkage, there is a need for noninvasive methods that can provide an assessment of tumor vasculature and pathophysiology in response to VDA therapy *in vivo*. The hemodynamic tumor response to VDA therapy can be monitored by dynamic contrast enhanced magnetic resonance imaging (MRI) using gadolinium(III) (Gd) chelates,[13−17] as well as by intrinsic-susceptibility MRI, which is sensitive to changes in blood oxygenation.[18,19] Otherwise, pathological changes have been observed by MR methodologies such as diffusion-weighted MRI[20−22] or necrosis-avid contrast agents capable of detecting tumor necrosis,[23] as well as methods to investigate apoptosis and cell death, such as choline spectroscopy[24] or targeted contrast agents.[25] Since all these imaging methodologies are responding to secondary changes at selected time points after VDA administration, then this suggests that VDA imaging itself could provide the means not only to reach a better understanding of drug biodistribution/pharmacokinetics, routes of clearance, etc., but also to simultaneously monitor pharmacodynamic phenotypic effects in real time as well as tumor necrosis in particular.

Previously, colchicine has been conjugated with imaging agents[26−31] including Gd-chelates,[32] but mainly for applications *in vitro* or in terminal *in vivo* studies. The aim of the study reported here was to conjugate an MRI contrast agent to colchicine in order to produce a novel theranostic VDA capable of remaining as a functional VDA as well as acting as a competent contrast agent for similtaneous diagnostic/real time MRI contrast imaging *in vivo*. Here, we describe the synthesis and characterization of such a theranostic VDA followed by a range of *in vitro* and *in vivo* imaging studies over 24 h post-VDA administration, concluding with histology and laser ablation inductively coupled mass spectrometry (LA-ICP-MS) to correlate Gd (III) distribution with associated relaxation time (T_1) changes shown by *in vivo* MR.

EXPERIMENTAL SECTION

Gerneral procedures. All chemicals were of analytical/high grade and purchased from Sigma-Aldrich (Dorset, U.K.) or Macrocyclics (Dallas, USA). Mass spectrometry (MS) were performed using VG-070B, Joel SX-102, or Bruker Esquire 3000 electrospray mass spectrometry (ESI) instruments. ^{1}H NMR spectra were recorded on a 400 MHz Bruker Advance 400 spectrometer. All MRI experiments were conducted on a 4.7 T Varian Direct Drive MRI scanner (Varian Inc., Palo Alto, CA, USA). All procedures on animals were carried out in accordance with U.K. Home Office regulations and the Guidance for the Operation of Animals (Scientific Procedures) Act (1986).

Chemical Synthesis. Colchicinic acid (Scheme 1) was synthesized according to the previously reported method by Satpati et al.[26] Tetraazacyclododecanetetraacetic acid (DOTA) in the form of DOTA·NHS ester (100 mg, 0.121 mmol) and colchicinic acid (41.55 mg, 0.121 mmol) were added to an air-evacuated round-bottom flask, and to this, dry dichloromethane (30 mL) followed by triethylamine (3 eq 0.363 mmol) was added and stirred at 45 °C for 12 h. The solvent was removed and the crude mixture purified by flash column chromatography using Merck 0.040 to 0.063 mm, 230 to 400 mesh silica gel, and the product eluted with dichloromethane/methanol/acetic acid (6:3:1 v/v). The collected fractions were reduced to yield a solid (87 mg, 98%) DOTA·Colchicinic acid (Scheme 1). R_f [dichloromethane/methanol/acetic acid, 6:3:1 v/v] 0.11. ^{1}H NMR (400 MHz, MeOD) 8.28 (s, br, 1H, −OH, H_{10}), 7.76 (s, 1H, H_8), 7.46 (s, 1H, H_{11}), 7.11 (d, 1H, H_{12}), 6.92 (d, 1H, H_4), 6.48 (s, br, 1H, $-CNHCOCH_2-$), 4.34 (d, 2H, $-NCOCH_2N-$), 3.64 (m, 16H, 4× $-NCH_2CH_2N-$), 3.26 (m, 6H, 3× $-NCH_2COOH$), 3.12, (s, 3H, -OCH3, H_1), 3.08 (m, 4H, $-CH_2CH_2-$, $H_{5,6}$), 2.77 (s, 3H, −OCH3, H_2), 2.63 (s, 3H, $-OCH_3$, H_3). MS (ESI+) calculated for $C_{35}H_{47}N_5O_{12}$ m/z 729.7740; found, 730.10 $(M + H)^+$.

A stoichiometric amount of gadolinium chloride (20.90 mg, 0.056 mmol) was added to DOTA·Colchicinic acid (41.06 mg, 0.056 mmol) and stirred in doubly distilled water (20 mL) at 90 °C overnight. The water was freeze-dried to yield a powder (50 mg, quantitative yield): Gd·DOTA·Colchicinic acid (Figure 1). R_f [dichloromethane/methanol/acetic acid, 6:3:1

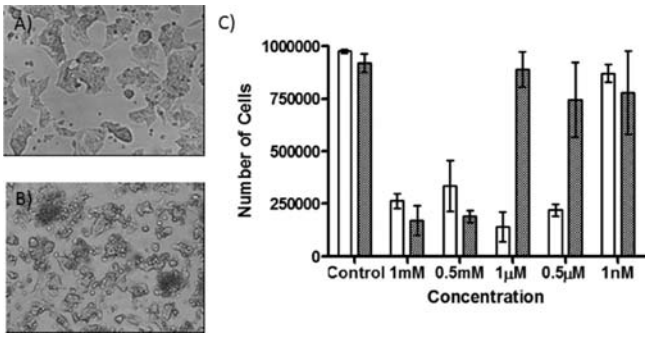

Figure 1. *In vitro* cell studies of DOTA·Colchicinic acid in OVCAR-3 cells. A histology picture of OVCAR-3 cells, (A) without and (B) with 1 mM 24 h after DOTA·Colchicinic acid; (C) cell counts for both colchicine (white) and DOTA·Colchicinic acid (gray) after 24 h at various concentrations. Magnification ×100.

v/v] 0.18. MS (ESI+) calculated for $C_{35}H_{44}GdN_5O_{12}$ m/z 884.00; found, 885.23 $(M + H)^+$. The gadolinium compound was characterized by ESI-MS, and the presence of free gadolinium ions was determined by the xylenol orange test previously described by Barge et al.[33]

In Vitro. *Phantom Studies.* 0.5 mM of Gd·DOTA·Colchicinic acid, DOTA·Colchicinic acid, Gd·DOTA (Dotarem, Guerbet, France), or water was used to assess signal enhancement. A range of 6 concentrations (0.03−0.5 mM) of Gd·DOTA·Colchicinic acid or Gd·DOTA was then used to calculate relaxivity for each contrast agent. Phantoms were placed in a quadrature ^1H volume coil and positioned into the MRI scanner. A spin−echo sequence with the following parameters was used to assess T_1: 10 TRs ranging from 50 to 7000 ms; TE = 10 ms; FOV = 45 × 45 mm; averages, 1; matrix size, 256 × 128 and a 2.0 mm thickness; and bore temperature, ∼ 20 °C.

Tissue Culture. Human ovarian carcinoma OVCAR-3 and IGROV-1 cell lines were grown in T175 flasks (Fisher Scientific, Loughborough, UK) in Dulbecco's modified Eagle's medium (DMEM) (Sigma), supplemented with 10% heat inactivated fetal calf serum (GIBCO, Grand Island NY, USA) in an incubator at 37 °C with 95% air and 5% CO_2. Cells were grown to 100% confluence before being trypsinized, counted, and then either plated for *in vitro* experiments or prepared for subcutaneous implantation.

Toxicity Studies. Cells were plated at 4×10^5 in 6 well plates 24 h prior to incubation with a range of concentrations (1 nM−1 mM) of either DOTA·Colchicinic acid or colchicine dissolved in serum free DMEM. Histological morphology of cells was recorded at 2 h intervals up to 8 h, and at 24 h using an Olympus IX71 microscope (Olympus, Middlesex, UK). The cells were harvested at the 24 h time point and the numbers counted using a hemocytometer.

Gd·DOTA·Colchicinic Acid Uptake. Cells were plated at 1.5×10^5 in T25 flasks 24 h prior to the incubation of 1 mL of 1 mM Gd·DOTA·Colchicinic acid (the most efficient incubation dose from toxicity studies). Cells were then washed, harvested, and pelleted and resuspended in 1% agarose (Sigma, UK) at 2 h intervals up to 8 h, and at 24 h after incubation and scanned as described for phantoms.

In Vivo. *MRI.* OVCAR-3 cells (5×10^6/0.1 mL) were inoculated into the flank of 6−8 weeks old Balb/c nude mice. Once palpable, tumors were measured in three orthogonal dimensions every 2 days up until treatment, then pre and 24 h post-treatment, using calipers. Tumor volumes were estimated assuming an ellipsoid shape using the formula volume = length × width × depth × $\pi/6$. When tumors reached approximately 7−10 mm^3, mice were anesthetized with an isoflurane/O_2 mix and scanned as described for phantoms using the parameters; 5 TRs ranging from 400−5000 ms; TE = 15 ms; FOV = 45 × 45 mm; averages, 1; matrix size, 256 × 128, 2.0 mm thickness; and 20 consecutive transverse slices covering the whole abdomen. Mice were removed from the magnet and a tail vein cannulated for the administration of 200 mg/kg (22.64 mmol) Gd·DOTA·Colchicinic acid (n = 4), 22.64 mmol DOTA·Colchicinic acid (n = 4), 22.64 mmol Gd·DOTA (n = 4), or 200 μL of saline (n = 4); 200 mg/kg was used as this is an optimal dose that has been used for both CA-4-P and ZD6126 in mice. Mice were then rescanned with the same parameters 2, 8, and 24 h post-injection. After the final scan mice were sacrificed, the tumor was excised and frozen for LA-ICP-MS and hematoxylin and eosin (H & E) staining. The liver and kidneys were also taken for H & E only.

MRI Data Analysis. A region of interest (ROI) was drawn around the whole tumor excluding the skin on MR images using Image J (National Institute of Health, USA).[34] Mean signal intensities of the ROIs at different TR values were measured and used to calculate the MR transverse relaxation time T_1 using Graphpad Prism (San Diego, California, USA). Mean T_1 values for each cohort were derived and a two-tailed unpaired t test assuming equal variances performed at each time point to determine significant difference, with a 5% level of statistical significance. Circular ROIs were then drawn in the liver and kidney to assess clearance and the signal intensities converted to T_1 as described above.

LA-ICP-MS. Frozen tissue was mounted onto a cryostat chuck using water/ice slush frozen to −20 °C and sections cut at 20 μm using a cryotome. The laser ablation system (LSX-200, Cetac, 266 nm Nd:YAG) was configured to perform multiple line rasters, generating 2D elemental distribution maps. A beam diameter of 50 μm was used for ablating tumor sections (with energy 0.6 mJ), a scanning speed of 50 μm/s and laser frequency of 10 Hz. For ICP-MS (Agilent, HP4500 Series 100), the elements Gd^{157} and Zn^{66} (an element widespread in biochemistry) were monitored in a time-resolved mode, isotopes were selected on the basis of high-percentage abundance, and minimal isobaric and polyatomic interferences. Tumor sample areas were in the range 130−190 mm^2. Elemental maps were produced using the Graphis software package (Kylebank Software Ltd., Ayr, UK). Adjacent sections where taken for H & E staining.

Histological Assessment. Sections were incubated with hematoxylin solution for 1 min, and then in freshly prepared eosin Y (both Sigma) for 30 s. The sections were then dehydrated with alcohol and passed through histoclear (Fisher Scientific), mounted with DPX (VWR), and imaged using the Olympus IX71 microscope as described in the toxicity studies.

RESULTS

Chemical Synthesis. The synthesis of Gd·DOTA·Colchicinic acid was carried out in three steps as shown in Scheme 1. The control compound DOTA·Colchicinic acid was obtained in good yield and was characterized by ^1H and MS spectroscopy. Complexation of Gd(III) within DOTA could not be confirmed by NMR due to the paramagnetic nature of Gd(III) and was therefore confirmed by ESI-MS and the xylenol orange assay. Isotopic peaks of Gd(III) were highly visible in the MS trace, and there were no significant free Gd(III) ions detectable after complexation according to the xylenol orange assay, thereby confirming the formation of Gd·DOTA·Colchicinic acid.

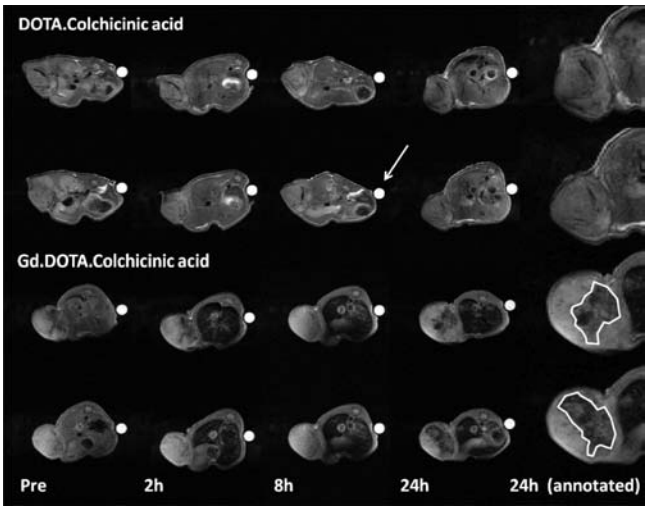

Figure 2. A set of two contiguous T_1 MRI images acquired from similar anatomic points from the same mouse bearing a subcutaneous OVCAR3 tumor pre, 2, 8, and 24 h after 200 mg/kg DOTA·Colchicinic acid or Gd·DOTA·Colchicinic acid administration. Column 24 h (annotated) shows the enlarged 24 h tumor image, which includes annotated areas of signal change in the Gd·DOTA·Colchicinic acid treated tumors. The white arrow denotes a phantom placed to correlate images.

In Vitro. Phantoms showed that Gd·DOTA·Colchicinic acid achieved a 96% reduction in T_1 compared to the same concentration of DOTA·Colchicinic acid or water, and its relaxivity was calculated at 3.83 $mM^{-1}s^{-1}$. This was equivalent to that of nonconjugated Gd·DOTA, which was calculated at 3.66 $mM^{-1}s^{-1}$. The efficiency of DOTA·Colchicinic acid for binding tubulin was assessed in two ovarian carcinoma cell lines. Normally, endothelial cell lines such as HUVEC's are used to assess the functionality of novel VDAs. However, the effects of tubulin-binding drugs are not specific to endothelial cells. Indeed, some tumor cell types are more sensitive to VDA tubulin depolymerization than endothelial cells.[35] The extent to which direct tumor cell death has contributed to VDA therapy is likely dependent on tumor type. Therefore, DOTA·Colchicinic acid was tested in tumor cells to assess tubulin binding and tubulin destabilization activities in order to obtain a better idea of the amount of cell death/antitumor effect that Gd·DOTA·Colchicinic acid may provide *in vivo*, in addition to VDA action.

Cell counts showed that colchicine was effective at significantly reducing cell numbers at all concentrations in both the OVCAR-3 and IGROV-1 cell lines, whereas DOTA·Colchicinic acid was only effective in the millimolar range, causing reductions in cell numbers in both cell lines (Fgure 1C). These high concentration effects were the same for the Gd(III) derivate (Gd·DOTA·Colchicinic acid) and correlated well with colchicine effects at the same high concentrations. Arguably, these data suggest that Gd·DOTA·Colchicinic acid may be much less cytotoxic than colchicine to cells in general but retains colchicine's drug-action mechanism in spite of the conjugated Gd·DOTA chelate (Figure 1C). Light microscopy demonstrated the emergence of initial cell shape changes as early as 2 h post-treatment with DOTA·Colchicinic acid, followed by rounding of the cells, and then detachment from the flask walls at 24 h (Figure 1A and B). MR images of cell pellets taken at specific time points after incubation with Gd·DOTA·Colchicinic acid (1 mM) showed a 54% reduction in T_1 at 2 h compared to that in control cells, which decreased further reaching a maximum of

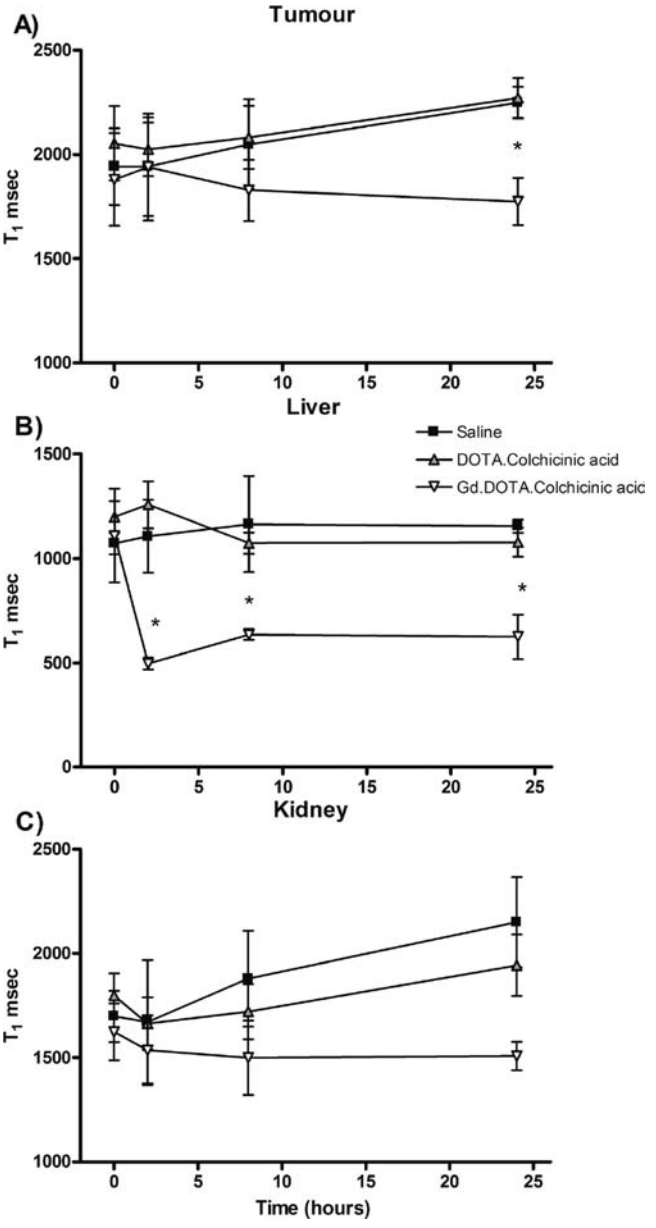

Figure 3. T_1 (ms) measured pre, 2, 8, and 24 h post-injection of 200 mg/kg (22.64 mmol) Gd·DOTA·Colchicinic acid, 22.64 mmol DOTA·Colchicinic acid, or 200 μL saline for (A) tumor, (B) liver, and (C) kidney. Data points ± standard error of the mean ($n = 4$ in each group). * = $P < 0.05$.

83% reduction at 6 h. After 6 h, T_1 recovered slightly, but at no point returned to baseline over the 24 h period (data not shown). These data are in accordance with the histology data and suggest that initial tubulin binding takes place *in vitro* within the first 2 h of incubation, followed by further cellular uptake and tubulin binding over 6 h.

In Vivo. Mice showed no adverse effects throughout the study. There was no significant difference in tumor size between cohorts, consistent with the fact that colchicine and its derivatives do not typically cause tumor shrinkage or growth delay. Images of pre-treated tumors appeared to be homogeneous in presentation. At 24 h, the tumor images showed evidence of morphological changes mainly evident in the central area of the tumor as areas of low signal intensity (dark areas) in 3 out of 4 of the Gd·DOTA·Colchicinic

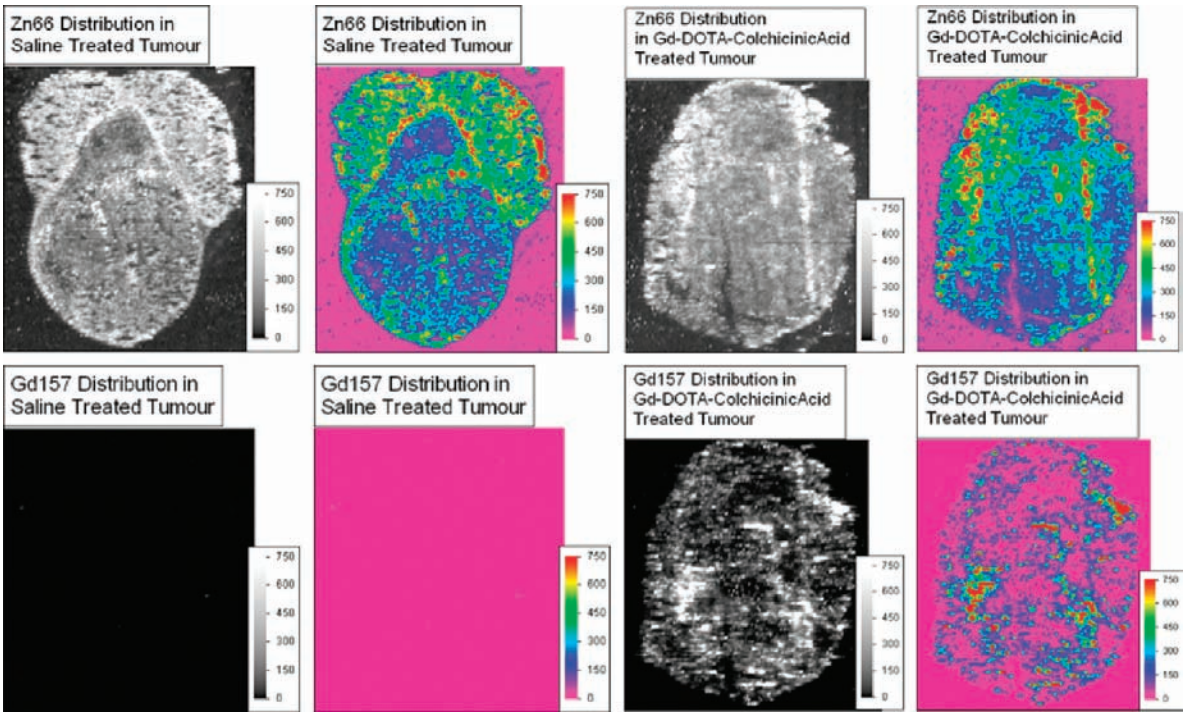

Figure 4. Laser ablation inductively coupled mass spectrometry data of Gd^{157} and Zn^{66} distribution in tumor sections of OVCAR3 tumors 24 h after 200 mg/kg Gd·DOTA·Colchicinic acid or 200 μL of saline administration.

acid treated mice (Figure 2). These changes in signal intensity were not observed at any time point, in any other cohort throughout the study.

Changes in mean T_1 are presented (Figure 3) for the tumor, liver, and kidney. Gd·DOTA exhibited similar values and trends as saline and DOTA·Colchicinic acid controls; therefore, these data have been omitted (from Figure 3). Tumor T_1 presented no change in mean T_1 from the baseline for any cohort at 2 h. A slight but nonsignificant reduction of 3% in mean T_1 was observed at 8 h post-Gd·DOTA·Colchicinic acid administration, which decreased further to become a significantly ($p < 0.05$) greater reduction of 6% in mean T_1 at 24 h post-administration in comparison with that in saline, Gd·DOTA, and DOTA·Colchicinic acid control cohorts (Figure 3A). A significant ($p < 0.05$) reduction of 55% in mean T_1 was also observed in the liver post-Gd·DOTA·Colchicinic acid administration at 2 h in comparison to that in saline, Gd·DOTA, or DOTA·Colchicinic acid control cohorts. This reduction in mean T_1 was sustained throughout, up until 24 h post-administration (Figure 3B). In the case of the kidney, no single significant change in T_1 was observed in any cohort (Figure 3C).

LA-ICP-MS. Elemental maps of Gd^{157} and Zn^{66} distribution in tumors against a saline control were generated 24 h post-Gd·DOTA·Colchicinic acid administration (Figure 4). LA-ICP-MS analysis indicated substantial amounts of Gd(III) present throughout the whole tumor. Using Zn^{66} as an indication of viable tissue, it can be clearly seen that the largest accumulation of Gd(III) takes place in complementary areas that may be necrotic. This suggests that Gd(III) has accumulated in tumor zones that were originally well perfused with blood vessels but became necrotic due to the occlusion of blood vessels post-VDA action. Our data indicate that the MRI-active VDA is still trapped within these apparently necrotic areas.

Histology. H & E staining showed that all tumors 24 h post-Gd·DOTA·Colchicinic acid or DOTA·Colchicinic acid administration possessed a large central core of necrosis with a rim of viable tumor tissue at the tumor periphery. Therefore, the degree of necrosis was not dependent on Gd(III) incorporation (Figure 5B). In contrast, tumors 24 h post-saline and Gd·DOTA administration possessed minimal necrosis and exhibited large areas of viable tumor tissue throughout the tumor (Figure 5A). Otherwise, the liver, which was also observed to accumulate substantial amounts of Gd(III) post-Gd·DOTA·Colchicinic acid as evidenced by substantial reductions in mean T_1 values (Figure 3B), showed no significant differences in liver morphology between animals treated with saline or any agent used in this work (Figure 5C and D). The kidney too was substantially unaffected by Gd·DOTA·Colchicinic acid administration or the administration of any other control compounds (data not shown).

DISCUSSION

In this study, we have synthesized and characterized a novel theranostic tubulin binding agent capable of working as a vascular disrupting agent that was capable of both reducing T_1 as well as keeping its efficacy to bind to tubulin *in vitro*, resulting in cell shape changes and central tumor necrosis *in vivo* characteristic of VDA treatment that could be followed with standard MR sequences longitudinally.

The conjugation of DOTA to colchicine resulted in DOTA·Colchicinic acid, which was complexed with gadolinium to produce the novel compound Gd·DOTA·Colchicinic acid. *In vitro* results showed that conjugation of Gd·DOTA to colchicine did not affect the relaxivity of the contrast agent as an MR probe. DOTA·Colchicinic acid was also found to be a functional therapeutic agent and was effective at causing characteristic VDA changes in both ovarian cell lines *in vitro* at concentrations of the millimolar range, suggesting that cells were less sensitive to the effects of cytotoxicity as afforded by unconjugated colchicine.

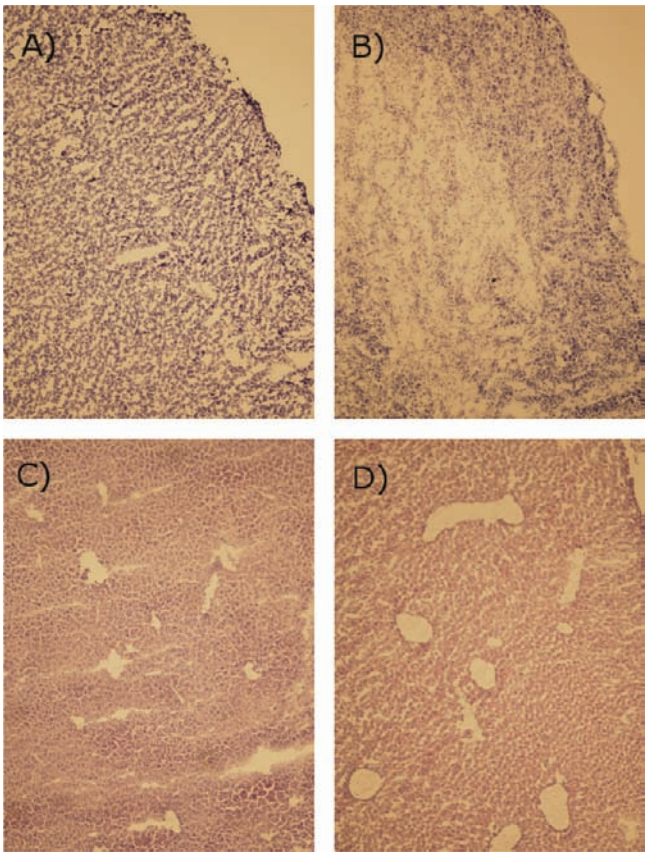

Figure 5. Hematoxylin and eosin stained sections of OVCAR-3 tumors (A,B) and normal liver parenchyma (C,D) 24 h after the administration of (A and C) saline and (B) 200 mg/kg Gd·DOTA·Colchicinic acid. Magnification is ×100.

Colchicine is too toxic for clinical use and is effective only at or close to its MTD, where direct cell cytotoxicity is the principal mechanism of action. A reduction in tumor cell cytotoxicity, therefore, suggests that DOTA·Colchicinic acid has a lower MTD and therefore a wider therapeutic window than colchicine, which would be well tolerated in animals.

DOTA·Colchicinic acid was tested in ovarian carcinoma cells initially *in vitro* instead of endothelial cells, as rapidly dividing tumor cells are also susceptible to VDA therapy and would give a better understanding about the secondary effects of VDA therapy on tumor cells that would be on top of the initial effect of vascular shut down.[35] Initial cell shape changes were observed at as early as 2 h after treatment with DOTA·Colchicinc acid, followed by cell rounding caused by the contraction of the tubulin cytoskeleton, decreasing intracellular adhesion, and subsequent cell loss due to detachment, similar to what has been shown in endothelial cells after doses of either ZD6126 or combretastatin derivatives *in vitro*.[9,36,37] Gd·DOTA·Colchicinic acid also caused T_1 reductions in cells *in vitro* at 2 h, which further decreased over 6 h. After 6 h, the T_1 recovery may be due to lower numbers of cells or changes in cell shape effecting water diffusion. However, as the T_1 does not recover completely, this implies that binding is irreversible as with colchicine itself,[38] resulting in long drug exposures that will therefore cause cell cytotoxicity, which would lead to increased tumor cell death.[39]

As expected for single dose VDA treatment, Gd·DOTA·Colchicinic acid did not cause tumor shrinkage or growth delay. Reductions in T_1 were apparent at 8 h and became significant at 24 h after treatment with Gd·DOTA.Colchcinic acid. As there was no change in T_1 for the saline or DOTA·Colchicinic acid cohorts, the decrease in T_1 relaxation is purely due to Gd·DOTA·Colchicinic acid acting as a contrast agent rather than effects caused by therapeutic effect, as these were not apparent in the nongadolinium derivative, which presented necrosis scores similar to that of Gd·DOTA.colchicinic acid by histology. Although Gd·DOTA also contains gadolinium, the nature of the molecule means that it has a short half-life and rapid clearance; therefore, the fact that there was no change in T_1 for this cohort suggests washout within the initial 2 h period. Morphological changes corresponding to necrosis were detected within the tumor at 24 h on MR images in the Gd·DOTA.Colchcicinic acid cohort only. Darkening of areas within the originally homogeneous tumor presentation were detected mainly within the center of the tumor and correlated well with the degree of necrosis by histology. LA-ICP-MS data revealed high concentrations of gadolinium throughout the tumor. Using Zn^{66} as a marker of viable tissue shows that areas assumed to be necrotic have high degrees of gadolinium present and therefore may represent previously well vascularised areas where Gd·DOTA·Colchicinic acid is still bound within the occluded vessels. The increased contrast between what is believed as the necrotic core and viable rim on images for the Gd·DOTA·Colchicinic acid cohort is most likely due to perfusion in the presence of bound Gd·DOTA·Colchicinic acid and is enough to enhance the signal intensity on T_1 images, whereas in areas of necrosis and increased paramagnetic substances due to therapy, such as increased permeability, platelet aggregation, coagulation, and hemorrhagic necrosis, it causes darkening on the image and therefore increases contrast between the two areas.[40] The liver also showed signal attenuation due to Gd·DOTA·Colchicinic acid accumulation, whereas no changes were observed in kidney T_1. As histology did not show any structural abnormalities and therefore no cyctoxicity to normal tissue in either organ, this may indicate the route of excretion as being via the liver and bile, which has also been shown for ZD6126 when tagged with carbon 14.[41,42]

The therapeutic effect of Gd·DOTA·Colchicinic acid is therefore comparable to changes induced by both CA-4-P and ZD6126 by MR where CA-4-P studies have shown early changes in signal with recovery to baseline at 24 h in both animal models and humans at clinically relevant doses,[17] whereas ZD6126 studies show no evidence of tumor recovery at 24 h[16,43] or up to 96 h after administration,[43] suggesting as with the *in vitro* data that the Gd·DOTA.Colchicine compound binds irreversibly in a similar manner to ZD6126.[38]

As well as carbon 14, colchicine has previously been conjugated to a wide range of imaging tracers, including Gd·DOTA, using the same demethylation of the methoxy group adjacent to the carbonyl.[26−32] These studies are mainly *in vitro* or if *in vivo* have required animal sacrifice at each end point, such as the radiolabeled studies,[26,30,31,41,42] and therefore do not provide longitudinal *in vivo* data. Studies that retained the toxicity of colchicine such as studies by Clark et al. evaluated the binding and subsequent cell changes *in vitro* but could not be used *in vivo*.[27] In other studies that reduced the toxicity of colchicines, although showing increased uptake and retention *in vitro*[32] and *in vivo*,[26] were unclear as to whether there was any significant therapeutic response.[26]

In conclusion, we have successfully synthesized and characterized a novel derivative of colchicine that is capable of functioning as a competent imaging tracer and as a therapeutic tubulin-binding agent *in vitro* and *in vivo*. The utilization of this has allowed for *in vivo* imaging of central necrosis as a therapeutic

response to VDA therapy in tumors in real time and has been validated by both histology and LA-ICP-MS. This has given a better understanding of the timing of necrosis and has strengthened the requirement for smart probes to be incorporated into the experimental design for *in vivo* applications.

Supporting Information

ABSTRACT: Gold magnetic particles (GMP) are magnetic iron oxide particles modified with gold nanoparticles. The gold particles of GMP specifically bind to cysteine and methionine through Au−S binding. The aim of the present study was to establish a quick and easy protein purification system using novel peptide tags and GMP. Here, we created a variety of peptide tags containing methionine and cysteine and analyzed their affinity to GMP. Binding assays using enhanced green fluorescent protein (EGFP) as a model protein indicated that the tandem methionine tags comprising methionine residues had higher affinity to the GMP than tags comprising both methionine and cysteine residues. Tags comprising both methionine and glycine residues showed slightly higher affinity to GMP and higher elution efficiency than the all-methionine tags. A protein purification assay using phosphorylcholine-treated GMP demonstrated that both a tandem methionine-tagged EGFP and a methionine and glycine-tagged EGFP were specifically purified from a protein mixture with very high efficiency. The efficiency was comparable to that of a histidine-tagged protein purification system. Together, these novel peptide tags, "methionine tags", specifically bind to GMP and can be used for a highly efficient protein purification system.

INTRODUCTION

Protein purification using ion exchange, gel filtration, and affinity chromatography is commonly used to study protein function. Affinity chromatography is a powerful tool to purify a target protein by single column chromatography. Several protein and peptide tags are used for affinity chromatography such as glutathione S-transferase,[1] maltose-binding protein,[2,3] FLAG-tag,[4] hexahistidine tag,[5,6] calmodulin-binding peptide,[7] biotin acceptor peptide, [8] and strep-tag.[1,9] Each of these tags is fused to the target protein, and the tagged protein is purified using chemically modified beads with high affinity to the tag.

Magnet beads are used for protein purification. Because magnet beads in solution are easily collected with a magnet, these beads are used as biologic research tools for molecular interaction analysis, nucleic acid/protein purification in gene delivery,[10] cell separation,[11,12] tumor targeting,[13] magnetic resonance imaging,[14,15] and hyperthermic cancer therapy.[16,17] In most cases, chemically modified magnetic beads are used to immobilize a molecule (e.g., protein or DNA molecule) on the bead surface.[18]

The gold magnetic particle (GMP) is a novel magnetic bead on which nanoscale gold particles are immobilized.[19,20] Molecules including sulfur atoms (thiol sulfide and disulfide groups) bind to GMP through Au−S binding without the need for chemical linkers.[21,22] Only amino acids with sulfur atoms, such as cysteine and methionine residues, specifically bind to GMP.[23] In the present study, we developed novel peptide tags that strongly and specifically bind to GMP and successfully established a novel efficient protein purification system using these tags and GMP.

EXPERIMENTAL PROCEDURES

Preparation of Gold Magnetic Particle. Gold magnetic particles (GMP) were synthesized as previously described.[24] Briefly, 20 to 30 nm Fe_3O_4 nanoparticles (Nanostructured & Amorphous Materials, Inc., Houston, TX) were dispersed in water containing 0.5 mM $HAuCl_4$, 125 mM 2-propanol, and 1 mg/mL poly(vinyl pyrrolidone) (molecular weight 40 k) to prepare a 0.1 mg/mL Fe_3O_4 suspension. This suspension was irradiated with a 4.8 MeV high-energy electron beam at a dose rate of 3k Gy/s for 2 s in a glass vial. The resulting Au/Fe_3O_4 nanoparticles were collected with a magnet, washed with water three times, and resuspended in water. Production of Au/Fe_3O_4 particles containing 2 to 4 nm Au particles immobilized on the surface of Fe_3O_4 particles was confirmed by transmission electron microscopy. GMPs are now commercially available (Act Nonpareil, Osaka, Japan; URL: http://www.act-nonpareil.com/en/).

To generate GMP-PC, gold magnetic particles were treated with phosphorylcholine.

Construction of Expression Vectors. Each tandem methionine tag was fused to enhanced green fluorescent proteins (EGFP) by a polypeptide linker that includes a protease recognition site, a helix linker, and a tag sequence (Supporting Information Figure S1). To generate pET-15b-EGFP-linker-MMM, a DNA fragment encoding the linker and the tandem methionine tag was generated by annealing several oligonucleotides. This fragment was cloned into *Eco*RI and *Bgl*II sites of pCruz-GFP (Santa Cruz Biotechnology, Santa Cruz, CA) (Supporting Information Figures S2 and S3). pCruz-EGFP-linker-MMM was then digested with *Nco*I and *Bgl*II, and the resulting fragment encoding EGFP-linker-MMM was inserted into the *Nco*I and *Bam*HI sites of pET-15b (Merck KGaA, Darmstadt, Germany) (Supporting Information Figure S3).

To generate the other tagged EGFP expression vectors, oligonucleotides encoding the tag sequences were cloned into *Not*I and *Sac*II sites of pCruz-EGFP-linker-MMM (Supporting Information Figure S2). The resulting plasmids were digested with *Nco*I and *Bgl*II, and the resulting fragments encoding the EGFP-linker-tag were inserted into the *Nco*I and *Bam*HI sites of pET-15b. The DNA sequences of each of the constructs were verified by automated DNA sequencing.

To generate pET-15b-CBFβ-linker-M3G4, a DNA fragment encoding CBFβ and a part of the polypeptide linker sequence was amplified by PCR. The resulting PCR product was digested with *Nco*I and *Sma*I, and cloned into the *Nco*I and *Sma*I sites of pET-15b-EGFP-linker-M3G4.

Preparation of the Tagged EGFPs. To prepare the tagged EGFPs, each of expression vectors for the tagged EGFP was transfected into *E. coli* strain BL21(DE3). The resulting *E. coli* were cultured in Luria−Bertani medium containing 50 μg/mL carbenicillin. When the OD_{600} reached 0.3, isopropyl β-D-thiogalactoside was added to a final concentration of 1 mM to induce the tagged EGFP. The cells were incubated for another 3 h at 30 °C and harvested. The cells were washed twice and resuspended with Buffer I (20 mM Tris-HCl [pH 8.0], 50 mM NaCl, 1 mM dithiothreitol (DTT), and protease inhibitor cocktail [Nacalai Tesque, Kyoto, Japan]). The resulting cell suspension was sonicated to extract and resolve the tagged EGFP. To purify the tagged proteins, the cell extract was applied to an Econo pack High Q cartridge (Bio-Rad, Hercules, CA). The column was then washed with Buffer II (20 mM Tris-HCl [pH 8.0], 80 mM NaCl, 1 mM DTT) and eluted with an 80−110 mM NaCl linear gradient. Fractions containing the tagged EGFP were collected and concentrated using Vivaspin 20 cartridges (Sartorius Stedim Biotech, Aubagne, France). The fluorescence intensity of the purified, tagged EGFP was measured using Gemini XPS (Molecular Devices, Sunnyvale, CA).

Protein Binding/Purification Assay and Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE) Analysis. For the protein binding assay, 15 000 fluorescence units of the tagged protein was mixed with GMP containing 10 mg iron in 300 μL of binding buffer (20 mM Tris-HCl [pH 8.0], 100 mM NaCl) and incubated for 30 min at 4 °C. The GMP in the resulting solution was collected with a magnet, and the fluorescence intensity of the supernatant was measured. The collected GMP was washed twice with binding buffer and incubated in 300 μL of binding buffer containing 24 mM 2-mercaptoethanol (2-ME) following for 30 min at 4 °C. The fluorescence intensity of the eluted proteins was measured. The same procedure was used for the protein purification assay with nonpurified *E. coli* extract containing 15 000 fluorescence units of the tagged EGFPs. For the protein purification assay using histidine tagged EGFP, Dynabeads TALON (Invitrogen, Carlsbad, CA) was used. Crude protein extract and eluted protein were subjected to SDS-PAGE following Coomassie Brilliant Blue staining.

RESULTS

Three Amino Acid Tags Comprising Methionine and/or Cysteine. A goal of our research was to prepare a protein purification system using a novel peptide tag and GMP. To that end, we planned to develop novel peptide tags that specifically bind to GMP with high affinity. We first prepared eight peptide tags that included methionine and/or cysteine (MMM, CMM, MCM, MMC, CCM, CMC, MCC, and CCC), and each of them was fused to the C-terminus of EGFP with a polypeptide linker (Figure 1A and Supporting Information Figure S1). The tagged proteins were expressed in *E. coli* and purified with Q-Sepharose column chromatography (Figure 1B).

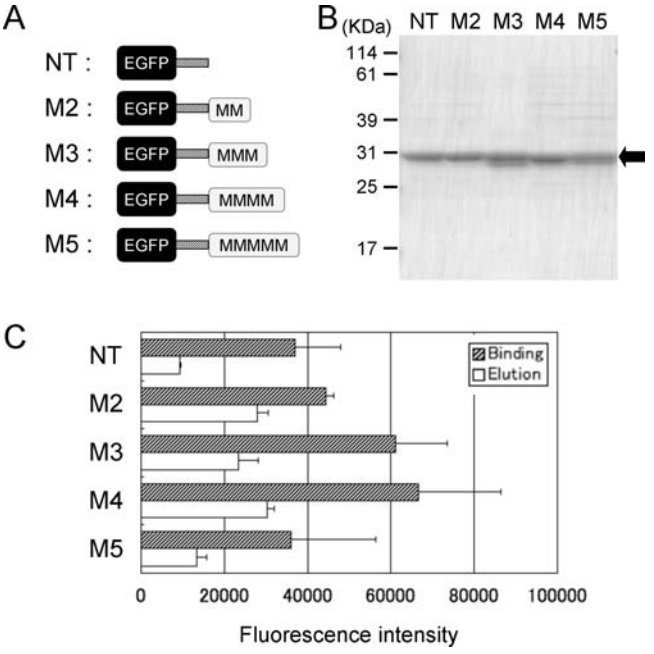

Figure 2. Binding affinity of tags comprising tandem methionine sequences. (A) EGFPs tagged with or without peptides comprising tandem methionine sequence. (B) SDS-PAGE analysis of the tagged protein purified by ion exchange column chromatography. The gel was stained with Coomassie Brilliant Blue. The arrow indicates bands of tagged EGFPs. (C) Fluorescence intensities of the binding and eluted proteins obtained in the protein binding assay. The assay was performed three times. Each bar represents mean ± SD.

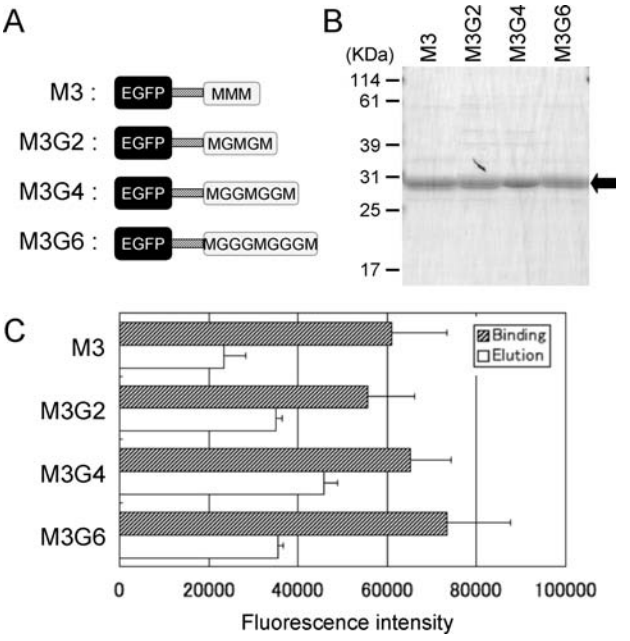

Figure 3. Binding affinity of the tags comprising methionine and glycine residues. (A) EGFPs tagged with the peptides comprising methionine and glycine residues. (B) SDS-PAGE analysis of the tagged protein purified by ion exchange column chromatography. The gel was stained with Coomassie Brilliant Blue. The arrow indicates bands of tagged EGFPs. (C) Fluorescence intensities of the binding and eluted proteins obtained in the protein binding assay. The assay was performed three times. Each bar represents mean ± SD.

A binding assay was performed to evaluate the affinity of the tagged proteins to GMP (Supporting Information Figure S4). Each of the tagged proteins was mixed with GMP for a binding reaction between GMP and the protein. The resulting GMP-protein complex was collected with a magnet and washed with the buffer to remove nonspecific binding proteins. The specific binding proteins were then eluted with the buffer containing 2-ME. Fluorescence intensities derived from binding and eluted protein were calculated by measuring the intensities of input, removed and eluted fractions (Figure 1D). MMM had the highest binding affinity for GMP. CMM and MMC had intermediate affinity for GMP (63% and 67% of the MMM intensity, respectively). MCM, CCM, CMC, MCC, CCC had low affinity for GMP (43%, 25%, 35%, 48%, and 37% of the MMM intensity, respectively). The fluorescence intensity of the eluted fraction showed the same pattern, that is, MMM had the highest intensity. CMM and MMC had intermediate affinity to GMP (78% and 66% of the MMM intensity, respectively). MCM, CCM, CMC, MCC, and CCC had low affinity to GMP (42%, 25%, 31%, 29%, and 29% of the MMM intensity, respectively). These results suggested that tags containing tandem methionine residues (e.g., MMM, CMM, and MMC) have high affinity to GMP.

Tandem Methionine Tags Containing Various Numbers of Methionine Residues. To further improve the binding affinity of the tandem methionine tag to GMP, we prepared tandem methionine tags comprising various numbers of methionine residues (M2, M4, and M5) and a control tag without methionine (NT) and coupled them to the C-terminus of EGFP (Figure 2A). These proteins were expressed in *E. coli* and purified with Q-Sepharose column chromatography (Figure 2B). Binding assays using these proteins showed that the fluorescence intensity of bound M3 and M4 was significantly higher than that of NT (1.7- and 1.8-fold compared to NT, respectively; Figure 2C). M2 had a moderately stronger intensity than NT (1.2-fold), while M5 and NT showed the similar intensities. A similar pattern was observed with the fluorescence intensities of the eluted proteins, with the exception of the strong intensity of M2 (the intensities of M2, M3, M4, and M5 were 3.0-, 2.6-, 3.3-, and 1.5-fold compared to NT). Together, these results indicate that the tags including three or four tandem methionine residues had the highest binding affinity to GMP and high elution efficiency from GMP.

Tags Comprising Three Methionine and Glycine Residues. To investigate whether the distance between methionine residues in the tag affects the binding affinity to GMP, 1 to 3 glycine residues (containing no sulfur atoms) were inserted between methionine residues of the M3 tag, and three new tags were prepared (Figure 3A). These tags were fused to the C-terminus of EGFP, and the tagged proteins (M3G2, M3G4, and M3G6) were expressed in *E. coli* and purified with Q-Sepharose column chromatography (Figure 3B). Binding assays using these proteins showed that the fluorescence intensity of binding proteins of M3G2, M3G4, and M3G6 were similar to that of M3 (0.9-, 1.1-, and 1.2-fold compared with M3, respectively; Figure 3C and Supporting Information Figure S5). In contrast, the fluorescence intensities of the eluted proteins containing M3G2, M3G4, and M3G6 were significantly higher than that of M3 (1.5-, 1.9-, and 1.5-fold compared to M3, respectively). This finding suggests that insertion of a glycine between methionine residues does not change the binding affinity of the tagged protein to GMP, and rather improved the elution efficiency.

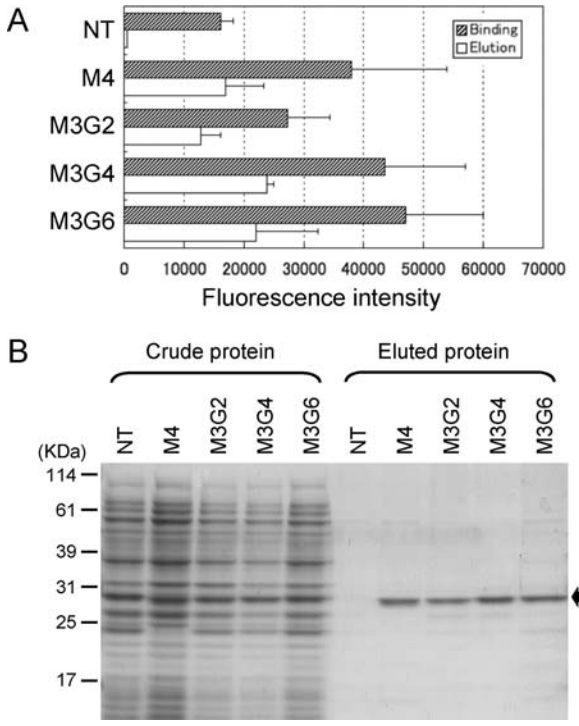

Figure 4. Purification of the tagged EGFPs from *E. coli* extract. (A) Fluorescence intensities of the binding and eluted proteins obtained in the protein purification assay. The assay was performed three times. Each bar represents mean ± SD. (B) SDS-PAGE analysis of the crude extract and purified protein. The arrow indicates bands of tagged EGFPs. The gel was stained with Coomassie Brilliant Blue.

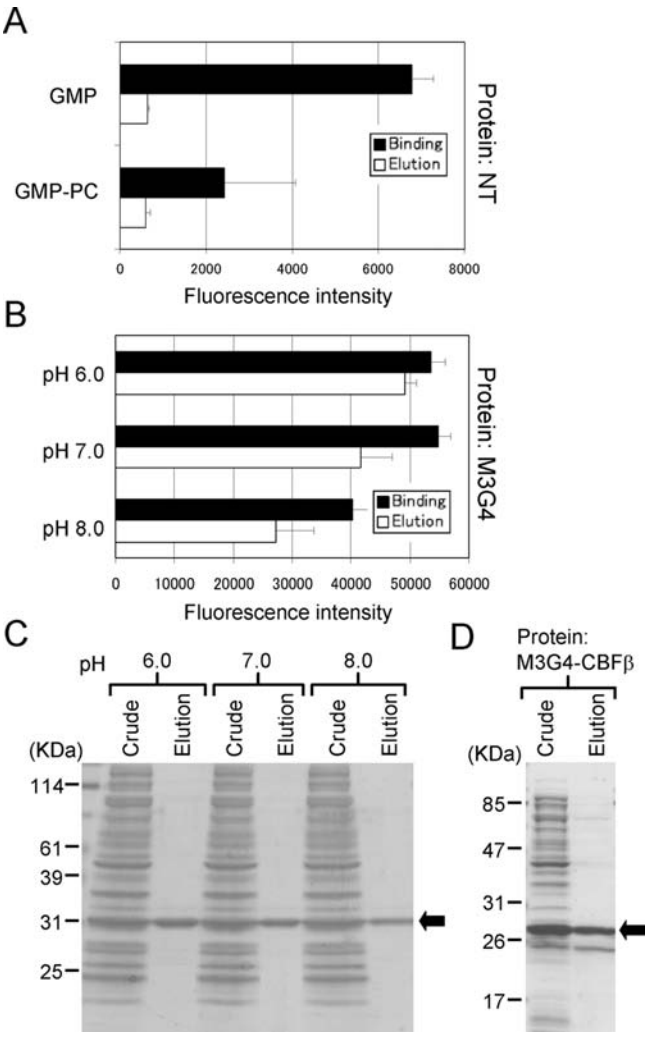

Figure 5. Treatment of GMP with phosphorylcholine improves the protein purification efficiency. (A) Fluorescence intensities of the binding and eluted proteins obtained in the protein purification assay using GMP or GMP-PC, and crude extract including NT. The assay was performed three times. Each bar represents mean ± SD. (B) Fluorescence intensities of the binding and eluted proteins obtained in the protein purification assay in pH 6−8 using GMP-PC and crude extract including M3G4. The assay was performed three times. Each bar represents mean ± SD. (C) SDS-PAGE analysis of the crude extract and purified protein. The arrow indicates bands of tagged EGFPs. The gel was stained with Coomassie Brilliant Blue. (D) Protein purification assay was performed using GMP-PC and *E. coli* extract containing M3G6 tagged CBFβ. The crude and eluted protein was analyzed by SDS-PAGE followed by Coomassie Brilliant Blue staining. The arrow indicates a band of tagged CBFβ.

Purification of the Tagged Protein from *E. coli* Extract. To investigate whether the tagged proteins can be purified from *E. coli* extract, each of five tagged or nontagged EGFPs (M4, M3G2, M3G4, M3G6, or NT) was expressed in *E. coli*. Crude protein extracts were prepared from *E. coli* and subjected to a protein purification assay. Fluorescence intensities of the binding proteins of M4, M3G2, M3G4, and M3G6 were significantly higher than that of NT (2.4-, 1.7-, 2.7-, and 2.9-fold, respectively; Figure 4A). Fluorescence intensities of the eluted proteins of M4, M3G2, M3G4, and M3G6 were also significantly higher than that of NT (51-, 38-, 72-, and 66-fold, respectively). These results indicate that tagged proteins were specifically purified by this purification step, though tag-independent nonspecific binding was observed with NT.

To further investigate the efficiency of the purification, the crude and eluted protein fractions were analyzed by SDS-PAGE following Coomassie Brilliant Blue staining (Figure 4B). The result indicated that the tagged EGFPs, but not the nontagged EGFP, were specifically purified from *E. coli* extract in very high purity. Together, these results indicated that the tagged proteins, including M4, M3G2, M3G4, and M3G6, can be purified from *E. coli* extract.

Improvement of the Purification Efficiency. A protein purification assay using tagged proteins indicated that there was tag-independent protein binding to GMP. To decrease this tag-independent protein binding to GMP, we treated GMP with phosphorylcholine (PC) and created GMP-PC. A binding assay using GMP or GMP-PC with NT showed that PC treatment resulted in a 65% decrease of the tag-independent protein binding to GMP, whereas the elution efficiency was not different between GMP and GMP-PC (Figure 5A). In addition, this PC treatment did not inhibit protein binding to GMP through gold nanoparticles (Supporting Information Figure S6). To determine the optimal pH for protein purification using GMP-PC, a protein purification assay was performed using M3G4 and buffers at pH 6, 7, and 8 (Figure 5B). The pH 6 and 7 buffers resulted in high fluorescence intensity of the binding proteins, while the pH 8 buffer resulted in 73% of intensity compared with the pH 6 and 7 buffers. In contrast, the fluorescence intensity of eluted protein was highest with the pH 6 buffer, while the pH 7

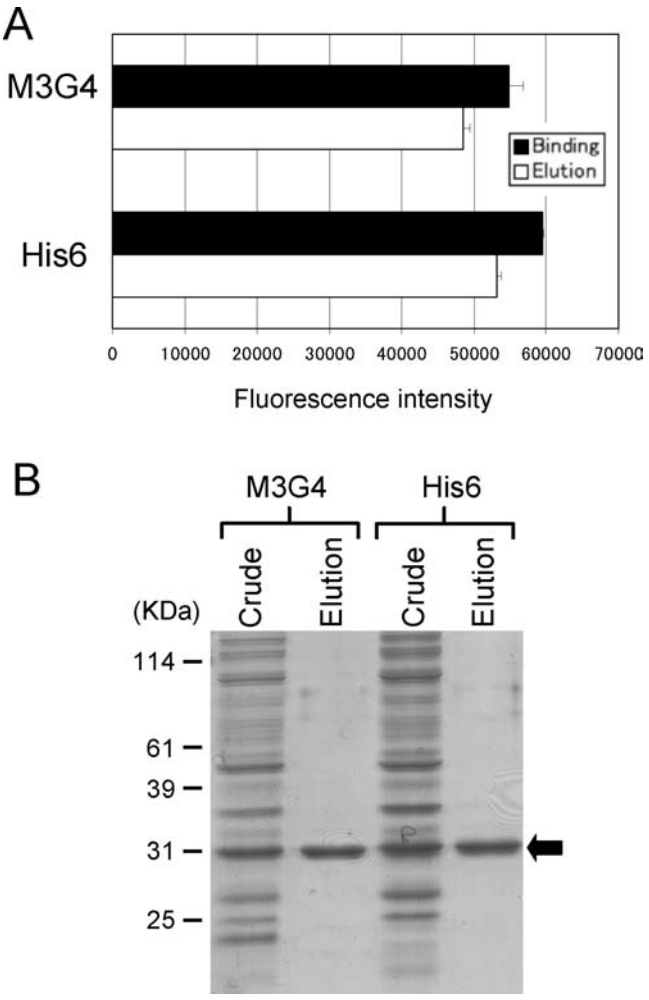

Figure 6. Comparison of the purification efficiency between system using a methionine tag or histidine tag. (A) Fluorescence intensities of the binding and eluted proteins obtained in the protein purification assay. The assay was performed three times. Each bar represents mean ± SD. (B) SDS-PAGE analysis of the crude extract and purified protein. The arrow indicates bands of tagged EGFPs. The gel was stained with Coomassie Brilliant Blue.

and 8 buffers showed reduced intensities (84% and 55% compared with pH 6, respectively). In this assay, 91%, 75%, and 67% of the binding proteins were eluted in pH 6, 7, and 8 buffers, respectively. To investigate the purity of the eluted protein, SDS-PAGE analysis was performed using crude and purified protein fractions (Figure 5C). The result showed that the tagged protein, M3G4, was specifically purified in all three buffers. In addition, another tagged protein, M3G4-CBFβ was also purified with GMP-PC in high purity (Figure 5D). Together, these results indicate that PC treatment of the GMP suppressed the tag-independent protein binding and significantly improved the efficiency of protein purification in buffer at a certain pH.

Comparison of Purification Efficiencies between Methionine Tag and Histidine Tag. To evaluate the efficiency of the established protein purification system in comparison with the common protein purification system, histidine-tagged EGFP (His6) was prepared. M3G4 or His6 was expressed in *E. coli*, and crude protein extracts were prepared. The same fluorescence intensity of the M3G4 and His6 was purified with the same amount (same iron weight) of GMP-PC or Co^{2+} chelated magnetic beads. Fluorescence intensities of both binding and eluted proteins of M3G4 were comparable to those of His6 (Figure 6A). SDS-PAGE analysis indicated that both M3G4 and His6 were specifically purified from the crude extract (Figure 6B). Together, these results indicate that the novel protein purification system using a methionine tag and GMP-PC has comparable efficiency to a common protein purification system.

DISCUSSION

We previously demonstrated that cystine (comprising 2 cysteine residues) and methionine specifically bind to GMP through Au−S binding and that cystine showed the significantly higher affinity to GMP than methionine.[23] On the basis of this finding, we hypothesized that peptide tags including methionine and/or cysteine residues would strongly bind to GMP. The aim of this study was to establish a novel protein purification system using novel peptide tags. To that end, we first generated the peptide tags comprising three amino acid peptide tags including methionine and/or cysteine residues. The tags with a tandem methionine sequence had high affinity to GMP and high elution efficiency from GMP. Unexpectedly, the tags with a number of cysteine residues had low affinity to GMP and also low elution efficiency, although cystine showed very strong affinity to GMP in our previous study.[23] We speculated that cysteine residues in the C-terminus of EGFP form intra- and/or intermolecular disulfide bonds, and that these might disturb the binding between the tags and GMP. In terms of the low elution efficiency of the tags with more than 2 cysteine residues, excessively strong binding between cysteine and GMP might inhibit the elution of the tagged EGFP.

The assay using three amino acid peptide tags indicated that tandem methionine residues improved the binding affinity of the tag. The binding assay using tandem methionine tags comprising different numbers of methionine residues indicated that increasing the number of methionine residues to four improved the binding affinity of the tag to GMP. However, the tag with five methionine residues has significantly decreased binding affinity to GMP. We speculated that the tag with five tandem methionine residues (M5) contributes to a hydrophobic interaction between tagged-EGFPs, which disturbs the Au−S binding between the tag and GMP. In addition, M5 expression level in *E. coli* was very low compared with that of M2, M3, or M4 (data not shown). A five tandem methionine sequence may disturb the protein expression in *E. coli*. This finding suggests that the tags with three or four methionine residues are preferable for protein purification.

We next hypothesized that the insertion of glycine residues between methionine residues would provide the peptide with a flexible conformation, thus making all the methionine residues contribute to Au−S binding, and we performed the assays using M3G2, M3G4, and M3G6. The insertion of glycine residues, however, did not change the binding affinity, but slightly improved the elution efficiency. Insertion of glycine residues might induce conformational changes of the tags and these tagged-EGFPs might then slightly increase the elution efficiency by improving the accessibility of 2-ME to the GMP.

The protein purification assays demonstrated that M4, M3G2, M3G4, and M3G6 can be purified from a protein mixture. However, not all the binding proteins were eluted from GMP, and this decreased the yield of the eluted protein. We speculated that this low purification efficiency derived from the nonspecific protein binding to GMP, which was observed in the binding assay

using NT. To decrease the nonspecific binding of protein to GMP, we treated GMP with PC that is known to have high free water fraction and decreased protein adsorption onto the polymer surface.[25−27] Treatment of GMP with PC and optimization of the buffer pH significantly reduced the nonspecific protein binding and increased the yield of the purified protein. Efficiency of the optimized protein purification system is comparable to that of the system using the histidine tag.

Thus, we successfully established a novel protein purification system using the novel peptide tags "methionine tags" and GMP. This purification system has several merits that are found in other protein purification systems. For example, the small tag sequence hardly interferes with protein expression in cells and does not affect protein structure and functions. Specialized binding buffers and substrates for protein elution are not necessary. All of the purification steps can be easily and quickly performed by using a magnet instead of a centrifuge. Thus, this protein purification system is convenient and useful. In addition, GMPs conjugated with methionine-tagged protein might be useful as tools for biological and clinical research.

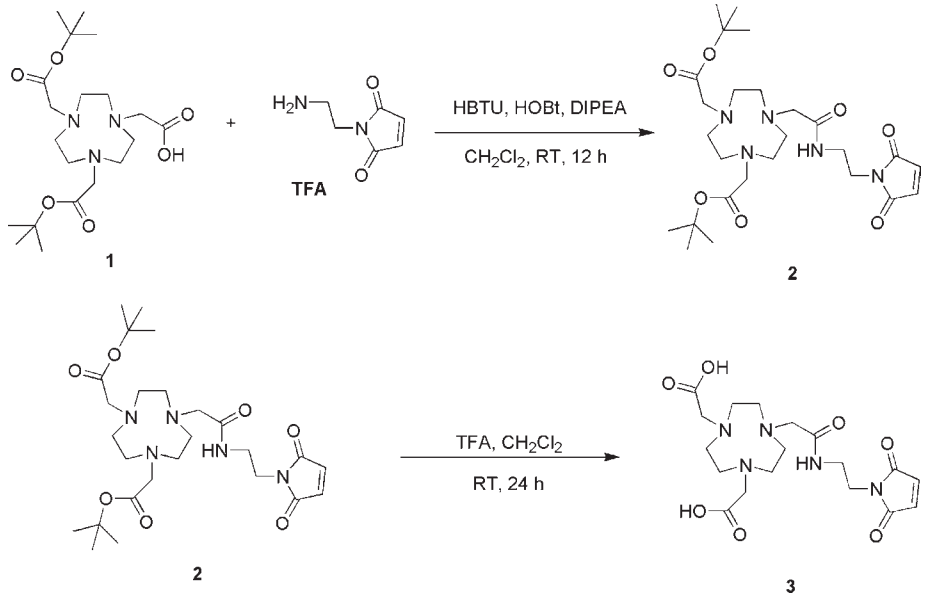
ABSTRACT: Radionuclide molecular imaging has the potential to improve cancer treatment by selection of patients for targeted therapy. Affibody molecules are a class of small (7 kDa) high-affinity targeting proteins with appreciable potential as molecular imaging probes. The NOTA chelator forms stable complexes with a number of radionuclides suitable for SPECT or PET imaging. A maleimidoethylmonoamide NOTA (MMA-NOTA) has been prepared for site-specific labeling of Affibody molecules having a unique C-terminal cysteine. Coupling of the MMA-NOTA to the anti-HER2 Affibody molecule $Z_{HER2:2395}$ resulted in a conjugate with an affinity (dissociation constant) to HER2 of 72 pM. Labeling of [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ with ^{111}In gave a yield of >95% after 20 min at 60 °C. In vitro cell tests demonstrated specific binding of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ to HER2-expressing cell lines. In mice bearing prostate cancer DU-145 xenografts, the tumor uptake of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was 8.2 ± 0.9% IA/g and the tumor-to-blood ratio was 31 ± 1 (4 h postinjection). DU-145 xenografts were clearly visualized by a gamma camera. Direct in vivo comparison of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ demonstrated that both conjugates provided equal radioactivity uptake in tumors, but the tumor-to-organ ratios were better for [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ due to more efficient clearance from normal tissues. In conclusion, coupling of MMA-NOTA to a cysteine-containing Affibody molecule resulted in a site-specifically labeled conjugate, which retains high affinity, can be efficiently labeled, and allows for high-contrast imaging.

INTRODUCTION

Increasing specificity of cancer treatment is currently based on molecular targeting of malignancy-associated molecular alterations in cancer cells. Both patient stratification for therapy and monitoring of therapy response require accurate detection of the expression level of a molecular target at the onset of therapy and during treatment.[1,2] Radionuclide imaging of molecular targets might be a valuable clinical tool, since it is less sensitive to heterogeneity of target expression and noninvasive permitting serial investigations, which is essential for pharmacodynamic studies.[1,2]



A new category of promising radionuclide imaging probes, scaffold-based proteins, has emerged during recent years.[3] The scaffold is a protein framework that can carry altered amino acids providing new binding specificities. Affibody molecules are a successful example of the application of the scaffold principle for the development of imaging agents.[4] The small size (ca. 7 kDa) and high affinity (low nanomolar to picomolar level) of Affibody molecules provide rapid extravasation and diffusion inside tumors, stable binding to molecular targets, and rapid clearance of nonbound probe, making high-contrast imaging possible. The robust disulfide-independent structure and rapid high-fidelity refolding of Affibody molecules in the physiological environment permit their labeling in harsh conditions.[5]

Site-specific labeling is important to provide chemically uniform radioconjugates with well-defined in vivo properties. For short peptides, such site-specificity is easy to achieve by incorporation of a chelator during peptide synthesis. This approach has been successfully applied to Affibody molecules as well.[5] It would be attractive, however, to be able also to label site-specifically recombinant proteins, since efficient peptide synthesis of, e.g. multimeric constructs or fusion proteins, is problematic. The feasibility of site-specific labeling of recombinant

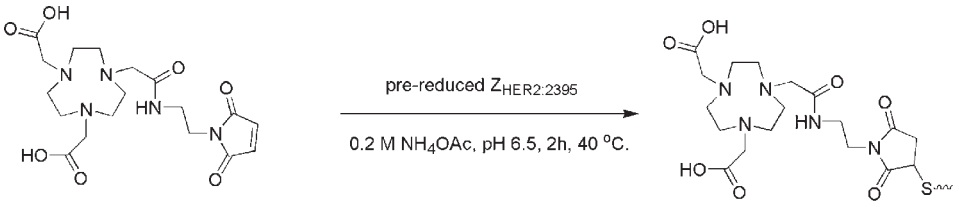
Affibody molecules would provide high flexibility for production even of monomeric forms. The absence of cysteines in Affibody molecules enables us to solve this problem by the introduction of a unique cysteine residue in a desirable position and the use of thiol-directed chemistry for labeling or chelator coupling.[5] This approach has been used for labeling of Affibody molecules with radiobromine,[6] radioiodine,[7] ^{18}F,[8,9] ^{99m}Tc,[10] ^{111}In,[11−13] ^{57}Co,[14] and ^{64}Cu.[15,16]

A maleimido derivative of the macrocyclic chelator DOTA was used for labeling of Affibody molecules with ^{111}In, ^{57}Co, and ^{64}Cu. The use of DOTA provides stable coupling of many nuclides to targeting proteins.[17] However, DOTA is not always the chelator of choice. For example, DOTA is a suboptimal chelator for copper isotopes due to in vivo instability.[18] The use of NOTA[19] or cross-bridged chelators[20,21] for labeling with radiocopper provides more stable labeling than the use of DOTA, as well as lower liver uptake. Moreover, different chelators influence in different ways the affinity of an imaging peptide, the cellular processing and retention of a radionuclide, the biodistribution of a targeting peptide, and the excretion pathways of a nonbound tracer and radiocatabolites.[22] This influences the sensitivity and specificity of the imaging. Therefore, several chelators should be evaluated for each targeting protein to select the most suitable for each particular application.

NOTA (2,2′,2″-(1,4,7-triazacyclononane-1,4,7-triyl)triacetic acid) is a promising chelator for labeling of targeting agents with a number of radiometals. NOTA provides more stable complexes with gallium and indium than DOTA.[23,24] Several NOTA derivatives have been used for labeling of targeting peptides with Ga isotopes[25−27] and ^{111}In.[25] Biodistribution data indicate adequate in vivo stability of the conjugates. The feasibility of ^{68}Ga-labeling of NOTA-conjugated peptides at room temperature within a reasonable time (10 min) has been shown.[28] Recently, a very elegant method for labeling of peptides with ^{18}F using the formation of [^{18}F]aluminum fluoride and its complexation with NOTA has been proposed.[29] Taken together, derivatives of NOTA are very promising chelators for radiolabeling of targeting proteins and peptides.



The goal of this study was to develop a maleimido derivative of NOTA (maleimide monoamide NOTA; MMA-NOTA), couple it to the HER2-binding Affibody molecule $Z_{HER2:2395}$ ([Ala^1, Glu^2,Thr^{23},Val^{59},Asp^{60},Cys^{61}]$Z_{HER2:342}$) having a C-terminal cysteine, and evaluate the ^{111}In-labeled conjugate in vitro and in vivo. ^{111}In is a widely used nuclide for single-photon emission tomography (SPECT). Indium forms stable hexacoordinate complexes with NOTA in aqueous solutions.[30] Although one carboxylic arm of NOTA participates in an amide bond in the case of MMA-NOTA, it was demonstrated earlier that the amide carbonyl oxygen can contribute to stable chelation of indium.[31]

MATERIALS AND METHODS

Material. $Z_{HER2:2395}$, a variant of $Z_{HER2:342}$ having a C-terminal cysteine, was produced according to Ahlgren and coworkers.[11] The commercially available (4,7-bis-*tert*-butoxycarbonylmethyl-[1,4,7]triazonan-1-yl)-acetic acid (NOTA(tBu)$_2$) was provided by CheMatech (Dijon, France). MMA-DOTA was purchased from Macrocyclics (Dallas, TX, USA). The purity and identity of all macromolecules and their conjugates was confirmed using high-performance liquid chromatography with on-line mass spectrometric detection, as described below. All purified proteins demonstrated a single peak with a mass coinciding with the theoretical molecular weight calculated with an accuracy of ±1.5 Da, which is within the accuracy of the instrument. Buffers, such as 0.1 M phosphate buffered saline (PBS), pH 7.5, and 0.2 M ammonium acetate, pH 6.5, were prepared using common methods from chemicals supplied by Merck (Darmstadt, Germany). High-quality Milli-Q water (resistance higher than 18 MΩ/cm) was used for preparing solutions. Buffers, which were used for conjugation and labeling, were purified from metal contamination using 2−3 g Chelex 100 resin per liter (Bio-Rad Laboratories, Richmond, CA, USA). NAP-5 size exclusion columns were from GE Healthcare Bio-Sciences (Uppsala, Sweden). [^{111}In]indium chloride was purchased from Covidien. The yield and radiochemical purity of the labeled Affibody constructs were analyzed using 150−771 dark

green, Tec-Control chromatography strips from Biodex Medical Systems (New York, USA). The accuracy of radio-ITLC analysis was cross-validated by SDS-PAGE. Ketalar [ketamine] (50 mg/mL, Pfizer, NY, USA), Rompun [xylazin] (20 mg/mL, Bayer, Leverkusen, Germany), and Heparin (5000 IE/mL, Leo Pharma, Copenhagen, Denmark) were obtained commercially. The radioactivity was measured using an automated gamma counter with a 3-inch NaI(Tl) detector (1480 WIZARD, Wallac Oy, Turku, Finland). Distribution of radioactivity along the thin layer chromatography strips was measured on a Cyclone Storage Phosphor System and analyzed using the *OptiQuant* image analysis software. Cells were counted using an electronic cell counter (Beckman Coulter). Data on cellular uptake and biodistribution were analyzed by unpaired, two-tailed *t*-test using *GraphPad Prism* (version 4.00 for Windows GraphPad Software, San Diego, USA) in order to determine any significant differences ($P < 0.05$).

Synthesis and Characterization of ((4-Carboxymethyl-7-{[2-(2,5-dioxo-2,5-dihydro-pyrrol-1-yl)-ethylcarbamoyl]-methyl}-[1,4,7]triazonan-1-yl)-acetic acid) (MMA-NOTA, compound 3) (Scheme 1). Mass spectra were recorded on a Bruker Micro ToFQ Instrument in electrospray ionization (ESI) mode. NMR spectra were recorded on a 300 MHz BRUKER Avance spectrometer. Measurements were made using the "Plateforme d'Analyse Chimique et de Synthèse Moléculaire de l'Université de Bourgogne" (PACSMUB).

N,N-Diisopropylethylamine (DIPEA, 63 mg, 48 mmol, Acros, Geel, Belgium) was added to a solution of 100 mg (0.24 mmol) of NOTA(tBu)$_2$ (**1**), 97 mg (0.25 mmol) of 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate, (HBTU, Iris Biotech, Maktrewitz, Germany), 39 mg (0.29 mmol) of hydroxybenzotriazole (HOBt) (Sigma-Aldrich, Saint Quentin Fallavier, France), and 67 mg (0.25 mmol) of *N*-(2-aminoethyl)maleimide (Sigma-Aldrich, Saint Quentin Fallavier, France) in 12 mL of CH_2Cl_2 (Sigma-Aldrich, Saint Quentin Fallavier, France). The mixture was stirred at room temperature for 12 h. The solution was then diluted with 100 mL of CH_2Cl_2 and washed with 30 mL of 2.2 mM citric acid, 30 mL of an aqueous solution of $NaHCO_3$ (5%), and 50 mL of water. The organic phase was dried on $MgSO_4$ (Acros, Geel, Belgium), and the solvent was removed under vacuum. The residue, a yellow oil, was dissolved in 50 mL of diethyl ether (Sigma-Aldrich, Saint Quentin Fallavier, France). The white precipitate formed after filtration, and diethyl ether was removed under vacuum. The remaining oil was purified by chromatography (SiO_2, CH_2Cl_2, then EtOH/CH_2Cl_2 5/95 to 10/90). Compound **2** was obtained as a pale yellow oil (m = 80 mg, yield = 62%).

NMR ^{1}H ($CDCl_3$, 298 K, 300 MHz): δ 1.45 (s, 18H), 2.60 (br, 4H), 2.83 (br, 8H), 3.19 (s, 2H), 3.32 (S, 4H), 3.45 (m, 2H), 3.61 (m, 2H), 6.67 (s, 2H), 9.15 (s, 1H). ESI-MS m/z: calcd [MH]+, 537.32; found 537.33. Anal. ($C_{26}H_{43}N_5O_7$) C,H,N: calcd C, 58.08; H, 8.06; N, 13.03; found C, 57.83; H, 7.88, N, 12.77.

For deprotection, trifluoroacetic acid (TFA, 290 μL) was added to a solution of 38 mg of **2** in 192 μL of CH_2Cl_2. The mixture was stirred at room temperature for 24 h. The solvents were removed by heating under vacuum at maximum 35 °C. When the evaporation was almost complete, 10 mL of diethyl ether was added. A white precipitate was formed, filtered, and washed several times with diethyl ether. Compound **3** was obtained as a white hygroscopic powder (m = 10 mg).

NMR ^{1}H (D_2O, 298 K, 300 MHz): δ 3.07 (t, 4H, J = 5.6 Hz), 3.25 (t, 4H, J = 5.6 Hz), 3.32 (s, 4H), 3.42 (m, 2H), 3.59 (s, 2H), 3.64 (m, 2H), 3.92 (s, 4H). ESI-MS m/z: calcd [MH]+ 426.20; found 426.19. Anal. ($C_{18}H_{27}N_5O_7$, 1.5TFA) calcd C, 50.82; H, 6.40; N, 16.40; found C, 50.61; H, 6.21; N, 16.19.

Coupling of MMA-NOTA (3) to Affibody Molecules and Characterization of Conjugate (Scheme 2). Conjugation of MMA-NOTA (**3**) to $Z_{HER2:2395}$ was performed similarly to the coupling of MMA-DOTA described earlier.[11] Briefly, $Z_{HER2:2395}$ (stock solution, 5 mg/mL) was incubated during 2 h in 30 mM DTT at 40 °C to reduce any spontaneously formed disulfide bonds. After incubation, the reduced $Z_{HER2:2395}$ was purified using a NAP-5 column pre-equilibrated and eluted with degassed 0.2 M ammonium acetate, pH 6.5. The solution of freshly reduced Affibody molecules was mixed with a precalculated amount of a freshly prepared solution of MMA-NOTA in 0.2 M ammonium acetate, pH 6.5, (1 mg/mL) to obtain a chelator-to-protein ratio of 1:1 or 3:1. The vial was filled with argon gas, and the mixture was incubated at 40 °C for 2 h.

The coupling efficiency was determined using analytical RP-HPLC (Agilent 1200 series) with a Zorbax 300SB-C18 4.6 × 150 mm column with 3.5 μm particle size (Agilent, Santa Clara, CA, USA). A flow rate of 1 mL/min and a gradient of 25−45% B over 25 min (solvent A = 0.1%TFA-H_2O and solvent B = 0.1%TFA-CH_3CN) were used for analysis. The Affibody molecule conjugated with a chelator-to-protein ratio of 3:1 was purified for further experiments by semipreparative RP-HPLC, using a Reprosil Gold 300 C18 10 × 250 mm column with 5 μm particle size (Dr. Maisch, HPLC, GmbH, Ammerbuch, Germany). The flow rate was 2.5 mL/min and the gradient the same as above. The purified fraction was then analyzed by analytical RP-HPLC, as described above. The degree of conjugation as well as the final purity of the purified conjugate were determined by integrating the area of the peaks in the HPLC elution profiles. The molecular weights were determined by ESI-Q-TOF (Agilent).

The binding kinetics of the purified [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ Affibody molecule were investigated by real-time biospecific interaction analysis, using BIAcore 3000 (GE Healthcare, Uppsala, Sweden). The binding kinetics of [MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ and parental $Z_{HER2:342}$ were investigated at

the same time, to avoid intra-assay variability. Human HER2-ECD (R&D systems, Minneapolis, MN, USA), recombinantly produced as an Fc-chimera, was diluted to 5 μg/mL in 10 mM NaOAc, pH 4.5, and immobilized by EDC/NHS-mediated coupling on a carboxymethylated dextran-coated CM5 chip. A flow cell activated with EDC/NHS and deactivated with ethanolamine was used as reference. All samples were diluted in HBS-EP buffer (10 mM HEPES, 150 mM NaCl, 3.4 mM EDTA, 0.05% Tween20, pH 7.2) and analyzed in duplicate in 6 concentrations ranging from 0.3 nM to 10 nM at a flow rate of 50 μL/min with a 5 min association phase and a 10 min dissociation phase. After each cycle. 15 mM HCl was injected to regenerate the surface. The final response was calculated by subtracting the reference surface, and the kinetic analysis was performed using *BIAevaluation 4.1* software using a 1:1 Langmuir model.

In order to measure the melting point of the [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ conjugate, variable temperature measurements were performed using a JASCO J-810 instrument (JASCO, Tokyo, Japan). The sample was diluted to 0.5 mg/mL in PBS (pH 7.2) and measured at 221 nm in a 1 mm optical cuvette. The temperature was increased by 5 °C/min ranging from 20 to 90 °C. The secondary structure was determined at 20 °C before and after melting point measurements using circular dichroism (CD) with wavelengths ranging from 195 to 250 nm.

Labeling [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ with ^{111}In. To establish the optimum labeling temperature, a solution of [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ (30 μg, 4 nmol) in 54 μL 0.2 M ammonium acetate, pH 5.5, was mixed with 40 μL ^{111}In chloride solution (15 MBq at calibration time). The mixture was incubated at room temperature, 40 or 60 °C. At 10, 20, and 30 min after the start of the incubation, a small aliquot (0.8 μL) of reaction mixture was taken and analyzed by radio-ITLC eluted with 0.2 M citric acid, pH 2.0. In this system, radiolabeled Affibody molecules remain at the application point while free ^{111}In or ^{111}In-chelates migrate with the solvent front. The analytical system was verified using a blank experiment, where no Affibody molecule was added to the reaction mixture. Blank experiments showed that less than 0.5% of radioactivity remained at the application point of ITLC. The experiments were performed at least in duplicate. For further experiments (stability tests, in vitro and in vivo studies), labeling at 60 °C during 30 min was selected.

An EDTA-challenge test was performed to evaluate the labeling stability of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$. Two samples were diluted with a 1000-fold molar excess of the disodium salt of EDTA solution in water, while two control samples were diluted with equal amount of PBS. After four-hour incubation at room temperature, all samples were analyzed using radio-ITLC.

Labeling of [MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ with ^{111}In for comparative biodistribution experiments was performed as described by Ahlgren and co-workers.[11]

In Vitro Studies. For cell studies, the HER2-expressing ovarian carcinoma SKOV-3 (1.2×10^6 HER2 receptors per cell[32]) and prostate carcinoma DU-145 cell line ($\sim 5 \times 10^4$ HER2 receptors per cell, A. Orlova, unpublished results) (ATCC, purchased via LGC Promochem, Borås, Sweden) were used. The cell lines were cultured in RPMI medium (Flow Irvine, UK) supplemented with 10% fetal calf serum (Sigma, USA), 2 mM L-glutamine, and PEST (penicillin 100 IU/mL and 100 μg/mL streptomycin), all from Biokrom AG, Germany.

An in vitro specificity test was performed according to the methods described earlier.[33] Briefly, a solution of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ (0.015 ng protein per dish, 2 nM) was added to six Petri dishes (ca. 10^6 cells in each). For blocking, an excess of nonlabeled recombinant $Z_{HER2:342}$ (2.5 μg) was added 10 min before [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ to saturate the receptors. The cells were incubated during one hour in a humidified incubator at 37 °C. Thereafter, the media was collected, the cells were detached by trypsin-EDTA solution, and the radioactivity in cells and media was measured to calculate a percentage of cell-bound radioactivity.

A comparison of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ internalization by DU-145 cells was performed according to the method developed and validated by Wållberg and Orlova.[33] The cells (ca. 10^6 per dish) were incubated with the labeled compounds (0.015 ng protein per dish, 2 nM) at 37 °C, 5% CO_2. At predetermined time points (1, 2, 3, 4, and 8 h after incubation start), the media from a set of three dishes was removed and the cells were washed three times with ice-cold serum-free medium. The cells were then treated with 0.5 mL 0.2 M glycine buffer with 4 M urea, pH 2.5, for 5 min on ice. The acidic solution was collected and the cells were washed additionally with 0.5 mL glycine buffer, which was collected and pooled with the first fraction. The radioactivity in the acid wash fractions was considered as membrane-bound radioactivity. After addition of 0.5 mL 1 M NaOH, cells were incubated at 37 °C for 0.5 h before the alkali containing cell debris was collected. The cell dishes were washed with an additional 0.5 mL NaOH, and the alkaline fractions were pooled. The radioactivity in the alkaline fractions was considered internalized. A percent of internalized radioactivity was calculated for each time point.

Animal Studies. The animal experiments were planned and performed in accordance with the national regulation on laboratory animals' protection. The animal study plans have been approved by the local Ethics Committee for Animal Research in Uppsala. Nude male NMRI nu/nu mice bearing DU-145 prostate cancer xenografts were used. The mice were kept using standard sterile diet, bedding, and environment with free access to food and water. The mice were acclimatized for one week at the Rudbeck Laboratory animal facility before any experimental procedures. For tumor implantation, 5×10^6 DU-145 cells in Matrigel (BD Bioscience) were implanted on the right flank. Average tumor weight was 0.67 ± 0.26 g at the time of experiment. Average animal weight was 30 ± 2 g.

The mice were randomized into groups of four. Animals were injected intravenously (tail vein) with 0.3 μg conjugate (50 kBq) in 100 μL PBS. At four hours after injection, a mixture of Ketalar—Rompun (20 μL of solution per gram body weight; Ketalar, 10 mg/mL; Rompun, 1 mg/mL) was intraperitonealy injected and the mice were euthanized by a heart puncture using a 1 mL syringe, prewashed with diluted heparin (5000 IE/mL). Blood as well as lung, liver, spleen, kidneys, tumor, samples of muscle and bone, gastrointestinal tract (with its content), and remaining carcass were collected in preweighed plastic vials. Organs and tissue samples were weighed and measured for radioactivity using an automatic gamma counter. The tissue uptake values were calculated as percent injected activity per gram tissue (% ID/g), except for the gastrointestinal tract and the carcass, which were calculated as % ID per whole sample. The radioactivity in the gastrointestinal tract with its contents was used as a measure of hepatobiliary excretion.

To confirm that the xenograft accumulation of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was HER2-specific, the receptors in one

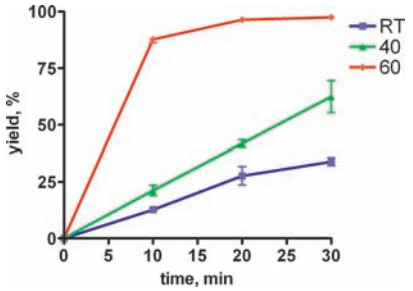

Figure 1. Labeling yield of [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ with ^{111}In in 0.2 M ammonium acetate buffer, pH 5.5, as a function of time at different temperatures. Data are presented as mean values of the results of two to eight experiments ± standard deviations.

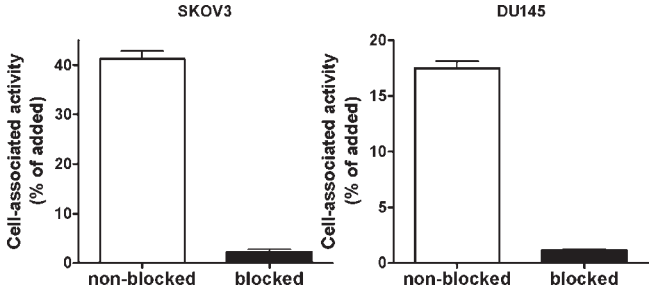

Figure 2. Cell-binding specificity of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ labeled at 60 °C during 30 min. The test was performed with ovarian cancer cell line SKOV-3 and prostate cancer cell line DU145. In the blocking experiment, binding sites were saturated by adding to the cells an excess of nonlabeled $Z_{HER2:342}$. Data are presented as mean values for three samples ± maximum errors.

group of mice were presaturated by subcutaneous injection of 500 μg of unlabeled $Z_{HER2:342}$ 60 min prior to the injection of radiolabeled Affibody molecule, while another group was injected with [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ without preblocking. For comparison, the biodistribution of [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ was studied in DU-145 xenograft-bearing mice.

For gamma camera imaging, two DU-145 xenograft-bearing mice were injected with 2 MBq ^{111}In-[MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ (amount of protein 1 μg). Four hours post-injection, the animals were sacrificed by overdosing Ketalar/Rompun followed by cervical dislocation. After euthanasia, the urine bladders were excised and cadavers were stored on ice until imaging. Imaging was performed at the department of Nuclear Medicine at Uppsala University Hospital using a GE Infinia gamma camera equipped with a medium energy general purpose (MEGP) collimator. Static images (40 min), obtained with a zoom factor of 2, were digitally stored in a 256 × 256 matrix. The evaluation of the images was performed using the *Osiris 4.19* software (University Hospital of Geneva, Switzerland). In each animal, a region of interest (ROI) was drawn around the tumor. The same region was copied to a contralateral thigh. Tumor-to-contralateral thigh ratios were calculated based on total counts in the ROIs.

RESULTS

Coupling of MMA-NOTA and Characterization of Conjugate. The degree of MMA-coupling to the Affibody molecules was determined by RP-HPLC analysis. Conjugation of MMA-NOTA to $Z_{HER2:2395}$-Cys using a chelator-to-protein ratio of 1:1 resulted in 49% conjugated protein, 3% nonconjugated disulfide-linked dimeric protein and the remaining found as nonconjugated monomeric protein. Increasing the chelator-to-protein molar ratio to 3:1 resulted in 80% of MMA-NOTA-conjugated $Z_{HER2:2395}$, while 17% was found as dimeric nonconjugated protein. The purification of [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ by RP-HPLC provided a product with 96% purity. This protein was used for further analysis.

Binding analyses of the conjugated molecules were performed using SPR-based biosensor interaction. The dissociation constant (K_D) for the interaction between the Affibody conjugate and the extracellular domain of the HER2 receptor (recombinantly produced as an Fc-chimera) was calculated to be 72 pM from the association rate constant (k_a) and the dissociation rate constant (k_d). In the same experiment, the dissociation constants for [MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ and parental $Z_{HER2:342}$ were determined to be 74 pM and 78 pM, respectively.

The secondary structure determined by CD spectra showed α-helical content both before and after variable temperature measurements, indicating that the molecule refolds after heat treatment. The melting point of [MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ was determined to be 68 °C.

Labeling [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ with ^{111}In. The kinetics of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ formation at different temperatures is presented in Figure 1. The labeling at room temperature was inefficient. Increasing the reaction temperature to 40 °C improved the yield; however, the analytical radiochemical yield was only 62 ± 7% (n = 3) after 30 min incubation. Further temperature increase to 60 °C resulted in an increase of the radiochemical yield to 97.5 ± 0.5% (n = 12) within 30 min. For further experiments, the [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was labeled at 60 °C and used without further purification. Conjugates with a specific radioactivity of 14.5 GBq/μmol (2 MBq/μg) were obtained with the yield of more than 95% (labeling at 60 °C), when indium-111 was used for labeling three days after production.

The stability of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was evaluated by challenge with a 1000-fold molar excess of EDTA over 4 h. The EDTA challenge demonstrated very high labeling stability. The radiochemical purity of the treated samples was 96.2 ± 0.6% (average ± SEM), while the purity of the untreated control was 98.7 ± 0.1%, i.e., the difference was within the accuracy of the analytical method.

In Vitro Studies. Binding specificity tests demonstrated that the binding of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ to living HER2-expressing cells was receptor-mediated, because saturation of the receptors by preincubation with nonlabeled $Z_{HER2:342}$ significantly decreased the binding of the radiolabeled Affibody molecule (for all studied cell-lines, $p < 0.0001$) (Figure 2). The level of cell-associated radioactivity was appreciably lower for the nonblocked DU-145 cell line than for the SKOV-3 cell line, reflecting the lower expression level of HER2.

A comparison of the internalization of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ by DU-145 prostate cancer cells is presented in Figure 3. The internalization of both compounds was relatively slow, although internalized fractions increased continuously throughout the experiment. The internalization rate of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was slightly higher than the rate of [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$. After 8 h incubation, 27 ± 1% and 21.5 ± 0.6% of the cell-associated radioactivity was internalized for ^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$, respectively.

Animal Studies. In order to verify the specificity of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ accumulation in HER2-expressing DU-145 xenografts, its biodistribution (4 h pi) was studied after saturating the binding epitope of HER2 by preinjection of a large excess of nonlabeled $Z_{HER2:342}$ (Figure 4). The tumor uptake was reduced from 8.3 ± 1.0% to 0.53 ± 0.5% IA/g ($p < 0.0001$), demonstrating specificity of HER2 targeting.

A comparison of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ biodistribution is presented in Figure 5. Tumor targeting was equally efficient for both variants, and there was no significant difference in the tumor radioactivity accumulation. Both conjugates demonstrated rapid clearance from blood and the majority of normal organs and tissues. The renal excretion was dominating, which resulted in a low radioactivity accumulation in the gastrointestinal tract but high accumulation in kidneys due to reabsorption. There were, however, certain differences in biodistribution of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$. Radioactivity cleared more rapidly from blood in the case of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$. Significantly ($p < 0.005$) lower radioactivity concentration was also found in lung, liver, spleen, kidney, and bone (Figure 5a). Accordingly, [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ provides significantly higher tumor-to-blood, tumor-to-lung, tumor-to-spleen, tumor-to-muscle, and tumor-to-bone ratios (Figure 5b).

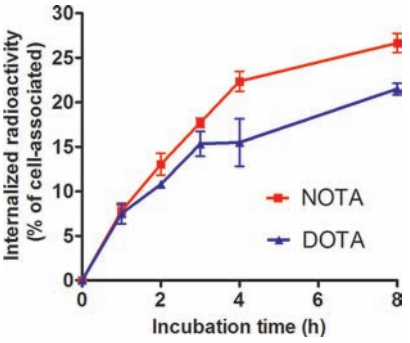

Figure 3. Internalization of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ by HER2-expressing DU-145 cell line. Cells were incubated with radiolabeled Affibody molecules at 37 °C. Data presented as a percentage of internalized radioactivity (an average of three samples with standard deviations); error bars might be not seen because they are smaller than the symbols.

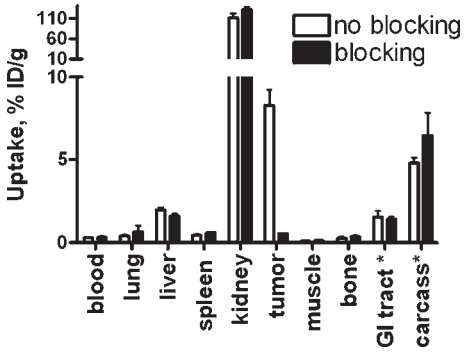

Figure 4. Specificity of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ uptake in DU-145 xenografts 4 h after injection. To saturate HER2 in tumors, a group of animals in the blocking experiment was preinjected with 500 μg of nonlabeled $Z_{HER2:342}$ 60 min before injection of radiolabeled conjugate (designated as blocked). All animals were injected with 0.3 μg of labeled Affibody molecules. Data are expressed as %ID/g and are presented as mean ± SD for 4 animals. * Data for GI tract (with content) and carcass are presented as %ID per whole sample.

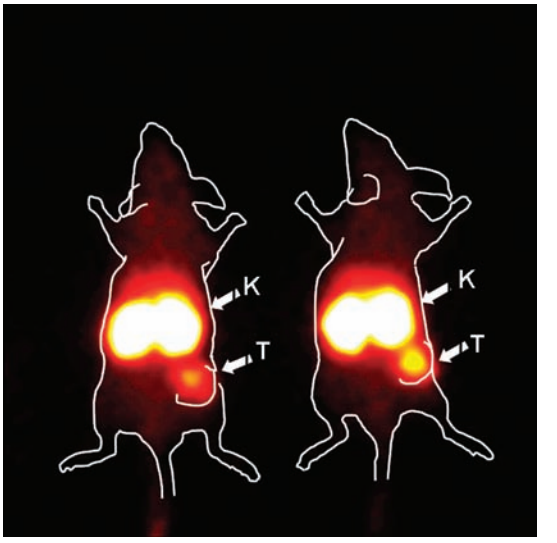

Figure 6. Anterior gamma camera images of nude mice bearing DU-145 xenografts 4 h after injection of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$. Contours derived from a digital photograph were superimposed over gamma camera images to facilitate interpretation. Arrows point at tumors (T) and kidneys (K).

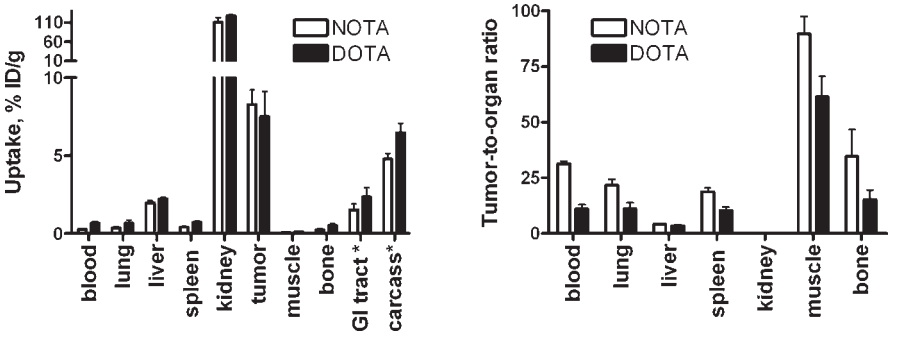

Figure 5. Comparison of targeting of DU-145 xenografts using [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$. Data are presented as an average from four animals ± SD. Left panel: Biodistribution 4 h p.i. Data are expressed as % ID/g. *Data for the gastrointestinal tract (with its content) and for carcass are presented as % ID per whole sample. Right panel: Tumor-to-organ ratios 4 h p.i.

dx.doi.org/10.1021/bc100470x |*Bioconjugate Chem.* 2011, 22, 894–902

Images acquired four hours after the i.v. injection of the [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ into mice bearing DU-145 xenografts confirmed the capacity of this conjugate to visualize HER2-expression (Figure 6). In agreement with the biodistribution data, a prominent radioactivity uptake was observed in the kidneys. No radioactivity accumulation in other healthy organs and tissues was observed. Tumors were clearly visualized already at 4 h p.i. (tumor-to-contralateral side ratio 8.3 ± 0.8).

DISCUSSION

Currently, a major approach for the treatment of disseminated cancer is based on identification of molecular abnormalities causing malignant transformation of cells and molecular recognition of such abnormalities for selective treatment of cancer while sparing healthy tissues. One such abnormality is the overexpression of the transmembrane tyrosine kinase HER2, which is widely used as a target for different therapeutic strategies mainly in breast cancer.[34,35]

Expression of HER2 has also been suggested as one of the possible molecular pathways to androgen independence of prostate cancer.[36] Preclinical data suggest that HER2-targeting therapies can be efficient against androgen-independent prostate cancer.[37,38] However, treatment of prostate cancer with the HER2-targeting monoclonal antibody trastuzumab or the tyrosine kinase inhibitor lapatinib has failed to demonstrate efficacy in clinical trials.[39−41] The failure of these trials was attributed to the absence of patient stratification according to the HER2 expression level.[39] Since only a fraction of tumors express HER2, the patients should be stratified according to expression levels to select those who would most likely benefit from HER2-targeting therapy. This would make cancer treatment more personalized and, thus, more efficient. Radionuclide molecular imaging is a promising way to detect the HER2 expression level, since it is noninvasive and may overcome issues associated with heterogeneity of HER2 expression in primary tumors and metastases.[42] However, due to the relatively low level of HER2 expression in prostate cancer (Human Protein Atlas, http://www.proteinatlas.org/), further perfection of the radionuclide imaging probes is desirable.

Comparison of preclinical literature data suggests that small targeting agents provide higher tumor-to-organ ratios of radioactivity concentration and, for this reason, higher sensitivity of HER2 detection.[42] Particularly, Affibody molecules have demonstrated superior imaging properties in comparison with monoclonal antibodies and their fragments due to small size (7 kDa) and picomolar affinity. Direct head-to-head comparison of the ^{124}I-labeled anti-HER2 Affibody molecule $Z_{HER2:342}$ and the anti-HER2 antibody trastuzumab confirmed conclusions derived from literature data.[43] However, further improvement of imaging sensitivity is required, particularly for visualization of tumors with relatively low HER2 expression level, such as in castration-independent prostate cancer.

Besides selection of optimal targeting proteins, optimization of labeling chemistry might improve the sensitivity of radionuclide molecular imaging, as labeling chemistry can influence the targeting properties of an imaging agent.[22] NOTA and its derivatives seem to be attractive chelators for labeling of targeting proteins because of the versatility and high stability of the chelates with a number of nuclides suitable for imaging.

The use of site-specific labeling is essential, since this provides uniform biodistribution properties of the radiolabeled conjugates.[7] To provide site-specific chelator coupling, a cysteine was engineered at the C-terminus of anti-HER2 Affibody molecule $Z_{HER2:342}$, providing an Affibody molecule $Z_{HER2:2395}$ with a unique binding site for thiol-directed coupling of chelators.[11] To use this approach for NOTA coupling, a maleimido derivate of NOTA was developed in this study.

The synthesis of MMA-NOTA is based on a commercially available precursor NOTA(tBu)$_2$. It is straightforward and provides a reasonable overall yield of ∼20%. MMA-NOTA was efficiently coupled to prereduced $Z_{HER2:2395}$. Importantly, coupling of this chelator did not cause any measurable decrease of $Z_{HER2:2395}$ affinity to HER2 (the observed difference in K_D for [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$, [MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$, and parental $Z_{HER2:342}$ was within the accuracy of the SPR method). This preservation of affinity is essential for targeting of cancer with low level of HER2 overexpression, such as prostate cancer. CD spectra have demonstrated that the coupling of MMA-NOTA does not prevent accurate refolding of [MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ after heat treatment, permitting the use of elevated temperatures for the labeling reaction. This was essential, since efficient labeling with ^{111}In required some moderate (up to 60 °C) warming (Figure 1). Literature data suggest that warming (up to 70 °C) is required also for labeling of NOTA with copper radioisotopes.[19] In agreement with CD data, [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was capable of specific binding to HER2-expressing cells after labeling at 60 °C (Figure 2).

It has been shown earlier that different chelators have different influence on the internalization rate of radiolabeled peptides, e.g., somatostatin analogues, by cancer cells.[44−46] Previous data indicated that internalization of $Z_{HER2:342}$ and its derivatives, including $Z_{HER2:2395}$, by HER2-expressing cancer cell lines is slow and that the influence of a chelator on the internalization rate is small.[10,11,33] However, our latest data suggested that internalization of [^{99m}Tc(CO)$_3$]$^+$-labeled $Z_{HER2:342}$ can depend on the nature of histidine-containing chelators.[47] The current study is another demonstration of the influence of the chelator on the internalization rate of Affibody molecules. Though the overall internalization rate of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ was still slow (27 ± 1% of cell-bound radioactivity was internalized at 8 h), it was higher than the internalization of [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ (21.5 ± 0.6% internalized at 8 h) (Figure 3). The internalization of tracers labeled using residualizing radiometals is considered an important and useful factor for the accumulation of radiotracer in a cancer cell,[48] so the increased internalization rate is a positive influence of maleimido-NOTA on the targeting properties of $Z_{HER2:2395}$.

The excellent binding properties of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ enables specific targeting of DU-145 prostate cancer xenografts, despite the relatively low HER2 expression of this cell line (Figure 5). Gamma camera experiments confirmed the results of the biodistribution studies demonstrating clear visualization of DU-145 xenografts 4 h p.i. (Figure 6). This was achieved despite location of the xenografts close to the kidneys, an organ with a high level of radioactivity accumulation.

The targeting properties of [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ and [^{111}In-MMA-DOTA-Cys^{61}]-$Z_{HER2:2395}$ were compared in nude mice bearing DU-145 prostate cancer xenografts (Figure 5). There was no significant difference between these conjugates in accumulation of radioactivity in tumors. However, [^{111}In-MMA-NOTA-Cys^{61}]-$Z_{HER2:2395}$ cleared more rapidly from blood, lung, liver, and spleen. Bone uptake of

radioactivity was also lower for this conjugate. This is important in the case of prostate cancer, where bones are the major metastatic site. This resulted in significantly higher tumor-to-organ ratios in the case of NOTA-conjugated Affibody molecules. This should provide better contrast on HER2 imaging and, hopefully, better sensitivity in clinical settings.

Apparently, the use of MMA-NOTA is not limited to site-specific labeling of Affibody molecules. Advantages of this chelator, such as high complex stability and thiol-directed site-specific labeling, can be used for development of a variety of targeting agents, such as scaffold-based affinity proteins and Fab′ antibody fragments.

In conclusion, MMA-NOTA is a very promising bifunctional chelator for thiol-directed site-specific labeling of Affibody molecules and other targeting proteins for in vivo radionuclide molecular imaging.

Site-Specific Modification of Recombinant Proteins: A Novel Platform for Modifying Glycoproteins Expressed in *E. coli*

Grant E. Henderson Kevin D. Isett and Tillman U. Gerngross*

ABSTRACT:

The site-specific modification of proteins is expected to be an important capability for the synthesis of bioconjugates in the future. However, the traditional repertoire of reactions available for the direct modification of proteins suffers from lack of specificity, necessitating costly downstream processing to isolate the specific species of interest.[1] Here, we use a well-established, glycan-specific chemistry to PEGylate model glycoproteins, each containing a unique reactive GalNAc attached to a specifically engineered threonine residue. By engineering *E. coli* to execute the initial steps of human, mucin-type O-glycosylation, we were able to obtain homogeneous site-specifically modified glycoproteins with fully human glycan linkages. Two mucin-based reporters as well as several fusion proteins containing eight-amino-acid GalNAc-T recognition sequences were glycosylated in this engineered glycocompetent strain of *E. coli*. The use of one sequence in particular, PPPTSGPT, resulted in site-specific glycan occupancy of approximately 69% at the engineered threonine. The GalNAc present on the purified glycoprotein was oxidized by galactose oxidase and then coupled to hydroxylamine functionalized 20 kDa PEG in the presence of aniline. The glycoprotein could be converted to the PEGylated product at approximately 85% yield and >98% purity as determined by comparison to the products of control reactions.

INTRODUCTION

To date, modification of proteins at naturally occurring functional groups has been the predominant strategy for the synthesis of bioconjugates.[1] However, complications arise when proteins contain multiple reactive sites and/or have a reactive conjugation site near the active site. Traditionally, these problems have been solved by simply removing the reactive residues to convert the protein to a more suitable starting material or controlling the reaction to promote selectivity for the desired product. This process can be time-consuming and unreliable; therefore, new methods for protein modification are required. In order to improve upon traditional protocols, new methods should provide control over the conjugation reaction with minimal disruption of protein structure. This goal can be achieved through the selective targeting of bioorthogonal groups which have been engineered at desired locations within proteins of interest.[2−5] The targeting of glycans for chemical modification is not unprecedented. In particular, metabolic labeling of glycan structures through the use of chemically modified monosaccharides has found use in basic research involving the detection and characterization of glycosylation events *in vivo* [6−8] and likely could be employed for the synthesis of therapeutic bioconjugates in the future. However, this technique is limited to cell types with endogenous glycosylation capabilities, which due to heterogeneity in glycan structure and localization are not necessarily ideal hosts for the production of glycoprotein precursors for bioconjugation.

Since aldehyde groups are typically absent in proteins and biocompatible aldehyde-specific reactions have been reported, we developed a new, glycosylation-based method to introduce

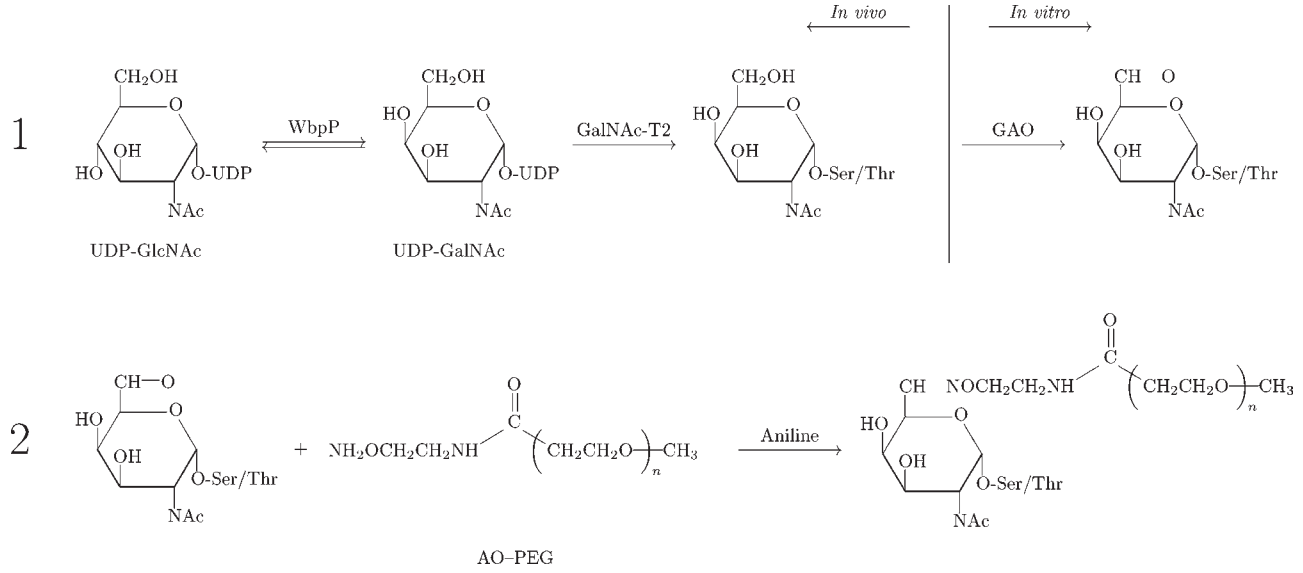

Figure 1. Reaction schematic: 1. The epimerization of UDP-GlcNAc to UDP-GalNAc by WbpP from *P. aerugosa* and transfer of GalNAc to Ser/Thr residues in *E. coli* followed by *in vitro* oxidiation by galactose oxidase resulting in aldehyde functionalized glycoproteins. 2. Subsequent nucleophilic addition of hydroxylamine-functionalized poly(ethylene glycol) in the presence of aniline.

aldehydes in a site-specific manner, resulting in the capability for site-specific protein modification. Although the functional groups typically found within proteins are not easily oxidized to carbonyls in a site-specific manner, the hydroxyls present on certain glycans *are* easily converted to aldehydes with high selectivity.[9−23] The use of galactose oxidase (GAO) in particular for the oxidation of glycoproteins is well-documented, but seems to have fallen out of use in favor of the alternative method of periodate oxidation of vicinal diols. Unfortunately, periodate can oxidize cysteine, methionine, tryptophan, tyrosine, and histidine residues regardless of their location within a protein, and serine and threonine are oxidized when located at the N-terminus. Furthermore, the subsequent labeling of periodate oxidized glycoproteins tends to result in heterogeneous product mixtures with higher than expected extents of conjugation.[19] In applications such as the modification of therapeutic proteins, where product homogeneity, structure, and function are extremely important, oxidation by GAO is preferred. Galactose oxidase is active toward several primary alcohols including but not limited to the C-6 hydroxyls of Gal and GalNAc.[24] While both the oxidation kinetics and equilibrium conversion have been reported to be affected by the microenvironment of the C-6 hydroxyl of the terminal sugar,[25] activity toward a diverse set of substituted Gal variants including both α- and β-linked GalNAc have been reported.[9,10]

The initiating step of mucin-type O-glycosylation in vertebrates involves the enzymatic transfer of GalNAc from UDP-GalNAc to certain serine and threonine residues of nascent glycoproteins resulting in proteins decorated with a single αGalNAc at the designated site. This basic process been studied extensively and the substrate requirements have been determined.[26,27] Nonpathogenic *E. coli* strains contain intracellular UDP-GlcNAc but not UDP-GalNAc; therefore, for cytoplasmic expression of GalNAc decorated glycoproteins, the initiating step of the mucin-type glycosylation pathway was reconstituted by coexpressing UDP-GlcNAc C-4 epimerase and UDP-GalNAc/polypeptide UDP-GalNAc transferase (GalNAc-T) along with a suitable target protein. The human GalNAc-T2 isoform was chosen for this study based on its relatively high *in vitro* activity and the abundance of information pertaining to potential O-glycosylation recognition sequence (OGRS).

In order to achieve mucin-type O-glycosylation in *E. coli*, we produced several reporter proteins, (i) a glutathione S-transfease/MUC1 fusion protein and (ii) a panel of OGRS peptides fused to human antibody fragments (Fabs) directed against TNF-α in a glycoengineered *E. coli* strain. In contrast to oligosaccharyltransferase-mediated transfer of N-glycans to asparagines within the recognition sequon Asn-X-Ser/Thr, which occurs *en bloc*, O-glycosyltransferases add sugars sequentially, requiring just the appropriate OGRS and UDP-GalNAc for the first addition. Gupta et al. have developed an OGRS database, O-GlycBase,[28] which has in the past been used to train computational neural networks for the prediction of O-glycosylation sites.[29,30] Although these programs can be used for generally predicting O-glycosylation sites, they cannot be used to model individual transferases due to the overlapping activities of the various GalNAc-T isoforms. To determine recognition sequence requirements for individual transferases, *in vitro* reactions involving purified enzymes and substrates are typically used[31−39] (a pH-based high-throughput assay for glycosyltransferase activity has been described, but it has not yet been used for the characterization of GalNAc-T isoforms[40]). Recently, the *in vitro* use of glycosyltransferases has been extended to engineering applications such as the generation of glycopeptide libraries[41] and use in bioconjugate chemistry.[42] To find a suitable OGRS for hGalNAc-T2, we evaluated a small subset of the OGRS present in *O-GlycBase* v 6.00 for use as glycosylation targets on recombinant proteins. Since GalNAc-T2 is an initiating transferase, only OGRS without trans-acting glycosylation sites were considered. The literature suggests that the eight amino acids from −3 to +4 relative to the glycosylated serine or threonine are involved in recognition by GalNAc-T. Ultimately, 17 eight-amino-acid sequences were selected. While this small library was by no means exhaustive, screening members for glycosylation resulted in the identification of an OGRS with relative high occupancy. In addition, this approach provides a simple

demonstration of the utility of O-glycocompetent *E. coli* for basic research on GalNAc-T substrate specificity.

Following the expression and purification of a glycosylated OGRS/Fab fusion protein selected from the library, we used a well-established glycan labeling technique to PEGylate the site-specifically placed *N*-acetylgalactosamine (GalNAc). In summary, this method entails enzymatic oxidation by GAO and reaction of the resultant aldehydes with hydroxylamine-functionalized molecules of interest in the presence of aniline to form stable oxime bonds (Figure 1). While this method has been used extensively for the labeling of glycoproteins, its use as a site-specific bioconjugation technique has been limited by the ability to produce homogeneously glycosylated proteins with unique oxidizable sugars. As previously discussed, we circumvented this problem by engineering *E. coli* with the ability to O-glycosylate proteins rather than using eukaryotic hosts, which typically contain an array of glycosylation modifications leading to numerous potentially reactive glycans. In contrast to previously reported techniques for glycoPEGylation,[42] the method reported here does not require an exogenous source of UDP-GalNAc and all enzymes and reagents are available from commercial sources.

EXPERIMENTAL PROCEDURES

Construction of the Glycosylation Helper Plasmid. An existing *BsaI* site was removed from the pUC19 origin and β-lactamase resistance marker by overlap PCR using oGH174 and oGH175 as flanking primers and oGH176 and oGH177 as internal overlapping primers (see Tables 1 and 2 for lists of primers and plasmids). The resulting DNA fragment contains *Eco*RI and *NcoI* sites at the 5′ and 3′ ends, respectively. The multiple cloning site from pGH11[43] was excised using *Eco*RI and *AscI*. A *BsmBI* site was removed from the lacI open reading frame by overlap PCR using oGH178 and oGH179 as flanking primers and oGH180 and oGH181 as internal overlapping primers. The resulting DNA fragment contains *AscI* and *NcoI* sites at the 5′ and 3′ ends, respectively. The three fragments were joined by triple ligation to make pMGV. The gene encoding polypeptide GalNAc transferase 2 was amplified from a human brain cDNA library using primers oGH119 and oGH120, which add *Bam*HI and *NotI* sites to the 5′ and 3′ ends, respectively. The PCR product was cloned between the *Bam*HI and *NotI* sites in pET21a(+) to make pET21GT2. The gene, along with the 6×His tag, was amplified from pET21GT2 using primers oGH199 and oGH200, which add *SacI* and *AgeI* sites to the 5′ and 3′ ends, respectively. The PCR product was cloned between the *SacI* and *AgeI* sites in pMGV to make pMGV(GT2). The gene encoding UDP-GlcNAc C-4 epimerase from *P. aeruginosa* was codon optimized for expression in *E. coli* and synthesized by DNA 2.0 (Menlo Park, CA) along with its endogenous promoter. The promoter and gene were amplified using primers oGH196 and oGH286, which add *NotI* and *AgeI* sites to the 5′

and 3′ ends, respectively. The PCR product was cloned between the *NotI* and *AgeI* sites in pMGV to make pMGV(wbpP). The 1.5 kb *AscI*/*SphI* fragment of pMGV(wbpP) was cloned between the *BsmBI* and *SphI* sites in pMGV(GT2) to make pMGV(GT2, wbpP). This plasmid encodes the GalNAc-T and epimerase necessary for glycosylation of target proteins in the *E. coli* cytoplasm.

Cloning and Expression of the GST-Mucin Fusion Reporter Protein. The tandem repeat region of mucin was amplified from pPB230 using oGH589 and oGH590 to add a *SacI* site to the 3′ end. GST was amplified from pGal1-GST using oGH528 and oGH529 to add an *NheI* site to the 5′ end. pBAD33(MC3) was amplified using oGH530 and oGH531 to add *SacI* and *XbaI* sites to the 5′ and 3′ ends, respectively. The PCR products were digested with the enzymes listed above and ligated to form pBAD33(MC3)GST::4×Muc1. Shuffle T7 Express (NEB, Ipswich, MA) was transformed with pBAD33(MC3)GST::4×Muc1 either alone or in combination with pMGV(GT2, wbpP). Transformants were grown to approximately 1 g/L DCW in 5 mL LB containing 25 g/L chloramphenicol and 100 g/L ampicillin prior to induction by addition of 62.5 μL 40% arabinose. Cultures were induced overnight, and cell pellets were harvested by centrifugation at 5000 *g* for 5 min. The pellets were resuspended in 0.5 mL PBS containing 1× complete, EDTA free protease inhibitor (Roche). The cells were lysed by ultrasonication and insoluble lysate was removed by centrifugation at 16 000 *g*. Soluble lysates were analyzed for glycosylation by Western blot using HRP-conjugated *Vicia villosa* lectin (EY Laboratories, San Mateo, CA).

Cloning of anti-TNFα Fab and Creation of OGRS Fusions. The genes encoding heavy and light chain of anti-TNFα Fab secreted via OmpA leader peptides were synthesized by overlap extension PCR using oligonucleotides, L1-L18 for light chain and H1−H18 for heavy chain.[44] The PCR products were cloned between the *SacI* and *AgeI* sites in pMGV. The light chain was amplified using primers oKI160 and oKI62, and the heavy chain was amplified using primers oKI158 and oKI161. The PCR products were digested with *SacI* (light) or *AgeI* (heavy) and cloned between the *SacI* and *AgeI* sites of pMGV. The leaders were removed by quick-change PCR using primers oKI458−461. The leaderless construct was amplified using oKI464 and oKI465, which add *Eco*RI and *SphI* sites to the 5′ and 3′ end, respectively. The PCR product was cloned between the *Eco*RI and *SphI* sites in pBAD33(MC3)[45] to make pBAD33-(MC3)TNFαFab. The mucin-based OGRS was added by quick-change PCR using phosphorylated primers, oKI481 and oKI482 to make pBAD33(MC3)TNFαFab00. All other OGRS were added by quick change PCR using a phosphorylated reverse primer, oGH601, and a nonphosphorylated forward primer (oGH602−618) encoding an OGRS to make pBAD33(MC3)OgTNF01−17.

Screening of Glycosylation Activity against a Panel of Selected OGRS. Shuffle T7 Express (NEB, Ipswitch, MA) was transformed with pMGV(GT2,wbpP) and pBAD33-(MC3)OgTNF## (where ## corresponds to the OGRS peptide fusion; see Table 3). anti-TNFα Fab was expressed identically to the GST-Mucin reporter described above. Soluble lysates were analyzed for glycosylation by Western blot using HRP-conjugated *Vicia villosa* lectin.

Expression and Purification of Glycosylated Fabs. sGH741 was grown at 30 °C to approximately 1 g/L DCW in 800 mL LB media containing 25 g/L chloramphenicol and 100 g/L ampicillin. To induce Fab expression, arabinose was added at a final concentration of 0.5% and the cultures were incubated at 30 °C for an additional 20 h. The cultures were centrifuged at 5000 *g* for 5 min, and the cell pellets were resuspended in 800 mL LB containing 25 g/L chloramphenicol, 100 g/L ampicillin, and 0.2% dextrose. The cultures were incubated at 30 °C for an additional 3 h. After the second incubation, the cultures were centrifuged at 5000 *g* for 5 min and the cell pellets were resuspended in 50 mL lysis buffer (100 mM Tris HCl, pH 7.4; 10 mM EDTA). The cells were incubated overnight at 50 °C with shaking. The 50 °C incubation disrupts the cell membrane and precipitates poorly assembled Fab. After the 50 °C incubation, the lysate was centrifuged at 12 000 *g* for 30 min. The supernatant was passed through a 0.45 μm filter prior to Fab purification by FPLC. Protein-L resin was equilibrated using 10 colume volumes of PBS at 1 mL/min prior to loading the soluble lysate. After loading, the column was washed with 10 column volumes of PBS and Fab was eluted in 50 mM glycine HCl, pH 3.0. The pH was immediately adjusted to 6.5 by addition of 1 M Tris, pH 8.0. Fractions containing Fab were pooled, concentrated to 4 g/L, and aliquoted into 100 μL fractions.

PEGylation of Recombinant Glycoproteins. Glycoproteins (100 μM) and 20 kDa Aminooxy-PEG (AO-PEG) (1 mM) were reacted at room temperature in 100 mM anilinium acetate, pH 4.6, for two hours. The products were separated by SEC-HPLC on an agilent 1200 series HPLC equipped with a Bio Sil SEC 250 column from BioRad. The fractions containing unreacted protein were pooled and suspended in 50 mM sodium phosphate, pH 7.4, at a concentration of 100 μM. The glycoproteins were incubated for 20 h at room temperature in the presence of 5 μM galactose oxidase. Oxidized glycoproteins were passed over a zeba spin column pre-equilibrated with anilinium acetate, pH 4.6, and reacted with 1 mM 20 kDa Aminooxy-PEG for one hour.

Analysis of PEGylated Proteins. PEGylation reactions were analyzed by RP-HPLC, MALDI-TOF, and SDS-PAGE. For RP-HPLC, reactions were loaded directly onto the column. Fractions containing reacted and unreacted protein were collected and analyzed by MALDI-TOF. For SDS-PAGE analysis, unreacted AO-PEG was removed by protein-L immunoprecipitation prior to loading. In a 1.5 mL microcentrifuge tube, 15 μL Protein-L agarose (GenScript) was washed three times with PBS. Then, the PEGylation reactions were added and the tubes were incubated at room temperature for three hours with shaking. The supernatant containing unreacted Aminooxy-PEG was discarded, and the protein-L resin was washed once with PBS. Proteins were eluted by boiling in SDS-Loading buffer (Invitrogen) containing 100 mM DTT for 10 min.

RESULTS

***In Vivo* Glycosylation of Mucin-Based Reporter Proteins.** While activity has been observed for recombinant GalNAc-T expressed in eukaryotic cells, a literature search did not identify any studies involving soluble expression of active GalNAc-T in prokaryotes. In our hands, human GalNAc-T2 could be expressed under the control of the T7 promoter in *E. coli* only when cultures were not induced with IPTG. A Western blot using HRP conjugated *Vicia villosa* lectin showed that the GST::4×Muc1

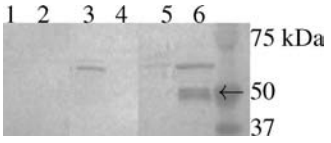

Figure 2. *Vicia villosa* lectin Western blot of the glycosylated mucin fusion protein: lane 1, UDP-GlcNAc C-4 epimerase only; lane 2, GST-Mucin coexpressed with UDP-GlcNAc C-4 epimerase; lane 3, GalNAc-T2 only; lane 4, GST-Mucin coexpressed with GalNAc-T2; lane 5, UDP-GlcNAc C-4 epimerase and GalNAc-T2; lane 6, GST-Mucin coexpressed with UDP-GlcNAc C-4 epimerase and GalNAc-T2. The arrow indicates the GST-Mucin fusion protein. Reactivity with vva lectin in lane 6 but not in lanes 1−5 shows that the reporter protein is only glycosylated in the presence of both epimerase and GalNAc-T2.

VRPTSAVA	human apolipoprotein C−III precursor	−

[a] − not glycosylated, + weak glycosylation, ++ moderate glycosylation, +++ strong glycosylation.

fusion protein was glycosylated in cells coexpressing GalNAc-T2 and epimerase, but not in the absence of either, indicating that the epimerase and transferase are required and sufficient to impart *E. coli* with the ability to O-glycosylate proteins *in vivo* (Figure 2). Detailed analysis of the GST::4×Muc1 was not done because the eight potential glycosylation sites present in this reporter likely would have complicated the analysis. However, fusion of a fifteen amino acid mucin-based peptide, CDNKPAPGSTAPPAA, to an anti-TNF-α antibody fragment also resulted in O-glycosylation as determined by Western blot. Analysis of this protein by LC/MS revealed an increase in molecular weight of 203 Da as is expected for addition of a single GalNAc (data not shown).

Screening OGRS Selected from O-GlycBase v 6.00. OGRS were selected from the OGlycBase database of mammalian O-glycoproteins. Several GalNAc-T isoforms are able to glycosylate nascent proteins, but others require prior glycosylation events. To enrich for OGRS that are recognized by initiating GalNAc-T isoforms, only sites that were separated from other

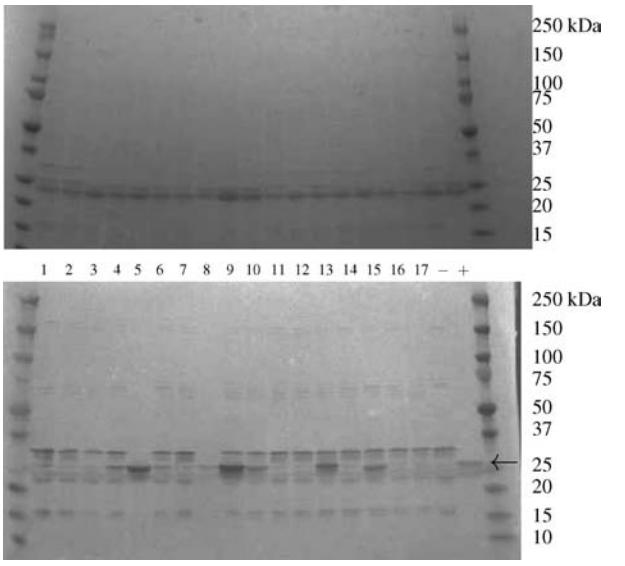

Figure 3. Coomasie stained SDS-PAGE (top) and *Vicia villosa* lectin Western blot (bottom) of Fab fused to OGRS #1−17: OGRS #1−17 were selected from O-GlycBase v 6.00 and fused to the C-terminus of Fab. The OGRS fusions were expressed in the glycocompetent *E. coli* strain and glycosylation was assessed by reactivity with vva lectin. The results of the screen are summarized in Table 4.

glycosylation sites by at least 30 amino acids were chosen. The selected OGRS were expressed as C-terminal fusions to the heavy chain of anti-TNF-α Fab separated by a single Gly-4-Ser linker. The fusion proteins were expressed in glycocompetent *E. coli* and reporters were screened for glycosylation by Western blot using VVA-lectin HRP conjugate, which is specific for terminal GalNAc. The results of the screen are shown in Table 4 and Figure 3. It is hypothesized that OGRS that did not interact with GalNAc-T2 were either structurally altered due to the presentation as C-terminal fusions or they are the targets for other GalNAc-T isoforms. The OGRS from *Sus scrofa* plasminogen, PPPTSGPT, showed the greatest degree of staining on *Vicia villosa* lectin Western blots, and subsequent LC-MS analysis confirmed a glycosidic linkage to HexNAc (Figure 4). This glycoprotein was purified by protein-L chromatography and further analysis showed up to 69% occupancy at Thr-4 (Figure 5).

PEGylation of O-Glycosylated anti-TNF-α Fab. The glycosylated PPPTSGPT peptide fused to anti-TNF-α Fab was PEGylated at the engineered GalNAc by reacting with a 10-fold molar excess 20 kDa AO-PEG in 100 mM anilinium acetate pH 4.6 following oxidation by GAO. Aniline catalyzed oxime bond formation is a generally accepted method for labeling glycans, and excess aniline can be easily removed by SEC following the reaction. The product was either precipitated on protein-L sepharose and checked by SDS-PAGE (Figure 6) or isolated by SEC-HPLC and analyzed by MALDI-TOF (Figures 7 and 8). On the basis of an estimated occupancy of 69%, the extent of conversion of the glycoprotein is 0.85 after one hour and the purity is >98% by comparison to control reactions containing nonoxidized glycoprotein.

Surprisingly, it was found that freshly purified glycoprotein reacts with AO-PEG to some extent even without prior oxidation (Figure 7). After direct reaction with AO-PEG, approximately 5−10% of the starting material is converted to a high molecular

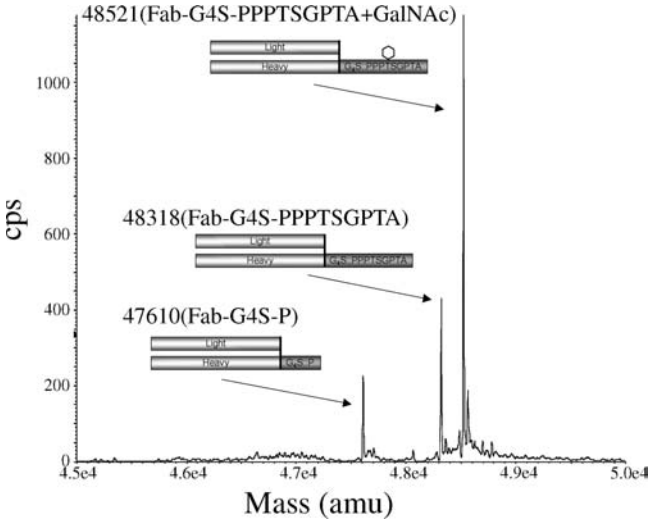

Figure 4. Analysis of glycosylated anti-TNFαFab09 by LC/MS: Glycoprotein was isolated as described and analyzed without further processing. The glycoprotein (MW 48524) comprises approximately 69% of the total. The unglycosylated full-length (MW 48318) and unglycosylated C-terminal degradation product (MW 47610) comprise the remaining 31%. The shift of 203 Da is expected upon glycosidic linkage to a single HexNAc. Lack of glycosylation of the proteolytically degraded product suggests that the glycosylation event was unique to the engineered peptide.

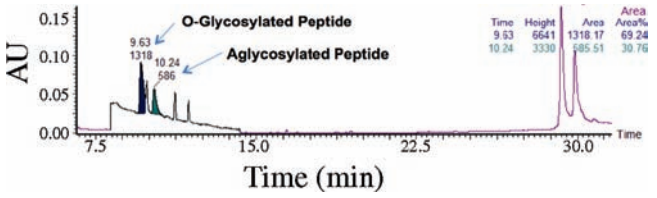

Figure 5. Quantification of glycan occupancy at OGRS peptide Thr-4 by RP-UPLC: The C-terminal glycopeptide elutes at 9.6 min and the aglycosylated C-terminal peptide elutes at 10.3 min. The glycopeptide and aglycopeptide are estimated at 69% and 31%, respectively.

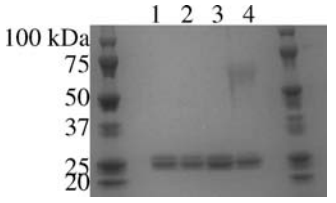

Figure 6. SDS-PAGE showing PEGylation of glycosylated Fab: After the reaction, excess 20 kDa AO-PEG was removed by immunoprecipitation using protein-L agarose. Lane 1, overnight incubation in oxidation reaction buffer followed by 1 h incubation in PEGylation buffer; lane 2, overnight incubation with GAO followed by 1 h incubation in PEGylation buffer; lane 3, overnight incubation in oxidation reaction buffer followed by 1 h incubation with 20 kDa AO-PEG; lane 4, overnight incubation with GAO followed by 1 h incubation with 20 kDa AO-PEG. The results indicate that sequential oxidation and incubation with AO-PEG are required for PEGylation. The light chain (bottom band) serves as a convenient internal control. Migration of the heavy chain to a single high molecular weight species in lane 4 indicates that the reaction is specific to a single location on that subunit.

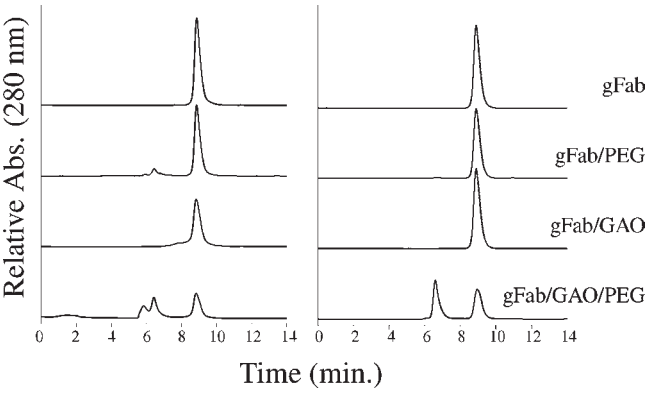

Figure 7. Analysis of PEGylation reactions by SEC-HPLC: Reactions were performed without removal (left) and with removal (right) of the contaminating reactive species. Without removal of the contaminant, approximately 6% of the nonoxidized starting material is converted to the high molecular weight species. Upon oxidation, the conversion increases to 70%. When the contaminant is removed, less than 2% of the nonoxidized starting material is converted, while 65% is converted after oxidation.

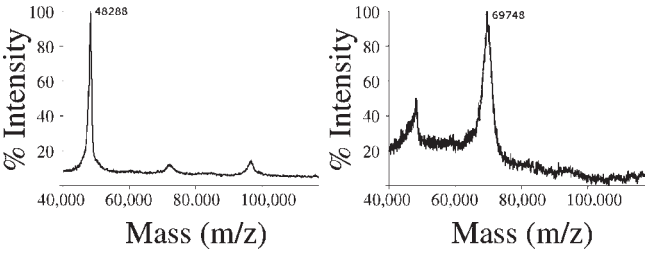

Figure 8. Analysis of PEGylation products by MALDI-TOF: The reaction products were separated by SEC-HPLC and fractions from each peak were pooled for MALDI-TOF analysis. Representative data from each peak is presented showing that the slow eluting peak is composed of unreacted Fab and the fast eluting peak is the PEGylated product as expected. The PEGylated product cannot be well-resolved due to the polydispersity of the 20 kDa AO-PEG.

weight product after four hours. The conversion does not increase appreciably when the reaction is allowed to proceed for an additional sixteen hours and the product is not hydrolyzed upon removal of the excess AO-PEG (data not shown) indicating a fast, irreversible reaction. This suggests that a reactive contaminant is present in the starting protein preparation, currently hypothesized to be due to carbonylation of a susceptible residue in the anti-TNF-α Fab. Indeed, UPLC analysis showed that approximately 5−10% of the purified Fab has a molecular weight 16 Da greater than the expected mass of the intact protein confirming the presence of an additional oxygen atom (data not shown). On the basis of the assumption of a reactive contaminant, the starting material was pretreated with AO-PEG and the high molecular weight product was removed by SEC-HPLC. The unmodified Fab was used as starting material for subsequent oxidation and PEGylation reactions. Nonoxidized control reactions run using this clean starting material resulted in <2% conversion to the side product indicating that the reactive contaminant had been removed by reaction with 20 kDa AO-PEG and SEC-HPLC (Figure 7).

DISCUSSION

We have developed a general method for the site-specific modification of proteins using a glycoengineered strain of *E. coli*. Once a sugar is placed on the recombinant protein, conventional techniques can be used to first oxidize and then conjugate any aminooxy-functionalized molecule of interest. Of central importance is the presence of a single reactive glycan moiety per glycoprotein molecule. The use of *E. coli* rather than a eukaryotic host offers the advantage that the glycans are uniform and placed at the desired location. Unlike previous studies utilizing aldehydes, we were able to achieve excellent conversion of the glycoprotein precursor with minimal contamination by non-site-specifically modifying side products through the removal of reactive contaminants. Carrico et al.[3] describe the reaction of aminooxy functionalized PEG with genetically encoded formylglycine residues, while the authors claim that this reaction scheme is site-specific (figure 2c of that publication shows multiple species). In each case, the spacing between the additional species corresponds to the size of an additional PEG molecule being added to the target protein. Thus, this reaction likely involves more than one PEG addition, implying that additional residues other than the engineered formylglycine are being modified. Furthermore, in another recent publication,[46] biological samples were shown to be susceptible to low levels of biotinylation by hydroxylamine functionalized reagents without the prior conversion to aldehydes. Taken together, it seems likely that the lack of specificity reported here is of general concern for aldehyde-based modification of biomolecules and that the removal of carbonylated species could be a valuable strategy for improving the purity of the PEGylated products when using these types of reactions. Considering the high level conversion of glycoprotein to the PEGylated product, further improvements to glycan occupancy would be expected to ultimately result in greater yield of PEGylated product. The PEGylated product is easily removed from the reactant pool by SEC-HPLC, but due to the physical properties of PEG, other chromatographic techniques such as ion exchange could be employed.

Repetition of the workflow described herein using the remaining initiating GalNAc transferases should allow for the creation of a small database linking GalNAc-T isoforms with their cognate OGRS. This database may prove useful for the introduction of OGRS at novel sites within proteins with minimal disruption of the native structure. In addition to providing precursors for bioconjugation, the ability to direct O-glycosylation in *E. coli* should provide tools for basic research on GalNAc-T as well as the ability to produce O-glycosylated mucin proteins.

ABSTRACT: Integrin $\alpha_V\beta_3$ plays a critical role in tumor angiogenesis and metastasis. Suitably radiolabeled cyclic RGD peptides can be used for noninvasive imaging of $\alpha_V\beta_3$ expression. The aim of this research was to prepare a multimeric system of technetium-99m-labeled gold nanoparticles conjugated to c[RGDfK-(C)] and to evaluate its biological behavior as a potential radiopharmaceutical for molecular imaging of tumor angiogenesis. Hydrazinonicotinamide-GGC (HYNIC-GGC) and c[RGDfK(C)] peptides were synthesized and conjugated to gold nanoparticles (AuNP, 20 nm) by means of spontaneous reaction of the thiol groups of cysteine. The nanoconjugate was characterized by TEM, FT-IR, UV−vis, XPS, and Raman spectroscopy. To obtain ^{99m}Tc-HYNIC-GGC-AuNP-c[RGDfK(C)] (^{99m}Tc-AuNP-RGD), the ^{99m}Tc-HYNIC-GGC radiopeptide was first prepared and added to 1.5 mL of AuNP solution (1 nM) followed by c[RGDfK(C)] (10 μL, 50 μM) at 18 °C with stirring for 15 min. Radiochemical purity (RP) was determined by size-exclusion HPLC and ITLC-SG analyses. *In vitro* binding studies were carried out in $\alpha_V\beta_3$ receptor-positive C6 glioma cancer cells. Biodistribution studies were accomplished in athymic mice with C6-induced tumors with blocked and nonblocked receptors, and images were obtained using a micro-SPECT/CT. TEM and spectroscopy techniques demonstrated that AuNPs were functionalized with peptides. RP was 96 ± 2% without postlabeling purification. ^{99m}Tc-AuNP-RGD showed specific recognition for $\alpha_V\beta_3$ integrins expressed in C6 cells, and 3 h after i.p. administration in mice, the tumor uptake was 8.18 ± 0.57% ID/g. Micro-SPECT/CT images showed evident tumor uptake. ^{99m}Tc-AuNP-RGD demonstrates properties suitable for use as a target-specific agent for molecular imaging of tumor $\alpha_V\beta_3$ expression.

INTRODUCTION

Angiogenesis is a physiological process involving the growth of new blood vessels by the sprouting of existing vessels in avascular tissue. Angiogenesis is a requirement for tumor growth and metastasis. The angiogenic process is regulated by cell adhesion receptors, such as integrins. The $\alpha_v\beta_3$ integrin is expressed on the surface of normal endothelial cells at low levels, but is overexpressed in the tumor neovasculature and tumor cells of osteosarcoma, neuroblastoma, glioblastoma, melanoma, lung carcinoma, and breast cancer.[1,2]

Radiolabeled peptides based on the Arg-Gly-Asp (RGD) sequence have been reported as radiopharmaceuticals with high affinity and selectivity for the $\alpha_v\beta_3$ integrin and are therefore useful in the noninvasive monitoring of tumor angiogenesis by molecular imaging techniques.[3,4] Monomeric RGD radiopharmaceuticals tend to have fast blood clearance but relatively good tumor uptake and rapid tumor washout, whereas dimeric, tetrameric, and octameric cyclic-RGD peptides exhibit increased affinity and enhanced adhesion to target $\alpha_v\beta_3$ integrin due to an increase in multivalent sites.[1,2,5,6]

Nanoparticles can be defined as particles of any material having dimensions of 100 nm or less with novel properties that distinguish them from bulk materials due to size and surface effects, and they can be prepared as stable, homogeneous, and well-characterized systems in size and shape.[7,8] Nanoparticles produce multivalent effects due to multiple simultaneous interactions between the biomolecules

conjugated on the nanoparticle surface and the cell surface, with specific receptors for those biomolecules.[8] Recent studies have demonstrated that conjugating peptides to gold nanoparticles (AuNP) produces biocompatible and stable multifunctional systems with target-specific molecular recognition.[9−16] Peptides can be conjugated to one AuNP by spontaneous reaction of the AuNP surface with a thiol (cysteine) or an N-terminal primary amine.[9,11] The thiol group is considered to be the most important type of molecule to stabilize any size of AuNPs, by forming a "staple motif" chemical model of two thiol groups interacting with three gold atoms in a bridge conformation.[17]

Hydrazinonicotinamide (HYNIC) is a good chelator for technetium-99m and is suitable for radiolabeling peptides with high specific activity and favorable pharmacokinetics for imaging purposes.[18,19]

The aim of this research was to prepare a multimeric system of ^{99m}Tc-labeled gold nanoparticles (20 nm) conjugated to HYNIC-Gly-Gly-Cys-NH_2 (HYNIC-GGC) and cyclic[Arg-Gly-Asp-Phe-Lys(Cys)] (c[RGDfK(C)]) peptides and to evaluate its biological behavior as a potential specific radiopharmaceutical for tumor $\alpha_V\beta_3$ expression imaging.

EXPERIMENTAL PROCEDURES

Materials. *o*-Chlorotrityl chloride resin (Advanced Chem Tech), *N*,*N*-diisopropylethylamine (DIPEA), dichloromethane (DCM), dimethylformamide (DMF), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), hydroxybenzotriazole (HOBt), piperidine, trifluoroacetic acid (TFA), 2,2,2-trifluoroethane (TFE), triisopropylsilane, 1-propanephosphonic acid cyclic anhydride (T3P), 4-dimethylaminopyridine (DMAP), Fmoc-Gly-OH, Fmoc-Arg(Pbf)-OH, Fmoc-D-Phe-OH, Fmoc-Asp(OtBu)-OH, Fmoc-Lys(Boc)-OH, Boc-Cys(Trt)-OH, and 20 nm gold colloid solution (AuNP-citrate, 6.99×10^{11} particles/mL, absorbance at 520 nm = 0.91) were purchased from Sigma-Aldrich Chemical Co. and used as received.

Synthesis of HYNIC-Gly-Gly-Cys-NH_2 (HYNIC-GGC). In the HYNIC-GGC molecule design, HYNIC was added as a ^{99m}Tc chelator group, -Gly-Gly- was used as a spacer, and -Cys- was used as the active group to interact with the gold nanoparticle surface (Figure 1). The HYNIC-GGC-NH_2 was synthesized following the method described by Ocampo-Garcia et al.[16]

Synthesis of cyclo[Arg-Gly-Asp-D-Phe-Lys-(Cys)] (c[RGDfK(C)]). In the c[RGDfK(C)] molecule design, the sequence -Arg-Gly-Asp- (-RGD-) acted as the active biological site, Phe (f) and Lys (K) residues completed the cyclic and pentapeptide structure, and Cys (C) was the spacer and active group to interact with the gold nanoparticle surface (Figure 1).

The synthesis of the linear peptide started with the incorporation of glycine onto an *o*-chlorotrityl chloride resin (with a 0.9 mmol/g load) at a 0.07 mmol scale by mixing the resin with a solution of Fmoc-Gly-OH (20.9 mg, 0.21 mmol) and DIPEA (33 μL, 0.20 mmol) in dry DCM in a peptide synthesis vessel. After shaking the reaction mixture for 2.5 h, it was removed and the resin was washed with DCM, followed by addition of 100 μL

dx.doi.org/10.1021/bc100551s |*Bioconjugate Chem.* 2011, 22, 913–922

of DIPEA in 2 mL of methanol to cap the unreacted sites on the resin. After 30 min, the resin was washed with DMF. The Fmoc-protecting group was then removed with a 20% solution of piperidine in DMF. Amino acids were then attached by using single-step couplings of 3 equiv of Fmoc-amino acid, 2.9 equiv HBTU and HOBt, and 6 equiv DIPEA in DMF in the order Fmoc-Arg(Pbf)-OH, Fmoc-Lys(Boc)-OH, Fmoc-D-Phe-OH, and Fmoc-Asp(OtBu)-OH, for 2 h each. The linear RGDfK peptide was cleaved from the resin without affecting other protecting groups by treating with 5 mL of a mixture of acetic acid, TFE, and DCM (1:1:3) for 1 h at room temperature. The resin was washed twice with 5 mL of the same mixture and then three times with DCM. The eluents were combined and concentrated. The excess acetic acid was removed by repeatedly adding hexanes to the residue and removing them by rotary evaporation. The head-to-tail cyclization was performed by slowly adding a solution of the linear peptide in 5 mL of DCM to a solution of 50% T3P in EtOAc (200 μL), DIPEA (200 μL), and DMAP (1 mg) in 5 mL of DCM. After stirring overnight, the reaction mixture was concentrated and purified by silica flash chromatography (methanol/ethyl acetate, 1:9) to afford 75 mg (MW = 1118.39, 96%) of the protected cyclic peptide as light-yellow solid. The previous intermediate was dissolved in 5 mL 2% hydrazine in DMF and stirred for 30 min at room temperature. The solvent was removed in vacuum, and the residue was triturated with water. The precipitated peptide was isolated by centrifugation. Coupling of Boc-Cys(Trt)-OH followed by reacting the cyclic peptide with 3 equiv of the amino acid, 2.9 equiv HBTU and HOBt, and 6 equiv DIPEA in DMF. The solvent was removed in vacuum, and the residue was triturated with water. The precipitated peptide was isolated by centrifugation. Coupling of Boc-Cys(Trt)-OH was followed by reacting the cyclic peptide with 3 equiv of the amino acid, 2.9 equiv HBTU, and HOBt, and 6 equiv DIPEA in DMF. The solvent was removed by rotary evaporation, and the residue was taken into DCM and washed with water. The collected organic phase was dried with anhydrous Na_2SO_4 and filtered, and the solvent was removed. The product was purified by silica flash chromatography (methanol/ethyl acetate, 1:9). The remaining protecting groups of the above cyclic peptide were removed by stirring the peptide for 2 h with 95% TFA, 2.5% triisopropylsilane, and 2.5% water mixture. The solvent was removed by rotary evaporation, and the residue was purified by HPLC with a gradient of water/acetonitrile containing 0.1% TFA from 90/10 to 10/90 in 35 min and lyophilized, giving 14 mg of c[RGDfK(C)] peptide (28% overall yield). R_t = 9.5 min (MALDI+) m/z = 707.36 $[M+H]^+$ (calcd. 707.81).

Synthesis of HYNIC-GGC-AuNP-c[RGDfK(C)]. The preparation was carried out by mixing 0.05 mL of HYNIC-GGC (0.025 mM in injectable-grade water) and 0.05 mL of c[RGDfK-(C)] (0.025 mM in injectable-grade water) with 1 mL of the AuNP solution (1 nM). The molar ratio for AuNP/HYNIC-GGC and AuNP/c[RGDfK(C)] was 1:1250. The mixture was stirred for 15 min to permit complete exchange of citrate with thiol on the particle surface. The AuNP−peptide conjugate (20 nm AuNP−peptide = 2.46×10^5 Au atoms, MW $\approx 4.8 \times 10^7$ g/mol, 0.034 mg Au/mL) was purified by size-exclusion chromatography (PD-10 column) using injectable water as eluent. The first eluted peak (3.0−4.0 mL) corresponded to the functionalized AuNP (AuNP−peptide); free peptides appeared at the 5.0−7.0 mL eluted fraction, and unfunctionalized AuNP remained trapped in the column matrix. Ten preparations of HYNIC-GGC-AuNP-c[RGDfK(C)] (10 mL) were mixed as a batch and stored for 9 months at 4 °C. During this time, the color of the solution did not change (no aggregation), no precipitate was observed, and the surface resonance plasmon (SRP = 522 nm) remained stable. AuNP-c[RGDfK(C)] without HYNIC-GGC was also prepared for comparative spectroscopic analyses.

Estimation of the Number of Peptide Molecules per AuNP. The number of peptides per nanoparticle was calculated by UV−vis titration of peptides (8 μM) using increasing gold nanoparticle concentration (from 0 to 1 nM). The peptide and AuNP−citrate solutions were incubated for 15 min at room temperature. AuNPs were removed by ultrafiltration (Ultrafree-PF filters 10 000 NWWL, Millipore), and the concentration of remaining free peptide in solution was measured from the absorbance at 280 nm. From a linear fit of data points, the number of HYNIC-GGC peptides per particle was calculated as 1.35 peptides/nm^2. As a 20 nm AuNP size was used (surface area = 1260 nm^2, 37 000 surface Au atoms), the maximum number of peptides bound to one AuNP was 1701. In the case of AuNP-c[RGDfK(C)], the free peptide concentration was quantified by UV-HPLC with a 1 mL injector loop and a μ-Bondapak C18 column (Waters, 3.9 × 300 mm), at a flow rate of 1 mL/min using a linear gradient of 0.1% TFA/water (solvent A)/0.1% TFA/CH_3CN (solvent B) from 0% to 50% of solvent B in 10 min, which was then maintained for 10 min (t_R = 8 min). From the linear fit of data points, the number of c[RGDfK(C)] was calculated as 520 peptides bound to one AuNP (0.41 peptides/nm^2). In the HYNIC-GGC-AuNP-c-[RGDfK(C)] preparation, approximately 850−900 HYNIC-GGC (free peptide determined by HPLC t_R = 5.1 min) and 260−280 c [RGDfK(C)] molecules were measured per AuNP molecule.

Chemical Characterization. *TEM.* The morphology and size distribution of AuNP and AuNP-peptides were analyzed by transmission electron microscopy (TEM) in a JEOL JEM 2010 HT microscope operating at 200 kV. Samples were prepared for analysis by evaporating a drop of aqueous product on a carbon-coated TEM copper grid.

Infrared Spectroscopy. The IR spectra of lyophilized samples were acquired on a PerkinElmer System 2000 spectrometer with an ATR platform (Pike Technologies) by applying the attenuated total reflection fourier transform infrared (ATR-FTIR) spectroscopy from 570 to 4400 cm^{-1}.

Raman Spectroscopy. Raman spectra of the samples were acquired on a MicroRaman (JOBIN-Yvon-Horiba, LABRAM HR800) spectrometer with optical microscope (OLYMPUS BX 41) and He−Ne Laser (632.817 nm) as excitation source, a D0.6 filter and a 100 micro Hole. Ten scans of 60 s were acquired.

On a pretreated cover glass (washed in three steps: 1HNO_3/3HCl (v/v) solution, bi-distilled water, and injectable water), 10 μL aliquots of the sample were deposited and dried under nitrogen atmosphere at room temperature in a laminar flow hood.

XPS. X-ray photoelectron spectra were acquired on a Jeol JPS 9200 spectrometer equipped with a MgK_α X-ray source (1253.6 eV). The source was operated at 10 kV/20 mA and calibrated using Au $4f_{7/2}$ (84.0 eV) and Ag $3d_{5/2}$ (368.2 eV) from foil samples. The samples were introduced into an ultrahigh-vacuum (UHV) chamber of the spectrometer (1.05×10^{-8} Torr) and measured at 24 °C (room temperature). The spot size in the beam was 100 μm. The pressure did not change during the analysis, and 10 scans for Au 4f were done with energy step size of 0.1 eV. The binding energies were referenced to the C 1s peak at 284.3 eV. From all spectra, a Shirley background was subtracted to perform the peak fitting with a symmetric Gauss-Lorentz sum function (*SpecSurf* software).

UV−vis Spectroscopy. Absorption spectra in the range 400−700 were obtained with a PerkinElmer Lambda-Bio spectrometer using 1 cm quartz cuvette. Nanoconjugates were measured by UV−vis analysis to monitor the AuNP surface plasmon resonance band (520 nm) shift.

Preparation of ^{99m}Tc-EDDA/HYNIC-GGC-AuNP-c[RGDfK(C)] (^{99m}Tc-AuNP-RGD) and ^{99m}Tc-EDDA/HYNIC-GGC-AuNP (^{99m}Tc-AuNP). *^{99m}Tc-EDDA/HYNIC-GGC.* To 5 μL of HYNIC-GGC (0.5 mg/mL, injectable-grade water) 0.5 mL of EDDA-tricine solution was added, which was prepared by mixing 30 mg of EDDA (*N*,*N*-ethylene diamine diacetic acid) in 1.5 mL of 0.1 M NaOH and 60 mg of tricine (*N*-tris[hydroxymethyl]methylglycine) in 1.5 mL of 0.2 M phosphate buffer, pH = 7. Finally, 10 μL of a freshly prepared anhydrous stannous chloride solution (1 mg/mL in 0.012 M HCl) was added, followed immediately by 1000−2400 MBq (0.5 mL) of ^{99m}Tc-pertechnetate, and then incubation at 92 °C for 20 min in a dry block heater. A radiochemical purity of ^{99m}Tc-EDDA/HYNIC-GGC higher than 95% was verified by ITLC-SG analyses using two different mobile phases: 2-butanone to determine the amount of free $^{99m}TcO_4^-$ (R_f =1), and methanol/1 M ammonium acetate (1:1 v/v) for ^{99m}Tc-colloid (R_f = 0). R_f values of the radiolabeled peptide in these three systems were 0.0 and 0.7−1.0, respectively.

^{99m}Tc-AuNP-RGD. To 1.5 mL of AuNP solution (1 nM, 1.05×10^{12} particles) 120 μL (120−288 MBq) of ^{99m}Tc-EDDA/HYNIC-GGC (0.3 μg of peptide; 4.9×10^{14} molecules of HYNIC-GGC; ∼465 HYNIC-GGC molecules per AuNP) was added. After 1 min of stirring, 10 μL of c[RGDfK(C)] (50 μM; 3×10^{14} molecules of peptide; peptide:AuNP ratio 285:1) was added with stirring for 15 min. No further purification was carried out. In order to determine the exact number of peptide molecules per AuNP, in some experiments AuNPs were removed from the ^{99m}Tc-AuNP-RGD solution (1 mL) by ultrafiltration (Ultrafree-PF filters 10 000 NWWL, Millipore), and the free peptide concentration was quantified by UV-HPLC with a 1 mL injector-loop following the procedure described above.

^{99m}Tc-AuNP. To 1.5 mL of AuNP solution (1 nM, 1.05×10^{12} particles), 120 μL (120−288 MBq) of ^{99m}Tc-EDDA/HYNIC-GGC (0.3 μg of peptide; 4.9×10^{14} molecules of HYNIC-GGC; ∼465 HYNIC-GGC molecules per AuNP) was added, and after 3 min under stirring, 25 μL of HYNIC-GGC (50 μM; 7.5×10^{14} molecules of peptide; peptide/AuNP ratio 715:1) was added. No further purification was carried out.

Radiochemical Purity of Radiolabeled AuNP. ITLC-SG/2-butanone (R_f value of the radiolabeled AuNP and ^{99m}Tc-EDDA = 0.0 and 1.0 for $^{99m}TcO_4^-$) and size-exclusion chromatography were used as radiochemical control methods for the final radiopharmaceutical solution. In a PD-10 column, using injectable water as eluent, the first and red radioactive eluted peak (3.0−4.0 mL) corresponds to the radiolabeled AuNP; the free radiolabeled peptide appears at the 5.0−7.0 mL eluted fraction, and $^{99m}TcO_4^-$ remains trapped in the column matrix. In the HPLC system (ProteinPak 300SW, Waters, 1 mL/min, injectable water), radiolabeled AuNP showed t_R = 4.5−5 min, t_R = 8 min for free ^{99m}Tc-peptide, and t_R = 11 min for $^{99m}TcO_4^-$. Ultrafiltration was also used as described above; radiolabeled AuNP remained in the filter, free ^{99m}Tc-peptide and $^{99m}TcO_4^-$ pass through the filter.

Preparation of ^{99m}Tc-EDDA/HYNIC-cRGDyK (^{99m}Tc-RGD). In order to compare the *in vivo* biodistribution between multimeric and monomeric RGD systems, a lyophilized formulation containing 20 μg of HYNIC-cRGDyK (Pichem Co., Austria), EDDA (10 mg), tricine (20 mg), mannitol (50 mg), and stannous chloride (0.02 mg) was prepared. The radiolabeling procedure was carried out by adding 1 mL of 0.2 M phosphate buffer pH 7.0 to the freeze−dried kit formulation and immediately adding 740−1110 MBq (1 mL) of ^{99m}Tc-pertechnetate followed by incubation in boiling water for 15 min. A radiochemical purity of ^{99m}Tc-RGD higher than 95% was verified by ITLC-SG analyses using three different mobile phases: 2-butanone to determine the amount of free $^{99m}TcO_4^-$ (R_f = 1), 0.1 M sodium citrate pH 5 to determine ^{99m}Tc-EDDA, and $^{99m}TcO_4^-$ (R_f = 1), and methanol/1 M ammonium acetate (1:1 v/v) for ^{99m}Tc-colloid (R_f = 0). R_f values of the radiolabeled peptide in these three systems were 0.0, 0.0, and 0.7−1.0, respectively.

***In Vitro* Stability Assay of ^{99m}Tc-AuNP-RGD in Human Serum.** To determine the stability of ^{99m}Tc-AuNP-RGD in serum, 200 μL of radiolabeled gold nanoparticles was diluted in the ratio 1:5 with fresh human serum and incubated at 37 °C. The chemical stability was determined by UV−vis analysis to monitor the AuNP surface plasmon resonance band (520 nm) at 1 and 24 h after dilution. Radiochemical stability was determined by taking samples of 0.01 mL at 1 and 24 h for ITLC-SG/2-butanone analysis and ultrafiltration as described above.

***In Vitro* Binding Assay.** Integrin $\alpha_v\beta_3$ receptor-positive C6 glioma cells (originally obtained from ATCC, USA) supplied in fresh medium were centrifuged at 2000 *g* for 20 min, and the pellet was diluted to 1×10^6 cells/tube with binding buffer (0.6 mL, pH 7.5; 1 M NaCl, 0.05 M $CaCl_2$, 0.05 M $MgCl_2$, 0.05 M Tris-HCl, 0.1% human serum albumin) and incubated with 0.05 mL (3.7 MBq) of ^{99m}Tc-AuNP-RGD or ^{99m}Tc-AuNP (n = 4) at 37 °C for 24 h. The test tubes were centrifuged at 2000 *g* for 20 min and washed with injectable water, and the activity of the cell pellet was determined in a crystal well-type scintillation detector. An aliquot with the initial activity was taken to represent 100%, and the percent of cell uptake activity was then calculated. Nonspecific binding (blocked $\alpha_v\beta_3$ integrin receptors) was determined in parallel, in the presence of 10 μM cRGDfK (Bachem, USA), with 1 h of preincubation.

***In Vivo Studies*.** Athymic female mice (20−25 g) were used. Tumors were induced by subcutaneous injection of C6 glioma cells (1×10^6 cells suspended in 200 μL of phosphate-buffered saline) in the dorsal surface of the scapula. The sites of injection were observed at regular intervals for the appearance of tumor formation and progression. The tumor type and tumor size play an important role in the radiopeptide uptake;[2] therefore, only mice with tumors between 0.1 and 0.3 g were selected in order to diminish the biological variability due to the physiologic nature of $\alpha_v\beta_3$ expression. All experiments were carried out in agreement with the Official Mexican Norm 062-ZOO-1999 for laboratory animal handling. Mice were kept in sterile cages with a sterile wood-shavings bed, constant temperature, humidity, noise, and 12:12 h light periods. Water and feed (standard PMI 5001 feed) were given *ad libitum*.

Biodistribution Studies. Ten groups (n = 3) of athymic nude mice bearing C6 human gliomas (20−25 g) were used. ^{99m}Tc-AuNP-RGD (3.7 MBq, 0.05 mL) was injected in the tail vein (four groups) or intraperitoneally (four groups). Complete dissection was carried out at 0.5, 1, 3, or 24 h. Whole heart, spleen, pancreas, and kidneys and samples of tumor, lung, liver, brain, blood, intestines, and muscle were saline-rinsed, paper-blotted, and placed into preweighed plastic test tubes. The activity was determined in a well-type scintillation detector (Canberra) along with 6 × 0.5 mL aliquots of the diluted standard representing

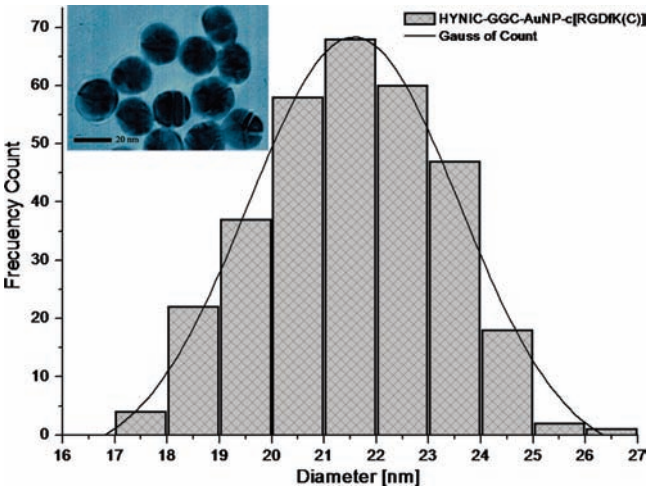

Figure 2. TEM image and size distribution of HYNIC-GGC-AuNP-c[RGDfK(C)].

100% of the injected dose. Mean activities were used to obtain the percentage of injected dose per gram of tissue (% ID/g).

A blocking study was performed in two groups of three athymic nude mice bearing C6 human gliomas. One hundred microliters (0.1 mM) of unlabeled cRGDfK (Bachem) was intraperitoneally administered one hour before intravenous ($n = 3$) or intraperitoneal ($n = 3$) injection of ^{99m}Tc-AuNP-RGD (3.7 MBq, 0.05 mL), and complete dissection was carried out 1 h after radiopharmaceutical administration, as described above.

^{99m}Tc-AuNP or ^{99m}Tc-RGD (monomer) were also administered in athymic mice with a C6-induced tumor and complete dissection carried out at 1 h after administration ($n = 3$).

Imaging Studies. Three mice with the implanted tumors were i.v. injected with 0.1 mL (7.4 MBq) of ^{99m}Tc-AuNP-RGD and anaesthetized with isoflurane 1 h later. Static images were obtained using a micro-SPECT/PET/CT system (ONCOVISION, Spain).

Statistical Analysis. Comparisons between groups in the binding assay and blocking assay were made using Student's t test (significance was defined as $P < 0.05$).

RESULTS

Chemical Characterization. *TEM.* Images of HYNIC-GGC-AuNP-c[RGDfK(C)] showed monodispersed solutions with an average particle diameter of 21.70 ± 0.07 nm. A higher diameter was observed with respect to AuNP stabilized with citrate (18.64 ± 0.13 nm) due to an increase of the hydrodynamic diameter. It was possible to observe a "corona" around the gold nanoparticle due to the poor interaction of the electron beam with the peptide molecules (low electron density), in contrast to the strong scattering of the electron beam when it interacted with the metallic nanoparticles (Figure 2).

IR Spectroscopy. In the c[RGDfK(C)] spectrum, the weak bands at 2574 cm^{-1} and at 722 cm^{-1} corresponding to the thiol (−SH) in AuNP-c[RGDfK(C)] disappeared, suggesting the formation of thiolate (−S−AuNP).[20] The strong band at 1636 cm^{-1} assigned to the guanidine group (C−N stretch vibration) in c[RGDfK(C)] was shifted to 1677 cm^{-1}, indicating some weak interaction on the AuNP surface.[21] In the HYNIC-GGC-AuNP-c[RGDfK(C)] spectrum, amide I (~1646 cm^{-1}, C═O stretching) and amide II (~1550 cm^{-1}, N−H bending) regions were shifted to higher energy by 20 cm^{-1} with respect to the free peptides, confirming the presence of peptides on the AuNP surface.

Raman Spectra. AuNP functionalized with c[RGDfK(C)] yielded a structured Raman spectrum in the 1800−600 cm^{-1} region (Figure 3). Several well-defined bands were observed with vibrational frequencies in the region of those associated with the main functional groups seen in the c[RGDfK(C)] spectrum, but they were characteristic of AuNP-c[RGDfK(C)] and HYNIC-GGC-AuNP-c[RGDfK(C)] because of shifts to lower or higher energies and increases in the band intensities (Figure 3). The 1605 cm^{-1} band observed in the c[RGDfK(C)] spectrum was assigned to the arginine guanidinium group (CN_3, stretch), and in the AuNP-c[RGDfK(C)] spectrum, the band shifted to 1611 cm^{-1} and increased in intensity, which indicates some interaction on the AuNP surface.[22] Gold nanoparticle interactions with amide groups AI (C═O, stretch), AII (N−H, bend), and AIII (C−N stretch) were also observed (1693 cm^{-1}, 1549 cm^{-1}, and 1231 cm^{-1}, respectively).

XP Spectroscopy. The AuNP spectrum (Figure 4) showed two main peaks corresponding to the binding energies (B.E., eV) of electrons in Au 4f orbitals at 87.0 eV (Au $4f_{5/2}$) and 83.4 eV (Au $4f_{7/2}$) with a characteristic difference of 3.6 eV and an intensity ratio of 3:4 between the two peaks.[23] The AuNP-c[RGDfK(C)] spectrum (Figure 4) showed two main peaks at 87.3 and 83.7 eV with a positive shift of 0.3 eV and a third peak at 89.1 eV due to atoms with different oxidative states.[17,23] The HYNIC-GGC-AuNP-c[RGDfK(C)] spectrum revealed a peak at 84.0 eV with a positive shift of 0.6 eV with respect to Au $4f_{7/2}$ of citrate-stabilized nanoparticles. The peak that correlated with the Au $4f_{5/2}$ orbital appeared at 87.4 eV, and the deconvoluted spectrum showed peaks at 87.4, 88.1, and 89.0 eV (Figure 4). The orbital energies of Au−Au or Au−citrate (Au^0) and Au−S- (Au^{1+}) bounds are related to changes in the oxidative states (Au^0 to Au^{1+}), so the shift of electron binding energies to higher values is an intrinsic property of the interaction between gold core electrons and peptides.[23]

UV−vis Spectroscopy. The AuNP spectrum showed a surface plasmon resonance at 520 nm. A red-shift to 522 nm was observed in the AuNP-c[RGDfK(C)] and HYNIC-GGC-AuNP-c[RGDfK(C)] spectra due to changes in the refraction index and the surrounding dielectric medium as a consequence of the interaction between the peptide and the AuNP surface.[24,25]

Preparation of ^{99m}Tc-AuNP-RGD and ^{99m}Tc-AuNP. After the labeling procedure, the radiochemical purity of ^{99m}Tc-AuNP-RGD and ^{99m}Tc-AuNP was 96 ± 2% ($n = 20$) without postlabeling purification. In both radiopharmaceuticals, the specific activity was 80−192 GBq/nmol. In the ^{99m}Tc-AuNP-RGD solution, the total number of HYNIC-GGC peptide molecules per AuNP was 460 (1.05×10^{12} gold particles and 1.05×10^{14} HYNIC-GGC molecules in 1.5 mL) and the total number of RGDfK(C) molecules per AuNP was at least 200 (1.05×10^{12} gold particles and 3×10^{14} HYNIC-GGC molecules in 1.5 mL), since no free peptide was detected by UV-HPLC (detection limit 0.1 μg at 260 nm = 5×10^{13} peptide molecules).

Human Serum Stability. ^{99m}Tc-AuNP-RGD diluted in human serum was stable over 24 h, because at this time, the radiochemical purity was 92.0 ± 1.1%. The SPR, characteristic of gold nanoparticles, remained stable and shifted slightly to higher energy (524 nm) because of protein interactions (Figure 5).

***In Vitro* Cell Binding Assay.** As shown in Table 1, ^{99m}Tc-AuNP-RGD had specific recognition, because the $\alpha_v\beta_3$ integrin receptor-positive cell uptake was 2.3 times higher with respect to that of ^{99m}Tc-AuNP ($p < 0.05$), and its specificity was confirmed

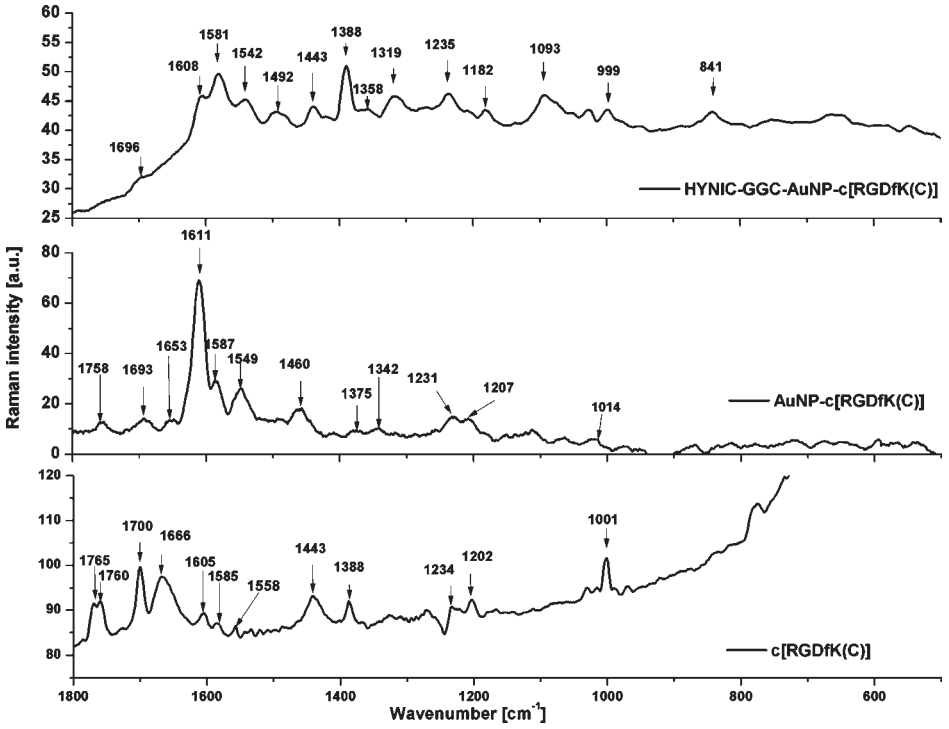

Figure 3. Raman spectra of c[RGDfK(C)], AuNP-c[RGDfK(C)], and HYNIC-GGC-AuNP-c[RGDfK(C)].

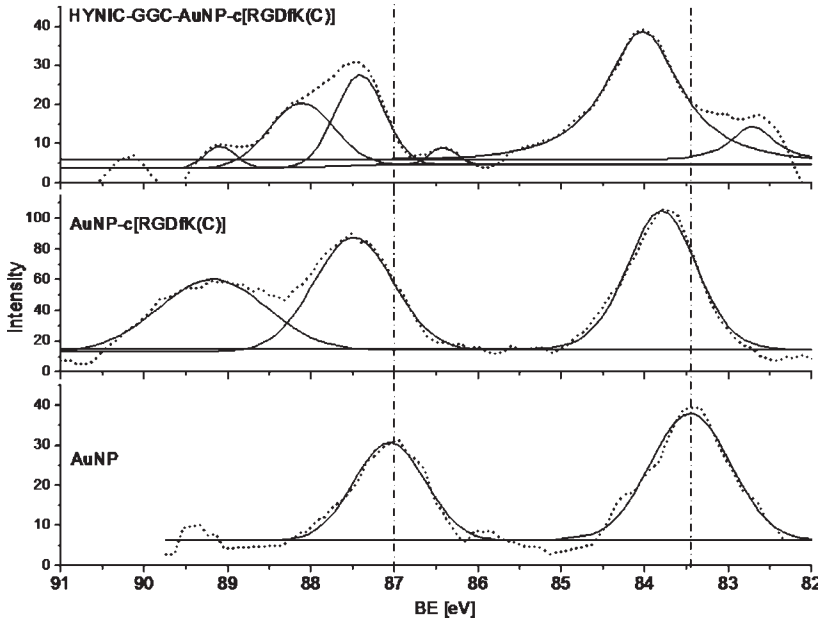

Figure 4. XPS spectra of c[RGDfK(C)], AuNP-c[RGDfK(C)], and HYNIC-GGC-AuNP-c[RGDfK(C)]. Experimental bands (dotted line) and deconvoluted experimental bands (solid line).

with the receptor blocking study (Table 1). The ^{99m}Tc-AuNP accumulation (14.97 ± 2.39%) in C6 cells could have been related to a passive uptake, because gold nanoparticles can be taken up by all mammalian cells due to their nanometric size (20 nm),[26] but with the conjugation of c[RGDfK(C)] to AuNPs, the tumor cell uptake was significantly increased (34.72 ± 1.42%). The significant difference in cell binding results (34.72% vs 14.97%) was due to active targeting, meaning specific $\alpha_v\beta_3$ integrin receptor recognition.

***In Vivo* Studies.** Biodistribution studies (Table 2, Table 3, and Figure 6) and *in vivo* micro-SPECT/CT images of mice (Figure 7) after ^{99m}Tc-AuNP-RGD administration showed evident tumor uptake via intravenous injection (3.65 ± 0.19% i.a. at 1 h) as well as intraperitoneal injection (8.18 ± 0.57% i.a. at 3 h). Liver and spleen uptake were significant due to their radiopharmaceutical colloidal nature. Tumor-to-blood, tumor-to-muscle, tumor-to-liver, and tumor-to-spleen ratios were 7.4, 10.0, 0.2, and 0.7, respectively, for the intravenous administration at 1 h; and for the intraperitoneal

dx.doi.org/10.1021/bc100551s |*Bioconjugate Chem.* 2011, 22, 913–922

administration, these ratios were 20.5 (tumor-to-blood), 27.3 (tumor-to-muscle), 2.1 (tumor-to-liver), and 3.4 (tumor-to-spleen). These results were expected because intravenous administration of nanoparticles results in opsonization followed by substantial uptake by macrophages present in the liver and spleen. The *in vivo* ^{99m}Tc-AuNP-RGD tumor uptake was significantly higher ($P < 0.05$) than that of ^{99m}Tc-AuNP or ^{99m}Tc-RGD (monomeric system) at 1 h after i.v. administration. Recently, Sadauskas et al.[27] demonstrated that the intraperitoneal mode of administration results in minimal uptake of AuNPs by Kupffer cells in the liver as compared to the intravenous route, and Chanda et al.[28] found that intraperitoneal injection of AuNP decreases uptake by organs of the reticuloendothelial system while maximizing receptor-mediated uptake in desired sites. Nevertheless, the maximum tumor uptake is faster (at 1 h) with the intravenous mode of administration and maybe more convenient for diagnostic imaging purposes than with the intraperitoneal mode (maximum tumor uptake at 3 h), in which there is a radiopharmaceutical absorption process and some remaining abdominal activity.

The specificity was confirmed by a receptor blocking study, in which the previous injection of cRGDfK diminished the activity in tumors. Reductions in tumor uptake percentages were 60% with intravenous administration (3.65% ID/g vs 1.46% ID/g, $P < 0.05$) and 64% with intraperitoneal administration (3.28% ID/g vs 1.18% ID/g, $P < 0.05$) (Tables 2 and 3). In general, the blood activity was slightly but significantly higher in the blocked groups with respect to unblocked. The uptake in nontargeted tissues was not significantly reduced by the blocking dose.

In spite of gold nanoparticles being taken up by all mammalian cells due to their nanometric size, ^{99m}Tc-AuNP-RGD was not taken up by all cells in the whole body of mice because nanoparticles cannot cross normal blood vessels (normal endothelium: gaps ~2−5 nm). As expected, the major accumulation occurred in the tumor (cancer endothelium: gaps ~400−800 nm) and reticuloendothelial system organs.

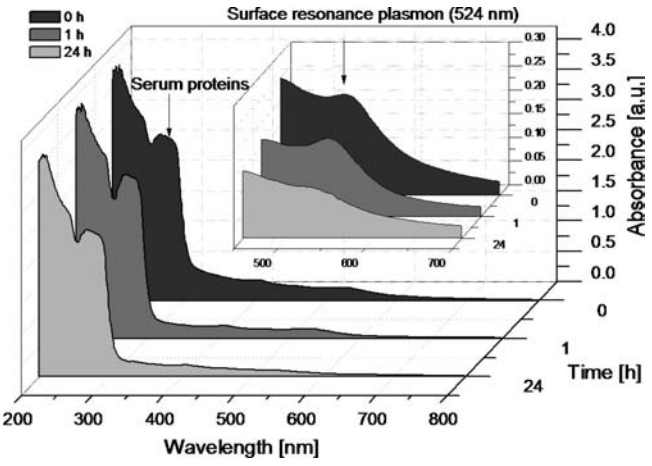

Figure 5. Stability in human serum of ^{99m}Tc-AuNP-RGD. Surface plasmon resonance (524 nm) remained stable for 24 h.

DISCUSSION

TEM and spectroscopy techniques demonstrated that AuNPs were functionalized with HYNIC-GGC and c[RGDfK(C)] through thiol groups and the presence of peptide molecules on the AuNP surface.

The aim of the development of cancer-receptor-specific AuNPs is to maximize the binding affinity via multimeric peptides based on the multivalency principle. For the multimeric RGD system reported in this study and intravenously administered, the C6 tumor-to-muscle ratio was 10 at 1 h, which is similar to that reported for tetrameric (U87MG tumor-to muscle ratio ≈ 10) and

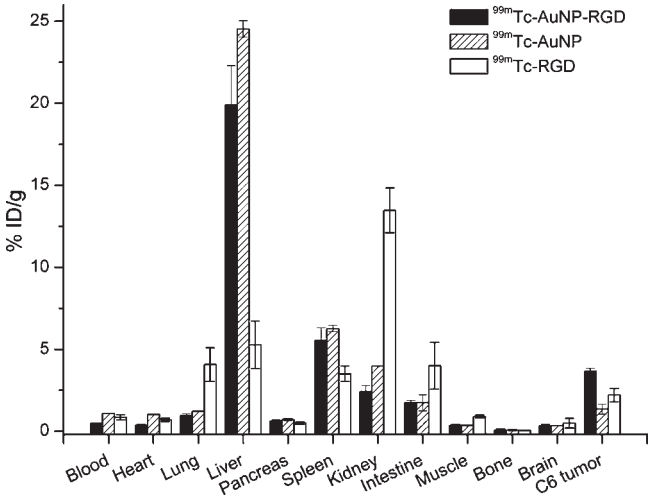

Figure 6. Biodistribution of ^{99m}Tc-AuNP-RGD, ^{99m}Tc-AuNP, and ^{99m}Tc-RGD (monomer) in athymic mice with a C6-induced tumor at 1 h after i.v. administration (n = 3). Tumor uptake was significantly higher (P < 0.05) for the ^{99m}Tc-AuNP-RGD multimeric system with respect to ^{99m}Tc-RGD or ^{99m}Tc-AuNP.

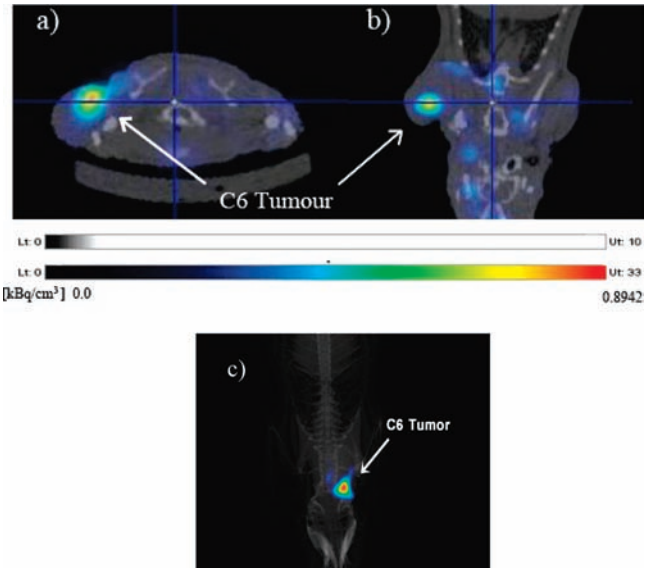

Figure 7. (a) Transaxial and (b) coronal micro-SPECT/CT images of an athymic mouse with a C6-induced tumor 1 h after ^{99m}Tc-AuNP-RGD intravenous administration. (c) Coronal micro-SPECT/CT image of an athymic mouse with a C6-induced tumor 3 h after ^{99m}Tc-AuNP-RGD intraperitoneal administration. SPECT image in the abdominal region was not included to highlight tumor uptake.

octameric (U87MG tumor-to muscle ratio ≈ 11) RGD peptides.[6] However, it is important to mention that the number of $\alpha_v\beta_3$ integrin receptors per cell in C6 gliomas is, on average, 1480, and in U87MG gliomas, the number is 2 orders of magnitude higher (128 000 receptors/cell).[29] Because the integrin $\alpha_v\beta_3$ level on tumor cells plays a significant role in radiopharmaceutical tumor uptake, it is expected that, in tumors with high $\alpha_v\beta_3$ density and therefore with short distances between integrin receptors, the multimeric ^{99m}Tc-AuNP-RGD radiopharmaceutical will achieve easier multivalency with a significant increase in the tumor uptake. For example, Liu et al.[30] investigated the biodistribution of ^{64}Cu-labeled single-walled carbon nanotubes (SWNTs) conjugated to PEG and RGD in mice with U87MG-induced tumors by positron emission tomography (PET) and ex vivo biodistribution, obtaining a high tumor conjugate accumulation (~7% at 1 h), which was attributed to the multivalent effect of the SWNTs.[30] Furthermore, ^{99m}Tc-AuNP-RGD does not have linkers with long chains as spacers between AuNP and RGD or RGD-RGD molecules, since it has been proven that the introduction of spacers and the increase of linker lengths significantly affecting the RGD multivalency effect may be related to the decrease of the effective RGD molarity.[31]

Detailed procedures for the preparation of RGD conjugated to other nanoparticles such as quantum dots or nanocrystals (semiconductor nanoparticles, 2−10 nm) have been reported with successful results to obtain *in vivo* imaging of human glioblastoma or melanoma tumors based on fluorescence imaging.[32,33] Recently, near-infrared gold nanoparticles (nanorods, 42 nm in

length, 10 nm in width) have proven useful as a new class of tracers for photothermal therapy, although they could also be used for near-infrared (NIR, 700−1000 nm wavelength) fluorescence-based imaging.[34] However, in human tissues these optical imaging methods have poor spatial resolution and limited optical signal penetration depth (<7 mm by fluorescence resonance imaging). ^{99m}Tc-AuNP-RGD could be used to detect tumor angiogenesis by binding to the specific $\alpha_v\beta_3$ receptor and producing images with high spatial resolution (e.g., 1.6 mm) and no depth limit in soft tissue, because nuclear imaging is an established clinical molecular imaging modality that offers good sensitivity deep in tissue.

Because of its colloidal nature, the intravenous administration of ^{99m}Tc-AuNP-RGD showed high spleen and liver uptake, which was significantly reduced when the intraperitoneal administration mode was used. However, this multimeric system (i.v. or i.p. administration) could be successfully used, for example, to acquire transaxial, coronal, and sagittal tomographic images using single-photon emission computed tomography (SPECT) or SPECT/CT systems for early detection of a primary breast tumor (by $\alpha_v\beta_3$ overexpression in both endothelial and breast cancer cells) and the involved axillary lymph nodes because the abdominal background-radiation interference would be minimal in breast cancer patients. Molecular imaging of $\alpha_v\beta_3$ integrin expression during tumor angiogenesis using ^{99m}Tc-AuNP-RGD could be useful in visualizing and quantifying $\alpha_v\beta_3$ expression level, in selecting patients more appropriately, and in monitoring treatment efficacy in $\alpha_v\beta_3$-positive patients.

CONCLUSIONS

TEM and spectroscopy techniques demonstrated that AuNPs can be successfully conjugated to HYNIC-GGC and c[RGDfK-(C)] through interactions with the thiol groups of cysteine. ^{99m}Tc-AuNP-RGD, with radiochemical purity ≥94%, is highly stable in human serum and shows high and specific $\alpha_v\beta_3$-positive tumor uptake in mice. Therefore, it is a potential target-specific radiopharmaceutical for molecular imaging of tumor $\alpha_V\beta_3$ expression.

Supporting Information

ABSTRACT: A novel fluorescence-quenching screening method for protein kinase C (PKC) ligands was developed utilizing solvatochromic fluorophores. Solvatochromic dyes, highly sensitive to the presence or the absence of competitive ligands in their binding to the C1b domain of PKCδ (δC1b), were combined with a known pharmacophoric moiety of 1,2-diacylglycerol (DAG) lactones, PKC ligands. Addition of δC1b to the fluorescent compounds caused a gradual increase in the fluorescent intensity in proportion to the increase of δC1b. As a competitive ligand was added to the complex of δC1b domain and fluorescent compounds, a gradual decrease in the fluorescent intensity was observed. The relative binding affinities of known ligands were successfully determined by this fluorescent method and corresponded well to the K_i values measured by a radioisotope method. These results indicate that washing, which is a laborious step in binding evaluations, is not required for this environmentally sensitive fluorophore based system. Screening with the system was performed for 2560 preselected library compounds with possible pharmacophores, and some lead compounds were found. This fluorescence-based method could be applied widely to known ligand−receptor combinations.

INTRODUCTION

Solvatochromic fluorophores are sensitive to immediate changes in their environment such as binding of ligands to proteins,[1] and significant biological issues have been examined by chemical probes with fluorescent dyes.[2,3] The major advantage of the fluorescence-based methods in the observation of physiological phenomena in cells is that detection and evaluation can be performed in real-time directly by microscopy. In these techniques, the signal/background ratio is critical to avoid the observation of artifacts or to obtain clearer images at high resolution. Screening methods of bioactive compounds have been developed as another application of fluorescence.[4] From the aspect of sensitivity, radioisotope (RI) based methods are more efficient but involve laborious experimental procedures. For the development of convenient screening procedures, a simple method for evaluation of binding is needed. By attachment of solvatochromic fluorophores to known ligands, the binding affinity of unknown ligands can be evaluated and related to RI methods.[5] Fluorescent intensity is highly dependent on the binding state to a target protein, and the signal/background ratio would be sufficient without washing steps, which are normally necessary in fluorescent analysis.[6,7]

In this study, we have developed reporter compounds containing solvatochromic dyes for the detection of ligand binding to a target protein and applied them to the screening of chemical libraries. Protein kinase Cδ (PKCδ) was chosen as a target protein because of its importance in physiological phenomena. The 11 isozymes that constitute PKC play pivotal roles in physiological responses to growth factors, oxidative stress, 1,2-diacylglycerol (DAG), and tumor promoters, such as phorbol esters. These responses regulate numerous cellular processes,[8,9] including proliferation,[10] differentiation,[11] migration,[12] and apoptosis.[13,14] Membrane translocation of PKC is caused by binding of ligands to the C1b domain and has been recognized as an important phenomenon in signal transduction because the localization of PKC is key in determining isozyme-specific functions by defining binding partners for downstream signaling.[15] Despite the complex regulatory mechanisms of PKC activation, considerable progress has been made in understanding isozyme-specific functions[16] and several ligands with high specificity for PKC isozymes have been developed as potential drugs.[17−23] Through the development of DAG-lactones, whose design is based on the endogenous ligand DAG, the importance of maintaining intact the pharmacophore triad of two carbonyl groups (*sn*-1 and *sn*-2) and the primary alcohol has been established as a requirement in high affinity ligands for PKC (Figure 1).[16] Various PKC ligands have been synthesized and found to be inhibitors of tumor promotion or of other diseases.

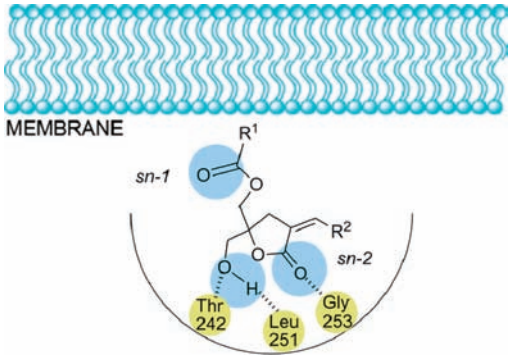
However, there are limitations to the design of compound templates so far. Thus, in this study, we have attempted to develop the screening methods aimed at discovery of novel template structures for PKCδ ligands as drug leads.

EXPERIMENTAL PROCEDURES

General. ^{1}H NMR spectra were recorded using a Bruker AV500 spectrometer. Chemical shifts were reported in δ (ppm) relative to Me_4Si (in $CDCl_3$) as an internal standard. Low- and high-resolution mass spectra were recorded on a JMS-T1000LC AccuTOF and Bruker Daltonics microTOF-2focus in both positive and negative detection modes. Wakogel C-200 (Wako Pure Chemical Industries, Ltd.) and silica gel 60 N (Kanto Chemical Co., Inc.) were employed for flash chromatography. Fluorescent spectra were recorded on a JASCO FP-6600 spectrofluorometer and JASCO V-650 spectrophotometer using a quartz cell with 1.0 cm path length. Fluorescent intensities of samples in 96-well plates were recorded on Wallac ARVO MX.



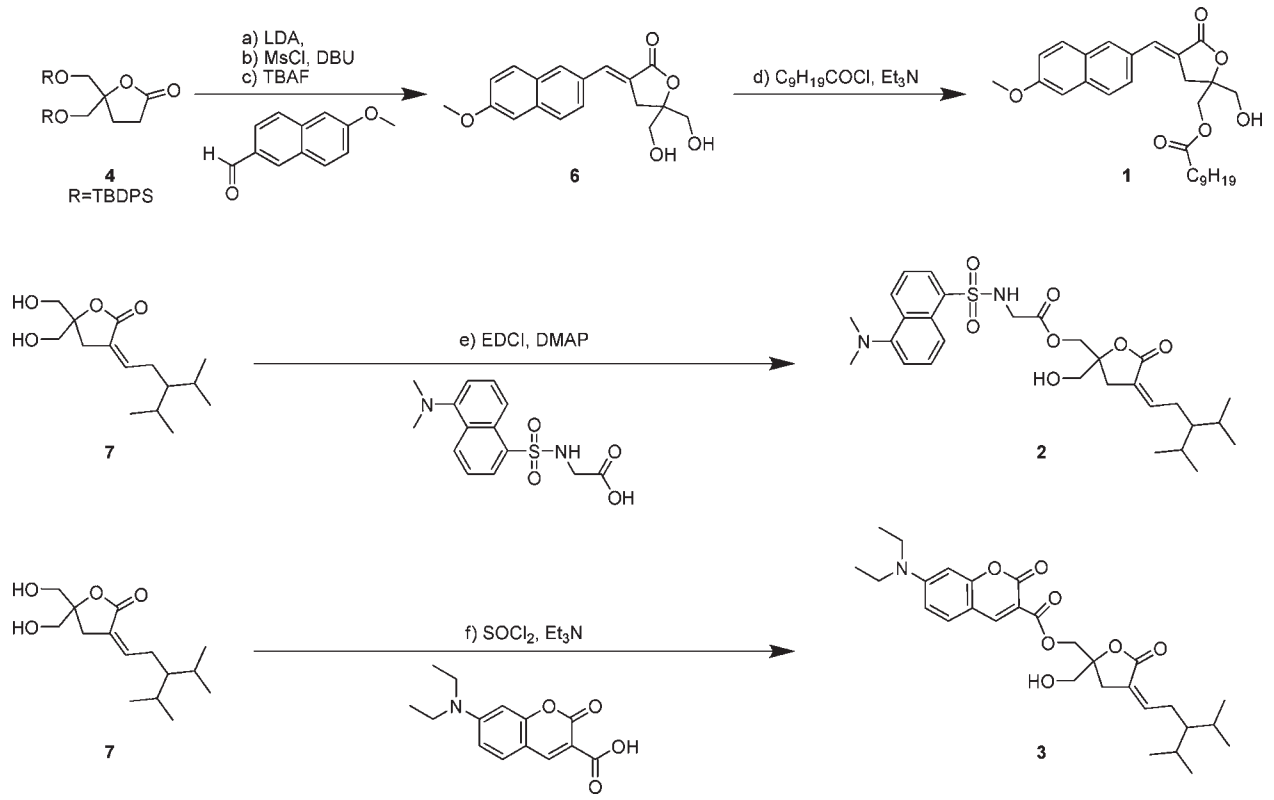


Figure 1. Binding mode of DAG-lactone derivatives to the δC1b domain. The *sn*-1 and *sn*-2 carbonyl groups are indicated. Three important pharmacophores are indicated by light blue spheres. Amino acid residues interacting with these pharmacophores (threonine at 242, leucine at 251, and glycine at 253) are indicated by red spheres.

Standard Monoacylation Procedure. Under argon, Et_3N (3 equiv) was added at 0 °C to a solution containing 5,5-bis(hydroxymethyl)oxalan-2-one in THF, and the mixture was stirred at 0 °C for 30 min. Then 0.2−1.1 equiv of a carboxylic acid derivative (an acyl chloride or carboxylic anhydride) was added. This mixture was stirred at 0 °C for a further 4 h. After evaporation of the solvent, the obtained residue was purified by flash column chromatography.

Preparation of Compounds 7, 10−13, 16, 17, and 19−21. Compounds **7**, **10**−**12**, and **16** were prepared as described in ref 17. Compounds **13** and **17** were prepared as described in refs 24 and 25. The synthesis of **19** is described elsewhere.[26] Compounds **20** and **21** are commercially available.

Expression and Purification of the δC1b Domain. DNA coding C1b domain of mouse PKCδ (231−280)[27] was subcloned into *Bam*H1 and *Eco*RI sites of pGEX-2tk (GE Healthcare) and expressed as gluthatione-*S*-transferase (GST) fusion protein in *Escherichia coli* C41 which contains extension sequences Gly-Ser-Arg-Arg-Ala-Ser-Val-Gly-Ser and Glu-Phe-Ile-Val-Thr-Asp at the N- and C-termini, respectively. The δC1b

domain after cleavage contains 65 amino acid residues. Cells were grown at 37 °C in LB medium and induced with 0.3 mM IPTG at growth phase. Cells were cultured overnight at 20 °C after induction. Cells were collected and lysed in 50 mM Tris·HCl buffer (pH 8.0) containing 100 mM NaCl, 1 μg/mL leupeptine, 1 mM PMSF, and 1 mM DTT. Expressed protein was extracted by sonication, then purified by affinity chromatography utilizing glutathione-Sepharose 4B beads resin. GST moiety was cleaved by 300 units of thrombin at 4 °C overnight. The cleaved protein was eluted and further purified on a 2.6 cm × 60 cm Superdex S-75 gel filtration column. Purification was by FPLC system at a flow rate of 1 mL/min utilizing 0.1 M triethanolamine·HCl (pH 7.0) containing 0.5 M NaCl.

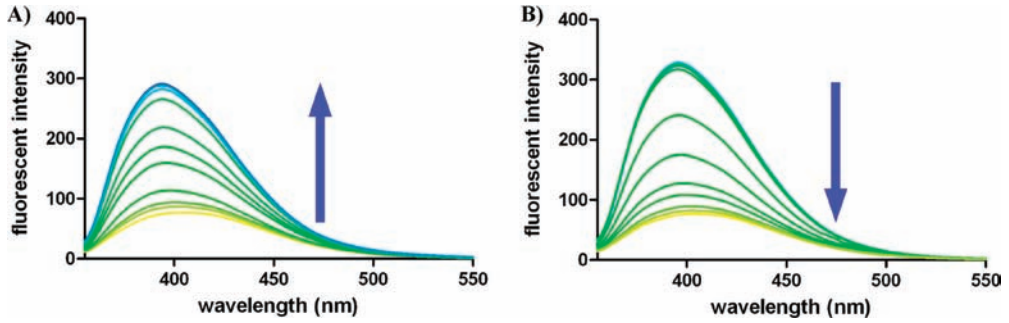

Figure 4. Changes of fluorescent spectra of compound **1** during titration of the δC1b domain (A) and during titration of PDBu (compound **8**) (B) after δC1b binding. The concentration of the δC1b domain was increased to 1.28 μM (6.4 equiv to compound **1**) by titration. The concentration of PDBu was increased to 10.2 μM (51.2 equiv to compound **1**) by titration.

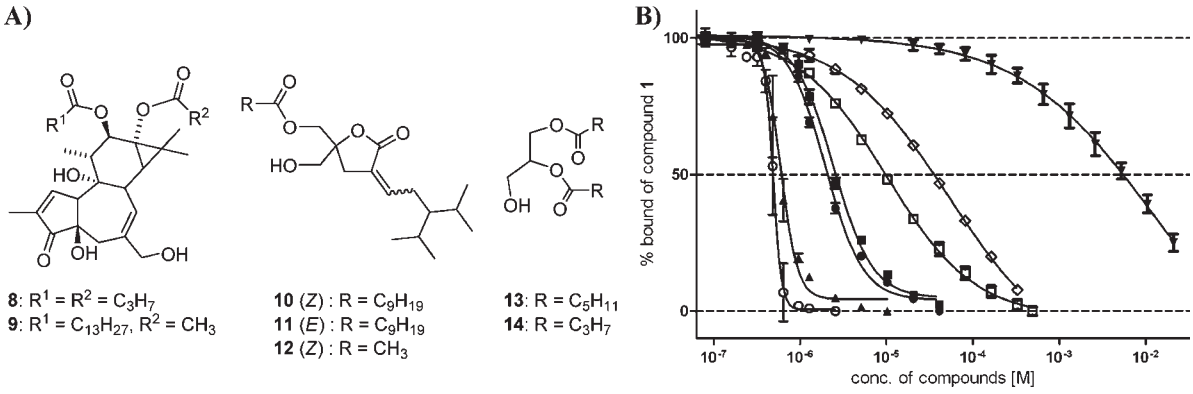

Figure 5. Competitive assay against compound **1** based on fluorescent intensity (spectrofluorometer). (A) Structures of test compounds. (B) Inhibition curves indicate results of compounds **8** (▲), **9** (○), **10** (●), **11** (■), **12** (□), **13** (◇), and **14** (▼).

Determination of K_i of Compounds for Full Length PKCδ. Enzyme−ligand interaction was assessed in vitro as the ability of the ligand to displace bound [20-^{3}H]phorbol 12,13-dibutyrate ([^{3}H]PDBu) from recombinant human PKCδ in the presence of phosphatidylserine (PS) in an experimental procedure that was described previously.[28] In constant concentration analysis, the concentrations of compounds were fixed at 100 nM for known compounds and at 10 μM for library compounds. The other procedures were the same as those of the standard evaluation.

Fluorescent Titration of the δC1b Domain. An amount of 25 μL of a solution of PS in chloroform (10 mg/mL) was evaporated to dryness under nitrogen. Then 50 mM Tris·HCl buffer (pH 7.4) was added and the PS was sonicated with a Microtip for a total of 15 s. A stock solution of compound **1** was diluted with 50 mM Tris·HCl buffer (pH 7.4) containing 100 μg/mL PS to prepare a 0.2 μM solution. The recombinant δC1b domain was added to the 0.2 μM solution of compound **1**, and fluorescent spectra (λ_{ex} = 340 nm) were measured at 25 °C. The concentration of the recombinant δC1b domain started at 0.01 μM and increased to 1.28 μM by titration. The final concentrations of compounds **2** and **3** were 0.2 and 0.05 μM, respectively. Change of fluorescent intensity (ΔF) was calculated at the following wavelengths, which showed λ_{max} in each evaluation; compound **1**, 406 (F_0) and 394 (F_1) nm; compound **2**, 520 (F_0) and 480 (F_1) nm; compound **3**, 463 (F_0) and 461 (F_1) nm. Wavelengths recorded before and after the addition of the δC1b domain.

Fluorescent Titration of Candidate Ligands. Compound **1** was diluted with 50 mM Tris·HCl (pH 7.4) containing 100 μg/mL PS to obtain a solution with a 0.2 μM final concentration. The δC1b domain was added to the above solution of compound **1** to be 0.96 μM. A candidate ligand was added to the solution, and fluorescent spectra were recorded with a spectrofluorometer at 25 °C. Fluorescent titration curves (λ_{em} = 407 nm) were analyzed by nonlinear regression, and IC_{50} values were estimated by a nonlinear least-squares curve-fitting method using GraphPad Prism 5 (GraphPad Software, Inc., La Jolla, CA, U.S.). In the constant concentration analysis, the concentrations of known compounds were fixed at 100 nM and of library compounds at 10 μM. The other procedures were the same as those in the standard evaluation.

Fluorescence-Quenching Analysis for Library Screening Recorded by Microplate Reader. Fluorescence intensity was recorded on Wallac ARVO MX (PerkinElmer) using a 96-well black plate. Compound **1** was diluted with 50 mM Tris·HCl (pH 7.4) containing 100 μg/mL PS to obtain a solution with a 0.2 μM final concentration. The δC1b domain was added to the above solution of compound **1** to be 0.96 μM. A candidate ligand (10 μM) was added to the compound **1**−δC1b domain complex solution, and fluorescent intensities (λ_{ex} = 355 nm, λ_{em} = 405 nm) were measured at 25 °C.

RESULTS AND DISCUSSION

Synthesis and Fluorescent Properties of Compounds 1−3. Three representative solvatochromic fluorophores, involving 6-methoxynaphthalene,[29] 5-(dimethylamino)naphthalene-1-sulfonyl (dansyl),[6,30,31] and diethylaminocoumarin,[32−35] have

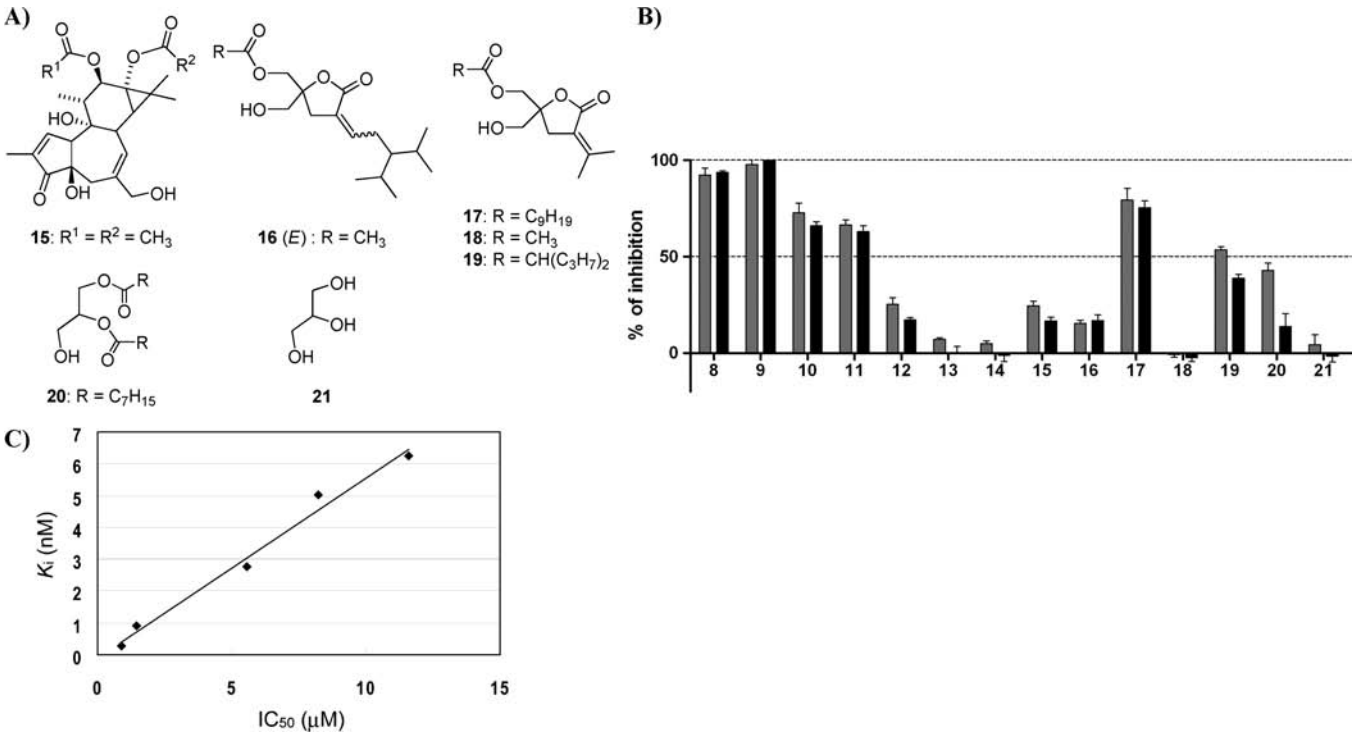

Figure 6. Comparison of inhibition percentages between the fluorescent assay (microplate reader) and the RI assay at a constant concentration of test compounds. (A) Structures of test compounds. (B) Inhibition of binding of compound **1** (fluorescent assay, left gray bars) or [^{3}H]PDBu (RI assay, right black bars) in the presence of test compounds (10 μM in the fluorescent assay and 100 nM in the RI assay). The final DMSO concentration is 4%. (C) Plots of IC_{50} values (μM) by the fluorescent assay versus K_i (nM) by the RI assay for compounds **8**, **9**, **10**, **11**, and **17**.

been utilized. The 6-methoxynaphthalene was incorporated at the α-carbon of the *sn*-1 carbonyl group of the DAG-lactone structure (Scheme 1). The dansyl and diethylaminocoumarin were incorporated into the *sn*-2 carbonyl group. In comparison with the fluorescent spectra of these compounds, obtained in various solvents, compound **1** showed the most variation with solvent polarity (Figure 2). It is known that solvatochromic fluorophores show higher fluorescent intensity in hydrophobic environments and that the fluorophores are sensitive to the environment of a binding pocket in target proteins. The fluorescent intensity of labeled DAG-lactones should reflect its binding to a target protein, PKCδ (Figure 3), and as expected, our reporter compounds **1** and **2** containing solvatochromic fluorophores exibited a remarkable increase of fluorescent intensity in the proximity of the C1b domain of PKCδ (δC1b), which is a specific target of DAG-lactone derivatives (Table 1 and Figure 4A). This indicates that in the binding of compounds **1** and **2** to the δC1b domain, the 6-methoxynaphthalene and dansyl moieties are located in the hydrophobic environment. However, for compound **3**, the fluorescent intensity was decreased as the concentration of δC1b increased. The spectra in various solvents showed dependence of the fluorescent intensity of the compound **3** on solvent polarity, and it was suggested that in the binding of compound **3** to the δC1b domain, the diethylaminocoumarin moiety could be located in the hydrophilic environment. The changes of fluorescent intensity of the synthetic compounds are summarized in Table 1. The binding constants of fluorescent compounds were evaluated by [^{3}H]PDBu competitive assay. Compound **1** showed the highest binding affinity for the δC1b domain. In the fluorescence-based analysis of binding, two factors are key to the sensitivity of the assay system: (i) the fluorescent change as a function of the ligand binding and (ii) the binding affinity of a reporter compound.

Evaluation of Binding to PKCδ by Fluorescent Change of Compound 1. The results obtained supported the selection of compound **1** as a reporter compound for further study. In competitive assays, when candidate ligands of PKCδ are present, they replace the fluorescent compounds, which are formerly bound to δC1b, and the fluorescent intensity should decrease. Practically, addition of PDBu to the complex of compound **1** and δC1b resulted in a remarkable decrease of fluorescent intensity (Figure 4B). By utilization of compound **1** as a reporter, binding analysis of known PKCδ ligands was performed to assess the reliability of the assay system. Compounds **8**−**14** were prepared as test compounds (Figure 5A), and their IC_{50} values, determined by the fluorescence-based competitive assay with a fluorospectrophotometer against compound **1**, were 0.60, 0.49, 1.95, 2.42, 10.0, 54.2, and 1.22 × 10^4 μM, respectively (Figure 5B). The order of the IC_{50} values of compounds **8**−**11** is identical to that of the K_i values (0.91, 0.26, 5.0, and 6.2 nM, respectively) determined by the [^{3}H]PDBu competitive assay.

The Binding Analysis by Competition with Compound 1 Showed Linearity with the Classical RI Assay. To further assess the collinearity of the fluorescent assay on microplates and the [^{3}H]PDBu assay, the inhibition percentages by compounds **8**−**21** in both assays (Figure 6A) at constant concentration were compared. The compound concentrations were set at 10 μM for the fluorescent assay and at 100 nM for the [^{3}H]PDBu assay. As shown in Figure 6B, the inhibition percentages of compounds **8**−**21** are similar in both assays. Comparison of the IC_{50} and K_i of compounds **8**, **9**, **10**, **11**, and **17**, possessing more than 60% inhibition percentages, showed acceptable linearity (Figure 6C).

dx.doi.org/10.1021/bc100567k |*Bioconjugate Chem.* 2011, 22, 923–930

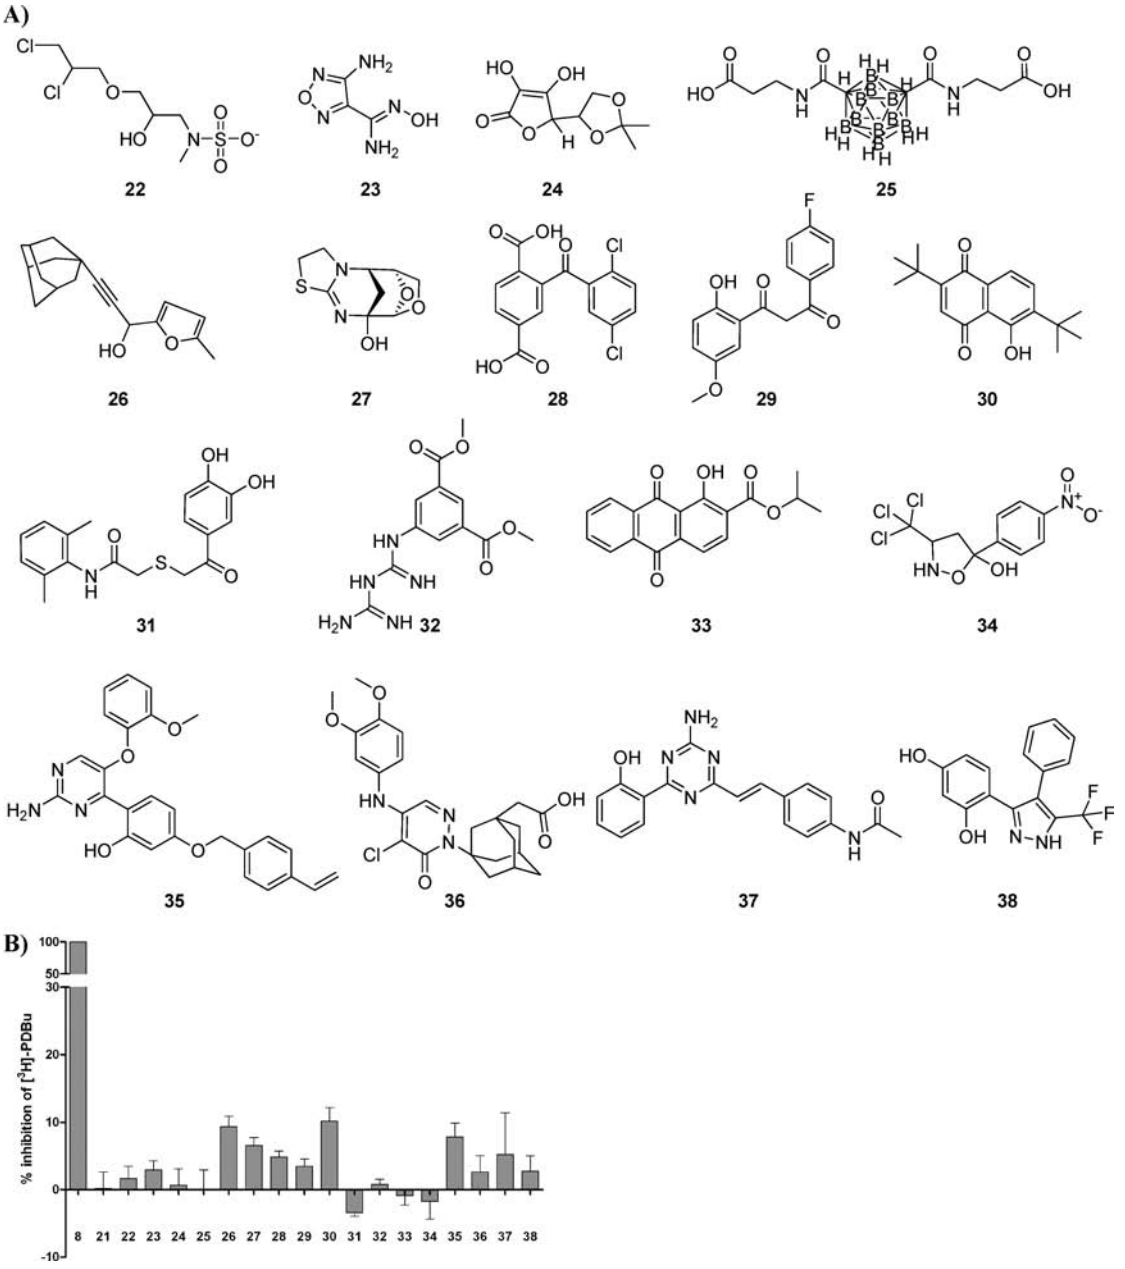

Figure 7. The RI competition assay of positive hit compounds found in fluorescent screening utilizing compound **1**. (A) Structures of test compounds obtained from screening. (B) Results of the inhibition assay based on RI methods. The concentration of compounds was fixed at 10 μM. The *X* axis indicates compound numbers. Columns show average inhibition obtained from triplicated experiments. Bars indicate standard errors.

In view of the above results, the present fluorescence-based evaluation of binding to the δC1b domain on microplates was deemed to be a promising alternative for the classical RI assay.

Expansion of the Fluorescence Evaluation to Screening of Library Compounds. As a proof-of-concept study, compound **1** was utilized in screening of a chemical library, supplied by the Screening Center at the Tokyo Medical and Dental University Screening Center. The structures of the library compounds were analyzed in advance of screening. For binding to the δC1b domain, pharmacophores including the carbonyl and hydroxy groups are necessary and only compounds including these functional groups were chosen. In the analysis of the library on microplates, compounds with more than 20% decrease of fluorescent intensity determined by triplicated assays were selected as candidates for further study. Compounds **22**−**38** were found from 2560 library compounds (Figure 7A) as candidate δC1b ligands. To further assess the binding affinity of these compounds, evaluation of binding by competition with the [^{3}H]PDBu was performed at a fixed concentration (10 μM) (Figure 7B). In this analysis, compounds **30** and **26**, with inhibition percentages at 10 μM of 10.2% and of 9.4%, respectively, showed the most and the second most potent binding affinities for the δC1b domain. The binding affinities of these compounds are still very low compared to that of DAG-lactones, but an SAR study of these compounds could lead to novel structure templates for synthetic PKC ligands. This analysis also revealed that compounds **24**, **25**, **31**, **32**, **33**, and **34** are false positive hits. The results obtained indicate that our screening system with a fluorescent

dx.doi.org/10.1021/bc100567k |*Bioconjugate Chem.* 2011, 22, 923–930

DAG-lactone derivative could be utilized for discovery of novel chemical leads for PKCδ.

CONCLUSION

A fluorescence-based method for chemical library screening has been developed. This method, which requires no washing steps, provides a linear response in relative binding affinity between compounds and is compatible with the classical RI assay for PKC ligands. By screening of more than 2500 library compounds, the method was proven to be a reliable means of discovery of compounds that bind to the C1b domain of PKCδ. The method would provide potent lead compounds that bind to the isozyme utilized in the assay. By utilization of the difference of the binding affinity of reporter compounds to different isozymes, it is possible that this screening system can provide an efficient selection of lead compounds highly specific to a target isozyme. This fluorescence-quenching method should be applicable to other known receptor−ligand combinations.

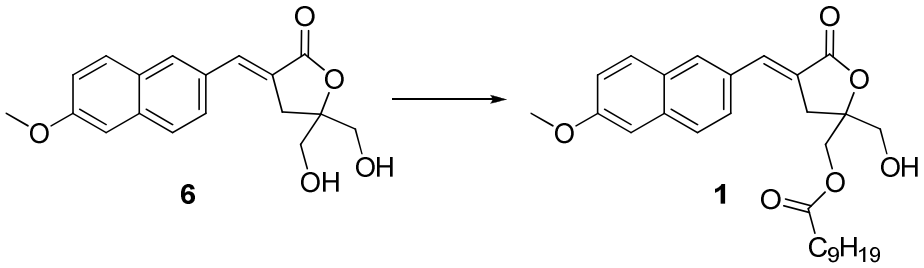
Synthesis of compound 1

(*E*)-5,5-Bis(hydroxymethyl)-3-((6-methoxynaphthalen-2-yl)methylene)dihydrofura n-2(*3H*)-one (6): Under argon, a -78 °C solution of **4** (1.24 g, 2.00 mmol) in THF (13 mL) was treated dropwise with LDA (2.00 mL, 2 M solution in heptane/THF/ethylbenzene) and stirred at -78 °C for 2 h. 6-Methoxy-2-naphtaldehyde (1.13 g, 4.00 mmol) was added slowly maintaining the same temperature, and the reaction was monitored by TLC. After 2 h's treatment, the reaction was quenched with saturated aqueous NH_4Cl and then warmed to room temperature. The aqueous layer was extracted 3 times with chloroform (50 mL x 3). The combined organic layer was wahed with water, dried over $MgSO_4$ and concentrated to give the alkylation crude product as an oil, which was used without further purification. A solution of the alkylation crude product in CH_2Cl_2 (40 mL) was treated with MsCl (330 μL, 4.00 mmol) and Et_3N (1.39 mL, 10.0 mmol) at 0 °C. This mixture was stirred at 0 °C for 30 min and then at room temperature at 2 h. The reaction mixture was then cooled to 0 °C, DBU (1.84 mL, 12.4 mmol) was added, and the resultant solution was stirred at room temperature overnight. The reaction mixture was diluted by chloroform, washed with saturated aqueous NH_4Cl, and dried over $MgSO_4$, and concentrated to give crude **5** as an oil, which was used in the next step without further purification. A stirred solution of crude **5** (1.58 g, 2.00 mmol) in THF (8.0 mL) was treated with a THF solution of tetrabutylammonium fluoride (1 M, 8.00 mL) at room temperature for 1 h. After the volatiles were removed under reduced pressure, the residue was partitioned between chloroform and water. The organic layer was separated and dried over Na_2SO_4. After evaporation of the solvent, the obtained residue was purified by flash column chromatography over silica gel using $CHCl_3$/MeOH (30:1) as eluant. The compound **6** (*E* isomer, 491 mg, 78% from **4**) was obtained as white crystals, mp 182-184 °C [from $CHCl_3$/MeOH (30:1)]. The *E* isomer was exclusibely obtained, which was based on tentative assignment.[1]

^{1}H-NMR (500 MHz; DMSO)

δ 8.17 (s, 1H), 7.97 (d, J = 9.0 Hz, 1H), 7.94 (d, J = 8.6 Hz, 1H), 7.75 (dd, J = 7.2, 1.4 Hz, 1H) 7.5 (t, J = 2.8 Hz, 1H) 7.42 (d, J = 2.4 Hz, 1H) 7.26 (dd, J = 6.4, 2.6 Hz, 1H),



5.17 (t, *J* = 5.8 Hz, 2H), 3.94 (s, 3H), 3.54-3.62 (m, 4H), 3.21-3.21 (m, 2H).

^{13}C-NMR (125 MHz; DMSO)

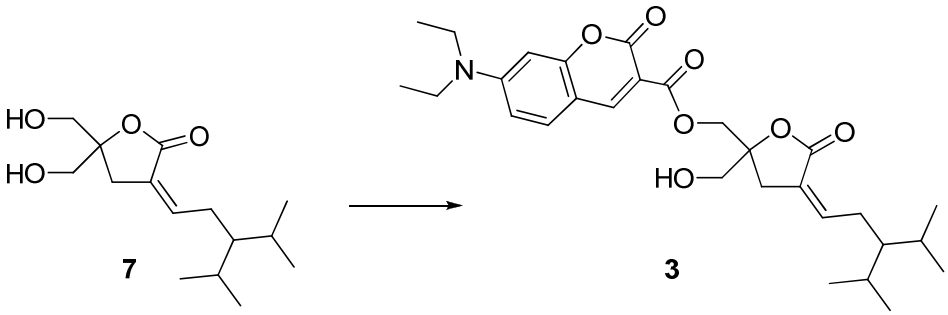
FAB-HRMS (*m*/*z*): Found [MH$^+$] 469.2601. $C_{28}H_{37}O_6$ requires *M*+H, 469.2590.

IR (neat): 3369 (OH), 2933, 1709 (C=O), 1626 cm^{-1}.

Synthesis of compound 2

(*Z*)-(2-(Hydroxymethyl)-4-(3-isopropyl-4-methylpentylidene)-5-oxotetrahydrofuran-2-yl)methyl 2-(5-(dimethylamino)naphthalene-1-sulfonamido)acetate (2): Under argon, a 0 °C solution of **7** (7.0 mg, 26 μmol) in CH_2Cl_2 (10 mL) was treated with DMAP (0.3 mg, 2.6 μmol) and EDCI (3.8 mg, 20 μmol) and stirred at 0 °C for 30 min. N^{α}-Dansyl-glycine (5.6 mg, 20 μmol) was added slowly maintaining the same temperature. This mixture was stirred at room temperature for 8 h. After evaporation of the solvent, the residue obtained was purified by flash column chromatography over silica gel using $CHCl_3$/MeOH (60:1) as eluant. The compound **2** (5.0 mg, 34%) was isolated as a yellow oil.

^{1}H-NMR (400 MHz; $CDCl_3$)



δ 8.57 (d, J = 8.5 Hz, 1H), 8.22-8.28 (m, 2H), 7.50-7.62 (m, 2H), 7.20 (d, J = 7.6 Hz, 1H), 6.24-6.28 (m, 1H), 5.27 (br s, 1H), 4.19-4.22 (m, 1H), 4.07-4.10 (m, 1H), 3.74 (d, J = 5.6 Hz, 2H), 3.57 (d, J = 6.0 Hz, 2H), 2.89 (s, 6H), 2.78-2.82 (m, 1H), 2.67-2.72 (m, 2H), 2.58-2.63 (m, 1H), 1.72-1.81 (m, 2H), 1.09-1.13 (m, 1H), 0.835-0.904 (m, 12H).

^{13}C-NMR (125 MHz; DMSO)

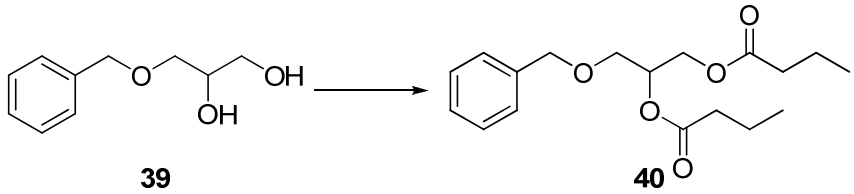
δ 168.8, 168.5, 151.2, 144.6, 136.0, 129.4, 129.0, 128.9, 127.8 (2), 123.9, 123.4, 119.1, 115.0, 82.4, 65.8, 63.2, 63.0, 50.0, 45.5, 45.0, 43.4, 32.1, 28.7, 28.6, 25.3, 21.3, 21.2, 19.2.

FAB-HRMS (*m*/*z*): Found [MH^+] 561.2632. $C_{29}H_{41}N_2O_7S$ requires *M*+H, 561.2634.

Synthesis of compound 3

(*Z*)-(2-(Hydroxymethyl)-4-(3-isopropyl-4-methylpentylidene)-5-oxotetrahydrofura n-2-yl)methyl 7-(diethylamino)-2-oxo-2*H*-chromene-3-carboxylate (3): To a stirred solution of 7-diethylamino coumarin 3-carboxylic acid (27.4 mg, 0.105 mmol) in THF (8 mL) were added dropwise thionyl chloride (8 μL, 0.116 mmol) and DMF (0.8 μL) at room temperature, and the mixture was refluxed at 70 °C for 2 h. The reaction mixture was concentrated to give 7-diethylamino coumarin 3-carbonyl chloride as a solid, which was used without further purification. The standard monoacylation procedure starting from **7** (40.0 mg, 0.150 mmol) was applied using 7-diethylamino coumarin 3-carbonyl chloride (29.4 mg, 0.105 mmol). After flash column chromatography with $CHCl_3$/MeOH (20:1), the compound **3** (27.9 mg, 36%) was isolated as orange-colored crystals, mp 97-98 °C [$CHCl_3$/MeOH (20:1)].

^{1}H-NMR (400 MHz; DMSO)



δ 8.45 (s, 1H), 7.58-7.61 (m, 1H), 6.77-6.80 (m, 1H), 6.54 (d, 1H, J = 2.3 Hz), 6.22-6.26 (m, 1H), 5.27 (t, 1H, J = 5.8), 4.28-4.36 (m, 2H), 3.58 (d, J = 6.0 Hz, 2H), 3.48 (q, J = 7.0 Hz, 4H), 2.78-2.89 (m, 2H), 2.61-2.68 (m, 1H), 2.50-2.51 (m, 1H), 1.64-1.74 (m, 2H), 1.10-1.16 (m, 6H), 1.06-1.09 (m, 1H), 0.742-0.853 (m, 12H).

^{13}C-NMR (100 MHz; DMSO)

δ 168.7, 162.8, 158.1, 156.7, 153.0, 149.4, 144.4, 131.7, 124.1, 109.8, 106.9, 106.4, 95.8, 82.9, 65.5, 63.1, 50.0, 44.3, 32.5, 28.9, 28.7, 28.6, 25.3, 21.3 (2), 19.2, 19.1, 12.2 (2)

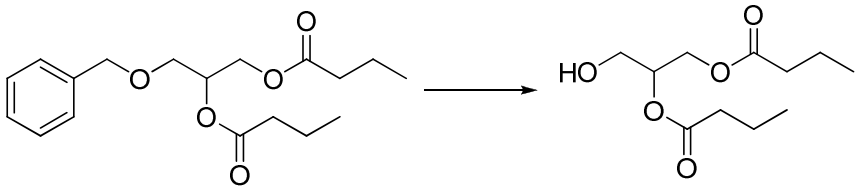
FAB-HRMS (*m*/*z*): Found [MH^+] 514.2804. $C_{29}H_{40}NO_7$ requires *M*+H, 514.2805.

Synthesis of compound 14

39 **40**

3-(Benzyloxy)propane-1,2-diyl dibutyrate (40): Under argon, a solution of racemic 1-benzyl-glycerol **39** (0.74 g, 4.0 mmol)[2] in CH_2Cl_2 (5 mL) was treated with Et_3N (2.3 mL, 16 mmol) and stirred at room temperature for 15 min, and then treated with butanoic anhydride (2.0 mL, 12 mmol) and refluxed at 75 °C. After 3.5 h's reaction, the solvent was evaporated. The residue obtained was purified by flash column chromatography over silica gel using hexane/EtOAc (15:1) as eluant. The racemic compound **40** (1.18 g, 92%) was isolated as a light yellow oil.

^{1}H-NMR (500 MHz; $CDCl_3$)



δ 7.26-7.35 (m, 5H), 5.23-5.27 (m, 1H), 4.51-4.57 (m, 2H), 4.34-4.37 (m, 1H), 4.18-4.21 (m, 1H), 3.58-3.60 (m, 2H), 2.25-2.32 (m, 4H), 1.58-1.73 (m, 4H), 0.916-0.961 (m, 6H).

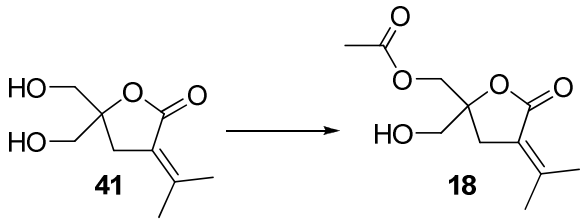
^{13}C-NMR (125 MHz; $CDCl_3$)

δ 173.3, 172.9, 137.7, 128.4, 127.8, 127.7, 73.3, 70.0, 68.3, 62.7, 36.2, 36.0, 18.4 (2), 13.6 (2).

FAB-HRMS (*m*/*z*): Found [MH^+] 323.1853. $C_{18}H_{27}O_5$ requires *M*+H, 323.1858.

IR (neat): 2965-2876, 1740 (C=O) cm^{-1}.

40 **14**



3-Hydroxypropane-1,2-diyl dibutyrate (14): A solution of **40** (1.12 g, 3.41 mmol) in EtOH (18 mL) was hydrogenated for 5 h under a balloon of hydrogen in the presence of 10% palladium on carbon (0.300 g). The reaction mixture was filtered, and the filtrate was concentrated in vacuo. The residue was purified by flash column chromatography over silica gel using hexane/EtOAc (2:1) as eluant. The compound **14** (0.580 g, 73%) was isolated as a light yellow oil.[3]

^{1}H-NMR (500 MHz; $CDCl_3$)

δ 5.08-5.12 (m, 1H), 4.32-4.36 (m, 1H), 4.20-4.24 (m, 1H), 3.73 (d, J = 5.0 Hz, 2H), 2.79

(br s, 1H), 2.30-2.35 (m, 4H), 1.61-1.70 (m, 4H), 0.935-0.973 (m, 6H).

ABSTRACT: Because of the recent observation of the toxic side effects of Gd(III) based MRI contrast agents in patients with impaired renal function, there is strong interest on developing alternative contrast agents for MRI. In this study, macrocyclic Mn(II) chelates were conjugated to nanoglobular carriers, lysine dendrimers with a silsesquioxane core, to synthesize non-Gd(III) based MRI contrast agents. A generation 3 nanoglobular conjugate of Mn(II)-1,4,7-triaazacyclononane-1,4,7-triacetate-GA amide (G3-NOTA-Mn) was also synthesized and evaluated. The per ion T_1 and T_2 relaxivities of G2, G3, G4 nanoglobular Mn(II)-DOTA monoamide conjugates decreased with increasing generation of the carriers. The T_1 relaxivities of G2, G3, and G4 nanoglobular Mn(II)-DOTA conjugates were 3.3, 2.8, and 2.4 mM^{-1} s^{-1} per Mn(II) chelate at 3 T, respectively. The T_1 relaxivity of G3-NOTA-Mn was 3.80 mM^{-1} s^{-1} per Mn(II) chelate at 3 T. The nanoglobular macrocyclic Mn(II) chelate conjugates showed good in vivo stability and were readily excreted via renal filtration. The conjugates resulted in much less nonspecific liver enhancement than $MnCl_2$ and were effective for contrast-enhanced tumor imaging in nude mice bearing MDA-MB-231 breast tumor xenografts at a dose of 0.03 mmol Mn/kg. The nanoglobular macrocyclic Mn(II) chelate conjugates are promising nongadolinium based MRI contrast agents.

Mn(II) based nanoglobular MRI contrast agent

INTRODUCTION

Gadolinium-based chelates are the most commonly used contrast agents for clinical magnetic resonance imaging (MRI). However, the recently reported nephrogenic system fibrosis associated with Gd(III) based contrast agents causes serious safety concerns, especially for use in patients with abnormal kidney function.[1−3] There is continual interest in developing alternative MRI contrast agents with much less toxicity. Manganese(II) is an essential element for humans, and has relatively high electronic spins (5/2) and fast water exchange rate.[4] It is less toxic than other paramagnetic metal ions at low concentrations. Mn(II) chelates have been investigated as MRI contrast agents over the past decades. Two Mn(II) based contrast agents, hepatocyte-specific Mn(II) dipyridoxal diphosphate (Mn-DPDP) and an oral formulation containing $MnCl_2$, have been clinically used for liver imaging and gastro-intestinal imaging.[5] As compared to Gd(III) based agents, Mn(II) based MRI contrast agents have been investigated less.

The main challenges for Mn(II) based MRI contrast agents are the low chelation stability and low relaxivity of Mn(II) chelates. Low stability of Mn(II) chelates can result in the release of free Mn(II) ions in vivo. Overexposure to free Mn(II) ions could lead to neurodegenerative damage, such as Parkinson's disease.[6] The design of Mn(II) chelates with high stability is essential to minimize their potential toxicity as MRI contrast agents. Macrocyclic chelates of transition metal ions have shown higher kinetic stability than linear chelates. Mn(II) forms thermodynamically and kinetically stable chelates with macrocyclic ligands, such as DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10- tetraacetic acid), DO3A (1,4,7,10-tetraazacyclododecane-1,4,7-triacetic acid), and NOTA (1,4,7-triaazacyclononane-1,4,7-triacetic acid).[4,7,8] Stability constants (log K) of Mn(II)-DOTA, Mn(II)-DO3A7, and Mn(II)-NOTA8 are 19.89, 19.4, and 14.9, respectively. The macrocyclic Mn(II) chelates with high kinetic and thermodynamic stability can minimize in vivo release of free Mn(II) ions from the contrast agents.

Low relaxivity of Mn(II) based contrast agents could be overcome by conjugating multiple stable Mn(II) chelates to biocompatible polymers. Dendrimers are a class of highly functionalized macromolecules with precisely defined structures.[9] A large number of Mn(II) chelates can be conjugated to the surface of dendrimers, resulting in nanosized contrast agents with high overall relaxivity and improved contrast enhancement at reduced doses. Lysine dendrimers with a symmetric silsesquioxane cubic core were recently reported as a nanoglobular platform for the delivery of therapeutics and

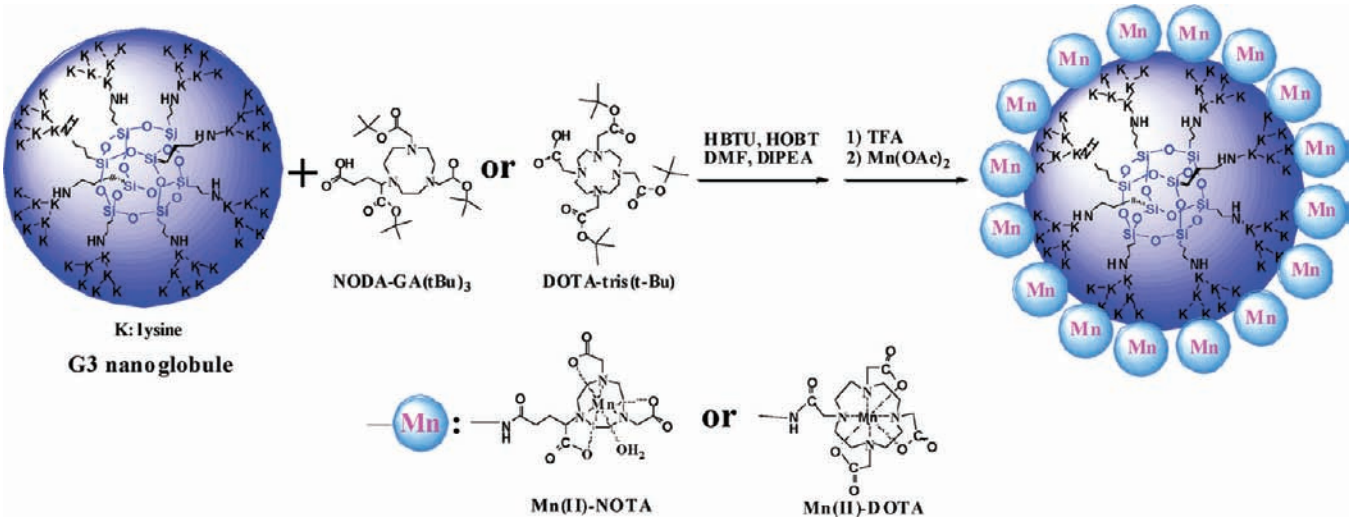
diagnostics.[10−12] Generations 1−3 nanoglobular Gd-DOTA monoamide conjugates have shown increased relaxivity and size-dependent contrast enhancement for magnetic resonance angiography and cancer imaging.[11] The conjugation of Mn(II)-DOTA into a CLT1 peptide targeted G3 nanoglobular lysine dendrimer resulted in a tumor specific contrast agent with high overall relaxivity and significant tumor enhancement at a low dose.[13]

In this study, we synthesized Mn(II)-DOTA monoamide conjugates of generations 2−4 nanoglobules to study size effect on the Mn(II) based nanoglobular MRI contrast agents. A generation 3 nanoglobular Mn(II)-NOTA-GA conjugate was also synthesized to study ligand effect on the relaxivity and in vivo contrast enhancement of the agents. The nanoglobular Mn(II)-based MRI contrast agents were characterized by mass spectrometry and inductively coupled plasma-optical emission spectroscopy (ICP-OES). The relaxivities of the nanoglobular Mn(II) agents were measured. The effectiveness of the Mn(II) based contrast agents in contrast enhanced MRI were evaluated in mice bearing breast cancer xenografts at a low dose.

MATERIALS AND METHODS

4-(4,7-Bis(2-*tert*-butoxy-2-oxoethyl)-1,4,7-triazonan-1-yl)-5-*tert*-butoxy-5-oxopentanoic acid [NODA-GA(tBu)$_3$] was purchased from CheMatech (Dijon, France). 1-Hydroxybenzotriazole (HOBt), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), and N_α,N_ε-di-*t*-BOC-L-lysine dicyclohexylammonium salt [(di-*t*-BOC)$_2$-L-lys-OH•DCHA] were purchased from Nova Biochem (Darmstadt, Germany). 1,4,7,10-Tetraazacyclododecane-1,4,7-tris-*tert*-butyl acetate-10-acetic acid [DOTA-tris(t-Bu)] was purchased from Macrocyclics (Dallas, TX). *N*,*N*-Diisopropylethyl amine (DIPEA), trifluoroacetic acid (TFA), and *N*,*N*-dimethylformamide anhydrous (DMF) were purchased from Alfa Aesar (Ward Hill, MA). Kaiser test kit was purchased from Sigma-Aldrich, Inc. (Louis, MO). All reagents were used without further purification unless otherwise stated. Dendrimers and their conjugates were purified by ultrafiltration with Millipore's Amicon Ultra-15 centrifugal filter of 3 kDa molecular weight cutoff in deionized water. Matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectra were acquired on a Voyager DE-STR spectrometer (PerSpeptive BioSystems) in linear mode with α-cyano-4-hydroxycinnamic acid as a matrix. The Mn(II) content was measured by inductively coupled plasma-optical emission spectroscopy (ICP-OES Optima 3100XL, Perkin-Elmer, Norwalk, CT).



Synthesis of Nanoglobule-(Mn-DOTA) Monoamide Conjugates. Generations 2−4 (G2, G3, and G4) nanoglobules with an OAS core were synthesized using standard solution-phase peptide synthesis chemistry.[11,14] Octa(3-aminopropyl)-silsesquioxane hydrochloride (OctaAmmonium POSS-HCl) (0.70 g, 0.597 mmol), HOBt (2.70 g, 20.0 mmol), and (di-*t*-BOC)$_2$-L-lys-OH•DCHA (10.4 g, 20.0 mmol) were dissolved in 30 mL DMF. To the above solution was added 10 mL of DIPEA, and the mixture was stirred at room temperature for 48 h. The reaction mixture was added to 400 mL of 0.5 M citric acid aqueous solution giving a white, sticky precipitate. The precipitate was then treated with acetonitrile giving a colorless solid. The solid product was collected by filtration and dried under vacuum. Yield of [(t-BOC)$_2$-L-lysine]$_8$-OAS was 1.67 g, 80%. [(t-BOC)$_2$-L-lysine]$_8$-OAS (1.67 g) was dissolved in 7 mL ice-cold trifluoroacetic acid (TFA) and stirred at room temperature for one hour to remove t-BOC protection. The residue was treated with anhydrous diethyl ether giving a colorless solid product. The yield of (L-lysine)$_8$-OAS trifluoroacetate (G1) was 1.32 g (59.6%). The generations 2-4 nanoglobules were synthesized following the general procedure of G1.

The synthesis of G2 nanoglobular Mn(II)-DOTA monoamide was used as an example. G2 nanoglobule (50 mg, 6.57 μmol), DOTA-tris(*t*-Bu) (240 mg, 420 μmol), HBTU (159 mg, 420 μmol), HOBt (57 mg, 420 μmol), and DIPEA were dissolved in DMF (2.5 mL) and stirred at room temperature for 24 h. The product was precipitated by adding diethyl ether into the reaction mixture. The oily precipitate was washed several times with diethyl ether, and the *t*-butyl groups were removed by dissolving the precipitate in a mixture of trifluoroacetic acid and methylene chloride (6 mL, volume/volume = 1:1) for 4 h at room temperature. The residue was treated with ice-cold diethyl ether and purified with ultracentrifugation and then by dialysis to give a white solid after lyophilization. Yield of G2-DOTA monoamide conjugate was 65 mg, 70.6%, based on the G2 dendrimer. MALDI-TOF (m/z, $[M+H]^+$): 12 855 (calculated for G2 with 23 DOTA on average), 12 848 (observed). A mixture of G2 nanoglobule−DOTA conjugate (31 mg, 2.2 μmol) and Mn(OAc)$_2$ (70 mg, 282 μmol) in 1 mL 0.5 M ammonium acetate solution was refluxed for 50 min. The final product G2 nanoglobule-(Mn-DOTA) monoamide conjugate was further purified by dialysis with a membrane of 1000 Da molecule weight cutoff to remove the excess free Mn(II) ions. The yield of purified G2 nanoglobule-(Mn-DOTA) monoamide conjugate was 14 mg, 41%. The G3 and G4 nanoglobule-(Mn-DOTA) monoamide conjugates were similarly synthesized. Yield of G3-DOTA conjugate was 85 mg, 91%. MALDI-TOF (m/z, $[M+H]^+$): 28 560 (calculated for G3 with 53 DOTA on average), 28 785 (observed). Yield of G4-DOTA conjugate was 82 mg, 76.7%. MALDI-TOF (m/z, $[M+H]^+$): 54 465 (calculated for G4 with 99 DOTA on average), 54 399 (observed).

Synthesis of G3 Nanoglobule-(Mn-NOTA-GA) Conjugate. G3 nanoglobule (30 mg, 1.95 μmol), NODA-GA(tBu)$_3$ (100 mg, 184 μmol), HBTU (71 mg, 184 μmol), and HOBt (25 mg, 184 μmol) with DIPEA were reacted according to the above procedure to give G3 nanoglobular NOTA-GA conjugate. MALDI-TOF (m/z, $[M+H]^+$): 27 584 (calculated for G3 with 55 NOTA); 27 637 (observed). Yield of G3-NOTA conjugate was 55 mg, 92%. The complexation of G3 nanoglobule-(NOTA)$_{55}$ conjugate (40 mg, 1.45 μmol) with 4-fold excess Mn(OAc)$_2$ gave G3 nanoglobule-(Mn-NOTA)$_{55}$ as colorless solid (44 mg, 97%).

Measurement of Relaxivities of the Nanoglobular Contrast Agents. The T_1 and T_2 values of the aqueous solutions containing contrast agents were determined on a Siemens 3T MRI scanner at room temperature. The water proton T_1 relaxation times without and with the agents at different concentrations were measured using an inversion recovery prepared turbo spin echo imaging pulse sequence. The inversion times (TI) were 25, 35, 50, 75, 100, 200, 400, 800, 1600, and 3200 ms with repetition time (TR) = 5000 ms and echo time (TE) = 16.0 ms. The net magnetization of each sample was fit for multiparametric nonlinear regression analysis using a Marquardt−Levenberg algorithm and a *MATLAB* program to calculate T_1 and M_0. Relaxivity r_1 was determined from the slope of $1/T_1$ versus $[Mn^{2+}]$ plot. The T_2 relaxation times of the samples were measured using a

Scheme 1. Synthesis of G3 Nanoglobular Macrocyclic Mn(II) Chelate Conjugates

turbo spin echo sequence with turbo factor 3. The parameters were TE = 12, 24, 35, 47, 59, 71, 83, 94, and 106 ms, and TR = 3000 ms. T_2 values were calculated from $M_{TE} = M_0\, e^{(-TE/T_2)}$ after nonlinear regression with various TE values. The r_2 relaxivity was determined from the slope of $1/T_2$ versus $[Mn^{2+}]$ plot. The Mn(II) concentrations of the samples were measured by ICP-OES for r_1 and r_2 calculation.

Animal Tumor Model. Human breast cancer MDA-MB-231 cells were grown in L-15 medium supplemented with 10% fetal bovine serum and 1% penicillin at 37 °C in 5% CO_2. Female athymic nu/nu mice (6 weeks, 20−25 g) were purchased from the National Cancer Institute (Frederick, MD). Each mouse was subcutaneously implanted in both flanks with 2×10^6 MDA-MB-231 cells mixed with an equal volume of in a mixture of Matrigel (50 μL culture medium and 50 μL Matrigel). Three to four weeks after inoculation, tumors reached an average size of 0.5 cm in diameter. The mice were randomly divided into groups with three mice per group for MRI study. All animal experiments were performed in accordance with an animal protocol approved by the IACUC of the University of Utah.

Contrast Enhanced MRI. The mice were anesthetized by injecting a mixture of 12 mg/kg xylazine and 80 mg/kg ketamine. MRI contrast agents were administered via a tail vein at a dose of 0.03 mmol Mn/kg. The contrast agent $MnCl_2$ was injected at 0.05 mmol/kg. The mice were placed in a human wrist coil and scanned in a Siemens Trio 3 T MRI scanner before injection and at 2, 5, 10, 15, 20, and 25 min postinjection using a fat suppression 3D FLASH sequence (TR = 7.8 ms, TE = 2.74 ms, 25° flip angle, 0.4 mm slice thickness, 128 × 256 × 48 matrix size, 50 × 100 × 24 mm^3 field of view, 0.39 × 0.39 × 0.5 mm^3 spatial resolution, 4 averages, 47.3 s acquisition time for one image set, 25 min for full set of dynamic images). Axial tumor images were also acquired using a 2D spin−echo sequence (400 ms TR, 8.9 ms TE, 90° flip angle, 2.0 mm slice thickness, 0.125 × 0.5 mm^2 in-plane view, 384 × 192 matrix size, 48 × 96 mm^2 field of view, 76.8 s acquisition time for one image set, 2 averages, 25 min for full set of dynamic images) immediately after the acquisition of the 3D FLASH images. Signal intensity of the regions of interest (ROIs) was measured using *Osirix* software. Signal enhancement ratios (ER) in the liver, kidneys, and tumor at each time point were calculated using the equation $ER = S_{post}/S_{pre}$, where S_{post} (postinjection) and S_{pre} (preinjection) denote the signal within the ROIs, and averaged from three different mice ($N = 3$). Statistical analysis was performed using a two-way ANOVA with Bonferroni's, assuming statistical significance at $p < 0.05$.

RESULTS AND DISCUSSION

Chemistry and Characterization. The nanoglobular Mn(II)-DOTA monoamide and Mn(II)-NOTA conjugate were designed as the Mn(II) based macromolecular MRI contrast agents to improve their relaxivities. Macrocyclic ligands NOTA and DOTA monoamide were used to chelate paramagnetic Mn(II) ions. NOTA had a coordination number of 6 and DOTA monoamide had a coordination number of 8. The ligands with different coordination number were used to investigate the ligand effect on relaxivities of the agents. The synthetic procedure of nanoglobular Mn(II)-DOTA and Mn(II)-NOTA conjugates is depicted in Scheme 1. One-fold excess of DOTA-tris(*t*-Bu) and 50% excess of NODA-GA$(tBu)_3$ to the number of amines on the dendrimers were used for the conjugation of the ligands to the nanoglobules. The Boc protection was removed with TFA to yield nanoglobule-DOTA-monoamide or nanoglobule-(NOTA-GA) conjugates. Nanoglobular Mn(II) complexes were prepared by reacting the nanoglobular ligand conjugates with 4-fold excess $Mn(OAc)_2$ to each ligand molecule. High temperature (100 °C) was used to achieve complete complexation of Mn(II) with the ligands.[15] Both ultrafiltration and dialysis were effective to remove low molecular weight impurities before and after complexation with Mn(II) ions. Approximately 70−86% of the surface amino groups of the nanoglobules were conjugated with macrocyclic Mn(II) chelates (Table 1). Complete conjugation of the surface amino groups of nanoglobules was difficult to achieve due to steric hindrance. Higher conjugation degree might be achieved if a much larger excess of the protected ligands was used in the conjugation.

The physicochemical parameters of the nanoglobular Mn(II) complexes are summarized in Table 1. The manganese content of the agents was 1.45−1.89 mmol/g nanoglobules, as determined

dx.doi.org/10.1021/bc100573t |*Bioconjugate Chem.* 2011, 22, 931–937

by ICP-OES. Interestingly, the r_1 and r_2 relaxivities per Mn(II) chelate of the nanoglobular Mn(II)-DOTA conjugates decreased with increasing generation of the agents from G2 to G4, contrary to the observation of the nanoglobular Gd-DOTA monoamide conjugates.[11] The G2 nanoglobular conjugate, G2-DOTA-Mn, showed the highest relaxivities per Mn(II) chelate among the three nanoglobular Mn(II)-DOTA monoamide conjugates. The reverse size effect of nanoglobular Mn(II)-DOTA monoamide conjugates could be attributed to the saturated complexation of Mn(II) ions. Since Mn(II) has a maximum coordination of 7 with macrocyclic chelators,[7,16] the coordination of Mn(II) in Mn(II)-DOTA monoamide is saturated by the ligand without water molecules directly bound to it in the inner sphere. The water molecules immediately surrounding the Mn(II) macrocyclic chelates form a relatively ordered secondary solvation sphere due to hydrogen bonding between to the water molecules and the metal complexes. Water molecules beyond the secondary sphere are less organized and referred to as the outer solvation sphere where water diffuses freely.[17] For the paramagnetic metal chelates of saturated coordination, the contribution to their overall relaxivities could be mainly from the relaxivities of the secondary and outer solvation spheres, which were determined by the relaxation time (T'_{im}) and residency time (τ'_m) of secondary and outer sphere water molecules.[17] With the increased number of Mn(II) chelates on the surface and amino groups of larger nanoglobules, the residency time (τ'_m) of water molecules in the secondary sphere might increase due to the increased probability of hydrogen bonding of the water molecules. The increased residency time might outweigh the reduced relaxation times of water molecules in the secondary and outer sphere due to increased rotational correlation time (τ_R) of larger nanoglobular complexes. In addition, it may be possible that the DOTA chelates are buried in the G3 or G4 dendrimers and less accessible to solvation as compared to the G2 dendrimer. Consequently, the relaxivities per Mn(II) chelate of the nanoglobular Mn(II)-DOTA conjugates would decrease with the increased size and number of chelates of the agents.

The r_1 relaxivity of G2-DOTA-Mn was 3.32 mM^{-1} s^{-1} per Mn(II) chelate, about 9-fold higher than that (0.37 mM^{-1} s^{-1}) of MnO nanoparticle-based MRI contrast agent with a size of 7 nm.[18] The r_1 relaxivity of the nanoglobular Mn(II)-NOTA conjugate was 3.8 mM^{-1} s^{-1} per Mn(II) chelate, 35% higher than that of the corresponding G3-DOTA-Mn agent. NOTA is a hexadentate ligand with three oxygen and three nitrogen as donor atoms.[19] Mn(II)-NOTA chelate is not a saturated complex due to the ability of Mn(II) to form seven-coordinated complexes. A water molecule may complex to Mn(II) in the inner sphere of the Mn(II)-NOTA chelate to complete seven-coordination. Higher relaxivity G3-NOTA-Mn might be due to a bound water molecule in the inner solvation site. It was shown that the higher coordination number resulted in the lower relaxivity for the Mn(II) complexes of cyclen derivatives at 20 MHz.[4] The result in this study was consistent with what was previously observed. Most of the nanoglobular Mn(II) complexes had higher per-ion r_1 relaxivity than $MnCl_2$ except for G4-DOTA-Mn. The overall relaxivities of the nanoglobular Mn(II)-DOTA conjugates increased with size of the agents because of an increased number of chelates in higher generation nanoglobules. The overall r_1 relaxivity of G4-DOTA-Mn was as high as 233 mM^{-1} s^{-1} per molecule.

The ratio of the r_1 to r_2 relaxivities of the nanoglobular Mn(II) chelate conjugates was much lower than that of the corresponding nanoglobular Gd(III) chelates. High r_2 relaxivity could result in significant reduction signal intensity in T_1-weighted contrast enhancement. The ratio of the r_1 to r_2 relaxivities of the nanoglobular Mn(II) chelate conjugates was much higher than that of $MnCl_2$. As reported in the literature, $MnCl_2$ had r_2 relaxivity as high as 103.5 s^{-1} mM^{-1} at 3 T[20] and very high r_2 relaxivity at high magnetic field strength.[17] The complexation of Mn(II) resulted in significantly reduced r_2 relaxivity.

In Vivo MR Imaging. The effectiveness of the Mn(II) based nanoglobular MRI contrast agents, G2, G3, G4-DOTA-Mn, and G3-NOTA-Mn, were evaluated in female athymic nu/nu mice bearing MDA-MB-231 human breast carcinoma xenografts with $MnCl_2$ as a control. Figure 1 shows the dynamic 2D coronal images of mice before and at various time points after the injection of $MnCl_2$ at a dose of 0.05 mmol-Mn/kg and the nanoglobular agents at a dose of 0.03 mmol-Mn/kg. Little enhancement was observed in the blood pool for all agents, which could be attributed to rapid vascular clearance of the agents. Strong contrast enhancement was observed for all of the nanoglobular agents for the fluid in the urinary bladder 10−15 min after the injection, indicating rapid excretion of the nano-sized contrast agents via renal filtration. Little enhancement was observed inside the bladder for the mice injected with $MnCl_2$, indicating the uptake of Mn^{2+} ions in the body. $MnCl_2$ resulted in stronger liver enhancement than the chelated nanoglobular contrast agents. The nanoglobular Mn(II)-DOTA monoamide conjugates showed generation-dependent liver enhancement. G2-DOTA-Mn and G3-NOTA-Mn resulted in slightly stronger signal enhancement in the liver than the other nanoglobular agents, and G4-DOTA-Mn produced the least liver enhancement. $MnCl_2$ also resulted in stronger and more prolonged enhancement in the myocardium than the nanoglobular chelates. It is known that free Mn(II) ions can preferentially accumulate in the liver, myocardium, and other normal tissue through Ca^{2+} channels,[21,22] resulting in prolonged strong liver and myocardium enhancement. The relatively weak liver and myocardium enhancement of the nanoglobular agents suggested that these agents with macrocyclic Mn(II) chelates were stable in the

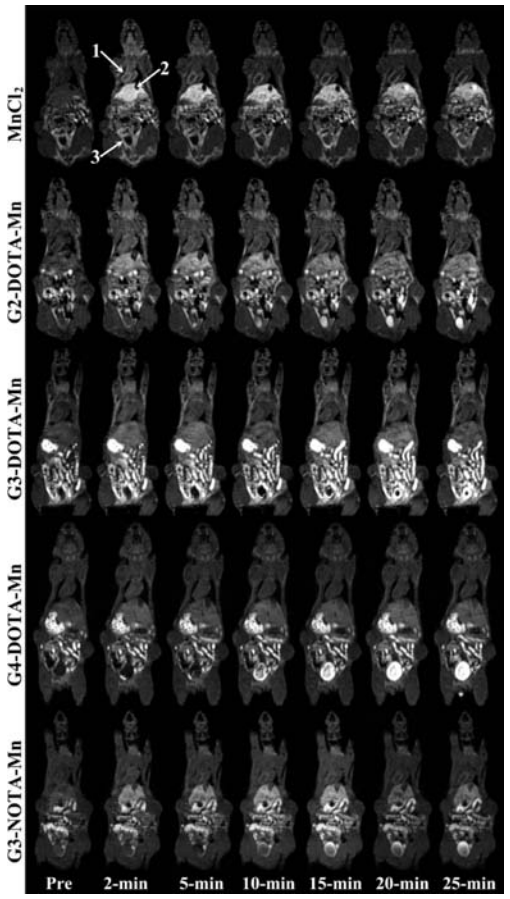

Figure 1. Representative 2D coronal T_1-weighted MR images of tumor bearing mice injected with Mn(II)-based nanoglobular MRI contrast agents G3-NOTA-Mn and G2, G3, G4-DOTA-Mn at 0.03 mmol-Mn/kg and $MnCl_2$ at 0.05 mmol/kg. Arrows 1, 2, and 3 point to the heart, liver, and bladder, respectively.

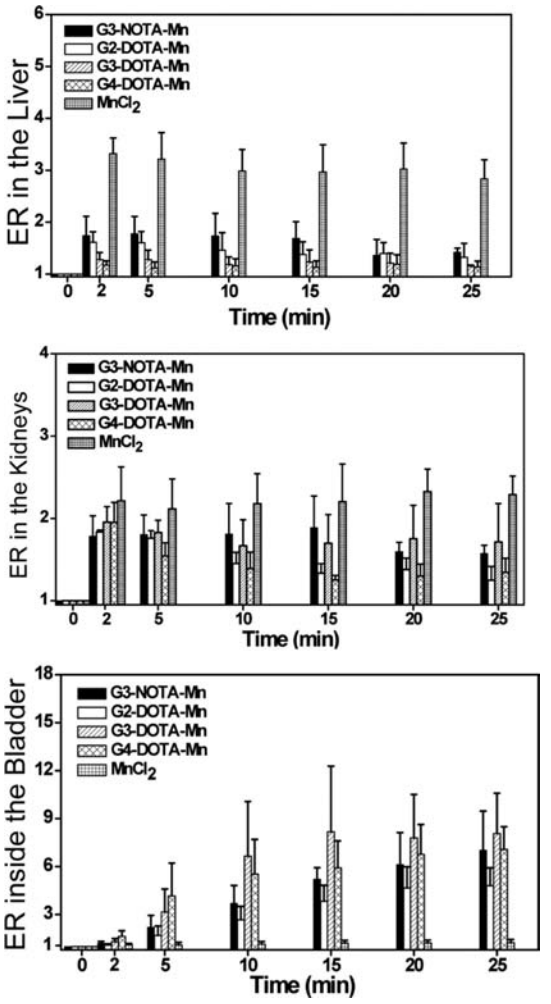

Figure 2. Enhancement ratio (ER) of the MR signal postinjection to that of preinjection in the liver and kidneys and inside the bladder of the nude mice with nanoglobular macrocyclic Mn(II) chelate conjugates G2, G3, G4-DOTA-Mn and G3-NOTA-Mn at 0.03 mmol-Mn/kg and $MnCl_2$ at 0.05 mmol/kg.

body within the time frame of the MRI study. Further detailed studies are required to demonstrate the in vivo stability of these agents.

The signal intensity of the liver, kidneys, and the fluid in the bladder was measured before and at various time points after injecting the contrast agents. Figure 2 shows the enhancement ratio, the ratio of the signal intensity postinjection to that before injection. $MnCl_2$ resulted in at least 2.8-fold signal increase in the liver due to high liver accumulation of free Mn^{2+}, which was much higher than the 1.2- to 1.8-fold signal increase generated by the nanoglobular complexes. The difference of the enhancement ratios in the liver among the nanoglobular agents was not significant. $MnCl_2$ also resulted in higher signal increase in the kidneys than the nanoglobular chelates, but the difference was not as significant as in the liver ($p > 0.05$), especially in the first 2 min postinjection. The enhancement ratio in the kidneys for the nanoglobular complexes decreased gradually during the period of 25 min post injection and the enhancement ratio inside the bladder correspondingly increased (Figure 2), indicating renal excretion of the agents. In comparison, the enhancement ratio in the kidneys for $MnCl_2$ did not change during the period and no enhancement was shown in the bladder, suggesting retention of Mn^{2+} ions in the tissue within the 25 min time frame of this study.

Figure 3 shows the axial 2D T_1-weighted spin−echo images of tumor tissue contrast enhanced by $MnCl_2$ and the nanoglobular MRI contrast agents. Substantial contrast enhancement was observed in the tumor after the injection of the nanoglobular contrast agents. It appears that G3-NOTA-Mn generated more tumor enhancement than the nanoglobular Mn(II)-DOTA monoamide conjugates. Quantitative analysis of the contrast enhancement ratio (ER) in the tumor tissue also suggested that G3-NOTA-Mn resulted in significantly higher enhancement ratio in tumor than the other tested agents after 2 min postinjection ($p < 0.05$) (Figure 4), possibly because of its larger r_1 relaxivity.

This study showed the conjugation of macrocyclic Mn(II) chelates on the highly functionalized nanoglobular dendrimers resulted in nongadolinium(III) based macromolecular MRI contrast agents with high overall relaxivities. The data of macrocyclic Mn(II) chelates suggested good in vivo stability against transmetalation with the endogenous metal ions, including Ca^{2+}, Cu^{2+}, and Zn^{2+}, which was similar to macrocyclic Gd chelates.[23] Consequently, the agents could readily clear from the major organs, particularly from the liver, and excrete via renal filtration.

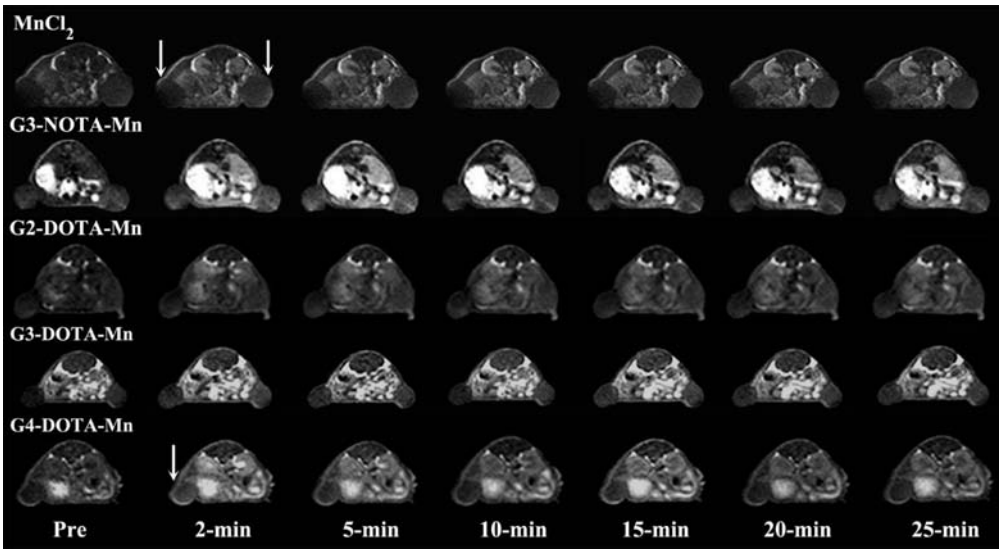

Figure 3. 2D axial T_1-weighted spin−echo MR images of MDA-MB-231 tumor xenografts in nu/nu female mice before and after the tail-vein injection of $MnCl_2$ at 0.05 mmol-Mn/kg and nanoglobular macrocyclic Mn(II) chelate conjugates G2, G3, G4-DOTA-Mn and G3-NOTA-Mn at 0.03 mmol-Mn/kg. Arrows point to the tumors.

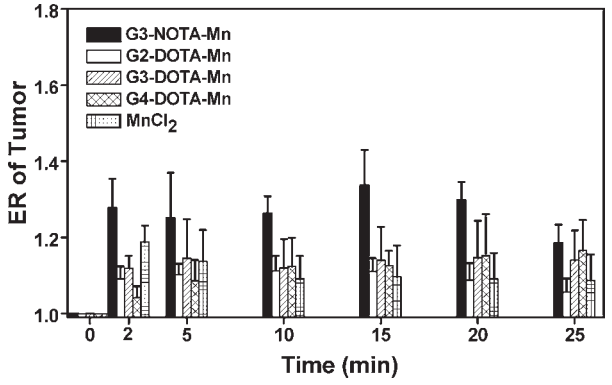

Figure 4. Enhancement ratio (ER) of the MR signal postinjection to that of preinjection in the tumor before and at various time points after injection of the nanoglobular MRI contrast agents G2, G3, G4-DOTA-Mn and G3-NOTA-Mn at 0.03 mmol Mn/kg and $MnCl_2$ at 0.05 mmol/kg in nu/nu female mice bearing MDA-MB-231 tumor xenografts.

As compared to the corresponding nanoglobular Gd(III)-DOTA monoamide conjugates,[11] G2-DOTA-Mn had similar in vivo enhancement as the G2-DOTA-Gd because both agents were rapidly excreted via renal filtration. G3-DOTA-Mn and G3-NOTA-Mn were less effective than the corresponding G3 Gd-DOTA monoamide conjugate for both blood pool and cancer imaging at the same dose, even though both Mn(II)-based agents had high overall T_1 relaxivity. It is plausible to assume that much higher T_2 relaxivity of nanoglobular Mn(II) complexes may reduce MR signal in the T_1-weighted contrast enhancement. The use of smaller macrocyclic ligand NOTA improved the relaxivity and in vivo contrast enhancement of the Mn(II)-based contrast agent. Nevertheless, we have shown in this study that it is possible to design macromolecular Mn(II) complexes to improve their relaxivity and for in vivo MR imaging. Future studies on the design and development effective Mn(II) based MRI contrast agents should focus on further improvement of the stability and T_1 relaxivity of Mn(II) chelates and reduction of the T_2 effect.

CONCLUSIONS

Nanoglobular Mn(II)-DOTA-monoamide and Mn-NOTA conjugates were synthesized as non-Gd(III) based macromolecular contrast agents for magnetic resonance imaging. The relaxivities per ion of the nanoglobular macrocyclic Mn(II) chelates decreased with the increasing generation of the dendrimers. The G3 nanoglobular Mn(II)-NOTA conjugate had higher relaxivities than the corresponding Mn(II)-DOTA conjugate. The nanoglobular macrocyclic Mn(II) chelates were readily excreted via renal filtration. They showed less nonspecific liver enhancement than $MnCl_2$. The Mn(II)-based nanoglobular agents were effective for contrast enhanced cancer imaging in the mouse tumor model at a low dose. The nanoglobular macrocyclic Mn(II) chelate conjugates are promising for MR cancer imaging as nongadolinium(III) based contrast agents.

Supporting Information

ABSTRACT: Antibody-directed enzyme prodrug therapy (ADEPT) utilizing β-glucuronidase is a promising method to enhance the therapeutic index of cancer chemotherapy. In this approach, an immunoenzyme (antibody-β-glucuronidase fusion protein) is employed to selectively activate anticancer glucuronide prodrugs in the tumor microenvironment. A major roadblock to the clinical translation of this therapeutic strategy, however, is the low enzymatic activity and strong immunogenicity of the current generation of immunoenzymes. To overcome this problem, we fused a humanized single-chain antibody (scFv) of mAb CC49 to S2, a human β-glucuronidase (hβG) variant that displays enhanced catalytic activity for prodrug hydrolysis. Here, we show that hcc49-S2 displayed 100-fold greater binding avidity than hcc49 scFv, possessed greater enzymatic activity than wild-type hβG, and more effectively killed antigen-positive cancer cells exposed to an anticancer glucuronide prodrug as compared to an analogous hβG immunoenzyme. Treatment of tumor-bearing mice with hcc49-S2 followed by prodrug significantly delayed tumor growth as compared to hcc49-hβG. Our study shows that hcc49-S2 is a promising targeted enzyme for cancer treatment and demonstrates that enhancement of human enzyme catalytic activity is a powerful approach to improve immunoenzyme efficacy.

INTRODUCTION

Conventional chemotherapy represents an important treatment option for advanced cancers, but the limited therapeutic index of most antineoplastic drugs can cause normal tissue toxicity and severe side effects. Antibody-directed enzyme prodrug therapy (ADEPT) seeks to increase tumor selectivity and reduce undesirable side effects of chemotherapy by targeting an antibody–enzyme conjugate (immunoenzyme) to cancer cells for preferential activation of nontoxic anticancer prodrugs in the tumor microenvironment.[1−3] We previously reported that immunoenzymes formed by chemical linkage of anticancer antibodies and *E. coli* β-glucuronidase could selectively activate glucuronide prodrugs at antigen-positive cancer cells, enhance antitumor immune responses, and produce long-term tumor regression in syngenic and xenograft cancer models.[4−9] However, a major impediment to clinical translation of immunoenzymes containing microbial enzymes is their high immunogenicity in patients, which dramatically hinders tumor targeting and prevents effective therapy.[10−12]

Immunoenzymes incorporating human enzymes should be nonimmunogenic but are limited by the relatively low activity of many human enzymes as compared to their bacterial counterparts and the possibility of systemic prodrug activation by endogenous enzymes present in patients.[13] Human β-glucuronidase (hβG) is a good target for creating human immunoenzymes[14−16] because hβG is largely sequestered in lysosomes, which limits hydrolysis of hydrophilic glucuronide prodrugs that do not readily diffuse across the plasma membrane of cells,[17,18] resulting in minimal in vivo prodrug toxicity.[19] hβG, however, displays relatively low enzymatic activity as compared to bacterial βG.[20,21] To preserve the advantages of human enzymes in ADEPT while overcoming the limitation of limited catalytic activity, we previously employed directed molecular evolution to create human enzyme variants with enhanced catalytic activity against anticancer prodrugs.[21] Here, we fused either wild-type hβG or a hβG variant (S2) with enhanced catalytic activity to a humanized single-chain antibody fragment (scFv) of CC49,[22] which binds the TAG-72 antigen expressed on many human tumor cells.[23,24] The humanized immunoenzymes retained enzymatic activity and bound antigen-positive cancer cells

with high avidity. Importantly, hcc49-S2 in combination with an anticancer prodrug displayed significantly greater antitumor activity against human colorectal xenografts than an equivalent immunoenzyme containing wild-type hβG, demonstrating that enhancement of human enzyme activity can improve the therapeutic efficacy of ADEPT. Our results suggest that creation of highly active humanized immunoenzymes is feasible and may help overcome limitations of using microbial enzymes for ADEPT.

EXPERIMENTAL PROCEDURES

Cell Lines. BALB/3T3 fibroblasts (ATCC CCL-163) were grown in Dulbecco's Modified Eagle's Medium (high glucose) supplemented with 10% bovine serum, 2.98 g/L HEPES, 2 g/L $NaHCO_3$, 100 U/mL penicillin, and 100 μg/mL streptomycin. EJ human bladder carcinoma cells,[25] LS174T human colon adenocarcinoma (ATCC CCL-188), MCF-7 human breast adenocarcinoma (ATCC HTB 22), and HT-29 colorectal adenocarcinoma (ATCC HTB-38) cells were cultured in RPMI-1640 medium containing the same supplements. The cells were free of mycoplasma as determined by PCR.

Reagents and Antibodies. Fluorescein di-β-D-glucuronide (FDGlcU), ELF-97 alcohol and ELF-97 β-D-glucuronide (ELF = enzyme-labeled fluorescence) were from Molecular Probes (Eugene, OR, USA).[26] CPT-11, ovalbumin (A-2512), bovine serum albumin (A-7906), and catalase from bovine liver (C-3155) were from Sigma-Aldrich (St. Louis, MO, USA). Rabbit anti-6xHis was from LTK BioLaboratories (Bade, Taiwan). Biotinylated anti-HA antibody was from Vector Laboratories (Burlingame, CA, USA). Rhodamine-conjugated streptavidin was from Jackson ImmunoResearch Laboratories (Westgrove, PA, USA). Monoclonal antibody (7G8) against hβG has been described.[27] 7G8 was directly labeled with FITC as described.[28] HAMG was synthesized as described.[29]

Immunoenzymes. To construct a tumor targeting immunoenzyme, the variable regions of the heavy chain (V_H) and light chain (V_L) of a humanized single-chain antibody fragment of CC49 (hcc49 scFv)[22] were assembled with synthetic oligonucleotides P1 to P10 and P18 to P26 for V_H and P10 to P17 and P26 to P34 for V_L (Supporting Information Table 1) by a primerless PCR gene-assembly method.[30] PCR was carried out as follows: 95 °C for 5 min; 22 cycles at 95 °C for 30 s, 63 to 53 °C touchdown for 1 min (decrease 1 °C every 2 cycles), 72 °C for 1 min; 16 cycles at 95 °C for 30 s, 53 °C for 1 min, 72 °C for 1 min; 72 °C for 10 min. The V_H fragment was amplified with primers P1 and P36, and the V_L fragment was amplified with primers P34 and P35 by standard PCR. The V_H and V_L fragments were joined and amplified as hcc49 scFv using primers P1 and P34, which contain Sfi I and Xba I restriction sites, respectively. The PCR products were digested with Sfi I and Xba I and then subcloned into pLHCX-L6-hβG[31] to generate pLHCX-hcc49-hβG-myc-His. The hβG and S2 genes in pLNCX-hβGs-eB7 and pLNCX-S2-eB7[21] were ligated into the *Not*I and *Sal*I sites in pLHCX-hcc49-hβG-myc-His to remove the myc tag and generate pLHCX-hcc49-S2-His and pLHCX-hcc49-S2-His. pLHCX-αDNS-S2-His was generated by transferring the antidansyl scFv gene from pLNCX-DNS-eB7[19] in place of the hcc49 scFv gene present in pLHCX-hcc49-S2-His.

Production of Recombinant Proteins. To generate His-tagged immunoenzyme producer cells, plasmid DNA was co-transfected with pVSVG into GP293 cells (Clontech, Mountainview, CA) to produce recombinant retroviral particles. At 2 days after transfection, the culture medium was added to 3T3 cells in the presence of 8 μg/mL Polybrene. Stable cell lines were selected in medium containing 0.5 mg/mL G418 (Calbiochem, San Diego, CA). Recombinant his-tagged proteins were purified from the stable 3T3 fibroblast lines as described.[31]

Western Blot Analysis. His-tagged recombinant hcc49 scFv and immunoenzymes were boiled in reducing SDS buffer, electrophoresed on a 12.5% SDS-PAGE, and transferred to PVDF membranes. Membranes were sequentially stained with rabbit anti-His or rabbit anti-hβG antibody followed by HRP-conjugated secondary antibody. Bands were visualized by ECL detection (Pierce, Rockford, IL, USA).

HPLC Size Exclusion Analysis. Samples (10 μL, 1 mg/mL) were injected into an Aligent Bio SEC-5 column (300 × 7.8 mm, 300 Å) and separated at 1 mL/min in 150 mM sodium phosphate buffer, pH 7. Protein peaks were detected at 214 nm. Standard proteins included ovalbumin (44 kDa), bovine serum albumin (66 kDa), bovine liver catalase (250 kDa), and recombinant human β-glucuronidase (320 kDa).

Enzyme Assays. The enzyme activities of recombinant wild-type hβG, the hβG variant S2, hcc49-hβG, hcc49-S2, and αDNS-S2 were measured in triplicate with 0.1 mM ELF-97 β-D-glucuronide at 37 °C for 30 min at pH 7 in βG reaction buffer (50 mM bis-tris, 50 mM triethanol amine, 100 mM acetic acid, 100 ng/mL bovine serum albumin). The reaction was terminated by adding an equal volume of stop buffer (2 M tris-HCl, 0.8 M sodium bicarbonate, pH 8). The fluorescence of ELF-97 alcohol was measured at excitation/emission wavelengths of 355/555 nm in a Gemini EM microplate spectrofluorometer (Molecular Device, Sunnyvale, CA). To measure enzyme kinetic values, ELF-97 β-D-glucuronide (2 mM) in pH 4.5 or pH 7 βG reaction buffer was diluted 1:1 with defined concentrations of recombinant proteins. Fluorescence was immediately measured under thermal control at 37 °C for 8−10 min. The measurement was repeated using the same amount of enzyme for different concentrations of substrate over an optimal range. The acquired readings were converted to product concentration by pre-established standard curves. Double reciprocal plots were used to determine K_m and k_{cat}. Kinetic assays were performed at least 3 times and mean values were calculated.

Surface Plasmon Resonance. The binding kinetics of immunoenzymes and CC49 scFv were measured on a BIAcore (GE Lifesciences Uppsala, Sweden). Bovine submaxillary gland mucin was immobilized on the CM5 chips by amine coupling. BSA was immobilized as a negative control. Binding analysis was performed as described.[32]

Flow Cytometer Analysis. Cells were stained with immunoenzymes followed by FITC-conjugated mouse anti-hβG (7G8-FITC).[21] For competition assays, hcc49-S2 was mixed with various amounts of CC49 antibody[33] before staining MCF-7 cells. The surface immunofluorescence of 10^4 viable cells was measured with a FACScaliber flow cytometer (Becton Dickinson, Mountain View, CA, USA) and fluorescence intensities were analyzed with Flowjo (Tree Star Inc., San Carlos, CA, USA).

Immunofluorescence Staining. MCF-7 cells (5×10^5) were cultured overnight in 12-well plates. hcc49-S2 or αDNS-S2 (2 μg/well) was added to the cells at 37 °C for 1 h. After washing 3 times with PBS, the cells were incubated in complete medium at 37 °C. At defined times, the cells were washed with PBS and fixed with 2% paraformaldehyde in PBS for 15 min at room temperature. After washing, the cells were stained with 4 μg/mL 7G8-FITC for 45 min at 4 °C. The cells were viewed under a phase contrast microscope and a digital fluorescence microscope.

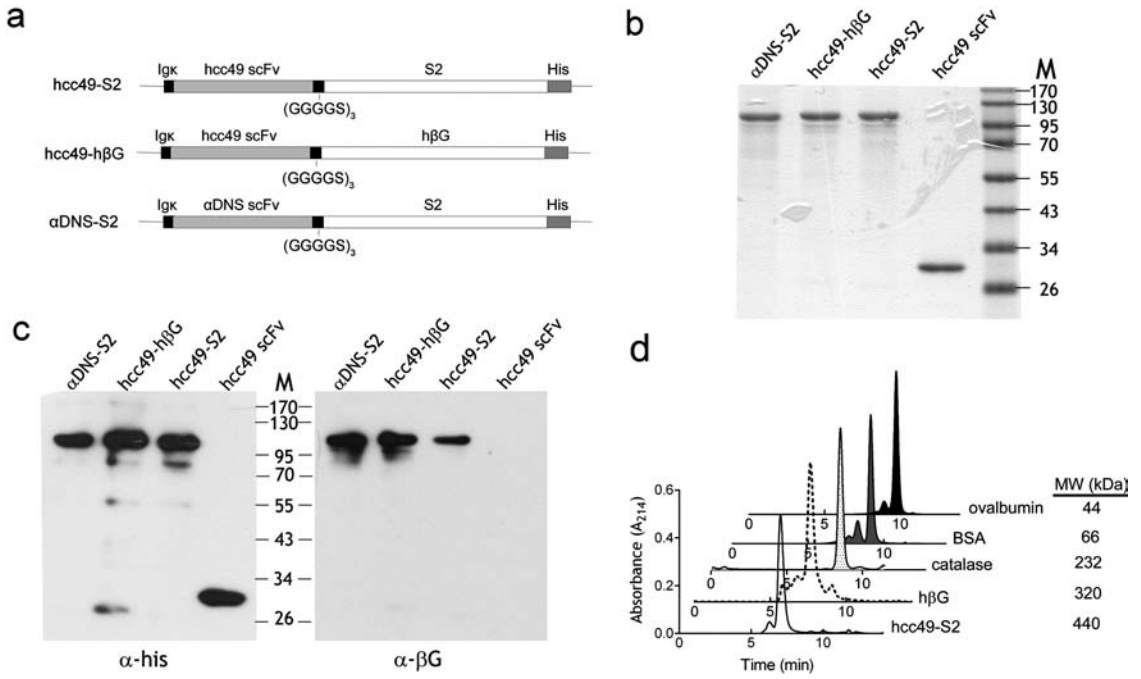

Figure 1. Analysis of purified scFv and immunoenzymes. (a) Schematic of immunoenzyme constructs. (b) Reducing SDS PAGE showing the Coomassie Blue staining of hcc49 scFv and immunoenzymes. (c) Western blots stained with anti-His (left) or anti-hβG (right) antibodies. (d) HPLC size exclusion chromatographs of ovalbumin, bovine serum albumin, catalase, hβG, and hcc49-S2.

^{3}H-Thymidine Incorporation Assay. hcc49-hβG, hcc49-S2, or αDNS-S2 (1 μg/well) were added to LS174T, MCF-7, or HT-29 cells at 37 °C for 1 h. After washing twice with PBS, graded concentrations of *p*-hydroxyaniline mustard (pHAM) or *p*-hydroxyaniline mustard glucuronide (HAMG) were added in triplicate at pH 6.8 for 48 h at 37 °C. The cells were then pulsed for 16 h with ^{3}H-thymidine (1 μCi/well). Results are expressed as percent inhibition of ^{3}H-thymidine incorporation into cellular DNA in comparison to untreated cells.

Radioiodination. Immunoenzymes were labeled with ^{131}I using a variation of the original iodogen method.[34] In brief, 120 μCi sodium [^{131}I]-iodide in 100 μL reaction buffer (0.1 M Na_2HPO_4, pH 6.5) was added to an iodogen precoated tube (Pierce Chemical Co.) followed by 50 μL hcc49-S2 or αDNS-S2 (2 mg/mL in PBS) and incubated for 10 min at room temperature. The reaction was terminated by transferring the reaction mixture to an Eppendorf tube and adding 50 μL reaction buffer. The radiochemical purity of ^{131}I-hcc49-S2 or ^{131}I-αDNS-S2 was 90−92% as measured by TLC using silica gel (Silica gel 60; Merck) and the specific activity was 57−66 Ci/mmol.

In Vivo Imaging and Biodistribution of Radiolabeled Immunoenzymes. BALB/c nu/nu mice bearing LS174T tumors (150−200 mm^3) in their right flank were i.v. injected with 100−115 μCi ^{131}I-hcc49-S2 or ^{131}I-αDNS-S2. The mice were killed after 24, 48, 72, and 96 h, and the radioactivity in the tissues was measured in a multichannel gamma counter. Whole-body scintigraphy of anesthetized mice was performed at 5 and 48 h with a gamma camera (Siemens ECAM+DHC) using a pinhole collimator.

In Vivo Pharmacokinetics. To determine the pharmacokinetics of immunoenzymes, Beige/SCID mice bearing LS174T tumors (150−200 mm^3) in their right flank were i.v. injected with 100 μg hcc49-hβG or hcc49-S2. Blood samples were collected from the tail vein of the mice or by retro-orbital punctuation. Plasma was prepared by centrifugation (5 min, 12 700 × *g*) and further diluted in pH 4.5 βG reaction buffer. The immunoenzyme levels in plasma were determined by measuring βG activity after capture of immunoenzymes on mucin-coated plates or by directly measuring βG activity. The initial and terminal half-lives of the immunoenzymes were estimated by fitting the data to a two-phase exponential decay model with *Prism 5* software (Graphpad Software, San Diego, CA, USA).

Imaging of Immunoenzyme Localization in Mice. BALB/c nu/nu mice (n = 3) bearing subcutaneous LS174T tumors (100−150 mm^3) in their right flank were i.v. injected with 200 μg immunoenzyme. After 2 or 48 h, mice were i.v. injected with 500 μg FDGlcU. After 30 min, mice were sacrificed and organs were excised. Images of tumors, liver, and muscles of mice were obtained on a Xenogen IVIS Spectrum imaging system.

In Vivo Antitumor Activity. Groups of BALB/c nu/nu mice (n = 8) bearing 50−100 mm^3 subcutaneous LS174T tumors in their right flank were intravenously injected with PBS or 500 μg immunoenzymes on days 0 and 8 and intravenously injected with three hourly doses of 70 mg/kg HAMG or PBS on days 1 and 10. Tumor sizes were measured every 2−3 days. Tumor volume was calculated according the formula: length × width × height × 0.5.

Haematological and Biochemical Evaluation. Groups of BALB/c nu/nu mice (n = 4−6) bearing ∼100 mm^3 subcutaneous LS174T tumors in their right flank were intravenously injected with PBS or 500 μg hcc49-S2 on day 0 and intravenously injected with three hourly doses of 70 mg/kg HAMG or PBS on day 1. Blood was collected in serum separation or blood collection tubes on day 8. Serum was obtained by leaving blood at room temperature for 30 min to clot and then centrifuged at 1000 × *g* at 4 °C for 10 min. Hepatic injury was assessed by measuring serum AST, ALT, and TBIL levels using a Fuji Dri-Chem 3500 biochemistry analyzer (Fujifilm, Japan). Hematological toxicity was determined by counting lymphocytes and red blood

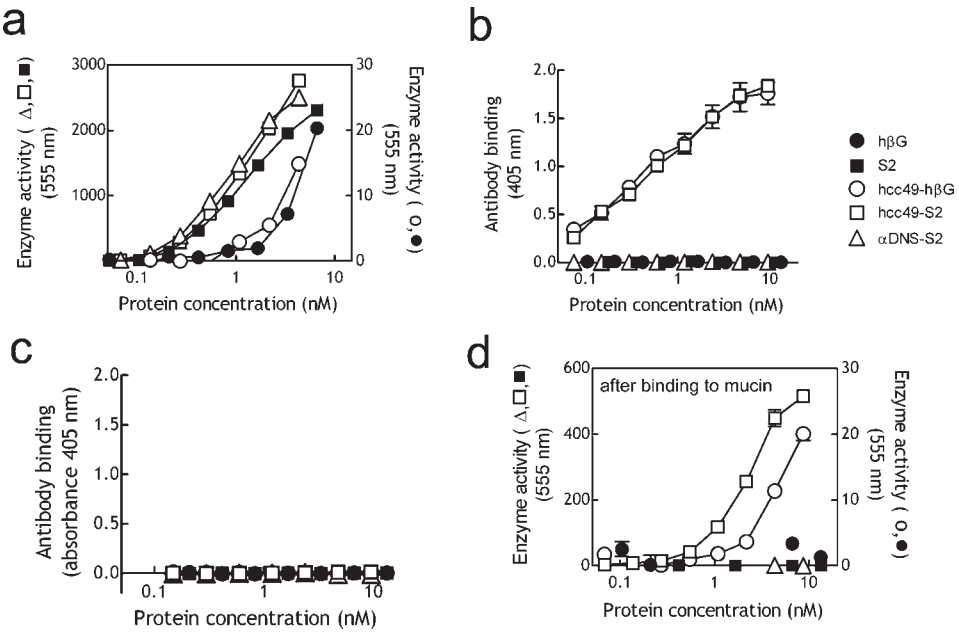

Figure 2. Enzyme and antibody-binding activity of immunoenzymes. (a) Enzyme activity of immunoenzymes and their parent enzymes was determined by measuring the fluorescence generated upon hydrolysis of ELF-97 β-D-glucuronide at pH 7. The left axis shows the activity of S2, hcc49-S2, and αDNS-S2, whereas the right axis displays the activity of hβG and hcc49-hβG. (b,c) Graded concentrations of the indicated recombinant proteins were incubated in mucin (b) or bovine-serum albumin-coated (c) microtiter plates. After washing, binding was determined by direct ELISA. (d) Graded concentrations of immunoenzymes and their parent enzymes were first incubated on mucin-coated plates. The plates were washed and bound βG enzyme activity was determined by measuring the fluorescence generated upon hydrolysis of ELF-97 β-D-glucuronide at pH 7. The left axis shows the activity of S2, hcc49-S2, and αDNS-S2, whereas the right axis displays the activity of hβG and hcc49-hβG. Error bars: SEM, $n = 3$.

cells with a Cell-Dyn hematology analyzer 3700 (Abbott Diagnostic Division, USA).

RESULTS

Expression and Purification of Humanized Immunoenzymes. A humanized cc49 scFv gene was fused to genes coding wild-type hβG or the enhanced activity hβG variant S2 to create hcc49-hβG and hcc49-S2, respectively (Figure 1a). The control immunoenzyme (αDNS-S2), with antigen-binding specificity for the chemical hapten dansyl, was also generated by fusing the antidansyl scFv and S2 genes. The immunoenzyme genes were inserted into a retroviral expression vector (pLHCX) to generate stable 3T3 fibroblast producer cell lines. Immunoenzyme proteins that were purified from the culture medium displayed the expected molecular sizes on a 12.5% SDS-PAGE (Figure 1b). Western blot analysis of purified hcc49 scFv and immunoenzymes with anti-His antibody (Figure 1c, left panel) or anti-hβG antibody (Figure 1c, right panel) showed that the immunoenzymes possessed both scFv and hβG moieties and displayed the expected molecular weights of approximately 110 kDa. Recombinant hcc49 scFv migrated with an apparent molecular weight of 30 kDa. HPLC size exclusion analysis of hcc49-S2 showed that it eluted before hβG and displayed an apparent molecular weight of ~440 kDa (Figure 1d), consistent with a tetrameric structure as found for wild-type hβG.[35]

Immunoenzymes Selectively Bind Antigen-Positive Cancer Cells with High Avidity. The immunoenzymes were characterized for antigen-binding activity and enzymatic activity. βG enzymatic activity was determined by incubating purified proteins with the βG substrate ELF-97 β-D-glucuronide. Hcc49-S2 displayed high enzymatic activity with kinetic properties that were similar to those of the S2 protein (Figure 2a, Table 1). Hcc49-hβG also possessed similar βG activity and kinetic properties to wild-type hβG. Both hcc49-hβG and hcc49-S2 immunoenzymes bound to bovine submaxillary gland mucin-coated 96-well microtiter plates,[36] whereas negligible mucin binding was observed for anti-DNS-S2 (Figure 2b). Binding appeared to be specific, because neither hcc49-hβG nor hcc49-S2 bound to BSA coated plates (Figure 2c). Surface plasmon resonance was used to quantify the binding kinetics of hcc49 scFv and hcc49 immunoenzymes. Hcc49 scFv displayed a K_D of $(4.4 \pm 1.2) \times 10^{-8}$ M (Table 2), which is similar to murine CC49 scFv.[32] The hcc49 immunoenzymes, on the other hand, displayed stronger binding avidity with K_D values of $\sim 4 \times 10^{-10}$ M, likely due to the attachment of four scFv molecules to each βG tetramer. βG activity was also examined after immunoenzymes were allowed to bind to mucin. βG activity of hcc49-S2 was about 20-fold higher than that of hcc49-hβG after binding to mucin-coated plate (Figure 2d). The enhanced enzymatic activity of hcc49-S2 reflects the greater βG activity of S2 (Figure 2a). Taken together, the data show that

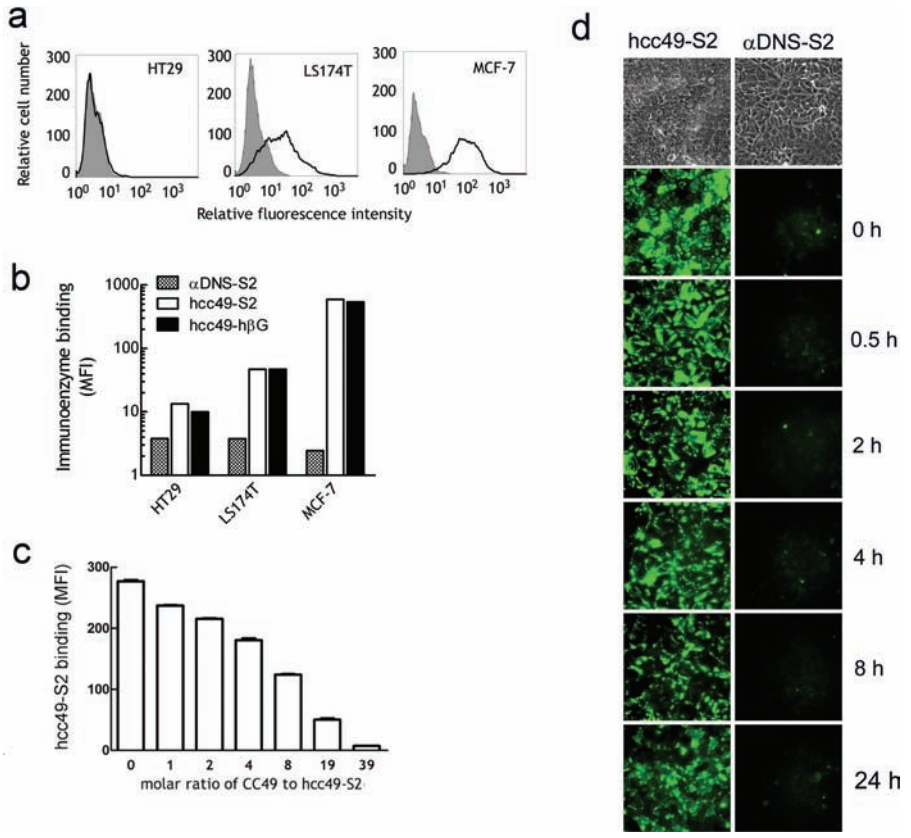

Figure 3. Binding of hcc49-S2 and hcc49-hβG to cancer cells. (a) mAb CC49 (solid line) or isotype control mAb 7G8 (gray filled) were incubated with HT29, LS174T, or MCF-7 cells followed by FITC-labeled goat antimouse second antibody. The results show the fluorescence of 10 000 live cells measured by flow cytometry. (b) HT29, LS174T, and MCF-7 cells were incubated with αDNS-S2 (shaded bars), hcc49-S2 (white bars), or hcc49-hβG (black bars) followed by FITC-labeled anti-hβG antibody before the fluorescence of 10 000 live cells was measured on a flow cytometer. (c) Increasing amounts of CC49 antibody were added with a fixed amount of hcc49-S2 to compete immunoenzyme binding. The binding of hcc49-S2 to MCF-7 cells was determined by flow cytometry. Bars, SEM ($n = 3$). (d) MCF-7 cells were incubated with hcc49-S2 (left panels) or αDNS-S2 (right panels), washed, and then incubated in complete medium at 37 °C. Cells were washed and fixed at the indicated times and then stained with anti-hβG-FITC conjugate to visualize immunoenzyme on the cells.

hcc49-S2 displayed antigen-binding activity with enhanced enzymatic activity as compared to hcc49-hβG.

To examine the binding ability of the immunoenzymes on tumor cell lines, we first utilized mAb CC49[37] to measure TAG-72 expression levels on HT29, LS174T, and MCF-7 cancer cell lines. Figure 3a shows that HT29 cells expressed undetectable levels of TAG-72, LS174T cells expressed moderate levels, and MCF-7 cancer cells expressed high levels of TAG-72, in agreement with previous reports.[38,39] The binding of immunoenzymes to these cancer cells was then examined by FACS analysis. hcc49 immunoenzymes bound HT29 cells at low background levels but selectively bound TAG-72 positive LS174T and MCF-7 cells (Figure 3b). In addition, soluble mAb CC49 competed with hcc49-S2 binding to MCF-7 cells in a dose-dependent fashion (Figure 3c), confirming that murine CC49 antibody and hcc49-S2 bind the identical epitope on TAG-72. To examine the persistence of hcc49-S2 binding to TAG-72 positive cells, MCF-7 cells were incubated with saturating concentrations of hcc49-S2 or αDNS-S2, washed, and then incubated at 37 °C for various times before surface immunoenzyme was detected by anti-hβG-FITC staining. Figure 3d shows that hcc49-S2 was clearly visible on MCF-7 cells even after 24 h, indicating prolonged retention of immunoenzyme on TAG-72 positive cells.

hcc49-S2 Can Effectively Activate a Prodrug at Antigen-Positive Cancer Cells. To examine if the immunoenzymes could preferentially activate glucuronide prodrugs at TAG-72 positive cells in vitro, MCF-7, LS174T, and HT-29 cells were incubated with hcc49 immunoenzymes or αDNS-S2, washed, and then exposed to the glucuronide prodrug HAMG (Figure 4a). None

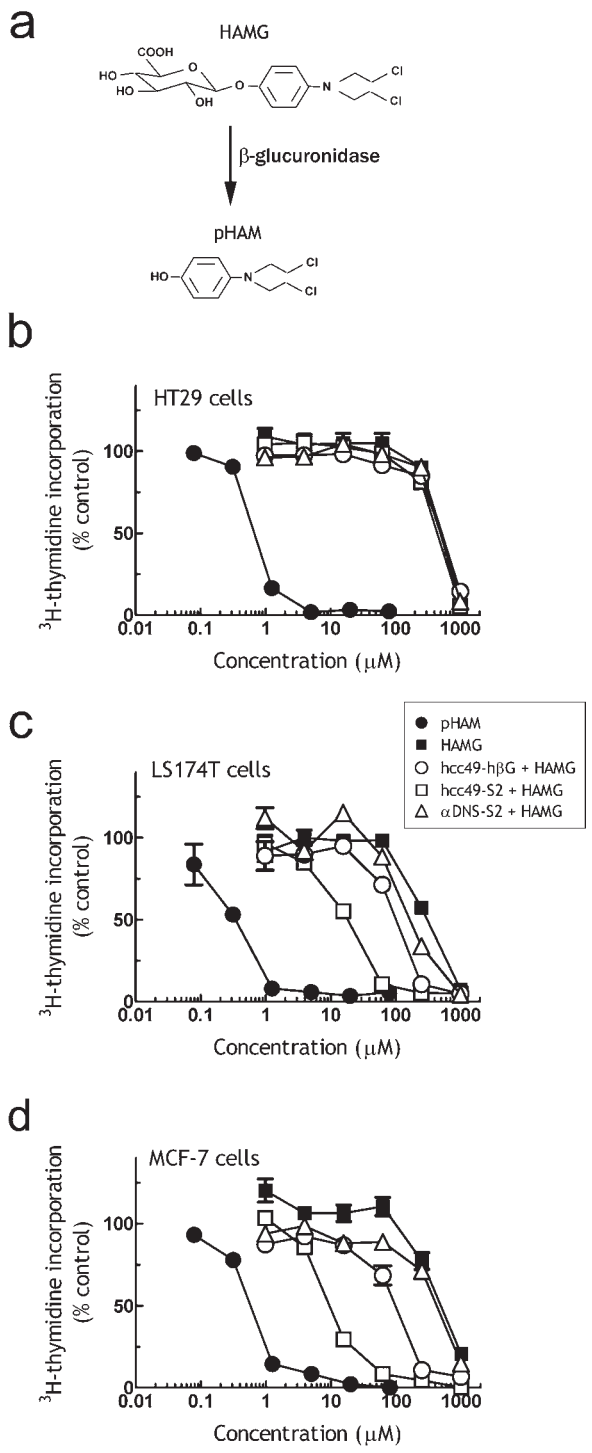

Figure 4. In vitro prodrug activation by immunoenzymes. (a) Hydrolysis of HAMG by βG releases the alkylating agent pHAM. HT-29 (b), LS174T (c), or MCF-7 (d) cells were incubated with PBS or 5 μg/mL immunoenzymes, washed, and then exposed to graded concentrations of pHAM or HAMG. The incorporation of ^{3}H-thymidine into cellular DNA was measured 48 h later. Bars, SEM (n = 3).

of the immunoenzymes increased the cytotoxicity of HAMG to TAG-72 negative HT29 cells (Figure 4b). On the other hand, LS174T (Figure 4c) and MCF-7 (Figure 4d) cells treated with hcc49-hβG and hcc49-S2 displayed augmented sensitivity to HAMG. There was a trend of increased cytotoxicity for cells treated with hcc49-S2 and for MCF-7 cells, indicating that both enhanced enzymatic activity and higher antigen levels promoted prodrug activation. Pretreatment of MCF-7 or LS174T cells with the control αDNS-S2 immunoenzyme produced similar IC_{50} values as prodrug alone, further demonstrating a requirement for antigen binding for effective prodrug activation by immunoenzymes.

Pharmacokinetics of Immunoenzymes in Tumor Bearing Mice. The plasma half-lives of the immunoenzymes were determined after i.v. injection of 100 μg hcc49-S2 or hcc49-hβG in Beige/SCID mice bearing 100−200 mm^3 LS174T tumors. Although MCF-7 cells expressed higher levels of TAG-72 antigen than did LS174T cells, we examined LS174T tumors in all in vivo experiments due to the more reproducible and uniform growth of these tumors. Immunoenzyme concentrations were determined by direct ELISA against mucin-coated microtiter plates (Figure 5a) or by directly measuring βG activity in blood samples (Figure 5b). The initial and terminal half-lives of the immunoenzymes were approximately 0.15 and 2.1 h, respectively, for hcc49-hβG, and 0.11 and 1.9 h for hcc49-S2. Direct measurement of enzymatic activity was more sensitive than ELISA, but both methods gave comparable results, indicating that the immunoenzymes retained both antigen-binding and enzymatic activity in vivo.

Imaging and Biodistribution of Immunoenzymes in Tumor-Bearing Mice. We first examined the tumor localization of the immunoenzymes by whole-body imaging in mice. Nude mice bearing 100−200 mm^3 LS174T xenografts were first imaged 5 and 48 h after i.v. injection of ^{131}I-hcc49-S2 (Figure 5c). After 48 h, ^{131}I-hcc49-S2 showed increased accumulation at the tumor site. ^{131}I-hcc49-S2 also clearly accumulated in the liver (Figure 5c). To further determine the amount of immunoenzymes in tumors, nude mice bearing 100−200 mm^3 LS174T xenografts were i.v. injected with 100 μg radiolabeled hcc49-S2 or αDNS-S2. The tumoral accumulation of ^{131}I-hcc49-S2 was stable after 24 h post injection (Table 3). By contrast, the accumulation of ^{131}I-αDNS-S2 decreased after 24 h post injection, indicating retention of hcc49-S2 but not αDNS-S2 in tumors. Liver uptake for both ^{131}I-hcc49-S2 and ^{131}I-αDNS-S2 was approximately 1% of the injected dose of radiolabeled fusion protein per gram of liver (% ID/g) after 48 and 72 h (Table 3). This might be due to the carbohydrate-mediated hepatic uptake of hβG.[40,41] Although the amount of ^{131}I-labeled hcc49-S2 was higher in the liver than in tumors, i.v. injection of FDGlcU resulted in significantly higher fluorescence signals in tumors as compared to the liver (Figure 5d). This result indicates that hcc49-S2 in the liver is likely sequestered inside cells and is not assessable for hydrolysis of glucuronide substrates. By contrast, the highly fluorescent signal in tumors shows that βG activity of hcc49-S2 is available for glucuronide hydrolysis in the tumor microenvironment.

ADEPT Therapy of Human Cancer Xenografts. To evaluate the therapeutic effect of tumor targeting immunoenzymes combined with prodrug treatment in vivo, BALB/c nu/nu mice bearing LS174T tumors were first i.v. injected with PBS or 500 μg/kg immunoenzyme on days 0 and 8. Mice were i.v. injected with PBS or three hourly doses of 70 mg/kg HAMG on days 1 and 10. Significant suppression of tumor growth with partial regression was observed in the mice injected with hcc49-S2 and HAMG (Figure 6a). By contrast, treatment of mice with hcc49-hβG and HAMG did not significantly suppress tumor growth as compared to treatment with αDNS-S2 and HAMG (p > 0.58). These data indicate that enhancing the enzymatic activity of hβG immunoenzymes resulted in greater therapeutic efficacy. Although previous data showed that liver accumulation of hcc49-S2 did not

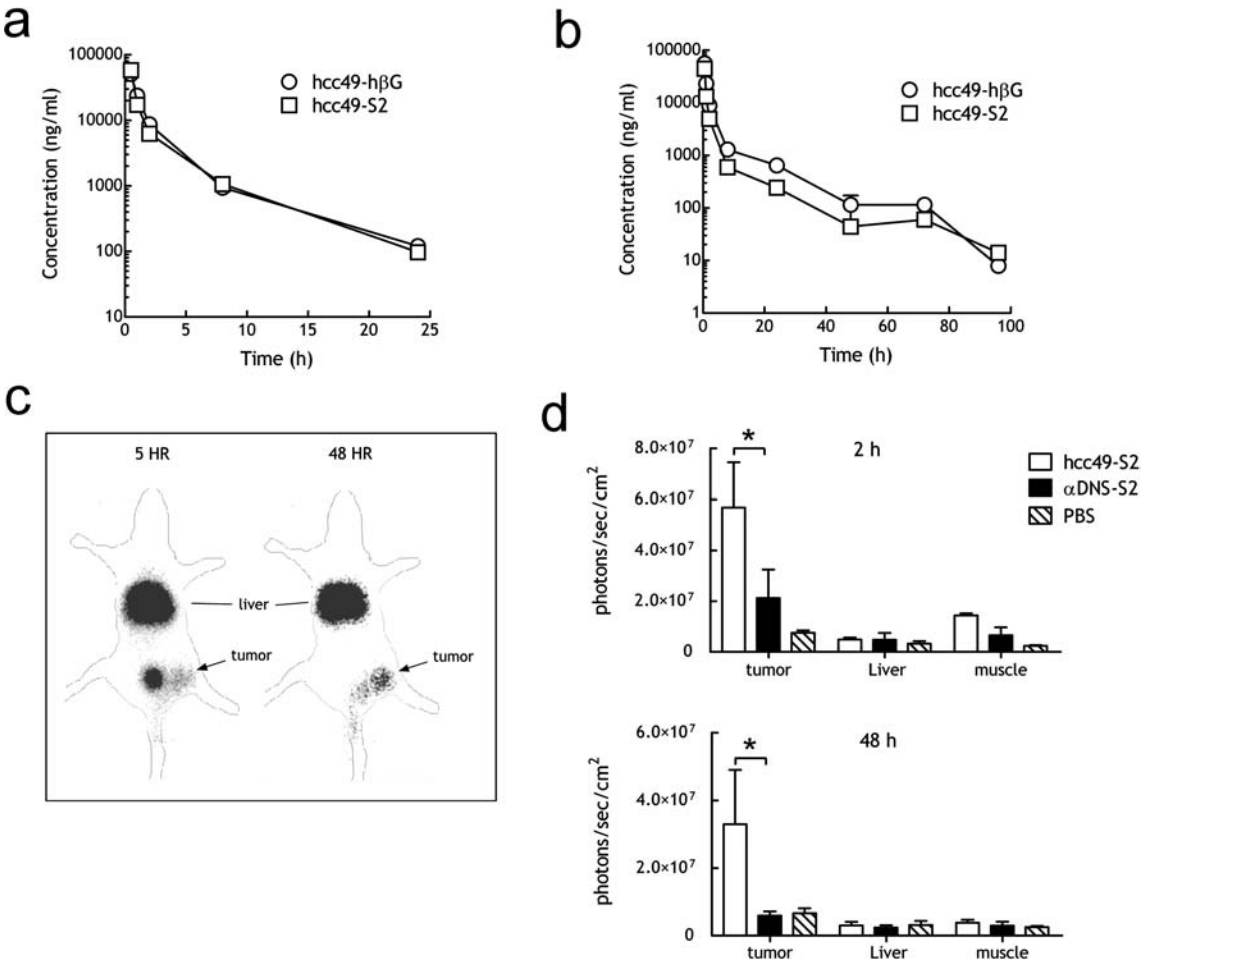

Figure 5. Pharmacokinetics of immunoenzymes in mice. Beige/SCID mice were i.v. injected with 100 μg hcc49-hβG or hcc49-S2. Mean plasma concentrations of the immunoenzymes were determined by measuring βG activity after capture of immunoenzymes on mucin-coated plates (a) or by directly measuring βG activity in serum (b). Bars, SEM (n = 3 mice). (c) Whole-body image of a representative nude mouse bearing a s.c. LS174T xenograft on the right flank at 5 and 48 h after i.v. injection of 100 μg of ^{131}I-hcc49-S2 (89 μCi). The images were obtained from the same mouse. (d) FDGlcU was administrated through the tail vein at 2 h (upper panel) or 48 h (lower panel) after i.v. injection of PBS, hcc49-S2, or αDNS-S2. The fluorescence intensity of tumor or liver was measured 30 min after injection of FDGlcU on an IVIS Imaging System (Xenogen, Alameda, CA, USA). The tumors and liver were analyzed with *Living Image* software. Significant differences between hcc49-S2 and αDNA-S2 fluorescence are indicated: *, $p < 0.05$.

hydrolyze a glucuronide substrate in the liver, we further investigated possible liver toxicity by measuring several hepatic enzyme markers 7 days after administration of immunoenzyme and HAMG. We also measured red blood cells (RBCs) and white blood cells (WBCs) because alkylating agents such as HAMG can cause dose-limiting leucopenia.[5] The mean numbers of RBCs in mice injected with hcc49-S2 and HAMG was slightly but not significantly lower (p = 0.19) than those of vehicle-treated mice (Figure 6b). Importantly, the number of WBCs in mice was not affected by immunoenzyme and prodrug treatment (p = 0.29). Likewise, the serum levels of hepatic enzyme markers were not significantly elevated in mice treated with immunoenzyme and HAMG (p = 0.09, 0.75, and 0.81 for AST, ALT, and TBIL, respectively) as compared to vehicle-treated mice (Figure 6c). Taken together, the hematological and hepatic enzyme measurements indicate that uptake of immunoenzymes in the liver did not cause excessive toxicity.

DISCUSSION

ADEPT is an attractive strategy to selectively treat cancer, but low catalytic activity and/or strong immunogenicity of currently investigated immunoenzymes has hampered clinical adoption. To help solve this problem, we created immunoconjugates linking the scFv fragment of a humanized CC49 antibody to S2, a hβG variant with enhanced enzymatic activity. We found that humanized immunoenzymes retained enzymatic activity and displayed exceptional antigen binding avidity ($K_D \approx 4 \times 10^{-10}$ M). The immunoenzymes could selectively bind and activate anticancer prodrug at TAG-72 positive cancer cells with more effective prodrug activation being achieved with hcc49-S2 as compared to hcc49-hβG. Importantly, the growth of human tumor xenografts in mice was significantly suppressed by treatment with hcc49-S2 and prodrug. Our results offer a promising approach to create highly active humanized immunoenzymes for ADEPT.

The use of hβG in immunoenzymes has been hampered by its relatively low enzymatic activity as compared to microbial sources of βG.[14−16] For example, the activity of *E. coli* βG is about 200-fold greater than hβG at pH 7,[27] and βG from *Staphylococcus* sp. displays about 2000-fold higher activity than hβG.[20] To help overcome this limitation, we recently developed a mammalian surface display system to facilitate the directed

molecular evolution of human enzymes.[21] We successfully generated the hβG variant S2, which displays about 60-fold higher activity against ELF-97G and about 8-fold higher activity against several anticancer prodrugs.[21] Indeed, the immunoenzyme utilizing the S2 hβG variant more effectively activated a glucuronide prodrug at antigen-positive cancer cells (Figure 4) and produced significantly greater antitumor activity in vivo (Figure 6). Although it seems intuitive that more activity enzymes would improve prodrug activation in the tumor microenvironment, mathematical models have predicted that utilization of lower activity enzymes may be advantageous for ADEPT.[42,43] Our results, however, support the development of human enzymes with enhanced catalytic activity as an approach to improve the efficacy of ADEPT. We recently developed a more general screening approach for creating highly active human enzymes and successfully created hβG variants with 30-fold greater activity for anticancer glucuronide prodrugs (manuscript in preparation). Given the high activity of microbial sources of βG, we suspect that hβG variants with much higher catalytic activity can be generated. This approach should also be applicable to enhance the enzymatic activity of other human enzymes for ADEPT including β-galactosidase, β-glucosidase, carboxypeptidase A1, carboxylesterase, α-mannosidase, and purine nucleoside phosphorylase.[44−47]

In addition to enhanced enzymatic activity, hcc49-S2 displayed about 100-fold greater binding avidity for mucin as compared to hcc49 scFv (Table 2). The avidity of hcc49-S2 (K_D = 4.45 × 10^{-10} M) was also greater than that of the intact CC49 IgG molecule (K_D = 8.77 × 10^{-9} M[48]). The high avidity of hcc49-S2 is likely attributable to the tetrameric structure of hβG, which is required for enzymatic activity.[35] Thus, each immunoenzyme contains four scFv molecules (Figure 1d). The high affinity of hcc49-S2 should be beneficial for ADEPT because tumor retention correlates with antibody affinity.[49]

We observed that hcc49-hβG and hcc49-S2 were rapidly cleared from the circulation (Figure 5a,b). Imaging and radiolabeled immunoconjugate data demonstrated rapid liver uptake of the immunoenzyme, likely via mannose receptors (MR) and mannose 6-phosphate receptors (M6PR).[41,50] Fortunately, internalized immunoconjugates did not appear to be available for prodrug activation (Figure 5). On one hand, the rapid clearance of immunoenzyme from the circulation allows the tumor-to-plasma ratio to quickly reach suitable levels for prodrug administration. On the other hand, rapid clearance of immunoenzyme might hamper tumor localization. Chemical modification of hβG to hinder the uptake by MPR and M6PR on liver cells or pegylation of the immunoenzyme are approaches that may prolong immunoenzyme circulation to allow increased accumulation of immunoenzyme in tumor.[8,51,52] Future studies are required to determine the optimal half-life of the immunoconjugates for cancer therapy by ADEPT.

Strong immune response against antibody−enzyme conjugates adversely affects tumor localization and treatment efficacy in clinical trials of ADEPT, even with the administration of immunosuppressive drugs.[10,12] Murine antibodies such as CC49 also induce immune responses in patients that hamper antibody effectiveness.[53,54] Because humanized antibodies are less immunogenic as compared to murine and chimeric antibodies,[55] we utilized a humanized CC49 scFv to construct immunoenzymes.[22] However, reducing the immunogenicity of the enzyme portion of the immunoenzymes is more problematic. Besides using immunosuppressive drugs to blunt antienzyme immune responses,[56] foreign enzymes have been engineered to remove immunogenic epitopes[57,58] and catalytic antibodies have been employed to replace the enzyme portion of the immunoenzyme.[59] However, besides exhibiting limited effectiveness in suppressing strong immune responses against microbial enzymes, immunosuppressive drugs can cause undesirable side effects and may suppress desirable antitumor immune responses in cancer patients.[60] Removal of all immunogenic B cell and T cell epitopes of highly divergent foreign enzymes with retention of activity and stability remains a challenging problem[61,62] and creation of catalytic antibodies with enzymatic activities comparable to natural enzymes is not easily achieved.

Utilization of highly active human enzyme variants is an alternative approach that is expected to reduce immunoenzyme immunogenicity as compared to those incorporating microbial enzymes. For example, the amino acid sequence of *E. coli* βG differs from hβG at 322 positions and differs from mouse βG at 323 positions. Immunoenzymes utilizing *E. coli* βG are therefore highly immunogenic in mice.[7,63] By contrast, the S2 variant differs from hβG by only four amino acids, suggesting that immune responses against hcc49-S2 should be mild as compared to immunoenzymes created with microbial sources of βG. Studies showing that even partial replacement of mouse immunoglobulin sequences (57−72% identity to human immunoglobulin[64]) with the corresponding human immunoglobulin sequences can substantially reduce the immunogenicity of mouse antibodies also suggest that human enzymes with limited numbers of amino acid alterations should be less immunogenic than microbial enzymes.[55,65] However, further studies in appropriate transgenic mouse models or in human subjects will be required to define actual immunogenicity of human enzyme variants.

hcc49-S2 possesses potential advantages for cancer therapy. The high avidity of hcc49-S2 may promote better tumor delivery[66] and facilitate prolonged retention of the immunoenzyme at tumor cells in vivo (Table 3), resulting in high immunoconjugate tumor/blood ratios. The wide distribution of the TAG-72 antigen in colorectal, gastric, pancreatic, ovarian, endometrial, breast, nonsmall cell lung cancer, and prostate carcinomas suggests that hcc49-S2 may be useful for the treatment of many types of cancer.[67] The plethora of anticancer glucuronide prodrugs available also means that effective

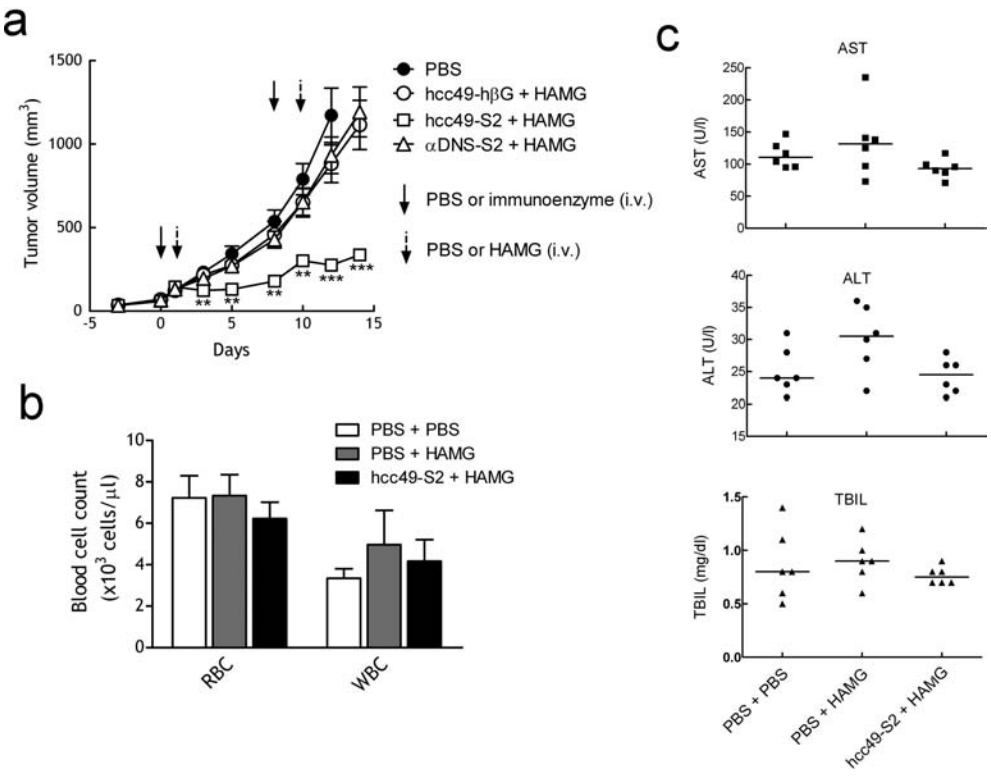

Figure 6. ADEPT with humanized immunoenzymes. (a) Nude mice bearing 50−100 mm^3 s.c. LS174T tumors were i.v. injected with PBS or 500 μg hcc49-hβG, hcc49-S2, or αDNS-S2 on days 0 and 8 and i.v. injected with three fractionated doses of 70 mg/kg HAMG or PBS on days 1 and 10. Bars, SEM (n = 8). Significant differences in mean tumor size in mice treated with hcc49-S2 or hcc49-hβG and HAMG are indicated: **, $p \leq 0.005$; ***, $p \leq 0.0005$. (b, c) Nude mice were i.v. injected with 500 μg hcc49-S2 or PBS, and after 24 h, mice were i.v. injected with three fractionated doses of 70 mg/kg HAMG or PBS. The numbers of the WBCs and RBCs (b) and the serum concentrations of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and total bilirubin (TBIL) (c) were measured 7 days after HAMG administration. Bars, SD (n = 4−6).

combinations may be utilized depending on the tumor type under therapy. The enzymatic amplification of drug activity and the relatively fast diffusion of activated drug molecules within solid tumors may also help effectively treat antigen-negative and antigen-escape cancer cell variants.

In conclusion, our study demonstrates that hcc49-S2, a humanized immunoenzyme with enhanced enzymatic activity, displays promising therapeutic effects in combination with glucuronide prodrug in a human tumor xenograft model. Our study suggests that further improvement of treatment efficacy may be achieved by generation of more active enzyme variants and optimization of immunoenzyme pharmacokinetic properties, and possibly by utilization of more potent prodrugs or development of prodrugs with enhanced binding affinity to hβG variants. We hope that further development of highly active humanized immunoenzymes can accelerate the translation of ADEPT from the lab to the clinic.

Supporting Information

ABSTRACT: Biotherapeutic delivery is a rapidly growing field in need of new materials that are easy to modify, are biocompatible, and provide for triggered release of their encapsulated cargo. Herein, we report on a particulate system made of a polysaccharide-based pH-sensitive material that can be efficiently modified to display mannose-based ligands of cell-surface receptors. These ligands are beneficial for antigen delivery, as they enhance internalization and activation of APCs, and are thus capable of modulating immune responses. When compared to unmodified particles or particles modified with a nonspecific sugar residue used in the delivery of antigens to dendritic cells (DCs), the mannosylated particles exhibited enhanced antigen presentation in the context of major histocompatibility complex (MHC) class I molecules. This represents the first demonstration of a mannosylated particulate system that enables enhanced MHC I antigen presentation by DCs *in vitro*. Our readily functionalized pH-sensitive material may also open new avenues in the development of optimally modulated vaccine delivery systems.

INTRODUCTION

Vaccination has been successful in preventing various diseases; however, the development of vaccines for illnesses such as cancer, AIDS, and malaria still suffers from ineffective or insufficient generation of protective immunity. One of the great challenges in the development of improved vaccines involves tailoring the type of immune response that a vaccine elicits to most effectively treat specific pathogens or cancers.[1] For example, cytotoxic T lymphocyte (CTL)-mediated immunity is believed to be critical for full protection from illnesses, such as HIV, malaria, and cancer.[2,3] Therefore, much effort has been put into guiding antigen into major histocompatibility complex (MHC) class I processing pathways of antigen presenting cells (APCs), which is critical for the generation of CTL responses.[4]

Dendritic cells (DCs)—the most potent APCs—endocytose, process, and load antigens onto MHC class I or II molecules for presentation to naïve $CD8^+$ or naïve $CD4^+$ T cells, respectively.[5] This MHC presentation, along with costimulatory signals, results in the activation of T cells, which then become effector T cells. DCs also express pathogen recognition receptors, such as Toll-like receptors (TLRs) and C-type lectins, with which DCs sense and/or capture microbes.[6,7] Targeting DCs with ligands specific for particular TLRs or C-type lectins can provide opportunities to alter the signaling pathways of DCs during activation, thus modulating the ultimate form of the cellular and/or humoral immune response that is generated.[8−10] Therefore, it is of great importance to develop a modular vaccine delivery system that can be used to address different activation mechanisms of the immune system.

Nanoparticles have received some attention for application as vaccine carriers because their size is in the range that can be taken up by phagocytic cells for the passive targeting of APCs. They can absorb, encapsulate, or be conjugated to antigens, and it is possible to incorporate ligands for the recognition and activation of APCs.[11−13] Besides targeting antigens to APCs, it is equally important to deliver those antigens into desired intracellular compartments.[14] Our group and others have reported acid-sensitive antigen delivery systems that allow antigens to be released under acidic conditions upon endocytosis by APCs and enter the MHC I presentation pathway.[15−21] Recently, we have developed a simple approach to modify dextran, a clinically approved biopolymer, into an acid-sensitive micro- or nanoparticulate delivery system, where dextran is rendered water-insoluble by modifying its hydroxyl groups with acid-labile acetal groups, forming acetalated dextran (AcDEX).[22] When tested *in vitro*, AcDEX particles encapsulating a model protein antigen led to significant enhancement of MHC class I presentation compared to the free protein or antigens delivered by commonly used materials such as poly(lactic-*co*-glycolic acid) (PLGA) or iron oxide particles, thus demonstrating the potential of AcDEX in vaccine development.[16]

We have now engineered the AcDEX system to display reactive groups on the particle surface, which can be readily functionalized with ligands capable of modulating immune

responses. In this report, we demonstrate that introduction of mannose residues onto the surface of particles can enhance MHC I antigen presentation by DCs *in vitro*.

EXPERIMENTAL PROCEDURES

General Materials and Methods. All chemical reagents were purchased from Sigma-Aldrich (St. Louis, MO) and used as supplied, unless otherwise noted. Phosphate buffered saline (pH 7.4, PBS) was purchased from Invitrogen-Gibco (Carlsbad, CA). Water (dd-H_2O) was purified to a resistance of 18 MΩ using a NANOpure purification system (Barnstead, USA). All reactions were conducted under nitrogen. Organic solvents in reactions were purified by passing through two columns of neutral alumina on a commercial push still apparatus (Glass Contour, SG Water, NH). Analytical thin layer chromatography (TLC) was performed on silica gel 60-F_{254} (Merck). Plates were visualized by ultraviolet light or charring with basic potassium permanganate solution, triphenylphosphine/ninhydrin solution or ethanolic sulfuric acid-anisaldehyde solution. Column chromatography used silica gel (SiliCycle, F60, 40−63 μm, 60 Å) and solvents were of reagent grade, and used as supplied. ^{1}H NMR spectra were recorded at 400 or 500 MHz, and ^{13}C NMR spectra were recorded at 100 MHz. First-order chemical shifts are reported in δ (ppm) using residual solvent signals from deuterated solvents as references. For samples in D_2O, the chemical shifts are referenced to acetone (0.1% v/v) at δ 2.225. Signals in ^{1}H spectra were assigned with corresponding coupling constants or COSY spectra. NMR data reported are labeled according to IUPAC nomenclature for carbohydrate molecules. Mass spectrometry was performed under positive/negative-mode high-resolution electrospray ionization (ESI) on an Orbitrap instrument by the Chemistry Mass Spectrometry Facility of the University of California, Berkeley. Fourier transform infrared spectroscopy (FT-IR) was carried out on a Varian 3100 FT-IR spectrometer (Varian, USA). Particles used in the studies were suspended by alternately vortexing and sonicating in a VWR model 75 water bath. Fluorescence measurements for microplate-based assays were obtained on a Spectra Max Gemini XS (Molecular Devices, USA), usage courtesy of Professor Jonathan Ellman. UV−vis absorbances for microplate-based assays were measured using Spectra Max 190 (Molecular Devices, USA), and flow cytometry was performed using Becton-Dickinson Biosciences FACSCalibur flow cytometer, usage courtesy of Professor Carolyn Bertozzi.

Cell Lines and Culture. DC 2.4 cells were generously donated by Professor Kenneth Rock (University of Massachusetts Medical Center) and were cultured in RPMI 1640 (Invitrogen) supplemented with 10% fetal bovine serum (FBS, from Hyclone), 2 mM GlutaMAX (Invitrogen), 100 U/mL penicillin (Invitrogen), 100 μg/mL streptomycin (Invitrogen), 10 mM MEM Non-Essential Amino Acids (NEAA, from Invitrogen), 10 mM HEPES buffer (Invitrogen), and 0.055 mM 2-mercaptoethanol (Invitrogen). RAW 309 and RAW 264.7 macrophages were purchased from ATCC (Manassas, VA) and were cultured in Dulbecco's Modified Eagle Medium (DMEM, Invitrogen-Gibco 11960) supplemented with 10% FBS, 100 U/mL of penicillin, 100 μg/mL streptomycin, and 2 mM GlutaMAX. B3Z ($CD8^+$) cells were kindly provided by Professor Nilabh Shastri (University of California, Berkeley) and were cultured in RPMI 1640 supplemented with 10% FBS, 2 mM GlutaMAX, 100 U/mL penicillin, 100 μg/mL streptomycin, 1 mM sodium pyruvate (Invitrogen), and 0.055 mM 2-mercaptoethanol. Cells were incubated in a water-jacketed incubator at 37 °C with 5% CO_2.

Synthesis of Azido-Dextran. To a solution of dextran (MW = 10 500 g/mol, 1.57 g, 0.15 mmol) in anhydrous DMSO (30 mL) was added imidazole-1-carboxylic acid 2-[2-(2-azido-ethoxy)-ethoxy]-ethyl ester (2.61 g, 9.705 mmol) and 4-dimethylamino-pyridine (DMAP, 1.30 g, 10.676 mmol). The reaction mixture was stirred for 2 days under argon and dialyzed using regenerated cellulose-based dialysis bag (MWCO = 3 kDa) against 8 × 4 L distilled water over 3 days. Lyophilization gave the product as a white fluffy powder (1.88 g, 85.3%). IR (KBr, cm^{-1}): 3409, 2929, 2362, 2340, 2115, 1751, 1268, 1150, 1104, 1017. ^{1}H NMR (400 MHz, D_2O): δ 5.01−4.88 (m, 1.4H, H-1), 4.40−4.26 (br, 1H, $CH_2OC{=}O$), 4.02−3.42 (m, 12.9H, H-2, H-3, H-4, H-5, H-6, CH_2O, CH_2N_3). ^{13}C NMR (125 MHz, D_2O): δ 155.7, 155.0, 97.8, 80.3, 73.4, 71.4, 70.9, 70.2, 69.8, 69.7, 69.6, 69.4, 69.3, 68.4, 67.9, 67.5, 65.6. 50.2, 38.8.

Synthesis of Acetalated Azido-Dextran (Azido-AcDEX). Azido-dextran (MW = 14 700 g/mol, 1.47 g, 0.100 mmol) was dissolved in anhydrous DMSO (10 mL) in a 20 mL scintillation vial, followed by addition of 2-methoxypropene (3.4 mL, 37 mmol) and pyridinium *p*-toluenesulfonate (15.6 mg, 0.062 mmol). The reaction flask was sealed with parafilm, and the reaction was allowed to proceed for 2 h (fast-degrading azido-AcDEX) or 20 h (slow-degrading azido-AcDEX) at r.t.[16] Triethylamine (0.1 mL, 0.7 mmol) was added to quench the reaction, and the dextran derivative was precipitated in dd-H_2O (pH 8, 100 mL). The product was collected by centrifugation at 14 000 × *g* for 10 min, and washed with dd-H_2O (pH 8, 2 × 50 mL). The resulting pellet was then lyophilized to yield a white power (1.07 g). ^{1}H NMR (500 MHz, CD_2Cl_2): δ 5.18 (1H), 4.95 (2H), 4.28 (2H), 3.97−3.65 (19H), 3.49 (2H), 3.38 (2H), 3.24−3.21 (4H), 2.50 (1H), 1.42, 1.38−1.34 (20H) (all reported as broad peaks).

Preparation of Nanoparticles Encapsulating Proteins (Azido-AcDEX). Ovalbumin (OVA) or bovine serum albumin (BSA) labeled by fluorescein isothiocyanate (FITC) was encapsulated into nanoparticles using a double emulsion water/oil/water (w/o/w) evaporation method similar to that described previously.[16] Briefly, OVA or BSA-FITC (8 mg) was dissolved in phosphate buffered saline (PBS, 137 mM NaCl, 10 mM phosphate, 2.7 mM KCl, pH 7.4, 40 μL), and added to an azido-AcDEX (160 mg) solution in CH_2Cl_2 (1.6 mL). This mixture was then vortexed immediately and emulsified for 30 s on ice using a probe sonicator (Branson Sonifier 450, output setting at 5.5, duty cycle at 70%). An aqueous solution of poly(vinyl alcohol) (PVA, M_w = 13 000−23 000 g/mol, 87−89% hydrolyzed, 3.2 mL, 3% w/w in PBS) was added to the first emulsion, and sonicated for 30 s on ice using the same settings. The resulting double emulsion was immediately transferred into a second PVA solution (16 mL, 0.3% w/w in PBS) and stirred for 2 h to evaporate the CH_2Cl_2. The particles were isolated by centrifugation (14 000 × *g*, 15 min) and washed with dd-H_2O (pH 8, 3 × 15 mL). The particle pellets were sonicated to a nice suspension between each wash. The washed particles were suspended in dd-H_2O (pH 8, 2 mL) and lyophilized to give a white fluffy solid (105 mg).

Preparation of Empty Nanoparticles (Azido-AcDEX). Particles containing no protein were made in the same manner as above without the first emulsion with the OVA solution.

Preparation of Microparticles Using Emulsion Method. Micrometer-sized particles were prepared in a similar manner as that previously described.[23] Azido-AcDEX (50 mg) was dissolved

in ice-cold CH_2Cl_2 (1 mL) in a 15 mL round-bottom polypropylene tube. PBS buffer (50 μL) was added, and the first solution and the mixture were sonicated for 5−10 s to a milky emulsion using a Branson Sonifier 450 (Branson Ultrasonics, Danbury, CT) with a 1/8 in microtip, an output setting of 1, and a continuous duty cycle. This primary emulsion was transferred dropwise to an ice-cold solution of PVA (12.5 mL, 3% w/w in PBS) that was being homogenized at 9600 rpm using an IKA T-25 Ultra-Turrax digital homogenizer with an S25N-10G generator. The homogenization was allowed to proceed for 30 s, and the resulting double emulsion was poured into a second PVA solution (25 mL, 0.3% w/w in PBS) and stirred for 2 h to evaporate CH_2Cl_2. Particles were centrifuged (4000 × *g*, 4 min), washed with dd-H_2O (3 × 20 mL, pH 8), resuspended in dd-H_2O (1 mL, pH 8) and lyophilized to yield a white fluffy solid (46 mg, 92%).

Quantification of Encapsulated OVA. Particles containing OVA were suspended at 5 mg/mL in 30 mM acetate buffer (pH 5.0) and incubated at 37 °C under gentle agitation for 2 days using a Thermomixer R heating block (Eppendorf). After complete degradation, protein content was analyzed by a microplate assay using fluorescamine (1 mM in acetone) as described in the literature.[24] Empty Ac-DEX particles were degraded in a similar fashion and used to determine background fluorescence.

Quantification of Encapsulated BSA-FITC. Particles containing BSA-FITC were suspended at 5 mg/mL in dd-H_2O (pH 8) in a microplate, and fluorescence of FITC was measured in triplicate and analyzed against a standard fluorescence curve of BSA-FITC.

Size Measurements of Nanoparticles by Dynamic Light Scattering. Particles were suspended in dd-H_2O (pH 8) in a disposable sizing cuvette at a concentration of 1 mg/mL. Particle size distributions and average particle diameters were determined in three measurements by dynamic light scattering using a Zetasizer Nano ZS (Malvern Instruments, United Kingdom). Size distributions in the text are described as average particle diameters ± half width of the distribution at half maximal height.

Size Measurements of Microparticles by Light Scattering. The size distribution of the microparticles was determined using a Horiba Partica LA-950 laser scattering particle size distribution analyzer after suspending the particles at 2 mg/mL in PBS. The reported results represent the geometric mean ± standard deviation of the size distribution.

Scanning Electron Microscopy. Suspensions of nanoparticles or microparticles (1 mg/mL) in dd-H_2O (pH 8) were dripped onto silicon wafers and allowed to dry in the air. The particles were then sputtercoated with a 2 nm layer of a palladium/gold alloy and imaged using an S-5000 microscope (Hitachi, Japan) or TM-1000 microscope (Hitachi, Japan).

Preparation of Mannosylated or Galactosylated Particles (Man-AcDEX or Gal-AcDEX). Azido-AcDEX nanoparticles or microparticles (20 mg) were suspended in a 2 mL N_2 protected aqueous solution of copper sulfate (1 mM), potassium 5,5′,5″-(2,2′,2″-nitrilotris(methylene)tris(1*H*-benzimidazole-2,1-diyl))tripentanoate $(BimC_4A)_3$ (1.2 mM), ascorbic acid (10 mM), and HEPES buffer (0.1 mM, pH 8.5), and the reaction mixture was stirred for 1 h at r.t. The particles were then isolated by centrifuge (14 000 × *g*, 10 min), washed with EDTA solution (10 mM in dd-H_2O, 3 × 2 mL, pH 8) and dd-H_2O (3 × 2 mL, pH 8), and resuspended in dd-H_2O (pH 8, 1 mL). The suspension was lyophilized to give white fluffy powder (18 mg, 90%).

Quantification of Mannose or Galactose Incorporation. Man-AcDEX or Gal-AcDEX particles (2 mg) were suspended in D_2O (0.7 mL) in an NMR tube, and DCl (5 μL) was added to the inside rim of the tube. The NMR tube was then capped and sealed immediately, and the suspension inside was mixed well until clear. After 10 min, NaOD (6 μL, 40 wt % in D_2O) was added to adjust the pH to 12. The solution was kept at r.t for 10 min, and ^{1}H NMR spectrum was acquired to observe the disappearance of the peak corresponding to ethylene protons adjacent to carbonate group (4.2−4.3 ppm), indicating the cleavage of the side chains from the dextran backbone. Spin−lattice relaxation times (T1) of the triazole proton of the mannoside and H-1 of glucose residue of dextran were measured (2.29 and 1.53 s, repsectively), and the values were used in the acquisition of ^{1}H NMR spectrum of the mixture of dextran, mannoside, and azido-TEG. The ratio of the integration of triazole and glucose H-1 gave the ratio of mannoside residue and glucose residue of dextran.

Release of OVA from Particles. Particles containing OVA were suspended at 5 mg/mL in either a sodium acetate buffer (30 mM, pH 5.0) or PBS buffer (pH 7.4, GIBCO, 1×), and gently agitated at 37 °C using a Thermomixer R heating block (Eppendorf). At desired time points, aliquots (100 μL) were removed and centrifuged at 14 000 × *g* for 10 min. The supernatant was collected, stored at −20 °C, and analyzed for the presence of protein using a microplate fluorescamine assay as described before.

Confocal Microscopy. Azido-AcDEX, Man-AcDEX, Gal-AcDEX, and HO-AcDEX microparticles (100 μg) were incubated with ConA-FITC (1 mg/mL) in PBS buffer (pH 7.4, 100 μL) with BSA (3 wt %) in the dark for 10 min at r.t. The particle suspension was then centrifuged (10 000 *g*, 3 min), washed with PBS buffer (1 mL × 3), resuspended in PBS buffer (2 mL), and loaded in a 35 mm #1.5 glass-bottomed tissue culture dish (MatTek, MA). Imaging was performed using a Zeiss LSM 510 Meta confocal microscope with an Apo 63× water dipping objective (Carl Zeiss, Germany) using an excitation wavelength of 488 nm for FITC.

Particle Uptake. DC 2.4 cells were seed to a 24-well tissue culture plate (Corning-Costar, NY) at 3.0 × 10^5 cells/well (1 mL/well) in growth medium. After overnight incubation at 37 °C, the medium was aspirated, and suspensions of particles encapsulating BSA-FITC at 2 mg/mL (250 μL/well) were added. At the indicated time points, medium was removed, and cells were washed with PBS buffer (Ca^{2+}-, Mg^{2+}-, 3 × 300 μL), trypsinized (50 μL trypsin/well), collected in PBS (300 μL), centrifuged (3000 × *g*, 5 min), and fixed in PBS buffer (300 μL) containing 4% paraformaldehyde (Electron Microscopy Sciences, Hatfield, PA). Cells were analyzed for particle uptake by a Becton-Dickinson Biosciences FACSCalibur flow cytometer (San Jose, CA) with 488 nm excitation. The fluorescence of cells incubated with different particles was normalized by the amount of BSA-FITC encapsulated in each type of particles.

MHC Class I Presentation (B3Z) Assay. B3Z cells[21] were freshly thawed and cultured in growth medium over 5 days. Dendritic cells (DC2.4, 5 × 10^4/well) were cultured overnight in a 96-well plate and subsequently incubated with particles encapsulating OVA or free OVA. After 6 h, the cells were washed carefully with the medium for B3Z cells (3 × 100 μL/well), and B3Z cells (1 × 10^5/well) were added to the dendritic cells and co-cultured for 16 h. The medium was replaced with 100 μL of CPRG buffer (91 mg of chlorophenol red β-D-galactopyranoside (CPRG, Roche, USA), 1.25 mg of NP40 (EMD Sciences, USA),

and 900 mg $MgCl_2$ per 1 L of PBS). The plates were kept in the dark at r.t. for 72 h, and the absorbance at 595 nm was measured (microplate reader, SpectraMax 190, Molecular Devices).

Mannose Inhibition MHC Class I Presentation (B3Z) Assay. Dendritic cells DC 2.4 (5×10^4/well) were cultured overnight in a 96-well plate. The medium was then aspirated and OVA-containing particles suspended in medium containing various concentrations of free mannose were added to the cells. After 6 h, the cells were washed carefully and B3Z cells (1×10^5/well) were added to the dendritic cells/macrophages and co-cultured for 16 h. The medium was replaced with 100 μL of CPRG buffer, the plates were kept in the dark at r.t. for 72 h, and the absorbance at 595 nm was measured.

Cell Viability Assay. Viability of cells was assessed using a standard MTT assay. Briefly, dendritic cells were seeded onto 96-well microtiter plates (Corning-Costar, NY) at 5×10^4 cells/well, respectively, for 24 h. The growth medium was replaced with 100 μL suspensions of particles or solutions of their degraded compounds at various concentrations. After incubation for 24 h, a 3 mg/mL solution of MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide) in growth medium (40 μL) was added directly to each well and the plates were returned to incubator. After 30 min (for DC 2.4 cells), purple crystals were observed at the bottom of each well. The plates were centrifuged ($500 \times g$, 5 min), and the medium was replaced with DMSO (200 μL/well) to dissolve the crystals of formazan. Glycine buffer (25 μL/well, 0.1 M glycine, 0.1 M NaCl, pH 10.5) was added, and absorbances at 570 nm were measured (Spectra Max 190 plate reader, Molecular Devices). Cell viability was normalized in percentage as the ratio of the absorbances measured from treated and untreated cells.

RESULTS AND DISCUSSION

Preparation and Modification of "Clickable" pH-Sensitive Dextran Particles. We developed a general protocol to prepare pH-sensitive AcDEX particles that can be modified to introduce multiple copies of a ligand on their surface. In a first step, a fraction of the hydroxyl groups of dextran were modified with an amphiphilic linker bearing a reactive functional group. This was followed by a second step in which the majority of the remaining hydroxyl groups were protected by acetal moieties to render the modified dextran organic-soluble in order to enable particle fabrication via a double emulsion process. We hypothesized that these amphiphilic linkers would be oriented to the interface between water and organic solvent phase during particle formation, so that the reactive functional groups would largely be located on the surface of the particles, thus accessible for future modification (Figure 1).

We used azido groups as the reactive functionalities at the termini of the linkers due to their ease of conjugation in aqueous phase via a variety of bio-orthogonal approaches such as azide–alkyne cycloaddition, Staudinger ligation, and others.[25,26] In this instance, dextran was modified using carbonyldiimidazole-activated azido-triethylene glycol (azido-TEG) to afford azido-dextrans with various degrees of modification (Figure 1 and Supporting Information Figure S1).[27] These azido-dextran materials were then acetalated by reaction with 2-methoxypropene to obtain the acid-sensitive azido-AcDEX polymer. The resulting water-insoluble polymer containing 0.4 azido-TEG/glucose residue was then used to prepare particles using standard emulsion-based techniques,[22] to afford nanoparticles with low polydispersity

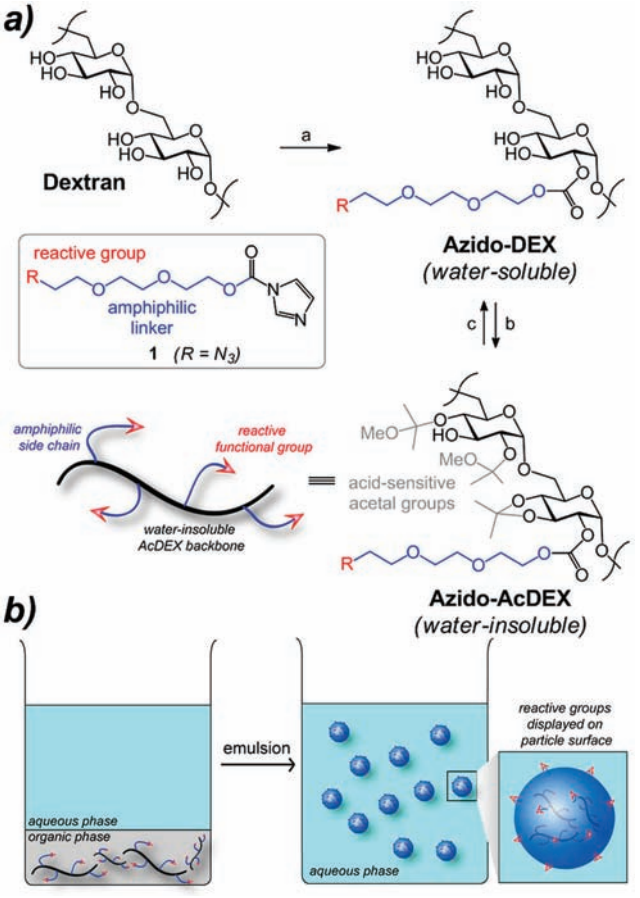

Figure 1. Preparation of "clickable" acid-sensitive dextran nanoparticles. (a) Synthesis of azido-AcDEX material. Reagents and conditions: a. **1**, DMSO, DMAP; b. (0.070) as measured by dynamic light scattering (DLS) (Figure 2). It should be mentioned that aggregation of particles was observed when using azido-AcDEX materials with degree of modification higher than 0.4 azido-TEG per glucose residue.

We then explored the surface modification of the azido-AcDEX nanoparticles with an appropriately functionalized mannose derivative. As a proof of concept, the ligand-assisted copper-catalyzed azide–alkyne cycloaddition (CuAAC) was used because it is a very efficient reaction for which Cu-ligands capable of significantly increasing the coupling rate are available.[28] Briefly, azido-AcDEX particles were suspended in HEPES buffer (0.1 M, pH 8.0) and stirred with an alkynylated mannoside in the presence of Cu(I) and its ligand $(BimC_4A)_3$ (Figure 2).[29] To monitor the heterogeneous CuAAC reaction, aliquots of the particle suspension were removed at desired time points, washed to remove unbound molecules and salts, and lyophilized. The dry particles were then degraded in D_2O by addition of DCl to hydrolyze the acetal groups, followed by addition of NaOD solution to cleave the carbonate bonds linked to dextran (Supporting Information Figure S3. The solutions of degraded particles were then examined by ^1H NMR, and the signal corresponding to the triazole proton (the product of azide alkyne cycloaddition at 8.0 ppm was used to monitor the progress of the reaction (Figure S3). Using the integration of the triazole proton relative

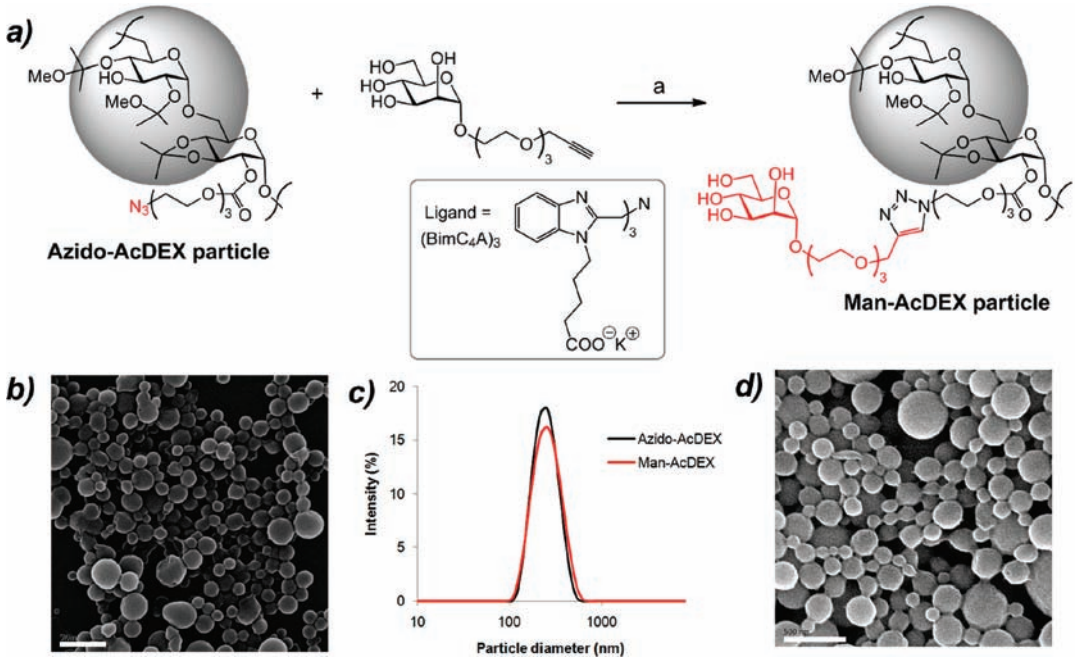

Figure 2. Synthesis of mannosylated AcDEX particles by CuAAC. (a) Synthetic scheme. Reagents and conditions: a. $CuSO_4$, ligand, ascorbic acid, HEPES buffer. (b) SEM image of Azido-AcDEX particles. to the anomeric proton, the number of mannose residues conjugated to particles were quantified by NMR and found to reach 2 mannose/100 glucose residues on dextran, leading to the estimate that a particle 200 nm in diameter would contain a few million mannose residues.

To verify that the reaction occurs at the surface of the particles, we prepared micrometer-sized particles large enough to visualize using confocal microscopy. These microparticles were subjected to the same reaction conditions as used for the nanoparticles and were surface-modified with mannoside, galactoside, or hydroxylated moieties, the latter two samples serving as negative controls. This was followed by incubation of the three types of modified microparticles with fluorescein isothiocyanate (FITC)-labeled concanavalin A (ConA), a reagent that specifically binds to α-mannose residues.[30] The particles were then washed to remove unbound reagents, and visualized using confocal microscopy (Figure 3). Only the mannosylated particles (Man-AcDEX) showed surface-associated fluorescence. In sharp contrast, galactosylated (Gal-AcDEX), hydroxylated, and unmodified azido-AcDEX particles showed no visible fluorescence, suggesting that the fluorescence halo around Man-AcDEX particles was due to specific binding between ConA and mannose residues on the particle surface.

Since all the above-mentioned particles could be used in the delivery of therapeutics, the cytotoxicity of the particles and that of the soluble materials obtained after their degradation were evaluated. All particles had a cytotoxicity comparable to that of PLGA and were fully degradable affording free dextran and nontoxic small molecules (Supporting Information Figure S4), supporting their potential use as biocompatible delivery vehicles.

Mannosylation of Particles Enhances MHC I Antigen Presentation by DCs. Recent reports have shown that soluble protein antigens taken up by DCs via mannose receptor[31]-mediated endocytosis bypass intracellular diversion and enter the MHC I antigen presentation pathway directly.[32] Therefore, targeting MRs of DC could constitute a useful route to enhance MHC class I antigen presentation. It is known that MRs contains 8 carbohydrate recognition domains (CRDs), 5 of which (CRDs 4−8) are involved in binding and endocytosis of mannose and related structures.[33,34] Therefore, using multivalently displayed ligands to target the CRDs of MR or multiple MRs can be a reasonable strategy to deliver antigens into MR-mediated endocytosis pathway. A terminal mannose monosaccharide is known to be a favorable ligand for MRs, but other C-type lectins, including DEC-205, Endo180, dendritic cell-specific intercellular adhesion molecule grabbing nonintegrin (DC-SIGN), Dectin-2 and langerin, can also interact with mannose-containing structures.[35] Hence, in practice, it is difficult to direct mannose-conjugates exclusively to MRs. However, differences in the spatial display of these mannose structures can produce a distinct set of carbohydrate recognition profile for each receptor. For example, DC-SIGN prefers to bind internal structures of high mannose oligosaccharides, therefore providing a certain degree of selectivity.[36−40]

Particulate systems provide a scaffold to incorporate multiple copies of targeting groups, which can help to increase the overall binding avidity to the cell surface receptors.[41] For example, mannose residues can be directed to the surface by self-assembly as seen in the preparation of liposomal or micellar carriers.[42−45] However, few reports exist on the development of mannosylated polymer-based particles.[46−51] Since it is not known if mannosylated particulate systems can improve the level of antigen presentation via the MHC class I pathway, we used our newly devised "clickable" particle system to study this effect. Mannosylation of our particles afforded a dense surface layer of mannose monosaccharide (up to 10^6/particle) while also preserving the integrity of the particles and their acid-degradability, thus supporting their use as a carrier for the delivery of protein antigen to DCs.

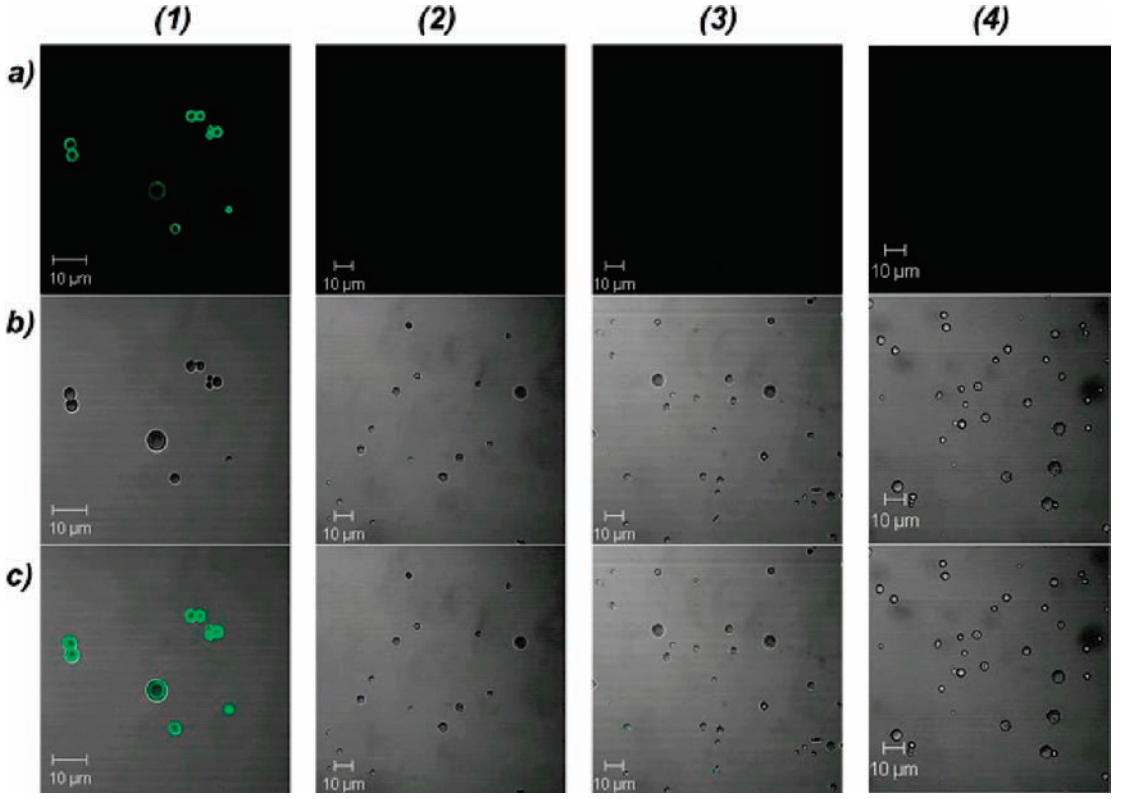

Figure 3. Confocal microscope images of microparticles ((1) Man-AcDEX particles, (2) azido-AcDEX particles, (3) Gal-AcDEX particles, (4) HO-AcDEX particles) after incubation with ConA-FITC. (a) Fluorescence image obtained using excitation wavelength of 488 nm; (b) differential interference contrast image; (c) merge of panels (a) and (b).

To test this hypothesis *in vitro*, we used a DC 2.4 cell line derived from murine bone marrow DCs[52] that is known to express MRs on its cell surface.[43] We first performed a cellular uptake experiment to see whether the mannose residues on the particle surface were available to MRs, and how that might contribute to particle internalization. FITC-labeled bovine serum albumin (FITC-BSA) was encapsulated into AcDEX or azido-AcDEX particles, and the latter were modified by the protocol described above to yield dye-containing Man-AcDEX and, as a negative control, Gal-AcDEX particles (Figure 2). These particles were then incubated with DC 2.4 cells for fixed lengths of time before they were washed and collected. Flow cytometry was then used to analyze the cellular uptake of particles (Figure 4). At all time points, Man-AcDEX particles showed a 1.5- to 2-fold increased uptake when compared to Gal-AcDEX particles and unmodified azido-AcDEX or AcDEX particles, respectively. Given that DCs also perform phagocytosis, macropinocytosis, and other receptor-mediated uptake, mannosylation was not expected to cause a drastic increase in cellular internalization. However, this finding suggests that mannose residues were accessible to MRs on DCs and that mannose targeting groups may indeed help enhance cellular uptake to an appreciable extent.

MHC I presentation of antigen-derived peptides from DC 2.4 was examined using the B3Z cell assay.[16,17,21,53,54] B3Z cells are $CD8^+$ T cell hybridomas engineered to express β-galactosidase when their T cell receptor recognizes the OVA-derived SIINFEKL epitope ($OVA_{257-264}$) in the context of MHC I molecules. We first prepared AcDEX or azido-AcDEX particles encapsulating

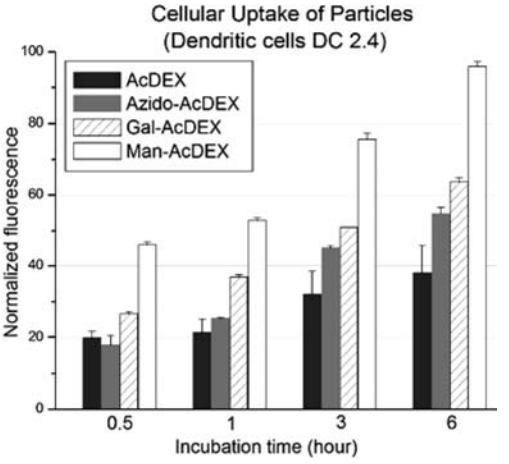

Figure 4. Cellular uptake of particles by DC 2.4 cells. Particles (2 mg/mL) were incubated with DC 2.4 at 37 °C. The fluorescence of cells was analyzed by a Becton-Dickinson Biosciences FACSCalibur flow cytometer with 488 nm excitation, and was normalized by the amount of BSA-FITC encapsulated in each type of particles.

OVA using a traditional double emulsion technique,[55] then surface-modified the latter with mannose or galactose, and incubated these particles with DC 2.4 cells (Figure 5). Antigen presentation was then determined using the B3Z assay. While all particulate formulations of OVA enhanced MHC I antigen presentation compared to free OVA, the performance of Man-AcDEX was about 5-fold better than that of Gal-AcDEX. This

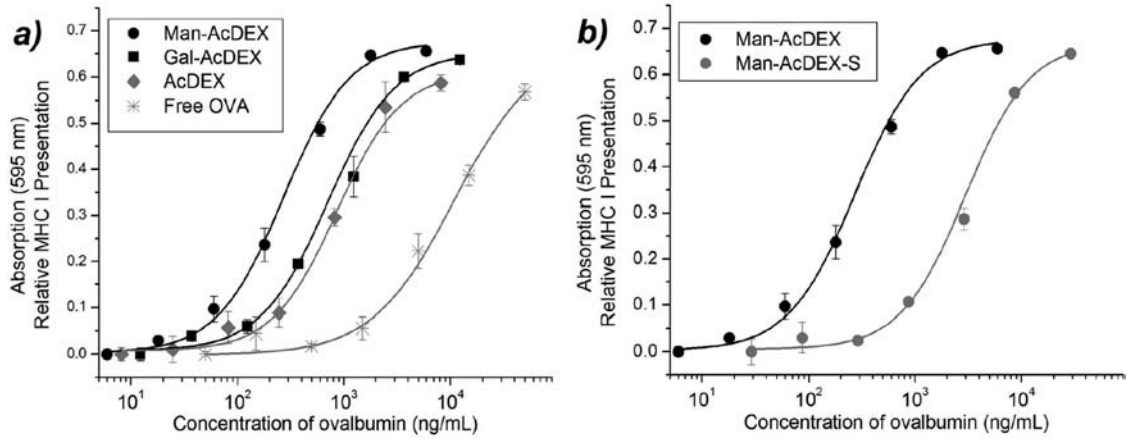

Figure 5. MHC I antigen presentation (B3Z assay) by DC 2.4. (a) Comparison of MHC I antigen presentation of OVA encapsulated in Man-AcDEX, Gal-AcDEX, and AcDEX particles, and free OVA. (b) Comparison of MHC I antigen presentation of OVA encapsulated in Man-AcDEX (fast-degrading) and Man-AcDEX-S (slow-degrading).

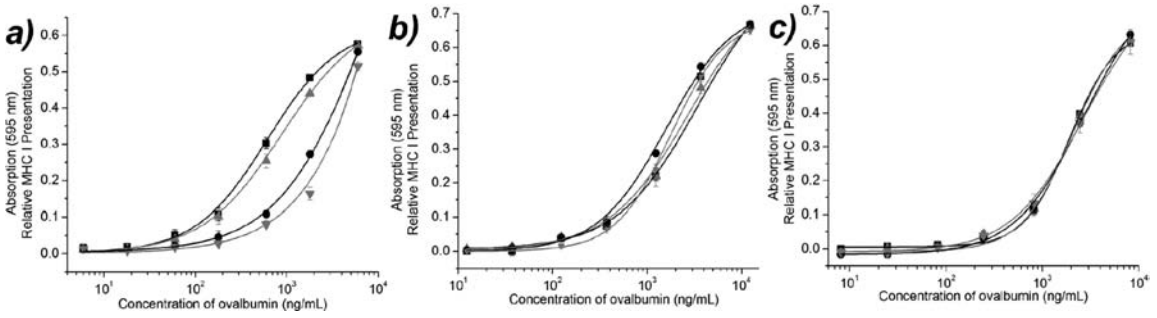

Figure 6. Mannose inhibition B3Z assay of DC 2.4. (a), (b), and (c) are Man-AcDEX, Gal-AcDEX, and AcDEX particles, respectively. Square, no addition of free mannose; triangle, with 10 mM free mannose; circle, with 50 mM free mannose; inverse triangle, with 100 mM free mannose.

finding could not be attributed to differences in antigen-release profiles, as both particles released antigen at similar rates at endosomal pH (Figure 5 and Supporting Information Figure S5). In addition, this may not be explained solely by the 1.5-fold difference in uptake of Man-AcDEX particles relative to Gal-AcDEX particles. One possible reason for this can be that these two types of particles go through different cellular uptake pathways, which causes differences in antigen presentation levels.

To verify that the enhanced MHC I antigen presentation from Man-AcDEX particles was indeed related to the surface-bound mannose groups, we incubated particles with DCs in the presence of free mannose, thus serving as a competitive ligand for the MRs (Figure 6). For Man-AcDEX particles, antigen presentation was suppressed upon addition of free mannose, and this inhibition was proportional to the concentration of free mannose. However, addition of free mannose did not inhibit antigen presentation from Gal-AcDEX or AcDEX particles. Collectively, these observations suggest that MRs and/or related C-type lectins were involved in the delivery and presentation of antigens in the case of Man-AcDEX particles, but not Gal-AcDEX or AcDEX particles.

In a previous report, we demonstrated that particle degradation and antigen release rates can influence the levels of antigen presentation observed—fast-degrading particles led to more efficient and enhanced class I presentation than slow-degrading particles.[16] However, besides the differences in particle degradation kinetics, particles made from the two types of materials may go through different internalization pathways due to their different surface chemistry. Hence, we prepared particles using a slower-degrading azido-AcDEX material (azido-AcDEX-S) and modified the particles with mannose to obtain slow-degrading Man-AcDEX particles (Man-AcDEX-S), to compare their antigen presentation efficiency to that of Man-AcDEX particles. Because both particles had the same surface modification, they should go through the same cellular uptake mechanism, so that the only difference would be their degradation rate. The use of the faster-degrading Man-AcDEX polymer led to a 10-fold increase in the levels of MHC I presentation compared to Man-AcDEX-S (Figure 5). AcDEX particles used in this study degraded faster than Man-AcDEX or Gal-AcDEX particles (Supporting Information Figure S5), and they showed similar antigen presentation abilities as Gal-AcDEX particles. Since receptors on DCs may also bind galactose, the difference in degrading speed between AcDEX particles and Gal-AcDEX particles might be partially offset.[56] On the other hand, possible uptake of Gal-AcDEX via receptors that recognize galactose may also compensate for the difference in antigen presentation compared to Man-AcDEX.[57]

■ CONCLUSION

We have reported a particulate system made of a dextran-based pH-sensitive material that can be engineered to display

immunomodulatory properties. The feasibility of the novel system was evaluated by conjugating mannose to the particles using a simple procedure that complements the chemoselective ligation method we introduced earlier for dextran particles.[58] We have found that mannose monosaccharide-targeted cellular uptake by DCs led to enhanced MHC I antigen presentation compared to nontargeted particles. To our knowledge, this is the only example of a mannosylated particulate system leading to enhanced MHC I antigen presentation by DCs.

Delivery systems that can be engineered for immunomodulation are beneficial in a multitude of areas.[59] For vaccine development, conjugation of cell-surface receptor ligands can deliver antigens to specific intracellular pathways, providing opportunities to better control the antigen presentation to T cells. The materials used for these systems can also be modified by ligands to produce specific "danger" signals to manipulate the cytokine production and activation of APCs. Besides offering benefits for medical advances, such materials can also perform as model systems, providing help to better understand basic immunobiology.

■ ACKNOWLEDGMENT

This research was funded through the Fréchet "various gifts" fund for the support of research in new materials. We also thank Ann Fischer in the U.C. Berkeley Cell Culture Facility for her help with cell culture preparation, Dr. Valentin Rodionov for providing ligand used in CuAAC reactions, and Dr. Chris Canlas and Dr. Eric M. Bachelder for helpful discussions.

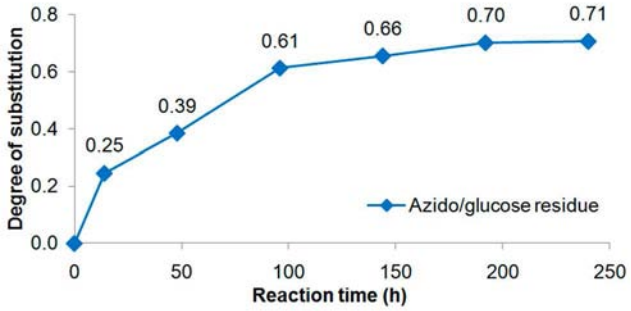
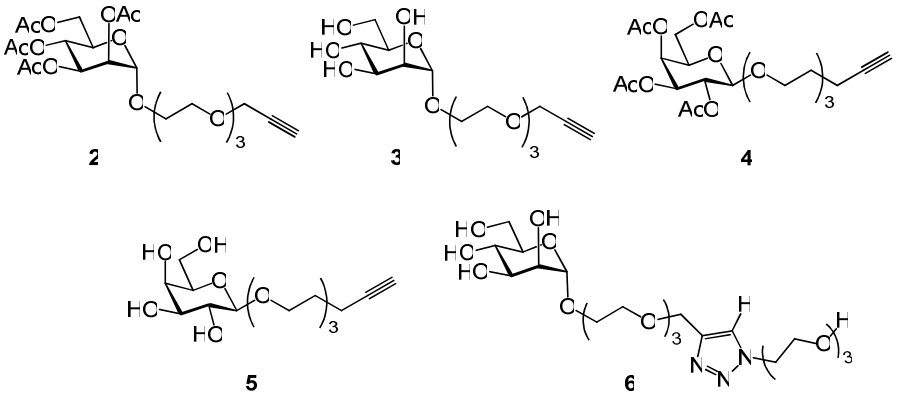
Synthesis of CDI-TEG-Azide (1). Azidotriethylene glycol (4.00 g, 22.88 mmol) (1) was stirred with molecular sieves (5.00 g, 4 Å) in THF (50 mL) for 30 min. under argon, and 1,1'-carbonyldiimidazole (CDI) (2.55 g, 25.06 mmol) was added to the reaction mixture. The reaction was complete in 1 h, then the molecular sieves were filtered, and THF was evaporated. The crude residue was then dissolved in ethyl acetate (200 mL) and washed with ammonium chloride (10%, 200 mL) then brine (100 mL) and then dried over magnesium sulfate. Evaporation of the solvents gave the product as a colorless clear oil (6.00 g, 98%). IR (KBr, cm^{-1}): 2913, 2870, 2109, 1748, 1443, 1265, 1124, 1063. ^{1}H NMR (500 MHz, $CDCl_3$): δ 7.97 (s, 1H, imidazole-H2), 7.71 (s, 1H, imidazole-H4), 7.08 (s, 1H, imidazole-H5), 4.27 (dd, 2H, J = 4.8, 4.0 Hz, CH_2OC=O), 3.72 (dd, 2H, J = 4.8, 3.7 Hz, CH_2O), 3.66-3.64 (m, 6H, CH_2O), 3.37 (t, 2H, J = 5.1 Hz, CH_2N_3). ^{13}C NMR (125 MHz, $CDCl_3$): δ 155.0, 135.1, 121.6, 70.6, 70.5, 70.0, 68.9, 67.0, 50.6.

Synthesis of Alkynyl Mannoside 2. Propargyl triethylene glycol (0.46 g, 2.44 mmol) and glycosyl donor 2,3,4,6-tetra-*O*-acetyl-D-mannopyranosyl trichloroacetamide (1.80 g, 3.66 mmol) were dissolved in dry dichloromethane (20 mL). Molecular sieves (2.0 g, 4 Å) were added and the mixture was stirred for 1 h at room temperature under argon. The reaction mixture was cooled to 0 °C, and boron trifluoride etherate (0.60 mL) was added slowly over 5 min. The reaction was allowed warm to r.t. and the reaction finished in 1 h. Triethylamine (0.05 mL) was added to neutralize the solution, and column chromatography (1:8 acetone:toluene, R_f = 0.2) gave compound **2** as a yellowish syrup (α only, 1.14 g, 85%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 5.36–5.25 (m, 3H, H-2, H-3, H-4), 4.86 (s, 1H, H-1), 4.27 (dd, 1H, J = 12.5, 5.1 Hz, H-6a), 4.19 (s, 2H, OCH_2C≡CH), 4.09-4.04 (m, 2H, H-5, H-6b), 3.83-3.79 (m, 1H, CH_2O), 3.68-3.64 (m, 11H, CH_2O), 2.42 (s, 1H, $OCH_2C{\equiv}CH$), 2.14 (s, 3H, OAc), 2.09 (s, 3H, OAc), 2.03 (s, 3H, OAc), 1.97 (s, 3H, OAc). ^{13}C NMR (125 MHz, $CDCl_3$): δ 170.7, 170.1, 170.0, 169.7, 97.7, 79.7, 74.5, 70.7, 70.6, 70.4, 70.0, 69.6, 69.1, 68.4, 67.4, 66.2, 62.4, 58.4, 20.9, 20.8, 20.7, 20.6. ESI HRMS calcd for $C_{23}H_{34}O_{13}Na$ (M + Na): 541.1892, found: 541.1885.



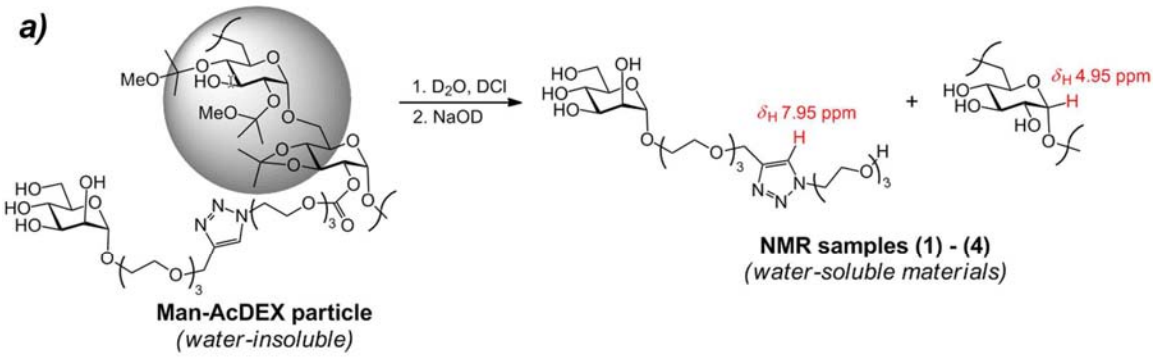
Synthesis of Alkynyl Mannoside 3. Compound **2** (702 mg, 1.35 mmol) was dissolved in dry methanol (5 mL) under argon. Sodium methoxide in methanol solution (25 wt%, 100 μL) was added, and the reaction mixture was stirred at r.t. for 15 min. Dowex 650C H^+ resin was added to

neutralize the solution, and the resin was removed by filtration. The filtrate was evaporated to dryness and the residue was purified by a C_{18} silica column (SepPak-10g, Waters) with a MeOH-H_2O gradient to afford compound **3** as a clear syrup (470 mg, 90%). IR (KBr, cm^{-1}): 3353, 2887, 2113, 1133, 1091, 1060, 1029. ^{1}H NMR (500 MHz, D_2O): δ 4.79 (d, 1H, *J* = 1.6 Hz, H-1), 4.16 (d, 2H, *J* = 2.4 Hz, OC*H*$_2$C≡CH), 3.87 (dd, 1H, *J* = 3.4, 1.7 Hz, H-2), 3.81-3.76 (m, 2H, H-6a, CH_2O), 3.72 (m, 1H, H-3), 3.69-3.53 (m, 14H, H-4, H-5, H-6b, CH_2O), 2.82 (t, 1H, *J* = 2.3 Hz, $OCH_2C{\equiv}CH$). ^{13}C NMR (125 MHz, D_2O): δ 100.0, 79.4, 76.1, 72.8, 70.5, 70.0, 69.7, 69.6, 69.5, 69.4, 68.7, 66.8, 66.4, 61.0, 57.9. ESI HRMS calcd for $C_{15}H_{26}O_9Li$ (M + Li): 357.1731, found: 357.1728.



Synthesis of Alkynyl Galactoside 4. Compound **4** was synthesized and purified in a similar manner as compound **2** as a yellowish syrup (β only, 1.30 g, 77%). ^{1}H NMR (500 MHz, $CDCl_3$): δ 5.40 (d, 1H, *J* = 3.2 Hz, H-4), 5.22 (dd, 1H, *J* = 10.0, 8.1 Hz, H-2), 5.04 (dd, 1H, *J* = 10.5, 3.4 Hz, H-3), 4.60 (d, 1H, J = 8.1 Hz, H-1), 4.23 (d, 2H, J = 2.2 Hz, OC*H*$_2$C≡CH), 4.21-4.13 (m, 2H, H-6a, H-6b), 4.00-3.92 (m, 2H, H-5), 3.81-3.75 (m, 1H, CH_2O), 3.75-3.63 (m, 11H, CH_2O), 2.46 (t, 1H, *J* = 2.2 Hz, $OCH_2C{\equiv}CH$), 2.17 (s, 3H, OAc), 2.09 (s, 3H, OAc), 2.07 (s, 3H, OAc), 2.01 (s, 3H, OAc). ^{13}C NMR (125 MHz, $CDCl_3$): δ 170.4, 170.3, 170.2, 169.5, 101.4, 79.7, 74.5, 70.9, 70.7, 70.6, 70.4, 70.3, 69.1, 69.0, 68.9, 67.1, 61.3, 58.4, .8, 20.7, 20.6, 20.5. ESI HRMS calcd for $C_{23}H_{34}O_{13}Na$ (M + Na): 541.1892, found: 541.1891.

Synthesis of Alkynyl Galactoside 5. Compound **5** was synthesized and purified in a similar manner as compound **3** as a clear syrup (β only, 370 mg, 78%). IR (KBr, cm^{-1}): 3408, 2882, 2115, 1718, 1077. ^{1}H NMR (500 MHz, D_2O): δ 4.27 (d, 1H, *J* = 7.9 Hz, H-1), 4.09 (m, 2H, OC*H*$_2$C≡CH), 3.93 (ddd, 1H, *J* = 11.3, 4.0, 4.0 Hz, H-5), 3.76 (d, 1H, *J* = 3.76 Hz, H-4), 3.71-3.52 (m, 14H, H-6a, H-6b, CH_2O), 3.50 (dd, 1H, *J* = 10.1, 3.7 Hz, H-3), 3.38 (dd, 1H, *J* = 10.0, 7.9 Hz, H-2), 2.73 (t, 1H, *J* = 2.4 Hz, $OCH_2C{\equiv}CH$). ^{13}C NMR (125 MHz, D_2O): δ 102.9, 79.5, 76.1, 75.2, 72.8, 70.8, 69.8, 69.6, 69.5, 69.4, 68.7, 68.6, 61.0, 57.9. ESI HRMS calcd for $C_{15}H_{26}O_9Li$ (M + Li): 357.1731, found: 357.1731.



Synthesis of Compound 6. Compound **3** (26.3 mg, 0.100 mmol) and azidotriethylene glycol (17.5 mg, 0.100 mmol) were subjected to the same reaction condition as that to prepare Man-AcDEX or Gal-AcDEX particles, except that the reaction was stopped after 30 min at r.t. The compound was purified by a C_{18} silica column (SepPak-10g, Waters) with a MeOH-H_2O gradient to afford compound **6** as a clear syrup (41 mg, 94%): ^{1}H NMR (500 MHz, D_2O): δ 7.95 (s, 1H, triazole-H), 4.71 (d, 1H, *J* = 1.4 Hz, H-1), 4.63 (d, 2H, OC*H*$_2$-triazole), 4.50 (t, 2H, *J* = 5.0 Hz, NC*H*$_2$$CH_2O$), 3.83 (t, 2H, *J* = 5.2 Hz, NCH_2CH_2O), 3.77 (dd, 1H, *J* = 3.4, 1.7 Hz, H-2), 3.76-3.45 (m, 23H, H-3, H-4, H-5, H-6a, H-6b, CH_2O), 3.40 (dd, 2H, *J* = 5.0, 3.5 Hz, C*H*$_2$OH). ^{13}C NMR (100 MHz, $CDCl_3$): δ 126.7 (triazole), 125.5 (triazole), 99.9 (C-1), 72.7, 71.6, 70.8, 70.4, 69.9, 69.6, 69.3, 68.8, 68.7, 66.7, 66.3, 63.0, 60.8, 60.3, 50.0. Metal Complex Mediated Conjugation of Peptides to Nucleus Targeting Acridine Orange: A Modular Concept for Dual-Modality Imaging Agents

Karel Zelenka,[†] Lubor Borsig,[‡] and Roger Alberto*[,†]

[†]Institute of Inorganic Chemistry and [‡]Institute of Physiology, University of Zürich, Winterthurerstrasse 190, 8057 Zürich, Switzerland

Supporting Information

ABSTRACT: To target the nucleus of specific cells, trifunctional radiopharmaceuticals are required. We have synthesized acridine orange derivatives which comprise an imidazole-2-carbaldehyde function for coordination to the $[Re(CO)_3]^+$ or $[^{99m}Tc(CO)_3]^+$ core. Upon coordination, this aldehyde is activated and rapidly forms imines with amines from biological molecules. This metal-mediated imine formation allows for the conjugation of a nuclear targeting portion with a specific cell receptor binding function directly on the metal. With this concept, we have conjugated the acridine orange part to a bombesin peptide directly on the ^{99m}Tc core and in one step. In addition, a linker containing an integrated disulfide has been coupled to bombesin. LC/MS study showed that the disulfide was reductively cleaved with a 60 min half-life time. This concept enables the combination of a nucleus targeting agent with a specific cell receptor molecule directly on the metal without the need of separate conjugation prior to labeling, thus, a modular approach. High uptake of the BBN conjugate into PC-3 cells was detected by fluorescence microscopy, whereas uptake into B16BL6 cells was negligible.

INTRODUCTION

Molecular imaging modalities such as single photon emission computed tomography (SPECT) and positron emission tomography (PET) are major methods for noninvasive diagnosis of organ malfunctions or diseases.[1] Over the past years, the combination of different imaging modalities has become a major focus in advanced imaging. By using different regions of the electromagnetic spectrum for imaging, complementary information about, e.g., physiology and metabolism of particular sites in cells or even in entire organisms may be received concertedly.[2,3] Combination of SPECT or PET and CT, for instance, is at the stage of clinical routine and allows for combining radionuclide distribution in tissue with anatomical information.[4,5] Although both SPECT and PET have achieved millimeter resolution, it would be desirable to combine either of these two methods with optical imaging techniques. Luminescence-based imaging allows at least on the *in vitro* level following in real time the compound in the intracellular space. Highly accurate sensing allows assessment of the particular intracellular compartment in which the compound accumulates. Numerous examples for fluorescence imaging appeared in the literature with organic or metal-based fluorescence markers.[6−11] Ideally, optical imaging would also be possible *in vivo*; however, many fluorescence markers are not suitable for deep-body penetration visualization of biological events. *In vitro* optical imaging does allow, however, localization of a compound on the subcellular level. This is particularly important if a diagnostic or therapeutic radionuclide-based agent is designed to target a particular cell compartment such as the cell nucleus. Confirmation of compound accumulation in the target is preferentially received from optical imaging since this modality allows nanometer resolution in cells. *In vitro* knowledge about site specificity of a compound can then be extended to the second modality, namely, *in vivo* radioimaging. For a successful combination of optical and radioimaging, chemical identification of the cold, luminescent, and radioactive compound is mandatory. An increasing number of publications are emphasizing the importance of single-compound-based dual-modality imaging based on a combination of subcellular luminescence and *in vivo* imaging from γ-emission.[12−14] One main strategy to target nuclei of living cells with radiolabeled compounds is based on conjugation of a suitable chelator to NLS (nucleus localizing signal) peptides.[15] Such cell and nucleus penetrating peptides can cargo various molecules such as simple metal complexes,[16] peptides, proteins, antisense PNA, or plasmid DNA[17] or are labeled with radioisotopes to quantify *in vitro* and *in vivo* biodistribution.[18−22]

In our own endeavors to target the nucleus of specific cells, we combined ^{99m}Tc as a favorable SPECT radionuclide with fluorescence markers such as acridine orange or pyrene.[21,23] The rationale behind these studies is to benefit from the Auger electrons of ^{99m}Tc to double-strand break DNA of, e.g., cancerous cells.[24−26] Along this strategy, a bioconjugate consists of a nuclear targeting agent (with luminescence properties) and a cell

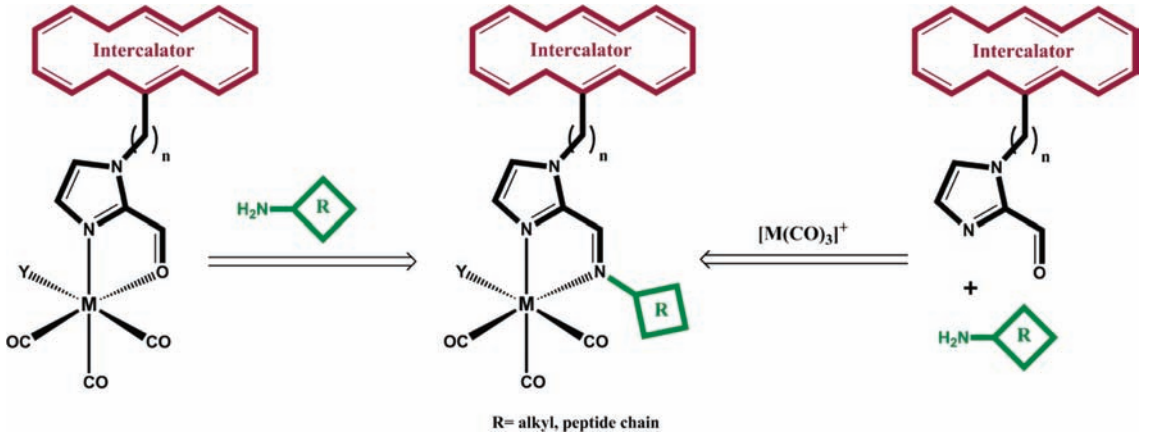
receptor specific compound such as a peptide (Scheme 1). The peptide moiety (e.g., bombesin) targets cells with a specific, strongly (over)expressed receptor (GRP receptor for bombesin). Active, receptor-mediated uptake results in site-specific accumulation of the conjugate. Degradation of the peptide in lysosomes sets the intercalator (fluorescent marker) free, which often exhibits strong interaction with and uptake into the DNA. Such fluorescent carriers enhance the accumulation of complexes in the cell nucleus. Optionally, a cleavable linker ensures the cleavage of the receptor targeting agent from the nucleus targeting complex. This bifunctional bioconjugate is then radiolabeled for *in vivo* imaging (Scheme 1).

The synthesis of such constructs is demanding, and any new combination entails a new "total synthesis" of DNA targeting agent, cell receptor specific moiety, and chelator. Lengthy procedures are not very convenient for efficient drug finding or development. Conjugating these two principles directly on the SPECT imaging modality (^{99m}Tc) introduces an *in situ* building block concept. The metal complex fragment does mediate the conjugation of the nuclear targeting and the cell targeting molecules. Accordingly, each individual vector can be replaced without the need of new additional syntheses.

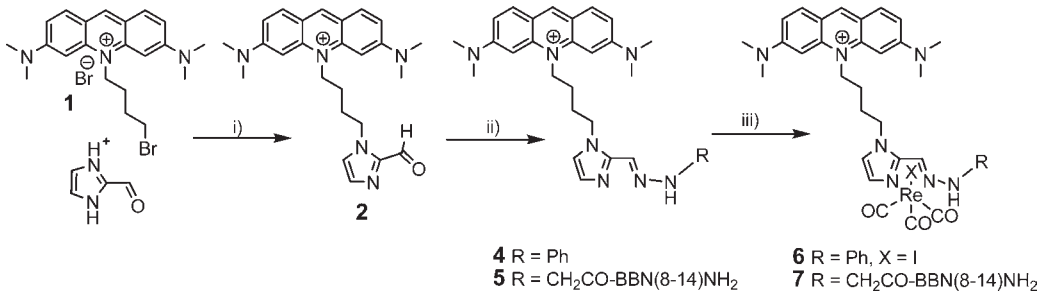
We present in this study the metal-mediated conjugation of a nuclear targeting agent (violet in Scheme 1) with cell receptor targeting peptides (green) and model molecules. In this approach, the aldehyde coordinates to the $[^{99m}Tc(CO)_3]^+$ moiety. The activated aldehyde is susceptible for imine formation with the H_2N-terminus of a peptide (Scheme 2). Fluorescence microscopy studies confirm highly selective uptake of this bioconjugate in the targeted cells.

Scheme 1. Concept of a Cell-Specific, Nuclear Targeting Trifunctional Bioconjugate



RESULTS AND DISCUSSION

Syntheses. In the building block approach, the combination of a nucleus targeting function and a cell targeting vector is bound to the $[^{99m}Tc(CO)_3]^+$ core via a bidentate imine or hydrazone chelator. The *in situ* formation of these bidentate ligands from an amine and aldehyde represents the base for the building block concept, since each part can be altered while maintaining an identical synthetic procedure. The resulting complex is cationic and of the general form $[Re(OH_2)(L^2)(CO)_3]^+$. An anion replaces the coordinated water ligand, yielding an overall neutral complex. Due to its strongly fluorescent properties, we have selected acridine orange (AO) as the intercalating nucleus targeting agent and imidazole-2-carboxyaldehyde (ima) as bidentate ligand. We and others have shown previously that heteroaromatic aldehydes are strong ligand groups for coordination to the $[^{99m}Tc(CO)_3]^+$ moiety.[27−31] Compound **1** was prepared according to a published procedure[32] followed by alkylation of the imidazole-2-carboxyaldehyde to yield **2** in reasonable yield. Coupling of a hydrazine model compound gave the corresponding hydrazone **4**, which now contains a strong bidentate chelator. Reaction with $[Re(OH_2)_3(CO)_3]^+$ in methanol/water gave the model complex **6**. Complex **7** which contains both the nucleus targeting agent and a receptor-specific bombesin peptide (BBN) was prepared similarly. The reaction of **2** with the bombesin peptide **3** afforded the hydrazone **5**. Subsequent addition of $[Re(OH_2)_3(CO)_3]^+$ gave the complex **7**. Complex **7** is now a model for trifunctional radiopharmaceuticals and comprises the nucleus targeting agent, the cell targeting vector, and the metal center (Scheme 3). Since the hydrazones **4** and **5** are water stable, they can directly be subjected to labeling studies.



A further building block for a final conjugate is the cleavable linker. Disulfide bonds are known to be cleaved by thiols via thiol/disulfide exchange.[33] They are frequently used in prodrug designs for pharmaceuticals. In the intracellular space, they are cleaved by reduction with GSH which sets the active drug free.[34−36] For our purposes, the disulfide containing cleavable linker **10** was prepared

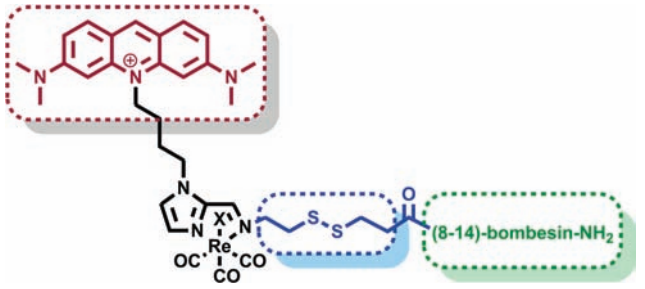
in a three-step synthesis. The amino groups of cysteamine were BOC-protected to give **8**. Thiolysis of the disulfide with mercaptopropionic acid afforded the acid **9**. The activated TFP ester **10** for coupling to terminal amines was prepared along standard procedures. The TFP ester **10** was then used for the preparation of compounds **12** and **13**. The free amines **14** and **15** were obtained after BOC deprotection (Scheme 4).

Hydrazones such as **4** or **5** are relatively stable toward hydrolysis, but imines are not. The model complex **17** was first prepared by the reaction of imine **16** with $[Re(OH_2)_3(CO)_3]^+$. Isolation of the free imines from the reaction of the aldehyde **2** with **14** or **15** was not possible due to their fast hydrolysis. To receive the true trifunctional compounds **19** and **20**, the aldehyde **2** was reacted in water with an excess of $[Re(OH_2)_3(CO)_3]^+$. The orange compound **18** precipitated from solution. In **18**, the aldehyde is coordinated to the rhenium center. ^1H NMR confirmed the presence of the coordinating aldehyde rather than a coordinated semiacetal.[27]



dx.doi.org/10.1021/bc2000269 |*Bioconjugate Chem.* 2011, 22, 958–967

Compound **18** is the key model compound for labeling reactions and therefore for the metal-mediated assembly of two different types of targeting agents. Compound **18** reacted with **14** or **15** under imine formation to give the trifunctional compounds **19** and **20**, respectively (Scheme 5). Important for the later labeling with ^{99m}Tc, the complexes **19** or **20** were also obtained from a "one-pot" reaction. Compound **2**, **14**, or **15** together with $[Re(OH_2)_3(CO)_3]^+$ was dissolved in a MeOH/PBS mixture (1:1). After 12 h at 50 °C, compound **19** or **20** could be purified by preparative HPLC chromatography. The yields after purification for both procedures were comparable.

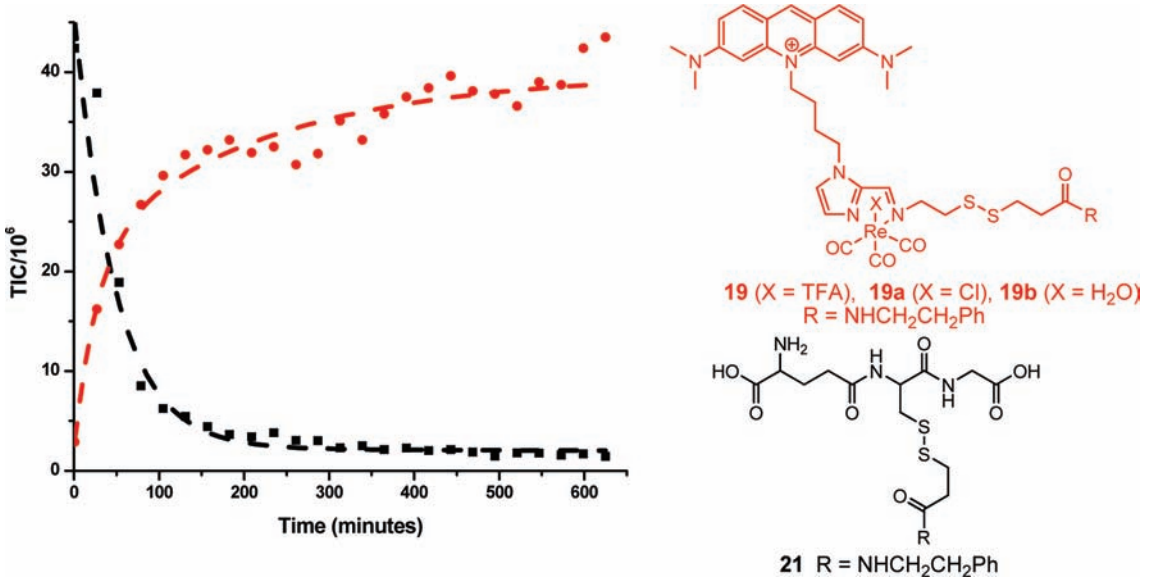
Complex **20** now comprises the nucleus targeting agent, the cell targeting vector with a disulfide cleavable linker, and the metal center (Scheme 6).

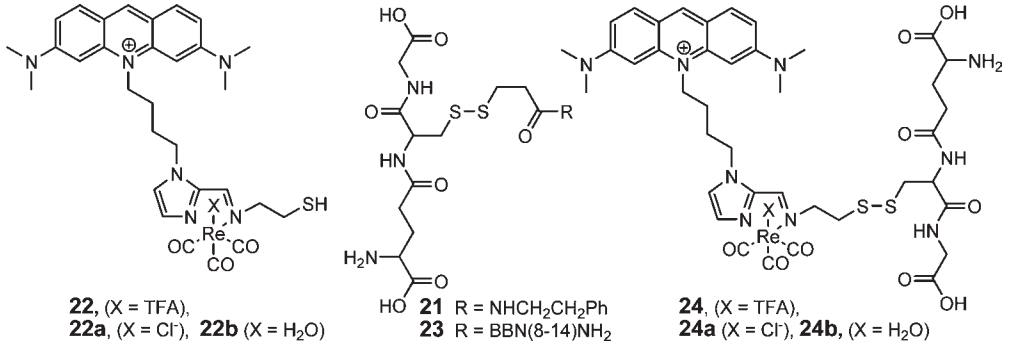
Ideally, complete complex **20** is taken up by the cell through receptor-mediated endocytosis, thus ensuring cell specificity. Inside the cell, the disulfide linker is cleaved with the reduced form of GSH, cleaving the peptide vector from the metal-nucleus targeting moiety complex. Since the remaining complex is relatively small, it can permeate the nuclear membrane without necessity of active transport. Intercalation with DNA proved to be a key process for accumulation of such conjugates in the cell nucleus.[24] The cleavage of the disulfide bond also prevents the exclusion of the complex from the cell through a receptor. The trifunctional complexes **19** and **20** are rhenium-based and can be used for fluorescence imaging (see later). Fluorescence microscopy allows for following the biological pathways of these compounds on the subcellular level, whereas the ^{99m}Tc homologues can be used for *in vivo* imaging. The unprecedented advantage of this building block principle is the fact that not only **14** and **15** but principally any amines can be selected to complete the trifunctional conjugates. Coordination of the aldehyde in **2** to the $[Re(CO)_3]^+$ center activates the carbonyl carbon. Although nucleophilic attack of water competes for imine formation, once formed, the imine complex (e.g., **17**) is so strong that the reaction is irreversible and runs to completion. This is crucial for the ^{99m}Tc experiments, since quantitative formation of the radiopharmaceutical is mandatory.

Scheme 6. Complex 20 Comprising Nucleus Targeting Agent (Red), Cell Targeting Vector (Green) with a Disulfide Cleavable Linker (Blue), and Hexacoordinated Metal Center

Cleavage Studies. Compounds **19** and **20** comprise the disulfide-cleavable linker which is expected to be reduced in the intracellular space and to release the nucleus targeting function. *In vitro* studies should elucidate rate and mechanism of glutathione GSH-mediated cleavage of the disulfide bond. Compound **19** (in PBS) was added to a freshly prepared GSH solution (in PBS). The final concentrations of the GSH and complexes were 0.5 mM and 0.01 mM, respectively. This GSH concentration is normally found in cells.[37] The solution was incubated at 37 °C and samples were taken every 26 min and analyzed with HPLC-MS (see Supporting Information). Figure 1 shows the progress of the cleavage reaction. The integrated chromatograms of total ion counts (TIC) of one of the cleavage products (**21** m/z: 515.3$[M]^+$) is plotted versus the starting materials (sum of the intensities of **19** m/z 1066.4 $[M]^+$, **19a** m/z 988.4 $[M\text{-}TFA+Cl]^+$, and **19b** m/z 476.7 $[M\text{-}TFA]^{2+}$ are plotted). Compounds **19a** and **19b** are formed in solution via slow anion exchange and change over time.

The TIC of complex **22a** (m/z: 781.3 $[M]^+$, major product) exhibits the same growing trend as **21**. The different physicochemical properties of **22a** influenced the MS measurement (ion trapping, ejection, and detection). The maximum of the **22a** signal was about three times below the trace of **21**. The disulfide bridge in **19** can be cleaved by GSH on the peptide side, resulting in **21**, or on the complex side resulting in **24**. HPLC-MS evidenced that the formation of undesired **24** (or **24a** and **24b**





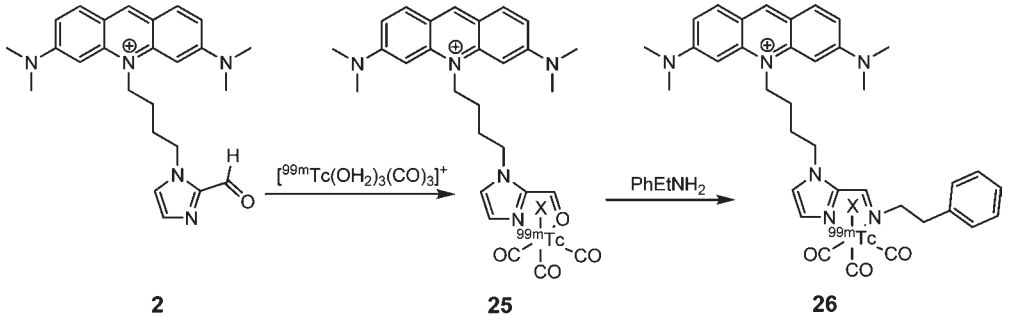


Figure 1. Plot of the time dependence of TIC intensities of **21** (red line) and **19** (sum of **19**, **19a**, and **19b**; black line).

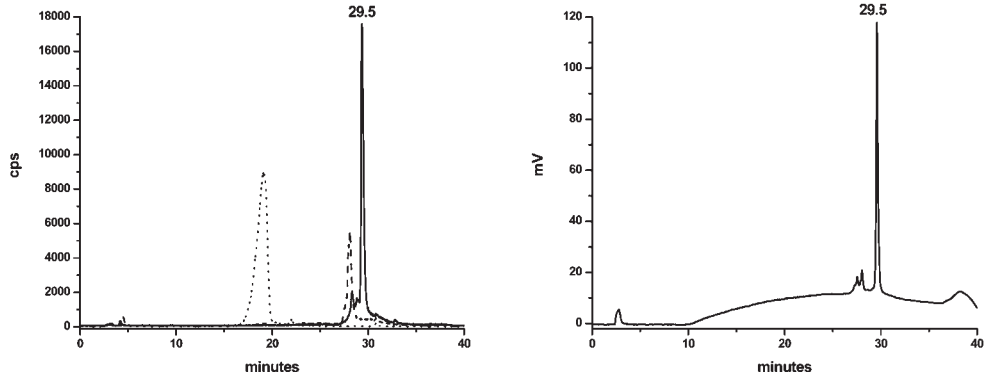

Figure 2. Left: radioactive HPLC traces of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (dotted line), **25** (dashed line), and **26** (solid line). Right: UV−vis trace of corresponding Re complex **17a** (X = Cl^-; see ESI); Gradient D.

after exchange of X) was negligible as compared to **22a** or **21**. The half-life of disulfide cleavage with the GSH was about 60 min. Due to "steady state" intracellular GSH concentration,[37,38] cleavage inside the cells could be even faster. A similar study was done with complex **20**. The formation of the cleavage products **22a** and **23** displayed similar trends as for **19** (Figure 1.). An overview for the cleavage products is given in the Scheme 7.

^{99m}Tc-Labeling Studies. The precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$ was prepared from $[^{99m}TcO_4]^-$ according to literature procedures or with the commercially available Isolink kit (Covidien, Tyco-Mallinckrodt Med. B.V. Petten, NL).[39,40] It should be emphasized that ^{99m}Tc concentrations are in the range of 10^{-6} to 10^{-9} M. After preparation, the solution was buffered with 0.1 M phosphate buffer to pH 7.4. Conversions to products were quantified by HPLC analyses with γ-detection. Reaction times, concentrations, and temperature varied.

Depending on the ligand, the synthesis of complexes of the general type $[^{99m}Tc(X)(L^2)(CO)_3]^+$ can be done in one or two steps. Solvent or an anion X is coordinated to the sixth available coordination site on the *fac*-$[^{99m}Tc(CO)_3]^+$. Labeling was first tested with a model amine and amino acids under various conditions to confirm the feasibility of the process with ^{99m}Tc. The preparation of complex **26** was done in two steps. The reaction of aldehyde **2** (0.1 mM, 30 min, 90 °C) with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (Figure 2, R_t = 19.2 min dotted line) gave the intermediate **25** (dashed line, R_t = 28 min). After addition of the phenylethylamine (0.2 mM), the mixture was heated to 90 °C for 45 min to yield the complex **26** (R_t = 29.5 min, solid line). The same result was also obtained from the "one-pot" preparation, mixing all components together and heating at 90 °C for 45 min. The formation of complex **26** was confirmed by comparing the retention time of with the Re analogue **17a** (Figure 2, also see ESI).

dx.doi.org/10.1021/bc2000269 |*Bioconjugate Chem.* 2011, 22, 958–967

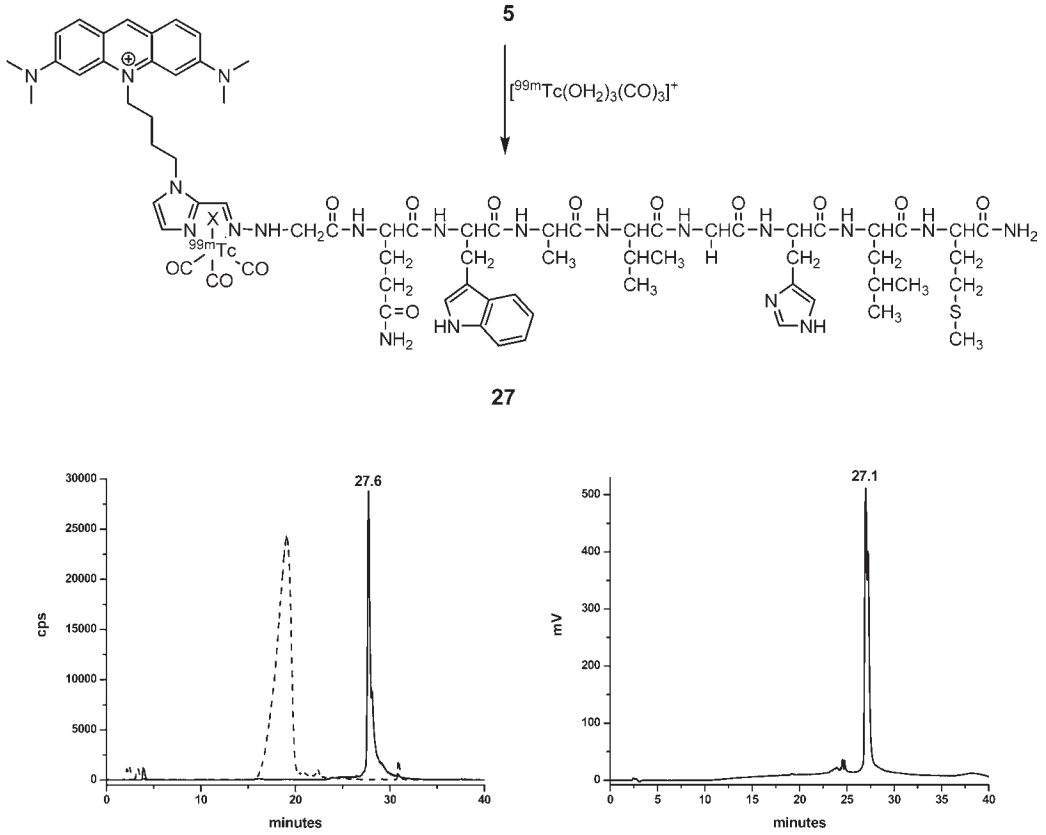

Figure 3. Left: radioactive HPLC traces of $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (dashed line) and **27** (solid line). Right: UV trace of corresponding Re complex **7** (Gradient D).

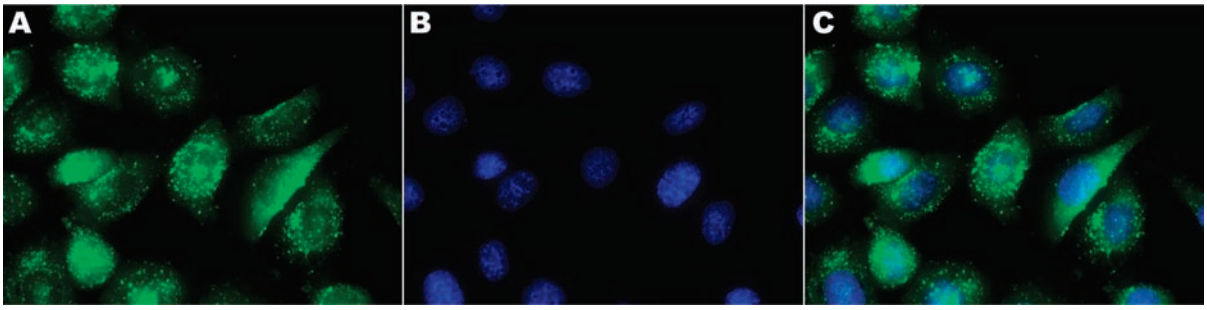

Figure 4. Uptake of the complex **20** into PC-3 cells by fluorescence microscopy. Cells were incubated with 20 μM complex **20** for 6 h, washed, then an additional 18 h in the fresh medium, followed by fixation of cells and nuclear staining by DAPI. (A) PC-3 cells, loaded with **20** in the cytoplasm (green), clear structured staining. (B) DAPI staining of nucleus (blue). (C) Merged image (overlay).

The same approach was used to prepare the ^{99m}Tc analogue of **20**. However, even by variation of gradients and solvents, the aldehyde complex **25** and resulting imine complex (**25** + **15**) were hardly distinguishable and displayed comparable retention times. For detailed labeling study and comparison with corresponding Re complex **20**, see ESI. The labeling of **5** (0.22 mM) with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ at 90 °C after 60 min provided product **27** with a retention time of 27.6 min (Figure 3, solid line).

Cell Uptake Studies. We selected a human prostate adenocarcinoma cell line, PC-3, which does express the GRP receptor and B16-BL6 mouse melanoma cell line with little or no expression of the GRP receptor. The cell uptake of complex **20** was monitored in the green fluorescence filter as described in the Experimental Section. To localize the compound in the cell, we stained nuclei with DAPI (4′,6-diamidino-2-phenylindol), routinely used in cell biology. The PC-3 cells were exposed to **20** (20 μM) and the uptake was followed by fluorescence microscopy (Figure 4). Complex **20** clearly accumulated in the cell. Green fluorescence was mainly detected in the cytoplasm, exhibiting substructured distribution, probably in lysosomes. There is no enhanced accumulation of fluorescence in the nucleus. Complex **7** was studied in a similar manner to **20**. The accumulation in the cell was also observed with comparable intensities to those for **20**.

The trifunctional complex **20** contains the cell-specific vector (truncated 8−14 BBN peptide). Thus, only cells with the corresponding receptor should accumulate **20**. To confirm such a specific uptake, cell studies were performed on a B16-BL6

dx.doi.org/10.1021/bc2000269 |*Bioconjugate Chem.* 2011, 22, 958–967

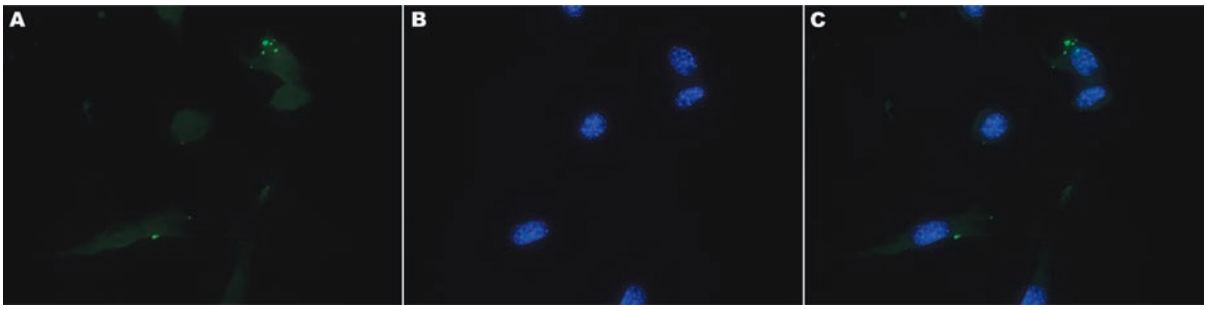

Figure 5. Uptake of complex **20** by B16BL6 cells, performed as described for PC-3. (A) Green channel image. (B) DAPI nucleus staining (blue). (C) Merged image (overlay).

mouse melanoma cell line which does not express the GRP receptor. The difference between the PC-3 (Figure 4) and B16-BL6 (Figure 5) is significant. While PC-3 cells were loaded with **20** in the cytoplasm, there was virtually no accumulation in the B16BL6 cell line. The uptake of complex **20** by PC-3 cells was consistent with the presence of the GRP receptor, indicating a receptor-mediated uptake.[32]

■ CONCLUSIONS

The efficient development of imaging probes containing a therapeutic modality demands a flexible building block concept. Herein, we presented an approach in which the conjugation of a nucleus targeting part with a cell-specific vector is metal-mediated, yielding a trifunctional diagnostic and potentially therapeutic radiopharmaceutical. A disulfide-based cleavable linker was introduced on the cell receptor targeting part. *In vitro*, the disulfide linker was cleaved with GSH at a reasonable rate. Fluorescence microscopy with rhenium analogues using GRP/non-GRP expressing cell lines confirmed the cell specificity concept. However, studies with complex **20** did not display increased uptake in the nucleus but stained mainly substructures of the cytoplasm for so far unknown reasons. Detailed cell studies with the trifunctional complex **20** and similar systems, prepared according to the presented building block concept, are currently under investigation. The approach represents a very general method for the *in situ* preparation of strong bidentate ligands and its use for further development of functional multimodality systems.

■ EXPERIMENTAL SECTION

General Information. The commercially available reagents were used as received without further purification. Analytical thin-layer chromatography (TLC) was carried out with aluminum-based plates (silica gel 60 F_{254}) from Merck. Plates were visualized under UV light (λ = 254 nm). Flash chromatography was carried out on Flashmaster Solo (Argonaut) by using Merck silica gel 60 (0.040−0.063 mm). Samples were applied as almost saturated solutions in the appropriate solvent. ^{1}H NMR and ^{13}C NMR spectra were performed on a Bruker 400 and 500 spectrometers at 400/500 and 100/125 MHz, respectively. The reported chemical shifts (in δ) are relative to the solvent protons and carbons as a reference. HPLC-MS (ESI) spectra were measured on a Bruker HCT spectrometer with Aquinity UPLC (Waters) with alternating polarity ion detection, using a Macherey-Nagel EC 250/3 Nucleodur C18 Gravity 5 μm. HPLC solvents were 0.1% formic acid (solvent A) and methanol (solvent B). The gradients used for analyses were as follows: Gradient A: 0−5 min 90% A, 5−17 min 90−0% A, 17−25 min 0% A, 25−27 min 0−90% A, 27−35 min 90% A, flow 0.3 mL.min^{-1}; Gradient B: 0−2 min 90% A, 2−12 min 90−0% A, 12−17 min 0% A, 17−18 min 0−90% A, 18−25 min 90% A, flow 0.25 mL.min^{-1}. HPLC analyses were performed on a Merck L7000 system using a Macherey-Nagel EC 250/3 Nucleodur C18 Gravity 5 μm for radioactive compounds. HPLC solvents were 0.1% trifluoroacetic acid (solvent A) and MeOH or MeCN HPLC grade (solvent B). Gradient C (MeOH): 0−5 min 90% A, 5−15 min 90−0% A, 15−20 min 0% A, 20−22 min 0−90% A, 22−30 min 90% A. Gradient D (MeCN): 0−5 min 90% A, 5−20 min 90−60% A, 20−23 min 60% A, 23−28 min 0% A, 28−33 min 0% A, 33−34 min 0−90% A, 34−40 min 90% A. Flow rates: 0.5 mL/min, detection with a γ-detector for the radiolabeled compounds. Preparative HPLC was performed on a Varian Pro Star system by using either a Macherey-Nagel VP 250/21 Nucleodur C18 Gravity 5 μm or a Macherey-Nagel VP 250/40 Nucleosil 100−7 C18 column with a flow rate of 12 mL.min^{-1} and 40 mL.min^{-1} respectively. The solvents were 0.1% trifluoroacetic acid (solvent A) and methanol or acetonitrile (solvent B).

Cell Culture and Complex Uptake. Human prostate cancer cells, PC-3 were incubated in F12K medium supplemented with 10% fetal calf serum. For microscopy, cells were cultured overnight on four-chamber slides (Nunc) in which ca. 50 000 cells were plated. Next day, cells were washed and fresh media containing complexes **20** or **7** (20 μm) were added. Cells were incubated with the complex for 6 h. After the loading with a complex, the fresh medium was added and the cells were incubated for additional 18 h, washed with phosphate buffer saline (PBS), and fixed in 4% paraformaldehyde for 10 min in at r.t. After three washings with PBS, cells were incubated in 1 mg.mL^{-1} 4′,6-diamidino-2-phenylindole (DAPI) for nuclear staining for 10 min at r.t. Cells were washed three times with phosphate-buffered saline (PBS), chambers from the slides were detached, and cells were covered with coverslips in Prolong Mounting medium (Invitrogen). Slides were evaluated on Zeiss Axiovert 200 m with the corresponding fluorescence filters for DAPI (λ_{ex} = 360 nm, λ_{em} = 420 nm) and acridine orange (λ_{ex} = 496 nm, λ_{em} = 525 nm).

General Remarks to the Re Complexes. Under common HPLC or HPLC-MS conditions, typically two peaks with a ratio of 1:10 (respectively 1:1 with TFA anion) were observed. The first peak represents the complex, where the anion is replaced with a solvent, while the second peak belongs to the original (whole) complex. During the MS acquisition, the coordinated solvent is usually lost. For complexes containing peptides, the sixth coordination position is probably occupied by imidazole from histidine. Both double- and single-charged species were

observed under HPLC-MS conditions. The elementary analyses were not performed due to the various content of TFA after purification with the preparative HPLC. Thus, to be consistent, the M.W. and concentrations of the compounds were calculated without counterions (e.g., as drawn in the schemes). If not specified in the scheme, the counterions are trifluoroacetates.

3,6-Bis(dimethylamino)-10-(4-(2-formyl-1*H*-imidazol-1-yl)-butyl)acridinium (2). A suspension of 1*H*-imidazole-2-carbaldehyde (11 mg, 0.11 mmol) and K_2CO_3 (100 mg, 0.72 mmol) in DMF (10 mL, dry) was stirred at r.t. under N_2. After 10 min, **1** (70 mg, 0.14 mmol) was added, and the mixture stirred and heated to 50 °C under N_2. After 16 h, the solvent was removed under HV. The residue was dissolved in 15 mL of CH_2Cl_2, filtered over Celite, and dried again. Purification by preparative HPLC afforded 36 mg **2** (75%) as an orange powder. ^{1}H NMR (CD_3CN, 400 MHz) δ 9.65 (d, ^4J = 0.8 Hz, 1H), 8.49 (s, 1H), 7.79 (d, ^3J = 9.3 Hz, 2H), 7.31 (bs, 1H), 7.18 (d, ^4J = 0.7 Hz, 1H), 7.14 (dd, ^3J = 9.3 Hz, ^4J = 2.2 Hz, 2H), 6.45 (d, ^4J = 1.8 Hz, 2H), 4.53 (bt, ^3J = 8 Hz, 2H), 4.43 (t, ^3J = 6.9 Hz, 2H), 3.20 (s, 12H), 2.07−1.97 (m, 2H), 1.93−1.83 (m, 2H). MS (ESI, Gradient B): t_R 9.3 min; positive mode *m/z* 448.2 (100) $[M + MeOH]^+$, 416.2 (33) $[M]^+$. MS (ESI) *m/z* (%) 416.2 (100) $[M]^+$, 448.2(17) $[M + MeOH]^+$; calcd for $C_{25}H_{30}N_5O^+$: 416.24 (100.0).

$NH_2NH_2CH_2CO$-Bombesin WAVGHLM (3). Truncated hydrazinoacetyl-bombesin **3** (sequence: WAVGHLM) was synthesized SPPS according to the procedure reported previously for hydrazino derivatives of peptides.[41] The product was then purified by reverse-phase HPLC on a preparative C18 column (Macherey-Nagel VP 250/40 Nucleosil 100−7 C18 column), fractions with the peptide were lyophilized, and pure peptide was kept under N_2 in the freezer at −25 °C. **3** was obtained as a white solid. HPLC-MS (ESI, Gradient A): t_R 13.4 min; positive mode *m/z* 884.5 (100) $[M+H]^+$; calcd for $C_{40}H_{61}N_{13}O_8S$: 883.45 (100.0); negative mode *m/z* 882.6 (60) $[M-H]^-$, 996.6 (100) $[M+TFA]^-$.

3,6-Bis(dimethylamino)-10-(4-(2-((2-phenylhydrazono)-methyl)-1*H*-imidazol-1-yl)butyl)acridinium (4). The aldehyde **2** (26 mg, 0.062 mmol) was dissolved in the EtOH (1 mL, dry), and phenyl hydrazine (7 mg, 6.3 μL, 0.062 mmol) was added to the mixture. Reaction was stirred and heated to 80 °C for 4 h; the solvent was then removed in vacuo. The crude product **4** (31 mg, 98%) was pure enough for use in the next step without further purification. ^{1}H NMR (CD_3CN, 400 MHz): δ 10.00 (bs, 1H), 8.42 (s, 1H), 7.94 (s, 1H), 7.70 (d, ^3J = 9.3 Hz, 2H), 7.12−6.93 (m, 8H), 6.75 (t, ^3J = 7.3 Hz, 1H), 6.40 (d, ^4J = 1.7 Hz, 2H), 4.55 (t, ^3J = 7.4 Hz, 2H), 4.35 (t, ^3J = 6.6 Hz, 2H), 3.08 (s, 12H), 2.10−2.01 (m, 2H), 2.01−1.92 (m, 2H). HPLC-MS (ESI, Gradient B): t_R 10.8 min; positive mode *m/z* 506.4 (100) $[M]^+$, $[M+H]^+$ 253.1 (40) $[M+H]^{2+}$; calcd for $C_{31}H_{36}N_7^+$: 506.3 (100).

3,6-Bis(dimethylamino)-10-(4-(2-((2-(2-(Bombesin 8−14)-2-oxoethyl)hydrazono)methyl)-1*H*-imidazol-1-yl)butyl)-acridinium (5). The aldehyde **2** (8 mg, 0.019 mmol) and hydrazino bombesin **3** (25 mg, 0.028 mmol) were dissolved in the PBS (15 mL, pH = 6.5). The mixture was stirred at r.t under N_2 for 3 days. The orange precipitate was filtered and washed with water and PBS. The crude product was purified by preparative HPLC to give **5** as orange powder in a yield of (12 mg, 48%). HPLC-MS (ESI, Gradient B): t_R 10.0 min; positive mode *m/z* 641.6 (100) $[M+H]^{2+}$, 1281.7 (75) $[M]^+$; calcd for $C_{65}H_{89}N_{18}O_8S^+$: 1281.7 (100.0).

$[Re(I)(4)(CO)_3]^+$ (6). The hydrazone **4** (8 mg, 0.016 mmol) and KI (50 mg, 0.3 mmol) were dissolved in the methanol/water mixture (6 mL, 2:1), then $[NEt_4]_2[ReBr_3(CO)_3]$ (15 mg, 0.019 mmol) was added. The mixture was stirred 3 h at 60 °C. The solvents were removed in vacuo, and the crude product was purified by preparative HPLC to give **6** as dark orange powder in a yield of (7 mg, 49%). ^{1}H NMR (DMSO-d_6, 400 MHz): δ 10.40 (s, 1H), 8.77 (s, 1H), 8.57 (s, 1H), 7.90 (d, ^3J = 9.4 Hz, 2H), 7.59 (d, J = 1.4 Hz, 1H), 7.45 (d, J = 1.4 Hz, 1H), 7.24 (dd, ^3J = 9.4 Hz, ^4J = 2.0 Hz, 2H), 7.18−7.12 (m, 2H), 7.05−7.00 (m, 3H),6.54 (bs, 2H), 4.78−4.63 (m, 2H), 4.32 (t, ^3J = 6.6 Hz, 2H), 3.20 (s, 12H), 2.03−1.93 (m, 2H), 1.77−1.67 (m, 2H). HPLC-MS (ESI, Gradient B): t_R 12.8 min; positive mode *m/z* 904.3 (100), 902.3 (58) $[M]^+$; calcd fro $C_{34}H_{36}IN_7O_3Re^+$: 904.15 (100.0), 902.15 (57.0).

$[Re(5)(CO)_3]^+$ (7). To a solution of **5** (10 mg, 0.007 mmol) dissolved in the acetonitrile/PBS mixture (4 mL, 1:1, pH = 7.4), $[NEt_4]_2[ReBr_3(CO)_3]$ (20 mg, 0.026 mmol) was added. The mixture was stirred under N_2 at 40 °C. After 2 d, the solvents were removed and the crude product purified by preparative HPLC to give **7** as orange powder in a yield of (4 mg, 33%). HPLC-MS (ESI, Gradient B): t_R 11.2 min; positive mode *m/z* 776.4 (100) $[M]^{2+}$, 1551.5 (10) $[M-H]^+$; calcd for $C_{68}H_{89}N_{18}O_{11}ReS^{2+}$: 1552.62 (100.0).

***N,N′*-Bis-*tert*-butoxycarbonylcystamine (8).** Compound **8** was prepared according to the published procedure and the analysis was similar to the literature.[42]

3-((2-(*tert*-Butoxycarbonylamino)ethyl)disulfanyl)propanoic acid (9). Compound **9** was prepared according to the published procedure[43] using the 3-mercaptopropanoic acid instead of 2-mercaptoacetic acid. 300 mg (yield 30%) of the acid **9** were obtained. TLC R_f = 0.26 ($CHCl_3$/MeOH, 9/1). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 4.93 (bs, 1H), 3.46 (bs, 2H), 2.95 (bt, ^3J = 6.9 Hz, 2H), 2.84−2.77 (m, 4H), 1.46 (s, 9H). MS (ESI) *m/z* (%) 304.1 (100) $[M + Na]^+$; 316.1(100) $[M + Cl]^-$, 280.4 (90) $[M - H]^-$; calcd for $C_{10}H_{19}NO_4S_2$: 281.08 (100.0).

2,3,5,6-Tetrafluorophenyl 3-((2-(*tert*-butoxycarbonylamino)ethyl)disulfanyl)propanoate (10). A solution of **9** (170 mg, 0.6 mmol) in DMF (1 mL, dry) was cooled to 4 °C and diisopropylcarbondiimid (93 μL, 76 mg, 0.6 mmol) was added. The mixture was stirred 15 min under N_2, and then 2,3,5,6-tetrafluorophenol (100 mg, 0.6 mmol) in DMF(0.5 mL, dry) was slowly added and reaction was stirred at r.t. After 12 h, CH_2Cl_2 (3 mL) was added, precipitate was filtered, and filtrate was evaporated to dryness. Purification by flash chromatography (gradient, hexane to hexane:MTBE 6:1) afforded compound **10** (100 mg, 38%) as a white solid. ^{1}H NMR ($CDCl_3$, 500 MHz) δ 7.05−7.00 (m, 1H), 4.90 (bs, 1H), 3.46 (bd, ^3J = 6.0 Hz, 2H), 3.13 (t, ^3J = 6.9 Hz, 2H), 3.05 (t, ^3J = 6.9 Hz, 2H), 2.83 (t, ^3J = 6.7 Hz, 2H), 1.45 (s, 9H). MS (ESI) positive mode *m/z* (%) 452.0 (100) $[M + Na]^+$, 467.9 (80) $[M + K]^+$; negative mode 464.0 (100) $[M + Cl]^-$; calcd 429.07 (100.0). Elemental analysis (%) calcd for $C_{16}H_{19}F_4NO_4S_2$: C 44.75, H 4.46, N 3.26, S 14.93; found C 44.52, H 4.47, N 3.00.

Bombesin WAVGHLM (11). Truncated bombesin **11** (sequence: WAVGHLM) was synthesized SPPS and purified according to the procedure reported previously[24]).

***tert*-Butyl 2-((3-oxo-3-(phenethylamino)propyl)disulfanyl)-ethylcarbamate.TFA (14).** A solution containing **10** (10 mg, 0.023 mmol) and Et_3N (6.4 μL, 4.7 mg, 0.046 mmol) in 0.3 mL of DMF was stirred for 30 min at room temperature. After addition of 2-phenylethanamine (3.2 μL, 3.1 mg, 0.025 mmol), the solution

was further stirred for 12 h. The removal of the solvent in vacuo afforded crude product **12**. The residue was dissolved in 1.5 mL of the mixture of dichloromethane−TFA (1:0.5). The mixture was stirred for 3 h under N_2 at r.t. After removal of the solvent in vacuo, the crude product was purified by preparative HPLC to afford 3 mg (31%) of compound **14** as a white solid. ^{1}H NMR ($CDCl_3$, 400 MHz): δ 8.31 (bs, 2H), 7.29−7.12 (m, 5H), 6.20 (t, ^3J = 5.6 Hz, 1H), 3.46 (q, ^3J = 6.5 Hz, 2H), 3.28 (bt, ^3J = 5.5 Hz, 2H), 2.94 (bt, ^3J = 6.0 Hz, 2H), 2.90 (t,^3J = 6.6 Hz, 2H), 2.77 (t, ^3J = 7.0 Hz, 2H), 2.49 (t, ^3J = 6.7 Hz, 2H). HPLC-MS (ESI, Gradient B): t_R 10.2 min; positive mode m/z: 285.3 (100) $[M+H]^+$; calcd for $C_{13}H_{20}N_2OS_2$: 284.11 (100.0).

Bombesin (15). Truncated bombesin **11** (40 mg, 0.049 mmol, prepared according to the literature) was dissolved in the DMF (dry, 0.5 mL) with Et_3N (20 μL, 15 mg, 0.148 mmol). The mixture was stirred at r.t under N_2. After 15 min, the solution of **10** (24 mg, 0.056 mmol) in DMF (0.5 mL) was added and mixture was stirred at r.t under N_2 for 20 h. The solvent was removed in vacuo to afford crude product **13**. The residue was dissolved in 1 mL of the mixture of dichloromethane−TFA (1:1). The mixture was stirred for 12 h under N_2 at r.t. After removal of the solvent in vacuo, the crude product was purified by preparative HPLC to afford 30 mg (62%) of compound **15** as a white solid. HPLC-MS (ESI, Gradient A): t_R 13.8 min; positive mode m/z 975.4 (100) $[M+H]^+$, 488.2 (66) $[M+2H]^{2+}$; negative mode m/z 1087.5 (100) $[M+TFA]^-$, 973.4 (15) $[M-H]^-$; calcd for $C_{43}H_{66}N_{12}O_8S_3$: 974.43 (100.0).

3,6-Bis(dimethylamino)-10-(4-(2-((phenethylimino)methyl)-1*H*-imidazol-1-yl)butyl)acridinium (16). 2-Phenylethanamine (6.12 μL, 5.9 mg, 0.048 mmol) was added to the suspension of **2** (8 mg, 0.019 mmol) with dry $MgSO_4$ (50 mg) in $CHCl_3$ (1 mL, dry). Reaction mixture was stirred at 60 °C for 12 h, filtered over Celite, and evaporated to dryness to give imine **16** (9.8 mg, 99%). ^{1}H NMR ($CDCl_3$, 400 MHz): δ 8.41 (s, 1H), 8.18 (s, 1H), 7.76 (d, ^3J = 9.3 Hz, 2H), 7.15−7.08 (m, 3H), 7.08−7.00 (m, 6H), 6.49 (bs, 2H), 4.62 (bt, ^3J = 7.8 Hz, 2H), 4.55 (t,^3J = 6.8 Hz, 2H), 3.74 (t,^3J = 7.2 Hz, 2H), 3.22 (s, 12H), 2.76 (t,^3J = 7.2 Hz, 2H), 2.11−2.01 (m, 2H), 1.95−1.84 (m, 2H). MS (ESI) m/z (%) 519.5 (100) $[M]^+$; calcd for $C_{33}H_{39}N_6^+$: 519.32 (100.0).

[Re(I)(16)(CO)$_3$]$^+$ (17). Imine **16** (10 mg, 0.019 mmol), KI (50 mg, 0.3 mmol), and $[NEt_4]_2[ReBr_3(CO)_3]$ (20 mg, 0.026 mmol) were consecutively dissolved in 4 mL of the mixture of MeOH and PBS (1:1, pH = 6.4). Reaction was stirred for 4 h at 40 °C under N_2. HPLC-MS analysis showed complete product formation. The solvent was removed in vacuo and the product was dried at high vacuum. The crude product was purified by preparative HPLC to afford 8 mg (45%) of compound **17** as a bright orange powder. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 8.94 (s, 1H), 8.78 (s, 1H), 7.90 (d, ^3J = 9.4 Hz, 2H), 7.70 (d, J = 1.3 Hz, 1H), 7.59 (d, J = 1.2 Hz, 1H), 7.24 (dd, ^3J = 9.4 Hz, ^4J = 2.0 Hz, 2H), 7.21−7.14 (m, 4H), 7.10−7.04 (m, 1H), 6.54 (bs, 2H), 4.78−4.73 (m, 2H), 4.36 (t, ^3J = 6.8 Hz, 2H), 4.19−4.09 (m, 2H), 3.20 (s, 12H), 3.17−3.07 (m, 1H), 3.06−2.96 (m, 1H), 2.04−1.94 (m, 2H), 1.75−1.64 (m, 2H). MS (ESI, Gradient B): t_R 13.5 min; positive mode m/z 917.2 (100) $[M]^+$, 915.2 (56) $[M]^+$; calcd for $C_{36}H_{39}IN_6O_3Re^+$: 917.17 (100.0), 915.17 (56.7).

[Re(TFA)(14)(CO)$_3$]$^+$ (19). The aldehyde **2** (2 mg, 0.005 mmol) and the $[NEt_4]_2[ReBr_3(CO)_3]$ (10 mg, 0.013 mmol) were dissolved in PBS (2 mL, pH = 6.5). The mixture was stirred and heated under N_2 at 50 °C for 30 min. The formed precipitate was spun down, and supernatant removed. The remaining precipitate was dissolved in the mixture of MeCN:PBS (14 mL, 9:5). The orange solution was added to the flask containing the amine **14** (3 mg, 0.007 mmol) and the mixture was stirred at r.t for 16 h; HPLC-MS showed the product formation. The product was purified by preparative HPLC to afford 1 mg (18%) of compound **18** as an orange powder. ^{1}H NMR (DMSO-d_6, 400 MHz): δ 9.09 (s, 1H), 8.77 (s, 1H), 7.94 (t, ^3J = 5.5 Hz, 1H), 7.90 (d, ^3J = 9.4 Hz, 2H), 7.78 (d, J = 1.3 Hz, 1H), 7.58 (d, J = 1.2 Hz, 1H), 7.27−7.07 (m, 7H), 6.54 (bs, 2H), 4.75−4.65 (m, 2H), 4.50−4.36 (m, 2H), 4.24−4.14 (m, 1H), 4.14−4.04 (m, 1H), 3.21−2.14 (m, 2H), 3.18 (s, 12H), 3.08−2.91 (m, 2H), 2.70 (t, ^3J = 7.0 Hz, 2H), 2.63−2.58 (m, 2H). 2.33−2.28 (m, 2H), 2.11−2.01 (m, 2H), 1.81−1.61 (m, 2H). HPLC-MS (ESI, Gradient B): t_R 12.5 min; positive mode m/z 1066.2 (100) $[M]^+$, 1064.3 (60) $[M]^+$; calcd for $C_{43}H_{48}F_3N_7O_6ReS_2^+$: 1066.26 (100.0), 1064.26 (58.6); t_R 11.0 min; positive mode m/z 476.6 (100) $[M\text{-}TFA]^{2+}$; calcd for $C_{41}H_{48}N_7O_4ReS_2^{2+}$: 953.28 (100).

[Re(15)(CO)$_3$] (20)$^+$. The aldehyde **2** (4.2 mg, 0.01 mmol) and the $[NEt_4]_2[ReBr_3(CO)_3]$ (22 mg, 0.028 mmol) were dissolved in PBS (5 mL, pH = 6.5). The mixture was stirred and heated under N_2 at 50 °C for 15 min. The formed precipitate was spun down, and supernatant removed. The remaining precipitate was dissolved in the mixture of MeCN:PBS (10 mL, 1:1, pH = 7.4). The orange solution was added to the flask containing the peptide **15** (30 mg, 0.03 mmol) and the mixture was stirred at 66 °C for 24 h. The crude product was purified by preparative HPLC to afford 4 mg (24%) of complex **19** as an orange powder. HPLC-MS (ESI, Gradient A): t_R 15.7 min; positive mode m/z 821.9 (100) $[M]^{2+}$, 1642.4 (50) $[M-H]^+$; calcd for $C_{71}H_{94}N_{17}O_{11}ReS_3^{2+}$: 1643.60 (100.0), 1644.61 (75.1).

General information:

The HPLC-MS data acquisition and processing were performed as described in experimental section. For the cleavage studies of compounds **19** and **20** with GSH, HPLC-ESI-MS-MRM (Multiple Reaction Monitoring) method was used to trap and accumulate selected ions. This method allows trapping and accumulation/fragmentation up to 10 different masses. In the cleavage experiment, only accumulation and TIC (total ion counts) of given mass were monitored. Expert setting of MS was following: Ultra Scan 100-2000 M.W., Scan delay= 0, Capillary -4000V, End plate offset -500V, Nebulizer 35 psi, Dry gas 8l/min, Dry temp 350°C, Skimmer 40V, Cap Exit 147.3V, Oct 1 DC 12V, Oct 2 DC 2.12V, Trap drive 67.8, Oct RT 200 Vpp, Lens 1 -5V, Lens 2 -60V; Mode positive MRM isolation on (isolation width was 4), Rolling averaging on (2). The HPLC was performed as described in experimental section. Several optimization runs were performed prior to measurement to find optimal conditions for acquisition. Monitored masses for **19** were: 1066.4, 988.4, 476.7, 515.3, 859.2, 781.3, 745.3, 373.0, 1086.6, 525.5 and for **20** : 1066.4, 988.4, 476.7, 1205.4, 781.3, 745.3, 373.0, 1086.6, 525.5 representing different starting/cleavage products (also see Scheme **7** in manuscript). The analyses were repeated under identical conditions to assure reproducibility.

Photoabsorption and Resonance Energy Transfer Phenomenon in CdTe−Protein Bioconjugates: An Insight into QD−Biomolecular Interactions

Aaydha C. Vinayaka and Munna S. Thakur*

Fermentation Technology & Bioengineering Department, Central Food Technological Research Institute (A constituent laboratory of Council of Scientific and Industrial Research, New Delhi), Mysore-570020, India

Supporting Information

ABSTRACT: Luminescent quantum dots (QDs) possess unique photophysical properties, which are advantageous in the development of new generation robust fluorescent probes based on Forster resonance energy transfer (FRET) phenomena. Bioconjugation of these QDs with biomolecules create hybrid materials having unique photophysical properties along with biological activity. The present study is aimed at characterizing QD bioconjugates in terms of optical behavior. Colloidal CdTe QDs capped with 3-mercaptopropionic acid (MPA) were conjugated to different proteins by the carbodiimide protocol using *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDC) and a coupling reagent like *N*-hydroxysuccinimide (NHS). The photoabsorption of these QD−protein bioconjugates demonstrated an effective coupling of electronic orbitals of constituents. A linear variation in absorbance of bioconjugates at 330 nm proportionate to conjugation suggests a covalent attachment as confirmed by gel electrophoresis. A red shift in the fluorescence of bovine serum albumin (BSA) due to conjugation inferred a decrease in Stokes shift and solvent polarization effects on protein. A proportionate quenching in BSA fluorescence followed by an enhancement of QD fluorescence point toward nonradiative dipolar interactions. Further, reduction in photobleaching of BSA suggests QD−biomolecular interactions. Bioconjugation has significantly influenced the photoabsorption spectrum of QD bioconjugates suggesting the formation of a possible protein shell on the surface of QD. The experimental result suggests that these bioconjugates can be considered nanoparticle (NP) superstructures for the development of a new generation of robust nanoprobes.

Schematic representation of photo-absorption and resonance energy transfer in protein bioconjugated CdTe quantum dots

INTRODUCTION

A quantum dot is a crystal of semiconductor material (periodic groups II−VI, III−V, or IV−VI elements) with a diameter on the order of the compound's exciton Bohr radius.[1] They display a characteristic size dependence of their electronic and optical properties due to a phenomenon known as quantum confinement effects. Properties such as high emission quantum yield, sharp emission spectra, broad absorption spectra, chemical and photostability, long lifetimes, and tunability of emission frequencies make them a superior tool as biomarkers for various applications.[2] The development of any QD-based biosensing modality would essentially require the generation of bioactive QD conjugates. The coupling of inorganic nanoparticles with biomolecules generates hybrid particles possessing unique photophysical properties along with biological activity.[3,4] Being novel constructs, such conjugates need to be characterized to understand the full range of their modified properties before they can be utilized for biosensor applications.

Forster resonance energy transfer (FRET) is a distance-dependent nonradiative energy transfer between the excited electronic states of fluorescent molecules. This phenomenon is a useful tool to study molecular dynamics such as biomolecular interactions and conformational changes.[5] The unique properties of QDs suggest that the replacement of organic fluorophores in FRET studies with QDs could lead to an experimental setup, which would be ultrasensitive, economical, and easy to configure, as well as provide the capability to make simultaneous measurements of different macromolecular systems.[6] Two-color organic/inorganic fluorophores are currently being used for coincidence detection based on FRET.[6,7] However, their functional limitations, such as the spectral cross-talk, nonuniform fluorophore photobleaching rates, and significant background fluorescence make subsequent quantification complicated. These limitations can be obviated by QDs, which have broad excitation and size-tunable photo luminescence spectra with narrow emission bandwidth, exceptional photochemical stability, and relatively high quantum yield. Further, the target signal can be amplified through enhanced energy-transfer efficiency by increasing the

number of acceptors linked to a donor. These features should allow QD-FRET-based nanosensors to generate a very distinct target signal effectively. QDs offer several advantages when used as FRET donors in place of organic dyes.[8] Their size-tunable and narrow emission spectra can considerably reduce donor spectral leakage into the acceptor channel. At the same time, their broad absorption spectrum at wavelengths to the blue of their emission allows choice of excitation that corresponds to the acceptor absorption minimum, substantially reducing direct excitation. QDs are expected to significantly improve assay performances in a wide variety of sensing schemes.

Although the interactions between QDs and biological molecules are known, complete characterization of such bioconjugates to understand the full range of their modified properties for biosensing applications has not been explored properly. The correlation between photoabsorption and resonance energy transfer phenomena in CdTe protein complexes has not been explored completely. The present work is aimed at characterizing QD bioconjugates based on the photoabsorption and other optical properties for the development of novel FRET-based biosensing formats. Thus, coupling the superior optical properties of QDs with a separation-free and immobilization-free FRET-based format may revolutionize the generation of robust nanobiosensors in the future.

EXPERIMENTAL SECTION

Materials and Instruments. Cadmium acetate [$Cd(CH_3COO)_2$], MPA, propionic acid (PA), sodium borohydride ($NaBH_4$), tellurium, *N*-(3-dimethylaminopropyl)-*N*-ethylcarbodiimide hydrochloride (EDC), *N*-hydroxysuccinimide (NHS), BSA, streptavidin (SA), alkaline phosphatase (ALP), and horseradish peroxidase (HRP) were procured from Sigma Chemicals, St. Louis, USA. All reagents used were of analytical grade and acquired from standard suppliers. Dialysis membranes having 6−8 kDa molecular weight cutoff and 1 kDa molecular weight cutoff were procured from Spectra/Por, USA. The following instruments were used: UV−vis spectrophotometer (UV-1601, Shimadzu, Japan), spectrofluorimeter (RF-5301 PC, Shimadzu, Japan), transmission electron microscope (Jeol 2100, USA). Samples were analyzed using a 400-mesh carbon grid obtained from Pacific Grid Technology (101 California Street, San Francisco, CA 94111, USA).

Synthesis of CdTe Qds. CdTe QDs of different fluorescent emission spectra (CdTe 523, 557, 573, 601, and 640 nm) were synthesized as reported by Li et al. (2007) with modification.[9] In brief, 25 mL of aqueous solution containing 0.02 M Cd-$(CH_3COO)_2$ was mixed with 0.05 M of MPA, and the solution was degassed followed by adjusting the pH to 9.2. In a separate reaction, sodium hydrogen telluride (NaHTe) was synthesized by reacting 0.03 M of $NaBH_4$ and 0.01 M of Te in ice-cooled water and purged with argon gas for 30 min. The metal dissolved, leaving a faint pinkish-colored solution. A few drops of NaHTe were added dropwise to the above synthesized solution until the solution turned orange. The solution was refluxed for 120 min. Transmission electron microscopy (TEM) determined the size of thus-synthesized QDs. These QDs were bioconjugated to different biomolecules as explained below.

Bioconjugation of QDs. The following two-step protocol was used for the conjugation of QD to primary amine-containing biomolecules.[10] 0.05 M EDC and 5 mM NHS were mixed and the pH adjusted to 7.4, followed by incubating with QD solution in PBS at 32 °C for 15 min at 110 rpm. The protein solution in PBS was added to the reaction mixture and further incubated at 32 °C for 150 min at 110 rpm. The solution was then kept at 4 °C overnight to deactivate the remaining EDC-NHS. The conjugate solution was then dialyzed against PBS using Spectra/Por dialysis membranes of 6−8 kDa cutoffs with 4 changes of buffer.

A standard protein, BSA, was conjugated to four different QDs to observe the difference in their conjugation efficiency. 50 μL aliquots of QD_{523}, QD_{557}, QD_{573}, QD_{601}, and QD-GSH in PBS were conjugated separately with 1 mg of BSA in 1000 μL by the above-mentioned EDC/NHS conjugation protocol.

Further, conjugation was also performed between varying concentrations of BSA in the first set of experiments keeping the QD concentration constant. 50 μL aliquots of QD_{557} in PBS were conjugated separately with 50, 100, 250, 500, 1000, and 2000 μg of BSA in 1000 μL by the EDC/NHS protocol. In the second set, the conjugation was performed between varying concentrations of QD (5, 10, 20, 50, 100, and 150 μL of QD_{557} in 1000 μL PBS) keeping the BSA concentration constant (50 μg) by the EDC/NHS protocol. In the third set of experiments, QD_{557} was conjugated with other proteins to formalize the results obtained with BSA conjugates. 50 μL of QD_{557} in PBS was conjugated separately with 50, 100, 250, and 500 μg of SA, ALP, and HRP sequentially in 1000 μL of PBS by the EDC/NHS protocol.

Absorption Spectrometry. The conjugates were subjected to spectrophotometry to probe the changes in the spectral properties of the conjugates due to the interfacing of inorganic nanoparticles with biomolecules. The absorbance spectra of QD bioconjugates were acquired in two ways: by restricting the protein concentration to 50 μg/mL and by restricting the QD concentration to 5 μL/mL.

Fluorescence Spectrometry. The influence of bioconjugation on QD photoluminescence (PL) was studied through fluorimetry. Fluorescence spectra were taken for QD-BSA conjugates restricting the protein concentration at 5 μg/mL and restricting the QD concentration at 2 μL/mL. The emission spectra were generated at the excitation wavelengths of 280, 320, and 350 nm in separate experiments. The excitation at 280 nm leads to excitation of both protein and QD components, while the excitation of 320 and 350 nm excites only the QD component of the conjugate.

Time course fluorescence of standard BSA and BSA-QD_{557} conjugate samples were obtained by monitoring emission (λ_{em}) at 350 nm for BSA component and 557 nm for QD_{557} component with excitation at 280 nm. This method was used for the calculation of photobleaching time and FRET efficiency.

Native PAGE. Native-PAGE analyses of QD−protein conjugates was performed to confirm bioconjugation and to monitor the effects of CdTe QD on the mobility of proteins under electric field. The electrophoresis was run on 10% separating gel and 5% stacking gel by the protocol described by Laemmli. To observe the difference in mobility of the conjugates, the gel was stained with silver nitrate stain.

RESULTS AND DISCUSSION

Synthesis and Bioconjugation of CdTe QDs. Thiol-stabilized CdTe QDs were synthesized by aqueous method to attain biocompatibility, which was the primary criterion necessary for bioconjugation. In aqueous method, synthesis of colloidal nanoparticles generally depends on the molar concentrations of precursors and capping material at a particular temperature.

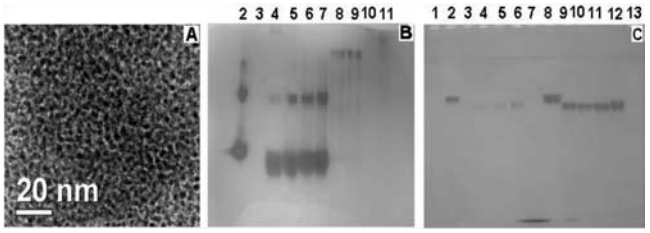

Figure 1. (A) Transmission electron micrograph of MPA capped CdTe QD (QD_{557}) taken on TEM Jeol 2100, USA, at 200 KV using 400 mesh carbon copper grid from pacific grid technology. (B) Native PAGE analysis of QD_{557} conjugates of BSA, ALP, and HRP. Standard BSA, ALP, and HRP were loaded on wells 2, 8, and 10, respectively. BSA-QD_{557} conjugates of conjugation ratios 3, 2, 1, and 0.5 were loaded in wells 4, 5, 6, and 7, respectively. ALP-QD_{557} and HRP-QD_{557} were loaded in wells 9 and 11. (C) Native PAGE analysis of QD_{557} conjugates of SA. Standard SA was loaded on well 2, while SA-QD_{557} conjugates of conjugation ratios 1, 0.5, 0.2, and 0.1 were loaded in wells 3, 4, 5, and 6, respectively, at 1 μg SA/well. A duplicate set was loaded onto wells 8 through 12 at higher protein loading of 5 μg SA/well. Standard QD_{557} was loaded on well 7.

Nanocrystal growth with the nucleation process is temperature dependent, wherein the precursors chemically transform into monomers to attain supersaturation and further atomic rearrangement.[11] CdTe QDs thus synthesized have shown convincing absorption and fluorescence properties (Figure 1S, Supporting Information). The presence of well-defined broad absorption spectra at shorter wavelength suggests the larger distances in the band gap of these particles. The shifts observed in the emission peak of thus-synthesized CdTe QDs were correlated to their size and in turn to the band gap energy of the particle. Thus, CdTe QDs having emission peaks at 523, 557, 576, and 601 nm with narrower full width at half-maximum (fwhm) in the range 45−70 nm and higher photoluminescence were synthesized at 100 °C in aqueous medium. Transmission electron microscopy (TEM) has determined the size of QD_{557} nanocrystal that is having a narrow size range of 3 ± 0.2 nm with good dispersion in aqueous medium without any aggregation (Figure 1A).

Since QDs are synthesized from organometallic precursors, they have no intrinsic aqueous solubility. The native coordinating organic ligands on the surface of QDs must either be exchanged or functionalized with a ligand that can impart both solubility and potential bioconjugation sites.[2] Ligands that form a capping layer on the surface of the QDs must be biocompatible as biomolecules, and most of biological reactions are highly hydrophilic in nature. Therefore, MPA was used to stabilize the QDs that impart biocompatibility and necessary functional carboxylic groups for bioconjugation in aqueous media. CdTe QDs having emission peaks at 523, 557, 576, and 601 nm were conjugated to BSA, and QD_{557} was further conjugated with ALP, HRP, and SA separately by two-step EDC/NHS protocol, as QD_{557} has shown very prominent absorption and higher photoluminescence compared to other QD particles. The protein-conjugated samples have shown strong fluorescence when exposed to UV light (366 nm) after 2 h of incubation at 32 °C followed by dialysis to remove unconjugated QDs inferring retention of conjugated QD_{557}, QD_{576}, and QD_{601}. However, conjugate samples with QD_{523} displayed no fluorescence under UV light.

Figure 1B,C represents native PAGE analysis of QD_{557} conjugated BSA, ALP, HRP, and SA. BSA-QD_{557} conjugates of varying conjugation ratio (3:1, 2:1, 1:1, and 0.5:1) were observed to have acquired greater mobility as compared to standard BSA. This can be ascribed to the increase in overall negative charge of the conjugates rendering them more mobility under electric field. Schroedter et al. (2002) has reported this property of nanoparticles to influence the charge density as a result of conjugation.[12] The increased molecular weight of conjugate was apparently overcome by the high negative charge and compactness of QD.[13] The observed drift in bands with an increase in conjugation ratio for BSA-QD_{557} conjugates has suggested a greater density of QD per protein molecule. ALP conjugate also showed an observable drift. However, HRP conjugate developed a diffuse band due to enhancement of overall negative charge. The SA conjugates of varying conjugation ratio also showed a pattern similar to that of BSA conjugates. The standard QD can be observed to have moved along with the electrophoretic front due to its high mobility caused by small size and a high negative charge.

Effect of Bioconjugation on Photoabsorption Properties. QD bioconjugates were subjected to photoabsorption studies to probe the changes in spectral behavior due to interactions of inorganic nanoparticles with biomolecules. Absorption spectra were taken for various protein conjugates of CdTe QDs. A remarkable change in the photoabsorption spectra was observed for all the protein bioconjugates of CdTe QDs. Protein bioconjugates of CdTe QDs such as QD_{523}, QD_{557}, QD_{576}, QD_{601} conjugated to BSA, and QD_{557} conjugated to different proteins such as ALP, HRP, and SA displayed a remarkable deviation from their individual components in terms of their absorption spectra (Figure 2A,B and Supporting Information Figure 2S).

A new peak was observed in the 320−330 nm range, which was absent in the spectra of both QD and protein standards. The peak was absent when QD_{557} and BSA were simply mixed in the same ratio, suggesting absorption at 320−330 nm could be due to covalent conjugation of QD_{557} and BSA but not some electrostatic interactions among them. However, there was an enhancement of absorption at 280 nm, characteristic of a protein molecule and a slight depression of absorption from 200 to 270 nm for BSA−QD_{557}, a region where QDs absorb strongly. Idowu et al. (2008) has reported the decrease of QD absorption due to conjugation with BSA.[14] Thus, the decrease in absorption of QD coupled to an increase in absorption of protein points toward coupling of the intrinsic energy states of two chromophores.

Absorption in the range 320−330 nm for QD−protein bioconjugates could be due to nonradiative dipole−dipole interaction among them. The intensity of absorption in the range 320−330 nm was found to correlate with percentage retention of QD from fluorescence data suggesting a link between absorption and the degree of conjugation. To probe this link, conjugations were performed varying the ratio between QD_{557} and in BSA concentration. It was observed that absorption in the range 320−330 nm was gradually decreased with increase in BSA concentration (50, 100, 250, 500, 1000, 1500, 2000 μg/mL) during bioconjugation (Figure 2C). A maximum absorption was observed for 50 μg/mL of BSA conjugated to QD_{557} (concentration of QD taken was 0.1 absorption unit at its excitation wavelength, 500 nm). Concomitantly, a gradual increase in absorption was observed when bioconjugation was done with increasing QD_{557} concentration at BSA concentration of 50 μg/mL (Figure 2D).

Absorption was found to decrease logarithmically with the increase in ratio between QD_{557} and different protein concentration, wherein absorption was correlated with percentage

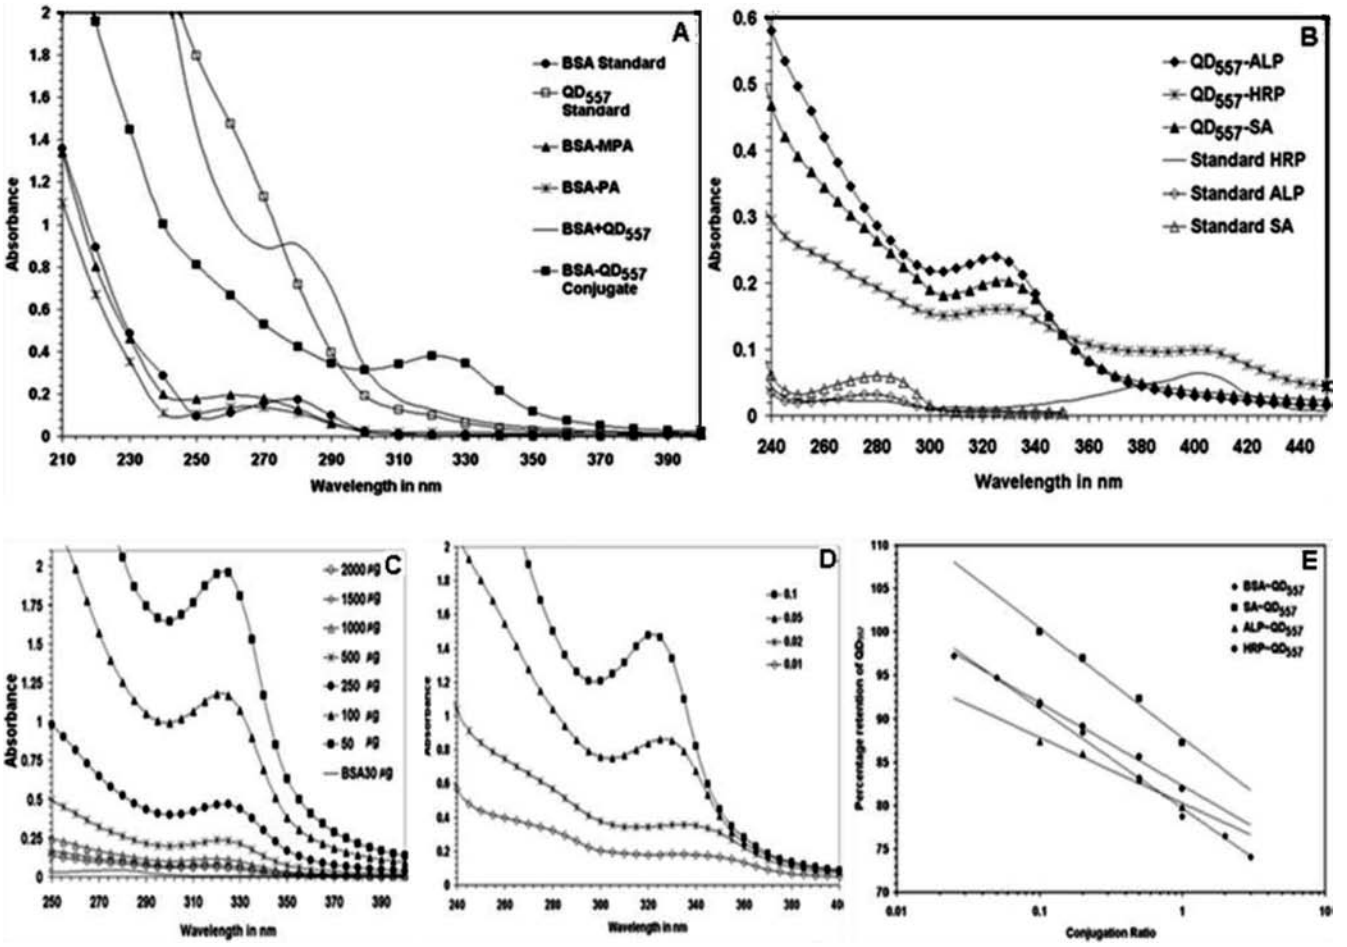

Figure 2. (A) Absorption spectra of BSA, CdTe QD_{557} standard, MPA, PA, BSA-QD_{557} conjugate, BSA-MPA conjugate, BSA-PA conjugate, and a mixture of BSA and QD_{557} in the amounts present in the conjugate sample. (B) Absorption spectra of QD_{557} conjugate with different proteins. (C) Variation of A_{330} for QD_{557} conjugates with different BSA concentration. (D) Variation of A_{330} with different QD_{557} concentration. (E) Variation of percentage retention of QD_{557} with the conjugation ratio in four different QD_{557}−protein bioconjugates from QD restricted absorbance spectrum. (QD_{557}:protein is 1:0.025, 0.05, 0.1, 0.2, 0.5, 1, 2, and 3).

retention of QD_{557} in the bioconjugates (Figure 2E). This suggests that absorption in the range 320−330 nm depends purely on the covalent attachment of protein to QD. Variation in slope can be attributed to the difference in percentage conjugation for different proteins. This further strengthens the above-mentioned hypothesis that absorption in the range 320−330 nm depends on covalent attachment of QD to protein alone. The occurrence of an absorption peak at 320−330 nm can thus be attributed to the effective coupling of the electronic orbitals of the conjugating entities. However, BSA-MPA and BSA-PA conjugates did not show any remarkable absorption in the range 320−330 nm that further confirms QD−biomolecular interactions (Figure 2A). Here, PA was used for conjugating BSA to ensure the absorption in the range 320−330 nm was not due to ligand binding which appeared in the presence of covalently conjugated CdTe QD. The deviation in optical behavior of protein-bioconjugated QD may be due to the formation of a possible protein shell on the surface of QD. Wang et al. (2006) have reported the use of denatured BSA to modify the surface of QDs to improve the chemical stability and photoluminescence. Further, Wang et al. (2006) have also reported a similar possibility when denatured BSA was used to modify the surface of CdTe QD.[15]

CdTe-QD Retention and Fluorescence Quenching in Bioconjugates. The fluorescence spectra were taken for QD-BSA conjugates (QD_{523}, QD_{557}, QD_{576}, and QD_{601}) restricting the protein concentration to 5 μg/mL for spectral analysis with excitation wavelength at 280, 320, and 350 nm separately. Fluorescence spectra gave a rough estimate of percentage retention of QD (Figure 3A). Additionally, blue shifts of 5 nm for QD_{557}, 8 nm for QD_{576}, and 13 nm for QD_{601} were observed in the fluorescence spectra of QD after conjugation with BSA inferring a net reduction in Stokes shift of the conjugate. In addition, varying levels of fluorescence quenching were observed for BSA in QD_{523}, QD_{557}, QD_{576}, and QD_{601} conjugates (Figure 3B).

Further, it was observed that the percentage retention of QD and the percentage quenching of BSA fluorescence were proportionate to each other (Table 1). BSA−QD_{557} conjugates have shown a red shift in the fluorescence peak of BSA with respect to conjugation ratio inferring solvent polarization effects on protein molecules due to the close proximity of QD (Figure 3S, Supporting Information). Generally, fluorescence spectra of proteins undergo a shift upon varying the polarity in the environment of aromatic amino acid residues as a result of binding of substrates, denaturation, and interactions with other

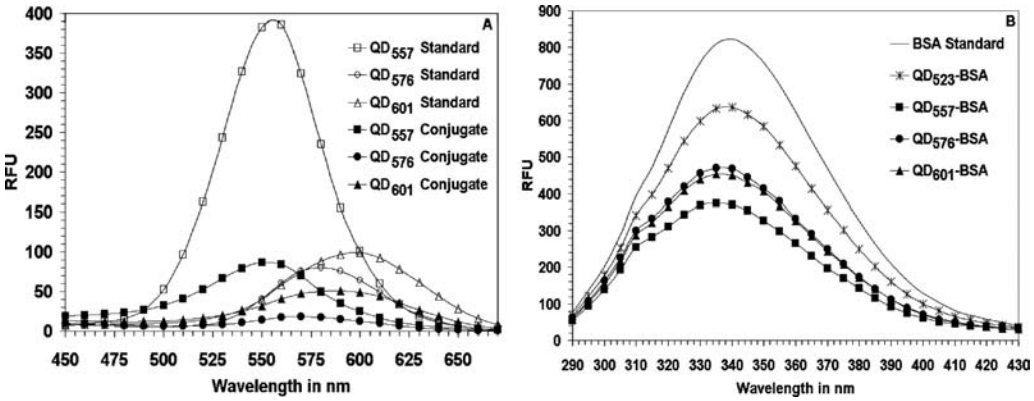

Figure 3. (A) Fluorescence spectra for standard QDs and their respective BSA conjugates. (B) Quenching of BSA fluorescence due to conjugation with various QDs.

Table 1. Percentage Retention and Percentage Quenching for BSA Conjugates with Different QDs

sample	percentage retention of QD (%)	percentage quenching of BSA fluorescence (%)
QD_{523}–BSA	56.89	25.7
QD_{557}–BSA	99.24	55.78
QD_{576}–BSA	73.67	42.1
QD_{601}–BSA	76.78	43.89

molecules.[16] A spectral blue shift of protein fluorescence may also occur due to the shielding of tryptophan residues from the hydrophilic environment.[16] Therefore, the red shift in protein fluorescence signifies the conformational changes induced by the interaction of QD and further exposure of tryptophan residues to the hydrophilic aqueous environment.[17] Generally, the tyrosine fluorescence (λ_{max} 303 nm) is not significantly influenced by the environmental conditions.[18] Furthermore, there was an enhancement of QD_{557} fluorescence at a higher ratio of QD_{557} to BSA in the range 400–650 nm as observed in Figure 4A. The degree of fluorescence enhancement was increased with an increase in the energy of excitation. While excitation at 350 nm caused an enhancement of 100%, excitation at 280 nm caused 200% enhancement.

The enhancement of QD fluorescence upon bioconjugation was ascribed to the passivation of the QD surface by proteins against solvent effects in the aqueous media. Different proteins displayed various enhancement profiles as evident from Figure 4B. Idowu et al. (2008) have reported enhancement of QD emission in the presence of BSA, which signifies inhibition of nonradiative recombination of the surface vacancies.[14] Thus, a decrease in fluorescence emission of BSA after bioconjugation with CdTe QD_{557} could be due to radiationless quenching and was found to be concentration-dependent. There was a linear decrease in BSA fluorescence with increasing concentration of CdTe QD after bioconjugation, suggesting an interaction between CdTe QD and BSA. Similar observations were made by Idowu et al. (2008), and it was reported that a progressive decrease in BSA fluorescence with increasing concentration of QD could be due to static and dynamic quenching together.[14] Fluorescence quenching as a result of the conjugation process may be due to energy transfer phenomena, excited-state reactions, or complex formation, which is referred to as static quenching.[19] The appearance of a new absorption peak in the range 320–330 nm further confirms such nanobiomolecular interactions and suggests CdTe QD-BSA complex formation, which could be due to the formation of a possible protein shell on the surface of QD. As CdTe QD was synthesized in aqueous environment, there is a possibility of having certain trap sites on the surface of QDs. During CdTe QD-BSA complex formation, the formation of a possible protein shell on the surface of QD may eliminate nonradiative transitions. Further, the protein shell may passivate the surface of QDs, thereby inhibiting the radiationless recombination at the surface vacancies (Figure 5).[19]

Photobleaching and Resonance Energy Transfer Phenomenon in CdTe QD Bioconjugates. Several studies have demonstrated the effective use of QDs as FRET donors. FRET is a distance-dependent dipole–dipole interaction phenomenon of nonradiative transfer of excited-state energy from an excited donor molecule to an acceptor molecule. Generally, FRET may lead to a decrease in the fluorescence of donor chromophores and subsequent increase in the fluorescence of an acceptor chromophores.[20] QDs have been used to detect small analytes by utilizing a common strategy that relies on conjugating QDs to target binding receptors.[7] The QD conjugates are then exposed to appropriate acceptor-labeled target analogues, which are brought in close proximity to the QD by binding to the receptors. In this initial state, the QD-donor PL is quenched by efficient FRET to the proximal acceptor-labeled analogues. The presence of the target then displaces bound analogues from the surrounding conjugated receptors that can be detected through a reduction in FRET efficiency and a concomitant increase in PL of QD. The main limiting factor for QDs as FRET donors lies in their size, as FRET efficiency depends on center-to-center separation between donor and acceptor chromophores. Three variables contribute to overall QD donor size: core shell radius, coating, and bioconjugation. Therefore, successful QD FRET designs most often include very thin solubilization layers and direct attachment of bioreceptors to the QD surface to overcome this limiting factor.[21] Covalent conjugations between protein moiety and nanoparticles may lead to dipolar resonance interactions resembling Forster resonance energy transfer phenomenon.[7,12,13] CdTe QD has a broad excitation spectrum by virtue of its nature, and thus, it may be possible for CdTe QD to influence the optical properties of proteins as a result of covalent conjugation. This tightly bound covalent attachment between protein and CdTe QD has resulted in spatial closeness of the

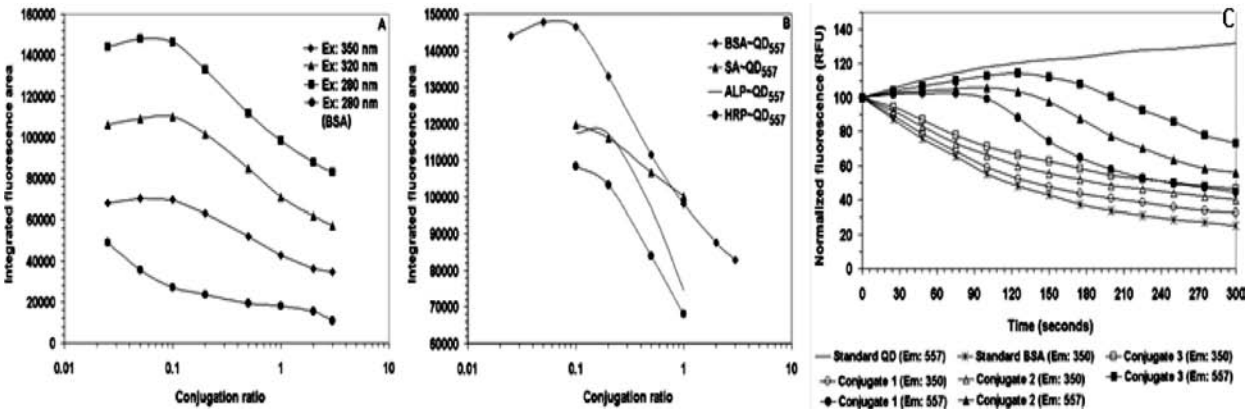

Figure 4. Variation in fluorescence emission spectra for protein−QD_{557} bioconjugates proportional to the conjugation ratio. (A) Variation of integrated fluorescence area for BSA−QD_{557} bioconjugates proportional to the conjugation ratios excited at three wavelengths: 280, 320, and 350 nm. The emission for QD component was collected from 450 to 650 nm, while that for the BSA component was collected in the 300−400 nm range. (B) Variation of integrated fluorescence area with conjugation ratio for QD_{557} conjugates of BSA, SA, ALP, and HRP excited 280 nm. Emission for the QD component was collected from 450 to 650 nm. (C) Variation of normalized fluorescence over time for standard QD_{557}, standard BSA, and BSA−QD_{557} conjugates of three different ratios (conjugate 1 is BSA−QD_{557} at 1:0.1, conjugate 2 is BSA−QD_{557} at 1:1, and conjugate 3 is BSA−QD_{557} at 1:3 ratio) from time course fluorescence spectra. The fluorescence of the BSA component was monitored at 350 nm, while that of the QD component was monitored at 530 nm.

molecules in the bioconjugate. Thus, covalent conjugation might have brought BSA and CdTe QD into such close proximity that has led to the appreciable spectral overlap between BSA and CdTe QD. This has resulted in the dipolar resonance interaction between BSA and CdTe QD as a donor−acceptor pair, respectively (Figure 5). This, in turn, might have allowed sufficient resonance energy transfer between BSA and CdTe QD in the BSA−QD_{557} complex. FRET efficiency for various BSA−QD_{557} conjugates were calculated by the following equation:[22,23]

$$E = 1 - F_{da}/F_{d} \quad (1)$$

where F_{da} is the integrated BSA fluorescence in the presence of QD_{557} and F_{d} is the integrated BSA fluorescence in the absence of QD_{557}.

FRET efficiencies can also be inferred from the photobleaching rates of the donor in the presence and absence of an acceptor.[24] Photobleaching is the irreversible photochemical destruction of a fluorophore and always occurs from its excited state.[22] Resonance energy transfer from an excited donor to an acceptor fluorophore prevents the photobleaching of that donor fluorophore, and thus, high FRET efficiency leads to a longer photobleaching decay time constant. The energy transfer efficiency for BSA−QD_{557} conjugate was determined by the following equation:[22]

$$E = 1 - \tau_{pb}/\tau'_{pb} \quad (2)$$

where τ'_{pb} and τ_{pb} are the photobleaching decay time constants of the donor in the presence and absence of the acceptor, respectively. The fact that time measurements are over seconds rather than nanoseconds makes measurement easier than fluorescence lifetime measurements, and because photobleaching decay rates do not generally depend on donor concentration, the careful control of concentrations needed for intensity measurements is not required. Time course fluorescence was obtained for standard QD_{557}, standard BSA, and BSA−QD_{557} conjugate samples excited at 280 nm. Fluorescence emission

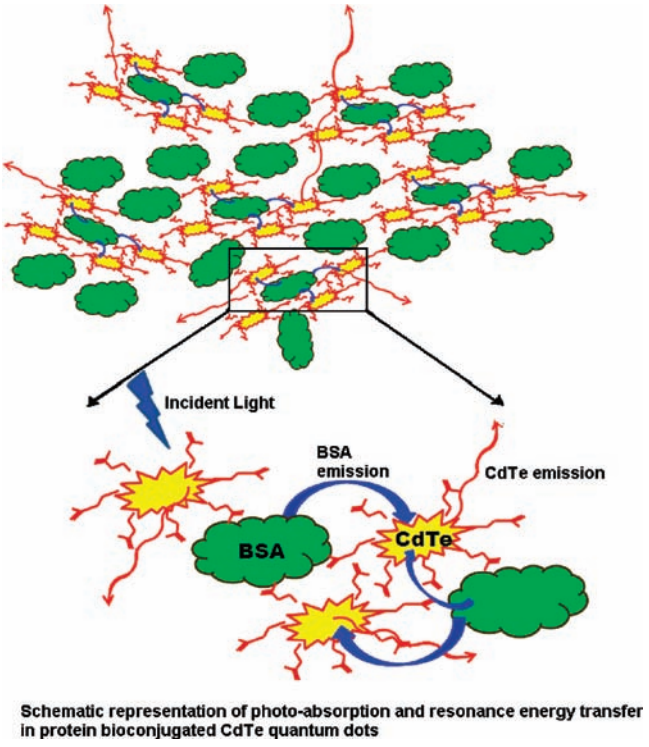

Figure 5. Schematic representation of possible QD-BSA complex formation and resonance photoenergy transfer phenomenon.

was monitored at 350 nm for the BSA component and 557 nm for the QD_{557} component (Figure 4C).

The energy transfer efficiency for BSA−QD_{557} conjugates was determined by making use of eq 1. Photobleaching lifetime was estimated for the BSA component by fitting the photobleaching curves to eq 2 (Table 2). Photobleaching-based calculation of FRET is based on the theory that the occurrence of resonance energy transfer reduces the fluorescence lifetime of the donor molecule, effectively protecting it against photobleaching.

Table 2. Photobleaching Time (τ_{pb}) and FRET Efficiency (E) Determined for BSA−QD_{557} Samples

sample	photobleaching time (s)	E (%)
BSA	68.5	-
BSA−QD_{557} (1:0.1)	82.6	17.11
BSA−QD_{557} (1:1)	92.6	26.02
BSA−QD_{557} (1:3)	106.4	35.61

Calculations of photobleaching FRET are based on the decreased rate of donor photobleaching relative to that measured for the donor in the absence of resonance energy transfer.

CONCLUSION

In summary, various optical and biological properties of CdTe-QD bioconjugates were characterized using absorption spectroscopy, fluorescence spectroscopy, and gel electrophoresis. Bioconjugation has significantly influenced the photoabsorption spectrum of QD−bioconjugates suggesting formation of a possible protein shell on the surface of QD. A proportionate quenching in BSA fluorescence with respect to conjugation ratio followed by an enhancement of QD fluorescence point toward possible nonradiative dipolar interactions between the two chromophores. Further, a reduction in photobleaching time for BSA as a result of bioconjugation with QD_{557} supports the possibility of dipolar interactions, which are attributed to the nanobiomolecular interactions between CdTe-QD and tyrosine/tryptophan moieties of protein molecule. Thus, the initial experimental results suggest these bioconjugates can be considered as nanoparticle (NP) superstructures for the development of new-generation robust nanoprobes.

ABSTRACT: Polyoxazoline polymers with methyl (PMOZ), ethyl (PEOZ), and propyl (PPOZ) side chains were prepared by the living cationic polymerization method and purified by ion-exchange chromatography. The following properties of polyoxazoline (POZ) were measured: apparent hydrodynamic radius by aqueous size-exclusion chromatography, relative lipophilicity by reverse-phase chromatography, and viscosity by cone−plate viscometry. The PEOZ polymers of different molecular weights were first functionalized and then conjugated to model biomolecules such as bovine serum albumin, catalase, ribonuclease, uricase, and insulin. The conjugates of catalase, uricase, and ribonuclease were tested for *in vitro* activity using substrate-specific reaction methods. The conjugates of insulin were tested for glucose lowering activity by injection to naïve Sprague−Dawley rats. The conjugates of BSA were injected into New Zealand white rabbits and serum samples were collected periodically and tested for antibodies to BSA. The safety of POZ was also determined by acute and chronic dosing to rats. The results showed that linear polymers of POZ with molecular weights of 1 to 40 kDa can easily be made with polydispersity values below 1.10. Chromatography results showed that PMOZ and PEOZ have a hydrodynamic volume slightly lower than PEG; PEOZ is more lipophilic than PMOZ and PEG; and PEOZ is significantly less viscous than PEG especially at the higher molecular weights. When PEOZ was attached to the enzymes catalase, ribonuclease, and uricase, the *in vitro* activity of the resultant bioconjugates depended on the extent of protein modification. POZ conjugates of insulin lowered blood glucose levels for a period of 8 h when compared to 2 h for insulin alone. PEOZ, like PEG, was also able to successfully attenuate the immunogenic properties of BSA. The POZ polymers (10 and 20 kDa) are safe when administered intravenously to rats, and the maximum tolerated dose (MTD) was greater than 2 g/kg. Blood counts, serum chemistry, organ weights, and the histopathology of key organs were normal. These results conclude that POZ has the desired drug delivery properties for a new biopolymer.

INTRODUCTION

Biocompatible polymers are used in drug delivery in a number of complex formats. They can be attached directly to pharmaceutical actives where they are part of the drug substance, conjugated to lipids where they become part of the liposomal delivery system, and linked with cationic molecules where they become part of a nucleic acid complexing polymer. Some examples of biostable and biodegradable polymers that have been tested in medicines are poly(ethylene glycol) (PEG), hyaluronic acid (HA), polysialic acid (PSA), hydroxyethyl starch (HES), polyglutamic acid (PGA), polylactic and polyglutaric acid (PLGA), *N*-(2-hydroxypropyl) methacrylamide (HPMA), polyvinylpyrrolidone (PVP), and polydextrans. From this list, PEG is the one polymer that has had wide success in delivering proteins, aptamers, and small molecule drugs. The conjugation of biopharmaceuticals to PEG by a process called "PEGylation" has led to the clinical and marketing success of a number of blockbuster macromolecule drugs for the treatment of hepatitis C, neutropenia, and anemia.[1] The polymer has the ability to negate several limitations of therapeutic proteins, such as rapid clearance, proteolysis, and immunogenicity. It provides a camouflaging shield around the protein and produces an apparent hydrodynamic size that reduces proteolysis and renal glomerular filtration. This shield also protects the drug from possible protein antigen−antibody-like reactions.

Although PEG has been clinically proven and more then ten conjugates are already on the market, this polymer is not completely devoid of technical and commercial challenges. Recent observations of specific antibodies against PEG were detected in the serum of patients treated with PEG-asparaginase[2] and PEG-uricase[3] that have resulted in a neutralizing effect with loss of therapeutic efficacy. These reports also suggest that pre-existing anti-PEG antibodies, of the IgM and IgG types, were identified in over 25% of patients, during screening, who never received prior treatment with PEG drugs.[4,5] This observation can be correlated to the large use of PEG in food, beauty, and body care products. Another controversy relates to possible kidney cell vacuolization observed in animals following repeated administration of PEG drug conjugates of hemoglobin,[6] TNF-α bp,[7] and leptin.[8] While marked vacuolation has been reported with the conjugates itself, these observations were not noted when PEG was administered alone. There are numerous patents on the

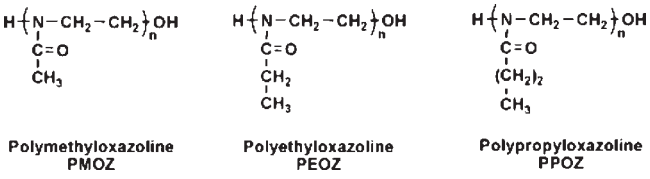

Figure 1. Chemical structures of three types of polyalkyloxazoline (POZ).

compositions and applications of PEG in drug delivery that hamper the ability to introduce new PEGylated therapies into the clinic. This hindrance in "freedom to operate" has forced drug companies to seek and test alternative polymers such as HPMA,[9] PSA,[10] and PVP.[11]

Another class of polymers called polyoxazolines (POZ) is described in this paper. These polymers can be made with high quality, of different architectures, and with different functional groups. They not only possess the key beneficial properties of PEG, but have characteristics that are novel and unique for different drug delivery applications. They are nonionic, stable, and highly soluble in water and organic solvent. The generic chemical structures of polymethyloxazoline (PMOZ), polyethyloxazoline (PEOZ), and polypropyloxazoline (PPOZ) are shown in Figure 1.

A review of the literature shows that the interest in POZ has existed for the past thirty years. It was first developed as a food additive in the early 1980s for which elaborate animal safety studies were completed and documented.[12] Studies reported by other scientists showed that POZ can be used in multiple pharmaceutical and medical applications.[13,14] It can be conjugated to protein and small molecule drugs,[15] grafted onto liposomal bilayers,[16,17] formulated into micelles,[18] and applied onto surfaces.[19] In all these applications, POZ has the same "stealth" properties as PEG without any adverse effects in animal models. Recent studies completed with radiolabeled POZ suggest that the polymer is rapidly excreted by the kidney with no significant accumulation in tissues.[20,21]

Polyoxazoline polymers are prepared by the living cationic polymerization method. A number of processes have been reported in the literature. One method discusses the stoichiometric addition of an electrophile initiator such as an alkyl tosylate or alky triflate to the oxazoline monomer that is dissolved in a dry organic solvent and in an inert atmosphere.[22−24] The propagation phase is conducted at 80 °C for approximately 1 to 3 days. In the second method, the polymerization is carried out with microwave energy to reduce the propagation time from days to hours.[25,26] In both cases, the living cation is terminated by the introduction of a nucleophile such as OH^-, NH^-, COO^-, or S^-. Termination is conducted with aqueous sodium carbonate to give a hydroxyl terminal group or by reacting with a secondary amine such as morpholine or piperidine to give a terminal tertiary amine. POZ can be monofunctionalized at one end of the chain during the initiation step[27] or at the termination step with the use of carboxylate ions.[28] POZ has also been synthesized with pendant functional aldehyde and amine groups and terminated with inert groups.[29,30] These chemistries allow for higher drug loading which is not possible with linear polymers like PEG.

The synthetic methods described in the above-mentioned references appear to be straightforward, but in reality, they do have a number of process difficulties in relation to scaling up and reproducibility. The various side reactions that occur have led to impurities that are difficult to remove, thereby creating products that are yellow in color and with polydispersity indices of >1.3. In addition, the termination with the weak nucleophile water does not always give the desired product of 5-position attack (the "thermodynamic" product), but rather gives an attack in the 2-position (the "kinetic" product). This kinetic product is not stable and can rearrange to give an ester product or undergo reversal to the cation.[31] These polymers have a high MW shoulder of approximately 5−10% and significant low MW tailing, when tested and detected by gel permeation chromatography.[32] It is generally stated in the literature that this broadening of the MW distribution is due to the chain transfer process through an elimination−dimerization mechanism, although structural details and experimental support for this process are scarce.[33] To the extent that chain transfer reactions do occur, such reactions then cannot be considered to be truly living polymerizations.

In this paper, the chemistry and properties of POZ are described and compared against PEG. In addition, the chemical and biological properties of POZ conjugates of some model proteins and peptides were determined and compared against similar PEG conjugates. Conjugates of ribonuclease (RNase), uricase, and catalase were prepared and their activity measured by *in vitro* assays. The activity of POZ insulin conjugates was determined *in vivo* by measuring the glucose lowering effect in normal rats. The ability of POZ to camouflage the immunogenicity of bovine serum albumin (BSA) was evaluated in a 72 day rabbit study. The acute toxicity of POZ was determined following single and repeated intravenous administration to rats.

MATERIALS AND METHODS

Materials. Bovine albumin, uricase, catalase, ribonuclease, cytidine 2′,3′-phosphate, uric acid, and hydrogen peroxide, *N*-hydroxysuccinimide (NHS), dicyclohexylcarbodiimide (DCC), 2,4,6-trinitrobenzene sulfonic acid (TNBS), trifluoroacetic acid (TFA), methyl trifluoromethylsulfonate (MeOTf), disuccinimidyl carbonate (DSC), *p*-nitrophenyl chlroformate (PNPC), potassium *t*-butoxide, and sodium hydride were purchased from Sigma-Aldrich, St. Louis, MO. The organic solvents acetonitrile, dichloromethane, dimethylacetamide, dichloromethane, dimethylformamide, chlorobenzene, chloroform, methanol, and diethyl ether were obtained from EMD Chemicals. The monomers of 2-methyl-2-oxazoline, 2-ethyl-2-oxazoline and 2-propyl-2-oxazoline were obtained from Sigma Chemicals and Acros Chemicals. Methyl 3-mercaptopropionate was obtained from Sigma Chemicals and Chevron-Philips, Belgium. Amberlite desalting resins IRA67 and IR120H were purchased from Dow Chemicals, Midland, MI, and ion-exchange media such as DEAE sepharose FF resin and SP Sepharose were purchased from GE Healthcare (Amersham Biosciences). Insulin and insulin glargine were obtained from Biocon Ltd., Bangalore, India. The bicinchoninic acid (BCA) assay kit is from Pierce. Poly(ethylene glycol) (PEGs) reagents of 5 and 10 kDa were purchased from LaysanBio, Huntsville, AL.

POZ Synthesis and Purification. The monomers and organic solvent were first dried by refluxing over calcium hydride and then distilled and collected in a dry flask containing molecular sieves. In a clean and dry flask and under an argon atmosphere, the organic solvent was first siphoned in. Different organic solvents were tested during the polymerization process. They were acetonitrile, chloroform, chlorobenzene, and dimethylacetamide. A measured amount of methyl or ethyl or propyl oxazoline M_0 was

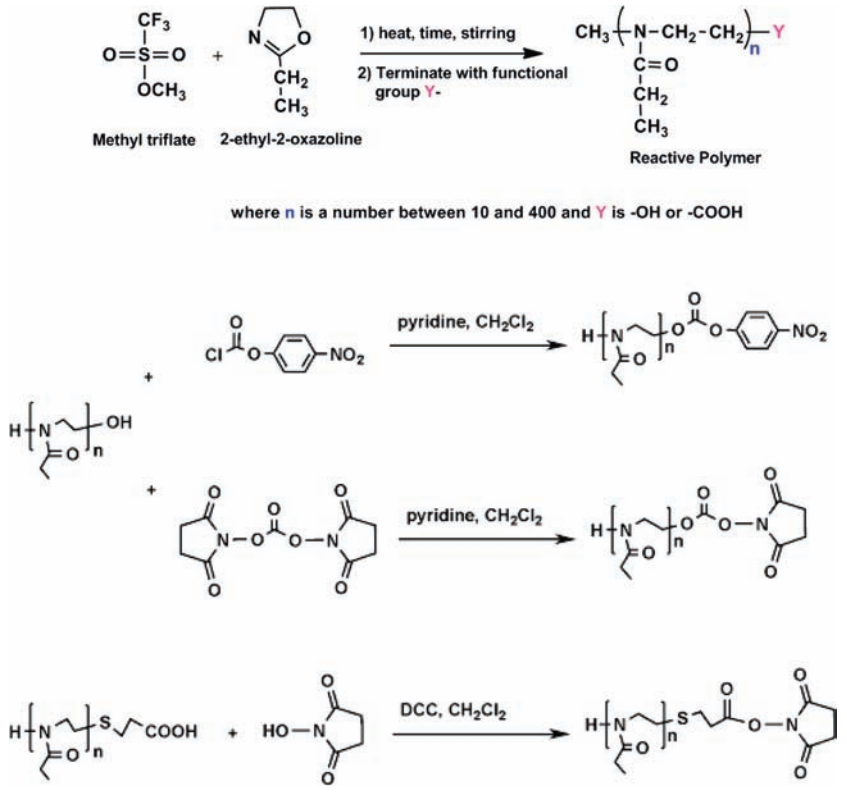

Figure 2. Synthetic schemes used to polymerize and functionalize POZ-OH and POZ-COOH.

next added, followed by an accurate measurement and transfer of the MeOTf initiator I_0. The molecular weight of the polymer being synthesized depends on the molar ratio of M_0/I_0. The contents in the flask were then heated at temperatures between 60 and 90 °C for extended periods of time, depending on the desired molecular weight of the polymer prepared and the boiling point of the solvent used. The flask was then cooled and the solution containing the living polymer was slowly transferred to a mixture of the terminating agent in dry organic solvent and mixed overnight with constant stirring. The terminating agent used depended on the end terminal group desired. When a hydroxy group was required, the terminating mixture was either a methanolic potassium hydroxide solution or a 5% sodium carbonate solution in water. When a carboxylic acid group was desired, the terminating mixture was methyl 3-mercaptopropionate and potassium *t*-butoxide. The solvent was then stripped from the polymer by rotary evaporation. The thiopropionate-terminated residue was dissolved in an aqueous solution containing 0.1 N sodium hydroxide and mixed for a couple of hours to hydrolyze the thiopropionate ester. Figure 2 outlines a general polymerization scheme.

The following example outlines the specific procedures used for the synthesis of a 5 kDa PEOZ polymer. Chlorobenzene (100 mL) and 2-ethyl-2-oxazoline (39.7 g, 400 mmol, 50 equiv) were mixed at room temperature under argon and in a 250 mL round-bottom flask. The initiator, methyl triflate (MeOTf, 880 μL, 8 mmol, 1 equiv), was carefully added into the flask with constant stirring. The mixture was then heated at 80 °C for 1.75 h and then rapidly cooled to room temperature by immersing the flask in an ice bath. When a 10 kDa PEOZ polymer was made, the amount of MeOTf used was less (440 μL, 4 mmol, 0.5 equiv) and the polymerization time was 3.5 h. When acetonitrile was used as the solvent, the polymerization was carried out at 80 °C for 28−30 h for the 5 kDa polymer and 40−42 h for the 10 kDa polymer. The termination of the polymerization was carried out as follows:

(a) When a hydroxy group terminus was required, 40 mL of a 5% sodium carbonate solution was added to the polymer solution (5 kDa or 10 kDa) and the mixture was stirred for 30 min. The aqueous layer was separated and the organic layer was extracted once more with an additional 40 mL of a 5% sodium carbonate solution. The aqueous layer was separated, combined and stirred overnight at room temperature. The cloudy mixture formed (~80 mL) was acidified with 40 mL of 0.5 M HCl acid in order to give a clear solution of pH < 6. The polymer was then extracted into methylene chloride (3 × 200 mL), and the combined organic layers were dried with anhydrous magnesium sulfate for one hour, concentrated to 25 mL, and precipitated by dropwise addition to 250 mL of diethyl ether. The resulting white solid was filtered and dried overnight in a vacuum oven.

(b) When a carboxylic acid group terminus was required, the polymer solution (5 kDa or 10 kDa) was transferred into a 500 mL round-bottom flask containing a mixture of chlorobenzene (100 mL), methyl 3-mercaptopropionate (1.3 g, 8 mmol, 2 equiv), and potassium *t*-butoxide (0.67 g, 6 mmol, 1.5 equiv), and stirred overnight at room temperature. The chlorobenzene in the mixture was evaporated out, and the residue of the thioester was hydrolyzed by dissolving in 100 mL of 0.1 M sodium hydroxide solution and stirring at room temperature for 4 h. The crude acid (POZ-COOH) was desalted in an Amberlite ion-exchange resin IRA67/IR120H bed and then purified by ion-exchange chromatography (IEC)

dx.doi.org/10.1021/bc200049d |*Bioconjugate Chem.* 2011, 22, 976–986

using a column packed with DEAE sepharose FF resin. The aqueous layer was extracted, precipitated, and dried as described above.

POZ Characterization. The purified POZ-OH and POZ-COOH of different molecular weights were analyzed by nuclear magnetic resonance (NMR), matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF), gel filtration chromatography (GFC), gel permeation chromatography (GPC), reverse-phase chromatography (RP), and viscometry. Proton NMR experiments were performed on a 500 MHz Varian NMR spectrometer. Samples (10−20 mg) were first dissolved in 0.75 mL of $CDCl_3$ or D_2O and then analyzed. Mass spectrometry measurements were performed on a Bruker Microflex MALDI time-of-flight instrument (Bruker-Daltonics, Billerica, MA, USA). A stock solution was prepared mixing equal volumes of 0.1% TFA in water and 0.1% TFA in acetonitrile. Separate solutions of the polymer, the matrix (α-cyano-4-hydroxycinnamic acid) and the salt (sodium iodide) solution were prepared in the stock solution. Equal and micromolar amounts of each solution were spotted on the target for mass and polydispersity measurements.

High-performance liquid chromatography (HPLC) was used for the both size exclusion methods. The GFC method was used to determine the relative hydrodynamic radius of each polymer type and size. A Bio-Sep-SEC-S-400 column (Phenomenex) was used and the mobile phase was 1 mM HEPES (pH 7.0) buffer. A GPC method was used to determine the size and polydispersity of each polymer. Two Phenogel columns (5 μ, 500A°, 300 × 7.8 mm, Phenomenex) were used in series and maintained at 60 °C, and the mobile phase was *N*,*N*-dimethylformamide (DMF). In the case of the lipophilicity method, a C-8 column was used and an isocratic mobile phase was used that comprised of a mixture of 70:30 methanol/water. In all these methods, an ultraviolet and refractive index detector were used in series.

The viscosity of PEOZ-OH of molecular weight 10−40 kDa was measured on a Brookfield LVDV-II cone and plate viscometer fitted with a temperature-controlled jacketed plate. The polymer sample (0.5 mL of a 10%, 20%, 30%, and 40% w/w solution in water) was placed on the center of the plate, which was attached to the main drive of the instrument. The cone (CPE-40) was rotated at different rates (rpm) and the viscosity (mPas) was recorded each time at 25 °C. The viscosities of similar concentrations of PEG-OH and branched $PEOZ_2$-OH were also measured for comparison.

Functionalizing POZ. POZ-OH and POZ-COOH were functionalized as follows. Figure 2 illustrates the different synthetic schemes for these reagents.

(a) Activation of POZ-OH with *p*-nitrophenylchloroformate: PEOZ-OH (5.3 kDa, 0.05 mmol, 1 equiv) was dissolved in toluene and dehydrated by azeotropic distillation to give a small amount of concentrated solution. It was cooled to room temperature before dichloromethane, *p*-nitrophenylchloroformate (pNPC, 0.95 mmol, 6 equiv), and pyridine were added. The mixture was stirred overnight at room temperature and then precipitated by dropwise addition to prechilled diethyl ether. The PEOZ-pNPC precipitate was collected and dried under vacuum to give a yield of 0.45 g or 95%. To determine the degree of pNPC substitution, an accurate amount of the reagent was dissolved in a known volume of 0.2 M NaOH solution. After 2 h at room temperature, the amount of *p*-nitrophenol released was measured by spectrophotometry at 410 nm ($\varepsilon = 1.7 \times 10^4\ M^{-1}\ cm^{-1}$). The degree of activation, evaluated on the basis of *p*-nitrophenol release, was 87%.

(b) Activation of POZ-OH with disuccinimidylcarbonate: PEOZ-OH (5.3 kDa, 0.05 mmol, 1 equiv) was dissolved in acetonitrile and dehydrated by azeotropic distillation to give a small amount of concentrated solution. After cooling to room temperature, disuccinimidyl carbonate (DSC, 0.2 mmol, 4 equiv) and pyridine were added and the mixture was stirred overnight. The solvent was removed using a rotary evaporator, and anhydrous dichloromethane was added to dissolve the residue. Any insoluble material was removed by filtration, and the filtrate was washed with a pH 4.5 sodium chloride saturated acetate buffer. The dichloromethane phase was separated, dried over anhydrous sodium sulfate, and then concentrated to a small volume before it was precipitated by slow addition to diethyl ether. The PEOZ-SC precipitate was collected and dried under vacuum to give a yield of 0.40 g or 80%. To determine the degree of SC substitution, an accurate amount of reagent was reacted with glycine−glycine (Gly-Gly) to evaluate the degree of amino group modification.[34] Briefly, a Gly-Gly solution of 0.285 mg/mL was prepared in borate buffer 0.2 M, pH 8. An equimolar amount of PEOZ-SC (10.8 mg) was added and the reaction mixture was stirred for 30 min. The assay was conducted by preparing two solutions: solution A: 950 μL of borate buffer (0.1 M, pH 9.3), 25 μL of the reaction mixture and 25 μL of 2,4,6-trinitrobenzene sulfonic acid solution (TNBS, 1% w/v in DMF); and solution B: 950 μL of borate buffer (0.1 M, pH 9.3), 25 μL of Gly-Gly, and 25 μL of TNBS solution. After 30 min, the absorbance of both solutions was measured by UV spectrophotometry at 420 nm, i.e., the amount of trinitrophenyl glycine−glycine complex formed from the coupling of unreacted Gly-glyamino group with TNBS was measured. The polymer activation was calculated by applying the following formula:

$$\text{polymer activation} = (\text{absorbance}_{\text{solution A}}/\text{absorbance}_{\text{solution B}}) \times 100$$

The percentage of activation of PEOZ-SC was 85%.

(c) Activation of POZ-COOH with *H*-hydroxysuccinimide: The purified PEOZ-COOH (5.3 kDa, 600 mg, 0.11 mmol) was dissolved in anhydrous dichloromethane, and *N*-hydroxysuccinimide (NHS, 104 mg, 0.9 mmol) and dicyclohexylcarbodiimide (DCC, 185 mg, 0.9 mmol) were added. The reaction mixture was allowed to react for 24 h, and the product (PEOZ-NHS) was precipitated in diethyl ether, collected, and dried. The degree of NHS activation was evaluated by the method described above and the percentage of activation was 90%.

(d) Hydrolysis and reactivity of PEOZ-NHS, PEOZ-p-NPC, and PEOZ-SC: In the hydrolysis experiments, the activated polymer was accurately weighed and dissolved in dioxane. 50 μL of this stock solution was withdrawn and added to 950 μL of borate buffer 0.1 M, pH 8.0, and at room temperature (5% of dioxane in the mixture). The rates of hydrolysis of the POZ reagents were evaluated by the release of *N*-hydroxysuccinimide and its absorbance measurement at 260 nm using a UV spectrophotometer

(Perkin-Elmer instruments, Northwolk, CT, USA). In the reactivity experiment, the stock solution was added to glycyl-glycine dissolved in borate buffer 0.1 M, pH 8.0, and at room temperature (ratio of polymer reagent/glycyl-glycine was 1:1). The rate at which the primary amine of glycyl-glycine reacted with the POZ reagents to release of *N*-hydroxysuccinimide, was measured at 260 nm. The spectrophotometer was programmed to take a reading every 5 s, in order to plot the rate of the reaction. From these plots, the half-lives of hydrolysis and reactivity were calculated and reported in minutes.

POZ and PEG Conjugation to Enzymes. Three different enzymes, RNase, uricase, and catalase, were reacted with PEOZ-NHS (5.3 kDa) and PEG-NHS (5.5 kDa) reagents. The RNase, uricase, and catalase concentrations in the test solutions were measured by UV spectrophotometry using molar extinction coefficients of 9.45×10^3, 13×10^3, and 1.67×10^5 M^{-1} cm^{-1} at 280 nm, respectively. RNase has a molecular weight of 13.7 kDa and 11 amino groups available for conjugation; uricase has a molecular weight of 130 kDa and 100 amino groups for conjugation; and catalase has a molecular weight of 240 kDa and 112 available amino groups for conjugation. The ratios of polymer to the number of amino groups on each enzyme were 2:1 and 1:1. The conjugation reactions were carried out for 30 min in a 0.2 M borate buffer (pH = 8.5). To remove the unreacted polymer, the free *N*-hydroxysuccinimide (NHS), and any remaining native protein, the crude polymer−enzyme mixtures were purified using a Sephadex G-75 column, eluting with phosphate buffer 0.1 M, pH 7.4, at the flow rate of 1.5 mL/min. The effluent from the column was monitored at 226 nm. The first eluting fractions containing only the conjugated proteins were collected, concentrated, and desalted by dialysis. The samples were then lyophilized to give a dry powder. The purity of the collected fractions was verified by the gel filtration column. The protein content in each sample was determined by bicinchoninic acid reaction (BCA assay) using a Pierce protein assay kit and the degree of protein modification was evaluated spectrophotometrically by the trinitrobenzensulfonic acid reaction method described by Habeeb.[34] The results are expressed as a percentage of modified amino groups relative to the total amount of amine groups present on the enzyme.

Enzymatic Assays. *RNase Assay.* The enzymatic activity of the native and conjugated RNase was evaluated as described by Crook et al.[35] Briefly, 100 μL aliquots of free and conjugated enzyme (0.2−0.4 mg/mL) were added to 1 mL of 1.5 mg/mL of cytidine 2′,3′-cyclic monophosphate dissolved in 0.1 M Tris/acetate buffer pH 7.0. The solution was immediately transferred in a 1 cm cuvette and the hydrolysis of the substrate was measured by UV for 20 min at 287 nm. The data were plotted with a first-order rate equation, and the rate of the reaction was calculated. This kinetic rate is directly proportional to the activity of the enzyme. The activity of the POZylated or PEGylated enzyme is reported as a percentage of the native enzyme.

Uricase Assay. The method described by Mahler[36] was followed for uricase. Briefly, 100 μL of free and conjugated enzyme (0.5−1 mg/mL) was added to 1 mL of 0.002 mg/mL of uric acid dissolved in 0.05 M borate buffer pH 9.0. The solution was immediately transferred into a 1 cm cuvette, and the hydrolysis of the substrate was measured by UV for 3 min at 292 nm. The residual activity of the conjugates was calculated as reported above.

Catalase Assay. The catalase activity was determined according to the method of Beers and Sizer.[37] Briefly, 100 μL aliquots of free and conjugated enzyme (0.05−1 mg/mL) were added to 0.05% (v/v) of hydrogen peroxide in 0.01 M phosphate buffer pH 7.0. The solution was immediately transferred into a 1 cm cuvette and the hydrolysis of the substrate was measured by UV for 2 min at 240 nm. The residual activity of the conjugates was calculated as reported above.

Conjugation of POZ-NHS to Insulin. A suspension of insulin (250 mg, MW 5807 Da) in 5.6 mL of boric acid (50 mM) was slowly acidified by the addition of 1 N HCl until a clear solution was obtained. The solution pH was then adjusted to 10.5 by the addition of 1 N NaOH solution. To this solution was slowly added 6.9 mL of a solution of PEOZ-NHS 10K in HCl solution (pH 2.5, 70 mg/mL, 4.1×10^{-5} mol). The solution pH was adjusted to 10.5 by adding 0.5 N NaOH solution. The clear solution was allowed to mix gently at room temperature for 5−7 min, before it was acidified to 2.4 by the addition of 1 N HCl acid. This reaction was monitored by reverse phase HPLC using a C-18 column. The chromatogram showed that there was 48.5% monoconjugated PEOZ-Insulin and 10.6% diconjugated PEOZ-Insulin and the rest native insulin. The monoconjugated PEOZ-Insulin was separated primarily as the lysine (B29) conjugated species using ion-exchange chromatography (IEC, Sepharose SP column) and the eluent was desalted by buffer exchange into deionized water.[38] The product was analyzed for purity by SDS-PAGE and reverse-phase chromatography and for mass by MALDI-TOF.

Conjugation of POZ-NHS to BSA. BSA (90 mg, 1.344 μmol, with 60 available amino groups) was dissolved in 0.1 M sodium borate buffer pH 8.5, and a 5× molar excess of activated polymer, PEOZ-NHS 5 kDa, PEG-NHS 5 kDa, PEOZ-NHS 10 kDa, or PEG-NHS 10 kDa, was added. Each was mixed for several seconds until a homogeneous solution was obtained, then allowed to sit at room temperature for 5 h. The reaction was terminated by the addition of a 5× molar excess of glycine. An ultrafiltration cell with a 30 kDa molecular weight cutoff membrane (Amicon XM-30) was used to remove unreacted polymer. Cationic exchange chromatography was next used to separate the conjugate from the protein and polymer. A SP-Sephadex C-25 column (3 × 18 cm) was equilibrated with 20 mM phosphate buffer pH 3.9 and eluted with a 0 to 0.5 M sodium chloride gradient at a flow rate of 1 mL/min. The fractions containing the conjugated protein were collected and concentrated and desalted by ultrafiltration. The samples were then lyophilized to give a dry powder. The protein content in each sample was determined by the BCA assay, and the degree of protein modification was evaluated by the trinitrobenzensulfonic acid reaction method.

Erythrocyte Compatibility Study. One milliliter of freshly collected heparinized mouse blood was centrifuged at 2000 rpm for 10 min, and the precipitated erythrocytes were washed three times with PBS buffer. The red blood cells (RBCs) were resuspended in the buffer and diluted to have an optical density between 0.6 and 0.7 at 650 nm. This stock solution dispersion was freshly prepared and used within 48 h after preparation. Erythrocyte suspension (300 μL) was added to 300 μL of phosphated buffered saline solutions (PBS buffer) containing either PEOZ or PEG (0.2−10 mg/mL) at different molecular weights (5, 10, and 20 kDa), and the samples were incubated at 37 °C for 60 min under constant shaking. After centrifugation at 2000 rpm for 10 min, the released hemoglobin was measured by optical density (OD) at 414 nm. Complete hemolysis, as a

positive control, was achieved by using a 1% v/v solution of Triton X-100 in water, a surfactant known to lyse RBCs. The RBC-PBS solution was used as the negative control. The percentage RBC lysis was calculated according the following formula:

$$\%\text{lysis} = [(A_{\text{polymers}} - A_{\text{blank}})/(A_{100\%\text{lysis}} - A_{\text{blank}})]100$$

where A_{polymer} is the absorbance value of the hemoglobin released from the RBCs treated with the polymer solution; A_{blank} is the absorbance value of the hemoglobin released from the RBCs treated with PBS buffer; and $A_{100\%\text{lysis}}$ is the absorbance value of the hemoglobin released from RBCs treated with 1% Triton X-100.

Efficacy of POZ-Insulin in Rat Model. The effect of POZ conjugated insulin on blood glucose lowering in naïve rats was the efficacy model used to study the activity of the conjugate. An in-house institutional animal care and use committee (IACUC) reviewed and approved the study protocol. Four groups of female Sprague−Dawley rats (8−9 weeks, 200 g) with four animals per group were subcutaneously dosed with normal saline (control), insulin, insulin glargine, or PEOZ 10K insulin. The insulin and insulin glargine samples were dissolved in acidified normal saline. The dose of each insulin formulation was 10 IU/kg. At time intervals of 0, 0.5, 1, 2, 4, 6, 8, and 24 h, blood drops of 5−10 μL volume were removed from the tail vein through a needle prick. Each drop was analyzed with the aid of a blood glucose meter (OneTouch) and measurements were recorded in mg/dL of glucose.

Immunogenicity of POZ-BSA in Rabbit Model. The 70 day standard rabbit protocol was used in this study. An IACUC at the contract research laboratory reviewed and approved the study protocol. New Zealand white rabbits were divided into 5 groups of 2 animals per group. The test formulation for each group contained BSA, PEOZ 5 kDa BSA, PEG 5 kDa BSA, PEOZ 10 kDa BSA, and PEG 10 kDa BSA dissolved in normal saline. On day 0, 10 mL of blood was bled from each animal and spun to collect a baseline serum sample. The animals then received their primary immunization dose of 500 μg of antigenic protein injected subcutaneously. At the same time, Freund's adjuvant was also injected subcutaneously through a different site on the skin. Booster doses of 250 μg antigen and Freund's adjuvant were administered on days 14, 28, and 42. At time points of 35, 58, and 72 days, a 5 mL sample of blood was collected from each animal for serum sample analysis.

Each serum sample was assayed by ELISA for antibodies to BSA. 96 well flat-bottom high binding polystyrene plates (Immulon 2HP, ThermoFisher) were coated with BSA dissolved in borate buffer and allowed to incubate overnight in a refrigerator. The next day, the excess buffer was discarded and each well was washed. A measured amount of rabbit serum was added to the first well, mixed, and then appropriately diluted to the adjacent well by a factor of 2 each time. The plate was then incubated overnight in a refrigerator. The secondary antibody, HRP-SA 2° (goat antirabbit) dissolved in blocking buffer, was added to each well and the plate allowed to stand at room temperature for 3 h. The developer solution consisted of 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) in citrate buffer with 30% hydrogen peroxide. A measured volume of the developer solution was added to each well, and after 20 min, the color produced was measured at 405 nm in a plate reader.

Toxicity Studies. Two acute dose studies were performed in female Sprague−Dawley rats (8−9 weeks, ~200 g) to determine the maximum tolerated dose (MTD) of a PEOZ−OH 10 kDa polymer. The animals (3 per dose group) were intravenously administered the test article dissolved in 0.9% sodium chloride injection. A control group was administered 0.9% sodium chloride injection.

In the single acute dose tolerance study, the doses were 0.5, 1, and 2 g/kg. Blood was collected 1 and 7 days postdose for serum and complete blood count (CBC) analysis. Animals sacrificed on day 7 for gross examination of organs. In the repeat dose study, the animals received 4 weekly doses of 0.5, 1, and 2 g/kg. Blood was collected 1 and 7 days after the last day of dosing for serum and CBC analysis. Animals were sacrificed for gross examination of organs.

One multiple dose study was performed in female Sprague−Dawley rats (8−9 weeks, ~200 g) to determine the maximum tolerated dose (MTD) of a PEOZ-COOH 20 kDa polymer. Eight animals were dosed intravenously (tail vein) at a dose of 50 mg/kg on days 0, 2, 4, 7, 9, 11, and 14. The dose volume was between 0.3 and 0.5 mL. Blood was collected on days 15 and 21 for serum chemistry analysis and comprehensive CBC. Half the number of animals was sacrificed on day 15 and the rest on day 21. The kidneys (left and right), liver, and spleen were harvested from each animal and stored in 10% neutral buffered formalin. Each organ was imbedded in wax, sectioned, fixed on slides, and examined under a light microscope.

■ RESULTS AND DISCUSSION

Polymer Properties. Different solvents were tested as suitable polymerization media in the preparation of PEOZ, PMOZ, and PPOZ. Acetonitrile and chloroform were the desired solvents for PMOZ, PEOZ, and PPOZ, while chlorobenzene and dimethylacetamide worked well with PEOZ and PPOZ only. The polymerization times ranged from 1 to 40 h and this was dependent on the molecular weight being synthesized, the solvent selection, and the temperature of the reaction. Each batch of POZ-OH and POZ-COOH was characterized by ^{1}H NMR spectroscopy, MALDI-TOF mass spectrometry, and size exclusion chromatography (SEC). The ^{1}H NMR data of a typical PEOZ sample showed the pendent peaks at 1.12 ppm ($\boldsymbol{CH_3}CH_2CO-$); 2.41 ppm ($CH_3\boldsymbol{CH_2}CO-$), and the backbone peak of 3.47 ppm (-N$\boldsymbol{CH_2CH_2}$N-) as shown in Figure 3. When methyltriflate was used as the initiator, the initiating methyl peak appeared as two singlets at 2.9 ppm (small) and 3.05 ppm (large) ($\boldsymbol{CH_3}$-NCH_2CH_2-). When the polymer was terminated with a

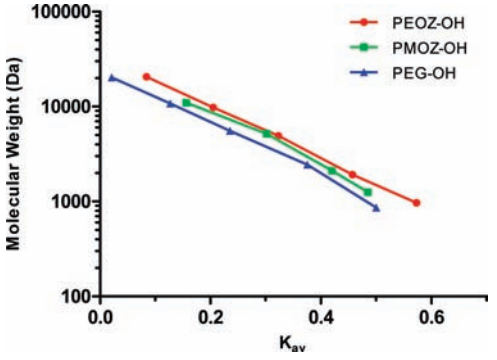

Figure 5. Correlation of hydrodynamic volume and molecular weight of PEG, PEOZ, and PMOZ determined by aqueous size-exclusion chromatography. The hydrodynamic volume is directly related to the distribution coefficient (K_{av}).

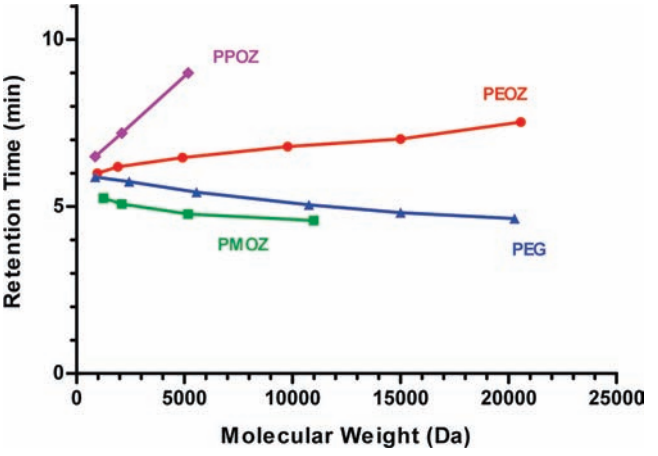

Figure 6. Correlation of the hydrophilicity−lipophilicty balance of PEG, PMOZ, PEOZ, and PPOZ as determined by reverse phase chromatography.

hydroxyl group, the terminal methylene group appeared at 3.8 ppm (-$\boldsymbol{CH_2}$-OH).

MALDI-TOF mass spectrometry was also performed to evaluate the polymer distribution. The polymers showed a monomodal polymer distribution with main mass signals spaced by $\Delta m/z$ = 99 in agreement with the monomer unit mass of ethyloxazoline = 99.13 g/mol. Figure 4 is an example of a 5 kDa PEOZ-OH polymer.

GPC chromatographic analyses were used to confirm that purified POZ reagents had a defined molecular weight (MW) with polydispersity indices 1.02−1.10. Their retention times were comparable to PEG reagents of similar molecular weights. However, GFC analyses showed that PEG has a hydrodynamic volume slightly larger than that of PMOZ and PEOZ. Figure 5 compares the molecular weight (log scale) against the distribution coefficient (K_{av}) for each polymer type and size. The value of K_{av} is calculated from the solute elution volume, the void volume, and the volume of the SEC media in the columns used.[39] The data also suggest that POZ is less hydrated than PEG, a property that can be verified by microcalorimetry. This observation suggests that POZ is less of a desiccant than PEG.

RP-HPLC chromatography of PMOZ, PEOZ and PPOZ showed differences in retention times relative to polymer type and size. Figure 6 shows that, as the molecular weights of PMOZ and PEG increase, their retention times decrease thereby suggesting increased hydrophilic behavior. On the other hand, the retention time of PEOZ and PPOZ increase with increasing molecular weights. This suggests that PEOZ is relatively more lipophilic than PMOZ and PEG. It is important to note that PMOZ and PEOZ are highly water-soluble, while PPOZ is sparingly water-soluble.

The viscosity of aqueous PEG and PEOZ solutions is illustrated in Figure 7. The plot compares the viscosity of a 40% w/v solution of PEG and PEOZ at molecular weights of 10, 20, 30, and 40 kDa. The results show that linear and branched PEOZ have a significantly lower viscosity than PEG especially at the higher molecular weights of 20, 30, and 40 kDa. This property is important, as it allows for ease of formulation, filterability, and syringeability of POZ conjugates at higher concentrations.

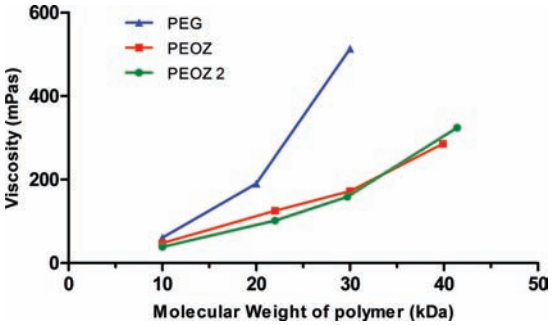

Figure 7. Viscosity of PEG and PEOZ of different molecular weights at 40% w/v solution and at 25 °C.

Table 1. Hydrolysis and Reactivity Rates of PEOZ and PEG Reagents

	half- life, $t_{1/2}$, at pH 8.0 (min)	
polymer	hydrolysis	reactivity with glycyl-glycine
PEOZ-SC (5 kDa)	5.40	3.28
PEG-SC (5 kDa)	5.90	3.02
PEOZ-p-NPC (5 kDa)	31.02	19.10
PEG-p-NPC (5 kDa)	40.03	25.14
PEOZ-NHS (10 kDa)	15.47	7.54
PEOZ-NHS (5 kDa)	14.08	5.75
PEG-NHS (5 kDa)	20.08	6.02

Functional POZ. In order to investigate the different strategies employed in POZ conjugation to proteins or peptides, several functional POZ reagents had to be made and characterized. The procedures previously described for other polymer activation were found to be suitable for the synthesis of electrophilic reagents such as PEOZ-NHS, PEOZ-p-NPC, and PEOZ-SC. Kinetic investigation of these POZ reagents showed that they had comparable reactivity towards amino groups on proteins and peptides, but slightly weaker stability in alkaline water, when compared to similar PEG reagents. The half-lives ($t_{1/2}$) for the hydrolysis of PEOZ-NHS, PEOZ-p-NPC, and PEOZ-SC in pH 8 borate buffer are 14.08, 31.02, and 5.4 min as shown in Table 1. The $t_{1/2}$ hydrolysis values were about 75% the value of their PEG counterparts. The $t_{1/2}$ reactivity values of PEOZ and PEG SC and NHS reagents were similar, but the PEOZ-p-NPC reagent was about 75% that of the corresponding PEG reagent. A comparison of $t_{1/2}$ values of each reagent showed that the reactivity rates with glycyl-glycine were twice as fast as their corresponding hydrolysis values. Even though one cannot rule out the effect of alkaline pH conditions on the premature release of *N*-hydroxysuccinimide, one must note that the fast amine-directed reactivity rate would be an important property when describing the functionality of these POZ reagents.

Enzyme Conjugation. To study the conjugation of PEG and POZ to enzymes, we selected three different candidates, namely, RNase, catalase, and uricase. They were chosen because their natural molecular conformation, i.e., a monomeric form for RNase, the dimeric form for catalase, and the tetrameric form for uricase. The molar ratios of polymer to available amino groups on each enzyme were 1:1 and 2:1. Each conjugation mixture was analyzed by gel filtration HPLC and then purified to remove free polymer or proteins. As an example, Figure 8 shows

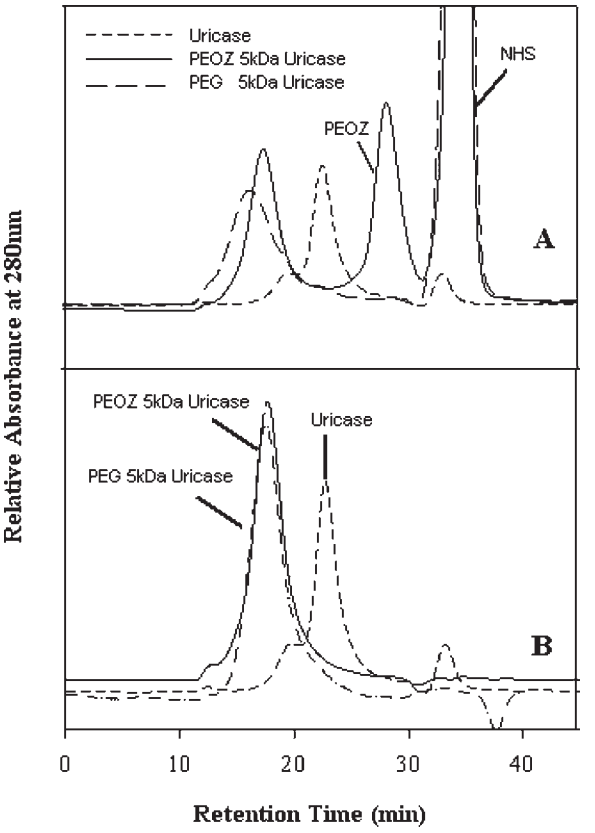

Figure 8. Panel A: HPLC-GFC profiles of uricase, PEOZ 5 kDa uricase, and PEG 5 kDa uricase in reaction mixtures after 30 min of mixing. Panel B: HPLC-GFC profiles of native uricase, PEOZ 5 kDa uricase, and PEG 5 kDa uricase after purification with Sephadex G-75.

the chromatographic elution of uricase conjugates before (panel A) and after purification (panel B). Uricase almost completely reacts with the functional polymers, and after purification, the excess of PEOZ and free *N*-hydroxysuccinimide (NHS) was removed. The degree of conjugation was determined by the Habeeb method,[34] and each enzyme had its own biological activity tested as mentioned in the Methods and Materials section. The results showed that the degree of modification and the *in vitro* bioactivity for each enzyme conjugate were similar for PEOZ and PEG of 5 kDa and 10 kDa molecular weights (Table 2). As expected, when the degree of enzyme modification was lower (as in the case of the 1:1 conjugates), the enzyme activity was higher.

Insulin Conjugation. The pure lyophilized PEOZ 10 kDa insulin product was analyzed by reverse phase chromatography and shown to have a purity of >97%. SDS-PAGE was used to verify a single monoconjugated species, and the mass was measured by MALDI-TOF as 16 496 Da. The IEC method was able to identify the desired B29 conjugated isomer from the A1 and B1 conjugated isomers.

BSA Conjugation. BSA was chosen as the model antigenic protein because of its known immunogenicity in different animal models. The method of conjugation employed uses a large excess of PEOZ-NHS or PEG-NHS at molecular weights of 5 and 10 kDa.[40] The titration of the free amino groups in the conjugated samples showed that both POZ and PEG provided similar degrees of modification. They were about 60% for the 5 kDa polymers and about 74% for the 10 kDa polymers

Table 2. Characteristics of Polymer−Enzyme Conjugates

compounds	polymer:NH_2 molar ratio	% of modified amino groups	% activity
RNase			100
PEOZ 5 kDa RNase	1:1	50	30
PEOZ 5 kDa RNase	2:1	70	25
PEG 5 kDa RNase	1:1	48	35
PEG 5 kDa RNase	2:1	72	27
uricase			100
PEOZ 5 kDa uricase	1:1	38	70
PEOZ 5 kDa uricase	2:1	50	45
PEG 5 kDa uricase	1:1	35	72
PEG 5 kDa uricase	2:1	53	48
catalase			100
PEOZ 5 kDa catalase	1:1	35	90
PEOZ 5 kDa catalase	2:1	37	88
PEG 5 kDa catalase	1:1	38	85
PEG 5 kDa catalase	2:1	40	79

Table 3. Characteristics of Polymer Conjugates for the Immunogenic Studies

compounds	protein content[a] (wt)%	% of modified amino groups	M_w[b] (kDa)
BSA			66
PEOZ 5 kDa BSA	0.18	60	151.8
PEG 5 kDa BSA	0.11	66	145.2
PEOZ 10 kDa BSA	0.034	74	158.4
PEG 10 kDa BSA	0.016	72	168.3

[a] Protein content evaluated in 1 mg of conjugates. [b] Estimated by SEC using protein standards.

(Table 3). Each PEOZ conjugate was analyzed by GPC for apparent molecular weights and for traces of free polymer or BSA. After purification, the amounts of free BSA and unreacted PEOZ were below quantifiable limits.

Erythrocyte Compatibility Study. The effect of POZ on the integrity of the erythrocyte membrane was investigated by the hemolysis study. The percent of cell lysis, as observed by absorbance measurements at 414 nm, showed that the $A_{polymers}$ value for POZ was negligible even at the polymer concentration of 10 mg/mL. The A_{blank} value, which corresponded to the solution of RBCs incubated with PBS, was slightly higher than that of the $A_{polymers}$ solution. This observation is consistent with reports on other polymers like PEG, where it is suggested that nonionic polymers might have a protective effect on cell membranes. It is important to note that the plasma was washed out in this study. This would make the RBCs more sensitive to cell-to-cell contact, external stress, and lytic agents. Therefore, POZ acts like a protective agent in the same way that plasma proteins behave in providing hemocompatibility against external stress and foreign bodies.[41]

Efficacy of POZ-Insulin in Rat Model. The blood glucose lowering in naïve rats is the quickest and most efficient way to determine the activity of polymer conjugated insulin. It provides two parameters, the initial onset of action in lowering of blood glucose levels (an indirect t_{max} parameter) and the sustainability of blood glucose lowering (a steady-state pharmacodynamic parameter). Figure 9 illustrates the glucose lowering effect of insulin, insulin-glargine, and PEOZ 10 kDa insulin after subcutaneous administration in naïve female Sprague−Dawley rats. The results showed that the test compounds were active and were able to lower the blood glucose levels from 120 to about 40 mg/dL. This effect was achieved within 1 h, 2 h, and 4 h for insulin, insulin-glargine, and PEOZ 10 kDa insulin, respectively. The effect was reversed after 2 and 4 h for insulin and insulin-glargine, respectively. However, the blood glucose lowering effect was sustained for about 8 h in the case of PEOZ 10 kDa insulin. This suggests that PEOZ was able to protect insulin from rapid clearance and proteolysis.

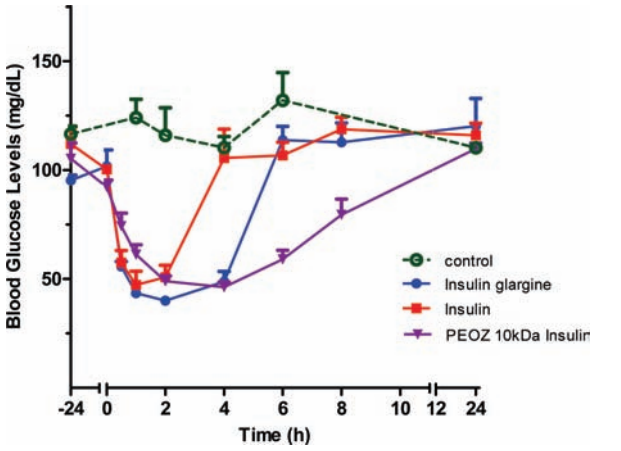

Figure 9. Effect of subcutaneous injection of insulin, insulin glargine, and PEOZ 10 kDa insulin on the blood glucose levels in male Sprague−Dawley rats (dose = 10 U/kg; n = 4; mean ± SEM).

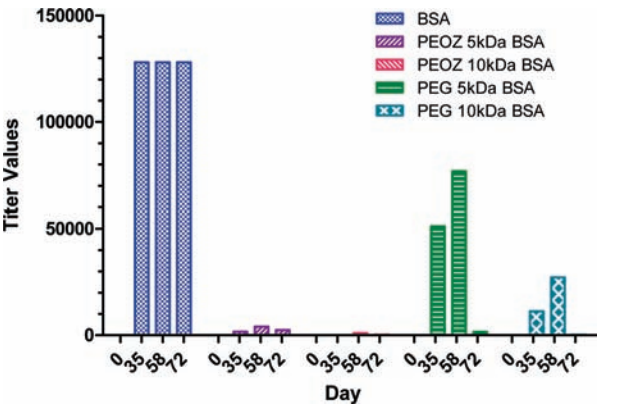

Figure 10. Relative immunogenicity of BSA, PEG BSA, and PEOZ BSA in rabbits treated as measured by anti-BSA antibody levels. Animals with treated with immune booster on days 1, 14, 28, and 42.

Immunogenicity Studies of BSA Conjugates. The ability of POZ to camouflage the immunogenicity of BSA was determined in a 72 day rabbit protocol study. The animals were dosed on days 1, 14, 28, and 42 and the serum samples collected on days 0, 35, 58, and 72. Figure 10 shows that antibody titer values for BSA were extremely high and the maximum limit of the ELISA assay. PEOZ BSA and PEG BSA dosed animals had significantly lower titer values and the 10 kDa conjugate was better than the 5 kDa conjugates because of the higher degree of amine modification and the larger hydrodynamic volume of the conjugate (Table 3). POZ had a slightly higher attenuation of BSA immunogenicity than PEG at each molecular weight tested.

Table 4. Differences in Properties between PEG and POZ

PEG	POZ
Difficult polymerization process and there are limited suppliers of quality raw PEG	POZ easily synthesized with standard glassware and with nonexplosive materials
Forms peroxides (need to add antioxidant)	Does not form peroxides
Stable only at temperatures < −20 °C	Stable at room temperature and in water
Diol content of 2−6%	No Diol
Highly viscous when in aqueous solutions	Low viscosity
Low drug loading	High drug loading
Difficult to actively target	Active targeting possible with pendent polymers
Can accumulate in some organs and form vacuoles because of desiccant nature of PEG	Readily cleared from body and is not hygroscopic

Toxicity Studies. In the acute dose studies, PEOZ 10 kDa was administered intravenously to Sprague−Dawley rats, in single and multiple injections at doses of 500, 1000, and 2000 mg/kg. No adverse events were observed. The body weights and food intake levels of each animal were normal. Blood counts and serum chemistry were normal when compared to the control group that received 0.9% (w/v) sodium chloride. The key organ (liver, kidney, lung, spleen, heart, and gastrointestinal tract) sizes, weights, morphology, and texture were also normal. In the multiple dose study, rats received seven intravenous doses of 50 mg/kg of PEOZ 20 kDa, over a period of 14 days. The blood counts and serum chemistry at days 15 and 21 were normal when compared to the control group. The key organ sizes, weights, morphology, and texture were also normal, and the histopathology of the kidney and spleen showed no microscopic differences when compared against the organs from the control animals. PEOZ was well-tolerated at the molecular weights of 10 and 20 kDa.

CONCLUSIONS

Three types of POZ polymers were prepared and characterized. Linear POZ with molecular weights of 1−40 kDa were synthesized, with high batch to batch reproducibility, low polydispersity values, and yields of ∼60−80%. The polymers prepared had no chain transfer biproducts and no high molecular weight species. Characterization studies show that both PMOZ and PEOZ are highly water-soluble; they have hydrodynamic volumes that are comparable and slightly lower than PEG; PEOZ is slightly more lipophilic than PMOZ and PEG, and is also significantly less viscous than PEG. The latter observation allows for the delivery of high dose proteins and peptides where viscosity is a hindrance in product formulation and administration. POZ can be easily functionalized from the terminal hydroxyl or carboxyl group to allow for conjugation to amine, thiol, aldehyde, ketone, and acetylene groups. POZylation of enzymes, proteins, and peptides produced conjugates with retained bioactivity that were comparable to similar conjugates modified with PEG. The attachment of POZ 10 kDa to lysine B29 of insulin produced a monoconjugate product that was able to lower blood glucose levels and also sustain its activity for a period of 8 h. In future papers, we will discuss other types of POZ attachments using click chemistry and enzyme catalyzed techniques. Toxicity studies in rats showed that PEOZ is safe when administered intravenously and the maximum tolerated dose (MTD) was greater than 2 g/kg. In addition, PEOZ can shield the immunogenic sites on an antigenic protein such as BSA.

POZ is a suitable alternative to PEG. Table 4 list the areas where POZ has many advantages over PEG. Another advantage not discussed in this paper is the ability to link several small drug molecules to a single polymer backbone, sometimes called "pendant drug attachment". The terminal end of the polymer remains free and can be functionalized for the attachment of targeting moieties. Hence, POZ not only has the ability to increase drug loading, but also the ability to carry this payload to specific molecular receptors.

Life Technologies, 29851 Willow Creek Road, Eugene, Oregon 97402, United States

ABSTRACT: The use of genetically encoded small peptide tags such as polyhistidine and tetracysteine tags has become important for protein purification and enrichment. An improved affinity purification of tetracysteine (CCXXCC) tagged proteins has been achieved using a nonfluorescent, photochemically stable bisarsenical affinity ligand SplAsH. The photochemical stability of the SplAsH-biotin, shown in compound **5**, is superior to FlAsH-EDT$_2$ and ReAsH-EDT$_2$. An application of the SplAsH tag for affinity purification of tetracysteine-tagged proteins is reported.

INTRODUCTION

Protein modification with reporter tags has allowed the study of protein localization and protein−protein interactions inside living cells.[1−3] Traditionally, the protein of interest has to be isolated *in vitro*, labeled with a reporter tag, then reintroduced into cells by microinjection or electroporation. The use of genetically encoded fluorescent proteins such as green fluorescent protein (GFP) has provided a simple and powerful tool to study protein dynamics in cell biology.[4,5] However, GFP is a large protein (27 kDa), which could interfere with the physiological role of the protein of interest.[6,7] Small peptide tags, such as the hexahistidine (His$_6$) tag and tetracysteine (CCPGCC) tag, have greater advantage than GFP in protein labeling, because the small tags have minimal interference with the protein of interest.[6,8] The tetracysteine tag combined with either fluorescein arsenical hairpin binder (FlAsH-EDT$_2$, Figure 1) or Resorufin arsenical hairpin binder (ReAsH-EDT$_2$, Figure 1) provide useful tools for site-specific labeling of recombinant proteins inside live cells.[9−12] An especially important and useful feature of these molecules is their fluorogenicity; the small molecules FlAsH-EDT$_2$ and ReAsH-EDT$_2$ are membrane-permeant and almost nonfluorescent, so they can easily get into cells, then they bind with high affinity and specificity to the tetracysteine domain, causing the protein-bound dyes to become highly fluorescent.

On the basis of the high affinity and high specificity of the interaction of biarsenical dyes with the tetracysteine motif, methods using biarsenicals immobilized on a matrix as a stationary phase for affinity purification of tetracysteine-tagged proteins have been developed.[11,13,14] The interaction between biarsenical dyes and the tetracysteine motif can be easily reversed by incubation with dithiols such as 1,2-ethanedithiol (EDT) or dithiothreitol (DTT). This gives a gentle and mild elution condition with minimal disruption of protein structure and activity.

The most commonly used His$_6$-tag proteins are purified by binding to metal ions (Ni^{2+} or Co^{2+}) which are chelated to an affinity matrix followed by elution with high concentrations of imidazole or low pH.[15] This condition may disrupt some protein structure and activity.[16] In addition, the purified protein is often contaminated with intrinsic histidine-rich proteins and small amounts of metal ions, which may inhibit many enzyme activities.[11,13]

The major limitation to using the FlAsH affinity matrix for purification of tetracysteine-tagged proteins is a stability issue. The compounds FlAsH-EDT$_2$ and ReAsH-EDT$_2$ are photochemically unstable,[17] which limits their wide application in purification of tetracysteine-tagged proteins. We report herein on our successful efforts to apply a photochemically stable bisarsenical affinity ligand for affinity purification of tetracysteine-tagged proteins.

EXPERIMENTAL PROCEDURES

General Materials and Methods. All chemicals and solvents were purchased from Aldrich, Acros, or TCI and were used without further purification. Thin layer chromatography (TLC) was performed on aluminum-backed plates with silica gel 60 with F_{254} indicator. Flash column chromatography was carried out on silica gel (230−400 mesh). High-performance liquid chromatography (HPLC) analysis was performed on a Waters 600 instrument equipped with a Waters photodiode array detector. All moisture- or air-sensitive reactions were carried out under a static argon atmosphere. ^{1}H NMR (400 MHz) spectra were recorded at room temperature on a Bruker ADVANCE-400 spectrometer with residual proton resonances in deuterated solvents (DMSO-d_6, or MeOD-d_4) as the internal standard. LC/MS spectra were obtained with a Waters micromass ZQ instrument.

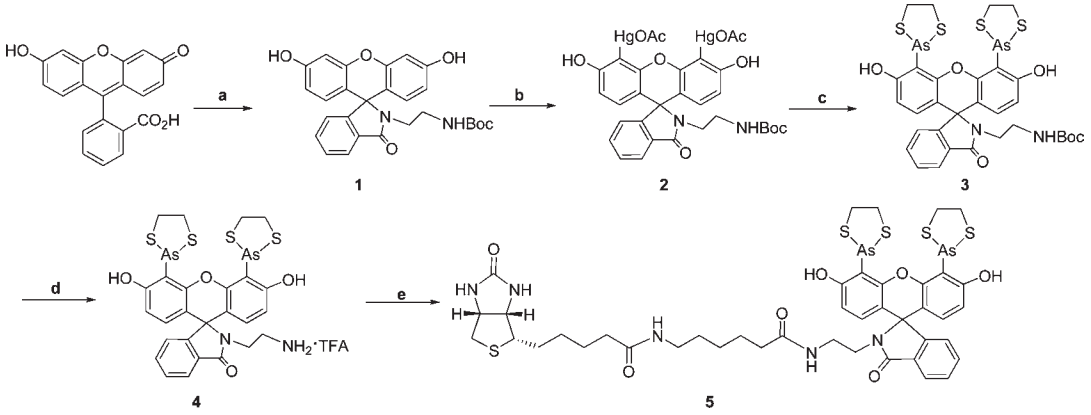
fluorescein in 95% yield.[18] Fluorescein methyl ester (1.0 g, 2.9 mmol), and BocHNCH$_2$CH$_2$NH$_2$·HCl (1.14 g, 5.8 mmol) were dissolved in 10 mL DMF. Triethylamine (806 μL, 5.8 mmol) was added. The reaction mixture was heated at 100 °C overnight in a sealed pressure tube. After cooling to room temperature, the solvent was evaporated *in vacuo*. The residue was dissolved in ethyl acetate (80 mL); washed with H$_2$O (40 mL), 0.1 M HCl (40 mL), and brine (40 mL); dried over Na$_2$SO$_4$; and concentrated *in vacuo*. The crude mixture was purified by column chromatography on SiO$_2$ (EtOAc/Hexane = 1:1−2:1) to afford **1** (1.12 g, 2.4 mmol, 82% yield) as a white solid. The obtained compound matches with data that is in the literature.[17]

***tert*-Butyl 2-(4′,5′-bis(mercuric acetate)-3′,6′-dihydroxy-3-oxospiro[isoindoline-1,9′-xanthene]-2-yl) ethylcarbamate (2).** Compound **1** (1.1 g, 2.3 mmol) was dissolved in 60 mL ethanol, then the solution was added to a solution of mercuric acetate (1.53 g, 4.8 mmol) in 4 mL HOAc and 100 mL H$_2$O. The reaction mixture was stirred at 65 °C overnight in a sealed pressure tube. After cooling to room temperature, the resulting white precipitate was filtered through filter paper, washed with H$_2$O (3 × 20 mL), and then dried under high vacuum to afford **2** (2.05 g, 2.1 mmol, 90% yield) as a white solid. The obtained compound matches with data that is in the literature.[17]

***tert*-Butyl 2-(4′,5′-bis(1,3,2-dithiaarsolan-2-yl)-3′,6′-dihydroxy-3-oxospiro [isoindoline-1,9′-xanthene]-2-yl) ethylcarbamate (3).** Compound **2** (1.0 g, 1.0 mmol) was suspended in 20 mL THF. Di-isopropylethylamine (DIPEA, 1.4 mL, 8.0 mmol), AsCl$_3$ (1.6 mL, 20 mmol, caution: very toxic), and Pd(OAc)$_2$ (20 mg) were added. The reaction mixture was stirred at 50 °C for 2 h under argon, then at room temperature overnight under argon. The reaction mixture was poured into acetone/aqueous phosphate buffer (1:1, 0.5 M K$_2$HPO$_4$, pH 7, 100 mL) containing ethanedithiol (EDT, 3 mL). After stirring for 30 min, CHCl$_3$ (50 mL) was added, and the mixture was stirred for another 30 min. The organic layer was collected, and the aqueous layer was washed with CHCl$_3$ (3 × 30 mL). The combined organic layers were dried over Na$_2$SO$_4$ and concentrated *in vacuo*. The crude mixture was purified by column chromatography on SiO$_2$ (elute first with toluene to remove arsenic−EDT complex, then elute with EtOAc/Hexane = 2:3) to afford **3** (760 mg, 0.94 mmol, 94% yield) as a white solid. The obtained compound matches with data in the literature.[17]

2-(2-Aminoethyl)-4′,5′-di(1,3,2-dithiarsolan-2-yl)-3′,6′-dihydroxyspiro[isoindoline-1,9′-xanthen]-3-one (4). Compound **3** (300 mg, 0.37 mmol) was dissolved in 8 mL CH$_2$Cl$_2$ at 0 °C. TFA (4 mL) was added. The reaction mixture was stirred at 0 °C for 2 h. The reaction mixture was concentrated *in vacuo*. The residue was precipitated in diethyl ether and dried under reduced pressure via a vacuum pump to afford **4** (290 mg, 0.35 mmol, 95% yield) as a yellow solid. ^{1}H NMR (400 MHz, DMSO-d_6): δ 10.01 (s, 2H), 7.85 (dd, 1H, J = 2.0, 6.6 Hz), δ 7.60 (s, 2H), 7.56 (m, 2H), 7.05 (dd, 1H, J = 2.0, 6.6 Hz), 6.52 (m, 4H), 3.50 (m, 8H), 3.26 (t, 2H, J = 5.8 Hz), 2.39 (m, 2H). ESI-MS $[M+H]^+$ m/z calcd. for 706.91, found 706.87.



***N*-(2-(4′,5′-Di(1,3,2-dithiarsolan-2-yl)-3′,6′-dihydroxy-3-oxospiro[isoindoline-1,9′-xanthene]-2-yl)ethyl)-6-(5-((3a*S*,-4*S*,6a*R*)-2-oxohexahydro-1*H*-thieno[3,4-*d*]imidazol-4-yl)pentanamido)hexanamide (5).** Compound **4** (72 mg, 0.09 mmol) and 6-((biotinoyl)amino)hexanoic acid succinimidyl ester (40 mg, 0.09 mmol, Life Technologies) were dissolved in 3 mL dry DMF. TEA (37 μL, 0.26 mmol) was added. The reaction mixture was stirred at room temperature for 1 h. Diethyl ether (20 mL) was added to the reaction mixture. The precipitate was collected by centrifuge and purified by column chromatography on SiO$_2$ (CHCl$_3$/MeOH = 10:1) to afford **5** (80 mg, 0.08 mmol, 85% yield) as a white solid. ^{1}H NMR (400 MHz, DMSO-d_6): δ 7.95 (s, 2H), 7.90 (dd, 1H, J = 2.0, 6.6 Hz), 7.58 (m, 2H), 7.06 (dd, 1H, J = 2.0, 6.6 Hz), 6.50 (m, 4H), 4.50 (m, 1H), 4.30 (m, 1H), 3.60 (m, 8H), 3.18 (m, 5H), 2.99 (m, 3H), 2.71 (m, 1H), 2.19 (t, J = 7.2 Hz, 2H), 2.03 (t, J = 7.2 Hz, 2H), 1.66−1.30 (m, 12H). ESI-MS $[M+H]^+$ m/z calcd. for 1046.07, found 1046.34.

Synthesis of Affinity Matrix 6. CrAsH-EDT$_2$ succinimidyl ester was prepared according to a literature procedure.[11] To a 20 mL plastic, fritted column with a Teflon stopcock and a cap to seal the column, 10 mL of amino-agarose (Affi-Gel 102, Biorad) in PBS buffer containing 0.1 mM EDTA, 5 mM β-mercaptoethanol (BME), and 0.1 mM EDT, pH 7.4 was added, followed by addition of 1 mL of CrAsH-EDT$_2$ succinimidyl ester (10 mM solution in DMSO, 10 μmol) and 0.5 mL of 1 M NaHCO$_3$. The resin was mixed at RT for 4 h by end-to-end rotation, and washed extensively with the same buffer. Capping of free amines was achieved by treatment with a 10-fold excess of *N*-acetoxysuccinimide (prepared from acetic acid and *N*-hydroxysuccinimide with dicyclohexylcarbodiimide in CH$_2$Cl$_2$) over total amines (~12 μmol/mL) in the same phosphate buffer with slow rotation for additional 2 h. The immobilized affinity matrix **6** was washed and stored in 50% EtOH at 4 °C.

Synthesis of Affinity Matrix 7. To a 20 mL plastic, fritted column with a Teflon stopcock and a cap to seal the column, 10 mL of *N*-hydroxysuccinimidyl ester (NHS) activated agarose (Affi-Gel 10, Biorad) in 1/1 isopropanol/DMF was added, followed by addition of 1 mL of compound **4** (20 mM solution in DMSO, 20 μmol) and 0.2 mL of TEA. The resin was mixed at RT for 2 h by end-to-end rotation, and washed with isopropanol and DMF. Unreacted NHS groups were quenched by treatment with 0.5 M ethanolamine in isopropanol for an additional 1 h. The immobilized affinity matrix **7** was washed with PBS buffer containing 0.1 mM EDTA, 5 mM BME, and 0.1 mM EDT, pH 7.4, and stored in 50% EtOH at 4 °C.

Affinity Purification of Tetracysteine-Tagged Proteins Using Affinity Matrixes 6 and 7. The GFP with a *C*-terminal CCPGCC tag as well as a *N*-terminal his$_6$ tag was overexpressed

Scheme 1. Synthesis of Nonfluorescent SplAsH-Biotin 5[a]

[a] Reaction conditions: (a) H_2SO_4, MeOH; $BocHNCH_2CH_2NH_2HCl$, TEA, DMF; (b) $Hg(OAc)_2$, HOAc, EtOH/H_2O; (c) $AsCl_3$, DIPEA, $Pd(OAc)_2$, THF; ethandithiol, acetone/PBS; (d) TFA, DCM; (e) 6-((Biotinoyl)amino) hexanoic acid succinimidyl ester, TEA, DMF.

in *Escherichia coli* using standard methods.[5] The collected cell pellet was lysed in 250 mM KCl, 50 mM KPO_4, 1 mM EDTA, 10 mM 2-mercaptoethane-sulfonate (MES), and 1 mM tris-(carboxyethyl) phosphine (TCEP), pH 7.5, by sonication. The total protein concentration of the lysate was measured using EZQ protein quantitation kit (Life Technologies), and GFP concentration was quantified by GFP intrinsic fluorescence. The freshly prepared GFP lysate (1 mL, ~2.5 mg/mL) was added to 0.5 mL of affinity matrixes **6** and **7**, respectively. The resin was mixed at RT for 2 h by end-to-end rotation. The mixture was transferred to a short column, the unbound material was collected, and the resin was washed with buffer (250 mM KCl, 50 mM KPO_4, 1 mM EDTA, 10 mM MES, 1 mM TCEP, pH 7.5, 3 × 2 mL), and then eluted with buffer (250 mM KCl, 50 mM KPO_4, 1 mM EDTA, 10 mM 2,3-dimercapto-propanesulfonate (DMPS), 3 × 0.5 mL). Fractions were analyzed by SDS-PAGE (NuPAGE, 4−12% Bis-Tris Gel, Life Technologies).

Purification by the polyhistidine tag was done using the standard immobilized metal affinity chromatography method (Life Technologies), as follows. The freshly prepared GFP lysate (1 mL) in 50 mM NaH_2PO_4, 500 mM NaCl, pH 8.0, was incubated with 1 mL of Ni^{2+}-NTA resin at RT for 1 h by end-to-end rotation. The mixture was transferred to a short column, the unbound material was collected, and the resin was washed with buffer (50 mM NaH_2PO_4, 500 mM NaCl, 20 mM imidazole, pH 8.0, 3 × 5 mL) and then eluted with buffer (50 mM NaH_2PO_4, 500 mM NaCl, 250 mM imidazole, pH 8.0, 3 × 0.5 mL). Fractions were analyzed by SDS-PAGE (NuPAGE, 4−12% Bis-Tris Gel, Life Technologies).

Kinetic Measurement of Binding Affinity of SplAsH-biotin 5 and Tetracysteine-Tagged Protein (GFP). The kinetic measurement of binding affinity of SplAsH-biotin **5** and tetracysteine-tagged protein (GFP) was carried out using the ForteBio system, which is a label-free, real-time detection system.[19] The streptavidin biosensor tips from ForteBio were prewet for 30 min in water prior to use. All interaction analyses were conducted at 25 °C in PBS buffer (pH 7.2) containing 5 mM MES, 0.1% BSA, and 0.05% Tween-20. The streptavidin biosensor tips were first incubated with SplAsH-biotin **5** (50 μM) to immobilize the SplAsH ligand onto the tips. Then, the SplAsH ligand coated tips were incubated with purified tetracysteine-tagged GFP (50 nM) in duplicate to generate the association curve. As a reference control, the SplAsH ligand coated tip was also incubated with a buffer solution. The dissociation curve was generated by incubating these tips with the PBS buffer described above. The *ForteBio Data Analysis Octet* software was used to process the curve by subtracting a sample curve from the reference curve, and the kinetic data were calculated by curve fitting.

RESULTS AND DISCUSSION

To improve the utility of carboxy-FlAsH-EDT_2 (CrAsH-EDT_2, Figure 1) in affinity purification of tetracysteine-tagged proteins,[11,20,21] our focus is to apply a photochemically stable FlAsH−EDT_2 analogue. Recently, a fluoro-substituted FlAsH (F_2FlAsH, Figure 1) has been reported to dramatically improve photostability.[22] However, the synthesis of F_2FlAsH gives poor overall yield (<4%), which limits its practical usefulness in applications in affinity purification.

We decided to focus on the use of a readily available nonfluorescent SplAsH **4** (Spirolactam Arsenical Hairpin binder, Scheme 1). SplAsH **4** was prepared according to the published procedure.[17] Briefly, fluorescein was converted to fluorescein methyl ester in MeOH using H_2SO_4 as a catalyst,[18] then the ester was reacted with mono Boc-protected ethylenediamine to give fluorescein spirolactam **1**.[23] The fluorescein spirolactam **1** was then converted to the bis-mercuric acetate derivative **2**[13] and then to the bis-arsenical derivative **3** by transmetalation with palladium acetate as a catalyst.[9] After cleavage of the Boc protecting group with TFA, SplAsH **4** was obtained in 63% overall yield in six steps. This synthesis can be easily scaled up for the preparation of multigram amounts of **4**. Compared to the synthesis of CrAsH-EDT_2 (16% overall yield),[11] the synthesis of SplAsH **4** has great advantages in terms of easy preparation and easy purification. The SplAsH **4** can be easily converted to SplAsH-biotin **5**. The absorbance maximum of SplAsH-biotin **5** was shifted from 509 to 242 nm with ε_{242} = 26 000 compared to FlAsH-EDT_2 (Figure 2), thus providing no inherent fluorescence whether or not it is bound to the tetracysteine motif.

To test the photochemical stability, CrAsH-EDT_2 and SplAsH-biotin **5** were each prepared in 100 μM concentration in degassed PBS buffer with 1 mM EDT, and 1 mL of each sample in a sealed quartz curvette was irradiated with a xenon arc lamp at 250 mW/cm^2. Samples were checked by HPLC every 30 min,

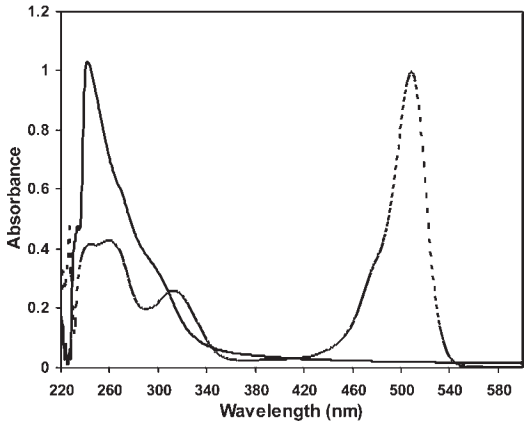

Figure 2. Absorbance spectra of FlAsH-EDT$_2$ (···) and SplAsH-biotin **5** (—) at PBS buffer.

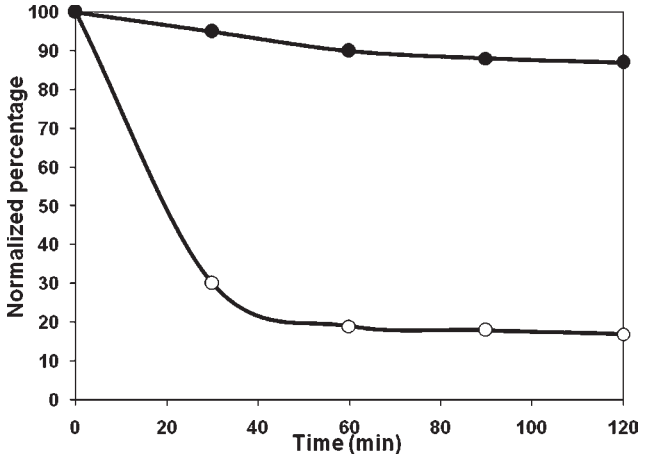

Figure 3. Photostability of CrAsH-EDT$_2$ (○) and SplAsH-biotin **5** (●) irradiated with a xenon arc lamp at 250 mW/cm^2.

and the results are shown in Figure 3. The results clearly show that the CrAsH-EDT$_2$ exhibits poor photochemical stability.[17] SplAsH-biotin **5** exhibits remarkably improved photochemical stability because blocking the quinoid tautomer formation by spirolactam formation eliminates the excited state that serves as an intermediate in the photobleaching process.[24]

In order to measure the binding affinity of SplAsH and tetracysteine-tagged protein, SplAsH-biotin **5** was first immobilized onto streptavidin sensor tips through biotin−streptavidin interaction. Then, the SplAsH coated sensor tips were incubated with tetracysteine-tagged GFP to generate the association curve, followed by incubating in buffer to get the dissociation curve (Figure 4). On the basis of the on-and-off rate, the dissociation constant K_D was calculated to be approximately 2.4 ± 1.2 nM. Compared to the dissociation constant K_D (~μM) for the interaction between His tag and Ni_2^+-NTA,[25] the SplAsH ligand has more than 1000-fold higher affinity (stronger, tighter binding) and thus should be much more useful for the capture and purification of low-abundance proteins.

To evaluate the application in affinity purification of tetracysteine-tagged proteins, the CrAsH-EDT$_2$ succinimidyl ester was coupled to Affigel-102 (Biorad), and the remaining free amines were capped with excess of *N*-acetoxysuccinimide.[11]

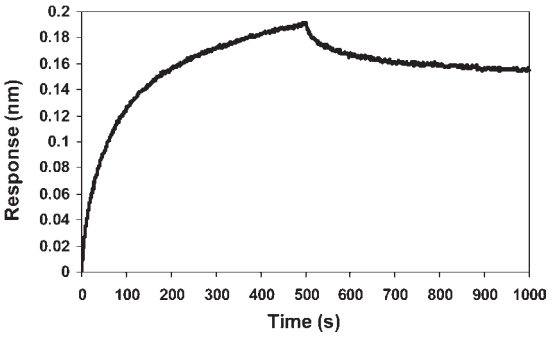

Figure 4. Kinetics of association and dissociation of SplAsH-biotin **5** and tetracysteine-tagged GFP.

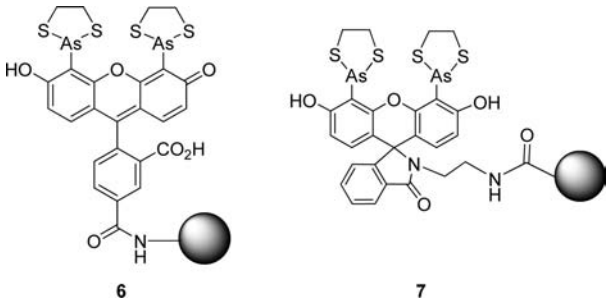

Figure 5. Affinity matrixes **6** and **7** used for purification of tetracysteine-tagged proteins.

SplAsH **4** was conjugated with Affigel-10 (Biorad), and unreacted NHS groups were quenched with ethanolamine. We chose the GFP with a *C*-terminal CCPGCC tag as well as a *N*-terminal his$_6$ tag as model test protein, because its recovery yield can be easily quantified by measuring the intrinsic fluorescence, and it can also be used to evaluate whether the two different purification methods will affect the GFP fluorescence property.[5,26] In separate, parallel experiments, the freshly prepared GFP lysate was mixed with CrAsH-EDT affinity matrix **6** and the new nonfluorescent affinity matrix **7** (Figure 5) in a buffer containing 250 mM KCl, 50 mM KPO_4, 1 mM EDTA, 10 mM MES, 1 mM TCEP, pH 7.5, for 2 h. The supernatant was collected from each, then each resin was washed with buffer, followed by eluting with buffer containing 10 mM DMPS. Fractions were analyzed by SDS-PAGE. For another comparsion, the same protein construct was purified by the conventional His$_6$:Ni^{2+}-NTA column.

It is well-known that the FlAsH ligand binds to the tetracysteine motif with high affinity and specificity, and the binding can be easily reversed by competing ligands, such as EDT, DTT, and DMPS.[11] These methods can be useful for the purification of native tetracysteine-tagged proteins. However, due to poor photochemical stability of CrAsH-EDT$_2$, the CrAsH-EDT affinity matrix **6** gave inconsistent results. Instead, SplAsH **4** displays superior photochemical stability. As shown in Figure 6, by using the new nonfluorescent affinity matrix **7** the desired protein was specifically captured and then eluted with DMPS to afford highly purified protein (90% purity) with reasonable yield (52% yield). Using the conventional His$_6$:Ni^{2+}-NTA method, the GFP was isolated in 92% purity and 70% recovery yield. The lower recovery yield is probably due to a stability issue of tetracysteine tag *in vitro*, by

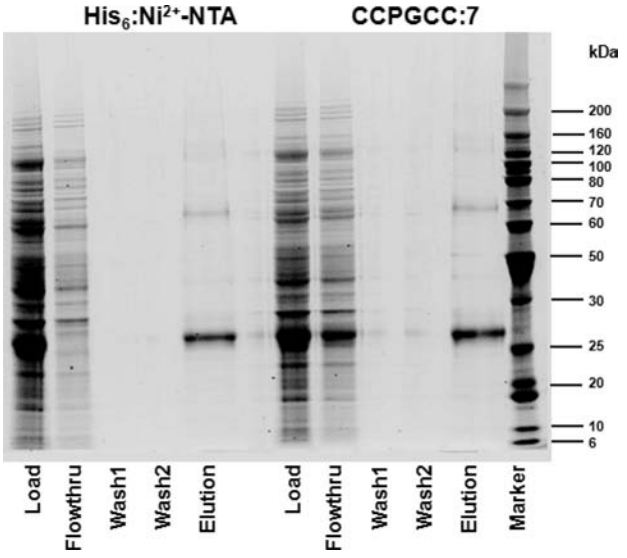

Figure 6. Affinity purification of a tetracysteine-tagged and his_6-tagged GFP using affinity matrix **7** and Ni^{2+}-NTA column. GFP lysate (load) was incubated with two supports, separated by pouring into columns (flowthrough), washed (wash), and eluted with either 10 mM DMPS or 250 mM imidazole (elution), respectively. The collected fractions were analyzed by a reducing 4−12% SDS-PAGE gel and stained with SYPRO-Ruby.

air oxidation and inactivation of the tetracysteine tag, and not due to instability of the new nonfluorescent affinity matrix **7**.

CONCLUSION

In summary, the superior photochemical stability of SplAsH **4** compared to CrAsH-EDT_2 can be applied for a new, improved method for protein affinity purification. SplAsH **4** can be easily prepared in large scale and high yield. SplAsH **4** retains high affinity and specificity for tetracysteine tags. This provides better affinity purification of tetracysteine-tagged proteins with SplAsH **4** than with CrAsH-EDT_2. In addition, SplAsH **4** is nonfluorescent whether or not it is bound to tetracysteine tags. This quenched property of SplAsH **4** provides an opportunity for potential surface-based applications by immobilizing SplAsH **4** onto beads or array surfaces to capture tetracysteine-tagged proteins, then performing protein detection, quantitation, and functional assays using dye-labeled detection antibody. Detailed studies of surface-based applications are currently underway.

Biologically Optimized Nanosized Molecules and Particles: More than Just Size

Michelle R. Longmire, Mikako Ogawa, Peter L. Choyke, and Hisataka Kobayashi*

Molecular Imaging Program, National Cancer Institute, National Institutes of Health, 10 Center Drive, Bethesda, Maryland 20892-1088, United States

ABSTRACT: The expanded biological and medical applications of nanomaterials place a premium on better understanding of the chemical and physical determinants of in vivo particles. Nanotechnology allows us to design a vast array of molecules with distinct chemical and biological characteristics, each with a specific size, charge, hydrophilicity, shape, and flexibility. To date, much research has focused on the role of particle size as a determinant of biodistribution and clearance. Additionally, much of what we know about the relationship between nanoparticle traits and pharmacokinetics has involved research limited to the gross average hydrodynamic size. Yet, other features such as particle shape and flexibility affect in vivo behavior and become increasingly important for designing and synthesizing nanosized molecules. Herein, we discuss determinants of in vivo behavior of nanosized molecules used as imaging agents with a focus on dendrimer-based contrast agents. We aim to discuss often overlooked or, yet to be considered, factors that affect in vivo behavior of synthetic nanosized molecules, as well as aim to highlight important gaps in current understanding.

INTRODUCTION

To create the least toxic and most biocompatible imaging agents, we must understand the behavior of nanosized particles and molecules in the human system. Defining optimal size, shape, and flexibility; determining core and surface modifications that alter in vivo behavior; as well as using methods for characterizing particles during synthesis that are predictive of in vivo behavior, will be important measures for successful clinical translation. Among the various nanomaterials, dendrimers are a promising platform for biomedical imaging and targeted drug delivery. Their versatility, tunable size, and highly adaptable surface chemistry make these particles advantageous for numerous imaging applications. Herein, we discuss often overlooked factors influencing the pharmacokinetics of nanosized molecules and particles designed for imaging and drug delivery, with a focus on dendrimer-based imaging agents. In addition, we aim to address broader issues related to nanotoxicology as it applies to the translation of nanomaterial science into clinical nanomedicine.

IDEAL IN VIVO BEHAVIOR

Ideally, all nanosized imaging agents would demonstrate high target tissue accumulation, rapid clearance from the body, and no associated toxicity. Although such an agent does not currently exist, the rational design of probes optimized for the above end points will lead to the development of better nanosized molecule-based imaging probes. Regardless of the nanomaterial employed, reducing exposure by optimizing clearance is a central principle for minimizing unwanted effects of foreign materials within the human body. Of course, the material must exist within the system for sufficient time to produce desired effects such as tumor accumulation for imaging or drug delivery. Ideally, however, the agent would be cleared as soon as this was achieved. Nanosized molecules and particles are cleared from the vascular compartment through three primary mechanisms: renal clearance with excretion into the urine, hepatic clearance with biliary excretion, or uptake by macrophages into the reticuloendothelial system (RES) (liver, spleen, bone marrow).[1−13] Within the kidney, molecules may be cleared through glomerular filtration or tubular excretion. Generally, molecules approximately 6 nm or smaller in diameter may be excreted through glomerular filtration.[11,14−16] Glomerular filtration represents the ideal mechanism for nanoparticle clearance from the body, as molecules are excreted without requisite cellular internalization or metabolism as is required for renal tubular secretion, as well as the two other modes of clearance. Renal clearance is achieved rapidly with glomerular filtration, making this a desired route for excretion.[5,11,17] However, after the particle has undergone filtration, the surface should be designed to avoid tubular reabsorption.[11] We propose that the design of nanosized molecules or particles for human application should focus on optimization of particles for renal clearance.

DEFINING IDEAL MATERIAL CHARACTERISTICS

Given the enormous diversity of nanomaterials and rapid growth in the field of nanoscience, efficient translation of nanomaterials into medicine will likely rely upon effective categorization of particles based on in vivo properties such as pharmacokinetics and toxicity. However, this is challenging as the huge variation among nanomaterials makes relevant categorization difficult. Currently, the US Food and Drug Administration (FDA) groups nanoparticles by chemical composition of the material. Yet, from a biological perspective, this division may not be the most relevant to human health. For example, when considering nanoparticles that undergo renal clearance, the short life of the particle in the human body markedly reduces exposure and the chance for "off target" effects. Other particle properties such as particle size are therefore equally, and possibly more, relevant than chemical composition when thinking about nanotoxicology. Tomalia recently proposed classifying nanomaterials as "hard" or "soft" based on compositional/architectural criteria for traditional organic and inorganic materials.[18] Within this classification system, the soft group includes the following: dendrimers, nanolatexes, polymeric micelles, proteins, viral capsids, and polynucleic acids. So-called "hard" categories include the following: metal nanoclusters, metal chalcogenic nanocrystals, metal oxide nanocrystals, silica nanoparticles, fullerenes, and carbon nanotubes.[18] The system is based on the premise of building blocks that are primarily defined by the nature of the core material and subsequently modified by the addition of other nanomaterials, to achieve further classification as soft−soft (e.g., dendrimer core with dendrimer shell) or soft−hard (e.g., dendrimer core with silica nanoparticle shell). Further work is needed to determine if these proposed divisions translate into biologically relevant or useful groups, but at a glance, the division of hard versus soft will likely have greater medical relevance in terms of toxicity and biological properties for agents that do not undergo renal clearance, as these agents will be retained by the body over sufficient time course to observe material-specific pathological or biological effects. The hard versus soft distinction may have special relevance for intermediate-sized particles that are capable of undergoing renal clearance with a given degree of particle flexibility. As of yet, the broad field of nanoscience as applied to medicine lacks clear direction in terms of classifying and defining agent behavior in vivo, an undoubtedly important aspect for clinical translation. Herein, we discuss what is known and what remains to be explored regarding the rational design of nanosized particles- or molecule-based agents for medical applications and address basic design strategies for minimizing toxicity and nonspecific probe uptake, while maximizing tumor accumulation. Therefore, the majority of nanosized agents, which are discussed in this review, avoid nonspecific RES uptake by appropriate surface modifications and are excreted through other physiologic mechanisms, i.e., renal excretion or biliary excretion.

SIZE

The impact of particle size on in vivo behavior is one of the most well studied aspects of nanoparticle pharmacokinetics and biodistribution. It is generally accepted that particles smaller than 5.5 nm primarily undergo renal clearance, whereas particles of intermediate size are more variable and those >12 nm primarily undergo hepatic clearance. Research demonstrates that spherical particles smaller than 5.5 nm reliably are excreted by the kidneys,[5,19] while larger particles demonstrate more variable behavior that is determined in part by shape, rigidity of the material, particle charge, and architectural flexibility. However, a factor limiting generalization of the role of size on nanosized particle/molecule behavior is that research has been limited primarily to spherical particles. We hypothesize, however, that regardless of shape, the majority of particles smaller than 5.5 nm will undergo renal clearance. Yet, more work needs to be done to determine if this is indeed the case. This size issue has been investigated in the case of a few nanomaterials including dendrimers[14,19] and metal nanocrystals. [5] A series of dendrimers with similar spherical shapes and identical core and surface chemistry but with differences in diameter were synthesized, and their pharmacokinetics, whole-body retention, and dynamic magnetic resonance imaging (MRI) were evaluated in mice. Polypropylenimine (PPI) dendrimer-based agents cleared more rapidly from the body than polyamidoamine (PAMAM) dendrimer-based agents with the same number of branches.[14] Smaller dendrimer conjugates were more rapidly excreted from the body than the larger dendrimer conjugates.[14,20]

The size measurements of macromolecules or nanoparticles have been obtained with mass spectroscopy for molecular mass, the electron microscope for crystallized size, and dynamic light scattering (DLS) and size-exclusion liquid chromatography (SE-LC) for functional hydrodynamic size in solution. The hydrodynamic size of a particle in solution is generally thought to be the most relevant measurement technique to predict in vivo behavior. SE-LC is theoretically the most relevant for predicting particle vascular permeability and renal filtration, as this measurement technique involves physical flow through pores. However, the functional size measured by DLS or SE-LC is an average regardless of particle shape and flexibility. Therefore, these measurements do not comprehensively reflect the in vivo functional behavior of macromolecules or nanoparticles. Developing and/or utilizing measurement techniques that gauge other particle traits, such as flexibility and shape, are necessary for designing more biocompatible nanosized agents.

SHAPE

Taking into consideration the vast array of naturally occurring biomolecules, it is rational to hypothesize that shape is an important determinant of biological function. However, our current understanding of in vivo behavior is derived from studies limited to average sizes of nanoparticles.[21] While this work is valuable, it also has important limitations: (1) most naturally occurring matter is nonsperical, as are many available and emerging nanomaterials, and (2) biological processes occur under dynamic conditions in which the motion of spherical and nonspherical objects will differ.[21] The construction possibilities of nanoparticles are nearly infinite, and many nonspherical particles have been created and have demonstrated preclinical promise. Additionally, given the role of shape in biological function of molecules, this same parameter is likely important in achieving optimal function from nanoparticles. In this section, we will review current insights into the influence of shape on in vivo nanoparticle behavior.

Although the effect of shape on in vivo behavior has not yet been extensively explored, several studies have evaluated this topic. A comparison of linear copolymers to branched spherical PAMAM hydroxylated dendrimers with regard to biodistribution found that the molecular weight, hydrodynamic size, and polymer architecture (or shape) affected biodistribution. [22] The

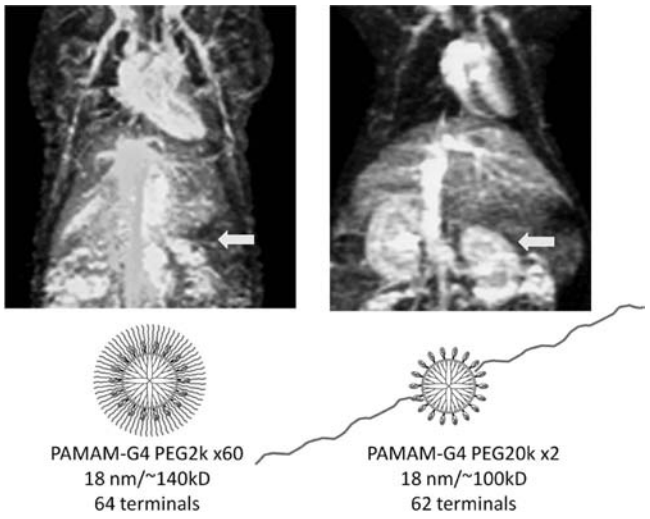

Figure 1. Two long, linear PEG (20 kD) conjugated PAMAM-G4-Gd shows renal excretion. However, short PEG (2 kD) conjugated PAMAM-G4-Gd of similar physical size shows no renal excretion.

dendrimers were retained in the kidney for over 1 week, while copolymers of approximately the same molecular weight were excreted into the urine and did not show persistent renal accumulation. [22] Another group compared the effect of nanoparticle shape on flow and drug delivery by comparing linear polymer micelles known as filomicelles to spheres of the same chemistry in rodents. Filomicelles remained in circulation ten times longer than their chemically similar spherical counterparts, suggesting that shape played a significant role in in vivo behavior. [23] Another group compared the biodistribution of PEGylated rod-shaped gold nanoparticles with PEGylated spherical counterparts and found that the gold nanorods were taken up to a lesser extent by the liver and had longer circulation time in the blood and higher accumulation in tumors, compared to their spherical counterparts. Additionally, the rods were taken up to a lesser extent than the spheres by macrophages. [24]

Traditionally, dendrimers were synthesized as spherical nanoparticles. However, recently surface modifications conjugating linear molecules to the surface produce nonspherical shapes with different pharmacokinetics. Despite a large particle size conferred by one or two linear, long PEGylated tails,[10] the particles may still undergo relatively rapid renal clearance. In contrast, the same generation of dendrimers with short PEG tails does not show renal clearance (Figure 1). [25]

SURFACE MODIFICATIONS TO ALTER BIODISTRIBUTION

To achieve target tissue accumulation, probes must avoid nonspecific uptake. Of the strategies to alter in vivo behavior, addition of poly(ethylene glycol) (PEG) is among the most widely utilized approaches. One consistent limitation to the use of polymeric nanoparticles in vivo is their premature elimination from the circulatory system by the mononuclear phagocyte system.[7,26] This process is initiated by serum opsonins attaching to the surface of nanoparticles in circulation. Following opsonization, macrophages recognize, phagocytose, and then sequester the particles in the liver, spleen, and/or bone marrow. PEGylation is one method to camouflage nanosize molecules and to prevent adhesion of opsonins so that the particles remain in

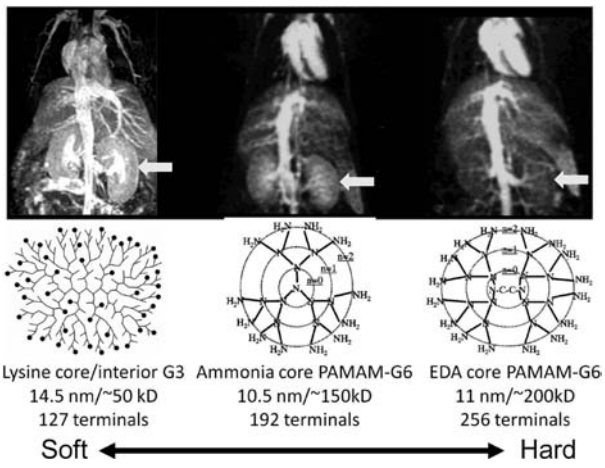

Figure 2. Despite the small size, hard interior (high density) EDA-core PAMAM-G6 does not show renal excretion. Two other "softer" interior dendrimers show renal excretion.

circulation and evade the reticuloendothelial system, a process referred to as the "stealth effect".[7] It is proposed that PEG reduces opsonization through steric and hydration effects.[7,27] Interestingly, although PEGylation increases size, which has been associated with faster uptake by the liver and RES, numerous reports indicate that PEGylation increases circulatory retention times and decreases liver uptake.[28]

FLEXIBILITY

At this time, particle flexibility is not widely considered an important determinant of in vivo nanosized molecule or particle behavior. However, given the dynamic nature of living systems and the time course over which particles interact with internal tissues, particle flexibility may have an important role in how nanosized molecules or particles interface with living tissues. Research suggests flexibility is an important determinant of in vivo behavior. Given the highly adaptable nature of these particles, it is possible to achieve high degrees of intramolecular flexibility. Dendrimers may represent an ideal particle to study the effects of particle flexibility in living systems as well as an ideal platform to then harness the insights for optimizing particle platforms. In one example, in a large particle conferred by one or two linear, long PEGylated tails[17] or the use of more flexible interiors including lysine dendrimers[29] or ammonia core PAMAM dendrimer,[30] the more flexibile particle demonstrated increased renal clearance (Figure 2). In contrast, less flexible ethylenediamine (EDA) core dendrimers[17] or dendrimers grafted with short PEG tails did not show renal clearance.[25] Interestingly, flexible dendrimer-based MR contrast agents exhibited improved renal clearance but retained similar relaxivity compared with "hard" dendrimers, which were not excreted by the kidneys.[19]

BIOLOGICAL APPLICATION OF PHYSICAL CHARACTERISTICS

The in vivo affinity of nanoparticles for specific anatomic locations and their behavior at specific biological interfaces plays an important role in probe characteristics and toxicity. Specific interfaces include the glomerular basement membrane, the blood-brain barrier, vascular and lymphatic endothelial linings, and hepatic sinusoids. The ability or inability of nanoparticles to

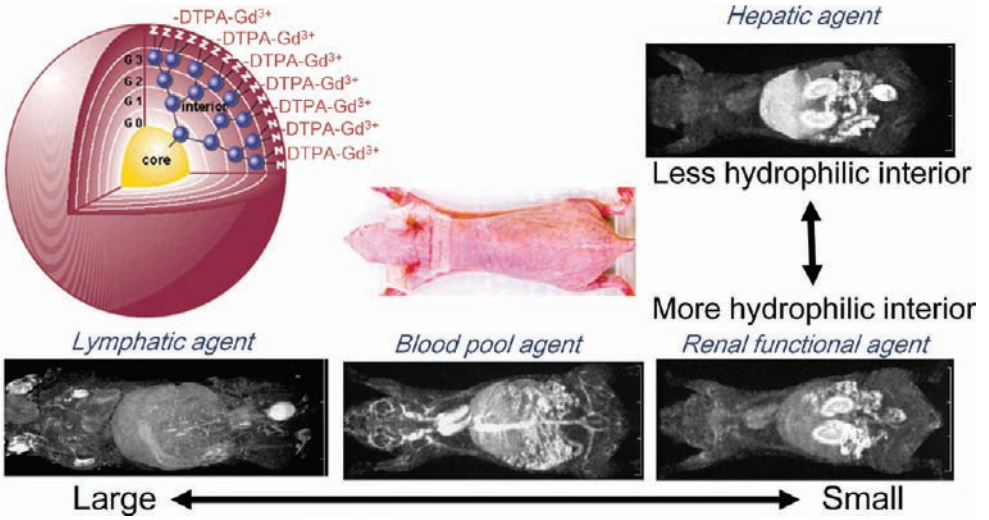

Figure 3. Strategic use of dendrimer size to achieve organ-specific imaging. This schema depits a generation 3 dendrimer,with core chemistry, shape, and surface modifications functionalized for use as an MRI contrast agent. Images of mice demonstrate that strategic selection of dendrimer size enables target organ-specific imaging. For example, PAMAM-G8 shows the lymphatic system; PAMAM-G6 shows the blood pool; PAMAM-G4 depicts renal function; and PPI/DAB-G4 depicts liver parenchyma.

cross these interfaces will in large part determine their biodistribution and hence their utility.

Dendrimers have been shown to be useful imaging agents of various anatomic and physiologic processes. Preclinical studies demonstrate PAMAM-based contrast agents are effective for MR liver imaging,[31,32] renal functional imaging,[33,34] and angiography[35−37] and lymphography[20,38] (Figure 3). Macromolecular MR contrast agents prepared from dendrimers have the advantage of uniform molecular weight distribution, relatively controlled structure, high relaxivities, and high loading of gadolinium chelates on the surface.[39,40] Dendrimers are particularly well suited for lymphatic imaging,[41−43] as this requires a modality with high spatial resolution and high sensitivity for contrast agents, since the lymphatics themselves are so small.[19,41−52] Dendrimers are retained within the lymphatics, especially when their surface charge is modified with an appropriate coating or when conjugated to specific fluorophores.[35,40,53−55] Smaller molecules (<6 nm) are taken up by the lymphatics, but do not remain in the lymphatic vessels, whereas large molecules (>20 nm) are taken up very slowly but are retained.[41] Dendrimer-based contrast agents between 6 and 10 nm are retained within the lymphatic system but are cleared from the sentinel lymph nodes within a day, which enables repeated injections. Additionally, these particles can be labeled with organic fluorophores (for optical imaging), radioisotopes (for scintigraphy), and paramagnetic lanthanide ions (for MRI).[40] Preclinical MR lymphangiography demonstrates that intradermally injected dendrimers are effective for imaging lymphatics in small and large animal models.[41,43] This may eventually play a vital role in identifying otherwise life-threatening thoracic duct injuries that occur during some pediatric cardiovascular surgeries.

Dendrimers are also useful nanoparticles for urinary tract imaging as well as for studying nanosized molecular pharmacokinetics. PAMAM-based Gd(III) complexes have shown size-dependent pharmacokinetics and renal filtration.[19] For instance, particles 2 nm in size are handled very similarly to low molecular weight contrast agents; yet, chemically similar but larger (6 nm) probes undergo comparatively slow renal clearance and particles that are 11 nm or larger do not undergo renal clearance at all.[56] Research suggests that the generation-4 (G4) dendrimer, which is approximately 6 nm in diameter, is ideal for renal imaging.[15,57] When administered in a normally functioning kidney, the G4 dendrimer accumulates in the proximal tubules, which is seen on imaging as enhancement of the outer stripe of the medulla.[56] This phenomenon enables the depiction of acute tubular injury (seen as loss of the medullary stripe), which correlates with the extent of renal impairment.[16] Advancements in dendrimer-based contrast agents include the advent of biodegradable agents, which typically rely on endogenous enzymes to cleave the probe, creating smaller, more easily cleared biproducts. Recently, a biodegradable macromolecular dendrimer-based agent, nanoglobule-G4-cystamin-(Gd-DO3A) conjugate, was created as an extracellular degradable nanosized contrast agent for dynamic contrast enhanced MRI. A disulfide spacer was introduced to accelerate the renal excretion of gadolinium chelates by reducing the spacer with free endogenous thiols and homocysteine in the plasma such that released chelates underwent rapid renal filtration with subsequent urinary tract accumulation sufficient for MR urography. The nanoglobular dendrimer demonstrated lower cytotoxicity, relatively rapid renal filtration, and low liver uptake[58] and in vivo studies demonstrated fast elimination kinetics that were ideal for evaluation of the kidneys.[59]

■ EFFECT OF TARGETING ON BIODISTRIBUTION

Conjugation of targeting ligands directly and indirectly alters biodistribution and clearance of nanoparticle-based imaging agents. Numerous strategies have been developed to manipulate in vivo behavior of nanoparticles by modifying the surface chemistry. Among the various nanoparticles, dendrimers present an ideal platform for conjugation of various targeting ligands, such as folic acid, avidin−biotin complex, RGD peptides, and carbohydrate molecules. Attachment of such ligands alters particle shape, flexibility, and size. Yang et al. conjugated anti-epidermal growth factor (EGF) antibody to boronated PAMAM-G4 dendrimers for targeting to EGF receptor expressing tumor cells and found that, at

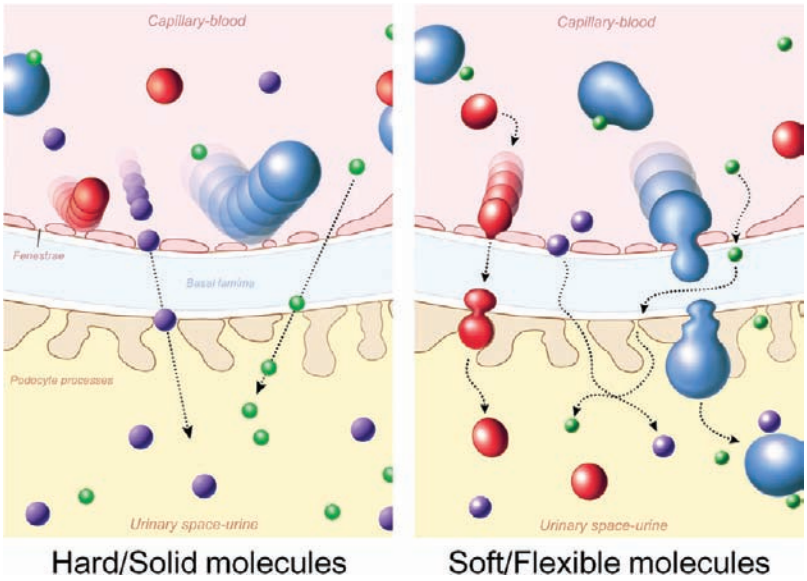

Figure 4. Schema for glomerular filtration of hard and soft nanosized molecules or particles.

24 h postinjection, the conjugates were highly localized in EGF-positive glioma with a tumor to blood ratio substantially higher than mice bearing tumors without EGF receptors or mice injected with nonconjugated PAMAM dendrimers.[60] Dendrimers have also been targeted with smaller molecules such as folate.[61−67] Folate-modified PAMAM dendrimers showed significantly high probe accumulation; however, hepatic and renal accumulation was also observed, likely due to the presence of folate receptors in hepatic macrophages and renal proximal tubules.[68]

Another targeting molecule is the avidin−biotin complex system, which selectively targets various types of tumors. Wilbur et al. showed that ^{125}I-labeled iodobenzoate-biotinylated PAMAM dendrimers (G0−4) were quickly cleared, giving low blood levels and high kidney and liver accumulation compared to unmodified counterparts.[68,69] G4 dendrimers complexed with olig-DNA and ^{111}In demonstrated lower hepatic uptake and higher kidney and spleen uptake than similar constructs without a dendrimer carrier. A similar construct containing oligo-DNA and avidin−biotin conjugated to a G4 dendrimer demonstrated very high uptake in the lung, which was thought to be due to trapping of large molecular weight complexes within the lung.[70] Avidin−biotin targeting has been extended for MRI, Gd-neutron capture therapy, and gene delivery.[71,72] After intraperitoneal administration, avidin-conjugated PAMAM-G6-Gd conjugates exhibited specific accumulation in intraperitoneally disseminated SHIN3 ovarian cancer tumors with 366- and 3.4-fold greater values than Gd-DTPA and unconjugated PAMAM-Gd, respectively.[71]

Baker et al. have used PAMAM dendrimers as a vehicle to achieve cancer-targeted drug delivery by functionalizing the particles with riboflavin, methotrexate, and other tumor-cell binding moieties.[73−75] By utilizing generation-5 PAMAM dendrimers, it is possible to deliver sizable chemotherapeutic payloads, and the particles can be synthesized as an appropriately monodispersed product that demonstrates optimal pharmacokinetics.

CONCLUSION

To effectively move nanosized molecules or particles from the bench to human applications requires gaining a better understanding of their in vivo behavior. At this time, our understanding is rather limited, as studies have primarily focused on the pharmacokinetics of relatively spherical molecules and size has been the primary parameter evaluated. To improve upon this, we need to consider other molecular parameters such as shape and flexibility, as well as expand biodistribution studies beyond hard and spherical particles (Figure 4). As more information becomes available regarding the effects of these other parameters and particle types, we may move toward categorization systems that reflect in vivo behavior. Such a step forward will facilitate efficient and effective design and chemical synthesis and may also expedite the approval process for use in humans.

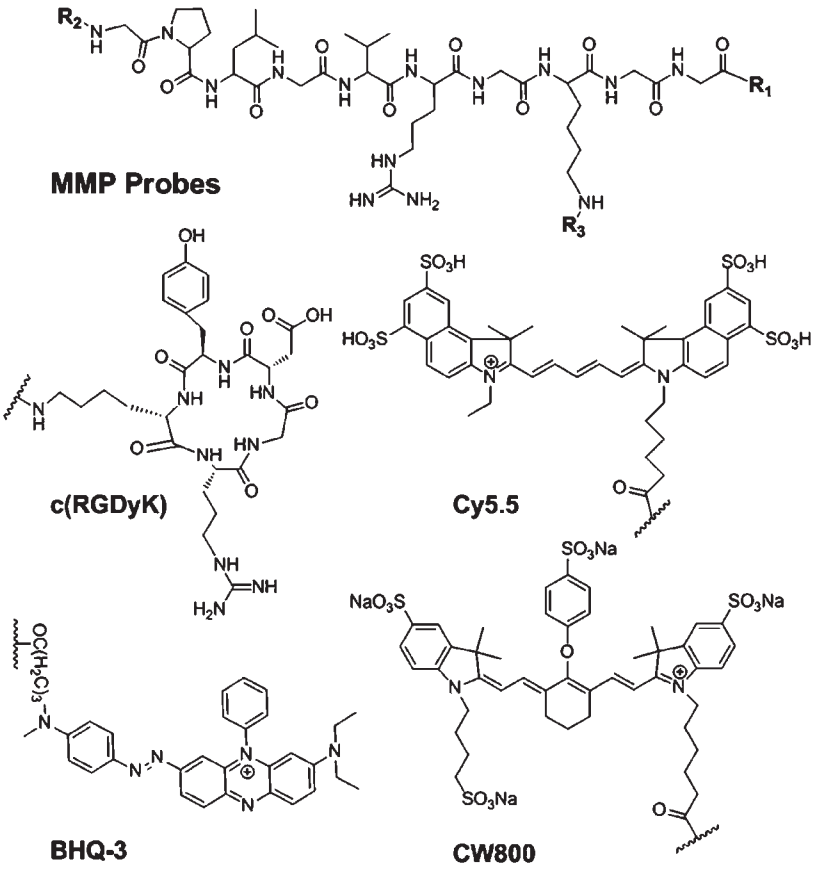
Supporting Information

ABSTRACT:

Herein, we report a new type of *in vivo* fluorogenic probe that enables simultaneous and active targeting of overexpressed receptors, $\alpha_V\beta_3$ integrins, and extracellular proteases, matrix metalloproteinases (MMPs), in the tumor regions. This c(RGDyK)-conjugated MMP fluorogenic probe efficiently targets the tumor regions with high retention time while maintaining receptor binding affinity and substrate activity. The probe minimizes nonspecific accumulation, thus demonstrating improved tumor-to-background signal ratio (T/N) in both $\alpha_V\beta_3$ integrin- and MMP-overexpressing U87MG tumor-bearing mouse model. This strategy can be easily tuned for a wide array of applications targeting various receptors and extracellular proteases *in vivo*.



Fluorogenic substrates, consisting of protease substrates labeled with a fluorescent reporter and a quencher dye, are highly sensitive and sequence specific and have long been used in in vitro diagnostic assays. Recent advances in optical imaging instrumentation and development of various near-infrared (NIR) fluorescent dyes and NIR quenchers enabled the use of conventional fluorogenic substrates for in vivo imaging applications. Any reported fluorogenic substrate with known sequences can be easily modified to NIR fluorogenic probes, so-called peptide-based activatable probes,[1−6] for in vivo imaging by replacing conventional dye molecules to a NIR fluorescent dye/quencher pair. Although reported NIR fluorogenic probes showed potential in in vivo imaging, short half-life, poor pharmacokinetic profiles, instability, and high background induced by a nonspecific degradation of fluorogenic substrates still hamper its application.

Development of novel techniques for noninvasive imaging of specific protease activity is critical and urgently needed. Proteases are known as extremely important signaling molecules that are involved in numerous pathological processes including cancer, inflammatory, neurological, and cardiovascular diseases.[7−9] Successful protease imaging techniques can be used for studying the role of protease expressions in protease-associated disease animal models or monitoring therapeutic efficacy of a number of newly developed protease inhibitors in vivo. Various unique forms of protease-activatable probes have been designed in combination with fluorogenic substrates and materials including targeting ligands, polymers, and inorganic metals such as gold nanoparticles and quantum dots.[1−6,10−18] Although the use of activatable probes seems to be popular, surprisingly, very limited platforms of activatable probes are available which can clearly image proteases' activity in vivo after systemic administration. Unfortunately, the majority of reported systems demonstrate their proof-of-concept only in vitro or in ex vivo conditions such as after intratumoral injection in tumor models.

Ideal activatable probes can be designed by increasing in vivo stability and/or target (i.e., tumor) specificity of the fluorogenic probe while maintaining biological activity against specific proteases. Chemically, these improvements can be achieved by modifying fluorogenic peptides with water-soluble biomacromolecules such as PEGylated poly(L-lysine)[11,19] or tumor-homing polymeric nanoparticles,[10] since both polymers can increase the circulation half-life and efficiently deliver fluorogenic probes to

the tumor mainly by the enhanced permeability retention (EPR) effect.[20] Indeed, these concepts showed promising results in many in vivo models; however, there are some drawbacks. For example, such probes take a long time for full activation due to the decreased substrate sensitivity from the conjugated high molecular weight polymer backbone, and more importantly, their EPR effect may cause nonspecific uptake causing false fluorescence signals in vivo.

In this study, we report a fluorogenic probe with an active targeting ligand that can be used as an efficient optical imaging probe to monitor extracellular protease expressions. We hypothesize that a targeting ligand will efficiently increase the retention time of the probe in the target region and maintain substrate activity, minimizing nonspecific accumulation and enhancing tumor-to-background signal ratio. To test the rationale of our strategy, we adopted a cyclic Arg-Gly-Asp peptide, c(RGDyK), a well-known $\alpha_v\beta_3$ integrin ligand that is overexpressed on the surface of angiogenic endothelial cells that mediates cell adhesion.[21−23] We synthesized c(RGDyK)-labeled matrix metalloproteinase (MMPs) specific fluorogenic probes, confirmed their enzyme and receptor activity in vitro, and demonstrated enhanced imaging of MMPs in both an $\alpha_v\beta_3$ integrin- and MMP-overexpressing tumor-bearing mouse model. MMPs are a large family of zinc-dependent proteases and play a crucial role in a variety of pathological disorders including cancer and inflammation diseases.[24] Accordingly, MMPs are important pharmaceutical and diagnostic targets for treatment of these diseases.

Our lead compound, MMP-P-RGD conjugate **4**, is composed of (i) Cy5.5 as a NIR dye (ex/em; 675/695 nm), (ii) the MMP-cleavable substrate G*PLGVR*GKGG as a recognition site indicated by italics with the cleavage site between Gly and Val, (iii) NIR dark quencher BHQ-3[25] (abs. 650 nm), and (iv) c(RGDyK) as a targeting ligand. Two Gly residues were incorporated as a spacer between the MMP-activatable fluorogenic peptide and the targeting ligand. Figure 1 shows the chemical structure of **4**. The multistep synthetic route involves three parts: (i) conjugation of c(RGDyK) to NHS ester activated C-terminal carboxyl group in

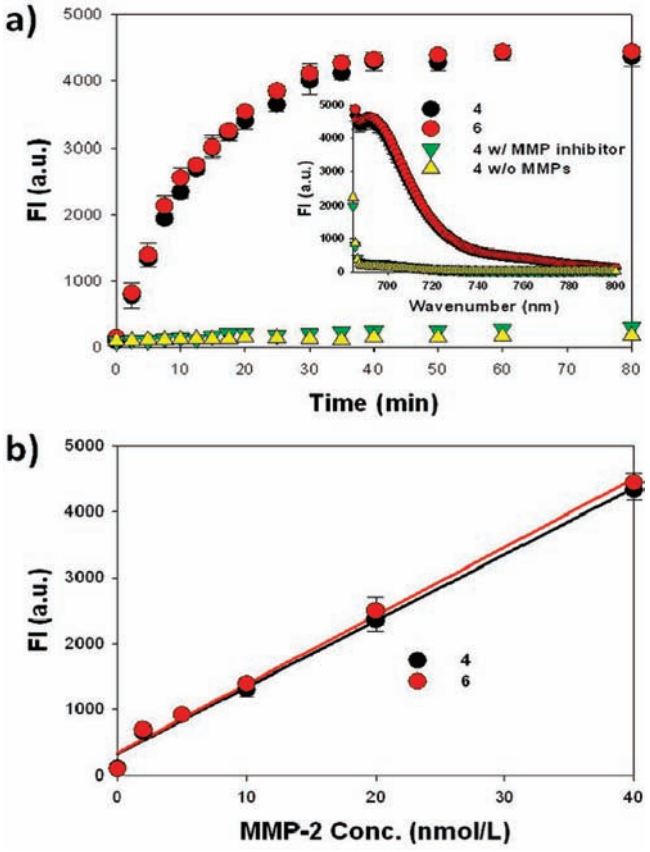

Figure 2. In vitro MMP specificy of MMP-P-RGD **4** and MMP-P **6**. (a) Fluorescence emission kinetic spectra of the probes in the presence of MMP-2 with and without a broad spectrum MMP inhibitor. Inset: Fluorescence emission spectra of the probes at 80 min. (b) Fluorescence intensities of the probes in the presence of various concentrations of activated MMP-2 (0, 2, 5, 10, 20, and 40 nM) following an 80 min incubation. Means ± SD (n = 3).

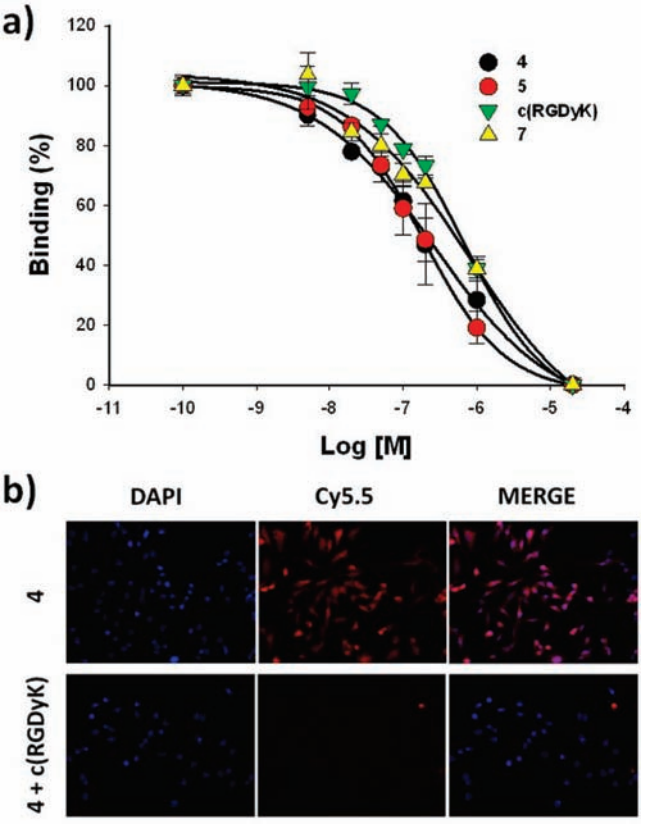

Figure 3. (a) Competitive $\alpha_v\beta_3$ integrin receptor assay of c(RGDyK), **4**, **5**, and **7** to U87MG human glioma cells. Means ± SD (n = 3). (b) Specific $\alpha_v\beta_3$ integrin receptor binding of **4**. NIR fluorescence images of U87MG cells were taken after 30 min incubation at 37 °C in the presence of **4** with and without a blocking dose of c(RGDyK) (10 μM).

fully protected MMP substrate **1**, Fmoc-GPLGVR(Pbf)GK-(tboc)GG; (ii) labeling NHS ester of NIR Cy5.5 dye to the Fmoc-deprotected N-terminal α-amino group of **2**, GPLGVR-(Pbf)GK(tboc)GG-c(RGDyK); (iii) conjugation of NHS ester of NIR dark quencher BHQ-3 to the ε-amino group of lysine followed by TFA cleavage of **3**, Cy5.5-GPLGVRGKGG-c-(RGDyK). The peptide sequence of **1** was synthesized by standard solid-phase Fmoc peptide chemistry. In addition, only Cy5.5-labeled analogue, Cy5.5-MMP-RGD **5**, was prepared for cellular imaging. As controls, an MMP fluorogenic peptide without c(RGDyK) ligand, MMP-P **6**, and CW800 dye (ex/em; 775/790 nm)-labeled c(RGDyK), CW800-RGD **7**, were also synthesized. Serial conjugation and deprotection of the peptide was performed in solution followed by preparative HPLC purifications. Purified products were confirmed by analytical HPLC and LC/MS (see Supporting Information for details).

First, the MMP specificity of **4** was compared to that of **6** to confirm whether conjugation of the targeting ligand affects its enzyme specificity. In vitro enzyme specificity was measured in the reaction buffer (100 mM Tris, 200 mM NaCl, 5 mM $CaCl_2$, 0.1% Brij, pH 7.5) containing activated MMP-2 with and without a homophenylalanine-hydroxamine acid based broad spectrum MMP inhibitor (EMD Bioscience) using a spectrofluorometer. The MMP-2 was activated by incubation of 2.5 mM of *p*-aminophenyl mercuric acid (APMA) in the reaction buffer for 2 h at 37 °C prior to use. As shown in Figure 2a, MMP-2 (40 nM) treatment of **4** and **6** (15 nM) resulted in an increased recovery of the NIR fluorescence signal and showed greater than 20-fold increase relative to the control sample without MMP-2. The fluorescence recovery of **4** was inhibited in the presence of the MMP inhibitor indicating probe selectivity. Similar experiments were performed by incubating **4** in the presence of different concentrations of MMP-2 (0, 2, 5, 10, 20, 40 nM) and the recovery of fluorescence was dependent on the MMP-2 concentration (Figure 2b). The overall MMP specificity of **4** against MMP-2 was similar to that of **6**. These results indicate that conjugation of the targeting ligand c(RGDyK) did not alter the MMP specificity of the probe.

Second, the effect of a bulky fluorogenic peptide on the $\alpha_v\beta_3$ binding affinity of c(RGDyK) was measured by a competitive cell-binding assay in U87MG cells. ^{125}I-eschistatin was used as a specific radioligand for competitive displacement. The U87MG cell is known to have high $\alpha_v\beta_3$ integrin density on the cell surface. All analogues containing c(RGDyK) ligand maintained reasonable binding affinities to its receptor. The IC_{50} values of c(RGDyK), **4**, **5**, and **7** were 592, 267, 184, and 456 nM, respectively (Figure 3a). Next, receptor specificity of the probes in cell culture was verified by fluorescent microscopic studies. The probes were incubated in fixed U87MG cells with and without a blocking dose of c(RGDyK) (10 μM). Since **5**, the nonquenched form of **4**, showed similar $\alpha_v\beta_3$ binding to **4** and **5**

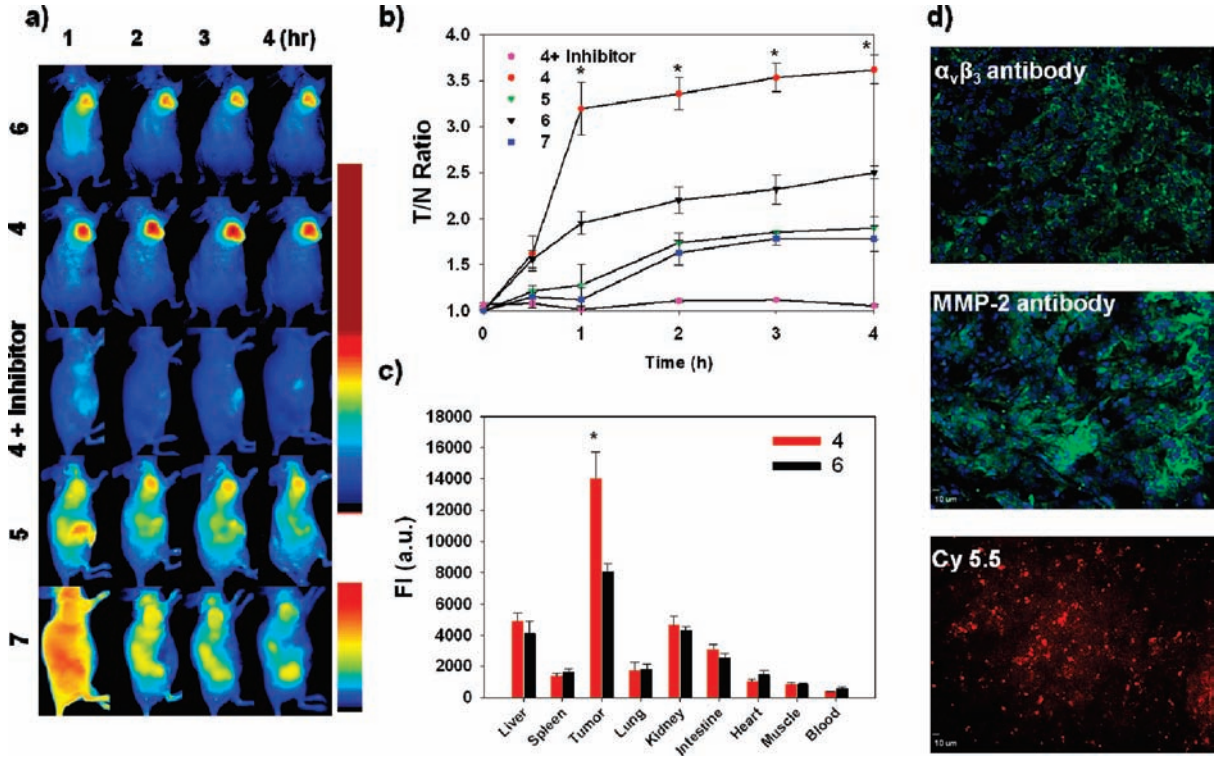

Figure 4. (a) Representative serial in vivo NIR fluorescence images of MMP- and $\alpha_V\beta_3$ integrin receptor-positive U87MG tumor-bearing mice injected intravenously with **4**, **5**, **6**, **4** with MMP inhibitor, and **7**. Images were acquired at the indicated time points and were normalized by the maximum average value. The color bar indicates radiant efficiency (upper bar; for Cy5.5, low 0, high 0.111, lower bar; for CW800, low 0, high 0.03 scaled counts/s). (b) T/N ratio analysis of NIR fluorescence intensity of U87MG tumor in vivo. (c) Biodistribution of **4** and **6**. Means ± SD ($n = 3$), * $P < 0.05$. (d) Tumor section counterstained with FITC-labeled antibody for $\alpha_V\beta_3$ integrin receptor (upper) and MMP-2 (middle). NIR fluorescence microscopy of tumor section injected with **4** (lower).

was used for in vitro cellular imaging studies. As shown in Figure 3b, **5** showed strong positive fluorescent signals on the cell membranes after 30 min of incubation at 37 °C. Since receptor blocking with an excess c(RGDyK) significantly decreased binding of **5**, the probe exhibits significant receptor specificity. Taken together, an NIR fluorogenic probe containing c-(RGDyK) ligand shows specific activities against both MMP-2 and $\alpha_v\beta_3$ signifying **4** could be used as an $\alpha_v\beta_3$ receptor-targeted MMP-specific molecular beacon.

To investigate whether the receptor-targeting ligand can enhance the visualization of extracellular protease expression in vivo, 3 nmol of **4** was intravenously injected into U87MG tumor-bearing mice treated with and without an MMP inhibitor. In order to inhibit the activity of MMPs in U87MG tumor, MMP inhibitor was intratumorally injected 30 min before the injection of **4**. To demonstrate the superiority of this new receptor-targeted fluorogenic probe over existing NIR dye-labeled receptor-targeted peptides in tumor imaging, **5** and **7** (0.5 nmol) were each also injected into an U87MG tumor model. It should be noted that only a limited dose of dye-labeled peptide probe like **5** and **7** can be injected for whole body imaging because of its high fluorescent background from the dye. In contrast, since fluorogenic probes are strongly quenched and a majority of the probe is activated at the target site, higher doses of the probe can be injected to enhance the ratio of region-of-interest (ROI) signal of tumor to normal tissue, muscle (T/N), at very early times. After injection, in vivo optical imaging was performed for 4 h using a small animal imaging system (Maestro 2) equipped with appropriate filters for Cy5.5 and CW800. Figure 4a shows representative serial images of mice at selected time points. Both **4** and **6** enabled visualization of MMP expression in an MMP-positive tumor, but **4** provided brighter NIR fluorescent images compared to **6** from 1 h postinjection. As expected, when MMP expression was inhibited by MMP inhibitors, the NIR fluorescence signal from the tumor was significantly reduced. In addition, tumor uptake was effectively blocked at 30 min postinjection with an excess amount of unlabeled c(RGDyK) (200 nmol) with **4** demonstrating the c(RGDyK)-mediated specific binding of **4** in vivo (see Supporting Information, Figure S3). Like other conventional types of NIR dye-labeled peptide probes, **5** and **7** showed gradually increased fluorescent signals in the tumor after the probe was slowly cleared from the blood and other organs. T/N ratios are illustrated in Figure 4b. **4** showed enhanced T/N and were up to 2.3, 1.5, 2.0, and 3.4-fold higher than **5**, **6**, **7**, and **4** treated with an inhibitor, respectively. After whole-mouse imaging at 4 h time point, tumors and organs were carefully removed and the biodistribution of **4** and **6** was evaluated (Figure 4c). Ex vivo biodistribution studies also indicated that **4** was predominantly activated in the tumors among other organs and compared to other groups. Selective tumor tissues were also analyzed by immunohistochemistry and NIR fluorescent microscopy to confirm the expression of biomarkers and accumulation of the probe. As shown in Figure 4d, $\alpha_v\beta_3$ integrin and MMP-2 antibody staining revealed strong expression of biomarkers in U87MG tumors and NIR fluorescence microscopy images showed a strong Cy5.5 signal, consistent with in vivo imaging.

Overall, our in vivo results markedly supported the role of c-(RGDyK) as a receptor-targeting ligand.

Tumor-targeting fluorogenic probes and dye-labeled peptide ligands have different targets; fluorogenic probes target overexpressed enzymes around the tumor site and peptide ligands target overexpressed receptors in the tumor. Yet, both probes can be used in combination to target the entire tumor area. Our results demonstrate the advantages of receptor-targeted fluorogenic probes for in vivo imaging applications. We anticipate that the combination of NIR fluorogenic probes and peptide ligands becomes applicable to a wide variety of target extracellular proteases and receptors, offering a series of receptor-targeted fluorogenic probes as novel imaging probes with improved efficacy in vivo.

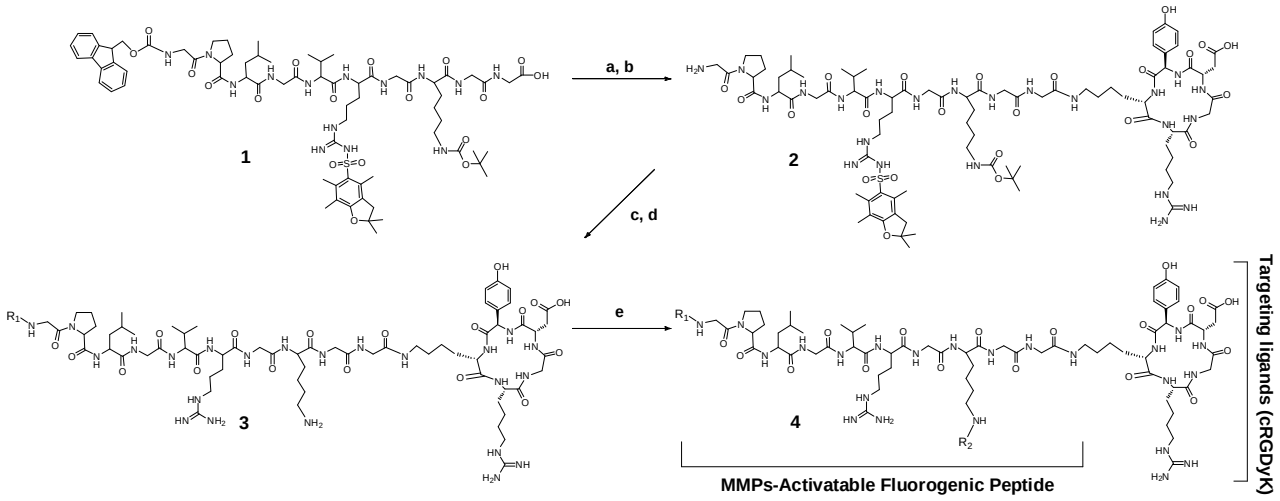
Dual-Functional, Receptor-Targeted Fluorogenic Probe for In Vivo Imaging of Extracellular Protease Expressions

Lei Zhu,[†, ‡] Jin Xie,[†] Magdalena Swierczewska,[†, §] Fan Zhang,[†] Xin Lin,[†] Xuexun Fang,[‡] Gang Niu,[†] Seulki Lee[†, *] and Xiaoyuan Chen[†,*]



Cell culture. The U87MG human glioblastoma multiforme cell line was obtained from American Type Culture Collection (ATCC, Manassas, VA). U87MG cells were cultured in DMEM medium containing 10% (v/v) fetal bovine serum (GIBCO, Grand Island, NY) supplemented with penicillin (100 μg/mL), streptomycin (100 μg/mL), non-essential amino acids (100 μM) and sodium pyruvate (1 mM) at 37 ˚C with 5% CO_2.

Animal models. Female athymic nude mice were supplied from Harlan (Indianapolis, IN) at 4 to 5 wk of age. U87MG tumor model was generated by subcutaneous injection of 5×10^6 cells in Matrigel into the right front flank of female athymic nude mice at a volume of about 80 μL. The mice were used for optical studies when the tumor volume reached about 300 mm^3. All animal studies were conducted in accordance with the principles and procedures outlined in the

Guide for the Care and Use of Laboratory Animals and were approved by the Institutional Animal Care and Use Committee of Clinical Center, NIH.

Peptide probes. The peptide sequence of 1 was synthesized by standard solid-phase Fmoc peptide chemistry. To synthesize 4 (Scheme S1), 5 mg of 1 was dissolved in 500 µl N,N-dimethylformamide (DMF) solution containing 2% diisopropylethyalamine (DIPEA). 2 mg N,N,N',N'-Bis(tetramethylene)-O-(N-succinimidyl)uronium hexafluorophosphate (HSPyU) was added into the solution to activate the C-terminal carboxylic group and stirred for 30 min at room temperature. Next, 2.5 mg of c(RGDyK) was dissolved in 250 µl DMF solution containing 2% DIPEA and mixed with the activated 1. The reaction mixture was stirred at room temperature and monitored by analytical HPLC. To remove the Fmoc group, 10% piperidine was added into the solution and stirred for 30 min. The crude product was precipitated in cold ether and the pellet was lyophilized and purified by preparative HPLC. The collected fraction 2 was lyophilized and labelled with Cy5.5 NHS ester in DMF solution containing 2% DIPEA. The reaction solution was precipitated against cold ether, lyophilized, and subjected to TFA/H2O/TIS/EDT (85/5/5/5, v/v/v/v) cocktail to remove the protection groups. Crude product was purified by preparative HPLC. The desired fraction containing 3 was collected and lyophilized. In the last step, BHQ-3 NHS ester was conjugated and the final compound 4 was was purified by HPLC on a C18 semi-preparative column using a linear gradient of 10% to 55% acetonitrile/water (0.1% trifluoroacetic acid), for 30 min at a 10 mL/min flow rate. 5 and 6 were synthesized by serial conjugations and deprotections of the peptides as described followed by preparative HPLC purifications. 7 was synthesized by conjugation of CW800 NHS ester and c(RGDyK) in DMF solution containing 2% DIPEA. The reaction solution was precipitated

against cold ether, lyophilized, and purified by HPLC. All purified products were confirmed by analytical HPLC and LC/MS. Figure S1 shows the representative HPLC and LC/MS spectra of 4.

.

In vitro enzyme test. The fluorogenic property of the peptide probes was examined by incubating the probes in the reaction buffer (100 mM Tris, 200 mM NaCl, 5 mM $CaCl_2$, 0.1% Brij, pH 7.5) containing 40 nM of APMA-activated recombinant human MMP-2. Fluorescence intensity was monitored using a spectrofluorometer (F-7000 Fluorescence Spectrophotometer, Hitach, Tokyo, Japan) every 10 min at 37 °C using quartzose cuvette. The excitation wavelength

was set at 675 nm and emission spectra recorded from 680 to 800 nm. The same experimental conditions were applied to various concentrations of MMP-2 in the presence of fixed concentrations of the probes.

Receptor binding assay. Briefly, U87MG cell line was cultured in DMEM medium containing 10% (v/v) fetal bovine serum supplemented with penicillin (100 μg/mL), streptomycin (100 μg/mL), non-essential amino acids (100 mM) and sodium pyruvate (1 mM) at 37˚C with 5% CO_2. After reaching 80% confluence, cells were scraped off and suspended with binding buffer (25 mM 2-amino-2-(hydroxymethyl)-1,3-propanediol, hydrochloride (Tris-HCl), pH 7.4, 150 mM NaCl, 1 mM $CaCl_2$, 0.5 mM $MgCl_2$ and 1 mM $MnCl_2$, 0.1% bovine serum albumin (BSA)) at a final concentration of 4×10^6 cells/mL. In a 96-well plate, 2×10^5 U87MG cells/well were incubated with ^{125}I-Echistatin (0.02 mCi/well, PerkinElmer Inc.) in binding buffer in the presence of different concentrations of c(RGDyK) and the peptide probes at room temperature for 2 hrs. After incubation, the plate was washed three times with PBS containing 0.1% BSA, and the radioactivity was measured by γ-counting. The IC_{50} values were calculated by nonlinear regression analysis.

***IN VIVO* optical imaging.** Optical imaging acquirement and analysis were done using Maestro 2.10 in vivo imaging system (Cambridge Research & Instrumentation, Woburn, MA, USA). U87MG tumor-bearing mice were injected via tail vein with **4**, 5, **6**, **7**, and **4** with MMP inhibitor or unlabeled c(RGDyK), respectively, under isoflurane anaesthesia (n = 3 per group).

The molar concentration of each samples were calculated by the sample weight. 1, 2, 3, 4 hrs post-injection, the mice were subjected to optical imaging using appropriate filters for Cy5.5 and CW800. For the inhibition experiment, MMP inhibitor was intratumorally injected into tumor-bearing mice 30 minutes before the probe injection. After image acquisition, spectral unmixing yielded the pseudocolor images of the pure spectrum of respective dyes. Images were normalized and analyzed using Maestro software. For quantitative comparison, regions of interest (ROI) were drawn over tumors and muscle, and the average signal (10^6 photons×cm^{-2}×s^{-1}) for each area was measured. Values were expressed as mean ± SD for a group of three animals.

***EX VIVO* biodistribution.** *Ex vivo* imaging of excised tumor and organs further confirm the targeting specificity and activation of the probes (Figure S4). At 4 hrs post-injection, the mice were sacrificed and major organ tissues and tumors were harvested, and placed on black paper for *ex vivo* imaging. For quantitative comparison, ROIs were drawn over tumors and the other organs, and the average signal for each area was measured. The results were presented as the average scaled signal from the organs and tumors. Values were expressed as mean ± SD for a group of three animals.

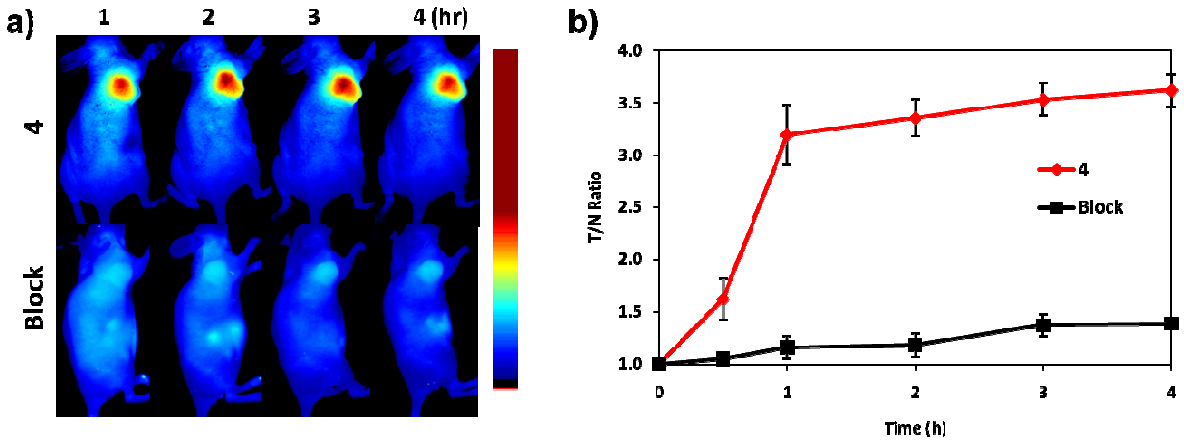

Figure S3. (a) Representative serial in vivo NIR fluorescence images of U87MG tumor-bearing mice injected intravenously with **4** and **4** with unlabeled c(RGDyK) (block). (b) T/N ratio analysis of NIR fluorescence intensity of U87MG tumor *in vivo*.

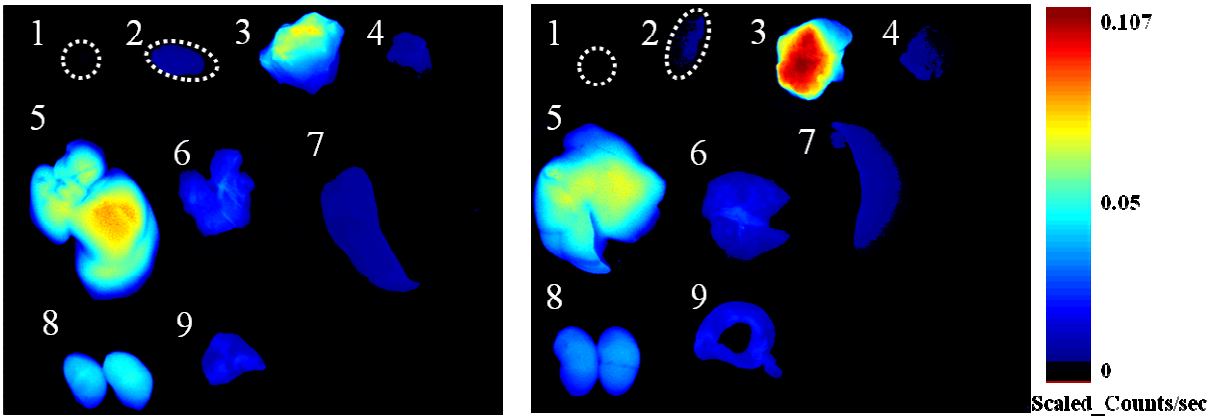

Figure S4. Biodistribution of **4** (left) and **6** (right).

Immunohitochemistry. Frozen U87MG tumor tissue slices (4 μm) from the tumor-bearing nude mice were fixed with cold acetone for 20 min and dried in air for 30 min at room temperature. After blocking with 10% BSA for 30 min, the sections were incubated with Rabbit anti-integrin αvβ3 and Rabbit anti-MMP-2 and antibodies (10 μg/mL) for 60 min at room temperature in the dark. Samples were then visualized with FITC-conjugated donkey anti-rabbit secondary antibody. Finally, the slices were mounted with DAPI-containing mounting medium under an epifluorescence microscope (Olympus, X81). The tumor slices were also observed directly after mounting with DAPI-containing mounting medium under an epifluorescence microscope and fluorescence images were taken using Cy5.5 filter settings.

Statistical analysis. Results were expressed as mean ± SD. Two-tailed paired and unpaired Student's t tests were used to test differences within groups and between groups, respectively. P values < 0.05 were considered statistically significant.

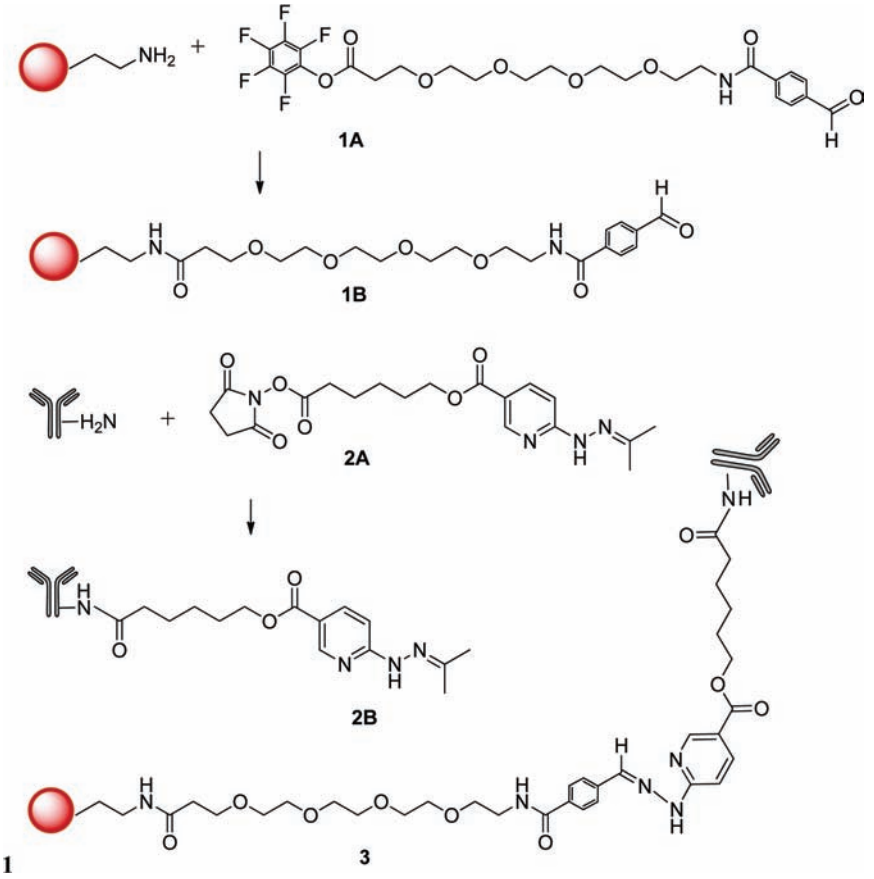
Supporting Information

ABSTRACT: We present a robust scheme for preparation of semiconductor quantum dots (QDs) and cognate partners in a conjugation ready format. Our approach is based on bis-aryl hydrazone bond formation mediated by aromatic aldehyde and hydrazinonicotinate acetone hydrazone (HyNic) activated peptide coated quantum dots. We demonstrate controlled preparation of antibody—QD bioconjugates for specific targeting of endogenous epidermal growth factor receptors in breast cancer cells and for single QD tracking of transmembrane proteins via an extracellular epitope. The same approach was also used for optical mapping of RNA polymerases bound to combed genomic DNA in vitro.

Biofunctionalization of quantum dots (QDs) for both *in vitro* and *in vivo* applications is challenging, since many criteria, such as long-term stability, overall size, efficient and straightforward conjugation of functional biomolecules, and easy QDs targeting to cellular components all have to be simultaneously optimized. We have previously developed a compact surface coating chemistry that employs synthetic peptides for solubilization, biofunctionalization, and long-term stabilization of colloidal QD solutions (>6 month).[1,2] These peptide coated QDs (pcQDs) have been targeted in cells and animals using various small functional groups such as biotin,[2,3] FITC,[4] or DOTA.[5,6] The results have provided ample proof of pcQDs advantages for both live cell single molecule imaging[7] and whole animal imaging applications. However, as recently demonstrated by the monofunctional conjugation of avidin to pcQDs[7] conjugation of large molecules to QDs is still challenging because steric hindrance, geometry, stoichiometry of the conjugate, and its final functional activity have to be addressed. For that reason, we have focused our efforts here on developing "conjugation-ready" pcQDs that are stable at 4 °C for >4—6 months and provide a flexible approach for rapid bioconjugation to antibodies and other biomolecules in aqueous buffers and with precise and reproducible control over the conjugate stoichiometry. Previously, commercial linkers and activators have been used for various types of pcQD conjugation reactions with mixed success. For instance, cetuximab, a clinical anti-EGFR (epidermal growth factor receptor) antibody conjugated to QDs via EDC (1-ethyl-3-(3 dimethylaminopropyl) carbodiimide hydrochloride) was observed to have low reactivity and the QD conjugates were prone to aggregation.[8] Alternative QD—cetuximab conjugation strategies using succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) or *N*-succinimidyl-6-(3′-(2-pyridyldithio)-propionamido)-hexanoate LC-(SPDP)/SMCC linkers were more successful but required multiple preparative steps and reduction of the antibody which could compromise its activity.[8]



To overcome some of these limitations, we developed a bis-aryl hydrazone linkage strategy for the coupling of pcQDs to antibodies. We demonstrate the utility of this approach in live cells labeling and for in *vitro* applications. This reaction is based on the bio-orthogonal stable Schiff base mediated conjugation between aromatic aldehydes and aromatic hydrazines.[9−11]

In this scheme, UV traceable bifunctional linkers, succinimidyl-4-formylbenzamide (NHS-FB) or pentafluorophenyl-poly(ethylene glycol)-4-formylbenzamide (PF-PEG-FB) and succinimidyl-6-hydrazinonicotinate acetone hydrazone (NHS-HyNic) were conjugated to pcQD and antibodies, respectively, and further reacted together to yield stable QD conjugates via the formation of a covalent bis-aryl hydrazone bond with virtually no competing side reactions (Scheme 1). These linkers can be used interchangeably on pcQDs and antibodies or other biomolecules without a loss of generality, yield, or stability. Bis-aryl hydrazone bond formation can also be catalyzed and reaction kinetics improved 10—100-fold in the pH range 5—8 in the presence of aniline.[12−14] The reaction of

Scheme 1. Preparation of Aromatic Benzaldehyde Capped CdSe/ZnS Peptide Coated QDs and Aromatic Hydrazine Functionalized Antibodies[a]

[a] Not to scale. Peptide coated quantum dots (pc-QDs) are modified with PEG-4FB, **1A**, via their primary amines to yield PEG-4FB-pcQDs, **1B**. Antibodies are modified with C6-SANH, **2A**, via surface exposed primary amines to yield C6-SANH-Abs, **2B** (nucleophilic aromatic hydrazine is protected as an acetone hydrazone); **1B** is conjugated to **2B** to form a pc-QD-Abs, **3**, bioconjugate via stable uv-traceable bis-aryl hydrazone linkage.

aromatic aldehyde with aromatic hydrazine is also completely bioorthogonal, as the functional linkers do not cross-react with other side groups present in the side chains of natural amino acids or oligonucleotides. To provide additional flexibility and control for conjugation, QDs were also coated with peptides directly synthesized with an N-terminal HyNic group. This approach saves an extra step for the preparation of reactive pcQDs and permits better control of the number of HyNic reactive groups available at the surface of QDs using mixture of peptides with different functionalities during the coating procedure.[1,2]

CdSe/CdS/ZnS QDs emitting at 630 nm (Supporting Information Figure S.1) were synthesized as described previously.[15] CdSe/ZnS QDs emitting at 605 nm were obtained in their hydrophobic form from commercial vendors. Both types of QDs were coated with glycine or lysine N-terminated synthetic peptides which resulted in available primary amines[1,2] for NHS-FB or PF-PEG-FB modifications of pcQD (see Supporting Information methods for peptide sequences). For the production of hydrazine functionalized QDs, QDs were directly coated with HyNic N-terminated synthetic peptides (HyNic-pcQD). The mean core/shell diameter of these 630 or 605 nm red-emitting QDs was ~7.5 nm and ~5.0 nm, respectively, based on TEM measurements[16] (Supporting Information Figure S.1) and their hydrodynamic diameter increased to ~12.0 nm and ~9.5 nm, respectively, once coated with peptides.[17]

Scheme 1 illustrates one approach for the conjugation of pcQDs to antibodies via bis-aryl hydrazone linkage. NHS-FB or PF-PEG-FB (**1A**) were mixed with amine terminated pcQDs either in DMSO or directly in aqueous buffer at pH 7.2 to obtain pcQDs activated with FB or with PEG-FB which further enhances the solubility pcQDs. The resulting FB-activated pcQDs (**1B**) were purified via gel filtration using water as mobile phase and rapidly exchanged into a 100 mM Na-phosphate, 150 mM NaCl, pH 6.0 conjugation buffer in which they were reactive and stable for more than 6 months when kept at 4 °C. To generate a cognate aromatic hydrazine reactive molecule, NHS-HyNic (**2A**) was similarly reacted with amine groups on anti-EGFR or anti-GFP antibodies to obtain HyNic-activated antibodies (**2B**). Once desalted into a buffer containing 100 mM Na phosphate, 150 mM NaCl, pH 6.0, HyNic-activated antibodies possessed surface exposed alkyl hydrazones that maintained a dynamic equilibrium between alkyl protecting groups and reactive hydrazine groups[18] primed to receive FB-activated pcQDs and to yield a stable QD-antibody conjugate (**3**). The QD-antibody conjugate was stored in 0.01% Tween-20 and 0.1% BSA at 4 °C. The functional stability of the conjugate was confirmed by labeling EGFR on the cell surface of live MCF-7 cells two months after 4 °C storage. It is important to note that QD-conjugates prepared using this method should be stored undiluted in micromolar concentrations.

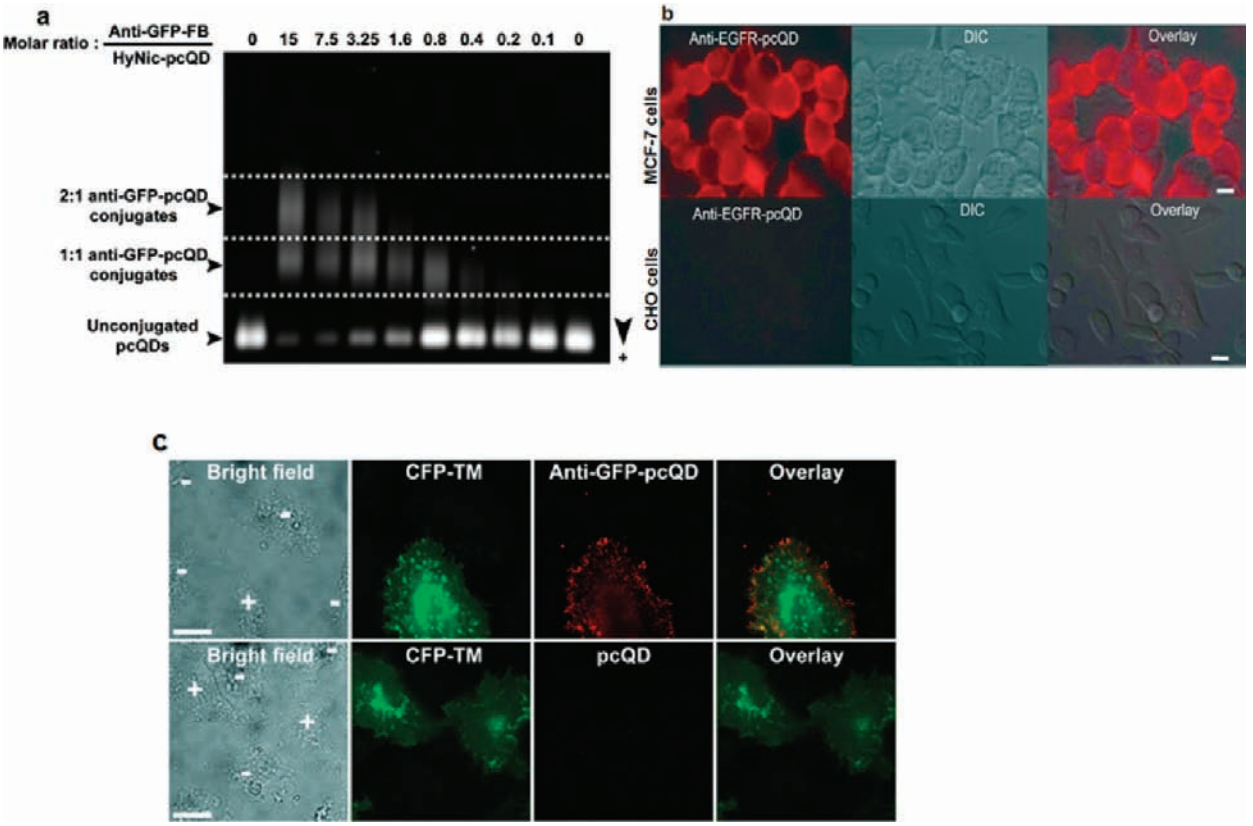

Figure 1. Cell labeling with antibody−peptide quantum dots conjugates formed by bis-aryl hydrazone linkage chemistry. (a) Gel electrophoresis of conjugation reactions between anti-GFP-FB and HyNic-pcQDs at different molar ratio. The faster migrating unconjugated HyNic-pcQD fluorescence band is depleted with increasing conjugation ratio, and discrete 1:1 and 2:1 stoichiometry anti-GFP-pcQD conjugate bands migrating more slowly in the gel appear. The side arrow indicates the direction of the electric field. (b) Labeling of live breast cancer cells MCF-7 overexpressing EGFR at the plasma membrane showing specificity with anti-EGFR-pcQD conjugate (top left); DIC image (top center) and overlay (top right). Corresponding labeling of nonexpressing EGFR live CHO cells shows no binding of anti-EGFR-pcQDs as seen in bottom right and overlay. Scale bar: 5 μm. (c) Labeling of live HeLa cells with anti-GFP-pcQD conjugates formed by the reaction of HyNic-activated anti-GFP IgG with FB-activated pcQDs (top) or with unconjugated FB-activated pc-QDs (bottom). Anti-GFP-pcQD conjugates specifically bind the plasma membrane of HeLa cell expressing a transmembrane CFP-TM receptor (+) with little nonspecific binding to nonexpressing cells (−). In the absence of antibody conjugation, no labeling to expressing cells was observed. Scale bars: 20 μm.

While generating the complementary and reactive QD (**1B**) and antibody (**2B**) species, it was important to validate the presence and to quantify the respective cross-linkers on the QDs and the antibodies. This was done using absorbance spectroscopy (Supporting Information Figure S.2) followed by a calculation of the molar substitution ratios (MSR) of each reaction. The presence and quantity of FB or HyNic groups on the surface of pcQDs and on secondary antimouse $F(ab)_2$ antibodies (used as substitutes to the more expensive anti-EGFR or anti-GFP antibodies) were measured by monitoring the increase in absorbance at 350 and 390 nm. No further increase in absorbance was observed after 100 min of reaction (Supporting Information Figure S2). The MSR of FB-activated pcQDs and HyNic-activated $F(ab)_2$ antibodies was calculated to be 10 and 1.15, respectively. In general, increasing the linker concentration beyond a maximum of 20 mol equiv for NHS-FB, PF-PEG-FB, or NHS-HyNic resulted in precipitation of the antibodies or pcQDs. For the conjugation of anti-EGFR antibodies to pcQDs, the reaction was optimized using PEG-FB-pcQDs and HyNic-modified anti-EGFR at a 1:4 molar ratio. For conjugation to anti-GFP, a 1:10 molar ratio of FB-pcQDs to HyNic-modified anti-GFP antibodies was used. When reactive groups were reversed, for instance, using HyNic-pcQD and FB-activated anti-GFP antibodies, the reaction ratio was optimized by gel electrophoresis. As shown in Figure 1a, the conjugation efficiency increased with increasing anti-GFP-FB:HyNic-pcQD ratios and was characterized by the depletion in unconjugated HyNic-pcQD fluorescent bands and the appearance of discrete and gel-shifted anti-GFP-pcQDs 1:1 and 2:1 conjugate bands. The distribution of stoichiometries (of anti-GFP-pcQDs and free pcQDs) was in good agreement with the expected Poisson distribution as previously observed for monofunctional bioconjugation of pcQD[17] (Supporting Information Figure S.3).

To demonstrate the activity of the different antibody-pcQD conjugates obtained by bis-aryl hydrazone chemistry, we tested their ability to specifically recognize membrane bound antigens in living cells. EGFR, which is often overexpressed on the cell surface in several cancers is a potential target for clinical therapy, was specifically recognized by anti-EGFR-pcQD conjugates in live MCF-7 breast cancer cells (Figure 1b) and in live U87 human glioblastoma cells (Supporting Information Figure S.4). No cell membrane staining was observed for CHO cells (Figure 1b) that do not express EGFR. An overlay of the fluorescent and DIC channel clearly confirmed the localization of the anti-EGFR-pcQD

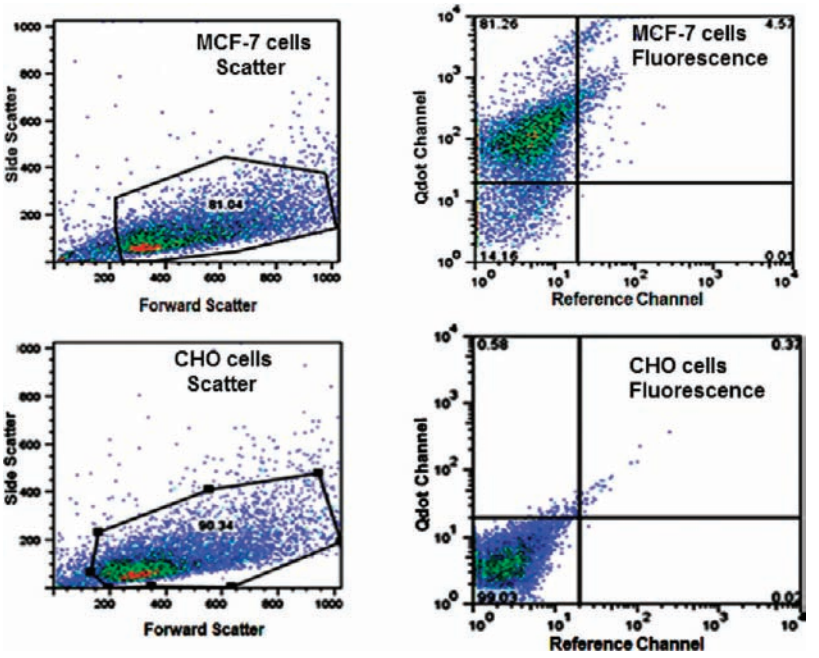

Figure 2. Flow cytometry analysis of live MCF-7 and CHO cells labeled with anti-EGFR-pcQDs. Top panel shows specific binding of 25 nM of anti-EGFR-pcQD conjugates to MCF-cells overexpressing EGFR while the bottom panel shows absence of binding to EGFR negative CHO cells at a similar concentration.

conjugates on the cell surface of cancer cells (Figure 1b), and the limited nonspecific binding observed was likely due to the presence of PEG in the linker. Similar results were obtained with anti-GFP-pcQD conjugates that specifically cross-reacted with cyan fluorescent protein (CFP) fused to the transmembrane domain of the platelet-derived growth factor receptor (CFP-TM) when expressed in the plasma membrane of HeLa cells (Figure 1c, Supporting Information Figure S.5). Again, minor nonspecific binding to nonexpressing cells was observed and cells were not labeled with unconjugated pc-QDs (Figure 1c, Supporting Information Figure S.5). Single QD tracking of CFP-TM receptors in the plasma membrane of live HeLa cells could be achieved using monofunctional anti-GFP-pcQD conjugates (Supporting Information video 1). When delivered within the cytoplasm of living cells, for instance, using INFLUX pinocytic loading[19] anti-GFP-pcQD conjugates also efficiently targeted intracellular GFP fusion proteins such as the integral membrane anchored caveolin-1-GFP (Supporting Information Figure S.6, video 2).

To extend the utility of anti-EGFR-pcQD conjugates, in particular, for immunophenotyping experiments,[20] titration and binding efficiencies were compared for EGFR overexpressing MCF-7 breast cancer cells versus nonexpressing CHO cells by flow cytometry measurements (Figure 2, Supporting Information Figure S.7). More than 80% of MCF-7 cells were fluorescent when stained with a 25 nM concentration of anti-EGFR-pcQD, while less than 1% CHO cells were labeled under the same conditions (Figure 2). Control experiments with pcQD reacted with a normal mouse IgG_{2a} isotypic antibody (25 nM IgG_{2a}-pcQDs) via the same bis-aryl hydrazone conjugation strategy showed an absence of cell surface staining for both MCF-7 and CHO cell lines (Supporting Information Figure S.8). The combined results from fluorescence microscopy and flow cytometry experiments clearly demonstrate the utility of this bis-aryl hydrazone conjugation chemistry for the production of relatively small size, active antibody-QD conjugates. In addition to pcQDs,

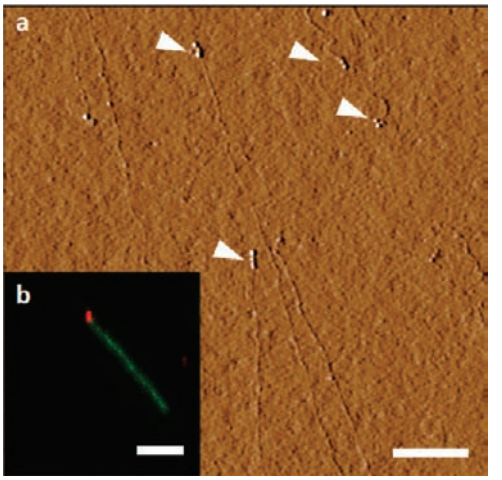

Figure 3. *In vitro* detection of DNA binding proteins using antiRNAP-pcQDs. (a) AFM height image of extended T7 bacteriophage DNA reacted with *E. coli* RNAPs. The protrusions at the end of the DNA fiber (arrows) confirm specific binding of RNAPs to their expected location on the T7 genome. Scale bar 1 μm. (b) Fluorescence image of the same sample after incubation with pcQDs conjugated to antibodies against *E. coli* RNAP allows specific QD recognition of RNAP on the T7 genome. Scale bar 5 μm.

commercial amine-PEG-545 nm and amine-coated 611 nm QDs (Life Technologies or eBioscience) conjugated to antibodies via the same bis-aryl hydrazone linkage showed similar conjugation kinetics and labeling efficiency in living cells, although their larger size compared to pcQDs prevented the isolation of antibody-QD conjugates with well-defined stoichiometry (unpublished results).

To further demonstrate the utility of bis-aryl hydrazone linked antibody-pcQD conjugates, we employ them for an *in vitro* optical imaging application. The detection of *E. coli* RNA polymerases

(RNAPs) interacting with T7 bacteriophage genomic DNA combed on glass surfaces was taken as a model system. *E. coli* RNAPs strongly interact with binding sites (promoters) in the first 750 base pairs of the T7 genome[21] as confirmed by atomic force microscopy (AFM) imaging[22] (Figure 3a). For optical detection of RNAPs along the T7 genome, hydrophobic QDs emitting at 605 nm were coated with peptides described above and conjugated to antibodies directed against the β subunit of *E. coli* RNAP. The anti-RNAP-pcQD conjugates were reacted with the T7-genome/RNAP complex and the sample was stretched on a polylysine modified glass coverslip after staining with YoYo-1, a DNA intercalating dye (Life Technologies). When the complexes were imaged by fluorescence microscopy, anti-RNAP-pcQDs (Figure 3b, red) were detected at the extremity of the T7-genomic DNA (Figure 3b, green), an indication of effective and specific RNAP targeting *in vitro*.

A substantial body of work related to hydrazone bonds have been implemented for a variety of pH-sensitive conjugates of anticancer drug doxorubicin with antibodies, polymers, micelles, and particles.[23,24] The stability of certain types of hydrazone linkers is well documented at 7.4, while at a lower pH 5.0 these linkers undergo hydrolysis.[23,25] Few examples of hydrazone linker technology incorporated in antibody drug conjugates are as follows: (i) Mylotarg,[26] (ii) the antibody−calicheamicin conjugate,[27] and (iii) CMC-544, a promising drug−antibody conjugate—N-acetyl γ calicheamicin dimethylhydrazide (CalichDMH) conjugated to humanized anti-CD22 monoclonal antibody.[28] While Mylotarg was recently withdrawn from the market by FDA due to fatalities reported in humans, CMC-544 is currently being evaluated in a phase III study for the treatment of B-lymphoid malignancies. Both drugs have incorporated the concept of acid hydrolyzable linker which is different from the aromatic bis-aryl hydrazone conjugate used in this study. The aromatic bis-aryl hydrazone is more stable in the pH range 5−8 relevant to *in vitro* and cell surface labeling experiments. It would therefore be interesting to test in the future the efficacy and stability of the bis-aryl hydrazone linker technology in preclinical settings in mice.

There are several advantages to the aromatic aldehyde-hydrazone QD conjugation strategy described here. First, FB-pcQDs, PEG-FB-pcQDs, or HyNic-pcQDs obtained after purification of the linkers or removal of excess coating peptides, can be stored for 4−6 months at 4 °C with minimal loss in activity. Second, proteins or other biomolecules conjugated with either of these linkers can themselves be conserved for extensive periods by freezing. Third, the internal UV traceable markers built in both types of linkers allows for easy monitoring and control of the MSR when modifying QDs or proteins. Fourth, bioconjugation only requires mixing the two active (QD and protein) components and the reaction efficiency of bis-aryl hydrazone formation can be further improved in the presence of aniline.[11,12,29,30] In this context, a method for controlled assembly of QD-biomolecule hybrids using aniline catalyzed hydrazone ligation has been successfully demonstrated.[31] Further utility of the aniline catalyzed hydrazone reaction has been shown for attaching protein capture reagents to model silicon dioxide surface suggesting that it can be used for biosensor applications in the biomedical field.[32] Fifth, the small size of pcQDs and that of the antibody-pcQD conjugates allows for an easy production and purification of monofunctional conjugates and antibody-pcQDs with well-defined stoichiometry. Sixth, the bioorthogonal reactivity of the bis-aryl hydrazone linkage should favor the control grafting of multiple proteins or reactive moieties on the surface of individual pcQD, and should facilitate the production of multifunctional QD probes. Finally, for bioorthogonal site-specific targeting and imaging in living cells, a formylglycine aldehyde tag[33,34] can be genetically engineered into proteins, which can be potentially targeted via hydrazone activated pc-QDs.

Figure S3 Analysis of heterogeneities in the conjugation of anti-GFP-FB with HNA-pcQDs. Mean fluorescence intensity values were determined from region of interests corresponding to discrete bands in the agarose electrophoresis gel (ROI, white squares), and were corrected for background fluorescence (red square). For each conjugation molar ratios, the distribution intensity of each discrete bands (N=0, 1, 2 and 3) was reported and compared to the theoretical distribution in stoichiometry expected for a Poisson statistical process (Table). *Ratios* corresponds to the ratio of anti-GFP-FB:HNA-pcQD in the coupling solution. *Average* is the average number of conjugated anti-GFP-pcQDs for a given ratio. *M* is the measured fraction of HNA-pcQDs for a given ratio of anti-GFP-FB. *P* is the theoretical fraction $P(N) = a^N e^{-a}/N!$ computed for a Poisson distribution with average value a = *Average*. For all conjugation ratio tested, the distribution in stochiometry of anti-GFP-pcQDs and free pcQDs was in good agreements with that expected for a Poisson statistic.

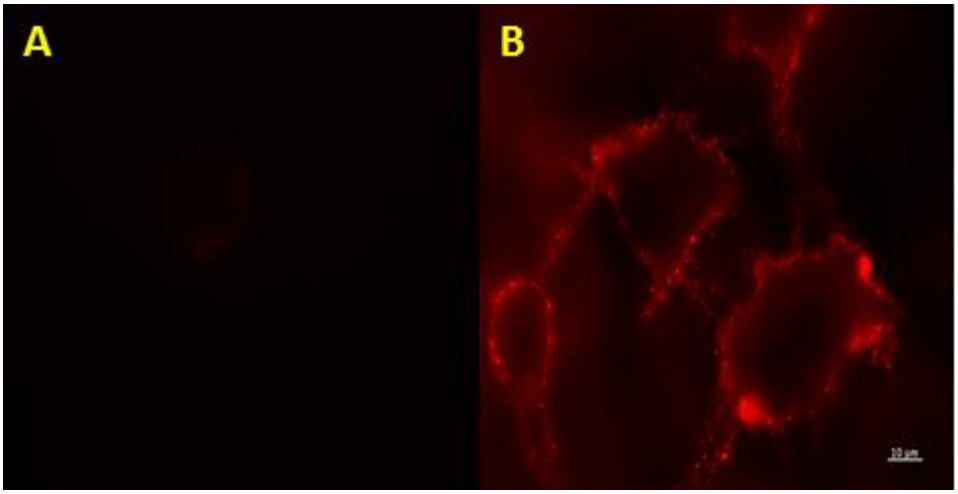

Figure S4. Fuoresence microscopy images of endogenous overexpressing EGFR receptors on plasma membrane of U87 Glioblastoma cells. (A) Cells were labeled with PEG4-4FB pcQDs showing absence of labeling of EGFR. (B) Same cells were labeled with anti-EGFR-PEG4-4FB pc-QDs showing distinct labeling of EGFR on the cell surface. Scale bar: 10 μm.

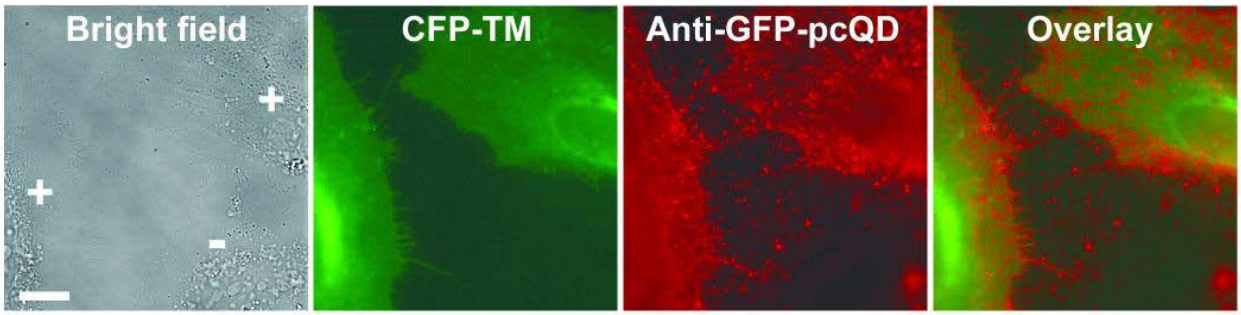

Figure S5. Labeling of live HeLa cells with 1:1 anti-GFP-pcQD conjugates formed by the reaction of anti-GFP-4FB with HyNic-pcQDs at 1.6 molar ratio. As observed for other conjugates, HeLa cells expressing the transmembrane CFP-TM receptors (+) are specifically labeled. Scale bar: 10 μm.

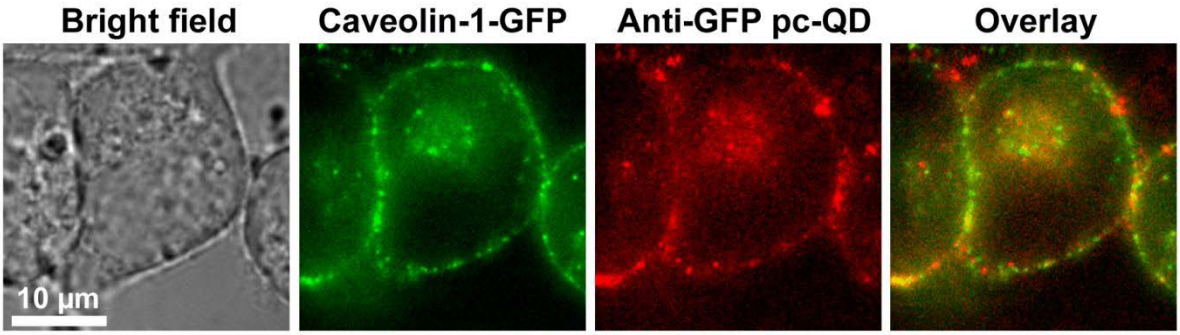

Figure S6. Live cells intracellular protein staining with peptide-coated QD-antibody conjugates

Living HeLa cells expressing the intracellular and integral plasma membrane protein caveolin-1-GFP are labeled with peptide-coated QDs conjugated to anti-GFP antibodies by the reaction of HyNic-activated anti-GFP IgG with FB-activated pc-QDs. QD-anti-GFP conjugates are translocated to the cells' cytoplasm by pinocytic loading using INFLUX reagent. When imaged by wide field fluorescence microscopy, the typical punctuated pattern of caveolae-associated cav-1-GFP at the plasma membrane of HeLa cells and a perinuclear pool of cav-1-GFP are visible in the GFP channel. When the cells are imaged in the QD channel, a similar staining pattern is observed indicating effective targeting of cav-1-GFP by the QD conjugate. Colocalization of caveolae and QD-anti-GFP is observed at the plasma membrane despite the presence of a few QDs still associated with pinosomes and not released during pinocytic loading.

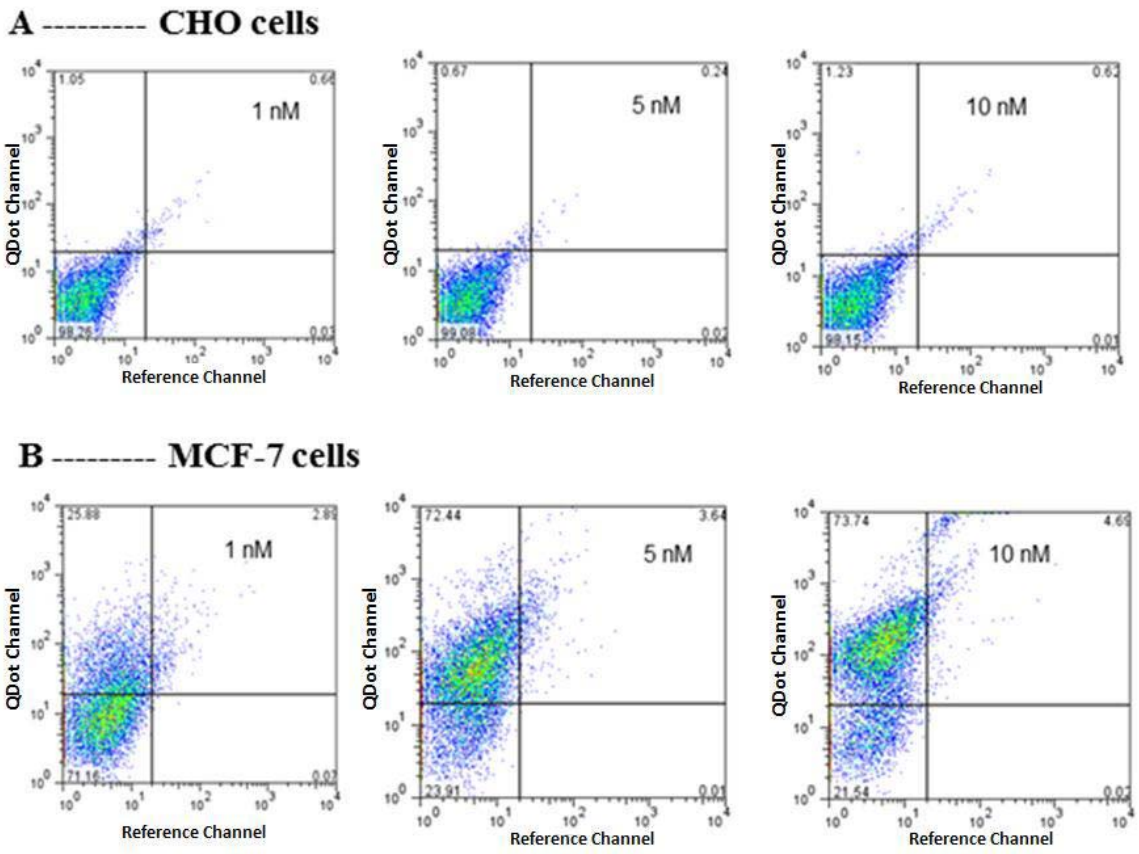

Figure S7. Flow cytometry of Chinese Hamster ovary non expressing EGFR and MCF-7 breast cancer cells overexpressing EGFR. Staining of CHO cells (A-top panel) and MCF-7 cells (B-bottom panel) was carried out by titrating anti-EGFR PEG4-4FB-pcQDs at 1, 5 and 10 nM concentration. A clear labeling of EGFR receptors on MCF-7 cells was observed with increasing concentration while it was absent in CHO cells at similar range of concentration of pc-QD bioconjugate.

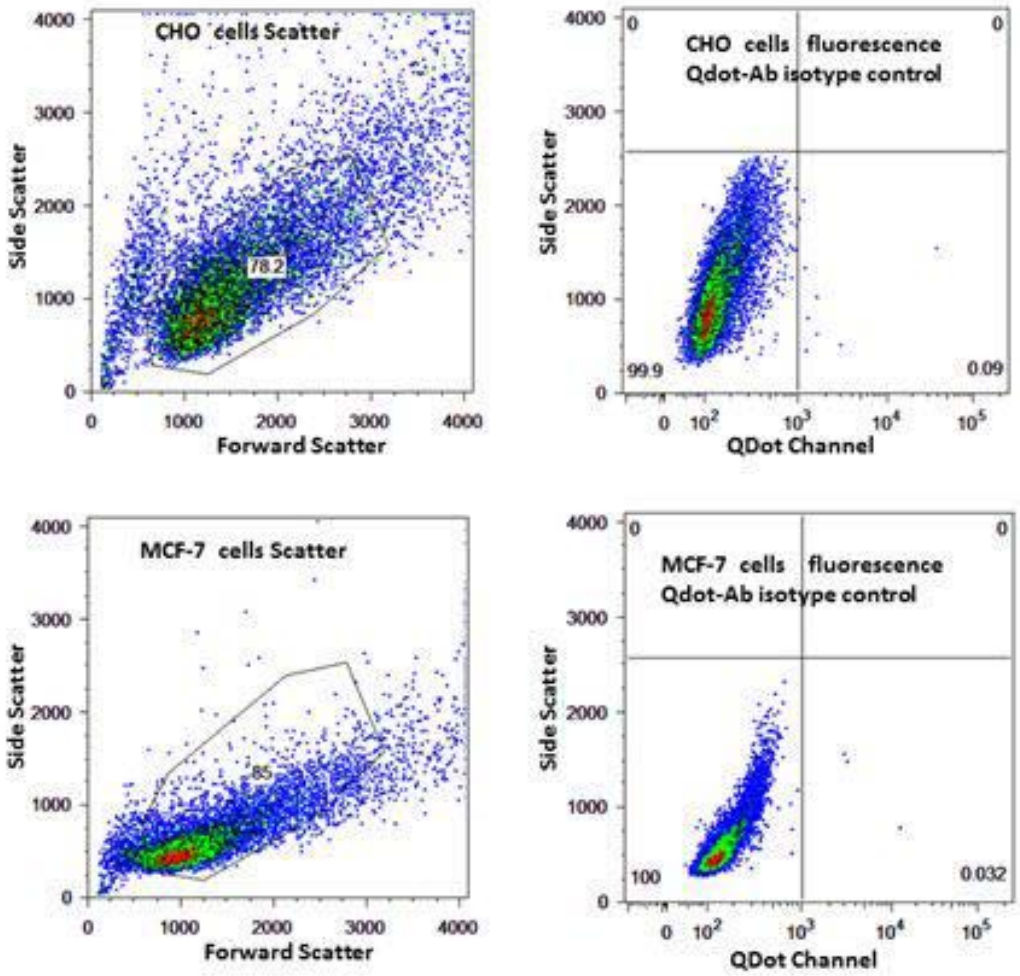

Figure S8.

Flow cytometry of and Chinese Hamster ovary non expressing EGFR (top) and MCF-7 breast cancer cells overexpressing EGFR (bottom) using normal mouse IgG_{2a} isotype control conjugated to pc-QDs. Staining of CHO cells (top panel) and MCF-7 cells (bottom panel) was carried out at 25 nM concentration. A clear absence of labeling of cell surface of either cell line using the isotype control suggested the specificity of the antibodies to EGFR-pcQDs using this conjugation strategy as shown in Figure S7.

Experiment Details

Preparation of Quantum dots: The synthesis of CdSe/CdS/ZnS core/shell QDs followed the description in reference (Li, JACS 2003). Post-synthesized CdSe was purified from the excess ligands and the unreacted precursors. Predegassed hexadecylamine and 1-octadecene were mixed with purified CdSe core for core/shell growth. SILAR approach was applied for multiple shells growth by dripping Cd, S and Zn precursor solutions (all at 0.04M) alternatively and sequentially into the reaction media at 235ºC. Shell growth was allowed for about 10 min following the finish of each precursor addition. With a 3.8 nm CdSe core, 3 layers of CdS and 2 layers of ZnS were grown intentionally. The final absorption was peaked at 608 nm, emission at 629 nm. Transmission Electron Microscopy (TEM) images were taken on Titan 80-300 kV S/TEM (FEI) on ultra-thin carbon coated copper grids.

Commercial Quantum dots: NH_2-PEG 545 nm (Invitrogen), Amine-605nm (Ebioscience) and inorganic 611 nm in toluene (Evident Technologies) CdSe/ZnS QDs was purchased for this study.

Modification of terminated peptide-coated quantum dot with 4-formylbenzoate and PEG4-4FB: Hydrophobic CdSe/ZnS QDs (Evident Technology, λ_{em} =605 nm) were coated with 100% of lysine and glycine terminated phytochelatin-related peptides using published procedures (Pinaud, King et al. 2004; Iyer, Pinaud et al. 2007). In brief, 45 µL of QD stock solution in toluene was heated fully to remove the toluene solvent and redispersed in 450 µL of pyridine, under gentle heating. 4 mg of an N-terminal acetylated $_{ac}$-FCCFCCFCCFGSESGGSESGK

peptide and Amide FCCFCCFCCFGSESGGSESG-NH_2 (New England Peptide) was dissolved in 50 µL dimethyl sulfoxide (DMSO), mixed with the QDs in pyridine, and peptide exchange was triggered by the addition of 10 µL of tetramethylammonium hydroxide (25% w/v in methanol). After centrifugation and redissolution in DMSO, pcQDs were eluted through a G25 Sephadex column equilibrated with H_2O and excess non-bound peptides were removed by two consecutive run on G-50 spin columns (Harvard Apparatus) equilibrated with 50 mM borate + 50 mM NaCl pH 7.4 buffer. Lysine terminated pcQDs at ~ 400 nM were kept at 4°C until further use. For activation of lysine terminated pcQDs with succinimidyl 4-formylbenzoate (SFB), a SureLINK™ bionconjugation kit (KPL) was used. A fresh solution of SFB and PEG4-4FB was prepared in DMSO at 6 mM and a 20-fold molar excess of SFB and PEG4-4FB was incubated with lysine and glycine terminated pcQdots for 2 hours at room temperature in 50 mM borate + 50 mM NaCl pH 7.4 buffer. After conjugation excess SFB was removed by two consecutive run on G-10 spin columns (Harvard Apparatus) equilibrated with 100 mM NaCl + 50 mM Na-phosphate pH 5.7. FB-activated pcQdots at ~400 nM were kept at 4°C until further use.

Quantum dot coating with hydrazine functionalized synthetic peptides. Hydrophobic CdSe/ZnS QDs (Evident Technology, λ_{em} =605 nm) were coated with 100% of phytochelatin-related peptides synthesized with HydraLinK™ 6-Fmoc-HNA reagent (Merck4Biosciences) to add the 6-hydrazinonicotate (HNA) at the N-terminus of the peptide as follow : HNA-GGSESGGSESGFCCFCCFCCF$_{\text{-amide}}$. Peptide coating was performed exactly as above, except that excess non-bound peptides were removed by two consecutive run on G-50 spin columns equilibrated with 100 mM NaCl + 50 mM Na-phosphate pH 5.7. HNA-pcQDs at ~400 nM were kept at 4°C until further use.

Modification of anti-GFP,anti-EGFR and secondary $F(ab)_2$ antibodies with 6-hydrazinonicotinate acetone hydrazone (HyNic), Succinidyml-C6-HyNic (C6-SANH) or 4-formylbenzoate. For 6-hydrazinonicotinate acetone hydrazone modification, anti-GFP rabbit IgG antibodies that cross reacted with CFP (Invitrogen) at 2 mg/ml in PBS buffer PH 7.2 were reacted with a 20 fold molar excess of succinimidyl 6-hydrazinonicotinate acetone hydrazone (SHNA) in DMSO from the SureLINK™ bionconjugation kit. Incubation was done for 2 hours at room temperature and excess SHNA was removed by two consecutive run on G-10 spin columns equilibrated with 100 mM NaCl + 50 mM Na-phosphate pH 5.7. HNA-activated anti-GFP IgG at ~2 mg/ml were kept at 4°C until further use. For C6-SANH modification, anti-EGFR monoclonal antibodies (sc-120, 200 μg/ml. special order, gelatin free, Santa Cruz Biotechnology) and goat anti-mouse $F(ab)_2$ at 2mg/ml (Pierce biotechnology) were reacted with a 15 fold molar excess of C6-SANH and incubated for 2 hours at room temperature. Excess linkers were removed and exchanged into 150 mM NaCl + 100 mM Na-phosphate pH 6.0 using pre-equilibrated 2 ml Pierce desalting column. C6-SANH antibodies obtained were quantified using a uv-vis spectrophotometer at 280 nm and stored at 1-2 mg/ml concentration. For 4-formylbenzoate modification, anti-GFP rabbit IgG antibodies at 2 mg/ml in PBS buffer PH 7.2 were reacted with a 20 fold molar excess of SFB from the SureLINK™ bionconjugation kit, and incubated for 2 hours at room temperature. Excess SFB was clean by two consecutive run on G-10 spin columns equilibrated with 100 mM NaCl + 50 mM Na-phosphate pH 5.7, and FB-activated anti-GFP IgG at ~2 mg/ml were kept at 4°C until further use.

Conjugation of anti-GFP and anti-EGFR antibodies to pcQD: A 10-fold molar excess of HNA-activated anti-GFP IgG was reacted with 300 nM of FB-activated pcQdots in 100 mM NaCl + 50 mM Na-phosphate pH 5.7 for 3 hours at 4°C, and use without further purification for

cell labeling assays. 0.5 nmole of PEG4-4FB-pcQDs was reacted with 3.6 nmole of C6-SANH-anti-EGFR antibodies and $F(ab)_2$antibody conjugation in 150 mM NaCl + 100 mM Na-phosphate pH 6.0 overnight at 4°C for 24 hours and used without further purification for cell labeling assays. The reaction of HNA-pcQDs with FB-activated anti-GFP IgG for gel assays was optimized by incubating of 1 µl of 400 nM HNA-pcQDs with 1 µl of FB-activated anti-GFP IgG at the indicated final molar ratio. The incubation was performed for 3 hours at room temperature before immediate loading on agarose gels. The reaction of HNA-pcQDs with FB-activated anti-GFP IgG for cell staining was done by incubating 20 µl of 400 nM HNA-pcQDs with 20 µl of FB-activated anti-GFP IgG at 750 nM (1.8 molar excess) for 150 min at room temperature. The reaction was then quenched by the sequential addition of 600 µM 4-nitrobenzaldehyde and 500 µM 2-hydrazinopyridine and further incubation for 2 hours. Half of the reaction volume was analyzed by agarose gel electrophoresis, while the other half was used for cell staining.

Gel electrophoresis. Conjugation reactions at different molar ratio between HNA-pcQDs and FB-activated anti-GFP IgG were loaded on 0.8% agarose gels in x1 TAE buffer (40 mM Tris, 40 mM acetate, 1 mM EDTA, pH 8.3). The 2 µl samples were diluted into 6 µl loading buffer and gel where run for 40 minutes at 110V, before being imaged using ultraviolet excitation and detection with a CCD camera (Kodak). For electrophoresis of large volumes of HNA-pcQDs / FB-activated anti-GFP conjugates at 1.8 molar ratio, half of the reaction was loaded into five different wells, and electrophoresed on a 0.8% agarose gels in x0.5 TAE buffer for 40 min at 35V. After electrophoresis, fluorescence bands corresponding to anti-GFP-pcQD conjugates or to non-conjugated pcQDs were cut and QDs were eluted from the gel as previously described(Pinaud, Clarke et al. 2010).

Estimation of 4FB groups on pc-QDs: 0.5 mM of 2-hydrazinopyridine-2HCl (2HP) solution was prepared in fresh 2-(N-morpholino) ethanesulfonic acid (MES) buffer, pH 5.0. 10µl of 0.5 nmole 4FB activated pc-QDs solution was mixed with 90 µl 2HP reagents at room temperature. Reaction kinetics of bis aryl-hydrazone bond formation between 2HP and FB-QDs was monitored for 100 min at 350 nm using a uv-vis spectrophotometer. After 100 min, the molar substitution ratio for FB-QDs was calculated to be 10 using the extinction coefficient at 18000 for the hydrazone chromophore (Solulink).

Estimation of HyNic groups on antibodies: 0.5 mM solution of p-nitrobenzaldehdye (pNB) solution in fresh 2-(N-morpholino) ethanesulfonic acid (MES) buffer, pH 5.0. 10 uL of the C6-SANH activated $F(ab)_2$ antibodies was reacted with 90 ul pNB solution at room temperature. The formed hydrazone bond was monitored by UV-Vis at 390 nm and the molar substitution ratio for protein was 4.15 using the extinction coefficient at 24,000 (Solulink).

Cells staining and imaging. HeLa and MCF-7 cells were maintained at 37 °C and 5% CO_2 in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 µg/mL streptomycin while CHO cells were maintained under identical conditions in F-12 media. One day before transfection, HeLa cells were plated on fibronectin-coated glass coverslips to achieve a confluency of 50-80% while MCF-7 and CHO cells were plated on 35 mm Mattek No 1.5 glass bottomed petridishes. Cells were transfected with a plasmid encoding the transmembrane domain of the platelet-derived growth factor receptor fused to CFP (AP-CFP-TM, a gift from Alice Ting) using Fugene 6 (Roche). 48 hours after transfection, cells were briefly washed with HBSS buffer + 1% BSA, and incubated in this buffer for 3 minutes at 37°C, before adding anti-GFP-pcQD and anti-EGFR-pcQD conjugates at 5 nM

and 10 nM final concentration and incubating for 10 min at 37°C. Cells were then washed with HBSS buffer before being imaged. Imaging of HeLa cells was done in HBSS buffer at 37°C on an inverted wide-field epifluorescent microscope (IX70, Olympus) equipped with a 100X oil objective (NA=1.45, Olympus) a broad-spectrum mercury lamp excitation source and appropriate emission filters for CFP and pcQD-605 while imaging of MCF-7 and CHO cells was done on with a Zeiss 200M epifluorescence microscope with a 63× water-immersion objective (NA)=1.2 (Carl Zeiss) equipped with a motorized platform for *z*-stack imaging and deconvolution, a 100 W mecury lamp as excitation source and appropriate emission cubes for pcQD-630 nm. Images were acquired with a QuantEM:512SC EMCDD camera (Photometrics).

Flow cytometry. Labeled mammalian MCF-7 and CHO cells were measured using the BD FACSAria (Becton Dickinson, Franklin Lakes, NJ) digital cell sorter equipped with BD FACSDiVa software. The cytometer has three lasers emitting at 488, 633, and 405 nm. The 405 laser nm laser was used to excite anti-EGFR pcQDs whose emission was detected using a 630/30 band pass filter. Cells were gated based on their forward versus side scatter profile and fluorescence was measured in a 2-dimensional plot of FITC versus QD. A negative control which were unlabeled cells was used to check the voltages for leak through and no compensation was necessary. Titration experiments with anti-EGFR emitting 630 QDs were carried out at 1, 5, 10 and 25 nm concentrations.

Supplementary video 1: Cell membrane diffusion of targeted anti-GFP-pcQD conjugates. anti-GFP-pcQD were incubated for 10 min with CFP-TM expressing (bottom) and non-expressing (top) HeLa cells. Anti-GFP-pcQD conjugates specifically recognize the CFP-TM receptors and diffuse in the plasma membrane. The video is a composite overlay of a fixed CFP-TM fluorescence image (green) and its corresponding anti-GFP-pcQDs video taken at a rate of 100

ms per frame (red). The last frames correspond to the maximum intensity projection image for all the frames of the anti-GFP-pcQDs video (red) overlaid with the CFP-TM fluorescence image (green). Playback: 30 fps.

Video 2. Sequential video imaging of cav-1-GFP (green, top) and QD-anti-GFP conjugates (red, bottom) of cav-1-GFP expressing or non-expressing HeLa cells after cytoplasmic delivery of QD-anti-GFP conjugates by pinocytic loading. Please note the similar staining patterns of GFP and QD for expressing cells and the absence of QD plasma membrane staining for the non-expressing cell. Acquisition: 100 ms/frame; Playback: 30 frames/s.

ABSTRACT: Nanoparticle-supported liposomes can be a promising platform for drug delivery, vaccine development, and biomedical imaging. Single-walled carbon nanohorns are a relatively new carbon nanomaterial, and they could be used as carriers of drug and imaging reagents. Assembling lipids around carbon nanohorns would confer this nanomaterial much broader applications such as vaccine development and targeted drug delivery by embedding a target protein or immunogenic protein into the lipid bilayer structure. Here, we show the assembly of functionalized single-walled carbon nanohorns ($-CH_2-CH_2-COOH)_x$, ~100 nm) with positively charged lipids through a freeze and thaw cycle. The assembled complex particles can be readily separated from individual nanohorns or liposomes under specific centrifugation conditions. The results from transmission electronic microscopy, flow cytometry through nitrobenzoxadiazole labeled lipids, and zeta potential analysis clearly show that the nanohorns are encapsulated by liposomes with a median size of ca. 120 nm.

Liposomes and many types of nanoparticles have been studied as potential drug delivery vehicles. Despite the similarities, i.e., they both can have a desirable loading capacity and release the contents at a controlled rate in a specific location when attached with targeting ligands, liposomes and nanoparticles are complementary delivery systems because (1) nanoparticles tend to have a longer half-life during the circulation in blood and the extravasations from plasma to the tumor cells;[1,2] (2) liposomes provide a better chance to deliver drugs across cell membrane at the targeting site; and (3) they have different drug preferences, loading, and releasing chemistry.[1,2] However, the combination of the two types of particles could possess unique advantages over any of the particles alone. Nanoparticle supported liposomes (NsLs) have recently been assembled and described.[3] Nanoparticles usually stabilize the liposomes through electrostatic interactions and may also increase the concentrations of poly(ethylene glycol) (PEG) that can be attached to the surface of liposomes, resulting in NsLs, when intravenously injected, with improved ability to evade clearance by the reticuloendothelial system (RES).[3] NsLs could have a large loading capacity and a desirable controlled release rate depending on the large adsorption area and special pore surface chemistry of the encapsulated nanoparticle.[4] Moreover, a targeting ligand attached liposome could transport nanoparticles into cells through receptor-mediated endocytosis. This is critical when large molecule drugs or therapeutic genes are to be released into the cytoplasm.[5]

In this report, functionalized (carboxylated) carbon single-walled nanohorns, SWNH $(-CH_2-CH_2-COOH)_x$, were prepared to provide SWNHs with hydrophilic surfaces for encapsulation into the liposomes. The SWNH$(-CH_2-CH_2-COOH)_x$ are nontoxic[6,7] nanoparticle aggregates of single graphene tubules and are spherical dahlia-like-shaped with a narrow diameter range reported as 80−100 nm.[8] The surface area of SWNHs range from 300 to 1000 m^2/g.[9] The functionalization process introduces mesoporous structures on the SWNHs, and consequently, drug molecules could bind not only to the surface, but also to the inner graphene wall. Research has also shown that molecules that have stacking aromatic rings once diffused into SWNHs will release in a slow and stable manner.[10]

Single-walled nanohorns were synthesized by Nd:YAG laser vaporization of graphite rods in an argon atmosphere at 1100 °C as described in detail elsewhere.[11,12] Functionalized SWNH-$(-CH_2-CH_2-COOH)_x$ with carboxyl groups was obtained by high-speed vibration milling as previously described.[13] Briefly, a mixture of nanohorns and succinic acid acyl peroxide (1:100 in mass) was vigorously shaken in a stainless steel capsule for 1.5 h. The ground ultrafine powder was washed three times with acetone and centrifuged to collect the sediment. Twenty minute

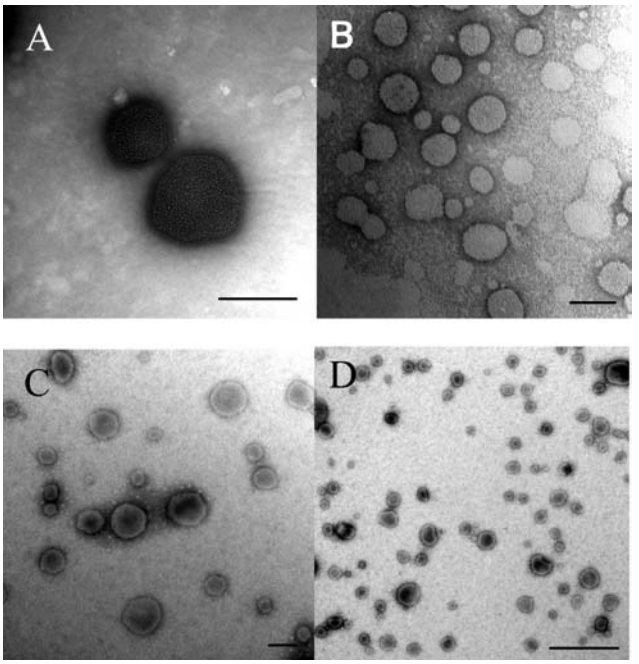

Figure 1. Representative TEM images of (A) SWNH($-CH_2-CH_2-COOH)_x$, (B) hollow DOTAP liposomes, and (C) and (D) SWNH($-CH_2-CH_2-COOH)_x$ supported liposomes. Scale bar in (A), (B), and (C) = 100 nm. Scale bar in (D) = 500 nm. Samples were deposited onto carbon coated copper grids. Negative staining was performed using 2% phosphotungstic acid.

sonication was performed to dissolve the sediment in ultrapure water yielding solutions of SWNH($-CH_2-CH_2-COOH)_x$. On the other hand, cationic liposomes were made by extruding 0.4 mg hydrated 1,2-dioleoyl-3-trimethylammonium-propane (DOTAP) lipid film through polycarbonate membranes with pore sizes of 100 nm. The hydration buffer contains 0.9 NaCl, 5% dextrose, and 10% sucrose in Tris-HCl buffer with a pH at 7.4. SWNH($-CH_2-CH_2-COOH)_x$ were briefly sonicated to break up aggregates and incubated with freshly made cationic liposomes. Particles of these functionalized SWNHs and liposome were quantified by flow cytometer (FCM), and the concentrations were both optimized to ~100 particles/μL. After gently homogenizing the optimized samples at a volume ratio of 1:10 SWNH($-CH_2-CH_2-COOH)_x$:liposomes, a ratio chosen to ensure there are excessive liposomes for functionalized SWNHs, three freeze and thaw cycles were applied using liquid nitrogen and a warm water bath. Samples were then centrifuged under 10 000 rcf for 10 min, and SWNH($-CH_2-CH_2-COOH)_x$ supported liposomes were collected in the top layer. It was also found that, in the presence of 10% sucrose, DOTAP liposomes could be collected in the top layer after 30 min of centrifugation under 16 000 rcf, and SWNH($-CH_2-CH_2-COOH)_x$ could be collected in the top liquid layer after 30 min of centrifugation under 10 000 rcf. Therefore, washing the SWNH($-CH_2-CH_2-COOH)_x$ supported liposomes with the hydration buffer and repeating the centrifugation (10 000 rcf, 10 min) can significantly increase the purity.

Transmission electronic microscopy (TEM) images for SWNH($-CH_2-CH_2-COOH)_x$, hollow liposomes, and SWNH-($-CH_2-CH_2-COOH)_x$ supported liposomes are shown in Figure 1. As can be seen, all particles are of spherical shape and

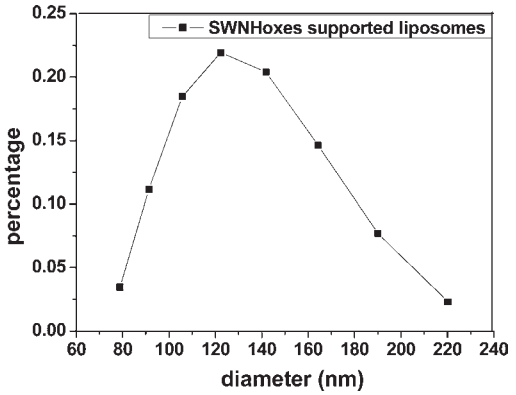

Figure 2. Size distribution of SWNH($-CH_2-CH_2-COOH)_x$ supported liposomes. Refractive index = 1.33. Viscosity = 0.8872 cP. Samples were measured at 25 °C.

have a narrow distribution centered at around 120 nm, which was confirmed by the dynamic light scattering test result shown in Figure 2. As shown in Figure 1C, a SWNH($-CH_2-CH_2-COOH)_x$ supported liposome is a combination of the particles shown in (A) and (B). A negatively charged SWNH($-CH_2-CH_2-COOH)_x$ is encapsulated in a cationic liposome and could stabilize and support the liposome from inside. The large-scale view of the particles shown in Figure 1D illustrates that a high purity of the assembled complex particles can be achieved by the centrifugation step described above. Centrifugation in the presence of 10% sucrose was performed only once in this case, but no hollow liposome or unencapsulated SWNH($-CH_2-CH_2-COOH)_x$ was observed in Figure 1D.

To further confirm the structure of the particles, nitrobenzoxadiazole (NBD) labeled 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine was added to the lipid mixture (up to 15% mass ratio) to produce NBD-DOTAP liposomes and SWNH($-CH_2-CH_2-COOH)_x$ supported NBD-DOTAP liposome assembly. Results of the fluorescence of different particles detected by FCM are shown in Figure 3. The overlay histogram shows a similar fluorescence intensity shared by NBD-DOTAP liposomes and SWNH($-CH_2-CH_2-COOH)_x$ supported NBD-DOTAP liposomes, and SWNH($-CH_2-CH_2-COOH)_x$ particles without liposomes assembled around show no fluorescence signal. These results indicate that the surface structure of SWNH($-CH_2-CH_2-COOH)_x$-supported liposome samples is most likely the same as that of hollow NBD-DOTAP liposomes, since the granularity and fluorescence intensity are almost identical (see FCM scatter plots in Figure 3). Zeta potential and electrophoresis mobility of the three particles shown in Table 1 further confirm the similar surface characteristics of DOTAP liposomes and SWNH($-CH_2-CH_2-COOH)_x$-supported DOTAP liposomes (N^-sL^+, negatively charged nanohorn supported positively charged liposomes), since their zeta potentials significantly differ from that of SWNH($-CH_2-CH_2-COOH)_x$. As expected, those N^-sL^+ particles and SWNH($-CH_2-CH_2-COOH)_x$ particles travel in opposite directions in an applied electric field. These results confirm the encapsulation of SWNH-($-CH_2-CH_2-COOH)_x$ in liposomes and that the gray circle surrounding SWNH($-CH_2-CH_2-COOH)_x$ in Figure 1C and D represents DOTAP lipid bilayers. The FCM results shown in Figure 3 also serve as a strong indication that a high purity of the N^-sL^+ particles can be achieved using the purification method described above.

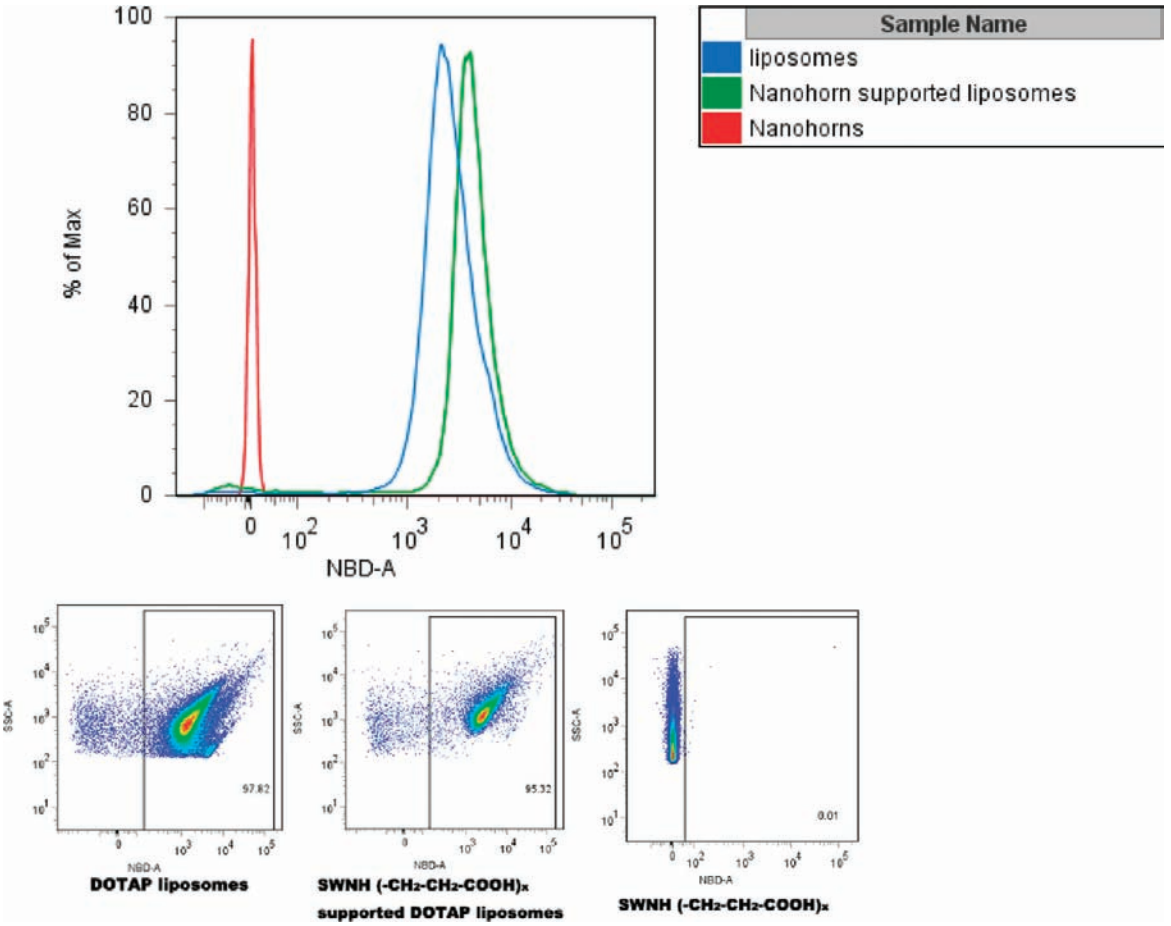

Figure 3. Fluorescent intensity of different particles. The histogram shows the fluorescent intensity distribution of NBD-DOTAP liposomes (blue), SWNH$(-CH_2-CH_2-COOH)_x$ (red), and SWNH$(-CH_2-CH_2-COOH)_x$ supported liposomes (green). The three corresponding FCM scatter plots show distribution of fluorescent intensity (horizontal axis, NBD-A) versus granularity (vertical axis, SSC-A).

Table 1. Zeta Potential and Electrophoresis Mobility of Particles[a]

sample	zeta potential (mv)	electrophoretic mobility (μm·cm/V·s)
hollow DOTAP liposome	24.6	1.928
nanohorn	34.4	−2.694
SWNH$(-CH_2-CH_2-COOH)_x$ supported liposome	22.1	1.732

[a] All samples are in the hydration buffer (pH = 7.4), 25 °C.

Conceivably, functionalized nanohorn supported liposomes will not be limited just to N^-sL^+ types of particles. Positively charged nanohorns can be synthesized by the aryl diazonium functionalization as reported,[14] and therefore, it is possible to assemble the complex particles using negatively charged lipids (N^+sL^-), which are more commonly found in various biological membranes, for biomimetic purposes. The combination of positively or negatively charged nanohorns with anionic or cationic liposomes will significantly broaden the types of drugs that can be loaded, depending specifically on their charge or hydrophobicity. So far, many successful cases have shown that SWNH$(-CH_2-CH_2-COOH)_x$ could be a very promising drug delivery vehicle in terms of the loading capacity and the controlled release. A good example is the anticancer drug cisplatin, which has recently become a commonly used molecule to test the two properties of certain functionalized nanohorns mentioned above.[15,16] However, the effects were mainly evaluated by directly providing cancer cell cultures with treatment of the drug carrying nanohorns. The targeting effect of nanohorns *in vivo* has not been well addressed. How many of the particles injected would nonspecifically bind to normal living cells and lead to their apoptosis is still unknown. On the other hand, liposomes conjugated with targeting ligands such as antibodies can navigate themselves to the cells that have corresponding receptors presented on the cell surface.[17] The particles assembled by the combination of ligand-attached liposomes and nanohorns could present a new and much improved drug delivery platform. For example, cisplatin could be loaded into SWNH$(-CH_2-CH_2-COOH)_x$ particles,[15,16] which could subsequently be assembled with liposomes that contain lipids sensitive to the change of pH (such as dioleoyl-phosphatidyl-ethanolamine, DOPE). Targeting antibodies, such as antihuman epidermal growth factor receptor-2 (HER2) antibody (Herceptin),[18] could be attached to the assembled particles via poly(ethylene glycol) (PEG) on PEGylated phospholipids.[3] The presence of the lipid

bilayer will deter the escape of cisplatin from the particles through diffusion during circulation in blood. However, once the particles enter the targeted cells (such as breast cancer cells via Herceptin-HER interaction[18]), defects will appear on the lipid bilayer structure due to the presence of pH-sensitive lipids,[19] and cisplatin will be released from the particles via the lipid bilayer defects. Research on this novel drug delivery system is currently under investigation in our laboratories.

Functionalized single-walled nanohorn supported liposomes can have more novel applications beyond drug delivery systems. Magnetic resonance imaging (MRI) contrast agents containing Gd^{3+} ions have been loaded into SWNH$(-CH_2-CH_2-COOH)_x$ in the form of $Gd_3N@C_{80}$, trimetallic nitride template endohedral metallofullerenes (TNT-EMFs)[10] to lower the toxicity to the host because (1) lower amount is required due to the high ^1H magnetic resonance (MR) relaxivities of these TNT-EMF contrast agents[20] and (2) the encapsulation of $(Gd_3N)^{+6}$ clusters into fullerene cages limits the exposure to free Gd^{3+} ions.[12] Gadolinium containing SWNH$(-CH_2-CH_2-COOH)_x$ supported liposomes reveal an opportunity to make the drug carrier itself an MRI biosensor. This allows the in situ monitoring of the in vivo biodistributions of drugs in a macro or real-time manner.[21] For example, clearance of liposomes from the bloodstream by the RES, which has greatly limited the development and applications of liposomal models, can be further studied and understood in detail. Locating the pathogenic cells also becomes a possibility when using $Gd_3N@C_{80}$ TNT-EMFs encapsulated targeting nanohorn supported liposomes. The SWNH$(-CH_2-CH_2-COOH)_x$ along with the contrast agent will most likely be found inside the cytoplasm and remain there allowing a slow release of the therapeutic drugs, as the $(Gd_3N)^{+6}$ clusters remain detectable for several days post infusion.[12]

Liposomal vaccines are a new type of vaccine that are assembled by associating antigens with liposomes, and they have attracted much attention because of their high immunogenicity[22] and gene-free nature.[23] Size, exposure of epitopes, and stability of the liposomal vaccine particles are parameters most critical for their immunogenicity.[24,25] A commonly accepted measure to increase the stability is to incorporate PEGylated phospholipids into the liposome, especially when the vaccines are to be injected intravenously. However, the grafting density and polymer length of PEG strongly influence the exposure of the epitopes that need to be presented.[26] SWNH$(-CH_2-CH_2-COOH)_x$ stabilizes liposomes from inside and enables the entire liposome surface to be solely used for epitope presenting, and the size of the assembled particle (80−220 nm, see Figure 2) falls within the range that can be efficiently taken up by dendritic cells.[24]

In summary, we have shown the assembly and structure of SWNH$(-CH_2-CH_2-COOH)_x$ supported DOTAP liposomes. The combination of functionalized single-walled nanohorns with liposomes reveals a variety of opportunities for the complex particle not only as drug delivery vehicles in terms of high loading capacity, broad drug selectivity, cell targeting, and controlled release, but also as many more potential promising applications such as drug biodistribution real-time MRI, MRI contrast agent targeting, and liposomal vaccine assembly. It can be a useful platform to load with different types of molecules or a promotion for developing other similar nanoparticle complexes for various applications.

Supporting Information

ABSTRACT: Here, we describe a novel method for the site-specific C-terminal PEGylation of recombinant proteins. This general approach exploits chemical cleavage of precursor intein-fusion proteins with hydrazine to directly produce recombinant protein hydrazides. This unique functionality within the protein sequence then facilitates site-specific C-terminal modification by hydrazone-forming ligation reactions. This approach was used to generate folded, site-specifically C-terminal PEGylated IFNalpha2b and IFNbeta1b, which retained excellent antiviral activity, demonstrating the utility of this technology in the PEGylation of therapeutic proteins. As this methodology is straightforward to perform, is compatible with disulfide bonds, and is exclusively selective for the protein C-terminus, it shows great potential as general technology for the site-specific engineering and labeling of recombinant proteins.

Recombinant protein therapeutics have emerged as an effective treatment for a variety of conditions ranging from cancer to metabolic disorders and autoimmune diseases, but they are commonly limited by their poor pharmacokinetics and immunogenicity. Arguably, the most widely used and accepted method for improving the pharmacokinetics of proteins is through PEGylation.[1,2] The covalent attachment of poly(ethylene glycol) (PEG) increases the half-life of the protein *in vivo* by decreasing renal clearance, due to the large hydrodynamic radius of the polymer, as well as masking potentially immunogenic epitopes and protease cleavage sites. Furthermore, PEGylation of a target protein can substantially improve its solubility and stability. There are currently nine PEGylated protein therapeutics approved for clinical use;[1] however, established methods for PEGylation are generally non-site-selective, resulting in a mixture of protein PEG-positional isomers with significantly decreased biological activity. For example, ViraferonPEG/PegIntron (Schering Plough), approved for the treatment of Hepatitis C, is produced by conjugating recombinant interferon alpha2b (IFNalpha2b) to a single chain 12 kDa succinimidyl carbonate PEG. This results in 95% monoPEGylated protein comprising 14 positional isomers, and as a consequence, PegIntron retains only 28% antiviral activity in *in vitro* assays compared to non-PEGylated IFNalpha2b.[3]

There is therefore a pressing need for methods to site-specifically PEGylate proteins. By incorporating a single PEG moiety at a defined position within the protein sequence, the deleterious effects associated with nonselective PEGylation may be minimized. In addition, approaches that yield homogeneous PEGylated proteins are potentially attractive from a regulatory perspective. While a number of protein engineering approaches have been applied to this end,[4−6] one particularly versatile technology for site-specific protein modification is expressed protein ligation (EPL). The basis of EPL is the production of recombinant C-terminal thioester proteins through thiol-mediated cleavage of the corresponding intein fusion protein.[7,8] The protein thioester functionality enables peptides and labels to be chemoselectively attached to the protein using the well-established native chemical ligation reaction.[9] In addition, C-terminal cleavage of the protein thioester with nucleophiles has also been used to introduce reactive moieties into proteins to enable subsequent modification through alternative chemistries.[10−12] While the EPL approach has proven extremely powerful, the steps are performed in the presence of thiol additives, which may compromise its use with certain protein families (for example, disulfide bond containing proteins), and the protein thioesters themselves are often labile.

Here, we report the development of a versatile complementary protein ligation approach for site-specific protein PEGylation, which is compatible with folded disulfide bond-containing proteins. This process is based on chemical interception of intein-mediated protein splicing,[13] to create C-terminal hydrazide recombinant proteins. This facile production of recombinant hydrazide proteins then facilitates direct site-specific C-terminal PEGylation (or other modifications) of the target protein using hydrazone bond-forming reactions[14,15] (Figure 1). In principle, any PEG derivative (or alternative label) containing the appropriate functionality, namely, a ketone or aldehyde, can be chemoselectively attached to the C-terminus of the protein in this one-step process. For the approach described here, we have developed novel pyruvoyl PEG derivatives for attachment to the

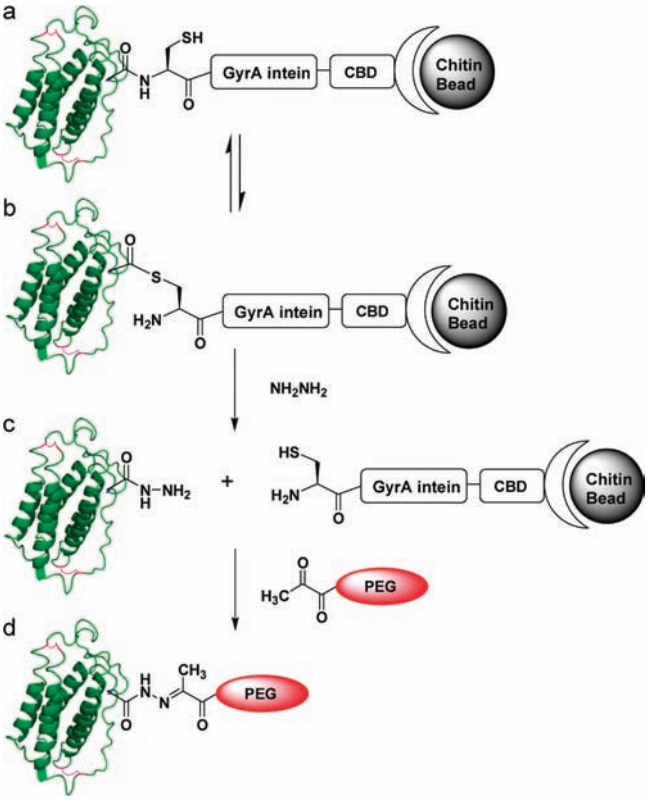

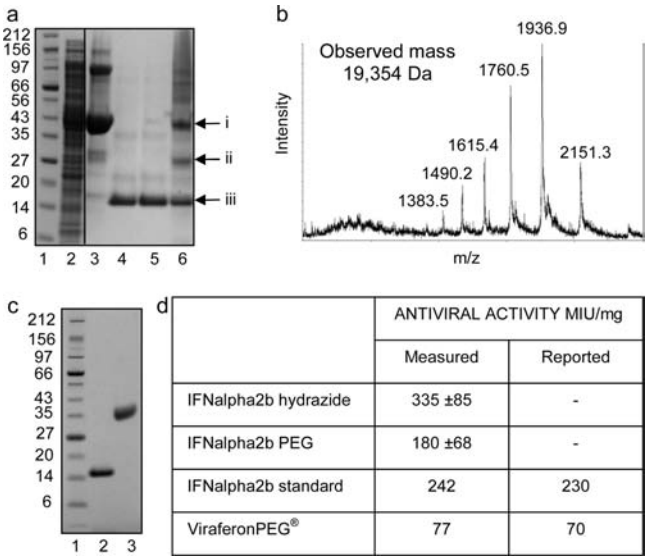

Figure 1. Use of intein technology to generate recombinant C-terminal hydrazide proteins for site-specific PEGylation. (a) The recombinant protein of interest (IFNalpha2b shown here) is genetically fused to the N-terminus of an engineered GyrA intein and chitin binding domain (CBD), expressed in *E. coli* and purified by immobilization onto chitin beads. (b) The first residue of this intein domain is a cysteine. The properties of the intein domain are such that it induces an N to S acyl shift at this protein-intein junction to form a branched thioester intermediate. (c) This thioester intermediate is chemically cleaved using hydrazine to liberate the corresponding C-terminal hydrazide derivative of the target protein. The intein-CBD remains bound to the chitin beads. (d) The protein C-terminal hydrazide chemoselectively reacts with ketone or aldehyde containing moieties. Here the reaction with a pyruvoyl functionalized PEG is shown, resulting in site-specific C-terminal PEGylation of the target protein via the resonance stabilized α-oxo hydrazone linkage.

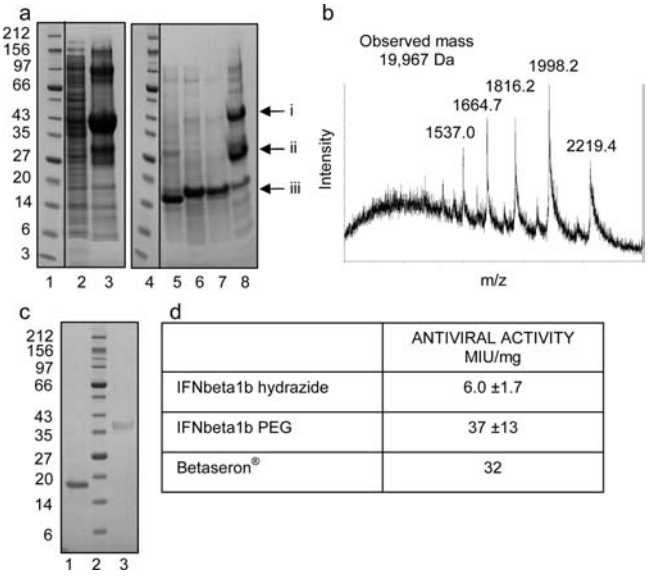
Figure 2. Generation and antiviral activity of site-specifically C-terminal PEGylated IFNalpha2b. (a) SDS PAGE analysis of IFNalpha2b-intein-CBD fusion protein expression in *E. coli*, purification using chitin beads and hydrazine cleavage. Protein standard (lane 1), cell lysate (lane 2), IFNalpha2b-intein-CBD purified by immobilization on chitin beads (lane 3), supernatant from hydrazine cleavage (lane 4), supernatant from washed beads (lane 5), cleaved and washed chitin beads (lane 6). Arrows indicate IFNalpha2b-intein-CBD fusion protein (i), intein-CBD (ii), and IFNalpha2b C-terminal hydrazide (iii). (b) Electrospray mass spectra of purified IFNalpha2b hydrazide, expected mass (without the N-terminal methionine) is 19 340 Da. The higher observed mass probably reflects methionine oxidation, previously reported for IFNalpha2b and shown not to significantly affect the activity of the protein.[24] (c) SDS PAGE analysis of IFNalpha2b hydrazide (lane 2) and purified C-terminal PEGylated IFNalpha2b (lane 3). (d) Antiviral activity of IFNalpha2b derivatives in a cytopathic effect inhibition assay using human A549 lung carcinoma cells and EMC virus. Measured activities are in million international units, MIU/mg IFNalpha2b protein ± SD where appropriate; IFNalpha2b hydrazide and C-terminal PEGylated IFNalpha2b ($n = 8$), IFNalpha2b standard ($n = 2$) and ViraferonPEG ($n = 2$). For reported values, see Supporting Information. IFNalpha2b standard and ViraferonPEG activities are in line with previous reports.[3].

protein C-terminus, as the resulting α-oxo hydrazone bonds are stabilized through resonance effects.[16,17]

IFNalpha2b was chosen as our initial target for this C-terminal PEGylation approach. As discussed above, this therapeutically important protein is currently administered as the PEG isomer mixture, and thus there is scope for improvement through site-specific PEGylation. IFNalpha2b was expressed in *E. coli* as a soluble N-terminal fusion to the *Mycobacterium xenopi* GyrA intein, and purified from the supernatant by immobilization on chitin beads using a chitin binding domain (CBD) fused to the C-terminus of the intein domain (Figure 2a lane 3 and Supporting Information). The immobilized IFNalpha2b-intein-CBD protein was cleaved with hydrazine to generate the corresponding IFNalpha2b C-terminal hydrazide (Figure 2a,b). The isolated protein (Figure 2c lane 2) contained two disulfide bonds (Supporting Information) and had potent antiviral activity (Figure 2d) indicating that folded IFNalpha2b C-terminal hydrazide was directly produced after expression and hydrazine cleavage of the corresponding intein fusion protein. This is in contrast to standard intein cleavage methods that use thiols such as dithiothreitol (DTT) and sodium mercaptoethylsulfonate (MESNa) that usually reduce disulfide bonds within the target protein.

For the PEGylation reactions, a pyruvoyl derivative of 10 kDa PEG was synthesized and incubated with IFNalpha2b hydrazide as described in the Supporting Information. This typically afforded 60−75% yield of the C-terminal PEGylated IFNalpha2b protein (Supporting Information, Figure S1). Importantly, no PEGylation product was observed when a C-terminal thioester derivative of IFNalpha2b was incubated with pyruvoyl PEG under the same conditions, consistent with site-specific PEGylation via the C-terminal hydrazide group only (data not shown). PEGylated IFNalpha2b was purified in 2 steps: ion exchange to remove unreacted pyruvoyl-PEG, followed by gel filtration to separate PEGylated IFNalpha2b from any unreacted IFNalpha2b hydrazide (Supporting Information, Figure S2) to yield pure C-terminal, mono PEGylated IFNalpha2b (Figure 2c, lane 3).



The antiviral activities of the C-terminally PEGylated IFNalpha2b and IFNalpha2b hydrazide control purified under the

same conditions were measured in a cytopathic effect inhibition assay with human A549 lung carcinoma cells and encephalomyocarditis (EMC) virus (Figure 2d). The site-specifically C-terminal PEGylated IFNalpha2b retained 74% of the activity of the standard IFNalpha2b protein, more than double that of the current heterogeneous PEGylated IFNalpha2b therapeutic ViraferonPEG, clearly demonstrating the advantage of this technology.

To further exemplify this site-specific C-terminal PEGylation technology, IFNbeta1b was deemed to be an attractive target. This protein is also an important therapeutic, but currently there are no PEGylated versions approved. Betaseron (Betaferon in the EU, Bayer Shering Pharma) and more recently Extavia (Novartis) are recombinant IFNbeta1b proteins used in the treatment of multiple sclerosis, and are under clinical evaluation for the treatment of other diseases including hepatitis and certain cancers.[18,19] IFNbeta1b is rapidly cleared from blood necessitating frequent administration regimes that can result in injection site necrosis and decreased patient compliance. Neutralizing antibodies are also problematic, with up to 35% of patients developing these in one reported study.[20] In addition, IFNbeta1b is a very unstable protein, prone to aggregation.[21] Work to address these issues includes random PEGylation of side-chain primary amines, which results in a mixture of 5 major positional isomers, and PEGylation of (predominantly) the N-terminal amine, resulting in products with 22−31% and 19−66% activity of the unmodified IFNbeta1b, respectively.[22] Attempts at site specific PEGylation using an engineered free cysteine residue at either position 79 (the natural glycosylation site) or the N- or C-termini were unsuccessful due to insufficient site specific attachment.[22] Another strategy used bicin (bis-*N*-2-hydroxyethylglycinamide) linkers to randomly attach 2−3 PEG molecules. Under physiological conditions, rapid hydrolysis of the bicin releases the PEG to leave the active IFNbeta1b. However, the activity of these releasable PEGylated forms was only between 7% and 27% that of the unmodified IFNbeta1b.[23]

We expressed soluble IFNbeta1b-intein-CBD fusion protein in *E. coli* and purified the target protein through immobilization onto chitin beads. Intein cleavage was induced by overnight treatment with hydrazine and the resulting IFNbeta1b-hydrazide was purified by gel filtration (Figure 3a,b; Supporting Information). As with IFNalpha2b, IFNbeta1b C-terminal hydrazide was generated with the natural disulfide bond intact indicating that the protein was correctly folded (Figure 3a and Supporting Information). To generate site-specifically C-terminal PEGylated IFNbeta1b, IFNbeta1b C-terminal hydrazide was mixed with the pyruvoyl PEG 10 kDa derivative and left overnight at room temperature. This typically gave ~55% yield of the C-terminal PEGylated protein (Supporting Information, Figure S3a). No PEGylation product was observed when IFNbeta1b C-terminal acid was incubated with pyruvoyl PEG under similar conditions, consistent with site-specific PEGylation via the C-terminal hydrazide group only (Supporting Information, Figure S3b).

The site-specifically C-terminal PEGylated IFNbeta1b was purified by ion exchange and gel filtration as described in the Supporting Information to generate pure C-terminal PEGylated IFNbeta1b (Figure 3c lane 3). The antiviral activity was measured in a cytopathic effect inhibition assay with human A549 lung carcinoma cells and EMC virus (Figure 3d). The activity of IFNbeta1b hydrazide was lower than that reported for Betaseron, potentially due to the inherent instability of the protein and the lack of stabilizing ingredients in our formulation. Site-specifically

Figure 3. Generation and antiviral activity of site-specifically C-terminal PEGylated IFNbeta1b. (a) SDS PAGE analysis of IFNbeta1b-intein-CBD fusion protein expression in *E. coli* and the subsequent purification and hydrazine cleavage. Samples were reduced with DTT after heating in loading buffer unless stated otherwise: protein standard (lanes 1 and 4), cell lysate (lane 2), IFNbeta1b-intein-CBD purified by immobilization on chitin beads (lane 3), hydrazine cleavage supernatant without DTT (lane 5), hydrazine cleavage supernatant (lane 6), supernatant from washed beads (lane 7), cleaved and washed chitin beads (lane 8). Arrows indicate IFNbeta1b-intein-CBD fusion protein (i), intein-CBD (ii), and IFNbeta1b C-terminal hydrazide (iii). There is clearly a shift in the migration of cleaved IFNbeta1b hydrazide upon DTT treatment, consistent with the native disulfide bond being intact in the liberated protein. (b) Electrospray mass spectra of purified IFNbeta1b hydrazide, expected mass 19 950 Da. The higher observed mass probably again reflects methionine oxidation. (c) SDS PAGE analysis of purified IFNbeta1b hydrazide (lane 1) and C-terminal PEGylated IFNbeta1b (lane 3); protein standard (lane 2). (d) Antiviral activity of IFNbeta1b derivatives in a cytopathic effect inhibition assay using human A549 lung carcinoma cells and EMC virus. Activities are in million international units, MIU/mg IFNbeta protein ± SD; $n = 8$. The reported antiviral activity of Betaseron, the current IFNbeta1b therapeutic, is also shown (Betaseron prescribing information; http://berlex.bayerhealthcare.com/html/products/pi/Betaseron_PI.pdf). WHO calibrated IFNbeta protein was used as a standard in the assays.

C-terminal PEGylated IFNbeta1b showed greater activity than the hydrazide, probably reflecting the increased protein stability brought by the PEGylation, and this activity was in line with that reported for the current unPEGylated IFNbeta1b therapeutic, Betaseron. This, to the best of our knowledge, represents the most potent PEGylated IFNbeta1b derivative generated to date.

In summary, we have demonstrated the feasibility of generating active, site-specifically C-terminal PEGylated therapeutic proteins through cleavage of the corresponding soluble intein fusion proteins with hydrazine, followed by reaction of the resulting protein hydrazide with pyruvoyl functionalized PEG. Importantly, this approach is compatible with proteins containing disulfide bonds, enabling folded proteins to be directly produced as the C-terminal hydrazide derivatives in high yield, with the integrity of any disulfide bonds and tertiary structure maintained during the PEGylation reaction. While the potential of this technology has been highlighted through the generation of

highly active C-terminal PEGylated derivatives of IFNalpha2b and IFNbeta1b, we have now used this technology to C-terminally PEGylate proteins from a variety of classes, including antibody fragments, with PEGs of different molecular weights. In addition to PEGylation, this technology has broader applications in protein engineering and has been successfully used to attach an array of probes and labels, including fluorophores and synthetic peptides, onto a variety of recombinant proteins in a site-specific fashion (unpublished data). Given the ease of the process, the yields of the associated steps, and the compatibility with disulfide bond-containing proteins, this technology offers an attractive approach for the site-specific PEGylation and modification of therapeutically important proteins and is an attractive addition to the repertoire of methodologies available for protein engineering, opening up new opportunities in this field.

SUPPORTING INFORMATION

General methods

SDS PAGE analyses used NuPAGE 4-12% Bis-Tris gels run in MES buffer (Invitrogen) and coomassie staining, unless otherwise indicated. Analytical RP HPLC was carried out on an Agilent 1100 or 1200 series system with a Jupiter C5 column (Phenomenex). All runs used linear gradients of water/acetonitrile containing 0.1% TFA, with a flow rate of 1 ml/min. Electrospray mass spectroscopy was performed on either a Mariner Time of Flight or Brucker micrOTOF instrument. Protein concentrations were determined from the UV absorbance at 280 nm (Varian Cary 50 UV-Vis Spectrophotometer) using the protein's extinction coefficient generated by ProtParam (http://www.expasy.org/tools/protparam.html).

Generation of pyruvoyl PEG

A 10.4 kDa PEG target compound (4), containing an N-terminal pyruvoyl functionality, was prepared as shown in Scheme S1 below.

Scheme S1

This was achieved by overnight acylation of the commercially available PEG amine (3) with the preformed pyruvoyl chloride (2). The PEG amine was obtained from Nektar [MeO-PEG-NH2Nektar/2M2U0l01/PT03F24] and was, at the time and to the best of our knowledge, the closest in size commercially available PEG amine to that used by Schering Plough in their PEGylated IFNalpha2b (ViraferonPEG® / PegIntron®)[1].

The acid chloride (**2**) was formed by treatment of pyruvic acid (**1**) with α,α-dichloromethyl methyl ether. α,α-dichloromethyl methyl ether (5.16 ml, 57.0 mmol) was added dropwise under N_2 to pyruvic acid (5.00 g, 57.0 mmol) with stirring. The reaction mixture was heated at 50 °C for 30 min. Evaporation of the methyl formate byproduct (at 20 °C to avoid product degradation) afforded the crude acid chloride as a yellow oil (4.92 g, 82 % yield), in sufficient purity (as determined by ^{1}H NMR) to be used directly in the next step.

The target compound (**4**) was formed in 89 % yield by overnight coupling between acid chloride (**2**) and PEG amine (**3**). Briefly, MeO-PEG-NH_2 (500 mg, 50.0 mmol) in anhydrous DCM (5 ml) was treated with

pyruvoyl chloride (**2**, 10.0 mg, 100 mmol) under N_2 in the presence of triethylamine (11 µl, 100 mmol) at 0 ^{o}C. The reaction mixture was allowed to warm to room temperature and stirred overnight. Aqueous workup and trituration with Et_2O afforded the pure product as a white solid (425 mg, 82 % yield). ^{1}H NMR (500 MHz, $CDCl_3$): δ 3.64 (s, $(CH_2)_n$), 3.38 (s, 3H), 2.47 (s, 3H). ^{13}C NMR (125 MHz, $CDCl_3$): δ 197.0, 156.5, 90.5, 73.0-68.0$(CH_2)_n$, 58.5, 51.0, 41.5, 39.0, 23.5.

Generation of IFNalpha2b hydrazide

IFNalpha2b cDNA (IMAGE clone 30915269) was purchased from Gene Service Ltd, UK. The IFNalpha2b coding sequence was amplified by PCR using the following primers:

The forward primer was designed to include an *Nde*I site immediately prior to the 5' IFNalpha2b sequence:

5' – GGTGGTCATATGTGTGATCTGCCTCAAACCC – 3'

The reverse primer was designed to eliminate the STOP codon at the end of the IFNalpha2b coding sequence, replacing it with a glycine codon followed immediately with a *Sap*I site:

5' – GGTGGTTGCTCTTCCGCACCCTTCCTTACTTCTTAAACTTTCTTGC – 3'

The resulting PCR product was cloned into the *Nde*I *Sap*I sites of the pTXB1 vector (New England Biolabs). This pTXB1 IFNalpha2b GLY construct encodes a fusion protein whereby IFNalpha2b is linked via glycine to the N-terminus of *Mycobacterium xenopi* GyrA intein that is in turn fused to the N-terminus of a chitin binding domain (CBD). This was transformed into *E. coli* Rosetta gami B (DE3) pLysS cells (Novagen) and protein expression was induced with 0.2 mM IPTG overnight at 18 ºC. Cells were pelleted by centrifugation and lysed in lysis buffer (20 mM sodium phosphate pH 7.4, 0.5 M NaCl, 0.5 mM EDTA, 15 % glycerol, 0.1 % Sarkosyl NL) with 1 mM AEBSF by sonication. The soluble fraction was mixed with chitin beads pre-equilibrated in lysis buffer, 4 ºC for 1.5 hours. The beads were then washed extensively with lysis buffer followed by cleavage buffer (200 mM sodium phosphate pH 7.4, 200 mM NaCl, 0.05% Zwittergent 3-14) to yield purified IFNalpha2b GyrA intein CBD fusion protein immobilized on chitin beads. These beads were mixed with 1% hydrazine in cleavage buffer with 1 mM EDTA at room temperature overnight. The soluble supernatant contained the cleaved IFNalpha2b hydrazide, which was purified by RP HPLC on a Gilson preparative HLPC system with a Jupiter C5 column (Phenomenex) in water with 0.1 % TFA over a linear gradient of acetonitrile 0.1% TFA. Fractions were analyzed by electrospray mass spectrometry and analytical RP HPLC. Pure fractions were pooled and lyophilised. A typical yield is ~0.7 mg / L cell culture. The sequence of the IFNalpha2b hydrazide made here is:

CDLPQTHSLGSRRTLMLLAQMRRISLFSCLKDRHDFGFPQEEFGNQFQKAETIPVLHEMIQQIFNLFSTKDS
SAAWDETLLDKFYTELYQQLNDLEACVIQGVGVTETPLMKEDSILAVRKYFQRITLYLKEKKYSPCAWEVVR
AEIMRSFSLSTNLQESLRSKEG-$NHNH_2$

Reaction with N-ethyl maleimide (NEM) was used to confirm that the IFNalpha2b C-terminal hydrazide was correctly folded. A few µg of IFNalpha2b C-terminal hydrazide or positive control peptide CERGDKGYVPSVF (Almac Sciences, UK) were dissolved in 20 µl water. 10 µl was removed for the control (no NEM) and 5 µl 1 mg/ml NEM was added to the remaining and incubated at room temperature for at least 30 mins. Reactions were analyzed by electrospray mass spectrometry. NEM reacts with free cysteines resulting in an increase in mass of 125 Da. IFNalpha2b has 4 cysteines that form 2 disulfide bonds in the folded protein. The IFNalpha2b C-terminal hydrazide did not react with NEM in contrast to the positive control peptide that increased in mass by 125 Da under the same conditions (data not shown).

IFNalpha2b C-terminal thioester was prepared by cleaving the IFNalpha2b-intein-CBD beads with 100 mM MESNa in cleavage buffer and purified and analyzed as above.

PEGylation of IFNalpha2b

IFNalpha2b C-terminal hydrazide was dissolved in 100 µl 40 % acetonitrile with 0.1 % TFA to a final concentration of ~250 µM. A 20 fold molar excess of pyruvoyl-PEG 10K was added and reactions left at room temperature overnight (~16 hours).

The PEGylation reaction was diluted 10 fold in buffer A (20 mM Tris-HCl pH 7.3, 0.05 % Zwittergent 3-14) and loaded onto a 1 ml HiTrap Q FF anion exchange column via AKTA purifier system (GE Healthcare). The column was washed with 5-10 CV buffer A to remove the unbound, unreacted pyruvoyl-PEG and the bound protein was eluted over a 0-1 M NaCl gradient (20 CV). Unbound and eluted fractions were analyzed on duplicate SDS PAGE gels; one was stained with coomassie and the other was stained for PEG, based on the methods in the literature[2,3]. The fractions containing the desired PEGylated IFNalpha2b were concentrated using VivaSpin2 3K MWCO centrifugal concentrators (Sartorius) and run through a Superdex 200 10/300 GL column (GE Healthcare) in 10 mM sodium phosphate pH 7.4, 50 mM NaCl, 0.05 % Zwittergent 3-14. This yielded pure site-specifically C-terminal PEGylated IFNalpha2b.

Generation of IFNbeta1b hydrazide

DNA encoding the IFNbeta1b protein sequence with an additional C-terminal glycine:

SYNLLGFLQRSSNFQSQKLLWQLNGRLEYCLKDRMNFDIPEEIKQLQQFQKEDAALTIYEMLQNIFAIFRQDS
SSTGWNETIVENLLANVYHQINHLKTVLEEKLEKEDFTRGKLMSSLHLKRYYGRILHYLKAKEYSHCAWTIVR
VEILRNFYFINRLTGYLRNG

was optimized for expression in *E. coli* and synthesized by GeneArt with the following flanking DNA sequences containing a 5' *Nde*I site and a 3' *Sap*I site:

5’ - GGT GGT CAT . . . [IFNbeta1b sequence] . . . TGC GGA AGA GCA ACC ACC – 3’

Digestion of the supplied DNA with *Nde*I and *Sap*I resulted in an IFNbeta1b fragment that could be directly ligated into a similarly digested pTXB1 vector. This pTXB1 IFNbeta1b GLY construct encodes a fusion protein whereby IFNbeta1b is linked via glycine to the N-terminus of *Mycobacterium xenopi* GyrA intein that is in turn fused to the N-terminus of a chitin binding domain (CBD). This was transformed into *E. coli* Origami (DE3) cells (Novagen) and expression induced with 0.2 mM IPTG overnight at 18 ºC. Cells were pelleted by centrifugation and lysed by sonication in lysis buffer (20 mM sodium phosphate pH 7.4, 0.5 M NaCl, 0.5 mM EDTA, 15 % glycerol, 0.1 % Sarkosyl NL) containing 1 mM AEBSF. The soluble fraction was mixed with chitin beads pre-equilibrated in lysis buffer, 4 ºC for 1.5 hours. The beads were then washed extensively with lysis buffer followed by cleavage buffer (200 mM sodium phosphate pH 7.4, 200 mM NaCl, 0.05% Zwittergent 3-14) to yield purified IFNbeta1b GyrA intein CBD fusion protein immobilized on chitin beads. These beads were mixed with 1% hydrazine in cleavage buffer with 1 mM EDTA at room temperature overnight. The soluble supernatant containing the cleaved IFNbeta1b hydrazide was purified on a Superdex 75 column (GE Healthcare) in 5 mM acetic acid pH 3.5 with 0.05 % Zwittergent 3-14 and 1mM EDTA to give the pure protein hydrazide. Aliquots were lyophilized with 50 µg mannitol / µg IFNbeta1b hydrazide. These IFNbeta1b hydrazide control aliquots were redissolved immediately prior to use in 10 mM sodium phosphate pH 7.4 to give final buffer composition 10 mM sodium phosphate pH 7.4, 50 mM NaCl, 0.05% Zwittergent 3-14 and 50 µg mannitol / µg IFNbeta1b.

Reaction with N-ethyl maleimide (NEM) was used to indicate that the IFNbeta1b C-terminal hydrazide was correctly folded. A few µg of IFNbeta1b C-terminal hydrazide or positive control peptide CERGDKGYVPSVF (Almac Sciences, UK) were dissolved in 20 µl 40 % acetonitrile. 10 µl was removed for the control (no NEM) and 5 µl 1 mg/ml NEM was added to the remaining sample and incubated at room temperature for at least 30 mins. Reactions were analyzed by electrospray mass spectrometry. IFNbeta1b has 2 cysteines that form a disulfide bond in the folded protein. The IFNbeta1b C-terminal hydrazide did not react with NEM in contrast to the positive control peptide that increased in mass by 125 Da under the same conditions (data not shown).

A small amount of the IFNbeta1b C-terminal acid was generated by leaving the IFNbeta1b-intein-CBD beads in cleavage buffer with 1 M imidazole to catalyze hydrolysis of the intein. Protein was purified as described above and analyzed by SDS PAGE, RP HPLC and electrospray mass spectroscopy.

PEGylation of IFNbeta1b

The pooled IFNbeta1b C-terminal hydrazide containing Superdex 75 fractions (~4 µM) were immediately added to 1 mM pyruvoyl PEG 10K and left at room temperature overnight (~16 hours). The IFNbeta1b PEG reaction was diluted 5 fold in buffer A (25 mM sodium phosphate pH 7.4, 0.05 % Zwittergent 3-14, 1 mM EDTA) and loaded onto a 1 ml HiTrap SP XL cation exchange column via AKTA purifier system (GE Healthcare). The column was washed with 5 CV buffer A to remove unbound, unreacted pyruvoyl-PEG and the bound protein was eluted over a 0-0.5 M NaCl gradient (20 CV). Fractions were analyzed by Western blot using sheep polyclonal anti human IFNbeta primary antibody (PBL Interferon Source) and rabbit anti sheep HRP conjugated secondary antibody (Invitrogen). Fractions containing the C-terminal PEGylated IFNbeta1b were concentrated using VivaSpin2 3K MWCO centrifugal concentrators (Sartorius) and run through a Superdex 200 10/300 GL column (GE Healthcare) in PBS (Sigma tablets) with 0.05 % Zwittergent 3-14 and 1 mM EDTA to separate the PEGylated IFNbeta1b from the unreacted IFNbeta1b hydrazide. The fractions were analysed by Western blot as above and the pure fractions were concentrated, aliquotted and lyophilized with 50 µg mannitol / µg IFNbeta1b. Aliquots were redissolved in water to give the final buffer composition PBS with 0.05% Zwittergent 3-14, 1 mM EDTA and 50 µg mannitol / µg IFNbeta1b.

Antiviral activity assays

Cytopathic effect inhibition assays using human A549 lung carcinoma cells and Encephalomyocarditis virus (EMCV) were run by PBL Interferon Source, NJ, USA (#91199-1 and #91400-1 for IFNalpha2b and IFNbeta1b assays respectively). Cells were plated in a 96 well plate at 100,000 cells/ml. Serial two fold dilutions of IFN samples were incubated with the cells for 18-24 hours. A dilution of EMCV pre-determined to kill 100 % of the cells was added to each well and incubated for 42-56 hours. Cell controls (no IFN, no virus), virus controls (no IFN, virus added) and dilutions of PBL WHO calibrated IFN standards were run for every 2 samples. The media was removed, live cells fixed and stained with crystal violet and dried overnight. The $OD_{562\text{-}570}$ for each well was read on a plate reader and transformed to % protection by setting the cell control as 100% and the virus control as 0%. The data was graphed and the unit activity of samples (i.e. the quantity of IFN required to produce a cytopathic effect of 50 %) was adjusted to International units (IU) using the PBL WHO calibrated IFN standards.

ViraferonPEG® with a reported activity of ~70 x 10^6 IU / mg IFNalpha2b was purchased through Almac Clinical Services. Human IFNalpha2b standard with a reported activity of 230 x 10^6 IU / mg was purchased from PBL Interferon Source (#11105-1).

ABSTRACT:

Breast cancer is the second leading cause of cancer-related death in women. Approximately 85% of patients with advanced cases will develop spinal metastases. The vertebral column is the most common site of breast cancer metastases, where overexpression of matrix metalloproteinases (MMPs) promotes the spread of cancer. Current therapies have significant limitations due to the high associated risk of damaging the spinal cord. An attractive alternative is photodynamic therapy providing noninvasive and site-selective treatment. However, current photosensitizers are limited by their nonspecific accumulation. Photodynamic molecular beacons (PP$_{MMP}$B), activated by MMPs, offer another level of PDT selectivity and image-guidance preserving criticial tissues, specifically the spinal cord. Metastatic human breast carcinoma cells, MT-1, were used to model the metastatic behavior of spinal lesions. *In vitro* and *in vivo* evidence demonstrates MMP specific activation of PP$_{MMP}$B in MT-1 cells. Using a clinically relevant metastatic model, fluorescent imaging establishes the specific activation of PP$_{MMP}$B by vertebral metastases versus normal tissue (i.e., spinal cord) demonstrating the specificity of these beacons. Here, we validate that the metastasis-selective mechanism of PP$_{MMP}$Bs can specifically image breast cancer vertebral metastases, thereby differentiating tumor and healthy tissue.

INTRODUCTION

Metastatic spread of tumor cells is the most devastating attribute of cancer and is often the cause of mortality. Due to the unique microenvironment of the bone, it is the most common site of distant metastases from cancers of the breast, lung, kidney, thyroid, and prostate.[1] The bone provides a fertile environment for the growth of cancer and promotes the aggressive behavior of tumor cells, since the mineralized bone matrix houses many growth factors, bone-destroying osteoclasts and bone-forming osteoblasts.[1] Approximately 85% of breast cancer patients with metastatic disease will develop bone metastases, in which the vertebral column is the most common site for metastatic formation.[2,3] Matrix metalloproteinases (MMPs) are a family of structurally related, zinc-dependent endopeptidases implicated in the invasion and metastasis of cancer through the degradation of the basement membrane and collagen-rich extracellular matrix.[4−7] Furthermore, MMPs are exquisite regulators of the tumor microenvironment by

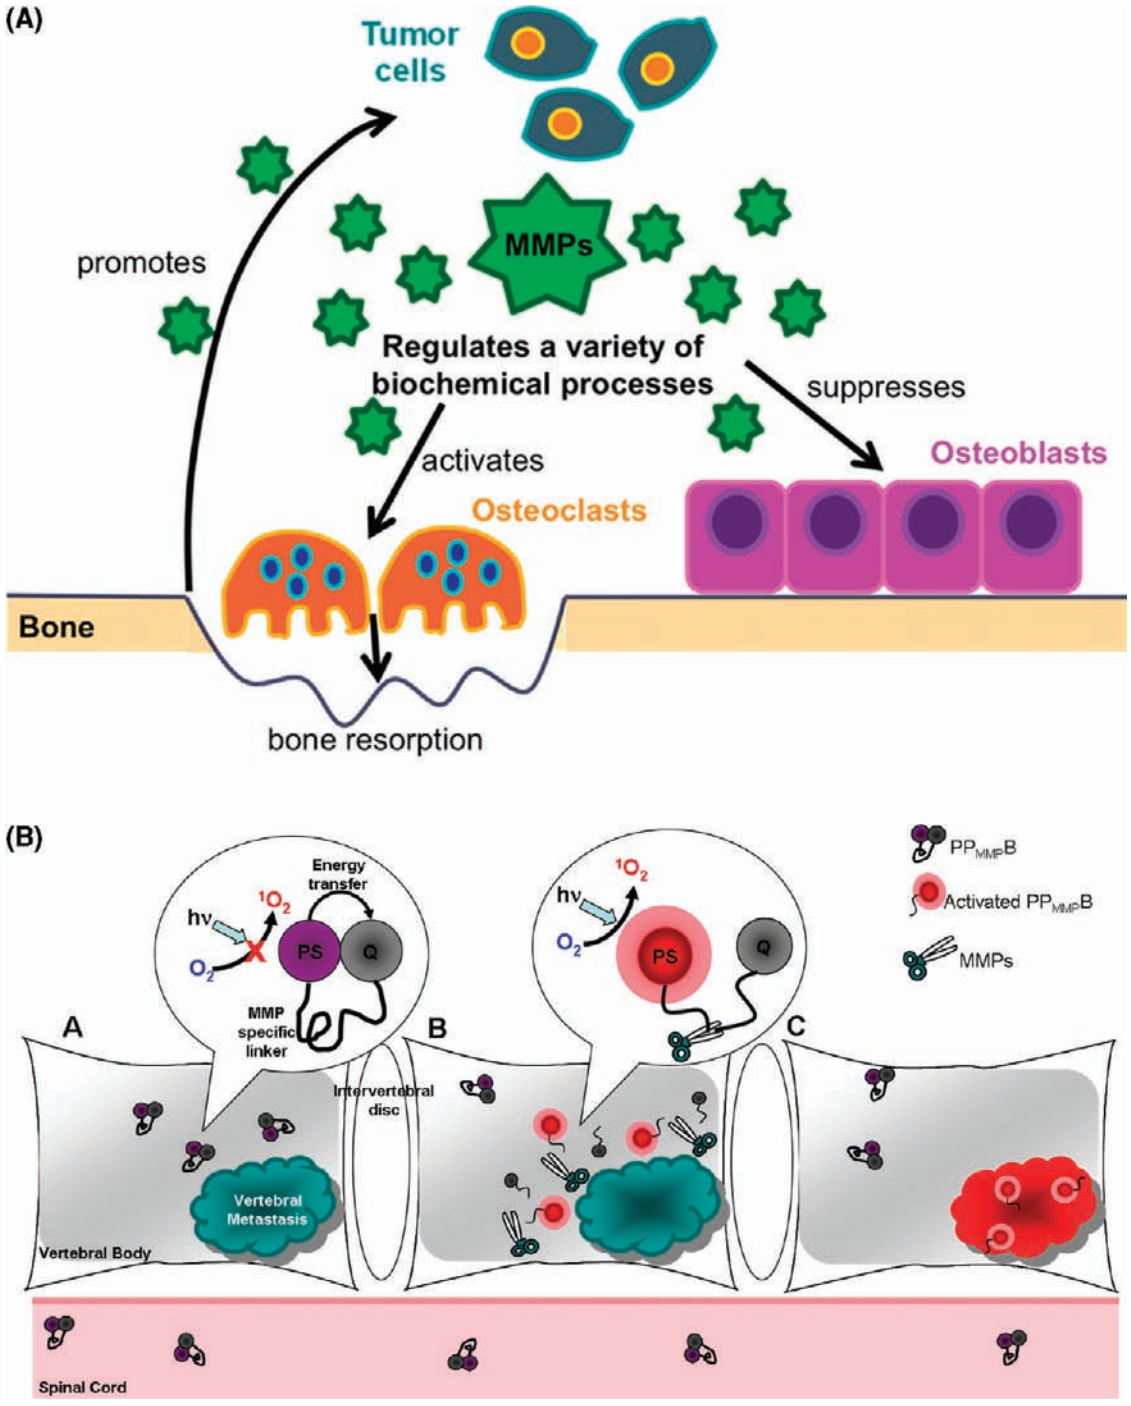

Figure 1. (A) MMP involvement in the tumor-bone vicious cycle. MMPs directly promote tumor progression but also indirectly promote tumor progression by activation of osteoclasts and suppressing osteoblasts. (B) Schematic of photodynamic molecular beacon ($PP_{MMP}B$) activation by vertebral metastases. The beacon accumulates in tissue but remains photodynamically and optically silent (A) until cleaved by MMPs at sites of vertebral metastases (B), which restores both its fluorescence for imaging and generation of singlet oxygen for treatment (C).

virtue of their ability to process many biological modulators, such as cytokines and growth factors within the bone matrix.[4−6]

Breast cancer spinal metastases are predominantly osteolytic (bone destructive), which is associated with an increase in osteoclast activity.[1] Metastasis disrupts the dynamic balance between bone resorption by osteoclasts and bone formation by osteoblasts, inducing a vicious cycle whereby tumor cells reprogram osteoclasts, leading to osteolysis and promotion of tumor growth.[1,2] MMPs play a vital role in signaling cascades involved in metastatic growth, and their upregulation leads to the processing of many growth factors, including TGF-β,[8] IGFs,[9] E-caderin,[10] and RANKL,[11] that are all essential for metastatic tumor progression within the vertebral body.[7,12,13] MMPs themselves also destroy healthy tissue, particularly in the bone, since the matrix is composed primarily of mineralized fibrillar type I collagen,[7] a main substrate of many MMPs. The upregulation of MMPs is thus critically involved in the

destruction of the delicate balance between bone formation and degradation, reducing bone integrity (Figure 1A).[1,2] Hence, MMPs not only aid the spread of tumor cells to distant sites, but are also involved in the local dissolution of the vertebral body and promote tumor progression within the vertebrae.

The resulting osteolysis causes bone pain, vertebral pathological fractures, progressive deformity, hypercalcemia, and spinal instability.[1,2] Patients with spinal metastases have a high risk of spinal cord compression, resulting in motor dysfunction, neurological compromise, and an overall poor prognosis.[1,2] The associated 5-year survival rate in patients with spinal metastases is below 20% compared to a 5-year survival rate over 85% in patients with early stage breast cancer.[14] Regardless of the symptoms, all patients suffering from spinal metastases experience a substantial decrease in their quality of life. Surgery and radiation therapy are the main treatment options for these patients. Surgical treatments, however, carry a high risk of morbidity due to the proximity of the spinal cord, while radiation therapy is limited to a level far below the optimal therapeutic dose because of the low tolerance of the spinal cord.[15] Clinical studies of radiotherapy have reported recurrence of symptoms, and pain relief is not experienced until at least 3 months after treatment.[16] Lastly, although pain relief and, in part, tumor regression are addressed by radiation treatment, spinal instability is not. Therein lies the need for improved therapies that specifically target metastatic tumor cells while preserving the spinal cord to address pain relief, tumor regression, and mechanical instability of the spine.

Protease activatable probes have been generating a great amount of promise for cancer imaging. They offer control of fluorescence emission in response to specific cancer targets and, thus, are useful tools for *in vivo* imaging. With our increasing knowledge about the human genome in health and disease, peptide-based "smart" probes are continually developed for *in vivo* optical imaging of specific molecular targets, biological pathways, and cancer progression. We introduced photodynamic molecular beacons which provide an additional therapeutic mechanism by exploiting the intrinsic fluorescence capabilities of photosensitizers.[17] Photosensitizers are light activated drugs used in photodynamic therapy (PDT). PDT is an approved cancer treatment modality that destroys target cells when light activates a nontoxic photosensitizer (PS) to generate cytotoxic excited-state (singlet) oxygen.[18−20] Photodynamic molecular beacons provide an additional mechanism of selectivity in PDT over and above the targeting afforded by current photosensitizers and specific light delivery.[17] This is illustrated in Figure 1B. The beacons comprise a photosensitizer and a quencher moiety, linked, in the present case, by a MMP-cleavable peptide ($PP_{MMP}B$). They remain "optically silent", i.e., photodynamically inactive, until transformed into an activated state through cleavage of the linker, upon which both the PDT activity and PS fluorescence are restored, the latter providing the potential for real-time image guidance.[17] Furthermore, as $PP_{MMP}Bs$ are only activated in the presence of these secreted tumor-specific proteases, normal tissues, including the spinal cord, should remain relatively protected.[17] One concern is that uptake of activated $PP_{MMP}Bs$ by the spinal cord may occur if activated beacons are allowed sufficient time to diffuse from the tumor to normal tissues. Here, as a first step in implementing $PP_{MMP}Bs$ as a therapeutic strategy for the management of vertebral metastases, we validate that the metastasis-selective mechanism of $PP_{MMP}Bs$ can specifically target breast cancer vertebral metastases, thereby differentiating tumor and healthy tissue.

MATERIALS AND METHODS

Study Design. $PP_{MMP}B$ activation was validated *in vitro* using the human MT-1 metastatic breast cancer cell line. Breast cancer tissue and cell lines have been shown to overexpress MMPs (Supporting Information Figure S1).[21,22] Preliminary *in vivo* activation was demonstrated in MT-1 xenografts grown subcutaneously on the flank of athymic mice. A scrambled beacon, $PP_{scrambled}B$, in which the peptide linker sequence is not cleavable by MMPs,[20] was used to validate the specific activation of $PP_{MMP}B$ by the MT-1 cells. As a relevant preclinical model of vertebral metastases, MT-1 cells were injected intracardially to establish metastases in athymic rats. The activation of $PP_{MMP}B$ within the spinal column was assessed at each of 2, 4, 12, and 24 h after intravenous injection of $PP_{MMP}B$. $PP_{MMP}B$ activation was further compared in tumor-bearing versus healthy animals, at 2 and 4 h post injection. The fixed dose of $PP_{MMP}B$ was 3 mg per kg bodyweight, equivalent to that using Visudyne in previous studies with this model.[23]

$PP_{MMP}B$ Synthesis. The $PP_{MMP}B$ consists of the photosensitizer Pyropheophorbide-α (PS) and black hole quencher 3 (Q), linked by the amino acid sequence GPL*G*LARK, which is an MMP-cleavable peptide: italics indicate the cleavage site. It was synthesized as described previously.[17] $PP_{scrambled}B$ comprises the same PS and Q but with a linker sequence, tsgpnqeqk, composed of D-amino acids that has been shown not to be cleaved by MMPs.[24]

Cells. MT-1 cells, a human metastatic breast cancer cell line, were kindly provided by Dr. O. Engebraaten, Norwegian Radium Hospital, Norway.[25,26] Cells were grown and maintained in Roswell Park Memorial Institute (RPMI) 1640 media supplemented with 10% fetal bovine serum at 37 °C in an atmosphere of 5% CO_2 in a humidified incubator. The MT-1 cells were stably transfected with a double-fusion plasmid (luciferase and green flurescent protein, GFP) kindly provided by Dr. Joseph Wu (Stanford University) and a lentivirus kindly provided by Dr Ren-Ke Li, (University of Toronto). The expression of GFP and luciferase provides a means to identify the cells and assess their viability.[23,27−31]

***In Vitro* Model.** *In vitro* activation of $PP_{MMP}B$ was evaluated by both confocal microscopy and flow cytometry. $PP_{MMP}B$ (2 nmol) or $PP_{scrambled}B$ (2 nmol) were first dissolved in 2% dimethyl sulfoxide, DMSO (Sigma Aldrich), and 0.025% Cremophore.[17] The solutions were then diluted with the culture medium to a final concentration of 10 μM (molecular weight of the $PP_{MMP}B$ is 1856 g/mol). 2×10^4 cells in 0.4 mL of culture medium per well were seeded in Nunc Laboratory-TekII-CC2 8-well chamber slides and incubated for 2 days at 37 °C under 5% CO_2 in a humidified incubator to grow to 80% confluency. $PP_{MMP}B$ activation after 6 h incubation of MT-1 cells was assessed using a laser scanning confocal microscope (Olympus FluoView 1000: 633 nm excitation, >650 nm detection). To quantify $PP_{MMP}B$ fluorescence activation and uptake in MT-1 cells, 2×10^5 cells in 2 mL of medium per well were inoculated in 6-well plates and incubated for 2 days at 37 °C under 5% CO_2 in a humidified incubator. The cells were then incubated with 1 mL of $PP_{MMP}B$ or $PP_{scrambled}B$ solution (10 μM) for 1 and 6 h, respectively (similar to previous studies[17]), at 37 °C under 5% CO_2. The beacon solution was then removed after the above incubation times and assessed by HPLC-MS to confirm the beacon cleavage. The cells were trypsinized from the well plates and transferred to a 15 mL centrifuging tube containing 2 mL PBS. The cells were centrifuged at 1000 rpm for 6 min and the

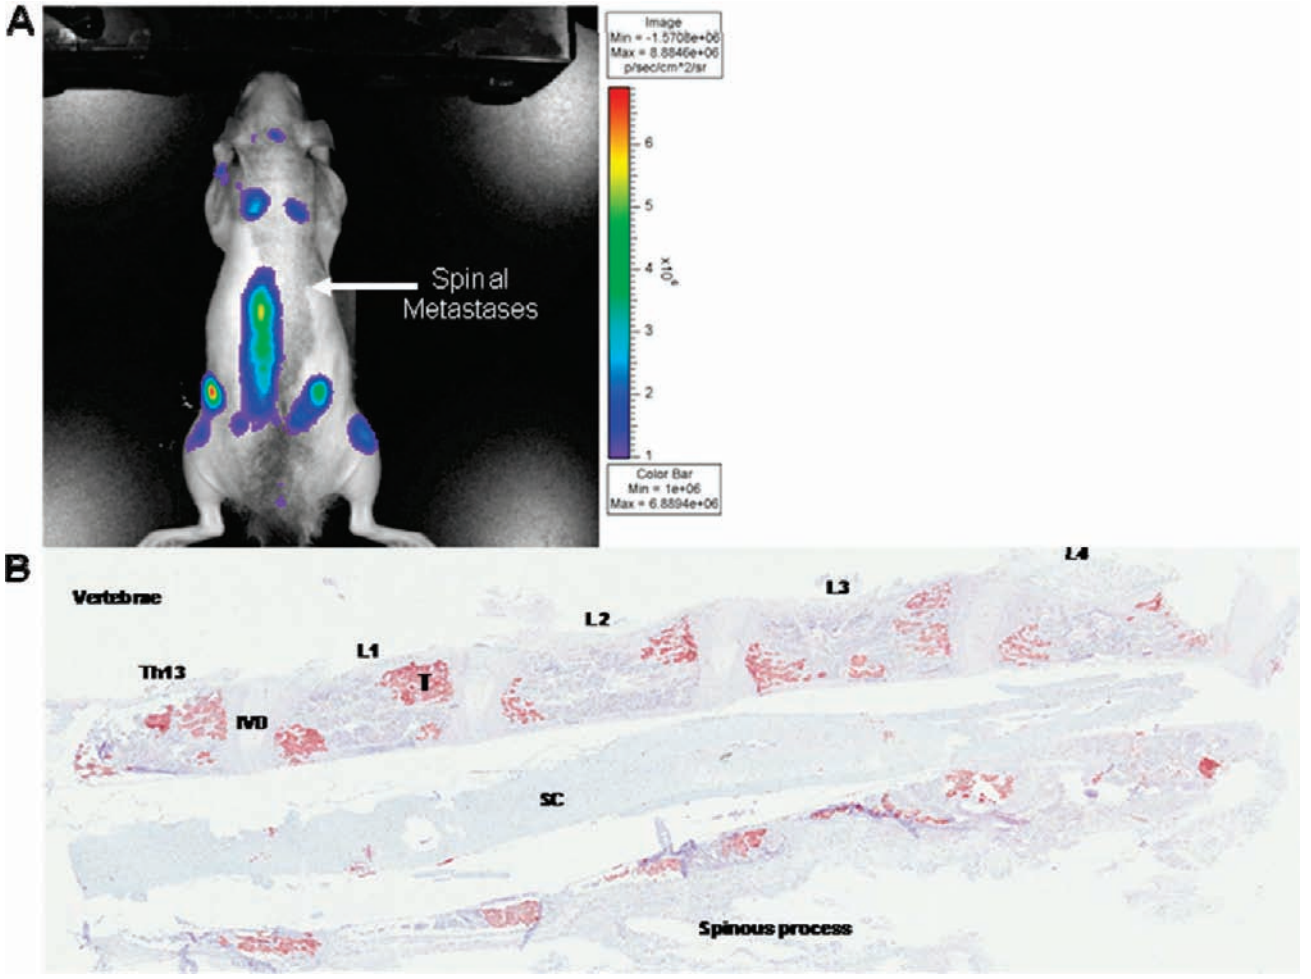

Figure 2. *In vivo* breast cancer vertebral metastases model. (A) Example of bioluminescent imaging of MT-1 vertebral metastases development at 14 days after intracardiac injection of 1×10^6cells, showing multiple sites of metastitic growth, including in the spine. (B) Example of immunohistology section of vertebral column where hEGFr immunhisto stains for viable tumor (red sections) (T - tumor, SC - spinal cord, IVD - intervertebral disk, L - lumbar, Th - thoracic).

PBS was removed. This rinsing procedure was repeated 3 times. The cells were fixed by a 2% paraformaldehyde solution for 10 min, after which they were centrifuged and rinsed twice with PBS. The fluorescence intensities of the cells were measured by flow cytometry (CytomicsFC 500, Beckman Coulter, CA, USA: 633 nm excitation, 660−690 nm detection). The maximum cell count was approximately 10 000 in each sample.

***In Vivo* Xenograft Model.** All animal studies were carried out under institutional approval (University Health Network, Toronto, Canada). Adult athymic female nude mice (Hsd:Athymic Nude-Foxn1^{nu}; Harlan, Indianapolis, IN, USA) were inoculated subcutaneously with 1×10^6 MT-1 cells in 200 μL of media in both the left and right flanks for intratumoral injection studies of $PP_{MMP}B$. To evaluate the activation of $PP_{MMP}B$ by a systemic injection, mice were inoculated similarly only on the right flank. Animals were maintained in pathogen-free conditions in autoclaved microisolator cages. After 2 weeks, by which time the tumors were 5−10 mm in diameter, the mice were fed a low-fluorescence diet (Harlan Tekland) for 4 days to reduce the autofluoresence background. A 2 mg/kg dose of $PP_{MMP}B$ or $PP_{scrambled}B$ (corresponding to the dose used in previous studies[17]) was formulated in 30 μL of aqueous solution with 2% DMSO and 0.5% Tween-80.[17] Under general anesthesia (isofluorane in oxygen), a 27G needle was used to inject this in multiple locations in the tumor to improve the distribution. A 2 mg/kg intravenous injection (tail vein) of $PP_{MMP}B$ was formulated in 150uL of aqueous solution with 2% DMSO and 0.5% Tween-80. Whole-body *in vivo* fluorescence imaging was performed before and at multiple time points after injection (Maestro, CRi: 650 nm excitation, ≥700 nm detection, auto-exposure integration time).

***Ex Vivo* Xenograft Studies.** MT-1 tumors harvested from mice 24 h following intratumor injections of beacon and were snap-frozen in liquid nitrogen and stored at −70 °C. Frozen sections (10 μm) were cut on a cryostat. After 5 min at room temperature, the slides were immersed in PBS for another 5 min, then dried, and 4 μL of mounting solution with DAPI, 4′,6-diamidino-2-phenylindole (Vector laboratories. Inc.), was added as a nuclear stain. The sections were covered by a coverslip and imaged by confocal microscopy similar to the *in vitro* studies above.

***In Vivo* Vertebral Metastases Model.** Female 5−6-week-old athymic rats (rnu/rnu; Harlan Sprague−Dawley, Indianapolis, IN, USA) were used as a model to mimick vertebral metastatic spread. The activation of $PP_{MMP}B$ was compared in the spinal column in tumor-bearing and healthy animals. Under general

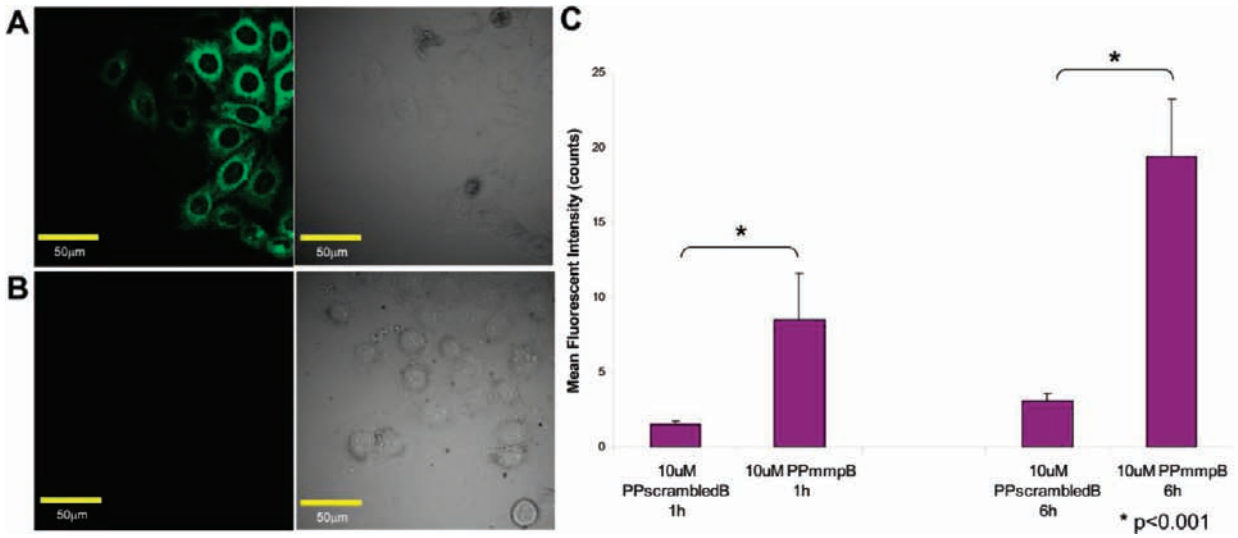

Figure 3. *In vitro* fluorescence and corresponding brightfield images of MT-1 cells after 6 h incubation in (A) 10 μM $PP_{MMP}B$, (B) 10 μM $PP_{scrambled}B$. (C) Comparison of the fluorescence intensity of MT-1 cells incubation with $PP_{MMP}B$ and $PP_{scrambled}B$ for 1 or 6 h monitored by flow cytometry ($n = 3$ samples, $p < 0.001$).

inhalation anesthesia (isofluorane in oxygen), MT-1 cells were injected intracardially at a concentration of 2×10^6 in 0.2 mL of RPMI 1640 media. Fourteen days later, *in vivo* bioluminescence imaging was performed as follows to confirm the establishment of metastases. Luciferin (Xenogen Corp., MA, USA) was dissolved in 0.9% NaCl at a concentration of 30 mg/mL and a single dose of 60 mg/kg was injected intraperitoneally into anaesthetized animals. Bioluminescent images were taken 15 min post luciferin injection where animals were placed ventrally in a whole-body bioluminescence imager (IVIS Spectrum: Caliper Life Sciences, CA, USA), integrating the counts over 30 s (Figure 2A). Following this, 3 mg/kg of $PP_{MMP}B$ (corresponding to equivalent Visudyne dose used in previous PDT studies[23,30,31]) in 2.5% DMSO, 0.5% Tween80 was injected through the tail vein and, at each time point above, cohorts were euthanized by pentobarbital overdose.

***Ex Vivo* Vertebral Metastases Studies.** At the time of necroscopy in these animals, the T13−L4 vertebrae were harvested intact, transferred to PBS, and immediately cut in the sagittal plane using a low-speed precision saw (IsoMet, Buehler, Illinois). $PP_{MMP}B$ activation by MT-1 vertebral tumors was assessed by confocal microscopy of the cut surface (633 nm excitation, >650 nm detection) at 10× magnification. These images were overlaid by corresponding GFP images from the MT-$1^{luc/GFP}$ cells (488 nm excitation, >520 nm detection), in order to evaluate the specific activation of $PP_{MMP}B$ *in vivo* by MT-1 metastases. Using commercial software (*Olympus Fluoview FV 1000*), the degree of colocalization of $PP_{MMP}B$ and MT-1 metastatic cells within the vertebral column was assessed by calculating the Pearson coefficient between the two fluorophores (activated $PP_{MMP}B$ and GFP), with −1 representing no overlap and +1 representing 100% concordance of localization. $PP_{MMP}B$ activation was quantified in these samples using the Maestro imaging system (650 nm excitation, ≥700 nm detection, autoexposure integration time), normalizing the total fluorescence signal within a defined region of interest (ROI) by the exposure time and the ROI area. The values used were based on the midsagittal images of the fluorescence within the vertebral body and the spinal cord, and the difference between these was compared using a Student *t* test. To confirm metastatic formation within the vertebral column, the spines were then fixed in 10% buffered formalin, decalcified, sectioned (10 μm), and stained either with H&E or immunhistochemically using a mouse-antihuman epidermal growth factor receptor (hEGFr) antibody (Zymed, Laboratories Inc., San Francisco, CA, USA). This antibody does not cross react with rat tissues, enabling specific visualization of the metastatic human breast cancer cells withzin the rat vertebral bone and bone marrow compartments (Figure 2B).

RESULTS

The *in vitro* specific activation of $PP_{MMP}B$ by MT-1 cells was compared with that of the scrambled beacon ($PP_{scrambled}B$) in which the linker is not MMP cleavable, as illustrated by confocal fluorescence microscopy: Figure 3A and B. HPLC-MS of the culture media following incubation with cells shows 2 peaks corresponding to the expected MMP cleaved fragments of $PP_{MMP}B$, Pyro-GPLG and LARK-BHQ3 (SI Figure S2). Examples of flow cytometry quantifying the fluorescence intensity of $PP_{MMP}B$ and $PP_{scrambled}B$ in cells incubated for different times are shown in Figure 3C. At all time points, the fluorescence intensity was 5- to 10-fold higher in cells incubated with $PP_{MMP}B$ than with the scrambled beacon ($p < 0.001$). The distributions and shape of the cells are largely homogeneous after incubation with the beacons, suggesting minimal toxicity (SI Figure S3).

The activation of $PP_{MMP}B$ *in vivo* was first examined in subcutaneous MT-1 xenografts, following i.v. administration of 2 mg/kg $PP_{MMP}B$, monitoring whole-body fluorescence following cleavage of $PP_{MMP}B$. A strong fluorescence signal localized within the tumor was seen in experimental animals (Figure 4A), demonstrating $PP_{MMP}B$ activation in the tumor. To further validate the *in vivo* MMP specificity, mice bearing tumors on both flanks were injected intratumorally with 2 mg/kg of either $PP_{MMP}B$ (left) or $PP_{scrambled}B$ (right) and followed over time. Initially, little fluorescence was observed in either tumor. However, at 6 h a 9-fold increase in tumor fluorescence was observed with $PP_{MMP}B$ (3.5 ± 0.02 average fluorescent counts/(s × area)) compared with $PP_{scrambled}B$ (0.4 ± 0.09

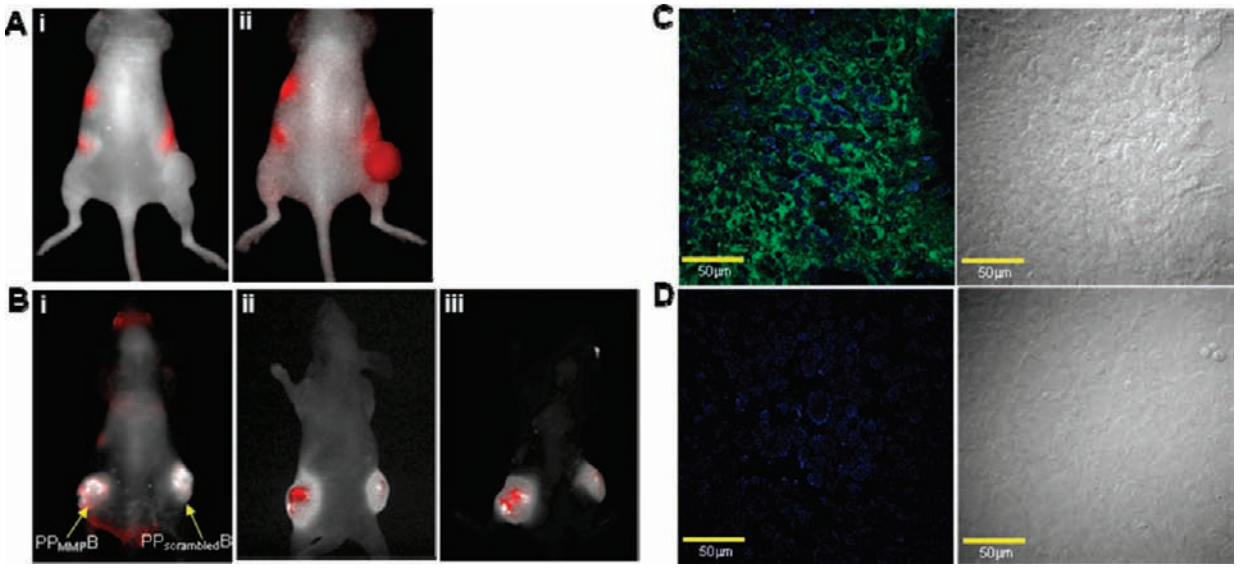

Figure 4. *In vivo* fluorescence images in the MT-1 subcutaneous xenograft tumor model: (A) before (i) and 17 h after (ii) i.v. injection of 2 mg/kg $PP_{MMP}B$ and (B) $PP_{MMP}B$ (left tumor) versus $PP_{scrambled}B$ (right tumor) images at (i) 10 min, (ii) 6 h, and (iii) 24 h post intratumor injection. Fluorescence micrographs and corresponding differential contrast images of MT-1 frozen tissue sections 24 h after administration of $PP_{MMP}B$ (C) or $PP_{scrambled}B$ (D) (n = 5, Green - activated $PP_{MMP}B$ fluorescence, DAPI - blue nucleus stain).

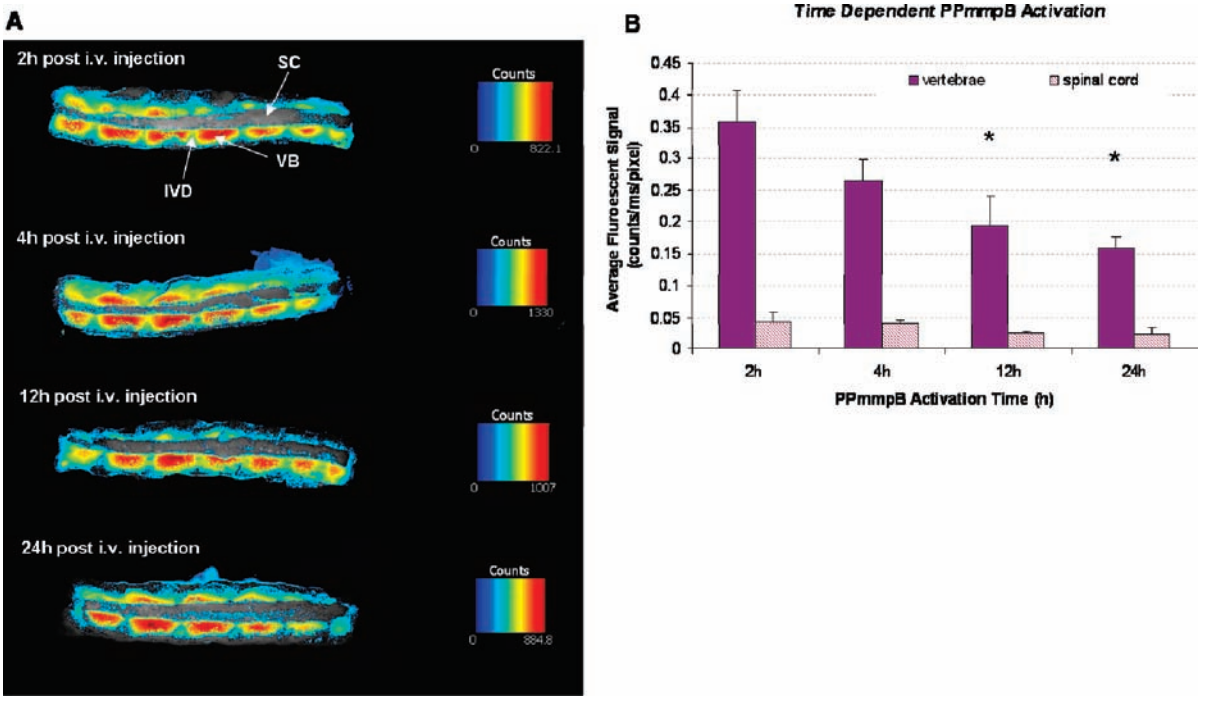

Figure 5. Time-dependent activation of $PP_{MMP}B$ by vertebral metastases imaged *ex vivo*. (A) Composite fluorescence images at 2, 4, 12, and 24 h after intravenous injection of 3 mg/kg $PP_{MMP}B$: SC – spinal cord, VB – vertebral body, IVD – intervertebral disk. (B) Average fluorescent signal comparing $PP_{MMP}B$ activation in the vertebrae and spinal cord: * indicates statistically significant difference ($p < 0.05$) in $PP_{MMP}B$ activation between vertebrae and spinal cord at all imaging time points (n = 4 for 2 and 4 h time points, n = 2 for 12 and 24 h).

average fluorescent counts/(s × area)), the latter showing minimal change in fluorescence (Figure 4B). Even after 24 h, confocal images of frozen sections of harvested tumors confirmed that fluorescence was only detectable in tumors injected with $PP_{MMP}B$ (Figure 4C).

Although these results are promising, evaluation of $PP_{MMP}B$ specific activation in veretebral metastases is necessary to validate the PDT beacon concept for this particular clinical application. Following intracardiac injection of MT-1 cells, metastatic spread to the spine was seen in all animals using bioluminescent imaging. *Ex vivo* fluorescence imaging of the sagitally cut spine over 24 h evaluated $PP_{MMP}B$ activation in vertebral metastases. As shown in Figure 5, the highest fluorescence signal was between 2 and 4 h and then significantly decreased ($p < 0.05$) at 12 and 24 h.

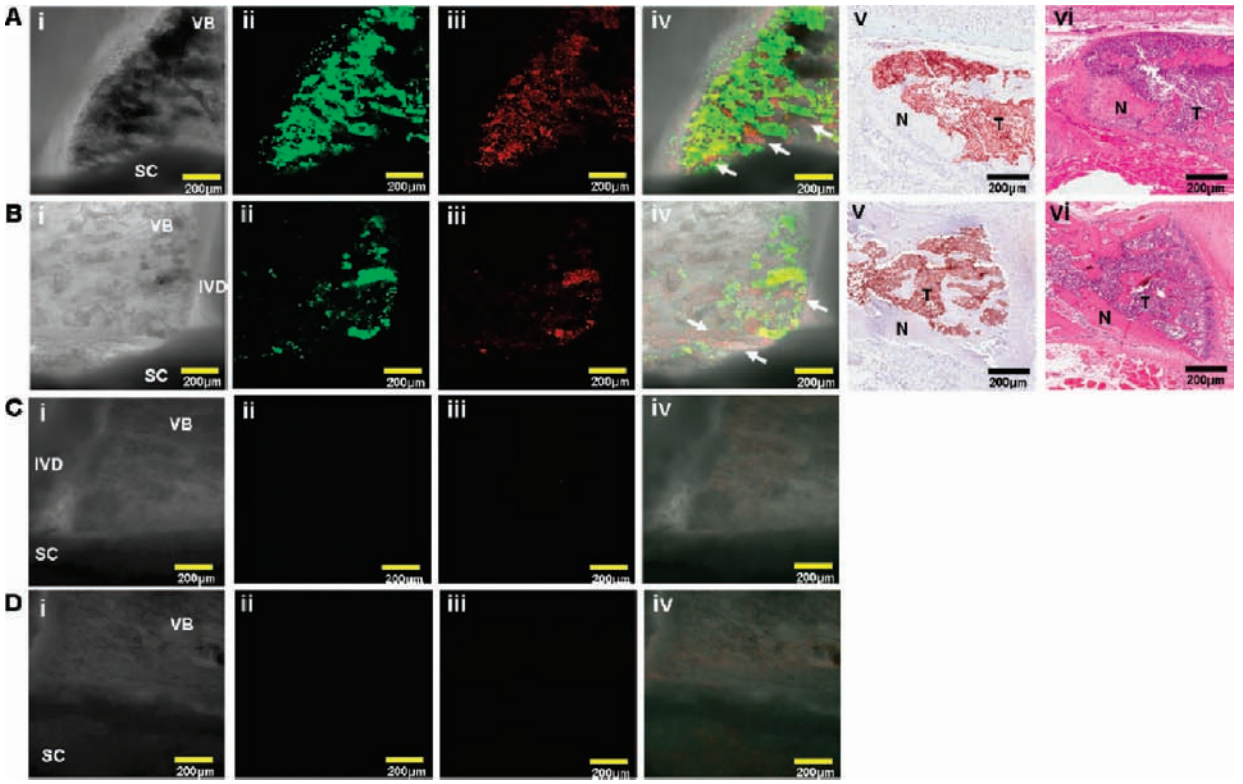

Figure 6. Micrographs of vertebrae at 2 h post i.v. injection of 3 mg/kg $PP_{MMP}B$ into (A,B) MT-1 tumor-bearing rats, (C,D) healthy rats. (i) brightfield image, (ii) GFP image showing the MT-1 cells, (iii) activated $PP_{MMP}B$, (iv) merged images of GFP and cleaved beacon (VB − vertebral body, IVD − intervertebral disk, SC − spinal cord) and corresponding (v) hEGFr and (vi) H&E stained histology sections (T −tumor, N − normal, 5× magnification). Note: in the merged images in panel iv $PP_{MMP}B$ activation extends beyond the GFP, indicating uptake/activation by surrounding tumor stroma (white arrows).

Importantly, no fluorescence signal from activated beacons was detected above background within the spinal cord at any time point (Figure 5B and SI Figure S4). Weak fluorescence was observed within the intervertebral discs (Figure 5A). The strongest fluorescence was within the vertebral body, where metastases most commonly form. At all imaging time points, the fluorescence intensity was 6- to 9-fold higher in the vertebral body versus the spinal cord ($p < 0.05$) (Figure 5B), demonstrating that $PP_{MMP}B$ activation is substantively confined to sites where vertebral metastases develop, with rapid onset of beacon activation after administration. Thus, either the beacon is not significantly taken up in or activated by the spinal cord or, at least over the time period of observation, there is no significant diffusion of cleaved $PP_{MMP}B$ activated by tumors (local or distant) into the spinal cord.

To ensure that $PP_{MMP}B$ activation was a result of the vertebral metastases expressing MMPs and not due to normal bone tissues, spines from tumor-bearing and healthy animals were imaged *ex vivo* at 2 and 4 h after i.v. administration of $PP_{MMP}B$. No fluorescence was observed in the spinal cord in either case. Under confocal microscopy, in which the unquenched beacon fluorescence was overlaid with the GFP signal of the cells, sites with positive GFP showed detectable activation (Figure 6A,B), whereas no activation was detected in the healthy animals (Figure 6C,D). Furthermore, no $PP_{MMP}B$ activation was seen within the spinal cord. The Pearson coefficients for the degree of overlap between $PP_{MMP}B$ activation and MT-1 vertebral tumors (Figure 6A,B and SI Figure S5) were 0.76 and 0.68 at 2 and 4 h post injection, respectively. This was not applicable in the healthy animal cohort, since no signal was detected in either imaging channel (tumor or cleaved beacon).

DISCUSSION

These data demonstrate that specific activation (enzymatic cleavage resulting in unquenching of the photosensitizer fluorescence) of $PP_{MMP}Bs$ is mediated by breast cancer vertebral metastases that express MMPs. Among the MMPs, other than MMP 7, $PP_{MMP}B$'s peptide linker sequence, GPLGLA, can also be specifically cleaved by MMP 10 and MMP 12, although at a lower rate than MMP 7 (data not shown). However, this additional cleavage would not be a disadvantage in this application, since both MMP 10 and 12 also play roles in bone development and bone matrix solubilization.[32−35] Since tumor cells have already hijacked the normal osteolytic cycle, MMP 10 and 12-mediated beacon activation may then aid in further disrupting the vicious tumor-bone cycle. The *in vitro* studies confirm this specific activation by the MT-1 breast cancer cells. The *in vivo* experiments in MT-1 xenografts demonstrate specific activation of $PP_{MMP}B$ by these tumors, using both systemic (i.v.) and intratumoral injection of the beacon. In the more clinically relevant metastatic model, fluorescent imaging also confirmed tumor-specific activation of $PP_{MMP}B$. There are, however, limitations with this model. The attenuation of the fluorescent signal by the overlying bone and soft tissue confounds quantitative *in vivo* imaging to determine the activation kinetics. Nevertheless, this could be determined by imaging the sectioned vertebrae *ex vivo*, albeit at only select time points, and showed that the beacon can reach and target

the intravertebral tumor tissue. In addition, it remained inactive (uncleaved) within the spinal cord, which is the critical dose-limiting tissue. It may be anticipated then that $PP_{MMP}Bs$ may serve as both a vertebral metastases-specific imaging agent and a directed PDT agent, and thus, there are a number of potential applications of $PP_{MMP}Bs$ in the treatment of patients with spinal metastases.

Surgical debulking is currently a main treatment option for spinal metastases, but recurrence is common due to incomplete resection. The strong fluorescence signal and specificity of $PP_{MMP}B$ could enable intraoperative image guidance to increase the completeness of resection and to aid in the intraoperative detection of small metastatic lesions that are otherwise not visible. Thereby, the risk of recurrence would be reduced. This is also analogous to fluorescence image-guided tumor resection in other organs.[18,36−41] Original protease activatable probes were developed to differentiate tumor versus healthy tissue, better defining surgical margins.[42−45] Thus, the initial *in vivo* and clinical application of beacons was intended for fluorescence image-guided tumor resection.[19,43,45−48] We have demonstrated tumor-specific activation for both systemic and local administration in tumor xenografts. Intratumoral injection was not technically feasible in the vertebral metastasis model due to the size limitation, but this will not be the case in patients. It is encouraging that activation occurs fairly rapidly, so that the beacon could be administered shortly before or during surgery, assuming comparable activation kinetics in humans after a local injection at the tumor site.

Furthermore, since pyropheophorbide-α is a potent PDT agent[17,24] in addition to being a fluorescence marker, PDT could be used as a means to "clean up" the surgical bed following resection, as has been used in gliomas with conventional photosensitizers.[36,49] The high degree of quenching in the intact beacon (>99%) and the tumor specificity of activation are then distinct advantages, by markedly reducing the risk of collateral damage to normal tissues that are within range of the photoactivating light. Thus, PDT treatment of the entire surgical bed post resection could result in the eradication of any residual tumor mass and microscopic vertebral metastatic deposits, while preserving normal tissues, specifically the spinal cord. Furthermore, based upon the confocal imaging of tumor cell GFP and beacon activation in vertebral metastases (Figure 6Aiv and Biv), there is evidence of beacon uptake by tumor stroma as well as by the tumor cells themselves. This is not too surprising, since it is known that MMPs are also secreted by tumor stroma.[4,5] This multicompartment targeting provides a further means to interrupt the signaling between the stroma and adjacent cancer cells by identifying cells hijacked by the tumor to promote osteolysis. Hence, eradication of the tumor microenvironment could result in further synergistic effects.

The metastases-specific activation of $PP_{MMP}B$ with its ability to remain inactive in critical normal tissues (i.e., spinal cord) combined with the potent PDT capability of Pyro in beacons makes $PP_{MMP}B$ highly attractive by providing an additional mechanism of selectivity in PDT. [17,24] PDT has been proposed as a promising therapeutic strategy for patients suffering from spinal metastases. It is an approved cancer treatment modality with several potential advantages over current cancer treatments due to its minimally invasive nature, selectivity, ability to treat patients with repeated doses without initiating resistance or exceeding total-dose limitations, fast healing that results in little or no scarring, the ability to administer in an outpatient setting, minimal associated side effects, and lack of contraindication with other modalities.[18−20] We have previously proposed and reported several preclinical studies on the concept of using PDT for destroying spinal metastases, particularly to debulk lesions as an adjuvant to vertebroplasty or kyphoplasty in order to mechanically stabilize weak or fractured vertebrae:[23,27,30,31,50,51] These surgical procedures involve injection of a plastic compound or placement of an inflatable balloon into the vertebral body, which is often limited by the space-occupying tumor mass. We have shown that not only can PDT (using the clinical photosensitizer Visudyne) ablate spinal metastatic tumors,[23] but unexpectedly it also enhances vertebral mechanical stability.[30,31] This has led to a phase I clinical trial with the clinically approved photosensitzer Visudyne (QLT Inc., Vancouver, BC, Canada), in which the objective is to debulk the intravertebral space-occupying tumor mass that often impedes these surgical approaches. However, current photosensitizers are limited by their nonspecific accumulation in normal tissues, e.g., Visudyne has nonspecific uptake in the spinal cord, limiting the therapeutic window which, in turn, reduces the aggressiveness of treatment in order to stay well within safe dose limits.[23,27] Clearly, preservation of spinal cord structure and function is critical in the management of vertebral metastases. $PP_{MMP}B$ potentially addresses this limitation and may be a key component in the use of PDT as a new, minimally invasive, safe, and effective therapy for the management of patients with spinal metastases. Although in this initial study we have not directly tested the photodynamic efficacy of the cleaved beacon against the tumor tissue, previous studies of a variety of PDT beacons in tumor xenograft models[17] have shown that this tracks with the fluorescence characteristics, as would be expected from the photophysics. Direct studies of the PDT effect are in progress, although a second limitation of the intracardiac-injection metastatic model is that the animals survive for only a few weeks[23] due to widespread disease, so that long-term treatment responses cannot be evaluated. Due to the small size of the animals, evaluation of the PDT effect due to an intratumoral injection of $PP_{MMP}B$ within the vertebrae is not possible.

In summary, we have demonstrated the specific activation of $PP_{MMP}B$ by MMP-expressing vertebral metastases in a relevant preclinical model illustrating defined kinetics and the ability to target intravertebral metastatic tumors with minimal uptake or activation in the spinal cord. This is a first step in the further development of such beacons and their potential translation into useful clinical tools for a range of applications.

Supporting Information

ABSTRACT: In recent years, numerous research activities have been devoted to the controlled release of nitric oxide (NO) due to its potential as a restenosis inhibitor which inhibits the proliferation of vascular smooth muscle cells, the apoptosis of vascular endothelial cells, and aggregation of platelets. This work has demonstrated the development of a novel NO-conjugated gel system comprising of thermosensitive Pluronic F127, branched polyethylenimine (BPEI), and diazeniumdiolates (NONOates). Synthesis of conjugated Pluronic-BPEI-NONOates involved coupling of activated F127 to BPEI followed by the installation of NONOates at the secondary amine sites of branched PEI backbone under high pressure. NO-conjugated gel system, F127-BPEI-NONOates, reduced the initial burst of NO release and prolonged NO release. Furthermore, F127-BPEI-NONOates polymer coated on cell culture dish displayed much higher increase of endothelial cell proliferation and reduction of smooth muscle cell proliferation than that exhibited by non-NO releasing control. Such an NO-releasing device can operate locally and has a great potential in several biomedical applications due to high biocompatibility imparted by the conjugated F127.

INTRODUCTION

Nitric oxide (NO) is a small reactive molecule that plays a major role in proliferation and apoptosis of cells, neurotransmitters, and regulation of vasomotor tone.[1−3] Especially in vascular vessels, NO has been known to affect relaxation, inhibition of proliferation, and induction of apoptosis of vascular smooth muscle cells. In contrast to these effects on vascular smooth muscle cells, NO is also known to induce the growth of endothelial cells.[4,5] In addition, NO exerts an inhibitory effect on platelet aggregation, which can cause thrombogenicity.[6−8]

Despite the various and selective functions of NO, as well as in vivo generation of NO by three types of nitric oxide synthase, it is very difficult to apply NO to biomedical and therapeutic fields because NO could easily react with other components to produce a variety of nitrate/nitrite and could be released very rapidly from NO donors. Thus, there has been enormous interest in developing biomaterials which could facilitate the controlled and prolonged release of NO for modulating its concentration-dependent functions.[9] Several types of NO donors have been developed and evaluated in vitro and in vivo. Nitroglycerin,[10] sodium nitroprusside,[11] *S*-nitrosothiol,[12−15] NO aspirin,[16−18] and 1-substituted diazen-1-ium-1,2-diolates (NONOates)[19−28] and its derivatives[16,29] are typical examples of NO donors. Among these types of NO donors, NONOates, containing the $[N(O)NO]^-$ functional group, are considered as the most attractive candidates for practical application due to their spontaneous dissociation under physiological conditions to yield 2 mol of NO per mole of $[N(O)NO]^-$ functional group and structural flexibility of synthesis.[26]

Recently, NO donors were incorporated into stents covalently and noncovalently and thus used as restenosis inhibitors.[12,14,20−22,25,27] There are mainly two distinct structural systems which are utilized as NO donors in coating materials for drug-eluting stent (DES). The majority of the NO-releasing polymers incorporate NO through covalent conjugation as found in diaminoalkyltrimethoxylsilane silicone rubber-NONOates (DACA/NONO-SR),[27] polypropylenimine dendrimers-NONOates,[22] and polyethyleneimine-NONOates.[19] Using this system, it is possible to incorporate NO in abundance into polymers; however, a supporting material which could bind NO donors into the substrate is essential. Unless NONOates polymers remain bound to the supporting material, the detached

polymer could be dispersed into the body through the bloodstream and may induce toxicity. Another type of NO donor includes a mixture of small NO donor noncovalently mixed with polymers, for example, the mixture of diethylamine-NONOates (DEA-NONO) with poly(ethylene glycol) (PEG),[28] diethylenetriamine-NONOates (DETA-NONO) with polycaprolactone,[28] *S*-nitrosoglutathione with poly(vinyl alcohol)/poly(vinyl pyrrolidone) film,[15] and *S*-nitrosoglutathione or *S*-nitroso-*N*-acetylcysteine with Pluronic F127 gel.[14] Especially, it has been reported that NO release from *S*-nitrosoglutathione or *S*-nitroso-*N*-acetylcysteine in thermosensitive Pluronic F127 hydrogel is slower than that in H_2O. However, these mixed systems may induce leaching out of small molecules, which can cause cytotoxicity.

In this study, we developed a conjugated gel system by integrating advantageous features of two distinct systems in a single system. We used Pluronic F127, a commercially available thermosensitive triblock copolymer which was approved by FDA, to prolong the NO release by a cage recombination mechanism.[14] In addition, we have conjugated BPEI which has a large amount of secondary amines, designed for conjugation of NONOates to Pluronic F127. We have also investigated the kinetics of NO release from F127-BPEI-NONOates hydrogel and their effects on endothelial as well as smooth muscle cell proliferation.

EXPERIMENTAL PROCEDURES

Materials. Branched PEIs (BPEI, MW 600 Da, 10 kDa,) were obtained from Polyscience, Inc., (Warrington, PA) and high molecular weight BPEI (MW 25 kDa), sodium methoxide (NaOMe), Pluronic F127, and *p*-nitrophenyl chloroformate (*p*-NPC) were purchased from Sigma Aldrich (St. Louis, MO). Tetrahydrofuran (THF) and diethyl ether were purchased from Dae Jung Chemical Co. (Seoul, Korea). Dichloromethane (DCM) was purchased from Samchun Chemical Co. (Korea). Methyl alcohol (MeOH) was purchased from Mallinckrodt (St. Louis, MO). A Griess assay system was purchased from Promega (Madison, WI). Nitric oxide (NO) and argon (Ar) gases were obtained from HANA gas (Gimhae, Korea). Human umbilical vein endothelial cells (HUVEC), coronary artery smooth muscle cells (SMC), endothelial basal medium-2 (EBM-2) with full supplements (EGM-2 siglequots), and smooth muscle basal medium (SmBM) with full supplements were obtained from Lonza (Walkersville, MD). Dulbecco's phosphate buffered saline (DPBS) was purchased from Invitrogen-Gibco (Carlsbad, CA). Cell viability was estimated by Cell Counting Kit-8 obtained from Dojindo Molecular Technologies, Inc. (Gaithersburg, MD).

Synthesis and Charaterization of BPEI-NONOates. BPEI-NONOates was prepared as previously reported.[19] Briefly, a solution of BPEI (0.5 g each for M_w: 600 Da, 10 kDa, and 25 kDa) in dry MeOH (10 mL) and dry THF (20 mL) was prepared in 100 mL beaker. After the solution was stirred, NaOMe (1 mol equiv with respect to the total amine sites) in MeOH (10 mL) was added to the BPEI solution and placed in an in-house high-pressure reactor. The high-pressure reactor was flushed with 20 psi Ar (g) twice and then subsequently charged with NO (g) at 80 psi. After 3 days, NO was vented and the reactor was flushed with 20 psi Ar (g) twice before each product was precipitated with cold dry ether. The solvent was quickly removed by filtration, and the product was washed with cold dry ether and then vacuum-dried to yield a light yellow product. The products were stored at −20 °C. The conjugation ratios of BPEI-NONOates were characterized by ^{1}H NMR in D_2O using 300 MHz NMR spectrometer (Bruker, Germany). The characteristic absorption bands for NONOates and *N*-nitrosoamine were 250−260 nm and 330−360 nm, respectively, as measured by UV/vis spectrophotometry (UV 2550, Shimadzu, Japan).

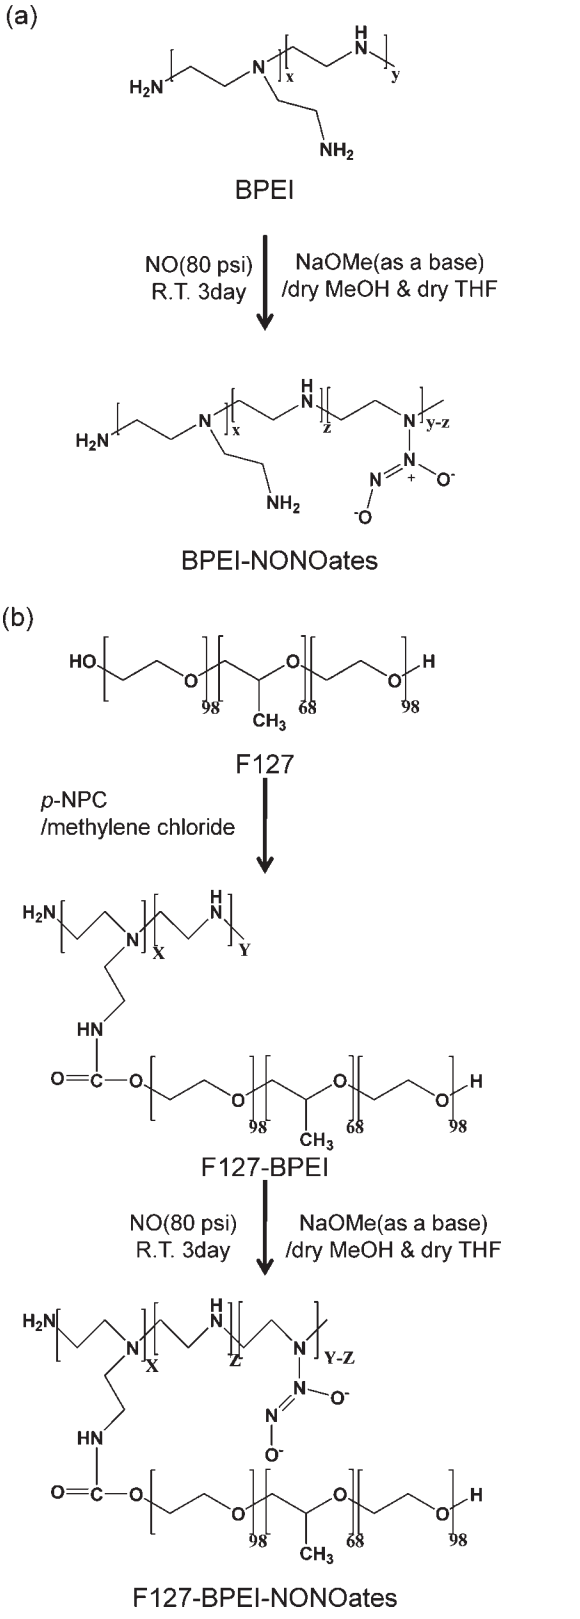
Measurement of NO Release from BPEI-NONOates by Griess Assay. NO release profile was monitored using the Griess assay (Promega), which quantifies the amount of nitrites, the primary degradation byproduct of NO. In brief, each 250 mg aliquot of BPEI-NONOates was incubated in DPBS (50 mL) at 37 °C. After sampling 60 μL in predetermined time intervals, fresh DPBS (60 μL) was added to the vial to maintain the overall volume. After mixing the acquired samples with DPBS, the samples (50 μL) were added to a sulfanilamide solution (50 μL) and incubated in the dark at room temperature for 5 min. Naphthylethylenediamine (50 μL) was added to the mixture to stimulate a colorimetric change; intensity was measured at 548 nm by microplate spectrofluorometer (VICTOR3 V Multilabel Counter, Perkin-Elmer, Wellesley, MA) and compared to known sodium nitrite standards.

Synthesis and Characterization of F127-BPEI. F127-BPEI was prepared using the modified method as reported previously.[30,31] To prepare the hydroxyl-activated Pluronic F127, Pluronic F127 (10 g, 0.79 mmol) was dissolved in anhydrous DCM (70 mL). The solution was added dropwise to a stirred solution of *p*-NPC (1.29 g, 6.35 mmol) in anhydrous DCM (70 mL). The reaction was carried out for 24 h at room temperature with gentle stirring under nitrogen atmosphere. The activated Pluronic F127 was precipitated by addition of ice-cold ether and dried under vacuum. To synthesize the F127-BPEI, a DCM solution (20 mL) containing activated Pluronic F127 (0.6 g) was added dropwise to a solution of BPEI600 (1.5, 3, and 10 mol equiv with respect to activated F127) and triethylamine (1 mL) in DCM (20 mL) at ice-cold conditions. The reaction was carried out for 24 h at room temperature with gentle stirring under nitrogen atmosphere. After evaporating the DCM and dissolving with water, each product was dialyzed by a Spectra/Por dialysis membrane M_w cutoff of 10 000 against water. The conjugation ratios of F127-BPEI were determined by ^{1}H NMR taken in D_2O using 300 MHz NMR spectrometer (Bruker, Germany). Temperature-responsive sol−gel transition behaviors were monitored using a modified vial tilting method.[32]

Synthesis and Characterization of F127-BPEI-NONOates. To a solution of F127-BPEI (0.5 g) in dry THF (2.3 mL) was added a solution of NaOMe in dry MeOH (0.5 M, 2.3 mL). The solution was stirred for 30 min and was then placed in a high-pressure reactor. The high-pressure reactor was flushed with 20 psi Ar (g) twice and subsequently charged with NO (g) at 80 psi. After 3 days, NO was vented and the reactor was flushed with 20 psi Ar (g) twice before each product was precipitated with cold dry ether. The solvent was quickly removed by filtration, and the product was washed with cold dry ether and then vacuum-dried. The products were stored at −20 °C. The conjugation ratios of BPEI-NONOates were determined by ^{1}H NMR in D_2O using 300 MHz NMR spectrometer (Bruker, Germany).

Measurement of NO Release from F127-BPEI-NONOates by Griess Assay. Each of F127-BPEI-NONOates (150 mg) was dissolved in deionized water at 4 °C to prepare 20 wt % solutions and incubated in 600 μL DPBS at 37 °C. Release of NO was monitored using the Griess assay (Promega). In brief, after sampling 600 μL at predetermined time intervals, fresh DPBS (600 μL) was added to the vial. A sample (50 μL) was added to a

sulfanilamide solution (50 μL) and incubated at room temperature for 5 min, protected from light. Then, naphthylethylenediamine (50 μL) was added to the mixture to stimulate a colorimetric change; intensity was measured at 548 nm by microplate spectrofluorometer (VICTOR3 V Multilabel Counter, Perkin-Elmer, Wellesley, MA) and compared to known sodium nitrite standards.



In Vitro Cell Proliferation Test. All materials such as F127, F127-BPEI, F127-BPEI-NONOates, deionized water, DPBS, and media were sterilized under UV for 30 min prior to carrying out the in vitro experiments. F127 (100 mg), a mixture of F127 (50 mg) and F127-BPEI (50 mg) or a mixture of F127 (50 mg) and F127-BPEI-NONOates (50 mg) were dissolved separately in deionized water at 4 °C to yield 25 wt % solutions and kept at 4 °C for 1 h, and then gelation was performed on the cell culture dish at 37 °C for 2 min. HUVEC and SMC were seeded on the coated cell culture plates (24 well) at a density of 1×10^4 cells/well and further incubated at 37 °C for 24 h. After 24 h incubation, cell proliferation was investigated by cell counting kit-8 (CCK-8) assay.[33] This CCK-8 uses the water-soluble tetrazolium salts (WST-8) (2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfophenyl)-2*H*-tetrazolium) which is a derivative of MTT (3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide).

RESULTS AND DISCUSSION

Synthesis and Characterization of BPEI-NONOates. Three types of BPEI-NONOates having BPEI with different MW were synthesized by the method described above, and the structural characteristics of each type of BPEI-NONOates were confirmed by ^{1}H NMR and UV/vis spectroscopy (Scheme 1, and Figures 1 and 2). In ^{1}H NMR, the proton signals of methylene groups adjacent to amine sites of BPEI at 2.7 ppm were shifted downfield to about 3.1 ppm in BPEI-NONOates due to the electron-withdrawing effect of the NONOates group. The integration of the shifted proton signals compared to the total proton integration of each type of BPEI-NONOates revealed that the conjugation ratios of NONOates to BPEI600, BPEI10K, and BPEI25K were 15.3%, 13.8%, and 16.0%, respectively (Figure 1 and Table 1). The UV/vis absorption spectra also showed the characteristic absorption peaks for NONOates at about 250 nm[19] as measured in DPBS buffer (Figure 2).

NO Release Profile of BPEI-NONOates. NO release from three types of BPEI-NONOates was measured in DPBS solution at physiological temperature using a Griess assay (Figure 3) method for nitrite measurement based on the oxidation of highly reactive NO to nitrite. As shown in NO release profile in Figure 3, at initial stages NO was released rapidly from BPEI25K-NONOates and release was completed within 10 h. Likewise, BPEI10K-NONOates showed a similar initial NO release profile, but the NO release was completed within 22 h. However, BPEI600-NONOates having low MW of BPEI showed a different NO release profile. NO was released rapidly at the initial few hours, but showed a sustained NO release pattern. Moreover, NO was released from BPEI600-NONOates for an extended time over 50 h. Longevity can be defined as the duration of NO release, while sustainability can be defined as the degree of sustained release of NO at the initial state, and quantitative evaluation of longevity and sustainability of NO release was summarized in Table 1. These results could be rationalized by considering the protonation of the primary amine group. The protonated primary amine groups (pK_a = 9.73−11.02) are expected to confer stability to NONOates derivative through the hydrogen bonding formation between protonated primary

amine group and NONOates anion.[34] Therefore, the presence of primary amine in close proximity of the NONOate moieties could be an important factor, which may regulate the extent of stabilization of NONOates. In other words, sustained release of NO through the dissociation of NONOates depends on the relative disposition of primary amine and NONOate groups within the polymeric framework. In BPEIs used in this study, the ratio of primary to secondary amine is almost constant, which implies that the dissociation kinetics is governed by some other

factors presumably by the degree of stabilization of NONOates moieties conferred by primary amine groups. The assumption could be extended further to assign the crucial role of the three-dimentional structure in regulating the distance between primary amine and NONOates, which in turn could govern the extent of stabilization of NONOate moieties. The primary amines are believed to be populated primarily on the surface and thereby have less opportunity to stabilize the NONOates which are attached to secondary amines and reside at the interior core of the three-dimensional structures (Figure 3b). The increase in molecular weight or size of the polymers increases the distance between primary amine at the surface and secondary amines at the core, which leads to less stabilization and hence faster release of NO. This hypothesis can be substantiated firmly from the following correlations among the molecular weight, size, and NO release profile of the respective BPEI-NONOates. As the radius of BPEI600 is smaller than BPEI10K and BPEI25K, the primary amines in BPEI600-NONOates are located much closer to the NONOates compared to BPEI10K and BPEI25K. Consequently, primary amines of BPEI600-NONOates impart greater stabilization to the NONOate moieties leading to slower NO release. These results are in good agreement with previous reports,[34] and it is expected that F127-BPEI600-NONOates will show slow and sustained NO release compared to high MW BPEIs counterparts.

Synthesis and Characterization of F127-BPEI. The half-life of BPEI600-NONOates, which demonstrated slow and sustained NO release, is only 1 min, and this is considered unfavorable for the actual application of NO donor. In order to increase

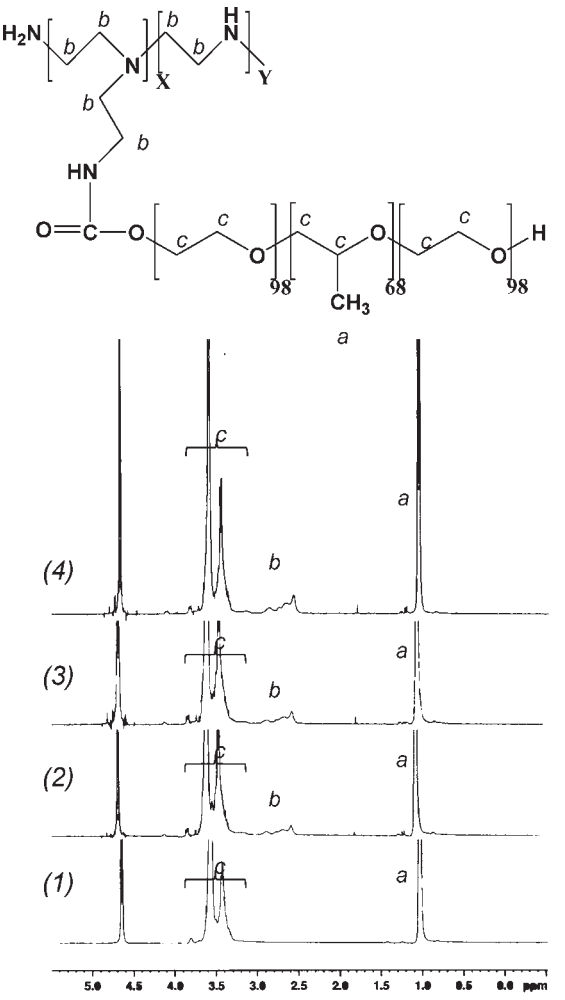

Figure 4. ^{1}H NMR spectra of (1) F127, (2) F127-BPEI0.8, (3) F127-BPEI1.0, and (4) F127-BPEI1.3.

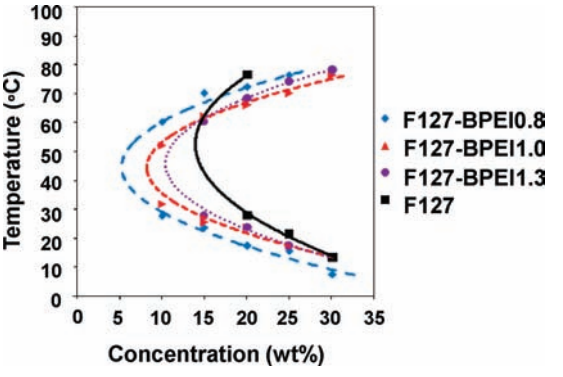

Figure 5. Thermosensitive sol−gel transition behavior of hydrogels formed by F127 and F127-BPEI.

the half-life of NO release, BPEI600 was conjugated to the thermosensitive Pluronic F127 polymer. It is assumed that in the gel state NONOates remains caged in the F127 gel. However, it could be dissociated, and NO release could be triggered by the initial inclusion of water and accelerated further by the disruption of gel.

Three types of F127-BPEI were synthesized by changing the feed ratio of the BPEI600 to the F127 (Scheme 1), and the structural characteristics of each type of F127-BPEI were confirmed by ^{1}H NMR. In the ^{1}H NMR spectrum, the proton signals of methylene groups in F127 were observed at 1.15 ppm and methylene proton signals of BPEI were detected at 2.7 ppm -(Figure 4). The relative integration of the proton signals of BPEI compared to the methylene groups in F127 revealed conjugation ratios. There were no large differences in conjugation ratios of F127 to the BPEI, although the feed ratios of the F127 to BPEI were 1:1.5, 1:3, and 1:10. F127-BPEI0.8, F127-BPEI1.0, and F127-BPEI1.3 represent F127-BPEI conjugates having F127 and BPEI residues in a molar ratio of 0.8, 1.0, and 1.3, respectively.

Generally, Pluronic F127 shows thermosensitive sol−gel transition properties as a function of concentration. Therefore, to study the effect of BPEI conjugation on the thermosensitive properties of F127-BPEI, the sol−gel transition profile was investigated under different concentrations by the tilting method.

As shown in Figure 5, F127-BPEI showed decreased critical gelation concentrations and narrower curve of gelation temperature compared to unmodified F127. This change in gelation profile could be attributed to the incorporation of the hydrophilic BPEI to the F127. The hydrophilic part is known to stabilize the micelle−micelle interaction through the bridge effect and thereby facilitates the formation of three-dimensional micelle networks leading to gelation at lower concentration. However, as shown in Figure 5, though incorporation of hydrophilic BPEI certainly lowers the critical gelation concentration in comparison

dx.doi.org/10.1021/bc100405c |*Bioconjugate Chem.* 2011, 22, 1031–1038

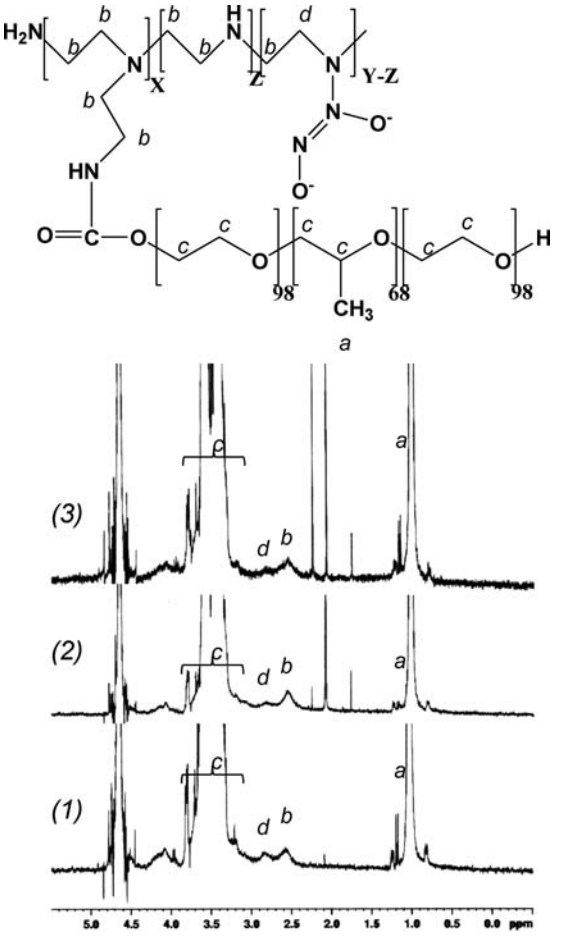

Figure 6. ^{1}H NMR spectra of (1) F127-BPEI0.8-NONOates, (2) F127-BPEM.O-NONOates, and (3) F127-BPEI1.3-NONOates.

to unmodified F127, the trends within F127-BPEI derivatives contradict the above logic. The F127-BPEI polymers with the increasing proportion of BPEI to F127-BPEI, as estimated in F127-BPEI0.8, F127-BPEI1.0, and F127-BPEI1.3, demonstrated gradual increase in critical gelation concentration. Such an increase in critical gelation concentration with increasing BPEI content in F127-BPEI derivatives is in agreement with the observed increase in the critical gelation temperature.[35−38] We assume that, though hydrophilic BPEI moiety favors stabilization of micelle−micelle interaction, the BPEI part might also impart some sort of destabilization to the micelle framework due to the electrostatic repulsion. The BPEI content may influence stabilization and destabilization differently under different concentration.

Synthesis and Characterization of F127-BPEI-NONOates. Three types of F127-BPEI which have secondary amines were modified with NONOates. F127-BPEI-NONOates were synthesized by the method described above (Scheme 1), and the synthesis was confirmed by ^{1}H NMR (Figure 6). In comparison to the proton signals in F127-BPEI, F127-BPEI-NONOates showed a downfield shift of proton signals of methylene groups adjacent to amine sites in BPEI to 3.1 ppm. Therefore, the conjugation ratio of the NONOates to the F127-BPEI could be determined by the same method described earlier. The amounts of NONOate groups that were incorporated in F127-BPEIs during NONOates reaction were found to be 35.1%, 33.1%, and 35.1% for F127-BPEI0.8-NONOates, F127-BPEI1.0-NONOates,

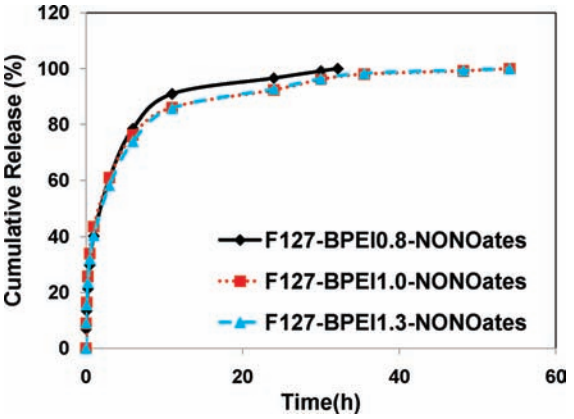

Figure 7. Cumulative NO release (%) from three types of F127-BPEI-NONOates in DPBS at 37 °C. Data are represented as mean ± SD (n = 3).

and F127-BPEI1.3-NONOates, respectively. The extent of conjugation through incorporation of NONOates to F127-BPEI was found to be much higher than that observed for BPEI600-NONOates formation using the same amount of BPEI. This observation could be rationalized by considering the structural features of the polymers. In the case of F127-BPEI, F127 having higher MW acts as a template for BPEI, and therefore, the reactive secondary amine functionalities of BPEI remain largely exposed toward the external agents such as NaOMe and NO gas. On the contrary, these secondary amines are somewhat concealed inside the molecular framework of BPEI, resulting in lower conjugation ratio for BPEI600-NONOates.

NO Release Profile of F127-BPEI-NONOates. We have investigated NO release profile of three types of F127-BPEI-NONOates. The half-life of NO release from F127-BPEI-NONOates was 1.68 to 2.0 h, which was considerably higher compared to unmodified BPEI only (Figure 3, Figure 7, and Table 1). It can be argued that F127-BPEI-NONOates polymer formed a hydrogel at critical concentration and NO was released slowly by the cage recombination effect,[14] which reduces the diffusion of NO in the gel. The NONOate moieties are believed to be encaged inside the gel and such physical shielding averts rapid mixing of NONOate functionalities with water which may otherwise trigger rapid uncontrolled NO release. The slow diffusion of water leads to slow and sustained release of NO. However, the sustainability among F127-BPEI-NONOates does not differ appreciably. On the other hand, as shown in Figure 7, there was a considerable difference in longevity among F127-BPEI-NONOates. In case of F127-BPEI0.8-NONOates, NO release was completed within 32.2 h, while F127-BPEI1.0-NONOates and F127-BPEI1.3-NONOates released NO over an extended period of time. This difference in longevity is considered to be related to the decay process of Pluronic gel. In the case of F127-BPEI0.8-NONOates, gel decayed rapidly after 28 h incubation time, and thus, NO was released rapidly after this point in time. On the other hand, in the case of F127-BPEI1.0-NONOates and F127-BPEI1.3-NONOates, the gel state was maintained up to 54 h incubation time, and after this point, gel started decaying and NO was released rapidly.

In terms of gelation properties as observed in Figure 5, F127-BPEI0.8 forms the most stable gel whereas F127-BPEI1.3 forms the most unstable gel; therefore, it is expected that F127-BPEI0.8-NONOates should release NO during a longer incubation time. However, the reverse trend was observed in the NO

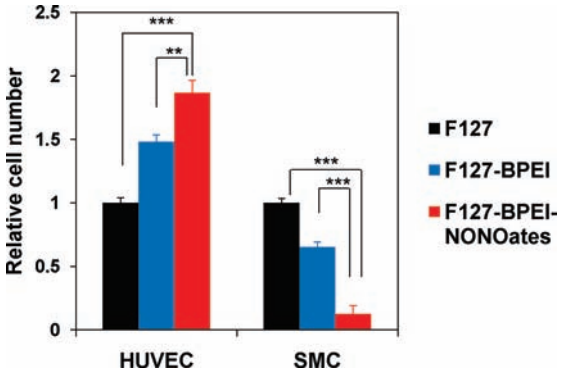

Figure 8. Cellular proliferation test for HUVEC and SMC on F127, F127-BPEI, or F127-BPEI-NONOates-coated plate. Data are represented as a mean ± SD (n = 3). release profile of F127-BPEI0.8-NONOates. These results could be explained by the salting-out effect as reported by Silvia Mike Shishido et al.[14] Generally, adding a salting-out salt such as NaCl to the thermosensitive gel reduces critical micelle concentration (cmc) and accelerates stable gelation at low temperature and concentration, while salting-in salt such as NaSCN increases cmc. Salting-out salts such as NONOates and its derivatives, NO^{2-} and NO^{3-}, which are generated from F127-BPEI-NONOates gel accelerate gelation and thus stabilize gels. Therefore, F127-BPEI1.0-NONOates and F127-BPEI1.3-NONOates gels in which larger amount of NONOates are conjugated in gels are more stable than F127-BPEI0.8-NONOates due to the salting-out effect. The salting-out effect of NONOates is different with a mixed system. In the report of Silvia et al., *S*-nitrosothiol was mixed with F127, and gelation temperature of F127 was increased by the salting-in effect of *S*-nitrosothiol and its salt. However, the gelation temperature of the NONOates-conjugated system in F127 was decreased, implying stabilization of the gel formation by the salting-out effect, although the precise mechanism was not explored yet. These results imply that conjugation to F127 is more useful to the cage effect-mediated gel system than a simple mixing system.

Considering the practical use of this NO-hydrogel system in vivo, the NO release profile in varied conditions needs to be investigated such as under hypoxic vs normoxic and different pH conditions. Accordingly, we investigated the NO release profile under hypoxic as well as normoxic conditions. For the hypoxic condition, we added DPBS to the F127-BPEI1.3-NONOates hydrogel under the N_2-purged condition and then monitored NO release. As shown in Supporting Information Figure S2, the NO release pattern under hypoxic conditions was similar to that observed under normoxic condition. We also evaluated pH-dependency of NO release from NONOates hydrogel. The NONOates hydrogel (F127-BPEI1.3-NONOates) was formed, and then DPBS at various pH conditions (pH 5.2, 7.0, and 9.0) was added to the hydrogel to initiate the NO release. The pH-dependency of the NO release was shown in Supporting Information Figure S3. The NO release pattern did not vary at different pH conditions of releasing buffer surrounding the hydrogel. These results conform to those reported by Masters et al.[39]

In Vitro Cell Proliferation Test. NO has been known to accelerate endothelial cell proliferation and inhibit smooth muscle cell proliferation[12,20] when administered in optimal amounts. To ascertain the effectiveness of NONOates-hydrogel in releasing NO in a controlled manner and at a prolonged time span, we have investigated the HUVEC and SMC proliferation study on the cell culture plates coated with F127, F127-BPEI, and NO-releasing F127-BPEI-NONOates. As shown in Figure 8, F127-BPEI-NONOates demonstrated 48.1% and 26.1% enhancement in the proliferation of HUVEC compared to those achieved by F127 and F127-BPEI mediated proliferation, respectively. Furthermore, the proliferation of SMC was significantly reduced by 35.0% and 80.8% on the F127-BPEI-NONOates-coated plates compared to F127 and F127-BPEI-coated plates, respectively. It was known that inhibition of smooth muscle cell proliferation had a pronounced effect on the blocking restenosis, as well as that exerted by acceleration of endothelial cells.[40,41] Therefore, this hydrogel-based NO-releasing system could provide an efficient strategy to inhibit restenosis. The observation clearly substantiates the effectiveness of F127-BPEI-NONOates in enhancing HUVEC proliferation and inhibiting SMC proliferation through sustained release of NO. Therefore, F127-BPEI-NONOates could be applied as stent coating materials to accomplish efficient restenosis inhibition.

CONCLUSION

In this study, we have successfully developed NO-releasing polymers which can release NO slowly over an extended period of time. The NO-release profile varies with the change in the MW of BPEI conjugated to the F127. This unique feature obviously enables us to modulate the NO-release profile easily by altering the MW of BPEI and thus provides us with the simple and facile strategy to manipulate the NO-release profile and design an optimal NO-release polymer. Apart from the manipulation in conjugation ratio, application of various NO donor polymers could also be exploited to develop an efficient stent coating material to inhibit restenosis.

Figure S1. FT-IR spectra of F127-BPEI1.3 and F127-BPEI1.3-NONOates

Fourier transform infrared (FT-IR) spectra were recorded on a BRUKER VORTEX 70 spectrometer over the frequency range 2300−700 cm^{-1} system using KBr as media.

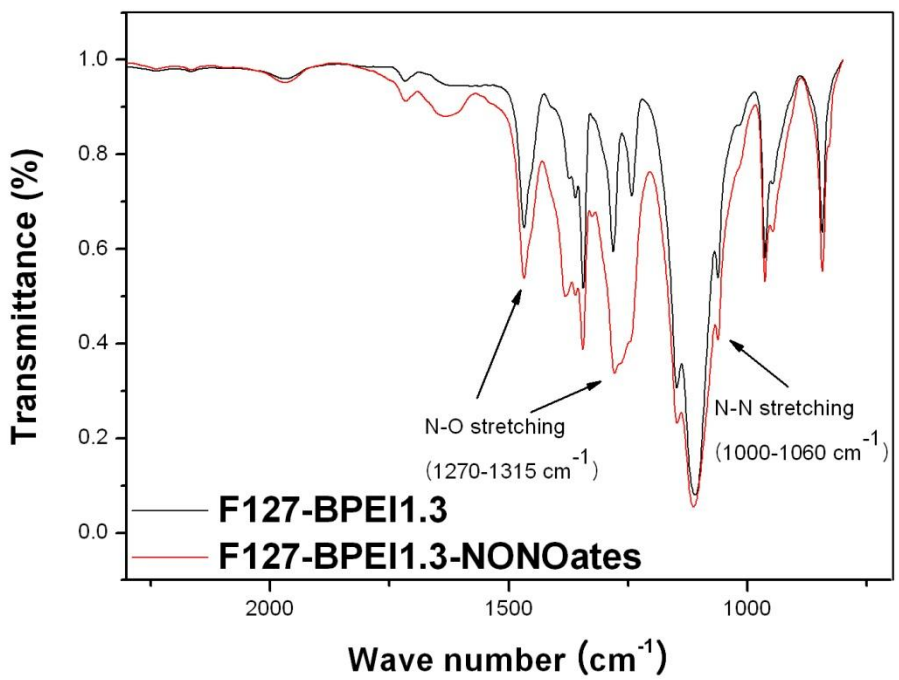

Figure S1. FT-IR spectra of F127-BPEI1.3 and F127-BPEI1.3-NONOates

Figure S2. Measurement of NO release in normoxic and hypoxic condition

F127-BPEI1.3-NONOates (75 mg) was dissolved in deionized water at 4 ˚C to prepare 20 wt% solutions and incubated in 300 mL N_2-purged DPBS at 37 ˚C. Release of NO was monitored using the Griess assay (Promega). In brief, after sampling 300 mL in predetermined time intervals, fresh N_2-purged DPBS (300 mL) was added to the vial. A sample (50 mL) was added to a sulfanilamide solution (50 mL) and incubated at room temperature for 5 min, protected from light. Then, naphthylethylenediamine (50 mL) was added to the mixture to stimulate a colorimetric change; intensity was measured at 548 nm by microplate spectrofluorometer (VICTOR3 V Multilabel Counter, Perkin-Elmer, Wellesley, MA) and compared to known sodium nitrite standards.

Stabilizing Effect of Propionic Acid Derivative of Anthraquinone−Polyamine Conjugate Incorporated into α−β Chimeric Oligonucleotides on the Alternate-Stranded Triple Helix

Tomohisa Moriguchi, A. T. M. Zafrul Azam,[†] and Kazuo Shinozuka*

Department of Chemistry and Chemical Biology, Graduate School of Engineering, Gunma University, 1-5-1 Tenjin-cho, Kiryu, Gunma 376-8515, Japan

Supporting Information

ABSTRACT: Two types of anthraquinone conjugates were synthesized as non-nucleosidic oligonucleotide components. These include an anthraquinone derivative conjugated with 2,2-bis(hydroxymethyl)propionic acid and an anthraquinone−polyamine derivative conjugated with 2,2-bis(hydroxymethyl)propionic acid. The conjugates were successfully incorporated into the "linking-region" of the α−β chimeric oligonucleotides via phosphoramidite method as non-nucleosidic backbone units. The resultant novel α−β chimeric oligonucleotides possessed two diastereomers that were generated by the introduction of the anthraquinone conjugate with a stereogenic carbon atom. The isomers were successfully separated by a reversed-phase HPLC. UV-melting experiments revealed that both stereoisomers formed a substantially stable alternate-strand triple helix, irrespective of the stereochemistry of the incorporated non-nucleosidic backbone unit. However, the enhancing effect on thermal stability depended on the length of the alkyl linker connecting anthraquinone moiety and the propionic acid moiety. The sequence discrimination ability of the chimeric oligonucleotides toward mismatch target duplex was also examined. The T_m values of the triplexes containing the mismatch target were substantially lower than the T_m values of those containing the full-match target. The thermodynamic parameters ($\Delta H°$, $\Delta S°$, and $\Delta G°$) required for the dissociation of the triplexes into the third strand and target duplex were also measured.

INTRODUCTION

Synthetic oligonucleotide-directed triple-helix formation presents a promising way to interfere with gene expression through direct interaction with genomic dsDNA and has become an area of intense investigation,[1−4] as demonstrated by many recent *in vitro* and *in vivo* experiments.[5−7] Indeed, the oligonucleotides forming a triplex with certain gene promoters can modulate the level of transcription of that gene (antigene strategy).[8−11] The limitation to the application of this approach in therapeutics and biotechnology is related to the relatively low stability of triple helical complexes under physiological conditions; sufficiently stable triplexes can be obtained only by targeting substantially long (at least 16−17 bases) tracts of homopurines, which are rarely found in biologically relevant DNA sequences. Considerable effort has been devoted to overcoming such limitations of the antigene strategy. A possible method to extend the range of targets is to utilize a specifically designed triplex forming oligonucleotide (TFO) capable of forming a triplex with adjacent and alternating homopurine strands because such a sequence would be more conceivable. On the basis this logic, Horne and Dervan reported a unique type of TFO consisting of 3′-3′ linked polythymidylate.[12] In the TFO, two short homopyrimidine strands were coupled by 1,2-dideoxy-D-ribose through a 3′-3′ phosphodiester linkage. Thus, the TFO formed a so-called "alternate-stranded triplex" with an adjacent and alternating homopurine strand in the manner of parallel orientation through Hoogsteen hydrogen bonds. In the TFO, the 1,2-dideoxy-D-ribose moiety served as the "linker" portion connecting two independent TFO molecules.

Many 3′-3′ or 5′-5′ linked TFOs capable of forming an alternate-strand triple helix by switching strand at the junction between the oligopurine and the oligopyrimidine domain via a Hoogsteen-hydrogen bonding pattern were reported.[13−22] However, these TFOs are constructed with a natural β-anomeric polypyrimidine strand in combination with a specifically designed "linker molecule". To create a new class of TFOs based on the strategy described above, we have developed a unique class of chimeric TFOs composed of a contiguous β-anomeric polypyrimidine strand and an α-anomeric polypyrimidine strand.[23] In the TFO, mononucleotide units are connected through natural 3′-5′ phosphodiester linkages, although the 3′-half of the linkage exclusively consists of α-anomeric polypyrimidylate, and the

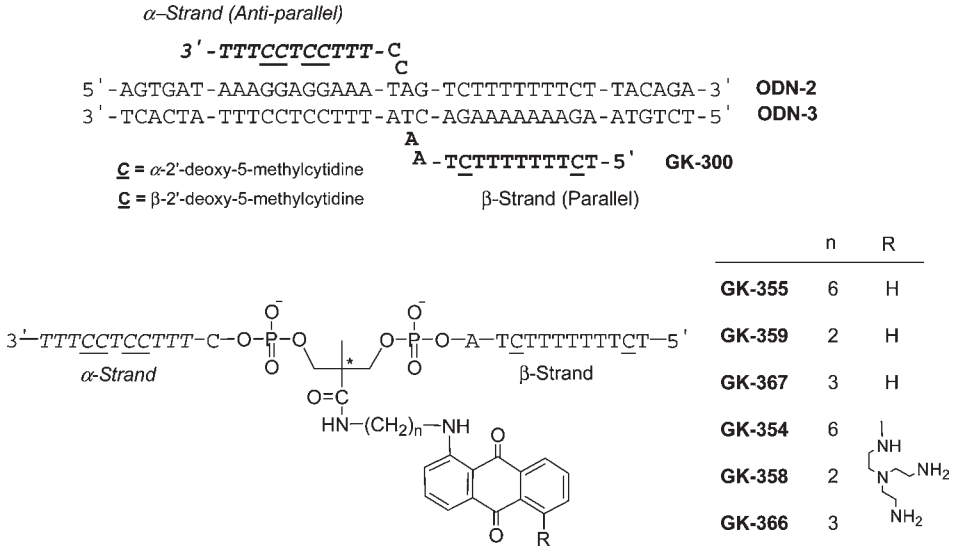

Figure 1. Sequence and structure of α–β chimeric TFO. In the sequence, italic letters represent the α-anomeric polypyrimidylate component and Roman letters represent the β-anomeric polypyrimidylate component, respectively. The linker portion of the chimera TFO consist of a β-anomeric 5′-AACC-3′ sequence in **GK-300**, whereas AC of the portion is replaced with a non-nucleotidic anthraquinone bearing unit in modified TFOs.

remaining portion consists of β-anomeric polypyrimidylate. In the TFO, the 3′-half binds to the purine tract of a target dsDNA in an antiparallel orientation, while the remaining β-DNA portion, except that which serves as a "linker" connecting the α- and β-DNA portions, binds to another purine tract in a parallel orientation.

Several approaches have been attempted to stabilize the triple helix, which is relatively less stable than the double helix. One approach is the conjugation of the intercalation moiety to TFO.[23−28] In this study, we found that the substitution of a normal nucleoside unit in the linker region of the original chimeric TFO[29] with a multiconjugate of the non-nucleosidic unit, 2,2-bis(hydroxymethyl)propionic acid, and an intercalator-polyamine complex substantially improves the thermal stability of the resulting alternate-strand triplex. This may be due to the intercalation of the complex to the target dsDNA.[30,31] In this paper, we will describe the results of our detailed study on the triplex-forming ability of the modified complex including the triplex-stabilizing effect of the polyamine moiety connected to the intercalator and the length of the alkyl chain linking the non-nucleosidic unit and the complex, as well as the sequence-discriminating ability of the modified chimeric TFO.

RESULTS AND DISCUSSION

Synthesis and Purification of Modified α–β Chimeric TFOs with an Anthraquinone Conjugate as a Non-Nucleosidic Oligonucleotide Component. Two types of anthraquinone conjugates were utilized as non-nucleosidic oligonucleotide components. These included an anthraquinone derivative conjugated with 2,2-bis(hydroxymethyl)propionic acid and an anthraquinone–polyamine derivative conjugated with 2,2-bis-(hydroxymethyl)propionic acid.[32] Synthesis of the modified chimeric chimeric triplex forming oligonucleotides (TFOs), **GK-354**, **GK-355**, **GK-358**, **GK-359**, **GK-366**, and **GK-367** along with the parental unmodified chimeric TFO (**GK-300**) (Figure 1) were carried out by an automated DNA synthesizer starting from CPG-bound α-thymidine, which was prepared

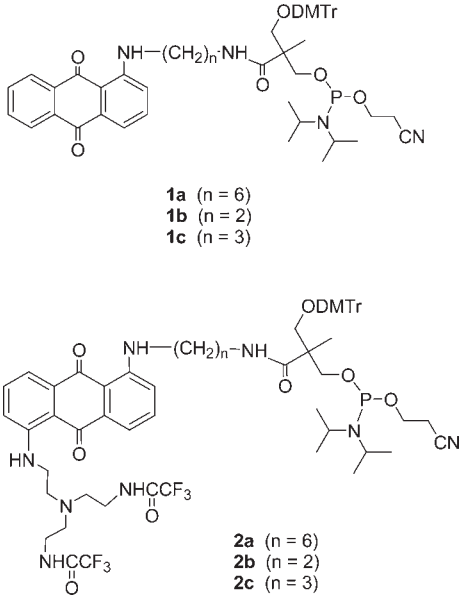

Figure 2. Structure of the phosphoramidite derivatives **1** and **2** bearing conjugated anthraquinone.

according to a previously described procedure.[32] The phosphoramidite derivatives bearing conjugated-anthraquinone (**1a**,**b**,**c** and **2a**,**b**,**c**, Figure 2) were incorporated into the middle of the "linker" region of the chimera TFOs instead of a normal nucleotide unit. It should be noted that, in the chimera TFOs, the central 5′-AC-3′ portion of the linker region of the parental **GK-300** was substituted with the conjugate as shown in Figure 1. The coupling reaction of the phosphoramidite reagents of anthraquinone conjugate was carried out for 360 s with a double coupling procedure using 0.3 M CH_3CN solution instead of normally used 0.1 M solution. Under the conditions, the coupling yields of **1a**,**b**,**c** and **2a**,**b**,**c** estimated from the conventional trityl assay were 93%, 86%, 88%, 93%, 96%, and 90%, respectively. The incorporation of other unnatural α-nucleoside

units into the chimera TFO was also accomplished within the extended coupling period (360 s). The obtained CPG-bound oligomers were treated with concentrated ammonia at 55 °C for 12 h.

The obtained oligomers were purified by reversed-phase HPLC. As stated previously, the DMTr-off form of the α−β chimeric oligonucleotides bearing the anthraquinone conjugates gave two peaks with almost equal intensity because of the existence of diastereomers. Thus, the faster elutes (**GK-354A**, **GK-355A**, **GK-358A**, **GK-359A**, **GK-366A**, and **GK-367A**) and the slower elutes (**GK-354B**, **GK-355B**, **GK-358B**, **GK-359B**, **GK-366B**, and **GK-367B**) were separately isolated. The oligomers were further purified by ethanol precipitation followed by Sephadex G-25 gel filtration. The modified TFO, **GK-368**, with a 3-nucleotide (nt) linker (5′-AAC-3′, Figure 3) was also synthesized as the reference oligomer according to standard solid-phase DNA synthesis. The yield and characterization data of the oligomers are listed in Supporting Information Table S1.

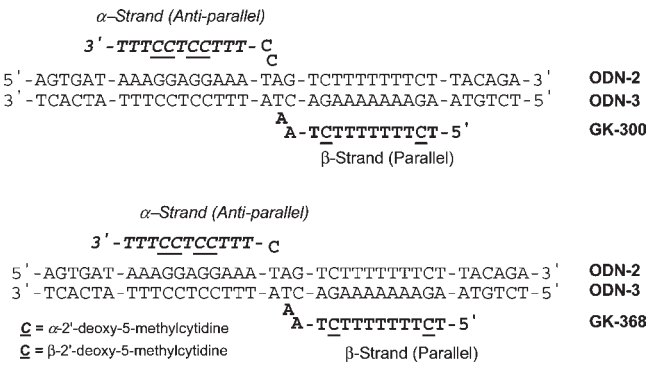

Figure 3. Sequence and structure of α−β chimeric TFO (**GK-300** and **GK-368**). In the sequence, italic letters represent the α-anomeric polypyrimidylate component and Roman letters represent the β-anomeric polypyrimidylate component, respectively. The linker portion of the chimera TFO consist of a β-anomeric 5′-AACC-3′ sequence in **GK-300** and β-anomeric 5′-AAC-3′ sequence in **GK-368**.

UV-Melting Experiment of Chimera TFOs. The formation and thermal stability of the triplex were examined by UV-melting experiments under slightly acidic and neutral conditions (pH 6.1, 6.5, and 7.0) in appropriate buffer systems. The melting temperature (T_m) was calculated from the first derivative of the melting curve obtained (Supporting Information Figures S1−S3) for all the system studied, and the results are summarized in Table 1. **GK-368** with the 3-nt linker stabilizes the triplex more efficiently than **GK-300** with the 4-nt linker (ΔT_m > 2.5 °C) at all pH values. Thus, the use of 3-nt linker instead of the original 4-nt linker in chimera TFOs is more feasible for the triplex formation. In addition, all modified TFOs with the anthraquinone moiety formed a much more stable triplex than the unmodified **GK-300** and **GK-368**. The magnitude of the stabilizing effect on modified TFOs for the triple helix, however, varied considerably. TFOs with a longer linker arm between the anthraquinone and 2,2-bis(hydroxymethyl)propionic acid moieties tend to form a more stable triplex than those with a shorter linker arm.

As shown in Table 1, the T_m values of the triplex consisting of modified TFO and full-matched target (**ODN-2**:**ODN-3**) are considerably higher (ΔT_m > 10−17 °C) than that of the triplex containing unmodified **GK-300**. The triplex-stabilizing effect, however, depends on the length of the alkyl linker connecting the anthraquinone and propionic acid moieties in the incorporated anthraquinone conjugate. Thus, the TFO bearing a longer alkyl linker (**GK-354** and **GK-355**) exhibited higher T_m values compared to the TFO bearing a shorter alkyl linker (**GK-358**, **-359**, **-366**, **-367**). On the other hand, no apparent difference in thermal stability was observed between the TFOs consisting of two carbon alkyl linkers (**GK-358** and **GK-359**) and three carbon alkyl linkers (**GK-366** and **GK-367**) at pH 6.1 (Table 1).

[a] n indicates the amount of carbon in the alkyl linker that connects anthraquinone moiety with the propionic acid moiety. [b] T_m values (°C) were determined by computer fitting of the first derivative of the absorbance with respect to $1/T$. Each T_m value is the average of three separate experiments. [c] ΔT_m indicates the deviation from the T_m value of the corresponding triplex consisting of **GK-300** and the duplex. [d] ΔT_m indicates the T_m differences between diastereomeric counterparts.

dx.doi.org/10.1021/bc100446w |*Bioconjugate Chem.* 2011, 22, 1039–1045

The T_m values tend to depend on the pH of the media. The T_m values showed a greater decrease at high pH values than at low pH values. For example, the T_m of **GK-354A** decreased from 56.2 to 40.4 °C when the pH changes from 6.1 to 7.0. This may be due to inadequate protonation of cytidine residues in the TFOs. However, even at pH 7.0, the T_m values of **GK-354** and **GK-355** exceeded the physiological temperature.

Interestingly, the data in Table 1 also reveal that the difference in the T_m values between the two diastereomers **A** and **B** was very low in all TFOs at all pH values (<1.5 °C). This small difference in the T_m values between the diastereomers indicates that the environment around the linker region of the modified TFOs is very flexible. It also suggests that it is highly versatile, since the modification at the linker region of the chimera TFOs with this type of non-nucleosidic unit can functionalize it without taking into account the stereochemistry of the modification. Thus, both **GK-354A** and **GK-354B** stabilized an alternate-strand triplex at a temperature of >16 °C with a single modification of the parental chimera TFO.

Sequence Discrimination Ability of the Modified Chimera TFOs. Generally, the thermal stability of a triplex decreases substantially (>10 °C) in the case of a mismatch between the TFO and the target duplex.[33] To estimate the specificity of modified TFOs in triplex formation, a single mismatch target duplex **ODN-4:ODN-5** was prepared as shown in Figure 4. The T_m values of the triplex consisting of the modified chimera TFO and the mismatch target duplex were measured using the thermal denaturation study, as described in the previous section.

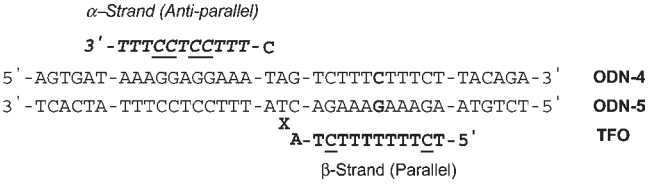

Figure 4. Alternate-stranded triplex consisting of modified chimera TFOs and single mismatch target duplex (**ODN-4:ODN-5**). X represents the non-nucleosidic anthraquinone conjugate.

The T_m values of the triplexes consisting of the modified TFOs and the mismatched target (**ODN-4:ODN-5**) decreased significantly as shown in Table 2. The magnitude of T_m decrement for the tested TFOs was nearly the same as that of the parental unmodified **GK-300** at all pH values (6.1, 6.5, and 7.0). The results clearly indicate that the modified TFO retains at least the same degree of sequence discrimination ability as the unmodified TFO. Thus, the introduction of the intercalator−propionic acid conjugate to the chimeric TFO will not abolish its ability to discriminate between sequences, despite apparent enhancement of the thermal stability with the full-matched target.

The magnitude of T_m decrement with respect to the corresponding diastereomer is also quite small, as shown in Table 2. Thus, the results clearly indicate that the sequence discrimination ability of the modified TFOs is not influenced by the existence of the stereogenic carbon in them.

Effect of Polyamine Moiety on the Thermal Stability of the Alternate-Strand Triplex. To check the effect of polyamine moiety on the thermal stability of the alternate-strand triplex, T_m differences among the sets of corresponding TFOs with or without the polyamine moiety on the anthraquinone moiety were analyzed. As shown in Table 3, T_m values increased in the presence of polyamine in the TFO, but only by a small margin (0.2−3.0 °C). Such smaller T_m increments might be due to the apparent distance of the polyamine moiety from the interacting target duplex. In the case of the short alkyl linker between anthraquinone and 2,2-bis(hydroxymethyl)propionic acid (**GK-359** and **GK-358**), the T_m increment was slightly higher (2.0−3.0 °C) than that in the case of the long alkyl linker (**GK-355** and **GK-354**), because of the presence of the polyamine moiety on the anthraquinone moiety. In this case, the polyamine moiety could interact with the target duplex more easily than in the above case. This notion can be supported by the observation of similar effects of the polyamine moiety on the thermal stability of the triplex consisting of modified TFOs and single mismatch target duplex (Table 3, mismatch).

Temperature-Dependent UV-Absorption Changes of the Anthraquinone Moiety. To confirm the interaction of the anthraquinone moiety in the modified TFOs with the

[a] $\Delta\Delta H°$, $\Delta\Delta S°$, and $\Delta\Delta G°_{37}$ values indicate the deviation from the corresponding value of the triplex consisting of the unmodified parental **GK-300** and the duplex.

double-stranded portion of the target dsDNA, experiments monitoring changes in the UV-absorption of the anthraquinone moiety with increasing temperature were carried out. The complex formed between **GK-354A** or **GK-355A** and the dsDNA (**ODN-2:ODN-3**) was heated at an elevated temperature from 20 to 80 °C, and the UV-absorbance was monitored in the range 400−700 nm. In this experiment, the same buffer system as that for the UV-melting experiment (pH 6.1) was used, although the concentration of oligomers was increased to 28.0 μM for clear monitoring of the anthraquinone-based absorbance changes. As shown in Supporting Information Figure S7(A), anthraquinone-based absorbance in **GK-354A** bearing the anthraquinone−polyamine multiconjugate exhibited a marked shift to the shorter wavelength (blue shift, 551.0−543.5 nm) according to the elevation of the temperature.[34−36] At the same time, the absorption maximum also increased (hyperchromicity, 12.4%). A combination of these characteristic behaviors in UV-spectroscopy strongly suggests that the anthraquinone moiety actually intercalates to the target dsDNA when the modified TFO binds to form the triplex. Similarly, **GK-355A** bearing the anthraquinone conjugate without the polyamine moiety showed a blue shift (536.0−525.5 nm) and hyperchromicity (12.4%) in UV spectroscopy (Supporting Information Figure S8(A)). Similar patterns of blue shift and hyperchromicity were observed in the case of other TFOs also (data not shown).

Subsequently, the UV-absorbances of **GK-354A** at 550 nm and **GK-355A** at 535 nm were plotted against temperature and the results are shown in Supporting Information Figures S7(B) and S8(B), respectively. The plots show a prominent increment in the absorbance between 50 and 60 °C. Essentially identical results were obtained from the corresponding experiment for the other modified TFOs. The obtained plots would reflect the association and dissociation of the anthraquinone conjugate from the target dsDNA. The results indicate that the anthraquinone conjugate in the modified TFO strongly intercalates with dsDNA.

Thermodynamic Analysis of the Triplex. The thermodynamic values of the triplex containing TFOs (**GK-300**, **GK-354A**, **GK-354B**, **GK-358A**, and **GK-358B**) and the full-match duplex **ODN-2:ODN-3** were measured at pH 6.5 by using the same buffer system as the UV-melting experiment at different oligomer concentrations (2.5 μM, 1.25 μM, 0.625 μM, and 0.313 μM). Supporting Information Figure S3 showed the van't Hoff plot of $1/T_m$ vs ln C_t for the transition of the triplex to the third strand and corresponding target duplex. The plots obtained for **GK-354A** and **GK-354B** were almost identical, confirming almost identical stability between the two diastereomers. A similar observation was made in the case of the diastereomers **GK-358A** and **GK-358B**.

The thermodynamic values, calculated from the slope and intercept of the van't Hoff plot by using the appropriate equations,[37−41] are summarized in Table 4. Inspection of these data revealed that the triplex consisting of the anthraquinone−polyamine conjugate was thermally more stable than the triplex consisting of the unmodified parent. In terms of enthalpy, **GK-354A** and **GK-354B** were more stable than those with a shorter alkyl linker (**GK-358A** and **GK-358B**). The significant difference in enthalpy data revealed that the modified triplex is more favorable than the unmodified parental TFO (**GK-300**). On the other hand, oligomers with longer alkyl linkers showed a

significant loss of entropy than the oligomers with shorter alkyl linkers ($\Delta\Delta S^\circ = -30$ cal mol^{-1} K^{-1}) and **GK-300**.

Comparing the ΔG°_{37} values of the triplex, **GK-354B** formed the most stable triplex (-15.7 kcal mol^{-1}). The ΔG°_{37} value of **GK-300** (-7.3 kcal mol^{-1}) was significantly smaller than those of the other triplex consisting of modified TFOs, indicating that it has relatively low stability. As a total effect, modified TFOs with longer alkyl linkers result in more stable triplex compared to those with shorter linkers. For instance, **GK-354A** ($\Delta G^\circ_{37} = -15.4$ kcal mol^{-1}) had greater stability than **GK-358A** ($\Delta G^\circ_{37} = -12.9$ kcal mol^{-1}). The thermodynamic values of the two diastereomers **A** and **B** in both **GK-354** and **GK-358** are essentially identical; as mentioned above, this indicates the structural flexibility of the two isomers.

CONCLUSION

Chimera TFO bearing non-nucleosidic anthraquinone conjugates with or without a polyamine moiety on anthraquinone moiety exhibited more significant thermal stability than the unmodified parental TFO **GK-300** because of the interaction of the anthraquinone moiety with the target dsDNA. The enhancing effect depended on the length of the alkyl linker between the anthraquinone and propionic acid moieties. However, no apparent differences were observed in the thermal stability of the two diastereomeric counterparts **A** and **B** in any case. This indicates that the extent of the intercalation of the anthraquinone moiety to the dsDNA is almost independent of the stereochemistry of the conjugate. It also indicates that the environment around the linker region of the modified TFOs is very flexible.

On the other hand, TFOs bearing the polyamine moiety on the anthraquinone ring showed higher stability than those without the polyamine moiety, but with a relatively small margin. The polyamine moiety was found to be more effective in stabilizing the triplex in the case of TFOs bearing shorter alkyl linkers. This may be because the polyamine moiety with a short alkyl linker would be located near the dsDNA, and therefore would interact more efficiently than its counterpart with a longer alkyl linker. Even in this case, however, the thermal stability of the two diastereomeric counterparts was observed to be almost the same. This result indicates that the polyamine moiety introduced into DNA did not distinguish both diastereoisomers.

The mismatch studies revealed that T_m values of triplexes consisting of modified TFOs and mismatch target duplex are significantly reduced (about -10 °C). The extent of T_m decrement is almost the same as that of the unmodified parental **GK-300** which indicates that the modified TFOs retain, at least, the same degree of sequence discrimination ability without abolishing the sequence specificity as the unmodified **GK-300**.

The thermodynamic values also revealed that the alternate-stranded triplex consisting of modified TFO and target dsDNA is thermodynamically more stable than the parental **GK-300**, whereas the TFOs having a longer alkyl linker result in a more stable triplex compared to that of short linker. The effect is brought about by the favorable enthalpic factor.

All the above-mentioned properties would make the modified TFOs a unique class of alternate-stranded triplex-forming oligonucleotide feasible for practical use as a gene-regulating agent.

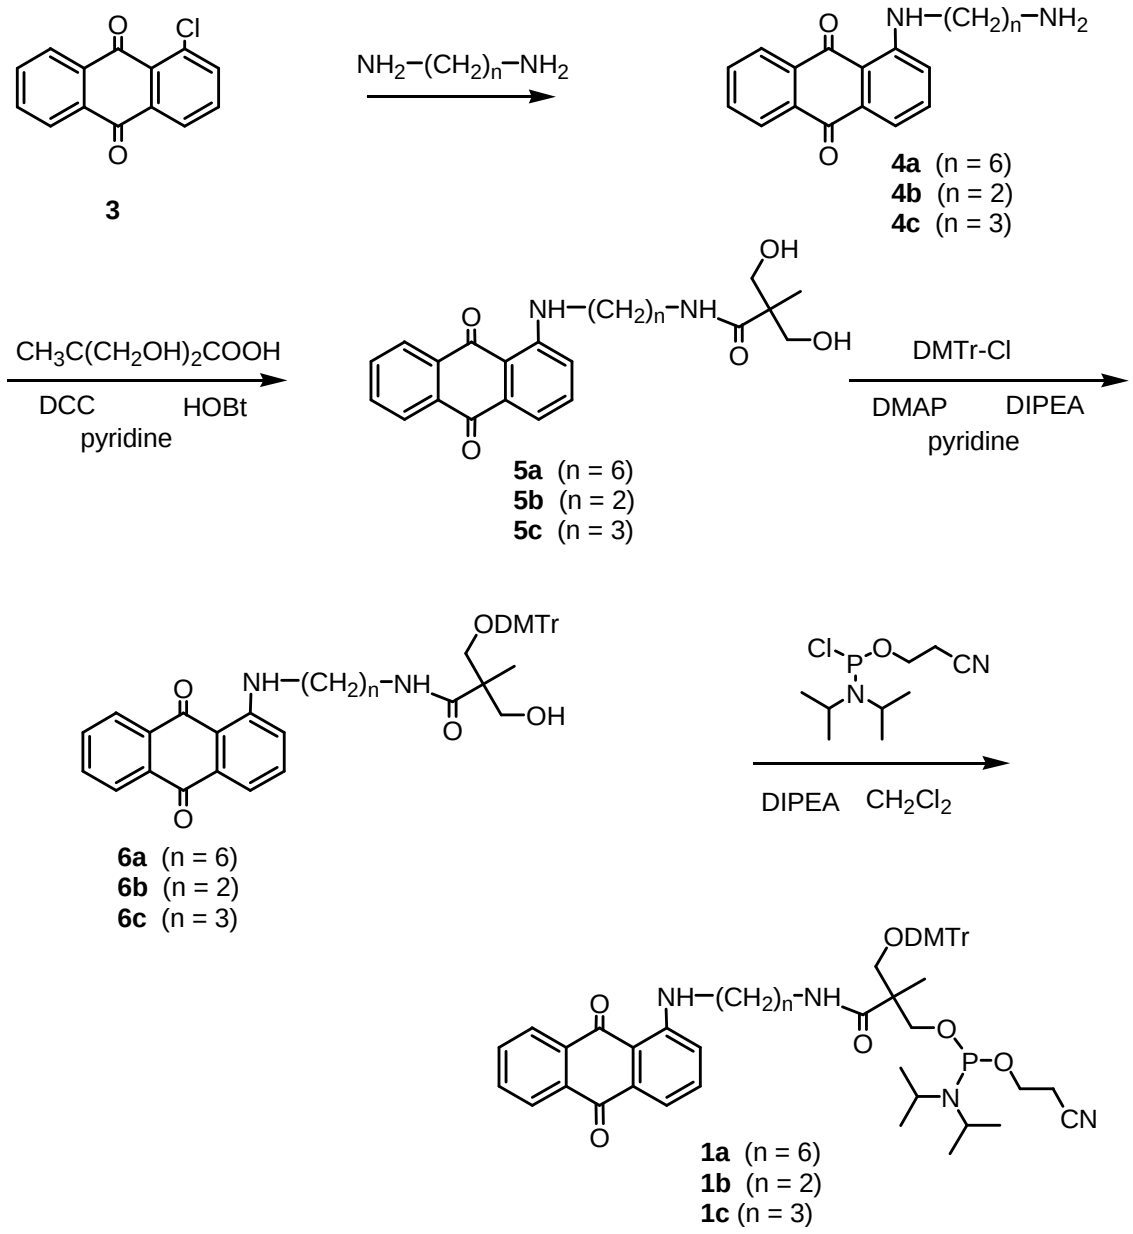
Experimental Procedures

General remarks

Thin layer column chromatography was carried out on Merck silica gel 60 F254-precoated plate. Column chromatography was performed with silica gel 60 N (neutral, spherical, 63-210 μm). ^{1}H NMR and ^{31}P NMR spectra were recorded on JOEL (JNM-AL300) FT NMR SYSTEM at 300 MHz, using tetramethylsilane as internal standard. ESI-Mass spectra were recorded on Perkin Elmer API-100 ESI-MS Spectrophotometer. Reversed-phase HPLC was carried out with quaternary gradient pump (PU-2089 plus, JASCO) attached with UV-vis detector (SPD-10A VP, SHIMADZU) and chromatopac (C-R8A, SHIMADZU) using Wakosil 5C18 Column (ø 4.6 mm X 250mm). Elemental analyses were performed by the Microanalytical Laboratory, Faculty of Engineering, Gunma University. Melting point was measured with the melting point apparatus (Sibata).

Oligonucleotides Synthesis.



Oligonucleotides were synthesized on an Applied Biosystems 392 DNA/RNA synthesizer on 0.2 μmol scale, using standard phosphoramidites from Glen Research. The synthesized oligonucleotides were purified by a standard procedure.

Melting Temperature Analysis.

UV absorbance was measured with a Shimadzu UV-2450 spectrophotometer equipped with a Temperature Controller. The rate of heating or cooling was 0.1 °C/min. Tm values were obtained in 10 mM sodium phosphate buffer (pH 7.2) containing 100 mM NaCl and 1 mM EDTA. Absorbance and temperature data were analyzed by a TMSPC-8 Tm analysis system.

Thermodynamic Parameter.

Thermodynamic parameters for the triple helix formation were determined by plotting the reciprocal of the melting temperature (T_m^{-1}), versus ln C_t, where C_t is the total concentration of strands.

Scheme S1 Preparation of anthraquinone bearing phosphoramidite reagents for the automated solid-phase oligonucleotide synthesis.

1-(6-Aminohexylamino)anthraquinone (4a)

The mixture of 1,6-hexanediamine (10.4 g, 89.4 mmol) and 1-chloroanthraquinone (**3**) (2.17 g, 8.94 mmol) was stirred at 55 °C for 24 h. Then the reaction mixture was dissolved in CH_2Cl_2 (200 ml) and washed with 1.0 N KOH solution (2 × 200 ml) and sat. $NaHCO_3$ solution (200 ml). The organic layer was dried over Na_2SO_4, and evaporated under reduced pressure. The residue was chromatographed on a column of silica gel with CH_2Cl_2/MeOH/aq.NH_3 (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **4a** (2.0 g, 69.4%) as red foam. ^{1}H NMR ($CDCl_3$) δ 1.22 (br. 2H, NH_2), 1.36-1.73 (m, 6H, CH_2), 1.73-1.83 (m, 2H, CH_2), 2.69 (t, *J* = 6.9 Hz, 2H, CH_2), 3.30 (dd, *J* = 12.3, 6.9 Hz, 2H, CH_2), 7.03 (dd, *J* = 8.1, 1.2 Hz, 1H, H-Ar of Aq), 7.49-7.56 (m, 2H, H-Ar of Aq), 7.66-7.78 (m, 2H, H-Ar of Aq), 8.21-8.24 (m, 2H, H-Ar of Aq), 9.73 (br. 1H, NH).

1-(2-Aminoethylamino)anthraquinone (4b)

Compound **4b** was obtained by the reaction of ethylenediamine (12.4 ml, 185 mmol) and 1-chloroanthraquinone (**3**) (3.0 g, 12.4 mmol) by same manner as compound **4a**. The product was chromatographed on a column of silica gel with CH_2Cl_2/MeOH/aq.NH_3 (5:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **4b** (2.98 g, 90.5%) as red solid. m.p. 152-155 °C. ^{1}H NMR ($CDCl_3$) δ 3.08-3.11 (m, 2H, CH_2), 3.41-3.47 (m, 2H, CH_2), 7.08 (d, *J* = 8.1 Hz, 1H, H-Ar of Aq), 7.51-7.62 (m, 2H, H-Ar of Aq), 7.68-7.78 (m, 2H, H-Ar of Aq), 8.22-8.30 (m, 2H, H-Ar of Aq), 9.92 (br. 1H, NH).

1-(3-Aminopropylamino)anthraquinone (4c)

Compound **4c** was obtained by the reaction of 1,3-propanediamine (12.9 ml, 155 mmol) and 1-chloroanthraquinone (**3**) (2.5 g, 10.3 mmol) by same manner as compound **4a**. The product was chromatographed on a column of silica gel with CH_2Cl_2/MeOH/aq.NH_3 (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **2c** (2.47 g, 85.5%) as red solid. m.p. 130-32 °C. ^{1}H NMR ($CDCl_3$) δ 1.21 (br. 2H, NH_2), 1.87-1.96 (m, 2H, CH_2), 2.91-2.96 (m, 2H, CH_2), 3.40-3.46 (m, 2H, CH_2), 7.07 (d, *J* = 8.1 Hz, 1H, H-Ar of Aq), 7.51-7.78 (m, 4H, H-Ar of Aq), 8.22-8.28 (m, 2H, H-Ar of Aq), 9.76 (br. 1H, NH).

***N*-[6-(Anthraquinon-1-ylamino)hexyl]-2,2-bis(hydroxymethyl) propionamide (5a)**

2,2-Bis(hydroxymethyl)propionic acid (0.54 g, 3.99 mmol) was added to a solution of **3a** (0.99 g, 3.07 mmol) in dry pyridine (31 ml). Then *N,N'*-dicyclohexyl carbodiimide (1.27 g, 6.14 mmol) and 1-hydroxybenzotriazole monohydrate (0.70 g, 4.61 mmol) were added to the mixture under cooling with ice then stirred at room temperature for 4 h. After the removal of precipitated dicyclohexyl urea, the filtrate was evaporated in vacuo. The residue was dissolved in CH_2Cl_2 (150 ml) and washed with sat. $NaHCO_3$ solution (3 × 150 ml). The organic layer was dried over Na_2SO_4, and evaporated under reduced pressure. The residue was chromatographed on a column of silica gel with 10% MeOH in CH_2Cl_2. Collection and evaporation of appropriate fractions afforded compound **5a** (0.99 g, 73.5%) as red solid.

***N*-[2-(Anthraquinon-1-ylamino)ethyl]-2,2-bis(hydroxymethyl) propionamide (5b)**

Compound **5b** was obtained from compound **4b** (1.95 g, 7.32 mmol) by the reaction with 2,2-bis(hydroxymethyl)propionic acid (1.28 g, 9.52 mmol), *N,N'*-dicyclohexyl carbodiimide (3.78 g, 18.3 mmol) and 1-hydroxybenzotriazole monohydrate (1.68 g, 11.0 mmol) in dry pyridine (73 ml) by same manner as compound **5a**. The product was chromatographed on a column of silica gel with 15% MeOH in CH_2Cl_2. Collection and evaporation of appropriate fractions afforded compound **5b** (2.46 g, 87.8%) as red solid.

***N*-[3-(Anthraquinon-1-ylamino)propyl]-2,2-bis(hydroxymethyl) propionamide (5c)**

Compound **5c** was obtained from **4c** (1.25 g, 4.46 mmol) by the reaction of 2,2-bis(hydroxymethyl)propionic acid (0.78 g, 5.80 mmol), *N,N'*-dicyclohexyl carbodiimide (2.3 g, 11.1 mmol) and 1-hydroxybenzotriazole monohydrate (1.0 g, 6.69 mmol) in dry pyridine (45 ml) by same manner as compound **5a**. The product was chromatographed on a column of silica gel with 10% MeOH in CH_2Cl_2. Collection and evaporation of appropriate fractions afforded compound **5c** (1.51 g, 85.4%) as red solid. ^{1}H NMR ($CDCl_3$) δ 1.11 (s, 3H, CH_3), 1.96-2.04 (m, 2H, CH_2), 3.29-3.51 (m, 4H, CH_2OH), 3.29-3.51 (m, 2H, CH_2) 3.73-3.83 (m, 2H, CH_2), 7.01 (d, J = 8.4 Hz, 1H, H-Ar of Aq), 7.48-7.77 (m, 4H, H-Ar of Aq), 8.19-8.23 (m, 2H, H-Ar of Aq), 9.72 (br. 1H, NH).

2-(Dimethoxytrityloxymethyl)-2-methyl-*N*-[6-(anthraquinon-1-ylamino)hexyl] -3-hydroxypropionamide (6a)

4,4'-Dimethoxytrityl chloride (1.0 g, 2.94 mmol) and *N,N*-diisopropylethylamine (0.98 ml, 5.65 mmol) were added to a solution of **5a** (0.99 g, 2.26 mmol) in dry pyridine (45 ml) in the presence of 4-dimethylaminopyridine (14 mg, 0.113 mmol). The mixture was stirred at room temperature for 4 h. The reaction was quenched by adding of dry MeOH (2 ml). After the evaporation of the mixture in vacuo, resulted oil was dissolved in CH_2Cl_2 (100 ml) and washed with sat. $NaHCO_3$ solution (2 × 100 ml). The organic layer was collected and dried over Na_2SO_4, and then evaporated under reduced pressure. The residue was chromatographed on a column of silica gel with AcOEt/CH_2Cl_2 (1:1, v/v) containing 1% TEA. Collection and evaporation of appropriate fractions afforded compound **6a** (1.03 g, 61.6%) as red foam. Elem. anal. calcd. for $C_{46}H_{48}N_2O_7$.0.2 TEA: C, 74.48; H, 6.75; N, 4.05 %; Found: C, 74.60; H, 6.81; N, 4.28 %. ^{1}H NMR ($CDCl_3$) δ 1.20 (s, 3H, CH_3), 1.37-1.54 (m, 8H, CH_2), 3.21-3.37 (m, 4H, CH_2O), 3.21-3.37 (m, 2H, CH_2), 3.59-3.61 (m, 2H, CH_2), 3.77 (s, 6H, OCH_3 of DMTr), 6.82-6.85 (m, 4H, H-Ar of DMTr), 6.99 (m, 1H, H-Ar of Aq),7.02-7.41 (m, 9H, H-Ar of DMTr), 7.51-7.76 (m, 4H, H-Ar of Aq), 8.23-8.29 (m, 2H, H-Ar of Aq), 9.74 (br., 1H, NH).

2-(Dimethoxytrityloxymethyl)-2-methyl-N-[2-(anthraquinon-1-ylamino)ethyl] -3-hydroxypropionamide (6b)

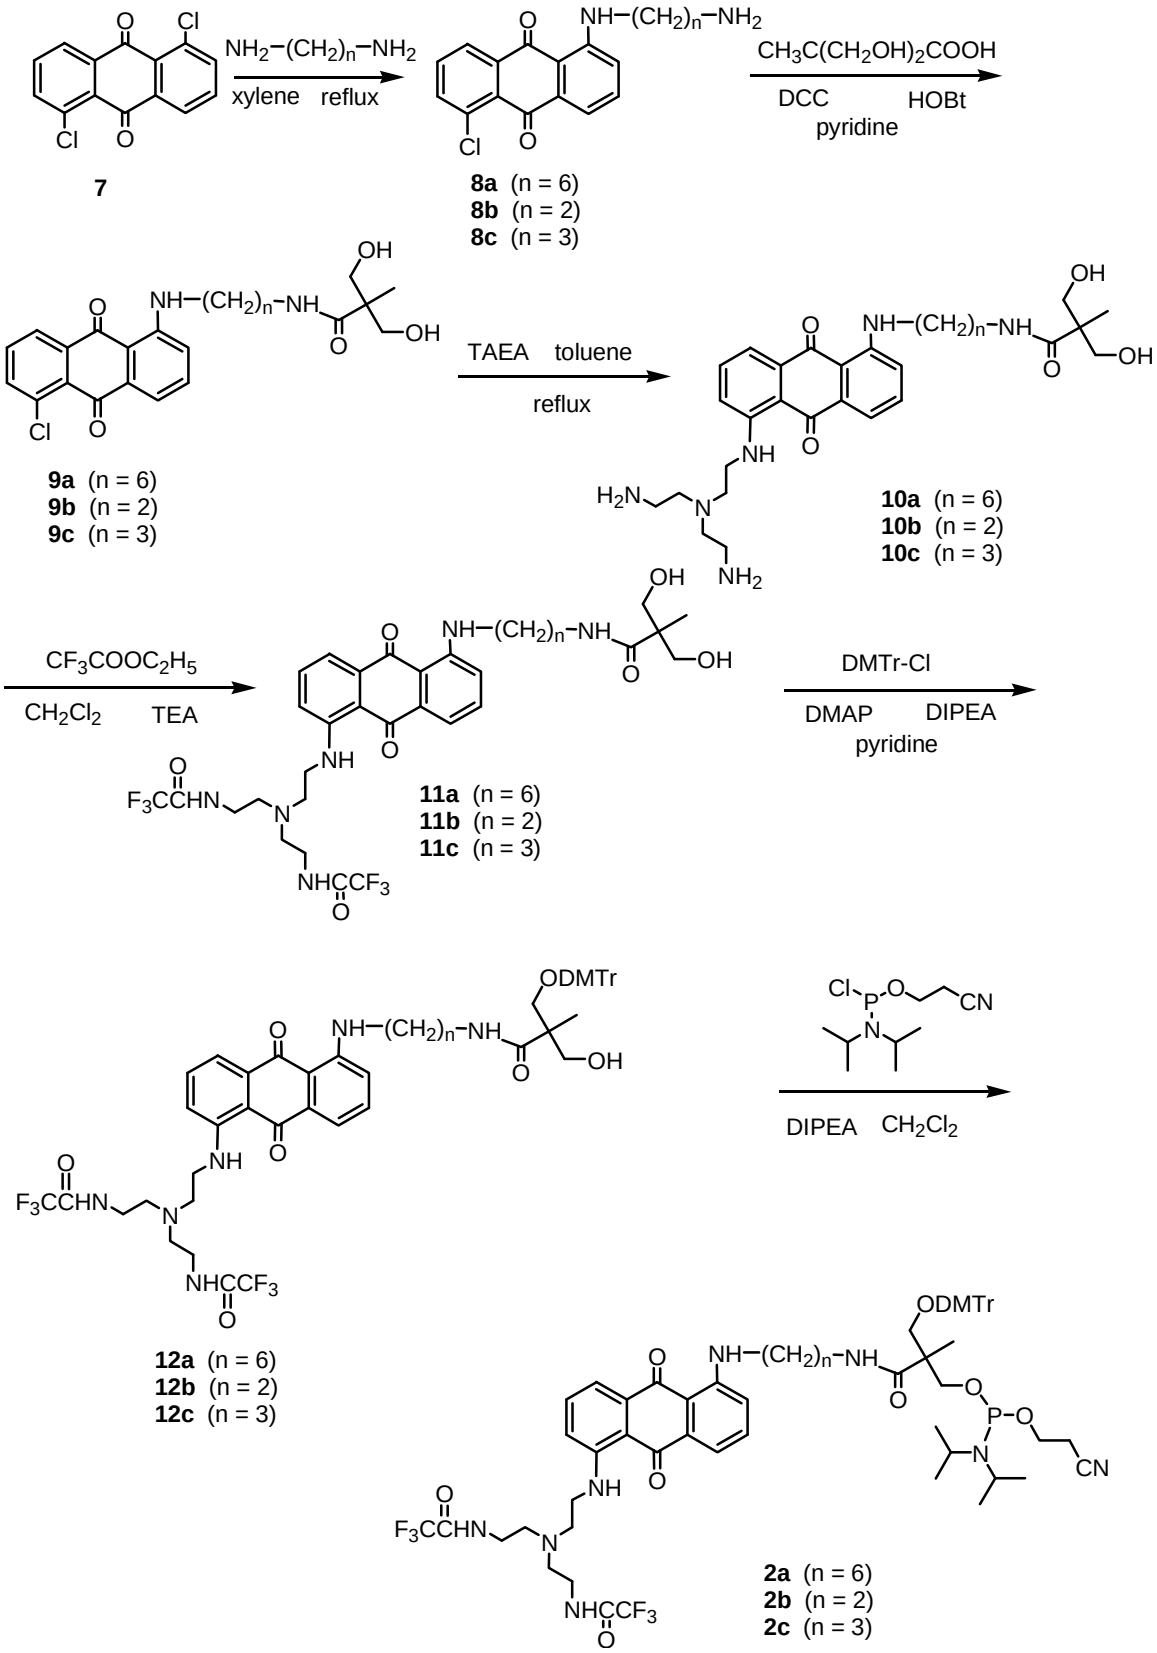
Compound **6b** was obtained from compound **5b** (2.46 g, 6.43 mmol) by the reaction of 4,4'-dimethoxytrityl chloride (2.6 g, 7.72 mmol) and *N,N*-diisopropylethylamine (2.2 ml, 12.9 mmol) in dry pyridine (96 ml) in the presence of 4-dimethylaminopyridine (40 mg, 0.322 mmol) by same manner as compound **6a**. The product was chromatographed on a column of silica gel with AcOEt/CH_2Cl_2 (1:1, v/v) containing 1% TEA. Collection and evaporation of appropriate fractions afforded compound **6b** (2.76 g, 62.6%) as red foam. Elem. anal. calcd. for $C_{42}H_{40}N_2O_7$.0.25 AcOEt. 0.5 TEA: C, 72.95; H, 6.59; N, 4.62 %; Found: C, 72.89; H, 6.26; N, 4.78 %. ^{1}H NMR ($CDCl_3$) δ 1.24 (s, 3H, CH_3), 3.31-3.45 (m, 4H, CH_2), 3.31-3.45 (m, 4H, CH_2O), 3.69 (s, 6H, OCH_3 of DMTr), 6.74-6.76 (m, 4H, H-Ar of DMTr), 7.08-7.16 (m, 1H, H-Ar of Aq), 7.24-7.37 (m, 9H, H-Ar of DMTr), 7.52-7.70 (m, 4H, H-Ar of Aq), 8.15-8.20 (m, 2H, H-Ar of Aq), 9.74 (br., 1H, NH).

2-(Dimethoxytrityloxymethyl)-2-methyl-*N*-[3-(anthraquinon-1-ylamino)propyl] -3-hydroxypropionamide (6c)

Compound **6c** was obtained from compound **5c** (1.37 g, 3.46 mmol) by the reaction of 4,4'-dimethoxytrityl chloride (1.4 g, 4.15 mmol) and *N*,*N*-diisopropylethylamine (0.8 ml, 4.493 mmol) in dry pyridine (52 ml) in the presence of 4-dimethylaminopyridine (21 mg, 0.173 mmol) by the same manner as compound **6a**. The product was chromatographed on a column of silica gel with AcOEt/CH_2Cl_2 (1:1, v/v) containing 1% TEA. Collection and evaporation of appropriate fractions afforded compound **6c** (1.07 g, 44.3%) as red foam. Elem. anal. calcd. for $C_{43}H_{42}N_2O_7$.0.25 AcOEt. 0.25 TEA: C, 73.24; H, 6.45; N, 4.22 %; Found: C, 73.39; H, 6.17; N, 4.48 %. ^{1}H NMR ($CDCl_3$): δ 1.23 (s, 3H, CH_3), 1.91-1.96 (m, 2H, CH_2), 3.24-3.45 (m, 4H, CH_2OH), 3.24-3.45 (m, 2H, CH_2) 3.63-3.65 (m, 2H, CH_2), 7.74 (s, 6H, OCH_3 of DMTr), 6.78-6.94 (m, 4H, H-Ar of DMTr), 7.14-7.26 (m, 1H, H-Ar of Aq), 7.28-7.45 (m, 9H, H-Ar of DMTr), 7.47-7.79 (m, 4H, H-Ar of Aq), 8.23-8.28 (m, 2H, H-Ar of Aq), 9.73 (br. 1H, NH).

2-(Dimethoxytrityloxymethyl)-2-methyl-*N*-[6-(anthraquinon-1-ylamino)hexyl]prop ionamido-3-yl 2-cyanoethyl *N*,*N*-diisopropyl phosphoramidite (1a)

Compound **6a** (0.53 g, 0.715 mmol) was co-evaporated twice with dry pyridine then dissolved in dry CH_2Cl_2 (11 ml) and chilled in ice bath. DIPEA (0.50 ml, 2.86 mmol) followed by 2-cyanoethyldiisopropylchlorophosphoramidite (0.48 ml, 2.146 mmol) were added dropwise to the chilled mixture then the mixture was stirred at room temperature for 30 min. The excess phosphoramidite reagent was decomposed by addition of dry MeOH (2.5 ml). After the evaporation of the mixture under reduced pressure, resulted oil was dissolved in AcOEt (50 ml) and washed with sat. $NaHCO_3$ solution (2 × 50 ml), followed by sat. NaCl solution (50 ml). The organic phase was collected and dried over Na_2SO_4 then evaporated under reduced pressure. The residue was chromatographed on a column of silica gel with AcOEt/CH_2Cl_2/TEA (45:45:10, v/v/v). The pure compound **1a** was dissolved in small amount of CH_2Cl_2 and dropwised to rapidly stirring cold hexane (150 ml) to precipitate as red solid (0.44 g, 65.4%). ^{1}H NMR ($CDCl_3$) δ 1.08-1.23 (m, 14H, iPr), 1.16 (s, 3H, CH_3), 1.26-1.69 (m, 8H, CH_2), 2.52-2.54 (m, 2H, CH_2 of amidite), 3.20-3.30 (m, 4H, CH_2O), 3.20-3.30 (m, 2H, CH_2 of amidite), 3.53-3.74 (m, 4H, CH_2), 3.77 (s, 6H, OCH_3 of DMTr), 6.81-6.84 (m, 4H, H-Ar of DMTr), 6.98-7.01 (m, 1H, H-Ar



of Aq), 7.20-7.58 (m, 9H, H-Ar of DMTr), 7.68-7.74 (m, 4H, H-Ar of Aq), 8.20-8.27 (m, 2H, H-Ar of Aq), 9.73 (br., 1H, NH), ^{31}P NMR ($CDCl_3$) δ 148.43.

2-(Dimethoxytrityloxymethyl)-2-methyl-*N*-[2-(anthraquinon-1-ylamino)ethyl]propionamido-3-yl 2-cyanoethyl *N*,*N*-diisopropyl phosphoramidite (1b)

Compound **6b** (0.50 g, 0.730 mmol) was converted to the corresponding phosphoramidite derivative (**7b**) by same manner as compound **1a**. The product was chromatographed on a column of silica gel with AcOEt/CH_2Cl_2/TEA (45:45:10, v/v/v). The pure compound **7b** was isolated by precipitation in the same manner as compound **1a** as red solid (0.46 g, 71.2%). ^{1}H NMR ($CDCl_3$) δ 1.06-1.30 (m, 14H, iPr), 1.18 (s, 3H, CH_3), 2.50-2.54 (m, 4H, CH_2 of amidite), 3.40-3.56 (m, 4H, CH_2O), 3.40-3.56 (m, 4H, CH_2), 3.72 (s, 6H, OCH_3 of DMTr), 6.75-6.79 (m, 4H, H-Ar of DMTr), 7.13-7.18 (m, 1H, H-Ar of Aq), 7.21-7.42 (m, 9H, H-Ar of DMTr), 7.54-7.75 (m, 4H, H-Ar of Aq), 8.22-8.25 (m, 2H, H-Ar of Aq), 9.74 (br., 1H, NH), ^{31}P NMR ($CDCl_3$) δ 148.54, 148.59.

2-(Dimethoxytrityloxymethyl)-2-methyl-*N*-[3-(anthraquinon-1-ylamino)propyl]propionamido-3-yl 2-cyanoethyl *N*,*N*-diisopropyl phosphoramidite (1c)

Compound **6c** (0.51 g, 0.730 mmol) was converted to the corresponding phosphoramidite derivative (**1c**) by same manner as compound **1a**. The product was chromatographed on a column of silica gel with AcOEt/CH_2Cl_2/TEA (45:45:10, v/v/v). The pure compound **1c** was isolated by precipitation in the same manner as compound **1a** as red solid (0.35 g, 53.3%). ^{1}H NMR ($CDCl_3$) δ 1.07-1.29 (m, 14H, iPr), 1.13 (s, 3H, CH_3), 1.86-1.91 (m, 2H, CH_2), 2.50-2.56 (m, 2H, CH_2 of amidite), 3.26-3.37 (m, 4H, -CH_2O), 3.26-3.37 (m, 2H, CH_2 of amidite), 3.26-3.37 (m, 2H, CH_2), 3.51-3.54 (m, 2H, CH_2), 7.74 (s, 6H, OCH_3 of DMTr), 6.79-6.82 (m, 4H, H-Ar of DMTr), 6.91-6.94 (m, 1H, H-Ar of Aq), 7.19-7.50 (m, 9H, H-Ar of DMTr), 7.57-7.78 (m, 4H, H-Ar of Aq), 8.23-8.28 (m, 2H, H-Ar of Aq), 9.71 (br. 1H, NH), ^{31}P NMR ($CDCl_3$) δ 148.45.

Scheme S2 Preparation of 5-tris(aminoethyl)anthraquinone bearing phosphoramidite reagents for the automated solid-phase oligonucleotide synthesis.

1-(6-Aminohexylamino)-5-chloroanthraquinone (8a)

The mixture of 1,6-hexanediamine (5.5 g, 47.6 mmol) and 1,5-dichloroanthraquinone (**7**) (4.4 g, 15.9 mmol) in xylene (48 ml) was reacted under reflux at 150 °C for 30 min. After the evaporation of the mixture under reduced pressure, the residue was dissolved in CH_2Cl_2 (300 ml) and washed with 1.0 N KOH solution (2 × 300 ml) and sat. $NaHCO_3$ solution (2 × 300 ml). The organic layer was collected and dried over Na_2SO_4 then evaporated under reduced pressure. The residue was purified by a column of silica gel with CH_2Cl_2/MeOH/aq.NH_3 (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **8a** (3.19 g, 56.3%) as red solid. ^{1}H NMR ($CDCl_3$) δ 1.40-1.60 (m, 6H, CH_2), 1.73-1.80 (m, 2H, CH_2), 2.70-2.74 (m, 2H, CH_2), 2.30-3.37 (m, 2H, CH_2), 7.00-7.05 (m, 1H, H-Ar of Aq), 7.50-7.72 (m, 4H, H-Ar of Aq), 8.27 (dd, *J* = 7.5, 1.2 Hz, 1H, H-Ar of Aq), 9.61 (br. 1H, NH).

1-(2-Aminoethylamino)-5-chloroanthraquinone (8b)

Compound **8b** was obtained by the reaction of ethylendiamine (2.2 ml, 32.5 mmol) and 1,5-dichloroanthraquinone (**7**) (3.0 g, 10.8 mmol) in xylene (32.5 ml) by the same manner as compound **8a**. The product was chromatographed on a column of silica gel with CH_2Cl_2/MeOH/aq.NH_3 (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **8b** (1.84 g, 56.5%) as red solid. ^{1}H NMR ($CDCl_3$) δ 3.08-3.48 (m, 4H, CH_2), 7.00-7.05 (m, 1H, H-Ar of Aq), 7.51-7.70 (m, 4H, H-Ar of Aq), 8.25 (dd, *J* = 7.5, 1.2 Hz, 1H, H-Ar of Aq), 9.51 (br. 1H, NH).

1-(3-Aminopropylamino)-5-chloroanthraquinone (8c)

Compound **8c** was obtained by the reaction of 1,3-propanediamine (3.6 ml, 43.3 mmol) and 1,5-dichloroanthraquinone (**7**) (4.0 g, 14.4 mmol) in xylene (43 ml) by the same manner as compound **8a**. The product was chromatographed on a column of silica gel with CH_2Cl_2/MeOH/aq.NH_3 (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **7c** (2.54 g, 55.9%) as red powder. ^{1}H NMR ($CDCl_3$) δ 1.18 (br., 2H, NH_2), 1.86-1.95 (m, 2H, CH_2), 2.90-2.95 (m, 2H, CH_2), 3.39-3.48 (m, 2H, CH_2), 7.02-7.06 (m, 1H, H-Ar of Aq), 7.52-7.71 (m, 4H, H-Ar of Aq), 8.27 (dd, *J* = 7.8, 1.5 Hz, 1H, H-Ar of Aq), 9.61 (br. 1H, NH).

***N*-{3-(5-chloroanthraquinon-1-ylamino)hexyl}-2,2-bis(hydroxymethyl)propionamide (9a)**

The compound **8a** (1.54 g, 4.32 mmol) was converted to the compound **9a** (1.66 g, 81.3%) as red solid by same manner as compound **5a**. ^{1}H NMR ($CDCl_3$) δ 1.10 (s, 3H, CH_3), 1.37-1.79 (m, 8H, CH_2), 3.22-3.36 (m, 4H, CH_2), 3.72-3.76 (m, 4H, CH_2OH), 6.99-7.03 (m, 1H, H-Ar of Aq), 7.51-7.72 (m, 4H, H-Ar of Aq), 8.25-8.28 (m, 1H, H-Ar of Aq), 9.59 (br. 1H, -NH-).

***N*-{3-(5-chloroanthraquinon-1-ylamino)ethyl}-2,2-bis(hydroxymethyl)propionamide (9b)**

Compound **8b** (1.84 g, 6.12 mmol) was converted to compound **9b** (1.54 g, 60.4%) as red solid (sticky) by same manner as compound **5a**.

***N*-{3-(5-chloroanthraquinon-1-ylamino)propyl}-2,2-bis(hydroxymethyl)propionamide (9c)**

Compound **8c** (2.45 g, 7.78 mmol) was converted to compound **9c** (2.70 g, 80.5%) as red solid (sticky) by same manner as compound **5a**. ^{1}H NMR ($CDCl_3$): δ 1.10 (s, 3H, CH_3), 1.94-2.02 (m, 2H, CH_2), 3.37-3.3.41 (m, 4H, CH_2OH), 3.44-3.83 (m, 2H, CH_2), 6.96-6.99 (m, 1H, H-Ar of Aq), 7.49-7.70 (m, 4H, H-Ar of Aq), 8.19-8.58 (m, 1H, H-Ar of Aq), 9.56 (br. 1H, NH).

***N*-[3-[5-[2-{Bis(2-aminoethyl)amino}ethylamino]anthraquinon-1-ylamino]hexyl]-2,2-bis(hydroxymethyl)propionamide (10a)**

Tris(2-aminoethyl)amine (3.15 ml, 21.1 mmol) was refluxed with **9a** (1.66 g, 3.51 mmol) in dry toluene (28 ml) at 110-115 °C for 6 h. After cooling down and evaporation of the mixture, resulted oil was dissolved in CH_2Cl_2 (250 ml) and washed with water (2 × 250 ml). The organic layer was collected and dried over Na_2SO_4 then evaporated under reduced pressure. The residue was undergone silica gel column chromatography using CH_2Cl_2/MeOH/NH_3aq. (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **10a** (1.33 g, 65.0%) as red oil, ^{1}H NMR ($CDCl_3$) δ 1.03 (s, 3H, CH_3), 1.23-1.53 (m, 6H, CH_2), 1.64-1.71 (m, 2H, CH_2), 2.56-2.60 (m, 4H, CH_2), 2.77-2.84 (m, 6H, CH_2 of polyamine), 3.17-3.28 (m, 4H, CH_2 of polyamine), 3.32-3.37

(m, 2H, CH_2 of polyamine), 3.64-3.71 (m, 4H, CH_2OH), 6.85-6.91 (m, 2H, H-Ar of Aq), 7.41-7.50 (m, 4H, H-Ar of Aq), 9.60 (t, *J* = 5.4 Hz, 1H, NH), 9.86 (t, *J* = 4.5 Hz, 1H, NH).

***N*-[3-[5-[2-{Bis(2-aminoethyl)amino}ethylamino]anthraquinon-1-ylamino]ethyl]-2, 2-bis(hydroxymethyl)propionamide (10b)**

Tris(2-aminoethyl)amine (3.96 ml, 26.5 mmol) was refluxed with **9b** (1.84 g, 4.41 mmol) in dry toluene (35 ml) at 110-115 °C for 6 h. After cooling down and evaporation, resulted oil was undergone silica gel column chromatography using CH_2Cl_2/MeOH/aq.NH_3 (4:1:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **10b** (1.2 g, 51.6%) as red oil, ^{1}H NMR (D_2O) δ 0.93 (s, 3H, CH_3), 2.74-2.78 (m, 6H, CH_2 of polyamine), 2.97-3.01 (m,4H, -CH_2 of polyamine), 3.19-3.27 (m, 4H, CH_2 of polyamine), 3.32-3.40 (m, 4H, CH_2OH), 3.47-3.51 (m, 2H, CH_2O), 6.72-6.75 (m, 1H, H-Ar of Aq), 6.81-6.84 (m, 1H, H-Ar of Aq), 6.99-7.03 (m, 2H, H-Ar of Aq), 7.23-7.31 (m, 2H, H-Ar of Aq).

***N*-[3-[5-[2-{Bis(2-aminoethyl)amino}ethylamino]anthraquinon-1-ylamino]propyl]-2,2-bis(hydroxymethyl)propionamide (10c)**

Compound **9c** (2.54 g, 5.90 mmol) was converted to compound **10c** by the same manner as compound **10b**. The product was undergone silica gel column chromatography using CH_2Cl_2/MeOH/aq.NH_3 (3:2:0.2, v/v/v). Collection and evaporation of appropriate fractions afforded compound **10c** (1.95 g, 61.2%) as red oil, ^{1}H NMR (D_2O) δ 1.06 (s, 3H, CH_3), 1.73-1.75 (m, 2H, CH_2), 2.79-2.86 (m, 6H, CH_2 of polyamine), 2.04-3.06 (m, 6H, CH_2 of polyamine), 3.20-3.25 (m, 4H, CH_2OH), 3.47-3.51 (m, 2H, CH_2O), 3.60-3.64 (m, 2H, CH_2O), 6.64-6.71 (m, 2H, H-Ar of Aq), 6.89-6.91 (m, 2H, H-Ar of Aq), 7.16-7.27 (m, 2H, H-Ar of Aq).

***N*-[6-[5-[2-[Bis{2-(2,2,2-trifluoroacetamino)ethyl}amino]ethylamino]anthraquinon-1-ylamino]hexyl]-2,2-bis(hydroxymethyl)propionamide (11a)**

Ethyl trifluoroacetate (1.36 ml, 11.4 mmol) was added to the mixture of **10a** (1.33 g, 2.28 mmol) in dry CH_2Cl_2 (45 ml) and dry TEA (4.8 ml, 34.23 mmol) and the mixture was stirred at room temperature for 2 h. After the evaporation of the mixture, resulted oil was dissolved in CH_2Cl_2 (200 ml) and washed with water (2 × 200 ml). The organic layer was collected and dried over Na_2SO_4 then evaporated under reduced pressure. The

residue was undergone silica gel column chromatography using 10% MeOH in CH_2Cl_2. Collection and evaporation of appropriate fractions afforded compound **11a** (1.51 g, 85.4%) as red foam, ^{1}H NMR ($CDCl_3$) δ 1.10 (s, 3H, CH_3), 1.43-1.62 (m, 6H, CH_2), 1.75-1.80 (m, 2H, CH_2), 2.74-2.77 (m, 4H, CH_2 of polyamine), 2.87-2.90 (m, 2H, CH_2 of polyamine), 3.27-3.3.35 (m, 6H, CH_2 of polyamine), 3.45-3.46 (m, 4H, CH_2), 3.70-3.75 (m, 4H, CH_2OH), 6.91-6.99 (m, 1H, H-Ar of Aq), 7.00-7.03 (m, 1H, H-Ar of Aq), 7.50-7.62 (m, 3H, H-Ar of Aq), 7.93-7.95 (m, 1H, H-Ar of Aq), 9.77 (br., 1H, NH), 9.93 (br., 1H, NH).

***N*-[2-[5-[2-[Bis{2-(2,2,2-trifluoroacetamino)ethyl}amino]ethylamino]anthraquinon-1-ylamino]ethyl]-2,2-bis(hydroxymethyl)propionamide (11b)**

Compound **10b** (0.99 g, 1.88 mmol) was converted to compound **11b** by same manner as compound **10a**. The product was isolated by silica gel column chromatography in the same manner as compound **10a** to afford compound **11b** (0.82 g, 60.7%) as red foam, ^{1}H NMR ($CDCl_3$) δ 1.10 (s, 3H, CH_3), 2.73-2.76 (m, 4H, CH_2), 3.30-3.33 (m, 2H, CH_2 of polyamine), 3.42-3.54 (m, 6H, CH_2 of polyamine), 3.62-3.65 (m, 4H, CH_2 of polyamine), 3.74-3.85 (m, 4H, CH_2OH), 6.88-6.91 (m, 1H, H-Ar of Aq), 7.04-7.09 (m, 1H, H-Ar of Aq), 7.44-7.56 (m, 3H, H-Ar of Aq), 7.93-7.97 (m, 1H, H-Ar of Aq), 9.82 (br., 1H, NH), 9.89 (br., 1H, NH).

Supporting Information

ABSTRACT: In this study, we introduced histidine residues into L-arginine grafted PAMAM G4 dendrimers to enhance proton buffering capacity and evaluated the physicochemical characteristics and transfection efficacies in vitro. The results showed that the synthesized PAMAM G4 derivatives effectively delivered pDNA inside cells and the transfection level improved considerably as the number of histidine residues increased. Grafting histidine residues into the established polymer vector PAMAM G4-arginine improved their proton buffering capacity. The cytotoxicity of PAMAM G4 derivatives was tested and it was confirmed that they displayed relatively lower cytotoxicity compared to PEI25KD in various cell lines. Also, confocal microscopy results revealed that PAMAM G4 derivatives effectively delivered pDNA into cells, particularly into the nucleus. These PAMAM dendrimer derivatives conjugated with histidines and arginines may provide a promising polymeric gene carrier system.

INTRODUCTION

The development of an effective and safe gene delivery carrier has become one of the most important factors enabling gene therapy. In the past decade, numerous studies have developed efficient transfection methods for delivering therapeutic genes into cells for human gene therapy. Viral and nonviral vector systems are the two major systems that transfer genetic material into cells. Currently, using adenoviruses and retroviruses to transfer genetic material (DNA or RNA) into cells is the general method in most ongoing gene therapy clinical trials. The viral vector system provides attractive advantages such as efficient transfection and high gene expression efficiency. However, there are some concerns such as immunogenicity, high toxicity, and the possibility of destructive integration into the human genome. Due to the disadvantages of viral vectors, the demands for alternatives to the viral vector system have increased.[1,2] Although they display lower transfection efficiency than viral vectors, using nonviral vectors to deliver therapeutic genes into cells has several advantages. Nonviral vectors can deliver a relatively larger size of DNA into cells, and they have lower cytotoxicity and greatly reduced immunogenicity.

Various methods are utilized to transfer genes into cells by nonviral approaches. Physical methods include a gene gun, electroporation, and hydrodynamic and ultrasound-mediated injection. These physical transfer techniques induce transient impacts on plasma membranes, so that genetic materials can be introduced. Compared with physical approaches, using chemical methods to transfer genes has also been investigated. Cationic lipids condense pDNA, which is negatively charged due to its phosphate backbone. Many cationic lipid-mediated gene delivery strategies have been studied since a report published by Felgner et al. in 1987.[3] Similar to cationic lipids, cationic polymers condense negatively charged pDNA through electrostatic interaction. Cationic polymers condense pDNA effectively and facilitate cellular uptake via endocytosis.[4−8] Cationic polymers include polyethyleneimine (PEI), polyamidoamine (PAMAM) dendrimer, chitosan, dextran, protamine, and cationic polypeptides such as poly(L-lysine).

PAMAM dendrimers are one of the most popular polymers used as a nonviral gene carrier because of their unique characteristics such as uniform size distribution, relatively higher transfection efficiency, and lower cytotoxicity compared to other traditional cationic polymers.[9,10] Many studies have investigated the enhanced transfection efficiency of modified PAMAM dendrimer derivatives. Grafting of specific ligands for certain receptors (e.g., RGD sequence for $\alpha_v\beta_3$ integrins) provides enhanced targeting effects to carriers.[11] Moreover, the acetylation of PAMAM dendrimers decreases cytotoxicity

while maintaining membrane permeability.[12] In our previous study, we synthesized an arginine-conjugated PAMAM dendrimer, which shows enhanced transfection efficiency compared to the native PAMAM dendrimer. [13]

A PAMAM dendrimer has positively charged amine groups on the peripheral ends to allow interaction with the negatively charged pDNA phosphate backbone.[14,15] Therefore, it is essential that newly designed vectors have cationic functional groups in their structure. Moreover, several physiological barriers must be overcome to achieve effective transfection.[16] It is known that polyplexes could be internalized into cells by endocytosis forming endosomes.[17] These endosomes progress into a lysosome state, which has an acidic environment to digest external materials. Therefore, most of the complexes in lysosomes will collapse. Thus, the proton buffering ability of the carrier is needed to overcome this acidic environment of the lysosome. Although PAMAM dendrimers have proton buffering abilities (hypothesized proton sponge effect) in their tertiary amine, insertion of additional functional groups that act as proton sponges is required to enhance endosomal release.[18,19]

Durability against the acidic environment should increase the number of complexes escaping from endosomes to the cytosol. The histidine conjugation method could be helpful for increasing buffer capacity against acidic conditions due to the presence of imidazole ring groups that have pK_a of 6.0, which is a unique property that provides protonation ability in an acidic environment. Although native PAMAM dendrimers condense pDNA efficiently, additional conjugation with amino acids, such as histidine, arginine, and lysine, to the peripheral amine functional groups could contribute to their multifunctional properties. Particularly, histidine conjugation of a conventional polymer vector system has advantages not only in enhancing complexation ability but also in improving physicochemical strength against an acidic condition via the proton sponge effect. Some groups have reported applications of histidine as a proton buffering agent during liposomal delivery[20,21] and polyhistidine as a proton sponge unit.[22]

In this study, we conjugated histidine and arginine residues to PAMAM dendrimers to obtain higher proton buffering capacity with ionizable imidazole groups on histidine units together with the high gene expression ability of PAMAM G4-Arg. We investigated the physicochemical properties, polyplex formation, cytotoxicity, and transfection efficiency of PAMAM G4 derivatives. The intracellular distribution of synthesized PAMAM G4 derivatives was also confirmed using confocal microscopy.

MATERIALS AND METHODS

Materials. PAMAM generation 4, *N*,*N*-diisopropylethylamine (DIPEA), ammonium persulfate (APS), *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine (TEMED), and *N*,*N*-dimethylformamide (DMF) were purchased from Sigma-Aldrich (Seoul, South Korea). *N*-Hydroxybenzotriazole (HOBt), 2-(1*H*-benzotriazole-1-yl)-1,1,3,3-tetra-methyluronium (HBTU), and Fmoc-His(trt)-OH were purchased from Anaspec (San Jose, CA, USA), and Fmoc-Arg-(pbf)-OH was obtained from Novabiochem (San Diego, CA, USA). Fetal bovine serum (FBS), Dulbecco's modified Eagle's medium (DMEM), and 100× antibiotic−antimycotic agent were purchased from Gibco (Gaithersburg, MD, USA). The luciferase expression plasmid was prepared as reported previously.[23] The luciferase assay kit was purchased from Promega (Madison, WI, USA). The Micro BCA Protein Assay Kit was obtained from Pierce (Rockford, IL, USA).

Synthesis of PAMAM G4-$His_{(1,2,3)}$-Arg. Fourth-generation PAMAM was reacted with 4 equiv of Fmoc-His(trt)-OH, HBOt, and HBTU and 8 equiv of DIPEA in anhydrous DMF solution for 16 h at room temperature (R.T.). Then, the intermediate product was precipitated with an excess amount of cold ethyl ether. The precipitated intermediate was dissolved with 30% piperidine solution (v/v) and reacted for 1 h to deprotect the Fmoc group on the histidine unit. After the deprotection procedure, the intermediate product was precipitated with cold ethyl ether. Additional histidine elongation could be conducted by repeating the synthetic process described above. After elongation of the histidine unit, 4 equiv of

Fmoc-Arg(pbf)-OH, HOBt, and HBTU and 8 equiv of DIPEA were reacted with the intermediate product using the same method described above. After precipitation with cold ethyl ether, the intermediate product was reacted with 30% piperidine solution for 1 h to remove the Fmoc group on the arginine unit. Then, the product was washed and precipitated with cold ethyl ether. The precipitated product was dissolved with deprotection reagent (95:2.5:2.5, trifluoroacetic acid/triisopropylsilane/H_2O, v/v, respectively) and stirred for 6 h at R.T to deprotect the pbf and trt groups on each amino acid unit. The unrefined product was dialyzed with distilled water using dialysis membrane (MWCO 3,500, Spectra/por) for 24 h to purify the product from unreacted amino acids or coupling reagents. After dialysis, the final product was freeze−dried. Overall schemes for the synthesis of PAMAM conjugates are presented in Figure 1.

Agarose Gel Retardation Assay and Dynamic Light Scattering Analysis. A complex test was conducted to analyze the complex formation of PAMAM derivatives with plasmid DNA under various charge ratio conditions. Complexes were prepared containing polymers and plasmid DNA with different charge ratios by incubating them in HEPES buffer (25 mM, pH 7.4). A fixed volume of plasmid DNA and HEPES buffer with different polymer charge ratios was mixed at R.T. for 30 min. Each complex sample was analyzed on a 0.7% agarose gel containing ethidium bromide (0.5 μg/μL gel). Agarose gel electrophoresis typically required 30 min at 100 V. The size distribution and zeta potential of the polyplexes were measured using a Zetasizer Nano-Zs (Malvern Instruments, Worcestershire, U.K.).

PAGE Study. Native polyacrylamide gel electrophoresis study of PAMAM derivatives was performed on a Mini-Protean Tetra Cell System (Biorad, Hercules, CA, USA). Citrate buffer (pH 3.0, 0.1 M) was used as the buffer system, and 6% T gels (T = g acrylamide + g *N,N′*- methylenebisacrylamide/100 mL solution) were prepared with a 30% acrylamide mixture solution (Biorad) with a combination of APS, TEMED, and Tris-HCl buffer (pH 7.5). The 6% T gels were acidified (pH 2) before adding the APS and TEMED using 5 N HCl to protonate the polymers and produce a narrow band. Reverse polarity (with the cathode at the bottom of the gel) was used for analysis of the positively charged PAMAM derivatives. Native PAGE typically required 50 min at 100 V.

Polymer samples (1 μg) were prepared, and 1 μL of tracking dye (50% sucrose solution containing 1% methylene blue) was added to the samples for loading. Gels were stained overnight with 0.025% Coomassie Blue R-250 in 40% methanol and 7% acetic acid aqueous solution. After the staining process, the gels were destained with 10% (v/v) methanol and 10% acetic acid in water.

Acid−Base Titration Assay. The protonation ability of PAMAM derivatives was determined by the acid−base titration method. PEI25KD (2 mg, 8×10^{-8} mol) and the same equivalents of PAMAM G4, PAMAM G4-Arg, and PAMAM G4-$His_{(1,2,3)}$-Arg were titrated with 0.1 N HCl. NaCl (150 mM) and H_2O were titrated as a control group. The pH value was determined with a pH-meter (pH211 microprocessor pH meter, HANA Instruments, Seoul, South Korea).

Briefly, each titration sample was prepared by adding an equivalent amount of sample (8×10^{-8} mol) in 4 mL of 150 mM NaCl, and 100 μL of 1 N NaOH was added to the sample solution. Samples were titrated by adding aliquots (20 μL) of 0.1 N HCl until pH 3.0 was reached.

Cytotoxicity Assay. The cytotoxicity of the PAMAM derivatives was assessed using the EZ-Cytox Reagent (Daeil Lab Service, Seoul, South Korea) based on the WST-1 method. Briefly, HepG2, 293, and NIH 3T3 cells were seeded in 96-well plates at a density of 2×10^4 cells/well except for HeLa cells (1×10^4 cells/well) and incubated in 100 μL of DMEM containing 10% FBS. After a 1-day incubation, the cells were treated with various concentrations of PEI25KD, PAMAM G4, and PAMAM derivatives. After further incubation for 24 h, 10 μL of EZ-Cytox Reagent was added to each well and incubated for an additional 4 h. Absorbance was measured at 450 nm using a VESAmax microplate reader (VERSAmax, Molecular Devices, Sunnyvale, CA, USA).

Confocal Microscopy Study. HeLa cells (5×10^3 cell/well) were seeded on culture slides and incubated at 37 °C. After a 24 h incubation, the cells were treated with polyplexes composed of various polymers with Alexa Fluor 532 labeled pDNA. Alexa Fluor 532 labeled pDNA was prepared according to the manufacturer's protocol. After a further incubation for 24 h, old medium was removed, and the cells were washed with PBS. Cells were fixed in 4% paraformaldehyde for 10 min, and the nuclei were stained with 10 μg/mL bisbenzimide (Hoechst 33342) for 7 min and then washed with PBS several times. The plastic chamber on the glass slide was detached, and the cells were treated with mounting medium (Dako, Carpinteria, CA, USA) and covered with a coverslip. The fluorescent signal was analyzed using a Zeiss LSM 5 Live confocal laser microscope.

Cell Culture and Transfection Assay. Human hepatocellular liver carcinoma HepG2 cells, human embryonic kidney 293 cells, murine fibroblast NIH3T3 cells, and human epithelial carcinoma HeLa cells were maintained at 37 °C in an incubator (5% CO_2, 95% relative humidity). All cells were maintained in T25 flasks using DMEM supplemented with 10% FBS and 1% antibiotics. Cells were subcultured using a 0.25% trypsin/ethylenediaminetetraacetic acid solution when confluence reached 70−90%.

For the transfection study, cells were seeded in a 24-well plate at a density of 2×10^5 cells/well except for HeLa cells (1×10^5 cells/well) and incubated for 24 h to reach 70−80% confluency. The transfection complex was prepared by mixing 1 μg of plasmid DNA with various amounts of PAMAM derivatives containing 10% FBS for 30 min at R.T. To compare the transfection efficiency, PEI25KD/pDNA (polymer nitrogen(+)/pDNA phosphate(−) (N/P) ratio: 7/1, optimal condition) and PAMAM G4/pDNA (N/P ratio: 4/1, optimal condition) complexes were prepared as a control group. PAMAM G4 derivatives were prepared with N/P ratios of 4:1 to 8:1 to compare gene transfection efficiency in terms of charge ratios. Then, cells were treated with the complex solution and incubated for 24 h at 37 °C. Old medium was removed, and the cells were washed with DPBS and lysed for 30 min using reporter lysis buffer (Promega). Luciferase activity was measured using Lumat LB 9507 (Berthold Technology, Bad Wildbad, Germany), and protein content was measured using the Micro BCA Protein Assay Kit (Pierce).

Statistical Analysis. The statistical analysis was performed using the unpaired Student's *t*-test (*GraphPad Prism 5*). Differences between groups were considered statistically significant at $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***).

RESULTS AND DISCUSSION

Synthesis of PAMAM G4-$His_{(1,2,3)}$-Arg. This study was based on our previous report in which we demonstrated that the transfection efficiency of the PAMAM G4 dendrimer is enhanced by surface modification with L-arginine. It was confirmed that introducing L-arginine to the surface of the PAMAM dendrimer enhanced transfection efficiency.[13] Some reports have indicated

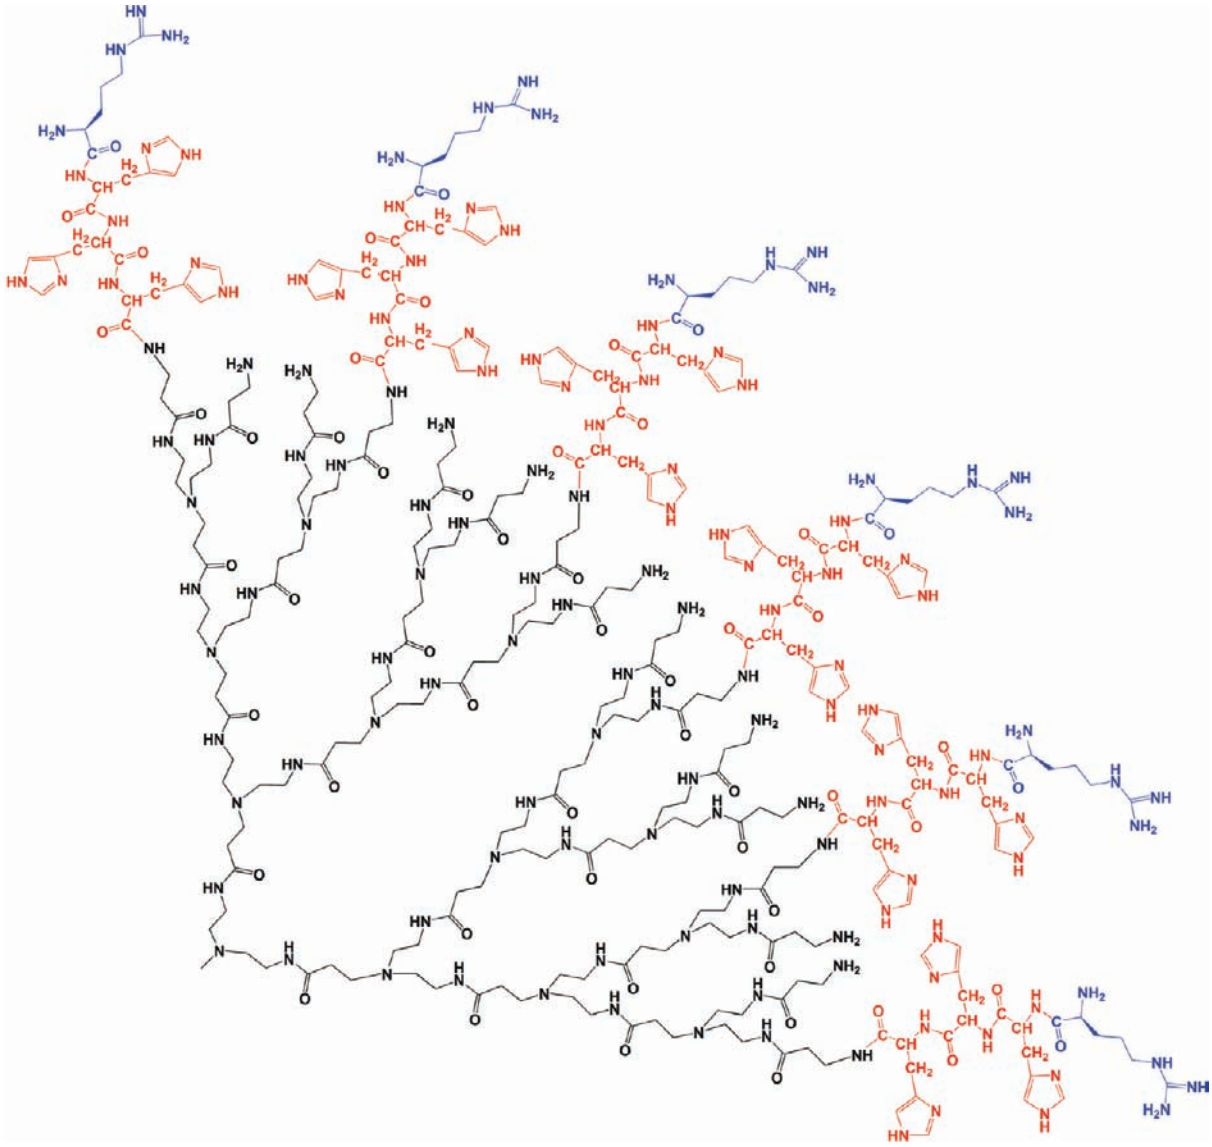

Figure 2. Chemical structure of PAMAM G4-His_3-Arg (quarter section). PAMAM G4 dendrimer core appears in black, histidines in red, and arginines in blue, respectively.

that arginine-rich peptides can deliver oligo DNAs and even proteins *in vivo*.[24,25] Furthermore, many groups have reported that oligo-arginine can serve as a membrane translocational signal.[26] Meanwhile, in 2008, Asayama et al. presented carboxymethyl poly(L-histidine) as a pH-sensitive polypeptide to enhance the transfection efficiency of polyplex gene delivery.[27] Recently, in 2009, Nakamura et al. reported that the conjugation of histidine with mannosylated cholesterol derivatives showed significantly higher cellular uptake in macrophages.[28] More recently, in 2010, Song et al. introduced histidine residues into the TAT peptide and applied them to a magnetofection system, and the transgene expression via ternary magnetofection complexes displayed a 4-fold improvement *in vitro*.[29] Many other groups have utilized polyhistidine to increase transfection efficiency.[30]

The histidine imidazole group has a pK_a value of 6.0 and plays a role as a proton sponge in a slightly acidic environment. Furthermore, the escape of pDNA from the endosome is one of the important steps for successful nonviral transfection methods, and the proton buffering ability of the gene carrier is necessary to increase transfection efficiency. Hence, in this study, we introduced histidine units into the L-arginine grafted PAMAM G4 dendrimer to enhance proton buffering capacity.

The synthesized PAMAM G4-$His_{(1,2,3)}$-Arg was confirmed by ^{1}H nuclear magnetic resonance (NMR) spectroscopy (Supporting Information, Figure S1). The number of histidine and arginine units conjugated to PAMAM G4 was calculated based on the ^{1}H NMR data. Arginine units had characteristic peaks at 1.5 ppm and 3.76 ppm, whereas the histidine units showed characteristic peaks at 4.5 ppm, 6.8 ppm, and 7.6 ppm. From the ^{1}H NMR results, it was confirmed that more than 60 histidine and arginine units were conjugated to the surface primary amines of PAMAM G4. This number of conjugated units means that more than 95% of the surface amines were covered with $histidine_{(1,2,3)}$-arginine peptide. The overall schematic synthesis process of PAMAM G4-$His_{(1,2,3)}$-Arg is presented in Figure 1, and the structural representation of the histidine-arginine peptide conjugated to PAMAM G4 (a quarter section) is shown in Figure 2.

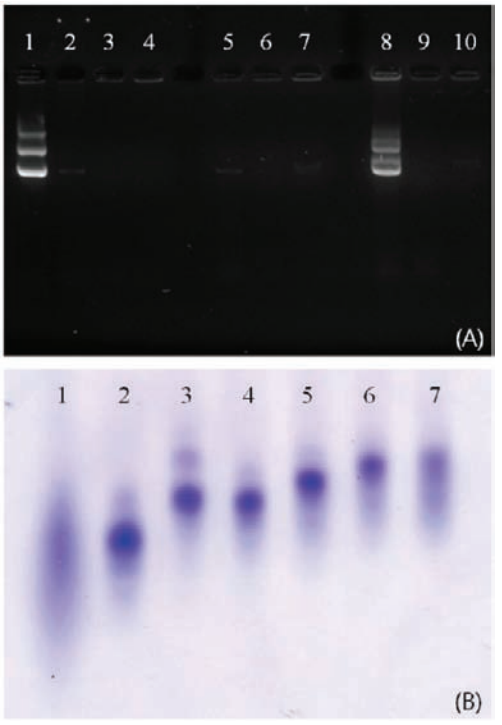

Figure 3. (A) Agarose gel electrophoresis retardation assay of pDNA by PAMAM G4 derivatives. pDNA only (lane 1); polymer/DNA charge ratio 1:1 (lanes 2, 5, and 8); 2:1 (lanes 3, 6, and 9); 4:1 (lanes 4, 7, and 10). Lanes 2−4, 5−7, and 8−10 represents PAMAM G4-His_1-Arg, PAMAM G4-His_2-Arg, and PAMAM G4-His_3-Arg with pDNA, respectively. (B) Native PAGE analysis of PAMAM G4 derivatives. PEI25KD, PAMAM G4, PAMAM G5, PAMAM G4-Arg, PAMAM G4-His_1-Arg, PAMAM G4-His_2-Arg, and PAMAM G4-His_3-Arg in lanes 1, 2, 3, 4, 5, 6, and 7, respectively.

Analysis of the Agarose Gel Retardation Assay. An agarose gel retardation assay was performed to confirm the complex formation of PAMAM derivatives with pDNA. Because the PAMAM derivatives have positively charged amine groups on their arginine units, they can interact with the negatively charged pDNA phosphate backbone. Each PAMAM derivative was complexed with a fixed amount of pDNA at an N/P ratio of 1:1 to 4:1. As shown in Figure 3A, PAMAM G4-His_1-Arg and PAMAM G4-His_2-Arg retarded pDNA at an N/P ratio of 1:1. However, PAMAM G4-His_3-Arg showed complete retardation at an N/P ratio of 2:1.

It is thought that the increased ratio of PAMAM G4-His_3-Arg compared to His_1 and His_2 is due to an increase in molecular weight and a decrease in charge density. Molecular weight and charge density of polycationic polymers are the most significant factors for forming mature polyplexes. It is generally accepted that polycationic vehicles, which have a high charge density, condense pDNA more effectively.[31] Furthermore, the distance between the DNA phosphate backbone and the polycation molecule is just as important to formation of polyplexes as the charge density.[32] The pK_a of the imidazole group on histidine is approximately 6.0; thus, these groups might remain poorly protonated in a physiological environment (pH 7.4). Hence, forming polyplexes with arginine residues on the peripheral end of a functional group occurs more often than that of histidine residues. It is thought that only a small portion of the protonated histidines participate in forming polyplexes, and that the surface arginines provide a main force for complexation with pDNA.

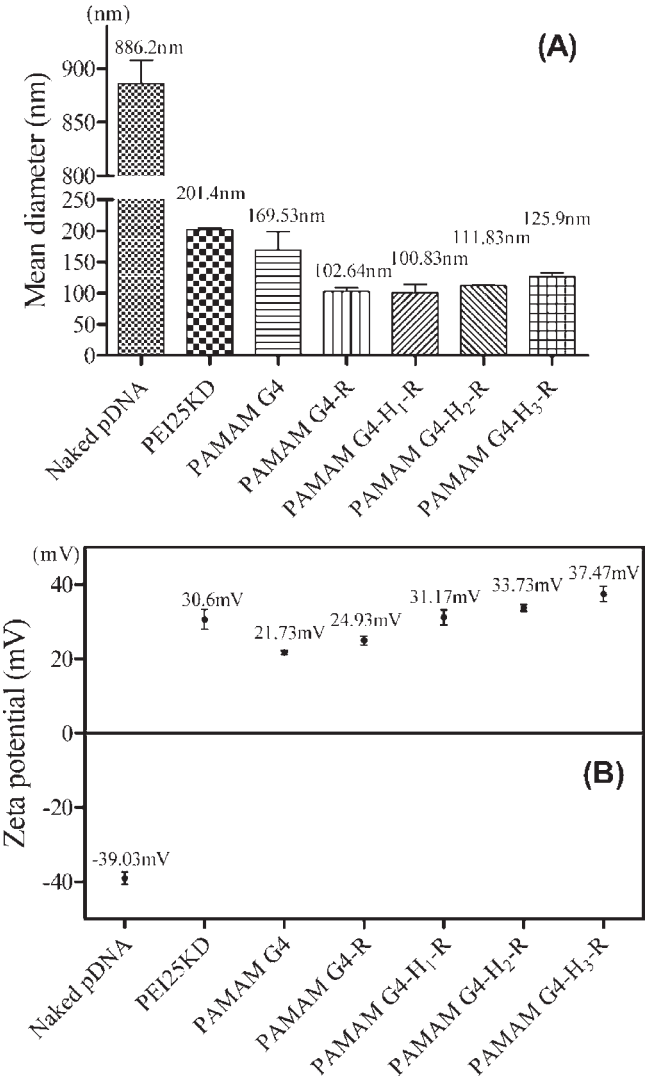

Figure 4. (A) Average diameter and (B) zeta potential values of pDNA and polymer/pDNA complexes. Data are expressed as mean ± standard deviation (n = 3).

Although grafting histidine units between the PAMAM G4 dendrimer and L-arginine may not play a major role in the formation of complexes, the results indicate that histidine-arginine peptide conjugated PAMAM derivatives could also effectively condense pDNA via electrostatic interactions at a relatively low N/P ratio.

Size Measurement and Zeta Potential Analysis of Polyplexes. Delivering the naked plasmid DNA into cells is very limited due to enzymatic degradation, the polyanionic character of pDNA, and its large size. Cationic proteins, such as serum proteins, can bind with pDNA in the bloodstream, and enzymes such as DNase may degrade the pDNA. Therefore, safe and efficient introduction of DNA into cytoplasm and translocation into the nucleus are essential steps for successful gene therapy.

In this study, the mean diameter and zeta potential values of each polyplex were examined at the optimum charge ratio. The charge ratio of PEI25KD was 7:1. PAMAM G4 and derivatives were examined at a charge ratio of 8:1. As shown in Figure 4A, the mean diameter of the naked pDNA was approximately 900 nm. The PEI25KD/pDNA complex showed a mean diameter of 201.4 ± 4.86 nm, and the native PAMAM G4 polyplex was

169.53 ± 49.92 nm. Interestingly, the arginine-grafted PAMAM G4 dendrimer revealed a size of 102.64 ± 11.12 nm compared to native PAMAM G4. The sizes of the PAMAM G4-His_1-Arg, PAMAM G4-His_2-Arg, and PAMAM G4-His_3-Arg polyplexes were 100.83 ± 22.81 nm, 111.83 ± 1.85 nm, and 125.9 ± 11.52 nm, respectively. From the results, the synthesized PAMAM derivatives, including PEI25KD and native PAMAM G4, formed nanometer-sized polyplexes effectively.

As shown in Figure 4B, the zeta potential values of the PAMAM derivatives increased along with the elongation of histidine units. PEI25KD showed a highly positively charged zeta potential value of 30.6 ± 4.60 mV and that of PAMAM G4 was 21.73 ± 0.93 mV. As expected, arginine- and histidine-coupled PAMAM derivatives showed increased zeta potential values compared to native PAMAM G4. The zeta potential value for PAMAM G4-Arg was 24.93 ± 2.03 mV, and this increased value seemed to come from the increased surface charge of polyplexes. Similar results were revealed for PAMAM G4-$His_{(1,2,3)}$-Arg with zeta potentials of 31.17 ± 3.46 mV, 33.73 ± 1.56 mV, and 37.47 ± 3.50 mV, respectively. As the guanidine group of arginine and the imidazole group of histidine have pK_a of 12.0 and 6.0, respectively, the $His_{(1,2,3)}$-Arg conjugated PAMAM derivatives displayed a positive charge under neutral conditions. Taken together, these results suggest that PAMAM derivatives can effectively condense pDNA into a nanometer size (around 100 nm) and possess zeta potential values of approximately 35 mV.

The actual size and shape of each polyplex were further obtained using atomic force microscopy (AFM) (Supporting Information, Figure S2). PEI25KD showed a mostly globular shape, and some large polyplexes were also observed. Particularly, PAMAM G4-Arg had a very compact particle size (<100 nm) and narrow size distribution compared to native PAMAM G4. PAMAM G4 and the His_3-Arg-conjugated PAMAM G4 displayed almost the same size distribution (100−200 nm), which is slightly larger than the DLS results. The difference in size distribution between the DLS and AFM images seems to have occurred because the AFM images are usually taken from dehydrated complexes that were prepared not in a buffer with salt but in deionized water, which is an unnatural condition compared with that of the DLS experiment.

Analysis of Native PAGE Assay. Figure 3B shows the relative size distribution of each synthesized PAMAM derivative. A reverse polarity system was applied because of the cationic nature of the PAMAM derivatives, including PEI25KD. A 0.1 M citrate solution was used as the buffer system because an acidic environment is essential for protonating samples and allows sample migration on a polyacrylamide gel. PEI25KD appeared as a broad band because of its high polydispersity nature (lane 1). Lanes 2, 3, and 4 represent PAMAM G4, PAMAM G5, and PAMAM G4-Arg, respectively. These groups are presented as control groups. Lanes 5, 6, and 7 are PAMAM G4-His_1-Arg, PAMAM G4-His_2-Arg, and PAMAM G4-His_3-Arg, respectively. The PAGE results showed that a different size distribution was observed as the histidine conjugation number increased. PAMAM G4-His_3-Arg showed less migration than other low molecular weight derivatives. Even though this method provides insufficient information about the molecular weights of the synthesized polymers, this PAGE result could be helpful for qualitative assessing and comparing the size distribution between the PAMAM derivatives.

Titration of PAMAM G4 Derivatives. The side group of histidine has a pK_a of 6.0, so it should be much less protonated at physiological pH than primary amine groups. Therefore, an increased number of histidine units on PAMAM derivatives

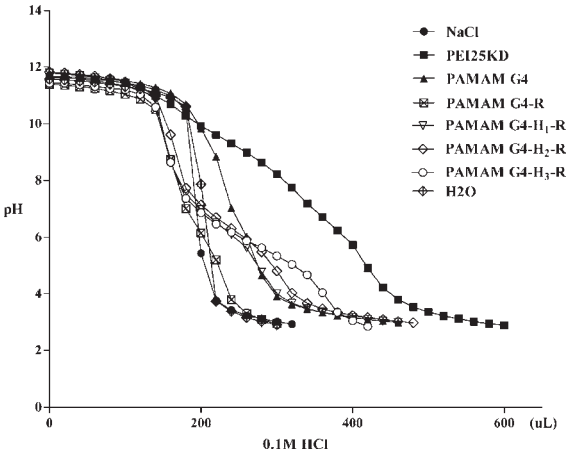

Figure 5. Acid−base titration profiles of the polymers.

may play an important role in increasing the buffer capacity at an acidic pH. This may also explain why $His_{(1,2,3)}$-Arg peptide-conjugated PAMAM G4 derivatives displayed much higher potency than PAMAM G4 and PAMAM G4-Arg in terms of the proton sponge effect. The acid−base titration profile of the $His_{(1,2,3)}$-Arg peptide conjugated to PAMAM G4 is presented in Figure 5. PEI25KD showed the strongest buffering ability, whereas native PAMAM G4 showed less buffering capacity. An overall decrease in buffering capacity was observed when only arginine was grafted to the PAMAM G4 dendrimer. Interestingly, restoration of the buffering effect in the pH range 6−7 was observed in the $His_{(1,2,3)}$-Arg conjugated PAMAM G4 dendrimer. More interestingly, an increase in buffering ability was observed in the pH range 3.5−6, as the number of histidines increased. Although the $His_{(1,2,3)}$-Arg peptide-conjugated PAMAM derivatives showed relatively low buffering ability compared to PEI25KD, they revealed increased buffering capacity in a slightly acidic pH range as the number of histidine residues increased. Moreover, the $His_{(1,2,3)}$-Arg peptide conjugation remarkably influenced the proton buffering ability compared with native PAMAM G4. This result could be strong evidence for the greatly increased proton buffering efficiency of the PAMAM G4-$His_{(1,2,3)}$-Arg derivatives through the protonation of imidazole rings in an acidic condition.

Cytotoxicity Study. The cytotoxicity of PAMAM G4 derivatives was confirmed using the EZ-Cytox Cell Viability Assay Kit based on the WST-1 assay. WST-1 (4-[3-(4-iodophenyl)-2-(4-nitrophenyl)-2*H*-5-tetrazolio]-1,3-benzene disulfonate) has been used to determine cytotoxic effects on mammalian cells.[33] Similar to the MTT assay, WST-1 reacts with mitochondrial succinate-tetrazolium reductase and forms a water-soluble formazan dye. MTT forms a water-insoluble formazan dye, so the use of WST-1 is convenient because the additional solubilization step can be omitted. To examine the cytotoxicity of polymer vectors, PEI25KD, native PAMAM G4, and PAMAM G4-Arg were compared with PAMAM derivatives at various concentrations in HepG2, 293, NIH3T3, and HeLa cells (Figure 6). Each cell line was incubated for 48 h with increasing amounts of polymers. The results showed that PEI25KD was highly toxic in every cell line, and that PAMAM derivatives were much less toxic. This is consistent with previous reports that the increased charge density of gene delivery carriers generally produces greater cytotoxicity.[5,34] Even though PAMAM G4-His_2-Arg showed a slight cytotoxic effect in 293 and HeLa cells as the polymer concentration increased, the $His_{(1,2,3)}$-Arg peptide

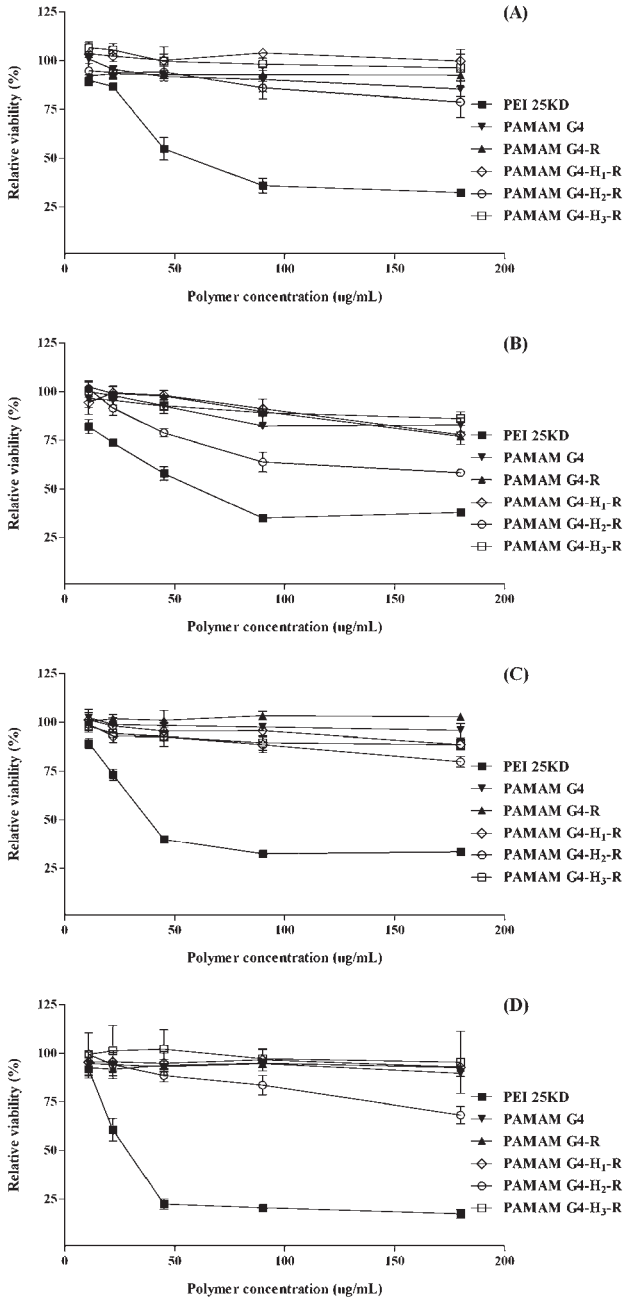

Figure 6. Cytotoxicity assay for (A) HepG2 cells, (B) 293 cells, (C) NIH3T3, and (D) HeLa cells. Each point indicates the average and standard deviation from triplicates.

conjugated PAMAM G4 derivatives displayed much lower and moderate cytotoxicity than PEI25KD at all concentration levels tested in this study.

Intracellular Distribution of Polyplexes. PAMAM G4 derivatives were complexed with Alexa Fluor 532-labeled pDNA at optimal charge ratios and transfected into HeLa cells to analyze the cellular distribution of polyplexes. After a 24 h incubation at 37 °C, the intracellular distribution of the polyplex was confirmed by confocal microscopy.

As shown in Figure 7, no signals were observed from the cell only (- pDNA/- polymer) sample group due to the lack of polymers delivering fluorescently labeled pDNA (A). Delivering

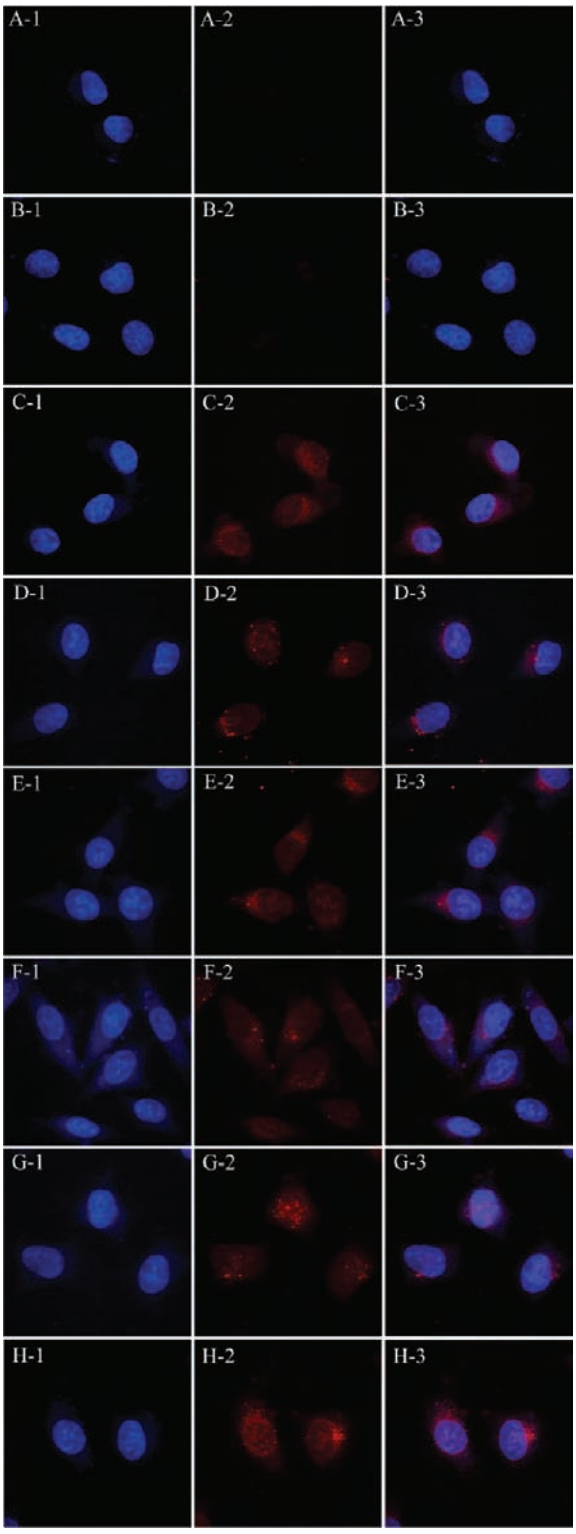

Figure 7. Confocal microscopy images. (A) HeLa cells only; (B) HeLa cells with pDNA; (C) PEI25KD/pDNA; (D) PAMAM G4/pDNA; (E) PAMAM G4-Arg/pDNA; (F) PAMAM G4-His_1-Arg/pDNA; (G) PAMAM G4-His_2-Arg/pDNA; and (H) PAMAM G4-His_3-Arg/pDNA polyplexes in HeLa cells. Bisbenzimide (Hoechst 33342) was used to stain the nucleus (blue, image 1) and Alexa 532-labeled pDNA was used to localize pDNA and polymer/pDNA complexes (red, image 2). The merged image of the respective image 1 and 2 is shown as image 3.

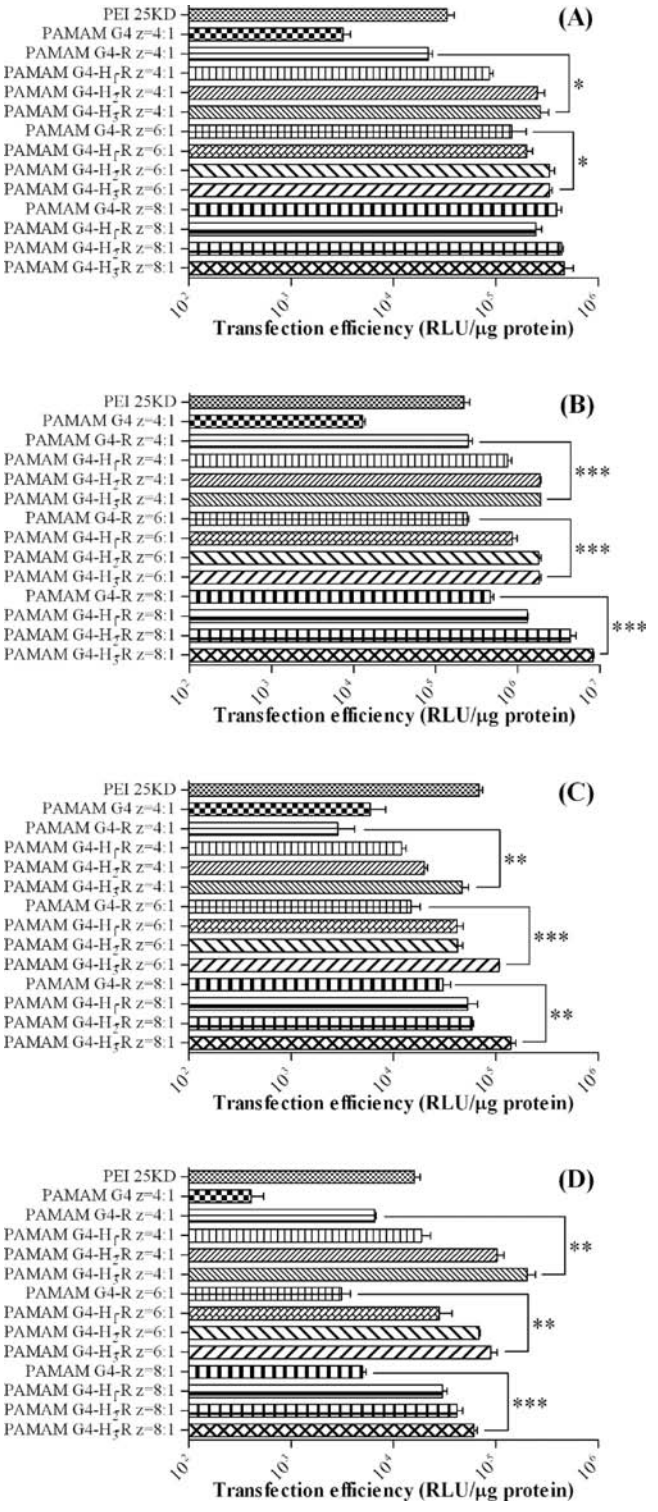

Figure 8. Transfection efficiencies of PAMAM G4 derivatives on (A) HepG2 cells, (B) 293 cells, (C) NIH3T3, and (D) HeLa cells. Data are shown as mean ± standard deviation ($n = 3$). *$p < 0.05$, **$p < 0.01$, and ***$p < 0.001$.

pDNA without polymer vectors also resulted in no pDNA signals in the cytoplasm or the nucleus (B). The PEI25KD polyplex showed a regular pattern of pDNA distribution, whereas PAMAM G4 and its derivatives showed a spot pDNA signal pattern (C, D). It was believed that PEI25KD had a high proton buffering ability, so that the polyplex could escape easily from endosome to the cytoplasm. However, PAMAM G4 and its derivatives showed much less proton buffering capacity than PEI25KD, so they localized in endosomes more than the PEI25KD polyplex. Because of these differences in proton buffering capacity, they were localized in different locations in the cells after the 24 h transfection. Interestingly, as shown in Figure 7 (F,G,H), the pDNA signal increased in both the cytoplasm and the nucleus as the histidine elongation number increased. The strongest pDNA signal was observed in three histidine units conjugated to the PAMAM G4 dendrimer (H). A more interesting point is that the pDNA signal increased inside the nucleus as the histidine elongation number increased. These results clearly indicate that inserting histidine units into PAMAM G4-Arg increased the cellular uptake and localization of polyplexes to the nucleus.

Transfection Efficiency of Different Cell Lines. HepG2, 293, NIH3T3, and HeLa cells were incubated with PAMAM G4 derivatives at various charge ratios to determine the transfection efficiency of the synthesized PAMAM G4 derivatives. Transfection efficiency was evaluated as the expressed luciferase activity divided by total cellular protein in the presence of 10% serum. PEI25KD, native PAMAM G4, and PAMAM G4-Arg were used as control reagents under optimal conditions. In general, an excess amount of polycationic polymers can condense oppositely charged DNA more compactly;[35] thus, excessive PAMAM G4 derivatives along with the polyplexes could have a positive effect on gene transfer, although the transfection efficiency may be saturated under optimum conditions. As shown in Figure 8, PAMAM G4 derivatives generally showed higher transfection efficiencies than the native PAMAM G4 dendrimer and even better than PEI25KD (N/P ratio of 7:1). Moreover, the transfection efficiency of the PAMAM G4 derivatives seemed to be dependent upon the number of histidines and the charge ratio. Interestingly, the highest transfection efficiency appeared at an N/P ratio of 4:1 in the case of HeLa cells. For HepG2, 293, and NIH3T3 cells, PAMAM G4 derivatives displayed higher gene expression levels as the number of conjugated histidines and the charge ratio increased. Interestingly, a significant increase in the gene expression level was observed in the $His_{(1,2,3)}$-Arg conjugated PAMAM G4 derivatives compared to PAMAM G4-Arg for the cell lines. The gene expression level increased up to 10-fold compared to PAMAM G4-Arg at a charge ratio of 8:1. This result indicates that the $His_{(1,2,3)}$-Arg conjugated PAMAM G4 dendrimer could improve gene transfection efficiency and suggests that the proton buffering effect of the imidazole group should improve complex durability and enhance the localization of complexes into the nucleus as well as the cytoplasm.

CONCLUSION

We synthesized PAMAM G4 derivatives with histidine and arginine residues and effectively transfected various cell lines through enhanced proton buffering capacity induced by histidine residue conjugation. Synthesized PAMAM G4 derivatives effectively condensed pDNA at a low charge ratio, and the transfection activity improved considerably when the number of histidine residues increased. Adding histidine units into the established PAMAM G4-Arg polymer vectors improved their proton buffering capacity in the pH range 3.5−6. The cytotoxicity of PAMAM derivatives was tested, and it was confirmed that they displayed relatively low cytotoxicity compared to PEI25KD in various cell lines. The confocal microscopy results revealed that PAMAM G4 derivatives effectively delivered pDNA into the cells, particularly into the nucleus.

In summary, PAMAM G4 derivatives showed remarkable transfection efficiency, low cytotoxicity, and improved proton buffering capacity and are highly promising as a new gene delivery vector system.

arginine, 122 H), 1.61 (-HCC***H₂***CH_2CH_2NH- of arginine, 122 H), 2.28 (-NCH_2C***H₂***CO- of PAMAM unit, 248H), 2.53 (-$CONHCH_2$C***H₂***N- of PAMAM unit, and –NC***H₂***C***H₂***N- of PAMAM unit), 2.70 (-$CONHCH_2$C***H₂***NH_2 of PAMAM unit and –NC***H₂***CH_2CO- of PAMAM unit), 2.84 (-$HCCH_2CH_2$C***H₂***NH- of arginine unit), 3.09 (-CONHC***H₂***CH_2N- of PAMAM unit, -$CONHCH_2$C***H₂***NH_2- of PAMAM unit and –HCC***H₂***C- of histidine unit), 3.65 (-***H***CCH_2C- of arginine unit, 63 H), 4.36 (-***H***CCH_2C- of first histidine unit, 63 H), 4.43 (-***H***$CCH_2CH_2CH_2$NH- of second histidine unit, 61 H, and -***H***CCH_2C- of third histidine unit, 61 H), 6.78 (-NHCHNC***H***CCH_2CH- of imidazole group of histidine), 7.60 (-NHC***H***NCHCCH_2CH- of imidazole group of histidine). The number of histidine and arginine residues conjugated was calculated from ^{1}H NMR data. More than 61molecules of histidine and arginine were conjugated to a single PAMAM G4 dendrimer. According to ^{1}H NMR data, 61 histidine and arginine molecules were coupled to single PAMAM G4 dendrimer (PAMAM G4-His_1-Arg). In case of PAMAM G4-His_2-Arg, 63 histidine (first and second unit) and 64 arginine molecules were conjugated to the PAMAM G4 dendrimer. Also, the spectra of PAMAM G4-His_3-Arg showed each 63 histidine molecules (first and second histidine unit) and 61 histidine, arginine molecules (third histidine and arginine molecules) were coupled with PAMAM G4 dendrimer, respectively.

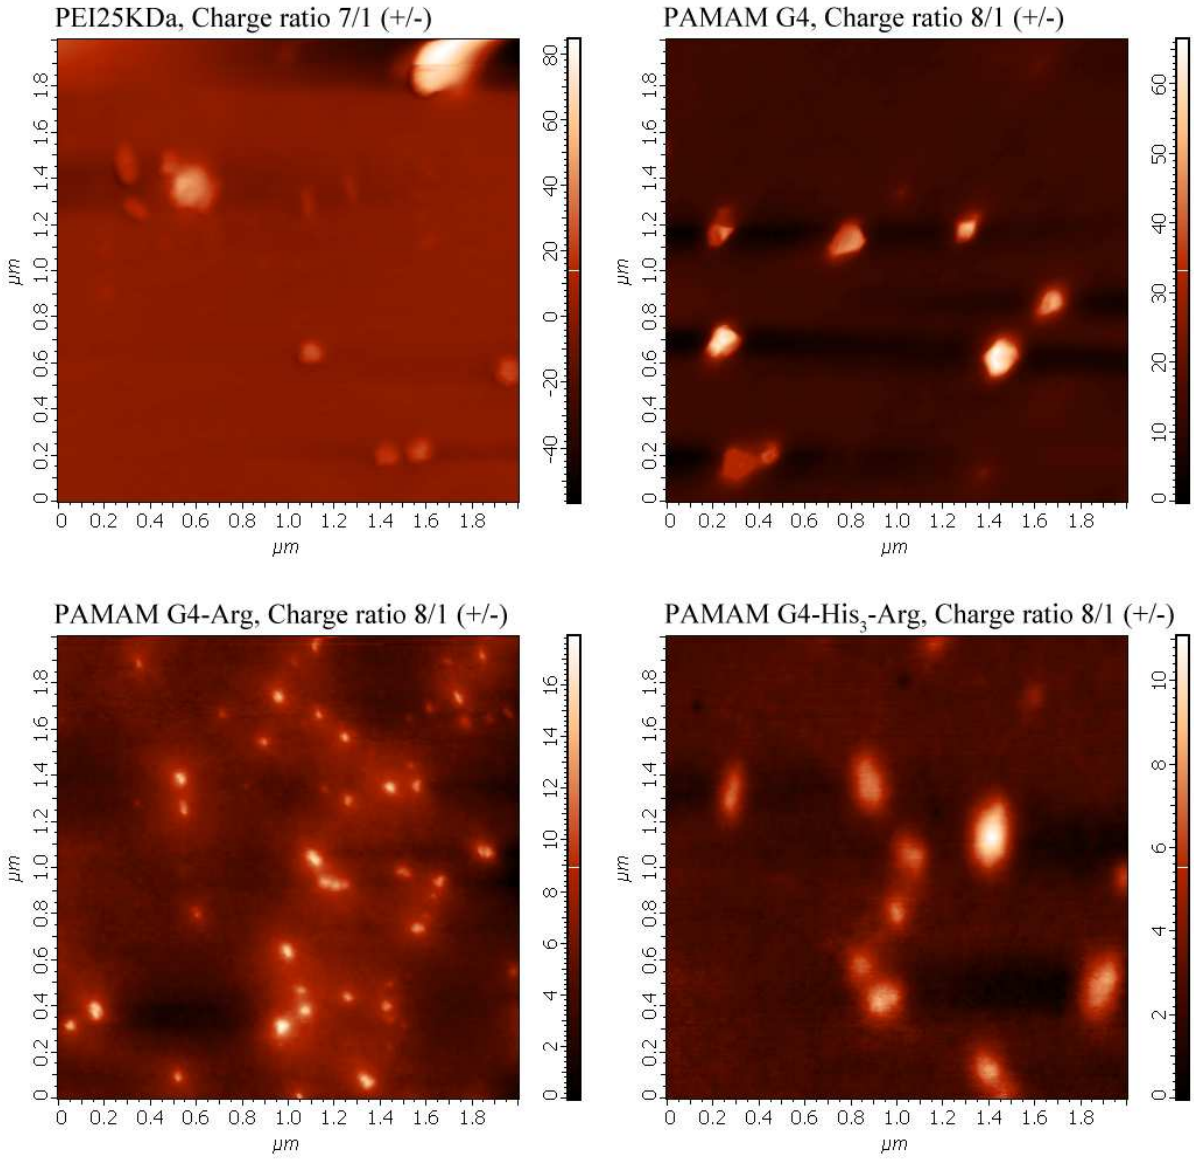

Figure. S2. Atomic force microscopy images of polymer/pDNA complexes.

Atomic force microscopy (AFM; NTEGRA-Spectra, NT-MDT, Moscow, Russia) was used to image the size and shape of the polyplex formation. Briefly, polymer/pDNA polyplexes at a charge ratio of 8:1 (except for PEI25KD, 7:1, optimal ratio) and a final pDNA concentration of 10 ng were prepared in deionized water. Polyplex solution (10 µl) was loaded onto the center of a silicon wafer, and the silicon wafer surface was dried at room temperature before taking images. AFM images were collected in tapping mode (semi-contact) at a scanning speed of 1 Hz. Images were analyzed using Nova software (Ver. 1.0.26).

Acid-Degradable Cationic Dextran Particles for the Delivery of siRNA Therapeutics

Jessica L. Cohen, Stephanie Schubert,[†] Peter R. Wich, Lina Cui, Joel A. Cohen,[‡] Justin L. Mynar, and Jean M. J. Fréchet*

College of Chemistry, University of California, Berkeley, California 94720-1460, United States

ABSTRACT: We report a new acid-sensitive, biocompatible, and biodegradable microparticulate delivery system, spermine modified acetalated-dextran (Spermine-Ac-DEX), which can be used to efficiently encapsulate siRNA. These particles demonstrated efficient gene knockdown in HeLa-*luc* cells with minimal toxicity. This knockdown was comparable to that obtained using Lipofectamine, a commercially available transfection reagent generally limited to *in vitro* use due to its high toxicity.

INTRODUCTION

RNA interference (RNAi) has drawn much attention in the field of medicine due to its potential for treating chronic diseases and genetic disorders by harnessing the endogenous RNAi pathway.[1−3] RNAi is a biological mechanism wherein double-stranded RNAs can be used to reduce expression of target proteins.[4,5] Once the RNA is present in the cytoplasm of the cell, it is shortened and processed by the RNase III enzyme, Dicer,[6] and incorporated into a protein complex called the RNA-induced silencing complex (RISC).[7] One of the two strands of the short, double-stranded RNA is cleaved, and the activated RISC (which contains the guide strand of the RNA) binds to a complementary sequence of mRNA and results in its degradation.[8] The activated RISC is capable of multiple rounds of mRNA cleavage, which propagates gene silencing.[9] Due to its potential to silence genes in a sequence-specific manner, RNAi holds promise for treating many diseases that may not otherwise be accessed with current therapeutic technology.[1]

Various approaches have been developed that allow for exploitation of the RNAi process, principally through the use of exogenous synthetic small interfering RNA (siRNA), double-stranded RNAs that are typically 19−23 base pairs in length. Synthetic siRNA can be designed to target nearly any gene in the body, and is therefore attractive for a variety of medical applications. Previous reports have demonstrated that synthetic siRNAs are capable of knocking down targets in several diseases *in vivo*, including hepatitis B virus, human papillomavirus, and ovarian cancer.[10] Despite great therapeutic potential, the clinical application of siRNA is limited by delivery problems. siRNA does not cross cellular membranes efficiently due to its relatively large size, negative charge, and hydrophilicity. In addition, siRNA is unstable under *in vivo* conditions due to rapid degradation by serum nucleases.[11] Thus, the widespread use of RNAi therapeutics for disease prevention and treatment requires the development of clinically suitable, safe, and effective delivery vehicles.[10] In order to induce effective RNAi, these vehicles must overcome a variety of extracellular and intracellular obstacles; i.e., they should provide protection against nuclease activity and facilitate internalization and intracellular trafficking of the siRNA.[12] Even though significant advances have been made in the field, the development of vehicles that can efficiently deliver RNAi therapeutics both *in vitro* and *in vivo* remains a major challenge.

Both viral and non-viral carriers have been developed for the delivery of siRNA.[12−16] Although viral vectors are very efficient, they can cause immunogenic and inflammatory responses,[17,18] which raise concerns about their safety as delivery vectors. Non-viral vectors provide opportunities for improved safety, greater flexibility, and more facile manufacturing; however, most of the existing carriers suffer from low delivery efficiencies. The most common non-viral vectors involve complexes formed between cationic lipids[19,20] or polymers[21,22] and siRNA through electrostatic interactions between the negative phosphates along the nucleic acid backbone and the positive charges displayed on the vector. In addition to low transfection efficiencies, these systems also suffer from high toxicity due to their polycationic nature and limited stability *in vivo* due to non-specific interactions with serum proteins. The limitations associated with current delivery vehicles motivate the development of novel systems for siRNA delivery that may be able to overcome these obstacles.

Among many alternatives to cationic polymers and lipids commonly used to form polyplexes/lipoplexes with genetic material,[10,23,24] particles made from biodegradable and non-toxic materials such as slow-hydrolyzing poly(lactic-*co*-glycolic acid) (PLGA),[25,26] fast-degrading polyesters (such as DEAPA-PVA-PLGA),[27]

and acid-sensitive poly(orthoesters) (POEs)[28] have been explored as *in vivo* gene delivery vectors. Another system based on acid-sensitive polyketals has also recently shown promise for delivery of siRNA both *in vitro* and *in vivo*.[29] These prior examples of particulate systems for siRNA and DNA delivery typically employ small quantities of cationic polymers[25,30] (i.e., poly(β-amino ester), PBAE, or polyethyleneimine, PEI), lipids such as DOTAP,[29] or small molecules such as spermine[26] blended with the carrier polymer to enhance loading of DNA/RNA and delivery efficiency. Formed by standard emulsion techniques, these particles combine physical entrapment of their payload with electrostatic complexation of genetic material while retaining biocompatible degradation mechanisms. However, some limitations of these systems relate to the synthetic flexibility, biocompatibility of the degradation products, and the paucity of chemical methods for the modification of the particle surface. For example, despite the promising transfection results obtained from PLGA microspheres, they still suffer from slow release rates[31] and the formation of DNA-damaging acidic by-products.[32,33]

Dextran, a homopolysaccharide of glucose, appears to be well poised for use as a polymeric carrier due to its biodegradability, wide availability, and ease of modification.[34] In addition, dextran already has a history of human use in clinical applications for plasma volume expansion and plasma substitution. The potential application of dextran for siRNA delivery has recently been demonstrated.[35−37] Previously, we described the development of a modular and tunable particle system based on acetal-modified dextran (Ac-DEX).[38,39] We have shown that Ac-DEX particles prepared by standard emulsion techniques—either water in oil (w/o) or water in oil in water (w/o/w)—have high encapsulation efficiencies for both hydrophobic small molecules[40] and high molecular weight hydrophilic cargoes,[38,39] such as proteins, and that the release rate of the encapsulated cargo was tunable.[39] These acid-degradable Ac-DEX particles were capable of delivering protein antigens to macrophages and dendritic cells. Besides their use as a successful vaccine carrier, microparticles prepared from Ac-DEX blended with a cationic polymer proved effective at delivering plasmid DNA to both phagocytic and non-phagocytic cells.[41] Although siRNA and plasmid can be applied to achieve similar functional outcomes, successful plasmid delivery carriers cannot necessarily achieve efficient siRNA delivery due to the major intrinsic structural differences and different location of action for siRNA and plasmid.[42−44] For example, reports from other groups have shown the difficulty of encapsulating the highly charged, hydrophilic, and rigid siRNA in particles by w/o/w emulsion, presumably due to leakage into the outer water phase.[45]

We now describe the preparation and preliminary evaluation of a new polymeric platform—spermine-modified Ac-DEX (spermine-Ac-DEX)—for the delivery of siRNA. The new system combines facile synthesis and biocompatibility with the additional benefit of controlled payload release sensitive to physiologically relevant acidic conditions. Acid-sensitive systems have particularly desirable characteristics, as cargo release can be triggered in response to endosomal acidification upon cellular uptake. Acid-catalyzed hydrolysis of spermine-Ac-DEX generates spermine-modified dextran, which may be able to be further metabolized by enzymes *in vivo*.[46−52]

The ability of spermine-Ac-DEX particles to overcome a variety of cellular obstacles and function as an efficient delivery vehicle for siRNA can be rationalized by its tailor-made design

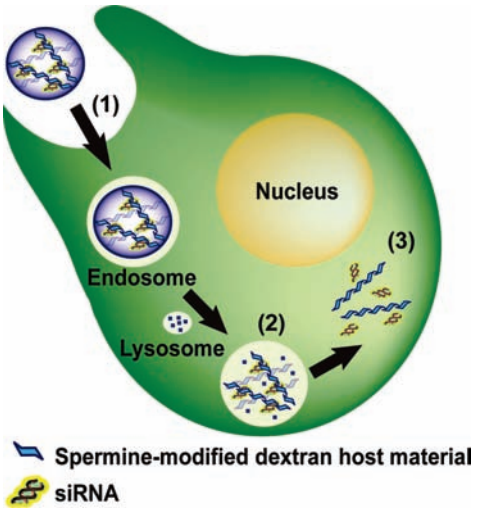

Figure 1. Particles are expected to efficiently transfect HeLa-*luc* cells due to their ability to overcome several obstacles to gene delivery. Ac-DEX particles should protect siRNA from degradation. (1) The particles are endocytosed by HeLa cells, and the vesicle is acidified upon fusion of the endosome with the lysosome. (2) Spermine Ac-DEX particles degrade in the acidic environment of the endolysosome and (3) the siRNA is released into the cytoplasm.

(Figure 1). We hypothesize that particulate formulation should provide protection of the encapsulated siRNA against chemical and enzymatic degradation. The cationic characteristics of spermine-Ac-DEX can facilitate the encapsulation of siRNA inside particles, and it may also favorably contribute to cellular uptake by enhancing interaction of the particles with negatively charged cell membranes. Once inside cells, hydrolysis of the polymer in the acidic endolysosomal compartment can allow the siRNA to be released from the particles. Endosomal escape may be achieved via the "proton sponge" effect of the amine moieties, as well as increased endosomal osmotic pressure by degradation of the spermine-Ac-DEX material. Overall, we speculate that it is the combination of protection and endolysosomal release that would be the most likely contributors to the successful delivery of siRNA using a spermine-Ac-DEX carrier.

EXPERIMENTAL PROCEDURES

General Materials and Methods. All chemicals were from Sigma-Aldrich (St. Louis, MO) unless otherwise noted. The antiluciferase siRNA (sense strand: 5′-CUU ACG CUG AGU ACU UCG A dTdT-3′) was obtained from Dharmacon (Lafayette, CO) and Silencer Negative Control #1 siRNA was purchased from Ambion (Austin, TX). Phosphate buffered saline (PBS, pH 7.4) was from Invitrogen (Carlsbad, CA). Reactions requiring anhydrous conditions were performed in flame-dried vessels and under a positive pressure of dry nitrogen. Water (dd-H_2O) for buffers and particle washing steps was purified to a resistance of 18 MΩ using a NANOpure purification system (Barnstead, USA). When used in the presence of acetal containing materials, dd-H_2O was rendered basic (pH 8) by the addition of triethylamine (TEA) (approximately 0.01%). ^{1}H NMR spectra were recorded at 400 or 500 MHz on a Bruker spectrometer. Elemental analyses were performed at the UC Berkeley Mass Spectrometry Facility. Fluorescence measurements were obtained using a Spectra Max Gemini XS plate-reading fluorimeter

(Molecular Devices, USA), usage courtesy of Prof. Carolyn Bertozzi. Absorbance measurements were obtained using a Spectra Max 190 microplate reader (Molecular Devices, USA), usage courtesy of Prof. Carolyn Bertozzi. Luminescence measurements were obtained using a GloMax 96 microplate luminometer (Promega, USA), usage courtesy of Prof. Eva Harris.

Synthesis of Spermine-Ac-DEX. *Partial Oxidation of Dextran.* Dextran (5.0 g, 30.9 mmol, M_w 9−11 000 g/mol, from *Leuconostoc mesenteroides*) was dissolved in 20 mL water. After adding sodium periodate (1.1 g, 51.4 mmol), the solution was stirred for 5 h at rt. The product was purified by dialysis of the solution against distilled water using a regenerated cellulose membrane with a MWCO of 3500 g/mol. The water was changed 5 times and the sample was lyophilized to obtain a white powder (4.2 g, 8.4 mol aldehyde functions/100 mol anhydroglucose unit, AGU). The degree of oxidation was determined colorimetrically (UV absorption at 562 nm) using a microplate reductometric bicinchoninic acid assay (Micro BCA Protein Assay Kit, Pierce, USA) according to the manufacturer's protocol and glucose monohydrate for calibration.

Synthesis of Partially Oxidized Acetalated Dextran. Acetalation of partially oxidized dextran was performed in a similar manner as described previously.[38] Briefly, 3.0 g partially oxidized dextran (18.5 mmol, 8.4 mol aldehyde functions/100 mol AGU) was modified with 2-methoxypropene (10.6 mL, 111 mmol) yielding partially oxidized acetalated dextran (4.3 g) containing 100 mol acyclic and 72.5 mol cyclic acetals/100 mol AGU. The degree of functionalization was determined by ^{1}H NMR spectroscopy in DCl/D_2O according to the method described by Broaders et al.[39] ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.40 (s, br, acetal), 3.25 (br, acetal), 3.45, 3.50−4.10, 4.90, 5.10 (br, dextran).

Synthesis of Spermine-Ac-DEX. Partially oxidized Ac-DEX (2.0 g, 12.3 mmol) was stirred with spermine (4.0 g, 19.8 mmol) in 10 mL DMSO at 50 °C for 22 h. The reduction was performed for 18 h at room temperature by adding $NaBH_4$ (2.0 g, 52.9 mmol) to the DMSO solution. The spermine modified dextran was precipitated in dd-H_2O (40 mL). The product was isolated by centrifugation at 4000*g* for 5 min, and the resulting pellet was washed thoroughly with dd-H_2O (5 × 40 mL, pH 8) by resuspension followed by centrifugation and removal of the supernatant. Residual water was removed by lyophilization, yielding spermine functionalized acetalated dextran, spermine-Ac-DEX, (1.6 g) as a white powder containing 6.6 mol spermine/100 mol AGU. The degree of functionalization was determined by elemental analysis using the nitrogen content. Anal. (spermine-Ac-DEX) C, found 55.79; H, found 8.29; N, found, 1.24. ^{1}H NMR (400 MHz, $CDCl_3$): δ 1.40 (s, br, acetal), 1.60, 1.80, 2.60, 2.65, 2.75 (br, spermine), 3.25 (br, acetal), 3.45, 3.50−4.10, 4.90, 5.10 (br, dextran).

Synthesis of PBAE. PBAE, a white solid, was synthesized by the Michael-type addition of 4,4′-trimethylenedipiperidine to 1,4-butanediol diacrylate in THF as the solvent according to the method described by Lynn et al. (GPC: M_n = 42.6 kDa, PDI = 2.78).[53]

Preparation of Particles. *Particles Encapsulating siRNA.* Ac-DEX particles containing siRNA were prepared using a double emulsion water/oil/water (w/o/w) evaporation method similar to that described previously.[38,39] Stock siRNA solutions (2.66, 5.32, or 10.64 mg/mL depending on the desired initial siRNA feed) were prepared in nuclease-free distilled water. Spermine-Ac-DEX (25 mg) was dissolved in ice-cold CH_2Cl_2 (0.5 mL). The stock siRNA solution (25 μL) was added and the mixture was sonicated for 30 s on ice using a probe sonicator (Branson Sonifier 450) with a 1/2 in. flat tip, an output setting of 5, and a duty cycle of 80%. This primary emulsion was then added to an aqueous solution of poly(vinyl alcohol) (PVA, M_w = 13 000−23 000 g/mol, 87−89% hydrolyzed) (1 mL, 3% w/w in PBS) and sonicated for an additional 30 s on ice using the same settings. The resulting double emulsion was immediately poured into a second PVA solution (5 mL, 0.3% w/w in PBS) and stirred for 3 h at rt allowing the organic solvent to evaporate. The particles were isolated by centrifugation (10 250 rpm, 30 min) and washed with PBS (25 mL) and dd-H_2O (2 × 25 mL, pH 8) by vortexing and sonication followed by centrifugation and removal of the supernatant. The washed particles were resuspended in dd-H_2O (2 mL, pH 8) and lyophilized to yield a white, fluffy solid. Yields were typically between 50% and 85% per batch based on starting polymer and siRNA mass (12.5−21 mg of particles).

Ac-DEX/PBAE Particles. Particles consisting of Ac-DEX and PBAE were made in the same manner as described above, except that unmodified Ac-DEX and 10 wt % PBAE were used instead of spermine-Ac-DEX.

Empty Particles. Particles that did not contain siRNA were made in the same manner described above, except that the aqueous buffer in the primary emulsion consisted of dd-H_2O (25 μL) and no siRNA.

Quantification of Encapsulated siRNA. Particles containing siRNA were suspended at a concentration of 10 mg/mL in a 0.3 M acetate buffer (pH 5) and incubated at 37 °C under gentle agitation for 3 d using a Thermomixer R heating block (Eppendorf). After the particles had been fully degraded, aliquots were taken and analyzed for siRNA content using the Quant-iT Picogreen dsDNA assay (Molecular Probes) according to the manufacturer's instructions. Empty Ac-DEX particles were degraded in a similar fashion and used to determine background fluorescence. For this experiment, all solutions included heparin at 10 mg/mL to disrupt electrostatic interactions between blend polymers and siRNA to enable quantification. The results were compared to a standard curve and the mass of siRNA encapsulated was calculated. Fluorescence was measured using a SpectraMax Gemini XS microplate reader (Molecular Devices, Sunnyvale, CA, ex. 480 nm, em. 520 nm).

Zeta-Potential Analysis. Zeta-potentials of particles were measured using a Nano ZS ZetaSizer (Malvern Instruments, UK) at 25 °C after suspending particles in HEPES buffer (5 mM, pH 7.4) at 0.1 mg/mL. Data shown represent the average zeta-potential ± standard deviation of distributions of five sequential measurements.

Characterization of Particle Size by Scanning Electron Microscopy (SEM). Particles were suspended in dd-H_2O (pH 8) at a concentration of 0.3 mg/mL and the resulting dispersions were dripped onto silicon wafers. After 15 min, the water was wicked away using tissue paper and the samples were further dried under a stream of N_2 gas. The particles were then sputter-coated with a 2 nm layer of a palladium/gold alloy and imaged using a scanning electron microscope (S5000, Hitachi). The particle diameter and size distribution of the particles were determined by measuring 100 particles and analyzing the data using *Excel*. These micrographs were also used to assess particle morphology.

pH-Dependent Degradation of Ac-DEX Particles. Empty Ac-DEX particles were suspended in triplicate at a concentration of 1 mg/mL in either a 0.3 M acetate buffer (pH 5.0) or PBS (pH 7.4) and incubated at 37 °C under gentle agitation using a Thermomixer R heating block (Eppendorf). At various time

points, 50 μL aliquots were removed, centrifuged at 14 000*g* for 4 min to pellet out insoluble materials, and the supernatant was stored at −20 °C. The collected supernatant samples were analyzed for the presence of reducing polysaccharides using a microplate reductometric bicinchoninic acid based assay (UV absorption at 562 nm) according to the manufacturer's protocol (Micro BCA Protein Assay Kit, Pierce, USA). The curve was made by applying a Boltzmann fit.

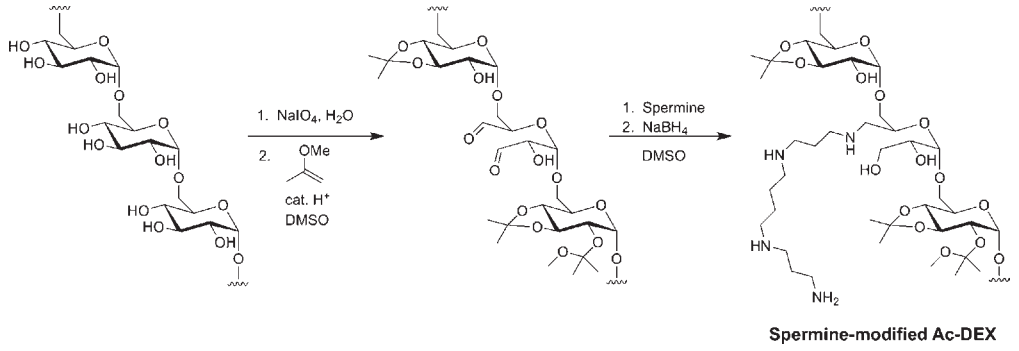
pH-Dependent Release of siRNA from Ac-DEX Particles. This experiment was performed essentially in the same manner as above except siRNA-loaded particles were used instead of empty particles. The quantity of siRNA in the supernatant samples was determined by using the Quant-iT Picogreen dsDNA assay (Molecular Probes) according to the manufacturer's instructions. The amount of siRNA in each sample was calculated by fitting the emission to a calibration curve using the Quant-iT Picogreen dsDNA assay (Molecular Probes). For this experiment, all solutions included heparin at 12.5 mg/mL to disrupt electrostatic interactions between blend polymers and siRNA to enable quantification. The curve was made by applying a Boltzmann fit.

Cell Lines and Culture. HeLa cell lines stably expressing firefly luciferase (HeLa-*luc*) were maintained in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% (v/v) fetal bovine serum (FBS), 1% GlutaMAX, and 500 μg/mL Zeocin (all from Invitrogen except the serum, which was from Hyclone (Logan, UT)). Cell incubations were performed in a water-jacketed 37 °C/5% CO_2 incubator.

***In Vitro* siRNA Transfection Assay.** HeLa-*luc* cells were seeded (15 000 cells/well) into each well of a 96-well clear tissue culture plate (Costar, Corning, NY) and allowed to attach overnight in growth medium. Growth medium was composed of DMEM (with phenol red), 10% FBS, and 1% GlutaMAX. Particle samples (encapsulating either luciferase siRNA or control siRNA) were prepared in culture medium (without antibiotics) by alternately vortexing and sonicating in a Branson 2510 water bath for 20 s to generate homogeneous suspensions. The samples were then serially diluted in medium to give the indicated particle concentrations or equivalent siRNA doses. Existing medium was replaced with 100 μL of each particle dilution (2.19−35 pmol siRNA) in quadruple wells. The cells were allowed to grow for an additional 48 h before being analyzed for gene expression. Lipofectamine 2000 (Invitrogen, Carlsbad, CA) was used as a positive control for siRNA delivery and was prepared according to the manufacturer's instructions. Complexes containing equivalent doses of siRNA to particles were prepared by mixing Lipofectamine 2000 and siRNA (3:5:1 ratio). As negative controls, both equivalent doses of free siRNA in medium and medium alone were used.

After 48 h, the cells were washed with PBS (containing Mg^{2+} and Ca^{2+}, 3 × 100 μL), Glo Lysis Buffer (120 μL, Promega, Madison, WI) was added to each well, and the plate was vortexed at rt for 20 min. Samples from each well (100 μL) were transferred to the wells of a white 96-well tissue culture plate (Corning, Lowell, MA). Steady-Glo luciferase assay reagent (Promega) was reconstituted according to the manufacturer's instructions and injected into each well in series (100 μL/well) using a GloMax 96 microplate luminometer (Promega). After a 10 s post-injection delay, each well was read with a 2 s integration time.

Total Protein Assay. Cells treated identically and in parallel with transfection assays were tested on a second 96-well plate. After washing, the cells were lysed with M-PER Mammalian Protein Extraction Reagent (50 μL/well, Pierce, Rockford, IL) by incubating for 10 min at rt. PBS (50 μL/well) was then added, and the plate was briefly vortexed. Samples from each well (50 μL) were transferred to a black 96-well plate (Corning) already containing PBS (100 μL/well). A solution of 3 mg/mL fluorescamine in acetone (50 μL) was added to each well and mixed well using a multichannel pipet. After 5 min, fluorescence was measured using a SpectraMax Gemini XS reader (ex. 400 nm, em. 460 nm). Protein concentrations were determined using bovine serum albumin as a standard. Relative light units (RLU) from the luminometer were normalized to the total mass of cellular protein. The resulting data (RLU/mg of protein) are given as a mean ± standard deviation of four independent measurements. Percentage knockdown was calculated by comparison of treated cells to untreated cells. The data was compared to the knockdown of cells treated with particles loaded with control siRNA or control siRNA/Lipofectamine complexes.



Viability Assay. Cells treated identically and in parallel with transfection assays were tested on a third 96-well plate. A 3.0 mg/mL solution of MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide) in medium (40 μL) was added directly to each well, and the plate was incubated for an additional 30 min. The medium was then replaced with DMSO (200 μL/well), 100 μL of which was transferred to another clear-bottom 96-well assay plate (Pro-Bind, Falcon) containing 100 μL DMSO and 25 μL of glycine buffer (0.1 M glycine, 0.1 M NaCl, pH 10.5) per well. The absorbances at 570 nm were measured using a SpectraMax 190 reader (Molecular Devices). Cell viability was normalized to the absorbance measured from untreated cells. Data are represented as a mean ± standard deviation of four measurements.

RESULTS AND DISCUSSION

Synthesis of Spermine-Modified Ac-DEX. Ac-DEX has several characteristics that make it well suited for the delivery of bioactive cargoes. Although this system has been used to successfully deliver protein antigens, adjuvants, and small molecule agents, the neutrally charged polymer cannot efficiently encapsulate siRNA. Taking advantage of the blend approach described above, we have recently reported the preparation of particles encapsulating plasmid DNA by formulating Ac-DEX with small amounts of the cationic polymer PBAE.[41] These particles were able to efficiently transfect both phagocytic and non-phagocytic cells *in vitro*. Inspired by this work, we tried to prepare Ac-DEX particles encapsulating siRNA by blending with either small polyamines or cationic polymers. While high loading and efficient delivery of plasmid DNA was achieved by blending Ac-DEX with PBAE, attempts to prepare siRNA-loaded particles by the same method only afforded particles with low loading and low encapsulation efficiency.

Domb and co-workers have reported the synthesis of various oligoamine polysaccharide conjugates for use in gene delivery.[54] They found that, of 300 different polycations prepared, only a few were active in transfecting cells. Dextran-spermine displayed especially high transfection efficiency, which they attributed to unique complexation properties between DNA and the grafted spermine moieties.[54] Dextran-spermine, and derivatives thereof, have shown high transfection of plasmid DNA both *in vitro* and *in vivo*.[55,56] Combining this pioneering work with the unique characteristics of our Ac-DEX, we have modified Ac-DEX with spermine for use in siRNA delivery.

Scheme 1. Schematic Illustration of the Synthesis of Spermine-Modified Ac-DEX

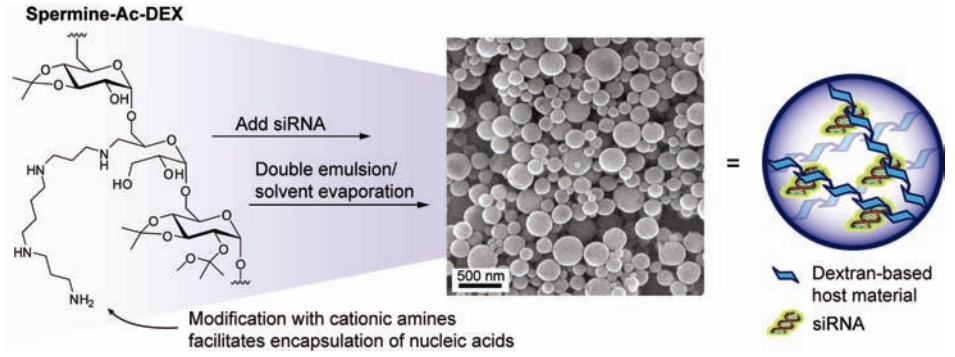


Figure 2. Preparation of spermine-modified Ac-DEX particles encapsulating siRNA showing a representative scanning electron micrograph of particles (scale bar = 500 nm) (center) and a cartoon illustration of siRNA-loaded particles (right).

Spermine-Ac-DEX was prepared by using reductive amination chemistry for the conjugation of spermine to Ac-DEX (Scheme 1). To increase the number of available aldehyde functionalization sites beyond the reducing chain ends of the polysaccharide, dextran was first lightly oxidized with sodium periodate, thus increasing significantly its aldehyde content[57] as evaluated by a reductometric bicinchoninic acid assay (BCA assay). Using this method, we settled on a loading of 8.4 aldehyde functions per 100 anhydroglucose units (AGU). Reaction of the remaining hydroxyl groups with 2-methoxypropene afforded partially oxidized Ac-DEX, an acid-sensitive, hydrophobic polymer that can be easily processed into microparticles. Finally, amine modification was performed between spermine and aldehyde-containing-Ac-DEX using sodium borohydride as the reducing agent. The amount of spermine conjugated to the dextran, calculated from the nitrogen content (%N) as determined by elemental analysis, averaged 6.6 spermine units per 100 AGU.

Preparation and Characterization of Spermine-Ac-DEX Particles. Spermine-Ac-DEX particles encapsulating siRNA were prepared via a standard double-emulsion technique (Figure 2). Particles prepared from unmodified Ac-DEX and Ac-DEX blended with 10 wt % PBAE, a formulation previously used for plasmid DNA, were also made for comparison purposes. The particles were visualized by scanning electron microscopy (SEM) to determine the average particle size and morphology. All particles were found to be spherical in shape with diameters in the range of 180 to 230 nm in the dry state, irrespective of particle formulation. The surface charge of the particles was determined by zeta-potential measurements. Unmodified Ac-DEX particles have a slightly negative zeta-potential due to the encapsulated siRNA. Blending the polymer with PBAE made the surface charge less negative owing to the cationic nature of the polymer, while the surface charge of spermine-Ac-DEX particles was positive. As expected, the surface charge decreased with increasing loadings of siRNA but remained positive for all particle formulations. Various particle characteristics are known to influence particle behavior *in vivo*, including particle size, shape, and surface charge.[58] When administered intravenously, positively charged particles are susceptible to opsonization by negatively charged serum proteins and clearance by cells of the reticuloendothelial system (RES). While a positive surface charge might be disadvantageous for delivery into the bloodstream, pulmonary delivery represents an attractive alternative delivery strategy for which there is precedent of success utilizing positively charged particles.[59,60] Indeed, we envision utilizing aerosolization for the delivery of our particles to the lungs.

The siRNA loading and loading efficiencies were determined by degrading a sample of particles under acidic conditions and analyzing the siRNA concentration using a Picogreen dsDNA assay (Table 1). The siRNA loading efficiency for unmodified Ac-DEX particles was low (5%), as expected based on previous reports with other particle systems, such as PLGA.[26] Blend particles formulated from Ac-DEX and a cationic polymer poly(β-amino ester) (PBAE) also showed low encapsulation efficiency for siRNA (7%), much lower than the plasmid encapsulation achieved with a similar particle formulation. This lower encapsulation efficiency for siRNA as compared to plasmid DNA may be due to the fact that siRNA has a lower molar mass than plasmid DNA (approximately 250× less) and, thus, may be

Table 1. Characterization of Particle Formulations

particle formulation (siRNA, feed)[a]	diameter[b,c] [nm]	zeta-potential[b] [mV]	siRNA loading[b,d] [μg mg^{-1}]	loading efficiency[b] (%)
Ac-DEX (Luc, 5)	230 ± 80	−5.5 ± 0.42	0.26	5
Ac-DEX/10% PBAE (Luc, 5)	N.D.	−3.4 ± 0.44	0.34	7
Spermine Ac-DEX (Luc, 10)	178 ± 76	9.2 ± 0.69	7.95	76[e]
Spermine Ac-DEX (Luc, 5)	229 ± 59	16.2 ± 0.58	4.70	91
Spermine Ac-DEX (Luc, 2.5)	185 ± 65	19.7 ± 0.63	2.28	95[f]
Spermine Ac-DEX (Control, 5)	195 ± 45	16.1 ± 0.71	5.11	98

[a] Luc − antiluciferase siRNA, Control − Silencer Negative Control #1 siRNA, Feed − amount of siRNA used in particle preparation, μg of siRNA per mg of polymer. [b] Characterized as described in the main text. [c] Some particle aggregation was observed upon resuspension following lyophilization. The mean particle diameter determined by light scattering for Spermine Ac-DEX (Luc, 5) and Spermine Ac-DEX (Control, 5) was 2.71 ± 1.54 μm and 6.45 ± 2.47 μm, respectively (Horiba Partica LA-950, Horiba Scientific). [d] siRNA loading in μg of siRNA per mg of particles (100% efficiency ≈ 5.0 μg of siRNA per mg of particles). A loading of 5 μg of siRNA per mg of particles corresponds to an N/P ratio of approximately 100. [e] 100% efficiency ≈ 10 μg of siRNA per mg of particles. [f] 100% efficiency ≈ 2.5 μg of siRNA per mg of particles. N.D. = not determined.

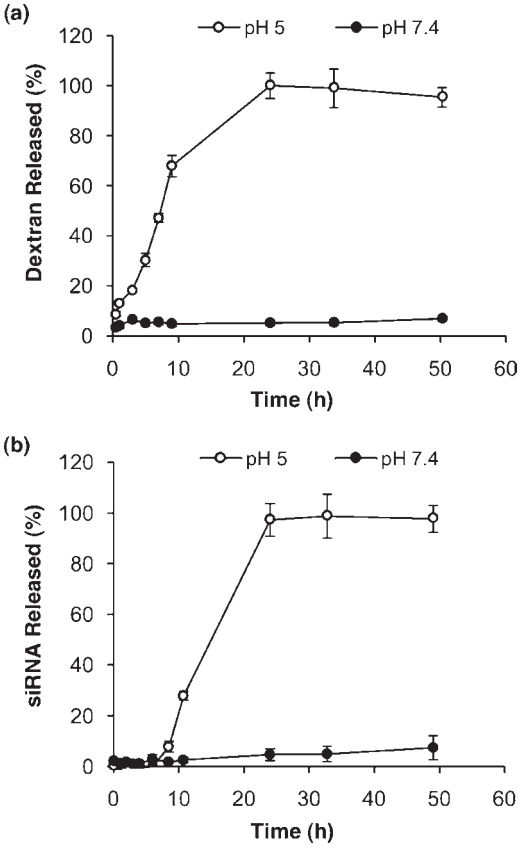

Figure 3. (a) Degradation of particles when incubated at pH 7.4 (black circles) and pH 5 (white circles), as determined by analysis of released soluble dextran. (b) Release of siRNA from spermine Ac-DEX particles when incubated at pH 7.4 (black circles) or pH 5 (white circles). Data represent the mean ± standard deviation of triplicate measurements.

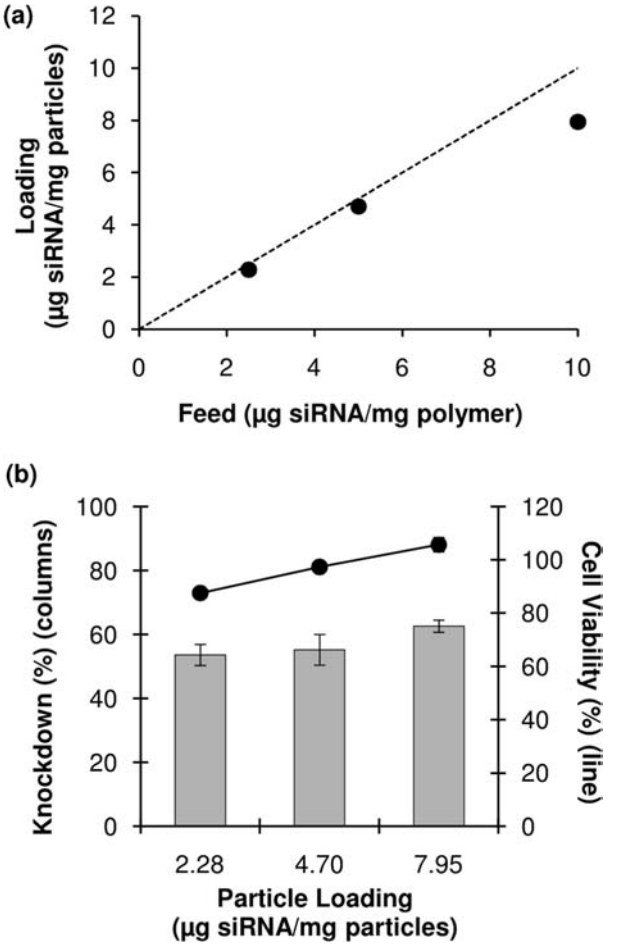

Figure 4. Optimized siRNA loading in particles and its effect on luciferase knockdown. (a) siRNA loading in particles compared with the feed amount of siRNA used in particle synthesis. Dashed diagonal line represents 100% loading efficiency. (b) Knockdown of luciferase activity with varying siRNA loadings. HeLa-*luc* cells were treated with particle doses equivalent to 17.2 pmol siRNA/well. Results were compared to untreated cells and the percentage knockdown of luciferase expression was calculated. Results (columns) are combined with results from a concurrently performed cytotoxicity assay (closed circles and line). Knockdown correlates with siRNA concentration, not particle loading.

more able to diffuse through the condensing polymer during the emulsion process, resulting in reduced loading efficiency.[61] Improved loading efficiencies (75−98%) were obtained for particles prepared from spermine-Ac-DEX. This loading compares favorably with other particle formulations, such as PLGA blended with spermidine for which 56% of the siRNA was encapsulated.[26] In contrast to previously reported particulate delivery systems, however, particles prepared using spermine-Ac-DEX did not require blending of a cationic material with the polymer due to the ability of the polymer to electrostatically interact with siRNA.

dx.doi.org/10.1021/bc100542r |*Bioconjugate Chem.* 2011, 22, 1056–1065

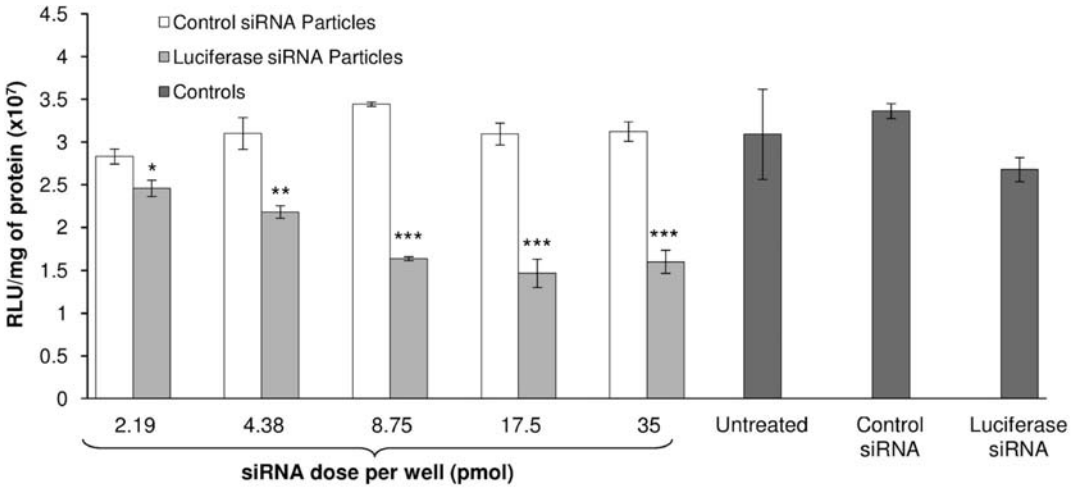

Figure 5. Spermine Ac-DEX particles can efficiently deliver siRNA to HeLa-*luc* cells. *In vitro* transfection of HeLa-*luc* cells with siRNA-loaded spermine Ac-DEX particles. HeLa-*luc* cells were treated with particles encapsulating either luciferase siRNA or control siRNA at various concentrations. Relative light units (RLU) from the luminometer were normalized to the total mass of cellular protein determined from a fluorescamine assay. Data represent the mean ± standard deviation of quadruplicate measurements. Statistical difference was performed with Student's *t*-test between untreated cells and each treatment group: $p < 0.05$ were marked with *, $p < 0.01$ with **, and $p < 0.001$ with ***.

A significant limitation of other commonly used particle delivery systems is their lack of ability to tune the release rate of the encapsulated cargo. Ac-DEX particles are designed to be relatively stable under physiological conditions (pH 7.4) but degrade under the mildly acidic conditions typically found in the lysosome (pH 5.0−5.5), thus allowing for the selective release of the therapeutic agent once inside the cell. We have shown that the rate of microparticle degradation can be easily varied by controlling the type of acetals (i.e., cyclic vs acyclic) formed on the dextran.[39] To determine the degradation rate of spermine-Ac-DEX particles, empty particles were incubated at 37 °C at either pH 5.0 or pH 7.4 and monitored for the release of soluble dextran (Figure 3a). No soluble dextran was detected after 48 h for the particles incubated at pH 7.4. In contrast, particles incubated in pH 5.0 buffer showed continuous release of dextran in the first 24 h at 37 °C, with a degradation half-life of 8 h. We also monitored the release of siRNA from the particles at pH 5.0 and pH 7.4 to determine if the release occurred in a pH-controlled manner (Figure 3b). Little or no release was observed at pH 7.4 after 48 h, while continuous release of siRNA was observed over 24 h at pH 5.0.

To study siRNA loading, three differently loaded batches of spermine-Ac-DEX particles encapsulating luciferase siRNA were prepared. The feed values for these particles were 2.5, 5.0, and 10 μg of siRNA per mg of polymer, respectively. Following preparation, the siRNA loading of the particles was quantified as described above (Figure 4a). Loadings of up to 8.0 μg of siRNA per mg of particle were achieved and the loading efficiency was above 75% for all particle batches. Efficient loading of siRNA into spermine-Ac-DEX particles is important because of the high cost of siRNA.

***In Vitro* Analysis of siRNA Delivery to HeLa Cells.** To test the transfection efficiency of spermine-Ac-DEX particles *in vitro*, we chose to knockdown a model reporter protein, firefly luciferase. HeLa cells that stably express firefly luciferase (HeLa-*luc* cells) were used as a model cell line. A more effective delivery system will lead to more cytosolic siRNA and luciferase mRNA cleavage, and thus a lower expression of luciferase protein. Firefly luciferase catalyzes the mono-oxygenation of luciferin, and during this process, a photon of light is produced. Thus, reduced expression of luciferase will result in the generation of fewer photons when the cells are incubated with the enzyme substrate.

We were interested in determining if particle loading or concentration influences the delivery efficiency of siRNA-loaded particles. Differentially loaded particles were prepared and HeLa-*luc* cells were incubated with particle doses equivalent to 17.2 pmol of siRNA per well. All of the particles could reduce luciferase expression of the cells (approximately 55−60% compared to untreated cells) with low toxicity (greater than 85% viability) (Figure 4b). The luciferase expression was comparable for all three batches of particles indicating that the particle loading and concentration within the tested range have a minimal impact on the overall performance, and the knockdown resulted from successful delivery of siRNA.

To determine if the knockdown was dose-dependent, HeLa-*luc* cells were incubated with varying siRNA doses for 48 h and analyzed for the expression of luciferase. As shown in Figure 5, spermine-Ac-DEX particles containing luciferase-specific siRNA efficiently knock down luciferase expression at all siRNA concentrations tested. Transfection with luciferase siRNA loaded spermine-Ac-DEX particles resulted in significant gene silencing (up to 60% knockdown compared with untreated cells). In comparison, treatment of cells with free siRNA did not affect the luciferase expression, indicating the importance of encapsulation of siRNA in particles. The extent of gene silencing depends on the amount of siRNA incubated with the cells (Figure 5). Treating cells with lower particle concentrations, and thus less siRNA, resulted in reduced knockdown. The optimal knockdown was obtained with the three highest siRNA dosages tested (8.75, 17.5, and 35 pmol of siRNA). This silencing effect was sequence specific as spermine-Ac-DEX particles loaded with a non-specific siRNA sequence (Silencer Negative control #1 siRNA) did not result in obvious reduction of luciferase expression. Importantly, there was no significant cytotoxicity associated with intracellular accumulation of spermine-Ac-DEX particles. MTT assay of cells incubated with particles showed greater than 80% cell viability for all particle concentrations tested (Figure 6).

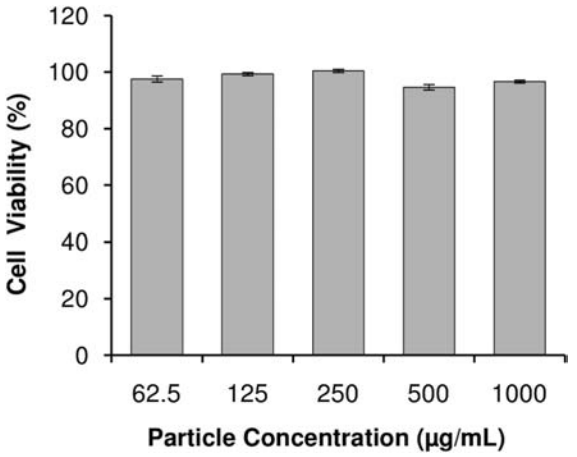

Figure 6. Spermine Ac-DEX particles are nontoxic at concentrations up to 1 mg/mL. MTT assay was used to measure cell viability compared with untreated cells. Data represent the mean ± standard deviation of quadruplicate measurements.

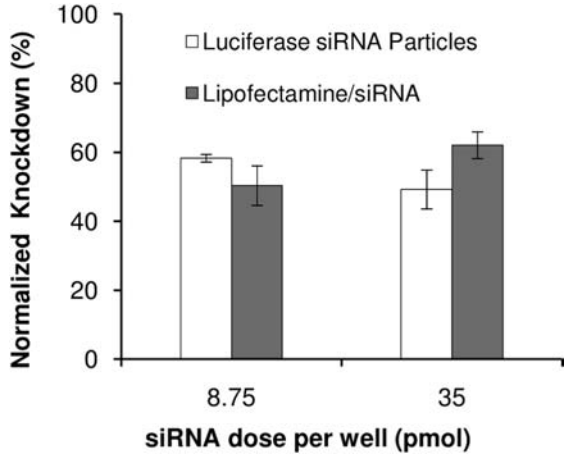

Figure 7. Spermine Ac-DEX particles show comparable activity compared with Lipofectamine 2000. Knockdown was normalized to the data from the cells treated with the control siRNA particles or complexes. Data represent the mean ± standard deviation.

Lipofectamine 2000, a commercially available cationic lipid-based reagent, was used as a positive control in the transfection experiment. This reagent is commonly used for *in vitro* transfection,[62] but it faces several obstacles for clinical translation.[63] Lipofectamine complexes with the luciferase-targeting siRNA as well as with the control siRNA were prepared so that the dose of siRNA would match that used with two of the particle concentrations tested (35 pmol siRNA per well and 8.75 pmol siRNA per well). We observed some non-specific reduction of luciferase expression using Lipofectamine 2000, most likely due to slight toxicity of the complexes. Thus, the knockdown was normalized to the data from the cells treated with the control siRNA complexes. The knockdown obtained with the spermine-Ac-DEX particles was comparable to that obtained with Lipofectamine 2000 at both siRNA doses tested (Figure 7). Due to their ability to provide efficient siRNA delivery with reduced cytotoxicity (97% cell viability for spermine-Ac-DEX particles compared to 75% for Lipofectamine), spermine-Ac-DEX particles represent an attractive delivery system that may offer several advantages over previously reported materials for siRNA delivery.

CONCLUSION

In summary, spermine-Ac-DEX particles represent a novel delivery vehicle which can efficiently deliver siRNA to cancer cells with minimal toxicity. Spermine-Ac-DEX combines the attractive properties of cationic polymers with those of polymeric particles affording a material that is safe and effective for gene delivery. Spermine modification of Ac-DEX facilitated the preparation of particles capable of encapsulating siRNA with high loading efficiency. *In vitro* evaluation demonstrated that the particles are capable of knocking down luciferase expression in HeLa-*luc* cells in a dose-dependent manner with low cytotoxicity. In comparison to previously reported gene delivery materials, spermine-Ac-DEX shows attractive new transfection and biodegradability features, and in addition can be easily modified[64] (for example, with peptide targeting ligands). Due to its acid-sensitivity, spermine-Ac-DEX allows for the selective release of siRNA after cellular internalization, with potential tunability of cargo release rate. Thus, spermine-Ac-DEX expands the potential application of Ac-DEX based particles and represents a promising vehicle for siRNA delivery. Future studies will explore the feasibility of using these particles to regulate protein expression *in vivo*.

ACKNOWLEDGMENT

This project has been funded in part with Federal funds from the National Heart, Lung, and Blood Institute, National Institutes of Health, Department of Health and Human Services, under Contract No. HHSN268201000043C, and in part through the Fréchet "various gifts" fund for the support of research in new materials. We thank Ann Fischer and Michelle Yasukawa for help with cell culture, Dr. Peter Friebe and Dr. Eva Harris for assistance with and the use of their luminescence plate reader, and Dr. Chris Contag for kindly providing the HeLa-*luc* cell line. S. Schubert gratefully acknowledges the Deutsche Forschungsgemeinschaft (DFG) and P. R. Wich thanks the Alexander von Humboldt Foundation (AvH) for funding.

Supporting Information

ABSTRACT: Poly(vinyl alcohol) microcapsules have been tailored as carriers to deliver camptothecin, an anticancer drug poorly soluble in water. The capsules have been reacted with a chitosan−folate complex in order to selectively target cancer cells overexpressing the folic acid receptor. Microcapsules decorated with the chitosan−folate complex have been characterized in their uptake and release of camptothecin, following the absorption band at λ = 370 nm diagnostic of the drug molecule. The selectivity of chitosan−folate microcapsules in targeting cancer cells has been demonstrated by fluorescence microscopy using HeLa cells, overexpressing the folate receptor and NIH3t3 fibroblasts as a negative control. The chitosan−folate microcapsules loaded with camptothecin significantly reduce the proliferation of HeLa tumor cells, while they have a negligible effect on fibroblasts. This work demonstrates that the chitosan−folate microcapsules represent a promising system to selectively target hydrophobic drugs, such as camptothecin, to tumor cells.

INTRODUCTION

Camptothecin (CPT) and its derivatives are chemical poisons that specifically target topoisomerase I, forming a stable ternary complex with the enzyme and DNA, inhibiting the unknotting process that is associated with replication and transcription.[1−3] These drugs are used in the treatment of ovarian carcinoma[4] (the fifth leading cause of cancer deaths in women) and in the treatment of small-cell lung cancer (SCLC) recurrent disease, which is among the most lethal malignancies.[5,6] Unfortunately, such chemical agents display a high degree of toxicity also against normal tissues that show enhanced proliferation rates, such as the bone marrow, gastrointestinal tract, and hair follicles.[7,8] Several systems have been devised to better deliver CPT, as those based on lipid nanoparticles,[9,10] dendrimers,[11] solid lipid nanoparticles,[12] and perfluorocarbon nanoemulsions,[13] but the main problem remains the selectivity toward tumor cells. Various approaches have been used to selectively target drugs against the tumor[14−16] such as the use of monoclonal antibodies,[17] or systems able to sense the changes in temperature and redox signals,[18] pH,[19] or membrane potential between normal cells and cancer cells, and similar strategies have been recently applied for the transport of CPT.[20,21] A promising strategy concerns the use of ligands specific for membrane receptors differentially expressed on pathological cells.[22,23]

Folate receptors (FR) are vastly overexpressed in a wide variety of human tumors, including ovarian, endometrial, colorectal, breast, lung, renal cell carcinomas, brain metastases derived from epithelial cancers, and neuroendocrine carcinomas, but rarely are found on normal cell surface . Folate (FA) has been conjugated to many polymers, such as polyethylenimine,[24] poly(L-lysine),[25] poly(ethylene glycol), and chitosan,[26] to give complexes that can be internalized by cells through a FR-mediated endocytic mechanism.[27] Among the various polymers, chitosan displays important useful properties being biodegradable and biocompatible since it can be degraded by lysozymes into *N*-acetyl-glucosamine, that is subsequently excreted as carbon dioxide via the glycoprotein synthetic pathway.[26] For this reason, chitosan has been widely used for different pharmaceutical and medical applications[28] and has also been used for gene complexation.[29−32] The delivery systems made by folate-conjugated polymers increase either the intracellular uptake of proteins or the transfection rate of DNA compared with unmodified polymer delivery systems.[33,34]

Poly(vinyl alcohol) (PVA) is a water-soluble and injectable polymer, which can be used as the basis for the construction of various structures. PVA has been recently used to produce microbubbles, air-filled biocompatible spherical structures that can be used as novel polymer based ultrasound contrast agents

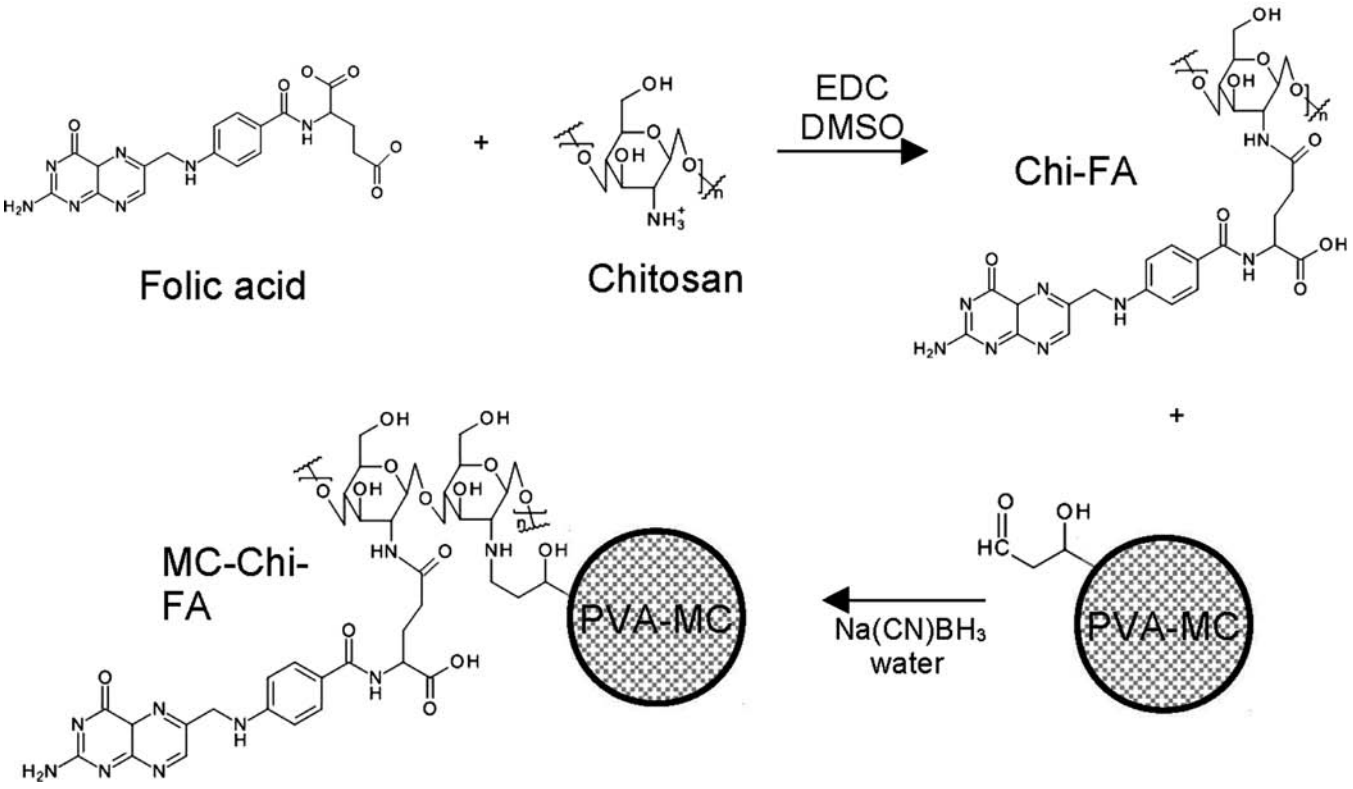

Figure 1. General scheme for the synthesis of chitosan−folate modified microcapsules (MC-Chi-FA). The chitosan−folate (Chi-FA) derivative is obtained by reacting chitosan and folate in DMSO using EDC to activate the COOH folate groups. Chi-FA is linked to MC using a reductive amination procedure.

(UCA),[35] as well as other already commercially available enhancers for echographic investigations.[36] In the presence of ethanol, the air present in PVA microbubbles is replaced by the solvent, giving rise to microcapsules (MC), that retain the spherical shape, with a mean diameter ranging from 3 to 5 μm depending on the preparations.[37] They are versatile and biocompatible microstructures whose surface has free OH groups and reactive aldehydes that can be used to functionalize them with different molecules.[37]

In this work, folic acid has been bound on a flexible arm of chitosan, which has then been conjugated to the PVA microcapsules (Figure 1), in order to be specifically directed against tumor cells of epithelial origin such as the HeLa cells. The loading and release of the antitumor drug CPT has been investigated, in both concentration and rate, for chitosan and chitosan-folate modified and unmodified microcapsules, and the specific interaction with tumor cells has been assayed by fluorescence microscopy. The results indicate that the chitosan−folate modified microcapsules specifically target tumor cells and strongly reduce their proliferation, while having a negligible effect on control cells, suggesting that they can represent an interesting system to be taken in consideration toward applications of targeted delivery.

MATERIALS AND METHODS

Materials. All solvents and reagents were of analytical grade and were used as received. Poly vinyl alcohol (PVA) was obtained from Sigma Aldrich. Number average molecular weight determined by membrane osmometry was 30 000 (5000 g/mol). Weight average molecular weight, determined by static light scattering, was 70 000 (10 000 g/mol). Low molecular weight (50 kDa) chitosan, 75−85% deacetylated, rhodamine-β-isothiocyanate, (*S*)-(+)-camptothecin, 95% HPLC, Triton X-100, folic acid, and dimethyl sulfoxide (DMSO) were Sigma products. Sodium periodate, and inorganic acids and bases, used for telechelic PVA preparation and microballoon synthesis and modifications, were RPE products from Carlo Erba. Cell culture media were obtained from Gibco. Alexa-488-conjugated phalloidin was obtained from Molecular Probes.

Instruments. High-resolution ^{1}H NMR spectra were recorded on a Digital NMR Spectrospin AVANCE 300, Bruker. Chitosan and chitosan−folate 3 mg/mL are dissolved in D_2O with 3% v/v CD_3COOD solution, using tetramethylsilane (TMS) as the internal standard. The release kinetics of the drug were performed using Perkin-Elmer Lambda 2 UV/vis double beam spectrophotometer. Fluorescence microscopy images were obtained with the DeltaVision system (Applied Precision, Washington, USA) equipped with an Olympus inverted microscope IX 70. The image workstation includes *SoftWoRx* software for digital image acquisition, deconvolution, and optical sectioning.

Synthesis of PVA-Coated Microbubbles and Conversion into Microcapsules. Synthesis of telechelic PVA was previously described.[38,39] Stable (air-filled) PVA-coated microbubbles were prepared by cross-linking telechelic PVA at the water/air interface. Vigorous stirring at room temperature for 2 h of 2% telechelic PVA aqueous solution (200 mL) by an Ultra-Turrax T-25 at 8000 rpm equipped with a Teflon coated tip generated a fine foam of telechelic PVA acting both as colloidal stabilizer and as air bubble coating agent. The cross-linking reaction was carried

out at room temperature. Floating microbubbles were separated from solid debris and extensively dialyzed against Milli-Q water. The aqueous suspensions of microbubbles were obtained and used for microcapsule preparation.

PVA microbubbles were converted into solvent-filled microcapsules by equilibrating an aqueous suspension in ethanol 70% solution. The microcapsule suspension was then extensively washed by a series of centrifugations at 1000*g* to remove excess ethanol.

Chemical Modifications. *Rhodamination of PVA-MC.* Suspensions of 1 mg/mL of MC were added with 10 μL of rhodamine-β-isothiocyanate[40] solution 2.3 mg/mL in DMSO and stirred for 1 h. The rhodamine excess was removed by at least 5 centrifugation steps at 1000*g* for 10 min, changing the external medium.

Synthesis of Chi-Rod. Chitosan 0.5% (w/v) was suspended in 100 mL of acetic acid 3% (v/v) solution. 50 mg of rhodamine-β-isothiocyanate was then added and stirring maintained for 48 h in the dark at 4 °C. The solution was adjusted to pH 9 with NaOH, and unreacted rhodamine-β-isothiocyanate was removed carrying out at least 5 centrifugation steps at 1000*g* for 10 min. The synthesized compound was extensively dialyzed against Milli-Q-water.

Synthesis of Chi-FA and Chi-FA-Rod. 1.2 mmol of EDC (*N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride) were added to 3 mmol of FA dissolved in 50 mL of DMSO, and left to react for 1 h in the dark at room temperature. Then, 50 mL of a 1% (w/w) chitosan or chitosan−rhodamine in 20 mM acetate buffer pH 4.7 was added to the reaction. After 16 h, the solution was brought to pH 9 with NaOH, and the compound purified by centrifugation followed by 3 days of dialysis against acetate buffer and extensive dialysis against Milli-Q water using a 12 kDa cutoff dialysis membrane. The compound was then freeze−dried.

Preparation of Chitosan Functionalized Microcapsules. Chitosan was conjugated to microcapsules by reductive amination. Chi or Chi-FA was dissolved in a sodium acetate 0.2 M, acetic acid 0.3 M buffer at pH 4.5 to a concentration of 0.15% (w/v). A 10 mL sample of 1 mg/mL microcapsule aqueous suspension was added with 4 μL of Chi or Chi-FA solution at room temperature. The pH was carefully adjusted to 5.0 with acetate buffer, following the addition of $Na(CN)BH_3$. The resulting suspension was stirred for 1 day at room temperature. The microcapsule suspension was then extensively dialyzed and washed to remove low molecular weight reaction products and unreacted chitosan.

Adsorption of the CPT on MC or MC-Chi-FA and Evaluation of Drug Release Kinetics. Suspensions of 1 mg/mL of MC or MC-Chi-FA were added with CPT in DMSO at a final concentration of 100 μM and stirred for 4 days in the dark. Then, three washes were performed by centrifugation at 1000*g* to remove the drug that was not adsorbed. The concentration of drug in the washing is calculated by spectrophotometer following the absorption at λ = 370 nm. The percentage of CPT adsorbed on microcapsules was indirectly estimated by subtracting the total concentration of drug present in the wash to the total drug used for the adsorption.

A suspension of MC o MC-Chi-FA 1 mg/mL (20 mL), previously adsorbed with CPT 100 μM, was resuspended in Dulbecco's modified Eagle's medium (D-MEM) without phenol red, with or without 10% fetal calf serum (FCS), and subdivided into 20 aliquots of 1 mL. The MC was kept in an incubator shaking at 140 rpm, 37 °C. At different times, the samples were centrifuged for 5 min at 2000*g* and the supernatant was read spectrophotometrically at λ = 370 nm. Absorption values were fitted with the equation $A = A_{max}[1 - \exp(Kt)]$ to estimate the time constant of the kinetics (K^{-1}) and maximum release A_{max}.

Cell Culture and Proliferation Assay. HeLa cells were cultured in RPMI-1640 and NIH3t3 cells were cultured in D-MEM, supplemented with 10% fetal calf serum (FCS), 200 mM glutamine, 100 U/mL penicillin, and 0.1 mg/mL streptomycin, and maintained in humidified atmosphere of 5% CO_2 at 37 °C. Cells were harvested twice a week and used at about 80% confluence.

For proliferation studies, cells were detached with trypsin/EDTA for 5 min and centrifuged. Cells were resuspended in RPMI-1640 medium without folate and seeded in 96-well culture dishes (2.5×10^3 cells per well) and cells were left to grow for 48 h. After this time, medium was refreshed and cells were incubated for additional 48 h with MC, MC-Chi, and MC-Chi-FA (either adsorbed with CPT or not). At the end of incubation, medium was refreshed again, and after 48 h, the percentage of cell proliferation was evaluated by the sulforhodamine assay,[41] calculating the values as a percentage of the control, considered to be 100%. Proliferation assays were also carried out by cell counting using a Neubauer modified chamber. In this case, cells are seeded in 12-well culture dishes at 7.5×10^3 cells per well. This protocol was established in order to discriminate between the antiproliferative effect due to the diffusion of CPT released from the microcaplules in the media and the one due to the direct cell−microcapsule interaction.

Microcapsule Localization. For fluorescence studies, cells were grown in Lab-Tek chamber slides (Nunc Inc.) in RPMI-1640 medium without folate and treated with MC as described previously. After 48 h of incubation, cells were washed, fixed with 3.8% paraformaldehyde solution in phosphate buffered saline, and permeated by using 0.1% Triton X-100. Actin filaments were labeled by using Alexa-488-conjugated phalloidin according to the manufacturer's instructions. Fluorescent signals were detected and photographed using a Delta Vision 3.0 microscope. To assess the direct involvement of folate mediated interaction, localization experiments have been carried out also in the presence of free folate. After 48 h of culture in folate-free medium, MC-Chi-FA were given to cells in either folate-free or folate-supplemented medium (final concentration 4 mg/L). Cells were fixed and stained after the 2 day treatment and localization assays were performed as described.

RESULTS AND DISCUSSION

Chitosan−Folate Complex Formation and Functionalization of Microcapsules. Chitosan−folate has been synthesized using published protocols[42] by reacting the NH_2 group of chitosan with the COOH groups of folate (Figure 1). The γ-carboxylate group is the most reactive one, although the α-carboxylate is also available for conjugation. The reaction has been verified through ^{1}H NMR spectroscopy that is not able to distinguish between the two contributions. The ^{1}H NMR spectrum of chitosan (Figure 2a) shows a series of peaks corresponding to protons linked to the C3, C4, and C2 carbon atoms of the sugar and to the methyl protons, falling at 3.90, 3.77, 3.18, and 2.07 ppm, respectively. The degree of chitosan deacetylation, obtained from the ratio of the integrals of the methyl peak over the C2 one, is found to be 85%. The NMR proton spectrum of chitosan−folate (Figure 2b), when

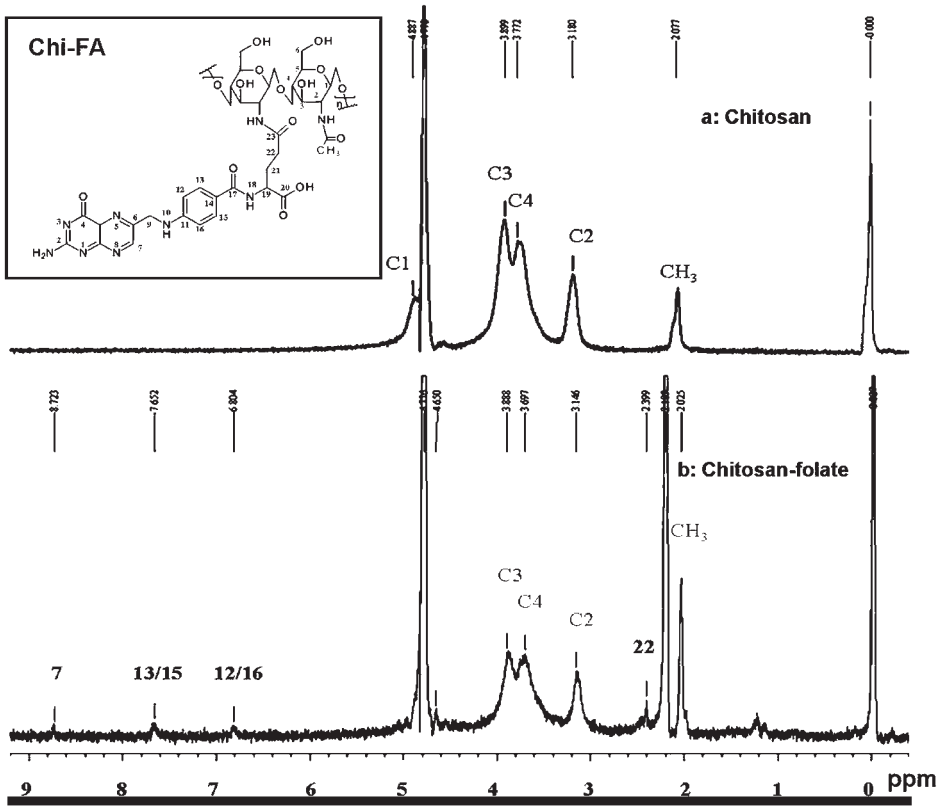

Figure 2. NMR spectra of chitosan and of the chitosan−folate derivative. (a) ^{1}H-NMR spectrum of chitosan solution in D_2O with 3% (v/v) CD_3COOD; (b) ^{1}H-NMR spectrum of 3 mg/mL of the chitosan−folate adduct in D_2O with 3% (v/v) CD_3COOD. Inset: Chemical structure of the chitosan−folate complex. In gray, the numbering of carbons of chitosan; and in black, the numbering of folate (see text for peak assignments).

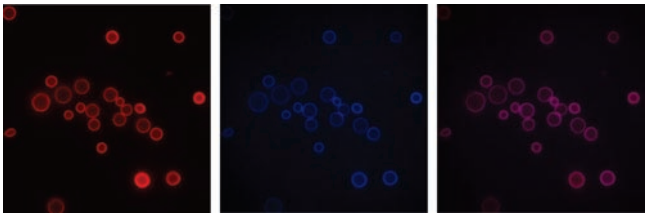

Figure 3. Fluorescence microscopy of decorated MC, adsorbed with CPT. Fluorescence microscope images of MC labeled with chitosan−rhodamine−folate, and absorbed with camptothecin. Left panel shows the rhodamine signal (red) on MC, the middle one the CPT signal (blue), and the right one the overlay of the two signals (violet).

compared to chitosan, shows additional peaks at 8.73, 7.66, and 6.83 ppm due to the folate aromatic rings and one at 2.40 ppm due to the protons linked to C22 (see inset of Figure 2 for the labeling of the different groups). The ratio between the integral of one of the folate aromatic peaks and the chitosan C2 peak at 3.14 ppm allows us to quantify the percentage of folate substitution on the chitosan NH_2 groups that is found to be 5%. On the basis of nominal molecular weight, this percentage corresponds to 15 folates per chitosan. Chitosan (Chi) and chitosan−folate (Chi-FA) have been also functionalized with rhodamine (Rod)[43] to give the Chi-Rod and Chi-FA-Rod complex. All the synthesized complexes have been then conjugated to microcapsules (MC) using the reductive amination procedure in the presence of $Na(CN)BH_3$,[35,37] to yield MC-Chi, MC-Chi-FA, and their rhodaminated counterparts MC-Chi-Rod and MC-Chi-FA-Rod.

The success of decoration and the ability of the modified MC's to incorporate CPT has been verified by incubating the microcapsules with 100 μM CPT for four days and observing their fluorescence microscopy images. Figure 3, representing the MC-Chi-FA-Rod system, shows that the red signal coming from rhodamine (λ_{ex} = 540 nm, λ_{em} = 625 nm, left panel) colocalizes with the blue signal originating from CPT (λ_{ex} = 370 nm, λ_{em} = 420 nm, middle panel), since they have an identical shape. The colocalization is confirmed by the overlay of the two images (right panel), that gives spheres characterized by a violet color. To our knowledge, this is the first time that CPT adsorbance on PVA MC is reported.

CPT Adsorption and Release. The adsorption of the drug has been carried out incubating the MC or MC-Chi-FA with camptothecin for 4 days with continuous stirring. The microcapsules have then been extensively washed in water and the concentration of drug bound on the MC's has been indirectly estimated quantifying the drug present in the washes by absorption spectroscopy measurements at λ = 370 nm, corresponding to the maximum in the camptothecin absorption spectrum. Considering an extinction coefficient ε = 17 670 $(M\ cm)^{-1}$ for CPT at λ = 370 nm, it has been evaluated that MC and MC-Chi-FA adsorb about 68% and 82% of the external drug concentration, respectively. When resuspended in D-MEM at 37 °C, the maximum of released drug, in the case of MC, is obtained after one hour, while in the case of MC-Chi and MC-Chi-FA, it is obtained after about 5 h. In detail, fitting the data, reported as percentage of release normalized to maximum released drug, gives rise to a rate of release of 2.4 ± 0.2 h^{-1} for MC, 0.68 ± 0.02

h^{-1} for MC-Chi, and $0.52 \pm 0.02\ h^{-1}$ for MC-Chi-FA (Figure S1). Figure 4 shows the release kinetics of CPT from MC, MC-Chi and MC-Chi-FA at 37 °C in the culture medium supplemented with 10% serum. The release properties of the microcapsules are influenced by the presence of serum in the medium; in fact, the release rates, obtained by fitting the data as described in the Methods section, correspond to $1.4 \pm 0.2\ h^{-1}$ for MC, $1.4 \pm 0.3\ h^{-1}$ for MC-Chi, and $2.7 \pm 0.8\ h^{-1}$ for MC-Chi-FA, values larger than those obtained in the absence of serum.

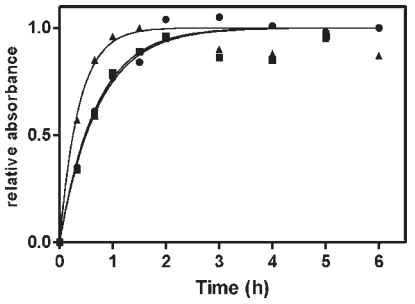

Figure 4. Drug release kinetics from MC. CPT release kinetics in D-MEM medium supplemented with 10% FCS at 37 °C, for nude microcapsules (MC, circles), chitosan microcapsules (MC-Chi, squares), and chitosan−folate microcapsules (MC-Chi-FA, triangles).

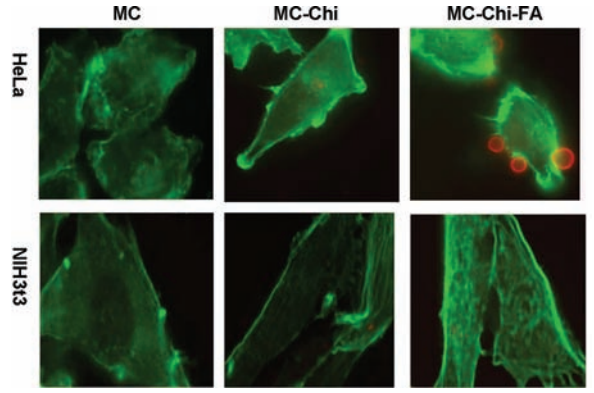

Figure 5. Localization of MC on the cells. Fluorescence microscopy image of HeLa tumor cells (up) and NIH3t3 fibroblast cells (down), treated for 48 h with MC (left), MC-chitosan (middle), and MC-chitosan-folate (right). The cells have been cultured in folate-free medium.

Interaction of MC with Different Cell Lines. The ability of MC and MC-Chi-FA to interact with cells has been tested incubating the capsules with two different cell types: HeLa cells, that overexpress the FR, and NIH3t3 fibroblasts, not expressing the receptor on their surface, as a negative control. The cells have been incubated for two days with 100 μg/mL of MC, MC-Chi, and MC-Chi-FA, all labeled with rhodamine-β-isothiocyanate on PVA, and then they have been extensively washed, stained, and imaged. Representative images from these experiments are shown in Figure 5. Control cells, fibroblasts, show no uptake of MC, independent of their functionalization, while HeLa cells exhibit a folate-dependent interaction. In our experiments, the unfunctionalized MC have never been found to interact with HeLa cells, while a small number of adhesions has been occasionally found for MC-Chi, likely due to a fusogenic activity of chitosan. In marked contrast, MC-Chi-FA frequently interact with the surface of HeLa cells and sometimes are also internalized, as reported in Figure S2 showing a large number of microcapsules bound to cells. The internalization of MC-Chi-FA by HeLa cells can be appreciated through a series of optical sections above and below the focal plane of the cell, such as the ones reported in Figure S3, where a representative sequence from outside to inside the cell is shown. A further hint to the nature of folate-mediated interaction is given by competition experiments, in which functionalized MC have been administered to cells together with folate in the medium. The effect of competition is striking, as in this case the uptake of MC-Chi-FA is substantially suppressed (Figure S2).

Effect of MC on Cell Proliferation. The impact of MCs on healthy and cancer cells has been followed, incubating cells in the presence of MC, MC-Chi, and MC-Chi-FA, either previously adsorbed with CPT or not. For drug adsorption, the microcapsules have been incubated with 100 μM CPT, and the amount of drug adsorbed was quantified. The quantity of MC used for the cell treatment is different and depends on the MC functionalization. For each experiment, we have taken care to have a concentration of adsorbed CPT equal to the IC_{50} of the specific cell line. In detail, a CPT concentration of 40 nM, corresponding to the IC_{50} value for the HeLa cells,[44] and one of 12 μM, corresponding to the IC_{50} for the NIH3t3,[45] have been used. The cells have been incubated with the microcapsules for 48 h and

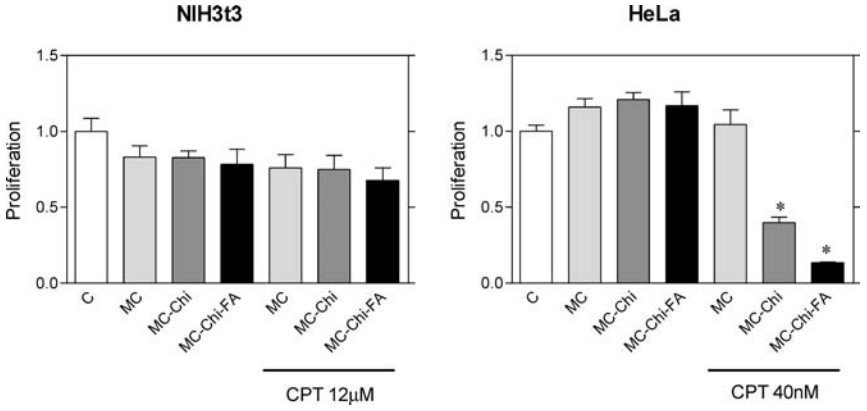

Figure 6. Effect of the decorated MC on cell lines. Proliferation of NIH3t3 fibroblast (left) and HeLa cells (right), treated for 48 h with MC, MC-chitosan (MC-Chi), and MC-chitosan-folate (MC-Chi-FA), with or without CPT adsorption. The treatment was removed and substituted with fresh medium, and then the proliferation was assayed after 48 h. Asterisks mark statistical significance ($p < 0.01$).

allowed to grow on fresh medium for additional 48 h before being assayed on their proliferation (Figure 6). This method has been established to allow the discrimination of the effect due to the diffusion of the drug lost from the capsules in the media from the one due to a direct capsules−cell interaction. Evaluation of cell proliferation after 48 h treatment indicates that the nude MC, previously incubated with CPT, has the same effect on HeLa viability as the chitosan−folate functionalized ones (Figure S4). Analysis of antiproliferative effect after media change and incubation for two additional days highlights the mortality due to a direct microcapsule−cell interaction (Figure 6). In the absence of CPT, a difference in proliferation no larger than 10% has been found on both cell lines for any kind of incubated MC. The antiproliferative effect of the microcapsules is slightly larger in the HeLa than in the control NIH3t3 cells for the MC-Chi system, a phenomenon that is not easy to interpret, although a more intense interaction of chitosan with HeLa cells could account for it. The most striking difference is observed upon incubation with the MC-Chi-FA. In this latter case, in fact less than 20% cells survive in the case of HeLa cells, while more than 80% of NIH3t3 cells are still active. The same results were obtained with the alternative method of cell counting, described in the Methods section, for which control cell numbers were approximately 2×10^5 and 3×10^5 per well, for HeLa and NIH3t3, respectively. This result confirms that the overexpression of the folate receptor permits a very efficient and selective targeting of HeLa cells from the MC-Chi-FA.

CONCLUSION

In this work, PVA microcapsules have been functionalized with chitosan or chitosan−folate and have been characterized for their ability to absorb and release CPT. The presence of chitosan or chitosan−folate on MC leads to greater absorption of the drug, likely because of an increased surface area of the functionalized microstructures, that can then accommodate a greater amount of drug.

Notably, MC-Chi-FA are able to bind and to be internalized by HeLa cells overexpressing the folate receptor, while no interaction is observed with NIH3t3 fibroblasts used as negative control (Figures 5 and S5). MC-Chi are found to occasionally adhere to both cell lines, likely because of the fusogenic properties of chitosan, due to the positive charges that allow electrostatic interactions with the negatively charged cell surface.[32,46] The results of cellular localization fully match proliferation experiments; in fact, MC-Chi-FA, interacting with HeLa cells, impact their proliferation while not perturbing the growth of NIH3t3 cells (Figure 6).

These results indicate that microcapsules modified with chitosan folate are a promising system to target camptothecin in tumors of epithelial origin since the presence of folate allows a selective recognition of HeLa tumor cells. Other studies will be performed on different cell lines also using functionalized microbubbles in the effort to design multivalent therapeutic agents that combine detectability (e.g., contrast agents for imaging techniques) with tissue specific drug delivery.

Supporting Information

ABSTRACT: Core/shell quantum dots (CdSe/Zns) conjugated with various nuclear localization signaling (NLS) peptides, which could facilitate the transportation of quantum dots across the plasma membrane into the nucleus, have been utilized to investigate the uptake mechanism of targeted delivery. Because of their brightness and photostability, it was possible to trace the trajectories of individual quantum dots in living cells using both confocal and total internal reflection microscopes. We found that, when the quantum dots were added to a cell culture, the peptide-coated quantum dots entered the cell nucleus while the uncoated quantum dots remained in the cytoplasm. At 8 nM, most of the peptide coated quantum dots were found in the cytoplasm due to aggregation. However, at a lower concentration (0.08 nM), approximately 25% of the NLS peptide-coated quantum dots entered the cell nucleus. We also found that some quantum dots without NLS coating could also enter the nucleus, suggesting that the size of the quantum dots may play an important role in such a process.

INTRODUCTION

There are increasing demands for the development of new materials and techniques to investigate the behavior of living cells where the cellular structures, biochemical activities, and interactions between cells and responses to exogenous reagents can be monitored as a function of time. To reveal the detailed mechanisms of the complicated intra- and intercellular events that occur in living cells, it is desirable to develop live-cell imaging techniques where the spatial and temporal information of the selected biomolecules or biological events can be recorded continuously during a biochemical process. Therefore, one of the most important issues in the development of live-cell imaging techniques is the ability to tag and track subcellular structures in living cells. Conventional approaches to investigate the spatiotemporal intracellular and intercellular events rely on fluorescently tagging the organelles or the biomolecules of interest using various organic fluorophores.[1] While plenty of dynamic and structural information has been obtained by organic fluorophores, their rapid photobleaching and broad, overlapping emission spectra sometimes limit this application in living-cell studies. Recent advances in the development of engineered fluorescent proteins provide an alternative approach to monitoring the dynamic behavior of living cells at the molecular level. However, fluorescent proteins also suffer in photostability when used in long-term observations.[2] To observe biochemical events in living cells for longer times, there is increasing interest in developing more robust inorganic nanomaterials such as metallic nanoparticles and semiconductor nanocrystals for live-cell imaging.[3−5] Whereas metallic nanoparticles, such as those including gold and silver, have been widely used for various analytical and therapeutic applications, it remains difficult to track individual metallic nanoparticles due to their inherent optical properties.[6] Semiconductor nanocrystals, also known as quantum dots, exhibit superior optical properties, allowing the tracking of individual cellular events with the advantages of a single excitation source, size-dependent emission spectra, a narrow spectral width, and excellent photostability. It has been demonstrated that the uptake of bioconjugated quantum dots can be tracked in living cells, and this has provided new insights into nanoparticle delivery mechanisms.[7−9]

When nanoparticles were used to study living cells, it was found that the uptake efficiency of the nanoparticles depended on their size and shape[10] and that most of the nanoparticles aggregated in the plasma membranes after entering the cells.[11,12] When investigating the behavior of living cells, it is always desirable to control the final destination of nanoparticles. One of the greatest challenges in targeted delivery is the delivery of nanoparticles into cell nuclei, but this is an important goal because the cell nucleus is the place where the genetic material is stored and the cell's function is regulated through the expression of genes. Understanding the targeted nuclear delivery process would advance our capabilities in the diagnosis of disease genotypes, also understanding biological processes in the nucleus.

To enhance the efficiency of targeted delivery, a common approach is to modify the surfaces of nanoparticles that carry probes or drugs with a wide range of biomolecules, followed by introducing the nanoparticles to cells by microinjection or transfection reagents.[9] However, if the nanoparticles are added directly into cell cultures, the nanoparticles aggregate near the cell membrane. Recently, some proteins or peptides with protein transduction domains have been shown to be capable of carrying proteins to penetrate the nuclear membrane. Several targeted delivery strategies have been developed using these biomolecules

to decorate the surfaces of nanoparticles. For example, it has been reported that gold nanoparticles conjugated with nuclear localization signaling (NLS) peptides derived from adenoviral fiber proteins[13] are capable of penetrating the cell membrane of HepG2 cells, the membranes of which are known to be difficult to cross. However, no gold nanoparticles were found in the nucleus when the nanoparticles were modified only with NLS peptides. Only when the surfaces of these nanoparticles were modified with both NLS and the receptor-mediated endocytosis (RME) signaling peptide did the accumulation of gold nanoparticles in the cell nucleus become evident. NLS peptide-conjugated quantum dots have also been used to investigate the mechanism of nuclear targeting. Experimental evidence has shown that quantum dots with NLS coatings could be delivered into cell nuclei as long as the quantum dots are transfected into cells either through microinjection or incorporated with transfection reagents such as cationic liposomes.[14−17]

Here, we present studies of the trajectories of peptide-modified quantum dots without transfection reactions in living cells using both confocal and total internal reflection microscopy. Targeted nuclear delivery processes were investigated by quantum dots conjugated with NLS peptides derived from the adenoviral, SV40 virus, HIV-1 Tat protein, and adenoviral receptor mediated endocytosis (RME).

EXPERIMENTAL SECTION

Quantum Dot−Peptide Bioconjugates. In this experiment, cysteine-terminated nuclear localization signal (NLS) peptides derived from the adenovirus (CGGFSTSLRARKA), SV40 large T antigen (CGGGPKKKRKVGG), and HIV-1 Tat proteins (CGGRKKRRQRRRAP) and the peptides for receptor-mediated endocytosis (RME) (CKKKKKKSEDEYPYVPN) were purchased from MDBio Company (Taiwan) with purity of 77.72%, 80.77%, 95%, and 76.57%, respectively. These peptides were then conjugated to amine-derivatized, PEG-coated quantum dots (Qdot 545 Amino-PEG; Invitrogen). All peptides were first mixed with 10 mM dithiothreitol (DTT) for one hour and then purified using D-salt dextran desalting columns (Pierce) with phosphate-buffered saline buffer at pH 7.4. Sulfo-succinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (Sulfo-SMCC, Pierce) was used to couple the cysteine-terminated peptides to the amino-terminated quantum dots. A 2.5 mg/mL Sulfo-SMCC solution was mixed with the peptide solutions for two hours before adding to an 8 μM quantum dot solution. A NAP-10 column with PBS was equilibrated to remove excess reactants. The hydrodynamic diameters of the peptide-coated quantum dots were determined by gel filtration (Supporting Materials Figure S1). The hydrodynamic diameters of QDs-RME, QDs-HIV, QDs-NLS, and QDs-SV40 were measured to be 18 nm, 16.5 nm, 14.3 nm, and 14.1 nm, respectively.

Cell Culture. CHO-K1 cells were seeded in 30 mm plates on 90% Ham's F-12K medium, and supplemented with 10% (v/v) fetal bovine serum (FBS). NIH/3T3 fibroblast cells were grown in 90% Dulbecco's modified Eagle's medium, supplemented with 10% (v/v) calf serum that had been adjusted 4 mM L-glutamine, 1.5 g/L sodium bicarbonate, and 4.5 g/L glucose. CV-1 and HepG2 cells were grown in 90% minimum essential medium and Earle's BSS medium, supplemented with 10% (v/v) fetal bovine serum (FBS) that had been contained 2 mM L-glutamine, 1.5 g/L sodium bicarbonate, 0.1 mM nonessential amino acids, and 1.0 mM sodium pyruvate. All cell cultures were incubated at 37 °C and 5% CO_2.

Cytotoxicity of the Peptide-Conjugated QDs. To determine the cytotoxicity of the peptide-conjugated QDs, the cells were first seeded in 96-well plates at a density of 1×10^5 cells/mL. After 24 h of culture, the wells were refilled with fresh medium, and a serial dilution of peptide-conjugated QDs with QD concentrations ranging from 0.08 to 8 nM was added to each well. Control experiments were carried out with cells treated with an equivalent volume of medium without QDs. The cells were then incubated for 24 h at 37 °C. Cytotoxicity was measured using an MTT (3-(4,5-dimethylthiazol-2-yl) 2,5-diphenyltetrazolium bromide) assay. PBS solutions containing 10 μL of 5 mg/mL MTT stain (*in vitro* toxicology kit, Sigma) were added to each well, and the plates were incubated for four hours. After mixing, 90 μL of MTT solubilization solution was added to each well. The stain was aspirated, and the purple-colored crystals were dissolved with acidic isopropyl alcohol. After 15 min, the absorbance in each well was measured at 570 nm in a microplate reader (SpectraMax, Molecular Devices). Background absorbance was measured at 660 nm in PBS solution without the presence of cells and QDs. All experiments were repeated three times.

Imaging QDs in Living Cells. Approximately 1×10^5 cells/mL were seeded onto sterile 25 mm coverslips and cultured overnight at 37 °C. A total of 20 μL of peptide-coated QDs were mixed with 500 μL of serum-free medium. Subsequently, we added the mixture to the cell culture containing 1 mL of growth medium after observation. For the QD tracking experiment, we used 0.08 nM of the peptide-coated QDs. To visualize the cell nucleus, we stained the cells with DAPI (Molecular Probes). Uptake of the peptide-coated QDs was observed using a laser-scanning confocal microscope (Leica, SP5) and a total internal reflection microscope (Leica, AM TIRF MC) equipped with incubators. The trajectories of the QDs were identified and tracked using the Diatrack program (Semasopht, Chavannes, Switzerland). To track the trajectories of QDs in the cell nucleus, the locations of QDs were first identified by the confocal microscope. To ensure that each time only one quantum dot was monitored, the blinking phenomenon of single QDs was employed to identify the existence of single QDs using the criteria established in a previous experiment[18] where single QD displayed reproducible discrete "on" and "off" intensity.

RESULTS AND DISCUSSION

Cytotoxicity of Peptide-Conjugated QDs. Cytotoxicity is one of the major concerns when using semiconductor quantum dots in biomedical applications.[19,20] Many reports have focused on quantum dot toxicity for *in vitro* and *in vitro* studies. A wide range of results has been reported so far. However, it is now generally believed that well-capped quantum dots do not exhibit cytotoxicity for short times. The cytotoxicity of amino-PEG-modified quantum dots (Invitrogen) were measured at three different concentrations in CV-1 cell lines after 4 and 24 h of incubation. No sign of cytotoxicity was observed as shown in Figure S2 of the Supporting Information. We also used the MTT assay to evaluate the cytotoxicity of the peptide-conjugated quantum dots used in this experiment. Again, no significant cytotoxicity was observed as shown in Figure 1. For all evaluated concentrations, very little cytotoxicity was detected. No dependence on the concentration and incubation time was observed in the tested samples, indicating that the cytotoxicity of the quantum

dots used was negligible during the course of the experiment. Noted that prolonged UV−vis illumination of QDs may lead to the generation of toxic ion and oxidative radicals. However, such a phototoxicity effect was not significant under current experimental conditions.

Distribution of Peptide-Coated Quantum Dots in Cells. One of the advantages of using quantum dots for biomedical applications is their bright and robust emission, which allows the tracking of quantum dots for long times.[14,21,22] In this experiment, one of our goals was to investigate the translocation of nanoparticles through the cell membrane using quantum dots coated with NLS peptides derived from viruses. The peptide-coated quantum dots were added directly to the cell culture without transfection reagents, which may cause the aggregation of quantum dots. After one hour of incubation, the excess quantum dots in the culture medium were removed by washing the cells one time with a PBS solution, and fresh growth medium was added before observation. In this experiment, we first investigated the uptake of peptide-coated quantum dots in four different cell lines, including CHO, NIH 3T3, CV-1, and Hep G2 cells. For this experiment, we used two microscopic techniques: total internal reflection microscopy and confocal microscopy. At a higher concentration of QDs (8 nM), it was observed that most of the peptide-coated quantum dots could be internalized by all the cell lines tested in this experiment, as shown in Figure 2. The SV40 large T-antigen NLS (Tag-NLS) peptide-coated quantum dots were located in the cytoplasm of the HepG2 cells (Figure 2a). Similar behavior was also observed for the RME peptide-coated quantum dots inside the CV1 cells (Figure 2b). In contrast, the quantum dots without peptide coating were mostly found to stay outside of the cells as shown in Supporting Information Figure S3. The accumulation of quantum dots inside the cytoplasm can be attributed to the aggregation of quantum dots inside cells under such conditions. To avoid aggregation, we used a much lower concentration (0.08 nM). At this concentration, individual quantum dots were found to locate, not only in the cytoplasm, but also inside the cell nucleus. The behavior of HIV Tat NLS (Tat-NLS) peptide-coated quantum dots was

observed in the living cells using a total internal reflection fluorescence microscope (TIRFM), which allows the visualization of a very thin (~200 nm) cross section of the cell near the glass−cell interface. Figure 3 shows TRIFM images of the NLS peptide-coated quantum dots in 3T3 and CV-1 cells. Because TRIF microscopy can be used to monitor the trajectories of NLS peptide-coated quantum dots during their uptake, it may provide a great opportunity to investigate the internalization pathway of peptide quantum dots. This may in turn help us to understand the pathway of virus internalization. To improve the cellular uptake efficiency and to visualize the endocytotic delivery processes within cells, quantum dots were coated with Tag-NLS peptides and Tat-NLS peptides and incubated with NIH 3T3 cells for two hours. Both types of peptide-coated quantum dots were found to enter cell nuclei; the cellular uptake and intracellular transport required approximately 30 min. Typical confocal images of single quantum dot inside the cell nucleus are shown in Figure 4, which shows 545 nm quantum dots coated with Tag-NLS peptides in the nucleus of NIH/3T3 cells.

Our results suggested that both Tag-NLS and Tat-NLS peptide-coated quantum dots could translocate across the cellular membrane barrier via a lipid raft-mediated endocytotic mechanism into the cell nucleus. It was reported previously that cell penetration peptides could enter the cell by hydrophilic macromolecules through the plasma membrane and into the nucleus, without the need for specific receptors.[9,23−28] To demonstrate the importance of the surface modification, we investigated the final locations of amino-PEG quantum dots without peptide coatings by confocal microscopy. We found that the quantum dots without targeting peptides did not enter the cell nuclei. However, they remained outside the cell nuclei, indicating that they are not capable of diffusing across the nuclear pore complex or within close proximity of the cell nuclei. When amino-PEG quantum dots were conjugated with targeting peptides, they could be used to penetrate or fuse with and thereby cross the plasma membrane without disruption or interference of the cell function. Therefore, it should be possible to use various targeting peptides to increase the permeability of drugs during

drug delivery or to identify targeted molecules for the treatment of various diseases.

Diffusion Dynamics of Single Peptide-Coated Quantum Dots. The bright and robust emission from peptide-coated quantum dots allows us to track the trajectories of individual quantum dots during endocytosis and translocation events, as monitored using both total internal reflection microscopy and confocal microscopy.[2,29−35] To investigate the short-term diffusion behavior of quantum dots in the proximity of the nucleus, we used a total internal reflection microscope equipped with a CCD camera capable of recording the motion of quantum dots in the millisecond region. For visualization, we stained the cell nucleus with DAPI. During this experiment, we found that the trajectories of NLS-coated quantum dots were quite different. The trajectories can be classified into two types: "diffusive" and "trapped". The quantum dots in the "diffusive" state could travel more than one micrometer during the experiment, while the overall movement for quantum dots in the "trapped" state was less than one micrometer. To investigate the behavior of the peptide-coated quantum dots, we analyzed the mean square

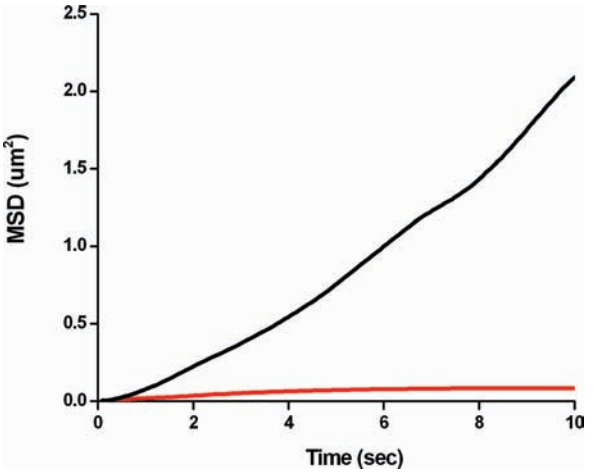

Figure 5. MSD as a function of time for Tat-NLS peptide coated quantum dots in the "diffusive" state (black line) and "trapped" state (red line).

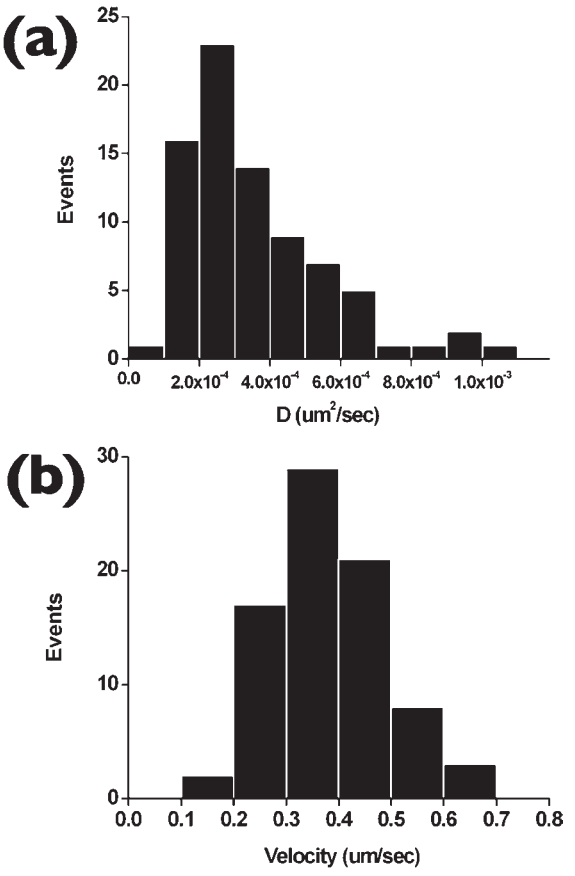

Figure 6. Histogram of the (a) diffusion coefficients and (b) average velocity of Tag-NLS peptide-coated quantum dots in CHO cells.

displacements of NLS peptide-coated quantum dots. The mean square displacements of the diffusive quantum dots in a few seconds were approximately a few micrometers squared.[36−38] However, for the trapped quantum dots, the mean square displacements in the same period of time were 1 to 2 orders of magnitude lower. Shown in Figure 5 is the MSD analysis of Tat-NLS peptide-coated quantum dots in the "diffusive" state

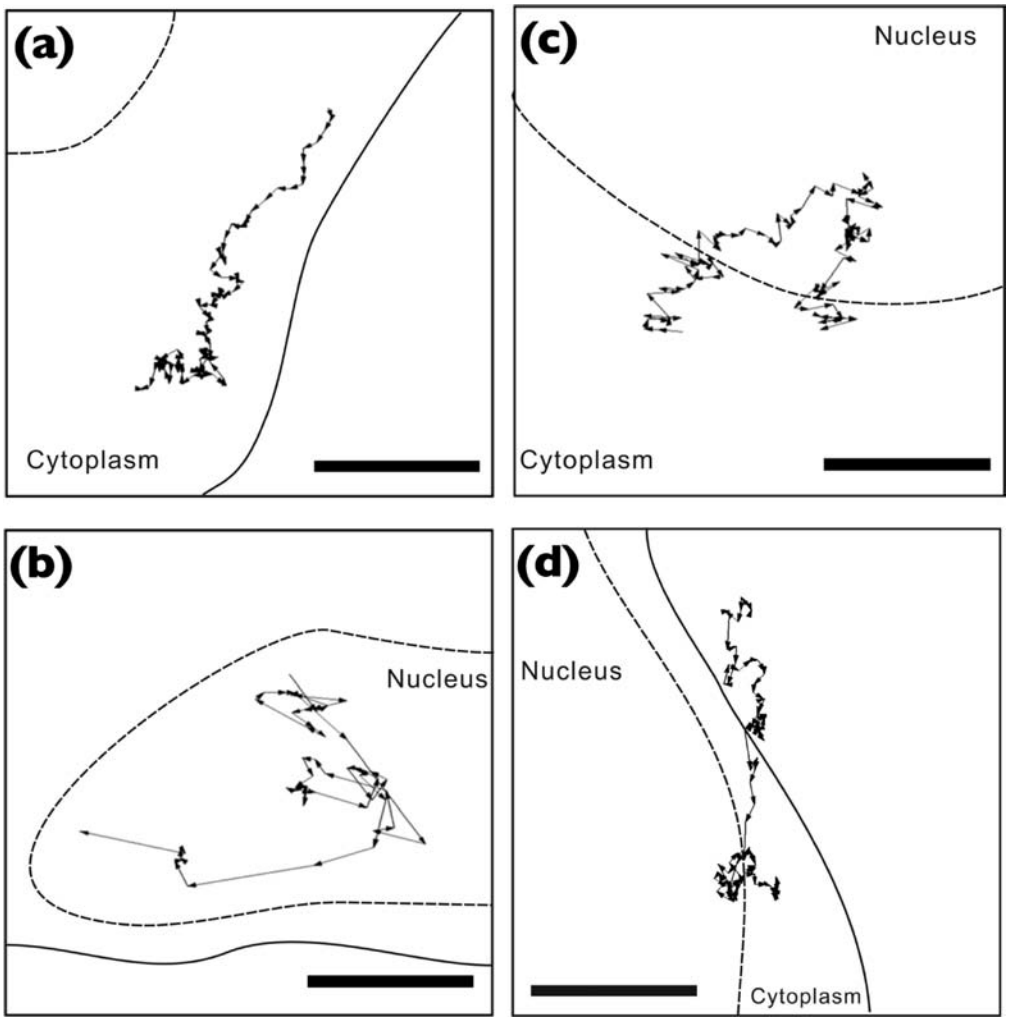

Figure 7. Four representative trajectories of RME peptide-coated quantum dots were cultured in CHO cells. (a) Staying in the cytoplasm. (b) Inside the nucleus. (c) Moving in out of the nuclear region. (d) From the nucleus to the cytoplasm. Scale bar: 5 μm.

(black line) and "trapped" state (red line). More MSD analysis can be found in the Supporting Information. We found that NLS peptide-coated quantum dots could easily access the perinuclear region. However, most of them became immobile after reaching this region. The velocity and diffusion coefficient distributions measured for 80 Tag-NLS peptide-coated quantum dots are plotted in Figure 6a and b. The average velocity measured for the "trapped" quantum dots in the cell nucleus was $0.38 \pm 0.1\ \mu$m/s; this immobile fraction of NLS peptides with particles could represent peptides trapped at the periphery of the cell nucleus, toward the cytoplasm. It was also observed that these particles clustered in within the nucleus. The average diffusion coefficient for the immobile fraction of Tag-NLS peptide-coated quantum dots was $(3.6 \pm 2.1) \times 10^{-4}\ \mu m^2/s$. For the "diffusive" quantum dots, the average velocity was also around 0.4 μm/s, however, the diffusion coefficient was about $6 \times 10^{-3} \mu m^2/s$. During this experiment, ~92% of the Tag-NLS peptide-coated quantum dots were in the "trapped" state.[39,40]

Overall, we analyzed the trajectories of 400 tracks of Tag-NLS peptide-coated quantum dots to determine their behavior. It was found that approximately 28% of these quantum dots could enter the cell nucleus, and approximately 92% of the quantum dots in the cell nucleus were in the "trapped" state, indicating a crowded environment inside the cell nucleus. A similar result was observed for Tat-NLS peptide-coated quantum dots, where approximately 25% of the quantum dots (34 out of 136) could enter the cell nucleus. However, only approximately 66% of them were in the "trapped" state. In other words, 8% of the Tag-NLS peptide-coated quantum dots were in the "diffusive" state whereas that for Tat-NLS peptide-coated quantum dots was measured to be 34%.

During long-term observation of the nuclear trafficking experiment, we used confocal microscopy to investigate quantum dots conjugated with receptor-mediated endocytosis (RME) signaling peptides, as these have been shown to directly access the cell nucleus through interaction with the nuclear pore complex. The RME peptide-coated quantum dots could undergo a receptor-mediated endocytotic pathway to enter the nuclei of CHO cells. The trajectories of RME-coated quantum dots can be classified into the following categories: inside the nucleus; from the nucleus to the cytoplasm; from the media to the cytoplasm, then into the nucleus; and staying in the cytoplasm. In this experiment, we monitored the trajectories of RME peptide-coated quantum dots in 60 cells. It was found that the majority of the trajectories (83%) reflected random motion inside the cytoplasm (Figure 7a). However, approximately 5% of the trajectories remained in the cell nucleus (Figure 7b), approximately 1.6%

of the trajectories moved in out of the nuclear region (Figure 7c) and 10% moved in out of cytoplasm to the nuclear region (Figure 7d). The trajectories are summarized in Figure 7.

CONCLUSIONS

We have synthesized various quantum dots conjugated with a range of nuclear localization signal peptides derived from viruses, which are known to associate with protein translocation into cell nuclei. At a high concentration, most of the peptide-coated quantum dots were internalized in the cytoplasmic region. However, they clustered near vesicles in the cytoplasm due to aggregation. At a lower concentration, we tracked the trajectories of individual quantum dots using both confocal microscopy and total internal reflection microscopy. It was found that approximately 28% of the Tag-NLS peptide-coated quantum dots and 25% of Tat-NLS peptide coated quantum dots could be delivered into the cell nucleus. Our results indicate that using specific NLS sequence of peptides for nuclear trafficking allowed us not only to understand the biological process pathway, but also to advance delivery technologies, such as gene therapies. We were able to use specific peptides coated quantum dots for carrier delivery in living cells, directly identifying the biofunctional interaction between the specific carriers and the cell nuclei of living cells. Single quantum dots are trafficked in and out of the nuclear periphery and toward the cytoplasmic region. These physical trajectories resolve the diffusion of molecules across the nuclear periphery and provide insight into the transport mechanisms and the dynamics of intracellular trafficking processes by peptides with diverse characteristics.

Supporting Information

ABSTRACT: Conventional quantum dots have great potential in cancer-related imaging and diagnostic applications; however, these applications are limited by concerns about the inherent toxicity of their core materials (e.g., cadmium, lead). Virtually all imaging applications require conjugation of the imaging agent to a biologically active molecule to achieve selective uptake or binding. Here, we report a study of biocompatible silicon quantum dots covalently attached to biomolecules including lysine, folate, antimesothelin, and transferrin. The particles possess desirable physical properties, surface chemistry, and optical properties. Folate- and antimesothelin-conjugated silicon quantum dots show selective uptake into Panc-1 cells. This study contributes to the preclinical evaluation of silicon quantum dots and further demonstrates their potential as an imaging agent for cancer applications.

INTRODUCTION

Quantum dots (QDs) are semiconductor nanocrystals, 1−10 nm in diameter, that typically consist of combinations of elements from groups II and VI (CdSe, CdTe, CdS, ZnS, and ZnSe), groups IV and VI (PbS and PbSe), or groups III and V (GaAs, GaN, InP, and InAs) of the periodic table.[1,2] They are attractive for optical imaging because of their size-tunable luminescence, high photostability, brightness, and broad excitation spectra that allow QDs with multiple emission wavelengths to be excited with a single source.[3−5] By adopting techniques from drug delivery and targeted imaging technologies, heavy metal based quantum dots have been rapidly developed and investigated for many biological applications including optical imaging,[6] sentinel lymph node mapping,[7] and multiplex imaging.[8] However, translation of these well-studied quantum dots to the clinic is inhibited by toxicity concerns that stem from their incorporation of toxic heavy metals such as cadmium.[9−12] This has led to encapsulations strategies that create complex nanostructures with different toxicity profiles.[13]

Even though extensive studies have been performed to monitor the safety of II−VI quantum dots, completely overcoming the toxicity concerns is not yet possible.[14−17] Thus, a re-evaluation of the fundamental materials at the core of the quantum dots is warranted. Silicon (Si) QDs may provide a breakthrough for quantum dot technology because they are based on a nontoxic element that is essential for human health, and the product of their degradation, silicic acid, can be readily excreted via the urine.[4,18,19] Even though Si QDs are attractive from a toxicity perspective, key challenges must be overcome to ensure that Si QDs can match the promise of better-studied quantum dots for biological applications. In particular, high quantum yield (QY) and long-term stability in water and biological media are essential.

The surface chemistry of Si QDs is of great interest, not only because this chemistry is much different from that of heavy metal based semiconductor nanostructures, but also because the Si QD's optical properties, which are the basis of their utility in bioimaging, strongly depend on the surface state of the particles. There have been a few reports on the synthesis and surface modification of Si QDs to improve their competitiveness with traditional quantum dots. Kortshagen's group has produced surface-modified Si QDs with QY above 70% at near-infrared wavelengths, for particles dispersed in organic solvents.[20] However, such high QY has not been achieved at shorter wavelengths or for Si QDs in aqueous dispersions. Sailor's group recently developed biodegradable porous silicon for imaging tumors via the enhanced permeation and retention (EPR) effect[21] and showed that clearance of the material was satisfactory. The free-standing Si QDs used here and Sailor's porous silicon particles are expected to have similar degradation routes and low toxicity from the core material. However, there are substantial differences in the chemistry, structure, and luminescence properties, to the extent that Si QDs may be considered a different nanostructure from porous silicon. To demonstrate the potential for multiphoton excitation of Si QDs, He et al. measured emission of Si QDs upon two and three photon excitation QDs,[22] while Kauzlaurich

recently demonstrated two photon cellular imaging in macrophages.[23] Though promising, the luminescence from the Si QDs used for two photon cellular imaging was limited to the blue range of the spectrum. Tilley et al. showed nonspecific uptake of allylamine terminated blue-emitting Si QDs in HeLa cells.[24] Reipa's group[25] conjugated red emitting silicon nanoparticles to streptavidin, and demonstrated specific binding of the nanoparticles to biotinylated polystyrene beads. However, after bioconjugation, the particles emitted blue luminescence. Development of bioconjugation chemistry that maintains the size-tunable luminescence of Si QDs thus remains an important need for biological applications such as targeted imaging, where emission that does not compete with autofluorescence is desired. We previously fabricated micelle-encapsulated Si QDs with size-tunable emission wavelength for targeted imaging of cancer cells. This method takes advantage of the interaction between hydrophobic groups that allow Si QDs to be encapsulated into the hydrophobic core of the micelle. These were first demonstrated for *in vitro* imaging[4] and more recently for *in vivo* targeted tumor imaging in small animals.[26] However, those micelle-encapsulated constructs, in which each micelle typically contains many Si QDs, are not ideal for all purposes. Thus, bioconjugation of individual Si QDs remains of great interest, especially through the direct conjugation to surface carboxyl groups.[27]

Conventional QDs can be modified for targeting purposes via bioconjugation techniques that render them useful for multiple imaging applications. *In vivo*, long circulation times and clearance mechanisms that raise toxicity concerns may be overcome by using smaller particles that have short circulation times and can be excreted rapidly through the kidneys.[28] Though this is encouraging, it poses a different challenge because receptors for some biomolecules (such as folate) are present on renal cells.[29] Folate receptors (FR) are overexpressed on many types of cancer cells compared to normal cells, and they have some advantages compared to monoclonal antibodies, such as prolonged circulation times, low cost, and tumor to nontarget tissue ratios. FR's are also overexpressed in the kidneys. If heavy metal based quantum dots are used with folate-based targeting, toxicity concerns in the kidney would be increased just as they are for cancer therapeutic folate-toxin conjugates that undergo renal clearance. Even though there are no prior reports of Si-folate conjugates, renal toxicity from Si-folate conjugates is not an anticipated issue because no toxic components are included in the formulation. We recently observed low toxicity of folate-conjugated micelle-encapsulated silicon nanoparticle formations in MTS cytotoxicity assays.[4]

Here, we report the development of Si QD probes directly bound to biomolecules, including folate and antimesothelin, for targeted cancer cell imaging. As synthesized, carboxyl terminated Si QDs provide (i) stable luminescence; (ii) modifiable surface characteristics; and (iii) the potential to interface with biologically relevant molecules for an array of applications such as targeted cellular imaging. Undecylenic acid was the carboxylic acid of choice because of its demonstrated low toxicity (5000 mg/kg in mice), and it is one of the most effective ways of preventing the influences of oxidation of the silicon core.[27] Biologically relevant molecules conjugated via carbodiimide chemistry to the carboxylic acid group of the undecylenic acid included amino acids, vitamins, enzymes, proteins, and antibodies. Because folate has been demonstrated to be effective for targeting cancers in humans, folate terminated Si QDs were evaluated as imaging agents. A schematic of the conjugation process is shown in Figure 1.

EXPERIMENTAL METHODS

Materials. Silane (SiH_4, Voltaix, electronic grade, 99.999%), hydrofluoric acid (HF, Acros Organic, 48−51%), nitric acid (HNO_3, EMD, 68−70%), undecylenic acid (Acros Organic, 99%), lysine (Sigma-Aldrich, 95%), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC, Pierce Biotechnology, 98−100%), dimethyl sulfoxide (DMSO, Fisher Scientific, 99.9%), folic acid (Sigma-Aldrich, >98%), antimesothelin (clone 5B2, dilution 1:20; Novocastra, Newcastle Upon Tyne, United Kingdom), apo-transferrin (Sigma-Aldrich, ≥97%), and *N*-hydroxysulfosuccinimide (Sulfo-NHS, Fluka, ≥98.5%) were all used as received if not otherwise noted. The silicon nanoparticles were prepared by decomposing silane (SiH_4) via high-temperature CO_2 laser pyrolysis in an aerosol reactor based on the method developed by Li et al.[30,31] The raw product was a dark brown powder that was not photoluminescent. This product was collected without exposure to air and handled in a glovebox to prevent oxidation. The typical primary particle diameter in the aggregated raw silicon powder was approximately 10 nm.

Etching Procedure. To produce hydrogen-terminated photoluminescent Si QDs, the raw particles were dispersed in methanol, then etched in a mixture of hydrofluoric acid (48 wt %) and nitric acid (69 wt %) (10/1, v/v) for 2 to 4 min. Typically, 300 mg of silicon nanoparticles were dispersed in 30 mL of methanol by sonication. The silicon−methanol mixture was added to the acid mixture and stirred until the luminescence emission spectrum approached the desired color. At that point, 400 mL of methanol was added to quench the reaction. After washing the etched particles with a water−methanol mixture (3/1, v/v) three times (500 mL, 500 mL, 250 mL) to remove the adsorbed acid, we collected the particles on a poly(vinylidene fluoride) (PVDF) membrane filter (Millipore, hydrophilic Durapore, 0.1 μm pore size). Finally, the membrane was rinsed with pure methanol. The particles were finally sonicated from the membrane into vials containing undecylenic acid. All these steps were completed in the glovebox to prevent the oxidation of the Si QDs, which can reduce their photoluminescence quantum yield. The size of the particles after etching ranges from 5 nm down to 1 nm depending on the desired emission wavelength.

Si QD Functionalization. The hydrogen-terminated silicon QDs were dispersed in 20 mL of undecylenic acid to give a cloudy suspension. The reactant and the silicon particles were then transferred to a three-necked flask, and 20 mL of ethanol was added. Three freeze−pump−thaw cycles were used to remove dissolved oxygen from the mixture before reaction. The flask was then heated to 78.9 °C for 3 h, with stirring, under an argon atmosphere. The double bond on undecylenic acid reacts with the hydrogen-terminated silicon surface by hydrosilylation to give a covalent Si−C linkage on the surface of the Si QDs (Figure 1a). These surface-modified QDs can be dispersed in most nonpolar solvents such as chloroform, hexane, and toluene. After the reaction, the initially cloudy silicon dispersion became optically clear, confirming that reaction had occurred and the modified particles were dispersible in ethanol. To remove excess undecylenic acid, the silicon QDs were dialyzed against 3 L of ethanol three times with solvent change points of 30 min, 3 h, and 24 h in bags with MW cutoff of 7000. The purity of particles was verified by rotary evaporation, which produces a film

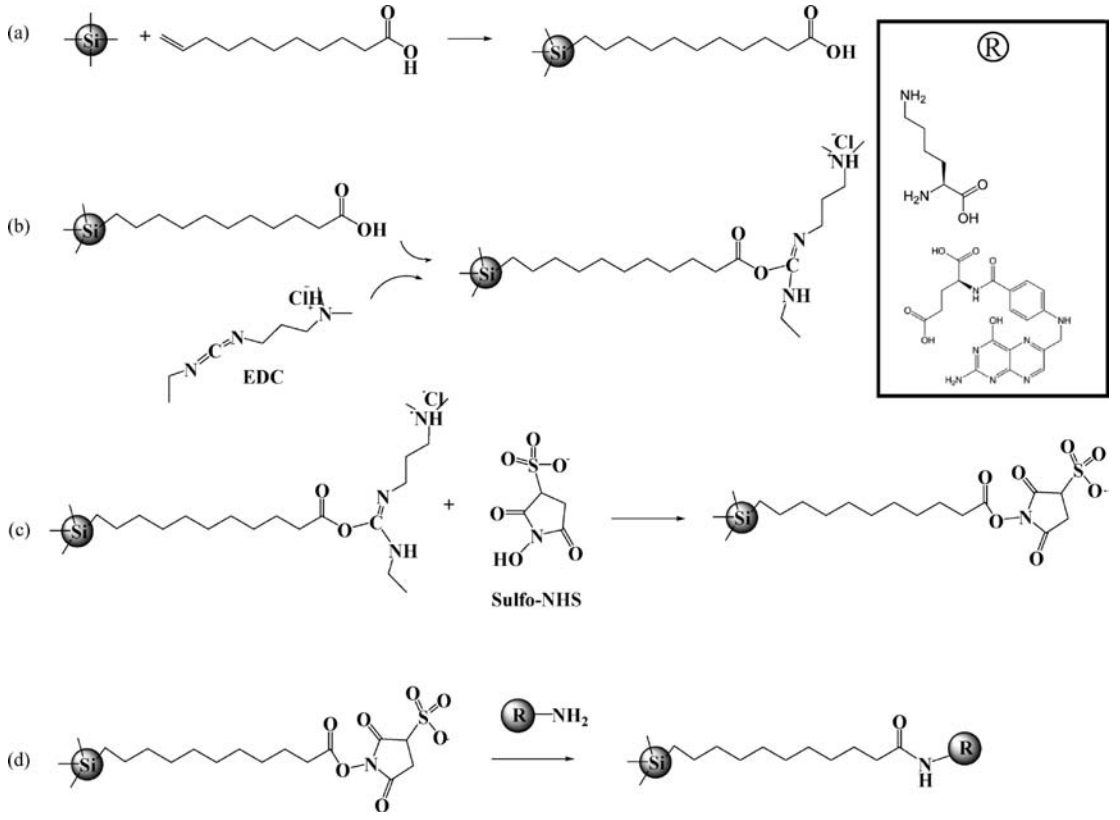

Figure 1. Schematic of surface functionalization and bioconjugation of silicon quantum dots: (a) hydrosilylation with undecylenic acid; (b) EDC coupling to form the o-acylisourea ester; (c) semistable amine reactive NHS-ester formation; (d) bioconjugation.

of undecylenic acid terminated Si QDs that can be readily dispersed in a variety of solvents and termination can be verified by FTIR.

Bioconjugation. In separate experiments, the Si QDs were conjugated to lysine, folic acid, antimesothelin, or apo-transferrin. An EDC-coupling reaction was used to form an amide bond between the carboxyl group on the Si QDs and a primary amine group on these reactants (Figure 1). Because the intermediate product of the EDC coupling was an unstable reactive o-acylisourea ester which could easily react with H_2O to regenerate the carboxyl group, we reacted sulfo-NHS with the o-acylisourea ester to produce a semistable amine-reactive NHS-ester. This amine-reactive NHS-ester consistently reacted with primary amines to yield a stable amide bond to the Si QDs. This implies that, ideally, we could conjugate any compound that has a primary amine group with Si QDs. To conjugate the Si QDs to folic acid, lysine, or transferrin, we started from 5 mL of the Si QD/ethanol sample and removed the ethanol by rotary evaporation. We next dissolved the Si QDs in 1 mL of DMSO. Eight milligrams of EDC and 8 mg of sulfo-NHS were each dissolved in 1 mL of LAL reagent water (LRW) or HPLC water, separately. These two compounds are unstable in water and must be freshly prepared for each experiment. The desired functional compound was also prepared in water (lysine or transferrin) or DMSO (folic acid) at 2 mg/mL. To start the EDC coupling reaction, 40 μL of EDC−water solution was added into the vial containing the Si QDs. After stirring for 1 min, 40 μL of sulfo-NHS was added, and stirring continued for 1 h to generate the semistable amine reactive NHS-ester. After forming the semistable intermediate, we separated the luminescent particles from the DMSO, EDC, and sulfo-NHS mixture by centrifugation. The particles then were introduced into the lysine or transferrin aqueous solution (0.8 mL containing 1.6 mg biomolecule) or folic acid DMSO solution (60 μL containing 0.12 mg folic acid). Initially, the mixture was cloudy, but after 15 min, the particles became well-dispersed. This reaction was carried out at room temperature for 1 h. Reaction products were separated by centrifugation at 10 000 *g* for 15 min after adding 1 mL of methanol to adjust the polarity of the solution to reduce the Si QD's dispersibility. The particles were washed by dispersing them in water, then collecting them by centrifugation thrice. For comparison, experiments were also performed using a one-step bioconjugation protocol, in which Si QDs were not separated from excess EDC and sulfo-NHS before adding the biomolecule to be conjugated to the particles. In the one-step protocol, the biomolecule was added to the reaction mixture ~5 min after adding the sulfo-NHS. The one-step method is more convenient and leads to fewer particle losses, but can also lead to cross-linking of biomolecules that have both amine and carboxyl functional groups, as discussed further below.

Cellular Imaging. Human pancreatic cancer cells (Panc-1) maintained in DMEM medium, with 10% fetal bovine serum (FBS) and appropriate antibiotic, were used for cellular imaging studies. As a standard, 8×10^5 cells are seeded for 100% confluency. One day before the treatment, an appropriate number of cells for 70−80% confluency were seeded in 35 mm cell culture dishes. On the day of treatment, the cells were incubated with bioconjugated Si QDs for 2 h at 37 °C at a confluency of 70−80%. After 2 h, cells were washed thrice with PBS, then imaged using a Leica laser scanning confocal microscope. The excitation wavelength used was 405 nm which was the shortest available wavelength on the microscope.

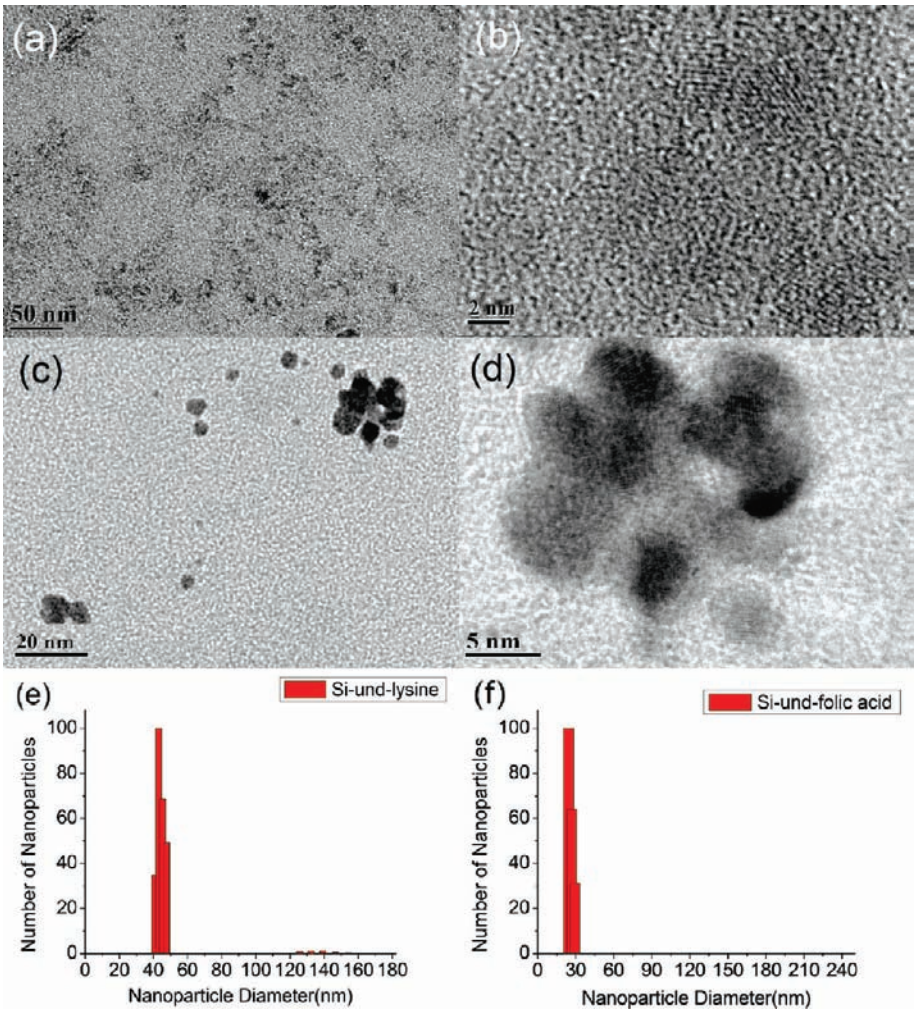

Figure 2. TEM images of (a,b) undecylenic acid terminated Si QDs and (c,d) Si QDs after bioconjugation to lysine. Hydrodynamic diameter distributions measured by DLS for (e) lysine-conjugated and (f) folic acid conjugated Si QDs. The mean diameter of Si-and-lysine particles is 46.7 nm, and the size of Si-and-folic acid particles is 26 nm.

Si QD Characterization. The silicon nanoparticles were characterized by transmission electron microscopy (TEM, JEOL 2010) before and after bioconjugation. Photoluminescence spectra (fluorescence spectra) were recorded with a Perkin-Elmer LS 50 fluorescence spectrometer with a 351 nm band-pass filter used to suppress any scattered light from the source. The excitation wavelength was set to 350 nm and the emission cutoff filter was set to 390 nm. Fluorescence quantum yield s (QYs) of the QD dispersions were determined by comparing the integrated emission from the QDs to rhodamine 6G dye solutions of matched absorbance. FTIR spectra were measured on a Bruker Vertex 70 spectrometer in attenuated total reflectance mode. The hydrodynamic diameter was measured by dynamic light scattering (BIC, 90 Plus). The uptake of bioconjugated Si QDs into pancreatic cancer cells was confirmed by laser confocal imaging (Leica Microsystems Semiconductor GmbH, Wetzlerm Germany, laser excitation at 405 nm).

RESULTS AND DISCUSSION

The size of the silicon nanoconstructs is shown in Figure 2. Figure 2a,b shows TEM images of the undecylenic acid-coated Si QDs at low and high magnification, respectively. Particles around 4−5 nm with lattice fringes are observed in Figure 2b. The average hydrodynamic diameter from DLS measurements was 23 nm. The large hydrodynamic diameter, relative to the crystalline core diameter, is attributed to the organic ligand on the surface of the silicon nanocrystals. These particles were conjugated with lysine using EDC and sulfo-NHS as depicted in Figure 1. After bioconjucation to lysine, some clusters are observed in the TEM images. The clusters are around 20 nm as seen in Figure 2d. The clusters consist of crystalline silicon QDs. Before the addition of lysine, the silicon content is estimated to be as high as 70% based on thermogravimetric analysis methods discussed previously,[32] and the QY is 15 ± 5% before bioconjugation and 5 ± 3% after bioconjugation. The DLS-measured hydrodynamic diameter increased from 23 to 46 nm after bioconjugation with lysine. These sizes are from the two-step reaction. This increase in size is attributed to possible aggregation and cross-linking between lysine molecules. The lysine molecules possess carboxyl groups that form semistable NHS-ester groups and readily react with available amine groups of other lysine molecules. When the particles were conjugated in a one-step process, in which EDC, sulfo-NHS, and lysine were added sequentially without intermediate separation steps, the

size of the particles was around 100 nm in TEM images (Supporting Information Figure S1) and the DLS-measured mean hydrodynamic diameter was 150 nm. Even though it is much larger than the initial particle, the size of around 100 nm is favorable for some biological applications. To reduce cross-linking, a protocol that involved centrifugation between steps C and D in Figure 1 was used, as described above. This resulted in NHS-terminated Si QDs that were directly reacted with the amine groups of the lysine particles. The overall diameter of the particles was smaller in the two-step process because the excess lysine did not react with itself as much as in the one-step protocol. Similarly, the folate-conjugated particles had a hydrodynamic diameter of 26 nm using the two-step protocol and 120 nm using the one-step protocol. These data indicate that the carboxyl group on lysine has a higher tendency to cross-link to form larger particles or that these particles are less hydrophilic and have some tendency to aggregate in water.

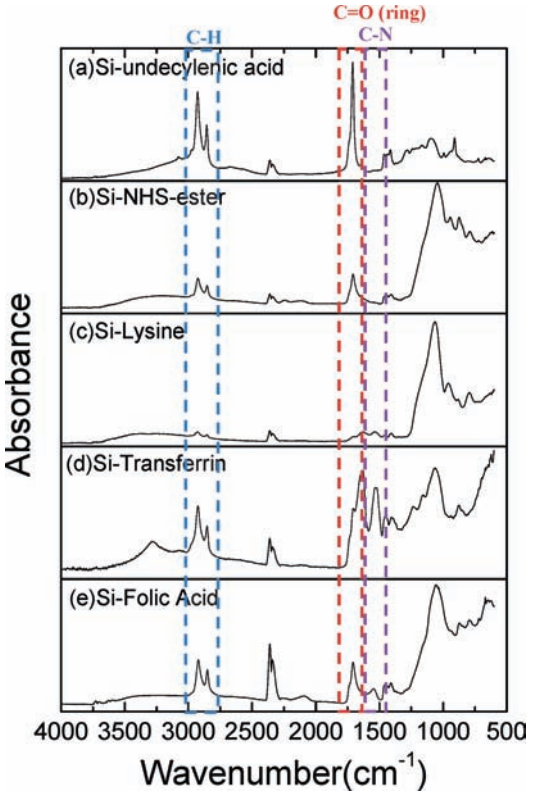

Figure 3. FTIR spectra of Si QDs after each step of the bioconjugation process.

Figure 3a displays the FTIR spectra of Si QDs after the hydrosilylation. The C−H stretch (2929, 2855 cm^{-1}), C−H bend (1461, 1438, 1416 cm^{-1}), and C═O stretch (1716 cm^{-1}) from the undecylenic acid are present in the spectrum. The absorbances at 3080, 2979, 2676, and 913−947 cm^{-1} are assigned to the deformation bend and stretch vibrations of O−H (COOH) bond. Growth of the Si−C peak at 1240 cm^{-1} and the absence of the Si−H peaks near 2100 cm^{-1} indicate the full removal of Si−H bonds in the hydrosilylated nanoparticles[32] (see Supporting Information Figure S2 for undecylenic acid FTIR spectrum). Figure 3b shows the FTIR spectrum of the semistable amine-reactive NHS-ester, in which the peak at 1707 cm^{-1} peak corresponds to the five-membered ring structure (see Supporting Information Figure S3 for the sulfo-NHS FTIR spectrum). Parts c, d, and e of Figure 3 show the IR spectra of the bioconjugated Si QDs. Figure 3d shows bands at 3270 cm^{-1} and 1635 cm^{-1} for amide A and amide I modes, respectively.[33] The amide III band is usually weak, but can be found at 1270 cm^{-1}. The absorbances at 1633 cm^{-1} and 1648 cm^{-1} in Figure 3d are assigned to α-helix and β-sheet structures. The peak at 1550 cm^{-1} is assigned to the C−N bond from the amide II group and the peak at 2252 cm^{-1} is from the

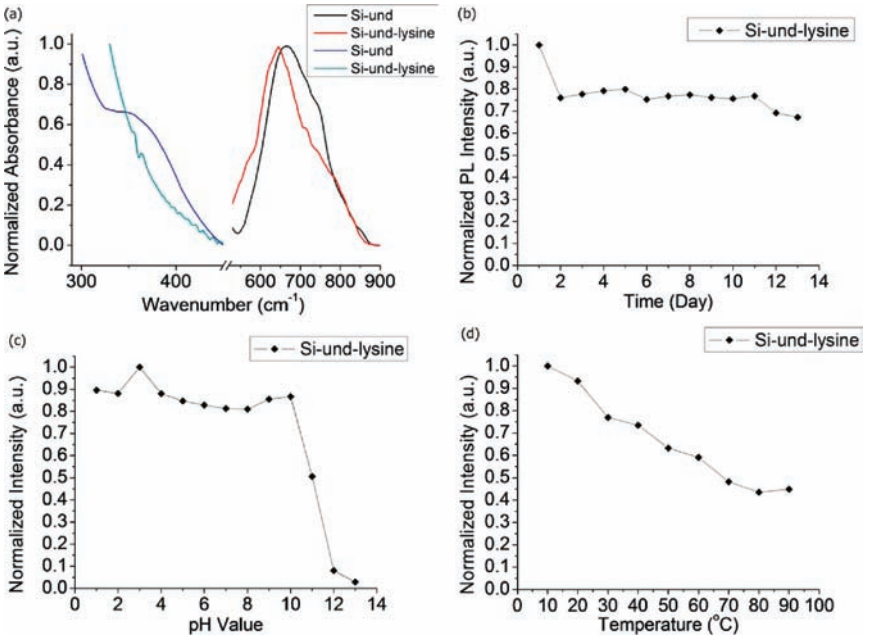

Figure 4. (a) Absorption and PL spectra undecylenic acid coated Si QDs (Si-und) and of lysine grafted Si QDs (Si-und-lysine) in a 50/50 (by volume) water/ethanol mixture. Stability of photoluminescence intensity from lysine grafted Si QDs in water, (b) over 13 days of storage at 4 °C, (c) at different pH levels in water, and (d) after heating to different temperatures in water. An average of three samples was used in the plots.

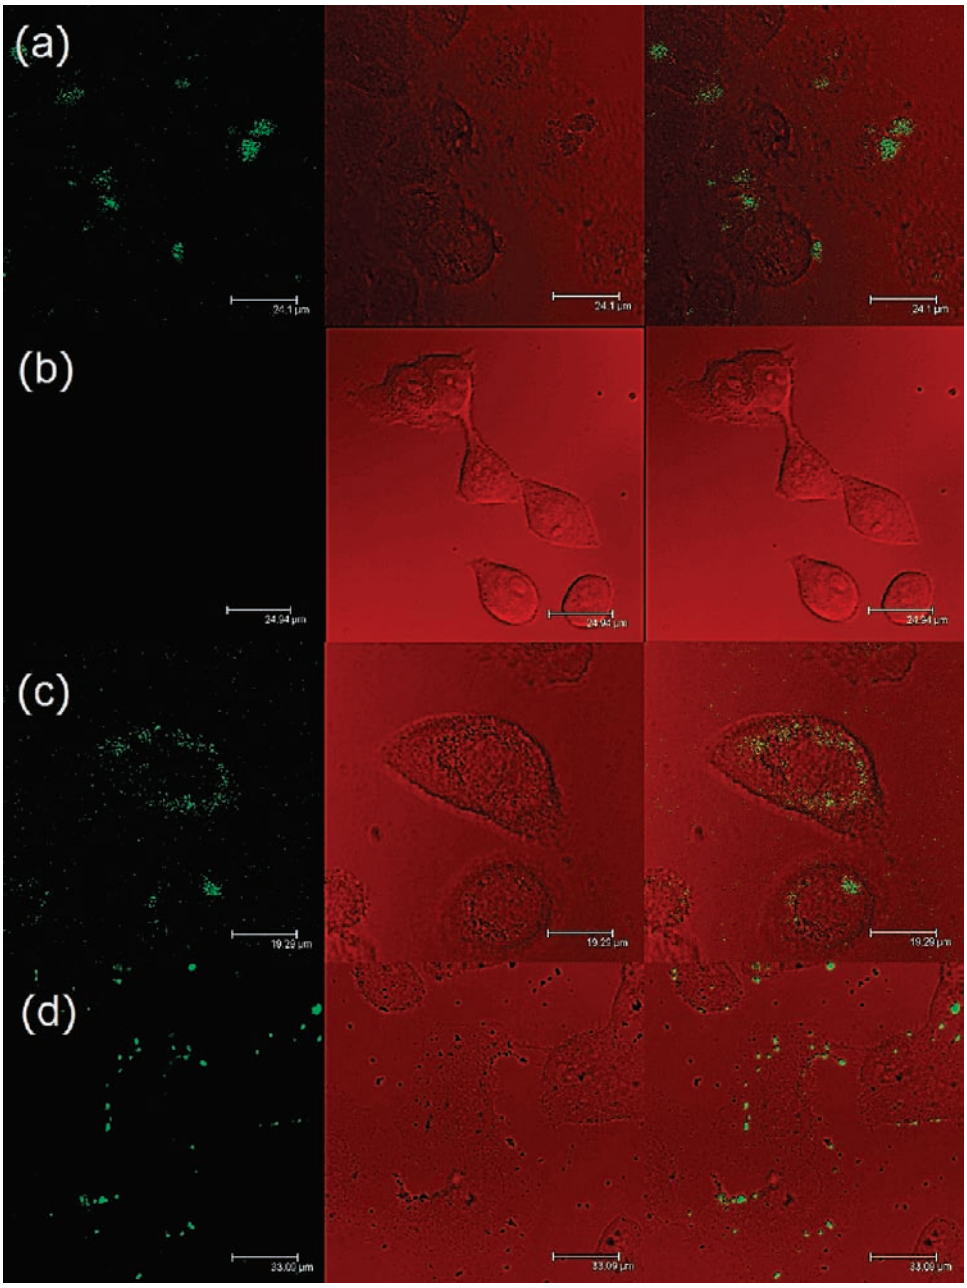

Figure 5. False-color confocal images of Panc-1 cells incubated with (a) lysine grafted Si QDs; (b) folic acid grafted Si QDs after incubation with excess folic acid; (c) folic acid grafted Si QDs; and (d) antimesothelin grafted Si QDs. From left to right, the panels show the luminescence images, the transmission images, and the overlay of the two. The scale bars are 24.1 μm, 24.94 μm, 19.29 μm, and 33.09 μm, respectively, in panels (a) through (d).

N−H bond on the silicon.[34] The six-membered ring structure has a very strong peak at 1710 cm^{-1} which confirmed the attachment of folic acid on Si QDs.

Figure 4a shows the absorption and PL emission spectra of undecylenic acid coated Si QDs and the PL of lysine-conjugated Si QDs. The emission peak shifts from 662 nm to 645 nm after the Si QDs are conjugated with lysine. Figure 4b shows the PL stability of the Si-lysine particles in water for 13 days. The first day after the bioconjugation, the Si QDs have the strongest photo luminescence intensity. Although the intensity dropped to 76% on the second day, the intensity remained stable for the next 11 days, until the 12th day when it dropped to 69%. This indicates that the undecylenic acid group was reasonably effective in protecting the Si QDs from oxidation. Even after the lysine conjugation and dispersion in water, the luminescence remained sufficiently stable for practical use over a period of at least two weeks. Figure 4c shows the PL intensity of lysine grafted Si QDs at different pH. From pH 1 to 10, it shows that Si QDs maintained a PL intensity that was at least 80% of the highest intensity at pH 3. Above pH 11, the PL intensity dropped drastically to 50.5% at pH 11, 8% at pH 12, and only 2% at pH 13. However, the PL is clearly stable over the entire range of biologically relevant conditions. Figure 4d displays the PL intensity of lysine-grafted Si QDs after heating to various temperatures. Although there is an obvious temperature dependence, the PL of the particles was higher than 40% of their initial

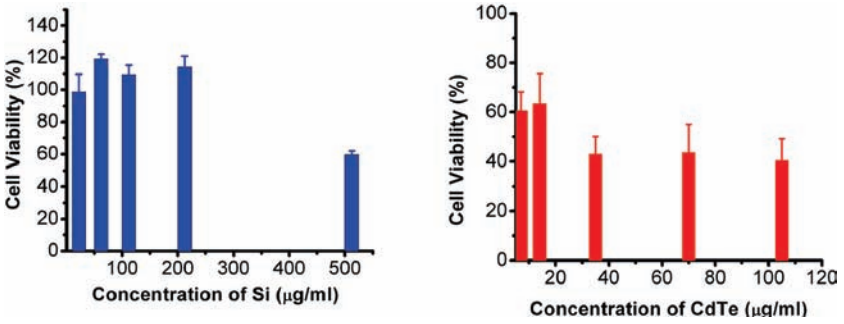

Figure 6. Cytotoxicity of (A) Si and (B) CdTe quantum dots toward Panc-1 cells. Error bars represent one standard deviation ($N = 3$). Note that the concentration range is much higher in (A) than in (B).

PL intensity at temperatures up to 90 °C. For in vivo application (30−40 °C), the PL intensity is more than 70% of the intensity at 10 °C.

To utilize Si QDs as an efficient targeted contrast agent for in vitro or in vivo imaging, the Si QDs must be conjugated with specific biorecognition molecules. Here, we present the conjugation of Si QDs with folate, antimesothelin, and transferrin. Panc-1 cells are an appropriate model to test cancer specific targeting by folate, transferrin, and antimesothelin because panc-1 cells have receptors for all three biomolecules.[35,36] Since folate, transferrin, and anti mesothelin receptors are minimally distributed in normal cells/tissues, they serve as excellent ligands for preferentially targeting cancerous cells and tissues in vitro and in vivo. The biomolecule-conjugated nanoprobes are transported into cells or localized on the membrane through the corresponding receptor. Figure 5 shows confocal microscopy images of panc-1 cells stained with the Si QD bioconjugates. Figure 5a shows the nonspecific targeting of lysine coated Si-QDs. As seen in the images, the Si bioconjugates are associated with the cells, but do not appear to have been internalized.

Figure 5b shows the cellular image obtained when Panc-1 cells were presaturated with excess folic acid for 2 h then incubated with folic acid-conjugated Si QDs (FA-Si QDs). There is no visible luminescence from the image indicating that FA-Si QDs are not taken up when the folate receptors are presaturated. Figure 5c shows the confocal image of Panc-1 cells incubated with FA-Si QDs for 2 h, without the folic acid pretreatment. The FA-Si QDs appear to be transported into cells through the corresponding receptor, demonstrating selective uptake via the folate receptors. Transferrin-grafted Si QDs also labeled the cancer cells, though less effectively than the FA-Si QDs (Supporting Information Figure S4). Figure 5d is shows Panc-1 cells incubated with antimesothelin grafted Si QDs (AM-Si QDs). The particles appear to be localized on the membrane of the cells indicating the efficacy of AM-Si QDs. The lack of any visible cell damage in all images is consistent with the expected biocompatibility of the Si QDs.

As cell morphology is not ideal for evaluating the toxicity of nanoparticle alone, MTS assays were used for comparative studies between toxicity profiles of hydrogen-terminated Si QDs with cysteine-capped CdTe QDs. The minimal encapsulation (cysteine is used in the CdTe QD synthesis) is intended to assess the inherent cytotoxicity of the core components. Figure 6 shows the in vitro cytotoxicity results for Si and CdTe QDs on a human pancreatic cancer (Panc-1) cell line at 24 h post-treatment. The inhibitory particle concentrations corresponding to 50% cell viability (IC_{50}) were ~40 μg/mL for CdTe compared to >500 μg/mL for the Si QDs. This demonstrates a significantly better toxicity profile for Si QDs when compared to Cd-based QDs.

DISCUSSION

Si QDs are beginning to become accepted as a nontoxic alternative to toxic quantum dots. The chemistry however has to be properly defined, and bioconjugation is one of the most important areas that must be investigated for the practical applications of SiQDs. The bioconjugation of SiQD can be challenging because standard protocols that are used for conventional quantum dots are not directly applicable to the functionalization of SiQDs. Short chain carboxyl groups like butenoic acid (results not shown) can produce bright orange luminescent particles; however, upon conjugation to lysine, the particles' emission becomes blue. This blue shifting also occurred when octane-terminated silicon nanoparticles were conjugated to DNA as luminescent labels.[37] It is important to maintain optical properties for imaging applications. Oxidation is normally responsible for the blue shift, and the method presented here prevents that complete blue shift from occurring. There is a very slight blue shift after conjugation; however, the particles are relatively stable as depicted in Figure 4. The particles are useful for labeling cancer cells with different targeting agents, which is of importance because targeted diagnosis and therapies are gaining traction in biomedical research.

CONCLUSION

A bioconjugation protocol for preparing smaller water-dispersible Si QDs has been developed and presented. A variety of appropriate functional groups for bioconjugation can be linked to the Si QDs for biological labeling. Antimesothelin and folic acid conjugated Si QDs were successfully applied for fluorescence imaging of pancreatic cancer cells. The excellent stability of the Si QDs in water provides longer observation time scale for targeting tumor cells without observable in vitro toxicity. Thus, the bioconjugated Si QDs presented here complement the larger micelle-encapsulated Si QD nanostructures we have previously developed, broadening the range of potential applications of Si QDs in biological imaging and diagnostics. This suggests that the Si QDs can be viable candidates for use in long-term and real-time cellular labeling and imaging.

Supporting Information

ABSTRACT: Evaluation of monoclonal antibody (mAb) fragments (e.g., Fab′, Fab, or engineered fragments) as cancer-targeting reagents for therapy with the α-particle emitting radionuclide astatine-211 (^{211}At) has been hampered by low in vivo stability of the label and a propensity of these proteins localize to kidneys. Fortunately, our group has shown that the low stability of the ^{211}At label, generally a *meta*- or *para*--[^{211}At]astatobenzoyl conjugate, on mAb Fab′ fragments can be dramatically improved by the use of *closo*-decaborate(2-) conjugates. However, the higher stability of radiolabeled mAb Fab′ conjugates appears to result in retention of radioactivity in the kidneys. This investigation was conducted to evaluate whether the retention of radioactivity in kidney might be decreased by the use of an acid-cleavable hydrazone between the Fab′ and the radiolabeled *closo*-decaborate(2-) moiety. Five conjugation reagents containing sulfhydryl-reactive maleimide groups, a hydrazone functionality, and a *closo*-decaborate(2-) moiety were prepared. In four of the five conjugation reagents, a discrete poly(ethylene glycol) (PEG) linker was used, and one substituent adjacent to the hydrazone was varied (phenyl, benzoate, anisole, or methyl) to provide varying acid sensitivity. In the initial studies, the five maleimido-*closo*-decaborate(2-) conjugation reagents were radioiodinated (^{125}I or ^{131}I), then conjugated with an anti-PSMA Fab′ (107−1A4 Fab′). Biodistributions of the five radioiodinated Fab′ conjugates were obtained in nude mice at 1, 4, and 24 h post injection (pi). In contrast to *closo*-decaborate(2-) conjugated to 107−1A4 Fab′ through a noncleavable linker, two conjugates containing either a benzoate or a methyl substituent on the hydrazone functionality displayed clearance rates from kidney, liver, and spleen that were similar to those obtained with directly radioiodinated Fab′ (i.e., no conjugate). The maleimido-*closo*-decaborate(2-) conjugation reagent containing a benzoate substituent on the hydrazone was chosen for study with ^{211}At. That reagent was conjugated with 107−1A4 Fab′, then labeled (separately) with ^{125}I and ^{211}At. The radiolabeled Fab′ conjugates were coinjected into nude mice bearing LNCaP human tumor xenografts, and biodistribution data were obtained at 1, 4, and 24 h pi. Tumor targeting was achieved with both ^{125}I- and ^{211}At-labeled Fab′, but the ^{211}At-labeled Fab′ reached a higher concentration (25.56 ± 11.20 vs 11.97 ± 1.31%ID/g). Surprisingly, while the ^{125}I-labeled Fab′ was cleared from kidney similar to earlier studies, the ^{211}At-labeled Fab′was not (i.e., kidney conc. for ^{125}I vs ^{211}At; 4 h, 13.14 ± 2.03 ID/g vs 42.28 ± 16.38%D/g; 24 h, 4.23 ± 1.57 ID/g vs 39.52 ± 15.87%ID/g). Since the Fab′ conjugate is identical in both cases except for the radionuclide, it seems likely that the difference in tissue clearance seen is due to an effect that ^{211}At has on either the hydrazone cleavage or on the retention of a metabolite. Results from other studies in our laboratory suggest that the latter case is most likely. The hydrazone linkers tested do not provide the tissue clearance sought for ^{211}At, so additional hydrazones linkers will be evaluated. However, the results support the use of hydrazone linkers when Fab′ conjugated with *closo*-decaborate(2-) reagents are radioiodinated.

INTRODUCTION

The α-particle-emitting radionuclide astatine-211 (^{211}At), when combined with tumor-targeting agents, has great potential in the development of new radiopharmaceuticals for treatment of cancer,[1] particularly for blood-borne (e.g., lymphoma;[2] leukemia[3,4]), compartmentalized cancer (e.g., ovarian cancer[5−7]), minimal residual disease after surgical tumor resections,[8] and metastatic cancer.[9−11] Although most of the current investigations use intact monoclonal antibodies (mAb) or their F(ab′)$_2$ fragments for delivery of ^{211}At to cancer cells in vivo, some studies have shown that cancer-targeting agents with biological half-lives that are matched to the physical half-life of ^{211}At ($t_{1/2}$ = 7.21 h) can be effective therapeutic agents, even in solid tumors.[10] This later fact is of particular interest, as metastatic cancer can form tumors where barriers to penetration of intact MAbs have become present.[12,13] Therefore, we believe that the optimal cancer-targeting agents for carrying ^{211}At may be antibody Fab′ fragments, divalent genetically engineered mAb fragments such as

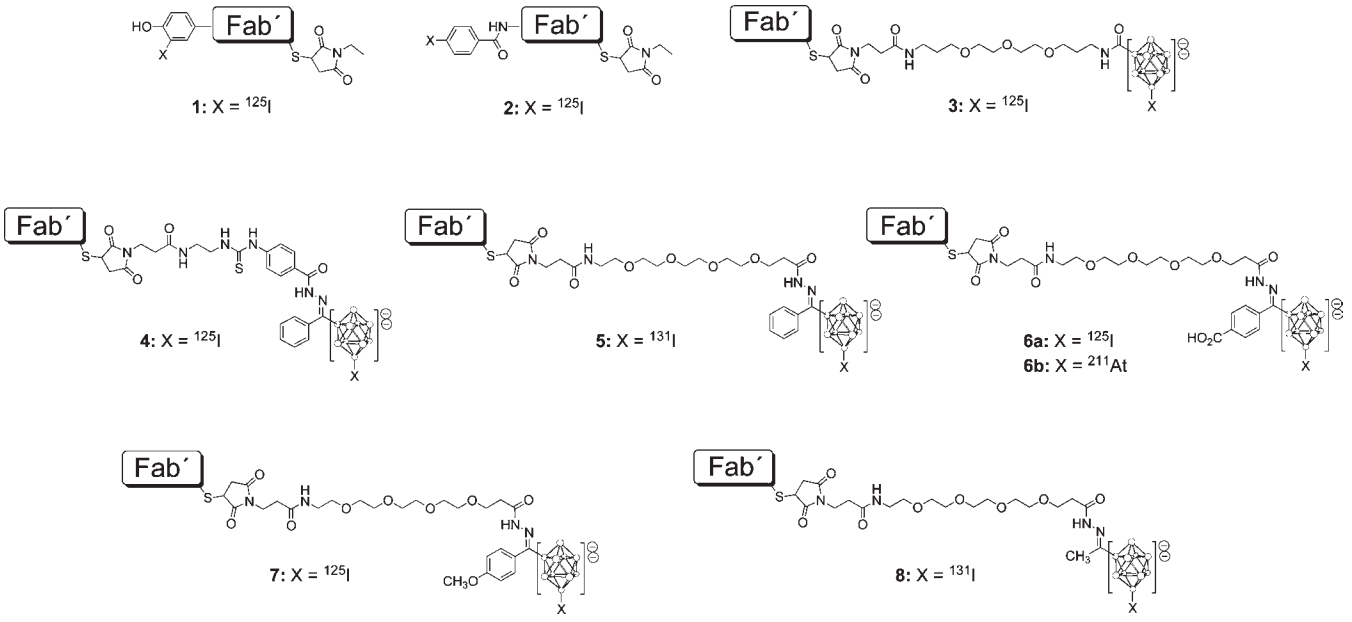

Figure 1. Depiction of radiolabeled 107−1A4 Fab′ conjugates showing chemical structures of directly radioiodinated Fab′, [^{125}I]**1**, versus Fab′ radiolabeled by conjugation with a lysine amine, [^{125}I]**2**, or conjugation with a free sulfydryl group, [^{125}I]**3**, [^{125}I]**4**, [^{131}I]**5**, [^{125}I]**6a**, [^{211}At]**6b**, [^{125}I]**7**, and [^{131}I]**8**. Note that Fab′ conjugates **4**−**8** contain acid-cleavable hydrazone functionalities.

diabodies,[14,15] or nanomolecular constructs that have biological half-lives closely matched to the half-life of ^{211}At.

Until recently, development of endoradiotherapy agents based on mAb Fab′ (or Fab) fragments or small genetically engineered mAb fragments has been problematic due to an inherent instability of ^{211}At label in vivo.[16] However, we have demonstrated that conjugates of ^{211}At-labeled mAb Fab′ fragments can be stabilized to deastatination by using nonahydro-*closo*-decaborate(2-) conjugates.[17] Despite this advancement, there is another major impediment to overcome before ^{211}At-labeled mAb Fab′ fragments can be effectively used in cancer therapy. That impediment is the inherent kidney localization of Fab′ and similar molecular weight engineered mAb fragments. Unlike intact MAbs or their F(ab′)$_2$ fragments, Fab′ fragments have a molecular size and shape that allows them to be filtered by the kidney glomerulus.[18,19] Like other proteins, once filtered Fab′ undergo reabsorption into the proximal tubule cells, presumably by binding megalin and cubulin receptors,[20−22] where they are ultimately degraded in the lysosomes.[23] There is evidence that complete degradation of the protein occurs by lysosomal peptidases; however, the radiolabeled metabolite, an amino acid adduct,[24,25] can have a slow release from the kidney. The retention of radiolabeled metabolites in kidneys is a critical issue when α-emitting radionuclides are used. Although therapy with ^{213}Bi-labeled Fab′[26] and ^{211}At-labeled diabodies[10] has been shown to be effective despite kidney localization, such reagents must be considered nonoptimal as therapeutic agents due to potential kidney toxicity. To address this issue, we have incorporated pH-sensitive hydrazone functionalities between the mAb Fab′ fragment and the *closo*-decaborate(2-) radiolabeling moiety as a potential means of obtaining a more rapid release of ^{211}At from kidneys. Although the hydrazone functionality has been used to release drugs within cells,[27] examples of its use in releasing radioactivity from kidneys were not readily found.

In this investigation, five hydrazone-containing *closo*-decaborate(2-) conjugates of anti-PSMA antibody, 107−1A4,[28] Fab′ (**4**−**8**) were prepared and evaluated in vivo to compare the release of ^{125}I or ^{211}At in kidney and other tissues. To better assess the effect of the hydrazone linker, biodistribution data previously reported for the same Fab′ directly radioiodinated, [^{125}I]**1**, radioiodinated with *N*-hydroxysuccinimidyl *para*-[^{125}I]iodobenzoate, **2**, and radioiodinated with a noncleavable *closo*-decaborate(2-) reagent, **3**,[17] were included in the comparison. Depictions of the radiohalogenated Fab′ conjugates are provided in Figure 1. The key feature of the Fab′ conjugates prepared in this study is that they contain hydrazone functionalities in molecular linkers between the Fab′ and the *closo*-decaborate(2-) moiety used for radiolabeling. Initial in vivo studies were conducted with ^{125}I- or ^{131}I-labeled Fab′ conjugates. In the studies, sulfhydryl-reactive, hydrazone-containing, *closo*-decaborate(2-) derivatives were radiolabeled prior to conjugation with Fab′-SH to ensure that the radioiodine was on the *closo*-decaborate(2-) cage moiety. In a later biodistribution study, Fab′-SH was conjugated prior to radiolabeling with the hydrazone-containing *closo*-decaborate(2-) derivative found in the first biodistribution studies to have the most favorable in vivo characteristics. That Fab′ conjugate was directly labeled with ^{211}At and (separately) ^{125}I, then the in vivo distribution of the coadministered ^{211}At and ^{125}I-labeled Fab′ was evaluated. The experiments conducted and results obtained in the investigation are reported herein.

EXPERIMENTAL PROCEDURES

General. Chemicals purchased from commercial sources were analytical grade or better and were used without further purification. Decaborane ($B_{10}H_{14}$) was obtained from Alfa Aesar (Ward Hill, MA). DL-Dithiothreitol (DTT), chloramine-T (ChT), and phosphate buffered saline (PBS) were obtained from Sigma-Aldrich (Sigma, St. Louis, MO). MPS-EDA.TFA (TFA salt of *N*-(2′-aminoethyl)-3-(maleimido)propionamide), **13**, and MAL-dPEG$_4$-*t*-boc-hydrazide, **16**, were obtained from Quanta

BioDesign (Powell, OH; quantabiodesign.com). *N*-Chlorosuccinimide (NCS), 4-aminobenzoic hydrazide, **10**, acetyl chloride, trifluoroacetic acid (TFA), and most other chemicals were obtained from Sigma-Aldrich (Milwaukee, WI). Solvents for HPLC analysis were obtained as HPLC grade and were filtered (0.2 μm) prior to use. Sephadex G-25 desalting columns (PD-10 and NAP-10) were obtained from Amersham Biosciences (Piscataway, NJ). Melting points were obtained in open capillary tubes on an EZ-Melt automated melting point apparatus (Stanford Research Systems, Sunnyvale, CA), and are uncorrected.

Radioactive Materials. All radioactive materials were handled according to approved protocols at the University of Washington. Standard methods for safely handling radioacative samples were employed.[29] Na[^{125}I]I was purchased from PerkinElmer Life Sciences (Billerica, MA) as high concentration/high specific activity radioiodide in 0.1 N NaOH. Measurement of ^{125}I and ^{211}At was conducted on a Capintec CRC-15R Radioisotope Calibrator using calibration numbers 319 and 44, respectively (designated by Capintec Technical Services). Tissue samples containing ^{211}At and ^{125}I were counted in a Wallac 1480 Wizard gamma counter (PerkinElmer Life and Analytical Services, Wellesley, MA). The tissue samples were initially counted to obtain both ^{211}At and ^{125}I counts, then were recounted after 3−5 days (0.1% or less ^{211}At remaining) to obtain ^{125}I counts. Radioactivity counts were imported into an *Excel* spreadsheet (Microsoft Corp., Redmond, WA) where calculations were made. The ^{211}At counts were obtained by subtracting ^{125}I counts from total counts. Individual tissue counts for ^{211}At were corrected for decay from the time of counting the first standard (at the beginning of the tissue counting process).

^{211}At was produced by irradiation of a thin layer (0.007 in.; 0.18 mm) of bismuth metal (99.999%, Aldrich) with 28.0 MeV α-particles on a Scandatronix MC-50 cyclotron using the conditions previously described.[30] All handling and processing of the irradiated target was done in a glovebox (Innovative Technologies, Inc., radioisotope glovebox) which was vented through a charcoal filter.

"Wet Chemistry" Isolation of Na[^{211}At]At. Briefly, an irradiated aluminum-backed bismuth target containing ~19.4 mCi of ^{211}At was placed in a 1 L polypropylene dissolution chamber and 10 mL of conc. HNO_3 was added (note: measurement of ^{211}At activity in the target must be considered an approximation due to attenuation and geometry). The HNO_3 solution was removed from the chamber using a pipet after 10 min, and was placed in a 50 mL round-bottom flask. An additional 5 mL of conc. HNO_3 was added to the dissolution chamber containing the irradiated target (as a rinse). After 5 min, the HNO_3 solution was removed and placed in the round-bottom flask with the other HNO_3 solution. The flask containing HNO_3 solution was connected to a distillation apparatus. A hotplate (preheated) at 260 °C was used to distill the HNO_3 leaving a white residue (~50 min). After cooling the flask containing the white residue, 8 mL of 8 M HCl was added with stirring to dissolve it. The resultant clear solution was removed and placed in a 20 mL scintillation vial. The flask was rinsed with an additional 2 mL 8 M HCl, and that was placed in the scintillation vial. An 8 mL quantity of diisopropyl ether (DIPE) was added to the scintillation vial, and that mixture was stirred at room temperature for 10 min. The 8 M HCl was removed by pipet to waste, and an additional 2 mL of 8 M HCl was added and stirred for 5 min. The 8 M HCl was removed to waste, and then 3 mL of 4 M NaOH was added. The NaOH solution was placed in a distillation apparatus and the H_2O was removed. The resulting residue was dissolved in 1 mL of H_2O and was adjusted to pH 9−10 by addition of 4 M HCl. A white gel was obtained, so an additional 1 mL of H_2O was added. That solution was filtered through a 0.2 mm Acrodisc to obtain a colorless solution (5.37 mCi), with 3.46 mCi remaining in the flask (did not rinse) and 8.6 mCi ^{211}At being retained on the filter. This was an early attempt at the wet chemistry approach to isolation of Na[^{211}At]At. Optimization was not done at that time, as the amount recovered was much more than required for the labeling experiment (note: the wet chemistry isolation procedure has been modified since the described experiments were conducted. The modified wet chemistry ^{211}At isolation procedure provides higher radiochemical yields (85 ± 11% decay corrected yields); a description of the modified ^{211}At isolation procedure will be published elsewhere). The Na[^{211}At]At vial was tightly sealed, placed in sealed (Ziploc) plastic bag, then transferred from the glovebox to a radiolabeling enclosure within a fume hood.

All radiohalogenation reactions were conducted in a charcoal-filtered Plexiglas enclosure (radioiodine fume hood, 20 × 24 × 36 in.^{3}, Biodex Medical Systems Inc., Shirley, NY) housed within a radiochemical fume hood. The radiohalogenation reactions were conducted in vials capped with Teflon-coated septa and were vented through a 10 mL charcoal filled syringe. Additions of reagents to, or removal of materials from, the radiohalogenation vessel were conducted by passing a syringe needle through the septa.

Spectral Analyses. ^{1}H NMR and ^{11}B NMR spectra were obtained on a Bruker AV 500 (500 MHz) instrument. Proton chemical shifts are expressed as ppm using tetramethylsilane as an internal standard (δ = 0.0 ppm). Boron chemical shifts used $BF_3.OEt_2$ as an external standard. High-resolution mass spectral (HRMS) data were obtained on a Bruker APEX III 47e Fourier transform mass spectrometer using electrospray ionization. For analysis, the samples were dissolved in 50/50 MeOH/H_2O and were introduced by an integral syringe infusion pump (Cole Parmer series 74900).

Chromatography. All synthetic reactions were monitored by HPLC. Analytical samples were assessed on a system that contained a Hewlett-Packard quaternary 1050 gradient pump, a variable wavelength UV detector (254 nm), and an Alltech ELSD 2000 evaporative light-scattering detector (Deerfield, IL). Analyses of HPLC data were conducted using Hewlett-Packard *HPLC ChemStation* software. Reversed-phase HPLC chromatography was carried out on an Alltech Altima C-18 column (5 μm, 250 × 4.5 mm) using a gradient solvent system at a flow rate of 1 mL/min. A gradient of MeOH and 0.05 M Et_3NHOAc was used. Starting with 0% MeOH, the initial solvent mixture was increased to 100% MeOH over the next 15 min, then held at 100% MeOH for 5 min. Retention times (t_R) obtained under these conditions are provided in the experimental procedures.

Preparative chromatography was conducted on most nonradioactive compounds for purification. Purification was accomplished using a Biotage SP Flash Purification System (Charlottesville, VA) on a reversed-phase C18 Flash 25+M or 40+M column, eluting with a mixture of MeOH and 0.05 M triethylammonium acetate (Et_3NHOAc) in water. A gradient was used which started with 100% Et_3NHOAc and was increased over 20 min to 100% MeOH. Fractions containing the desired product were combined and evaporated to dryness under vacuum on a rotary evaporator.

The product mixtures from radioiodination reactions of **14** and **17a**−**17d** were analyzed by, and radioactive peaks containing [^{125}I]**15**, [^{131}I]**18a**, [^{125}I]**18b**, [^{125}I]**18c**, and [^{131}I]**18d** were isolated from, a radio-HPLC using a C-18 column (Altima C-18, 5 mm, 250 × 4.5 mm; Alltech, Deerfield, IL) eluting at a flow rate of 1 mL/min using the same gradient conditions as described for nonradioactive iodination products. It should be noted that the pH of the Et_3NHOAc elution buffer was brought to 7.2 due to concerns for cleaving the hydrazone moiety during isolation. The HPLC equipment used in the analyses consisted of a Hewlett-Packard quaternary 1050 gradient pump, Waters 601 UV detector, and a Beckman model 170 radioisotope detector. Analysis of the HPLC data was conducted on Hewlett-Packard *HPLC ChemStation* software. The retention times (t_R) of the radioiodinated compounds are provided in the Experimental Procedures.

Size exclusion HPLC (SE-HPLC) separations of the conjugates of Fab′ were obtained on a Hewlett-Packard isocratic system consisting of a model 1050 pumping system and a model 1050 Multiple Wavelength Detector (280 nm). Proteins were evaluated on a Protein Pak 300 SW glass size exclusion column (10 mm, 8 mm × 30 cm, Waters Corporation, Milford, MA) run at 1.0 mL/min eluting with 50 mM sodium phosphate buffer (pH 6.8) which contained 300 mM NaCl, 1 mM EDTA, and 1 mM sodium azide. Analyses of the HPLC data were conducted using Hewlett-Packard *HPLC ChemStation* software. Retention times (t_R) for Fab′ and their conjugates were ∼11 min.

Compound Syntheses. Preparations of the following compounds were conducted as previously described: $[Et_3NH]_2B_{10}H_{10}$;[31] $[Et_3NH]_2B_{10}H_9$−CO−C_6H_5, **9a**;[32] $[Et_3NH]_2B_{10}H_9$−CO−$C_6H_4CO_2H$, **9b**,[32] $[Et_3NH]_2B10H_9$−CO−C_6H_4OMe, **9c**.[32]

$[Et_3NH]_2B_{10}H_9$−CO−CH_3, 9d. A solution of $[Et_3NH]_2B_{10}H_{10}$ (2 g; 6.2 mmol) and acetyl chloride (10 mL; 141 mmol) in anhydrous CH_3CN (25 mL) was stirred at room temperature for 4 min. After that time, the solution was triturated with diethyl ether (100 mL) and filtered. The crude product was dissolved in MeOH/H_2O (1:1) and purified via Biotage (C18 FLASH 40+M column) to yield 1.55 g (69%) of a red tacky solid. ^{1}H NMR (CD_3OD, 500 MHz): δ −0.20−1.06 (m, 9H), 1.31 (t, J = 7.5 Hz, 18H), 1.95 (s, 3H), 3.22 (q, J = 7.5 Hz, 12H). ^{11}B NMR (CD_3OD, 106.4 MHz): δ 5.10 (1B), 2.42 (1B), −19.30 (1B), −22.90 (1B), −25.38 (1B), −26.14 (1B), −26.98 (1B), −27.90 (1B), −29.14 (1B), −29.98 (1B). [Attempts to obtain HRMS data were unsuccessful.] HPLC: t_R = 7.1 min.

$[Et_3NH]_2B_{10}H_9$−C(C_6H_5)═NNH−CO−C_6H_4−NH_2, 11. A solution of $[Et_3NH]_2B_{10}H_9$−CO−C_6H_5, **9a** (200 mg, 0.469 mmol), 4-aminobenzoic hydrazide, **10** (85 mg, 0.562 mmol), and MeOH (8 mL) was stirred at room temperature for 16 h. The crude product solution was purified directly via Biotage (C18 FLASH 25+M column) to yield 242 mg (92%) of **11**. ^{1}H NMR (CD_3OD, 500 MHz): δ −0.08−1.13 (m, 9H), 1.23 (t, J = 7.4 Hz, 18H), 3.09 (q, J = 7.4 Hz, 12H), 6.65 (d, J = 8.8 Hz, 2H), 7.15−7.17 (m, 3H), 7.61−7.63 (m, 2H), 7.69 (d, J = 8.8 Hz, 2H). ^{11}B NMR (CD_3OD, 160.4 MHz): δ 0.69 (2B), −23.24 (1B), −26.65 (7B). HRMS (ES$^-$) $C_{14}H_{22}B_{10}N_3O$ $(M+H)^-$ calcd: 358.2693. Found: 358.2688. HPLC: t_R = 10.5 min.

$[Et_3NH]_2B_{10}H_9$−C(C_6H_5)═NNH−CO−C_6H_4−NCS, 12. A solution of **11** (100 mg, 0.18 mmol), TCDI (46.7 mg, 0.262 mmol) and anhydrous DMF (4 mL) was stirred at room temperature for 1 h. The solution was washed with 20% EtOAc/hexanes (5 × 15 mL), dried under vacuum for 2 h to yield 106 mg (99%) of a light-yellow tacky solid. ^{1}H NMR (CD_3OD, 500 MHz): δ −0.12−1.34 (m, 9H), 1.25 (t, J = 7.3 Hz, 18H), 3.14 (q, J = 7.3 Hz, 12H), 7.19−7.22 (m, 3H), 7.36 (d, J = 8.8 Hz, 2H), 7.60−7.62 (m, 2H), 7.98 (d, J = 8.8 Hz, 2H). ^{11}B NMR (CD_3OD, 160.4 MHz): δ 2.69 (1B), 1.78 (1B), −21.78 (1B), −25.80 (7B). HRMS (ES$^-$) $C_{15}H_{20}B_{10}N_3OS$ $(M+H)^-$ calcd: 400.2258. Found: 400.2250. HPLC: t_R = 13.7 min.

$[Et_3NH]_2B_{10}H_9$−C(C_6H_5)═NNH−CO−C_6H_4−EDA−MAL, 14. MPS-EDA.TFA, **13** (85 mg, 0.26 mmol) was added to a solution of **12** (100 mg, 0.17 mmol), NEt_3 (56 μL, 0.40 mmol) and anhydrous DMF (6 mL). The resultant solution was stirred at room temperature for 2 h, then volatile materials were removed under vacuum by rotary evaporation. The crude product was dissolved in MeOH/water (1/1) and purified via Biotage (C18 FLASH 25+M column) to provide 92 mg (68%) of a colorless solid. ^{1}H NMR (CD_3CN, 500 MHz): δ −0.08−0.93 (m, 9H), 1.16 (t, J = 7.4 Hz, 18H), 2.96 (q, J = 7.4 Hz, 12H), 3.29−3.33 (m, 2H), 3.41−3.45 (m, 2H), 3.50−3.53 (m, 2H), 3.54−3.65 (m, 2H), 6.72 (s, 2H), 7.16−7.21 (m, 3H), 7.46−7.50 (m, 2 H), 7.54−7.57 (m, 2H), 7.88 (d, J = 8.7 Hz, 2H). ^{11}B NMR (CD_3CN, 160.4 MHz): δ 2.65 (1B), 1.82 (1B), −21.73 (1B), −25.72 (7B). HRMS (ES$^-$) $C_{24}H_{32}B_{10}N_6O_4S$ $(M+H)^-$ calcd: 611.3215. Found: 611.3236. HPLC: t_R = 11.2 min.

$[Et_3NH]_2B_{10}H_9$−C(R)═NNH−CO−dPEG$_4$-MAL, 17a−17d. A solution of MAL-dPEG$_4$-CONHNH-BOC, **16** (1 g, 1.885 mmol), and neat TFA (4 mL) was stirred at room temperature for 3 min. After volatile materials were evaporated by a stream of argon, the acyl hydrazine derivative was washed with 10% EtOAc/hexanes (2 × 15 mL), and dried under vacuum overnight to provide a colorless oil. HPLC: t_R = 9.4 min. This material was used in the next step without further purification.

A methanol solution of MAL-dPEG$_4$-$CONHNH_2$, **16** (TFA salt; 100 mg, 0.184 mmol), and $[Et_3NH]_2B_{10}H_9$−CO−R (0.184 mmol) was stirred at room temperature for 1−4 h, then the volatile materials were removed on a rotoevaporator under vacuum. The crude products (**17a**−**17d**) were dissolved in MeOH/water (1/1) and purified via Biotage (C18 FLASH 25+M column). The gradient mixture was composed of MeOH and 0.05 M triethylammonium acetate. Starting with 100% 0.05 M triethylammonium acetate, increased to 100% MeOH over the next 20 min).

17a: R = C_6H_5; reaction time = 4 h; 118 mg (77%) yield. ^{1}H NMR (CD_3CN, 500 MHz): δ −0.22−0.99 (m, 9H), 1.22 (t, J = 7.2 Hz, 18H), 2.36−2.46 (m, 4H), 3.03 (q, J = 7.2 Hz, 12H), 3.27−3.35 (m, 2H), 3.47−3.52 (m, 2H), 3.54−3.64 (m, 16H), 3.66−3.81 (m, 7H), 6.79 (s, 2H), 7.11−7.22 (m, 3H), 7.50−7.63 (m, 2H). ^{11}B NMR (CD_3CN, 106.4 MHz): δ 1.44 (2B), −22.79 (1B), −26.27 (7B). HRMS (ES$^-$) $C_{25}H_{43}B_{10}N_4O_8$ $(M+H)^-$ calcd: 637.4017. Found: 637.4048. HPLC: t_R = 11.6 min.

17b: R = C_6H_4−CO_2H; reaction time = 1 h; 107 mg (66%) yield. ^{1}H NMR (CD_3CN, 500 MHz): δ −0.33−0.84 (m, 9H), 1.18 (t, J = 7.3 Hz, 18H), 2.31−2.44 (m, 4H), 2.51, 2.55 (2d, J = 3.8 Hz, 1H), 2.78, 2.81 (2d, J = 8.4 Hz, 1H), 3.13 (q, J = 7.3 Hz, 12H), 3.20−3.32 (m, 3H), 3.45 (q, J = 5.0 Hz, 3H), 3.52−3.59 (m, 9H), 3.63−3.67 (m, 4H), 3.69−3.73 (m, 1H), 3.93 (dd, J = 3.8, 8.4 Hz,1H), 5.21 (s, 1H), 6.75 (s, 2H), 6.92 (s, 1H), 7.54 (d, J = 8.7 Hz, 1H), 7.79 (d, J = 8.7 Hz, 1H), 8.22 (s, 1H). ^{11}B NMR (CD_3CN, 106.4 MHz): δ 1.60 (2B), −22.79 (1B), −26.01 (7B). HRMS (ES$^-$) $C_{26}H_{43}B_{10}N_4O_{10}$ $(M+H)^-$ calcd: 681.3915. Found: 681.3897. HPLC: t_R = 9.8 min.

17c: R = $C_6H_4-OCH_3$; reaction time = 1 h; 129 mg (81%) yield. ^{1}H NMR (CD_3CN, 500 MHz): δ −0.27−0.93 (m, 9H), 1.24 (t, J = 7.4 Hz, 18H), 2.37−2.49 (m, 4H), 3.13 (q, J = 7.4 Hz, 12H), 3.21−3.25 (m, 2H), 3.40−3.45 (m, 2H), 3.48−3.61 (m, 16H), 3.64−3.72 (m, 4H), 3.80−3.89 (m, 3H), 6.74 (s, 1H), 6.75 (s, 1H), 6.88 (d, J = 8.8 Hz, 1H), 6.94 (d, J = 8.8 Hz, 1H), 7.68 (d, J = 8.8 Hz, 1H), 7.78 (d, J = 8.8 Hz, 1H). ^{11}B NMR (CD_3CN, 106.4 MHz): δ 5.36 (1B), 3.03 (1B), −19.33 (1B), −21.51 (1B), −24.75 (2B), −25.48 (2B), −26.15 (2B). HRMS (ES^-) $C_{26}H_{45}B_{10}N_4O_9$ $(M+H)^-$ calcd: 667.4123. Found: 667.4128. HPLC: t_R = 11.8 min.

17d: R = CH_3; reaction time = 1 h; 72 mg (50%) yield. ^{1}H NMR (CD_3CN, 500 MHz): δ −0.34−0.97 (m, 9H), 1.21 (t, J = 7.4 Hz, 18H), 1.88 (s, 3H), 2.32−2.45 (m, 4H), 3.05 (q, J = 7.4 Hz, 12H), 3.21−3.31 (m, 2H), 3.41−3.46 (m, 2H), 3.48−3.59 (m, 16H), 3.61−3.69 (m, 4H), 6.74 (s, 1H), 6.75 (s, 1H). ^{11}B NMR (CD_3CN, 160.4 MHz): δ 4.30 (1B), 0.26 (1B), −20.08 (1B), −24.18 (1B), −26.64 (2B), −27.45 (2B), −28.18 (2B). HRMS (ES^-) $C_{20}H_{41}B_{10}N_4O_8$ $(M+H)^-$ calcd: 575.3860. Found: 575.3868. HPLC: t_R = 10.5 min.

General Procedure for Preparing Iodinated HPLC Standards; $[Et_3NH]_2B_{10}H_8I-C(R)=NNH-CO-dPEG_4-MAL$, 18a−18d. A 12 μmol quantity (159 μL; 10 mg/mL in MeOH) of *N*-chlorosuccinimide (NCS) was added to a solution containing 24 μmol of the *closo*-decaborate(2-) derivative (**17a**−**17d**), 12 μmol of NaI (17.9 μL; 100 mg/mL in deionized H_2O), and 5% HOAc/MeOH (0.5 mL). The reaction solution was stirred at room temperature for 1 min, then 12 μmol $Na_2S_2O_5$ (113 μL; 20 mg/mL in deionized H_2O) was added and the resultant solution was stirred at room temperature for 1 min. A small quantity of iodinated product was isolated from an analytical HPLC column for mass spectral analysis and to be used as a HPLC retention time standard for the radioiodination reactions. The identity of each standard was confirmed by high-resolution mass spectral data.

18a: R = C_6H_5; HRMS (ES^-) $C_{25}H_{42}IB_{10}N_4O_8$ $(M+H)^-$ calcd: 763.2978. Found: 763.3029 . HPLC: t_R = 12.5 min.

18b: R = $C_6H_5-CO_2H$; HRMS (ES^-) $C_{26}H_{42}IB_{10}N_4O_{10}$ $(M+H)^-$ calcd: 807.2876. Found: 807.2867. HPLC: t_R = 11.7 min.

18c: R = $C_6H_5-OCH_3$; HRMS (ES^-) $C_{26}H_{44}IB_{10}N_4O_9$ $(M+H)^-$ calcd: 793.3084. Found: 793.3100. HPLC: t_R = 12.3 min.

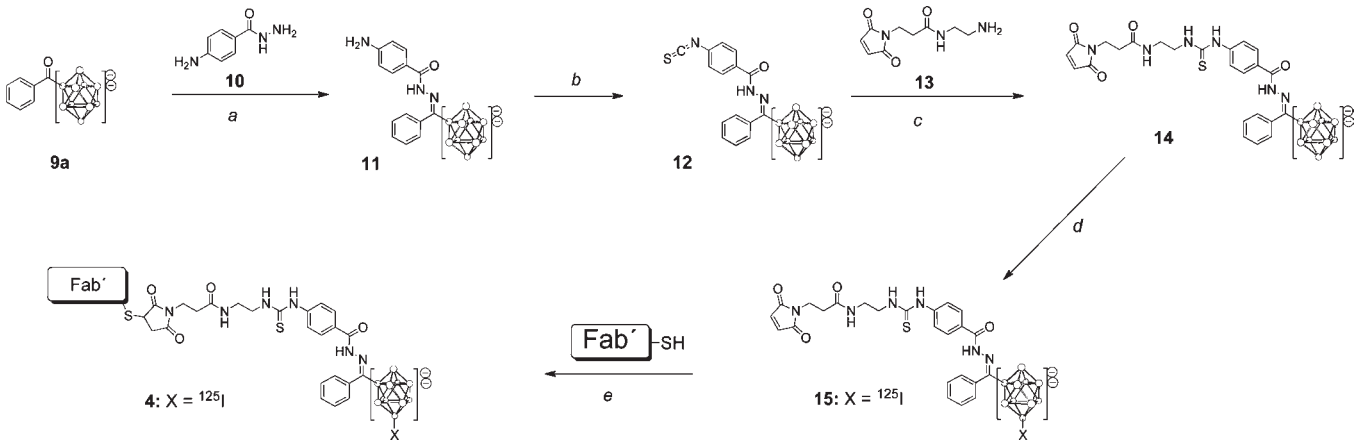
18d: R = CH_3; HRMS (ES^-) $C_{20}H_{40}IB_{10}N_4O_8$ $(M+H)^-$ calcd: 701.2821. Found: 701.2809. HPLC: t_R = 11.9 min.

General Procedure for Preparing [^{125}I]15, [^{131}I]18a, [^{125}I]18b, [^{125}I]18c, and [^{131}I]18d. To 50 μL of 1.0 mg/mL solution of the **14**, **17a**, **17b**, **17c**, or **17d** dissolved in a MeOH/2.5% HOAc mixture was added 1.1−1.4 mCi of Na[^{125}I]I or Na[^{131}I]I in 0.1 N NaOH. To this mixture was added 20 μL of 1 mg/mL *N*-chlorosuccinimide solution. The reaction was allowed to proceed at room temperature for 1 min, then 20 μL of 1 mg/mL sodium metabisulfite solution was added to quench. To this solution was added 50 μL of PBS and the volume was reduced to 50% under a stream of argon. The solutions containing radioiodinated derivatives ([^{125}I]**15**, [^{131}I]**18a**, [^{125}I]**18b**, [^{125}I]**18c**, or [^{131}I]**18d**) were used directly in the subsequent conjugation reactions.

Preparation of 107−1A4 and Its F(ab′)$_2$ Fragment. The monoclonal antibody 107−1A4, an IgG_1 mAb, which is reactive with the prostate-specific membrane antigen found in prostate tissue and upregulated in prostate cancer,[33] was obtained and purified as previously described.[28] The F(ab′)$_2$ fragment was prepared from intact mAb by digestion using pepsin (5.2 μg/mL in 80 mM NaOAc, pH 3.9) at 37 °C for 24 h. The F(ab′)$_2$ produced was purified on a Protein A column followed by a Fractogel TMAE column (EM Science, Gibbstown, NJ). The purified F(ab′)$_2$ was stored at refrigerator temperature. The 107−1A4 F(ab′)$_2$ was converted to Fab′-SH just prior to conjugation as described in the Experimental Procedures below.

Preparation of Fab′-SH Conjugate, 19. To 1.5 mL of 2.9 mg/mL F(ab′)$_2$ in PBS was added 60 μL of 100 mM DTT to make a final concentration of 4 mM DTT. This was gently mixed for 45 min at room temperature before passing through a PD-10 column eluting with PBS pH 6.5 with 1 mM EDTA. Protein containing fractions were combined to give 5 mL at 0.77 mg/mL Fab′-SH.

To 2.5 mL (1.9 mg; 0.038 μmol) of the Fab′-SH was added 30 μL of 11 mg/mL (0.33 mg; 0.48 μmol) **17b** in DMF. After 30 min at room temperature, a 10 μL aliquot of a 23.8 mg/mL *N*-ethylmaleimide (NEM) solution in DMF was added to react with the remaining sulfhydryl groups. After 10 min at room temperature, the mixture was split in half and each half was run over a PD-10 column. The protein fractions, containing **19**, were eluted in PBS and combined to yield 1.3 mg (64% protein recovery).



General Procedure for Conjugating [^{125}I]15, [^{131}I]18a, [^{125}I]18b, [^{125}I]18c, or [^{131}I]18d with 107−1A4 Fab′-SH. To 357 μL of 8.4 mg/mL 107−1A4 F(ab′)$_2$ in PBS was added 14.3 μL of 100 mM DTT to make a final concentration of 4 mM DTT. This was gently mixed for 45 min at room temperature before eluting over a PD-10 column (Sephadex G-25) with PBS pH 6.5 with 1 mM EDTA. Protein containing fractions were combined to give 2.5 mL at 1.25 mg/mL Fab′-SH.

A 0.5 mL aliquot of the Fab-SH solution was added to a PBS solution containing [^{125}I]**15**, [^{131}I]**18a**, [^{125}I]**18b**, [^{125}I]**18c**, or [^{131}I]**18d**. After 30 min at room temperature, 13 μL of 2 mg/mL *N*-ethylmaleimide in DMSO was added to cap the remaining sulfhydyl groups. After another 10 min at room temperature, the reaction mixture was passed over a PD-10 column by eluting with PBS. The protein-containing fractions were combined to give 85% recovery of protein with 30−40% radiochemical yields for [^{125}I]**15**, [^{131}I]**18a**, [^{125}I]**18b**, [^{125}I]**18c**, or [^{131}I]**18d**.

Assessment of Fab′-Hydrazone Cleavage with Acid. Fab′ conjugates [^{125}I]**3** and [^{125}I]**6a** were prepared by radioiodination of *N*-(15-(aminoacyldecaborate)-4,7,10-trioxatri-decanyl)-3-maleimidopriopionamide[17] and **17b**, respectively, followed by conjugation with Fab′ and purification as described above. Aliquots of the purified radioiodinated Fab′ conjugates (100 μL, 20 μg/2−6 μCi) were placed in three vials containing 200 μL of 50 mM sodium acetate solutions adjusted to pH 7, 4.5, and 2.0 using HCl. The radioiodinated Fab′ conjugate solutions were incubated at 37 °C for 26 h. Samples taken at 1, 4, and 26 h were placed in ultracentrifugation filters (Microcon YM-10), spun at 10 000 rpm for 10 min, then washed 3× with 200 μL PBS. The retentate and filtrate were counted in a gamma counter to provide the percent radioactivity bound to the protein.

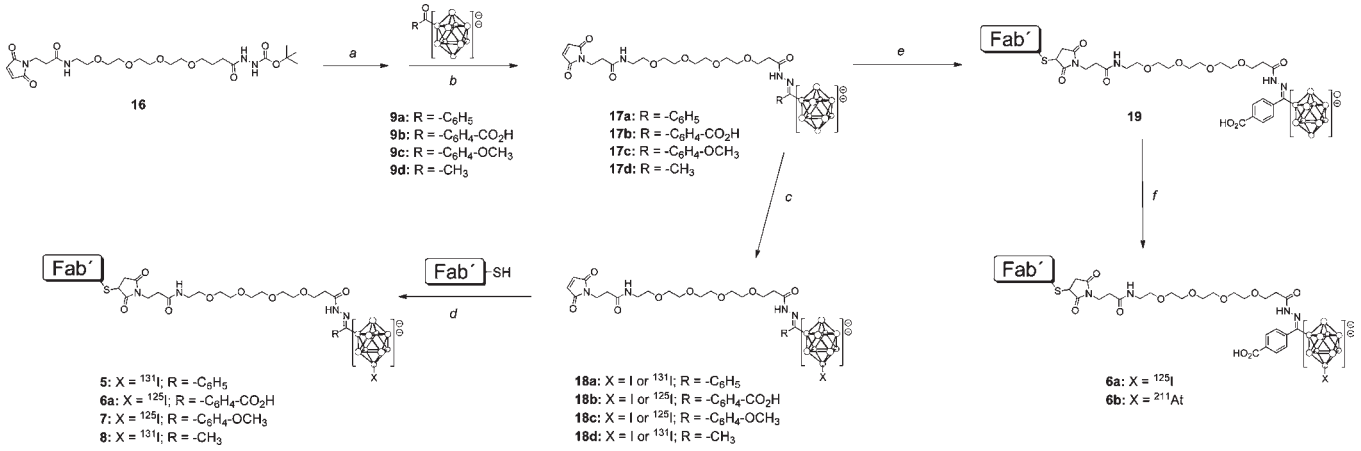
Preparation of [^{125}I]6a by Direct Labeling. To 25 μL of 500 mM sodium phosphate pH 7.4 was added ~1 μL (157 μCi) Na[^{125}I]I in 0.1 N NaOH. To this, 22 μL of **19** (6.9 mg/mL) was added, followed by 10 μL of a solution containing 1 mg/mL chloramine-T in water. After 1 min at room temperature, the reaction was quenched with 10 μL of 1 mg/mL sodium metabisulfite in H_2O solution. The mixture was eluted on a NAP-10 column (Sephadex G-25) with PBS. The protein fractions were combined to give 149 μCi (95% radiochemical yield) of [^{125}I]**6a**.

Scheme 1[a]

[a] (a) MeOH, rt, 16 h, 92%; (b) TCDI, anhyd. DMF, rt 1 h, 99%; (c) **13**, Et_3N, anhyd. DMF, rt, 2 h, 68%; (d) MeOH, HOAc, Na[^{125}I]I, NCS, rt, 1 min; (e) Fab′-SH/PBS, 30 min, rt, NEM/DMSO, 10 min, rt.

Preparation of [^{211}At]6b. To 200 μL of 500 mM sodium phosphate pH 7.4 was added 300 μL (573 μCi) of Na[^{211}At]At solution, pH 9. To this, 22 μL of **19** (6.9 mg/mL) was added, followed by 50 μL of 1 mg/mL chloramine-T in H_2O. After 1 min at room temperature, the reaction was quenched with 50 μL of 1 mg/mL sodium metabisulfite in water. The mixture was run over a PD-10 column eluting with PBS. The protein fractions were combined to give 367 μCi (64% radiochemical yield) of [^{211}At]**6b**.

Biodistribution Studies. Biodistribution studies were conducted under a protocol approved by the Institutional Animal Care and Use Committee (IACUC) at the University of Washington. Male nude (nu/nu) and C.B.-17 SCID mice, obtained from Charles River Laboratories (Hollister, CA), were housed for 1 week in the isolator facility prior to beginning the study. The biodistribution experiments were conducted, when possible, by evaluation of two compounds (dual labeled; ^{125}I and ^{131}I, or ^{125}I and ^{211}At) in a single set of mice to decrease the number of mice required for the study. In the initial biodistribution studies, nude mice were injected with [^{125}I]**4**, an admixture containing [^{131}I]**5**/[^{125}I]**6** or an admixture containing [^{125}I]**7**/[^{131}I]**8**. The admixtures were prepared to provide a total of 30 μg of Fab′ conjugate having preset amounts of μCi of each radiolabeled compound. A later experiment evaluated an admixture of the directly labeled [^{125}I]**6a** and [^{211}At]**6b** in mice bearing the LNCaP tumor xenografts. The radioactive admixtures were diluted with phosphate buffered saline (PBS) to prepare an injection volume of ~100 μL and were injected into each of the nude mice via the lateral tail vein. The actual amount of injectate each animal received was determined by weighing the administering syringe before and after injection. Groups of 3−5 mice were sacrificed by cervical dislocation (under anesthesia) at 1 and 4 h post injection. The tissues were excised, blotted free of blood, weighed, and counted. Blood weight was estimated to be 6% of the total body weight.[34] Calculation of percent injected dose (%ID) and percent injected dose per gram (%ID/g) for the collected tissues was accomplished using internal standards for ^{125}I, ^{131}I, or ^{211}At counts. The full data obtained in each biodistribution study, including amounts injected, animal weights, and results of statistical significance (using Student's *t* test) are provided as Tables S1−S4 in the Supporting Information.



RESULTS

Syntheses of Maleimido-*closo*-decaborate(2-) Derivatives. Five *closo*-decaborate(2-) derivatives containing the maleimide functionality were targeted for conjugation with Fab′-SH. The synthetic pathways used to prepare the maleimido-*closo*-decaborate(2-) derivatives **14**, **17a**, **17b**, **17c**, and **17d** are shown in Schemes 1 and 2.

The initial synthesis was conducted to prepare the maleimide derivative **14**, as shown in Scheme 1. The first step to prepare **14** involved formation of the hydrazone functionality by reaction of *para*-aminobenzoic hydrazide, **10**, in MeOH at room temperature for 16 h with the readily prepared triethylammonium salt of the benzoyl adduct of *closo*-decaborate(2-) **9a**.[32] A 92% yield of the adduct **11** was obtained. Following that step, the aniline was converted to an isothiocyanate by reaction with thiocarbonyldiimidazole (TCDI) in anhydrous DMF. The crude isolated isothiocyanate derivative **12** was reacted with commercially available *N*-(2′-aminoethyl)-3-(maleimido)propionamide, **13**, to provide 68% of **14** after purification by reversed-phase flash chromatography.

In the structures of maleimido-*closo*-decaborate(2-) derivatives **17a**, **17b**, **17c**, and **17d**, the hydrazone functionality was changed from a phenacyl hydrazone (in **14**) to an alkyl acyl hydrazone to alter the sensitivity to acid cleavage. Within the group of compounds the nature of the functional group (R) bonded with the ketone carbon of the hydrazone was varied (i.e., phenyl, benzoate, anisole, and methyl) for the same purpose. A poly(ethylene glycol) (PEG) linker was incorporated to improve the aqueous solubility of the conjugation molecule. To simplify the syntheses, a commercially available PEG derivative (**16**) that contained both maleimide and acyl hydrazone functionalities was used. Thus, a one-pot, two-step synthesis could be used to prepare *closo*-decaborate(2-)-containing maleimide derivatives **17a**, **17b**, **17c**, and **17d**, as shown in Scheme 2. In those syntheses, the commercially available tBoc protected maleimido-dPEG$_4$-acylhydrazide, **16**, was deprotected in neat TFA, then that crude product was directly reacted with the readily prepared acyl derivatives of *closo*-decaborate(2-), **9a**−**9d**,[32] in MeOH at room temperature for 1−4 h to provide 50−81% yields of **17a**−**17d**.

Scheme 2[a]

[a] (a) TFA, rt, 3 min; (b) MeOH, **16** (TFA salt), **9a**, **9b**, **9c**, or **9d**, rt, 1−4 h, 50−81%; (c) NaI or Na[$^{125/131}$I]I, MeOH, HOAc, NCS, rt, 1 min; (d) Fab′-SH/PBS, 30 min, rt, NEM/DMSO, 10 min, rt, 30−40%; (e) Fab′-SH/PBS, **17b**/DMF, 30 min, rt, NEM/DMF, 10 min, rt, 64%; (f) sodium phosphate (0.5 M, pH 7.4), Na[^{125}I]I or Na[^{211}At]At, ChT, 1 min, $Na_2S_2O_5$, 95% and 64%, respectively.

Radioiodination of Maleimido-*closo*-decaborate(2-) Derivatives. Prior to incorporation of radioiodine, **14**, **17a**, **17b**, **17c**, and **17d** were iodinated by reaction of *N*-chlorosuccinimide (NCS) and NaI in 5% HOAc/MeOH solution. Small quantities of the iodinated product were obtained for use as HPLC retention time standards in the radioiodination studies. The nonradioactive iodinated derivatives were isolated using analytical reversed-phase HPLC. The identities of the isolated iodinated products were confirmed by high-resolution mass spectrometry.

Radioiodination reactions were conducted by reacting 50 μg quantities of the maleimido-*closo*-decaborate(2-) derivatives **14**, **17a**, **17b**, **17c**, and **17d** with 1−1.4 mCi of Na[^{125}I]I or Na[^{131}I]I in MeOH/2.5% HOAc and *N*-chlorosuccinimide to form [^{125}I]**15**, [^{131}I]**18a**, [^{125}I]**18b**, [^{125}I]**18c**, and [^{131}I]**18d**. After 1 min reaction time, sodium metabisulfite was used to quench the reaction. The MeOH solutions were diluted with phosphate buffered saline, and that solution was reduced to 50% volume under a stream of argon to remove organics. The crude isolated radioiodinated products were used directly in the Fab′ conjugation reactions.

Conjugation of Maleimido-*closo*-decaborate(2-) Derivatives. The protein used in the investigation was a Fab′ fragment of the anti-PSMA antibody, 107−1A4.[28] To prepare the Fab′ fragment, the intact antibody was digested following standard procedures employing pepsin at 37 °C for 24 h to form the F(ab′)$_2$ fragment. The F(ab′)$_2$ fragment was purified on a Fractogel column and was stored at refrigerator temperature until used. Just prior to running the conjugation reactions, the F(ab′)$_2$ was converted to the Fab′-SH fragment by reducing with 4 mM dithiothreitol (DTT) for 45 min at room temperature. After reduction, the Fab′ was purified over a size exclusion column (PD-10).

Radioiodinated maleimido-*closo*-decaborate(2-) derivatives [^{125}I]**15**, [^{131}I]**18a**, [^{125}I]**18b**, [^{125}I]**18c**, and [^{131}I]**18d** were reacted with Fab′-SH for 30 min at room temperature, then *N*-ethylmaleimide (NEM) was added to cap any unreacted thiol groups. The radioiodinated Fab′ conjugates were purified by elution on size exclusion columns. This overall radiolabeling procedure provided isolated radiochemical yields of 30−40% for [^{125}I]**4**, [^{131}I]**5**, [^{125}I]**6**, [^{125}I]**7**, and [^{131}I]**8**.

A nonradioactive Fab′ conjugate was prepared by reaction with the maleimido-*closo*-decaborate(2-) derivative **17b** with 107−1A4 Fab′-SH. The selection of Fab′ conjugated with maleimide derivative containing a benzoic acid moiety adjacent to the hydrazone, **17b**, was made based on the favorable biodistribution of its radioiodinated counterpart (see Figure 2). The conjugation reaction was conducted with a ratio of 1 Fab′-SH to 13 equiv of **17b**. The conjugation was allowed to run for 30 min at room temperature, then the remaining thiols were capped with NEM and the conjugate was purified by size-exclusion chromatography (PD-10). The isolated Fab′ conjugate was analyzed by size-exclusion HPLC to determine the peak shape, retention time, and number of species present.

Fab′-Hydrazone Cleavage with Acid. Fab′ conjugates [^{125}I]**3** and [^{125}I]**6a** were incubated at 37 °C in 50 mM sodium acetate solutions adjusted to pH 7, 4.5, and 2.0 for 26 h to assess the cleavage of the hydrazone functionality in [^{125}I]**6**. The control (noncleavable) Fab′ conjugate, [^{125}I]**3**, had no cleavage (97−98% protein-bound activity) after 26 h. However, acid-promoted cleavage (99% protein-bound at pH 7.0; 81% protein-bound at pH 4.5; 70% protein-bound at pH 2.0) was observed for the Fab′ conjugate, [^{125}I]**6a**, after 26 h of incubation time.

Radiohalogenation of Fab′-SH Conjugate 19. Direct radiohalogenation of Fab′ conjugate **19** was accomplished with ^{125}I and ^{211}At. Radioiodination of **19** was accomplished by reaction of Na[^{125}I]I and chloramine-T (ChT) for 1 min at room temperature. After quenching the reaction with sodium metabisulfite, elution of the labeled Fab′ conjugate over a size-exclusion column provided a 95% isolated radiochemical yields of [^{125}I]**6a**. Similarly, astatination of **19** was accomplished by reaction of Na[^{211}At]At with ChT for 1 min at room temperature to provide a 64% isolated radiochemical yield of [^{211}At]**6b** after quenching and purification.

Biodistributions of Radiolabeled Fab′-SH Derivatives. Three biodistribution studies were conducted using hydrazone-containing radioiodinated Fab′ conjugates to determine if the concentrations of radioiodine localized to kidney were effected by the inclusion of the hydrazone moiety. Dual-label biodistribution studies were conducted where possible to minimize the use of animals in the study. Thus, the initial three biodistribution

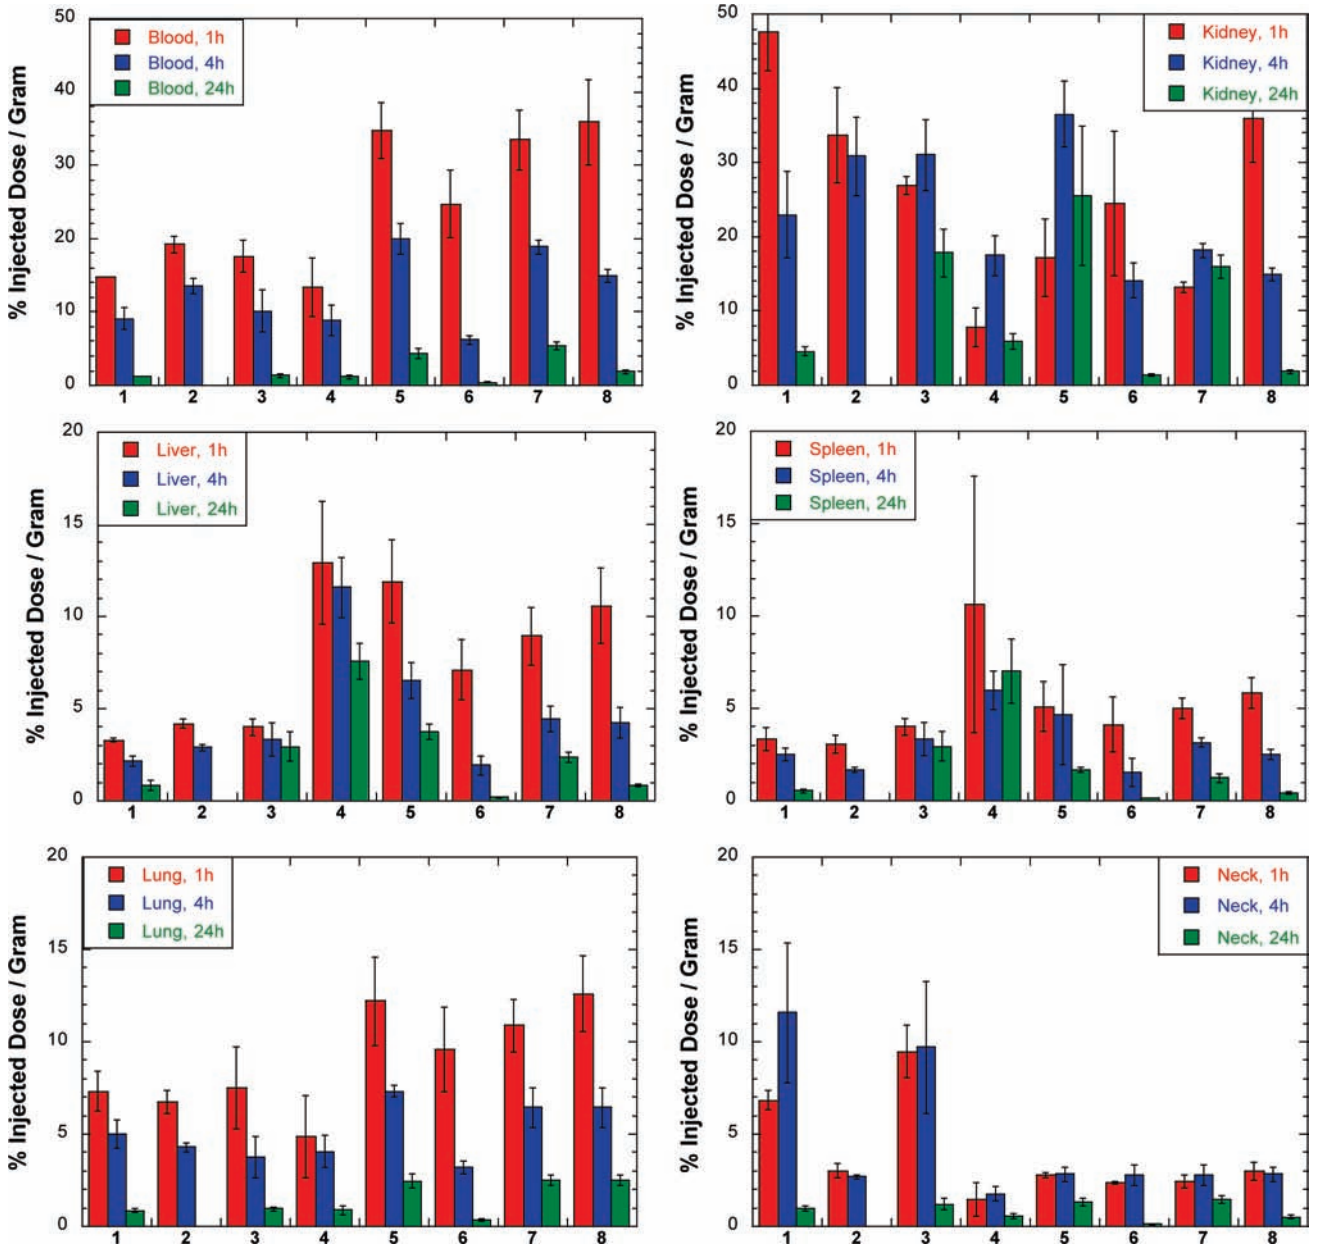

Figure 2. Bar graphs representing tissue concentrations (% ID/g) of radioiodinated 107−1A4 Fab′ and radioiodinated 107−1A4 Fab′ conjugates in selected tissues. The numbers on the *x*-axis represent the radioiodinated Fab′ derivatives depicted in Figure 1. Data plotted for directly labeled Fab′-NEM, [^{125}I]**1**, *para*-iodobenzoate-labeled Fab′-S-NEM, [^{125}I]**2**, and noncleavable radioiodinated Fab′-SH conjugate [^{125}I]**3** were obtained from the literature.[17] Data plotted for hydrazone-containing conjugates [^{125}I]**4**, [^{131}I]**5**, [^{125}I]**6a**, [^{125}I]**7**, and [^{131}I]**8** were obtained in this study. Identification of the tissue graphed is provided in the boxed legend within the graph. The percent injected dose/gram (%ID/g) values shown in each bar are average values in that tissue for 3−5 mice, and the error bars represent the standard deviation of those values. The first bar (red) represents values obtained at 1 h post injection (pi), the second bar (blue) represents values obtained at 4 h pi, and the third bar (green) represents values obtained at 24 h pi. Note that the range in %ID/g for the blood and kidney graphs (top) is 0−50%ID/g, whereas the range for the other 4 graphs is 0−20% ID/g. The data plotted in the bar graphs are provided as Tables S1, S2, and S3 in Supporting Information.

studies evaluated the following Fab′ conjugates: (1) [^{125}I]**4**; (2) [^{131}I]**5** and [^{125}I]**6a**; (3) [^{125}I]**7** and [^{131}I]**8**. The amount of protein injected into each mouse was kept constant throughout the groups (i.e., 30 μg/mouse). It was of high interest to compare the results obtained in this investigation with previous results obtained with a noncleavable maleimido-*closo*-decaborate(2-) Fab′ conjugate, [^{125}I]**3**. It was also of interest to compare the biodistribution results obtained in this study with results obtained from direct radioiodination, [^{125}I]**1**, and conjugation of a *para*-[^{125}I]iodobenzoate derivative, [^{125}I]**2** with the same Fab′. To highlight the comparison, the tissue concentrations (% injected dose/gram) of [^{125}I]**4**, [^{131}I]**5**, [^{125}I]**6a**, [^{125}I]**7**, and [^{131}I]**8** have been plotted along with published data for [^{125}I]**1**, [^{125}I]**2**, and [^{125}I]**3**. The comparison graphs for selected tissues are provided in Figure 2. The radioiodine concentrations obtained for selected tissues and blood in this study are provided as Tables S1, S2, and S3 in Supporting Information.

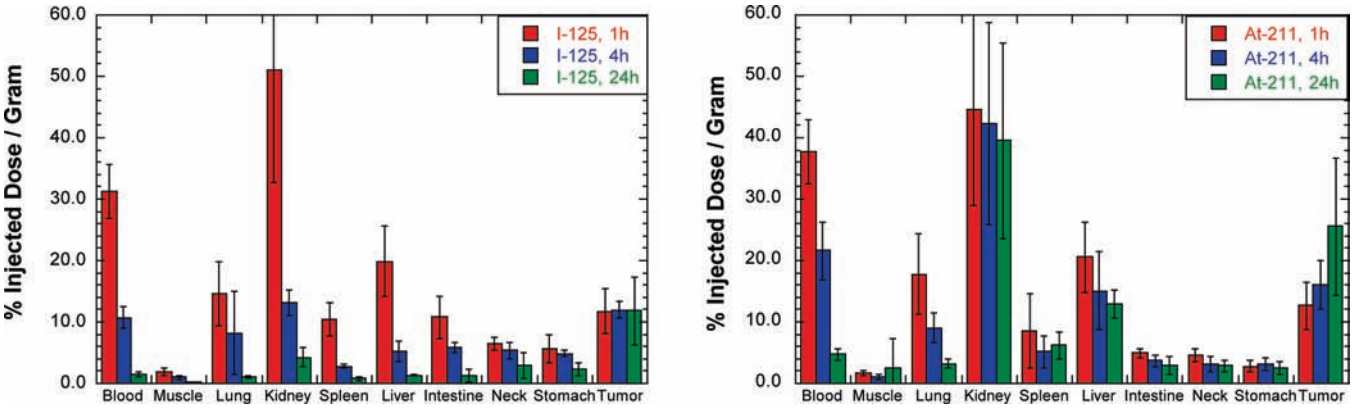

Figure 3. Bar graphs depicting the tissue concentrations (%ID/g) of [^{125}I]**6a** (left panel) and [^{211}At]**6b** (right panel). The Fab′-SH conjugates were prepared, then directly labeled with ^{125}I and (separately) ^{211}At. The labeled Fab′ conjugates were mixed and coadministered so that tissue comparisons could be made in the same animal. Each bar represents the average %ID/g obtained in a group of 5 mice for that radionuclide in a selected tissue, and the error bars represent the standard deviation of those values. The red bars are tissue concentrations at 1 h post injection (pi), blue bars at 4 h pi, and green bars at 24 h pi. The radionuclide being represented is shown in the boxed legend within the graph. The complete set of data for the values plotted are provided as Table S4 in the Supporting Information.

When examining the tissue concentrations in Figure 2, the values for tissue concentrations of Fab′ conjugates **1**, **2**, and **3** (from literature) should not be compared directly with those of Fab′ conjugates **4** through **8** evaluated in this study, as the studies were not conducted under exactly the same conditions. In general, it appears that the reported concentrations of radioiodinated Fab′ **1** through **3** are lower in most tissues than those obtained in this study for radioiodinated Fab′ conjugates **4** through **8**, except kidney and neck. The reasons for the differences are not known. While the relative concentrations are not evaluable, trends regarding clearance of radioiodine from tissues can be compared for all of the Fab′ conjugates. The tissue of highest interest in this study is kidney, as the high localization of radioactivity to that tissue is dose limiting for radiolabeled Fab′. In the mouse model, radioiodinated Fab′ [^{125}I]**1** produced by direct labeling of tyrosine residues was highly localized in kidney, but was cleared from that tissue within 24 h. In contrast to this, Fab′ conjugates [^{125}I]**2** and [^{125}I]**3** prepared by a two-step method using a *para*-[^{125}I]iodobenzoyl labeling reagent, or direct labeling after conjugation of a maleimido-*closo*-decaborate(2-) reagent, had little kidney clearance over a 24 h period.

It can be noted in Figure 2 that the kidney concentrations and clearance for Fab′ conjugates [^{125}I]**4**, [^{131}I]**5**, [^{125}I]**6a**, [^{125}I]**7**, and [^{131}I]**8** varied considerably. The concentration of [^{125}I]**4** in kidney was low, and appeared to clear over the 24 h period. With exception of the liver, there was a lower concentration of [^{125}I]**4** relative to [^{131}I]**5**, [^{125}I]**6a**, [^{125}I]**7**, and [^{131}I]**8** in the other tissues. The lower tissue concentrations may be an indication that the hydrazone in [^{125}I]**4** has a lower overall in vivo stability. The higher liver concentrations seen for [^{125}I]**4** may be due to a higher lipophilicity of the conjugate metabolites. The kidney concentrations of [^{131}I]**5** and [^{125}I]**7** did not decrease significantly over the 24 h period, indicating either that the hydrazone was not as readily cleaved or that the metabolites were retained. In contrast, kidney concentrations of [^{125}I]**6a** and [^{131}I]**8** decreased dramatically over the 24 h period. Indeed, the clearance from kidney of [^{125}I]**6a** and [^{131}I]**8** was similar to that seen with directly labeled Fab′ (i.e., [^{125}I]**1**).

A fourth biodistribution was conducted in nude mice bearing LNCaP human prostate cancer xenografts to compare the pharmacokinetics, tissue concentrations, and tumor localization of [^{125}I]**6a** and [^{211}At]**6b**. The results of that study are depicted in the bar graphs shown in Figure 3, and the data are provided as Table S4 in Supporting Information. In the coinjected, dual-labeled (^{125}I and ^{211}At) study, it was anticipated that the distribution of ^{125}I and ^{211}At would be very similar, as that had been the case in most prior studies using *closo*-decaborate(2-) protein conjugates and small molecules. It is apparent in Figure 3 that kidney (and liver) retention is much higher in the ^{211}At-labeled Fab′ conjugate. Interestingly, while the tumor concentration appeared to stay constant in the ^{125}I-labeled Fab′ conjugate, the concentration was higher and increased with time in the ^{211}At-labeled Fab′ conjugate.

DISCUSSION

An objective in our laboratory is to obtain a tumor-targeting agent for use with ^{211}At that has a blood half-life similar (e.g., 6−8 h) to the physical half-life of ^{211}At (7.21 h), so that tumor masses can be readily penetrated and an efficient delivery of that radionuclide to the tumor can be obtained. Intact MAbs have relatively long biological half-lives and do not penetrate tumors within a half-life of ^{211}At, making them unattractive as carriers of ^{211}At (for most cases). In contrast, small proteins (25 kDa or less) and peptides penetrate tumor masses readily, but are rapidly cleared from blood, so only a small fraction of the injected radioactivity gets to the tumor site(s). This latter point is important, as cost and availability of ^{211}At must be considered in developing a reagent that uses it. This makes mAb fragments, such as Fab′, of high interest as cancer targeting agents for ^{211}At, since they are small enough to penetrate tumors and have a long enough biological half-life (e.g., 6.8 h in mice[35]).

Our investigation of ^{211}At endoradiotherapy was hampered for a number of years by the fact that many ^{211}At-labeled tumor-targeting agents undergo deastatination in vivo, including Fab′ fragments.[16] However, more recently we demonstrated that switching from bonding of the ^{211}At with an aromatic carbon atom to bonding with a boron atom in an aromatic boron cage moiety provides high in vivo stability toward deastatination.[17,31,36] Of the boron cage moieties evaluated, the nonahydro-*closo*-decaborate

(2-) cage has become the ^{211}At-labeling moiety of choice, because it (a) is easily prepared, (b) is very reactive with electrophilic halogens, (c) is quite stable in vivo, and (d) appears to have minimal affect on the biodistribution of compounds studied. Although only small differences in biodistribution of radiohalogens are observed with *closo*-decaborate(2-) conjugates, it has been noted that the radiohalogens localized to kidney and/or liver can have slow clearance from those tissues.

In previous studies, we found that mAb Fab′ fragments conjugated with a noncleavable *closo*-decaborate(2-) moiety can have in vivo pharmacokinetics and tissue distributions that are quite different from the same protein directly labeled with radioiodine.[17] The difference is particularly noticeable in kidney. That difference can be readily seen in Figure 2 (top right panel), where the concentration of radioiodine-labeled Fab′, [^{125}I]**1**, decreases over a 24 h period, whereas in a radioiodinated Fab′ containing a noncleavable *closo*-decaborate(2-) conjugate, [^{125}I]**3**, the radioactivity is generally retained over that time period. It seems unlikely that the longer kidney retention is due to the dianionic *closo*-decaborate(2-) moiety, as similar kidney retention is observed when the same mAb Fab′ is radioiodinated using *N*-hydroxysuccinimidyl *para*-[^{125}I]iodobenzoate (to give [^{125}I]**2**). The retention of radiohalogens in kidney prompted us to survey literature approaches for diminishing the uptake of ^{211}At-labeled Fab′ or, alternatively, for releasing metabolites from kidneys.

Several different approaches have been studied to reduce renal localization and retention of radiolabeled proteins, their enzymatically produced fragments, and genetically engineered fragments.[23,37,38] An attractive approach is to decrease uptake of ^{211}At-labeled Fab′ without alteration of the Fab′ or labeling molecule. Such an approach, that of infusing basic amino acids, has been investigated for Fab′,[39−44] however, that approach can be difficult to control and the decrease in kidney concentration may not be enough to be useful for ^{211}At-labeled Fab′ (although it might be useful in combination with other approaches). Since it did not appear that infusion of basic amino acids would provide adequate clearance, approaches where the Fab′ was modified were considered. One possible modification would be to conjugate another molecule (e.g., large poly(ethylene glycol)) to the Fab′, such that its modified size/shape would block filtration by the glomerulus. Although attractive as an approach, based on literature reports we surmised that approach would likely lead to a loss of immunoreactivity of the Fab′ before complete blockage of filtration was achieved.[45] Likewise, alteration of the pI on the Fab′ by succinylation[46] or glycolation[47−49] also seemed likely to have a negative affect its antigen binding.

An alternate approach to blocking uptake in the kidney is to build functional groups into conjugation reagents that can be cleaved in the kidney to provide metabolites that are more readily cleared from kidneys. Several approaches have been described in the literature for decreasing the retention of radioactivity in the kidney after administration of radiolabeled antibodies or their fragments.[37,50] In one approach, investigators used enzymatically based methods to decrease the retention of radiolabeled molecules in the kidney. Those methods are based on the use of conjugation linkers containing esters susceptible to esterases[51−55] or specific peptide sequences that can be cleaved by pepidases.[56−61] While enzyme-mediated release of radioactive metabolites from kidneys functioned as designed, the results (kinetics and kidney concentrations) point to the need to explore additional methods. An alternate method is the use the low pH in lysosomes (pH 4.5−5.0[62,63]) for release of radioactivity from kidneys. That method was of particular interest, as the cleavage process is nonspecific and release kinetics can be optimized by chemical modification of the acid-cleavable chemical functionality. It has been shown that lysosomal pH can be used for release of drugs from antibodies.[27] While pH-sensitive *cis*-aconatyl[64] and acetal[65] linkages have been described, the use of readily prepared hydrazone-linked antibody−drug conjugates[66−70] appeared most promising.

Prior to this study, we evaluated the tissue distributions of a series of radioiodinated *closo*-decaborate(2-) compounds in mice to determine which structural features provided the lowest tissue concentrations.[32] In that study, compounds containing a hydrazone moiety had favorable pharmacokinetics and low tissue concentrations. While the study did not provide information that could be directly used to predict tissue distributions of metabolites of Fab′ radioiodinated on a *closo*-decaborate (2-) moiety, it did provide information on the distribution of radioiodinated hydrazone derivatives that were introduced into blood. The rapid clearance from blood and release of radioiodine from kidney encouraged us to prepare and evaluate radiolabeled Fab′ conjugated with sulfhydryl-reactive *closo*-decaborate(2-) derivatives containing a hydrazone functionality. In this study, mAb Fab′ fragments were used because they are of interest not only as a carrier molecule, but also as a model where differences in clearance rates between the radiohalogenated proteins could readily be observed.

Radioiodinated Fab′-hydrazone-*closo*-decaborate(2-) conjugates [^{125}I]**4**, [^{131}I]**5**, [^{125}I]**6a**, [^{125}I]**7**, and [^{131}I]**8** were prepared for the study using a two-step labeling approach. Radioiodinations of the maleimido-derivatives (**14**, **17a**, **17b**, **17c**, and **17d**) were conducted prior to conjugation with the Fab′ to ensure that all of the radioiodine was on the *closo*-decaborate(2-) moiety. By doing this, the interpretation of the tissue clearance was not confounded by having some of the radioactivity on protein tyrosine residues. In prior studies, thyroid and stomach concentrations of mAb fragments radioiodinated after conjugation with *closo*-decaborate(2-) indicated that some of the radioiodine reacted with protein tyrosine residues. Importantly, in those studies it appears that more than one *closo*-decaborate(2-) per antibody conjugate is required to ensure that the radioiodine only reacts with that moiety.

The data depicted in tissue bar graphs shown in Figure 2 show that the hydrazone-containing Fab′ conjugates, [^{125}I]**6a** and [^{131}I]**8**, have kidney clearance rates similar to that of directly (tyrosine) labeled Fab′, [^{125}I]**1**. Although the blood clearances are similar, Fab′ conjugates [^{125}I]**4**, [^{131}I]**5**, and [^{125}I]**7** have kidney localization and retention profiles that are very different from [^{125}I]**6a** and [^{131}I]**8**, or directly labeled [^{125}I]**1**. Tissue concentrations for [^{125}I]**4** are lower in general than for the other conjugates, with the exception of liver and spleen concentrations. Those concentrations are higher than for the other conjugates, perhaps indicating that some aggregation or serum protein binding occurred with the Fab′ conjugate or its metabolites. Release of ^{125}I from the liver also appears to be most efficient for [^{125}I]**6a** and [^{131}I]**8**. The only other major differences were seen in the neck (containing thyroid), where directly labeled [^{125}I]**1** was high at 1 and 4 h pi, as expected. As indicated previously, the high concentration of ^{125}I in neck for the noncleavable *closo*-decaborate(2-) conjugate [^{125}I]**3** may be attributable to some of the ^{125}I reacting with tyrosine residues on the Fab′ conjugate rather than the *closo*-decaborate(2-) cage. From these data, it was concluded that Fab′ conjugates [^{125}I]**6a** and [^{131}I]**8** have the most favorable in vivo characteristics for further study.

The ultimate goal in developing *closo*-decaborate(2-) conjugation reagents is to use them for direct labeling of the proteins with ^{211}At, as that is the simplest labeling procedure and provides the highest radiolabeling yields (up to 92% in our studies). Thus, conjugation of the maleimido-*closo*-decaborate(2-) reagent should be done prior to labeling. Although a two-step labeling procedure was used in the initial biodistribution studies to be certain that the radioiodine was bonded to the *closo*-decaborate(2-) moiety, ^{211}At does not stably bond to tyrosine residues, so direct labeling only occurs on the *closo*-decaborate(2-). An important issue that arose was to make a decision on which hydrazone-containing conjugation reagent to use. Although both of the labeling reagents, [^{125}I]**6a** and [^{131}I]**8**, were of interest, the choice of hydrazone derivative to use was limited to the conjugate containing a benzoic acid moiety, **17b**. This choice was made, as the acetyl-*closo*-decaborate(2-), **9d**, and its hydrazone-containing maleimido-*closo*-decaborate(2-) adduct, **17d**, were found to be somewhat unstable and difficult to purify.

It was of interest to determine if the Fab′ conjugate of choice, [^{125}I]**6a**, which contained a hydrazone functionality substituted with a *closo*-decaborate(2-) moiety and a *para*-benzoate moiety was cleaved under mild acid conditions. The use of hydrazone-containing linkers as a means of releasing radioactivity from kidney was based on previous literature reports that demonstrated antibody−drug conjugates containing hydrazone linkers released the drug under mild acid conditions (e.g., pH 4.5), but not at neutral pH.[66,67,71−74] The rate of acid cleavage can be dependent on the electronic nature of substituents on the hydrazine and aldehyde or ketone reacted that form the hydrazone,[75] making it possible to form hydrazone linkers that are too rapidly cleaved for in vivo use or, alternatively, very slowly cleaved under in vivo conditions.[76] Importantly, none of the previous hydrazone conjugates contained the dianionic *closo*-decaborate(2-) moiety. The results obtained from the in vitro acid-catalyzed cleavage analysis indicate that acid-catalyzed cleavage of the hydrazone functionality does occur for Fab′ conjugate [^{125}I]**6a**. The observed acid-catalyzed cleavage supports our hypothesis for the mechanism of in vivo release of radioactivity from the kidney and liver (Figure 2), but the kinetics of the cleavage under the in vitro conditions used appear much slower than the release of radioactivity from tissues. It seems likely that, at least in part, the biological mechanism for release of radioactivity from tissue is acid-catalyzed cleavage of the hydrazone functionality. However, to be certain of the actual mechanism of release from the kidneys, studies of metabolites in blood, urine, and feces would be required. Such metabolite studies are beyond the scope of this investigation.

All of the initial developmental studies were conducted with radioiodinated Fab′ conjugates, but the ultimate goal is to use them for targeting ^{211}At to cancer cells in vivo. In the final Fab′ study, **17b** was conjugated with 107−1A4 Fab′, then directly labeled with ^{125}I to prepare [^{125}I]**6a** and (separately) with ^{211}At to prepare [^{211}At]**6b**. An important difference in this biodistribution study was that the radiohalogenated Fab′ were evaluated in mice bearing LNCaP human prostate tumor xenografts. The 107−1A4 is an anti-PSMA antibody that binds with the prostate-specific membrane antigen (PSMA), which is highly expressed on the LNCaP cells.[28] This model was used to demonstrate that tumor targeting could be achieved, and to assess whether the cleavable hydrazone group caused a decrease in tumor concentration at the later time points. The biodistribution data are plotted in Figure 3. It had been presumed that the tissue distribution of the Fab′ conjugate [^{211}At]**6b** would be very similar to that of [^{125}I]**6a**. This presumption was based on many prior studies, where the two radionuclides had similar distributions when the carrier molecules were conjugated with a *closo*-decaborate(2-) moiety. The results show that the use of ^{211}At changes the retention of radioactivity in kidney, liver, and tumor from that obtained with the same Fab′ conjugate labeled with ^{125}I. The neck and stomach concentrations indicate that [^{211}At]astatide is not being released, so it seems likely that another metabolite is being retained. Although the nature of that metabolite is not known for certain, it should be noted that we have obtained similar differences in kidney retention for ^{125}I- and ^{211}At-labeled biotin derivatives that contain a ketone coupled to a *closo*-decaborate(2-) cage (unpublished results). Importantly, the kidney retention differences observed for that biotin derivative were alleviated by conversion of the ketone to an oxime derivative. That finding is suggestive that the nature of the conjugated ketone or other metabolite is changed when the *closo*-decaborate-(2-) is substituted with ^{211}At rather than ^{125}I. It also suggests that alternate hydrazone structures might provide the faster renal clearance being sought.

In conclusion, this study has demonstrated that chemical linkers containing hydrazone moieties can be used to increase the rate of clearance of radioactivity (radioiodine) from kidneys and other tissues. The differences in tissue clearance data indicate that changing the nature of the hydrazone and substituents attached to it can change the tissue clearance rates. The striking differences in tissue clearance observed between radioiodinated and astatinated Fab′ conjugate were surprising. That data indicate that additional studies must be conducted before effective hydrazone-containing linkers are found that function with ^{211}At. In contrast, the data obtained indicate that use of a hydrazone containing *closo*-decaborate(2-) labeling moiety might be highly beneficial for radioiodinated proteins or peptides that are localized to kidney.

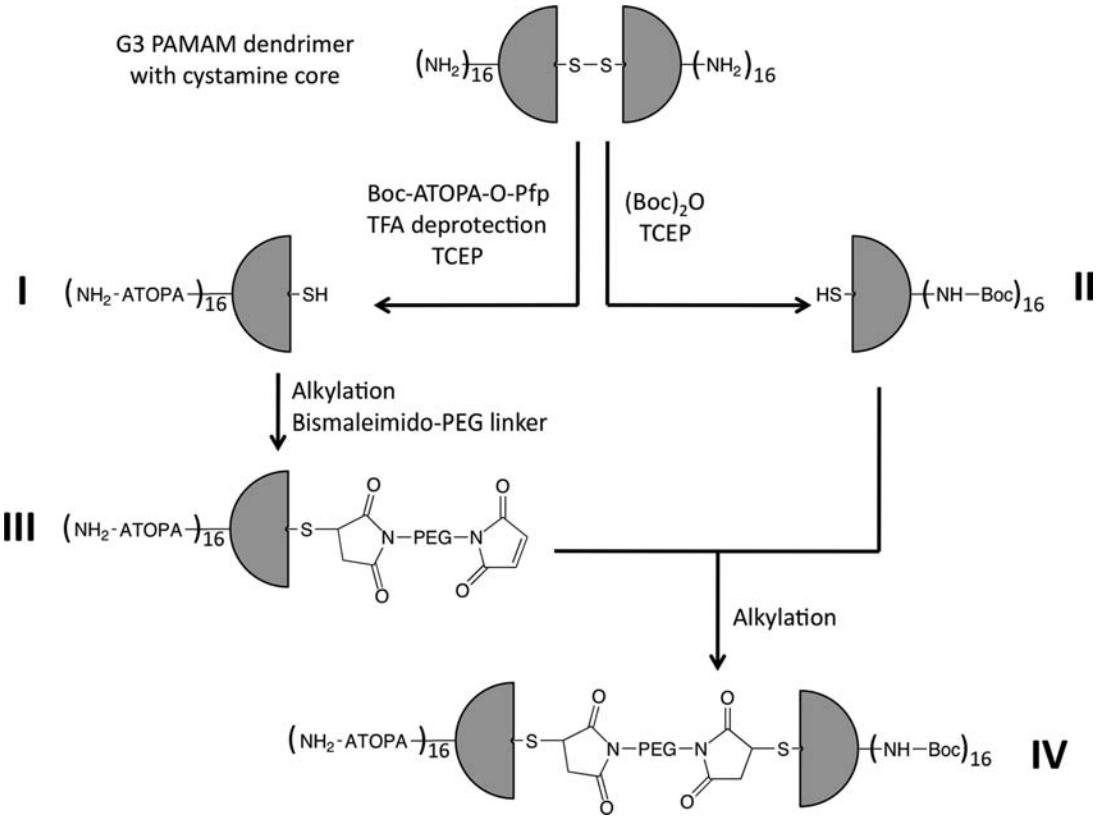
Supporting Information

ABSTRACT: Nanoparticles carrying biologically active functional sets (e.g., targeting moiety, payload, tracer) have potential use in a wide range of clinical applications. Though complex, such constructions should, as far as possible, have a defined molecular architecture and be monodisperse. However, the existing methods to achieve this goal are unsuitable for the incorporation of peptides and proteins, and those that provide for orthogonal introduction of two different types of functional element are incompatible with the use of commercially available materials. In this study, we have developed approaches for the production of nanoparticles based on commercially available polyamidoamine (PAMAM) dendrimers. First, we identified an optimized oxime conjugation strategy under which complex dendrimers can be fully decorated not only with model peptides, but also with recombinant proteins (insulin was taken as an example). Second, we developed a strategy based on a two-chain covalent heterodendrimer (a "diblock") based on cystamine core PAMAM dendrimers and used it to generate heterodendrimers, into which a peptide array and a mannose array were orthogonally introduced. Finally, by incorporating a functionalized linker into the diblock architecture we were able to site-specifically introduce a third functional element into the nanoparticle. We exemplified this approach using fluorescein, a mannose array, and a peptide array as the three functionalities. We showed that incorporation of a mannose array into a nanoparticle strongly and specifically enhances uptake by sentinel cells of the immune system, an important property for vaccine delivery applications. These PAMAM dendrimer-based approaches represent a robust and versatile platform for the development of bioactive nanoparticles.

INTRODUCTION

Dendrimers are branched polymers synthesized in a stepwise manner from a central core to generate particles that combine a precise, potentially monodisperse molecular architecture carrying a high density of surface functional groups. These properties make dendrimers attractive scaffolds for the generation of bioactive nanoparticles for clinical applications including drug and gene delivery, tumor targeting, bioimaging, tissue remodelling, generation of antiviral products, and vaccine delivery.[1−3]



For these uses, it is highly desirable to obtain fully decorated scaffolds, thereby maximizing the possible benefits to biological activity of multivalent display,[4] as well as ensuring homogeneity and reproducibility from batch to batch and within each batch. While close to complete decoration of large, complex dendrimers has been achieved in the development of sugar arrays,[5,6] decoration with peptides and proteins has proven to be more challenging. None of the peptide/protein conjugation chemistry approaches explored so far, including hydrazone and oxime chemistry,[7,8] native chemical ligation,[9] click chemistry,[10,11] and noncovalent synthesis of protein dendrimers,[12] have proven powerful enough to fully decorate dendrimers more complex than tetramers and octamers.

A second challenge lies in developing the capacity to orthogonally introduce more than one active substituent into the nanoparticle architecture (e.g., a targeting moiety, a drug payload, a fluorescent tracer).[1,2] Approaches that enable multiple functional units to be independently attached to dendrimers via precision conjugation would be of significant value, enabling the copy numbers of different functional units to be optimized independently of one another. While several different strategies for the production of heterodendrimers carrying two different functional units have been presented,[8,13,14] none of these are

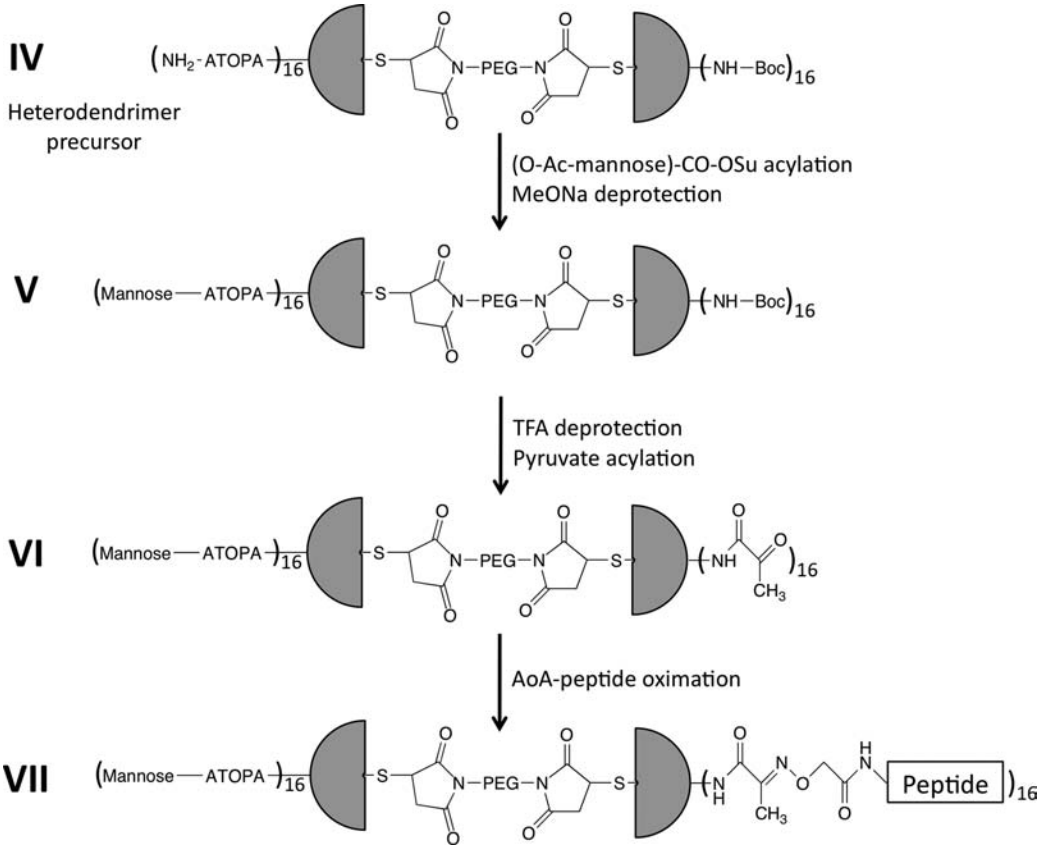
Scheme 1. Diblock Approach Based on Cystamine Core PAMAM Dendrimers for the Preparation of Heterodendrimers Carrying Protein/Peptide Plus an Additional Functional Unit Set

compatible with the use of commercially available dendrimers as starting materials.

In this study, we present a robust strategy for conjugation of commercially available polyamidoamine (PAMAM) dendrimer scaffolds with peptides and proteins. This work is based on oxime chemistry, building on two recent discoveries in the field: first, that an alkoxyamine reacts much more readily with pyruvic acid than with N-terminal glyoxyl groups,[15] and second, that oxime ligation can be significantly accelerated and provide quantitative yields when aniline is used as a small-molecule organocatalyst.[16,17]

We have also developed an orthogonal diblock strategy for the generation of heterodendrimers from PAMAM dendrimers carrying a cystamine core. This approach is centered on the production of a key intermediate structure (Scheme 1) that is subsequently (i) acylated on the surface amines of one-half-dendrimer, those of the other half-dendrimer being temporarily protected and, following deprotection of the latter, (ii) decorated with an array of oxime-conjugated peptides on the other (Scheme 2). We exemplified this approach by producing G-3 heterodendrimers in which one half-dendrimer is decorated with mannose and the other with peptide.



A potentially useful application of mannose−peptide/protein nanoparticles is in vaccine delivery: directly targeting a peptide or protein antigen to mannose-receptor-expressing sentinel cells of the immune system by incorporating it into a mannose-coated particle.[18−21] We produced such a heterodendrimer, further enhanced by the functionalization of the linkage between the two halves with fluorescein. This fluorescent mannose−peptide heterodendrimer was used to demonstrate the effect of incorporating a mannose array on the specific uptake of nanoparticles by dendritic cells and macrophages.

EXPERIMENTAL PROCEDURES

General Methods. Unless stated otherwise, all solvents and other chemicals were obtained from commercial sources and used as received. Amine-terminated PAMAM dendrimers were supplied by Sigma-Aldrich and Dendritic Nanotechnologies (Mount Pleasant, MI, USA). Analytical reverse-phase high-pressure liquid chromatography (HPLC) was performed on a Waters 2795 HPLC module coupled with 214 nm UV detection, using a Macherey Nagel 300A, 5 μm C8 column. Preparative HPLC was performed on a Delta 600 module coupled with a 2487 UV detector using a Vydac C8 column (250 × 22 mm i.d., 10 μm particle size) under previously described conditions.[17] Electrophoresis of peptide and protein constructs was performed on NuPage 12% Bis-Tris Gel from Invitrogen (MOPS buffer, 100 V). Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) spectra were obtained on a Perspective Biosystems Voyager SSTR or on a Shimadzu AXIMA CFR Plus mass spectrometer using sinapinic acid, 2,5 dihydroxybenzoic acid, or 2′,4′,6′-trihydroxyacetophenonemonohydrate as matrix. Electrospray ionization mass spectrometry (ESI-MS) spectra were measured on either a MicroMass Quattro Micro Mass Spectrometer or a Waters Q-TOF Ultima Mass Spectrometer, both used in positive ionization mode.

Generation of Pyruvate Dendrimers. *Succinimide Activated Pyruvate (pyruvate-OSu).* Pyruvate succinimide ester was prepared by activation of pyruvic acid (50 mg/mL) with 1 equiv dicyclohexylcarbodiimide and 1 equiv N-hydroxysuccinimide in CH_2Cl_2. The mixture was stirred overnight and filtered to remove the dicyclohexylurea precipitate. The solvent was evaporated

Scheme 2. Production of Mannose−Peptide Heterodendrimers

using reduced pressure, and the powder obtained was used without further purification.

PEG-Elongation of Dendrimer Arms. Where required, dendrimer arms were elongated with Boc-amino-PEG-COOH chains (either 2-[2-(Boc-amino)ethoxy]ethoxy}acetic acid (Boc-AEEA) or Boc-15-amino-4,7,10,13-tetraoxapentanedecanoic acid (Boc-ATOPA)), activated by esterification with pentafluorophenol (see Supporting Information for details of synthesis).

Dendrimer Functionalization. The dendrimer solution obtained from the supplier (20% w:v in MeOH) was diluted with 9 vol of CH_2Cl_2 containing 5 equiv of pyruvate-OSu per amino group. The solution was stirred overnight at room temperature and reaction completion was verified by the Kaiser test.[22] The solution was then concentrated under reduced pressure and the material resolubilized in CH_3CN/water (1:1 v/v) containing 0.1% w/v trifluoroacetic acid (TFA). The soluble fraction was further purified by preparative HPLC, using a 0−50% gradient elution system between 0.1% (w/v) TFA (solvent A) and acetonitrile/TFA/water, 900:1:100 (v:w:v) (solvent B) over 50 min, at 15 mL/min.

Conjugation of Pyruvate Dendrimers with Aminooxy-Functionalized Peptides and Insulin. The linear peptides LYRAG (Leu-Tyr-Arg-Ala-Gly) and the measles virus hemeagluttenin-derived peptide MVHA49−72 (Leu-Ile-Gly-Leu-Leu-Ala-Ile-Ala-Gly-Ile-Arg-Leu-His-Arg-Ala-Ala-Ile-Tyr-Thr-Ala-Glu-Ile-His-Lys) were synthesized according to standard automated techniques as previously described.[23] They were substituted at their α-amino groups with the aminoxyacetyl group (AoA), protected with the Boc function by reaction with Boc-aminooxyacetyl-OSu. AoA-Phe^{B1}-insulin was prepared according to standard techniques.[7] The derivatized products were single components on HPLC and had the expected mass spectra when analyzed by ESI-MS.

All conjugation experiments were performed in a 0.1 M acetate buffer containing 20% CH_3CN (v:v) or 8 M urea and 0.1 M anilinium acetate, pH 4.6. AoA-derivatized products (1.5−2.0 equiv) were mixed with 1 equiv of pyruvate dendrimer, and the reaction was allowed to proceed at room temperature for 20−40 h. The conjugation products were isolated by HPLC or, in the case of MVHA (49−72) conjugates, by dialysis.

Construction of Diblock Dendrimer Template. *G-3(ATOPA-NH_2)$_{16}$-S-PEG-maleimide (II in Scheme 1). Extension of Cystamine Core Dendrimer Arms with ATOPA Linker.* Boc-ATOPA-pentafluorophenyl ester (300 mg; for details of synthesis, see Supporting Information) was solubilized in 1 mL CH_2Cl_2 and added to 300 μL of a solution of G-3 cystamine core dendrimer (20% w/v in MeOH) at a 2-fold molar excess with respect to dendrimer surface amino groups. After overnight incubation at 20 °C, reaction completion was verified using a ninhydrin test. The reaction medium was then concentrated, solubilized in MeOH/CH_2Cl_2 (1:1 v/v), and purified on a LH-20 column equilibrated in the same solvent mixture.

Reduction of Cystamine Core to Produce Half-Dendrimers. The purified product (**I** in Scheme 1; 130 mg) was then deprotected in 4 mL TFA for 10 min at room temperature. TFA was removed under vacuum, and the remaining material was taken up in water and freeze−dried. This material was resuspended in 4 mL water, mixed with 1 mL of a 0.1 M tris(2-carboxyethyl)phosphine solution, and the pH adjusted to 5.0 with 1 M NaOH. After 2 h incubation at 20 °C, the material was purified by preparative

dx.doi.org/10.1021/bc1005653 |*Bioconjugate Chem.* 2011, 22, 1103–1114

HPLC on a C8 column using a 0−50% solvent B gradient over 50 min. The isolated material was characterized by ESI-MS (observed average mass 7456.9 ± 0.9 Da; calculated 7458.8 Da).

Attachment of Linker to Half-Dendrimer Sulfhydryl Group. 50 mg of the previous material was alkylated with a 2-fold molar excess of bismaleimido-4,7,10-trioxa-1,13-tridecanediamine linker (for linker synthesis, see Supporting Information) in a 0.1 M MES, 5 mM EDTA buffer pH 6.0 containing 50% CH_3CN. After 2 h incubation at 20 °C, the alkylated material (**III** in Scheme 1) was isolated by preparative HPLC and characterized by ESI-MS (observed average mass 8008.2 ± 0.4 Da; calculated 8008.4 Da). Material recovered: 44 mg.

*G-3(NH-Boc)$_{16}$-SH (**II** in Scheme 1).* A solution (300 μL) of a cystamine core G-3 dendrimer (20% (w:v) in MeOH) was added to $(Boc)_2O$ (5-fold molar excess over dendrimer surface amine groups) dissolved in 1 mL CH_2Cl_2. After overnight incubation at 20 °C, the material was purified on a LH20 column equilibrated in MeOH:CH_2Cl_2, 1:1 (v:v), and dried. The recovered material (65 mg) was solubilized in 3 mL MeOH:water 1:1 (v/v), TCEP was added to final concentration of 20 mM, and the pH was adjusted to 5.0 with 1 M NaOH. After 2 h incubation at 20 °C, the material was purified by preparative HPLC on a C4 column using a 20−60% B gradient over 40 min. Material recovered: 37 mg.

*G-3(ATOPA-NH$_2$)$_{16}$-S-PEG-S-G-3(NH-Boc)$_{16}$ (**IV** in Scheme 1).* Some 30 mg G-3(NH-Boc)$_{16}$-SH (**II** in Scheme 1) was reacted with a 1.5 molar excess of G-3(ATOPA-NH$_2$)$_{16}$-S-PEG-maleimide (**III** in Scheme 1) in 4 mL 50% MeOH containing 0.1 M MES, 5 mM EDTA, pH 6.0. After 3 h incubation at room temperature, the conjugation product (**IV** in Scheme 1) was purified by preparative HPLC on a C4 column and characterized by ESI-MS (observed average mass 13 112.9 ± 0.3 Da; calculated average mass 13108.9Da). Material recovered: 39 mg.

Production of Mannosylated Heterodendrimers. *Coupling Mannose to Unprotected Surface Amines.* Coupling of the succinimide ester of 3-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosylthio) propionic acid (see Supporting Information for details of synthesis) with G-3(ATOPA-NH$_2$)$_{16}$-S-PEG-S-G-3(Boc)$_{16}$ was carried out at 50 mg/mL in a MeOH/CH_2Cl_2 (1:1, v/v) at 20 °C for 15 h using a 2-fold molar excess of the activated ester with respect to the primary amino groups on the dendrimer, with a 3-fold excess of *N*-methylmorpholine. Complete acylation was verified using the ninhydrin test, and the carbohydrate dendrimer was isolated by chromatography on a LH20 column equilibrated in MeOH/CH_2Cl_2 (1:1 v/v). Material recovered: 37 mg. Deprotection of the acetylated mannose−dendrimer was achieved by treating the sample in MeOH/water (1:1 v/v) at 10 mg/mL at room temperature to which catalytic amounts of 0.3 M methanolic solution of MeONa (a total of 1 mol MeONa per mole of sugar 5−6 days) were added so that the pH was maintained at 8.5. The reaction was followed by analytical HPLC and considered to be complete after a total shift of the initial material into a more hydrophilic, symmetrical peak after 5−6 days of incubation.

Boc-Deprotection and Pyruvate Acylation. The resulting material was isolated by preparative HPLC on a C4 column, Boc-deprotected in neat TFA at 10 mg/mL for 5 min at room temperature, dried, and acylated with a 5-fold molar excess of Pyr-OSu under the same conditions used for homodendrimers (see pyruvate acylation) except that *N*-methylmorpholine was added to neutralize dendrimer solution in MeOH. The Boc-deprotected intermediate was characterized by MALDI-TOF-MS: observed envelope of 12 000−16 000 with an apex at 15000; calculated average mass: 15511.6 Da.

Peptide Oximation. Conjugation with AoA-LYRAG (AoA-Leu-Tyr-Arg-Ala-Gly) was carried out as for homodendrimers (see above) in 0.1 M sodium acetate buffer (pH 4.6) containing 20% CH_3CN (v:v) and 0.1 M anilinium acetate, using a 1.5−2.0 molar excess of peptide over dendrimer pyruvate groups. The conjugation product was isolated after 20 h incubation at room temperature by HPLC.

Construction of Fluorescein-Labeled Homo- and Heterodendrimers. *G-3(ATOPA-NH$_2$)$_{16}$-S-FAM.* G-3(ATOPA-NH$_2$)$_{16}$-SH (15 mg, **I** in Scheme 2) was alkylated with a 5-fold excess of 4-iodoacetamidofluorescein (4-iodoacetamido-FAM) in 1 mL of semiaqueous buffer of 50 mM NaH_2PO_4, 5 mM EDTA, containing 50% acetonitrile at pH 7.0. After 2 h incubation at room temperature, the conjugation product was isolated by preparative HPLC and characterized by ESI-MS (observed average mass 7845.6 ± 1.1 Da; calculated average mass 7847.1 Da). Material recovered: 12 mg.

G-3(ATOPA-Mannose)$_{16}$-S-FAM. G-3(ATOPA-NH$_2$)-S-FAM was acylated with a 2-fold molar excess of the succinimide ester of 3-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosylthio) propionic acid as described above. Material was purified after deprotection by gel filtration on a Phenomenex S2000 column equilibrated in 20% CH_3CN containing 0.1% TFA. Material recovered: 10 mg.

G-3(ATOPA-Pyr)$_{16}$-S-FAM. G-3(ATOPA-NH$_2$)-S-FAM (7 mg) was acylated with a 5-fold molar excess of Pyruvate-OSu in the presence of 3 equiv of *N*-methylmorpholine per free amino group in a MeOH/CH_2Cl_2 (1:1) mixture overnight at room temperature. The reaction medium was dried, purified by preparative HPLC, and characterized by ESI-MS (observed average mass 8966.3 ± 0.6 Da; calculated average mass 8968.1 Da. Material recovered: 8 mg.

G-3(ATOPA-Pyr=AoA-LYRAG)$_{16}$-S-FAM. AoA-LYRAG was conjugated to G-3(ATOPA-Pyr)$_{16}$-S-FAM by 48 h reaction at room temperature at a concentration of 0.2 mM using a 2-fold excess of peptide (with respect to the number of pyruvate functional groups on the dendrimer) in a buffer containing AcONa 0.1 M: CH_3CN (4:1 v/v) and 0.1 M anilinium acetate, pH 4.6. The conjugate was isolated by semipreparative HPLC on a C8 column and characterized by MALDI-TOF-MS (observed average mass for the highest substituted entity 19 143 Da (Na adduct); calculated mass 19 108).

G-3(ATOPA-Mannose)$_{16}$-S-AEEA-Lys(FAM)-ADOOA-S-G-3-(Pyruvate)$_{16}$ (bm). Construction of the heterodendrimer via a maleimido-AEEA-Lys(FAM)-ADOOA-maleimide linker (bm, see Supporting Information for details of synthesis) was carried out as with the nonlabeled PEG linker for the synthesis of G-3(ATOPA-NH$_2$)$_{16}$-S-PEG-S-G-3(NH-Boc)$_{16}$ (see above).

G-3(ATOPA-Mannose)$_{16}$-S-AEEA-Lys(FAM)-ADOOA-S-G-3-(Pyruvate)$_{16}$ (iac). The G-3(Boc)$_{16}$-SH half-dendrimer was alkylated with an iodoacetamide-AEEA-Lys(FAM)-ADOOA-iodoacetamide linker (iac, see Supporting Information for details of synthesis) by reacting a 2-fold molar excess of linker with the dendrimer in 0.1 M NaH_2PO_4 buffer containing 5 mM EDTA and 50% CH_3CN, pH 7.0. The conjugate was isolated by preparative HPLC on a C4 column, after overnight incubation, and characterized by ESI-MS (average observed mass 6091 ± 3 Da, calculated mass 6088 Da). The resulting material (2.1 μmol) was then reacted at room temperature with a 1.5-fold molar excess of G-3(ATOPA-NH$_2$)-SH in 0.1 M NaH_2PO_4 buffer containing 5 mM EDTA and 50% MeOH, pH 7.0, and the conjugate was isolated after 24 h incubation and characterized by ESI-MS (average observed mass 13 420.4 ± 2.9 Da, calculated mass 13 419.2 Da).

Table 1. Mass Spectrometric Characterization of Pyruvate-Conjugated Dendrimers

dendrimer	calculated average mass (Da)	observed mass (Da) ESI-MS
G-1$(Pyr)_8$	1990.4	1990.4 ± 0.4
G-2$(Pyr)_{16}$	4377.0	4376.7 ± 0.1[a]
G-3$(Pyr)_{32}$	9150.9	9170.1 ± 0.8[a]
G-1$(AEEA\text{-}Pyr)_8$	3151.8	3151.5 ± 0.1
G-2$(ATOPA\text{-}Pyr)_{16}$	8333.9	8333.4 ± 0.5

[a] ESI-MS spectra also identified contaminating products of 200 Da lower mass than the expected value (spectra are provided in Supporting Information).

Further functionalization with mannose and pyruvate was carried out as described for the nonfluorescent heterodendrimers.

Isolation of Lymph Node Dendritic Cells and Macrophages and Uptake Experiments. Balb/c mice (8−10 weeks old, Charles River Laboratories, L'Arbresle, France) were bred and kept according to requirements of the University of Geneva and Swiss and European guidelines. Single-cell suspensions of inguinal, axial, and brachial lymph nodes were prepared by enzymatic digestion as described.[24]

Cells (2×10^6 in 200 μL) were incubated with dendrimer preparations for 1 h at 37 or 4 °C. Cells were then preincubated with rat anti-CD16/32 mAb (2.4G2 clone) to block nonspecific antibody binding, and stained with conjugated antibodies against CD11c (HL3 clone), CD11b (M1/70 clone), and B220/CD45R (RA3−6B2 clone) (BD Pharmingen, San Diego, CA). Each sample was acquired on a FACS Canto cytometer and data were analyzed using *FlowJo* software (Tree Star, Ashland, OR). Total lymph-node cells were determined by forward/side scatter. Within this gate, $CD11c^+$ cells were taken to be dendritic cells, $CD11b^+$ $CD11c^-$ cells were taken to be macrophages, and $B220^+$ $CD11c^-$ $CD11b^-$ cells were taken to be B lymphocytes.

RESULTS

Pyruvate Conjugation of Dendrimers. Pyruvate dendrimers were successfully synthesized by acylation of the amine terminal groups of G-1, G-2, and G-3 PAMAM dendrimers with succinimide−activated pyruvate to yield G-1$(Pyr)_8$, G-2$(Pyr)_{16}$, and G-3$(Pyr)_{32}$ (see Scheme 1). Pyruvate acylation was also carried out on dendrimers of which the arms had been elongated through acylation with the amino-PEG-acids 2-[2-(Boc-amino) ethoxy]ethoxy}acetic acid (Boc-AEEA) and Boc-15-amino-4,7,-10,13-tetraoxapentanedecanoic acid (Boc-ATOPA) to yield G-1-$(AEEA\text{-}Pyr)_8$ and G-2$(ATOPA\text{-}Pyr)_{16}$.

All pyruvate conjugation reactions went to completion as determined by the ninhydrin test for remaining free amines. The resulting pyruvate dendrimers had the expected masses (Table 1) except the G-2$(Pyr)_{16}$ and G-3$(Pyr)_{32}$ pyruvate dendrimers, which gave ESI-MS data consistent with contaminating products of 200 Da lower mass than the expected value (spectra are provided in Supporting Information). These lower-mass products are most likely derived from lower-valency contaminants in the starting material. A loss of 200 Da corresponds not just to the lack of two pyruvate units but to the absence of two complete −$(NHCH_2CH_2NH\text{-pyruvate})$ units. Such contamination of higher-generation dendrimers with material lacking two terminal amine groups has been described.[6] The phenomenon is thought to be due to the formation of an intramolecular bis-amide instead of the addition of two ethylene diamines during manufacture.

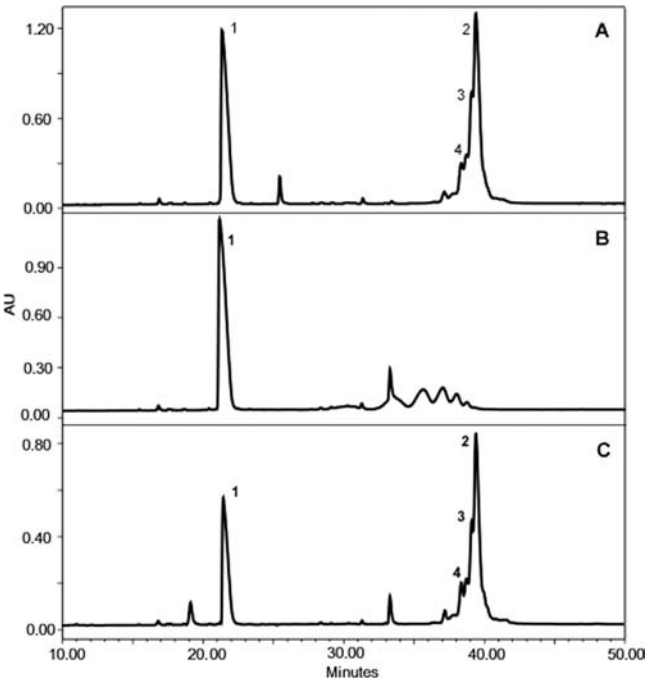


Figure 1. Importance of aniline catalysis for full decoration of pyruvate dendrimers by AoA-peptides and proteins. HPLC analyses of polyoxime formation after 15 h incubation at room temperature at various pH values, monitored at 214 nm. Reactions were carried out on 50 nmol G1-D$(Pyr)_8$ using 1.5 equiv AoA-LYRAG per dendrimer Pyr- group (excess elutes at 21.5 min). Peak 1 corresponds to the excess of AoA-peptide and peak 2 to the target octaoxime, while peaks 3 and 4 correspond to lower valency constructs (hexa- and pentaoxime). Trace A, reaction at pH 3.0 without anilinium acetate; trace B, reaction at pH 4.6; trace C, reaction at pH 4.6 in the presence of 0.1 M anilinium acetate.

Optimizing Conditions for Conjugation of Proteins and Peptides. The conditions for pyruvate−dendrimer conjugation with aminooxy-functionalized peptides and proteins were first optimized using the G-1$(Pyr)_8$ dendrimer and a small model peptide, AoA-LYRAG. Under previously established standard conditions for oxime ligation[7] but using pH values between 2 and 3 instead of the usual value of 4.6, the reaction goes essentially to completion (Figure 1A), with the hexa- and penta-oxime contaminants likely to have resulted from the decoration of lower-valency contaminants in the original dendrimer preparation (see above). Carrying out the reaction at pH 4.6 results in the formation of a mixture of conjugates containing mainly partially substituted intermediates and only traces of the fully substituted octamer (Figure 1B). When the reaction is carried out at pH 4.6 in the presence of 0.1 M aniline, however, the reaction goes essentially to completion (Figure 1C), yielding the fully substituted octamer together with the hexa- and penta-oxime contaminants seen in Figure 1A (these are also likely to have resulted from the decoration of lower valency contaminants in the original dendrimer preparation).

Evaluation of Mass Spectrometric Characterization Methods. Characterization of complex dendrimers with large peptide and protein substituents presents a methodological challenge, and we opted to evaluate ESI-TOF-MS (electrospray ionization time-of-flight mass spectrometry) and MALDI-TOF-MS as characterization tools. As reference materials, we used the octameric

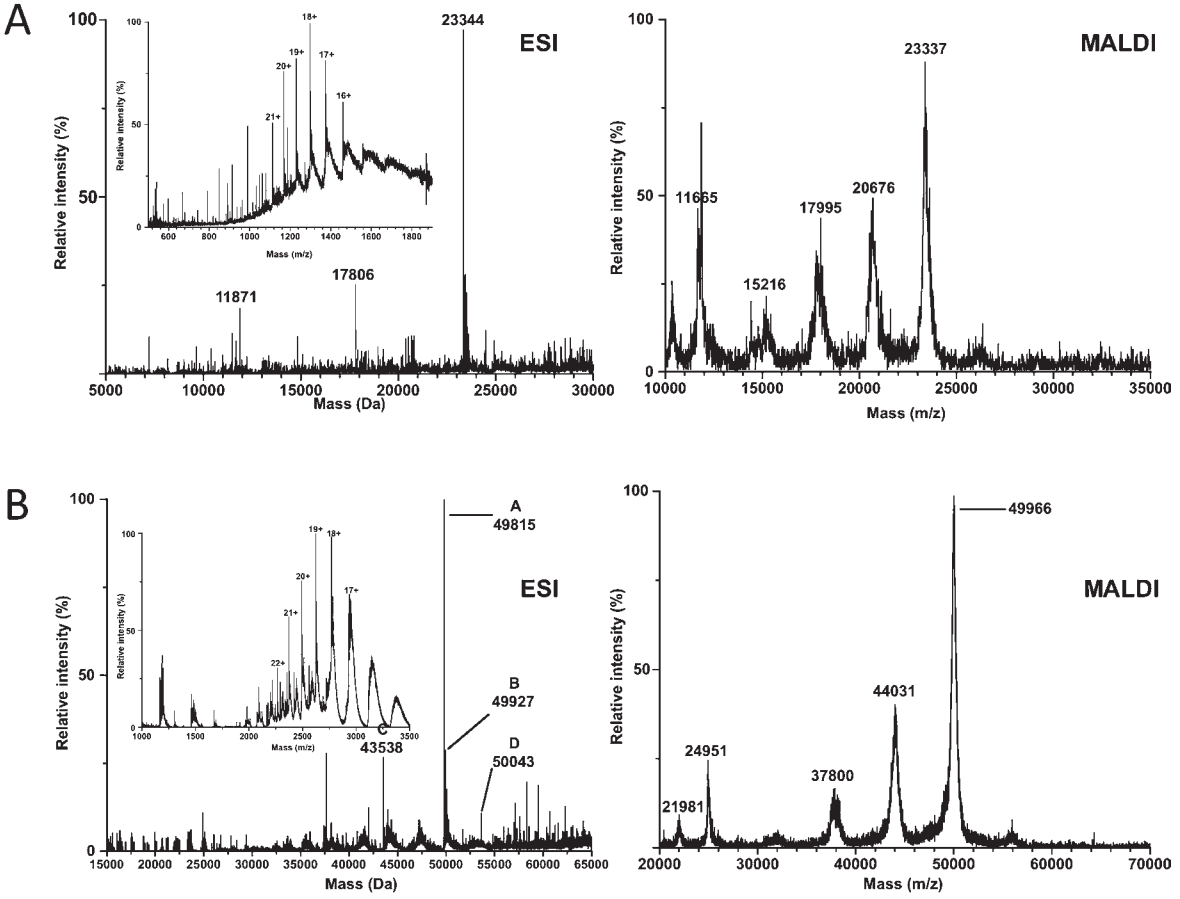

Figure 2. Experimental (inset) and deconvoluted ESI-TOF-MS of G-1(AEEA-Pyr=AoA-MVHA49−72)$_8$ (A) and G-1(AEEA-Pyr=AoA-Insulin)$_8$ (B) as compared with MALDI-TOF-MS. While ESI-TOF-MS analysis indicates that the samples predominantly contain fully decorated dendrimer with no traces of lower substituted contaminants, MALDI-TOF-MS analysis of the same samples reveals a mass component corresponding to the fully substituted dendrimer, plus mass components corresponding to the dendrimer lacking one, two, and three substituent moieties.

dendrimers resulting from the decoration of G-1(Pyr)$_8$ dendrimers with either AoA-MVHA49−72, yielding G-1(Pyr=AoA-MVHA49−72)$_8$, or AoA-insulin, yielding G-1(AEEA-Pyr=AoA-Insulin)$_8$. ESI-TOF-MS (Figure 2A) clearly indicated that in both cases the major component in the reaction mixture was indeed the fully decorated octamer (for AoA-MVHA49−72 observed average mass 23 343.8 ± 0.7 Da, calculated mass 23 344.5 Da; for AoA-insulin observed average mass 49 809 ± 5 Da, calculated mass 49 821.2 Da). The absence in the mixture of detectable levels of incompletely decorated material is indicative of the homogeneity of the reaction products. Analysis of the same material by MALDI-TOF-MS (Figure 2B) revealed peaks corresponding to the expected masses of the fully decorated octamers (observed average mass 23 401 Da for AoA-MVHA49−72; observed mass 48 862 Da for AoA insulin) plus a series of peaks corresponding to the expected masses minus multiples of the mass of the substituent moiety (i.e., approximately 2700 Da for MHVA(49−71) and 5800 Da for insulin). The absence of these lower mass species in the ESI-TOF mass spectra indicates that they do not correspond to incompletely decorated dendrimers but artifacts resulting from the destructive effect on the oxime bonds of the MALDI laser pulses, as described previously.[25] Hence, while ESI-TOF-MS has the advantage of being a non-destructive characterization method for the dendrimers in this study, it has the drawback of having, at least in our case, a ceiling size limit for detection at around 50 kDa. On the other hand, while MALDI-TOF-MS has the advantage of being able to detect dendrimers of higher mass, analysis of the results obtained should take account of the destructive effect of the laser pulses on oxime bonds.

Synthesis of Peptide and Protein-Conjugated Dendrimers. We next used the optimized oxime conjugation conditions to decorate a wider range of dendrimers (up to G-3), with or without arms extended by short PEG spacers, using the short LYRAG peptide, the longer measles virus hemeagluttenin (49−72) peptide, and recombinant insulin. The reaction products were characterized by mass spectrometry (Table 2).

These results indicate that the optimized oxime procedure yields fully decorated dendrimers from G-1 to G-3 either with or without PEG-extended arms and using three different aminooxy conjugated substituents. While the MALDI-TOF-MS spectra included signals corresponding to lower-substituted products, these would be expected to be due at least in part to the destructive effect of the laser desorption on oxime bonds (Figure 2).

Size exclusion chromatography of the reaction products revealed single symmetrical peaks for each product, with rank order of elution time (fastest to slowest) corresponding to rank order target size (largest to smallest; see Supporting Information, Figure S2).

Characterization of Insulin Dendrimers by SDS-PAGE. In order to further investigate the homogeneity of the dendrimer

Table 2. Peptide and Insulin Dendrimers Obtained by Aniline Catalyzed Oxime Bond Formation[a]

dendrimer	calculated average mass (Da)	observed average mass (Da) ESI-MS, ESI-TOF-MS MSMS	observed average mass (Da) MALDI-TOF-MS
G-1(Pyr=AoA-LYRAG)$_8$	7060.2	7060.1 ± 0.3	7061
G-2(Pyr=AoA-LYRAG)$_{16}$	14516.6	14517.4 ± 1.1	14520
G-3(Pyr=AoA-LYRAG)$_{32}$	29430.3	nd	envelope of 16000−29500
G-1(AEEA-Pyr=AoA-LYRAG)$_8$	8221.6	8221.5 ± 0.6	nd
G-2(ATOPA-Pyr=AoA-LYRAG)$_{16}$	18473.6	18472.6 ± 0.8	nd
G-1(Pyr=AoA-MVHA49−72)$_8$	23344.5	23344.4 ± 0.7	23450 ± 250
G-2(Pyr=AoA-MVHA49−72)$_{16}$	47113.3	nd	47200 ± 2003
G-3(Pyr=AoA- MVHA49−72)$_{32}$	94594.7	nd	envelope of 56000−95000
G-1(AEEA-Pyr=AoA-Insulin)$_8$	49821.2	49815.0 ± 1.0	49970 ± 500
G-2(ATOPA-Pyr=AoA-Insulin)$_{16}$	101672.8	nd	101500 ± 1000
G-1(Pyr=AoA-Insulin)$_8$	48659.8	nd	48700 ± 100
G-2(Pyr=AoA-Insulin)$_{16}$	97743.8	nd	98000 ± 1000
G-3(Pyr=AoA-Insulin)$_{32}$	195855.8	nd	envelope of 130000−190000

[a] All MALDI-TOF-MS mass determinations contain signals (probably artifactual, see text) attributable to lower substituted constructs (nd; not determined).

products, we used SDS-PAGE to analyze a series of insulin-decorated dendrimers of increasing complexity: G-1 (Pyr=AoA-Insulin)$_8$, G-1 (Pyr=AoA-Insulin)$_{16}$, and G-1 (Pyr=AoA-Insulin)$_{32}$ (Figure 3). Each sample appeared on the gel as a slower-migrating major component together with relatively few minor bands. On the basis of the mass spectrometric analysis of the same samples (Table 2), the major components most likely correspond to the fully decorated dendrimers. If this is the case, it would imply that size-dependent migration of the dendrimers on SDS-PAGE is not proportional to that of the globular protein markers, with the fully decorated G-1, G-2, and G-3 dendrimers, which have calculated masses of approximately 49, 98, and 196 kDa, respectively, migrating at positions corresponding to approximately 36, 50, and 100 kDa.

Comparison of the appearance of the G-1 (Pyr=AoA-Insulin)$_8$ sample on the gel with the corresponding ESI-TOF mass spectrum (Figure 2) indicates that sample treatment prior to gel loading is partially destructive. This is mostly likely because heating the samples in gel loading buffer led to brief exposure to basic pH levels at which oxime bonds are labile.[7] Despite this, the tight clustering bands close to the slowest migrating species, together with the absence of bands corresponding to unsubstituted material, provide further evidence of the high homogeneity of the decorated dendrimer samples.

Diblock Approach. The option of independently attaching multiple functional units to dendrimers via precision conjugation would be of significant value in the development of bioactive nanoparticles, and several different strategies have been employed to generate asymmetric bifunctional dendrimers.[8,13,14] With this aim in mind, we next worked on the development of a generic diblock heterodendrimer approach to be used as a scaffold for the display of an oxime-linked protein or peptide array together with an array corresponding to a second functional unit (Scheme 1).

A sample of G-3 PAMAM dendrimer with a cystamine core was divided into two batches, with one batch acylated with ATOPA and the other Boc-protected (**I** and **II** in Scheme 1). The modified dendrimer batches were then reduced, opening the cystamine core to yield sulfhydryl-bearing half-dendrimers. The ATOPA half-dendrimer (**I** in Scheme 1) was then alkylated with a moderate excess of bismaleimido-PEG linker, and the resulting monomaleidimido product (**III** in Scheme 1) was used to alkylate the Boc-protected half dendrimer (**II** in Scheme 1). This yields the heterodendrimer precursor, G-3(ATOPA-NH$_2$)$_{16}$-S-PEG-S-G-3(Boc)$_{16}$ (**IV** in Scheme 1).

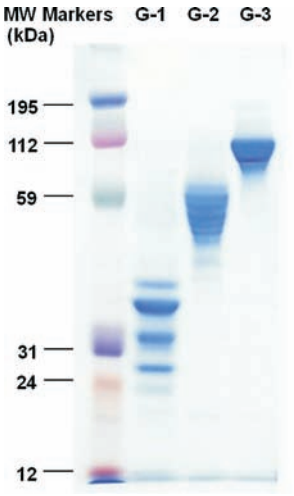

Figure 3. SDS-PAGE analysis of G-1 (Pyr=AoA-Insulin)$_8$, G-2 (Pyr=AoA-Insulin)$_{16}$, and G-1 (Pyr=AoA-Insulin)$_{32}$ (indicated as G-1, G-2, and G-3) indicating that dendrimer samples from each reaction show very limited dispersity.

This heterodendrimer precursor provides a versatile diblock platform for producing nanoparticles carrying two different sets of functional units. The first type of functional unit can be attached by acylation of the ATOPA amine groups on one-half of the heterodendrimer; then, a deprotection step can be used to reveal the amine groups on the other half of the heterodendrimer for attachment of the second type of functional unit.

Mannosylated Dendrimers. We chose to use the diblock approach to produce a heterodendrimer carrying a peptide on one side and a mannose array on the other (Scheme 2). Nanoparticles of this kind are of interest in the development of vaccine delivery vehicles, where the peptide or protein cargo would be an immunizing antigen and purpose of the mannose array is to

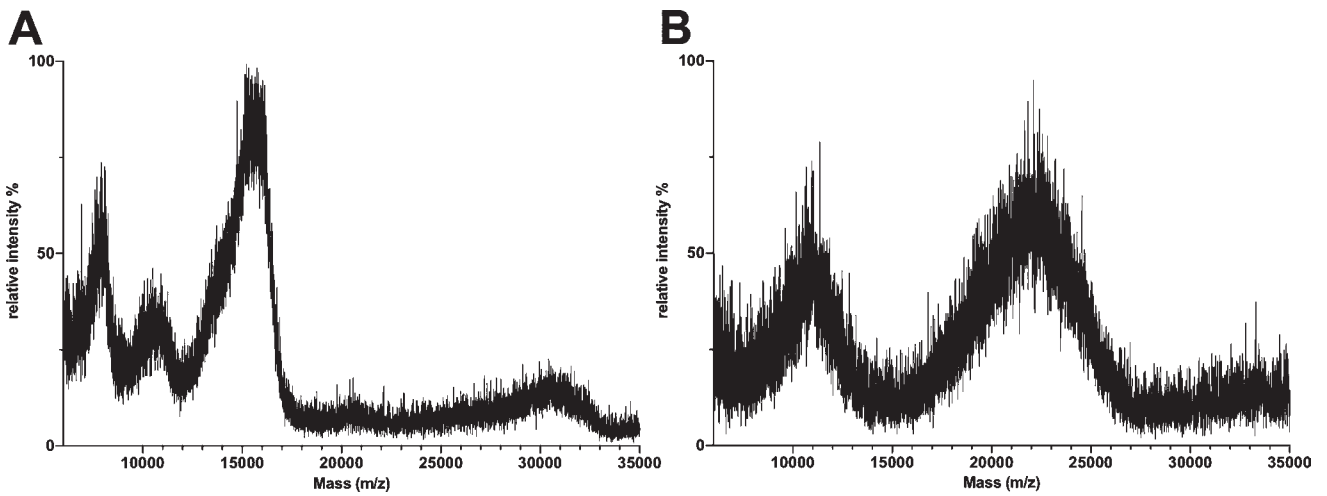

Figure 4. MALDI-TOF-MS characterization of G-3 (ATOPA-Mannose)$_{16}$-S-PEG-S-G-3(Pyruvate)$_{16}$ and the peptide-conjugated product. Respective theoretical average masses of fully substituted compounds are 16 633 and 26 772 Da.

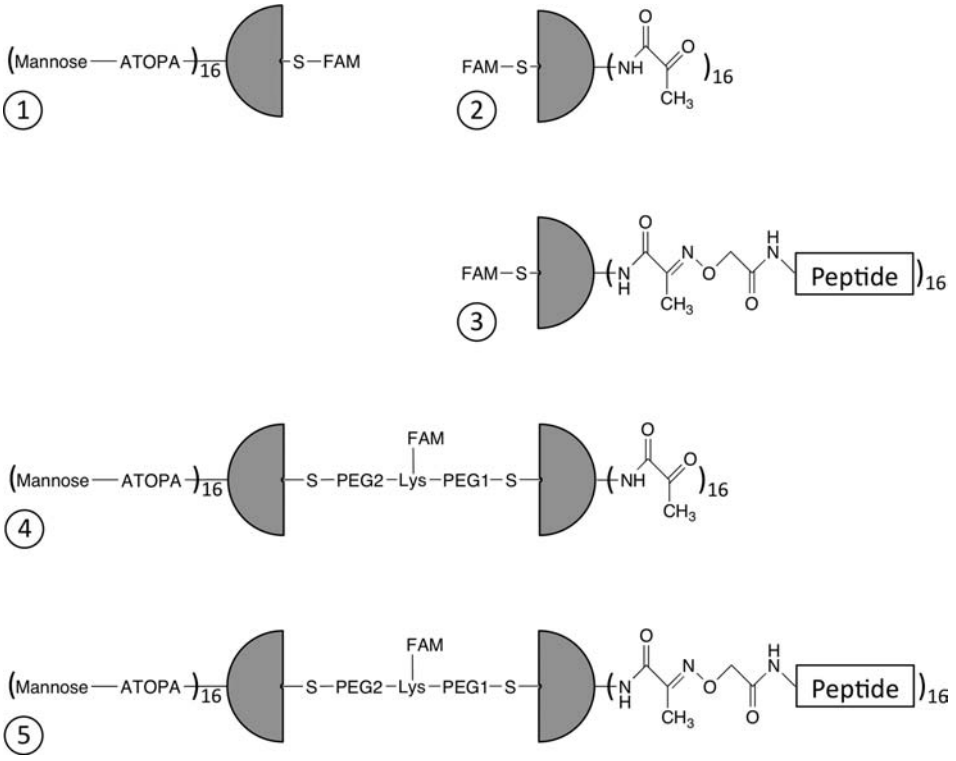
specifically target the particle to macrophages and dendritic cells, whose efficient uptake of particulate antigens is crucial in the generation of strong immune responses.[19,20] While dendrimer conjugation with mannose has been achieved using both 4-isothiocyanatophenyl-α-D-mannopyranoside and 3-(2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosylthio)propionic acid,[5] the phenyl ring in the thiourea linker of the former reagent leads to a significantly hydrophobic product, and in the interest of hydrosolubility of the final product, we opted for the latter. The resulting mannosylated heterodendrimer (**V** in Scheme 2) was then Boc-deprotected and acylated with pyruvate, yielding a mannosylated pyruvate dendrimer (**VI** in Scheme 2) ready for oxime conjugation with aminooxy-peptides or proteins. For the purposes of this study, we used the model peptide AoA-LYRAG to produce the final product, a mannose−peptide heterodendrimer (**VII** in Scheme 2).

As expected, the heavily glycosylated mannose heterodendrimers migrated as diffuse bands on SDS-PAGE (data not shown), and as a consequence, this analytical method was not useful for their characterization. With regard to mass spectrometric analysis, while the starting heterodendrimer G-3 (ATOPA-NH_2)$_{16}$-S-PEG-S-G-3(Boc)$_{16}$ had a mass low enough to be characterized by ESI-MS (observed average mass 13 112.9 Da; calculated mass 13 108.9 Da), ESI-MS could not be used for analysis of the higher-molecular-weight glycodendrimers due to limitations of the technology, as noted previously.[26] According to MALDI-TOF-MS, mannose functionalization resulted in increased dispersity seen as a broadened peak with an envelope ranging between 6600 and 11 800 Da, apex at 9800 Da, for an expected value of 11 852 Da (Figure 4). The level of polydispersity introduced into our constructs at this stage is comparable with that seen in the work of others on carbohydrate conjugation of dendrimers,[6,26] including experiments in which dendrimers were directly modified with unprotected *p*-isothiocyanatophenyl α-D-mannopyranoside.[5]



As expected, conjugating the mannosylated pyruvate heterodendrimer with AoA-LYRAG generated a mass shift (Figure 4), but while the theoretical shift is from 16 633 to 26 772 Da, the apexes of the observed peaks shifted from 15 500 to 22 100 Da, with the envelope of the product peak broadening further to span the range 16 000−26 000 Da. The lower apex mass value and further broadening of the product peak are most likely consequences of damage to oxime linkages during the MALDI process, as seen earlier with the insulin octamers (Figure 2). Hence, our results are consistent with complete peptide decoration of the mannosylated heterodendrimer.

Polymannose-Decorated Dendrimers Efficiently and Specifically Target Dendritic Cells and Macrophages. In order to investigate whether addition of a mannose array to dendrimers enhances uptake by sentinel cells, it was necessary to site-specifically incorporate a fluorescent label. We designed a panel of fluorescein-labeled constructs, three half-dendrimers labeled by alkylation of their core sulfhydryl group, and two diblock constructs labeled on the linker used to join the two half-dendrimers together (a G-3(ATOPA-NH_2)$_{16}$-S-PEG-S-G-3(Boc)$_{16}$ heterodendrimer in which N^{ε}-fluoresceinyl-lysine was introduced into the structure of the linker) (Scheme 3).

We had initially attempted to produce the labeled heterodendrimers by replacing the bismaleimidoPEG linker (see Scheme 2) with a maleimido-AEEA-Lys(FAM)-ADOOA-maleimide linker, but as previously seen for immunoconjugates,[27] these maleimide-linked structures showed limited stability at basic pH. Since mild basic conditions are required for the per-O-acetylmannose deprotection, we opted to make use of a diiodoacetyl analogue of the linker (see Supporting Information for further details) instead. Analysis by MALDI-TOF-MS confirmed that the fluorescent heterodendrimers made in this way were decorated with mannose and peptide to levels comparable with the nonfluorescent versions (see Supporting Information).

These fluorescent constructs (II through V in Scheme 3) were evaluated for specific *in vitro* uptake by sentinel cells using a flow cytometry technique on cell populations prepared from mouse lymph nodes (Figure 5). Lymphocytes predominate in this mixed population, which also contains dendritic cells and macrophages. While fluorescence uptake across the whole cell population was relatively low (Figure 5A), it was strongly and specifically enriched in the dendritic cell and macrophage groups (Figure 5B, C). Within these groups, mannose-functionalized half-dendrimers show a strongly increased uptake compared with the corresponding pyruvate functionalized dendrimers (Figure 5B,C). In the same way, uptake of the pyruvate-functionalized mannosylated heterodendrimer is strongly increased compared to the corresponding pyruvate-conjugated half-dendrimer. Importantly,

Scheme 3. Fluorescent Dendrimers Used in the Study of Mannose-Specific Uptake by Sentinel Cells[a]

[a] (1) Mannose G-3 half-dendrimer; (2) pyruvate G-3 half-dendrimer; (3) LYRAG peptide G-3 half-dendrimer; (4) mannose-pyruvate G-3 heterodendrimer; (5) mannose-LYRAG peptide G-3 heterodendrimer. Details of the structure and synthesis of the fluorescein linker (FAM) are provided in Supporting Information.

incorporation of mannose into dendrimers did not increase fluorescence incorporation into lymphocytes, which do not express mannose receptors (Figure 5D). Uptake of mannosylated dendrimer was blocked when incubation carried out at 4 °C (data not shown) and in the presence of mannan, a mannose receptor ligand (data not shown) suggesting an active uptake process by the macrophage and dendrimer cells groups mediated by mannose receptors.

Hence, in agreement with previous observations,[18,21] our results indicate that incorporation of a mannose array into nanoparticles strongly and specifically enhances uptake by macrophages and dendritic cells, most likely via surface lectin-mediated endocytosis. Enhanced uptake is not hindered by incorporation of a second half-dendrimer displaying a peptide array. Conjugating the pyruvate dendrimers with the LYRAG peptide also leads to a modest increase in incorporation, whether or not the particles carry mannose. The effect is nonspecific, i.e., nonsentinel cells showed similar levels of uptake as sentinel cells. LYRAG is a basic sequence, and this phenomenon is almost certainly a consequence of the polycation-mediated cell uptake a well-known and generalized phenomenon, exploited in gene delivery[28] and peptide transduction[29] strategies.

■ DISCUSSION

Dendrimers are readily synthesized, low-cost, monodisperse, high-valency molecular scaffolds, and as such represent promising building blocks for the generation of bioactive nanoparticles for use as both clinical and experimental tools.[1,2] However, a major obstacle in their use in these applications has been the absence of a conjugation chemistry powerful enough to fully decorate high-valency dendrimers with protein and peptide ligands.

In this study, we have made use of recent advances in oxime technology to develop an optimized conjugation strategy for decorating PAMAM dendrimers with peptides and proteins. The size range of the target products is close to or beyond the upper limit for the characterization methods typically used in protein chemistry, and although we opted to use different characterization methods, each one was subject to particular limitations: (i) the ESI-TOF-MS facilities that we used had an upper detection limit of 50 kDa for dendrimer-derived products; (ii) the MALDI-TOF-MS desorption process is partially destructive toward molecules containing oxime bonds [25] (Figure 2), as is (iii) heating samples in loading buffer prior to SDS-PAGE (Figure 3). Nonetheless, the combined evidence obtained from these three methods indicates that our conjugation strategy readily yielded highly homogeneous preparations of fully decorated dendrimers of up to 32 valency (G-3) obtained using both a synthetic 23mer virus-derived peptide and porcine insulin. This is an important breakthrough, since previous work on dendrimer conjugation has not yielded fully decorated dendrimers more complex than octamers. Because of the difficulties involved in the characterization of very large molecular products, we did not attempt to conjugate dendrimers of higher generation than G-3 in this study. Full decoration of larger, higher valency scaffolds should nonetheless be feasible, as long as the surface density of reactive groups does not reach a level where conjugation is limited by steric blockade. Should that occur, the problem could readily be addressed by

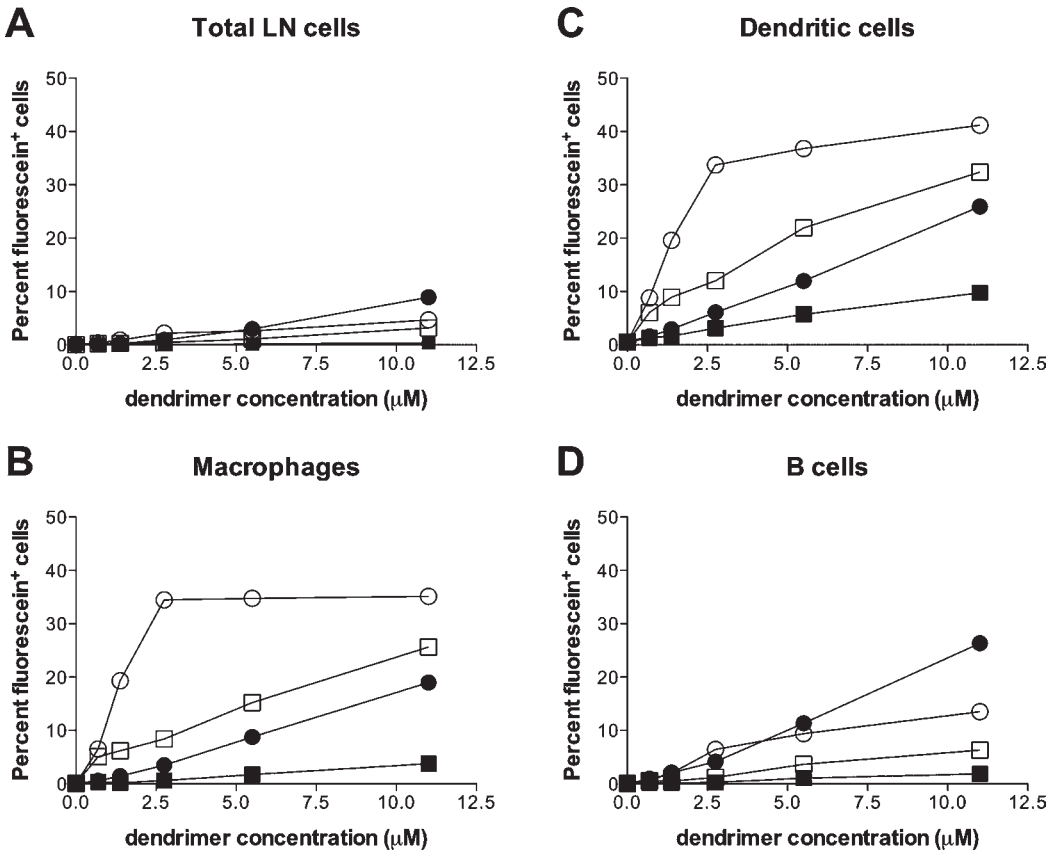


Figure 5. Specific mannose-dependent uptake of dendrimer nanoparticles by sentinel cells. Uptake of fluorescein-conjugated dendrimers (see Scheme 3) by cells prepared from mouse lymph nodes was detected by flow cytometry (FL-1 channel) on gated subpopulations (as indicated) after incubating the total cell population with dendrimers at different concentrations for 1 h at 37 °C. Filled squares, pyruvate G-3 half-dendrimer (16mer) (**2**); filled circles, LYRAG peptide G-3 half-dendrimer (16mer) (**3**); empty squares, mannose-pyruvate G-3 heterodendrimer (16mer + 16mer) (**4**); empty circles, mannose-LYRAG G-3 heterodendrimer (16mer + 16mer) (**5**).

elongation of the dendrimer arms through the attachment of flexible precision PEG chains such as AEEA or ATOPA (Table 2).

Importantly, the oxime conjugation strategy that we have developed is likely to be robust enough to be readily usable with a wide range of peptides and proteins, of both synthetic and recombinant origin. Use of recombinant proteins will generally require the introduction of an appropriate molecular hook for aminooxy modification. This could involve engineering either an extra surface cysteine residue to provide a free sulfhydryl group or an N-terminal serine or threonine residue, which could be quantitatively oxidized under extremely mild conditions to yield an aldehyde[30] for further functionalization.

Diblock Dendrimers: A Platform for Orthogonal Attachment of Two Functional Sets. Techniques that enable the specific incorporation of more than one functional unit (e.g., targeting ligand, payload, tracer) into the dendrimer architecture would be advantageous in the development of bioactive nanoparticles,[1,2] and a number of strategies for the generation of heterodendrimers have been proposed.[8,13,14] These approaches have the drawback of not being compatible with the use of commercially available starting materials, and in this context, it is significant that the orthogonal diblock strategy developed in this study centers on readily produced, commercially available cystamine core PAMAM dendrimers.

We chose to use mannose as the first functional unit, as there has been considerable interest in the development of carbohydrate-conjugated dendrimers,[5,6] and incorporation of a mannose array into a nanoparticle-based vaccine vehicle has the potential to increase immunogenicity by enhancing uptake processing and presentation by sentinel cells such as macrophages and dendritic cells.[19−21] An array of short synthetic peptide molecules attached via oxime conjugation was used as the second functional unit. Notwithstanding the additional challenge to characterization imposed by the incorporation of mannose residues into the dendrimers, we were able to confirm (Figure 4) that (i) the mannose-conjugated heterodendrimers could be fully decorated with a peptide array using the optimized oximation approach and (ii) mannose conjugation levels comparable to those reported in previous studies were obtainable. More efficient mannose conjugation might be achieved through the use of Cu(I) catalyzed azide−alkyne cycloaddition[10] because it is compatible with direct use of unprotected carbohydrate.

In order to visualize uptake of these particles by sentinel cells, it was necessary to devise a conjugation approach for site-specific conjugation of a third functional unit so that the particles could be derivatized with a fluorochrome. With the resulting trifunctionalized dendrimers, we were able to demonstrate that, in agreement with previously published work,[18−21] incorporation of a mannose array strongly and specifically enhances uptake of the dendrimers by sentinel cells. Mannose heterodendrimers may represent promising vaccine delivery vehicles for peptide and protein cargoes, and the conjugated linker could be used either to attach a fluorescent dye to aid the study of vehicle uptake *in vivo*[31]

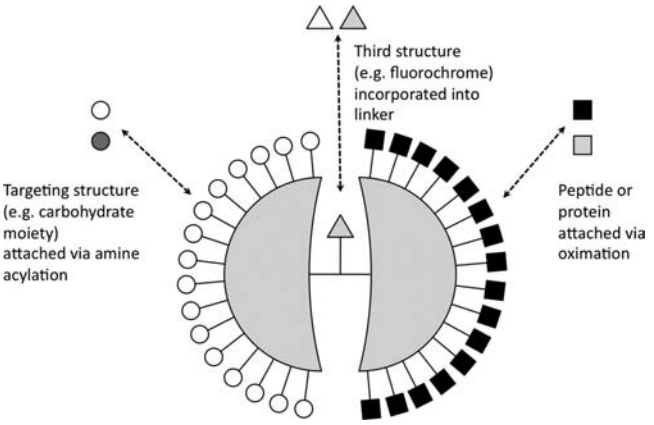

Figure 6. Versatile platform for synthesis of bioactive nanoparticles.

or to attach an immune modulator structure (e.g., a Toll-like receptor ligand) to enhance adjuvant activity.[32]

CONCLUSION

We believe that we have developed a robust new dendrimer conjugation strategy which can be used not only for the production of large multivalent dendrimers fully decorated with proteins and peptides, but also for the generation of specifically bi- and trifunctionalized dendrimers (Figure 6).

Given the mild conjugation conditions involved, the strategy should be applicable for dendrimer derivatization using a wide range of biologically relevant structures, providing a convenient platform for the production of bioactive nanoparticles for use in a wide range of clinical applications.

1. Characterization of pyruvate–functionalized PAMAM dendrimers

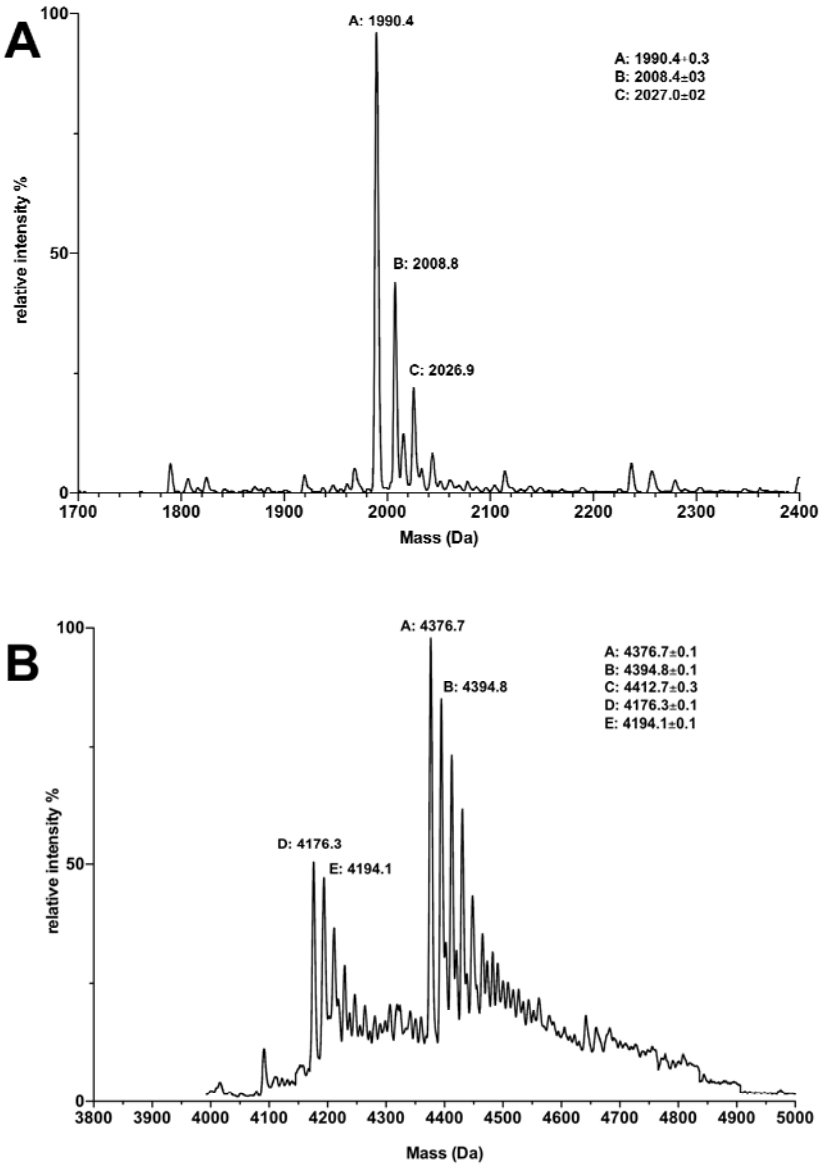

Figure S1. ESI-MS of G1-$(Pyr)_8$ (I) and G2-$(Pyr)_{16.}$ (II). **(A)** The spectrum of (I) is that of a major component of average mass 1990.4 in agreement with the calculated average value of 1990.4 Da. Minor signals are consistent with the presence of water adducts and a truncated parent compound of mass 1790 Da. **(B)** For G2-$(Pyr)_{16}$, the major component of average mass 4376.7 Da (calculated: 4377.0) is contaminated with a truncated parent compound of mass 4176.3 Da. Both components show water adducts.

NMR characterization of G2-(Pyr)16

^{1}H NMR (500 MHz, CD3OD) : δ = 2.52 (s, 48 H, CH3), 2.81-3.05 (m, CH2), 3.42-3.84 (m, CH2).

^{13}C NMR (125.76 MHz, CD3OD) : δ = 18.36, 24.91, 25.59, 29.52, 29.80, 35.57, 39.52, 39.79, 39.93, 40.26, 51.19, 51.46, 53.71, 58.31, 67.89, 71.33, 79.46, 97.85, 114.65, 116.98, 119.31, 121.64, 162.33, 162.88, 163.21, 172.69, 172.79, 172.87, 173.65, 174.51, 197.68.

2. Size exclusion chromatography analysis of peptide-decorated dendrimers

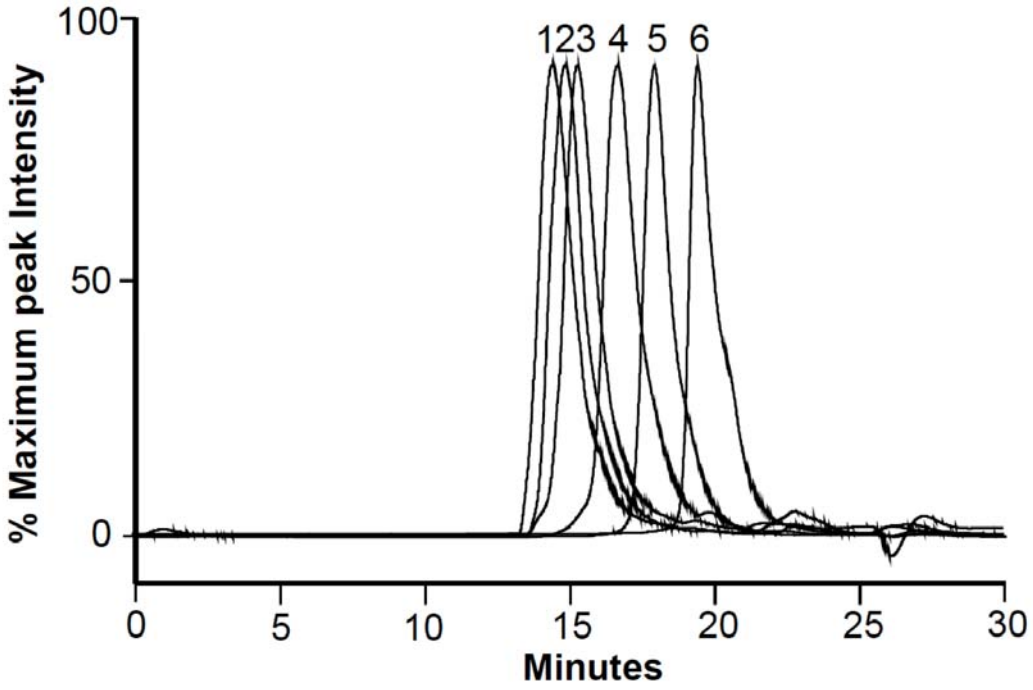

Figure S2. Size exclusion chromatography of peptide and insulin-dendrimers was performed on a Phenomenex BioSep-Sec-S2000 600 x 7.8mm column equilibrated in 0.1% TFA, 20% (v:v) CH_3CN, flow rate 1ml/min. Peaks eluted in the expected order with respect to target product size (largest to smallest): (1) G-3(Pyr=AoA-Insulin)$_{32}$, (2) G-2(ATOPA-Pyr=AoA-Insulin)$_{16}$ (3) G-2(Pyr=AoA-Insulin)$_{16}$, (4) G-1(Pyr=AoA-Insulin)$_{8}$, (5) G-2(Pyr=AoA-LYRAG)$_{16}$ and (6) G-1(Pyr=AoA-LYRAG)$_{8}$. For calculated average masses, see Table 2 in main text.

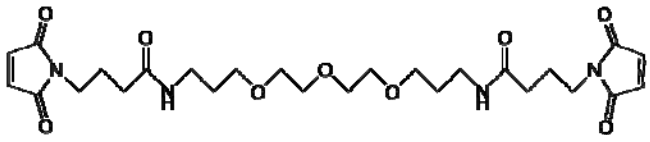
3. Synthesis of PEG linkers for dendrimer arm extension

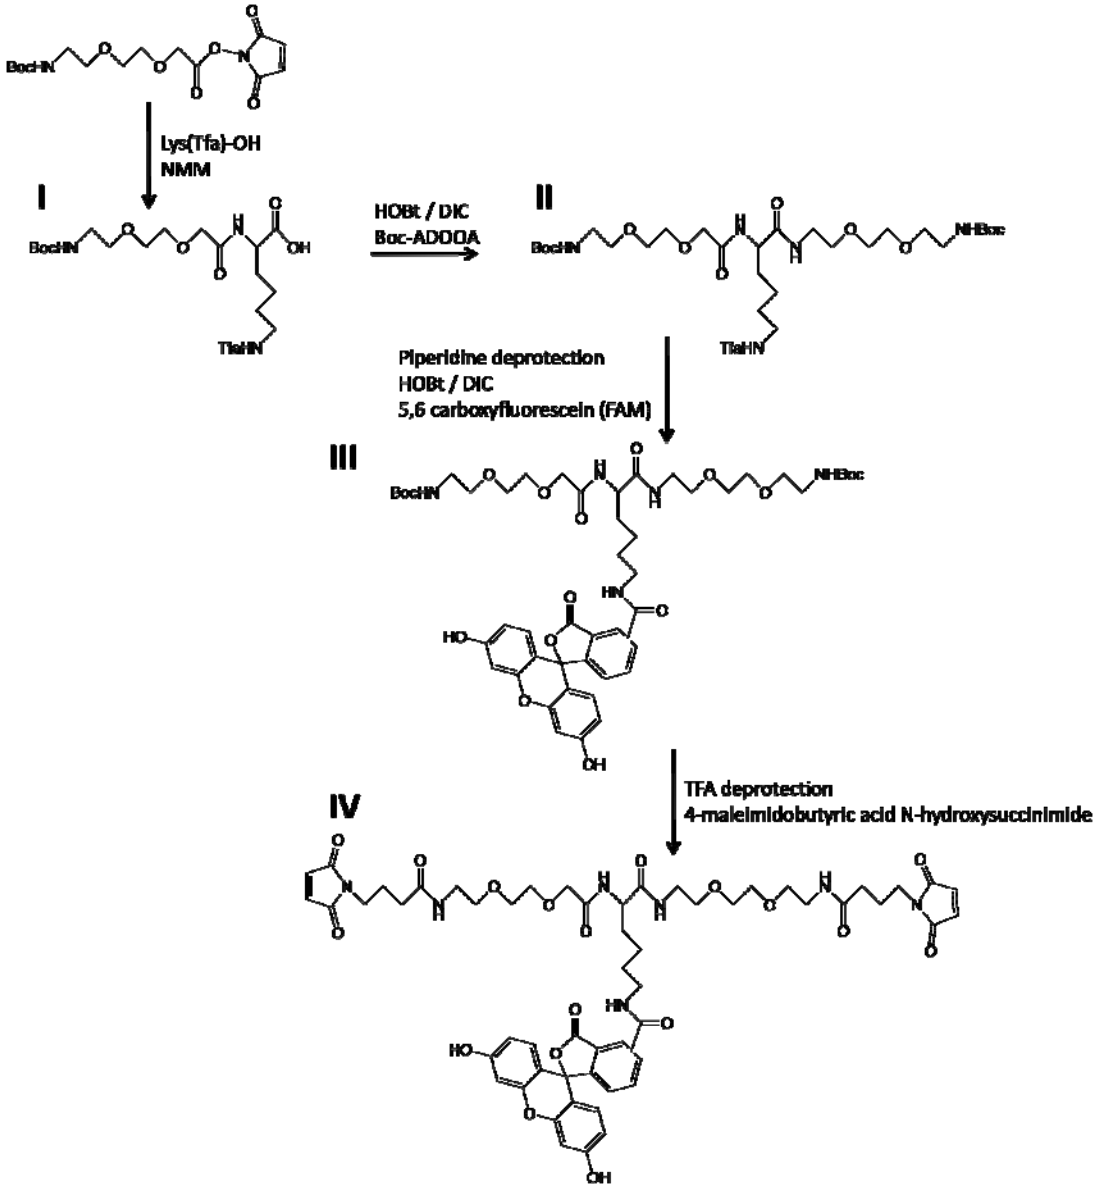


Boc-ATOPA-OPfp

The pentafluorophenol ester (-OPfp) was prepared by activation of Boc-15-amino-4,7,10,13-tetraoxapentanedecanoic acid (Boc-ATOPA) with 1 equivalent of DCC and 1 equivalent of N-hydroxysuccinimide (NHS) in ethyl acetate (EtOAc). The mixture was stirred overnight and filtered to remove the precipitate. The solvent was evaporated under reduced pressure and the oily product obtained was used without further purification. Boc-ATOPA-OPfp was preferred over the -OSu derivative because use of the latter compound resulted in significant formation of β-alanine adducts during coupling to the dendrimer, probably through Lossen rearrangement as previously described for PEG succinimide carbonates (*21*).

4. Synthesis and characterization of bifunctional linkers

Bismaleimido-4,7,10-trioxa-1,13-tridecanediamine



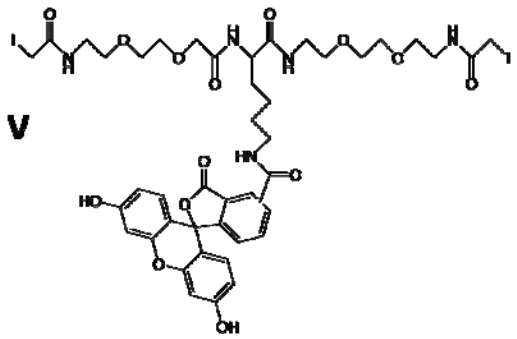
4-Maleimidobutyric acid N-hydroxysuccinimide ester was reacted in a 1.5-fold excess over amino groups of 4,7,10-trioxa-1,13-tridecanediamine (ATOTA) in DMF. After 3 h incubation, the bis-maleimido-ATOTA linker was isolated by preparative HPLC and characterized by ESI-MS ($[M+H]^+$ expected: 551.6; observed: 551.6).

Bismaleimido-4,7,10-trioxa-1,13-tridecanediamine linker

Maleimido-AEEA-Lys (FAM)-ADOOA-Maleimide

The fluorescein-labelled linker was prepared by incorporation of a side chain-protected lysine residue between {2-[2-(Boc-amino)ethoxy]ethoxy} acetic acid (Boc-AEEA) and 1-(Boc-amino)-3,6-dioxa-8-octaneamine (Boc-ADOOA), 5,6 carboxy-fluorescein (FAM) being attached on the lysine side chain. The separate steps involved in the synthesis are shown below.

Scheme S1. Synthesis of maleimido-AEEA-Lys (FAM)-ADOOA-Maleimide linker (**IV**)



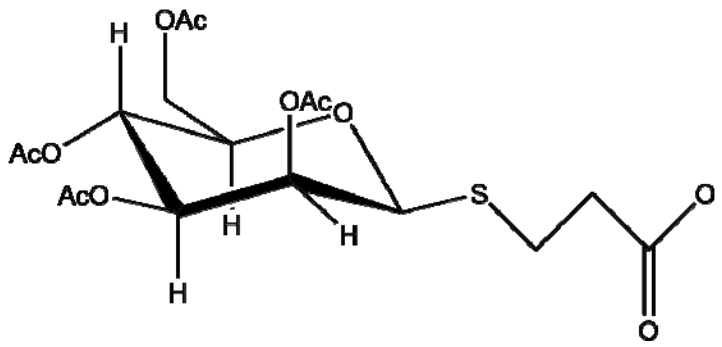
(i) Boc-AEEA-Lys-ADOOA-Boc. {2-[2-(Boc-amino)ethoxy]ethoxy} acetic acid N-hydroxysuccinimide (Boc-AEEA-OSu) was reacted with a 1.2 fold excess of Lys(TFA)-OH in DMSO in the presence of NMM. The resulting product, Boc-AEEA-Lys(TFA)-OH (**I** in Scheme S1) was isolated by preparative HPLC and characterized by ESI-MS ($[M+H]^+$ expected: 487.3; observed: 487.1). This material was activated with equimolar amounts of HOBt and DIC in DMF and added to a 2-fold molar excess of Boc-ADOOA. After overnight incubation, the product (**II** in Scheme S1) was isolated by preparative HPLC and characterized by ESI-MS ($[M+H]^+$ expected: 622.8; observed: 622.4). The dried material was solubilised in 50% MeOH and piperidine was added to a 1 M final concentration. After overnight incubation at 20°C, the mixture was adjusted to pH 3.0 and deprotected material was isolated by preparative HPLC using a 0-50% B gradient over 50 min at 15 mL/min.

(ii) AEEA-Lys(FAM)-ADOOA. FAM was activated for 5 min with equimolar amounts of HOBt and DIC in DMF then added in a 1.3-fold excess to Boc-AEEA-Lys-ADOOA-Boc that had previously been solubilised in DMF and neutralised with a 3 molar excess of NMM. After incubation for 15 h in the dark, the product (**III** in Scheme S1) was purified by preparative HPLC, dried and deprotected in neat TFA and freeze-dried after TFA evaporation; ESI-MS m/z $[M+H]^+$ expected: 781.1; observed: 780.4.

(iii) Maleimido-AEEA-Lys(FAM)-ADOOA-maleimide. 4-Maleimidobutyric acid N-hydroxysuccinimide ester was reacted in DMF with AEEA-Lys(FAM)-ADOOA at a 1.5-fold excess over amino groups of the linker for 3 h. The final product (**IV** in Scheme S1) was characterized by ESI-MS (m/z $[M+H]^+$ expected: 1115.7; observed: 1116.0).

Iodoacetamide-AEEA-Lys(FAM)-ADOOA-iodoacetamide

This analogue of the maleimido-AEEA-Lys(FAM)-ADOOA-maleimide linker was obtained by acylation of the bis-amino intermediate (**III** in Scheme S1) with iodoacetic acid N-hydroxysuccinimide ester instead of 4-Maleimidobutyric acid N-hydroxysuccinimide ester (reaction carried out under the same conditions). The final product was characterized by ESI-MS m/z $[M+H]^+$ (expected: 1111.4; observed: 1110.6).



Iodoacetamide-AEEA-Lys(FAM)-ADOOA-iodoacetamide linker (V)

5. Synthesis and characterization of linker-conjugated mannose

3-(2,3,4,6-Tetra-O-acetyl-α-D-mannopyranosylthio)propionic acid

Preparation of per-O-acetylthioglycoside-propionate involved peracetylation with acetic anhydride (Ac_2O) followed by thioglycosydation with 3-thiopropionic acid in the presence of borontrifluoride diethyl etherate (BF_3OEt_2) as described previously (*20*), except that final material was purified by preparative HPLC using a 15-25 % solvent B gradient over 40 min.

3-(2,3,4,6-Tetra-O-acetyl-α-D-mannopyranosylthio)propionic acid

Succinimide activation was carried out with 1 equivalent dicyclohexylcarbodiimide (DCC) and 1 equivalent N-hydroxysuccinimide (NHS) in dimethoxyethane (DME). The mixture was stirred overnight and filtered to remove the precipitate. The solvent was evaporated using reduced pressure and the powder obtained was used without further purification.

The succinimide-activated product was characterized by using it in the synthesis of a mannose-coated dendrimer by direct acylation of G-2(ATOPA-NH_2)$_{16}$, followed by Zemplen deacylation. Both the protected intermediate and final compound were characterized by NMR.

Supporting Information

ABSTRACT: Previously, G protein-coupled receptor (GPCR) agonists were tethered from polyamidoamine (PAMAM) dendrimers to provide high receptor affinity and selectivity. Here, we prepared GPCR ligand−dendrimer (GLiDe) conjugates from a potent adenosine receptor (AR) antagonist; such agents are of interest for treating Parkinson's disease, asthma, and other conditions. Xanthine amine congener (XAC) was appended with an alkyne group on an extended C8 substituent for coupling by Cu(I)-catalyzed click chemistry to azide-derivatized G4 (fourth-generation) PAMAM dendrimers to form triazoles. These conjugates also contained triazole-linked PEG groups (8 or 22 moieties per 64 terminal positions) for increasing water-solubility and optionally prosthetic groups for spectroscopic characterization and affinity labeling. Human AR binding affinity increased progressively with the degree of xanthine substitution to reach K_i values in the nanomolar range. The order of affinity of each conjugate was $hA_{2A}AR > hA_3AR > hA_1AR$, while the corresponding monomer was ranked $hA_{2A}AR > hA_1AR \geq hA_3AR$. The antagonist activity of the most potent conjugate **14** (34 xanthines per dendrimer) was examined at the G_i-coupled A_1AR. Conjugate **14** at 100 nM right-shifted the AR agonist concentration−response curve in a cyclic AMP functional assay in a parallel manner, but at 10 nM (lower than its K_i value), it significantly suppressed the maximal agonist effect in calcium mobilization. This is the first systematic probing of a potent AR antagonist tethered on a dendrimer and its activity as a function of variable loading.

INTRODUCTION

We have used poly(amidoamine) (PAMAM) dendrimers as polymeric nanocarriers for drugs that bind to G protein-coupled receptors (GPCRs) located on the cell surface.[1−3] These receptors are an important area of drug discovery. Agonists and antagonists of rhodopsin-like GPCRs constitute a large fraction (~30%) of the 324 molecular targets of FDA-approved drugs.[4] Multivalent GPCR ligand−dendrimer (GLiDe) conjugates, in which a strategically derivatized agonist or antagonist is covalently tethered from a high molecular weight PAMAM dendrimer, have displayed enhanced pharmacodynamic properties in comparison to those of the monomeric ligands.[2,3,5] One of the objectives of this approach is to favorably alter the pharmacokinetics of the drug in vivo when bound to the nanocarrier. It is also feasible to target the binding of a polymeric drug to aggregates of GPCRs, which have been shown to exist and have been postulated to be major participants in the varied biological effects of a given receptor.[6] GPCR dimers, including heterodimers of two different receptor classes, have already been established to have an altered pharmacology compared to that of homomeric GPCRs.[7] We have shown with molecular modeling that GLiDe conjugates of sufficient molecular size can adopt a suitable geometry to bridge multiple binding sites in such receptor aggregates.[8]

We initially reported the use of PAMAM dendrimers as scaffolds for the presentation of nucleosides and nucleotides that selectively activate adenosine receptors (ARs, particularly the A_{2A} and A_3 subtypes) or antagonize P2Y receptors (specifically the $P2Y_1$ subtype) to modulate intracellular signaling,[1,2,9] with both of these receptor families being GPCRs. These GLiDe conjugates are stable and biologically active without requiring the release of small molecules or cellular internalization, which are often an integral part of other polymeric drug delivery schemes.[10] Recently, we showed that a potent A_3AR agonist conjugate displayed cytoprotective effects in a cardiomyocyte culture heterologously expressing the A_3AR.[11] The present study extends the GLiDe conjugate approach for the first time from AR agonists to multivalent conjugates of AR antagonists. AR antagonists, the naturally occurring xanthines theophylline **1** and caffeine **2** being prototypical examples (Figure 1), are of therapeutic interest in the treatment of Parkinson's disease, diabetes, asthma, cancer, and other conditions.[4,12] The structure−activity relationship (SAR) of xanthine derivatives as AR antagonists has been exhaustively explored.[13,14] One of the earliest high affinity AR ligand probes was the 8-phenyl derivative xanthine amine congener (**3**, XAC), which is a moderately selective antagonist of the A_1AR subtype in the rat and is relatively nonselective in binding to human (h) ARs.[15] XAC contains an amine-terminal chain placed at an insensitive site on the pharmacophore and was designed as a functionalized

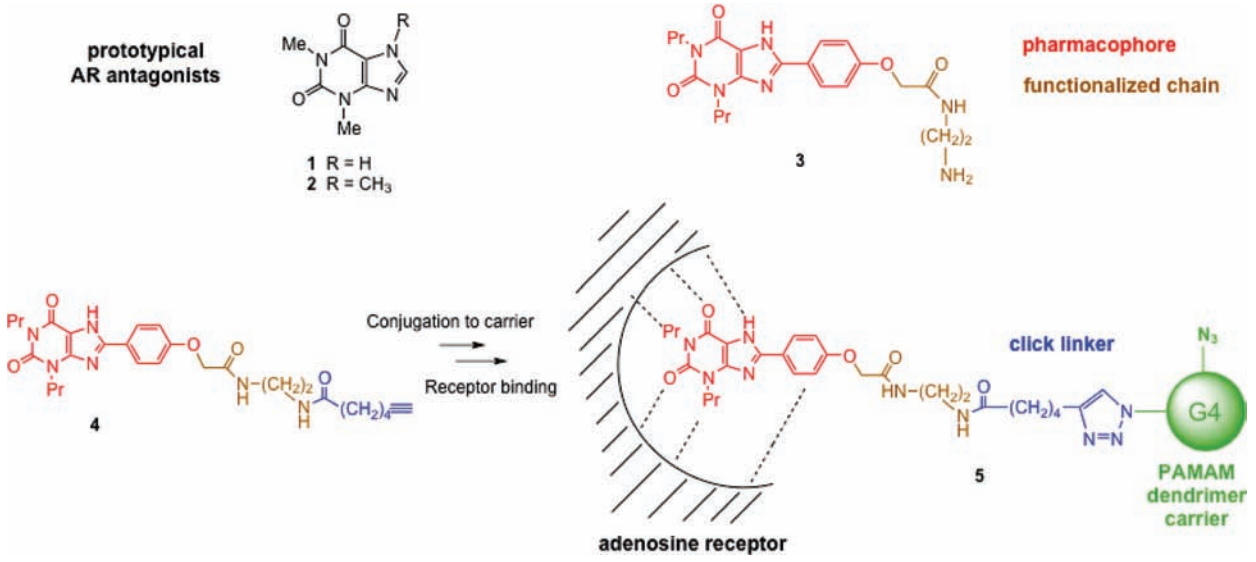

Figure 1. Structures of nonselective AR antagonists (**1**−**3**) and the design of a series of multivalent dendrimer conjugates of a potent xanthine, represented by the triazole derivative of unspecified stoichiometry in the general formula (**5**). Compound **3** is a functionalized XAC congener designed for attachment to carrier moieties with retention of the ability to bind potently to ARs. The conjugation of alkyne derivative **4** is performed using click chemistry, which forms a triazole linker on an insensitive site on the xanthine with respect to receptor recognition.

congener,[16] i.e., for attachment to larger carrier moieties and reporter groups with retention of the ability to bind potently to ARs.

In this study, we have identified a means of linking XAC to water-soluble PAMAM dendrimers by Cu(I)-catalyzed click chemistry between an alkyne and an azide,[17] which we found to preserve the high receptor affinity in this series. The degree of substitution by XAC and by polyethylene glycol (PEG) water-solubilizing chains was systematically varied and the effects on receptor affinity studied. This analysis suggests that each GLiDe conjugate molecule may bind to multiple AR binding sites in the vicinity on the cell surface. Furthermore, the ability to introduce prosthetic groups for receptor localization or characterization on the carrier without interfering with the high affinity in receptor binding was shown.

EXPERIMENTAL PROCEDURES

Chemical Synthesis. *Materials and Methods.* All reactions were carried out under a nitrogen atmosphere. We purchased *N*-ethyl-*N*′-dimethylaminopropylcarbodiimide hydrochloride (EDC.HCl) and the G4 PAMAM dendrimer (5 wt % solution in methanol) with an ethylenediamine core **6a** from Sigma-Aldrich (St. Louis, MO). All other reagents and solvents, except those indicated, came from Sigma-Aldrich. We purchased dialysis membranes (Spectra/Pore Membrane, MWCO 3500, flat width 18 mm) from Spectrum Laboratories (Rancho Dominguez, CA). Imidazole-1-sulfonyl azide hydrochloride was prepared.[18] Synthesis of XAC **3** is described elsewhere.[14] Active esters IRDye800CW **23** and IRDye700DX **24** were obtained from LI-COR Biosciences (Lincoln, NE). Amicon centrifugal ultrafilters (molecular weight cutoff 3000) were used.

Proton nuclear magnetic resonance (NMR) spectra were recorded on a Bruker DRX-400 spectrometer with d_6-DMSO as a solvent. The chemical shifts are reported in parts per million (ppm) relative to tetramethylsilane (δ 0.0 ppm) or in D_2O relative to HOD (4.80 ppm). ESI−high resolution mass spectroscopic (HRMS) measurements were performed on a proteomics optimized Q-TOF-2 (Micromass-Waters) using external calibration with polyalanine and matrix-assisted laser desorption ionization (MALDI) time-of-flight MS experiments on a Waters LCT Premier mass spectrometer at the Mass Spectrometry Facility, National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), NIH. Observed mass accuracies are those expected on the basis of known performance of the instrument as well as the trends in masses of standard compounds observed at intervals during the series of measurements. Reported masses are observed masses uncorrected for this time-dependent drift in mass accuracy. IR spectra were recorded using a PerkinElmer Spectrum One FT-IR spectrometer (applied as a DMSO solution).

*Azido-Derivatized G4 PAMAM dendrimer (**6b**).* The G4 PAMAM dendrimer containing an ethylene diamine core was obtained from Sigma-Aldrich and terminal amines reacted with imidazole-1-sulfonyl azide hydrochloride.[3] K_2CO_3 (3.48 g, 30.15 mmol), $CuSO_4 \cdot 5H_2O$ (34.6 mg, 0.163 mmol), and imidazole-1-sulfonyl azide hydrochloride (3.0 g, 1.04 mol) were added to a solution of G4 PAMAM dendrimer **6a**, (20 g, 10 w% in methanol, $[NH_2]$ = 16.3 mmol) in anhydrous methanol (11 mL), and the reaction mixture was stirred at room temperature overnight. The mixture was then dialyzed in deionized water for 7 days (changing water 4 times per day). Lyophilization after dialysis provided the azide-derivatized G4 dendrimer **6b** (3.2 g, 58%) as a solid. IR ν_{max} 2110 cm^{-1}. ESI-MS: calcd, 15,611; found, 15,545.

*G4 PAMAM, Conjugated with PEG [8] (**8**).* The azide-derivatized G4 PAMAM dendrimer **6b** (111 mg, 7.1 μmol) and a poly(ethylene glycol)methyl ether derivative of butynoic acid **7** (MW 2000, Aldrich Chemical Co., 114 mg, 57 μmol) were added to a mixture of DMSO (4 mL) and water (4 mL). The solution was treated with freshly prepared aqueous sodium ascorbate (1 M solution, 228 μL), followed by the addition of 7.5% aqueous cupric sulfate (380 μL, 113 μmol). The reaction mixture was stirred at room temperature (rt) overnight, and the product was purified by extensive dialysis in water (changing water 4 times per day for 2 days). The mixture was lyophilized to give compound **8**

(153 mg, 67%) containing ~8 equivalents of PEG per dendrimer molecule as a colorless foamy solid. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.10 (br s), 4.35 (s), 4.13 (s), 3.5 (s), 3.41−3.44 (m), 3.33 (br s), 3.24 (s), 2.67−2.87 (m), 2.26 (br s). ESI-MS: calcd, 31,545; found, 32,077.

*G4 PAMAM, Conjugated with PEG [22] (**9**).* Compound **9** (74%) containing ~22 equivalents of PEG per dendrimer molecule was synthesized from dendrimer **6b** following the same method as that for compound **8**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.03 (br s), 4.35 (s), 4.25 (s), 3.59 (s), 3.39−3.44 (m), 3.32 (br s), 3.24 (s), 2.87 (br s), 2.66 (br s), 2.33 (s), 2.24 (br s). ESI-MS: calcd, 59,545; found, 59,855.

*N-(2-(2-(4-(2,6-Dioxo-1,3-dipropyl-2,3,6,7-tetrahydro-1H-purin-8-yl)phenoxy)-acetamido)ethyl)hept-6-ynamide (**4**).* 6-Heptynoic acid (33 μL, 0.27 mmol) and EDC (68.8 mg, 0.36 mmol) were added to a solution of compound **3** (77 mg, 0.18 mmol) in anhydrous DMF (3 mL) and stirred overnight at rt. Solvent was evaporated, and the residue was purified using flash silica gel column chromatography to give compound **4** (69 mg, 72%) as a colorless solid. ^{1}H NMR (CD_3OD, 400 MHz) δ 8.05 (d, J = 8.8 Hz, 2H), 7.14 (d, J = 8.8 Hz, 2H), 4.61−4.63 (m, 2H), 4.14 (t, J = 7.2 Hz, 2H), 4.01 (t, J = 7.6 Hz, 2H), 3.41−3.65 (m, 6H), 2.19−2.13 (m, 5H), 1.86−1.70 (m, 1H), 1.69−1.64 (m, 4H), 1.52−1.46 (m, 1H), 1.15 (d, J = 6.4 Hz, 1H), 1.17−0.95 (m, 6H). HRMS calculated for $C_{28}H_{37}N_6O_5$ (M + H)$^+$: 537.2825; found, 537.2823.

*G4 PAMAM, Conjugated with PEG [22] and the XAC [6] Derivative (**10**).* The azide-derivatized G4 PAMAM dendrimer **6b** (10.5 mg, 0.17 μmol) and a XAC alkyne derivative **4** (0.54 mg, 1.02 μmol) were added to a mixture of DMSO (0.4 mL) and water (0.4 mL). The solution was treated with freshly prepared aqueous sodium ascorbate (1 M solution, 3 μL), followed by the addition of 7.5% aqueous cupric sulfate (2.3 μL, 0.7 μmol). The reaction mixture was stirred at rt overnight, and the product was purified by extensive dialysis in water (changing water 4 times per day for 2 days). The mixture was lyophilized to give compound **10** (6.9 mg, 66%) containing ~22 equivalents of PEG and ~6 xanthine equivalents per dendrimer molecule as a foamy solid. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.15 (br s), 8.09 (d, J = 8.8 Hz), 7.71−7.97 (m), 7.16 (d, J = 9.2 Hz), 4.54 (s), 4.24−4.36 (m), 4.12 (br s), 4.04 (t, J = 7.6 Hz), 3.81 (t, J = 7.6 Hz), 3.54−3.67 (m), 3.49 (br s), 3.14−3.47 (br m), 2.63−2.71 (br m), 2.07−2.33 (m), 1.42−1.81 (br m), 0.84−0.92 (br m). ESI-MS: calcd, 63,074; found, 63,069.

*G4 PAMAM, Conjugated with PEG [22] and the XAC [8] Derivative (**11**).* Compound **11** (70%) was synthesized from PEG conjugated dendrimer **9** following the same procedure as that for compound **10** using 8 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.13 (br s), 8.10 (d, J = 8.8 Hz), 7.87−7.93 (m), 7.11 (d, J = 9.2 Hz), 4.55 (s), 4.32−4.36 (m), 4.12 (br s), 4.04 (t, J = 7.6 Hz), 3.85 (t, J = 7.6 Hz), 3.59−3.67 (m), 3.46 (br s), 3.14−3.42 (br m), 2.67−2.86 (br m), 2.05−2.33 (m), 1.51−1.75 (br m), 0.86−0.91 (br m). ESI-MS: calcd, 64,147; found, 64,251.

*G4 PAMAM, Conjugated with PEG [22] and the XAC [19] Derivative (**12**).* Compound **12** (75%) was synthesized from PEG conjugated dendrimer **9** following the same procedure as that for compound **10** using 19 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.17 (br s), 8.07 (d, J = 8.8 Hz), 7.69−7.93 (m), 7.11 (d, J = 9.2 Hz), 4.54 (s), 4.30−4.35 (m), 4.13 (br s), 4.02 (t, J = 7.6 Hz), 3.84 (t, J = 7.6 Hz), 3.58−3.68 (m), 3.51 (br s), 3.13−3.48 (br m), 2.62−2.7 (br m), 2.05−2.33 (m), 1.39−1.81 (br m), 0.86−0.92 (br m). ESI-MS: calcd, 70,050; found, 70,074.

*G4 PAMAM, conjugated with PEG [22] and XAC [23] derivative (**13**).* Compound **13** (78%) was synthesized from PEG conjugated dendrimer **9** following the same procedure as that for compound **10** using 23 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.13 (br s), 8.09 (d, J = 8.8 Hz), 7.91−7.86 (m), 7.11 (d, J = 9.2 Hz), 4.54 (s), 4.32−4.34 (m), 4.12 (br s), 4.04 (t, J = 7.6 Hz), 3.86 (t, J = 7.6 Hz), 3.58−3.68 (m), 3.44 (br s), 3.14−3.44 (br m), 2.67−2.87 (br m), 2.03−2.33 (m), 1.49−1.75 (br m), 0.86−0.92 (br m). ESI-MS: calcd, 72,197; found, 72,320.

*G4 PAMAM, Conjugated with PEG [22] and the XAC [34] Derivative (**14**).* Compound **14** (84%) was synthesized from PEG conjugated dendrimer **9** following the same method as that for compound **10** using 34 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.11 (br s), 8.09 (d, J = 9.2 Hz), 7.90−7.85 (m), 7.11 (d, J = 9.2 Hz), 4.54 (s), 4.02 (t, J = 6.0 Hz), 3.87 (t, J = 7.6 Hz), 3.12−3.71 (br m), 2.67−2.74 (m), 2.30−2.38 (m), 2.10−2.14 (m), 2.05 (t, J = 7.2 Hz), 1.72−1.79 (m), 1.53−1.61 (m), 1.37−1.41 (m), 0.86−0.92 (br m). ESI-MS: calcd, 78,100; found, 77,999.

*G4 PAMAM, Conjugated with PEG [8] and the XAC [4] Derivative (**15**).* Compound **15** (67%) was synthesized from PEG conjugated dendrimer **8** following the same method as that for compound **10** using 4 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.14 (br s), 8.08 (d, J = 8.8 Hz), 7.72−7.90 (m), 7.10 (d, J = 8.8 Hz), 4.54 (s), 4.34 (br s), 4.13 (br s), 4.02 (t, J = 7.6 Hz), 3.86 (t, J = 7.5 Hz), 3.60−3.67 (m), 3.49 (br s), 3.08−3.44 (br m), 2.67−2.87 (br m), 2.22−2.33 (br m), 1.48−1.68 (br m), 0.86−0.92 (br m). ESI-MS: calcd, 34,223; found, 34,377.

*G4 PAMAM, Conjugated with PEG [8] and the XAC [16] Derivative (**16**).* Compound **16** (72%) was synthesized from PEG conjugated dendrimer **8** following the same method as that for compound **10** using 17 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.15 (br s), 8.09 (d, J = 8.8 Hz), 7.81−7.86 (m), 7.11 (d, J = 8.8 Hz), 4.54 (s), 4.34 (s), 4.19 (t, J = 7.5 Hz), 4.04 (t, J = 7.6 Hz), 3.52 (br s), 3.14−3.44 (br m), 2.62−2.74 (m), 2.03−2.33 (m), 1.39−1.75 (br m), 0.89−0.92 (br m). ESI-MS: calcd, 40,662; found, 40,461.

*G4 PAMAM, Conjugated with PEG [8] and the XAC [25] Derivative (**17**).* Compound **17** (80%) was synthesized from PEG conjugated dendrimer **8** following the same method as that for compound **10** using 26 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.16 (br s), 8.09 (d, J = 8.8 Hz), 7.86−7.88 (m), 7.11 (d, J = 8.8 Hz), 4.54 (s), 4.02 (t, J = 6.8 Hz), 3.89 (t, J = 6.7 Hz), 3.51 (br s), 3.14−3.32 (m), 2.10−2.14 (m), 2.04 (t, J = 7.2 Hz), 1.72−1.77 (m), 1.51−1.61 (m), 1.35−1.43 (m), 0.81−0.92 (br m). ESI-MS: calcd, 45,492; found, 45,223.

*G4 PAMAM, Conjugated with PEG [8] and the XAC [37] Derivative (**18**).* Compound **18** (84%) was synthesized from PEG conjugated dendrimer **8** following the same method as that for compound **10** using 37 equivalents of the XAC alkyne derivative **4**. ^{1}H NMR (DMSO-d_6, 400 MHz) δ 8.18 (br s), 8.08 (d, J = 9.2 Hz), 7.86−7.88 (m), 7.11 (d, J = 8.8 Hz), 4.54 (s), 4.02 (t, J = 6.0 Hz), 3.87 (t, J = 6.8 Hz), 3.12−3.62 (br m), 2.67−2.74 (m), 2.33 (br s), 2.10−2.13 (m), 2.05 (t, J = 6.8 Hz), 1.72−1.77 (m), 1.53−1.61 (m), 1.37−1.43 (m), 0.88−0.92 (br m). ESI-MS: calcd, 51,931; found, 52,035.

*G4 PAMAM, Conjugated with PEG [8], XAC [37], and Alexa Fluor 488 (**20**).* A solution of Alexa Fluor 488 alkyne **19** (0.5 mg, 0.64 μmol) in water (0.5 mL) and freshly prepared sodium ascorbate (1 M, 5 μL) were added to a solution of the XAC-dendrimer conjugate **18** (8.2 mg, 0.16 μmol) in DMSO (0.5 mL). Then, 7.5% aqueous cupric sulfate (6 μL, 113 μmol) was added to the reaction mixture, which was stirred overnight at rt. The dendrimer derivative was purified by extensive dialysis in water, and lyophilization of the resulting solution gave compound **19** (5.9 mg, 66%) as an orange colored solid. ESI-MS: calcd, 57,065; found, 57,079.

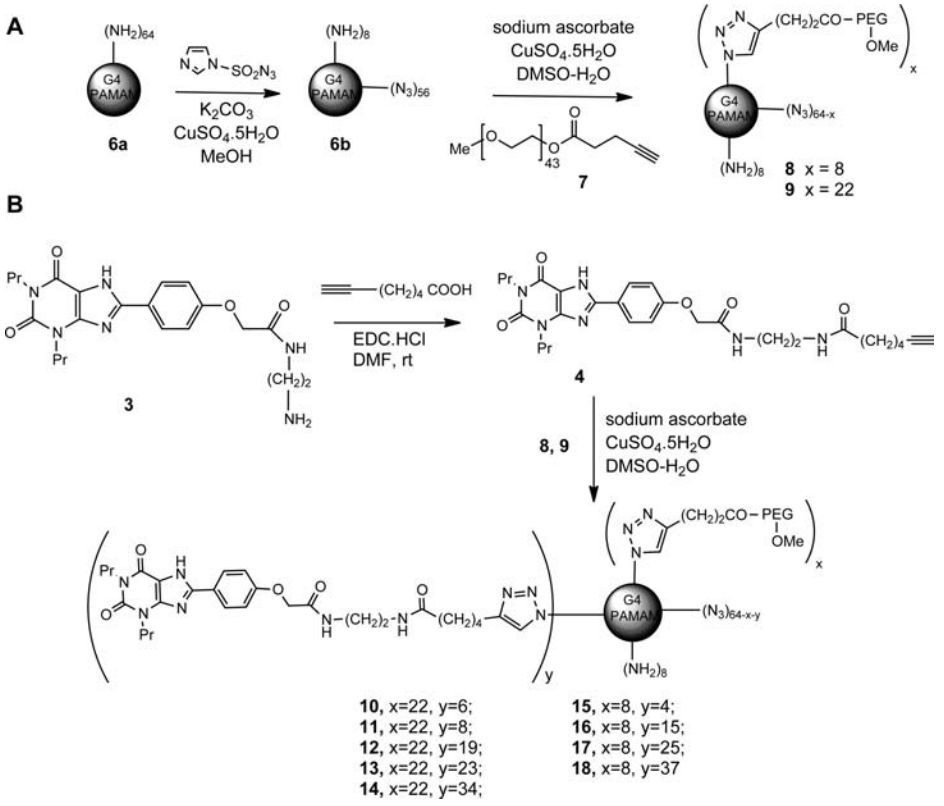
*4-(2-Hept-6-ynamidoethyl)benzene-1-sulfonyl Fluoride (**21**).* 6-Heptynoic acid (11 μL, 0.09 mmol), HATU (31 mg, 0.08 mmol), and diisopropyl ethylamine (14 μL, 0.08 mmol) were added to a solution of 4-(2-aminoethyl)benzene-1-sulfonyl fluoride (Aldrich, 15 mg, 0.06 mmol) in anhydrous DMF (1 mL). The reaction mixture was stirred overnight at rt. The solvent was evaporated, and the residue was purified using flash silica gel column chromatography (hexane/ethyl acetate = 2:1) to give compound **21** (15.2 mg, 78%) as a colorless solid. ^{1}H NMR (CD_3OD, 400 MHz) δ 8.00 (d, J = 8.4 Hz, 2H), 7.60 (d, J = 8.0 Hz, 2H), 3.52−3.48 (m, 2H), 2.98 (t, J = 6.8 Hz, 2H), 2.32 (t, J = 7.2 Hz, 2H), 2.23−2.20 (m, 2H), 1.75−1.44 (m, 5H). HRMS calculated for $C_{15}H_{19}NO_3SF$ $(M + H)^+$: 312.1070; found, 312.1073.

*G4 PAMAM, Conjugated with PEG [8], XAC [37], Alexa Fluor 488, and the Benzene-sulfonyl Fluoride Derivative (**22**).* Benzene-sulfonyl fluoride alkyne derivative **21** (0.5 mg, 1.6 μmol) and freshly prepared sodium ascorbate (1 M, 3 μL) were added to a solution of XAC-dendrimer conjugate **20** (5.6 mg, 0.1 μmol) in DMSO (0.4 mL). Then, 7.5% aqueous cupric sulfate (4 μL, 0.9 μmol) was added to the reaction mixture, which was stirred overnight at rt. The dendrimer derivative was purified by extensive dialysis in water, and lyophilization of the resulting solution gave compound **22** (4.2 mg, 73%) as an orange colored solid. ESI-MS: calcd, 58,945; found, 59,155.

*G4 PAMAM, Conjugated with PEG [22], XAC [34], and the IR Dye 800 Derivative (**25**).* A solution of IR dye 800CW NHS ester **23** (0.5 mg, 0.42 μmol) in DMF (0.3 mL) was added to a solution of compound **14** (2.66 mg, 0.05 μmol) in DMF (1 mL) followed by triethylamine (10 μL, 0.42 μmol) and stirred overnight at rt. The dendrimer derivative was purified by extensive dialysis in water, and lyophilization of the resulting solution gave compound **25** (2.13 mg, 76%) as a green colored foamy solid. ESI-MS: calcd, 81,943; found, 82,258.

*G4 PAMAM, Conjugated with PEG [22], XAC [34], the IR Dye 700 Derivative (**26**).* A solution of IR dye 700DX NHS ester **24** (0.5 mg, 0.25 μmol) in DMF (0.3 mL) was added to a solution of compound **14** (2.32 mg, 0.03 μmol) in DMF (1 mL) followed by sodium tetraborate buffer (20 μL, 0.25 μmol), and the reaction mixture was stirred overnight at rt. The dendrimer derivative was purified by extensive dialysis in water, and lyophilization of the resulting solution gave compound **26** (2.19 mg, 83%) as a green colored foamy solid. ESI-MS: calcd, 88,511; found, 89,063.

Biological Methods. *Materials.* Penicillin−Streptomycin−Glutamine and Hygromycin B were purchased from Invitrogen (Carlsbad, CA). [^{3}H]*R*-*N*^{6}-(2-Phenylisopropyl)adenosine ([^{3}H]R-PIA, 42.6 Ci/mmol) was obtained from Moravek Biochemicals (Brea, CA). [^{125}I]4-Amino-3-iodobenzyl-5′-*N*-methylcarboxamidoadenosine ([^{125}I]I-AB-MECA, 2200 Ci/mmol) and [^{3}*H*]-2-[*p*-(2-carboxyethyl)phenylethylamino]-5′-*N*-ethylcarboxamidoadenosine ([^{3}H]CGS21680, 40.5 Ci/mmol) were purchased from PerkinElmer (Waltham, MA). DMEM/F12 medium, 1 M Tris-HCl (pH 7.5), and G418 Sulfate were purchased from Mediatech, Inc. (Herndon, VA). The calcium assay kit was from Molecular Devices (Sunnyvale, CA). All other reagents were from standard sources and are of analytical grade.



We prepared test compounds as 0.1 mM stock solutions in DMSO and stored them at 4 °C. Adenosine deaminase (25.3 U/mg) was purchased from Worthington Biochemical Corporation (Lakewood, NJ.)

Cell Culture and Membrane Preparation. We cultured Chinese hamster ovary (CHO) cells stably expressing the recombinant hA_1AR, $hA_{2B}AR$, and hA_3AR and human embryonic kidney (HEK) 293 cells stably expressing the $hA_{2A}AR$ in DMEM and F12 (1:1) supplemented with 10% fetal bovine serum (FBS), 50 U/mL penicillin, and 50 μg/mL streptomycin.[19] In addition, we added 800 μg/mL Geneticin to the $hA_{2A}AR$ media and 500 μg/mL Hygromycin B to the hA_1AR, $hA_{2B}AR$, and hA_3AR media. After harvesting the cells, we centrifuged them at 250*g* for 5 min at 4 °C. The pellet was resuspended in 50 mM Tris-HCL buffer (pH 7.5), containing 10 mM $MgCl_2$. The suspension was homogenized with an electric homogenizer for 10 s and was then recentrifuged at 20,000*g* for 30 min at 4 °C. The resultant pellet was homogenized again, resuspended in the buffer mentioned above in the presence of 3 U/mL adenosine deaminase, finally pipetted into 1 mL vials, and then stored at −80 °C until the binding experiments were conducted. We measured the protein concentration with BCA Protein Assay Kit from Pierce Biotechnology (Rockford, IL).[20]

Binding Assays. Binding assays using standard AR ligands were performed using the general methods reported.[21−23] Each tube in the binding assay contained 50 μL of increasing concentrations of the test ligand in Tris-HCl buffer (50 mM, pH 7.5) containing 10 mM $MgCl_2$, 50 μL of the appropriate agonist radioligand, and 100 μL of membrane suspension, added sequentially. For the hA_1AR (20 μg protein/tube), we used the radioligand [^{3}H]R-PIA (0.2 nM, precise final concentration is calculated for each experiment). For the $hA_{2A}AR$ (20 μg protein/tube), we used the radioligand [^{3}H]CGS21680 (10 nM). For the hA_3AR (20 μg protein/tube), we used the radioligand [^{125}I]I-AB-MECA (0.89 nM). We determined nonspecific binding with a final concentration of 10 μM unlabeled NECA diluted with the buffer. We incubated the mixtures at 25 °C for 60 min in a shaking water bath. We terminated binding reactions by filtration through Brandel GF/B filters under reduced pressure with an M-24 cell harvester (Brandel, Gaithersburg, MD). We washed filters three times with 3 mL of 50 mM ice-cold Tris-HCl buffer (pH 7.5). We then placed filters for hA_1AR and $hA_{2A}AR$ binding in scintillation vials containing 5 mL of Hydrofluor scintillation buffer and counted with a PerkinElmer Liquid Scintillation Analyzer (Tri-Carb 2810TR). We counted filters for hA_3AR binding with a Packard Cobra II γ-counter (PerkinElmer).

Cyclic AMP Accumulation Assay. CHO cells expressing the A_1AR or $A_{2B}AR$ were seeded in 24-well plates and incubated at 37 °C overnight. The following day, the medium was removed and replaced with DMEM containing 50 mM HEPES, 10 μM rolipram, 3 U/mL adenosine deaminase, and increasing concentrations of agonists. For measurements at the A_1AR, forskolin (10 μM) was added 30 min after the addition of agonists and incubated for another 15 min. Antagonists were added 20 min before the addition of agonists. The medium was removed, and the cells were lysed with 200 μL of 0.1 M HCl. One hundred microliters of the HCl solution was used in the Sigma Direct

Scheme 1. Use of Click Chemistry in Sequential Steps to Synthesize PAMAM Dendrimer Derivatives 9−18, Containing a Functionalized AR Antagonist (Average Structures Shown)[a]

[a] (A) PEG moieties were added as water-solubilizing groups, followed by conjugation of the xanthine alkyne derivative **4** (B). Compound **7** was calculated to contain approximately 43 PEG groups on the basis of its molecular weight (2000 D).

cAMP Enzyme Immunoassay following the instructions provided with the kit. The results were interpreted using a BioTek ELx808 Ultra Microplate reader (BioTek, Winooski, VT) at 405 nm.

Intracellular Calcium Mobilization. CHO cells expressing the A_1AR cells were grown overnight in 100 μL of media in 96-well flat bottom plates at 37 °C at 5% CO_2 or until 80−90% confluency. The calcium assay kit (Molecular Devices, Sunnyvale, CA) was used as directed without washing cells and with probenecid added to the loading dye at a final concentration of 2.5 mM to increase dye retention. Cells were loaded with 50 μL of dye with probenecid to each well and incubated for 60 min at rt. The compound plate was prepared using dilutions of various compounds in Hanks Buffer (pH 7.4). Samples were run on a FLIPR^{TETRA} (Molecular Devices) in duplicate at rt. Antagonists were added 20 min before the addition of agonists. Cell fluorescence was measured (excitation at 485 nm; emission at 525 nm) following exposure to agonists. Increases in intracellular calcium are reported as the maximum fluorescence value after exposure minus the basal fluorescence value before exposure.

Data Analysis. We initially measured the concentrations of the dendrimer−ligand complexes by the concentration of the dendrimer, not the attached ligand. We determined EC_{50} and apparent K_i values with Prism software (GraphPad, San Diego, CA); they are presented as the mean ± SE. The number of xanthine moieties on a given dendrimer that are accessible to receptors is uncertain; the data are therefore shown as apparent K_i values. Later, the same data were converted to the concentration of the xanthine moieties for graphic presentation. We repeated all experiments at least three times.

RESULTS

Chemical Synthesis. We prepared generation 4 (G4) PAMAM dendrimer conjugates of the potent, nonselective hAR antagonist XAC **3** (Scheme 1 and Table 1, **9**−**18**) to act as multivalent ligands of the receptors. The peripheral groups of the precursor dendrimer **6a** were modified to contain predominantly azido groups in place of the 64 terminal primary amines by reacting with imidazole-1-sulfonyl azide hydrochloride in methanol to give compound **6b**.[3,18] The same approach of preparing the PAMAM dendrimer for click chemistry by the substitution of amino groups with azides was taken in the synthesis of conjugates of AR agonists and $P2Y_1$ receptor antagonists.[3,9] Mass spectral data of **6b** indicated that 8 amino groups out of the 64 remained unreacted, and the presence of azido groups was confirmed by a strong IR peak at 2110 cm^{-1}. The presence of these residual amines was later used for synthetic advantage in the coupling of additional prosthetic groups. Prior to coupling of the pharmacophoric species, the dendrimer was appended with PEG moieties by a Cu(I)-catalyzed click cyclization using an alkyne-derivatized PEG **7** (end-capped by a methyl ether and a butynoyl ester) to yield the water-soluble and mainly uncharged PAMAM derivatives **8** and **9**, having 8 or 22 PEG moieties per dendrimer, respectively. Thus, two degrees of substitution with PEG of the 64-terminal groups of the G4 dendrimer were compared.

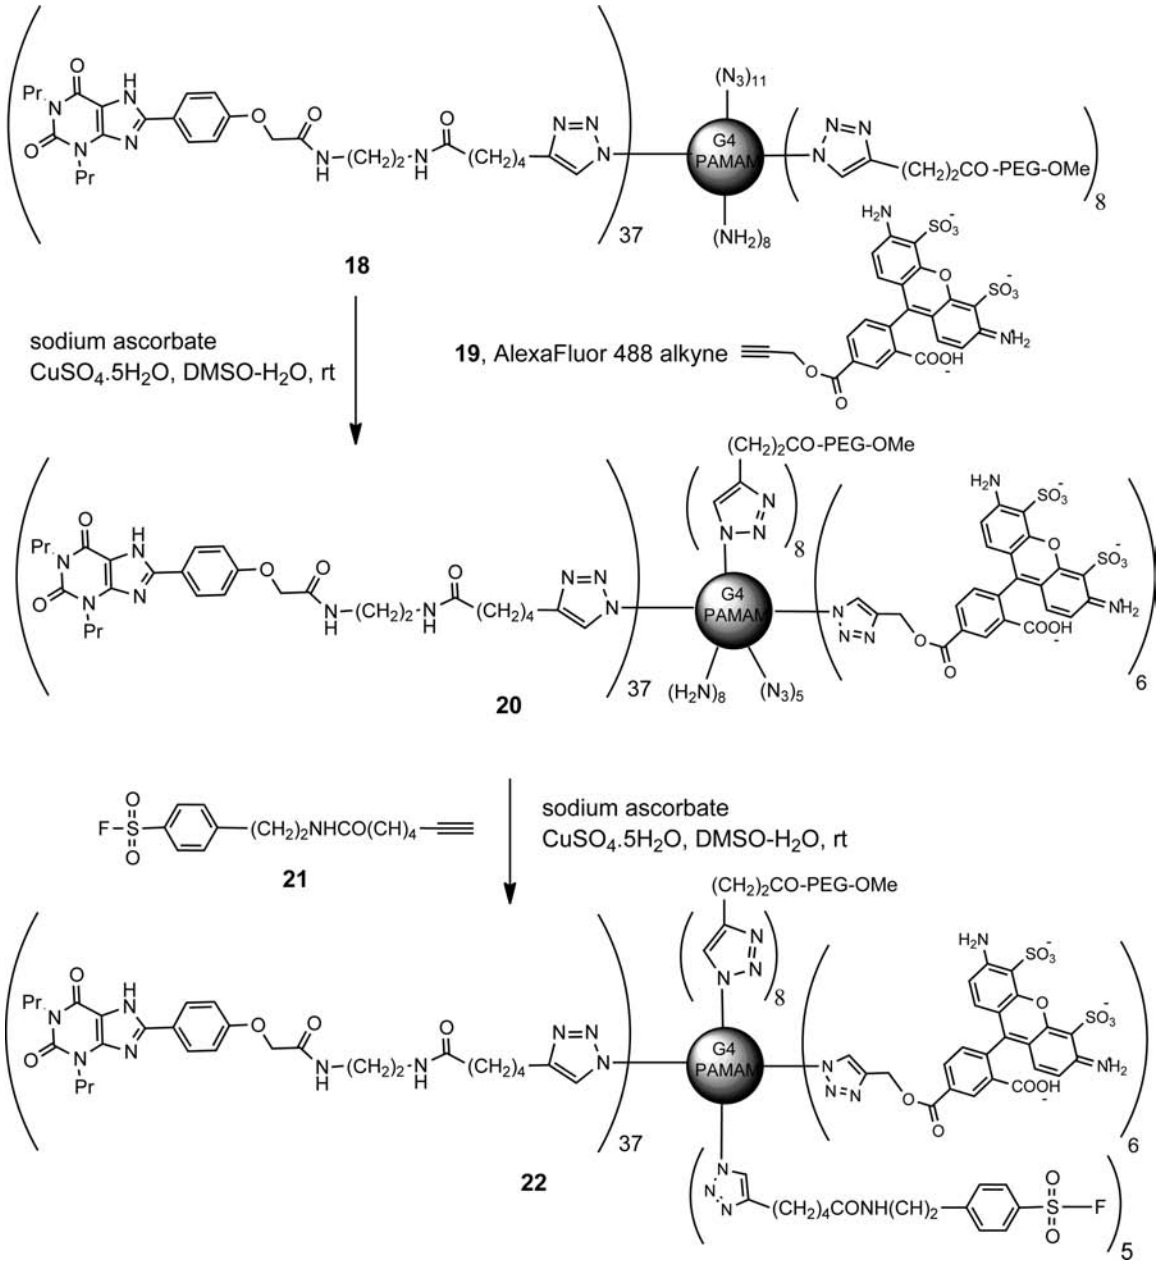
[a] All experiments were done on CHO (A_1 and A_3AR) or HEK293 ($A_{2A}AR$) cells stably expressing one of four subtypes of human ARs. The binding affinity for A_1, A_{2A}, and A_3ARs was expressed as K_i values ($n = 3-5$) and was determined by using agonist radioligands ([^{3}H]R-PIA, [^{3}H]CGS21680, or [^{125}I]I-AB-MECA, respectively), unless noted. The percentage inhibition refers to the inhibition of radioligand binding at the concentration of 1 μM. The concentrations of the dendrimer−ligand complexes were measured by the concentration of the dendrimer, not the ligand. Therefore, all binding K_i values of dendrimers are expressed as K_{iapp} values. ND: not determined. [b] **3**, XAC; **4**, MRS5398; **14**, MRS5359; **18**, MRS5385; **25**, MRS5421; **26**, MRS5422. [c] PEGylated dendrimer **9** is the precursor of **10**−**14**; PEGylated dendrimer **8** is the precursor of **15**−**18**. Xanthine-derivatized **18** is the dendrimer precursor of **20** and **22**. Xanthine-derivatized **14** is the dendrimer precursor of **25** and **26**.



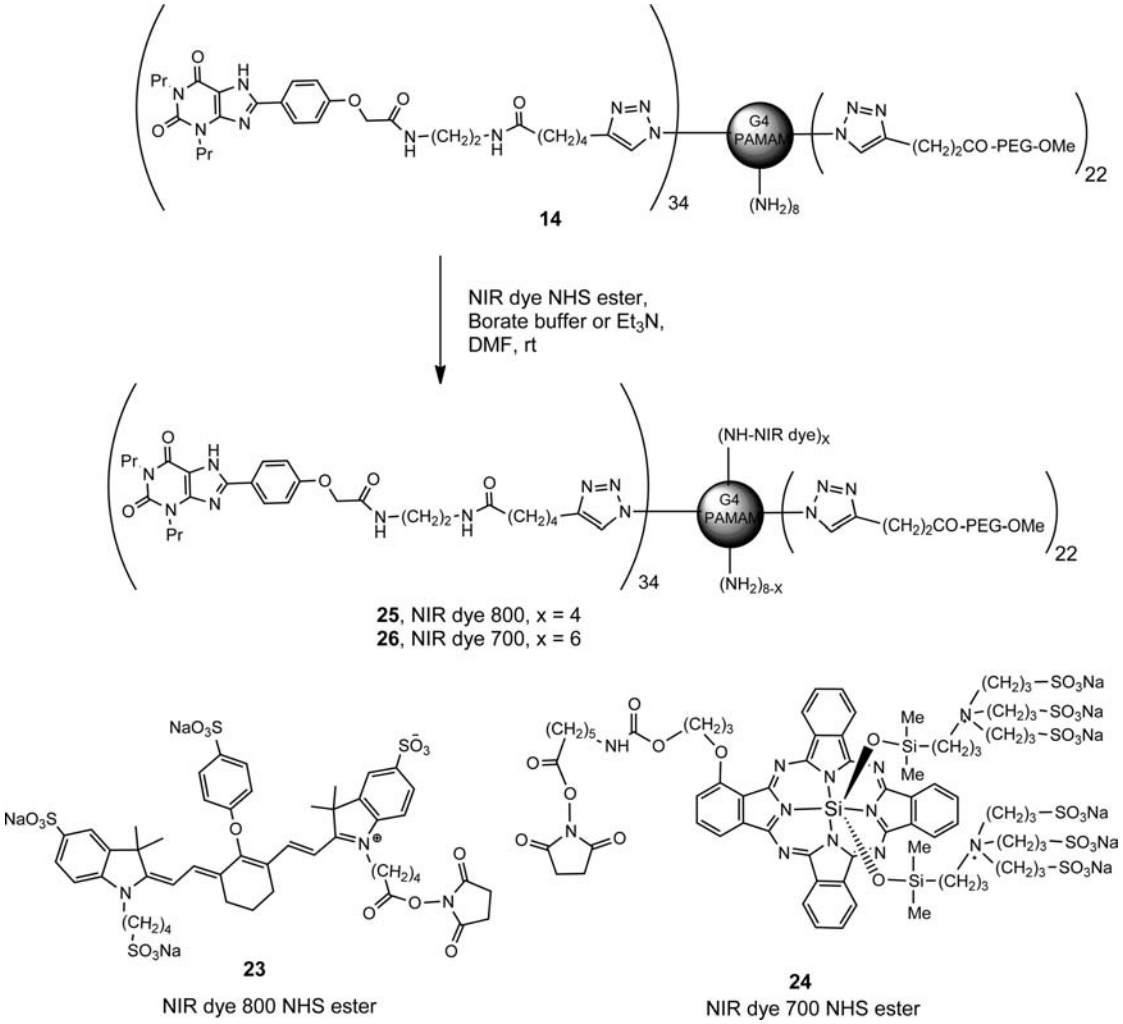
The synthetic method for cross-linking the receptor ligand to the nanocarriers **8** and **9** by click chemistry[3] required the introduction of an alkyne at an insensitive site on the xanthine moiety, and for this purpose, the hexynoyl amide derivative of XAC **4** was prepared. We have explored in detail the SAR at ARs at the distal region of the chain extended from the *para* position of the 8-phenylxanthines.[15,16] This is a site for unlimited chain derivatization, and thus, the alkyne-functionalized chain was used to provide click products with the azide-functionalized dendrimers.[3] We systematically varied the degree of substition of the dendrimer carrier with the GPCR ligand, i.e., the nonselective AR antagonist, ranging from substitution of an average of 4 to 37 of the terminal groups with the xanthine moiety. The efficiency of incorporation of the xanthine was nearly quantitative depending on the equivalents of **4** added to the click reaction, as indicated by mass spectroscopy. A fully XAC-substituted dendrimer was not prepared due to the limitation of aqueous solubility, which presented a concern in the absence of tethered PEG groups.

XAC conjugate **18**, which contained a random distribution of an average of 37 xanthine moieties and 8 PEG groups, was further derivatized with functional prosthetic groups that were coupled by click chemistry (Scheme 2). A fluorescent prosthetic group for spectroscopic characterization (Alexa Fluor 488) was included in conjugates **20** and **22**.[24] Alexa Fluor 488, which has emission and excitation maxima at 495 and 519 nm, respectively, has already been used as a fluorophore in small ligand probes of the $A_{2A}AR$.[25] Conjugate **22** also contained an aryl sulfonyl fluoride (an average of 5 moieties incorporated per PAMAM dendrimer) for affinity labeling of the receptor.[26] Aryl sulfonyl fluorides readily react irreversibly with proximal nucleophilic amino acids on a receptor yet are sufficiently stable to be applied in aqueous media. Two near-infrared (NIR) dyes[27] with absorption in the range of 800 nm (**25**) and 700 nm (**26**) were included in conjugates containing an average of 34 xanthine moieties per dendrimer. The NIR dyes were amide-linked to dendrimer **14** using the active ester precursors **23** and **24**, leading to an average degree of incorporation of 4 or 6 dye moieties incorporated per PAMAM dendrimer in **25** and **26**, respectively, as shown in Scheme 3.

Radioligand Binding. We tested the xanthine−dendrimer conjugates in binding assays at three hAR subtypes; we used standard radioligands[21−23] and membrane preparations from CHO cells (hA_1AR and hA_3AR) or HEK293 cells ($A_{2A}AR$) stably expressing a hAR subtype.[28,29] Binding affinity at the $A_{2B}AR$ was not determined because of the lack of a facile radioligand binding assay, but one representative conjugate was examined in a functional assay at this subtype.[19] Binding results shown in Table 1 indicated that receptor affinity was maintained in many of the conjugates. We used a previously reported monomeric antagonist of the ARs, XAC **3**,[16] and its hexynoyl derivative **4**, the synthetic precursor of the conjugates, for comparison in the binding assays. We included the parent dendrimers **8** and **9**, which contained a mixture of PEG, azido, and amino terminal groups, as controls; they were inactive or only weakly active in inhibiting the binding of hA_1AR and $hA_{2A}AR$ radioligands. The parent dendrimers **8** and **9** at 1 μM inhibited binding at the hA_3AR by 72% and 52%, respectively. However, we were not able to plot a full sigmoidal curve in the competition binding experiments to determine a K_i value. The relatively high displacement of radioligand at the hA_3AR by the parent dendrimers in high concentration may be related to the presence of aromatic triazolo rings on the surface of the dendrimer.

Inhibition of radioligand binding by dendrimer conjugates **14** and **18** in membranes of CHO cells expressing the hA_1 and A_3

Scheme 2. Synthesis of PAMAM Dendrimer Derivatives That Combined an Antagonist of the ARs and Functional Prosthetic Groups That Were Coupled by Click Chemistry (Average Structures Shown)[a]



[a] These consisted of conjugates for fluorescent detection (**20**) and for irreversible binding to the receptors (**22**). The dendrimer precursor **18** contained a random distribution of 37 xanthine moieties.

ARs and HEK-293 cells expressing the $hA_{2A}AR$ is shown in Figure 2B,C. Inhibition of radioligand binding by the xanthine monomer **4** is shown for comparison in Figure 2A. The results were also plotted graphically to illustrate the dependence of the affinity on the degree of substitution (Figure 3). Two methods of calculating the data were used: initially according to the concentration of the dendrimer, which is a single multivalent molecule as was done in previous studies,[1,2,5,9] or according to the concentration of the pendant xanthine moieties. The latter method is a mathematical construct, not an authentic equilibrium constant, because the xanthine moieties could not all be available to compete for receptor binding sites, by virtue of spatial limitations.

There was a smooth dependence of the affinity on the degree of substitution of the XAC-derivatized click-linked dendrimers in both series containing 8 or 22 PEG groups out of a total of 64 terminal sites. The more highly substituted dendrimer derivatives were considerably more potent than lightly substituted conjugates in binding assays at the hA_1AR, $hA_{2A}AR$, and hA_3AR. Thus, there was a regular progression toward increased affinity at each of these AR subtypes for **10**−**14** (from 6 to 34 xanthine moieties) in the more heavily PEGylated series and for **15**−**18** (from 4 to 37 xanthine moieties) in the more lightly PEGylated series. The dendrimer conjugates having 8 PEG groups displayed K_i values at the $hA_{2A}AR$ that varied from 33 nM to 4 nM ($n = 3$), for **15** and

Scheme 3. Synthesis of PAMAM Dendrimer Conjugates That Combined an Antagonist of the ARs and Prosthetic Groups for NIR Detection That Were Coupled through Amide Linkage (Average Structures Shown)[a]

[a] The dendrimer precursor **14** contained a random distribution of 34 xanthine moieties.

18, respectively. The gain of affinity for the more highly PEGylated dendrimer series (Figure 3C and D) was steeper than the gain in the less highly PEGylated dendrimer series (Figure 3A and B). Thus, the affinity of the most highly substituted conjugate having 22 PEG groups (**14**) in binding to the ARs was particularly high, with K_i values of 15, 2.6, and 8.9 nM at hA_1AR, $hA_{2A}AR$, and hA_3AR, respectively. Therefore, the binding affinity at hAR subtypes (inversely related to apparent K_i) of these multivalent conjugates depended mainly on the degree of loading with the pharmacophore and secondarily on the degree of PEG substitution.

The order of affinity at AR subtypes for each conjugate was generally $hA_{2A}AR > hA_3AR > hA_1AR$. Therefore, a slight selectivity of these xanthine−dendrimer conjugates for the $hA_{2A}AR$ in comparison to that of the other ARs was demonstrated (3- to 6-fold for **14** and 4- to 7-fold for **18**). However, the corresponding monomers **3** and **4** displayed affinity in the order of $hA_{2A}AR > hA_1AR \geq hA_3AR$. Therefore, conjugation to the carrier altered the pharmacological profile of the xanthine by relatively increasing the A_3AR affinity. It is unknown whether this difference is due to the multivalency or to the chemical nature of the linker and its effect on interaction with the extracellular regions of the receptor.

The association of binding activity of the conjugate with a macromolecular species was confirmed by filtering a solution of compound **14** through a 3000 MW cutoff centrifugal filter. Both the UV absorption of the retained fraction and its binding activity were maintained following ultrafiltration. Thus, the observed activity was due to the intact conjugate, rather than a diffusable small molecular weight impurity.

High affinity in AR binding was maintained in the conjugates containing prosthetic groups for receptor characterization (**20**, **22**, **25**, and **26**). In fact, the K_i values of these conjugates were nearly the same as those of the precursors, i.e., XAC-conjugates **14** and **18**. This was a striking observation considering the structural diversity of the attached prosthetic groups. Compound **22** might have a component of nonequilibrium binding because of the chemically reactive sulfonyl fluoride group, but this was not evident from these binding results. The affinity of the 800 nm NIR dye in **25** was identical to precursor **14**, but the more sterically bulky NIR dye in **26** caused a slight (3-fold) loss of affinity at the A_3AR.

We further examined the A_1AR antagonist activity of compound **14**, one of the most potent conjugates for the AR subtypes

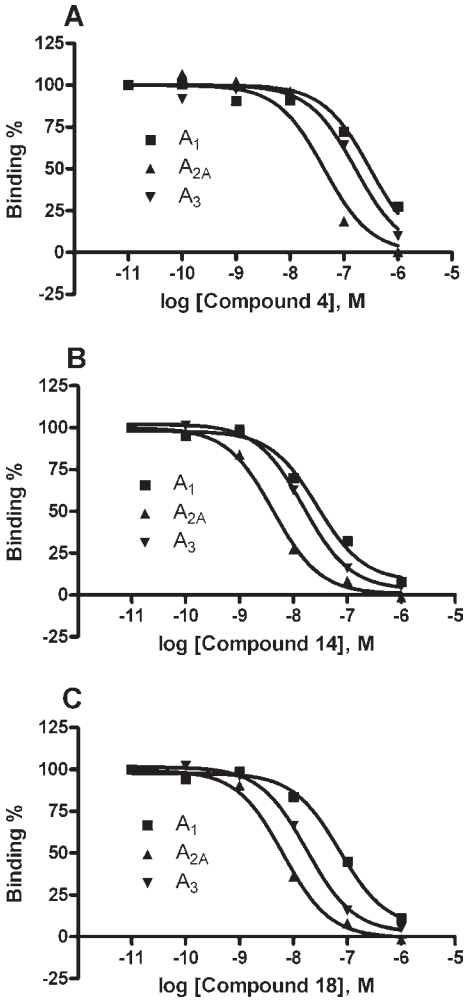


Figure 2. Inhibition of radioligand binding by xanthine monomer **4** (A) and dendrimer conjugates **14** (B) and **18** (C) (according to the concentration of the dendrimer) in membranes of CHO cells expressing the hA_1 and A_3 ARs and HEK-293 cells expressing the $hA_{2A}AR$.

in two types of functional assays in stably transfected CHO cells. We did not assay the functional effects at all the ARs; the G_i-coupled A_1AR is only representative of the full biological spectrum of the xanthines, and the behavior of the conjugate could be different at each of the AR subtypes. It was found that **14** at 100 nM right-shifted the concentration−response curve to the potent A_1AR agonist N^6-cyclopentyladenosine (CPA) in the cyclic AMP functional assay (inhibitory) in a parallel manner (Figure 4A). The EC_{50} values of CPA in the absence and presence of compound **14** at 100 nM were 1.5 ± 0.3 and 45 ± 17.2 nM, respectively. The activation of the A_1AR is also reported to stimulate mobilization of intracellular Ca^{2+} in various cells, which is likely dependent on $G\beta\gamma$ subunits.[30] CPA stimulated Ca^{2+} mobilization with an EC_{50} of 57.5 ± 16.8 nM (Figure 4B), and compound **14** at a concentration (10 nM) lower than its K_i value both right-shifted the CPA curve and suppressed the maximal effect, suggesting qualitative pharmacological differences between the conjugates and monomers. In contrast, the monomer XAC **3** at 10 nM or 100 nM (Figure 4C) inhibited CPA-induced calcium mobilization in A_1AR-expressing CHO cells in a competitive fashion. In the presence of 100 nM XAC, CPA displayed an EC_{50} of 346 ± 58 nM, corresponding to a 6-fold reduced potency.

A representative conjugate **14** was examined as an antagonist in a functional adenylate cyclase assay at the G_s-coupled $hA_{2B}AR$ expressed in CHO cells.[19] The multivalent xanthine at a concentration of 10 nM produced an 18-fold right-shift of the NECA response curve (Figure 5).

DISCUSSION

In this study, we used the Cu(I)-catalyzed alkyne−azide click reaction as a chemically and biologically effective means of linking a functionalized congener of a potent AR antagonist to PAMAM dendrimers. Click chemistry was previously used to link small molecular AR agonists to dendrimeric structures,[30] but this is the first systematic probing of PAMAM dendrimer conjugates of small-molecular AR antagonists. As with the agonist conjugates, high affinity of the GLiDe conjugates was achieved. The efficiency of the click reaction readily allowed a high degree of substitution in the dendrimer derivatives that could be varied by the proportion of PEG-alkyne or XAC-alkyne to dendrimer molecules that was added to the reaction.

The effectiveness of PEGylation of polymeric drug conjugtes to enhance polymer architecture, self-assembly, and bioavailability has been demonstrated.[31] In the present conjugates of a hydrophobic xanthine pharmacophore, water-solubility was increased, and the characteristic aggregation of PAMAM dendrimers was reduced by the presence of PEG groups. We compared different degrees of loading of the GPCR ligand and of PEG groups to the dendrimeric carrier. The ability to bind the ARs was not prevented by attached PEG groups (each approximately 43 oxoethylene units in length), similar to previous findings with AR agonist GLiDe conjugates.[32]

More highly XAC-substituted dendrimer derivatives prepared by click chemistry were particularly potent in binding to the ARs, with some selectivity for the $hA_{2A}AR$ subtype in comparison to that for hA_1 and hA_3ARs. There was also indication of high potency antagonist activity at the hA_{2B} for a representative derivative **14**. Nearly nanomolar affinities in binding to three AR subtypes were attained in the most highly XAC-substituted conjugates, with affinity enhancement for the conjugates versus monomer **4** being most pronounced for the A_3AR. The phenomenon of progressively increased affinity upon greater xanthine substitution was evident in both series of high and low PEG content. However, the function of the gain in AR affinity with increasing xanthine content did vary somewhat with different degrees of PEG substitution. The conjugates with an average of 22 PEG units, corresponding to a total of 44,000 D added to the molecular weight of the PAMAM, were initially weaker in binding to ARs than the 8 PEG series but gained more rapidly with increasing xanthine substitution. The molecular weights of the highly substituted conjugates **14** and **18** were ~78 and ~53 kD, respectively. Thus, the PEG content of these two conjugates amounted to approximately 56% and 30%, respectively, of the total mass.

Substitution with additional prosthetic groups of varied structure attached either by click or amide-forming reactions did not appreciably alter the binding affinity. For example, two sterically bulky NIR dyes with absorption in the range of 800 and 700 nm that are used in imaging in vivo[33] were incorporated in conjugates with retention of high receptor binding affinity. For example, conjugate **25** is identical in A_3AR affinity to its precursor and contains an average of 4 equivalents of IR dye 800CW, which is excited at 785 nm and fluorescence can be measured at 830 nm,

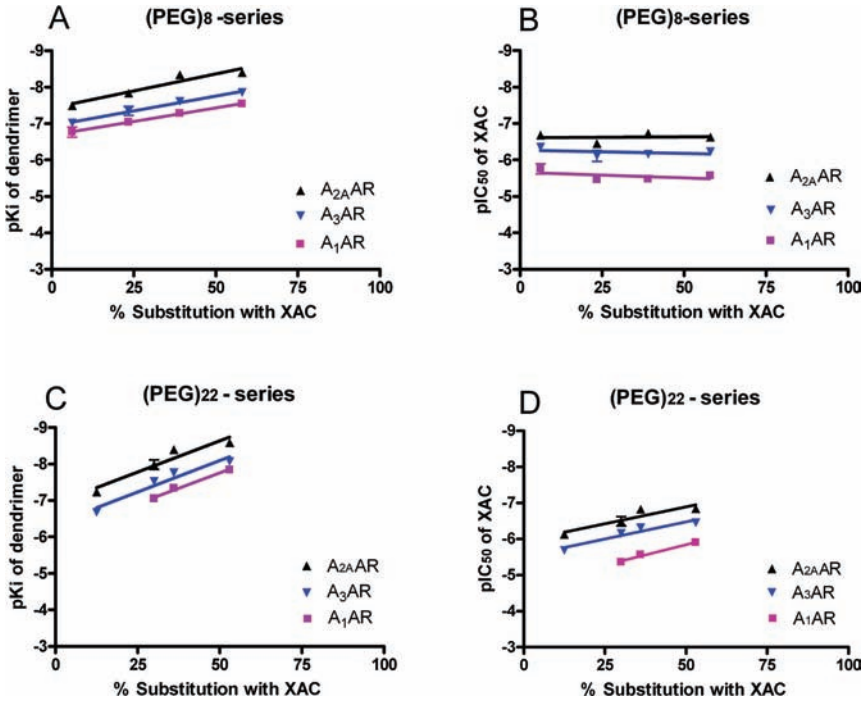

Figure 3. Inhibition of radioligand binding by dendrimer nucleoside conjugates in membranes of CHO cells expressing the hA_1 and A_3 ARs and HEK-293 cells expressing the $hA_{2A}AR$ showing dependence on the degree of substitution with the AR antagonist pharmacophore (XAC). Two methods of calculating the data were used on the basis of the definition of antagonist concentration: according to the concentration of the dendrimer (A,C) or according to the concentration of the pendant xanthine moieties (B,D). The conjugates were generally slightly selective for the $hA_{2A}AR$ in comparison to the hA_1 and hA_3ARs.

which is suitable for whole body imaging in small animals. Such GLiDe conjugates might eventually be useful for in vivo diagnostic imaging of tissue overexpressing ARs, such as occurs in disease states.[34] Thus, the ability to substitute the dendrimer with chemically diverse prosthetic groups in this series of AR conjugates allows for considerable structural breadth for probing and possibly targeting of the conjugates to the ARs or to cells having specific markers on the surface.

The advantages of nanocarriers for small molecular weight drugs include enhanced pharmacokinetic and pharmacodynamic properties. Our approach derivatizes a small molecular GPCR ligand for coupling to a carrier but allows it to remain active while covalently attached.[1,15] Internalization is not needed or desired because the binding sites of the receptors are accessible only from the extracellular medium. Molecular modeling indicated that flexible PAMAM dendrimers are able to spread over the cell surface, and purine conjugates of G3 dendrimers and higher generations can readily adopt a conformation that can bridge multiple GPCR binding sites.[8] In the theoretical model of a dendrimer conjugate of an $A_{2A}AR$ agonist bridging adjacent binding sites of an $A_{2A}AR$ homodimer, the distance between the two sites was ~35 Å, which was easily accommodated by two intermediate-spaced arms of the G3 dendrimer in a nonextended conformation. This roughly spherical G3 dendrimer conjugate had a diameter of ~67 Å, and the xanthine moieties of the present G4 conjugates in a non-extended conformation might be expected to achieve an estimated maximum separation of ~80 Å. This distance would be increased by stretching of the dendrimer over a surface.[35]

GPCRs tend not to be evenly or randomly distributed over the surface of a given cell; we demonstrated this for the hA_3AR expressed heterologously in CHO cells.[2] In general, GPCRs may exist as complexes with other receptors and associated proteins. The receptors to which a given GPCR pairs or forms a higher-order aggregate can dramatically affect its pharmacology, and the binding of an agonist to both protomers does not have equivalent pharmacological effects.[36] Thus, a multivalent GPCR ligand might display unanticipated, complex effects.[5] There is a lack of GPCR ligands that are designed specifically to interact with dimeric and oligomeric receptors. We do not have effective ligand tools for separating the effects of one receptor dimeric combination from another. The approach of mixing ligands for two different receptors[3,37,41] promises to be a means of achieving selectivity for receptors in a given tissue, on the basis of association or aggregation of GPCRs, in comparison to another tissue in which the same receptor may be alternatively paired. At this early stage, we do not know the topological requirements for selectively targeting these combinations of receptors because we are just beginning to detect their existence. Nevertheless, providing tools for studying these receptor aggregates is one of the objectives of this study. The multivalent binding to other types of cell surface receptors has been explored through sytematic structural modification of the carrier polymer.[42]

There is evidence here for multivalent binding of the same conjugate to more than one AR site. The fact that the AR affinity rose substantially with increased xanthine content, even when calculating IC_{50} values according to the concentration of the pharmacophore rather than the dendrimer as shown in Figure 3D, suggests that the same GLiDe conjugate molecule may bind to multiple AR binding sites. The interaction of the multivalent GLiDe conjugates can now be studied in cells expressing varying levels of a given AR or with other receptors coexpressed.

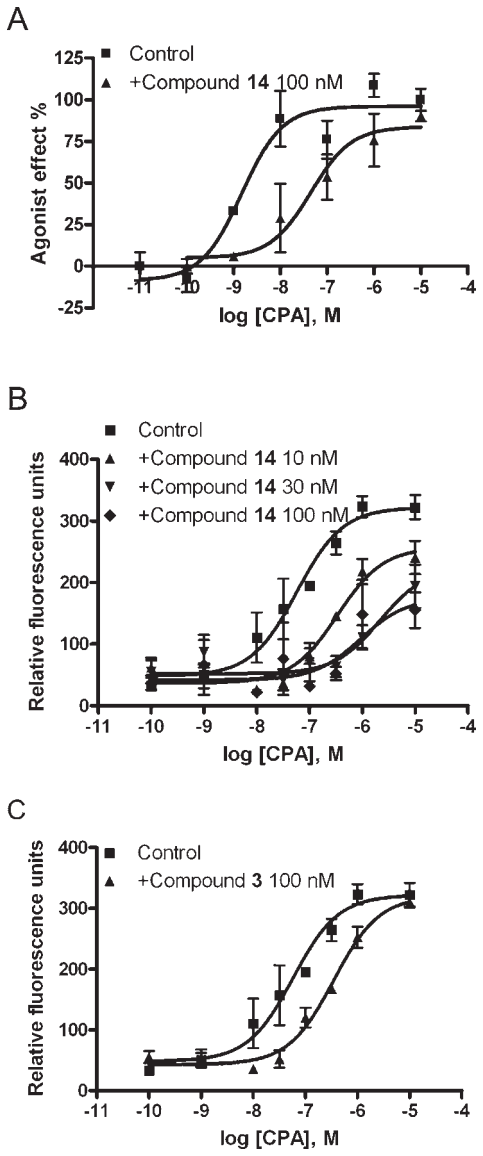

Figure 4. Antagonist activity of compound **14** in the inhibition of forskolin-stimulated cyclic AMP accumulation induced by agonist CPA (A) and the inhibition by **14** of CPA-induced calcium mobilization (B) in CHO cells stably expressing the hA_1AR. Part C shows the comparable inhibition by XAC **3** of CPA-induced calcium mobilization in hA_1AR-expressing CHO cells. Each curve is representative of three determinations. The EC_{50} values are listed in the text.

In previous studies, we have noted that the pharmacological profile of GLiDe conjugates can differ from that of the monomeric ligands both quantitatively and qualitatively.[5,11] For example, the dendrimer conjugates of AR agonists have displayed a shift in the AR subtype selectivity or in the correspondence between the binding and functional potencies.[2,11] Here, we have detected a qualitative difference in the A_1AR antagonistic response between a potent, multivalent xanthine conjugate and its corresponding monomer. Conjugate **14** acted as a competitive antagonist of the $G_{i\alpha}$-dependent effect of inhibition of adenylate cyclase, but at comparable concentrations acted as a noncompetitive inhibitor of calcium mobilization, which is likely independent of $G_{i\alpha}$. The functional effects at other AR subtypes were not determined here and will be the subject of further studies.

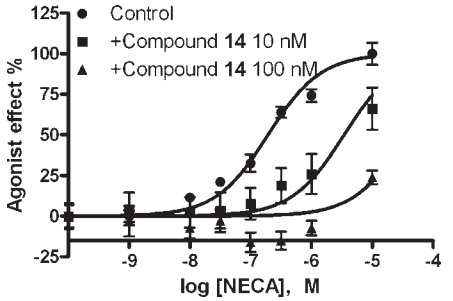

Figure 5. Antagonist activity of compound **14** in the stimulation of cyclic AMP accumulation induced by agonist NECA in CHO cells stably expressing the $hA_{2B}AR$. Each curve is representative of three determinations. The EC_{50} values for NECA in the absence and presence of 10 nM **14** are 194 nM and 3.46 μM, respectively.

In conclusion, we have synthesized and characterized pharmacologically a series of multivalent dendrimeric derivatives of a potent strategically functionalized AR antagonist. GLiDe conjugates provide different quantitative and qualitative pharmacological properties than do monomers. Prosthetic groups designed for therapeutic targeting or reporter groups for diagnostic purposes might be introduced. Various therapeutic applications[12] may be proposed for multivalent conjugates of AR antagonists. In vivo studies will be needed to fully characterize these potent ligands biologically and determine their advantage over monomeric drugs.

S *Supporting Information*

ABSTRACT:

A new bifunctional ligand 3p-*C*-DEPA was synthesized and evaluated for use in targeted α-radioimmunotherapy. 3p-*C*-DEPA was efficiently prepared via regiospecific ring opening of an aziridinium ion and conjugated with trastuzumab. The 3p-*C*-DEPA-trastuzumab conjugate was extremely rapid in binding $^{205/6}$Bi, and the corresponding $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab complex was stable in human serum. Biodistribution studies were performed to evaluate *in vivo* stability and tumor targeting of $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab conjugate in tumor bearing athymic mice. $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab conjugate displayed excellent *in vivo* stability and targeting as evidenced by low organ uptake and high tumor uptake. The results of the *in vitro* and *in vivo* studies indicate that 3p-*C*-DEPA is a promising chelator for radioimmunotherapy of ^{212}Bi and ^{213}Bi.

INTRODUCTION

The α-emitting radioisotopes, ^{212}Bi ($t_{1/2}$ = 60.6 m) and ^{213}Bi ($t_{1/2}$ = 45.6 m), have proven to be effective for radioimmunotherapy (RIT) of cancers.[1] The α-emitters with high α-energy (5−8 MeV) and a short emission path length (50−80 μm) can be closely deposited in the target tumor cells resulting in minimum damage to normal tissues.[2] The radionuclides, ^{212}Bi and ^{213}Bi, with very short half-lives decay ultimately to stable bismuth nuclides and are considered to be suitable for convenient outpatient RIT.[3] The therapeutic efficacy of ^{212}Bi and ^{213}Bi has been demonstrated in numerous preclinical and clinical trials involving cancer patients with leukemia, melanoma, and glioblastoma.[4−7]

Three optimal components, a bifunctional ligand, an antibody, and a radioisotope, are required for a successful RIT. An effective bifunctional ligand that can rapidly form a stable complex with the radionuclide should be employed to minimize toxic side effects related to biological deposition of the radionuclide if it becomes dissociated from the radiolabeled ligand−antibody conjugate during RIT.[8] Research efforts have been directed toward improving chelation chemistry for RIT. *C*-DOTA and *C*-DTPA (Figure 1) analogues are two bifunctional ligands that are frequently explored for RIT applications.[3] *C*-DOTA forms a kinetically inert and stable complex with Bi(III); however, the slow complex formation kinetics render this chelator unacceptable for use in RIT when employing short-lived radionuclides such as ^{213}Bi and ^{212}Bi.[9,10] The acyclic bifunctional ligand, *C*-DTPA, displayed rapid and high-yield radiolabeling with Bi(III) radioisotopes.[3] However, *C*-DTPA produced a less stable Bi(III)-*C*-DTPA complex than that of Bi(III)-*C*-DOTA,[3,11,12]

We recently reported the synthesis and evaluation of DEPA (Figure 1, 7-[2-(bis-carboxymethyl-amino)-ethyl]-4,10-bis-carboxymethyl-1,4,7,10-tetraaza-cyclododec-1-yl-acetic acid).[10] DEPA is a decadentate ligand in a hybridized form of the macrocyclic DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracarboxylic acid) and the acyclic DTPA (diethylenetriamine pentaacetic acid). This novel bimodal ligand DEPA was hypothesized to rapidly form a stable complex with a metal based on cooperative coordination of the macrocyclic and acyclic binding moieties. DEPA radiolabeled with $^{205/6}$Bi ($t_{1/2}$ = 15.3 d for ^{205}Bi; $t_{1/2}$ = 6.24 for ^{206}Bi), a γ-emitting surrogate of ^{212}Bi and ^{213}Bi was indeed found to be stable in human serum without any loss of the radioactivity for two weeks and displayed excellent *in vivo* stability in mice.[10]

With the promising complexation kinetics and stability data for DEPA, we sought preparation of an effective bifunctional

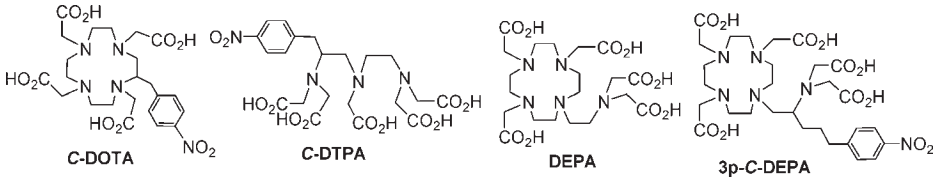

Figure 1. Ligands in clinical and preclinical use for RIT.

version of DEPA for RIT. In this paper, we report the synthesis and evaluation of a bifunctional DEPA analogue, 3p-*C*-DEPA (Figure 1, 2-[(carboxymethyl)][5-(4-nitrophenyl-1-[4,7,10-tris-(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl]pentan-2-yl)-amino]acetic acid), which contains the parent DEPA backbone and the isothiocyanate (NCS) group for conjugation to an antibody or a peptide. 3p-*C*-DEPA was synthesized, characterized, and conjugated to trastuzumab. Trastuzumab is a HER2 (human epidermal growth factor receptor 2) targeting antibody which has been reported to selectively target the HER2 protein overproduced in various tumors, including 90% of colorectal carcinomas.[13,14] The corresponding 3p-*C*-DEPA-trastuzumab conjugate was evaluated for its radiolabeling reaction kinetics with $^{205/6}$Bi. *In vitro* analysis of the 3p-*C*-DEPA-trastuzumab conjugate radiolabeled with $^{205/6}$Bi included assessment of its stability in human serum and retention of reactivity with HER2 using a radioimmunoassay. Finally, the *in vivo* biodistribution and tumor uptake of the $^{205/6}$Bi-labeled 3p-*C*-DEPA-trastuzumab was assessed in mice bearing s.c. tumor (LS-174T) xenografts. For comparison and as a reference standard, the *C*-DOTA-trastuzumab conjugate was evaluated in the same *in vitro* and *in vivo* studies.

EXPERIMENTAL PROCEDURE

Instruments and Methods. ^{1}H and ^{13}C NMR spectra were obtained using a Bruker 300 instrument and chemical shifts are reported in ppm on the δ scale relative to TMS or solvent. Electrospray iodization (ESI) high-resolution mass spectra (HRMS) were obtained on JEOL double sector JMS-AX505HA mass spectrometer (University of Notre Dame, IN). Analytical HPLC was performed on an Agilent 1200 instrument (Agilent, Santa Clara, CA) equipped with a diode array detector (λ = 254 and 280 nm), a thermostat set at 35 °C, and a Zorbax Eclipse XDB-C18 column (4.6 × 150 mm, 80 Å, Agilent, Santa Clara, CA). The mobile phase of a binary gradient (0−100% B/40 min; solvent A, 0.05 M AcOH/Et_3N, pH 6.0; solvent B, CH_3OH for method 1) at a flow rate of 1 mL/min was used for analytical HPLC. Semiprep HPLC was performed on an Agilent 1200 equipped with a diode array detector (λ = 254 and 280 nm), a thermostat set at 35 °C, and a Zorbax Eclipse XDB-C18 column (9.4 × 250 mm, 80 Å). The mobile phase of a binary gradient (0−100% B/160 min; solvent A = 0.05 M AcOH/Et_3N, pH 6.0; solvent B = MeOH for method 2) at a flow rate of 2 mL/min was used for semiprep HPLC. Size-exclusion HPLC (SE-HPLC) chromatograms were obtained on Agilent 1200 equipped with a diode array detector and an in-line IN/US γ-Ram model 2 radiodetector (Tampa, FL), fitted with Bio-Silect SEC 250−5 column (Biorad, Hercules, CA) or a TSKgel G3000PW column (Tosoh Biosep, Montgomeryville, PA).

Reagents. All reagents were purchased from Sigma-Aldrich (St. Louis, MO) and used as received unless otherwise noted. Trastuzumab (Herceptin; Genentech, South San Francisco, California) was obtained through the Veterinary Resources Program (National Institutes of Health, Bethesda, MD). ^{205,6}Bi was produced using a CS30 cyclotron (PET Dept, Clinical Center, NIH) and purified as described previously.[15] *C*-DOTA was purchased from Macrocyclics (Dallas, TX).

***tert*-Butyl-2,2′,2″-(10-(2-(bis(2-*tert*-butoxy-2-oxoethyl)-amino)-5-(4-nitrophenyl)-pentyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetate (4).** To a solution of **1**[16] (547.7 mg, 1.06 mmol) and DIPEA (410.9 mg, 3.18 mmol) in CH_3CN (10 mL) was added trisubstituted cyclen **3** (546.6 mg, 1.06 mmol). The resulting mixture was stirred for 4 weeks at room temperature while monitoring the reaction progress using TLC. The reaction mixture containing the starting materials and the product **4** was concentrated to dryness. The residue was purified via column chromatography on silica gel (220−440 mesh) eluted with 3% CH_3OH in CH_2Cl_2. The fractions containing the product **4** along with the starting material **3** as impurity were combined. After evaporating the solvent, ether (20 mL) was added to the residue, and the starting material **3** formed a slurry which was removed by filtration. The filtrate containing the product **4** was washed with DI water (2 × 10 mL). The ether layer was dried over $MgSO_4$, filtered, and concentrated *in vacuo* to provide pure **4** (610 mg, 61%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.37−1.45 (m, 45 H), 1.60−1.78 (m, 2 H), 1.81−1.95 (m, 1 H), 2.02−2.19 (m, 1 H), 2.39−2.50 (m, 3H), 2.56−2.83 (m, 18 H), 3.21 (s, 4H), 3.26 (s, 2 H), 3.36 (dd, J = 16.9, 21.9 Hz, 4 H), 7.36 (d, J = 8.6 Hz, 2 H), 8.09 (d, J = 8.7 Hz, 2 H); ^{13}C NMR ($CDCl_3$, 300 MHz) δ 27.89 (t), 28.11 (q), 28.22 (q), 30.98 (t), 35.91 (t), 52.04 (t), 52.11 (t), 52.20 (t), 53.09 (t), 53.19 (t), 56.34 (t), 56.44 (t), 58.38 (t), 60.08 (d), 80.41 (s), 80.57 (s), 123.43 (d), 129.30 (d), 146.18 (s), 151.17 (s), 170.98 (s), 171.10 (s), 171.41 (s). Tri-*tert*-butyl-10-(2-(*tert*-butoxycarbonyl)-5-(4-nitrophenyl)-pentyl)-1,4,7,10-tetraazacyclo-dodecane-1,4,7-tricarboxylate (7). To a mixture of **5** (1.24 g, 3.85 mmol) and **6** (1.82 g, 3.85 mmol) in 1,2-dichloroethane (30 mL) was added portionwise sodium triacetoxyborohydride (1.14 g, 5.4 mmol). The mixture was stirred at room temperature for 14 h. The reaction mixture was quenched with saturated $NaHCO_3$ (40 mL), and the product was extracted while washing with CH_2Cl_2. The combined organic layers were dried over $MgSO_4$, filtered, and concentrated *in vacuo*. The residue was purified by silica gel (60−230 mesh) column chromatography eluted with 25% EtOAc in hexanes to provide **7** (1.90 g, 63%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.03−1.51 (m, 36 H), 1.51−2.01 (m, 4 H), 2.50−3.99 (m, 21 H), 7.30 (d, J = 8.5 Hz, 2 H), 8.08 (d, J = 8.4 Hz, 2H); ^{13}C NMR ($CDCl_3$, 300 MHz) 24.69 (t), 27.16 (t), 28.57 (q), 28.69 (q), 35.13 (t), 35.68, (t), 36.64 (t), 47.49 (t), 48.46 (d), 50.54 (t), 51.20 (t), 58.18 (t), 58.64 (t), 79.18 (s), 79.28 (s), 79.57 (s), 123.56 (d), 129.19 (d), 146.27 (s), 150.39 (s), 155.14 (s), 155.73 (s),

155.95 (s), 156.72 (s). HRMS (Positive ion ESI) Calcd for $C_{39}H_{67}N_6O_{10}$ $[M + H]^+$ m/z 779.4913, Found: $[M + H]^+$ m/z 779.4890.

5-(4-Nitrophenyl)-1-(1,4,7,10-tetraazacyclododecan-1-yl)-pentan-2-amine (8). Compound **7** (1.84 g, 2.36 mmol) at 0−5 °C was treated dropwise with 4 M HCl (g) in 1,4-dioxane (18 mL) over 20 min. The resulting mixture was warmed to room temperature and stirred for 22 h. Ether (100 mL) was added and stirred for 10 min. The resulting mixture was capped and placed in the freezer for 1 h. The slurry formed was filtered, washed with ether, and quickly dissolved in deionized (DI) water. The aqueous solution was concentrated *in vacuo* to provide **8** as an acidic salt (1.17 g, 89%). ^{1}H NMR (D_2O, 300 MHz) δ 1.50−1.71 (m, 4 H), 2.50−2.80 (m, 6 H), 2.82−3.40 (m, 15 H), 7.30 (d, J = 8.7 Hz, 2 H), 8.00 (d, J = 8.7 Hz, 2 H); ^{13}C NMR (D_2O, 300 MHz) δ 25.65 (t), 30.63 (t), 34.46 (t), 41.30 (t), 42.13 (t), 44.21 (t), 48.56 (t), 48.57 (d), 56.81 (t), 123.66 (d), 129.40 (d), 145.90 (s), 150.21 (s). HRMS (Positive ion ESI) Calcd for $C_{19}H_{35}N_6O_2$ $[M + H]^+$ m/z 379.2816. Found: $[M + H]^+$ m/z 379.2804.

A solution of the acidic salt **8** (670 mg, 1.7 mmol) in DI water (5 mL) was neutralized using 0.5 M NaOH. The aqueous layer was then extracted with $CHCl_3$ (2 × 25 mL). The aqueous layer was further adjusted to pH 10 and re-extracted with $CHCl_3$ (2 × 25 mL). The organic layers extracted from both neutral (pH 7) and basic (pH 10) solutions were combined, dried over $MgSO_4$, filtered, and concentrated *in vacuo* to provide free amine **8** (452 mg, 100%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ 1.20−1.49 (m, 2 H), 1.60−1.89 (m, 2 H), 2.15−3.00 (m, 21 H), 7.33 (d, J = 8.6 Hz, 2 H), 8.14 (d, J = 8.6 Hz, 2 H); ^{13}C NMR ($CDCl_3$, 300 MHz) δ 27.26 (t), 35.00 (t), 35.64 (t), 45.16 (t), 46.01 (t), 46.95 (t), 48.71 (d), 52.10 (t), 62.56 (t), 123.27 (d), 129.00 (d), 145.94 (s), 150.24 (s).

Synthesis of 4 from Compound 8. To a solution of **8** (170.3 mg, 0.45 mmol) in CH_3CN (5 mL) was added *tert*-butyl bromoacetate (438.9 mg, 2.25 mmol) and K_2CO_3 (311.0 mg, 2.25 mmol). The resulting mixture was heated at 65 °C and stirred for 13 h while monitoring the reaction progress by analytical HPLC. The reaction mixture was cooled to room temperature, and the solvent was evaporated. The residue was purified by semi-prep HPLC (method 2, 138−143 min) to afford **4** (37 mg, 9%).

2-[(Carboxymethyl)][5-(4-nitrophenyl-1-[4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclo-dodecan-1-yl]pentan-2-yl)-amino]acetic Acid (9). Compound **4** (77.0 mg, 0.08 mmol) at 0−5 °C was treated dropwise with 4 M HCl (g) in 1,4-dioxane (15 mL) over 20 min. The resulting mixture was allowed to warm to room temperature for 22 h. Ether (∼20 mL) was added and continuously stirred for 10 min. The resulting mixture was capped and placed in the freezer for 1 h. The solid formed was filtered, washed with ether, and quickly dissolved in DI water. Evaporation of the aqueous solution gave **9** (68.0 mg, 97%) as an off-white solid. ^{1}H NMR (D_2O, 300 MHz) δ 1.26−1.40 (m, 1H), 1.48−1.70 (m, 3H), 2.52−2.78 (m, 2H), 2.90−3.70 (m, 27H), 3.75−3.98 (m, 2H), 7.35 (d, J = 8.3 Hz, 2H), 8.06 (d, J = 8.2 Hz, 2H); ^{13}C NMR (D_2O, 300 MHz) δ 27.08 (t), 34.64 (t), 48.45 (t), 48.82 (t), 50.22 (t), 51.09 (t), 52.40 (t), 53.58 (t), 54.28 (t), 55.46 (t), 59.43 (d), 123.55 (d), 129.40 (d), 145.71 (s), 150.54 (s), 169.54 (s), 172.97 (s), 173.93 (s); HRMS (Positive ion FAB) Calcd for $C_{29}H_{45}N_6O_{12}$ $[M + H]^+$ m/z 669.3095. 2,2′,2″-(10-(5-(4-Aminophenyl)-2-(bis(carboxymethyl)-amino)pentyl)-1,4,7,10-tetraaza-cyclododecane-1,4,7-triyl)-triacetic acid (10). To a solution of **9** (46.0 mg, 68.8 μmol) in DI H_2O (12 mL) was added dry 10% Pd/C (14.0 mg) under argon. The reaction mixture was subject to hydrogenation in a hydrogenation apparatus set at the constant pressure (15 psi) of H_2 (g) for 19 h. The resulting mixture was filtered over a Celite bed and washed thoroughly with DI H_2O. The filtrate was concentrated *in vacuo* to provide a light yellow solid **10** (44 mg, 100%). ^{1}H NMR (D_2O, 300 MHz) δ 1.22−1.38 (m, 1H), 1.43−1.68 (m, 3H), 2.45−2.63 (m, 2H), 2.81−3.70 (m, 27H), 3.80−3.98 (m, 2H), 7.17 (d, J = 8.5 Hz, 2H), 7.24 (d, J = 8.5 Hz, 2H); ^{13}C NMR (D_2O, 300 MHz) δ 27.04 (t), 27.46 (t), 34.18 (t), 48.50 (t), 48.98 (t), 50.28 (t), 51.12 (t), 52.50 (t), 53.69 (t), 54.50 (t), 55.49 (t), 59.40 (d), 123.01 (d), 127.55 (s), 130.10 (d), 143.28 (s), 169.50 (s), 173.13 (s), 174.22 (s); HRMS (positive ion ESI) Calcd for $C_{29}H_{47}N_6O_{10}$ $[M + H]^+$ m/z 639.3348. 2,2′,2″-(10-(2-(Bis(carboxymethyl)amino)-5-(4-isothiocyanatophenyl)pentyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triyl)triacetic Acid (11). To a solution of **10** (7.0 mg, 8.2 μmol) in water (0.1 mL) was added $CSCl_2$ (7.0 μL, 7.0 μmol) in $CHCl_3$. The resulting mixture was stirred at room temperature for 2 h. The aqueous layer was isolated and concentrated *in vacuo* to give pure 3p-*C*-DEPA-NCS **11** as a solid (8.0 mg, 100%). ^{1}H NMR (D_2O, 300 MHz) δ 1.23−1.72 (m, 4H), 2.40−2.58 (m, 2H), 2.80−3.98 (m, 29H), 7.13 (s, 4H). HRMS (Positive ion FAB) Calcd for $C_{30}H_{43}N_6O_{12}S$ $[M + H]^+$ m/z 679.2761. Found: $[M + H]^+$ m/z 679.2747.

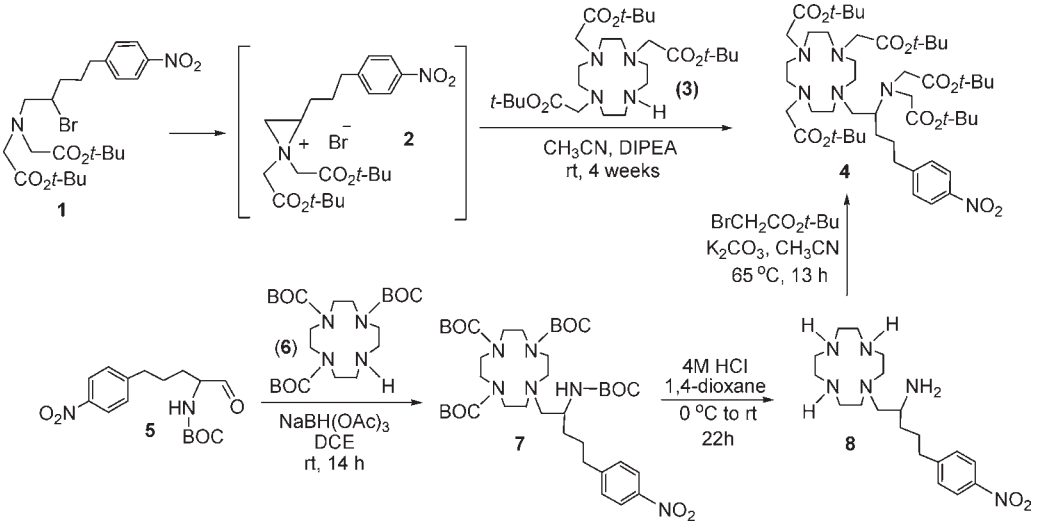
Conjugation of 3p-*C*-DEPA-NCS to Trastuzumab. All absorbance measurements were obtained on an Agilent 8453 diode array spectrophotometer equipped with a 8-cell transport system (designed for 1 cm cells). Metal-free stock solutions of all buffers were prepared using Chelex-100 resin (200−400 mesh, Bio-Rad Lab, Hercules, CA, Cat no 142−2842). Chelex resin (2.5 g) was added into the buffer solution (250 mL) and the mixture was shaken overnight in a shaker and filtered through a Corning filter system (Cat no 430513, pore size 0.2 μm). Disposable PD-10 Sephadex G-25 M columns (GE Healthcare, #17−0851−01) were rinsed with 25 mL of the appropriate buffer prior to addition of antibody or its ligand conjugates. Amicon centricon C-50 (50 000 MWCO) centrifugal filter devices (Millipore, Cat no UFC805008) were used for purification of trastuzumab conjugate (Bedford, MA). The initial concentration of trastuzumab was determined by the UV/vis spectroscopic method. Phosphate buffered saline (PBS, 1×, 11.9 mM Phosphates, 137 mM NaCl, and 2.7 mM KCl, pH 7.4) was purchased from Fisher and used as received. Conjugation buffer (50 mM HEPES, 150 mM NaCl, pH 8.6) were prepared as 1× solutions, chelexed, and filtered through the Corning filter. Trastuzumab (6.67 mg) was diluted to 1.6 mL using conjugation buffer (1:0.6), and the resulting solution was added to a PD-10 column. Conjugation buffer (10 mL) was added to the PD-10 column to exchange the buffer solution of the antibody and collected in a sterile test tube and checked for the presence of trastuzumab via analysis of the UV/vis spectrum at 280 nm. To a sterile test tube containing the recovered trastuzumab (6.14 mg) was added a 10-fold excess of 3p-*C*-DEPA-NCS (39.6 μL, 10 mM). The resulting solution was gently agitated for 16 h at room temperature and placed on a Centricon C-50 membrane and spun down to reduce volume. PBS (3 × 2 mL) was added to the remaining solution of the 3p-*C*-DEPA-trastuzumab conjugate, followed by centrifugation in order to remove unreacted ligand. The volume of purified conjugate antibody was brought to 1.0 mL with PBS. To measure [trastuzumab] in the 3p-*C*-DEPA-trastuzumab conjugate, a

UV/vis spectrometer was zeroed against a cuvette filled with 2.0 mL of PBS with a window open from 190 to 1100 nm. A 50 μL portion of PBS was removed and discarded, 50 μL of the 3p-*C*-DEPA-trastuzumab conjugate solution was added, and absorbance at 280 nm was noted. Beer's Law was used to calculate [trastuzumab] in the conjugate with molar absorptivity of 1.42. After centrifugation, 2.98 mg (2.02×10^{-5} M, 49.0%) of the trastuzumab remained.

Spectroscopic Determination of Ligand to Protein (L/P) Ratio. A stock solution of the Cu(II)-AAIII reagent was prepared in 0.15 M NH_4OAc, pH 7.0 by adding an aliquot of copper atomic absorption solution (1.55×10^{-2} M) into a 10 μM solution of AAIII to afford a 5 μM solution of Cu(II).[17] This solution was stored in the dark to avoid degradation over time. A UV/vis spectrometer was zeroed against eight well-dried blank cuvettes with a window open from 190 to 1100 nm. A cuvette was filled with AAIII solution (2 mL), and the other seven cuvettes with the Cu(II)-AAIII solution (2 mL). Cu(II)-AAIII solution (50 μL) in the seven cuvettes was removed and discarded. Milli-Q water (50 μL) was added to the second cuvette, and one to five 10 μL additions of 3p-*C*-DEPA (0.1 mM) were added to the five cuvettes to give a series of five different concentrations (2 mL total volume). The solutions in the third to the seventh cuvette were diluted to 2.0 mL by adding an aliquot of Milli-Q water. 3p-*C*-DEPA-trastuzumab conjugate (50 μL) was added to the eighth cuvette containing Cu(II)-AAIII reagent (1950 μL). After addition of 3p-*C*-DEPA-trastuzumab conjugate to the Cu(II)-AAIII solution, the resulting solution was equilibrated for 10 min. The absorbance of the resulting solution at 610 nm was monitored every 30 s over 6 min. The average of the absorbance of each solution was calculated, and the absorbance data from the Cu(II)-AAIII solutions containing six different concentrations were used to construct a calibration plot of A_{610} versus [3p-*C*-DEPA] by the equation, $Y = 0.0663 - (1.5284 \times 10^4)$[3p-*C*-DEPA] ($R^2 = 0.9969$), wherein $Y = A_{610\,nm}$. The concentration of 3p-*C*-DEPA in the 3p-*C*-DEPA-trastuzumab conjugate was calculated (3.98×10^{-5} M). The L/P ratio of the 3p-*C*-DEPA-trastuzumab conjugate ($[3.98 \times 10^{-5}\ M]/[2.02 \times 10^{-5}\ M]$) was measured to be 1.97.



Radiolabeling of 3p-*C*-DEPA-trastuzumab or *C*-DOTA-Trastuzumab Conjugates with $^{205/6}$Bi. All HCl solutions were prepared from ultrapure HCl (Fisher, Cat no A466−500). For metal-free radiolabeling, plasticware including pipet tips, tubes, and caps was soaked in 0.1 M HCl overnight, washed thoroughly with Milli-Q (18.2 MΩ) water, and air-dried overnight. Ultrapure NH_4OAc (Aldrich, #372331) was purchased from Aldrich and used to prepare all NH_4OAc buffer solutions (0.1 M, pH 7). The buffer solutions were treated with Chelex-100 resin (Biorad, #142−2842, 1 g/100 mL buffer solution), shaken overnight at room temperature, and filtered through 0.22 μm filter (Corning, #430320) prior to use. To a buffer solution (120 μL, pH 7) in a capped microcentrifuge tube (1.5 mL, Fisher Scientific #05−408−129) was sequentially added a solution of *C*-DOTA-trastuzumab (30 μg) in PBS (13.5 μL) and $^{205/6}$Bi (0.1 M HI, 60.5 μCi, 12.7 μL) or 3p-*C*-DEPA-trastuzumab (30 μg) in PBS (9.6 μL) and $^{205/6}$Bi (0.1 M HI, 60.5 μCi, 12.7 μL). The final volume of the resulting solution was 146.2 and 142.3 μL for *C*-DOTA-trastuzumab and 3p-*C*-DEPA-trastuzumab, respectively, and the pH of the resulting reaction mixture was 5.5 for both conjugates. The reaction mixture was agitated on the thermomixer (Eppendorf, #022670549) set at 1000 rpm at room temperature for 1 h. The labeling efficiency was determined by SE-HPLC (Biorad, Bio-Silect SEC 250−5 column, 7.8 × 30 cm, eluent, PBS; flow rate, 1 mL/min). A solution of radiolabeled mixture (10 μL for *C*-DOTA-trastuzumab and 7 μL for 3p-*C*-DEPA-trastuzumab) was withdrawn at the designated time points (1 min, 5 min, 10 min, 20 min, 30 min, and 60 min), and DTPA solution (10 mM, 1 or 1.4 μL) was added to the mixture, and the resulting mixture was left for at least 20 min. HPLC samples were prepared and evaluated by SE-HPLC. Peaks for bound and unbound radioisotope appeared around 8.3 and 11 min, respectively.

***In Vitro* Stability of $^{205/6}$Bi-3p-*C*-DEPA-Trastuzumab Conjugate.** $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab was prepared by reaction of 3p-*C*-DEPA-trastuzumab with $^{205/6}$Bi at either RT or 37 °C (5.0 M NH_4OAc, pH 5.5). The complex formed was purified from $^{205/6}$Bi by gel filtration chromatography using PD-10 column (Disposable PD-10 Sephadex G-25 M columns, GE Healthcare, Cat no 17−0851−01) eluted with PBS (pH 7.4, Fisher Scientific, Cat no BP2438−4). The fractions containing $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab (700 μL, 22 μCi) were combined and added into human serum (700 μL, Gemini Bioproducts, #100110) in a microcentrifuge tube (Fisher Scientific, #05−408−129). The stability of the purified $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab was evaluated for 4 days. The serum stability of the radiolabeled complexes was assessed by measuring the transfer of the radionuclide from each complex to serum proteins using SE-HPLC (TSKgel G3000PW column, 7.5 × 30 cm, eluent, PBS; flow rate, 1 mL/min). A solution of the radiolabeled complex in serum (20−80 μL) was withdrawn at the designated time point, treated with DTPA (5 mM, 1.0 μL), incubated at room temperature for 20 min, and then diluted with PBS (pH 7.4, 50−100 μL) prior to SE-HPLC.

Preparation of $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab and $^{205/6}$Bi-*C*-DOTA-trastuzumab for Immunoreactivity and *In Vivo* Studies. For use in the *in vitro* binding and *in vivo* biodistribution and tumor targeting studies, $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab and $^{205/6}$Bi-*C*-DOTA-trastuzumab with high specific activity were prepared. In this instance, two aliquots of $^{205/6}$Bi solution (100 μL in 0.1 M HI, 1.1 mCi each) were each neutralized to pH 5.5 with NH_4OAc solution (10 μL, 5 M, pH 7). An aliquot of each immunoconjugate containing 50 μg of protein in PBS was added to one or the other $^{205/6}$Bi solution. The mixtures were vortexed briefly and incubated at 37 °C. After 30 min, EDTA solution (5 μL, 0.1M) was added to each reaction, vortexed briefly, and further incubated for 5 min. The products were purified by gel filtration chromatography using disposable PD-10 columns. The labeling efficiencies were 85.8% and 67.3% for $^{205/6}$Bi-3p-*C*-DEPA-trastuzumab and $^{205/6}$Bi-*C*-DOTA-trastuzumab, respectively, as determined by the labeled products collected from the PD-10 columns. The purity of the labeled products as determined by SE-HPLC (TSKgel G3000PW column, PBS eluate at 0.5 mL/min) were >98% for each product. The specific activities were 16 mCi/mg and 13.6 mCi/mg for$^{205/6}$Bi-3p-*C*-DEPA-trastuzumab and $^{205/6}$Bi-*C*-DOTA-trastuzumab, respectively.

Radioimmunoassay. The immunoreactivity of the $^{205/6}$Bi-labeled trastuzumab conjugates was assessed in a radioimmunoassay using purified recombinant human Erb2/Fc chimera (rhErb2/Fc). Briefly, 50 ng aliquots of the rhErb2/Fc in PBS with Mg^{2+} and Ca^{2+} (50 μL) were added to each well of a 96-well plate and allowed to adsorb to the well at 4 °C. Following an overnight incubation, the solution was removed and 100 μL of 1% BSA in PBS (BSA/PBS) was added to each well and

Scheme 1. Synthesis of Precursor Molecule 4 to 3p-C-DEPA

incubated at room temperature for 30−60 min. Serial dilutions of $^{205/6}$Bi-trastuzumab conjugate (~300 000 to ~12 500 cpm in 50 μL of BSA/PBS) were added to the wells in duplicate, covered, and incubated at 37 °C for 4 h. The radiolabeled antibody was then removed and the wells were washed three times with PBS. The radioactivity was removed from the wells with a solution of 0.2 M NaOH with 1 mM EDTA (100 μL), adsorbing the solution to cotton filters, and transferring the filters to 12 × 75 mm polypropylene tubes. The radioactivity was measured in a γ-scintillation counter (WizardOne, Perkin-Elmer, Shelton, CT), and the percentage binding calculated for each dilution. The values presented are an average of the percent bound for the serial dilutions. The specificity of the radiolabeled trastuzumab was confirmed by incubating one set of wells with radiolabeled trastuzumab and 10 μg of unlabeled trastuzumab.

***In Vivo* Biodistribution and Tumor Targeting Studies.** *In vivo* studies were conducted using the human colon carcinoma cell line, LS-174T (kindly provided by Dr. J. Greiner, NCI). The LS-174T cell line was grown in Dulbecco's minimum essential medium (DMEM) supplemented with 10 mM glutamine along with 10% FetalPlex (Gemini Bio-Products, Woodland, CA) and 1 mM nonessential amino acids. Media and supplements were obtained from Lonza (Walkersville, MD). All *in vivo* studies were performed using 4−6 week old female athymic (nu/nu) mice (Charles River Laboratories, Wilmington, MA). All animal protocols were approved by the National Cancer Institute Animal Care and Use Committee. Mice were injected subcutaneously (s.c.) in the right rear leg with 2 × 10^6 LS-174T cells in media (200 μL) with 20% Matrigel (BD Biosciences, San Jose, CA). Mice were utilized in studies when the tumor xenografts maximal diameter measured 0.4−0.6 cm. Mice (n = 4 per time point) were injected intravenously (i.v.) with the $^{205/6}$Bi-labeled trastuzumab conjugates (~7.5 μCi on 0.6 μg) and sacrificed by exsanguination at 2, 6, and 24 h. The blood, tumor, and major organs were collected, wet-weighed, and counted in a γ-scintillation counter. The percent injected dose per gram (%ID/g) and standard deviation were calculated.

RESULTS AND DISCUSSION

The synthesis of the new bifunctional ligand 3p-C-DEPA is outlined in Scheme 1. An intramolecular substitution reaction of *N,N*-bisubstituted β-amino bromide **1** produced aziridinium ion **2** which was then reacted with trisubstituted cyclen **3** (1,4,7,10-tetraazacyclododecane). Regiospecific ring-opening of **2** by nucleophilic attack of bulky cyclen analogue **3**[10] occurred at the less hindered methylene carbon in **2** to provide **4** as the exclusive product (61%). The reaction was carried out at room temperature, although it proceeds extremely slowly at this mild condition (4 weeks). An intramolecular rearrangement product of **1** was obtained when the reaction was under reflux. The desired coupling product **4** was isolated via column chromatography and characterized by ^{1}H and ^{13}C NMR, analytical HPLC, and HRMS. To confirm the regiochemistry observed in the nucelophilic ring-opening of the aziridinium ion **2** at the methylene carbon, compound **4** was separately prepared via another synthetic route starting from **5** as shown in Scheme 1. Reductive amination of **5** with **6** using sodium triacetoxyborohydride provided **7** which was subsequently treated with HCl (g) in 1,4-dioxane to afford **8**. A base-promoted reaction of **8** with *tert*-butyl bromoacetate produced compound **4**, and comparison of the spectroscopic data of **4** that was separately produced via the two synthetic routes confirmed regiochemistry in the ring-opening of **2**. Synthesis of the bifunctional ligands 3p-*C*-DEPA (**9**) and 3p-*C*-DEPA-NCS (**11**) is shown in Scheme 2. The *tert*-butyl groups in **4** was removed by the reaction of **4** with 4 M HCl (g) in 1,4-dioxane to provide 3p-*C*-DEPA (**9**). The nitro group in **9** was transformed into the amino group by hydrogenolysis of **9** on Pd/C to provide **10** which was subsequently reacted with thiophosgene (g) in $CHCl_3$ to the desired bifunctional ligand 3p-*C*-DEPA-NCS (**11**) containing the isothiocyanate group for conjugation to an antibody.

3p-*C*-DEPA-NCS was conjugated to trastuzumab, and the concentration of trastuzumab in 3p-*C*-DEPA-trastuzumab conjugate was quantified by UV spectroscopic assay.[18] The Cu(II)-AAIII based UV−vis spectrophotometric assay was used for the determination of the number of 3p-*C*-DEPA ligand linked to trastuzumab (L/P ratio).[17] The ligand to protein (L/P) ratio for 3p-*C*-DEPA-trastuzumab conjugate was measured to be 1.97. For comparison, *C*-DOTA-NCS (Macrocyclics, TX) was conjugated to trastuzumab as reported previously.[19]

The purified 3p-*C*-DEPA trastuzumab conjugates (30−50 μg) in 0.25 M NH_4OAc buffer solution at pH 5.5 was radiolabeled

Scheme 2. Synthesis of 3p-C-DEPA (9) and 3p-C-DEPA-NCS (11)

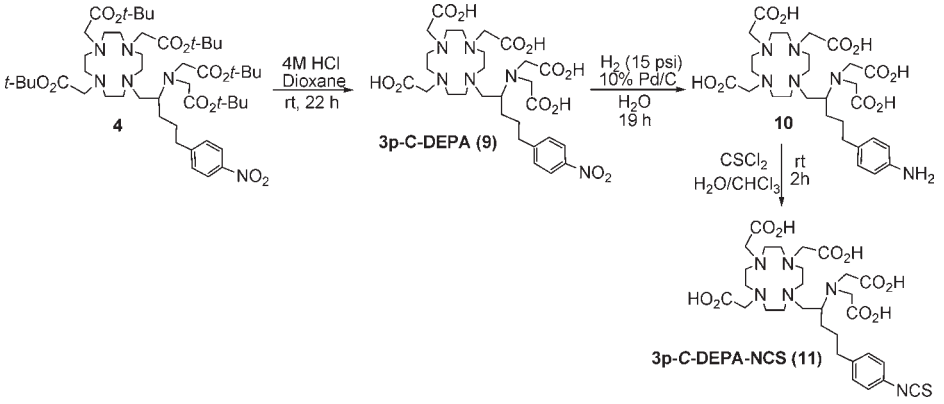


Table 1. Radiolabeling Efficiency (%) of Bifunctional Ligand-Trastuzumab Conjugates with $^{205/6}$Bi (0.25 M NH_4OAc, pH 5.5, RT)*

time (min)	3p-C-DEPA	C-DOTA
1	93.6 ± 0.4	8.4 ± 1.9
5	94.7 ± 0.9	17.2 ± 4.3
10	95.0 ± 0.4	28.7 ± 4.5
20	94.1 ± 0.6	38.0 ± 4.9
30	94.4 ± 1.6	49.7 ± 9.0
60	94.5 ± 0.5	60.2 ± 8.0

* Radiolabeling efficiency (mean ± standard deviation) was measured in triplicate.

with $^{205/6}$Bi (0.1 M HI) (60 μCi) at room temperature (RT). During the reaction time (1 h), the radiolabeling kinetics was determined by taking aliquots of the reaction mixture at 6 time points (1 min, 5 min, 10 min, 20 min, 30 min, and 60 min). The components were analyzed using SE-HPLC after challenging the reaction mixture with 10 mM DTPA, and the radiolabeling efficiency (%) was determined (Table 1 and the Supporting Information). The data indicate that $^{205/6}$Bi labeling of 3p-C-DEPA-trastuzumab conjugate were extremely rapid (1 min, >93%) at RT. As expected, radiolabeling of C-DOTA-trastuzumab conjugate with $^{205/6}$Bi was slow and incomplete at 24 h (60.2 ± 8.0%). The $^{205/6}$Bi-3p-C-DEPA conjugate was further evaluated for *in vitro* serum stability. The $^{205/6}$Bi-3p-C-DEPA conjugate was freshly prepared, purified, and incubated in human serum at 37 °C. At each time point (0 h, 1, 2, 3, 4 d), aliquots of the reaction mixture were analyzed using SE-HPLC after challenging the reaction mixture with 5 mM DTPA. $^{205/6}$Bi-3p-C-DEPA-trastuzumab was found to be stable in human serum without release of the radioactivity for at least 4 days (the Supporting Information).

The $^{205/6}$Bi-3p-C-DEPA-trastuzumab and $^{205/6}$Bi-C-DOTA-trastuzumab conjugates were independently prepared at 37 °C and pH 5.5 for specific activity and immunoreactivity evaluations prior to performing comparative *in vivo* biodistribution studies. The respective specific activities of 16.0 mCi/mg and 13.6 mCi/mg were measured for $^{205/6}$Bi-3p-C-DEPA and $^{205/6}$Bi-C-DOTA. The radiolabeling yields of 85.8% and 67.3% were determined for $^{205/6}$Bi-3p-C-DEPA and $^{205/6}$Bi-C-DOTA, respectively. Immunoreactivity of $^{205/6}$Bi-C-DOTA-trastuzumab and $^{205/6}$Bi-3p-C-DEPA-trastuzumab was assessed in a radioimmunoassay using recombinant human ErbB2/Fc Chimera (R&D Systems, Minneapolis, NM). The respective specific binding of 82.6% and 83.2% was measured for $^{205/6}$Bi-3p-C-DEPA-trastuzumab and $^{205/6}$Bi-C-DOTA-trastuzumab. In the presence of excess trastuzumab, $^{205/6}$Bi-3p-C-DEPA-trastuzumab and $^{205/6}$Bi-C-DOTA-trastuzumab exhibited the same nonspecific binding (7.6%).

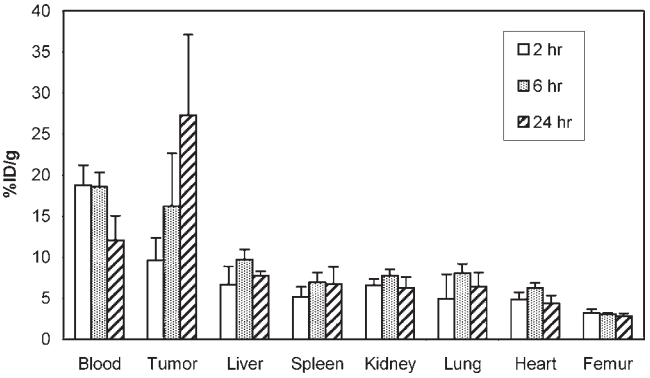

Figure 2. Biodistribution of $^{205/6}$Bi-3p-C-DEPA-trastuzumab conjugate in athymic mice bearing s.c. LS-174T tumors.

The *in vivo* stability and tumor targeting of $^{205/6}$Bi-3p-C-DEPA—trastuzumab was evaluated by performing biodistribution studies in LS174T-bearing athymic mice (i.v. injection, n = 4). $^{205/6}$Bi-C-DOTA-trastuzumab conjugate was evaluated for comparison. The mice were euthanized at 2 h, 6 h, and 24 h. Tumors, selected organs, and the blood were harvested, wet-weighed, and the radioactivity measured in a γ-counter (Figures 2 and 3). The highest tumor uptake was observed at 24 h for $^{205/6}$Bi-3p-C-DEPA-trastuzumab and $^{205/6}$Bi-C-DOTA-trastuzumab (27.3% and 25.8%, respectively). Among the organs, the highest accretion of radioactivity was observed in the liver: 7.73% for $^{205/6}$Bi-3p-C-DEPA-trastuzumab (6 h) and 8.02% for $^{205/6}$Bi-C-DOTA-trastuzumab (24 h). Both of the $^{205/6}$Bi-labeled conjugates exhibited the highest radioactivity level in the blood at 2 h which decreased over time. Renal and liver uptake of $^{205/6}$Bi-3p-C-DEPA-trastuzumab peaked at 6 h and decreased by 24 h. $^{205/6}$Bi-3p-C-DEPA-trastuzumab and $^{205/6}$Bi-C-DOTA-trastuzumab resulted in the respective radioactivity level of 6.27% and 5.52% in the kidney at 24 h. $^{205/6}$Bi-C-DOTA-trastuzumab exhibited an upward trend in the accumulation of radioactivity in the liver over the study period. Femur uptake of $^{205/6}$Bi-3p-C-DEPA-

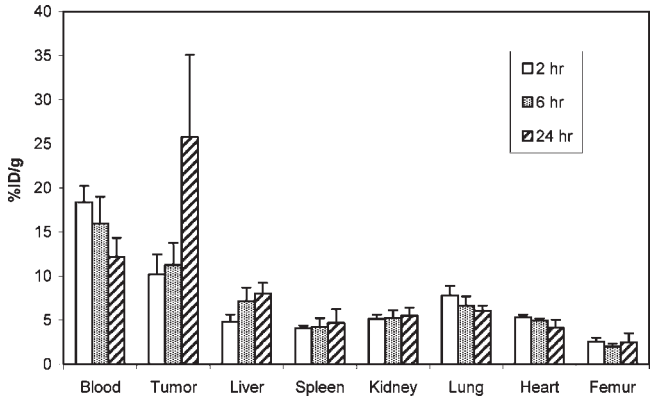

Figure 3. Biodistribution of $^{205/6}$Bi-*C*-DOTA-trastuzumab conjugate in athymic mice bearing s.c. LS-174T tumors.

trastuzumab peaked at 2 h (~3%) and decreased over the rest of the time points, while $^{205/6}$Bi-C-DOTA-trastuzumab displayed increased femur uptake from 2.00% at 6 h to 2.49% at 24 h. The respective tumor-to-blood ratio of $^{205/6}$Bi-3p-C-DEPA and $^{205/6}$Bi-*C*-DOTA at 24 h was 2.26 and 2.15. Both radioimmunoconjugates exhibited low blood to tissue ratios (<0.7) in all tissues and higher radioactivity level in tumor as compared to the normal organs over the time points.

In summary, the *in vitro* and *in vivo* experimental results indicate that the new ligand 3p-C-DEPA possesses great potential for RIT of ^{212}Bi and ^{213}Bi. Given complete and ongoing numerous preclinical and clinical studies of *C*-DOTA for alpha RIT, this new ligand deserves more extensive evaluations as a chelator of other potent α-emitters with a longer half-life including ^{212}Pb ($t_{1/2}$ = 10.64 h) and ^{225}Ac ($t_{1/2}$ = 10 d). ^{212}Pb is investigated as an *in vivo* generator of ^{212}Bi to abrogate the short half-life of the daughter isotope.[20] ^{225}Ac with the advantage of multiple α emissions is a potent α emitter and known to induce apoptosis even with a single particle traversal of the cell.[21] Although encouraging results on the therapeutic efficacy of *C*-DOTA-antibody conjugates radiolabeled with ^{212}Pb or ^{225}Ac as demonstrated in the preclinical studies using tumor-bearing mice was reported,[22−25] *C*-DOTA-antibody conjugates radiolabeled with ^{203}Pb or ^{225}Ac were less stable in serum.[21,26,27] The decadentate chelator 3p-C-DEPA possesses a larger macrocyclic backbone than *C*-DOTA and may be a suitable ligand for effectively sequestering ^{212}Pb and ^{225}Ac. 3p-C-DEPA will be further evaluated for various alpha RIT applications.

CONCLUSION

The new bifunctional ligand 3p-C-DEPA was efficiently prepared based on the synthetic route including the key reaction step, regiospecific ring-opening of aziridinium ion by nucleophilic trisubstituted cyclen. 3p-C-DEPA conjugated with trastuzumab was extremely rapid in binding $^{205/6}$Bi, and the corresponding $^{205/6}$Bi-3p-C-DEPA-trastuzumab complex was stable in human serum over a 4 day study period, well beyond any concerns of stability with ^{212}Bi and ^{213}Bi. *In vivo* biodistribution data indicate that 3p-C-DEPA-trastuzumab radiolabeled with $^{205/6}$Bi displayed excellent *in vivo* stability as evidenced by low organ uptake and excellent tumor targeting that was favorably compared to those of $^{205/6}$Bi-*C*-DOTA-trastuzumab. *In vitro* and *in vivo* data demonstrate that 3p-C-DEPA is a promising ligand for RIT applications of ^{212}Bi and ^{213}Bi.

Real-Time Monitoring of Actin Polymerization in Living Cells Using Split Luciferase

ABSTRACT: Real-time monitoring of actin polymerization in living cells is beneficial for characterizing cellular activities such as migration, proliferation, and death. We developed new bioluminescence-based probe proteins that enable the monitoring of actin polymerization in living cells. Unlike other ordinary split luciferase probes, our probes were incorporated in endogenous actin filament that enabled it to measure the actin polymerization quantitatively. The probe proteins exhibited a dose-responsive decrease in photon emission intensity in response to the filamentous (F)-actin-disrupting agent latrunculin A. This technique has a high sensitivity with a high signal-to-noise ratio and is nontoxic compared with other methods of monitoring actin polymerization in living cells. Using this technique, we succeeded in monitoring the F-actin level in living cells during apoptosis progression induced by UV irradiation continuously for 12 h. F-actin was transiently upregulated after UV irradiation. Since UV-induced cell death was enhanced by treatment with latrunculin A during the period which F-actin is increased, transient upregulation of F-actin after UV is likely a protective reaction against UV-induced cell death. Our novel technique is an effective tool for investigating actin polymerization in living cells.

INTRODUCTION

Actin is a major cytoskeletal protein, the sequence of which is highly conserved among all eukaryotes, and is of two dynamic forms, globular (G) actin and its polymerized form, filamentous (F) actin. The organization of F-actin has been considered important for many cellular functions such as migration,[1,2] cancer cell invasion,[3] synaptic plasticity,[4,5] and cell death.[6,7] Measurement of the level of F-actin is important for analyzing cell activity. However, the conventional methods for analyzing F-actin have some limitations. Rhodamine-phalloidin (R-P) staining[8] cannot be used for the long-term and real-time monitoring of F-actin in living cells, since it requires cell fixation. Fluorescent probe proteins such as GFP-actin[9] and lifeact[10] are not suitable for the quantification of F-actin since their monomers can emit fluorescence. Recently, the fluorescence resonance energy transfer (FRET) technique has been used to monitor F-actin,[11] although the FRET signal intensity is not in proportion to the level of F-actin.[12] Furthermore, all the fluorescence-based methods have phototoxicity caused by excitation light. Thus, we tried to develop novel probe proteins to measure the F-actin level in living cells over a long period. The firefly split luciferase technique, which has been developed by several groups in the past decade,[13−15] was employed to develop probe proteins, since bioluminescence-based methods have some advantages in terms of the viability of cells and linearity of signal intensity. In this report, we describe the development of novel probe proteins for monitoring actin polymerization.

To validate the usefulness of our probe proteins, we focused on the regulation of actin polymerization in cell death. The disruption of F-actin induces apoptotic cell death in T cells and MCF10A cells, and enhances apoptosis by cytokine withdrawal in CTLL-20 cells.[16−18] These reports suggest that actin polymerization has a protective role against the cell death. However, few reports have described the detailed time course and quantification of the actin polymerization in cell death due to lack of appropriate method. Using our probe proteins, we attempt to elucidate the precise time course of actin polymerization after cell death stimulus and try to predict the critical period that F-actin works protectively.

EXPERIMENTAL PROCEDURES

Plasmid Construction. A MultiSite Gateway Three-Fragment Vector Construction kit (Invitrogen) was used for plasmid

construction in accordance with the manual. This method is based on site-specific recombination of DNA fragments.[19,20] Briefly, PCR-fragments flanked by recombination sites were inserted to donor vectors to generate 5′, center, and 3′ entry clones by recombination called BP reaction. These three entry clones were reacted with destination vector to generate expression clones through site-specific recombination called LR reaction. This reaction allows construction of respective PCR-fragments in a definite order. However, after LR reaction, DNA sequences coding KGGRADPAFLYKVE, which originates from the sequence of recombination site, remain between center-clone-derived sequence and 3′-clone-derived sequence. All the expression clones are driven by an SV40 enhancer promoter sequence of the 5′ entry clone and have an SV40 poly A signal sequence at the 3′ region derived from pGL4.13 (Promega). The PCR-amplified amino (N)-terminal part, 1−1245 bases, of the luciferase (lucN) sequence (1 corresponding to A at the translational initiation site methionine codon ATG) and the carboxyl (C)-terminal part, 1246−1650 bases, of the luciferase (lucC) sequence derived from pGL4.13, and a β-actin protein coding sequence (Genbank: X03672) amplified from mouse cDNA were used for the construction of the split luciferase probe expression clones. The protein coding sequences of the expression clones nos. 1, 2, 3, and 4 are actin-KGGRADPAFLYKVE-lucN, actin-KGGRADPAFLYKVE-lucC, lucN-KGGRADPAFLYKVE-actin, and lucC-KGGRADPAFLYKVE-actin, respectively (Figure 1B). The linker sequence was further modified by the inverse PCR method[21] using a KOD plus mutagenesis kit (Toyobo). The protein coding sequences of the expression clones nos. 5, 6, 7, 8, 9, and 10 are lucN-GGGGSGGGGSKGGRADPAFLYKVE-actin, lucC-GGGGSGGGGSKGGRADPAFLYKVE-actin, lucN-actin, lucC-actin, lucN-GGGGSGGGGSGGGGS-actin, and lucC-GGGGSGGGGSGGGGS-actin, respectively (Figure 1B).

The MultiSite Gateway system was also used to generate a Cofilin-myc expression clone. A Cofilin (Genbank: BC058726) ORF and a Myc-Tag sequence (EQKLISEEDL) were amplified by PCR and inserted into the center and 3′ entry clones, respectively. Both clones were reacted with pDEST R4-R3, and the 5′ entry clone to obtain a Cofilin-KGGRADPAFLYKVE-Myc-expressing clone driven by an SV40 enhancer promoter.

For the GST fusion lucN-actin and lucC-actin protein expression in *Escherichia coli*, lucN-actin (No. 9) and lucC-actin (No. 10) were amplified by PCR using primers with a *Bam*HI site and a *Not*I site at each end. Amplified fragments were digested with *Bam*HI and *Not*I, then subcloned into the *Bam*HI and *Not*I sites of pGEX-6p-1 (GE Healthcare). All the constructs were confirmed by DNA sequencing using ABI3100 (Applied Biosystems).

Cell Culture and DNA Transfection. HEK293T (1.5×10^5 cells/dish or 0.5×10^5 cells/well) cells were cultured in DMEM supplemented with 10% FCS at 37 °C in 5% CO_2 on a 3-cm-diameter dish (Falcon) for UV irradiation and 3-(4,5-dimethyl-2-thizolyl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) assay, and on a glass base dish (Iwaki) for R-P staining. HEK293T cells were transiently transfected using Lipofectamine 2000 (Invitrogen) in accordance with the manufacturer's instructions. Two microgram aliquots of each plasmid were used for cotransfection. When a 24-well culture plate was used for transfection, 4-fold smaller amounts of the reagent and DNA were used. Photon intensity emitted from cells was measured 48 h after transfection.

Cell Viability and Caspase-3 Assays. Cell viability was determined by MTT assay in accordance with the manual attached to the MTT cell viability assay kit (Biotium Inc.). After incubation with the tetrazolium salt MTT (1 mg/mL) for 2 h at room temperature, the harvested cells were solubilized with 1 mL of dimethyl sulfoxide. We measured the absorbance at wavelengths of 570 and 630 nm using a spectrophotometer (Gene Quant 1300, GE Healthcare). The sample signal intensity was obtained by subtraction of OD at 630 nm from OD at 570 nm and indicated as a percentage of the control value. To determine caspase-3 activity, we employed the Caspase 3&7 FLICA kit (ImmunoChemistry Technologies). The cellular substrate FAM-DEVD-FMK was added to the culture medium of the UV-irradiated cells. Fluorescence signals were detected by confocal microscopy (TCS-SP5, Leica).

Western Blotting. Cells were harvested and lysed using M-PER solution (Thermo Scientific). Proteins separated by SDS-PAGE were electrically transferred onto a PVDF membrane (GE Healthcare). The membrane was incubated with an anti-actin primary antibody (1:1000, Santa Cruz) or a polyclonal antiluciferase antibody (1:1000 Promega) in the Can Get Signal solution (Toyobo) at 4 °C overnight. The membrane was reacted with a secondary HRP-conjugated antibody (1:2000, Bio Rad) and visualized using an ECL plus Western blotting reagent (GE Healthcare). Chemiluminescence signals were detected using the LAS-1000 plus system (Fujifilm).

In Vitro Actin Polymerization Assay. Fifty micrograms of pyrene-conjugated actin[22] (Cytoskeleton) with or without probe proteins (1 μg each) was suspended in 2 mL of general actin buffer (5 mM Tris-HCl (pH 8.0), 0.2 mM $CaCl_2$, 0.2 mM ATP, 0.5 mM DTT) and centrifuged at 15 000 *g* for 30 min to remove residual F-actin. To polymerize actin, 1/10 vol of 10× polymerization buffer (500 mM KCl, 20 mM $MgCl_2$, 10 mM ATP) was added. Fluorescence signal intensity was measured every 5 min using a F-4500 spectrophotometer (Hitachi) at an excitation wavelength of 360 ± 10 nm and an emission wavelength of 405 ± 10 nm.

F/G Actin Separation of Cell Lysate by Ultracentrifugation. A G-actin/F-actin *in vivo* assay kit (Cytoskeleton) was used to separate F- and G-actin from the HEK293T lysate. HEK293T cells were lysed in the cell lysis and F-actin stabilization buffer that was provided in the kit. The cell lysate was centrifuged at 100 000 *g* for 1 h at room temperature. The pellet and supernatant were collected as the F-actin-and G-actin-containing fractions, respectively.

Expression of GST-Fusion Probe Proteins in *E. coli*. *E. coli* BL21 (DE3) was transformed by pGEX-6p-1-derived plasmids that encoded GST-lucN-actin and GST-lucC-actin. *E. coli* cells were homogenized by ultrasonication in 1% NP-40 in PBS (pH 7.4). Fusion proteins were purified by binding to glutathione-Sepharose 4B (GE Healthcare). Then, the bound fusion proteins were cleaved with PreScission Protease (GE Healthcare) to obtain lucN-actin and lucC-actin.

Immunoprecipitation Assay. Cofilin-myc and one of the probe proteins (lucN-actin or lucC-actin) were expressed in HEK293T cells. The cells were harvested in PBS, homogenized using a polytron homogenizer (Kinematica), and centrifuged at 2000 *g* for 5 min to remove debris. The protein solution was incubated with 1 μg of an antimyc antibody (Santa Cruz) or 5 μg of an antiluciferase antibody (Promega) bound to 25 μL of protein-G Sepharose (GE Healthcare) for 3 h at 4 °C. Then, the mixtures were washed 5 times, and the precipitates were analyzed by Western blotting using the antimyc (1:1000) and antiluciferase (1:1000) antibodies.

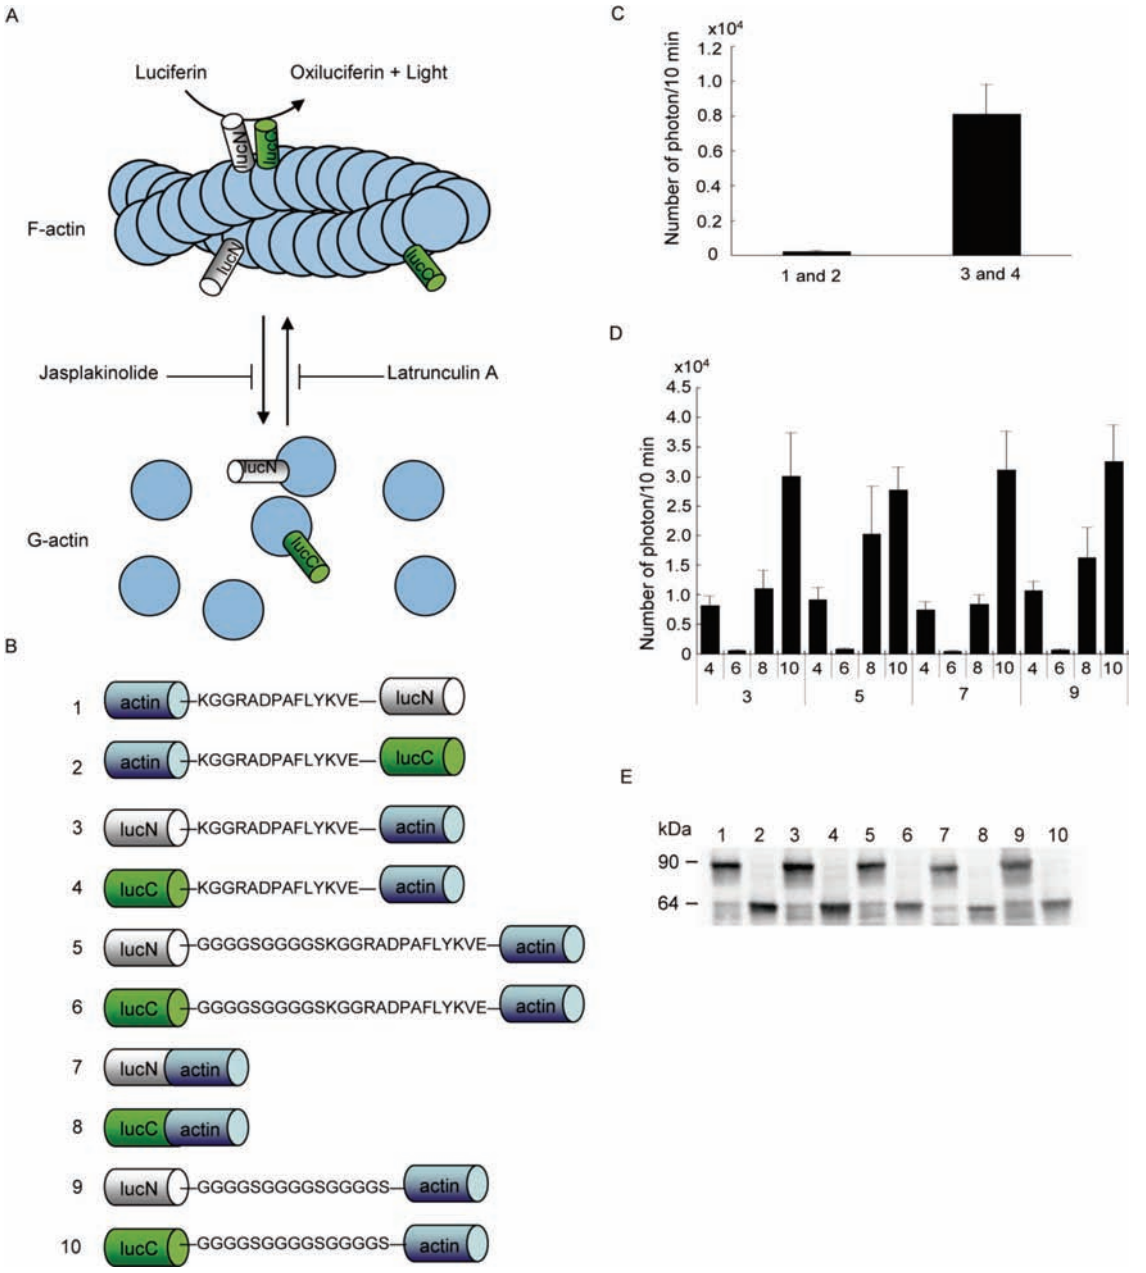

Figure 1. Development of probe proteins to measure actin polymerization. (A) Schema of measurement of level of F-actin based on bioluminescence intensity. LucN and lucC derived from firefly luciferase are fused with actin. Each probe protein is incorporated in the endogenous actin filament. When the lucN and lucC locate close to each other, they recover their luciferase activity and emit light. Jasplakinolide and latrunculin A are the agents that stabilize and inhibit actin polymerization, respectively. (B) Schematic structures of the actin probe proteins encoded by the expression clones nos. 1 to 10. LucN and lucC represent N-terminal and C-terminal split segments of the firefly luciferase, respectively. Amino acid sequences of the linker are indicated as single letters. (C) Combinations of expression clones nos. 1 and 2 and nos. 3 and 4 were expressed in HEK293T and the emitted photons were counted for 10 min using an image intensifier/CCD camera. (D) The numbers of photons emitted from all the combinations of odd and even numbers of clone shown in B except clones nos. 1 and 2 were measured. The numbers on the horizontal axis represent the combinations of probe proteins. All the data are presented as mean ± SEM $n = 4$. (E) The amount of each expressed probe protein was analyzed by Western blotting.

Measuring Photon Intensity Emitted from Cultured Cells. We used an Aequoria-2D/C8600 system (Hamamatsu Photonics) for photon counting. *Wasabi* software (U9304−02) was used for data acquisition and analysis. Cultured cells were taken out from a CO_2 incubator. The culture medium was changed to L15 medium containing 0.5 mM luciferin EF (Promega). The culture plate was placed in a dark box for 30 min. Then, the number of photons emitted from one culture dish well was measured using a charge coupled device (CCD) camera with an image intensifier attached to the top of the dark box. Photon intensity was measured every 5 min continuously for 12 h after UV irradiation or latrunculin A treatments and shown in Figure 4D,E. The numbers of emitted photon from wells were normalized to those from nontreated wells (control) and were plotted as relative intensity.

Cytochemical Staining and Image Acquisition. HEK293T cells were fixed with 4% paraformaldehyde in PBS. Cells were

incubated with 0.14 μM rhodamine-phalloidin (R-P)/PBS for 1 h at room temperature and washed with PBS. Hoechst staining was carried out in accordance with the manual of Caspase 3&7 FLICA kit (ImmunoChemistry Technologies). Fluorescence and bright field images were acquired using a laser confocal microscopy system (TCS-SP5, Leica) with a 63× Plan-Apochromat 1.4 NA lens (Leica) with immersion oil (Type F, Leica) at room temperature. Images were acquired using data acquisition/analysis software of the microscopy system (Leica application suite). No additional software adjustments were performed on images after acquisition. For the R-P signal quantification, the fluorescence intensity of eight randomly taken images using a 20× Plan-Apochromat 0.7 NA lens (Leica) was quantified using the Leica application suite. The intensity of the rhodamine signal was divided by that of the Hoechst staining signal of the same field. Calculated values are represented as a percentage of the control.

UV Irradiation. UV irradiation (at 254 nm, 9.6 kJ/m^2) was performed using a UV cross-linker (Spectrolinker XL-1000, Spectronics). HEK293T cells cultured in 3-cm-diameter dishes were taken out from a CO_2 incubator. The medium was changed to 2 mL of L15 medium (Invitrogen). The cells were irradiated with UV without removing the medium. After the irradiation, the cells were incubated at room temperature for 18 h.

Statistical Analysis. Data are presented as mean ± standard error of the mean (SEM). In the MTT assay, two-tailed Student's *t* test was used to determine statistical significance.

RESULTS

Development of Bioluminescence Probes for Long-Term Monitoring of Polymerization of Actin in Living Cells. We developed a novel method to measure the actin polymerization in living cells. The schema to measure the level of F-actin using split luciferase in living cells is shown in Figure 1A. The lucN-actin and lucC-actin fusion proteins are expressed in the cells and are incorporated in the actin filament randomly. When some of the lucN-actin and lucC-actin fusion proteins locate close to each other, they recover their enzymatic activity to emit light. Consequently, the intensity of photon emission is considered to depend on the level of F-actin. We screened the brightest pair of probe proteins. On the basis of the reported optimized cleavage site of firefly luciferase,[14,23] we constructed various luc-actin fusion probe proteins (Figure 1B). Combinations of expression clones nos. 1 and 2 and nos. 3 and 4 were expressed in HEK293T, and the emitted photons were counted for 10 min using the image intensifier/CCD camera. We found that the number of photons emitted from combination of nos. 3 and 4 was about 40 times larger than that of the combination of nos. 1 and 2 (Figure 1C). This result indicated that the N-terminal location of the luc fragment and the C-terminal location of actin are important for emission efficiency. Next, we tested all the combinations of odd and even numbers of expression clones nos. 3−10 (Figure 1B) to determine the brightest probe proteins. We found that the combination of the probe proteins nos. 9 and 10, which contained the flexible linker $(GGGGS)_3$,[24] showed the largest average photon count (Figure 1D) and decided to use this combination in the experiments reported here. To examine whether there were differences in expression level among probe proteins, lucN-actin (~87 kDa) and lucC-actin (~57 kDa) were analyzed by Western blotting using antiluciferase antibody. The difference in expression level of each probe protein was much smaller than the difference in light intensity seen in Figure 1C,D (Figure 1E). We used probes no. 9 (lucN-actin) and 10 (lucC-actin) in the following study.

Characterization of Developed Probe Proteins. To confirm the expression of probe proteins in living cells, lysates from HEK293T expressing probe proteins were analyzed by Western blotting using antiactin antibody. By comparing the intensities of the bands representing lucN-actin (87 kDa), lucC-actin (57 kDa), and endogenous actin (42 kDa), we found that the expression levels of probe ptoteins were less than 5% of endogenous actin (Figure 2A). Next, we determined whether incorporation of probe proteins in F-actin affected the kinetics of actin polymerization *in vitro*. Pyrene-conjugated actin and *E. coli* expressed probe proteins at a molar ratio of 25:1 were mixed in general actin buffer. Then, the polymerization buffer was added to start actin polymerization. The intensity of the fluorescence was measured for 90 min. We observed that the increasing ratio of fluorescence intensity was not changed by the existence of the probe proteins (Figure 2B). Subsequently, the samples used in the reaction were centrifuged to collect the F-actin fraction and analyzed by Western blotting. We detected bands corresponding to lucN-actin and lucC-actin for the sample that was treated with polymerization buffer (probes + P buffer) but not for the sample with general actin buffer alone (probes). This result indicates that incorporation of the probe proteins in F-actin did not affect the kinetics of actin polymerization in vitro (Figure 2C). Next, we confirmed whether the probe proteins were incorporated in F-actin in living cells. To separate F-actin and G-actin, HEK293T cells expressing probe proteins were harvested and ultracentrifuged.[25] The F-actin fraction in the pellet and the G-actin fraction in the supernatant were analyzed by Western blotting using the antiactin and antiluciferase antibodies, and we found that both lucN-actin and lucC-actin probe proteins were contained in each fraction. The ratio of probe proteins in the G-actin fraction to the F-actin fraction was similar to that of endogenous actin (Figure 2D). Then, we examined whether probe proteins could bind to one of the actin-binding proteins. Cofilin,[26] a well-defined actin-binding protein, was fused with the myc-tag sequence and expressed with probe proteins in HEK293T cells. The lysates from HEK293T cells were analyzed by co-immunoprecipitation using antimyc or antiluciferase antibodies. We found that probe proteins and cofilin-myc were contained in precipitated fractions with anti-myc and antiluciferase antibodies, respectively (Figure 2E). These results demonstrated that probe proteins associated with cofilin in the living cells. Finally, we tested whether the probes affect cell proliferation rate. HEK293T cells were transfected with probe proteins or wild-type luciferase (Luc). We did not find any difference in the intensity of MTT signals between the probe proteins- or Luc-expressing cells and the cells treated with lipofectamine alone (Figure 2F). Since light emission levels by luciferase−luciferin reaction and actin polymerization are both ATP-dependent, we tested whether luciferase activity affected the normal actin polymerization. HEK293T cells expressing probe proteins are treated with luciferin for 12 h, and then F- and G-actin fractions were separated. The ratio of F- and G-actin was similar to the control cells that were not treated with luciferin (Figure 2G). Thus, it is considered that normal actin polymerization is not affected by ATP consumption by probe proteins.

Developed Probe Proteins Can Measure the Level of F-Actin in Living Cells. Using the developed probe proteins, we examined whether the intensity of photons emitted by the

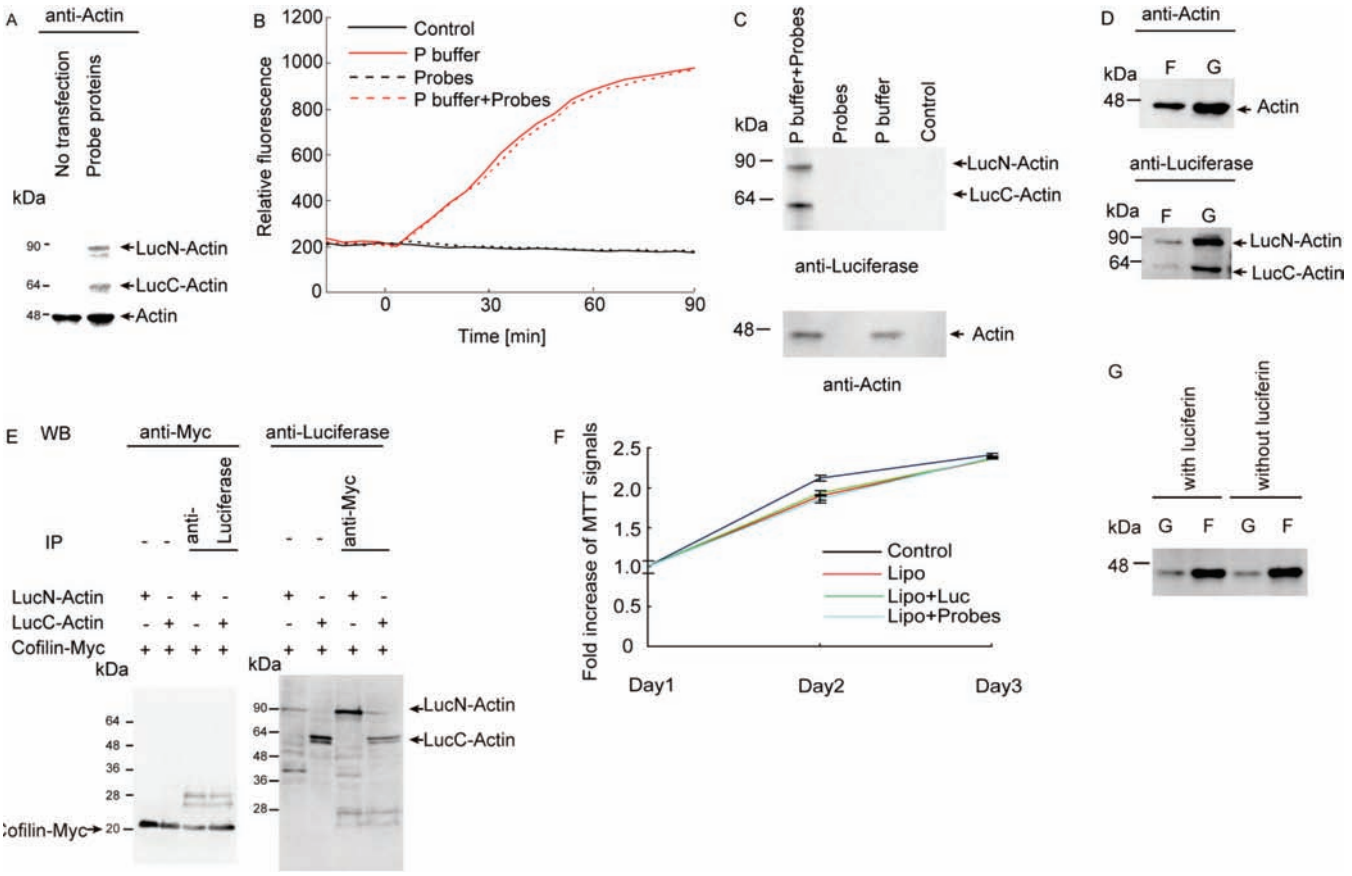

Figure 2. Characterization of probe proteins in vitro and in vivo. (A) Western blotting analysis of endogenous actin and probe proteins. HEK293T cells expressing probe proteins were analyzed by Western blotting using the antiactin antibody. The contrast of the image was adjusted to visualize the luc-actin fusion proteins. (B) Change in fluorescence intensity of pyrene-conjugated actin with probe proteins. Pyrene-actin with (dotted line) or without (solid line) probe proteins was treated with (red line) or without (black line) polymerization (P) buffer, then fluorescence intensity was measured every 5 min for 90 min. (C) Coprecipitation of probe proteins and pyrene-conjugated actin. After the fluorescence observation shown in B, each sample was centrifuged to precipitate F-actin. The pallet was analyzed by Western blotting using the antiluc antibody (upper panel). Then, antiluc antibody was stripped and the membrane was reacted with the antiactin antibody (lower panel). (D) Incorporation of probe proteins in F-actin in cells. HEK293T cells expressing probe proteins were harvested and ultracentrifuged to obtain F-actin in the pellet and G-actin in the supernatant fraction. The pellet was resuspended to the same volume as the supernatant fraction and analyzed by Western blotting. (E) Binding of probe proteins to an actin binding protein cofilin. Cofilin-myc and probe proteins were expressed in HEK293T cells and subjected to immunoprecipitation assay using the antimyc and antiluc antibodies. Total proteins from HEK293T cells expressing both cofilin-myc and one of the probe proteins were incubated with the antiluc (left panel) and antimyc (right panel) antibodies bound to protein-G Sepharose. The immunoprecipitates were analyzed by Western blotting (right two lanes of each panel). The lysate (1%) of transfected cells was directly analyzed by Western blotting as controls (left two lanes of each panel). (F) HEK293T cells were transfected with the plasmids that encoded wild-type luciferase (Luc) or probe proteins (Probes), the combination of nos. 9 and 10 (Figure 1B), using lipofectoamine 2000 (Lipo) on day 1. In the control, no plasmid or lipofectamine 2000 was added (Control). Cell viability was measured by the MTT method on days 1−3. Data are presented as mean ± SEM, $n = 4$. (G) F- and G-actin fractions from the cells expressing probe proteins in the presence (left) or absence (right) of luciferin were analyzed by Western blotting. In each Western blot, the locations of molecular weight markers (kDa) are shown on the left. Arrows indicate the locations of the bands corresponding to lucN-actin, lucC-actin, endogenous actin, and cofilin-myc.

probe proteins precisely reflected the level of F-actin in the cells. We added various concentrations of latrunculin A, which disrupts the actin filament by binding to G-actin,[27] to the culture medium of HEK293T expressing the probe proteins. After 3 h incubation with latrunculin A, luciferin was added and photon intensity was measured using the image intensifier/CCD camera in a dark box. We did not set any threshold to cut off the background noise. Depending on the latrunculin A concentration, photon intensity decreased (Figure 3A). At the highest concentration (50 μM) of latrunculin A, the photon emission was diminished almost completely. In the control experiment, Luc was expressed in the HEK293T cells and treated in the same manner as in Figure 3A. We observed no reduction in photon intensity following the treatment (Figure 3B). These results demonstrated that latrunculin A did not affect the activity of wild-type luciferase. Next, we evaluated the measurement of F-actin level in the cells using a conventional F-actin staining method. Cells were fixed after latrunculin A treatment and stained with R-P. Fluorescence microscopy analysis showed a dose-responsive decrease in fluorescence signal intensity, which represented the level of F-actin, accompanied with rounding of the cell shape (Figure 3C). The fluorescence signal intensity decreased with increasing concentration of latrunculin A (Figure 3D). However, at the highest concentration of latrunculin A (50 μM), the fluorescence intensity was about 30% of that of control cells and did not completely disappear (Figure 3D). Furthermore, the effect of an F-actin-

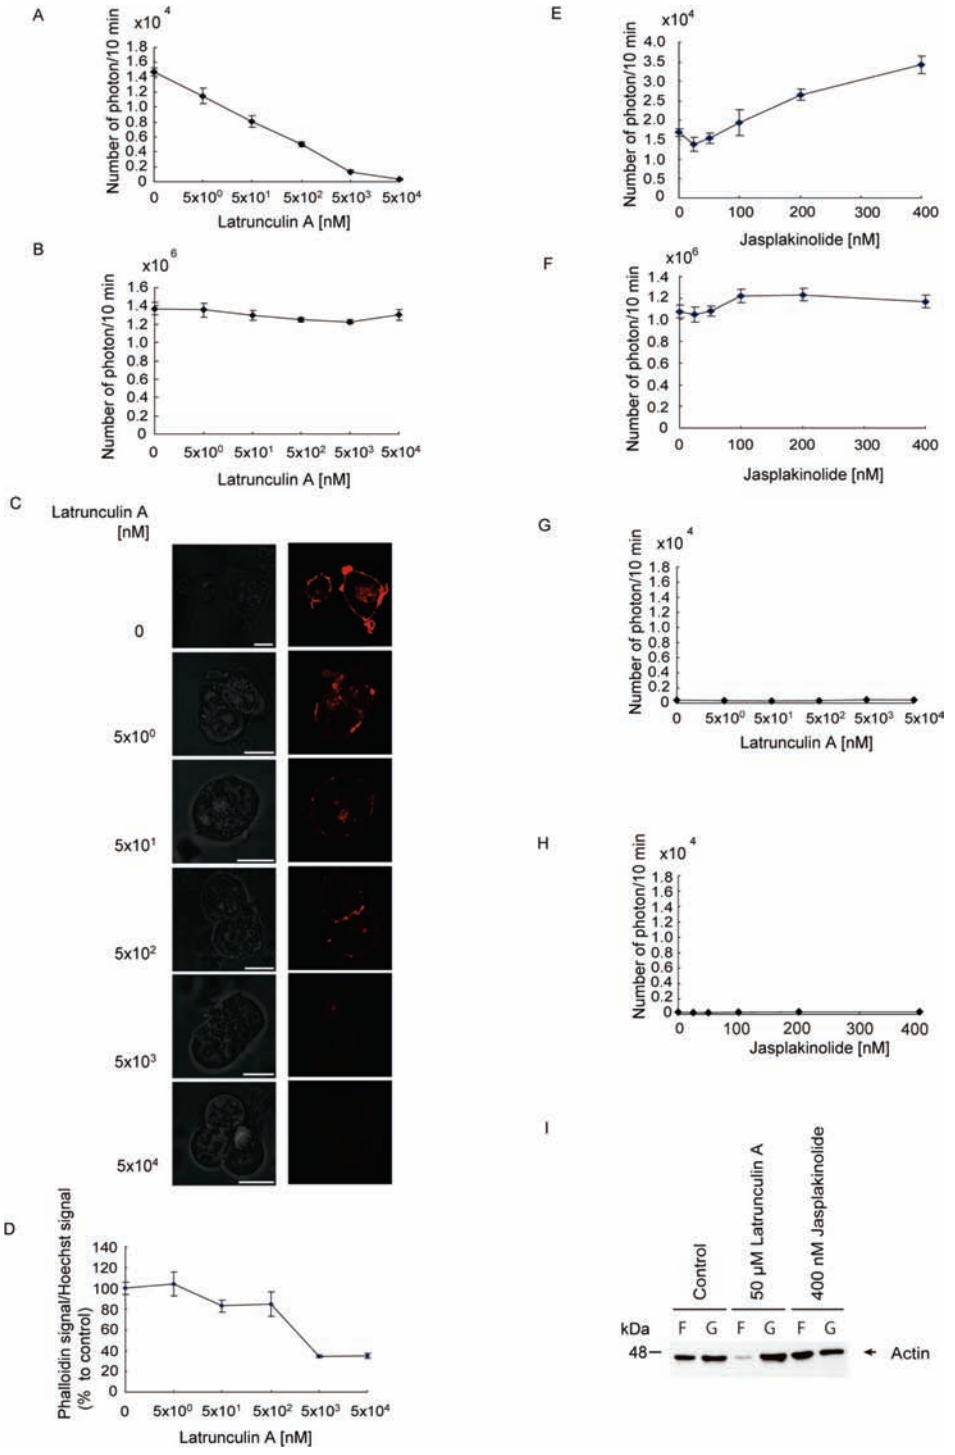

Figure 3. Effect of latrunculin A treatment on photon emission from F-actin probe proteins. (A) Concentration-dependent inhibition of photon emission from F-actin probe proteins by latrunculin A. The combination of probe proteins nos. 9 and 10 (Figure 1B) was expressed in HEK293T cells. Cells were treated with the indicated concentration of latrunculin A for 3 h. The intensity of photon emission in a period of 10 min from each culture well was measured. (B) Effect of latrunculin A on wild-type luciferase. The intensity of photon emission from the culture well expressing wild-type luciferase was measured as in (A). (C) Effects of latrunculin A on rhodamine-phalloidin (R-P) staining of HEK293T cells. Cells were treated with latrunculin A for 3 h and fixed. Red fluorescence represents F-actin. Fluorescence and bright field images were obtained by confocal microscopy. Bars indicate 10 μm. (D) Effects of latrunculin A on R-P staining of F-actin. R-P fluorescence signal intensity was normalized with Hoechst signal intensity. The values are expressed as a percentage of the control experiments without latrunculin A treatment. (E) Concentration-dependent increase in the intensity of photon emission from F-actin probe proteins after treatment with jasplakinolide. (F) Effect of jasplakinolide on wild-type luciferase. Photon emission was measured in the same manner as in (E). (G) Effects of latrunculin A on photon emissions from the cells expressing lucN and lucC. (H) Effects of jasplakinolide on photon emissions from the cells expressing lucN and lucC. (I) The amounts of F- and G- actin were analyzed by Western blotting after latrunculin A and jasplakinolide treatment. All the data are presented as mean ± SEM, n = 4 in (A, B, E, F, G, and H). n = 8 in (D).

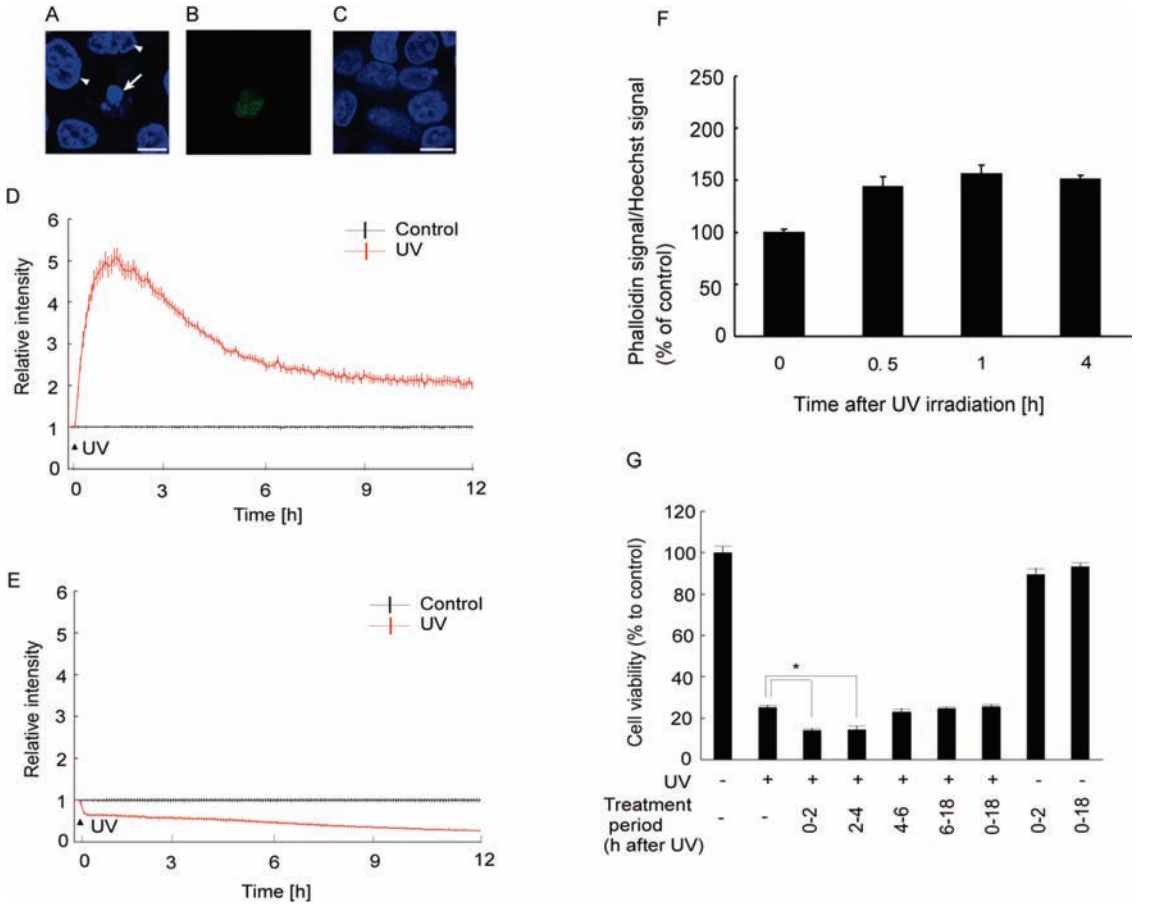

Figure 4. Effects of latrunculin A treatment on UV-induced apoptosis of HEK293T cells. (A) Cytochemistry of UV-irradiated cells stained with Hoechst (blue) 8 h after UV irradiation. The arrow indicates a cell with a condensed nucleus. Arrowheads indicate nuclear-membrane-localized chromatin stained with Hoechst. (B) Cells shown in A stained with caspase-3 activity indicator (green). (C) Non-UV-irradiated cells stained with Hoechst (blue). Bars indicate 10 μm in (A) and (C). (D) Time course of relative intensity of photon emission from F-actin probe proteins after UV irradiation (arrowhead). The red line represents the data from UV-irradiated cells. The black line represents that from the non-UV-irradiated control. (E) Time course of relative intensity of photon emission from cells expressing wild-type luciferase after UV irradiation. (F) Effects of UV on R-P staining of F-actin. The R-P fluorescence signals were normalized with Hoechst signals. The values are expressed as a percentage of the signal at time 0. (G) Effects of UV irradiation and latrunculin A treatment on cell viability assayed by the MTT method. Cells with and without UV irradiation were treated with or without 500 nM latrunculin A for indicated periods. Eighteen hours after UV irradiation, cell viability was measured. Cell viability is represented as a percentage of the viability of the control cells without UV irradiation and latrunculin A treatment. All the data are presented as mean ± SEM, $n = 4$, in (D,E,G). $n = 12$ in (F). * $p < 0.05$.

stabilizing reagent, jasplakinolide,[28] on photon emission from the probe proteins was tested. When jasplakinolide of more than 200 nM was added to the cells expressing the probe proteins, the cells emitted a significantly stronger light than when lower concentrations (<100 nM) were added (Figure 3E). We also tested a higher concentration (>400 nM) of jasplakinolide on the transfected cells and observed the tendency to emit a stronger light, but in those cases, the cells were often detached from the culture dishes (data not shown). We found that the photon emission of wild-type luciferase was not affected by jasplakinolide treatment (Figure 3F). The effects of jasplakinolide treatment on photon emission also support the idea that the photon intensity emitted from probe proteins quantitatively reflects the level of F-actin. Analysis of the effects of jasplakinolide on R-P staining of cells was not carried out because the binding sites of phalloidin and jasplakinolide are the same.[28] In order to confirm that lucN and lucC without actin fusing them do not interact each other, we measured the light intensity from the cells expressing lucN and lucC. The light intensity was much lower than the cells expressing lucN-actin and lucC-actin and did not react to latrunculin A and jasplakinolide (Figure 3G,H) as reported before.[29] To test whether latrunculin A and jasplakinolide change the amount of F-actin, HEK293T cells treated with the compounds were harvested, and F- and G- fractions were separated by centrifuge. The amount of F-actin was markedly reduced by latrunculin A and increased by jasplakinolide (Figure 3I). These changes of F-actin level are similar to the changes of light intensities seen in Figure 3A and E, supporting the functionality of the probe proteins.

Measurement of Actin Polymerization in HEK293T after UV Irradiation. We next applied these probe proteins to analyze the state of actin polymerization during apoptosis. First, we tried to characterize the HEK293T cell death induced by UV irradiation as a model. Fluorescence microscopy revealed that UV-irradiated cells exhibited nuclear condensation and chromatin localization at the nuclear membrane, as shown by Hoechst staining (Figure 4A), compared with the control cells (Figure 4C). In the cells that exhibited nuclear condensation, caspase-3 activation was observed (Figure 4B). These cells were

frequently detached from the culture dish (data not shown). Since these features were reported in lower-intensity UV- and cadmium-induced HEK293 apoptosis,[30,31] we assumed that the UV irradiation induced the apoptotic cell death. Then, we monitored the change in F-actin level after UV irradiation in real time and in living cells. Cells expressing the probe proteins were irradiated with UV, in the same manner as shown in Figure 4A, and photon emission intensity was measured continuously for 12 h after irradiation. We found that the relative photon intensity transiently increased after irradiation and gradually decreased after 2 h (Figure 4D). In the control experiment, Luc-expressing cells showed a decrease rather than an increase in photon emission intensity, which might be due to the toxic effect of UV irradiation (Figure 4E). Using conventional R-P staining, a transient increase of F-actin after UV irradiation was also detected, but the increase in signal was lower than that of our probes (Figure 4F). Considering the result of Figure 4D, we predicted that transient upregulation of F-actin in early phase (0−4 h) of apoptosis progression would be a protective reaction of the cell as reported in different cell lines.[16−18] To test this prediction, we determined the effects of latrunculin A on UV-induced HEK293T cell death. After the UV irradiation, 500 nM latrunculin A was added to the cells. Cell death was measured 18 h after irradiation by the MTT method. We found that the treatment with latrunculin A for 0−2 and 2−4 h after irradiation significantly enhanced UV-induced cell death (Figure 4G). In contrast, latrunculin A treatment 4 h after UV irradiation did not change the MTT signal intensity. Since latrunculin A treatment without UV did not induce significant cell death (Figure 4G), these results indicate that latrunculin A treatment accelerates UV-induced cell death only in the early period (0−4 h) after the irradiation. The period during which F-actin upregulation peaked (1−2 h after UV irradiation) (Figure 4D) overlapped with the period during which latrunculin A (500 nM) effectively enhanced the UV-induced cell death (0−2 h after UV irradiation) (Figure. 4G), suggesting a protective role of upregulated F-actin against apoptosis.

DISCUSSION

Characterization of the Probe Proteins We Developed. We successfully developed and improved the photon emission intensity of probe proteins to monitor actin polymerization (Figure 1). Expression of the probe proteins did not have any effect on HEK293T cell proliferation and actin polymerization ratio in vitro (Figure 2B,F). The probe proteins were incorporated in F-actin in vitro and in vivo (Figure 2C,D), and photon emission intensity decreased with increasing latrunculin A concentration (Figure 3A). The changes in photon emission of probe proteins induced by UV irradiation and latrunculin A treatments were consistent with those of R-P staining (Figure 3C,D). Above all, we conclude that our probe proteins can be used to precisely monitor actin polymerization in living cells. In previous studies, phalloidin has served as a useful tool to stain F-actin;[8] however, this reagent cannot be used in living cells because it requires cell fixation. The fluorescent GFP-actin protein[9] and lifeact[10] have been utilized to image the subcellular distribution of F-actin in living cells. However, these fusion proteins emit fluorescence even if they are monomers, and so are not suitable for quantification of the level of F-actin. Recently, the FRET technique has been employed to monitor F-actin,[11] although the FRET signal intensity is not in proportion to the level of F-actin.[12] These methods based on fluorescence observation have limits of autofluorescence noise and phototoxicity.[32] On the other hand, our probe proteins have little noise and no phototoxicity since no excitation light is required. These advantages enable us to carry out long-term quantitative measurement of F-actin in living cells (Figure 4). Since actin is a universal protein among all eukaryotic cells, and many cellular events are related to F-actin organization, our novel probe proteins can be applied to the analysis of a wide variety of phenomena involving actin polymerization in cells.

The increasing ratio of photon emission from probe proteins (Figure 4D) was higher than that of R-P signals (Figure 4F) in response to UV irradiation. Even if a high concentration of latrunculin A (50 μM) was added, we detected fluorescent signals from cells (Figure 3D), whereas the photon intensity from our probe proteins was diminished almost completely (Figure 3A). Thus, the main reason for this difference might be considered to be that the R-P signals contain about 40% of autofluorescence noise. In addition, another possibility that some F-actin was detected by R-P method and not by our method may explain the remained R-P fluorescence in Figure 3D. This point should be elucidated in the future.

The expression levels of our probe proteins are lower than that of GFP-actin.[33] Since GFP is known to have high stability,[34] it is possible that luc-actin fusion proteins are easier to be degraded than GFP-actin protein. This is a disadvantage because the degradation of probes reduces signal intensity. On the other hand, lower stability of our probe proteins may be an advantage, as they do not affect normal cell activities such as proliferation (Figure 2F).

Transient Increase in F-Actin Level Is Likely a Defensive Reaction of Cells. Some reports indicated F-actin disruption induced the apoptosis, and other reports showed enhancement of apoptosis by treatment with F-actin disruptive agent after apoptosis-inducing stimulation.[16−18] Thus, it is suggested F-actin has a protective role for the cells. However, the precise time course of actin polymerization during cell death has not been elucidated. Using our probe proteins, we succeeded in real-time monitoring of the actin polymerization in living cells after apoptosis induction and found that F-actin level was upregulated transiently after UV irradiation (Figure 4D). Furthermore, F-actin disruption with latrunculin A in the early period (0−2, 2−4 h after UV irradiation) enhanced the cell death, whereas later treatment (4−6, 6−18 h after UV irradiation) did not (Figure 4G). These results indicate that actin polymerization occurs in the early phase of apoptosis and support the hypothesis of protective role of actin polymerization against the cell death. In UV-induced apoptosis, several pathways are reported;[35] further study combined with pharmacological methods will reveal the mechanism of protective effect of actin polymerization on cell death.

ABSTRACT: Nanometric hybrid gadolinium oxide particles (Gado-6Si-NP) for diagnostic and therapeutic applications (mean diameter 3−4 nm) were obtained by encapsulating Gd_2O_3 cores within a polysiloxane shell, which carries organic fluorophore (Cy 5) and is derivatized by a hydrophilic carboxylic layer. As residency time in the living body and methods of waste elimination are crucial to defining a good nanoparticle candidate and moving forward with steps for validation, this study was aimed at evaluating the biodistribution of these multimodal Gado-6Si-NP in rodents. Gado-6Si-NP were imaged following intravenous injection in control Wistar rats and mice using MRI (7 T), optical fluorescent imaging, and SPECT. A clear correlation was observed among MRI, optical imaging, and SPECT regarding the renal elimination. Quantitative biodistribution using gamma-counting of each sampled organ confirmed that these nanoparticles circulated freely in the blood pool and were rapidly cleared by renal excretion without accumulation in liver and RES uptake. These results demonstrate that Gado-6Si-NP display optimal biodistribution properties, enabling them to be developed as multimodal agents for *in vivo* imaging and theragnostics, especially in oncological applications.

INTRODUCTION

Explosive growth in the field of personalized medicine and nanotechnology has enabled advances in molecular imaging and therapies.[1,2] Numerous strategies are explored in order to apply nanoparticles with multiple functions to clinical use.[3] Some nanoparticles have multimodal properties that are interesting for medical imaging,[4−6] while others are developed for therapeutic purposes only[7−9] or for theragnostic use.[10−12] Whatever the nanoparticle's composition, the hydrodynamic diameter and the surface of the nanoparticle are important parameters that potentially modify the biodistribution of the nanoparticle within the body. Most available nanoparticles have a hydrodynamic diameter greater than 10 nm. According to several studies,[13−16] different types of nanoparticles with a hydrodynamic diameter between 3 and 7 nm demonstrate optimal circulation lifetime with efficient clearance and the ability to be filtered through the kidneys. Ideally, these compounds should behave as closely as possible to molecules already used as contrast agents or for therapeutic purposes. Because of surface differences, nanoparticles with a small hydrodynamic diameter behave differently once injected in a living organism. Therefore, it is mandatory that we accurately and quantitatively evaluate the biodistribution of the nanoparticle studied.

Our group has developed a unique nanoparticle platform which is able to be detected regardless of the imaging modality used in humans, and which can be used for therapy as a radiosensitizer, or with a specific labeling as a tool for internal radiotherapy. These nanoparticles are composed of a core of rare-earth atoms (gadolinium), surrounded by a silica shell which can be used to covalently label specific targeting molecules. Because of their composition, no rapid degradation is expected, and it is therefore crucial to understand their behavior in a living organism. On a first move, the biodistribution of the nanoparticle platform should be evaluated and optimized as necessary, prior to developing targeted nanoparticles. A previous study[17] has shown that these nanoparticles were filtered by the kidney, and that the nanoparticles were recovered without modification in the urine. Our study was aimed at assessing the exact repartition of the nanoparticles in control rats and mice over an 18-day period by labeling the nanoparticles with Indium 111.

MATERIALS AND METHODS

Chemicals. Gadolinium chloride hexahydrate ($GdCl_3 \cdot 6H_2O$, 99.99%) was purchased from Metall Rare Earth Limited. Sodium hydroxide (NaOH, 99.99%), tetraethyl orthosilicate ($Si(OC_2H_5)_4$, TEOS, 98%), (3-aminopropyl)triethoxysilane ($H_2N(CH_2)_3$ $Si(OC_2H_5)_3$, APTES, 99%), Hepes solution (solution in water, pH 7.0−7.6), sodium chloride (NaCl), triethylamine (TEA, 99.5%), and nitric acid (HNO_3, 65%), dimethyl sulfoxide anhydrous ($(CH_3)_2SO$, DMSO >99.9%) diethyl ether ($(CH_3CH_2)_2O$ > 99%) were purchased from Aldrich Chemical (France). Cy5 mono-NHS-ester was purchased from Amersham Bioscience. Diethylenetriamine pentaacetic dianhydride ($C_{14}H_{19}N_3O_8$, DTPA-ba >98.0%) was purchased from TCI Europe. Ethanol, diethylene glycol (DEG, 99%), and other organic solvents (reagent grade) were purchased from SDS (France) and used as received. For the preparation of an aqueous nanoparticle solution, Milli-Q water (F > 18 MΩ) was used. Ultrafiltration was carried out using Vivaspin 5000 Da purchased from GE Healthcare.

Synthesis of NPs. The particles Gado-6Si-NP were provided from Nano-H SAS and prepared as previously described.[17] Briefly, gadolinium oxide (Gd_2O_3) nanoparticles embedded in a polysiloxane shell whose inner part is functionalized by Cy5 and outer part by carboxylic acid were synthesized as follows. In the first step, gadolinium oxide particles were obtained via precipitation at temperatures below 200 °C by applying a modified "polyol" synthesis.[18] In the second step, controlled polysiloxane shell growth was induced on the gadolinium nano-oxide cores (six silicium/one gadolinium) via hydrolysis/condensation of a mixture of TEOS and APTES. At this stage, Cy5 could be grafted inside the polysiloxane shell at the desired percentage by introducing the reaction product between Cy5 NHS ester with APTES in dry DMSO.[19] Finally, because of the presence of amine functions of APTES in the polysiloxane network, a postfunctionalization was carried out using DTPA-ba (via the formation of an amide linkage). Typically, a colloidal solution of hybrid nanoparticles in DEG (50 mL, [Gd] = 37 mM) was added into a suspension of DTPA-ba (4 equiv/Gd) in anhydrous DMSO (60 mL). The reaction mixture was stirred overnight at room temperature. Next, a mixture of acetone and diethyl ether (1:1, v:v) was poured into the reaction. A precipitate was formed, and a purification step was carried out via initial centrifugation at 6000 rpm for 5 min, and redispersion in ethanol and subsequent centrifugation (3-fold, 6000 rpm for 10 min). The nanoparticles were then redispersed in Milli-Q water at a high concentration. The colloidal solution was transferred into a Vivaspin 5000 Da, and ultrafiltration was performed. Finally, a freeze−drying protocol of Gado-6Si-NP was carried out.

NP Characterization. Direct measurements of particle size distribution were taken using the Zetasizer Nano S (Malvern Instruments, Malvern, U.K.). The hydrodynamic diameter of Gd_2O_3 core (in DEG) and Gado-6Si-NP (in water, pH = 7.4) was evaluated using photon correlation spectroscopy (PCS). Direct measurements of zeta potential of Gado-6Si-NP were performed using the Zetasizer Nano S (Malvern Instruments, Malvern, U.K.). Prior to the experiment, the solution was diluted in an aqueous solution containing 0.01 M NaCl and adjusted to the desired pH. Determination of the gadolinium content in a sample was performed using inductively coupled plasma-optical emission spectrometer (ICP-OES) analysis with a Varian 710-ES. Before measuring Gd concentration, samples of lyophilizat were redispersed in 10 mL Milli-Q water, and 1 mL of this colloidal solution was diluted in 14 M HNO_3 (1:1, v/v). After 30 min at 80 °C, the solution was diluted in HNO_3 (5%; 1:25, v/v). HRTEM was applied to obtain detailed structural and morphological information about the architecture of the core/shell. It was carried out using a JEOL 2010 microscope operating at 200 kV. Samples were prepared by diluting nanoparticle solution and depositing a drop on a copper grid coated by a thin film of amorphous carbon, allowing the liquid to dry in air at room temperature. Determination of the number of DTPA molecules per particle was calculated from the N/Gd ratio obtained by chemical analyses (ICP-OES and energy dispersive X-ray) taking into account the particle size.

Radiolabeling with Indium-111. For *in vivo* and quantitative biodistribution studies, hybrid gadolinium oxide nanoparticles were labeled using Indium-111 radionuclide (stability constant DTPA-In^{3+} close to 10^{29}).[29] Briefly, 370 MBq of high-purity ^{111}In-chloride (specific activity >185GBq/μg indium) in diluted hydrochloric acid (Covidien, Petten, The Netherlands) was added to 1 mL of a saline solution of hybrid nanoparticles ([Gd] = 100 mM]). Indium-111 links to the DTPA hydrophilic layer of the nanoparticles via coordination bonds.

The mixture was incubated for 30 min at room temperature. Gado-6Si-NP−^{111}In were separated from ^{111}In-chloride by PD-10 column (GE Healthcare Bio-Sciences AB, Uppsala, Sweden) as follows. The PD-10 column was first washed with 15 mL of 50 mM citrate buffer (pH = 5). The radiolabeling solution was then loaded on the PD-10 column, and fractions of 0.5 mL were eluted with 50 mM citrate buffer (pH = 5). Gado-6Si-NP−^{111}In were first eluted. The radioactivity of each fraction was counted using an ionization chamber (Capintec Radioisotope Calibrator CRC-15, Capintec Inc.). Finally, the four fractions with the highest radioactivity were pooled. The solution was then challenged with 200 μL of the complexing chelating agent diethylenetriaminepentaacetic acid (DTPA; 20 μmol) for 5 min to scavenge potential unbound ^{111}In. Another elution was performed on a PD-10 column using 50 mM citrate buffer (pH = 5) as eluent. The DTPA complex was eluted following Gado6Si-NP−^{111}In. Radiochemical purity was determined by instant thin layer chromatography (ITLC).

ITLC of the purified Gado-6Si-NP−^{111}In was performed using silica gel plates (Gelman Science Inc., Ann Arbor, MI, USA) in 50 mM citrate buffer (pH = 5) as the solvent, and a TLC scanner (MiniGita, Raytest, Isotopenmessgeräte, GmbH, Straubenhardt, Germany) in order to determine the percentage of free ^{111}In-chloride. Gado-6Si-NP−^{111}In remained at the origin, whereas residual ^{111}In-chloride migrated with an Rf of 0.8.

Stability of Gado-6Si-NP−^{111}In Nanoparticles. The purified Gado-6Si-NP−^{111}In were incubated in rat serum at 37 °C and 20 mM DTPA solution (pH = 7.4) for 4 h, 24 h, and 7 days. Radiochemical purity was determined as described previously.

Animals. All animal experiments were approved by the local animal ethics committee of University Claude Bernard Lyon 1, according to French legislation, and carried out in line with current guidelines. Adult male Wistar rats (200−250 g) and nude Swiss mice (20−25 g) were obtained from Charles River Laboratory (L'Arbresle, France). All animals were housed under standard environmental conditions (free access to food and water and a 12/12 h light/dark cycle), and acclimated for at least 48 h before experimentation.

For all experiments except scintigraphic and optical dynamic acquisition, a gaseous anesthesia protocol was applied using

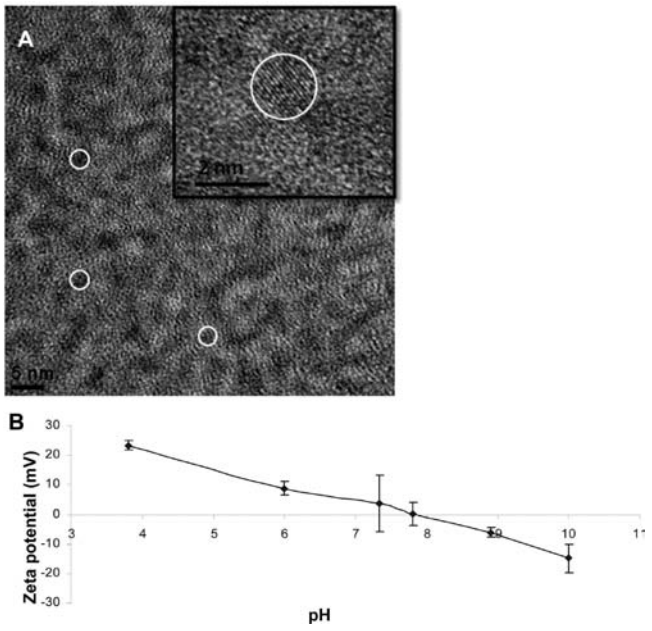

Figure 1. (A) HRTEM images of gadolinium oxide core nanoparticles representative of the whole sample. (B) Zeta potential of Gado-6Si-NP (n = 3).

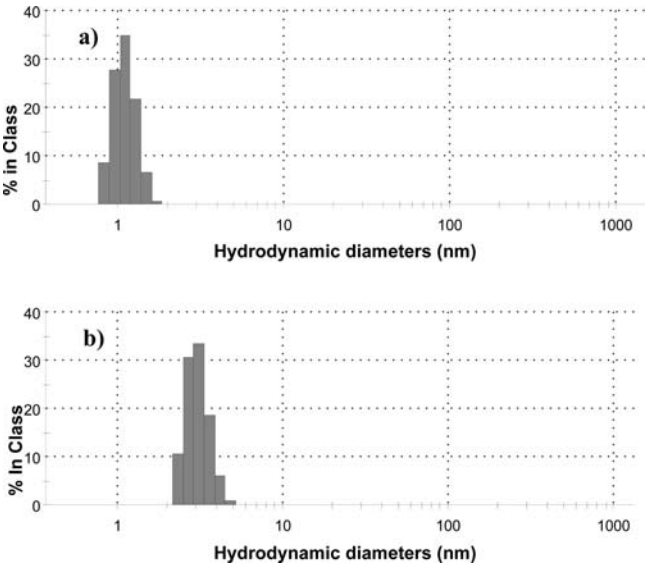

Figure 2. Size distribution determined by photon correlation spectroscopy (PCS) of gadolinium oxide core nanoparticles (a) and Gado-6Si-NP (b).

1−2% isoflurane (Laboratoire Bellamont, Boulogne Billancourt, France) in a mixture of O_2/N_2 (25/75%) at 0.8 L/min after an induction process. To avoid the absence of renal excretion by isoflurane gaseous anesthesia, scintigraphic and optical dynamic acquisition were performed immediately after chemical anesthesia (Ketamine1000, Virbac, Carros, France) at a dose of 0.15 mg per gram of body weight by IM injection, followed with medetomidine (Domitor, Orion Pharma, Espoo, Finland) at a dose of 0.5 (in rats) to 1 (in mice) μg per gram of body weight by IP. Anesthesia was monitored using a small animal respiratory monitoring system (Sa Instrument, Inc., NY, USA).

Biodistribution Study. Biodistribution of Gado-6Si-NP−^{111}In was studied in order to evaluate the potential of the multimodal nanohybrid agent. Radiolabeled nanoparticles in HEPES buffer containing 150 mM NaCl were injected intravenously through a caudal vein in rats after anesthesia had been administered. Rats were sacrificed at 2 h, 24 h, 72 h, 10 days, and 18 days postinjection, and organs of interest, such as the heart, lungs, spleen, liver, brain, kidneys, bones, muscles, skin, digestive tract, and cadaver were collected. Urine and feces were also collected each day and weighed and counted for 5 min in an automatic gamma scintillation counter (Wizard gamma counter, Perkin-Elmer, USA). Tissue distribution was expressed as the percentage injected dose per gram tissue (% ID/g) and as the percentage injected dose per organ (%ID/organ). The injected dose was calculated by adding activity of all organs, cadaver, and excretions (feces and urine). Renal and hepatobiliary eliminations were evaluated by measuring respectively urine and feces activities and expressed as cumulated radioactivity under total injected radioactivity.

Blood Circulation Half-Life of Radiolabeled Gado-6Si-NP. After IV injection of 10 MBq of Gado-6Si-NP−^{111}In in rats (n = 3), blood samples were removed at suitable time intervals (5 min, 10 min, 20 min, 30 min, 60 min, 120 min, and 240 min). Samples were weighed and counted for 5 min in an automatic gamma scintillation counter. Data points were fit to an exponential decay function to determine blood circulation half-life.

Imaging Studies. *Dynamic Scintigraphy and SPECT.* Acquisitions were obtained using a small animal Nano-SPECT/CT system (Bioscan, Washington, DC, USA). This system consists of four detectors (215 × 230 mm^2 NaI, 33 PMTs) equipped with interchangeable multipinhole apertures. Dynamic and SPECT/CT acquisitions were performed after IV injection of Gado-6Si-NP−^{111}In in 17 rats. Double phase (12 × 10 s images and 116 × 30 s images) dynamic acquisition was initiated immediately following the IV injection of Gado-6Si-NP−^{111}In in rats in supine position placed directly on the planar low-energy ultrahigh-resolution collimator set in order to verify the quality of the injection and analyze early organ nanoparticle uptake. X-ray CT (tube voltage of 55 kVp, exposure time of 500 ms, and 180 projections) and SPECT acquisitions were performed in rats in a supine position, placed in a temperature-controlled bed (Minerve, Esternay, France), in order to maintain body temperature (set to 37 °C). Afterward, the SPECT (20 000 cps per projection/20 projections) were acquired using a rat whole-body high-resolution aperture.

All image data was reconstructed and analyzed using InVivoScope (Bioscan, Washington, DC, USA).

In Vivo and Ex Vivo Optical Imaging. Fluorescence images as well as black and white pictures were acquired via a back-thinned CCD-cooled camera (ORCAIIBT-512G, Hamamatsu phonics, Massy, France) using a colored glass long-pass RG 665 filter (Melles Griot, Voisins les Bretonneaux, France), which cuts off all excitation light. Ventral, dorsal, and lateral views were acquired prior to Gado-6Si-NP injection in order to estimate the self-fluorescence level. Immediately after direct IV injection of 50 μL of Gado-6Si-NP in HEPES buffer containing 150 mM NaCl ([Gd] = 100 mM) in two nude Swiss mice under chemical anesthesia, a set of 2 s ventral (in one mouse) or dorsal (in the another mouse) images was acquired over 60 min. Ventral, dorsal, and lateral static views were then obtained using the parameters applied prior to injection. Euthanasia was performed 2 h after injection, and the liver, kidneys, brain, spleen, lungs, heart, skin, muscle, bone, and intestine were

[a] Data are expressed as percentage injected dose per gram of tissue (%ID/organ, mean ± standard deviation).

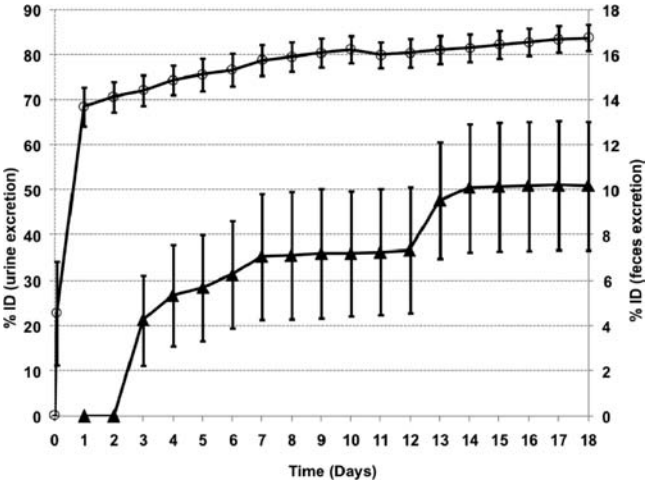

Figure 3. Elimination of Gado-6Si-NP—^{111}In after IV injection in Wistar rats. Values are expressed as percentage of cumulative activity measured in urine (circle) and feces (triangle) per injected dose (%ID). Data was expressed as mean ± standard deviation.

then collected in order to be imaged and compared with the same *ex vivo* organs of noninjected mice.

In Vivo MR Imaging. Two positioned supine Wistar rats were imaged using a 7-T system (Biospec; Bruker, Ettlingen, Germany) equipped with a 400 mT/m gradient under gaseous anesthesia. Three direction localizers were first used to localize kidneys, liver, and bladder. The imaging protocol consisted of a dynamic series of two coronal slices centered on the kidneys, bladder, and liver, and obtained using a T1-weighed MSME sequence (180° flip angle, 118/10.6 [repetition time ms/echo time msec], 3 mm section thickness, 100 mm field of view, 256−256 matrix, and 16.6kHz bandwidth) and respiratory triggered (Rapid Biomedical GmbH, Rimpor, Germany). Acquisition was initiated, and during the fourth repetition, bolus IV injection of 50 μL of Gado-6Si-NP in HEPES buffer containing 150 mM NaCl ([Gd] = 100 mM) was performed. Duration of each repetition was approximately 3 min. Rat body temperature was regulated at 37 °C. Positive enhancement of the signal (EHC) in each tissue was calculated as $(S_t - S_0)/S_0$, where S_t was the signal intensity value measured at each time after injection, and S_0 the signal value prior to injection.

RESULTS

NP Characterization. The nanoparticles used are core−shell particles with a core of gadolinium oxide. Gadolinium content was estimated to approximately 16% per particle. According to HRTEM (Figure 1), this core was well-crystallized with a bcc structure belonging to the *Ia*3 space group and with a size between 1.4 and 2 nm. This size is in line with the hydrodynamic diameter measured for the noncoated particles (Figure 2), of 1.2 ± 0.3 nm. After the hydrolysis−condensation, functionalization steps leading to the growth of a polysiloxane shell were evidenced by TEM and chemical analysis (EDX), and correlated with hydrodynamic diameter measured by DLS as 3.8 ± 0.1 nm (Figure 2). As previously stated, organic fluorophores conjugated to APTES were included during this coating step. This confers fluorescence properties to the hybrid gadolinium oxide nanoparticles.[20] Zeta potential measurements of Gado-6Si-NP in the pH range from 4 to 10 are shown in Figure 1. The iso-electric point was evaluated at pH 7−8.

Radiolabeling of Nanoparticles with ^{111}In. Gado-6Si-NP nanoparticles were labeled with $^{111}InCl_3$ in citrate buffer at pH 5. Nonspecifically bound ^{111}In was removed from Gado-6SiNP—^{111}In by adding excess DTPA, followed by a purification step using a PD-10 column. Nevertheless, a very small amount of radioactivity was separated from the nanoparticles by DTPA, indicating efficient and stable labeling. Following purification, radiochemical purity exceeded 99%. Radiochemical yield was 35 ± 3% (n = 10).

Solution Stability. Negligible radioactivity was lost from Gado-6Si-NP—^{111}In nanoparticles after 4 h incubation in both solutions. After 24 h and 7 days incubation, radiochemical purity was greater than 93% and 91%, respectively. This indicated that Gado-6Si-NP—^{111}In remained stable for at least 7 days in rat serum or aqueous 20 mM DTPA solutions.

Biodistribution Studies. When injecting a nontargeted nanoparticle using IV administration, optimal biodistribution should show dominant renal elimination, associated with the absence of reticulo-endothelial system uptake and the absence of significant uptake in other tissues.

Quantitative tissue distribution was performed over 18 days at 5 intervals (2 h, 24 h, 72 h, 10 days, and 18 days) following IV injection in order to evaluate the biodistribution of Gado-6Si-NP labeled with indium 111. Tissue distribution of Gado-6Si-NP expressed as the percentage injected dose per gram tissue as well as the percentage injected dose per organ are presented in

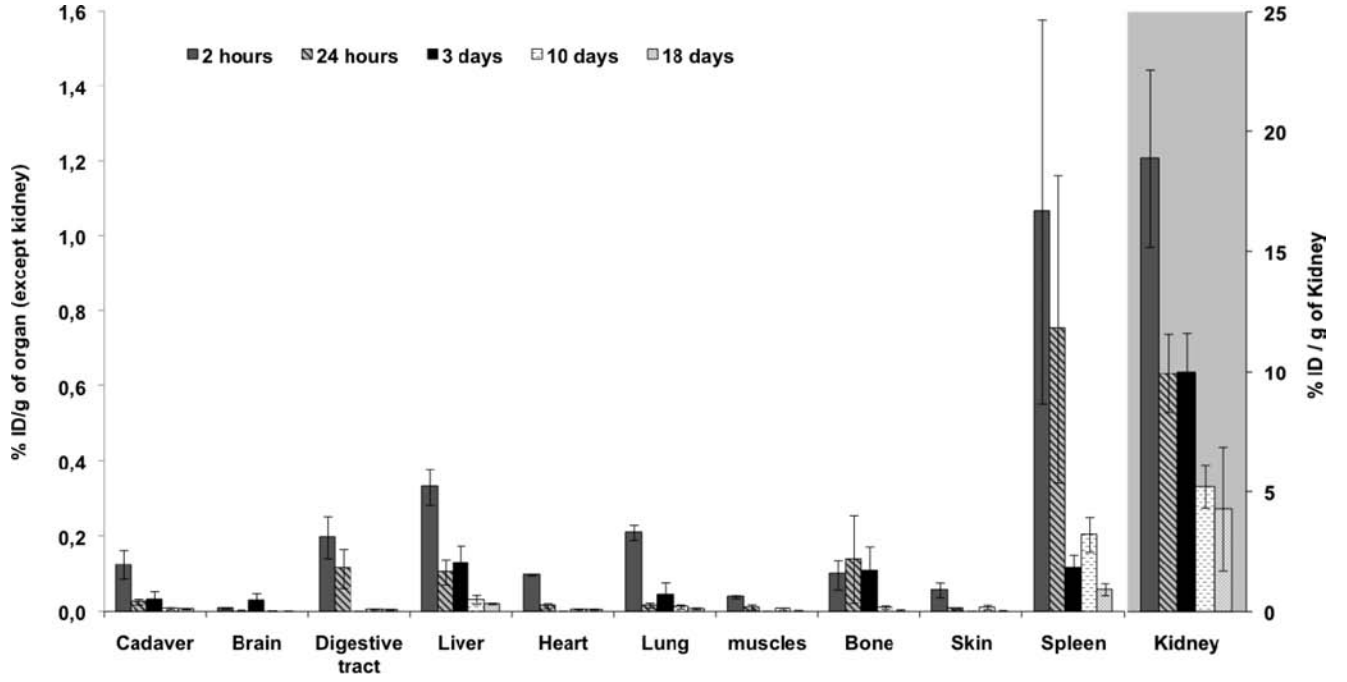

Figure 4. Biodistribution of Gado-6Si-NP—^{111}In in Wistar rats. Group of rats (n = 3 except at days 3 and 18, n = 4) were sacrificed at 2 h, 1 day, 3 days, 10 days, and 18 days after injection, and selected organs were sampled and measured for ^{111}In activity. Left axis: data is expressed as percent injected dose per gram of tissue (%ID/g). Right axis: data is expressed as percent injected dose per gram of kidney (shaded area).

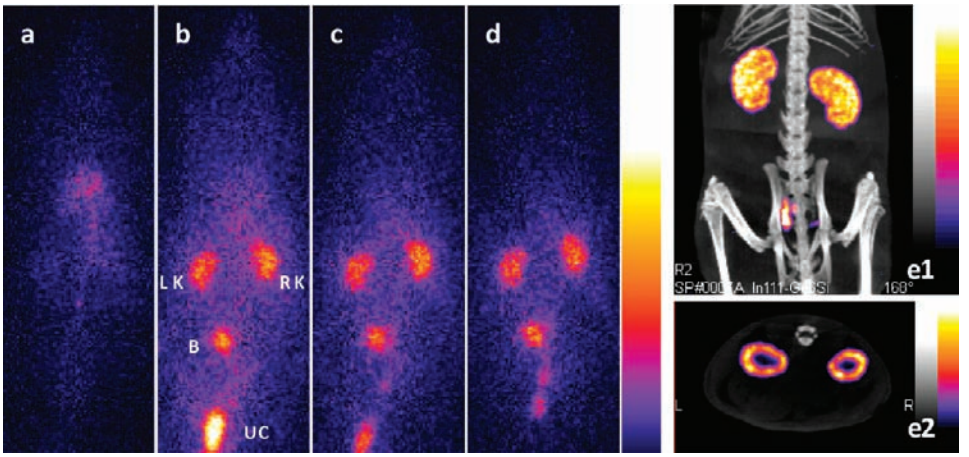

Figure 5. SPECT/CT *in vivo* imaging in Wistar rats. Planar sequential scintigraphic images acquired (a) during IV injection of 25 MBq of Gado-6Si-NP—^{111}In, (b) 15 min, (c) 30 min, and (d) 60 min after injection. Tomographic scintigraphy and X-ray CT of the whole body of the rat acquired at day 2, posterior projection (e1) and transversal slice (e2). LK: left kidney; RK: right kidney; B: bladder. UC: urine collector.

Figure 4 and Table 1. High levels of radioactivity were quickly observed in the kidneys after IV administration (35.2%ID/organ at 2 h), and were reduced from 18.6% at 3 days to 3.9% at 18 days. The blood circulation half-life of labeled Gado-6Si-NP was evaluated at 42 ± 3 min. Renal and liver excretion of Gado-6Si-NP were evaluated by measuring urine and feces activity, and expressed as cumulated radioactivity under total injected radioactivity (Figure 3). Gado-6Si-NP were dominantly and rapidly eliminated through renal excretion with 67 ± 4%ID and 84 ± 3% ID, compared to liver excretion with 4 ± 2%ID and 10 ± 3%ID after 1 day and 18 days, respectively, as demonstrated by the quantitative biodistribution study. Similar results were observed in scintigraphic imaging (Figure 5), MR imaging (Figure 6), and optical imaging (Figure 7), where injection signal increased rapidly in the kidneys, with initial increase in the cortex, followed by an increase in the pelvis and then the bladder. MRI dynamic acquisition (Figure 6) evidenced a moderately increased EHC signal (38% at 39 min) in the area of the liver, but this was not due to RES uptake, as no significant Gado-6Si-NP accumulation has been observed in the quantitative biodistribution analysis. This increase seems to be related to liver elimination of the Gado-6Si-NP, as radioactivity was found in the feces at later time points. The absence of Gado-6Si-NP accumulation in the liver, as well as in the spleen, lung, and bones (medulla) supported the absence of RES uptake (Table 1). This finding was confirmed using scintigraphic and optical imaging, where no significant signal was

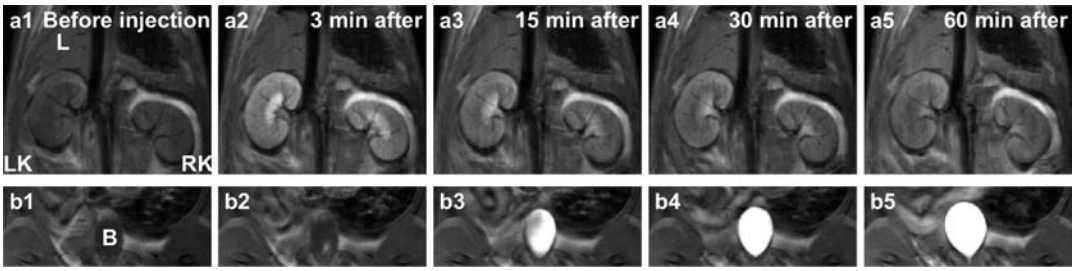

Figure 6. T1w.seq. coronal images acquired before and at 3, 15, 30, and 60 min after IV injection of 50 μL of Gado-6Si-NP, centered on kidneys (a) and bladder (b).

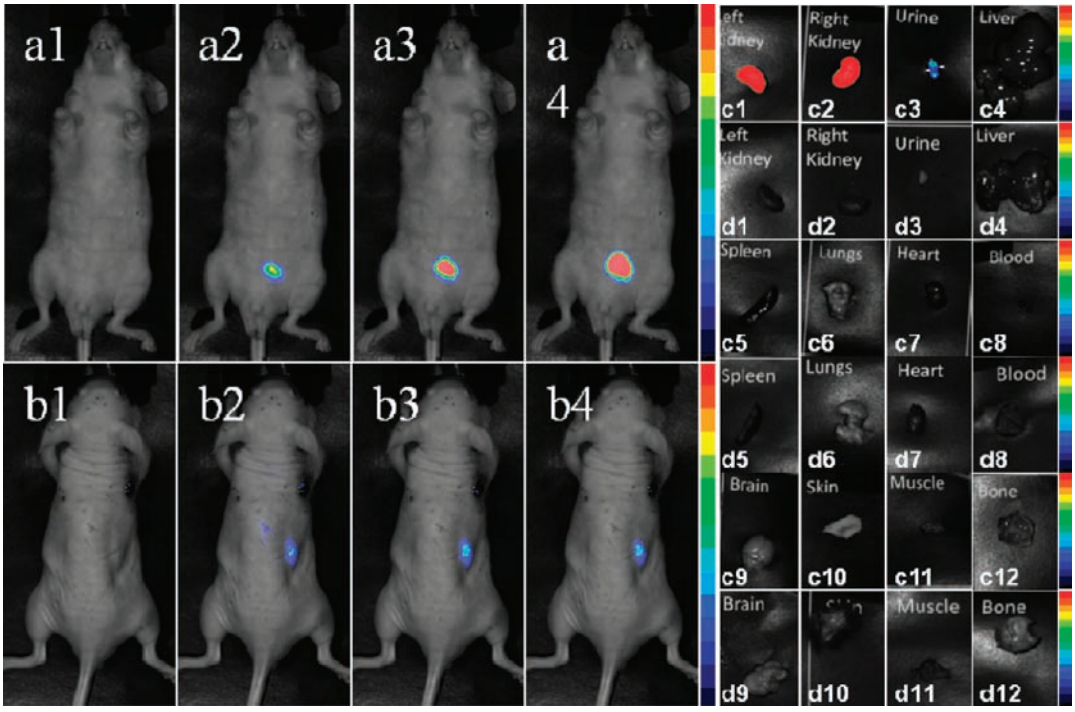

Figure 7. Ventral (a1,2,3,4) and dorsal (b1,2,3,4) planar fluorescence reflectance images acquired at the end of IV injection of Gado-6Si-NP (a1, b1), at 15 min (a2, b2), 30 min (a3, b3), and 60 min (a4, b4) postinjection. c 1 to 12: Fluorescence reflectance imaging of major organs after dissection of a nude mouse. Dissection was performed 2 h after IV injection of Gado-6Si-NP. d 1 to 12: Fluorescence reflectance imaging of some organs after dissection of a control nude mouse. Each image was acquired with an exposure time of 2 s.

seen in spleen, lung, and bones as shown in Figures 5 and 7. Finally, our study demonstrated the absence of brain uptake.

DISCUSSION

Quantitative *in vivo* biodistribution has shown that multimodal Gado-6Si-NP display excellent properties as contrast agents, with excellent renal filtration, and can be detected using different imaging modalities such as optical (fluorescence), MR, or isotopic (SPECT) imaging. This was an important step, as it is essential in determining the biodistribution and clearance of nanoparticles that may be used for imaging and theragnostic applications prior to their clinical use. Such a long-term quantitative distribution of silica nanoparticles has not yet been extensively reported.[21]

Overall, radiolabeling nanoparticles allows for whole-body imaging with high sensitivity and quantitative *ex vivo* biodistribution, which is considered to be a robust and reliable method for evaluating the *in vivo* behavior of a nanoprobe.[22] Nevertheless, the stability of the radiolabeling should be carefully controlled *in vitro* and *in vivo,* in order to ensure the accurate evaluation of *in vivo* biodistribution. No significant release of Indium 111 has been observed *in vivo,* as no significant bone uptake was measured, taking into account that trivalent radiometals such as indium are known to be taken up by bones[23] indicating an *in vivo* stability of the radiolabeling. Stability of the radiolabeling was also confirmed *in vitro*; due to their multimodal properties, it was possible to compare the biodistribution obtained using three different modalities in order to confirm the efficiency and stability of radiolabeling. In our study, indium 111 with a half-life of 2.8 days was used for this long-term biodistribution quantitative analysis over 18 days. Other radioisotopes could have been used to complex DTPA, such as technetium 99m (half-life: 6 h) or PET emitter gallium 68 (half-life: 1.13 h). However, due to their short half-lives, they were not suitable for long-term biodistribution assessment.

Biodistribution and clearance of nanoparticles depend on their chemical and biochemical properties such as size, surface functionality, and charge. In general, it is well-established that nanoparticles are taken up by the RES system following IV administration, leading to the clearance of nanoparticles from systemic circulation.[24]

In this study, a high rate of renal elimination of Gado-6Si-NP following IV injection was evidenced with more than 95% of Gado-6Si-NP eliminated 18 days after injection. Our γ-counting data revealed that Gado-6Si-NP showed minimal particle retention in major organs (especially RES tissue), and the major route of elimination was renal excretion (Table 1), which is consistent with results obtained from optical imaging, where the fluorescence signal could be observed in the urinary bladder and kidneys. This is attributed to the presence of hydrophilic molecules (DTPA), which functionalize these hybrid gadolinium oxide nanoparticles, as generally observed for other PEG-capped nanoparticles.[25−27] The derivatization of Gado-6Si-NP noticeably decreased liver retention and increased renal filtration into the bladder, whereas underivatized nanoparticles frequently accumulated in the liver and spleen.[17] This demonstrates that biodistribution and pharmacokinetics of Gado-6Si-NP were well-controlled. No significant Gado-6Si-NP accumulation was observed in lungs (Table 1). This result demonstrated that hydrophilic carboxylic DTPA coating prevents Gado-6Si-NP aggregation under *in vitro* and *in vivo* conditions, as usually observed with PEG coating.[28] Moreover, hydrodynamic particle size is known to be a key factor in the biodistribution of long-circulating nanoparticles,[16,29,30] and large nanoparticles tend to accumulate in the liver.[31] Burns et al.[15] have shown that the optimal probe size to obtain a reasonable circulation lifetime and efficient clearance is between 3 and 7 nm in hydrodynamic diameter, as the capillary pore diameter is estimated to be around 5 μm. The small size of these Gado-6Si-NP nanoparticles (mean diameter 3−4 nm) reduced plasma protein adsorption, opsonization, and hepatic filtration. Gado-6Si-NP can be effectively cleared out by renal excretion with more than 75%ID eliminated after 48 h, which is consistent with similar-sized probes.[13,14,32] Finally, another very interesting finding was the absence of significant uptake in any other tissues.

Since these nanoparticles are multimodal, they can be used with different imaging modalities, each modality having its own advantages and drawbacks.[33] MRI produces excellent spatial resolution, though sensitivity and specificity are critical issues. Optical imaging provides good sensitivity, but penetration of near-infrared light in tissues is limited to a few centimeters[34] with a high autofluorescence background, and with limited abilities to provide quantitative biodistribution *in vivo*. Isotopic imaging displays excellent sensitivity but low spatial resolution. Interests in multimodality imaging are numerous and offer many opportunities as multimodality imaging provides complementary information that cannot be discerned easily from one type of image modality alone, combining the benefits of each modality. The presence of gadolinium ions inside the organic shell, which is one the most efficient contrast agents for MRI, provides a strong positive contrast and allows for high-resolution soft tissue images *in vivo* (Figure 6), as predicted in a previous publication.[17]

In addition to imaging, the presence of gadolinium (atomic number $Z = 64$), which has a huge neutron capture cross section, provides opportunities for radiosensitization mainly based on the action of Auger electrons and γ-rays generated by ^{155,157}Gd after neutron capture.[35] Due to the high number of gadolinium ions per particle (about 40), irradiation of these hybrid gadolinium oxide nanoparticles has been shown to generate an *in vitro* cytotoxic effect.[36]

Finally, these nanoparticles exhibit multiple DTPA molecules (about 160 per particle) and can be functionalized with a large number of ligands, increasing the affinity to their biological target. The theragnostic approach of these nanoparticles, guided by multimodal imaging, allows us to envisage their application in oncology. Targeting these nanoparticles is currently being researched.

CONCLUSION

This study reports the *in vivo* biodistribution of hybrid gadolinium oxide nanoparticles using different imaging modalities and γ *ex vivo* counting. The biodistribution of these nanohybrid agents by MRI, optical and radionuclide, demonstrates that Gado-6Si-NP circulate freely in the blood pool, without RES uptake, and are eliminated by renal excretion. The understanding of the biodistribution and pharmacokinetics of nanoparticles is a key factor in the process of successfully developing new multimodal agents. Multimodal and quantitative biodistribution of this new category of nanoparticles shows promising properties that may enable us to develop them as targeted or nontargeted contrast media or therapeutic agents.

Linear Cationic Click Polymers/DNA Nanoparticles: In Vitro Structure−Activity Relationship and In Vivo Evaluation for Gene Delivery

Yu Gao, Qi Yin, Lingli Chen, Zhiwen Zhang, and Yaping Li*

Center of Pharmaceutics, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai 201203, China

Supporting Information

ABSTRACT: The aim of this work was to explore the structure−activity relationships (SAR) of a series of novel linear cationic click polymers with various structures for in vitro gene delivery and in vivo gene transfer. The experimental results revealed that the minimal structure variation could result in a crucial effect on DNA-binding ability, buffering capacity, and the cellular delivery capacity of polymer, all of which brought about the obvious effects on their transfection efficiencies. The polymer synthesized from diazide monomer containing bis-ethylenediamine unit and dialykene monomer containing bis-ethylene glycol unit (B_2) could effectively condense DNA into complex nanoparticles (B_2Ns), which showed the highest in vitro transfection efficiency. The biodistribution and transfection efficiency of B_2Ns in nude mice bearing tumor demonstrated the ability of effectively delivering DNA into tumor tissue. These results implied that this gene vector based on linear cationic click polymer could be a promising gene delivery system for tumor gene therapy.

INTRODUCTION

One of the hurdles to successful application of gene therapy is the development of a safe and efficient gene vector.[1,2] Nonviral vectors, in particular, cationic polymers, have received increasing attention due to easy manufacturing and low immunogenicity, which are commonly associated with the viral vectors.[3,4] However, nonviral vectors show less efficacy than viral vectors because of a lack of adequate function to overcome the intracellular barriers for efficient gene delivery.

Recently, many strategies have been undertaken in polymer science to realize the full potential of gene therapy. The modification of the existing polymers with functional groups such as imidazoles or targeting ligands to overcome the entry-based barriers is an effective tool to improve transfection efficiency.[5−7] Synthesis of biodegradable polycations containing a hydrolyzable ester bond or enzyme-degradable amide bond is one of the potential means to reduce the intrinsic toxicities of polymers.[8−10] The use of low molecular weight polymers, which can be eliminated via the kidney, is also a logical choice to increase safety.[11] However, there are still many problems in the existing cationic polymers, and the ideal polymers for gene transfer have not been found yet. Thus, the rational design of the biocompatible polymers that are well-defined and chemically tailored for clinical application of gene therapy remains a significant challenge.

Cationic polymers mediate gene transfer via condensing genes into nanometer-scale structure small enough to enter cells via endocytosis and intracellular trafficking of the genes.[12] Several recent reports have revealed that the related cationic polymers with small structural changes could result in a significant difference in transfection efficiency.[13−15] Polyplexes from poly(aspartamide) bearing two different side chains with one methylene variation showed completely different transfection and cytotoxicity profiles.[13] Altering the hydroxyl number and stereochemistry by the carbohydrate moieties in poly(glycoamidoamine)s resulted in dissimilar gene expression profiles.[14] Therefore, parallel synthesis and study on the structure−activity relationships (SAR) could be a powerful approach for the rapid identification of novel polymers for efficient gene delivery.[16,17]

The copper-catalyzed azide−alkyne cycloaddition has emerged as a unique ligation method combining selective reactivity and easy manufacturing,[18,19] and is used in a variety of polymer syntheses including the linear polymer, in which the azide- or alkyne-functionalized monomers could be easily tailored to form the different copolymers with different chemical and biological properties.[20,21] The amide−triazole moiety, which was formed during polymerization, could be an H-bond acceptor and increase the hydrophobic interactions of the polymer with DNA, thus improving the polymer−DNA binding stability.[22] Therefore, we

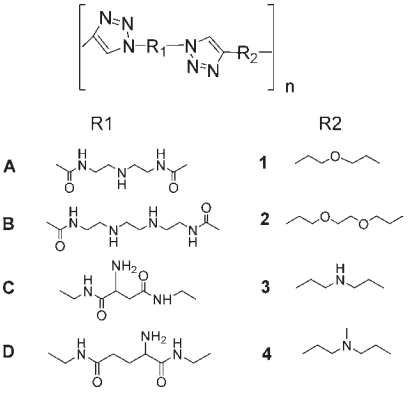
could take advantage of the characteristics of click polymerization to develop a gene delivery system based on linear cationic click polymers (CPs). The amide−triazole moiety in the CP backbone could promote the strong polymer−DNA complexation and increase the serum stability of complexes. With the azide- or alkyne-functionalized monomers varied, the differences in efficacy between two polymers could be easily investigated to find out how the structural units affected the characteristics of the polymers or which structural unit played a key role during gene transfer. Consequently, the polymers that were designed to be nontoxic and effective could be found through the SAR study.

In our previous work, a series of novel linear CPs were designed and synthesized with various structural changes including the type of charge groups, the number of methylene or ethylene glycol groups, and the distance between charge groups, and the biocompatibility of CPs were evaluated.[23] From study based on the structure-biocompatibility relationships, we chose two CPs with good biocompatibility to preliminarily evaluate their in vitro transfection efficiency. The two CPs showed in vitro effective gene transfection, which indicated that CPs could be promising gene carriers and inspired us to investigate the behaviors of these CPs during gene transfer further. In this work, we aimed to explore the in vitro SAR of these click polymers and in vivo gene transfer. We examined the DNA-binding efficiency, buffering capacity, cellular uptake of DNA, and in vitro transfection efficiency of these polymers and tried to find out how the structural units affected the characteristics of the polymers, and which structural unit played a key role during gene transfer. Finally, a candidate polymer from the SAR was selected for the investigation of in vivo gene transfer.



EXPERIMENTAL PROCEDURES

Materials. Trypsin-EDTA, phosphate buffered saline (PBS), and agarose were obtained from Gibco-BRL (Burlington, ON, Canada). The Dulbecco's modified Eagle medium (DMEM), RPMI 1640 medium, antibiotics, DNA loading buffer, and fetal bovine serum (FBS) were purchased from Invitrogen GmbH (Karlsruhe, Germany). YOYO-1 was purchased from Molecular Probes (Eugene, OR, USA). Ethidium bromide, trypan blue, and branched polyethylenimine (PEI, 25 kDa) were purchased from Sigma (St. Louis, MO, USA). Sixteen click polymers were synthesized using "click chemistry" and named $\mathbf{A_1}$−$\mathbf{A_4}$, $\mathbf{B_1}$−$\mathbf{B_4}$, $\mathbf{C_1}$−$\mathbf{C_4}$, and $\mathbf{D_1}$−$\mathbf{D_4}$ as described in our previous work (Scheme 1).[23] All other chemicals and solvents if not mentioned were of analytical grade and used as received without additional purification.

Plasmid EGFP-N1 (4.7 kb) encoding enhanced green fluorescent protein driven by immediate early promoter of CMV was purchased from Clontech (Palo Alto, CA, USA), and plasmid DNA containing random sequences was used as negative control (neg-DNA). pGL3-control vector was purchased from Promega (Madison, WI, USA). The plasmid DNA (pDNA) grown in DH5α strain of *E. coli* was isolated with the EndFree Plasmid Mega Kit (Qiagen GmbH, Hilden, Germany). The purity was confirmed by spectrophotometry (A260/A280), and DNA concentration was measured by UV absorption at 260 nm.

Cell Cultures. The cell lines HEK 293 (human embryonic kidney cell) and MDA-MB-468 (human breast cancer cell) cells were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). HEK 293 cells were grown in DMEM containing 10% fetal bovine serum (FBS), 100 U/mL penicillin G sodium, and 100 μg/mL streptomycin sulfate. MDA-MB-468 cells were cultured in RPMI 1640 medium supplemented with 10% FBS and 1% antibiotics (100 U/mL penicillin G and 0.1 mg/mL streptomycin). Cells were maintained at 37 °C in a humidified and 5% CO_2 incubator.

Scheme 1. Cationic Click Polymers Used in This Study

Animals. BALB/c nude mice (18−20 g, 6 weeks old) were purchased from Shanghai Experimental Animal Center (Shanghai). All animal procedures were performed according to the protocol approved by the Institutional Animal Care and Use Committee at the Shanghai Institute of Materia Medica, Chinese Academy of Sciences.

Preparation and Characteristics of CP/DNA Complex Nanoparticles (CPNs). CPNs were prepared by the following procedures: briefly, pDNA (100 μg/mL) dissolved in sterile water was added to the CP solution diluted in sterile water with equal volume to obtain the desired polymer-amine to DNA-phosphate ratio (N/P ratio). Subsequently, solution was immediately vortexed for 30 s (XW-80A Votex mixer, Shanghai). The complex nanoparticles were allowed to sit at room temperature for 30 min. As positive control, PEI 25K/DNA complex nanoparticles (PEINs) were prepared with the same procedure as CPNs.

The particle size and zeta potential of CPNs were determined by the laser light scattering measurement using a Nicomp 380/ZLS zeta potential analyzer (Particle Sizing System, USA). The CPNs were prepared as described above, and the size measurement was performed at 25 °C at a 90° scattering angle and recorded for 300 s for each measurement.

The formation of CPNs was evaluated by agarose gel electrophoresis. After the DNA loading buffer was added to CPNs, CPNs containing 0.1 μg DNA at various N/P ratios were applied to a 1.0% agarose gel in Tris-acetate-EDTA (TAE) buffer containing 0.5 μg/mL ethidium bromide. Electrophoresis was carried out at 80 V for 45 min in TAE buffer. The resulting DNA migration pattern was revealed under UV irradiation.

Acid−Base Titration. The buffer capacity of CP was determined by acid−base titration assay over the pH values ranging from 10 to 2 as described previously.[24] Each CP was dissolved in 150 mM NaCl solution at an amino group concentration of 5 mM. The pH of the polymer solution was raised to 10 using 1 M NaOH. The resulting solution was then incrementally titrated with 0.1 M HCl. The pH of the solution was monitored with a Sartorius PB-10 pH meter. The experiment was performed at room temperature, each data point was collected at about 5 min after addition of the acid, and the time interval was the same

for all the samples. The pH profile was obtained for each polymer, and graphs of the data were generated accordingly.

Cellular Uptake Experiment. MDA-MB-468 cells were seeded in a 24-well plate with 0.5 mL growth medium and allowed to attach for 24 h. Nanoparticles were prepared at N/P ratio 32 for CPs with YOYO-1-labeled DNA concentration of 50 μg/mL. The DNA/YOYO-1 complex was prepared with 1 nM dye molecule/μg DNA and incubated 1 h at room temperature in the dark. The cells were then incubated with CPNs (DNA concentration 2.5 μg/well) in complete growth medium for 2 h at 37 °C followed by washing three times with PBS (pH 7.4), then trypsinized and resuspended in the medium. The residual fluorescence out of the cell membrane was quenched with 0.4% trypan blue for 2 min.[25] Then, cells were centrifuged and washed three times with PBS. The cell resuspension was finally subjected to flow cytometry (FACSCalibur, Becton Dickinson, USA) and analyzed with *CellQuest* software through fluorescence channel 1 (FL1).

Observation of Intracellular Distribution of CPNs. MDA-MB-468 cells were seeded on 35 mm glass-based dishes with 0.5 mL growth medium and allowed to attach for 24 h. After incubation with CPNs (N/P ratio 32, DNA concentration 2.5 μg/well) for 2 h at 37 °C, the medium was removed, and the cells were washed three times with PBS. The intracellular distribution of CPNs was observed by confocal laser scanning microscopy (CLSM) after staining lysosomes with LysoTracker Red (Molecular Probes, Eugene, OR, USA) and nuclei with Hoechst 33342 (Sigma, USA). The CLSM observation was performed using Leica TCS SP2 confocal spectral microscope (Leica Microsystems, Germany) with a 63× objective (Leica, Wetzlar, Germany) at excitation wavelengths of 633 nm (He−Ne laser), 488 nm (Ar laser), and 351 nm (UV laser) for LysoTracker Red (red), YOYO-1 (green), and Hoechst 33342 (blue), respectively.

In Vitro Transfection Experiment. Cells (HEK 293 and MDA-MB-468) were seeded in 24-well plates at a density of 1×10^5 cells per well in 500 μL of complete medium and incubated for 24 h prior to transfection. Then, the media were replaced with fresh complete growth medium containing CPNs with DNA concentration 2.5 μg/well at various N/P ratios. Media were replaced by fresh culture medium after 24 h, and cells were incubated for an additional 24 h. The expressed green protein could be observed under a fluorescence microscope. Finally, cells were collected and resuspended in PBS (pH 7.4). The transfection results were measured using a FACSCalibur through FL1 and the percentage of cells which expressed EGFP was counted (Supporting Information Figure S1). As control, naked DNA and click polymers/neg-DNA complex nanoparticles were used on cell cultures and examined as described above. As positive control, PEINs with mass ratio of 3 were prepared and transfected with media without FBS for 2 h before the medium was replaced with fresh complete growth medium.

In Vivo Biodistribution and Transfection Efficiency. For biodistribution study, female nude mice were inoculated with 100 μL of phosphate buffered saline (pH 7.4) containing 1×10^6 MDA-MB-468 cells by subcutaneous injection in the left flank. Tumors were allowed to grow to a volume of 200−300 mm^3. For qualitative evaluation, B_2/DNA nanoparticles (B_2Ns) with pDNA labeled by the cell-impermeable fluoresecnt dye YOYO-1 at N/P ratio 32 was injected into mice bearing breast tumor via the tail vein at a dose of 2 mg/kg. Mice were sacrificed at different time intervals after injection (n = 4 at each time point), and the principal organs were isolated. The extracted tissues were homogenized with lysis buffer (Promega, Madison, WI, USA), and the samples were centrifuged at 10 000 rpm for 5 min. The supernatant was measured using a microplate reader (Infinite F200, TECAN, Austria) with an excitation at 485 nm and exmission at 520 nm. The data were normalized to the tissue weight.

For in vivo transfection efficiency, female nude mice were inoculated with 100 μL of phosphate buffered saline (pH 7.4) containing 1×10^6 MDA-MB-468 cells by subcutaneous injection in the left flank. Experiments were performed at day 10 after inoculation when the tumor volume reached approximately 100 mm^3. For quantitative evaluation, B_2Ns formed with pGL3-contral vector at N/P ratio 32 were injected into the mice bearing breast tumor via the tail vein at a dose of 2 mg/kg in a 200 μL injection volume. For comparison, PEINs at mass ratio 1 were intravenously injected at the same DNA dosage. Animals were killed 48 h after i.v. injection, and the tissues were isolated. The organs were washed with cold saline and then homogenized with 1 mL lysis buffer using a tissue homogenizer. The homogenate was centrifuged at 15 000 × g for 15 min, and the luciferase activity was quantified by Luciferase Assay System using a chemiluminometer (NOVOSTAR, German). Relative light units (RLU) were measured for 5 s at room temperature, and the transfection efficiency was expressed as RLU/g tissue.

Statistical Analysis. Statistical analysis was performed using a Student's t-test. The differences were considered significant for p value < 0.05 and p < 0.01 indicative of a very significant difference.

RESULTS AND DISCUSSION

Buffering Capacity of CPs. It was assumed that the buffering capacity of cationic polymers like PEI could facilitate the endosomal escape of polyplexes by so-called "proton sponge effect". This capacity was a relevant physicochemical parameter in the transfection efficiency of the cationic polymer.[24,26] In order to understand the relationship between polymer buffering capacity and polymer structure, and how the buffering capacity affected the transfection efficiency of polymer, the acid−base titration experiment was performed to estimate the buffering capacity of CPs (Figure 1). The titration was monitored over the range of pH 10−2.0 in 150 mM NaCl solution to mimic the physiological condition.

It was expected that the presence of different amino groups with different pK_a would increase the buffer capacity of polymer. However, the titration curves did not show such trends. The flat slope in pH 5−7 which was relevant to the overall gene transfection process indicated the higher buffer capacity of CPs containing only one type of amine than that of CPs with two types of amine. $\mathbf{C_1}$, $\mathbf{C_2}$, $\mathbf{D_1}$, or $\mathbf{D_2}$ showed some buffering capacity in pH 5−7 (Figure 1C,D). When tertiary amine or secondary amine was added to CP, the buffering capacity of $\mathbf{C_3}$, $\mathbf{C_4}$, $\mathbf{D_3}$, or $\mathbf{D_4}$ decreased significantly, which was also found in polymers $\mathbf{A_4}$ and $\mathbf{B_4}$. $\mathbf{C_4}$ and $\mathbf{D_4}$ showed higher buffering capacity than $\mathbf{C_3}$ and $\mathbf{D_3}$, respectively, which demonstrated that CPs containing primary amine and tertiary amine had higher buffering capacity than polymers with primary amine and secondary amine (Figure 1C,D). $\mathbf{A_4}$ and $\mathbf{B_4}$ showed obviously low buffering capacity, which indicated that polymers containing both secondary amine and tertiary amine had weak ability in accepting hydrogen ions. From the above-mentioned, it was found that the different types

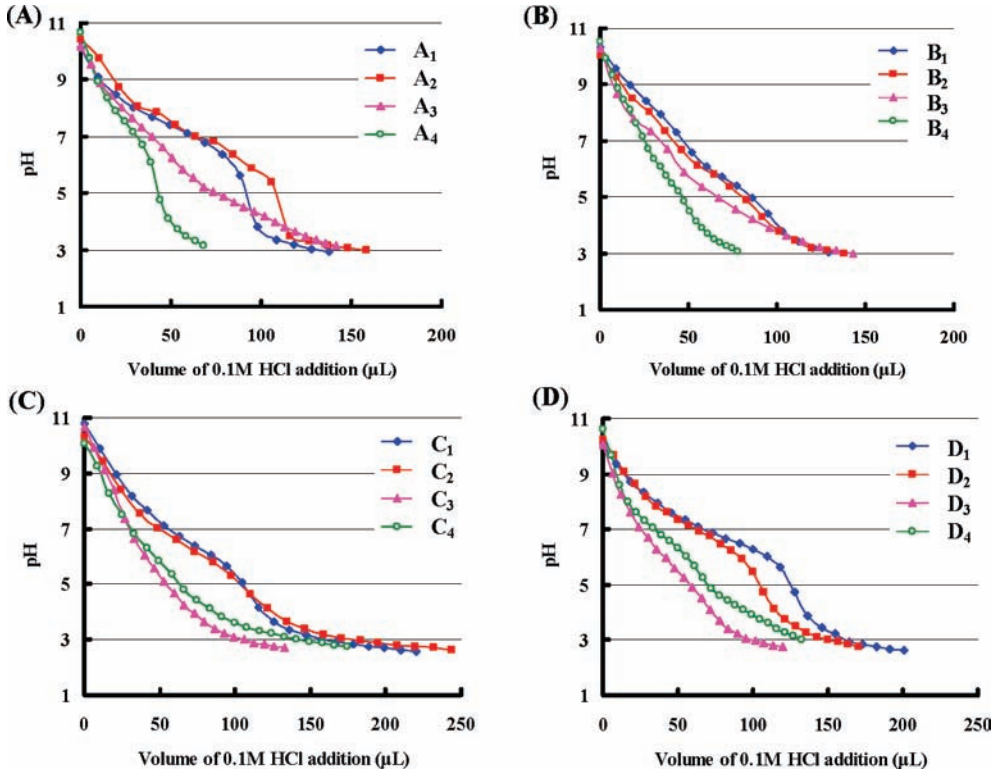


Figure 1. Titration curves of CPs at an amino group concentration of 5 mM.

of amines in CPs contributed differently to the buffering capacity of CPs.

The different polymers with the same secondary amine showed different buffering capacities. The buffering capacity of polymers in pH 5−7 decreased as the number of amines increased in the repeat unit ($\mathbf{A_1}$ > $\mathbf{B_1}$, $\mathbf{A_2}$ > $\mathbf{B_2}$), and also decreased as the number of amines increased in different monomers ($\mathbf{A_1}$ > $\mathbf{A_3}$, $\mathbf{B_1}$ > $\mathbf{B_3}$) (Figure 1A,B), which could be due to the protonation of an amine group electrostatically suppressed the protonation of the neighboring amines.[21] As a result, the correlation between the buffering capacity and polymer structure was not as direct as the correlation between the amount of the buffering groups and the structural variations.

Finally, the effects of methylene moiety and the ethylene glycol unit on the buffering capacity of CPs were evaluated. No obvious difference was found between polymers containing monomer **C** and **D** (Figure 1C,D), which indicated that the influence of the methylene moiety on the buffering capacity was negligible. The buffering capacities of polymers synthesized by monomers **A**, **B**, and **C**, but not monomer **D**, increased with ethylene glycol group in the polymer backbone increasing.

DNA Binding Ability. For efficient gene transfer and expression, the polymer should have the ability to condense DNA into nanoparticles and consequently mediated cell entry via endocytosis. CPs were examined for their ability to bind negative plasmid EGFP-N1 using a gel electrophoretic shift assay (Figure 2). Each polymer was combined with pDNA to form CPNs at various N/P ratios between 1 and 64. N/P ratios were calculated by the number of amine groups in the polymer repeat unit but not the amide nitrogens. All four CPs synthesized by monomer **A** or **B** could form complexes with DNA efficiently, it could be observed that the free DNA band completely disappeared at N/P ratio 2 for $\mathbf{A_1}$-$_4$ or $\mathbf{B_1}$-$_4$. $\mathbf{A_3}$ and $\mathbf{B_3}$ showed the strongest DNA binding ability with complete binding DNA at N/P ratio 1. However, CPs synthesized from monomer **C** or **D** could not bind DNA efficiently. $\mathbf{D_1}$ could not bind DNA completely even at N/P ratio 64. The differences in number and type of amines in the polymer backbone strongly affected its DNA binding ability. In the case of one type of amine in the polymer backbone, it was obvious that the secondary amine showed a stronger ability in DNA binding than primary amine in CP backbone by comparing $\mathbf{A_1}$-$_2$ with $\mathbf{C_1}$-$_2$. In the case of two types of amines in the polymer backbone, polymers with different combinations of amine types showed different DNA binding abilities. $\mathbf{C_4}$ showed greatly improved DNA binding ability compared with $\mathbf{C_1}$-$_2$ when tertiary amine was introduced into the backbone of the original polymer which only has a primary amine. However, no obvious difference was observed between $\mathbf{C_3}$ and $\mathbf{C_1}$-$_2$. By comparing $\mathbf{A_4}$ with $\mathbf{A_3}$ or $\mathbf{B_4}$ with $\mathbf{B_3}$, we could find that the DNA binding ability decreased a little by replacing the secondary amine with the tertiary amine. Comparing **C** series with **D** series, it was found that one more methylene group in the polymer backbone could greatly reduce the DNA binding ability no matter the types of amines on the polymer backbone. No obvious difference was observed between polymers containing **1** and **2**, which indicated that the influence of the ethylene glycol moiety on the DNA binding ability was neglectable. These results demonstrated that, besides the electronic interaction between polymer and DNA, other interactions such as hydrophobic interactions or $\pi-\pi$ interactions might also be very important.

Particle size is one of the important factors influencing the internalization of complexes. The size of particles less than 200 nm could be preferably internalized into most types of cells,[27] and a positive surface charge could lead to great interaction with the

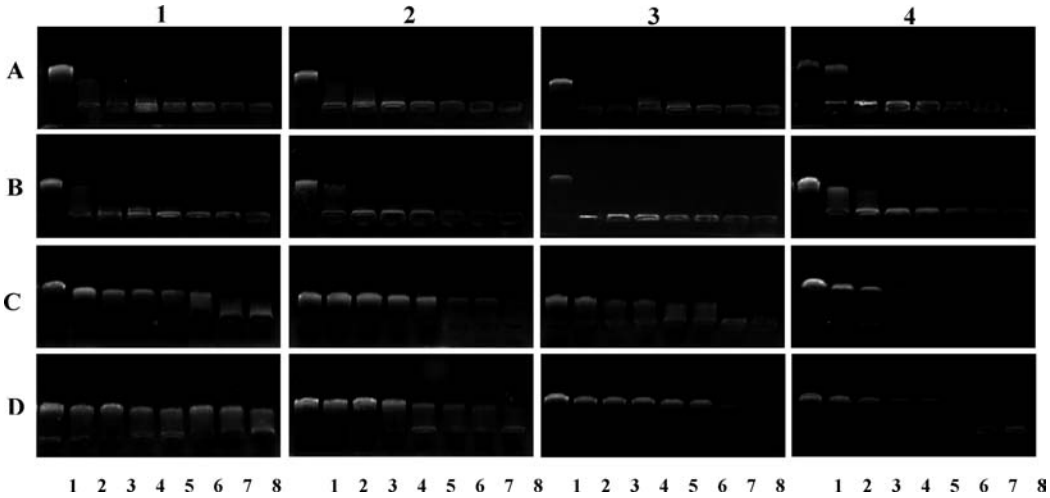

Figure 2. Agarose gel electrophoresis of CPNs at various N/P ratios. Lane 1: naked DNA control. Lanes 2 to 7: complexes prepared at N/P ratios of 1, 2, 4, 8, 16, 32, and 64 in water, respectively.

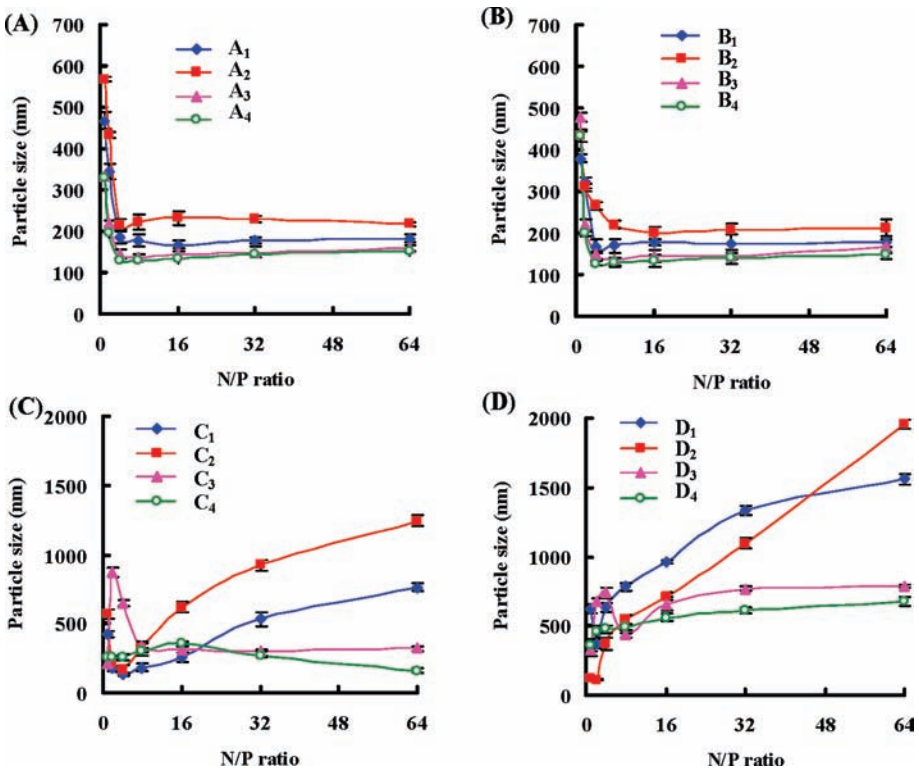

Figure 3. Average particle size of CPNs at different N/P ratios.

negative cell membrane.[28] In this study, all CPs could form nanoparticles with DNA in water. The average particle size of CPs as a function of N/P ratio was evaluated. Figure 3 showed some clear correlations between CP structure and the particle size. Polymer **A** series and **B** series formed smaller particles than polymer **C** series or **D** series, and showed constant particle sizes as N/P ratios increasing from 4 to 64. These results were in good agreement with the agarose gel electrophoresis assay that polymer **A** or **B** series showed stronger DNA binding ability with condensing DNA into smaller particles than polymer **C** or **D** series. Replacement of the azide-functionalized monomers containing ethylene glycol groups with monomers containing secondary amines or tertiary amines could significantly decrease the particle size of complex nanoparticles. The particle size of complex nanoparticles of **A**, **B**, or **C** series obviously increased with the ethylene glycol group in polymer backbone increasing. These results demonstrated that the polymers with higher amine density could yield stronger DNA condensation ability. Except C_4, the average sizes of polymer **C** series or **D** series increased with N/P ratio increasing, especially the polymers synthesized by azide-functionalized monomers containing the ethylene glycol groups. It was reported that the different polyplexes showed

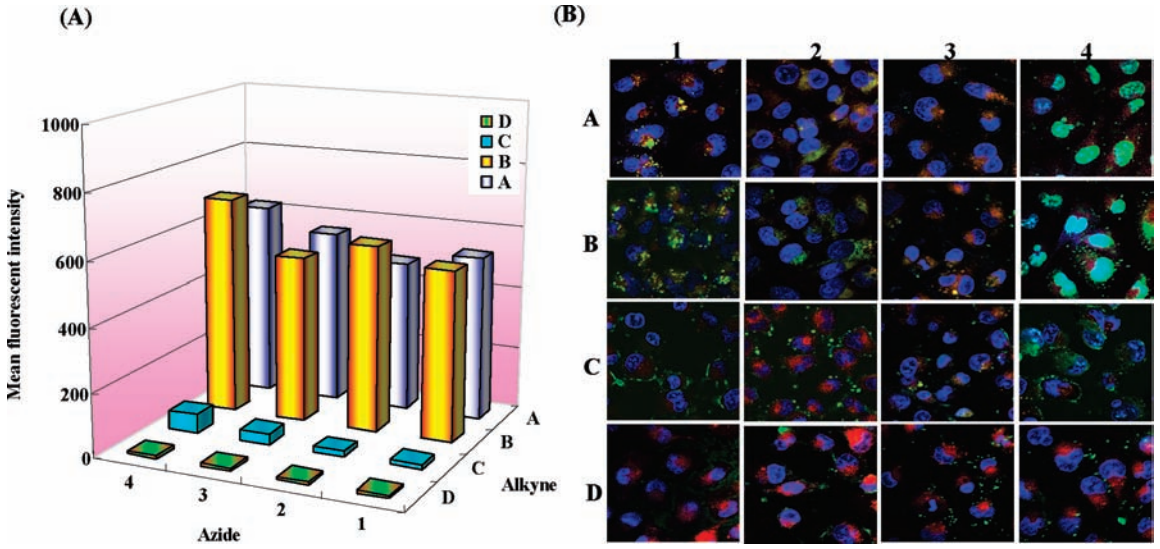

Figure 4. Cellular uptake (A) and intracellular distribution (B) of YOYO-1 labeled pDNA complexed with CPNs at N/P ratio 32 in MDA-MB-468 cells. Cells were incubated with CPNs with DNA concentration 5 μg/mL for 2 h. The nucleus and lysosome were stained by Hoechst 33342 (blue) and LysoTracker (red), respectively.

different structural property such as rods, toroids, aggregates, flower-like structures, and nanoparticles, and the molecular morphologies were strongly dependent on the charge ratios and polymer properties.[29] Polymer-DNA showed different condensate formation at different charge ratios. We assumed that complex nanoparticles formed by $\mathbf{C_1}$-$_2$ or $\mathbf{D_1}$-$_2$ could have more incompact structures at higher charge ratios.

Cellular Delivery of CPNs. The ability of different polymers to mediate the cellular uptake of DNA was measured in MDA-MB-468 cells by introducing a fluorescence based flow cytometry protocol. The pDNA was labeled with YOYO-1, an intercalating dye with a high affinity to DNA. The average fluorescence intensity per cell could be quantitatively assessed via flow cytometry. By this technique, the pDNA delivery efficiency could be directly determined as a function of polymer structure. Cells were incubated with complexes formed at the same N/P ratio of 32 for 2 h. There seems to be a positive correlation between DNA binding ability of CPs and cellular uptake of the corresponding CPNs. As shown in Figure 4A, the polymers synthesized by monomer **A** or **B** showed superior cellular uptake to monomer **C** or **D**. Due to the inefficiency in complexing DNA, nanoparticles formed by polymer **D** series showed negligible cellular uptake. In polymer **C** series, the cellular uptake of CPNs could increase by introducing a secondary amine or tertiary amine into the polymer backbone. The stronger DNA binding ability of $\mathbf{C_4}$ could be the main contribution to the cellular uptake. In polymers synthesized by monomers **A** and **B**, the replacement of the ethylene glycol unit with a tertiary amine in the polymer backbone could increase cellular uptake of CPNs, but not the secondary amine, which demonstrated that the polymer with a different amine would facilitate cellular DNA uptake. More ethylene glycol units in the polymer backbone synthesized using monomer **B** could increase cellular uptake, while the opposite result was acquired in polymers synthesized using monomer **A**.

The intracellular distribution of CPNs was further investigated with pDNA labeled by YOYO-1 (green), and nucleus and lysosome stained by Hoechst 33342 (blue) and LysoTracker (red), respectively. The intracellular distribution of different CPNs in MDA-MB-468 cells after 2 h incubation was significantly different (Figure 4B). The polymers synthesized using monomer **A** or **B** could facilitate the YOYO-1 labeled DNA into the whole cytoplasm. However, the green fluorescence was mostly around the cell membrane in cells treated with CPNs formed by polymers synthesized using monomer **C** or **D**, which were accordant with the result from flow cytometry. With the cellular uptake improved by introducing tertiary amine into the polymer backbone, the green fluorescence could be seen inside cells when incubated with complexes formed by $\mathbf{C_4}$. However, the colocalization of green and red fluorescence could not be easily observed, which demonstrated that the complexes formed by $\mathbf{C_4}$ endocytosed into cells were not sequestrated in lysosomes. In confocal images of cells treated with CPNs formed by $\mathbf{A_3}$ or $\mathbf{B_3}$, obvious yellow regions where YOYO-1 labeled DNA was localized in lysosomes could be observed, which suggested the segregation of YOYO-1 labeled DNA in lysosomal compartments without diffusing into cytoplasm. The confocal images of cells treated with CPNs formed by $\mathbf{A_1}$, $\mathbf{A_2}$, $\mathbf{B_1}$, or $\mathbf{B_2}$ displayed much more green regions in cytoplasm, which indicated that $\mathbf{A_1}$, $\mathbf{A_2}$, $\mathbf{B_1}$, or $\mathbf{B_2}$ complexes showed good endosomal escaping behavior which was consistent with the results of the buffering capacity. However, to our surprise, the green fluorescence was mostly in neclei when cells were incubated with complexes formed by $\mathbf{A_4}$ or $\mathbf{B_4}$, which had poor buffering capacity. Membrane destabilization of cationic polymers under different pH conditions was reported recently.[20] Membrane destabilization happened at either the acidic pH in the late endosomal compartment or the physiological pH at the cytoplasm, and would perturb either the membranes of cytoplasmic vesicles or organelles at physiological pH. In our previous study about the structure−biocompatibility relationship of these click polymers, polymers $\mathbf{A_4}$ and $\mathbf{B_4}$ demonstrated severe cytotoxicity and could disturb the erythrocyte membrane with high hemolysis ratio.[23] So, we inferred that these two polymers could have strong membrane destabilization effects, and the injury of the nuclear membrane would facilitate the nuclear delivery of DNA.

Transfection Efficiency of CPNs. In our pre-experiment, we found that most of the 16 CPNs showed the best transfection

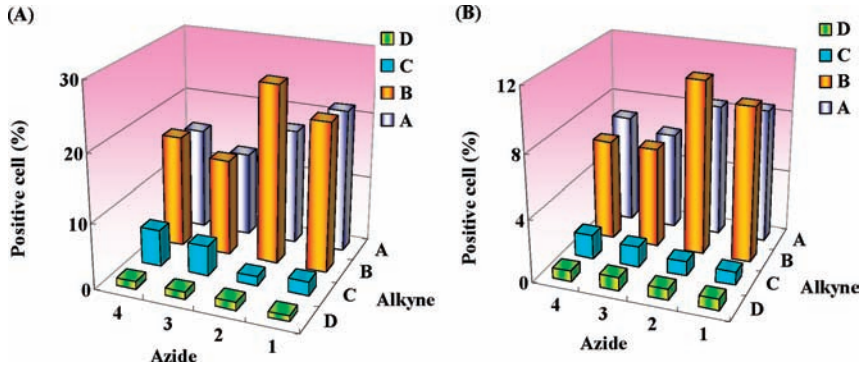

Figure 5. Transfection efficiency of CPNs at N/P ratio 32 with DNA concentration 5 μg/mL in HEK 293 cells (A) and MDA-MB-468 cells (B).

efficiency at N/P ratio 32, and considering that most CPs had good DNA binding ability and DNA condensing efficiency at N/P ratio 32, as a result, the transfection efficiency of 16 CPNs at N/P ratio 32 was compared to investigate the relationships of structure/transfection efficiency. Figure 5A,B showed the different transfection efficiency of 16 CPNs on the HEK293 and MDA-MB-468 cells. From the histograms, we could find that CPNs demonstrated the similar relationship of structure/transfection efficiency in the two cell lines. Complexes of **D** series could not transfect both of the cell lines. Complexes formed by $\mathbf{C_3}$ or $\mathbf{C_4}$ demonstrated the improved transfection efficiency compared with $\mathbf{C_1}$ and $\mathbf{C_2}$, which indicated that cellular uptake was a limiting factor with polymers of the **C** series. Among 16 CPNs, the complexes formed by $\mathbf{B_2}$ (B_2Ns) mediated the highest transgene expression in both cell lines, which was comparable to the PEINs group. Cells transfected with complexes formed with $\mathbf{A_1}$ or $\mathbf{B_1}$ also showed high gene expression. Complexes formed by polymers of **B** series displayed higher transfection efficency than that of **A** series, which indicated that the number of secondary amines in the polymer backbone could affect the gene expression. Complexes formed by polymer $\mathbf{A_3}$ or $\mathbf{B_3}$ demonstrated lower gene expression than B_2Ns, which indicated that endosomal escape of these polymers could be a limiting factor in promoting high gene expression. Cytotoxicity of polymers also is a very important parameter affecting transfeciton efficiency. From the results of cellular uptake, it could be found that the complexes formed by polymer $\mathbf{A_4}$ or $\mathbf{B_4}$ delivered a relatively high amount of DNA into each cell (Figure 4A), but they revealed a relatively low gene expression compared with B_2Ns (Figure 5). Among all 16 polymers, $\mathbf{A_4}$ and $\mathbf{B_4}$ showed the strongest cytotoxicity and induced the highest hemolysis rate.[23] The strong membrane destabilization effects of these two polymers could facilitate the nuclear delivery of DNA, but at the same time, destroy the normal function of cells, thus affected gene transfection and protein expression. The above results demonstrated that DNA-binding ability, buffering capacity, cytotoxicity, or the cellular delivery capacity of polymers could affect their complex transfection efficiencies.

In Vivo Biodistribution and Transfection Efficiency. According to the above structure−activity relationship, B_2Ns demonstrated high transfection efficiency with low toxicity. As a result, polymer $\mathbf{B_2}$ was chosen for further in vivo studies as follows.

The lethal toxicity was first investigated in MDA-MB-468 breast tumor-bearing mice. No lethal toxicity was observed for B_2Ns at N/P ratio 32 at 3 mg DNA/kg. Because the i.v. injection of B_2Ns in mice had a maximum volume, and the complex nanoparticles were apt to assemble under high concentration, the toxicity of B_2Ns at over 3 mg DNA/kg was difficult to determine, but it was easy to find that B_2Ns did not induce the obvious toxicity in mice under the experimental dose level (2 mg DNA/kg).

The biodistribution characteristics of nonviral vectors were among the most important factors affecting gene transfection efficiency. The difference in polymer structures and surface properties of nanoparticles leads to the difference in vivo biodistribution. It was reported that over half of the administered PEI/siRNA nanoparticles distributed to the liver in mice,[30] but the polyphosphazene/DNA nanoparticles mainly distributed into the lung in a short period of time.[31] As a result, it is necessary to investigate the biodistribution characteristics of newly synthesized click polymer/DNA complex nanoparticles.

To investigate the biodistribution of B_2Ns in tumor bearing mice, fluorescent dye YOYO-1 was chosen to label DNA. It is a cell-impermeant stain which shows over a thousandfold increase in its green fluorescence when bound to dsDNA. Tumor was allowed to grow to a volume of 200−300 mm^3 to facilitate qualitative observation of the fluorescence in each tissue under a real-time in vivo fluorescence imaging system. Then, the fluorescence was quantitatively evaluated. At the DNA concentration range 0−5 μg/mL, there is a perfect linear relationship between DNA concentration and fluorescence intensity.

The biodistribution profiles of B_2Ns in MDA-MB-468 solid tumor-bearing mice were shown in Figure 6A. B_2Ns could rapidly distribute into several principle tissues at 15 min after intravenous administration. A large amount of B_2Ns accumulated in the liver which could be due to the Kupffer cells scavenging charged particles.[30] At 15 min, some B_2Ns could be detected in tumor, and maximal accumulation of B_2Ns in tumor tissue was observed 1 h after administration. The distribution in tumor tissue was much higher than in heart, spleen, lung, and kidney, which could be attributed to the EPR effect.[32,33] The accumulation in each tissue decreased over time, and after 24 h, almost all B_2Ns was eliminated. These results demonstrated that the complex nanoparticles fromed by click polymers could not accumulate in the body.

The in vivo transfection efficiency of B_2Ns was compared with PEINs in MDA-MB-468 solid tumor-bearing mice. Due to the severe toxicity of PEI, the mass ratio of the administered complexes could not be over 1 under the experimental dose level (2 mg DNA/kg). The luciferase expression in heart, liver, spleen, lung, kidney, and tumor at 48 h after i.v. was shown in Figure 6B. The highest levels of luciferase expression were found in tumor, and much higher luciferase activity was detected in liver

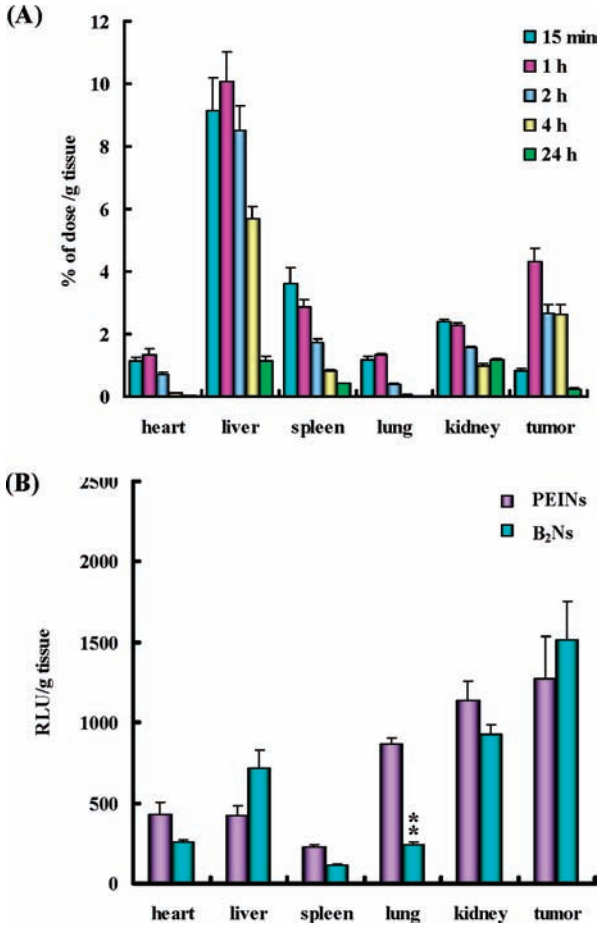

Figure 6. (A) Biodistribution of B_2Ns in nude mice bearing MDA-MB-468 tumor. Data were given as mean ± SD (n = 3). (B) Quantitative gene expression in vivo. Luciferase expression 48 h after intravenous administration of B_2Ns formed by polymer $\mathbf{B_2}$ into nude mice bearing MDA-MB-468 tumor at a dose of 2 mg DNA/kg. $^{**}p < 0.01$ compared with PEINs. Luciferase expression is plotted as RLU/g tissue. Data were given as mean ± SD (n = 3).

and kidney than other organs via injection of B_2Ns. The high tumor gene expression could be due to the targeting of nanoparticles to tumor via the EPR effect. In tumor, the gene expression of B_2Ns was a little higher than PEINs. In heart, spleen, and lung, the luciferase activity of PEINs was higher than that of B_2Ns, expecially in the lung. It was reported that PEI could induce severe aggregation of erythrocytes after intravenous injection, and the aggregation was apt to block pulmonary capillary, which provided enough time for gene expression in the lung.[34] However, in our previous work, $\mathbf{B_2}$ did not induce the obvious erythrocyte aggregation,[23] and the strong binding ability of triazole-amide to DNA could effectively overcome aggregation of nanoparticles in blood circulation. Therefore, the gene expression of B_2Ns in lung was significantly lower than that of PEINs ($p < 0.01$). The reduced distribution to lung tissue gave B_2Ns more opportunity to distribute to tumor and acquire more gene expression.

CONCLUSIONS

In vitro structure−activity relationship of 16 linear cationic click polymers and in vivo gene transfection of a candidate polymer selected from SAR study were evaluated in this work. Comparative analysis of 16 polymers revealed that the minimal structure variation had a crucial effect on buffering capacity, DNA-binding ability, or the cellular delivery capacity of polymer, all of which produced striking effects on their complex transfection efficiencies. The parallel screening led to the identification of a candidate polymer $\mathbf{B_2}$, which could effectively deliver DNA into tumor tissue. These results implied that gene vector based on this linear cationic click polymer could be a promising gene delivery system for tumor gene therapy.

Supporting Information

ABSTRACT: Hyperbranched poly(amido amine)s (HPAAs) containing different amounts of β-cyclodextrin (β-CD) (HPAA-CDs) were synthesized in one-pot by Michael addition copolymerization of *N,N′*-methylene bisacrylamide, 1-(2-aminoethyl)piperazine, and mono-6-deoxy-6-ethylenediamino-β-CD. In comparison to pure HPAA, the fluorescence intensity of HPAA-CDs was enhanced significantly while the cytotoxicity became lower. Ascribed to plenty of amino groups and strong photoluminescence, HPAA-CDs could be used as nonviral gene delivery vectors, and the corresponding gene transfection was evaluated. The experimental results indicated that HPAA-CDs condensed the plasmid DNA very well. By utilizing the fluorescent properties of HPAA-CDs, the cellular uptake and gene transfection processes were tracked by flow cytometry and confocal laser scanning microscopy without any fluorescent labeling. The transfection efficiencies of HPAA-CDs were similar to that of pure HPAA. In addition, the inner cavities of β-CDs in HPAA-CDs could be used to encapsulate drugs through host−guest interaction. Therefore, the HPAA-CDs may have potential application in the combination of gene therapy and chemotherapy.

INTRODUCTION

Nonviral gene delivery vectors especially cationic polymers are receiving more and more attention because of their easy manufacture, high compound stability, and low immunogenicity over viral vectors.[1−8] To achieve a safe and efficient DNA delivery, the exploration of polyplex formation between the polycations and the plasmid DNA (pDNA) and subsequent cellular uptake and trafficking of genetic materials in the cells is indispensable. By attaching the fluorescent probes onto polycations, the gene delivery process could be tracked.[9−12] However, the fluorescent labeling usually requires multiple complicated reactions. Even worse, the introduction of fluorescent probes might change the physical/chemical properties of gene vectors, resulting in a negative effect on the biocompatibility as well as on the transfection efficiency. Therefore, the preparation and application of photoluminescent polycationic vectors have become very attractive in the field of gene delivery.

In recent years, some polycations including poly(amido amine) and polyethylenimine were found to be photoluminescent polymers which could be used for fluorescence imaging.[13−20] However, comparing fluorescent materials with traditional fluorophores, the photoluminescence intensity of these polycations is still very weak.[20−22] We have noted that the photoluminescent property of polymers is closely related to their molecular conformations. By enhancement of the chain rigidity, the photoluminescence intensity of polymers can be improved.[19] For the traditional linear polycations, only limited end-groups are available for further modification. In contrast to the linear polymers, the highly branched polycations have a great number of various amine groups, which favors the following functionalization. At the same time, the highly branched polycations exhibit low cytotoxicity and high transfection efficiency because of their compact and globular structures.[23−27] In the present work, the biodegradable β-cyclodextrin (β-CD) with low cytotoxicity was incorporated into hyperbranched poly(amido amine) (HPAA) by a simple and efficient one-step Michael addition copolymerization. The introduction of big β-CD molecules enhanced the molecular rigidity of HPAA greatly, resulting in a dramatic improvement of

photoluminescence. Using this fluorescent hyperbranched polycation as a nonviral gene vector, the cellular uptake and trafficking of genetic materials in the cells could be tracked. Furthermore, the inclusion capability of the β-CD cavities in this photoluminescent polycation provided a possible application in the combination of gene therapy and chemotherapy.

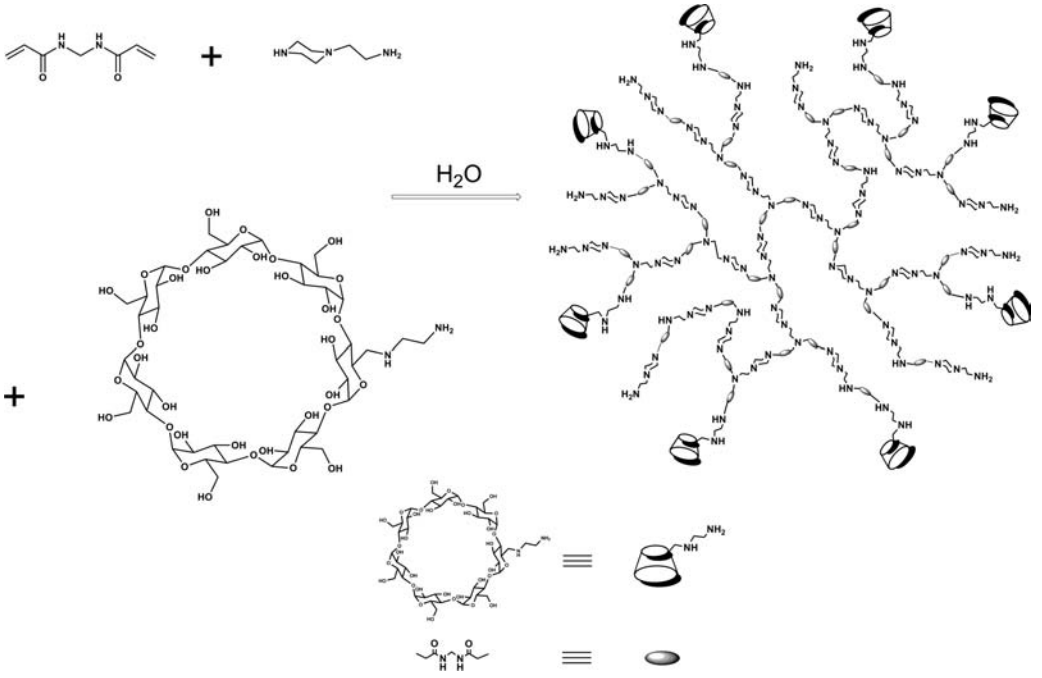
MATERIALS AND METHODS

Materials. 1-(2-Aminoethyl)piperazine (AP, 99%), poly(ethylenimine) (PEI, water free, M_w = 25 kDa, M_n = 10 kDa) and 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Aldrich. *N,N′*-Methylenebis(acrylamide) (MBA, 96%), *p*-toluenesulfonyl chloride, 1,2-ethylenediamine (EDA), acetone, dimethyl sulfoxide (DMSO), sodium hydroxide (98%) were supplied by Shanghai Sinopharm Chemical Reagent Co., Ltd. Dulbecco's Modified Eagle's Medium (DMEM), fetal bovine serum (FBS), phosphate buffered solution (PBS), penicillin, and streptomycin were purchased from PAA Laboratories GmbH. All these chemicals were used as received without any further purification. Clear polystyrene tissue culture treated 6-well and 96-well plates were purchased from Corning Costar. β-CD was obtained from Shanghai Sinopharm Chemical Reagent Co., Ltd., and purified once by recrystallization from deionized water before use. Mono-6-deoxy-6-ethylenediamino-β-CD (EDA-β-CD) used here was synthesized according to the method reported in our previous work.[28]

Synthesis of HPAA and HPAA-CDs. Both HPAA and its β-CD derivatives (HPAA-CDs) were synthesized via the Michael addition polymerization in nitrogen atmosphere.[28] A typical procedure is as follows: MBA (3.0830 g, 20 mmol) was dissolved in 20 mL of ultrapure water under stirring. Then, AP (2.5190 g, 19.5 mmol) and EDA-β-CD (0.5885 g, 0.5 mmol) were dissolved in 10 mL of ultrapure water and also added into the above solution. The mixture was stirred vigorously at 60 °C in the dark for 60 h. At last, the mixture was precipitated in acetone, dried under vacuum at 50 °C, and a light yellow powder was obtained (4.64 g, yield: 75%). The β-CD content of the polymers (1.3% and 6.1% for the two samples) was determined by quantitative ^{13}C NMR. Thus, the two samples were named HPAA-CD1.3 and HPAA-CD6.1, respectively.

Complexation of HPAA-CDs and Rhodamine B. Rhodamine B (RB) was used as a model drug. Certain amounts of RB were added into HPAA-CD aqueous solutions. After stirring overnight, the RB-loaded polymer solutions were dialyzed against distilled water for 48 h to remove free RB, followed by lyophilization to give the HPAA-CD/RB complexes.

Characterization of Polymers. ^1H, ^{13}C, $^1H-^1H$ COSY, and $^{13}C-^1H$ HSQC NMR spectra were recorded on a Varian Mercuryplus-400 spectrometer with DMSO-d_6 as solvent. The resonance frequencies for ^1H and ^{13}C were 400 and 100 MHz, respectively. Quantitative ^{13}C NMR spectra were measured by the method of inverse gated ^1H decoupling. The molecular weights and their distributions of the synthesized samples were evaluated by GPC-MALLS (gel permeation chromatography - multiangle laser light scattering). The GPC-MALLS system consisted of a Waters 2690D separations module, a Waters 2414 refractive index detector (RI), and a Wyatt DAWN EOS MALLS detector. Two chromatographic columns (Shodex OH-pak SB-803 and SB-802.5, Showa Denko, Japan) with a precolumn (Shodex SB-G) were used in series. The sodium acetate (NaAc) solution was prepared by dissolving a calculated amount of sodium acetate in reverse osmosis water (0.3 M), and the pH was adjusted to 4.4 with acetic acid. The eluent was filtrated through a 0.22 μm HPLC filter and degassed prior to use by ultrasonic bath. The flow rate of the mobile phase was 0.6 mL/min. The data were processed with *Astra* software (Wyatt Technology). Fourier transform infrared (FTIR) measurements were performed on a Perkin-Elmer Spectrum 1000 FTIR spectrometer. The UV−vis spectra were recorded on a Perkin-Elmer Lambda 750s UV−vis spectrophotometer. The fluorescence spectra were measured on a QM/TM/RM fluorescence spectrophotometer (Photon Technology International, Inc.). Differential scanning calorimeter (DSC) measurements were conducted on a TA Instruments Q2000 under a nitrogen atmosphere. The heating rate was 20 °C/min.



Agarose Gel Electrophoresis Experiments. Each polymer was examined for its ability to bind pDNA through gel electrophoresis experiments. All polymer stock solutions were prepared and mixed with pDNA solution at different N/P ratios (molar ratios of polymer nitrogen to pDNA phosphorus, N/P = 0, 5, 10, 20, 30, 40, 60, and 90) for 30 min at room temperature, and then analyzed on 1% agarose gel containing 0.5 μg/mL ethidium-bromide (EtBr). Then, gel electrophoresis was carried out in Tris-acetate-EDTA (TAE) running buffer with a current of 100 V for 60 min in a Sub-Cell system (Bio-Rad Laboratories, CA). DNA bands were visualized and photographed by a UV transilluminator and BioDoc-It imaging system.

Cell Cultures. COS-7 cells (a cell line derived from kidney cells of the African green monkey) were maintained in DMEM (4.5 g/L glucose) supplemented with 10% FBS, penicillin (100 units/mL), and streptomycin (100 units/mL) at 37 °C in a 5% CO_2 humidified atmosphere. Confluent cells were subcultured every 3 days using standard procedure.

Cell Viability Assay. For MTT assay, COS-7 cells were seeded into 96-well plates at a seeding density of 10 000 cells/well in 200 μL medium. After COS-7 cells were incubated for 24 h at 37 °C and 5% CO_2, the adherent cells reached approximately 60−70% confluence. Growth medium in the 96-well plates was then removed carefully by a transfer pipette and replaced with 200 μL medium containing serial dilutions of the polymers. The cells were grown for 24 h. Then, 20 μL of 5 mg/mL MTT assays stock solution in PBS was added to each well. After incubating the cells for 4 h, the medium containing unreacted dye was removed by a transfer pipette carefully. The obtained blue formazan crystals were dissolved in 200 μL/well DMSO and measured spectrophotometrically in a Perkin-Elmer 1420 Multilabel counter at a wavelength of 490 nm.

Cell Internalization. The cellular uptake experiments of HPAA-CD/pDNA complexes were characterized by flow cytometry and confocal laser scanning microscopy (CLSM). Flow cytometry was used to provide statistics on the uptake of HPAA-CD/pDNA into COS-7 cells. COS-7 cells (5.0×10^5 cells per well) were seeded in a 6-well tissue culture plate in 1 mL complete DMEM and cultured for 24 h until the adherent cells reached approximately 60−70% confluence, followed by removing the culture medium by a transfer pipette and replacing with fresh and prewarmed DMEM in the absence of 10% FBS. Then, the HPAA-CD/pDNA complexes in PBS (corresponding to 4 μg plasmid/well, N/P = 30) were added to different wells and the cells were incubated at 37 °C for predetermined time intervals. After the incubation, samples were prepared for flow cytometry analysis by removing the cell growth medium by a transfer pipette, rinsing with PBS buffer, and treating with trypsin.

Scheme 1. Synthetic Procedure of HPAA-CDs

Data for 1.0×10^4 gated events were collected and analysis was performed by means of a BD FACSCalibur flow cytometer and *CELLQuest* software.

For CLSM studies, COS-7 cells were seeded in 6-well plates at 2×10^5 cells/well in 1 mL complete DMEM and cultured for 24 h, followed by removing culture medium from the 6-well plates and washing with DMEM in the absence of 10% FBS. Then, the HPAA-CD/pDNA complexes (1 mL DMEM medium in the absence of 10% FBS) at the plasmid concentration of 4 μg/mL were added to each well. After incubation at 37 °C for predesignated time, culture medium was removed carefully by a transfer pipette and cells were washed with PBS three times. Then, the cells were fixed with 4% formaldehyde for 30 min at room temperature, and the slides were rinsed with PBS three times. Finally, the cells were stained with 2-(4-amidinophenyl)-6-indolecarbamidine dihydrochloride (DAPI) for 10 min and again the slides were rinsed with PBS three times. The slides were mounted and observed by a LSM 510META.

***In Vitro* Transfection Assay.** For transfection studies, cells were seeded at a density of 1×10^5 cells/well in 96-well plates and incubated for 16−24 h until 60−70% confluent at 37 °C and 5% CO_2. Immediately prior to transfection, the medium was removed by a transfer pipette. Then, cells were washed and replaced with fresh and prewarmed DMEM in the presence or absence of 10% FBS. The HPAA-CD/pDNA complexes (corresponding to 0.2 μg plasmid/well) were added to each well and the cells were incubated at 37 °C for 4 h. The medium was then replaced with fresh DMEM supplemented with 10% FBS and incubated for additional 48 h. The luciferase assay was carried out according to manufacturer's protocol (Promega). Relative light units (RLU) were measured with Varioskan Flash (Thermo Scientific, USA) GloMaxTM 96 microplate luminometer (Promega, USA). The obtained RLUs were normalized with respect to protein concentration in the cell extract determined using the BCA protein assay kit (Beyotime, China).

RESULTS AND DISCUSSION

Synthesis of HPAA-CDs. As mentioned in the introduction part, poly(amido amine) is a kind of cationic polymers with photoluminescence. Unfortunately, its photoluminescence is very weak. To improve its photoluminescence intensity, we introduced big β-CD molecules onto the surface of HPAA to enhance the molecular rigidness. The synthetic procedure of HPAA-CD is shown in Scheme 1. The monomers MBA, AP, and EDA-β-CD with an equal feeding molar ratio of MBA to AP/EDA-β-CD but different molar ratio of AP to EDA-β-CD (see Table 1) were mixed in water at 60 °C. After reaction for 60 h, HPAAs with different β-CD content (HPAA-CDs) were synthesized through Michael addition copolymerization. The experimental conditions and corresponding characterization data are summarized in Table 1, which confirms the formation of polymerized products. The actual β-CD content was calculated from quantitative ^{13}C NMR spectra. It is found that the β-CD contents of the polymers are 1.3% and 6.1%, named HPAA-CD1.3 and HPAA-CD6.1, respectively.

The resulting polymers were characterized by FTIR measurements. Figure 1 gives the FTIR spectra of pure HPAA, HPAA-CD1.3, and HPAA-CD6.1. For pure HPAA, the broad N−H stretching vibration around 3283 cm^{-1} indicates the existence of many amino groups. The bands at 2946 and 2820 cm^{-1} correspond to the antisymmetric and symmetric $-CH_2-$ stretching vibration, respectively. The absorption peaks of amide groups are clearly observed at 1647 and 1538 cm^{-1}, while the band at 1460 cm^{-1} results from the deformation vibration of the $-CH_2-$ groups. The FTIR spectral profile of HPAA-CD1.3 and HPAA-CD6.1 is quite similar to that of pure HPAA, suggesting that all polymers share the basic molecular structure. In the meantime, by comparison with pure HPAA, a new absorption at 1033 cm^{-1} appears in the curves of HPAA-CD1.3 and HPAA-CD6.1 and can be attributed to the C−O−C stretching vibrations of β-CDs.

Table 1. Reaction Conditions and Results of Michael Addition Copolymerization of MBA, AP, and EDA-β-CD

	monomer molar ratio								
entry	MBA (mmol)	AP (mmol)	EDA-β-CD (mmol)	actual CD content (%)[a]	M_n[b] (× 10^4)	M_w[b] (× 10^4)	M_w/M_n[b]	DB[a]	T_g[c] (°C)
HPAA	20	20	0	0	1.23	2.02	1.64	0.33	32.2

HPAA-CD6.1	20	18	2	6.1	1.44	3.40	2.36	0.30	65.7

[a] Actual CD content in the resultant polymers and the degree of branching (DB) were calculated from quantitative ^{13}C NMR analysis. [b] Molecular weights and polydispersities were determined by GPC-MALLS. [c] T_g was measured by DSC.

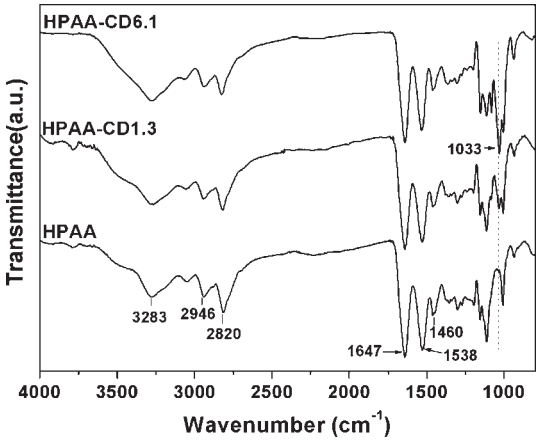

Figure 1. FTIR spectra of pure HPAA and HPAA-CDs.

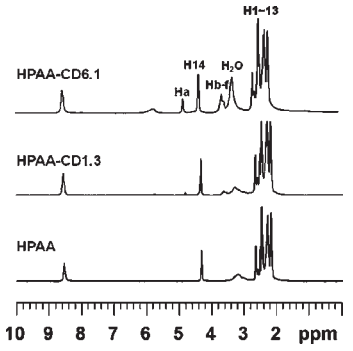

Figure 2. ^{1}H NMR spectra of pure HPAA and HPAA-CDs.

With the increase of β-CD content, the peak intensity of 1033 cm^{-1} band increases. The NMR studies further confirmed the formation of HPAA-CDs. In the ^{1}H NMR spectrum of pure HPAA (Figure 2), the signals at 2.1−2.7 ppm are attributed to the methylene groups in AP units, while the peak at 4.3 ppm comes from the protons of methylene groups between two amide groups in MBA units. After surface modification of HPAA by β-CDs, several new signals at 3.3−3.8, 4.8, and 5.7 ppm corresponding to the protons of β-CD appear. Figure 3 gives the quantitative ^{13}C NMR spectra of HPAA, HPAA-CD1.3, and HPAA-CD6.1. For pure HPAA, the carbonyl peak is located at 173 ppm while all methylene signals are found in the high field region between 32 and 62 ppm. In the ^{13}C NMR spectra of HPAA-CD1.3 and HPAA-CD6.1, the signals at 101, 81, 72, and 61 ppm are assigned to the methylene and methine groups of β-CD and become strong with the increase of β-CD content. Both FTIR

Scheme 2. Schematic Illustration of the Molecular Structure of HPAA-CDs

and NMR studies demonstrate that different amounts of β-CDs have been successfully incorporated onto the surface of HPAA.

In order to calculate the degree of branching (DB) of pure HPAA and HPAA-CDs, all possible structure units including linear, branched, and terminal units are listed in Scheme 2. The two-dimensional NMR (2D-NMR) technique was used to assign the molecular structure.[29,30] As one example, Figure 4 gives the ^{1}H−^{1}H COSY and ^{13}C−^{1}H HSQC NMR spectra of HPAA-CD6.1. On the basis of the cross-peaks in the 2D-NMR spectra, the assignment of each structural unit for HPAA-CD6.1 is performed, and the corresponding details are given in Figure 4.

dx.doi.org/10.1021/bc200010w |Bioconjugate Chem. 2011, 22, 1162–1170

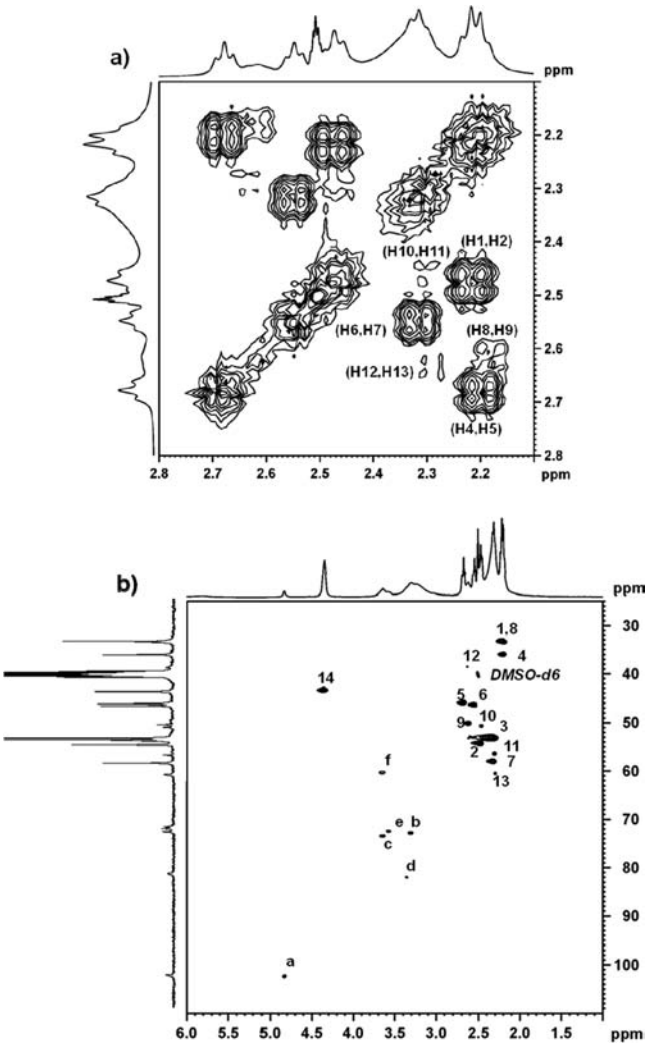

Figure 4. 2D NMR spectra of HPAA-CD6.1: (a) $^{1}H-^{1}H$ COSY spectrum, (b) $^{13}C-^{1}H$ HSQC spectrum.

Correspondingly, the DB values can be calculated according to the following equation:[31]

$$DB = (D + T)/(D + T + L)$$

where D, T, and L represent the fractions of the branched, terminal, and linear units, respectively. As listed in Table 1, the DB values of polymerized samples are higher than 0.30, suggesting the formation of hyperbranched polymers.

UV−vis and Fluorescent Properties of HPAA-CDs. Although without traditional fluorescent functional groups, both poly(amido amine) (PAMAM) dendrimer and hyperbranched poly(amido amine) (HPAA) are found to exhibit photoluminescence. It is believed that the key unit for the photoluminescence property of PAMAM dendrimer and HPAA is the tertiary amine with lone pair electrons inside the tight structure of highly branched polymers.[17,20] However, the photoluminescence of these polymers is weak. In the present work, different amounts of β-CD were incorporated onto HPAA to form HPAA-CDs, which limited the molecular mobility and then improved the photoluminescence. The optical properties of HPAA-CDs were studied by UV−vis and fluorescence spectroscopy. Figure 5a gives the UV−vis spectra of different polymer aqueous solutions with

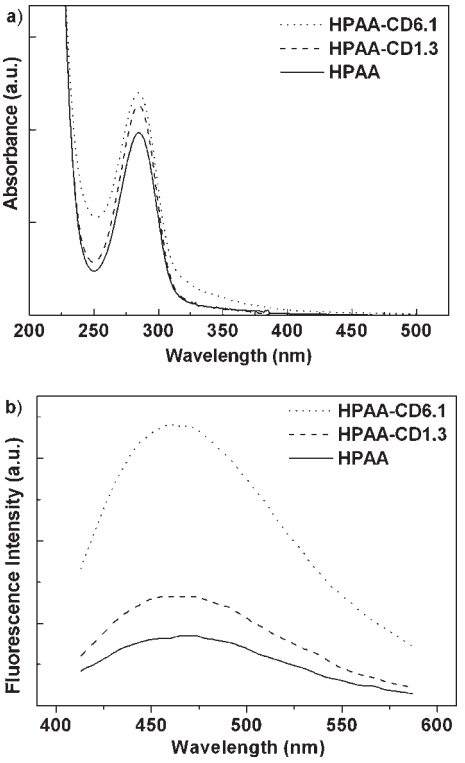

Figure 5. (a) UV−vis spectra and (b) fluorescence emission spectra of pure HPAA and HPAA-CDs in aqueous solutions (1 mg/mL) measured at room temperature, λ_{ex} = 375 nm.

a concentration of 1 mg/mL. An obvious absorption band at 295 nm related to the tertiary nitrogen can be observed. This UV−vis absorption increases with the β-CD content, because of the improved molecular rigidity of the HPAA backbone. Figure 5b shows the corresponding fluorescence emission spectra. It can be found that the HPAA-CD displays a broad fluorescent band at ~465 nm under excitation at 375 nm. With the increase of β-CD content from 0% to 6.1%, the fluorescence at 465 nm is enhanced significantly. The photoluminescence enhancement of HPAA-CDs may result from the restricted rotational motion of the terminal chains caused by the steric hindrance of big β-CD units, which decreases the collisional relaxation and fluorescence self-quenching.[19] The quantum yields of HPAA, HPAA-CD1.3, HPAA-CD6.1, and NH_2-terminated G4 PAMAM dendrimer were determined to be 0.59%, 0.68%, 0.73%, and 0.25%, respectively. Although the quantum yields of all the samples are not large, that of HPAA-CDs seem to be higher than that of G4 PAMAM dendrimer. The fluorescence emission spectra show that HPAA-CDs emit much stronger fluorescence than G4 PAMAM dendrimer with the same solution concentration. The experimental details are given in the Supporting Information. The strong fluorescence and cationic characteristics of HPAA-CD make it an excellent fluorescent nonviral gene delivery vector without fluorescent probes.

Cytotoxicity of HPAA-CDs. It is very important to evaluate the potential toxicity of polymeric materials for biomedical applications. Here, the *in vitro* cytotoxicity of the pure HPAA and two HPAA-CD samples was evaluated using the MTT assay against COS-7 cells with PEI (M_w = 25 kDa) as a control. The MTT assay is based on the ability of a mitochondrial dehydrogenation enzyme in viable cells to cleave the tetrazolium rings of

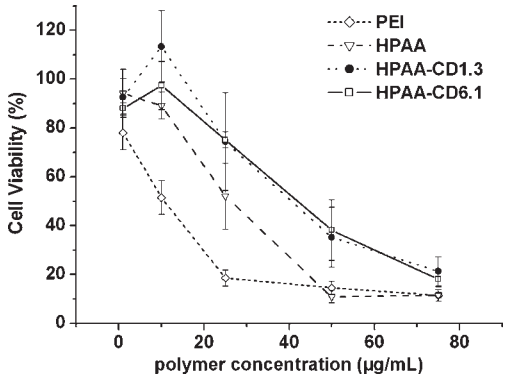

Figure 6. Cell viability of COS-7 against PEI, pure HPAA, and HPAA-CDs after culturing for 24 h. Results are presented as the mean ± SD (n = 6).

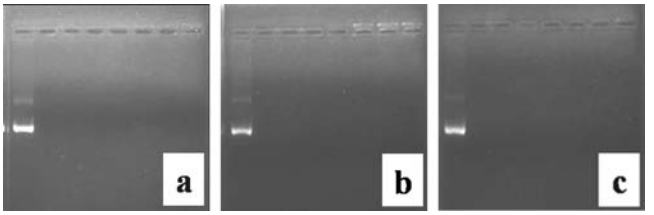

Figure 7. Agarose gel electrophoretic images. For each polymer, gel electrophoresis assays were performed at the N/P ratios of 0, 5, 10, 20, 30, 40, 60, and 90 from left to right in each image. The left lane (N/P = 0) contains DNA alone (no polymer) and is used as a control in each image. (a−c): Agarose gel electrophoresis data of DNA released from the complex with pure HPAA, HPAA-CD1.,3 and HPAA-CD6.1, respectively.

the pale-yellow MTT and form formazan crystals with dark-blue color. Therefore, the number of surviving cells is directly proportional to the level of formed formazan.[32,33] Figure 6 presents the cell viability after 24 h incubation with polymer samples at different concentrations. All the samples show cytotoxicity when the polymer concentration is above 50 μg/mL. It has been well reported that the strong positive charge of primary amino groups increases the cytotoxicity significantly.[34] Moreover, increasing molecular weight of polymers also induces enhanced cytotoxicity.[35] Thus, the relatively high cytotoxicity of HPAA and its CD-based derivatives may be attributed to the strong positive charges of primary amines and the high molecular weight. In comparison to the PEI control, both pure HPAA and HPAA-CD samples exhibit less toxicity in COS-7 cells and the cytotoxicity decreases with the incorporation of β-CDs. β-CD has been demonstrated to be biodegradable, which is of great importance in reducing toxicity by integrating it into polycations.[36] After the surface β-CD modification, a part of the primary amines of HPAA is replaced by the biodegradable and low cytotoxic β-CDs, resulting in the reduced cytotoxicity.

Polymer/pDNA Complexes. As one of the promising biodegradable polymers, poly(amido amine) was applied as an efficient nonviral gene vector. Considering the similar structure, the possibility of photoluminescent HPAA-CDs to be used as nonviral gene vectors was also evaluated. First, the ability of HPAA-CDs to form complexes with pDNA was examined by agarose gel electrophoresis at various molar ratios of polymer nitrogen to pDNA phosphorus (N/P ratios). Figure 7 shows the gel retardation results of the HPAA-CD/pDNA complexes.

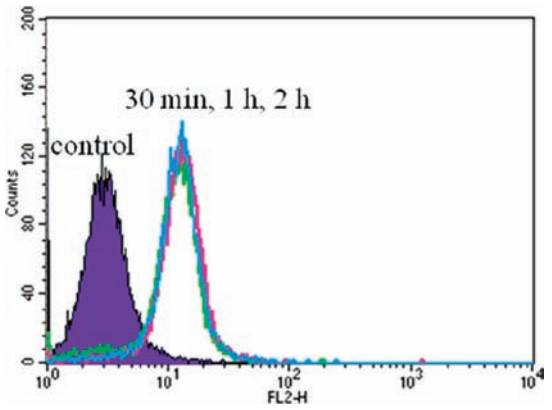

Figure 8. Flow cytometry histogram profiles of COS-7 cells incubated with the HPAA-CD6.1/pDNA complexes.

It indicates that, when the N/P ratio is higher than 5, the migration of pDNA is retarded completely for pure HPAA, HPAA-CD1.3, and HPAA-CD6.1. The agarose gel electrophoresis results clearly demonstrate that HPAA-CDs can condense pDNA very well.

Cell Internalization Studies. Benefiting from the strong photoluminescence of HPAA-CD, the cell internalization studies of HPAA-CD/pDNA complexes could be performed conveniently without fluorescent labeling. The cellular uptake of HPAA-CD6.1 which emitted the strongest fluorescence was determined by measuring the intracellular fluorescence intensity using flow cytometry. The HPAA-CD6.1/pDNA complexes (N/P = 30) were added to culture medium, and the COS-7 cells were incubated at 37 °C for the desired time. Here, COS-7 cells without any treatment were used as a blank control. Figure 8 gives the histograms of cell-associated HPAA-CD6.1 fluorescence. The relative geometrical mean fluorescence intensities of the HPAA-CD6.1/pDNA complex pretreated cells are much higher than that of non-pretreated cells. These prominent fluorescence signals are associated with the uptake of the HPAA-CD6.1/pDNA complexes into COS-7 cells. The mean fluorescence intensities almost do not change for incubation intervals longer than 30 min, indicating the rapid cellular internalization of the HPAA-CD6.1/pDNA complexes.

To further confirm the cell permeability of the HPAA-CD6.1/pDNA complexes, CLSM measurements were performed. In CLSM studies, the COS-7 cells were incubated with the HPAA-CD6.1/pDNA complexes for predesignated time (0.5 h, 2 h, 6 h, 10 h, and 24 h), and then the cell nucleus was stained with DAPI. The pretreated cells were observed under CLSM. Figure 9 shows that the HPAA-CD6.1 fluorescence appears in all cells but mainly in the cytoplasm. These results indicate that the HPAA-CD6.1/pDNA complexes are successfully internalized by COS-7 cells and mainly resided in cytoplasm. Actually, this is very important for intracellular applications of the polymer complexes, such as intracellular gene delivery.

***In Vitro* Transfection Assay.** Considering the high DNA condensation ability and low cytotoxicity, HPAA-CDs can be used as an efficient nonviral vector for gene delivery. *In vitro* transfection activity of HPAA-CD/pDNA complexes was evaluated in COS-7 cells in DMEM supplemented with or without 10% FBS in comparison with PEI by the luciferase assay. All transfection efficiencies were obtained in the absence of chloroquine, a reagent known to disrupt the endosomal membrane

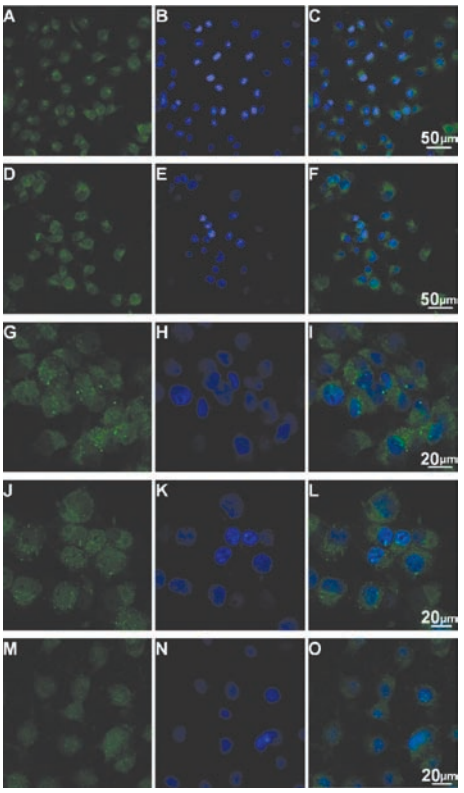

Figure 9. CLSM images of COS-7 cells incubated with HPAA-CD6.1/pDNA complexes for predesignated time (from top to bottom: 0.5 h, 2 h, 6 h, 10 h, 24 h). The green fluorescence is from HPAA-CD6.1 (A, D, G, J, M), and the blue is from the nuclei (cell nuclei were stained with DAPI) (B, E, H, K, N). The third column illustrates overlaid images (C, F, I, L, O).

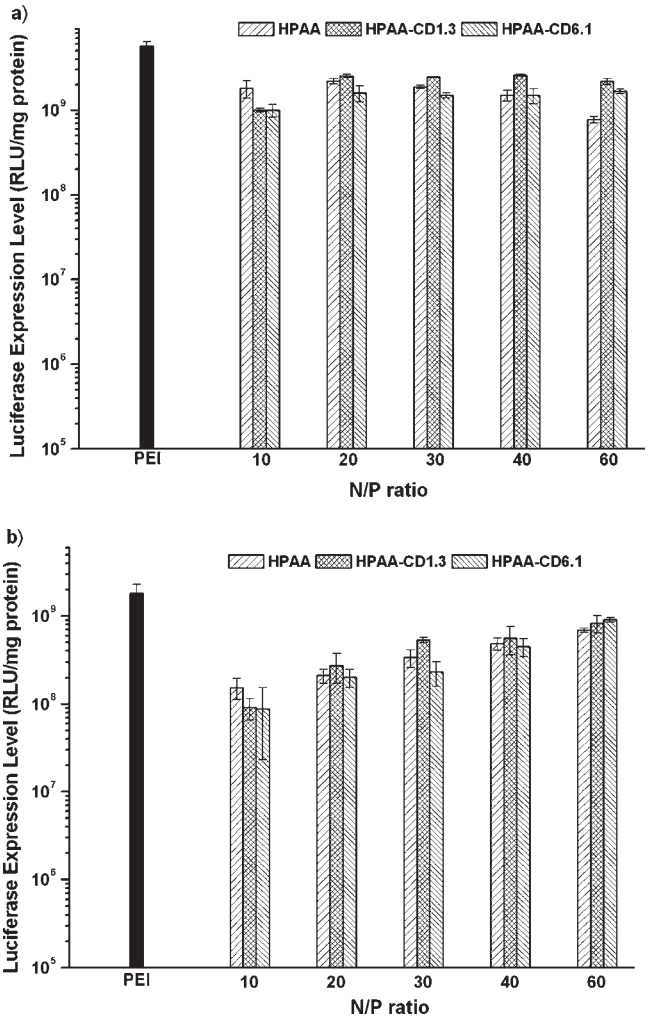

Figure 10. Transfection efficiency of pure HPAA and HPAA-CDs at various N/P ratios and branched PEI (25 kDa) at the optimal N/P ratio of 15 in COS-7 cells in different media: (a) serum free DMEM, (b) DMEM containing serum. Luciferase expression levels were measured 48 h later. Results are presented as the mean ± SD (n = 3).

and to enhance transfection of DNA complexes by trafficking through the endolysosomal pathway. Figure 10a shows that HPAA-CD/pDNA complexes in the serum-free medium have similar transfection efficiencies at different N/P ratios, which are slightly smaller than that of the PEI control. The β-CDs seem to have no remarkable effect on the transfection efficiency in the system. For potential *in vivo* applications, the evaluation of transfection activity in the presence of serum is indispensible. Because the formation and stability of vector/pDNA complexes can be easily changed by the medium, many cationic vectors used for gene transfer experiments are no longer effective in the systems containing serum.[37] In comparison to Figure 10a, Figure 10b shows that the transfection ability of HPAA-CD/pDNA complexes decreases at low N/P ratios in the presence of 10% FBS. With the increase of N/P ratios from 10 to 60, the transfection efficiencies of HPAA-CD complexes improve and finally become quite close to that of the PEI control, indicating the high stability of HPAA-CD/pDNA complexes in the presence of serum.

Complexation with Rhodamine B as Model Drug. It is well-known that β-CD has important applications in pharmaceutical fields due to its strong ability to selectively form inclusion complexes with a wide range of guest molecules.[38−44] For HPAA-CDs, the cavities of surface β-CDs can also be utilized to encapsulate drug molecules with proper size. Rhodamine B (RB) was chosen as a model drug. The obtained HPAA-CD/RB complexes were dissolved in water, and the fluorescent spectra

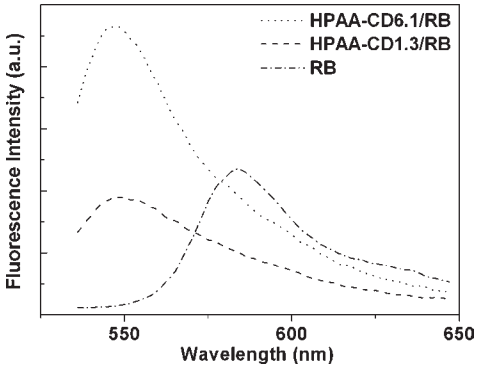

Figure 11. Fluorescence emission spectra of free RB in aqueous solution (0.005 mg/mL) and RB-loaded HPAA-CDs in aqueous solutions(0.5 mg/mL), λ_{ex} = 520 nm.

were acquired as shown in Figure 11. By comparison with the spectrum of free RB aqueous solution, the fluorescence of HPAA-CD/RB complexes shows an obvious blue shift from

585 to 545 nm. With the increase of β-CD content, the fluorescence intensity increases rapidly. These observations demonstrate that RB has been successfully included into the cavity of β-CD. Therefore, the introduction of CD onto the surface of HPAA provides a novel photoluminescent delivery material in the combination of gene therapy and chemotherapy.

CONCLUSIONS

Hyperbranched poly(amido amine)s (HPAAs) containing different amounts of β-CD (HPAA-CDs) have been synthesized by Michael addition copolymerization of MBA, AP, and EDA-β-CD. In comparison with pure HPAA, HPAA-CDs show lower cytotoxicity and significantly enhanced photoluminescence. HPAA-CDs can condense pDNA very efficiently. The cell internalization of the HPAA-CD/pDNA complexes has been studied through flow cytometry and CLSM by detecting the fluorescence of HPAA-CD itself, which avoids the fluorescent labeling process. It demonstrates that the cellular uptake of HPAA-CD/pDNA complexes is very fast and HPAA-CDs mainly locate in the cytoplasm of the cells during the gene transportation process. At the same time, the inner cavities of β-CDs in HPAA-CDs can be used as drug containers. Thus, HPAA-CDs may have potential applications as delivery materials in the combination of gene therapy and chemotherapy.

The quantum yields of hyperbranched poly(amido amine) (HPAA), HPAAs containing different amount of β-cyclodextrin (HPAA-CDs) and NH_2-terminated G4 poly(amido amine) (PAMAM) dendrimer were measured using quinine sulfate in 0.05 M sulfuric acid (Φ_Q = 0.52 with excitation of 346.5 nm) as a reference standard[1] using the following equation:[2]

$$\Phi_S = \Phi_Q (F_S/F_Q) (A_Q/A_S) (n_s/n_Q)^2$$

Where F is the area under the fluorescence spectra, A is the absorbance. n is the refractive index of the solvent, and the subscript Q and S represent quinine sulfate and sample, respectively. The quantum yields of HPAA, HPAA-CD1.3, HPAA-CD6.1 and NH_2-terminated G4 PAMAM dendrimer are 0.59%, 0.68%, 0.73% and 0.25%, respectively. Although the quantum yields of all the samples are not large, HPAA-CDs seem to be higher than PAMAM dendrimer. The fluorescence emission spectra in Figure S1 show that HPAA-CDs emit much stronger fluorescence than G4 PAMAM dendrimer with the same solution concentration.

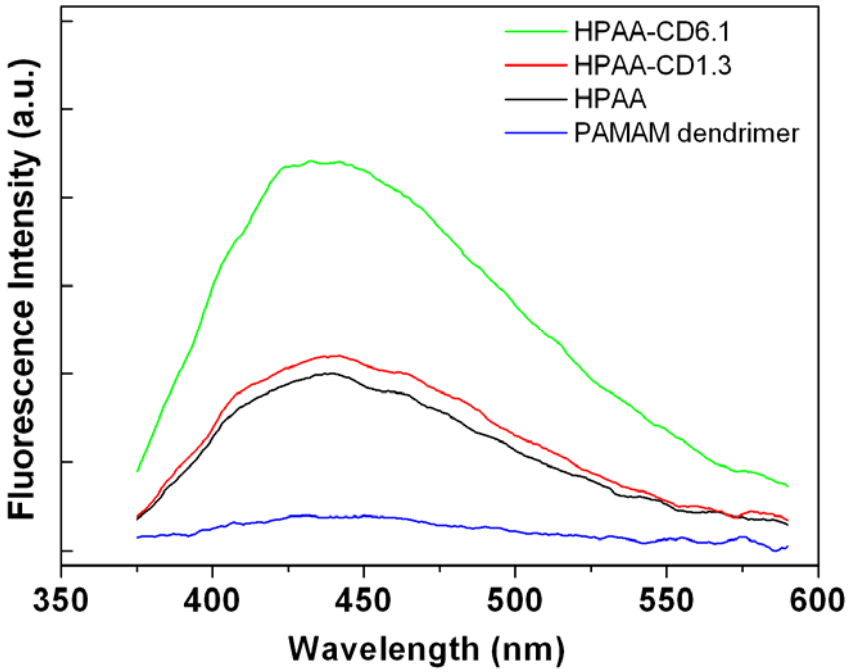

Figure S1. Fluorescence emission spectra of pure HPAA, HPAA-CDs and NH_2-terminated G4 PAMAM dendrimer in aqueous solutions (1 mg/mL), λ_{ex} = 350 nm.

ABSTRACT: A brain drug delivery system for glioma chemotherapy based on transferrin-conjugated biodegradable polymersomes, Tf-PO−DOX, was made and evaluated with doxorubicin (DOX) as a model drug. Biodegradable polymersomes (PO) loaded with doxorubicin (DOX) were prepared by the nanoprecipitation method (PO−DOX) and then conjugated with transferrin (Tf) to yield Tf-PO−DOX with an average diameter of 107 nm and surface Tf molecule number per polymersome of approximately 35. Compared with PO−DOX and free DOX, Tf-PO−DOX demonstrated the strongest cytotoxicity against C6 glioma cells and the greatest intracellular delivery. It was shown in pharmacokinetic and brain distribution experiments that Tf-PO significantly enhanced brain delivery of DOX, especially the delivery of DOX into brain tumor cells. Pharmacodynamics results revealed a significant reduction of tumor volume and a significant increase of median survival time in the group of Tf-PO−DOX compared with those in saline control animals, animals treated with PO−DOX, and free DOX solution. By terminal deoxynucleotidyl transferase-mediated dUTP nick-end-labeling, Tf-PO−DOX could extensively make tumor cell apoptosis. These results indicated that Tf-PO−DOX could significantly enhance the intracellular delivery of DOX in glioma and the chemotherapeutic effect of DOX for glioma rats.

INTRODUCTION

Treatment of malignant gliomas represents one of the most formidable challenges in oncology.[1] Despite combined therapies of surgery, radiotherapy, and chemotherapy, the prognosis for gliomas remains very poor, especially for glioblastoma, which has a median survival of 12 to 15 months.[2] Even with steady advances in drug discovery and targeted therapeutics that improve long-term control in systemic cancers, there has been little impact on the prognosis of patients with malignant gliomas.[1] The most notable obstacle underlying the disappointing results in glioma therapeutics is the presence of the blood-brain barrier (BBB), which serves to prevent delivery of potentially active therapeutic compounds.[3] Moreover, limited tumor cell drug uptake, intracellular drug metabolism, inherent tumor sensitivity to chemotherapy, and cellular mechanisms of resistance also contribute much to the poor effectiveness of treatment for glioma.[4] Therefore, a great deal of effort is presently focused on developing strategies to effectively deliver active drugs to brain tumor cells, improving therapeutic opportunities, efficiency, and patient survival, while decreasing side effects to normal cells. Magnetic resonance imaging (MRI)-guided focused ultrasound-induced BBB disruption and convection-enhanced delivery have emerged as leading investigational delivery techniques for the treatment of malignant gliomas.[2,5,6] However, expensive medical devices and potential hazards produced from repeated BBB opening or invasive neurosurgery greatly limit their application in glioma therapy. Thus, targeting drug delivery to glioma cells noninvasively using nanocarrier systems such as micelles, liposomes, nanoparticles (NPs), and dendrimers may be a better approach and has been widely investigated recently.[7−9]

As a new class of synthetic thin-shelled capsules based on block copolymer chemistry, polymersomes are self-assembled vesicles of amphiphilic block copolymers that currently attract great interest for their structural analogies with living organelles and potential applications as nanosized reactors or drug delivery systems.[10−13] Over the past decade, polymersomes were revealed to be promising alternatives to phospholipid-based vesicles regarding their remarkable, attractive, and feasible characteristics such as stealthiness, improved stability, and ease of functionalization.[13−15] Compared with liposomes (3−5 nm bilayer), polymersomes are extremely stable and robust with high membrane stability and low membrane permeability, which

ACS Publications © 2011 American Chemical Society

can overcome most of the stability problems (mainly drug leakage and disintegration of membrane) encountered in lipidic vesicles due to the high fluidity of their bilayers.[16,17] In addition, it has been evidenced that the physical and chemical properties of polymersomes including particles size, drug loading, surface modification, and even in vivo behavior may be broadly controlled and modulated through rich diversity of block copolymer chemistries (block fraction, block architecture).[13] Furthermore, desirable smart polymersomes can be designed to combine features required for drug delivery application, such as biodegradability,[18,19] targeting capability,[20,21] and responsiveness to biologically relevant stimuli [22] such as pH,[23] temperature,[24] light,[25] and reductive environment.[26] Therefore, polymersomes are good candidates for drug delivery carriers, which are currently being developed by many groups. However, the vast majority of present efforts are focused on the fabrication of novel functional polymersomes including biomimetic polymersomes for glioma cells treatment in vitro,[27] while in vivo exploitation of biodegradable polymersomes as brain drug delivery systems has rarely been reported.

The anthracycline doxorubicin, one of the most powerful anticancer agents, like most small-molecule anticancer agents, has a poor effect on glioma therapy for its inability to cross the BBB and achieve effective concentrations in the glioma cells. Although liposomal doxorubicin has been shown to be a safe treatment with moderate activity that might lead to long-term stabilization in recurrent high-grade glioma patients,[28] its poor blood-brain barrier penetration, limited intracellular delivery, and instability are still major limitations in the treatment of malignant glioma. By a secondary targeting strategy,[29] liposomes conjugated with two different targeting ligands might possess the ability to traverse the BBB and reach the secondary target (glioma cell), greatly improving gene therapy for glioma rats.[30] However, the preparation of two ligand-conjugated liposomes might be rather complicated and uncontrollable. Moreover, the high density of different surface ligands on liposomes might not only increase the possibility to opsonization and accelerate the blood clearance,[31] but also aggravate the instability of liposomes. As promising alternatives to liposomes, biodegradable poly(ethylene glycol)-poly(ε-caprolactone) (PEG-PCL) polymersomes functionalized with lactoferrin were proven to cross BBB and accumulate at the glioma site in our previous report.[32] However, the large vesicle size above 200 nm might accelerate the blood clearance and minimize the likelihood of crossing the BBB.[33] In addition, insufficient intracellular delivery also decreased the doxorubicin concentration in glioma cells. Thus, biodegradable polymersomes with better vesicle properties such as rational size and surface modification are still necessary for effective glioma targeting delivery.

In this study, doxorubicin, as a model small-molecule anticancer agent, was encapsulated into biodegradable PEG-PCL polymersomes with small vesicle size. As a classic both BBB targeting and tumor targeting ligand,[34] transferrin, was conjugated to the surfaces of polymersomes to prepare "Trojan horse" (Tf-PO−DOX) for glioma drug delivery. A single targeting ligand that could mediate both transport across the BBB and internalization into glioma cells represented the simplest approach for secondary targeting delivery. Enhanced intracellular delivery and glioma drug delivery were investigated in glioma bearing rats and then verified by pharmacodynamics tests including tumor volume, survival monitoring, and tumor cell apoptosis.

MATERIALS AND METHODS

Materials and Animals. The MPEG3k-PCL15.8k or Maleimide-PEG3.4k-PCL16k diblock copolymers were synthesized by ring-opening polymerization of ε-CL using MPEG (M_w 3000 Da, NOF Corporation, Japan) or Maleimide-PEG (M_w 3400 Da, NEKTAR, USA) as described elsewhere.[35] Doxorubicin (DOX) and daunorubicin was purchased from Beijing Huafeng United Technology (China) and National Institute for the Control of Pharmaceutical and Biological Products (China), respectively. Holo-transferrin, 2-iminothiolane (Traut's reagent), and phenylmethyl sulfonyl fluoride (PMSF) were ordered from Sigma and 5,5-dithiobis (2-nitrobenzoicacid) (Ellmann's reagent) was from Acros (Belgium). Human transferrin ELISA quantitation kit was obtained from Bethyl (Montgomery, TX, USA). Neuro-TACS II *In Situ* Apoptosis Detection Kit was purchased from R&D systems (Minneapolis, MN). C6 glioma cell line from rat was obtained from the American Type Culture Collection. Fetal bovine serum (FBS) and related cell culture medium were purchased from Invitrogen (Gibco, Carlsbad, CA). Plastic cell culture dishes, plates, and flasks were ordered from Corning Incorporation (Lowell, MA). Double distilled water was purified using a Millipore Simplicity System (Millipore, Bedford, MA, USA). All the other chemicals were analytical reagent grades and used without further purification. Wistar strain rats (weighing 200−230 g) were obtained from Shanghai SLAC Laboratory Animal Co. Ltd. (Shanghai, China). The animals involved in this study were treated according to protocols evaluated and approved by the ethical committee of Fudan University.

Preparation of Transferrin Conjugated Biodegradable Polymersomes. Biodegradable polymersomes were prepared with a blend of MPEG-PCL and Maleimide-PEG-PCL by the nanoprecipitation method.[12] Briefly, 20 mg of MPEG-PCL and 1 mg of Maleimide-PEG-PCL were dissolved in 1.0 mL of tetrahydrofuran (THF). The polymer solution was then injected slowly into 10 mL of 0.2 M citrate buffer (pH 4.0). Mild stirring was performed to induce self-assembly for 30 min. To remove THF and exchange the external buffer, the solution was dialyzed against 0.01 M PBS buffer (pH 7.4) for 12 h using dialysis membranes (MW cutoff, 14 000 Da) and the buffer solution is replaced by fresh PBS every 4 h. For DOX loading, 2 mg of DOX was added and the mixed solution was incubated in the dark at 40 °C for 24 h. By means of ultrafiltration, unencapsulated DOX was eluted and the vesicle dispersion was concentrated to yield DOX-loaded polymersome (PO−DOX).

Transferrin conjugation with DOX-loaded polymersomes was made as described previously.[35] In brief, transferrin was thiolated using 2-iminothiolane (Traut's reagent), then incubated with polymersomes for 6 h with a 1:3 molar ratio of thiolated transferrin to maleimide. By means of ultrafiltration again, unconjugated protein was removed and Tf-conjugated DOX-loaded polymersome (Tf-PO−DOX) solution was concentrated. All operations were conducted away from light.

Characterization of Tf-Conjugated DOX-Loaded Polymersome. The formation of blank polymersomes was visualized by cryo-transmission electron micrograph (Cryo-TEM, JEOL 2010, Japan).[35] The shape and size of unloaded polymersomes were observed by transmission electron microscope (TEM, JEM-1230, JEOL, Japan) following negative staining with 1% uranyl acetate solution. The mean diameters and zeta potential of Tf-PO−DOX were determined by dynamic light scattering (DLS) using a Zeta Potential/Particle Sizer NICOMP 380 ZLS (PSS.

NICOMP Particle Size System, Santa Barbara, CA, USA). Surface transferrin densities were determined by ELISA method combined with turbidimetry method as previously described.[35] Drug loading efficiency and in vitro release of DOX from Tf-PO−DOX was determined using fluorescence spectrometry (Ex: 480 nm and Em: 580 nm). In the latter, drug loaded polymersomes were suspended in a dialysis system which was monitored by periodic withdrawals of drug released into 0.01 M PBS (pH 4 and 7.4) or 10% rat plasma in PBS.[36]

Cell Uptake and Intracellular Drug Distribution of DOX-Loaded Polymersomes. A 24-well plate was seeded with C6 cells at a density of 10^5 per well, and the cells were allowed to attach for 24 h. Dispersions of PO−DOX and Tf-PO−DOX as well as free DOX solution were each added into the medium in triplicate to make a final DOX concentration at 4 μg/mL in each well. After 4 h incubation at 37 °C, the medium was removed and the cells were stained with 1 μg/mL of 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI) for 10 min at room temperature. After PBS washing, the plate was subjected to observation under the fluorescence microscope (Olymus IX71, Japan).

Quantitative Determination of Cell Uptake of DOX-Loaded Polymersomes. Similarly to the above, C6 cells were seeded onto 24-well plates at a density of 10^5 per well, and the cells were allowed to attach for 24 h. Three groups of DOX preparations were respectively added into the medium to make a final DOX concentration at 4 μg/mL in each well (triplicate for each formulation). The plates were incubated for 1, 2, 4, 8, or 12 h at 37 °C. For each time point, cells in each well of the corresponding plate were washed three times with ice-cold PBS to remove surface-bound polymersomes and further incubated with 0.4 mL of 1% Triton X-100 at 4 °C overnight. Afterward, 25 μL of the cell lysate from each well was sampled to determine the total cell protein content using the BCA protein assay kit. The rest of the cell lysate was used for extraction and HPLC determination of DOX (Agilent 1200) with fluorescence detector at an excitation wavelength of 480 nm and an emission wavelength of 550 nm.[37] The uptake index (UI) was expressed as DOX (μg)/cellular protein (mg).

Intracellular Drug Distribution. Intracellular drug distribution studies were carried out as previously described with a little modification.[38] Briefly, C6 cells were seeded onto 6-well plates at 10^6 cells per well and allowed to attach for 12 h. Three groups of DOX preparations were respectively added into the medium to make a final DOX concentration at 4 μg/mL in each well (triplicate for each formulation). The plates were incubated for 1, 2, 4, 8, or 12 h at 37 °C. For each time point, cells in each well of the corresponding plate were washed three times with ice-cold PBS to remove surface-bound polymersomes and further collected by centrifugation at 3000 rpm for 5 min after cell dissociation. The resulting cell pellets were washed thrice with 3 mL ice-cold PBS, resuspended in 300 μL TM-2 buffer (0.01 M Tris−HCl, pH 7.4, 0.002 M $MgCl_2$, 0.0005 M PMSF), and incubated at room temperature for 1 min followed by ice water for 5 min. Triton X-100 was added to the suspension to a final concentration of 1% (v/v) and the suspension was incubated in ice water for an additional 5 min. After centrifugation at 1000 rpm at 4 °C for 10 min, the supernatant was transferred to determine the drug amount in cytoplasm and the isolated pellet was resuspended in 0.5 mL of TM-2 buffer for determination of the drug levels in nuclei. The drug levels of both cytoplasm and nuclei were determined by HPLC method as described above. The corresponding protein concentrations were measured using BCA protein assay kit. The uptake index (UI) was expressed as DOX (μg)/cellular protein (mg).

In Vitro Cytotoxicity of DOX-Loaded Polymersomes against C6 Cells. C6 cells were seeded onto a 96-well plate at a density of 10^4 per well and incubated for 24 h before exposure to different DOX formulations with a series of concentrations for a further 24 h at 37 °C. Eight wells for untreated cells were prepared as controls. After exposure, the cytotoxicity of these formulations was assayed by the MTT method. The experiments were performed in quadruplicate.

Tumor Implantation. Male rats were maintained at 22 ± 2 °C on a 12 h light−dark cycle with access to food and water ad libitum. For tumor implantation, animals were anesthetized with chloral hydrate (0.4 g/kg) intraperitoneally and then subjected to stereotaxic injection of approximately 3×10^5 of C6 cells (in 5 μL of RPMI-1640 medium) into the caudate nucleus region.[39] The injection location was 1 mm posterior and 2 mm right to the bregma, and 4.5 mm beneath the exposed dura mater. The burr hole in the skull was sealed with bone wax and the scalp incision was sutured.

Pharmacokinetics and Tissue Distribution of Tf-PO−DOX. Animal experiments were performed as previously described.[32] In brief, 12 days after tumor implantation, male rats were randomly divided into 3 groups for pharmacokinetics or tissue distribution studies and administrated intravenously with a dose of 5 mg/kg DOX in solution, PO and Tf-PO. For pharmacokinetics study, blood samples were collected from the retro-orbital plexus at 0.083, 0.25, 0.5, 1, 2, 4, 8, and 12 h following i.v. injection. At 24 h, the animals were decapitated and the brain tissues including cerebral cortex, left striatum, and right striatum (tumor tissue) were excised followed by quick washing with cold saline to remove surface blood. Blood sample and major organs including liver, spleen, kidney, lung, and heart were also collected. For tissue distribution at 4 h, the animals were decapitated and the brain tissues, blood sample, and other major organs were collected as described above.

Fluorescent imaging of brain and other major organs was investigated by a CRi in vivo fluorescent imaging system (CRI, Woburn, MA, USA) consisting of a highly sensitive Peltier cooled backlit CCD camera (2184 × 1472 pixels). In brief, the organs were placed in the light-tight chamber, the filter for emission was set at 550 nm, respectively, and the photon emission was integrated over a period of 5 s. After that, a grayscale reference image was collected under white light. For localization of the photon emission, grayscale and pseudocolor images were merged using *WinLight 32* software.

HPLC analysis was performed for determining levels of DOX in biological specimen.[37] In brief, the tissue samples were homogenized on ice with 3-fold volumes of deionized water followed by addition of 10 μL of daunorubicin (internal standard, 10 μg/mL). The samples were extracted with 2 mL of chloroform/methanol (4:1, v/v) following intense vortexing for 2 min. After centrifugation at 4000 *g* for 10 min, the subnatant was transferred and evaporated under a gentle stream of nitrogen at 40 °C. The residue was dissolved in 200 μL of methanol, and 20 μL was injected into the HPLC system. The blood plasma samples were extracted without the addition of water and reconstituted in the same manner. The chromatographic analysis was performed on the HPLC system (Shimadzu Scientific Instrument Inc., Japan) including a pump (model LC-10AT) and a fluorescence detector (model RF-10AXL; λ_{ex} = 480 nm, λ_{em} = 550 nm). Using potassium dihydrogen phosphate/

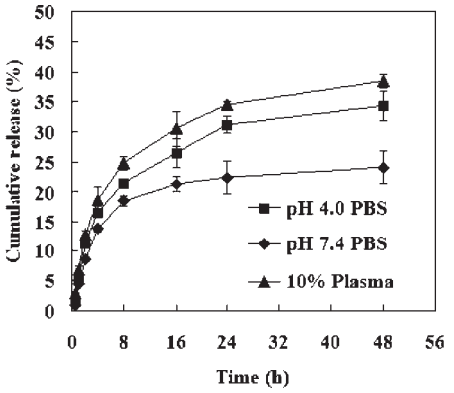

Figure 2. Cumulative releases (%) of doxorubicin from Tf-PO−DOX in different media.

acetonitrile/glacial acetic acid (70:30:0.3, v/v) with pH 3.0 as the mobile phase at a flow rate of 1.2 mL/min, chromatographic separations were achieved with a C_{18} analytical column (5 μm, 4.6 × 200 mm, Diamonsil, Dikma) equipped with a guard column (Nova-Pak, Waters) at 35 °C. The retention time of DOX and internal standard (daunomycin) was about 3.7 and 8.2 min, respectively.

For data analysis, the plasma data were fitted to a biexponential equation: $A(t) = A_1e^{-k1t} + A_1e^{-k2t}$, where $A(t)$ was %ID per mL of plasma (%ID, percentage of injected dose).[40] Pharmacokinetic parameters, such as plasma clearance (Cl) and steady-state volume of distribution (V_{ss}), were calculated from A_1, A_2, k_1, and k_2. Area under the blood concentration curve (AUC) was calculated by noncompartmental data analysis of blood concentrations. The brain permeability surface area (PS) product and brain uptake (expressed as %ID per g of tissue) were calculated as described elsewhere.[41]

Antitumor Efficacy in Rats Bearing Glioma. Tumor-bearing animals were equally and randomly divided into 4 groups, which received saline, DOX solution, PO−DOX, and Tf-PO−DOX, respectively. These preparations were i.v. injected at 2, 5, 8, and 11 days after glioma implantation, dosing at 1.5 mg/kg DOX.[32,42] On the 7th and 14th days, 6 rats per group were randomly sacrificed. Heart perfusion with 10% neutral buffered formalin was conducted after sacrifice, and the brain tissue sample was collected and fixed with 10% neutral buffered formalin for at least 48 h and then embedded in paraffin followed by routine hematoxylin and eosin (H&E) staining on 5-μm-thick sections using routine protocols.[43] The maximum diameter (a) and minimum diameter (b) of glioma tissue was measured under stereomicroscope, and the tumor volume (V) in each animal was calculated as $V = 0.5ab^2$. Paraffin-embedded brain tumor tissue sections (5 μm) were also prepared for apoptosis detection by Tdt-mediated dUTP nick-end labeling (TUNEL) according to the protocol of NeuroTACS II *In Situ* Apoptosis Detection Kit. Samples were counterstained with hematoxylin while positive signals were developed by diaminobenzidine (DAB).

Twelve tumor-bearing rats of each group were followed by survival monitoring. Survival data were analyzed with log-rank test in a Kaplan−Meier nonparametric analysis and summarized descriptively by means of median survival times with their respective 95% confidence intervals.

Statistical Analysis. Statistical differences in uptake index, pharmacokinetic parameters, and tumor volume were determined by one-way analysis of variance (ANOVA), followed by post hoc analysis of Bonferroni for multigroup comparison. $P < 0.05$ was considered significant.

RESULTS

Characterization of DOX-Loaded Polymersomes. Cryo-TEM results revealed that a blend of MPEG3k-PCL15.8k and Maleimide-PEG3.4k-PCL16k spontaneously assembled into polymersomes which were generally round with a diameter of approximately 100 nm. Moreover, the hydrophobic core of the membrane provided the contrast, and the membrane thickness was homogeneous with a measured width d of about 16 nm (Figure 1A), which is considerably greater than any previously studied lipid system. The self-assembled bilayers was also thicker than that we previously reported (10 nm)[35] due to the higher molecular weight of block polymer PCL, as this is clear and already has been demonstrated.[44] The TEM examination demonstrated that polymersomes were of vesicle-like shape with averaged diameters around 100 nm (Figure 1B), in good accordance with DLS results. A slight diameter increase was observed following DOX loading and Tf conjugation. The final average diameters of PO−DOX and Tf-PO−DOX were 101.8 ± 9.2 nm and 107.7 ± 11.3 nm, respectively. The zeta potential values of PO−DOX and Tf-PO−DOX in 0.001 M NaCl solution were −9.1 ± 0.6 mV and −9.3 ± 0.5 mV, respectively, indicating Tf conjugation had no influence on the zeta potential value of polymersomes. Drug loading capacity of DOX in the polymersomes was about 4.4% with entrapment efficiency above 96%. The mean Tf molecule numbers per polymersome on the surface of Tf-PO−DOX was 35.1 ± 6.2, which was a reasonable density for brain targeting justified in other studies.[41,45]

As shown in Figure 2, under three releasing conditions, the release profile of DOX from Tf-PO−DOX displayed a biphasic pattern that was characterized by a first rapid release (~17% of DOX was released within 4 h) followed by a slower and sustained release. After a 48 h incubation period, about 34.3%, 24.1%, and 38.4% of DOX were released from Tf-PO−DOX in pH 4.0, 7.4 PBS, and rat plasma, respectively. DOX was released much more rapidly in pH 4.0 than in pH 7.4 PBS, which might be attributed to acid-catalyzed hydrolysis of the PCL membrane[46] and increased hydrophilicity of DOX in acid condition.[47] The cumulative release of DOX from Tf-PO−DOX at 8 h in rat plasma was below 25% indicating that DOX entrapped in Tf-PO might be mostly preserved during the brain uptake process of Tf-PO−DOX.

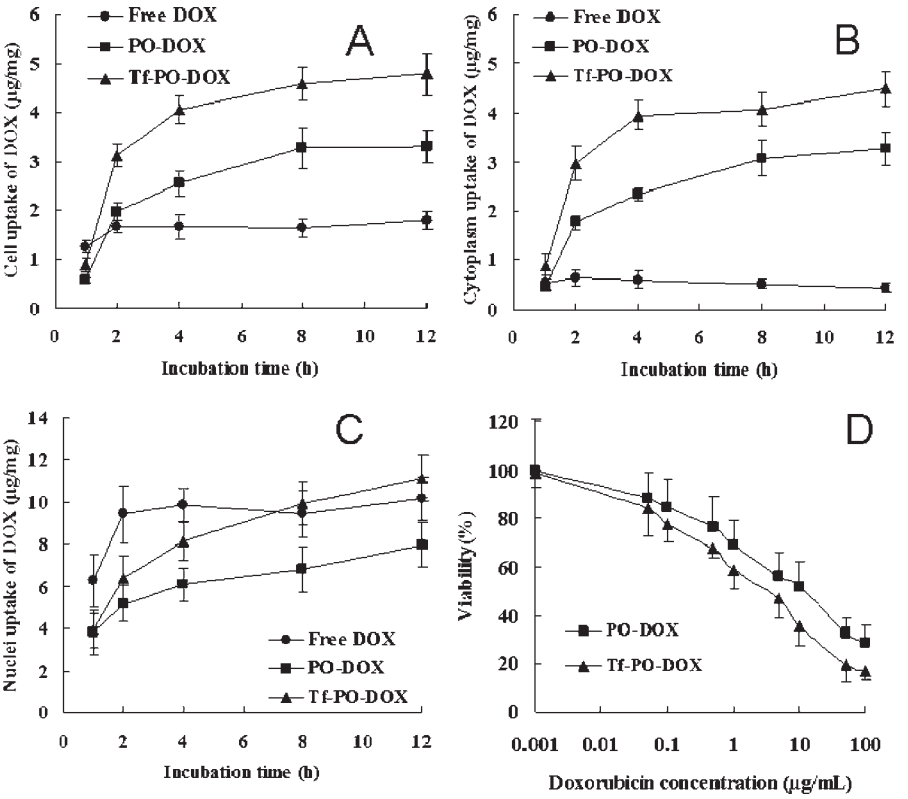

Figure 3. Cell uptake and intracellular distribution of free DOX, PO−DOX, and Tf-PO−DOX (4 μg/mL DOX) in C6 cell line from 1 to 12 h. Relative uptake in cell (A), cytoplasm (B), and nuclei (C). (D) C6 viability inhibition-logarithmic doxorubicin concentration curve of DOX loaded polymersomes.

Tf-PO−DOX and PO−DOX were 4.8 and 3.3 μg/mg, respectively. The uptake of polymersomes in cytoplasm presented an initial rapid increase before 4 h (Figure 3B). After that, the uptake curve for polymersomes showed a slow decrease and tended to reach a plateau as the incubation time prolonged. A low cytoplasmic uptake of free DOX was obviously observed during the incubation period. In nuclei, the uptake for DOX-loaded polymersomes increased with time, while the uptake for free DOX rapidly reached the highest value at 4 h (Figure 3C). By 12 h, the uptake for Tf-PO−DOX into nuclei was significantly more than that for PO−DOX (P < 0.01), which might be attributed to higher cytoplasmic uptake for Tf-PO−DOX.

MTT assay on C6 cells viability showed that the cytotoxicity of Tf-PO−DOX and PO−DOX depended on their concentration. Viability−concentration curves (Figure 3D) demonstrated that the IC_{50} (DOX concentration of 50% inhibition) of these two formulations was 3.6 and 13.5 μg/mL, respectively, manifesting a 3.75× intensification of cell inhibition of Tf-PO−DOX compared to PO−DOX. The results indicated a significantly improved cytotoxicity mediated by Tf, which was in agreement with the higher intracellular delivery and higher nuclei uptake of Tf-PO−DOX than those of PO−DOX as presented above.

Intracellular distribution of polymersomes into C6 cells was also demonstrated by fluorescence microscopy photographs in which red fluorescence represented DOX and blue fluorescence referred to nuclei stained with DAPI (Figure 4). For free DOX, the red fluorescence nearly completely overlaid with the blue fluorescence, indicating that free DOX diffused into the cells and mainly concentrated at the nucleus, which agreed well with the results of quantitative determination. With Rregard to polymersomes, the same as the quantitative results, the red DOX fluorescence distributed mainly in the cytoplasm of cells except for partly in the nucleus, indicating that cell uptake of DOX-loaded polymersomes was not through the same diffusion mechanism as free DOX, but in a different way, possibly by endocytosis.

Pharmacokinetics and Tissue Distribution of Tf-PO−DOX. As shown in Figure 5 A, the blood clearance of DOX for free DOX, PO−DOX, and Tf-PO−DOX in rats occurred in a biexponential manner. In the group of free DOX, disappearance of DOX from the blood circulation was very rapid with the plasma concentration of only 0.19%ID/mL at 15 min. On the contrary, the plasma DOX concentration for PO−DOX and Tf-PO−DOX remained high for a long time. Even at 24 h after administration, the plasma DOX concentrations for PO−DOX and Tf-PO−DOX were 0.06%ID/mL and 0.03%ID/mL, which were 11.9-fold and 6.3-fold that for free DOX, respectively, exhibiting a remarkable prolonged plasma clearance. Pharmacokinetic parameters calculated from Figure 5 revealed that Tf-PO−DOX and PO−DOX significantly decreased the plasma clearance (Cl) of DOX from 1038 mL/h/kg to 101 and 76 mL/h/kg, respectively (P < 0.01). Meanwhile, AUC increased by 19.1- and 24.8-fold as compared to free DOX. However, there was no significant difference in Cl and AUC between Tf-PO−DOX and PO−DOX (P > 0.05), indicating that surface modification of Tf on polymersomes did not significantly change the blood clearance of polymersomes.

In order to investigate the brain delivery property of Tf-PO−DOX, brain uptake and PS product of brain tissue including

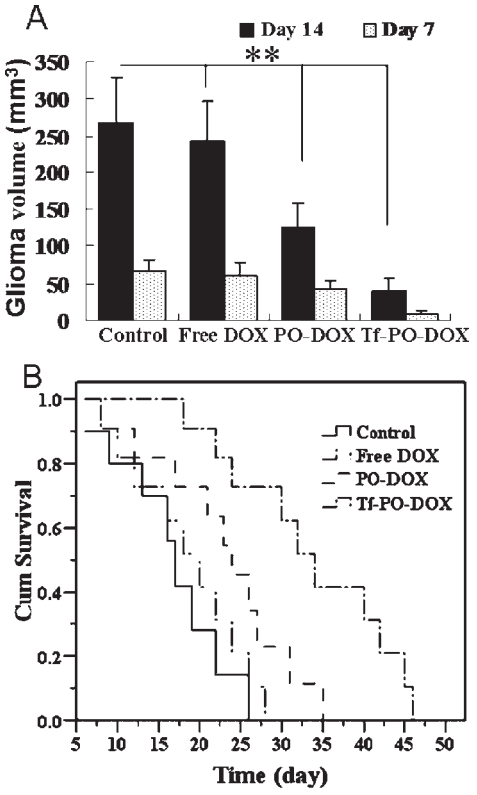

Figure 6. Antitumor effects of DOX-loaded polymersomes in glioma-bearing rats. (A) Glioma volume of different therapeutic groups at the 7th and 14th days (n = 4). ** P < 0.01 vs Tf-PO−DOX group. (B) Percentage of survival (Kaplan−Meier plot) of C6 glioma rat models.

cortex, left striatum, and glioma were quantitatively analyzed (Figure 5B,C). Although free DOX has the highest PS value of 0.040 mL/h/g (Figure 5B), the average brain uptake for free DOX was only around 0.007%ID/g (Figure 5C), which might be attributed to the rapid plasma clearance of free DOX. For free DOX, there was no significant difference of PS value and tissue uptake between cortex, left striatum, and glioma. For PO−DOX, despite the marked increase in plasma AUC, the BBB PS value was reduced to almost zero, resulting in poor uptake in brain cortex and left striatum. The glioma uptake of PO−DOX was as 2.4-fold that of free DOX, which might be due to the EPR effect of tumor tissue. Conversely, the use of Tf conjugated polymersomes significantly increased the PS value and brain uptake (P < 0.01). As compared to PO−DOX, the PS values of Tf-PO−DOX for cortex, left striatum, and glioma at 4 h were 3.7-fold, 3.8-fold, and 3.2-fold those of PO−DOX, respectively. The tissue uptake of Tf-PO−DOX for cortex, left striatum, and glioma at 4 h were 3.6-fold, 3.6-fold, and 3.0-fold those of PO−DOX, respectively. Although the PS value was only 37% that of free DOX, the average %ID/g glioma tissue for Tf-PO−DOX was 0.053%, which increased by 7.1-fold compared with free DOX, suggesting that Tf-PO might be a promising carrier for brain drug delivery, especially for glioma drug delivery.

Brain delivery and tissue distribution of DOX-loaded polymersomes were also determined by fluorescent imaging of main organs at 4 h after i.v. injection of 5 mg/kg of doxorubicin solution, PO−DOX, and Tf-PO−DOX in C6 glioma transplanted rats. As shown in Figure 5D, although PO−DOX showed intensified fluorescence intensity at the glioma site compared with free DOX, Tf-PO−DOX group demonstrated the highest brain fluorescence intensity especially at the glioma site among three groups, which agreed well with quantitative results presented above. DOX distribution in other tissues showed that polymersomes accumulated most in the liver but little in the heart, suggesting that polymersome DOX might have similar potential as Doxil (liposomal doxorubicin) to decrease heart toxicity of DOX.

Pharmacodynamics Experiments in Glioma Model Rats. The antitumor effects of DOX-loaded polymersomes in glioma-bearing rats were shown in Figure 6. The Tf-PO−DOX group presented the smallest glioma volume for rats sacrificed on the same day (Figure 6A), especially on the 14th day. On day 14, the tumor volume of the Tf-PO−DOX group was significantly lower than that of any other group (P < 0.01), indicating that Tf-PO−DOX treatment effectively inhibited the rapid growth of glioma. Life-span extension treated with a multidose of 1.5 mg/kg DOX on days 2, 5, 8, and 11 after glioma implantation was shown in Figure 6B. By log-rank test (Table 1), the median survival times of two polymersome groups were all significantly prolonged compared with that of saline control. However, the increase in survival times (IST) of the Tf-PO−DOX group was more considerable when compared with any other group (P < 0.05), which reached nearly 100% and 70% life-span extension compared with the saline control and free DOX group, respectively, indicating that Tf-PO−DOX possessed the most powerful antitumor activity.

The TUNEL assay further detected DNA fragmentation, a marker of late apoptosis, in nuclei of tumor cells on days 7 and 14 following chemotherapy with 4 different formulations (Figure 7). As shown in Figure 7D, for rats treated with Tf-PO−DOX, significant apoptotic responses of tumor cells in the periphery of tumor were obviously observed on day 7. However, little apoptosis was detected in any tumor tissues treated by free DOX and PO−DOX when compared with saline control (Figure 7B,C). Furthermore, much more apoptotic tumor cells in Tf-PO−DOX treated tumor tissues after 14 days (Figure 7H) were detected compared with any other treatment (Figure 7), although many were presented in PO−DOX treatment.

DISCUSSION

The thin film hydration method was commonly used to prepare biodegradable polymersomes; however, the hydration process needed a high temperature for a long time,[46] which might cause hydrolysis of polyesters block and unfavorable formation of polymersomes. The relative broad size distribution and large vesicle size[32,46] were also unfavorable defects for in vivo drug delivey.[48] Thus, in this study, the nanoprecipitation method was applied to prepare polymersomes, and small-sized polymersomes (107 nm) with a narrow size distribution (polydispersity index, PDI < 0.16 as determined from DLS) were formed, which agreed well with previous reports.[19] Compared with our previously reported large polymersomes (220 nm), small-sized polymersomes with the same zeta potential showed a higher cell uptake by C6 cells than that (1.5 μg/mg) for large polymersomes,[32] indicating that C6 cells favored the uptake of smaller polymersomes. Moreover, blood clearance of small-sized polymersomes was slower than that (156 mL/h/kg, unpublished data) for large polymersomes. These results agreed with previous research that particle size played a key role in cell uptake of stealth particles. For macrophage, large particle sizes were phagocytized more

Table 1. Median Survival Time for Glioma Implanted Rats of Different Therapeutic Groups (n = 12)

group[a]	median	standard error	95% confidence interval	Log-rank test	ISTc	ISTs
Control	17.0	1.3	14.5−19.5	-	-	-
Free DOX	20.0	3.0	14.1−25.9			-
PO−DOX	24.0	2.5	19.0−29.0	[b]	41.2	
Tf-PO−DOX	34.0	3.0	28.1−39.9	[c,d,e]	100.0	70.0

[a] Dosage of DOX is 4 × 1.5 mg/kg. [b] $P < 0.05$, [c] $P < 0.01$ vs control. [d] $P < 0.01$ vs DOX solution. [e] $P < 0.05$ vs PO−DOX. The increases in survival times (%) are compared to control (ISTC) or to DOX solution (ISTS).

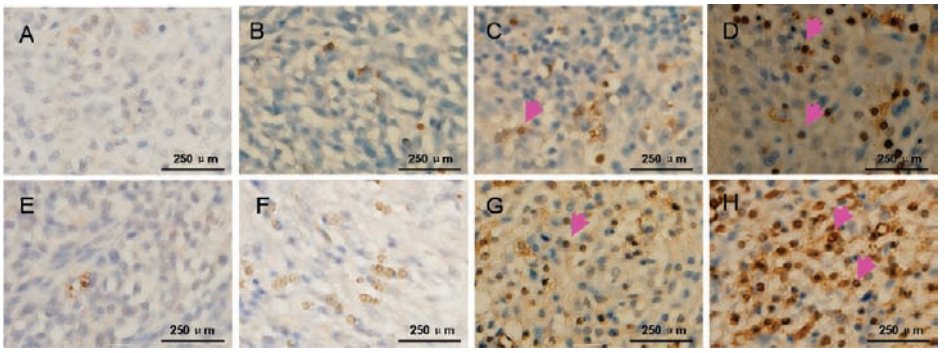

Figure 7. TUNEL staining of tumor tissue sections obtained from rat models 7 days (upper row) and 14 days (lower row) post C6 implantation, following i.v. injection of 1.5 mg/kg DOX on days 2, 5, 8, and 11. Saline control group, (A) and (E); Free DOX treatment, (B) and (F); PO−DOX treatment, (C) and (G); Tf-PO−DOX treatment, (D) and (H). Positive signals were developed by DAB. Cell nuclei were counterstained with hematoxylin.

efficiently while nonphagocytic uptake favored smaller particles.[49] Thus, small-sized polymersomes might have the advantages of both decreasing blood clearance and increasing intracellular delivery to glioma cells.

Considering that chemical and physical properties of the nanoparticles, including size, surface charge, and surface chemistry, are important factors that determine their pharmacokinetics (PK) and biodistribution, it was of significance to control vesicle size of polymersomes to around 100 nm, which is most optimal for improving the PK of polymersomes[48] and advantageous for endocytosis by brain capillary endothelial cells.[41,50] The zeta potential of drug-loaded polymersomes ranged from −10 to −9 mV, which agreed well with the optimal zeta potential within 10 mV, and might help to decrease MPS uptake and prolong blood circulation compared to the charged ones.[31,49] Moreover, the fully hydrophilic PEG (100%) content on the surface of polymersomes could confer good resistance to opsonization and extend vesicle circulation times.[13] Therefore, in this study, Tf-PO−DOX and PO−DOX greatly decreased the plasma clearance of DOX and increased AUC, which might be attributed to the optional particle size, surface charge, and surface chemistry of biodegradable polymersomes.

Inclusion of active targeting ligands in nanosized drug delivery systems was usually used to increase the rate of intracellular delivery and bioavailability of the drug.[31] In this study, Tf molecules with moderate density were conjugated to the polymersome surface to increase both the BBB permeability and intracellular delivery to glioma cells. In fact, despite the fact that PO−DOX could intensively increase the plasma AUC, the brain uptake was very low because of its poor BBB permeability. On the contrary, as compared to PO−DOX, Tf conjugated polymersomes significantly increased the BBB permeability and brain uptake by 3.7-fold and 3.6-fold, respectively, indicating that Tf modification with moderate density greatly facilitated the delivery of polymersomes across BBB. To create pharmacological efficacy, a major challenge was that the encapsulated drug must be delivered and released to the target cells. Although in vitro release of DOX from polymersomes was relatively slow, cell uptake and intracellular distribution results revealed that surface Tf conjugation to polymersomes significantly improved cell uptake and nuclei uptake of DOX, manifesting a significantly enhanced cytotoxicity against C6 cells. Moreover, the enhanced cytotoxicity was consistent with the in vivo efficacy of the Tf-PO−DOX in glioma rats. Compared with PO−DOX and free DOX, Tf-PO−DOX exhibited the most powerful antitumor activity by reducing the tumor volume, increasing median survival time of glioma rats, and extensively producing tumor cell apoptosis. The effect might be attributed to three factors as follows. First, optional chemical and physical properties of the polymersomes decreased the plasma clearance of DOX in the circulation and increased the possibility to cross BBB. Second, the Tf conjugation facilitated the BBB delivery of polymersomes and increased intracellular delivery of DOX in glioma cells, especially in nuclei, where its cytotoxicity was exerted. Finally, EPR effects at advanced stages of solid brain tumor also contributed much to accumulation of polymersomes in glioma.[51]

ABSTRACT:

A multifunctional iron oxide based nanoformulation for combined cancer-targeted therapy and multimodal imaging has been meticulously designed and synthesized using a chemoselective ligation approach. Novel superparamagnetic magnetite nanoparticles simultaneously functionalized with amine, carboxyl, and azide groups were fabricated through a sequence of stoichiometrically controllable partial succinylation and Cu (II) catalyzed diazo transfer on the reactive amine termini of 2-aminoethylphosphonate grafted magnetite nanoparticles (MNPs). Functional moieties associated with MNP surface were chemoselectively conjugated with rhodamine B isothiocyanate (RITC), propargyl folate (FA), and paclitaxel (PTX) via tandem nucleophic addition of amine to isothithiocyanates, Cu (I) catalyzed azide−alkyne click chemistry and carbodiimide-promoted esterification. An extensive *in vitro* study established that the bioactives chemoselectively appended to the magnetite core bequeathed multifunctionality to the nanoparticles without any loss of activity of the functional molecules. Multifunctional nanoparticles, developed in the course of the study, could selectively target and induce apoptosis to folate-receptor (FR) overexpressing cancer cells with enhanced efficacy as compared to the free drug. In addition, the dual optical and magnetic properties of the synthesized nanoparticles aided in the real-time tracking of their intracellular pathways also as apoptotic events through dual fluorescence and MR-based imaging.

Superparamagnetic magnetite nanoparticles with tailored, biocompatible surfaces have elicited phenomenal interest among the scientific community with regard to their multifarious biomedical applicability including magnetic resonance imaging (MRI) contrast enhancement, magnetically modulated drug and gene delivery or hyperthermic treatment of malignant cells.[1−3] Surface engineering of superparamagnetic nanoparticles rely on two major approaches: (i) noncovalent approaches, such as the biotin-streptavidin technology or substrate passive adsorption,[4,5] and (ii) covalent approaches, based on the formation of relatively stable, covalent connections between hydroxyl groups on the nanoparticle surface and a suitable anchoring agent present in a specific position of the target molecule of interest.[6,7] Although the latter approach significantly improves the quality of hybrid nanoparticles (NPs), it suffers from the necessity to affect a great deal of complicated and hard-working chemical modifications, often involving nonaqueous solvents, harsh conditions, and tedious protection−deprotection sequences that is quite impracticable with complex biomolecules such as proteins, carbohydrates, or nucleic acids. Further, in many areas of pharmaceutical research, viz., drug delivery or nanomedicine, targeting molecules, chemotherapeutic drugs, or imaging agents need to be simultaneously integrated on the nanoscale delivery vehicles for the convenience of detection, evaluation, and treatment. However, controlled implementation of varied functions onto a single platform is difficult because all the functional groups

present on the surface of nanoparticles have comparable reactivity. Simultaneously, an attempt to immobilize multiple functional entities on a symmetrically functionalized nanoplatform is fraught with the possibility of nonselective cross reactions. Magnetic nanoparticles (MNPs), bearing more than one type of surface functionality and different chemical reactivity, may be prospective precursors for such theragnostic systems, but their synthesis as well as precise characterization appears to be highly challenging. Ideally, a multifunctional surface should be designed in such a manner that all functional groups associated with a NP can react with its target bioactive at a site, complementary and chemoselective to its functional motif. An efficient method to produce such a multifunctional surface would be to grow a single-structured MNP based platform in bulk and then tune up its surface functionality as per the desired application. Such a strategy makes the initial part of the synthesis more amenable to large-scale production.

In recent years, "click chemistry" with its unique features such as high aqueous competency, chemical orthogonality, and applicability toward diverse substrates[8] has emerged as a burgeoning strategy for the development of surface-engineered polymers and nanoparticles with high selectivity and efficiency. Although a myriad of reactions fulfill the "click criteria", in view of their fast, complete transformability and 100% selectivity for the 1,4-disubstituted 1,2,3-triazole, the Cu (I) catalyzed Huisgen 1,3-dipolar cycloaddition of azides with terminal alkynes (CuAAc reaction) has emerged as the frontrunner under this category. We reasoned that an intelligent combination of "click chemistry" with conventional bioconjugation strategies will cut short the multistep reactions, commonly involved in the preparation of multifunctional nanobio hybrids with concomitant improvement in the selectivity of bioconjugation. In the present account, we describe a complete covalent approach towards the development of a multifunctional nanoplatform for combined cancer-targeted therapy and multimodal imaging using a unique collage of classical bioconjugation strategies with surface diazo transfer and "click chemistry". This multifunctional system comprises of four key components: (i) an iron-oxide based nanomagnetic core enveloped by a hydrophilic, biocompatible coating of 2-aminoethyl phosphonic acid to allow magnetic targeting, as well as T_2 weighted MR contrast enhancement, (ii) a fluorescent dye, viz., rhodamine B isothicyanate (RITC) to enable optical imaging, (iii) a cancer targeting molecule, viz., folic acid (FA) to target the folate-receptor (FR) overexpressed cancer cells, and (iv) a chemotherapeutic drug, viz., Paclitaxel (PTX) to induce cytotoxicity to cancer cells. Magnetite nanoparticles bearing three different functional moieties, viz., amine, azide, and carboxyl groups on a single-structured surface, were used as a synthon for the proposed nanomedical platform. Chemoselective conjugation of RITC and alkyne-functionalized FA and PTX was consummated via nucleophilic addition of amine to isothiocyanate, azide−alkyne click chemistry, and carbodiimide promoted esterification, respectively. Although combination of surface diazo transfer and click chemistry has been previously used by Polito et al. for the bioengineering of magnetic nanoparticles,[9] they used symmetrically functionalized nanoparticles that could accommodate only one ligand at a time. To the best of our knowledge, this is the first report on the systematic fabrication of amine-carboxyl-azide trifunctionalized magnetite nanoparticles and their chemoselective ligation with multiple diagnostic and therapeutic entities. Extensive physicochemical characterizations were undertaken to establish the feasibility of the proposed chemoselective trifunctionalization. Finally, in the course of extensive *in vitro* studies, we demonstrated that the synthesized nanoparticles could serve as a novel platform for "smart" cancer diagnosis and therapy.

MATERIAL AND METHODS

Materials. Anhydrous ferric chloride ($FeCl_3$) and ferrous chloride tetrahydrate ($FeCl_2 \cdot 4H_2O$) were obtained from Merck, Germany. Folic acid (FA), dicyclohexyl carbodiimide (DCC), *N*-hydroxysuccinimide (NHS), 1-[3-(dimethylamino) propyl]-3-ethylcarbodiimide hydrochloride (EDC), propargyl amine, triflic anhydride (Tf_2O), sodium azide (NaN_3), copper sulfate pentahydrate ($CuSO_4 \cdot 5H_2O$), sodium ascorbate, Rhodamine (B) isothiocyanate (RITC), Paclitaxel (PTX), MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium], propidium iodide (PI), RNase A, Trypsin, 4′,6-diamidino-2-phenylindole dihydrochloride (DAPI), and agarose were purchased from Sigma Chemical Co. (St. Louis, MO, USA). 2-Aminoethyl phosphonic acid was prepared by refluxing *N*-2-(bromoethyl phthalimide) with triethyl phosphate under inert atmosphere. Commercially available dimethyl sulphoxide (DMSO) was dried over calcium hydride and purified via reduced pressure distillation. Pyridine (C_5H_5N) and triethyl amine (Et_3N) were dried over KOH and distilled prior to use. Dichloromethane (DCM) was dried over P_2O_5 and purified by normal distillation.

Synthesis Methodology. *Synthesis of Triflic Azide from Triflic Anhydride.* Triflic azide was synthesized from triflic anhydride following a reported protocol[10] with minor modifications. In brief, a mixure of DCM:MeOH:H_2O (3:10:3) was added to an aqueous solution (2 mL) of sodium azide (545 mg, 8.38 mmol) and the resultant mixture was cooled to 0 °C under vigorous stirring. Following the dropwise addition of triflic anhydride (896 μL, 4.19 mmol) and further vigorous stirring for 30 min at 0 °C, the temperature was raised to 10 °C and the biphasic mixture was stirred for 2 h. A saturated aqueous solution of sodium hydrogen carbonate was added dropwise until gas evolution had ceased. The two phases were separated and the aqueous layer was extracted with toluene (2 × 2 mL). The combined organic layers were used in the subsequent diazo transfer reactions.

Synthesis of Folic Acid Alkyne Derivative. Alkyne derivative of folic acid was prepared, following the previously reported literature procedures.[11] Briefly, folic acid (1 mmol) was reacted with DCC (1.5 mmol) in the presence of pyridine and DMSO under inert atmosphere. Following carbodiimide activation, propargyl amine (1.5 mmol) was added dropwise to the reaction mixture and left stirring overnight. The precipitated dicyclohexyl urea (DCU) was removed by filtration. The filtrate was added dropwise to ice-cold diethyl ether (Et_2O) at 0 °C to precipitate out the desired propargyl-folate derivative as a yellow−orange solid product (91% yield). ^{1}H NMR (DMSO-d_6, δ ppm) 8.62 (s, PtC_7 H, 1H), 8.2−8.35 (d, PtC6-CH_2NH-Ph 1H, J = 5.3 Hz), 7.95−8.1 (d,-CONHCHCOOH, 1H, J = 7.6 Hz), 7.6−7.65 (d, PhC_2H and Ph−C_6H, 2H, J = 8.2 Hz), 6.91 (br s, NH_2, 2H), 6.63−6.61 (d, Ph−C_3H and Ph−C_5H, 2H, J = 8.4 Hz), 4.49−4.48 (d, PtC_6−CH_2NH-Ph, 2H, J = 5.6 Hz), 4.32−4.45 (d, PtC_6−CH_2NH-Ph), 3.8 (m, -CONH−CH_2CCH, 2H), 3.8 (m, -CONH−CH_2CCH, 2H), 3.1 (t, −CONH−CH_2CCH, 1 Hz, J = 2.6 Hz), 2.5 (s, -CONH−CH_2CCH, 1H), 2.52 (br s, −OH,1H), 2.3 (m, −CH_2CO_2H, 2H), 2.07 (m, −$CHCH_2CH_2$, 1H), 1.7 (m, −$CHCH_2CH_2$, 1H). Synthesis of ***MNP 1***. Bare magnetite nanoparticles were synthesized by alkaline coprecipitation of Fe^{3+} and Fe^{2+} and subsequently modified with 2-aminoethyl phosphonic acid according to our previously published procedure.[12] Typically optimized for the generation of the hybrid surface proposed, 1 mmol of magnetite (Fe_3O_4) was reacted with 0.25 mmol of 2-aminoethyl phosphonic acid (APA). The suspension was ultrasonicated for 0.5 h, left to stirring at room temperature for 24 h, and finally, the modified nanoparticles (**MNP 1**) were recovered via magnetic decantation.

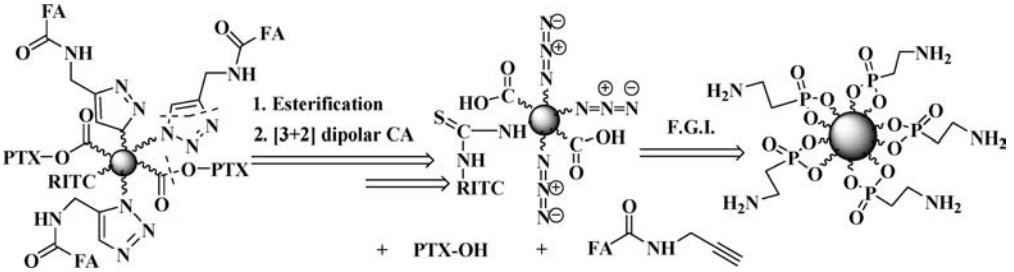
Synthesis of ***MNP 2***. The transformation of **MNP 1**-**MNP 2** was executed via desymmetrization of the primary amine functions on **MNP 1** to an amine-carboxyl-azide trifunctionalized surface through a sequence of (i) controlled, ring-opening linker elongation reaction with succinic anhydride and (ii) high-yielding Cu(II) catalyzed diazo transfer reactions with triflic azide. In brief, succinic anhydride (0.2 mmol) was added to an ultrasonicated suspension of **MNP 1** (200 mg) in anhydrous, distilled DMSO. The pH of the reaction mixture was adjusted to 8 by adding a few drops of triethylamine and left to stir for 24 h. Hybrid MNPs containing both amine and carboxyl groups were thoroughly washed with distilled water and finally isolated through magnetic decantation. An aqueous suspension (20 mL) of partially succinylated **MNP 1** (100 mg) was added to a freshly prepared solution of triflic azide, preactivated with $CuSO_4$ (0.05 mmol) and triethyl amine (0.5 mmol). Methanol (2 mL) was added to the reaction mixture and the suspension was left to stirring at room temperature. After 12 h, the reaction mixture was divided into two parts: one part was separated through magnetic concentration, washed thoroughly with deionized water, and freeze−dried for surface characterizations; while the other part was used in the subsequent steps without further isolation.

For preparing the magnetofluorescent analogue **MNP 2**, 1 mg of rhodamine isothiocyanate (RITC) was dissolved in 1 mL of DMSO−H_2O (1:1). The pH of the resultant mixture was adjusted to ∼8 with 1−2 drops of NaOH solution (0.1 N) and added dropwise to the suspension of **MNP 2** and stirred for 1 h in the dark. A small portion of the reaction mixture was separated through magnetic concentration, washed thoroughly, and freeze−dried for surface characterizations while the other part was kept undisturbed for the subsequent steps.

Synthesis of ***MNP 3***. The click reaction was performed in the same pot as the Cu(II) catalyzed diazo transfer. Cu(II), which was used as catalyst in the previous step, could effectively catalyze the click reaction through generation of Cu(I) in the presence of sodium ascorbate. In brief, sodium ascorbate (catalytic amount) was added to the suspension of **MNP 2**. Alkyne derivative of folic acid (0.25 mmol) was dissolved in DMSO−H_2O mixture (1:1) and the reaction mixture was stirred for 8 h. The "clicked" MNPs (**MNP 2**) were thoroughly washed with a 40% solution of ammonia, followed by repeated washing with distilled water to completely free the nanoparticles from Cu(II). The nanoparticles were finally washed with acetone, separated via magnetic decantation, freeze−dried, and used for subsequent conjugation with Paclitaxel (PTX).



Synthesis of ***MNP 4***. Paclitaxel was conjugated with **MNP 3** via carbodiimide promoted esterification between the hydroxyl groups of PTX and surface-pendant carboxyl groups. In brief, an ultrasonicated suspension of **MNP 3** (5 mg) in DMSO (5 mL) was activated with EDC (0.0075 mmol). A few drops of Et_3N were added to maintain the solution pH at around 8. A solution of PTX (0.005 mmol) in DMSO (1 mL) was added to the resultant mixture and left stirring at room temperature for 48 h. The resulting conjugate (**MNP 4**) was thoroughly washed with distilled water, then acetone, and finally isolated using a rare earth magnet to afford the target nanoconstruct.

Characterizations. The phase analysis of the synthesized magnetite nanopowder was performed on an X'pert Pro Phillips X-ray diffractometer. High-resolution transmission electron microscopy (JEOL 3010, Japan) was employed to characterize the microstructure of the different nanoparticle preparations. The hydrodynamic (HD) size of the particle aggregates was measured by laser light scattering using a Brookhaven 90 Plus particle size analyzer. The surface charge of the nanoparticles was investigated through zeta potential measurements (Zetasizer 4, Malvern Instruments, U.K.) after dilution of the samples in 0.01 (M) phosphate buffer at pH 7.4. Surface chemistry of the nanoparticles was studied using a Thermo Nicolet Nexus FTIR model 870 spectrometer. The surface compositions of the different nanoparticle preparations were obtained by analyzing X-ray photoelectron spectroscopic (XPS) data using Al K_α excitation source in an ESCA-2000 Multilab apparatus (VG microtech). For a detailed structure-resolved analysis of the surface-bound ligands, high-resolution magic angle spinning (HR-MAS) nuclear magnetic resonance (NMR) experiments were pursued. Samples for MAS experiments were prepared by suspending 10 mg of each nanoparticle preparation in a 1:1 mixture of DMSO-d_6:D_2O (500 μL). HRMAS−NMR analysis was carried out with a 400 MHz FT-NMR spectrometer (Avance 400), equipped with a 5 mm HRMAS probe. For further authentication of PTX immobilization on the surface of **MNP 4**, the as-prepared conjugate (∼50 mg) was incubated with porcine liver esterase (PLE) at pH 8 for 72 h to ensure complete detachment of the drug molecules from NP surface. The hydrolysis solution was partitioned between chloroform and water, following which the organic layer was dried over sodium sulfate, concentrated in vacuum, and finally subjected to FTIR and NMR analysis. The data was authenticated by comparison against standard FTIR and NMR data for pure paclitaxel. All measurements unless otherwise specified were performed in triplicate ($n = 3$) and the results were averaged with percentage error determined through calculating the standard deviation from the mean.

Total Iron Determination and Quantification of Functional Molecules on NPs. Iron concentration in the various synthesized nanoparticles was determined spectrophotometrically as described in our previous reports.[13] The determination of amino groups on the surface of **MNP 1** was performed using the 2,4,6-trinitrobenzenesulfonic acid (TNBS) method as described earlier.[11] The transformation of **MNP 1** to **MNP 2** was tracked by monitoring the systematic reduction in amine density on the surface of nanoparticles, determined via the TNBS assy. The average number of RITC and FA molecules immobilized per particle was determined spectrophotometrically according to the protocol adopted in ref 13. For quantifying the amount of PTX immobilized on the surface of MNPs, **MNP 4** was suspended in a mixture of methanol:PBS (1:1) at pH 8 for 72 h to ensure complete detachment of the drug from the nanoparticle surface and analyzed by high-performance liquid chromatography (HPLC) at 227 nm.

Drug Release Studies. To obtain the PTX release profile from the drug-loaded nanoparticles, **MNP 4** (10 mg) was

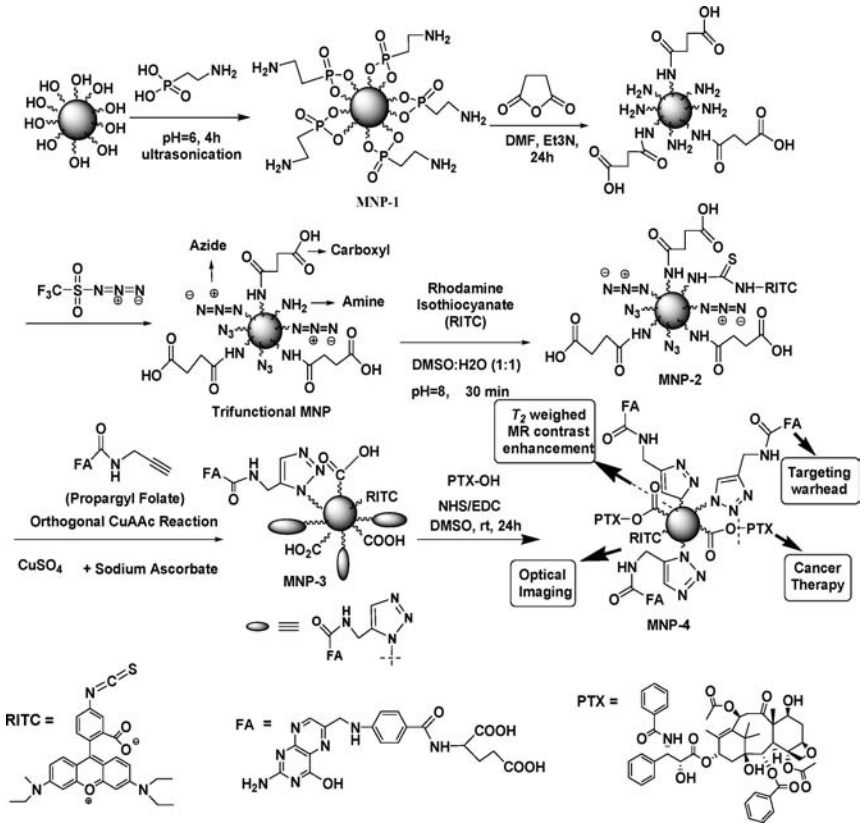
Scheme 1. Retrosynthesis of the Target Multifunctional Nanohybrid

suspended in 10 mL of 1:1 (v/v) mixture of methanol and phosphate buffered saline (PBS) at 37 °C under constant stirring. The solution was divided into two sets, and pH of the individual sets was adjusted by titration with 0.1 (M) NaOH or 0.1 (M) HCl to achieve the pH values of 4 and 7.4, respectively. At different time intervals, 0.5 mL of the aliquot was withdrawn from the mixture and replaced with an equivalent amount of the release medium. The aliquot was centrifuged and the supernatant was analyzed for PTX content using HPLC analysis.

Cell Uptake Studies. The cells cultivated for *in vitro* experiments were human cervix adenocarcinoma, HeLa, and human osteosarcoma, MG-63 cell lines, obtained from the National Centre for Cell Sciences (NCCS) Pune, India. All cell lines were cultured on folate-free Dulbecco Modified Eagle's Medium (FFDMEM) and Minimal Essential Medium (MEM), respectively, with 10% fetal calf serum, 100 units mL^{-1} penicillin, and 100 $\mu g\ mL^{-1}$ streptomycin, 4 mmol L^{-1} glutamine at 37 °C in a 5% CO_2 and 95% air humidified atmosphere. Nanoparticle uptake by different cell lines was studied by magnetically activated cell sorting (MACS) and fluorescence microscopy.

The effect of surface-coating on the uptake of nanoparticles by HeLa cells was evaluated by culturing these cells with different nanoparticle preparations in the absence of folic acid in the culture medium. After 4 h of incubation, the cells were washed to remove free nanoparticles and cell sorting was performed with magnetically activated cell sorting (MACS). Three replicates were measured and the results were averaged with percentage error determined by calculating the standard deviation from the mean. To further evaluate the specificity of cellular targeting of the nanoparticle conjugates, the uptake of iron oxide folate conjugates by HeLa cells was also compared with the uptake by MG-63 cells that do not express the folate receptor as well as HeLa cells incubated with free folate.

***In Vitro* Cellular MR Imaging.** Samples for MR phantom imaging were prepared by suspending 10^6 cells in 50 μL low-melting 1% agarose gel. Cell suspensions cultured with different nanoparticle concentrations (0.01−0.1 mg/mL) were loaded into 1.5 mL eppendorf tubes and allowed to solidify at 4 °C. Samples were then sealed with additional agarose to avoid air susceptibility artifacts. MR imaging was performed with a 0.3 T clinical MRI scanner (Hitachi, Airis), using a prefabricated sample holder. A spin−echo multisection pulse sequence was selected from the Hitatchi Medical System (v 7.0) to acquire MR phantom images. Repetition time (TR) of 2100 ms and variable echo times (TE) of 95−150 ms were used. The spatial resolution parameters were set as follows: an acquisition matrix of 256 × 256, field of view of 240 × 240 mm^2, section thickness of 8 mm, and 2 averages. The MRI signal intensity (SI) was measured using the built-in software. T_2 values were obtained by plotting the SI of each sample over a range of TE values. T_2 relaxation times were then calculated by fitting a first-order exponential decay curve to the plot. The fitting equation can be expressed as $SI = A \times e^{(-TE/T_2)} + B$, where SI is the signal intensity, TE is the echo time, A is the amplitude, and B is the offset. The relaxivity, the R_2 value, was also calculated as the inverse of T_2.



Nanoparticle Induced Cytotoxicity. HeLa cells (4×10^5) were seeded to 96 well tissue culture plates in a total volume of 180 μL of complete media and kept for 18 h, following which 20 μL of different nanoparticle preparations were added to the cells at different concentrations, incubated for 1 h at 37 °C in a humidified incubator (HERA cell) maintained at 5% CO_2. Thereafter, cells were washed thoroughly with PBS to remove the non-internalized particles and re-incubated for different time periods (1−48 h), MTT (4 mg/mL) was added to each well at the strength of 10% (v/v) and incubated for further 4 h at 37 °C. Subsequently, the media containing MTT was removed, and 200 μL of DMSO was added to dissolve the formazan crystals. The absorbance was measured using an ELISA plate reader (Biorad, USA) at 595 nm.

Nanoparticle Induced Apoptosis: Analysis of Cell-Cycle and Nuclear Morphology. For fluorescence microscopy, HeLa cells were treated with 200 μg/mL of different nanoparticle preparations for 0.5 h, washed thoroughly with PBS to remove the noninternalized particles, and incubated at 37 °C for 8, 12, and 24 h, respectively. Following incubation, the cells were smeared on a clean glass slide, fixed with 3.7% formaldehyde for 15 min, permeabilized with 0.1% Triton X-100, and stained with 1 μg/mL DAPI for 5 min at 37 °C. The cells were then washed with PBS and examined by fluorescence microscopy (Olympus IX 70). For cell-cycle analysis, HeLa cells were treated with 200 μg/mL of both **MNP 3** (used as control) and **MNP 4** for 0.5 h, washed thoroughly with PBS to remove the noninternalized particles, and incubated at 37 °C for 8, 12, and 24 h, respectively. Following incubation, the cells were washed with ice-cold PBS (10 mmol, pH 7.4) and resuspended in 200 μL of PBS followed by incubation with 20 μL DNase free RNase (10 mg/mL) and 20 μL of DNA intercalating dye propidium iodide (PI) (1 mg/mL) at 37 °C for 1 h in dark. Apoptotic cells were determined by their hypochromic subdiploid staining profiles. The distribution of cells in the different cell-cycle phases was analyzed from the DNA histogram using Becton-Dickinson FACS Caliber flow cytometer and *Modfit* software.

■ RESULTS AND DISCUSSION

The retrosynthesis of our target, presented in Scheme 1, shows two important reactions: formation of a pH-labile ester bond between hydroxyl groups of PTX and carboxyl functions on the

Scheme 2. Synthesis of the Target Nanoconstruct MNP 4 via a Chemoselective Protocol

nanoparticle surface and formation of a stable, biocompatible triazole linkage between alkyne functionalized folic acid and azide-terminated nanoparticles. While the former was executable through the classical carbodiimide promoted esterification reaction, the latter, in principle, could be achieved via orthogonal copper-catalyzed azide alkyne cycloaddition (CuAAc) reaction. Further retrosynthetic analysis suggested the involvement of a mixed amine-carboxyl-azide-terminated, trifunctional MNP intermediate, which, in principle, could be synthesized from an amine-functionalized nanomagnetite precursor through partial interchange of these amino functions with carboxyl functions, followed by a diazo transfer with the residual surface amino groups.[9] Notably, the ratio of different functional groups on the surface could be manipulated by playing with the stoichiometry of substrate/reactants involved in each functionalization step.

As a preliminary step toward the synthesis of our target, amine-functionalized magnetite nanoparticles (**MNP 1**) were prepared on a large scale by chemisorption of APA on magnetite nanoparticles.[12] The number of amine groups on the surface of **MNP 1** was determined by TNBS assay, as described in our earlier reports.[12] From this analysis, the numbers of amine groups on **MNP 1** was determined to be around 1.56 μmol/mg. Before proceeding for heterotrifunctionalization, model studies were conducted to check the feasibility and effectiveness of partial succinylation and Cu(II) catalyzed diazo transfer on single-structured aminated support. As evident from the loss of surface amine groups, **MNP1** was amenable to both succinylation and surface diazo transfer with conversion efficiencies of 75−80% and 90% (results not shown) respectively. On the basis of these preliminary observations, we sought to interchange only 50% of the surface amine groups with carboxyl groups while the remaining halves were left intact for diazo transfer. The primary amine functions on **MNP 1** were desymmetrized into the amine-carboxyl-azide trifunctionalized **MNP 2** through sequential ring-opening linker elongation reaction with succinic anhydride followed by a high-yielding Cu(II) catalyzed diazo transfer with triflic azide (Scheme 2). While surface amine density after succinylation was determined to be around 0.82 μmol/mg, following diazo transfer, the value declined to 0.09 μmol/mg, implying that there was no change in the efficiency of amine to azide transformation, even after heterobifunctionalization of the surface. The final amine/carboxyl/azide ratio of MNP 2 was 1:8:8. We chose to attach three types of functional molecules with **MNP 2**: (i) a fluorescent dye (viz. RITC); (ii) a targeting agent (viz. FA); and (iii) a chemotherapeutic drug (viz. PTX). Subsequently, a magnetofluorescent analogue of **MNP 2** was prepared by nucleophilic addition of surface-pendant amine functions with the isothiocyanate group of RITC. To check the orthogonality of bioconjugation, single-structured MNPs bearing either carboxyl or azide groups were synthesized and RITC conjugation was attempted maintaining exactly identical reaction conditions. However, as observed by UV and fluorescence spectroscopy, no detectable fluorescence was perceived with the resulting particles, implying that isothiocynate groups react selectively with amine groups. Starting from the magnetofluorescent analogue of **MNP 2**, we reached our target nanoconstruct **MNP 4** in just two steps, which involved simple Cu(I) catalyzed clicking of alkyne-terminated folate onto the surface azido

dx.doi.org/10.1021/bc2000484 |*Bioconjugate Chem.* 2011, 22, 1181–1193

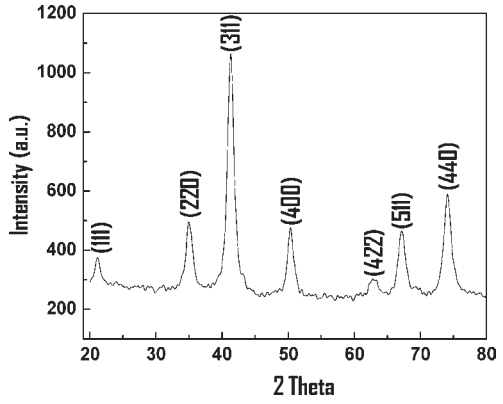


Figure 1. X-ray diffraction pattern of **MNP 1**.

groups, followed by carbodiimide-activated coupling between hydroxyl (−OH) groups of PTX and free carboxyl groups of **MNP 3**. To further testify whether the transformation of **MNP 2**-**MNP 3** was orthogonal, single-structured azide-terminated MNPs were reacted with both RITC and PTX under click conditions, and progress of the reaction was monitored through FTIR analysis. While almost complete disappearance of azide peaks (2041 cm^{-1}) was perceived in the case of reaction between azido-MNPs and propargyl folate only after 6 h (results not shown), FTIR spectra of MNPs reacted with RITC as well as PTX revealed no significant change in the intensity of the azide peak even after prolonged reaction (24 h), suggesting that neither isothiocyanate nor hydroxyl groups (the most reactive functional sites of RITC and PTX for complementary attachment) react under click conditions. In this regard, it should be mentioned that 2′- and 7-hydroxyl groups in PTX are the most suitable positions for its structural modification. Owing to the complexity of our system, it was not possible to determine the exact position of linkage between PTX and MNPs. However, as suggested by the earlier reports, it might be assumed that the 2′-hydroxyl position is less sterically hindered and more reactive than the 7-hydroxyl position reacted specifically with the free carboxyl groups of **MNP 3**.[14] By maintaining a very low fraction of surface reactive amino groups (only 5.8% of the total surface functional groups) on **MNP 2** and further blocking the same with excess of RITC, we eliminated the chance of interparticle cross-linking between the surface-pendant amine and carboxyl groups also as any nonspecific targeting within the biological system. It was further interesting to note that the Cu(I) species, required for the Hüisgen cycloaddition reaction, was generated *in situ*, deriving directly from Cu(II) salts used in the diazo transfer step. In fact, the addition of sodium ascorbate after the completion of diazo transfer initiates the reduction of Cu(II) to Cu(I), which, once formed, becomes immediately accessible to promote orthogonal coupling with the complementary alkyne, so that the transformation of **MNP 1**−**3** proceeded smoothly in a single pot, without necessitating the recovery of the intermediates.

The extent of RITC, FA, and PTX conjugation on **MNP 4** was quantified using UV spectrophotometry and HPLC analyses, respectively. From this analysis, the conjugation efficiency of RITC, FA, and PTX immobilized per unit mass (mg) of MNPs was calculated to be around 0.076, 0.574, and 0.362 μmol/mg, respectively. Since each particle contained magnetite (d = 5.214 g cm^{-3}) with an average radius of 4.5 nm, the average volume and mass of Fe_3O_4 particles are 3.8151 × 10^{-25} m^3 and 1.987 × 10^{-18} gm, respectively. Hence, 1 mg of Fe_3O_4 comprises 5.032 × 10^{14} particles. From these values, the average numbers of RITC, FA, and PTX immobilized per particle were determined to be around 88.89, 688.26, and 433.24, respectively. This concentration, however, was optimal for attaining a high targeting and chemotherapeutic efficiency *in vitro*.

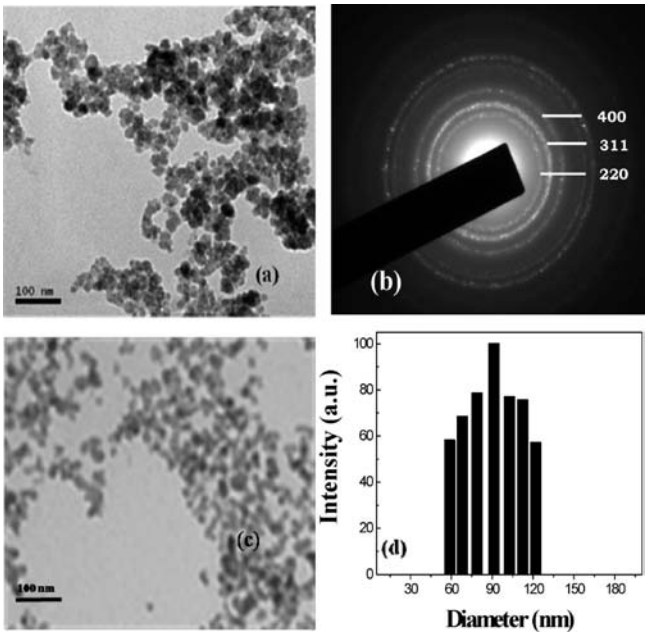

Figure 2. (a) Transmission micrograph of **MNP 1**; (b) SAED pattern of **MNP 1**; (c) TEM micrograph of **MNP 4**; and (d) particle size distribution (PSD) histogram of **MNP 4**, measured using DLS technique.

The high-resolution X-ray diffraction pattern of **MNP 1**, presented in Figure 1, corresponded to that of inverse spinel magnetite [Fe_3O_4] (JCPDS card no. 85−1436). The broadening of peaks indicated the nanocrystalline nature of **MNP 1**, which translated into an average core size of about 9.84 nm using the Debye−Scherrer formula for spherical particles. The selected-area diffraction (SAED) pattern (inset image) indicated the polycrystalline nature of the embedded magnetite particles. The individual planes identified from the SAED pattern correlated well with that of the X-ray diffraction pattern. Transmission electron microscopy (TEM) studies of **MNP 1** (Figure 2) revealed that the as-synthesized magnetite nanoparticles were close to spherical with an average diameter of 9 ± 0.5 nm. Representative TEM images of **MNP 4** indicated the presence of nearly spherical particles with average size in the range 10−15 nm. As evident from TEM, as well as dynamic light scattering (DLS) studies, the "clicked" nanoparticles, in particular, **MNP 4**, displayed much better dispersal and stability at physiological pH as compared to its amine-functionalized precursor (**MNP-1**), which is possibly due to the presence of a highly hydrophilic triazole moiety and the negative surface charge arising out of the free, deprotonated carboxyl and hydroxyl groups of FA and PTX, respectively. An aqueous suspension of **MNP 4** presented a mean HD of 91 ± 4 nm (PDI = 0.191 ± 0.009) with a surface charge of −41.4 ± 2 mV at neutral pH. These functional nanoaparticles were highly stable in aqueous medium as their HD, PDI, zeta potential, and T_2 relaxivity remained unaffected over a long period of time (Table 1).

Table 1. Stability Analysis of MNP 4

time (weeks)	1	2	3	4	6	8	12
HD (nm)	91.6 ± 4.6	89.7 ± −4.2	93.2 ± 5.1	92.9 ± 4.9	94.1 ± 3.7	93 ± 4.1	94.9 ± 5.4
PDI	0.197 ± 0.012	0.184 ± 0.009	0.193 ± 0.017	0.191 ± 0.014	0.204 ± 0.019	0.216 ± 0.022	0.198 ± 0.017
Zeta-potential (mV)	−43.4 ± 3.8	−43.8 ± 4.2	−41.9 ± 4.4	−40.7 ± 5.5	−38.6 ± 3.7	−39.3 ± 3.6	−37.6 ± 4.1
r_2 (s^{-1} mM^{-1})	70.8 ± 4.5	70.96 ± 5.19	69.7 ± 5.9	67.4 ± 5.6	65.7 ± 6.2	66.8 ± 6.3	65.8 ± 6.8

Exposure of **MNP 4** to various culture media (DMEM, RPMI, etc.) in the presence of serum revealed no significant alteration in hydrodynamic sizes and surface charge up to 72 h of incubation (results not shown), confering the suitability of these nanoparticles for biomedically relevant applications.

The FTIR spectrum of **MNP 1** (Figure 3) displays a strong band around 594 cm^{-1} attributed to the Fe−O vibration related to the magnetite core. A broad band, associated with the overlapping of Fe−O−P and P═O stretching, appears between 1160 and 928 cm^{-1}, which unambiguously suggests that a strong interaction between the phosphonate headgroup and the Fe_3O_4 surface is present. The band at 1633 cm^{-1}, associated with −NH bending (scissoring) vibration, however, testifies to the successful modification of magnetite surface by primary amine groups. Chemical treatment of these surface amine groups with succinic anhydride led to the partial interchange of these amine functions with carboxyl functions. The typical vibrations of $-CO_2H$ group (1704 cm^{-1}) and the amide linkage [1637 (amide I) and 1556 cm^{-1} (amide II)] appeared in the corresponding FTIR spectrum, which evidence the successful derivatization of the surface-amino group with succinic anhydride. It should, however, be noted that relative weakness in the intensity of the $-CO_2H$ vibration at 1710 cm^{-1} is possibly a consequence of intraparticle hydrogen bonding between the surface $-CO_2H$ groups. This, however, shifts the >C═O stretching bands of carboxylic acids to a much lower wavenumber (∼1625−1650 cm^{-1}) and superimposes with the amide I band. As a consequence of diazo transfer, an extra band appears in the FTIR spectrum of **MNP 2** at approximately 2041 cm^{-1} due to the asymmetric stretching of the N═N═N bond of the azide group. As already discussed, RITC comprised only 4−5% of the total surface functional groups and, therefore, could not be detected by FTIR analysis, albeit spectrophotometric studies clearly corroborated the successful labeling of MNPs with RITC. The successful immobilization of FA on **MNP 2** was clearly indicated by the disappearance of the 2041 cm^{-1} band and concomitant appearance of the characteristic bands of FA at 1603 and 1656 cm^{-1}. After PTX conjugation, the only distinguishable change in the spectrum was the appearance of a weak but fairly prominent band at approximately 1736 cm^{-1}, possibly associated with C═O stretching vibrations arising out of the covalent attachment of PTX to the carrier surface via an ester linkage. The relatively weak intensity of the ester stretching frequency might be a consequence of multiple ligand attachment on the nanoparticle surface. The surface of MNPs being shared by multiple functional molecules, relative fraction of individual functional entities associated with the nanoparticle surface, may be lower than the detection limit of the available spectroscopic techniques.[15]

The successful transformations of **MNP 1** to **MNP 3** via partial succinylation, surface diazo transfer, and CuAAc reactions were also studied using XPS analysis. The high-resolution N1s spectrum of **MNP 1** (Figure 4) reveals a broad shoulder at 398.6 eV corresponding to the free amino groups on the surface. At the ring-opening linker elongation step, the intensity of the -NH_2 peak gradually diminishes with concomitant appearance of a new peak at 400.6 eV, indicating the formation of amide (−NHCO) linkage between the amine groups of APA and succinic anhydride. A high-resolution spectrum of the nitrogen 1s binding energies of **MNP 2** reveals two distinct peaks, one centered at around 400 eV and another at 405 eV, with approximately 2:1 ratio of the peak areas. The relatively lower intensity, higher energy 405 eV peak is unusual for organic nitrogen, and this peak can be assigned to the central, electron-deficient nitrogen in the azide group. Reaction of **MNP 2** with the propargyl folate, linked via the click reaction, reduced the 405 eV peak to the level of noise. The nitrogen 1s signal at 400 eV broadens, indicating the presence of chemically distinct nitrogen atoms corresponding to the nitrogen atoms of the triazole linkage and amide bonding inside FA structure and partially succinylated surface amine functions as well. Assuming that the azide disappearance is correlated only to product formation, this provides additional evidence that the transformation is nearly quantitative.[16]

In general, ^{1}H NMR spectroscopy of ligands, bound to paramagnetic nanocrystals are difficult to perform because of large broadening effects, caused by paramagnetic features. Recently, Polito et al. have explored the possibility of using the high-resolution magic angle spinning (HRMAS) technique for the fine-structure-resolved characterization of even complex organic molecules bound to paramagnetic nanocrystals, such as nanosized iron oxides, while minimizing the effect of paramagnetic broadening. In line with Polito's approach, we tried to apply the HRMAS technique for further detailed structure-resolved analysis of the organic layer, associated with our multifunctional nanoconjugate. A comparison of the ^{1}H NMR of **MNP 2** and **MNP 3** unambiguously confirmed the presence of FA on **MNP 3**, as indicated by characteristic signals from pteridine ring proton (δ 9.2 ppm) and aromatic protons of the PABA moiety of FA (δ 8.1−7.9 ppm and 7.3−6.9 ppm), which, however, were absent in **MNP 2** (Figure 5). The presence of a prominent peak at 8.2 ppm in the NMR spectrum of **MNP 3** due to the triazole proton further testified to the successful end-functionalization of **MNP 2** via 1,3-dipolar cycloaddition. Careful inspection of these ^{1}H HRMAS NMR spectra, however, revealed that the spectral intensity of a proton was directly proportional to its distance from the nanoparticle surface, i.e., the longer the distance, the stronger the intensity. For example, the intensity of the triazole proton as well as aromatic protons of FA was disproportionally higher than the methylene protons of FA and phosphonic acid, lying in close proximity to the NP surface. The observation, however, is in close accordance with some of the earlier reports[17] and is attributed to (i) the restricted motion for protons closer to the MNP surface, (ii) heterogeneity caused by MNP surface features (terraces, edges, or vertices) of various sizes or facets, and (iii) spin−spin relaxation (T_2) broadening effect, which also depends on the size of NPs. In the case of **MNP 4**, overlap of aromatic protons of FA and PTX caused an inherent broadness in

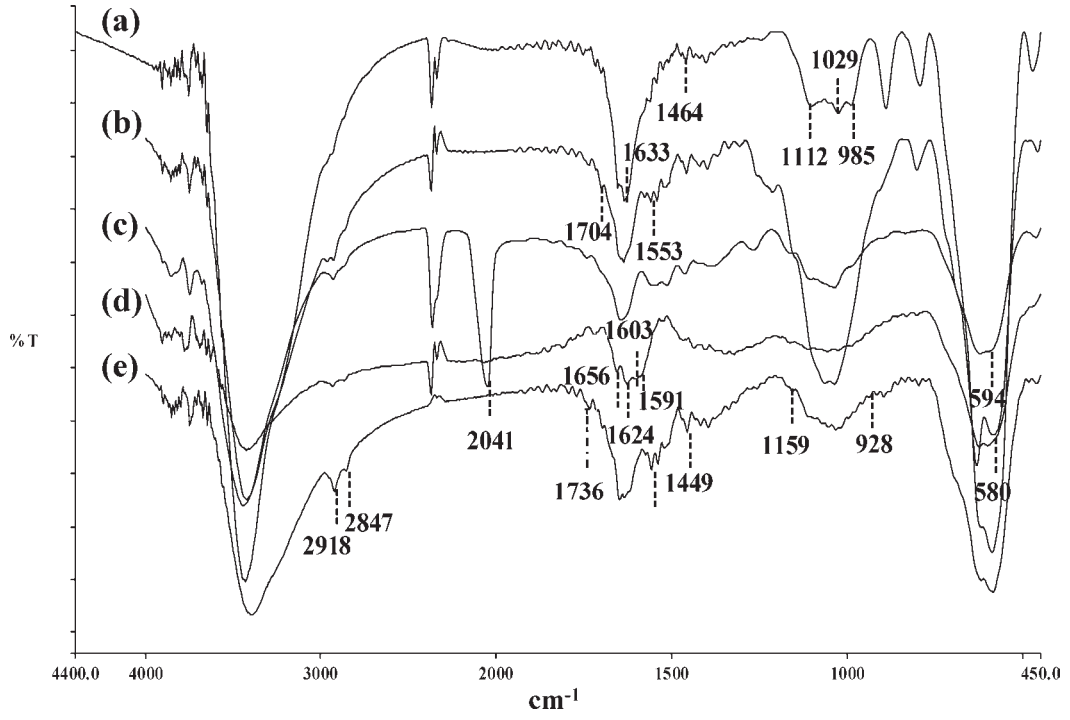

Figure 3. FTIR spectra of (a) **MNP 1**; (b) **MNP 1** (after succinylation); (c) **MNP 2**; (d) **MNP 3**; and (e) **MNP 4**.

the spectrum between δ 9.8 and 7.3 ppm and also in the lower aliphatic range (results not shown). Consistent with the findings of FTIR, spectral intensity of some of the key peaks of FA as well as PTX was too low to make a definitive structural assignment. To confirm the successful immobilization of PTX on MNP surface, we relied on an alternative strategy, which consisted of detachment of PTX from the surface of **MNP 4** through a base-catalyzed ester hydrolytic cleavage, followed by a mini-workup and subsequent characterization of the organic layer by FTIR and NMR analysis.

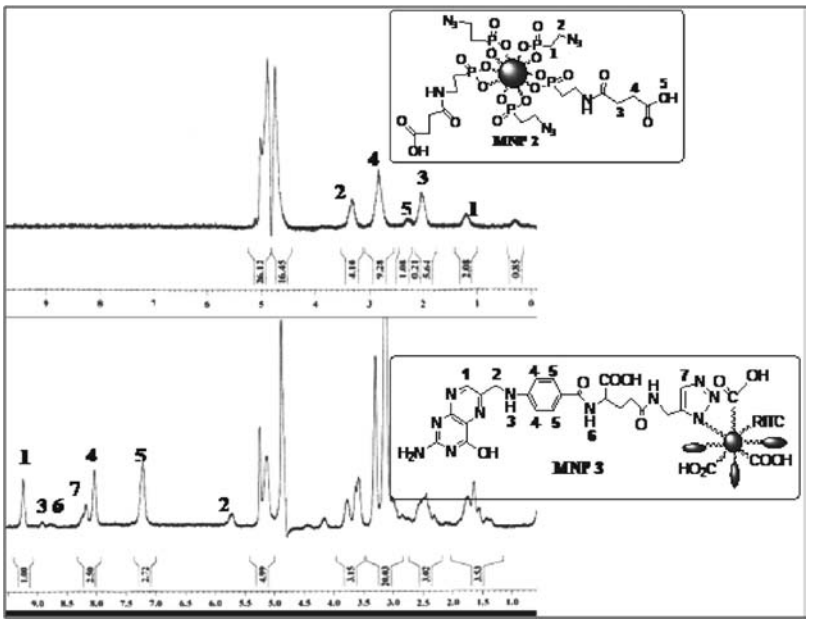

Figure 5. Structure-resolved analysis of "clicked" MNPs using HRMAS-NMR spectroscopy.

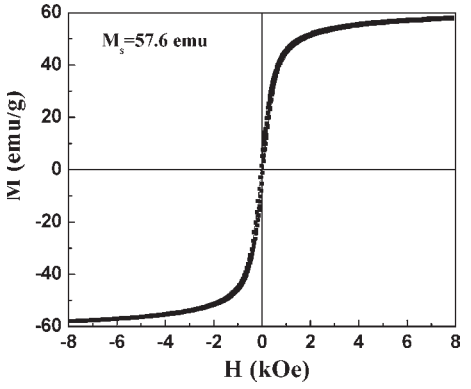

Figure 6. Magnetization (M-H) curve of **MNP 4**.

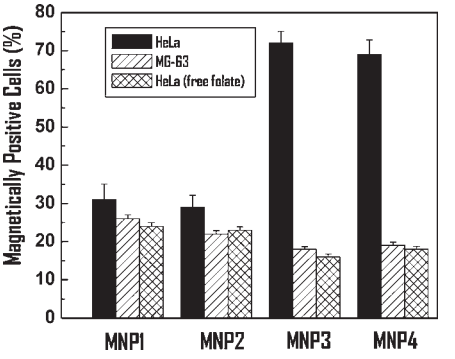

Figure 7. Quantification of **MNP** uptake by FR positive HeLa, FR negative MG-63 cell lines, and HeLa cells incubated with excess free folate via magnetically activated cell-sorting (MACS) analysis.

It should however be mentioned in this regard that surface modification had no detrimental effect on the intrinsic superparamagnetism of Fe_3O_4. Absence of hysteresis, coercivity, and remenance in the magnetization curve (Figure 6) corroborated the superparamagnetic nature of **MNP 4**. The saturation magnetization (57.3 emu/g) was, however, lower than that of bare Fe_3O_4 MNPs (~91 emu/g) ascribed to the organic coating associated with the nanomagnetite core. Proton relaxation measurements of **MNP 4** using a 0.3 T clinical MRI scanner further indicated the presence of superparamagnetic iron-oxide nanoparticles with appreciably high T_2 relaxation (70.794 s^{-1} mM^{-1}), ensuring their potential application as a MR contrast agent.

To further demonstrate the potential biomedical applications of the synthesized functional **MNP 4**, we evaluated the selective uptake of **MNP 1**−**4** against folate-receptor overexpressing human cervical carcinoma HeLa cells. Preliminary studies using magnetically activated cell sorting (MACS) indicated that cellular uptake of the conjugates containing FA as the targeting molecule was significantly enhanced in comparison to their nontargeted control (Figure 7). The observations demonstrated active targeting of magnetite nanoparticles through the interaction between the folate groups on nanoparticle surface and receptors of HeLa cells. With the aim to confirm the receptor specificity for the conjugate, the uptake of **MNP 1**−**4** by HeLa cells was compared with the uptake by (i) folate-receptor negative human osteosarcoma, MG-63 cell-line, and (ii) HeLa cells, preincubated with free folate. As internalization of the folate functionalized NPs was nominal in both cases, we corroborated the receptor-mediated internalization of our folate decorated MNPs.

To further evaluate the detectibility of **MNP** internalized cells by MRI and confirm their association with FR-overexpressing HeLa cells, MR phantom samples were prepared by suspending HeLa cells incubated with **MNP 1**−**4** for two hours in agarose. The T_2 weighed phantom image of cells, incubated with **MNP 3**−**4**, showed a significant negative contrast enhancement in comparison to their nontargeted control **MNP 1**, suggesting effective nanoparticle internalization inside the target cells (Figure 8). Slight losses in signal intensity were, however, observed for HeLa cells incubated with **MNP 1**, when compared to blank cells cultured without nanoparticles, attributed to some

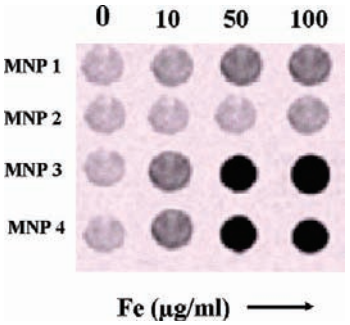

Figure 8. T_2-weighted spin−echo MR phantom images of HeLa cells incubated with 0−100 μg/mL of **MNP 1**−**4** for 2 h.

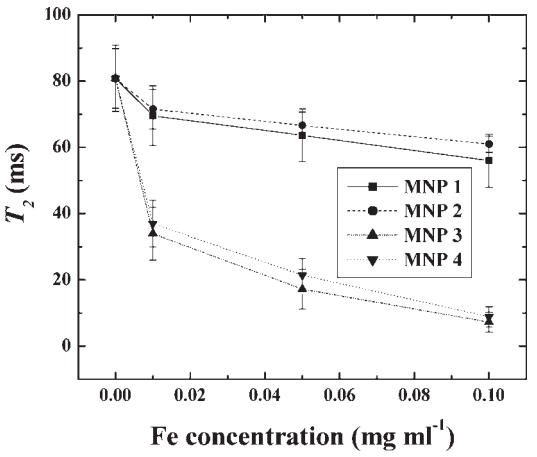

Figure 9. T_2 relaxation analysis of HeLa cell suspensions magnetically labeled with **MNP 1**−**4**.

nonspecific internalization of these nanometer-sized particles inside the target cells. The relative relaxation times of **MNP 1**−**4** were quantified through T_2 weighted spin−echo MR images. Figure 9 shows the T_2 relaxation time as a function of particle concentration in cell culture media. HeLa cells cultured with **MNP 3**−**4** had a shorter T_2 relaxation time (higher relaxivity) than **MNP 1**−**2** due to enhanced magnetism, which resulted from higher uptake of the former by HeLa cells in comparison to the latter. All these results unequivocally establish the potential of our as-prepared nanoformulation as a cancer-targeted, MR imaging probe.

In vitro stability or drug release studies, conducted with **MNP-4** at pH 4 and 7 using a 1:1 mixture of methanol and PBS (v/v) as the release medium showed a typical release profile, i.e., an initial burst release, followed by a sustained release pattern (Figure 10). The overall release rate was much higher at pH 4 and negligible drug release was observed at physiological pH (pH 7.2). Around 66.37% of the conjugated PTX was found to be released from **MNP 4** exposed to the release medium at pH 4 whereas only 35% release was observed at pH 7.5. This pH-dependent release behavior suggested that PTX will be released more in acidic tumor sites than in the normal tissues. Once the particles are internalized inside the cells through FR mediated endocytosis, the decreased pH values are supposed to induce further accelerated release inside the acidic endosomes of tumor cells through the rupture of acid as well as base-cleavable linkage between **MNP 4** and PTX.

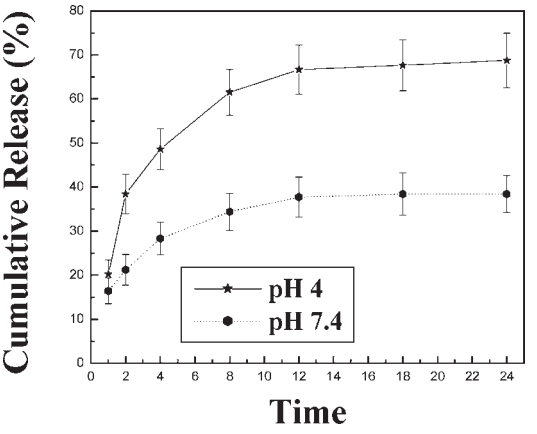

Figure 10. Drug release profile of **MNP 4** under different pH conditions.

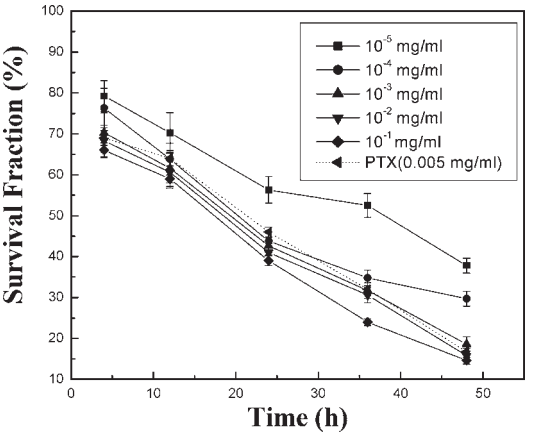

Figure 11. Reduction in viability of HeLa cells as a function of time and nanoparticle concentration in culture medium.

To further test the efficacy of PTX cleavage inside the target cells, HeLa cells were cultured with **MNP 1**−**4** and free PTX in a FA deficient medium. Nanoparticle-induced cytotoxicity was determined by the MTT assay. While nanoparticles deprived of PTX were shown to be noncytotoxic, both **MNP 4** and free PTX (dissolved in a 1:1 (v/v) mixture of MeOH and PBS) reduced the cellular viability in a time and dose-dependent fashion, establishing the ability of the cells to cleave PTX inside the acidic tumor endosomes (Figure 11). Cells exposed to PTX modified NPs demonstrated a notable downward trend in viability, following 24 h in culture. It was further observed that, for concentrations of PTX grafted nanoparticles at or higher than 10 μg/mL (equivalent PTX concentration of 4.792 μg/mL of PTX), the cells showed almost comparable reduction in cellular viability. Notably, cytotoxic activity of **MNP 4** was even higher than equivalent amount of the free drug under similar experimental conditions. The ability of these drug modified nanoparticles to induce significant cytotoxicity in such low concentrations promises the desired chemotherapeutic effect in the target site in very low dosages.

To verify whether **MNP-4** could induce cell death through the initiation of apoptosis, HeLa cells were exposed to 0.1 mg/mL of **MNP 1**, **3**, and **4** for 0.5 h, washed to remove the noninternalized nanoparticles, incubated at 37 °C for 24 h, and subsequently

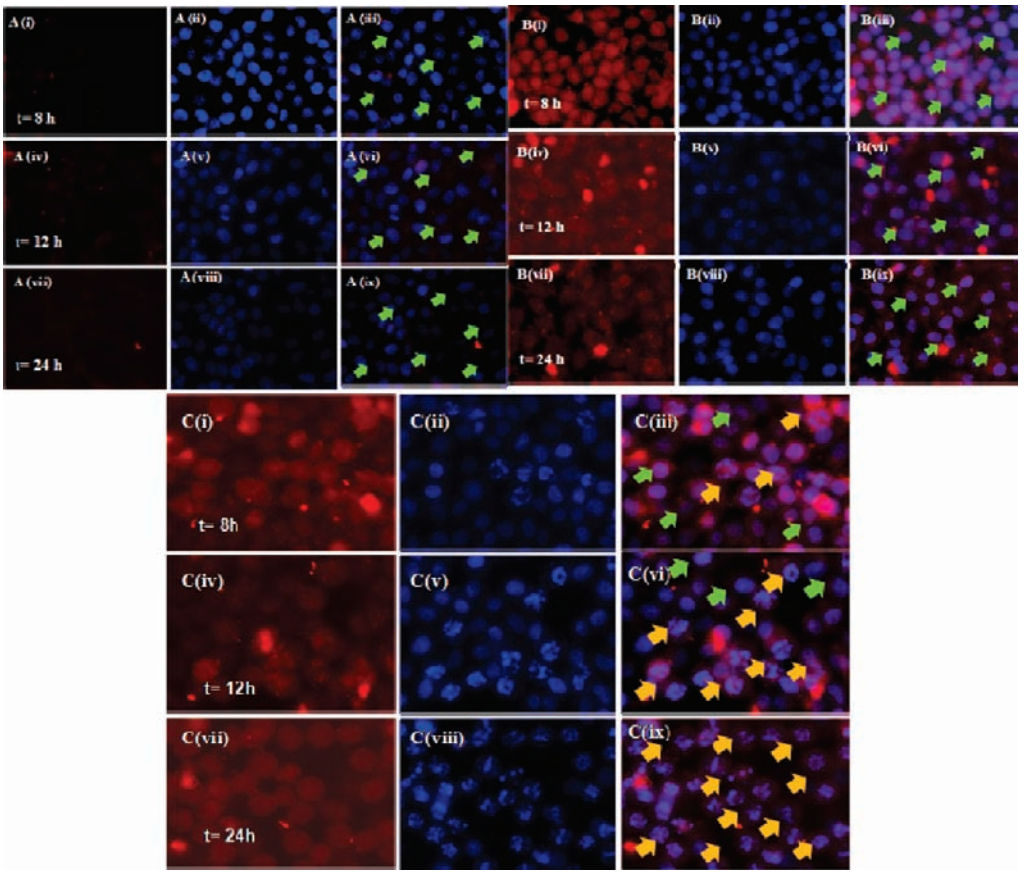

Figure 12. Fluorescence micrograph of [A(i−ix)] HeLa cells incubated with **MNP 1**, [B(i−ix)] **MNP 3**, and [C(i−ix)] **MNP 4** for 8, 12 and 24 h, respectively. The green and yellow arrows denote healthy and apoptotic nuclei, respectively. The left (i, iv, viii) and middle (ii, v, viii) panels of each incubation type represent RITC and DAPI fluorescence, respectively, while the right (iii, vi, ix) panel is the merged RITC and DAPI fluorescence images.

visualized using fluorescence microscopy. Results showed little or practically no internalization of the nontargeted controls **MNP 1**, as expected. On the contrary, intense red fluorescence was detected in the cytoplasm of cells treated with the folate targeted nanoparticles (**MNP 3**−**4**), demonstrating their cellular internalization through receptor-mediated endocytosis (Figure 12). With an aim to examine the nuclear morphology and identify cell death, cell nuclei were further stained with 4′,6-diamidino-2-phenylindole (DAPI), a nuclear staining dye known to exhibit strong blue fluorescence, when bound to DNA. As predicted from the cytotoxicity experiments, fluorescence images of HeLa cells, incubated with **MNP 1** and **MNP 3** for 8, 12, and even 24 h showed well-preserved nuclear structures without any detrimental effect on structural integrity. In contrast, typical features of nuclear apoptosis were prominent in cells incubated with **MNP 4** as early as 8 h. Cell nuclei segregated into segments accompanied by severe fragmentation, suggesting a major breakdown of the chromatin followed by DNA condensation in these nuclei. By the end of 24 h, massive fragmentation was observed leading to a huge population of apoptotic bodies.

To further quantify the extent of nanoparticle induced apoptosis, cell-cycle analysis was performed using the standard propidium iodide (PI) flow cytometric assay. Classification of HeLa cells into the various phases of the cell cycle following their incubation with **MNP 3** and **MNP 4** for different time spans (8−24 h) has been shown in Figure 13. Apoptosis, which is hallmarked by DNA fragmentation, was almost negligible in the case of both untreated cells and cells treated with control **MNP 3**, even after 24 h of incubation. On the contrary, significant DNA fragmentation could be envisaged in HeLa cells treated with **MNP 4** under similar experimental conditions, evidenced as a "sub-G1" peak in the DNA fluorescence histogram. Time-dependent cell cycle analysis of **MNP-4** incubated HeLa cells clearly indicated that the number of cells in the G_0/G_1 phase gradually decreased as a function of time with a concomitant elevation of both G_2/M and sub-G1 or apoptotic phases. While the ratio of cells present in G_0/G_1 to G_2/M phases after 8 h was 1.87, following 12 and 24 h of incubation the values decreased to 1.24 and 0.64, respectively, relative to 3.53 and 2.47 for untreated cells and cells incubated with **MNP 3** for 24 h. For **MNP 4**, massive cell death was observed at the end of 24 h as dead cells accounted for 92.59% of the total population, relative to only 53.69% for HeLa cells incubated with an equivalent amount of free PTX (cell cycle distribution not shown). The data not only are in good agreement with our fluorescence microscopic observations, but also correlate well with the cell cycle distribution profile of other PTX-based drug delivery systems based on biodegradable polymers like PLGA or chitosan.[18,19] In fact, the sub-G1 population for HeLa cells (92.59%) incubated with 0.2 mg/mL of **MNP 4** (equivalent paclitaxel concentration of 0.11 μmol) was appreciably higher than that for A549 cells (73.32%) incubated with wheat germ agglutinin (WGA) conjugated, PTX loaded PLGA nanoparticles (equivalent PTX concentration 20 μmol). The results unambiguously suggest that **MNP 4**

developed in the course of the present research can effectively arrest the cell cycle in the G_2/M phase, which was responsible for the morphological alterations visualized by fluorescence microscopy and ultimately causes cell death.

CONCLUSION

In conclusion, a biocompatible, theragnostic iron oxide nanoformulation for combined cancer-targeted therapy and multimodal imaging has been designed and successfully synthesized using a chemoselective protocol. Magnetite nanoparticles simultaneously bearing three types of functional groups, viz., amine, carboxyl, and azide groups, were used as the bioconjugating precursor. Such a trifunctional surface was executable through a sequence of highly controlled, partial succinylation, followed by Cu (II) catalyzed diazo transfer on APA functionalized magnetite nanoparticles. Chemoselective conjugation of cancer-targeting FA and chemotherapeutic PTX on the hybrid MNP surface was accomplished via CuAAc reactions and carbodiimide promoted esterification, respectively. The feasibility of chemoselective ligation on these bifunctional MNPs was demonstrated with extensive FTIR, XPS, and HRMAS-NMR analysis. *In vitro* cell uptake, MR imaging, and apoptosis studies established that that the bioactives chemoselectively appended to the nanomagnetite core allowed the nanoparticles to simultaneously target, image, and kill folate-receptor (FR) overexpressing cancer cells with enhanced efficacy as compared to the free drug. In a scientific panorama, in which the emergence of "smart", multifunctional nanoparticles appears to be one of the major breakthroughs in cancer theragnostics, the fabrication of these newly synthesized amine-carboxyl-azide trifunctionalized magnetite nanoparticles contributes a new toolbox for the non-polymer-based, chemoselective biofunctionalization of inorganic nanoparticles. Further, the positive attributes of *in vitro* study make these trifunctional nanoparticles a "smart" theragnostic platform for further *in vivo* evaluation.

ABSTRACT: Radioactive decay of some radionuclides produces a shower of Auger electrons, potent ionizing radiation within a very short range in living tissue (typically ca. 100 nm). Therefore, they must be brought to DNA-containing cell compartments and preferentially directly to DNA to be fully biologically effective. They may be used for a triple-targeting approach (first targeting, polymer-based system targeting into tumor tissue due to EPR effect; second targeting, pH-controlled release of intercalator-bound Auger electron emitter in slightly acidic tumor tissue or endosome; third targeting, into DNA in cell nucleus by the intercalator) minimizing radiation burden of healthy tissues. We describe a first system of this type, an ellipticine derivative-bound iodine-125 attached to hydrazide moieties containing poly[*N*-(2-hydroxypropyl)methacrylamide]. The system is stable at pH 7.4 (0% intercalator released after 24 h incubation), while iodine-containing biologically active intercalator is released upon decrease of pH (25% intercalator released after 24 h incubation at pH 5.0—model of late endosomes). Both 2-*N*-(2-oxobutyl)-9-iodoellipticinium bromide and the noniodinated 2-*N*-(2-oxobutyl)ellipticinium bromide are potent intercalators, as proven by direct titration with DNA and ethidium displacement assay, and readily penetrate into cell nuclei, as proven by confocal microscopy. They retain chemotherapeutical antiproliferative properties of ellipticine against Raji, EL-4, and 4T1cells with IC_{50} in the range 0.27−8.8 μmol/L. Polymer conjugate of 2-*N*-(2-oxobutyl)-9-iodoellipticinium bromide is internalized into endosomes, releases active drug, possesses cytotoxic activity, and the drug accumulates in cell nuclei.

INTRODUCTION

Radiotherapy with radionuclides is common to treat various cancer types such as thyroid cancer.[1,2] For such radiotherapy, mostly β^- emitters are used.[1,3] Radioactive decay of many radionuclides (e.g., ^{111}In, ^{125}I, or ^{99m}Tc) is accompanied with emission of several so-called Auger electrons (AEs) with relatively low energy, which are emitted during reorganization of the electron shell of the atom after decay. Since a charged particle, like an electron, loses its energy in material most effectively (i.e., has the highest linear energy transfer, LET) just before it completely stops ("Bragg peak"[4]), AEs are biologically potent ionizing radiation within a very short range in living tissue (typically ca. 100 nm[2]). However, their very short range means that, if AE emitting radionuclides are intended to be used as radiotherapeuticals, they must be brought into cell nucleus and preferentially directly into DNA, as the main ionizing radiation biological target, to be effective by inducing double-strand breaks.[2,5,6] Especially advantageous in such cases are AE emitter-bearing antisense oligonucleotides,[7] nucleosides,[5,6] and intercalators,[8−11] e.g., ^{125}I-iodinated daunorubicin derivative,[8−10] which target and accumulate the radionuclide directly in DNA. Such isotopically labeled intercalators would be extra beneficial in connection with drug delivery system (see Figure 1), which would ensure selective targeted delivery of the radionuclide into tumor tissue (first targeting by enhanced permeation and retention - EPR - effect). Solid tumors spontaneously accumulate biocompatible polymers, polymer micelles, liposomes, and nanoparticles of the <200 nm size due to the leaky nature of the newly formed tumor neovasculature and poor or missing lymphatic drainage in the solid tumor tissue. Polymer size is thus the targeting mechanism here. This so-called EPR effect is quite universal for many solid tumors. In the tumor tissue, an intercalator bearing the radionuclide is released in its active form (second targeting by pH or enzyme-triggered release). The intercalator then brings the radionuclide into the cell nuclei (third targeting). This would decrease the main disadvantage of radionuclide delivery system—radiation burden of healthy tissues during transport into target tumor tissue—while keeping the advantage of the possibility to follow the biodistribution by real time γ-imaging from the primary γ-rays of the decay (which are far less biologically effective than AEs). To the best of our knowledge, the system described in this paper is the first one of this type in the literature to date.

In this paper, we describe a new polymeric system with AE emitter ^{125}I covalently bound in the form of DNA-intercalating ellipticine (5,11-dimethyl-6*H*-pyrido[4,3-*b*]carbazole) derivative 1-(9-iodo-5,11-dimethyl-6*H*-pyrido[4,3-*b*]carbazol-2-ium-2-yl)-2-butanone

conjugated to biocompatible poly[*N*-(2-hydroxypropyl)methacrylamide-*co*-1-*N*-(6-hydrazino-6-oxohexyl)-2-methylacrylamide] (pHPMA-MAAcap hydrazide) via hydrolytically labile hydrazone bonds. To study biological and physicochemical properties of the system in detail and to compare the effect of iodination on chemotherapeutical cytostatic effectivity, intracellular distribution, intercalation ability, and so forth, we synthesized, as models, the system substituted with natural (stable) iodine and the system with the ellipticinium derivative without iodine.

EXPERIMENTAL PROCEDURES

Materials. No-carrier-added $Na^{125}I$ solution (24 GBq/mL) was purchased form Lacomed Ltd. (Czech Republic). All other chemicals were purchased from Sigma-Aldrich Ltd. (Prague, Czech Republic). The 9-iodoellipticine (**1b**) was synthesized by acetomercuration of ellipticine followed by the reaction with iodine according to ref 12.

Quaternization of Ellipticine and 9-Iodoellipticine (see Figure 2 for scheme). Ellipticine (**1a**, 10 mg, 0.041 mmol) or 9-iodoellipticine (**1b**, 15 mg, 0.041 mmol), respectively, and 1-bromo-2-butanone (25 μL, 0.245 mmol, 6 equiv) were added to methanol (1 mL) and the reaction mixture was stirred overnight at room temperature. Then, the reaction mixture was evaporated under reduced pressure and recrystallized from hexane-diethyl ether (2:1 v/v) to give **2a** or **2b**, respectively.

Melting point temperatures were determined on a Kofler' s block (VEB Analytik Dresden, Germany). NMR spectra were measured on a Bruker Avance MSL 300 MHz NMR spectrometer (Bruker Daltonik, Germany). UV/vis spectra were measured on a SPECORD 205 Spectrometer (Analytik Jena AG, Germany).

*2-N-(2-Oxobutyl)ellipticinium Bromide (**2a**).* Yield 11 mg (68%) of orange crystals, mp (hexane-diethyl ether 2:1 v/v) = 213−215 °C; R_f (ethanol−water 5:1 v/v) = 0.15; anal. Conjugation of 2a and 2b with pHPMA-MAAcap Hydrazide (see Figure 2 for scheme). The pHPMA-MAAcap hydrazide (weight average molecular weight M_w = 26.8 kDa, polydispersity $I = M_w/M_n$ = 1.87, where M_n is number-average molecular weight, 7.5 mol % hydrazide monomeric unit) was synthesized by radical

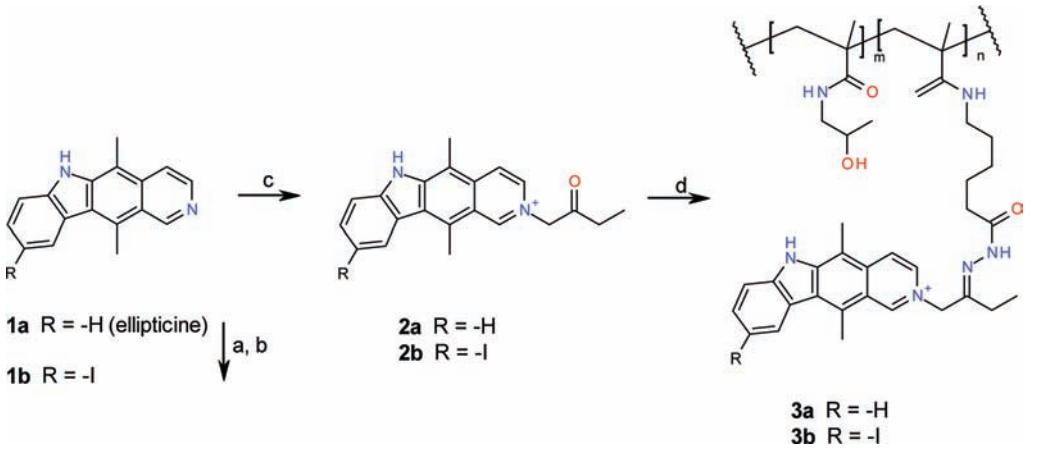

Figure 2. Synthesis of polymer-bound ellipticine and 9-iodoellipticine derivatives. Reagents and conditions: (a) $Hg(OAc)_2$, AcOH, 60 °C; (b) I_2; (c) 1-bromo-2-butanone, MeOH, RT; (d) pHPMA-MAAcap hydrazide, 9:1 MeOH/AcOH, RT.

copolymerization of 1-*N*-(2-hydroxypropyl)methacrylamide with 1-*N*-(6-hydrazino-6-oxohexyl)-2-methylacrylamide using azobis-(isobutyronitrile) as an initiator according to ref 13. The solution of pHPMA-MAAcap hydrazide (40 mg), ellipticinium derivative **2a** or **2b**, respectively (10 mg) and acetic acid (100 μL) in methanol (900 μL) was stirred at room temperature for 4 days. The polymer was then isolated by gel filtration on Sephadex LH-20 column (60 mL bed volume) using methanol as eluent, concentration of polymer-containing fractions under reduced pressure, precipitation into diethyl ether (5 mL), filtration, and drying. Yield 32 mg of **3a** and 38 mg of **3b**, respectively.

The drug content was assayed by UV−vis spectrophotometry in methanol using above-stated maximum wavelengths and molar absorbtivities. Molecular weights of the polymers were determined by gel permeation chromatography (GPC) in a mixture of acetate buffer (pH 6.5, 0.3 mol/L) and methanol (20:80 v/v) on a TSK 4000 column (Polymer Laboratories Ltd., U.K.) using a HPLC System Shimadzu (Shimadzu GmbH., Czech Republic) equipped with RI, UV, and multiangle light-scattering DAWN DSP-F detectors (Wyatt, U.S.A.).

Synthesis of [^{125}I]-2b and [^{125}I]-3b. The [^{125}I]-**2b** was synthesized by the same method as nonradiolabeled **2b** starting from 3.0 mg of ellipticine with additional $Na^{125}I$ stock solution (10 μL, 240 MBq) being added to nonradioactive iodine carrier. Yield 2.5 mg (39% chemical yield after two steps) of [^{125}I]-**2b** containing 20.4 MBq ^{125}I (8.5% radiochemical yield), i.e., specific radioactivity 8.2 MBq/mg.

Radioactivity of the product was measured on a ionization chamber Bqmetr 4 (Empos Ltd., Czech Republic). Purity was assayed by HPLC an a Shimadzu HPLC system (Shimadzu GmbH, Czech Republic) using a reverse-phase column (Chromolith Performance RP-18e 100 × 4.6 mm, Merck Ltd., Czech Republic) with UV−vis diode array detection. A mixture of water−acetonitrile was used as the eluent at a gradient 0−100 vol % and a flow rate of 2 mL/min. The product was homogeneous (single peak, R_t = 9.06 min) with all radioactivity in the **2b** peak (the particular fraction was collected and compared to radioactivity of the injected amount; nonradiolabeled **2b** was used as standard).

Conjugation to polymer was done in the same way as for the nonradiolabeled polymer, but using higher excess of polymer (15 mg) to *N*-2-oxobutyl-9-iodoellipticinium (2.0 mg). Yield 15 mg of the conjugate containing 1.95 wt % 9-iodoellipticine (UV−vis), 187 kBq/mg ^{125}I.

In Vitro Drug Release Study. Solutions of the drug conjugates (1 mg mL^{-1}, 1 mL) in phosphate buffered saline of pH 5.0, 6.5, and 7.4, respectively, were incubated in a water bath at 37 °C. At each time point, a sample (10 μL) was taken from each solution, diluted with dry methanol (990 μL), and filtered through a 0.22 μm syringe filter. Immediately after that, the amount of released ellipticinium derivative was determined by gel permeation chromatography in a mixture of acetate buffer (pH 6.5, 0.3 mol·L^{-1}) and methanol (20:80 v/v) on a TSK 3000 column (Polymer Laboratories Ltd., U.K.). UV−vis detection at absorbance maxima of the corresponding free drugs, i.e., 295 nm for **2a** and 315 nm for **2b**, were used for calculation of the drug release according to eq 1

$$r = S_f/(S_f + S_p) \times 100 \quad (1)$$

In eq 1, r is the released amount of drug in %, S_f is the peak area of free drug (low-molecular-weight fraction) and S_p is the peak area of polymer-bound drug (high-molecular-weight area). All experiments were carried out in duplicate.

In Vitro DNA Intercalation Studies. To evaluate the intercalating ability of synthesized compounds, both direct titration of DNA and ethidium bromide displacement assay by a modified procedure according to reported method[11] were used. In the direct titration method, the concentration dependence of fluorescence intensity of synthesized compounds with and without the presence of DNA was determined. So, the different volumes of the solution of measured compound in phosphate buffer saline (pH = 7.4) were added into two cuvettes with the 2 mL of phosphate buffer saline (pH = 7.4) with and without calf thymus DNA (100 μg.mL^{-1}). After 5 min incubation at room temperature, the fluorescence excitation and emission spectra of both samples were recorded in the particular emission/excitation maxima.

In the ethidium displacement method, the binding affinity of compounds to DNA was measured as the dependence of DNA−ethidium bromide complex fluorescence intensity decrease with ascendant concentration of the measured compound. Different volumes of measured compounds were added to the cuvette containing calf thymus DNA (100 μg.mL^{-1}) and ethidium bromide (50 μg.mL^{-1}). After 5 min of incubation, the intensity of emission at 583 nm was measured (excitation wavelength 546 nm, using this excitation, the fluorescence intensity of free ellipticine derivatives, as well as their complexes with DNA, was neglectable at this wavelength).

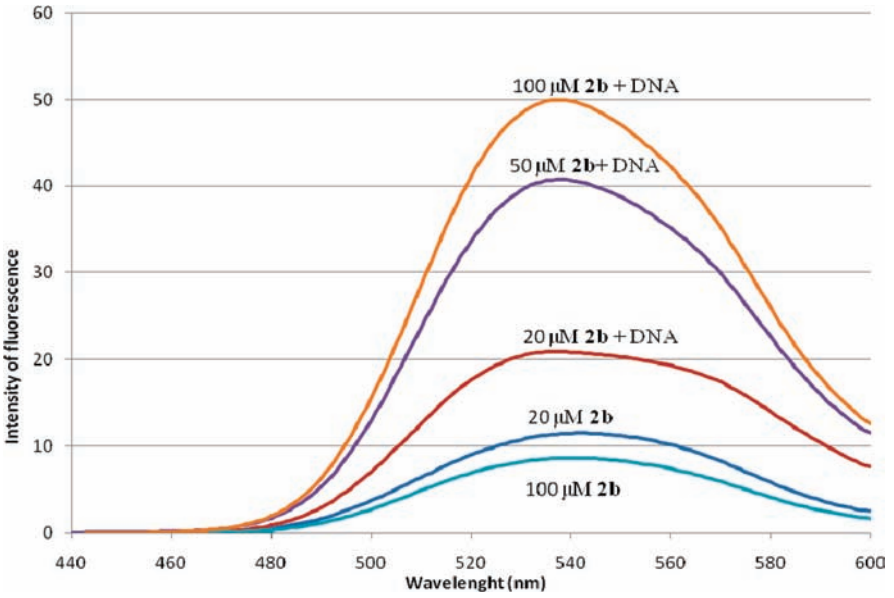

Figure 3. Fluorescence emission spectra of different **2b** concentrations with and without DNA (excitation wavelength at 310 nm).

In Vitro Cytotoxicity Assay and Internalization into the Cells. In vitro cytotoxicity of the micelles was assessed with either human or murine cancer cell lines. Ninety-six-well flat-bottomed microplates (NUNC, Roskilde, Denmark) were seeded with cancer cells: Raji, human B-cell lymphoma (1×10 cells per well); EL-4, murine T-cell lymphoma (5×10^3); 4T1, murine mammary tumor cell line (1×10^4 cells per well). The tested samples (in triplicates) were then added to the wells to obtain the desired drug concentration (0.1−2660 ng mL^{-1} free drug equivalent). The plates were incubated at 37 °C in humidified 5% CO_2 + 95% air atmosphere for 72 h. Cell viability was then evaluated by a standard MTT test according to ref 14. This assay is based on bioreduction of the yellow soluble 3-(4,5-dimethyldiazol-2-yl)-2,5 diphenyl tetrazolium bromide (MTT) to insoluble blue formazan by mitochondria. Formazan is then solubilized with detergent and measured spectrophotometrically at 540 nm. Cells cultivated in fresh medium were used as controls. The results are the means of four independent experiments; the standard deviation was lower than 5%.

Internalization of the ellipticine derivatives and conjugates into cells was assayed with 4T1 cells on confocal microscope using the intensive ellipticine-fluorophore caused fluorescence in analogy as described for doxorubicin conjugates.[15] Cell nuclei were visualized with the Hoechst 33342 nucleic acid dye.

RESULTS AND DISCUSSION

Ellipticine (**1a**) is natural alkaloid from plant *Ochrosia elliptica* with well-known anticancer properties; several of its derivatives have been introduced into clinical practice. We have chosen it as an ^{125}I carrier because of its potent DNA-intercalating activity and for its fluorescent properties (i.e., its intracellular fate may be easily followed by fluorescence microscopy without additional labeling). Furthermore, its electrophilic iodination via acetomercuro intermediate proceeds easily and leads to defined chemically stable 9-iodoellipticine (**1b**).[12] Although biological characterization of **1b** was not reported, 9-bromoellipticine was reported[16] to have similar IC_{50} values to ellipticine against selected cancer cell lines, so we expected the iododerivative to retain intercalating activity. We synthesized "cold" (stable natural iodine containing) **1b** in high yield (74%) by acetomercuration of ellipticine and subsequent one-pot exchange of the acetomercuro group with iodine to form the iododerivative **1b** (see Figure 2).

A hydrazone bond was chosen to connect ellipticine derivatives to polymer because of its susceptibility to hydrolysis under acidic conditions, as well as relative stability toward hydrolysis at neutral pH.[13,17−19] The conjugate would thus be relatively stable during transport in blood plasma at pH 7.4.[17,18] However, in more acidic tumor tissue (pH ca. 6.5[17,18]) or even after internalization into the tumor cell (pH in late endosomes is ca. 5.0[17,18]) the active intercalator would be rapidly released from the polymer carrier. Considering that ellipticine does not contain ketone, aldehyde, or hydrazide group, it has to be derivatized with a suitable linker. For this derivatization, we have chosen the tertiary isoquinoline-type nitrogen in position 2, which may be quaternized with suitable alkylating agent containing ketone moiety. Quaternization introduces permanent positive charge into the molecule, which increases solubility in water (this is important since both ellipticine and 9-iodoellipticine are only poorly soluble in water) and should contribute to the intercalation effectivity since DNA has negative charge due to phosphates. Quaternary ellipticine derivatives (as Celiptium) show similar or even higher activity than parent ellipticine while being readily water-soluble. For this purpose, commercially available 1-bromo-2-butanone was used. It readily reacts at room temperature with both ellipticine (**1a**) and 9-iodoellipticine (**1b**) to form the 2-*N*-(2-oxobutyl)ellipticinium derivatives **2a** and **2b**, respectively, in high yields (68% and 88%, respectively). These derivatives are readily soluble in both water and methanol in contrast to unquaternized compounds. When radiolabeled [^{125}I]-**2b** is synthesized, radioiodine should be introduced before quaternization since the positive charge decreases reactivity toward conventional electrophilic radioiodination and also bromide counteranion interferes by simultaneous electrophilic bromination.

All synthesized compounds retain strong fluorescent properties of ellipticine, makes following of intracellular fate of these derivatives easier (see below). The original ellipticine (**1a**) has emission maximum in acetic acid (i.e., in protonated form) at 517 nm with excitation maxima 277, 316, 356, and 413 nm

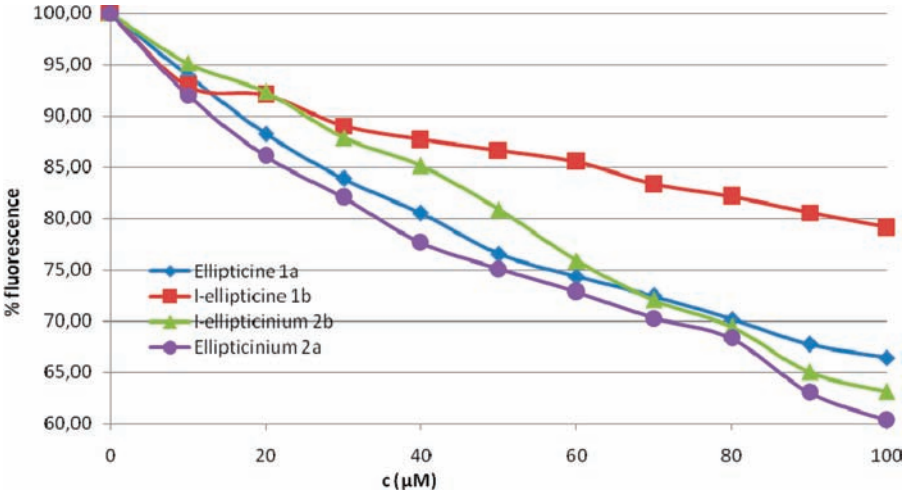

Figure 4. Decrease of ethidium bromide/DNA emission fluorescence intensity at 583 nm as a function of intercalator concentration (excitation wavelength 546 nm).

(relative intensities normalized to peak at 277 nm = 1.00 are 0.72 for 316 nm, 0.36 for 356 nm, and 0.27 for 413 nm), while **2a** has emission maximum shifted toward longer wavelengths at 540 nm. Also, the excitation spectrum of **2a** is shifted toward longer wavelengths (maxima at 283, 317, 363, and 425 nm; the relative intensities normalized to peak 283 nm = 1.00 are 0.65 for peak 317 nm, 0.31 for peak 363 nm, and 0.25 for peak 425 nm). The emission spectra of iodoellipticine **1b** has emission maximum at 451 nm, the excitation maxima were 283, 332, and 385 nm (relative intensity 1.00, 0.17, and 0.14, respectively), whereas the emission maximum of **2b** was at 532 nm and the excitation maxima at 310, 360, and 421 nm (relative intensities 1.00, 0.14, and 0.10, respectively).

Intercalation abilities of synthesized compounds were tested both directly on DNA (change in fluorescence intensity when added to DNA) and by ethidium bromide displacement assay. In direct intercalation titration, the fluorescence spectra at different concentration of **2b** in the presence of calf thymus DNA, as well as without it (blank sample), were measured. It was clearly observed that the intercalation of **2b** into the DNA caused enhancement of quantum fluorescence yield and therefore increase of fluorescence intensity in comparison with the blank sample (Figure 3). Self-quenching, high for free drug, was also suppressed by DNA-intercalation.

To determine the DNA-binding affinity of prepared compounds [which is the driving force of accumulation of the (radiolabeled) intercalator in DNA in cell nuclei due to shifting equilibrium toward intercalator binding to DNA], the decrease of ethidium bromide (50 μg.mL^{-1})−calf thymus DNA complex fluorescence intensity with rising concentration of all compounds was measured. All compounds showed similarly strong affinity to the DNA (Figure 4). For each compound, an attempt to measure EC_{50}, the concentration that caused the 50% decrease of ethidium bromide/DNA fluorescence intensity, has been done. The EC_{50} values of quaternized products **2a** and **2b** were 170 μM and 140 μM, respectively. However, the EC_{50} of ellipticine (**1a**) and 9-iodoellipticine (**1b**) could not be determined due to their poor solubility (which is also probably the main reason for lower apparent binding of **1b** compared to other ellipticine derivatives tested; however, since **1b** is only a synthetic intermediate in our case, we did not go into detailed study). The ellipticine derivatives thus proved to have sufficient DNA binding potential; however, for accumulation in cell nuclei, the ability to also penetrate into the cell nucleus is essential. This was tested in *in vitro* cell culture (see below). Mitochondrial DNA is generally considered as a less important target of DNA-damaging agents compared to nuclear DNA, mainly due to the overwhelming amount of DNA in cell nuclei compared to mitochondria, and also intercalators may easily pass through nuclear pore, but to reach mitochondrial DNA, they need to translocate across the mitochondrial membranes. This is why mitochondrial DNA was not considered in our study as a primary target.

Both ketones **2a** and **2b** were conjugated with polymer pHPMA-MAAcap hydrazide by acetic acid-catalyzed condensation in analogy to conjugation of anticancer anthracycline antibiotic doxorubicin,[13,17,18] also containing ketone moiety, forming derivatives **3a** and **3b**, respectively (the obtained drug loading was 10.0 wt % for **3a** and 8.5 wt % for **3b**). No significant change in molecular weights of the conjugates was observed, confirming no cross-linking or other side reactions.

Drug release in vitro was followed in phosphate buffered saline, pH 7.4 (pH of blood plasma), pH 6.5 (typical pH of tumor interstitial space due to partly hypoxic lactic acid metabolism), and pH 5.0 (typical pH of late endosomes after internalization of the system into cells). The drug release profiles for both **3a** and **3b** (see Figure 5) show similar trends—relatively fast release at pH 5.0 (22.8% released drug after 24 h for **3a** and 25.1% for **3b**)—while the conjugates are stable at both pH 6.5 and pH 7.4 (1.4% released drug after 24 h for **3a** and 1.5% for **3b** at pH 6.5 and 0.3% released drug after 24 h for **3a** and 0% for **3b** at pH 7.4). This means that the conjugate should be stable during transport in blood and the active intercalator should be released only after uptake by cells in their endosomes.

If we compare these release profiles with other hydrazones, one can see that the drug release rate as a function of pH highly depends on the chemical surrounding of hydrazone bond to be hydrolyzed, sterical aspects, eventual conjugation with adjacent double bonds, and electron density on the C=N carbon (on which hydrolysis takes place) play a role. In our case, as we hypothesize due to vicinity of the quaternary ammonium cation, the release rate is highly pH dependent. This is similar to the release rates of doxorubicin,[13,17,18] where vicinity of the hydroxyl groups plays the

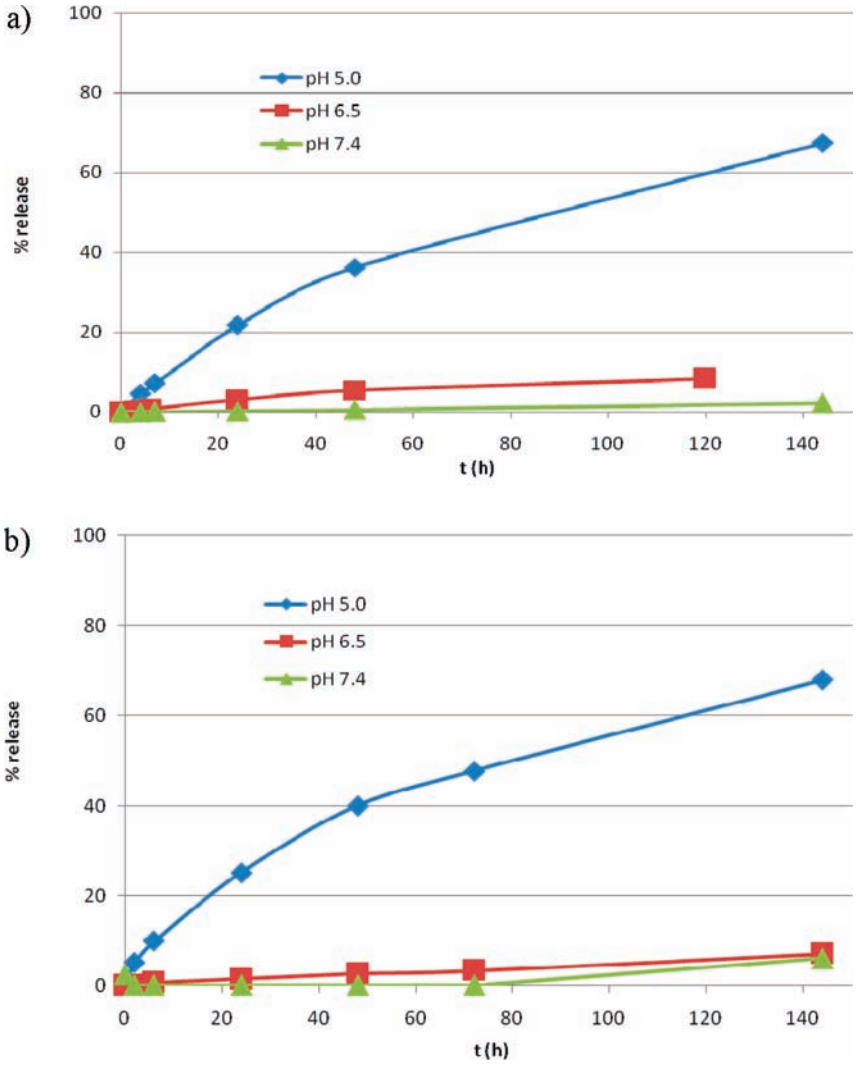

Figure 5. In vitro release of derivatives **3a** (above; a) and **3b** (below; b).

Table 1. Cytotoxicities of Ellipticine Derivatives on the Selected Cell Lines[a]

derivative	IC_{50} (Raji)	IC_{50} (EL4)	IC_{50} (4T1)
1a	8.8	0.27	6.7
1b	3.6	1.4	1.7
2a	2.0	1.3	6.9
2b	1.0	2.3	7.7
3b	7.6	11.5	16.5

[a] Raji, EL4, and 4T1; the IC_{50} values are stated in μmol/L.

critical role. However, the release rate in our case is considerably slower than that described for doxorubicin.[13,17,18] On the other hand, hydrazones with the same hydrazide part but with 2-hexanone or levulinic acid as ketone components are hydrolyzed much more rapidly and with lower relative pH dependence (fast hydrolysis of these compounds readily occurred even at neutral conditions)[20] than the (9-iodo)ellipticinium derivatives described in this paper or doxorubicin described in refs 13,17,18. However, fast hydrolysis of these compounds readily occurred even at pH-neutral conditions.

The radioiodinated derivatives were synthesized in analogy with the stable-iodine-containing derivatives. We first tested the no-carrier-added approach with direct radioiodination of ellipticine to **1b** using the chloramine method; however, high amounts of ellipticine-*N*-oxide and radioiodinated ellipticine-*N*-oxide were produced as byproducts. This is why we have chosen the analogy with the synthesis of nonradioactive **1b** (acetomercuration with subsequent reaction with iodine). This approach gave radiolabeled **1b**; although chromatographic purification is necessary, carrier-added iodine must be used and the yield is relatively low. The relatively low radiochemical yield may be mostly explained by the fact that one-half of the radioiodine is wasted as mercury-bound iodide during exchange reaction with the acetomercuro intermediate. The subsequent quaternization to **2b** and conjugation with polymer was than done in analogy with the nonradiolabeled conjugate.

We tested antiproliferative activity of the synthesized derivatives on selected cell lines (Raji, EL4, and 4T1, respectively; see Table 1 for the IC_{50} values). Antiproliferative activity is useful if the conjugates would be used as chemotherapeuticals and for the indirect demonstration of the ability of the ellipticine derivatives to achieve DNA in living cells, because intercalation activity is essential for the cytotoxicity of ellipticine derivatives. The MTT test was used to assay

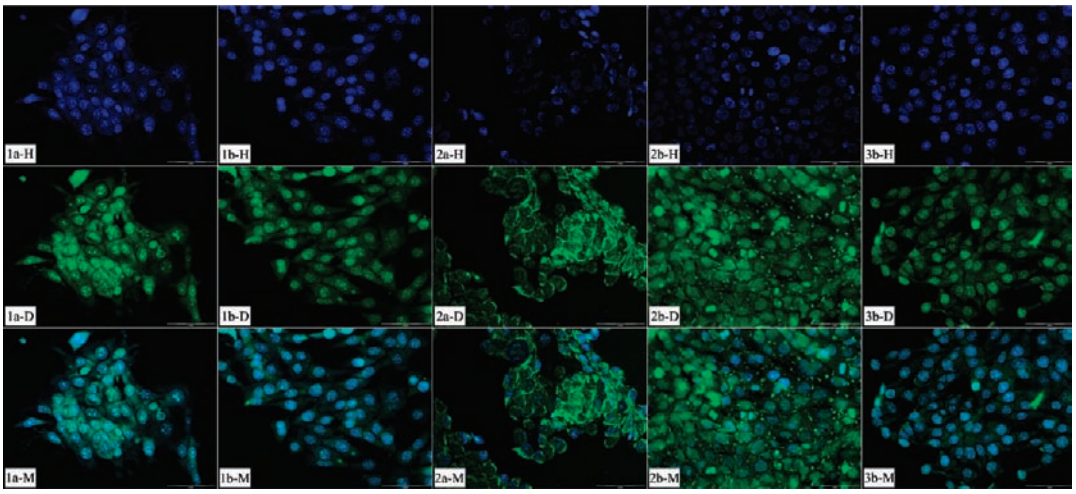

Figure 6. Internalization of ellipticine derivatives into cells. The images are marked as follows: substance tested stain; stains on the same particular cells: H, Hoechst 33342 dye; D, the particular drug or conjugate; M, merged channels H + D to confirm colocalization in cell nuclei.

cytotoxicity, since the standard [^{3}H]-thymidine assay would be useless for radioactive samples containing ^{125}I due to interference with radioactivity of tritium. Cytotoxicity of ellipticine and its low-molecular-weight derivatives was in the range 0.27−8.8 μmol/L. The cell lines differ in their sensitivity toward **1a**, **1b**, **2a**, and **2b** within ca. 1 order of magnitude, with EL-4 being more sensitive than the other lines for all the substances tested except **2b**. Iodination of ellipticine **1a** to 9-iodoellipticine **2b** increases its cytotoxic activity for the Raji and 4T1 cell lines but decreases the activity against the EL-4 cell line, but all effects were within 1 order of magnitude. Quaternization with 1-bromo-2-butanone also has effects only within 1 order of magnitude, for Raji cell line toxicity was increased by quaternization for both iodinated and noniodinated ellipticine and for EL4 and 4T1 cell lines quaternization somehow decreased cytotoxicity. One can thus conclude that the chemical modifications necessary to make ellipticine radioiodinable and conjugable with polymer (iodination and quaternization) did not compromise its biological effectivity. This is in agreement with expectations that 9-bromoellipticine does not differ in its cytotoxicity from ellipticine[16] and quaternary ellipticinium derivatives as Celiptium (N^2-methyl-9-hydroxyellipticinium) are effective anticancer agents.

We also studied cytotoxicity of polymer-bound **2b** (i.e., **3b**) to confirm that the effective **2b** may be released from the hydrazone conjugate **3b** in living cells. Polymer conjugates usually show lower cytotoxicity than free drugs, because the conjugate is ineffective in its polymer form unless free drug is released, so the main power of polymer conjugate is in selectivity of toxicity toward cancer cells. The polymer conjugate **3b**, a nonradioactive model of the AE emitter delivery system, was only 2−8-times (dependent on cell line) less effective than free drug **2b**. This means that the polymer **3b** is able to be internalized into the cells and to release free drug **2b** more effectively than similar hydrazone conjugates described in literature. For comparison, doxorubicin hydrazone conjugates are usually more than 10-times less biologically effective in vitro than the corresponding free drug.[13,17,18] This should be beneficial for the biological effectivity, because of low necessary dosage of the radiolabeled intercalator. Cytotoxicity also depends on the capacity of endocytosis of the cells, which is higher for tumor cells than for normal cells, which may further contribute to selectivity of the anticancer effect. Detailed study of the contribution of this factor in vitro and in vivo in the murine model will be a topic of further contributions.

The next step was direct proof that the ellipticine derivatives studied in this paper are effective intercalators not only on isolated DNA (see above the fluorescence studies), but also inside living cells. One can clearly see from the internalization study using fluorescence microscopy (Olympus, AX70-Provis) that ellipticinium derivative-related fluorescence is visible in cell nuclei for all **1a**, **1b**, **2a**, **2b**, and **3b** (see Figure 6). Localization in cell nuclei was confirmed by simultaneous staining of nuclear DNA by the Hoechst 33342 dye and overlay of the images.

Since only low specific activities (8.2 MBq/mg for [^{125}I]-**2b** and 187 kBq/mg for [^{125}I]-**3b**) compared to daunorubicin derivatives described in the literature[9] (ca. 100 GBq/mg) were obtained, only statistically insignificant differences between cytotoxicities of radiolabeled and nonradiolabeled **2b** and **3b** were obtained (data not shown). Improvement of both radiochemical yield and specific activity of the radiolabeled derivatives is thus still a challenge for future work.

CONCLUSIONS

The new type of polymer conjugates carrying Auger electron emitter-labeled intercalator was successfully synthesized and characterized. The system is designed for a triple-targeting approach (first targeting, polymer-based system targeting into tumor tissue; second targeting, pH-controlled intratumoral or intracellular release; third targeting, into cell nucleus by a DNA intercalator) minimizing the radiation burden of healthy tissues. The system is stable at the pH of blood plasma (pH 7.4) and releases active intercalator in acidic milieu with pH close to late endosome content (pH 5). It was confirmed that the studied ellipticine derivatives retain intercalation and cytotoxic properties of ellipticine and are accumulated in cell nuclei after exposure to cells in vitro. The system was synthesized in radiolabeled form; however, to achieve effective Auger electron cytotoxic effect specific radioactivity of the intercalator still has to be improved.

Supporting Information

ABSTRACT: A Fischer carbene complex was grafted onto self-assembled monolayers (SAMs) on gold or glass by a copper-free "click" reaction. Pendant lysine residues of protein A obtained from *Staphylococcus aureus* rapidly reacted with the electrophilic metal complex on SAM effecting a covalent attachment of protein A with the surface. The protein A coated surface further led to bioaffinity immobilization of rabbit IgG in an oriented manner, a feature that also permits its purification from rabbit serum. Rabbit IgG could be removed from protein A coated surface by pH adjustment. The regenerated protein A surface was reused three times without loss of activity.

INTRODUCTION

Research in current years has revealed a huge potential of organometallic bioconjugates[1] in radiopharmaceuticals, novel drugs, and even organometallic bioanalysis. Coupling of an organometallic carboxylic acid to amino acids and peptides via amide formation is probably the most extensively studied conjugation reaction.[2,3] Biomolecules that have pendant primary amino or unhindered secondary amino groups react instantly and often quantitatively with electrophilic alkoxy Fischer carbene complexes of general formulas $(CO)_5W{=}C(OR^1)R^2$ to yield corresponding amino carbene complexes that are stable Fischer carbene bioconjugates.[4] Progress of this reaction can easily be monitored by the typical shift of W—CO stretch in the region 1900−2010 cm^{-1} which is transparent to most organic functional groups and water.[5] By adopting appropriate techniques, it is possible to place a Fischer carbene complex at the external terminus of a densely packed, stable, self-assembled monolayer (SAM) on a flat (e.g., glass slide) or a curved (e.g., colloidal gold) solid surface.[6−8] The exposed Fischer carbene complex on the molecular film can then be utilized to covalently graft a protein to the SAM on glass or gold as reported earlier.[6,8]

One of the most advanced applications of SAMs on solid surface is the design of biosensors.[9−14] Immobilization of proteins with retention of their activity on highly ordered monolayers is of paramount importance in diagnostic, affinity separation, and biomaterials technology.[15−17] The key factor behind the development of the immunosensor is the efficient immobilization of an antibody on the solid surface of assay device.[18,19]A number of techniques have been developed to immobilize antibodies on solid surfaces: physicochemical adsorption[20−26] on poly(L-lysine) coated glass, plastic, or nitro-cellulose membrane, Langmuir−Blodgett methods,[27,28] and covalent attachment.[29−36] Physical adsorption proves to be the easiest of procedures, but the method often suffers from relative instability, random orientation, and denaturation of attached antibodies, yielding poor reproducibility. Covalent attachment yields more stable, functional monolayers, but the orientation of proteins is often uncontrolled.

Bioaffinity interactions, being much more specific in structural recognition features, can guarantee a certain mode of orientation during binding of one protein with another. Protein A binds specifically to the Fc region of immunoglobulin molecules derived from various mammal species.[37−43] If protein A is covalently bound to a surface and its interaction with IgG is affinity controlled (hence potentially reversible by altering pH conditions), one can have a bioactive surface that can sense IgG protein and can be regenerated after each run. The present paper describes the results of such an approach.

We describe the following sequence: (a) formation of a highly ordered, densely packed monolayer on gold using C_{11}-chains with a triethylene glycol spacer and terminal Fischer carbene complex; (b) covalent immobilization of protein A by aminolysis reaction with the help of Fischer carbene termini on SAM; (c) bioaffinity immobilization of rabbit IgG and its detection on glass surface by fluorescence microscopy; and, finally, (d) recycling of the protein A slide for iterative purification. Atomic force microscopy (AFM) and ATR-IR were the two surface analytical techniques primarily used for following the chemistry and topology of SAM on gold surfaces.

EXPERIMENTAL PROCEDURE

General Methods and Materials. Thin-layer chromatography was performed on TLC Silica gel 60 F_{254} purchased from Merck and visualized by UV and I_2 adsorption. Column chromatography was typically performed using 230−400 mesh silica gel. NMR spectra were recorded on Bruker Advance 200 or 300 MHz spectrometers at room temperature with $CDCl_3$ as solvent and TMS as internal reference. ATR-IR spectra were recorded on Nicolet 380 spectrometer. Contact angles were measured with a digidrop from GBX (Romans sur Isère, France). The thickness of self-assembled monolayers (SAMs) on gold slides was investigated by an ellipsometer (Sentech SE 500) operating at a 70° incidence angle. Fluorescence images were acquired using a Leica DM 3000 Upright Trinocular Research Microscope with Leica DFC 425 Scientific digital camera and LAS software. The topography of the protein coated surface was investigated by atomic force microscopy (diCP-II) with DI Company *SPMlab Analysis* software. Protein A from *Staphylococcus aureus* (MW 42 KDa),[44] IgG from rabbit serum (Reagent grade, > 95%, MW 150 KDa),[45,46] and gold coated slides (coated successively with a 20-Å-thick layer of titanium and a 100-Å-thick layer of gold) were purchased from Sigma-Aldrich. Gold chloride and BSA were obtained from SRL. Solvents like ethanol, DMF, and toluene were purchased from SRL and dried using standard procedure. Reagents were purchased from Sigma-Aldrich and were used as received.

***S*-11-(2-(2-(2-Bromoethoxy)ethoxy)ethoxy)undecylethanethioate (4).** Synthesis of 2--(2-(2-(undec-10-enyloxy)ethoxy)ethoxy)ethanol (**2**) and *S*-11-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)undecylethanethioate (**3**) from 11-bromoundecene (**1**) was carried out following a procedure reported in literature.[7] To a solution of *S*-11-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)undecylethanethioate (**3**) (2 g, 5.2 mmol) in dry DCM (16 mL) under argon atmosphere, carbon tetrabromide (2.1 g, 6.3 mmol) was added slowly. The reaction mixture was cooled to 0 °C and triphenyl phosphine (2 g, 7.6 mmol) in dry DCM (4 mL) was added dropwise to it. After stirring for 6 h, the solvent from the reaction mixture was evaporated out. The product was extracted with petroleum ether (3 × 15 mL), the combined organic layers were evaporated under vacuum, and the product was purified by flash column chromatography (30% ethyl acetate/petroleum ether). Product obtained was 2 g (86%). ^{1}H NMR ($CDCl_3$, 300 MHz): 1.21−1.26 (m, 14H), 1.49−1.56 (m, 4H), 2.30 (s, 3H), 2.84 (t, J = 6 Hz, 2H), 3.44 (q, J = 6 Hz, 4H), 3.55−3.67 (m, 8H), 3.80 (t, J = 6 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): 26.16, 27.14, 28.89, 29.18, 29.24, 29.53, 29.57, 29.63, 29.71, 30.36, 30.72, 70.15, 70.70, 70.80, 71.31, 71.64, 196.17. HRMS (ESI) m/z $[M+Na]^+$, calcd for $C_{19}H_{37}BrO_4SNa$ 463.1494; found 463.1498.

11-(2-(2-(2-Bromoethoxy)ethoxy)ethoxy)undecane-1-thiol (5). *S*-11-(2-(2-(2-Bromoethoxy)ethoxy)ethoxy)undecylethanethioate (**4**) (2 g, 4.5 mmol) was dissolved in dry methanol (15 mL) under argon atmosphere. To it 0.1 mL of concentrated HCl was added and the reaction mixture was heated under reflux for 5 h. Then, the crude reaction mixture was cooled and the solvent was concentrated under reduced pressure. Flash column chromatography (25% ethyl acetate/petroleum ether) afforded 1.6 g (89%) of compound (**5**). ^{1}H NMR ($CDCl_3$, 300 MHz): 1.23−1.31 (m, 14H), 1.51−1.61 (m, 4H), 2.48 (q, J = 6 Hz, 2H), 3.42 (q, J = 6 Hz, 4H), 3.54−3.63 (m, 8H), 3.78 (t, J = 6 Hz, 2H). ^{13}C NMR ($CDCl_3$, 75 MHz): 24.72, 26.17, 28.45, 29.14, 29.55, 29.57, 29.63, 29.72, 30.38, 34.13, 70.15, 70.65, 70.70, 70.80, 71.30, 71.62. HRMS (ESI) m/z $[M+Na]^+$, calcd for $C_{17}H_{35}BrO_3SNa$ 421.1388; found 421.1380.

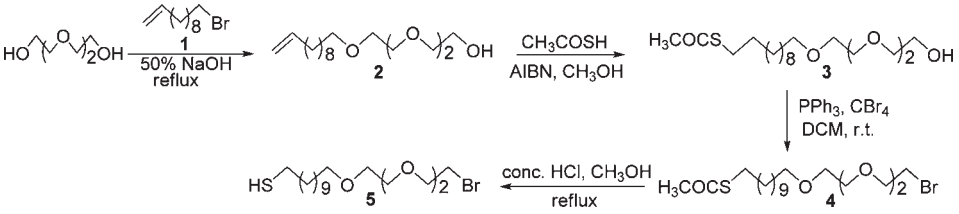
Preparation of SAM with Compound 5. The gold surface (11 mm × 11 mm) was immersed in a mixture of concentrated H_2SO_4 and 30% aq. H_2O_2 (70:30 v/v) for 1 min, then washed with distilled water and dried under N_2. The cleaned gold surfaces were dipped in a freshly prepared 1 mM solution of compound **5** in dry ethanol for 36 h. The slides were then rinsed thoroughly with absolute ethanol in order to remove excess absorbate and dried under argon atmosphere.

Surface Modification by S_N2 Reaction from Bromide to Azide SAM. Nucleophilic displacement of bromide by azide was carried out in DMF with sodium azide. The bromo terminated gold substrate was incubated in a saturated solution of sodium azide in DMF and stirred for 48 h. The surface was then washed with water and dried under nitrogen.

Grafting of Fischer Carbene Complex (6) via Cu Free "Click" Cycloaddition Reaction. The alkynyl Fischer carbene complex **6** was synthesized using a reported procedure.[6] The gold slides covered with azido terminated monolayers were dipped in a 10 mM solution of Fischer carbene complex **6** in dry toluene under argon atmosphere at 50 °C for 4 h. It was then washed with dry toluene followed by absolute ethanol in order to ensure complete removal of excess Fischer carbene complex. Finally, the surface was dried under argon.

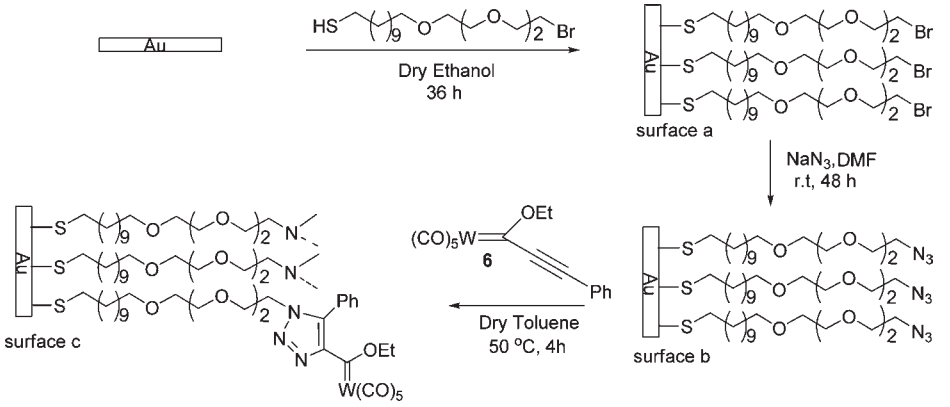
Covalent Immobilization of Protein A. Gold surfaces coated with Fischer carbene was immersed in a solution of protein A (10 mg/L) in phosphate buffer (pH 8.0) for 10 min at room temperature. The substrates were rinsed thoroughly with buffer solution (thrice), then with milli-Q water (thrice), and dried under argon atmosphere. The residual Fischer carbene complexes were blocked by treatment with 1 M ethanolamine (pH 9.0) for 30 min. Finally, the surfaces were treated with 1% (w/v) BSA in phosphate buffer (pH 8.0) for 2 h to block nonspecific binding. Then, the surfaces were extensively rinsed with milli-Q water and dried under argon.

Recognition of Rabbit IgG. The recognition experiment was carried out as following: protein A coated gold surfaces were incubated in a solution of rabbit IgG (50 μg/mL) in phosphate buffer (pH 8.0) for 1 h. The surfaces were extensively washed with phosphate buffer containing 0.05% Tween (v/v), followed by milli-Q water, and dried under argon atmosphere.



Regeneration of Protein A Coated Surface after Extraction of Rabbit IgG. The rabbit IgG coated surface was incubated in citrate buffer (pH 3.5) for 15 min. The slide was then immersed in phosphate buffer (pH 9.0) for 15 min to recover the protein A coated slide that was reused.

RESULTS AND DISCUSSION



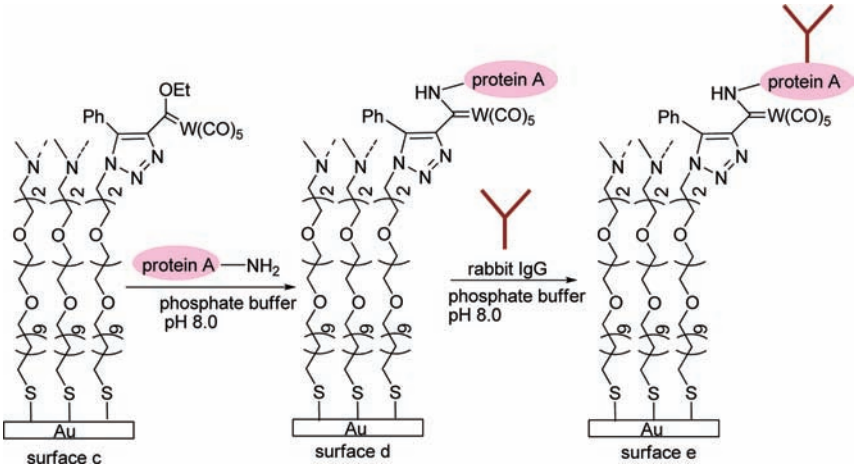
Synthesis of Bromo Terminated Long Chain Thiol with TEG Spacers. The bromo terminated long chain thiol was synthesized from triethylene glycol (TEG) according to the reaction sequence represented in Scheme 1.

The long chain thiol comprises four distinct parts: (i) thiol group for chemisorptions on Au surface, (ii) long hydrocarbon chain for creating a densely packed monolayer, (iii) a hydrophilic TEG spacer for maximum availability of the functional tether extending in water, and (iv) bromo group at the terminus of chain to be converted to the Fischer carbene moiety. TEG was first converted to monoalkene-TEG **2** by treatment with 11-bromoundecene in the presence of sodium hydroxide. Radical mediated addition of thiolacetic acid across the double bond in **2** followed by treatment with carbon tetrabromide and

Scheme 1. Synthesis of 11-(2-(2-(2-bromoethoxy)ethoxy)ethoxy)undecane-1-thiol (5)

Scheme 2. Grafting of Bromo Terminated Long Chain Thiol (5) and Sequential Chemical Modification of the Terminal Functional Group

triphenylphosphine afforded the brominated product **4**. The compound **4** was then hydrolyzed with catalytic amount of conc. HCl to obtain the desired thiol **5** in good yield. Each compound was purified by column chromatography and characterized by standard spectroscopic analyses.



Formation of Fischer Carbene Terminated SAM on Gold Surface. A monolayer of bromo terminated thiol **5** was self-assembled on gold surface (surface a) following usual procedure. After thorough washing with ethanol, the gold surface was analyzed by ATR-IR spectroscopy. The presence of strong absorption bands at 2960.0 cm^{-1} and 2840.0 cm^{-1} (aliphatic C−H stretching) clearly indicated the presence of bromo terminated chains on the monolayer. The bromo terminated surface was then treated with saturated solution of sodium azide in DMF for 48 h at room temperature leading to surface b. The presence of a typical band at 2118.9 cm^{-1} established nucleophilic displacement of the bromine atom by azido group. The gold substrate was then treated with a solution of alkoxy Fischer carbene complex **6** in toluene at 50 °C for 4 h. Since the triple bond is highly activated due to the presence of strong electron withdrawing tungsten pentacarbonyl moiety, no Cu(I) salt is required as catalyst for the 1,3-dipolar cycloaddition reaction.[47] After thorough washing with toluene, it was analyzed by ATR-IR. The asymmetric stretch of the azido group at 2118.9 cm^{-1} was no longer visible. Instead, new absorption bands appeared at 2065.1 $cm^{-1}$and 1930.6 cm^{-1} for W—CO stretching. These clearly revealed that the Fischer carbene moiety was now covalently bound to the SAM (surface c).

Chemical modifications on the gold surface were also monitored by ellipsometry. Thickness of the initially formed bromo terminated monolayer was 2.87 nm. After nucleophilic substitution reaction with azido group, the thickness reduces to 2.74 nm, and after the "click" cycloaddition reaction with the activated triple bond in alkynyl Fischer carbene, the thickness of SAM increases to 3.43 nm reflecting the introduction of a much larger group on the SAM terminus. Contact angle measurements were also carried out on the gold-coated surfaces. While the contact angle of the bromo terminated SAM was found to be 99.8 ± 0.2°, it decreased to 85.6 ± 1.5° on displacement with azido group, which further decreased to 82.3 ± 1.1° on cycloaddition with Fischer carbene complex. These results are consistent with the changes brought about on the functionality of SAM on the gold surface.

Covalent Attachment of Protein A on SAM Leads to Bioaffinity Immobilization of Rabbit IgG. In immunoaffinity systems, one of the most important steps is immobilization of the antibody on the substrate surface, which can then be used for bioaffinity separation or biorecognition. Staphylococcal protein A is known to bind the Fc region of immunoglobulin molecules with high affinity; as a result, the Fab fragments point away from the surface, in order to allow for easy antigen−antibody binding.[48−50] This affinity between protein A and IgG is also extensively used for the development of an affinity system for antibody purification.[51] Accordingly, we sought to immobilize IgG molecules in an oriented fashion on surface-bound protein A.

Protein A consists of a single polypeptide chain of molecular weight 42 000. The three-dimensional structure of the protein A molecule is very stable to heat, denaturing agent, and a large pH interval (0.99−11.8) (see Supporting Information).[52] High frictional ratio of 2.1−2.2 and intrinsic viscosity of 29 mL/g suggest that protein A is not a typical globular protein but rather has a markedly extended shape having approximate dimensions of 2.5 × 25 nm.[44,53] At first, the Fischer carbene coated surface was treated with protein A solution in phosphate buffer (pH 8) at room temperature for 10 min (surface d, Scheme 3). The primary amino groups of the pendant lysine residues of protein A reacted

Scheme 3. Immobilization of Protein A and Rabbit IgG on Gold Surface

rapidly with the electrophilic carbene carbon resulting in the formation of new C—N bonds and thereby anchoring the protein covalently to the surface. This protocol was perceived as a mild, rapid, and reliable procedure for protein immobilization that would minimize multilayer formation. Physically adsorbed protein A molecules were then removed by repeated washing with the buffer solution and milli-Q water. The slides were then dried under a stream of argon.

The protein A coated surface was characterized by ATR-IR and AFM. After aminolysis, the absorption peaks for W—CO stretching show a decrease of 8 cm^{-1}. For AFM imaging, a noncontact mode was employed. Figure 1B represents the image of the surface after incubation in protein A solution for 10 min. A dense coverage was observed throughout the protein-coated surface, whereas the Fischer carbene terminated SAM did not show any significant undulation of the surface (Figure 1A). The

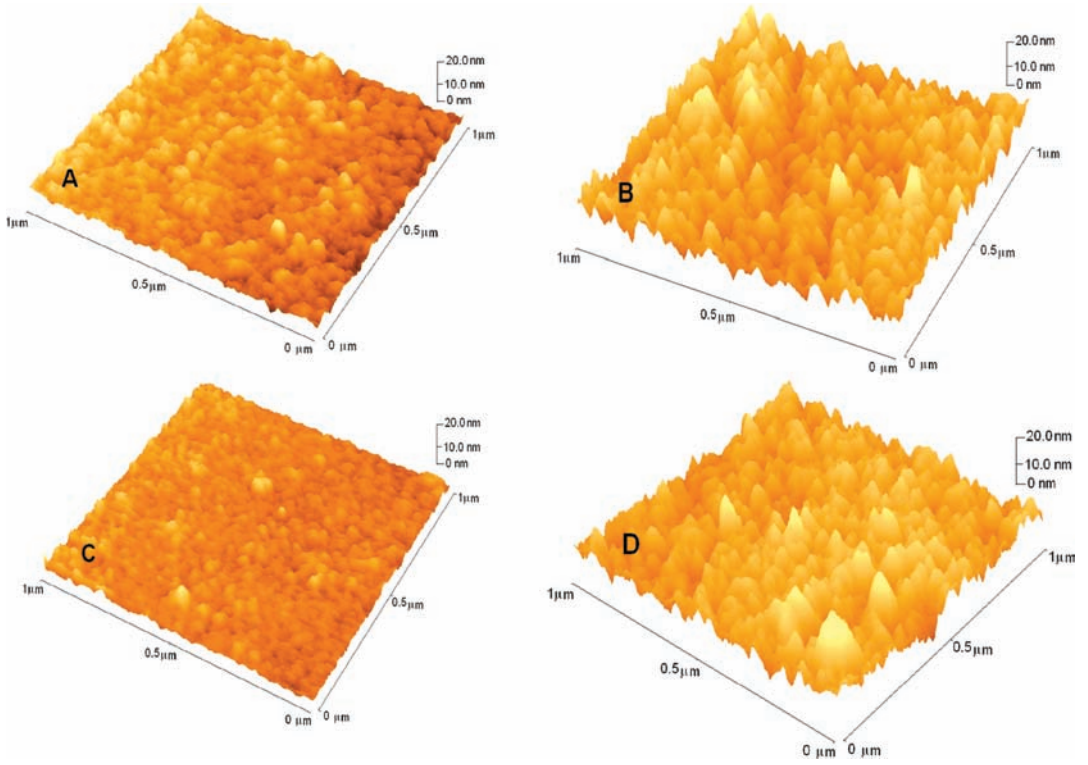

Figure 3. AFM topographic image of (A) protein A slide and (B) rabbit IgG after second cycle, (C) protein A slide, and (D) rabbit IgG coated slide after third cycle.

average height and the average roughness (Ra) of the Fischer carbene terminated gold surface were 4.23 and 0.61 nm, respectively. After protein A immobilization, the height and Ra increased to 7.13 and 0.95 nm, respectively (Figure 1B). The increase in height by 2.9 nm is consistent with the reported size of protein A molecule.

The protein A coated slide was then incubated in rabbit IgG solution in phosphate buffer (pH 8.0) for 1 h at room temperature.[54] Excess IgG was removed by washing with buffer and milli-Q water several times. Surface e in Scheme 3 represents the substrate surface carrying oriented IgG molecules on the self-assembled monolayer. ATR-IR spectrum of the IgG coated surface showed that the amino carbene band remained at the same position 2064.5 cm^{-1} and 1922.2 cm^{-1} which established that Fischer carbene complex did not undergo significant decomposition (Figure 2A). Figure 2B displays the AFM image of the IgG immobilized on protein A bonded surface. From AFM images, it was evident that the average height of the immobilized protein A (Figure 1B) increased from 7.13 to 15.78 nm and Ra changed to 1.59 nm after incubation in rabbit IgG. The change in height by 8.65 nm roughly corresponds to the height of IgG (8.5 nm).[55] The section analysis of the gold surfaces modified with Fischer carbene complex, protein A, and rabbit IgG are included in the Supporting Information.

Recycling of the Protein A Coated SAM on Flat Gold Surface. The interaction between protein A and rabbit IgG is affinity-driven. The immobilized IgG can be debased by changing the pH of the buffer medium. This ought to give rise to a free protein A surface which can be recycled. As described below, this expectation was indeed realized.

The initial average height of the protein A coated slide was found to be 7.13 nm by AFM (Figure 1B). After incubation with rabbit IgG, the height increased to 15.78 nm (Figure 2B). After removing the rabbit IgG, by treating the gold surface with a typical elution buffer like citrate buffer (pH 3.5) for 15 min the average height decreased to 7.11 nm (Figure 3A). After that, the slide was immersed in a neutralizing buffer like phosphate buffer (pH 9.0) for 15 min to restore original protein conformation. When it was incubated again in rabbit IgG solution, the average height increased to 15.81 nm (Figure 3B). On repeating the process for the third time, we observed that the height changed from 7.06 nm (Figure 3C) to 15.69 nm (Figure 3D). Thus, in all three cycles the change in height with immobilization of rabbit IgG is consistent with the height of IgG.

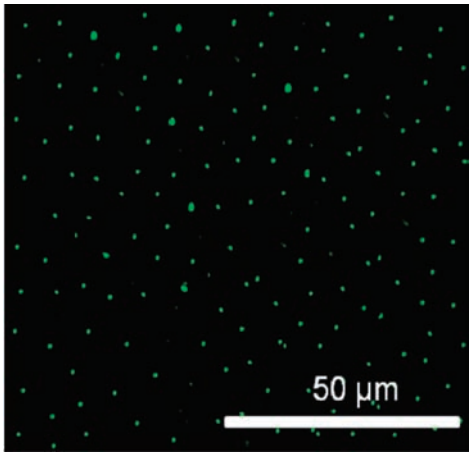

Figure 4. Fluorescence image of rabbit IgG coated slide, incubated in solution of FITC tagged goat antirabbit IgG in phosphate buffer.

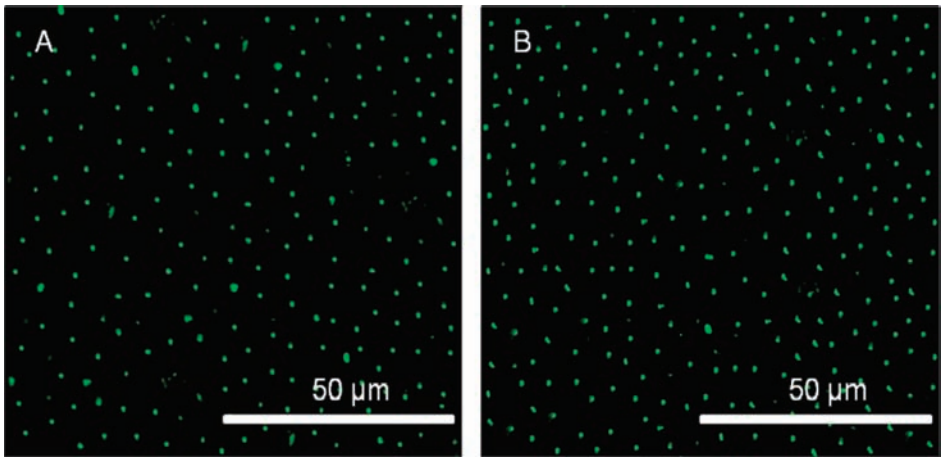

Figure 5. Fluorescence microscopy image of rabbit IgG coated slide after incubation in FITC tagged goat antirabbit IgG solution in phosphate buffer after (A) second cycle and (B) third cycle.

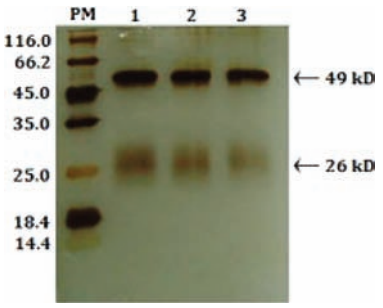

Figure 6. Picture of SDS-PAGE analysis of rabbit IgG fraction obtained by chemical reduction with 2-mercaptoethanol. Molecular weight standard is on lane (PM) and chemically reduced IgG after first cycle (lane 1), second cycle (lane 2), and third cycle (lane 3).

Detection of Rabbit IgG on Glass Using Fluorescence Microscope. The presence of rabbit IgG can also be proven visually by fluorescence microscopy techniques. These experiments were performed on glass slides using 11-bromoundecyltrichlorosilane as the primary chain. The bromo terminated surface was converted to the Fischer carbene terminated surface as depicted in Scheme 1. The Fischer carbene coated slide was subsequently treated with protein A solution and then with rabbit IgG solution as described before. After thorough washing by buffer, the IgG coated slide was immersed in a solution of FITC tagged goat anti rabbit IgG in phosphate buffer (pH 8). After careful washing with buffer and milli-Q water, the slide was observed under fluorescence microscope. Bright fluorescent spots were observed (Figure 4).

Fluorescence microscopy was also used to verify the regeneration of protein A after extraction of IgG on glass slides. The FITC tagged goat antirabbit IgG was used and fluorescence spots of nearly equal distribution of density were observed across several cross sections of the slide indicating high reproducibility (Figure 5).

Since protein A binds specifically with the Fc region of rabbit IgG, this property allows the use of surface-bound protein A for purification of rabbit IgG from rabbit serum. We used protein A coated microscopic glass slides and immersed it in a solution of rabbit serum (50 μg/mL) in phosphate buffer (pH 8.0) for 1 h. After thorough washing with buffer and milli-Q water, the slides were immersed into eluting buffer (citrate buffer pH 3.5) for 15 min. The citrate buffer containing the rabbit IgG was readily neutralized with Tris-HCl buffer (pH 9.0) and concentrated. The purified IgG was analyzed by SDS-PAGE gel after chemical reduction using 2-mercaptoethanol. IgG has a molecular mass of 150 kD and contains two heavy chains of 50 kD and two light chains of about 25 kD. By reduction with 2-mercaptoethanol, the heavy and the light chains were resolved. This is depicted in Figure 6. The spot at 49 kD represents the heavy chain and the spot at 26 kD represents the light chain. The cycle was repeated three times. No contaminants are visible in the purified IgG (Figure 6).

CONCLUSION

In conclusion, we have successfully applied a relatively mild protocol to modify Au/glass surface with Fischer carbene function that allows rapid immobilization of protein A on surface, which lead to oriented immobilization of rabbit IgG. The surfaces at different stages were characterized by ATR-IR and AFM. We also demonstrated that a protein A slide prepared by following our protocol can be used successively three times to purify rabbit IgG from rabbit serum. The work described above widens the scope of employing Fischer carbene complexes both in biological and biomedical studies.

1. Synthesis of 11-(2-(2-(2-bromoethoxy)ethoxy)ethoxy)undecane-1-thiol:[1]

(a) Synthesis of 2-(2-(2-(undec-10-enyloxy)ethoxy)ethoxy)ethanol (**2**):

A degassed solution 50% aqueous solution of NaOH (1.24 ml, 15.9 mmol) was added slowly with stirring to trigol (11.46 g, 76.3 mmol) under argon atmosphere. The resulting mixture was heated at 100 ^{o}C for 45 mins. After cooling it to room temperature, 11-bromoundecene (3.7 g, 15.9 mmol) was added dropwise. The mixture was heated under reflux for 24 h, cooled and then extracted with ethylacetate (3x10 ml). The collected ethylacetate layer was dried over sodium sulphate and concentrated under reduced pressure. Flash column chromatography (65% ethylacetate/petroleum ether) afforded 3.5g of pure product.

^{1}H NMR ($CDCl_3$): 1.21-1.26 (m, 12H), 1.53-1.57 (m, 2H), 1.97-2.04 (m, 2H), 2.77 (br, 1H), 3.42 (t, J=6Hz, 2H), 3.54-3.71 (m, 12H), 4.88-4.99 (m, 2H), 5.73-5.82 (m, 1H).

^{13}C NMR ($CDCl_3$): 26.11, 28.97, 29.14, 29.48, 29.49, 29.63, 33.87, 61.78, 70.08, 70.41, 70.65, 70.67, 71.64, 72.64, 114.20, 139.27.

(b) Synthesis of *S*-11-(2-(2-(2-hydroxyethoxy)ethoxy)ethoxy)undecylethanethioate (**3**):[1]

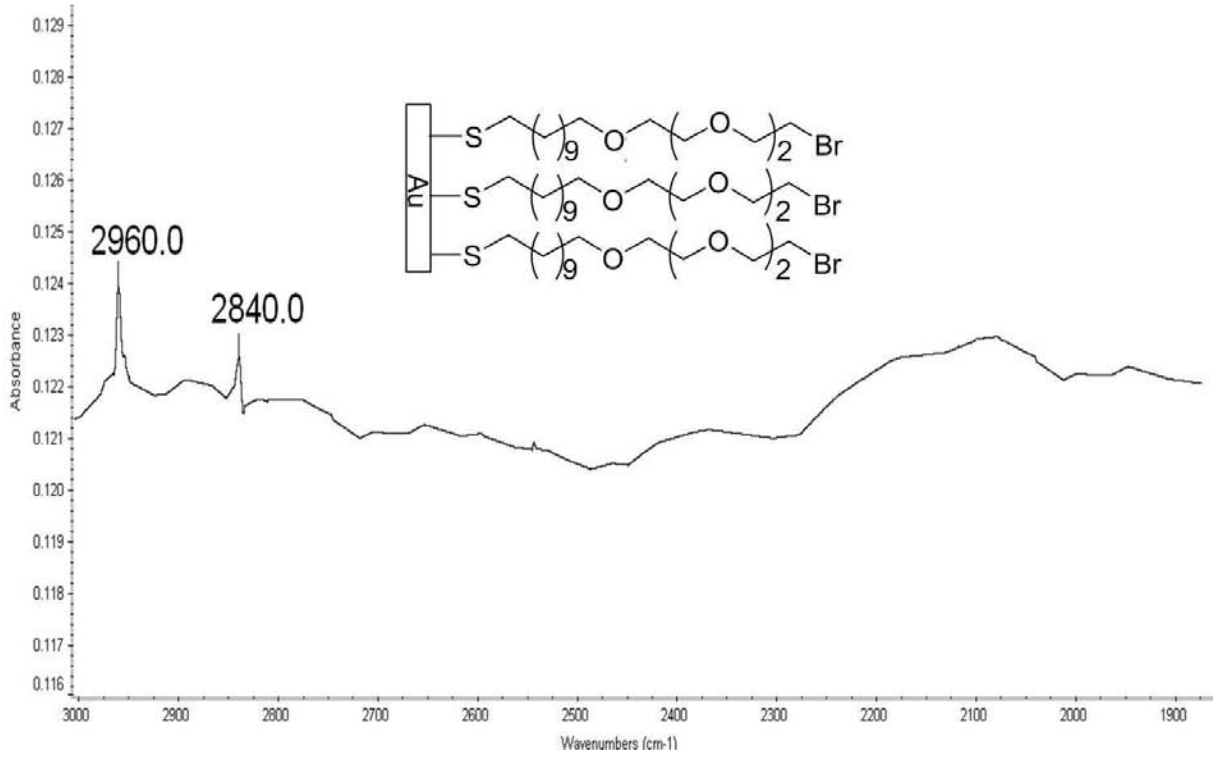
Thiolacetic acid (0.94g, 12.34 mmol) was added to a solution of compound **2** (1.5 g, 4.9 mmol) in dry methanol (20 ml) under argon atmosphere. AIBN (7 mg) was then added, after which the reaction mixture was irradiated by 450 W medium pressure mercury 1 amp for 7 h in a pyrex tube. The solvent was evaporated. Flash column chromatography (65% ethylacetate/pet ether) afforded 1.75g of pure product.

^{1}H NMR ($CDCl_3$): 1.18-1.21 (m, 14H), 1.46-1.53 (m, 4H), 2.27 (s, 3H), 2.81 (t, J=6 Hz, 2H), 3.40 (t, J=6Hz, 2H), 3.53-3.69 (m, 12H).

^{13}C NMR ($CDCl_3$): 26.11, 28.85, 29.15, 29.20, 29.49, 29.54, 29.59, 29.61, 30.68, 61.75, 70.06, 70.39, 70.64, 71.62, 72.66.

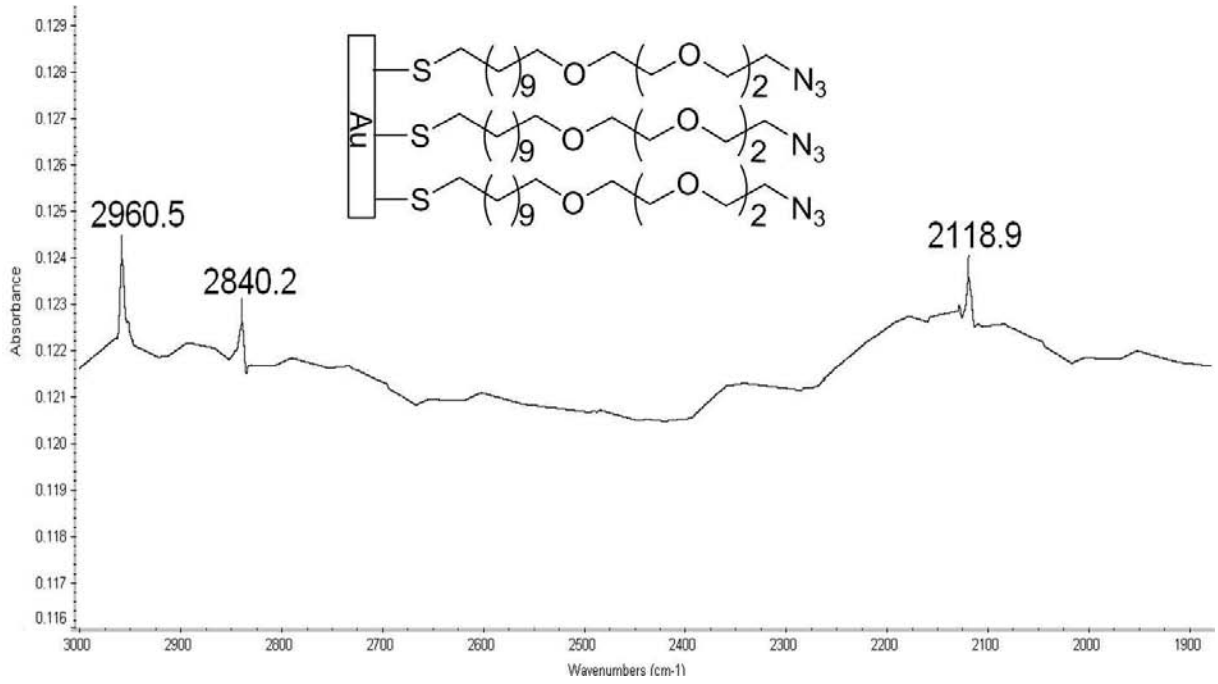
2. Synthesis of alkoxyalkynyl Fischer carbene (6):[2]

In a 100 ml two neck r. b. flask, 3.06 gm phenylacetylene (30 mmol) was taken in 30 ml dry ether under Argon. The stirred solution was cooled to -50 ºC and 19 ml of ^{n}BuLi in hexane (1.6 M, 30 mmol) was added drop wise. Stirring was continued for 1 h. In another 100 ml r. b. flask, 10.5 gm (30 mmol) of $W(CO)_6$ was taken in 30 ml dry ether under Ar and the suspension was cooled to -50 ºC. The phenylacetylide solution was then added to the tungsten hexacarbonyl suspension. The temperature was raised to 0 ºC and stirred for 1 h. The ether was evaporated and the salt dissolved in minimum amount of ice-cold water, to which 30 ml of Meerwin's salt solution (1 mM, 30 mmol) was added. The resulting dark red solution was extracted with petroleum ether (4 x 50 ml), concentrated and purified by flash column chromatography (pet ether: acetone 90:10) under N_2. Yield 76%, 10.9 gm.



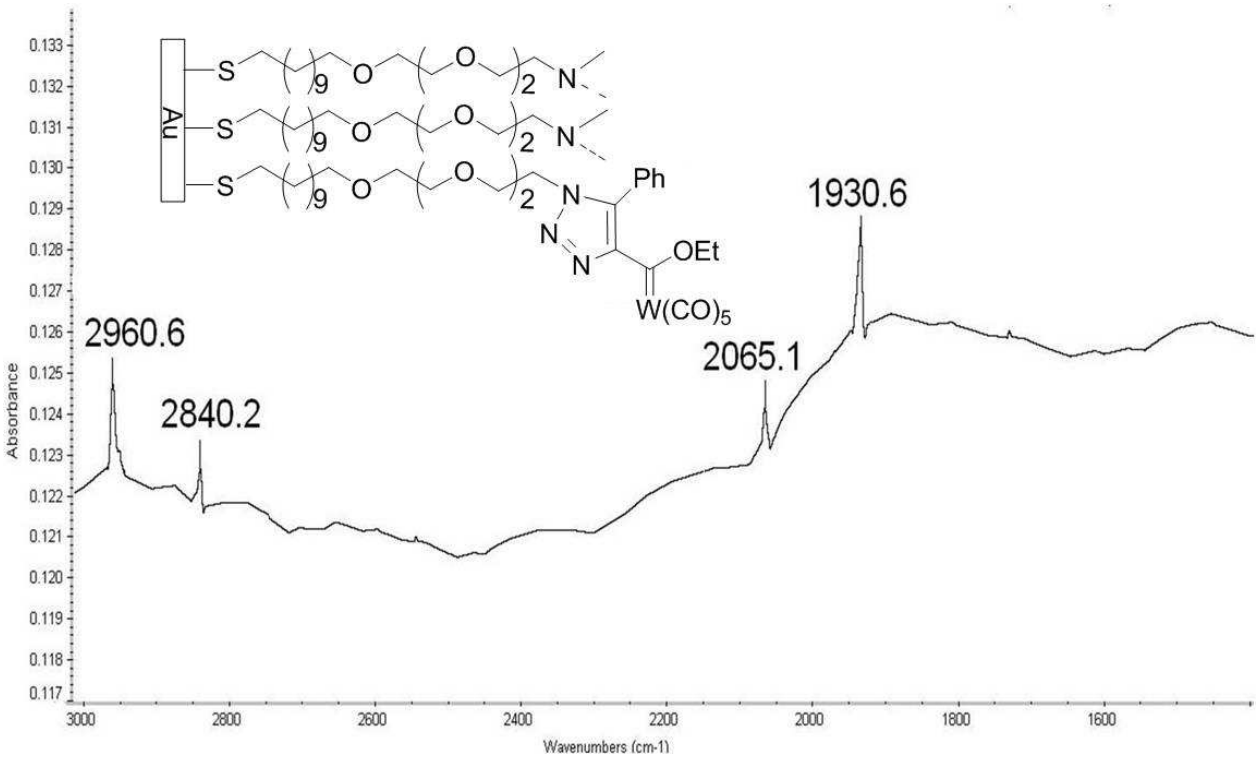
3. Physicochemical properties of protein A:[3,4]

Property	Value
$s^0_{20,w}$ (S)	2.1
Stokes radius (nm)	5.0
$D_{20,w}$ (cm^2/s)	4.3×10^{-7}
Huggins constant, K	0.66
$A^{1\%}_{280}$ (nm)	1.40
$A^{1\%}_{275}$ (nm)	1.65

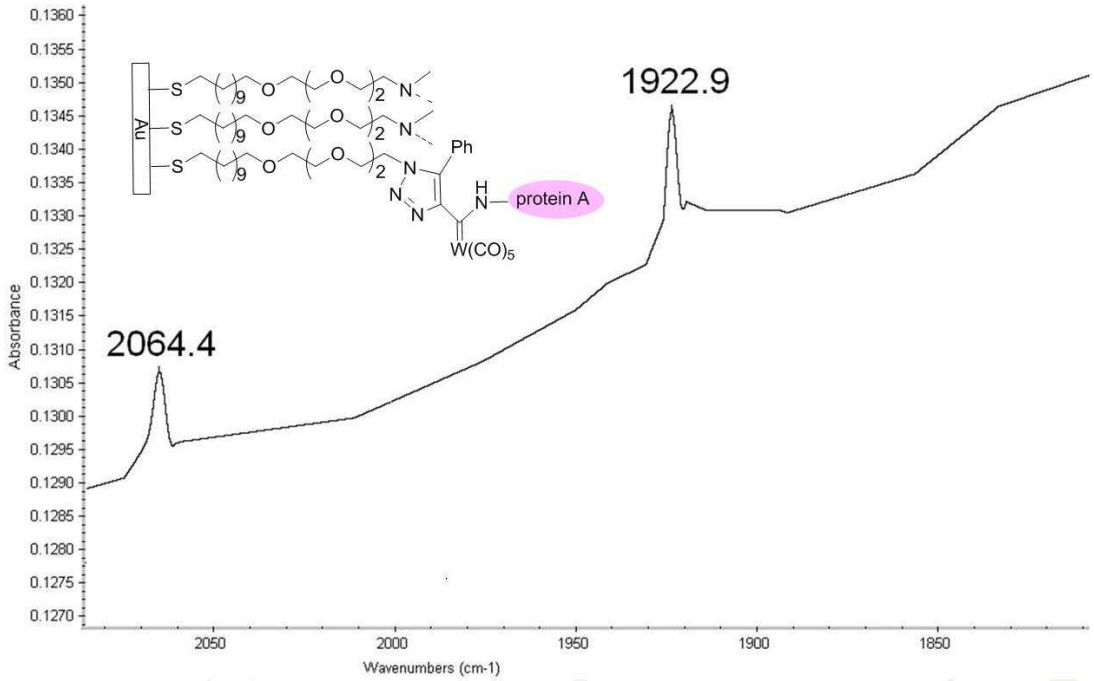


Its isoelectric point is 4.85 – 5.15. Protein A contains 50 % α-helical structure and 10 – 20 % β structures. It has four chemically equivalent tyrosine residues which are fully exposed on the surface. These tyrosine residues can be modified by tetranitromethane and acetylimidazole and are probably responsible for the protein's biological activity.

4. ATR-IR spectroscopy measurement of gold surface:



The bromo terminated SAM shows strong absorption band at 2960.0 $cm^{-1}$and 2840.0 cm^{-1}.



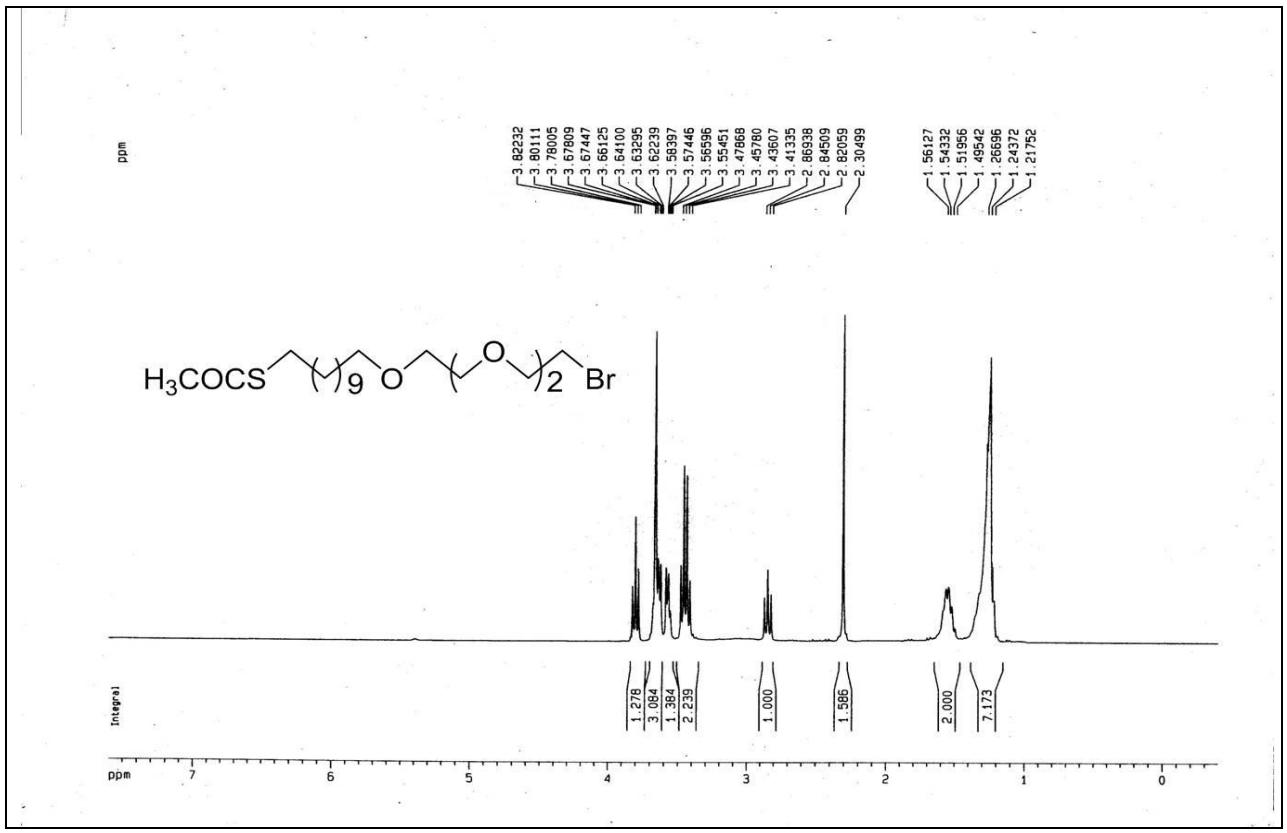
After nucleophilic displacement with sodium azide a new band originate at 2118.9 cm^{-1}.

After the ‘click’ cycloaddition reaction with alkynyl Fischer carbene the peak at 2118.9 cm^{-1} vanishes and two new band appeared at 2065.1 cm^{-1} and 1930.6 cm^{-1}.

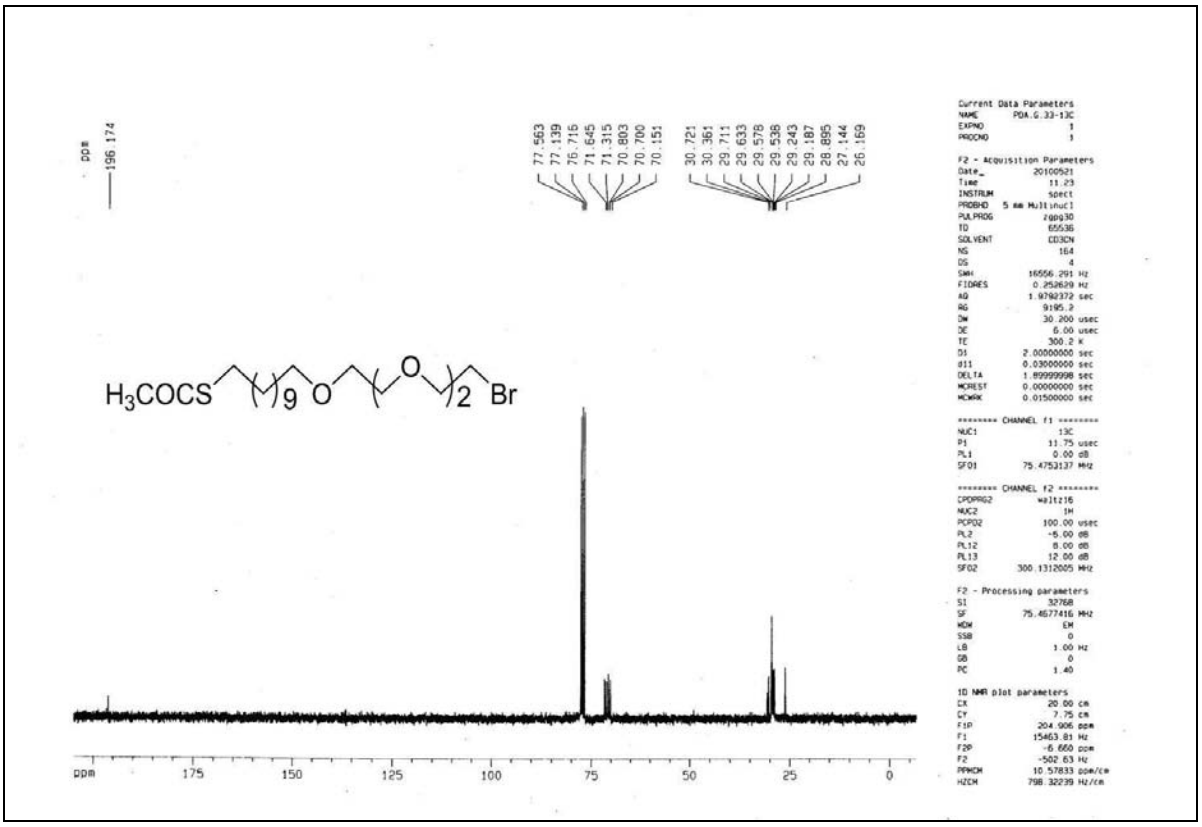
After aminolysis with primary amine groups of pendant lysine residues of protein A the new W-CO stretching of amino carbene appeared at 2064.4 cm^{-1} and 1922.9 cm^{-1}.

5. Functionalization of glass surface:

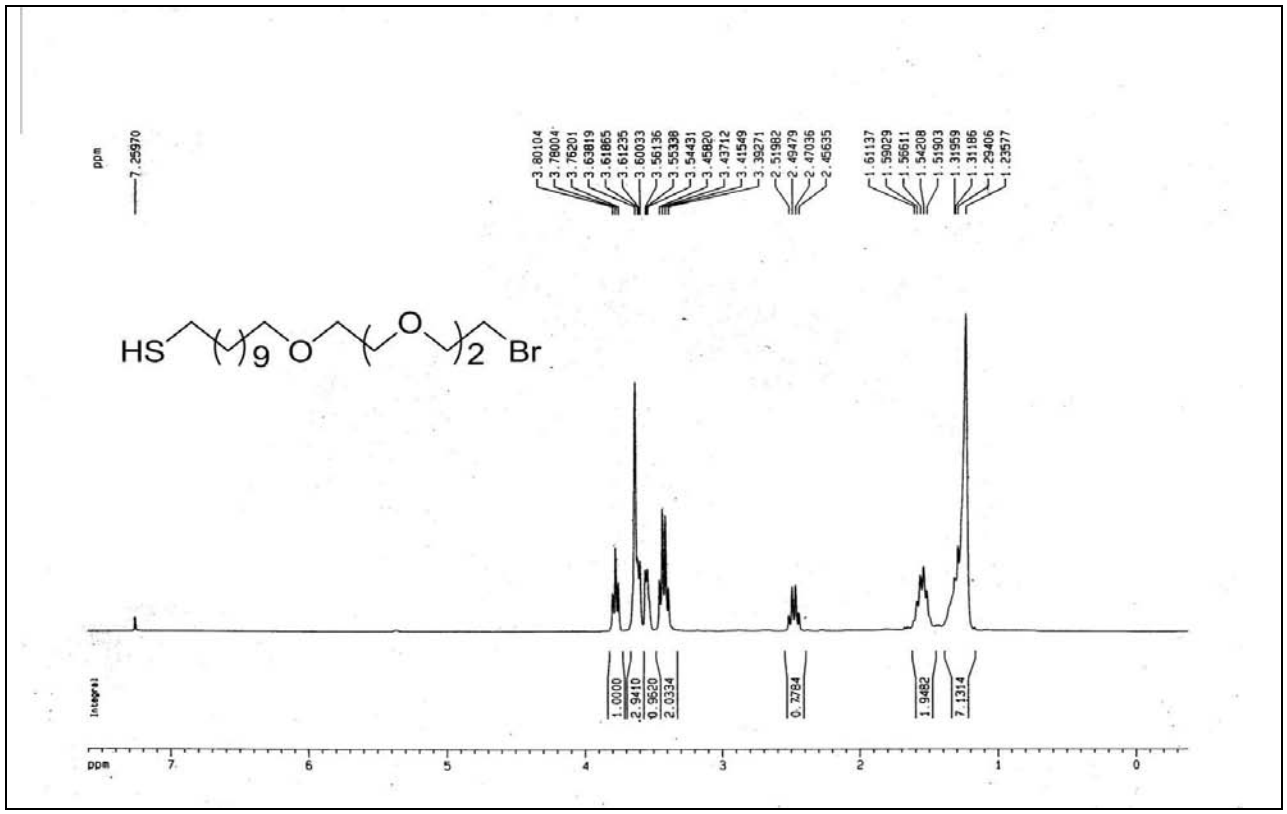
i) Preparation of self assemble monolayer with 11-bromo-undecyl-trichlorosilane (BUTS):
The glass substrates were sequentially cleaned with piranha solution (a mixture of concentrated H_2SO_4 and 40% aq. H_2O_2) and water. Finally was dried under nitrogen. The cleaned glass surface was immersed in a 1% v/v solution of BUTS in dry toluene for 45 mins. After washing with dry toluene and ethanol the coated glass substrate was kept in oven at 100 ^oC for 10 mins.



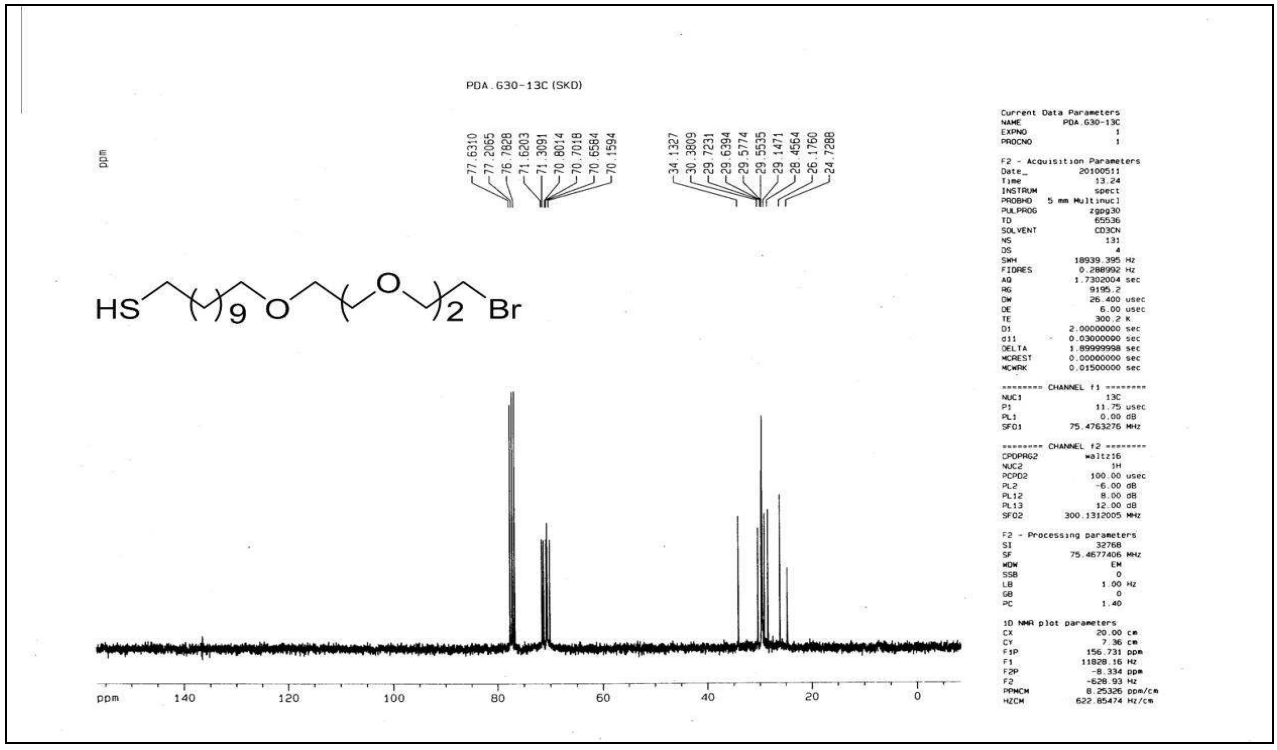
ii) Nucleophilic displacement with sodium azide:
The bromo coated glass slides was incubated in a saturated solution of NaN_3 in DMF and stirred for 48 h at room temperature. The slide was then extensively washed with distilled water and dried under nitrogen.



iii) Grafting of Fischer carbene complex (**6**) on glass surface via Cu free 'Click' cycloaddition reaction:
The azido coated glass slide was treated with 10 mM solution of Fischer carbene complex (**6**) in dry toluene at 50 ^oC for 4 h under argon. It was then washed with toluene followed by ethanol and dried under argon.



iv) Immobilization of protein A:
Glass surfaces coated with Fischer carbene was immersed in a solution of protein A (10 mg/L) in phosphate buffer (pH 8.0) for 10 min at room temperature. The substrates were rinsed thoroughly with buffer solution (thrice), then with milli-Q water (thrice) and dried under argon atmosphere. The remaining Fischer carbene complexes were blocked by treatment with 1M ethanolamine (pH 9.0) for 30 min. Finally, the surfaces were treated with 1 % (w/v) BSA in phosphate buffer pH 8.0 for 2 h to block non-specific binding. Then the surfaces were extensively rinsed with milli-Q water and dried under argon.



v) Successive binding of rabbit-IgG and FITC tagged goat anti-rabbit IgG:
Protein A coated glass surfaces were incubated in a solution of rabbit IgG (50 µg/ml) in phosphate buffer (pH 8.0) for 1 h. The surfaces were extensively washed with phosphate buffer containing 0.05 % Tween (v/v), followed by milli-Q water and dried under argon atmosphere. The IgG coated glass slide was further incubated in FITC tagged goat anti-rabbit IgG in phosphate buffer pH 8.0 for 1 h. Finally the surface was rinsed vigorously with phosphate buffer containing 0.05% Tween (v/v), followed by milli-Q water and dried under argon.

6.^{1}H NMR and ^{13}C NMR of compound (4) and (5).

ABSTRACT: Cytokines are important mediators coordinating inflammation and wound healing in response to tissue damage and infection. Therefore, immobilization of cytokines on the surface of biomaterials is a promising approach to improve biocompatibility. Soluble cytokines signal through receptors on the cell surface leading to cell differentiation, proliferation, or other effector functions. Random immobilization of cytokines on surfaces will result in a large fraction of inactive protein due to impaired cytokine−receptor interaction. We developed a strategy that combined (i) directed covalent coupling of cytokines, (ii) quantification of coupling efficiency through fluorescence detection, and (iii) a reliable protease cleavage assay to control orientation of coupling. For this purpose, fusion proteins of the SNAP-tag followed by an enterokinase recognition site, yellow fluorescent protein (YFP), and the cytokine of interest being either interleukin-6 (IL-6) or oncostatin M (OSM) were generated. The SNAP-tag is a derivative of O^6-alkylguanine-DNA alkyltransferase that couples itself covalently to benzylguanine. Bioactivities of the SNAP-YFP-cytokines were shown to be comparable with the nontagged cytokines. Efficient coupling of SNAP-YFP-cytokines to benzylguanine-modified beads was demonstrated by flow cytometry. The fact that enterokinase treatment released most of the fluorescence from the beads is indicative for directed coupling and only marginal adsorptive binding. Cellular responses to SNAP-YFP-cytokine beads were analyzed in cellular lysates and by confocal microscopy indicating that the directionally immobilized cytokines are fully signaling competent with respect to the activation of ERK and STAT3. The strategy presented here is generally applicable for the directed covalent immobilization of fluorescently labeled proteins including the convenient and reliable control of coupling efficiency and orientation.

1. INTRODUCTION

Cytokines are a large and heterogeneous group of proteins consisting of interleukins, interferons and growth factors.[1] These important and versatile mediators of intercellular communication are involved in virtually all physiological processes in the developing and adult organism. Depending on the individual cytokine and the cellular context, these proteins stimulate proliferation or differentiation of cells and may act in a pro- or anti-inflammatory manner on immune responses. Because of these properties, cytokines are promising molecules to modulate the response of the body to biomaterials. Therefore, immobilization of cytokines on the surface of biomaterials to direct the fate of adhered cells, augment wound healing, and control inflammatory responses is an active field of research.[2−4]

Cytokines bind specifically to cytokine receptors which consist of two or more subunits. These subunits can be different proteins (heterooligomeric receptors) or two or more copies of the same protein (homooligomeric receptors).[5] Shared subunits are known, which are used by different cytokines.[6] Gp130 is the shared receptor subunit of the IL-6 family of cytokines.[7] Two IL-6 molecules assemble two IL-6 receptor α-subunits (IL-6Rα) and two gp130 molecules leading to the formation of a hexameric receptor complex.[8] Other cytokines of this family such as oncostatin M (OSM) and leukemia inhibitory factor (LIF) bind to a heterodimer of gp130 with the OSM receptor (OSMR) or LIF receptor (LIFR), respectively, resulting in a heterotrimeric receptor complex.[9] In all cases, large surface areas of the cytokine must be accessible for the interaction with the receptor subunits to allow receptor complex formation. Therefore, random adsorptive or chemical immobilization of cytokines will lead to a large fraction of inactive protein. One could even imagine the generation of partial agonists by inadequate immobilization of cytokines leading to skewed signaling.

Signal transduction downstream of gp130 always involves the transcription factor STAT3 and the RAS/RAF/ERK cascade.[7] Depending on the cytokine, other pathways may also be activated. The hallmark of STAT3 activation is the phosphorylation of tyrosine residue 705 (Y705) by receptor associated Janus

kinases (JAKs) and subsequent nuclear accumulation of the transcription factor.[10] ERK activation involves phosphorylation of the TEY-motif by the upstream kinase MEK. The kinetics of ERK activation determines the cellular response.[11] It is still a matter of debate as to what extent these key signaling events are initiated at the plasma membrane or after internalization of the receptor complex at signaling endosomes.[12] This issue is of considerable importance as soon as cytokines are immobilized on surfaces. Cytokines bound to surfaces cannot be internalized and therefore cannot signal from endosomes, raising the possibility that signaling from soluble and immobilized cytokines may differ.[13,14]

Furthermore, endocytosis of receptor complexes is a way to desensitize cells from further stimulation.[15] However, for gp130 it is known that the signaling cascade is downregulated by a classic feedback mechanism: activated STAT3 induces the suppressor of cytokine signaling 3 (SOCS3) protein expression.[16] Then, SOCS3 blocks further STAT3 activation at the gp130 receptor complex by mechanisms which are incompletely understood. Therefore, it will be interesting to see as to what extent immobilization of the cytokine interferes with the kinetics of the signaling events. Prerequisite for these investigations is a reliable technique to covalently immobilize cytokines on surfaces in a bioactive form.

We used cytokines of the IL-6-family to develop a new strategy for cytokine immobilization on surfaces that guarantees (i) site-directed covalent coupling through a tag that does not involve the cytokine itself, (ii) straightforward analysis of coupling efficiency by fluorescence detection, and (iii) proof of orientation of coupling by protease cleavage. Cytokines immobilized by this strategy are useful tools for basic research on cytokine signal transduction and the improvement of biomaterials.

2. EXPERIMENTAL PROCEDURES

2.1. Chemicals and Antibodies. PEGylated aminobenzylguanine (BG-PEG-NH_2) was provided by New England Biolabs (Ipswich, USA). Magnetic micromer-M PEG-COOH beads with a diameter of 3 μm were produced by Micromod (Rostock, Germany). Primary antibodies were purchased from the following companies: GFP, phosphorylated STAT3, and phosphorylated ERK1&2 (Rockland, Gilbertsville, USA), STAT3 and ERK1&2 (Santa Cruz, Santa Cruz, USA), IL-6, OSM, PE-conjugated IL-6 and PE-conjugated OSM (R&D, Minneapolis, USA), and SNAP (Open Biosystems, Huntsville, USA). Secondary antibodies were purchased from DAKO (Glostrup, Denmark). Enterokinase-kit was obtained from EMD Chemicals (Gibbstown, USA). Eukaryotic cell-culture media and antibiotics (Pen Strep) were purchased from Invitrogen (Carlsbad, USA).

2.2. Recombinant Plasmids and Proteins. The expression vector pET-17b from EMD Chemicals was used for the production of YFP-OSM and YFP-IL-6 in *E. coli*. The constructs consist of a hexahistidine (his)-tag, followed by a enterokinase recognition site (DDDDK), YFP, and the respective mature human cytokine. SNAP-YFP (fusion protein without cytokine) was also produced in *E. coli*. SNAP-YFP-cytokines were cleaved in *E. coli* and therefore produced in mammalian cells. The pcDNA5/FRT/TO vector of the Flp-In system (Invitrogen) was used for the expression of SNAP-YFP-OSM and SNAP-YFP-IL-6 in HEK293 cells. The constructs encode the signal sequence of IL-6 for secretion, followed by a his-tag, a SNAP-tag (New England Biolabs), the enterokinase recognition site, the enhanced yellow fluorescent protein (YFP), and finally the respective mature human cytokine. The YFP cDNA originated from the pEYFP-N1-vector (Clontech, Mountain View, USA).

2.3. Protein Expression. Flp-In T-Rex HEK293 were stably transfected with expression vectors encoding SNAP-YFP-cytokines using the T-Rex system (Invitrogen). For protein expression, cells were cultured in serum-free DMEM medium in a water-saturated atmosphere containing 5% CO_2 at 37 °C. Protein expression was induced by the addition of doxycycline (50 ng/mL). 72 hours after induction, the supernatant was collected and concentrated 20-fold by ultrafiltration using a Vivaspin 20 device (Sartorius Stedim biotech, Aubagne, France). For further characterization, SNAP-YFP-cytokines were purified using a Ni-NTA Spin-column according to the instructions of the manufacturer (Qiagen, Hilden, Germany). The different fractions were analyzed by SDS−PAGE, followed by Coomassie-staining or Western blotting. SNAP-YFP cytokines were quantified by ELISA using antibodies against the SNAP and YFP-moieties. SNAP-YFP served as a standard.

YFP-cytokines and SNAP-YFP were expressed in *E. coli* (strain BL-21 (DE3) pLysS) by the use of the pET-system.[17] Bacteria were grown at 37 °C in LB medium in the presence of 100 mM $ZnCl_2$ to an OD_{600} of 0.6−0.8. After the addition of IPTG (0.4 mM) and DTT (1 mM), the culture was incubated at 25 °C for 20 h. Bacteria were sedimented by centrifugation, the pellet shock-frozen and resuspended in lysis-buffer (20 mM phosphate buffer, pH 8.0, containing 500 mM NaCl). Lysozyme (1 mg/mL), benzonase (25 U/mL) and Triton-X100 (1%) were added to complete the lysis of bacteria. Lysates were shaken at 4 °C for 4 h and the recombinant proteins purified as described above. To determine the concentration of SNAP-YFP in the eluate, the absorbance at 514 nm was measured (NanoDrop, NanoDrop products, Wilmington, USA; extinction coefficient of YFP = 83,400 M^{-1} cm^{-1}).

2.4. Immobilization of SNAP-YFP-Cytokines. For immobilization, 50 μL of a suspension of micromer-M PEG-COOH beads (3.4×10^6 beads/μL) was functionalized with 50 μL of BG-PEG-NH_2 (2 mg/mL in 10% DMSO and 90% PBS pH 7.4) through EDC/NHS-chemistry:[18] At first, beads were shortly washed twice in MES-buffer (25 mM, pH 5.0) and then incubated (30 min, room temperature) in a freshly prepared mixture of 25 μL EDC solution (50 mg/mL) and 25 μL of NHS solution (50 mg/mL) in MES-buffer (25 mM, pH 5.0). After incubation, the supernatant was removed, and the beads were washed again with MES-buffer for 4 min. Then, 50 μL of BG solution was added, and the suspension was incubated for 16 h (4 °C) with slow tilt rotation. After washing four times with 100 μL of 0.05 mM Tris-HCl, pH 7.4, 10 μL of the bead suspension (1.6×10^6 beads/μL) was incubated for 16 h with 50 μL of purified SNAP-YFP-cytokine (1 μM) or concentrated supernatants of SNAP-YFP-cytokine producing cells. Incubation of beads with YFP-cytokine (no SNAP-tag) and incubation of unmodified beads (no benzylguanine on the surface) with SNAP-YFP-cytokine served as controls. Beads were washed with 100 μL of phosphate-buffer (0.1 M, pH 8.0) containing 2% BSA. After washing, beads were analyzed by flow cytometry or by confocal microscopy. SNAP-YFP-cytokine beads were stored at −80 °C in phosphate buffer (0.1 M, pH 8.0) containing 2% BSA. The concentrations of SNAP-YFP-IL-6 in the coupling buffer before and after coupling were determined with a previously described ELISA[19] using a biotinylated GFP antibody (Rockland).

2.5. Analysis of Beads by Flow Cytometry and Confocal Microscopy. Three microliters of a suspension of SNAP-YFP-cytokine beads (1.6×10^5 beads/μL) and the control beads were mixed with 100 μL of BD FACSFlow Sheath Fluid

(BD Bioscience, Franklin Lakes, USA). Beads were analyzed by flow cytometry (FACS Canto II, BD systems) using the appropriate adjustments for YFP detection. For cytokine detection, 7.5 μL of a suspension of SNAP-YFP-cytokine beads were incubated for 30 min in 25 μL of 0.1 M phosphate buffer (pH 8.0) containing 1 μL of a phycoerythrin (PE)-conjugated cytokine antibody (or without PE-antibody as a control). After incubation, 10 μL of bead suspension was mixed with 100 μL of BD FACSFlow Sheath Fluid and analyzed as described above detecting PE and YFP fluorescence.

For confocal microscopy, 2 μL of a suspension of SNAP-YFP-cytokine beads (1.6×10^5 beads/μL) was mixed with 5 μL of Shandon Immu-Mount (Thermo Fisher Scientific Inc., Waltham, USA) on a microscope slide and covered with a coverslip. After a short drying period, probes were analyzed using a Zeiss LSM 510 confocal microscope.

2.6. Stability of Coupling and Enterokinase Cleavage. Fifteen microliters of a suspension of SNAP-YFP-cytokine beads was incubated in 500 μL of serum free medium (DMEM-F:12 including Pen Strep) and incubated for different times at 37 °C. Then, the medium was removed by centrifugation, and beads were washed with 50 μL of 0.1 M phosphate buffer (pH 8.0). Detection of YFP and PE fluorescence by flow cytometry was performed as described above.

To 15 μL of a suspension of SNAP-YFP-cytokine beads (1.6×10^5 beads/μL), 50 μL of enterokinase solution was added. After incubation for 16 h at 4 °C, the beads were prepared for flow cytometry as described above.

2.7. Immobilization on NCO-sP(EO-*stat*-PO)-Coated Glass Coverslips. Glass coverslips (18 mm diameter, purchased from Menzel (Braunschweig, Germany)) were cleaned by sonication in water, acetone, and 2-propanol for 5 min each, followed by drying in a stream of nitrogen. Afterward, the substrates were transferred to a Unilab glovebox (MBraun, Garching, Germany) and treated with a solution of 0.3 mL of *N*-[3-(trimethoxysilyl)-propyl]ethylendiamine in 50 mL of dry toluene for 2 h, washed several times with dry toluene, and used without further storage. The spin coating solution was prepared by dissolving 10 mg/mL of the NCO-*s*P(EO-*stat*-PO) prepolymer (M_n = 12,000 g mol^{-1}; PDI = 1.15) in 1 mL of dry THF and adding 9 mL of deionized water. The solutions were used for layer preparation 5 min after mixing. For spin-coating, the samples were placed on the spin-coater, covered by the spin coating solution, and then accelerated within 5 s to 2500 rpm for 40 s.[20] Afterward, the samples were stored for 10 min and then used for immobilization of BG-PEG-NH_2 by dip-coating of the samples in a filtered solution of 0.5 mM BG-PEG-NH_2 in H_2O/DMSO 9:1 for 12 h. Then the samples were washed several times with H_2O and dried in a stream of nitrogen. A sticky μSLIDE-insert (IBIDI, Martinsried, Germany) with two chambers was fixed on the coverslip surface. The two chambers were incubated with SNAP-YFP-OSM or YFP-OSM (0.1 μM each) in phosphate buffer (0.1 M, pH 8.0) containing 2% BSA for 16 h at 4 °C. Chambers were washed as described in the immobilization section. Fluorescence was detected with a fluorescence scanner using 488 nm laser light for excitation and a 500−540 nm bandpass filter for detection. (Typhoon, GE Healthcare, Buckinghamshire, UK).

2.8. Stimulation of Cells. HepG2 cells were seeded on a 24-well plate and grown to 70% confluence. After starvation in serum free medium for 2 h, cells were incubated at 37 °C with varying concentrations of recombinant cytokines for different times as indicated in the figure legends. Cellular lysates were analyzed by SDS−PAGE and Western blotting using antibodies against phosphorylated STAT3, total STAT3, phosphorylated ERK and total ERK. For stimulation with immobilized cytokines cells were treated as described above but seeded on 24-well plates. Then 15 μL SNAP-YFP-cytokine beads (1.6×10^5 beads/μL) were added. Benzylguanine-modified beads were used as a control. Cells were incubated for different times. Cellular lysates were analyzed by SDS−PAGE and Western blotting as described above.

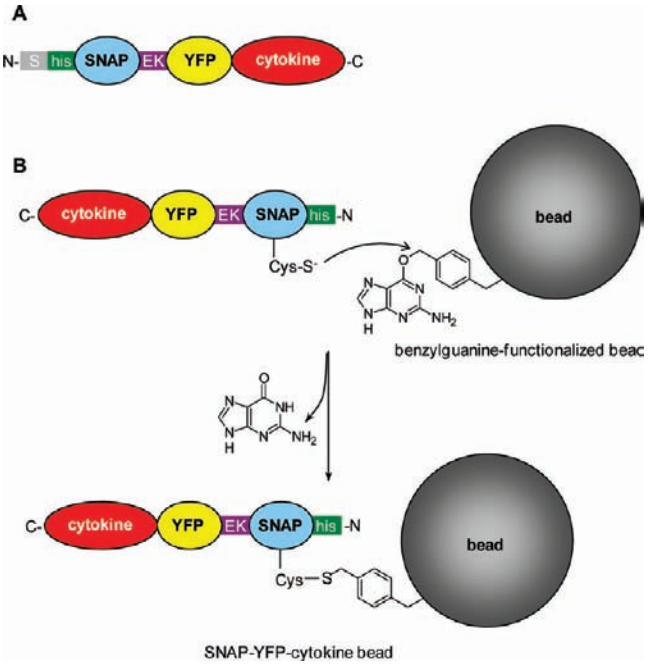

Figure 1. Scheme of a SNAP-YFP-cytokine and its surface coupling. (A) Schematic representation of the SNAP-YFP-cytokine construct encoded by the expression vector for the production of recombinant protein in mammalian cells. N, N-terminus; S, signal sequence (is cleaved-off during secretion); his, his-tag; SNAP, SNAP-tag; EK, enterokinase recognition site; YFP, yellow fluorescent protein; C, C-terminus. (B) Directed immobilization of a recombinant SNAP-YFP-cytokine through the SNAP-tag on a benzylguanine-functionalized bead surface. In this study, PEGylated aminobenzylguanine (BG-PEG-NH_2) was used. The three ethylene-glycol units that act as a spacer between benzylguanine and the bead are not shown.

2.9. Confocal Microscopy of Cells. HEK293 cells transiently transfected with gp130id-CFP[21] and OSMR were seeded on glass coverslips. SNAP-YFP-OSM (1 nM) or SNAP-YFP-OSM beads (1.6×10^5 beads/μL) were added. Cells were fixed with Shandon Immu-Mount and analyzed by confocal microscopy (Zeiss LSM 510) for CFP and YFP fluorescence. After induction with doxycycline (50 ng/mL) for 72 h, YFP fluorescence of HEK293 cells expressing SNAP-YFP-IL-6 was analyzed in a similar way.

Murine embryonic fibroblasts stably transfected with STAT3-CFP[22] were seeded on coverslips and grown to 40% confluence. Coverslips were transferred to a live-cell imaging chamber, and 15 μL of a suspension of SNAP-YFP-IL-6 beads (1.6×10^5 beads/μL) was added. After sedimentation of the beads, cells were stimulated by the addition of sIL-6Rα (final concentration 0.5 μg/mL). Images of CFP and YFP fluorescence were recorded every 20 min.

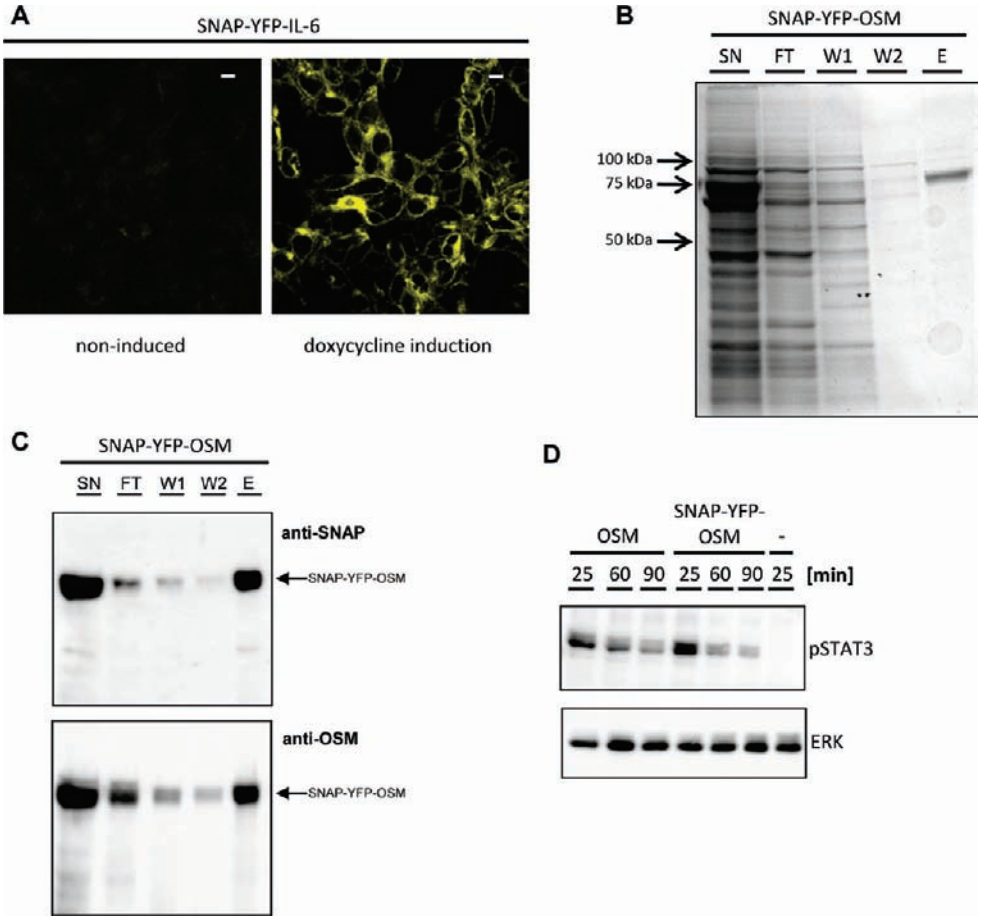

Figure 2. Inducible expression, purification, and activity of SNAP-YFP-cytokines. (A) HEK293 cells stably transfected with an expression vector encoding SNAP-YFP-IL-6 were seeded on coverslips. Protein expression was induced by the addition of doxycycline (50 ng/mL) for 72 h as indicated. Subsequently, cells were fixed and analyzed by confocal microscopy. Scale bars represent 5 μm. (B) Purification of SNAP-YFP-OSM by Ni-chelate affinity chromatography through the his-tag of the fusion protein. Fractions were analyzed by SDS−PAGE and subsequent Coomassie-staining of the gel. SN, supernatant from HEK293 cells stably expressing SNAP-YFP-OSM after induction with doxycycline (50 ng/mL) for 72 h; FT, flowthrough of the affinity column; W1 and W2, wash fractions; E, concentrated eluate. (C) Western blot analysis of the fractions described in B with SNAP and OSM antibodies. (D) HepG2 cells were stimulated with OSM (1 nM) or SNAP-YFP-OSM (1 nM) for different times. Cellular lysates were prepared and analyzed for OSM-induced phosphorylation of STAT3 by Western blotting. Detection of ERK served as a loading control. A representative example of three independent experiments is shown.

3. RESULTS

3.1. Expression, Purification, and Activity of SNAP-YFP-Cytokines. Cytokine constructs were designed that should permit (i) directed and specific coupling to a functionalized surface, (ii) straightforward detection and quantification of coupling efficiency, (iii) proof of directed coupling versus random coupling or unspecific adsorption, and (iv) purification of the recombinant protein. For this purpose, expression vectors were constructed encoding fusion proteins consisting of an N-terminal hexahistidine (his)-tag (aim iv), followed by a SNAP-tag (aim i), a recognition site for the protease enterokinase (aim iii), a yellow fluorescent protein (YFP, aims ii and iii), and finally the cytokine (Figure 1A). The SNAP-tag is derived from the human DNA repair protein O^6-alkylguanine-DNA alkyltransferase. The SNAP-tag couples itself autocatalytically to benzylguanine derivatives.[23] The chemistry of specific covalent coupling of the SNAP-tag to a benzylguanine-functionalized surface is shown in Figure 1B. YFP is a red-shifted variant of the green fluorescent protein (GFP) and can be detected separately from the cyan fluorescent protein (CFP), a blue-shifted variant of GFP.[24]

Flp-In T-Rex HEK293 cells were stably transfected with SNAP-YFP-OSM and SNAP-YFP-IL-6 using the Flp-In T-Rex expression system for targeted recombination and inducible expression of the transgene. Expression of the fluorescent cytokine upon induction with doxycycline is detectable by confocal microscopy (Figure 2A). The recombinant protein is mainly found within the membrane structures of the secretory pathway. The purification of SNAP-YFP-OSM from supernatants of stably transfected HEK293 cells by Ni-chelate affinity chromatography is shown in Figure 2B. SNAP-YFP-OSM elutes as a 75 kDa protein. The apparent molecular mass is in good agreement with the estimated molecular mass of the glycosylated fusion protein. In a Western blot, the protein is recognized by both a SNAP antibody and an OSM antibody documenting the integrity of the fusion protein (Figure 2C). SNAP-YFP-OSM and nontagged OSM induce equal STAT3 phosphorylation in HepG2 hepatoma cells (Figure 2D). SNAP-YFP-IL-6 was expressed, purified, and characterized in a similar way as a bioactive cytokine (data not shown).

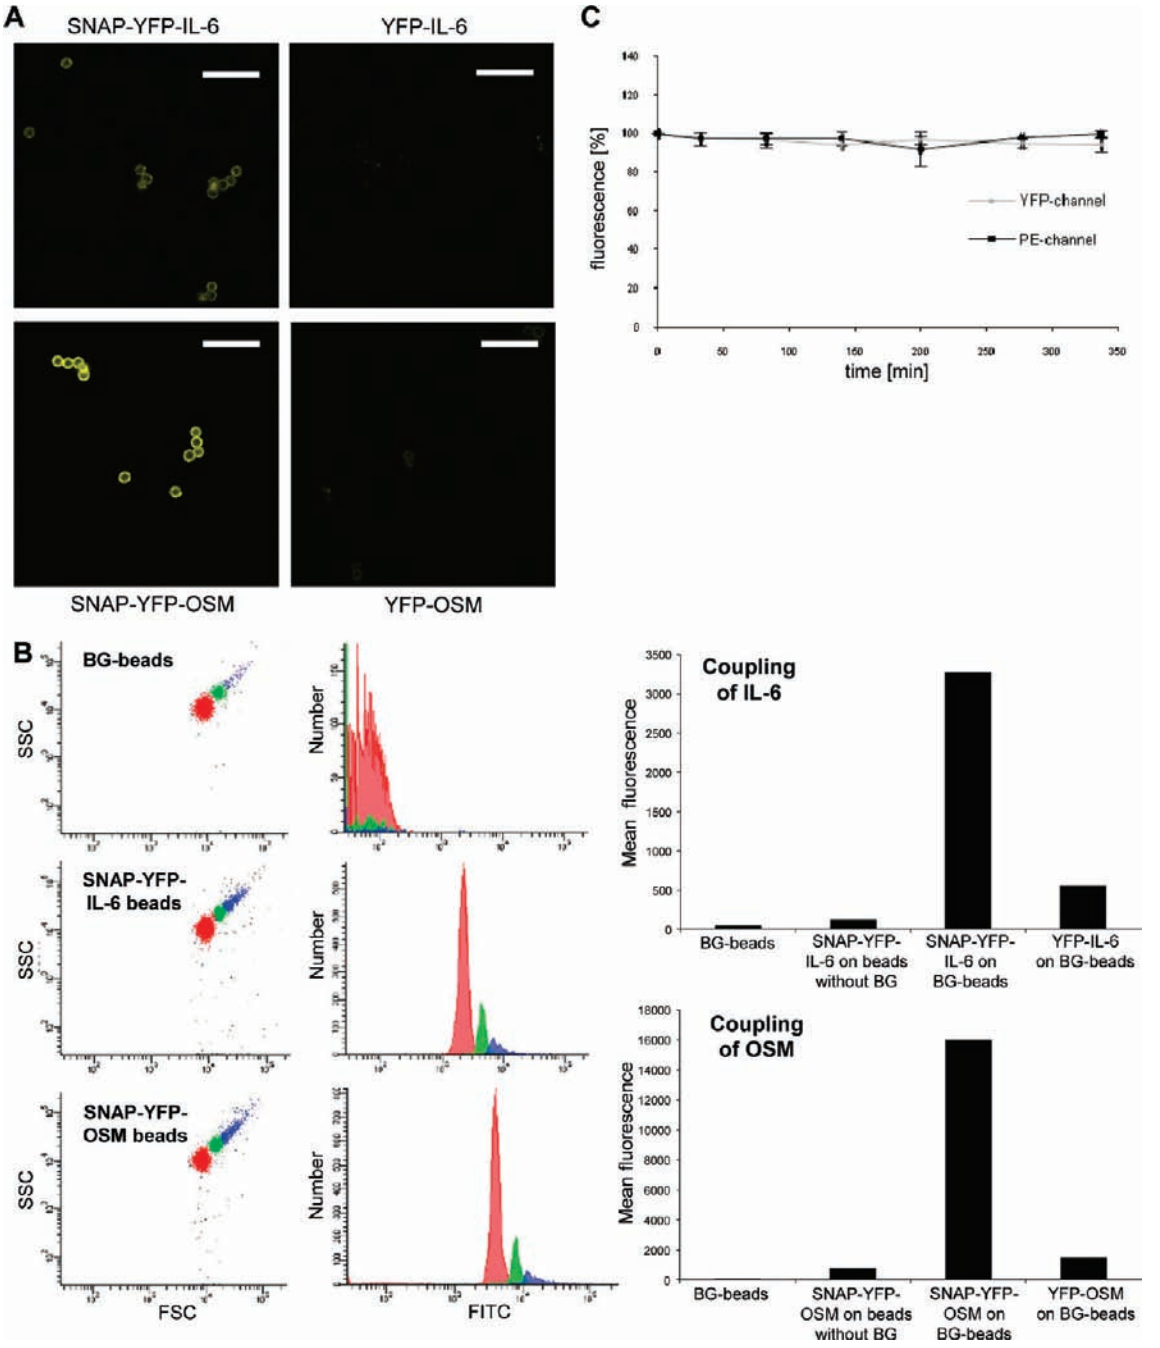

Figure 3. Immobilization of SNAP-YFP-cytokines on BG-modified beads. (A) BG-beads were treated for 16 h with SNAP-YFP-cytokines (1 μM) or YFP-cytokines (1 μM) as indicated. Subsequently, beads were analyzed by confocal microscopy using identical settings for laser intensity and detector gain. Scale bars represent 15 μm. (B) Unmodified beads or BG-beads were incubated for 16 h with YFP-IL-6, YFP-OSM, SNAP-YFP-IL-6, or SNAP-YFP-OSM (1 μM each). Fluorescence of the beads was analyzed by flow cytometry. Histograms of BG-beads, SNAP-YFP-IL-6 beads, and SNAP-YFP-OSM beads are shown with different bead populations in red (monomers), green (dimers), and blue (multimers). Mean fluorescence of the beads as measured by FACS is depicted as bar charts. A representative example of three independent experiments is shown. (C) SNAP-YFP-OSM beads were incubated for different times in cell culture medium at 37 °C. At the indicated time points, fluorescence of the beads was analyzed by flow cytometry. Besides YFP-fluorescence, phycoerythrin (PE) fluorescence of a PE-labeled hOSM antibody was detected to confirm the stability of the recombinant protein on the bead surface.

3.2. Coupling of SNAP-YFP-Cytokines to Benzylguanine-Modified Surfaces. We used beads as a substrate for surface immobilization of SNAP-YFP cytokines. We took advantage of the fact that beads can be analyzed by flow cytometry and added as a suspension to cell cultures. The surface of micromer-M-COOH beads (diameter, 3 μm) was functionalized with PEGylated aminobenzylguanine (BG-PEG-NH_2) using NHS/EDC coupling chemistry. The benzylguanine (BG) modified beads were incubated with SNAP-YFP-cytokines or YFP-cytokines and subsequently analyzed by confocal microscopy (Figure 3A). BG-beads treated with SNAP-YFP-cytokines show a strong ring-shaped fluorescence, whereas the fluorescence of the YFP-cytokine

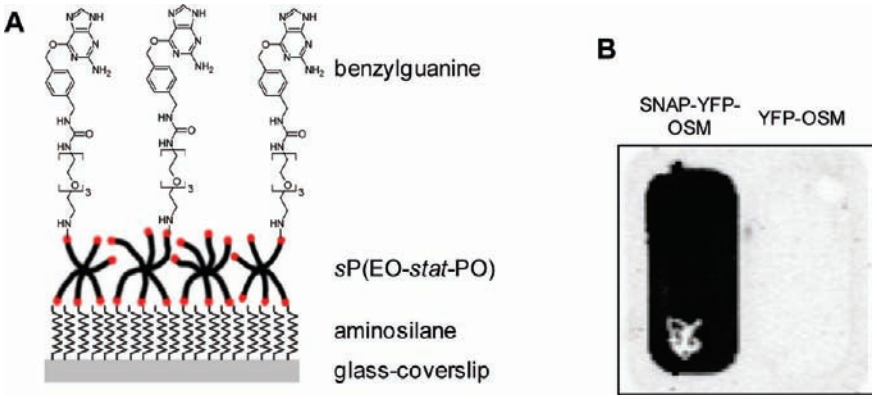

Figure 4. Immobilization of SNAP-YFP-cytokines on a BG-modified, star-PEG-coated surface. (A) Glass coverslips were first aminosilanized and then covered with *s*P(EO-*stat*-PO). BG-PEG-NH_2 was covalently attached through the reactive NCO-groups (red dots) of *s*P(EO-*stat*-PO). (B) The BG-modified *s*P(EO-*stat*-PO)-coated surface was incubated with SNAP-YFP-OSM (1 μM) or YFP-OSM (1 μM) for 16 h at 4 °C in two chambers on a glass slide. After washing, the fluorescence of the surface was analyzed by fluorescence scanning.

treated BG-beads is rather weak indicating a specific coupling of SNAP-YFP-cytokines to BG-modified beads. The weak fluorescence of YFP-cytokine treated BG-beads is most probably due to unspecific binding since micromer-M-COOH beads show almost no autofluorescence (not shown). Furthermore, the confocal images confirm that the micromer-M-COOH beads are monodisperse with a diameter of about 3 μm. The modified beads show a tendency to form aggregates.

Flow cytometry was used to analyze the relative amounts of immobilized SNAP-YFP-cytokines on BG-modified beads in a quantitative manner (Figure 3B). According to their sizes, three populations of BG-beads can be differentiated (depicted in red, green, and blue in Figure 3B). The red population most probably represents single beads. The green and blue populations represent aggregates of two (green) or three and more beads (blue). The BG-modified beads show almost no fluorescence. After incubation with SNAP-YFP-cytokine, the fluorescence of all populations of BG-beads strongly increases. The representation of several measurements as bar charts shows a strong increase of fluorescence when BG-modified beads were treated with SNAP-YFP-cytokines. A relatively weak fluorescence is measured when nonmodified beads were treated with SNAP-YFP-cytokines or when BG-modified beads were treated with YFP-cytokines lacking the SNAP-tag. These experiments strongly suggest a specific coupling of SNAP-YFP-cytokines to BG-modified beads through the SNAP-tag.

The concentrations of SNAP-YFP-IL-6 in the coupling buffer before and after coupling to a defined number of beads were determined by ELISA. From the difference of the concentrations, we calculated that about 550.000 molecules of SNAP-YFP-IL-6 are coupled to each bead. On the basis of the known dimensions of YFP, we estimated that a single SNAP-YFP-IL-6 molecule in an extended conformation would occupy 10 nm^2. If the beads are regarded as ideal spheres with a diameter of 3 μm, this would result in a surface occupancy of about 20%.

To test the stability of coupling, the SNAP-YFP-OSM beads were incubated under cell culture conditions for several hours at 37 °C (Figure 3C). At different times, beads were stained with an OSM specific PE-conjugated antibody. YFP and PE fluorescence was measured by flow cytometry. The almost constant fluorescence of the beads over time in both channels suggests that no SNAP-YFP-OSM is released from the SNAP-YFP-OSM beads and that no cleavage of OSM from the bead surface occurs.

To test the versatility of the approach, SNAP-YFP-OSM was immobilized on a flat glass surface. For this purpose, an aminosilanized glass coverslip was first covered with an isocyanate-terminated, star shaped copolymer containing poly(ethylene oxide) and poly(propylene oxide) (NCO-*s*P(EO-*stat*-PO) by spin-coating [20] (Figure 4A). The high reactivity of the hydrogel layer shortly after the coating procedure toward amines allowed the covalent attachment of BG-PEG-NH_2 by linkage of the amine group to the isocyanate group. The BG-modified surface of the glass slide was incubated with YFP-OSM or SNAP-YFP-OSM. Binding of the YFP-labeled cytokines was analyzed with a fluorescence scanner (Figure 4B). As a consequence of silanization and *s*P(EO-*stat*-PO) coating, no unspecific binding of YFP-OSM to the BG-modified surface was detected. The strong fluorescence of the surface area that was incubated with SNAP-YFP-OSM indicates a specific binding mediated by coupling of the SNAP-tag to benzylguanine.

3.3. Proof of Directed Coupling of SNAP-YFP Cytokines to BG-Modified Beads. The enterokinase cleavage site introduced between the SNAP-tag and YFP enabled us to unambiguously prove the directed coupling of SNAP-YFP cytokines to BG-modified beads (Figure 5A). BG-beads were incubated with SNAP-YFP-OSM or SNAP-YFP-IL-6. After the coupling reaction, a fraction of the beads was treated with the protease enterokinase. Subsequently, beads were incubated with PE-conjugated OSM or IL-6 antibodies, respectively. YFP and PE fluorescence of the beads were measured by flow cytometry. The results are summarized in Figure 5B. Enterokinase treatment reduces the YFP and PE fluorescence of the SNAP-YFP-cytokine beads by more than 80% indicating that the YFP-cytokine has been cleaved off from the bead surface by the protease. This result clearly shows that the SNAP-YFP-cytokines are bound to the bead surface by directed coupling via the SNAP-tag. Furthermore, the fact that the immobilized cytokines are accessible to the protease indicates that the immobilized cytokines are exposed on the bead surface. Remaining fluorescence of the beads after enterokinase treatment might reflect unspecifically bound protein, incomplete protease cleavage, or both.

3.4. Biological Activities of Immobilized SNAP-YFP-Cytokines. The activities of SNAP-YFP-cytokine beads were analyzed in cell culture. Beads were incubated with medium for 1 h under cell culture conditions. Subsequently, the activities of the supernatants of

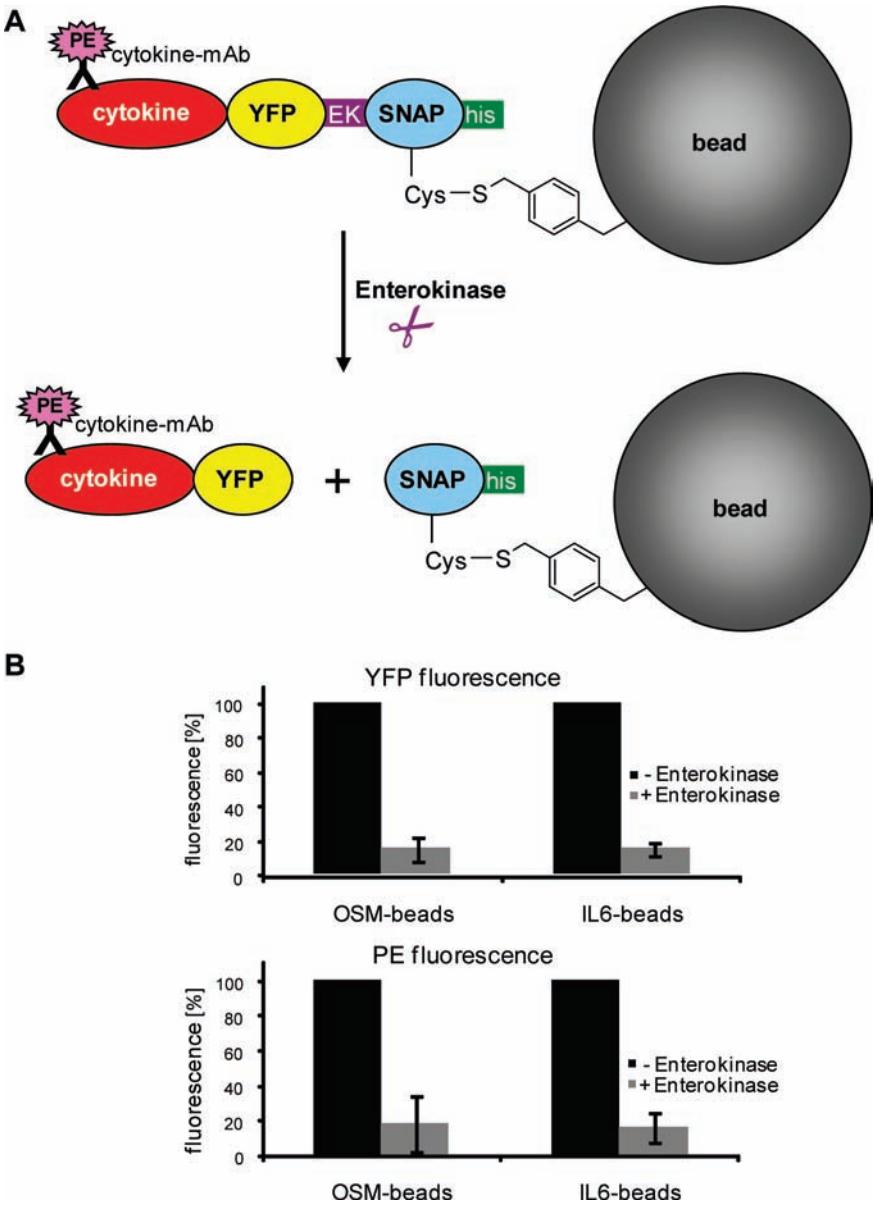

Figure 5. Proof of directed coupling of SNAP-YFP-cytokines. (A) Cleavage of the immobilized SNAP-YFP-cytokine by enterokinase releases the YFP-cytokine moiety. his, his-tag; SNAP, SNAP-tag; EK, enterokinase recognition site; YFP, yellow fluorescent protein. (B) SNAP-YFP-cytokine beads were incubated with enterokinase (0.02 U/μL) for 16 h at 4 °C. Beads were incubated with the respective PE-conjugated cytokine antibody and analyzed by flow cytometry f or PE and YFP fluorescence. Mean fluorescence of the beads is depicted in the bar chart. Fluorescence of beads without enterokinase was set to 100%.

the beads and the beads themselves were analyzed. The Western blot in Figure 6A shows that SNAP-YFP-IL-6 beads induce STAT3 phosphorylation in HepG2 cells, whereas the supernatant does not. This experiment shows that IL-6 immobilized through the SNAP-tag on BG-beads is biologically active. The observed response does not result from released cytokine because the supernatant of the preincubation of the beads is devoid of any activity. Empty beads show no activity. Interestingly, the time courses of phosphorylation induced by free IL-6 and immobilized IL-6 differ. A similar experiment was performed with free and immobilized SNAP-YFP-OSM (Figure 6B). In addition to STAT3, ERK phosphorylation was analyzed. Again the phosphorylation induced by the beads is delayed in comparison to the free cytokine. Supernatants of the SNAP-YFP-OSM beads show only very low activity indicating that the response mainly results from the immobilized cytokine and not from cytokine released from the beads.

3.5. Interaction of SNAP-YFP-OSM Beads with Cells Expressing gp130-CFP. OSM signals through the cytokine receptors gp130 and OSMR. HEK293 cell were transiently transfected with an expression vector encoding internalization-deficient (id) gp130 fused with the cyan fluorescent protein (gp130id-CFP). The lack of the internalization motif of gp130 increases the cell surface expression of the receptor. Nonlabeled OSMR was cotransfected. These cells were incubated with SNAP-YFP-OSM and after fixation analyzed by confocal microscopy (Figure 7A). Surface staining was observed after 30 min that increases during the following 60 min indicating the binding of SNAP-YFP-OSM to the cell surface receptors.

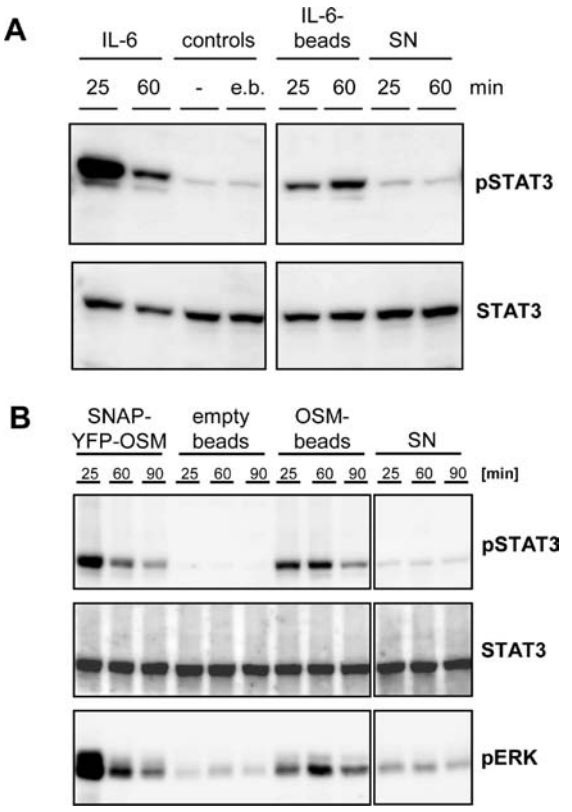

Figure 6. Biological activities of SNAP-YFP-cytokine beads. (A) SNAP-YFP-IL-6 beads were incubated with medium for 60 min at 37 °C. HepG2 cells were stimulated with the incubation supernatant (SN) or with the SNAP-YFP-IL-6 beads (IL-6-beads). In parallel, cells were stimulated with IL-6 (1 nM), incubated with medium alone (−) or empty beads (e.b.). Twenty-five minutes after stimulation, cells were lysed. STAT3 phosphorylation was analyzed by Western blotting (pSTAT3). Detection of total STAT3 served as a loading control. (B) In an experiment similar to that described in A, the activity of SNAP-YFP-OSM-beads was compared with free SNAP-YFP-OSM. ERK phosphorylation was also analyzed (pERK). Representative examples of three independent experiments are shown.

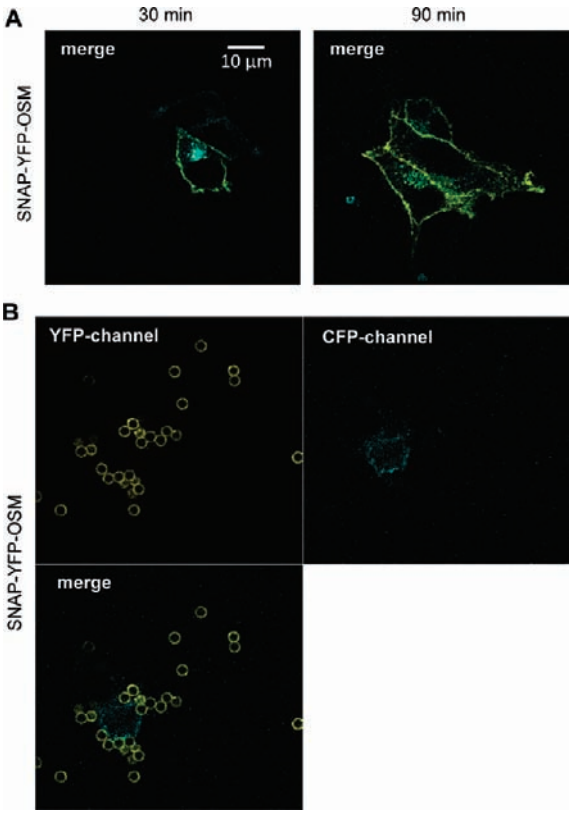

Figure 7. Confocal analysis of cell surface-binding of SNAP-YFP-OSM and SNAP-YFP-OSM beads. (A) HEK293 cells were transiently transfected with gp130id-CFP and OSMR. Cells were incubated with SNAP-YFP-OSM (1 nM) for the indicated times and subsequently fixed for microscopy. Images were taken by confocal laser-scanning microscopy. A merge of the YFP and CFP channels is shown. (B) The same experiment as that described in A was performed with SNAP-YFP-OSM beads. The cells were fixed after 60 min of incubation. Representative examples of three independent experiments are shown.

When the same cells were incubated with SNAP-YFP-OSM beads, enrichment of the beads around a transfected cell was observed (Figure 7B). The image of the CFP channel shows that the cell encompasses the beads to some extent, suggesting an interaction of the cell surface receptors with the SNAP-YFP-OSM beads.

3.6. Effect of SNAP-YFP-Cytokine Beads on the Subcellular Distribution of STAT3-CFP. Tyrosine phosphorylation of STAT3 in response to IL-6 and related cytokines leads to nuclear accumulation of the transcription factor. Murine embryonic fibroblasts (MEFs) lacking endogenous STAT3 ($MEF^{\Delta/\Delta}$) were stably transfected with STAT3 fused to the cyan fluorescent protein (STAT3-CFP). Since MEFs do not express the IL-6 receptor α-subunit (IL-6Rα), these cells respond to IL-6 only in the presence of soluble IL-6Rα (sIL-6Rα). Therefore, the time-point of stimulation is defined by the addition of sIL-6Rα.

$MEF^{\Delta/\Delta}$-STAT3-CFP cells were seeded on coverslips and analyzed under cell culture conditions at the confocal microscope. Upon stimulation with SNAP-YFP-IL-6 beads in the presence of sIL-6Rα, nuclear translocation of STAT3 during 60 min of observation is clearly visible (Figure 8A). After 60 min, a z-stack of sections was recorded and displayed as a three-dimensional (3D) image (Figure 8B). The image demonstrates that all cells showing nuclear accumulation of STAT3-CFP are in contact with SNAP-YFP-IL-6 beads. The confocal images shown in Figure 8C were made from fixed samples. Cells without contact to beads in the neighborhood of stimulated cells do not show any nuclear accumulation of STAT3-CFP. The right image shows that a bead close to cells but without contact does not stimulate the surrounding cells. These observations demonstrate that there is no significant release of free cytokine from the beads. Interestingly, a single bead−cell contact is sufficient for stimulation (left image).

In a similar experiment, HEK293-STAT3-CFP cells were incubated with SNAP-YFP-OSM beads. The 3D image after 90 min of stimulation shows nuclear accumulation of STAT3 (Figure 8D) and formation of nuclear bodies as described earlier.[10] In particular, after rotation of the image by 180° it is clearly visible that all stimulated cells are in close contact with SNAP-YFP-OSM beads.

On rare occasions, an accumulation of STAT3-CFP at the cell membrane engulfing a SNAP-YFP-IL-6 bead is visible (Figure 9, arrowhead). In this cell, nuclear accumulation of STAT3-CFP is to some extent inhibited.

4. DISCUSSION

In this study, we presented a versatile method for the directed covalent immobilization of proteins on surfaces which includes

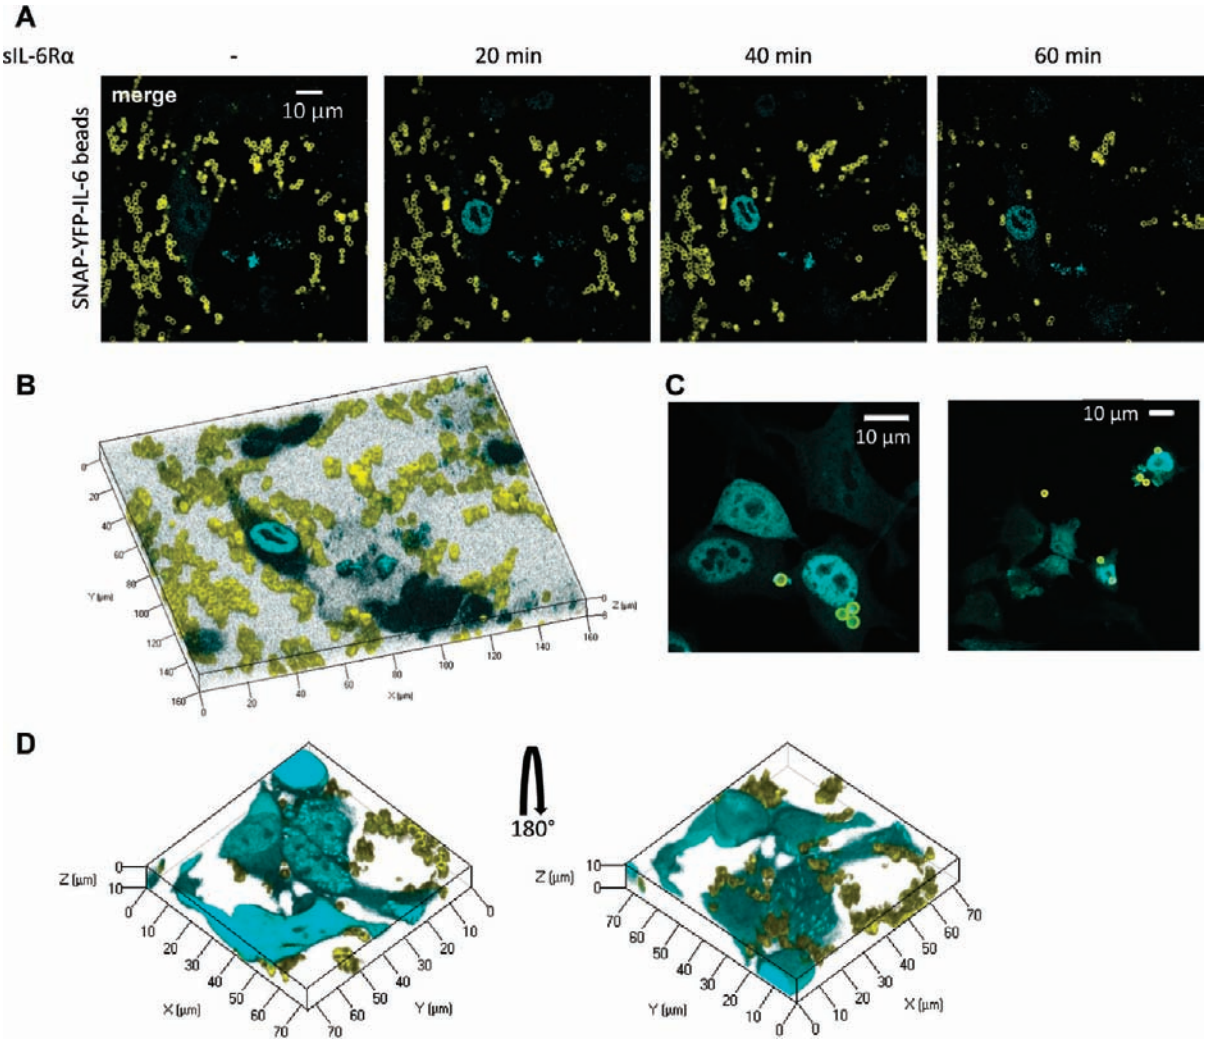

Figure 8. Analysis of SNAP-YFP-cytokine beads by confocal live-cell imaging. (A) MEF$^{\Delta/\Delta}$-STAT3-CFP cells were incubated with SNAP-YFP-IL-6 beads under cell culture conditions at the confocal microscope. Stimulation of the cells was initiated by the addition of sIL-6Rα (0.5 μg/mL), and images were taken at the indicated times. (B) A z-stack of images after 60 min of stimulation from the experiment shown in A is depicted as a 3D representation. (C) Another experiment, as described in A, was performed, and the samples were fixed after 30 min of stimulation. Only cells in contact with SNAPYFP-IL-6 beads show nuclear accumulation of STAT3-CFP (left and right image), and contact with a single bead is sufficient (left image). A bead close to cells but without contact is not sufficient for stimulation (right image). (D) HEK293-STAT3-CFP cells were incubated with SNAP-YFP-OSM beads for 90 min. A z-stack of images is depicted as 3D representations. All experiments have been repeated at least 3 times. Representative examples are shown.

the convenient and reliable control of efficiency and orientation of coupling. The method is based on the use of the SNAP-tag for immobilization on benzylguanine-modified surfaces.[25] The SNAP-tag is followed by a recognition site for the protease enterokinase, a YFP-tag, and finally the protein of interest. In addition, a his-tag was fused to the N-terminus for purification purposes. The enzyme-like activity of the SNAP-tag has the advantage of performing the coupling reaction under mild conditions without affecting protein structure and function.[23] The 1:1 stoichiometry of fluorescent label and protein of interest in the fusion protein allows quantification of the relative amount of immobilized protein even when different proteins of interest are analyzed such as SNAP-YFP-OSM and SNAP-YFP-IL-6 characterized in this study.

Directed coupling through a tag versus random chemical coupling of a protein of interest has the great advantage that the site of coupling on the protein is well-defined, and inactivation can be prevented. The tag used for coupling can be arranged in a way that protein function will not be affected. For the cytokines of the IL-6 family, it is known that the C-terminus is involved in receptor recognition.[26] Therefore, the tags were fused to the N-terminus of the protein. Indeed, characterization of the purified tagged fusion proteins revealed no difference in bioactivity compared to that of the nontagged cytokines. For proteins with a functionally important N-terminus, a C-terminal tag with YFP-EK-SNAP-his should be considered. The array of tags also serves as a spacer between surface and cytokine. The resulting exposition and flexibility of the cytokine facilitates receptor complex formation on the cell surface. This is of particular importance for IL-6 where two molecules of cytokine are needed to form a stable receptor complex.[8] Nevertheless, restriction of receptor movement can alter the cellular response.[27]

A general issue in directed protein immobilization on surfaces is the ratio of desired site-specific and covalent coupling versus unspecific adsorptive binding. The latter will lead to a large fraction of inactive or misbehaving proteins. To discriminate

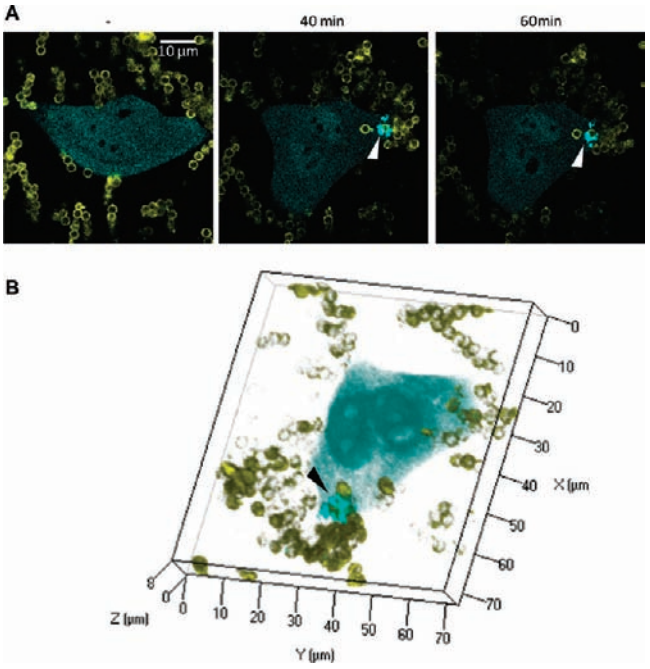

Figure 9. Unusual accumulation of STAT3-CFP around a SNAP-YFP-IL-6 bead. (A) MEF$^{\Delta/\Delta}$-STAT3-CFP cells were incubated with SNAP-YFP-IL-6 beads. Stimulation of the cells was initiated by the addition of sIL-6Rα (0.5 µg/mL), and confocal images were taken at the indicated times. (B) A z-stack of images after 60 min of stimulation from the experiment shown in A is depicted as a 3D representation. Arrowheads mark the site of STAT3-CFP accumulation.

between these two types of protein binding to surfaces, the enterokinase recognition site was introduced into the fusion protein. Treatment with enterokinase will in the case of directed coupling release the YFP-cytokine moiety of the fusion protein. Thus, a strong loss in fluorescence of the surface upon enterokinase treatment is indicative of directed, covalent coupling. In this study, materials with low protein adsorption were used. Therefore, a large fraction of fluorescence was released by enterokinase treatment clearly demonstrating oriented coupling. Depending on the application, materials with higher protein adsorption may be used. In such a situation, the cleavage assay will be of great value to quantify the amount of site-specifically immobilized protein. Moreover, one can envisage drug delivery systems, in which a protease can be used to release the protein of interest in a controlled manner.[28,29] In such a case, labeling with a fluorescent protein will be of great advantage to monitor the release process.

After establishing directed coupling, SNAP-YFP-cytokine beads were analyzed with respect to their bioactivity. Immobilized IL-6 and OSM activate STAT3 and ERK indicating that the immobilized cytokines are bioactive. Compared to the free cytokines, STAT3 and ERK phosphorylation in response to the immobilized cytokines is somewhat delayed and prolonged. After the stimulation of cells with beads, the immobilized cytokines may need more time to gain access to receptors than freely diffusing soluble cytokines. A similar delay of signaling was observed with cells seeded on growth-factor-modified surfaces.[3] ERK and STAT3 phosphorylation in response to stimulation with both free OSM and SNAP-YFP-OSM beads are transient indicating that feedback inhibition of the signaling pathway works for the free as well as the immobilized cytokine. Taken together, immobilization does not interfere with the basic signaling characteristics of the examined IL-6 family cytokines. Because covalently immobilized cytokines cannot be internalized, these findings indicate that internalization of the cytokine is neither necessary for activation of the signaling pathways nor for their attenuation. This conclusion is substantiated by earlier studies showing that feedback inhibition by SOCS3 rather than internalization is required for the transience of IL-6 signaling.[30] Thus, adequately immobilized cytokines of the IL-6 family can be used to functionalize surfaces of biomaterials and to investigate signal transduction. Accordingly, it has been shown that immobilized LIF is able to maintain the undifferentiated state of murine embryonic stem cells.[31,32] For growth factors that signal through receptor tyrosine kinases, endocytosis of the receptor complex seems to be more important for signaling and downregulation.[33] Therefore, immobilization of these kinds of mediators has a stronger impact on the kinetics of the signal.[34]

Fluorescently labeled and properly immobilized cytokines are a valuable tool to study localized signaling events by confocal microscopy and live cell imaging. In the case of the use of SNAP-YFP-cytokine beads for microscopic studies, the fluorescence label fits two purposes: (i) it allows localization of the beads and (ii) provides information of the cytokine load. The latter information is not directly accessible when nonfluorescent proteins are immobilized on fluorescent beads.[35] In a first approach, we studied the response of cells transfected with gp130-CFP or STAT3-CFP to stimulation with SNAP-YFP-cytokine beads. Accumulation of receptors was observed at the sites where beads contacted the cells. As a downstream response, nuclear accumulation of STAT3-CFP could be clearly detected. These experiments clearly show that STAT3 finds its way into the nucleus after activation at the plasma membrane and does not require directed transport through the endocytotic pathway. This does not exclude that STAT3 is also activated at signaling endosomes in response to stimulation with free cytokines,[36] but it seems that there is no strict requirement of signaling endosomes for STAT3-signaling in response to cytokines of the IL-6 family. However, concerning the high cytokine load of the beads some release of bioactive cytokine by, e.g., proteolytic cleavage after receptor binding cannot be entirely excluded.

Endocytosis of beads is restricted to nanoparticles with diameters in the submicrometer range because the vesicles formed during the process have a diameter of 100−500 nm.[37] Therefore, the 3 µm beads we used in this study can serve as a model system to mimic the activities of cytokines immobilized on larger surfaces, e.g., on biomaterials. However, occasionally we observed that the cell "tries" to engulf these particles (Figure 9) leading to mislocalization of signaling proteins such as STAT3. On the basis of these initial observations, it will be interesting to analyze signaling of cytokines immobilized to nanoparticles of different sizes by confocal microscopy.

Design, Synthesis, and Evaluation of 2-Diethanolamino-4,8-diheptamethyleneimino-2-(*N*-aminoethyl-*N*-ethanolamino)-6-(*N*,*N*-diethanolamino)pyrimido[5,4-*d*]pyrimidine-fluorescein Conjugate (8MDP-fluor), As a Novel Equilibrative Nucleoside Transporter Probe

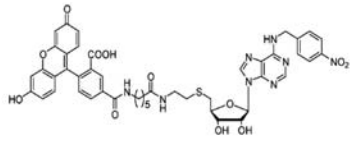
Wenwei Lin and John K. Buolamwini*

Department of Pharmaceutical Sciences, College of Pharmacy, 847 Monroe Avenue, Suite 327, University of Tennessee Health Sciences Center, Memphis, Tennessee 38163, United States

ABSTRACT: Nucleoside transporters are integral membrane glycoproteins that play critical roles in physiological nucleoside and nucleobase fluxes, and influence the efficacy of many nucleoside chemotherapy drugs. Fluorescent reporter ligands/substrates have been shown to be useful in the analysis of nucleoside transporter (NT) protein expression and discovery of new NT inhibitors. In this study, we have developed a novel dipyridamole (DP)-based equilibrative nucleoside transporter 1 (ENT1) fluorescent probe. The potent ENT1 and ENT2 inhibitor analogue of dipyridamole, 2,6-bis(diethanolamino)-4,8-diheptamethyleneiminopyrimido[5,4-*d*]pyrimidine (**4**, 8MDP), was modified to replace one β-hydroxyethyl group of the amino substituent at the 2-position with a β-aminoethyl group and then conjugated through the amino group to 6-(fluorescein-5-carboxamido)hexanoyl moiety to obtain a new fluorescent molecule, 2-diethanolamino-4,8-diheptamethyleneimino-2-(*N*-aminoethyl-*N*-ethanolamino)-6-(*N*,*N*-diethanolamino)pyrimido[5,4-d]pyrimidine-fluorescein conjugate, designated 8MDP-fluorescein (8MDP-fluor, **6**). The binding affinities of 8MDP-fluor at ENT1 and ENT2 are reflected by the uridine uptake inhibitory K_i values of 52.1 nM and 285 nM, respectively. 8MDP-fluor was successfully demonstrated to be a flow cytometric probe for ENT1 comparable to the nitrobenzylmercaptopurine riboside (NBMPR) analogue ENT1 fluorescent probe SAENTA-*X*8-fluorescein (SAENTA-fluor, **1**). This is the first reported dipyridamole-based ENT1 fluorescent probe, which adds a novel tool for probing ENT1, and possibly ENT2.

INTRODUCTION

Specialized integral membrane glycoproteins known as nucleoside transporters (NTs) are required for the influx and/or efflux of physiological nucleosides and many synthetic analogues.[1−3] Nucleoside transporters are classified into two families, namely, the equilibrative nucleoside transporter (ENT) and the concentrative nucleoside transporter (CNT) families, which are also known as the SLC29 and SLC28 gene families, respectively.[4,5] ENTs are the more widely distributed of the two NT families in mammalian tissues and possess broad substrate specificities for both purine and pyrimidine nucleosides, with ENT2 also efficiently transporting nucleobases.



Nucleoside transporters play key roles in nucleoside and nucleobase uptake in salvage nucleotide synthesis and are also critical for the cellular uptake of several nucleoside analogues used in the treatment of cancers and viral infections, and serve as biomarkers of drug efficacy and drug resistance.[1,6,7] In addition, by regulating the concentration of adenosine available to cell surface adenosine receptors, they influence physiological processes such as cardiovascular activity, neurotransmission, and kidney function among others.[3,8−10] Distinct regional distributions of ENT1 and ENT2 have been observed in the human central nervous system.[11] It has also recently been shown that ENT1 and ENT2 play crucial roles in regulating the cystic fibrosis-related chloride transporter (CFTR) in human airway epithelia.[12] The inhibition of adenosine transport by NT inhibitors can potentially be exploited for site- and event-specific therapeutic approaches to treating ischemic heart disease and stroke.[13−18] Specific/selective inhibitors and ligands bound with high affinity are needed to track and quantify NT protein expression as well as to investigate their physiological roles and explore their therapeutic potential.

In the evaluation of nucleoside transporter inhibitors, radioligand uptake/displacement experiments have been widely used since nonradioactive methods are largely unavailable. Fluorescent probes are now available for ENT1,[19−21] but there are no such probes for other ENTs or CNTs. The fluorescent probes allow ligand−cell/protein interactions to be analyzed by flow cytometry, a facile technique that can eliminate problems associated with

the use of radioactive materials. 5-(SAENTA)-*X*8-fluorescein (SAENTA-fluor, SF, **1**) is an example of an ENT1 fluorescent probe.[20] As an analogue of nitrobenzylmercaptopurine riboside (NBMPR, **2**), it has been used in several studies for nonradioactive assays of compounds' ENT1 inhibitory activities.[22−26]

2 (NBMPR)

3 (Dipyridamole, DP)

4 (Heptamethyleneimine DP analog, 8MDP)

In our attempts to develop new ENT fluorescent probes, we have concentrated on the best compound we identified from a structure−activity relationship study of a series of dipyridamole (DP, **3**) analogues that we synthesized recently as ENT1 and ENT2 inhibitors.[23,27] This compound, the 8-membered ring dipyridamole analogue, compound **4** (8MDP) had K_i values of 0.97 nM and 90.8 nM against hENT1 and hENT2, respectively,[27] indicating much higher binding affinities than DP, which had K_i values of 14.5 nM and 308 nM against hENT1 and hENT2, respectively.[27] In the current study, we attached a fluorescent reporter group to a modified 8MDP to obtain a new fluorescent probe, which was successfully used in flow cytometric analysis of ENT1 protein expression as well as the measurement of relative affinities of ENT1 ligands.

EXPERIMENTAL PROCEDURES

Chemistry. Thin-layer chromatography (TLC) was conducted on silica gel plates (Analtech). Compounds were visualized by UV light (254 and 365 nm). 1D NMR spectra were recorded on a Varian Inova 500 MHz NMR instrument, using $CDCl_3$ or $(CD_3)_2SO$ as solvents and tetramethylsilane (TMS) as an internal standard. Flash column chromatography was performed on Fisher silica gel (170−400 mesh). Melting points were determined using a Fisher-Johns melting point apparatus and were reported uncorrected. Mass spectra were obtained on a Bruker-HP ESQUIRE Ion Trap LC/MS system. Elemental analyses were performed by Atlantic Microlab Inc., Norcross, GA. All solvents and reagents were purchased from Aldrich or other major chemical companies and used without further purification. All reactions were carried out under argon gas. Analytic high performance liquid chromatography (HPLC) was performed on a 150 mm × 2.00 mm Phenomenex Luna C_{18} column (3-μm particle size), protected by a Phenomenex SecurityGuard guard column (cartridge 4 mm × 2.00 mm internal diameter); and gradient CH_3CN/H_2O; 0 to 100 (15 min) with detection at 224 nm. The HPLC system consisted of an automated system with two Shimadzu LC-10AD VP liquid chromatography pumps, an SCL-10A VP system controller, a SIL-10AD VP auto injector, a sample cooler kept at 4 °C, and an SPD-M10A VP diode array detector. Chromatograms were acquired and analyzed with the Schimadzu Class-vp 7.3 SP1 software running on a Dell computer.

*2-Diethanolamino-4,8-diheptamethyleneimino-6-chloropyrimido[5,4-d]pyrimidine (**6**).* To a solution of 2,4,6,8-tetrachloropyrimido[5,4-*d*]pyrimidine (TCPP, **5**) (0.54 g, 2 mmol) in anhydrous THF (20 mL), heptamethyleneimine (1.06 mL, 8.4 mmol) was added. The reaction was stirred in an ice−water bath for 20 min, and then water (150 mL) was added to precipitate the reaction intermediate. After drying over a P_2O_5 desiccator, the intermediate was dissolved in dimethylsulfoxide (DMSO) (10 mL) with diethanolamine (3 mL, 30 mmol). The reaction was stirred at 120 °C for 3 days. The product, compound **6** (445 mg, 45% overall yield in 2 steps), was purified by flash silica gel chromatography (hexane/acetone = 5/1). Mp: 122−124 °C; MS (ESI) *m*/*z* 492 $(M + H)^+$, 514 $(M + Na)^+$. ^{1}H NMR (DMSO-d_6) δ 4.737 (t, 2H, exchanged with D_2O, 2 × OH, J = 5 Hz), 3.868 (m, 8H, 2 × $N(CH_2CH_2CH_2)_2CH_2$), 3.589 (t, 8H, $N(CH_2CH_2OH)_2$, J = 5 Hz), 1.796 (s, 8H, 2 × $N(CH_2CH_2CH_2)_2CH_2$), 1.534 (s, 8H, 2 × $N(CH_2CH_2CH_2)_2CH_2$), 1.495 (s, 4H, 2 × $N(CH_2CH_2CH_2)_2CH_2$). Anal. ($C_{24}H_{38}ClN_7O_2$) C, H, N.

*2-Diethanolamino-4,8-diheptamethyleneimino-6-[(N-dibenzylaminoethyl)-ethanolamino]-pyrimido[5,4-d]pyrimidine (**7**).* Compound **6** (370 mg, 0.75 mmol) was heated with 2-(2-dibenzylamino-ethylamino)-ethanol (3 g, 10 mmol) at 150 °C overnight. The product, compound **7** (130 mg, 23%), was purified by flash silica gel chromatography (hexane/acetone = 2/1) as a yellow sticky solid. MS (ESI) *m*/*z* 762 $(M + Na)^+$. ^{1}H NMR (DMSO-d_6) δ 7.306 - 7.251 (m, 10H, Ar), 7.181 (m, 4H, 2 × CH_2), 4.698 (s, 2H, disappeared after addition of D_2O, 2 × OH), 4.606 (s, 1H, disappeared after addition of D_2O, OH), 4.007−3.677 (*br* s, 8H, 2 × $N(CH_2CH_2CH_2)_2CH_2$), 3.575 (s, 12H, $N(CH_2CH_2OH)_2$, NCH_2CH_2OH), 3.520 (d, 4H, NCH_2CH_2ON, J = 6.5 Hz), 1.726 (*br* s, 8H, 2 × $N(CH_2CH_2CH_2)_2CH_2$), 1.496 (*br* d, 12H, 2 × $N(CH_2CH_2CH_2)_2CH_2$). LC retention time 5.804 min.

*2-Diethanolamino-4,8-diheptamethyleneimino-6-[(N-6-(fluorescein-6-carboxamido)-hexanoylaminoethyl)- ethanolamino]-pyrimido[5,4-d]pyrimidine (**8**).* The benzyl groups on compound **7** (100 mg, 0.13 mmol) were removed by hydrogenation in the presence of a catalytic amount of 10% Pd−C in methanol. After filtration and evaporation, the residue was reacted with commercially available 6-(fluorescein-5-carboxamido)hexanoic acid succinimidyl ester (10 mg, 17 μmol) in dimethylformamide (DMF) (3 mL) for 2 h. The solvent was removed under reduced pressure, and the residue was purified by sephadex LH-20 gel filtration with MeOH as the elution solvent to obtain the product **8** (7.2 mg, 41%) as a sticky gum. MS (ESI) *m*/*z* 1029 $(M - H)^-$. LC retention time 11.368 min.

Biological Testing. *[^{3}H]Uridine Uptake Experiments with K562 Cells Used to Determine ENT1 Inhibitory Activities of Test Compounds.* Human chronic myelogenous leukemia K562 cells (American Type Culture Collection (ATCC), Manassas, VA) were maintained in RPMI 1640 medium containing 10% fetal bovine serum and amikacin (60 mg/Liter), at 37 °C in 5% CO_2 and 95% air atmosphere. All experiments were done in sodium free uptake buffer (20 mM Tris/HCl, 3 mM K_2HPO_4, 1 mM $MgCl_2 \cdot 6H_2O$, 2 mM $CaCl_2$, 5 mM glucose, and 130 mM *N*-methyl-D-glucamine/HCl, pH 7.4). 5×10^5 K562 cells/sample were harvested and washed once with sodium free uptake buffer and resuspended in 50 μL of the same buffer. Uptake buffer

containing varying concentrations of compounds was then added, followed by 15 min of incubation, and then [^{3}H]uridine (37 mCi/mL) at a final concentration of 0.5 μM was added, followed by 2 min of incubation. Uptake was stopped by fast filtration to remove extracellular radioactive material, followed by 5 rapid washes with ice-cold uptake buffer. Cells were then solubilized overnight in 0.5 mL of 5% Triton X-100, and radioactivity was measured by β-scintillation counting.

[^{3}H]Uridine Uptake Experiments with PK15 Cells Stably Expressing Recombinant hENT2 Protein. The ENT2 cell line (porcine PK15 cells stably transfected with recombinant human ENT1 (hENT1)[28] was generously provided by Dr. Chung-Ming Tse, Johns Hopkins University. Cells were maintained in minimum essential (MEM) Alpha medium, with 5% fetal bovine serum, penicillin/streptomycin (50,000 units/L, 50 mg/L), and 0.1 mM nonessential amino acids, at 37 °C with 5% CO_2 and 95% air mixture. Cells were seeded at 40,000 cells/well in 48-well plates 24 h prior to uptake experiments. All experiments were performed at room temperature in sodium-free uptake buffer (140 mM *N*-methyl-D-glucamine, 5 mM HEPES, 5 mM KH_2PO_4, 1.0 mM $CaCl_2$, 1.0 mM $MgCl_2$, and 10 mM glucose, pH 7.4). Cells at 60−80% confluency were washed 3 times with uptake buffer, followed by 10 min of preincubation in the same buffer. Solutions containing varying concentrations of test compounds in uptake buffer were then added, followed by 15 min of incubation and addition of [^{3}H]uridine (0.2 μM, 37 mCi/mL specific activity). After 2 min of incubation with [^{3}H]uridine, cells were rapidly washed 3 times with ice-cold phosphate-buffered saline (pH 7.4) to stop uptake and remove extracellular [^{3}H]uridine. The cells were then solubilized overnight in 0.5 mL of 5% Triton X-100, and radioactivity was measured by a β-scintillation counter.

Uptake Inhibition Data Analysis. Percentage (%) inhibition was calculated for each sample by eq 1.

$$\%\ \text{inhibition} = 100\% - \frac{([^3\text{H}]\text{uridine}_s) \times 100\%}{([^3\text{H}]\text{uridine})} \quad (1)$$

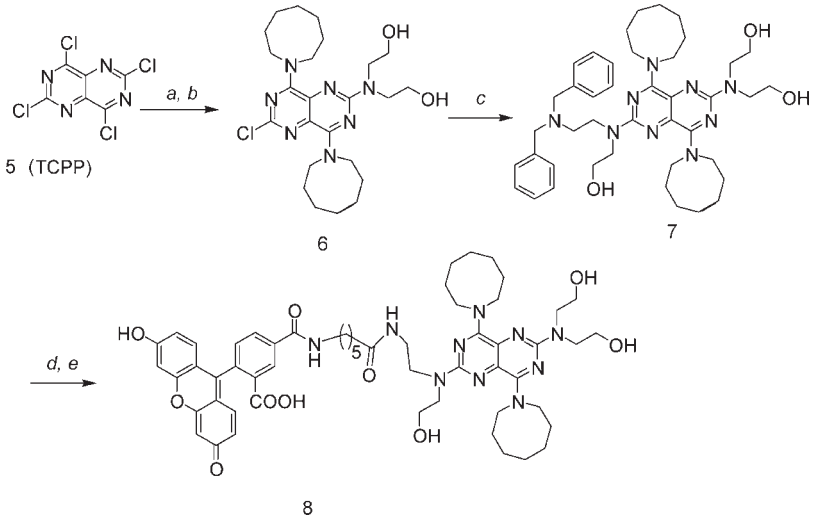
where [^{3}H]uridine$_s$ is the amount of [^{3}H]uridine transported by hENT1 (or hENT2) in the presence of the test compound, and [^{3}H]uridine is the amount of [^{3}H]uridine transported in the absence of the test compound. The results were fed into the PRISM program (GraphPad, San Diego, CA) to derive concentration-inhibition curves. From these curves, the IC_{50} values were obtained and used to calculate the inhibition constant (K_i) value by eq 2.[29]

$$K_i = \text{IC}_{50}/(1 + [L]/K_L) \quad (2)$$

where [L] is the concentration of [^{3}H]uridine in individual tests (0.5 μM for hENT1; 0.2 μM for hENT2), and K_L is the K_m values for the uptake of [^{3}H]uridine by the corresponding transporter, 229 μM for hENT1 and 250 μM for hENT2.[28] The K_i values were used to compare the abilities of compounds to inhibit [^{3}H]uridine uptake and, for that matter, their inhibitory activity against hENT1 (or hENT2).

Flow Cytometry Assays. The compounds were tested to determine their ENT1 binding ability by a flow cytometric assay.[22] Briefly, K562 cells growing in RPMI 1640 medium were washed once, resuspended at 1.6×10^6 cells/mL in phosphate-buffered saline at pH 7.4, and incubated with SAENTA-fluorescein (30 nM) or 8MDP-fluor (40 nM) in the presence or absence of varying concentrations of test compounds at room temperature for 45 min. Flow cytometric measurements of cell-associated fluorescence were then performed with a FACSCalibur flow cytometer (Becton Dickinson, San Jose, CA) equipped with a 15 mW-argon laser (Molecular Resources Flow Cytometry Facility, University of Tennessee Health Sciences Center). In each assay, 5,000 cells were analyzed from suspensions of 4×10^5 cells/mL. The units of fluorescence were arbitrary channel numbers. Percentage (%) inhibition (i.e., ENT1-specific fluorescence in the presence of SAENTA-fluorescein or 8MDP-fluor) was calculated for each sample by eq 3.

$$\%\ \text{inhibition} = 100\% - \frac{(F_s) \times 100\%}{(F_f)} \quad (3)$$



where F_s is the ENT1-specific fluorescence in the presence of test compounds, and F_f is the ENT1-specific fluorescence without the test compound, in mean channel numbers. The results were used to derive concentration-inhibition curves (Prism program) for IC_{50} values, which were used to calculate K_i values using eq 2, where [L] and K_L are the concentrations of the fluorescent probe (30 nM for SAENTA-fluor and 40 nM for 8MDP-fluor) and K_d values of the fluorescent probes (1.8 nM for SAENTA-fluor and 52.1 nM for 8MDP-fluor), respectively. The K_i values were used to compare the affinities of compounds for hENT1.

RESULTS

Chemistry. The synthetic route we followed, Scheme 1, resulted in the successful preparation of the new fluorescent probe. Starting with the reaction between 2,4,6,8-tetrachloropyrimido[5,4-*d*]pyrimidine (TCPP, **5**) with excess heptamethyleneimine (4.2-fold ratio) at 0 °C gave the 2,6-dichloro-4,8-diheptamethyleneimido intermediate. Reaction of the 2,6-dichloro intermediate with one equivalent of diethanolamine at 120 °C yielded the monochloro precursor compound **6** in overall yield of 45% for the two steps. Compound **6** was in turn reacted with 2-(2-dibenzylaminoethylamino)-ethanol at 150 °C to produce the protected amine compound, **7**. Removal of the benzyl groups of compound **7** was successfully effected by catalytic hydrogenation, which was followed by the reaction of the resulting primary amine with the activated fluorescein derivative, 6-(fluorescein-5-carboxamido)hexanoic acid succinimidyl ester to afford the target fluorescent probe, 8MDP-fluorescein conjugate, 8MDP-*X*8-fluorescein (8MDP-fluor, **8**) in 43% yield overall from the latter two steps.

Biology. *ENT1 and ENT2 Inhibitory Activities and 8MPD-Fluor.* For a probe to be useful, it must be bound by its intended molecular target(s) with high affinity, in this case ENT1 and ENT2. To assess this for the new fluorescent probe, we measured its ability to inhibit [^{3}H]uridine uptake by hENT1 expressed in K562 cells or recombinant hENT2 stably expressed in K15NTD cells. Dose−response experiments were carried out, and the IC_{50} values were used to derive inhibition constant (K_i) values according to eq 2, which are presented in Table 1 along with the K_i values of known equilibrative nucleoside transporter inhibitors that were also determined by the same methods, including dipyridamole and 8MDP (**4**, the most potent dipyridamole analogue ENT inhibitor reported to date). The results show that 8MDP-fluor (**8**) exhibited a reasonably high-affinity binding by hENT1 with a K_i value of 52.1 nM and a moderate-affinity binding by hENT2, with a K_i value of 285 nM, which is reasonable, considering that dipyridamole, the prototype ENT2 inhibitor, exhibited an ENT2 inhibitory K_i of 308 nM.

Scheme 1. Synthesis of 8MDP-Fluor (8)[a]

[a] Reagents: (a) heptamethyleneimine, anhydrous THF, ice−water bath; (b) diethanolamine, DMF, 120 °C; (c) 2-(2-dibenzylamino-ethylamino)-ethanol,[27] DMSO, 150 °C; (d) hydrogen, 10% Pd−C, MeOH; (e) 6-(fluorescein-5-carboxamido)hexanoic acid succinimidyl ester, DMF.

Table 1. hENT1 and hENT2 Inhibitory Activities of 8MPD, Its fluorescent Analogue 8MPD-F and Other Inhibitors

	hENT1 inhibitory activity		hENT2 inhibitory activity	
compound	% inhibition (at 10 μM)	K_i (nM)	% inhibition (at 10 μM)	K_i (nM)
DMSO	2.8 ± 0.1	NA[a]	0.0 ± 1.8	NA

1 (SAENTA-fluor)	92.6 ± 0.8	1.8	83.5 ± 0.4	4,436

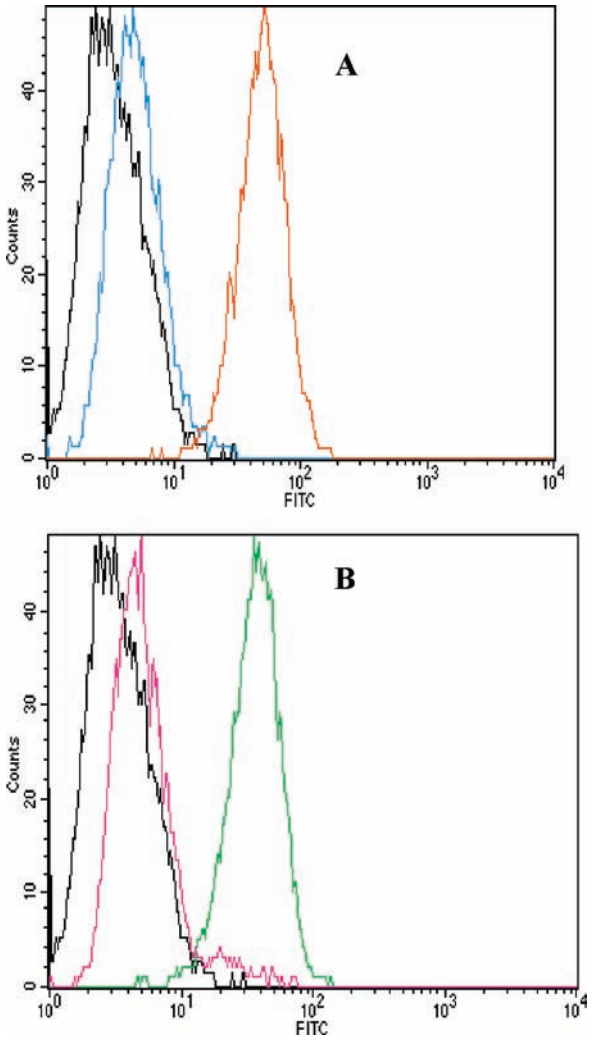
[a] NA means not applicable.

8MDP-Fluor Exhibits Specific Staining of hENT1. To assess the effectiveness of 8MDP-fluor as a fluorescent probe, we compared it with SAENTA-fluorescein, which is used in flow cytometric analysis of ENT1 protein expression and testing of ENT1 ligands in our laboratory and by others.[22,26,30] Again, human CML K562 cells were used since they grow in suspension culture, which makes them highly suitable for use in flow cytometry experiments, unlike attached cells which have to be first detached and suspended for flow cytometry. As shown in Figure 1, the new 8DMP-fluor stained K562 cells in an ENT1-specific manner comparable to that by SAENTA-fluor. It took 40 nM concentration of 8DMP-fluor to obtain ENT1 staining comparable to that by 30 nM of SAENTA-fluor. This reflects the lower ENT1 binding affinity for 8MDP-F compared to that of SAENTA-fluor, as evident from Table 1. The interesting thing is that the higher concentration of 8DMP-fluor did not result in higher nonspecific staining as shown by staining in the presence of the standard ENT1 inhibitor NBMPR.

Comparison of 8MDP-Fluor and SAENTA-Fluor As Fluorescent Ligands for Use in Flow Cytometric Determination of the Relative Affinities of ENT1 Interacting Compounds. To test the potential utility of this new fluorescent molecule (8MDP-fluor) as a probe for assessing other molecules' ability to bind to ENT1, NBMPR, lidoflazine, dipyridamole, and 8MDP were used to displace 8MDP-fluor (8MDPF) from K562 cells in a concentration-dependent manner in flow cytometry experiments. For comparison, the same tests were performed with SAENTA-fluor (SF) as the fluorescent ligand. Radioligand binding studies have indicated that NBMPR, dipyridamole, and lidoflazine displace each other from ENT1.[31−33] Dipyridamole itself is fluorescent, with $Ex_{\lambda max}$ and $Em_{\lambda max}$ of 280 and 490 nm, respectively.[34] At the experimental dipyridamole concentrations and wavelengths used in the flow cytometric assay (Ex_{λ} = 488 nm and Em_{λ} = 533 nm), dipyridamole and 8MDP did not emit fluorescence that would interfere with the detection of bound 8MDP-fluor or SAENTA-fluor.

The dose-response displacement curves are shown in Figure 2, and the K_i values derived from them are presented in Table 2. Flow cytometric experiments using 8MDP-fluor as probe afforded K_i values of 0.81, 5.41, 12.9, and 181 nM for NBMPR, 8MDP, dipyridamole, and lidoflazine (**9**), respectively, whereas experiments that used SAENTA-fluor as the probe afforded K_i values of 0.43, 0.50, 8.18, and 279.9 nM, for NBMPR, 8MDP, dipyridamole and lidoflazine, respectively. Although the use of either the 8MDP-fluor or SAENTA-fluor as the probe indicated correctly the same relative order of ENT1 binding affinities for the inhibitors, it

dx.doi.org/10.1021/bc2000758 |*Bioconjugate Chem.* 2011, 22, 1221–1227



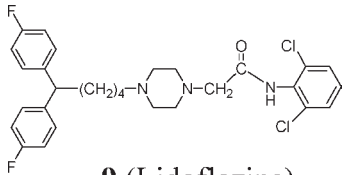


Figure 1. Flow cytometric histograms showing the ENT1 specific labeling in K562 leukemic cells by 8MDP-fluor (8MDPF, 40 nM; panel A) or SAENTA-fluorescein (SF, 30 nM; panel B). The binding of both fluorescent probes was effectively reversed by the presence of 10 μM NBMPR, the prototype ENT1 inhibitor, showing ENT1 affinity for the probes. Color-coding legend of histograms: black, K562 cells' autofluorescence; orange, K562 cells + 30 nM SF; blue, 30 nM SF + K562 cells +10 μM NBMPR; green line, K562 cells + 40 nM 8MDP-F; and red, K562 cells + 40 nM 8MDP-F + 10 μM NBMPR.

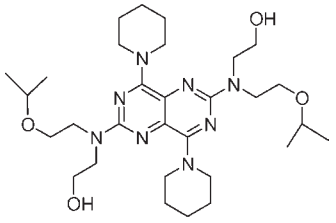

can be seen that the absolute K_i values differed depending on whether 8MDP-fluor or SAENTA-fluor was the fluorescent ligand.

9 (Lidoflazine)

DISCUSSION

Dipyridamole (DP, **3**) has displayed potent inhibitory activity against ENT1 (although not as good as NBMPR) and moderate inhibitory activity against ENT2.[35] It thus provides a good template for optimization to obtain more potent ENT1 and ENT2 inhibitors and probes since it is a clinically used drug. In the course of our structure−activity relationship (SAR) studies of DP analogues, we discovered that replacement of one each of the hydroxyl groups on each diethanolamine substituent at the 2- and 6-positions to give compound **6** had no detrimental effect on ENT1 binding activity but rather enhanced the binding affinity.[23] The high potency of compound **10** (ENT1 K_i = 4.3 nM; ENT2 K_i = 175 nM),[23,27] in which two of the hydroxyl groups of dipyridamole had been replaced by isopropoxy groups, suggested to us that the hydroxyl groups of dipyridamole provide possible attachment positions for reporter groups such as fluorophores. Thus, we took advantage of this opportunity to append a fluorescein group to the most potent dipyridamole analogue ENT1 and ENT2 inhibitor identified to date, compound **4** (8MPD).[23,27] To make the linkage resistant to hydrolysis, one of the hydroxyl groups of compound **4** was replaced by an amino group, which also provided an excellent nucleophilic handle (Scheme 1). The target probe, designated 8MDP-fluorescein conjugate (8MDP-fluor, **8**) was designed to attach the same fluorescent group used to synthesize SAENTA-fluorescein (**1**).[19,20]

10

In the synthesis, the key to achieving selective and sequential substitution of the different chlorines on the starting material, TCPP, was the control of reaction temperature, time, and reactant stoichiometries. The 4- or 8-position chlorine substituents are easier to substitute than the 2- and 6-position chlorines and were replaced at the low temperature of 0 °C, with the sparing of the 2- and 6-position chlorine substituents.

As might be expected, the attachment of a fluorescein moiety and replacement of O with NH in the new fluorescent probe (8MDP-fluor, **8**) significantly lowered inhibitory activities against hENT1 and hENT2, compared to that of the parent compound, 8MDP (**4**), but the fluorescent compound still retained enough potency to serve as an effective probe for ENT1. Interestingly, it still retained higher potency than dipyridamole as an ENT2 ligand and thus could potentially be developed as an ENT2 probe as well. This is not the case with SAENTA-fluor, which hENT2 binds with much lower affinity (K_i = 4,436 nM). Thus, unlike the 8MDP-fluor, SAENTA-fluor can serve as an effective hENT1 probe but not a probe for hENT2.

The results of the flow cytometric determination of the ability of other ENT1 inhibitors to displace 8MDP-fluor or SAENTA-fluor not only showed that the two fluorescent probes can both be used to correctly rank-order the relative affinities of ENT1 ligands but also showed interestingly that it was generally easier to displace SAENTA-fluor from hENT1 than it was to displace the new 8MDP-fluor. This could be due to the larger size of 8MDP-fluor relative to SAENTA-fluor. The only hENT1 inhibitor that deviated from this generalization was lidoflazine (**9**). The reason for this is not apparent, but might be related to possible different binding kinetics of the two fluorescent ligands and/or differences in their binding modes or sites relative to

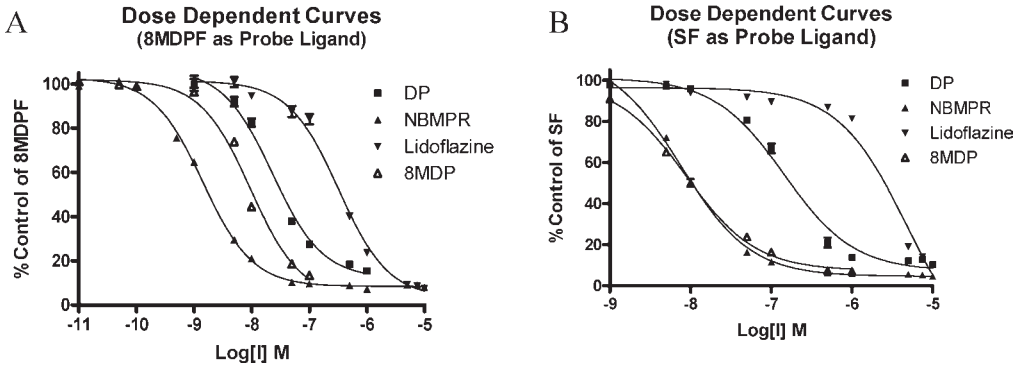

Figure 2. Dose-inhibition curves for the inhibition of 8MDP-fluor (A) or SAENTA-fluor (B) binding to hENT1 determined by a flow cytometric assay using K562 leukemic cells.

Table 2. Use of 8MDP-Fluor and SAENTA-Fluorescein As Ligands for Flow Cytometric Determination of Binding of Standard Inhibitors to hENT1 in K562 Cells

	8MDP-fluor as probe	SAENTA-fluor as probe
compound	K_i (nM)	K_i (nM)
9 (lidoflazine)	182	280
2 (NBMPR)	0.81	0.43
3 (dipyridamole, DP)	12.9	8.18
4 (8MDP)	5.41	0.50

lidoflazine binding. This observation might be worth a follow-up study.

In conclusion, we have synthesized and evaluated a new dipyridamole analogue-based fluorescent probe, which is a high-affinity ligand of both ENT1 and ENT2. We have demonstrated its ability to be an effective flow cytometry probe for the analysis of hENT1 protein expression and for the assessment of relative tightness of binding of compounds that interact with hENT1. Its significant binding to hENT2 suggests that it also has the potential to be used as an ENT2 fluorescent probe.

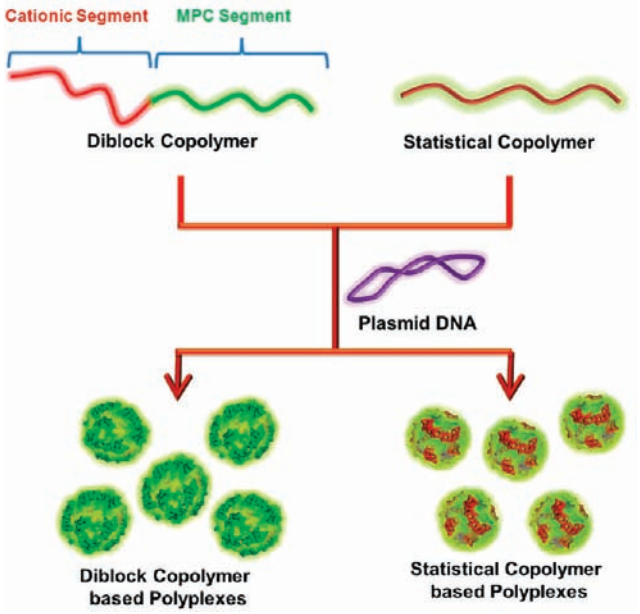
Supporting Information

ABSTRACT: The facile synthesis of biocompatible and nontoxic gene delivery vectors has been the focus of research in recent years due to the high potential in treating genetic diseases. 2-Methacryloxyethyl phosphorylcholine (MPC) copolymers were recently studied for their ability to produce nontoxic and biocompatible materials. The synthesis of well-defined and water-soluble MPC polymer based cationic vectors for gene delivery purposes was therefore attractive, due to the potential excellent biocompatibility of the resulting copolymers. Herein, cationic MPC copolymers of varying architectures (block versus random) were produced by the reversible addition−fragmentation chain transfer (RAFT) polymerization technique. The copolymers produced were evaluated for their gene delivery efficacy in the presence and absence of serum. It was found that copolymer architectures and molecular weights do affect their gene delivery efficacy. The statistical copolymers produced larger particles, and showed poor gene transfection efficiency as compared to the diblock copolymers. The diblock copolymers served as efficient gene delivery vectors, in both the presence and absence of serum *in vitro*. To the best of our knowledge, this is the first report where the effect of architecture of MPC based copolymer on gene delivery efficacy has been studied.

INTRODUCTION



The successful treatment of genetic disorders by gene therapy is dependent on the facile synthesis of nonimmunogenic and nontoxic gene delivery vectors in reproducible manner.[1,2] A variety of nonviral gene delivery vectors have been produced and their transfection efficiencies are being evaluated, in an effort to determine the ideal gene delivery vector with enhanced gene expression and low toxicity.[2−11] Poly(ethylene glycol) (PEG) is one of the water-soluble and low-toxicity polymers that has been extensively explored in cationic gene delivery vectors to decrease the immunogenicity and toxicity of the later.[3,5,8,10,12] The drawbacks associated with PEGylated gene delivery systems are the low uptake of polyplexes and hence lower gene expression. Therefore, there is a need to develop alternative biocompatible polymers, which can be used as cationic gene delivery vehicles.[5]

The role of phospholipid polymers for biological functions is well-studied and it has been found that these polymers have the potential to produce bioinert surfaces for specific biological applications.[13,14] 2-Methacryloxyethyl phosphorylcholine (MPC) has a phosphorylcholine group in the molecule and shows very high water-solubility.[15] The MPC can be polymerized by a variety of radical polymerization techniques to yield the phospholipid polymers.[16] Hence, the production of the cationic MPC copolymer based vectors for gene delivery purposes is thought to be a useful technique to produce gene delivery agents of desired properties.[17−21] Lam et al. and others have produced block-type MPC copolymers by incorporation of tertiary amines with MPC polymer segments via the atom transfer radical polymerization technique (ATRP) and their role for gene and drug deliveries are investigated.[18] The incorporation of MPC units into tertiary amines is found to impact the DNA condensation ability and gene transfer efficiencies of cationic polymers.[17,21] Chim et al. further explored the role of DNA condensation abilities of cationic MPC block copolymers using atomic force microscopy (AFM) and transmission electron microscopy (TEM).[19] The increase in the MPC polymer segment in diblock copolymers is found to decrease the DNA condensation efficacies and hence the gene expression of the corresponding block copolymers.[17,20] It is shown that an approximately 3-fold increase in the tertiary amine component of copolymers is required to produce enhanced

Scheme 1. Synthesis of Statistical and Diblock Copolymer Based Polyplexes Using β-Galactosidase Plasmid

gene expression *in vitro*.[20] However, an increase in cationic character also induces severe toxicity, and hence produces a major barrier toward the synthesis of biocompatible nonviral gene delivery vector.

We propose the synthesis of water-soluble and cationic polymers composed of the MPC and methacrylate with primary amine as block and random architectures by the reversible addition−fragmentation chain transfer (RAFT) method. The RAFT process is extensively studied for the synthesis of a range of polymeric materials for biomedical applications[22] and is chosen here due to the ease of synthesis of those hydrophilic polymers under aqueous conditions. The role of primary amines in gene delivery is well studied and is found to be superior to tertiary amines.[2] The synthesis of cationic polymers composed of the MPC and methacrylate with primary amine for gene delivery purposes is thought to improve the gene expression of the MPC copolymers, by promoting enhanced DNA condensation abilities. The predetermined ratio of MPC units to primary amine components is targeted to be 1. The determination of this ratio of monomers for copolymer synthesis is based on the previous work, which shows that polymers of this composition can deliver the gene of interest with higher efficacies and low toxicity and their gene expression is dependent on the architecture of the polymers.[23] The cationic polymers and MPC based copolymers of varying degree of polymerization were synthesized and their toxicity profiles were determined. These polymers were then tested for their DNA condensation ability and gene expression. To the best of our knowledge, this is the first approach where cationic MPC copolymers of similar compositions and of different architectures (block versus random; Scheme 1) are synthesized by RAFT method and their gene transfer abilities are explored in detail.

The polyplexes were synthesized at varying polymer to DNA ratios and their sizes and net charges were determined using transmission electron microscopy (TEM), dynamic light scattering (DLS), and zeta potential, respectively. The polyplexes synthesized were subjected to agarose gel electrophoresis to determine their stability in an electrophoretic environment. The gene expression of polyplexes synthesized using copolymers of block and random architectures in the presence and absence of serum was then compared and their toxicities after transfection were evaluated. Moreover, the uptake of polyplexes in Hep G2 cells was studied in detail using confocal microscopy and flow cytometry.

MATERIAL AND METHODS

Materials. *O*-Nitrophenyl β-D-galactopyranoside, (ONPG) (enzymatic), 37 wt % formalin, fluorescein isothiocyanate (FITC), β-mercaptoethanol, MTT assay kit to determine cell viability, phosphotungstic acid (PTA), and 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS) were purchased from Sigma Aldrich. Linear polyethyleneimine (PEI) (M_w = 25 kDa) was purchased from Polysciences Inc. Cell Culture media Dulbecco's Modified Eagle Medium (DMEM; low glucose with glutamine and sodium pyruvate), penicillin (10 000 U/mL), and streptomycin (10 mg/mL), 0.25% trypsin, Dulbecco's modified Phosphate Buffer Saline (DPBS), and fetal bovine serum (FBS) were obtained from Invitrogen. Micro BCA assay kit was obtained from Fisher Scientific. Gwiz β-galactosidase plasmid was purchased from Aldevron. MPC was obtained from NOF Co, Tokyo, Japan, which was produced by the previously reported method.[15,16] Cy5′ plasmid labeling kit was purchased from Bio Mirus. 4-Cyanopentanoic acid dithiobenzoate (CTP) was synthesized in the laboratory and 4,4′-azobis (4-cyanovaleric acid) (ACVA) was from Sigma Aldrich.

Synthesis of Monomers and Polymers. The cationic monomers and polymers of varying degree of polymerization and architecture were synthesized according to previously reported protocols.[21,23]

Synthesis of P(AEMA) macroCTA by RAFT Polymerization. MPC macroRAFT agent was synthesized using our previous protocol.[21] 2-Aminoethyl methacrylamide hydrochloride (AEMA) (1.0 g, 6.0×10^{-3} mol), 4-cyanopentanoic acid dithiobenzoate (CTP) (0.042 g, 1.5×10^{-4} mol), and 4,4′-azobis(4-cyanovaleric acid) (ACVA) (0.014 g, 5.0×10^{-5} mol) were dissolved in 2.0 mL water in a 10 mL reactor. The solution was purged with nitrogen for 30 min. After degassing, the solution was placed in an oil bath at a temperature of 60 °C. The reaction was stopped after 6 h by quenching in liquid nitrogen. Polymer was obtained by precipitating the mixture in acetone and washing 3−4 times to obtain a white powder. Any remaining traces of monomer were removed by washing the solution in water/acetone (1:7). The final powder was freeze−dried. The P(MPC_{18}) macroCTA molecular weight and PDI were found to be 2.5×10^3 g/mol and 1.2, respectively, by gel permeation chromatography.

Synthesis of P(AEMA-*b*-MPC) by RAFT Polymerization. Chain extension was carried out using MPC as the second block and AEMA/APMA macroRAFT agent. In a typical reaction procedure, MPC (0.40 g, 2.4×10^{-3} mol) and AEMA macroCTA (0.20 g, 8.0×10^{-5} mol) were dissolved in 2 mL water. Stock solution of ACVA (0.011 g, 4.0×10^{-5} mol) in 2-propanol was prepared and mixed with the reaction solution. The reactor was placed in an oil bath at 70 °C for 20 h. The diblock copolymer P($AEMA_{15}$-*b*-MPC_{17}) was obtained by precipitating the solution in acetone and washing the solution with methanol/acetone (1:7). The final powder was freeze−dried. The molecular weight of the resulting copolymer was found to be 7.6×10^3 g/mol and PDI 1.3.

dx.doi.org/10.1021/bc2001159 |*Bioconjugate Chem.* 2011, 22, 1228–1238

Synthesis of P(AEMA-*st*-MPC) by RAFT Polymerization. The random copolymers of MPC and AEMA were synthesized by adding the monomers in the required molar ratio. A typical polymerization procedure for the copolymerization of MPC and AEMA in ratio 4:3 is given as follows: MPC (0.48 g, 1.6×10^{-3} mol) and AEMA (0.20 g, 1.2×10^{-3} mol) were dissolved in 3 mL water. CTP (0.022 g, 8.1×10^{-5} mol) and ACVA (7.0 mg, 2.7×10^{-5} mol) were dissolved in 1.0 mL of 2-propanol and mixed with the aqueous solution of monomers. The reaction mixture was degassed and is kept at 70 °C in an oil bath for 20 h. The reaction was stopped by quenching in liquid nitrogen. The polymer was precipitated in acetone and washed repeatedly to obtain a powder. Any unreacted monomer was removed by washing the powder with water/acetone (1:7). The powder was freeze−dried to remove any traces of acetone. The molecular weight of the resultant copolymer P($AEMA_{15}$-*st*-MPC_{10}) was found to be 6.0×10^3 g/mol and the PDI was found to be 1.2 by aqueous GPC.

The molecular weight and molecular weight distributions of homo- and copolymers were determined using aqueous GPC (Viscotek GPC system). The sodium acetate/acetic acid (0.50 mol/L/0.50 mol/L) buffer was used as eluent at room temperature and at a flow rate of 1.0 mL/min and pullulan standards ($M_w = 5.0 \times 10^2 - 4.0 \times 10^6$ g/mol) were used for calibration. The compositions of statistical copolymers were analyzed using ^{1}H NMR.

Formation of Polyplexes. Polyplexes were made by mixing varying concentrations of polymers with 0.4.0 mg/mL of *gwiz-β*-galactosidase plasmid in OMEM. The complexes were vortexed and incubated for 30 min before their analysis. The particle sizes and surface charges were measured using Brookhaven Zeta Plus (zeta potential and particle size analyzer) instrument.

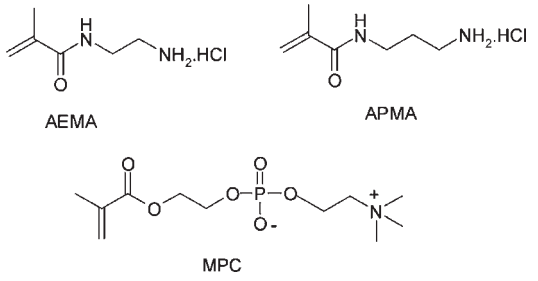
Cell Culture. Hela and Hep G2 cells were maintained in DMEM supplemented with 5.0 and 10% FBS, respectively, and 1.0% penicillin/streptomycin solution in a humidified atmosphere in the presence of 5% CO_2 at 37 °C. Upon 80% confluency, the cells were trypsinized with 0.25% trypsin and were seeded in tissue culture plates.

Determination of Lethal Dose50 (LD_{50}) Values. Hela cells were seeded in 96 well tissue culture plates at the density of 9.0×10^3 cells per well. The cells were incubated overnight and were treated with varying concentrations of polymers in the presence of serum containing media. The cells were further incubated for 12 h and 25 μL of MTT dye was added per well. After 2 h, 100 μL of lysis buffer was added and cells were allowed to lyse overnight. The absorbance was read at 570 nm using TECAN Genios pro microplate reader. The untreated cells and media alone were used as positive and negative controls, respectively. The percent cell viability was calculated (% cell viability = (treated cells − negative control)/(untreated cells − negative control). LD_{50} values for different polymers were determined using *Origin Pro* software and data were analyzed using Boltzman function to provide a sigmoidal fit.

Transfection. Hep G2 cells were seeded at the density of 1.0×10^5 cells per well in 24 well tissue culture plates and were incubated overnight. The media was removed and 150 μL of serum free OMEM or serum containing media was added followed by the addition of varying concentrations of polyplexes. The cells were incubated for four hours and polyplexes containing media were replaced with fresh serum containing media. The cells were allowed to grow for 48 h before their lysis (CHAPS in sodium phosphate lysis buffer) (pH = 7.5) followed by a freeze−thaw cycle. The activity of β-galactosidase was detected using β-galactosidase assay, as described before.[23]

Toxicity after Transfection. Hep G2 Cells were seeded in 24 well tissue culture plates as described above and were transfected with polyplexes in the manner identical to transfection conditions. 48 h post-transfection, 125 μL MTT dye was added per well followed by the addition of 500 μL of lysis buffer after two hours of incubation. The absorbance was read at 570 nm using TECAN plate reader. The untreated cells and media alone were used as positive and negative controls, respectively, and percent cell viability was determined as mentioned in the LD_{50} section.

Fluorescence Labeling of Copolymers. Fluorescein isothiocyanate (FITC) was dissolved in DMSO at 1.0 mg/mL concentration. P($AEMA_{26}$-*b*-MPC_{27}) and P($AEMA_{19}$-*st*-MPC_{21}) (57 mg/mL) were dissolved in 4.0% Na_2CO_3 (pH was adjusted to 8.5). Small aliquots of FITC (2.4 mg of FITC per 100 g of polymer) were slowly added to the polymer solutions in the dark while vortexing. The solution was incubated in the dark overnight. The solution was dialyzed in the dark (MWCO = 6000−8000 Da) against deionized water, and purified solution was stored in the dark at room temperature.



Fluorescent Labeling of Plasmid. *Gwiz-β*-galactosidae plasmid was labeled according to the manufacturer protocol. In brief, plasmid DNA (1.0 μg) was incubated with DNA labeling buffer and cy5′ fluorescent dye at 37 °C for 2 h. The cy5′-labeled plasmid was purified and labeling of plasmid was confirmed using confocal microscopy.

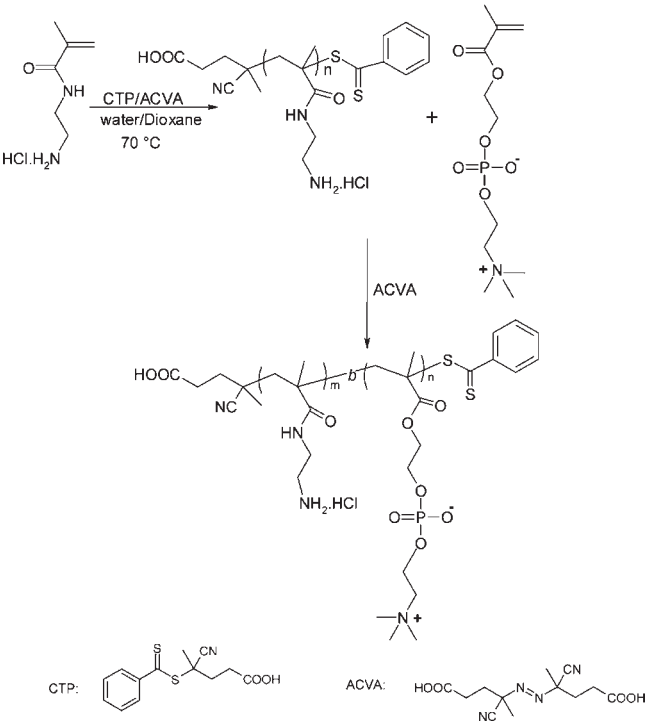
Uptake of Polymers and Polyplexes using Confocal Microscopy. Hep G2 cells were seeded in 6 well tissue culture plates containing glass coverslips. Upon 80% confluency, media was removed and cells were treated with FITC-labeled polymers alone, FITC-labeled polyplexes, or with cy5′-labeled polyplexes in the presence or absence of serum. The untreated cells were used as negative controls. The cells were incubated for 4 h, media was removed, and the cells were washed twice with DPBS before fixation using 3.7% formalin in DPBS. The cells were rehydrated with DPBS and fixed on microscope slides. The samples were analyzed using a Fluoview FV10i Olympus confocal microscope and samples were excited at 485 and 650 nm and detected at 535 and 670 nm, for FITC and Cy5′-labeled samples respectively, using 60× objective.

Flow Cytometry. Hep G2 cells were grown on 24 well tissue culture plate at the density of 1.0×10^5 cells per well and were allowed to adhere overnight. The media was then replaced with 150 μL of OMEM followed by the treatment with FITC-labeled polymers or polyplexes and cy5′-labeled polyplexes in the presence or absence of serum. The cells were further incubated for 3−4 h. The cells were rinsed with DPBS two times to remove the adherent polyplexes from the surface of cells, and were trypsinized and suspended in DPBS containing 3.7% formalin. The uptake of polymers and polyplexes was quantified using Beckman Coulter Quanta SC flow cytometer and FACS Quanta using FL1 channel for FITC and FL-4 channel for cy5′-labeled samples, respectively. The untreated cells were used as negative controls.

Agarose Gel Electrophoresis. The polyplexes were synthesized using conditions identical to transfection experiment and were loaded in 1.0% agarose gel containing 1.0 μg/mL ethidium bromide in 1× Tris acetate/EDTA buffer, and the gel was run at 140 V for 30 min and the DNA bands were visualized using UV transilluminator (Alpha Innotech; San Leandro, CA).

Scheme 2. Structures of Monomers, 2-Aminoethylmethacrylamide (AEMA), 3-Aminopropylmethacrylamide (APMA), and 2-Methacryloxyethyl Phosphorylcholine (MPC)

Stability of Polyplexes in the Presence of Serum Proteins. $P(AEMA_{26}$-*b*-$MPC_{27})$ and $P(AEMA_{19}$-*st*-$MPC_{21})$ polyplexes were prepared in OMEM as described above, and their size was determined using DLS. The polyplexes were then incubated with 10% fetal bovine serum, and the change in size and polydispersity of polyplexes as a function of time was monitored for four hours.



Determination of Protein Content on the Surface of Polyplexes. $P(AEMA_{26}$-*b*-$MPC_{27})$ and $P(AEMA_{19}$-*st*-$MPC_{21})$ polyplexes were prepared in deionized water under conditions used for transfection purposes. The polyplexes were incubated with 10% fetal bovine serum for 30 min. The polyplexes were centrifuged at 14 000 *g* for 60 min and supernatant was collected. The polyplexes were redispersed in deionized water and were washed two more times to ensure the removal of free proteins in solution. The supernatant and polyplexes were subjected to BCA assay to determine the amount of protein in the supernatant and on the surface of the polyplexes. The percent protein in solutions was determined by dividing the protein in solution by the total amount of protein added to the sample.

Transmission Electron Microscopy. Transmission electron microscope (TEM) images of polyplex samples stained with phosphotungstic acid (PTA) (synthesized using conditions identical to transfection experiments) were obtained using Philips transmission electron microscope equipped with a CCD camera.

RESULTS AND DISCUSSION

Phospholipid polymers, in particular, the phosphorylcholine groups bearing polymers, have high potential in the biomedical field due to the excellent biocompatibility of the resulting biomaterials.[24−27] Among them, the water-soluble MPC polymers are attractive for the development of gene delivery vectors that show biocompatible properties, including low toxicity and low protein activation ability. The copolymers composed of the MPC unit and methacrylates with primary amines (AEMA and APMA) units were prepared by the reversible addition−fragmentation chain transfer (RAFT) polymerization method, which allowed the production of a series of cationic copolymers of controlled dimensions and architecture in the absence of metal catalysts.[21,23] The chemical structures of MPC, APMA, and AEMA were shown (Scheme 2). The synthesis of statistical and diblock copolymers composed of the MPC polymer segment and AEMA polymer or APMA polymer segment was depicted in Schemes 3 and 4.

Scheme 3. RAFT Synthesis of Diblock Cationic MPC Polymers using CTP as Chain Transfer Agent and ACVA as Initiator at 70 °C

The cationic homopolymers and their corresponding MPC copolymers of varying degrees of polymerization and molecular weights were synthesized and their GPC data were shown in Table 1 (Supporting Information Figure S1 and S2). Subsequently, the copolymers were evaluated for their transfection efficiencies as a function of their molecular weight and architectures.

The copolymers (statistical and blocks) were designed in such a way that they have similar contents of cationic and phosphorylcholine groups. Such a composition was targeted to generate cationic vectors of low toxicity and improved DNA condensation ability and hence gene expression. Evaluation of a series of polymers for gene delivery is one way to select and understand the gene delivery efficacy of such materials.[29−32] Lam et al. synthesized a variety of MPC block copolymers with tertiary amine groups by ATRP, and their detailed study allowed the selection of copolymers with superior gene expression. However, the study revealed that a very high content of tertiary amine to the MPC unit is required to produce stable polyplexes for moderate gene expression.[18] In this work, we evaluated the transfection efficiencies of primary amine based cationic homopolymers and their corresponding MPC copolymers of varying architecture (block vs statistical) and chain length.

One of the important criteria that determines the biocompatibility of these copolymers was their cytotoxicity. The homopolymer and copolymers synthesized were subjected to cell viability assay, and their LD_{50} values were determined in Hela cells (Table 2). As expected, the cationic homopolymers P(AEMA) and P(APMA) showed high transfection efficacy and high toxicity as compared to the P(MPC) which were highly cell viable but with no gene expression.[2,17,18] The combination of these two systems was therefore expected to produce nontoxic

and efficient gene delivery vectors, once the copolymers of specific architecture and compositions were identified. As expected, the presence of MPC polymer segment in cationic copolymers strongly enhanced the cell viability, regardless of the copolymer architecture (Table 2). The previous studies showed the synthesis of the MPC copolymers as gene delivery vectors; however, no toxicity data were provided.[20] In general, homopolymers of low molecular weights $P(AEMA)_{15}$ and $P(APMA)_{18}$ showed lower toxicity than their corresponding higher molecular weight counterparts. In contrast, P(MPC) showed no significant toxicity at the concentration of 750 μM. The statistical copolymers were found to be more cell viable than their corresponding block copolymers. For example, $P(AEMA_{19}$-*st*-$MPC_{21})$ showed higher cell viability, indicating LD_{50} of 165 μM as compared to $P(AEMA_{26}$-*b*-$MPC_{27})$, for which LD_{50} was 92.6 μM. Moreover, P(APMA) and their corresponding copolymers were found to be more toxic than P(AEMA). The LD_{50} value for $P(AEMA)_{15}$ was found to be 141 μM, as compared to $P(APMA)_{18}$ for which LD_{50} was 12.4 μM. The increased cell viability for AEMA based polymers compared to APMA based polymers was thought to be due to the greater distance between amine group and backbone of polymers in the case of APMA compared to AEMA, hence contributing to higher toxicity.[29] These results were consistent with previous study, where the effect of architecture of cationic glycopolymers on cell viability was studied.[29]

The MPC copolymers synthesized were then studied for their DNA complexation ability at various w/w ratios. The complexation of plasmid DNA with MPC copolymers was achieved by titrating the copolymers with fixed amount of DNA (1.2 μg), and the resulting polyplexes were studied by DLS for their sizes. At lower plasmid/polymers w/w ratios, aggregates ranging from 2

to 5 μm were observed. The increase in w/w ratio led to formation of stable polyplexes and the sizes of these polyplexes were measured using DLS and their charges were studied with zeta potential analyzer. The DLS data showed the presence of stable nanoplexes of in the range 50−200 nm in diameter in deionized water with strong net positive zeta values (Figure 1). These results were consistent with previous study, where polyplex formation using MPC block copolymers was studied.[19] In general, polyplexes synthesized using statistical copolymers were larger in diameter, as compared to the corresponding diblock copolymers. In contrast, P(MPC) did not allow the formation of stable polyplexes at any concentration of polymers to DNA ratios, as studied by DLS (data not shown).

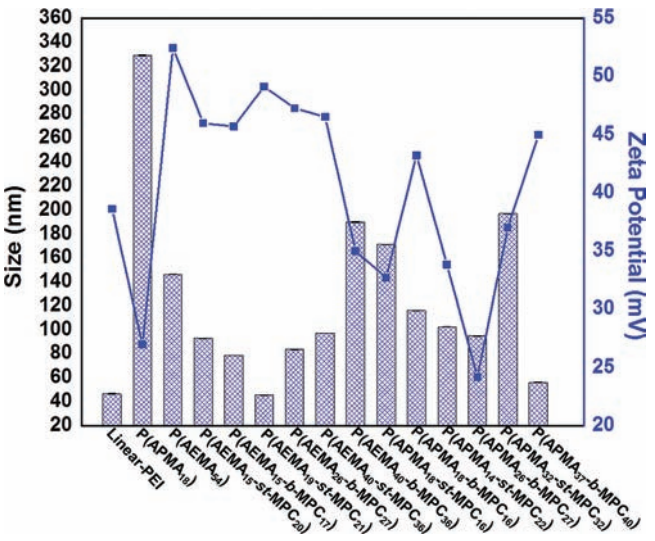

Figure 1. Dynamic light scattering (DLS) and zeta potential data for the MPC copolymers-DNA polyplexes. All samples were prepared in deionized water at fixed plasmid concentration, while polymer concentrations were varied to obtain stable particles.

The instability of MPC diblock copolymer based polyplexes in physiological conditions was found to be a major hurdle to their usage for gene delivery purposes.[16] Thus, only a few reports were available that showed the use of MPC diblock copolymers for gene or drug delivery purposes.[17−20] The conditions were optimized for the formation of polyplexes with net positive zeta values in OMEM media. The polyplexes were also subjected to agarose gel electrophoresis to determine their stability in the media (Supporting Information, Figure S3). The TEM images of polyplexes were then obtained to determine the role of polymer architecture on polyplex morphology (Figure 2).

Diblock copolymer based polyplexes such as P($AEMA_{26}$-*b*-MPC_{27}) and P($APMA_{26}$-*b*-MPC_{27}) showed the presence of spherical particles as compared to their statistical copolymer based polyplexes, such as P($AEMA_{19}$-*st*-MPC_{21}) and P-($APMA_{14}$-*st*-MPC_{22}) based polyplexes, which showed irregular shapes. Hence, in addition to the composition of copolymers, their architecture was found to play a dominant role in determining the shape of the polyplexes. These results were also in agreement with DLS data, where the net diameter of statistical copolymer based polyplexes was found to be greater than that of their corresponding diblock copolymers. The DNA condensation ability of MPC block copolymers was discussed by others with the help of TEM images.[18,19] It was shown that, for tertiary amine and MPC block copolymers, content of the MPC unit to amine ratios higher than 2 were required to produce spherical, well-condensed particles, and MPC unit to amine ratios lower than 2 produced irregular structures ranging from toroids to rods.[18,19] It should be noted that in our case the diblock copolymers with an equal amount of primary amine and MPC polymer segment produce spherical, well-condensed particles, as revealed by TEM images.

The stable polyplexes synthesized were tested for their gene delivery efficacy in Hep G2 cells using β-galactosidase assay. The

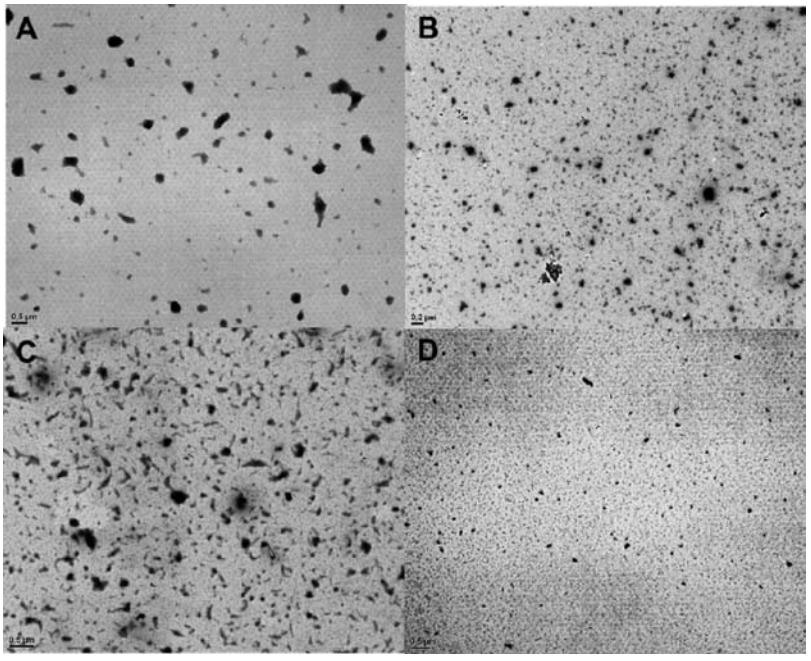

Figure 2. TEM images of polyplexes stained with PTA: (A) P($AEMA_{19}$-*st*-MPC_{21})-polyplexes, (B) P($AEMA_{26}$-*b*-MPC_{27})-polyplexes, (C) P($APMA_{14}$-*st*-MPC_{22})-polyplexes, (D) P($APMA_{26}$-*b*-MPC_{27})-polyplexes. The scale bar is 0.5 μm for images A, C, and D and 0.2 μm for B.

hydrolysis of substrate due to the production of β-galactosidase enzymes was detected by measuring the absorbance at λ = 420 nm. Figure 3 showed the gene transfection ability of MPC copolymers of varying degrees of polymerization. The gene expression of these copolymers was found to be dependent on the copolymer architectures and molecular weights of the copolymers. The copolymers of low molecular weights (6−7 kDa) showed lower gene expression, as compared to the copolymers of high molecular weights (10−12 kDa), for DNA dose of 0.6 μg, and the gene expression was comparable to that of linear PEI, which was used as a positive control. Further increase in molecular weights of copolymers (17−18 kDa) led to a decrease in gene expression most likely due the high toxicity of these copolymers.

Hence, the copolymers P($AEMA_{26}$-*b*-MPC_{27}) and P($APMA_{26}$-*b*-MPC_{27}) showed superior gene transfection as compared to the other copolymers of varying molecular weights. The gene expression of low molecular weight cationic homopolymer was higher than that of other homopolymers and copolymers; however, the toxicity of the homopolymers was a major issue for their use for gene delivery agents. Moreover, the statistical copolymers showed lower gene expression as compared to their corresponding block copolymers. For example, gene expression was found to be 23 ± 1 U/mg for P($AEMA_{26}$-*b*-MPC_{27}) and was 1.9 ± 0.1 U/mg for P($AEMA_{19}$-*st*-MPC_{21}). This significant difference in gene expression was attributed to the architecture of copolymers, which was also shown to affect the polyplex morphology. Sakaki et al. produced MPC copolymers having primary amino group of statistical architecture, which were shown to possess some gene delivery efficacy.[17] The block copolymers composed of the MPC polymer segment and polymer segments with tertiary amines have also been prepared and are shown to possess gene expression, and the optimum gene expression is obtained at tertiary amine to cationic ratio of 2 or higher.[18] However, to the best of our knowledge, there is no study where the effect of MPC copolymer architecture on gene expression has been studied. Herein, it is clearly shown that, in addition to the copolymer compositions, the architecture of copolymers plays a significant role in determining the gene expression. The effect of DNA dose on gene expression was further studied, in an effort to produce enhanced gene delivery using these copolymers (Figure 4). As shown in Figure 4, the AEMA copolymers showed improved gene transfection ability at higher DNA dose (1.2 μg) as compared to APMA-based copolymers. The gene expression was found to be highest (35 ± 4 U/mg) for P($AEMA_{26}$-*b*-MPC_{27}) based copolymers; although P($AEMA_{40}$-*b*-MPC_{36}) based polyplexes also showed enhanced gene expression (38 ± 8 U/mg), the toxicity of these copolymers was a major drawback at the higher DNA dose.

An important factor that determined the gene expression of polymeric vectors was their cellular uptake, which was dictated by a number of factors including the net charge of polyplexes, their morphology, and the content of serum proteins on the surface of polyplexes.[1,2] Although all MPC copolymer-based polyplexes showed strongly positive zeta potential values, as determined, the morphology of these polyplexes was found to vary as a function of copolymer architecture, as shown by TEM images. To determine if lower gene expression of statistical copolymer based polyplexes was related to their cellular uptake, β-galactosidase plasmid and copolymers individually were labeled to fluorescent dyes and their uptake by HepG2 cells was explored using confocal microscopy and flow cytometry. The FITC-labeled copolymers of P($AEMA_{26}$-*b*-MPC_{27}) and P($APMA_{26}$-*b*-MPC_{27}) and cy5′-labeled plasmid were used for this purpose. The polyplexes were formed by the incubation of cy5′-label-free plasmid with FITC-labeled polymers. These polyplexes and polymers alone were incubated with Hep G2 in the absence of serum, and uptake of polymers and polyplexes was studied using confocal microscopy and flow cytometry (Figure 5, Supporting Information Figure S5). These images showed that FITC-labeled polymers and polyplexes were well taken up by HepG2 cells, regardless of polymer architecture. The uptake of FITC-labeled copolymers and their corresponding polyplexes was further confirmed and quantified by flow cytometer analysis. It was shown that P($AEMA_{26}$-*b*-MPC_{27}) and P($AEMA_{19}$-*st*-MPC_{21}) and their polyplexes were taken up by Hep G2 cells, and lower transfection of statistical copolymer was not related to their lower uptake.

To further confirm that these results reflected the uptake of plasmid DNA and not the polymers alone (although these

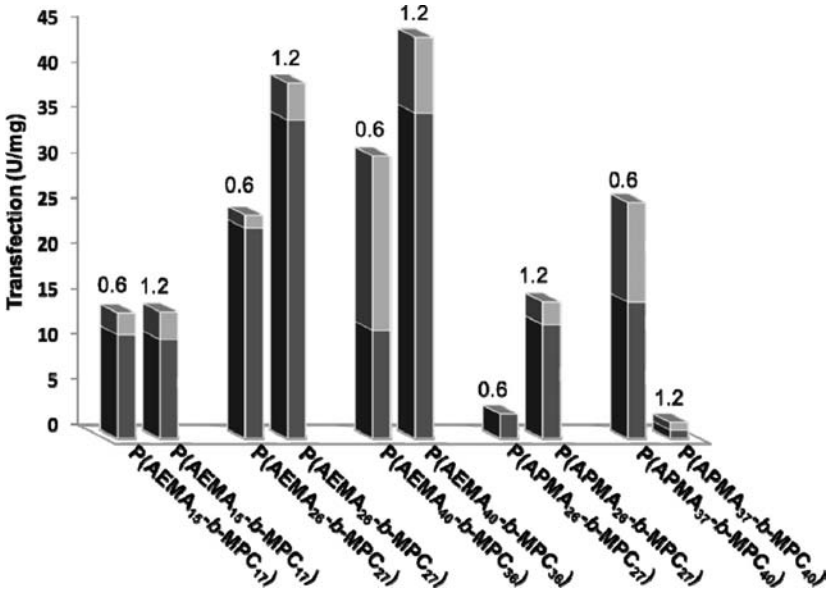

Figure 4. Gene expression of diblock copolymers in the absence of serum proteins using Hep G2 cells. The transfection efficiencies are determined using β-galactosidase assay at DNA doses 0.6 and 1.2 μg, as indicated on the graph. The standard deviations are indicated by light colors on the columns.

polyplexes were found to be stable as determined by agarose gel electrophoresis, the association of polyplexes with cell membrane proteins can lead to dissociation of plasmid from polyplexes, hence attributed toward lower uptake of polyplexes). β-Galactosidase plasmid was labeled with cy5′ fluorescent dye and cy5′-labeled polyplexes were then prepared by incubating label-free copolymers with labeled plasmid. The uptake of cy5′-labeled polyplexes was then studied using confocal microscopy and flow cytometry as before. (Figures 5 and 6).

The results obtained further supported the previous results that uptake of polyplexes by Hep G2 cells was independent of copolymer architecture and polyplexes produced as both block and statistical copolymers were well taken up. Hence, lower gene expression of statistical copolymers was not related to their lower uptake. The modification of living cells by exogenous DNA is a complex process, and successful uptake of foreign gene not always results in its expression. Layman et al. and others have also studied the relation between the cellular uptake of polyplexes and their gene expression, and it has been shown that successful uptake of polyplexes is not always related to the transfection.[33,34] It was thought that the mechanisms of uptake of block and statistical copolymer based polyplexes were different. The diblock copolymer based polyplexes were probably taken up by endocytosis owing to the smaller size of the particles and hence the facile release of DNA from the polyplexes, which contribute to their higher gene expression, as compared to the statistical copolymer-based polyplexes.

The main purpose for producing MPC copolymers for gene delivery purposes was to produce gene delivery vectors that showed minimum toxicity with enhanced gene expression, as well as minimal or no interactions with serum proteins.[2] The previous studies indicated that MPC polymers served as an excellent stealth layer and did not allow the adsorption of proteins on cationic or anionic surfaces modified with MPC polymer segments.[13] Although a handful of studies show the significance of synthesis of cationic MPC copolymers, no data have been shown so far that indicate the successful use of these copolymer based polyplexes in the presence of serum.[14−17] Chim et al. produced tertiary amine and MPC copolymers and it was shown that incorporation of an MPC polymer segment in the cationic segment greatly compromised the DNA protection ability of these copolymers from serum proteins and nucleases.[19] These data indicated that MPC copolymers were not ideal polymeric vectors to deliver the exogenous DNA in physiological conditions. The synthesis of MPC copolymers with primary amines was expected to change their physiological properties. The primary amine based polymers show better DNA condensation ability and DNA protection, and thus show better gene expression.[2] It was thought that synthesis of primary amine based copolymers would offer greater DNA protection from serum proteins and nucleases. However, a major concern in this approach was to determine if an MPC polymer segment was able to mask the cationic component of these copolymers. For this purpose, selected MPC copolymer based polyplexes, P($AEMA_{26}$-*b*-MPC_{27}) and P($AEMA_{19}$-*st*-MPC_{21}) based polyplexes, were prepared under conditions identical to those used for transfection purposes, and these polyplexes were incubated with 10% serum for four hours. The polyplexes were centrifuged to remove the excess of serum proteins and were washed three times with deionized water. The amount of serum proteins in the supernatant and on the surface of polyplexes was determined quantitatively using BCA assay (Supporting Information, Table S1). It was found that, regardless of polymer architecture, almost 89−90% of protein was present in supernatant 1 and a minimal amount of serum protein was detected in supernatant 2 and 3 and on polyplex surfaces. These results further confirmed the antifouling properties of MPC polymer based vectors, indicating that these copolymers had the potential to be used for gene delivery purposes site specifically. Moreover, the stability of these polyplexes in serum media as a function of time was determined using DLS. The polyplexes synthesized using MPC copolymers were found to be relatively stable in serum containing media; the slight aggregation of these polyplexes was reflected by higher polydispersity of the polyplexes upon the addition of serum proteins (Supporting Information, Table S2). This slight aggregation of polyplexes was also apparent by confocal microscope images

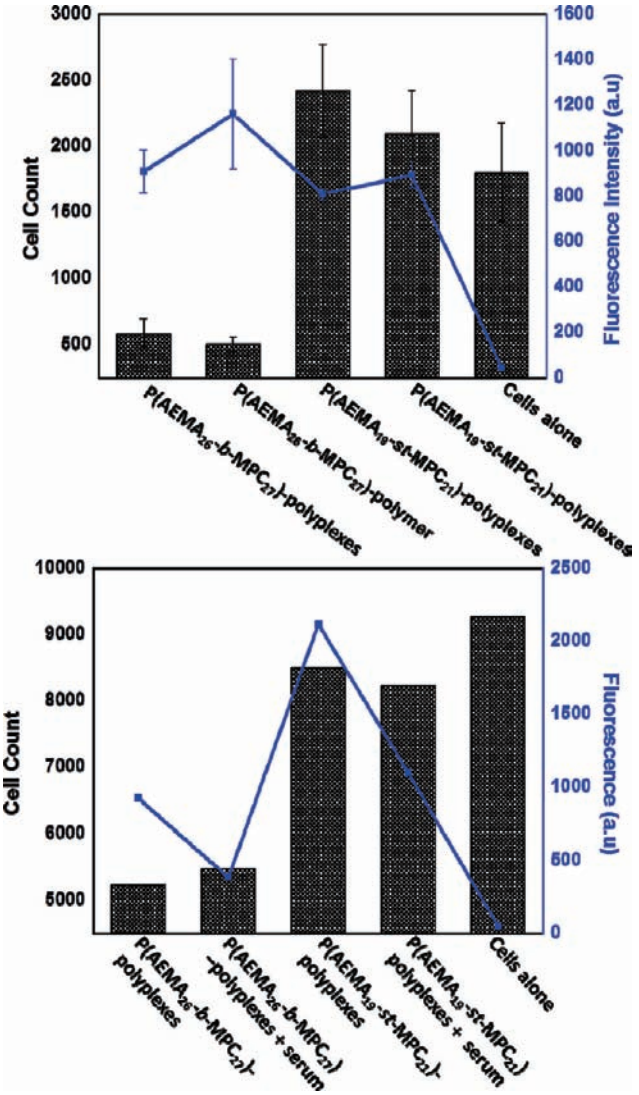

Figure 5. Polyplex uptake by Hep G2 cells after four hours of incubation by flowcytometer analysis. (A) FITC-labeled polymers and polyplexes in the absence of serum proteins. (B) Cy5′-labeled polyplexes in the presence and absence of serum proteins. The data indicate the amount of plasmid delivered to the cells (in line) and number of cells counted (in bars).

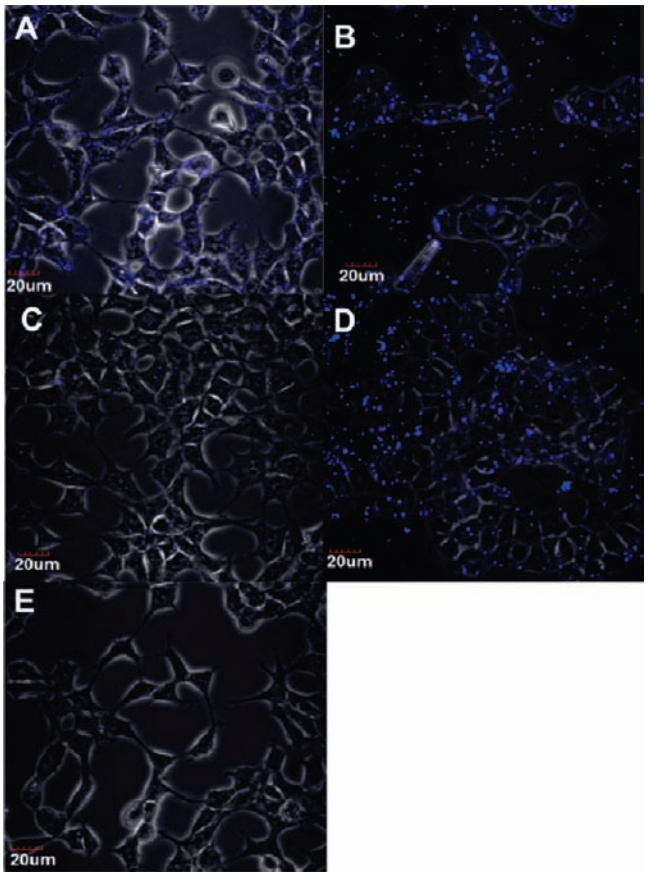

Figure 6. Confocal microscopy images of polyplex uptake by Hep G2 cells after four hours of incubation: (A) P(AEMA$_{26}$-*b*-MPC$_{27}$)-cy5′ labeled polyplexes in the absence of serum proteins, (B) P(AEMA$_{26}$-*b*-MPC$_{27}$)-cy5′ labeled polyplexes in the presence of serum proteins, (C) P(AEMA$_{19}$-*st*-MPC$_{21}$)-cy-5′ labeled polyplexes in the absence of serum proteins, (D) P(AEMA$_{19}$-*st*-MPC$_{21}$)-cy-5′ labeled polyplexes in the presence of serum proteins, (E) untreated cells.

(Figure 6B,D); the increase in polyplex size in these images, as compared to no serum treatments (Figure 6A,C) further supported the DLS data obtained. It should be noted that, after the addition of serum, polyplexes were strongly associated to the cell surface; however, their aggregation did not hinder the uptake of polyplexes by cells completely, which was further confirmed using flow cytometry analysis (Figure 6B,D,F). The data indicated that fluorescence intensity was reduced by almost half upon the addition of serum to the labeled polyplexes, possibly due to the aggregation of polyplexes. The results obtained showed that this trend of polyplex uptake and aggregation was independent of copolymer architecture. P(AEMA$_{26}$-*b*-MPC$_{27}$) and P(AEMA$_{19}$-*st*-MPC$_{21}$) based polyplexes were then subjected to transfection, and as expected, a slight decrease in gene expression was observed, possibly due to the lower uptake of these polyplexes in the presence of serum. However, it should be noted that the gene expression was still significantly comparable to serum-free treatments.

The toxicity after transfection of selected copolymer samples was then determined in Hep G2 cells (Figure 7, Supporting Information, Figure S6). These results further concluded that P(AEMA$_{26}$-*b*-MPC$_{27}$) based copolymers were excellent gene delivery agents and showed enhanced gene expression with minimum toxicity (~60% cell viability).

In short, the synthesis of a variety of MPC copolymers by RAFT allowed the careful selection of copolymers of specific architecture and molecular weight, which were found to show enhanced cell viability and gene expression. It was found that type of cationic monomer and molecular weight of copolymers and their architecture plays a significant role in determining the transfection efficacies of these copolymers. The low molecular weight copolymers of MPC (~7 KDa) were found to be less efficient in gene transfer, while in the case of high molecular weight copolymers (~18 KDa), the gene expression was compromised due to their high toxicity. In addition to molecular weight, the architecture of the copolymers was also found to be an important criterion in gene delivery. The statistical copolymers (regardless of their molecular weights) did not show any gene expression. P(AEMA$_{26}$-*b*-MPC$_{27}$) based polyplexes were found to be ideal MPC copolymers for gene delivery purposes, which retained antifouling properties of MPC units, in combination

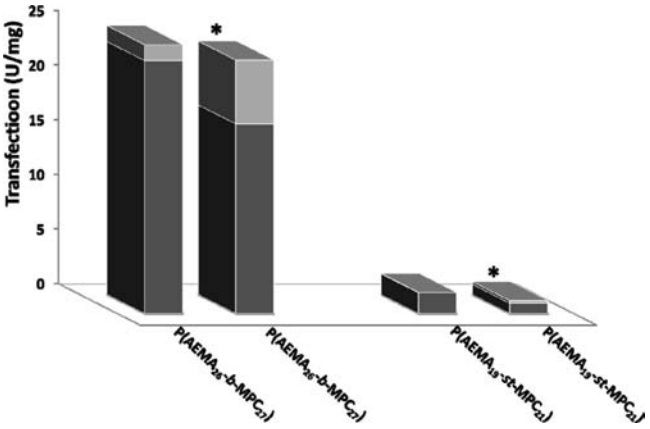

Figure 7. Gene expression of copolymers of varying architectures in the presence (*) and absence of serum proteins using Hep G2 cells. The transfection efficiencies are determined using β-galactosidase assay at DNA dose 0.6 μg.

with enhanced gene expression of amine component. These polymers were found to work well in the presence and absence of serum. These diblock copolymers and their corresponding polyplexes also showed high cellular uptake in the presence and absence of serum, which further supported their role as an ideal candidate for higher gene expression. Further studies will be performed to produce MPC copolymers for targeting purposes, and their role as a specific gene delivery agent *in vitro* and *in vivo* will be evaluated.

Supporting Information

ABSTRACT: The measuring tip of an atomic force microscope (AFM) can be upgraded to a specific biosensor by attaching one or a few biomolecules to the apex of the tip. The biofunctionalized tip is then used to map cognate target molecules on a sample surface or to study biophysical parameters of interaction with the target molecules. The functionality of tip-bound sensor molecules is greatly enhanced if they are linked via a thin, flexible polymer chain. In a typical scheme of tip functionalization, reactive groups are first generated on the tip surface, a bifunctional cross-linker is then attached with one of its two reactive ends, and finally the probe molecule of interest is coupled to the free end of the cross-linker. Unfortunately, the most popular functional group generated on the tip surface is the amino group, while at the same time, the only useful coupling functions of many biomolecules (such as antibodies) are also NH_2 groups. In the past, various tricks or detours were applied to minimize the undesired bivalent reaction of bifunctional linkers with adjacent NH_2 groups on the tip surface. In the present study, an uncompromising solution to this problem was found with the help of a new cross-linker ("acetal-PEG-NHS") which possesses one activated carboxyl group and one acetal-protected benzaldehyde function. The activated carboxyl ensures rapid unilateral attachment to the amino-functionalized tip, and only then is the terminal acetal group converted into the amino-reactive benzaldehyde function by mild treatment (1% citric acid, 1−10 min) which does not harm the AFM tip. As an exception, AFM tips with magnetic coating become demagnetized in 1% citric acid. This problem was solved by deprotecting the acetal group before coupling the PEG linker to the AFM tip. Bivalent binding of the corresponding linker ("aldehyde-PEG-NHS") to adjacent NH_2 groups on the tip was largely suppressed by high linker concentrations. In this way, magnetic AFM tips could be functionalized with an ethylene diamine derivative of ATP which showed specific interaction with mitochondrial uncoupling protein 1 (UCP1) that had been purified and reconstituted in a mica-supported planar lipid bilayer.

INTRODUCTION

Atomic force microscopy (AFM) can operate in aqueous solution under physiological conditions[1] and reveal fine details not resolved by electron microscopy.[2] AFM is thus well-suited for the structural analysis of biomolecules and their assemblies.[1,3] In addition, an AFM tip can be functionalized with one or several probe molecules (e.g., antibodies) whereupon it can be used as a specific biosensor by which cognate target molecules (e.g., antigens) are detected when the tip is moved over the sample surface.[4−6] Binding is detected as a rupture event which is sensed by a vertically oscillated cantilever[7] preferably under simultaneous monitoring of sample topography.[8,9] Alternatively, the tip can be vertically oscillated at a fixed $X-Y$ position above a target molecule, in which case repeated binding−unbinding events are recorded as force−distance profiles. When repeating force−distance cycles at different force loading rates,[10] detailed biophysical parameters of the noncovalent bond can be calculated from the force data.[4,5,11−14]

Linear polymers, such as carboxymethylamylose,[15−18] poly(*N*-succinimidyl acrylate),[19] or poly(ethylene glycol) chains (PEG),[6,12,14,20−31] have regularly been used as flexible tethers

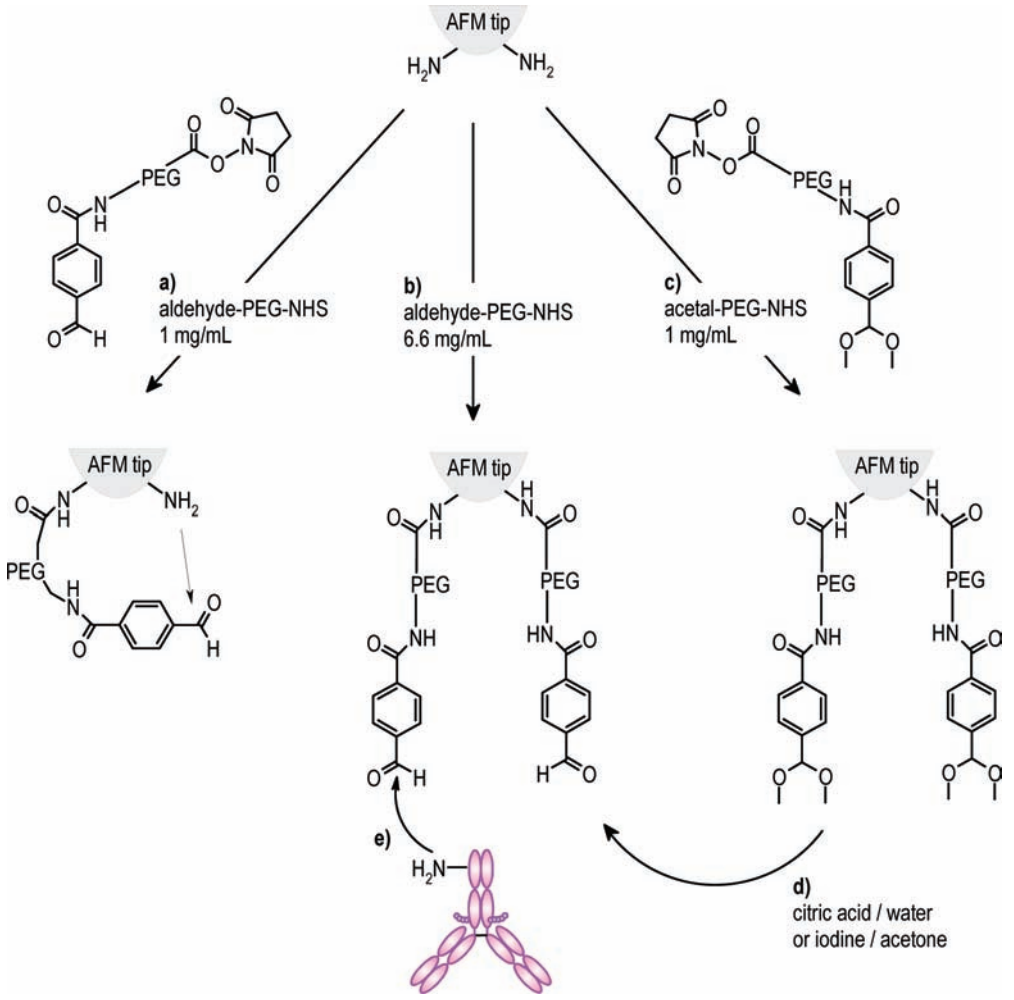

Figure 1. AFM tip functionalization with aldehyde-PEG-NHS as compared to acetal-PEG-NHS. Loop formation between adjacent amino groups can occur with aldehyde-PEG-NHS (a); it is largely suppressed at high concentrations of aldehyde-PEG-NHS (b). No loop formation occurs with acetal-PEG-NHS (c), since the acetal is converted into aldehyde only after derivatization of all NH_2 groups on the AFM tip (d). Lysine residues of proteins can be coupled to terminal benzaldehyde functions (e).

between the tip and the probe molecule, resulting in much higher probability for binding between the probe molecule on the tip and the target molecules on the sample surface. Tethering of probe molecules via linear polymers is usually performed in three stages. First, reactive sites are generated on the tip surface. Second, a linear polymer ("cross-linker") is attached with one reactive end while reserving the other end for the probe molecule. Third, the probe molecule is coupled to the free end of the polymer chain. The most straightforward scheme comprises (i) amino-functionalization of the tip, (ii) amide bond formation with a heterobifunctional cross-linker that has one amino- and one thiol-reactive end group, and (iii) attachment of a thiol-carrying probe molecule to the free end of the cross-linker.[6,8,9,25,28,32]

Unfortunately, antibodies and many other proteins possess no free thiols (cysteines) but lots of reactive amino functions (lysines, e.g., 80−90 per antibody).[33] At the same time, amino-functionalization is the predominant method of tip surface activation. This poses the problem of connecting tip-NH_2 with NH_2-protein with a bifunctional cross-linker, while preventing cross-linker loops between adjacent NH_2 groups on the tip surface. The nontrivial task has been solved by several strategies, each having its own advantages and drawbacks.

The simplest approach is to use a heterobifunctional cross-linker, as described above, and to pre-derivatize the protein with a reagent that introduces free thiol residues[20,24,25] or pentynoyl groups (for coupling to an azide on the linker via click chemistry).[22,34] These methods work well, yet ~0.2 mg of precious antibody is required per batch, and gel filtration is needed for rigorous removal of reagents. Consequently, the derivatized antibody is rather dilute which prevents refreezing of unused portions.

For minimization of antibody consumption, several methods have been developed in which the lysine residues of antibodies (or other proteins) are directly coupled to tip-bound cross-linker, without pretreatment of the protein. (i) Gold-coated tips were covered with a SAM containing exposed thiol groups to which a heterobifunctional linker (maleimide-PEG-NHS) was bound with its maleimide function.[12,14] In this way, the amino-reactive NHS ester group was spared for subsequent coupling of protein via lysine. (ii) Gold-coated tips were amino-functionalized with cystamine, and carboxymethylamylose was bound via some of its many NHS ester functions, leaving the other NHS ester groups for coupling of protein.[17,18] In both methods, the large radius of the gold-coated tips reduces their usefulness for high-resolution imaging. (iii) Silicon nitride tips were amino-silanized and

NHS-activated carboxymethylamylose was applied in the analogous way.[15,16] (iv) Silicon nitride tips were silanized with a mixture of aminosilane and a large excess of an inert silane, aiming at such a low surface density of NH_2 functions that homobifunctional NHS-PEG-NHS could react with one NHS ester function only, whereupon protein could react with the second NHS ester group.[30]

All NHS ester methods (i–iv) have in common that coupling of protein is fast and efficient, provided that the concentration of protein is high enough and the optimal pH value is chosen to outrun premature hydrolysis of the NHS ester functions.[35,36] In this respect, aldehyde functions are a promising alterative because they cannot hydrolyze. Under comparable conditions, coupling of amino groups to aldehydes is much slower than to NHS esters.[36,37] In a recent study, we took advantage of this kinetic difference by devising a new heterobifunctional cross-linker (aldehyde-PEG-NHS)[38] for AFM tip functionalization (Figure 1a,b). When applying the same concentration as with other cross-linkers (1 mg/mL), the tendency for loop formation between adjacent NH_2 groups was very pronounced (Figure 1a). At high concentration (6.6 mg/mL), however, the majority of NH_2 functions on the tip was rapidly consumed by reaction with NHS esters (Figure 1b); thus, most benzaldehyde functions were spared for coupling of protein.[38] This method was successfully used in a number of AFM studies.[21,23,38–49]

In the present study, the benzaldehyde function was kept in a protected form until all NH_2 groups on the tip surface had formed amide bonds with a new linker (acetal-PEG-NHS, Figure 1c). Subsequently, the acetal functions were converted into reactive aldehyde moieties. Dilute citric acid was found to cleave all acetal functions without harmful effects on the tip surface and on the gold mirror on the top side of the cantilever. This strategy affords effective tip functionalization at low cross-linker concentration, which adds to the advantage that synthesis of acetal-PEG-NHS is much simpler than of aldehyde-PEG-NHS.

EXPERIMENTAL PROCEDURES

Materials. Analytical-grade solvents and reagents were used as long as they were commercially available. Muscovite mica sheets were supplied by Christiane Gröpl (Austria). Si_3N_4 measuring tips were purchased from Veeco (Santa Barbara, CA) and Si_3N_4 chips from Wacker-Chemitronic GmbH (Germany). APTES was obtained from Aldrich. $NaCNBH_3$ was purchased from Fluka. Avidin, D-biotin, EAP, and ethanolamine hydrochloride were obtained from Sigma-Aldrich. EDA-ATP was obtained from BioLog (Bremen, Germany). NH_2-PEG-COOH was synthesized as described.[50] Acetal-PEG-NHS and aldehyde-PEG-NHS were synthesized as outlined in Figure 3 (see Supporting Information for details). Biotin-IgG was prepared by derivatization of goat IgG with biotin-cap-NHS as described.[25] Buffer A contained 100 mM NaCl, 50 mM NaH_2PO_4, and 1 mM EDTA (pH 7.5 adjusted with NaOH). Buffer B contained 300 mM NaH_2PO_4 and 1 mM EDTA (pH 7.5 adjusted with NaOH). PBS contained 150 mM NaCl and 5 mM NaH_2PO_4 (pH 7.4 adjusted with NaOH). Mitochondrial uncoupling protein 1 (UCP1) was purified and reconstituted into mica-supported bilayers as described in the Supporting Information.

Functionalization of AFM Tips with Acetal-PEG-NHS and Antibodies. AFM Tips (Si_3N_4) were amino-functionalized either with a solution of ethanolamine hydrochloride in DMSO ("room temperature method")[51] or with APTES from gas phase,[51,52] as specified. Attachment of acetal-PEG-NHS was performed by 2 h incubation of the tips in 0.5 mL of chloroform containing 1 mg/mL acetal-PEG-NHS and 0.5% (v/v) of TEA. Subsequently, the tips were rinsed in chloroform (3×). Two alternate methods were used for conversion of the acetal functions into aldehyde groups: (i) immersion in acetone containing 0.1% iodine for 5 min and rinsing in pure acetone (3 × 5 min), (ii) immersion in water containing 1% citric acid for 10 min and rinsing with water (3 × 5 min). For the coupling of the antibody, tips were transferred into a mixture of 50 μL biotin-IgG solution (0.2 mg/mL in buffer A) with 2 μL 1 M $NaCNBH_3$ stock solution (to reach a final concentration of 40 mM $NaCNBH_3$) for one hour. Subsequently, 5 μL of ethanolamine hydrochloride stock solution (1 M, preadjusted to pH 9.6 with 20% NaOH) was mixed into the biotin-IgG solution and incubation was continued for 10 more minutes. Finally, the tips were washed in PBS (3 × 5 min) and stored in PBS at 4 °C until use (up to 3 days). A detailed illustration of tip functionalization is found in the Supporting Information (Figure S5).

Monitoring of Single Unbinding Events between Tip-Bound Biotin-IgG and Mica-Bound Avidin by AFM. Avidin (1 mg/mL in PBS) was diluted with 1 mM NaCl to a final concentration of 0.5 μg/mL and absorbed to freshly cleaved mica. After 15 min, the substrate was rinsed with 1 mM NaCl (10×) and subsequently with PBS (10×). Force measurements with biotin-IgG-functionalized AFM tips were performed in a fluid cell of a commercial AFM (PicoSPM, Agilent, Tempe, AZ). Force–distance cycles were recorded at a 1 Hz vertical scan rate and 100–300 nm *z*-amplitude. The measurements were performed at a constant trace and retrace velocity. All measurements were done in PBS. For specific blocking of avidin–biotin interaction, the biotin residues on tip-bound IgG were masked by addition of free streptavidin (0.5 mg/mL final concentration) to the bath solution. The spring constants of the levers were determined by thermal noise method.[53,54]

Functionalization of Silicon Nitride Chips with Amino Groups, Acetal-PEG-NHS, and Biotin-IgG, with Quantitative Assay for Chip-Bound Biotin-IgG. Silicon nitride chips were precut, cleaned with chloroform (3×), dried with nitrogen, immersed in a piranha solution (70/30, H_2SO_4/H_2O_2, caution: piranha is extremely corrosive and can explode) for 30 min, extensively rinsed in water, dried with nitrogen, and heated to 160 °C for 5 min. The amino-functionalization was performed with the "room temperature method" as described before.[51] After washing in DMSO (3×) and ethanol (3×), the chips were dried in nitrogen and derivatized with acetal-PEG-NHS as described above for AFM tips. Cleavage of the acetal functions was always performed with citric acid (1%, in water, 1 or 15 min) and washing with water (3 × 5 min) or with iodine (0.1% in acetone, 5 min) and washing with acetone (3 × 5 min), as specified. Coupling of biotin-IgG was performed as described above for AFM tips, except that the concentration of biotin-IgG was varied as specified in the tables. Unused aldehyde functions were blocked with ethanolamine or with glycine, as specified. The surface density of biotin-IgG bound to the silicon nitride chips was determined by specific binding of ExtrAvidin-Peroxidase (EAP) as described before.[51] A detailed illustration of chip functionalization and estimation of its efficiency is found in the Supporting Information (Figure S6).

RESULTS AND DISCUSSION

Synthesis of Acetal-PEG-NHS and Aldehyde-PEG-NHS. The synthesis route for the new cross-linker acetal-PEG-NHS followed the typical scheme for long heterobifunctional

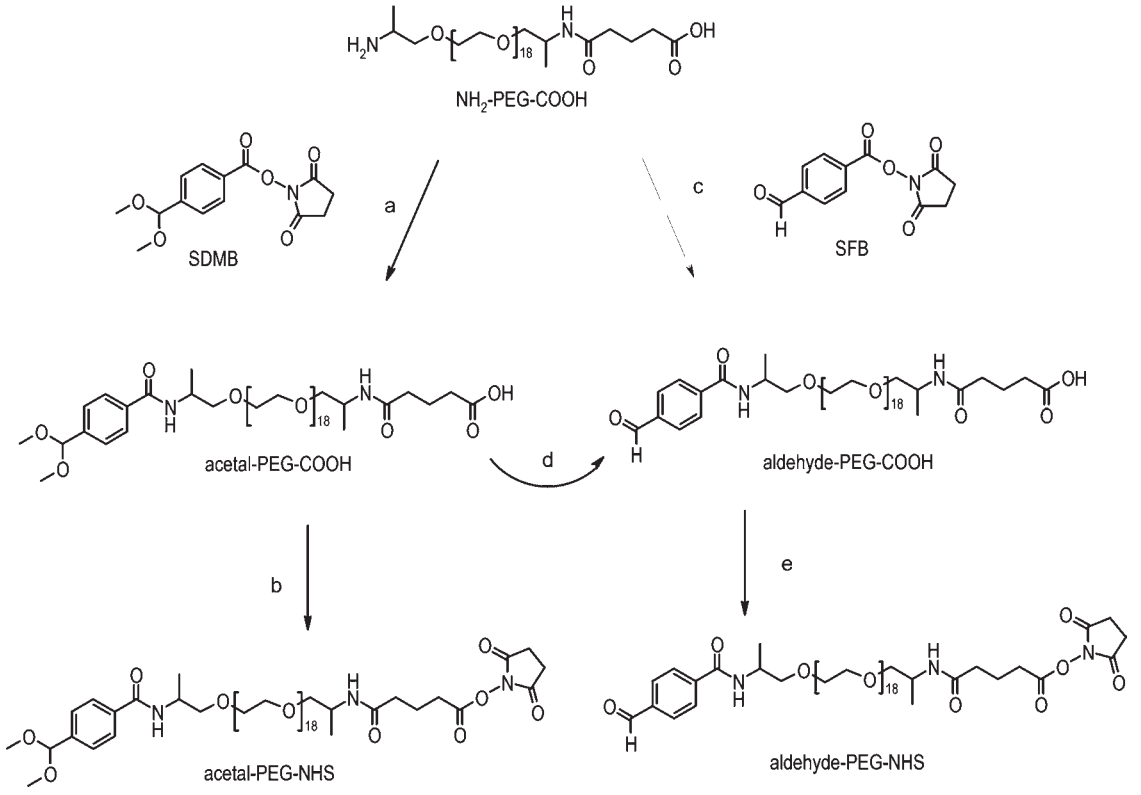

Figure 2. Synthesis of acetal-PEG-NHS and aldehyde-PEG-NHS. (a) NH_2-PEG-COOH was reacted with SDMB to give acetal-PEG-COOH. (b) The terminal carboxyl function was activated by conversion into an NHS ester (acetal-PEG-NHS). (c) Previously published method of preparing aldehyde-PEG-COOH by use of SFB.[38] (d) New synthesis of aldehyde-PEG-COOH by cleavage of the acetal function. (e) Conversion of the terminal COOH group into an aminoreactive NHS ester (aldehyde-PEG-NHS). Experimental details of the syntheses are found in the Supporting Information.

cross-linkers[25,38,50,51] in the sense that a short cross-linker (SDMB) was attached to the *N*-terminus of NH_2-PEG-COOH in the first step (Figure 2a). To our knowledge, the short cross-linker SDMB has been synthesized for the first time (see Figure S1 in the Supporting Information). After removal of all small molecules (excess of SDMB, free NHS, TEA), the carboxyl group of acetal-PEG-COOH was converted into an NHS ester, resulting in the heterobifunctional cross-linker acetal-PEG-NHS (Figure 2b).

As can be seen from Figure 2, the new module acetal-PEG-COOH served a second purpose also: cleavage of the acetal by iodine/acetone (0.1%, 10 min) or citric acid/water (1%, 10 min) afforded pure aldehyde-PEG-COOH (Figure 2d) which was easily converted into the previously published linker acetal-PEG-NHS (Figure 2e). In contrast to the new synthetic route (Figure 2a,d), the old method of reacting NH_2-PEG-COOH with SFB (Figure 2c)[38] had given a significant fraction of Schiff base adducts besides the desired amide product; thus, a cumbersome extraction scheme was required for purification of aldehyde-PEG-COOH from undesired PEG derivatives.[38] The new synthetic route for preparation of the old linker aldehyde-PEG-NHS (Figure 2, steps a, d, and e) is important because the new linker acetal-PEG-NHS can replace the old one in most but not all AFM applications (see Figure 5).

AFM Tip Functionalization, Using Iodine/Acetone for Cleavage of Tip-Linked Acetal Functions. As can be seen from Figure 1, the essential improvement of the new tip functionalization method rests on the use of a masked aldehyde (i.e., an acetal) which remains unreactive while amide bonds are formed between the linker and the amino groups on the tip surface. In the next step, the acetal function on the free end of the tip-bound linker was converted into an amino-reactive benzaldehyde function (step d). Hereby, it was critical to select the mildest available method in order to prevent damage to the tip surface and to the light-reflecting metal film on the top side of the cantilever. In a recent study, it had been found that dimethylacetals of aromatic aldehydes are cleaved within 5 min by 0.6% iodine in anhydrous acetone under neutral conditions.[55] In the present study, we further lowered the iodine concentration to 0.1% and found it fully sufficient to completely deprotect acetal-PEG-COOH within 5−10 min in bulk solution (Figure 2, step d). Consequently, acetone with 0.1% iodine was also applied to tip-linked acetal functions (Figure 1, step d).

After deprotection, the functionality of "tip-PEG-acetal" was examined by a established validation method:[25,38] Biotin-IgG was coupled to the tip-bound benzaldehyde functions (Figure 1, step e), using $NaCNBH_3$ for concomitant fixation of the initially formed Schiff base bonds (see Figure S5). The tip was then mounted in the AFM and the ligand function of the biotin residues was tested by repeated approach to, and retraction from, the test sample which consisted of a dense monolayer of avidin, bound to mica by electrostatic adsorption (Figure 3A).[51] A typical example of the resulting force curves is shown in Figure 3B. The *X*-axis corresponds to the vertical movement of the piezo which carries the cantilever, while the *Y*-axis mirrors the deflection of the cantilever (converted into force values by multiplying the deflection amplitude with the force constant of the particular cantilever). During the approach (gray line), the cantilever is in the resting position up to the point of contact.

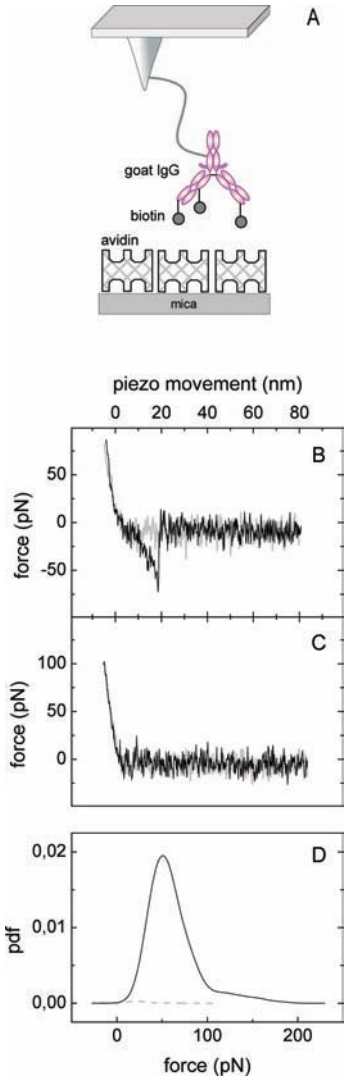

Figure 3. Force spectroscopy of single avidin−biotin interactions. (A) The AFM tip was functionalized with biotin-IgG, as outlined in Figure 1cd (or in greater detail in Figure S5, Supporting Information), using ethanolamine hydrochloride for tip amino-functionalization and iodine/acetone for cleavage of the acetal functions. In parallel, avidin was irreversibly adsorbed onto freshly cleaved mica. (B) Example of a force−distance cycle showing specific avidin−biotin unbinding. The piezo movement in the approach-and-retraction cycles was ±100 nm in 1 s, the force constant of the cantilever was 18 pN/nm, and the loading rate at unbinding was calculated as 1180 pN/s. Unbinding occurred at a rupture force of 51 pN and a tip−mica distance of 22 nm. (C) Example of a force−distance cycle performed in the presence of free streptavidin (0.5 mg/mL final concentration in PBS). (D) Probability density function (pdf) of the unbinding forces observed in 199 out of 948 force−distance cycles (solid line, 21% binding probability). In the presence of free streptavidin, only 3 out of 198 force−distance cycles showed apparent unbinding events (dashed gray trace, 1.5% binding probability).

Further approach causes upward bending of the cantilever. Retraction causes relaxation of cantilever bending, which does not stop at zero force but proceeds to negative values at further retraction. The reason is binding of a tip-tethered biotin residue to mica-bound avidin which causes progressive stretching of the PEG chain. At the critical force of 51 pN, the avidin−biotin bond is suddenly ruptured and the cantilever jumps to its resting position. The probability density function (pdf)[56] of 199 unbinding events (Figure 3D, solid line) shows the expected average avidin−biotin rupture force, as previously observed a the same force loading rate.[25,38,51]

The specificity of avidin−biotin interaction was demonstrated by blocking the biotin residues on the tip with free streptavidin from solution. As a consequence, most force−distance cycles showed only upward bending of the cantilever (Figure 3C) and only 1.5% of the force distance cycles showed downward deflection, in contrast to 21% before the addition of free streptavidin. This difference in binding probability is reflected by the much lower area of the unbinding force distribution function in the presence of streptavidin (dashed gray line in Figure 3D), as compared to the condition with no streptavidin (solid line).

For independent validation of the new tip functionalization method (Figure 1c,d,e), the procedure was applied to chips (5 mm × 5 mm) consisting of the same material as the AFM tips (Si_3N_4) and the area density of immobilized biotin-IgG was estimated from binding of EAP which is a conjugate between avidin and horse radish peroxidase.[25,38,51] Specific binding (Table 1, column 5) was calculated by subtracting nonspecific binding in the presence of free D-biotin (column 4) from total binding in the absence of free D-biotin (column 3). The results show that specific binding of EAP to immobilized biotin-IgG is far more pronounced than nonspecific adsorption. The actual numbers in columns 3−5 are similar as previously obtained with aldehyde-PEG-NHS,[38] except that aldehyde-PEG-NHS must be used at high concentrations (Figure 1b,e) in order to suppress loop formation on the surface (Figure 1a), whereas the new linker acetal-PEG-NHS can be used at the low concentration of 1 mg/mL (Table 1, column 1). From these findings, we conclude that all available amino groups on the tip surface fully react with the NHS ester function of acetal-PEG-NHS (1 mg/mL in chloroform with 0.5% TEA, 60 min), thereby eliminating the danger of loop formation on the tip surface when/after the acetal is converted into a benzaldehyde function in the next step (Figure 1d).

Table 1 also shows that there is no need to use antibody concentrations higher than 0.15 mg/mL (column 2). The same phenomenon has been observed when other PEG linkers were used for antibody linking to AFM tips.[25,38] It was conclusively explained by weak preadsorption of protein to the tip surface, with the effect that one protein molecule adsorbed within reach of a 6-nm-long PEG linker has an effective local concentration of 3 mM.[25] As a consequence, very low protein concentrations suffice to equip all PEG linkers on the AFM tip with a protein molecule. In practice, we have seen efficient tip functionalization with ≥0.03 mg/mL antibody concentration (data not shown).

AFM Tip Functionalization, using Dilute Citric Acid for Cleavage of Tip-Linked Acetal Functions. The above-described method of tip functionalization has successfully been applied in several AFM laboratories when suddenly the users complained that the gold mirror on the top side of the cantilever got destroyed during tip functionalization. Detailed analysis showed that this destruction occurred during acetal cleavage with iodine/acetone (Figure 1d) and that it only happened with cantilevers purchased after the producer had changed the production method. As a consequence, several publications could only be finished by switching back to tip functionalization with aldehyde-PEG-NHS (Figure 1b,e).[39,41,49]

In search for an alternative to iodine/acetone a study was found in which the diethylacetal of a PEG-linked benzaldehyde had completely been hydrolyzed within 5 h at pH 5, which had been adjusted with HCl.[57] This condition seemed promising in

Table 1. Tethering of Biotinylated IgG to Silicon Nitride Chips via Acetal-PEG-NHS (Iodine Method)[a]

[PEG linker] (mg/mL)	[biotin-IgG] (mg/mL)	total sites (μm^{-2}) [b]	nonspecific sites (μm^{-2}) [b]	specific sites (μm^{-2}) [b]
1	2	805 ± 124	27 ± 4	778 ± 143
10	2	742 ± 81	27 ± 4	715 ± 94
1	0.15	777 ± 136	151 ± 51	626 ± 153

[a] Silicon nitride chips were derivatized according to the scheme shown in Figure S6. Ethanolamine hydrochloride was used for amino-functionalization of silicon nitride (step a in Figure S6). Iodine (0.1%, in acetone, 5 min) was applied for cleavage of the acetal function (step c). [b] The number of biotin-IgG molecules per μm^2 (specific sites) was estimated from the difference EAP binding, measured in the absence (total sites, step f) and in the presence of free D-biotin (nonspecific sites, step e).

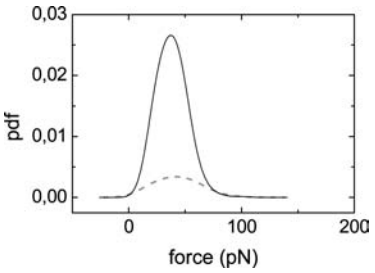

Figure 4. Force measurements of single avidin−biotin interactions. Tip functionalization and force spectroscopy were performed as in Figure 3, except that citric acid (1%, in water, 15 min) was used in place of iodine/acetone for conversion of acetal into aldehyde functions. The piezo movement in the approach-and-retraction cycles was ±150 nm in 1 s, the force constant of the cantilever was 37 pN/nm, and the loading rate at unbinding was calculated as 720 pN/s. The graph shows the probability density function (pdf) of the unbinding forces observed in 321 out of 985 force−distance cycles (solid line, 32.6% binding probability). In the presence of free streptavidin, only 41 out of 938 force−distance cycles showed apparent unbinding events (dashed gray line, 4.4% binding probability).

terms of mildness, but shorter reaction times and a more reliable way to adjust pH were required for practical purposes. For a first test, we treated acetal-PEG-COOH with 1% citric acid (pH 2.2, Figure S4) for 10 min and found that at least 99.6% (or more) of the acetal functions had been converted into benzaldehyde functions (see Supporting Information). Consequently, the AFM test experiment from Figure 3 was repeated, except that conversion of "tip-PEG-acetal" into "tip-PEG-aldehyde" was performed with 1% citric acid instead of iodine/acetone. The results are summarized in Figure 4. The unbinding force distribution shows the expected average unbinding force of ~50 pN, as well as high binding probability (32.6%, solid line) before and low binding probability (4.4%, dashed line) after specific block of avidin−biotin interaction with excess of streptavidin.

The modified tip functionalization protocol with 1% citric acid in place of iodine/acetone was again validated by imitation of tip functionalization on silicon nitride chips (Table 2). Columns 1 and 5 confirm the well-known trend that higher densities of amino groups are achieved with ethanolamine/DMSO as compared to gas-phase silanization with APTES.[51,52] In addition, the ethanolamine/DMSO method is less critical and easier to perform by newcomers. Nevertheless, the APTES method is to be preferred for high-quality AFM measurements.[58] When varying the incubation time with 1% citric acid (column 2), it was found that even the short time interval of 1 min was sufficient to deprotect 60−90% of the benzaldehyde functions on the chip (see column 5). From these data, it appears that 3−5 min of treatment with 1% citric acid is the best compromise between efficient acetal cleavage and minimal chemical stress on AFM tips.

Table 3 addresses the question regarding whether it is necessary to block potentially unused benzaldehyde functions on the AFM tip. Now, all chips were amino-functionalized with APTES in the gas phase, followed by reaction with acetal-PEG-NHS, cleavage of tip-bound acetal functions with 1% citric acid, and coupling of biotin-IgG to the resulting benzaldehyde functions on the chip. In case unused benzaldehyde functions are present on the chip surface, this should lead to covalent coupling of the ExtrAvidin-Peroxidase (EAP), which we use for "counting" of the biotin-IgG molecules on the chip surface. Such covalent coupling would contribute to nonspecific binding (column 4 in Table 3), in contrast to the specific interaction of EAP with biotin-IgG (column 5) which is blocked by excess of free D-biotin. Previously, it was shown that the terminal benzaldehyde is efficiently blocked by free ethanolamine in presence of $NaCNBH_3$.[38] Now, free ethanolamine was applied after coupling of biotin-IgG (lines 3 and 4) and compared to controls in which no attempt was made to block unused benzaldehyde functions (lines 1 and 2). However, no significant difference was found with respect to the extent of nonspecific binding. The same result was also obtained when glycine was used in place of ethanolamine (lines 5 and 6).

Lines 1, 3, and 5 in Table 3 differ from all chip functionalization assays in this and previous studies[25,38,51,52] by omission of Tween 20 in the incubation step with ExtrAvidin-Peroxidase (EAP). Absence of detergent was expected to enhance adsorption, and thereby also to accelerate covalent coupling of EAP to surface-bound benzaldehyde residues,[25] in case not all of them had reacted with biotin-IgG in the preceding step. The data in Table 3, however, do not show a significant difference in the extent of nonspecific binding of EAP to the chip surface, whether Tween 20 was present or not (columns 2 and 4). It is, therefore, concluded that nonspecific binding was merely caused by physical adsorption of ExtrAvidin-Peroxidase and not by covalent coupling to unused benzaldehyde functions. With respect to AFM tip functionalization, this means that all (or almost all) benzaldehyde groups on the tip surface appear to react with a protein molecule under the standardized reaction conditions and that blocking of putatively unused benzaldehyde groups is merely optional. In case blocking is desired, glycine is to be preferred over ethanolamine, because the lower pK_a of glycine allows for a more neutral pH during the blocking step (see legend to Table 3). An alternate method for blocking of potentially unused aldehyde functions at pH ~ 7.7 is described in the Supporting Information (part 4).

Rapid Imaging of Mitochondrial Uncoupling Protein with ATP-Functionalized AFM Tips. As describe above, citric acid (1%) allows for conversion of "tip-PEG-acetal" into "tip-PEG-aldehyde" without adverse effects on standard AFM cantilevers. Unfortunately, this is not true for MAC levers, the magnetic

Table 2. Tethering of Biotinylated IgG to Silicon Nitride Chips via Acetal-PEG-NHS (citric acid method).[a]

amino-functionalization	1% citric acid (min)	total sites (μm^{-2}) [b]	nonspecific sites (μm^{-2}) [b]	specific sites (μm^{-2}) [b]
ethanolamine	1	1389 ± 146	159 ± 49	1230 ± 169
	15	1486 ± 151	159 ± 49	1327 ± 185
APTES	1	645 ± 141	118 ± 27	527 ± 163
	15	1009 ± 95	118 ± 27	891 ± 117

[a] Silicon nitride chips were derivatized according to the scheme shown in Figure S6. The concentration of acetal-PEG-NHS was 1 mg/mL (step b in Figure S6). Citric acid (1%, in water, treatment time either 1 or 15 min) was applied for cleavage of the acetal function (step c). The concentration of biotin-IgG was 0.22 mg/mL (step d). [b] The number of biotin-IgG molecules per μm^2 (specific sites) was estimated from the difference in EAP binding, measured in the absence (total sites, step f) and in the presence of free D-biotin (nonspecific sites, step e).

Table 3. Comparison of Different Methods for Blocking of Unused Aldehyde Functions (citric acid method).[a]

blocking method	Tween 20[d]	total sites (μm^{-2}) [e]	nonspecific sites (μm^{-2}) [e]	specific sites (μm^{-2}) [e]
none	-	933 ± 133	142 ± 39	791 ± 92
	+	898 ± 344	96 ± 17	802 ± 344
ethanolamine [b]	-	775 ± 24	146 ± 28	629 ± 37
	+	715 ± 107	138 ± 26	577 ± 110
glycine [c]	-	1053 ± 345	81 ± 12	972 ± 345
	+	865 ± 146	90 ± 32	775 ± 149

[a] Silicon nitride chips were derivatized according to the scheme shown in Figure S6. APTES was used for amino-functionalization of the silicon nitride chips (step a in Figure S6). The concentration of acetal-PEG-NHS was 1 mg/mL (step b). Citric acid (1%, in water, 15 min) was used for cleavage of the acetal function (step c). The concentration of biotin-IgG was 0.15 mg/mL (step d). [b] Ethanolamine hydrochloride (0.05 volumes of a 1 M stock solution, adjusted to pH 9.6 with NaOH) or [c] glycine (0.05 volumes of a 1 M stock solution, adjusted to pH 8.3 with NaOH) was added to the biotin-IgG solution on the AFM tips after 1 h incubation and allowed to react for 10 min (step f in Figure S5). [d] The minus or plus signs indicate absence or presence of Tween 20 (0.1%) during incubation with EAP. In any case, Tween 20 was used in the subsequent washing steps. [e] The number of biotin-IgG molecules per μm^2 (specific sites) was estimated from the difference in EAP binding, measured in the absence (total sites, step f in Figure S6) and in the presence of free *d*-biotin (nonspecific sites, step e in Figure S6).

coating of which has been observed damaged to variable degrees by treatment with 1% citric acid (data not shown). MAC levers are indispensable for simultaneous "topography and recognition imaging" (TREC). In the so-called TREC mode, a biofunctionalized tip is magnetically oscillated near its resonance frequency while rapidly scanning the sample surface. Hereby, topographic features dampen the downward amplitudes of tip oscillation, while recognition of a target molecule on the sample surface by a tip-bound sensor molecule causes stretching of the PEG linker between the tip and the sensor molecule, which dampens the upward amplitudes of tip oscillation. Consequently, the envelope of the lower amplitudes yields the topographic image (Figure 5B), while the envelope of the upper amplitudes yields a map of recognition sites (Figure 5C). A more detailed explanation of the TREC imaging method can be found at the end of the Supporting Information.

Given the poor resistance of the magnetic coating of MAC levers to 1% citric acid, the new tip functionalization protocol with acetal-PEG-NHS cannot be applied to tips used for recognition imaging, and the older method with aldehyde-PEG-NHS must be used instead.[38] Nevertheless, the present study provides for a major improvement of the older method, albeit in an indirect way. Figure 2 depicts a new route for the synthesis of the old linker aldehyde-PEG-NHS (steps a, d, and e). Previously, the old linker was prepared by reaction of NH_2-PEG-COOH with succinimidyl formylbenzoate (SFB, step c). Unfortunately, SFB has two amino-reactive ends, thus several side products are formed in the reaction with NH_2-PEG-COOH which are difficult to remove and cause low yields of aldehyde-PEG-COOH. No such problem is encountered when reacting the new module SDMB with NH_2-PEG-COOH (step a) because it possesses only one amino-reactive group. Consequently, the yield of acetal-PEG-COOH is high and the intermediate is obtained in good yield. Cleavage of the acetal function (step d) and activation of the terminal carboxyl (step e) are also simple, thus the old linker aldehyde-PEG-NHS is obtained in high yield from the valuable starting material NH_2-PEG-COOH.

For the "proof of principle", the binding of ATP to the mitochondrial uncoupling protein, UCP1, was studied.[59] UCP1 is an anion transporter, which dissipates the mitochondrial inner membrane proton gradient and can be inhibited by di- or triphosphate nucleotides. Although some plausible models were proposed (for review, see Krauss et al.[60]), the exact mechanism of UCP1 inhibition remains unknown. In the absence of the protein crystallographic structure, the studies using tip-tethered ATP molecules are a powerful tool to elucidate different parameters of ATP-UCP interaction, such as location of the nucleotide binding site inside the membrane and a binding force of the nucleotide-protein interaction. The latter is a subject of our subsequent study.

The newly synthesized "old linker" acetal-PEG-NHS was used for flexible attachment of an ATP derivative to a MAC lever, as depicted in Figure 5A (for details, see Supporting Information). The functionalized tip was scanned over a mica-supported phospholipid bilayer which contained purified UCP1. The individual UCP1 molecules were nicely visible as round structures of defined size in the topographic image (Figure 5B). The specific recognition of the ATP-binding sites is mirrored in the recognition image (Figure 5C) of the TREC mode. For the competitive blocking of ATP-binding sites in the control experiment, 4.8 mM of free ATP was added to the buffer solution before scanning. Figure 5D shows that the protein spots in the

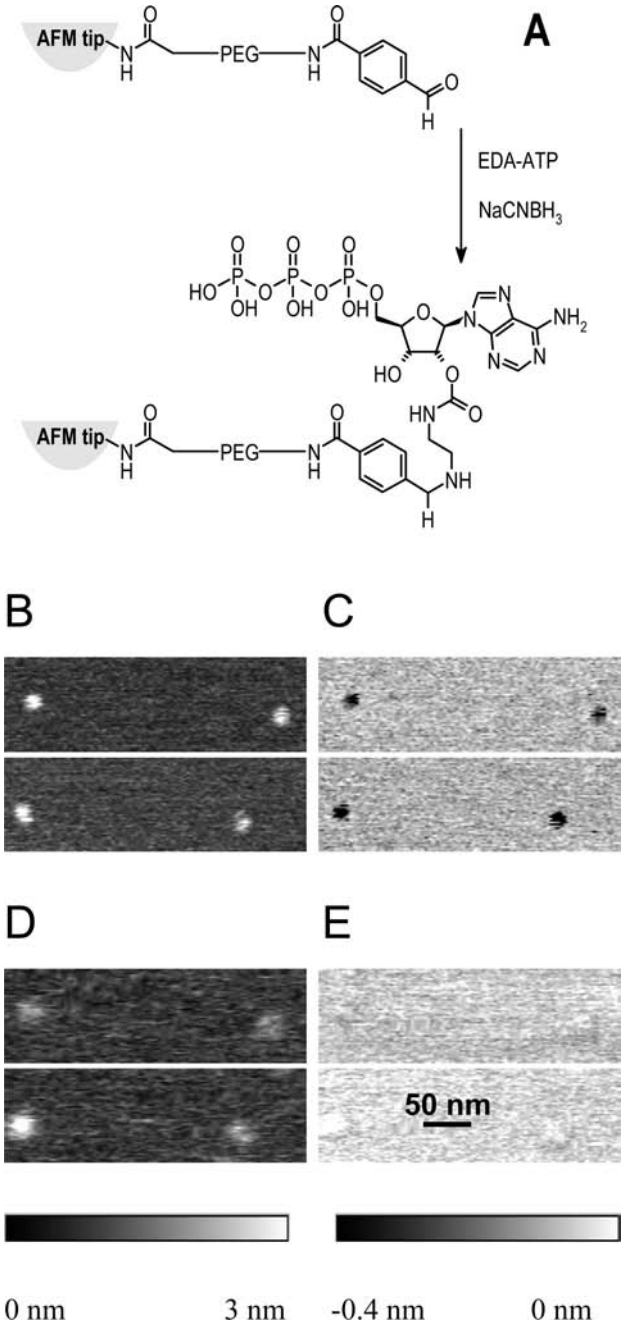

Figure 5. Topographic and recognition imaging of uncoupling protein 1 (UCP1) in planar supported bilayer with an ATP-functionalized AFM tip. (A) Reaction of tip-PEG-aldehyde with an ethylene diamine derivative of ATP (EDA-ATP) with concomitant reduction of the C═N bond by $NaCNBH_3$. Topographic images (B) and simultaneously acquired recognition images (C) of two different bilayer patches (top and bottom strip) in the absence of free ATP. Topographic images (D) and simultaneously acquired recognition images (E) of the same sample areas as in (B) and (C) after the addition of free ATP (final concentration 4.8 mM).

topographic image persisted, whereas only very dim shadows with the opposite amplitude were observed in the recognition image (Figure 5E), revealing the tiny amplitude of the spillover from the topographic image into the recognition image. The complete loss of the recognition after addition of free ATP (Figure 5E) clearly confirms that all recognition spots in Figure 5C were caused by specific binding of tip-linked ATP to UCP1 molecules in the planar lipid membrane.

CONCLUSIONS

The present study offers an uncompromised and simple solution to the nontrivial problem of linking the NH_2 groups of biomolecules to the NH_2 groups of amino-functionalized AFM tips. In contrast to previous methods, a bifunctional linker with a single amino-reactive end is used which is reacted with all available NH_2 groups on the tip surface. Subsequently, the free-tangling end of the PEG linker is converted into an amino-reactive aldehyde function which provides for coupling of sensor molecules via their NH_2 functions. In this way, the undesired cross-linking of adjacent NH_2 functions on the tip surface is perfectly avoided. The method is particularly suited for proteins, which are usually abundant in lysine residues. Other obvious applications are synthetic oligonucleotides with NH_2 groups on their 5′ or 3′ end, as well as small biomolecules or drugs with endogenous or artificially introduced amino functions.

The only weak point of the new tip functionalization protocol is the adverse effect of the acetal-to-aldehyde conversion step on the magnetic coating of cantilevers which are needed for fast imaging of recognition sites on the sample surface. Such cantilevers must be functionalized with the old linker aldehyde-PEG-NHS. Nevertheless, this older method has also profited from the present study because a simpler and more efficient synthesis route to aldehyde-PEG-NHS was found. The experiments with reconstituted UCP1 demonstrate a great application potential of recognition force microscopy for the functional studies of biomolecules which is not easily gained from other techniques.

PART 1

SYNTHESES OF CROSSLINKERS

Materials listed in the Supporting Information only. 4-Formylbenzoic acid and NHS were obtained from Aldrich. Ninhydrine was purchased from Merck. DCC and TSTU were obtained from Fluka. PEG_{18} diamine was purchased from Polypure (Norway).

Thin layer chromatography. Merck plastic sheets (silica gel 60) with fluorescent indicator were used for TLC. Eluents I, II, and III contained 70 parts of chloroform, 30 parts of methanol, and 4 parts of concentrated ammonia, or water, or acetic acid, respectively. Eluent IV contained 8 parts of chloroform and 2 parts of methanol. Acetal-protected and unprotected benzaldehyde residues were selectively detected as dark spots on plates with fluorescent indicator when illuminating at 254 nm. Amino groups were specifically stained with ninhydrine (0.1% ninhydrine and 2% acetic acid in 1-butanol) and heating to 120°C. All other components were visualized in iodine vapor.

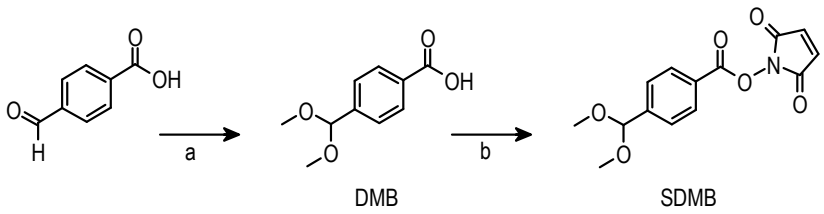

Figure S1. Synthesis of DMB (a, methanol/NH_4Cl) and SDMB (b, DCC/NHS).

Synthesis of 4-(Dimethoxymethyl)-benzoic Acid (DMB). The product was synthesized as described [Roberts et al., 2003], with slight modifications. 4-Formylbenzoic acid (2 g, 13.3 mmol) was dissolved in dry methanol (40 mL, pre-dried with 3 Å molecular sieves) and NH_4Cl (4 g, 74.8 mmol) was added. The reaction mixture was heated under reflux for 20 h. For maximization of the degree of acetalization, 3Å molecular sieves (~5 g) were added and the reaction mixture heated under reflux for an additional 2 h. The solid material was removed by filtration and the mixture was taken to dryness. The residue was dissolved in chloroform and the solution was filtered again. The solvent was removed and the product was recrystallized from n-hexane/chloroform (v/v, 3/1), filtered while still hot, and allowed to crystallize overnight (10 °C), yielding 1.83 g (9.33 mmol) product. According to TLC, the recrystallized product (R_f^{IV} = 0.4) appeared to contain a small fraction educt (R_f^{IV} = 0.2). However, no aldehyde signal was seen in the NMR spectrum. This finding suggests that the product was partially deprotected on the TLC plate. ^{1}H-NMR (200 MHz, $CDCl_3$) δ (ppm): 3.36 (6H, s, C***H***$_3$-O-) 5.48 (1H, s, -C***H***-(O-CH_3)$_2$) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.58 (2H, d, J = 8.4 Hz, H3 and H5 of aromatic ring, next to the acetal function) 8.14 (2H, d, J = 8.4 Hz, H2 and H6 of the aromatic ring, next to the COOH group).

Synthesis of *N*-Succinimidyl 4-(dimethoxymethyl)-benzoate (SDMB). DMB (1.33 g, 6.8 mmol) and hydroxysuccinimide (806 mg, 7 mmol) were dissolved in THF (25 mL, dried over basic Al_2O_3) and the solution was cooled using an ice bath. A solution of DCC (1.40 g, 6.8 mmol) in THF (10 mL) was added drop wise under argon while stirring. After 2 hours the ice-bath was removed and the reaction mixture was allowed to react overnight at RT. The supernatant was filtered and taken to dryness. The oily residue was dissolved in DCM, filtered, taken to dryness, and recrystallized from 2-propanol to yield 1.34 g (4.6 mmol) product which was pure by TLC (R_f^{IV} = 0.83), except for a trace of free acid (R_f^{IV} = 0.4). ^{1}H-NMR (200 MHz, $CDCl_3$) δ (ppm): 2.90 (4H, s, NHS) 3.32 (6H, s, C***H***$_3$-O-) 5.46 (1H, s, -C***H***=(O-CH_3)$_2$) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.60 (2H, d, J = 8.4 Hz, H3 and H5 of aromatic ring, next to the acetal function) 8.13 (2H, d, J = 8.4 Hz, H2 and H6 of the aromatic ring, next to the COOH group).

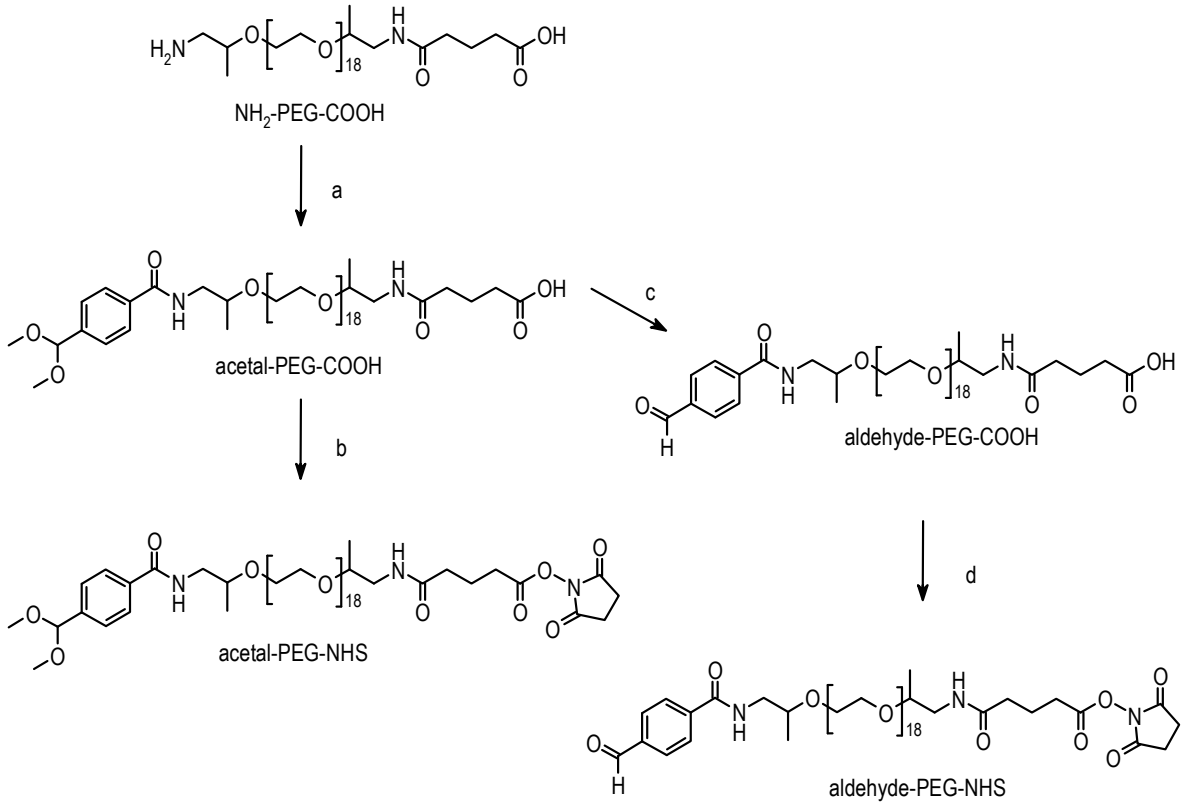

Figure S2. Synthesis of acetal-PEG-NHS and aldehyde-PEG-NHS. a: SDMB/chloroform/TEA, b: DMF/pyridine/TSTU, c: citric acid/water, d: DMF/pyridine/TSTU. According to the manufacturer of NH_2-PEG-NH_2, the molecular mass of the PEG chain was 800 g/mol. Mass spectrometry revealed the chain length distribution was n = 18 ± 4 [51].

Synthesis of α-{2-[4-(Dimethoxymethyl)-benzoyl]-aminopropyl}-ω-{2-[4-carboxy-butanoylamido]-propyl}-poly(oxyethylene)-800 (acetal-PEG-COOH). NH_2-PEG-COOH (503.10 mg, 471.38 µmol) was dissolved in chloroform (6.5 mL) and SDMB (247.80 mg, 845.36 µmol, dissolved in a minimal volume of chloroform) was added, followed by addition of TEA (232 µl, 1,68 mmol). The progress of the reaction was monitored by TLC in eluent III. When all ninhydrine-positive educt had been consumed, the solvent was removed and the residue was dissolved in methanol (5 mL). The solution was filtered and loaded on a size exclusion column (Sephadex^{TM} LH-20, 1.5 cm diameter, 97 cm bed height, solvent methanol, flow 0.4 mL/min). Fractions of 3.2 mL were collected and analyzed by TLC in Eluent II. Product fractions were combined, taken to dryness and dried under vacuum over night, yielding 570,3 mg (468.4 µmol, acetal-PEG-COOH) of viscous product which was pure by TLC (iodine: $R_f{}^{I'} = 0.56$, $R_f{}^{II} = 0.70$, $R_f{}^{III} = 0.74$, ninhydrine: $R_f{}^{II} = 0.70$, $R_f{}^{III} = 0.74$). ^{1}H NMR (200 MHz, $CDCl_3$) δ (ppm): 1.04-1.36 (10 H, m, NH_2-CH<(C***H***$_3$)-CH_2-O and NH_2-CH<(C***H***$_2$-C***H***$_3$)-CH_2-O of PEG_{800}) 1.92 (2 H, quin, J = 6.8 Hz, CO-CH_2-C***H***$_2$-CH_2-CO, position β' in glu) 2.28 (2 H, t, J = 7 Hz, NH-CO-C***H***$_2$-CH_2-CH_2-COOH, position γ' in glu) 2.38 (2 H, t, J = 6.7 Hz, NH-CO-CH_2-CH_2-C***H***$_2$-COOH, position α' in glu) 3.29 (6 H, s, (C***H*****$_3$**-O)$_2$-CH-)) 3.39-3.51 (6 H, m, N-C***H***<(CH_3)-C***H***$_2$-O and N-C***H***<(CH_2-CH_3)-C***H***$_2$-O of PEG_{800}) 3.63 (72 H, s, O-C***H***$_2$-C*H*$_2$-O, 18 ethylene glycol units) 5,41 (1 H, s, -C***H***=(O-CH_3)$_2$) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.50 (2°H, d, J = 8.2 Hz, ***H3*** and ***H5*** of aromatic ring) 7.80 (2 H, d, J = 8.2 Hz, ***H2*** and ***H6*** of aromatic ring).

Synthesis of α-{2-[4-(Dimethoxymethyl)-benzoyl]-aminopropyl}-ω-{2-[4-(*N*-succinimidyloxycarbonyl)-butanoylamido]-propyl}-poly(oxyethylene)-800 (acetal-PEG-NHS). Acetal-PEG-COOH (570.3 mg, 468 µmol) was dissolved in DMF (6 mL) and pyridine (3 mL) and TSTU (216 mg, 717 µmol) was added. After 2 h of stirring at RT, the mixture was taken to dryness. The residue was dissolved in a mixture of chloroform (50 ml) and methanol (10 mL), stirred for 20 min, the solid material was removed by filtration, and additional chloroform (40 mL) was added. The solution was swirled with cold buffer A (100 mM NaCl, 50 mM NaH_2PO_4, 1 mM EDTA, pH 7.5 adjusted with NaOH) for 2 min (2 × 100 mL). It was washed with water (3 × 40 mL), dried with as little Na_2SO_4 as was required to clarify the solution, and filtered through paper. The organic solvents were removed and the residue dried at 1-10 Pa overnight yielding 510.9 mg (393.6 µmol) of product which was pure by TLC (iodine: $R_f{}^{I} = 0.66$, $R_f{}^{II} = 0.68$, $R_f{}^{III} = 0.65$). ^{1}H NMR (200 MHz, $CDCl_3$) δ (ppm): 1.04-1.36 (10 H, m, NH_2-CH<(C***H***$_3$)-CH_2-O and NH_2-CH<(C***H***$_2$-C***H***$_3$)-CH_2-O of PEG_{800}) 2.08 (2 H, quin, J = 6.8 Hz, CO-CH_2-C***H***$_2$-CH_2-CO, position β' in glutaryl residue) 2.28 (2 H, t, J = 6.6 Hz, NH-CO-C***H***$_2$-CH_2-CH_2-COOH, position γ' in glutaryl residue) 2.68 (2 H, t, J = 6.8 Hz, NH-CO-CH_2-CH_2-C***H***$_2$-COOH, position α' in glutaryl residue) 2.85 (4 H, s, CO-C***H***$_2$-C***H***$_2$-CO of succinimidyl group) 3.32 (6 H, s, (C***H*****$_3$**-O)$_2$CH-)) 3.49-3.51 (6 H, m, N-C***H***<(CH_3)-C***H***$_2$-O and N-C***H***<(CH_2-CH_3)-C***H***$_2$-O of PEG_{800}) 3.63 (72 H, s, O-C***H***$_2$-C***H***$_2$-O, 18 ethylene glycol units) 5.41 (1 H, s, -C***H***=(O-CH_3)$_2$) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.50

(2°H, d, J = 8.2 Hz, ***H3*** and ***H5*** of aromatic ring) 7.80 (2 H, d, J = 8.2 Hz, ***H2*** and ***H6*** of aromatic ring).

Synthesis of α-{2-[4-Formylbenzoyl]-aminopropyl}-ω-{2-[4-carboxybutanoyl-amido]-propyl}-poly(oxyethylene)-800 (aldehyde-PEG-COOH). Acetal-PEG-COOH (736.4 mg, 591 µmol) was dissolved in acetone (30 mL) under argon, iodine (30 mg) was added and the solution was allowed to stir for 10 min. For removal of iodine the acetone fraction was mixed with water (50 mL) and washed with toluene (3 x 50 mL). The aqueous layer was taken to dryness and the residue dried at 1-10 Pa overnight yielding 679.4 mg (580 µmol) of product which was pure by TLC (iodine: R_f ^{II} = 0.59). ^{1}H NMR (200 MHz, $CDCl_3$) δ (ppm): 1.04-1.26 (10 H, m, NH_2-CH<(C***H***$_3$)-CH_2-O and NH_2-CH<(C***H***$_2$-C***H***$_3$)-CH_2-O of PEG_{800}) 1.96 (2 H, quin, *J* = 6.6 Hz, CO-CH_2-C***H***$_2$-CH_2-CO, position β' in glutaryl residue) 2.27 (2 H, t, J = 6.8 Hz, NH-CO-C***H***$_2$-CH_2-CH_2-CO-NH, position γ' in glutaryl residue) 2.40 (2 H, t, J = 6.7 Hz, NH-CO-CH_2-CH_2-C***H***$_2$-CO-NH, position α' in glutaryl residue) 3.33-3.52 (6 H, m, N-C***H***<(CH_3)-C***H***$_2$-O and N-C***H***<(CH2-CH_3)-C***H***$_2$-O of PEG_{800}) 3.66 (72 H, s, O-C***H***$_2$-C**H**$_2$-O, 18 ethylene glycol units) 4.04-4.44 (2 H, broad s, CO-N***H***-CH<(C)-CH_2-O of PEG_{800}) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.9-8.3 (4 H, m, aromatic ring) 10.09 (1 H, s, aldehyde). As a more convenient alternative to iodine/acetone, the acetal function was hydrolyzed with 1% citric acid (in water, 10 min, room temperature) in a parallel batch, whereupon the product was extracted into chloroform. The chloroform solution was washed with brine, dried with Na_2SO_4, filtered, and taken to dryness, yielding pure aldehyde-PEG-COOH, as well.

Synthesis of α-{2-[4-Formylbenzoyl]-aminopropyl}-ω-{2-[4-(*N*-succinimidyloxy-carbonyl)-butanoylamido]-propyl}-poly(oxyethylene)-800 (aldehyde-PEG-NHS). The synthesis of aldehyde-PEG-NHS followed the same protocol as the synthesis of acetal-PEG-NHS (see above) yielding a viscous product which was pure by TLC (iodine: R_f $^{I'}$ = 0.05, 0.68, R_f ^{II} = 0.70, R_f ^{III} = 0.66). ^{1}H NMR (200 MHz, $CDCl_3$) δ (ppm): 1.04-1.26 (10 H, m, NH_2-CH<(C***H***$_3$)-CH_2-O and NH_2-CH<(C***H***$_2$-C***H***$_3$)-CH_2-O of PEG_{800}) 2.08 (2 H, t, J = 6.6 Hz, CO-CH_2-C***H***$_2$-CH_2-CO, position β' in glutaryl residue) 2.26 (2 H, t, J = 6.8 Hz, CO-CH_2-C***H***$_2$-CH_2-CO, position γ' in glutaryl residue) 2.68 (2 H, t, J = 7.0 Hz, NH-CO-C***H***$_2$-CH_2-CH_2-CO-NH, position α' in glutaryl residue) 2.85 (4 H, s, CO-C***H***$_2$-C***H***$_2$-CO of succinimidyl) 3.33-3.58 (6 H, m, N-C***H***<(CH_3)-C***H***$_2$-O and N-C***H***<(CH_2-CH_3)-C***H***$_2$-O of PEG_{800}) 3.66 (72 H, s, O-C***H***$_2$-C*H*$_2$-O, 18 ethylene glycol units) 3.95-4.15 (2 H, broad s, CO-N***H***-CH<(C)-CH_2-O of PEG_{800}) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.9-8.3 (4 H, m, aromatic ring) 10.09 (1 H, s, aldehyde).

Synthesis of *α,ω-bis*-{2-[4-(Dimethoxymethyl)-benzoyl]-aminoethyl}-octadeca(oxyethylene) (acetal-PEG$_{18}$-acetal). PEG_{18} diamine (466 mg, 0.52 mmol) was dissolved in 6 mL chloroform and stirred under argon atmosphere. SDMB (245 mg, 0.84 mmol) and TEA (230 µL, 1.65 mmol) were added, and stirring was continued at room temperature under argon atmosphere. After 2 h the mixture was taken to dryness at the

rotavap, the residue was dissolved in methanol (5 mL) and subjected to chromatography on Sephadex LH-20 in methanol (column dimensions 1.5 cm × 95 cm, flow 0.4 mL/min, fraction size 3.2 mL). Elution of the product was detected by TLC in eluent II. The fractions containing pure product were combined and taken to dryness, yielding 570 mg (0.45 mmol). ^{1}H-NMR (200 MHz, $CDCl_3$) δ (ppm): 3.30 (12 H, s, C***H*****$_3$**-O-) 3.61 (80 H, broad s, PEG chain, including the two terminal O-C***H*****$_2$**-C***H*****$_2$**-NH- groups) 5.40 (2 H, s, -C***H***=(O-CH_3)$_2$) 6.98 (2 H, broad s, N***H***) 7.48 (2 H, dd, J_1 = 8.2 Hz, J_2 = 1.4 Hz, ***H3*** and ***H5*** of both aromatic residues) 7.26 (s, trace of C***H***Cl_3 in $CDCl_3$) 7.80 (2 H, dd, J_1 = 8.2 Hz, J_2 = 1.4 Hz, ***H2*** and ***H6*** of both aromatic residues).

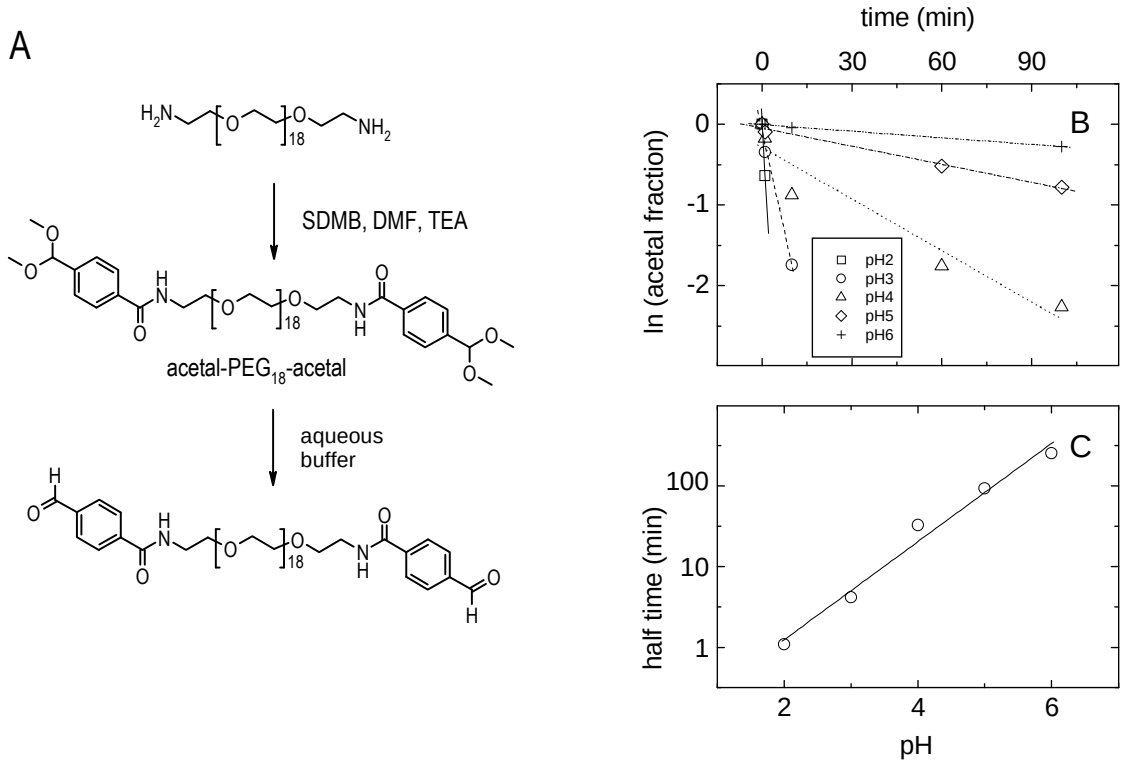

Figure S3. Synthesis of "acetal-PEG_{18}-acetal" and kinetics of acetal cleavage at different pH values. (A) PEG_{18} diamine was derivatized with SDMB on both amino functions (see above). (B) The time course of acetal cleavage at a given pH value was measured by dissolving 100 mg of acetal-PEG_{18}-acetal in 10 mL aqueous buffer (prepared by adjusting 5% citric acid to the specified pH with NaOH) and removing 1 mL aliquots at defined time intervals. The PEG components of the aliquot were extracted into chloroform. The chloroform solution was dried with Na_2SO_4, filtered, and taken to dryness and redissolved in $CDCl_3$. The change in the acetal content was calculated from the decrease of the methoxy signal (3.30 ppm) relative to the PEG signal (3.61 ppm) in the ^{1}H-NMR spectrum. The time courses were fit to monoexponential functions (lines in panel B) and the resulting half times are shown as a function of pH (panel C).

PART 2

KINETICS OF ACETAL CLEAVAGE BY ACID IN WATER

Figure S3 describes a series of experiments in which the pH dependence of acetal cleavage was studied under controlled conditions. The logic model compound for such a study would have been "acetal-PEG-COOH" (see Figure S2). Unfortunately, large amounts of this valuable compound would have been destroyed in the five time series at different pH values (Figure S3B), therefore "acetal-PEG_{18}-acetal" was prepared as a cheaper substitute (Figure S3A). Five different citric acid buffers were prepared by 5% citric acid (pH 1.9, see Figure S4) to pH 2, 3, 4, 5, or 6 with concentrated NaOH. For each time series, acetal-PEG-acetal was dissolved in the corresponding buffer to start the acetal cleavage process at the defined pH value. Aliquots were removed at different time intervals and the cleavage process was terminated by instantaneous partitioning of all PEG components into chloroform and the extent of acetal cleavage was calculated from the ^{1}H-NMR spectrum (see legend to Figure S3). The time series data were fit to monoexponential decay functions (shown in a linearized form in Figure S3B) and the corresponding half times were plotted as a function of pH (Figure S3C).

It is interesting to compare the results obtained with acetal-PEG-acetal (Figure S3) with the kinetics of acetal cleavage observed for free acetal-PEG-COOH (Figure S2) in 1% citric acid. According to Figure S4, an aqueous solution of citric acid (1%) has a pH value of 2.2. When synthesizing aldehyde-PEG-COOH from acetal-PEG-COOH (Figure S2), we regularly performed acetal cleavage by 10 min treatment in 1% citric acid. The ^{1}H-NMR spectrum of the resulting product was completely free from any trace of the methoxy signal (3.30) ppm, in spite of the fact that this 6-proton singlet is particularly sharp and intense. Consequently, we estimate that treatment with 1% citric acid cleave at least 99.6% of the acetal functions within 10 min. In a monoexponential time course, 99.6% turnover is reached after 8 half times. Consequently, a maximal half time of 10/8 = 1.25 min is calculated for the 10 min treatment of acetal-PEG-COOH. This estimate agrees reasonably well with the half time of 1.6 min interpolated in Figure S3C for cleavage of acetal-PEG_{18}-acetal in 5% citric acid (adjusted to pH 2.2 with NaOH). The minor discrepancy may relate to slight differences in the buffer systems and in the molecular structures.

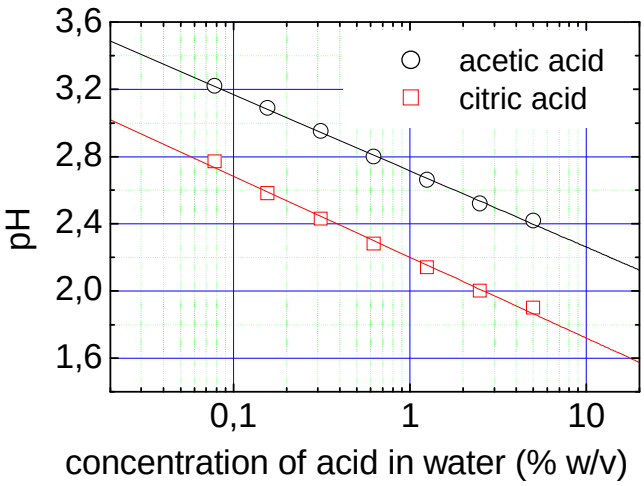

Figure S4. Dependence of pH on the concentration of unbuffered citric acid or acetic acid in pure water.

PART 3

ILLUSTRATIONS OF TIP / CHIP FUNCTIONALIZATION WITH ACETAL-PEG-NHS

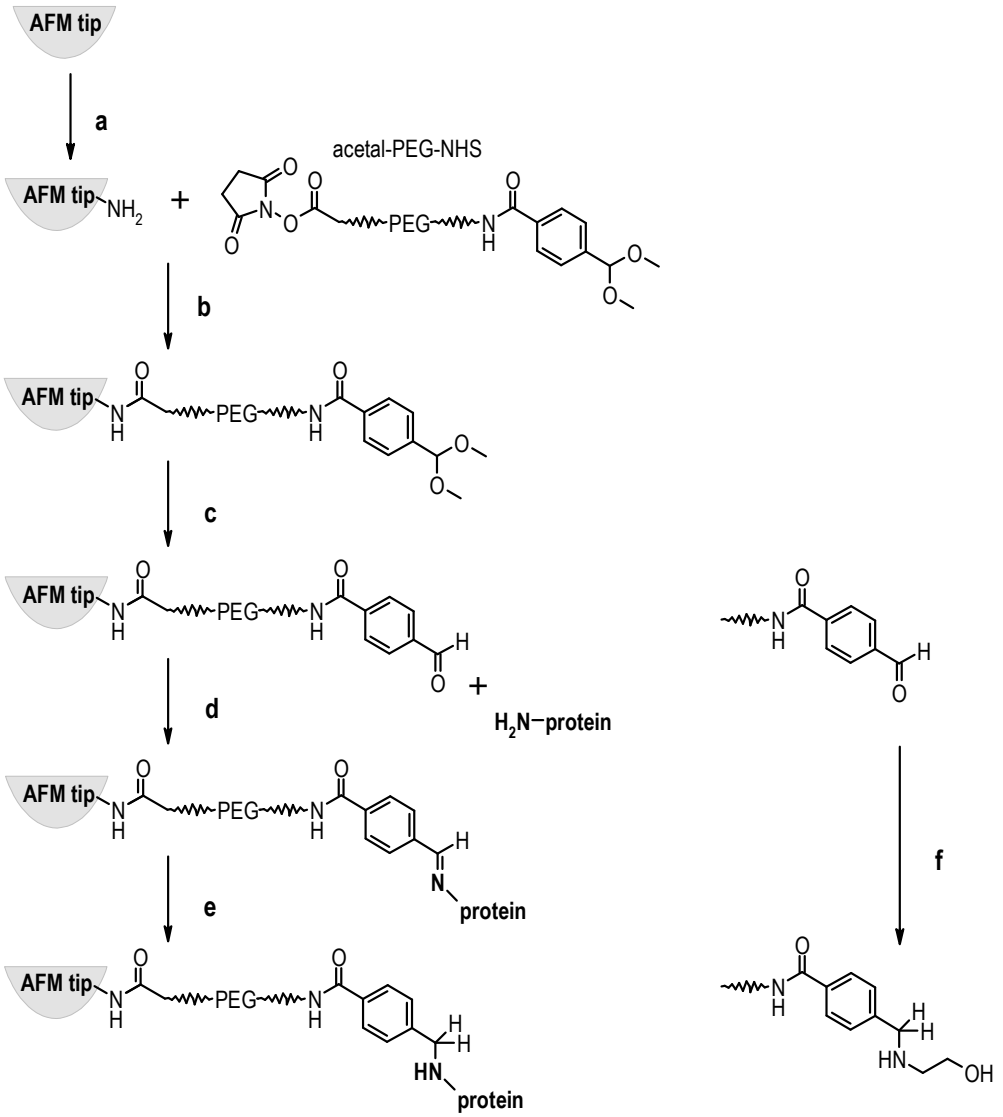

Figure S5. Scheme for tethering of proteins to AFM tips, using of acetal-PEG-NHS as heterobifunctional crosslinker. a) Aminofunctionalization of silicon nitride tip with ethanolamine hydrochloride in DMSO or with APTES in the gas phase. b) Amide bond formation in chloroform with TEA (0.5%). c) Deprotection with 0.1% iodine in acetone (5 min, iodine method) or with 1% citric acid in water (1-15 min, citric acid method). d) Schiff base formation with the lysine residue of a protein (e.g. 0.2 mg/mL antibody) in PBS (pH 7.4). e) Schiff base reduction with $NaCNBH_3$ (20 mM). In practice, step d and e are performed simultaneously since $NaCNBH_3$ is applied together with the antibody (1 h at RT). f) Blocking of unused benzaldehyde functions on the AFM tip by addition of 0.05 volumes of ethanolamine hydrochloride solution (1 M, pH 9.6 pre-adjusted with NaOH) or 0.05 volumes of glycine solution (1 M, pH 8.0 pre-adjusted with NaOH) and incubation for 5 min.

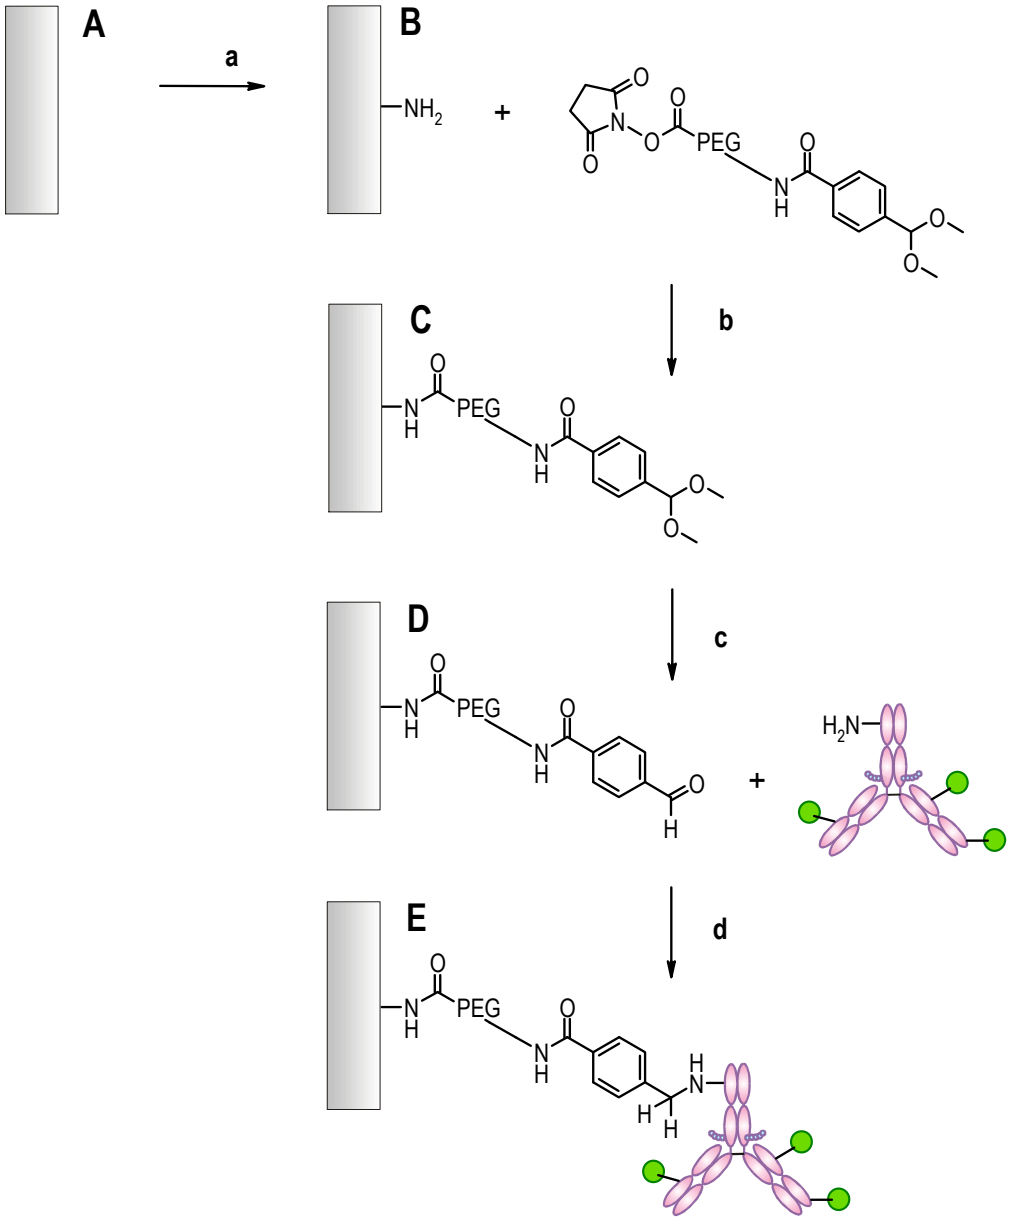

Figure S6. Schematic representation of chip functionalization and characterization. (a) Silicon nitride chips (A) were aminofunctionalized, either with ethanolamine hydrochloride in DMSO or with APTES in the gas phase (B). (b) Aminofunctionalized silicon nitride chips were reacted with acetal-PEG-NHS, resulting in amide-bond linked PEG chains with an acetal function (i.e., a protected aldehyde) on their free end (C). (c) Conversion of the acetal function into an aldehyde function (D) by use of iodine/acetone (0.1%, 5 min) or citric acid/water (1%, 15 min or 1 min, as specified), as stated for particular data. (d) Coupling of protein (biotin-IgG) by Schiff base formation with a lysine residue and concomitant fixation of the C=N double bond by reduction with $NaCNBH_3$ gives a stable C-N single bond (E). Continued on the next page.

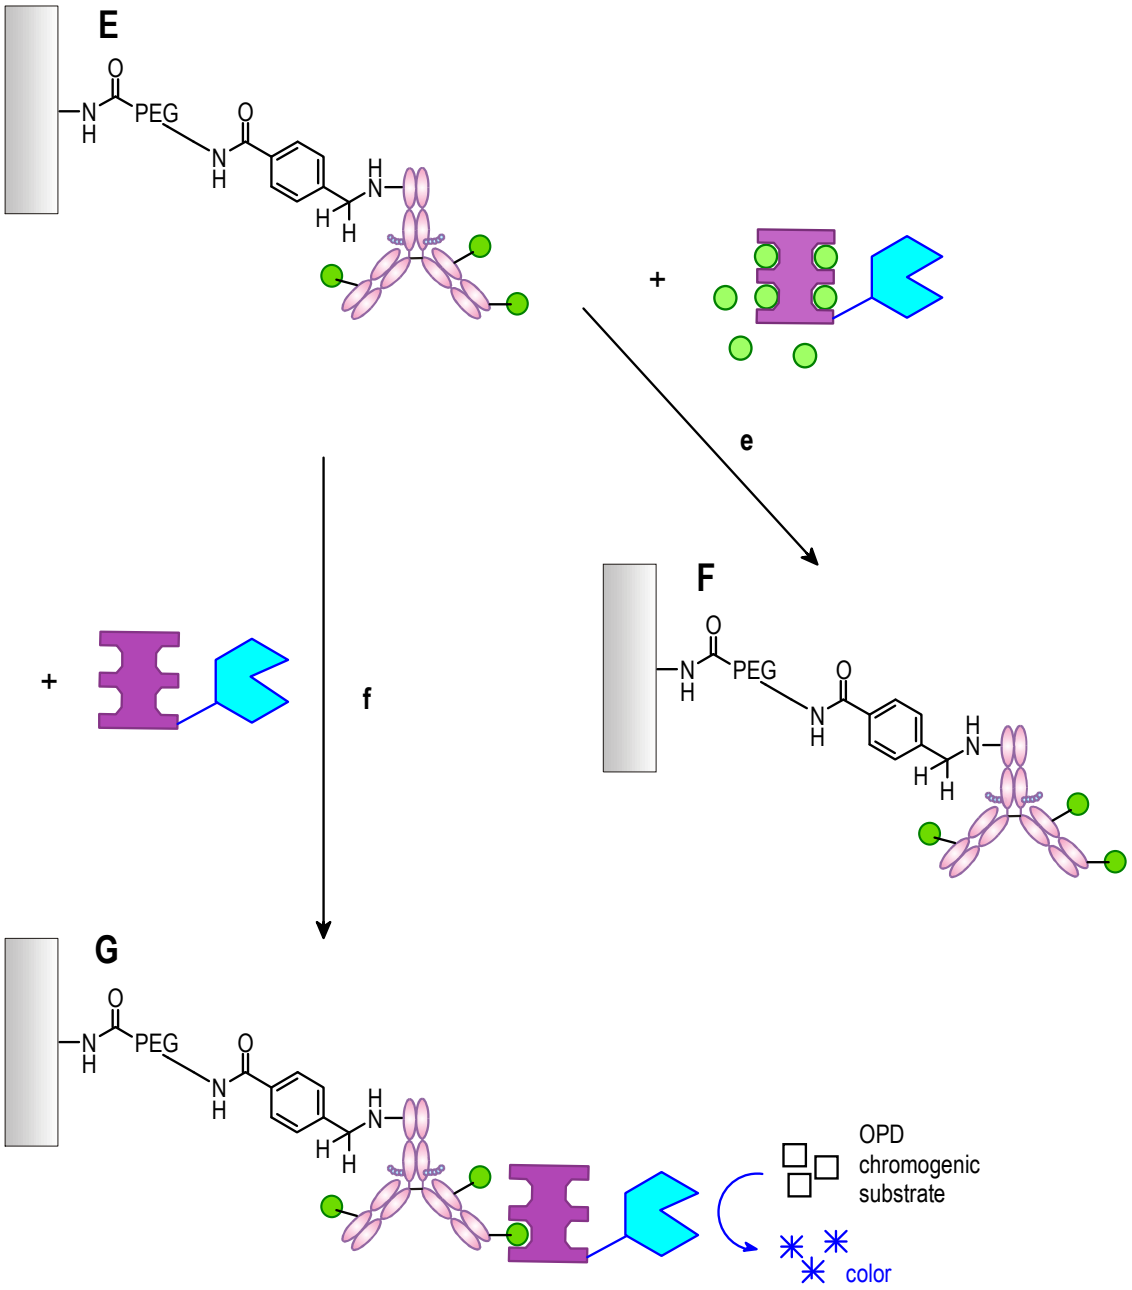

Figure S6 (continued from the previous page). (e) Control experiment for non-specific adsorption of ExtrAvidin®-peroxidase (EAP) to chips carrying biotin-IgG covalently bound via PEG linkers. The biotin-binding sites of EAP were pre-blocked by a large excess of free *d*-biotin, thus EAP cannot bind to immobilized biotin-IgG (F) and only nonspecific adsorption of EAP to the chip can occur. The amount of adsorbed EAP is estimated from the rate of color production, as explained below. (f) In the absence of free *d*-biotin, EAP is bound to the chip both by nonspecific adsorption (not shown) and by specific interaction (stage G). After removal of unbound EAP by washing, a chromogenic substrate is added and the amount of bound enzyme is calculated from the rate of color production [38, 51].

PART 4

TIP FUNCTIONALIZATION WITH ALDEHYDE-PEG-NHS AND EDA-ATP

Magnetically coated cantilevers (MAC levers, Agilent) were functionalized with the ethylene diamine-derivative of ATP (EDA-ATP, 2'-/3'-O-(2-aminoethylcarbamoyl)-adenosine-5'-O-triphosphate, BioLog) by a well established three-step procedure: (i) aminofunctionalization, (ii) attachment of the heterobifunctional polyethylene glycol linker (aldehyde-PEG-NHS, synthesized by the new synthesis route Figure S2acd), and (iii) reaction of "tip-PEG-aldehyde" with the amino group of EDA-ATP, using $NaCNBH_3$ for reduction (fixation) of the initially formed Schiff base conjugate (compare steps d and e in Figure S5).

Commercial MAC® levers were cleaned with chloroform and aminofunctionalized with APTES in the gas phase as described previously [51]. For attachment of aldehyde-PEG-NHS, the cantilevers were put in the solution of the crosslinker in chloroform at a concentration of 6.6 mg/ml. TEA at final concentration of 0.5% was added to deprotonate the amino functions on the tip and ensure amide bond formation. After about 1.5 hours of reaction, the cantilevers were washed in chloroform (3 ×) and dried in air.

Fifty µL aliquots of the commercial EDA-ATP solution (10 mM, in water, from BioLog) were pipetted into Eppendorf reaction vials, and frozen in liquid nitrogen. The vials were placed in a pre-cooled round-bottomed flask which was attached to a cold trap and evacuated at 1-10 Pa, in order to evaporate the water content in the frozen state. For coupling to "tip-PEG-aldehyde", one dried portion of EDA-ATP was redissolved in 9 µL of buffer B (1 mM EDTA and 300 mM NaH_2PO_4, pH adjusted to 7.5 with NaOH) and 1 µL of a 0.2 M solution of $NaCNBH_3$ (freshly prepared by dissolving 32 mg $NaCNBH_3$ in a mixture of 50 µL 100 mM NaOH plus 450 µL water, and diluting with 2 mL buffer B) was added. After mixing, this solution was transferred onto a sheet of clean Parafilm in a polystyrene Petri dish. Several cantilevers were immersed in the 10 µL droplet with their tips and incubated for 1 h. Subsequent deactivation of residual aldehyde functions on the tip was performed by addition of 0.5 µl 1 M ethanolamine hydrochloride solution (pre-adjusted to pH 9.6 with NaOH and stored in small aliquots at -25°C) and incubation for 10 min. The tips were washed 3 times and stored in buffer B treated with argon at 4°C.

The addition of 0.5 µL (0.05 vol) 1 M ethanolamine (pH 9.6) to 10 µL buffer B caused little change in pH. This was demonstrated by mixing 5 mL buffer B with 0.25 mL (0.05 vol) 1 M ethanolamine (pH 9.6) whereby the final pH rose from 7.5 to 7.7. The small extent of the pH change is due to the high phosphate concentration (300 mM) of buffer B. In contrast, regular buffer A does not have sufficient buffering capacity, as shown by mixing of 5 mL buffer A (50 mM phosphate only!) with 0.25 mL (0.05 vol) 1 M ethanolamine (pH 9.6) which gave a final pH of 9.2.

PART 5

RECONSTITUTION OF UCP1 IN PLANAR BILAYER AND RECOGNITION IMAGING WITH ATP-FUNCTIONALIZED TIPS

The coding region of murine Uncoupling protein 1 (UCP1) was amplified by PCR from a mouse EST clone and cloned into the expression vector pET-24a (Novagen, Germany), as described in [Rupprecht et al., 2010]. For protein expression E. coli strain Rosetta (DE3) (Novagen, Germany) was transformed. Inclusion body purification was performed according to the procedures, described previously [Smorodchenko et al., 2009; Rupprecht et al., 2010]. In brief, cells were disrupted by French press and centrifuged to eliminate cell debris. The inclusion bodies were obtained after supernatant centrifugation at 14000 g for 10 min. 2.5 mg protein from inclusion bodies per 100 mg lipid was used for the subsequent UCP1 purification. The inclusion bodies were washed in TRIS/glycerol buffer (100 mM Tris base, 5 mM EDTA, 10% glycerol, pH 7.5) with additional 2 % Triton X-100 first and then with 0.1 % sodium lauryl sulfate (SLS). For solubilization, the inclusion bodies were incubated at room temperature in TRIS/glycerol buffer with 2 % SLS and 1 mM DTT. After centrifugation the supernatant was incubated overnight with the mixture of 100 mg E. coli polar lipid (Avanti Polar Lipids, USA), 400 mg Triton X-114, 100 mg octyl-polyoxyethylene, 1 mM DTT and 1 mM ATP, then concentrated with Amicon Ultra-15 filters (Millipore, Germany) and dialyzed for two hours against TRIS/glycerol buffer supplemented with 1 mg/mL BSA and 1 mM DTT. Two further dialysis cycles were performed without DTT for a minimum of 12 h. Three final dialyses were completed with the assay buffer (see below).

Aggregated proteins were eliminated by centrifugation of the dialysate at 14000 g for 10 min. To eliminate incorrectly folded proteins, the supernatant was run over a column containing 1 g hydroxyapatite (Bio-Rad, Germany) [Lin & Klingenberg, 1980; Lin & Klingenberg, 1982]. For removal of non-ionic detergent, the sample was incubated with Bio-Beads SM-2 (Bio-Rad, Germany) [Rigaud et al., 1995]. The protein content of the obtained proteoliposomes was measured by Micro BCA Protein Assay (Perbio Science, Germany).

The AFM sample plate (Agilent Technologies, USA) with the coil for magnetic field application was covered with a small piece of aluminum foil, the centre of which was marked with a small dot to indicate the cantilever position for the charge-coupled device (CCD) camera. Freshly cleaved mica was placed on the aluminum film and mounted with a flow-through fluid cell. Ten µl stock solution of UCP1 proteoliposomes (with a lipid concentration of 4-5 mg/mL and a protein/lipid ratio of 0.02-0.03) was diluted with 240 µL of assay buffer (50 mM Na_2SO_4, 20 mM MES, 20 mM TRIS, 0.6 mM EDTA, pH 7.2). After short vortexing, the solution was injected into the fluid cell on the mica surface. After incubation for 8 min, the mica surface was thoroughly washed with buffer. Finally, 600 µL buffer was left in the fluid cell for measurements.

Mac-mode AFM imaging was performed using a PicoPlus 5500 AFM (Agilent). Recognition images [8, 9] were simultaneously recorded using the ATP-functionalized cantilever, which was driven by an alternating magnetic field at its resonant frequency. Images were recorded at an amplitude set-point of 2.3-8.4 nm, and with a ratio of 88-97 % to the amplitude observed before the cantilever touched the sample surface. The scanning speed for imaging was 2-4 µm/s. Experiments on the blocking of the recognition were conducted by injecting free ATP solution into the measurement solution at a final concentration of 4.8 mM. Both topography and recognition images were displayed after leveling by mean plane subtraction and scanning line correction (Gwyddion 2.9).

PART 6

EXPLANATION OF SIMULTANEOUS TOPOGRAPHY AND RECOGNITION IMAGING WITH MAGNETICALLY COATED AFM CANTILEVERS.

Topography and recognition imaging (TREC) is based on tapping mode AFM. A magnetic coil mounted either above or below the magnetically coated cantilever generates a sinusoidal oscillation of the cantilever when using a driving frequency which is adjusted to ~0.5 kHz below the resonance frequency of the cantilever. This allows for gentle and noninvasive scanning of the surface which is a prerequisite when using ligand-functionalized cantilevers for imaging purposes. In contrast to the conventional magnetical tapping mode (MAC®-Mode, Agilent), recognition imaging not only yields sample topography but also a simultaneously acquired map of recognition sites. For this purpose, the lower and the upper parts of the cantilever oscillation trace are separated by an electronic circuit which is termed the TREC box [8, 9] (see Figure S7A). The lower parts are only affected by the sample topography and used for the piezo feedback loop, resulting in the topographical image. In the case of a complex formation of a tip-bound ligand with a surface-embedded receptor, changes of the upper parts of the amplitude become observable. An important prerequisite is the stable tethering of the ligand to the tip with a distensible polymer linker. The chain length is typically chosen to be 3-9 nm and the working amplitude of cantilever oscillation is kept smaller than the sum of linker chain length plus the height of the receptor-ligand complex, thereby avoiding a forced rupture of the receptor-ligand complex while scanning above the receptor site [Preiner et al., 2009] A typical example is shown in Figure S7. [Ebner et al., 2005]. Individual avidin molecules were adsorbed to mica and the surface was scanned with a tip carrying a biotin residue via a 6 nm long PEG linker. The height of the avidin molecules resulted in a damping of the lower parts of the amplitude used for driving the piezo feedback loop (Figure S7A, blue trace). In parallel, the formation of an avidin-biotin complex while scanning over avidin hinders the upwards movement in the oscillation and results in a ~1nm lowered upper peak amplitude when using a peak-to-peak amplitude that is smaller than the length of the PEG chain (~6 nm) plus the height of avidin (~4 nm). Changes in the upper part

of the amplitude can directly be translated in recognition signals. As a result TREC allows for mapping of recognition sites simultaneously with gentle imaging of the sample surface, both at high resolution and a fast lateral scan rate.

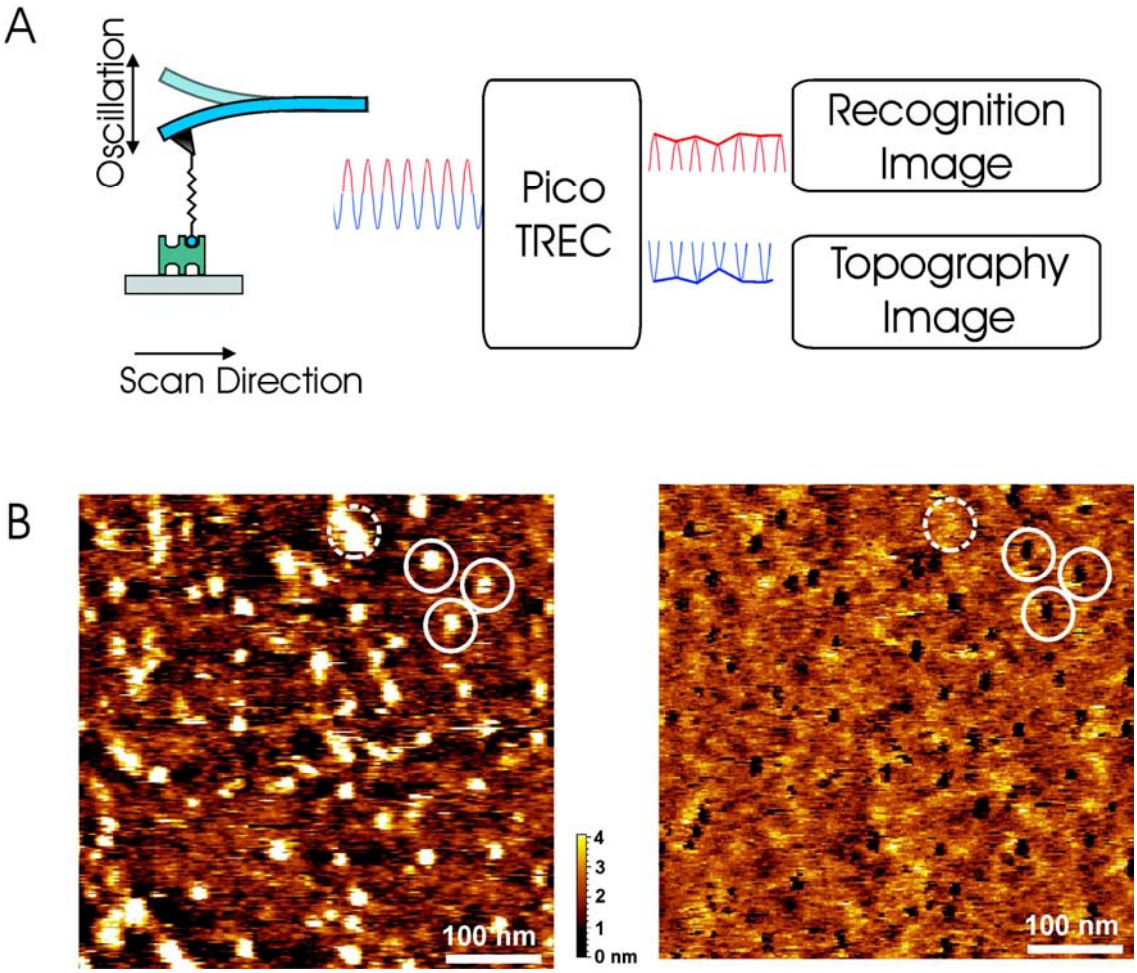

Figure S7. TREC imaging (Ebner et al. 2005). (A) Principle: The cantilever oscillation is split into lower and upper parts, resulting in simultaneously acquired topography and recognition images. (B) Avidin was electrostatically adsorbed to mica and imaged with a biotin-tethered tip. A good correlation between topography (left image, bright spots) and recognition (right image, dark spots) was found (exemplified by the three solid circles). Topographical spots without recognition indicate structures lacking specific interaction (dashed circle). The scan size was 500 nm × 500 nm. Reproduced with permission from [Ebner et al., 2005].

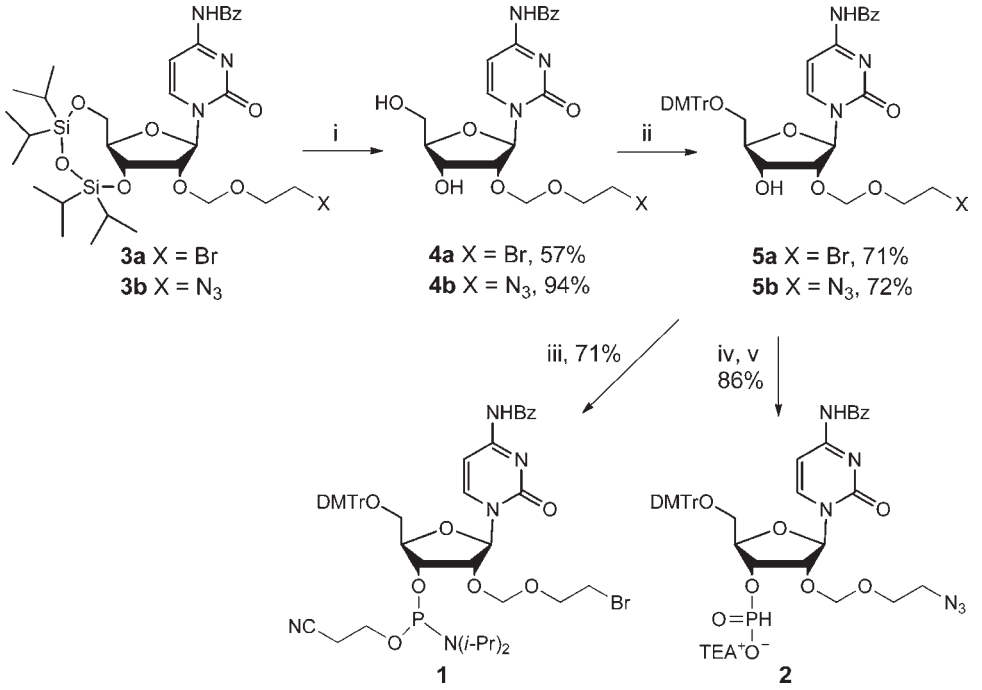
Supporting Information

ABSTRACT: 2′-*O*-[(2-Bromoethoxy)methyl]cytidine and 2′-*O*-[(2-azidoethoxy)methyl]cytidine have been prepared and introduced as appropriately protected 3′-phosphoramidite (**1**) and 3′-(*H*-phosphonate) (**2**) building blocks, respectively, into 2′-*O*-methyl oligoribonucleotides. The support-bound oligonucleotides were subjected to two consecutive conjugations with alkynyl-functionalized monosaccharides. The first saccharide was introduced by a Cu(I) promoted click reaction with **2** and the second by azidation of the 2-bromoethoxy group of **1** followed by the click reaction. The influence of the 2′-glycoconjugations on hybridization with DNA and 2′-*O*-methyl RNA targets was studied. Two saccharide units within a 15-mer oligonucleotide had a barely noticeable effect on the duplex stability, while introduction of a third one moderately decreased the melting temperature.

INTRODUCTION

Among various oligonucleotide conjugates, the 2′-conjugates have received special interest for the reason that upon formation of an A- or B-type duplex, the conjugate group is accommodated in the minor or major grooves, respectively, and hence, the duplex is not markedly destabilized.[1,2] Introduction of reactive functionalities in the 2′-position of nucleosides, incorporation of the resulting monomers into oligonucleotides, and their subsequent reactions with appropriately functionalized conjugate groups has been rather recently reviewed.[3] Somewhat surprisingly, such a stepwise protocol has only once been utilized for solid phase-synthesis of 2′-glycoconjugates, potentially useful for the delivery and targeting of therapeutic oligonucleotides,[4−8] although several procedures for the derivatization of other intrachain positions, including the C4′-position,[9,10] internucleosidic phosphoramidate linkage,[11,12] or intrachain non-nucleosidic units,[13−18] have been described. Very recently,[19] saccharide ligands have been conjugated by Cu(I) promoted click reaction[20,21] to 2′-*O*-(2-propynyl) groups on-support. Otherwise 2′-glycoconjugates have been obtained by converting prefabricated 2′-*O*-glycosyl nucleosides with all four natural heterocyclic bases[22] into phosphoramidite building blocks and introducing them into oligonucleotides on a solid-support.[23−26] The *cis* diol of the 2′-*O*-glycosyl group, when oxidized to dialdehyde with sodium periodate, has been shown to allow affinity labeling of different enzymes.[27−29]

We now report on a solid-supported conjugation method that enables the attachment of two different carbohydrate ligands to the 2′-position at desired sites within the chain. For this purpose, two building blocks, viz. 2′-*O*-[(2-bromoethoxy)methyl]-5′-*O*-(4,4′-dimethoxytrityl)cytidine 3′-(2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite) (**1**) and 2′-*O*-[(2-azidoethoxy)methyl]-5′-*O*-(4,4′-dimethoxytrityl)cytidine 3′-(*H*-phosphonate) (**2**) monomers, were prepared and incorporated into 2′-*O*-methyl oligoribonucleotides. The azido group of the nucleoside units **2** was first subjected to a click reaction,[20,21] with a propynyl functionalized monosaccharide on-support. The bromo substituent of unit **1** was then displaced with azide ion on-support, as shown previously by Pourceau et al.,[14] and another click reaction was carried out. The hybridization efficiency of the conjugates with cDNA- and 2′-*O*-Me-RNA-oligonucleotides was assessed by UV-melting studies and compared to the hybridization of the corresponding unmodified sequence.



EXPERIMENTAL PROCEDURES

General Remarks. Synthetic reactions were monitored by TLC (Merck DC Kieselgel 60F_{254}), using UV light, iodine vapors, or heating with 10% H_2SO_4 (aq) for detection. Column chromatography was performed on Silica gel 60 (Fluka, 0.040−0.063 mm). The NMR spectra were recorded at 400 or 500 MHz. Chemical shifts are given in parts per million (ppm) and measured relative to the solvent signals (^{1}H and ^{13}C). Appropriate 2D NMR methods (COSY and HSQC) were used for peak assignment. Solvents were dried with 4 Å molecular sieves (DCM, pyridine and MeCN) or by distillation and storage over CaH_2 (Et_3N). The mass spectra were recorded using ESI ionization methods. RP HPLC analysis of the oligonucleotide conjugates was performed on a Thermo ODS Hypersil C18 (250 × 4.6 mm, 5 μm) analytical column, applying a gradient elution from 0 to 50% MeCN in

Scheme 1[a]

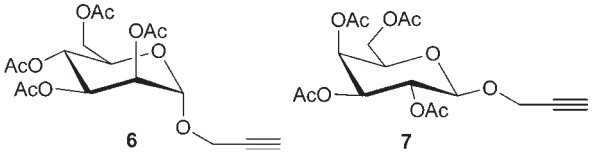
[a] Reagents: (i) Bu_4NF, THF; (ii) DMTrCl, pyridine; (iii) 2-cyanoethyl *N,N*-diisopropylphosphoramidochloridite, Et_3N, DCM; (iv) diphenyl *H*-phosphonate, pyridine; (v) Et_3N, H_2O.

0.1 mol L^{-1} TEAA (aq, Et_3NHOAc) buffer over 60 min, at a flow rate of 1 mL min^{-1}, and detection at 260 nm.

2′-*O*-(2-Bromoethoxymethyl)-*N*^{4}-benzoylcytidine (4a). Nucleoside **3a** (1.30 g, 1.79 mmol), prepared as described earlier,[30] was dissolved in Bu_4NF trihydrate in THF (0.25 mol L^{-1}; 4.8 mL), kept for 10 min at 20 °C, evaporated to dryness, coevaporated with chloroform (2 × 10 mL), and applied onto a column with silica gel (25 g). The column was washed with DCM (100 mL), DCM-EtOH (97:3, v/v), and then eluted with DCM-EtOH (95:5) to obtain **4a** (490 mg, 57%) as a white amorphous foam (Scheme 1). ^{1}H NMR [400 MHz, $CDCl_3/CD_3OD$ (9:1)] δ_{ppm} 8.47 (d, 1H, J = 7.5 Hz, H-6), 7.98−7.40 (m, 6H, Bz, H-5), 5.88 (d, 1H, J = 2.2 Hz, H-1′), 5.02 (d, 1H, J = 6.5 Hz, OCHHO), 4.92 (d, 1H, J = 6.5 Hz, OCHHO), 4.33 (dd, 1H, $J_{2',3'}$ = 5.0 Hz, H-2′), 4.26 (dd, 1H, $J_{3',4'}$ = 7.5 Hz, H-3′), 4.07 (dt, 1H, $J_{4',5'a}$ = $J_{4',5'b}$ = 2.2 Hz, H-4′), 3.99 (dd, 1H, $J_{5'a,5'b}$ = 12.8 Hz, H-5′a), 3.89 (dd, 2H, J = 6.2 Hz, 5.9 Hz, OCH_2CH_2Br), 3.81 (dd, 1H, H-5′b), 3.44 (dd, 2H, OCH_2CH_2Br). ^{13}C NMR ($CDCl_3/CD_3OD$ (9:1)) δ_{ppm} 167.1 (C═O), 163.1 (C-4), 146.0 (C-6), 133.3, 129.0, 128.0 (Ph), 97.3 (C-5), 95.3 (OCH_2O), 90.9 (C-1′), 84.7 (C-4′), 79.9 (C-2′), 68.8 (C-3′), 68.0 (OCH_2CH_2Br), 60.1 (C-5′), 30.5 (OCH_2CH_2Br).

2′-*O*-(2-Azidoethoxymethyl)-*N*^{4}-benzoylcytidine (4b). Analogous to the preparation of **4a**, the desilylation of **3b** (1.12 mg, 1.63 mmol) yielded **4b** (683 mg, 94%) as a white amorphous foam. ^{1}H NMR (400 MHz, $CDCl_3$) δ_{ppm} 8.48 (d, 1H, J = 7.5 Hz, H-6), 8.00−7.40 (m, 6H, Bz, H-5), 5.88 (d, 1H, J = 2.5 Hz, H-1′), 5.03 (d, 1H, J = 6.5 Hz, OCHHO), 4.93 (d, 1H, OCHHO), 4.48 (dd, 1H, J = 5.3 Hz, H-2′), 4.41 (dd, 1H, J = 6.5 Hz, H-3′), 4.16 (ddd, 1H, $J_{4',5'a}$ = 1.9 Hz, $J_{4',5'b}$ = 1.5 Hz, H-4′), 4.08 (dd, 1H, $J_{5'a,5'b}$ = 12.5 Hz, H-5′a), 3.92 (dd, 1H, H-5′b), 3.82−3.71 (m, 2H, $OCH_2CH_2N_3$), 3.46−3.37 (m, 2H, $OCH_2CH_2N_3$). ^{13}C NMR (MHz, $CDCl_3$) δ_{ppm} 167.2 (C═O), 163.1 (C-4), 155.4 (C-2), 146.2 (C-6), 133.3, 129.0, 128.0 (Bz), 97.3 (C-5), 95.5 (OCH_2O), 91.2 (C-1′), 84.9 (C-4′), 79.9 (C-2′), 68.2 (C-3′), 67.4 ($OCH_2CH_2N_3$), 60.4 (C-5′), 50.9 ($OCH_2CH_2N_3$).

2′-*O*-(2-Bromoethoxymethyl)-5′-*O*-(4,4′-dimethoxytrityl)-*N*^{4}-benzoylcytidine (5a). Nucleoside **4a** (357 mg, 0.74 mmol) was dried by coevaporation with pyridine (2 × 20 mL). The residue was dissolved in dry pyridine (10 mL), 4,4′-dimethoxytrityl chloride (351 mg, 1.04 mmol) was added, and the resulted solution was kept in the dark for 16 h at 20 °C. MeOH (1 mL) was added and after 30 min, the mixture was concentrated in vacuo to near dryness. The residue was dissolved in DCM (50 mL) and washed with a 10% aqueous solution of sodium bicarbonate (20 mL) and water (2 × 20 mL). The organic layer was dried over anhydrous Na_2SO_4, the solvent was removed in vacuo, and the residue was coevaporated with toluene (2 × 10 mL) and purified by column chromatography on silica gel (20 g). The column was washed with a mixture of DCM, hexane, and Et_3N (75:23:2, v/v/v, 200 mL), followed by DCM, and the product was eluted with a mixture of DCM and Et_3N (98:2, v/v) to give **5a** (412 mg, 71%) as a foam. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 9.63 (br s, 1H, NH), 8.53 (d, 1H, J = 7.5 Hz, H-6), 8.00−7.94 (m, 2H, Bz), 7.60 (m, 1H, Bz), 7.52−7.46 (m, 4H, Bz, DMTr), 7.41−7.32 (m, 6H, DMTr), 7.29−7.22 (m, 2H, DMTr, H-5), 6.94−6.88 (m, 4H, DMTr), 5.92 (s, 1H, H-1′), 5.17 (d, 1H, J = 6.5 Hz, OCHHO), 4.95 (d, 1H, J = 6.5 Hz, OCHHO), 4.58 (m, 1H, H-3′), 4.38 (d, 1H, J = 5.0 Hz, H-2′), 4.15 (m, 1H, H-4′), 4.00−3.89 (m, 2H, OCH_2CH_2Br), 3.78 (s, 6H, DMTr-OMe), 3.56−3.46 (m, 4H, OCH_2CH_2Br, H-5′). ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 167.2 (Bz-C═O), 163.0 (C-4), 158.8, 158.8 (DMTr), 154.9 (C-2), 144.9 (C-6), 144.5, 136.0, 135.6 (DMTr), 133.5, 132.9 (Bz), 130.2, 130.0 (DMTr), 128.7, 128.3, 128.1, 128.1 (DMTr, Bz), 127.1, 113.3 (DMTr), 96.5 (C-5),



94.3 (OCH_2O), 89.8 (C-1′), 86.8 (DMTr-C_q), 82.6 (C-4′), 78.9 (C-2′), 68.3 (OCH_2CH_2Br), 68.0 (C-3′), 61.2 (C-5′), 55.0 (DMTr-OMe), 31.5 (OCH_2CH_2Br). HRMS(ESI): $[MH]^+$ $C_{40}H_{41}BrN_3O_9$ requires 786.2021, found 786.2019.

2′-*O*-(2-Azidoethoxymethyl)-5′-*O*-(4,4′-dimethoxytrityl)-β-D-*N*⁴-benzoylcytidine (5b). Analogous to the preparation of **5a**, the tritylation of nucleoside **4b** (778 mg, 1.74 mmol) yielded **5b** (940 mg, 72%) as a foam. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 9.29 (br s, 1H, NH), 8.48 (d, 1H, J = 7.5 Hz, H-6), 8.00−7.95 (m, 2H, Bz), 7.66 (m, 1H, Bz), 7.57−7.52 (m, 2H, Bz), 7.51−7.48 (m, 2H, DMTr), 7.41−7.35 (m, 6H, DMTr), 7.30 (m, 1H, DMTr), 7.18 (br d, 1H, J = 6.5 Hz, H-5), 6.96−6.91 (m, 4H, DMTr), 5.91 (d, 1H, J = 1.0 Hz, H-1′), 5.16 (d, 1H, J = 7.0 Hz, OCHHO), 4.94 (d, 1H, J = 6.5 Hz, OCHHO), 4.52 (m, 1H, H-3′), 4.32 (d, 1H, J = 5.0 Hz, H-2′), 4.11 (ddd, 1H, J = 9.0 Hz, 2.5 Hz, 2.5 Hz, H-4′), 3.88−3.76 (m, 8H, DMTr-OMe, $OCH_2CH_2N_3$), 3.53−3.37 (m, 5H, H-5′, $OCH_2CH_2N_3$, 3′−OH). ^{13}C NMR (125 MHz, CD_3CN) δ_{ppm} 167.2 (Bz-C=O), 162.9 (C-4), 158.8, 158.8 (DMTr), 154.8 (C-2), 144.9 (C-6), 144.5, 136.0, 135.6 (DMTr), 133.5, 132.9 (Bz), 130.2, 130.0 (DMTr), 128.7 (Bz), 128.2, 128.1, 128.1 (DMTr, Bz), 127.1, 113.3 (DMTr), 96.3 (C-5), 94.4 (OCH_2O), 89.8 (C-1′), 86.7 (DMTr-C_q), 82.6 (C-4′), 79.0 (C-2′), 68.0 (C-3′), 66.9 ($OCH_2CH_2N_3$), 61.2 (C-5′), 55.0 (DMTr-OMe), 50.7 ($OCH_2CH_2N_3$). HRMS(ESI): $[MH]^+$ $C_{40}H_{41}N_6O_9$ requires 749.2930; found, 749.2935.

2′-*O*-(2-Bromoethoxymethyl)-5′-*O*-(4,4′-dimethoxytrityl)-β-*N*⁴-benzoylcytidine 3′-(2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite) (1). Compound **5a** (0.29 g, 0.37 mmol) was predried over P_2O_5 in a vacuum desiccator and dissolved in DCM (5 mL). Et_3N (260 μL, 1.85 mmol) and 2-cyanoethyl *N*,*N*-diisopropylphosphoramidochloridite (99 μL, 0.44 mmol) were added under nitrogen. After 2 h, the mixture was filtered through a short dried silica gel column (60−70% EtOAc in hexane and 0.1% Et_3N). The mixture of phosphoramidite **1** R_P- and S_P-diastereomers (0.26 g, 71%) was obtained as a colorless oil. ^{1}H NMR (500 MHz, CD_3CN) δ_{ppm} 9.22 (br, 1H, NH), 8.50 [d, 0.5H, J = 7.5 Hz, H-6 (*diast. I*)], 8.45 [d, 0.5H, J = 7.0 Hz, H-6 (*diast. II*)], 8.00−7.94 (m, 2H, Bz), 7.66 (m, 1H, Bz), 7.58−7.48 (m, 4H, Bz, DMTr), 7.43−7.34 (m, 6H, DMTr), 7.31 (m, 1H, DMTr), 7.11 [br, 0.5H, H-5 (*diast. 2′-*O*-(2-Azidoethoxymethyl)-5′-*O*-(4,4′-dimethoxytrityl)-*N*⁴-benzoylcytidine 3′-(*H*-phosphonate) Triethylammonium Salt (2). Compound **5b** (0.37 g, 0.5 mmol) was dissolved in dry pyridine (2 mL), and diphenyl *H*-phosphonate (0.7 mL, 3.6 mmol) was added. After 45 min, water (0.6 mL) and Et_3N (0.6 mL) were added, and the reaction mixture was stirred for an additional 15 min. After evaporation, the residue was partitioned between DCM (20 mL) and 5% aq $NaHCO_3$ (20 mL). The organic layer was dried with Na_2SO_4, evaporated, and purified by silica gel chromatography (5−10% MeOH in DCM + 0.1% Et_3N), yielding product **2** (0.39 g, 86%) as a white foam. ^{1}H NMR (500 MHz, $CDCl_3/CD_3OD$ (1:1)) δ_{ppm} 8.53 (m, 1H, H-6), 7.99−7.94 (m, 2H, Bz), 7.61 (m, 1H, Bz), 7.55−7.49 (m, 2H, Bz), 7.47−7.40 (m, 2H, DMTr), 7.37−7.14 (m, 8.5H, DMTr, H-5, PH (0.5H)), 6.92−6.85 (m, 4H, DMTr), 6.19 (br, 0.5H, PH), 6.09 (s, 1H, H-1′), 5.05 (d, 1H, J = 7.0 Hz, OCHHO), 4.97 (d, 1H, J = 7.0 Hz, OCHHO), 4.92 (m, 1H, H-3′), 4.52 (m, 1H, H-2′), 4.35 (d, 1H, J = 7.0 Hz, H-4′), 3.87−3.76 (m, 8H, DMTr-OMe, $OCH_2CH_2N_3$), 3.64 (d, 1H, J = 11.0 Hz, H-5′a), 3.52 (d, 1H, J = 11.0 Hz, H-5′b), 3.43 (m, 2H, $OCH_2CH_2N_3$), 3.13 (br q, 6H, J = 6.5 Hz, CH_2 of Et_3N), 1.31 (t, 9H, J = 7.3 Hz, CH_3 of Et_3N). ^{13}C NMR (125 MHz, $CDCl_3/CD_3OD$, 1:1) δ_{ppm} 167.3 (Bz-C=O), 163.3 (C-4), 158.8 (DMTr), 156.2 (C-2), 144.8 (C-6), 143.9, 135.4, 135.1 (DMTr), 133.1, 133.0 (Bz), 130.2, 130.1 (DMTr), 128.7 (Bz), 128.3, 127.9, 127.9 (DMTr, Bz), 127.1, 113.2 (DMTr), 97.6 (C-5), 94.9 (OCH_2O), 89.4 (C-1′), 87.2 (DMTr-C_q), 82.0 (C-4′), 78.5 (C-2′), 70.1 (C-3′), 67.1 ($OCH_2CH_2N_3$), 60.9 (C-5′), 54.9 (DMTr-OMe), 50.7 ($OCH_2CH_2N_3$), 46.3 (CH_2 of Et_3N), 8.3 (CH_3 of Et_3N). ^{31}P NMR (200 MHz, $CDCl_3/CD_3OD$, 1:1) δ_{ppm} 2.53. Chart 1

Synthesis of 2′-*O*-Me-oligoribonucleotides. Oligonucleotides incorporating **1** and **2** were synthesized in a 1.0 μmol scale using commercial 500 Å CPG-succinyl-2′-*O*-Me-adenosine support. For the synthesizer, a protocol including both the phosphoramidite/tetrazole and *H*-phosphonate/pivaloyl chloride couplings was generated. For the coupling of phosphoramidite block **1** (0.13 mol L^{-1} solution in dry MeCN) and the commercial 2′-*O*-Me-nucleoside phosphoramidites, standard RNA phosphoramidite protocol was applied, with the exception of an extra detritylation step for monomer **1**. For the *H*-phosphonate monomer **2** [35 mmol L^{-1} solution in dry MeCN/pyrine (1:1, v/v)], a previously generated protocol was utilized.[9] Accordingly, the coupling time was 570 s on using pivaloyl chloride at a concentration of 100 mmol L^{-1} in dry MeCN/pyrine (1:1, v/v). An additional detritylation step was used also for monomer **2**. After the oligonucleotide assembly, the support-bound material was removed from the synthesizer, oxidized with iodine (0.1 mol L^{-1}) in wet pyridine (98:2, v/v) at rt for 1 h, washed with pyridine/MeCN/MeOH, and dried in vacuum. The oligonucleotides were released from the support and deprotected with concentrated ammonia (33% aqueous NH_3) at 55 °C overnight.

On-Support Click Conjugation. Alkynyl-functionalized ligands **6**[9] and **7**[31] (Chart 1) were conjugated to the azido groups of the support-bound oligonucleotides as follows. The ligands in MeOH (50 mmol L^{-1}, 15 equiv/azido group) were added onto the support. After that, $CuSO_4$ and tris[(1-benzyl-1,2,3-triazol-4-yl)methyl]amine (TBTA-ligand) were added as a 25 mmol L^{-1}

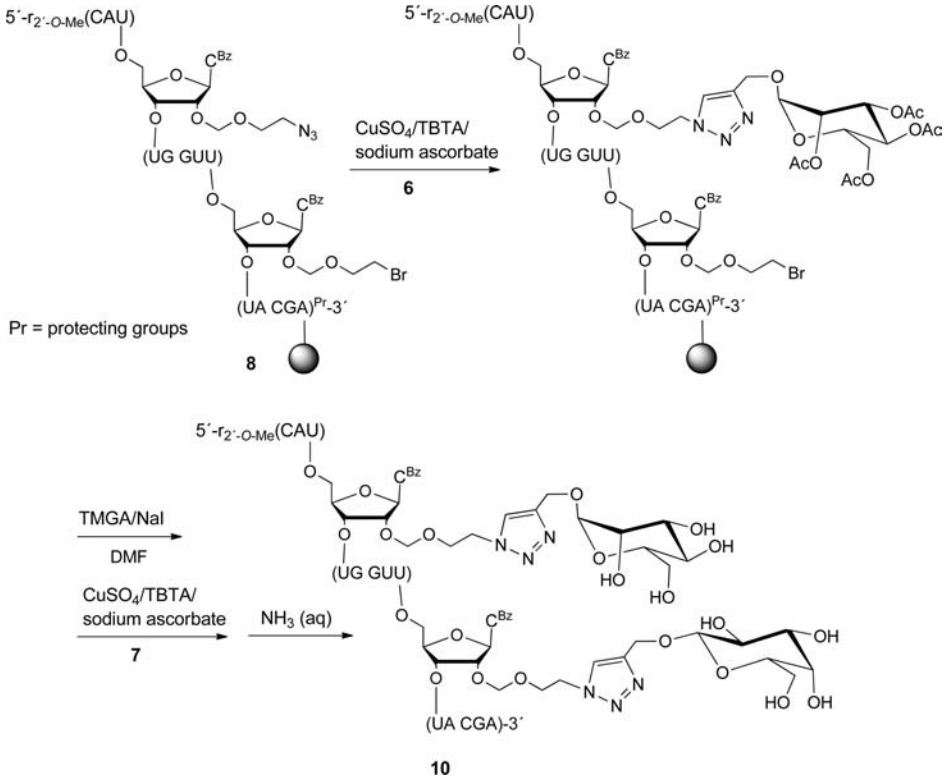

Figure 1. Solid-supported introduction of two different sugar ligands into 2′-positions within a 2′-*O*-Me-oligoribonucleotide (**10**).

solution in a 12:3:1 (v/v/v) mixture of water, DMSO, and 2-butanol (7.5 equiv/azido group). Finally, sodium ascorbate (15 equiv/azido group) as a 0.1 mol L^{-1} aqueous solution was added. The mixture was shaken at room temperature for 5 h. The support was collected by filtration and washed first with water, DMF, and MeOH. To remove the copper salt and TBTA ligand as quantitatively as possible, the support was then treated for 10 min with aqueous EDTA solution (0.1 mol L^{-1}), washed with water, and then for another 10 min with an aqueous solution of neomycin trisulfate (0.1 mol L^{-1}). Finally, the support was washed with water, DMF, DCM, MeOH, and MeCN.

On-Support Azidation. The support-bound oligonucleotides (0.5 μmol) were treated with a solution of tetramethylguanidinium azide (TMGA, 15.8 mg, 200 equiv) and NaI (15.0 mg, 200 equiv) in dry DMF (500 μL) for 1.5 h at 65 °C.[13] The support was collected by filtration and washed with DMF, DCM, water, and MeOH.

Characterization of the Conjugates. The identity of the sugar conjugates **10** and **11** was verified by ESI-MS. Observed masses are calculated from [(M-4H)/4]. ON**10** requires an isotopic mass of 5527.08; found, 5527.15. ON**11** requires an isotopic mass of 5830.19; found, 5830.18.

Melting Temperature Studies. The melting curves (absorbance versus temperature) were measured at 260 nm on a Perkin-Elmer Lambda 35 UV−vis spectrometer equipped with a multiple cell holder and a Peltier temperature controller. The temperature was changed at a rate of 0.5 °C/min (from 15 to 90 °C). The measurements were performed in 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 mol L^{-1} or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their cDNA or 2′-*O*-methyl RNA targets were used at a concentration of 2 μmol L^{-1}. T_m values were determined as the maximum of the first derivate of the melting curve.

RESULTS AND DISCUSSION

Synthesis of Monomeric Building Blocks. An *O*-glycosylation approach[30,32] was applied to the preparation of the 2′-*O*-(2-bromoethoxy)methyl (**3a**) and 2′-*O*-(2-azidoethoxy)methyl (**3b**) substituted cytidine monomers. Accordingly, 3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxane-1,3-diyl)-N^4-benzoylcytidine[33,34] was treated with (2-bromoethoxy)methyl acetate in the presence of tin tetrachloride at −12 °C.[30] Nucleoside **3a** was isolated in 88% yield, and conversion to the corresponding 2′-*O*-(2-azidoethoxy) methyl derivative (**3b**) by displacement of the bromo substituent with NaN_3 in DMF was virtually quantitative. The 3′,5′-cyclic silyl protecting group was removed from **3a** and **3b** with Bu_4NF in THF, and the 5′-OH of the deprotected nucleosides (**4a**,**b**) was protected with a 4,4′-dimethoxytrityl group to obtain **5a**,**b**. Finally, **5a** and **5b** were converted to 3′-(2-cyanoethyl-*N*,*N*-diisopropylphosphoramidite) (**1**) and 3′-(*H*-phosphonate) (**2**), respectively. Owing to the presence of the azido group, **5b** undergoes a Staudinger reaction upon phosphitylation, which prevents its conversion to a phosphoramidite reagent.[9,35]

The alkynyl-derivatized monosaccharide ligands, viz. propargyl 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranoside (**6**) and propargyl 2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranose (**7**), used in the click conjugation were prepared from peracetylated α-D-mannopyranose and β-D-galactopyranose by boron trifluoride etherate promoted glycosidation with propargyl alcohol. The compounds exhibited ^1H and ^{13}C NMR chemical shifts identical to those reported earlier.[9,31]

Oligonucleotide Synthesis and Click Conjugation. The appropriately protected phosphoramidite (**1**) and *H*-phosphonate (**2**) building blocks were incorporated into 15-mer 2′-*O*-methyl oligoribonucleotides: 5′-(CAU $\mathbf{C^2}$UG GUU $\mathbf{C^1}$UA

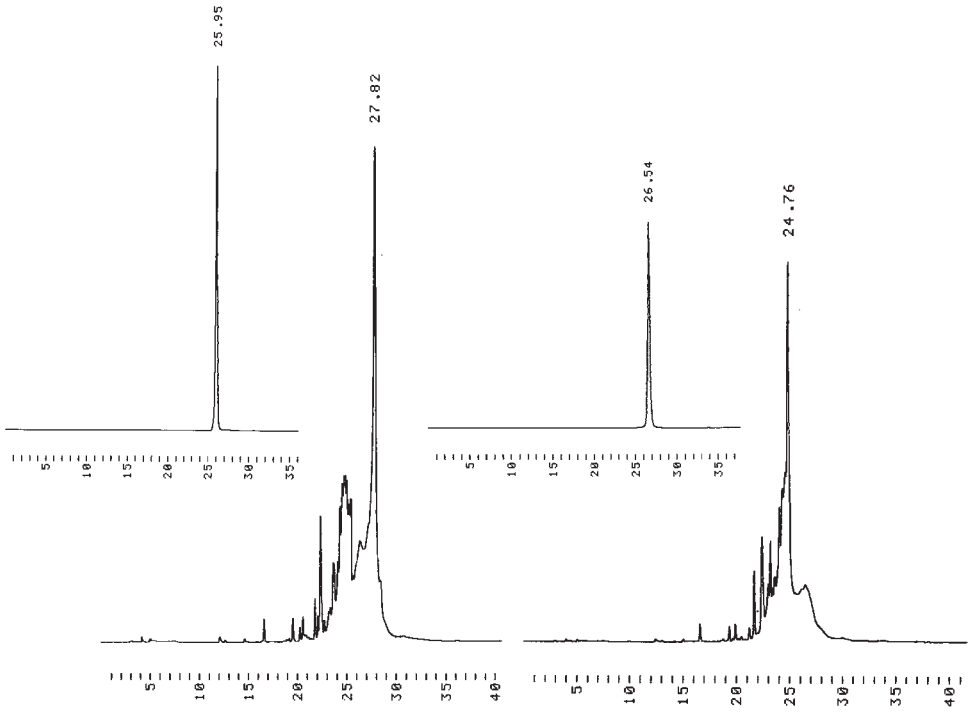

Figure 2. RP HPLC traces of the crude and purified oligonucleotide glycoconjugates **10** and **11**, respectively. For the chromatographic conditions, see the Experimental Procedures Section.

CGA)-3′ (**8**) and 5′-(CAU $\mathbf{C^1}$UG GUU $\mathbf{C^2}$UA $\mathbf{C^1}$GA)-3′ (**9**) ($\mathbf{C^1}$ and $\mathbf{C^2}$ refer to nucleosidic units derived from **1** and **2**, respectively). The oligomers were assembled by phosphoramidite chemistry, with the exception of the insertion of **2**, which was carried out by pivaloyl chloride promoted *H*-phosphonate coupling. As also shown previously, the presence of an azido group in the growing solid-supported oligonucleotide chain does not disturb the phosphoramidite coupling of subsequent monomers.[9] The coupling yield of building block **1** was ∼99%, but the *H*-phosphonate block **2** was coupled in only 85% yield.

After completion of the chain assembly, oligonucleotides **8** and **9** were conjugated with the two alkynyl-functionalized monosaccharide ligands (**6** and **7**) (Figure 1). The azido group of monomeric unit **2** was first subjected to Cu(I) promoted click reaction with propargyl α-D-mannopyanoside tetraacetate (**6**), using a mixture of $CuSO_4$ and sodium arcorbate in the presense of tris[(1-benzyl-1,2,3-triazol-4-yl)methyl]amine (TBTA-ligand) as the source of Cu(I) ion (5 h, r.t.). The bromo substituent of monomeric unit **1** was then displaced with an azide ion, as reported previously by Pourceau et al.[13,14] Both tetramethylguanidinium azide[36] (TMGA/NaI/DMF, 65 °C) and less soluble NaN_3 (NaN_3/NaI/DMF, 65 °C) were used as a source of azide ions. The second click reaction was then performed using propargyl β-D-galactopyranoside tetraacetate (**7**) as the alkyne component. The oligonucleotide conjugates obtained (**10** and **11**) were deprotected and released from the support by standard ammonolysis (33% aq NH_3, 55 °C, overnight). The crude products were purified by RP-HPLC, and their identity was verified by ESI-MS. Figure 2 shows the HPLC traces of the crude conjugates and the homogeneity of the products after purification.

Melting Temperature Studies. It has been shown previously that oligonucleotides bearing a β-D-ribofuranosyl group at an intrachain 2′-O form stable complexes with RNA (ΔT_m = 0 °C) and maintain A-type helical geometry with the additional 2′-*O*-ribose moiety located in the minor groove.[2,24] Consistent with these findings, the sugar ligands attached in the present study to 2′-*O* via a [2-(4-hydroxymethyl-1*H*-1,2,3-triazol-1-yl)ethoxy]-methyl linker only slightly destabilize the duplex. Table 1 records the melting temperatures (T_m) for the duplexes of oligonucleotide conjugates **10** and **11** with the full cDNA and 2′-*O*-methyl RNA sequences at pH 7.

The saccharide ligands accommodated quite well in the duplex structure. Oligonucleotide **10** bearing two saccharide units in an

intrachain position exhibited even a slight stabilization of the duplex with the DNA target at a low ionic strength (ΔT_m = +0.5 °C) and a slight destabilization at a high ionic strength (ΔT_m = −1.1 °C). Addition of a third saccharide ligand to obtain conjugate **11** resulted in a moderate destabilization even at a low ionic strength (ΔT_m = −3.1). At high ionic strength, the destabilization was less prominent (ΔT_m = −1.5 °C). With the 2′-*O*-Me RNA target, two saccharide ligands within conjugate **10** were similarly well tolerated (ΔT_m = −0.5 °C), but with **11**, containing three saccharides, T_m again dropped significantly (ΔT_m = −3.8 °C). A tentative explanation for the marked destabilizing influence of the third saccharide, especially at low ionic strength, is that two of the sugars are rather close to each other within conjugate **11**, viz. in positions 10 and 13.

■ CONCLUSIONS

A convenient and reliable method for solid-phase introduction of two different types of saccharide ligands in desired positions of an oligonucleotide has been developed. The underlying principle is regiospecific introduction of azido- and bromo-functionalized building blocks into the oligonucleotide upon chain assembly and their subsequent derivatization on the support. A propynyl-functionalized saccharide is first attached to the azido groups by Cu(I) promoted 1,3-dipolar cycloaddition, and the same reaction is utilized to conjugate the second propynyl saccharide after conversion of the bromo substituents to azido groups by displacement with the azide ion. For the chain assembly, conventional phosphoramidite chemistry may be applied, except for the introduction of the azido functionalized building blocks that have to be coupled as *H*-phosphonates. The saccharide ligands are quite well accommodated to the duplexes formed with both DNA and 2′-*O*-Me RNA targets

Figure S2. MS(ESI) spectrum of pure **11** S3
Figure S3. T_m curves of ON**10** and ON**11** with cDNA S3
Figure S4. T_m curve of ON**10** and ON**11** with 2´-*O*-methyl RNA S4

General procedures

The mass spectra of the oligonucleotides **10** and **11** were recorded by ESI ionization method. The melting curves (absorbance versus temperature) were measured at 260 nm on a Perkin-Elmer Lambda 35 UV-vis spectrometer equipped with a multiple cell holder and a Peltier temperature-controller. The temperature was changed at a rate of 0.5 ºC / min (from 15 to 90 ºC). The measurements were performed in 10 mmol L^{-1} potassium phosphate buffer (pH 7) containing 0.1 mol L^{-1} or 1.0 mol L^{-1} NaCl. The oligonucleotide conjugates and their complementary DNA or 2´-*O*-methyl RNA targets were used at a concentration of 2 μmol L^{-1}.
