Supporting Information

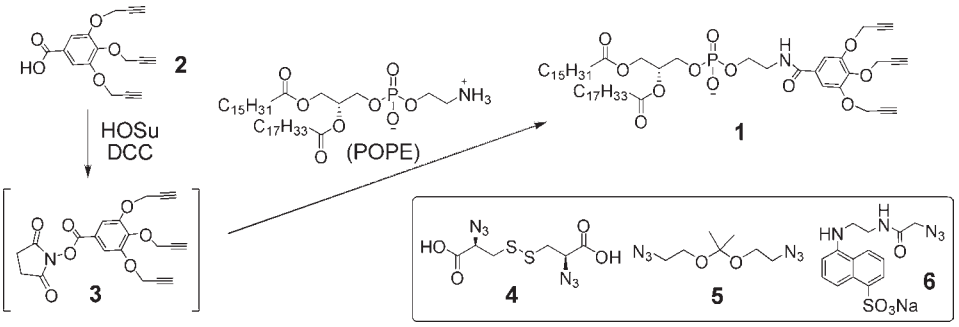
ABSTRACT: A gallate derivative with three propargyl groups was coupled to palmitoyl oleoyl phosphoethanolamine (POPE). The resulting anionic lipid was formulated with common lipids such as palmitoyl oleoyl phosphatidyl choline (POPC) to form large unilamellar vesicles (LUVs). Polymerization of the LUVs was accomplished by the Cu(I)-catalyzed click reaction between the propargyl groups and the azide groups in the cross-linker. When the cross-linker contained a disulfide or ketal group, the resulting polymerized liposomes depolymerized and released entrapped contents upon the addition of a reducing thiol or under weakly acidic conditions. The click reaction allowed simultaneous multivalent surface functionalization during cross-linking, making these cleavable polymerized liposomes (CPLs) potentially very useful in the delivery and controlled release of pharmaceutical agents.

An ideal drug-delivery vehicle unloads its contents only at the target site. Liposomes have many of the desired features of "smart" drug-delivery systems including large encapsulating capacity, ease of surface decoration, and biocompatibility.[1−7] A number of liposomal drug formulations have been approved by FDA and numerous others are undergoing clinical trials.[1−7] In recent years, there has been growing interest in developing liposomes that release their contents under specific stimuli including pH,[5,8−19] enzymes,[20−23] temperature,[24] redox signals,[25−27] and light.[12,28−32] The majority of the reported methods focus on the design of responsive lipids. Typically, the stimulus triggers changes in the lipid structure and, in turn, causes destabilization and leakage of liposomes.

An important challenge faced by liposomal delivery lies in the stability of the noncovalently assembled structures. Formation of liposomes is driven by hydrophobic interactions among the lipid tails. After entering the vascular system, liposomes are destabilized through the loss of lipid molecules to hydrophobic entities such as biomembranes and plasma proteins, resulting in premature leakage of entrapped contents. Many approaches have been developed to improve liposomal stability, including tuning of membrane fluidity, incorporation of cholesterol, and surface protection with poly(ethylene glycol).[1−7] More recently, cholesterol-derived lipids[33,34] and polymers[35] were found to be particularly effective at enhancing liposomal stability.

Polymerization of liposomes, whether near the headgroup or in the lipid tails, can stabilize the structure as well.[36−40] Although some polymerized liposomes are known to survive harsh treatment including dehydration and rehydration, their usage in clinical drug delivery is hampered by the poor biocompatibility of the polymerized materials. Whereas most lipids used in common liposomal formulations are bio-originated and thus fully biodegradable, the polymerized materials, often connected by carbon−carbon bonds, are macromolecules very difficult to degrade.

In this paper, we report a simple method to prepare cleavable polymerized liposomes (CPLs). Our approach combines the simplicity of polymerization-derived stabilization with the flexibility of small-molecule lipids. Our method can be easily applied to common lipid formulations to create liposomes with controlled-release properties under biologically relevant conditions. The chemistry employed to polymerize the liposomes permits facile conjugation of the liposomes with functional ligands such as fluorescent labels, making it convenient to track the fate of the liposomes.



Polymerizable lipid **1** is a derivative of common POPE lipid. As shown by Scheme 1, a propargylated gallic acid (**2**) was activated by *N*-hydroxysuccinimide (HOSu). The resulting activated ester (**3**) reacted with the amino group of POPE in the presence of diisopropylethylamine to afford **1**. The product was purified by column chromatography and characterized by ^{1}H and ^{13}C NMR spectroscopy, as well as mass spectrometry. The three propargyl groups of **1** are included for polymerizing the liposomes by azide-containing cross-linkers such as **4** and **5** through the highly efficient click reaction (i.e., the 1,3-dipolar cycloaddition between terminal alkyne and azide). The high-yield, selectivity, and outstanding tolerance of functional groups of the click reaction[41−43] enabled its numerous applications in biolabeling,[44,45] surface modification,[46] dendrimer synthesis,[47−49] and polymer formation.[46] Click chemistry has also been applied to liposomes in recent years,[35,50−55] but mostly for their conjugation with ligands or functional labels.

Scheme 1. Synthesis of Cross-Linkable Lipid 1

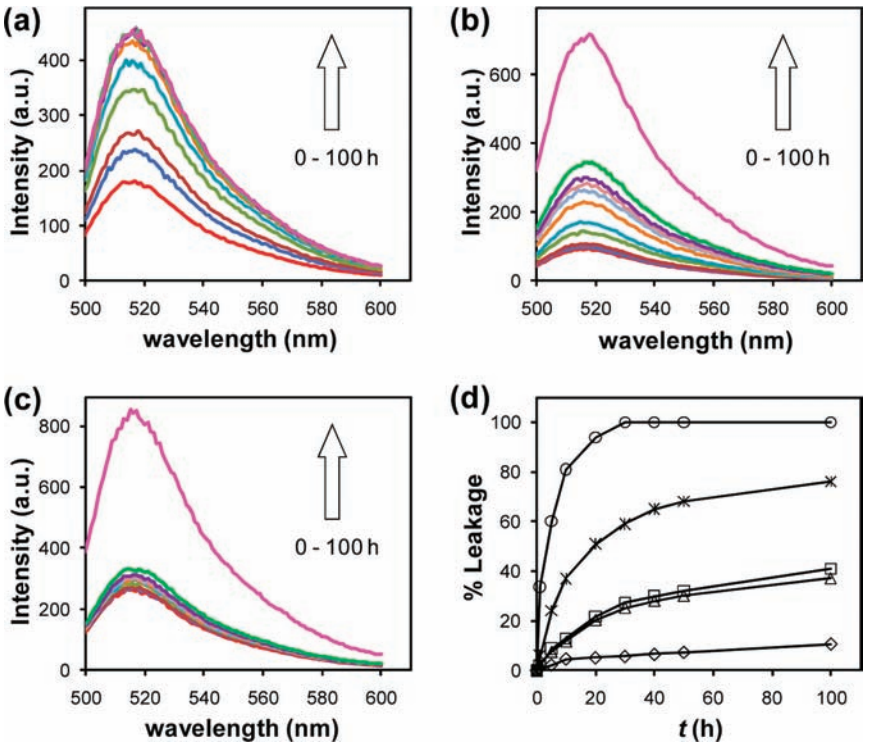

Figure 1. Fluorescence spectra of CF-containing LUVs prepared with (a) **1**, (b) 1:1 [**1**]/[POPC], and (c) POPC at ambient temperature. $[CF]_{initial}$ = 50 mM in 10 mM HEPES buffer. [NaCl] = 0.1 M. The spectra were recorded at 0, 0.5, 1, 5, 10, 20, 30, 40, 50, and 100 h after the liposomes were prepared. (d) Percent leakage of CF from LUVs prepared with different lipid formulations. [**1**]/[POPC] = 1:0 (○), 2:1 (×), 1:1 (□), 1:2 (△), 0:1 (◇).

Lipid **1** could be easily formulated with POPC to form liposomes. We employed the well-established carboxyfluorescein (CF) leakage assay[56] to understand the effect of lipid formulation on liposomal stability. Briefly, CF was trapped inside large unilamellar vesicles (LUVs) at a concentration (50 mM) that gave significant self-quenching. Any leakage of the dye would dilute the probe and enhance its fluorescence. Figure 1a−c shows the fluorescence spectra of several CF-containing LUVs over a period of 100 h. The spectra in violet were recorded at the end of the 100 h after 1% Titron X-100 aqueous solution was added to lyse the liposomes. The spectrum after Triton addition thus corresponded to 100% leakage and the percent leakage of CF at different times was calculated accordingly and summarized in Figure 1d.[57] From the leakage profile, we can easily see that, by itself, **1** did not make very stable liposomes—the majority of CF leaked out in 10−20 h (Figure 1d, ○). The stability of the liposomes improved significantly when **1** was formulated with POPC. The liposomes with **1**/POPC = 1:1 or 1:2, for example, retained over 60% of the dye at 100 h.

The POPC LUVs leaked very little even at 100 h (Figure 1c). Because polymerized liposomes are expected to be more stable than unpolymerized ones, the normal CF assay might not be sensitive enough for their characterization. A common way to speed up the leakage is to apply an osmotic gradient across the membranes.[33,58−60] Indeed, the LUVs with [**1**]/[POPC] = 1:1 lost all the entrapped CF in 5 M NaCl in only 12 h (Figure 2a, ▲), whereas the same lost <40% after 100 h when the buffer contained 0.1 M NaCl (Figure 1d, □). An increase of POPC in the formulation stabilized the liposomes (Figure 2a), as it did without the osmotic stress. Note that, in all the assays, the leakage

dx.doi.org/10.1021/bc1003197 |*Bioconjugate Chem.* 2011, 22, 523–528

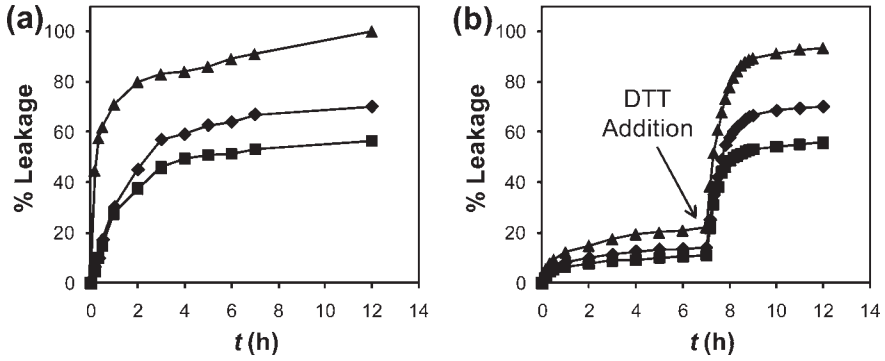

Figure 2. Percent leakage of CF from LUVs (a) before and (b) after polymerization. [CF] = 50 mM in 10 mM HEPES buffer. [NaCl] = 5 M; [**1**]/[POPC] = 1:1 (▲), 1:2 (♦), and 1:5 (■); DTT = dithiothreitol.

was fast initially and leveled off afterward. This was a reasonable result. The exchange of water and/or salt probably occurred when the dye escaped from the liposomes. As the osmotic pressure decreased across the lipid membranes, the driving force for leakage became smaller over time.

Polymerization of the LUVs was accomplished by $CuCl_2$/sodium ascorbate in the presence of 1.5 equiv of cross-linker **4**.[61] The stoichiometry was chosen because **1** contained three alkynyl groups and **4** two azides. The organic HEPES buffer was found to interfere with the click reaction and a white precipitate formed when Cu(II) salt was added to the buffer. Assuming the precipitate was a complex between copper ions and the organic amine HEPES, we added 4 equiv of *N,N,N′,N″,N″*-pentamethyldiethylenetriamine (PMDETA), a water-soluble amine known to complex with the copper catalyst used in the click reaction.[62] The click reaction indeed proceeded smoothly (vide infra) without any precipitation. The experimental details are given in the Supporting Information.

We polymerized liposomes with three different formulations —[**1**]/[POPC] = 1:1, 1:2, and 1:5. Liposomes with higher POPC are more stable according to Figure 1d but would give a lower degree of polymerization. As expected, polymerization suppressed the CF leakage to a large extent in all three liposomes. Instead of 50−90% leakage prior to polymerization (Figure 2a), the cross-linked LUVs displayed 10−20% leakage when placed in 5 M NaCl solution before dithiothreitol or DTT was added (Figure 2b). It was surprising, however, that the relative stability of the three liposomes (■ > ♦ > ▲) stayed the same, and the most polymerized liposomes (▲) were the least stable among the three. Polymerization clearly improved the liposomal stability, but it was puzzling that the degree of polymerization did not correlate with the stability. Possibly, the sensitivity toward osmotic pressure derived partly from the ionic nature of lipid **1** (which would not change upon polymerization). Figure 1d indicates that neutral POPC is far more resistant to leakage than the anionic **1**. Regardless of the exact reason for the retained order of stability, the result was actually quite desirable. For any practical applications, one would rather not have to use a lot of a specially synthesized lipid to improve stability.

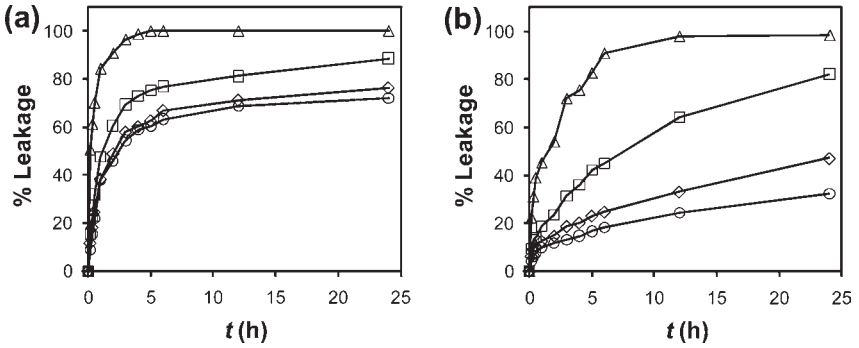
The disulfide-containing cross-linker (**4**) permitted the cleavage of the polymerized liposomes with a commonly used reducing thiol, DTT. Because thiol concentration reaches 10 mM in the cytosol and is only about 10 μM in the plasma, the disulfide−thiol conversion is widely used for cellular delivery.[63] Thiol-triggered release is also useful for delivering anticancer drugs because the thiol concentration could be seven times higher near some tumors than in normal tissues.[64]

To our gratification, DTT (ca. 0.3 mM) was able to completely reverse the effect of polymerization on the CF leakage. Fast leakage started as soon as the thiol was added and the leakage profiles were nearly identical to those before the polymerization (compare Figures 2a and 2b after DTT addition). In our method, the copper catalyst was added after the formation of the liposomes and the water-soluble copper catalyst should not permeate the bilayers easily. Polymerization, as a result, was anticipated to occur predominantly on the external leaflets of the bilayers. Such a configuration is beneficial from the viewpoint of release, as it is certainly easier to cleave the disulfide bonds in the external leaflets than those in the interior by external stimuli.

For the polymerized LUVs, mass spectrometry indeed revealed high M.W. species (Figure 1S, Supporting Information). Nonetheless, since there was no guarantee that all polymeric species ionized to the same extent, the peaks in the MS might not accurately represent the polymerized lipids. To better understand the click polymerization, we took advantage of the reversible nature of the cross-linkage and studied the depolymerized LUVs to probe the cross-linking density. This method was used previously to characterize similar, click-cross-linked materials.[61] The depolymerized LUVs were obtained after the CPLs ([**1**]/[POPC] = 1:1) were incubated with 0.3 mM DTT for 24 h and were then immediately analyzed by ESI-MS. Although we could not assign every single peak due to the complexity of the system, two major peaks in the mass spectrum were identified as **7** (m/z = 1229.59) and **8** (m/z = 1276.60). We did not detect any significant amount of **9** (m/z = 1424.62). Thus, the MS results indicated that the majority of lipid **1** underwent two cycloadditions and some reacted only once under our experimental conditions.

There could be several reasons why the click reaction did not result in high cross-linking density. The click reaction was performed in fairly dilute liposomal solutions, with [**1**] = 0.26 mM. Since both the liposomes and the cross-linked **4** were anionic, it could be difficult for the cross-linker to access the alkynyl groups of the anionic **1**. Moreover, because of the hydrophobicity of the propargylated gallate, the alkynyl groups could be buried within the hydrophobic membranes instead of being exposed to the aqueous phase. Finally, electrostatic interactions among the lipids demanded that the anionic **1** be dispersed as far from one another as possible in the matrix of POPC. All of these could have contributed to the low cross-linking density of the CPLs. It should be noted, nevertheless, that

dx.doi.org/10.1021/bc1003197 |*Bioconjugate Chem.* 2011, 22, 523–528



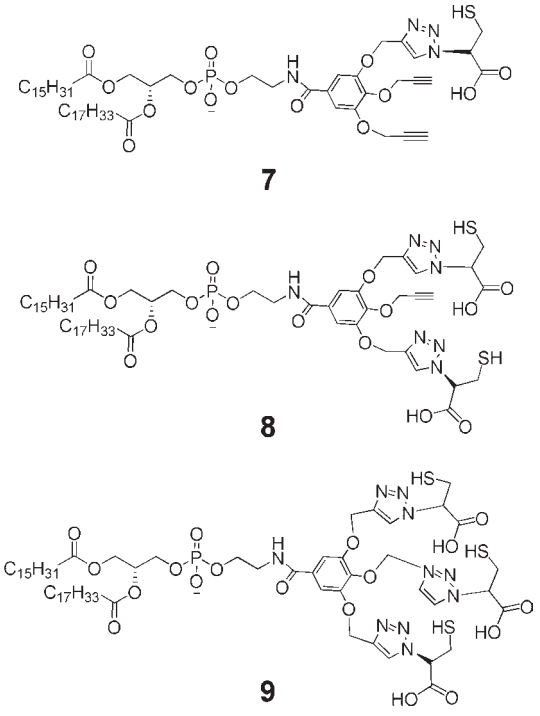


Figure 3. Percent leakage of ANTS/DPX from LUVs (a) before and (b) after polymerization. [ANTS/DPX] = 12.5/45 mM in 5 mM TES buffer. [**1**]/[POPC] = 1:2; [NaCl] = 5 M; pH = 7.0 (○), 6.0 (◊), 5.0 (□), and 4.0 (△).

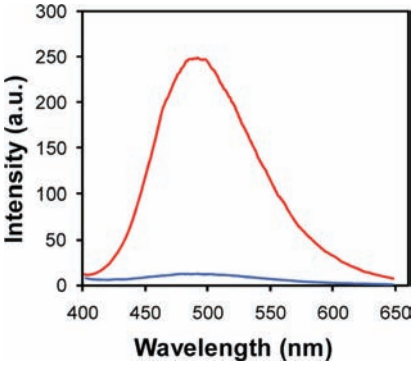

Figure 4. Fluorescence spectra of click-labeled LUVs (red) and the control LUVs (blue) after gel permeation chromatography (λ_{ex} = 345 nm). The control LUVs were prepared exactly the same as the click-labeled LUVs except that no copper catalyst was added in the process. [**1**]/[POPC] = 1:2.

the leakage assays suggested that the low cross-linking density might not be a bad result at all—even though the CPLs were significantly more stable than the unpolymerized materials, the release started as soon as the cleavage agent was added.

The outstanding tolerance of the click reaction made it easy to incorporate cross-linkers sensitive to other stimuli. Cross-linker **5**, for example, contained a ketal bond that could hydrolyze easily under acidic conditions. Acid-triggered release is important to many delivery applications. Endocytotic delivery often exploits the higher acidity of endosomes compared to cytosols.[65] Cancerous and inflammatory tissues are also known to be more acidic than normal tissues.[66−68] We prepared CPLs with a composition of [**1**]/[POPC] = 1: 2 with a slightly modified procedure. Cross-linker **5** was not soluble in water; we thus could not add the cross-linker to preformed liposomal solution. Instead, we mixed **1**, POPC, and **5** together during lipid film formation and prepared LUVs with **5** already in the lipid bilayers. Polymerization was accomplished by Cu(I) catalysts added to the aqueous solution.

We could not use the CF leakage assay for acid-triggered release because of its acid-sensitivity.[15] Instead, we employed the ANTS/DPX assay, known to work well under acidic conditions.[69,70] ANTS is a fluorescent dye and quenched strongly by DPX. When trapped together inside the liposomes, the pair gives little fluorescence. Leakage of one or both compounds reduces the concentration-dependent quenching and can be easily detected.

The ANTS/DPX assay worked well for both unpolymerized liposomes and the CPLs. As shown by Figure 3a, leakage occurred readily when the LUVs was subjected to the 5 M NaCl osmotic stress. In general, the fastest leakage took place within the first 5 h of time and leveled off afterward. Polymerization changed the release profiles significantly. The polymerized liposomes had considerably higher stability at pH 7 (Figure 3b, ○). Whereas the unpolymerized LUVs lost over 70% of the probes after 24 h, the CPLs only lost ∼30%. As the solution became more acidic, the effect of polymerization disappeared gradually. At pH 6 (◊), for example, the 24 h leakage was ∼50% and 80% for the polymerized and unpolymerized LUVs, respectively. When the solution pH decreased further to 5 (□) and 4 (△), polymerization no longer affected the 24 h leakage, but the initial rates of release, judged by the slopes of the curves in the early stage of the assays, were clearly smaller for the polymerized liposomes.

Covalent labeling of the liposomes was extremely easy with our method. As a proof of concept, compound **6** (Scheme 1) was prepared by a one-step reaction from a commercially available probe (see Supporting Information for details). Cross-linking and fluorescent labeling occurred simultaneously when **4** and **6** were added together during polymerization. After gel permeation

dx.doi.org/10.1021/bc1003197 |*Bioconjugate Chem.* 2011, 22, 523–528

chromatography (GPC) over Sephadex G-50 resins, the CPLs emitted much more strongly than the control liposomes, in which no catalyst was added (Figure 4). GPC separates molecules by their sizes. Without cross-linking, most of the dye was removed from the control liposomes during chromatography. The weak emission from the control LUVs (Figure 4, blue) probably came from physically adsorbed **6**.

In summary, polymerization of liposomes is an effective strategy to improve their stability. Introduction of multiple "clickable" functionalities on the headgroup of the lipid and the subsequent click polymerization with cleavable cross-linkers such as **4** and **5** create novel CPLs that readily depolymerize under biologically relevant conditions. In contrast to conventional free radical polymerization, the click reaction retained the benefits of polymerization (i.e., enhanced stability) without the problem of polymer-related poor biodegradability. The simplicity of the synthesis, the facile implementation of the technique in common liposome formulations, and the convenient multivalent surface modification make this method highly attractive in the controlled release and delivery of pharmaceutical agents.

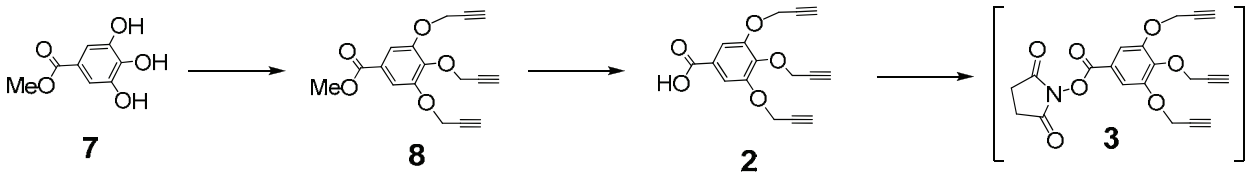
Controlled Release from Cleavable Polymerized Liposomes upon Redox and pH Stimulation

Shiyong Zhang and Yan Zhao*

Department of Chemistry, Iowa State University, Ames, Iowa 50011-3111, USA



General Method

All reagents and solvents were of A.C.S.-certified grade or higher, and were used as received from commercial suppliers. Millipore water was used in all aqueous experiments. All glassware and syringes were dried in an oven at least overnight prior to use. NMR spectra were recorded on a BRUKER DRX-400 or a VARIAN VXR-400 spectrometer. ESI-MS was performed on a FINNIGAN TSQ700 mass spectrometer. Fluorescence spectra were recorded at ambient temperature on a VARIAN Cary Eclipse Fluorescence spectrophotometer.

Caution: *Small organic azides are potentially explosive* and must be handled with care and avoid high temperatures, particularly in concentrated forms and/or in large quantities.

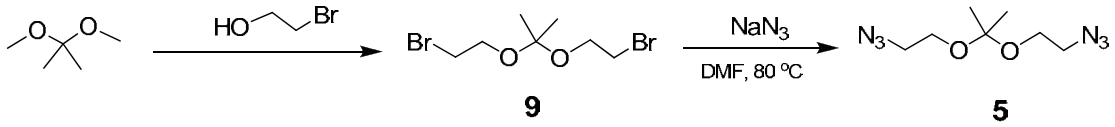
Synthesis

Scheme 1S

Methyl 3,4,5-Triproparyloxybenzoate (8).[1] A mixture of methyl 3,4,5-trihydroxybenzoate (**7**, 1.84 g, 10 mmol), propargyl bromide (80% wt in toluene, 3.4 mL, 31 mmol), K_2CO_3 (5.53 g, 40 mmol), and 18-crown-6 (13.2 mg, 0.05 mmol) in acetone (50 mL) was heated to reflux for 24 h. The solid was removed by filtration and the acetone was removed by rotary evaporation. Water (50 mL) was added and the mixture was extracted with CH_2Cl_2. The organic phase was dried over Na_2SO_4 and the solvent was removed *in vacuo* to give the desired product as a white powder (2.63 g, 88 %). ^{1}H NMR (400 MHz, $CDCl_3$, δ): 7.47 (s, 2H), 4.83-4.80 (m, 6H), 3.91 (s, 3H), 2.53 (s, 2H), 2.46 (s, 1H).

3,4,5-Triproparyloxybenzoic Acid (2). Compound **8** (2.63 g, 8.8 mmol) was dissolved in MeOH (100 mL). A solution of 2 M LiOH (22 mL) in water as added. The reaction mixture was stirred at room temperature for 12 h and monitored by TLC. The solvent was removed by rotary evaporation and HCl (2.0 M) was added to the mixture to adjust the pH ≈ 2. The mixture was extracted with EtOAc. The organic phase was dried over Na_2SO_4 and the solvent was removed *in vacuo* to afford **2** as a white powder (2.22 g, 89%). ^{1}H NMR (400 MHz, DMSO-*d6*, δ): 7.38 (s, 2H), 4.89 (d, *J* = 2.4 Hz, 4H), 4.72 (d, *J* = 2.4 Hz, 2H), 3.62 (t, *J* = 2.0 Hz, 2H), 3.48 (t, *J* = 2.4 Hz, 1H).

Lipid 1. Compound **2** (284 mg, 1.00 mmol), *N*-hydroxysuccinimide (115.1 mg**,** 1.00 mmol), and 1,3-dicyclohexylcarbodiimide (DCC, 206.3 mg, 1.00 mmol) were dissolved in 10 mL of CH_3CN. The mixture was stirred at room temperature for 6 h. The precipitate was removed by filtration and the filtrate evaporated to dryness, affording compound **3** as a light yellow powder (377.5 mg, 99%). A portion of this compound (27.9 mg, 0.0731 mmol), diisopropylethylamine (61 μL, 0.348 mmol), and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE, 50 mg in 2



[1] Camponovo, J.; Ruiz, J.; Cloutet, E.; Astruc, D. *Chem.–Eur. J.* **2009**, *15*, 2990–3002.

mL $CHCl_3$, 0.0696 mmol) were dissolved in 4 mL of CH_3Cl_3/MeOH (2:1, v/v). The mixture was stirred at room temperature for 24 h. The solvents were removed by rotary evaporation and the product was purified by preparative TLC with $CHCl_3$/MeOH = 7/1 as the developing solvents to give a viscous liquid (37.5 mg, 55%). ^{1}H NMR (400 MHz, $CDCl_3/CD_3OD$ = 1:1, δ): 7.30 (s, 2H), 5.33 (b, 2H), 5.3 (b, 1H), 4.79-4.76 (m, 6H), 4.33-4.31 (m, 1H), 4.11-4.06 (m, 1H), 3.96-3.92 (m, 4H), 3.59 (s, 2H), 2.69 (s, 2H), 2.58 (s, 1H), 2.26 (b, 4H), 1.99 (d, *J* = 5.2 Hz, 4H), 1.55 (b, 4H), 1.23 (s, 48H), 0.86 (t, *J* = 6.0 Hz, 3H). ^{13}C NMR (100 MHz, CD_3OD, δ): 175.0, 174.95, 174.66, 152.96, 141.23, 130.99, 130.90, 109.23, 79.90, 79.40, 77.58, 77.02, 63.78, 61.14, 58.27, 55.88, 43.87, 35.25, 35.06, 33.24, 30.99, 130.83, 30.79, 30.65, 30.64, 30.53, 30.43, 30.38, 30.35, 28.33, 26.17, 23.91, 14.65, 13.32. ESI-MS (*m/z*): [M^-], calcd for $C_{55}H_{85}NO_{12}P^-$ 983, found 983.

Compound 4.[2] Triflic anhydride (1.3 mL, 10 mmol) was added over 5 min to a mixture of sodium azide (2.1 g, 10 mmol) in H_2O (10 mL) and CH_2Cl_2 (15 mL) at 0 °C. After the mixture was stirred for 3 h, the organic phase was separated. The aqueous layer was extracted with CH_2Cl_2 (2 × 10 mL). The combined organic phases were cooled by an ice bath and washed once with saturated Na_2CO_3 and added to a solution of L-cystine (0.24 g, 1 mmol), K_2CO_3 (0.41 g, 3 mmol), and $CuSO_4 \cdot 5H_2O$ (5.0 mg, 0.02 mmol) in H_2O (10 mL) and CH_3OH (10 mL). The mixture was stirred at room temperature overnight. The organic solvents were removed by rotary evaporation. The aqueous slurry was diluted with H_2O (50 mL) and acidified to pH 6 with concentrated HCl. The mixture was diluted with 0.25 M pH 6.2 phosphate buffer (100 mL) and extracted with EtOAc (4 × 50 mL) to remove the sulfonamide byproduct. The aqueous phase was then acidified to pH 2 with concentrated HCl and extracted with EtOAc (5 × 50 mL). The combined organic phases were dried ($MgSO_4$), and concentrated *in vacuo* to give a light yellow oil (34 mg, 12%). ^{1}H NMR (400 MHz, CD_3OD, δ): 4.37-4.34 (m, 2H), 3.30-3.28 (m, 2H), 3.08-3.02 (m, 2H); ^{13}C NMR (100 MHz, CD_3OD, δ): 172.73, 63.03, 41.78; High resolution EI-MS (*m/z*): calcd for $C_6H_8N_6O_4S_2$, 292.0048; found 292.0053.

Scheme 2S

9 **5**

Compound 9. A mixture of 2-bromoethanol (5.0 mL, 6.6 mol), 2,2-dimethoxypropane (4.0 mL, 3.0 mol), benzene (16 mL), and *p*-toluenesulfonic acid (5.0 mg) were placed into a 50 mL round-bottomed flask fitted with a fractional distillation head. The mixture was heated with an oil bath. When the fraction at 62–65 ^{o}C started to distill, the oil bath was removed and the mixture was cooled to room temperature. A solution of sodium methoxide (0.1 g) in methanol (2 mL) was added rapidly under stirring. The distillation was resumed and the fraction at 80–83 ^{o}C was collected. The crude product was a 50:50 mixture of 2-bromoethanol and the desired product, as indicated by ^{1}H NMR spectroscopy, and was used in the next step without further purification.

Compound 5. A mixture of crude **9** (2.32 g, ca. 5.6 mmol), sodium azide (5.2 g, 80 mmol), and DMF (20 mL) was stirred at 80 °C for 10 h. The mixture was poured into water and the mixture was extracted with hexane (3 × 50 mL). The combined organic phases were washed with brine, dried over anhydrous Na_2SO_4, and concentrated *in vacuo* to give a yellow oil (0.87 g, 73%). ^{1}H NMR (400 MHz, $CDCl_3$, δ): 3.66 (t, J = 4.0 Hz, 4H), 3.39 (t, J = 4.0 Hz, 4H), 1.40 (s, 6H).

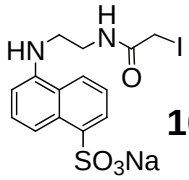
Preparation of CF-Containing LUVs. A solution of POPC (3.0 mg, 0.004 mmol) and lipid **1** (3.9 mg, 0.004 mmol) in chloroform (0.3 mL) was placed in a 10 mL test tube and dried under a stream of nitrogen. The residue was dried further under high vacuum overnight. The resulting lipid film was hydrated in 10 mM HEPES buffer (0.3 mL, 50 mM CF, 10 mM NaCl, pH = 7.4) for 30 min with occasional vortexing. The opaque dispersion was subjected to ten freeze–thaw cycles. The resulting mixture was extruded twenty-nine times through a polycarbonate filter (diameter = 19 mm, pore size = 100 nm) at room temperature using an Avanti Mini-Extruder. A portion (0.1 mL) of the liposome solution was passed through a column of Shepadex G-50 using 10 mM HEPES buffer (pH = 7.4) containing 107 mM NaCl as the eluent. The liposome fractions were combined and diluted to 5.0 mL with the same HEPES buffer. The concentration of the total phospholipids in the stock solution was 5.3×10^{-4} M.

Polymerization of LUVs. To the liposome solution (1 mL), cross-linker **4** (10 μL of 0.04 M aqueous solution, 0.4 μmol), Cu-complex (10 μL of 0.053 M aqueous solution, 0.53 μmol),[3] and sodium ascorbate (10 μL of 27 mg/mL aqueous solution, 1.4 μmol) were added. The reaction mixture was slowly stirred at room temperature for 24 h. A portion (0.2 mL) of the CPLs solution was passed through a column of Shepadex G-50 using 10 mM HEPES buffer (pH = 7.4) containing 107 mM NaCl as the eluent. The liposome fractions were combined and diluted to 5.0 mL with the same HEPES buffer. The concentration of the total phospholipids in the stock solution was 2.12×10^{-5} M. Our experiments showed that the minute amount of copper ions in the reaction mixture did not affect the results of the leakage assays if the leakage experiment was performed immediately after the click polymerization.

CF Leakage Assay. An aliquot (40.0 μL) of the above liposomal solution was added to 1.96 mL of 10 mM HEPES buffer (pH = 7.4) containing the appropriate concentration of NaCl.[4] The lipid concentration in the sample was 4.8 μM. The fluorescence emission at 520 nm (λ_{ex} = 492 nm) was measured overtime. At the end of the assay, 40 μL of Triton X-100 (1%) was added, disrupting the vesicles and releasing the remaining CF (100% release). The percent leakage at any given time was calculated using Eq. (1), in which I_0 and I_t are the initial and intermediate emission intensity, respectively.

$$\% \text{ leakage} = (I_t - I_0)/(I_\infty - I_0) \times 100 \quad (1)$$

Preparation of ANTS/DPX-Containing LUVs. A typical procedure is as follows. A solution of POPC (4.0 mg, 0.0053 mmol) and lipid **1** (2.7 mg, 0.0027 mmol) in chloroform (0.3 mL) was placed in a 10 mL test tube and dried under a stream of nitrogen. The residue was dried further under high vacuum overnight. The resulting lipid film was hydrated in 5 mM TES buffer (12.5 mM ANTS, 45.0 mM DPX, 20 mM NaCl, pH = 7.0) for 30 min with occasional vortexing. The opaque dispersion was subjected to ten freeze–thaw cycles. The resulting mixture was extruded twenty-nine times through a polycarbonate filter (diameter = 19 mm, pore size = 100 nm) at room temperature using an Avanti Mini-Extruder. A portion (0.1 mL) of the liposome solution



[3] The preparation of the stock solution of the Cu-complex is as follows: To a 3 mL aqueous solution of $CuCl_2$ (71.3 mg, 0.53 mmol) was added 3 mL of an aqueous solution of PMDETA (442 μL, 2.1 mmol). The resulting blue solution was stirred for 2 h and then diluted to 10 mL with water. The concentration of the Cu-complex in the stock solution was 0.053 M.

[4] The concentration of NaCl was 107 mM for the 100 h assay and 5 M for the accelarated assay.

was passed through a column of Shepadex G-50 using 5 mM TES buffer (pH = 7.0) containing 100 mM NaCl as the eluent. The liposome fractions were combined and diluted to 5.0 mL with the same TES buffer. The concentration of the total phospholipids in the stock solution was 5.3×10^{-4} M.

ANTS/DPX Leakage Assay. An aliquot (100 μL) of the above liposomal solution was added to 1.90 mL of the appropriate buffer.[5] The fluorescence emission at 510 nm (λ_{ex} = 353 nm) was measured overtime. After 24 h, 40 μL of Triton X-100 (1%) was added, disrupting the vesicles and releasing the remaining CF (100% release). The percent leakage at any given time was calculated using equation (1).

Polymerization and Labeling of LUVs. A solution of POPC (4.0 mg, 0.0053 mmol) and lipid **1** (2.7 mg, 0.0027 mmol) in chloroform (0.3 mL) was placed in a 10 mL test tube and dried under a stream of nitrogen. The residue was dried further under high vacuum overnight. The resulting lipid film was hydrated in 10 mM HEPES buffer (0.3 mL, 50 mM CF, 10 mM NaCl, pH = 7.4) for 30 min with occasional vortexing. The opaque dispersion was subjected to ten freeze–thaw cycles. The resulting mixture was extruded twenty-nine times through a polycarbonate filter (diameter = 19 mm, pore size = 100 nm) at room temperature using an Avanti Mini-Extruder. The resulting liposome solution was diluted to 4 mL with the same buffer. The concentration of **1** in the stock solution was 6.75×10^{-4} M. Separately, a commercially available dye, 1,5-I-AEDANS (**10**, 4.3 mg, 0.010 mmol), was allowed to react with sodium azide (1.0 mg, 0.12 mmol) in water (1 mL) for 12 h. Aliquots of the resulting solution (10 mM, 14 μL, 0.14 μmol), cross-linker **4** (10 μL of 20 mg/mL aqueous solution, 0.675 μmol), Cu-complex (10 μL of 0.034 M aqueous solution, 0.34 μmol),[3] and sodium ascorbate (10 μL of 27 mg/mL aqueous solution, 1.4 μmol) were added to the liposomal solution (1 mL). After 24 h, the mixture was passed through a column of Sephadex G-50 with 10 mM HEPES buffer (107 mM NaCl, pH=7.4) as the eluent. The liposome fractions were combined and diluted to 5.0 mL with the same HEPES buffer. A portion (2.5 mL) or the resulting solution was placed in a plastic cuvette for fluorescence measurement (λ_{ex} = 345 nm). The control LUVs were prepared exactly the same as the click-labeled LUVs except that no copper catalyst and sodium ascorbate were added in the process.

10

[5] pH = 7.0: 5 mM TES, 100 mM NaCl; pH = 6.0: 10 mM PBS, 5 M NaCl; pH = 5.0: 10 mM acetate, 5 M NaCl; pH=4.0: 10 mM acetate, 5 M NaCl.

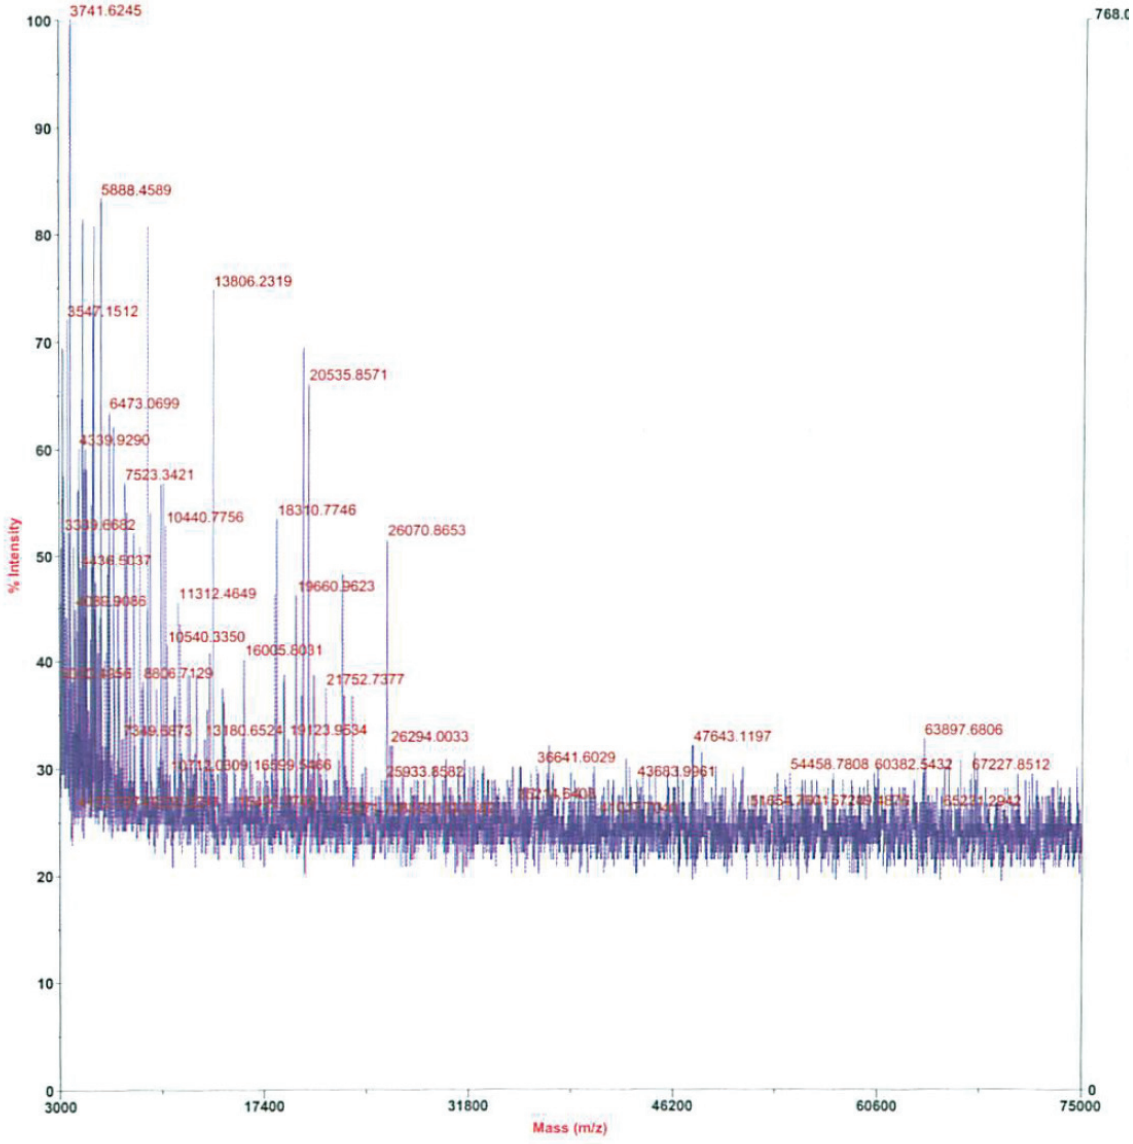


Figure 1S. MALTI-TOF mass spectrum of the CPLs prepared with [**1**]/[POPC] = 1:1.

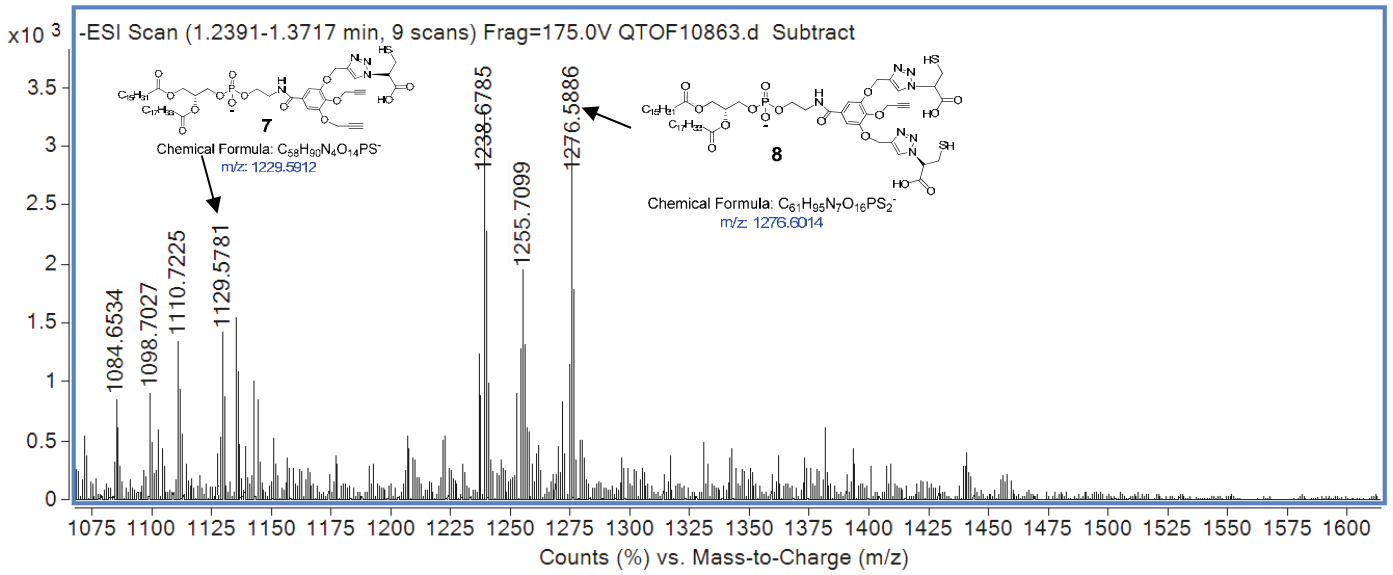

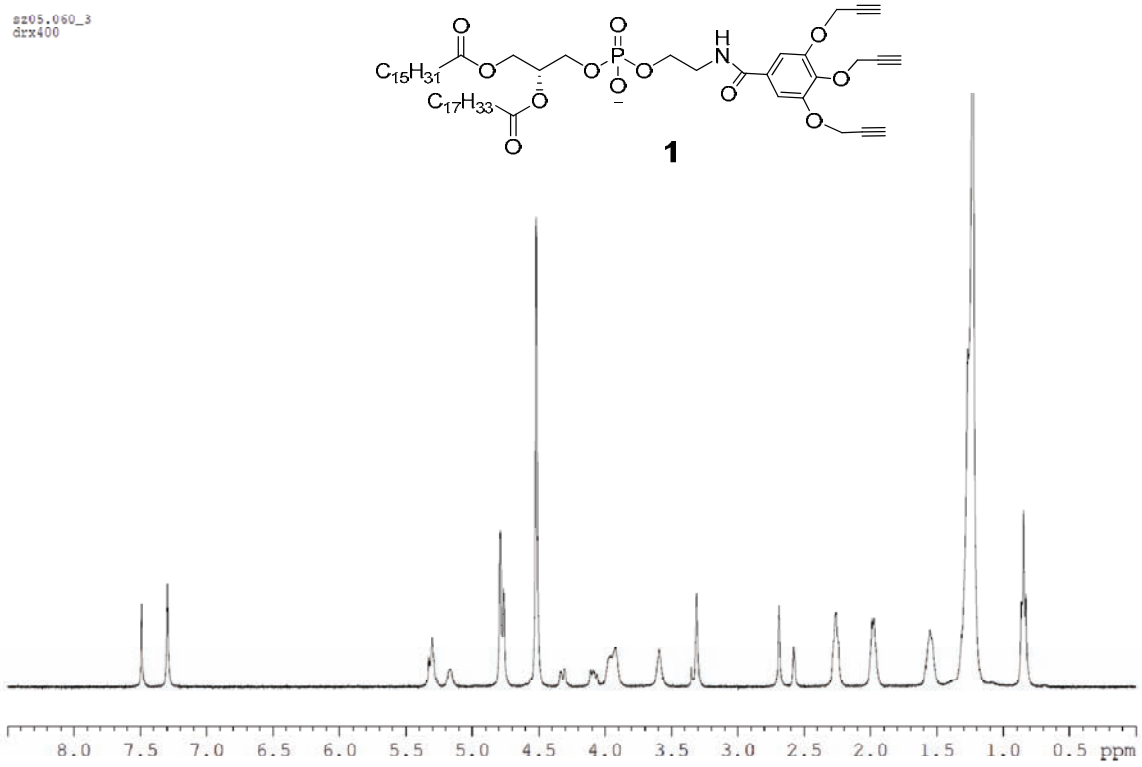

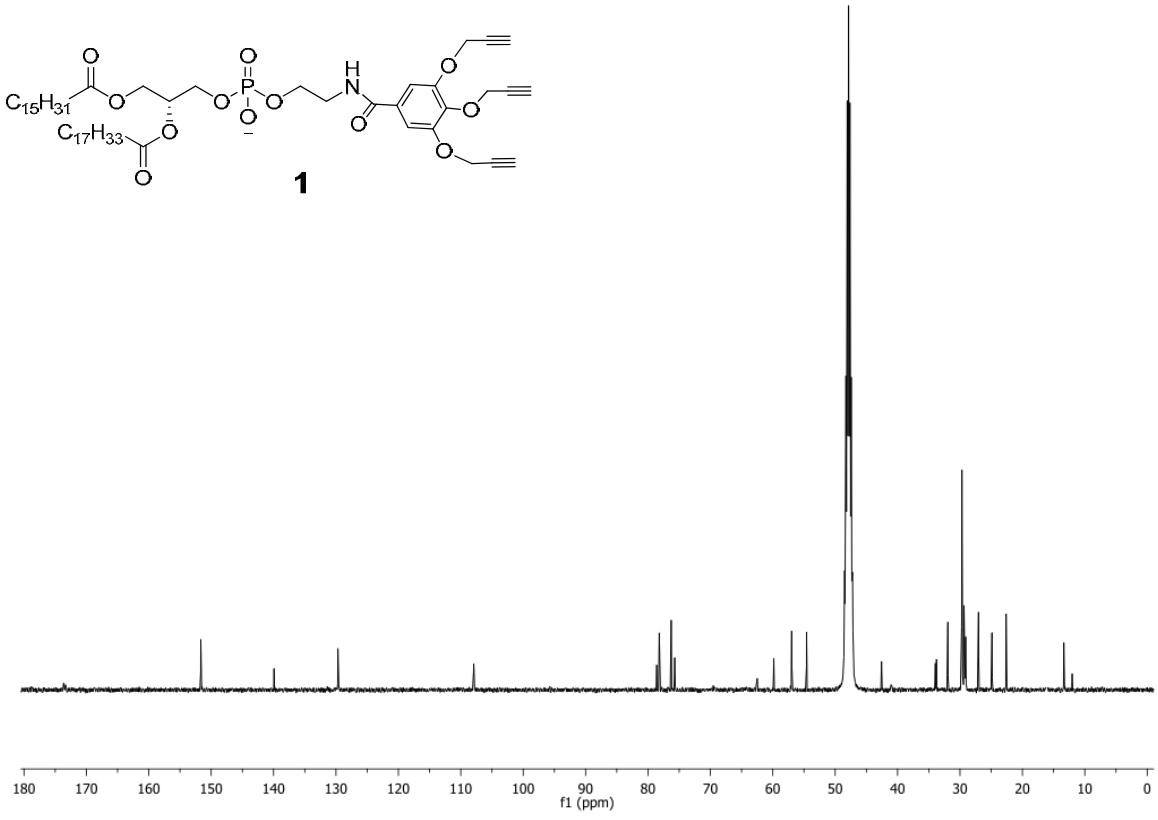

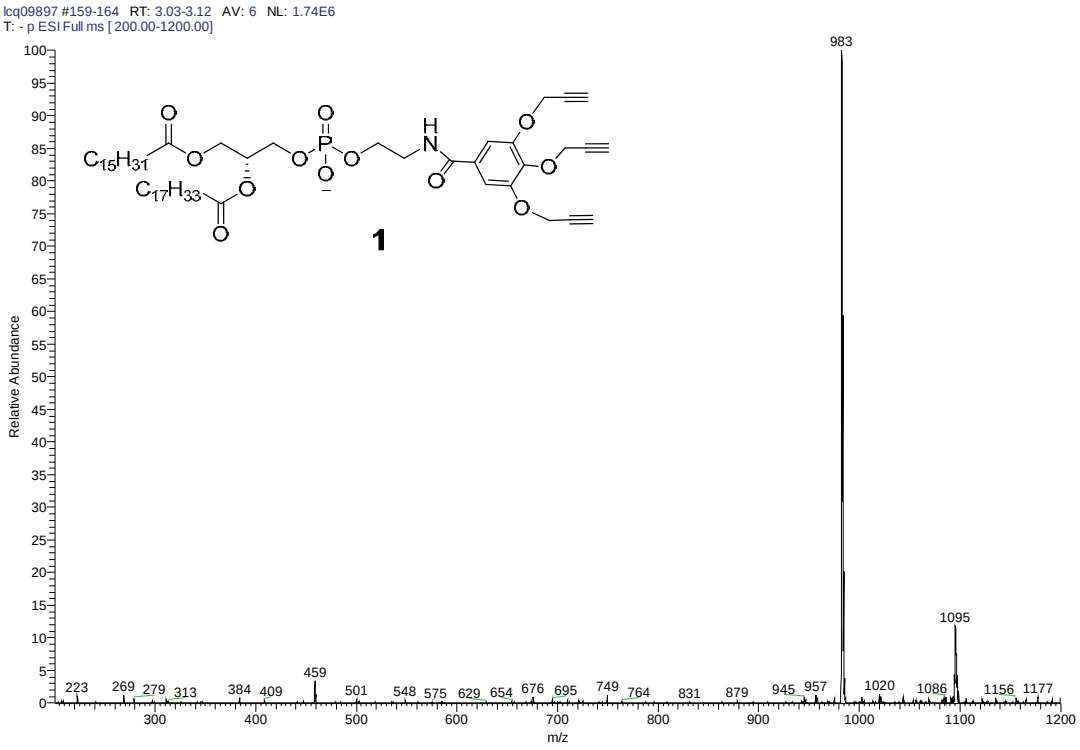

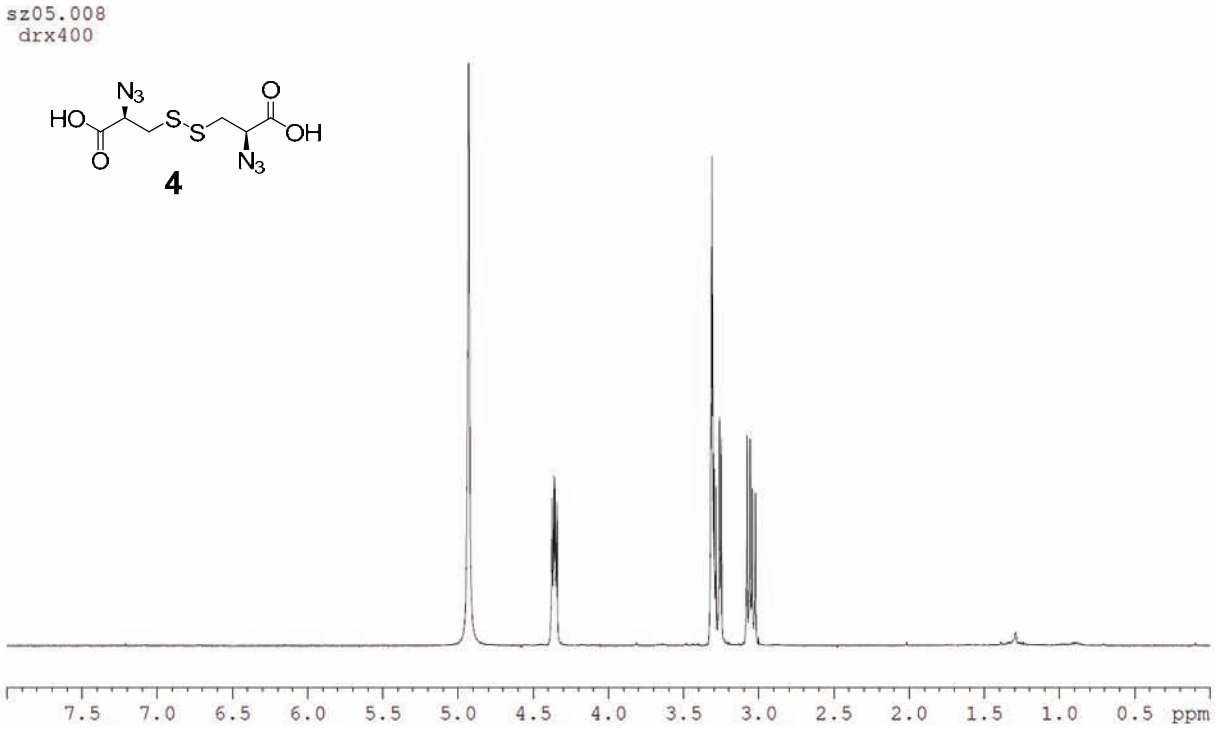

Figure 2S. ESI mass spectrum of the depolymerized CPLs. Depolymerization was accomplished by incubation of the CPLs with 0.3 mM of DTT for 24 h at room temperature.

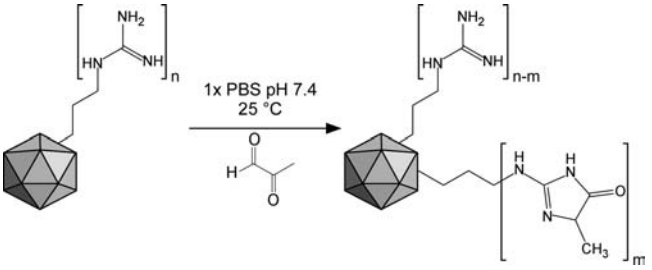
ABSTRACT: A chemical approach for selective masking of arginine residues on viral capsids featuring an exogenous glycation reaction has been developed. Reaction of adeno-associated viral (AAV) capsids with the α-dicarbonyl compound, methylglyoxal, resulted in formation of arginine adducts. Specifically, surface-exposed guanidinium side chains were modified into charge neutral hydroimidazolones, thereby disrupting a continuous cluster of basic amino acid residues implicated in heparan sulfate binding. Consequent loss in heparin binding ability and decrease in infectivity were observed. Strikingly, glycated AAV retained the ability to infect neurons in the mouse brain and were redirected from liver to skeletal and cardiac muscle following systemic administration in mice. Further, glycated AAV displayed altered antigenicity demonstrating the potential for evading antibody neutralization. Generation of unnatural amino acid side chains through capsid glycation might serve as an orthogonal strategy to engineer AAV vectors displaying novel tissue tropisms for gene therapy applications.

Protein engineering tools have played a central role in understanding structure-function correlations of viruses.[1,2] The application of site directed mutagenesis to elucidate the structural basis of virus-receptor interactions is particularly noteworthy in this regard.[3,4] Altering virus-receptor interactions by selective incorporation of unnatural amino acids or chemical masking of amino acid residues, exposed on the viral capsid surface, could greatly expand the ability to discover receptor footprints on viral capsid surfaces, as well as design new viral vectors and vaccines.

Several studies exploring the genetic incorporation of unnatural amino acids and/or chemoselective ligation to viral capsids have been reported.[5] For instance, viral capsids containing unnatural amino acids with alkyne,[5] azide,[5] or aminophenyl[6] side chains have been generated for coupling of drugs and/or targeting ligands. Synthetic strategies for chemoselective ligation to naturally occurring amino acid residues such as Lys, Glu, Cys, Trp, and Tyr on the surface of viral capsids have also been developed.[7−11] However, the application of such chemistries toward reengineering viruses for gene delivery remains unexplored thus far.

In the current study, we focused on exploiting the naturally occurring chemical reaction involving α-dicarbonyl compounds with proteins, which leads to the formation of advanced glycation end-products (AGE).[12] We hypothesized that methylglyoxal, an intermediate of the Maillard reaction, will selectively form adducts with the guanidinium side chain of surface-exposed Arg residues on viral capsids (Scheme 1). The reaction proceeds readily in aqueous solution and has been shown to predominantly modify Arg residues in various proteins with high efficiency. Proteomic analysis of Arg adducts has previously demonstrated the formation of dihydroxyimidazolidines followed by subsequent rearrangement into hydroimidazolones.[13,14]



AAV is a small nonenveloped ssDNA virus that is rapidly gaining momentum as a vector in human gene therapy applications.[15] The AAV capsid is composed of 60 capsid protein subunits assembled in icosahedral symmetry ($T = 1$). Each capsid protein subunit contains a β-barrel core with long loops between the β-strands that create striking surface features. Surface spikes located at the threefold symmetry axes are most prominent and have been implicated in receptor binding and cell entry. The remarkable plasticity of the AAV virion shell has been demonstrated through extensive mutagenesis studies.[15]

Of several strains isolated to date, AAV serotype 2 is the most studied and binds to its primary receptor heparan sulfate using a basic cluster of amino acids (R484, R487, K532, R585, and R588) located at the threefold axis of symmetry.[16,17] Previous site-directed mutagenesis studies have demonstrated the critical role played by this continuous basic patch in cell surface recognition as well as liver tropism in mice.[18,19] In particular, mutation of Arg

Scheme 1. Glycation of AAV Vectors with Methylglyoxal

residues within this basic cluster has been shown to confer muscle tropism. However, the potential for generating atypical tissue tropisms through the latter approach is restricted by the ability to only incorporate naturally occurring amino acids with limited side chain diversity.

We hypothesized that an orthogonal approach based on selective chemical masking of Arg residues with α-dicarbonyl compounds would enable display of unnatural amino acid residues with diverse functional groups on the AAV capsid surface. Such modification of amino acid side chains might enable design of viral vectors displaying atypical tissue tropisms. As proof of principle, we chose methylglyoxal (MGO), a highly reactive compound derived from glycolysis and known for its propensity to form Arg and Lys adducts.[14] It should be noted that chemical conjugation to Lys residues on AAV2 capsids are routinely carried out and demonstrate no adverse effect on capsid infectivity.[20]

Overnight reaction of AAV2 with methylglyoxal at neutral pH produced glycated AAV vectors. Characterization of the glycated vectors was carried out using MALDI-TOF/MS of trypsin-treated capsid proteins. Rationale for such analysis is based on earlier observations that altered tryptic digestion of glycated proteins enables proteomic analysis of MGO adducts.[13] Tryptic fragments obtained from the major AAV capsid protein subunit (VP3; Genbank# AAC03779.1) were subject to MALDI-TOF/MS analysis. Peak signals were normalized to that of a peptide fragment located within the capsid interior[16] containing residues L299 through K309 (m/z = 1375.7), which are expected to remain unmodified when subject to glycation. Analysis of mass spectra using the MASCOT search engine revealed a decrease in peak signal intensities corresponding to peptide fragments containing Arg residues and, to a lesser extent, Lys residues (Supporting Information). Specifically, the MGO-derived hydroimidazolone adduct is expected to add 54 m/z units to the modified peptide fragment. New peak signals, observed between m/z 2400 and 2600 were specifically assigned to peptide fragments containing hydroimidazolone adducts at R585 and R459 positions (Figure 1a). Computation of the ratio of peak signal intensities pertaining to the latter residues before and after glycation indicates that 29.5% of R585 and 58.9% of R459 residues are glycated. Although the latter results indicate the potential formation of mixtures of variably glycated capsids and are semiquantitative in nature, we have optimized chemical modification of AAV vectors to consistently generate the same phenotype (Supporting Information). Moreover, the aforementioned results are in agreement with earlier studies and corroborate the notion that surface-exposed Arg residues on proteins are preferred targets for glycation.[13,14]

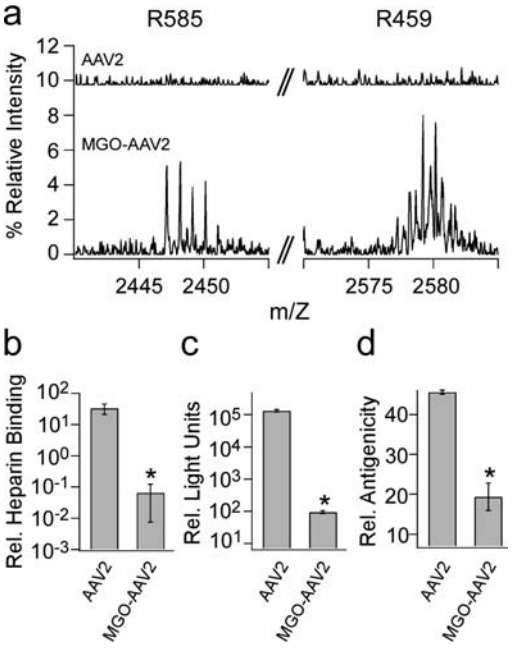

Figure 1. (a) Tryptic digestion of chemically modified AAV2 VP3 capsid proteins demonstrates two preferred sites for Arg adduct formation. The increase in signal at m/z 2446.1 and 2577.2 corresponds to the hydroimidazolone adduct at R585 and R459 positions within the peptides 566-TTNPVATEQYGSVSTNLQRGNR-588 (expected adduct m/z = 2446.173) and 448-TNTPSGTTTQSRLQFSQAGAS-DIR-471 (expected adduct m/z = 2577.231), respectively. (b) Solid-phase binding assay of unmodified and glycated AAV2 capsids to heparin-coated plates. Binding is relative to the charge neutral dextran. (c) In vitro infectivity assay of unmodified and glycated AAV2 in HEK293 cells (10 000 viral genomes/cell). (d) Solid-phase binding assay of unmodified and glycated AAV2 capsids to plates coated with the monoclonal antibody A20. Binding is relative to an isotype-matched antibody control. Error bars represent standard deviation (n = 3). Asterisks represent statistical significance ($p < 0.05$). Additional experimental details available in Supporting Information.

The ability of glycated AAV2 to bind heparin was determined using a streptavidin-coated 96-well assay plate coated with biotinylated heparin. Binding was determined using Q-PCR and binding to biotinylated dextran was utilized as a control. Glycated AAV2 capsids display a significant loss ($p < 0.05$) in heparin binding ability in comparison with unmodified AAV2 capsids (Figure 1b). Further, MGO-modified AAV2 vectors demonstrate an approximately 1000-fold decrease in gene transfer efficiency in HEK293 cells (Figure 1c). These results corroborate the notion that glycated AAV2 is unable to bind its cognate attachment receptor, heparan sulfate.[21] Of the five residues (R484, R487, K532, R585, and R588) located within the heparan sulfate receptor footprint, R585 or R588 has been shown to be indispensable for heparin binding and infectivity.[18,19] Taken together with MS data, the aforementioned results suggest that conversion of the guanidinium side chain of R585 into the hydroimidazolone derivative likely disrupts the heparan sulfate footprint on the AAV2 capsid surface. It should also be noted that, although glycation of R459 was observed, this residue has not been implicated in heparin binding or infectivity.[18,19]

Another observation supporting the chemical masking of arginine residues within surface-exposed domains is the altered antigenicity of glycated AAV2 vectors. Using a solid-phase

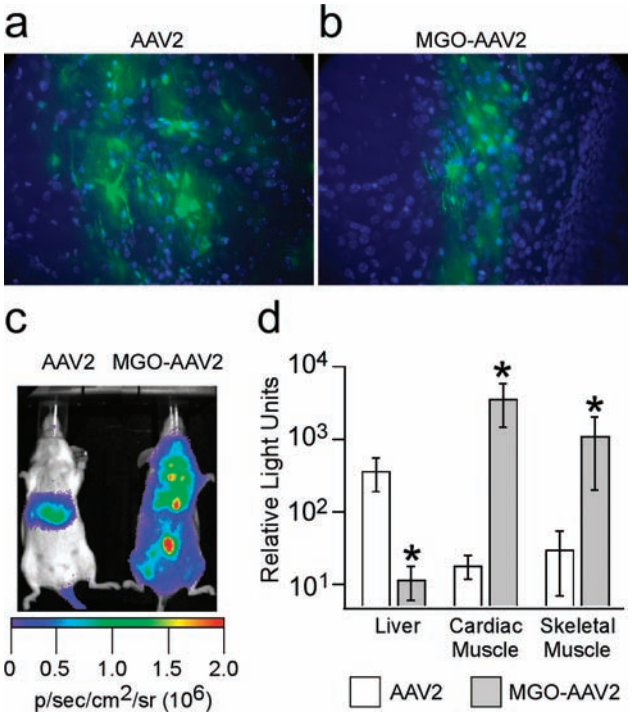

Figure 2. Epifluorescence images of neuronal GFP expression in 40 μm brain sections obtained from BALB/c mice injected intracranially with 7.5×10^8 (a) untreated AAV2 and (b) MGO-treated AAV2 vectors. Brain sections were taken 2 weeks post-injection and stained with DAPI prior to imaging. (c) Live animal bioluminescent images of BALB/c mice ($n = 3$) injected with untreated and MGO-treated AAV2 vectors. Mice were injected via tail vein at a dose of 5×10^{10} viral particles. Mice were imaged 4 weeks post-injection. Changes in luciferase expression patterns indicate altered tissue tropism profiles and are represented on a rainbow scale. (d) Luciferase expression from untreated and MGO-treated AAV2 vectors in different tissue lysates. Relative light units represent luciferase transgene expression and levels are normalized to tissue mass. Error bars represent standard deviation ($n = 3$). Asterisks represent statistical significance ($p < 0.05$). Additional experimental details available in Supporting Information.

binding assay, we determined that MGO-modified AAV2 vectors showed a >2-fold decrease in binding to a prototypical monoclonal antibody (A20), which recognizes intact AAV2 capsids (Figure 1d). An isotype matched antibody served as control. These results indicate the potential for glycated AAV vectors to evade pre-existing neutralizing antibodies in the human population.[22]

Despite demonstrating decreased infectivity *in vitro*, glycated AAV2 capsids infect neurons as efficiently as untreated AAV2 following intracranial injection into the mouse brain (Figure 2). Taken together with the altered antigenicity described earlier, these results suggest that glycated AAV2 vectors might be well suited for CNS gene transfer applications. Further, bioluminescent images of mice obtained following intravenous (tail vein) administration of glycated AAV2 show expansion of viral tissue tropism beyond the liver to other systemic organs (Figure 2c). Quantitation of luciferase expression in tissue lysates reveals approximately 100-fold higher transgene expression levels in cardiac and skeletal muscle with MGO-treated AAV2 in comparison with untreated AAV2 vectors (Figure 2d). In addition, a concomitant decrease in transgene expression within the liver (over 10-fold) is observed. These results demonstrate the feasibility of chemical redirection of AAV2 capsids from liver to muscle tissue and corroborate a similar transduction profile obtained by mutagenesis of R585/R588 residues within the heparan sulfate footprint.[19,23]

In conclusion, the aforementioned studies validate the notion that selective chemical masking of Arg residues with α-dicarbonyl compounds can serve as an orthogonal approach to reengineer viral surface topology and consequently, antigenicity, receptor usage and tissue tropism. This initial study is one of the first to demonstrate the feasibility of displaying unnatural hydroimidazolone side chains on viral capsids. A broad range of α-dicarbonyl compounds ranging from glyoxal to oxo-(7-oxoacetyl-9*H*-fluoren-2-yl)-acetaldehyde are currently being explored for formation of diverse Arg adducts on AAV capsids. An increase in complexity of the α-dicarbonyl side chain may allow generation of novel tissue tropisms, while simultaneously enabling design of AAV vectors capable of evading neutralizing antibodies. This chemical approach represents a new dimension in viral capsid engineering and is likely to impact viral vector design for human gene therapy applications.

Glycated AAV Vectors: Chemical Redirection of Viral Tissue Tropism

Eric D. Horowitz, Mark S. Weinberg and Aravind Asokan

Supporting Information

Methods

Chemicals and reagents. Methylglyoxal (MGO) was purchased from Acros Organics (Morris Planes, NJ) as a 40% wt/v solution and was used without further purification. Streptavidin-coated and protein A-coated plates were purchased from Pierce Scientific and used as received. Biotinylated dextran (Biotium Inc., Hayward, CA) and biotinylated heparin (Invitrogen, Carlsbad, CA) were dissolved in dH_2O to a concentration of 10 μg/mL before use. Luciferin for *in vitro* luciferase assays (Promega, Madison, WI) and *in vivo* live animal imaging (Caliper Life Sciences, Hopkinton, MA) were diluted in phosphate-buffered saline (PBS, pH 7.4) as required.

Virus production and purification. Adherent human embryonic kidney (HEK293) cells were grown in Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum, penicillin, streptomycin, and amphotericin B. Cells were grown at 37 ˚C and 5% CO_2. AAV2 vectors packaging either a firefly luciferase gene driven by chicken β-actin promoter (CBA-Luc) or a self-complementary GFP gene driven by the cytomegalovirus promoter (CMV-GFP) were produced using the triple plasmid transfection method as described previously.[1] Viral titers, which ranged from 5×10^{11} vg/mL to 2×10^{12} vg/mL, were determined using Q-PCR.

AAV glycation and mass spectrometric analysis. AAV2 CBA-Luc capsids in 1× PBS were mixed with MGO at 4 mM. Reactions were allowed to proceed at room temperature for 20 hrs. Similarly untreated virus was also allowed to sit at room temperature for 20 hrs. Reactions were then dialyzed against 1× PBS for 5 hrs at 4 ˚C. Virus was then used immediately afterwards without additional freeze-thaws.

For mass spectroscopic analysis of glycated viral particles, 5×10^{10} glycated particles were first separated by SDS/PAGE (10% Bis/Tris). Viral proteins were visualized using Brilliant Blue R-250 Coomassie stain (Bio-Rad, Hercules, CA). The VP3 band visualized at 60 kDa was excised and subjected to in-gel tryptic digestion (Applied Biomics, Hayward, CA). After peptide extraction and desalting the digested peptides were spotted on a MALDI source and separated by MALDI/TOF/TOF. Fragments were then identified using the NCBI MASCOT database. All peak intensities were normalized to an internal peptide fragment.

Solid phase binding assays. Solid phase binding studies were performed by binding either biotinylated heparin or biotinylated dextran (10 μg/mL) to a streptavidin-coated 96-well plate. After washing the plate of unbound heparin and dextran, reacted and unreacted AAV2 CBA-Luc (1×10^9 vg) was allowed to bind to the plates for 60 minutes at 37 ˚C. After thorough washing with PBS, bound virus was degraded using proteinase K and was quantified by Q-PCR amplification of the vector genome. Dextran binding served as a control for non-specific binding.

Similarly, antibody recognition was determined by binding A20 (1μg/mL) or Rabbit antihuman (1 μg/mL) antibodies to a protein A-coated 96-well plate. After washing the plate of unbound antibody, reacted and unreacted AAV2 CBA-Luc (1×10^9 vg) was allowed to bind to the plates for 60 minutes at 37 ˚C. After thorough washing with PBS, bound virus was degraded using proteinase K and was quantified by Q-PCR amplification of the vector genome. The isotype-matched rabbit antihuman antibody binding served as a control for non-specific binding.

Transduction assays. Transduction efficiency was determined by adding glycated AAV2 CBA-Luc to HEK293 cells in a 96-well plate at 10,000 viral genomes per cell. Transgene expression was determined by luminometric analysis using a Perkin Elmer Victor luminometer 18 hrs post infection.

Animal Studies. Housing and handling of BALB/c mice used in the current study were carried out in compliance with National Institutes of Health guidelines and approved by IACUC at University of North Carolina-Chapel Hill (protocol #09–117). Unreacted or glycated AAV2 CBA-Luc were administered intravenously in a volume of 200 μl PBS. Luciferase expression in animals was imaged using a Xenogen IVIS-Lumina imaging system (Caliper Life Sciences, Hopkinton, MA) after intraperitoneal injection of luciferin substrate (120 mg/kg; Nanolight). Image analysis was carried out using the Living Image software. Luciferase transgene expression in various tissue types was determined using a luminometric assay (Promega, Madison, WI) from tissue lysates and normalized per μg of protein determined by Bradford assay. Vector genome copy numbers were determined by Q-PCR after extraction of genomic DNA at different time intervals from various tissue types using a DNeasy kit (Qiagen, Valencia, CA).

For vector infusions into the mouse brain, animals were anesthetized with isofluorane and placed into a stereotaxic frame. Using a 32-gauge stainless steel injector and a Fisher Scientific infusion pump, mice (n=4) received 0.5 μl per hemisphere (total of 7.5×10^8 vg) of AAV2 CMV-GFP (right hemisphere) and the glycated AAV2 (left hemisphere) into the striatum (bregma +0.5 mm, lateral +/-1.5 mm, vertical -4.0 mm based on a brain atlas over 5 min. The injector was left in place for 3 min after infusion to allow diffusion from the injector. Two weeks after intracerebral injection, animals received an overdose of avertin (0.2 mL/10g of a 1.25% solution, intraperitoneally) and were perfused transcardially with ice-cold sodium phosphate-buffered saline (PBS pH 7.4), followed by 4% paraformaldehyde in phosphate buffer (PB, pH 7.4). After brains were post-fixed 24 hours at 4°C in the paraformaldehyde–PB, 40 μm coronal sections were cut using a vibrating blade microtome and subjected to immunohistochemical processing for GFP.

Statistical Analysis. All statistical analyses were performed using a two-tailed, unpaired Student's t-test. All error bars represent standard deviation (n=3).

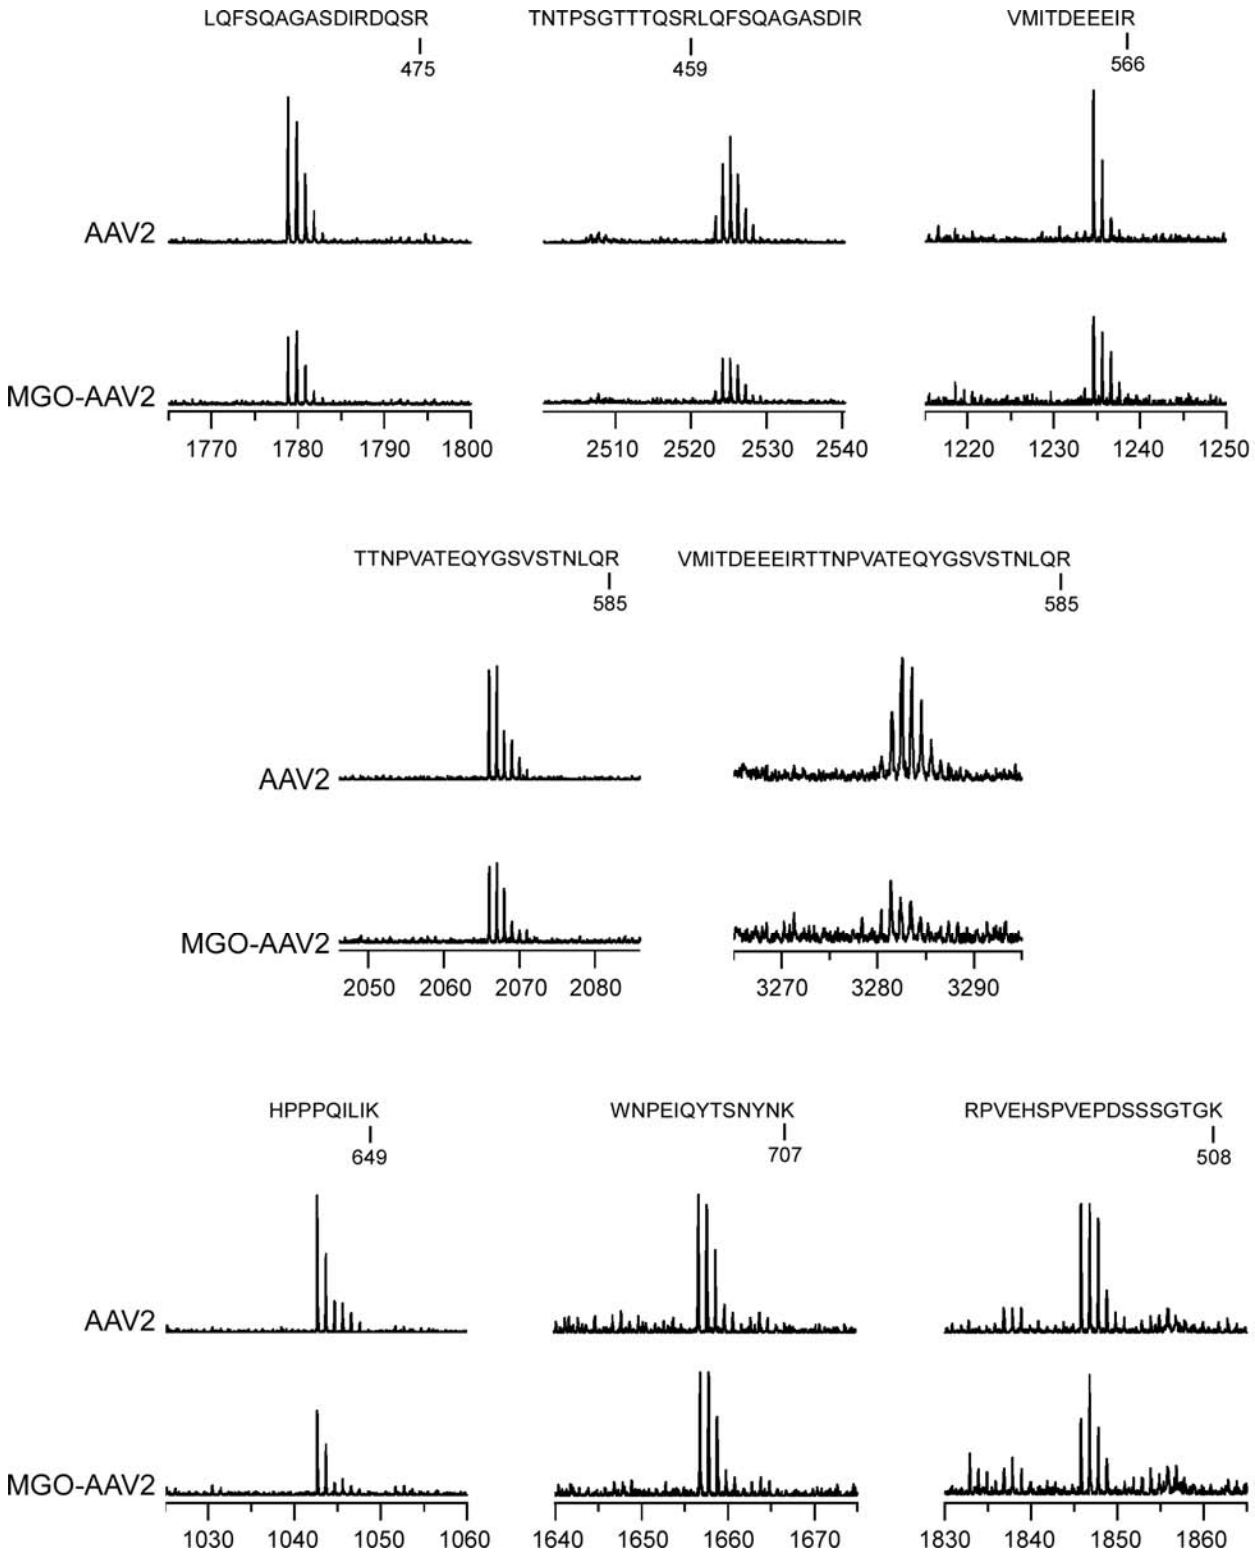

Figure S1. Analysis of MS peaks corresponding to peptide fragments which decrease tryptic digestion after glycation. Loss of tryptic digestion corresponds to the chemical modification of the terminal positively charged residue.

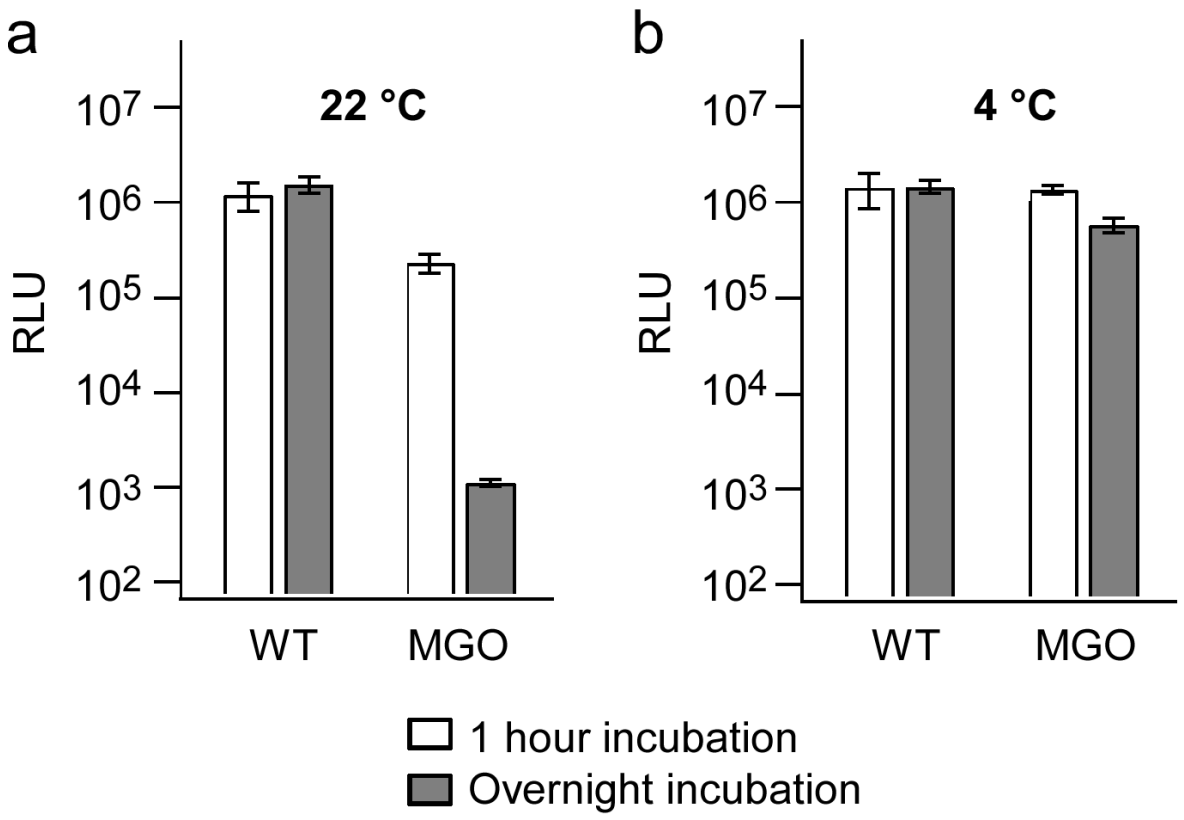

Figure S2. Optimization of glycation reaction. Glycation reactions were performed at two different time points 1 hr or overnight. Reactions were also performed at either a) 22 ˚C or b) 4 ˚C. Extent of glycation was determined by loss of infectivity on HEK293 cells (MOI = 10,000).

Supporting Information

ABSTRACT: Mixmer LNA/DNA fluorescent probes containing the 1-(phenylethynyl)pyrene fluorophore attached to 2′-*arabino*-uridine were synthesized and studied. The conjugates displayed significantly higher hybridization affinity to target DNA, increased fluorescence quantum yields of single-stranded oligonucleotides and their duplexes, and improved ability to form an interstrand excimer compared to analogous non-LNA probes.

INTRODUCTION

DNA- and RNA-derived fluorescent probes of various constructs that result in clear fluorescence signals upon binding to targets constitute a paradigm for modern, relatively inexpensive, and sequence-specific, homogeneous detection of nucleic acids.[1,2] For effective nucleic acid targeting, high-affinity and sequence-specific synthetic oligonucleotides (ONs) are required. Locked nucleic acid (LNA, Chart 1) is a synthetic nucleotide analogue[3−7] that provides high-affinity and selective recognition of cDNA and RNA.[8−13] High-affinity LNA/DNA ONs containing different fluorescent dyes have recently been applied for single-nucleotide polymorphism (SNP) analysis,[9−13] real-time PCR,[14−16] FISH analysis,[17−20] and other applications.[21,22] In all these assays, fluorescent LNA/DNA probes were superior in thermal affinity (T_m values increased up to 8 °C per one LNA monomer incorporation measured in a medium salt buffer) and in SNP discrimination of target sequences, when compared to the analogues DNA probes.

Another important aspect of fluorescent ON probes is suitable fluorescent dyes or dye pairs that are sensitive, photostable, and relatively inexpensive. Most fluorescent LNA/DNA probes reported so far have contained terminally attached fluorescent dyes of the xanthene or cyanine families (e.g., FAM, JOE, HEX, Cy5, etc.), which signal hybridization by fluorescence effect of choice (e.g., by dye-quencher proximity or by light-up effect of a single dye).[23−30] However, being exposed into the medium, these dyes did not allow more informative studies of biomolecules and their segments, or of their specific interactions.

Fluorescent ONs containing polyaromatic hydrocarbons (PAHs) are alternative probes for nucleic acid studies which due to the PAH electronic $\pi-\pi^*$ structure sense even minor changes in their microenvironment by fluorescence.[31] Among various PAH dyes, pyrene is of increased interest because of the long lifetime of its excited state and its ability in π-stacking, resulting in exciplex and excimer formation.[31] The main disadvantage of the pyrene label is its low quantum yields within biomolecules and relatively short absorption and emission wavelengths crossing the autofluorescence region of cells. Recently, the 1-(phenylethynyl)pyrene fluorophore (1-PEPy, Chart 1) was introduced as a refined alternative to parent pyrene with advantages of increased absorption, bathochromic shift of the absorption and emission maxima, and increased fluorescence quantum yield within biomolecules.[32−35] Previously, we attached the 1-PEPy fluorophore to 2′-*arabino*-uridine via a carbamate linker and showed the utility of this modification for detection of nucleic acid hybridization.[36] Even though 1-PEPy attached to DNA exhibited short excited lifetime (0.96−2.40 ns), the dye was able to form inter- and intrastrand excimers.[36] On the other hand, we observed that internal 1-PEPy modification, i.e., 1-PEPy attached to an internal 2′-*arabino*-uridine monomer, significantly reduced thermal stabilities of DNA duplexes (T_m values decreased by 3−8 °C per one modification in a medium salt buffer) which can become an obstacle for its utility.[36] The negative effect of 1-PEPy on probe affinity can be reduced by incorporation of two or more LNA nucleotides into ONs. However, recent structural investigations of LNA/DNA ONs have showed that, being a RNA mimic, LNA nucleotides significantly change duplex geometry by decreasing the B-type character of double-stranded DNA toward intermediate A/B-type.[8−13] Therefore, we propose that the effect of LNA within ONs on spectral properties of any PAH label can be significant and need to be studied in detail.

We herein evaluate ONs having the 1-PEPy label attached to 2′-*arabino*-uridine via a carbamate linker in combination with LNA nucleotides. We report synthesis, thermal denaturation,

[a] Absorption and steady-state fluorescence emission spectra measured in a medium salt buffer using 0.1−1.0 μM concentrations of ONs. λ^{abs}_{max} and λ^{fl}_{max} are absorption and fluorescence maxima, respectively; τ_1 and τ_2 are two fluorescence lifetime components; S_1 and S_2 are contribution of τ_1 and τ_2 components in percentages; average fluorescence lifetime $\langle\tau_f\rangle$ is calculated using equation: $\langle\tau_f\rangle = \Sigma S_i\tau_i / \Sigma S_i$.[26]

RESULTS AND DISCUSSION

Initially, we prepared four different ONs having the 1-PEPy fluorophore (monomer **X**)[36] and two LNA nucleotides[3−7] in four different relative positions (Table 1; **ON2**−**ON5**). Synthesis of the modified ONs was performed using phosphoramidite derivative **1**[36] and commercially available LNA phosphoramidites.[3−7] Additionally, compounds **1** and **2**[36] were utilized to prepare six complementary sequences to **ON2**−**ON5** having monomers **X** and **Y** positioned near the 5′-end (Table 1; **ON6**−**ON11**). The latter was done in order to study 1-PEPy interstrand excimer formation within DNA duplexes. Finally, we prepared the LNA-free fluorescent probe **ON13**, which was used as a reference to verify the effect of LNA on 1-PEPy properties. The sequence of **ON13** was equivalent to the one that was previously used to investigate 1-PEPy-2′-*arabino*-uridine attached to DNA.[36] All modified oligonucleotides were prepared using standard protocols except for extended coupling times (10 min) for the phosphoramidites of monomers **X** and **Y**, and for LNA phosphoramidites. Moreover, we observed better coupling yields of the phosphoramidite reagents **1** and **2** using 0.6 M pyridine hydrochloride in MeCN as activator in comparison with standard 1*H*-tetrazole in MeCN (99% vs 89−90%, respectively). All modified ONs were purified by RP-HPLC and their identities and purities were confirmed by MALDI-MS and IC-HPLC, respectively.

First, we investigated the binding of **ON2**−**ON5** and **ON13** to DNA by UV thermal denaturation experiments using a medium salt buffer (100 mM NaCl, 10 mM Na-phosphate, 0.1 mM EDTA, pH 7.0), and compared the data to the unmodified and **X**-labeled references **ON12**:**ON1** and **ON13**:**ON1**, respectively (Table 1). Insertion of the two LNA monomers completely neutralized the destabilizing effect of 1-PEPy-2′-*arabino*-uridine (Table 1, T_m and ΔT_m data for **ON2**−**ON5**). Interestingly, the specific positioning of the LNA monomers along the probe sequences had a remarkable effect on T_m values as well. The highest duplex stabilization by LNAs was observed for the duplex **ON4**:**ON1** having LNA monomers separated by two nucleotides from the 1-PEPy (ΔT_m = +12.0 °C compared to **ON13**:**ON1**).

Next, we evaluated spectroscopic and photophysical properties of the 1-PEPy-containing LNA/DNA conjugates (Table 2). Steady-state fluorescence emission spectra were recorded in a medium salt buffer using an excitation wavelength of 360 nm. Generally, all spectra exhibited a typical 1-PEPy-monomer emission of the 1-PEPy dye in the region 380−480 nm with $\lambda^{fl}_{max} \sim$ 400 nm. The insertion of LNA monomers into **ON2**−**ON5** did not significantly affect either absorption or fluorescence emission wavelengths of the 1-PEPy dye. Next, fluorescence quantum yields Φ_f of single-stranded **ON2**−**ON5** and their duplexes Φ_f = 16−76% were approximately 160−390% higher than those for **ON13** and also remarkably higher that typical quantum yields of pyrene label attached to DNA. We propose that the high quantum yields of 1-PEPy within LNA/DNA conjugates might result from combination of two factors: (1) short fluorescence lifetime of 1-PEPy and (2) shielded positioning of the 1-PEPy fluorophore within the polar groove environment preventing interactions of the fluorophore with quenchers of fluorescence such as medium, oxygen, and nucleobases. As it was demonstrated for the fluorescent pyrene label attached directly to 2′-amino-LNA,[37,38] this specific positioning can be achieved due to structural alterations within the duplexes induced by the LNA nucleotides. The high fluorescence quantum yields of the 1-PEPy-LNA/DNA significantly decrease probe detection limits, which is of high importance for biological studies and biomedical assays.

However, the high Φ_f values of conjugates **ON2**−**ON5** (0.25−0.63) were only slightly affected by hybridization with complementary unmodified DNA. Additionally, slightly increased average fluorescence lifetimes of the 1-PEPy dye within LNA-containing ONs and duplexes compared to the references **ON13** and **ON13**:**ON1** were observed. Moreover, even in presence of the two RNA-mimicking LNA nucleotides still two fluorescent excited states of the 1-PEPy were observed, and both had fluorescence lifetimes and contribution values of the same range as **ON13**. This implies that insertion of the LNA nucleotides remarkably affects positioning of the fluorophore within the probes and increase their fluorescence quantum yields without affecting basic photophysical characteristics of the dye, such as the number of fluorescent excited states and their lifetimes.

Remarkably high Φ_f values were observed for both single-stranded **ON4** and its duplex **ON4**:**ON1** in which 1-PEPy and LNAs were separated by two nucleotides (Table 2). Such high fluorescence quantum yields of the dye within a single-stranded conjugate are quite surprising and may result from LNA-induced formation of a secondary structure in **ON4** preventing quenching interaction of the fluorophore. The formation of a preorganized structure by **ON4** was also suggested by the more structured CD

dx.doi.org/10.1021/bc1005027 |*Bioconjugate Chem.* 2011, 22, 533–539

spectra obtained for single-stranded **ON4** compared to the CD spectra of LNA/DNA probes **ON2**, **ON3**, and **ON5**, and reference probe **ON13** (Figure 1 in Supporting Information).

To further investigate how the 1-PEPy can be protected from quenchers of fluorescence within single-stranded LNA/DNA, molecular models were built (Figure 2). They showed that stacked structures from two spatially accessible G:C base pairs allow placing of 1-PEPy in a cave isolating it from quenching by the buffer medium, oxygen, or nucleobases (Figure 2C,D).

Next, pyrene excimer fluorescence ($\lambda^{fl}_{max} \sim 480$ nm) is proven to be a useful tool for structural studies in biochemistry and molecular biology as "probing of proximity" since the excimer signal is observed when the two pyrenes display some degree of coplanarity and are positioned within a distance less than 4 Å.[31,39−41] Previously, pyrene attached to the sugar part of different nucleosides formed interstrand excimers being located in "+2 zipper",[42−44] "+1 zipper,[37,43,44] or "−1 zipper"[37,45] modes (for description of the "zipper" nomenclature, see caption of Table 3). Recently, we also confirmed weaker inter- and intrastrand excimers formed by 1-PEPy, although it has such a short excited lifetime (<2.5 ns).[36]

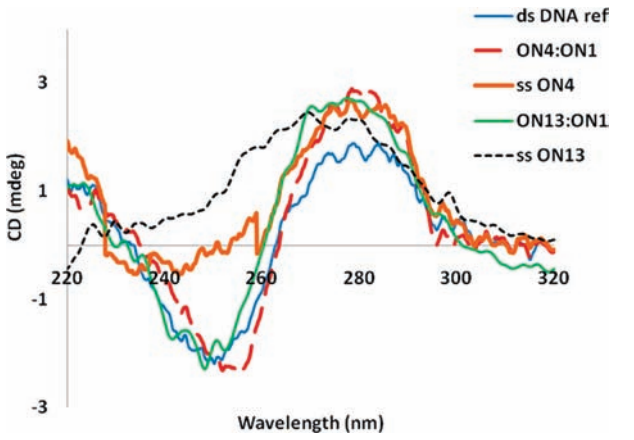

Figure 1. CD spectra of modified single-stranded (ss) oligonucleotides **ON4** and **ON13** and their duplexes with cDNA **ON1**. Double-stranded DNA reference (ds DNA ref) represents the corresponding unmodified duplexes of the same sequence. The spectra were recorded in a medium salt buffer at 19 °C using 1.5 μM concentration of complementary strands.

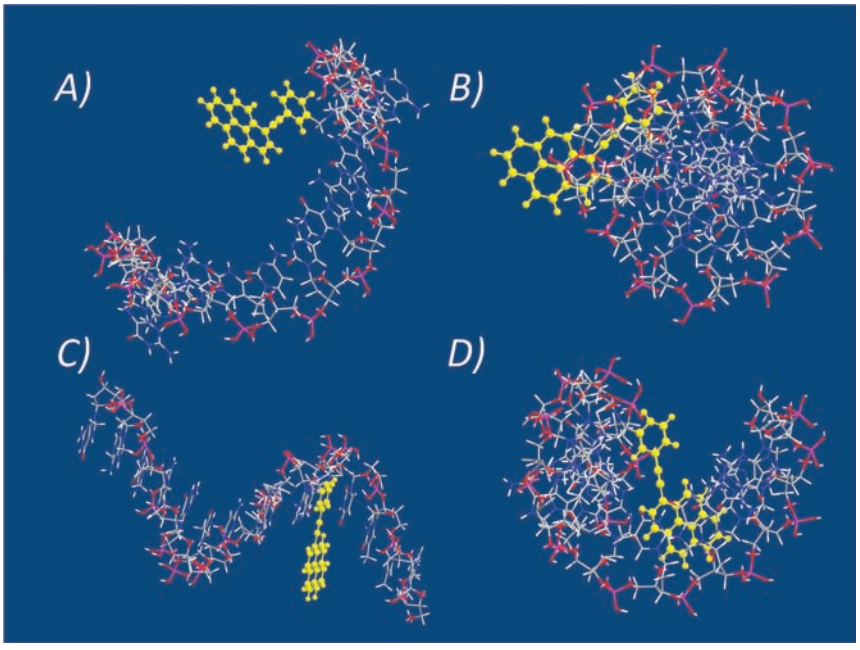
Herein, we have investigated the influence of LNA nucleotides on interstrand excimer formation between 1-PEPy fluorophores of different geometries (*meta*- and *para*-isomers, Chart 1) being incorporated into "+2-", "+3-", and"+4-zipper" constructs (Table 3). We used excimer-to-monomer fluorescence intensity ratio, I_{500}/I_{402}, as the excimer formation criterion, which was measured to be approximately 0.1 in the absence of excimer emission. Next, in the case of excimer formation the 1-PEPy dyes showed a broad emission band around λ^{fl}_{max} 500 nm (Figure 3) and I_{500}/I_{402} ratios of more than 12% (Table 3). As expected, the excimer-to-monomer fluorescence intensity ratio I_{500}/I_{402} was highly sensitive to the location of additional LNA monomers along the sequence. Hybridization of the probes **ON2** and **ON3** containing LNA close to the 1-PEPy with modified complementary strands **ON6**−**ON11** resulted in effective excimer formation for both *para*- and *meta*-1-PEPy dyes. The excimer signal for both 1-PEPy-isomers was also remarkably improved compared to the LNA-free complexes (Table 3, I_{500}/I_{402} values = 12−80% for **ON2** and **ON3**, compared to I_{500}/I_{405} = 15−45% for analogues **ON13**), and it always increased in order "+4 zipper" < "+3 zipper" < "+2 zipper". No excimer signal was detected only for the "zipper" complexes formed by **ON4** (Figure 3). The complete absence of excimer emission in these complexes suggests that the 1-PEPy moieties cannot come into close proximity, probably due to unfavorable orientations of the fluorophores upon duplex formation. Finally, all duplexes of **ON5** with **ON6**−**ON11** exhibited the same I_{500}/I_{402} values as those observed in the absence of LNA (I_{500}/I_{405} = 20−50%). We presume that the LNA modifications in **ON5** are positioned too far from the fluorophore to affect its microenvironment and



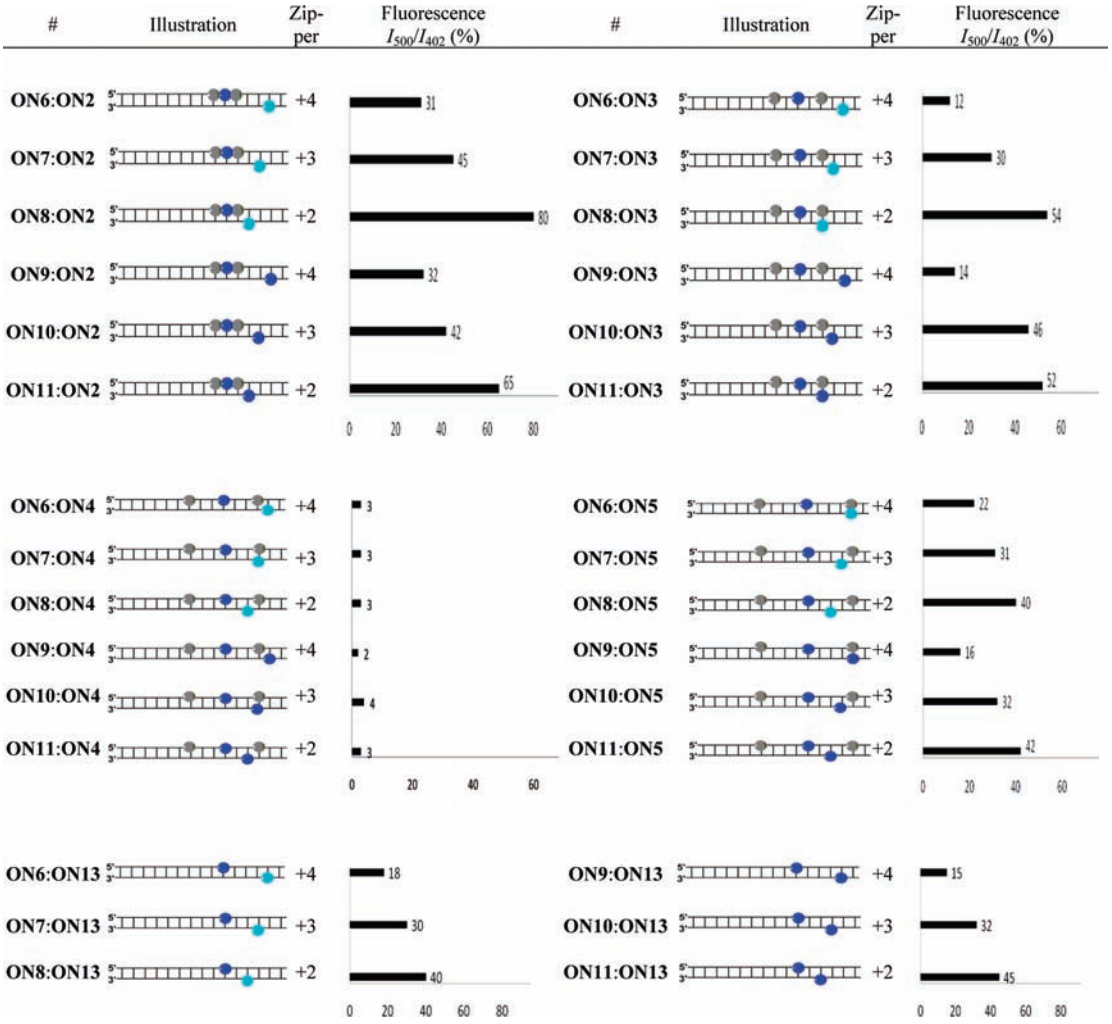


Figure 2. Truncated representations of the lowest energy structure obtained from molecular modeling of single-stranded oligonucleotides **ON2** (view from side (A) and top (B)) and **ON4** (C,D). 1-PEPy residue is shown in yellow.

Table 3. Fluorescent Properties of Modified Duplexes Having LNA Monomers and *para*- and *meta*-1-PEPy Pairs located in "+2", "+3", and "+4 Zipper" Modes[a]

[a] For the conditions of fluorescence measurements, see Figure 3 and the Supporting Information. [b] The "zipper" nomenclature defines arrangements of modified duplexes containing monomers in both complementary strands. An "*n* zipper" describes the arrangement of two modified nucleotides of interest, positioned in opposite strands of a DNA duplex. The number *n* indicates the distance in base pairs between the two nucleotides. If *n* is positive, the two modified monomers are positioned relatively toward the 5′-end of the two strands, and if *n* is negative, the two modified monomers are positioned relatively toward the 3′-ends of the two strands.

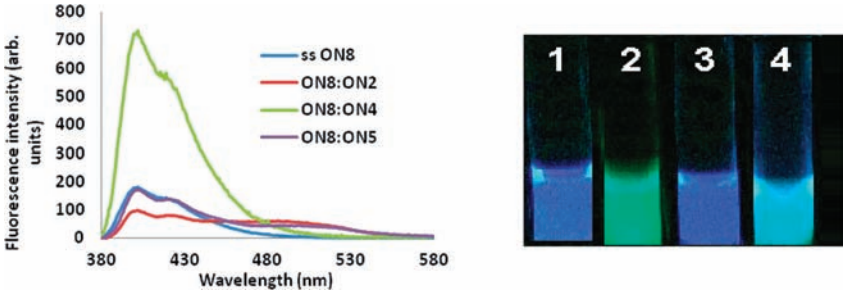

Figure 3. (left) Representative steady-state fluorescence emission spectra of 0.2 μM duplexes having 1-PEPy monomers in both complementary strands in a medium salt buffer using λ_{ex} 360 nm. (right) Photographs of the fluorescence emission in a medium salt buffer: the buffer (negative control, vial 1); **ON8**:**ON2** (vial 2); **ON8**:**ON4** (vial 3), and **ON8**:**ON5** (vial 4). Photographs were taken with a digital camera using a laboratory UV-lamp (λ_{ex} = 365 nm) and 2.0 μM concentration of complementary strands.

therefore have no impact on fluorescence properties of the probes.

Increased 1-PEPy-excimer formation induced by the neighboring LNA nucleotides was additionally monitored by the

change in fluorescence color of the probes upon excitation with a standard laboratory UV-lamp. An intensive excimer emission signal at $\lambda^{fl}_{max} \sim 500$ nm by the complex **ON8**:**ON2** resulted in a green color of its solution (Figure 3, vial 2, I_{500}/I_{405} = 80%), while an increasing predominance of 1-PEPy-monomer emission led to cyan and blue fluorescence of **ON8**:**ON5** and **ON8**:**ON2** solutions, respectively (Figure 3, vials 3−4, I_{500}/I_{405} = 40% and 5%, respectively).

In conclusion, synthesis and spectral properties of fluorescent oligonucleotides containing combinations of a microenvironment sensitive dye, 1-PEPy, and two LNA nucleotides in different positions relative to the fluorophore have been reported. We observed that insertion of the LNA nucleotides into the probes resulted in high binding affinity to cDNA and improved fluorescence quantum yields. Moreover, incorporation of two LNA monomers into neighboring positions of the 1-PEPy modification resulted in significant improvement of excimer formation (I_{500}/I_{405} = up to 80%) compared to the LNA-free reference. Besides, the possibility of stable secondary structure formation by single-stranded probes reported herein is an important detail, which has to be considered while designing fluorescent LNA/DNA probes. Overall, increased fluorescence quantum yields, increased tendency to form excimers, and the ability to modulate binding affinity without modifying the actual sequence makes such fluorescently labeled LNA/DNA probes promising constructs for nucleic acid based diagnostics and studies.

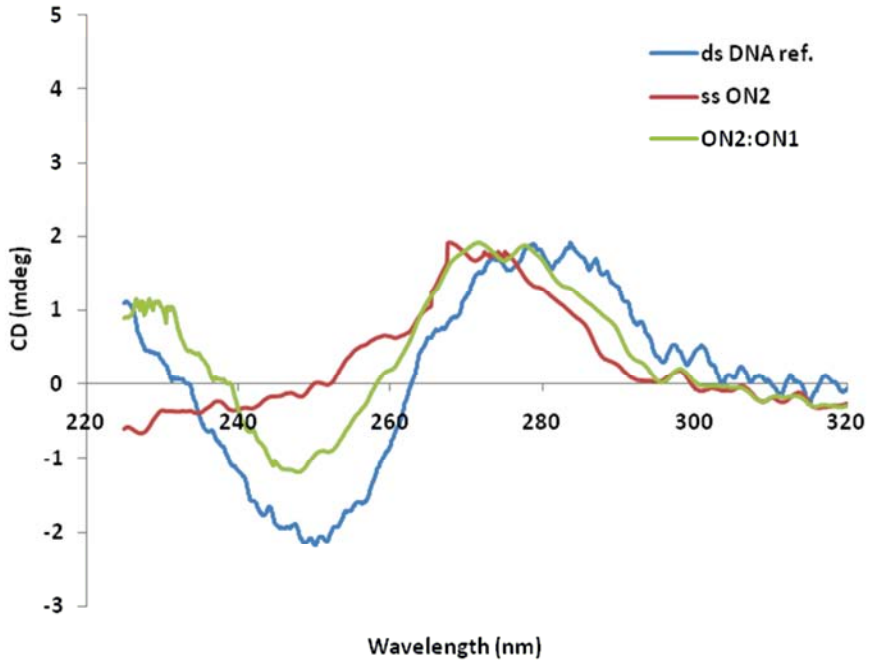
EXPERIMENTAL PROCEDURES

General. 3′-*O*-(*N*,*N*-Diisopropylamino-2-cyanoethoxyphosphinyl)-5′-*O*-(4,4′-dimethoxytrityl)-2′-*O*-[3(4)-(pyren-1-ylethynyl]phenylmethylaminocarbonyl)uracil-1-*β*-D-arabinofuranosides **1** (*1*) and **2** (*1*), 5-(pyrene-1-ylethynyl)-2-deoxyuridine (*2*) were prepared as described; LNA phosphoramidites were obtained from commercial supplier (Exiqon).

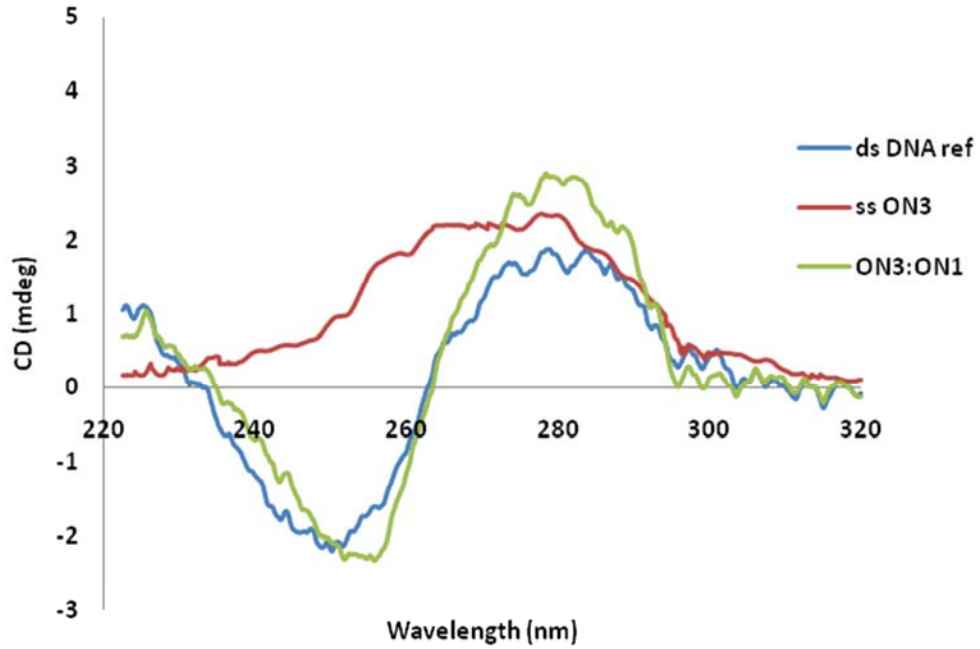
Synthesis and purification of modified oligonucleotides. Oligonucleotide (ON) synthesis was carried out on a Perseptive Biosystems Expedite 8909 instrument in 200 nmol scale using manufacturer's standard protocols, except for increased coupling time for modified phosphoramidies **1** and **2** (*1*) and LNA phosphoramidites (*3*–*7*) (10 min using 0.6 M pyridine hydrochloride or 1*H*-tetrazole in MeCN as activator, respectively). Coupling yields based on the absorbance of the dimethoxytrityl cation released after each coupling were approximately 99% for modified phosphoramidites **1** and **2**, LNA phosphoramidites, and unmodified DNA phosphoramidites. Cleavage from solid support and removal of nucleobase protecting groups were performed using standard conditions (32% aqueous ammonia for 12 h at 55 ºC). Unmodified DNA/RNA strands were obtained from commercial suppliers and used without further purification, while all the modified ONs were purified by DMT-ON RP-HPLC using Waters Prep LC 4000 equipped with Xterra MS C18-column (10 μm, 300 mm × 7.8 mm). Elution was performed starting with an isocratic hold of A-buffer for 5 min followed by a linear gradient to 55 % B-buffer over 75 min at a flow rate of 1.0 mL/min (A-buffer: 95% 0.1 M NH_4HCO_3, 5% CH_3CN; B-buffer: 25% 0.1 M NH_4HCO_3, 75% CH_3CN). RP-purification was followed by detritylation (80% aq. AcOH, 20 min), precipitation (abs. EtOH, -18 ºC, 12 h) and washing with abs. EtOH three times. The identity and purity of ONs were verified by MALDI-TOF mass spectrometry (recorded on an Applied Biosystems Voyager-DE STR spectrometer) and IC-HPLC, respectively. Measured masses $[M-H]^-$ of the ONs (calculated masses *m/z* for $[M-H]^-$): **ON2**: 4938 (4941); **ON3**: 4913 (4913); **ON4**: 4910 (4913); **ON5**: 4912 (4913); **ON6**: 5006 (5005); **ON7**: 5006 (5008); **ON8**: 5006 (5006); **ON9**: 5006 (5006); **ON10**: 5006 (5006); **ON11**: 5006 (5006); **ON13**: 4776 (4774).

UV-visible absorption and thermal denaturation studies. UV-visible absorption spectra and thermal denaturation experiments were performed on a Perkin Elmer Lambda 35 UV/VIS Spectrometer equipped with PTP 6 (Peltier Temperature Programmer) element in a medium salt buffer (100 mM sodium chloride, 10 mM sodium phosphate, 0.1 mM EDTA, pH 7.0). Concentrations of ONs were calculated using the following extinction coefficients (OD_{260}/μmol): G, 10.5; A, 13.9; T/U, 7.9; C, 6.6; **X**, 17.3; **Y**, 20.0. ONs (1.0 μM each strand) were thoroughly mixed, denaturated by heating and subsequently cooled to the starting temperature of experiment. Thermal denaturation temperatures (T_m values, ºC) were determined as the maxima of the first derivative of the thermal denaturation curves (A_{260} vs. temperature). Reported T_m values are an average of two measurements within ± 1.0 ºC.



Fluorescence steady-state emission studies, and quantum yield and fluorescence lifetime determinations. Fluorescence spectra were obtained in a medium salt buffer (see above) using a PerkinElmer LS 55 luminescence spectrometer equipped with a Peltier temperature controller using an excitation wavelength of 360 nm, excitation slit of 4.0 nm, emission slit of 2.5 nm, scan speed of 120 nm/min and 0.2 μM concentrations of the single-stranded probe or the corresponding duplex. The fluorescence quantum yields (Φ_f) were measured by the relative method (*8*) using 5-(pyrene-1-ylethynyl)-2-deoxyuridine (Φ_f 0.45) (*2*) in abs. EtOH as a standard. The optical density of the solutions in a 1-cm quartz cuvette at the excitation wavelength did not exceed 0.1. The values of Φ_f were corrected with the refractive index of the solvent; the measured refractive indexes of abs. ethanol and phosphate buffer were 1.361 and 1.334 at 20 ºC, respectively. Fluorescence lifetimes were determined by the method of time-correlated single-photon counting using a PRA model 3000 nanosecond lifetime fluorometer. The parameters of the fluorescence decays were analyzed using T900 software (Edinburgh Instruments). The samples used in quantum yield and lifetime fluorescence measurements were not degassed; concentrations were 3.0×10^{-6} M.

CD measurements. CD spectra were recorded on a JASCO J-815 CD Spectrometer equipped with CDF 4265/15 temperature controller. Samples for CD measurements were prepared as described for the



thermal denaturation studies section except that a concentration of 1.5 μM of the two complementary ONs was used. Quartz optical cells with a path-length of 0.5 cm were used.

Molecular modelling. ON4 was built in standard B-type helical geometry and further analyzed by MacroModel V9.1 (*9*). When doing this the structure of **ON4** was minimized using the Polak–Ribiere conjugate gradient method, the all-atom AMBER force field (*10–11*), and the GB/SA solvation model (*12*) as implemented in MacroModel V9.1. Non-bonded interactions were treated with extended cut-offs (van der Waals 8.0 Å and electrostatics 20.0 Å). The minimized structures were then (using the same constraints as described above) submitted to 3 ns of stochastic dynamics (simulation temperature 300 K, time step 2.2 fs, SHAKE all bonds to hydrogen), during which 300 structures were sampled and subsequently minimized.

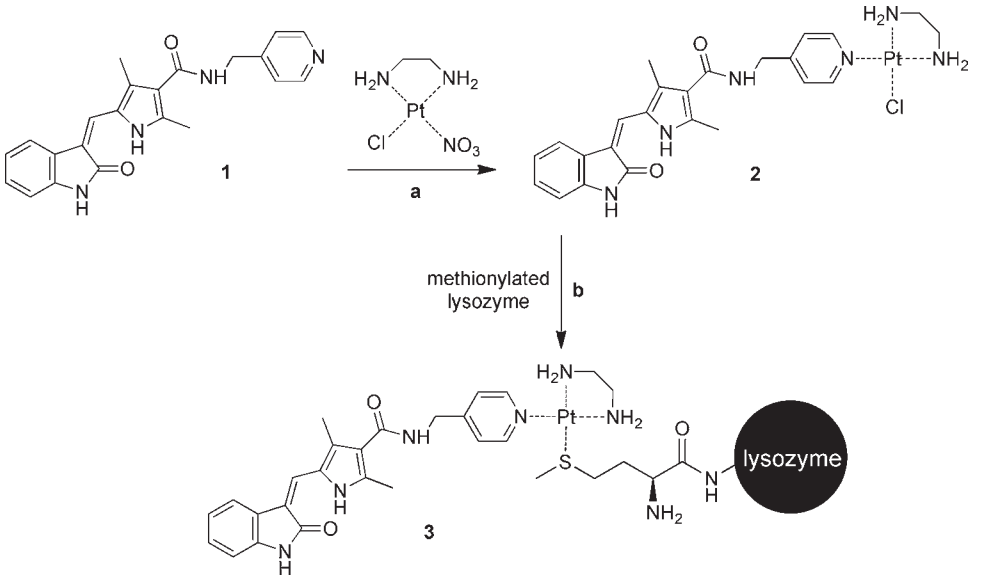
ABSTRACT: Multikinase inhibitors are potent anticancer drugs that simultaneously intervene in multiple related signaling cascades, thus being capable of blocking salvage pathways that may play a role in the development of drug resistance. Multikinase inhibitors are increasingly evaluated for indications other than cancer, but long-term safety risks dictated by off-organ toxicities of these agents may prevent their safe and effective use. Here, we describe a new approach in which platinum coordination chemistry is applied for the development of a cell-selective multikinase inhibitor bioconjugate. The platinum(II) kinase inhibitor bioconjugate was designed to be active with the linker attached to the inhibitor and displayed improved activity by enhanced cell specificity as well as enhanced intracellular retention, thereby prolonging its pharmacological activity. In addition, the utilized platinum-based linkage technology potentiated the inhibitory activity of the multikinase inhibitor. These features in combination with carrier-mediated uptake in the target cells may revolutionize dosing regimens and safety profiles of (multi)kinase inhibitors.

In recent years, kinase inhibitors have emerged as highly successful anticancer drugs. Initially designed to inhibit specific protein kinases such as BCR-ABL (e.g., imatinib), later multikinase inhibitors (e.g., sunitinib) were developed to concomitantly interrupt multiple distinct signaling pathways. Apart from cancer therapy, multikinase inhibitors are currently increasingly investigated for less life-threatening diseases as well; i.e., sunitinib has been shown to potently ameliorate liver cirrhosis[1] and chronic airway inflammation,[2] while the related oxindole-based intedanib (BIBF-1120) shows potential in the treatment of idiopathic pulmonary fibrosis.[3] A point of concern, however, is the safety profile of multikinase inhibitors.[4] The most commonly reported multikinase inhibitor related toxicities include rash, diarrhea, and nausea, while long-term toxicities include fatigue, hypothyroidism, and even cardiotoxicity.[5,6] Although these off-target toxicities are more acceptable in cancer therapy, they complicate long-term use of these agents in chronic, less life-threatening illnesses.



To address these safety issues, we developed a multikinase inhibitor bioconjugate that accumulates in disease-inflicted organs in a target cell-selective manner by recognition of surface-exposed receptors that facilitate internalization. This approach permits lower drug dosages due to increased drug accumulation at the designated pathological tissue while avoiding uptake in healthy tissues and, thus, decreases the risk of off-organ toxicities. Furthermore, the uptake into specific cell types within the targeted organ will greatly improve the specificity profile of such cellular targeted drugs. We have previously demonstrated that renal tubular cells can be targeted with drug−lysozyme conjugates.[7] In the present study, we will use this type of drug−protein conjugate as the platform technology for a new type of intrinsically active multikinase inhibitor bioconjugates.

The linkage of the multikinase inhibitor to its carrier was achieved by the platinum(II)-based Universal Linkage System (ULS, Scheme 1). This bioinorganic linker afforded a straightforward linking protocol and also ensured the formation of a conjugate that can be dissociated within cells by competitive displacement of the platinum ligands by endogenous thiols such as glutathione (GSH). Since previous studies had demonstrated that drug−platinum conjugate linkages have a very long intracellular half-life after in vivo accumulation in target tissues, we now have designed a new class of kinase inhibitor−platinum

Scheme 1. Synthesis of a Platinum Coordinated Multikinase Inhibitor Bioconjugate[a]

[a] The multikinase inhibitor **1** is complexed with monochloromononitrate−(ethylenediamine)platinum(II) (ULS) via binding to the pyridine nitrogen. The resulting drug−platinum complex **2** is conjugated to methionyl groups in lysozyme, yielding **3**. Reagents and conditions: (a) DMF, 37 °C, 84.0% of **2**; (b) 0.02 M tricine/sodium nitrate buffer, pH 8.5, 72% of **3**. DMF = *N*,*N*-dimethylformamide.

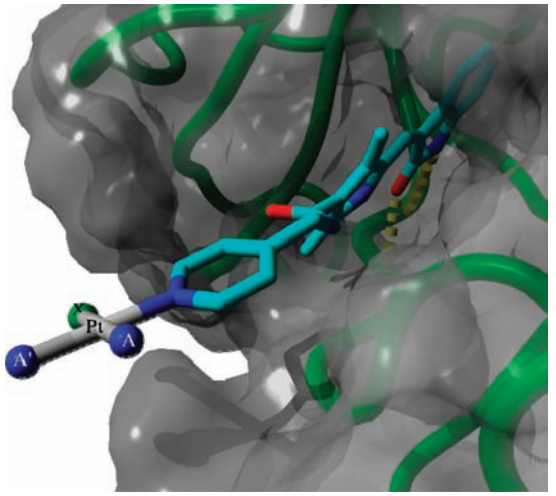

Figure 1. Illustration of the square-planar multikinase inhibitor−platinum complex **2** (as depicted in Scheme 1) bound to the ATP-binding pocket of the protein kinase c-KIT. The 4-(amidomethyl)pyridine is sticking outward permitting binding to the platinum(II) atom and leaving enough space to accommodate a drug carrier at position X. Ethylenediamine is complexed at position A and A′.

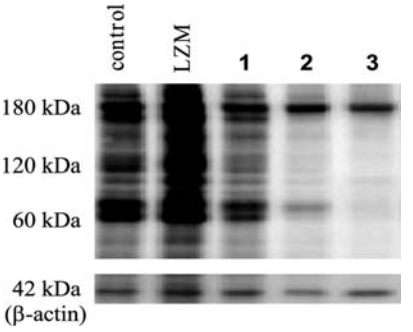

Figure 2. Pharmacologic activity of multikinase inhibitors. Cell lysate of immortalized proximal tubular cells (HK-2) was preincubated with equimolar amounts (2 μM) of **1**, **2**, **3**, unconjugated lysozyme (LZM), or water (control) and activated with ATP. Phosphorylation was detected with an antibody raised against phosphorylated tyrosine residues (pY-20). While **1** showed only some inhibitory effects on total tyrosine phosphorylation, significant inhibitory effects were observed with **2** and **3**. β-Actin was used as loading control.

adducts that can bind into the ATP pocket of kinases when platinum is still bound to the parent drug. Such an approach infers that the ULS linker and the pending cell-specific carrier are conjugated to the multikinase inhibitor via a functional group that protrudes from the ATP pocket.

Therefore, we first investigated how oxindole-based multikinase inhibitors generally are oriented inside the active site of their target kinases. Analysis of published protein structures cocrystallized with oxindole-based inhibitors revealed that the oxindole pharmacophore scaffold binds deeply within the ATP-binding pocket[8,9] with the pyrrolylmethylidenyl and the pending side groups oriented toward the outside. Next, we synthesized an oxindole-based inhibitor **1** with a 4-(amidomethyl)pyridine side chain[10] that permitted complexation to the platinum(II)-based linker. As shown in Figure 1, the multikinase inhibitor **1** binds to the ATP-binding site of its target kinase while leaving enough space to accommodate the platinum-based ULS linker and even a drug carrier at the X position without directly disrupting inhibitor−kinase interactions. We therefore postulated that this type of inhibitor−platinum complex could be used as intrinsically active, target cell-selective conjugates. Complexation of **1** with ULS (monochloromononitrate−(ethylenediamine)platinum(II)) for 4 h at 37 °C in the dark afforded complex **2** (84.0%). Finally, **2** was coupled to the prototypic drug-carrier protein lysozyme

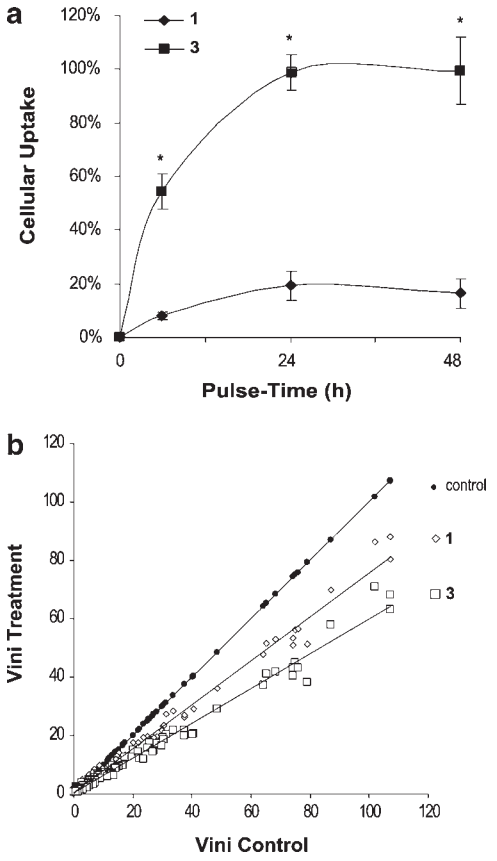

Figure 3. (a) Cellular uptake of multikinase inhibitors in renal tubular cells. Uptake was determined by incubating HK-2 cells with 10 μM **1** or **3** for different time intervals (pulse time). Maximal uptake of cellular targeted complex **3** was set at 100%. Significance was determined for each time point versus $t = 0$ h (*, $P < 0.05$). (b) Pharmacological profile of inhibitors in HK-2 cells. A flow-through tyrosine kinase peptide array was used to determine the inhibitory activity of **1** and **3**. Peptide phosphorylation was detected in real time with a monoclonal antiphosphotyrosine antibody (pY-20) coupled to FITC. Data were expressed as Vini (initial linear rate of tyrosine residue phosphorylation) and ranked based on strongest pY inhibition compared to control. The slope of the plotted curves is a measure for pan-tyrosine pY inhibition (control slope = 1).

(LZM), which is a low-molecular weight protein that selectively accumulates in renal proximal tubular cells. The molar coupling ratio of **2** to LZM was determined to be 0.9:1.

We evaluated whether platinum coordination affected the pharmacological activity of **1** by spiking freshly prepared human proximal tubular cell lysate with 2 μM concentration of **1**, of the intermediate complex **2**, or of conjugate **3** and analyzing total tyrosine kinase phosphorylation in the lysate. Interestingly, **2** and **3** inhibited tyrosine phosphorylation more potently than **1** (Figure 2). As anticipated, these results demonstrate that the multikinase inhibitor−lysozyme conjugate is intrinsically active and, second, that the platinum(II)-based ULS positively contributes to the pharmacological activity of **1**, most likely through electrostatic interactions of the platinum(II) scaffold with electron donating groups within the target protein(s).

Next, we investigated the capability of target cells to internalize **3**. Lysozyme is freely filtered through the glomerular barrier into the tubular lumen and is reabsorbed by proximal tubular cells via megalin and cubilin receptor-mediated endocytosis.[7] We

studied drug uptake in immortalized human proximal tubular cells (HK-2), a cell line that can be used for in vitro testing of uptake of megalin ligands.[11] We exposed these cells to 10 μM **1** or **3** for different time intervals and determined absolute intracellular drug accumulation. As shown in Figure 3a, the uptake of **3** reached a steady state after 24 h. Moreover, the intracellular drug accumulation in the cells treated with **3** was 5 times higher than in cells treated with **1**.

We additionally determined which intracellular kinases were affected by treatment with **1** and **3** by means of a flow-through tyrosine kinase peptide array.[12] We observed that **3** was more potent than **1** (Figure 3b). Interestingly, the most inhibited peptide residues (Table 1) correspond with proteins that are either direct targets of similar oxindole-based kinase inhibitors sunitinib and indetanib[13−15] (vascular-endothelial growth factor receptor (VEGFR)-2, platelet-derived growth factor receptor (PDGFR)-β) or lie downstream of these receptors (phosphoinositol-3-kinase (PI3K), paxillin, Ras p21 protein activator (RASA1), cyclin-dependent kinase (CDK)-2, and c-FES). These kinases play important roles in pathophysiological processes like angiogenesis, cell adhesion, and migration, processes that underlie pathologies such as arteriosclerosis, rheumatoid arthritis, and fibrosis.

To further evaluate whether platinum complexation or bioconjugation would affect the inhibitory activity of compound **1** toward its target kinases, we evaluated the inhibitory activity of **1**, **2**, and **3** against recombinant PDGFRβ and c-KIT. As shown in Figure 4 and Table 2, complexation of platinum with **1** did not affect the inhibitory activity of **1** against PDGFRβ and increased the inhibitory activity against c-KIT 3-fold. Interestingly, **1** and **2** were as potent as the clinically approved oxindole-based multikinase inhibitor sunitinib (Table 2). Conjugation to LZM slightly decreased the inhibitory activity toward both kinases, which might be due to steric hindrance of the relatively large LZM homing ligand. This part of the conjugate will be degraded into smaller peptide fragments upon internalization and hence will not interfere with the kinase inhibitory activity of compound **2**.

To study the effect of drug conjugation on drug efflux, a pulse-chase experiment was conducted. HK-2 cells were exposed for 24 h to **1** or **3**, after which the cells were allowed to efflux in blank

dx.doi.org/10.1021/bc1005637 |*Bioconjugate Chem.* 2011, 22, 540–545

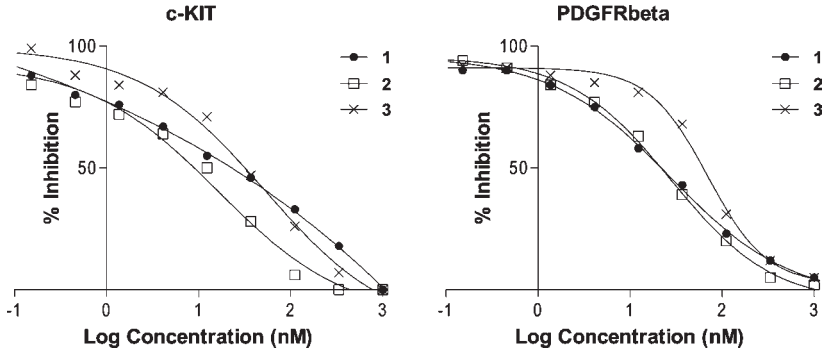

Figure 4. IC_{50} determinations of compounds **1**, **2**, and **3** against recombinant c-KIT and PDGFRβ. Radiometric protein kinase assays were performed with the indicated compounds at various concentrations (0.03−1000 nM). Kinase inhibition was plotted as (%) of total kinase activity (control).

sunitinib	23	14

medium (chase time t = 2, 24, 48 h). As shown in Figure 5a, cells treated with **1** rapidly cleared the drug (<2 h), while in the cells treated with **3**, the drug was still detectable after 48 h. Because of its rapid intracellular turnover rate, it is expected that the lysozyme part of the drug conjugate (**3**) is fully degraded within 48 h. In addition, since **1** is rapidly cleared from the cell, we conclude that the oxindole inhibitor is still attached to platinum. In turn, complex **2** could be attached to degradation residues of the lysozyme such as methionine but could also have competitively reacted with GSH or other strong electron-donating-group-rich molecules such as thiol/methionine-rich proteins, thereby creating an intracellular depot of **2′** (representing any metabolite of **2** that is formed by binding at the X-position) from which **1** is slowly released. To verify whether intracellular processing affects the pharmacological activity of **3**, the total tyrosine phosphorylation state was determined in the chased cells. Figure 5b shows that **1** significantly decreased the total endogenous phosphorylation status, but because of its rapid clearance, no significant decrease could be observed 24 and 48 h after exposure. In contrast, treatment with equimolar amounts of **3** produced sustained inhibition on total endogenous tyrosine-residue phosphorylation of >10% for up to 48 h, confirming the presence of pharmacological active **2′** in the cells. These results demonstrate that complexation of **1** to platinum positively alters the efflux kinetics of this multikinase inhibitor without adversely affecting its pharmacological activity.

Taken together, the complexation of platinum to the oxindole-based multikinase inhibitor **1** did not affect its pharmacological activity but additionally provided superior cellular kinetics compared to the free drug. Although the use of platinum as a linker would probably raise questions concerning safety, we have shown that drug−ULS complexes are by far less toxic than the prototypical platinum drug *cis*-diamminedichloroplatinum (CDDP).[16,17] Apart from platinum,[18] several other transition metals such as ruthenium,[19] osmium,[20] iridium,[21] and iron[22] have been complexed to kinase inhibitors without adversely affecting

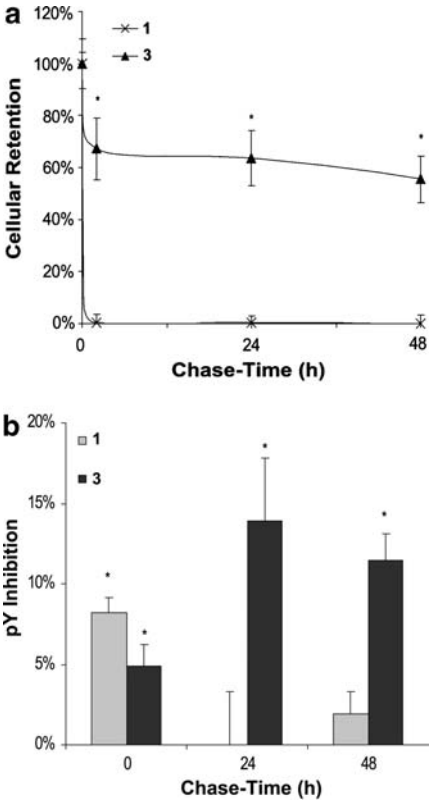

Figure 5. (a) Effect of platinum-based conjugation on cellular retention. Proximal tubular cells (HK-2 cells) were incubated for 24 h (pulse time) with equimolar amounts (10 μM) of **1** or **3**, after which cells were allowed to efflux in blank medium for 0, 24, or 48 h (chase time). Values were normalized to the absolute **1** or **3** levels at t = 0 h (100%) and expressed as % cellular retention. Significance of cellular retention was determined by comparing the intracellular concentration at different time points with the intracellular concentration at t = 0 h (∗, $P < 0.05$). (b) Inhibitory effect of **1** and **3** on the intracellular phosphorylation of tyrosine residues (pY). HK-2 cells were exposed for 24 h (pulse time) with **1** (10 μM) or **3** (10 μM). After the pulse time, the incubation medium was replaced with blank medium (t = 0). At t = 0, 24, and 48 h (chase time) the endogenous pY state was determined by immunostaining of phosphorylated proteins with the anti-pY antibody pY-20. Total pY signal of treated cells was normalized to total pY signal of control cells and expressed as percentage pY inhibition (0% in control cells) (∗, $P < 0.05$).

their pharmacological activity. However, a major difference between these compounds and the now reported platinum

dx.doi.org/10.1021/bc1005637 |*Bioconjugate Chem.* 2011, 22, 540–545

complex is that platinum served as a linker for attachment to a cell-selective carrier and as part of the pharmacophore of the multikinase inhibitor. Organometallic chemistry opens new opportunities in kinase inhibitor drug discovery, as well as in drug delivery research.[23−25] One or more (kinase inhibiting) drugs can be bound to a transition metal center, while drug carriers such as antibodies, peptides, or proteins can be coordinated at another metal ligand-binding site. When properly designed, these complexes will provide intrinsically active-site-selective drug bioconjugates. This could reduce off-target toxicities and eventually enable the clinical use of drugs with currently unfavorable safety or pharmacokinetic profiles.

In conclusion, we have developed an intrinsically active multikinase inhibitor bioconjugate in which platinum not only enabled straightforward linkage but also contributed to improved retention of the multikinase inhibitor in the target cells, thereby prolonging the pharmacological activity of the delivered compound. The developed cell-selective multikinase inhibitor bioconjugate may eventually provide a safe and efficient way to administrate such agents in less life-threatening diseases without inducing dose-limiting off-organ toxicities.

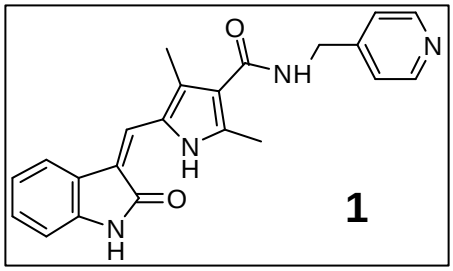
Development of a Cell-Selective and Intrinsically Active Multikinase Inhibitor Bioconjugate

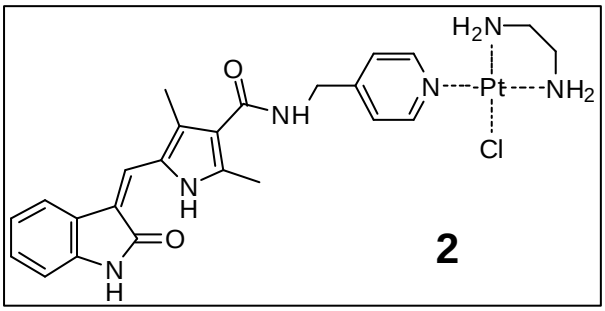
Stefan Harmsen, M.E. (Emmy) M. Dolman, Zoltan Nemes, Marie Lacombe, Bálint Szokol, János Pató, György Kéri, László Őrfi, Gert Storm, Wim E. Hennink, and Robbert J. Kok



1. Materials and Methods

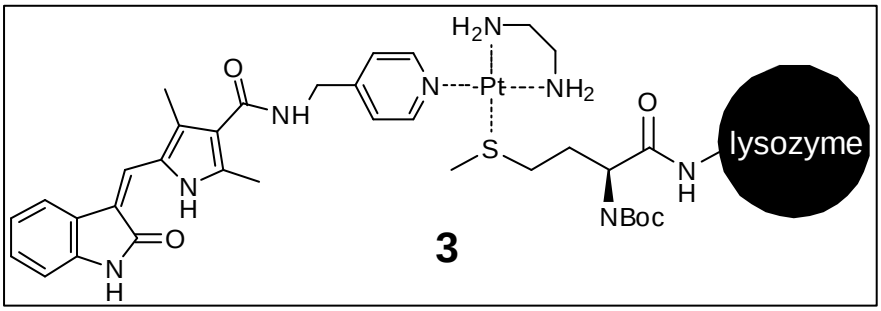
All chemicals used in this study were of analytical grade or equivalent and obtained from Sigma Aldrich (Zwijndrecht, the Netherlands) and used without further purification unless otherwise stated. The multikinase inhibitor precursor (*Z*)-2,4-dimethyl-5-((2-oxoindolin-3-ylidene)methyl-1*H*-pyrrole-3-carboxylic acid was synthesized by Vichem Chemie (Budapest, Hungary). Universal Linkage System™ (monochloro-mononitrato(ethylenediamine)platinum(II)) was provided by Kreatech (Amsterdam, the Netherlands). HPLC grade acetonitrile (ACN), methanol (MeOH), isopropanol (IPA), formic acid (FA) and *N,N'*-dimethylformamide (DMF) which was dried over molecular sieve before use were purchased from Biosolve (Valkenswaard, the Netherlands). Products were characterized by $^{1}H/^{195}Pt$ NMR and LC-MS/MS. $^{1}H/^{195}Pt$ NMR spectra were recorded on a Varian Gemini (300 MHz; 298 K; Varian Associates Inc., NMR Instruments, Palo Alto, CA) NMR spectrometer. The LC-MS/MS equipment consisted of an Accela pump and autosampler and a TSQ Quantum Ultra quadrupole mass spectrometer with heated electrospray ionization (Thermo Fisher Scientific, San Jose, CA, USA). Data were recorded on and the system was controlled by a Dell Precision T3400 personal computer, equipped with the Thermo Fisher Xcalibur software (version 2.07). 5-µl injections were made on an Aquity UPLC® BEH C18 column (30 × 2.1mm × 1.7 µm; Waters, Milford, USA) with the corresponding VanGuard pre-column (5 × 2.1mm × 1.7 µm; Waters, Milford, USA). Column temperature was maintained at 40˚C and the autosampler was maintained at 4˚C. A 20-90% gradient of solvent B over 2.5 min with a 0.5 ml/min flow rate was used. Solvent A consisted of 0.1% (v/v) formic acid in water and solvent B of methanol. The eluate was totally led into the electrospray probe, oriented at "+1" in the X-, at "1" in the Y- and at "C" in the Z-direction, from 0.7 min after injection. Electrospray (ESI+) settings were a 4000 V spray voltage, 350°C capillary and vaporizer temperatures and a 1.0 mTorr argon collision pressure. The mass resolution was set at 0.7 full with at half height (unit resolution) for both separating quadrupoles.

2. Molecular Modeling of an oxindole-based inhibitor in the ATP-binding pocket of c-KIT



YASARA (www.yasara.org; version 10.6.1) was used to evaluate how oxindole-based multikinase inhibitors generally bind to their targets. Therefore, protein structures co-crystallized with either sunitinib (3G0E) or intedanib (3C7Q) were downloaded from www.pdb.org and their orientation in the binding pocket of their target kinases was studied. YASARA was additionally used to generate a graphic representation of how compound **2** would bind to c-KIT by modification of the structure used in 3G0E.

3. Synthesis of the multikinase inhibitor (1), multikinase inhibitor platinum complex (2) and drug-lysozyme conjugate (3)



Synthesis of multikinase inhibitor (1) ((*Z*)-2,4-dimethyl-5-((2-oxoindolin-3-ylidene)methyl)-*N*-(pyridin-4-ylmethyl)-1*H*-pyrrole-3-carboxamide)

Compound **1** was synthesized according to methods described by Sun *et al*[1]. In brief, (*Z*)-2,4-dimethyl-5-((2-oxoindolin-3-ylidene)methyl-1*H*-pyrrole-3-carboxylic acid (1.0 g, 3.5 mmol) was suspended in 40 ml dry DMF and 4-(aminomethyl)pyridine (0.38 g, 3.5 mmol), EDC (0.81 g, 4.2 mmol), HOBt (0.57 g, 6.0 mmol) and triethylamine (0.74 ml, 5.3 mmol) were added to the suspension and stirred at 50^{o}C for 72 hours. The solvent was removed under reduced pressure and the residue was taken up with water and the product was filtered off yielding compound **1** (0.72 g, 54%). ^{1}H NMR (300 MHZ, DMF-d_7): δ (ppm): 10.87 (s, 1H, NH); 8.55 (d, 2H, 2CH, ^{3}J=4.2 Hz); 8.11 (t, 1H, NH); 7.85 (d, 1H, CH, ^{3}J=7.6 Hz); 7.79 (s, 1H, CH); 7.41 (d, 2H, 2CH, ^{3}J=5.0 Hz); 7.18 (t, 1H, CH, ^{3}J=7.6 Hz); 7.02 (t, 1H, CH, ^{3}J=7.6 Hz); 6.97 (d, 1H, CH); 4.60 (d, 2H, CH_2, ^{3}J=6.1); 2.56 (s, 3H, CH_3); 2.55 (s, 3H, CH_3). MS (ESI^{+}) calcd. for $C_{22}H_{20}N_4O_2H^{+}$ $[M+H]^{+}$ 373, detected 373.

Synthesis of multikinase inhibitor platinum(II) complex (2)

Compound **1** (15.0 mg, 40.3 μmol) was reacted with monochloro-mononitrato (ethylenediamine)platinum(II) (Universal Linkage System (ULS)^{TM}- nitrate; 14.2 mg , 40.3 μmol) in DMF for 2 hours at 37^{o}C to yield compound **2** (23.1 mg, 83.4%). ^{195}Pt NMR (300 MHz, DMF-d_7) -2492 ppm (N3PtCl). ^{1}H NMR (300 MHz, DMF- d_7): δ (ppm): 10.91 (s, 1H, NH); 8.80 (d, 2H, 2CH, ^{3}J=5.6 Hz); 8.23 (t, 1H, NH); 7.86 (d, 1H, CH); 7.81 (s, 1H, CH); 7.62 (d, 2H, 2CH, ^{3}J=6.2 Hz); 7.19 (t, 1H, CH, ^{3}J=7.7 Hz); 7.04 (t, 1H, CH, ^{3}J=7.4 Hz); 7.00 (d, 1H, CH); 6.31 (s, 2H, NH_2), 5.89 (s, 2H, NH_2); 4.69 (d, 2H, CH_2,^{3}J=5.7 Hz); 2.58 (s, 3H, CH_3); 2.57 (s, 3H, CH_3); 1.56 (t, 2H, CH_2); 1.29 (s, 2H, CH_2).MS (ESI^{+}) calcd. for $C_{24}H_{28}N_6O_2HPtCl$ $[M+H]^{+}$ 663, detected 663 $[M+H]^{+}$.

Conjugation of a multikinase inhibitor platinum(II) complex to methionylated lysozyme (3)

Methionylated lysozyme was synthesized as previously described by Fretz *et al.*[2]. Compound **2** (15.5 mg, 23.3 μmol) was reacted with methionylated lysozyme (112.1 mg, 7.8 μmol overnight in 0.02 M tricine/sodium nitrate buffer (pH 8.5). The product was purified by dialysis (molecular weight cut-off 10,000 Da) against ultrapure water (MilliQ, Millipore, Bedford, MA, USA) and lyophilized. MS (ESI^{+}) calcd. for

$C_{24}H_{28}N_6O_2HPt$-LZM $[M+H]^+$ 14930, detected 1493.0 $[M+H]^{10+}$ and 1357.2 $[M+H]^{11+}$ corresponding with 14930 $[M+H]^+$. Conjugation efficiency was determined as described previously[2]. Liberated **1** was quantified in samples containing **3** incubated overnight at 80°C in the presence of the strong platinum ligand thiocyanate (SCN; 0.5 M) thereby competitively displacing compound **1** from ULS by HPLC-photodiodearray (PDA) analysis at 431 nm. The HPLC system consisted of a Waters 717 autosampler, Waters 600 pumps and a Waters 2996 Photodiode Array Detector (Waters, Milford, USA). Data were recorded with Empower software (version2.0; Waters). 50-µl injections were made on SunFire™ C18 column (150 × 4.6mm × 5 µm; Waters). Gradient elution according to table S1 at 1 ml/min was used with solvent A consisting of 5 % ACN in water + 0.1 % TFA (w/w) and solvent B of 0.1 % TFA (w/w) in ACN. The molar coupling ratio was determined to be 0.9:1 (drug-ULS:LZM). ChemDraw Ultra 12.0 was used to prepare draw the above molecular structures and those in scheme 1.

4. Determination of intrinsic activity

Cell lysate was prepared by lyzing serum-starved HK-2 cells using mammalian protein extraction reagent (M-PER) containing protease and phosphatase inhibitors (Thermo Fischer Scientific, Etten-Leur, the Netherlands). Protein concentrations were determined using the BCA protein determination assay (Thermo Fischer Scientific). HK-2 cell lysate (0.1 mg/ml) was pre-incubated with equimolar amounts of **1**, **2** complex, or the **3** drug conjugate at room temperature for 30 minutes. Phosphorylation was initiated by adding 1 µM ATP in Abl kinase assay buffer (50 mM Tris–HCl [pH

7.5], 10 mM $MgCl_2$, 1 mM ethyleneglycoltetraacetic acid (EGTA), 2 mM dithiothreitol (DTT), and 0.01% Brij-35). The reaction mixture was incubated at 37°C for 60 minutes. Phosphorylation was terminated by adding reducing sample buffer (Invitrogen, Breda, the Netherlands) containing a final concentration of 40 mM DTT and 0.1% (w/v) SDS. Total protein (10 μg) was separated by SDS-polyacrylamide gel electrophoresis using NuPage novex 4-12% bis-tris gradient gels (Invitrogen, Breda, the Netherlands). Proteins were electroblotted onto Immobilon P polyvinylidenefluoride (PVDF) membranes (Millipore). After blocking (1 hour at RT) with 3% (w/v) BSA in tris-buffered saline containing 0.1% (v/v) Tween-20, the membranes were incubated for 1 hour at RT with a murine monoclonal anti-phosphotyrosine (pY) primary antibody (pY-20; 1:500; Abcam, Cambridge, UK) coupled to horse radish peroxidase (HRP). β-actin (1:10000; AC-15; Abcam, Cambridge, UK) was used as a loading control. The proteins were visualized by a chemiluminescence-based detection reagent (SuperSignal West Femto; Thermo Fischer Scientific, Etten-Leur, the Netherlands) and band density was determined on a Gel Doc XRS Imaging system with Quantity One analysis software (Bio-Rad, Hercules, CA, USA).

5. Cellular uptake and retention

Cell culturing

The human kidney proximal tubular cell line HK-2 (ATCC, LGC Standards, Middlesex, UK) was cultured in Dulbecco's Modified Eagle's Medium (DMEM) containing 3.7 g/L sodium bicarbonate, 1.0 g/L glucose, supplemented with 10% (v/v) fetal bovine serum, penicillin (100 U/L), streptomycin (100 μg/mL) and amphotericin B (0.25 μg/mL) at 37°C with 5% CO_2 in humidified air. All cell culture related media were obtained from PAA Laboratories GmbH (Pasching, Austria).

Cellular uptake

HK-2 cells (1.5×10^4 cells/well) were seeded onto 96-well plates. Cells were serum-starved overnight before the uptake experiments were initiated. Cellular uptake was studied by incubating the HK-2 cells with **1** (10 μM) or **3** (10 μM) for different time

intervals (t=0, 1, 2, 3, 24, 48, 72 h) at 4°C (only 1, 2, 3 h) or 37°C. Uptake was determined by measuring the cellular optical density (OD) at 431 nm of **1** and 700 nm (reference wavelength) with a Versamax microplate reader (Molecular Devices, Sunnyvale, CA, USA). Values were normalized to the number of living cells (as determined with an Alamar Blue assay). The obtained data were analyzed and processed with Microsoft Excel (figure 3a).

Cellular retention

Cellular retention was studied by incubating serum-starved HK-2 cells (1.5×10^4 cells/well) with either 10 μM **1** or 10 μM **3**. After 24 h (indicated as t = 0 h), cells were washed thrice with phosphate buffered saline (PBS) and medium was replaced with blank serum-free DMEM medium every 24 hours. Cellular retention was determined by measuring the cellular $OD_{431/700}$ (normalized to the number of living cells (Alamar Blue). The obtained data were analyzed and processed with Microsoft Excel (figure 4a).

6. Cellular activity

PamChip® Peptide microarray

A microarray-based multiplex method with real-time detection was used to determine the inhibitory activity of **3** on the phosphorylation of peptide substrates that correspond with human proteins. In brief, HK-2 cell lysate (prepared from lysis with MPER) spiked with **1** (2 μM) or **3** (2 μM) were incubated on a tyrosine kinase PamChip® microarray (PamGene International BV, 's-Hertogenbosch, the Netherlands) with 10 μM ATP at 30°C in a total volume of 25 μL. Just prior to the incubations, the PamChip was blocked with 2% (w/v) BSA in water and washed three times with Abl kinase assay buffer. After application onto the array, the incubation mixture was pumped up and down through the array for 152 cycles at a rate of 2 cycles per minute. Peptide phosphorylation was detected with a monoclonal murine anti-phosphotyrosine primary antibody (pY-20) coupled to FITC. Images of each array were taken every fifth cycle.

Data generated on PamChip peptide microarrays were analyzed with Bionavigator software (PamGene). The software quantifies signal intensity in each spot and its background, calculates signal minus background[3]. The obtained data was ranked based on strongest pY inhibition compared to control, and graphics were prepared with Microsoft Excel (figure 3b).

IC_{50} determination

IC_{50} determinations of the compounds **1**, **2** and **3** against platelet derived growth factor receptor (PDGFR)-β and c-KIT were performed by SignalChem (Richmond, Canada). In brief, protein kinase assays were performed in duplicate at room temperature for 30 min in a final volume of 25 µL containing ~10-20 nM recombinant kinase, peptide substrate (0.2 µg/µL), 5 µM ^{33}P-ATP (0.04 µCi; PerkinElmer, Waltham, MA, USA), and the indicated compounds at concentrations ranging from 0.03 nM-1000 nM in kinase buffer. After the incubation period, the assay was terminated by spotting 10 µL of the reaction mixture onto Multiscreen phosphocellulose P81 plate. The Multiscreen phosphocellulose P81 plate was washed 3 times 15 minutes in a 1% phosphoric acid solution. The radioactivity on the P81 plate was counted in the presence of scintillation fluid in a Trilux scintillation counter. The data was analyzed with Prism 5.0 (Graphpad Software Inc, La Jolla, CA, USA).

In-cell Western blotting

After incubation, cells were washed thrice with ice-cold PBS and were fixed with 3% (v/v) formaldehyde (Sigma Aldrich) for 15 minutes. Cells were permeabilized by washing five times with 0.1% (v/v) triton X-100 (Sigma Aldrich) in PBS for 5 minutes and blocked for 1 h with 3% (w/v) BSA. After blocking, cells were incubated with a horseradish peroxidase coupled primary antibody raised against phosphorylated tyrosine residues (pY-20; Abcam, Cambridge, UK). After 1 h, cells were washed thrice with PBS and phosphorylation was visualized with a chemiluminescence-based detection reagent (SuperSignal West Femto; Pierce, Rockford, IL, USA). The signal intensities were determined on a Gel Doc XRS Imaging system with Quantity One

analysis software (Bio-Rad, Hercules, CA, USA). The obtained data were analyzed with Microsoft Excel (figure 4b).

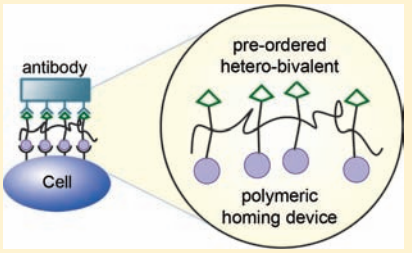
Supramolecular Complexing of Membane Siglec CD22 Mediated by a Polyvalent Heterobifunctional Ligand that Templates on IgM



Lina Cui,[†] Pavel I. Kitov,[†] Gladys C. Completo,[‡] James C. Paulson,[‡] and David R. Bundle*[,†]

Supporting Information

ABSTRACT: We report the synthesis and *in vitro* evaluation of a multivalent homing device, a polymer which contains preordered pendant groups with dual specificity, a trisaccharide moiety, which is specific for the siglec CD22, and an antibody specific hapten, nitrophenol. The device efficiently attracts antihapten IgM to the surface of human lymphoma B cells as well as to CD22-conjugated magnetic beads by mediating the formation of a ternary complex on the surface of the target.

Directing neutralizing proteins such as antibodies to pathogenic agents using heterobifunctional ligands that contain binding fragments for both receptors has emerged as a promising therapy against cancer,[1−5] viral or bacterial infection,[6−16] and Alzheimer's disease.[17] Surface-bound receptors and oligomeric proteins that possess multiple unidirectional binding sites can bind multiple copies of heterobifunctional ligands, allowing the other head groups to attract their cognate proteins to form supramolecular ternary complexes.[18] Due to saving of binding entropy, the efficiency of the ligand binding to its target can be enhanced by several orders of magnitude, while the templating protein can perform additional effector functions.[8,14,15]

Our efforts are directed to application of supramolecular templating to cancer immunotherapy. CD22, a member of the siglec family of glycan-binding proteins, is expressed on the B cell surface as a key regulator of signaling[19] and has been identified as a target for immunotherapy (B cell depletion therapy) to treat B cell lymphomas and autoimmune diseases.[20] However, targeting CD22 using its glycan ligands is challenging due to the low intrinsic affinity that CD22 exhibits for its native ligands (NeuAcα(2−6)Galβ, $K_d \approx 0.2$ mM). Additionally, CD22 is glycosylated with the self-ligand and these *cis* interactions mask the ligand binding sites.[21,22]

Previously, we reported heterobifunctional ligands, which comprise CD22 ligand, NeuAcα(2−6)Galβ(1−4)GlcNAc, modified at the C-9 position of neuraminic acid with biphenyl carbonylamido (BPC) substituent, which is known to increase the affinity for CD22 by a factor of 100.[21] The heterodimer of this ligand with a nitrophenol (NP) moiety was able to overcome receptor-masking *cis* interactions and dock anti-NP antibodies to B cell.[23] We sought to develop an efficient way to construct polyvalent heterobifunctional ligands and to evaluate the influence of polyvalency on the ligand-mediated assembly of supramolecular immune complexes on cell membrane (Figure 1).

We have previously found that the supramolecular templating effect is not observed when the two binding functionalities are independently distributed on a polymer scaffold.[16] In order to mediate the formation of ternary complexes, the pendant ligands must be arranged as heterobifunctional units on the polyvalent scaffold; hence, we designed a homing device comprising 5 major components: a mulvalent scaffold, polyacrylamide (PAA); a spacer, tri(ethylene glycol) derivative; a bifurcation unit, selectively protected lysine; and 2 specific ligands, trisaccharide and nitrophenol.

Compound **1** (Figure 2) was assembled by sequential elaboration of polyacrylamide (Scheme 1). First, a spacer was introduced by trans-amination of PAA. To the resulting polymeric amine an orthogonally protected glycine derivative (Boc and Fmoc) was attached to provide a bifurcation fragment, which permits sequential installation of two different ligands. Removal of Fmoc protection followed by acylation of the liberated amine with the NHS ester of 4-hydroxy-3-nitrophenylacetic acid yielded polymer **6**. After removal of Boc, the second amine was capped as propargyloxycarbamoyl **7**. The trisaccharide ligand **8** was synthesized chemo-enzymatically as previously reported[24] and incorporated into the polymer *via* copper(I)-catalyzed Huisgen cyclization to give the desired polyvalent heterobifunctional ligand **1**.

To evaluate the ability of the polyvalent ligand **1** to drive complex formation between IgM and CD22 on B cells, human

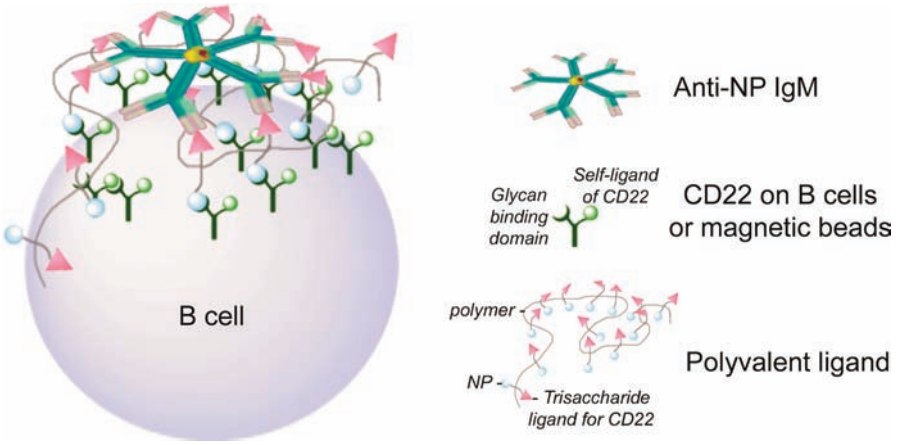

Figure 1. Assembly of immune complex of IgM and CD22 mediated by a polyvalent heterobifunctional ligand.

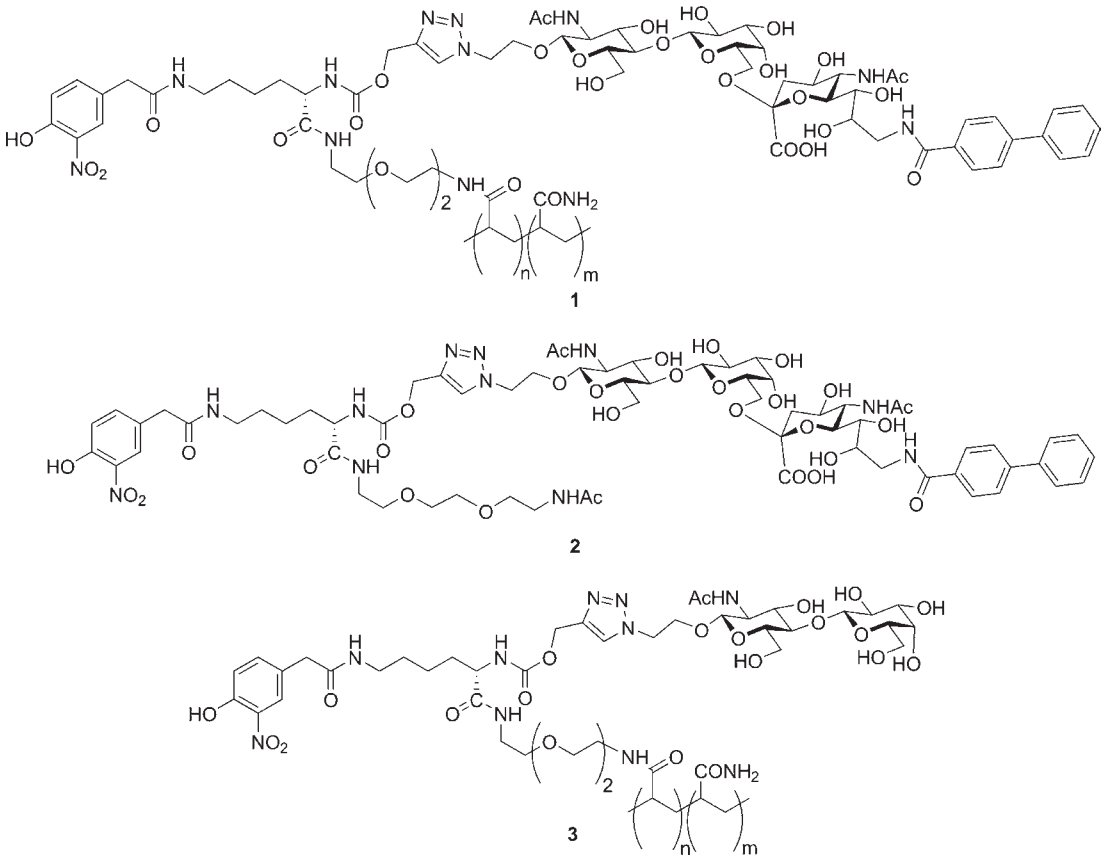

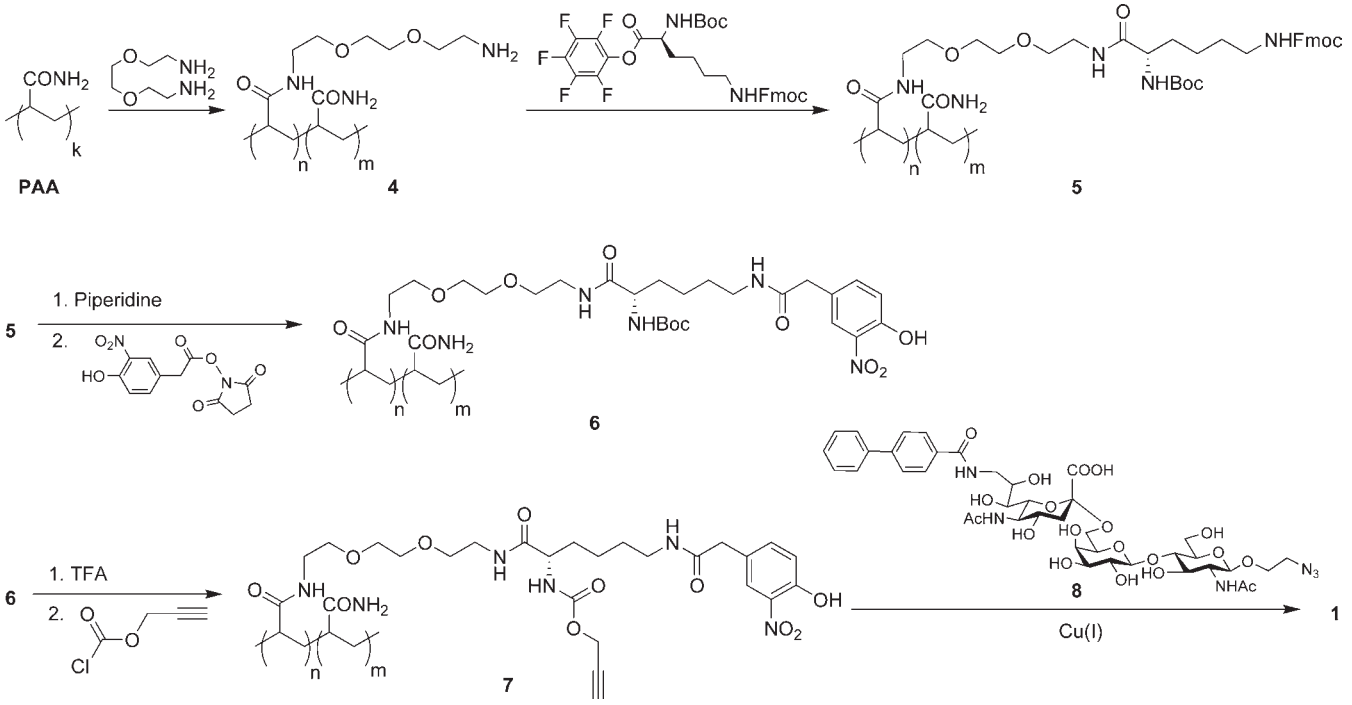

Figure 2. Structures of polyvalent heterobifunctional ligand **1**, its unimeric control ligand **2**, and its polyvalent LacNAc control ligand **3**.

lymphoma cells (BJAB) were incubated with anti-NP IgM at fixed concentration (10 μg/mL), and polyvalent ligand **1**, its unimeric analogue **2**, then stained with FITC-labeled anti-IgM antibody, and analyzed by flow cytometry. As shown in Figure 3, only in the presence of ligand **1** (at all tested concentrations higher than 0.04 μg/mL) was anti-NP IgM associated with B cells. In comparison, only background fluorescence was observed for the unimeric ligand **2**. In separate experiments, the polyvalent LacNAc control (compound **3**), lacking the terminal neuraminic acid moiety, showed no binding to the BJAB cells (not shown). This is consistent with our previous observations that, although the longer linker between the ligand and antigen (NP) reduces the ability of the heterobivalent ligand to mediate formation of a ternary complex between two multivalent proteins due to the loss of conformational entropy,[23] it still allows templating on anti-NP-IgM when presented on a polymeric scaffold.[15] If confirmed by further examples, this effect may have important implications for the design of multivalent heterobifunctional homing devices.

Complex formation between IgM and CD22 on B cells was concentration dependent for polyvalent ligand **1** and, as expected, was described by a bell-shaped curve (Figure 3b). The binding peaked at 2.5 μg/mL of ligand **1** and became inhibitory at higher concentrations, presumably due to saturation of one or

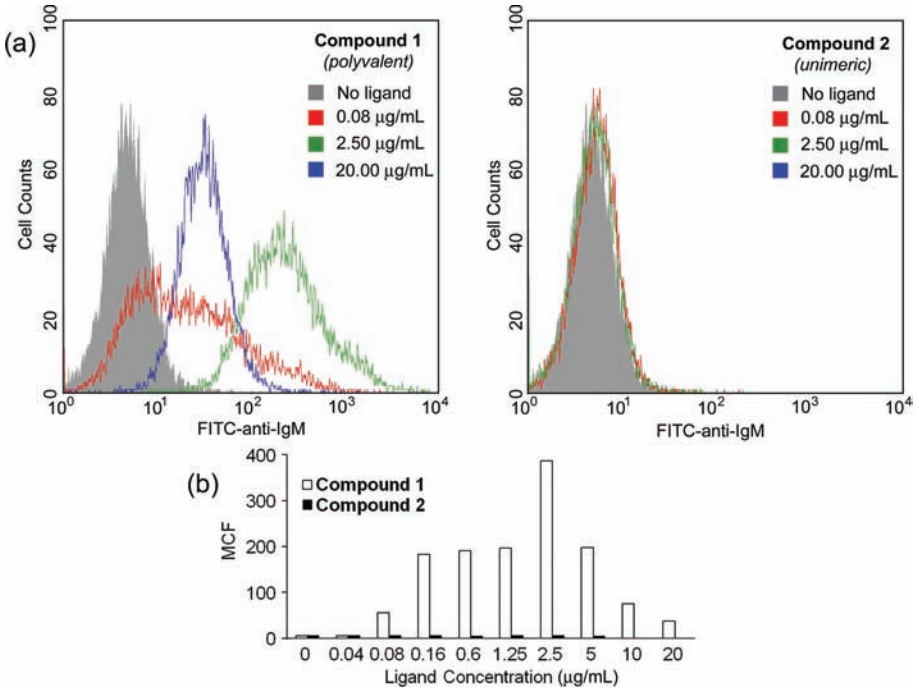

Figure 3. Binding of anti-NP IgM to CD22 on BJAB cells. Formation of IgM-CD22 complex was assessed by incubating BJAB cells with ligands at various concentrations and FITC labeled anti-NP IgM at 10 μg/mL, staining with FITC-anti-IgM, and measuring cell fluorescence by flow cytometry. (a) Histograms of cells treated with polyvalent ligand **1** (left) and unimeric ligand **2** (right). (b) Comparison of mean channel fluorescence (MCF) of cell samples treated with **1** and **2** at various concentrations.

both proteins by the ligand. Such dose dependence is typical for cross-linked complexes and was previously observed by us[23] and others.[25,26]

To eliminate cell-related effects such as ligand-mediated endocytosis and lateral mobility of CD22 in the cell membrane, we also evaluated complex formation using magnetic beads with immobilized CD22 (Figure 4). Anti-NP IgM and magnetic beads were incubated with ligand **1** at various concentrations at both 37 and 4 °C, and the beads were treated with FITC-anti-IgM antibody and analyzed using flow cytometry. The results agreed

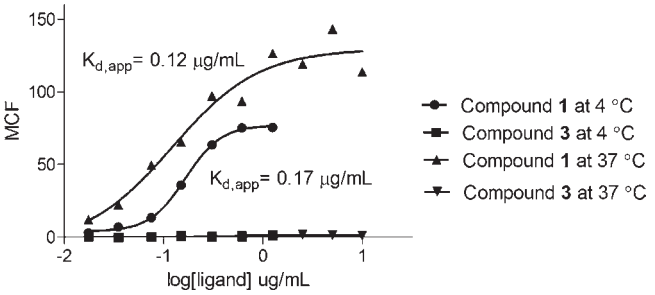

Figure 4. Avidity of complex formation mediated by ligands **1** and **3** was analyzed by titrating ligands in the presence of CD22 immobilized on magnetic beads and FITC labeled anti-NP IgM (5 μg/mL) and measuring bead fluorescence by flow cytometry. Mean channel fluorescence (MCF) is plotted against ligand concentration.

well with the experiments performed on B cells. Complex formation was a dose-dependent process at both temperatures, and more IgM were associated with magnetic beads with the increase of the concentration of ligand **1** until a plateau was reached. Neither the polyvalent control lacking the CD22 ligand (compound **3**) nor the monovalent compound **2** (not shown) supported binding of the anti-NP antibody to beads. The apparent K_d values were found to be 0.12 μg/mL (0.024 nM per pendant ligand) and 0.17 μg/mL (0.034 nM per pendant ligand) at 37 and 4 °C, respectively. This represents a 5000-fold (at 37 °C) and 200-fold (at 4 °C) higher binding affinity over the best univalent ligand identified previously.[23]

More interestingly, the polymeric heterobifunctional ligand exhibited significantly positive binding entropy with little temperature dependency (very similar K_d's at different temperatures) (Figure 4). This is in sharp contrast with previously examined unimeric ligands, which showed a 10- to 20-fold decrease in affinity when temperature increased from 4 to 37 °C due to faster dissociation at higher temperature.[23] Considering mainly the entropic nature of the multivalency effect, which reduces entropy loss upon complex formation (smaller value of ΔS term in binding energy), the weak dependence of the apparent binding constants on temperature for multivalent ligands is expected. Binding of carbohydrate ligands to lectins is often accompanied by a large favorable enthalpy change (ΔH), which is partially offset by an almost equally large unfavorable entropy term ($-T\Delta S$) resulting in low net change in free energy.[27] Multivalent presentation leads to the decrease in absolute value of both thermodynamic terms per pendant ligand with entropy term changing faster.[28] It has also been shown that ΔS can even change the sign and become positive for polymeric ligands.[29] In accord with higher avidity, an increase in net binding of IgM to the beads was observed at 37 °C, which can be attributed to a reduced rate of dissociation and more IgM retention after washing steps as discussed previously in our report on unimeric heterobifunctional ligands.[23]

In conclusion, we report a polymer-based heterobifunctional ligand as a potent homing device that redirects antibodies to cell-surface receptors that are overexpressed on lymphoma B cells. These data suggest new applications of polymeric drugs in targeted cancer therapy that together with other properties, such as enhanced permeability and retention (EPR) effect and prolonged retention in the circulatory system, render them attractive as potential therapeutics.

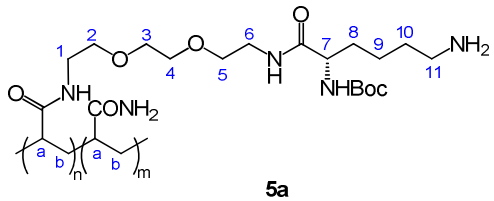
General Methods. All reagents and solvents were purchased from Sigma-Aldrich (reagent grade) and used as supplied unless otherwise noted. TLC plates were visualized by ultraviolet light (254 nm), or charred with ethanolic solution of ninhydrin or sulfuric acid containing anisaldehyde. High performance liquid chromatography (HPLC) was performed using a Waters 2487 Dual λ UV absorbance detector and separations were done on a Beckman C_{18} silica column. ^{1}H NMR spectra were recorded at 600 MHz or 800 MHz. First order chemical shifts are reported in δ (ppm) referenced to external acetone (0.1% v/v) at δ2.225. Signals in ^{1}H spectra were assigned with the aid of two dimensional COSY, HMQC and HMBC spectra. For some signals in ^{1}H NMR spectra, the coupling patterns were reported as multiplets due to high order coupling or signal overlap.

IgM Binding to BJAB Cells. BJAB cells were suspended in RPMI medium supplemented with 10% FBS and 50 μM 2-mercaptoethanol at 4×10^6 cells/mL containing anti-NP IgM at 10 μg/mL. Ligands were diluted to various concentrations in RPMI medium at 50 μL/sample. Aliquots of 50 μL of the cells were added to the ligand dilutions, followed by incubation at 4 °C for 7 h. Cells were then washed with 0.2 mL of HBSS/BSA containing 100 nM ligand and then incubated with FITC-labeled anti-IgM antibody (10 ug/mL) for 30 min on ice. After washing, the cells were analyzed by BD FACS Calibur Flow Cytometer using CellQuest software.

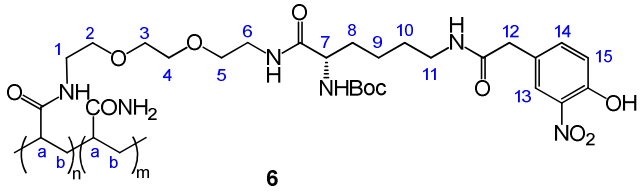
IgM Binding to CD22-Fc Magnetic Beads. hCD22-Fc, which comprises a chimera of the constant fragment of a human IgG fused to the C-terminus of the extracellular portion of CD22, was immobilized onto Protein A-conjugated magnetic beads (Dynal Biotech) by adding 5 mL of culture supernatant containing hCD22-Fc chimera to 20 μL of bead slurry and incubating overnight at 4 °C with end-over-end rotation. Beads were isolated by exposure to a magnet, washed three times with HBSS/BSA, and then resuspended in 200 μL of HBSS/BSA. Aliquots of 2 μL of beads were added to 2 μL of anti-NP IgM (5 μg/mL in HBSS/BSA) containing the various concentrations (0.0175-10.0 μg/mL, obtained by 2-fold dilutions) of ligand, for a final volume of 100 μL. Incubation was done for at least 14 h at 4 °C or 37 °C to allow complex formation to reach equilibrium. Beads were then isolated and washed with 300 μL of HBSS/BSA. Beads were then incubated for 30 min at 4 °C in 100 μL of HBSS/BSA containing FITC-anti-IgM to detect bound IgM. Beads were isolated and washed with 300 μL of HBSS/BSA and then resuspended in 200 μL of the same buffer and analyzed by a FACS Calibur Flow Cytometer using CellQuest software. Curves were generated by nonlinear regression analysis of the data using the equation for log (agonist) versus response-variable slope in GraphPad Prism software (Version 5.0a).



Synthetic procedures.

4

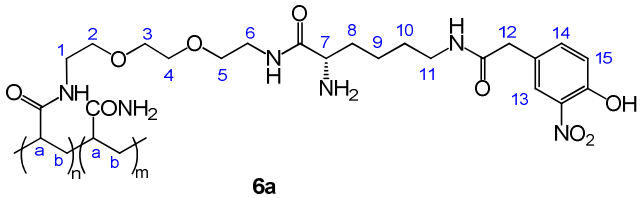
2-[2-(2-aminoethoxy)ethoxy]ethylamidopolyacrylamide (4)



To a solution of polyacrylamide (10.0 g, *M.W.* ~ 40 kDa) in water (100 mL) was added 2,2'-(ethylenedioxy)bis(ethylamine) (100 mL). The reaction mixture was heated at 80 °C for 15 min, and was immediately cooled in an ice bath. The solution was then dialyzed and lyophilized to obtain the desired product as a white foam: ^{1}H NMR (600 MHz, D_2O): δ 3.75 (app. s, 2H, H-2), 3.75-3.68 (m, 4H, H-3, H-4), 3.63 (app. s, 2H, H-5), 3.39 (app. s, 2H, H-1), 3.21 (app. s, 2H, H-6), 2.40-2.05 (m, H-a), 1.85-1.40 (m, H-b).

5a

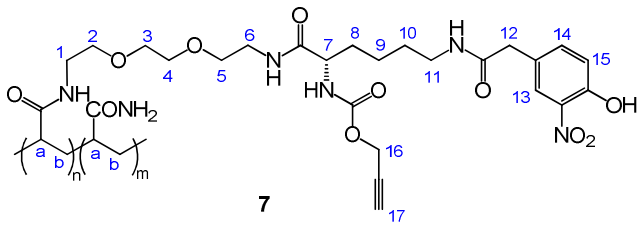
2-{2-[2-(N_α-Boc-lysine)amidoethoxy]ethoxy}ethylamidopolyacrylamide (5a)



Aminated polymer **4** (510 mg) was dissolved in buffer (pH 8.0, 10 mL), and a solution of Fmoc-Lys(Boc)-OPfp (312 mg, 3 eq.) in DMF (20 mL) was added to obtain a semitransparent mixture, which was then stirred for 18 h at r.t. and a white precipitate formed, which disappeared after sonication. TLC was used to monitor the reaction using ninhydrin stain. Disappearance of red spot on TLC indicated formation of compound **5**. Then piperidine (3 mL, 10 %) was added when the solution turned clear. A new white precipitate began to form gradually after 5 min and progressed until the reaction mixture turned into a gel. The reaction tube was centrifuged and the supernatant solution was dialyzed. Lyophilization gave the product **5a** as a white foam: ^{1}H NMR (600 MHz, D_2O): δ3.95 (app. s, 1H, H-7), 3.76 (app. s, 2H, H-5), 3.22 (app. s, 2H, H-6), 3.06 (m, 2H, H-11), 2.40-2.00 (m, H-a), 1.87 (app. s, 2H, H-8), 1.85-1.35 (m, H-b, H-9, H-10), 1.42 (s, 9H, Boc).

6

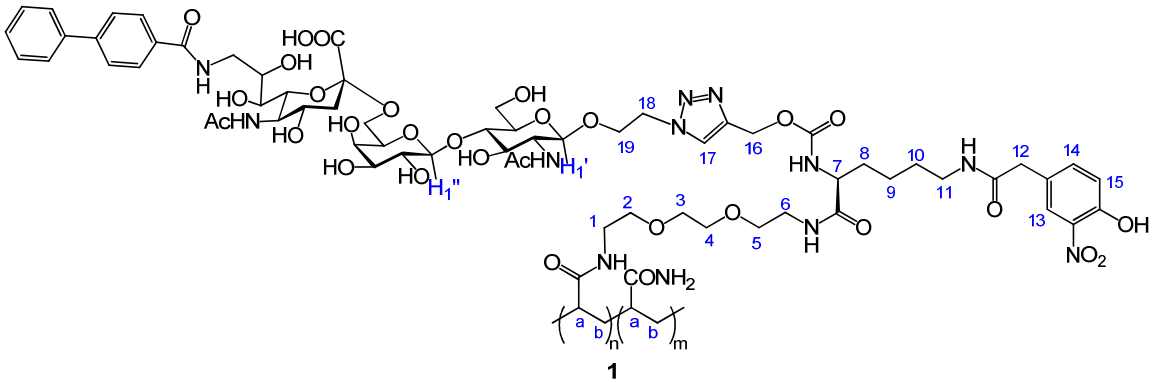
2-{2-{2-[N_α-Boc-N_ε-(4-hydroxy-3-nitro-phenyl)acetamido-lysine]amidoethoxy}-ethoxy}ethylamidopolyacrylamide (6)



To a solution of **5a** (40 mg) in buffer (pH 8.0, 2 mL) and DMSO (0.2 mL) was added 4-hydroxy-3-nitrophenylacetyl-hydroxysuccinimide ester (Biosearch Technologies, 12 mg, 3 eq.). The reaction mixture was stirred for 18 h at r.t. to give a clear bright orange solution, which was dialyzed to produce a faint yellow solution. Upon lyophilization, a yellow foam product was obtained. ^{1}H NMR (600 MHz, D_2O): δ8.02 (s, 1H, H-13), 7.57 (m, 1H, H-14), 7.20 (m, 1H, H-15), 4.25 (m, 1H, H-7), 3.02 (app. s, 2H, H-12), 2.40-2.00 (m, H-a, H-8), 2.00-1.30 (m, H-b, H-9, H-10), 1.42 (s, 9H, Boc).

6a

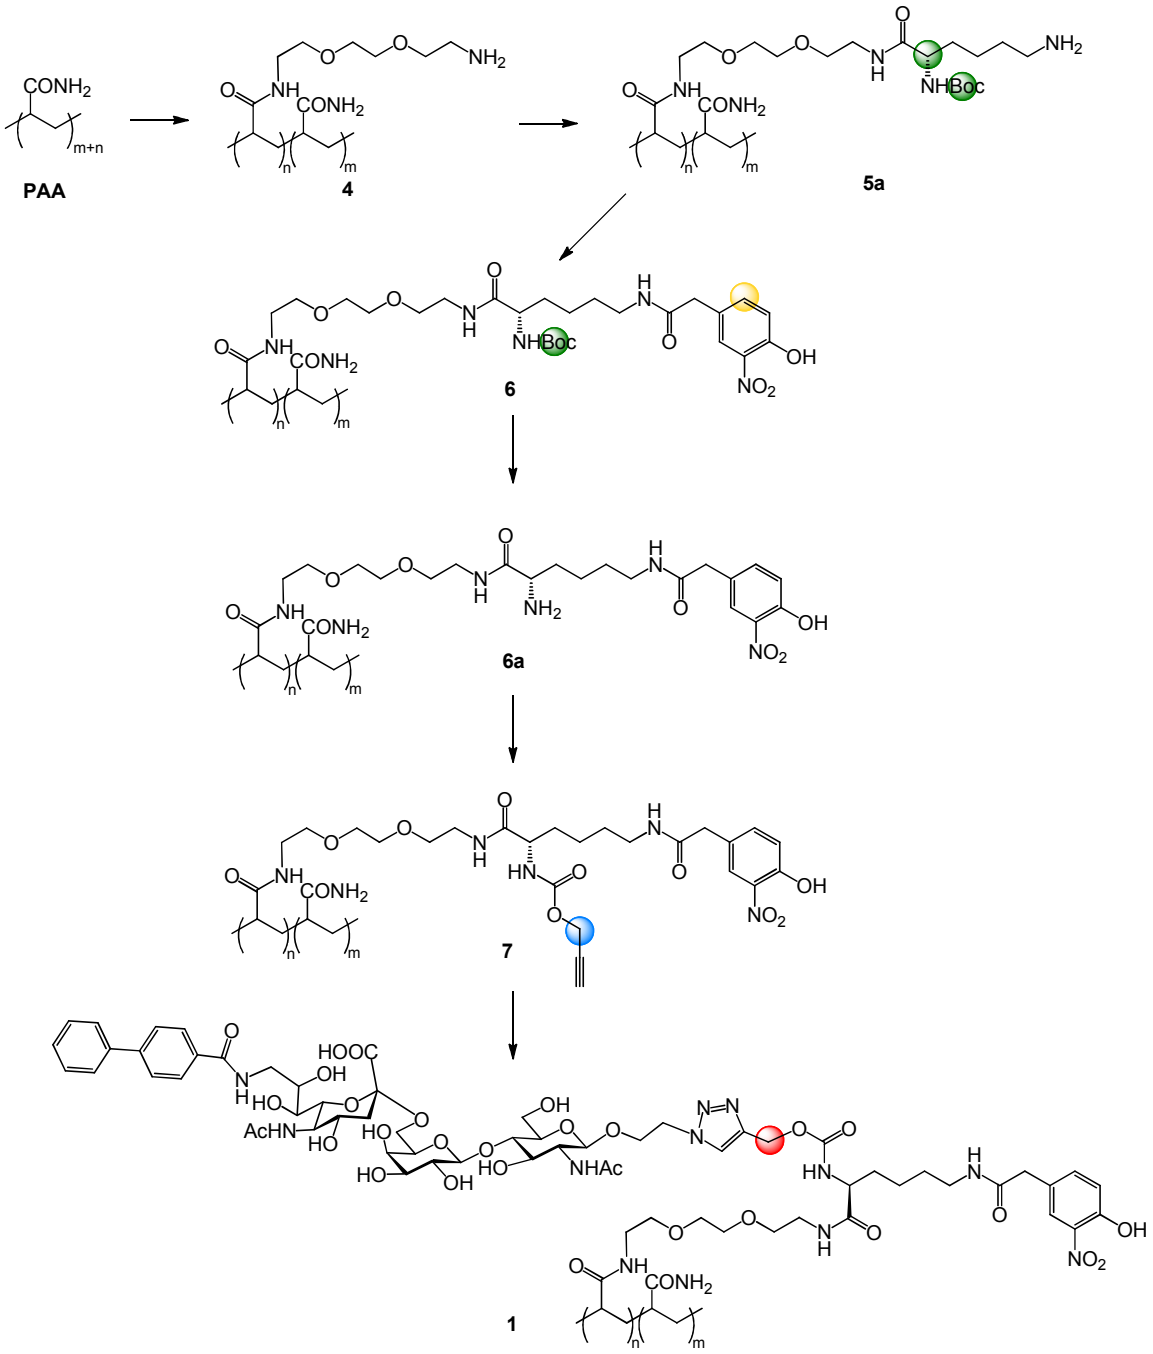
2-{2-{2-[N_ε-(4-hydroxy-3-nitro-phenyl)acetamido-lysine]amidoethoxy}ethoxy}ethyl-amidopolyacrylamide (6a)



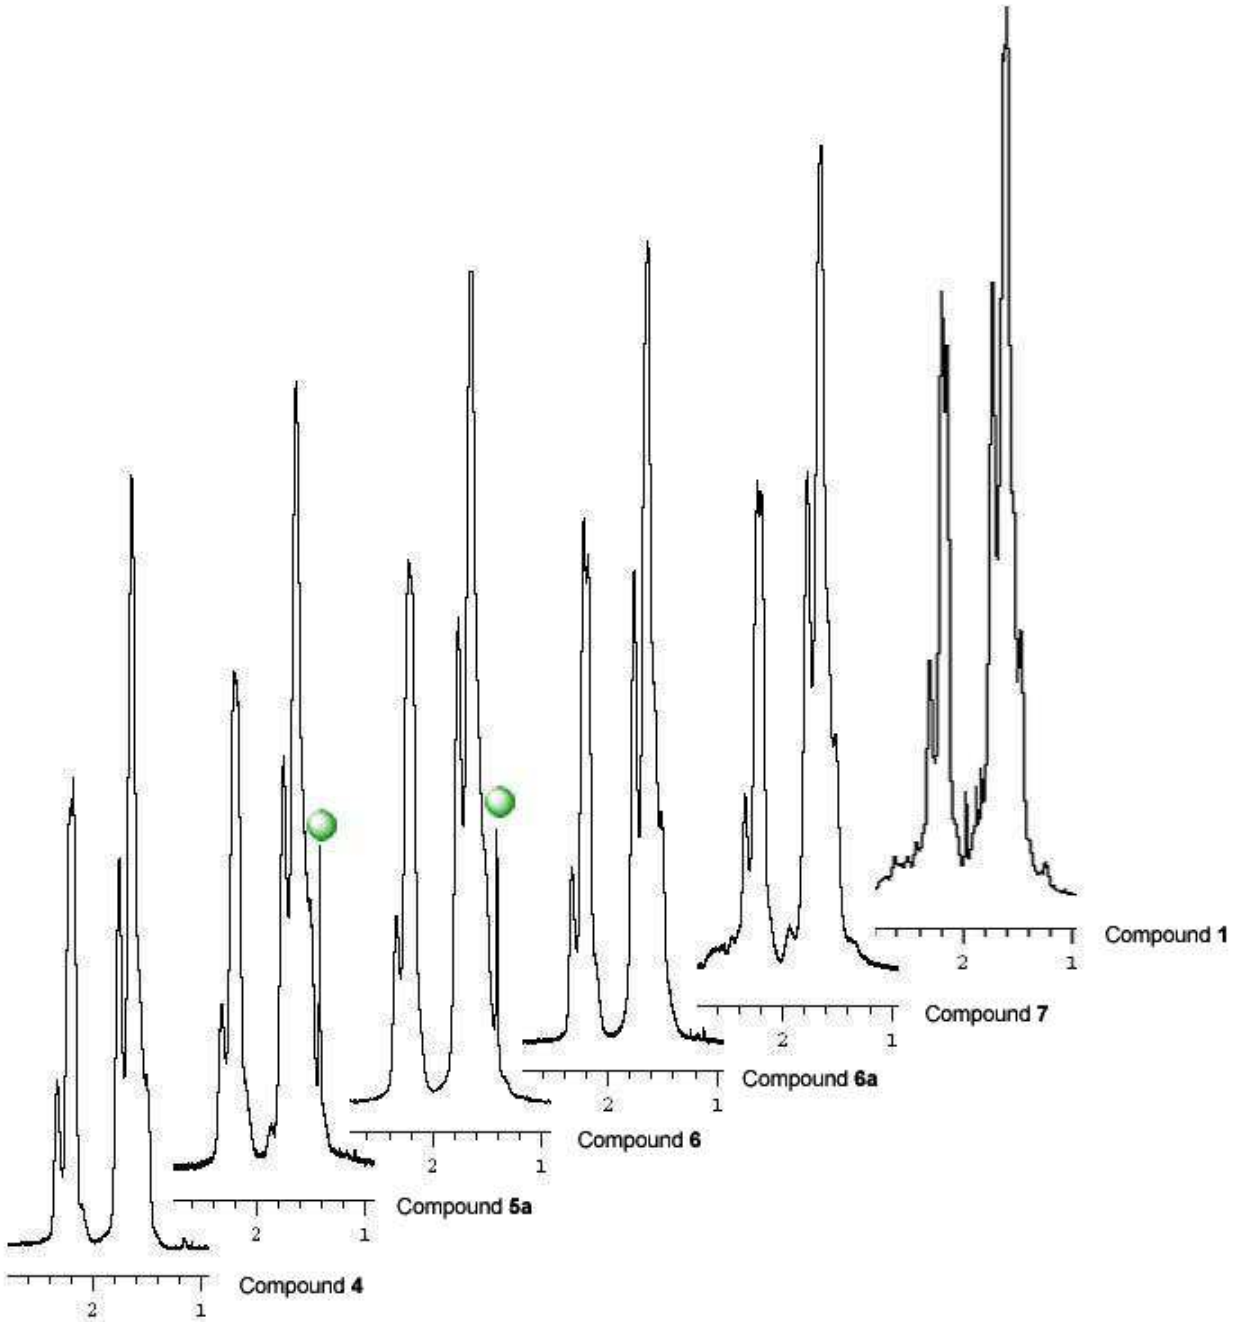
Polymer **6** (39 mg) was dissolved directly in TFA (2 mL) and was stirred at r.t. for 30 min. The reaction was quenched by diluting with water (2 mL) and neutralizing carefully with sodium carbonate powder. The bright yellow solution was then dialyzed and lyophilized to give the product as a yellow foam. ^{1}H NMR (600 MHz, D_2O): δ8.02 (s, 1H, H-13), 7.59 (app. s, 1H, H-14), 7.19 (app. s, 1H, H-15), 4.26 (app. s, 1H, H-7), 2.97 (app. s, 2H, H-12), 2.40-2.00 (m, H-a, H-8), 2.00-1.30 (m, H-b, H-9, H-10).

7

2-{2-{2-[N_ε-(4-hydroxy-3-nitro-phenyl)acetamido-N_α-propargyloxycarbonyl-lysine]-amidoethoxy}ethoxy}ethylamidopolyacrylamide (7)

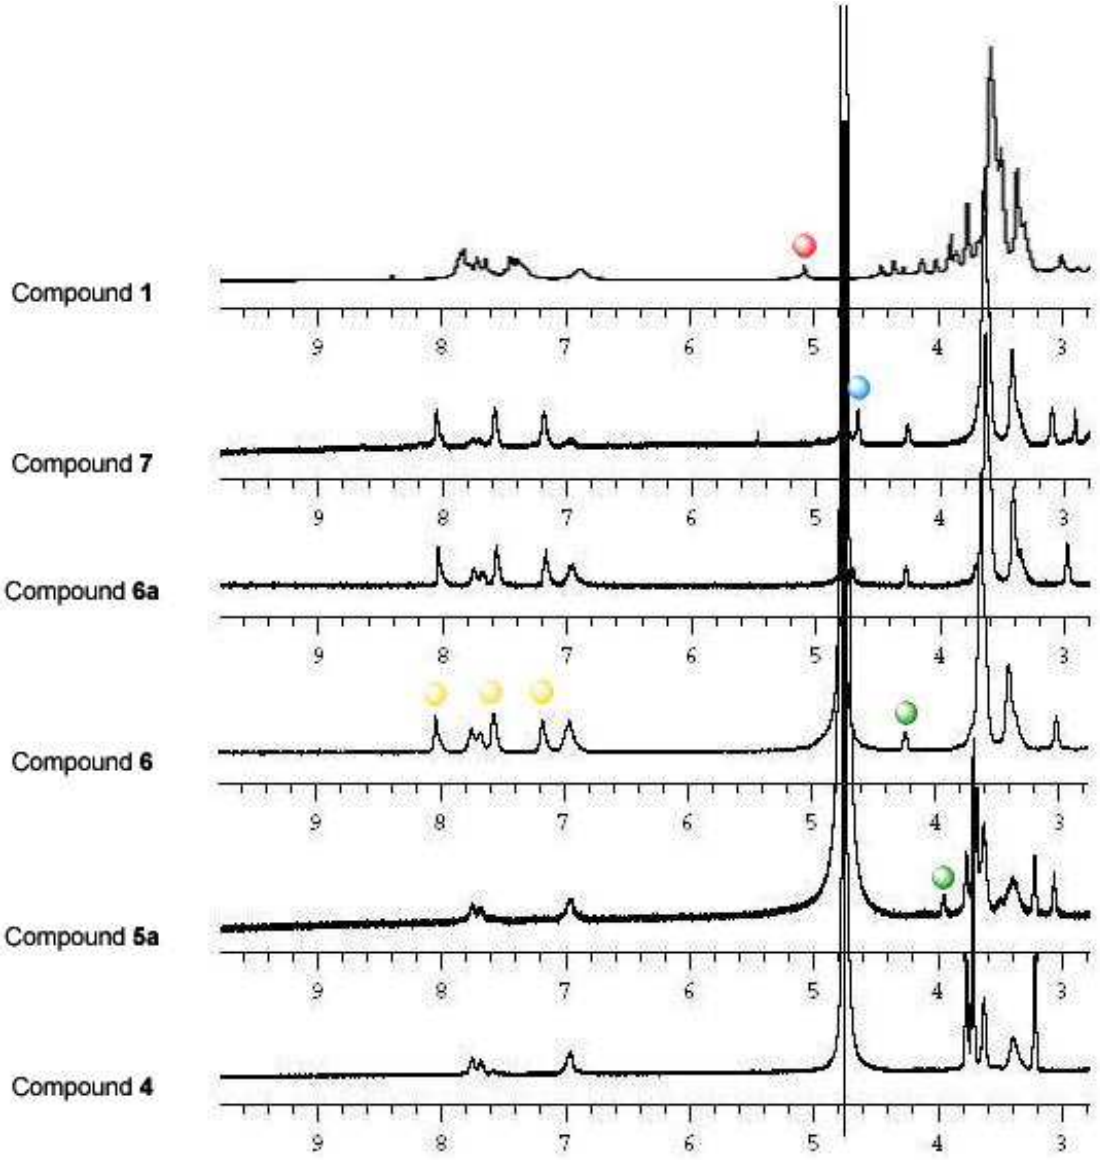


Amino polymer **6a** (34 mg) was dissolved in water (2 mL) and sodium carbonate powder was added to adjust the pH to 10. Propargyl chloroformate (8.4 μL, 10 eq.) was added with vigorous stirring until the oily beads disappeared. TLC staining indicated disappearance of primary amine. Another portion of propargyl chloroformate (8.4 μL, 10 eq.) was added to ensure the complete capping of the amino groups. The resulting solution was close to neutral as indicated by pH paper, and was dialyzed. Lyophilization gave the product as a yellow foam. ^{1}H NMR (600 MHz, D_2O): δ8.03 (s, 1H, H-13), 7.59 (app. s, 2H, H-14), 7.20 (app.s, 2H, H-15), 4.66 (app. s, 2H, H-16), 4.26 (app. s, 1H, H-7), 3.10 (app. s, 2H, H-12), 2.90 (s, 1H, H-17), 2.80-2.00 (m, H-a, H-8), 2.00-1.30 (m, H-b, H-9, H-10).



1

Polyvalent heterobifunctional ligand 1



A mixture of **7** (10 mg), ^{BPC}Neu5Ac-α-(2-6)-Gal-β-(1-4)-GlcNAc-$OCH_2CH_2N_3$ (**8**, 4.5 mg, 2 eq.), and copper powder (30 mg) in water (0.5 mL) was degassed, and a Cu(I)-bathophenanthroline solution (25 μL, 0.04 M) was added. The reaction was allowed to proceed for 40 h at room temperature, and ethylenediamine (50 μL) was added to displace the copper ions chelated with the polymer. The solution was then dialyzed, and lyophilization gave the product as a yellow foam. ^{1}H NMR (600 MHz, D_2O): δ 7.90-6.60 (m, H-17, H-13, H-14, H-15), 5.10 (s, 2H, H-16), 4.50 (app. s, 2H, H-18), 4.36 (m, 2H, H-1′, H-1″) 4.30 (app. s, 1H, H-7), 2.90-0.60 (m, H-a, H-b, H-8, H-9, H-10).

S1: *The synthetic scheme for polyvalent heterobifunctional ligand **1**. The circles in different colors indicate the signature protons of each compound.*

S2: *NMR spectra of polymer backbone of compounds **1** to **7**.*

S3: *Ligand region in NMR spectra of compounds **1** to **7**. The circles in different colors indicate the resonances of the signature protons in each compound.*

Removal of Boc group to restore the amino functionality in compound **6a** was confirmed by the missing peak at δ_H 1.42 ppm in the NMR spectrum (S1, S2, green circle). Formation of compound **7** was verified by the new peak at δ_H 4.66 ppm, representing the propargyl protons (S1, S3, blue circles). Emergence of the proton resonance at δ_H 5.10 ppm in the NMR spectrum of compound **1** suggested the successful formation of the triazole ring via "click chemistry" between azido and alkynyl compounds (S1, S3, red circles).

ABSTRACT:

We describe the simple bioconjugation strategy in combination of periodate chemistry and unnatural amino acid incorporation. The residue specific incorporation of 3,4-dihydroxy-L-phenylalanine can alter the properties of protein to conjugate into the polymers. The homogeneously modified protein will yield quinone residues that are covalently conjugated to nucleophilic groups of the amino polysaccharide. This novel approach holds great promise for widespread use to prepare protein conjugates and synthetic biology applications.

Protein conjugation plays an important role in the development of effective vaccines, affinity matrices, drug delivery systems, and functional hydrogels.[1] These conjugations occur commonly in nature, but experimentally it is difficult to prepare or adapt such biochemical approaches. Chemical activation of polysaccharide and proteins during the conjugation step is complex and also technically difficult. Generally, protein conjugation methods rely on chemoselective modification of canonical amino acids of the protein.[2] To date, several approaches such as simple absorption and protein trapping with gel matrix or through covalent linkage have been used in preparing the bioconjugates.[3,4] Among them, the most common and frequently employed approach is covalent linkage. Covalent linkages typically occur through amine coupling of lysines and sulfhydryl coupling of cysteine residues of protein.[5,6] Cysteine is relatively a rare amino acid, and its thiol group can undergo disulfide exchange to form mixed disulfides, which is very important in preserving protein structure and function. Although amine coupling of lysine residues is considerably more prevalent in bioconjugation studies, it should be noted that reagents used for lysine modification can additionally modify the N termini of proteins.[5] Therefore, it is a challenging goal to modify these residues. Furthermore, modification of these residues through chemical reactions is reversible, slow, and also inefficient.[7] In general, approaches for the site-specific modification of canonical amino acid and finding ideal chemical candidate molecules that precisely modify the side chains for bioconjugation is highly challenging. Recently, protein−polysaccharide conjugates were achieved through tyrosinase mediated oxidation of tyrosine in the recombinant protein to form a reactive *ortho*-quinone. Further, bioconjugation was achieved through the nonenzymatic reaction of the nucleophilic amino groups of the polymer with

electrophilic *ortho*-quinones of the protein.[8] This method was successfully used for fabricating biological samples and in developing a novel microdevice which investigates how bacteria communicate with each other for enhancing their resistance toward drugs.[9] However, in this approach it is very difficult to maintain specificity, monitor product formation, and remove the enzymes after the reaction.

Since preparing conjugates is a difficult process, a new bioconjugation reaction is currently of high interest to develop a systematic approach for coupling a specific protein of interest with polysaccharide targets. In an effort to establish a valuable protein−polysaccharide complex, we aimed to replace the tyrosine amino acid of recombinant protein with 3,4-dihydroxy-L-phenylalanine (L-DOPA). DOPA is an important neurotransmitter biosynthesized naturally in humans by tyrosinase-catalyzed oxidation of tyrosine in a melanin biosynthetic pathway, and by tyrosine hydroxylase in brain for catecholamine neurotransmitter biosynthesis. It also play an important role in adhesive and cross-linking property of mussel adhesive proteins.[10] Recently, genetic incorporation of L-DOPA was achieved through a site specific suppression method, and it is significantly used in exploring protein−protein interaction.[11,12] However, the practical importance of this method is still limited by low protein yields due to cellular toxicity.[13] On the other hand, DOPA has also been incorporated into proteins by in vitro protein synthesis and solid-phase peptide synthesis.[14] Here, we demonstrate the successful in vivo incorporation of L-DOPA in a residue specific manner, which also enables development of an efficient and improved bioconjugation strategy (Scheme 1).

This improved bioconjugation method will facilitate the synthesis of homogeneously modified protein with reactive chemical groups that can be utilized to create novel protein−polysaccharide complexes. DOPA-enriched recombinant proteins are selectively oxidized by periodate to form an *ortho*-quinone intermediate which is then subsequently attacked by the amino groups of chitosan resulting in a nonenzymatic cross-linking reaction through Michael addition.[14] To evaluate the scheme shown above, we chose green fluorescent protein (GFP) as a model protein since its functional and spectral properties were well-studied and characterized.[15] Our current GFP variant contains eight tyrosine residues which will be replaced with L-DOPA through an in vivo incorporation method. The detailed sequence information about the GFP variant used in the study was mentioned in Table S1 (Supporting Information). Chitosan, an aminopolysaccharide, is selected as a target polysaccharide for the bioconjugation reaction. It is an attractive material in the biomedical field and has a wide range of applications in drug delivery, gene therapy, and tissue engineering due to its high biocompatibility and biodegradability properties.[16] This polysaccharide molecule contains primary amino groups, which are nucleophilic and undergo reactions with a variety of electrophiles such as aldehyde and quinones. In this study, we expressed our recombinant protein by replacing tyrosine residues with unnatural amino acid L-DOPA by the selective pressure incorporation (SPI) method, which is a highly efficient method to express protein with high yield.[17] It enables the simple residue specific incorporation of unnatural amino acids into different recombinant proteins.[18] Cells containing recombinant GFP were expressed in minimal medium containing the 20 natural amino acids, 19 amino acid lacking tyrosine, and 19 amino acids plus L-DOPA and subjected to the SDS-PAGE analysis. Since oxidation of L-DOPA leads to the formation of highly toxic quinone moiety,[19] we performed a series of optimization experiments with different reducing agents such as dithiothreitol (DTT) and L-ascorbic acid at various concentrations. To verify whether the reducing agent selectively plays any role in L-DOPA incorporation, crude bacterial lysates were subjected to gel electrophoresis. The band intensity of the DOPA protein expressed in the presence of the reducing agent was comparable with that of the band expressed in the absence of the reducing agent. This result suggests that the reducing agent played little or no effect in the expression and efficiency of L-DOPA incorporation into GFP (Figure 1a). Furthermore, GFP and GFPdopa were purified on a Ni-NTA affinity column and gel permeation chromatography (GPC) by AKTA Explorer FPLC system in the absence of reducing agent at 4 °C, respectively (Supporting Information Figure S1). The purification yield of GFPdopa was approximately 32 mg/L, which was similar to that of wild type GFP (34 mg/L). Interestingly, incorporation of L-DOPA into GFP altered the spectral properties; a distinct 19 nm red shift was observed in the emission peak (530 nm) when compared with the GFP protein (511 nm) and a distinct 11 nm shift was observed in the excitation peak (512 nm) compared to the GFP protein (501 nm) (Figure 1c). This shift might be due to the presence of additional hydroxyl group (electron donor) of L-DOPA when compared with L-tyrosine (Y66), which alters the chromophore chemistry. Further, to identify that L-DOPA was incorporated into the GFP protein, we employed a redox staining method using nitroblue tetrazolium (NBT) which detects proteins containing *o*-catechols, like DOPA, after their separation by SDS-PAGE and western transfer to the polyvinylidene membranes.[20] This staining method confirmed the presence of L-DOPA only in the GFPdopa (Supporting Information Figure S2). Next, we investigated that this replacement occurred specifically in place of tyrosine, which is further confirmed by LC-MS/MS and ESI-MS

Scheme 1. Schematic Representation of the Proposed Approach for Bioconjugation of L-DOPA Containing Protein with a Polysaccharide

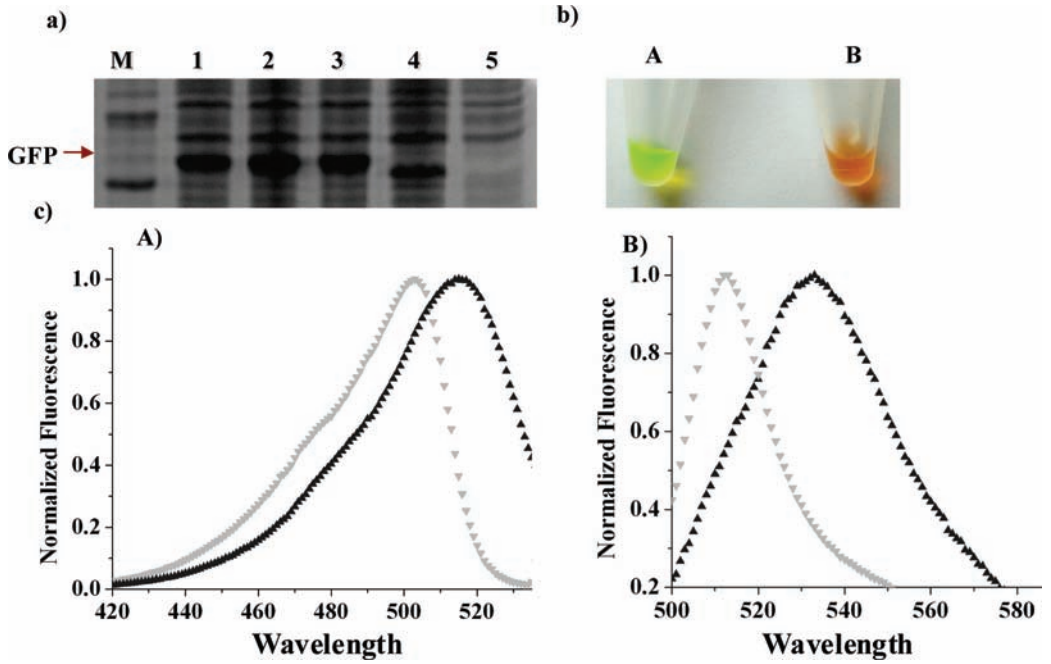

Figure 1. (a) Polyacrylamide gel electrophoresis of protein labeled with L-DOPA. The labeled proteins are indicated by an arrow. Lane M: protein ladder (Promega prestained Ladder). Lane 1: positive control (expressed with all 20 canonical amino acid). Lane 2: test (expressed with 19 amino acid plus L-DOPA). Lane 3: test 1 (expressed with 19 amino acid plus L-DOPA with L-ascorbic acid). Lane 4: test 2 (expressed with 19 amino acid plus L-DOPA with DTT). Lane 5: negative control (expressed only with 19 amino acids). (b) Purified GFP shows the green native color (A) and GFPdopa shows changed color (B). (c) Normalized fluorescence excitation spectrum (A), emission spectrum (B) of GFP (▼), and GFPdopa (▰).

(Supporting Information Table S2 and Figure S3), and the efficiency is >90%.

The successful design and confirmation of a protein with a novel L-DOPA moiety further allowed us to prepare functional protein−polysaccharide complexes. To substantiate the reaction outlined in Scheme 1, purified GFP and GFPdopa was treated with sodium periodate ($NaIO_4$) and incubated with chitosan at room temperature. We could observe the slight fluorescence reduction in GFP and GFPdopa (less than 10%) during $NaIO_4$ treatment; however, the amount of reduction is negligible (Supporting Information Figure S4−S5). Initially, we have evaluated the pH dependency of GFP and GFPdopa. The GFP-chitosan conjugation efficiency was estimated by using the intensity of the fluorescence at different conditions such as precipitation, washing, and resolubilization (Supporting Information). It indicates that GFP and GFPdopa fluorescence also depends on the pH of the environment (Supporting Information Figure S6) and also well correlated with the earlier report about the effect of pH on GFP.[15] On the basis of the observation, pH 6.0 was selected for estimating fluorescence in the conjugation experiment. Initially, individual proteins were pretreated with periodate to convert DOPA into an *ortho*-quinone intermediate. After conjugation, chitosan was precipitated by raising the pH of solution to basic. Subsequently, the pellet and supernatant retrieved after centrifugation were subjected to fluorescence analysis and the relative amounts of proteins that conjugated successfully were assessed. As shown in Figure 2, fluorescence was almost exclusively observed (only 10% reduction was observed) in the supernatant of GFP, GFPdopa not treated with $NaIO_4$, and $NaIO_4$ treated GFP. Such a 10% reduction of fluorescence might be due to the $NaIO_4$ effect on the protein. In contrast, a strong reduction in fluorescence was observed in $NaIO_4$ treated GFPdopa. To measure the relative amount of protein conjugated with chitosan, we compared the initial fluorescence with the fluorescence retained in supernatants. On the basis of fluorescence intensity of the supernatant, efficiency of conjugation between GFPdopa and chitosan in the presence of $NaIO_4$ was around 90%. GFP and GFPdopa pellets obtained by centrifugation were washed with PBS buffer to remove physically bound proteins and then resolubilized in aqueous acetic acid solution (Supporting Information). A strong fluorescence appeared in the resolubilized pellet of $NaIO_4$ treated GFPdopa−chitosan conjugates. A modest level of fluorescence was observed in $NaIO_4$ treated GFP reacted with chitosan; it may be due to unspecific binding of the protein rather than the GFP−chitosan bioconjugation (Figure 2a). Similarly, we observed a little fluorescence in the GFPdopa−chitosan conjugates, which are prepared in the absence of $NaIO_4$. This little fluorescence may be due to the nonspecific binding of GFPdopa with chitosan during precipitation. This observation clearly indicates that cross-linking occurred specifically between the DOPA-containing protein and chitosan only in the presence of periodate. To be specific, the fluorescence results suggest that >90% of the initial fluorescence of GFPdopa was in the pellet after $NaIO_4$ activation, whereas 10% when GFP treated with $NaIO_4$ had occurred by physical entrapment. This demonstrates that conjugation of GFPdopa with chitosan occurs only through the quinone moiety rather than the canonical amino acids. Strong evidence that the quinone containing GFPdopa can be conjugated to chitosan is provided in Figure 2b. The cast chitosan films were incubated with GFP and GFPdopa in the presence and absence of $NaIO_4$ (Supporting Information). These treated films were observed to have a relatively significant increase in absorbance at wavelengths above 350 nm. Control films incubated with or without protein show little absorbance above

dx.doi.org/10.1021/bc2000066 |*Bioconjugate Chem.* 2011, 22, 551–555

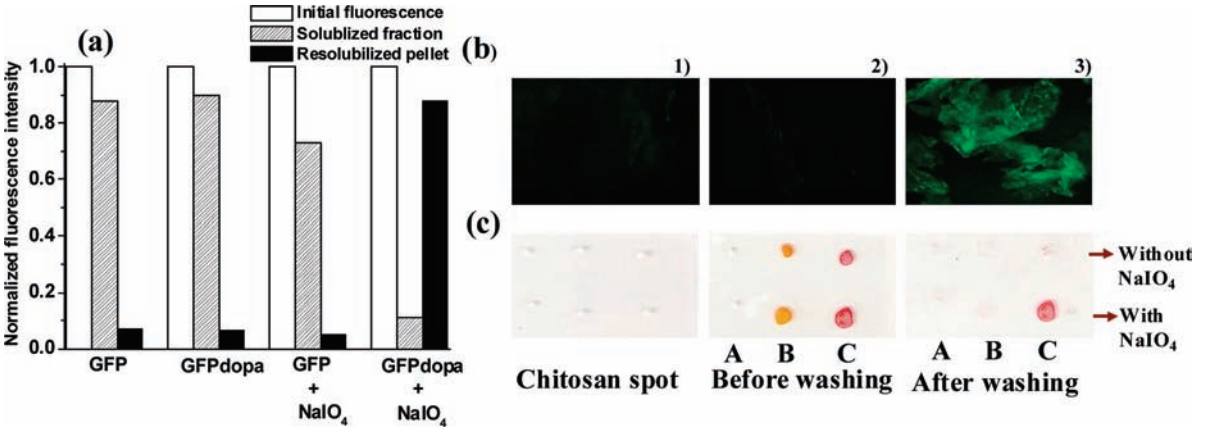

Figure 2. (a) Fluorescence analysis of periodate initiated conjugation of GFPdopa with chitosan (see Supporting Information for the detailed experimental conditions). (b) Fluorescence microscopic analysis of chitosan hydrogel and each set of images obtained under identical conditions. (1) Chitosan. (2) Chitosan conjugated with $NaIO_4$ treated GFP. 350 nm, and the films incubated with the GFP protein, $NaIO_4$, show no increased absorbance above 350 nm. Increased absorbance in the UV−vis range was identified in chitosan films incubated with $NaIO_4$ treated GFPdopa protein, which provide the evidence for quinone mediated reaction (Supporting Information Figure S7). It indicates that $NaIO_4$ selectively generates the quinone from the GFPdopa and facilitates the assembly onto the chitosan. To evaluate our currently developed bioconjugation method, proteins were further conjugated to chitosan hydrogels under heterogeneous conditions. Chitosan hydrogels were prepared as described earlier[8] (see Scheme S1 in Supporting Information). After the hydrogel preparation, $NaIO_4$ solution was spread onto the surface and treated with GFP and GFPdopa protein, respectively. After incubation, to remove nonspecifically bound proteins hydrogels were thoroughly washed with PBS buffer and imaged using a fluorescence microscope. Hydrogel samples were prepared for fluorescence analysis and each set of images obtained under identical condition. As expected, the hydrogel treated with the GFPdopa protein in the presence of $NaIO_4$ had a high level of fluorescence, whereas gels treated with chitosan and GFP in the presence of $NaIO_4$ has no significant fluorescence (Figure 2b). Interestingly, the initial bioconjugation study with chitosan solution shows around 10% physical entrapment of protein. However, in the bioconjugation study with hydrogel, we could not observe such physical entrapment of GFPdopa protein on chitosan.

This indicates that the nonspecific binding of GFPdopa protein is higher with chitosan solution when compared to the chitosan hydrogel. This is due to the interior physical entrapment of proteins by chitosan, which occurred when the pH was raised for precipitation. During the washing step, the nonspecifically bound protein onto chitosan surface could be easily removed, but the proteins which are trapped in the interior are very difficult to remove in the washing process. On the other hand, in the case of the bioconjugation reaction with hydrogel and spot assay, binding occurs only on the surface of the chitosan, and these nonspecifically bound GFP and GFPdopa proteins could be removed during the washing step. Next, we utilized this current strategy to develop the protein spot. For this purpose, we prepared chitosan on glass side, and further, quinone containing GFPdopa was covalently assembled onto the chitosan surface (Figure 2c) (Supporting Information Figure S8). Binding was quantified densitometrically using the *Scion Image* PC software package. Densitometric analysis revealed the high abundance binding of GFPdopa protein with chitosan coated in the glass slide (Supporting Information, Figure S8).

In conclusion, we developed a simple, efficient, and facile method to prepare bioconjugates by activating protein genetically encoded with L-DOPA, which allows it to be covalently coupled with chitosan. This is the first report that demonstrates the effective protein−polysaccharide bioconjugation through a combination of periodate mediated oxidation chemistry and genetic code engineering. The combination of biochemical conjugation with selective cross-linking chemistry will provide an alternative approach for the assembly of proteins onto the patterned surfaces. This approach can be used to explore the role of the adhesive and cross-linking nature of DOPA in mussel adhesive protein, which can be used in developing novel biosensor and in synthetic biology applications.

Materials

PCR reagents, T4 DNA ligase and restriction endonucleases were purchased from Promega (Madison, WI, USA). The isopropyl-D-thiogalactopyranoside (IPTG) was purchased from sigma chemicals (St. Louis, MO, USA). The host bacterium *Escherichia coli* strain XL1-blue (Stratagene, CA, USA) was used for plasmid DNA preparation, in this study. *E. coli* cells with plasmids were grown aerobically in Luria-Bertani (LB) broth (Difco Laboratories, Detroit, Michigan, USA) or on LB agar plate, supplemented with appropriate antibiotics for the selection of transformants. Natural amino acids, unnatural amino acid 3, 4-dihydroxy-L-phenylalanine (L-DOPA) and chitosan were purchased from Sigma (St. Louis, MO, USA). The nickelnitrilotriacetic acid (Ni-NTA) affinity column was purchased from Qiagen (Valencia, CA, USA). *E.coli* strain JW2581 tyrosine auxotroph was obtained from *E. coli* Genetic Stock Centre, Yale University, New Haven, USA and plasmid pQE-80 L was obtained from Qiagen (Valencia, CA, USA).

Construction of plasmids and strains

The DNA manipulations were performed according to the procedures described by Sambrook and Russel.[1] The PCR reaction (50 µl) contains 10 pM of each primer, 50 ng of template DNA, 1X Taq DNA polymerase buffer, 1 U of *Taq* DNA polymerase (Promega, Madison, WI, USA), 0.2 mM of each deoxyribonucleotide triphosphates and 1.5 mM $MgCl_2$. Amplification was performed in a DNA thermal cycler (Master Gradient thermal cycler, Eppendorf, Hamburg, Germany) programmed for an initial denaturation (94 ºC for 1 min) followed by 30 cycles of 1 min at 94ºC, 1 min at 60ºC and 0.5 min at 72ºC with an extension at 72ºC for 10 min. pQE-60 bearing GFPhs2 containing eight tyrosine residues was constructed by cloning it in the pQE-80 L using *BamH*1 and *Hind*III restriction enzymes.[2] The constructed pQE80-GFPhs2 (hereafter it will be mentioned as GFP) plasmid was transformed into *E. coli* JW2581 tyrosine auxotroph for the production of recombinant natural and unnatural recombinant proteins. All these constructs were sequenced and confirmed for their target protein sequence.

Incorporation of L-DOPA into recombinant protein and SDS-PAGE analysis

The above mentioned constructs were grown in M9 minimal medium supplemented with 0.4% (w/v) of glucose, 0.1 mM of $CaCl_2$, 1.0 mM of $MgSO_4$, 35 µg/mL of thiamine, 20 amino acids (40 mg/L), and appropriate antibiotics. When an optical density of the culture reaches 0.8 to 1.0 at 600 nm, then its centrifuged for 10 min (5,000 rpm) at 4 °C. The cell pellets were washed twice with 0.9% (w/v) of NaCl solution. The cells were then resuspended in M9 minimal medium supplemented with 19 amino acids (40 mg/L) lacking tyrosine. The resuspended cells were added to different test tubes containing M9 minimal medium containing L-tyrosine (40 mg/L) as a positive control, L-DOPA (1 mM) as a test. Reducing agent such as DTT (concentration varied from 100 to 500 µM) and ascorbic acid (concentration varied from 1 to 10 mM) at different concentrations was added to

medium supplemented with L-DOPA. After incubating at 37^0C for 10 min, 1 mM of IPTG was added to induce the protein expression. The cells were harvested finally after 6 hrs of induction and OD_{600} was measured. The harvested cells by centrifugation were stored at -70°C until further use. Cell lysis was carried out by using BugBuster protein extraction kit (Novagen) followed by sonication. Briefly, collected cell pellet corresponding to 1 mL of culture was resuspended in 100 µl of lysis buffer, incubated at room temperature for 10 min., and centrifuged at 9000g, 4ºC for 20 min. The supernatant was saved as a soluble protein fraction, and analyzed by SDS-PAGE (12% acrylamide gel).

Table S1. Amino acid sequences of the GFP. The GFP expressed as recombinant protein contains a hexahistidine tag sequence of the vector pQE80L (MRGSHHHHHHGF) was appended to the N-terminus of each protein for Ni-NTA purification.

Protein purification

The pQE80-GFP in *E. coli* tyrosine auxotroph was grown to OD_{600} of 0.6 in 100 mL M9 medium, induced with 1 mM IPTG for 6 hrs and pelleted. Purification of recombinant proteins were performed by using Ni-NTA HisBind Resin (Novagen). Further Histag purified samples were subjected to gel permeation chromatography (GPC) purification by AKTA Explorer FPLC system containing Superdex 75 HR column at 4 °C.

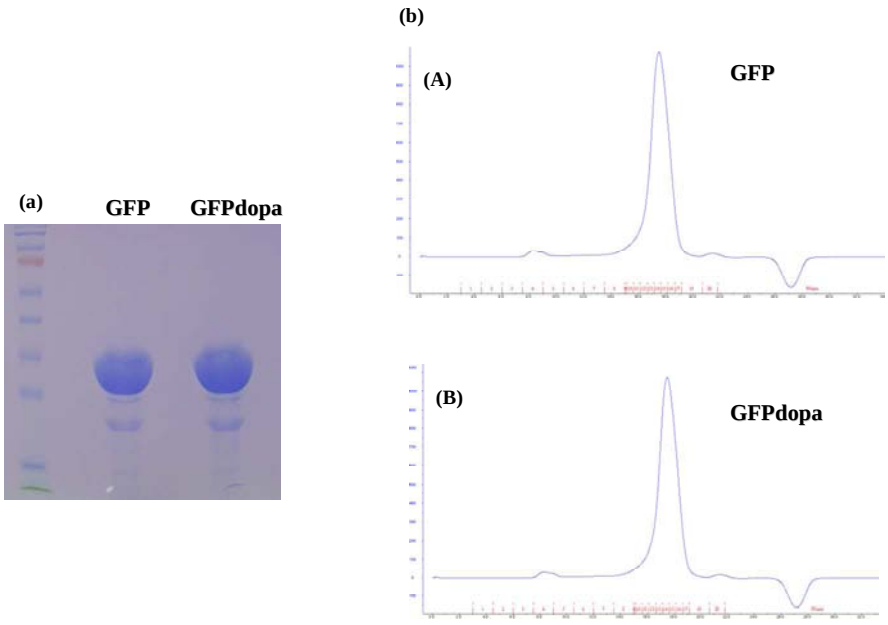

Figure S1. (a) GFP and GFPdopa proteins were purified by nickel affinity chromatography column (b) Gel permeation chromatography of purified GFP and GFPdopa proteins. GFP (A) and GFPdopa (B) proteins were applied to a gel permeation column and eluted with PBS (100 mM NaH_2PO_4, 500 mM NaCl, pH 6.8) at 0.75 mL/min. at 4°C. For each run, 1 mL of 5 mg/mL protein was injected. The elution pattern was monitored by measuring the absorbance at 280 nm.

Protein quantification and fluorescence analysis

Absorption spectrum and quantification of proteins were measured as describe elsewhere. Fluorescence spectra (2 μM protein samples were excited at 470 nm by using excitation/emission slits of 5.0 nm) were recorded on a JASCO FP-777 spectrofluorimeter equipped with digital software.

Redox-cycling staining of DOPA containing proteins

The GFP containing tyrosine and GFPdopa containing L-DOPA was obtained as described in the previous section. GFP and GFPdopa were blotted electrophoretically onto poly vinylidene difluoride membrance (PVDF) and visualized by staining the membrane with nitroblue tetrazolium (NBT). The membrane was incubated in the NBT staining solution (2 M sodium glycinate, 0.24 mM NBT, pH 10.0) in dark room for 3 h.

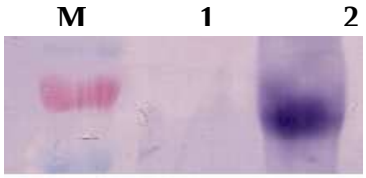

Figure S2. Detection of DOPA incorporation in GFP variants by redox-cylcing staining. Approximately equal amounts (12.5µg) of each of the purified samples were separated on SDS-PAGE gel and stained by NBT. Protein Ladder (Promega prestained Ladder); Lane 1: Positive control (expressed with 19 amino acid plus L-tyrosine); Lane 2: test (expressed with 19 amino acid plus L-DOPA (residue specific incorporation)).

In-gel digestion

Samples were resolved by SDS-PAGE and stained with Colloidal Coomassie blue R250 solution (ProteomeTech Inc. Korea). Protein in-gel digestion was performed with modifications as described previously[3]. Gel bands were sliced into 1 mm^3 cubes and washed twice with 50 mM ammonium bicarbonate containing 50% acetonitrile. Protein reduction and alkylation were performed consecutively with 10 mM DTT in 50 mM ammonium bicarbonate for 1 h at 56 °C and then with 10 mM acrylamide in 50 mM ammonium bicarbonate for 45 min at room temperature, respectively. Gel pieces were washed twice with 50 mM ammonium bicarbonate, 50% acetonitrile, dehydrated with 100% acetobitrile, and dried in a speed vac. The dried gel pieces were rehydrated with 20 ng µL-1 sequencing grade trypsin (Promega, CA, USA) in 50 mM ammonium bicarbonate and incubated overnight at 37 °C. Supernatants were transferred to fresh tubes, and the remaining peptides in gel slices were extracted by sonicating with 50% acetonitrile in 5% TFA in water bath for 40 min. The extracts were combined, dried about 2 µL and desalted using a GeLoader tip column packed with POROSR2/R3 (Applied Biosystems, CA, USA) and the eluted peptides were subjected to mass spectrometric analysis.

Nano LC-MS/MS

Tryptic digests were separated by an Ultimate nanoLC systems including the FAMOS autosampler and Switchos column switching valve (LC-Packings, Amsterdam, The Netherlands) and on-line analyzed by a QSTAR Mass spectrometer (Applied Biosystems, CA, USA) with a nanospray interface as described.[4] Peptide binding was occurred in a 2 cm 200 μm ID self-packed column Zorbax 300SB-C18, 5μm (Agilent) with 5% acetonitrile in 0.1% formic acid with a flow rate 4 μL /min for 10 min. The bound peptides were separated in a 15 cm fused silica emitter (75 μm ID) in-house packed with the same resin, eluted with 5 – 50 % (v/v) acetonitrile in 0.1 % formic acid over 45 min at a flow rate of 0.2 μL /min. MS/MS spectra were acquired in an automated switching mode tandem mass spectrometer with m/z-dependent set of collision offset values.

Peptide identification via MASCOT database search

The mass spectral data were processed into peak lists with Analyst QS (version 1.1; Applied Biosystems) and searched against GFP protein sequences using in-house Mascot server (version 2.1, matrix Sciences, UK). The initial mass tolerance in MS mode was set to 0.3 Da and MS/MS mass tolerance was 1 Da. Two tryptic missed cleavages were allowed and L-DOPA (Y^{*}) were searched as variable modifications. The candidate peptides whose probability MOWSE scores are significant ($p<0.05$) were considered and selected. The MS/MS spectra of selected peptides were manually validated as well.

Table S2. List of peptide amino acid sequences of samples observed by ESI-MS/MS.

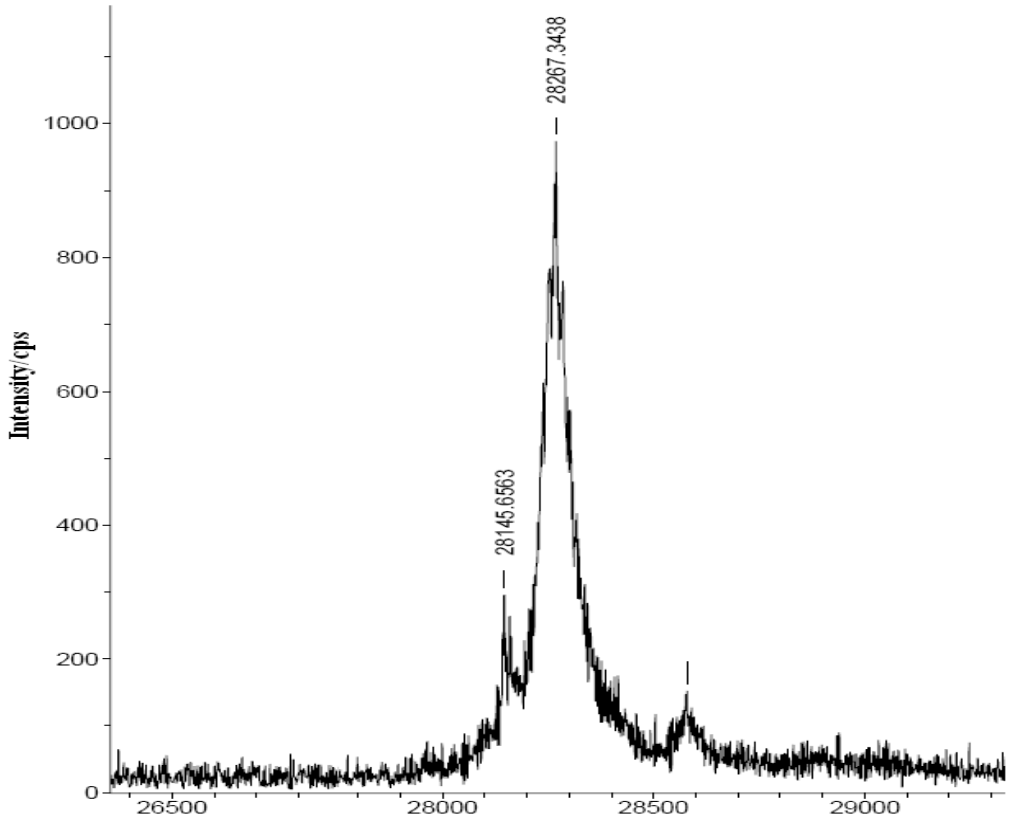

Figure S3. ESI-MS analysis of GFPdopa. ESI-MS profile showed the match with calculated mass (28274.7) with found mass (28267.3) for the incorporation of L-DOPA and minor side peak matched the GFP mass (28145.7).

Bioconjugation reaction of genetic code engineering protein with chitosan

A concentrated chitosan solution was prepared by adding 1.6 g chitosan to 100 ml of cold 0.25 N HCl with vigorous stirring and kept at 4°C overnight. After stirring overnight, the undissolved materials were removed by filtration. This chitosan solution was diluted and the pH was slowly raised to 5.8–6.0 by adding 1M NaOH. This pH was selected to balance chitosan's solubility and maintain the protein stability. Solutions (pH 6.0) were prepared with GFP and GFPdopa protein (30µg/mL) either in the absence (controls) or presence (samples) of sodium periodate (1mM) and mixed with chitosan (0.7% w/v). After five hours incubation at room temperature, conjugant's were precipitated by raising the pH with phosphate buffer (pH >7) and centrifuged to measure the fluorescence of the supernatant. In all the steps such as precipitation, washing, and resolubilization, the sample pH was adjusted to 6.0 and fluorescence was estimated by Jasco Fluorescence spectrophotometer. The pellet was washed several times with PBS buffer to remove physically bound protein and then resolubilized in aqueous acetic acid solution (0.5 v/v %) (**Figure S4).**

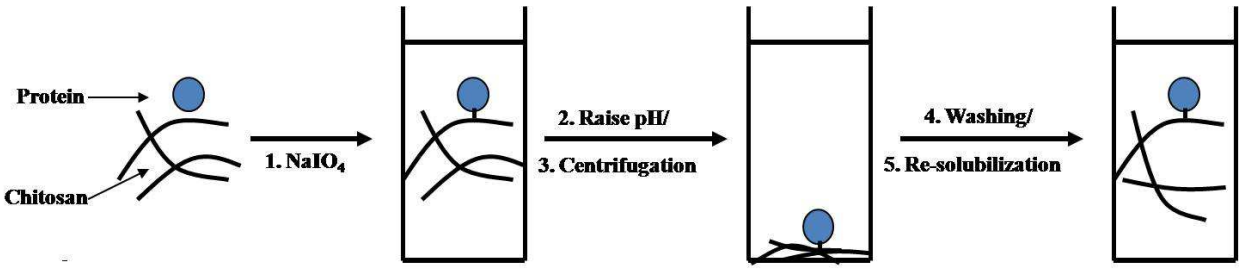

Figure S4. Schematic representation of the periodate mediated protein-polysaccharide conjugation

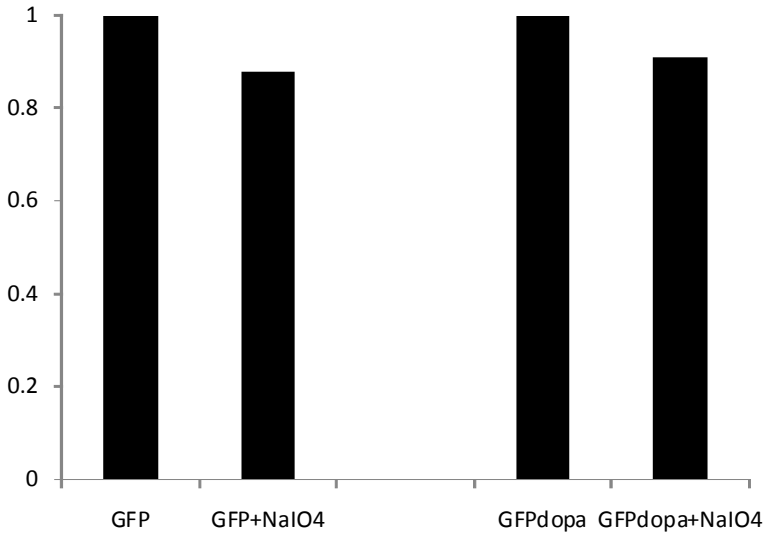

Figure S5. Effect of periodate on GFP and GFPdopa proteins (in the absence of chitosan)

Effect of pH on GFP and GFPdopa protein

The pH of the proteins was adjusted from 3 to 11, with MOPS buffer, in increments of 1 pH unit.[3] The fluorescence emission of each protein was recorded using Jasco Fluorescence spectrophotometer.

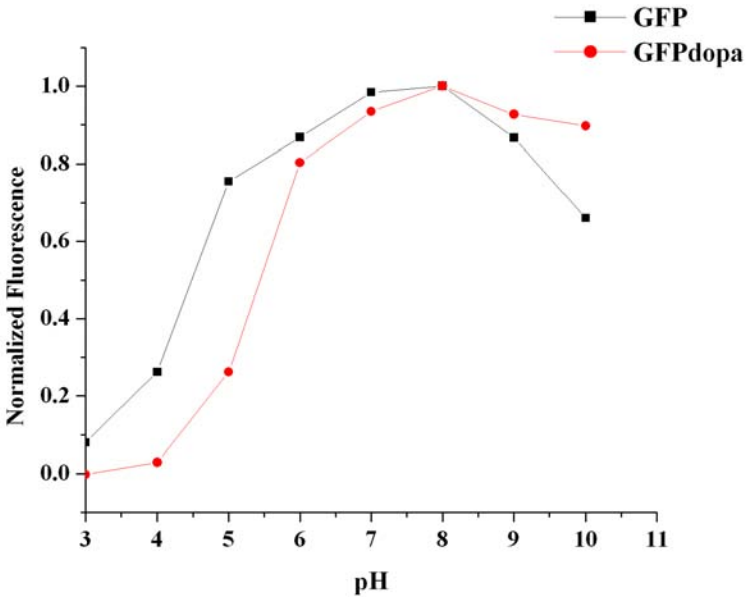

Figure S6. Effect of pH on GFP and GFPdopa proteins

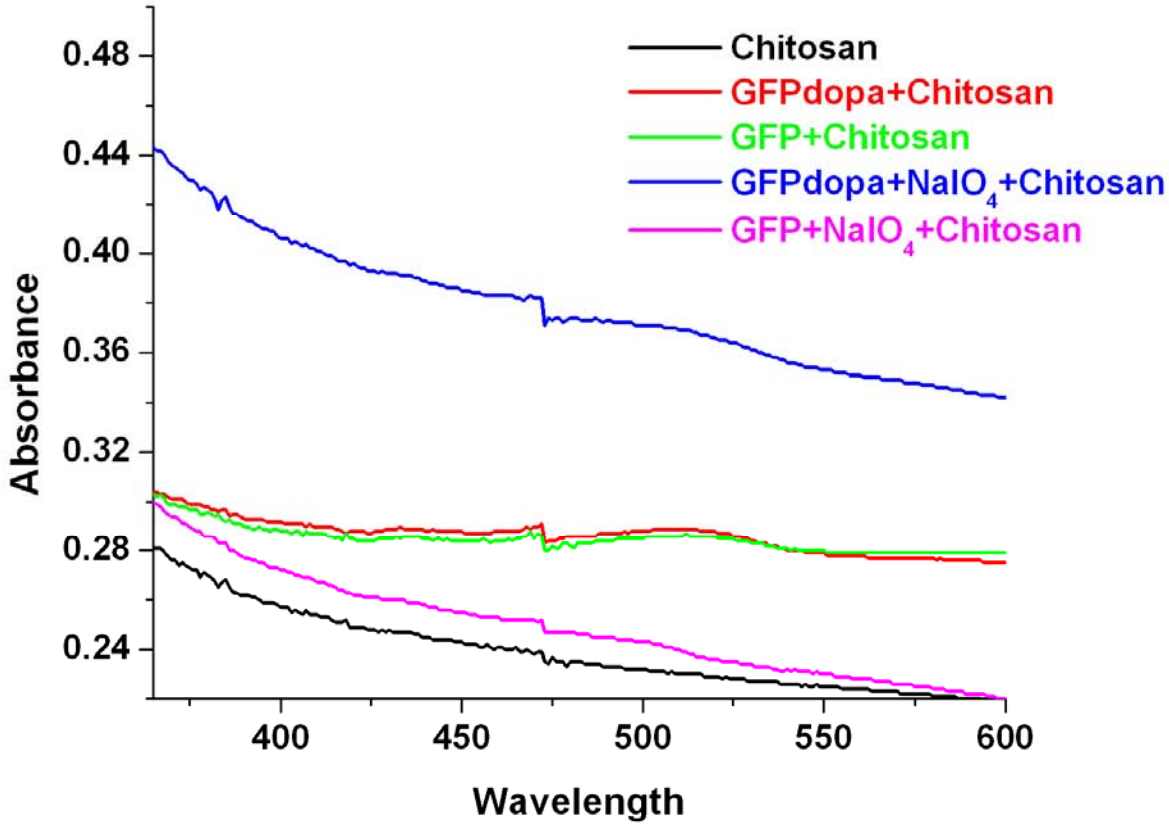
Preparation of chitosan film and GFPdopa conjugation

For chitosan film conjugation study, chitosan films were prepared by pouring 0.5% chitosan solution into a small Petri dish and then dried overnight at 45°C. Then these chitosan films were neutralized with NaOH for 30 min and washed several times with 0.01M PBS. Further, the chitosan films were then peeled from the Petri dish and a UV-Vis spectrum was measured[5]. The conjugation reactions were then performed by incubating the chitosan films with the combination of GFP (30 µg/ml) and GFPdopa (30 µg/ml) and $NaIO_4$ (1mM) solution for 1 h. The resulting films were rinsed several times with PBS and to obtain UV spectra the glass slides were placed in the spectrophotometer perpendicular to the light-path such that the light passed directly through the film. The difference between the UV-Vis spectrums provides the absorbance GFP and GFPdopa on chitosan films.



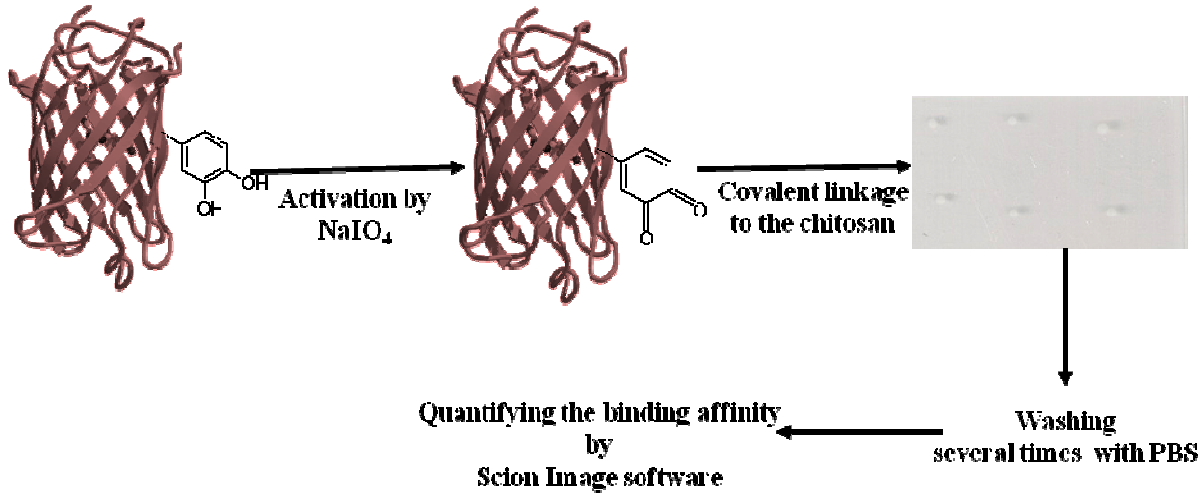


Figure S7. GFP and GFPdopa bioconjugation with chitosan film

Preparation of hydrogels and fluorescence microscopy analysis

Chitosan hydrogels were prepared by pouring 10 ml of 2% chitosan solution into a small Petri dish and then dish was immersed in a caustic solution (1 M NaOH). After gel formation, the gels were washed extensively with water and PBS buffer. GFP and GFPdopa proteins (2 ml at 40µg/ml) treated with 1 mM $NaIO_4$ were spread on the surface of the chitosan hydrogel. The solution was incubated at room temperature for 5 hrs to cross link with chitosan hydrogel. After cross linking, gels were thoroughly washed with PBS buffer to remove the unspecific binding of proteins. Images were obtained on a Zeiss Axiovert 200 fluorescence microscope with mercury vapour lamp illumination and FITC and Cy3 filter sets. Images were captured on a Hamamatsu ORCA-ER grey scale digital camera using simple PCI software. For colour panels in figure 2 separate grey scale images were taken with FITC and Cy3 filter sets with the auto exposure setting in simple PCI. The grey scale images were combined and false colored using Corel Draw. The images were taken with a gain of 255 and an exposure of 0.0125 seconds.

Fabrication of well type chitosan

Well-type chitosan arrays were fabricated by dropping 0.5% chitosan solution into a glass slides and then dried overnight at 45°C. The chitosan films were neutralized with NaOH for 30 min and washing several times with 0.01M PBS. Further, conjugation reactions were then performed by incubating the chitosan spots with the combination of GFP (30 µg/ml) and GFPdopa (30 µg/ml) with $NaIO_4$ (1mM) solution for 1 h. The resulting films were rinsed several times with PBS and Scanned. The images were imported as TIFF file and densitometry analysis was carried out using Scion Image package (Scion Corp., Frederick, MD).

Supporting Information

ABSTRACT: Initial cellular uptake of cell penetrating peptide (CPP) linked macromolecules is usually endosomal, with passage from endosome to cytosol a major limitation to efficient delivery. To gain a better understanding of the passage of the CPP-linked proteins, we studied the uptake and localization of CPP-linked proteins that contained two different forms of fluorescent markers, GFP protein and chemically conjugated tetramethylrhodamine, in living cells. Rhodamine labeled TAT-GFP was internalized in multiple cell lines including HEK293, N18-RE-105, hippocampal slices, and human neural progenitor cells and showed predominantly endosomal localization of both fluorescent markers. Cytosolic localization of some rhodamine label was detected to suggest that some of the GFP label had exited from the endosome. However, quantification of the distribution of the rhodamine and GFP label indicated that the protein location was primarily endosomal and that the distribution of TAT-GFP was not significantly different than that of an exclusively endosomal localized exogenous protein (tetanus toxin fragment C - TTC). As a result, photochemical internalization (PCI) was evaluated and caused a significant quantitative redistribution of cellular fluorescence of rhodamine and GFP labels to demonstrate increased cytosolic delivery of GFP. While rhodamine-labeled TAT-GFP showed cytosolic delivery with exposure to specific wavelengths of fluorescent illumination, a similarly labeled GFP fusion protein containing the membrane binding domain of TTC did not mediate PCI in N18-RE-105 cells.

INTRODUCTION

Internalization and delivery of cargo proteins from the extracellular fluid across biological membranes and into the cytosol can be accomplished by attaching cationic peptides to the macromolecule of interest. Such peptides are the functional regions responsible for the ability of certain natural and recombinant proteins to enter into a cell and have been termed cell-penetrating peptides (CPPs) or protein transduction domains (PTDs). When fused with a number of potential therapeutics for delivery into the cell, these peptides greatly increase the traffic of desired therapeutics into cytosolic targets within the cell. Protein transduction domains have been used to translocate small cargo such as peptides and oligonucleotides, as well as larger cargo such as DNA complexes and full-length proteins. Although these peptides have been extensively studied and reviewed, some aspects of their efficiency are not yet fully resolved [1,2] (for other reviews, see refs 3−7). Among the different cell penetrating peptides, perhaps the most well-studied include a small domain from HIV transactivating transcriptional activator, TAT(47−57). Other well-studied natural and synthetic CPPs include penetratin from *Drosophila* Antennapedia, transportan (a chimeric peptide), VP22 from Herpes simplex virus type 1, and polyarginine.[8] The efficiency of uptake and the ability to translocate across a cell membrane varies with several factors including cargo, cell type, and type of cell penetrating peptide.[9,10]

Although initial studies suggested that these peptides and their cargo passed directly through the plasma membrane into the cytosol, most studies have shown delivery by protein transduction with a predominant endosomal vesicle localization. While the most widely accepted mechanism for cytosolic entry is the clathrin- and receptor-independent, lipid raft-dependent macropinocytosis,[9,11] many previous studies relied on post-mortem imaging of fixed cells.[12] Later studies including imaging of living cells showed that methanol[13] or paraformaldehyde[14] fixation changed the distribution of CPP-cargo proteins suggesting that cytosolic labeling in earlier studies may have been artifactual. Also, while initial work in the cell penetrating peptide field showed highly efficient delivery of peptides,[15] subsequent work utilizing the fusion of cell penetrating peptides to larger cargo proteins decreased the efficiency in the delivery and cytosolic

distribution of CPP-cargo proteins.[16] Finally, much of the initial work with protein transduction cargo was done with denatured protein.[2] Later studies showed that natured protein was able to enter cells with only a slightly decreased transduction efficiency and that total denaturation was not necessary to translocate a cargo protein.[17] The use of fluorescent cargo proteins such as GFP, however, introduced the possibility of artifactual underestimation of cytosolic translocation, since denaturation of such proteins leads to elimination of their native fluorescence. While there have been many studies of mechanisms, the efficiency of cytosolic transfer of the cell penetrating peptides and protein cargoes in many studies has been far from optimal. Tracking the transduction of full length protein delivery by means of two fluorophores, one of which would fluoresce despite denaturation, would allow for the clarification of these issues of efficiency of translocation of CPP-linked cargo proteins.

It is generally accepted that the exit of protein from the endosome into the free cytosol is the primary limitation for protein transduction-based delivery using TAT and other similar peptides. Photochemical internalization (PCI) is one of several strategies to facilitate the cytosolic release of cargo molecules trapped within endocytic vesicle membranes [18−20]. PCI uses a photosensitizer, often based on porphyrin structure, which localizes to endosomal membranes and, when exposed to light, activates the release of cargo contained in the vesicle by forming reactive oxygen species which rupture the membrane.[21,22] Photochemical internalization, an offshoot of photodynamic therapy, has been primarily used for delivery of plasmid genes,[23−25] cytotoxic proteins,[26−29] and adenovirus.[30,31] PCI has also recently been used to deliver siRNA[32] and CPP-small nucleic acid combinations.[33]

The current study attempts to clarify some of the issues regarding transduction of CPP-linked cargo protein, particularly the efficiency of movement from the endosomal compartment into the cellular cytosol, using cargo that contains both a fluorescent protein and a small nonprotein fluorophore. To estimate efficiency of cytosolic transfer from endosomes, the cellular distribution of the test cargo GFP protein with TAT as a CPP was quantified and compared to the distribution of a similarly labeled protein, the binding domain of the heavy chain of tetanus toxin, fragment C (TTC), known to undergo only endosomal internalization without membrane translocation.[34] The distribution of fluorescent proteins after PCI was also evaluated, as this process appears to alter distribution of endosomal localized exogenous proteins.

EXPERIMENTAL PROCEDURES

Plasmid Construction and Expression of Recombinant Proteins. In order to create and express the recombinant proteins TAT-GFP and TTC-GFP, the following strategies were employed. The oligonucleotides for the TAT(47−57) sequence (YGRKKRRQRRR) were synthesized and purified by the Biopolymer Laboratory of the University of Maryland at Baltimore. The annealed oligos were cloned into the *Bam*HI-*Eco*RI sites of the pGEX6P-3 (GE Healthcare, Piscataway, NJ) expression vector. Primers were used to amplify EGFP from the pEGFP-1 vector (Clontech, Palo Alto, CA) and cloned into the *Eco*RI-*Sal*I site of the pGEX6P-3 TAT construct. cDNA for TTC (tetanus toxin fragment C) was a gift of Dr. Neil Fairweather of Imperial College, London, U.K. EGFP DNA fragments were amplified by PCR for cloning into the pGEX4T-3 bacterial expression vector. The TTC PCR primers were designed with a *Bam*HI site and a *Bgl*II-NotI site. The EGFP primers were designed with a *Bgl*II site and a NotI site. The fragments were then cloned into the respective sites. All constructs were sequenced to determine that fragments were in frame and there were no mutations generated.

The bacterial clones containing the plasmids were cultured at 37 °C to an OD600 of 0.6. The cultures were moved to 25 °C and induced with a final concentration of 1 mM IPTG (isopropyl-β-D-thiogalactopyranoside, Invitrogen) and incubated overnight. After incubation, the cultures were centrifuged and the cell pellets resuspended in 1× PBS (phosphate buffered saline) with 10 mg/mL lysozyme (Sigma), sonicated, and centrifuged. The GST-linked recombinant proteins were purified from the soluble fraction using glutathione sepharose, dialyzed against 1× PBS, cleaved overnight with PreScission Protease for TAT-GFP and thrombin for TTC-GFP, and the desired proteins purified away from GST using glutathione sepharose (Figure 1).

Preparation of Fluorescent Labeled Proteins. Rhodamine-labeled fusion proteins (Rh-TAT-GFP and Rh-TTC-GFP) were generated using a FluoReporter Tetramethylrhodamine Protein Labeling kit according to the manufacturer's protocol (Molecular Probes) followed by dialysis in 1× PBS at 5 times molar ratios of rhodamine to protein. Across multiple labelings, an average of 3 rhodamine groups were attached per molecule of TAT-GFP at a labeling efficiency of 60% and 3.7 rhodamine groups per molecule of TTC-GFP at a labeling efficiency of 74% as measured by a standard fluorescence curve in a Perkin-Elmer VICTOR.

Cell Culture and Exposure to Test Proteins. *HEK 293* cells were plated in 2 well Lab-Tek Chamber Coverglass slides at 40 000 cells/mL in MEM containing 10% fetal bovine serum, 2 mM L-glutamine, and pen/strep (Invitrogen, Carlsbad, CA) and allowed to expand for 3 days before treatment. N18-RE-105 cells were plated in chamber slides at 20 000 cells/mL in DMEM containing 10% fetal bovine serum, HAT supplement, and pen/strep (Invitrogen, Carlsbad, CA) and allowed to grow for 3 days before treatment. Hippocampi of postnatal day 7 rats were dissected free and 300-μm-thick slices cut using a McIlwain tissue chopper under aseptic conditions. Slices were placed on filter inserts (Millipore) in six-well dishes in maintenance medium (Invitrogen, Carlsbad, CA; 33.3% basal medium Eagle, 33.3% Hank's buffered saline solution, 33.3% horse serum, 25 mM D-glucose, 2 mM L-glutamine) and maintained for 7 days

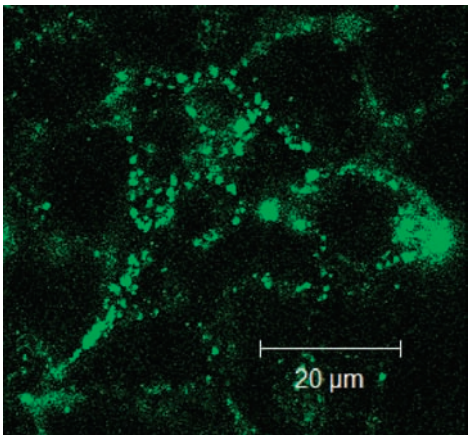

Figure 2. Confocal fluorescent microscopy of HEK 293 culture of TAT-GFP transduced cells. HEK 293 cells were incubated with 75 μg of TAT-GFP for 24 h, washed three times in media, and imaged live using a 40× objective.

before treatment. Human neural progenitor cells (hNPCs, Lonza) were plated in chamber slides at a density of 40 000 cells/well using a combination of hNPC starting medium [35] and 5% horse sera in MEM and allowed to expand for 7 days before treatment. All cultures were maintained at 37 °C in a 5% CO_2 humidified incubator.

Cells were given a complete media change before being treated with test proteins in reduced 4% sera media (HEK 293 and N18 RE-105), maintenance medium (slices), or starting medium (hNPCs) (2.5 μM TAT-GFP, 1.0 μM TTC-GFP). After 0.5, 2, 24, or 48 h, cells were washed 3 times with 1 mL media and immediately imaged.

Confocal Microscopy. Fluorescence was detected on a Zeiss LSM 510 laser scanning confocal microscope. Images were taken with a Zeiss Plan-apochromat 63×/1.4 oil DIC objective. Fluorophores were excited with an argon laser at 488 nm for GFP and a HeNe laser at 543 nm for rhodamine. Emission was filtered through a 505−530 BP filter and a 585 LP filter, respectively. Channels were collected in multitrack scan mode to prevent crosstalk between fluorophores. Pinholes were set to equate optical slice thicknesses. Fluorescence intensity histograms, pixel quantitation, and mean fluorescence intensities were analyzed with LSM (Carl Zeiss, Inc.) and *Slidebook 4.2* (Intelligent Imaging Innovations) software. Quantitative comparison of the distribution of fluorescence intensity was utilized as a reflection of cytosolic (diffuse, uniform) versus vesicular (punctate, highly nonuniform) distribution of the fluorescent protein as derived from previous studies.[36−38] Photochemical internalization was performed under the conventional fluorescence mode by exposing cultures continuously to the fluorescent light source through a TRITC filter for 0.5 to 5 min, followed immediately by imaging.

RESULTS

Cellular Distribution of TAT-Linked Proteins. Initial experiments with recombinant TAT-GFP demonstrated that at all time points of incubation evaluated (0.5, 2, 24, 48 h) the vast majority of labels in HEK 293 cells had a punctate cellular distribution consistent with an endocytic vesicle distribution (Figure 2). In order to determine if TAT-GFP had escaped into the cytosol, similar studies were performed with rhodamine labeled TAT-GFP (Figure 3). GFP fluorescence was excited at 488 nm, while rhodamine was excited at 543 nm. The distribution of pattern GFP fluorescence from Rh-TAT-GFP was similar to that of TAT-GFP to indicate that the localization of this protein was not altered by the rhodamine labeling process (Figure 3A). Comparison of cellular cytosolic GFP fluorescence to baseline background cell-free levels did not reveal a high GFP cytosolic signal. However, the rhodamine fluorescence in Figure 3B appeared to have nonzero levels of cytosolic fluorescence between the brightly labeled endosomic vesicles as compared to cell-free background areas. The amount of rhodamine fluorescence is shown for a larger selection of cells at lower magnification in Figure 3D. In order to evaluate the amount of rhodamine fluorescence, the average rhodamine fluorescence levels were quantified in the cytosolic regions excluding endosomes and compared to background fluorescence levels as shown in Figure 3E. These findings indicate that there was a quantitative increase in rhodamine labeling in the cytosol for the Rh-TAT-GFP protein to suggest that some TAT-GFP may have localized to the cytosol.

Delivery of an Endosomal Localized Control Labeled Protein. In order to confirm that cytosolic rhodamine fluorescence after Rh-TAT-GFP transduction did not represent dissociation of the rhodamine moiety from the fusion protein, similar studies were performed using a rhodamine-labeled protein with known endosomal uptake but without membrane translocation capacity.[39] A rhodamine labeled form of the binding domain of tetanus toxin (TTC) fused to GFP was created. This GFP fusion protein was expressed in a similar manner to the TAT-GFP protein. This protein was also rhodamine labeled at equal per molecule ratios of protein to fluorophore. Analysis of the cellular distribution of rhodamine labeled TTC-GFP served as an endosomally localized control. Shown in Figure 4 is an image of Rh-TTC-GFP transduction in N18-RE-105 neuroblastoma cells. These cells were used because they express surface ganglioside compositions similar to normal brain tissue and are well-known to bind tetanus toxin.[40,41] Rh-TAT-GFP also transduced N18-RE-105 cells in similar distribution patterns seen in HEK 293 cells (not shown). As shown in Figure 4A, the green GFP labeling appears less broadly distributed as compared to Figure 3A and is limited more to punctate structures consistent with endosomes. The red rhodamine fluorescence chemically conjugated to the TTC-GFP molecules is seen in Figure 4B and is also limited more to endosomal vesicular labeling. The Rh-TTC-GFP protein fluorescence was also examined at lower magnification as shown in Figure 4D. The red fluorescence also appears to be limited to endosomes, consistent with the restricted distribution of Figure 4A and B and significantly less distributed than the rhodamine fluorescence of Figure 3D. Unlike Rh-TTC-GFP, Rh-TAT-GFP transduced N18-RE-105 cells with the similar wide distribution pattern seen in HEK 293 cells (data not shown). Average rhodamine fluorescence levels were quantified in the cytosolic regions excluding endosomes and compared to background fluorescence levels shown in Figure 4E. The cytosolic rhodamine fluorescence levels for Rh-TTC-GFP were not significantly above background.

Quantification of Distribution of Cellular Fluorescence after Incubation with Fluorescent Proteins. The frequency distribution of pixel fluorescent intensity has been used to quantify the degree to which a fluorophore has endosome (nonuniform) versus cytosolic (uniform) distribution.[36−38,42]

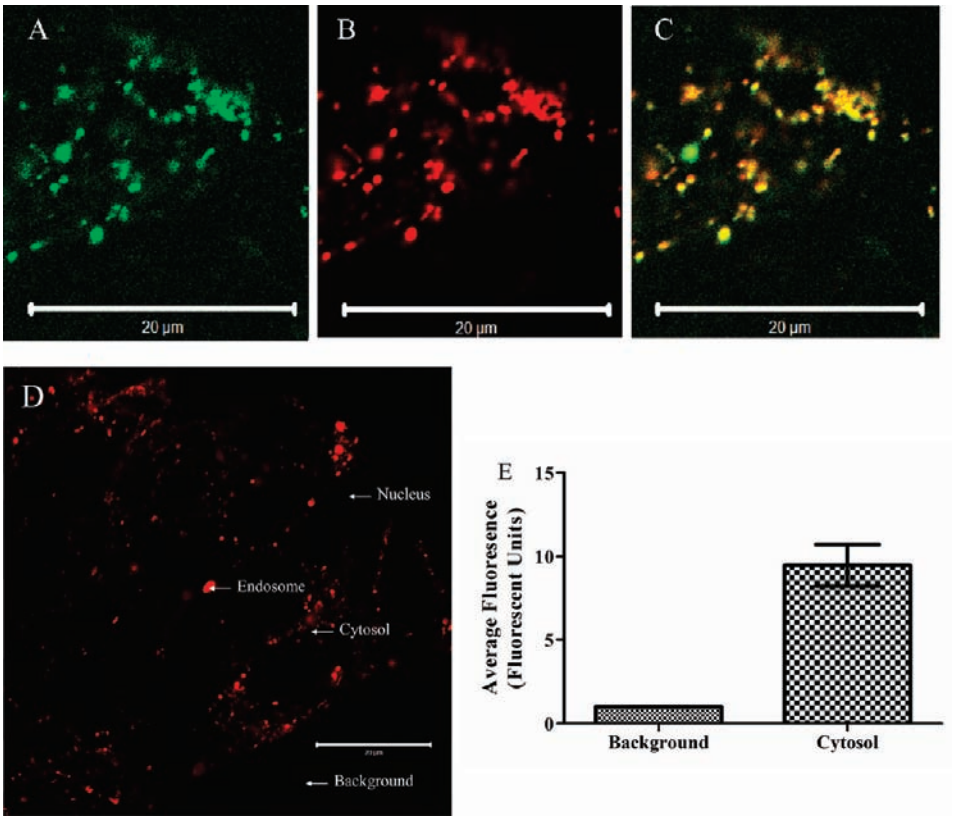

Figure 3. Dual-labeled rhodamine-TAT-GFP in HEK 293 cells. Cells were incubated with 75 μg of Rh-TAT-GFP for 24 h, washed three times in media, and imaged live using a 63× objective: (A) GFP, (B) rhodamine, (C) merge, (D) wide rhodamine field, and (E) average fluorescence units. Scale Bar 20 μm.

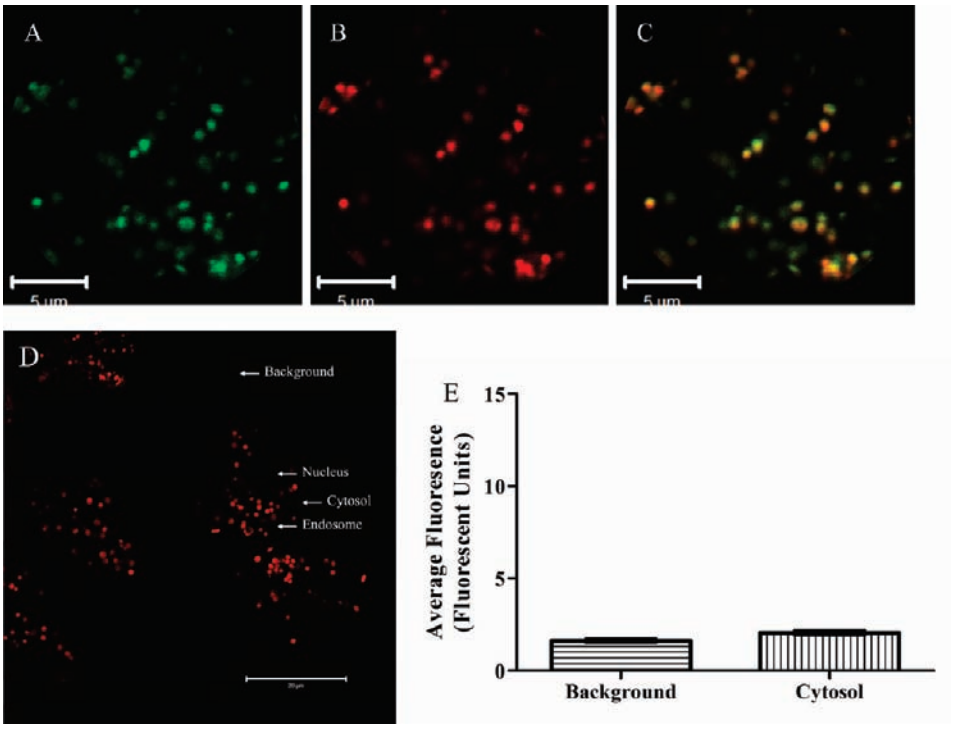

Figure 4. Rhodamine labeled TTC-GFP in N18-RE-105 Neuroblastoma cells. Both GFP (A) and rhodamine (B) fluorescence are localized exclusively to punctate structures consistent with the known endosomal localization of TTC linked proteins. Both moieties show completely overlapping distributions (C) with no detectable cytosolic rhodamine fluorescence demonstrating a stable linkage between the two chromophores without dissociation of the rhodamine moiety. (D) Wide rhodamine field. (E) Average fluorescence units. (A−C) Scale Bar 5 μm. (D) Scale Bar 20 μm.

dx.doi.org/10.1021/bc900445g |*Bioconjugate Chem.* 2011, 22, 556–566

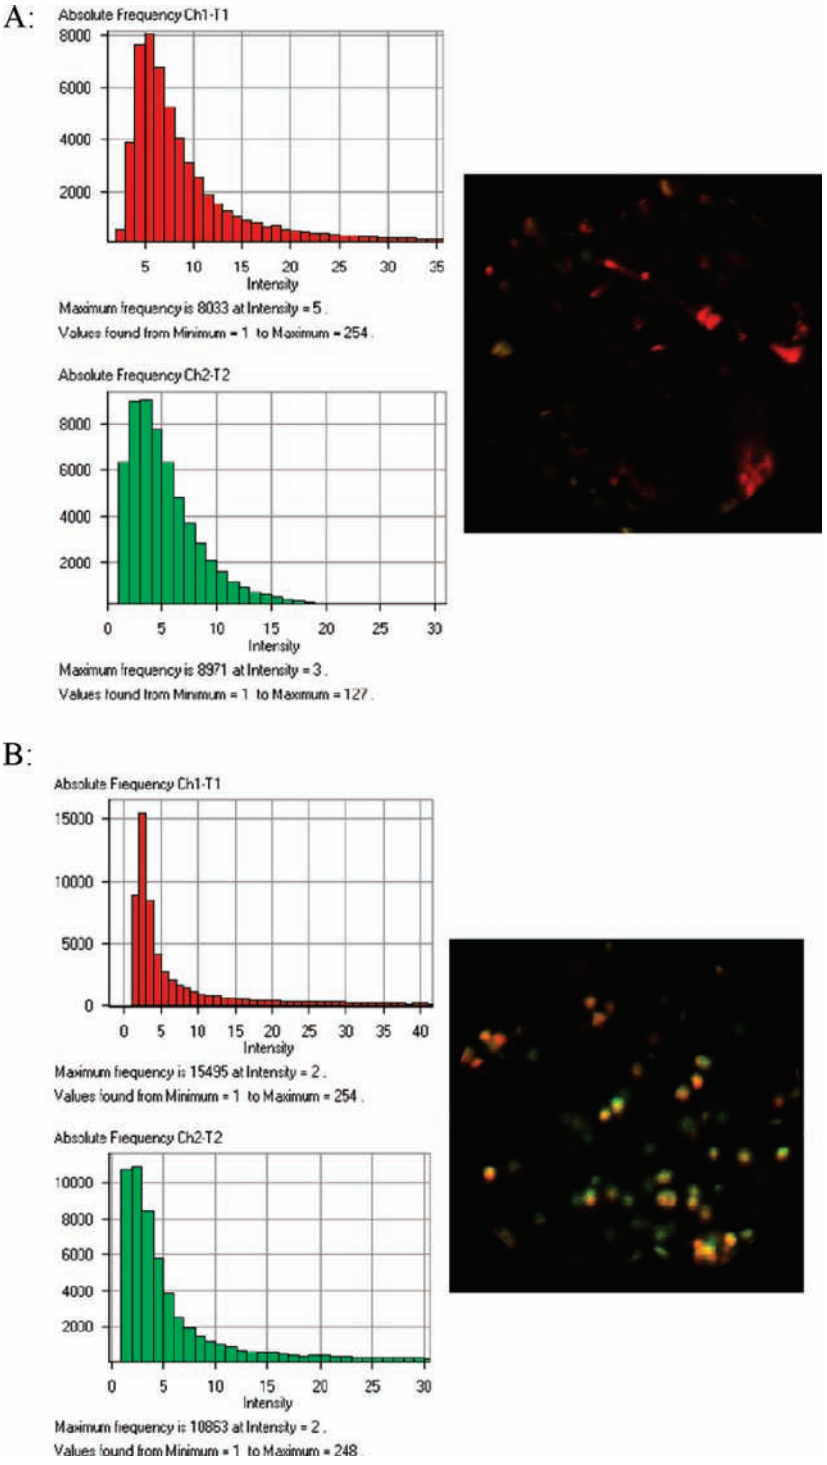

Figure 5. Rh-TAT-GFP (A) and Rh-TTC-GFP (B) taken with equal gain and comparable average fluorescence show similar frequency distributions of fluorescence. Distribution of fluorescence and uniformity from TAT-GFP is not quantitatively different than total endosomal labeled TTC-GFP, in spite of the qualitative cytosolic difference in red fluorescence between the two proteins. Images 20 μm across.

A narrow distribution of fluorescence frequency with a low average fluorescence is a sign of nonuniformity and punctate labeling. In such cases, fluorescent signal is localized primarily in small compartments and the majority of pixel intensities within the cytoplasm are zero or baseline. When little to no protein is distributed throughout the cytosol, the maximum number of the pixels is measured as zero or baseline fluorescence. A wide distribution of fluorescence frequency with a higher average fluorescence implies uniformity and an increased delivery of protein throughout the cytoplasm. Fluorescence intensities in Rh-TAT-GFP and Rh-TTC-GFP exposed cells were compared. Proteins were conjugated and cells were treated such that the total average fluorescence per cell was comparable between the two proteins. Shown in Figure 5 are the frequency distributions

dx.doi.org/10.1021/bc900445g |*Bioconjugate Chem.* 2011, 22, 556–566

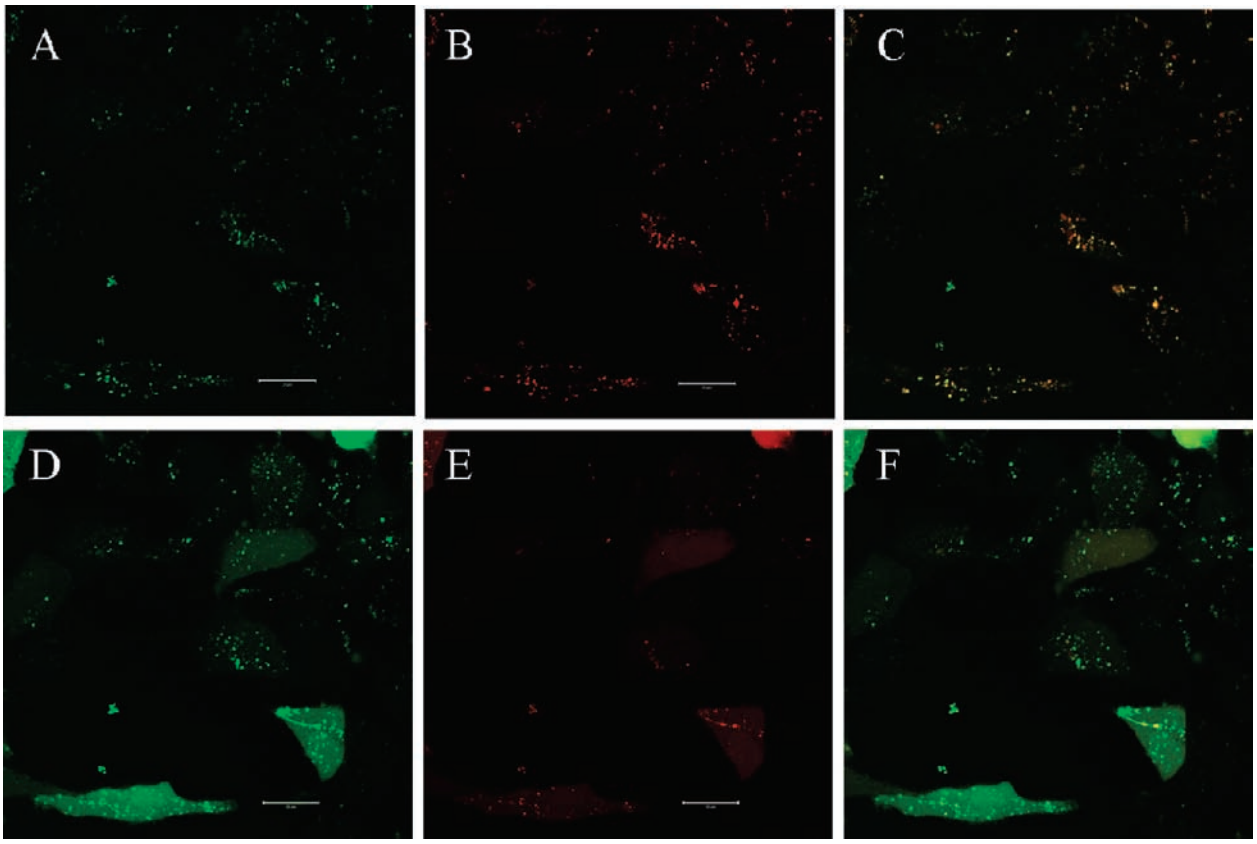

Figure 6. Protein transduction and photochemical internalization of rhodamine labeled TAT-GFP in HEK 293. (A−C): Preinternalization: (A) GFP, (B) rhodamine, (C) merge. (D−F): Post-photochemical internalization: (A) GFP, (B) rhodamine, (C) merge. Scale bar 20 μm.

of fluorescent intensity measurements per pixel in selected fields in Rh-TAT-GFP (A) and Rh-TTC-GFP (B) transduced cells. Both red (rhodamine) and green (GFP) distributions showed a maximum intensity frequency near baseline levels for both Rh-TAT-GFP and Rh-TTC-GFP. Analysis of Rh-TTC-GFP incubated control cells (Figure 5B) showed a predictable distribution with the majority of pixels measured as little to no intensity representing blank cytosol in between endosomes. Although there was a slight increase in the maximum frequency point from 2 units per pixel for rhodamine labeld TTC-GFP (Figure 5B) to 5 units per pixel for rhodamine labeled TAT-GFP (Figure 5A), the change in the fluorescent distribution was not deemed to be statistically significant. Taken together, the images and fluorescent distributions of Rh-TAT-GFP and Rh-TTC-GFP suggest a qualitative difference in distribution and localization of the TAT transduced cargo within the cytosol compared to the TTC transduced cargo, but little to no quantitative difference in overall uniformity. These results are in agreement with previous studies suggesting that endosomal escape of TAT proteins is a highly inefficient process.

Photochemical Internalization. In view of the very limited transfer of TAT labeled protein from endosomes, a method to enhance escape of fluorescent labeled proteins from endosomes was explored. Interestingly, when viewed under a fluorescent light source microscope rather than a confocal laser, the rhodamine labeled TAT-GFP underwent a redistribution of fluorescence within the cell. This phenomenon has been referred to as photochemical internalization (PCI) or photoacceleration of protein release. After one to two minutes of exposure to fluorescent light using the TRITC (red emission) filter, individual endosomes appeared to release the encapsulated cargo.

Several different cell lines were examined for both the ability to internalize and transduce TAT linked cargo protein as well as undergo photochemical internalization using the conjugated rhodamine as a photosensitizer. As seen earlier, HEK 293 cells were transduced with the TAT cell penetrating peptide. Shown in Figure 6A−C is another example of the distribution of TAT transduced GFP in this cell line before photochemical internalization. Figure 6A shows the fluorescence from the initial GFP, primarily localized in vesicles or endosomes. Figure 6B shows the red fluorescence from the conjugated rhodamine to the TAT-GFP protein. After exposure to a fluorescent light source, the HEK 293 cells underwent photochemical internalization and were imaged in Figure 6D−F. Visible are intact endosomes which have not yet undergone photochemical internalization as well as fluorescence which has filled the entire cell. In contrast to previous evaluation of cells transduced with Rh-TAT-GFP, extensive green (GFP) and red (rhodamine) florescence are visible after photochemical internalization throughout the cytosol. A time-lapse movie of photochemical internalization of Rh-TAT-GFP in HEK 293 cells was taken with images every 500 ms following the red rhodamine fluorescence (Supporting Information S.1). This video shows how cells do not undergo PCI immediately or at the same time. Also, it shows that individual endosomes, often those with the highest fluorescence in the cell, open to fill the cell with fluorescence. When a cell underwent PCI, the fluorescence was visible and expanding away from the bright point of fluorescence representing the endosome.

Not every endosome appeared to open, and rarely, multiple endosomes in one cell underwent PCI; at most, two endosomes have been observed opening per cell.

In vitro cultures of embryonic rat hippocampal slices were incubated with Rh-TAT-GFP and assessed for photochemical internalization. This model system not only contains neuronal and astrocytic cell types, but has substantial thickness (100−200 μm) compared to isolated cell cultures. Rh-TAT-GFP successfully transduced cells in this hippocampal slice culture system. Again, labeling was primarily localized in endosomes before photochemical internalization (Figure 7A−C). After exposure to fluorescent light with the TRITC filter, cells in the slice underwent PCI (Figure 7D−F).

The third cell system in which TAT transduction and photochemical internalization was tested was human neural progenitor cells (hNPCs) from Lonza. Rh-TAT-GFP successfully transduced cells in this system and labeling was again primarily localized to endosomes before photochemical internalization (Figure 8A−C). hNPCs transduced with Rh-TAT-GFP were also susceptible to PCI (Figure 8D−F) and underwent significant redistribution of fluorescence in the cells. Axon-like areas and cell projections previously unlabeled with endosomes or cytosolic rhodamine-TAT-GFP were brightly visible after PCI redistribution. Pre- and post-PCI cells were analyzed similar to the comparison between Rh-TAT-GFP and Rh-TTC-GFP distributions. Figure 8G,H shows fluorescent intensity frequencies of Rh-TAT-GFP transduction in hNPCs pre-PCI. This distribution was similar to that seen in Figure 5A with low maximum frequency values. However, after undergoing photochemical internalization, the frequency distributions of fluorescent intensities shift significantly with the maximum well above the baseline intensity (Figure 8I,J). Indeed, the red rhodamine fluorescence maximum shifts 5-fold from 5 in Figure 8G to 26 in Figure 8I. These findings show that a majority of pixels in a photochemically internalized cell are filled with greater fluorescence and protein than those in a nonphotochemically internalized cell. As expected, the sum of the fluorescence intensities for rhodamine is roughly equivalent pre- and post-PCI. The green GFP fluorescence distribution undergoes a similar shift of maximum fluorescence between Figure 8H and J; however, the sum of total cell fluorescence intensities for GFP increased 1.5-fold after PCI.

To investigate the possible mechanism underlying PCI and assess the importance of the TAT domain on this process, the exposure of Rh-TAT-GFP was compared to our exclusively endosomally controlled Rh-TTC-GFP treated cells. Figure 9A−C shows an example of an HEK 293 cell which had undergone PCI from exposure to the TRITC filter for 0.5 min. Fluorescence filled the entire cell profile, more resembling a DNA transfected cell rather than a protein transduced cell. However, the majority of the visible endosomes had not released their encapsulated proteins. Similar results were obtained with the N18-RE105 cells (data not shown). This phenomenon could not be reproduced with the FITC (green emission) filter. Furthermore, no photochemical internalization was observed when cells treated with Rh-TTC-GFP were exposed to a fluorescent light source with either TRITC or FITC filter. Figure 9D−F shows an image of an N18-RE105 cell incubated with Rh-TTC-GFP after exposure to the fluorescent light source for 5 min with no detectable cytosolic GFP or rhodamine. After 10 min of fluorescence exposure, Rh-TTC-GFP-incubated cells still did not show any signs of undergoing photochemical internalization, in spite of an intensity of fluorescence exposure sufficient to cause photobleaching.

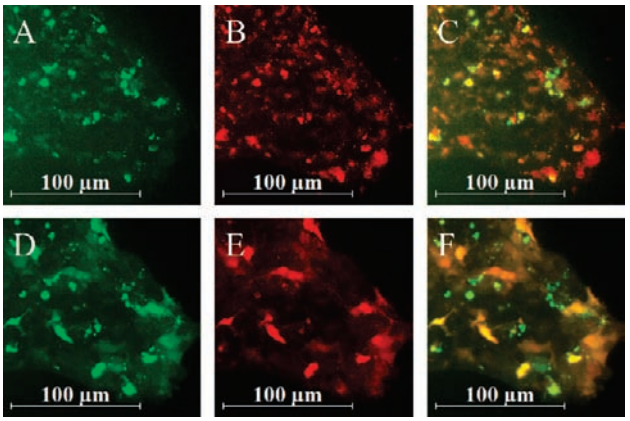

Figure 7. Protein transduction and photochemical internalization of Rh-TAT-GFP in hippocampal slices. (A−C) Preinternalization: (A) GFP, (B) rhodamine, (C) merge. (D−F) Post-photochemical internalization: (A) GFP, (B) rhodamine, (C) merge.

DISCUSSION

Protein transduction with cell penetrating peptides has been problematic due to the low efficiency of transductions. Some studies utilizing cargo proteins could not reproduce the cytosolic transfer seen with CPPs without a cargo protein,[16] and movement of target proteins across cell membranes was felt to be a postfixation artifact in other studies.[13,14] However, many studies of CPP-linked cargo proteins have demonstrated a biologic effect on a cytosolic or nuclear target, providing strong evidence of endosomal escape. In this study, the localization of a fusion protein containing both a widely used cell penetrating peptide, TAT from HIV−I, and a widely used labeled cargo protein (GFP) was imaged using live cell microscopy. This method eliminates the possibility of fixation-related artifactual change in cellular distribution of fluorescence. In order to control for possible artifactual underestimation of cargo protein translocation due to GFP denaturation, the GFP cargo protein was labeled with a small organic fluorescent dye—rhodamine.

There was a small change in the rhodamine fluorescence for cells transduced with Rh-TAT-GFP as compared to the endosomally localized control protein Rh-TTC-GFP. It is possible that the rhodamine could have been released from the TAT penetrating peptide and diffused into the cytoplasm. However, this same diffusion would have also been expected for the TTC peptide, and that was not evident even though the TTC peptide is larger than TAT. Taken together, the images and fluorescent distributions of Rh-TAT-GFP and Rh-TTC-GFP suggest that endosomal escape of TAT-linked proteins may occur to a slight degree. Nonetheless, this result confirms previous studies that the great majority of Rh-TAT-GFP remains trapped within endosomes.

The findings of the current study are consistent with previous studies where cell penetrating peptides could enhance the physiological effect of a cargo protein even without morphologic evidence of cytosolic transfer. Highly potent cargo proteins such as enzymes or transcription factors could easily have biologic activity at cytosolic levels below the threshold of fluorescence detection. In general, part of the misunderstanding of protein transduction stems from studies showing either negative

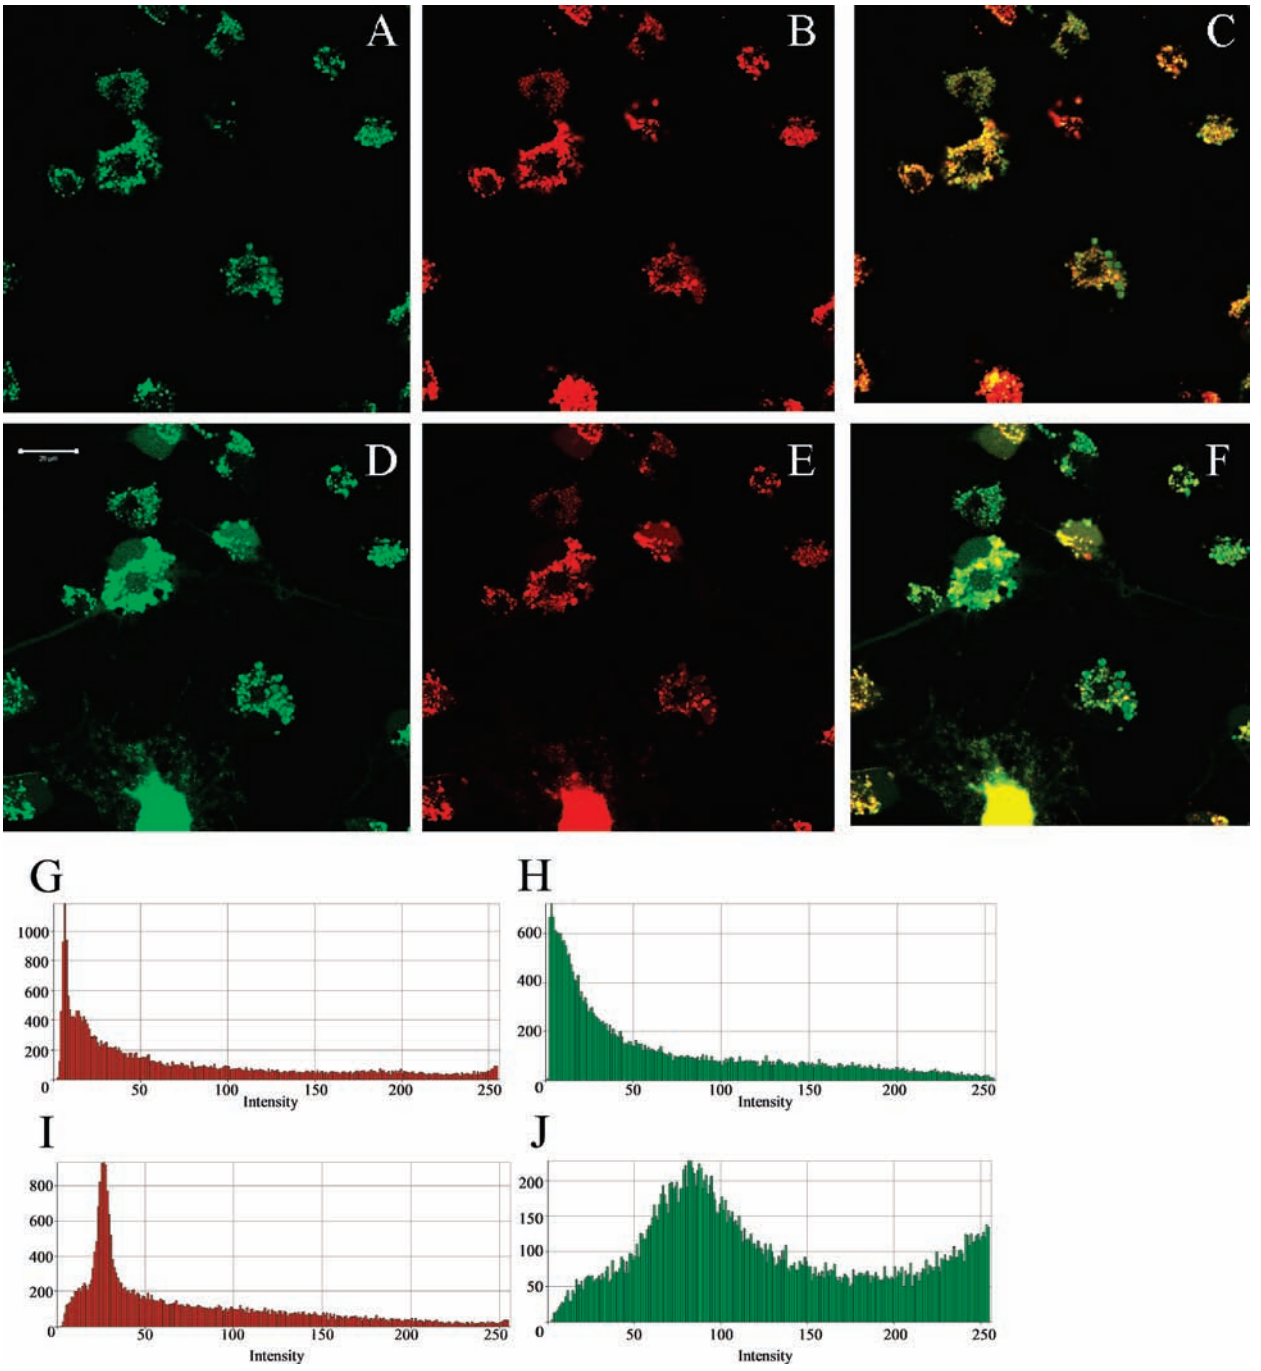

Figure 8. Protein transduction and photochemical internalization of Rh-TAT-GFP in human neural progenitor cells (Lonza) imaged with equal gain and comparable average fluorescence. (A−C) Preinternalization: (A) GFP, (B) rhodamine, (C) merge. (D−F) Postphotochemical internalization: (D) GFP, (E) rhodamine, (F) merge. (G−J) Fluorescence distributions showed change in intensity frequency maximum upon photochemical internalization. Total green fluorescence increased while total red total fluorescence was constant. (G) Rhodamine Pre-PCI; (H) GFP Pre-PCI; (I) Rhodamine Post-PCI; (J) GFP Post-PCI. Scale Bar 20 μm.

morphologic or positive physiological results, making estimation of efficiency of cytosolic transfer difficult. For example, TAT-Zfx[43] and TAT-HOXB4[44] showed an effect on hematopoetic stem cell expansion, where positively TAT-Zfx transduced cells were identified using FACS, which does not distinguish between intracellular protein localized in endosomal or cytosolic compartments. The study of TAT-HOXB4 assessed total cellular protein also without further subcellular localization. Constitutively active heat shock transcriptional factor 1 expressed as HSF1(+)-TAT was shown to upregulate HSP70 expression.[45] Total cellular HSF1(+)-TAT was assessed with immunoblot assay, while cytosolic HSF1(+)-TAT was detected with a highly sensitive luciferase reporter assay rather than localized with a direct morphologic method. In these examples, much of the total cellular protein likely remained trapped in endosomes, while a small proportion of protein released into the cytosol, although capable of a physiological effect, may well have been below the limits of detection with conventional fluorescent visualization.

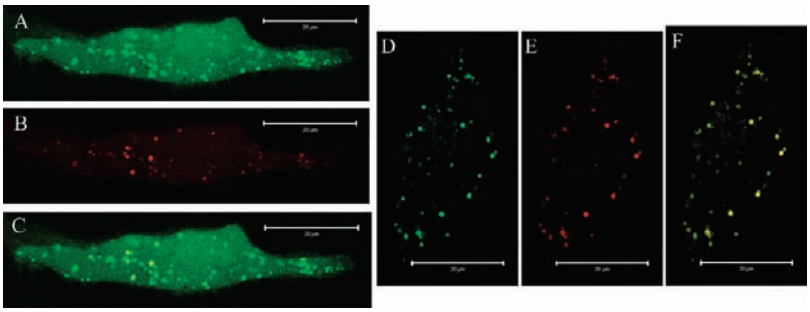

Figure 9. Photochemical internalization with chemically conjugated fluorophores occurs with TAT but not TTC linked cargo. (A−C) Cell treated with Rh-TAT-GFP after 0.5 min exposure to fluorescent light. (D−F) Cell treated with Rh-TTC-GFP after 5 min exposure to fluorescent light. Scale bar 20 μm.

Our study and previous studies indicate that, although cell penetrating peptide mediated translocation of a cargo protein into the cytosol appears to occur at least on a limited scale, a method that can potentially substantially improve the efficiency of endosomal escape of CPP-linked cargo proteins would be highly advantageous. Photochemical internalization (PCI) represents such a method. Both striking morphologic and quantifiable differences were observed in distribution of Rh-TAT-GFP after PCI.

In the current study, photochemical internalization was mediated with rhodamine as the photosensitizer directly conjugated to the cargo protein. This was accomplished using a simple procedure with inexpensive and readily available reagents in contrast to previous methods.[46−51] Direct conjugation of the photosensitizer to the cargo protein is preferable for both scientific and practical reasons. This method allowed observations regarding the relationship of the endosomal membrane to the photosensitizer. Previous studies have suggested the importance of the localization of the photosensitizer within the endocytic vesicles.[52] In this study, only a cargo protein possessing a CPP domain was able to mediate PCI, while a cargo protein similarly labeled but possessing a membrane binding domain (TTC-GFP) was not. The TAT cell-penetrating peptide appeared to allow for close integration of conjugated rhodamine into the membrane and subsequent PCI, while the surface receptor, neuronal ganglioside-bound TTC, did not. This study suggests a degree of intimacy between the photosensitizing agent and the endosomal membrane previously unappreciated and required to mediate this process.

These observations also suggest that PCI using a sensitizer directly linked to the cargo protein may cause oxidative injury in a very restricted location. Although few studies have assessed cell viability after PCI, it is a potentially toxic process requiring oxidative membrane damage.[53] Use of a photosensitizer linked only to the cargo protein may help limit oxidative injury to cargo-laden endosomes. In the current studies, there was no clearly evident effect on cell viability. However, studies need to be undertaken to more definitively track the effect of PCI on cell survival. The design of our experiments using actively proliferating cells for relatively short-term incubation periods is not suitable for assessment of the effect of PCI on cell viability. Future studies will be needed to optimize the conditions for PCI for both cargo delivery and cell viability before PCI can be considered an operational delivery method. The speed at which cells underwent photochemical internalization was affected by the intensity of the fluorescent light using neutral density filters, the amount of exposure time to fluorescent light, and the degree of labeling of the protein with rhodamine. Higher intensity light and the higher molar ratio of rhodamine to proteins decreased the exposure time necessary before PCI began to occur. This also suggests that the potential toxic effects of free radical generation of PCI may be further controllable. Thus, PCI could become a viable tool for use with proteins which have limited penetration into the cytosol with conventional CPP transduction and require relatively high cytosolic concentrations for their biologic effects.

ABSTRACT: E1/E3-deleted Adenovirus 5 (Ad.5) possesses a great potential in gene therapy because of its high efficacy in gene transfer and low toxicity. Studies have shown that Coxsackie-Adenovirus receptor (CAR) is the determinant factor for the targeting of Adenovirus vectors. To extend the natural targeting of Ad to low CAR expressing tumors, we covalently attached folic acid (FA) to E1/E3-deleted Ad.5 capsids. Near-infrared (NIR) fluorescent dye ICG-Der-02 was subsequently conjugated with FA-Ad particles for in vivo imaging. The cell experiments and acute toxicity studies demonstrated the low toxicity of FA-Ad-ICG02 to normal cell/tissues. The dynamic behavior and targeting ability of FA-Ad-ICG02 to different tumors were investigated by NIR fluorescence imaging. In vitro and in vivo studies demonstrated its high targeting capability to CAR or FR positive tumors. The results support the potential of using ligand-modified Ad probe for tumor diagnosis and targeted therapy.

INTRODUCTION

Adenovirus (Ad) vectors have received extensive clinical evaluation and constitute a quarter of all gene therapy trials,[1] because of their relatively high efficacy in accomplishing gene transfer in vivo. As a gene carrier, Ad vectors do not insert their genome into the host chromosome. In particular, the gene depleted adenovirus lacks replication potential. Thus, it possesses low immunogenicity and low toxicity compared with other virus carriers.[2] In addition, Ad features high infection ability compared with other nonvirus particles,[3] which allows a more effective drug delivery to tumor cells overexpressing the Ad receptor.

With the recent heightened interest in materials science and molecular medicine, Ad vectors are now finding new applications as carriers and delivery system for macromolecules other than DNA.[4] Ad capsids are particularly amenable to modifications, allowing the use of Ad as a more functional vehicle for delivering imaging agents and drugs to target tissue. Researchers have successfully modified different sites on the Ad capsids with diverse reporter agents and drugs, such as magnetic resonance imaging contrast agents,[5,6] radiation sensitizers,[7] paramagnetic nanoparticles,[8] and antigenic peptides for vaccines.[9,10]

Serotype 5 adenovirus (Ad.5) is routinely used as a vector for gene transfer.[11] However, the targeted delivery and infectivity of Ad.5 is dependent on high expression of Coxsackie adenovirus receptor (CAR). Although the CAR receptor is usually over-expressed on tumor cells, many tumor types have low levels of this receptor,[12,13] thereby limiting therapeutic gene transduction in such tumors.[14] Furthermore, the inherent hepatic tropism of intravascularly administered Ad vectors hinder targeted delivery to alternative organs or disease sites.[15] In addition, immune responses to Ad vectors represent a major limitation to their use in vivo, particularly when repeated administration is required to maintain a long-term sustainable effect.[16] To overcome the above limitations, numerous strategies have been developed to modify Ad tropism and enhance its targeting ability to pathological sites. These surface engineering strategies often involve genetic modification of Ad capsids,[17,18] physical modification of adaptive molecules,[19] and chemical modification by covalent conjugation.[20,21] Increasingly, more targeting ligands are chemically modified to Ad capsids surface for targeted delivery. Such modifications could also have the added benefit of reducing the immune response, and thus to minimize the vector-related toxicity.

One of the fully characterized ligands for selective delivery of imaging or therapeutic agents to tumor cells is the vitamin folic acid (FA).[22,23] Uptake of FA into cells is mediated by the folic acid receptor (FR), and the binding of FA to FR initiates receptor-mediated endocytosis and internalization of FA.[24] Normally, the expression of FR on normal tissue and cells is low, whereas the demand for FA increases during cellular activation and proliferation in malignant tumors.[25] Indeed, FR expression is upregulated on a variety of human tumors, including cancers of the colon, kidney, liver, testis, brain, lung, and myelocytic blood cells.[26,27] Thus, FA has been studied as a promising targeting ligand for cancer detection, imaging, and treatment.[28] In our previous work, we demonstrated the targeting of FA-labeled compounds to different tumors with upregulated FR expression.[29,30] In this study, we covalently attached FA to the Ad capsid to enhance the tumor targeting ability of Ad particles for optical imaging.

Biomedical optics is a rapidly expanding imaging field with direct applications in cellular biology, pharmacology, and disease diagnosis.[31,32] In particular, near-infrared (NIR) fluorescence imaging possesses many advantages as a noninvasive technique for real-time in vivo monitoring of biological information in living subjects without the use of ionizing radiation.[33,34] The wavelength of NIR light ranges from 700 to 900 nm. This spectral window minimizes the high absorption of light by intrinsic chromophores such as hemoglobin and water, which allows light to penetrate in deeper tissue relative to visible light. To harness this transparent imaging window, many NIR fluorescent dyes have been developed and used for tumor detection in vitro and in vivo.[35] Among them, indocyanine green (ICG) is a widely used organic dye in optical imaging. This dye is approved for human use by the U.S. FDA. For this reason, many research groups have focused on the synthesis of ICG derivatives for in vivo imaging.[36−38] We have synthesized a variety of ICG derivatives and developed different types of NIR imaging systems for noninvasive in vivo imaging research. In this study, we used one of our hydrophilic ICG derivative (ICG-Der-02) to label FA-modified Ad (FA-Ad-ICG02) for NIR tumor imaging. We studied the dynamic behavior of the material in nude mice and demonstrated the tumor targeting capability of FA-Ad-ICG02 probe in mice bearing different tumor cell lines.

EXPERIMENTAL PROCEDURES

Materials and Apparatus. E1- and E3-deleted Ad particles were purchased from Sino Geno Max Co (Beijing, China). FA (MW 441.4), *N*,*N*′-Dicyclohexylcarbodiimide (DCC), *N*-hydroxysuccinimide (NHS), 3-(4,5-dimethylthialzol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), RPMI 1640, fetal bovine serum (FBS), penicillin, streptomycin, and trypsin-EDTA were purchased from commercial sources. ICG-Der-02 (MW 995) was prepared in our laboratory. All reagents used in this study were certified analytical reagent grade.

Spectral measurements were recorded on a UV−vis spectrophotometer (JH 754PC, Shanghai, China) was used to record the absorbance measurements and a PHS-25 pH meter was used to determine the pH values. Sephadex G-25 was used to purify the products and a microscope equipped with a mercury vapor lamp, appropriate excitation and emission filters, a camera, and ACT1/DXM1200F software were used for recording images.

An NIR imaging system was used for real-time fluorescence imaging of the probe's distribution in animal subjects. This in-house built imaging system has been reported previously.[29,30] Briefly, the NIR imaging system is composed of an excitation laser (λ = 765.9 nm, NL-FC-2.0−763 laser light), a highly sensitive NIR CCD camera (PIXIS 512B), and an 800 nm long pass filter for capturing fluorescence from the tissue. A second 808 nm laser was used as background light to obtain the profile of the animal.

Synthesis of Folic Acid-Ad-Near Infrared Fluorescence Probe (FA-Ad-ICG02). FA and ICG-Der-02 were conjugated to the surface lysines on Ad capsid to form FA-Ad-ICG02 conjugate. The complex FA-Ad-ICG02 was synthesized in four steps, as shown in Figure 1. First, FA was reacted with DCC/NHS (molar ratio of FA:DCC:NHS is 1:1.2:2) in anhydrous dimethyl sulfoxide (DMSO, 2.5 mL) and the mixture was stirred in the dark for 6 h at 50 °C. The residue was removed by filtration under reduced pressure, and the activated FA was extracted with anhydrous acetone. Second, 1 mg of ICG-Der-02 in 100 μL DMSO was activated with EDC and NHS (molar ratio of ICG-Der-02:EDC:NHS is 1:1.5:1.5) at room temperature in the dark for 3 h. Third, the activated FA was dissolved in 2 mL of Tris buffer (10 mM, pH 8.0) and the Ad vectors were adjusted to a concentration of 2×10^8 plaque-forming units (pfu/mL) in 1 mL (4.74×10^9 VP/mL). The two solutions were then mixed in the above buffer (molar ratio of FA:Ad is 10^5:1).[39,40] After 3 h at −4 °C, the reaction mixture was purified by filtration over a Sephadex G-25 column equilibrated with Tris buffer (10 mM, pH 8.0) to remove unconjugated Ad and FA fragments. Last, the purified mixture was added to the above activated ICG-Der-02 (molar ratio of FA-Ad:ICG-Der-02 is 1:10^5) in Tris buffer (10 mM, pH 8.0). After 3 h, the reaction mixture was purified by filtration over a Sephadex G-25 column equilibrated with Tris buffer (10 mM, pH 8.0) to remove unconjugated FA-Ad and ICG-Der-02 fragments. The resulting product was stored at −20 °C. A similar method described above was used to synthesize the control Ad-ICG02. To determine the approximate number of viral particles (VP) per mL, the equation below was used. Tris buffer (10 mM, pH 8.0) was used as a blank.[40]

$$\text{VP/mL} = A_{260} \times \text{dilution factor} \times 10^{12}$$

Characterization of Folic Acid-Ad-Near Infrared Fluorescence Probe (FA-Ad-ICG02). The synthesized FA-Ad-ICG02 was evaluated by spectroscopic measurements at 365 nm, 260 nm, and 780 nm, which are the absorption peaks of FA, Ad, and ICG-Der-02, respectively. The influence of Ad particles on the absorption peaks of FA, Ad, and ICG-Der-02 were investigated by comparing the absorption spectra of FA, Ad, FA-Ad, and FA-Ad-ICG02. The modified number of FA molecules to the primary amino groups of viral particles was calculated by subtracting the unreacted FA from the initial total FA. The unreacted FA was obtained by following the recovery method (n = 4). The regression equation of the standard curve was obtained by dissolving different amounts of pure FA in Tris buffer (10 mM, pH 8.0). Different initial FA ratios (10^0−10^7 pmol) in FA-Ad-ICG02 particles (molar ratio of FA:Ad:ICG-Der-02 is 10^0−10^7:1:10^5) were used to optimize incorporated FA numbers in the Ad particle formulation for in vivo imaging. The number of particles generating the brightest fluorescence in tumor tissue (Bel-7402) was used as the optimal FA bonding number. The number of Ad particles for different initial FA was fixed at 2×10^8 pfu/mL (4.74×10^9 VP/mL). Accordingly, the amount of ICG-Der-02 for different initial FA ratio was fixed at 1 mg. The labeled numbers of ICG-Der-02 molecules were evaluated by UV−vis absorption spectroscopic at 780 nm (Tris buffer, pH 8.0).

In addition, the successful conjugation of FA to Ad was further confirmed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE).

Characteristics of Size and Morphology. The size and morphology of Ad, Ad-ICG02, and FA-Ad-ICG02 were measured by Mastersizer 2000 Laser Particle Size Analyzer.

Cell Culture and in Vitro Study. The human cell lines A549 (lung cancer), Bel-7402 (hepatocellular carcinoma cells), U87MG (glioblastoma cancer), and HELF (human embryonic lung fibroblast cell line) were all purchased from ATCC. These cell lines have been used for cytotoxicity and in vitro targeting studies.[41−43] All the cell lines were cultured at 37 °C in a humidified atmosphere containing 5% CO_2 in DMEM and RPMI1640 medium supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 μg/mL streptomycin.

Assessments of CAR and FA Receptor Expression Level. The three tumor cell lines (A549, Bel-7402, U87MG) were used to evaluate receptor expression. The expression levels of CAR and FA receptors were assessed by reverse transcriptase PCR. Briefly, total RNA was extracted from freshly isolated A549, Bel-7402, and U87MG tumor cells using RNeasy Kit. RNA (3 μg) from each cell line was converted into cDNA with Superscript III reverse transcriptase. Subsequently, 1.0 μL cDNA was used for PCR amplification with CAR-specific primers: sense, 5′-AAAAAGCCAAAGGGGAAACTG-3′, and antisense, 5′-TGAGCGCTAGAGCAAGCAAAG-3′. The product length was 669 base pair (bp). The cDNA (1.0 μL) was used for PCR amplification using FOL-specific primers: sense, 5′-ACACCAGCCAGGAAGCCCATA-3′, and antisense, 5′-GAGCAGCCACAGCAGCATTAG-3′. The product length was 563 bp. The product (5 μL) was used for 2% agarose gel electrophoresis.

In Vitro Cytotoxicity of FA-Ad-ICG02. To evaluate the cytotoxicity of FA modified Ad and Ad itself, MTT assay was conducted on different cell lines (tumor cell A549, Bel-7402, U87MG; and nontumor cell lines HELF) by following standard protocols.[44] Cells were plated at a density of 2×10^3 cells/well in 96-well plates and subsequently infected for 24 h with Ad, Ad-ICG02, and FA-Ad-ICG02 at a wide range of multiplicity of infection (m.o.i.) from 0.01 to 1000 pfu/cell. Every moi was

tested in 6 wells. Five days after infection, each well was replaced and the cells were washed three times with Dulbecco's phosphate buffered saline (PBS, pH 7.0) before addition of 180 μL of fresh DMEM and 20 μL of MTT solution (5 mg/mL). After incubation for another 4 h, the medium containing MTT was carefully removed from each well and 150 μL of DMSO was added to dissolve the formed crystals. The optical density (OD) was measured at 595 nm with a multiwell plate reader. The cell viability was calculated by the following equation:

$$\text{viable cells } (\%) = (\text{OD}_{\text{treated}}/\text{OD}_{\text{control}}) \times 100\%$$

where $\text{OD}_{\text{treated}}$ was obtained in the presence of Ad, Ad-ICG02, and FA-Ad-ICG02; $\text{OD}_{\text{control}}$ was obtained from the incubation medium.

Cellular Uptaken of FA-Modified Ad in Tumor Cells. To investigate the tumor cell targeting of Ad vector and FA-modified Ad vector, the Ad and FA-Ad vectors were labeled with visible fluorescent dye Rhodamine B (RhB) for microscopy. A visible dye was used because our fluorescence microscope is not equipped with NIR imaging capability. The labeling process was conducted by a similar method used for the synthesis of FA-Ad-ICG02 probe described above. The initial molar ratio of FA:Ad:RhB is 10^5:1:10^5, and the labeled molecules of Rhodamine B were calculated based on the fluorescence emission spectroscopic at 578 nm (Tris buffer, PH 8.0).

Cells (1×10^4) were seeded in 24-well plates and incubated in culture medium overnight. The cells were washed twice with PBS (pH 7.0) and suspended in 150 μL of fresh DMEM and RPMI1640 medium. Ad or FA-Ad vector (20 μL; 1×10^5 pfu; m.o.i.:10 pfu/cell) was added into each well. After incubating for 1 h at 37 °C, the cells were washed twice with PBS and suspended in binding buffer. The cells were directly visualized by fluorescence microscopy (40× objective magnification).

Cell cytometry was used to further quantify the uptake of FA-Ad-RdB and Ad-RdB into the tumor cells (Bel-7402, A549, and U87MG). Briefly, 5×10^5 cells were seeded in 6-well plates and incubated in culture medium overnight. The cells were washed twice with PBS (pH 7.0) and suspended in 200 mL of fresh RPMI1640 and DMEM mediums. Subsequently, 50 μL of 5×10^6 pfu Ad-RhB and FA-Ad-RhB (m.o.i.:10 pfu/cell) were added into each well. After incubating for 1 h at 37 °C, the cells were washed twice with PBS and detached by trypsin (0.25%), followed by centrifugation at 1000 rpm for 5 min. The medium was discarded and the cells were resuspended in 500 μL of PBS. The cell suspension was immediately analyzed by a flow cytometry.

To evaluate the effect of NHS on the ability of Ad infection, the same amount of Ad-RhB was added into 6-well plates (Bel-7402), with and without NHS solution (molar ratio of Ad-RhB:NHS is 1:10^5). After incubating for 1 h at 37 °C, the cells were washed twice with PBS and detached by trypsin (0.25%), followed by centrifugation at 1000 rpm for 5 min, and the medium was discarded. The cells were resuspended in 500 μL of PBS and immediately analyzed by a flow cytometry.

Animal Experiments. Athymic nude mice and normal (Kunming) mice were purchased from Charles River Laboratories (Shanghai, China). All animal experiments were carried out in compliance with the Animal Management Rules of the Ministry of Health of the People's Republic of China (document no. 55, 2001) and the guidelines for the Care and Use of Laboratory Animals of China Pharmaceutical University.

Acute Toxicity Test in Mice. The acute toxicity of the Ad, Ad-ICG02, and FA-Ad-ICG02 probes to animal subjects were investigated on the normal mice. Briefly, 80 Kunming mice (aged 3−4 weeks, weighed 18−22 g, equal number of male and female subjects) were divided into 10 groups, including the control group (n = 8, 4 males and 4 females in each group), three normal dose group (1×10^{10} pfu/kg of Ad defined as normal dose, n = 8 for each probe), 25× dose group ($25 \times 1 \times 10^{10}$ pfu/kg, $n = 8 \times 3$), and 50× dose group ($50 \times 1 \times 10^{10}$ pfu/kg, $n = 8 \times 3$). Different doses of the above probes (Ad, Ad-ICG02, and FA-Ad-ICG02), 0.2 mL 1×10^{10} pfu/kg, 0.2 mL 2.5×10^{11} pfu/kg, and 0.2 mL 5×10^{11} pfu/kg, were injected by tail vein into the different groups of mice. Mice in the control group were given PBS buffer in the same volume (0.2 mL). Blood was drawn from the eye socket at the 24 h, 48 h, and 2 week time points after injection. The serum biochemical parameters including aspartate aminotransferase (AST) and alanine aminotransferase (ALT) indexes of the blood samples were examined. Finally, the mice were sacrificed 2 weeks postinjection and the livers were excised for histopathology. The pathological changes of liver tissue from different groups of mice were assessed and compared.

Dynamics and Biodistribution of FA-Ad-ICG02 in Normal Nude Mice. Normal nude mice were used for the investigation of the dynamics of FA-Ad-ICG02 probe (n = 5). FA-Ad-ICG02 probe (0.2 mL, 1×10^{10} pfu/kg) was administered into the bloodstream of the subject mice through tail vein injection. Fluorescence imaging was acquired with our NIR imaging system using the method we reported previously.[29] A series of images were collected from mice and the background images were taken for each mouse prior to injection. To confirm the biodistribution of FA-Ad-ICG02 probes in different organs obtained from the NIR imaging, the mice were sacrificed at 8 h postinjection. Different organs were separated and washed by saline and assembled for ex vivo fluorescence imaging.

In Vivo Tumor Models. To investigate the targeting ability of the probes, three types of tumor models were established. Briefly, Bel-7402 (with high FR expression and low CAR expression) and A549 (with high CAR expression and FR negative expression) were implanted in the upper and lower axillary fossa in the same mouse of group I (n = 10). U87MG with intermediate expression in both FR and CAR were implanted in the upper left axillary fossa in the another group of mice (n = 5).

In Vivo Study. As the tumors grew up to a diameter of 0.4−0.6 cm, the mice were immobilized for in vivo optical imaging. Ad-ICG02 or FA-Ad-ICG02 (0.2 mL, 1×10^{10} pfu/kg) was injected into each mouse cohort. Imaging was performed with the NIR imaging system in a dark room. A series of images were collected at specific time intervals during 48 h postinjection. The accumulation of the probes in tumors was compared among different groups of mice. To quantify the targeting ability of the different probes in different tumors, the average fluorescence intensity in tumor regions was acquired by selecting the region of interests (ROI) and compared with normal muscle tissue.[45,46] Tumor to normal tissue contrast ratios (T/N) were calculated by using the ROI functions of *Living Image* software.

Statistical Analysis. All data are reported as the mean ± SD of n independent measurements. Statistical analysis was performed by using Student's t-test with statistical significance assigned for P value of <0.05.

RESULTS

Synthesis and Characterization of FA-Ad-ICG02 Probes. FA-Ad-ICG02 and Ad-ICG02 were synthesized by following the

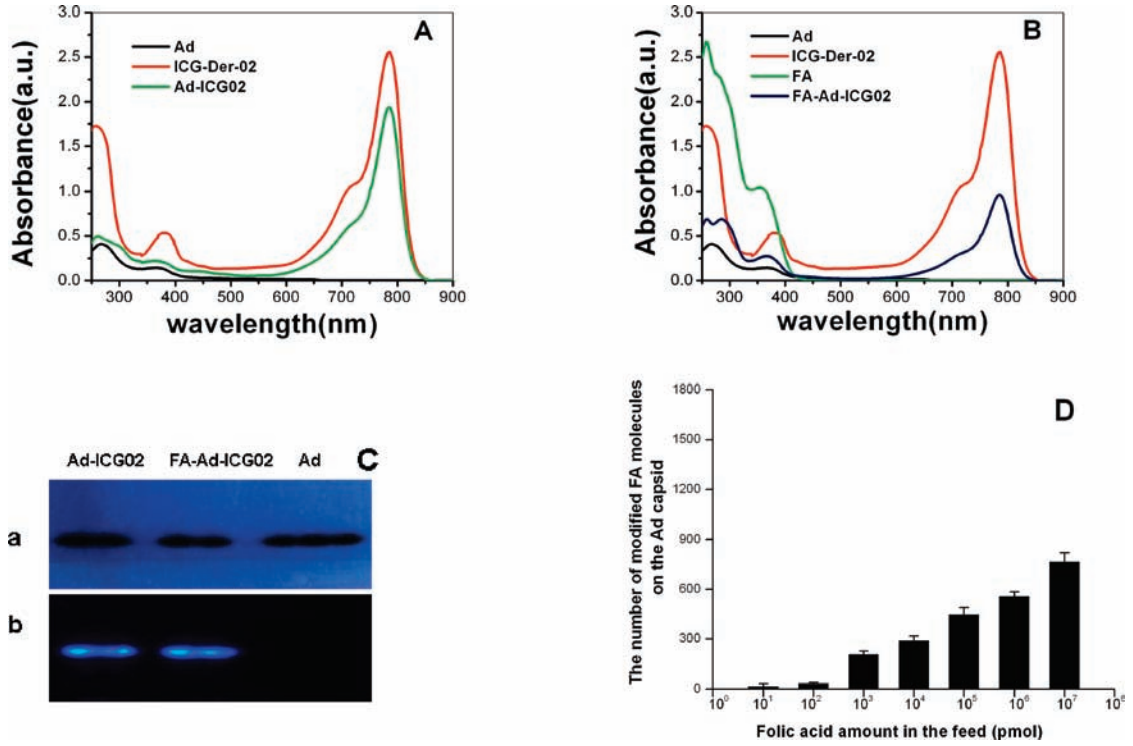

Figure 2. Characterization of FA-modified Ad probes. (A) Absorption spectra of synthesized Ad-ICG02 probe and Ad and ICG-Der-02 dye. The absorption peaks of Ad-ICG-02 overlaps the peaks of Ad and ICG-Der-02 at 260 and 780 nm, indicating the successful conjugation of Ad-ICG02. (B) Absorption spectra of FA-Ad-ICG02 probe, Ad, FA-Ad, and ICG-Der-02 dye. The absorption peaks at 260, 365, and 780 nm represent absorption of Ad, FA, and ICG-Der-02, respectively, indicating the successful preparation of FA-Ad-ICG02. (C) Gel electrophoresis further confirmed the successful synthesis of FA-Ad-ICG02 and Ad-ICG02. The fluorescence of ICG-Der-02 can be observed from the band of purified Ad-ICG02 and FA-Ad-ICG02 using NIR imaging system. (D) Number of modified FA molecules on the Ad capsid at different initial FA ratios. A total of 2×10^8 pfu/mL of Ad (4.74×10^9 VP/mL) was used for the modification. The number of modified FA molecules on the surface of Ad was determined by using the recovery method. The data are represented as mean ± standard deviation (SD), $n = 4$.

procedures described in the Experimental Section, as shown in Figure 1. The purified FA-Ad-ICG02 and Ad-ICG02 were evaluated by UV absorption spectrum analysis in the same Tris buffer with pH 8.0, as shown in Figure 2A and B. The absorption spectra of FA-Ad-ICG02 and Ad-ICG02 displayed all of the absorption peaks of the constituent components (Ad, FA, and ICG-Der-02 at 260, 365, and 780 nm, respectively) in the complex, indicating the successful conjugation of FA-Ad-ICG02 and Ad-ICG02. Successful FA-Ad-ICG02 and Ad-ICG02 conjugation was further confirmed by gel electrophoresis, as shown in Figure 2C. In addition, the fluorescence of ICG-Der-02 was observed from the band of purified Ad-ICG02 and FA-Ad-ICG02 under the NIR imaging system, which further demonstrated that the dye ICG-Der-02 was attached to the Ad particles.

To quantify the number of FA molecules to the amino groups of Ad surface, the recovery method was strictly followed in the calculation of unreacted FA based on the regression equation of the standard curve $Y(\mathrm{OD}) = 0.0544X\ (\mu\mathrm{g/mL}) + 0.1757$ ($r = 0.9998$). The linear rang of the standard curve was from 0.079 to 48.61 μg/mL. The relationship between the fraction of covalently bound and initial FA molecules is shown in Figure 2D. For the different initial ratios of 10^4:1, 10^5:1, and 10^6:1, the modified FA molecules were 289 ± 29, 448 ± 42, and 557 ± 28 per Ad ($n = 4$), respectively. The results indicates that the number of FA molecules conjugated to the surface amine groups of Ad particles increased with an increase in the amount of initial FA (Figure 2D).

The optimal number of FA molecule modified Ad particles is highly desirable to attain high accumulation of FA-Ad-ICG02 in tumors. From the in vivo experiment conducted with a different number of covalent FA molecules per Ad, it was found that the 448 ± 42 molecules of FA to per Ad, which was prepared from the initial FA to Ad ratio of 10^5:1 (pmol), showed the highest fluorescence signal in Bel-7402 tumors by the in vivo NIR imaging. Thus, Ad with 448 ± 42 molecules of FA modification was selected for all the experiments.

Similarly, the number of labeled ICG-Der-02 molecules on the surface of Ad was calculated by UV−vis and was found to be 293 ± 56 molecules per Ad ($n = 4$).

The size and morphology of Ad particles before and after modification were measured by LPSA and TEM, as shown in Figure 3A−C. The effective diameters of Ad, Ad-ICG02, and FA-Ad-ICG02 ($n = 4$) were 84.1 ± 18.6, 83.4 ± 15.3, and 81.8 ± 16.4 nm, respectively. No significant difference was observed between the Ad particles. Further, the morphologies of the three particles (Ad, Ad-ICG02, FA-Ad-ICG02) were obtained by negatively staining TEM images (Figure 3A−C). The results indicate that some aggregation occurred in the Ad particles itself (Figure 3A) and the chemical modification of Ad with ICG-Der-02 (Figure 3B) or FA (Figure 3C) resulted in highly monodisperse particles.

Cytotoxicity of FA-Ad-ICG02 Probe. MTT assay was used to quantify cell viability on the 4 human cell lines used in this study in the presence of FA-Ad-ICG02.[47] The results are displayed in

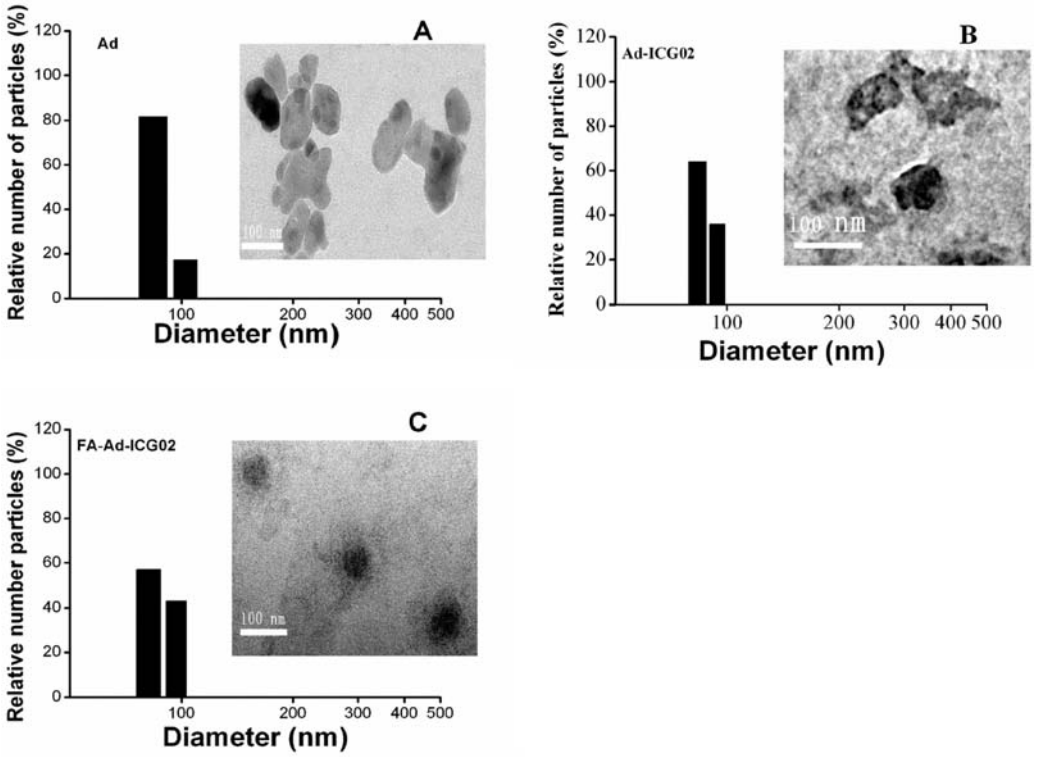

Figure 3. Size and morphology of Ad and modified particles were measured by LPSA and TEM. (A) The diameter of Ad was 84.1 ± 18.6 nm; the negative staining TEM picture shown some aggregation occurred in the Ad particles itself. (B)The diameter of Ad-ICG02 was 83.4 ± 15.3 nm. (C) The diameter of FA-Ad-ICG02 was 81.8 ± 16.4 nm. The negatively stained TEM images of FA-Ad-ICG02 showed that the Ad particles were well dispersed as individual particles with spherical shape.

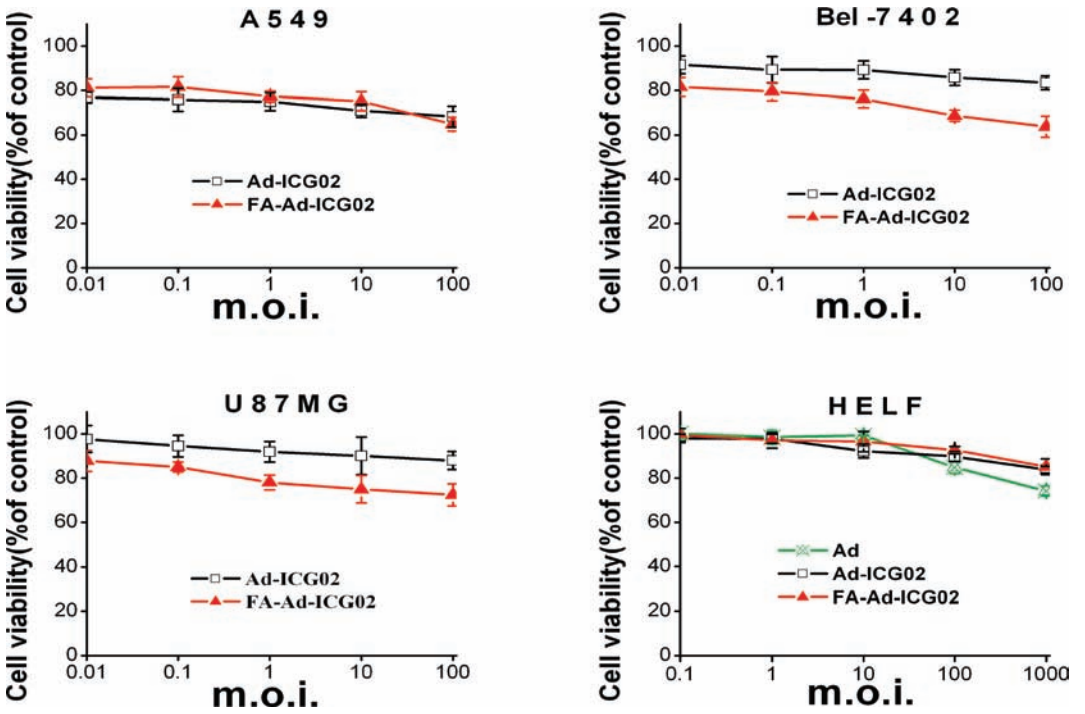

Figure 4. In vitro cytotoxicity of FA-Ad-ICG02. Cells at a density of 1×10^4 cells/well cultured in 96-well plates were infected with the indicated viruses in a wide range of m.o.i. Five days later, the cell viability was examined by MTT assay. Data showed that there is no obvious negative effect of FA-Ad-ICG02 on normal cells.

Figure 4. The cytotoxicity assay show that FA-Ad-ICG02 displayed very low toxicity to normal cells (HELF human embryonic lung fibroblast cell line) even at higher m.o.i. Cell viability was about 75% in FA-positive cells infected with

dx.doi.org/10.1021/bc100245t |*Bioconjugate Chem.* 2011, 22, 567–581

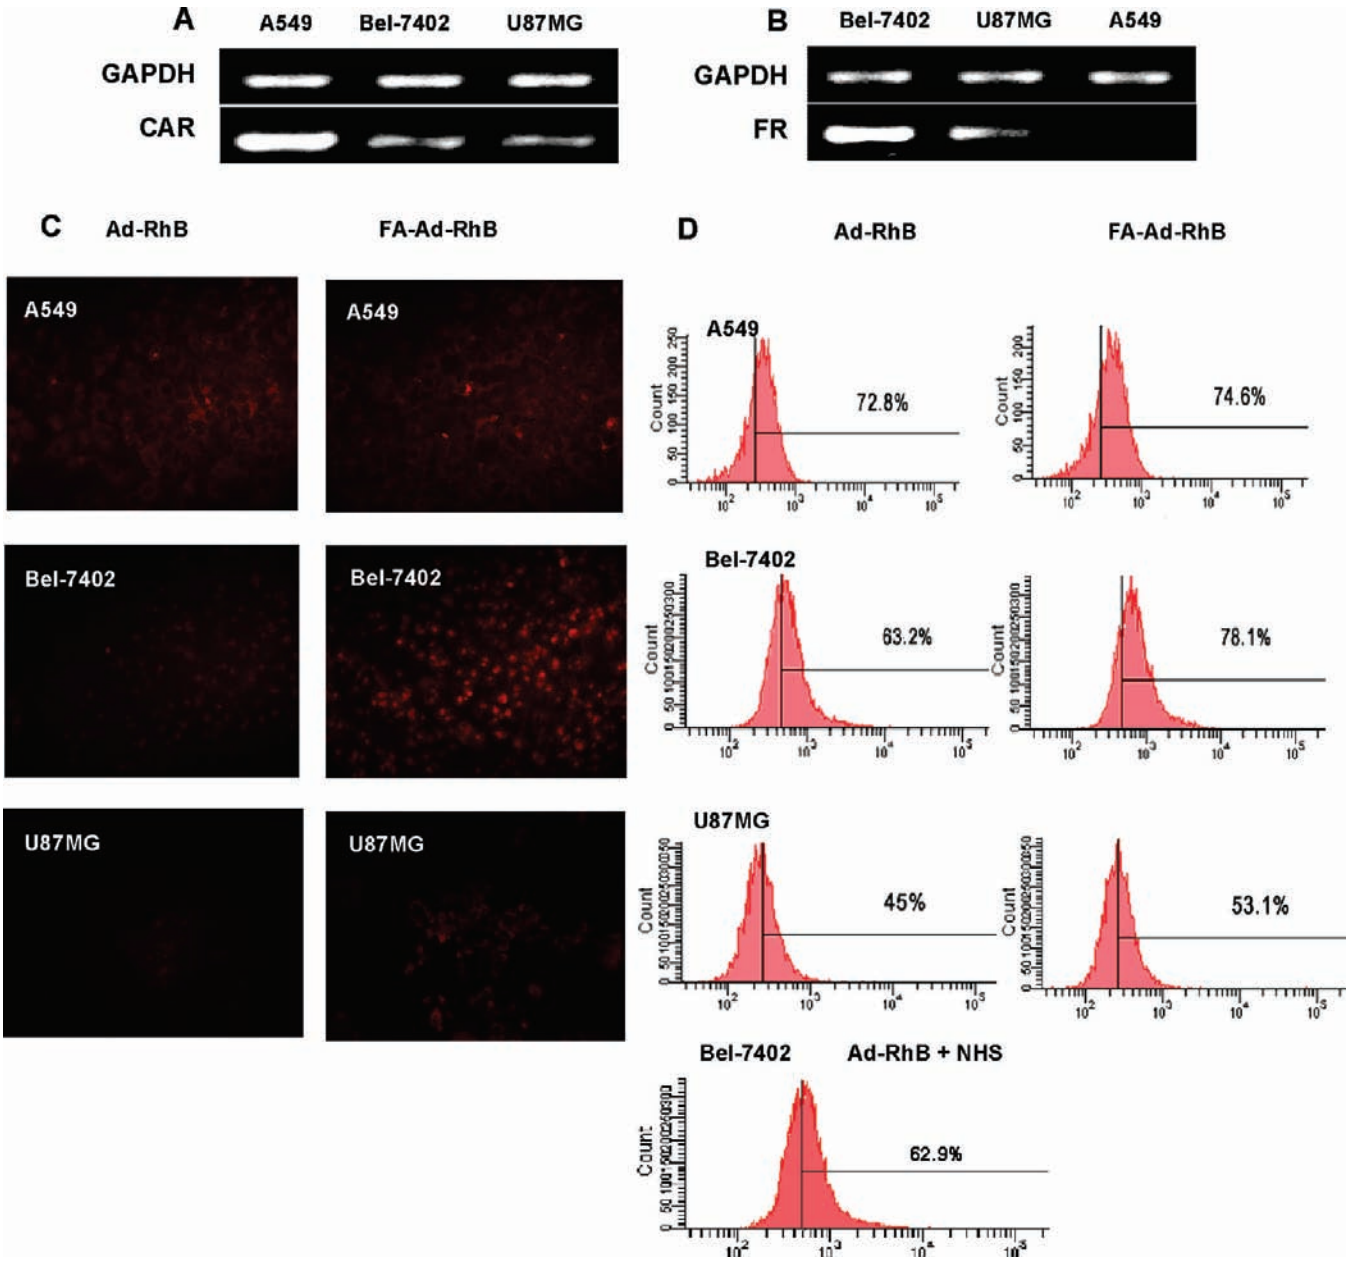

Figure 5. Targeting capability of FA-Ad particles in three different tumor cell lines compared to Ad particles. (A) mRNA levels of CAR on the three different tumor cells were determined by reverse transcriptase PCR. The CAR expression follows the order A549 > Bel-7402 > U87MG. (B) mRNA levels of FR was determined by reverse transcriptase PCR. The FA receptor expression follows the order Bel-7402 > U87MG >A549. (C) Targeting ability of FA-Ad-RhB and Ad-RhB particles in A549, Bel-7402, and U87MG cells imaged with a fluorescence microscope. FA-Ad-RhB and Ad-RhB were significantly retained in CAR overexpressed A549 cell lines. FA-Ad-RhB showed increased uptake in Bel-7402 and U87MG tumor lines (with low CAR expression and high FR expression) compared to Ad-RhB particles. (D) Flow cytometric analysis of FA-Ad-RhB and Ad-RhB particles in A549, Bel-7402, and U87MG cell lines. FA-Ad-RhB and Ad-RhB particles were taken into A549 cell lines at about 74.6% and 72.8%. FA-Ad-RhB showed increased uptake in Bel-7402 and U87MG cells (78.1% and 53.1%) compared to Ad (63.1% and 45.0%). Flow cytometric analysis of the effect of NHS on the infection of Ad particles to the tumor cell line. There is no obvious difference between Ad-RhB and mixture (Ad-RhB and NHS) (63.2%, 62.9%).

FA-Ad-ICG02 at m.o.i. of 1 pfu/cell but more than 90% in normal cells infected with these viruses at m.o.i. of 10 pfu/cell. The results demonstrated that FA-Ad-ICG02 displayed low cytotoxicity to all cells. More significantly, there is no obvious negative effect on normal cells, suggesting that the particles are safe for use in living systems.

In Vitro Cell Targeting. The FA-Ad-ICG02 was selectively retained in FA-positive (Bel7402 and U87MG) cells and CAR-positive (A549) cells at very low m.o.i. To explain the receptor mediated targeting of FA-modified Ad vectors to different tumors, A549, Bel-7402, and U87MG tumor cells with different CAR and FA receptor expression levels were first investigated by reverse transcriptase PCR, as shown in Figure 5A and B. The CAR receptor expression was found to decrease in the following order, A549 > Bel-7402 > U87MG, while the FA receptors expression follows the order Bel-7402 > U87MG >A549.

dx.doi.org/10.1021/bc100245t |*Bioconjugate Chem.* 2011, 22, 567–581

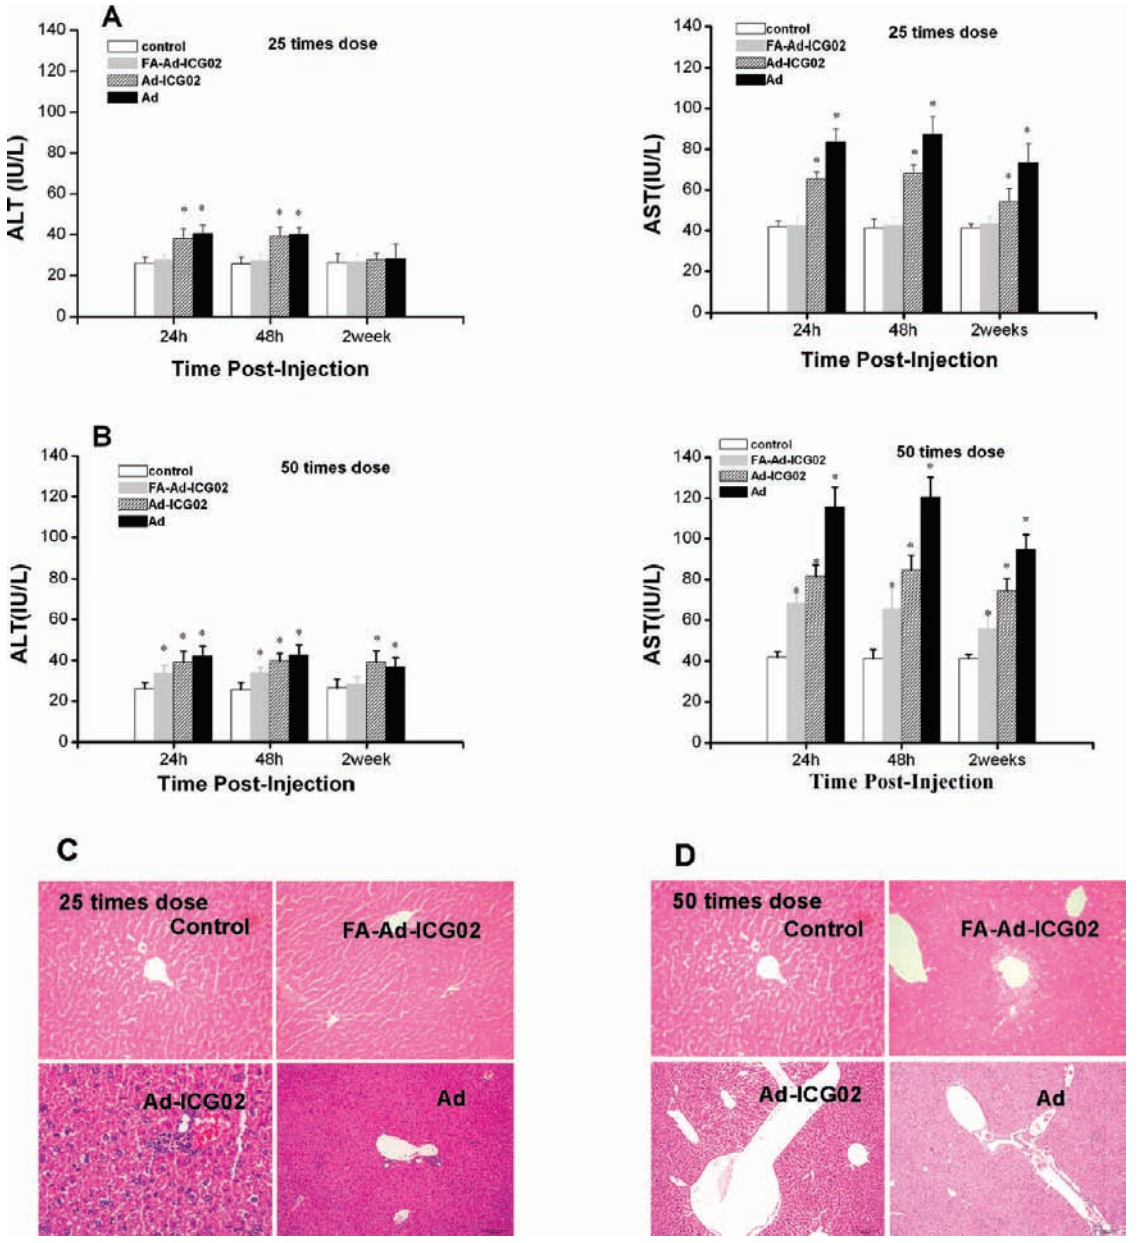

Figure 6. Acute toxicity of Ad, Ad-ICG02, and FA-Ad-ICG02 assessed on normal mice. (A) For the group treated with the 25× dose, the serum AST and ALT levels were significantly elevated after administration of Ad-ICG02 or Ad probes and peaked at about 24 and 48 h postinjection. Administration of FA-Ad-ICG02 did not induce any significant change in AST and ALT levels in mice. (B) AST and ALT levels in mice treated with a 50× dose were significantly elevated after injection of Ad or Ad-ICG02. The administration of FA-Ad-ICG02 probe at the 50× dose also caused a significant increase in both AST and ALT ($p < 0.05$). (C) Tissue sections of liver excised from the mice 2 weeks after administration of Ad, Ad-ICG02, and FA-Ad-ICG02 at 25× dose. No histologic change was observed in control and FA-Ad-ICG02 treated mouse groups. The liver tissue showed slight spotty necrosis and nuclear fission after administration of Ad-ICG02 or Ad particles (image magnification is 200×). (D) Tissue sections of liver excised from the mice 2 weeks after administration of Ad, Ad-ICG02, and FA-Ad-ICG02 at 50× dose. More than 90% of mice in the Ad and Ad-ICG02 treated groups showed hepatic tissue with slight spotty necrosis, nuclear fission, and venectasia under higher than normal doses. About 60% of the mice in the FA-Ad-ICG02 probe injected group exhibited different levels of toxicity, such as slight degree of inflammatory, spotty necrosis, and edemas diffusely distributed in the hepatic lobule (image magnification is 200×).

To visualize cellular uptake of FA-Ad and Ad, FA-Ad-RhB and Ad-RhB particles were, respectively, incubated in the above three tumor cell lines at 37 °C for 1 h. The number of RhB molecules was calculated based on fluorescence emission spectroscopic, which was found to be 312 ± 49 molecules per Ad particle ($n = 4$). The cellular uptake of these probes in cell lines was imaged by fluorescence microscopy and the results are shown in Figure 5C. FA-Ad and Ad particles were significantly retained in the CAR overexpressed A549 cells. The nonmodified Ad showed little uptake in the tumor lines with low CAR expression (Bel-7402 and U87MG). However, FA-Ad displayed increased uptake to FR overexpressed tumor cells (Bel-7402 and U87MG) compared to Ad. To determine the levels of cellular uptake of FA-Ad and Ad, flow cytometry data of

dx.doi.org/10.1021/bc100245t |*Bioconjugate Chem.* 2011, 22, 567–581

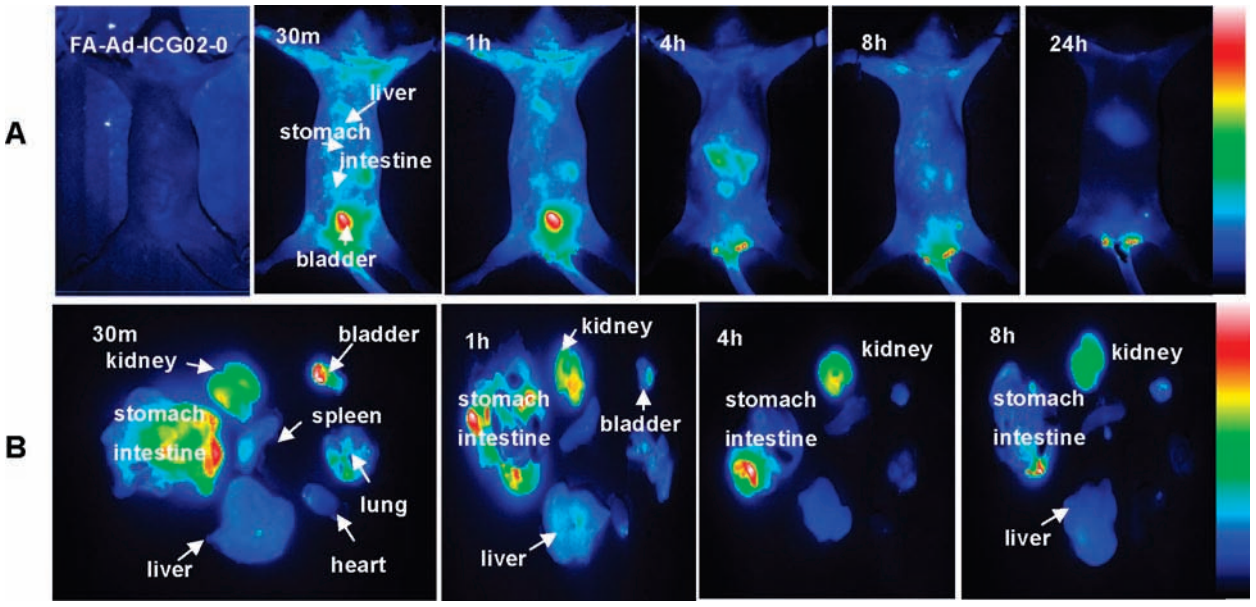

Figure 7. Dynamics of FA-Ad-ICG02 in normal nude mice monitored by NIR imaging system. (A) In vivo noninvasive monitoring of FA-Ad-ICG02 in mice within 24 h. Images show that the probe first accumulated in the liver and then cleared into the gastrointestinal and kidney−bladder pathway, respectively. (B) Fluorescence image of FA-Ad-ICG02 on the main organs excised from the mice within 8 h. Images show that the fluorescence accumulated in the liver gastrointestinal, kidney, and bladder after 1 h, which confirmed the real-time imaging data monitored with a noninvasive NIR imaging system.

FA-Ad-RhB and Ad-RhB were acquired, as shown in Figure 5D. Flow cytometry analysis indicated FA-Ad and Ad particles were taken in A549 cells at about 74.6% and 72.8%, respectively. FA-Ad in Bel-7402 and U87MG cells were retained at 78.1% and 53.1%, respectively, while Ad was retained in Bel-7402 and U87MG at about 63.2% and 45.0%, respectively. This finding suggests that FA modification enhanced the targeting capability of Ad particles to tumors overexpressing FR. The uptake levels of Ad particles in the three tumor cells are consistent with their mRNA levels.

To verify whether NHS affects the infection of Ad particle into tumor cells, the mixture of Ad-RhB and NHS was incubated with Bel-7402 cells. Flow cytometry analysis showed about 62.9% uptake of the particles (Figure 5D). There is no obvious difference between this mixture and Ad-RhB (63.2%), implying that NHS has no effect on the infection of Ad particles.

Acute Toxicity of the Probes on Normal Mouse Model. The acute toxicity of Ad, Ad-ICG02, and FA-Ad-ICG02 was assessed on normal mice. The biochemical parameters AST and ALT levels at 24 h, 48 h, and 2 weeks postinjection are shown in Figure 6. For the group treated with 25× of the normal dose (Figure 6A), serum AST and ALT were significantly elevated after injecting Ad-ICG02 or Ad probes. Peak levels were attained at about 24 h postinjection, while the administration of FA-Ad-ICG02 did not induce significant change of AST and ALT levels in the mice. Similarly, serum biochemical parameters AST and ALT were slightly elevated in the mice receiving a 50× dose after injection of Ad or Ad-ICG02 (Figure 6B). However, the administration of FA-Ad-ICG02 probe at 50× dose caused significant increase in both AST and ALT, suggesting some toxic effects at this high 50× dose. The above results suggest that the toxic effect only occurred in the high dosage of Ad particles, and ligand modified Ad could minimize liver toxicity compared with the nonmodified Ad.

To further evaluate the toxicity of Ad, FA-Ad-ICG02, and Ad-ICG02 on the animals, the main target organ, liver, was excised for pathology. Figure 6C,D is the representative tissue sections from different mouse groups. About 70% of the 25× dose group injected with Ad or Ad-ICG02 particles showed hepatic injury by 2 weeks, as evidenced by slight spotty necrosis and nuclear fission. More than 90% of mice in the Ad and Ad-ICG02 groups treated with 50× dose showed hepatic injury in the form of slight spotty necrosis, nuclear fission, and venectasia. As expected, the administration of FA-Ad-ICG02 did not render any significant pathologic changes at a 25× dose. No histological difference was observed in the control, normal dose, and 25× dose groups (Figure 6C) after FA-Ad-ICG02 injection. Moreover, 60% of the mice in the 50× dose group exhibited different levels of toxicity, such as slight degree of inflammatory, spotty necrosis, and edema that were diffusely distributed in the hepatic lobule (Figure 6D).

Dynamics of FA-Ad-ICG02 in Normal Nude Mice. To better understand the physiological behavior of FA-Ad-ICG02 probe, the dynamics of FA-Ad-ICG02 was first investigated in normal nude mice ($n = 5$) prior to using the tumor bearing mice. These mice were injected with FA-Ad-ICG02 probe (0.2 mL, 1×10^{10} pfu/kg) and monitored for 24 h. Representative images are shown in Figure 7A. The fluorescent probe FA-Ad-ICG02 initially spread in the whole body at about 30 min postinjection and gradually appeared in the excretion organs such as the liver, gastrointestinal system, and bladder. As the fluorescent probe in the liver gradually washed out in the first 8 h, the signal in the gastrointestinal organ and the bladder increased, as shown in the 8 h image (Figure 7A). At 24 h postinjection, the fluorescent probe has mostly cleared from the body. Typical of cyanine dyes, the probe probably entered liver and was subsequently transported to the gastrointestinal system. Another fraction of the probe was excreted by the kidney−bladder pathway.

dx.doi.org/10.1021/bc100245t |*Bioconjugate Chem.* 2011, 22, 567–581

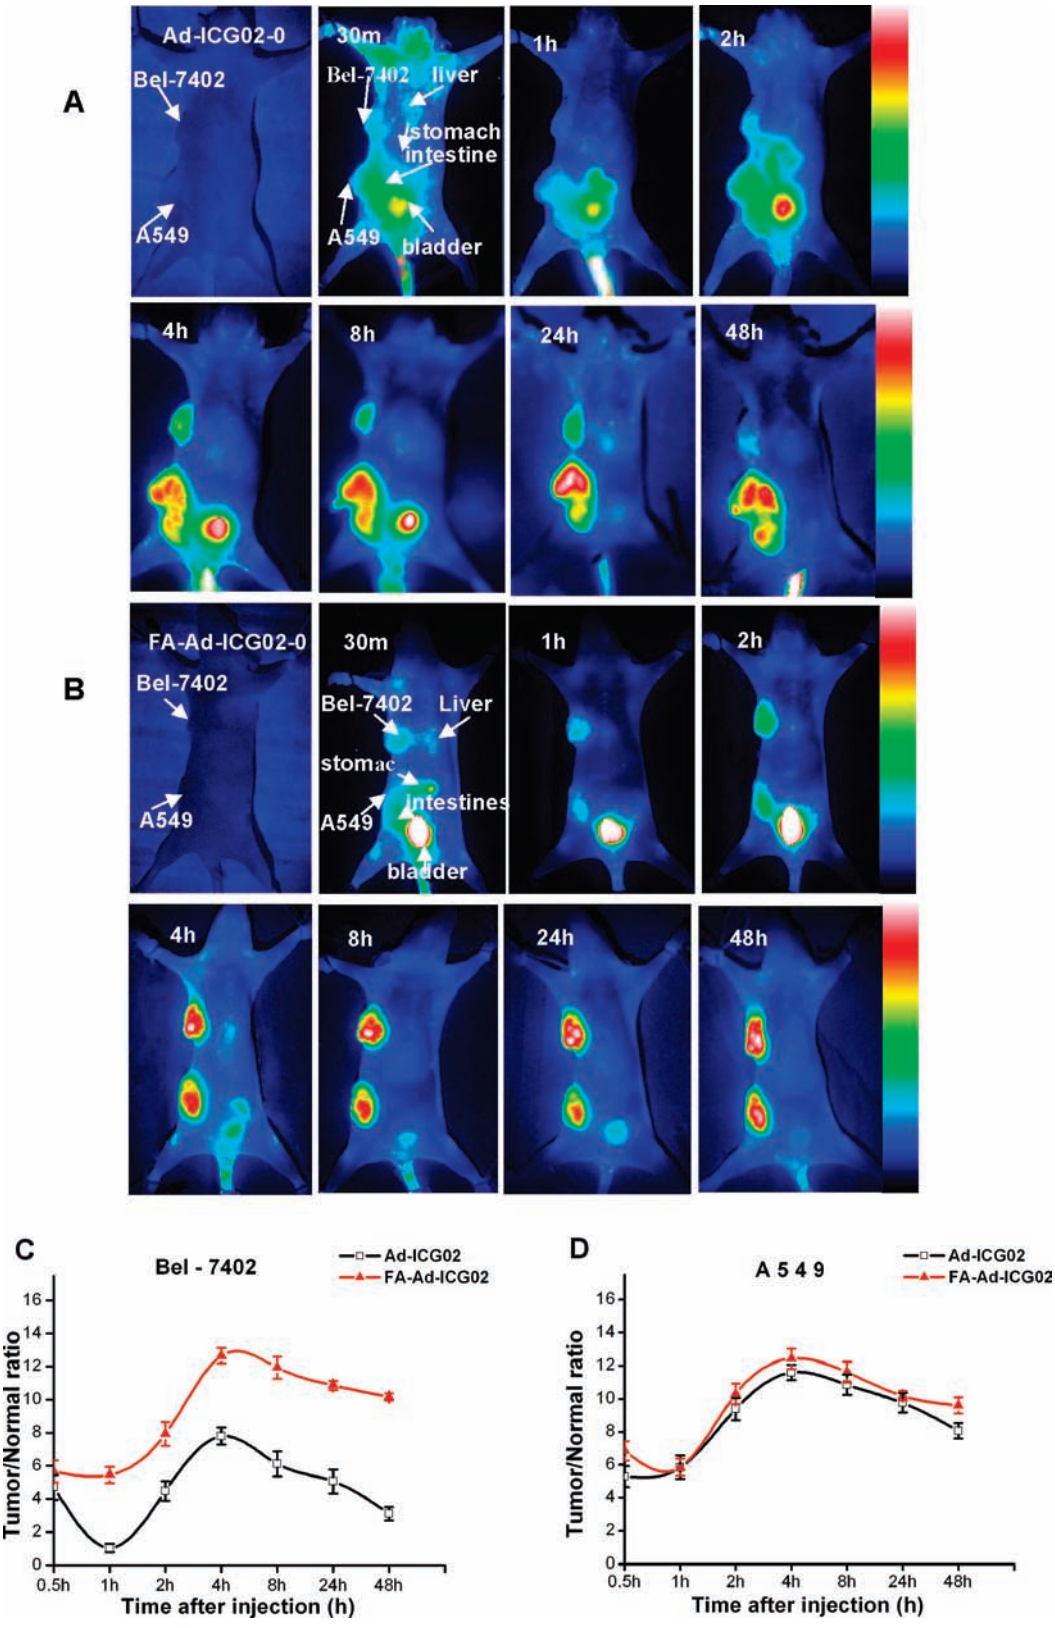

Figure 8. Tumor-targeting capability of FA-Ad-ICG02 and Ad-ICG02 in nude mice bearing Bel-7402 and A549 tumor xenograft monitored by NIR images system. (A) Fluorescence images of the mouse after administration of Ad-ICG02 within 48 h. Ad-ICG02 probe was targeted to CAR overexpressed A549 tumor and weak signal was displayed in the low CAR but high FR expressing Bel-7402 tumors. (B) Fluorescence images of the mouse after administration of FA-Ad-ICG02 within 48 h. FA-Ad-ICG02 displayed strong targeting capability to both A549 and Bel-7402. (C) Time courses of tumor-to-normal tissue (T/N) ratio in Bel-7402 tumor for Ad-ICG02 and FA-Ad-ICG02 probes. Statistical analysis indicates that there is a significant difference of T/N ratio in the Bel7402 tumors between the two probes ($p < 0.05$). (D) Time courses of tumor-to-normal tissue (T/N) ratio in A549 tumor. There is no significant difference in A549 tumors ($p > 0.05$). The data are represented as mean ± standard deviation (SD), $n = 5$/group.

To obtain detailed information about the probe's distribution in the main organs, the mice were sacrificed and the organs removed at 30 min, 1 h, 4 h, and 8 h ($n = 5$). Figure 7B shows the uptake of the fluorescent probes in representative organs ex vivo. Consistent with the in vivo observation, the fluorescent probe was first dispersed in all the organs and gradually moved to liver. At about 4 h, the probes were mainly observed in kidney and gastrointestinal system before clearing through urine and feces.

In Vivo Tumor Targeting Study. To investigate the tumor targeting capability of FA-Ad-ICG02 and Ad-ICG02, Bel-7402 and A549 cells that overexpress FA and CAR receptors, respectively, were used. The Bel-7402 and A549 cells were injected in the left axillary fossa and lower flank, respectively ($n = 10$). The in vivo distribution of the probes at specific time points was recorded with our NIR imaging system. Representative images are shown in Figure 8A and B. Similar to the profiles of the dynamics study described above, the probes were initially distributed all over the body and subsequently cleared by the hepatobiliary and renal pathways. However, the tumor sites were identifiable within one hour postinjection of the probes. Over time, the probe increasingly accumulated in the tumors and the fluorescence intensity peaked at about 4 h. For CAR receptor-positive A549 tumors, both Ad-ICG02 and FA-Ad-ICG02 displayed strong tumor-targeting capability, which further confirmed that CAR is the primary receptor for Ad. For Bel-7402 with FR overexpression, the FA-Ad-ICG02 probe showed higher targeting capability than Ad-ICG02, which is consistent with our previous findings. The bright fluorescence signal gradually disappeared after one week (data not shown).

To quantify the targeting ability of the probes, fluorescence intensity was analyzed by using ROI. The dynamics of the signals in tumors are depicted in Figure 8C and D. Fluorescence intensity ratio between Bel-7402 tumor and normal tissue (T/N) was 1.04 ± 0.24 at 1 h post injection of Ad-ICG02, reaching a peak at 4 h post injection (7.78 ± 0.51) and slowly declining to 3.11 ± 0.39 by 48 h (Figure 8C). In contrast, Bel-7402 tumor-bearing mice intravenously injected with FA-Ad-ICG02 probe showed a T/N ratio of 5.44 ± 0.49 after 1 h, and a peak uptake at 4 h reached 12.65 ± 0.48. Fluorescence intensity ratio between A549 tumor and normal tissue (T/N) was 5.83 ± 0.72 at 1 h after injection of Ad-ICG02 probe; a peak at 4 h reached 11.59 ± 0.46, and slowly declined to 8.06 ± 0.46 by 48 h (Figure 8D). Similarly, FA-Ad-ICG02 probe in A549 tumor bearing mice showed a T/N ratio of 5.84 ± 0.50 after 1 h, and a peak at 4 h reached 12.41 ± 0.61. Statistical analysis indicated a significant difference of T/N ratio in Bel-7402 tumors for the two probes ($p < 0.05$). There is no significant difference in the A549 tumors ($p > 0.05$). NIR images of mice with Bel-7402 and A549 tumor xenografts after injection of FA-Ad-ICG02 probe showed good fluorescence intensity and fast tumor targeting in vivo from 0.5 to 48 h.

To further explore the targeting capability of FA-Ad-ICG02 and Ad-ICG02, nude mice bearing U87MG tumor in the right axillary fossa were used. As shown in Figure 5A and B, U87MG displayed a relatively low expression in CAR and slightly higher level of FA receptor. Figure 9A and B shows two representative series of NIR images after administration of Ad-ICG02 and FA-Ad-ICG02, respectively. Fluorescence signal was clearly visualized in the U87MG tumor as early as 2 h for FA-Ad-ICG02 conjugate. Compared with FA-Ad-ICG02, Ad-ICG02 probe showed less targeting ability to U87MG tumor. Thus, the T/N tissue contrast ratio was less than that of FA-Ad-ICG02 probe (Figure 9C). The T/N ratio for FA-Ad-ICG02 probe peaked at about 4 h (6.84 ± 0.21), and the peak of Ad-ICG02 manifested at about 4 h (2.92 ± 0.23). Statistical analysis indicated the significant difference of T/N ratio existed in U87MG tumors for the two probes ($p < 0.05$). The results indicated that the targeting ability of FA-Ad-ICG02 probe to U87MG is stronger than that of Ad-ICG02 probe, which further confirms that FA modification can enhance the targeting ability of Ad to tumors with low CAR expression and high FA expression.

DISCUSSION

In this study, adenovirus capsids were covalently conjugated with FA ligands to extend the targeting ability of Ad particles to tumors with low CAR expression. To visualize the distribution of Ad in a living animal, the NIR fluorescence dye, ICG-Der-02, was subsequently attached to the Ad capsids. The number of FA incorporation to the Ad surface was calculated by following the recovery method (Figure 2D).The successful conjugation of FA-Ad-ICG02 was confirmed by the absorption and fluorescence spectra and electrophoresis (Figure 2A−C). It was previously reported that chemical modification of the Ad surface may alter their tropism and reduce infectivity because of the inherent CAR-mediated cellular uptake mechanism.

To modulate CAR binding and extend the applicability of the Ad particles, we chose FA for reasons given in the Introduction. In this configuration, it is important to incorporate an optimal number of FA per Ad particle for maximizing tumor targeting ability while substantially reducing normal tissues toxicity. In this study, the initial FA to Ad ratio was optimized to approximately 1×10^5 FA moieties per Ad particle, as shown by the in vivo imaging data. This corresponds to 448 ± 42 molecules of FA modification on the Ad surface (Figure 2D), which is similar to previously reported information.[40]

After chemical conjugation, the size and morphology of FA-Ad-ICG02 remained unchanged (Figure 3A−C). The TEM images of FA-Ad-ICG02 showed that the Ad particles were well dispersed as individual particles with spherical shape. However, in this study, FA was used as a cancer targeting moiety for Ad particles. The results reveal that FA-Ad-ICG02 could be delivered in more specific manner to target cells and tissues without undergoing a CAR-mediated viral infection mechanism. Our study demonstrates that retargeting of Ad particles is feasible by conjugating an appropriate targeting moiety on the surface, while maintaining high specific infection. The dynamics and biodistribution of FA-Ad-ICG02 in normal mice were traced by using NIR imaging system. The clearance profile of the functionalized Ad particles used in this study is consistent with that of Ad itself.[48−50]

Ad vector is a powerful tool in gene therapy. Immune toxicity of Ad is the key factor hindering the practical application of Ad particle.[51−53] Although E1- and E3-deleted Ad vector have defective replication abilities, innate and adaptive immune responses are still the main concern for the real application, especially when repeated administration is required.[54,55] Thus, toxicity study is crucial for the potential applications of new particles.

In this study, we assessed the toxicity of the probes in vitro and in vivo investigation. As in previous studies, MTT assay was conducted on different cell lines to evaluate the toxicity of the new probes (Figure 4). The results indicate that FA-Ad-ICG02 can selectively kill CAR and FA-positive cancer cells at low m.o.i.

There is no obvious toxicity to the normal cell (HELF). In the FA-Ad-ICG02 probe, the FA moiety is vitamin B_{11}, which is known to play an important role in DNA synthesis.[56,57] ICG-Der-02 is a derivative of ICG, approved by the U.S. FDA for human use.[58,59] Ad has the selective infectious ability to the specific cells. Our results confirmed that Ad has low infection to the cells without Ad specific receptors. Thus, the probe FA-Ad-ICG02 is relatively nontoxic to normal cells.

To further investigate the in vivo toxicity and acute toxicity, we studied these factors using conventional procedures. The liver expresses high levels of CAR, and it is the main target organ of toxicity.[60,61] Thus, pathologic status of liver and blood chemistry indexes was examined after intravenous administration of Ad, FA-Ad-ICG02, and Ad-ICG02 particles in normal mouse models. All data demonstrated that there was no obvious hepatotoxicity after injection of the three probes within the normal dose. The hepatotoxicity occurred at high doses of Ad and Ad-ICG02 injection, with significant increase of AST and ALT in 25× and 50× doses. However, the FA modified Ad FA-Ad-ICG02 did not induce any change even in the 25× dose. The cytotoxicity only occurred in the 50× high dose of FA-Ad-ICG02. The histologic examination showed that a small inflammation was observed in the 50× dose group (Figure 6). No obvious histologic changes were found, including focal necrosis, degeneration, and fibrosis in normal and 25× doses. These data suggest that even high doses of FA-Ad-ICG02 were not sufficient to cause damage to normal tissues compared to the nonmodified Ad.

The in vitro and in vivo toxicity studies indicate that FA-Ad-ICG02 is less toxic than Ad, which is consistent with a previous finding.[62] Usually, chemical modification of Ad particles could diminish the innate immune response due to the change of CAR dependent tropism. FA modification altered the tropism and thus decreased the Ad infection to liver cells. The in vivo imaging and pathological pictures also demonstrated the lower accumulation and reduced damage of FA modified Ad to the liver than that of Ad itself. Consequently, the modification to Ad may regulate the pharmacokinetics or part of the liver response, as reported in the literature.[40] The modified Ad has great potential for clinic application.

The primary purpose of this study is to extend the targeting ability of Ad to broad tumor types. FA was modified to the Ad capsids to improve the targeting of Ad to FA receptor over-expressed tumors except for the Ad specific tumors. In vitro studies in cell lines with different CAR and FA receptor expression (Figure 5A,B) showed that the targeting ability of Ad itself correlated with CAR expression, which corroborates other literature reports that infection of Ad is initiated by high-affinity binding of the fiber protein to CAR receptor.[63,64] Ad and FA-modified particles have almost identical infectivity in high expression CAR and FA negative cells (A549, Figure 5C,D). Differences were found in the low CAR expressing and FA-positive cells (Bel-7402 and U87MG, Figure 5C,D). The results showed that FA-modified Ad exhibited a relatively high targeting ability when compared with Ad particles in low CAR expressing and FA-positive cells. This suggests that FA-modified Ad infected Bel-7402 or U87MG cells via the dual recognition of CAR and FA receptors. The extent of enhancement in infectivity is consistent with the cell-surface FA expression level.

In vivo targeting capability of FA-Ad-ICG02 was investigated on different tumor bearing nude mouse models. Figures 8 and show that FA-Ad-ICG02 rapidly accumulates in tumors (Bel-7402 and U87MG), reaching the peak after 4 h postadministration. A significant amount of FA-Ad-ICG02 accumulated in the FA-positive and low CAR expressing tumor cells compared to Ad-ICG02. These results indicate that the tumor imaging ability of the probe correlated well with the receptor expression levels (Figure 5A and B), which is consistent with the in vitro experiments. In vitro and in vivo experiments all demonstrated that CAR is the primary receptor. FA modification could improve the targeting of Ad to low CAR and FA-positive tumors. FA-Ad-ICG02 can be used to enhance the ratio of tumor to normal tissue. Although the accelerated clearance of the modified Ad under repeated administration was reported,[16] the enhanced targeting ability and long retention time of the probes in the tumor site (one week) implies the possibility of sustained antitumor drug release to the tumors. This feature will decrease the need for repeated administration of the probe.

Ligand modification of the Ad surface is a more straightforward and versatile method than genetic modification of Ad surface with cell-recognizable proteins such as antibodies. Based on our results, we can deduce that Ad could be targeted to other tumor lines by chemically conjugating with the appropriate ligands. With the low toxicity of E1/E3-deleted Ad, FA-Ad-ICG02 probe has great potential for early tumor diagnosis and gene therapy.

In our previous studies, we have shown that the NIR molecular imaging technique is a useful tool to trace the dynamics of different probes in small animals.[29,30,47,65] This approach provides rapid, convenient, noninvasive, real-time, and inexpensive assays to monitor the distribution, magnitude, and duration of tumor targeting probes. In this study, the tool once again demonstrated its powerful ability in drug development.

CONCLUSIONS

In this study, FA was successfully conjugated to E1/E3-deleted Ad capsids (FA-Ad), which extended the targeting capability to low CAR expressing tumors. NIR fluorescent dye ICG-Der-02 was subsequently attached to the Ad (FA-Ad-ICG02) for in vivo fluorescence imaging. In vitro and in vivo studies demonstrated that the targeting capability of FA-Ad-ICG02 correlated well with the different receptor expression levels. CAR was shown to be the primary receptor of FA-Ad-ICG02 and FA modification enhanced the T/N tissue ratio in the CAR-negative and FR-positive tumors (Bel-7402, U87MG). The systemic toxicity study demonstrated the selective toxicity of FA-Ad-ICG02 to tumor tissue and low toxicity to normal tissues. The chemical modification of Ad decreased its toxicity. All the results support the hypothesis that the targeting capability of Ad could be extended to other Ad nonspecific tumors by chemical modification of the corresponding ligands. The modified E1/E3-deleted Ad has great potential for early tumor diagnosis and targeted therapy.

Supporting Information

ABSTRACT: In this study, the grafting of nicotinic acid and *p*-aminobenzoic acid (PABA) onto poly(ε-caprolactone)-poly(ethylene glycol)-poly(ε-caprolactone) was performed by Huisgen's 1,3-dipolar cycloaddition, also known as click chemistry. Concentrations used for grafting were 0.10, 0.20, and 0.30 molar ratios with respect to caproyl units. The grafted copolymers were successfully obtained at all ratios as confirmed by NMR, GPC, and FT-IR. According to the DSC results, the polymorphisms of these grafted copolymers were mostly changed from semicrystalline to amorphous depending on the type and the amount of grafting compounds. TGA thermograms showed different thermal stabilities of the grafted copolymers compared to the original copolymers. Cytotoxicity results from HUVEC models suggested that the toxicity of grafted nanoparticles increased with the molar ratios of grafting units. Due to differences in molecular structure between nicotinic acid and PABA, physicochemical properties (particle size and surface charge) of grafted copolymer nanoparticles were substantially different. With increasing molar ratio of the grafting units, the particle size of blank nanoparticles tended to increase, resulting from an increase in the hydrophobic fragments of the grafted copolymer. Ibuprofen was chosen as a model drug to evaluate the interaction between grafted copolymers and loaded drug. After ibuprofen loading, the particle size of the loaded nanoparticles of both grafted copolymers increased compared to that of the blank nanoparticles. Significant differences in loading capacity between nicotinic acid and PABA grafted copolymer nanoparticles were clearly shown. This is most likely a result of different compatibility between each grafting compound and ibuprofen, including hydrogen bond interaction, π−π stacking interaction, and steric hindrance.

INTRODUCTION

Over the past decades, the fabrication of copolymers of poly(ε-caprolactone) (PCL) and poly(ethylene glycol) (PEG) has been extensively developed to adapt their physicochemical and mechanical properties to much wider applications in pharmaceutical and medical fields.[1−12] PCL is a semicrystalline, hydrophobic, and biodegradable polymer, while PEG exhibits hydrophilic, crystalline, nontoxic, and biocompatible polymer properties.[13] The copolymer of these two materials can overcome the limitation of PCL after administration into the body by the stealth properties of the hydrophilic segment of PEG.[14] Therefore, this copolymer contributes to improvement of both properties and applications. To develop biomaterials for their use for novel drug delivery systems, one of the methods involves modification of the polymers by the attachment of attractive functional groups. Several reports have established the attachment of various functional groups such as hydroxyl, amino, and carboxylic acid groups onto the main polymer chain by different methods.[15] However, the aforementioned processes frequently exhibit several drawbacks such as incomplete conversion,[16] multiple synthesis steps,[17,18] and intra- and intermolecular transesterifications during the process of attachment.[19] Recently, the straightforward reaction for the grafting of functional groups along PCL has been successfully performed through "click chemistry" using versatile, easy, and mild conditions.[20−22] Riva et al.[23] reported successful grafting of benzoate, triethyl ammonium bromide, and poly(ethylene oxide) on PCL backbone by this reaction. In addition, Lee et al.[24,25] demonstrated the grafting of hexyne and proline to the methoxyPEG-*co*-PCL backbone and, recently, grafting of hexyne, decyne, and benzoate to the PEG-*co*-$(PCL)_2$ backbone. However, to the best of our knowledge, the grafting of pharmacologically active molecules along

the PCL-PEG-PCL backbone with various amounts of grafting units has not been established.

Most drugs on the market are sparingly water soluble principally due to the presence of heterocyclic and aromatic rings in their structures. Nicotinic acid and *p*-aminobenzoic acid (PABA) are two examples of sparingly water soluble drugs which have been investigated for their pharmacological actions and safety in biological systems.[26−31] As per consideration of the structure of these two compounds, the *para*-amino group on the aromatic benzene ring of PABA contributes to the acidic, protic, and hydrogen bonding donor properties.[32,33] The nitrogen atom in the pyridine ring of nicotinic acid, on the other hand, will serve as base and hydrogen bond acceptor. Previously, it was found that the different structures and properties of these two drugs affected the ease of the grafting reaction onto the PCL backbone and the properties of grafted copolymer.[34] From this finding, it is expected that similar effects would occur in the case of the amphiphilic PCL-PEG-PCL copolymer. Furthermore, the grafting compounds (herein referred to nicotinic acid and PABA) on the polymer may potentially influence nanoparticle formation and their properties, especially drug loading capacity and entrapment efficiency. In addition, it is of interest to investigate the contribution of interaction between the grafted copolymer and encapsulated drugs on drug loading capacity and entrapment efficiency.

Ibuprofen (IBU) is a common nonsteroidal anti-inflammatory drug that is being used worldwide. Its molecular structure consists of a phenyl ring, an alkyl group, and a carboxylic acid group. With the availability of its phenyl ring, IBU may form $\pi-\pi$ bonds with other aromatic rings. In addition, a carboxylic group may form hydrogen bonds with both hydrogen bond donors and acceptors presented on the polymer backbone. Such properties make this drug suitable as a model drug for our investigation.

Therefore, this study aimed toward synthesizing the randomly grafted PCL-PEG-PCL with nicotinic acid and PABA by Huisgen's 1,3-dipolar cycloaddition reaction, also known as "click chemistry". The reaction was performed according to our previously published method.[34] The effects of varied concentrations of the grafting compounds on physicochemical and thermal properties of the copolymer backbone were also investigated. After synthesis, all grafted copolymers were used to prepare nanoparticles. To ascertain its potential use in humans, all nanoparticle preparations were tested for their cytotoxicity. Subsequently, the effects of the grafting compounds on nanoparticle formation and properties including particle size, zeta potential, and drug loading capacity were evaluated.

EXPERIMENTAL PROCEDURES

Materials. ε-Caprolactone (CL; Aldrich, USA) was dried over calcium hydride for 48 h followed by distillation prior to use. *p*-Aminobenzoic acid (PABA) (Aldrich, USA) and nicotinic acid (Ajax Finechem, Australia) were used without purification. 3-Butyn-1-ol, copper (I) iodide (CuI), 1,8-diazabicyclo[5.4.0] undec-7-ene (DBU), stannous (II) octanoate ($Sn(Oct)_2$), dimethylsulfoxide (DMSO), L-glutamine, and fetal bovine serum (FBS) were purchased from Sigma-Aldrich Chemicals, USA. *N, N*-Dicyclohexylcarbodiimide (DCC), 4-dimethylaminopyridine (DMAP), and MTT (3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazoliumbromide) were purchased from Fluka Chemie, Germany. α-Chloro-ε-caprolactone (ClCL) was synthesized according to the previous report.[34] Poly(ethylene glycol) (M_w 4000 g/mol, PEG_{4000}) from Fluka Chemie, Germany, was purified by precipitation from chloroform solution with diethyl ether. Sodium azide was purchased from Fisher Scientific UK Limited, United Kindom. Dichloromethane (CH_2Cl_2), diethyl ether, dimethylformamide (DMF), and tetrahydrofuran (THF) were dried over molecular sieve 4 Å. Milli-Q water was used by purification with a Synergy (Millipore, France). Iscove's Modified Dulbecco Medium (IMDM) was obtained from Biochrom AG, Germany. Penicillin/streptomycin (Hoechst, Germany), sodium dodecyl sulfate (SDS) (MP Biochemicals, Germany), trypsin (Difco, Germany) and other organic solvents were used as received. Human umbilical vein endothelial cells (HUVECs) were isolated from human umbilical cord donated from Nordwest Krankenhaus (Nordwest Hospital, Germany). Acetonitrile and methanol were of HPLC grade from Merck, Germany. Glacial acetic acid (100%) was purchased from VWR International S.A.S., France.

Synthesis of PCL-*co*-PEG_{4000}-*co*-PCL Grafted with Nicotinic Acid and PABA. *Synthesis of Nicotinic Acid and PABA, 3-Butynyl Esters.* Prior to the Huisgen's 1,3-dipolar cycloaddition, azide pendants on polymer and terminal alkyne derivatives of model compounds are generally required for functionalization. Thus, but-3-ynyl nicotinate and but-3-ynyl-4-aminobenzoate were synthesized by esterification of acidic model compounds, nicotinic acid and PABA, and 3-butyn-1-ol using DCC and DMAP as catalysts as previously reported.[34] Briefly, known amounts of DCC and DMAP were dissolved in CH_2Cl_2 followed by the addition of an acidic compound. After stirring at room temperature for 30 min, 3-butyn-1-ol was introduced, and the reaction was conducted under argon atmosphere at room temperature for 24 h. The precipitate was filtered out, and the solvent was evaporated under reduced pressure. The crude product was purified by column chromatography on silica gel with the mobile of hexane (Hex), ethyle acetate (EtOAc), and CH_2Cl_2 (1:2:2) for but-3-ynyl nicotinate and Hex and EtOAc (1:1) for but-3-ynyl-4-aminobenzoate. The characteristics of the synthesized derivatives were assigned to their structures and agreed well with the previous report.[34]

But-3-ynyl nicotinate (1). ^{1}H NMR (DMSO-d_6): δ = 2.65 (m, 2H, CH_2C≡CH), 2.86 (t, J = 2.61 Hz, 1H, C≡C*H*), 4.35 (t, J = 6.48 Hz, 2H, COCH_2), 7.57 (m, 1H, pyridine), 8.28 (td, J = 7.96 Hz, 1H, pyridine), 8.80 (s, 1H, pyridine), 9.08 (s, 1H, pyridine).

But-3-ynyl-4-aminobenzoate (2). ^{1}H NMR ($CDCl_3$): δ = 2.04 (t, J = 2.5 Hz, 1H, C≡C*H*), 2.65 (td, J = 6.8, 2.6 Hz, 2H, CH_2C≡CH), 4.09 (s, 2H, NH_2), 4.38 (t, J = 6.8 Hz, 2H, COCH_2), 6.6 (d, J = 8.5 Hz, 2H, benzene), 7.88 (d, J = 8.5 Hz, 2H, benzene).

Synthesis of P(ClCL-ran-CL)-co-PEG_{4000}-co-P(ClCL-ran-CL) (P(ClCLCL)-PEG-P(ClCLCL)). The required amounts of ClCL and CL (Table 1) were added to the mixture of PEG_{4000} (0.8 g, 0.2 mmol) and $Sn(Oct)_2$ (81 mg, 0.2 mmol) in a dried round-bottom flask. The mixture was melted at room temperature under vacuum for 15 min. The reaction was initiated in an oil bath at 120 °C under argon atmosphere and conducted for 24 h. The copolymer was collected and dried under vacuum after precipitation of chloroform solution in cold Hex.

Synthesis of P(N_3CL-ran-CL)-co-PEG_{4000}-co-P(N_3CL-ran-CL) (P(N_3CLCL)-PEG-P(N_3CLCL)). The substitution reaction of chloride pendant by sodium azide was performed as reported elsewhere.[23] Briefly, 5 mL of copolymer solution in dry DMF

dx.doi.org/10.1021/bc100270m |*Bioconjugate Chem.* 2011, 22, 582–594

Table 1. Fed Composition of Copolymerization of ClCL and CL

copolymers	fed molar ratio of [ClCL]	fed weight (g)	
		ClCL	CL
0.10 P(ClCLCL)-PEG-P(ClCLCL)	0.10	0.29	2.05
0.20 P(ClCLCL)-PEG-P(ClCLCL)	0.20	0.59	1.82
0.30 P(ClCLCL)-PEG-P(ClCLCL)	0.30	0.89	1.60

containing 2.0 g of copolymer (1 equiv of chloride pendant) was stirred with sodium azide (1.02 equiv) overnight under argon atmosphere at room temperature in the dried flask. The mixture was dried under reduced pressure and redissolved in toluene to precipitate the coincident salt. The remaining precipitate was centrifuged at 4000 rpm for 15 min. The collected supernatant was evaporated under reduced pressure to collect the purified copolymer.

Typical Click Chemistry Reaction. Using the reaction of copper-catalyzed Huisgen's 1,3-dipolar cycloaddition, the 3-butynyl ester derivatives of nicotinic acid and PABA were grafted onto the P(N_3CLCL)-PEG-P(N_3CLCL) backbone at 0.10, 0.20, and 0.30 molar ratios based on caprolactone repeating units. The reaction was conducted according to our previous experiment.[34] Briefly, azide tethered amphiphilic copolymer solution (1.2 g, 1 equiv of azide) in 10 mL of dry THF was transferred into dried reaction flask followed by the ordered addition of butynyl ester derivative of model compound (1.5 equiv), CuI (0.2 equiv), and base (0.2 equiv). Under atmospheric argon, the reaction was stirred in a thermostated bath under temperature controlled at 40 °C. After 4 h reaction, the solution was precipitated in cold Hex and the collected copolymer was dried in a vacuum desiccator for another 24 h.

Polymer Characterization. *Typical Characterization Methods for Synthesis of Grafted Copolymers.* ^{1}H NMR spectra were recorded in $CDCl_3$ or DMSO-d_6 at 300 or 500 MHz in the FT mode with Bruker Avance 300 apparatus at 25 °C. Infrared spectra were recorded with Jasco FT-IR-4100 spectroscopy. Number- and weight-average molecular weights (M_n and M_w, respectively) were measured by a Waters 150-CV gel permeation chromatograph equipped with refractive index detector. THF was used as the mobile phase at a flow rate of 1 mL/min. Two columns of PLgel 10 μm mixed B were calibrated with polystyrene standards in the MW range 4490−1 112 000 g/mol.

Thermal Property Analysis by Differential Scanning Calorimetry (DSC) and Thermal Gravimetric Analysis (TGA). TGA was carried out with a TGA 7 Perkin-Elmer thermogravimetric analyzer at 10 °C/min. DSC was performed using a DSC 7 Perkin-Elmer differential scanning calorimeter calibrated with indium. Glass transition and melting temperatures (T_g and T_m, respectively) were measured according to running conditions: the sample was quenched to −80 °C, heated to 100 °C (first heating), cooled down to −80 °C, and heated again to 100 °C (second heating). Thermograms were recorded during the second heating cycle at 20 °C/min.

Formation of Nanoparticles. Fifty milligrams of grafted copolymer were dissolved in 5 mL of THF. The polymer solution was added dropwise to 8 mL of Milli-Q water under magnetic stirring (1000 rpm) at room temperature. The solvent was removed under reduced pressure. The final volume was adjusted by Milli-Q water to the initial volume. The nanoparticle suspension was filtered through a cellulose acetate membrane with a pore size of 0.45 μm to eliminate any aggregates. One milliliter of nanoparticle suspension was poured into 2 mL vials. After lyophilization for 48 h, the weight of the lyophilized powder was recorded. In the case of IBU-loaded nanoparticles, 10 mg of drug was initially added with the copolymers in the THF solution, and the nanoparticles were prepared as previously described.

Characterization of Nanoparticles. *Particle Size and Zeta Potential Analysis.* The average particle diameter and size distribution of particles were analyzed by photon correlation spectroscopy (PCS) using a Zetasizer 3000 HSA (Malvern, UK). The samples were measured after dilution with Milli-Q water. The surface charge of the nanoparticles was determined by zeta potential analysis with a Zetasizer 3000 HSA (Malvern, UK) after dilution in Milli-Q water. All measurements were performed with a HeNe laser at the wavelength of 633 nm, a 90° angle, and a temperature of 25 °C.

Cytotoxicity Testing of Nanoparticles. The cytotoxicity of grafted amphiphilic nanoparticles was evaluated by the MTT assay. HUVECs at passage 3−5 were cultured in IMDM solution supplemented with 1% penicillin/streptomycin, 2% glutamine, 3% bicarbonate solution, 15% FBS, and 0.1% fibroblast growth factor. A 50 μL of cells suspension at a density of 3×10^5 cells/mL was seeded in a 96-well plate and incubated at 37 °C in an atmosphere of 5% CO_2 for 24 h. Afterward, 50 μL of culture medium containing the nanoparticle dispersion was added to yield the final concentration of nanoparticles in the range 0.01−1.56 mg/mL, and the cells were then incubated for another 24 h. Subsequently, the cells were incubated with MTT solution (25 μL) for 24 h. After an SDS solution was added and incubated for 6 h to dissolve the metabolized formazan crystal, the absorbance of solution was measured and recorded at 560 and 620 nm. The difference in absorbance was calculated and expressed as % cell viability. The cells incubated with only medium were used as cell control and defined as 100% cell viability.

Drug Loading and Entrapment Efficiency Evaluation. The nanoparticle suspension was centrifugally filtered at 16 000 rpm for 10 min through Microcon Ultracel YM-30 tube (MW cutoff 30 000 Da) (Millipore, USA). The amount of drug in the filtrate was analyzed by HPLC. The lyophilized powder was dissolved in the mobile phase and ultrasonicated for 30 min. The precipitate was centrifuged at 16 000 rpm for 10 min. The supernatant was collected for quantitative analysis by HPLC. The amount of drug entrapped in nanoparticles was calculated from the different amounts of drug found in the lyophilized powder and that in the filtrate. Drug loading (% DL) and entrapment efficiency (% EE) were calculated according to eqs 1 and 2 as follows:

$$\%\ \text{Drug Loading} = \frac{\text{Amount of drug in lyophilized nanoparticles}}{\text{Amount of lyophilized nanoparticles}} \times 100 \quad (1)$$

dx.doi.org/10.1021/bc100270m |*Bioconjugate Chem.* 2011, 22, 582–594

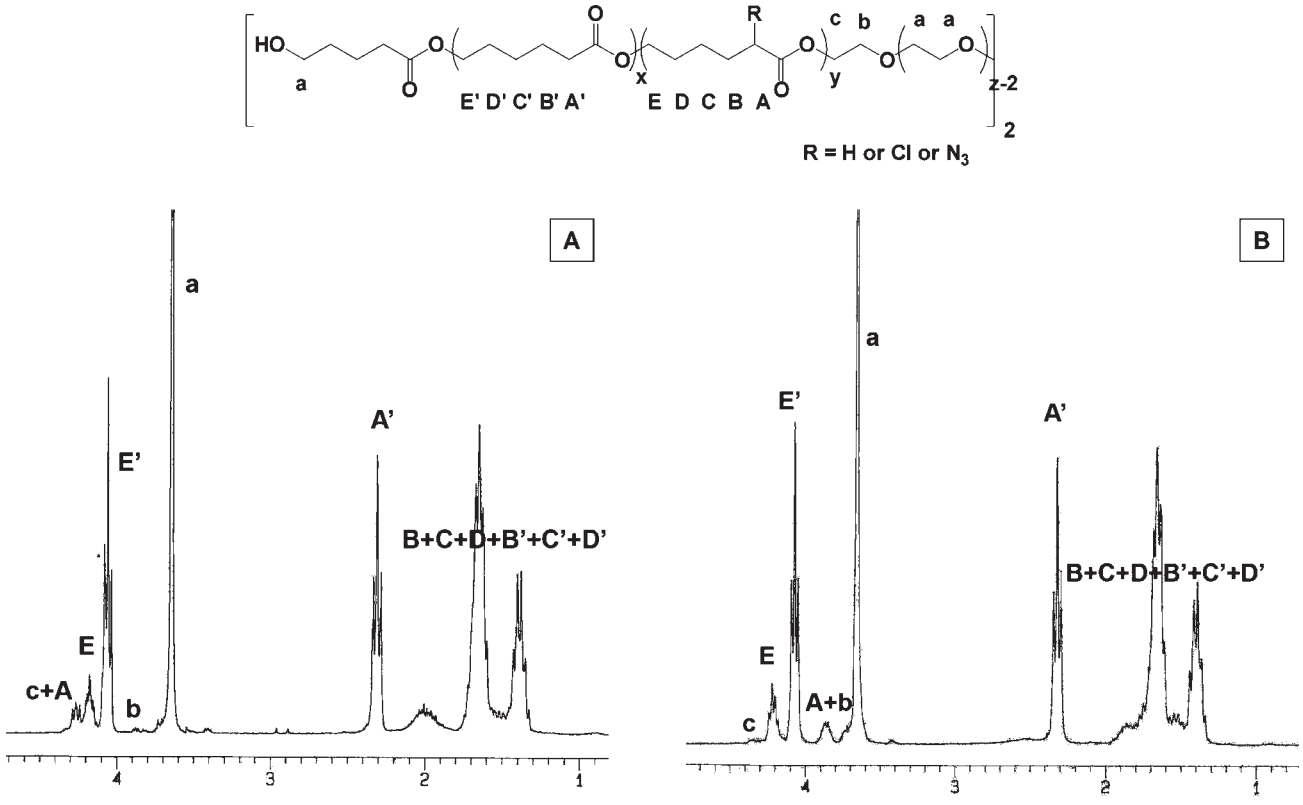

Figure 1. ^{1}H NMR spectra of P(ClCLCL)-PEG-P(ClCLCL) (A) and P(N_3CLCL)-PEG-P(N_3CLCL) (B), respectively.

$$\%\ \text{Entrapment Efficiency} = \frac{\text{Amount of drug in lyophilized nanoparticles}}{\text{Initial amount of drug added}} \times 100 \quad (2)$$

HPLC Measurement for Quantitative Analysis of Drug Loaded. IBU was quantitatively analyzed by HPLC (Shimadzu, Japan) consisting of an autoinjector SIL-10A (Shimadzu), a pump (Shimadzu LC-10AD), and a UV detector (Shimadzu SPD-10AV). This drug was eluted through a reverse-phase Hypersil ODS column, 5 μm particle size, 250 × 4.6 mm (Thermo Scientific, USA) using the mixture of methanol: water: acetonitrile: acetic acid (35:55:10:1) as a mobile phase at a flow rate of 1.4 mL/min. The peak area was calculated at wavelength of 264 nm using a calibration curve over the range 2.5−40 μg/mL.

Statistical Analysis. Results were recorded as mean ± SD of at least three measurements. The one way ANOVA with the Scheffe test applied post hoc for paired comparisons was performed to compare multiple groups. All analyses were performed using the SPSS program (*SPSS 13.0* for Windows), and differences were considered to be significant at a level of p-value < 0.05.

RESULTS AND DISCUSSION

Synthesis of P(ClCL-*ran*-CL)-*co*-PEG$_{4000}$-*co*-P(ClCL-*ran*-CL) (P(ClCLCL)-PEG-P(ClCLCL)). In order to graft the desired compounds on the PCL-PEG-PCL backbone, the chloride pending PCL-PEG-PCL was initially fabricated at the various ratios and further converted to the azide pending copolymer. P(ClCLCL)-PEG-P(ClCLCL) at molar ratios of 0.10, 0.20, and 0.30 relative to caproyl unit was successfully fabricated by ring-opening polymerization using PEG$_{4000}$ as an initiator and Sn(Oct)$_2$ as a catalyst (Scheme 1). The yield of all copolymers was higher than 80%. The M_n of the synthesized copolymers was calculated from the NMR spectrum (Figure 1A) according to eqs 3−6 as previously reported with some modification.[5,35] The molar ratios of ClCL units with respect to caproyl unit (F^a_{ClCL}) and polymer chain (F^b_{ClCL}) were calculated using eqs 7 and 8, respectively. All molecular parameters are listed in Table 2.

$$M_{n,\text{NMR}} = M_{n,CL} + M_{n,CICL} + M_{n,PEG} = 114x + 148.5y + 44z \quad (3)$$

$$\frac{2(x-1)}{I_{A'}} = \frac{4}{I_b} \quad (4)$$

$$\frac{3(y-1)+4}{(I_{A+cEE'} - I_{A'})} = \frac{4}{I_b} \quad (5)$$

$$\frac{4(z-2)+4}{I_a} = \frac{4}{I_b} \quad (6)$$

$$F^a_{\text{ClCL}} = \frac{\frac{1}{3}[I_{A+cEE'} - I_{A'} - I_b]}{\frac{1}{3}[I_{A+cEE'} - I_{A'} - I_b] + \frac{1}{2} I_{A'}} \quad (7)$$

[a] Molar ratio of ClCL or N_3CL units calculated based on caproyl unit. [b] Molar ratio of ClCL or N_3CL units calculated based on polymer backbone. [c] Determined by ^{1}H NMR spectroscopy. [d] $M_{n,theo} = \{([CL]/[PEG_{4000}]) \times 114\} + \{([ClCL \text{ or } N_3CL]/[PEG_{4000}]) \times M_{ClCL \text{ or } N3CL}\} + M_{n,PEG4000}$ (where [CL] and [ClCL or N_3CL] are the molar concentration of CL and ClCL or N_3CL, respectively. [PEG_{4000}] is the molar concentration of PEG_{4000} (initiator), $M_{ClCL \text{ or } N3CL}$ is the molecular weight of ClCL or N_3CL, respectively, and $M_{n,PEG4000}$ is the number-average molecular weight of PEG_{4000}). [e] Determined by GPC. [f] No peak observed.

$$F^b_{ClCL} = \frac{\frac{1}{3}[I_{A+cEE'} - I_{A'} - I_b]}{\frac{1}{3}[I_{A+cEE'} - I_{A'} - I_b] + \frac{1}{2}I_{A'} + \frac{1}{4}I_a} \quad (8)$$

where $I_{A'}$ is the integral of methylene proton of CL unit at 2.30 ppm, $I_{A+cEE'}$ is the integral of protons of ClCL unit in the range 4.00−4.25 ppm and methylene proton in PEG end unit at 4.23 ppm, I_a is the integral of methylene proton in PEG unit at 3.65 ppm, I_b is the integral of methylene proton in PEG end unit at 3.90 ppm, and x, y, and z are the corresponding repeating number of CL, ClCL, and PEG units, respectively.

From Table 2, the $M_{n,NMR}$ values of P(ClCLCL)-PEG-P(ClCLCL) were in agreement with the theoretical values. However, the $M_{n,GPC}$ values of the copolymers from GPC results were less than those from NMR. It could be attributed to the change in hydrodynamic volume of P(ClCLCL)-PEG-P(ClCLCL) bearing hydrophilic and hydrophobic segments. Another reasonable explanation is that the molecular weight of this amphiphilic copolymer was calculated relative to the hydrophobic poly(styrene) standard whose intrinsic viscosity is tremendously different from that of this copolymer.[36,37] However, the values of the molar ratios of substituted chloride (F^a_{ClCL} and F^b_{ClCL}) were consistent with the theoretical values (Table 2).

Synthesis of P(N_3CL-*ran*-CL)-*co*-PEG_{4000}-*co*-P(N_3CL-*ran*-CL) (P(N_3CLCL)-PEG-P(N_3CLCL)). P(N_3CLCL)-PEG-P(N_3CLCL) was obtained by the substitution reaction between P(ClCLCL)-PEG-P(ClCLCL) and sodium azide at room temperature prior to

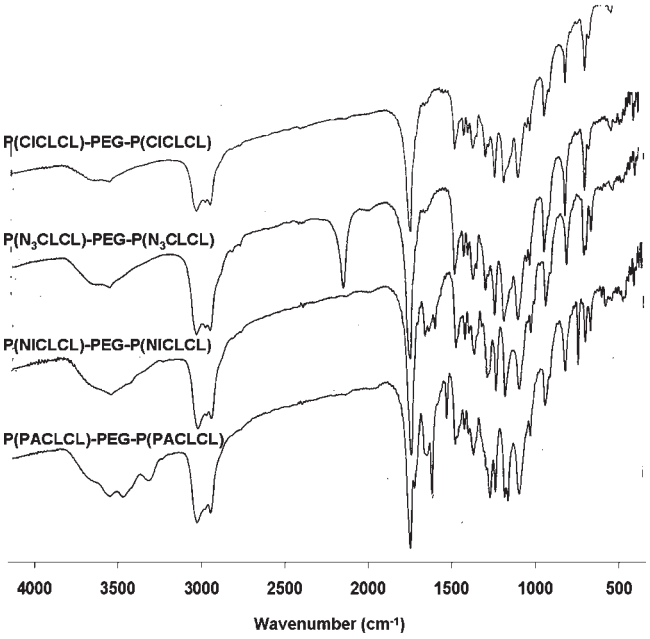

Figure 2. FT-IR spectra of P(NICLCL)-PEG-P(NICLCL) in the presence of DBU and P(PACLCL)-PEG-P(PACLCL) in the presence of TEA in comparison with P(ClCLCL)-PEG-P(ClCLCL) and P(N_3CLCL)-PEG-P(N_3CLCL).

grafting the selected molecules (Scheme 1). The conversion was complete after overnight reaction. As monitored by FT-IR, the characteristic peak of azide at 2100 cm^{-1} was apparent (Figure 2). ^{1}H NMR spectrum (Figure 1B) confirmed the complete conversion as seen by the entire disappearance of methyne proton peak (C*H*Cl) at 4.25 ppm and the presence of azide peak (C*H*N_3) at 3.85 ppm. The M_n of P(N_3CLCL)-PEG-P(N_3CLCL) was calculated from the NMR spectrum (Figure 1B) according to eqs 9−12 as previously reported with some modification.[5,23,35] The molar ratios relative to caproyl unit ($F^a_{N_3CL}$) and polymer backbone ($F^b_{N_3CL}$) were calculated according to eqs 13 and 14, respectively. The other molecular parameters are illustrated in Table 2.

$$M_{n,NMR} = M_{n,CL} + M_{n,N_3CL} + M_{n,PEG} = 114x + 155y + 44z \quad (9)$$

$$\frac{2(x-1)}{I_{A'}} = \frac{4}{I_c} \quad (10)$$

$$\frac{(y-1)+4}{I_{A+b}} = \frac{4}{I_c} \quad (11)$$

$$\frac{4(z-2)+4}{I_a} = \frac{4}{I_c} \quad (12)$$

$$F^a_{N_3CL} = \frac{(I_{A+b} - I_c)}{(I_{A+b} - I_c) + \frac{1}{2} I_{A'}} \quad (13)$$

$$F^b_{N_3CL} = \frac{(I_{A+b} - I_c)}{(I_{A+b} - I_c) + \frac{1}{2} I_{A'} + \frac{1}{4} I_a} \quad (14)$$

where $I_{A'}$ is the integral of methylene proton of CL unit at 2.30 ppm, I_{A+b} is the integral of methyne proton of N_3CL unit at 3.85 ppm and methylene proton in PEG end unit at 3.90 ppm, I_a is the integral of methylene proton in PEG unit at 3.65 ppm, I_c is the integral of methylene proton in PEG end unit at 4.23 ppm, and x, y, and z are the corresponding repeating number of CL, N_3CL, and PEG units, respectively.

The $M_{n,NMR}$ values of P(N_3CLCL)-PEG-P(N_3CLCL) were in agreement with the theoretical values. However, $M_{n,GPC}$ was lower than $M_{n,NMR}$ as previously discussed for P(ClCLCL)-PEG-P(ClCLCL). The molecular weight of P(N_3CLCL)-PEG-P(N_3CLCL) was decreased as compared to P(ClCLCL)-PEG-P(ClCLCL) due to a consequence of the hydrodynamic volume change in the substitution of chloride by azide.[23] The molar ratios of substituted azide ($F^a_{N_3CL}$ and $F^b_{N_3CL}$) agreed well with the theoretical values. The % conversion of chloride to azide was almost 100% indicating the completeness and feasibility of the reaction.

Grafting of Model Compounds along P(N_3CL-*ran*-CL)-*co*-PEG$_{4000}$-*co*-P(N_3CL-*ran*-CL) by Click Reaction. The 3-butynyl ester derivatives of two model compounds (nicotinic acid and PABA) were attached onto the backbone through copper-catalyzed Huisgen's 1,3-dipolar cycloaddition reaction using CuI and DBU as catalysts at 40 °C for 4 h (Scheme 1). The FT-IR spectra confirmed the conversion as the azide peak at 2100 cm^{-1} completely disappeared, while the presence of triazole peak at 1610 cm^{-1} was observed (Figure 2). Additionally, the characteristic peak of azide (C*H*N_3) at 3.85 ppm in NMR spectrum also disappeared and the methyne proton peak of triazole ring was observed at 7.70 ppm (Figure 3). From the NMR spectrum, the molar ratios of the grafting model compound based on the caproyl unit and polymer chain ($F^a_{grafted\text{-}CL}$ and $F^b_{grafted\text{-}CL}$, respectively) were calculated from the integration of the methyne proton of the grafted CL unit at 5.30 ppm (I_A, Figure 3) and the methylene proton of CL unit at 2.30 ppm (I_D, Figure 3) according to eqs 15 and 16, respectively.

$$F^a_{grafted\text{-}CL} = \frac{I_A}{\frac{1}{2} I_D + I_A} \quad (15)$$

$$F^b_{grafted\text{-}CL} = \frac{I_A}{\frac{1}{2} I_D + I_A + \frac{1}{4} I_H} \quad (16)$$

The calculation of grafting efficiency was made by the molar ratios of N_3CL unit and grafting unit using the characteristic methyne protons close to azide at 3.85 ppm and triazole ring at 5.30 ppm in the NMR spectra, respectively. Under this condition, the grafting efficiency of all copolymers was in the range 73−85%, depending on the type and amount of grafting compounds. In addition, the grafting molar ratios ($F^a_{grafted\text{-}CL}$ and $F^b_{grafted\text{-}CL}$) were in agreement with the theoretical values (Table 3).

Nicotinic Acid (P(NICLCL)-PEG-P(NICLCL)). The grafting of nicotinic acid (heterocyclic model compound) also was achieved. In addition to the apparent characteristic peak of triazole (Figure 3A), the peak of methyne proton close to azide at 3.85 ppm disappeared totally, and a peak at 5.30 ppm corresponding to the peak of methyne proton of caproyl unit adjacent to triazole ring was observed. The peaks at 7.45, 8.30, 8.70, and 9.25 ppm were assigned as the characteristic peaks of the proton in the pyridine ring of the

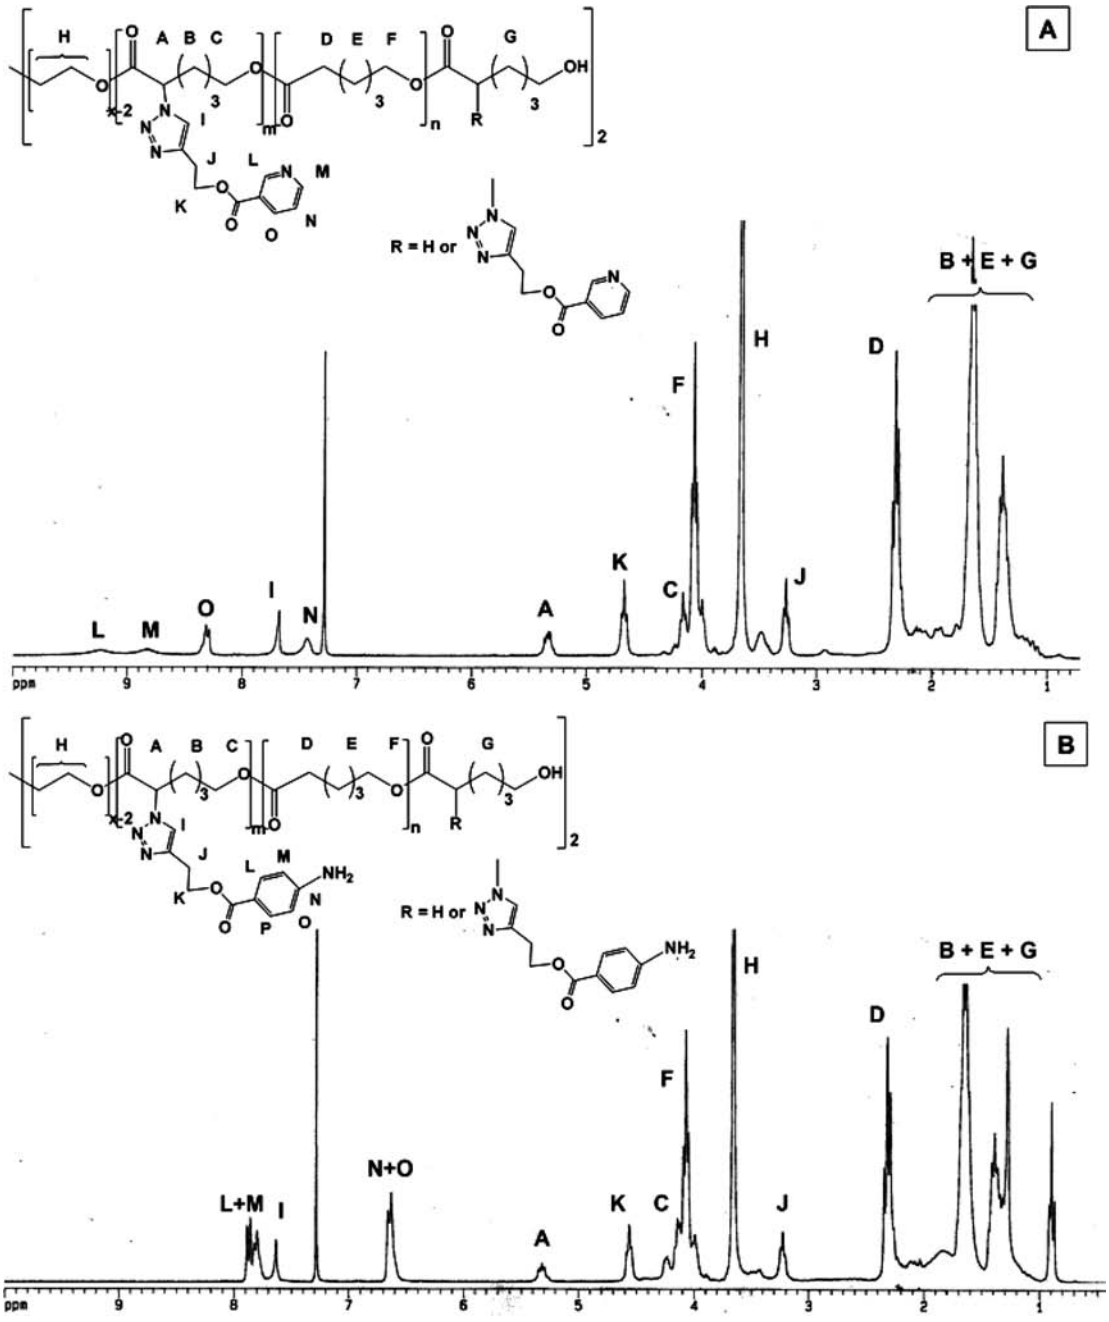

Figure 3. ^{1}H NMR spectra of P(NICLCL)-PEG-P(NICLCL) (A) and P(PACLCL)-PEG-P(PACLCL) (B) using DBU and TEA as base, respectively.

nicotinic acid molecule. Moreover, C═C stretching at 1590 cm^{-1} and C═N stretching at 1625 cm^{-1} were observed and contributed to the overlapping between the triazole and the pyridine ring of nicotinic acid (Figure 2). From $M_{n,GPC}$ values (Table 3), the molecular weight of the grafted copolymers was increased as compared to those of P(N_3CLCL)-PEG-P(N_3CLCL) (Table 2). The molecular weight distribution was narrower than those of the original polymers. The GPC chromatograms of most grafted copolymers (Figure 4A) revealed a unimodal peak indicating no degradation of the polymer chain. However, the GPC chromatogram of **0.30**P(NICLCL)-PEG-P(NICLCL) showed a small shoulder peak which may suggest slight degradation.

PABA (P(PACLCL)-PEG-P(PACLCL)). On the basis of our previous study,[34] it was notable that the aniline group induces the chain degradation under this condition, particularly that in presence of the strong base, DBU, leading to an occurrence of intra- and intermolecular transesterifications. In addition, in the case of hydroxyl group of propargyl alcohol,[23] the resulting grafted copolymers underwent a chain degradation when using DBU as base in the reaction. The extent of degradation appeared to be less with the use of triethylamine (TEA) instead of DBU. Therefore, TEA was used in this study for the grafting of PABA. Similarly to the grafting of nicotinic acid, the reaction was complete after 4 h under this condition. This successful approach could be visualized by the presence of the characteristic methyne proton of the triazole ring at 7.65 ppm and the benzene ring of PABA at 6.65 and 7.85 ppm, respectively (Figure 3B). In addition, the FT-IR spectrum showed the peaks of N−H

stretching at 3400 cm^{-1} and C═O stretching at 1725 cm^{-1} of PABA. The peaks of C═N stretching at 1626 cm^{-1} of the triazole ring and C═O stretching at 1725 cm^{-1} of the polyester polymer were also observed (Figure 2). At 0.10 and 0.20 molar ratios, the PABA grafted copolymers showed no degradation similar to the nicotinic acid grafted copolymers as supported by increasing $M_{n,GPC}$ values and narrowing molecular weight distribution (Table 3). Unlike the nicotinic acid grafted copolymers at 0.30 molar ratios, the PABA grafted copolymers showed no degradation as seen from the unimodal peak in the GPC chromatogram (Figure 4B).

Thermal Properties of Copolymers and Grafted Copolymers. The thermal properties of the grafted copolymers were evaluated by DSC and TGA because these properties may affect the rate of drug release from the polymeric carriers. The T_g and T_m values of all copolymers are illustrated in Tables 2 and 3. As shown in Table 2, the T_g values of P(N_3CLCL)-PEG-P(N_3CLCL) and P(ClCLCL)-PEG-P(ClCLCL) tended to increase as compared to those of the unsubstituted copolymer (PCL-PEG-PCL, $T_g \approx -60$ °C[38]). In the case of T_m, both chloride- and azide-substituted copolymers revealed a lower T_m than that of the unsubstituted material (PCL-PEG-PCL, $T_m \approx 55$ °C [38]). With increasing percent substitution, a trend in reduction of T_m values was observed. However, P(N_3CLCL)-PEG-P(N_3CLCL) provided a higher melting temperature than those of P(ClCLCL)-PEG-P(ClCLCL) at all ratios.

In the case of grafting nicotinic acid (heterocyclic model) and PABA (aromatic model) (Table 3), T_g was also recorded for all grafted copolymers. Both grafting model compounds showed an effect on thermal properties. Particularly with the grafting PABA, this effect was more pronounced than the grafting with nicotinic acid at all ratios. The heterocyclic compound yielded a lower T_g than the aromatic model, and T_g increased when the number of grafting units increased in both cases. In the case of the melting point, T_m of the nicotinic acid grafted copolymers decreased gradually with increasing number of grafting units. On the contrary, at 0.20 and 0.30 molar ratios of PABA, it did not yield a T_m indicating that PABA had more influence on crystallinity of the polymer backbone than the nicotinic acid at the same ratio. From the results, it can be concluded that grafting heterocyclic and aromatic models reduced the crystallinity of polymer. This might

dx.doi.org/10.1021/bc100270m |*Bioconjugate Chem.* 2011, 22, 582–594

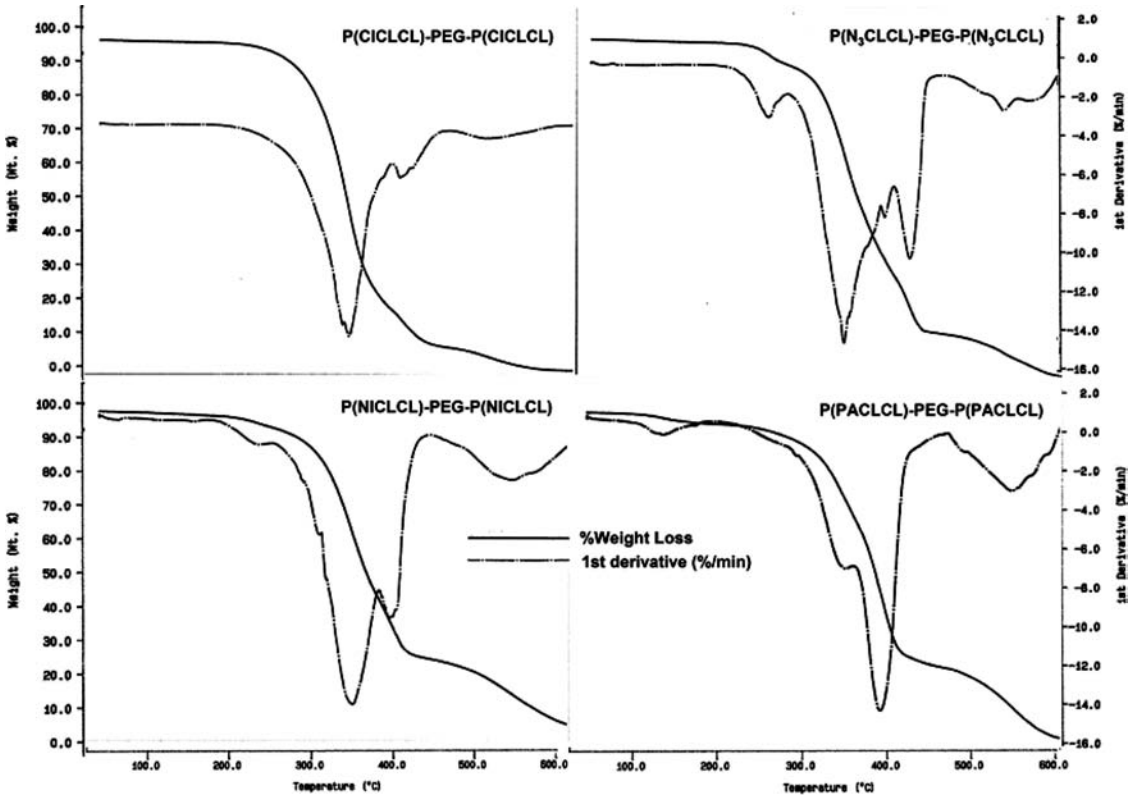

Figure 5. Thermal gravimetric diagrams of P(ClCLCL)-PEG-P(ClCLCL), P(N_3CLCL)-PEG-P(N_3CLCL), and P(NICLCL)-PEG-P(NICLCL) using DBU as base, and P(PACLCL)-PEG-P(PACLCL) using TEA as base, respectively.

be due to the fact that the sterically hindered molecule interrupted the orientation of the polymer chain and thus restricted the crystallization of polymer chain. The reduction of the crystallinity may affect the permeability of drug through the matrix of copolymer when forming the micro- and nanoparticulate systems.

The thermal stability of the grafted amphiphilic copolymers depends on the intrinsic properties of the materials, which is essential for practical use. To investigate the thermal degradation of the grafted copolymers, a TGA analysis was performed (Figure 5). It was found that P(ClCLCL)-PEG-P(ClCLCL) initially underwent thermal degradation at 250 °C similar to the degradation of poly(ClCL)[39] and had the inflection point at around 330 °C. The main degradation pattern was similar to PCL-PEG-PCL as previously reported by Gou et al.[1] However, a small peak of degradation at 400 °C was observed which may be attributed to the decomposition of the PEG segment at this high temperature.[37] Therefore, ClCL and CL were randomly copolymerized, since only one inflection point was detected in the main degradation curve. In the case of P(N_3CLCL)-PEG-P(N_3CLCL), the first step was attributed to the initial rupture of azide (N−N_2) starting at the temperature around 200 °C.[40,41] The last two steps of thermal decomposition were observed similar to those of P(ClCLCL)-PEG-P(ClCLCL). According to the thermograms of heterocyclic and aromatic grafted PCL-PEG-PCL, the small degradation peaks were observed at 240 °C for P(NICLCL)-PEG-P(NICLCL) and 140 °C for P(PACLCL)-PEG-P(PACLCL) with respect to about 9.4% and 6.5%, respectively. These results were consistent with the molar ratio of grafting unit along the whole polymer backbone. The first step degradation was supposed to be a consequence of the decomposition of grafting units. The main degradation peaks of grafted copolymers were observed at different temperatures, which were around 340 and 490 °C for P(NICLCL)-PEG-P(NICLCL) and P(PACLCL)-PEG-P(PACLCL), respectively, depending on the composition of copolymer. The last pattern of thermal degradation was typically detected corresponding to the degradation of PEG segment. However, further details are required to ascertain the underlying mechanism.

From these results, it can be concluded that grafting could change the polymer backbone from the semicrystalline to amorphous form, thus altering the thermal properties. With an increase in the molar ratios of grafting units, the copolymers became more amorphous. In addition, the grafting molecules affected the thermal stability of the copolymer.

Nanoparticle Formation with Grafted Amphiphilic Copolymers. Nanoparticles were prepared from heterocyclic and aromatic models grafted copolymers, and the effect of the different properties of the grafted copolymer on nanoparticle formation was studied. It was found that all nanoparticles prepared from P(NICLCL)-PEG-P(NICLCL) were significantly smaller than those from P(PACLCL)-PEG-P(PACLCL) (Table 3 and Figure 6). With both grafting compounds, the particle size of nanoparticles increased with increasing amounts of grafting untis (p-value < 0.05) except for **0.10**P(PACLCL)-PEG-P(PACLCL), whereas the size distribution tended to be smaller for P(NICLCL)-PEG-P(NICLCL) (p-value > 0.05). Indeed, it has been stated in general that the hydrophobic domain of amphiphilic copolymers has an effect on the formation of nanoparticles and micelles.[42−44] As the hydrophobic portion of the polymer chain increased, the size of particles became larger. In this study, the grafting heterocyclic ring of nicotinic acid

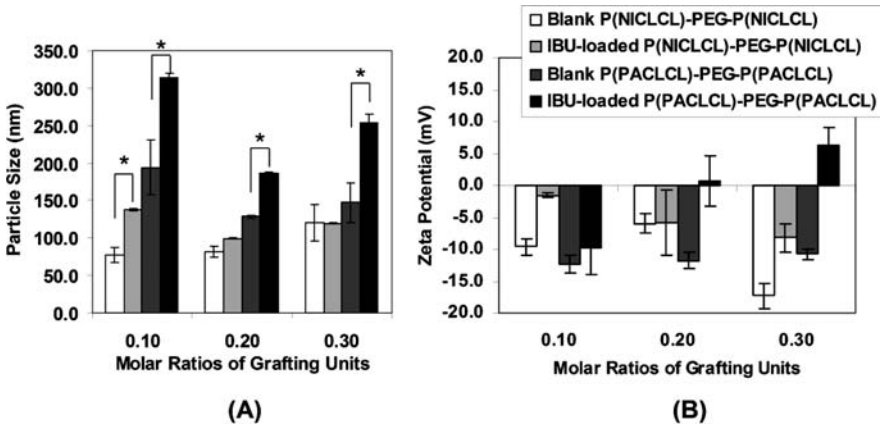

Figure 6. Particle size (A) and zeta potential (B) of blank and IBU-loaded nanoparticles (*p-value < 0.05).

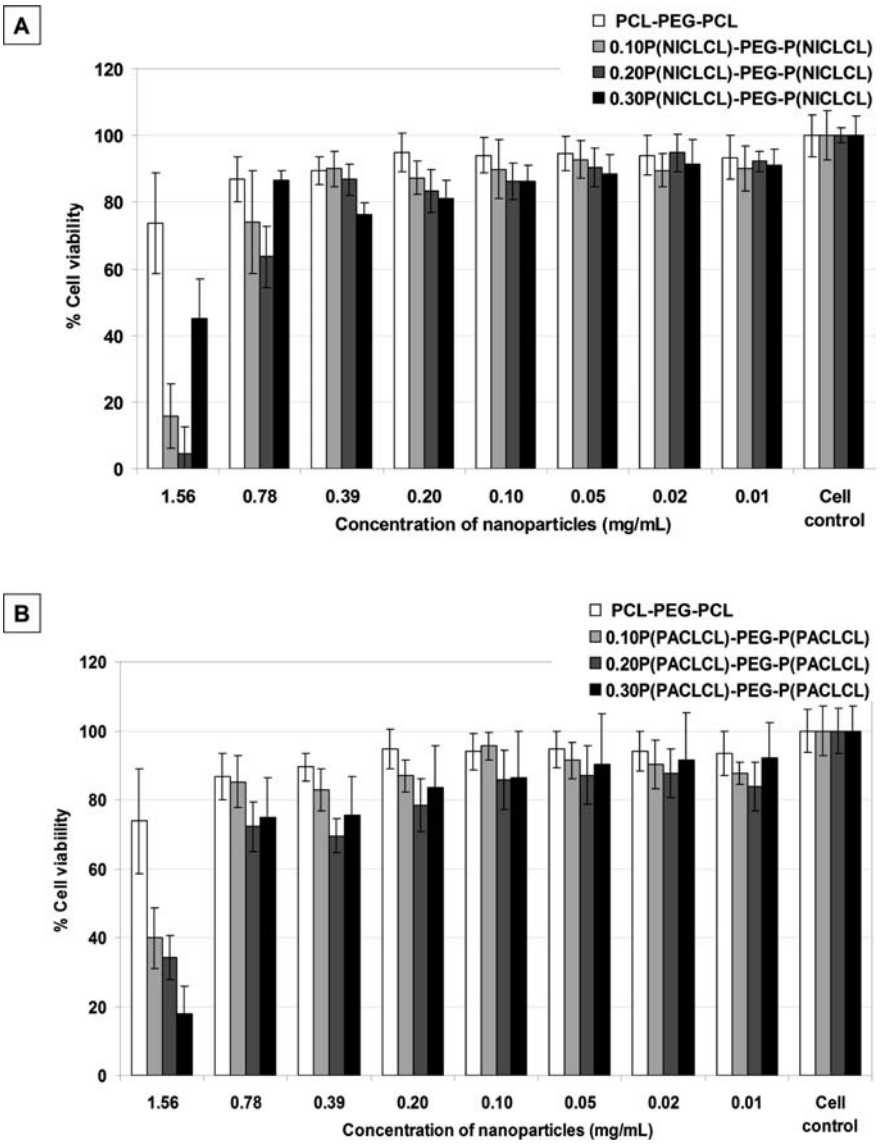

Figure 7. Cytotoxicity results of P(NICLCL)-PEG-P(NICLCL) and P(PACLCL)-PEG-P(PACLCL) nanoparticles at all molar ratios of grafting units compared to PCL-PEG-PCL nanoparticles.

and aromatic ring of PABA increased hydrophobicity of the polymer chain. In the case of **0.10**P(PACLCL)-PEG-P(PACLCL), the larger particles were observed owing to secondary aggregation. It has been stated that the secondary aggregates were a

dx.doi.org/10.1021/bc100270m |*Bioconjugate Chem.* 2011, 22, 582–594

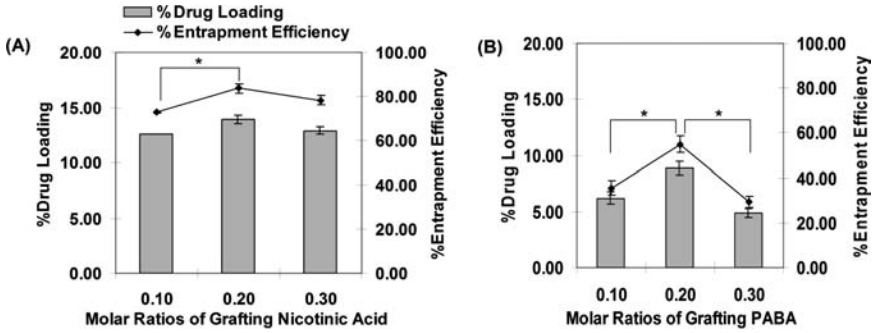

Figure 8. % Drug loading (column) and % entrapment efficiency (diamond) after incorporation with IBU into P(NICLCL)-PEG-P(NICLCL) (A) and P(PACLCL)-PEG-P(PACLCL) (B) nanoparticles (*p-value < 0.05).

consequence of hydrophobic−hydrophobic or van der Waals interactions between exposed cores from hydrophobic fragments of randomly grafted copolymer. Once the exposed cores are in close contact with water, they aggregate to large particles.[45,46] This could be confirmed by the bimodal peak observed in the PCS size distribution curve based on volume, whereas a unimodal peak was observed in the PCS size distribution curve based on intensity. The particle size shown in Table 3 was based on the intensity of the scattering light; therefore, the particle size of **0.10**P(PACLCL)-PEG-P(PACLCL) was the average diameter of two groups referring to individual nanoparticles and the secondary aggregates.

Considering the surface charge of nanoparticles (Table 3 and Figure 6), all nanoparticles of grafted copolymers showed more negative charge on their surface compared to the PCL-PEG-PCL nanoparticles which had a charge of almost zero (data not shown). This could be due to some grafted material present on the outer surface of the nanoparticles.

Cytotoxicity of Nanoparticles. To ascertain the safety of the grafted copolymers, all grafted copolymers were tested for their cytotoxicity using HUVECs. In order to avoid the use of organic solvents, the self-assembled nanoparticles were prepared and tested for their toxicity. These results are presented in Figure 7. It was observed that the PCL-PEG-PCL nanoparticles were toxic to HUVECs at the concentration of 1.56 mg/mL. The cytotoxic concentrations of **0.10**P(NICLCL)-PEG-P(NICLCL) and **0.10**P(PACLCL)-PEG-P(PACLCL) nanoparticles were found at 0.78 and 1.56 mg/mL, respectively. The increasing molar ratios of grafting nicotinic acid and PABA decreased the toxic concentration. The percent cell viability of **0.30**P(NICLCL)-PEG-P(NICLCL) at 0.78 mg/mL was higher than that at 0.39 mg/mL probably due to the variations in cells. From the results, it can be deduced that **0.10**P(PACLCL)-PEG-P(PACLCL) nanoparticles showed a similar toxicity compared to the PCL-PEG-PCL nanoparticles, whereas **0.10**P(NICLCL)-PEG-P-(NICLCL) nanoparticles showed a higher toxicity to HUVECs. In addition, the toxicity of the grafted nanoparticles increased when the molar ratios of grafting units increased.

IBU-Loaded Grafted Amphiphilic Nanoparticles. As stated earlier, the different structure between heterocyclic and aromatic models may affect the drug entrapment efficacy of the nanoparticles. In the present study, IBU was chosen as a model drug to investigate the effect of different structures and amount of grafting compounds on the loading efficiency of these nanoparticles. After encapsulation of drug in nanoparticles, the particle sizes of all grafted nanoparticles became larger as compared to the blank nanoparticles except for **0.30**P(NICLCL)-PEG-P(NICLCL) nanoparticles, for which the change in particle size was not significant (p-value > 0.05) (Figure 6A).

Concerning the efficiency of these carriers (Figure 8), the percentages of drug loading (% DL) and drug-entrapment (% EE) were evaluated. At all ratios of P(NICLCL)-PEG-P(NICLCL), the amount of IBU loaded into the nanoparticles was significantly higher than that into the nanoparticles prepared from P(PACLCL)-PEG-P(PACLCL) (p-value < 0.05). This result could be explained by the interaction between drug and grafting compounds of polymer. As mentioned previously, both nicotinic acid and PABA possibly interact with loaded drug by either $\pi-\pi$ stacking interaction or hydrogen bonding. In the case of $\pi-\pi$ stacking interaction from the aromatic ring, the extent of electron delocalization in the aromatic ring is in the following order: aniline of PABA > benzene of IBU > pyridine of nicotinic acid. The amino group of PABA mesomerically donates electrons to benzene ring, which is more predominant than electron withdrawal by the inductive effect of the nitrogen atom. Meanwhile, the nitrogen atom in the pyridine ring of nicotinic acid profoundly withdraws electrons leading to the localization of the electron in the pyridine ring and then showing a stronger basic effect. According to this fact, this $\pi-\pi$ stacking interaction in terms of electron charge transfer may be slightly involved because the benzene ring of IBU acts as an electron donor to the pyridine ring of nicotinic acid but as an electron acceptor for the aniline ring of PABA. Finally, the benzene ring of IBU can likely be in contact in planar formation with the aromatic ring of each compound.[47] In the case of hydrogen bonding, a hydroxyl group of carboxylic acid of IBU is more active than a carbonyl group due to the electron resonance between both groups of carboxylic acid of IBU. Thus, the carboxylic acid of IBU acts as a hydrogen bond donor rather than as an acceptor. By comparison of the pyridine ring of nicotinic acid and the aniline group of PABA with regard to the carboxylic acid of IBU, the hydrogen bonding thus predominantly occurs between the hydrogen bond donor of carboxylic acid of IBU and the hydrogen bond acceptor of the nitrogen atom in the pyridine. From the FT-IR results, it indicated that IBU formed hydrogen bonds with the pyridine ring of nicotinic acid grafted on the copolymer (data not shown). On the other hand, this bonding between IBU and PABA did not occur, since the amino group of PABA could donate electrons to the benzene ring indicating that it acted as a hydrogen bond donor. According to the proposed interaction between drug and copolymer, it was expected that % DL and % EE should increase with the molar ratios of grafting units. From the results, it was found that % DL and % EE increased with the increasing molar ratios of grafting units (p-value < 0.05) except for 0.30 molar

ratios of grafting units. The similar reduction in % DL and % EE of both nicotinic acid and PABA grafting at 0.30 molar ratios was observed probably because the steric hindrance of the grafting unit at 0.30 molar ratio might limit the drug encapsulation.

Regarding the zeta potential of the prepared nanoparticles (Figure 6B), it was found that the loaded nanoparticles displayed smaller zeta potential values to those of the blank nanoparticles. For all grafting of P(NICLCL)-PEG-P(NICLCL), increasing the molar ratios of grafting units led to less negative zeta potentials of the loaded nanoparticles. In contrast, at 0.20 and 0.30 molar ratios of P(PACLCL)-PEG-P(PACLCL), the reversal of the charges to positive was observed. It is well-known that the zeta potential can be employed as an overall charge measured at the shear plane of the particles. It is affected by the molecules surrounding the surface of particles, which may deposit directly on the outer particle surface or be present in the water closely to this surface. Therefore, the decrease in zeta potential might be caused by solubilized IBU in water, since the solubility of IBU is pH-dependent.[48] At the pH of Milli-Q water (~6.0−6.5), IBU dissolves in ionized form (solubility at pH 6.0 = 0.23 mg/mL[48]) in the dispersion medium. Due to the lower drug encapsulation of the drug-loaded P(PACLCL)-PEG-P(PACLCL) nanoparticles, the ionized IBU might be more available in the dispersion medium compared to that of P(NICLCL)-PEG-P(NICLCL). Therefore, more ionized molecules, especially protons of ionized IBU, might surround the surface of P(PACLCL)-PEG-P(PACLCL) nanoparticles and consequently led to the positive charge of the loaded nanoparticles at 0.30 molar ratio of grafting units.

CONCLUSIONS

The modification of grafting heterocyclic and aromatic models (nicotinic acid and PABA) along PCL-PEG-PCL with various molar ratios of grafting units was successfully achieved through copper-catalyzed Huisgen's 1,3-dipolar cycloaddition. The difference in the molecular structure of grafting compounds influenced the feasibility of the grafting reaction and the physicochemical and thermal properties of the copolymers. In addition, the nanoparticles prepared from the grafting compounds exhibited different characteristics in terms of particle size, surface charge, drug loading capacity, and entrapment efficiency depending on the different interaction between the grafting compounds and drug molecules. The toxicity study of grafted nanoparticles demonstrated the safety of the grafted nanoparticles at 0.10 molar ratios of grafting units up to the concentration of 0.78 mg/mL. The toxicity of grafted nanoparticles increased with the molar ratios of grafting units. According to the present study, it can be concluded that the grafting of interesting compounds onto biodegradable polymers could modify the physicochemical and thermal properties of the copolymer and also the characteristics of nanoparticles including particle size, surface properties, and drug loading capacity.

Supporting Information

ABSTRACT: Viruses are of particular interest as scaffolds for biotechnology applications given their wide range of shapes and sizes and the possibility to modify them with a variety of functional moieties to produce useful virus-based nanoparticles (VNPs). In order to develop functional VNPs for cell imaging and flow cytometry applications, we used the head of the T4 bacteriophage as a scaffold for bioconjugation of fluorescent dyes. Bacteriophage T4 is a double-stranded DNA virus with an elongated icosahedron head and a contractile tail. The head is ~100 nm in length and ~90 nm in width. The large surface area of the T4 head is an important advantage for the development of functional materials since it can accommodate significantly larger numbers of functional groups, such as fluorescent dyes, in comparison with other VNPs. In this study, Cy3 and Alexa Fluor 546 were chemically incorporated into tail-less T4 heads (T4 nanoparticles) for the first time, and the fluorescent properties of the dye-conjugated nanoparticles were characterized. The T4 nanoparticles were labeled with up to 19 000 dyes, and in particular, the use of Cy3 led to fluorescent enhancements of up to 90% compared to free Cy3. We also demonstrate that the dye-conjugated T4 nanoparticles are structurally stable and that they can be used as molecular probes for cell imaging and flow cytometry applications.

INTRODUCTION

Recently, the use of viral nanoparticles (VNPs) as materials for biotechnology applications has gained interest given their biocompatibility, the diversity of shapes and sizes, and the possibility to tailor their surface characteristics.[1−4] VNPs produced from plant and animal viruses and bacteriophages have been used in biosensing, imaging, vaccine development, and drug and gene delivery.[3−7] Of these, bacteriophages (or phages) are among the most promising candidates as scaffolds in biotechnology applications due to their robust nature and unique display system, which enables the expression of a wide variety of peptides and polypeptides rendering diverse surface functionality.[3,8,9] The phage head varies in shape and size from micrometer-size in the filamentous type (fd, M13) to a few hundred nanometers in the spherical (PhiX174, G4, S13) and icosahedral type (T7, T4, MS2) and the tail, when present, can be contractile or flexible.[3,10,11] Bacteriophage T4 has several characteristics that distinguish it from other phage species and make it an ideal scaffold for biotechnology applications. For instance, it has a flexible and unique display system[12−14] that has been demonstrated to display peptides and full-length proteins on the viral capsids. Combining this feature with the possibility to engineer its morphology[15] significantly increases the range of functional materials that can be devised. In addition, when functionalized through chemical conjugation, the large surface area of the head allows a higher loading capacity and spatial distribution of the functional groups, which presumably leads to higher sensitivity.[16] The size and shape are also advantageous, because it has been demonstrated that cellular uptake occurs preferentially with spherical particles with sizes between 70 and 100 nm over elongated ones even with the same dimensions.[17]

Figure 1a presents a schematic representation of bacteriophage T4 consisting of an icosahedral head, a contractile tail, and tail fibers, while Figure 1b shows the concept of a T4 nanoparticle obtained through genetic engineering. Deletion of the tail and its fibers results in nanoparticles with dimensions of ~100 × ~90 nm^2,[18,19] which can be functionalized with fluorescent dyes using standard bioconjugation techniques.

Bacteriophage T4 has been proven useful in sensor probes[20−22] and vaccine carriers,[23−25] and the use of tail-less T4 nanoparticles (T4 NPs) as detection elements has been suggested,[26] yet no practical applications have been reported to date. We previously used atomic force microscopy to examine the variables that influence tail-less T4 NP assembly on surfaces.[19] In the work presented here, we demonstrate, for the first time, the use of T4 NPs as fluorescent probes for cellular imaging and flow cytometry applications. The properties of the T4 NP give it the potential of becoming a viable scaffold for biomaterial applications, but we are currently limited by the scarcity of information on its surface chemistry. The large size of the T4 head makes it

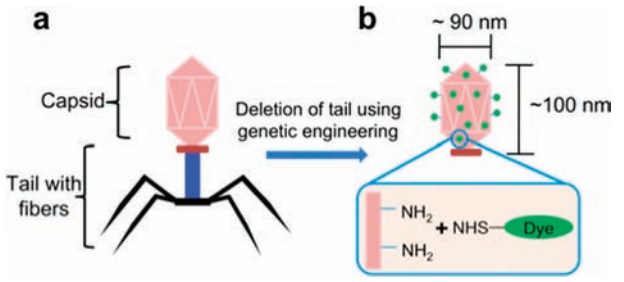

Figure 1. Experimental strategy for probe synthesis. (a) Schematic representation of bacteriophage T4. (b) Schematic representation of a tail-less T4 NP obtained by deletion of the tail using genetic engineering; functional T4 NPs can be developed by incorporating fluorescent dyes using standard bioconjugation techniques.

difficult to grow single crystals for X-ray crystallography at a resolution sufficient for determining the exact location of amino acids on the surface. The most current structure available comes from cryo-electron microscopy at a 2.2 nm resolution.[27] Thus, to further demonstrate its potential as an addressable nanobuilding block and understand its surface chemistry, the reactivity of the surface amines was investigated. While lysine groups are typically used to couple biomolecules due to their abundance and well-known chemistry, other amines may be available for conjugation as well. The total number of lysines on the T4 head is 32 303 (Supporting Information Table S1).

In the work presented here, we selected Cy3 and Alexa Fluor 546 as model dyes and characterized their performance on the T4 NP. These two fluorophores, while sharing similar excitation/emission spectra, have been reported to exhibit strikingly different performance characteristics, which are thought to be due, in part, to their molecular properties, but also to their neighboring interactions.[28,29] It is therefore relevant to understand their behavior on the T4 scaffold under a particular set of experimental conditions. Chemical bioconjugation of organic dyes has been utilized to prepare fluorescent probes using plant viruses such as cowpea mosaic virus (CPMV),[16,30−33] turnip yellow mosaic virus (TYMV),[34] tobacco mosaic virus (TMV),[35,36] and potato virus X (PVX);[37] however, there are fewer examples of the use of bacteriophages as scaffolds for this purpose.[38] In plant viruses containing small capsids, such as CPMV and TMV (30 and 28 nm in diameter, respectively), the number of dyes that can be incorporated is limited by the surface area of the capsids and corresponding reactivities of solvent-accessible amino acids on the virus surface. Precise control of the spacing between the dyes becomes more critical within this limited surface area in order to avoid dimer formation and quenching of the dyes.[32] While TMV with its "hollow-rod" shape has a larger surface area, the chemical conjugation is cumbersome, since commonly used residues, such as lysines, are not exposed on the surface.[35,39] PVX on the other hand has an elongated capsid (~500 nm × 18 nm), and even with this significantly larger surface area, the maximum number of dyes incorporated is only 1600 per capsid through primary amine modification.[37]

Here, we demonstrate that more than 1.9×10^4 dyes can be incorporated on a single T4 NP; to our knowledge, this is the highest number of dyes incorporated onto a single VNP. Our results also show that the T4 probes are so efficient that even those with dye numbers as low as 350 dyes per particle give good fluorescence intensities for *in vitro* applications. In addition, the dye-T4 NPs can be used to visualize cells and remain inside cells for at least 72 h.

EXPERIMENTAL SECTION

Purification of Tail-Less T4 Head Scaffolds. T4 K10 (38^- 51^-*denA*$^-$ *denB*$^-$), a kind gift from Dr. Lindsay Black at University of Maryland at Baltimore Medical School, was first propagated in the suppressor *Escherichia coli* host strain, CR63, to obtain the infectious phages. The infectious phages were then used to produce noninfectious tail-less T4 nanoparticles (T4 NPs) using the nonsuppressor host *E. coli* strain, Rosetta, modified from a previous procedure.[40] In brief, Rosetta grown in M9S (OD_{600} = 0.5) supplemented with 1/3 volume of Luria Broth were infected with K10 phage at a multiplicity of infection (MOI) = 3, followed by a repeated infection after 9 min and continued incubation for 2 h at 37 °C. Cells were spun down at 10 000 *g* for 10 min and resuspended in 50 mM potassium phosphate (pH 7.5) supplemented with 10 mM $MgCl_2$ and 2 mM $CaCl_2$; $CHCl_3$ (1/20 of total volume), DNase I (40 μg/mL), RNase I (50 μg/mL), and 0.4 μg of PMSF (phenylmethanesulfonylfluoride or phenylmethylsulfonyl fluoride) were then added to the cell suspension and the cells were gently shaken at 37 °C for 1−2 h. The cell debris was removed by spinning at 15 000 *g* for 30 min. The cell lysate containing the head scaffolds was concentrated through a Microcon YM-100 membrane according to the manufacturer's procedure (Millipore Corp, MA). The membrane was then washed 3−6 times with 50 mM potassium phosphate buffer, pH 7.5, supplemented with 10 mM $MgCl_2$ (50 KP/10 $MgCl_2$) and 0.1% sodium azide. The T4 NPs were then purified by gel filtration with Superose 6 (GE Healthcare Biosciences, NJ). The flowthrough and eluted fractions were then assessed using a 1.2% Tris-acetate agarose gel stained with either ethidium bromide or Coomassie blue.

Dye Conjugation. Tail-less T4 NP solutions in 50 KP/10 $MgCl_2$ and 0.1% sodium azide were desalted using a pre-equilibrated HiTrap Desalting Column (GE Healthcare Biosciences, Piscataway, NJ) and eluted fractions were analyzed by UV−vis spectroscopy (Cary 5000, Varian). The second 1.5 mL elution contained most of the T4 NPs. For the reaction optimization experiments, T4 NPs were reacted with fluorescein-5-isothiocyanate (FITC; Invitrogen, Carlsbad, CA) and Alexa Fluor 488 sulfodichlorophenol ester (Alexa488-SDP ester, Invitrogen) in various buffer conditions. When developing an optimally fluorescent dye-T4 NP, 9.0×10^{10} K10 heads (9 μg of protein) in 10% DMSO (Sigma-Aldrich, St. Louis, MO) were reacted with Cy 3 Mono NHS ester (Cy3-NHS; GE Healthcare Biosciences) or Alexa Fluor 546-NHS ester (Alexa 546-NHS; Invitrogen, Carlsbad, CA). Molar ratios of dye to T4 NP lysines were 0.1 (for Alexa Fluor 546 only), 0.6, 1.1, 1.5, 2.0, 2.8, 5, 10, 13, and 20. Prior to the addition of DMSO and dye, T4 NPs in 50 KP/10 $MgCl_2$ were incubated on ice for 5 min after which DMSO was added slowly with gentle mixing. Then, corresponding amounts of 10 μg/μL NHS-Cy3 or NHS-Alexa Fluor 546 in DMSO were added, and the mixture was vortexed. T4 NPs were kept at a concentration of 5.8×10^{11} particles/mL in the reaction mix, and the mixture was incubated at room temperature in the dark for 16 h. From these reactions, we obtained a series of samples containing a different number of dyes per T4 NP.

Dye-labeled T4 NPs were loaded separately into a Superose 6 prep grade (GE Healthcare Biosciences) column pre-equilibrated in 50 KP/10 $MgCl_2$/0.1% sodium azide. Individual 1 mL elutions were collected and analyzed by gel electrophoresis, atomic force microscopy, and UV−vis spectroscopy. For gel electrophoresis, 10 μL of unmodified and dye-labeled T4 NPs were loaded into a 1.2% agarose gel. The gel was visualized without staining using HP Scanjet 5590 scanner. DNA and protein visualization was also performed on the same gel using ethidium bromide and Coomassie blue staining, respectively. Images from

ethidium bromide staining were obtained using UVP Bio Doc-It system, a UV transilluminator. Coomassie blue stained images were captured by the HP scanner.

Spectroscopic Measurements. UV−vis spectroscopy was performed to determine the amount of T4 NPs and dye present in the reaction samples. Protein concentration was determined using a Bradford assay according to the manufacturer's procedure (Bio-Rad, Hercules, CA), and the number of T4 NPs per sample was then determined using the relationship that 1 mg of purified NPs is equivalent to 9.70×10^{12} tail-less T4 heads. The amount of Cy3 and Alexa 546 in the T4 solution was determined from absorbance at 550 and 555 nm, respectively, and by a standard curve produced using each free dye. UV−vis measurements were performed using Varian Cary-5000 UV−vis−near-IR spectrometer with Cary Win UV Scan Application v 3.00 software.

Fluorescence spectroscopy was also carried out to determine the fluorescence intensity (F.I.) of dye-T4 NPs. The Cy3-T4 and Alexa 546-T4 NPs were excited at 550 nm. The measurements were taken on a Cary Eclipse fluorescence spectrophotometer. To calculate the percentage of fluorescent enhancement, the following equation was used: ([dye-T4 complex F.I.] − [F.I. of free dye])/[dye-T4 complex F.I.] × 100.

Atomic Force Microscopy (AFM). For AFM characterization, 5 μL of the unmodified or dye-labeled T4 NPs were sonicated for 5−10 s, deposited on freshly cleaved mica, and kept in a humid environment at room temperature for 12 h. After adsorption of the T4 NPs onto the mica surface, the substrates were allowed to dry at room temperature, carefully rinsed with Milli-Q water, and allowed to dry at room temperature once more. Unmodified and conjugated T4 NPs were characterized using a Multimode scanning probe microscope (Veeco Instruments, Plainview, NY, USA) operated under tapping mode in air with a silicon cantilever (Nanoscience Instruments, Phoenix, AZ), 125 mm long, with an apex curvature radius of 5−6 nm, a resonant frequency of 300 kHz, and a spring constant of 40 N/m. The scanning rate was 0.5 Hz, at 0° angle. Image processing was performed using Research NanoScope II software ve 7.20. All images were filtered using the flattening built-in tool from NanoScope II software. Length and height values of the nanoparticles were obtained by utilizing the built-in tool for cross section analysis.

Cell Culture. A549 (American Type Culture Collection) lung cancer epithelial cells were grown at 37 °C under 5% CO_2 atmosphere in Dulbecco's modified Eagle's medium (DMEM), supplemented with 10% fetal bovine serum (FBS) (Cellgro, VA) and 1% (v/v) penicillin/streptomycin (Sigma, CA), and detached from culture flasks using trypsin-ethylenediamine-tetraacetic acid (EDTA) (Cellgro, VA). After the cells were harvested, they were counted and seeded onto microscope slides, 6-well tissue culture treated plates, or 24-well tissue culture treated plates and allowed to attach overnight.

Confocal Microscopy. A549 cells on microscope slides were treated with the dye-T4 NPs at varying times and concentrations in DMEM supplemented with 1% penicillin/streptomycin. The cells were then washed three times for 5 min each with 1 × PBS (phosphate buffered saline). The cells were fixed with 4% paraformaldehye in 1 × PBS for 15 min and then washed twice with 1 × PBS. The cells were then stained with 500 μM 4′,6-diamidino-2-phenylindole (DAPI) in 1 × PBS for 5 min and washed three times with 1 × PBS. Confocal microscopy was performed using a Nikon Eclipse TE2000 Confocal Imaging System, λ_{exe} = 402 nm (DAPI) and 561 (Cy3/Alexa 546). Images were taken with a 60× objective and are of integrated *Z*-stacks with 8 steps, 0.8 μm step size, and 10 averages per step.

Flow Cytometry. A549 cells on 24-well tissue culture plates were treated with 1×10^5 dye-T4 NPs per cell and analyzed at 4, 8, and 24 h. Following incubation, the cells were washed twice with 1 × PBS and harvested with trypsin−EDTA. The cells were then washed once with 1 × PBS and treated with a Live/Dead Fixable Far Red Dead Cell Stain Kit (Invitrogen, CA) according to the manufacturer's protocols. Following staining, the cells were washed twice in 1 × PBS, resuspended in 1 × PBS, and run on an Accuri C6 flow cytometer using standard lasers and filters for PE (FL-2) and APC (FL-4). For each sample, 2×10^4 events were collected in a gate corresponding to the cell population. To determine the percentage of live cells, a scatter plot showing the intensity of the Live/Dead reagent (FL-4) vs forward scatter (FSC) was gated for the population with the lowest fluorescence (live cells). The percentage of cells positive for the dye-T4 NPs was calculated using the histogram subtraction tool on FSC Express v 3.

Cell Tracking. A549 cells on 6-well tissue culture treated plates were treated for 6 h with 1×10^5 A546-T4 NPs per cell. The cells were then washed two times with 1 × PBS and harvested with trypsin−EDTA every 24 h up to 96 h. After harvesting, the cells were washed once with 1 × PBS and resuspended in 1 × PBS for counting and flow cytometry. The Nexcelom Cellometer Vision (Nexcelom, MA) with an optics module for Alexa 546 (VA-595−501) was used to count and measure the percentage of cells that contained A546-T4 NPs. Each time point was done in triplicate.

RESULTS AND DISCUSSION

Conjugation of Dyes on T4 NPs. The T4 phage head offers a spherical viral capsid that is similar in geometry to other widely used viral nanoparticles, but with the advantage of having a larger surface area for functionalization with dyes, proteins, antibodies, and inorganic nanoparticles. Large spherical viral capsids offer well-defined geometry, are relatively rigid, and offer better spatial distribution of conjugated functional groups. In order to create a noninfectious nanoparticle (NP) for various biomedical applications, the T4 bacteriophage was expressed without the tail (Figure 1b). The tail-less T4 NPs were purified from *E. coli*, and 3 mg T4 NPs/L of bacteria was recovered with >90% purity.

We then used the purified T4 NPs to explore the accessibility of the amine groups to dye modification. There is no information about the location or accessibility of the individual amino acids on the T4 NPs; therefore, by determining the number of reactive amines one can assess its utility for the applications presented here and as a potential scaffold for further chemical conjugation with antibodies, proteins, and targeting molecules.

Reaction conditions were selected based on the stability of the T4 NP and the reactivity of dyes in the selected conditions. In general, reactions carried out in buffer alone resulted in an average of 10× lower reactivity in comparison to reactions carried out in 90:10 buffer to DMSO, due to the enhanced solubility of the dye in DMSO. In addition, including $MgCl_2$ (1, 2, or 10 mM) in the reaction buffer enhanced the stability of T4 and did not affect the reactivity of the dyes. In early optimization reactions, fluorescein-5-isothiocyanate (FITC) and Alexa Fluor 488 sulfodichlorophenol ester (Alexa488-SDP ester) were compared to determine the level of reactivity of the T4 NP amines in different buffer conditions. Both dyes have similar spectral characteristics, which facilitates the comparison of UV−visible data when determining number of dyes per T4 NP. FITC is known to provide reasonable specificity toward the ε-amine of lysine,[30,41] while Alexa 488-SDP ester reacts with all primary amines in a similar manner as common NHS-ester dyes. By comparing FITC with Alexa 488-SDP, one can derive conclusions about the availability of amines on the T4 surface.

FITC demonstrated low labeling efficiency when the reaction was performed in the optimal T4 NP buffer (50 mM potassium

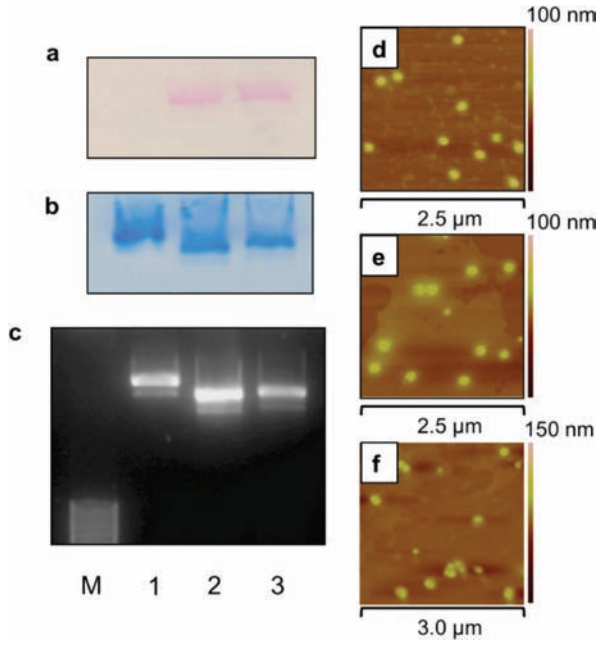

Figure 2. Characterization of the T4 NPs. Lane M: DNA marker. Lane 1: Unlabeled-T4 NP control. Lane 2: Alexa 546-T4 NP. Lane 3: Cy3-T4 NP. Right: Atomic force microscopy (AFM) topographical images of (d) unlabeled-T4 NPs, (e) Cy3-T4 NPs, (f) Alexa 546-T4 NPs. For AFM, 1.5×10^9 particles were deposited on freshly cleaved mica.

phosphate pH 7.5, 10 mM $MgCl_2$, 10% DMSO) instead of the manufacturer's recommended buffer (100 mM sodium bicarbonate, pH 9.0, 10% DMSO). However, the Alexa 488-SDP reacted similarly in both the optimal T4 NP buffer and its recommended buffer (100 mM sodium bicarbonate, pH 8.3, 10% DMSO). In order to compare the relative reactivity of FITC and Alexa 488-SDP ester, a series of reactions were performed in the recommended buffers for each dye. Our results showed a 30% higher load of Alexa 488 in comparison to FITC (data not shown). This result indicates that the SDP ester is labeling additional amines in comparison to FITC, presumably α-amines, since FITC is known to provide reasonable specificity toward ε-amines of lysines. On the basis of this information, for our current studies we used NHS ester-dyes, which are similar in reactivity to the SDP ester, but are available in a wider variety of dyes with different spectral characteristics. Cy3 NHS ester and Alexa Fluor 546 NHS ester dyes were reacted with T4 NPs at various molar ratios of dye to lysine to produce NPs with a range of dyes/virus (D/V).

Characterization of Dye-T4 NPs. To analyze the electrophoretic mobility and structural integrity of the T4 NPs after dye attachment and corresponding purification, the NPs were analyzed using agarose gel electrophoresis and atomic force microscopy (AFM). Figure 2 shows three views of an agarose gel that allows us to characterize different aspects of the Dye-T4 NPs. In Figure 2a, the gel has not been stained and the pink bands correspond to the dye conjugated on the NP. This indicates that the dye is coupled to the NP, since the band is running at the position expected for the unlabeled-T4 NP. Free dye, which is expected to run at a position closer to the bottom of the gel, was not observed, demonstrating the efficient purification of the dye-T4 NPs from free dye. Figure 2b shows a gel stained with ethidium bromide. The major band under UV irradiation indicates that the DNA is inside an intact NP. Figure 2c shows an agarose gel stained with Coomassie blue, which stains the intact T4 NPs. The fact that the bands in lanes 2 and 3 correspond to the same bands in all three visualization methods indicates that indeed the dyes are coupled to intact T4 NPs. When comparing the electrophoretic mobility of the unlabeled-T4 NP control (lane 1) and the dye-T4 NPs (lanes 2−3), it can be observed that the dye-T4 NPs have a net charge of higher negative character than the control, since both complexes ran farther into the agarose gel. This effect has been observed in the past with fluorescent dyes and is most likely due to the addition of negative charges associated with the binding of the dyes.[42] Both Cy3 and Alexa Fluor 546 NHS esters have a net negative charge (Supporting Information Figure S1) and eliminate one positive charge upon reacting with each amine group on the T4 surface.

In addition to the agarose gel, atomic force microscopy (AFM) topographical images were used to examine the structural features of the unlabeled and dye-labeled T4 NPs. Figure 2d−f shows that the T4-NPs with defined shapes and borders are well-dispersed. Cross-sectional analysis found that the average length of the unlabeled nanoparticle is 169 ± 14 nm, which is larger than the predicted length of 119.5 nm from the cryo-EM model.[43] Its average height is 39 ± 3 nm, half of what was predicted from cryo-EM (Figure 2d). The difference in length is mainly due to both virus collapsing and AFM tip effect; however, the differences in height of the T4 NPs prepared here can be explained by the loss of DNA from the NP during preparation. According to our solution spectroscopic analysis of the T4 NPs, 10% of the capsids still contain DNA. The empty NPs are collapsed to half of the original height during drying for AFM measurements and therefore are most likely flattened on the surface, which may also extend the length. Slight differences in the different labeled T4 NPs are most likely caused by varying degrees of collapse and flattening.

Overall, the height and length measurements of the unlabeled and dye-T4 NPs are comparable. The observed shape and close values of the average length and height between the unmodified and the modified T4 NPs indicate that the capsid withstands the conditions used for the chemical conjugation and purification. The relevance of assessing the structural stability of the T4 NPs after modification finds its rationale in the possible effects that dimethylsulfoxide (DMSO) can have on the cellular membrane and protein denaturation.[44,45] Although this solvent is widely used in many biology and molecular biology processes, DMSO can denature protein complexes such as the T4 NP. In the present study, the DMSO concentration was kept at 10%; however, we observed significant degradation of the scaffold at higher concentrations of DMSO (data not shown). This degradation is usually evident under AFM imaging as a layer of debris consisting of small clusters of material of irregular shape and size, as well as the presence of DNA. While other spherical virus capsids are less stable in the absence of DNA or RNA, the T4 NPs are stable under our reaction conditions as shown by gel electrophoresis and AFM.[46]

Spectroscopic Properties of Dye-T4 NPs. UV−vis measurements were taken of the Cy3-T4 and Alexa-T4 NPs and compared to spectra from the free dyes and unlabeled T4 NPs. Figure 3 shows T4 NP samples labeled with Cy3 and Alexa 546. The 260−280 nm peaks in the T4 spectra represent the

absorbance of the viral genomic DNA inside the T4 NP and the capsid proteins, respectively, while the peaks in the visible region represent the dye absorbance. There is a small red shift (5 nm) in absorption maxima of the Cy3 upon conjugation to the T4 NP, which is known to indicate cyanine dye−protein coupling.[47] Alexa 546-T4 NPs also show a slight shift in the dye absorbance compared to free Alexa 546, which is typical of other Alexa fluorophores.[48]

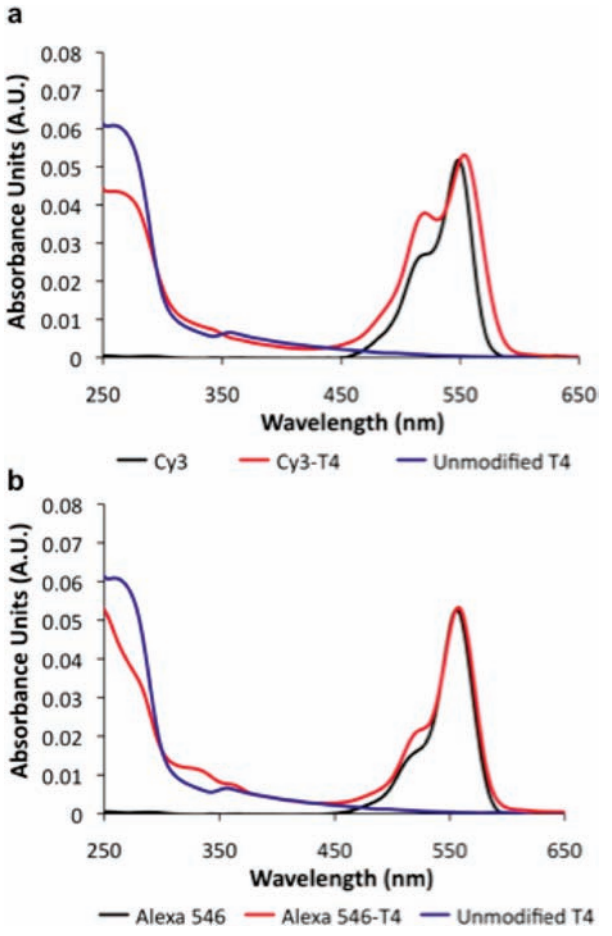

Figure 3. UV−vis spectra showing (a) Cy3 NHS ester (black), T4 NP after conjugation with Cy3 (red), and T4 NP (blue); (b) Alexa 546 NHS ester (black), T4 NP after conjugation with Alexa 546 (red), and T4 NP (blue). Absorbance is normalized relative to dye concentration.

Dye per Virus (D/V) Measurements. The absorbance measurements taken at the dye wavelengths for each dye-T4 NP sample along with the number of NPs present in each sample were used to calculate the D/V. As the molar excess of dyes to lysines was increased, the D/V increased up to 1.9×10^4 Alexa 546 dyes at 20 dyes to T4 NP lysines (Supporting Information Figure S2). This D/V ratio is 2 orders of magnitude higher than other isocosahedral viruses, such as CPMV[30] and 1 order of magnitude higher than the maximum D/V on the rod-shaped potato virus X and tobacco mosaic virus.[35,37] This high degree of labeling is possible due to the large number of amine groups present on the T4 NP (Supporting Information Table S1).

Fluorescence Properties of Dye-T4 NPs. Fluorescence emission of the dye-T4 complexes was studied as a function of D/V. As shown in Figure 4a and Supporting Information Table S2, fluorescence emission increases as the number of dyes in the Cy3-T4 is increased up to 715 D/V (orange line Figure 4a); beyond that point. fluorescence decreases as the number of dyes increases presumably due to quenching. In contrast, for the Alexa546-T4 series (Figure 4b) the best fluorescence output is obtained at 2166 D/V (orange line). To further analyze this phenomenon, the individual samples were compared to corresponding free dye in solution. Figure 5 shows the fluorescence enhancement obtained from the dye−T4 complexes calculated relative to a comparable amount of free dye in solution. All of the Cy3-T4 NPs examined showed enhanced fluorescence vs free Cy3 dye (Figure 5a) indicating that conjugation to the T4 changes the fluorescence characteristics of the dye. However, the enhancement of the Cy3-T4 NPs decreases linearly as the number of D/V increases (r = 0.99). In contrast, most of the Alexa546-T4 NPs examined show quenched fluorescence (negative enhancement) compared to free Alexa 546, and the effect is only linear up to 1500 D/V (r = 0.97 for Figure 5b, red squares only). Fluorescence enhancement has been observed previously in cyanine dyes and is caused by an increase in quantum yield, which is highly dependent upon solvent polarity and viscosity.[32,49,50] Upon binding to the T4, the Cy3 experiences a loss in conformational freedom, as well as a decrease in

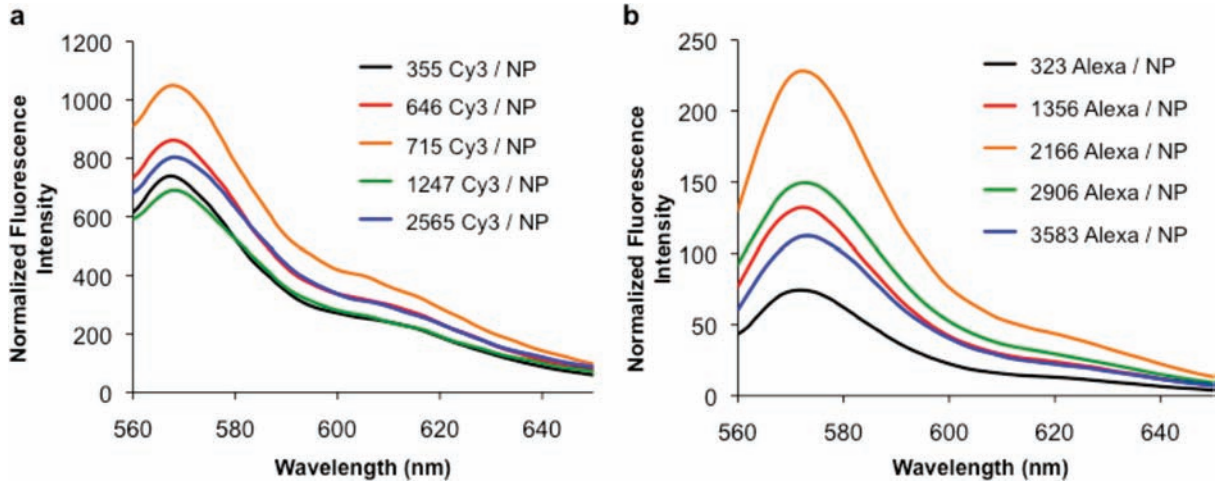

Figure 4. Fluorescence emission of dye-T4 NPs. Samples were excited at 550 nm and data were normalized relative to the number of unmodified T4 NPs: (a) Cy3-T4 samples, (b) Alexa 546-samples.

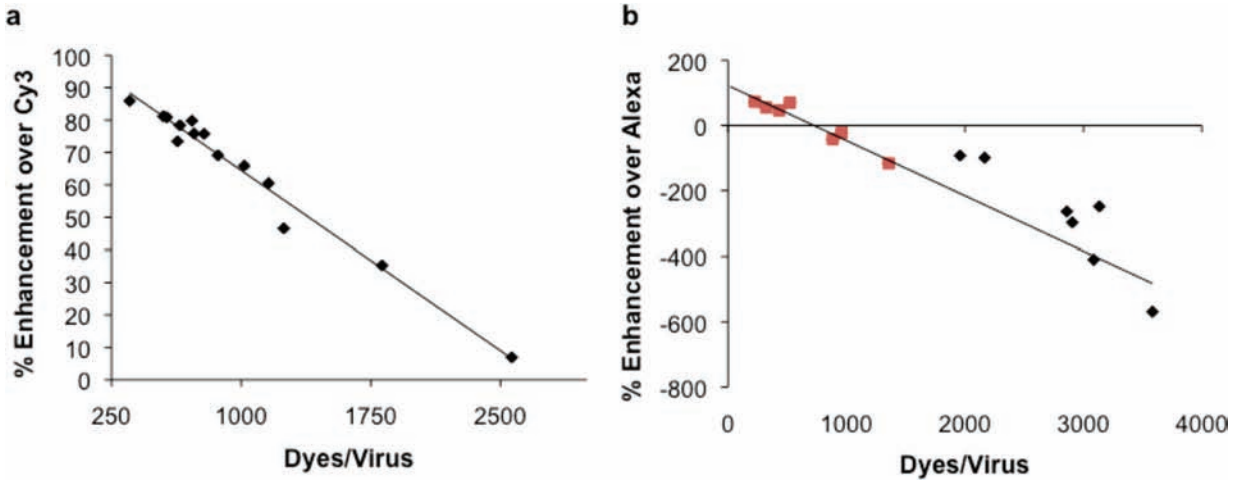

Figure 5. Fluorescence enhancement of dye-T4 NPs. Fluorescence enhancement of dye-T4 NPs as a function of dyes/virus calculated relative to free dye. Emissions of the Cy3-T4 and Alexa 546-T4 NPs were measured at 570 and 575 nm, respectively: (a) Cy3-T4 series; (b) Alexa 546-T4 series. Percentage of fluorescent enhancement is defined as follows: ([dye-T4 complex F.I.] − [F.I. of free dye])/[dye-T4 complex F.I.] × 100.

polarity at the site of binding, both leading to an increase in quantum yield.[50] Fluorescence enhancement in Alexa dyes has not been observed previously to our knowledge and may be due to energy transfer from the protein amino acids to the Alexa dye.

While fluorescence enhancement is occurring in Cy3 and to a lesser extent Alexa 546 when they are bound to the T4 NP, fluorescence quenching is causing the decreases in fluorescence at higher D/V in both dyes. Quenching can arise from dye−dye interactions and is often accompanied by a change in the absorption spectrum of the dye.[51,52] Evidence of dye−dye interactions (such as stacking or aggregate formation) can be observed in the absorption spectra of the Cy3 labeled T4 NP in Figure 3a. The free Cy3 dye has an absorption maximum at 555 nm with a shoulder at 520 nm. When the dye is bound to the T4 NP, there is an increase in the 520 nm peak in relation to the 555 nm peak. This increase in absorbance at 520 nm or blue shift can be attributed to nonfluorescent dimer formation.[50,51] A blue-shifted absorption band also appears to a lesser extent in the Alexa 546-T4 absorbance spectra and has been observed in Alexa dyes previously.[28,53] Dye−dye interactions are highly dependent on the location of the dyes on the virus, and while we have no information on the location of the dyes, the large surface area of the T4 NPs most likely prevents certain dye−dye quenching that would be observed with smaller VNPs.

Dye−protein interactions also cause quenching by photon-induced electron transfer (PET) and have been known to play a role in the quenching of Alexa dyes.[54] PET occurs when an excited dye molecule (donor) transfers its excited-state electron to another molecule (acceptor) when they are in close van der Waals contact. Recently, Chen et al. found that certain Alexa dyes were found to be quenched by interactions with tryptophan, tyrosine, methionine, and histidine residues.[54]

Dye-T4 NPs as Molecular Probes. The high fluorescence output and biocompatibility of dye-T4 NPs make them ideal molecular probes for cellular imaging and flow cytometry. To explore their application as molecular probes, the cellular uptake was explored using the lung cancer cell line, A549. Confocal microscopy was used to qualitatively investigate the interaction between the dye-T4 NPs and A549 cells at different incubation times (Figure 6). A549 cells were treated with Cy3-T4 (786 D/V) or Alexa 546-T4 NPs (2282 D/V) at a ratio of 1 cell to 10^5 T4 NPs. The nuclei were visualized by DAPI staining (blue), and the dye-T4 NPs are shown as small yellow spots distributed though the cell interior. Both dye-T4 NPs, Cy3-T4 and Alexa 546-T4 NPs, were clearly visible inside cells after 4, 8, and 24 h (Figure 6a−f). Unmerged and brightfield images of Alexa-546-T4 NP at 24 h incubation (Figure 6c) are shown in Figure S3 (Supporting Information).

The cellular uptake was also explored by flow cytometry, which can be used to separate and quantitatively measure fluorescently labeled cell populations using different molecular probes. We measured the cellular uptake by examining the change in fluorescence between the dye-T4 treated cells and the untreated cells. Figure 7a,b shows that a clear shift is present when cells are treated with both dye-T4 NPs in comparison to untreated cells. Furthermore, the results from the flow cytometry measurements were used to quantitatively measure the uptake of the dye-T4-NPs into cells at different time points. The percentage of cells positive for dye-T4 NPs was determined by subtracting the treated histograms from the untreated. Our results indicate that the percentage of cells that are positive for dye-T4 NPs is greater than 50% at all time points, suggesting that the uptake of T4 NP is quite efficient in our treatment condition. We also used flow cytometry to determine the cell viability after cellular uptake of dye-T4 NPs by staining both treated and untreated cells with a live/dead stain. More than 92% of the cells containing the dye-T4 NPs were alive compared with >95% of untreated cells (data not shown). This suggests that dye-T4 NPs have low cytotoxicity, even after 24 h. The ability to use dye-T4 NPs for flow cytometry opens the possibility of a number of applications including cell tracking, mechanistic studies, and immunoassays.

Aside from lung cancer cells, tail-less T4 NPs were also found to enter into noncancerous primary cultured cells, such as human endothelial cells, liver cells, and murine astrocytes in vitro (data not shown). While eukaryotic cells are not their natural hosts, coliphages along with their hosts are mammals' symbiots in the intestines and some phages may pass through the membrane and circulate in the blood system. Thus, T4 may adapt to the mammalian environment and likely interacts with eukaryotic

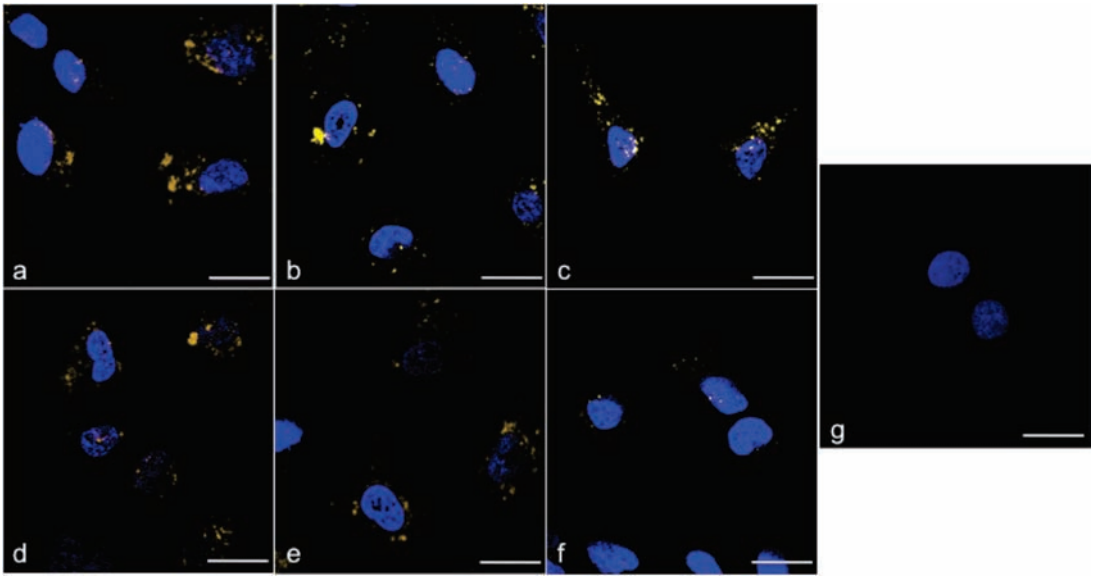

Figure 6. Confocal microscopy images of A549 cells after uptake of dye-T4 NPs at different time points. Uptake of Alexa 546-T4 NPs (2282 D/V): (a) 4 h after incubation, (b) 8 h, (c) 24 h. Uptake of Cy3-T4 NPs (786 D/V) after incubation at (d) 4 h, (e) 8 h, and (f) 24 h. (g) Untreated cells, negative control. Imaging was performed under 60× magnification. The scale bar is 10 μm.

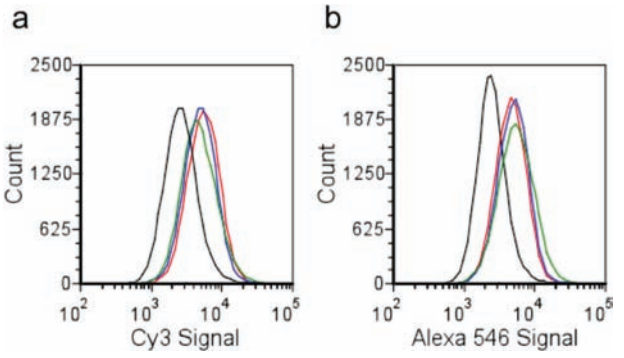

Figure 7. Flow cytometry histograms of A549 cells treated (a) Cy3-T4 NP (786 D/V) and (b) Alexa-T4 NP (2282 D/V) at different time points after incubation, 4 h (red), 8 h (blue), and 24 h (green); untreated cells after 24 h incubation are used as negative control (black line).

cells. It is believed that the interaction with eukaryotic cells is determined by the head surface protein contents and membrane proteins. Therefore, the uptake of dye-T4 by eukaryotic cells may be specific through certain molecular interactions. Some evidence suggests that bacteriophage T4 interacts with cancer cells in vitro by binding to integrin β3 through the Lys-Gly-Asp (KGD) amino acid motif, a homologue to Arg-Gly-Asp (RGD), within the minor capsid protein, gp24.[55] Likewise, our purified T4 NPs may preferentially bind and enter integrin $\beta3^+$ A549 and noncancerous primary cultured cells, possibly through receptor mediated endocytosis. We are currently investigating the cellular uptake mechanisms of dye-T4 NPs.

Interestingly, besides interacting with integrin β3, a nonessential head protein, Hoc, may also help to generate immune response by presenting phage T4 to macrophage and dendritic cells, through its three tandem immunoglobulin like domains.[56] This suggests that macrophage and dendritic cells may also preferentially take up dye-T4 NPs.

Table 1. Cell Proliferation Tracking over Time

time[a]	% positive[b]	total cells
0	93	81 900
24	84.2	105 700
48	24.8	161 000
72	4.6	382 600
96	1.4	1 105 000

[a] Time following 6 h T4 NP treatment. [b] % positive for A546 T4 NP as determined by Cellometer fluorescence measurements.

Cell Tracking. The ability to fluorescently label cells and track their proliferation can be useful in a variety of in vitro and in vivo studies. To explore this application for T4 NPs, we treated A549 cells with A546-T4 (2962 D/V) for 6 h and allowed the cells to grow for up to 96 h following treatment. A cell counter equipped with a fluorescence module was used to measure the number of cells and percentage of cells positive for T4-NPs. Table 1 shows that, as the cells divided and the number of total cells increased, the percentage of cells positive for A546-T4 NP decreased (Table 1). After 96 h, the percentage of cells positive for A546-T4 NPs decreased to 1.4%, a level equal to the background from untreated cells. We were also able to visualize this effect by taking images of the counted cells and observed a decrease in cellular fluorescence over time (Supporting Information Figure S4). When comparing the treated cells to untreated cells, there is no significant decrease in proliferation in dye-T4 NP treated cells (data not shown).

The fluorescence of the cells was also measured by flow cytometry. Figure 8 shows that, over time, as the cells proliferate, the fluorescence of the cell population decreases and the population becomes more heterogeneous (Figure 8). This supports the hypothesis that, over time, the fluorescence signals will decrease due to the dilution of A546-T4 NPs to newly divided cells. Our results demonstrate that the internal dye-T4 can

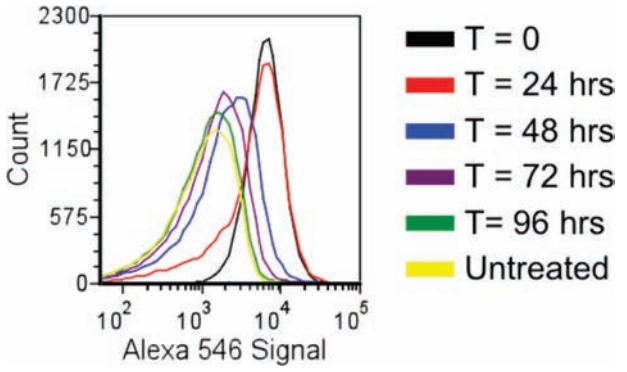

Figure 8. Flow cytometric detection of cell proliferation over time following A546-T4 NP treatment.

remain inside A549 cells for at least 72 h and dye-T4 NPs can be used to quantitatively track cellular proliferation.

CONCLUSIONS

We have successfully developed a novel viral nanoparticle, using tail-less T4 heads, as scaffolds for dye attachment, and moreover, the resulting fluorescent Cy3-T4 and Alexa 546-T4 can serve as molecular probes for cellular imaging and flow cytometry. Large surface areas and protein contents of T4 NPs give the tail-less T4 NPs more functional groups and more flexibility for dye conjugation than other viruses. The structure and size of dye-T4 NPs are close to that of unlabeled T4 NPs, and the T4 NPs are intact and stable after conjugation and purification. For the first time, we conclusively demonstrated that T4 enters eukaryotic cells using our dye-T4 NPs. Dye-T4 NPs can stay inside A549 cells at least 72 h and serve as ideal molecular probes for tracking cells, since cellular uptake of dye-T4 NPs can be clearly visualized by fluorescent microscopy, and cells positive for dye-T4 uptake can be distinguished and quantified by flow cytometry. The dye-T4 NPs can be used as a tool to understand in detail the molecular mechanisms of cell entry and the fate of the T4-NPs within cells. We are currently focusing on investigating this topic and the effect of surface modification on uptake into eukaryotic cells.

Besides using dye-T4 for in vitro studies, it is also possible to use dye-T4 NPs as *in vivo* molecular probes, although the chemical or genetic modification strategies for more surface functionalization with target ligands and chemicals are required.[6,7] The ability to conjugate the large surface area of the T4 NPs with up to 19 000 dyes/virus implies that the surface can be loaded with a variety of functionalities by using the available reactive amines. This functionalization capability will be useful in vivo when adding labels such as poly(ethylene glycol) (PEG) to prevent blood clearance, target antigens to ensure delivery to tumor tissues, and a large number of fluorescent dyes for highly fluorescent nanoprobes.

Synthesis of C-Linked Triazole-Containing AFGP Analogues and Their Ability to Inhibit Ice Recrystallization

Chantelle J. Capicciotti, John F. Trant, Mathieu Leclère, and Robert N. Ben*

Department of Chemistry, D'Iorio Hall, 10 Marie Curie, University of Ottawa, Ottawa, Ontario, Canada, K1N 6N5.

Supporting Information

ABSTRACT: C-Linked antifreeze glycoprotein (C-AFGP) analogues have been shown to have potent ice recrystallization inhibition (IRI) activity. However, the lengthy synthesis of these compounds is not amenable to large-scale preparation for the many commercial, industrial, and medical applications that exist. This paper describes the synthesis of triazole-containing AFGPs using a convergent solid-phase synthesis (SPS) approach in which multiple carbohydrate derivatives are coupled to a resin-bound synthetic peptide in a single step. Modified "Click" conditions using dry DMF as solvent with catalytic Cu(II), sodium ascorbate, and microwave radiation afforded the synthesis of AFGP analogues **9**−**12** in 16−54% isolated yield. Compound **9** demonstrated no IRI activity, while compounds **10**, **11**, and **12** were moderate inhibitors of ice recrystallization. These results suggest that, while the triazole group is a structural mimetic of an amide bond, the amide bond in C-AFGP analogue **3** is an essential structural feature necessary for potent IRI activity.

INTRODUCTION

Antifreeze glycoproteins (AFGPs) are found in many deep sea Teleost fish and serve to protect these organisms against cryoinjury and death. This is accomplished by inhibiting the growth of ice crystals *in vivo*—a phenomenon referred to as thermal hysteresis (TH). AFGPs are also potent inhibitors of ice recrystallization, and it has been recently hypothesized that this property would be beneficial for a cryoprotectant.[1] Cryopreservation experiments have been performed with AFGPs, but thermal hysteresis activity has been shown to cause significant cellular damage at temperatures below the thermal hysteretic gap,[2,3] thus ensuring that these compounds will not be further developed as cryoprotectants. However, AFGP analogues possessing "custom-tailored antifreeze activity" (i.e., are potent inhibitors of ice recrystallization but do not possess TH activity) have great potential as cryoprotectants that is presently unrealized.

During the past decade, our lab has been actively designing and synthesizing C-linked analogues of the native AFGP (C-AFGPs) in an effort to better understand their interactions at the ice−bulk water interface. Towards this end, we have reported the synthesis of several C-AFGP analogues (e.g., **3** and **5**) that exhibit potent ice recrystallization inhibition (IRI) activity but display no TH activity and have tremendous potential as novel cryoprotectants (Figure 1).[4,5] Structure−function studies on these C-AFGPs have questioned the functional importance of the amide bond in **3** for IRI activity. For instance, when the amide bond is removed as in C-serine analogue **5**, IRI activity is retained.[5] In contrast, other studies have shown that activity is significantly decreased when the length of the amide bond-containing side chain in **3** was either lengthened or shortened (Figure 1).[6] Molecular dynamics (MD) simulations and variable temperature (VT) NMR experiments suggest that the IRI activity of **3** is attributed to an unusual conformation in which the carbohydrate moiety folds back over the peptide chain creating a hydrophobic pocket. It was hypothesized that this "pocket" disrupts the ordering of water molecules in the primary hydration shell of the galactose moiety, resulting in IRI activity.[6] However, it is not known whether the amide bond in these analogues is an important structural feature necessary for this activity. One manner in which to probe the importance of this linkage is to utilize a suitable isostere. The 1,4-disubstituted triazole has been shown by Wong and co-workers to be an isostere of a *Z*-amide bond (Figure 2).[7,8] Furthermore, the mild, highly efficient copper-catalyzed Huisgen cycloaddition for the preparation of triazoles has facilitated their use in many biologically significant molecules.[9−19]

Prior syntheses of C-AFGPs by our laboratory have utilized a traditional linear synthesis requiring the preparation of a glycosylated amino acid prior to solid-phase synthesis (SPS). This approach can be lengthy and expensive.[20,21] Alternatively, convergent methodologies have been reported for the synthesis of glycoconjugates in which several carbohydrates are simultaneously coupled to the resin-bound peptide.[22−24] Two convergent syntheses of triazole-containing AFGP analogues have been reported. A triazole-containing proline AFGP analogue was

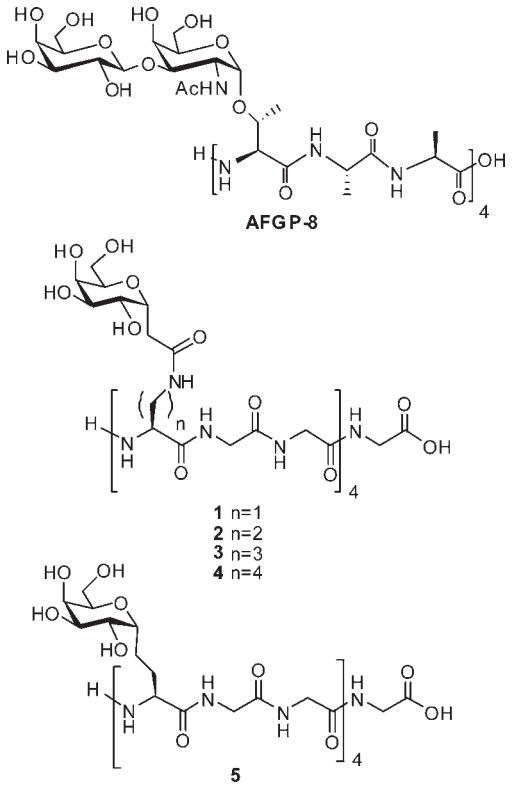

Figure 1. Previously prepared C-linked *C*-AFGP analogues.

synthesized in a solution-phase approach through coupling of an acetylenic carbohydrate derivative and an azido peptide using 10−20% $CuSO_4$ and 25−50% sodium ascorbate at 80 °C in the presence of microwaves.[25] In another approach, three AFGP peptoids (**6**, **7**, and **8**, shown in Figure 3) were prepared by coupling azido sugars with a resin-bound acetylenic peptoid using excess CuI and sodium ascorbate in anhydrous DMF and DIPEA.[26] On the basis of this precedent, we sought to prepare triazole-containing AFGP analogues of **3** using "Click" chemistry in a convergent solid-phase approach. The structures of these analogues (**9**−**12**) are shown in Figure 4. The goal of this study is to understand the functional importance of the amide bond in the side chain of *C*-AFGP analogue **3**.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All anhydrous reactions were performed in flame-dried glassware under a positive pressure of dry argon. Air- or moisture-sensitive reagents and anhydrous solvents were transferred with oven-dried syringes or cannulae. All flash chromatography was performed with E. Merck silica gel 60 (230−400 mesh). All solution-phase reactions were monitored using analytical thin layer chromatography (TLC) with 0.2 mm precoated silica gel aluminum plates 60 F254 (E. Merck). Components were visualized by illumination with a short-wavelength (254 nm) ultraviolet light and/or staining (ceric ammonium molybdate, potassium permanganate, or orcinol stain solution). Dry-vacuum chromatography was carried out according to the protocol outlined by Pedersen and Rosenbohm.[27] All solvents used for anhydrous reactions were distilled. Tetrahydrofuran (THF) was distilled from sodium/benzophenone under nitrogen. Dichloromethane (DCM), triethylamine,

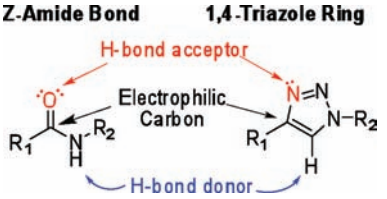

Figure 2. Electronic similarities between a Z-amide bond and a 1,4-disubstituted triazole ring.

and diisopropylethylamine (DIPEA) were distilled from calcium hydride. *N,N*-Dimethylformamide (DMF) was stored over activated 4 Å molecular sieves under argon. ^1H (400 or 500 MHz) and ^{13}C NMR (100 or 125 MHz) spectra were recorded at ambient temperature on a Bruker Avance 400, Bruker Avance 500, or Varian Inova 500 spectrometer. Deuterated chloroform ($CDCl_3$), methanol (CD_3OD), or water (D_2O) were used as NMR solvents. Chemical shifts are reported in ppm downfield from trimethylsilane (TMS) or the solvent residual peak as an internal standard. Splitting patterns are designated as follows: s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; and br, broad. Low resolution mass spectrometry (LRMS) was performed on a Micromass Quatro-LC Electrospray spectrometer with a pump rate of 20 μL/min using electrospray ionization (ESI), a Voyager DE-Pro matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) (Applied Biosystem, Foster City, CA) mass spectrometer operated in the reflectron/positive-ion mode with DHB in 20% EtOH/H_2O as the MALDI matrix, or a Bruker Microflex MALDI-TOF mass spectrometer with DHB in 20% acetonitrile/H_2O as the MALDI matrix. Analytical and preparatory scale RP-HPLC were carried out with Varian Polaris C-18 columns on a Varian Prostar HPLC system equipped with a variable wavelength detector (ProStar 330 PDA). Desalting was accomplished using C18 solid-phase extraction cartridges (Discovery, Supelco) using 40% acetonitrile in water for elution of glycopeptides. All yields are unoptimized.

Circular Dichroism. CD spectra of the glycopolymers **9**−**12** were obtained using a Jasco model *J*-810 automatic recorder spectropolarimeter interfaced with a Dell computer. All of the measurements were performed in quartz cells with 1.0 cm path length. Spectra were obtained with a 1.0 nm bandwidth, a time constant of 2 s, and a scan speed of 50 nm/min. Eight scans were added to improve the signal-to-noise ratio, and baseline corrections were made against each sample. All of the spectra were recorded between 190 and 300 nm, and all of the CD experiments were performed in doubly distilled H_2O at pH 7.4. Data obtained from CD spectroscopy were converted into molar ellipticities (deg cm^2 dmol^{-1}). Glycopeptide secondary structures were estimated using the deconvolution software *CD Pro*. The data from each spectrum were analyzed using three different deconvolution programs: SELCON3, CDSSTR, and CONTINLL. Of these three programs, SELCON3 and CONTINLL gave the most consistent results. IBASIS 5 was used as the set of reference proteins; it contains 37 proteins with α-helix, β-structure, polyproline II, and unordered conformations with optimal wavelengths of 185−240 nm.[6]

Thermal Hysteresis (TH) Assay. Nanoliter osmometry was performed using a Clifton nanoliter osmometer (Clifton Technical Physics, Hartford, NY), as described by Chakrabartty and Hew.[28] All of the measurements were performed in doubly distilled water. Ice crystal morphology was observed through a

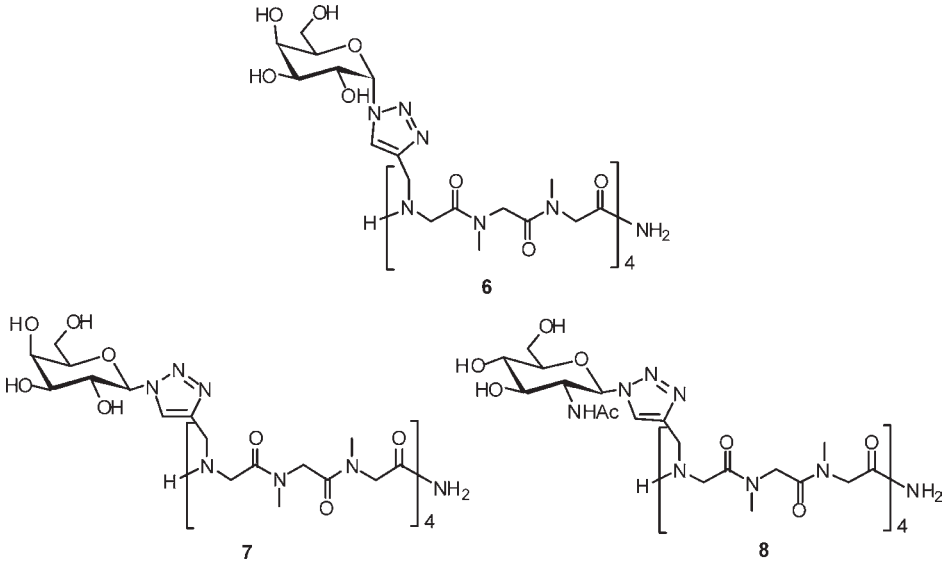

Figure 3. Triazole-containing peptoid analogues synthesized by Norgren et al.

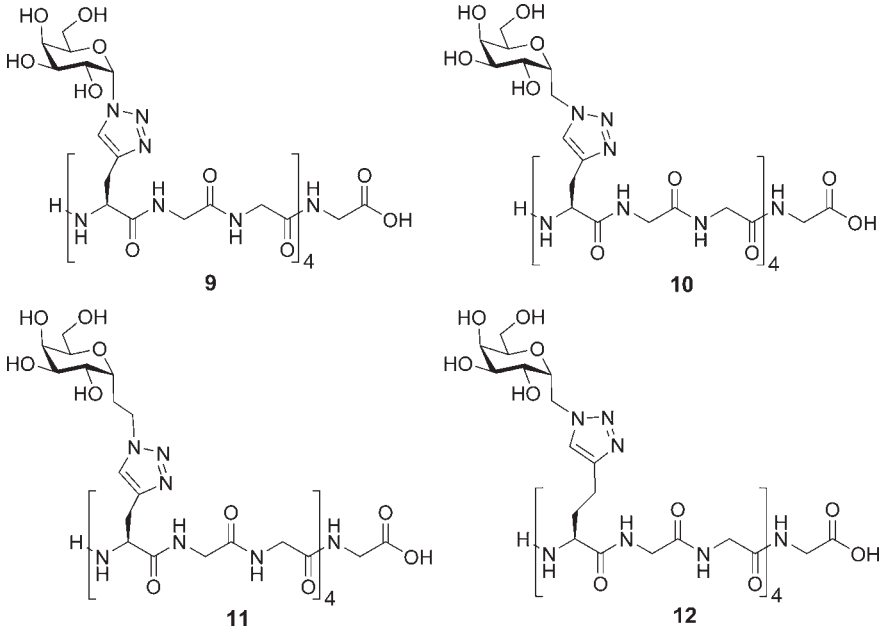

Figure 4. Proposed structures of triazole-containing AFGP analogues.

Leitz compound microscope equipped with an Olympus 20× (infinity-corrected) objective, a Leitz Periplan 32× photo eyepiece, and a Hitachi KPM2U CCD camera connected to a Toshiba MV13K1 TV/VCR system. Still images were captured directly using a Nikon CoolPix digital camera.

Ice Recrystallization Inhibition (IRI) Assay. Sample analysis for IRI activity was performed using the "splat cooling" method as previously described.[1] In this method, the analyte was dissolved in phosphate buffered saline (PBS) solution and a 10 μL droplet of this solution was dropped from a micropipet through a 2-m-high plastic tube (10 cm in diameter) onto a block of polished aluminum precooled to approximately −80 °C. The droplet froze instantly on the polished aluminum block and was approximately 1 cm in diameter and 20 μm thick. This wafer was then carefully removed from the surface of the block and transferred to a cryostage held at −6.4 °C for annealing. After a period of 30 min, the wafer was photographed between crossed polarizing filters using a digital camera (Nikon CoolPix 5000) fitted to the microscope. A total of three images were taken from each wafer. During flash freezing, ice crystals spontaneously nucleated from the supercooled solution. These initial crystals were relatively homogeneous in size and quite small. During the annealing cycle, recrystallization occurred, resulting in a dramatic increase in ice crystal size. A quantitative measure of the difference in recrystallization inhibition of two compounds X and Y is the difference in the dynamics of the ice crystal size distribution. Image analysis of the ice wafers was performed using a novel domain recognition software (DRS) program.[29]

dx.doi.org/10.1021/bc100394k |*Bioconjugate Chem.* 2011, 22, 605–616

This processing employed the Microsoft Windows Graphical User Interface to allow a user to visually demarcate and store the vertices of ice domains in a digital micrograph. The data was then used to calculate the domain areas. All data was plotted and analyzed using Microsoft *Excel*. IRI activity is reported as a ratio of the mean grain size (MGS) of ice crystals in the presence of the solute divided by the mean grain size (MGS) of ice crystals in a control solution of phosphate buffered saline (PBS). Small ratios indicate high levels of ice recrystallization inhibition.

***N*-[[(9*H*-Fluoren-9-ylmethoxy)carbonyl]amino]-L-propargylglycine allyl ester (13).** In a flame-dried round-bottom flask with 4 Å molecular sieves, Fmoc-L-Propargylglycine (338 mg, 1.01 mmol) was dissolved in anhydrous DCM (7 mL) under argon atmosphere. HBTU (460 mg, 1.2 mmol) was added and the mixture was stirred for 20 min. Allyl alcohol (347 μL, 5.1 mmol) was added, followed by a dropwise addition of DIPEA (355.5 μL, 2.04 mmol). The reaction was stirred at room temperature for 16 h. Upon consumption of starting material, the reaction was diluted with DCM, filtered through a Celite pad, and washed with 10% HCl, $NaHCO_3$, and brine successively. The final product was purified by dry vacuum chromatography (DVC) to yield 326 mg of a white powder (86% yield). ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 7.77 (d, 2H, J = 7.5 Hz), 7.61 (d, 2H J = 7.4 Hz), 7.40 (t, 2H, J = 7.5 Hz), 7.32 (ddd, 2H, J = 7.5, 4.3, 1.1 Hz), 5.92 (ddd, 1H, J = 16.4, 10.8, 5.6 Hz), 5.66 (d, 1H, J = 8.1 Hz), 5.36 (dd, 1H, J = 17.2, 0.8 Hz), 5.28 (dd, 1H, J = 10.4, 0.9 Hz), 4.70 (dd, 2H, J = 2.7, 1.3 Hz), 4.61−4.54 (m, 1H), 4.40 (d, 2H, J = 7.2 Hz), 4.25 (t, 1H, J = 7.2 Hz), 2.82 (dd, 2H, J = 4.5, 2.6 Hz), 2.08 (t, 1H, J = 2.4 Hz). ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.0, 155.6, 143.8, 143.7, 141.3, 131.3, 127.7, 127.1, 125.1, 120.0, 119.0, 72.0, 67.3, 66.4, 52.4, 47.1, 22.8. ESI-MS m/z calcd for $C_{23}H_{21}NO_4$ $[M+H]^+$: 376.154; $[M+Na]^+$: 398.137. Found: 376.14, 398.12.

2,3,4,6-Tetra-*O*-acetyl-α-D-galactopyranosyl Azide (14). 2,3,4,6-Tetra-*O*-acetyl-β-D-galactopyranosyl chloride[30] (4.68 g, 12.8 mmol) was dissolved in 15 mL of HMPA. Sodium azide (2.5 g, 38.4 mmol) was added and the reaction was stirred vigorously for 16 h at ambient temperature. The mixture was poured into an ice−water mixture and the solid was collected by filtration and washed with water. The product was recrystallized from ether and petroleum ether to yield 4.3 g of white crystals (89% yield). Characterization data are consistent with that reported previously in the literature.[31] ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 5.67 (d, 1H, J = 3.9 Hz), 5.46 (dd, 1H J = 2.9, 1.2 Hz), 5.25 (dd, 1H, J = 10.8, 3.0 Hz), 5.20 (dd, 1H, J = 10.8, 3.9 Hz), 4.37 (dd, 1H, J = 6.5, 6.5 Hz), 4.12 (dd, 2H, J = 6.5, 4.4 Hz), 2.15 (s, 3H), 2.11 (s, 3H), 2.06 (s, 3H), 2.00 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.4, 170.1, 170.0, 169.8, 86.7, 68.6, 67.6, 67.4, 67.2, 61.5, 20.67, 20.64, 20.60, 20.5. ESI-MS m/z calcd for $C_{14}H_{20}N_3O_9$ $[M+H]^+$: 374.12; $[M+Na]^+$: 396.10. Found: 374.09, 396.02.

1-Azido-2-(2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl) ethane (16). 2-(2,3,4,6-Tetra-*O*-acetyl-α-D-galactopyranosyl) acetaldehyde[5] (2.5 g, 6.7 mmol) was added to a round-bottom flask purged with argon and cooled to 0 °C. 70 mL of MeOH was then added followed by sodium borohydride (983 mg, 26 mmol) and the reaction was stirred for 40 min when TLC (1:1 hexanes:ethyl acetate) analysis showed consumption of starting material. The reaction was then quenched with 4 mL of acetic acid and the solvent was removed *in vacuo*. Following evaporation, the product was dissolved in ethyl acetate and washed successively with 10% HCl, sodium bicarbonate, and brine to yield 2.6 g of crude oil. The product was sufficiently pure to be used directly in the next transformation.

A round-bottom flask was cooled to 0 °C in an ice bath. Crude 2-(2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl)ethanol (2.6 g, 6.7 mmol) and methanesulfonylchloride (2.1 mL, 26.8 mmol) were then added to the flask and dissolved in 33 mL of pyridine (0.2 M). The reaction was stirred at 0 °C for 1.5 h. Once complete, the reaction was diluted with ethyl acetate and was washed successively with saturated aqueous copper(II) acetate, 10% HCl, saturated sodium bicarbonate, and brine. The organic layer was then dried with magnesium sulfate and the solvent removed *in vacuo* to yield a slightly brown solid. This crude product (2.2 g) was used directly without any further purification.

The crude mesylate (2.2 g, 4.8 mmol) was dissolved in 20 mL of DMF under argon. Sodium azide (760 mg, 11.7 mmol) was added and the reaction was stirred vigorously at room temperature overnight. The mixture was then poured into an ice−water mixture and the solid was filtered out and washed with water. Flash chromatography (7:3 ethyl acetate:hexanes) followed by recrystallization from ether and hexanes yielded 1.6 g (68.2% over three steps) of **16** as a pure white powder. Characterization data are consistent with that reported previously in the literature.[32] ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 5.42 (dd, 1H, J = 3.1, 3.1 Hz), 5.25 (dd, 1H, J = 8.7, 4.7 Hz), 5.18 (dd, 1H, J = 8.7, 3.3 Hz), 4.34−4.32 (m, 2H), 4.09 (ddd, 2H, J = 7.8, 5.9, 3.4 Hz), 3.43−3.41 (m, 2H), 2.12 (s, 3H), 2.10 (s, 3H), 2.07 (s, 3H), 2.05 (s, 3H), 1.99−1.87 (m, 1H), 1.75−1.65 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.6, 170.0, 169.8, 169.7, 69.0, 68.9, 68.2, 67.9, 67.2, 61.2, 47.7, 26.0, 20.8, 20.8, 20.7. ESI-MS m/z calcd for $C_{16}H_{23}N_3O_9$ $[M+H]^+$: 402.151; $[M+Na]^+$: 424.133. Found: 402.13, 424.11.

(2,3,4,6-Tetra-*O*-acetyl-α-D-galactopyranosyl)methyl Azide (24). Azido sugar **24** was synthesized according to a modified procedure[33] as indicated in Scheme 1 in the Supporting Information. Spectral data are consistent with previously published data. ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 5.44 (dd, 1H, J = 3.3, 3.3 Hz), 5.27 (dd, 1H, J = 8.4, 4.6 Hz), 5.22 (dd, 1H, J = 8.4, 3.2 Hz), 4.39 (m, 2H), 4.25 (ddd, 1H, J = 8.0, 4.5, 3.4 Hz), 4.11 (dd, 1H, J = 11.7, 4.7 Hz), 3.63 (dd, 1H, J = 13.5, 8.8 Hz), 3.24 (dd, 1H, J = 13.5, 3.7 Hz), 2.12 (s, 3H), 2.11 (s, 3H), 2.07 (s, 3H), 2.06 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.7, 169.8, 169.6, 169.5, 70.8, 69.8, 67.7, 67.5, 66.9, 60.7, 48.3, 20.67, 20.66, 20.59. ESI-MS m/z calcd for $C_{15}H_{21}N_3O_9$ $[M + K]^+$: 426.091. Found: 426.12.

(2*S*)-1-Allyl-2-[[(9*H*-Fluoren-9-ylmethoxy)carbonyl]amino]-3-(4-(2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl)-2,3,4-triazol-1-yl)-propanoate (15). Compounds **13** (10 mg, 0.027 mmol) and **14** (10 mg, 0.027 mmol) were dissolved in 200 μL of the organic solvent and 150 μL of water in a 3 mL culture tube. A 0.2 M cupric acetate solution (25 μL, 0.005 mmol) was then added and the reaction was sealed with a septum. The tube was flushed with argon for 10 min and then placed in a 40 °C oil bath. A 0.4 M sodium ascorbate solution (25 μL, 0.01 mmol) was added and the reaction was stirred until completion (for a maximum of 6 h). The reaction mixture was then cooled to room temperature, diluted with ethyl acetate, and washed with water and brine. Solvent was removed *in vacuo* and the crude product was purified by preparative TLC (6:4 ethyl acetate:hexanes). ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 7.76 (d, 2H, J = 7.5 Hz), 7.61 (t, 2H, J = 7.3 Hz), 7.40 (ddd, 2H, J = 7.4, 7.4, 3.3 Hz), 7.37−7.29 (m, 3H), 6.38 (d, 1H, J = 6.1 Hz), 6.16 (dd,

1H, J = 10.7, 3.3 Hz), 5.97−5.86 (m, 1H), 5.85 (d, 1H, J = 8.2 Hz), 5.65 (d, 1H, J = 3.1 Hz), 5.46 (dd, 1H, J = 10.8, 6.0 Hz), 5.35 (d, 1H, J = 17.1 Hz), 5.27 (d, 1H, J = 10.4 Hz), 4.73 (ddd, 1H, J = 8.2, 5.2, 5.2 Hz), 4.64 (d, 2H, J = 5.6 Hz), 4.60 (dd, 1H, J = 6.4, 6.4 Hz), 4.39 (d, 2H, J = 7.1 Hz), 4.24 (dd, 1H, J = 7.0, 7.0 Hz), 4.10 (dd, 1H, J = 11.3, 6.6 Hz), 4.00 (dd, 1H, J = 11.3, 6.5 Hz), 3.32 (d, 2H, J = 5.1 Hz), 2.19 (s, 3H), 2.01 (s, 3H), 1.95 (s, 3H), 1.88 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.6, 170.6, 170.3, 170.0, 169.4, 155.9, 143.8, 143.7, 142.0, 141.3, 141.2, 131.4, 127.8, 127.1, 127.1, 125.1, 124.5, 120.0, 119.2, 81.7, 70.5, 67.7, 67.5, 67.2, 67.2, 66.2, 61.2, 53.4, 47.1, 28.0, 20.61, 20.61, 20.6, 20.3. ESI-MS m/z calcd for $C_{37}H_{40}N_4O_{13}$ $[M+H]^+$: 749.2665; $[M+Na]^+$: 771.2490. Found: 749.22, 771.20.

(2*S*)-1-Allyl-2-[[(9*H*-fluoren-9-ylmethoxy)carbonyl]amino]-3-(4-(2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosylethyl)-2,3,4-triazol-1-yl)-propanoate (17). Compounds **13** (10 mg, 0.027 mmol) and **16** (11 mg, 0.027 mmol) were treated with the same conditions as the preparation of **15**. The crude product **17** was purified by preparative TLC (7:3 ethyl acetate: hexanes). ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 7.76 (d, 2H, J = 7.5 Hz), 7.59 (t, 2H, J = 7.4 Hz), 7.40 (t, 2H, J = 7.4 Hz), 7.37 (s, 1H), 7.31 (t, 2H, J = 7.5, 7.5 Hz), 5.94 (d, 1H, J = 8.9 Hz), 5.89 (m, 1H), 5.41 (t, 1H, J = 2.8, 2.8 Hz), 5.32 (d, 1H, J = 17.1 Hz), 5.25 (dd, 1H, J = 10.4, 1.1 Hz), 5.20 (d, 1H, J = 4.5 Hz), 5.17 (dd, 1H, J = 8.7, 3.1 Hz), 4.73 (dd, 1H, J = 13.3, 5.4 Hz), 4.66 (d, 2H, J = 5.7 Hz), 4.46 (ddd, 1H, J = 12.9, 7.9, 4.8 Hz), 4.41−4.27 (m, 4H), 4.23 (dd, 1H, J = 7.2, 7.2 Hz), 4.19−4.13 (m, 1H), 4.11−4.02 (m, 2H), 3.31 (d, 2H, J = 4.9 Hz), 2.31−2.17 (m, 1H), 2.10 (s, 3H), 2.07 (s, 6H), 2.03 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.8, 170.6, 169.9, 169.7, 169.7, 156.0, 143.8, 143.8, 142.7, 141.2, 141.2, 131.6, 127.7, 127.1, 125.2, 125.2, 122.8, 120.0, 118.7, 77.5, 77.2, 76.9, 69.2, 68.6, 68.0, 67.7, 67.1, 66.1, 61.1, 53.5, 47.1, 46.4, 28.1, 27.1, 20.77, 20.74, 20.71, 20.63. ESI-MS m/z calcd for $C_{39}H_{44}N_4O_{13}$ $[M+H]^+$: 777.2978. Found: 777.21.

General Method for Peptide Synthesis. The syntheses of the peptides were carried out using an Advanced Chem Tech Apex 396 automated peptide synthesizer (40 wells), equipped with a dual-arm system and argon atmosphere controlled from an IBM PC using *Advanced Chem Tech* v 1.6 software. Preloaded Fmoc-Gly-Wang or Fmoc-Ala-Wang resins were swollen in DMF for 1 h followed by filtration, and then were subjected to 20% piperidine in DMF twice successively for 30 min. Peptide couplings were performed using standard conditions for Fmoc solid-phase synthesis using HCTU as coupling agent.[34] Following the coupling of each residue, deprotection of the Fmoc moiety was accomplished by treatment with 20% piperidine in DMF. Between each deprotection and coupling, and after every coupling, the beads were shaken 4 times with 4 mL of DMF followed by filtration. Upon completion of the synthesis, the beads were washed extensively with DMF (6 × 4 mL), MeOH (6 × 4 mL), DCM (6 × 4 mL), hexanes (6 × 4 mL), and ethanol (3 × 6 mL) and then removed from the synthesizer and stored in a desiccator under vacuum in the presence of P_2O_5 until required. A small amount of the peptide was cleaved from the resin for characterization using 92.5:5:2.5 (v/v/v) TFA:triisopropylsilane:water. The peptides were purified using reversed-phase HPLC (ramp from 0% to 18% acetonitrile in water over 5 min followed by isocratic flow for 25 min) unless stated otherwise.

Resin-Supported Peptide 18. Peptide **18** was prepared using 100 mg of Wang resin using standard Fmoc-based SPS protocols.[34] 5 mg of resin was directly cleaved and the crude peptide was purified through preparatory TLC (30% water in methanol) to yield 0.8 mg of **18** as a white powder (91% based on resin loading). ^{1}H NMR (400 MHz, D_2O): δ_{ppm} 3.94−3.78 (m, 5H), 3.59 (d, 2H, J = 1.35 Hz), 2.64 (d, 2H, J = 3.23 Hz, 2H), 2.36 (t, 1H, J = 2.21). ^{13}C NMR (100 MHz, D_2O): δ_{ppm} 171.4, 171.32, 171.31, 168.9, 76.2, 74.4, 51.4, 42.6, 42.4, 42.3, 21.0. ESI-MS m/z calcd for $C_{11}H_{16}N_4O_5$ $[M+H]^+$: 285.1199. Found: 285.072.

Resin-Supported Peptide 20. Peptide **20** was prepared using 115 mg of Wang resin using standard Fmoc-based SPS protocols.[34] 18 mg of resin was cleaved directly and purified by reversed-phase HPLC to yield 3.0 mg of **20** as a white powder in 78% yield (based on resin loading). ^{1}H NMR (400 MHz, D_2O): δ_{ppm} 7.40−7.15 (m, 5H), 4.60 (dd, 1H, J = 8.2, 6.6 Hz), 4.30 (q, 1H, J = 7.3 Hz), 4.19 (t, 1H, J = 6.1 Hz), 3.91 (q, 2H, J = 16.9 Hz), 3.11 (dd, 1H, J = 13.9, 6.5 Hz), 2.96 (dd, 1H, J = 13.9, 8.3 Hz), 2.84 (td, 2H, J = 3.3, 2.9 Hz), 2.52 (t, 1H, J = 2.7 Hz), 1.33 (d, 3H, J = 7.3 Hz). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 176.7, 173.2, 171.0, 169.3, 136.8, 129.9, 129.4, 127.8, 83.2, 75.1, 55.4, 52.0, 49.3, 42.869, 42.861, 37.9, 21.7. ESI-MS m/z calcd for $C_{19}H_{24}N_4O_5$ $[M+H]^+$: 389.182; $[M+Na]^+$: 411.164. Found: 389.19, 411.17.

Resin-Supported Peptide 23. Peptide **23** was prepared using 115 mg of Wang resin according to standard Fmoc-based SPS protocols.[34] 10 mg of resin was cleaved directly and purified by reversed-phase HPLC to yield 1.8 mg of **23** as a white powder in 70% yield (based on resin loading). ^{1}H NMR (400 MHz, D_2O): δ_{ppm} 4.58 (m, 3H), 4.29 (t, 1H, J = 5.9 Hz), 4.19−3.79 (m, 18H), 2.93 (dd, 2H, J = 5.9, 2.8 Hz), 2.76 (bd, 6H, J = 6.1 Hz), 2.60 (t, 1H, J = 2.5 Hz), 2.46 (t, 3H, J = 2.4 Hz). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 172.7, 171.8, 171.5, 171.3, 168.8, 79.2, 76.2, 74.3, 72.2, 52.4, 52.3, 51.3, 42.5, 42.4, 42.2, 20.8. ESI-MS m/z calcd for $C_{38}H_{49}N_{13}O_{14}$ $[M+H]^+$: 912.3595; $[M+Na]^+$: 934.3420. Found: 912.34, 934.32.

Resin-Supported Peptide 25. Peptide **25** was prepared using 150 mg of Wang resin using standard Fmoc-based SPS protocols with amino acid **26** (Scheme 3b).[34] 20 mg of resin was directly cleaved and the crude peptide was purified by reversed-phase HPLC (isocratic flow with 10% acetonitrile in water for 5 min followed by a linear gradient from 10% to 60% acetonitrile in water) to yield 4.1 mg of **25** as a white powder in 48% yield (based on resin loading). ^{1}H NMR (500 MHz, D_2O, presaturation on HOD): δ_{ppm} 4.36 (m, 3H), 3.90−3.75 (m, 17H), 3.60 (s, 2H), 2.28−2.09 (m, 12H), 1.91 (m, 4H), 1.80 (m, 4H). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 176.4, 174.2, 174.2, 174.1, 171.9, 171.8, 171.7, 171.6, 171.5, 170.9, 83.3, 82.6, 70.8, 70.3, 52.9, 52.8, 52.8, 52.6, 43.1, 42.5, 42.4, 42.3, 29.3, 29.2, 14.4, 13.9. ESI-MS m/z calcd for $C_{42}H_{58}N_{13}O_{14}$ $[M+H]^+$: 968.42. Found: 968.76.

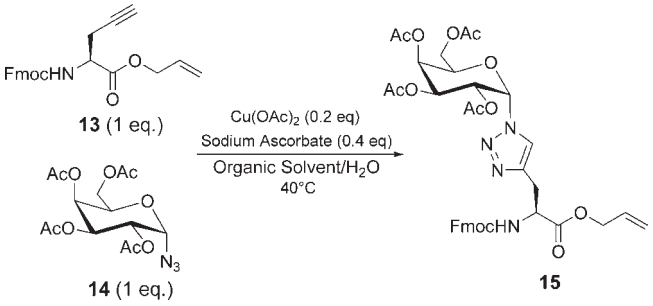
(*S*)-2-(9-Fluorenylmethoxycarbonylamino)-hex-5-ynoic Acid (26). Amino acid **26** was synthesized as indicated in Scheme 2 in the Supporting Information. ^{1}H NMR ($CDCl_3$/CD_3OD 2/1, 400 MHz): δ_{ppm} 7.71 (d, 2H, J = 7.6 Hz), 7.58 (dd, 2H, J = 7.1, 3.9 Hz), 7.35 (t, 2H, J = 7.6 Hz), 7.27 (t, 2H, J = 7.6 Hz), 4.35 (m, 3H), 4.18 (t, 1H, J = 6.8 Hz), 2.24 (m, 2H), 2.09 (m, 1H), 2.01 (t, 1H, J = 2.6 Hz), 1.86 (m, 1H). ^{13}C NMR ($CDCl_3$/CD_3OD 2/1, 100 MHz): δ_{ppm} 173.9, 156.7, 143.8, 143.7, 141.2, 141.2, 127.7, 127.0, 125.0, 119.8, 82.6, 77.5, 69.3, 66.9, 53.0, 47.1, 30.9, 14.9. ESI-MS m/z calcd for $C_{21}H_{19}NO_4$ $[M + Na]^+$: 372.12. Found: 372.24.

General Protocol for the Solid-Phase Organic Synthesis Microwave "Click" Reaction. A CEM Mars X Microwave System with 300 W maximum power and quartz reaction vessels

was used for these reactions. The resin supported peptide was initially stirred in DMF for 30 min under argon. Five equivalents of azide per mole of alkyne and 0.2 equiv of cupric acetate per mol of alkyne were added and the solution was degassed under argon. 0.4 equivalents of sodium ascorbate per mole of alkyne was then added and the stirbar was removed. The flask was sealed under argon and placed in the microwave and run under the following conditions: 2 min ramp to 90 °C then held at 15% power for 1.5 h. The solvent was then drained, and the beads were washed extensively with 1:1 water:isopropanol followed by 4 × 4 mL DMF, 4 × 4 mL MeOH, 4 × 4 mL DCM, and finally 4 × 4 mL hexanes. The beads were then stirred in 4 mL of 92.5:5:2.5 TFA:triisopropylsilane:water cleavage cocktail to remove the product off the resin. Solvent was evaporated at ambient temperature. The residue was washed with ether (4 × 5 mL), then dissolved in a solution of 0.01 M sodium methoxide in methanol with a drop of water and stirred for 1.5 h at room temperature. TFA was added until the pH of the solution was adjusted to 6. The mixture was evaporated to dryness, desalted, and resuspended in water and purified by reversed-phase HPLC.

Glycopeptide 21. Resin-supported **20** (80 mg, 0.046 mmol) was treated as per the general procedure described above with **14** (85.2 mg, 0.23 mmol), cupric acetate (1.7 mg, 0.0093 mmol), and sodium ascorbate (3.4 mg, 0.017 mmol). Purification by reversed-phase HPLC (1% acetonitrile in water for 12 min followed by a linear gradient from 1% acetonitrile in water to 10% acetonitrile in water over 28 min followed by a linear gradient from 10% acetonitrile in water to 98% acetonitrile in water over 40 min) yielded 16.7 mg of **21** as a white powder (61% based on resin-loading). ^{1}H NMR (500 MHz, D_2O): δ_{ppm} 8.01 (s, 1H), 7.38−7.15 (m, 5H), 6.26 (s, 1H), 4.69−4.56 (m, 1H), 4.51−4.42 (m, 1H), 4.35−4.15 (m, 2H), 4.13−3.96 (m, 3H), 3.89−3.75 (m, 2H), 3.70−3.56 (m, 2H), 3.33−3.09 (m, 3H), 3.04−2.95 (m, 1H), 1.33−1.18 (m, 3H). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 179.4, 171.8, 170.860, 170.7, 136.6, 129.1, 128.6, 1267.0, 74.9, 69.2, 68.7, 66.8, 61.1, 54.8, 54.2, 46.5, 42.4, 36.7, 17.5. ESI-MS m/z calcd for $C_{25}H_{35}N_7O_{10}$ $[M + H]^+$: 594.25. Found: 594.42.

Glycopeptide 22. Resin-supported **20** (24 mg, 0.0137 mmol) was treated as per the general procedure described above with **16** (27.5 mg, 0.0685 mmol), cupric acetate (0.5 mg, 0.0028 mmol), and sodium ascorbate (1 mg, 0.0051 mmol). Purification by reversed-phase HPLC (2% acetonitrile in water for 9 min followed by a linear gradient from 2% acetonitrile in water to 40% acetonitrile in water over 30 min) yielded 6 mg of **22** as a white powder (70% based on resin-loading). ^{1}H NMR (500 MHz, D_2O): δ_{ppm} 7.76 (s, 1H), 7.27−7.09 (m, 5H), 4.37 (dd, 2H, J = 14.0, 6.3 Hz), 4.18 (t, 1H, J = 6.3 Hz), 4.02 (dd, 1H, J = 14.3, 7.0 Hz), 3.76−3.85 (m, 3H), 3.74 (d, 1H, J = 1.6 Hz), 3.66−3.58 (m, 2H), 3.55 (d, 2H, J = 5.8 Hz), 3.18 (d, 1H, J = 6.3), 3.07 (dd, 1H, J = 13.9, 5.4 Hz), 2.87 (dd, 1H, J = 13.9, 9.3 Hz), 2.30−1.99 (m, 2H), 1.19 (d, 3H, J = 7.2 Hz). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 171.9, 170.4, 169.0, 162.8, 136.4, 129.2, 128.6, 127.0, 72.1, 69.5, 68.7, 67.6, 60.9, 54.8, 52.6, 47.0, 42.2, 36.9, 26.6, 24.6, 17.2. ESI-MS m/z calcd for $C_{27}H_{39}N_7O_{10}$ $[M+H]^+$: 622.284; $[M+Na]^+$: 644.266. Found: 622.15, 644.18.



Glycopeptide 9. Resin-supported **23** (60 mg 0.026 mmol) was treated as per the general procedure described above with **14** (190 mg, 0.51 mmol), cupric acetate (3.8 mg, 0.020 mmol), and sodium ascorbate (8.2 mg, 0.041 mmol). Purification by reversed-phase HPLC (1% acetonitrile in water for 12 min followed by a linear gradient from 1% acetonitrile in water to 10% acetonitrile in water over 28 min followed by a linear gradient from 10% acetonitrile in water to 98% acetonitrile in water over 40 min) yielded 9 mg of **9** as a white powder (20% based on resin loading). ^{1}H NMR (500 MHz, D_2O): δ_{ppm} 7.83 (s, 4H), 6.12 (d, 4H, J = 5.9 Hz), 4.33 (d, 4H, J = 10.1 Hz), 4.17 (dd, 4H, J = 10.0, 6.3 Hz), 3.93 (m, 5H), 3.86−3.71 (m, 17H), 3.60−3.47 (m, 12H), 3.18−2.98 (m, 12H). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 173.2, 173.0, 172.0, 171.9, 171.83, 171.76, 171.3, 171.28, 171.22, 171.1, 148.8, 125.3, 85.2, 74.8, 69.3, 68.7, 67.0, 61.1, 53.2, 53.16, 53.14, 46.57, 42.59, 42.2, 27.1, 26.9, 26.8, 26.7, 26.65, 26.59, 25.1, 23.7. MALDI-TOF MS m/z calcd for $C_{62}H_{93}N_{25}O_{34}$ $[M + Na + H]^{2+}$: 877.814. Found: 877.8.

Glycopeptide 10. Resin-supported **23** (70 mg 0.030 mmol) was treated as per the general procedure described above with **24** (94 mg, 0.24 mmol), cupric acetate (6.5 mg, 0.036 mmol), and sodium ascorbate (13 mg, 0.072 mmol). Purification by reversed-phase HPLC (1% acetonitrile in water for 12 min followed by a linear gradient from 1% acetonitrile in water to 10% acetonitrile in water over 28 min followed by a linear gradient from 10% acetonitrile in water to 98% acetonitrile in water over 40 min) yielded 25 mg of **10** as a white powder (45% based on resin loading). ^{1}H NMR (500 MHz, D_2O): δ_{ppm} 7.73 (s, 4H), 4.53 (m, 4H), 4.24 (s, 4H), 3.93 (m, 5H), 3.88−3.63 (m, 28H), 3.59−3.56 (m, 5H), 3.54−3.38 (m, 12H), 3.13−2.97 (m, 8H). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 171.4, 171.3, 171.2, 171.1, 171.1, 171.0, 170.9, 129.8, 122.6, 74.7, 74.6, 74.5, 72.5, 69.5, 69.4, 69.2, 68.7, 68.6, 68.4, 67.1, 60.8, 45.74, 45.70, 45.6, 42.6, 42.4, 42.3, 42.2, 27.2, 27.13, 27.09, 27.02. MALDI-TOF MS m/z calcd for $C_{66}H_{101}N_{25}O_{34}$ $[M + H]^+$: 1788.69. Found: 1788.6.

Glycopeptide 11. Resin-supported **23** (40 mg 0.017 mmol) was treated as per the general procedure described above with **16** (136 mg, 0.34 mmol), cupric acetate (2.5 mg, 0.0136 mmol), and sodium ascorbate (5.5 mg, 0.0275 mmol). Purification by reversed-phase HPLC (2% acetonitrile in water for 9 min followed by a linear gradient from 2% acetonitrile in water to 40% acetonitrile in water over 30 min) yielded 17 mg of **11** as a white powder (54% based on resin loading). ^{1}H NMR (500 MHz, D_2O): δ_{ppm} 7.84 (s, 1H), 7.76 (s, 3H), 4.62−4.51 (m, 4H), 4.40−4.32 (m, 9H), 4.26 (t, 1H, J = 6.40 Hz), 3.92−3.70 (m, 24H), 3.63 (dd, 12H, J = 10.1, 3.0 Hz), 3.58−3.53 (m, 8H), 3.25 (d, 2H, J = 6.2 Hz), 3.21−2.96 (m, 6H), 2.24−2.10 (m, 4H), 1.95−2.10 (m, 4H). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 173.0, 172.0, 171.87, 171.80, 171.69, 171.42, 171.4, 171.36, 171.32, 171.19, 169.8, 169.3, 126.2, 126.1, 72.2, 72.1, 72.0, 69.6, 68.8, 67.7, 65.8, 61.0, 54.4, 53.8, 53.3, 52.7, 47.0, 46.95, 46.91, 42.6, 42.6, 42.3, 42.2, 27.9, 27.2, 27.0, 26.9, 26.8, 26.6, 24.6, 22.2. MALDI-TOF MS m/z calcd for $C_{70}H_{109}N_{25}O_{34}$ $[M]^+$: 1843.76. Found: 1843.8.

Glycopeptide 12. Resin-supported **25** (25 mg, 0.011 mmol) was treated as per the general procedure described above with **24** (85 mg, 0.22 mmol), cupric acetate (1.6 mg, 0.009 mmol), and sodium ascorbate (3.6 mg, 0.018 mmol). Purification by reversed-phase HPLC (isocratic 1% acetonitrile in water for 10 min followed by a linear gradient from 1% acetonitrile in water to 30% acetonitrile in water over 30 min) yielded 3.3 mg of **12** as a white powder (16% based on resin loading). ^{1}H NMR (500 MHz, D_2O, presaturation on HOD): δ_{ppm} 7.71 (br s, 4H), 4.31 (s, 4H), 4.17 (s, 3H), 4.08−3.43 (m, 51H), 2.65 (m, 8H), 2.05−1.77 (m, 8H). ^{13}C NMR (125 MHz, D_2O): δ_{ppm} 174.2, 171.8, 171.0, 124.0, 96.4, 74.8, 72.5, 69.6, 68.7, 67.1, 60.8, 52.8, 45.5, 43.1, 42.5,

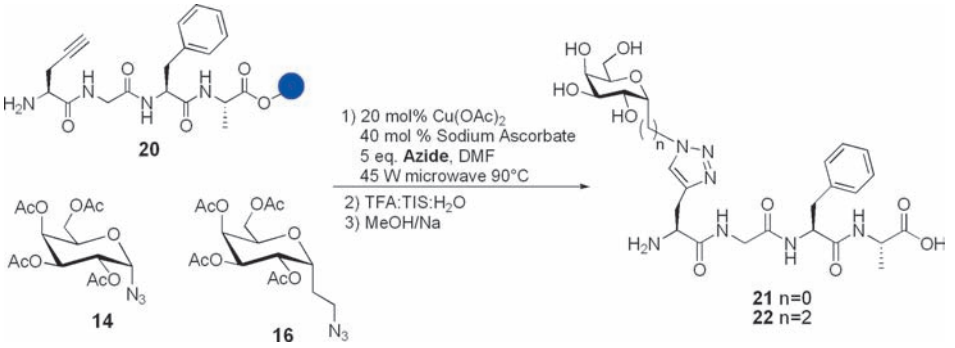
RESULTS AND DISCUSSION



Several modifications to the original "Click" reaction conditions for solid-phase applications have been reported.[16,17,35−39] We sought to utilize solvents that would permit reaction conditions with sub-stoichiometric amounts of copper and also facilitate swelling of the solid-phase resin. As a result, a number of organic solvents capable of swelling Wang resin were examined for the solution-phase reaction between alkyne **13** and azido sugar **14** before applying the conditions to the solid-phase synthesis of triazole-containing *C*-AFGP analogues.[40] The reaction between **13** and **14** was investigated using aqueous mixtures (50%) of *N*-methyl morpholine (NMP), tetrahydrofuran (THF), *N*,*N*-dimethyl formamide (DMF), dioxane and *tert*-butanol (Table 1). All of these solvents have excellent swelling properties for Wang resin except for *tert*-butanol, which swells resins poorly.[40] Under typical Sharpless reaction conditions

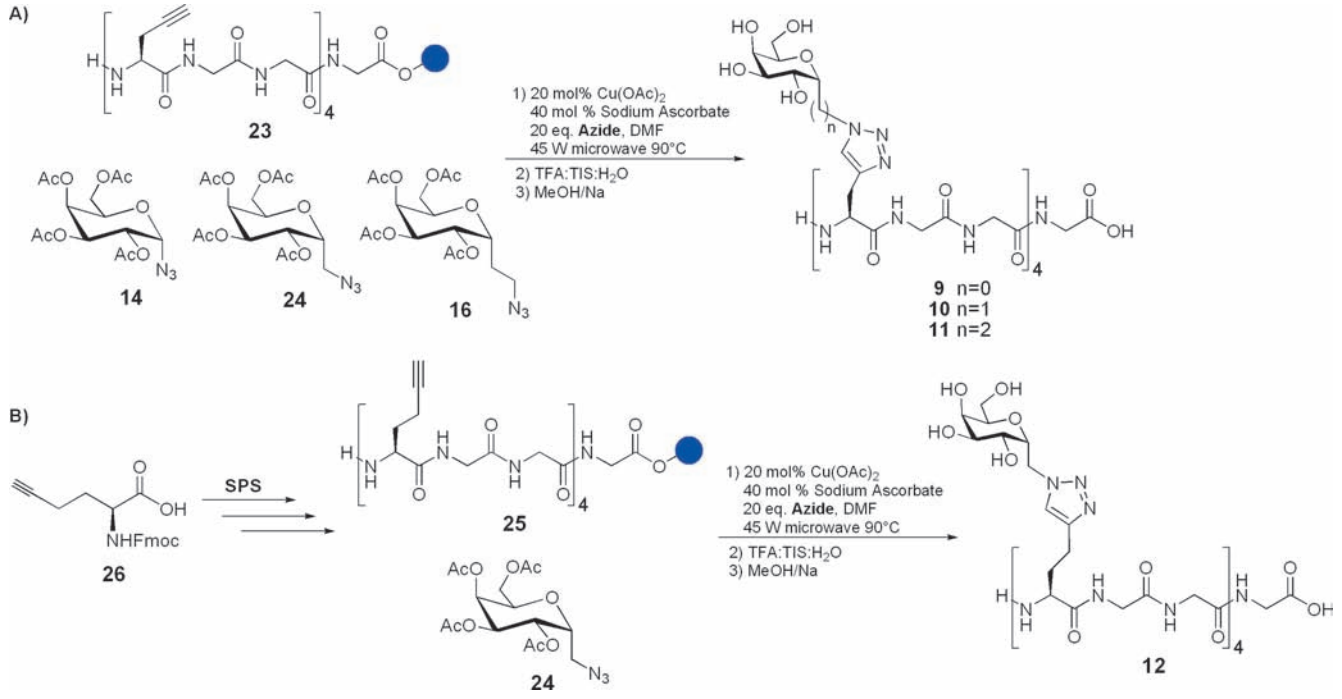
Scheme 2. Microwave Assisted Solid-Phase Synthesis of Triazole-Linked Glycopeptides



using *tert*-butanol,[11] **15** was formed, but reaction conversion was only 81% after 5 h (Table 1, entry 1). DMF resulted in only 76% conversion after 4 h (entry 2), while NMP resulted in complete conversion after 3 h (entry 3). In contrast, dioxane afforded 95% conversion after only 1 h (entry 4). However, the best results were obtained when THF was employed, with complete conversion after only 30 min (entry 5).

These solvent mixtures were also applicable with other azide substrates (Table 2). For instance, reaction of alkyne **13** with azido sugar **16** yielded similar results to those described above, but reaction times were generally shorter. When DMF was used as a cosolvent, glycoconjugate **17** was obtained in 78% conversion after only 15 min (Table 2, entry 1), as opposed to 76% conversion in 4 h for glycoconjugate **15** prepared from azido sugar **14** (Table 1, entry 2). Quantitative conversions for **17** were also obtained within 30 min when NMP, dioxane, and THF were employed (Table 2, entries 2−4). Overall, THF yielded the best results, showing it to be an ideal solvent for the solution-phase coupling regardless of the structure of the azide substrate.

As stated previously, a solvent system with minimal water content is desirable for solid-phase applications to ensure an efficient swelling of the resin. However, an aqueous component is necessary to dissolve the sodium ascorbate and facilitate reduction of Cu(II) to Cu(I).[9,41] Hence, the efficiency of the solution-phase Click reaction of alkyne **13** with azido sugar **14** was repeated using a decreased percentage of water in THF (Table 1, entries 6−9). Surprisingly, decreasing the water content had no effect upon conversions and reaction times were still less than one hour (entries 6−8). However, the reaction time could further be reduced to 15 min without decreasing reaction conversion by using a 10% water/THF solvent system in the presence of 5 equiv of azide (entry 9).

With optimized solution-phase results in hand, the solid-phase synthesis of a triazole-linked glycopeptide was attempted (Scheme 1). Initial attempts to couple resin-supported peptide **18** using the optimized conditions (10% water in THF, 0.2 equiv of $Cu(OAc)_2$, 0.4 equiv of sodium ascorbate) with azido sugar **14** (5 equiv) failed. Even upon heating the reaction for 96 h at 80 °C or adding 10 equiv of azido sugar **14**, the reaction still failed to yield glycopeptide **19**. Given the precedent for microwave accelerated Click couplings on solid-phase resins,[42] we investigated whether glycopeptide formation would occur in the presence of microwaves. Similar conditions were then attempted for the microwave accelerated "Click" coupling, but peptide **20** (Scheme 2) was utilized instead of **18**. Peptide **20** bearing a phenylalanine residue was selected, as the strong UV absorbance of this residue would facilitate purification by HPLC and anhydrous THF was used as the solvent. Consequently, resin-supported peptide **20** was reacted with azido sugar **14** in anhydrous THF, utilizing 0.2 equiv of $Cu(OAc)_2$, 0.4 equiv of sodium ascorbate, and microwave heating (300 W) for 2 h. Analysis by MALDI mass spectrometry of the crude reaction mixture failed to show a trace of product. However, when the solvent was changed to anhydrous DMF trace quantities of glycoconjugate **21** were detected after 2 h (the product was cleaved from the resin prior to analysis). By decreasing the power to 45 W, the reaction went to completion after only 1.5 h and glycoconjugate **21** was obtained in 61% yield after cleavage from the resin and subsequent deprotection and purification by reversed-phase HPLC (Scheme 2). Similarly, when resin-supported peptide **20** was reacted with azido sugar **16** under these

Scheme 3. Microwave Assisted Solid-Phase Synthesis of Glycopeptides 9−12

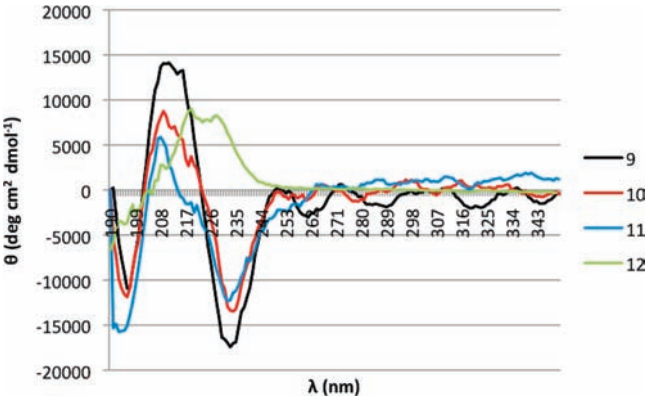


Figure 5. CD spectrum of glycopeptides **9**−**12**. All spectra were acquired at 22 °C, with a concentration of 43 μM. CD data has been normalized for concentration and number of chromophores.

reaction conditions, glycopeptide **22** was obtained in 70% isolated yield after cleavage from the resin, deprotection, and purification by reversed-phase HPLC.

With this promising result, the convergent syntheses of triazole-containing *C*-AFGP glycopeptides **9**, **10**, **11**, and **12** were attempted. Glycosyl azide **14** and resin-supported peptide **23** (prepared under standard Fmoc solid-phase coupling conditions) were subjected to microwave heating in DMF with 0.2 equiv of $Cu(OAc)_2$ and 0.4 equiv of sodium ascorbate (Scheme 3a). Glycoconjugate **9** was obtained in 20% isolated yield following cleavage from the Wang resin, deprotection, and purification by reversed-phase HPLC. Similarly, reaction of azido sugar **24** with resin-supported peptide **23** yielded glycopeptide **10** (45% yield), and when azido sugar **16** was utilized, glycopeptide **11** was obtained in 54% yield. Glycosyl azide **24** was also reacted with resin-supported peptide **25** (prepared under standard Fmoc solid-phase coupling conditions utilizing amino acid **26**) under the microwave "Click" conditions described above, and glycopeptide **12** was obtained in 16% yield (Scheme 3b).

Triazole-containing AFGP analogues **9**−**12** were first examined for TH activity using a nanoliter osmometer.[28] This instrument is regarded as the "gold standard" for assessing thermal hysteresis. All four *C*-AFGP analogues were found to exhibit no thermal hysteresis activity. Furthermore, no dynamic ice shaping was evident indicating there was no interaction with the ice surface, a result consistent with the lack of thermal hysteresis activity in previously reported ornithine analogues **1**−**4**.[4,6] Analysis of solution conformation using circular dichroism (CD) spectroscopy (Figure 5 and Table 3) suggests that the predominant secondary structure in solution is random coil with β-sheet being the next likely solution structure for glycopeptides **9**−**12**. This is consistent with the solution conformation reported for AFGP-8 and other *C*-AFGP analogues studied by our laboratory[2,4,43] and suggests that the lack of TH activity is not due to the fact that AFGP analogues **9**−**12** adopt different solution conformations compared to the native AFGP.

The triazole-containing *C*-AFGP analogues **9**−**12** were also screened for their ability to inhibit ice recrystallization (IRI

dx.doi.org/10.1021/bc100394k |*Bioconjugate Chem.* 2011, 22, 605–616

Chart 1. IRI Activity of *C*-Linked AFGP Analogues[a]

[a]PBS represents a positive control for ice recrystallization.

activity) using a splat cooling assay.[1,29] Chart 1 shows the IRI activity of triazole-containing *C*-AFGP analogues **9**−**12**, native AFGP-8, and previously synthesized *C*-AFGP analogues **1**−**4** (the latter contain an amide bond in the side chain).[6,44] In this assay, a phosphate buffered saline (PBS) solution is utilized as a positive control for ice recrystallization; thus, bars smaller than PBS indicate the ability to inhibit ice recrystallization. All samples have been normalized to PBS. As evident from Chart 1, triazole-containing AFGP analogue **9** failed to exhibit IRI activity. AFGP analogue **9** is closely related to peptoid AFGP analogue **6** (published by Norgren et al.) which also failed to exhibit IRI activity.[26] AFGP analogue **6** contains *N*-methyl glycine instead of glycine in the polypeptide backbone; however, the nature of the anomeric linkage, total length of the side chain, and the position of the triazole within the side chain are identical to those of AFGP analogue **9**. While these analogues did not inhibit the recrystallization of ice, the results are consistent with the suggestion that IRI activity is sensitive to the length of the side chain bearing the carbohydrate moiety. Similar results have been reported by our laboratory in analogues that contain an amide bond in the side

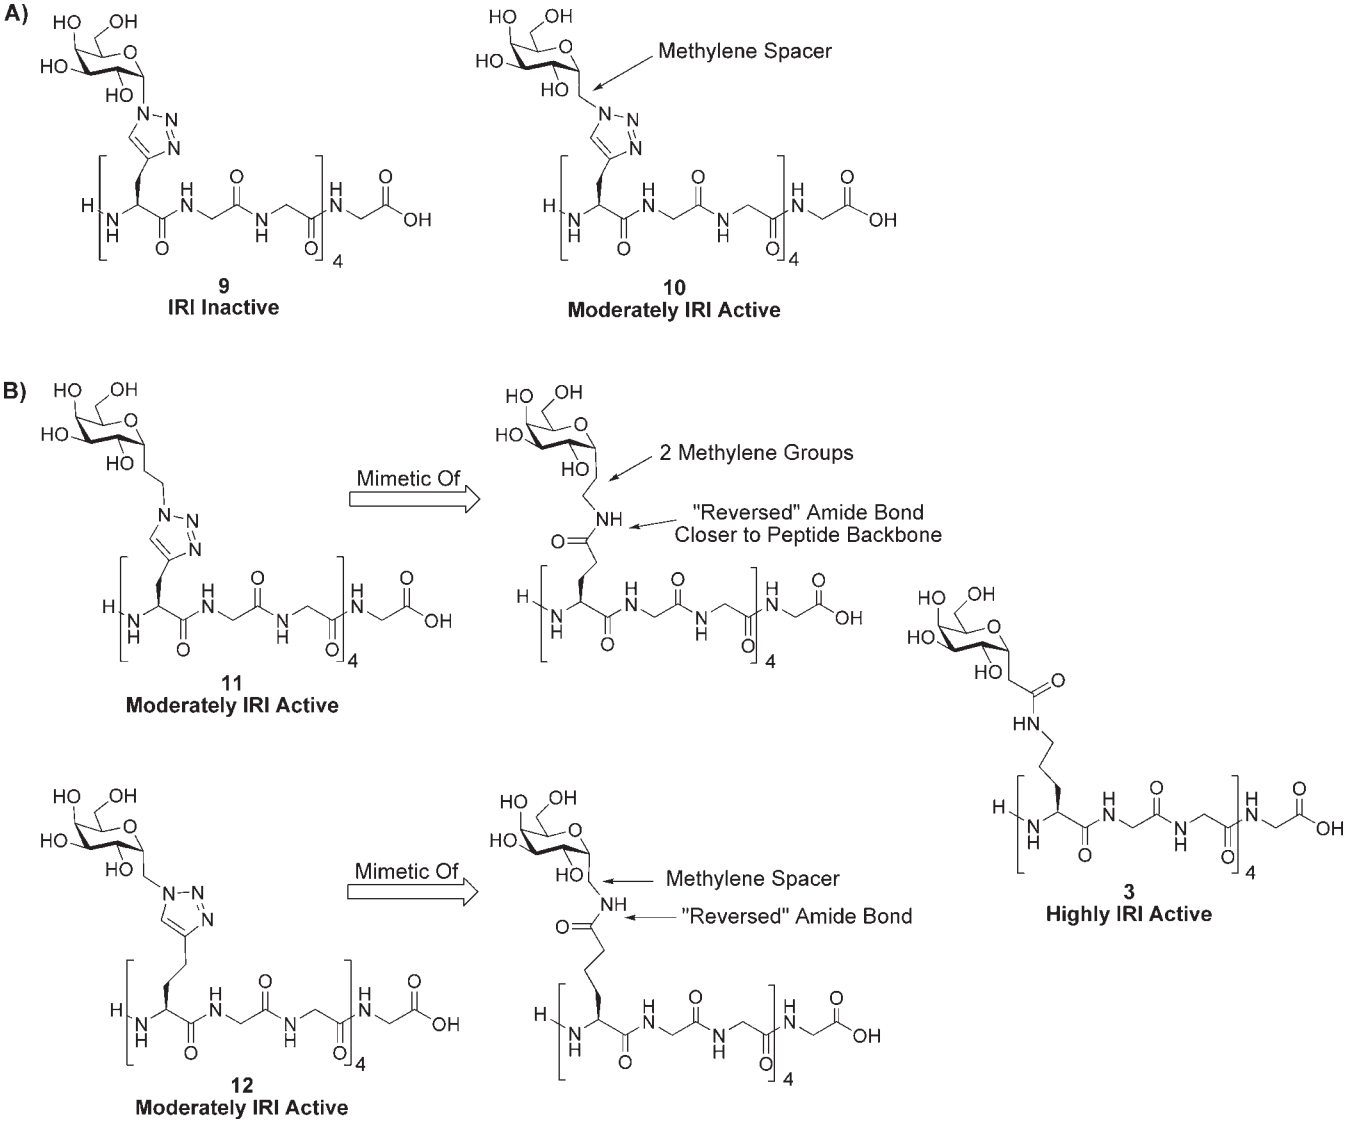

Figure 6. The presence of a hydrophobic methylene spacer and "reversed" directionality of the triazole moiety in AFGP analogues **9**−**12**.

dx.doi.org/10.1021/bc100394k |*Bioconjugate Chem.* 2011, 22, 605–616

chain instead of a triazole.[6] For instance, as the side chain of IRI active *C*-AFGP analogue **3** is shortened (compounds **1** and **2**) or lengthened (compound **4**) IRI activity is lost.[6]

Triazole-containing AFGP analogue **9** is also a close analogue of *C*-AFGP analogue **1**, which did not possess IRI activity. There are two key structural changes in AFGP analogue **9** relative to **1**. First, the triazole moiety has been employed to mimic the amide bond in **1**. Second, the orientation of the triazole in the side chain mimics an amide bond that is "reversed" in its orientation compared to **1**. These structural modifications in **9** do not restore IRI activity since this analogue failed to inhibit ice recrystallization. However, the fact that the lengths of the side chains in **9** and **1** are the same supports the hypothesis that the distance between the carbohydrate moiety and the peptide backbone is important for IRI activity.

Some of the most IRI active *C*-AFGP analogues prepared by our laboratory possess a methylene group between the carbohydrate moiety and the amide bond in the side chain. It has been proposed that the hydrophobic nature of this group is an important structural feature in *C*-AFGP analogue **3**. This methylene group is absent in triazole-containing AFGP analogue **9**. Interestingly, when this group is present as in triazole-containing *C*-AFGP analogue **10** (Figure 6a), the glycoconjugate is a moderate inhibitor of ice recrystallization, validating its importance.[6] Triazole-containing *C*-AFGP analogue **11** has two methylene groups incorporated between the carbohydrate moiety and the triazole linkage. This glycoconjugate has similar IRI activity as triazole-containing analogue **10**, further validating the importance of a hydrophobic group in the spacer close to the carbohydrate.[6] *C*-AFGP derivative **11** is also a close analogue of potent ice recrystallization inhibitor *C*-AFGP analogue **3**. However, **11** is not as active as **3**. The number of atoms between the carbohydrate moiety and the polypeptide backbone in analogues **3** and **11** is the same. However, the triazole moiety in **11** mimics an amide bond that has the directionality "reversed" relative to **3**. Furthermore, the position of the triazole linker in the side chain of **11** is different than the position of the amide bond in **3** (Figure 6b). The triazole linker in *C*-linked AFGP **11** is actually one atom closer to the polypeptide backbone than the amide bond in **3**. This structural modification is detrimental to IRI activity as analogue **11** is much less active than analogue **3**.

Triazole-containing *C*-AFGP analogue **12** is also a close analogue of **3** with the exception of the orientation of the triazole moiety. The orientation of the triazole mimics an amide bond that is "reversed" relative to **3** (Figure 6b). However, the length of the side chain between the carbohydrate and the peptide backbone, as well as the position of the triazole linker within this side chain, is the same (shown in Figure 6b). While triazole-containing analogue **12** exhibited moderate IRI activity, it is much less active than *C*-AFGP analogue **3**. These results indicate that while the presence of a hydrophobic methylene spacer and the length of the side chain bearing the triazole (or amide) linkage directly affect IRI activity, the amide bond in **3** is an essential structural feature necessary for potent IRI activity.

CONCLUSIONS

In summary, the synthesis of a series of triazole-containing AFGP and *C*-AFGP analogues has been reported. These compounds were prepared using a convergent solid-phase synthesis approach. "Click" chemistry conditions using Cu (II) (20 mol %) and sodium ascorbate as the *in situ* reductant in dry DMF in the presence of microwaves were utilized. Triazole-containing AFGP analogue **9** failed to exhibit IRI activity, while analogues **10**, **11**, and **12** exhibited moderate IRI activity. The results of this study suggest that substitution of the amide bond in *C*-AFGP analogue **3** with a triazole moiety is detrimental to IRI activity. In addition, a hydrophobic component (i.e., methylene spacer) close to the carbohydrate residue as well as the length of the side chain bearing the triazole (or amide) linkage is also important. This result is consistent with earlier findings by our laboratory. Molecular dynamics simulations and variable temperature NMR studies are currently being performed on analogues **10**, **11**, and **12** in an effort to elucidate how the methylene spacer and position of the triazole linker are influencing orientation of the carbohydrate residue. The results of these studies will be reported in due course.

Scheme 1. Synthesis of azido sugar **24**.

***E*-1-(2,3;4,6-di-*O*-isopropylidene-*α*-D-galactopyranosyl)-prop-1'-ene (28)**

Alkene **27**[1] was isomerized according to the procedure by Patnam.[2] (1,5-Cyclooctadiene)-bis-(methyldiphenylphosphine) Iridium (I) hexafluorophosphate (150 mg, 0.177 mmol) was suspended in 5 mL of THF under nitrogen with vigorous stirring. Hydrogen was bubbled into the mixture until the suspension dissolved giving a yellow solution. The solution was then flushed with Argon for 10 minutes and transferred via cannula into a flask containing **27** (2.31 g, 6.2 mmol) dissolved in THF. The reaction was stirred for 12 hours until complete conversion was observed by NMR. The solution was then concentrated under reduced pressure to yield 2.6 g of a crude yellow gel that was used without further purification.

The crude product was dissolved in 20 mL of a 0.1 M solution of sodium methoxide in methanol. The reaction was stirred for 1.5 hrs at room temperature whereupon DOWEX 50WX8 (50-100 mesh) ion exchange resin was added until the pH of the solution was neutral. The solution was filtered and concentrated to dryness to yield 1.3 g of a crude white solid which was used without any further purification.

The crude solid (1.3 g, 6.37 mmol) was dissolved in dry DMF under Argon with stirring. *Para*-toluenesulfonic acid monohydrate (100 mg, 0.525 mmol) was added followed by a dropwise addition of 2-methoxypropene (2.9 mL, 30 mmol). The reaction mixture was stirred for forty minutes. Upon complete consumption of starting material 500 μL of triethylamine was added and the solution was concentrated to dryness. The product was purified by flash chromatography (8:2 hexanes:ethyl acetate) to yield 1.53 g of **28** (87% yield over 3 steps). ^{1}H NMR (500 MHz, $CDCl_3$): δ_{ppm} 5.88 (dqd, 1H, J = 15.8, 6.4, 1.6 Hz), 5.60 (ddq, 1H, J = 15.8, 5.2, 1.6), 4.86 (t, 1H, J = 5.3 Hz), 4.45 (bs, 1H), 4.27 (dd, 1H, J = 9.9, 5.6 Hz), 4.09 (dd, 1H, J = 12.9, 2.1 Hz), 3.90 (dd, 1H, J = 12.9, 1.4 Hz), 3.67 (dd, 1H, J = 9.9, 2.9 Hz), 3.38 (dd, 1H, J = 3.2, 1.7 Hz), 1.74 (ddd, 3H, J = 6.5, 1.6, 1.6 Hz), 1.47 (s, 3H), 1.46 (s, 3H), 1.44 (s, 3H), 1.41 (s, 3H); ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 131.3, 123.3, 110.0, 98.5, 75.2, 74.4, 70.9, 67.7, 63.5,

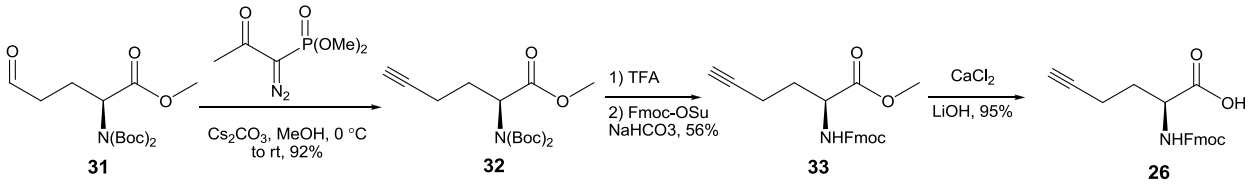
(2,3;4,6-di-*O*-isopropylidene-α-D-galactopyranosyl)methanol (29)

Compound **28** (430 mg, 1.51 mmol) was dissolved in 5 mL of DCM and cooled to -78º C. Ozone was bubbled through the solution until a blue colour persisted. The solution was then flushed with Nitrogen for 10 minutes until it became clear. Triphenylphosphine (800 mg, 3.05 mmol) was added and the reaction was allowed to warm to ambient temperature over 12 hours and then concentrated to dryness. The residue was immediately dissolved in methanol (10 mL) and cooled to 0 ºC. Sodium borohydride (340 mg, 9.0 mmol) was added portion wise and the reaction was stirred for 2 hrs. The reaction mixture was filtered through Celite and concentrated under reduced pressure. The residue was re-dissolved in ethyl acetate and washed sequentially with saturated sodium bicarbonate and brine, then dried with magnesium sulfate, filtered and concentrated *in vacuo*. The product was purified by flash chromatography (6:4 ethyl acetate: hexanes) to yield 261 mg of **29** as a clear oil (63% over 2 steps). ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 4.55 (td, 1H, *J* = 7.9, 5.9 Hz), 4.52-4.50 (m, 1H), 4.38 (dd, 1H, *J* = 10.1, 6.0 Hz), 4.12 (dd, 1H, *J* = 13.1, 2.2 Hz), 3.95 (dd, 1H, *J* = 13.0, 1.5 Hz), 3.93-3.85 (m, 2H), 3.81 (dd, 1H, *J* = 10.1, 2.9 Hz), 3.40 (dd, 1H, *J* = 3.2, 1.6 Hz), 1.50 (s, 3H), 1.49 (s, 3H), 1.48 (s, 3H), 1.44 (s, 3H); ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 110.3, 98.6, 75.5, 74.2, 70.3, 67.3, 64.5, 63.3, 58.7, 29.2, 26.6, 18.4. ESI-MS *m/z* calcd for $C_{13}H_{22}O_6$ $[M + Na]^+$: 297.13. Found: 297.17.



(2,3;4,6-di-*O*-isopropylidene-α-D-galactopyranosyl)methyl methanesulfonate (30)

Alcohol **29** (600 mg, 2.2 mmol) was dissolved in pyridine (12.5 mL) and cooled to 0 ºC. Methanesulfonyl chloride (620 µL, 8 mmol) was added dropwise and the mixture was stirred for 5 hours at 0 ºC. Upon complete consumption of starting material the reaction was diluted with DCM (50 mL) and washed twice with 10 % HCl (50 mL) and $NaHCO_3$ then dried with magnesium sulfate, filtered, and concentrated to yield 662 mg of **30** (86% yield) as a clear colourless oil. ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 4.70-4.61 (m, 2H), 4.51-4.48 (m, 1H), 4.35 (d, 1H, *J* = 10.0 Hz), 4.34 (dd, 1H, *J* = 15.7, 5.5 Hz), 4.13 (dd, 1H, *J* = 13.2, 2.1 Hz), 3.90 (dd, 1H, *J* = 13.2, 1.4 Hz), 3.61 (dd, 1H, *J* = 10.2, 2.8 Hz), 3.53 (dd, 1H, *J* = 3.1, 1.8 Hz), 3.09 (s, 3H), 1.48 (s, 3H), 1.46 (s, 3H), 1.45 (s, 3H), 1.40 (s, 3H); ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 110.8, 98.7, 74.5, 74.3, 69.2, 67.1, 64.7, 64.3, 63.2, 38.6, 29.2, 26.6, 26.5, 18.4. ESI-MS *m/z* calcd for $C_{14}H_{24}O_8S$ $[M + H]^+$: 353.12. Found: 353.16.

(2,3,4,6-Tetra-*O*-acetyl-α-D-galactopyranosyl)methyl azide (24)

Mesylate **30** (660 mg, 1.8 mmol) was dissolved in TFA (4 mL) and H_2O (1 mL) at room temperature. The reaction was stirred for 10 minutes and pyridine (10 mL) was added and solvent was removed *in vacuo*. The residue was immediately re-dissolved in pyridine (5 mL) and acetic anhydride (5 mL) and stirred for 4 hours. Solvent was removed *in vacuo* then the flask was flushed with Argon and the residue re-dissolved in DMF (1.5 mL). HMPA (500 µL) and sodium azide (400 mg, 6.1 mmol) were added and the reaction was heated to 85ºC for 12 hours. The solution was diluted with DCM, and washed sequentially with 10% HCl, saturated $NaHCO_3$, and brine. The organic layer was dried with magnesium sulfate, filtered, and concentrated. The final product was purified by DVC (100% hexanes to 100% ethyl acetate in 5% intervals) to yield 457 mg of residue that was recrystallized from diethyl ether/hexanes to yield 373 mg of **24** as a white crystalline solid (57% yield over 3 steps). Spectral data is consistent with previously published

data.[3] ^{1}H NMR (400 MHz, $CDCl_3$): δ_{ppm} 5.44 (dd, 1H, *J* = 3.3, 3.3 Hz), 5.27 (dd, 1H, *J* = 8.4, 4.6 Hz), 5.22 (dd, 1H, *J* = 8.4, 3.2 Hz), 4.39 (m, 2H), 4.25 (ddd, 1H, *J* = 8.0, 4.5, 3.4 Hz), 4.11 (dd, 1H, *J* = 11.7, 4.7 Hz), 3.63 (dd, 1H, *J* = 13.5, 8.8 Hz), 3.24 (dd, 1H, *J* = 13.5, 3.7 Hz), 2.12 (s, 3H), 2.11 (s, 3H), 2.07 (s, 3H), 2.06 (s, 3H); ^{13}C NMR (100 MHz, $CDCl_3$): δ_{ppm} 170.7, 169.8, 169.6, 169.5, 70.8, 69.8, 67.7, 67.5, 66.9, 60.7, 48.3, 20.67, 20.66, 20.59. ESI-MS *m/z* calcd for $C_{15}H_{21}N_3O_9$ $[M + K]^+$: 426.091. Found: 426.12.

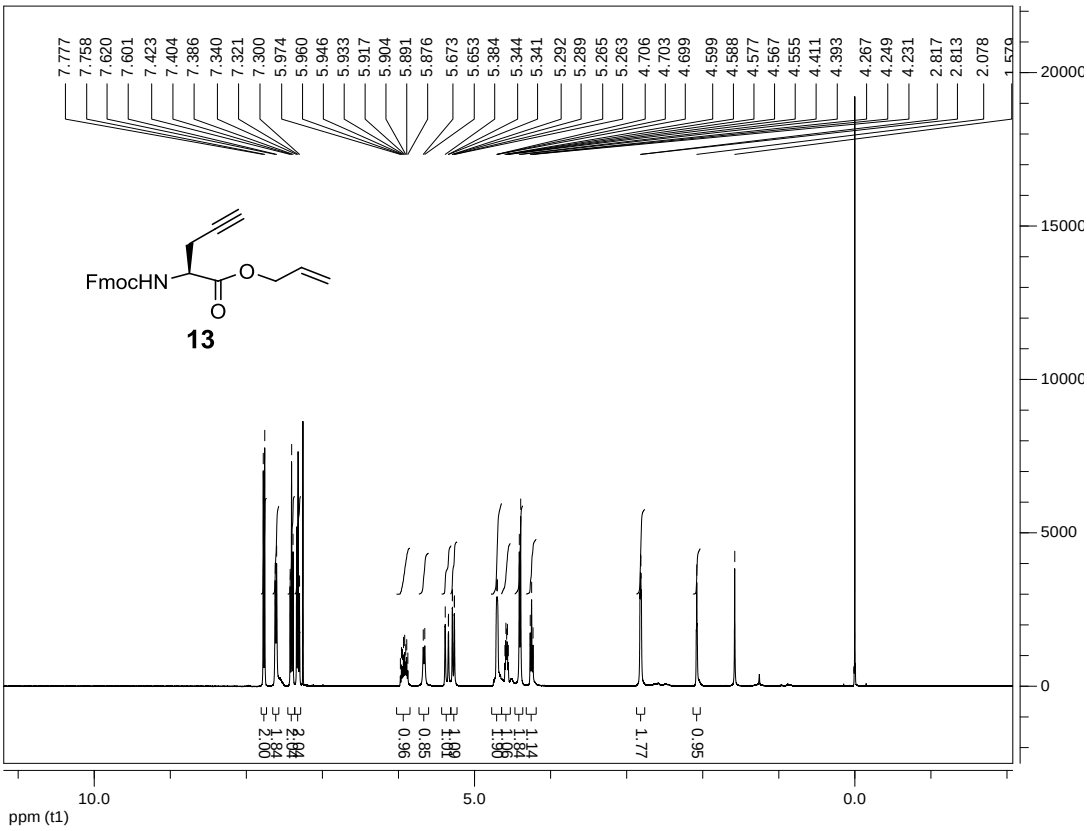
Scheme 2. Synthesis of amino acid **26**.

(S)-Methyl 2-{(tert-butoxy)-N-[(tert-butyl)oxycarbonyl]- carbonylamino}-hex-5-ynoate (32).

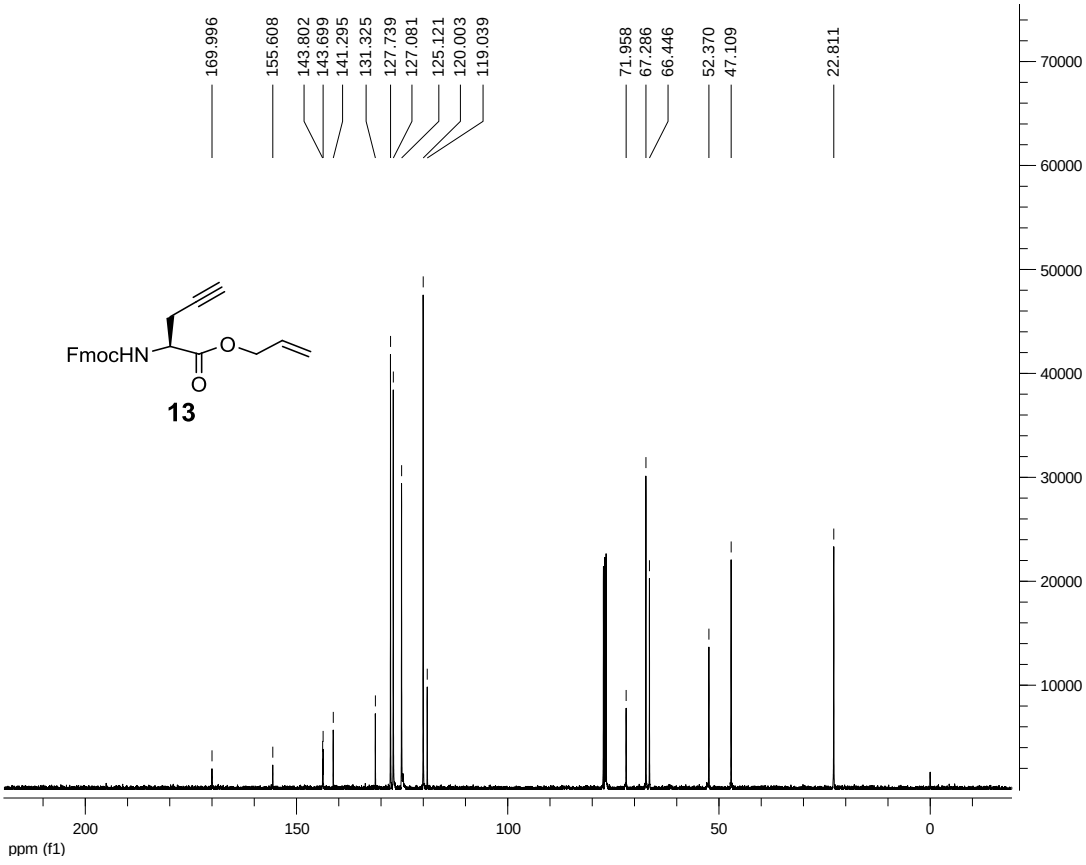
Aldehyde **31**[4] (1.9 g, 5.5 mmol) and dimethyl (1-diazo-2-oxopropyl)phosphonate (1.58 g, 8.25 mmol) were dissolved in 20 mL of dry MeOH. The solution was cooled to 0 ºC and Cs_2CO_3 (2.51 g, 7.7 mmol) was added in one portion. The mixture was warmed to room temperature and stirred for 3 hrs. The solution was concentrated and partitioned with ether and water (100 mL each). The organic layer was successively washed with water and brine, dried over Na_2SO_4 and concentrated. The crude product was redissolved in 100 mL of petroleum ether and the cloudy solution was filtered through a pad of Celite. Evaporation of the solvent afforded 1.80 g of **32** (95% yield) as a colorless oil. ^{1}H NMR ($CDCl_3$, 400 MHz): δ_{ppm} 4.98 (dd, 1H, J = 9.0, 5.0 Hz), 3.69 (s, 3H), 2.41-2.19 (m, 3H), 2.06 (m, 1H), 1.94 (t, 1H, J = 2.6 Hz), 1.47 (s, 18H). ^{13}C NMR (CDCl3, 100 MHz): δ_{ppm} 171.0, 151.9, 83.3, 83.2, 69.1, 57.2, 52.2, 29.3, 28.0, 15.7. ESI-MS *m/z* calcd for $C_{17}H_{27}NO_6$ $[M + Na]^+$: 364.17. Found: 364.30.

(*S*)-methyl 2-(9-fluorenylmethoxycarbonylamino)-hex-5-ynoate (33).

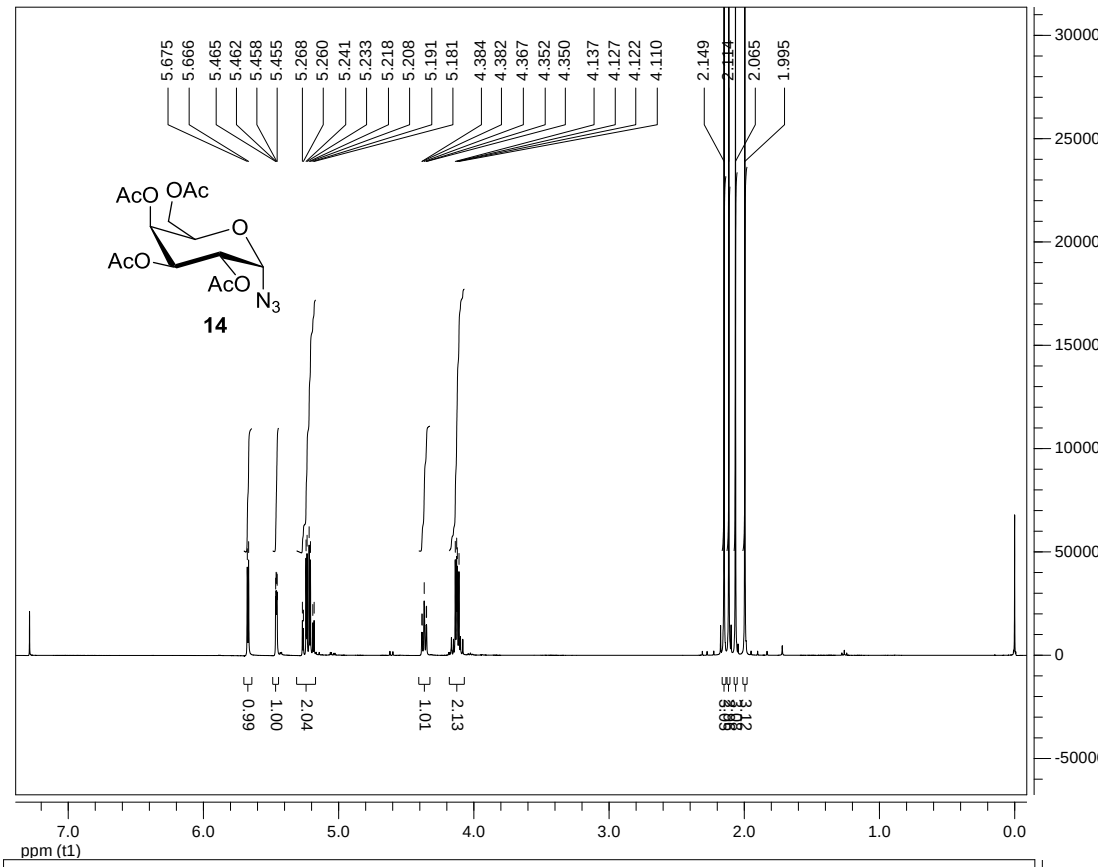
To a cold (0 ºC) solution of **32** (1.8 g, 5.3 mmol) in 5 mL of DCM was added dropwise 5 mL of TFA. The solution was warmed to room temperature and stirred until TLC (9:1 petroleum ether:ethyl acetate) showed disappearance of the starting material. The crude mixture was then concentrated and co-evaporated with toluene (3 x 20 mL) and dried under high vacuum for several hours. The crude material was re-dissolved in 2:1 dioxane:water (45 mL) and was cooled to 0 ºC. $NaHCO_3$ (1.7 g, 21.2 mmol) and Fmoc-OSu (1.96 g, 5.8 mmol) were successively added and the mixture was warmed to room temperature and stirred overnight. Dioxane was evaporated and the aqueous layer was extracted with ethyl acetate. The organic layer was then washed with water and brine, dried over Na_2SO_4 and concentrated. Purification of the crude by flash chromatography (3:1 DCM:Petroleum ether, followed by pure DCM) afforded 1.08 g of **33** (56%



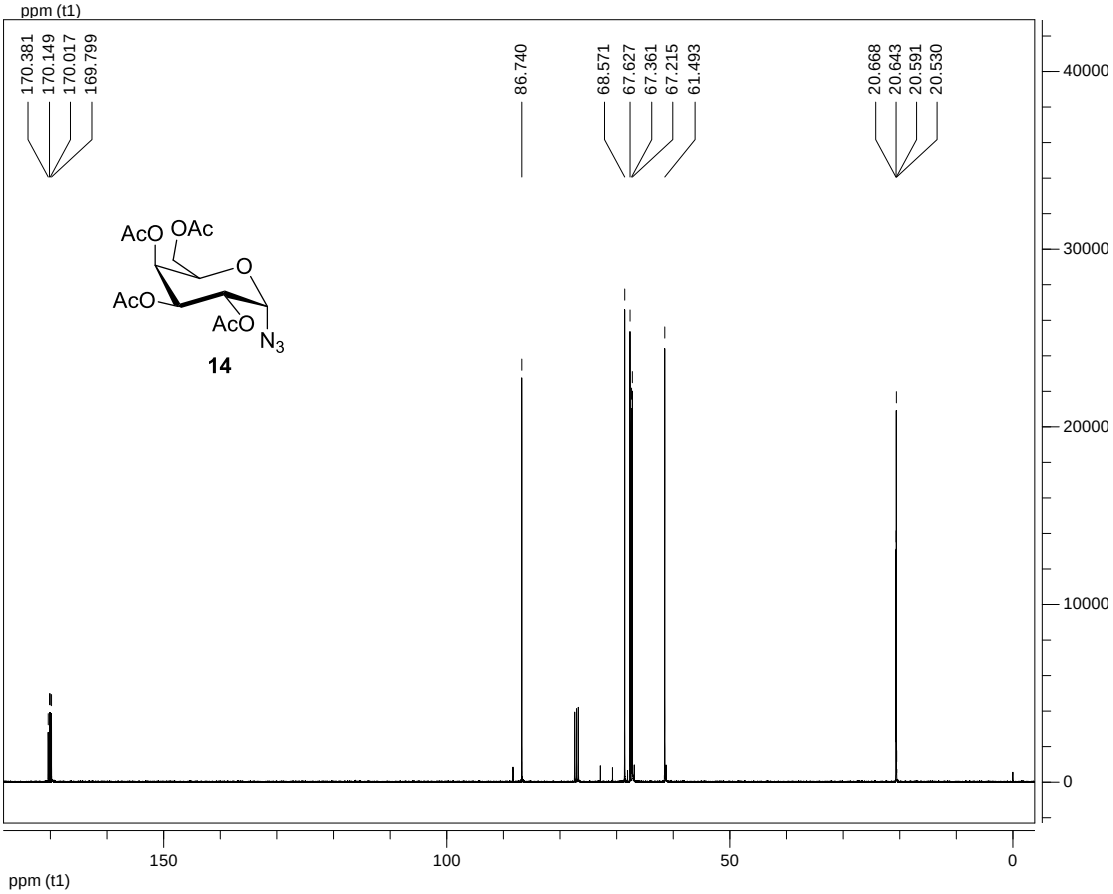
[3] Aldhoun, M., Massi, A., and Dondoni, A. (2008) Click Azide−Nitrile Cycloaddition as a New Ligation Tool for the Synthesis of Tetrazole-Tethered *C*-Glycosyl α-Amino Acids. *J. Org. Chem.* 73, 9565-9575.



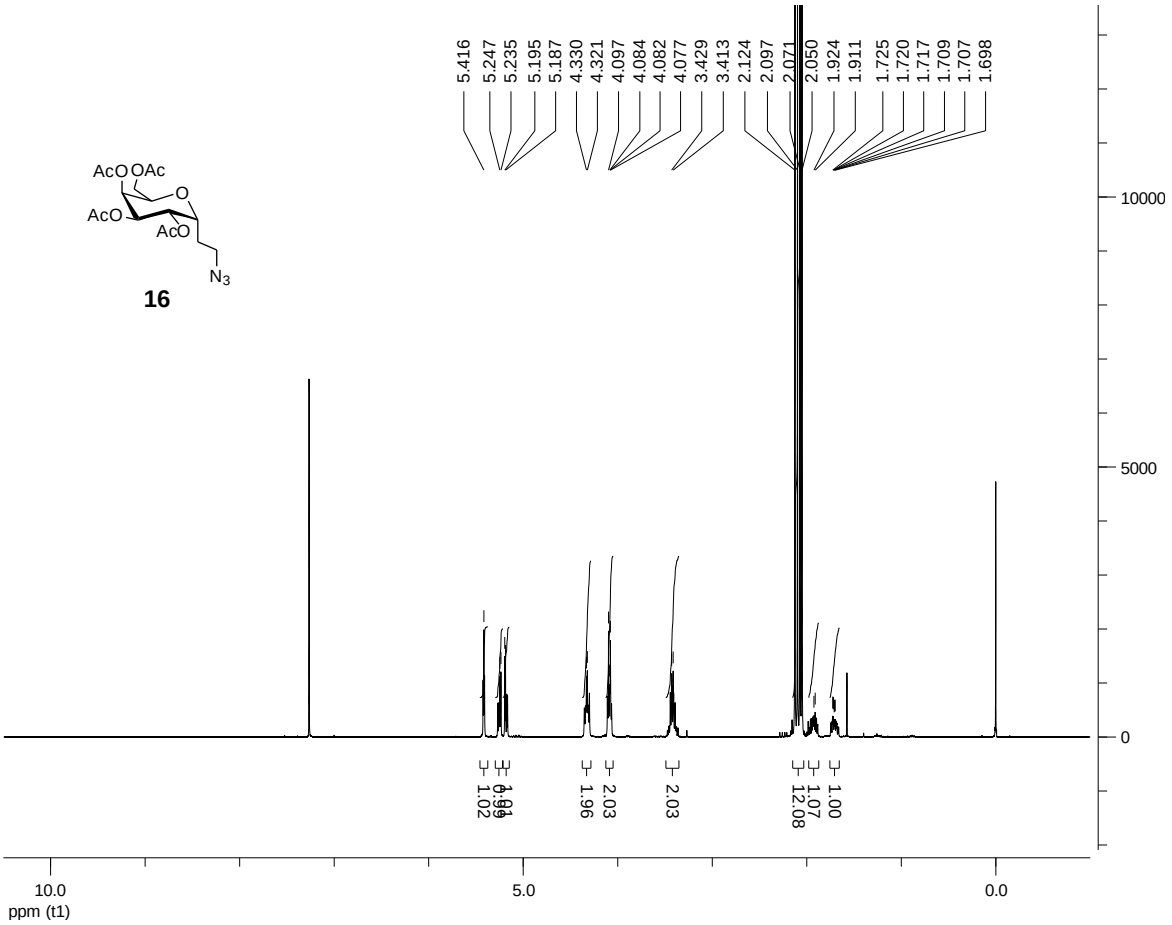
[4] Padrón J. M., Kokotos G., Martín T., Markidis T., Gibbons W. A., and Martín, V. S. (1998) Enantiospecific synthesis of α-amino acid semialdehydes: a key step for the synthesis of unnatural unsaturated and saturated α-amino acids. *Tetrahedron Asymmetry*. 9, 3381-3394.



yield over 2 steps) as a white solid. ^{1}H NMR ($CDCl_3$, 400 MHz) : δ_{ppm} 7.75 (d, 2H, J = 7.4 Hz), 7.59 (dd, 2H, J = 7.2, 3.2 Hz), 7.38 (t, 2H, J = 7.4 Hz), 7.30 (t, 2H, J = 7.5 Hz), 5.44 (d, 1H, J = 8.0 Hz), 4.48 (m, 1H), 4.40 (d, 2H, J = 7.0 Hz), 4.21 (t, 1H, J = 7.0 Hz), 3.74 (s, 3H), 2.26 (m, 2H), 2.13 (m , 1H), 1.99 (t, 1H, J = 2.4 Hz), 1.92 (m, 1H). ^{13}C NMR ($CDCl_3$, 100 MHz): δ_{ppm} 172.4, 155.9, 143.9, 143.7, 141.4, 141.3, 127.8, 127.1, 125.1, 120.0, 82.7, 77.3, 69.5, 67.0, 53.2, 52.6, 47.2, 31.3, 14.8. ESI-MS *m/z* calcd for $C_{22}H_{21}NO_4$ $[M + Na]^+$: 386.14. Found: 386.25.



(*S*)-2-(9-fluorenylmethoxycarbonylamino)-hex-5-ynoic acid (26).



To a solution of **33** (600 mg, 1.65 mmol) in a mixture of 25 mL of isopropanol and 6 mL of THF was added powdered $CaCl_2$ (2.8 g, 25 mmol). $LiOH.H_2O$ (280 mg, 6.6 mmol) in 7 mL of water was added and the mixture was vigorously stirred until TLC (98:2 DCM:MeOH) showed disappearance of the starting material (*ca*. 5 hrs). The pH was adjusted to 2 with 1% HCl and organic solvents were removed. The aqueous layer was extracted with DCM and the organic layer was washed with water and brine, dried over Na_2SO_4 and concentrated *in vacuo*. The product was purified by flash chromatography (98:2 DCM:MeOH) to yield 550 mg of **26** (95% yield) as a white solid. ^{1}H NMR (2:1 $CDCl_3/CD_3OD$, 400 MHz): δ_{ppm} 7.71 (d, 2H, J = 7.6 Hz), 7.58 (dd, 2H, J = 7.1, 3.9 Hz), 7.35 (t, 2H, J = 7.6 Hz), 7.27 (t, 2H, J = 7.6 Hz), 4.35 (m, 3H), 4.18 (t, 1H, J = 6.8 Hz), 2.24 (m, 2H), 2.09 (m, 1H), 2.01 (t, 1H, J = 2.6 Hz), 1.86 (m, 1H). ^{13}C NMR ($CDCl_3/CD_3OD$ 2/1, 100 MHz): δ_{ppm} 173.9, 156.7, 143.8, 143.7, 141.2, 141.2, 127.7, 127.0, 125.0, 119.8, 82.6, 77.5, 69.3, 66.9, 53.0, 47.1, 30.9, 14.9. ESI-MS *m/z* calcd for $C_{21}H_{19}NO_4$ $[M + Na]^+$: 372.12. Found: 372.24.

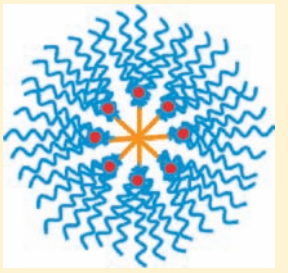
Synthesis and Properties of Star-Comb Polymers and Their Doxorubicin Conjugates



Bo Chen,[†,‡] Derek G. van der Poll,[‡] Katherine Jerger,[†] William C. Floyd,[‡] Jean M. J. Fréchet, and Francis C. Szoka*[,†]

[†]Department of Bioengineering, Therapeutic Sciences and Pharmaceutical Chemistry, University of California, San Francisco, California 94143-0912, United States

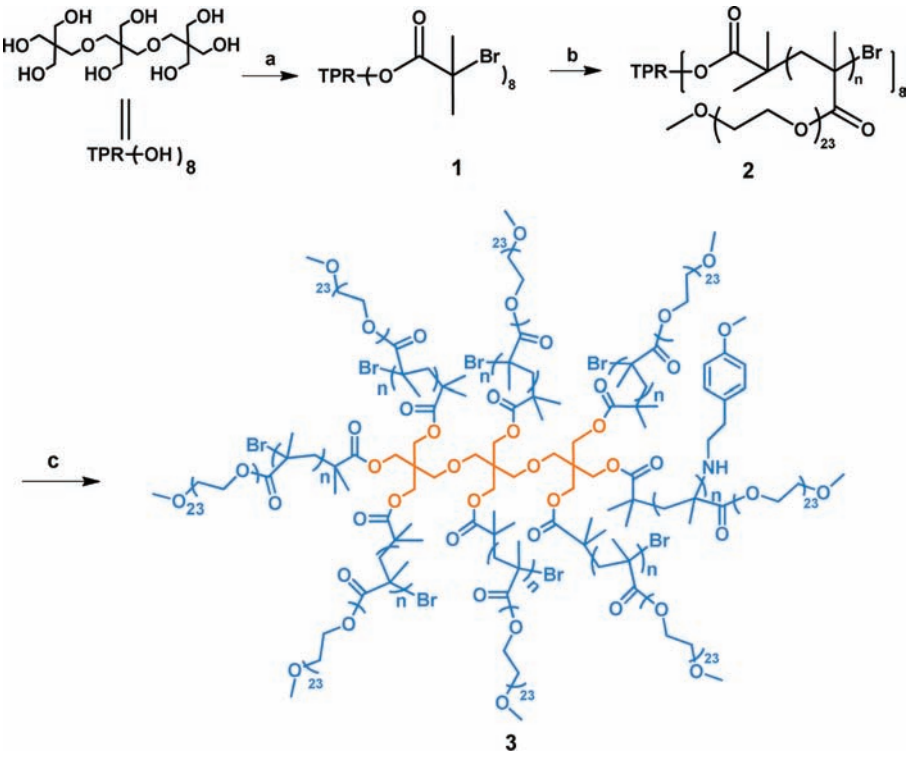
[‡]Department of Chemistry, University of California, Berkeley, California 94720-1460, United States

Supporting Information

ABSTRACT: We describe a six-step synthesis to water-soluble doxorubicin (DOX)-loaded biodegradable PEGylated star-comb polymers with favorable pharmaceutical properties by atom transfer radical polymerization (ATRP) starting with a commercially available tripentaerythritol carrying eight reactive sites. The low polydispersity polymers degrade in a stepwise manner into lower molecular weight (MW) fragments by 15 days at 37 °C at either pH 5.0 or pH 7.4. The half-life of the star-comb polymers in blood is dependent upon the molecular weight; the 44 kDa star-comb has a $t_{1/2,\beta}$ of 30.5 ± 2.1 h, which is not significantly changed (28.6 ± 2.7 h) when 6.6 wt % of DOX is attached to it via a pH-sensitive hydrazone linker. The star-comb polymers have low accumulation in organs but a high accumulation in C26 flank tumors implanted in Balb/C mice. The hydrodynamic diameter of polymer−DOX conjugates measured by dynamic light scattering increases from 8 to 35 to 41 nm as the loading is increased from 6.6 to 8.4 to 10.2 wt %. Although there is no significant difference in the $t_{1/2,\beta}$ or in the accumulation of polymer−DOX in C-26 tumors, the uptake of polymer in the spleen is significantly higher for polymers with DOX loadings greater than 6.6 wt %. Polymer accumulation in other vital organs is independent of the DOX loading. The facile synthesis, biodegradability, long circulation time, and high tumor accumulation of the attached drug suggests that the water-soluble star-comb polymers have promise in therapeutic applications.

INTRODUCTION

In the past three decades, there has been extensive exploration of a variety of polymers as drug carriers, a concept introduced by Kopecek, Ringsdorf, and Duncan.[1] In a recent exploration, PEGylated star polymers have been demonstrated to be well-suited for drug delivery applications due to their high solubility, biocompatibility, low toxicity, low organ accumulation, and high accumulation in tumor sites.[2−5] In contrast to traditional linear polymers, star polymers possess a very narrow polydispersity index and a defined number of functional groups; this enables a consistent drug loading and promotes reproducible pharmacokinetic behavior.[2,6] Polyester linkages provide the additional advantage of biodegradability,[7] and PEGylated polyester star polymers of high molecular weight show excellent promise as drug carriers.[2,6,8] The doxorubicin (DOX) conjugated "bow-tie" structure with a fourth generation of 2,2-bis(hydroxymethyl)propionic acid (bis HMPA) and eight 5 kDa PEG chains showed antitumor activity comparable to the FDA approved liposome DOX (DOXIL).[2]



PEGylated star polymers are commonly prepared by coupling activated PEG chains to dendrimer cores, which are prepared by a multistep synthetic procedure.[2,4,9−12] Specialized PEG reagents with reactive functionalities and long reaction times are required to transform the dendritic cores into high molecular weight, branched polymers. PEGylated star polymers have also been prepared by living polymerization, such as atom transfer radical polymerization (ATRP) of poly(ethylene glycol) methylether methacrylate (PEGMA) using dendritic cores as initiators, which allows for the rapid buildup of polymers while also providing for control over molecular weight and polydispersity.[10,13,14] However, the core initiators of these polymers either have a core that is difficult to synthesize[13] or are not biodegradable.[10] In addition, these PEGylated star polymers prepared by living polymerization have neither been characterized *in vivo* nor used as drug carriers.[14]

Herein, we describe a facile approach to biodegradable PEGylated star-comb polymers (Scheme 1) by using a commercially available "tripentaerythritol" with eight reactive sites. Due to the large amount of PEGMA incorporated into the carrier by grafting from the tripentaerythritol core, this structure should be inherently water-soluble and exist as a unimolecular species,[15,16] as opposed to noncovalent aggregate structures such as the micelles prepared from amphiphilic block copolymers[17−19] or other systems such as shell cross-linked knedel-like (SCK) nanoparticles.[20,21] We evaluated the pharmacokinetics of the star-comb polymers with various molecular weights in mice.

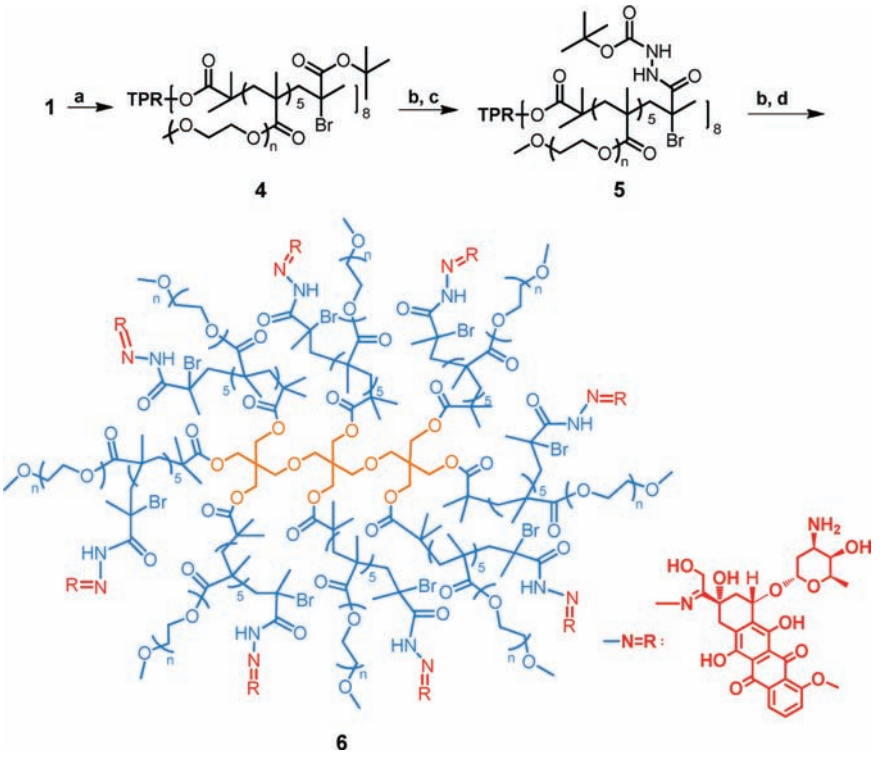
Scheme 1. Synthesis of Star-Comb Polymer with One Methoxyphenol Group[a]

[a] a. DCM, pyridine, 2-bromoisobutyryl bromide; b. PEGMA, CuBr, PMDETA, anisole; c. TEA, MPEA, DMF.

Following these initial studies, the polymer with a molecular weight of 45 kDa was selected to attach DOX via a pH-sensitive acyl hydrazone bond (Scheme 2).[2,22] We studied the biodistribution of this polymer−DOX conjugate to explore the potential of this star-comb polymer as an antitumor-modality.



MATERIALS AND METHODS

General Procedures and Materials. 2-(4-Methoxyphenyl) ethylamine (MPEA) was purchased from ARCO Chemical Company. All other chemicals of the highest grade available, including solvents, were purchased from Sigma-Aldrich and used without further purification. Poly(ethylene glycol) methyl ether methacrylate (PEGMA) with molecular weights of 1100 and 2080 Da was purchased from Sigma-Aldrich. High performance flash chromatography (HPFC) was carried out on a Biotage (Charlottesville, VA) Horizon system with prepacked silica gel columns. ^{1}H NMR spectra were recorded on a Bruker Avance 300 MHz ultrashield NMR. NMR chemical shifts are reported in ppm and calibrated against solvent signals. MALDI-TOF MS data were collected on a PerSeptive Biosystems Voyager-DE instrument in positive ion mode using a 2,5-dihydroxybenzoic acid (DHB) matrix and calibration against bovine insulin standards. Gel permeation chromatography (GPC) consisted of a Viscotek 1122 pump, a Viscotek 270 dual detector, and a Viscotek 3500 differential refractive index (RI) detector. GPC was performed at 1.0 mL/min in two Resipore (3 μm) columns (Polymer Laboratories, 300 × 7.5 mm) thermostatted to 50 °C using THF as the mobile phase and poly(methyl methacrylate) as the calibration standards. Refractive index increment (dn/dc) values are determined by plotting the refractive index values of polymer solutions versus varying polymer concentrations (2.5, 5.0, 10.0, and 15.0 mg/mL). The number average diameters of the polymer−DOX conjugates were determined by using dynamic light scattering. Experiments were performed three times at 25 °C in distilled water using filtered 1.0 mg/mL samples with a Zetasizer Nano ZS (Malvern Instruments, Malvern, U.K.) equipped with a 4 mW He−Ne laser at 633 nm.

ATRP Initiator (1). Tripentaerythritol (1.0 g, 2.7 mmol) was suspended in dry dichloromethane (25.0 mL), followed by the addition of pyridine (10.0 mL). The solution was then cooled by ice and 2-bromoisobutyryl bromide (9.7 g, 42.0 mmol) dissolved in 20.0 mL of dichloromethane was added dropwise over a period of 30 min. The reaction continued 2 days at room temperature. The mixture was washed with 0.3 M $NaHCO_3$ (3 × 50.0 mL), 0.3 M $NaHSO_4$ (3 × 50.0 mL), and water (2 × 50.0 mL). The organic layer was dried over Na_2SO_4 and filtered. The solution was concentrated by rotary evaporator and purified by HPFC to provide initiator **1** as a white solid (2.5 g, 61%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 1.94 (m, 48H), 3.60 (d, 8H), 4.29 (d, 16H). MALDI-TOF MS. $[M + H]^+$ Calcd: m/z = 1563.81. Found: m/z = 1565.15.

Synthesis of Polymer 2. In a typical experiment, initiator **1** (50.0 mg, 32.0 μmol) and PEGMA (1.1 kDa) (563.0 mg, 512.0 μmol) were added in anisole (0.5 mL) followed by the addition under argon of CuBr (55.5 mg, 384.0 μmol) and *N*,*N*,*N*′,*N*′,*N*″-pentamethyldiethylenetriamine (PMDETA) in a round-bottom flask equipped with a magnetic stir bar. The solution was deoxygenated by three freeze−pump−thaw cycles. The polymerization was carried out at 90 °C under argon and stopped after the appropriate time by being exposed to air and diluted with dichloromethane. The solution was passed through an alumina column to remove the copper catalyst. The excess solvent was removed on a rotary evaporator under reduced pressure. The

[a] Values are the mean ± S.D., n = 3.

unreacted PEG monomers were removed by precipitation of the polymer into diethyl ether. The molecular weight of polymers was determined by ^{1}H NMR and GPC (Table 1).

Synthesis of Polymer 3. Polymer **2** (0.1 g) was dissolved in 2.0 mL of anhydrous DMF, and 10 μL (12.0 equiv) of triethylamine was added, followed by MPEA (12.0 mg, 6.0 equiv per polymer hydroxyl). The reaction mixture was stirred at room temperature for 2 days and dialyzed against methanol to remove the unreacted MPEA. The degree of substitution on the polymer was quantified by ^{1}H NMR spectroscopy and ranged from 1.0 to 3.5/polymer (Table 2).

General Deprotection by Trifluoroacetic Acid. Polymer **4** or **5** (0.1 g) was dissolved in a 1:1 mixture of trifluoroacetic acid (TFA) and CH_2Cl_2. After stirring overnight, the solvents were removed under reduced pressure, and the products were precipitated into diethyl ether twice. ^{1}H NMR spectroscopy was used to verify the absence of residual *t*-butyloxycarbonyl protecting groups.

Synthesis of Polymer 4. Initiator **1** (50.0 mg, 32.0 μmol) and PEGMA (1.1 kDa) (1.7 g, 1.6 mmol) were added in anisole (1.7 mL) followed by the addition under argon of CuBr (55.5 mg, 0.4 mmol) and PMDETA (155 μL) in a round-bottom flask equipped with a magnetic stir bar. The solution was deoxygenated by three freeze−pump−thaw cycles. The polymerization was carried out at 90 °C, and degassed *t*-butyl methacrylate (420 μL, 2.9 mmol) was added after 50 min. After 2.5 h, the reaction was exposed to air and diluted with dichloromethane. The solution was passed through an alumina column to remove the copper catalyst. The excess solvent was removed on a rotary evaporator under reduced pressure. The unreacted PEG monomers and *t*-butyl methacrylate were removed by precipitation of the polymer into diethyl ether. The molecular weight of polymers was determined by GPC (M_n = 45 kDa, PDI = 1.13). About five molecules of PEGMA and one molecule of *t*-butyl methacrylate (tBMA) were added to each initiator site by ^{1}H NMR.

Synthesis of Polymer 5. The deprotected polymer **4** (820.0 mg, ~150.0 μmol of acid) was dissolved in 5.0 mL of DMF, and then 2-(1*H*-benzotriazol-1-yl)-1,1,3,3- tetramethyluronium

hexafluorophosphate (HBTU, 170.0 mg, 450.0 μmol) and hydroxybenzotriazole (HOBt, 61.0 mg, 450.0 μmol) were added. Next, *t*-butyl carbazate (59.0 mg, 450.0 μmol) and *N*,*N*-diisopropylethylamine (DiPEA, 270 μL) were added and the reaction mixture was stirred at room temperature for one day. The product was then precipitated into diethyl ether three times. The average number of *t*-butyl carbazate moieties attached to each polymer was about 8.2 by ^{1}HNMR. The average molecular weight (M_n) is about 46 kDa by GPC (PDI = 1.13).

Synthesis of the Acyl Hydrazone-Linked Polymer−DOX Conjugate (6). The deprotected polymer **5** (35.0 mg, 76.0 μmol) was dissolved in 0.4 mL methanol with 40 μL acetic acid and 40 μL pyridine. DOX HCl (3.3 mg, 5.7 mmol, 8.0 equiv) was added, and the reaction mixture was heated at 60 °C overnight in the dark. The reaction mixture was then purified by preparative SEC (Sephadex LH20, GE Healthcare, Piscataway, NJ) in methanol to separate polymer-bound DOX from free DOX. The high molecular weight fractions were evaporated, dissolved in water, and purified further by preparative SEC (Sephadex G25, GE Healthcare) in water. The high molecular weight fraction was lyophilized to provide the product as a red powder. The amount of DOX conjugated to the polymer was determined by measuring the absorbance at 485 nm of the polymer solution in water (Table 3).

Polymer Degradation Study. Polymer **2** (40 kDa) was dissolved at a concentration of 1.0 mg/mL in a solution containing either 30.0 mM acetate buffer (pH 5.0) with 70.0 mM $NaNO_3$ or 30.0 mM phosphate buffer (pH 7.4) with 70.0 mM $NaNO_3$. The samples were incubated at 37 °C, and a 0.3 mL aliquot was removed at intervals, lyophilized, and redissolved in THF, then measured by GPC.

Radioiodination of Methoxyphenol Functionalized Polymers. 2-(4-Methoxyphenyl) ethylamine functionalized polymers were iodinated based upon the method described by Krummeich et al.[23] In brief, 3.0 mg of polymer **3** was dissolved in 250 μL of trifluoroacetic acid (TFA), and 10 μL of an aqueous solution of ^{125}I was added containing 1.0 mCi ^{125}I. Chloramine T (540.0 μg) dissolved in 50 μL of TFA was added to the mixture, and the reaction was heated at 60 °C for 5 min. The reaction was stopped by the addition of sodium metabisulfite (1.0 mg in 10 μL of water), and the TFA was evaporated under a stream of nitrogen that was vented through a trap containing activated carbon (Dupont-New England Nuclear, MA). The residue was dissolved in 10 μL of 100.0 mM HEPES buffer (pH 7.4) and chromatographed on a column containing 1.8 mL bed volume of Dowex 2 anion-exchange resin in the chloride form. The radiolabeled polymer was eluted in the first 4.0 mL using water as the mobile phase. Polymers were separated from low molecular weight radioactive contaminants by SEC on Bio-Rad 10DG desalting columns equilibrated with phosphate buffered saline (PBS). The initial, high molecular weight fractions were collected and pooled. A suitable quantity of radiolabeled polymer was mixed with cold polymer in sterile PBS to create a solution with 5.0 mg/mL polymer and specific activities ranging from 3.0 to 25.0 μCi/mL.

Animal Experiments. All animal experiments were performed in compliance with the National Institutes of Health guidelines for animal research under a protocol approved by the Committee on Animal Research at University of California (San Francisco, CA) (UCSF). C26 colon carcinoma cells obtained from the UCSF cell culture facility were cultured in RPMI medium 1640 containing 10% FBS. Female BALB/c mice were obtained from Simonsen Laboratories, Inc. (Gilroy, CA).

Biodistribution Studies. Polymer solutions (200 μL) were administered intravenously via the tail vein to 6- to 8-week-old BALB/c female mice. The mice were sacrificed at seven different time points (three mice per group) ranging from 5 min to 48 h postinjection for biodistribution analyses. The blood (collected by heart puncture), heart, lungs, liver, stomach, spleen, intestines, kidney, body, tail, and head were weighed, and the amount of radioactivity present in each organ was quantified. Periodically, blood was also collected from the retroorbital sinus at intermediate time points to determine the dose of polymer in the blood. For the 24 h time points, mice were housed in metabolic cages to allow for the collection of urine and feces. The % injected dose per gram (% ID/g) of blood versus time curve was analyzed using a two-compartment model.[24]

Biodistribution Studies of Radiolabeled Polymer in Tumored Mice. The 6- to 8-week-old female BALB/c mice were injected with 3.0×10^5 C26 cells colon carcinoma cells on the right rear flank by subcutaneous administration. The mice (three per group) were injected intravenously via the tail vein with 200 μL of radiolabeled polymer solution prepared as described previously. The mice were sacrificed at 24 and 48 h postinjection; their blood, liver, muscle and tumor were collected and weighed; and the radioactivity in each was quantified.

Biodistribution Studies of Polymer−DOX Conjugates in Tumored Mice. The 6- to 8-week-old female BALB/c mice were injected with 3.0×10^5 C26 colon carcinoma cells on the right rear flank by subcutaneous administration. The mice (three per group) with tumor size about 100.0−250.0 mg were injected intravenously via the tail vein with 200 μL of polymer−DOX solution (8.0 mg Dox equiv/kg) in PBS. Two control mice were also injected with 200 μL of PBS. The mice were sacrificed 48 h postinjection. The blood (collected by heart puncture), heart, liver, spleen, kidney, muscle, and tumor were collected for analyses by following the procedure described before.[9] Briefly, each organ was weighed and 200−300 mg of the collected organs were homogenized with zirconium beads and 1.0 mL acidified isopropyl alcohol (75.0 mM HCl, 90% IPA). The samples then incubated at 4 °C for 24 h. Serum was collected using Microtainer serum separator vials and processed in the same manner as the organs. The samples were frozen in a −80 °C freezer until measurements could be made. At measurement time, samples were thawed, briefly vortexed, and centrifuged for 5 min at 14 000 rpm. Then, 80 μL of supernatant was combined with 920 μL of acidified IPA for fluorescence measurements. Dox fluorescence (excitation 485 nm; emission 595 nm) was measured on a Spex Fluorolog fluorimeter. Calibration curves were made from organ samples collected from an untreated mouse.

RESULTS AND DISCUSSION

A straightforward two-step synthesis was used to create the desired eight-arm star-comb architecture (Scheme 1). The

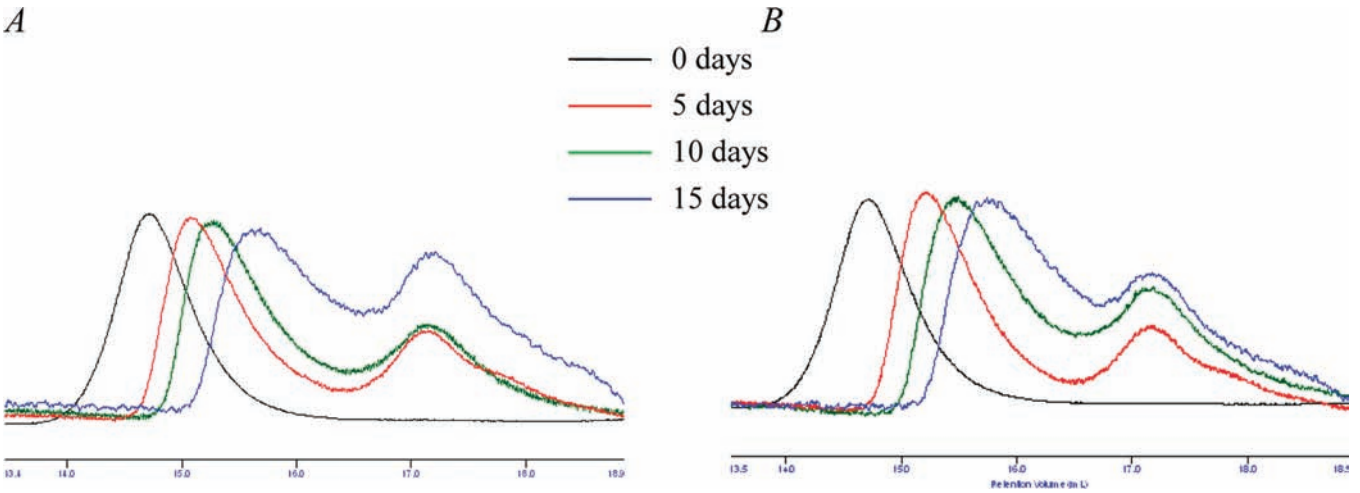

Figure 1. Time-dependent GPC profiles of the polymer (40 kDa) upon incubation in (A) pH 5.0 and (B) pH 7.4 buffer at 37 °C.

polymerization of PEGMA (1100 Da) was initiated by α-bromoisobutyryl functionalized tripentaerythritol. This novel dendritic core has eight sites that may be used to initiate polymerization. The molecular weights of the star-combs were adjusted by controlling the feed ratio and using appropriate reaction times (Table 1). The star-combs are soluble in a variety of common organic solvents and water. Precipitation in diethyl ether or dialysis using 50 000 molecular weight cutoff regenerated cellulose membranes against methanol was used to remove unreacted monomers, generally producing isolated yields of polymer greater than 60%. In the synthesis of polymers with molecular weight less than 32 kDa, the monomers react completely so that no further purification is required. The polydispersity index of all the eight-arm star-combs was less than 1.15, and their molecular weights were in good agreement with the theoretical molecular weight values. Furthermore, the eight reactive bromide functionalities that remain on each star-comb can easily be used to generate sites for drug attachment.[25,26] A drug such as DOX can be attached to the star-comb in six rapid and easily scalable synthetic steps, which is fewer than that typically used in the preparation of drug-loaded star polymers.[2] The starting materials, including tripentaerythritol and PEGMA, are inexpensive and commercially available.

PEG is attached to the backbone of the branches by ester bonds while the eight branches are themselves attached via ester bonds to the dendritic scaffold, and both ester linkages are susceptible to hydrolysis.[2] Complete ester hydrolysis should release PEG chains (1 kDa) as well as the dendritic core. To confirm that the polymeric carriers degrade under physiological conditions, a representative polymer (40 kDa) was incubated in pH 5.0 and pH 7.4 buffers at 37 °C, and the molecular weight distribution was monitored over time by SEC. At pH 5.0 and over a period of 5 days, there is an increase in the retention time of the peak corresponding to the PEG−dendrimer hybrid (Figure 1A), indicating a decrease in molecular weight due to polymer degradation. In addition, a new peak corresponding to the molecular weight of the 1 kDa PEG monomer appears in the chromatographic trace. Almost complete degradation was evidenced by the presence of a high proportion of low molecular weight material after 15 days. At pH 7.4 (Figure 1B), a similar decrease in the polymer molecular weight was observed with the appearance of a new peak with a retention time corresponding to a molecular weight of 1 kDa.

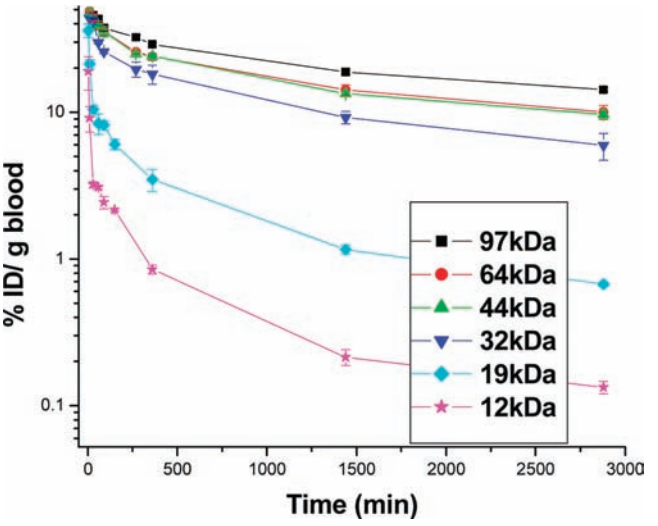

Figure 2. Polymer concentration in the blood over time as a function of time after intravenous administration (mean ± S.D., $n = 3$).

We also determined the time-dependent biodistribution profiles to examine the effect of molecular weight on bioaccumulation. In order to track the polymers *in vivo*, a number of terminal bromide groups of each star-comb polymer were substituted by 2-(4-methoxyphenyl) ethylamine (MPEA) as shown in Scheme 1. The number of MPEA molecules on the polymers were subsequently quantified by ^{1}H NMR spectroscopy (Table 2), and the polymers were then radiolabeled with ^{125}I using the electrophilic chloramine T method as previously described[23] before being administered to mice. Elimination half-lives ($t_{1/2}$) and areas under the % dose/g versus time curve from 0 to infinity ($AUC_{0\rightarrow\infty}$) were calculated using the two-compartment model[24] and are shown in Table 2. As expected, increasing the molecular weight of these star-comb polymers from 12 to 97 kDa leads to the expected increases in both the $t_{1/2,\,\beta}$ and $AUC_{0\rightarrow\infty}$ values (Figure 2). Interestingly, there is a sharp decrease of $t_{1/2,\,\beta}$ when the molecular weight was decreased from 32 to 19 kDa, which indicates that the threshold molecular weight for renal filtration is within this range. This value is lower than the molecular weight cutoff for renal filtration of 30 to 40 kDa previously described for linear PEG.[27] Indeed, these star-comb polymers showed much

dx.doi.org/10.1021/bc100400u |*Bioconjugate Chem.* 2011, 22, 617–624

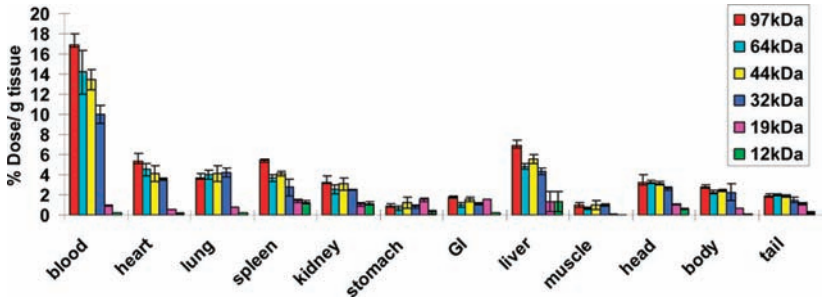

Figure 3. Biodistribution of drug-free polymers in nontumored mice at 48 h as a function of molecular weight reported as % dose/g tissue (mean ± S.D., $n = 3$).

longer circulation time than linear PEG. The $t_{1/2,\ \beta}$ value reported for linear 50 kDa PEG is 16.5 h and the corresponding $AUC_{0\rightarrow\infty}$ value is 600% dose h/g. In this study, the star-combs with molecular weights above 32 kDa had long blood circulation times. As molecular weight increases from 32 to 44, to 64, and to 97 kDa, $t_{1/2,\ \beta}$ increased from 24.5 to 30.5, 33.2, and 36.9 h, while the corresponding $AUC_{0\rightarrow\infty}$ values increased from 1110%, 1310%, 1540%, to 1800% dose h/g, respectively. We observed that the 44 kDa star-comb had similar $t_{1/2,\ \beta}$ and $AUC_{0\rightarrow\infty}$ values to a "bow-tie" dendritic polymer[2] with a molecular weight of 45 kDa and greater values than those of a PEGylated 42 kDa dendrimer with an aspartic acid modified bis-2,2-hydroxymethyl propanoic acid (bisHMPA) based core.[9] In contrast to polymers with higher molecular weights, the 19 and 12 kDa polymers are cleared rapidly from circulation. Significant amounts of polymer were found in urine (36% for 12 kDa and 29% for 19 kDa) and feces (15% for 12 kDa and 26% for 19 kDa), while only small amounts of polymers with molecular weights above 32 kDa were eliminated in urine (around 10%) and feces (<5%) at 24 h. No specific organ accumulation was observed for these macromolecules (Figure 3). The results indicate that the hydrolysis of the star-comb polymers larger than 32 kDa can lead to fast elimination, thus preventing their long-term accumulation.

A biodistribution study in BALB/c mice tumored with the C26 colon carcinoma in the flank was performed to evaluate the tumor accumulation of star-comb polymers with different molecular weights. Polymers with molecular weights of 97, 44, and 19 kDa were selected in order to span a range of circulation lifetimes. The concentration of polymer found in tumor tissue was directly related to molecular weight. Polymers having molecular weights of 19, 44, and 97 kDa had drug tumor levels of 2.8 ± 0.17%, 12.1 ± 3.3%, and 15.2 ± 3.1% dose/g, respectively, after 24 h and 2.2 ± 0.36%, 14.2 ± 1.9%, and 18.9 ± 0.62% dose/g, respectively, after 48 h (Figure 4). The 19 kDa star-comb had a maximum tumor accumulation at 24 h. The tumor concentration of star-combs with molecular weights of 44 and 97 kDa increased from 24 to 48 h. This can be ascribed to the EPR effect.[2,28,29] These values compare favorably with the tumor accumulations reported for other polymers such as PEGylated "bow-tie" dendrimer, HPMA, and PEO.[2,30,31] The tumor/muscles accumulation ratios for the 44 kDa polymer are 16 at 24 h and 11 at 48 h, and the ratios of the 97 kDa polymer are 11 at 24 h and 7 at 48 h on a % dose/g basis. The tumor/muscle ratios decrease from 24 to 48 h due to the increased accumulation in muscles for both polymers at 48 h. Such high levels of tumor accumulation should provide star-combs with the capability to effectively deliver drugs to tumor sites.

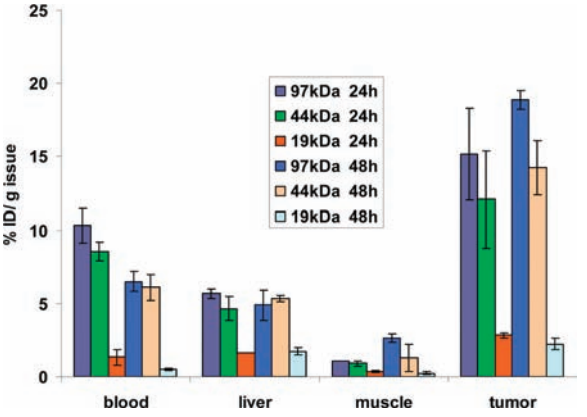

Figure 4. Biodistribution of drug-free polymers in mice bearing subcutaneous C26 tumors at 24 and 48 h based on % dose/g tissue (mean ± S.D., $n = 3$).

To further evaluate the potential of this polymer to be a drug carrier, DOX was conjugated to the 45 kDa star-comb through a hydrazone bond[2,22] to form a stealth PEG corona-drug core structure (Scheme 2). The molecular weight of 45 kDa was chosen because it provides a good balance between the theoretical drug loading and the circulation half-life based on the previous studies.[2,8,9] It is also easy to compare this polymer with other the DOX loaded polymers, such as PEGylated ester-amide dendrimer and polylysine dendrimer.[8,9] The hydrazone linkage can release DOX in its biologically active form after endocytosis but is stable at the physiological pH of 7.4. About one *t*-butyl methacrylate was introduced to each of the eight branches for attachment of *t*-butylcarbazate. Deprotection of the hydrazide Boc group followed by hydrazone formation with DOX in methanol afforded polymer containing DOX (Scheme 2). The loading of DOX is controlled by the molar ratio of DOX and hydrazide (Table 3). Interestingly, the size of the particles is dependent on the loading of DOX. As the loading increased from 6.6 to 8.4 and 10.2 wt %, the polymer−DOX conjugates formed aggregates and the particle size increased from 8 to 35 nm to 41 nm (Table 3). Even when 2 kDa PEGMA was used instead of the corresponding 1 kDa as monomer and the molecular weight of the polymer was kept at 45 kDa, aggregates were still observed (56 nm) at a loading of 8.4 wt %. Tumored mice were injected with polymer−DOX conjugates (**1**−**4**) at a dose of 8.0 mg DOX/kg. All the polymer−DOX conjugates, similar to the radiolabeled 44 kDa polymer, have $t_{1/2,\ \beta}$ values of about 30 h (Table 3). Therefore, their blood circulation time was not significantly changed by the addition of the functional moieties,

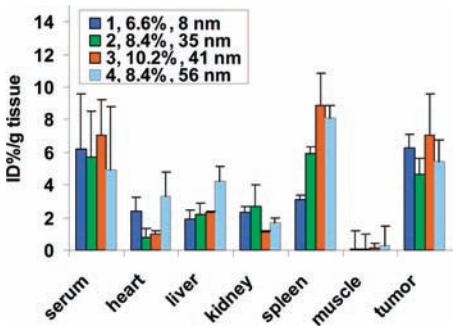

Figure 5. Biodistribution of polymer−DOX conjugates in mice bearing subcutaneous C26 tumors at 48 h based on % dose/g tissue (mean ± S.D., $n = 3$). **1**−**4** correspond to the samples in Table 3.

the attachment of a drug payload, or the diameter of the polymer−DOX conjugates.

Furthermore, the accumulation of DOX loaded polymers in the tumor (~6% ID/g tissue) is comparable to the levels of accumulation we have previously observed for related macromolecules.[2,8,9] The tumor accumulation of DOX for the polymer−DOX conjugates was also similar to what is observed for the PEGylated liposome formulation known as DOXIL (Figure 5).[9] Interestingly, the polymer−DOX conjugate with a diameter of 8 nm showed a lower accumulation in the spleen than the other three polymer−DOX conjugates with larger diameters or DOXIL with a diameter of 100 nm. All of the DOX-loaded polymers accumulated at less than 5% ID/g tissue in the other vital organs. Therefore, the polymer−DOX conjugate with a diameter of 8 nm has a more favorable tissue distribution compared to the other polymers, as it maintains a high drug concentration in the tumor while accumulating less in the organs. Because of this carrier's low toxicity and high tumor accumulation, it could provide an alternative solution to DOXIL for reducing the side effects caused by DOX.

In conclusion, a biodegradable polyester star-comb polymer-PEG hybrid was synthesized by ATRP using an inexpensive dendritic core that is accessible in a rapid, high yielding, and reproducible synthetic scheme. The polymer was also shown to deliver large dose percentages of DOX to C26 tumors when injected into mice.

ABSTRACT: Dimerization is viewed as the most effective means of increasing receptor binding affinity, and both dimerization and PEGylation effectively prolong the life spans of short-lived peptides and proteins in vivo by delaying excretion via the renal route. Here, we describe the high binding affinities of two long-acting exendin-4 (Ex4) conjugates, dimerized Ex4 (Di-Ex4) and PEGylated Di-Ex-4 (PEG-Di-Ex4). Di-Ex4 and PEG-Di-Ex4 were prepared using cysteine and amine residue specific coupling reactions using Ex4-Cys, bisMal-NH_2, and activated PEG. The Ex4 conjugates produced were of high purity (>98.5%), as determined by size-exclusion chromatography and MALDI-TOF mass spectrometry. The receptor binding affinity of Di-Ex4 on RIN-m5F cells was 3.5-fold higher than that of Ex4, and the in vivo antihyperglycemic efficacy of Di-Ex4 was also greater than that of native Ex4 in type 2 diabetic db/db mice. Furthermore, Di-Ex4 and PEG-Di-Ex4 were found to have greater blood circulating $t_{1/2}$ and AUC_{inf} values than native Ex4 by 2.7- and 13.7-fold, and by 4.0- and 17.3-fold, respectively. Accordingly, hypoglycemic durations were greatly increased to 15.0 and 40.1 h, respectively, at a dose of 25 nmol/kg (native Ex4 7.3 h). The results of this study show that combined dimerization and PEGylation are effective when applied to Ex4, and suggest that PEG-Di-Ex4 has considerable potential as a type 2 anti-diabetic agent.

INTRODUCTION

Exendin-4 (Ex4), a naturally occurring dipeptidyl peptidase-IV (DPP IV) resistant GLP-1 analogue and GLP-1 receptor agonist, was first isolated from the saliva of the Gila monster and shares 53% homology with glucagon-like peptide-1 (GLP-1).[1−3] Ex4 has several beneficial anti-diabetic effects in type 2 diabetes. It increases the glucose-dependent enhancement of insulin secretion, suppresses inappropriately high glucagon secretion, reduces gastric mobility and food intake, and increases β-cell mass.[4−6] Overall, Ex4 is viewed as a potent therapeutic agent for type 2 diabetic patients, but its short circulating life (4−6 h) means that high doses must be administered frequently. A previous detailed examination revealed that the short biological half-life of Ex4 is mainly due to its rapid glomerular filtration, which can be attributed to its low molecular weight (~4.2 kDa).[7,8]

To overcome this problem, numerous approaches, such as the use of long-acting incretin mimetics and/or sustained release mimetics, have been devised to improve the therapeutic level of Ex4.[9−12] In particular, our group has previously investigated the use of Ex4 bioconjugated with vitamins, fatty acids, and bile acids for oral or long-acting delivery.[13−16] More specifically, the strategies used included modifying GLP-1 receptor agonists by conjugating them with poly(ethylene glycol). The resulting PEGylated GLP-1 receptor agonists showed typical long-acting characteristics and enhanced circulation half-lives.[9,10]

Dimeric interactions are frequently used in nature to increase the affinity of ligand−receptor interactions,[17,18] and thus, this strategy has attracted the interest of researchers. As a result, several research groups have already produced compounds that enhance interactions between ligands and target cells.[19] Goel et al. radiolabeled divalent and tetravalent scFv's of mAb CC49 with ^{99m}Tc and analyzed the imaging potentials of these

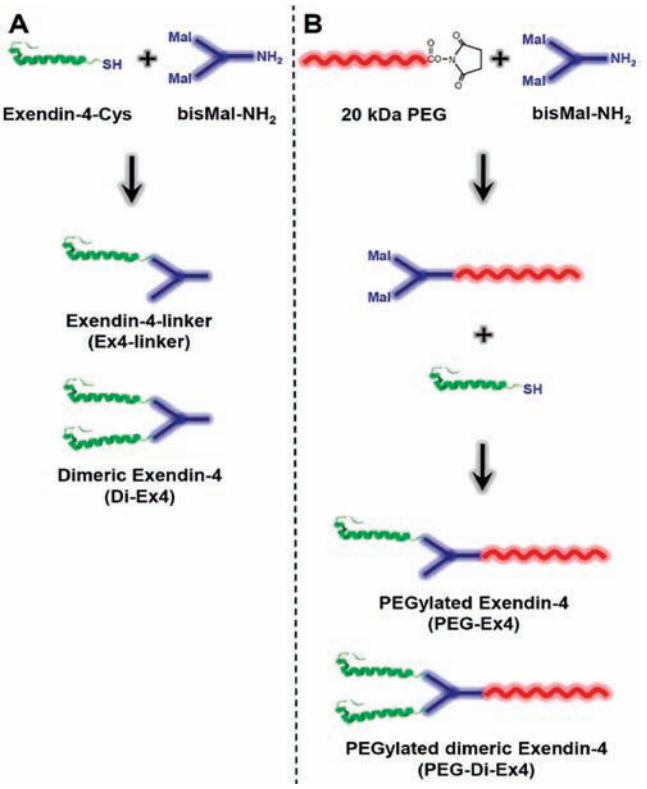
radio-immunoconjugates.[20] Similarly, dimerized interferon-α2b[21] and dimerized adducts of therapeutic antibodies[22] have also been examined.

The covalent attachment of poly(ethylene glycol) (PEG) to peptides and proteins (PEGylation) provides a means of enhancing their therapeutic values. This technique increases molecular size, shields metabolic sites, and masks immunogenic sites and, thus, increases plasma half-lives and in vivo stabilities and diminishes immunogenicity. Moreover, PEGylated peptides/proteins are much more resistant to renal clearance because the linear hydrophilic nature of PEG molecule effectively increases Stokes' radius,[23−25] and furthermore, PEGylation has been shown to prolong the pharmacokinetic and pharmacodynamic properties of these entities.[26−28]

On the basis of the above, we undertook to synthesize PEG-conjugated dimeric Ex4. We hypothesized that PEG-conjugated dimeric Ex4 would retain the advantages of PEGylation and have higher affinity for pancreatic β-cells. In the present study, we prepared dimerized Ex4 and PEG conjugated dimerized Ex4 constructs and then explored their physicochemical and biological characteristics. In addition, the pharmacokinetic and anti-diabetic characteristics were investigated using a diabetic mouse model to determine which has much better anti-diabetic properties.



EXPERIMENTAL PROCEDURES

Materials. Exendin-4-Cys (M_w: 4290.7) with the sequence HGEGTFTSDLSKQMEEEAVRLFIEWLKNGGPSSGAPPPSC was purchased from AnyGen Co. (Gwangju, Republic of Korea (ROK)). Bis-Maleimide amine (bisMal-NH_2, M_w: 660.64) and succinimidyl activated monomethoxy PEG (M_w: 20 kDa) were purchased from Quanta Biodesign (Powell, Ohio) and Nektar Therapeutics (Huntsville, AL), respectively. All other reagents, unless otherwise indicated, were purchased from Sigma-Aldrich (Saint Louis, MO) and were used as received.

Experimental Animals. Type 2 diabetic C57BL/6 db/db mice (male, 4−5 weeks old) were purchased from the Korean Research Institute of Bioscience and Biotechnology (Daejon, ROK). ICR mice (male, 4−5 weeks old), weighing 16−18 g, were purchased from the Hanlim Experimental Animal Laboratory (Seoul). Animals were cared for in accordance with the National Institute of Health (NIH) guidelines for the care and use of laboratory animals (NIH publication 80−23, revised in 1996). Animals were housed in groups of 6−8 under a 12 h light/dark cycle (lights on at 6 a.m.), allowed food and water ad libitum, and were acclimatized for 2 weeks. This study was approved by the Ethical Committee on Animal Experimentation at SungKyunKwan University.

Preparation of Dimerized Exendin-4 (Di-Ex4). As shown in Scheme 1A, Di-Ex4 was synthesized by utilizing a coupling reaction between bis-maleimide amine (bisMal-NH_2, M_w: 660.64) and the cysteine residues of Ex4 in organic solvent using a modification of a previously described procedure.[13,14] Briefly, 100 μL of bisMal-NH_2 (1.5 mg/mL in dimethylsulfoxide (DMSO) containing 0.3% triethylamine (TEA)) was reacted with 100 μL of Ex4 (10 mg/mL in DMSO with 0.3% TEA) (an Ex4/bisMal-NH_2 molar ratio of 2) at room temperature with gentle mixing for 1 h. The reaction was then stopped by adding 100 μL of stop solution (deionized water containing 1% trifluoroacetic acid (TFA)). Di-Ex4 was purified from reaction mixtures using semipreparative reversed-phase HPLC (RP-HPLC) and a Capcell-pak RP-18 column (250 × 10 mm, 5 μm, Shiseido, Japan) operated at

Scheme 1. Syntheses of Di-Exendin-4 and PEG-Di-Exendin-4

room temperature and a constant flow rate of 5.0 mL/min. Eluate was monitored using a 215 nm UV detector. The mobile phase consisted of 0.1% TFA in deionized water (eluent A) and acetonitrile containing 0.1% TFA (eluent B) using a linear gradient (36−42% B over 30 min). Eluting peaks were collected separately, acetonitrile was then removed with nitrogen, and the solutions so obtained were concentrated using a Centricon-10 (M_w cutoff 3000, Millipore Corp., Billerica, MA). Products obtained were characterized by analytical size-exclusion chromatography and MALDI-TOF mass spectroscopy, and stored at 4 °C until required.

Preparation of PEGylated Di-Exendin-4 (PEG-Di-Ex4). As shown in Scheme 1B, bisMal-NH_2 conjugated Ex4 and PEG (PEG-Ex4 and PEG-Di-Ex4) were prepared using a modification of a previously described procedure.[14,28] Briefly, 10 mg of activated PEG (M_w: 20 kDa) was mixed with 0.3 mg of bisMal-NH_2 in 5 mL of a mixture of dimethylsulfoxide and dimethylformamide (70:30) containing 0.3% dimethylaminopyridine at room temperature for 1 h. To this mixture was added 2 mg of Ex4, and the reaction was then allowed to continue for another 1 h. The reaction was then quenched by adding 5 mL of 1% TFA/DW and shaking thoroughly. The resulting mixture was quickly transferred to a Sephadex G-25 desalting column (GE Healthcare Life Sciences, Piscataway, NJ, USA) previously equilibrated with 10 mM PBS. The first fraction was collected and centrifuged using a Centricon-10 concentrator (Millipore Amicon, Beverly, MA, USA), and a portion (0.2 mL) of the supernatant (containing PEG-Ex4 and PEG-Di-Ex4) was purified by size-exclusion chromatography using a Biosep SEC-S2000 column (300 × 7.8 mm, 5 μm, Phenomenex, Torrance, CA) and eluted with 10 mM PBS (pH 7.4) at a flow rate of 0.75 mL/min. Eluates were monitored at

215 nm. The products so obtained were characterized by analytical size-exclusion chromatography and MALDI-TOF mass spectroscopy, and stored at 4 °C until required.

Characterizations of Di-Ex4 and PEG-Di-Ex4. Ex4 analogues were characterized by size-exclusion chromatography using a Superdex 200 HR 10/30 column (300 × 10 mm, GE Healthcare Life Sciences, Piscataway, NJ, USA) and eluted with 10 mM PBS (pH 7.4) at a flow rate of 0.6 mL/min. Chromatograms were recorded at 215 nm. MALDI-TOF MS and a Voyager-RP Biospectrometry Workstation (PerSeptive Biosystems, Cambridge, MA) were used to confirm molecular weights. Briefly, sample−matrix solutions were prepared by mixing a 1 μL aliquot with 2 μL of matrix solution (a saturated solution of α-cyanohydroxycinnamic acid (α-CHCA) in 50% of water/ACN containing 0.1% (v/v) TFA). One microliter of this sample−matrix solution was then deposited onto a well of a sample plate and dried rapidly under vacuum. Data generated by 2 ns pulses of a 337 nm nitrogen laser were averaged for each spectrum in reflective mode using positive ion TOF detection and an accelerating voltage of 25 kV.

Receptor-Binding Affinities of Di-Ex4 and PEG-Di-Ex4 to RIN-m5F Cells. The receptor-binding affinities of Ex4 analogues were determined using a modification of a previously described method.[13,14] Briefly, RIN-m5F cells (ATCC, Manassas, VA) were seeded in 12 well plates at 3×10^5 cells per well, grown for 48 h, washed twice with binding buffer (120 mM NaCl, 1.2 mM $MgSO_4$, 13 mM sodium acetate, 5 mM KCl, 1.2 g/L Tris, 2 g/L bovine serum albumin, and 1.8 g/L glucose, pH 7.6), co-treated with the unlabeled Ex4 analogues (final concentrations range: 0.001−1000 nM) with 30 pM of ^{125}I-exendin-4 (9−39, PerkinElmer, Boston, MA), incubated for 2 h at room temperature, and washed three times with chilled PBS containing 1 mg/mL of bovine serum albumin. Cells were then lysed with cell lysis buffer (0.5 N NaOH with 1% SDS) for 15 min, and ^{125}I radioactivity levels were measured using a γ counter (GMI, Inc., Ramsey, MN).

Proteolytic Stability Tests. The proteolytic stabilities of the Ex4 analogues against rat kidney homogenate and plasma were evaluated as previously described,[13] by incubating samples at 37 °C in rat kidney homogenate and plasma and measuring their degradation profiles by reverse-phase HPLC.

Radioiodination. Radioiodinated samples were prepared using a modification of the IODO-GEN method.[29,30] In brief,

dx.doi.org/10.1021/bc100404x |*Bioconjugate Chem.* 2011, 22, 625–632

100 μL of water-soluble Bolton-Hunter reagent (*N*-sulfosuccinimidyl-3,4-hydroxyphenyl propionate; 0.13 mg/mL, 36 nmol) in 10 mM PBS (pH 7.0) was mixed with 150 μL of the Ex4 analogues (0.5 mg/mL, 18 nmol) at room temperature for 90 min and briefly dialyzed to remove the reagent. Separately, a 100 μL aliquot of an IODO-GEN (Pierce, Rockford, IL) solution in methylene chloride (0.5 mg/mL) was dispensed into a fresh tube and evaporated under a nitrogen stream. To these tubes were added 50 μL aliquots of each sample (approximately 50 μg/mL) and 50 μCi of $Na^{125}I$ (Perkin-Elmer, Boston, MA) diluted with 10 mM PBS (pH 7.4). Reactions were allowed to proceed for 5 min, and then supernatants were loaded onto a Sephadex G-25 desalting column (GE Healthcare Life Sciences, Piscataway, NJ) previously equilibrated with 10 mM of PBS. ^{125}I-labeled fractions were collected and stored in 10 mM PBS (pH 7.4), and their radioactivities were measured by γ counting (CobraTM Series Auto-Gamma Counting System, Packard Instruments Co., Groningen, The Netherlands). The specific radioactivities of radioiodinated samples were in the range $(4.8-5.9) \times 10^5$ cpm/μg.

Pharmacokinetics Tests. The pharmacokinetics of the Ex4 analogues were evaluated using a modification of a previously described method.[26,28] Radioiodinated samples were administered to ICR mice (~2 μg, ~25 nmol/kg body wt., i.p.). Mice were sacrificed at predetermined times by heart puncture for blood collection, and the radioactivities of 0.2 mL blood samples were determined by γ counting and used to calculate blood concentrations. Pharmacokinetic parameters were calculated by two-compartmental analysis using *WinNolin* v 1.1 (Scientific Consulting, Inc., Cary, NC). In particular, AUC_{inf} values were obtained by computing areas under the curve from zero to infinity using the trapezoidal rule. Circulating half-lives ($t_{1/2}$) were calculated using the same method.

Antihyperglycemic Efficacies in Fasted Type 2 Diabetic *db/db* Mice. Oral glucose tolerance testing (OGTT) was performed to evaluate the antihyperglycemic efficacies of the Ex4 analogues after an overnight fast (18 h), as previously described.[26,28] One hour prior to first oral glucose challenge (0.2 mL, 1.0 g/kg body wt.) (0 h), male *db/db* mice (n = 4/group, 8−9 weeks old) were administered saline, Ex4, or Di-Ex4 (i.p., 25 nmol/kg body wt.). Injection dose was prepared based on the peptide portion of the conjugate. A drop of blood was drawn from a tail vein of each animal at 0, 0.25, 0.5, 0.75, 1, 1.5, 2, and 3 h, and blood glucose levels were determined using a one-touch blood glucose meter (ACCU-CHEK Sensor, Roche Diagnostics Corp., USA). Antihyperglycemic efficacies were evaluated by calculating the total hypoglycemic degrees (HD_{total}; using $HD_{total} = AUC_{saline,\ 0-3\ h} - AUC_{test,\ 0-3\ h}$).

Hypoglycemic Efficacies Tests in Nonfasted *db/db* Mice. Hypoglycemic efficacies of Ex4 analogues were evaluated using a modification of a previously described method[13−15] using male *db/db* mice (6−7 weeks old). Under nonfasting conditions with free access to food and water, animals received a single i.p. injection of saline, Ex4, Di-Ex4, PEG-Ex4, or PEG-Di-Ex4 (5, 25, 250 nmol/kg body wt.). Blood glucose levels were monitored using the procedure mentioned above. In addition, a drop of blood was drawn from a tail vein of each animal at different times (0, 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 36, 48, 60, 72, 96, 108 h) and blood glucose levels were determined using a one-touch blood glucose meter (ACCU-CHEK Sensor, Roche Diagnostics Corp., USA). Hypoglycemic efficacies are expressed as HD_{total}, as mentioned above, but measurement times differed in the saline, Ex4, Di-Ex4, PEG-Ex4, and PEG-Di-Ex4 groups (Figures 4B and 5). In addition, hypoglycemic durations to a blood glucose level of <8.35 nmol/L (150 mg/dL) were also checked.

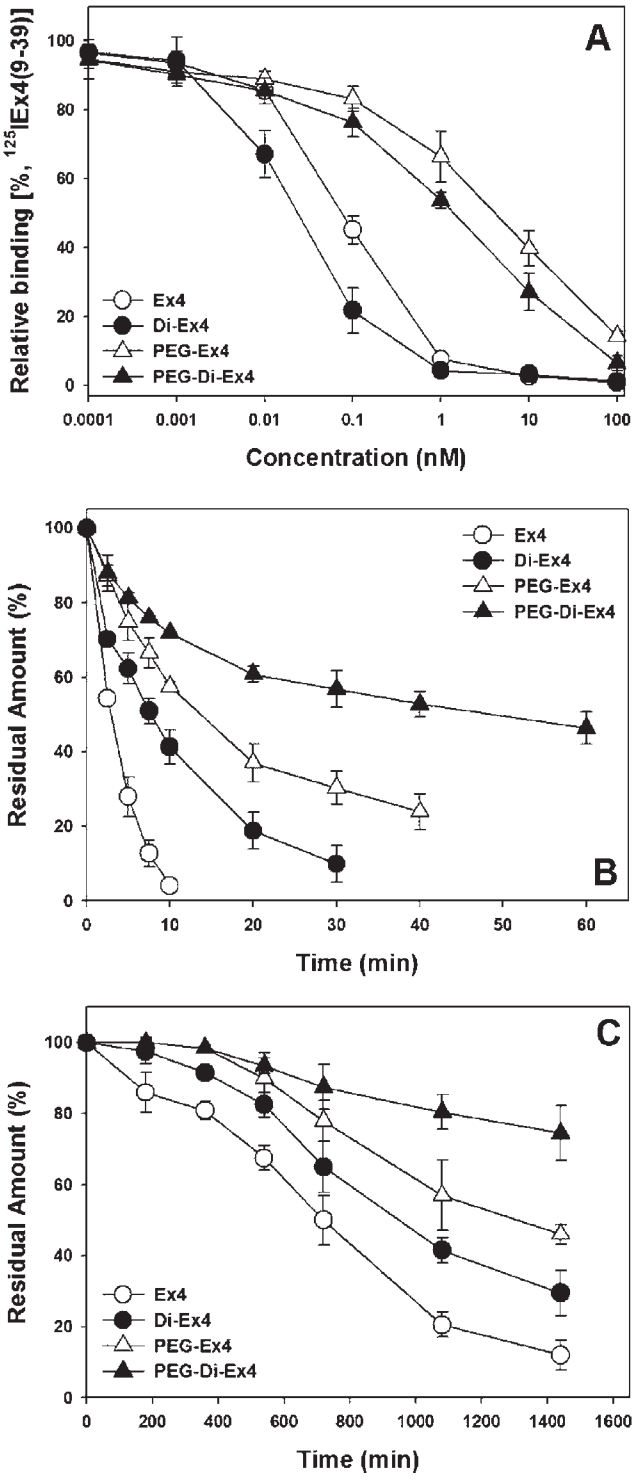

Figure 2. In vitro biological activity and proteolytic stability testing of Di-Exendin-4 and PEG-Di-Exendin-4. (A) Receptor-binding affinities of Exendin-4 analogues in RIN-m5F cells. (B) Stability testing of Ex4 analogues in rat kidney homogenate. (C) Stability testing of Ex4 analogues in rat plasma. Data represent the means ± SDs of five results.

Data Analysis. Data are presented as means ± SDs. Statistical significances were determined using one-way ANOVA, and P values of <0.05 were considered statistically significant.

Table 1. Pharmacokinetic Parameters of Ex4, Di-Ex4, PEG-Ex4, and PEG-Di-Ex4 in ICR Mice[a]

PK parameters	Ex4	Di-Ex4	PEG-Ex4	PEG-Di-Ex4
AUC_{inf} (ng/mL × h)	109.8 ± 28.4	433.7 ± 36.2	779.1 ± 42.7	1893.7 ± 152.4
Cl/F (mL/h)	9.1 ± 1.7	2.3 ± 0.4	1.2 ± 0.2	0.4 ± 0.1
$t_{1/2}$ (h, β)	2.1 ± 0.3	5.6 ± 1.3	11.8 ± 2.7	28.7 ± 2.4

[a] Data are means ± SDs. AUC_{inf} = area under the curve from zero to infinity; Cl/F = systemic clearance from zero time to last time; $t_{1/2}$ = half-life during the elimination phase (β).

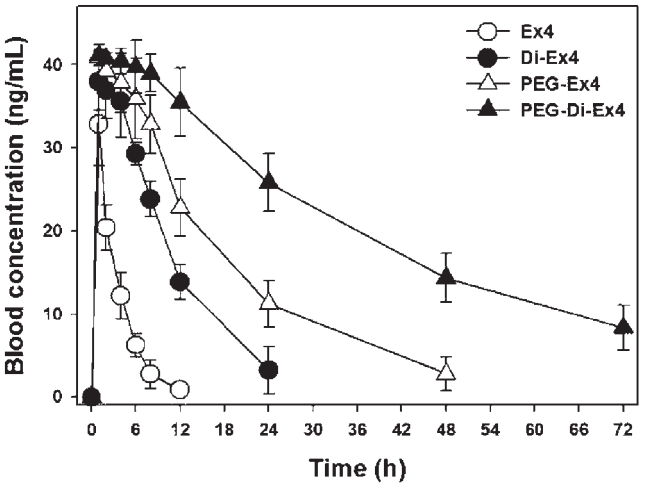

Figure 3. Pharmacokinetic profiles of Di-Exendin-4 and PEG-Di-Exendin-4 in ICR mice administered ~2 μg (approximately 25 nmol/kg) i.p. Data represent four mice and are presented as means ± SD.

Pharmacokinetic parameters were calculated by two-compartmental analysis (WinNolin, Scientific Consulting, Inc., Cary, NC).

RESULTS

Preparation and Characterization of Di-Ex4 and PEG-Di-Ex4. Di-Ex4 and PEG-Di-Ex4 were synthesized as described above, and finally, we obtained four different products containing control molecules (Scheme 1, Figure 1A,B). The four peaks in the size exclusion chromatogram corresponded to unreacted; Ex4 (elution time 33.4 min), Ex4-linker (elution time 33.3 min), Di-Ex4 (elution time 32.9 min), PEG-Ex4 (elution time 28.0 min), and PEG-Di-Ex4 (elution time 27.4 min). The size-exclusion chromatograms of the three purified Ex4 analogues showed that separations resulted in high-purity products (Figure 1C). The apparent molecular weights (M_w) of the three analogues were determined by MALDI-TOF MS. As shown in Figure 1D, their experimental mass-to-charge (m/z) ratios closely matched calculated values.

Receptor-Binding Affinities and Proteolytic Stabilities of Di-Ex4 and PEG-Di-Ex4. The receptor-binding affinities of Ex4 analogues were examined in RIN-m5F cells, which express high levels of GLP-1 receptor (GLP-1R). Di-Ex4 was found to have 3.5-fold higher affinity for GLP-1R (IC_{50} = 0.02 ± 0.12 nM) than native Ex4 (IC_{50} = 0.07 ± 0.05 nM), as shown in Figure 2A. Furthermore, PEG-Di-Ex4 was found to have 3.1-fold higher affinity for GLP-1R (IC_{50} = 1.34 ± 0.19 nM) than PEG-Ex4 (IC_{50} = 4.15 ± 0.14 nM) (Figure 2A). Ex4 was rapidly degraded by rat kidney homogenate (Figure 2B), with a $t_{1/2}$ of 1.88 ± 0.04 min, and Di-Ex4 was 4.99-fold more stable ($t_{1/2}$ = 9.38 ± 2.31 min).

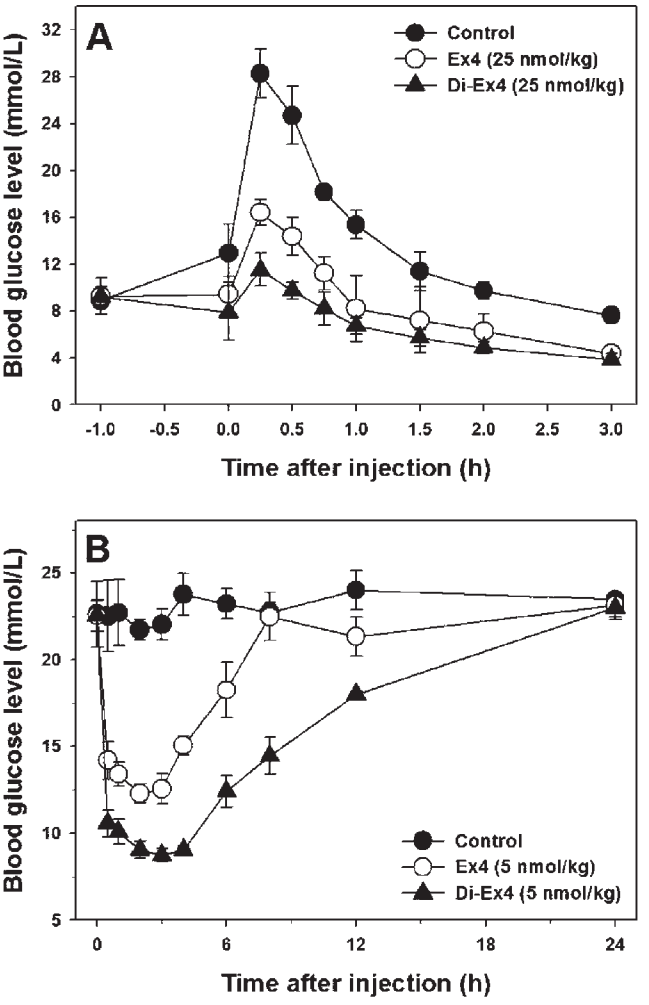

Figure 4. Antihyperglycemic activities of Exendin-4 and Di-Exendin-4 as determine by oral glucose tolerance testing in type 2 diabetic *db/db* mice fasted for 18 h and pretreated with each agent (25 nmol/kg, i.p.) (A). Hypoglycemic efficacies of low dose (5 nmol/kg) Exendin-4 and Di-Exendin-4 in nonfasted *db/db* mice (B). Data represent five mice and are presented as means ± SDs.

Furthermore, PEG-Di-Ex4 was 57.06-fold more stable than native Ex4 ($t_{1/2}$ = 107.29 ± 11.99 min) (Figure 2B). And plasma degradation of Ex4 analogues (Figure 2C) showed similar profile to kidney homogenate.

Pharmacokinetics Tests. The blood concentration vs time curves of Ex4 analogues were i.p. administered. As shown in Table 1 and Figure 3, Ex4 was rapidly removed from the circulation with a circulating $t_{1/2}$ of 2.1 ± 0.3 h, whereas Di-Ex4 was found to have a 2.66-fold longer presence ($t_{1/2}$ = 5.6 ± 1.3 h). Specifically, the $t_{1/2}$ of PEG-Di-Ex4 was 28.7 ± 2.4 h, which was

dx.doi.org/10.1021/bc100404x |*Bioconjugate Chem.* 2011, 22, 625–632

13.67 times greater than that of native Ex4, and its AUC_{inf} value (1893.7 ± 152.4 ng/mL × h) was 17.25 times greater than that of native Ex4 (109.8 ± 28.4 ng/mL × h). In addition, the systemic clearances (Cl/F) of Di-Ex4 and Di-PEG-Ex4 (2.3 ± 0.4 and 0.4 ± 0.1 mL/h) were 3.96- and 22.75-fold lower than those of native Ex4 (9.1 ± 1.7 mL/h).

Antihyperglycemic Efficacies in Fasted Type 2 Diabetic *db/db* Mice. The in vivo biological activities of Ex4 and of Di-Ex4 were examined in fasted type 2 diabetic *db/db* mice by performing oral glucose tolerance testing (OGTT) at 60 min after the i.p. administration of 25 nmol/kg. Blood glucose levels in the control group rapidly increased to 28.2 ± 1.9 mmol/L at 0.25 h after glucose administration and then decreased slowly. In accordance with their observed in vitro biological activities, maximum plasma glucose levels at 0.25 h after the administration of Di-Ex4 (11.5 ± 0.5 mmol/L; $P > 0.3$) were lower than that of Ex4 (16.3 ± 0.7 mmol/L) (Figure 4A). These results suggest that Di-Ex4 has higher in vivo biological activity than Ex4.

Hypoglycemic Duration Tests in Nonfasted *db/db* Mice. The hypoglycemic effects of the Ex4 analogues were examined at two doses (5 and 25 nmol/kg, i.p.) in *db/db* mice. At a dose of 5 nmol/kg, as shown in Figure 4B, the lowest glucose level (8.7 ± 0.5 mmol/L; $P > 0.2$) in Di-Ex4-treated mice was lower than in Ex4 treated mice (12.6 ± 0.4 mmol/L). At a dose of 25 nmol/kg, the HD_{total} values of Di-Ex4 and PEG-Di-Ex4 (504.1 ± 108.9 and 1427.6 ± 187.4 mmol × h/L, $P < 0.005$, respectively) were 1.65 and 4.66 times greater than that of native Ex4 (306.3 ± 86.3 mmol × h/L) (Figure 5A). Furthermore, hypoglycemic durations in Di-Ex4 or PEG-Di-Ex4 mice were much greater than Ex4, and the times required to rebound to a glucose level of 8.35 mmol/L were ~15.0 h and ~40.1 h in Di-Ex4 and PEG-Di-Ex4 mice as compared with ~7.3 h in Ex4 treated mice (Figure 5B). In particular, at the highest dose administered (250 nmol/kg), the $t_{\sim 8.35\ mmol/L}$ value of PEG-Di-Ex4 was 76.3 h, which means that a single PEG-Di-Ex4 administration stabilized blood glucose levels for nearly 3 days in *db/db* mice.

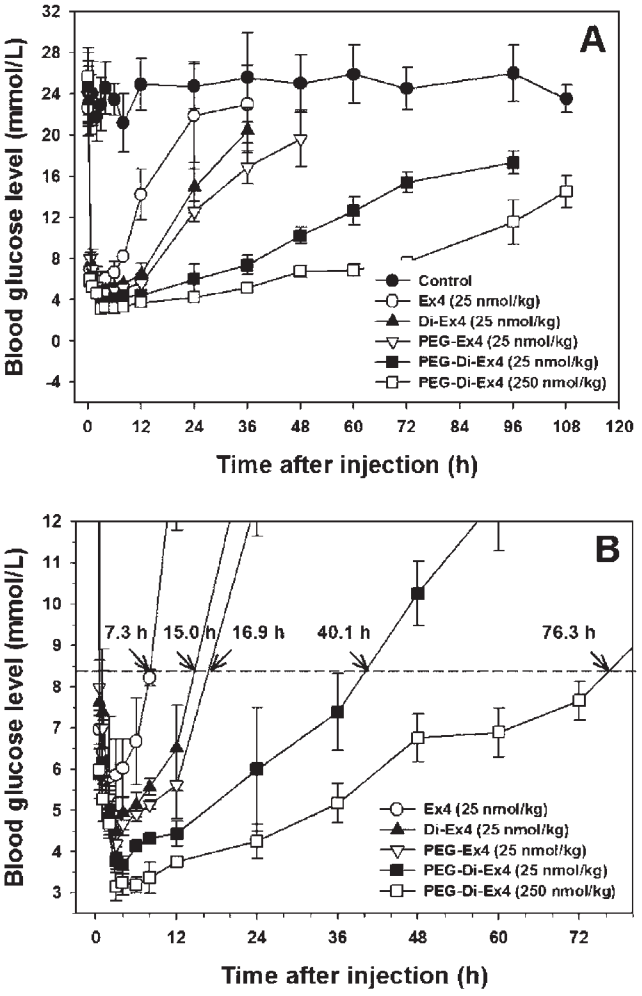

Figure 5. Hypoglycemic efficacies of high dose (25/250 nmol/kg) Exendin-4 analogues in nonfasted *db/db* mice (A). The focused profile of A (0−80 h, 3−12 mmol/L). Times depict hypoglycemic duration rebound to 8.35 mmol/L (B). Data represent five mice and are presented as means ± SDs.

DISCUSSION

Type 2 diabetes is a chronic, deteriorative metabolic disease, characterized by progressive hyperglycemia followed by dysfunctional insulin secretion and/or its impaired utilization. Progressive β-cell deficiencies associated with apoptosis and a malfunctional GLP-1 response after ingestion have encouraged researchers to consider incretin-based diabetic therapies.[1,7] Intensive research and developmental efforts have resulted in the clinical application of a DPP IV resistant GLP-1 receptor Ex4 agonist, which was first isolated from lizard saliva.[2,31]

Although the coadministrations of Ex4 and traditional hypoglycemic agents achieve better glycemic control and lower levels of glycated hemoglobins (HbA_{1C}) in serum and lower body weights,[31] the demand for more efficient incretin-based anti-diabetics has not been satisfied by Ex4 because of its short biological half-life and its rapid renal clearance.[8] In addition, recent research on long-acting incretin mimetics or sustained-release formula Ex4 systems has achieved more efficient glycemic control than twice-daily Ex4 injections.[32]

To develop efficient incretin-based anti-diabetics with protracted hypoglycemic efficacy in type 2 diabetes, we produced high binding affinity, long-acting Ex4 analogues, that is, Di-Ex4 (dimerized Ex4) and PEG-Di-Ex4 (PEGylated Di-Ex4), by PEGylating dimerized Ex-4. Di-Ex4 and PEG-Di-Ex4 were successfully prepared using cysteine and amine residue-specific coupling reactions using Ex4-Cys, bisMal-NH_2, and activated PEG (Scheme 1, Figure 1A,B). Interestingly, cysteine-specific (C-terminal domain) conjugations prevented the serious activity reduction caused by N-terminal conjugation (the N-terminal domain is known to play a crucial role during cellular response to GLP-1 signaling[9,33,34]). The Ex4 analogues were obtained in high purity (>98.5%), as determined by size-exclusion chromatography and MALDI-TOF (Figure 1C,D).

After dimerization, peptide and protein drugs often have higher binding affinities and therapeutic potencies than native drugs.[17−22] In the present study, we found that Di-Ex4 had 3.5-fold higher in vitro receptor-binding affinity than Ex4 (Figure 2A). Furthermore, in vivo OGTT results showed that the antihypoglycemic efficacy of Di-Ex4 was greater than that of native Ex4 (Figure 4A). However, the receptor binding affinity of PEG-Di-Ex4 was reduced by the presence of PEG (M_w: 20 kDa), which inhibits PEG-Di-Ex4 binding to GLP-1 receptor. Conversely, PEG-Di-Ex4 was found to have much greater resistance to rat kidney homogenate than Di-Ex4 (Figure 2B).

The improvements achieved to date provide reasons to extend the functional lifespan of Ex4 in vivo (Figure 3). In the present

Table 2. Pharmacological Scores of Ex4, Di-Ex4, PEG-Ex4, and PEG-Di-Ex4 in *db/db* Mice[a]

PK parameters	Ex4	Di-Ex4	PEG-Ex4	PEG-Di-Ex4
HD_{total} (5 nmol/kg) (mmol × h/L)	77.3 ± 18.2	161.2 ± 27.7	-	-
HD_{total} (25 nmol/kg) (mmol × h/L)	306.3 ± 86.3	504.1 ± 108.9	640.2 ± 124.2	1427.6 ± 187.4
HD_{total} (250 nmol/kg) (mmol × h/L)	-	-	-	1894.9 ± 193.3
hypoglycemic duration (h) (25 nmol/kg)	7.3	15.0	16.9	40.1
hypoglycemic duration (h) (250 nmol/kg)	-	-	-	76.3

[a] Data are means ± SDs.

study, dimerization and PEGylation greatly improved the pharmacokinetic profile of Ex4 (Table 2 and Figure 3), as the pharmacokinetic profiles of Di-Ex4 and PEG-Di-Ex4 were markedly better than that of Ex4 (their AUCs were 3.95- and 17.25-fold higher and their circulating $t_{1/2}$ values were 2.66- and 13.67-fold greater, respectively, than that of Ex4). Furthermore, the $t_{1/2}$ of Di-PEG-Ex4 in the circulation was 5.13-fold greater than that of Di-Ex4, probably due to the hydrodynamic size increase caused by the attached PEG. It should also be mentioned that Ex4 is a foreign material to mice, because of its reptile origins. So, it has the possibility for immunological side effects and responses. However, PEGylation diminishes immunogenicity, and thus, we suppose that the incorporation of PEG protects PEG-Di-Ex4 from mouse antibodies. The hypoglycemic durations of Di-Ex4 and of PEG-Di-Ex4 in *db/db* mice were also much greater than that of Ex4, regardless of the dose administered. In the present study, a blood glucose level of <8.35 mmol/L (150 mg/dL) was regarded as normal, and euglycemic durations under this value are considered a practical indication of potential for anti-diabetic treatment. The administration of Di-Ex4 or PEG-Di-Ex4 sustained normal glycemia for 2.05 or 5.49 times longer than Ex4. In addition, drug clearance in man is known to be much slower than in rodents, and thus, the anti-diabetic duration of PEG-Di-Ex4 may be substantially greater in man than the ~76 h observed in *db/db* mice in the present study.

Summarizing, both Di-Ex4 and PEG-Di-Ex4 were found to confer therapeutic benefits over Ex4. This study also shows that Di-Ex4 and PEG-Di-Ex4 have high GLP-1 receptor-binding affinity, better pharmacokinetics, and a markedly greater hypoglycemic duration than Ex4. Accordingly, we believe that PEG-Di-Ex4 should be viewed as a potential long-acting treatment for type 2 diabetes.

Supporting Information

ABSTRACT: Regulation of enzyme activity either by its substrates or by effectors is generally known as allostery. However, it has been considered hard to alter its effector specificity, despite its potential utility as a sensitive molecular sensor. To this end, we made fusion proteins consisting of an antibody variable region Fv and a circularly permutated TEM-1 β-lactamase cpBLA. Two expression vectors encoding Fv-cpBLA with different antigen specificities were made, in which cpBLA was inserted into the linker region of the single chain Fv that specifically binds either bone-related disease marker osteocalcin (BGP) C-terminal peptide or neonicotinoid insecticide imidacloprid (ICP). The cpBLA having new termini near the active site was activated upon binding with its cognate antigen, owing to the stabilization of tethered Fv by bound antigen. As a result, both Fv-cpBLA showed specific antigen binding as well as antigen-induced enhancement in catalytic activity. Moreover, *E. coli* cells expressing Fv-cpBLA for ICP showed ICP concentration dependent growth in the medium containing ampicillin. The system was also applied to select for Fv-cpBLA linker mutants that confer faster growth. This will be the first of an antibody-based small molecule indicator enzyme.

INTRODUCTION

Regulation of enzyme activity by specific small molecules would be a useful means for point-of-care diagnostics,[1] protein therapies,[2] and synthetic biology.[3−5] The activities of many natural proteins are regulated by posttranslational modifications or noncovalent interactions with an effector molecule. Such regulated enzymes will hereinafter be called protein biosensors. The most popular example of allostery is hemoglobin, a tetrameric protein that binds oxygen in a cooperative manner. The binding of O_2 to one subunit leads to conformational changes that increase the O_2 affinity of other subunits within the holoenzyme. Hemoglobin is thus a sensor and a carrier of oxygen. Allosteric proteins are fairly common in nature,[6] but are relatively difficult to design.[7,8]

Among protein biosensors, those utilizing antibody and enzyme are considered highly useful because of their potential in the range of recognition specificity as well as the affinity of the antibody, which will be enhanced by the signal amplification by biocatalysis. Until now, there have been a number of reports on such sensor proteins using an antibody and enzyme, in which the binding signal is detected as a change in catalytic activity. For example, epitope-inserted β-galactosidase,[9] alkaline phosphatase,[10] and β-lactamase[11] have been successfully controlled for their enzyme activity by the bound antibody to their inserted peptide. Also reported are fusion proteins consisting of a pair of antibody variable domain and β-galactosidase fragment,[12,13] a peptide tag, and a split TEM-1 β-lactamase,[14] and a peptide tag and β-glucuronidase[15] as the protein biosensors based on the protein-fragment complementation assay (PCA) principle. While these attempts are potentially useful for homogeneous immunoassays, they also have room for improvements. For example, epitope-inserted enzymes need the exogenous antipeptide antibody to perform the competitive assay, where one needs careful tuning of the assay conditions to attain acceptable sensitivity. Also, the detection of small chemicals is elusive, unless one can endeavor to obtain specific peptide aptamers. In the cases of PCA-based systems, noncompetitive detection of antigens including small haptens is possible without the need of additional antibodies. However, due to the nature of two-component systems, the system needs careful optimization of the protein concentrations since the error of each dispensed protein amount affects the signal. As a way to address these issues, here we attempt to create a single molecule antibody-based sensor protein utilizing a circularly permutated enzyme.

Circular permutation is a method to create mutant proteins that have a set of new N- and C-termini, with the original termini connected by a generally short peptide linker.[16−19] Using this method, while retaining the activity of original protein, functional linkage of large exogenous protein domains can be achieved by choosing appropriate new termini of the protein, which enables the fabrication of various functional fusion proteins.[20−22] For example, Guntas et al. created a maltose/glucose sensor with large switching dynamics, by fusing each circularly permutated maltose binding protein and TEM-1 β-lactamase (cpBLA).[23] As an extension of this approach, here we tried to make a sensor protein Fv-cpBLA in which cpBLA, as a signaling domain of the sensor protein, was inserted to the interdomain linker region of a single-chain antibody (scFv), as a ligand recognition moiety. cpBLA, having new termini near the active site, was expected to be stabilized and activated by the bound antigen, owing to the stabilization of tethered Fv by the bound antigen (Figure 1A). Through this approach, we observed antigen-dependent activation of β-lactamase (BLA) activity *in vitro* for two specific antibody−antigen pairs and also resultant antigen-dependent growth promotion of *E. coli* expressing the fusion protein, in the medium containing ampicillin. The system was also applied to select functional mutant Fv-cpBLAs that confer improved cell growth, from a small library of constructs with randomized linker residues.

MATERIALS AND METHODS

Materials. Oligonucleotides were obtained from Texas Genomics Japan (Tokyo). The BGP C-terminal peptides were obtained from Genscript (Piscataway, NJ). Polymerase chain reaction (PCR) was performed in a T3000 thermocycler (Biometra, Goettingen, Germany). DNA sequences were determined using a CEQ 8000 Genetic Analysis System (Beckman Coulter, Fullerton, CA). Beta-lactamase (BLA) activity was either measured with fluorocillin (Invitrogen, Tokyo, Japan) using a fluorescence plate reader GENios Pro (Tecan, San Jose, CA), or with nitrocefin (Calbiochem) as substrate using a microplate reader Model 680 (Bio-Rad, Heracules, CA). The chemicals and other reagents, unless otherwise indicated, were obtained from Sigma (St. Lois, MO), Nacalai Tesque (Kyoto, Japan), or Wako Pure Chemical Industries (Osaka, Japan).

Construction of the cpBLA Gene. The DNA fragment encoding 24th−70th residues with a short peptide linker (DKS) at the N-terminus was obtained by PCR using the primers BLA24rev (5′-CATTGGGACAAGAGCCACCCAGAAACGCTGGTGAAA-3′) and BLA170for (5′-GGCGATATCGGCTTCATTCAGCT CCGGTTC-3′), encoding the linker and *Eco*RV site (underlined) at their 5′-termini, respectively, pET20b(+) (Merck, Tokyo, Japan) as a template, and *Ex-Taq* DNA polymerase (Takara-Bio). Similarly, the fragment encoding the 168th to 286th residues with the linker at the C-terminus was obtained with BLA168rev (5′-GGCGATAT-CAATGAAGCCATACCAAAC-3′) and BLA286for (5′- TGGGT GGCTCTTGTCCCAATGCTTAATCAGTGA-3′), encoding the *Eco*RV site and the linker at their 5′-termini, respectively, as primers. With the gel-purified PCR products (100 ng each), overlap-extension PCR was performed with *Ex-Taq* DNA polymerase for 10 cycles without primers and 25 cycles with BLA168rev and BLA170-for primers. After purification, the fragment was cloned into pCR4-TOPO (Invitrogen) according to the manufacturer. Plasmid DNA was purified with Wiazrd plus SV Minipreps (Promega) and the sequence of cpBLA confirmed.

Construction of Fv-cpBLA Fusion Protein Expression Vectors. The expression vector for scFv recognizing BGP C-terminal peptide pET/scFv(BGP) was made from a phagemid encoding the scFv (pIT2/scFv(BGP)), which was made from the plasmid encoding V_H and V_L cloned from KTM-219 hybridoma.[24] pIT2/scFv(BGP) was digested with *Nco*I and *Not*I, and was inserted into pET26b(+) (Novagen) digested with the same, resulting in

pET/scFv(BGP). To insert the cpBLA gene into the linker region of scFv, a *Dra*I site was made in the middle by the QuikChange mutagenesis kit (Stratagene) with primers Link-Drarev (5′-GGTGGAGGCGGTTCAGGCTTTAAAGGCAGT GGCGGTGGCGGG-3′) and LinkDrafor (5′-CCCGCCACCG CCACTGCCTTTAAAGCCTGAACCGCCTCCACC-3′) containing the underlined *Dra*I sites. Then, the *Eco*RV-digested cpBLA gene with blunt ends was inserted into *Dra*I-digested pET/scFv(BGP). The clones with objective orientation were selected and designated pET/Fv-cpBLA(BGP) (Figure 1B). Also, pET/Fv-cpBLA(ICP) was constructed similarly from a phagemid vector encoding anti-imidacloprid scFv pIT2/scFv(ICP).

Expression and Purification of Fv-cpBLA(BGP). BL21(DE3, pLysS) cells were transformed with pET/Fv-cpBLA, and the transformed cells were cultured at 37 °C overnight in LB medium containing antibiotics (34 μg/mL chloramphenicol and 50 μg/mL kanamycin) (LBCK) and 1.5% agar. To recover soluble proteins, a single colony was picked and grown overnight at 37 °C in 4 mL of LBCK medium, from which 1 mL was used to inoculate 250 mL of LBCK medium. The cells were cultured at 27 °C until OD_{600} reached 0.6, when final 0.4 mM IPTG was added and incubated for a further 16 h at 27 °C. After centrifugation (6,000*g*, 10 min, 4 °C), 107.5 g of $(NH_4)_2SO_4$ was added to the supernatant and incubated for 16 h at 4 °C. The solution was centrifuged at 10,000*g* for 20 min at 4 °C, and the pellet resuspended in Talon buffer (50 mM sodium phosphate and 300 mM NaCl, pH 7.0). The solution was purified with 0.2 mL of Talon metal affinity resin according to the manufacturer (Clontech, Takara-Bio). The bound proteins were eluted in 0.5 mL fractions with elution buffer (125 mM imidazole in Talon buffer).

To recover Fv-cpBLA from the insoluble fraction, 1 mL of the 4 mL overnight culture was used to inoculate 160 mL of LBCK medium, and cultured and induced with IPTG similarly but at 37 °C. The pellet after centrifugation was homogenized in 25 mL of Talon buffer and sonicated on ice with a supersonic homogenizer VP-15S (Taitec, Saitama, Japan). The pellet after centrifugation at 10,000*g* for 60 min at 4 °C was washed 3 times with 25 mL of 1% Triton X-100 and 1 mM EDTA, pH 8.0, and subsequently centrifuged at 6,000*g* for 15 min at 4 °C. The resultant pellet was dissolved in 10 mL of Talon buffer containing 6 M GdnHCl and purified with Talon resin according to the manufacturer. Refolding of the fusion protein from the insoluble fraction was performed as described.[25]

Western Blotting. Proteins were transferred to a nitrocellulose membrane and detected with anti-BLA polyclonal antibody (Chemicon, Millipore, Tokyo, Japan) and HRP-goat antirabbit Ig (Biosource, Camarillo, CA), or directly with HRP-Penta-His (Qiagen, Tokyo). The washed membrane was developed with a West-Pico detection kit (Pierce Biochemicals) and a LAS-4000 luminoimager (Fujifilm, Tokyo, Japan). The band intensities were quantified using ImageJ software (http://rsb.info.nih.gov/ij/).

ELISA. After ICP-BSA or BSA (10 μg/mL in PBS: 10 mM phosphate, 137 mM NaCl, and 3.7 mM KCl, pH 7.2) was immobilized in Falcon 3912 microplate (BD Bioscience, Tokyo) wells at 4 °C for 16 h, blocked with 25% immunoblock (DS Pharma, Osaka, Japan) at 25 °C, 2 h, and washed 3 times with 0.1% Tween 20 in PBS (PBST), samples in 100 μL 5% immunoblock in PBS were applied and incubated at 25 °C for 1.5 h. After 3 washes with PBST, bound Fv-cpBLA was probed with 1/2000 diluted HRP-Penta-His at 25 °C for 1 h, washed 3 times with PBST, and developed with 100 μL/well substrate solution (100 μg/mL 3,3′,5,5′-tetramethylbenzidine (Sigma) and 0.04 μL/mL H_2O_2, in 100 mM NaOAc, pH 6.0). After incubation for 5 min, the reaction was stopped with 50 μL per well of 1 M sulfuric acid and the absorbance read at 450 nm with a reading at 655 nm as a control.

BLA Activity Assay. The BLA activity was either assayed with the chromogenic substrate nitrocefin or fluorogenic substrate fluorocillin.[26] For nitrocefin, the mixture of protein (5 μL), antigen solution (5 μL), and 90 μL of 1 mM nitrocefin in PBS was incubated at 25 °C for 40 h, and the absorbance was read at 490 nm. In the fluorometric assay, unless otherwise indicated, the sample (10 μL) was added with 90 μL of 0 to 50 μM fluorocillin in PBS, incubated at 25 °C for 30 min, and read for its fluorescence intensity in a white microplate (Corning Costar 3693) at 535 nm with 485 nm excitation. The initial velocity values were fit to the Michaelis−Menten and Hill equations as follows:

$$v_i = \frac{V_{max}[S]^n}{K_m^n + [S]^n}$$

where n is the Hill coefficient, a measure of cooperativity by the nonlinear least-squares algorithm of Kaleidagraph 4.1 (Synergy Software, Reading, PA, USA).

Growth Assay and Selection of the Fv-cpBLA Expressing Strain. BL21(DE3, pLysS) cells were transformed with pET/Fv-cpBLA(ICP) and were cultured at 27 °C overnight in LB medium containing antibiotics (34 μg/mL chloramphenicol and 50 μg/mL kanamycin) (LBCK) and 1.5% agar. A single colony was picked and grown overnight at 27 °C in 4 mL of LBCK medium, from which 4 μL was inoculated to 4 mL of fresh LBCK medium supplemented with 1 mM isopropyl β-D-thiogalactoside (IPTG), 0 or 100 μg/mL ampicillin, and 0 to 10 ng/mL ICP or thiacloprid (TCP). Cells were shaken at 27 °C for 40 h, with periodical monitoring of the optical density with Mini Photo 518R (Taitec, Saitama, Japan).

In the growth assay using a microplate, confluent BL21(DE3, pLysS, pET/Fv-cpBLA) cells from a single colony derived of libraries were 1/1000-diluted into LB medium containing 34 μg/mL chloramphenicol, 30 μg/mL kanamycin, and 0.4 mM IPTG, and cultured at 27 °C until OD_{660} reached 0.4. The cells were divided into the wells at 100 μL each, supplemented with 100 μg/mL ampicillin and ICP as indicated. A flat-bottom transparent microplate (Costar 3799) was shaken at 270 rpm at 27 °C and measured for the absorbance at 612 nm at 15 min intervals using a GENios Pro microplate reader.

RESULTS AND DISCUSSION

Construction of Expression Vectors. The schematic structure of our sensor protein is depicted in Figure 1A. Since many antibody variable regions specific for small haptens are known to be stabilized by the bound antigen,[27] we reasoned that through the appropriate design it is possible to create such a fusion protein that can be stabilized and also activated by the bound antigen. However, selection of a suitable enzyme that responds to the antigen bound to the tethered Fv portion could be a challenge. As a possible candidate enzyme, we chose a circularly permutated β-lactamase (cpBLA).

Previously, the fusion proteins of cpBLA and circularly permutated *E. coli* maltose binding protein (MBP) were reported to show significant maltose-dependent modulation of its catalytic activity.[23] On the basis of this observation, a circularly permutated TEM-1 β-lactamase (cpBLA) gene with its 168th and

170th residues as new N/C-termini, respectively, was prepared and used to join with antibody fragments. In the wild-type enzyme, the 168−170th residues and the substrate-binding residue Glu166 are in a part of the Ω-loop associated with catalytic activity.[28,29] To make a fusion protein with possible antigen-dependent catalytic activity, the cpBLA gene was inserted into the $(G_4S)_3$ linker region of a single-chain Fv (scFv) expression vector, designated pET/Fv-cpBLA (Figure 1B). Our primary attempt was based on the scFv for human osteocalcin (BGP), a bone-related disease marker, which specifically binds its C-terminal epitope. This Fv is known to be significantly stabilized by the addition of an antigen peptide such as the 7 aa C-terminal peptide BGP-C7 (FW: 894), which was previously confirmed by phage ELISA using immobilized MBP-V_L fusion protein and V_H fragment labeled with bacterial alkaline phosphatase (open sandwich ELISA).[24]

Expression and Purification of Fv-cpBLA(BGP) Protein. To investigate the properties of Fv-cpBLA(BGP) protein, BL21-(DE3, pLysS) cells were transformed with the expression vector, and the expression of the fusion protein with its His_6-tag was investigated for the culture supernatant, the intracellular soluble fraction, and the insoluble fraction. According to the SDS−PAGE and Western blot using the HRP-anti-His_5 (PentaHis) antibody, a minute protein band of expected size (58 kD) was observed for the intracellular soluble fraction, and a clearer band of the protein was detected in the insoluble fraction (Figure 1C and D). Taking the amount of the expressed protein into account, we decided to recover and purify the protein from the insoluble fraction. The purified denatured protein was subjected to refolding by a stepwise dialysis and oxidation, and this refolded sample was used for further analyses.

As a measure of the integrity of refolded protein, the antigen-binding activity of Fv-cpBLA was evaluated by a kinetic analysis using a surface plasmon resonance biosensor Biacore 2000. As a target ligand, the biotinylated C-terminal 11-mer BGP peptide was immobilized on the sensor chip with immobilized streptavidin, to see the BGP-binding activity of Fv-cpBLA and commercially available BLA as a control. As shown in Figure 1E, a significant binding signal was observed for Fv-cpBLA, and subsequently, its equilibrium dissociation constant K_d was calculated as 77.6 nM (Table 1). Since this value was comparable to that of the Fv (137 nM),[30] the refolded Fv-cpBLA was considered to retain sufficient antigen-binding activity. The somewhat superior binding activity was probably because of the covalent linkage of V_H/V_L like scFv, which favored their association. However, BLA at the same concentration gave no specific binding signal to the immobilized BGP-C11 peptide, which clearly showed the binding specificity of refolded Fv-cpBLA.

BGP-Dependent Activation of Fv-cpBLA(BGP) Protein *in Vitro*. Next, the catalytic activity as well as its antigen dose-dependency of Fv-cpBLA was investigated using a fluorogenic BLA substrate fluorocillin. Compared with the wild-type BLA, the enzyme without BGP-C7 peptide showed 0.87% of the specific activity, which was a value comparable to that of other BLA mutants (Table 2).[11,14] Because of its relatively low catalytic activity, the dose-dependency was evaluated taking the fluorocillin fluorescence without Fv-cpBLA but in the presence of the same amounts of antigen as controls. Under this condition, we could observe a clear dose-dependent enhancement in BLA activity of Fv-cpBLA (Figure 2A). According to the dose-dependency curve, the EC50 calculated from the curve-fitting was 1.47 nM, also indicating that as low as 1 ng/mL (1.1 nM) of BGP-C7 was effective in enhancing the observed BLA activity. Surprisingly, this concentration was lower than the detection limit previously obtained in open sandwich ELISA.[24] Also, the specificity of the response was investigated using other peptides as well as unrelated organic compounds ICP and TCP as an antigen (see later). As shown in Figure 2B, the activation was only observed for the cognate antigens, suggesting the specificity of observed enhancement. As a comparison, the effect of BGP-C7 on the catalytic activity of BLA was investigated (Figure 2C). The result clearly showed a negligible effect of BGP-C7 on BLA activity itself.

Then the specific activity k_{cat} and Michaelis constant K_m were calculated from the kinetic assays for both Fv-cpBLA and the wild-type BLA by nonlinear least-squares curve fittings

Table 1. Binding Constants for Biotinylated BGP-C11 Obtained with Biacore 2000

	k_a ($M^{-1}s^{-1}$)	k_d ($\times 10^{-6}$ s^{-1})	K_D ($\times 10^{-9}$ M)

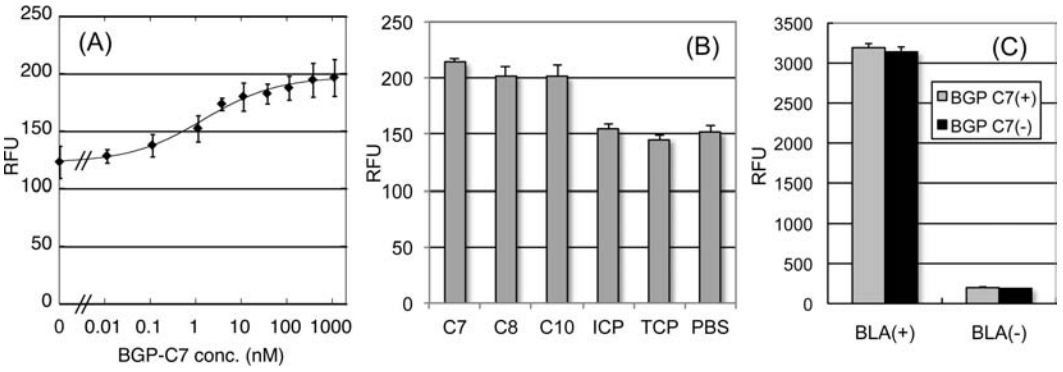

Figure 2. Antigen-dependent activation of Fv-cpBLA(BGP) catalytic activity. (A) Dose−response curve for BGP-C7 peptide. The mixture of 70 nM Fv-cpBLA, 1 μM fluorocillin, and 0−1100 nM BGP-C7 peptide in 100 μL of PBS was incubated at 27 °C for 1 h and read for fluorescence. Background fluorescence of the samples without Fv-cpBLA was subtracted for each BGP-C7 concentration. Averages of 3 samples with an error bar for 1 SD are shown. (B) Antigen specificity. Measurement was done as in A except that 1 μg/mL each of BGP-C8, BGP-C10 (peptides having additional one and three N-terminal residues to BGP-C7, respectively), ICP, and TCP were added instead of BGP-C7. (C) The effect of BGP-C7 on BLA activity. Measurement was done as in (B) except that BLA (37.5 nM) was used instead of Fv-cpBLA. Background fluorescence is also shown.

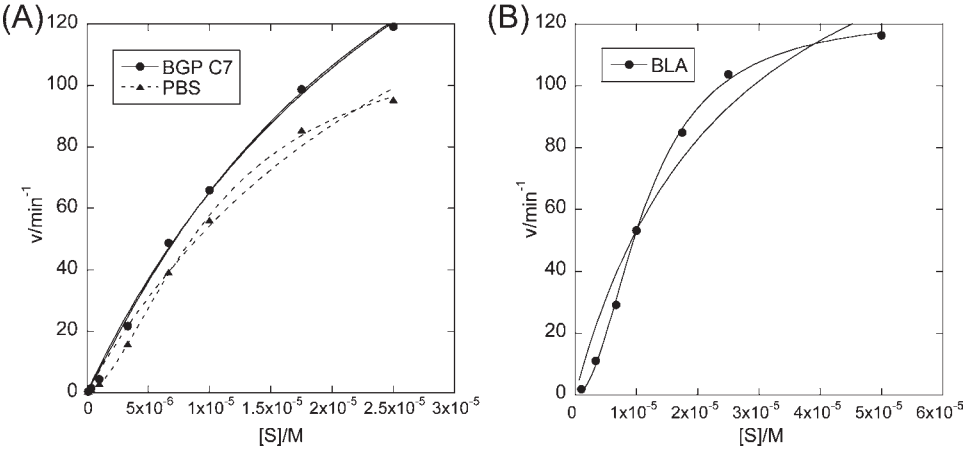

Figure 3. S−V plots for (A) FvcpBLA and (B) BLA. Fv-cpBLA (70.1 nM) was added with substrate fluorocillin as indicated in the presence or absence of antigen BGP-C7 (1.1 μM). Initial velocities are plotted against the substrate concentration. BLA (0.512 nM) was used as a comparison. Fitting curves based on Michaelis−Menten and Hill equations are shown for each condition.

(Figure 3). When we assumed Michaelis−Menten-type kinetics, the observed enhancement in k_{cat} was modest (26%) in the presence of 1.1 μM BGP-C7. However, when the Hill equation was employed for the fittings considering the sigmoid-like substrate dose-dependent activity, better fittings and calculated enhancement in specific activity as large as 110% was obtained (Table 2). To the best of our knowledge, this is the first report of allosteric behavior of the BLA enzyme. Though the reason for the sigmoidal kinetics observed especially for unliganded Fv-cpBLA and the wild-type BLA is unclear, and might be a substrate (fluorocillin)-specific phenomenon, the antigen-dependent catalytic behavior of Fv-cpBLA was clearly suggested.

Fv-cpBLA for Pesticide Also Showed Antigen Dependence. To show the generality of our attempt, another Fv-cpBLA recognizing different antigens was made and investigated for its catalytic properties. With an intention to make a sensor protein for environmental monitoring, the gene encoding antibody fragments of pET/Fv-cpBLA was swapped with those for the Fv that specifically binds a neonicotinoid insecticide imidacloprid (ICP, FW: 255.66) (Figure 4A). According to the Biacore measurement, the Fv and scFv showed dissociation constants K_d for the ICP-BSA conjugate of 67 and 12.7 nM, respectively. The Fv was also known to be stabilized by the addition of ICP, as well as by its analogue thiacloprid (TCP), to a lesser extent, which was confirmed by a phage ELISA using immobilized maltose binding protein−V_L fusion protein and the V_H fragment displayed on M13 phage (open sandwich ELISA, Figure S1 (Supporting Information)). The lower response to TCP was considered to reflect the cross-reactivity of this antibody to TCP (1.3%) obtained by a competitive assay.

When we prepared Fv-cpBLA for ICP in the same manner as that for BGP and used it to evaluate dose−response behavior, a similar ICP dose-dependent fluorescence was obtained (Figure 4B). The result again suggested the antigen-dependent catalytic activation of Fv-cpBLA protein *in vitro*. The calculated EC50 value was 20.3 nM (5.2 ng/mL), which was close to the K_d value of scFv. Moreover, when we tried to express Fv-cpBLA (ICP) at a lower temperature (27 °C), a limited amount of soluble protein was recovered from the culture supernatant (Figure S2A, Supporting Information). Hence, we used a concentrated, partially purified protein from the culture supernatant for further study. To confirm its antigen binding activity, ELISA

dx.doi.org/10.1021/bc1004125 |*Bioconjugate Chem.* 2011, 22, 633–641

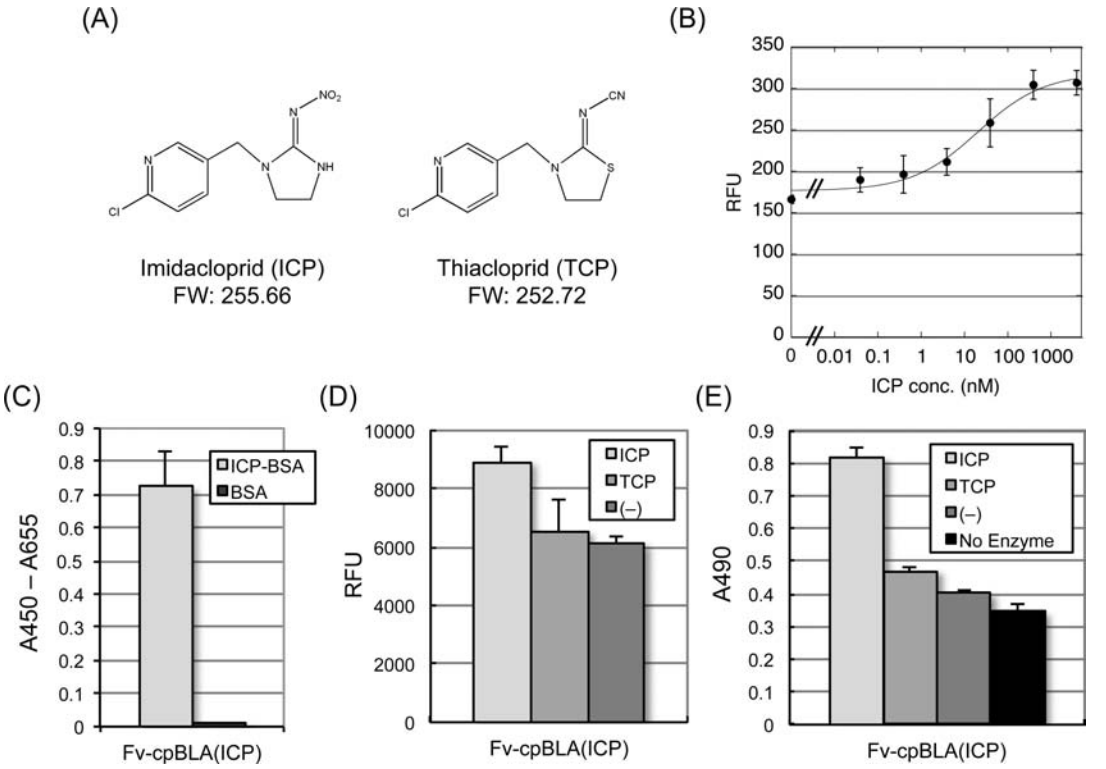

Figure 4. (A) Structures of ICP and TCP. (B) Dose−response curve for ICP pesticide with Fv-cpBLA recovered from the insoluble fraction. Other conditions are the same as in Figure 2A. (C) Specific binding of Fv-cpBLA(ICP) recovered from culture supernatant to immobilized ICP-BSA probed by ELISA. The names of immobilized protein are shown. Averages of 3 samples with an error bar showing 1 SD are shown. (D) BLA activity of Fv-cpBLA(ICP) measured with 9 μM fluorocillin. The names of antigen added are shown, and background fluorescence without Fv-cpBLA was subtracted. (E) BLA activity of the protein detected with nitrocefin. The names of antigen added are shown, while the background signal without the protein is shown as No Enzyme.

for the immobilized antigen was performed. The sample clearly showed a specific binding signal to ICP-BSA, while showing its negligible binding to carrier BSA (Figure 4C). We then evaluated its catalytic activity by using both fluorocillin and a more popular chromogenic substrate nitrocefin. When the catalytic activity was measured in the presence of ICP or its analogue TCP, the samples containing 500 ng/mL (~2 μM) of the antigen showed significantly higher activity than the control without ICP, irrespective of the substrate used (Figure 4D and E). These data suggest that Fv-cpBLA(ICP) recovered from the soluble fraction is also catalytically activated by its cognate antigen.

Control of Bacterial Growth. To investigate the possibility to utilize this antigen-dependent BLA activity as a means to control bacterial growth in the presence of a BLA substrate ampicillin, the effect of these insecticides on the growth of *E. coli* BL21(DE3, pLysS) cells was tested. When BL21(DE3, pLysS) cells without pET/Fv-cpBLA plasmid were cultivated with or without 100 ng/mL ICP, no significant difference in their growth was observed between the cultures, suggesting that ICP up to this concentration does not affect nor promote cell growth (data not shown). Next, to investigate the effect of ICP or TCP on BL21(DE3, pLysS) cells expressing Fv-cpBLA(ICP), the plasmid-bearing cells were cultured in LBCK medium supplemented with 1 mM IPTG at 27 °C. After dilution to the fresh LBCK medium containing 1 mM IPTG but without ampicillin, all the cells showed similar logarithmic growth curves irrespective of added ICP or TCP, which again suggests negligible toxicity of these pesticides to the bacteria (Figure 5A). The expression of Fv-cpBLA in the cell was confirmed by Western blotting using the anti-BLA polyclonal antibody, which clearly showed a 58 kD band corresponding to the expected size of the fusion protein. Also, the amount of protein was almost the same irrespective of added ICP or TCP in the culture media (Figure S2B, Supporting Information).

On the contrary, when the induced cells were diluted and cultivated in LBCK medium containing 100 μg/mL ampicillin (LBCKA) for more than 24 h at 27 °C, we could observe antigen-concentration dependent cell growth (Figure 5B). When TCP was added instead of ICP, the growth was slower but significantly faster than the culture without antigens, which was in accordance with the specificity of this antibody.

To further confirm ICP dose-dependent growth of the cells, the cells harboring pET/Fv-cpBLA were induced for protein expression for 3 h at 27 °C and diluted in microplate wells containing various concentrations (0−1000 ng/mL) of ICP to monitor their growth. As a result, in LBCKA media, the cells show a clear ICP dose-dependent growth (Figure S3, Supporting Information).

Selection of Fv-cpBLAs That Confer Superior Bacterial Growth. By taking advantage of the antigen-dependent growth behavior of the *E. coli*, we attempted to select functional Fv-cpBLA proteins from a library of constructs. To this end, two small libraries of variant Fv-cpBLA(ICP) were made, where the two flexible linkers between V_H and cpBLA, and cpBLA and V_L were substituted with two sets of α-helix-forming linkers (either EAAAK and $(EAAAK)_2$, or $(EAAAK)_2$ and $(EAAAK)_2$), and two junctional residues at the two termini of cpBLA were randomized

dx.doi.org/10.1021/bc1004125 |*Bioconjugate Chem.* 2011, 22, 633–641

(Figure 6A). The colonies (95 in total) from the two libraries were picked and screened on the microplate wells containing LBCKA medium with IPTG and ICP, and several clones that showed better growth than the original Fv-cpBLA-bearing cells were selected (Figure 6B and C, Table 3, and Figure S4, Supporting Information). One of the faster-growing clones that encoded an expected sequence of the second library V_H-$(EAAAK)_2$-N-cpBLA-K-$(EAAAK)_2$-V_L (AF6) was further analyzed for its catalytic property. When the purified protein refolded from the insoluble fraction was measured for its catalytic activity, the protein showed ICP-dependent BLA activity comparable to, or more than, the original Fv-cpBLA (G4S) in fluorocillin assay (Figure 6D). Because the increase in BLA activity of purified AF6 protein over G4S protein was minimal, the superior growth of the cells harboring AF6 would be mainly due to the improved stability/expression of soluble Fv-cpBLA in bacteria. To prove this possibility, Western blot analysis to quantify the amounts of soluble/insoluble Fv-cpBLA from the bacteria expressing either G4S or AF6 protein was performed (Figure 6E). The result clearly showed almost twice the soluble/insoluble ratio of AF6 (14.3%) compared with

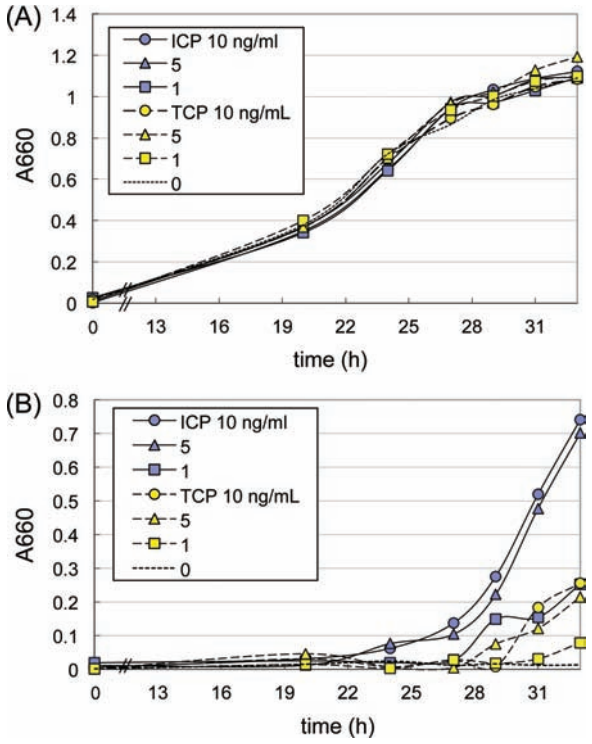

Figure 5. Growth curves of BL21(DE3, pLysS, pET26/Fv-cpBLA-(ICP)) in 4 mL of LBCK medium supplemented with (A) 0 or (B) 100 μg/mL ampicillin, at 27 °C.

Table 3. Amino Acid Sequences of the Linker Region for Selected Fv-cpBLA Clones

clone	V_H	linker		cpBLA		linker	V_L
WT		GGGGSG	F		K	GSGGGGS	
AC2		(EAAAK)	V		D	$(EAAAK)_2$	
AE2		(EAAAK)	Y		A	$(EAAAK)_2$	
AF2		(EAAAK)	S		T	$(EAAAK)_2$	
AC3	V_H	(EAAAK)	V	cpBLA	W	$(EAAAK)_2$	V_L

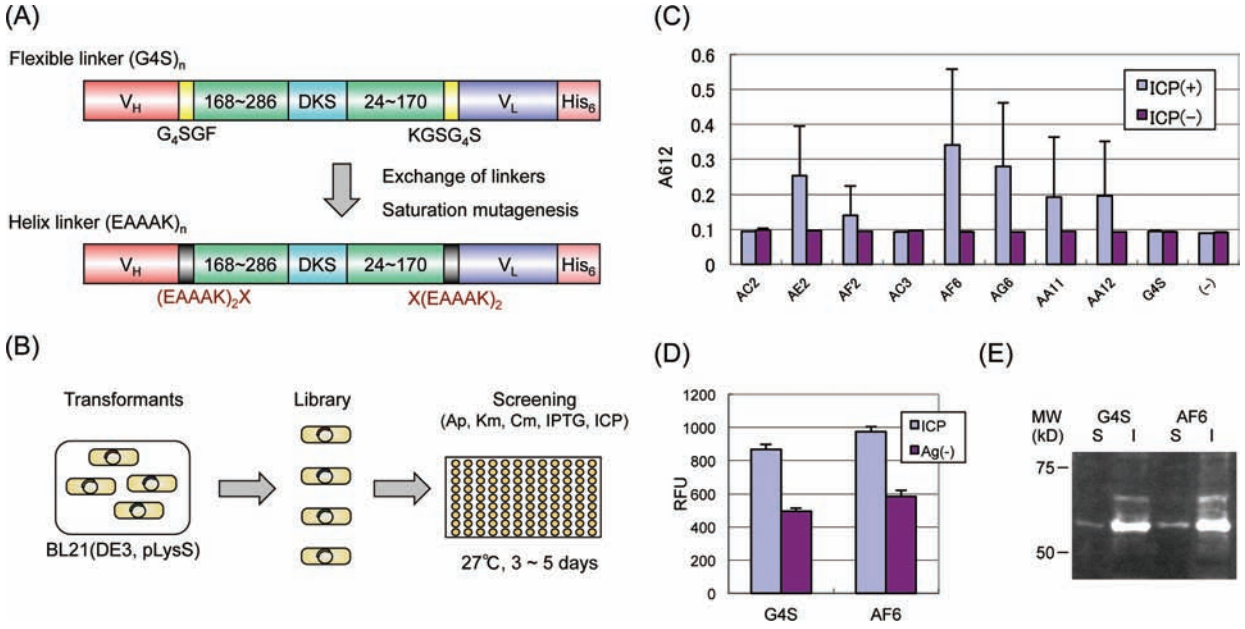

Figure 6. (A) Scheme of the linker engineering and (B) screening based on the bacterial growth in the presence of ampicillin and ICP. (C) The result of the growth screening of selected mutants with 100 mg/L ampicillin (n = 3). (D) Comparison of the BLA activity of refolded Fv-cpBLA (300 nM each) with the original linker (G4S) and one of selected linkers (AF6) with and without ICP (n = 3). (E) Western blot of Fv-cpBLA proteins recovered from the soluble (S) or insoluble (I) fractions after sonication detected using the anti-His5 antibody. The same amounts of cells were used for both G4S and AF6 samples.

dx.doi.org/10.1021/bc1004125 |*Bioconjugate Chem.* 2011, 22, 633–641

that of G4S (5.9%), suggesting that this was indeed the case. Also, since all the clones with faster growth showed functional Fv-cpBLA sequence without frame-shift or deletion, successful selection of antigen-responsive Fv-cpBLA proteins is strongly suggested.

Here, we constructed fusion proteins consisting of an antibody variable region and a circularly permutated β-lactamase Fv-cpBLA for two antibody−antigen systems. Unlike epitope-inserted enzymes,[9−11] Fv-cpBLA does not need additional antibodies and have the ability to noncompetitively detect small haptens. In addition, as a single molecule probe, optimization of probe concentration is not necessary and higher sensitivity can be expected than the corresponding bimolecular probe, which suffers from the entropic loss of the free energy upon complex formation of the probes and the target. This was actually proven true for both the BGP peptide and ICP pesticide detections by the respective Fv-cpBLA protein, where apparent EC50s of several ng/mL were attained. Though the obtained EC50 value for BGP was considerably lower than the K_d value obtained by Biacore, we think this might reflect the true affinity of the fully refolded Fv-cpBLA protein. Because of their sensitivity, the obtained Fv-cpBLA protein will be particularly useful as a biosensor protein, which can be directly utilized as an assay reagent of fluorescence-based homogeneous immunoassay.

The plausible working mechanism of the ICP sensor with *E. coli* growth as a signal was that the small difference in cellular and extracellular lactamase activity was reflected in the difference in lag periods of cell growth, which was required for the ampicillin concentration to be reduced to the threshold in which the surviving cells could grow. The system is potentially useful as an economical environmental monitor because our cells with Fv-cpBLA for ICP are sensitive enough to detect, for example, the Japanese criteria concentrations of ICP in agricultural crops (20 to 5,000 ng/mL). The current incubation period required for cell growth was rather long, probably due to the limited amount of soluble active Fv-cpBLA protein produced in bacteria. However, this problem was partially solved by the selection of faster-growth variant Fv-cpBLAs including AF6. The somewhat modest activity improvement of purified AF6 protein over the original Fv-cpBLA might be due to the suboptimal length of the encoded helical linkers in the library, or the intrinsic property of Fv-cpBLA. Possibly, circular permutation of Fv as well as BLA, connection of the domains with shorter linkers, and the selection based on the activity will enable us to create sensor proteins with more robust activity change.

Here, we showed that through the combination of rational design and molecular selection of antibody−enzyme fusion proteins, functional sensor enzymes whose BLA activity responds to a molecule of choice could be obtained. Considering similar dose−response curves obtained for the two different targets, the proposed strategy will be valid for many antibodies that recognize different types of antigens including haptens, peptides, and proteins. Since BLA can be utilized as a prodrug activator in antibody-directed enzyme prodrug therapy (ADEPT),[31] the use of antibody−enzyme conjugates with a sensor function might improve the specificity of anticancer ADEPT if we employ antibodies recognizing a suitable cell-surface cancer epitope. In the long term, our challenges will include a positive selection of novel Fv-cpBLAs with altered specificity from a library of randomized antibody domains. Hopefully, by selecting such libraries, many sensitive sensor enzymes with a specific antibody variable region will be created for a wide range of antigens.

Supporting Information

ABSTRACT: A novel fluorine-18 prosthetic ligand, 5-(1,3-dioxolan-2-yl)-2-(2-(2-(2-fluoroethoxy)ethoxy)ethoxy)pyridine [^{18}F]**2**, has been synthesized. The prosthetic ligand is formed in high radiochemical yield (rcy = 71 ± 2%, n = 3) with excellent radiochemical purity (rcp = 99 ± 1%, n = 3) in a short reaction time (10 min). [^{18}F]**2** is a small, neutral, organic complex, easily synthesized in four steps from a readily available starting material. It can be anchored onto a target molecule containing an aminooxy functional group under acidic conditions by way of an oxime bond. We report herein two examples [^{18}F]**23** and [^{18}F]**24**, potential imaging agents for β-amyloid plaques, which were labeled with this prosthetic group. This approach could be used for labeling proteins and peptides containing an aminooxy group. Biodistribution in male ICR mice for both oxime labeled complexes [^{18}F]**23** and [^{18}F]**24** were compared to that of the known β-amyloid plaque indicator, [^{18}F]-AV-45, florbetapir **1**. Oximes [^{18}F]**23** and [^{18}F]**24** are larger in size and therefore should reduce the blood-brain barrier (BBB) penetration. The brain uptake for oxime [^{18}F]**23** appeared to be reduced, but still retained some capability to cross the BBB. Oxime [^{18}F]**24** showed promising results after 2 min post injection (0.48% dose/gram); however, the uptake increased after 30 min post injection (0.92% dose/gram) suggesting an in vivo decomposition/metabolism of compound [^{18}F]**24**. We have demonstrated a general protocol for the fluoride-18 labeling with a new prosthetic ligand [^{18}F]**2** that is tolerant toward several functional groups and is formed via chemoselective oxime coupling.

8 [^{18}F]**2**

A new F-18 prosthetic ligand for oxime coupling

INTRODUCTION

The use of molecular imaging agents plays a significant role in the advancement of medical procedures and is an important part of ongoing research.[1] In the forefront of molecular imaging is the use of positron emission tomography (PET), which relies on a biomarker that is labeled with short-lived positron emitting radionuclides. These PET imaging agents produce "hot" spots, where a large abundance of radioactivity congregates, due to the radioactive molecular probes. Fluorine-18 is one isotope that is widely used for PET imaging due to its unique physical and nuclear characteristics (ease of formation, half-life of 109.7 min, high resolution, and relative minor radiation dose to patients).[2]

Two methods are commonly used to incorporate fluorine-18 into a molecule, either by an electrophilic substitution or through nucleophilic displacement.[1−5] Electrophilic fluorination reactions are typically used in the carrier added (ca) form of [^{18}F]F^+ or [^{18}F]F_2, but have the drawbacks of low specific activity (theoretical achievable maximum radiochemical yield is limited to 50%)[6] and difficulty in controlled labeling.[1] An alternative option is the use of [^{18}F]F^- for nucleophilic substitution. High specific activity (theoretically 1.71 × 10^3 Ci/μmol)[3,4] is one advantage nucleophilic displacement possess over electrophilic substitution, which is achieved when [^{18}F]F^- is produced by the proton irradiation of enriched [^{18}O] water via the reaction ^{18}O(p, n)^{18}F. Typical S_N2 reactions dominate this avenue of chemistry. Due to the fact that the fluoride anion is highly electronegative and it is produced in an aqueous media, it is strongly hydrated and hence is not sufficiently reactive for nucleophilic substitution reactions. The fluoride anion therefore needs to be activated in the form of a "naked" anion for nucleophilic substitution, usually with "crown" ether such as K[222]. The K[222] contains two highly basic tertiary nitrogen atoms. The strong basic conditions are not suitable for compounds containing acidic protons, and thus may lead to their decomposition. To circumvent this problem, pre-existing fluorine-18 labeled molecules, known as prosthetic ligands, or biofunctional-labeling agents, are used to indirectly attach the fluorine-18 radionuclide onto a desired ligand, providing the fluorine-18 radiolabeled molecule.[1,5]

Several prosthetic ligands have been used with compounds that otherwise could not be labeled via a direct fluoride-18 nucleophilic substitution. The incorporation of these groups onto a target molecule can be achieved by methods that include the formation of an acyl,[7−12] sulfide,[13−16] alkyl,[17−20] hydrozone,[21] or oxime[9,22−31] bond formation, or with the use of photochemistry[32] and click chemistry.[33−36] Most of these prosthetic ligands are not ideal for routine applications because they require time-consuming and labor-intensive procedures with tedious purification processes. In general, prosthetic ligands may also be restricted to the type of

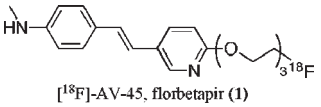
substrate used when coupled with the target ligand due to interfering nucleophilic groups. This may lead to cross-linked labeled products.[37] Therefore, site-specific linkage of a prosthetic ligand is necessary when attaching it to a target molecule.



The oxime bond formation is highly chemoselective[38,39] and takes place under acidic conditions between aminooxy groups and aldehydes or ketones. Since the reaction is chemoselective, the use of protecting groups is unnecessary and the oxime coupling reaction is functional group tolerant.

The approach in designing a new prosthetic ligand for labeling compounds that pose a problem to direct fluoride-18 nucleophilic substitution, such as biologically active peptides, will need to follow four criteria. First, the prosthetic group is labeled with a [^{18}F]fluoride anion via S_N2 displacement, forming a stable C−F bond on an sp^3 hybridized carbon atom. The prosthetic ligand containing an end-capped pegylated fluorine atom is similar to [^{18}F]-AV-45 (**1**),[40,41] which has been well tested and prepared at multicurie levels; therefore, we expect the fluorination reaction will proceed smoothly.

[^{18}F]-AV-45, (*E*)-4-(2-(6-(2-(2-(2-^{18}F-fluoroethoxy)ethoxy) ethoxy)pyridin-3-yl)vinyl)-*N*-methyl benzenamine, florbetapir (**1**) (Figure 1), is a new imaging agent targeting β-amyloid plaques in the brain.[40,41] This agent is currently under a phase III clinical study. It is a small, neutral, and moderately lipophilic agent (measured log D = 1.70, calculated log P = 2.85). We reasoned that compounds with similar structural features to **1** were good candidates to test the coupling reaction of the prosthetic group, validating the chemistry prior to its application to more complicated compounds, such as peptides and proteins.

A second criterion for the prosthetic ligand is that the compound be a neutral molecule, soluble in organic media, to aid in the purification process (solid-phase extraction). Third, the site at which the prosthetic group attaches to the target molecule (i.e., via an aldehyde) would need to form chemoselectively an oxime bond with an aminooxy functional group. Finally, it would be ideal for the coupling between both the prosthetic ligand and the aminooxy compound to occur quickly, in an environment suitable to tolerate many different functional groups. The use of an oxime coupling reaction with aldehydes, for the attachment of prosthetic groups, has been successfully reported.[22−27,29−31,42]

Herein, we report the synthesis and characterization of a novel radiolabeled ligand, [^{18}F]**2**, which meet all four criteria listed above as a suitable prosthetic group (Figure 2). To test and optimize the oxime coupling reaction, we synthesized two aminooxy compounds, **21** and **22**, and used them as model complexes for the labeling with our prosthetic ligand, [^{18}F]**2**. Biodistribution studies were performed for these two radiolabeled new oximes.

EXPERIMENTAL PROCEDURES

General Information. All reagents used were commercial products purchased from Sigma-Aldrich and were used without further purification unless otherwise indicated. Fluoride-18 (nca) was purchased from IBA Molecular North America, Inc. All anhydrous reactions were run under positive pressure of argon, ultrahigh-purity. All syringes and reaction flasks required for anhydrous reactions were flame-dried and then cooled under argon atmosphere. All anhydrous solvents were dried by passage through an alumina column using an Innovation Technology, Inc., system. Flash chromatography was carried out with silica gel 60 (230−400 mesh, Sigma-Aldrich). Analytical thin-layer chromatography (TLC) was performed on precoated aluminum-backed plates (silica gel 60 F_{254}). ^{1}H and ^{13}C NMR spectra were recorded on 200 MHz/50 MHz (Bruker DPX spectrometer), in deuterated chloroform ($CDCl_3$) with residual chloroform protons (δ 7.26 ppm for ^{1}H NMR and δ 77.23 ppm for ^{13}C NMR) as the internal reference. Chemical shifts are reported in parts per million (ppm). Coupling constants are reported in hertz (Hz). The multiplicity is defined by s (singlet), d (doublet), t (triplet), dd (doublet of doublets), ddd (doublet of doublets of doublets), br (broad), and m (multiplet). High-resolution mass spectrometry experiments were performed at University of Pennsylvania, Department of Radiology, Radiopharmaceutical Chemistry Section, using an Agilent Technologies LC/MSD TOF mass spectrometer.

*2-Bromo-5-(1,3-dioxolan-2-yl)pyridine (**6**).* Ethylene glycol (0.54 mL, 601 mg, 9.7 mmol) was added to a suspension of 6-bromo-3-pyridine carbaldehyde (**5**) (1.0 g, 5.4 mmol) and *p*-toluene sulfonic acid, monohydride (102 mg, 0.54 mmol), in 27 mL of benzene. The flask was then fitted with a reflux condenser and placed in an oil bath set to 92 °C. The reaction mixture was refluxed for 19 h, upon which time it was removed from the oil bath and allowed to cool to room temperature. The reaction was quenched with dilute K_2CO_3 (aq) solution to adjust the pH to ∼11. The reaction media were then partitioned between ethyl acetate and H_2O. The organic phase was separated from the aqueous phase with the use of ethyl acetate (3 × 50 mL). The combined organic layers were washed with brine (50 mL), dried over $MgSO_4$, filtered, and concentrated to afford 1.21 g (98%) of acetal **6**, a yellow oil. ^{1}H NMR was consistent with the reported literature.[43]

*2-(2-(2-(5-(1,3-Dioxolan-2-yl)pyridin-2-yloxy)ethoxy)ethoxy) ethanol (**7**).* Acetal **6** (302 mg, 1.31 mmol) was dissolved in 13 mL of anhydrous *N*,*N*-dimethyl formamide and added to a microwave reaction vessel containing Cs_2CO_3 (1.28 g, 3.93 mmol) and triethylene glycol (0.43 mL, 475 mg, 3.16 mmol). The reaction vessel was sealed and placed in a microwave reactor (Biotage Initiator) set at 150 °C for 50 min. The reaction was allowed to cool to room temperature and then vented with a needle prior to breaking the seal. The reaction mixture was partitioned between dichloromethane and H_2O. The organic phase was extracted from the aqueous phase with the use of dichloromethane (3 × 20 mL). The combined organic layers

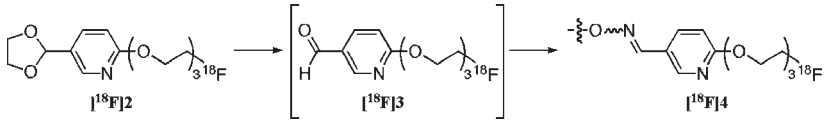

Figure 2. Structure of the prosthetic group [^{18}F]**2** and its transformation to fluorine-18 labeled oxime.

were washed with brine (25 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (100% ethyl acetate) afforded 240 mg (61%) of alcohol **7**, a viscous pale yellow oil. R_f = 0.16 (100% ethyl acetate). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.20 (d, J = 2.3 Hz, 1H), 7.68 (dd, J = 8.6, 2.4 Hz, 1H), 6.80 (d, J = 8.6 Hz, 1H), 5.60 (s, 1H), 4.52−4.47 (m, 2H), 4.16−3.97 (m, 4H), 3.87−3.82 (m, 2H), 3.71−3.58 (m, 8H), 2.49 (br, s, 1H, OH). ^{13}C NMR (50 MHz, $CDCl_3$): δ 164.7, 146.0, 137.5, 126.9, 111.6, 102.5, 72.7, 70.9, 70.6, 69.9, 65.5, 65.4, 62.0. HRMS (ESI) m/z calcd for $C_{14}H_{22}NO_6$ $[M+H]^+$ 300.1447, found 300.1440.

*2-(2-(2-(5-(1,3-Dioxolan-2-yl)pyridin-2-yloxy)ethoxy)ethoxy) ethyl 4-methylbenzenesulfonate (**8**).* Alcohol **7** (50 mg, 0.17 mmol) was added to a flame-dried round-bottom flask and dissolved in 1 mL anhydrous dichloromethane. Triethyl amine (30 μL, 25 mg, 0.25 mmol) was added and the reaction mixture was cooled to 0 °C. *p*-Toluenesulfonyl chloride (35 mg, 0.18 mmol) followed by *N*,*N*-4-dimethylaminopyridine (4.0 mg, 0.03 mmol) was quickly added and the reaction was placed in an ice/water bath at 0 °C. The reaction was allowed to warm to room temperature over the course of 5 h at which point it was partitioned between ethyl acetate and H_2O. The organic layer was then extracted from the aqueous layer with the use of ethyl acetate (3 × 10 mL). The combined organic layers were washed with brine (15 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (45−70% ethyl acetate/hexanes) provided 62 mg (82%) of tosylate **8**, a viscous cloudy oil. R_f = 0.27 (60% ethyl acetate/hexanes). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.20 (d, J = 2.4 Hz, 1H). 7.80 (d, J = 8.2 Hz, 2H), 7.68 (dd, J = 8.6, 2.4 Hz, 1H), 7.33 (dd, J = 8.6, 0.6 Hz, 2H), 6.78 (d, J = 8.6 Hz, 1H), 5.77 (s, 1H), 4.49−4.44 (m, 2H), 4.18−4.09 (m, 4H), 4.06−3.98 (m, 2H), 3.82−3.78 (m, 2H), 3.71−3.60 (m, 6H), 2.43 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 168.5, 164.6, 146.0, 137.4, 133.4, 130.1, 128.2, 126.8, 111.5, 102.4, 73.1, 71.0, 70.8, 69.9, 69.4, 68.9, 65.5, 65.4, 21.8. HRMS (ESI) m/z calcd for $C_{21}H_{28}NO_8S$ $[M+H]^+$ 454.1536, found 454.1524.

*5-(1,3-Dioxolan-2-yl)-2-(2-(2-(2-fluoroethoxy)ethoxy)ethoxy) pyridine (**2**).* Tosylate **8** (53 mg, 0.117 mmol) was dissolved in 2 mL of tetrahydrofuran and added to a 10 mL round-bottomed flask containing tetra-*n*-butylammonium fluoride hydrate (80 mg, 0.30 mmol). The color of the solution changes instantly upon addition from clear solution to a black solution. The 10 mL round-bottomed flask was then fitted with a reflux condenser and set in an oil bath at 76 °C. After 15 h, the reaction was removed from the heat, allowed to cool to room temperature, diluted with 15 mL ethyl acetate, and concentrated. Purification by flash chromatography (45−60% ethyl acetate/hexanes) provided 20 mg (57%) of a clear oil, compound **2**. R_f = 0.38 (60% ethyl acetate/hexanes). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.20 (d, J = 2.3 Hz, 1H), 7.68 (dd, J = 8.6, 2.4 Hz, 1H), 6.79 (d, J = 8.9 Hz, 1H), 5.77 (s, 1H), 4.70−4.65 (m, 1H), 4.52−4.42 (m, 3H), 4.17−3.98 (m, 4H), 3.88−3.80 (m, 3H), 3.74−3.65 (m, 5H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 164.7, 145.9, 137.3, 126.9, 111.5, 102.4, 85.1, 81.8, 71.1, 71.0, 70.9, 70.5, 70.0, 65.5. HRMS (ESI) m/z calcd for $C_{14}H_{11}FNO_5$ $[M+H]^+$ 302.1404, found 302.1398; HPLC conditions: Gemini 5 μ C18 110A column, 250 × 4.60 mm, 5 μm; r_t = 4.79 min (280 nm) in acetonitrile/10 mM ammonium formate buffer 60/40 with a flow rate of 1.0 mL/min.

*6-(2-(2-(2-Hydroxyethoxy)ethoxy)ethoxy)nicotinaldehyde (**9**).* Pyridinium *p*-toluenesulfonate (38.0 mg, 0.150 mmol) was added to a solution of acetal **7** (150 mg, 0.50 mmol) in 5 mL acetone and 9 μL H_2O. The flask was then fitted with a reflux condenser and placed in an oil bath set to 70 °C. After 3 h, the reaction was removed from the oil bath, allowed to cool to room temperature, and concentrated. The reaction mixture was then partitioned between dichloromethane and $NaHCO_3$ (aq, sat). The organic layer was separated from the aqueous layer with the use of 5% methanol/dichloromethane (5 × 10 mL). The combined organic layers were then washed with brine (20 mL), dried over $MgSO_4$, filtered, and concentrated to provide 114 mg (89%) of a thick pale yellow oil, aldehyde **9**. R_f = 0.08 (100% ethyl acetate). ^{1}H NMR (200 MHz, $CDCl_3$): δ 9.96 (d, J = 0.6 Hz, 1H), 8.62−8.61 (m, 1H), 8.08 (dd, J = 8.7, 2.4 Hz, 1H), 6.91 (ddd, J = 8.6, 0.7, 0.6 Hz, 1H), 4.63−4.58 (m, 2H), 3.92−3.87 (m, 2H), 3.76−3.68 (m, 6H), 3.65−3.60 (m, 2H), 2.34 (br, s, 1H, OH). ^{13}C NMR (50 MHz, $CDCl_3$): δ 189.6, 167.3, 152.7, 137.7, 126.9, 112.5, 72.6, 70.8, 70.5, 69.5, 66.2, 61.8. HRMS (ESI) m/z calcd for $C_{12}H_{17}NO_5Na$ $[M+Na]^+$ 278.1004, found 278.1005.

*2-(2-(2-(5-Formylpyridin-2-yloxy)ethoxy)ethoxy)ethyl 4-Methyl benzenesulfonate (**10**).* Alcohol **9** (52 mg, 0.20 mmol) was added to a flame-dried round-bottom flask, dissolved in 1 mL of anhydrous dichloromethane, and cooled to 0 °C. Anhydrous pyridine (50 μL, 48 mg, 0.61 mmol) was added to the reaction mixture at 0 °C. After allowing the reaction mixture to stir at 0 °C for 5 min, *p*-toluenesulfonyl chloride (58 mg, 0.31 mmol) was quickly added to the solution. After 10 min, the reaction mixture was removed from the ice/water bath and allowed to warm to room temperature overnight. After 19 h, the reaction mixture was diluted with ethyl acetate and partitioned between H_2O. The organic phase was extracted from the aqueous phase with the use of ethyl acetate (3 × 10 mL). The combined organic layers were washed with brine (10 mL), dried over Na_2SO_4, filtered, and concentrated. Purification by flash chromatography (50−60% ethyl acetate/hexanes) provided 70 mg (84%) of tosylate **10**, a thick, milky oil. R_f = 0.32 (60% ethyl acetate/hexanes). ^{1}H NMR (200 MHz, $CDCl_3$): δ 9.95 (d, J = 0.5 Hz, 1H), 8.60 (dd, J = 2.3, 0.5 Hz, 1H), 8.06 (dd, J = 8.7, 2.4 Hz, 1H), 7.82−7.76 (m, 2H), 7.35−7.31 (m, 2H), 6.87 (ddd, J = 8.7, 0.6, 0.6 Hz, 1H), 4.58−4.54 (m, 2H), 4.18−4.13 (m, 2H), 3.86−3.81 (m, 2H), 3.71−3.60 (m, 6H), 2.43 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 189.7, 167.5, 152.8, 145.0, 137.9, 130.1, 128.4, 127.1, 112.6, 71.0, 70.9, 69.7, 69.4, 69.0, 66.3, 21.8. HRMS (ESI) m/z calcd for $C_{19}H_{24}NO_7S$ $[M+H]^+$ 410.1273, found 410.1277.

*6-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)nicotinaldehyde (**3**).* Tosylate **10** (40 mg, 0.10 mmol) was dissolved in tetrahydrofuran (1 mL) and added to a round-bottom flask containing tetra-*n*-butylammonium fluoride hydrate (61 mg, 0.23 mmol). The flask was fitted with a reflux condenser and heated to 76 °C under an inert atmosphere of argon. After 18 h, the reaction was removed from the oil bath and allowed to cool to room temperature (note: most of the solvent had evaporated over the course of the reaction; the reflux condensers had a leak). The reaction media were then condensed and purified by flash chromatography (50% ethyl acetate/hexanes) to afford 10 mg (40%) of fluoride **3**, a thin clear oil. R_f = 0.35 (60% ethyl acetate/hexanes). ^{1}H NMR (200 MHz, $CDCl_3$): δ 9.95 (s, 1H), 8.60 (d, J = 2.3 Hz, 1H), 8.06 (dd, J = 8.9, 2.3 Hz, 1H), 6.88 (dd, J = 8.7, 0.5 Hz, 1H), 4.69−4.65 (m, 1H), 4.61−4.57 (m, 2H), 4.45−4.41 (m, 1H), 3.90−3.80 (m, 3H), 3.72−3.65 (m, 5H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 189.7, 167.5, 152.9, 137.8, 127.1, 112.6, 85.1, 81.7, 71.1, 71.0, 70.9, 70.5, 69.8, 66.4. HRMS (ESI) m/z calcd for $C_{12}H_{17}FNO_4$ $[M+H]^+$ 258.1142, found 258.1142.

*(E)-17-(5-(4-(tert-Butoxycarbonyl(methyl)amino)styryl) pyridin-2-yloxy)-3,6,9,12,15-pentaoxaheptadecyl 4-Methyl-benzenesulfonate (**12**).* Sodium hydride (60%, 22 mg, 0.54 mmol) was added to a flame-dried round-bottom flask.

Anhydrous *N,N*-dimethyl formamide (0.5 mL) was added, and the suspension was cooled to 0 °C. A solution of alcohol **11** (69 mg, 0.13 mmol), dissolved in 0.5 mL of anhydrous *N,N*-dimethyl formamide, was added to the reaction mixture at 0 °C. Diethylene glycol bis(*p*-toluenesulfonate) was then added to the reaction mixture at 0 °C, which was allowed to warm up to room temperature over the course of the night. After 24 h, the reaction was quenched with $NaHCO_3$ (sat. aq.) (10 mL). The organic phase was separated from the aqueous phase with the use of ethyl acetate (4 × 10 mL). The combined organic layers were then washed with brine (1 × 20 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (2−4% methanol/dichloromethane) afforded 73 mg (73%) of a yellow oil, tosylate **12**. R_f = 0.19 (5% methanol/dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.16 (d, J = 2.2 Hz, 1H), 7.78 (d, J = 8.4, 2H), 7.77 (d, J = 8.8 Hz, 1H), 7.43 (d, J = 8.6 Hz, 2H), 7.34−7.30 (m, 2H), 7.21 (d, J = 8.6 Hz, 2H), 6.95 (s, 2H), 6.77 (d, J = 8.8 Hz, 1H), 4.50−4.45 (m, 2H), 4.17−4.12 (m, 2H), 3.87−3.82 (m, 2H), 3.72−3.53 (m, 18 H), 3.26 (s, 3H), 2.42 (s, 3H), 1.45 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 163.3, 154.8, 145.8, 144.9, 143.4, 135.5, 134.3, 129.9, 128.1, 127.5, 126.9, 126.6, 125.7, 124.7, 111.6, 80.6, 70.9, 70.8, 70.7, 70.7, 69.9, 69.4, 68.8, 65.5, 37.3, 28.5, 21.8. HRMS (ESI) m/z calcd for $C_{38}H_{53}N_2O_{11}S$ $[M+H]^+$ 745.3370, found 745.3384.

*(E)-tert-Butyl-4-(2-(6-(2-(2-(2-azidoethoxy)ethoxy)ethoxy) pyridin-3-yl)vinyl)phenyl(methyl)carbamate (**14**).* Tosylate **12** (380 mg, 0.62 mmol) and sodium azide (121 mg, 1.86 mmol) were added to a flame-dried round-bottom flask. Anhydrous *N,N*-dimethyl formamide (6 mL) was added to the reaction mixture and placed in an oil bath set to 60 °C. After 4 h, the reaction mixture was removed from the heat, allowed to cool to room temperature, and then partitioned between ethyl acetate and H_2O. The organic phase was separated from the aqueous phase with the use of ethyl acetate (3 × 20 mL). The combined organic layers were then washed with brine (2 × 20 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (35−50% ethyl acetate/hexanes) afforded 300 mg (quantitative) of a clear oil, azide **14**. R_f = 0.48 (50% ethyl acetate/hexanes). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.19 (d, J = 2.4 Hz, 1H), 7.79 (dd, J = 8.8, 2.6 Hz, 1H), 7.45 (d, J = 8.6 Hz, 2H), 7.23 (d, J = 8.6 Hz, 2H), 6.97 (s, 2H), 6.80 (d, J = 8.6 Hz, 1H), 4.53−4.48 (m, 2H), 3.90−3.85 (m, 2H), 3.77−3.66 (m, 6H), 3.39 (t, J = 5.2 Hz, 2H), 3.27 (s, 3H), 1.46 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 163.4, 154.9, 145.9, 143.5, 135.6, 134.4, 127.5, 127.0, 126.7, 125.8, 124.8, 111.7, 80.6, 71.0, 70.3, 65.5, 50.9, 37.3, 28.6. HRMS (ESI) m/z calcd for $C_{25}H_{34}N_5O_5$ $[M+H]^+$ 484.2650, found 484.2546.

*(E)-tert-Butyl-4-(2-(6-(2-(2-(2-aminoethoxy)ethoxy)ethoxy) pyridin-3-yl)vinyl)phenyl(methyl)carbamate (**16**).* Triphenyl phosphine (271 mg, 1.03 mmol) was added to a solution of azide **14** (200 mg, 0.41 mmol) in 12.5 mL of tetrahydrofuran. After 1 h, water (1.5 mL) was added to the reaction mixture. The reaction mixture was heated to 60 °C for 18 h. The reaction was then removed from the heat and allowed to cool to room temperature and concentrated. Purification by flash chromatography (96:4:1−85:15:1 dichloromethane/methanol/ammonium hydroxide) provided 133 mg (70%) amine **16**, a white waxy material. R_f = 0.19 (8.5:1.5:0.1 dichloromethane/methanol/ammonium hydroxide). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.14 (d, J = 2.3 Hz, 1H), 7.74 (dd, J = 8.6, 2.4 Hz, 1H), 7.40 (d, J = 8.6 Hz, 2H), 7.18 (d, J = 8.5 Hz, 2H), 6.92 (s, 2H), 6.76 (d, J = 8.7 Hz, 1H), 4.48−4.43 (m, 2H), 3.85−3.80 (m, 2H), 3.71−3.58 (m, 4H), 3.49 (t, J = 5.2 Hz, 2H), 3.22 (s, 3H), 2.84 (t, J = 5.2 Hz, 2H), 2.30 (br, s, 2H, NH_2), 1.42 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 163.2, 154.7, 145.7, 143.3, 135.5, 134.2, 127.4, 126.9, 126.5, 125.6, 124.6, 111.5, 80.5, 73.0, 70.7, 70.4, 69.8, 65.3, 41.7, 37.3, 28.4. HRMS (ESI) m/z calcd for $C_{25}H_{36}N_3O_5$ $[M+H]^+$ 458.2655, found 458.2642.

*Dicarbamate (**19**).* Amine **16** (132 mg, 0.29 mmol) and succinimide **18** (108 mg, 0.38 mmol) were dissolved in 6 mL of anhydrous *N,N*-dimethyl formamide, and to this solution was added *N,N*-diisopropylethylamine (1.0 mL, 744 mg, 5.76 mmol). The reaction was allowed to stir at room temperature. After 1 h, the reaction was concentrated (23 mbar at 60 °C, to facilitate the removal of *N,N*-dimethyl formamide) and purified by flash chromatography (2−6% methanol/dichloromethane) to provide 81 mg (45%) of dicarbamate **19**, a clear gummy material. R_f = 0.29 (5% methanol/dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.18 (d, J = 2.2 Hz, 1H), 7.98 (br s, 1H, NH), 7.80 (dd, J = 8.7, 2.3 Hz, 2H), 7.44 (d, J = 8.6 Hz, 2H), 7.22 (d, J = 8.6 Hz, 2H), 6.96 (s, 2H), 6.80 (d, J = 8.7 Hz, 1H), 4.52−4.47 (m, 2H), 4.34 (s, 2H), 3.90−3.85 (m, 2H), 3.76−3.47 (m, 8H), 3.27 (s, 3H), 1.46 (s, 9H), 1.46 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 169.1, 163.2, 157.6, 154.8, 145.7, 143.3, 135.6, 134.3, 127.5, 126.9, 126.6, 125.6, 124.6, 111.6, 82.6, 80.6, 76.0, 70.7, 70.5, 69.8, 69.7, 65.4, 39.0, 37.3, 28.5, 28.3. HRMS (ESI) m/z calcd for $C_{32}H_{47}N_4O_9$ $[M+H]^+$ 631.3343, found 631.3345.

*(E)-2-(Aminooxy)-N-(2-(2-(2-(5-(4-(methylamino)styryl) pyridin-2-yloxy)ethoxy)ethoxy)ethyl)acetamide (**21**).* Trifluoroacetic acid (3 mL) was added to a solution of carbamate **19** (394 mg, 0.63 mmol) in dichloromethane (3 mL). The reaction was allowed to stir at room temperature for 3 h after which time the reaction mixture was concentrated down from 1 N HCl (2 × 3 mL) and placed under high vacuum for 30 min. Purification by flash chromatography (97:3:1−90:10:1 dichloromethane/methanol/ammonium hydroxide) provided 158 mg (59%) of aminooxy **21** a yellow, waxy solid. Due to its instability, full characterization was achieved from the subsequent step of the formation of oxime **23**; aminooxy **21** was determined by HRMS. R_f = 0.49 (9.0:1.0:0.1 dichloromethane/methanol/ammonium hydroxide). HRMS (ESI) m/z calcd for $C_{22}H_{31}N_4O_5$ $[M+H]^+$ 431.2294, found 431.2300.

*2-((E)-(6-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)pyridin-3-yl) methyleneaminooxy)-N-(2-(2-(2-(5-((E)-4-(methylamino)styryl) pyridin-2-yloxy)ethoxy)ethoxy)ethyl)acetamide (**23**).* A solution of aldehyde **3** (7 mg, 0.03 mmol) dissolved in 1.4 mL of ethanol, 0.1 mL of H_2O, and 20 μL of trifluoroacetic acid was added to hydroxylamine **21** (12 mg, 0.03 mmol). The reaction mixture was placed in an oil bath set to 70 °C. After 2 h, the reaction mixture was removed from the heat and allowed to cool to room temperature. The reaction was then quenched with Na_2CO_3 (aq) and partitioned between 10% methanol/dichloromethane. The organic layer was separated from the aqueous layer with the use of 10% methanol/dichloromethane (4 × 10 mL). The combined organic layers were washed with brine (15 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (97:3:0.5−93:7:0.5 dichloromethane/methanol/ammonium hydroxide) provided 9 mg (50%) of oxime **23**, a viscous yellow oil. R_f = 0.33 (9.5:0.5:0.1 dichloromethane/methanol/ammonium hydroxide). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.28 (s, 1H), 8.28−8.14 (m, 2H), 7.95 (ddd, J = 8.9, 8.7, 2.2 Hz, 2H), 7.37 (d, J = 8.7 Hz, 2H), 6.96−6.78 (m, 4H), 6.64 (d, J = 8.6 Hz,

2H), 4.67−4.62 (m, 3H), 4.49−4.39 (m, 6H), 3.87−3.79 (m, 5H), 3.69−3.58 (m, 12H), 3.50−3.46 (m, 2H), 2.83 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 172.5, 166.6, 164.0, 151.5, 149.6, 148.5, 146.3, 146.0, 137.7, 137.0, 130.3, 129.8, 128.8, 127.5, 123.2, 120.6, 113.6, 112.8, 112.2, 85.9, 82.6, 74.1, 72.0, 71.9, 71.5, 70.9, 70.7, 67.0, 66.7, 40.3, 30.8. HRMS (ESI) m/z calcd for $C_{34}H_{45}FN_5O_8$ $[M+H]^+$ 670.3252, found 670.3236. HPLC conditions: Gemini 5 μ C18 110A column, 250 × 4.60 mm, 5 μm; r_t = 6.83 min (280 nm) in acetonitrile/10 mM ammonium formate buffer 60/40 at a flow rate of 1.0 mL/min.

*(E)-17-(5-(4-(tert-Butoxycarbonyl(methyl)amino)styryl)pyridin-2-yloxy)-3,6,9,12,15-pentaoxaheptadecyl 4-Methylbenzenesulfonate (**13**).* Sodium hydride (60%, 22 mg, 0.54 mmol) was dissolved in 0.5 mL of *N,N*-dimethyl formamide in a flame-dried round-bottom flask. This solution was cooled to 0 °C. Alcohol **11** (69 mg, 0.13 mmol), dissolved in 0.5 mL of *N,N*-dimethyl formamide, was added to the reaction mixture at 0 °C. After 3 min of stirring at 0 °C, diethylene glycol bis(*p*-toluenesulfonate) (337 mg, 0.80 mmol) was added to the reaction. The ice/water bath was removed, and the reaction was allowed to warm to room temperature. After 24 h, the reaction media were buffered with $NaHCO_3$ (aq, sat) and partitioned between ethyl acetate. The organic layer was extracted from the aqueous layer with the use of ethyl acetate (4 × 20 mL). The combined organic layers were washed with brine (30 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (2−3% methanol/dichloromethane) provided 73 mg (73%) of tosylate **13**, a yellow oil. R_f = 0.19 (5% methanol/dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.16 (d, J = 2.2 Hz, 1H), 7.78 (d, J = 8.4 Hz, 2H), 7.77 (d, J = 8.8 Hz, 1H), 7.43 (d, J = 8.6 Hz, 2H), 7.34−7.30 (m, 2H), 7.21 (d, J = 8.6 Hz, 2H), 6.95 (s, 2H), 6.77 (d, J = 8.8 Hz, 1H), 4.50−4.45 (m, 2H), 4.17−4.12 (m, 2H), 3.87−3.82 (m, 2H), 3.72−3.53 (m, 18H), 3.26 (s, 3H), 2.42 (s, 3H), 1.45 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 163.3, 154.8, 145.8, 144.9, 143.4, 135.5, 134.3, 129.9, 128.1, 127.5, 126.9, 125.7, 126.9, 126.6, 125.7, 124.7, 111.6, 80.6, 70.9, 70.8, 70.7, 70.7, 69.9, 69.4, 68.8, 65.5, 37.3, 28.5, 21.8. HRMS (ESI) m/z calcd for $C_{38}H_{53}N_2O_{11}S$ $[M+H]^+$ 745.3370, found 745.3384.

*(E)-tert-Butyl 4-(2-(6-(17-azido-3,6,9,12,15-pentaoxaheptadecyloxy)pyridin-3-yl)vinyl)phenyl(methyl)carbamate (**15**).* Tosylate **13** (300 mg, 0.40 mmol) was added to a flame-dried flask containing a solution of sodium azide (79 mg, 1.21 mmol) in 4 mL of anhydrous *N,N*-dimethyl formamide. The reaction mixture was heated to 60 °C. After 3 h, the reaction mixture was removed from the heat and allowed to cool to room temperature. It was then partitioned between ethyl acetate and H_2O. The organic phase was separated from the aqueous phase with the use of ethyl acetate (3 × 40 mL). The combined organic layers were washed with brine (2 × 20 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (80−85% ethyl acetate/hexanes) gave 150 mg (60%) of a viscous yellow oil, azide **15**. R_f = 0.24 (85% ethyl acetate/hexanes). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.18 (d, J = 2.2 Hz, 1H), 7.79 (dd, J = 9.0, 2.6 Hz, 1H), 7.45 (d, J = 8.9 Hz, 2H), 7.23 (d, J = 8.6 Hz, 2H), 6.97 (s, 1H), 6.79 (d, J = 8.6 Hz, 1H), 4.52−4.47 (m, 2H), 3.89−3.84 (m, 2H), 3.71−3.65 (m, 18H), 3.41−3.36 (m, 2H), 3.27 (s, 3H), 1.46 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 163.3, 154.8, 145.8, 143.3, 135.3, 134.3, 127.5, 126.9, 126.6, 125.7, 124.8, 111.6, 80.6, 70.8, 70.8, 70.2, 69.9, 65.5, 50.8, 37.3, 28.5. HRMS (ESI) m/z calcd for $C_{31}H_{45}N_5O_8Na$ $[M+Na]^+$ 638.3166, found 638.3157.

*(E)-tert-Butyl 4-(2-(6-(17-amino-3,6,9,12,15-pentaoxaheptadecyloxy)pyridin-3-yl)vinyl)phenyl(methyl)carbamate (**17**).* Triphenyl phosphine (51 mg, 0.20 mmol) was added to a solution of azide **15** (48 mg, 0.08 mmol) in 2.7 mL of tetrahydrofuran. After 1 h, water (0.3 mL) was added to the reaction and heated to 60 °C for 17 h. The reaction was then removed from the heat and allowed to cool to room temperature and concentrated. Purification by flash chromatography (95:5:1−85:15:1 dichloromethane/methanol/ammonium hydroxide) provided 37 mg (80%) of amine **17**, a white wax. R_f = 0.28 (8.5:1.5:0.1 dichloromethane/methanol/ammonium hydroxide). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.23 (d, J = 2.3 Hz, 1H), 7.99 (dd, J = 8.8, 2.5 Hz, 1H), 7.55 (d, J = 8.6 Hz, 2H), 7.25 (d, J = 8.6 Hz, 2H), 7.12 (s, 2H), 6.85 (d, J = 8.7 Hz, 1H), 4.46−4.44 (m, 2H), 3.89−3.84 (m, 2H), 3.71−3.53 (m, 20H), 3.26 (s, 3H), 2.86 (t, J = 5.4 Hz, 2H), 1.47 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 164.6, 156.6, 146.9, 144.4, 137.2, 136.5, 128.8, 128.8, 127.9, 127.2, 125.8, 112.3, 82.0, 72.3, 71.7, 71.6, 71.4, 71.3, 70.8, 66.8, 41.9, 38.0, 28.7. HRMS (ESI) m/z calcd for $C_{31}H_{48}N_3O_8$ $[M+H]^+$ 590.3441, found 590.3442.

*Dicarbamate (**20**).* Amine **17** (37 mg, 0.06 mmol) dissolved in 2 mL of anhydrous *N,N*-dimethyl formamide was added to succinimide **18** (24 mg, 0.08 mmol) in a flame-dried 10 mL round-bottom flask. *N,N*-Diethyl *iso*-propyl amine (0.22 mL, 163 mg, 1.26 mmol) was then added to the reaction mixture and allowed to stir at room temperature. After 1 h, the reaction was concentrated (23 mbar at 60 °C, to facilitate the removal of *N,N*-dimethyl formamide) and purified by flash chromatography (2−4% methanol/dichloromethane) to provide 29 mg (60%) of dicarbamate (**20**), a clear, gummy compound. R_f = 0.31 (5% methanol/dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.18−8.17 (m, 2H), 7.87 (br, s, 1H, NH), 7.79 (dd, J = 8.6, 2.5 Hz, 1H), 7.44 (d, J = 8.6 Hz, 2H), 7.22 (d, J = 8.5 Hz, 2H), 6.96 (s, 2H), 6.78 (d, J = 8.6 Hz, 1H), 4.50−4.45 (m, 2H), 4.33 (s, 2H), 3.87−3.82 (m, 2H), 3.78−3.45 (m, 20H), 3.26 (s, 3H), 1.46 (s, 9H), 1.45 (s, 9H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 169.3, 163.3, 157.7, 155.0, 145.8, 143.5, 135.6, 134.4, 127.5, 127.0, 126.7, 125.8, 124.7, 111.6, 82.7, 80.7, 76.1, 70.8, 70.7, 70.5, 69.9, 69.8, 65.6, 53.3, 39.2, 37.5, 28.5, 28.4. HRMS (ESI) m/z calcd for $C_{38}H_{59}N_4O_{12}$ $[M+H]^+$ 763.4129, found 763.4130.

*(E)-2-(Aminooxy)-N-(17-(5-(4-(methylamino)styryl)pyridine-2-yloxy)-3,6,9,12,15-pentaoxaheptadecyl)acetamide (**22**).* Carbamate **20** (29 mg, 0.04 mmol) was dissolved in 1 mL dichloromethane and to it was added 1 mL of trifluoroacetic acid. The reaction was allowed to stir at room temperature for 5 h after which time the reaction mixture was concentrated down from 1 N HCl (2 × 3 mL) and placed under high vacuum to obtain 137 mg of a pale, yellow viscous oil of the aminooxy·*x*HCl salt **22**. Due to its instability, full characterization was achieved from the subsequent step of formation of oxime **24**.

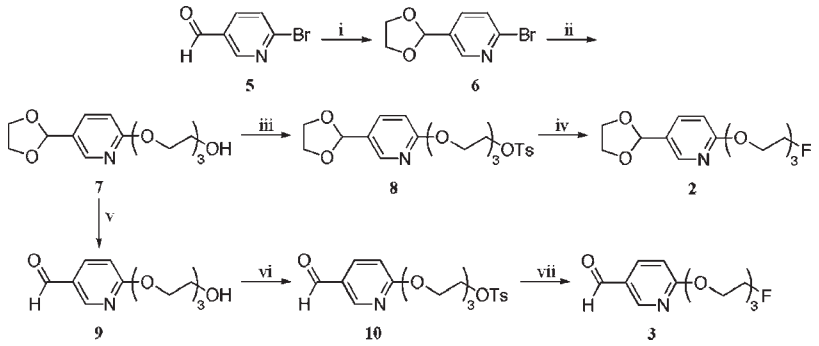
*2-((E)-(6-(2-(2-(2-fluoroethoxy)ethoxy)ethoxy)pyridin-3-yl) methyleneaminooxy)-N-(17-(5-((E)-4-(methylamino)styryl) pyridin-2-yloxy)-3,6,9,12,15-pentaoxaheptadecyl)acetamide (**24**).* Trifluoroacetic acid (10 μL) was added to a solution of acetal **2** (10 mg, 0.03 mmol) dissolved in 1.0 mL ethanol and 0.5 mL H_2O to lower the pH to ~0. This was then placed in an oil bath and heated to 60 °C. After 5 min, a solution of diamine **22** (21 mg, 0.04 mmol) in 0.7 mL ethanol and 0.1 mL H_2O was added to the reaction mixture at 60 °C. After 10 min, the reaction mixture was removed from the heat, allowed to cool to room temperature, and concentrated down from 1 N HCl (2 × 1 mL). The crude reaction mixture was then partitioned

between 50% $NaHCO_3$ (aq, sat)/ice and 5% methanol/ethyl acetate. The organic layer was separated form the aqueous layer with the use of 5% methanol/ethyl acetate (3 × 5 mL). The combined organic layers were washed with brine (10 mL), dried over $MgSO_4$, filtered, and concentrated. Purification by flash chromatography (5−10% methanol/dichloromethane) provided 18 mg (67%) of oxime **24**, a pale yellow material. R_f = 0.28 (5% methanol/dichloromethane). ^{1}H NMR (200 MHz, $CDCl_3$): δ 8.26−8.24 (m, 2H), 8.11 (d, J = 2.5 Hz, 1H), 7.93 (ddd, J = 16.6, 8.9, 2.3 Hz, 2H), 7.33 (d, J = 8.5 Hz, 2H), 7.02−6.75 (m, 4H), 6.60 (d, J = 8.6 Hz, 2H), 4.64−4.57 (m, 3H), 4.47−4.36 (m, 6H), 3.85−3.78 (m, 6H), 3.67−3.40 (m, 24H), 2.79 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$): δ 172.5, 166.5, 164.1, 151.5, 149.6, 148.5, 145.9, 137.8, 136.8, 130.3, 129.7, 128.8, 127.5, 123.3, 120.6, 113.6, 112.9, 112.3, 85.9, 82.6, 74.1, 71.9, 71.8, 71.7, 71.7, 71.6, 71.5, 70.9, 70.7, 70.6, 67.0, 66.7, 40.2, 30.7. HRMS (ESI) m/z calcd for $C_{40}H_{57}N_5O_{11}$ $[M+H]^+$ 802.4039, found 802.4016. HPLC conditions: Gemini 5 μ C18 110A column, 250 × 4.60 mm, 5 μm; r_t = 6.40 min (280 nm) in acetonitrile/10 mM ammonium formate buffer 60/40 with a flow rate of 1.0 mL/min.

Radiochemistry. A typical procedure for the formation of radioactive intermediate [^{18}F]**2** is as follows: A Sep-Pak light Accell Plus QMA (Waters Corporation) cartridge was activated with 1 N $NaHCO_3$ (10 mL), H_2O (10 mL), and dried with argon. [^{18}O]-Enriched aqueous solution of fluoride-18 (∼2 mCi) was taken up in 1 mL of H_2O (diluted) and passed through the activated QMA (light) cartridge. A solution of 1 mL (0.93 mL acetonitrile, 0.07 mL H_2O) containing Kryptofix[K222] (11 mg 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane) and 2 mg K_2CO_3, was then passed through the QMA cartridge into a reaction vessel to collect the K[222]^{18}F complex. This complex was dried at 110 °C with a flow of argon until most of the solvent was evaporated. The solution was further azeotroped with the use of acetonitrile (2 × 1 mL) at 110 °C with a stream of argon gas. A solution of tosylate **8** (1 mg) in 1 mL of anhydrous acetonitrile was added to the "dry" K[222]^{18}F complex at 110 °C. After 10 min, the reaction vessel was removed from the oil bath, cooled in an ice/water bath, and quenched with 8 mL of H_2O. The reaction medium was then passed through an OASIS HLB 3 cm^3 cartridge (activated by flushing with 3 mL ethanol followed by 10 mL H_2O). The OASIS cartridge was subsequently washed with H_2O (2 × 3 mL), and the desired radioactive ligand was eluted with ethanol (0.75 mL). The activity was measured from each washing to obtain the decay corrected radio chemical yield (rcy). The eluted ligand was used without any further purification. Radiochemical purity (rcp) of the prosthetic ligand [^{18}F]**2** was determined by HPLC. HPLC conditions: Gemini 5 μ C18 110A column, 250 × 4.60 mm, 5 μm; acetonitrile/10 mM ammonium formate buffer solution 60/40 with a flow rate of 1.0 mL/min; r_t = 4.79 min.

A typical procedure of the formation of oxime [^{18}F]**23** and [^{18}F]**24** is as follows: Water (0.2 mL) followed by trifluoroacetic acid (∼15 μL) was added to compound [^{18}F]**2**. The reaction vessel was then placed in an oil bath set to 70 °C. After 2 min at 70 °C, a solution of aminooxy **21** or **22** (∼4 mg, >1.1 equiv of tosylate **8**) in 0.3 mL of ethanol and 0.1 mL of H_2O was added to the reaction mixture. After an additional 25 min, the reaction vessel was removed from the oil bath, cooled in an ice/water bath, and quenched with 0.2 mL of 1 N $NaHCO_3$. This crude solution was then purified by HPLC (Gemini 5 μ C18 110A column, 250 × 10.00 mm, 5 μm; acetonitrile/10 mM ammonium formate buffer solution 60/40 as mobile phase with a flow rate of 2.0 mL/min; fractions were collected from 14.56 to 16.17 min). The fractions were then pooled together and diluted with 3 mL H_2O. The reaction media were then passed through an OASIS HLB 3 cm^3 cartridge (activated by flushing with 3 mL ethanol followed by 10 mL H_2O). The OASIS cartridge was washed with an organic solvent (ethanol or acetonitrile) (0.75 mL) to elute the desired radioactive oxime. The radiochemical purity and the specific activity for compounds [^{18}F]**23** and [^{18}F]**24** were determined by HPLC (Gemini 5 μ C18 110A column, 250 × 4.60 mm, 5 μm; acetonitrile/10 mM ammonium formate buffer 60/40 with a flow rate of 1.0 mL/min; retention time for [^{18}F]**23** r_t = 6.83 min; retention time for [^{18}F]**24** r_t = 7.37 min).

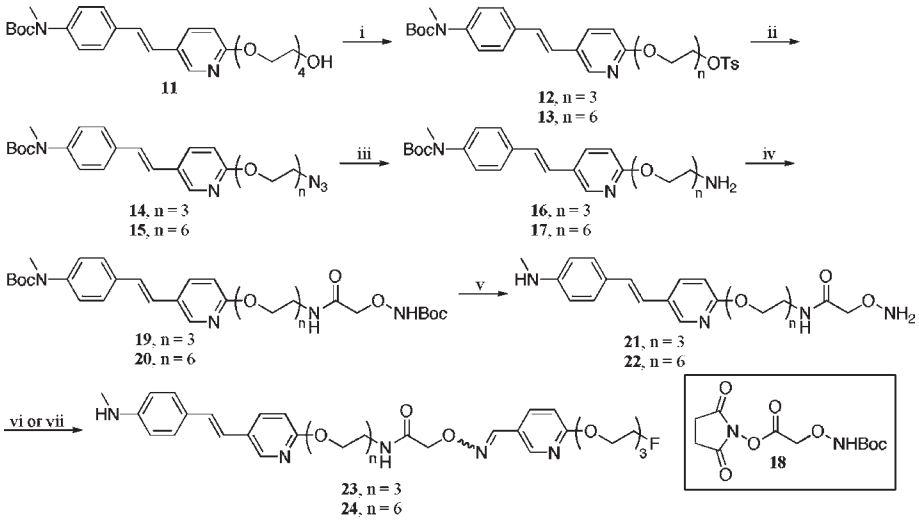
Biodistribution. *In Vivo Biodistribution Study in Mice.* Biodistribution studies were performed on ligands [^{18}F]**23** and [^{18}F]**24**, to evaluate their biological properties. Each of these radiotracers were tested in normal male ICR mice weighing 20−25 g. Each of the biodistribution studies used 6 mice per group with two time points taken at 2 and 30 min postinjection. The mice were put under isoflurane anesthesia (1−2%, 1 L oxygen/minute). A saline solution (0.15 mL) containing 25 μCi of each isomer, [^{18}F]**23** or [^{18}F]**24**, was injected via the lateral tail vein. The mice were sacrificed at 2 and 30 min postinjection by cardiac excision while under isoflurane anesthesia. The organs of interest were removed, weighed, and the radioactivity counted with a gamma counter (Packard Cobra). The percent dose per gram was calculated by a comparison of the tissue activity counts to counts of 1.0% of the initial dose. The initial dose consisted of 100× diluted aliquots of the injected material measured at the same rate.



RESULTS AND DISCUSSION

Chemical Synthesis. The formation of the "cold" prosthetic ligand **2** is depicted in Scheme 1. The synthesis began with the formation of acetal **6**[43] through an acid-catalyzed protection of 6-bromo-3-pyridine carbaldehyde **5**. The triethylene glycol chain was tethered onto the molecule under basic conditions (cesium carbonate) with the aid of a microwave reactor. Alcohol **7** was converted into tosylate **8**, which was subsequently refluxed in the presence of tetra-*n*-butylammonium fluoride hydrate to provide the desired acetal, compound **2**.

The formation of compound **3** is depicted in Scheme 1. The acetal functional group of intermediate **7** was removed under acidic conditions to provide aldehyde **9**. It should be noted that direct addition of triethylene glycol to 6-bromo-3-pyridine carbaldehyde **5**, the same conditions used to form intermediate **7**, proved to be incompatible, providing only 2% of the desired aldehyde **9**. Therefore, two steps were necessary to synthesize aldehyde **9**: nucleophilic substitution of triethylene glycol followed by the removal of the acetal protecting group. The alcohol functional group of compound **9** was converted into the tosylate to provide intermediate **10**. Compound **10** was transformed into aldehyde **3** with the use of tetra-*n*-butylammonium fluoride hydrate in refluxing tetrahydrofuran.



The syntheses of "cold" oximes **23** and **24** are illustrated in Scheme 2. Compound **13** was prepared from alcohol **11** (n = 4) with the use of sodium hydride and diethylene glycol bis(*p*-toluenesulfonate). Each of the tosylate groups in species **12** and **13**[44] were displaced with sodium azide at elevated temperatures. The azide functionality was then reduced to an amine, which led to the formation of compounds **14** and **15**, by way of a Staudinger

Scheme 1. Synthetic Pathway for the Preparation of Fluorides 2 and 3[a]

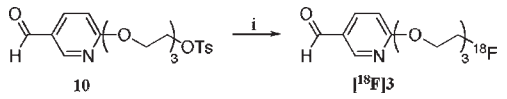
[a] Reagents and conditions: (i) ethylene glycol, *p*-TsOH, benzene, reflux (98%); (ii) triethylene glycol, Cs_2CO_3, DMF, microwave, 150 °C, 50 min (61%); (iii) *p*-TsCl, Et_3N, DMAP, CH_2Cl_2 (82%); (iv) TBAF·H_2O, THF, reflux (57%); (v) PPTS, acetone, H_2O, 70 °C (89%); (vi) *p*-TsCl, pyridine, CH_2Cl_2, 0 °C to rt (84%); (vii) TBAF·H_2O, THF, reflux (40%).

Scheme 2. Synthetic Pathway for the Formation of Oximes 23 (n = 3) and 24 (n = 6)[a]

[a] Reagents and conditions: (i) diethylene glycol bis(*p*-toluenesulfonate), NaH, DMF, 0 °C to rt (73%); (ii) NaN_3, DMF, 60 °C, 3 h (n = 3: 100%; n = 6: 60%); (iii) PPh_3, THF/H_2O (9:1), 60 °C (n = 3: 70%; n = 6: 80%); (iv) **18**, *i*-Pr_2NEt, DMF (n = 3: 45%; n = 6: 60%); (v) TFA/CH_2Cl_2, (1:1) (n = 3: 73%; n = 6: 100%); (vi) **3**, TFA, EtOH/H_2O, 70 °C (n = 3: 50%); (vii) **2**, TFA, EtOH/H_2O, 70 °C (n = 6: 67%).

reaction.[45,46] It was crucial that the correct reaction conditions be used to reduce only the azide functionality without saturating the carbon−carbon double bond. Succinimide **18**[47] was attached with **14** and **15** with excess Hünig's base to provide the dicarbamates **19** and **20**, respectively. Removal of both *t*-butoxycarbonyl (Boc) protecting groups was achieved using a 1:1 mixture of dichloromethane/trifluoroacetic acid. Subsequent addition of the free aminooxy compound into aldehyde **3** lead to the formation of the desired oxime **23** (n = 3). Likewise, aminooxy **22** was added to acetal **2** under acidic conditions to provide the desired oxime **24** (n = 6). The acetal group was removed in situ to form the aldehyde, which under an acidic environment has a high affinity to react with aminooxy groups.[38,39] The one pot deprotection/addition sequence to form the desired oxime proved to be essential for the radiosynthesis of compounds [^{18}**F**]**23** and [^{18}**F**]**24**. Although two isomers (*cis* and *trans*) are potentially formed, it appears that only one isomer was observed in the formation of both oximes **23** and **24** (confirmed by HPLC). It is hypothesized that this isomer is the more stable *trans*-complex. Work is currently underway to elucidate their structures by attempts to obtain crystal structures with the use of forming the salts with several different counterions. Oximes **23** and **24** are the "cold" standards for our labeling studies.

Radiolabeling. Our initial goal was to synthesize and evaluate a new prosthetic ligand with a future goal of radiolabel biologically active peptides and proteins by way of an oxime coupling reaction. Preliminary studies were done on two model aminooxy species, compounds **23** and **24**. We first fully characterized the "cold" oximes, and then radiolabeled each aminooxy compound with our prosthetic ligand. These small molecules were used as models, instead of the protein or peptide oxime adducts, due to their compatibility with more practical and manageable reagents and characterization methods (i.e., cost effectiveness and characterization without the use of MALDI). The radiolabeling of complexes **21** and **22** was used to demonstrate the capability of this methodology while attempting to optimize the reaction conditions to form the oxime bond.



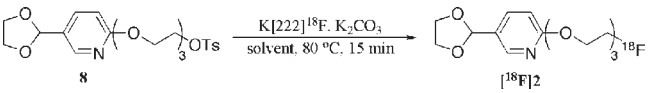
The first attempt at the formation of a prosthetic ligand was through the direct fluoride-18 (nca) labeling of aldehyde **10**

dx.doi.org/10.1021/bc1004262 |*Bioconjugate Chem.* 2011, 22, 642–653

(Scheme 3). The formation of an oxime with the use of an aminooxy group and an aldehyde under acidic conditions can be achieved. The fluoride-18 labeling of aldehyde **10** afforded compound [^{18}F]**3**. The formation of compound [^{18}F]**3** provided a reasonable radiochemical yield, however, with low radiochemical purity (42%). Several unidentified peaks were observed in the HPLC radioactive trace.

To circumvent the low radiochemical purity, the aldehyde group was protected prior to the fluoride-18 radiolabeling. Therefore, acetal **8** was used in place of aldehyde **10**. The formation of compound [^{18}F]**2** was achieved through a direct S_N2 displacement of a tosylate group (see Figure 3 for HPLC traces for cold and hot complexes). The acetal functionality protected the compound from the harsh environment present for the nucleophilic attack of a fluoride anion. The acetal, [^{18}F]**2**, is a stable, neutral molecule soluble in organic media. After successful fluoride-18 labeling, the acetal group was deprotected under an aqueous acidic media and converted to the aldehyde; aldehydes will chemoselectively react with aminooxy functional groups under these same conditions to provide an irreversible oxime bond.[38,39] This allows for both the deblocking of the acetal functionality and the formation of the oxime bond, to bestow the radiolabeled tracer.

Scheme 3. Direct Fluoride-18 (nca) Labeling of Aldehyde 10[a]



10 [^{18}F]**3**

[a] Reagents and conditions: (i) K[222]^{18}F, K_2CO_3, DMSO, 100 °C, 10 min (45% rcy; 42% rcp).

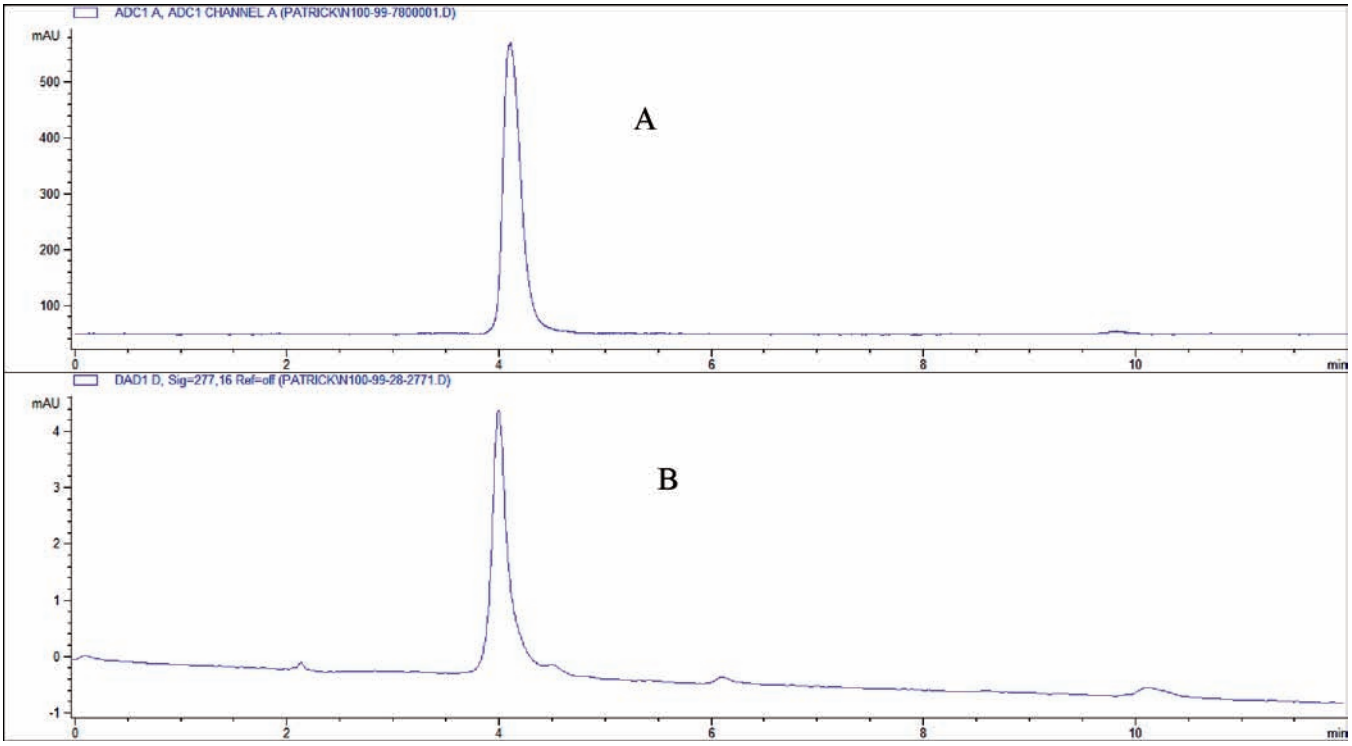
Several variables were studied (i.e., solvent, temperature, and time) to determine the most efficient and suitable conditions for radiosynthesis of acetal [^{18}F]**2**. A solvent screening was performed at a constant temperature (80 °C) and time (15 min) with the use of 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo-[8.8.8]-hexacosane (K[222]) and potassium carbonate as the catalysts for the preparation of "naked" fluoride (see Table 1). The radiochemical yields (rcy) were determined from the isolation of the product after solid-phase extraction (OASIS HLB 3 cm^3 cartridge), and the radiochemical purities (rcp) were determined by HPLC (for conditions, see Experimental Procedures section). These results suggested that dimethyl sulfoxide and acetonitrile are the solvents of choice. Due to the higher observed radiochemical purity (rcp) achieved with acetonitrile as the solvent (91 ± 4%, n = 3; see Table 1), all further experiments were performed with the use of acetonitrile.

A time study was performed for the radiolabeling of acetal [^{18}F]**2** in the presence of "dry" K[222]^{18}F catalyst (Table 2).

Table 1. Use of Varying Solvent for the Radiolabeling of Tosylate 8 (n = 3)

8 [^{18}F]**2**

entry	solvent	% rcy (isolated)	% rcp (HPLC)
1	DMSO	32 (±2)	84 (±15)
2	DMF	14 (±6)	78 (±11)
3	*t*-BuOH	7 (±2)	53 (±12)
4	ACN	35 (±2)	91 (±4)



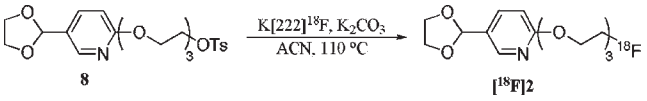


Figure 3. (A) HPLC profile of radiotrace [^{18}F]**2**. (B) HPLC profile of UV-spectra for compound **2** at 277 nm. Both samples were run on Gemini 5 μ C18 110A 250 × 4.60 mm column; ACN/10 mM AFB 60/40 with a flow rate of 1.0 mL/min; r_t = 4.10 min.

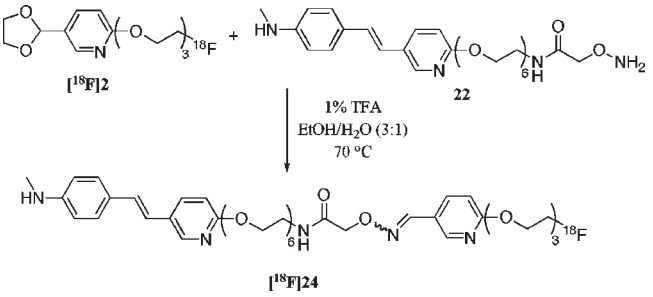
dx.doi.org/10.1021/bc1004262 |*Bioconjugate Chem.* 2011, 22, 642–653

Table 2. Time Study Results on the Radiochemical Synthesis of Compound [^{18}F]2

8 [^{18}F]2

entry	time (min)	% rcy (isolated)	% rcp (HPLC)
1	5	51	93
2[a]	10	71 (±2)	99 (±1)
3	15	65	96
4[b]	15	49	94
5	20	61	>99

[a] n = 3. [b] Reaction was run in a sealed tube.



Reproducibility and greatest radiochemical yields were obtained when compound **8** was heated in an open test tube at 110 °C for 10 min (rcy = 71 ± 2%; rcp > 99 ± 1%, n = 3, Table 2, entry 2). The radiochemical yield was lower for shorter time spans (5 min). Noticeably lower radiochemical yields were routinely observed when the reaction was allowed to proceed for more than 15 min. This suggests decomposition of the desired product at elevated temperatures over extended time periods (i.e., greater than 15 min). When the reaction was run in a sealed tube for 15 min at 110 °C, lower radiochemical yields and lower radiochemical purities were observed (Table 2, entry 4). The lower radiochemical yields observed in the sealed tube experiments may be caused by concentration: when the reaction was performed in an open test tube, solvent was able to evaporate (acetonitrile's bp = 82 °C). It is unclear yet as to why the radiochemical purities would decrease in a sealed environment.

As mentioned earlier, aminooxy groups readily form oximes with aldehydes under acid conditions. An acetal can be converted to an aldehyde, in situ, under aqueous acidic conditions. If the in situ formed aldehyde was then subjected to the aminooxy under these same conditions, labeling via the oxime bond would be accomplished in one pot. To test our theory, aminooxy **22** was added to an HCl acidic aqueous/ethanol solution with acetal [^{18}F]**2** at 70 °C (Table 3). The pH of the solution was estimated at 0. At 5 min time intervals, an aliquot (5 μL) was removed from the reaction vessel, neutralized with 1 N $NaHCO_3$ (10 μL, pH ~9), and diluted with 100 μL of acetonitrile. The relative rates of the formation of product, which were equal to the disappearance of the starting material, were analyzed by HPLC. The reaction appeared to be complete after 35 min, with no starting material observed by HPLC analysis.

Species [^{18}F]**24** could be purified and isolated by semipreparative HPLC with a reversed phase column ($r_t \approx$ 15 min) in 41% decay corrected radiochemical yield end of synthesis (eos) with a radiochemical purity of >99%. The total preparation time for [^{18}F]**24** was 100 min (over two steps). The specific activity at eos was ~100 Ci/mmol. The radiolabeling of oxime [^{18}F]**23** provided similar results to a decay corrected radiochemical yield (eos) of 38% (over two steps) and a radiochemical purity of 94%. The specific activity was not determined for oxime [^{18}F]**23**.

In Vitro Binding Assays. Human brain sections containing Alzheimer disease (AD) plaque were obtained. The gray matter was separated from the white matter. The gray matter containing the AD plaques was dissected and processed. The brain tissue homogenates were prepared in phosphate buffered solution

7	35	98

(PBS), pH = 7.2. The specific binding of [^{18}F]-AV-45 **1** was carried out in 12 × 75 mm borosilicate glass tubes. The reaction mixture contained 50 μL of brain homogenates (20−50 μg), 50 μL of ligand diluted in PBS, and 50 μL of inhibitors (10^{-5}−10^{-10} M diluted serially in PBS containing 0.1% bovine serum albumin in a final volume of 1 mL. Nonspecific binding was determined in the presence of IMPY (600 nM) within the same assay tubes. In competition experiments, compounds at concentrations up to 10^{-5} M were examined for their abilities to compete for the binding of [^{18}F]-AV-45 **1**. Incubations were carried out routinely at 37 °C for 120 min, and the bound and free radioactivity were separated by vacuum filtration. The samples were then filtered through glass fiber filters soaked in PBS (GF/B Whatman) using a Brandel M-24R cell harvester followed by 2 × 3-mL washes of PBS at room temperature. The filters containing bound [^{18}F] ligand were immediately counted with a gamma counter (Cobra II, Perkin-Elmer) with 70% counting efficiency. The results of the inhibition experiments were subjected to nonlinear regression analysis using equilibrium binding data analysis by which K_i values were calculated as [^{18}F]-AV-45 **1** K_i = 3.80 ± 1.82 nM (n = 5), [^{18}F]**23** K_i = 11.78 ± 3.06 nM (n = 5), [^{18}F]**24** K_i = 25.2 ± 0.9 nM (n = 6).

Biodistribution. Biodistribution studies of [^{18}F]**23** and [^{18}F]**24** were conducted in male ICR mice. The % dose/gram was compared to that of [^{18}F]-AV-45 (**1**) (Table 4). [^{18}F]-AV-45 (**1**)[40,41] is used as a PET imaging agent targeting β-amyloid plaques within the brain. Both oximes contain the core backbone structure found in [^{18}F]-AV-45 (**1**). The use of the neutral (calculated log P = 1.00) and hydrophilic spacer (triethylene glycol) on the prosthetic group was thought to increase the overall hydrophilicity and therefore deter the compound from passing the blood-brain barrier (BBB). Compounds [^{18}F]**23** and [^{18}F]**24** may be useful to image β-amyloid plaques located on the cerebral blood vessels outside the brain.

Table 4 depicts a comparison of the biodistribution for [^{18}F]-AV-45 (**1**), [^{18}F]**23**, and [^{18}F]**24** in normal mice. We were particularly interested in comparing the brain uptakes of [^{18}F]-AV-45

(**1**) and the two new derivatives, [^{18}F]**23** and [^{18}F]**24**. The addition of the prosthetic group led to AV-45 derivatives with a much higher molecular weight, exceeding the limit for penetrating the intact BBB.[48,49] As expected, [^{18}F]-AV-45 (**1**) (molecular weight = 359.43 g/mol) has a high initial brain uptake after 2 min post injection (7.77% dose/gram). The tracer then proceeds to gradually wash out after 30 min post injection. Initial brain uptake of oxime [^{18}F]**23** (molecular weight = 668.74 g/mol) was rather respectable (1.69% dose/gram). On the other hand, [^{18}F]**24** (molecular weight = 799.91 g/mol) showed significantly lower uptake (0.48% dose/gram) at the 2 min post injection mark, indicating a far less efficient passage of the tracer through the intact BBB. To our surprise, an increase of uptake in the brain at 30 min post injection (0.92% dose/gram) was observed. We are suggesting that in vivo metabolites of [^{18}F]**24** may have contributed to the increase in brain uptake.

Compounds [^{18}F]**23** and [^{18}F]**24** display high initial uptake and slow retention, remaining rather consistent throughout the 30 min, in most of the organs tested. Heart uptake and retention drop fairly rapidly with time, showing low heart activity at 30 min post injection. There was no significant uptake within the lung, along with no significant retention within the first arteriovenous capillary bed. Rapid uptake is observed within the kidneys but is soon excreted to the urinary bladder. It should be noted that each labeled oxime showed the washing out of activity through the liver. During the time frame of the studies performed, there is very little defluorination occurring as depicted from the values in the bone (femur).

CONCLUSIONS

A new prosthetic radiolabeled ligand, [^{18}F]**2**, was successfully synthesized in a total of four steps, starting with readily available 6-bromo-3-pyridine carbaldehyde **5**. The fluoride-18 labeling of this compound was achieved in high radiochemical yields (71 ± 2%, n = 3) with excellent radiochemical purity (>99%, based on HPLC analyses) in short reaction time (10 min). The species could be easily purified through a solid phase extraction (OASIS HLB 3 cm^3 cartridge), eluted with a small volume of ethanol, and used directly in the next step of the synthetic sequence without any further purification. The coupling with species [^{18}F]**2** was demonstrated in two model complexes, oximes [^{18}F]**23** and [^{18}F]**24**.

Biodistribution studies were performed on each of the labeled oximes [^{18}F]**23** and [^{18}F]**24**, and compared to that of [^{18}F]-AV-45 (**1**). The major differences among [^{18}F]-AV-45 (**1**), [^{18}F]**23**, and [^{18}F]**24** are their size (molecular weight) and the hydrophilic spacer (triethylene glycol) from the prosthetic ligand. [^{18}F]-AV-45 (**1**) is a small and neutral molecule designed to serve as a brain-imaging agent to target Aβ-plaques inside the brain. Compounds [^{18}F]**23** and [^{18}F]**24** are larger in size (PEG, n = 3 and n = 6, respectively); therefore, they should reduce the BBB penetration. The use of the hydrophilic spacer (triethylene glycol) on the prosthetic group was thought to increase the overall hydrophilicity of the molecule. The brain uptake for oxime [^{18}F]**23** appeared to be reduced, but it retained some capability to cross the BBB. Oxime [^{18}F]**24** showed promising results after 2 min post injection (0.48% dose/gram); however, the uptake increased after 30 min post injection (0.92% dose/gram) suggesting an in vivo decomposition/metabolism of compound [^{18}F]**24**.

The prosthetic ligand, [^{18}F]**2**, has several advantages over other known prosthetic ligands in the literature: high radiochemical yield, ease of formation, the ability to label base sensitive compounds, and the chemoselective formation of the oxime bond. Future work will focus on using this prosthetic ligand to label larger molecules that are incompatible with direct labeling with fluoride-18 (nca) anion. We intend to use this methodology to label biologically active peptides and proteins modified with an aminooxy functional group.

Supporting Information

ABSTRACT: The cKit87up sequence d($^{5'}$AGGGAGGGCGCTGGGAGGAGGG$^{3'}$) can form a unique G-quadruplex structure in the promoter region of the human c-kit protooncogene. It provides a peculiar platform for the design of selective quadruplex-binding agents, which could potentially repress the protooncogene transcription. In this study, we examined the binding of a small library of PNA probes (**P1**−**P5**) targeting cKit87up quadruplex in either K^+- or NH_4^+-containing solutions by using a combination of UV, CD, PAGE, ITC, and ESI-MS methodologies. Our results showed that (1) **P1**−**P4** interact with the cKit87up quadruplex, and (2) the binding mode depends on the quadruplex stability. In K^+ buffer, **P1**−**P4** bind the ckit87up quadruplex structure as "quadruplex-binding agents". The same holds for P1 in NH_4^+ solution. On the contrary, in NH_4^+ solution, **P2**−**P4** overcome the quadruplex structure by forming PNA/DNA hybrid complexes, thus acting as "quadruplex openers".

INTRODUCTION

Guanosine-rich nucleic acid sequences have a propensity to form DNA secondary structures, known as G-quadruplexes. These structures are made up of stacked G-tetrad subunits, wherein four coplanar guanines are linked together by Hoogsteen hydrogen bonds.[1] Recent studies have been reported about the high density of putative G-quadruplex-forming sequences in telomeres and in genomic regions adjacent to transcriptional start sites,[2−4] thus supporting the biological importance of these structures *in vivo*.[5−7] Evidence exists that GC-rich regions of gene promoters can transiently unwind and form single-stranded tracts, eventually folding into G-quadruplexes.[8] Hurley and coworkers have provided the direct evidence for a G-quadruplex structure formation in a promoter region of c-MYC and its stabilization with several small molecules, resulting in the repression of c-MYC transcription.[9,10] Two quadruplex-forming sequences have been identified in the promoter region of the c-kit gene. One sequence (c-Kit21) is located within −140 to −160 base pairs (bp) upstream of the transcription initiation site, and the other one (c-Kit87up) between −87 and −109 bp.[11,12] The alteration of c-kit expression has been implicated in a variety of human tumors.[13−16]

These findings suggest that G-quadruplex formation may be related to a general mechanism for gene regulation, and that the modulation of gene expression could be achieved by targeting these structures.[17] Therefore, molecules that selectively bind and stabilize G-quadruplex structures are emerging as attractive gene-related therapeutic agents.[18] A number of ligands able to bind telomeric G-quadruplexes have been investigated for their ability to disable the telomere maintenance in tumor cells,[19] but to date only a few molecules have been investigated for targeting G-quadruplex in gene promoter regions.[20,21]

Very interestingly, NMR analysis of the G-quadruplex structure formed by the 22-mer c-Kit87up sequence has revealed a highly unusual G-quadruplex folding topology.[22] It comprises three G-tetrads with all the guanines in an *anti*-glycosidic conformation and four characteristic loops, one of which comprises five

residues (Figure 1). Moreover, a bioinformatic study has shown that the c-Kit87up sequence is unique within the human genome.[23]

Among molecules designed to target G-quadruplexes, peptide nucleic acids (PNAs) represent a promising class of synthetic DNA analogues in which the entire sugar−phosphate backbone is replaced by a pseudopeptide.[24] The lower electrostatic repulsion, resulting from the absence of phosphate groups, allows PNAs to form very stable duplexes and triplexes by displacing the cDNA strand in DNA duplexes.[25,26] Strategies usually used for targeting G-rich sequences with PNAs are the formation of PNA/DNA hybrid quadruplexes[27,28] or the induction of G-quadruplex formation by displacing the G-rich/C-rich double-stranded DNA by using short G-rich PNAs that bind to the C-rich strand of DNA.[29]

Herein, we report for the first time the c-Kit87up sequence targeting with PNA probes. Our strategy is based on the identification of PNAs that recognize and stabilize the quadruplex formed by the c-Kit87up sequence. The design and synthesis of short PNAs potentially able to bind to suitable complementary sequences of loops and/or stem regions of the G-quadruplex structure formed by the c-Kit87up sequence are reported. To investigate the physicochemical properties underlying the molecular recognition between the c-Kit87up quadruplex-forming sequence and PNA molecules, circular dichroism (CD) and UV spectroscopies,[30−32] polyacrylamide gel electrophoresis (PAGE), electrospray mass spectrometry (ESI-MS),[33] and calorimetric techniques (ITC)[34] were employed.

EXPERIMENTAL PROCEDURES

Preparation of c-Kit87up Quadruplex and Its Complexes with PNAs. DNA and PNA sequences (Table 1) have been assembled using standard procedures (see Supporting Information).[35−38] The c-Kit87up quadruplex structure (**Q**) was formed by dissolving ckit87up (40 μM) in potassium buffer (10 mM KH_2PO_4, 40 mM KCl, 0.2 mM EDTA, pH = 7.0) or in 150 mM NH_4OAc solution, pH = 7.0 (Sigma Aldrich), and annealed by heating to 90 °C for 5 min followed by slow cooling to room temperature. The quadruplex solutions were then equilibrated at 4 °C for 24 h before addition of the suitable PNA. Each DNA-PNA complex was prepared by mixing equimolar amounts of **Q** and PNA at 25 °C and incubating the resulting mixture for 24 h at the same temperature before data acquisition.

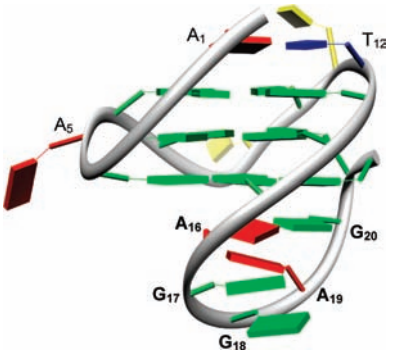

Figure 1. Schematic representation of ckit87up quadruplex structure annealed in K^+-containing solution. Guanine bases are in green, adenines are in red, cytosines are in yellow, and thymine is in blue. The residues belonging to loop-4 are in bold.

Circular Dichroism (CD). CD spectra of DNA, PNA, or mixed solutions (20 μM) were recorded by using a Jasco J-715 spectropolarimeter equipped with a Jasco JPT-423-S temperature controller in the 220−360 nm range, using 1 mm path-length cuvettes. Spectra were averaged over 5 scans, which were recorded at a scan rate of 100 nm/min with a response time of 1 s and a bandwidth of 1 nm. Buffer baseline was subtracted from each spectrum and the spectra were normalized to have zero ellipticity at 360 nm.

Thermal Difference Spectra (TDS) and UV-Melting Experiments. 20 μM solutions of DNA, PNA, and PNA/DNA mixture (0.5 mL) were placed in quartz cuvettes of 0.1 cm path length. Thermal difference spectra and UV-melting experiments were carried out using a Jasco V-530 UV−visible spectrophotometer equipped with a Jasco ETC-505-T temperature controller. TDS were obtained by recording the UV absorbance spectra in the range 220−320 nm at 5 and 90 °C and subsequently taking the difference between the two spectra.[32] UV-melting experiments were performed in the temperature range 5−90 °C by monitoring the absorbance at 295 nm,[31] at a 0.5 °C/min heating rate. The $T_{1/2}$ temperatures were calculated as previously reported by Mergny and Lacroix.[39]

Nondenaturing Polyacrylamide Gel Electrophoresis (PAGE). Nondenaturing gel electrophoreses were performed using 12% polyacrylamide gels, which were run in 1×TBE (Tris-Borate-EDTA) buffer supplemented with 50 mM KCl or 150 mM NH_4OAc, pH 7.0. Bands in the gels were visualized by SYBR Green staining (Sigma-Aldrich). A concentration of 10 μM was used for each sample.

ESI-Mass Spectrometry. ESI-MS studies were conducted using ammonium acetate at pH = 7.0.[33] The experiments were performed on a Q-TOF Ultima Global (Waters, Manchester, UK). The samples (DNA strand concentration = 10 μM) were infused at 4 μL/min in the electrospray source that operated in negative ion mode (capillary voltage = −2.2 kV). The source temperature was 80 °C and the nitrogen desolvation gas temperature was 100 °C. The pressure indicated on the source Pirani gauge was 3.0 mbar. For each sample, spectra were recorded using the following acceleration voltages: a cone voltage of 100 V, a RF Lens 1 voltage of 100 V, and a collision energy voltage (acceleration voltage before the collision hexapole) of 10 V. These voltage values represent a good compromise both to

dx.doi.org/10.1021/bc100444v |*Bioconjugate Chem.* 2011, 22, 654–663

preserve the ammonium cations inside the G-quadruplexes and to observe the PNA/DNA complexes.[40] Complexes of higher m/z are not transmitted efficiently at low voltages through the mass spectrometer and, therefore, are not efficiently detected. The spectra were smoothed (2× mean, 10 channels), background-subtracted (polynomial order = 50, 1% below curve), and converted to centroid. The compounds were manually searched with the assistance of the *MassLynx 4.0* software. The average mass was calculated with its standard deviation.

Isothermal Titration Calorimetry (ITC). ITC experiments were performed using a CSC 5300 Nano-ITC microcalorimeter from Calorimetry Science Corporation (Lindon, Utah) with a cell volume of 1 mL. The buffer conditions used for ITC measurements were the same reported for the other experiments. Before each ITC experiment, the reference cell was filled with deionized water, and the DNA solutions were degassed for 5 min to eliminate air bubbles. The experiments were carried out at 25 °C. Care was taken to start the titration after achieving baseline stability. In each titration, volumes of 5−10 μL of a PNA containing solution (80−300 μM) were injected into a solution of quadruplex DNA (10−20 μM) in the same buffer, using a computer-controlled 250 μL microsyringe. The interval between PNA injections was 400 or 500 s. The heat produced by PNAs dilution was evaluated in control experiments by injecting each PNA solution into the buffer alone. The interaction heat for each injection was calculated after correction for the heat of PNA dilution. Measurement from the first injection was discarded from the analysis of the integrated data, in order to avoid artifacts due to the diffusion through the injection port occurring during the equilibration of the baseline. The corrected heat values were plotted as a function of the molar ratio. The integrated heat data were fitted using a nonlinear least-squares minimization algorithm to a theoretical binding isotherm, by means of the Bindwork program supplied with the instrument, to give the binding enthalpy ($\Delta_bH°$), equilibrium binding constant (K_b), and binding stoichiometry (n). The Gibbs energy and the entropic contribution were derived using the relationships $\Delta_bG° = -RT \ln K_b$ ($R = 8.314$ J mol^{-1} K^{-1}, $T =$ 298 K) and $-T\Delta_bS° = \Delta_bG° - \Delta_bH°$.

Molecular Modeling. To obtain a molecular model of the complex between **P3** and ckit87up quadruplex, the NMR solution structure of the quadruplex was used (Protein Data Bank entry number 2O3M), while the molecular model of **P3** was built using the Builder module of *Insight II* package (www.accelrys.com). **P3** was manually placed at a position so that the "$c_2c_3t_4$" bases of PNA form Watson−Crick base pairing with complementary "$A_{16}G_{17}G_{18}$" bases of the loop-4 of **Q**. **P3** backbone was then adapted to the structure of **Q**. The coordinates of the resulting **Q**-**P3** complex were energy minimized under vacuum with the *HyperChem 7.5* software,[41] using the steepest descent method, keeping the DNA residues fixed in position and allowing only the PNA to relax, until convergence to a rms gradient of 0.1 kcal/mol Å was reached.

RESULTS

Evaluation of G-Quadruplex Formation and Stability. The formation of the G-quadruplex structure by the 22-mer ckit87up sequence in potassium or ammonium solution was investigated by using CD, TDS, UV-melting, and PAGE techniques. ESI-MS experiments were also performed according to previous studies.[33,40] The structure formed by ckit87up sequence in the two different cation solutions was evaluated in comparison with that of the unstructured d($^{5'}$CCCTCCTCCCAGCGCCCTCCCT$^{3'}$) 22-mer oligonucleotide by examining the mobility in nondenaturing polyacrylamide gels. Figure 2A shows that **Q** possesses the same mobility in K^+ and NH_4^+ solutions and run faster than the unstructured 22-mer oligonucleotide, thus suggesting that the ckit-87up sequence adopts analogous folding in both the analyzed conditions.

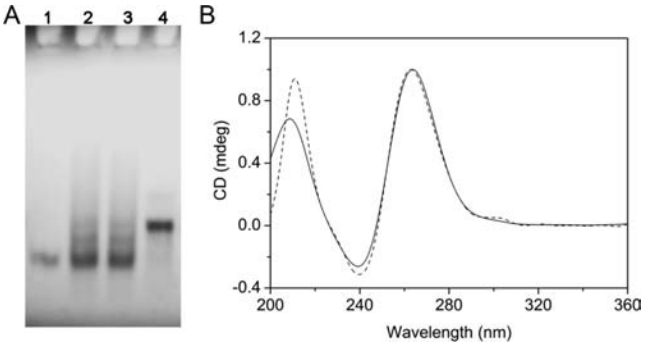

Figure 2. (A) PAGE of **Q** in K^+ and NH_4^+ containing solutions. Lane 1: [d(TGGGGT)]$_4$ in K^+ as quadruplex marker. Lane 2: **Q** annealed in K^+. Lane 3: **Q** annealed in NH_4^+. Lane 4: d($^{5'}$CCCTCCTCCCAGCGCCCTCCCT$^{3'}$) as unstructured 22-mer length marker. (B) Normalized CD spectra of ckit87up sequence annealed in K^+ (solid line) and NH_4^+ (dashed line) solutions.

To obtain a further structural insight into the above G-quadruplex structures,[42] CD spectra of **Q** were recorded either in potassium or in ammonium solution. Both spectra (Figure 2B) show two well-defined maxima around 210 and 263 nm and a minimum at 240 nm, suggesting that the oligonucleotide folds in a parallel-type quadruplex structure in both cases.[30] In addition, thermal difference spectra (TDS) were collected both in K^+ and NH_4^+ solutions. In agreement with CD experiments, the normalized differential absorbance signatures of **Q** show typical patterns of a G-quadruplex structure in both solution conditions (Figure 3, black traces), with two positive maxima at 243 and 273 nm and a negative minimum around 295 nm.[32] The temperature-dependent absorption of quadruplex-forming DNA was monitored at 295 nm (Supporting Information Figure S1). A hypochromic profile, characterized by a single transition, typical of the melting of a quadruplex structure,[31] is observed in both K^+ and NH_4^+ solutions. The thermal stability of **Q** was found to be higher in potassium ($T_{1/2}$ = 47.3 °C) than in ammonium solution ($T_{1/2}$ = 34.3 °C).

To gain information on the number of strands and cations involved in the quadruplex structure, electrospray mass spectrometry experiments were performed. The ckit87up ESI-MS spectrum (Supporting Information Figure S2) shows that the detected main species embeds two ammonium cations in the structure. In agreement with previous studies,[43] ammoniums are better preserved in ions of low charge states.

Evaluation of DNA-PNA Complex Formation. To probe the recognition phenomena between the ckit87up quadruplex-forming sequence and PNA molecules, the interaction of five different PNA sequences (Chart 1) was studied using CD, UV, ESI-MS, PAGE, and ITC techniques.

All the experiments were performed in K^+ and NH_4^+ solutions, except for the ESI-MS analyses that could only be performed in NH_4^+. **P1**−**P4** sequences can potentially target different tracts of the quadruplex structure (**Q**) formed by ckit87up. The 5-mer

P1 is fully complementary to the five bases $A_{16}-G_{20}$ (Figure 1), while **P2** and **P3** are complementary to the last seven and the first eight nucleosides of ckit87up sequence, respectively. The binding properties of these three shorter PNAs were compared to those of a 13-mer PNA strand, **P4**, which is fully complementary to the first thirteen nucleosides of ckit87up. **P2**−**P4** are also complementary to some residues belonging to loop-4 of **Q**. Finally, **P5**, an 8-mer poly-T PNA, noncomplementary to any portion of ckit87up, was used as a control sequence to show that the binding of PNA molecules is sequence specific.

The global structures of complexes formed by adding PNAs (**P1**−**P5**) to the prefolded quadruplex structure **Q**, either in NH_4^+ or in K^+ solutions, were compared by following their mobility on polyacrylamide gels. **Q**+**P1** and **Q**+**P5** mixtures (Figure 4, lanes 3 and 7) show almost the same mobility as **Q** (Figure 4, lane 2), in both potassium and ammonium solutions, while the remaining **Q**+(**P2**−**P4**) mixtures migrate with a lower mobility than **Q** (Figure 4, lanes 4, 5, and 6), thus suggesting the formation of different species.

Figure 5 shows circular dichroism spectra of 1:1 mixtures of **Q** with **P1**−**P4** (**Q**+**P1**, **Q**+**P2**, **Q**+**P3**, and **Q**+**P4**) recorded in potassium (panels A−D) and ammonium (panels E−H) solutions. The spectrum of each mixture is reported in comparison with the arithmetic sum of the individual components. The CD spectrum of **Q**+**P1** mixture recorded in potassium (Figure 5A) was almost identical to the sum of the spectra of the single components, displaying the CD signature characteristic of a parallel-stranded G-quadruplex. The CD spectra of mixtures obtained by adding **P2**, **P3**, or **P4** to **Q** in potassium buffer are all characterized by the maximum at 210 nm—ubiquitous for G-quadruplexes—and show the typical profile observed for parallel-type G-quadruplexes, although a small red-shift (2−5 nm) was observed for the minimum at 240 nm and the maximum at 263 nm (Figure 5, panels B, C, and D). The CD analysis of samples recorded in NH_4OAc solution revealed that the CD profile of the **Q**+**P1** mixture (Figure 5E) is almost superimposable to the sum of the single components, as observed in potassium buffer. Conversely, large changes in the CD spectra were observed upon addition of **P2**−**P4** PNAs to **Q**. Particularly, these mixtures showed significant shifts for the negative minimum (from 240 to 248 nm) and both positive maxima (from 210 to 223 nm and from 263 nm to 270−280 nm; Figure 5, panels F, G, and H). These values, namely, maxima at 223 and 280 nm and minimum at 248 nm, have been previously reported to be characteristic of hybrid PNA-DNA duplex tracts.[44,45] Finally, CD spectra of the **Q**+**P5** mixture recorded in both potassium and ammonium solutions are almost superimposable to the sum of the spectra of the single components, confirming, as expected, that no hybridization occurs in this case (Supporting Information Figure S3).

Figure 3 shows TDS signatures for the complexes formed by mixing equimolar quantities of **Q** and PNAs **P1**−**P4** in potassium buffer (A) and ammonium solution (B). The typical pattern of a G-quadruplex was observed for all the complexes in potassium

buffer. In particular, two positive maxima at 243 and 273 nm, a shoulder at 255 nm, and a negative minimum around 295 nm were observed in all the spectra. Conversely, TDS shapes of PNA-DNA complexes formed in ammonium solution showed the loss of the negative band at 295 nm, except for **Q**+**P1**. Moreover, the positive band at 273 nm was red-shifted to 277 nm, once again except for **Q**+**P1**. The loss of the negative band at 295 nm suggested the absence of Hoogsteen-bonded G-tetrads, while the presence of the peak at 277 nm is compatible with a Watson−Crick duplex-like structure[32] in all **Q**+(**P2**−**P4**) mixtures.

As previously described, a G-quadruplex structure melts with a characteristic hypochromic shift at 295 nm; thus, UV-melting experiments were performed for all the complexes, by recording the absorbance at 295 nm.[31] In potassium buffer, all the UV-melting profiles were consistent with the G-quadruplex foldings (Supporting Information Figure S1). The relative stabilities of PNA-complexed quadruplexes are reported in Table 2. In potassium, all complexes (Supporting Information Figure S1A) displayed $T_{1/2}$ values higher than that of **Q** (ΔT = 2−10 °C), with the exception of **Q**+**P4** for which a destabilizing effect is observed (ΔT = 5.5 °C). On the other hand, in ammonium solution, a hypochromic transition at 295 nm (Supporting Information Figure S1B) is observed only for **Q**+**P1**, once again suggesting the presence of the quadruplex structure. For all other samples, hyperchromic profiles are observed at this wavelength, suggesting the absence of the G-quadruplex scaffold in these complexes.

To better investigate the binding properties shown by the investigated PNA sequences (**P1**−**P4**), a calorimetric analysis of the interaction with **Q** was carried out both in K^+- and in NH_4^+-containing solutions (Figure 6). ITC experiments were also performed by using the poly-T PNA (**P5**, Table 1), as control sequence.

The results collected for titration of **Q** with the five PNAs in K^+ solution reveal that (a) **P1**, **P2**, and **P3** bind to the investigated quadruplex by forming a 1:1 complex; (b) **P4** interacts in a nonspecific manner with **Q**; (c) **P5** does not interact at all. The ITC data for the titrations of **Q** with **P1**, **P2**, and **P3** indicate that the interactions of the PNAs with the quadruplex are favored at 25 °C. However, the characterization of the binding reactions reveals that the interactions of the three PNAs are slightly different from a thermodynamic point of view (Table 4). In all three cases, the binding isotherms indicate exothermic interactions (Figure 6). Indeed, after each injection of PNA, less and less heat release was observed until constant values were obtained, hence reflecting a saturable process. The values of the binding constants clearly show that **P2** and **P3** bind to the investigated quadruplex with higher affinity (K_b = 1 and 3×10^6 M^{-1}, respectively) than **P1** ($K_b = 3 \times 10^5$ M^{-1}). In the cases of **P2** and **P3**, the values of $\Delta_bH°$ and $T\Delta_bS°$ show that the enthalpic contribution provides the driving force for the PNA−quadruplex interaction. However, the interaction of **P3** with **Q** is associated with a larger favorable enthalpy ($\Delta_bH°$ = −110 kJ mol^{-1}) as compared to **P2** ($\Delta_bH°$ = −90 kJ mol^{-1}). On the other hand, the interaction of **P1** is associated with a favorable enthalpic contribution ($\Delta_bH°$ = −12 kJ mol^{-1}) that acts together with the entropic one ($T\Delta_bS°$ = 19 kJ mol^{-1}). The favorable heat observed for the binding reaction is due to the net compensation of the exothermic heat from the formation of base pairs and the endothermic heats of possible H-bonds breaking. In the ITC titrations of **Q** with **P4**, a resolvable binding isotherm was never obtained using several combinations of reactant concentrations,

not allowing the determination of the thermodynamic parameters or the recognition of a defined stoichiometry. The raw ITC data for the titration of **Q** with **P5** (Supporting Information Figure S4) show constant heat release after each injection of PNA, only due to PNA dilution. A resolvable binding isotherm for the interaction with **Q** is not observed in this case as well, suggesting no affinity of **P5** for the investigated quadruplex.

When the same titrations were performed in the NH_4^+-containing solution, the binding behaviors turned out to be different, except for **P1**. As observed in K^+ solution, **P1** forms a 1:1 complex with **Q**. The thermodynamic parameters (Table 4) indicate that the interaction of **P1** is exothermic ($\Delta_bH^\circ = -13$ kJ mol^{-1}) and it is associated with a favorable entropic contribution ($T\Delta_bS^\circ = 18$ kJ mol^{-1}). On the other hand, the binding curves relative to **P2** and **P3** show less simple profiles compared to the analogous curves in K^+ solution (Figure 6). Indeed, at a molar ratio of 2:1 (PNA/DNA), fluctuating values of heat release were observed after injection of PNA, reflecting a nonsaturated process at that ratio. In NH_4^+ solution, **P4** shows behavior comparable to those of **P2** and **P3**, producing a similar binding profile. In particular, the **P2**−**P4** binding isotherms display a biphasic profile, revealing two consecutive binding events: (1) one PNA molecule interacts with the DNA; (2) a second PNA molecule binds to DNA, leading to the formation of a 2:1 PNA/DNA complex. The interpolation procedure of the experimental data has been carried out with a multiple-sites model. The thermodynamic results obtained from ITC data for **P2**, **P3**, and **P4** binding to DNA are given in Table 4. The thermodynamic characterization of the binding events revealed that the first binding event ($K_b = 2 \times 10^7$ and 3×10^7 M^{-1} for **P2** and **P3**, respectively; $K_b = 8 \times 10^7$ M^{-1} for **P4**) is stronger than the second one ($K_b = 8 \times 10^5$ M^{-1} for both **P2** and **P3**; $K_b = 1 \times 10^6$ M^{-1} for **P4**). Moreover, the analysis indicated that the two binding events are driven by a large enthalpic contribution, while there is an unfavorable entropic contribution.

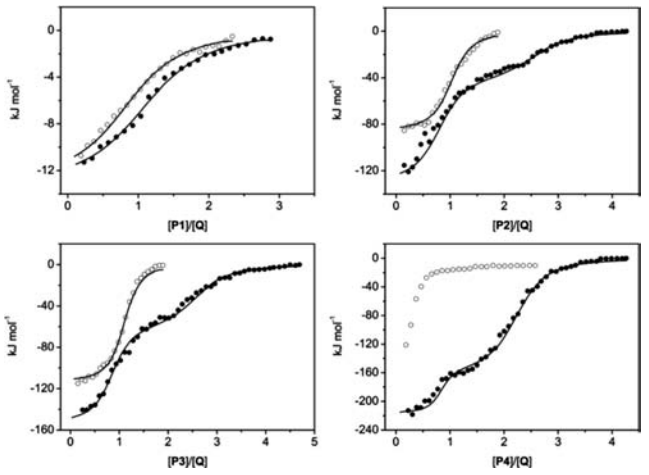

Figure 6. ITC profiles for the interaction between PNA sequences and ckit87up quadruplex in K^+ (open circles) and NH_4^+ (black circles) containing solution. The circles represent the experimental data obtained by integrating the raw data and subtracting the heat of PNA dilution. The lines represent the best-fit curve for the binding.

To establish the molecularity of the complexes in ammonium solution, MS spectra have been acquired by an ESI-Q-TOF instrument under conditions that preserve noncovalent interactions. ESI-MS was previously used to characterize intermolecular PNA/DNA complexes.[46] Here, ESI-MS was used to investigate the stoichiometry of the complexes formed when stoichiometric amounts of **P1**−**P5** are added to **Q** at room temperature (Supporting Information Figure S5). Table 3 summarizes the main species identified from the mass spectra of PNA/DNA complexes. The short **P1** probe interacts with **Q** without disrupting its scaffold, indeed the ESI-MS spectrum shows the presence of the $[\mathbf{Q}\text{-}(\mathbf{P1})_1]$ adduct with the inner ammoniums preserved (Figure 7). As expected for long PNA sequences, when **P2**−**P4** PNAs are mixed with **Q**, the main peaks observed correspond to 1:1 and 2:1 PNA/DNA hybrid complexes with $[\mathbf{ckit87up}\text{-}(\mathbf{P2}-\mathbf{P4})_1] > [\mathbf{ckit87up}\text{-}(\mathbf{P2}-\mathbf{P4})_2]$, in agreement with the ITC data. **Q** is less abundant, but always detected. Finally, the **Q**+**P5** spectrum shows no PNA/DNA complex formation, even by increasing PNA concentration (data not shown), thus suggesting that the PNA binding to DNA is sequence specific.

DISCUSSION

The present study reports the first example of PNA probes able to bind to a biologically relevant DNA quadruplex without disrupting its scaffold. While strand invasion of PNA into duplex and quadruplex DNA have been investigated in detail,[47,48] less attention has been paid to the ability of PNA to bind and stabilize the targeted quadruplex. We focused on some different PNA sequences and analyzed their interaction with the quadruplex formed by the ckit87up DNA sequence.

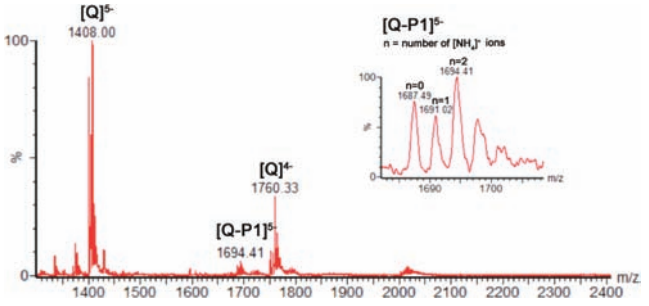

Figure 7. ESI-MS spectra of **Q**+**P1** in 150 mM NH_4OAc. The reported spectrum was acquired in the following soft source conditions: RF Lens1 = 100 V; cone = 100 V; collision energy = 10 V. The inset shows the distribution of the number of ammonium ions remaining in the G-quadruplex (from 0 to 2). [**Q**] = ckit87up quadruplex, namely, [M+2NH_4^+], where M is the single-stranded ckit87up ODN strand; [**Q-P1**] = **Q**+**P1** complex, namely [M+P1 + 2NH_4^+], in which the quadruplex is retained and coordinates two ammonium ions.

In general, the G-quadruplex structures are stabilized by monovalent cations, in particular, K^+ and to a lesser extent Na^+ and NH_4^+.[49] The ckit87up quadruplex predominantly exists in a parallel conformation *in vitro* in K^+ buffer, while in Na^+ solution, it forms aggregated species.[22] NH_4^+ stabilizes G-quadruplexes to an extent comparable with that observed for Na^+, but it displays a coordination geometry similar to that observed for K^+.[50] Therefore, to detect the differences in the molecular recognition process, the analysis was carried out in two different solutions, containing either potassium or ammonium ions.

The PAGE shows very similar behavior for **Q** annealed in K^+- or NH_4^+-containing solution, thus suggesting analogous folding in both ion conditions. Furthermore, ESI-MS data acquired in NH_4^+ solution (the ammonium is the only ion which can be used in the ESI-MS experiments) confirm the quadruplex structure adopted in ammonium showing that two NH_4^+ ions are retained in the quadruplex scaffold (see Supporting Information). In addition, CD and UV data also show the formation of a parallel quadruplex structure in both solutions and, as expected, UV-melting studies revealed that the thermal stability of **Q** in ammonium is lower than that observed in potassium solution.

Binding studies indicate that **P1**−**P4** PNAs are able to bind to ckit87up quadruplex-forming sequence. Interestingly, we observed that the different stability of the quadruplex arrangements affects the binding mode of three (**P2**, **P3**, and **P4**) out of four PNAs.

Our results show that the short **P1** probe binds to **Q** in both NH_4^+ and K^+ solutions without disrupting the target structure. The thermodynamic profiles determined by ITC for the **Q**−**P1** interaction, in the two different solutions, are qualitatively similar. In both cases, the 5-mer PNA binds to the quadruplex, even though with little affinity, and the stoichiometry observed is 1:1. Interestingly, the UV_{295}-melting experiments show that the **Q-P1** complex melts as a quadruplex structure at a temperature quite higher than **Q** alone in both NH_4^+ and K^+ solutions. CD, TDS, and PAGE studies suggested that the structure of the quadruplex is maintained upon **P1** addition in both investigated conditions. ESI-MS analysis confirms this result in ammonium solution. In fact, as for the quadruplex alone, the resulting **Q-P1** complex retains the two ammonium cations embedded in the structure (Figure 7). Since the 5-mer **P1** is complementary to the five bases A_{16}−G_{20} of the long loop-4 of **Q**, it is probably able to bind some of those bases, thus preserving the quadruplex scaffold. Since **Q** and **Q**+**P1** complexes run similarly on the gel, we suppose that the **Q**+**P1** complex retains the overall shape of free **Q**. On the other hand, the binding behavior of **P2**−**P4** PNAs was found to be completely different depending on the cation. Our data indicate that in ammonium solution **P2**−**P4** act as "openers" invading the quadruplex by forming PNA/DNA hybrid complexes. In that solution, the characteristic CD and TDS profiles of the quadruplex are lost upon addition of those PNAs and the typical UV_{295}-melting hypochromic transition of the quadruplex is not more observed. Nondenaturing gel electrophoresis show the formation of different species possessing lower mobility than **Q**, and the results of ESI-MS analysis are compatible with the formation of 1:1 and 2:1 PNA/DNA complexes without ammonium ions embedded, thus confirming that the G-quadruplex scaffold is not retained in these hybrid complexes. The thermodynamic characterization reveals some interesting features about the binding process in ammonium. In particular, ITC data clearly suggest that two consecutive binding events occur when a PNA solution is added in an incremental stepwise fashion to the DNA solution. The first, stronger, binding event has a binding stoichiometry of 1:1, then a weaker second process requiring a much higher PNA concentration for saturation occurs, suggesting that the resulting final complex is composed by two PNA and one DNA strands. The DNA/PNA

interaction yielded favorable, enthalpy-driven, free energy contributions, indicating that **P2**−**P4** are able to invade and disrupt the quadruplex structure by forming a stable product. The favorable heat for the first binding reaction is due to the net compensation of exothermic heat attributable to the formation of base-pair stacks and endothermic heat required for breaking the G-tetrad stacks of **Q**. The magnitude of the enthalpy values for the formation of 1:1 and 2:1 PNA/DNA hybrid complexes directly measured in ITC titrations increases by increasing the PNA length and clearly indicates the highest number of base-pair stacks formed in the case of **P4**. Therefore, all the above experiments demonstrate that in ammonium the **P2**, **P3**, and **P4** PNA probes can unfold the quadruplex structure, forming 1:1 and 2:1 PNA/DNA hybrid complexes with the target DNA. Since it is well-known that pyrimidine-rich PNA sequences are able to invade DNA strands by forming PNA-DNA-PNA triplexes, we believe that the 2:1 PNA:DNA complexes, observed in ammonium in the presence of an excess of **P2**, **P3**, and **P4**, can be PNA-DNA-PNA triplex-type complexes.[51]

Conversely, the results of the experiments performed in potassium-containing solution indicate that **P2**−**P4** PNAs are able to bind to **Q**, but none of them overcome the quadruplex structure. Indeed, CD, UV, and PAGE experiments reveal that the structure of the quadruplex is retained upon addition of **P2**, **P3**, or **P4**. Moreover, UV thermal denaturation data indicate that the binding of **P2** and **P3** to **Q** increases the $T_{1/2}$ values of the resulting quadruplex complexes. The energetic profiles, determined by ITC for the binding of **P2** and **P3** to **Q**, are qualitatively comparable, showing, in both cases, a single binding event with a stoichiometry of 1:1. The dissection of the Gibbs energy change into the enthalpy- and entropy-change contributions for the binding shows that the favorable Gibbs energy change is due to a favorable enthalpy change and an unfavorable entropy contribution. The entropy change values observed are the net compensation of (a) the unfavorable entropic contribution, due to the formation of a less relaxed complex with respect to unbounded components, and (b) the favorable entropic contribution, due to the release of coordinated water molecules to the bulk solvent. Moreover, the thermodynamic data revealed that **P3** has a higher affinity for **Q** (K_b for **P3** is three times larger than that for **P2**) and that its interaction is associated with a larger favorable enthalpy change. On the other hand, the ITC titration of **Q** with **P4** shows that the interaction between these molecules does not lead to the determination of thermodynamic parameters associated with a specific interaction.

The overall picture emerging from this study is that the investigated PNAs are able to interact with **Q** in both K^+ and NH_4^+ solutions, but with a different binding mode. As known, the nature of the cations in solution significantly influences the stability of G-quadruplexes. The different behavior of PNA molecules arises just from the relative stability of **Q** in the two ionic solutions. In NH_4^+ solution, the PNAs are able to overcome the less stable quadruplex structure of **Q** hybridizing the DNA sequence. Conversely, in K^+ solution, where the quadruplex structure stability is highest, the PNAs are still able to bind to the quadruplex without overcoming it. The melting experiments of the quadruplex structure in K^+ solution show that the binding of PNAs leads to a stabilization of **Q**, resulting in the following stability order: **Q-P3** > **Q-P2** > **Q-P1**. The ranking orders of binding constants and enthalpies found by ITC are in agreement with the order of thermal stability, and indicate that **P3** is the best quadruplex-binding agent among the investigated PNAs.

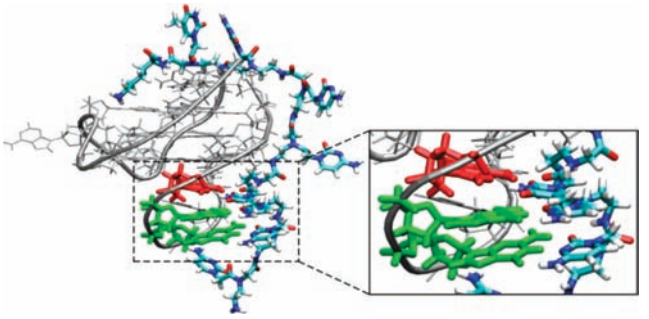

Figure 8. Molecular model of the complex between ckit87up quadruplex (**Q**) and **P3**. **Q** is in gray, and adenine (A_{16}) and guanine (G_{17} and G_{18}) bases involved in Watson−Crick base pairing with the complementary PNA residues are highlighted in red and green, respectively.

The NMR structure of **Q**[22] shows that the only residues potentially able to form Watson−Crick-type base pairs are the bases A_{16}, G_{17}, and G_{18} of the long loop-4; therefore, we speculate that the interaction with PNA involves one of its "c-c-t" stretch. Since **P2** and **P3** bind to **Q** with higher affinity than **P1**, we hypothesize that the best possible interaction occurs with the "c-c-t" motif at the N-terminus. Figure 8 shows a molecular model of **Q-P3** complex, built on the basis of these considerations. The model of the complex shows that the PNA molecule is able to form three Watson−Crick base pairing involving the "$c_2c_3t_4$" bases of **P3** and the complementary "$A_{16}G_{17}G_{18}$" bases. The model also shows that the PNA molecule can adapt its backbone to the structure of **Q**. The flexibility of PNA could allow the positively charged lysine residue to gain additional interactions with the backbone of the quadruplex. The origin of the nonspecific binding of **P4**, that match the C-terminus sequence of **P3**, could be due to the remaining bases at the N-terminus. These latter could also be responsible for the quadruplex destabilization observed in **Q-P4** complex in K^+.

In conclusion, in this paper we proposed a potential way to regulate the c-kit gene transcription by using short PNA sequences. The ckit87up sequence is unique within the human genome, and it folds into an unusual quadruplex structure embodying a peculiar long loop that may represent, as we have shown, the target of new quadruplex-binding agents. Our findings demonstrate that (i) PNAs can act as quadruplex-binding agents, that (ii) their affinity toward the quadruplex depends on PNA sequence and length, and that (iii) the binding mode could be related to the quadruplex stability. These studies open up new routes for the development of improved probes for the regulation of c-kit protooncogene transcription.

General Experimental Methods.

Synthesis of DNA sequences

The purine-rich 22-mer ODN corresponding to the c-Kit87up sequence $^{5'}$AGGGAGGGCGCTGGGAGGAGGG$^{3'}$ has been synthesized using the standard phosphoramidite chemistry on controlled pore glass supports using an Expedite 8909 DNA synthesizer (Applied Biosystems) (15 μmol). After automated synthesis, the oligonucleotides were detached from the support, deprotected, and purified by HPLC on an anion exchange column (Macherey Nagel Nucleogel Sax 1000-8), followed by desalting on a molecular exclusion column (BIORAD Biogel P-2 fine). The oligonucleotide was then characterized by MALDI-TOF mass spectrometry (Bruker Autoflex I instrument) using a mixture of picolinic/3-hydroxypicolinic acids in presence of ammonium citrate as the matrix. DNA concentration for all the experiments was determined by UV absorbance using the ε_{260} = 226700 M^{-1} cm^{-1}.

Synthesis of PNA sequences

The syntheses of PNA sequences H-ctcct-Lys-NH_2 (**P1**), H-ccctcct-Lys-NH_2 (**P2**), H-ccctccct-Lys-NH_2 (**P3**), H-cagcgccctccct-Lys-NH_2 (**P4**) and H-tttttttt-Lys-NH_2 (**P5**) were performed on a Rink-amide resin using the FMOC chemistry (27). PNAs were purified by RP-HPLC (0.05% TFA in

water; 0.05% TFA in CH_3CN) and characterized by ESI-MS (Applied Biosystem API 2000 mass spectrometer). Stock solutions of **P1**-**P5** were prepared in double distilled water and their concentration were calculated by UV absorbance using the ε_{260} (M^{-1} cm^{-1}): $\varepsilon_{\mathbf{P1}}$ = 38700; $\varepsilon_{\mathbf{P2}}$ = 53100; $\varepsilon_{\mathbf{P3}}$ = 60300; $\varepsilon_{\mathbf{P4}}$ = 119100, $\varepsilon_{\mathbf{P5}}$ = 65400.

Supporting Information

ABSTRACT: Integrin $\alpha_v\beta_3$ is an adhesion molecule involved in physiological and pathological angiogenesis as well as tumor invasion and metastasis. Therefore, it is considered an important target for molecular imaging and delivery of therapeutics for cancer, and there is a strong interest in developing novel agents interacting with this protein. Nevertheless, the interaction of individual ligands is often still weak for efficient tumor targeting, and many research groups have synthesized multivalent displays in order to overcome this problem. Gold nanoparticles can be considered a smart platform for polyvalent presentation on account of their globular shape, tunable size, facile surface chemistry, and biocompatibility. Moreover, their unique physical properties render gold nanoparticles ideal candidates for tumor diagnosis and therapy. Here, we report the synthesis and characterization of gold nanoparticles functionalized with cRGD integrin ligand and their employment for targeting human cancer cells expressing $\alpha_v\beta_3$ integrin.

INTRODUCTION

Integrins are heterodimeric transmembrane cell surface proteins expressed by most cell types.[1] $\alpha_v\beta_3$ integrin is the receptor for a variety of extracellular matrix proteins containing an RGD sequence[2,3] and serves as a marker of angiogenesis, tumor development, and metastasis, since it is barely detectable on quiescent vessels and highly expressed during the angiogenic switch.[4−6] It is also highly expressed by several solid tumors such as glioblastomas,[7] melanomas,[8] and ovarian, [9] breast, and prostate cancers,[10] where it is involved in processes governing metastatization. For these reasons, integrins are considered an important target for molecular imaging and drug delivery for cancer diagnosis and therapy, and many efforts have addressed the synthesis of integrin ligands. The most common integrin ligands are peptides, because they can be readily generated. Linear peptide sequences containing the RGD motif are known to bind integrins, and these have been employed as cell-targeting agents.[11] Nevertheless, on account of the low affinity and high biodegradability of such linear peptides, their utility for selective cell targeting is limited. Cyclic peptide derivatives, such as cyclo(RGDfV) or Cilengitide, have been used as tumor-homing agents due to their selectivity for $\alpha_v\beta_3$ integrin.[12−14]

In past years, our research group reported a library of 15-member cyclic RGD pentapeptide mimics based on 1-aza-oxobicyclo[X.3.0]alkane amino acids (Figure 1) containing specific high-affinity ligands for $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins.[15,16] However, the need of moieties suitable for conjugation prompted us to synthesize new cyclic RGD pentapeptide mimics based on functionalized azabycycloalkane scaffolds.[17] This small collection was found to contain specific ligands for $\alpha_v\beta_3$ integrin. Furthermore the functionalization of the azabicycloalkane scaffolds with heteroalkyl substituents enabled us to conjugate RGD containing compounds with different diagnostic or therapeutic entities[18] without losing activity.

Nevertheless, the affinity of individual ligands is seldom enough for efficient tumor detection or selective drug homing. For this reason, many research groups have designed multivalent displays based on dendrimers,[19−26] polymers,[27,28] liposomes,[29] and others[30] in order to exploit multiple interactions with integrin clusters on cell membrane to increase the binding. Thus, by increasing the peptide multiplicity, they significantly enhance the avidity of the multiple ligand for the $\alpha_v\beta_3$ integrin with a trend that is frequently proportional to the number of RGD moieties. On the other hand, the synthesis and purification of such multivalent systems are often challenging requiring efficient and chemoselective conjugation techniques.

In recent years, metal nanoparticles have generated much interest in biology and medicine due to their unique physical and

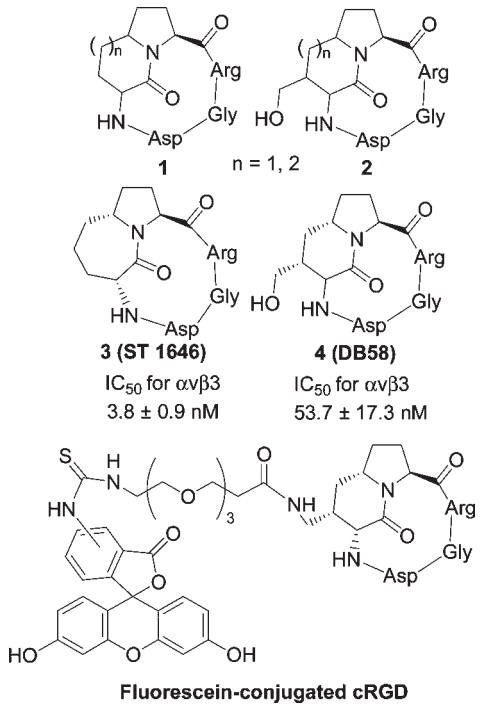

Figure 1. Most potent $\alpha_v\beta_3$ integrin inhibitors and Fluorescein conjugated cRGD synthesized by our research group.

chemical properties and have widely been employed in tumor targeting. Furthermore, they constitute a three-dimensional platform for multipresentation. Among them, gold nanoparticles (AuNPs) are particularly interesting for cancer diagnosis and therapy.[31,32] Their relatively easy preparation, tunable size, facile surface chemistry, and biocompatibility[32] render AuNPs very attractive as carriers for drug or gene delivery.[34−36] Moreover, their surface plasmon resonance (SPR) enhanced light scattering and absorption make colloidal AuNPs a potential candidate for optical imaging and hyperthermia therapy.

Gold nanoparticles with different characteristics can be obtained by varying size, shape, and stabilizing agent.[31] A large number of synthetic procedures are reported for preparing gold nanoparticles. The method reported by Turkevich[37] involves the citrate reduction of Au(III) to Au(0) in water. This method and further modifications[37,38] allow the synthesis of citrate coated nanoparticles within the 9−120 nm range. However, the replacement of the coating with another stabilizing agent and/or an appropriate ligand must be obtained in a further step of the preparation. The synthesis by the method of Brust[39] and the related method modified by Penades[40,41] involves the reduction of Au(III) to Au(0) by $NaBH_4$ in the presence of a thiol (or a mixture of thiols). It results in relatively small polydisperse thiolate monolayer protected AuNPs. These nanoparticles are characterized by a small core size (1−3 nm), and on this account, they partially lose the typical behavior of colloidal gold, making their application as diagnostic probes less efficacious. On the other hand, these synthetic procedures guarantee a chemically well-defined composition determined by the composition of the starting thiols mixture, thus making their employment as drug carriers less complex.

Here, we employed the method described by Penades for the synthesis of gold nanoparticles functionalized with cRGD peptidomimetic **4** (**DB58**, Figure 1) which showed the highest affinity for $\alpha_v\beta_3$ integrin in an *in vitro* binding assay.[17] The selected integrin ligand was functionalized with a short PEG linker armed with a thiol group and the so-synthesized molecule was employed in the preparation of the nanoparticles. In a similar way, nanoparticles functionalized with both cRGD and FITC were prepared.

The resulting cRGD functionalized nanoparticles were tested for their ability to bind $\alpha_v\beta_3$ integrin by means of a solid-phase receptor-binding assay, which is a simple and precise method to analyze protein−protein interactions.[13,16,17,42] The reported AuNPs showed a highly enhanced affinity in comparison with the unconjugated ligand. This positive result was also confirmed by *in vitro* studies on cell cultures showing how nanoparticles functionalized with cRGD were able to selectively interact with cells expressing $\alpha_v\beta_3$ integrin.

MATERIALS AND METHODS

General. All chemicals and solvents, purchased from Sigma-Aldrich, were of reagent grade and were used without further purification. Solvents were dried by standard procedures, and reactions requiring anhydrous conditions were performed under nitrogen or argon atmosphere. UPLC-MS analysis were obtained with an Aquity Waters apparatus. Mass spectra were obtained with an ESI apparatus Bruker Esquire 3000 plus. Semipreparative HPLC was carried out with a Atlantis Prep T3 OBD, 5 μm, 19 × 150 mm Waters column using gradient mixture of CH_3CN/H_2O + 0.1% TFA. ^1H and ^{13}C NMR spectra were recorded at 300 K on Bruker AVANCE 400 and 600 MHz. Chemical shifts δ are expressed in ppm relative to internal Me_4Si as standard. UV/vis spectra were measured with a Thermo Scientific, Evolution 600 UV−visible spectrophotometer. For transmission electron microscopy (TEM) characterization, a single drop (10 μL) of aqueous solution of gold NPs (ca. 0.1 mg/mL in Milli-Q water) was placed on a Formvar/carbon-coated copper grid (Electron Microscopy Science) and left to dry in air for several hours. The sample grids were examined by an EFTEM LEO 912AB microscope (Zeiss), operating at 80 kV. The average diameter of the AuNPs was obtained from evaluation of several TEM micrographs by means of an algorithm for automatic image analysis developed by our group.

Synthesis of Disulfide Linker ***8***. To a solution of commercially available linker **5** (50.0 mg, 0.11 mmol) in MeOH (2 mL), MeONa (25% in MeOH, 40 μL) was added. The reaction mixture was stirred for ca. 18 h at room temperature following the formation of the disulfide by UPLC-MS. After reaction completion, Amberlyst IRA 120 H+ was added until acid pH was reached. The solution was filtered and evaporated under reduced pressure yielding the disulfide linker **8** quantitatively. The product was used in the following reaction without any further purification.

Synthesis of cRGD Conjugated Compound ***9***. The disulfide linker **8** (30 mg, 0.033 mmol) and *N*-hydroxysulfosuccinimide sodium salt (18 mg, 0.0825 mmol) were solved in dry DMF (1.4 mL), and under argon and at room temperature, dicyclohexyl carbodiimide (15 μL, 0.099 mmol) was added. The reaction mixture was stirred for 24 h, and after this time, the solvent was removed under reduced pressure. The crude was dissolved in PBS/CH_3CN 3:1 (2 mL) and cRGD **6** in PBS (1.0 mL) was added. The pH was adjusted to pH 7.3 by adding NaOH 0.2 N, and the reaction mixture was stirred for ca. 24 h monitoring by UPLC-MS. After reaction completion, the solvent was evaporated under reduced pressure and the crude was

purified by HPLC. (Column: Waters Atlantis Prep 19 × 50 mm, 5 μm; 15 mL/min flow; gradient from 0% B to 50% B over 15 min, wash then 100% B for 3 min, A: H_2O + 0.1% TFA; B: CH_3CN + 0.1% TFA, collecting λ 216 nm). The desired product was collected in 52% yield. The monofunctionalized compound and the unreacted starting cRGD-NH_2 were also recovered (white solid). ^{1}H NMR (600 MHz, D_2O): δ 1.21 (m, 1H, *H*-5), 1.40−1.56 (m, 3H, 2 *Hγ* Arg, *Hβ* Arg), 1.60 (m, 1H, *H*-7), 1.82 (m, 1H, *H*-8), 2.01 (m, 1H, *Hβ* Arg), 2.34−2.45 (m, 5H, CH_2SH, *H*-5, *H*-7, *H*-8), 2.66 (dd, 1H, *J* = 16.9 Hz, *J* = 7.1 Hz, *Hβ* Asp), 2.72 (m, 1H, *H*-4), 2.87 (t, 2H, *J* = 6.5 Hz, CH_2NHCO), 3.03 (dd, 1H, *J* = 16.9 Hz, *J* = 7.5 Hz, *Hβ* Asp), 3.07 (m, 2H, C-4CH_2NH), 3.12 (m, 2H, 2 *Hδ* Arg), 3.45 (d, 1H, *J* = 14.6 Hz, *Hα* Gly), 3.55−3.65 (m, 28H, CH_2O), 3.67 (t, 2H, *J* = 6.0 Hz, OCH_2), 3.74 (t, 2H, *J* = 6.1 Hz, OCH_2), 3.95 (m, 1H, *H*-6), 4.20−4.27 (m, 2H, *Hα* Gly, *H*-9), 4.33 (d, 1H, *J* = 8.2 Hz, *H*-3), 4.46 (t, 1H, *J* = 7.3 Hz, *Hα* Asp), 4.53 (dd, 1H, *J* = 11.0 Hz, *J* = 3.7 Hz, *Hα* Arg,). ^{13}C NMR (150.9 MHz, D_2O): δ 174.9, 174.5, 174.3, 174.0, 173.0, 171.5, 170.2, 156.7, 69.6, 69.5, 69.4, 68.4, 66.7, 62.1, 56.0, 53.0, 51.6, 51.4. 42.4, 40.4, 38.7, 37.3, 36.0, 35.7, 33.4, 32.9, 32.6, 30.2, 26.9, 24.4. Synthesis of Functionalized Fluorescein ***7***. To a solution of Boc monoprotected 4,7,10-trioxa-1,13-tridecane diamine (34 mg, 0.11 mmol), in dry DCM (3 mL), FITC (50 mg, 0.13 mmol) in dry DMF (1 mL) was added, and finally TEA (50 μL, 0.36 mmol) was added. The reaction mixture was stirred at room temperature, in the dark, for ca. 18 h. After reaction completion, the PS-NH_2 resin was added (70 mg) and the mixture was stirred for ca. 4 h to remove unreacted FITC. After this time, the solution was filtered and the solvent was evaporated under reduced pressure. The crude was dissolved in CH_2Cl_2 (1 mL), and TFA (1 mL) was added. The mixture was stirred at room temperature in the dark for ca. 1 h, then the solvent was evaporated under reduced pressure and the product was dried under vacuum overnight. 88% yield. (yellow oil). ^{1}H NMR (400 MHz, methanol-d_4): δ 1.90−2.00 (m, 4H, $CH_2CH_2CH_2$), 3.11 (m, 2H, CH_2NH_2), 3.57−3.70 (m, 12H, CH_2O), 3.76 (m, 2H, CH_2NHCS), 6.70 (m, 2H, *aromatic protons*), 6.83−6.98 (m, 4H, *aromatic protons*), 7.23 (m, 1H, *aromatic proton*), 7.84 (m, 1H, *aromatic proton*), 8.24 (s, 1H, *aromatic proton*). ^{13}C NMR (100.6 MHz, methanol-d_4): δ 141.3, 129.7, 128.3, 113.8, 111.5, 102.1, 70.1, 70.0, 69.8, 69.7, 69.6, 68.8, 68.7, 47.7, 38.6, 28.6, 26.8. MS (ESI$^+$) *m*/*z*: 610.4 $(M+H)^+$.

Synthesis of Fluorescein Conjugated Compound ***10***. The disulfide linker **8** (24 mg, 0.026 mmol) and *N*-hydroxysulfosuccinimide (14 mg, 0.065 mmol) were solved in dry DMF (1.0 mL), and under argon and at room temperature, dicyclohexyl carbodiimide (12 μL, 0.078 mmol) was added. The reaction mixture was stirred for 24 h. After this time, a solution of functionalized fluorescein **7** (59.0 mg, 0.097 mmol) and TEA (280 μL, 2.0 mmol) in dry DMF (1.5 mL) was added. The reaction mixture was stirred for ca. 3 h monitoring by HPLC-MS. After reaction completion, the solvent was evaporated under reduced pressure and the crude was purified by HPLC. (Column: Waters Atlantis Prep 19 × 50 mm, 5 μm; 15 mL/min flow; gradient from 20% B to 80% B over 15 min, wash then 100% B for 3 min, A: H_2O + 0.1% TFA; B: CH_3CN + 0.1% TFA, collecting λ 216 nm).

The desired product was collected in 36% yield. The monofunctionalized compound and the unreacted starting compound **7** were also recovered. (yellow oil). ^{1}H NMR (400 MHz, methanol-d_4): δ 1.76 (m, 2H, $CH_2CH_2CH_2$), 1.99 (m, 2H, $CH_2CH_2CH_2$), 2.44 (m, 2H, CH_2CONH), 2.90 (m, 2H, CH_2S), 3.27 (m, 2H, CH_2NH), 3.53 (m, 2H, CH_2O), 3.55−3.80 (m, 44H, 21 CH_2O, CH_2NH), 6.85 (m, 2H, *aromatic protons*), 6.98 (s, 2H, *aromatic protons*), 7.10 (m, 2H, *aromatic protons*), 7.28 (m, 1H, *aromatic proton*), 7.94 (m, 1H, *aromatic proton*), 8.33 (s, 1H, *aromatic proton*). ^{13}C NMR (100.6 MHz, methanol-d_4): δ 172.5, 141.7, 130.5, 102.1, 70.2, 70.1, 70.0, 69.9, 69.8, 69.7, 69.1, 68.8, 68.5, 66.9, 48.1, 47.9, 42.3, 38.2, 36.5, 36.4, 29.3, 29.0, 28.5. MS (ESI$^+$) *m*/*z*: 1049.5 $(M+2H)^{2+}$.

General Procedure for Nanoparticles Preparation. A 0.012 M (3 equiv) methanolic solution of the commercially available linker **5** and cRGD derivative **9** (or a mixture of cRGD disulfide derivative **9** and fluorescein disulfide derivative **10**) was added to a solution of tetrachloroauric acid (0.025 M, 1 equiv) in water. An aqueous solution of $NaBH_4$ (1 M, 22 equiv) was then added in four portions, with rapid shaking. The black suspension formed was shaken for an additional 2 h at room temperature. After this time, the obtained suspension was centrifuged (4000 rpm for 15 min), then the supernatant was removed and the residue was dissolved in the minimum volume of Milli-Q water (ca. 5 mL) and purified by dialysis (ca.10 cm segments of SnakeSkin pleated dialysis tubing Ø 32 mm, 2500 MWCO, SIGMA) or by centrifugal filtration (10 000 MWCO, Vivaspin filters). The solution was finally lyophilized to afford the desired AuNPs. ^{1}H NMR spectra of the obtained AuNPs were recorded. The particle size distribution of the gold nanoparticles was evaluated from TEM micrographs by means of an automatic image analyzer. The average molecular formula of the nanoparticles was calculated on the basis of the average diameter obtained by TEM.[43]

AuNPs ***11***. Linker **5** (100%): Reaction of **5** (87.0 mg, 0.189 mmol) in methanol (15 mL) with $HAuCl_4.3H_2O$ (25 mg, 0.067 mmol) in 2.5 mL H_2O and $NaBH_4$ (1.4 mL, 1 M) gave AuNPs **11** (6.3 mg) as a dark-brown powder. TEM (average diameter and calculated number of gold atoms): 1.7 ± 0.4 nm, 140; UV/vis (H_2O, 0.1 mg/mL): surface plasmon band not present.

AuNPs ***12***. cRGD-derivative **9** (20%), linker **5** (80%): Reaction of cRGD-derivative **9** (11.0 mg, 0.0055 mmol) and linker **5** (15.0 mg, 0.033 mmol) in methanol (4.6 mL) with $HAuCl_4.3H_2O$ (7.1 mg, 0.018 mmol) in 720 μL H_2O and $NaBH_4$ (400 mL, 1 M) gave AuNPs **12** (2.5 mg) as a dark-brown powder. TEM (average diameter and calculated number of gold atoms): 2.0 ± 0.7 nm, 314; UV/vis (H_2O, 0.1 mg/mL): λ = 500 nm (surface plasmon band).

AuNPs ***13***. cRGD-derivative **9** (20%), fluorescein-derivative **10** (5%), linker **5** (75%): Reaction of cRGD-derivative **9** (24.0 mg, 0.012 mmol), fluorescein-derivative **10** (6.3 mg, 0.003 mmol), and linker **5** (41.3 mg, 0.09 mmol) in methanol (10 mL) with $HAuCl_4.3H_2O$ (15.7 mg, 0.04 mmol) in 1.6 mL H_2O and $NaBH_4$ (880 mL, 1 M) gave AuNPs **13** (3.2 mg) as a dark-brown powder. TEM (average diameter and calculated number of gold atoms): 1.9 ± 0.8 nm, 225; UV/vis (H_2O, 0.1 mg/mL): λ = 482 nm (surface plasmon band).

AuNPs ***14***. Fluorescein-derivative **10** (5%), linker **5** (95%): Reaction of fluorescein-derivative **10** (6.0 mg, 0.0028 mmol) and linker **5** (50.0 mg, 0.11 mmol) in methanol (9.5 mL) with $HAuCl_4 \cdot 3H_2O$ (15.0 mg, 0.038 mmol) in 1.5 mL H_2O and $NaBH_4$ (840 mL, 1 M) gave AuNPs **14** (1.0 mg) as a dark-brown powder. TEM (average diameter and calculated number of gold atoms): 1.8_0.5 nm, 201; UV/vis (H_2O, 0.1 mg/mL): surface plasmon band not observed.

Solid-Phase Receptor-Binding Assay. Purified $\alpha_v\beta_3$ receptor (Chemicon International, Inc., Temecula, CA) was diluted to 0.5 μg/mL in coating buffer containing 20 mmol/L Tris-HCl

(pH 7.4), 150 mmol/L NaCl, 1 mmol/L $MnCl_2$, 2 mmol/L $CaCl_2$, and 1 mmol/L $MgCl_2$. An aliquot of diluted receptor (100 μL/well) was added to 96-well microtiter plates (NUNC MW 96F Medisorp Straight) and incubated overnight at 4 °C. The plates were then incubated with blocking solution (coating buffer plus 1% bovine serum albumin (Sigma) for additional 2 h at room temperature to block nonspecific binding followed by 3 h incubation at room temperature with various concentrations (10^{-12}−10^{-5} M or 10^{-15}−10^{-8} in the case of nanoparticles) of test compounds in the presence of 1 μg/mL vitronectin biotinylated using EZ-Link Sulfo-NHS-Biotinylation kit (Pierce, Rockford, IL). After washing, the plates were incubated for 1 h at room temperature with streptavidin−biotinylated peroxidase complex (Amersham Biosciences, Uppsala, Sweden) followed by 30 min incubation with 100 μL Substrate Reagent Solution (R&D Systems, Minneapolis, MN) before stopping the reaction by addition of 50 μL of 1 N H_2SO_4. Absorbance at 415 nm was read in a Synergy HT Multi-Detection Microplate Reader (BioTek Instruments, Inc.). Each data point is the result of the average of triplicate wells and was analyzed by nonlinear regression analysis with *GraphPad Prism* program.

Reagents for Cellular Experiments. All reagents were purchased from Sigma-Aldrich (unless otherwise indicated). For all our tests, phosphate buffer saline (PBS) supplemented with calcium and magnesium (Euroclone) was used.

Cell Lines and Culture. MDA-MB-231 human breast adenocarcinoma cells and PC3 human prostate cancer cells were purchased from Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia (Brescia, Italy) and were grown on tissue flasks in medium RPMI supplemented with 10% fetal calf serum (FCS), 2 mM L-glutamine, penicillin (100 U/mL), and streptomycin (100 μg/mL). All cell lines were maintained at 37 °C in an atmosphere of 95% air and 5% CO_2.

Treatment of Cells with Compounds and Analysis. Cells (1.5×10^5/mL) were seeded and allowed to adhere overnight in complete medium on glass slides. Cells were treated 4 h at 37 °C with selected compounds diluted in fresh medium supplemented with 0.1% FCS. After the incubation, cells were extensively washed in PBS and fixed in 4% paraformaldehyde for 10 min at room temperature. Nuclei were then counterstained with 0.25 μg/mL 4′,6-diamidino-2-phenylindole (DAPI) diluted in PBS for 5 min at room temperature. Cells were finally mounted with Vectashield mounting medium and visualized with a Leica TCSNT confocal microscope (Leica Mikrisysteme Vertrieb GmbH, Germany). Experiments were repeated in triplicate.

RESULTS

Preparation of Thiol-Derivatizated Ligands. Among a small collection of functionalized cyclic RGD (**3**, Figure 1),[17] we chose compound **4** (**DB58**) that showed the highest affinity for $\alpha_v\beta_3$ integrin in an *in vitro* binding assay (IC_{50} of 53.7 ± 17.3 nM) as a good candidate for gold nanoparticle conjugation.

In order to conjugate cRGD to the AuNPs, we needed to introduce a spacer ending in a thiol group. The nature, the length, and the flexibility of this spacer can influence the way the ligands are presented on the surface of the gold cluster and their ability to bind the integrins. We chose the commercially available linker **5** (Scheme1) because its polyethylenic nature could favor nanoparticle stability in aqueous media and its flexibility could facilitate the interaction with integrin clusters on the cell surface. Furthermore, nanoparticles coated with poly(ethylene glycol)s are known to display stealth properties prolonging their circulation time and consequently the possibility of reaching the target organ.

To avoid the formation of complex mixtures during the synthesis, the linker was dimerized through the formation of a disulfide bridge. Divalent linker **8** was activated as *N*-hydroxysulfosuccinimide ester and then reacted with the amine derived cRGD **6** (prepared from **4** using the procedure reported in ref 17) in phospate buffer saline pH 7.3. Compound **9** was recovered after HPLC purification, together with the monoderivatized compound and the unreacted starting cRGD **6**.

Due to the small dimensions, the gold nanoparticles examined in this study partially lose the typical behavior of colloidal gold, thus not displaying the surface plasmon band. On this account, we were not sure that the usual techniques used to reveal gold nanoparticles inside the cells could be employed. On the other hand, other characteristics also, such as the fluorescence quenching of many fluorophores when they are in close proximity to gold surfaces, could be altered. For this reason, we prepared a fluorescein-derivatized linker in order to synthesize fluorescent gold nanoparticles.

Commercially available FITC was reacted with Boc (*N-tert*-butoxycarbonyl) monoprotected 4,7,10-trioxa-1,13-tridecane diamine, and after removal of the excess of FITC by PS-NH_2 resin, the protecting group was removed with TFA to yield **7**. Fluorescein derivative **7** was finally reacted with divalent linker **8** following the procedure reported above.

Nanoparticle Synthesis. The nanoparticles were synthesized using the procedure developed by Penades and co-workers.[37] This method involves the reduction of tetrachloroauric acid with an excess of sodium borohydride in the presence of a thiol or a mixture of thiols. The gold nanoparticles obtained by this procedure are characterized by a coating composition determined by the mixture of thiols used in their preparation. Thus, different AuNPs of controlled composition were prepared (Table 1). In particular, 20% cRGD density was chosen as a starting point. In fact, we supposed that, in nanoparticles with a high density of cRGD (>60%), the ligands would be too close to each other and this could not improve the binding. We prepared AuNPs **12** with 20% cRGD and AuNPs **13** with 20% cRGD and 5% fluorescein derivative (in order to visualize them inside the cells). AuNPs **11** without cRGD and nanoparticles **14** with 5% fluorescein derivative were also synthesized as negative controls.

All the synthesized AuNPs were water-soluble, although particles functionalized with 5% fluorescein partially precipitated after one night at 4 °C. Finally, all nanoparticles were characterized by transmission electron microscopy (TEM), ^{1}H NMR, and UV spectroscopy.

The TEM analysis showed AuNPs with a very small core (ca. 2 nm) and uniform dispersion. Moreover, nanoparticles did not appear to be aggregated. ^{1}H NMR spectrum of AuNPs **12**, although the broader feature of the peaks, confirmed the presence of the cRGD derivative on the surface of the nanoparticles (Figure 2). Furthermore, integrations of the proton signals were in agreement with a cRGD-PEG/HOOC-PEG ratio of 20:80 as expected. For FITC/cRGD fuctionalized NPs **13**, the ^{1}H NMR spectrum was similar (see Supporting Information, Figure 9). The peaks from fluorescein were barely detectable on account of low concentration.

The UV/vis spectra of AuNPs **12** and **13** showed a particularly weak surface plasmon band at around 500 nm. It is well known that in the case of nanoparticles smaller than 3 nm the surface

Scheme 1. Synthesis of Thiol Ending PEG Functionalized with cRGD or Fluoresceine and Their Employment in the Preparation of Gold Nanoparticles

14	5% FITC 95% linker **5**	1.79 ± 0.49	201	$(C_{50}H_{70}N_3O_{17}S_2)_3(C_{19}H_{37}O_{10}S)_{68}Au_{225}$	-	73 851

[a] The average number of gold atoms and hence the molecular formulas and the molecular weights of the nanoparticles were calculated according to the literature on the basis of the average gold diameters obtained by TEM.

plasmon band is not observed;[44] however, this hardly detectable band was probably due to the very small fraction of nanoparticles with a diameter bigger than 3 nm (see size distribution B, Figure 2 and Figure S8 in Supporting Information). In the UV/vis spectra of AuNPs **13**, the band due to the presence of the fluorescein was also visible, supporting the thesis that the fluorescence quenching does not occur.

On the basis of the gold nanoparticle core size (determined by TEM), an average molecular formula was determined according to the literature[43] and a molecular weight was calculated (Table 1).

Solid-Phase Receptor Binding Assay. The AuNPs **12** and **13** together with the negative controls AuNPs **11** and **14** were examined *in vitro* for their ability to inhibit the binding of biotinylated vitronectin to the isolated, immobilized $\alpha_v\beta_3$ integrin (Table 2). Affinity of compound **4** (**DB58**) was determined as reference, in the same assays. The divalent derivative **9** was also tested.

As a general remark, we observed that multivalent ligands displayed an enhanced affinity (avidity) in comparison with the monovalent ligand **4** (53.7 ± 17.3 nM). In particular, an increase in affinity was already evident in the case of divalent ligand **9** that showed an IC_{50} value of 6.8 ± 2 nM (Table 2). The improvement was even greater for AuNPs **12** (0.4 ± 0.1 nM, Table 2) that bound integrin $\alpha_v\beta_3$ more than 100-fold in comparison with compound **4**.

In order to evaluate the previously mentioned results, we divided the avidity by the average number of cRGDs, obtaining an absolute value, namely, enhancement factor (β) (Table 2, col. 5).[45,46] In this way, it has been possible to compare the strength of multivalent effects when cRGD peptides are attached to nanoparticles at different densities.

Thus, the dimeric derivative **9** displayed an enhanced affinity of 8 and a β of 4 (Table 2). The functionalized AuNPs **12** displayed a relevant enhancement in binding affinity (more than 100-fold) toward $\alpha_v\beta_3$ integrin when compared to the nanomolar reference and a β of 7. This result suggested that multivalent interactions between gold nanoparticles and $\alpha_v\beta_3$ integrins enhanced the binding strength in a way that was greater than the sum of the affinity of the involved ligands.

In order to evaluate the influence of fluorescein on the AuNPs, nanoparticles **13** were also tested. They still showed a high affinity for $\alpha_v\beta_3$ integrin, although the value of IC_{50} (1.7 ± 0.6 nM, Table 2) was lower if compared with AuNPs **12**. This could probably be due to an interference of fluorescein on the surface of the nanoparticles in the binding process.

In summary, these data showed that the functionalization of gold nanoparticles with cRGD generated a great increase in the binding activity on account of polypresentation, suggesting that AuNPs could be employed as a suitable platform for tumor-targeted drug delivery.

Gold Nanoparticle Detection in Human Cell Lines. The above results demonstrated that gold nanoparticles **12** have a high affinity for the $\alpha_V\beta_3$ integrin; and the copresence of fluoresceine on nanoparticle surfaces in AuNPs **13** does not

Table 2. Compound-Mediated Inhibition of Vitronectin Binding to $\alpha_V\beta_3$ Integrin[a]

compound	IC_{50} (nM) ± SD for $\alpha_V\beta_3$	increase in affinity	enhancement factor (β)[b]
Compound **4** (**DB58**)	53.7 ± 17.3	1	1
Compound **9**	6.8 ± 2	8	4
AuNPs **11**	inactive	-	-
AuNPs **12**	0.4 ± 0.1	134	7
AuNPs **13**	1.7 ± 0.6	31	2
AuNPs **14**	inactive	-	-

[a] IC_{50} values were calculated as the concentration of compound required for 50% inhibition of biotinylated vitronectin binding as estimated by the *GraphPad Prism* program. All values are the mean (±standard deviation) of triplicate determinations. [b] Enhancement Factor (β) = Increase in Affinity/Number of cRGD.

substantially alter their affinity. These data prompted us to test their possible use as vectors for cells highly expressing $\alpha_V\beta_3$ integrin.

Experiments were performed on PC-3 prostate cancer cells on account of their good responsiveness to fluorescein-conjugated cRGD compounds showed in previous experiments,[18] while MDA-MB-231 breast adenocarcinoma cells were used as a negative control due to the very faint levels of $\alpha_V\beta_3$ integrin expressed by this cell line.[47] All cell lines were exposed to scalar concentrations of gold nanoparticles. It was found that incubation with 1 μM AuNPs determined a good detection threshold in the tumor-derived cells expressing $\alpha_V\beta_3$ integrin.

PC-3 and MDA-MB-231 cells were exposed to a 4 h treatment with 1 μM AuNPs **13** and AuNPs **14** as a negative control. AuNPs **13** were demonstrated to positively stain prostate cancer cells with a spot-like pattern. The confocal analysis of PC-3 cells stained with AuNPs **13** revealed that the signal given by fluorescein and the reflection spectrum given by gold nanoparticles were perfectly merged and localized near the cell adhesive contacts (Figure 3). Therefore, this ultimately suggested that the internalization took place in the membrane zones where integrin $\alpha_V\beta_3$ is mainly expressed, which are focal contacts. Notably, breast adenocarcinoma cells subjected to the treatment previously described did not shown any sign of fluorescence or reflection. In addition, the control nanoparticles **14** gave no signal at all on both the cell lines (see Supporting Information, Figure 10), suggesting that the effectiveness and the specificity of AuNPs **13** were due to the presence of the cyclic RGD peptidomimetic.

dx.doi.org/10.1021/bc100448r |*Bioconjugate Chem.* 2011, 22, 664–672

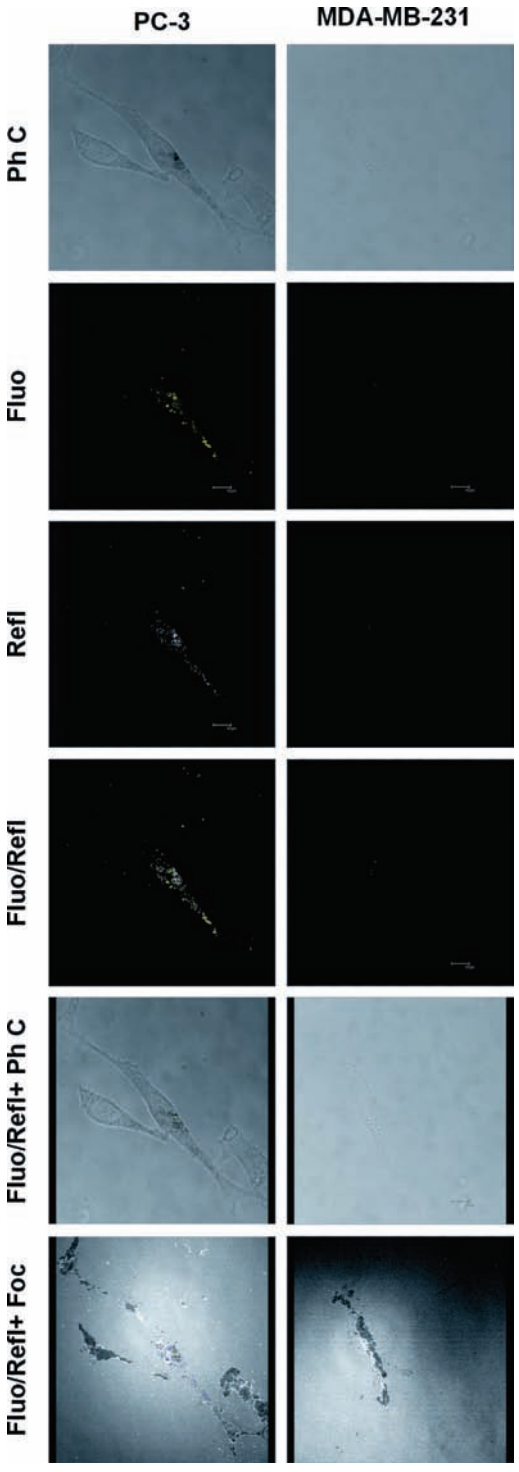

Figure 3. Biological activity of functionalized gold nanoparticles **13** on PC-3 and MDA-MB-231 cells. PC-3 and MDA-MB-231 cells were incubated 4 h with 1 μM AuNPs **13**. The signal provided by AuNPs **13** was detected in PC-3, but not in MDA-MB-231 cells. In particular, fluorescein signal and reflection spectrum of gold perfectly merged and were localized near the cell adhesive contacts. Ph C: phase contrast; Fluo: Fluorescence; Refl: Reflection; Foc: Focal adhesion. Gray: gold reflection; Green: fluorescein signal; Purple: merge. Original magnification 63×. Scale bar 10 μm.

AuNPs **12**, functionalized only with cRGD, were also tested on both PC-3 and MDA-MB-231 cell lines. As expected, the confocal analysis did not reveal any fluorescent signal, but only the reflection spectrum given by gold was detected in the case of PC-3 cells (see Supporting Information, Figure 11S). MDA-MB-231 cells showed only a slightly sign of reflection.

These data showed that gold nanoparticles fuctionalized with cRGD were able to interact specifically with cells expressing $\alpha_V\beta_3$ integrin; in fact, only a faint amount of gold nanoparticles were detected in the case of adenocarcinoma cells. It was interesting to note that the interaction occurred despite the negative charge present on the nanoparticle surfaces.

In order to evaluate the efficiency of gold nanoparticles in targeting $\alpha_V\beta_3$ expressing cells, we compared these results with data obtained with the most active fluorescein-conjugated compound (Figure 1) previously reported by our research group.[18] Surprisingly, we observed that the signal of PC-3 cells stained with 1 μM AuNPs **13** was stronger than the signal showed by the same cell line treated with a 10-fold higher concentration (10 μM) of fluorescein-conjugated cRGD (see Supporting Information, Figure 12). This result was in contrast with the expected quenching of the FITC signal by gold nanoparticles, but it was partially explained by the fact that very small gold nanoparticles are characterized by different properties in comparison with bigger AuNPs.

DISCUSSION

Gold nanoparticles are considered particularly interesting for cancer diagnosis and therapy on account of their unique physical properties. Moreover, the tunable size, the facile surface chemistry, and their reduced toxicity render Au nanoparticles even more attractive as polyvalent platform for targeted drug delivery.

In this paper, we describe the synthesis, characterization, and biological activity of gold nanoparticles conjugated on their surface with an RGD containing integrin ligand.

Gold nanoparticles **12** and **13** showed an enhanced ability to inhibit the binding of biotinylated vitronectin to immobilized $\alpha_V\beta_3$ integrin if compared with unconjugated compound **4** (**DB 58**), with affinity in the low or sub nanomolar range (0.4 nM and 1.7 nM, respectively). This result was obtained by the contemporary presentation of several cRGD ligands on the gold nanoparticles thus displaying a cooperative effect.

The cell studies showed that AuNPs **13** positively stained prostate cancer cells. In particular, the signal provided by fluorescein and that given by gold nanoparticles were perfectly merged and localized near the focal contacts. This evidence finally suggested that the internalization took place in the membrane zones where integrin $\alpha_V\beta_3$ is mainly expressed, that is, the cell adhesive contacts. The control nanoparticles **14** did not stain PC-3 cells at all. Moreover, MDA-MB-231 breast adenocarcinoma cells, expressing very low levels of $\alpha_V\beta_3$ integrin, did not show any sign of fluorescence either in the case of AuNPs **13** or AuNPs **14** treatment, thus demonstrating that AuNPs **13** interaction was specific for integrin $\alpha_V\beta_3$ overexpressing cells. AuNPs **12** revealed a similar behavior though they were detected only through the reflection signal given by gold.

In summary, the described cRGD conjugated gold nanoparticles display an enhanced affinity for $\alpha_V\beta_3$ integrin and *in vitro* positively and specifically target $\alpha_V\beta_3$ overexpressing cells, suggesting their potential future use as vectors for tumor targeted therapy.

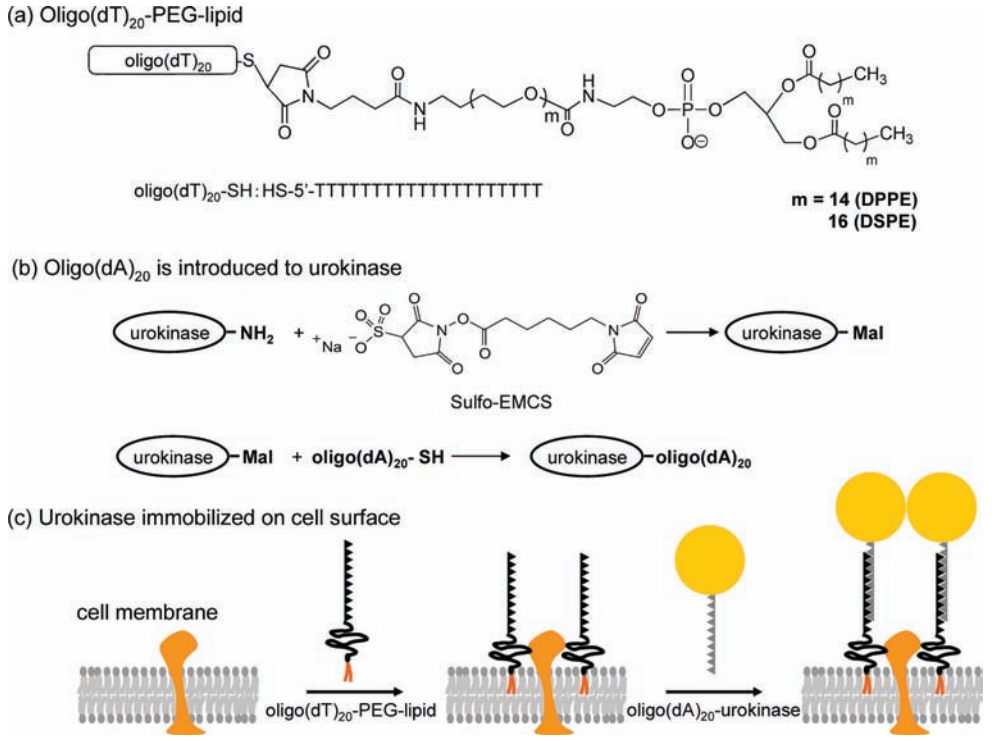
ABSTRACT: Transplantation of islets of Langerhans (islets) has been proposed as a safe, effective approach to treating patients with insulin-dependent diabetes mellitus (type I diabetes). It has been reported, however, that many islets are lost in the early phase after intraportal transplantation by instant blood coagulation-mediated inflammatory reactions. In this study, DNA hybridization was applied to conjugate the fibrinolytic enzyme urokinase on the islet surface. We synthesized amphiphilic polymers, PEG-lipids carrying oligo(dT)$_{20}$ (oligo(dT)$_{20}$−PEG-lipid; PEG MW = 5000) and urokinase (UK) carrying oligo(dA)$_{20}$. The oligo(dT)$_{20}$−PEG-lipid was spontaneously incorporated into the cell membrane through interactions between the hydrophobic parts of the PEG-lipids and the lipid bilayer, and UK was conjugated on the cell surface through DNA hybridization between oligo(dT)$_{20}$ on the cell and complementary oligo(dA)$_{20}$ on the UK. The activity of UK was maintained on the islet surface. The surface modification with UK did not influence islet morphology or islet ability to secrete insulin in response to changes in glucose concentration. No practical volume increase was observed with our method, indicating that islet graft loss could be suppressed at the early stage of intraportal islet transplantation.

INTRODUCTION

Transplantation of islets of Langerhans (islets) has been proposed as a safe and effective method for treating patients with insulin-dependent diabetes mellitus (type I diabetes).[1,2] Intraportal islet transplantation combined with the Edmonton protocol has had demonstrable clinical success. Multiple donors of pancreases, however, are still needed to achieve normalized blood glucose levels without insulin injection. This necessity is attributable to the loss of many islets in the early phase after intraportal transplantation by instant blood-mediated inflammatory reactions (IBMIR).[2−8] It has been reported that a lot of islets are known to be damaged by IBMIR within a few hours.[9] If blood coagulation induced by transplanted islets can be inhibited, most of the islets could be rescued.

Systemic administration of some anticoagulants has been tried to achieve this outcome,[6,7] but patients may then be at a high risk for bleeding. Recently, alternative ideas have been proposed for the suppression of IBMIR,[10−18] including islets coated with anticoagulants such as heparin,[10] thrombomodulin,[11] fibrinolytic urokinase (UK),[14,15] or living cells,[12,16,18] to localize their antithrombogenic effects. Various improvements are still needed, however, for clinical application of these approaches. In some studies, the biotin/streptavidin reaction has been used to conjugate antithrombogenic materials. Streptavidin, however, is an immunogenic protein derived from bacteria[19,20] and is likely not appropriate for use in surface modification of islets for clinical uses. In the other studies, chemical modification of membrane proteins has been employed, but this method is expected to deteriorate islet cell functions.

Our group has synthesized various amphiphilic polymers and applied them to surface modification of cells to conjugate antithrombogenic materials and modulate the immunogenicity of cells.[13−18,21−26] Poly(ethylene glycol)−phospholipid conjugates (PEG-lipids) have been successfully applied to cell surface modification. They are spontaneously incorporated into the cell membrane through interactions between the hydrophobic parts of the PEG-lipids and the lipid bilayer. We have further advanced our technology to easily modify the cell surface with various bioactive substances by conjugating single stranded DNA with PEG-lipids (ssDNA−PEG-lipids).[18,24] In this study, we employed DNA hybridization to modify the islet surface with the plasminogen activator UK using ssDNA−PEG-lipid.



EXPERIMENTAL PROCEDURES

Materials. α-*N*-Hydroxysuccinimidyl-ω-maleimidyl poly(ethylene glycol) (NHS-PEG-Mal, MW 5000), 1,2-dipalmitoyl-*sn*-glycerol-3-phosphatidylethanolamine (DPPE), and 1,2-distearoyl-*sn*-glycerol-3-phosphatidylethanolamine (DSPE) were purchased from NOF Corporation (Tokyo, Japan). Dichloromethane, chloroform, diethyl ether, dimethyl sulfoxide (DMSO), triethylamine (TEA), penicillin−streptomycin mixed solution, and heparin sodium salt were bought from Nacalai Tesque (Kyoto, Japan). Fetal bovine serum (FBS) was purchased from BioWest (Miami, FL, USA) and

Scheme 1. Method to Conjugate UK on the Cell Surface through DNA Hybridization[a]

[a] (a) Chemical structure of oligo(dT)$_{20}$-conjugated PEG-lipid (oligo(dT)$_{20}$−PEG-lipid). (b) UK is modified with Sulfo-EMCS to introduce maleimide groups, and then oligo(dA)$_{20}$-SH is conjugated on UK through the thiol/maleimide reaction. (c) Oligo(dT)$_{20}$−PEG-lipid is incorporated into the cell surface by the hydrophobic interaction between alkyl chains and the lipid bilayer of the cell membrane. Oligo(dA)$_{20}$-UK is applied to cells carrying oligo(dT)$_{20}$. UK is conjugated on the cell surface through oligo(dT)$_{20}$−oligo(dA)$_{20}$ hybridization.

phosphate-buffered saline (PBS) from Nissui Pharmaceutical, Co., Ltd. (Tokyo, Japan). Alexa 488-labeled rabbit antigoat IgG, HEPES buffer solution, Medium 199, and Hanks' balanced salt solution (HBSS) were purchased from Invitrogen, Co. (Carlsbad, CA, USA). Urokinase (UK) was purchased from American Research Products, Inc. (Belmont, MA, USA), polyclonal goat antihuman UK from Abcam plc. (Cambridge, UK), and *N*-[ε-maleimidocaproyloxy]sulfosuccinimide ester (Sulfo-EMCS) from Pierce Biotechnology, Inc. (Rockford, IL). Thrombin was obtained from Kayaku Co., Ltd. (Saitama, Japan). Fibrinogen type I, plasminogen (from human plasma), and oligo(dA)$_{20}$ and oligo(dT)$_{20}$ carrying a protected SH group at the 5′-end (oligo(dA)$_{20}$-SH, oligo(dT)$_{20}$-SH) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Oligo(dA)$_{20}$ and oligo(dT)$_{20}$ with a 5′-end SH group were prepared by reduction of the disulfide bond with dithiothreitol (DTT) according to the manufacturer's instructions.

Synthesis of Oligo(dT)$_{20}$−PEG-Lipids and Oligo(dA)$_{20}$-Conjugated UK. Oligo(dT)$_{20}$-conjugated PEG-lipids (oligo(dT)$_{20}$−PEG-DPPE, oligo(dT)$_{20}$−PEG-DSPE, Scheme 1(a)) were synthesized following the method reported previously.[18,24] UK (1 mg/mL in PBS, 100 μL) and sulfo-EMCS (0.38 mg/mL in PBS, 20 μL) were mixed together and left for 2 h at room temperature to prepare Mal-UK (Scheme 1(b)). Mal-UK was isolated with Sephadex G25 and freeze-dried. Mal-UK (1 mg/mL in PBS, 20 μL) was mixed with oligo(dA)$_{20}$-SH (150 μg/mL in PBS, 80 μL) for 2 h at room temperature to prepare oligo(dA)$_{20}$-UK.

Surface Modification of islets with UK through DNA Hybridization Using Oligo(dT)$_{20}$−PEG-Lipids. All animal experiments were approved and accepted by the animal care committee of Institute for Frontier Medical Sciences, Kyoto University. Pancreatic islets were isolated from the pancreas of Syrian hamsters (7 weeks old, female, Japan SLC, Inc., Shizuoka, Japan) by the collagenase digestion method.[27] As shown in Scheme 1(c), oligo(dT)$_{20}$−PEG-lipid was conjugated with islets as reported previously.[18,24] Briefly, oligo(dT)$_{20}$−PEG-lipid (500 μg/mL oligo(dT)$_{20}$−PEG-DPPE in PBS or 500 μg/mL oligo(dT)$_{20}$−PEG-DSPE in PBS containing 10% DMSO) was added to an islets suspension and left for 1 h at room temperature for oligo(dT)$_{20}$−PEG-DPPE or 30 min at 37 °C for oligo(dT)$_{20}$−PEG-DSPE. After the islets were washed with Medium 199 (serum free), oligo(dA)$_{20}$-UK (200 μg/mL) was added to the islets and left for 1 h at room temperature.

Immunostaining for UK was carried out as follows: UK-islets were incubated with 2% polyclonal goat antihuman UK antibody for 1 h at room temperature. After washing with medium, we incubated the UK-islets with fluorescence labeled secondary antibody and 0.2% Alexa 488-labeled rabbit antigoat IgG in medium for 1 h at room temperature, followed by washed with medium. Those islets were observed under a confocal laser scanning microscope (FV500; Olympus, Tokyo, Japan).

Measurement of UK Activity with the Fibrin Plate Assay. To examine the fibrinolytic activity of UK conjugated on islets, the fibrin plate assay was employed as previously reported with slight modifications.[28] Briefly, 8 mL of fibrinogen solution (10 mg/mL in saline supplemented with 0.2 mg plasminogen) was poured into a culture dish (ø =10 cm). A total of 30 μL of thrombin (60 IU/mL) was added to the solution and mixed well by rotating the plate. The plate was incubated for 3 h at room temperature to prepare a fibrin plate. The UK-islets (50 islets) cultured just after UK conjugation for 0 or 2 days and unmodified islets (50 islets) were applied to each spot on the fibrin plate. After incubation at 37 °C for 14 h, we

dx.doi.org/10.1021/bc100453r |*Bioconjugate Chem.* 2011, 22, 673–678

determined the size of the transparent area formed around the islet spots to measure fibrinolytic activity.

Glucose Stimulation Test of UK-Islets. Static insulin secretion tests were performed using 50 islets to examine their ability to change insulin secretion in response to changes in glucose concentration. Unmodified islets and UK-islets after 0 or 2 days in culture were used for the assay. Islets were exposed to 0.1 g/dL, then 0.3 g/dL, and finally 0.1 g/dL of glucose in Krebs-Ringer solution for 1 h each at 37 °C. The solutions were collected after the 1-h incubation in each glucose concentration, and insulin concentrations were determined in each solution by enzyme-linked immunosorbent assay (ELISA). The ELISA kit for the insulin assay was purchased from Shibayagi, Co., Ltd. (Gunma, Japan).

RESULTS

UK Conjugation on Islet Surfaces through DNA Hybridization. Scheme 1 shows the method for islet surface modification with UK through DNA hybridization using a ssDNA−PEG-lipid conjugate. When the oligo$(dT)_{20}$−PEG-lipid is mixed with islets, the hydrophobic lipid part is spontaneously incorporated into a lipid bilayer of the cell membrane through the hydrophobic interaction.[18,24] The oligo$(dT)_{20}$ segment of the oligo$(dT)_{20}$−PEG-lipid was presented on the cell surface. It can be used for the conjugation of bioactive substances on the cell surface through the hybridization of oligo$(dT)_{20}$−oligo$(dA)_{20}$.

Confocal Fluorescent Microscopic Observation of UK Conjugation on the Islet Surface. Islets were sequentially treated with oligo$(dT)_{20}$−PEG-DPPE or oligo$(dT)_{20}$−PEG-DSPE and oligo$(dA)_{20}$-UK as illustrated in Scheme 1(c). Oligo$(dA)_{20}$-modified UK was conjugated on a cell surface that had been modified with oligo$(dT)_{20}$−PEG-lipid. Figure 1 shows confocal laser-scanning fluorescence images of UK-islets, which were subjected to immunostaining for UK. Fluorescence was clearly observed on the UK-islets (Figure 1(a)). However, very weak fluorescence was observed on unmodified islets or islets treated with oligo$(dA)_{20}$-UK in the absence of oligo$(dT)_{20}$−PEG-lipids due to a nonspecific stain (Figure 1(b)). The conjugation of UK through DNA hybridization was also demonstrated on a gold surface carrying oligo$(dT)_{20}$ by surface plasmon resonance (SPR) measurement (see Figure S1 in Supporting Information). These results indicated that oligo$(dT)_{20}$ groups could be introduced onto the islet surface through the hydrophobic interaction between two long alkyl chains of the oligo$(dT)_{20}$−PEG-DPPE or oligo$(dT)_{20}$−PEG-DSPE and a lipid bilayer of the islet membrane, and oligo$(dA)_{20}$-UK could be conjugated through DNA hybridization onto the islet surface where oligo$(dT)_{20}$−PEG-lipids had been introduced.

The retention time of oligo$(dT)_{20}$−PEG-lipid on the cell membrane depends on the chain lengths of PEG-lipids.[26] Here, oligo$(dT)_{20}$−PEG-DPPE and oligo$(dT)_{20}$−PEG-DSPE with alkyl chains of 16 and 18 ($-CH_2-$) groups, respectively, were employed to determine the effect of chain lengths on the retention time of UK on islets. Oligo$(dA)_{20}$-UK could be conjugated onto the islet surface via oligo$(dT)_{20}$− oligo$(dA)_{20}$ hybridization without damaging islet morphology (Figure 1a). For 2 day cultures after conjugation, fluorescence was still observed for islets treated with oligo$(dT)_{20}$−PEG-DSPE, whereas fluorescence faded for those treated with oligo$(dT)_{20}$−PEG-DPPE. The retention of UK on the islet surface was prolonged with increasing alkyl chain length.

UK Conjugation onto the Islet Surface through DNA Hybridization. UK is a serine protease that activates plasminogen into plasmin, which dissolves fibrin blood clots. UK was

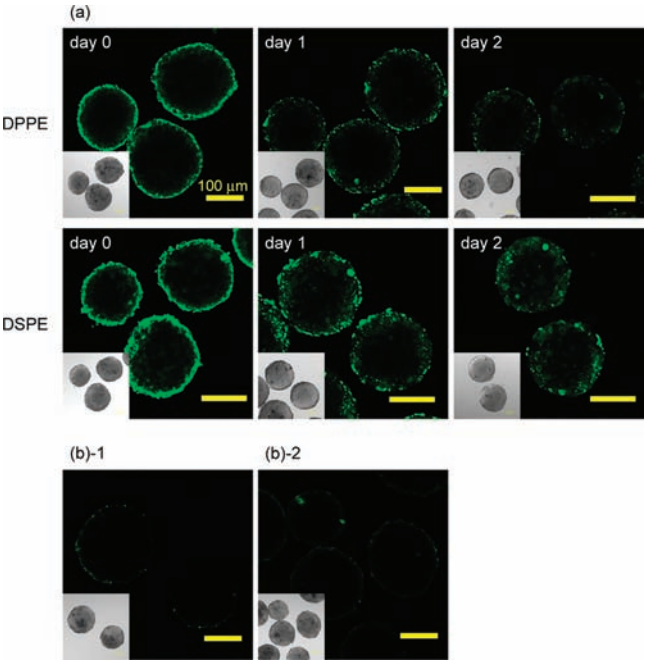

Figure 1. Confocal laser scanning microscopic images of UK-islets which were subjected to immunostaining for UK. (a) Islets were modified with oligo$(dT)_{20}$−PEG-DPPE or oligo$(dT)_{20}$−PEG-DSPE and then oligo$(dA)_{20}$-UK. The UK-islets just after treatment, after 1 and 2 days of culture. conjugated onto the surface of islets to dissolve blood clots surrounding islets in the liver for inhibition of the cascade reactions of IBMIR. Islets were treated with oligo$(dT)_{20}$−PEG-lipid (oligo$(dT)_{20}$−PEG-DPPE or oligo$(dT)_{20}$−PEG-DSPE) and then with oligo$(dA)_{20}$-UK as illustrated in Scheme 1(c). A fibrin plate−based assay was performed to assess the function of the UK conjugated on the islets. Fifty islets with/without UK were applied to each spot on a fibrin gel plate, and the area of dissolved fibrin formed around the spotted UK-islets was observed. Figure 2 shows the fibrin plate at 14 h after spotting of the UK-islets. Larger transparent areas were observed around the UK-islets than were seen surround the unmodified islets, as shown in Figure 2a 1, 2, and 4. These indicate that the UK retained its activity after conjugation on the islets. Islets that were cultured for 2 days after UK conjugation were also applied to the fibrin plate for the determination of the retention of UK activity. The transparent areas for the islets carrying UK through oligo$(dT)_{20}$−PEG-DSPE (Figure 2a 5) were slightly larger than that for the islets carrying UK through oligo$(dT)_{20}$−PEG-DPPE (Figure 2a 3). The morphology of all islets after modification with UK was maintained well after 7 days of culture in medium (Figure 2b). These results indicated that the conjugation of UK by DNA hybridization did not deteriorate the islets.

Glucose Stimulation Test of UK-Islets. Static glucose stimulation tests were performed to evaluate the effect of UK conjugation on the insulin-releasing ability of islets. The tests were performed just after UK conjugation or after an additional 2 days of culture. Figure 3 summarizes the results. When the glucose concentration was increased from 0.1 g/dL to 0.3 g/dL, amounts of released insulin increased from basal levels for all groups. Although the amounts of released insulin from UK-islets were less than those from the unmodified islets, the glucose

(1) Unmodified islets; (2) UK conjugated on islets through oligo$(dT)_{20}$−PEG-DPPE just after preparation; (3) UK conjugated on islets through oligo$(dT)_{20}$−PEG-DPPE after 2 days of culture; (4) UK conjugated on islets through oligo$(dT)_{20}$−PEG-DSPE just after preparation; and (5) UK conjugated on islets through oligo$(dT)_{20}$−PEG-DSPE after 2 days of culture. Fifty islets were applied to each spot, and the plate was observed after incubation at 37 °C for 14 h. (b) Morphology of UK conjugated islets after 1 and 7 days of culture.

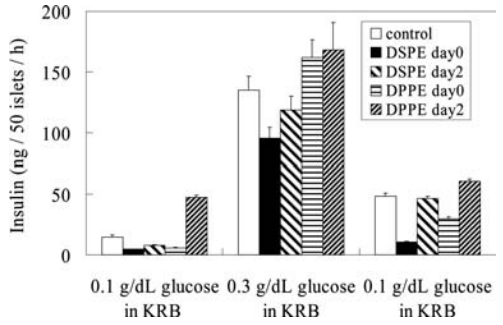

Figure 3. Glucose stimulation test. Bars from the left indicate amounts of insulin release for unmodified islets, UK-islets (oligo$(dT)_{20}$−PEG-DSPE) just after preparation, UK-islets (oligo$(dT)_{20}$−PEG-DSPE) after 2 days of culture, UK-islets (oligo$(dT)_{20}$−PEG-DPPE) just after preparation, and UK-islets (oligo$(dT)_{20}$−PEG-DPPE) after 2 days of culture.

stimulation indices for modified islets were greater than those of the unmodified islets. The amounts of released insulin decreased to basal levels when the islets were re-exposed to low glucose (0.1 g/dL). Although the surface modification with PEG-lipid and UK-conjugation slightly deteriorated the insulin secretion ability of islets, the modified islets controlled insulin release in response to glucose level changes.

DISCUSSION

Some obstacles remain for clinical islet transplantation, including the side effects of immune-suppressive drugs, low efficiency in islet isolation, difficulty of islet preservation, and early graft loss by IBMIR. With early graft loss induced by IBMIR, thrombotic reactions initiate when islets come into direct contact with blood in the portal vein. Blood coagulation triggers successive reactions, such as the inflammatory response, infiltration of leukocytes into islets, disruption of islet integrity, and resulting islet loss.[2−8] Therefore, it has been thought that suppression of blood coagulation would lead to better graft survival. To improve the blood compatibility of islets, the islet surface has been coated with anticoagulants such as heparin and thrombomodulin, or fibrinolytic UK, and the living cells examined.[10−18] Our group has reported some methods to conjugate bioactive substances onto the surface of islets using amphiphilic polymers such as PEG-lipid through hydrophobic interactions.[13−16] PEG-lipid is anchored to the lipid bilayer of the cell membrane through hydrophobic interactions, and the functional group at the other end of the PEG chain can be used for further conjugation of bioactive substances. In one study, we employed the biotin/streptavidin reaction;[14] although this reaction is strong and specific, it is difficult to apply in clinical islet transplantation because of the strong antigenecity of streptavidin, which is derived from bacteria. We also examined the thiol/maleimide reaction in another study[15] and found that the conjugation efficiency requires improvement because thiol groups easily form disulfide bonds under physiological conditions, resulting in low efficiency. We have sought improved methods to overcome these issues.

Further, our group has examined DNA hybridization to immobilize cells onto a surface. In a previous study,[24] oligo$(dT)_{20}$ carrying a thiol group was introduced onto a gold surface, and cells carrying oligo$(dA)_{20}$ were applied to the surface. The cells were locally immobilized on a specific site where oligo$(dT)_{20}$ was introduced. In the current study, we applied this method to conjugate UK on islets. We synthesized amphiphilic polymers, PEG-lipids carrying ssDNA. These were conjugated onto the cell membrane through interactions between the hydrophobic parts of the PEG-lipids and the lipid bilayer, and UK was conjugated on the cell surface through DNA hybridization between oligo$(dT)_{20}$ on the cell and complementary oligo$(dA)_{20}$ on the UK. As shown in Figures 1, 2, and 3, no adverse effect was observed in terms of islet morphology and function. This DNA hybridization is a versatile method for the conjugation of various bioactive substances on the cell surface. ssDNAs rapidly form a complex under physiological conditions, and the complex is biocompatible. Moreover, we expect that several different kinds of substances can be conjugated easily by using different DNA sequences.

The retention time of PEG-lipids on cell membranes depends on the alkyl chain length of lipids, and the retention time of PEG-DSPE on cell membranes is longer than that of PEG-DPPE.[26]

In this study, we expected UK to be retained longer on islets when oligo$(dT)_{20}$−PEG-DSPE was employed compared to when oligo$(dT)_{20}$−PEG-DPPE was employed; however, no clear prolongation was observed in UK activity, as shown in Figure 2a. UK activity disappeared during 4 days of culture in either case because the hydrophobicity of DSPE or DPPE was not great enough for the conjugation of a hydrophilic protein like UK with its high molecular weight (54 kDa).

Thrombosis formation initiates when islets come into direct contact with blood in the portal vein, resulting in early graft loss induced by IBMIR. On the basis of our findings, we expect that islets can be rescued by the conjugation of UK on the islet surface because UK controls thrombosis formation. The efficacy of our UK-islets in inhibiting IBMIR should be carefully examined using *in vivo* models.

CONCLUSIONS

Fibrinolytic UK can be conjugated on the surfaces of islets through DNA hybridization using ssDNA−PEG-lipid. The activity of UK was maintained on the islet surface, and the surface modifications did not influence islet morphology or islet ability to secrete insulin in response to changes in glucose concentration. We expect that UK on islets can inhibit instant blood coagulation-mediated inflammatory reactions, thus suppressing islet graft loss at the early stage of islet transplantation.

Surface plasmon resonance analyses of UK immobilization through DNA hybridization. To examine the conjugation of urokinase through DNA hybridization, an in-house–designed surface plasmon resonance (SPR) instrument (*1*) was used for monitoring the reaction. Gold-coated BK-7 glass plates (refractive index: 1.515, size: 25 × 25 × 1 mm, Arteglass Associates Co., Kyoto, Japan) were immersed in a solution of oligo$(dT)_{20}$-SH (50 μg/mL in PBS) for 24 h to conjugate oligo$(dT)_{20}$ onto the gold surface through Au/thiol bonding. The glass plates were washed thoroughly with pure water and 2-propanol sequentially. Each glass plate was set in the SPR flow cell, and a blocking solution of BSA (10 mg/mL in PBS) flowed onto the surface, followed by flowing of a solution of oligo$(dA)_{20}$-UK (5 μg/mL in PBS). In a control experiment, a solution of oligo$(dT)_{20}$-UK (5 μg/mL in PBS) was applied after flowing of blocking solution. The sample solutions and PBS were allowed to circulate through the flow cell at 4.0 mL/min, and all SPR measurements were performed at 37 °C.

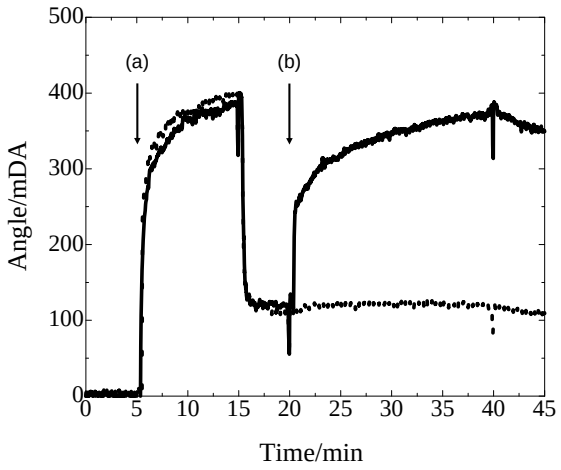

Figure S1. Surface plasmon resonance sensorigrams of interaction between oligo$(dA)_{20}$-UK and the oligo$(dT)_{20}$-incorporated surface. After a BSA solution was applied to block non-specific sites on the oligo$(dT)_{20}$-incorporated substrate (a), oligo$(dA)_{20}$-UK (solid line) or oligo$(dT)_{20}$-UK (dotted line) was allowed to flow (b).

The SPR method, which serves to monitor events on the gold surface, was employed to examine binding and stability of proteins through the DNA hybridization between oligo$(dA)_{20}$-modified proteins and oligo$(dT)_{20}$ on the gold thin layer in real time. Figure S1 shows the SPR profiles for interactions between oligo$(dA)_{20}$-UK or oligo$(dT)_{20}$-UK and oligo$(dT)_{20}$ on the substrate. The initial increases in the SPR profiles show conjugation of oligo$(dT)_{20}$-SH on the gold surface by the Au/thiol reaction. The surface was blocked by a BSA solution for 10 min before the addition of a oligo$(dA)_{20}$-UK or oligo$(dT)_{20}$-UK solution. The second increase in the solid line of Figure S1 shows the binding of oligo$(dA)_{20}$-UK onto the oligo$(dT)_{20}$ substrate, whereas no such increase was observed when oligo$(dT)_{20}$-UK was applied to the oligo$(dT)_{20}$ substrate, as shown by the dashed line in Figure S1. These results show that UK could be specifically conjugated on the surface through hybridization between oligo$(dA)_{20}$ on UK and oligo$(dT)_{20}$ on the surface. In addition, oligo$(dA)_{20}$-UK can be conjugated onto a cell surface modified with a oligo$(dT)_{20}$–PEG-lipid conjugate through DNA hybridization.

Supporting Information

ABSTRACT: A modular dendrimer-based drug delivery platform was designed to improve upon existing limitations in single dendrimer systems. Using this modular strategy, a biologically active platform containing receptor mediated targeting and fluorescence imaging modules was synthesized by coupling a folic acid (FA) conjugated dendrimer with a fluorescein isothiocyanate (FITC) conjugated dendrimer. The two different dendrimer modules were coupled via the 1,3-dipolar cycloaddition reaction ("click" chemistry) between an alkyne moiety on the surface of the first dendrimer and an azide moiety on the second dendrimer. Two simplified model systems were also synthesized to develop appropriate "click" reaction conditions and aid in spectroscopic assignments. Conjugates were characterized by ^{1}H NMR spectroscopy and NOESY. The FA-FITC modular platform was evaluated *in vitro* with a human epithelial cancer cell line (KB) and found to specifically target the overexpressed folic acid receptor.

INTRODUCTION

The high toxicity of conventional cytotoxic anticancer drugs often forces these agents to be given at suboptimal dosages, and this can result in treatment failure.[1] To resolve this problem, delivery platforms that can discriminate between healthy and malignant cells have been developed.[1,2] Actively targeted therapeutic delivery platforms consist of three different components: a targeting component comprising targeting ligands with affinities for molecules expressed on cancer cells; a payload consisting of drug and/or imaging agents; and a nanoscale structure to which the targeting and payload moieties are attached. This platform targeting of anticancer drugs with cancer cell-specific ligands can dramatically improve a drug's therapeutic index. Conjugating multiple targeting ligands to a single platform molecule further increases the potential for specific targeting of cancer cells by allowing the possibility of multivalent interactions.[3,4]

The structural design of these types of delivery platforms is critical to the success of the delivery device. Numerous classes of targeted drug delivery platforms have been developed that potentially meet the requirements needed to combine targeting ligands, imaging agents, and drug molecules together to deliver the therapeutic payload to a desired location in the body. These include drug-target conjugates, linear polymers, lipid-based carriers (liposomes and micelles), carbon nanotubes, inorganic nanoparticles, and dendrimers. Several of these different delivery platforms are progressing toward or through clinical trials for cancer treatments with promising results.[2] Each approach, however, is not without limitations and the potential for widespread application of these platforms in their present design is unclear.

Dendrimer-based platforms have a unique branching structure which results in exceptionally high degrees of monodispersity and well-defined terminal groups that provide the ability to form soluble conjugates containing multiple copies of hydrophobic drug and/or targeting molecules. The compact, branched structures appear to enhance the ability of the targeting molecules to interact in a fashion conducive to multivalent binding to cell membrane receptors.[3] The dendrimer's small size enables efficient diffusion across the vascular endothelium to find tumors and also allows the rapid clearance of these molecules from the bloodstream. This clearance avoids potential long-term toxicities and reduces the necessity of a rapidly degradable platform. The most widely used dendrimer in biomedical applications, poly(amidoamine) (PAMAM), is nonimunogenetic and nontoxic once the surface primary amines have been modified.[5−10] There have been numerous, recent examples describing the development of dendrimer-based targeted

delivery systems using a wide variety of targeting ligands including monoclonal antibodies,[11−15] peptides,[16] T-antigens,[17−19] and folic acid.[20−29]

Despite the success of these dendrimer-based platforms, this approach has several challenges associated with its implementation. First, the synthesis of dendrimers with different functional groups for targeted delivery (including targeting, drug, and imaging agents) requires a laborious chemical process that is unique for each different molecular combination. Second, the carrying capacity of a single dendrimer, although significantly better than other types of delivery platforms, is finite due to limits in surface molecule density and solubility. This becomes a problem when one attempts to conjugate multiple copies of the target, drug, and/or dye molecules to the same dendrimer. Third, significant increases in heterogeneity occur with the conjugation of each additional molecule to a single dendrimer platform due to the stochastic nature of these chemical reactions.[30] This has limited the flexibility of these systems.

To address the drawbacks of the single dendrimer platforms, several groups have sought to apply modular design concepts to dendrimer systems.[31−41] The common premise of this new approach is to use dendrimers or dendrons as modular units, each with multiple copies of a single functional molecule. Multifunctional platforms can be generated by combining different modules through a universal coupling mechanism. The main benefits of this design are twofold: First, segregating each functional group (drug/target/dye) to a different dendrimer module avoids the need to develop a new orthogonal coupling chemistry for each new combination of functional groups. This advantage should not be underestimated. Significant time is spent developing new orthogonal coupling strategies for desired functional combinations because many of the component drug molecules and targeting ligands (Taxol and RGD, for example) are susceptible to a loss of activity due to undesired cross reactions as well as degradation by hydrolysis. The second benefit of the modular strategy is a greater carrying capacity of the delivery platform, because the different functional molecules are localized on separate dendrimer units and the water solubilizing dendrimer backbone is effectively double the mass of the single dendrimer.

In the modular dendrimer systems synthesized to date, two coupling strategies have been used to combine different dendrimer-based modules together: oligonucleotide self-assembly and the 1,3-dipolar cycloaddition between an azide and an alkyne, commonly called "click" chemistry. Oligonucleotide self-assembly has been used to link both dendron and dendrimer modular units. Choi and co-workers demonstrated this strategy by using two complementary oligonucleotides to link two PAMAM dendrimers together.[31,32] DeMattie, Huang, and Tomalia used the same method to connect two unfunctionalized PAMAM dendrons together.[33] Characterization of these systems was accomplished by gel electrophoresis, AFM, MALDI, and UV/vis due to the small synthetic scales employed. For the dendrimer-based system, isolated dendrimer samples were not obtained; rather, the samples were generated in solution. Choi et al. did demonstrate biological functionality of the modular system in a cell culture assay[32] and an *in vivo* model.[34]

The use of "click" chemistry to create dendritic modular systems has mainly involved dendrons. "Click" chemistry is a particularly attractive coupling method because it can be performed with a wide variety of solvent conditions including aqueous environments. The stable triazole ring bridge, resulting from coupling alkyne with azide moieties, is frequently achieved at near quantitative yields and is considered to be biologically stable.[42−44] Furthermore, the "click" coupling chemistry is orthogonal to the coupling chemistries typically used to attach functional groups to the dendrimer. Lee and co-workers have detailed the synthesis of multimodule platforms using both unfunctionalized PAMAM dendrons[35−37] and unfunctionalized Frechet-type dendrons[38] for each of the modules. In all of these systems, the focal point of the dendron possessed either an azide or alkyne moiety. Wu and co-workers developed a 2,2-bis-(hydroxymethyl)propionic acid (bis-MPA) based asymmetric modular dendron with 16 mannose units and 2 coumarin chromophores, and demonstrated binding in a hemagglutination assay.[39] Goyal, Yoon, and Weck have also developed a poly(amine) dendrimer that possessed a single aldehyde or azide moiety on the dendrimer periphery capable of orthogonal functionalization by small molecule functional groups.[40,41] These approaches appear promising, but only the bis-MPA dendron system has been demonstrated to have function as a targeted drug delivery platform. In all cases, the dendrons used were G3 or smaller. This has significant limitations for widespread therapeutic use because of the limited carrying capacity of low generation dendrons. To date, click chemistry has not been applied to a modular dendrimer system.

In this paper, we report on a new modular approach based upon "clicking" together generation 5 (G5) PAMAM dendrimers containing either the targeting agent folic acid (FA) (**13**) or the dye fluorescein isothiocyanate (FITC) (**14**). The molecules were characterized by ^{1}H NMR spectroscopy and two-dimensional Nuclear Overhauser Effect Spectroscopy (NOESY). To the best of our knowledge, this is the first example of the successful "click" chemistry conjugation of dendrimers (as opposed to dendrons). Linking together two dendrimer-based modules was achieved by first conjugating one dendrimer module to an alkyne linker (**2b**) and conjugating a second dendrimer module to an azide linker (**3c**). The ability of this modular system to specifically target folic acid receptor (FAR) expressing cells has been verified by flow cytometric documentation of the uptake of the clicked FA-FITC modules into KB cells.

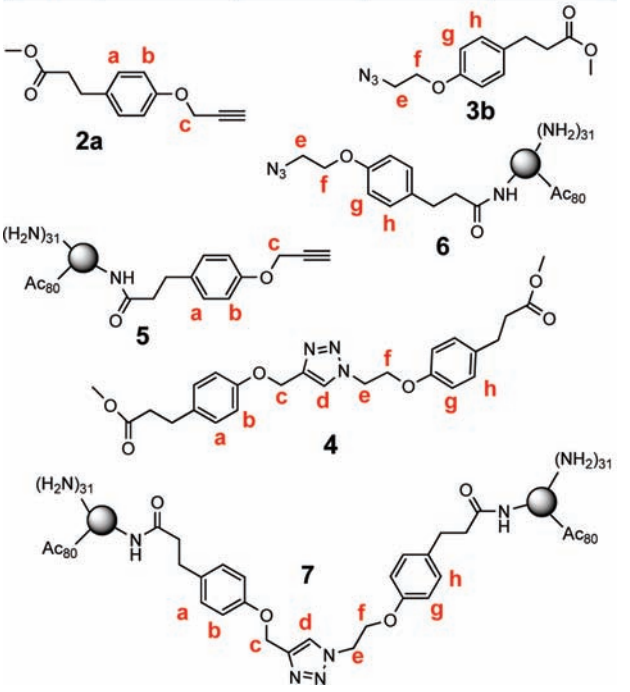
This dendrimer-based modular system has several potential benefits over predecessor systems. In using "click" chemistry rather than oligonucleotide linking, the modular system can be scaled up with far greater ease and at a substantially lower cost. Oligonucleotides are typically purchased in nanogram quantities, whereas the "click" linkers in this study were produced at the gram scale. Additionally, because the clicked dendrimers are covalently linked rather than joined via the hydrogen bond base-pairing oligonucleotide bridge, the platform is less likely to become unlinked. This characteristic proves beneficial when attempting to isolate and characterize multimodule platforms. In using generation 5 dendrimers with diameters of approximately 5 nm and over 630 hydrogen bonding sites, the carrying capacity is substantially greater than the previously used dendrons, which were approximately 2 nm in diameter and possess approximately 150 hydrogen bonding sites. In fact, efforts in our group to generate G2 and G3 PAMAM dendrons functionalized with folic acid, failed due to a loss of platform solubility.

EXPERIMENTAL PROCEDURES

Reagents and Materials. Biomedical grade, generation 5 PAMAM (poly(amidoamine)) dendrimer was purchased from Dendritech Inc. and purified by dialysis, as previously described,[30] to remove lower molecular weight impurities including trailing generation dendrimer defect structures.

MeOH (99.8%), acetic anhydride (99.5%), triethylamine (99.5%), dimethyl sulfoxide (99.9%), fluorescein isothiocyanate (98%), dimethylformamide (99.8%), 1-[3-(dimethylamino)-propyl-3-ethylcarbodiimide HCl (EDC) (98%), acetone (ACS reagent

grade ≥99.5%), methyl 3-(4-hydroxyphenyl)propanoate (97%), sodium azide (99.99%), 1-bromo-2-chloroethane (98%), ethyl acetate (EtOAc) (99.5%), copper sulfate pentahydrate (99%), sodium ascorbate, 18-crown-6, K_2CO_3, tetrahydrofuran (99.9%), *N*,*N*-diisopropylethylamine, benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (98%), D_2O, NaCl, 1 N HCl, 2 M KOH, and volumetric solutions (0.1 M HCl and 0.1 M NaOH) for potentiometric titration were purchased from Sigma Aldrich Co. and used as received. Hexanes (HPLC grade) and 10 000 molecular weight cutoff centrifugal filters (Amicon Ultra) were from Fisher Scientific. 1× phosphate buffer saline (PBS) (Ph = 7.4) without calcium or magnesium was purchased from Invitrogen. Sephadex G-25 and Sephadex LH-20 were purchased from GE Lifesciences.



Nuclear Magnetic Resonance Spectroscopy. All ^{1}H NMR experiments were conducted using a Varian Inova 500 MHz instrument. For all dendrimer samples, the delay time was 10s. No delay time was used for small molecule samples. NOESY experiments on the dendrimer samples found in Figure 1 and utilized for Table 1 were also conducted using a Varian Inova 500 MHz instrument. For these experiments, the mixing time was 250 ms, the relaxation time was 1 s, and the number of increments was 128 with 32 scans per increment. Temperature was controlled at 25 °C. The NOESY experiments on the small molecule model system found in Figure 1 and utilized in Table 1 were conducted using a Varian MR400 (400 MHz) instrument. For the experiments on the small molecules, the mixing time was 800 ms, the relaxation time was 1.2 s, and the number of increments was 200 with 4 scans per increment. On the basis of work published by Hoffman, the internal solvent reference peak for all experiments in $CDCl_3$ was set to 7.26 ppm. For experiments conducted in D_2O, the internal reference peak was set to 4.72 ppm.[45]

Gel Permeation Chromatography. GPC experiments were performed on an Alliance Waters 2690 separation module equipped with a 2487 dual wavelength UV absorbance detector (Waters Corporation), a Wyatt Dawn DSP laser photometer, and an Optilab DSP interferometric refractometer (Wyatt Technology Corporation). Columns employed were TosoHaas TSK-Gel Guard PHW 06762 (75 mm × 7.5 mm, 12 μm), G 2000 PW 05761 (300 mm × 7.5 mm, 10 μm), G 3000 PW 05762 (300 mm × 7.5 mm, 10 μm), and G 4000 PW (300 mm × 7.5 mm, 17 μm). Column temperature was maintained at 25 ± 0.1 °C with a Waters temperature control module. The isocratic mobile phase was 0.1 M citric acid and 0.025 wt % sodium azide, pH 2.74, at a flow rate of 1 mL/min. The sample concentration was 10 mg/5 mL with an injection volume of 100 μL. The weight average molecular weight, M_w, was determined by GPC, and the number average molecular weight, M_n, was calculated with *Astra 4.7* software (Wyatt Technology Corporation) based on the molecular weight distribution.

Reverse Phase High Performance Liquid Chromatography. HPLC analysis was carried out on a Waters Delta 600 HPLC system equipped with a Waters 2996 photodiode array detector, a Waters 717 Plus auto sampler, and Waters Fraction collector III. The instrument was controlled by *Empower 2* software. For analysis of the conjugates, a C5 silica-based RP-HPLC column (250 × 4.6 mm, 300 Å) connected to a C5 guard column (4 × 3 mm) was used. The mobile phase for elution of the conjugates was a linear gradient beginning with 90:10 (v/v) water/acetonitrile and ending with 10:90 (v/v) water/acetonitrile over 25 min at a flow rate of 1 mL/min. Trifluoroacetic acid (TFA) at 0.14 wt % concentration in water as well as in acetonitrile was used as a counterion.

Table 1. Good Correlation is Found between the Small Molecule Model System (2a, 3b, and 4) and the Dendrimer Model System (5, 6, and 7) for the Chemical Shifts (ppm) of Triazole Related Protons (a−h) both before and after the "Click" Reaction[a]

h	7.13	7.13	7.11	7.06

[a] Chemical shifts for protons in the model dendrimer system were detected primarily via NOESY experiments.

Cell Culture and Treatment. The uptake of the synthesized conjugates was performed using FA-receptor-expressing KB cells (ATCC #CCL-17) as we have described previously.[23] Cells were maintained in FA-free Roswell Park Memorial Institute-1640 (RPMI 1640) medium supplemented with 10% fetal bovine serum (FBS), 2 μM L-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin in 5% CO_2 at 37 °C. Cells were planted into 24 well plates at density of 250 000 per well and allowed to reach ~90% confluence on the day of the experiment. They were rinsed and incubated in serum free medium with conjugates for 1 h at 37 °C in 5% CO_2. In some wells, a 20-fold excess of free folic acid or the folic acid conjugated dendrimer was added 30 min prior to the addition of the dendrimer platform for the blocking of folate receptors.

Flow Cytometric Analysis. The cellular fluorescence was quantified on a Beckman-Coulter EPICS-XL MCL flow cytometer, and the data were analyzed using *Expo32* software (Beckman-Coulter,

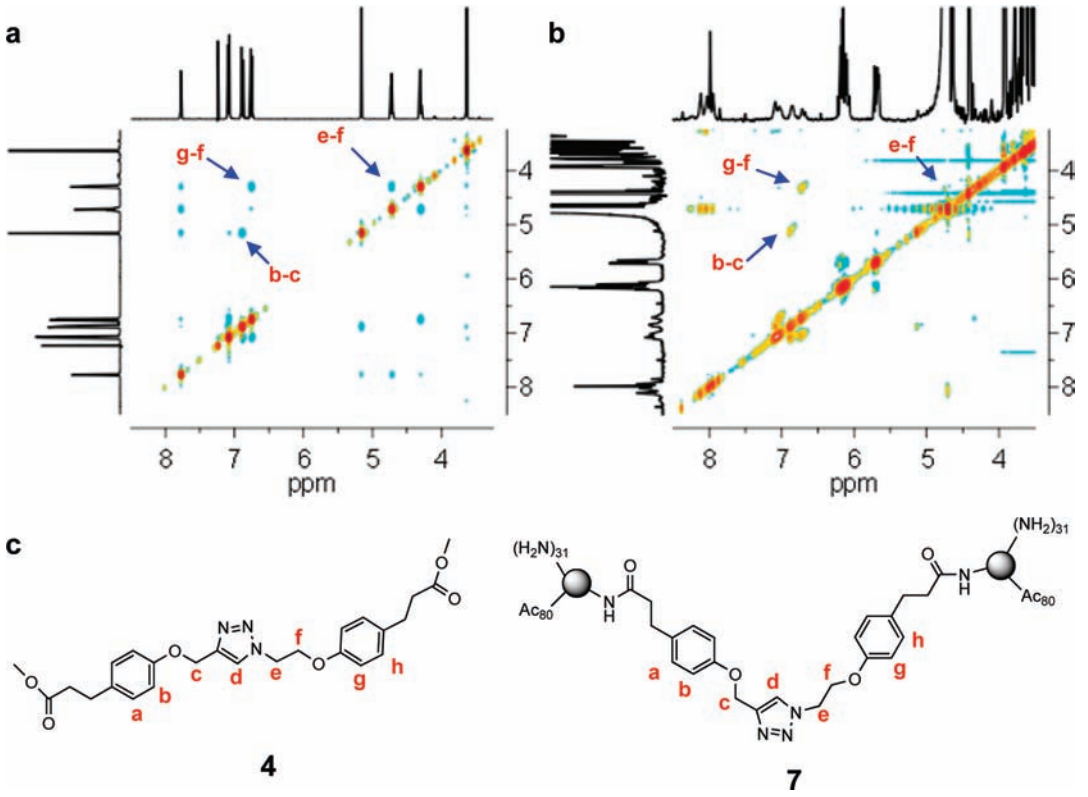

Figure 1. (a) NOESY of the small-molecule model system after the "click" reaction (**4**). NOE cross-peaks between triazole related protons (b, c, e, f, and g) are labeled. (b) NOESY of the model dendrimer system after the "click" reaction (**7**). NOE cross-peaks for the triazole related protons are similarly labeled. The cross-peaks in the 2D spectra reveal proton chemical shifts for the several of the triazole related protons that are otherwise obscured by overlapping dendrimer peaks. (c) Chemical structure and proton labels for the clicked small molecule model system (**4**) and the clicked dendrimer model system (**7**). The G5 PAMAM dendrimer is represented by a gray sphere.

Miami, FL). Cells were trypsinized, rinsed, and suspended in PBS containing 0.1% bovine serum albumin (PBSB). The viable cells were gated, and the mean FL1-fluorescence of 10 000 cells was quantified. Error bars are calculated using the half-peak coefficient of variation (HPCV).[46]

Synthesis. Dendrimers are identified by the core dendrimer (G5) and conjugated groups: Ac, Alkyne, Azide, FA, and FITC. In the cases where dendrimers are linked together via the triazole ring, alkyne and azide labels are replaced with "L." Ac refers to the acetamide termination, alkyne to linker **2b**, azide to linker **3c**, FA to folic acid, and FITC to fluorescein isothiocyanate.

Synthesis of Partially Acetylated Dendrimer ***1***. Partial acetylation of G5 PAMAM dendrimer was previously described.[5,30] The number average molecular weight (27 336 g/mol) and PDI (1.018) of the unacetylated dendrimer was determined by GPC. Potentiometric titration was conducted to determine the average number of primary amines per dendrimer (112 ± 5). Three batches of partially acetylated dendrimer were synthesized for further modification. **1′ G5Ac$_{72\%}$**: ^{1}H NMR integration determined the degree of acetylation to be 72%. Number average molecular weight (30 722 g/mol) was computed based on the addition of mass to the dendrimer from the acetyl groups as determined by NMR. PDI (1.019) of the purified acetylated dendrimer was determined by GPC. **1″ G5Ac$_{65\%}$**: ^{1}H NMR integration determined the degree of acetylation to be 65%. Number average molecular weight (30 394 g/mol) was computed based on the addition of mass to the dendrimer from the acetyl groups as determined by NMR. PDI (1.060) of the purified acetylated dendrimer was determined by GPC. **1‴ G5Ac$_{67\%}$**: ^{1}H NMR integration determined the degree of acetylation to be 67%. Number average molecular weight (30 473 g/mol) was computed based on the addition of mass to the dendrimer from the acetyl groups as determined by NMR. **1⁗ G5Ac$_{58\%}$**: ^{1}H NMR integration determined the degree of acetylation to be 58%. Number average molecular weight (30 064 g/mol) was computed based on the addition of mass to the dendrimer from the acetyl groups as determined by NMR. **1⁗′ G5Ac$_{68.8\%}$**: ^{1}H NMR integration determined the degree of acetylation to be 69%. Number average molecular weight (30 572 g/mol) was computed based on the addition of mass to the dendrimer from the acetyl groups as determined by NMR. **1⁗″ G5Ac$_{64\%}$**: ^{1}H NMR integration determined the degree of acetylation to be 64%. Number average molecular weight (30 347 g/mol) was computed based on the addition of mass to the dendrimer from the acetyl groups as determined by NMR.

Synthesis of Alkyne Linker (3-(4-(Prop-2-ynyloxy)phenyl)-propanoic Acid) ***2***. Synthesis of methyl 3-(4-(prop-2-ynyloxy)-phenyl)propanoate **2a** has been previously reported.[30] Synthesis of (3-(4-(prop-2-ynyloxy)phenyl)propanoic acid) **2b** has also been previously reported.[30]

Synthesis of Azide Linker (3-(4-(2-Azidoethoxy)phenyl)-propanoic Acid) ***3***. To a solution of methyl 3-(4-hydroxyphenyl)propanoate (1.699 g, 9.43 mmol) in dry acetone (47.5 mL) was added anhydrous K_2CO_3 (3.909 g, 0.0283 mol) followed by 1-bromo-2-chloroethane (1.56 mL, 0.0189 mol). The resulting suspension was refluxed for 43 h with vigorous stirring. The reaction mixture was cooled to room temperature and the salt was removed by filtration followed by washing with portions of

EtOAc (3 × 70 mL). The crude material was purified by silica chromatography (25:75 EtOAc/Hexane) and the solvent was removed under vacuum to give the desired product, methyl 3-(4-(2-chloroethoxy)phenyl)propanoate **3a**, as an oil (0.75 g, 33%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.12 (d, J = 8.7, 2H), 6.84 (d, J = 8.7, 2H), 4.21 (t, J = 5.9, 2H), 3.80 (t, J = 5.9, 2H), 3.66 (s, 3H), 2.90 (t, J = 7.8, 2H), 2.60 (t, J = 7.8, 2H).

To a solution of methyl 3-(4-(2-chloroethoxy)phenyl)propanoate **3a** (0.75 g 3.1 mmol) in anhydrous DMF (6.1 mL) was added 18-crown-6 (3.4 mg, 0.013 mmol) and sodium azide (0.44 g, 6.8 mmol). The resulting solution was heated at 78 °C for 11 h. The reaction mixture was cooled to room temperature, diluted with ethyl acetate (50 mL), washed with a saturated $NaHCO_3$ solution (4 × 70 mL), and then dried over $MgSO_4$. The solvent was removed under vacuum to give methyl 3-(4-(2-azidoethoxy)-phenyl)propanoate **3b** as a yellow oil (0.58 g, 75%) ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.12 (d, J = 8.6, 2H), 6.85 (d, J = 8.6, 2H), 4.13 (t, J = 5.0 2H), 3.67 (s, 3H), 3.58 (t, J = 5.0, 2H), 2.90 (t, J = 7.8, 2H), 2.60 (t, J = 7.8, 2H).

To a solution of methyl 3-(4-(2-azidoethoxy)phenyl)propanoate **3b** (3.88 g, 0.0156 mol) in methanol (102 mL) was added potassium hydroxide (2 M, 28.3 mL, 0.0566 mol). The resulting solution was refluxed at 70 °C for 3 h. The solution was cooled to room temperature and condensed under reduced pressure. The residue was dissolved in water (30 mL) and was acidified by addition of 1 N HCl to pH 1. The white cloudy solution was diluted with EtOAc. Layers were separated and the aqueous layer was extracted with EtOAc (2 × 70 mL). The combined organic extracts were washed with a saturated NaCl solution and dried over $MgSO_4$. Solvent was evaporated under vacuum to give the (3-(4-(2-azidoethoxy)phenyl)propanoic acid) **3c** as a white solid (3.44 g, 94%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.14 (d, J = 8.5, 2H), 6.86 (d, J = 8.5, 2H), 4.13 (t, J = 5.0 2H), 3.58 (t, J = 5.0, 2H), 2.91 (t, J = 7.7, 2H), 2.65 (t, J = 7.7, 2H).

Synthesis of Small Molecule Model System ***4***. The methyl ester forms of the alkyne linker **2a** (448.0 mg, 1.80 mmol) and azide linker **3b** (371.5 mg, 1.70 mmol) were dissolved in a mixture of THF (1.6 mL) and water (0.4 mL). To this mixture was added copper sulfate pentahydrate (43.1 mg, 86.0 μmol) and sodium ascorbate (170.9 mg, 431 μmol). The resulting reaction mixture was stirred at room temperature for 24 h. The solution was then diluted in EtOAc (60 mL) and water (60 mL). Layers were separated, and the aqueous layer was extracted twice with EtOAc solution (2 × 70 mL). The combined organic extracts were washed with a saturated $NaHCO_3$ solution (3 × 70 mL) and then with saturated NaCl solution (2 × 70 mL). The organic extracts were finally dried over $MgSO_4$. Solvent was evaporated under reduced pressure to give the desired product **4** as a white solid (0.54 g, 95%). ^{1}H NMR (500 MHz, $CDCl_3$) δ 7.80 (s, 1H), 7.108 (overlapping d, J = 8.4, 4H), 6.91 (d, J = 8.6, 2H), 6.78 (d, J = 8.6, 2H), 5.18 (s, 2H), 4.75 (t, J = 5.0, 2H), 4.33 (t, J = 5.0, 2H), 3.66 (s, 3H), 3.657 (s, 3H), 2.890 (t, J = 7.8, 2H), 2.88 (t, J = 7.7, 2H), 2.59 (t, J = 7.8, 2H), 2.59 (t, J = 7.7, 2H).

Synthesis of G5-Ac$_{72\%}$-Alkyne$_{1.4}$ ***5***. A solution of partially acetylated dendrimer **1′** (54.6 mg, 1.78 μmol) was prepared with anhydrous DMSO (12.133 mL). The alkyne linker **2b** (0.9 mg, 4.4 μmol) was dissolved in DMSO (453 μL) and added to the dendrimer−DMSO solution. To this mixture was added *N*, *N*-diisopropylethylamine (4.6 μL, 26 μmol) and the resulting solution was stirred for 45 min. Benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (2.3 mg, 4.4 μmol) was dissolved in DMSO (462 μL) and added in a dropwise manner to the dendrimer/alkyne linker solution. The resulting solution was stirred for 24 h. All reaction steps were carried out in glass flasks at room temperature under nitrogen.

The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of two cycles using 1× PBS and eight cycles using DI water. All cycles were 10 min at 5000 rpm. The resulting product **5** was lyophilized for three days to yield a white solid (41.5 mg, 75%). ^{1}H NMR integration determined an average of 1.4 alkyne linkers coupled to the dendrimer. The quantification of the number of linkers by NMR integration is described previously.[30] See Supporting Information for ^{1}H NMR spectrum of **5**.

Synthesis of G5-Ac$_{72\%}$-Azide$_{1.3}$ ***6***. A solution of partially acetylated dendrimer **1′** (60.5 mg, 1.97 μmol) was prepared with anhydrous DMSO (13.444 mL). The azide linker **3c** (1.2 mg, 4.9 μmol) was dissolved in DMSO (578 μL) and added to the dendrimer−DMSO solution. To this mixture was added *N*, *N*-diisopropylethylamine (5.1 μL, 30 μmol) and the resulting solution was stirred for 45 min. Benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (2.6 mg, 4.9 μmol) was dissolved in DMSO (511 μL) and added in a dropwise manner to the dendrimer/azide linker solution. The resulting solution was stirred for 24 h. All reaction steps were carried out in glass flasks at room temperature under nitrogen.

The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of two cycles using 1× PBS and eight cycles using DI water. All cycles were 10 min at 5000 rpm. The resulting product **6** was lyophilized for three days to yield a white solid (50 mg, 91%). ^{1}H NMR integration determined an average of 1.3 alkyne linkers coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **6**.

Synthesis of Model Dendrimer System G5-Ac$_{72\%}$-L-G5Ac$_{72\%}$ ***7***. Partially acetylated dendrimer with an average of 1.4 alkyne linkers **5** (15.30 mg, 0.493 μmol) and partially acetylated dendrimer with an average of 1.3 azide linkers **6** (15.4 mg, 0.496 μmol) was dissolved in deuterium oxide (0.820 mL) and placed in a glass microwave reactor vessel. Sodium ascorbate (6.9 mg, 35 μmol) and copper sulfate pentahydrate (5.9 mg, 24 μmol) was added to the dendrimer solution. The resulting solution was placed in a microwave reactor for 40 s at 100 W with a cutoff temperature of 100 °C. The microwave conditions were repeated for an additional 40 s. The cutoff temperature was then increased to 110 °C and the microwave was run at 100 W for 2 min. The resulting crude product was a turbid yellow. The crude product was transferred to an NMR tube and analyzed by NOESY and ^{1}H NMR. After two days, the crude product in solution turned to a red−brown solution with a precipitate at the bottom of the NMR tube. NOESY and ^{1}H NMR experiments were repeated at this time point. The supernatant was separated from the precipitate and lyophilized to yield 4.9 mg of a brown solid. See Supporting Information for ^{1}H NMR spectrum of **7**.

Synthesis of G5-Ac$_{65\%}$-Alkyne$_{1.6}$ ***8***. The alkyne linker was conjugated to the partially acetylated dendrimer in two consecutive reactions. First, a stock solution of the alkyne linker **2b** (9.5 mg, 0.047 mmol) was generated with a mixture of DMF (6.198 mL) and DMSO (3.099 mL). To this mixture was added EDC (124.9 mg, 0.651 mmol). The resulting solution was stirred for 2 h at room temperature to create the active ester form of the alkyne linker.

A solution of partially acetylated dendrimer **1″** (58.8 mg, 1.930 μmol) was prepared with DI water (13.099 mL). The active ester form of the alkyne linker (5.784 mL, 0.0289 mmol) in DMF/DMSO was added in a dropwise manner (0.13 mL/min) to the

dendrimer—water solution. The resulting reaction mixture was stirred for 2 days. All reaction steps were carried out in glass flasks at room temperature under nitrogen. The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of five cycles using 1× PBS and five cycles using DI water. All cycles were 30 min at 5000 rpm. The resulting product **8** was lyophilized for three days to yield a white solid (55 mg, 92%). ^{1}H NMR integration determined an average of 1.6 alkyne linkers coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **8**.

Synthesis of G5-Ac$_{65\%}$-Azide$_{2.5}$ ***9***. The azide linker was conjugated to the partially acetylated dendrimer in two consecutive reactions. First, a stock solution of the azide linker **3c** (7.6 mg, 0.032 mmol) was generated with a mixture of DMF (4.96 mL) and DMSO (2.48 mL). To this mixture was added EDC (86.7 mg, 0.452 mmol). The resulting solution was stirred for 1.75 h at room temperature to create the active ester form of the azide linker.

A solution of partially acetylated dendrimer **1**″ (58.8 mg, 1.930 μmol) was prepared with DI water (13.10 mL). The active ester form of the azide linker (6.66 mL, 0.0289 mmol) in DMF/DMSO was added in a dropwise manner (0.13 mL/min) to the first dendrimer—water aliquot. The resulting mixture was stirred for 2 days. All reaction steps were carried out in glass flasks at room temperature under nitrogen. The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of five cycles using 1× PBS and five cycles using DI water. All cycles were 10 min at 5000 rpm. The resulting product **9** was lyophilized for three days to yield a white solid (55 mg, 89%). ^{1}H NMR integration determined an average of 2.5 azide linkers coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **9**.

Synthesis of G5-Ac$_{65\%}$-Alkyne$_{1.6}$-FA$_{1.7}$ ***10***. Folic acid was conjugated to the alkyne linker-conjugated dendrimer **8** in two consecutive reactions. First, a solution of folic acid (1.9 mg, 4.26 μmol) was generated with a mixture of DMF (1.23 mL) and DMSO (0.62 mL). To this mixture was added EDC (11.4 mg, 59.7 μmol). The resulting solution was stirred for 1 h at room temperature to create the active ester form of folic acid.

A solution of partially acetylated dendrimer with an average number of 1.6 alkyne linkers **8** (20.8 mg, 0.752 μmol) was prepared with DI water (4.638 mL). The active ester form of folic acid (1.85 mL, 4.26 μmol) in DMF/DMSO was added in a dropwise manner to the dendrimer—water solution. The resulting reaction mixture was stirred for 3 days. All reaction steps were carried out in glass flasks at room temperature under nitrogen. The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of five cycles using 1× PBS and four cycles using DI water. All cycles were 10 min at 5000 rpm. The resulting product **10** was lyophilized for three days to yield a yellow solid (15.6 mg, 73%). ^{1}H NMR integration determined an average of 1.7 folic acid molecules coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **10**.

Synthesis of G5-Ac$_{65\%}$-Azide$_{2.5}$-FITC$_{3.2}$ ***11***. Partially acetylated dendrimer with an average number of 2.5 azide linkers **9** (21.5 mg, 0.694 μmol) was dissolved in DMSO (1.5 mL). Fluorescein isothiocyanate (1.4 mg, 3.5 μmol) was dissolved in DMSO (0.54 mL) and added in a dropwise fashion to the dendrimer solution. The resulting mixture was stirred for 24 h at room temperature. The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of six cycles using 1× PBS and six cycles using DI water. All 1× PBS cycles were 15 min at 5 000 rpm and all DI water cycles were 15 min at 5000 rpm. HPLC analysis of the lyophilized product detected unconjugated FITC remaining in the sample. To remove the remaining unreacted FITC, the conjugate was purified by size exclusion chromatography using Sephadex G-25 beads in 1× PBS. The dendrimer fraction was collected and the elution buffer was exchanged with DI water using 10 000 MWCO centrifugal filtration devices (four cycles of 10 min at 5000 rpm). The purified product **11** was lyophilized to yield a yellow—orange solid (10.1 mg, 46%). ^{1}H NMR integration determined an average of 3.2 FITC coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **11**.

Synthesis of G5-Ac$_{65\%}$-Alkyne$_{1.6}$-FA$_{3.5}$ ***12***. Additional folic acid was conjugated to the partially acetylated dendrimer with an average of 1.6 alkyne linkers and 1.7 folic acid molecules **10** in two consecutive reactions. First, a solution of folic acid (1.1 mg, 2.4 μmol) was generated with a mixture of DMF (0.69 mL) and DMSO (0.34 mL). To this mixture was added EDC (6.3 mg, 33 μmol). The resulting solution was stirred for 1 h at room temperature to create the active ester form of the folic acid.

A solution of partially acetylated dendrimer with an average number of 1.6 alkyne linkers and 1.7 folic acid molecules **10** (8.5 mg, 0.30 μmol) was prepared with DI water (1.90 mL). The active ester form of folic acid (1.03 mL, 2.4 μmol) in DMF/DMSO was added in a dropwise manner to the dendrimer—water solution. The resulting reaction mixture was stirred for 3 days. All reaction steps were carried out in glass flasks at room temperature under nitrogen. The reaction mixture was purified by size exclusion chromatography using Sephadex G-25 in 1× PBS. The dendrimer fraction was collected and the elution buffer was exchanged with DI water using 10 000 MWCO centrifugal filtration devices (four cycles of 10 min at 5000 rpm). The purified product **12** was lyophilized for three days to yield a yellow solid (7.0 mg, 80%). ^{1}H NMR integration determined an average of 3.5 folic acid molecules coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **12**.

Synthesis of G5-Ac$_{107}$-Alkyne$_{1.6}$-FA$_{3.5}$ ***13***. Partially acetylated dendrimer with an average number of 1.6 alkyne linkers and 3.5 folic acid **12** (7.0 mg, 0.22 μmol) was dissolved in anhydrous methanol (1.124 mL). Triethylamine (1.7 μL, 0.012 mmol) was added to this mixture and stirred for 30 min. Acetic anhydride (0.9 μL, 9.6 μmol) was added in a dropwise manner to the dendrimer solution. The reaction was carried out in a glass flask, under nitrogen, at room temperature for 24 h. Methanol was evaporated from the resulting solution and the product was purified by size exclusion chromatography using Sephadex LH-20 in methanol. The purified dendrimer **13** was lyophilized for three days to yield a yellow solid (6.6 mg, 90%). ^{1}H NMR integration determined the degree of acetylation to be 100%. See Supporting Information for ^{1}H NMR spectrum of **13**.

Synthesis of G5-Ac$_{106}$-Azide$_{2.5}$-FITC$_{3.2}$ ***14***. Partially acetylated dendrimer with an average number of 2.5 azide linkers and 3.2 FITC **11** (7.5 mg, 0.23 μmol) was dissolved in anhydrous methanol (1.21 mL). Triethylamine (1.8 μL, 0.013 mmol) was added to this mixture and stirred for 30 min. Acetic anhydride (1.0 μL, 10.0 μmol) was added in a dropwise manner to the dendrimer solution. The reaction was carried out in a glass flask, under nitrogen, at room temperature for 24 h. Methanol was evaporated from the resulting solution, and the product was purified by size exclusion chromatography using Sephadex LH-20 in methanol. The purified dendrimer **14** was lyophilized for

three days to yield a yellow solid (7.1 mg, 91%). ^{1}H NMR integration determined the degree of acetylation to be 100%. See Supporting Information for ^{1}H NMR spectrum of **14**.

Synthesis of Folic Acid Targeted Dendrimer System FA$_{3.5}$-G5-Ac$_{107}$-L-G5-Ac$_{106}$-FITC$_{3.2}$ ***15***. Dendrimer with an average of 1.6 alkyne linkers and 3.5 folic acid molecules **13** (3.1 mg, 91 nmol) and dendrimer with an average of 2.5 azide linkers and 3.2 FITC molecules **14** (3.0 mg, 88 nmol) were dissolved in deuterium oxide (0.65 mL) and placed in a glass microwave reactor vessel. Sodium ascorbate (1.1 mg, 4.5 μmol) and copper sulfate pentahydrate (1.1 mg, 5.4 μmol) was added to the dendrimer solution. The resulting solution was placed in a microwave reactor for 6.5 min at 100 W with a cutoff temperature of 100 °C. The reaction mixture was transferred to an NMR tube and analyzed by NOESY and ^{1}H NMR spectroscopy. Lyophilization yielded 6.7 mg of a red solid. See Supporting Information for ^{1}H NMR spectrum of **15**.

Synthesis of G5-Ac$_{67\%}$-Alkyne$_{1.3}$ ***16***. A solution of partially acetylated dendrimer **1‴** (176.7 mg, 5.8 μmol) was prepared with anhydrous DMSO (39.27 mL). The alkyne linker **2b** (2.6 mg, 13 μmol) was dissolved in DMSO (1.31 mL) and added to the dendrimer−DMSO solution. To this mixture was added *N*, *N*-diisopropylethylamine (13.4 μL, 76.7 μmol) and the resulting solution was stirred for 45 min. Benzotriazol-1-yl-oxytripyrrolidinophosphonium hexafluorophosphate (6.7 mg, 13 μmol) was dissolved in DMSO (1.331 mL) and added in a dropwise manner to the dendrimer/alkyne linker solution. The resulting solution was stirred for 24 h. All reaction steps were carried out in glass flasks at room temperature under nitrogen.

The reaction mixture was purified using 10 000 MWCO centrifugal filtration devices. Purification consisted of two cycles using 1× PBS and eight cycles using DI water. All cycles were 10 min at 5000 rpm. The resulting product **5** was lyophilized for three days to yield a white solid (116.2 mg, 65.2%). ^{1}H NMR integration determined an average of 1.3 alkyne linkers coupled to the dendrimer. See Supporting Information for ^{1}H NMR spectrum of **16**.

Synthesis of G5-Ac$_{110.7}$-Alkyne$_{1.3}$ ***17***. Partially acetylated dendrimer with an average number of 1.3 alkyne linkers **16** (22.6 mg, 0.737 μmol) was dissolved in anhydrous methanol (3.0 mL). Triethylamine (5.8 μL, 0.042 mmol) was added to this mixture and stirred for 30 min. Acetic anhydride (3.2 μL, 34 μmol) was added in a dropwise manner to the dendrimer solution. The reaction was carried out in a glass flask, under nitrogen, at room temperature for 24 h. Methanol was evaporated from the resulting solution and the product was purified by size exclusion chromatography using Sephadex LH-20 in methanol. The purified dendrimer **17** was lyophilized for three days to yield a white solid (19.1 mg, 80.5%). ^{1}H NMR integration determined the degree of acetylation to be 100%. See Supporting Information for ^{1}H NMR spectrum of **17**.

Synthesis of Untargeted Dendrimer System G5-Ac$_{110.7}$-L-G5-Ac$_{106}$-FITC$_{3.2}$ ***18***. Dendrimer with an average of 1.3 alkyne linkers **17** (1.0 mg, 31 nmol) and dendrimer with an average of 2.5 azide linkers and 3.2 FITC molecules **14** (1.0 mg, 29 nmol) were dissolved in deuterium oxide (0.74 mL) and placed in a glass microwave reactor vessel. Sodium ascorbate (0.36 mg, 1.8 μmol) and copper sulfate pentahydrate (0.38 mg, 1.5 μmol) were added to the dendrimer solution. The resulting solution was placed in a microwave reactor for 6.5 min at 100 W with a cutoff temperature of 100 °C. The reaction mixture was transferred to an NMR tube and analyzed by NOESY and ^{1}H NMR spectroscopy.

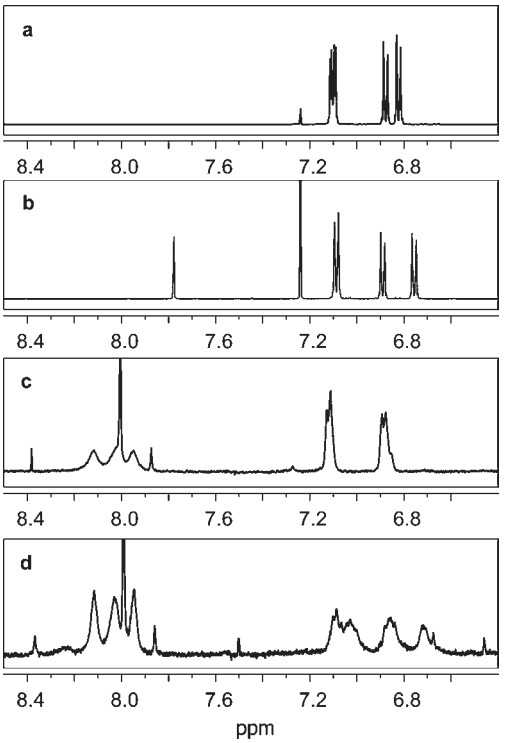

Figure 2. Proton NMR spectra of the small-molecule model system and model dendrimer system both pre- and post-"click" reaction. An upfield shift is observed for aromatic proton g as a result of the "click" reaction. (a) Spectrum of the small molecule model system before the "click" reaction (**2a** and **3b**), taken in $CDCl_3$. Proton g has a chemical shift of 6.85 ppm. (b) Spectrum of the small molecule model system after the "click" reaction (**4**), taken in $CDCl_3$. As a result of the "click" reaction, g has experienced an upfield change to 6.78 ppm. (c) Spectrum of the model dendrimer system before the "click" reaction (**5** and **6**), taken in D_2O. Proton g overlaps proton b at 6.90 ppm. (d) Spectrum of the model dendrimer system after the "click" reaction (**7**), taken in D_2O. Similar to the small molecule model system, proton g experiences an upfield change as a result of the "click" reaction. In the model dendrimer system, the new chemical shift is 6.74 ppm.

Lyophilization yielded 2.4 mg of a red solid. See Supporting Information for ^{1}H NMR spectrum of **18**.

RESULTS AND DISCUSSION

Synthesis and Characterization of the Small-Molecule Model System. A small molecule model system (**4**) was first synthesized to facilitate the spectroscopic assignment of triazole-related atoms resulting from successful "click" reactions between dendrimer modules with an azide linker (**3c**) and dendrimer modules possessing an alkyne linker (**2b**). This model system utilized the methyl ester forms of the two linkers (**2a** and **3b**). Proton assignments were based upon ^{1}H NMR and NOESY experiments in $CDCl_3$. Figure 1, panel a, displays the cross-peaks for the triazole related protons in the clicked product (**4**), and Table 1 contains the chemical shifts for these in both the pre- and post-"click" reaction states. Protons c, e, and f experience the greatest change in chemical shift as a result of the "click" reaction. Also of interest is the region between 6.4 and 8.5 ppm (Figure 2, panels a and b), which shows the upfield shift for peak g from 6.85 ppm to 6.78 ppm.

Synthesis and Characterization of the Model Dendrimer System. Dendrimers without target or dye functionalities, possessing

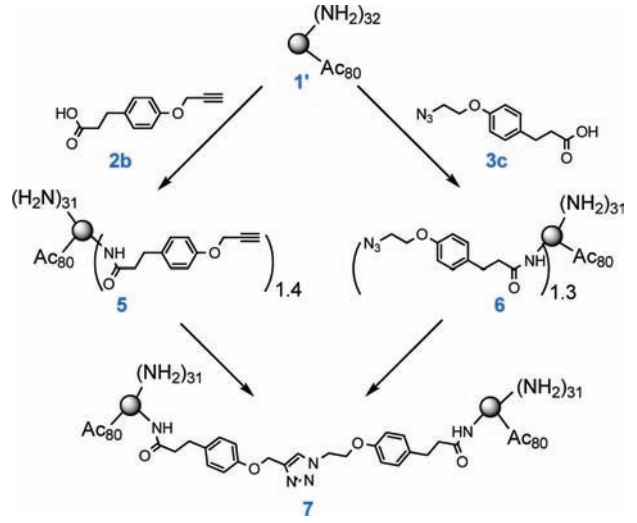

Figure 3. Synthetic scheme for the model dendrimer system (**7**). This simplified modular platform was developed to assist with the spectroscopic characterization of the folic acid targeted dendrimer system. The G5 dendrimer, used in this study, had an average of 112 end groups as determined by GPC and potentiometric titration.

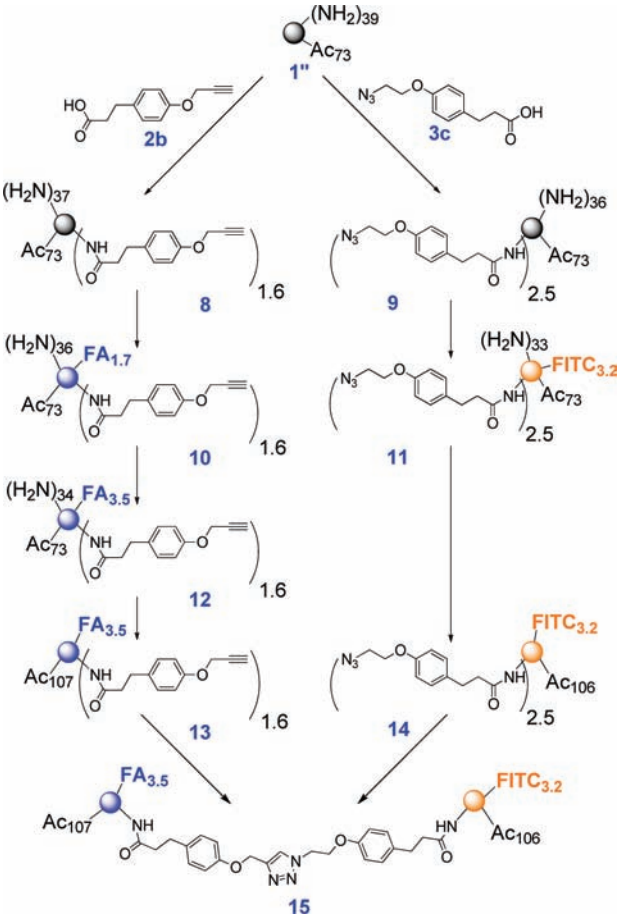

Figure 4. Synthetic scheme for the folic acid targeted modular dendrimer-based platform (**15**). A module possessing a terminal alkyne moiety and folic acid (**13**) is coupled to a second module possessing a terminal azide moiety and FITC (**14**) via the Cu-catalyzed 1,3-dipolar cycloaddition reaction. Both modules were fully acetylated to avoid nonspecific cellular interactions.

only the "click" reaction functional groups (**5** and **6**), were employed to develop "click" reaction conditions (Figure 3). Because many of the proton peaks associated with the dendrimer-conjugated alkyne and azide linkers (particularly those closest to the "click" reaction sites) overlap in the ^{1}H NMR spectra with other protons belonging to the PAMAM dendrimer, NOESY experiments were used to document proton chemical shifts via the resolution of cross peaks in the 2-D spectra (Figure 1, panel b). The chemical shifts for the triazole related protons in the dendrimer system both pre- and post-"click" reaction can be found in Table 1. The region between 6.4 and 8.5 ppm in the proton spectra for the pre- and post-"click"ed dendrimer samples can be found in Figure 2, panels c and d. In the spectra for the pre-"click" reaction mixture (panel c), both sets of aromatic protons overlap at 6.90 ppm (b and g) and 7.13 ppm (a and h). In the sample post-"click" reaction (panel d), the aromatic protons no longer overlap. Protons a and h partially overlap at 7.09 ppm and 7.06 ppm, and protons b and g are found at 6.90 ppm and 6.74 ppm, respectively.

A comparison of the chemical shifts in Table 1 for the small molecule system and the dendrimer system reveals good correlations for both the pre- and post-reaction states. This indicates that a successful "click" reaction has occurred between the azide and alkyne conjugated dendrimers. It is important to note that, whereas chemical shifts for the small molecule model system are determined in $CDCl_3$, the chemical shifts for the dendrimer sample were detected in D_2O. Although the different solvents could influence the proton chemical shifts, this does not appear to be an issue for these particular molecules.

A peak for the single proton in the triazole ring is absent from both the NOESY and 1D experiments. In the small molecule system, this peak is found at 7.80 ppm (Figure 2, panel b). Working with a similar system using PAMAM dendrons that contained the alkyne and azide moieties at the dendron focal point, Lee et al. found that the triazole proton peak gradually shifted downfield from 7.77 ppm to 7.93 ppm as the generation of the clicked dendrons increased from 1 to 3.[47] If this downfield change in chemical shift also holds for the generation 5 dendrimer case, the triazole proton would be overlapped by several peaks between 7.80 ppm and 8.20 ppm associated with the dendrimer (Figure 2, panel d). The NOESY spectra did not expose any cross peaks in this region with other protons in the linkers that are in close proximity to the triazole ring. The cross-peaks associated with the triazole proton appear to be below the intensity required for NMR detection.

Synthesis and Characterization of the Folic Acid Targeted Dendrimer System. Synthesis of the folic acid targeted modular dendrimer platform is outlined in Figure 4. Dendrimers with an average of 1.6 alkyne linkers (**8**) were functionalized with the targeting molecule folic acid. The formation of an amide linkage between one of the remaining primary amines on the dendrimer and one of the carboxylic acid groups in folic acid was achieved by EDC coupling chemistry as previously reported.[22] This reaction conjugated an average of 1.7 folic acid molecules per dendrimer as determined by NMR (**10**). Because this average was below the optimal range for multivalent binding,[3] the reaction was repeated using the dendrimer with an average of 1.6 alkyne linkers and 1.7 folic acid (**10**). The second reaction resulted in the addition of 1.8 folic acid molecules per dendrimer bringing the final average to 3.5 folic acid molecules per dendrimer (**12**). The remaining dendrimer primary amines were then fully acetylated to avoid positive charge-based cellular interactions (**13**).[6,9,10] Dendrimers

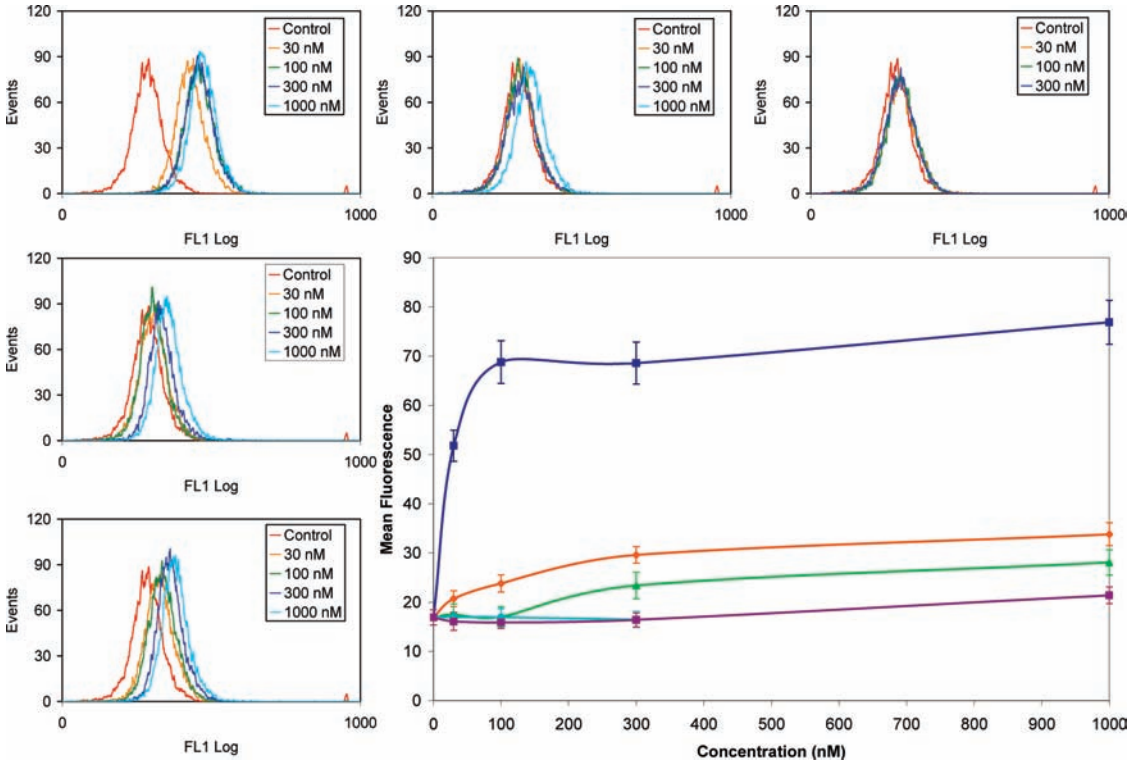

Figure 5. Binding and uptake of the fluorescent modular targeted dendrimer platform in KB cells as measured by flow cytometry. (a) Uptake of $FA_{3.5}$-G5-Ac_{107}-L-G5Ac_{106}-$FITC_{3.2}$ (**15**). (b) Uptake of G5-Ac_{106}-$Azide_{2.5}$-$FITC_{3.2}$ (**14**) is not observed for 30 nM, 100 nM, and 300 nM. Very minimal uptake of this untargeted module is observed at 1000 nM. (c) Similarly, no uptake is observed for an uncoupled mixture of G5-Ac_{106}-$Azide_{2.5}$-$FITC_{3.2}$ (**14**) and G5-Ac_{107}-$Alkyne_{1.6}$-$FA_{3.5}$ (**13**). (d) Uptake of $FA_{3.5}$-G5-Ac_{107}-L-G5Ac_{106}-$FITC_{3.2}$ (**15**) is successfully blocked using a 20-fold excess of free folic acid. (e) Uptake of $FA_{3.5}$-G5-Ac_{107}-L-G5Ac_{106}-$FITC_{3.2}$ (**15**) is also successfully blocked using a 20-fold excess (with respect to the folic acid content) of G5-Ac_{107}-$Alkyne_{1.6}$-$FA_{3.5}$ (**13**). (f) Summary of mean fluorescence values for **a**—**e**. Uptake of $FA_{3.5}$-G5-Ac_{107}-L-G5Ac_{106}-$FITC_{3.2}$ (**15**) is displayed in blue. Uptake of the targeted platform (**15**) blocked by a 20-fold excess of G5-Ac_{107}-$Alkyne_{1.6}$-$FA_{3.5}$ (**13**) is shown in orange. Uptake of the targeted platform (**15**) blocked by a 20-fold excess of free folic acid can be found in green. Uptake of a mixture of G5-Ac_{106}-$Azide_{2.5}$-$FITC_{3.2}$ (**14**) and G5-Ac_{106}-$Alkyne_{1.6}$-$FA_{3.5}$ (**13**) can be found in teal. Finally, uptake of G5-Ac_{106}-$Azide_{2.5}$-$FITC_{3.2}$ (**14**) can be found in purple. Error bars indicate standard deviation as computed from half-peak coefficient of variation (HPCV) values.

with 2.5 azide linkers (**9**) were functionalized with the dye molecule FITC. Using conditions similar to those in previously published work,[25] an average of 3.2 FITC molecules were coupled to the dendrimer via the formation of a thiourea bond between the primary amine on the dendrimer and the isothiocyanate group in FITC (**11**). This dendrimer conjugate also was fully acetylated (**14**). Reverse phase HPLC confirmed that any unreacted FITC or folic acid molecules had been removed by purification of dendrimer **13** and **14**.

The two dendrimer modules (**13** and **14**) were coupled together using the Cu-catalyzed 1,3-dipolar cycloaddition reaction under conditions similar to those used with the model dendrimer system. NOESY experiments provided direct spectroscopic proof that the functionalized dendrimers had been clicked together. Specifically, the AA′BB′ pattern was observed to shift in a fashion identical to that observed for the two model systems previously described (Table 1 and Figure 2).

***In Vitro* Testing of the Folic Acid Targeted Dendrimer System with KB Cells.** Cellular uptake of the folic acid targeted dendrimer system (**15**) at four different concentrations (30 nM, 100 nM, 300 nM, and 1000 nM of **15**) was measured in KB cells that express a high cellular membrane concentration of folic acid receptor (FAR). Fluorescence uptake was quantified by flow cytometry. As seen in Figure 5a and f-blue, a dose-dependent uptake was observed with saturation occurring at 100 nM. This binding affinity is consistent with previous studies on single dendrimer platforms possessing multiple FITC and multiple FA molecules.[23]

A series of control experiments were performed in order to ensure that uptake of the folic acid targeted dendrimer system (**15**) was occurring via receptor-mediated endocytosis and not nonspecific membrane interactions. The first set of controls measured uptake of single dendrimers possessing the azide linker and multiple FITC (**14**) at 30 nM, 100 nM, 300 nM, and 1000 nM (Figure 5b and f-purple). No uptake was observed for this sample above the background level. The second control sample contained a nonconjugated (unclicked) mixture of the two dendrimers functionalized with either FITC or folic acid (**13** and **14**). Uptake of this mixture was quantified at 30 nM, 100 nM, and 300 nM (Figure 5c and f-teal). At all three concentrations, no florescence uptake was observed. This control eliminates the possibility that the dendrimer modules could form a noncovalently linked complex that would be internalized. A third control sample (**18**) was composed of an untargeted dendrimer module (**17**) coupled to the FITC conjugated imaging module (**14**). The untargeted dual module platform (**18**) was assembled under the same conditions used to form the folic acid targeted platform (**15**). Mean fluorescence uptake of the untargeted platform can

be found in the Supporting Information. At concentrations up to 300 nM, no uptake was observed beyond the background level. This untargeted dendrimer platform is an essential control, because it matches the molecular weight and size of the folic acid targeted dendrimer system (**15**). This control will become even more important as evaluation of this system moves to an *in vivo* model.

The final set of controls investigated active blocking of the folic acid receptor by either free folic acid (Figure 5d and f-green) or a folic acid−dendrimer conjugate without a fluorescent dye (**13**) (Figure 5e and f-orange) to prevent the specific uptake of the folic acid targeted dendrimer system. A 20-fold excess of blocking agent was employed relative to the targeted platform. For the blocking experiment using the single dendrimer−folic acid conjugate (**13**), molar equivalence was based on the folic acid content of the sample rather than the dendrimer content. Both blocking agents were evaluated at 30 nM, 100 nM, 300 nM, and 1000 nM. Complete blocking is achieved using free folic acid concentrations up to 100 nM. While the dendrimer−folic acid conjugate is not as effective at blocking as the free folic acid, approximately 75% blocking is achieved. These binding data indicate that the cellular association of the folic acid targeted dendrimer system occurs through the folic acid receptor rather than via nonspecific interactions. On a more fundamental level, the biological results prove again that the folic acid conjugate dendrimer module is covalently linked by "click" chemistry to dendrimer module functionalized with FITC.

Design Analysis. One of the limitations of the modular platform design in its current iteration is that each module is composed of a heterogeneous distribution of dendrimer−ligand components.[30,48−50] To a first approximation, these distributions are consistent with Poissonian statistics. Not only are the modules composed of a distribution of dendrimer particles with different numbers of the biologically active ligand (folic acid, FITC), but the modules are also composed of a distribution of dendrimer with different numbers of the coupling ligands (azide and alkyne). The implication of these distributions is that the final "dual" module platform is most likely composed of a large number of different platforms with different numbers of modules linked together and different numbers of ligands per module. Future designs should incorporate characterization and control of these distributions in order to make a more controlled, reproducible material.

CONCLUSION

A delivery platform covalently linking two different PAMAM dendrimer modules through "click" chemistry was successfully designed and synthesized. Two model systems were also generated to assist in the NMR spectroscopy characterization of the modular platform. The folic acid targeted system was evaluated for functional activity *in vitro* with KB cells and found to selectively target the cancer cell line through the high-affinity folate receptor.

Supporting Information

ABSTRACT: A series of charge-reversal lipids were synthesized that possess varying chain lengths and end functionalities. These lipids were designed to bind and then release DNA based on a change in electrostatic interaction with DNA. Specifically, a cleavable ester linkage is located at the ends of the hydrocarbon chains. The DNA release from the amphiphile was tuned by altering the length and position of the ester linkage in the hydrophobic chains of the lipids through the preparation of five new amphiphiles. The amphiphiles and corresponding lipoplexes were characterized by DSC, TEM, and X-ray, as well as evaluated for DNA binding and DNA transfection. For one specific charge-reversal lipid, stable lipoplexes of approximately 550 nm were formed, and with this amphiphile, effective *in vitro* DNA transfection activities was observed.

INTRODUCTION

Gene therapy offers the potential to treat a variety of diseases by delivering a functional copy of a missing or defective gene. Current research in this field focuses on two major classes of DNA carriers: viral[1−5] and nonviral.[6−16] Viral vectors transfect a significantly greater percentage of genetic material than nonviral systems, but suffer from a number of drawbacks, including toxicity and induced immunological response.[17] As a consequence, interest in synthesizing and evaluating nonviral delivery systems, including amphiphilic small molecule and polymeric compounds, has increased over the last 10 years. Cationic lipids are one type of amphiphile that can intracellularly transport DNA. Several liposome formulations are commercially available with a few in clinical trials.[16,18] Three examples of such lipids (DOTAP, DOTMA, and DMRIE) are shown in Figure 1.

Following the initial success of these lipids for DNA transfection, a number of different lipid forming complexes of varying structure and composition have been investigated. Within this context, a few representative examples are described below for DNA delivery. The acyl chain length and linker bonds connecting the cationic head to the acyl tail(s) have been varied to enhance transfection efficiency and decrease cytotoxic effects (e.g., DOTMA).[19] Lipospermines, with polycationic headgroups, have been investigated to increase the affinity for DNA.[20] Fluorinated analogues of cationic lipids such as DOTMA have been explored, and these amphiphilies exhibited higher transfection activities *in vitro*[21] and *in vivo*.[22] A hydrophilic spacer (such as PEG) has been placed between the cationic headgroup and the hydrophobic chains[23] to improve transfection efficiency. Researchers have explored the use of glycosidic cationic head groups in an attempt to lower toxicity through tighter interactions with DNA[24−26] or peptide head groups to mimic peptide−DNA binding interactions.[27−30] Recent reports from our laboratory have also described the use of cationic lipids possessing nucleic acid recognition components for nucleic acid delivery in an effort to use more than one type of molecular interaction for complexation.[31−39]

In addition to using these strategies to overcome the low transfection efficiencies of synthetic vectors (estimated to be 0.1% to 1%), functional or stimuli-responsive vectors have also been developed and evaluated. These cationic amphiphiles are able to respond to a stimulus that changes their chemical or physical properties, facilitating DNA delivery. Synthetic vectors have been prepared that are responsive to pH,[40−49] reducing conditions,[50−59] enzymes,[43,60−62] or temperature.[63,64] Many of these functional vectors that degrade or change conformation were designed based on the specific steps in the transfection pathway. This pathway starts with cellular entry of the DNA−amphiphile complex by endocytosis, followed by endosomal escape, and finally nuclear targeting and DNA expression.

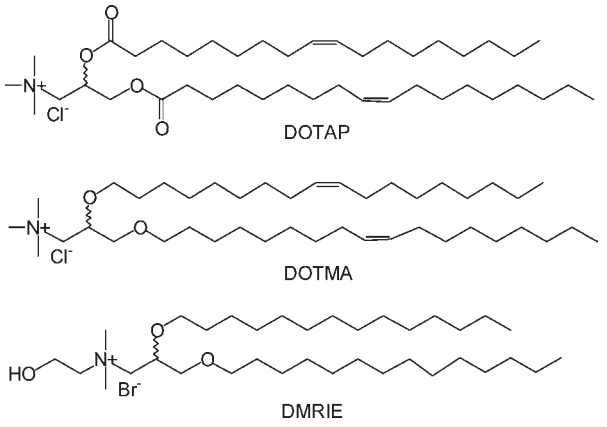

Figure 1. Chemical structures of several common cationic lipids.

Our research effort is centered on the release of DNA from the DNA−amphiphile supramolecular complex following cellular uptake, and as such, we have also focused on functional synthetic vectors. Given that a strong electrostatic assembly is formed between the cationic amphiphile and anionic DNA, and that this assembly is unlikely to disassemble spontaneously, we are interested in altering the electrostatic interaction to free the DNA.[54,65,66] To this end, we have synthesized and characterized new cationic amphiphiles that are capable of undergoing an intracellular electrostatic transition from cationic to anionic under the influence of esterases such as those found in cell lysosomes/endosomes.[67,68] This enables these amphiphiles to release DNA from the supramolecular assembly (Figure 2).

These charge-reversal or charge-switchable amphiphiles possess a positively charged ammonium headgroup that functions to complex DNA and lipophilic acyl chains to promote bilayer formation, similar to other cationic lipids like DOTAP (Figure 1). However, these new amphiphiles also contain ester functionalities near the terminal end of each acyl chain that, upon hydrolysis, switch the overall charge of the amphiphile from positive to negative. As an extension of our previous communication[54] in which we introduced the charge-reversal amphiphile, in this manuscript we have synthesized and investigated nine amphiphiles possessing C10, C12, or C16 acyl chain lengths terminally protected by benzyl, ethyl, butyl, or acetyl groups (Figure 3). The optimal chain length and terminal groups were determined based on amphiphile−DNA binding and DNA release. Standard ethidium bromide assays established the DNA binding capability of each of the vectors over a range of pH. The release of DNA from the DNA−amphiphile assembly was monitored also using an ethidium bromide assay. To determine the thermal and structural properties of the lipid and DNA−lipid complexes, differential scanning calorimetery (DSC), dynamic light scattering (DLS), transmission electronic microscopy (TEM), and X-ray diffraction were performed. Finally, the transfection of the amphiphile/DNA complexes was evaluated *in vitro* in several cell lines.

EXPERIMENTAL PROCEDURES

Please see the Supporting Information for complete experimental details.

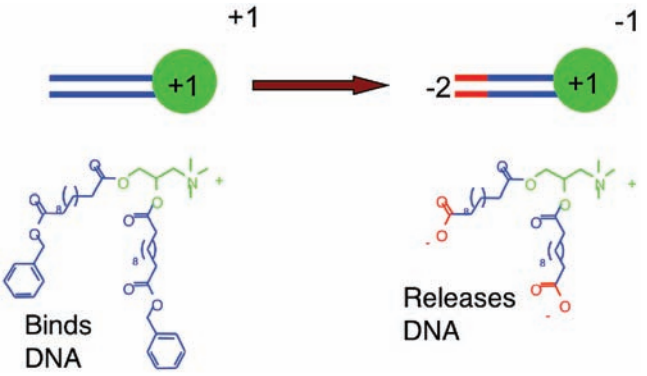

Figure 2. Charge-reversal or charge- switchable effect of the amphiphiles.

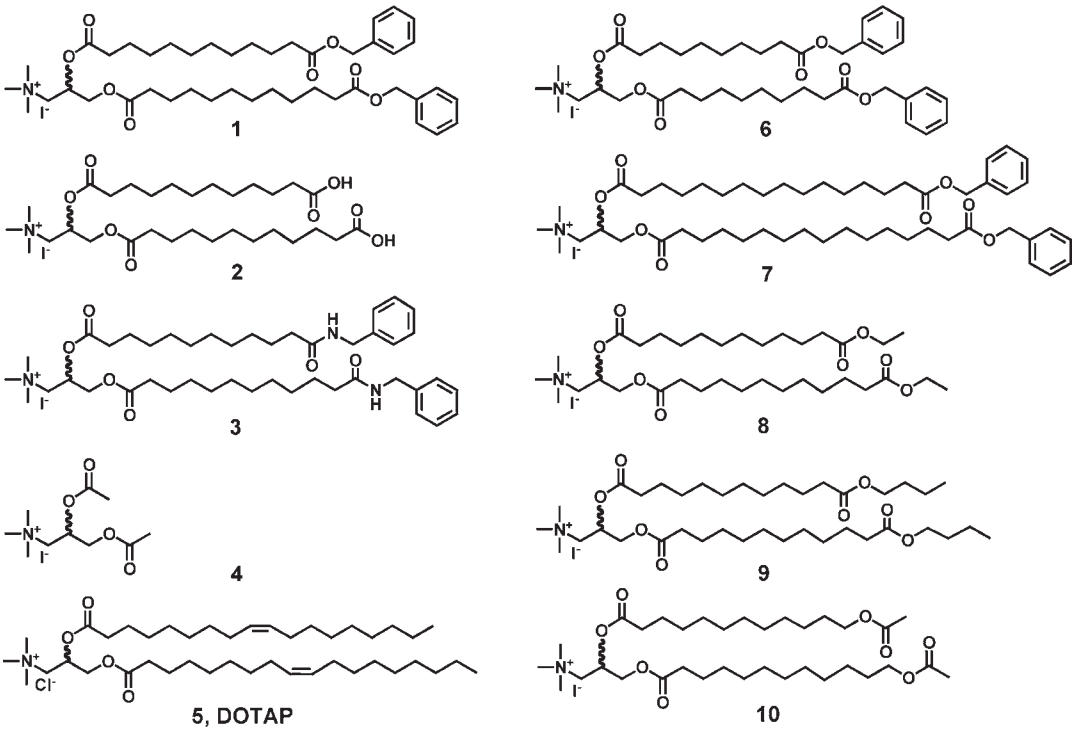
RESULTS AND DISCUSSION

To bind DNA, form lipoplexes, and then eventually release DNA, each amphiphile requires three distinct structural components: a cationic headgroup, hydrophobic chains, and terminal ester linkages. As shown in Figure 3, amphiphile **1** has a cationic headgroup to bind DNA, lipophilic acyl chains to form a bilayer, and ester linkages at the end of the acyl chains for enzymatic hydrolysis. We prepared the series of compounds **2**−**10**, shown in Figure 3, to systematically assess the role of each structural component and to evaluate the effects of amphiphile structure and reactivity (chain length, terminal end group, and ester or amide terminal group) on DNA binding/release, supramolecular assembly, and gene delivery efficacy. Specifically, amphiphile **1** possesses a cationic ammonium headgroup and two dodecanoic acid chains protected with benzyl esters. Hydrolysis of the benzyl esters of **1** affords compound **2**, which is negatively charged at neutral pH. Amphiphile **3** is an analogue of **1** that possesses noncleavable amide linkages, whereas compound **4** lacks the long acyl chains completely. Amphiphiles **6** and **7** are short and long acyl chain analogues of **1**, respectively, with the same terminal benzyl ester group. Amphiphiles **8** and **9** possess terminal alkyl ester linkages of two different chain lengths (ethyl and butyl ester, respectively). Finally, amphiphile **10** contains a similar terminal ester but upon hydrolysis affords two hydroxyl terminated acyl chains and thus remains cationic at neutral pH in aqueous solution.

The synthetic route to the amphiphiles is shown in Scheme 1. The preparation requires the use of functionalized fatty acids. The monoprotected benzyl ester fatty acids were prepared from the corresponding diacids (decanoic, dodecanoic, or hexanoic) with benzyl formate in the presence of Dowex 50W-X2 in octane at 80 °C. The butyl ester fatty acid was prepared in a similar manner using butyl formate. The ethyl ester fatty acids were obtained by the addition of ethanol to a solution of dodecanedioyl dichloride in tetrahydrofuran in the presence of triethylamine at 0 °C. The benzyl amide analogue was prepared in a similar manner using benzylamine. The acetylated fatty acid was prepared by acetylation of the hydroxydodecanoic acid using acetic anhydride in pyridine. Next, the monofunctionalized fatty acid derivatives were coupled to 3-dimethylaminopropanediol in the presence of DCC and DMAP in dichloromethane. The reaction yields ranged from 80% to 95% for all steps. Finally, the amphiphiles were reacted with methyl iodide in dichloromethane to quaternize the tertiary amine in quantitative yield. Complete details of the synthesis for each compound are found in the Supporting Information.



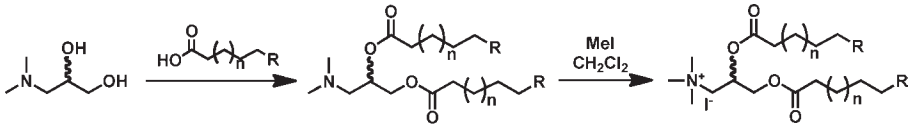


Figure 3. Structures of the charge-reversal amphiphiles under investigation for gene delivery.

Scheme 1. Synthesis of the Charge-Reversal Amphiphiles

1: n = 7; R = C(O)OBn
2: n = 7; R = C(O)OH
3: n = 7; R = C(O)NHBn
4: acetate derivative
6: n = 5; R = C(O)OBn
7: n = 11; R = C(O)OBn
8: n = 7; R = C(O)OEt
9: n = 7; R = C(O)OBu
10: n = 7; R = OC(O)CH3

As the first step toward evaluating these amphiphiles for the delivery of nucleic acids, we used an ethidium bromide displacement assay to determine whether the amphiphiles bind DNA.[69] This fluorescence quenching assay is an indirect method to measure DNA binding by monitoring the displacement of the ethidium bromide from DNA by the cationic amphiphile. This assay is widely used to assess small molecule/DNA binding, and it is assumed that the small molecule binder is responsible for displacing ethidium bromide and causing fluorescence decrease.

As shown in Figure 4, the fluorescence intensity decreases for amphiphiles **1**, **3**, **6**−**10**, and DOTAP upon addition to the ethidium bromide−DNA solution, but does not decrease for amphiphiles **2** and **4**. Amphiphile **2** possesses an overall negative charge and, consequently, does not bind DNA due to unfavorable electrostatic interactions. Compound **4** is a cationic amphiphile but does not bind DNA, indicating the importance of the hydrophobic acyl chains for the formation of a strong interaction with DNA.

The different terminal ester groups (ethyl, butyl, benzyl, acetyl) of the cationic amphiphiles do not appear to have a significant effect on DNA binding, as all of the amphiphiles bind DNA. The binding constants can be estimated and compared by measuring the loss of EtBr fluorescence as a function of the vector added. The concentration which produces 50% of the inhibition of fluorescence (IC_{50}) approximates the binding constant. The apparent binding constants were calculated as follows: $K_{app} = (1.26 \times 10^{-6}/\ IC_{50}) \times K_{EtBr}$ with $K_{EtBr} = 10^7\ M^{-1}$ as described elsewhere.[70] The binding constant for all the amphiphiles is on the order of $10^6\ M^{-1}$ and similar in magnitude to DOTAP ($K = 10^6\ M^{-1}$). These binding curves indicate that a ~1:1 charge complex is formed between DNA and most of these amphiphiles, except for **7**, which forms a ~ 2:1 charge complex with DNA.

We next determined the effect of pH on DNA binding for amphiphiles **1** and **2**. We chose two pH conditions near physiological pH (pH 7 and 8) and a lower pH of 5.5 that mimics the conditions of the early endosome. Figure 5 shows the fluorescence intensity as a function of amphiphile/DNA charge ratio for amphiphiles **1**, **2**, and **5** (DOTAP) at the three different pH conditions. The fluorescence intensity decreases as a function of charge ratio for both amphiphile **1** and DOTAP across all three

pHs. The binding curves look similar, with a 1:1 charge complex being formed between the amphiphile and DNA. The fluorescence intensity is constant and does not decrease for amphiphile **2**, indicating that **2** does not displace EtBr from DNA. This result is consistent with **2** being anionic over this pH range and as that the pK_a for the terminal carboxylic acids is below 5.5. Overall, these pH conditions do not play a significant role in DNA binding of the amphiphiles.

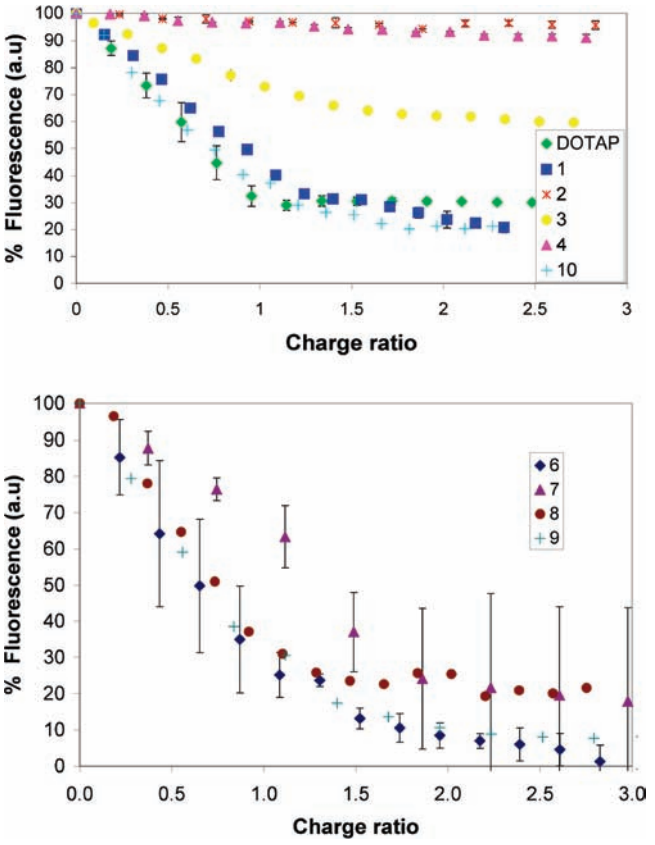

Figure 4. (top) Fluorescence intensity as a function of amphiphile/DNA charge ratio. (bottom) The fluorescence intensity as a function of amphiphile/DNA charge ratio for amphiphiles **1**, **6**−**10**, and DOTAP. N = 3 Avg ± SD.

To evaluate the release of the DNA from the amphiphile−DNA complex, the amphiphile/EtBr/DNA solution was incubated with a porcine liver esterase at pH 7.4 (1000 units/mL; 37 °C; 100 mM NaCl, 100 mM Tris buffer). For these release studies, the fluorescence intensities as a function of time for the various amphiphiles (including DOTAP) are shown in Figures 6 and 7. The increase in fluorescence from EtBr results from reintercalation of EtBr in the DNA; once the DNA is "free" from the amphiphile complex, ethidium bromide can bind with the DNA. As shown in Figure 6, amphiphile **1** no longer binds strongly to the DNA as a consequence of hydrolysis of its terminal benzyl esters. This result is consistent with the binding studies conducted with **2**, the hydrolyzed product of **1** prepared independently. However, in the presence of the enzyme, no increase in fluorescence over time is observed with amphiphile **3** or **5** (DOTAP), which possesses a terminal amide linkage or methyl group, respectively. A slightly slower increase in fluorescence is observed with compound **10**, which upon hydrolysis affords a neutral hydroxyl group.

To confirm that enzymatic hydrolysis cleaved the benzyl ester bond, liposomes formed from amphiphile **1** were incubated in PBS at 37 °C in the presence of porcine liver esterase, and the reaction products were examined by LC-MS. The results show that, within 30 min, ∼58% of **1** had converted to the hydrolyzed product **2**, and **1** was completely hydrolyzed by 2.5 h.

When the terminal ester is changed from a benzyl to an ethyl group as in compound **8**, similar EtBr−DNA binding curves to those of compound **1** are obtained (Figure 7). The increases in fluorescence indicate that both benzyl and ethyl terminal esters are readily hydrolyzed. Likewise, similar results are obtained when the acyl chain length is shortened from C12 to C10 (**1** vs **6**) while maintaining the terminal benzyl esters. However, upon extending the acyl chain length to C16 from C12 (**1** vs **7**), no increase in fluorescence is observed. Our interpretation of this

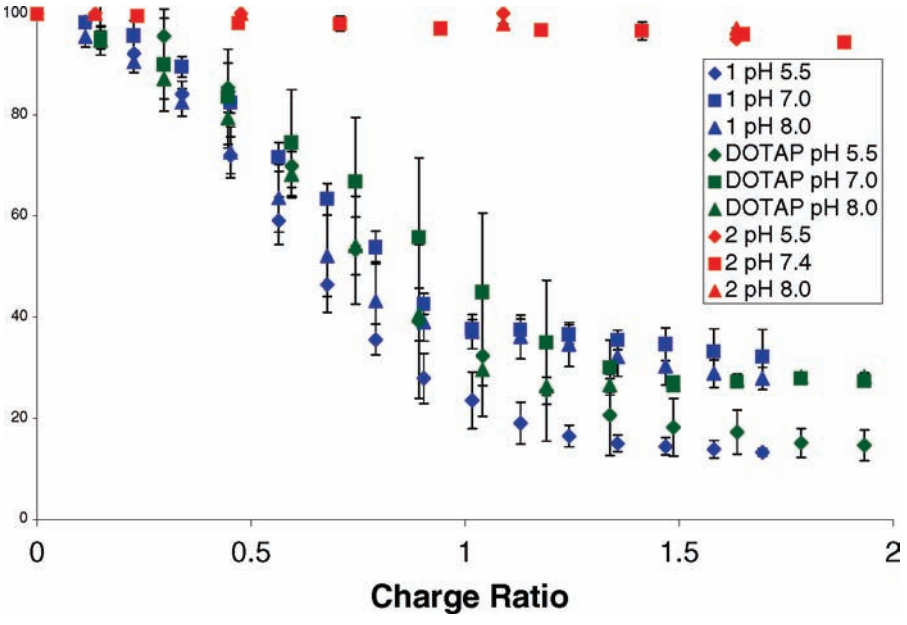

Figure 5. Fluorescence intensity as a function of amphiphile/DNA charge ratio in pH solutions of 5.5, 7.0 and 8.0. N = 3 Avg ± SD.

result is that the long chain analogue forms a more stable bilayer structure, reducing accessibility of the ester bonds to the enzyme, and therefore inhibiting hydrolysis. The phase-transition temperature (T_m) for **7** is 23 °C higher than for **1**, as shown in Table 1, which is consistent with this interpretation. Upon changing the benzyl to an ethyl ester but maintaining the chain length of C12, we observe a similar rate of hydrolysis (**6** vs **8**). However, **9**, which possesses an *n*-butyl ester as opposed to an ethyl ester (**9** vs **1**), shows a slower rate of fluorescence increase during the assay. In this amphiphile, the hydrolyzable ester is buried further in the hydrophobic chain, leading to a slower rate of hydrolysis. The enzymatic mechanism is still unknown, although we suspect that, during the flip-flop of the lipids, the enzyme hydrolyzes the terminal ester bonds.

Overall, the fluorescence data indicate that release of DNA from the supramolecular assembly does not occur for amphiphiles lacking a terminal hydrolyzable ester linkage, and those linkages near the headgroup or buried deeper in the chain are less accessible to enzymatic hydrolysis. The data also show the difference in DNA release from an amphiphilic complex that generates a resulting anionic amphilphile product versus a neutral one (**1** vs **10**).

Next, transfection experiments using the reporter gene, β-galactosidase (β-gal, pVax-LacZ1, Invitrogen), were performed with Chinese hamster ovarian (CHO) cells. The reporter gene was first mixed with the cationic lipid, at a defined amphiphile/DNA ratio, in potassium phosphate buffer (PBS) at room temperature.

Table 1. DSC Results for the Amphiphile Assemblies

compound	T_m (°C)	ΔH (kcal/mol)
1	52.55	2.03
6	46.32	3.18
7	75.45	1.57
8	78.44	8.47
9	76.14	3.78
10	50.77	0.102

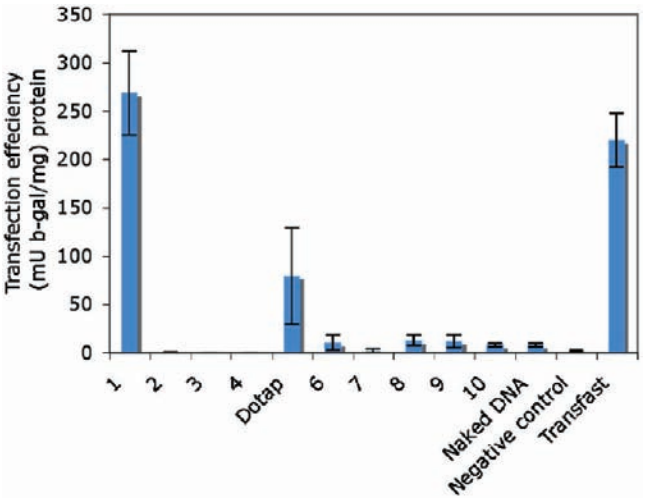

Figure 8. Transfection efficiency of the different amphiphiles in CHO cells. $N = 3$ Avg ± SD.

The complexes were added to CHO cells after 15 min. The amount of DNA used was the same as was used in the naked DNA control (no amphiphile) and positive control experiments (DOTAP and Transfast). The negative control was amphiphile **1** without DNA. After incubation at 37 °C and 5% CO_2 for 2 h, the solution containing the lipoplexes was removed and fresh growth medium with serum was added. Transfection efficiencies were assessed after 48 h using the β-galactosidase enzyme assay in conjunction with a standard curve. The efficacy of each transfection was calculated as β-gal activity normalized to total protein. We first performed a screen to identify the optimal amphiphile **1**/DNA ratio for greatest transfection examining ratios of 1:1, 2:1, 5:1, 10:1, 15:1, and 45:1. We also varied the time of incubation of the lipoplex with the cells from 30 min to 3 h, as well as performed analyses at the 24 and 48 h time points. On the basis of these experiments, the highest transfection efficiency was at a 5:1 ratio, an exposure time of 2 h, and analysis after 48 h. With these optimal conditions, we then performed a series of transfection experiments with the charge-reversal amphiphiles, as summarized in Figure 8. Amphiphile **1** was the most effective vector for transfection. The other compounds (**2**−**4** and **6**−**10**) showed minimal transfection activity, comparable to the negative control and naked DNA. The transfection efficacy of amphiphile **1** was significantly better than that of DOTAP ($p < 0.05$) and comparable to that of Transfast ($p > 0.05$). In the literature, it has also been shown that the addition of neutral lipids (i.e., helper lipids) such as dioleylphosphatidylethanolamine (DOPE) to a cationic lipid formulation can

dx.doi.org/10.1021/bc1004526 |*Bioconjugate Chem.* 2011, 22, 690–699

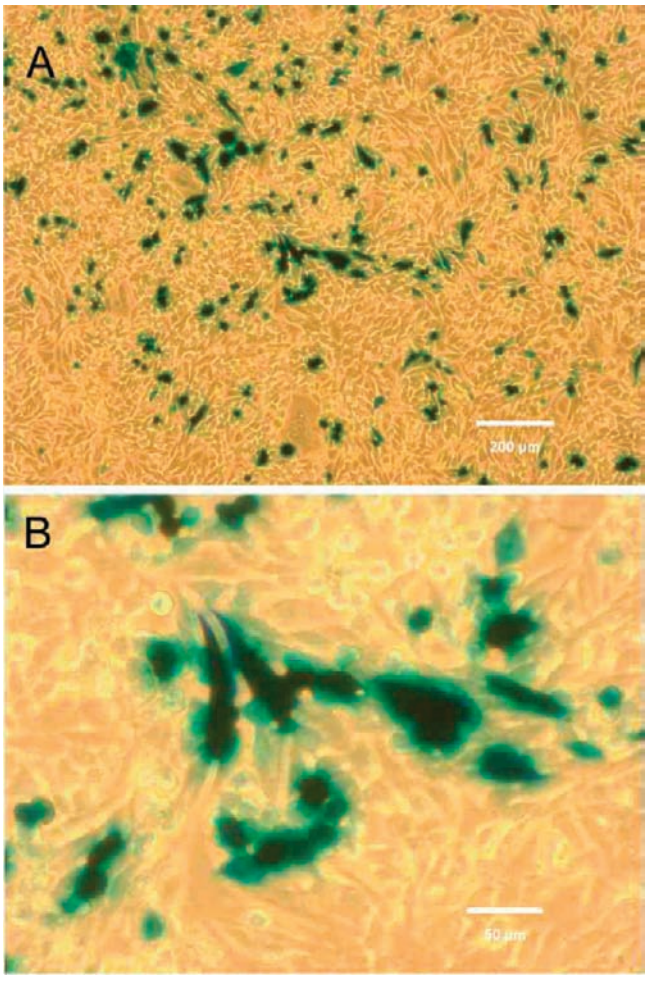

Figure 9. Photograph of β-galactosidase transfected cells using amphiphile **1** at low and high magnification. Dark blue stain represents B-gal expression.

improve DNA transfection efficiency.[19] Consequently, the above transfection experiments were repeated using the helper lipid, DOPE, and the charge-reversal amphiphiles at a 1:1 ratio. No increase in transfection efficiency was observed for these conditions (data not shown).

Micrographs of the β-galactosidase transfected CHO cells using amphiphile **1** are shown in Figure 9. This transfection experiment was conducted in a similar manner except it was done on a glass slide that had been previously modified with collagen to anchor the cells. The cells are expressing the protein β-gal (dark blue stain), and there appear to be few patches containing no cells, indicating minimal toxicity under these experimental conditions. This lack of cytotoxicity was quantitatively determined in our next set of experiments.

Cytotoxicity experiments were performed with CHO cells using both a formazan-based proliferation assay and a total protein assay. The cells were seeded onto a 96-multiwell microliter plate with an approximate density of 1×10^4 cells per well. The compounds were added to the cells 24 h later. After 24 h, cell proliferation was determined and expressed as a percentage of nontreated cells as shown in Figure 10. None of the amphiphiles showed a significant cytotoxicity, with values similar to the negative control (i.e., nontreated cells).

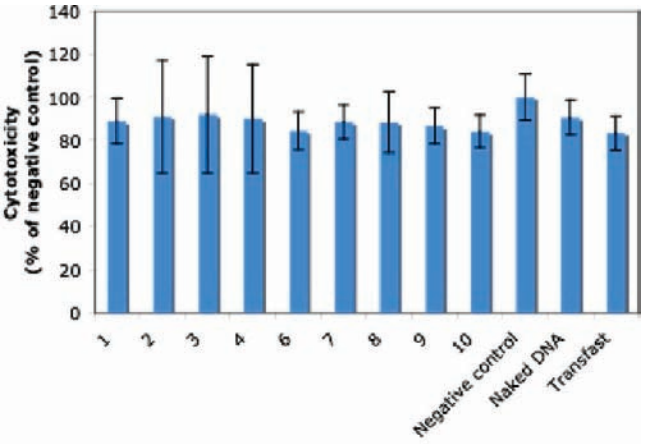

Figure 10. Cytotoxicity of the different lipids in CHO cells. $N = 3$ zAvg $\pm$ SD.

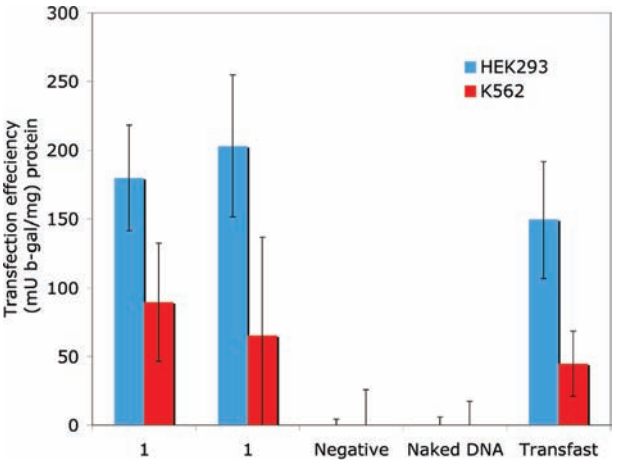

Figure 11. Transfection efficiency of amphiphile **1** with HEK293 and K562 cell lines. $N = 3$ Avg $\pm$ SD. First data set with **1** is at 15:1 and the second data set is at 45:1 charge ratio.

With these encouraging results, we then evaluated the transfection activity of amphiphile **1** in four other cell lines. Transfection experiments using human embryonic kidney (HEK293), erythroleukemic (K562), mouse fibroblast (NIH 3T3), and human liver carcinoma (HepG2) cell lines were performed with compound **1** (see Figure 11). Once again, we varied amphiphile **1**/DNA ratio, and only at high amphiphile/DNA ratio did we observe transfection (HEK 15:1; K562 45:1). Amphiphile **1** transfected DNA with similar efficiency to Transfast in the HEK293 and K562, but we did not observe significant transfection in the NIH 3T3 or HepG2 lines (data not shown).

With the above transfection activities recorded, we embarked on a series of physiochemical experiments to elucidate the key structural and physical properties of amphiphile **1** likely responsible for transfection activity. Given the polar headgroup and long hydrophobic acyl chains present in amphiphile **1**, it is likely to form bilayer structures in aqueous solution. To test this idea, differential scanning calorimeter (DSC), dynamic light scattering (DLS), transmission electron microscopy (TEM), and X-ray diffraction (XRD) experiments were performed. The samples were prepared for these studies by introducing a chloroformic

solution of amphiphiles into a pear-shaped flask. The solution was evaporated under vacuum, leaving a thin film deposited onto the flask wall. A total of 1 mL Tris buffer (100 mM Tris, 100 mM NaCl, pH 7.4) was then added, and the film was peeled off by vortexing. After 20 extrusions though a 50 nm polycarbonate membrane (Avanti Polar Lipids), the milky aqueous suspension turned into a homogeneous solution. The lipoplexes were prepared in an analogous manner by addition of the DNA to the previously prepared liposome solution.

DSC traces of the aqueous hydrated amphiphiles (**1**, **6**−**10**) show for each lipid a single phase-transition temperature (T_m). The T_m and transition enthalpy (ΔH) vary as the chain lengthens (C10, C12, and C16; **6** vs **1** vs **7**, respectively) when the end groups remain the same. For example, the T_m increases from 46 °C for **6** to 75 °C for **7**, indicating that amphiphile **7** forms a more stable structure than **1** or **6**. This trend with increasing chain length and higher T_m is true for T_m, but not for enthalpy. The enthalpy is smaller for **7** than for **6** or **1**. These results are consistent with reports on other lipid families (e.g., phosphatidylcholine and Avanti polar technical data). When the chain lengths are kept constant but the end group is changed from a benzyl to an alkyl ester on the amphiphile (e.g., **1** vs **8**), the T_m and enthalpy increase by about 25 °C. On the other hand, reversing the directionality of the ester linkage (**10** vs **8**) leads to a decrease in the T_m, possibly reflecting the greater ease that water molecules can hydrate and destabilize the terminal chain end group in **8** relative to **10**. In all, the DSC data showed that these charge-reversal lipids form organized structures with melting temperatures higher than 0 °C, the melting temperature of DOTAP, a common amphiphile used for gene transfection.

The mean diameter of the supramolecular structures formed by the different amphiphiles and by the amphiphile/DNA complexes was measured by dynamic light scattering (DLS). Compound **1** formed structures with a mean diameter of 110 nm, and the diameter increased to 562 nm in the presence of DNA. Amphiphile **6** formed structures with the same mean diameter (110 nm) and in presence of DNA formed structures with a mean diameter of 680 nm. Compounds **8** and **9** formed aggregates of 1 μm and larger in diameter as measured by DLS. Likewise, compounds **2**, **3**, **7**, and **10** afforded very large aggregates and precipitated products.

At 22 °C, X-ray diffraction patterns of amphiphile **1** in the absence of DNA gave three orders of a lamellar repeat period of 5.22 ± 0.03 nm with a sharp wide-angle spacing of 0.46 ± 0.01 nm. These data indicate that compound **1** formed gel-phase multibilayers at 22 °C, consistent with the DSC data (Table 1). In the presence of DNA, fully hydrated amphiphile **1** gave a lamellar repeat period of 5.31 ± 0.14 nm with a sharp wide-angle spacing of 0.46 ± 0.01 nm. Thus, the presence of the DNA did not significantly change d, indicating that the DNA was not intercalated between the lipid layers. Typically, an increase of 1 to 1.4 nm in d is observed with formation of a DNA−lipid sandwich structure.[71] These XRD data suggest a model where the DNA is entrapped at the surface or at the interface between the multilamellar vesicles (MLVs) in solution. This model is consistent with the increase in size observed by DLS, which could be caused by DNA bridging between these large MLVs. We were able to obtain a TEM image of amphiphile **1** in the presence, but not the absence, of DNA. The TEM micrograph showed multilamellar structures with an average vesicle diameter of 200 nm (Figure 12). Repeated attempts to obtain X-ray data on **6** in the presence and absence of DNA were unsuccessful.

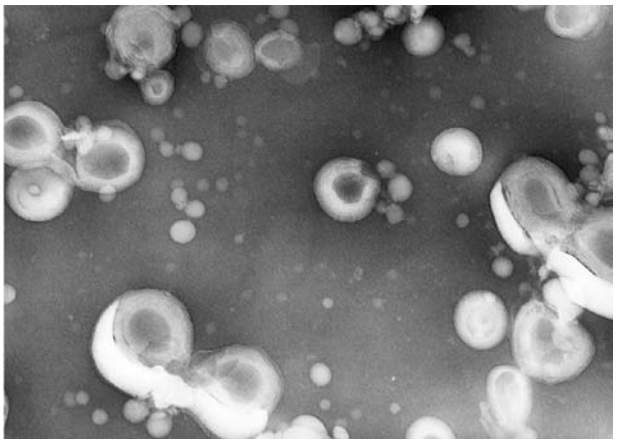

Figure 12. TEM micrographs of amphiphile **1** in aqueous solution, negative staining with ammonium molybdate 1% in water.

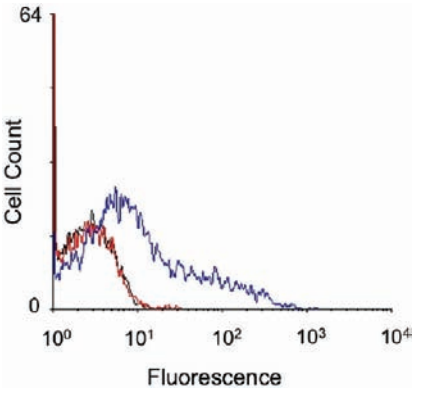

Figure 13. Flow cytometry histogram for CHO cells transfected with rhodamine-labeled DNA using either **1** (blue) or **6** (red). Negative control (black).

Of the amphiphiles, compound **6** has a melting temperature slightly lower than **1** and forms similarly sized structure by DLS as **1**, but does not give high transfection activity. We subsequently examined if the difference in activity between **1** and **6** was related to the amount of lipoplex taken up by the CHO cells. Cells were transfected with rhodamine-labeled DNA using either **1** or **6**, and the resulting cellular rhodamine fluorescence signal was recorded by flow cytometry. As shown in Figure 13, a significant amount of fluorescence was observed when DNA was delivered using **1**, while the fluorescence signal was almost the same as that of the negative control when delivered using **6**. Cell population analysis revealed that 27% of the cells were rhodamine-positive when transfected with **1**, compared to only 0.5% cells when transfected with **6**. These data suggest that the difference in cellular uptake may be responsible for the difference in the transfection activity between **1** and **6**. The underlying mechanism for the difference in cellular uptake is unknown and currently under investigation, but **6** does form a relatively weaker supramolecular structure than **1** as evident by the lower T_m.

Altogether, the results suggest a number of key findings responsible for the higher transfecton activity observed with amphiphile **1** compared to compounds **2**−**10**. First, compounds **2** and **4** do not bind DNA, while amphiphiles **1**, **3**, and **5**−**10** do bind DNA, at roughly the same magnitude. Amphiphiles **1**, **6**, **8**,

and **10** release DNA relatively rapidly in the presence of an esterase compared to the amphiphile **9**. Amphiphiles **3**, **5** (DOTAP), and **7** do not release DNA in the presence of an esterase. Amphiphiles **3**, **7**, **8**, **9**, and **10** formed aggregates of 1 μm or larger in diameter. Amphiphiles **1** and **6** both form similarly sized nanometer lipoplexes; however, more lipoplexes formed with amphiphile **1** are taken up by CHO than **6**.

In summary, *in vitro* gene delivery using charge reversal or charge switchable amphiphiles is a new approach and, like other functional delivery systems, provides a means to increase transfection activity, as well as potentially new reagents to study the transfection pathway. These amphiphiles were designed to transform from a cationic species that binds DNA to an anionic species that loses affinity to DNA after cleavage by an esterase. This charge-reversal effect would release DNA from the supramolecular complex. To evaluate the role of key amphiphile structural components, we synthesized in good yield a series of amphiphiles to determine the physicochemical properties and transfection efficiency of these amphiphiles. This series of amphiphiles included those that had C10 to C16 chains and a benzyl, *n*-butyl, or ethyl ester terminal group, as well as amphiphiles possessing very short alkyl chains and chains terminated with a carboxylate. All of these amphiphiles bind DNA and form amphiphile/DNA assemblies except for the compounds lacking long hydrophobic chains or those terminated with a carboxylate. The DNA release from the complexes and the dissociation rate of the complexes is controlled by the chemical structure of the lipid, which plays an important role in the stability and organization of the resulting supramolecular assembly. For example, the enzymatic hydrolysis rate of the ester linkage was dependent on hydrophobicity of the amphiphile, as the rate of hydrolysis was faster for the ethyl than the *n*-butyl analogue. The XRD data showed that amphiphile **1** forms bilayer organizations in the presence and absence of DNA, and DLS and TEM data showed that this amphiphile formed vesicles and lipoplexes with DNA on the order of 550 nm. The other amphiphiles organized themselves in larger aggregates. DSC data showed that the melting temperatures were between 45 and 80 °C, with those amphiphiles possessing the longer alkyl chains having higher melting temperatures.

The transfection experiments showed that the highest DNA transfection activity was observed for amphiphile **1**. This activity was observed in three different cell lines—Chinese hamster ovarian (CHO), human embryonic kidney (HEK293), and erythroleukemic (K562) cells. All other amphiphiles (except DOTAP and Transfast) showed minimal transfection activity, comparable to that of the negative control. Further studies will investigate the mechanism of cellular uptake and DNA delivery to the nucleus. This concept of charge reversal or charge switching has been successfully extended to additional cationic lipid structures,[66] zwitteronic lipids,[65] ferrocene-containing lipids,[55,56] and polymers[41,72] for DNA transfection, suggesting that this is an important, and potentially general, approach. Our data show that charge-reversal amphiphile **1** has all of the characteristics necessary for DNA delivery: it binds DNA, releases DNA upon charge reversal, forms well-ordered bilayers, forms lipoplexes of nanometer size, is taken up by cells, and efficiently transfects several cell types.

All solvents were dried and freshly distilled prior to use. All chemicals were purchased from Aldrich or Acros and used without further purification. All reactions were performed under nitrogen atmosphere. NMR spectra were recorded on a Varian INOVA spectrometer operating at 400 MHz (for ^{1}H and ^{13}C). Elemental analysis was obtained from Atlantic Microlab, Inc. A TA Instruments DSC 2920 Modulated DSC was used to collect Tm data. Calf thymus DNA and EtBr were purchased from Sigma. Fluorescence studies were carried out with a Fluorolog 3, ISA Jobin Yvon-Spex, Horiba group.

Dodecanedioic acid monobenzyl ester[1] : Dodecanoic diacid (1 mmol) and Dowex 50W-X2 (50-100 mesh) (1.0 g) were stirred in benzyl formate/ octane (2:8, 10 mL) at 80 ºC. The reaction was continued for 12 h. The solution was then filtrated and the filtrate evaporated. The crude product was purified by column chromatography to afford the compound as a white powder (79 % yield). ^{1}H NMR ($CDCl_3$) δ ppm 1.34 (m, 10 H, $(CH_2)_n$), 1.61 (m, 4H, CH_2), 2.32 (m, 4H, CH_2), 5.08 (s, 2H, CH_2), 7.34 (m, 5H, Ph); ^{13}C NMR ($CDCl_3$) δ ppm 25.16 (CH_2), 25.25 (CH_2), 29.40 $(CH_2)_n$, 29.57 $(CH_2)_n$, 29.71 $(CH_2)_n$, 34.40 (CH_2), 34.62 (CH_2), 66.55 (CH_2), 127.22 (CH), 127.86 (CH), 128.38 (CH), 128.76 (CH), 136.29 (CH), 174.04 (CO_2), 179.73 (CO_2H). MH^+ (GC-CIMS) = 321. The data agreed with the literature values (Saitoh, M., Fujisaki, S., Ishii, Y., Nishiguchi, T.,Tetrahedron Letters, 1996, *37*, 6733-6736).

Dodecanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester : To a solution of **7** (1.78 g, 5.5 mmol), 3-dimethylamino-propane-1,2-diol (0.3 mL, 2.5 mmol), DMAP (catalytic amount) in DCM (15 mL) and of DCC (1.1 g, 5.5 mmol) in DCM (5 mL) were added. The solution was subsequently stirred for 2 days. The reaction mixture was then filtered to remove the insoluble DCU. Concentration of the filtrate followed by chromatography (50% EtOAc/DCM to 100% EtOAc) afforded the product as colorless oil (80% yield). ^{1}H NMR ($CDCl_3$) δ ppm 1.23 (d, J = 4.8 Hz, 24H), 1.32 – 1.63 (m, 8H), 2.23 – 2.33 (m, 14H), 2.37 – 2.47 (m, 2H), 4.03 – 4.08 (m, 1H), 4.03 – 4.34 (m, 1H), 5.07 (s, 4H), 5.13 – 5.19 (m, 1H), 7.25 – 7.35 (m, 10H); ^{13}C NMR ($CDCl_3$) δ ppm 25.13 (CH_2), 29.30$(CH_2)_n$, 29.42$(CH_2)_n$, 29.58 $(CH_2)_n$, 34.17 (CH_2), 34.34 (CH_2), 34.51 (CH_2), 34.59 (CH_2), 46.22 $((CH_3)_3)N$), 59.55 (CH_2), 64.10 (CH_2), 66.10 (CH_2), 66.24 (CH_2), 69.36 (CH), 128.35 (CH), 128.73 (CH), 136.34 (CH), 173.38 (CO_2), 173.67 (CO_2), 173.84 (CO_2); HRMS calcd. for $[C_{43}H_{65}NO_8 + H]^+$ 724.4788, found 724.4785.

[2,3-Bis-(11-benzyloxycarbonyl-undecanoyloxy)-propyl]-trimethyl-ammonium; iodide (1): MeI (1 mL, 15 mmol) was added to a solution of **3** (0.9 g, 1.2 mmol) in DCM (5 mL). The solution was stirred for 4 hours and then concentrated. The residue was washed with ethyl ether to afford 0.9 g product (90 % yield) of a white powder. ^{1}H NMR ($CDCl_3$) δ ppm 1.22 (d, J = 3.6 Hz, 24H), 1.55 – 1.61 (m, 8H), 2.30 (t, J = 7.2 Hz, 8H), 3.49 (s, 9H), 3.82 – 3.87 (m, 1H), 4.08 – 4.13 (m, 1H), 4.45 – 4.49 (m, 2H), 5.07 (s, 4H), 5.57 (s, 1H), 7.27 – 7.34 (m, 10H); ^{13}C NMR ($CDCl_3$) δ ppm 24.78 (CH_2), 24.92 (CH_2), 25.11 (CH_2), 29.28 (CH_2), 29.38 (CH_2), 29.52 (CH_2), 29.56 (CH_2), 34.16 (CH_2), 34.38 (CH_2), 34.50 (CH_2), 54.95 (CH_2), 63.08 (CH_2), 65.89 (CH_2), 66.25 (CH_2), 66.38 (CH_2), 128.32 (CH), 128.35 (CH), 128.74 (CH), 136.32 (CH), 172.92 (CO_2), 173.37 (CO_2), 173.88 (CO_2); HRMS calcd. for $[C_{44}H_{68}NO_8I - I]^+$ 738.4945, found 738.4951. Elemental analysis: C, 61.28%; H, 8.10%; N, 2.33% (theory: C, 61.03%; H, 7.92%; N, 1.62%).

Dodecanedioic acid mono-tert-butyl ester:[2] To an ice-cold solution of dodecanedioic acid (15 g, 65 mmol), *tert*-butyl alcohol (64 mL, 650 mmol), DMAP (catalytic amount) in THF (80 mL) DCC (16 g, 78 mmol) in THF (20 mL) were added. The solution was subsequently warmed to room temperature and stirred for 24 hours. The reaction mixture was then filtered to remove the insoluble DCU. Concentration of the filtrate followed by chromatography (20% EtOAc / Hexane to 40% EtOAC / Hexane) afforded 9 g (50% yield) of the product. ^{1}H NMR ($CDCl_3$) δ ppm 1.23 (s, 12H), 1.40 (s, 9H), 1.51 – 1.60 (m, 4H), 2.16 (t, J = 7.2 Hz, 2H), 2.30 (t, J = 7.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ ppm 24.85 (CH_2), 25.28 (CH_2), 28.30 $(CH_3)_3$, 29.24 $(CH_2)_n$, 29.37 $(CH_2)_n$, 29.43 $(CH_2)_n$, 29.55 $(CH_2)_n$, 34.23 (CH_2), 35.81 (CH_2), 80.13 (C), 173.62 (CO_2), 180.08 (CO_2H).

Dodecanedioic acid 2-(11-tert-butoxycarbonyl-undecanoyloxy)-3-dimethylamino-propyl ester tert-butyl ester: To a solution of dodecanedioic acid mono-tert-butyl ester (4.6 g, 16 mmol), 3-dimethylamino-propane-1,2-diol (0.9 mL, 7.6 mmol), DMAP

(catalytic amount) in DCM (40 mL), and DCC (4 g, 20 mmol) in DCM (10 mL) was slowly added. The solution was subsequently stirred for 2 days. The reaction mixture was then filtered to remove the insoluble DCU. Concentration of the filtrate followed by chromatography (50% EtOAc / DCM to 100% EtOAc) afforded 2.3 g (46% yield) product as colorless oil. ^{1}H NMR ($CDCl_3$) δ = 1.23 (d, 24H), 1.42 (s, 18H), 1.58 (m, 8H), 2.23 (m, 8H), 2.47 (m, 4H), 2.62 (m, 2H), 4.03 – 4.34 (m, 2H), 5.19 (m, 1H); ^{13}C NMR ($CDCl_3$) δ = 25.33 $(CH_2)_n$, 29.30 $(N(CH_3)_3)$, 29.40 $(CH_2)_n$, 29.52 $(CH_2)_n$, 30.0 $(CH_2)_n$, 30.3 $(CH_2)_n$, 34.27 (CH_2), 34.32 (CH_2), 46.22 $(CH_3)_2$, 64.10 (CH_2), 66.10 (CH_2), 69.36 (CH), 173.28 (CO_2), 173.47 (CO_2).

[2,3-Bis-(11-tert-butoxycarbonyl-undecanoyloxy)-propyl]-trimethyl-ammonium; iodide: MeI (1 mL, 15 mmol) was added to a solution of dodecanedioic acid 2-(11-tert-butoxycarbonyl-undecanoyloxy)-3-dimethylamino-propyl ester tert-butyl ester (1.1 g, 1.7 mmol) in DCM (5 mL). The solution was stirred for 4 hours and then concentrated. The residue was recrystallized in DCM/Ethyl ether to afford 1.0 g product (75 % yield) as a white powder. ^{1}H NMR ($CDCl_3$) δ ppm 1.23 (s, 24H), 1.39 (s, 9H), 1.52 – 1.56 (m, 8H), 2.15 (t, J = 7.6 Hz, 4H), 2.29 – 2.33 (m, 4H), 3.50 (s, 9H), 3.82 – 3.88 (m, 1H), 4.08 – 4.12 (m, 1H), 4.45 – 4.49 (m, 2H), 5.07 (s, 4H); ^{13}C NMR ($CDCl_3$) δ ppm 24.78 (CH_2), 24.93 (CH_2), 25.28 (CH_2), 28.31 $(CH_3)_3$, 29.26 $(CH_2)_n$, 29.37 $(CH_2)_n$, 29.45 $(CH_2)_n$, 29.55 $(CH_2)_n$, 29.60 $(CH_2)_n$, 34.16 (CH_2), 34.38 (CH_2), 35.79(CH_2), 54.95 $(N(CH_3)_3)$, 63.05 (CH_2), 65.88 (CH_2), 66.34 (CH), 80.09 (C), 172.91 (CO_2), 173.37(CO_2), 173.53 (CO_2); HRMS calcd for $[C_{38}H_{72}NO_8I - I]^+$ 670.5258, found 670.5268.

[2,3-Bis-(11-carboxy-undecanoyloxy)-propyl]-trimethyl-ammonium; iodide (2) : 0.70 g of [2,3-bis-(11-tert-butoxycarbonyl-undecanoyloxy)-propyl]-trimethyl-ammonium iodide and TFA (6 mL) in DCM (24 mL) were stirred at room temperature for 4 hours. The solution was then concentrated and the residue was recrystallized in

MeOH/ethyl ether to afford 0.54 g (90 % yield) of the product. ^{1}H NMR (DMSO – d_6) δ ppm 1.19 (s, 24H), 1.41 – 1.48 (m, 8H), 2.13 (t, J = 7.6 Hz, 4H), 2.24 – 2.34 (m, 4H), 3.05 (s, 9H), 3.64 – 3.74 (m, 2H), 4.00 – 4.04 (m, 1H), 4.31 – 4.34 (m, 1H), 5.44 (d, J = 3.2 Hz, 1H), 11.95 (s, 2H); ^{13}C NMR (DMSO – d_6) δ ppm 24.76 (CH_2), 24.93 (CH_2), 25.14 (CH_2), 29.04 $(CH_2)_n$, 29.21 $(CH_2)_n$, 29.35 $(CH_2)_n$, 29.40 $(CH_2)_n$, 29.52 $(CH_2)_n$, 33.89 (CH_2), 34.18 (CH_2), 34.31 (CH_2), 53.80 ($N(CH_2)_3$), 63.69 (CH_2), 65.47 (CH_2), 66.60 (CH), 172.75 (CO_2), 173.14 (CO_2), 175.11 (CO_2H); HRMS calcd for $[C_{30}H_{56}NO_8I - I]^+$ 558.4006, found 558.4001. Elemental analysis: C, 52.22%; H, 8.20%; N, 2.01% (theory: C, 52.55%; H, 8.23%; N, 2.04%).

11-Benzylcarbamoyl-undecanoic acid: To a solution of dodecanedioic acid (15 g, 65 mmol), benzylamine (64 mL, 650 mmol) in THF (80 mL), and a solution of DCC (16 g, 78 mmol) in THF (20 mL) were added. The reaction mixture was stirred for 24 hours and then filtered to remove the insoluble DCU. Concentration of the filtrate followed by chromatography (20% EtOAc/hexane) yielded 9 g (50% yield) of the product as colorless solid. ^{1}H NMR (DMSO) **δ** = 1.18 (m, 12H), 1.44 (m, 4H), 2.11 (m, 4H), 4.20 (s, 2H), 7.23 (m, 5H), 8.21 (m, 1H); ^{13}C NMR (DMSO) **δ** 24.86 (CH_2), 25.89 (CH_2), 29.09 $(CH_2)_n$, 29.35 $(CH_2)_n$, 29.48 $(CH_2)_n$, 29.67 $(CH_2)_n$, 29.86 $(CH_2)_n$, 33.91 (CH_2), 34.28 (CH_2), 35.78 (CH_2), 46.34 (CH_2), 127.99 (CH), 128.75 (CH), 140.07 (CH), 173.01 (CONH), 178.12 (CO_2H); HRMS calcd for $[C_{19}H_{29}NO_3H]^+$ 319.2147, found 320.2241.

11-Benzylcarbamoyl-undecanoic acid 2-(11-benzylcarbamoyl-undecanoyloxy)-3-dimethylamino-propyl ester: To a solution of 11-benzylcarbamoyl-undecanoic acid (0.5 g, 1.56 mmol), 3-dimethylamino-propane-1,2-diol (0.08 mL, 0.78 mmol), DMAP (catalytic amount) in DCM (20 mL) and DCC (0.4 g, 20 mmol) in DCM (5 mL) were added. The solution was stirred for an additional 2 days. The reaction mixture was then filtered to remove the insoluble DCU. Concentration of the filtrate followed by

chromatography (EtOAc) afforded 0.56 g (46% yield) of product as a colorless oil. ^{1}H NMR ($CDCl_3$) δ = 1.20 (m, 24H), 1.59 (m, 8H), 2.25 (m, 14H), 2.37 (m, 2H), 2.60 (m, 4H), 4.02-4.34 (m, 2H), 5.04 (s, 4H), 5.17 (m, 1H), 7.22 (m, 10H); ^{13}C NMR ($CDCl_3$) δ = 25.13 (CH_2), 28.79 $(CH_2)_n$, 29.31 $(CH_2)_n$, 29.43 $(CH_2)_n$, 29.58 $(CH_2)_n$, 34.33 (CH_2), 34.53 (CH_2), 46.24 (CH_2), 59.57 (CH_2), 64.10 (CH_2), 66.22 (CH_2), 69.38 (CH), 128.23, (CH) 128.59 (CH), 133.55 (CH), 144.52 (CH), 173.38 (CO_2), 173.66 (CONH), 173.89 (CONH); HRMS calcd for $[C_{43}H_{67}IN_3O_6H]^+$ 722.5108, found 722.5095.

[2,3-Bis-(11-benzylcarbamoyl-undecanoyloxy)-propyl]-trimethyl-ammonium; iodide (3) : MeI (1 mL, 15 mmol) was added to a solution of 11-benzylcarbamoyl-undecanoic acid 2-(11-benzylcarbamoyl-undecanoyloxy)-3-dimethylamino-propyl ester (0.5 g, 0.7 mmol) in DCM (5 mL). The solution was stirred for 4 hours and then concentrated. The residue was washed with ethyl ether to afford 0.57 g product (95 % yield) as a white powder. ^{1}H NMR (DMSO) δ ppm 1.18 (s, 24H), 1.45 (m, 8H), 2.30 (m, 8H), 3.27 (s, 9H), 3.36 (dd, 2H), 4.08 (m, 2H), 4.37 (m, 4H), 5.44 (s, 1H), 7.19 – 7.30 (m, 10H); ^{13}C NMR (DMSO) δ ppm 24.78 (CH_2), 24.98 (CH_2), 26.37 (CH_2), 29.05 $(CH_2)_n$, 29.40 $(CH_2)_n$, 29.56 $(CH_2)_n$, 29.64 $(CH_2)_n$, 29.86 $(CH_2)_n$, 33.91 (CH_2), 34.20 (CH_2), 53.85 (CH_3), 70.24 (CH_2), 72.42 (CH_2), 72.44 (CH), 127.98 (CH), 128.83 (CH), 139.38 (CH), 172.74 (CO_2), 173.12 (CONH); HRMS calcd for $[C_{44}H_{70}IN_3O_6^+ - I]^+$ 736.5265, found 736.5260. Elemental analysis: C, 61.22%; H, 8.17%; N, 4.86% (theory: C, 61.17%; H, 8.05%; N, 4.81%).

(2,3-Diacetoxy-propyl)-trimethyl-ammonium; iodide (4): A mixture of 3-dimethyl -amino-propane-1,2-diol (0.30 mL, 2.5 mmol), acetyl anhydride (2 mL, excess) and DCM (5mL) was stirred overnight at room temperature. MeI (2 mL, excess) was then added to the solution, and the reaction was stirred for an additional 4 hours. Next, the solution was concentrated and ethyl ether (20 mL) was added to precipitate the product (0.73 g, 85 %

yield). ^{1}H NMR (DMSO – d_6) δ ppm 2.02 (d, J = 10.8 Hz, 6H), 3.07 (s, 9H), 3.68 – 3.73 (m, 2H), 4.04 – 4.08 (m, 1H), 4.25 – 4.29 (m, 1H), 5.40 (d, J = 4 Hz, 1H); ^{13}C NMR (DMSO – d_6) δ ppm 21.22 (CH_3), 21.59 (CH_3), 53.89 $(CH_3)_3$, 63.76 (CH_2), 65.38 (CH_2), 66.72 (CH), 170.33 (CO_2), 170.70 (CO_2); HRMS calcd for $[C_{10}H_{20}NO_4I - I]^+$ 218.1392, found 218.1398. Elemental analysis: C, 34.76%; H, 5.77%; N, 4.03% (theory: C, 34.80%; H, 5.84%; N, 4.06%).

Decanedioic acid monobenzyl ester: We followed the same procedure used for the preparation of dodecanoic acid monobenzyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 1.29 (m, 8 H, $(CH_2)_n$), 1.62 (m, 4H, CH_2), 2.34 (m, 4H, CH_2), 5.11 (s, 2H, CH_2), 7.34 (m, 5H, Ph); ^{13}C NMR ($CDCl_3$) δ ppm 24.61 (CH_2), 24.78 (CH_2), 28.88 $(CH_2)_n$, 28.91 $(CH_2)_n$, 33.96 (CH_2), 34.19 (CH_2), 66.14 (CH_2), 127.06 (CH), 127.51 (CH), 128.24 (CH), 128.48 (CH), 128.59 (CH), 136.09 (CH), 174.08 (CO_2), 178.86 (CO_2H). HRMS calcd. for $[C_{17}H_{24}O_4 + Na]^+$ 315.1572, found 315.1599.

Decanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-nonanoyloxy)-3-dimethylamino - propyl ester: We used the same procedure as that described for decanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-nonanoyloxy)-3-dimethylamino - propyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 1.25 (d, 18 H, $(CH_2)_n$), 1.58 (m, 8H, CH_2), 2.23 – 2.33 (m, 14H, CH_2), 2.41 (m, 2H, CH_2), 3.66 (m, 2H, CH_2), 4.05 (m, 1H, CH_2), 4.34 (m, 2H, CH_2), 5.08 (s, 4H, CH_2), 5.16 (m, 1H, CH_2), 7.32 (m, 10H, CH_2); 13C NMR ($CDCl_3$) δ ppm 25.43 (CH_2), 25.54 (CH_2), 29.71 $(CH_2)_n$, 34.68 $(CH_2)_n$, 34.93$(CH_2)_n$, 45.82 ($(CH_3)_3$)N), 59.45 (CH_2), 64.40 (CH_2), 66.73 (CH_2), 68.94 (CH), 128.82 (CH), 129.19 (CH), 136.75 (CH), 173.82 (CO_2), 174.04 (CO_2), 174.32 (CO_2), 174.35 (CO_2); HRMS calcd. for $[C_{39}H_{58}NO_8 + H]^+$ 668.4162, found 668.4183.

2,3-Bis-(11-benzyloxycarbonyl-nonanoyloxy)-propyl]-trimethyl-ammonium; iodide (6): We followed the same procedure used for synthesizing compound **1**. ^{1}H NMR ($CDCl_3$) δ ppm 1.28 (m, 28 H, $(CH_2)_n$), 1.58 (m, 12H, CH_2), 2.55 (m, 8H, CH_2), 3.51 (m, 9H, CH_3), 3.84 (m, 1H, CH_2), 4.14 (dd, 1H, CH_2), 4.34 (m, 1H, CH_2), 4.54 (m, 2H, CH_2), 5.10 (s, 4H, CH_2), 5.54 (m, 1H, CH), 7.35 (m, 10H, Ph); ^{13}C NMR ($CDCl_3$) δ ppm 19.22 (CH_2), 24.82 (CH_2), 25.15 (CH_2), 29.27 $(CH_2)_n$, 34.22 (CH_2), 34.55 (CH_2), 55.00 (($CH_3)_2$N), 63.18 (CH_2), 66.00 (CH_2), 66.38 (CH_2), 128.43 (CH), 128.85 (CH), 136.35 (CH), 172.99 (CO_2), 173.48 (CO_2), 173.97 (CO_2). HRMS calcd. for $[C_{40}H_{68}NO_8I - I]^+$ 682.9063, found 682.9076 . Elemental analysis: C, 70.30%; H, 8.86%; N, 2.05% (theory: C, 70.03%; H, 8.92%; N, 2.82%).

Hexadecanedioic acid monobenzyl ester : We used the same procedure as that described for dodecanoic acid monobenzyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 1.24 (m, 18 H, $(CH_2)_n$), 1.63 (m, 4H, CH_2), 2.35 (m, 4H, CH_2), 5.11 (s, 2H, CH_2), 7.35 (m, 5H, Ph); ^{13}C NMR ($CDCl_3$) δ ppm 24.88 (CH_2), 25.16 (CH_2), 29.26 $(CH_2)_n$, 29.34 $(CH_2)_n$, 29.45 $(CH_2)_n$, 29.64 $(CH_2)_n$, 29.77 $(CH_2)_n$, 29.80 $(CH_2)_n$, 34.21 (CH_2), 34.54 (CH_2), 66.27 (CH_2), 128.32 (CH), 128.70 (CH), 136.28 (CH), 173.91 (CO_2), 179.88 (CO_2H). HRMS calcd. for $[C_{23}H_{36}O_4+Na]^+$ 399.2511, found 399.2493.

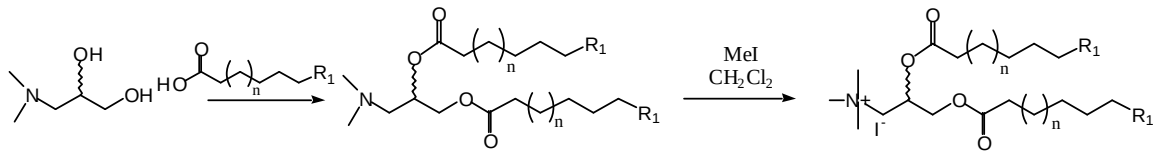
Hexadecanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester: We followed the same procedure used to prepare dodecanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 1.25 (d, 40 H, $(CH_2)_n$), 1.61 (m, 8H, CH_2), 2.26 – 2.34 (m, 16H, CH_2), 2.42 (m, 2H, CH_2), 3.64 (m, 2H, CH_2), 4.07 (m, 1H, CH_2), 4.35 (m, 2H, CH_2), 5.09 (s, 4H, CH_2), 5.17 (m, 1H, CH_2), 7.31 (m, 10H, CH_2); ^{13}C NMR ($CDCl_3$) δ ppm 25.16 (CH_2), 25.73 (CH_2), 29.33 $(CH_2)_n$, 29.44 $(CH_2)_n$, 29.53 $(CH_2)_n$, 29.66 $(CH_2)_n$, 29.80 (CH_2), 34.12 (CH_2), 34.54 (CH_2), 45.02 (($CH_3)_3$)N), 61.67

(CH_2), 64.78 (CH_2), 65.34 (CH_2), 66.27 (CH_2), 128.37 (CH), 128.74 (CH), 136.11 (CH), 173.97 (CO_2); HRMS calcd. for $[C_{51}H_{82}NO_8 + H]^+$ 836.6040, found 836.5977.

2,3-Bis-(11-benzyloxycarbonyl-nonanoyloxy)-propyl]-trimethyl-ammonium; iodide (7): We used the same procedure as described for compound **1**. ^{1}H NMR ($CDCl_3$) δ ppm 1.27 (m, 52 H, $(CH_2)_n$), 1.61 (m, 16H, CH_2), 2.36 (m, 8H, CH_2), 3.52 (m, 9H, CH_3), 3.88 (m, 1H, CH_2), 4.14 (m, 2H, CH_2), 4.53 (m, 2H, CH_2), 5.11 (s, 2H, CH_2), 5.61 (m, 1H, CH), 7.34 (m, 10 H, Ph); ^{13}C NMR ($CDCl_3$) δ ppm 24.89 (CH_2), 25.10 (CH_2), 29.27 $(CH_2)_n$, 29.41 $(CH_2)_n$, 29.49 $(CH_2)_n$, 29.61 $(CH_2)_n$, 29.67 $(CH_2)_n$, 29.79 $(CH_2)_n$, 34.08 (CH_2), 34.47 (CH_2), 54.86 ($(CH_3)_2N$), 60.31 (CH_2), 62.99 (CH_2), 65.80 (CH_2), 66.20 (CH_2), 128.28 (CH), 128.68 (CH), 136.23 (CH), 172.89 ($\underline{C}O_2$), 173.36 ($\underline{C}O_2$), 173.89 ($\underline{C}O_2$). HRMS calcd. for $[C_{52}H_{85}NO_8I - I]^+$ 851.6275, found 851.6229. Elemental analysis: C, 63.66%; H, 8.99%; N, 2.00% (theory: C, 63.85%; H, 8.66%; N, 1.43%).

Dodecanedioic acid monoethyl ester: To an ice-cooled stirred solution of dodecanedioyl dichloride in THF, a solution of ethyl alcohol and TEA in THF was added dropwise over 2 h. After the addition was complete, the mixture was stirred overnight at room temperature. Water was added to the mixture and phases were then extracted with AcOEt. The organic layers were subsequently dried over Na_2SO_4 and concentrated. The residue was purified by silica gel chromatography with Hexane/AcOEt (8:2) to afford the compound with a yield of 55 %. ^{1}H NMR ($CDCl_3$) δ ppm 1.24 (m, 16 H, $(CH_2)_n$), 1.58 (m, 4H, CH_2), 2.29 (m, 4H, CH_2), 4.10 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ ppm 14.45 (CH_3), 24.85 (CH_2), 25.16 (CH_2), 29.22 $(CH_2)_n$, 29.30 $(CH_2)_n$, 29.40 $(CH_2)_n$, 29.53 $(CH_2)_n$, 34.22 (CH_2), 34.58 (CH_2), 60.40 (CH_2), 174.22 (CO_2), 180.10 (CO_2H). HRMS calcd. for $[C_{14}H_{26}O_4+Na]^+$ 281.1729, found 281.1750.

Dodecanedioic acid ethyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester: We followed the same procedure used as for the preparation of dodecanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 1.21 (d, 30 H, $(CH_2)_n$), 1.56 (m, 8H, CH_2), 2.21 – 2.28 (m, 14H, CH_2), 2.41 (m, 2H, CH_2), 4.07 (m, 5H, CH_2), 4.35 (dd, 1H, CH_2), 5.14 (m, 1H, CH_2); ^{13}C NMR ($CDCl_3$) δ ppm 13.52 (CH_3), 24.22 (CH_2), 28.41 (CH_2), 28.57 (CH_2), 28.70 (CH_2), 33.31 (CH_2), 33.49 (CH_2), 45.30 ((CH_3)$_3$N), 58.71 (CH_2), 59.26 (CH_2), 63.17 (CH_2), 66.53 (CH), 172.30 (CO_2), 172.56 (CO_2), 172.88 (CO_2); HRMS calcd. for $[C_{33}H_{62}NO_8 + H]^+$ 600.4475, found 600.4485.



[2,3-Bis-(11-ethyloxycarbonyl-undecanoyloxy)-propyl]-trimethyl-ammonium; iodide (8): We followed the same procedure used as described for compound **1**. ^{1}H NMR ($CDCl_3$) δ ppm 1.25 (m, 25 H, $(CH_2)_n$), 1.61 (m, 12H, CH_2), 2.32 (m, 8H, CH_2), 3.54 (m, 9H, CH_3), 3.89 (m, 1H, CH_2), 4.14 (m, 5H, CH_2), 4.53 (m, 2H, CH_2), 5.61 (m, 1H, CH); ^{13}C NMR ($CDCl_3$) δ ppm 14.39 (CH_3), 24.71 (CH_2), 24.85 (CH_2), 25.08 (CH_2), 29.23 (CH_2)$_n$, 29.35 (CH_2)$_n$, 29.48 (CH_2)$_n$, 29.52 (CH_2)$_n$, 34.09 (CH_2), 34.49 (CH_2), 54.84 ((CH_3)$_2$N), 60.31 (CH_2), 62.99 (CH_2), 65.80 (CH_2), 66.16 (CH), 172.86 (CO_2), 173.33 (CO_2), 174.08 ($\underline{C}O_2$). HRMS calcd. for $[C_{34}H_{65}NO_8I - I]^+$ 615.4710, found 615.4708. Elemental analysis: C, 55.14%; H, 8.64%; N, 1.96% (theory: C, 55.05%; H, 8.70%; N, 1.89%).

Dodecanedioic acid monobutyl ester : Dodecanoic diacid (1 mmol) and Dowex 50W-X2 (50-100 mesh) (1.0 g) were stirred in butyl formate/ octane (2:8, 10 mL) at 80 ºC. The reaction was continued for 12 h. The solution was then filtrated and the filtrate evaporated. The crude was purified by column chromatography to afford the compound as a white powder (85 % yield). ^{1}H NMR ($CDCl_3$) δ ppm 0.86 (t, 3H, CH_3), 1.28 (m, 14 H, $(CH_2)_n$), 1.55 (m, 6H, CH_2), 2.25 (m, 4H, CH_2), 4.00 (t, 2H, CH_2); ^{13}C NMR ($CDCl_3$)

δ ppm 13.83 (CH_3), 19.33 (CH_2), 24.84 (CH_2), 25.18 (CH_2), 29.21 $(CH_2)_n$, 29.30 $(CH_2)_n$, 29.38 $(CH_2)_n$, 29.53 $(CH_2)_n$, 30.88 $(CH_2)_n$, 34.23 (CH_2), 34.58 (CH_2), 64.33 (CH_2), 174.30 (CO_2), 180.17 (CO_2H). HRMS calcd. for $[C_{16}H_{30}O_4+Na]^+$ 309.2042, found 309.2013.

Dodecanedioic acid butyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester: We followed the same procedure as to synthesize dodecanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 0.86 (t, 3H, CH_3), 1.28 (m, 28 H, $(CH_2)_n$), 1.55 (m, 12H, CH_2), 2.25 (m, 14H, CH_2), 2.50 (m, 2H, CH_2), 3.95 (m, 5H, CH_2), 4.23 (dd, 1H, CH_2), 5.24 (m, 1H, CH); ^{13}C NMR ($CDCl_3$) δ ppm 13.82 ($\underline{C}H_3$), 19.25 (CH_2), 24.95 (CH_2), 25.10 (CH_2), 29.23 $(CH_2)_n$, 29.34 $(CH_2)_n$, 29.49 $(CH_2)_n$, 30.82 $(CH_2)_n$, 34.17 (CH_2), 34.45 (CH_2), 45.50 ($(CH_3)_2N$), 59.02 (CH_2), 63.83 (CH_2), 64.33 (CH_2), 68.54 (CH), 173.23 (CO_2), 173.44 (CO_2), 174.00 (CO_2). HRMS calcd. for $[C_{37}H_{70}NO_8 + H]^+$ 656.5101, found 656.5167.

[2,3-Bis-(11-butyloxycarbonyl-undecanoyloxy)-propyl]-trimethyl-ammonium; iodide (9): We used the same procedure as that described for compound **1**. ^{1}H NMR ($CDCl_3$) δ ppm 0.86 (t, 6H, CH_3), 1.29 (m, 28 H, $(CH_2)_n$), 1.53 (m, 12H, CH_2), 2.25 (m, 8H, CH_2), 3.21 (m, 9H, CH_3), 3.00 (m, 8H, CH_2), 4.43 (dd, 1H, CH_2), 5.54 (m, 1H, CH); ^{13}C NMR ($CDCl_3$) δ ppm 13.70 (CH_3), 19.22 (CH_2), 24.81 (CH_2), 25.09 (CH_2), 29.21 $(CH_2)_n$, 29.33 $(CH_2)_n$, 29.50 $(CH_2)_n$, 30.75 $(CH_2)_n$, 34.25 (CH_2), 34.51 (CH_2), 54.55 ($(CH_3)_2N$), 59.02 (CH_2), 64.44 (CH_2), 64.53 (CH_2), 65.84 (CH_2), 173.50 (CO_2), 173.79 (CO_2), 174.70 ($\underline{C}O_2$). HRMS calcd. for $[C_{38}H_{73}NO_8I - I]^+$ 671.5336, found 671.5305. Elemental analysis: C, 58.63%; H, 9.36%; N, 1.67% (theory: C, 58.12%; H, 9.19%; N, 1.63%).

10: n = 7; R1 = OC(O)CH3

12-Acetoxy-dodecanoic acid : A mixture of 12-hydroxydodecanoic acid (0.30 mL, 2.5 mmol), acetyl anhydride (2 mL, excess), and pyridine (2 mL) was stirred overnight at room temperature. Next, the solution was concentrated and ethyl alcohol (20 mL) was added to precipitate the product (0.73 g, 95 % yield). ^{1}H NMR ($CDCl_3$) δ ppm 1.24 (m, 14 H, $(CH_2)_n$), 1.60 (m, 4H, CH_2), 2.01 (s, 3H, CH_3), 2.19 (d, 2H, CH_2), 2.42 (m, 2H, CH_2), 4.01 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$) δ ppm 21.25 (CH_3), 24.40 (CH_2), 24.88 (CH_2), 26.09 (CH_2), 28.79 $(CH_2)_n$, 29.06 $(CH_2)_n$, 29.23 $(CH_2)_n$, 29.39 $(CH_2)_n$, 29.43 $(CH_2)_n$, 29.56 $(CH_2)_n$, 29.65 $(CH_2)_n$, 34.07 (CH_2), 35.48 (CH_2), 64.88 (CH_2), 171.53 (CO_2), 179.09 (CO_2). HRMS calcd. for $[C_{14}H_{26}O_4+Na]^+$ 281.1729, found 281.1740.

12-Acetoxy-dodecanoic acid-1-(12-acetoxydodecanoyloxymethyl)-2-dimethylamino-ethyl ester: We followed the same procedure used for preparation of dodecanedioic acid benzyl ester 2-(11-benzyloxycarbonyl-undecanoyloxy)-3-dimethylamino - propyl ester. ^{1}H NMR ($CDCl_3$) δ ppm 1.24 (d, 15 H, $(CH_2)_n$), 1.58 (m, 4H, CH_2), 2.02 (m, 6H, CH_3), 2.26 (m, 8H, CH_3), 2.41 (m, 2H, CH_2), 4.03 (m, 5H, CH_2), 4.33 (dd, 1H, CH_2), 5.14 (m, 1H, CH_2); ^{13}C NMR ($CDCl_3$) δ ppm 21.52 (CH_3), 24.22 (CH_2), 28.41 (CH_2), 28.57 (CH_2), 28.70 (CH_2), 33.31 (CH_2), 33.49 (CH_2), 45.30 (CH_2), 58.71 (CH_2), 59.26 (CH_2), 63.17 (CH_2), 68.53 (CH), 172.30 (CO_2), 172.56 (CO_2), 172.88 (CO_2); HRMS calcd. for $[C_{33}H_{62}NO_8 + H]^+$ 600.4507, found 600.4485.

[2,3-Bis-(12-acetoxy-dodecanoyloxy)-propyl]-trimethyl-ammonium; iodide (10): Same procedure used then that described for compound **1**. ^{1}H NMR ($CDCl_3$) δ ppm 1.27

(d, 15 H, $(CH_2)_n$), 1.63 (m, 4H, CH_2), 2.05 (m, 4H, CH_3), 2.37 (m, 4H, CH_2), 3.54 (m, 9H, CH_3), 3.91 (m, 1H, CH), 4.03-5.15 (m, 5H, CH_2), 4.54 (dd, 1H, CH_2), 5.61 (m, 1H, CH_2); ^{13}C NMR ($CDCl_3$) δ ppm 21.23 (CH_3), 24.75 (CH_2), 24.88 (CH_2), 26.04 (CH_2), 26.51 (CH_2), 28.72 (CH_2), 29.22 (CH_2), 29.39 (CH_2), 29.63 (CH_2), 30.94 (CH_2), 34.12 (CH_2), 34.34 (CH_2), 54.88 ((CH_3)$_3$N), 63.00 (CH_2), 64.80 (CH_2), 65.82 (CH_2), 66.23 (CH), 171.47 (CO_2), 172.90 (CO_2), 173.37 (CO_2); HRMS calcd. for $[C_{34}H_{65}NO_8 + H]^+$ 615.4710, found 615.4688. Elemental analysis: C, 56.71%; H, 8.88%; N, 2.55% (theory: C, 55.05%; H, 8.70%; N, 1.892%).

Liposome preparation

Chloroform solutions of the amphiphiles were mixed and dried to a thin film by rotary evaporation. The residual solvent was removed under vacuum for 4h. The dried lipids were then dispersed with 100 mM Tris buffer, 100 mM NaCl, pH 7.4, and sonicated for 10 minutes.

Modulated differential scanning calorimetry.

0.5 mg of amphiphile in 5μL of water was hermetically sealed in an aluminum pan. The modulation was set to ±1.00 ºC every 40 s, and the pan was equilibrated at –15 ºC. The temperature was increased at 0.5 ºC/min to 70 ºC where it has held for 2 min. The temperature was then reduced to –10 ºC and held at this temperature for 2 min. This heating-cooling cycle was repeated two more times before the sample was held isothermal at –10 ºC for 20 min. The data colleted on the third cycle were analyzed.

DNA binding affinities [3]

DNA binding studies were carried out by competitive displacement fluorometric assay using ethidium bromide. This assay involves the addition of aliquots of the compound to

a 3 mL solution of EthBr (1.3 μM) and calfus thymus DNA (3 μM) in buffer (100 mM NaCl, 100 mM Tris, pH 7.4) with the decrease of fluorescence (λ_{exc}=546 nm, λ_{em}=600 nm; 1 cm path length glass cuvette, slit width 3 nm) recorded after 5 minutes of equilibrium time following each addition.

X-ray diffraction

The liposomes were centrifugated to give a hydrated pellet of multilamellar bilayers. The pellet was transferred then to a sealed quartz-glass X-ray capillary which was mounted in a temperature controllable chamber on a point-focus collimator. A stationary anode Jerrel-Ash generator (Jerrel-Ash Div., Fisher Scientific Co., Waltham, MA) was used to produce Cu Kα X-radiation.[4] Diffraction patterns were obtained using a flat plate film cassette loaded with Kodak DEF X-ray film. The specimen to film distance was 10 cm with exposure times of 2-6 hours. The low angle reflections were determined in accordance with Bragg's law $2d \sin\theta = h\lambda$, where λ is the wavelength (1.54Å), d is the repeat period, h is the number of the diffraction order, and θ is the Bragg angle.

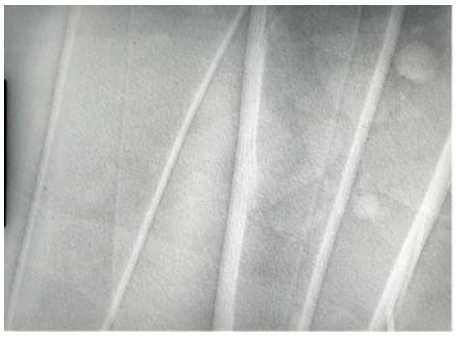


Figure S1. TEM micrographs of compound **7** in aqueous solution, negative staining with ammonium molybdate 1% in water.

TEM

TEM microscopy experiments were performed on a Philips CM 10 (negative staining with ammonium molybdate 1% in water, Cu/Pd carbon coated grids).

Besides, amphiphie **1**, all the the other amphilies gave large aggregarates except for amphiphile **7** that gave fiber-type structures upon extrusion as shown in Figure S1.

Cell culture and Transfection experiment

Chinese hamster ovarian cells (CHO, ATCC, Manassas, VA) were cultured in complete F12K media (ATCC) containing 10% fetal calf serum (Sigma) and 1% penicillin and streptomycin (500 IU/mL and 5000 μg/ml, respectively, Mediatech, Herndon, VA) at 37 ^{o}C in 5% CO_2 with humidity. When the CHO cells reached about 90% confluency, the cells were split into 24-well plates with a 1:6 ratio using a standard trypsin-based technique. Transfections were performed 24 hours later. Briefly stated, plasmid DNA coding for a reporter gene, β-galactosidase (β-gal, pVax-LacZ1, Invitrogen) was first mixed with lipids in potassium phosphate buffer (PBS) at room temperature. Depending on the experimental design, the ratio of DNA and amphiphile, the pH of the buffer used, or incubation time was varied. The mixture was incubated for 15 minutes at room temperature before adding to the cells. The amount of DNA used was the same as used in naked DNA control and positive control (commercially available transfection reagents). After incubation at 37 °C and 5% CO_2 for 2 hours, medium containing the mixtures was gently removed and fresh growth medium was added. Transfection efficiencies were assessed 48 h post transfection. Negative controls were constructed with 0.5 mL of serum-free F12 K medium and naked DNA controls were using 0.5 mL of serum-free F12 K medium with 1 μL (1 μg) of reporter gene. Positive controls were performed according to the manufacturer's protocol. Briefly stated, 2.0 μL of transfast® transfection reagent (1mg/mL) (Promega, Madison, WI) was mixed with 1 μL (1 μg) of reporter gene in 0.5 mL of serum free F12 K medium for 15 minutes at room temperature before transfecting cells.

Reporter gene transfection efficiency assay

Reporter gene (β-gal) assays were performed with a β-galactosidase enzyme assay system (Promega, Madison, WI) following the manufacturer protocol. Briefly cells were first lysed using M-PER buffer (Pierce, Rockford, Illinois) and enzyme activities were determined. A standard curve was constructed for each experiment using dilutions of purified β-gal protein. The β-gal activities from experimental samples were determined by comparison to the standard curve (enzyme activity vs. enzyme concentration). Efficiency of each transfection was calculated as β-gal activity normalized to total protein.

Cytotocixity

Cytotocixity was assessed using both a formazan-based proliferation assay (CellTiter 96 AQueous One Solution Cell Proliferation Assay kit, Promega) and a total protein-based assay (Pierce). Briefly stated, cells were seeded onto a 96-well plate with an appropriate density of 1×10^4 cells per well. A predetermined amount of test chemical was added onto the cells 24 hours later. After 24, 48, and 72 h MTS (substrates) were added to each well and the plate was incubated for 4 h at 37 ^{o}C in a humidified, 5% CO_2 incubator. The amount of soluble formazan produced by cellular reduction of the substrates MTS was recorded at 490 nm using a multi-well plate reader. For the total protein-based proliferation assay, cells were lysed at the same time when transfection efficiency was assayed. A 5 μL of lysates were transferred to a separate multi-well plate. Total protein contents were assessed using the Coomassie Blue protein kit (Pierce, Rockford, IL) following the manufacturer protocol. Negative and positive controls were non-treated cells and commercial lipids treated cells, respectively. The proliferation results were expressed as percentages of non-treated cells

Supporting Information

ABSTRACT: This report presents the synthesis and evaluation of ^{64}Cu(DO3A-xy-ACR) (DO3A-xy-ACR = 2,6-bis(dimethylamino)-10-(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)acridin-10-ium) as a radiotracer for imaging tumors in athymic nude mice bearing U87MG glioma xenografts by PET (positron emission tomography). The biodistribution data suggested that ^{64}Cu(DO3A-xy-ACR) was excreted mainly through the renal system with >65% of injected radioactivity being recovered from urine samples at 1 h post-injection (p.i.). The tumor uptake of ^{64}Cu(DO3A-xy-ACR) was 1.07 ± 0.23, 1.58 ± 0.55, 2.71 ± 0.66, 3.47 ± 1.19, and 3.52 ± 1.72%ID/g at 0.5, 1, 2, 4, and 24 h p.i., respectively. ^{64}Cu(DO3A-xy-ACR) had very high liver uptake (31.90 ± 3.98, 24.95 ± 5.64, 15.20 ± 4.29, 14.09 ± 6.82, and 8.18 ± 1.27%ID/g at 0.5, 1, 2, 4, and 24 h p.i., respectively) with low tumor/liver ratios. MicroPET studies showed that the tumors were clearly visualized as early as 30 min p.i. in the glioma-bearing mouse administered with ^{64}Cu(DO3A-xy-ACR). The high liver radioactivity accumulation was also seen. ^{64}Cu(DO3A-xy-ACR) had a relatively high metabolic stability during excretion via both renal and hepatobiliary routes, but it was completely decomposed in the liver homogenate. We explored the localization mechanism of Cu(DO3A-xy-ACR) using both U87MG human glioma and the cultured primary U87MG glioma cells. The results from the cellular staining assays showed that ^{64}Cu(DO3A-xy-ACR) is able to localize in the mitochondria of living U87MG glioma cells due to the enhanced negative mitochondrial potential as compared to normal cells. Although ^{64}Cu(DO3A-xy-ACR) is not an ideal PET radiotracer for tumor imaging due to its high liver uptake, the results from this study strongly suggest that ^{64}Cu-labeled acridinium cations are indeed able to localize in the energized mitochondria of tumor cells.

INTRODUCTION

Alteration in the mitochondrial potential ($\Delta\Psi_m$) is an important characteristic of cancer. It has been reported that the mitochondrial potential in carcinoma cells is significantly higher than that in normal epithelial cells.[1−5] Since the mitochondrial potentials are negative, the delocalized organic cations with appropriate structures tend to accumulate inside the energized mitochondria of carcinoma cells.[5] For example, rhodamine-123 and ^{3}H-tetraphenylphosphonium (^{3}H-TPP) have been used to measure mitochondrial potentials due to their preferential localization in tumor cells.[6−13] The observation that the enhanced mitochondrial potential is prevalent in tumor cell phenotype provides the conceptual basis to develop mitochondrion-targeting anticancer drugs and molecule imaging probes.[14−16]

We have been interested in ^{64}Cu-labeled phosphonium cations as PET (positron emission tomography) radiotracers for tumor imaging.[17−20] Biodistribution studies in the athymic nude mice bearing U87MG glioma xenografts showed that ^{64}Cu(DO3A-xy-TPEP) (Figure 1: DO3A-xy-TPEP = 2-(diphenylphosphoryl)ethyl)diphenyl(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)phosphonium) had a good tumor uptake with better tumor-to-background (T/B) ratios than those of ^{99m}Tc-Sestamibi.[19] Although *in vitro* assays indicated that ^{64}Cu radiotracers were able to localize in the tumor mitochondria, the evidence was not conclusive.[17] That has led us to explore other alternatives with the fluorescent emission so that their mitochondrial localization can be visualized.

Acridines are used as duplex DNA intercalators or "chemiluminescent agents" in many bioassays.[21] Recently, it was reported that the $Re(CO)_3$ complex [Re(3,6-bis-dimethylamino-10-(4-isocyanobutyl)acridinium)(2,4-pyridinedicarboxylato)$(CO)_3$]$^+$ ([Re(CN-C4-ACR)(2,4-pydic)$(CO)_3$]$^+$) was able to localize in the nuclei of tumor cells by binding to duplex and triplex DNAs.[22] Although the *in vivo* data were not reported, these promising results from *in vitro* assays have inspired us to prepare

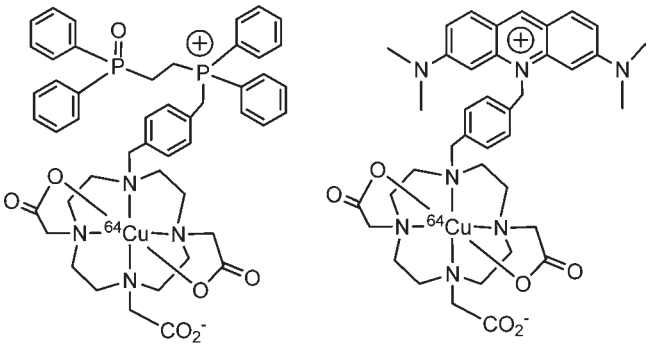

Figure 1. Proposed *Chemdraw* structures of ^{64}Cu(DO3A-xy-TPEP) and ^{64}Cu(DO3A-xy-ACR). Like 2-(diphenylphosphoryl)ethylphenyl-phosphonium (TPEP), the acridinium (ACR) cation is used as the mitochondrion-targeting molecule to carry ^{64}Cu into tumor cells, where the negative mitochondrial transmembrane potential is elevated.

the complex ^{64}Cu(DO3A-xy-ACR) (Figure 1: DO3A-xy-ACR = 2,6-bis(dimethylamino)-10-(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclododecan-1-yl)methyl)benzyl)acridin-10-ium). In this report, we present evaluation of ^{64}Cu(DO3A-xy-ACR) as a potential PET radiotracer for tumor imaging in athymic nude mice bearing U87MG glioma xenografts. We were interested in this tumor-bearing animal model because the xenografted U87MG glioma tissues have low expression of multidrug resistant P-glycoproteins (MDR Pgps) and multidrug resistance-associated proteins (MRPs).[20,23−26] Cu(DO3A-xy-ACR) was also prepared as a fluorescent probe for the cellular staining assay to demonstrate the intracellular location of ^{64}Cu-labeled ACR cations in tumor cells.

EXPERIMENTAL SECTION

Materials and Instruments. Acridine orange (ACR) and α,α′-dibromo-*p*-xylene were purchased from Sigma/Aldrich (St. Louis, MO). DO3A(OBu-t)$_3$ (1,4,7,10-tetraazacyclododecane-4,7,10-tris(*tert*-butyl acetate)) was obtained from Macrocyclics Inc. (Dallas, TX). NMR data were obtained using Bruker ARX 300 MHz FT NMR spectrometer. Chemical shifts are reported as δ in ppm relative to TMS. The ESI (electrospray ionization) mass spectral data were collected on a Finnigan LCQ classic mass spectrometer, School of Pharmacy, Purdue University. ^{64}Cu was produced using a CS-15 biomedical cyclotron at Washington University, School of Medicine, by the ^{64}Ni(p,n)^{64}Cu nuclear reaction.

HPLC Methods. The semiprep HPLC method (Method 1) used a LabAlliance system equipped with a UV/vis detector (λ = 254 nm) and Zorbax C_{18} semiprep column (9.4 × 250 mm, 100 Å pore size; Agilent Technologies, Santa Clara, CA). The flow rate was 2.5 mL/min and the mobile phase was isocratic with 60% A (0.1% TFA in water) and 40% B (0.1% TFA in methanol) at 0−5 min, followed by a gradient mobile phase going from 40% B at 5 min to 100% B at 20 min. The radio-HPLC method (Method 2) used the LabAlliance system equipped with a β-ram IN/US detector (Tampa, FL) and Vydac protein and peptide C_{18} column (4.6 × 250 mm, 300 Å pore size; Grace Davison Discovery Sciences, Hesperia, CA). The flow rate was 1 mL/min with the gradient mobile phase being isocratic with 90% solvent A (25 mM NH_4OAc, pH = 6.8) and 10% solvent B (acetonitrile) at 0−5 min, followed by a gradient mobile phase going from 10% B at 5 min to 90% B at 20 min. Method 3 used the LabAlliance HPLC system equipped with a UV/vis detector (λ = 254 nm), a β-ram IN-US detector and a Superose 12 10/300 GL size-exclusion column. The flow rate was 0.4 mL/min. The aqueous mobile phase was isocratic with 20 mM HEPES and 150 mM NaCl.

10-(4-(Bromomethyl)benzyl)-3,6-bis(dimethylamino)-acridin-10-ium Bromide (ACR-xy-Br). Acridine orange base (737 mg, 2.08 mmol) and α,α′-dibromo-*p*-xylene (500 mg, 1.89 mmol) were dissolved in 30 mL of toluene. The resulting mixture was refluxed for 20 h. After cooling to room temperature, the solid was filtered and washed with toluene (5 mL) and ether (5 mL) three times, respectively, and then dried under vacuum overnight. The yield was 580 mg (∼70%). ^{1}H NMR (in $CDCl_3$): 3.17 (s, 12H, NCH_3), 4.42 (s, 2H, CH_2Br), 6.25 (s, 2H, NCH_2), 6.66 (s, 2H, aromatic C_6H_3), 6.95 (d, 2H, aromatic C_6H_3), 7.27−7.40 (m, 4H, aromatic C_6H_4), 7.89 (d, 2H, aromatic C_6H_3), 8.27 (s, H, aromatic NC_5H_1).

2,6-Bis(dimethylamino)-10-(4-((4,7,10-tris(carboxymethyl)-1,4,7,10-tetraazacyclodo-decan-1-yl)methyl)benzyl)-acridin-10-ium (DO3A-xy-ACR). DO3A(OBu-t)$_3$ (22.8 mg, 44 μmol) and ACR-xy-Br (23.5 mg, 44 μmol) were dissolved in DMF (3 mL). To the mixture was added triethylamine (35 uL, 250 μmol). The reaction mixture was stirred at room temperature overnight. Upon removal of volatiles, the residue was dissolved in 3 mL of 12 N HCl. After being stirred at room temperature for 2 h, volatiles were completely removed. The residue was dissolved in 2 mL of 50% DMF/water mixture, and the solution was subjected to HPLC purification (Method 1). Fraction at 14.4 min was collected and lyophilized to give orange powder (19.7 mg, 63%). ESI-MS: m/z = 714.3 for $[M + H]^+$ (714.4 calcd. for $[C_{39}H_{52}N_7O_6]^+$).

Cu(DO3A-xy-ACR). To a clean vial containing DO3A-xy-ACR (16.9 mg, 22 μmol) and $Cu(OAc)_2 \cdot H_2O$ (9.2 mg, 45 μmol) was added 2.5 mL of NH_4OAc (0.5 M, pH = 5.5). The resulting solution was heated at 100 °C water bath for 30 min. After cooling it to room temperature, the product was isolated by HPLC (Method 1). Fraction 14 min was collected and lyophilized to give orange powder. The yield was 12.8 mg (75%). ESI-MS: m/z = 775.1 for $[M + H]^+$ (775.3 calcd. for $[C_{39}H_{49}CuN_7O_6]^+$). Anal. Calcd. for $C_{39}H_{49}CuN_7O_6 \cdot 2.5H_2O$: C, 57.09; H, 6.63; N, 11.95. Found: C, 56.94; H, 6.71; N, 11.70.

^{64}Cu-Labeling and Dose Preparation. To a clean Eppendorf tube was added 40 μg of DO3A-xy-ACR dissolved in 0.3 mL of 0.1 M NaOAc buffer (pH = 6.5) and 20 μL of $^{64}CuCl_2$ solution (∼500 μCi) in 0.05 N HCl. The reaction mixture was then heated at 100 °C for 20 min in a water bath. After heating, the vial was allowed to stand at room temperature for ∼5 min. The radiochemical purity was >95%. For biodistribution studies, ^{64}Cu(DO3A-xy-ACR) was prepared and purified by HPLC (Method 2). Volatiles in the HPLC mobile phase were removed on a rotary evaporator. Doses were prepared by dissolving the purified ^{64}Cu(DO3A-xy-ACR) in saline to ∼30 μCi/mL. The resulting solution was filtered with a 0.20 μm Millex-LG filter before being injected into animals. For the imaging study, ^{64}Cu(DO3A-xy-ACR) was prepared and the reaction mixture was then diluted to ∼5 mCi/mL with saline. The log *P* value of ^{64}Cu(DO3A-xy-ACR) was determined according to the literature procedure.[19]

Animal Model. Biodistribution studies were performed using athymic nude mice bearing U87MG human glioma xenografts in compliance with the NIH animal experiment guidelines

(*Principles of Laboratory Animal Care*, NIH Publication No. 86−23, revised 1985). The animal protocol was approved by the Purdue University Animal Care and Use Committee (PACUC). U87MG cells were cultured in the Minimum Essential Medium, Eagle with Earle's Balanced Salt Solution (nonessential amino acids sodium pyruvate) (ATCC, Manassas, VA) in humidified atmosphere of 5% CO_2, and were supplemented with 10% fetal bovine serum and 1% penicillin and streptomycin solution (GIBCO, Grand Island, NY). Female athymic nu/nu mice (5−6 weeks) were purchased from Harlan (Indianapolis, IN). Each mouse was implanted with 5×10^6 tumor cells subcutaneously into the left and right upper shoulder flanks. Four weeks after inoculation, the tumor size was 0.1−0.4 g, and animals were used for biodistribution studies.

Biodistribution Protocol. Twenty-five tumor-bearing mice (20−25 g) were randomly divided into five groups. Each animal was administered with ∼3 μCi of ^{64}Cu(DO3A-xy-ACR) by tail vein injection. Five animals were sacrificed by sodium pentobarbital overdose (∼200 mg/kg) at 0.5, 1, 2, 4, and 24 h p.i. Blood samples were withdrawn from the heart of tumor-bearing mice. The tumor, brain, eyes, heart, spleen, lungs, liver, kidneys, muscle, and intestine were harvested, dried with absorbent tissue, weighed, and counted in a γ-counter (Perkin-Elmer Wizard −1480, Shelton, CT). The organ uptake was calculated as % ID/g and %ID/organ. Biodistribution data (%ID/g) and T/B ratios are reported as an average with the standard deviation based on results from 5 tumor-bearing mice (10 tumors) at each time point. Comparison between two radiotracers was made using the two-way ANOVA test (*GraphPad Prism 5.0*, San Diego, CA). The level of significance was set at $p < 0.05$.

MicroPET. MicroPET scans were performed using an Inveon DPET scanner (Siemens Medical Solutions). The tumor-bearing nude mice (n = 3) were imaged in the prone position in the microPET scanner. Each mouse was injected with ∼250 μCi of ^{64}Cu(DO3A-xy-ACR) via the tail vein, then anesthetized with 2% isoflurane and placed near the center of the FOV. Multiple static scans were obtained at 0.5, 1, 2, 4, and 24 h p.i. The images were reconstructed by a three-dimensional ordered subsets expectation maximum (3D-OSEM) algorithm, and no correction was applied for attenuation or scatter. Image analysis was done using *ASI Pro VM* software.

Metabolic Stability. Normal athymic nude mice were used to study the metabolic stability of ^{64}Cu(DO3A-xy-ACR). Each mouse was administered with ∼100 μCi ^{64}Cu(DO3A-xy-ACR) via tail vein. Urine samples were collected at 30 and 120 min p.i. by manual void, and were mixed with equal volume of 50% acetonitrile aqueous solution. The mixture was centrifuged at 8000 rpm. The supernatant was collected and passed through a 0.20 μm Millex-LG filter. The filtrate was analyzed by radio-HPLC (Method 2). Feces samples were collected at 120 min p.i. and suspended in 50% acetonitrile aqueous solution. The mixture was vortexed for 5−10 min. After centrifuging at 8000 rpm, the supernatant was collected and passed through a 0.20 μm Millex-LG filter unit. The filtrate was analyzed by radio-HPLC (Method 2). The percentage radioactivity recovery was >90% for both urine and feces samples. The liver tissue was harvested at 120 min p.i., counted in a γ-counter, cut into small pieces, and then homogenized. The homogenate was mixed with 2 mL of 50% acetonitrile aqueous solution. The mixture was vortexed for ∼5 min. After centrifuging at 8000 rpm for 5 min, the supernatant was collected and counted in a γ-counter. The radioactivity recovery was ∼35% from the liver homogenate. After filtration through a 0.20 μm Milex-LG filter unit to remove the precipitate and particles, the filtrate was then analyzed by radio-HPLC (Method 2).

Cellular Culture. All cell lines were purchased from American Type Culture Collection (ATCC, Manassas, VA). U87MG human glioma cells were cultured in the Minimum Essential Medium supplemented with 10% fetal bovine serum (FBS, ATCC) and 1% penicillin and streptomycin (GIBCO) solution. Human fibroblasts were cultured in fibroblast dermal media supplemented with low serum growth kit (ATCC, including 7.5 mM L-glutamine, 5 ng/mL rh FGF β, 5 μg/mL insulin, 1 μg/mL hydrocortisone, 50 μg/mL ascorbic acid, and 2% serum). The primary U87MG glioma cells were extracted from xenografted U87MG tumors. Briefly, tumor tissues were cut and immersed immediately in completed Minimum Essential Medium (ATCC) media. The tumor tissues were rinsed twice with the Hanks' solution and dissected into small pieces with razor blades. Small tumor pieces were digested with 0.25% Trypsin

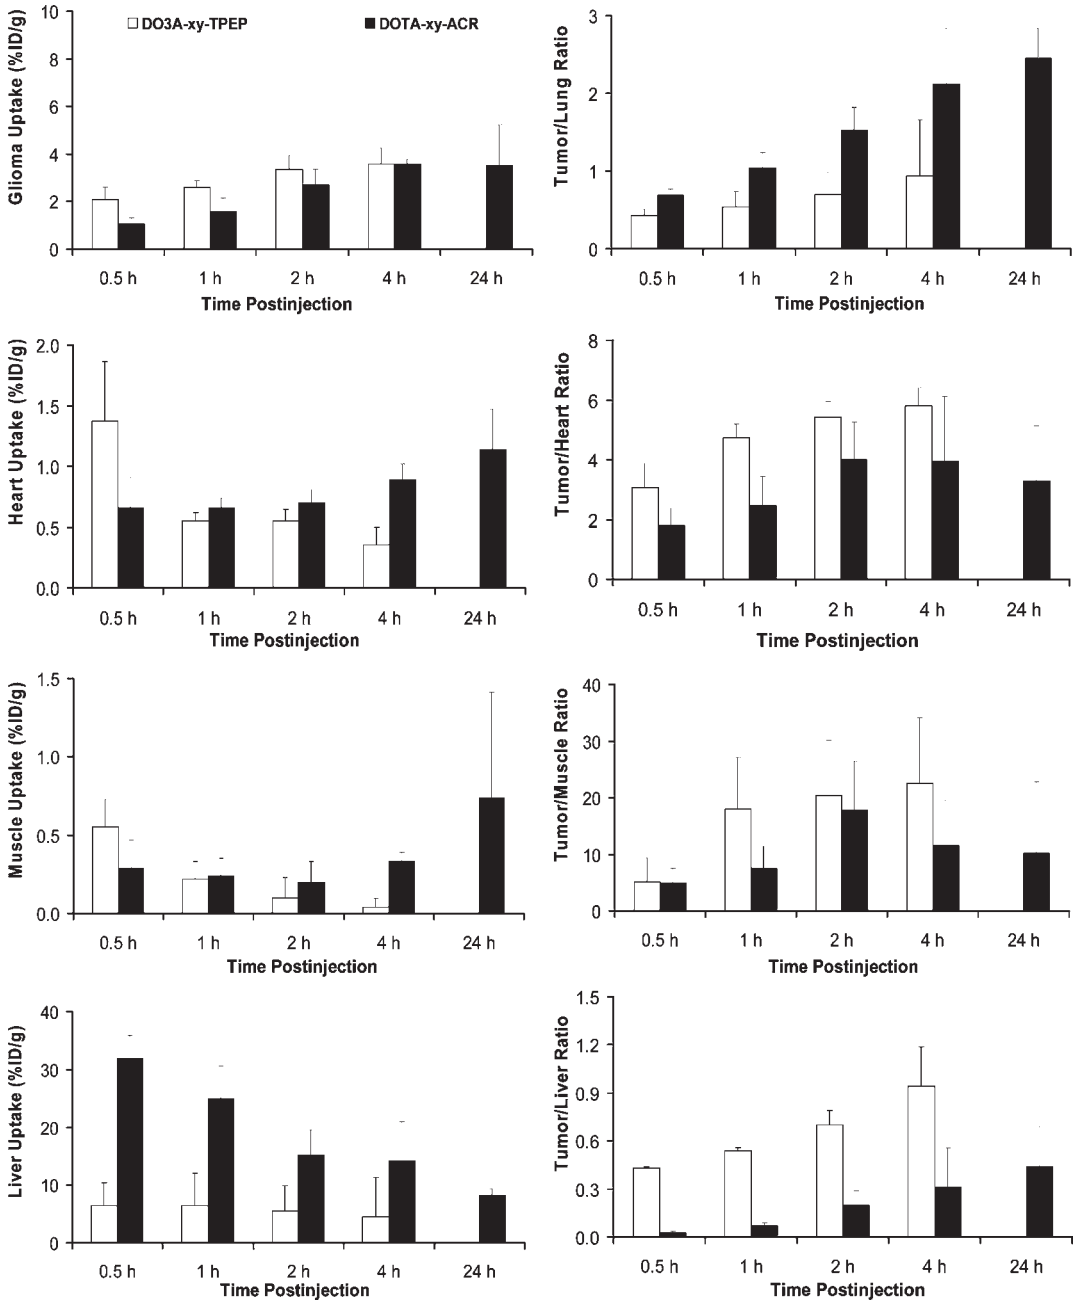

Figure 2. Comparison of the uptake (%ID/g) and T/B ratios for ^{64}Cu(DO3A-xy-ACR) and ^{64}Cu(DO3A-xy-TPEP) in selected organs of the athymic nude mice bearing U87MG human glioma xenografts.

(1 mM EDTA, without Ca^{2+} and Mg^{2+}) solution at 37 °C for 30 min, followed by vigorous pipetting and filtration through a 40 μm mesh nylon screen. After centrifugation at 1000 rpm for 5 min, the pellet was resuspended in the culture media. All cells were grown at 37 °C in a humidified atmosphere containing 5% CO_2.

Cellular Localization Study. Cells were allowed to culture in Lab-Tek 8-well glass chamber slides for at least 24 h before being used. Cu(DO3A-xy-ACR) was added into the culture media to achieve a concentration of 20 μM. Hoechst 33342 was added directly into the media to achieve 1 μM at 5 min before completion of incubation with Cu(DO3A-xy-ACR). After incubation for the indicated time, the cells were washed three times with phenol red-free Minimum Essential Medium. Lissamine (10 μM) was incubated along with Cu(DO3A-xy-ACR) to determine the mitochondrial localization. The fluorescence was visualized immediately with an Olympic BX51 fluorescence microscope (Olympus America Inc., Center Valley, PA) under 400× magnification. Images were acquired using a Hamamatsu digital CCD camera ORCA-R^2 (Hamamatsu Photonics K.K., Japan) with Olympus *MetaMorph* software.

RESULTS

DO3A-xy-ACR and Cu(DO3A-xy-ACR). DO3A-xy-ACR was prepared in two steps. First, ACR-xy-Br was allowed to react with DOTA(OBu-t)$_3$ in the presence of excess triehylamine in DMF. The intermediate DO3A(OBu-t)$_3$-xy-ACR was then hydrolyzed

dx.doi.org/10.1021/bc100458p |*Bioconjugate Chem.* 2011, 22, 700–708

to gave DO3A-xy-ACR in ~40% overall yield. Cu(DO3A-xy-ACR) was prepared by reacting DO3A-xy-ACR with one equivalent of Cu(II) acetate in 0.5 M NH_4OAc (pH = 5.5). Since phosphonium and acridinium cations share very similar structures, it is reasonable to believe that Cu(DO3A-xy-ACR) will exist in its zwitterion form, which has been established for ^{64}Cu-labeled phosphonium cations.[27] This statement is completely supported by the elemental analysis data.

Radiochemistry. ^{64}Cu(DO3A-xy-ACR) was prepared by reacting DO3A-xy-ACR with $^{64}CuCl_2$ in 100 mM NH_4OAc buffer (pH = 5.0) at 100 °C for 10 min. The radiochemical purity was >95% without HPLC purification with the specific activity of ~50 Ci/mmol. It had the log *P* value of -2.0 ± 0.2, which was more hydrophilic than ^{64}Cu(DO3A-xy-TPEP) (log $P = -1.7 \pm 0.1$).[19] ^{64}Cu(DO3A-xy-ACR) was stable for >24 h in the presence of excess EDTA (3 mg/mL in 25 mM phosphate buffer, pH = 7.4). Since Cu(DO3A-xy-ACR) and ^{64}Cu(DO3A-xy-ACR) share almost identical HPLC retention time in the concordance experiment (Supporting Information Figure SI1), it is reasonable to believe that they have the same chemical composition in solution.

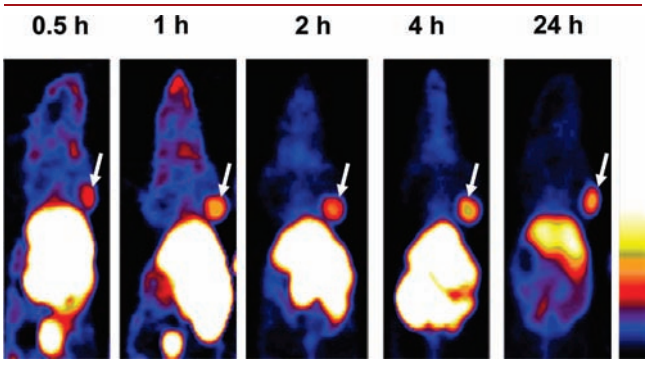

Figure 3. Decay-corrected whole-body coronal microPET images of the athymic nude mice bearing U87MG glioma xenografts administered with ~250 μCi of ^{64}Cu(DO3A-xy-ACR). Arrows indicate the presence of glioma tumors.

Biodistribution Characteristics. Selected biodistribution data for ^{64}Cu(DO3A-xy-ACR) are listed in Table 1. Figure 2 compares the organ uptake (%ID/g) and T/B ratios between ^{64}Cu(DO3A-xy-ACR) and ^{64}Cu(DO3A-xy-TPEP) in the same glioma-bearing animal model. ^{64}Cu(DO3A-xy-TPEP) was used only for comparison purposes since it has the best tumor uptake and T/B ratios among the ^{64}Cu-labeled phosphonium cations evaluated under the same conditions.[17−20] While its biodistribution data were obtained from our previous report,[19] the biodistribution data of ^{64}Cu(DO3A-xy-TPEP) at 4 h p.i. were added in this study. In general, ^{64}Cu(DO3A-xy-ACR) was excreted mainly through the renal route with >65% of injected radioactivity being recovered from urine samples at 1 h p.i. The tumor uptake of ^{64}Cu(DO3A-xy-ACR) was 1.07 ± 0.23, 1.58 ± 0.55, 2.71 ± 0.66, 3.47 ± 1.19, and 3.52 ± 1.72%ID/g at 0.5, 1, 2, 4, and 24 h p.i., respectively. The tumor uptake of ^{64}Cu(DO3A-xy-ACR) was significantly ($p < 0.05$) lower than that of ^{64}Cu(DO3A-xy-TPEP) at <1 h p.i., but this difference disappeared at 2−4 h p.i. The liver uptake of ^{64}Cu(DO3A-xy-ACR) was very high (31.90 ± 3.98, 24.95 ± 5.64, 15.20 ± 4.29, 14.09 ± 6.82, and 8.18 ± 1.27%ID/g at 0.5, 1, 2, 4, and 24 h p.i., respectively). As a result, it had very low tumor/liver ratios. The tumor/heart ratios (Figure 2) of ^{64}Cu(DO3A-xy-ACR) were comparable to those of ^{64}Cu(DO3A-xy-TPEP), but it had better tumor/lung ratios (Figure 2) than ^{64}Cu(DO3A-xy-TPEP).

MicroPET. Figure 3 shows microPET images of a glioma-bearing mouse administered with ~250 μCi of ^{64}Cu(DO3A-xy-ACR) at 0.5, 1, 2, 4, and 24 h p.i. The tumor was clearly visualized with excellent T/B contrast as early as 30 min p.i. High liver

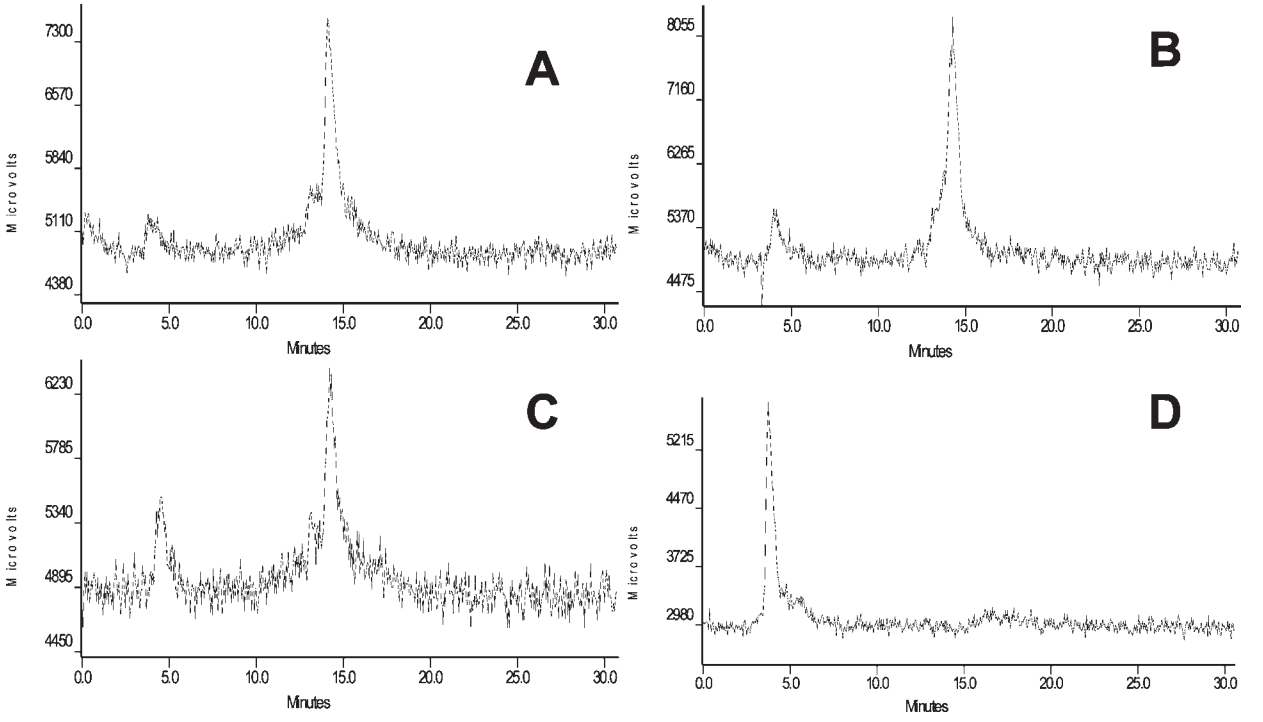

Figure 4. Representative radio-HPLC chromatograms of ^{64}Cu(DO3A-xy-ACR) in urine at 30 min (A) and 120 min p.i. (B), in feces at 120 min p.i. (C), and in the liver homogenate (D).

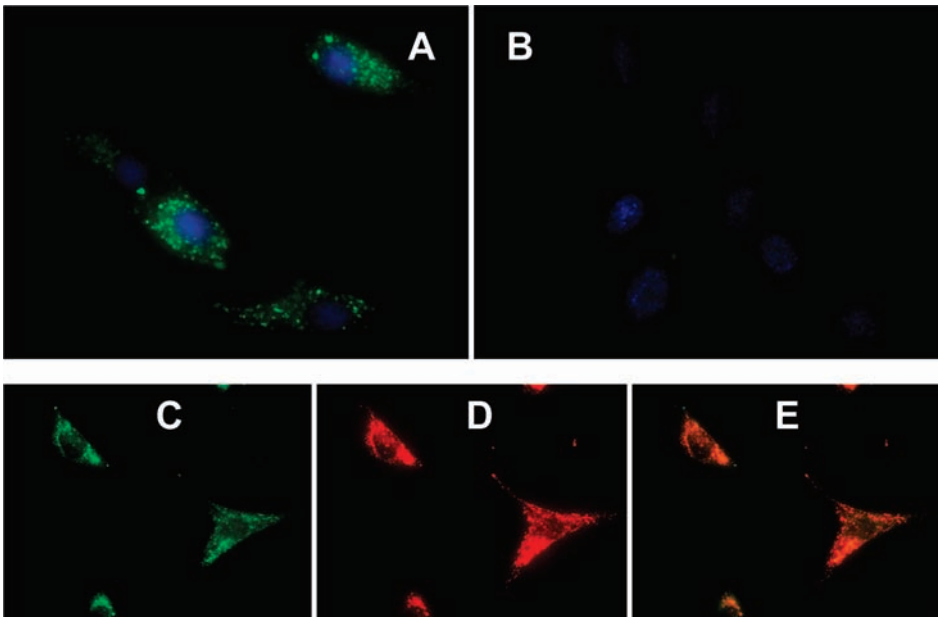

Figure 5. Representative microscopic images (magnification: 400×) of the cultured primary U87MG glioma cells (A) and normal human fibroblast cells (B) stained with 20 μM of Cu(DO3A-xy-ACR) (green color). The nuclei were stained with 1 μM of Hoechst 33342 (blue color). Normal fibroblast cell line was used as the "negative control" to demonstrate the tumor selectivity of ^{64}Cu(DO3A-xy-ACR). The colocalization experiment was performed using U87MG glioma cells stained with 40 μM of Cu(DO3A-xy-ACR) (C) and Lissamine Rhodamine B (D: red color), which was used as the "positive control" for mitochondrial staining of tumor cells. The orange color in the overlay image (E) indicates that Cu(DO3A-xy-ACR) is indeed able to selectively localize in the mitochondria of U87MG tumor cells.

uptake was seen at all time points. After normalization, the tumor uptake of ^{64}Cu(DO3A-xy-ACR) was calculated to be 0.8 ± 0.1, 1.0 ± 0.2, 1.4 ± 0.3, 2.27 ± 0.8, and 3.40 ± 0.25%ID/g at 0.5, 1, 2, 4, and 24 h p.i., respectively. These data were completely consistent with that observed in the biodistribution study (Figure 2).

Metabolic Stability. Figure 4 shows radio-HPLC chromatograms of ^{64}Cu(DO3A-xy-ACR). In general, ^{64}Cu(DO3A-xy-ACR) was stable in the urine sample over 2 h study period while ~80% of it remained intact in the feces sample. We also found that only ~35% of the liver radioactivity was recovered from the liver homogenate. The HPLC analysis showed only one radiometric peak at 4 min (Figure 4D) with no intact ^{64}Cu(DO3A-xy-ACR), and strongly suggested that ^{64}Cu(DO3A-xy-ACR) underwent complete transchelation in the liver during the 2 h study period.

Localization in Mitochondria. Figure 5 shows microscopic images of the cultured primary U87MG glioma and normal fibroblast cells stained with 20 μM of Cu(DO3A-xy-ACR). The human fibroblasts were used as the "negative control" to demonstrate the tumor selectivity of ^{64}Cu(DO3A-xy-ACR). Lissamine was used as the "positive control" since it is a well-known mitochondrion-targeting agent. Nuclear staining was achieved with Hoechst 33342 (1 μM). The orange color in the overlay image indicated that Cu(DO3A-xy-ACR) was able to colocalize with Lissamine in the tumor mitochondria. It was clear that Cu(DO3A-xy-ACR) (Figure 5A) localize mainly in the mitochondria of U87MG glioma cells. There was very little localization of Cu(DO3A-xy-ACR) in the nuclei of tumor cells. Similar results were also obtained with U87MG human glioma cells (Supporting Information Figure SI2). Although Cu(DO3A-xy-ACR) can localize in mitochondria of normal human fibroblasts, the fluorescent intensity was too low to be seen clearly using the same brightness and contrast as those for U87MG glioma cells. It is very interesting to note that the mitochondrial fluorescent intensity was dependent on the concentration (Supporting Information Figure SI3) and the incubation time (Supporting Information Figure SI4) of Cu(DO3A-xy-ACR). After 1 h incubation with 20 μM of Cu(DO3A-xy-ACR), the fluorescence was weak while the fluorescence in the U87MG glioma cells became much more intense after 24 h incubation (Supporting Information Figure SI4).

$[Re(CN\text{-}bn\text{-}ACR)(2,4\text{-}pydic)(CO)_3]^+$ was reported to localize in the tumor nuclei.[22] Since ^{64}Cu(DO3A-xy-ACR) and $[Re(CN\text{-}bn\text{-}ACR)(2,4\text{-}pydic)(CO)_3]^+$ share the same ACR cation, we decided to perform staining studies using both U87MG human glioma cells and the cultured primary U87MG glioma cells with ^{64}Cu(DO3A-xy-ACR) as a fluorescent probe. We found that, if U87MG glioma cells were not fixed with 4% formalin, the fluorescent signal was concentrated inside tumor mitochondria (Figure 6: left). If U87MG glioma cells were fixed with 4% formalin, the majority of fluorescence was inside the tumor cell nucleus while the remaining fluorescence was evenly distributed inside the cytoplasm of tumor cells (Figure 6: right). This distribution pattern was similar to that reported for $[Re(CN\text{-}C4\text{-}ACR)(2,4\text{-}pydic)(CO)_3]^+$ in B16-F1 and PC-3 cells fixed with 4% formalin;[22] but it was completely different from the "spotted" patterns in the tumor mitochondria without fixation (Figure 6: left). Obviously, the intracellular distribution patterns of ^{64}Cu(DO3A-xy-ACR) depend largely on formalin fixation.

DISCUSSION

In this study, we found that ^{64}Cu(DO3A-xy-ACR) and ^{64}Cu-(DO3A-xy-TPEP) shared similar tumor uptake (Figure 2) at 2−4 h p.i. Even though ^{64}Cu(DO3A-xy-ACR) (log P = −2.0 ± 0.2) is

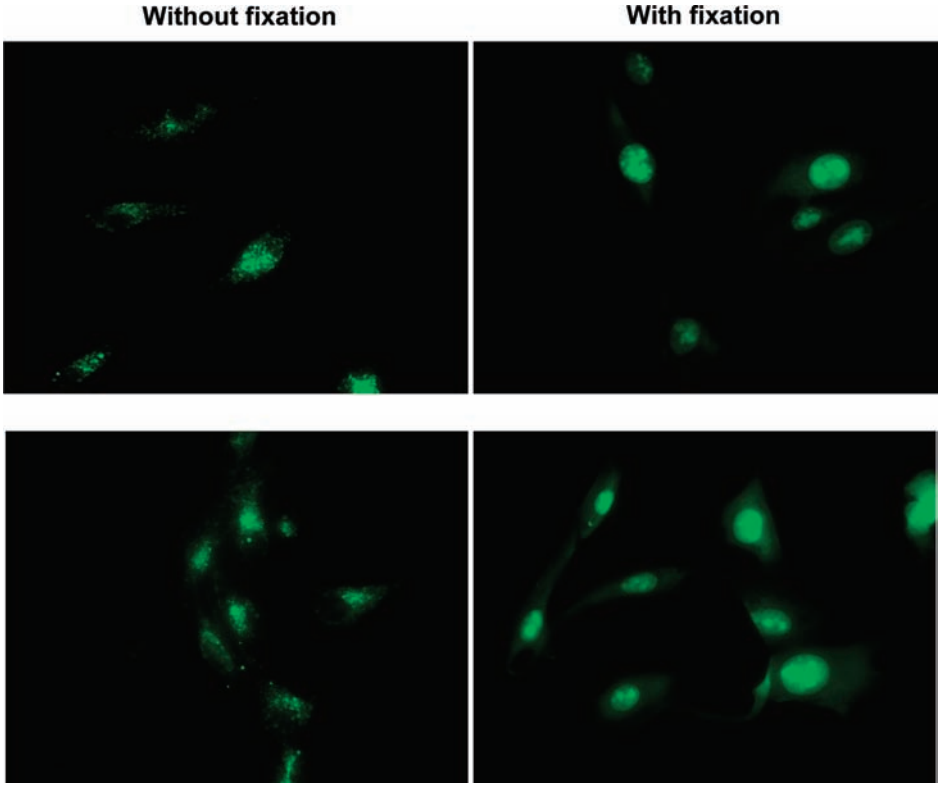

Figure 6. Microscopic images (magnification: 400×) of cultured primary U87MG (top) glioma cells and U87MG human cell line (bottom) stained with 40 μM of Cu(DO3A-xy-ACR) for 1 h with (right) and without (left) formalin fixation. All images were adjusted with the same brightness and contrast.

more hydrophilic than ^{64}Cu(DO3A-xy-TPEP) (log $P = -1.7 \pm 0.1$),[19] its liver uptake was very high with much lower tumor/liver ratios than those of ^{64}Cu(DO3A-xy-TPEP), suggesting that the radiotracer liver uptake is not completely due to its lipophilicity. Because of its lower liver uptake, ^{64}Cu(DO3A-xy-TPEP) is a better PET radiotracer than ^{64}Cu(DO3A-xy-ACR).

Another interesting finding of this study is that the targeting moiety has significant impact on metabolic stability of ^{64}Cu radiotracers. For example, ^{64}Cu(DO3A-xy-TPEP) has no metabolism during excretion from both renal and hepatobiliary routes.[19] However, ^{64}Cu-(DO3A-xy-ACR) has ~20% metabolism during hepatobiliary excretion (Figure 4C). We examined the liver stability of ^{64}Cu(DO3A-xy-ACR), and found that there was no intact ^{64}Cu(DO3A-xy-ACR) in liver homogenate (Figure 4D). Its HPLC profile is similar to that of ^{64}Cu(DO3A-xy-TPEP) in the liver homogenate.[19] Since Anderson's group has clearly demonstrated the in vivo instability of ^{64}Cu-labeled tetraazamacrocycles,[28−30] we believe that the observation of no intact ^{64}Cu(DO3A-xy-ACR) in the liver homogenate is most likely caused by transchelation of ^{64}Cu from ^{64}Cu(DO3A-xy-ACR) to the proteins in the liver.

The mitochondrial localization of ^{64}Cu(DO3A-xy-ACR) has been clearly demonstrated using Cu(DO3A-xy-ACR) as a fluorescent probe (Figure 5). Since Cu(DO3A-xy-ACR) can also localize in normal human fibroblasts with much less fluorescent intensity, the tumor selectivity of ^{64}Cu(DO3A-xy-ACR) is caused by the increased negative mitochondrial potential in U87MG glioma cells as compared with that in normal fibroblasts. The time-dependence (Supporting Information Figure SI4) of the mitochondrial fluorescent intensity for Cu(DO3A-xy-ACR) is consistent with the fact that ^{64}Cu(DO3A-xy-ACR) has a slow increase in the tumor uptake over the first 4 h p.i.

It must be noted that the cell fixation has a significant impact on the intracellular localization of fluorescent probes targeting mitochondria. For example, the fluorophor concentrates inside the tumor mitochondria with typical "spotted" patterns (Figure 6: left) if U87MG glioma cells are not fixed with 4% formalin. In the presence of formalin fixation, however, the intracellular distribution patterns (Figure 6: right) of ^{64}Cu-(DO3A-xy-ACR) are very similar to those of [Re(CN-bn-ACR)-(2,4-pydic)$(CO)_3$]$^+$ in of B16−F1 and PC-3 cells.[22] While there is no doubt that [Re(CN-bn-ACR)(2,4-pydic)$(CO)_3$]$^+$ is able to bind to duplex and triplex DNAs in the in vitro binding assays,[22] we believe that the nuclear localization (Figure 6: right) of ^{64}Cu(DO3A-xy-ACR) is most likely the artifacts caused by formalin fixation. Similar fixation artifacts were reported with the cell-penetrating peptides.[31−33] Cellular fixation with 3−4% formalin can cause significant damage in the mitochondrial membrane, which would result in the collapse of mitochondrial potential and lead to the localization of ^{64}Cu(DO3A-xy-ACR) inside cytoplasm and nuclei. Therefore, it is strongly recommended that living cells are used for studies related to the mitochondrial function.

CONCLUSION

In summary, we evaluated the potential of ^{64}Cu(DO3A-xy-ACR) as PET radiotracer for tumor imaging. Although tumors could be clearly visualized in the athymic nude mice bearing U87MG human glioma xenografts, ^{64}Cu(DO3A-xy-ACR) is not as good a PET radiotracer as ^{64}Cu(DO3A-xy-TPEP) because of

its much higher liver uptake. Even though it was reported that ($[Re(CN\text{-}C4\text{-}ACR)(2,4\text{-}pydic)(CO)_3]^+$) was able to localize in the nuclei of tumor cells by binding to the duplex and triplex DNAs,[22] our results from cellular staining assays show that Cu(DO3A-xy-ACR) is localized in the mitochondria of living U87MG glioma cells. Due to the similarity between ACR and TPEP cations with respect to their structure and overall molecular charge (Figure 1), ^{64}Cu(DO3A-xy-TPEP) also targets the tumor mitochondria, where negative mitochondrial transmembrane potential is significantly elevated as compared with normal cells of the surrounding tissues.

Site-Specific Conjugation of Monodispersed DOTA-PEGn to a Thiolated Diabody Reveals the Effect of Increasing PEG Size on Kidney Clearance and Tumor Uptake with Improved 64-Copper PET Imaging

ABSTRACT: Optimal PET imaging of tumors with radiolabeled engineered antibodies requires, among other parameters, matching blood clearance and tumor uptake with the half-life of the engineered antibody. Although diabodies have favorable molecular sizes (50 kDa) for rapid blood clearance ($t_{1/2}$ = 30−60 min) and are bivalent, thereby increasing tumor uptake, they exhibit substantial kidney uptake as their major route of clearance, which is especially evident when they are labeled with the PET isotope ^{64}Cu ($t_{1/2}$ = 12 h). To overcome this drawback, diabodies may be conjugated to PEG, a modification that increases the apparent molecular size of the diabody and reduces kidney uptake without adversely affecting tumor uptake or the tumor to blood ratio. We show here that site-specific attachment of monodispersed PEGn of increasing molecular size (n = 12, 24, and 48) can uniformly increase the apparent molecular size of the PEG-diabody conjugate, decrease kidney uptake, and increase tumor uptake, the latter due to the increased residence time of the conjugate in the blood. Since the monodispersed PEGs were preconjugated to the chelator DOTA, the conjugates were able to bind radiometals such as ^{111}In and ^{64}Cu that can be used for SPECT and PET imaging, respectively. To allow conjugation of the DOTA-PEG to the diabody, the DOTA-PEG incorporated a terminal cysteine conjugated to a vinyl sulfone moiety. In order to control the conjugation chemistry, we have engineered a surface thiolated diabody that incorporates two cysteines per monomer (four per diabody). The thiolated diabody was expressed and purified from bacterial fermentation and only needs to be reduced prior to conjugation to the DOTA-PEGn-Cys-VS. This novel imaging agent (a diabody with DOTA-PEG48-Cys-VS attached to introduced thiols) gave up to 80%ID/g of tumor uptake with a tumor to blood ratio (T/B) of 8 at 24 h when radiolabeled with ^{111}In and 37.9% ID/g of tumor uptake (T/B = 8) at 44 h when radiolabeled with ^{64}Cu in PET imaging in an animal model. Tumor uptake was significantly improved from the 50% ID/g at 24 h observed with diabodies that were pegylated on surface lysine residues. Importantly, there was no loss of immunoreactivity of the site-specific Cys-conjugated diabody to its antigen (TAG-72) compared to the parent, unconjugated diabody. We propose that thiolated diabodies conjugated to DOTAylated monodisperse PEGs have the potential for superior SPECT and PET imaging in a clinical setting.

INTRODUCTION

Optimal PET imaging of tumors with radiolabeled engineered antibodies requires, among other parameters, matching blood clearance and tumor uptake with the half-life of the engineered antibody.[1,2] Although diabodies have favorable molecular sizes (50 kDa) for rapid blood clearance ($t_{1/2}$ = 30−60 min) and are bivalent increasing tumor uptake, they exhibit substantial kidney uptake as their major route of clearance, which is especially evident when they are labeled with the PET isotope ^{64}Cu ($t_{1/2}$ = 12 h). To overcome this drawback, diabodies may be conjugated to PEG, a modification that increases the apparent molecular size of the diabody and reduces kidney uptake without adversely affecting tumor uptake or the tumor to blood ratio.[3] Recently, we have shown that monodispersed PEGs, as opposed to polymeric PEGs, not only can achieve this goal but also can incorporate bifunctional chelators such as DOTA to allow the preparation of a conjugate ready for radiolabeling with a variety of radiometals.[4] In that study, we synthesized a number of monodispersed PEGs of different sizes starting from FMOC-NH-PEGn-COOH (where n = 12, 24, 24, and 48) that had DOTA at the "amino-" terminus and cysteine at the

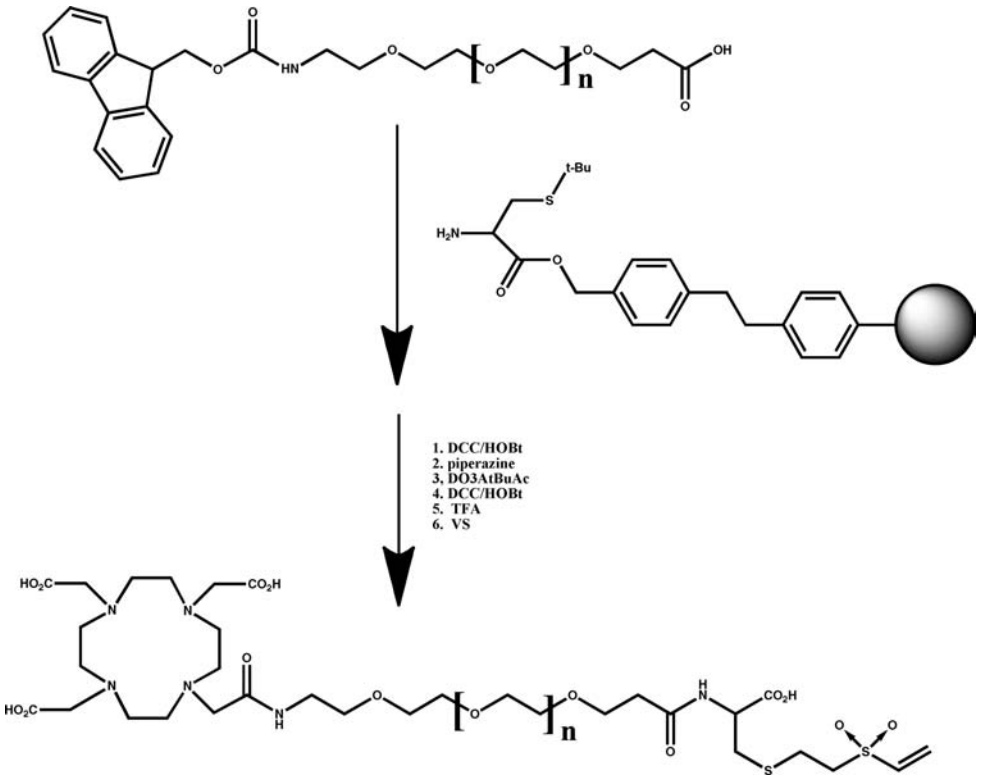
"carboxy-" terminus using a standard solid phase peptide synthesis approach. The product DOTA-NH-PEGn-Cys, which had a free thiol was derivatized with vinyl sulfone, yielding a product that could be conjugated to proteins by Michael addition to either the thiol or amino groups by control of the pH.[5] Since the starting diabody had no surface thiol groups, all of the conjugations were made to surface amino groups. Although, we were successful in demonstrating the principle that addition of monodispersed PEG could favorably modify the diabody improving biodistributions and subsequent imaging, this approach does not allow a precise control of the addition of the PEG conjugates and may not be generally applicable to diabodies where overconjugation with PEG to amino groups may lead to decreased immunoreactivity.

A potential solution to this problem has been proposed by a number of groups through the incorporation of site-specific amino acid replacements to add surface thiol residues into intact antibodies. This included the recent study by Tinianow et al.[6] who generated a thiolated mAb that was site-specifically conjugated to a maleimido-desferrioxamine and radiolabeled with ^{89}Zr for PET imaging. In that study, the half-life of the radiolabel ($t_{1/2}$ = 4d) was well-matched with the blood clearance of an intact mAb ($t_{1/2}$ = 2−3d). However, as noted by Janutula et al.,[7] most single-site cysteine additions result in intermolecular aggregation, variable conjugation, and result in poor expression yield for large scale processing. Furthermore, intact antibodies that were conjugated onto cysteine residues by partial reduction of interchain-disulfide bonds had variable stoichiometry (zero to eight drugs per antibody) and potentially yielded >100 species.[7] For diabodies, both additional C-terminal cysteine residues[8] and intrachain disulfides[9] have been designed, although production yields were low.

In this article, we designed a stable intradomain disulfide bond in a surface-exposed region of FR1 in the VL domain of an anti-TAG-72 diabody. Molecular modeling ensured the two cysteine residues were about 6−7 Å apart and positioned so that their side chain thiol groups were exposed to solvent and could form a disulfide bond. This resulted in a stable, well-folded diabody, produced by bacterial expression and which could be reduced and conjugated to our previously described DOTA-NH-PEGn-Cys-VS where n = 12, 24, and 48 at pH 7, a pH where the Michael addition reaction is specific for thiols. The resulting conjugates exhibited an average substitution of 3 PEGs per dimeric diabody out of a theoretical maximum of 4 PEGs per diabody. When studied in a mouse xenograft model, the three conjugates exhibited a monotonic decrease in kidney uptake in the order of n = 0, 12, 24, and 48, with n = 48 giving the least kidney uptake (15% ID/g at 4−72 h) and the highest tumor uptake (80% ID/g at 24−72 h). The series also gave a monotonic increase in blood clearance in the order of n = 0, 12, 24, and 48, with n = 0 giving a blood clearance of $t_{1/2}$ = 0.5 h, and n = 48 a blood clearance of $t_{1/2}$ = 6.0 h. Thus, it appears possible to fine-tune the biodistribution properties of a thiolated diabody with site-specific conjugation of monodispersed PEGs. Since the n = 48 conjugate had the lowest kidney uptake, the highest tumor uptake, and an acceptable tumor to blood ratio (T/B = 8), this conjugate was radiolabeled with ^{64}Cu (half-life well matched to blood clearance) and subjected to PET imaging in the mouse xenograft model. The resulting PET image was excellent in terms of tumor to blood contrast (T/heart = 8) with minimal imaging of other organs including the kidney and liver.

EXPERIMENTAL PROCEDURES

Materials, Radiolabels, and Mass Spectrometry. LS-174T cells were obtained from ATCC and maintained as previously described.[10] 1,4,7,10-Tetraazacyclododecane-1,4,7-tris(*t*-butyl acetate)-10-acetic acid was obtained from Macrocyclics, Inc., Dallas, TX. *N*-FMOC-amido-dPEG-12 (and -24) acid was purchased from Quanta Biodesign Ltd. (Powell, OH). ^{111}In chloride was from Amersham, ^{64}Cu chloride from Washington University School of Medicine, St. Louis, MO. Mass spectra were recorded on an Agilent 6520 Q-TOF LC/MS.



Construction, Cloning, Expression, and Purification of the Anti-TAG-72 diabody AVP04-50 from AVP04-07. The parent anti-TAG-72 diabody (AVP04-07)[4] was based on V-domains from the parent CC49 murine monoclonal antibody and derivative scFv fragments. The expression gene cassette had codons optimized for *E. coli* expression with the orientation V_H-V_L joined by a G_4S linker and included a C-terminal His_6 tail. Two cysteines were introduced by replacement of Pro at FR1−8 and Leu at FR1−11 in FR1 of the VL domain (Kabat numbering). This construct AVP04-50 was otherwise identical to the parent AVP04-07 except that it contained two additional cysteine residues per scFv monomer (4 cysteines per diabody). Molecular modeling had shown that these two cysteine residues were about 6−7 Å apart and positioned such that their side chain thiol groups could form a disulfide bond and, since exposed to solvent, could be reduced and labeled. Methods for determining solvent exposure or solvent accessible surface area included the Shrake-Rupley algorithm and LCPO method.[11] AVP04-50 was subcloned into *E. coli* BL21 (DE3)(F^- *ompT* $hsdS_B$(r_B^- m_B^-) *gal dcm* (DE3)) (Novagen) and produced in an 18 L fermentor. Bacterial lysate cleared by centrifugation (16,000*g*, 30 min) and filtration at 0.45 μm was purified using a three-step procedure (HisTrap, HiTrap SP HP, and Superdex 75 prep chromatography) on an AKTA Purifier 10 (GE Healthcare, Uppsala, Sweden). In this respect, the introduction of surface thiols into FR1 of the VL domain resulted in a well-folded diabody that could be expressed and purified from bacterial cell culture with equivalent yields to those reported earlier for the parent, nonthiolated, AVP04-07 diabody.[4]

Immunoreactivity. Binding of AVP04-50 to the TAG-72 antigen was determined using bovine submaxillary mucin (BSM, Aldrich-Sigma (St. Louis, MO) in a column shift assay (Superdex 200).

Synthesis of DOTA-PEGn-Cys-VS and Conjugation to AVP04-50. *N*-FMOC-amido-PEGn-acid (where n = 12 or 24) was coupled to Cys-polystyrene Wang resin, the FMOC removed, coupled to DO3AtBu-Acid, cleaved, and purified by RP-HPLC, reacted with a 10 molar excess of vinyl sulfone, and repurified by RP-HPLC. DOTA-PEGn-Cys-VS was reacted with reduced (10 molar excess of TCEP) AVP04-50 diabody in pH 7 PBS at a molar ratio of 50. PEG 48 was generated by coupling PEG24 twice followed by coupling DO3AtBu-Acid with the remaining steps identical to those described above. All conjugates were analyzed by mass spectrometry to determine their degree of substitution.

Radiolabeling of AVP04-50 and Its Conjugates. Radiometal labeling of DOTA-AVP04-50 was performed using $^{111}InCl_3$ (0.15 mBq/μg) or $^{64}CuCl_2$ (0.37 mBq/μg) as previously described.[12] Radiolabeling yields were typically 70−90%. The radiolabeled material was purified on Superdex-75 or 200 columns.

Scheme 1. Synthesis of DOTA-PEG-Cys-VS[a]

[a] FMOC-amido-PEG-acid was conjugated to *S*-*t*-butyl cysteine on Wang resin using standard activation chemistry (DCC/HOBt). The FMOC was removed with piperazine and conjugated to DO3AtBuAc using standard activation chemistry (DCC/HOBt). The product was removed from the resin with TFA, purified by reverse phase HPLC, reacted with excess vinyl sulfone in DMF, and repurified by reverse phase HPLC. $N = 12$ and 24. For $N = 48$, PEG24 was coupled twice prior to the addition of D03AtBu-Ac.

LS-174T Xenograft Model. Female, athymic *nu/nu* mice (Charles River Laboratories), 6−8 weeks old, were injected with LS-174T cells (10^6) s.c. in the flank. After 10 days, mice were injected i.v. with 150 kBq of ^{111}In-labeled AVP04-50 (2−6 μg of total protein) for biodistribution studies. Mice were euthanized at various time points: tumor, blood, and major organs were collected, weighed, and counted. Time−activity curves were corrected for radioactive decay and presented as percentage of injected dose/g tissue.

PET Imaging. Tumor-bearing mice were injected i.v. with ^{64}Cu-labeled DOTA-diabody or DOTA-PEGn-diabody conjugate and imaged at 1, 4, 21−22, and 45−46 h with a small-animal PET scanner (microPET Model R4; Siemens/CTIMI, Knoxville, TN). Mice anesthetized with isoflurane were scanned for 20 min for the 1 and 4 h time points, 45 min at 21−22 h, and 60 min at 44−45 h. Data were sorted into two-dimensional sinograms using the Fourier rebinning method and corrected for intrascan radiodecay, detector nonuniformity, and random coincidence noise. Images were reconstructed by the iterative three-dimensional ordered subsets expectation maximization (OSEM) method (2 iterations, 12 subsets), followed by a maximum a posteriori (MAP) algorithm (18 iterations).[13]

RESULTS

Generation and Characterization of AVP04-50 Diabody. The parent anti-TAG-72 diabody (AVP04-07)[4] was based on V-domains from the parent CC49 murine monoclonal antibody and derivative scFv fragments. The expression gene cassette had codons optimized for *E. coli* expression with the orientation V_H-V_L joined by a G_4S linker and included a C-terminal His_6 tail. Two cysteines were introduced by replacement of Pro at FR1−8 and Leu at FR1−11 in FR1 of the VL domain (Kabat numbering). This construct AVP04-50 was otherwise identical to the parent AVP04-07 except that it contained two additional cysteine residues per scFv monomer (4 cysteines per diabody). The AVP04-50 diabody expressed in *E. coli* and purified by a three-step method eluted as a single species on gel filtration as a monodispersed dimer with an apparent molecular mass of 52.5 kDa. The overall yield was 50−75% with immunoreactivity >99% as judged by a column shift assay (data not shown).

Synthesis and Biodistributions of DOTA-PEGn AVP04-50 Conjugates. Commercially available monodispersed PEG building blocks were converted into heterobifunctional reagents using a solid phase peptide synthesis methodology. First, we synthesized DOTA-PEGn-Cys-VS derivatives where $n = 12$, 24, and 48 as summarized in Scheme 1. Second, we conjugated DOTA-PEGn-Cys-VS to the surface thiols of the reduced diabody at pH 7.0 at a molar ratio of 50:1.[5] The unconjugated and conjugated versions of AVP04-50 were characterized by mass spectrometry (Figure 1). The unconjugated AVP04-50 had one major and two minor peaks, the major one ($m/z = 26822$) corresponding to the expected mass including the His6 C-terminal tag and a minor peak at $m/z = 25{,}999$ corresponding to the expected mass minus the His6 tag (a second minor peak corresponding to the loss of the His6 tag and two additional amino acids). The mass spectra of the conjugates reveals the presence of

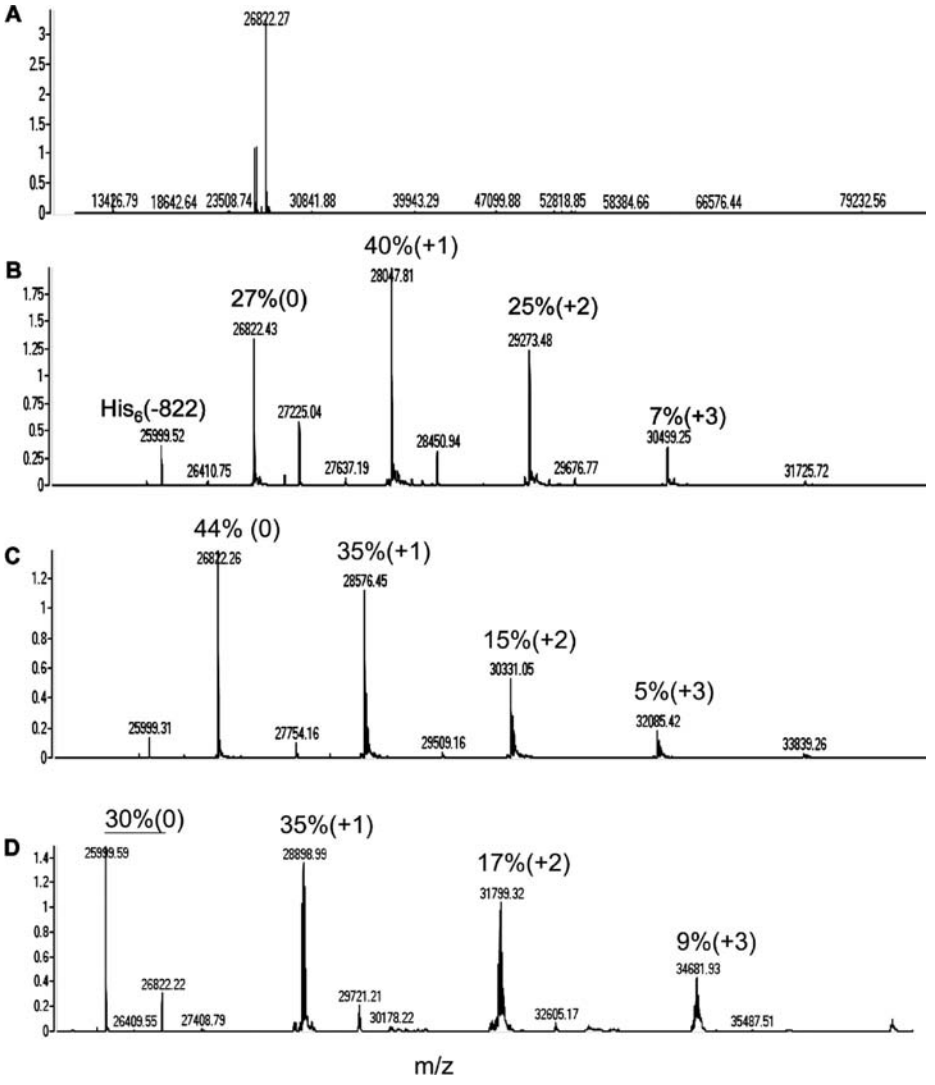

Figure 1. High resolution nanospray mass spectrometry analysis of PEGn AVP04-50 conjugates. (A) Deconvoluted mass spectrum for the non-PEGylated diabody (n = 0). (B) Deconvoluted mass spectrum for the PEG12 conjugate (n = 12). (C) Deconvoluted mass spectrum for the PEG24 conjugate (n = 24). (D) Deconvoluted mass spectrum for the PEG48 conjugate (n = 48). The percent peak height for unmodified (0), monoderivative (+1), and diderivatives (+2) are shown above the peaks. In the case of the PEG48 conjugate, the unmodified percent was summed for the parent mass (26,822) and the parent mass minus the His-6 tag (25,999).

both conjugated and unconjugated species demonstrating that the two cysteines per monomer are not fully substituted. However, since there are two monomers per diabody, the percent unsubstituted is reduced accordingly. Attempts to increase the degree of substitution by the use of higher reagent to diabody ratios revealed that no further substituion could be achieved. This result may indicate that the unconjugated species may have reformed their disulfide bonds and that the monoconjugated species may inhibit the addition of a second conjugate. The results may also indicate that the Michael addition reaction is incomplete under these reaction conditions. Nonetheless, a comparison of the spectra indicates a relatively uniform degree of substitution among the three conjugates with substantial levels for the 0, 1, and 2 levels of substitution. There is also evidence for a small amount of 3 substituents, perhaps due to a low level of reaction at surface amino groups.

The three conjugates and the unconjugated diabody (conjugated to DOTA) were radiolabeled with ^{111}In, purified by size exclusion chromatography, and subjected to biodistribution studies in athymic mice bearing LS-174T xenografts. The size exclusion chromatography profiles reveal an apparent shift to higher molecular size in the order of n = 0, 12, 24, and 48 for the PEG size corresponding to apparent molecular weights of 50 kDa, 60 kDa, 70 kDa, and 80 kDa, respectively (Figure 2). We conclude that increase in size of the monodispersed PEG is responsible for the uniform increase in the apparent size of the conjugates. In all cases, immunoreactivity of the conjugates was >95% (data not shown). Three major observations can be made from the biodistribution results shown in Figure 3A−D. First, the kidney uptake is uniformly reduced in the order n = 0, 12, 24, and 48 according to PEG size. For n = 0, kidney uptake is highest at 24 h with a value of 120% ID/g and lowest for n = 48 at 24 h with a value of 15% ID/g. This corresponds to an 8-fold reduction in kidney uptake. Higher n values for PEG were not tested due to their commercial unavailability and the fact that increasing blood clearance would eventually lead to diminishing returns. Our results are in agreement with the kidney threshold for protein clearance and are about 70−80 kDa. Second, tumor uptake

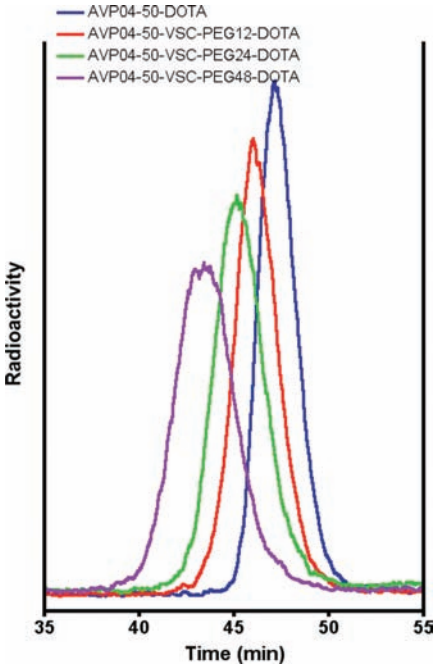

Figure 2. Size exclusion chromatography of radiolabeled uncojugated and PEGylated AVP04-50 diabody. All samples were radiolabeled with ^{111}In and run on a Superdex 75 size exclusion column as described in Experimental Procedures (radioactivity in arbitrary units). Blue: DOTA-non-PEGylated diabody conjugate. Red: DOTA-PEG12-diabody conjugate. Green: DOTA-PEG24-diabody conjugate. Purple: DOTA-PEG48-diabody conjugate.

is uniformly increased in the order n = 0, 12, 24, and 48 according to PEG size. Thus, tumor uptake for n = 0 at 24 h is 30% ID/g but rises to 80% ID/g for n = 48 at 24 h. Third, blood clearance uniformly decreased in the order n = 0, 12, 24, and 48 according to PEG size. For n = 0, the $t_{1/2}$ was about 0.5 h and for n = 48 about 6 h. The increase in blood clearance with n is expected to result in better absolute tumor uptake but can decrease the utility of the imaging agent if the T/B ratio starts to approach 1. A clinical consequence is the need to wait longer times for optimal T/B ratios, along with the need to match the radioisotope half-life with the blood clearance time. In this respect, the T/B for n = 0 is about 30 at 24 h and decreases to about 8 at 24 h for n = 48. In spite of these differences, it should be possible to image as early as 8 h for both conjugates, e.g., with the n = 0 conjugate, T/B = 6 at 8 h, compared to the n = 48 conjugate where T/B = 4 at 8 h. However, the high kidney uptake for the n = 0 conjugate and its reduced absolute tumor uptake compared to the n = 48 conjugate clearly make the n =48 conjugate the best choice of imaging agent for both the 8 h and 24 h times.

^{64}Cu PET Imaging of DOTA-PEG48 Conjugate of AVP04-50. On the basis of the ^{111}In-biodistribution results above, we concluded that the best candidate for ^{64}Cu PET imaging would be the n = 48 conjugate. This conjugate was expected to produce good tumor images as early as 8 h, reach a maximum of tumor uptake at 24−48 h, and have a very low kidney and blood background. Given the 12 h half-life of ^{64}Cu, imaging longer than 48 h is not feasible, especially in a clinical setting where large amounts of isotope would be required to extend imaging to longer time periods. When comparing the images of AVP04-50 with no PEG, PEG-12, PEG-24, and PEG-48, PEG-48 is the clear winner in terms of absolute tumor uptake and lowest kidney

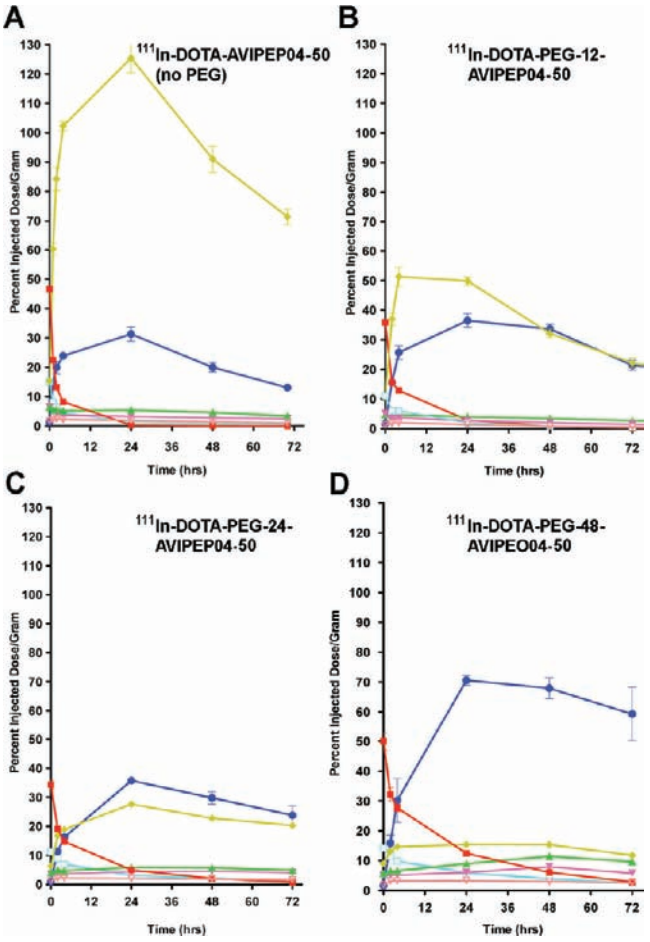

Figure 3. Biodistribution of DOTA-PEGn-AVP04-50 conjugates in athymic mice bearing LS-174T xenografts. The biodistribution of the constructs was determined in athymic mice bearing LS-174T xenografts as described in Experimental Procedures. (A) ^{111}In-DOTA-AVP04-50 (PEGn = 0). (B) ^{111}In-DOTA-PEG12-AVP04-50 (PEGn = 12). (C) ^{111}In-DOTA-PEG24-AVP04-50 (PEGn = 24). (D) ^{111}In-DOTA-PEG48-AVP04-50 (PEGn = 48). Key: yellow = kidney, dark blue = tumor, red = blood, green = liver, light blue = lungs, magenta = spleen, and orange = carcass.

uptake across the time points measured (Figure 4) or interms of time-activity curves (Figure 5). As expected, PET imaging of ^{64}Cu-labeled DOTA-PEG48-AVP04-50 (Figure 4D) demonstrated modest tumor uptake by 4 h and very high tumor uptake at 21 h and 44 h with very low backgrounds at the later time. The measured tumor uptake for the PEG48 conjugate was 37.9% ID/g at 44 h with a tumor to blood ratio of 8 and a tumor to liver ratio of 4. Under these conditions of PET imaging, there was no interference from kidneys. The ^{64}Cu-PET results are similar to those for the ^{111}In-labeled PEGn = 48 conjugate biodistribution study and suggest that choice of radiometal has little effect on the biodistribution, an observation we made previously for an anti-CEA diabody.[10]

DISCUSSION

Although antibodies have become an important source of targeted therapies, their routine use as imaging agents has not been fully realized. Obstacles to achieving this goal include matching the blood clearance half-life of the antibody with the radioisotope, maximizing both the absolute tumor uptake and

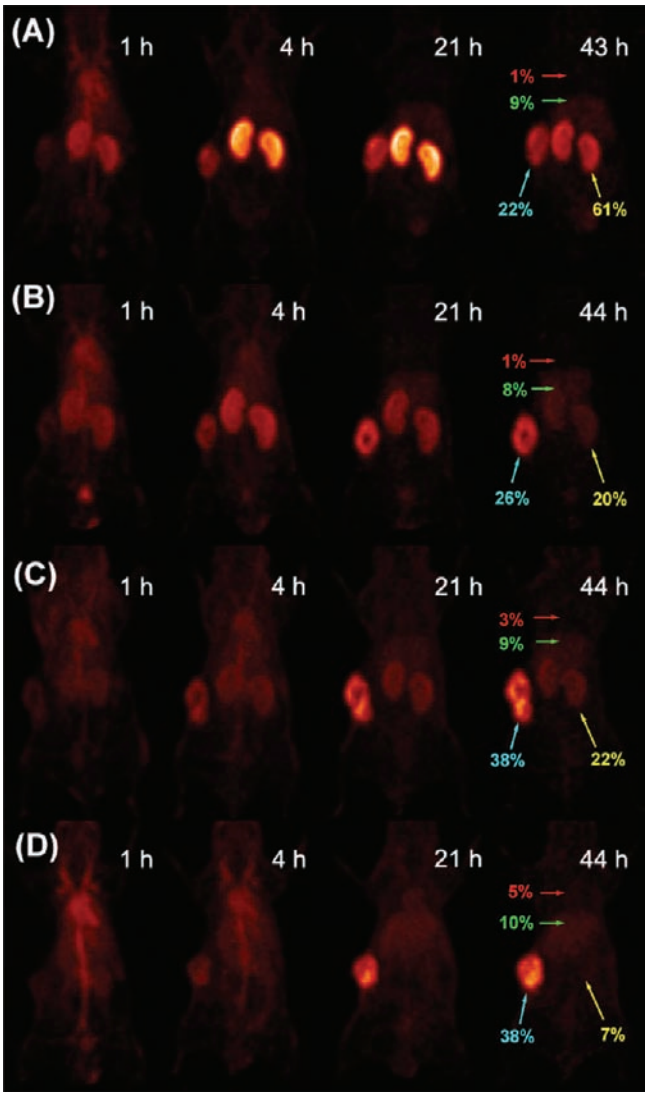

Figure 4. Serial PET imaging of ^{64}Cu-DOTA-PEGn-AVP04-50 in athymic mice bearing LS-174T xenografts. (A) PEG0, (B) PEG12, (C) PEG24, and (D) PEG48. Images are anterior-view maximum intensity projections (MIPs) normalized to reflect radiodecay-corrected relative image intensity per unit injected activity. Labels in red, green, yellow, and turquoise, respectively, show % ID/g in blood (heart), liver, kidney, and tumor as measured by direct assay following the final scan. Tumor weights at time of sacrifice were 314, 316, 382, and 341 mg in (A–D), respectively.

tumor to blood ratio, and minimizing uptake into nontarget organs such as the liver and kidney. Although several obstacles have been addressed by engineering antibody fragments of different molecular sizes, many of these approaches have led to compromises such as increased T/B at the expense of decreased absolute tumor uptake for scFvs.[14] In this respect, diabodies that maintain the bivalency of intact antibodies but have faster blood clearance, appear to be a good choice in terms of maintaining good T/B ratios and absolute tumor uptake.[15−18] With the selection of the diabody as the best candidate for imaging, one is left with selecting the best radioisotope and imaging modality. In terms of the latter, PET imaging emerges as the best choice in terms of its inherent quantitative nature and its ability to render good images at tumor to tissue ratios as low as 2:1.[19] In terms of the former, the choice of best PET isotope depends strongly on matching the half-life with the blood clearance and consideration of nontarget uptake. Two radiometals, namely, ^{64}Cu and ^{89}Zr, stand out as good candidates for PET imaging because of their ease of preparation, uncomplicated decays, and adequate yield of positron emissions.[19] In terms of matching half-lives with blood clearance, ^{64}Cu ($t_{1/2}$ = 12 h) is most appropriate for fast clearing diabodies and ^{89}Zr ($t_{1/2}$ = 4d) for slower clearing whole antibodies. However, their use is often offset by the tendency of their antibody conjugates to have high uptake in nontarget organs. Alternatively, ^{124}I ($t_{1/2}$ = 4d) has the attraction that it is rapidly metabolized in the liver and kidney, reducing the uptake in nontarget organs.[20] The chief drawback to the use of this isotope is reduced uptake in tumor due to uptake and metabolism in the tumor itself if the antibody is internalized.

Given these considerations, we chose to optimize imaging using ^{64}Cu labeled diabodies realizing that nontarget organ uptake, especially the kidney, required more work. The problem with kidney uptake is well-understood. The kidney is the major excretion route for proteins with a molecular size less than 70 kDa. Although such proteins are filtered by the kidney, they are reabsorbed in the tubules and subjected to rapid degradation and recycling of their constituent components, some returned to blood and some excreted into urine. In the case of radiometal conjugates, the chelate−metal complex is only slowly excreted and therefore accumulates in the kidney. There are at least two potential solutions to this problem, either

dx.doi.org/10.1021/bc100464e |*Bioconjugate Chem.* 2011, 22, 709–716

blocking the initial uptake or raising the apparent molecular size of the protein above the kidney threshold. Unfortunately, blocking kidney uptake requires administering high doses of amino acids such as lysine[21] and is never complete. Raising the apparent molecular size of the protein has become the most attractive approach in spite of the fact that this will also increase blood retention and reduce the T/B. Thus, to effectively optimize this approach, one must carefully analyze a series of proteins that uniformly assess the key parameters of blood clearance, absolute tumor uptake, and T/B.

In terms of the choice of diabody, we chose anti-TAG-72. The anti-TAG-72 antibody CC49 and a diabody derivative of CC49 have been previously described,[22−25] and CC49 intact IgG has been used in many clinical studies,[26−28] making CC49 a good choice for a comparative study. In order to uniformly increase the apparent molecular size of the diabody, we engineered two cysteines per monomer into FR1 of the VL domain. Using a hexahistidine-tagged, *E. coli*-produced version of the CC49 diabody, namely, AVP04-50, we found an absolute tumor uptake in the LS-174T mouse model at 24 h of 30% ID/g, superior to that previously reported for a $(scFv)_2$ version of CC49 (4% ID/g).[29]

PEG was chosen as the best approach for modifying the apparent molecular size of the diabody because of the extensive literature demonstrating its beneficial effects on preventing rapid blood clearance of other proteins.[30] We chose monodispersed rather than polydispersed PEG because it was necessary to increase its size in discrete increments, modify its structure to allow attachment of DOTA for radiolabeling purposes, and attach a linker moiety for conjugation to the diabody. We chose vinyl sulfone as the linker because of its ability to undergo site-specific Michael addition to cysteines engineered into the diabody. In addition, we had previously shown that conjugation of DOTA-PEG-Cys-VS to amino groups in the anti-TAG-72 diabody dramatically improved tumor uptake and reduced kidney clearance.[4] We now proceeded to improve our optimization of this imaging agent by systematically examining the effect of different PEG sizes when conjugated to a thiolated diabody in a site-specific manner.

The results were satisfying in that we observed a uniform decrease in kidney uptake with increasing PEG size and a uniform increase in tumor uptake with increasing PEG size without a substantial compromise in T/B. On the basis of the comparisons, we selected the PEG of $n = 48$ for the optimal imaging agent and demonstrated excellent PET images at 24−48 h when the DOTA-PEG48-diabody was radiolabeled with ^{64}Cu. Taken together, the stable production platform offered by antibody fragments,[4] coupled to the advantages of site-specific (thiol-targeted) conjugation for radiolabels (this article) and new data on thiol-targeted antibody−drug conjugations,[31] now extends the clinical opportunities of diabodies from SPECT and PET tumor imaging to drug-loaded delivery vehicles for tumor therapy.

Disulfide-Linked Antibody−Maytansinoid Conjugates: Optimization of In Vivo Activity by Varying the Steric Hindrance at Carbon Atoms Adjacent to the Disulfide Linkage

Brenda A. Kellogg, Lisa Garrett,† Yelena Kovtun, Katharine C. Lai, Barbara Leece, Michael Miller, Gillian Payne, Rita Steeves,‡ Kathleen R. Whiteman, Wayne Widdison, Hongsheng Xie,ζ Rajeeva Singh,* Ravi V. J. Chari, John M. Lambert, and Robert J. Lutz

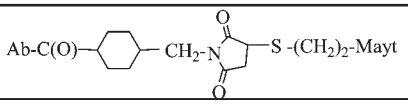
Supporting Information

ABSTRACT: In this report, we describe the synthesis of a panel of disulfide-linked huC242 (anti-CanAg) antibody maytansinoid conjugates (AMCs), which have varying levels of steric hindrance around the disulfide bond, in order to investigate the relationship between stability to reduction of the disulfide linker and antitumor activity of the conjugate *in vivo*. The conjugates were first tested for stability to reduction by dithiothreitol *in vitro* and for plasma stability in CD1 mice. It was found that the conjugates having the more sterically hindered disulfide linkages were more stable to reductive cleavage of the maytansinoid in both settings. When the panel of conjugates was tested for *in vivo* efficacy in two human colon cancer xenograft models in SCID mice, it was found that the conjugate with intermediate disulfide bond stability having two methyl groups on the maytansinoid side of the disulfide bond and no methyl groups on the linker side of the disulfide bond (huC242-SPDB-DM4) displayed the best efficacy. The ranking of *in vivo* efficacies of the conjugates was not predicted by their *in vitro* potencies, since all conjugates were highly active *in vitro*, including a huC242-SMCC-DM1 conjugate with a noncleavable linkage which showed only marginal activity *in vivo*. These data suggest that factors in addition to intrinsic conjugate potency and conjugate half-life in plasma influence the magnitude of antitumor activity observed for an AMC *in vivo*. We provide evidence that bystander killing of neighboring nontargeted tumor cells by diffusible cytotoxic metabolites produced from target cell processing of disulfide-linked antibody−maytansinoid conjugates may be one additional factor contributing to the activity of these conjugates *in vivo*.

INTRODUCTION

Several antibody−maytansinoid conjugates (AMCs) are currently undergoing clinical evaluation for treatment of different cancers.[1,2] Each AMC consists of an antibody linked at lysine residues via a cleavable disulfide linker or a noncleavable thioether linker to ∼3−4 cytotoxic maytansinoid molecules. Upon binding of the antibody component of the AMC to antigen on the surface of cancer cells, the AMC is internalized and cleaved proteolytically, releasing maytansinoids that bind tubulin and interfere with microtubule dynamics, leading to cell cycle arrest and ultimately to cell death.[3] The linker type—noncleavable or disulfide—for each AMC in the clinic is based upon selection of the optimal linker from preclinical evaluation of different linkers in xenograft models. The HER2-targeting AMC, trastuzumab-DM1, is in advanced clinical evaluation for metastatic breast cancer, and consists of a noncleavable thioether linker.[4,5] However, most AMCs that have entered the clinic have cleavable, disulfide linkers, for example, cantuzumab mertansine, IMGN901 (lorvotuzumab mertansine), IMGN388, and SAR3419.[6−9]



In an effort to understand the relationship of the lability of the disulfide linker to the activity of a conjugate, a study was initiated with a panel of huC242 conjugates containing linkers designed with different degrees of steric hindrance around the disulfide bond in order to vary the sensitivity of the disulfide linkage to cleavage via thiol−disulfide exchange reactions. HuC242 is a humanized IgG_1 antibody which recognizes CanAg, a tumor-specific antigen found on the surface of human colorectal carcinomas as well as a number of other human tumors.[10,11] The goal of the study was to select the disulfide linker with optimal *in vivo* efficacy and tolerability so as to maximize the therapeutic window for huC242 antibody−maytansinoid conjugates. The effect of altering disulfide bond reactivity toward thiol−disulfide exchange on the efficacy and tolerability of immunoconjugates is not easily predicted since the rate of cleavage of the disulfide bond is expected to influence both conjugate half-life in the plasma and rate of intracellular release of the cytotoxic agent.[12−16]

Here, we evaluate a panel of disulfide-linked huC242 AMCs, having varying degrees of steric hindrance around the disulfide

[a] *in vitro* cytotoxic potency of conjugate on COLO205 cells measured using a clonogenic assay with continuous exposure. EC_{50} is expressed as concentration of antibody; the AMCs contained, on average, 3.3 ± 1.0 conjugated DMx molecules per antibody molecule.

bond, for sensitivity to cleavage *in vitro* and *in vivo* and for efficacy in mouse xenograft models of human colon cancer expressing the CanAg antigen. We show that a huC242 conjugate with intermediate disulfide bond reactivity to thiol−disulfide exchange, having two methyl groups on the drug side of the disulfide bond and no methyl groups on the linker side, demonstrates the best activity *in vivo* in both homogeneous and heterogeneous CanAg expressing xenograft models. Comparisons of *in vitro* potency and bystander activity provide insights into the factors contributing to the superior activity observed for this conjugate.

EXPERIMENTAL PROCEDURES

General. Chemicals were from Sigma Aldrich. Human tumor cell lines were from ATCC. COLO205 (human colon cancer) and Namalwa (Burkitts lymphoma) cells were grown in RPMI containing 10% heat-inactivated FBS and 2 mM glutamine. HT29 (human colon cancer) cells were grown in DMEM containing 10% heat-inactivated FBS. The humanized anti-CanAg monoclonal antibody, huC242, and isotype matched nonbinding huIgG1 antibody (hu control mAb) were isolated at ImmunoGen. Maytansinoids and maytansinoid conjugates of the humanized C242 antibody (collectively referred to as huC242-DMx), with the exception of the 2:0 and 2:2 conjugates (see Table 1 for description of notation), were synthesized at ImmunoGen according to published procedures.[17,18] For the highly hindered 2:0 and 2:2 disulfide-linked conjugates with two methyl groups on the carbon atom adjacent to the sulfur of the linker, *N*-hydroxy succinimide (NHS) ester-bearing linker-maytansinoid reagents (sulfo-NHS-SMPP-DM1 and sulfo-NHS-SMPP-DM4 respectively, Figure 1B) were chemically synthesized and used for direct coupling to the antibody. The synthesis of these reagents are described in the Supporting Information. The conjugation reactions for the 2:0 and 2:2 conjugates were performed by adding 6−10-fold molar excess of purified NHS-ester-linker-maytansinoid reagent to antibody at a final concentration of 2.5 mg/mL in pH 7.5 phosphate buffer, 20% DMA (v/v). The reaction was left for 3 h at room temperature and then purified from excess reagent using G25 chromatography. The maytansinoid load on the final conjugate was characterized as previously described.[17]

Kinetic Studies to Measure Rates of Reduction of Disulfide Linkage in huC242−Maytansinoid Conjugates by Dithiothreitol (DTT). Reactions were initiated by addition of DTT to huC242−maytansinoid conjugates (1 mg/mL) equilibrated at 37 °C in 95% aqueous phosphate buffer, pH 6.5, (67 mM potassium phosphate, 67 mM NaCl, 2 mM EDTA) and 5% DMA (v/v). Maytansine (20 μM) was included as an internal standard. All reactions were carried out under pseudo first-order conditions with thiol (DTT) concentrations in excess to total accessible conjugate disulfide bonds. At several time points, aliquots of the reaction mixture were removed and quenched by addition to equal volumes of ice-cold ethanol (this does not cause protein precipitation) to promote dissociation of free drug from conjugate and then stored on dry ice prior to HPLC

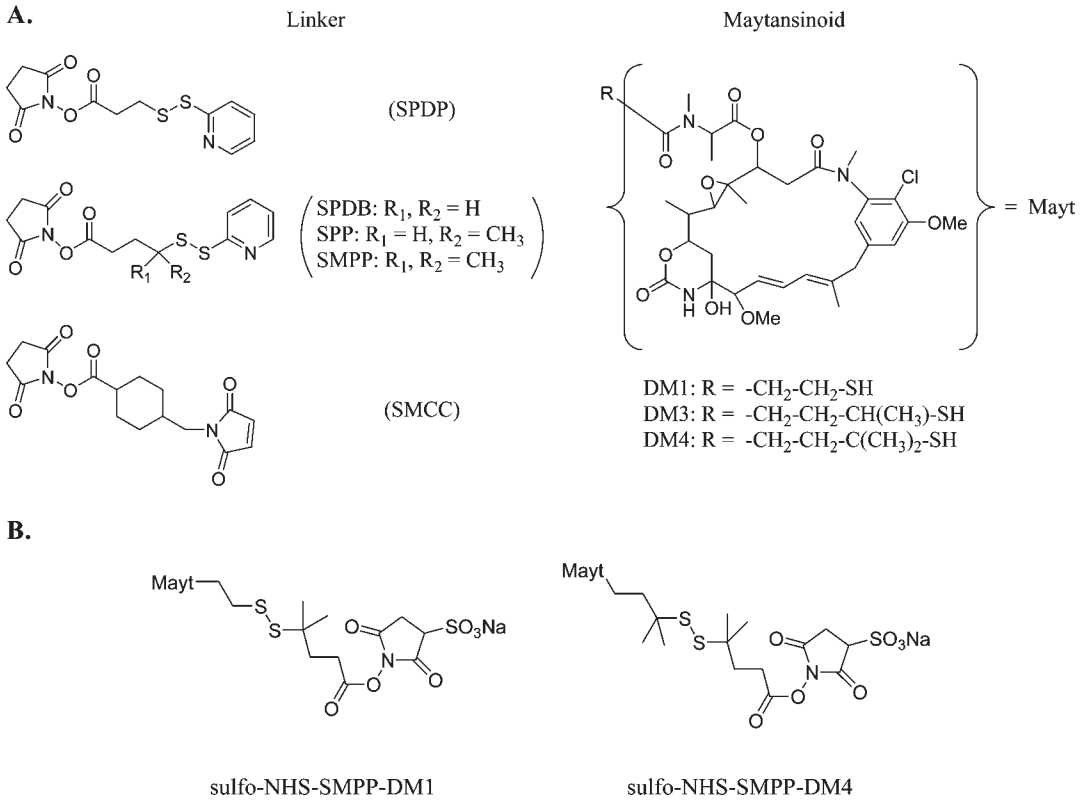

Figure 1. (A) Structures of linkers and maytansinoids utilized in antibody−maytansinoid conjugates (AMCs). In an AMC, a lysine residue on the antibody is connected via an amide bond to the linker moiety, and the maytansinoid thiol (DMx) is attached to the linker through a disulfide or thioether bond. Typically, AMCs contain about 3−4 maytansinoid molecules (average) per antibody molecule. (B) Structures of *N*-hydroxy succinimide (NHS) ester-bearing linker-maytansinoid reagents used for one step synthesis of the 2:0 and 2:2 conjugates.

Table 2. Rates of Reduction of Disulfide Bonds in AMCs by Dithiothreitol (DTT)[a]

disulfide conjugate	rate of reduction by thiol k (M^{-1} min^{-1})[b]	relative stability to thiol−disulfide exchange[c]
0′:0	14	1
1:0	2.0	7
0:2	0.98	14
2:0	0.83	17
0′:2	0.62	22
1:1	0.082	170
1:2	0.014	980
2:2	<6.4(10^{-4})	>22000

[a] Rates of reduction of disulfide-linked conjugates by dithiothreitol (DTT) were measured under pseudo first-order conditions (DTT in excess to total accessible disulfide bonds in the conjugate) at 37 °C in 95% aqueous phosphate buffer, pH 6.5, 2 mM EDTA/5% DMA (v/v). [b] k is the second-order rate constant obtained by dividing k_{obs} (pseudo first-order rate constant for release of maytansinoid from conjugate) by the concentration of DTT thiol. [c] Relative stability toward thiol−disulfide exchange normalized to the 0':0 conjugate (huC242-SPDB-DM1).

analysis. The quenched aliquots were brought to 4 °C and centrifuged at 14 000 rpm and then injected onto a Hisep HPLC column (Supelco) to separate the released maytansinoid thiol and the maytansine internal standard from the antibody species. A gradient of 25% CH_3CN (v/v) in 60 mM NH_4OAc aqueous buffer, pH 7.0, to 100% CH_3CN over 30 min was used for separation. Pseudo first-order rate constants were calculated by nonlinear regression fitting of the ratio of peak area of released maytansinoid (PA^{DMx}) to peak area of maytansine internal standard ($PA^{Internal\ std}$) vs time to a single exponential eq 1. Second-order rate constants (k) for the reaction of DTT thiol with the disulfide were calculated by dividing k_{obs} by the concentration of DTT thiol as determined by Ellman's assay.[19]

$$(PA^{DMx}/PA^{Internal\ std})_t = (PA^{DMx}/PA^{Internal\ std})_\infty [1 - \exp(-k_{obs}t)] \quad (1)$$

where PA^{DMx} = peak area at 252 nm due to the released DMx species; $PA^{Internal\ std}$ = peak area at 252 nm of the maytansine internal standard; t = time; k_{obs} = pseudo first-order rate constant for reduction of disulfide bond by DTT.

***In Vitro* Cytotoxicity.** Cytotoxicities of conjugates on COLO-205 cells were measured by a continuous exposure clonogenic assay. COLO205 cells were plated in round-bottom 96-well plates at 3, 10, 30, 100, 300, 1000, or 3000 cells per well with various concentrations of the huC242-DMx conjugates in 200 μL of the culture medium. The plates were incubated in a humidified incubator at 37 °C, 5% CO_2 for 14 days, and then scored under a microscope by counting the number of empty wells (wells with no viable cells or colonies). The plating efficiencies (PE) of the control (untreated) and conjugate-treated plates were calculated from eq 2 using the Poisson distribution:[20]

$$PE = \left[\frac{-\ln\left(\frac{\text{number of empty wells}}{\text{number of total wells}}\right)}{\text{number of cells plated per well}}\right] \quad (2)$$

dx.doi.org/10.1021/bc100480a |*Bioconjugate Chem.* 2011, 22, 717–727

To calculate the surviving fraction, the plating efficiency of the conjugate-treated plate was divided by the plating efficiency of the untreated (control) plates.

Cytotoxicities of unconjugated maytansinoids were measured using a continuous exposure cell viability assay. COLO205 and HT29 cells were initially plated at 1000 and 2000 cells/well, respectively, in flat-bottom plates. After 5 day incubation with the maytansinoids, WST-8 reagent (Dojindo Technologies) was added and absorbance at 450 nm was measured after 2 h at 37 °C.

Bystander Killing Assay. To test the bystander potency of the conjugates, antigen-negative Namalwa cells and antigen-positive COLO205 cells were mixed together at different ratios (5000 Namalwa cells/well plus 0, 125, 500, 1250, or 5000 COLO205 cells/well), and plated in 96-well round-bottomed plates. Then, 1 nM of huC242-DMx was added to the cell mixtures. This concentration of conjugate had previously been shown to kill all of the COLO205 cells but none of the Namalwa cells when each cell line was plated alone. Plates were incubated for 4 days at 37 °C, and viability of Namalwa cells in each well was determined using WST-8 reagent.

Pharmacokinetic Studies on huC242-DMx Conjugates in CD-1 Mice. CD-1 mice (9 mice/test substance) received 10 mg/kg of conjugate (antibody dose) as a single intravenous injection into a lateral tail vein. At 2 min, 30 min, and at 2, 4, and 8 h, and at 1, 2, 3, 5, 7, 10, 14, 21, and 28 days after administration of each test substance, approximately 70 μL of blood was collected from three mice per time point and centrifuged to separate the plasma. No mice were bled more than twice within 24 h. Plasma samples (~30 μL) were stored at −80 °C and assayed by ELISA for conjugate and antibody concentrations.

ELISA of Conjugate and Antibody. The huC242-DMx conjugate in mouse plasma was measured using a sandwich ELISA method, captured with murine monoclonal antimaytansinoid antibody (ImmunoGen, Inc.), and detected with horseradish peroxidase (HRP)-conjugated donkey antihuman IgG (H and L) antibody (Jackson Immunoresearch, cat no. 709−035−149). This format of the conjugate ELISA measures the concentration in plasma of conjugate with one or more conjugated maytansinoids per antibody. The antibody component of conjugate in plasma samples was measured by capturing with goat antihuman IgG antibody and detection with HRP-conjugated donkey antihuman IgG antibody.

Pharmacokinetic Analyses. Pharmacokinetic analyses were performed using the standard algorithm of the noncompartmental pharmacokinetic analysis program *WinNonlin* (Pharsight). First-order rate constants for the terminal elimination phase ($t_{1/2,\beta}$) were evaluated using the concentration data from 8 to 672 h postadministration. Where concentrations in plasma are expressed as percentage of injected dose, the plasma volume was assumed to be 4% of the body weight of mice.[21]

***In Vivo* Efficacy Studies with Human Tumor Xenograft Models in SCID Mice.** For the HT29 and COLO205 xenograft model of human colon adenocarcinoma, 2×10^6 and 3×10^6 cells, respectively, were injected subcutaneously into an area under the right shoulder. Dosing with 75 μg conjugated maytansinoid/kg/inj, qdx5, was initiated when the tumors had reached a size of approximately 100−200 mm^3. Volumes of administration were calculated based on antibody concentration and maytansinoid to Ab ratio (D/A) for each conjugate. Tumor size was measured twice weekly in three dimensions using a caliper. The tumor volume was expressed in mm^3 using the formula V = Length × Width × Height × 1/2.

Tolerability Studies in CD-1 Mice. CD-1 mice were randomly grouped according to their body weight with 12 mice per test substance. One to two intravenous injections of each conjugate were given through a tail vein. Animals were monitored daily for signs of toxicity including body weight loss, dehydration, hunched posture, ruffled fur, and loss of appetite or lethargy. If body weight loss exceeded 15% within the first 24 h after treatment or 20% at any other point in the study or if the animals were unable to reach food or water, they were sacrificed.

RESULTS

Synthesis and Nomenclature Used for Antibody−Maytansinoid Conjugates. In order to evaluate the impact of linker stability on the *in vivo* activity of disulfide linked AMCs, conjugates were synthesized using (1) a variety of linkers with different steric hindrance, 0, 1, or 2 methyl groups on the carbon atom next to the sulfur, and (2) three different maytansinoid thiols, DM1, DM3, and DM4 (collectively referred to as DM*x*), which differ in having 0, 1, or 2 methyl group substituents on the carbon next to the sulfur (Figure 1A). (Note: In these experiments, monosubstituted linker (SPP) and monosubstituted maytansinoid (DM3) were used, each being a mixture of stereoisomers at the monosubstituted carbon adjacent to the sulfur atom. As a result, conjugates made from these reagents are a mixture of diastereomers. The rates of reduction by a thiol such as cysteine or glutathione *in vivo* must then be considered to be a weighted average of the rates of reduction of each diastereomer in the mixture. It is possible that a diastereomerically pure conjugate might be reduced at a rate slightly different from that of the conjugate mixture used in these studies; however, we believe that the activities measured here, *in vitro* and *in vivo*, are likely reasonable estimates for the diastereomerically pure materials since it has been shown previously that for DM3 thiol the stereochemistry at the carbon adjacent to the thiol is not important for the activity of the free drug[18].) In the AMCs described here, the antibody is connected via lysine residues to one end of the bifunctional linker through an amide bond while the maytansinoid agent is connected to the other end of the linker through either a disulfide or a thioether bond. The steric hindrance around the disulfide bond of an antibody−maytansinoid conjugate will be specified using the notation *x*:*y*, where *x* = the number of methyl groups on the carbon adjacent to the sulfur on the linker side of the disulfide bond, and *y* = the number of methyl groups on the carbon adjacent to the sulfur on the maytansinoid side of the disulfide bond (see Table 1). In addition, two different carbon chain lengths were evaluated for unhindered disulfide linkers (derived from SPDP and SPDB) and are referred to as 0 or 0′, respectively, in the disulfide notation (Table 1). A nonreducible thioether-linked conjugate, huC242-SMCC-DM1, was also included in the analyses. All conjugates were characterized in terms of DMx/Ab ratio (3.3 ± 1.0), percent monomer (>95%), percent free drug associated with conjugate (<5%), and binding to CanAg positive tumor cell lines by FACS ($K_d^{conj}/K_d^{Ab} \leq 2.0$).

Rates of Reduction of Disulfide Linkage in AMCs *in Vitro*. In order to confirm that the level of steric hindrance around the disulfide bond altered the chemical stability of the linkage, the rate of reduction of disulfide-linked AMCs by DTT was measured at 37 °C, pH 6.5, using an HPLC assay to follow the release of maytansinoid. The measured second-order rate constants (k) for reduction are shown in Table 2. For cases where there is an

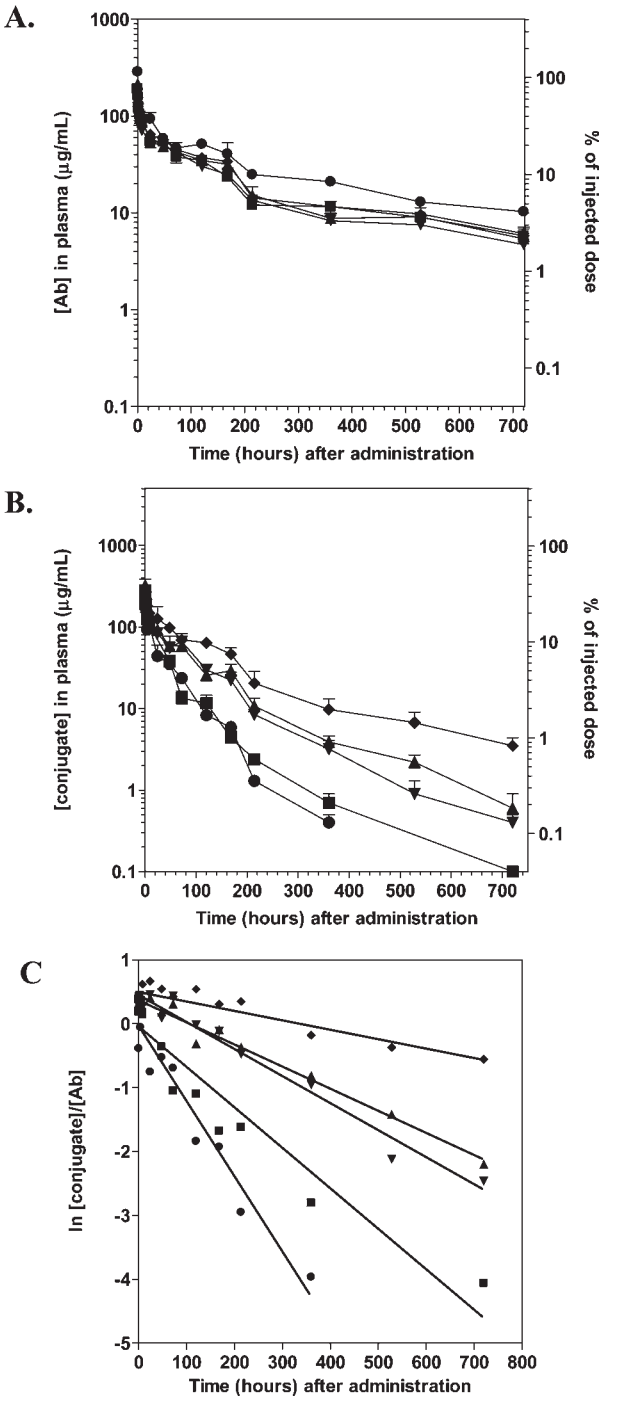

Figure 2. Representative pharmacokinetic study; CD-1 mice dosed with a single bolus IV injection of 10 mg/kg conjugate (Ab dose). (A) Concentration of the antibody moiety of AMCs in plasma; (B) concentration of AMC (conjugate) in plasma; (C) plot of ln-[conjugate]/[Ab] vs time for calculation of rate of maytansinoid cleavage from conjugate (k_{cl}) from the slope. Figure symbols: huC242-SMCC-DM1 (♦), huC242-SPDB-DM4 (0′:2; ▲), huC242-SPDP-DM4 (0:2; ▼), huC242-SPDB-DM3 (0′:1; ■), huC242-SPP-DM1 (1:0; ●).

equivalent degree of steric hindrance on both sides of the disulfide bond—0′:0, 1:1, and 2:2 conjugates—the rate constant represents the average of the rate of attack of DTT at each side of the disulfide bond. In cases where the disulfide is more sterically hindered on one side than the other, the rate constant is weighted toward attack of DTT at the less hindered side of the disulfide bond.

Introduction of steric hindrance at one side of the disulfide linkage (1:0, 0:2, 2:0, and 0′:2) results in a significant decrease in the rate of reduction compared to the unhindered (0′:0) conjugate. After normalizing the relative stability to reduction to the unhindered 0′:0 disulfide, the conjugates with steric hindrance at one side of the disulfide linkage (1:0, 0:2, 2:0, or 0′:2) are relatively more stable by 7-, 14-, 17-, and 22-fold, respectively. The 0′:2 conjugate appears to be slightly more stable to reduction than the 0:2 conjugate due to the longer carbon chain, which has been observed previously.[22] The similar rates of reduction of the 0:2 and 2:0 conjugates suggest that the location of steric hindrance on the disulfide bond (linker side vs DM*x* side) has little impact on stability to reduction *in vitro*.

Conjugates with hindrance on both sides of the disulfide linkage (1:1, 1:2, and 2:2) are much more stable to reduction compared to the unhindered 0′:0 conjugate and to conjugates with hindrance at only one side of the disulfide linkage (0:2, 2:0, 0′:2). The 1:1 conjugate is 170-fold more stable to reduction than the unhindered 0′:0 conjugate, while the most hindered 2:2 conjugate—with two methyl group substituents on carbon atoms on each side of the disulfide bond—is more than 22 000-fold more stable to reduction than the unhindered 0′:0 conjugate. Overall, the *in vitro* stability to reduction of various AMCs follows the order of increasing steric hindrance around the disulfide bond: 0′:0 < 1:0 < 0:2 ≈ 2:0 ≤ 0′:2 < 1:1 < 1:2 < 2:2.

Plasma Pharmacokinetic Studies of AMCs. To determine whether different disulfide bond stabilities translate to different pharmacokinetic properties for the AMCs, the plasma concentrations of several AMCs were measured over a four week period after a single intravenous administration of 10 mg/kg conjugate (antibody dose) in CD-1 mice. The concentrations of both total antibody and intact conjugate were measured using ELISA methods. The antibody and conjugate clearance curves for one representative PK study are shown in Figure 2A and B, respectively. For each conjugate, the slope of the linear plot of ln[conjugate]/[Ab] vs time was used to calculate the rate of maytansinoid cleavage from conjugate in plasma (k_{cl}) (Figure 2C). The complete set of PK parameters measured for conjugate clearance for the total set of AMCs tested in three independent PK studies are assembled in Table 3.

All of the AMCs tested in these studies have similar rates of clearance for the antibody moiety of the AMC (mean CL_{Ab} = 0.58 ± 0.15 mL/h/kg; mean $t_{1/2,\beta}^{Ab}$ = 226 ± 23 h). The volume of distribution (V_{ss}), C_{max}, and AUC parameters for the antibody component of the conjugates described in Table 3 also seem to be relatively unaffected by the nature of the linker and DM*x* moieties attached to the antibody (mean V_{ss} = 177 ± 34 mL/kg, mean C_{max} = 210 ± 50 µg/mL; mean AUC = 18593 ± 5706 µg·h/mL). Thus, the pharmacokinetic parameters describing antibody clearance and biodistribution appear to be relatively unaffected by the nature of the linker or maytansinoid moiety on the conjugate.

In contrast, the rate of conjugate clearance from plasma is significantly affected by the nature of the linker and maytansinoid moieties on the conjugate. As shown in Table 3, the conjugate half-life in plasma ($t_{1/2,\beta}^{conj}$) increases as the stability to reduction of the disulfide linker increases. The hindered conjugates with two methyl groups at the carbon adjacent to the disulfide linkage (0:2 or 0′:2) are significantly more stable in plasma ($t_{1/2,\beta}^{conj}$ of 87 and 102 h, respectively) compared to the less

[a] k_{cl} = rate of loss of maytansinoid from conjugate during circulation in the plasma due to a reductive cleavage event; measured from the slope of the plot of ln([conjugate]/[Ab]) vs time. [b] Relative stability to maytansinoid cleavage from conjugate *in vivo*, normalized to the rate of cleavage of the 0:0 conjugate (i.e., relative stability = $k_{cl}^{0:0}/k_{cl}^{x:y}$).

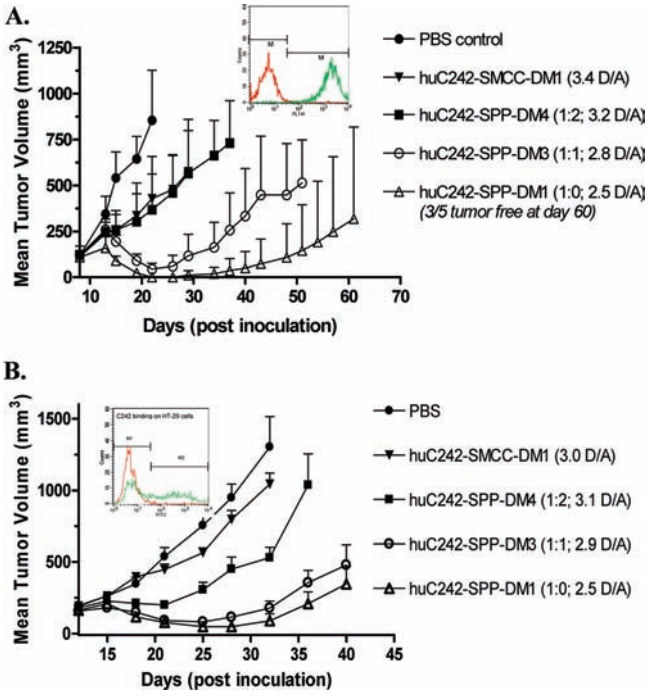

Figure 3. Comparison of antitumor activities of huC242 AMCs on human colon cancer xenograft models in SCID mice. Mice (5 per group) were dosed with 75 μg conjugated maytansinoid/kg/injection, daily for 5 days. AMCs with increasing steric hindrance on the maytansinoid side of the disulfide bond (1:0, 1:1, 1:2) were compared with the noncleavable SMCC-DM1 conjugate in COLO205 model (A) and HT29 model (B). The insets show CanAg expression levels determined by FACS on the two cell lines after staining with saturating huC242 antibody followed by FITC labeled goat antihuman IgG secondary reagent (M2 population) or secondary reagent only (M1 population). In cases where mice remained tumor free (TF) at the end of study, it is indicated in the figure.

hindered 1:0 or 0:0 conjugates ($t_{1/2,\beta}^{conj}$ of 47 and 15 h, respectively). The 1:2 conjugate with hindrance on both sides of the disulfide linkage is even more stable with $t_{1/2,\beta}^{conj}$ of 218 h. Conjugate clearance (CL_{conj}) represents the total clearance of conjugated maytansinoid from plasma due to a combination of antibody clearance (CL_{Ab}) and loss of maytansinoid from antibody due to a bond cleavage event. The rate constant k_{cl} for maytansinoid cleavage from antibody was calculated as described above for each conjugate and is given in Table 3. The relative stabilities of the conjugates to maytansinoid cleavage, normalized to the 0:0 conjugate ($k_{cl}^{0:0}/k_{cl}^{conj}$), are also shown in Table 3 and correlate with the level of steric hindrance around the disulfide bond, suggesting that the release of maytansinoid from conjugate during circulation in the blood is likely occurring through reductive cleavage.

***In Vivo* Efficacy of AMCs in Human Tumor Xenografts in SCID Mice.** Having determined that the level of steric hindrance around the disulfide bond impacts the chemical stability of the conjugate linkage, as well as the rate of clearance of conjugated maytansinoid during circulation in the blood, we evaluated the *in vivo* antitumor activity of a variety of the huC242-DM*x* conjugates in two human colon carcinoma xenograft models: COLO205 that expresses high levels of CanAg antigen homogeneously, and HT29 that expresses CanAg heterogeneously with a wide range of expression (see FACS histograms in Figure 3A and B).

In the first set of efficacy studies, we compared the activity of three different huC242-SPP-DMx conjugates having one methyl group on the linker side and increasing levels of steric hindrance on the maytansinoid side of the disulfide bond (1:0, 1:1, and 1:2; Figure 3A and B). The noncleavable huC242-SMCC-DM1 conjugate was also included. The level of efficacy varied greatly among the conjugates, with some showing partial and complete regressions and others having only minimal activity. In both the HT29 and COLO205 models, the order of efficacy observed was 1:0 > 1:1 > 1:2 = SMCC-DM1. Therefore, for conjugates with one methyl group on the linker side of the disulfide bond, increasing steric hindrance on the maytansinoid side leads to decreasing efficacy. These results suggest that, in this series of conjugates, the cleavability of the disulfide linkage is a more important determinant of antitumor activity than the increase in exposure (AUC) with increasing steric hindrance around the disulfide bond. The relative lack of activity for the noncleavable SMCC linked conjugate in these models supports this notion.

In a second set of efficacy studies (Figure 4), we compared the activity of conjugates having the same degree of steric hindrance on the maytansinoid side while having different steric hindrance on the linker side (1:0 and 2:0). In this case, there was little difference in the efficacy of these conjugates in either model. This again may suggest that there is an important balance between improved exposure vs ease of cleavability for *in vivo* activity. A nonbinding humanized IgG_1-SPP-DM1 conjugate had no activity in these models demonstrating that the activity observed for the huC242 conjugates is dependent on specific binding of conjugate to CanAg on the cell surface. In the same study, we also compared conjugates having the same degree of steric hindrance on the linker side vs the maytansinoid side of the disulfide bond

dx.doi.org/10.1021/bc100480a |*Bioconjugate Chem.* 2011, 22, 717–727

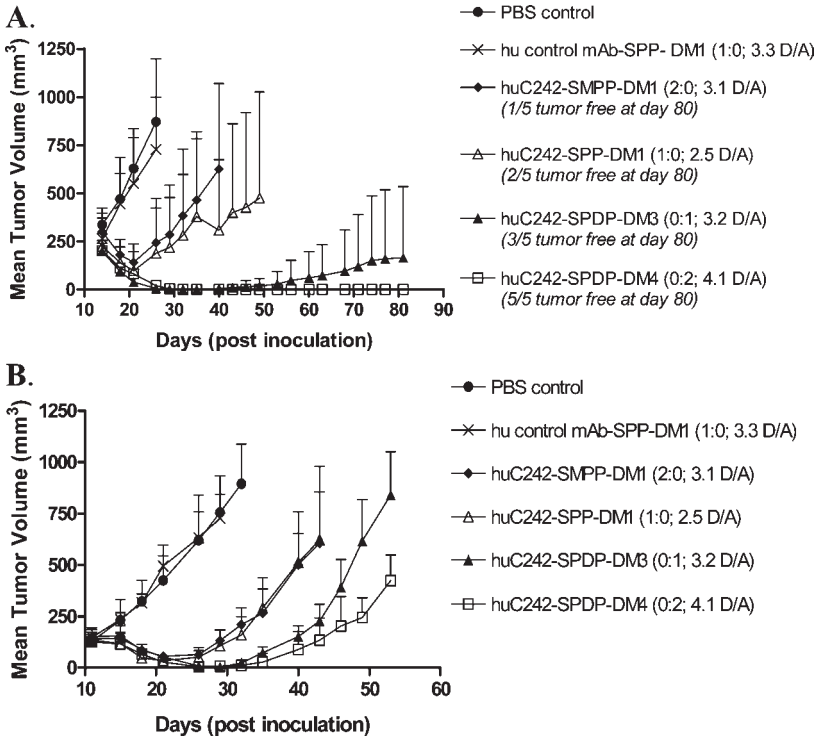

Figure 4. Panels (A) and (B) show results from a second set of efficacy studies in SCID mice comparing conjugates having the same level of steric hindrance, either on the linker side or on the maytansinoid side, of the disulfide bond (1:0 vs 0:1, 2:0 vs 0:2) on COLO205 and HT29, respectively. All other conditions are identical to those described in Figure 3.

(0:1 vs 1:0; 0:2 vs 2:0) to determine if the location of the steric hindrance impacted the efficacy of the conjugate. *In vivo* pharmacokinetic studies had demonstrated that the location of the hindrance did not appreciably change conjugate half-life or exposure (Table 3). In both the HT29 and the COLO205 efficacy studies, however, it was observed that the conjugate with the steric hindrance on the maytansinoid side of the disulfide bond was significantly more active than the corresponding conjugate with the same level of steric hindrance on the linker side. The order of activity of conjugates in both models was 0:2 > 0:1 > 2:0 ≈ 1:0. These results suggest that additional factors beyond PK exposure and cleavability of the disulfide linkage may be involved in determining *in vivo* efficacy.

In a further series of efficacy studies, we compared the activity of the 0:2 conjugate (SPDP-DM4) to the 0′:2 conjugate (SPDB-DM4) that has a longer linker carbon chain. The two conjugates had similar efficacy in the models tested (data not shown).

***In Vitro* Cytotoxicity of Unconjugated Maytansinoid Derivatives and AMCs.** In an effort to understand what additional factors may be involved in determining the *in vivo* efficacy of an AMC, we evaluated the intrinsic cytotoxic potency of the unlinked maytansinoids and various conjugates in *in vitro* cytotoxicity assays.

The *in vitro* cytotoxicity of unconjugated DM1 and DM4 maytansinoids were tested in COLO205 and HT29 cells as the stable *S*-methyl thioether species, since the potency of DM1 and DM4 measured in cell culture media can be variable due to formation of mixed disulfides by thiol/disulfide exchange with the cystine present in the media. In COLO205 cells, the IC_{50} values of the *S*-Me derivatives of DM1 and DM4 were 52 and 26 pM, while in HT29 cells, the IC_{50} values were 36 and 22 pM, respectively. These data suggest that introducing methyl groups on carbon adjacent to the thiol group (as in DM3 and DM4) may slightly increase the potency of these unconjugated maytansinoids relative to DM1, likely due to increased hydrophobicity resulting in greater membrane permeability and/or tighter binding to microtubules.

The cytotoxicity of huC242-DM*x* conjugates were tested in COLO205 cells *in vitro* using a clonogenic assay. All disulfide-linked conjugates were highly potent, with EC_{50} values ranging from 3.5 to 15 pM (antibody concentration; Table 1). There is no apparent correlation between the disulfide bond stability and the observed *in vitro* potency of the conjugates. Furthermore, the noncleavable thioether linked SMCC-DM1 conjugate showed similar *in vitro* cytotoxic potency to the disulfide-linked conjugates, suggesting that disulfide bond cleavage is not a critical factor for the *in vitro* cytotoxic potency of these conjugates, consistent with the demonstration of efficient lysosomal cleavage of AMCs in COLO205 cells.[3]

***In Vitro* Bystander Activity of Conjugates.** Previously, we have shown that, under conditions where cells are grown at very high densities, as in a solid tumor grown *in vivo*, disulfide-linked conjugates can kill neighboring nontargeted bystander cells after being internalized and processed by the target cell to generate diffusible cytotoxic metabolites.[23] This prompted us to investigate whether bystander killing potency of an AMC may vary with the stability of the disulfide linkage between antibody and maytansinoid and therefore be a factor that may contribute to *in vivo* efficacy. In Figure 5, we show the results of an experiment designed to measure the *in vitro* bystander killing activity of four maytansinoid conjugates: 1:0, 0:1, 0:2, and SMCC-DM1. In this experiment, COLO205 (antigen-positive) and Namalwa (antigen-negative) cells were mixed together in different ratios, and the huC242-DM*x* conjugates were added at a concentration

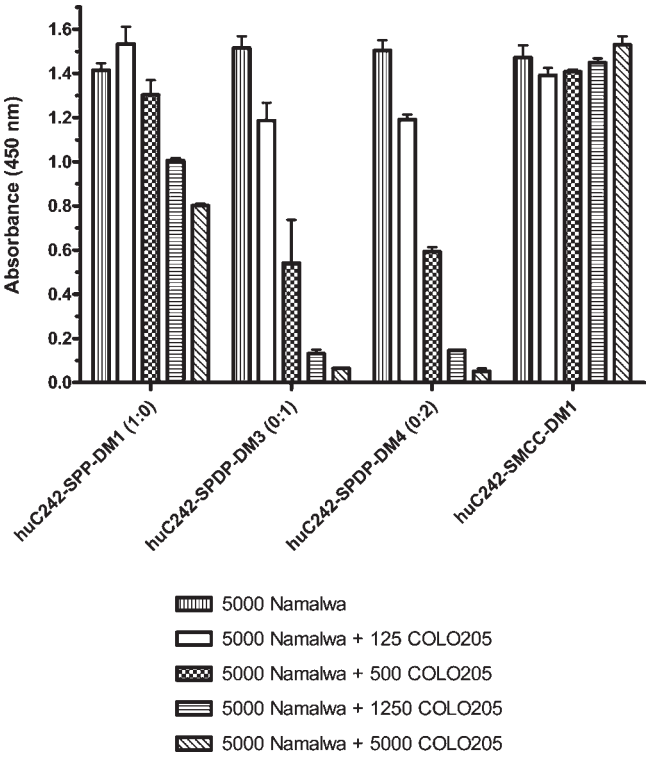

Figure 5. *In vitro* bystander killing of antigen-negative Namalwa cells by CanAg antigen-positive COLO 205 cells treated with huC242 AMCs. Namalwa and COLO205 cells were mixed in the ratios indicated and treated with one of C242-SPP-DM1 (1:0), C242-SPDP-DM3 (0:1), C242-SPDP-DM4 (0:2), or C242-SMCC-DM1 at 1 nM conjugate concentration. All conjugates had ~4 DM*x*/Ab. The absorbance at 450 nm is a measure of the viability of the Namalwa cells after a 4 day incubation with conjugate.

of 1 nM, sufficient to kill all the COLO205 cells but none of the Namalwa cells. In the absence of COLO205 cells, the Namalwa cells were not killed by any of the conjugates, as expected. In contrast, when COLO205 cells were present in the cell mixture, all of the disulfide-linked conjugates were able to kill surrounding antigen-negative Namalwa cells to some extent. However, the noncleavable SMCC-DM1 conjugate showed no bystander killing even at the highest ratio of COLO205:Namalwa cells used (1:1). These results are consistent with previously reported results showing that the cytotoxic metabolites produced upon target cell internalization of disulfide-linked conjugates include the membrane-permeable DM*x* thiol and *S*-methyl DMx species, while the sole metabolite produced from internalization of the SMCC-DM1 conjugate is the poorly membrane-permeable lysine-SMCC-DM1 species.[3,24] Overall, the trends in bystander killing potency *in vitro* agree well with the trends in antitumor activity of these conjugates *in vivo*, with 0:2 ≈ 0:1 > 1:0 > SMCC-DM1, suggesting that bystander killing may play a role in antitumor activity *in vivo*.

Tolerability of huC242-SPP-DM1 (1:0) and huC242-SPDB-DM4 (0′:2) Conjugates in CD-1 Mice. Interestingly, while the *in vivo* efficacy of the huC242-SPDB-DM4 (0′:2) conjugate is significantly greater than the huC242-SPP-DM1 (1:0) conjugate in the models tested, the acute toxicity of the two conjugates in mice is similar. CD-1 mice (12 mice/group) were dosed intravenously with either huC242-SPP-DM1 (1:0) or huC242-SPDB-DM4 (0′:2) conjugate. Measurements of toxicity based on body weight loss were similar for the two conjugates and the dose resulting in severe toxicity in 10% of the animals (STD_{10}) was found to be similar for the two conjugates (approximately 1.2 mg DM*x*/kg). These results suggest that the balance of factors determining efficacy and tolerability are different.

DISCUSSION

Cantuzumab mertansine (huC242-SPP-DM1), a disulfide-linked maytansinoid conjugate with sterically hindered (1:0) disulfide linkage, has been studied in several phase I human clinical trials, predominantly in subjects with colon cancer.[25−27] Because of its specificity and potency toward CanAg antigen-expressing tumors, the huC242-maytansinoid conjugate is able to selectively target malignant tumor cells for destruction while sparing healthy normal tissue. However, in humans[25] and in preclinical models,[6] the half-life of the conjugate in plasma was found to be significantly shorter than the half-life of the antibody component, likely due to reductive cleavage of DM1 from antibody as the conjugate circulates in the plasma compartment ($t_{1/2,\beta}$ conjugate = 41 h vs $t_{1/2,\beta}$ antibody = 230 h in humans). This observation prompted us to investigate whether huC242−maytansinoid conjugate activity might be improved by increasing the stability of the disulfide linker connecting the maytansinoid to the antibody toward thiol−disulfide exchange reactions, thereby increasing conjugate half-life and exposure of tumor to conjugated maytansinoid.

Toward this end, a panel of disulfide-linked huC242-DM*x* conjugates was generated with different degrees of steric hindrance around the disulfide bond, by introducing methyl groups on carbon atoms adjacent to the disulfide linkage (Table 1). The SMCC-DM1 conjugate with DM1 linked via a thioether bond was also included in this investigation to represent a conjugate with a nonreducible linker. Evaluation of this set of conjugates for their sensitivity to reductive cleavage *in vitro* demonstrated that as the degree of steric hindrance around the disulfide bond increased the rate of cleavage of maytansinoid from antibody decreased. *In vivo*, these conjugates showed an identical trend, with increasing steric hindrance around the disulfide bond leading to increased conjugate half-life in plasma, suggesting that maytansinoid is being lost from disulfide linked conjugates in plasma by a reductive cleavage event. The location of the steric hindrance (maytansinoid vs linker side) in the disulfide bond did not significantly influence the rate of cleavage of maytansinoid from conjugate, which is consistent with a chemical reduction occurring *in vivo* via a small molecule reductant like cysteine.[28] The rate of loss of maytansinoid from the AMCs *in vivo,* inferred from the pharmacokinetic measurements, is consistent with that predicted from the second-order rate constants for reduction measured *in vitro* (the second-order rate constant measured *in vitro* at pH 6.5 has to be adjusted upward by a factor of ~8 to correct for the higher pH found in plasma (7.4), which will lead to an 8-fold increase in the concentration of reactive thiolate nucleophile and a corresponding increase in rate of reduction) and the known concentrations of free thiol in plasma (~5 μM) in the form of cysteine.[28]

While the greater stability of the more sterically hindered disulfide-linked conjugates might be predicted to lead to increased tumor exposure and potentially greater efficacy for the more hindered conjugates, evaluation of the *in vivo* efficacy resulted in an unexpected ranking, with conjugates of intermediate disulfide bond stability having the greatest antitumor activity.

Overall, the order of efficacy observed was as follows: 0′:2 ≥ 0:2 > 0:1 > 1:0 ≈ 2:0 > 1:1 > 1:2 ≈ SMCC-DM1. The huC242−maytansinoid conjugates with a highly hindered disulfide linkage (1:2) or noncleavable thioether linkage (SMCC-DM1) were much less active suggesting that the reductive release of a maytansinoid thiol is required for maximal antitumor activity in these xenograft models.

We also observed that the configuration of steric hindrance at the disulfide bond for the conjugates with intermediate disulfide bond stability (the "sidedness") is important in determining the magnitude of antitumor activity. We found that having one or two methyl groups on the maytansinoid side of the disulfide bond confers an advantage relative to having the same degree of steric hindrance on the linker side, despite the fact that these conjugates have approximately equivalent *in vivo* plasma stability (Figure 4). This observation suggests that perhaps the nature of the maytansinoid metabolite released by reductive cleavage of the conjugate at the tumor cell is also important in determining conjugate activity (i.e., DM4 released from the 0:2 conjugate is more effective at inhibiting tumor growth than DM1 released from the 2:0 conjugate). Although the 0:2 and 0:1 conjugates do have slightly higher *in vitro* potencies than the corresponding 2:0 and 1:0 conjugates *in vitro* (Table 1), which is consistent with their greater activities *in vivo*, the order of intrinsic *in vitro* potency of the panel of conjugates taken as a whole does not adequately predict the trend in *in vivo* activities observed, suggesting additional factors contribute to activity *in vivo*. This is most clearly demonstrated by the fact that although the 0:2 and SMCC-DM1 conjugates have very similar potencies *in vitro*, the 0:2 conjugate is strikingly more active *in vivo*, despite having a shorter conjugate half-life in plasma and about half the plasma exposure ($AUC_{0-\infty}$).

One property differentiating tumor xenografts growing *in vivo* from tumor cells growing on a cell culture plate may be the presence of inaccessible (i.e., nontargeted) tumor cells in the tightly packed three-dimensional tumor spheroid *in vivo*. Such nontargeted cells may be tumor cells that lack expression of the target antigen (see, for example, the heterogeneous expression of the CanAg antigen in the HT29 xenograft model) or cells that are inaccessible to conjugate due to barriers to macromolecule delivery.[29,30] There is evidence in the literature from our group and others to support bystander killing of nontargeted tumor cells by immunoconjugates *in vivo*.[23,31] Bystander killing requires processing of the conjugate by target cells followed by release of a membrane-permeable cytotoxic metabolite which then diffuses into neighboring tumor cells. Disulfide-linked AMCs have been shown to be effective at bystander killing because target cell processing of these conjugates yields membrane-permeable DM*x* metabolites including the thiol and the *S*-methylated derivative of the thiol.[3,24] For bystander killing by disulfide-linked AMCs, release of the more hindered DM3 or DM4 thiols from a 0:1 or 0:2 conjugate might be expected to be more effective than release of the less hindered DM1 thiol from a 1:0 or 2:0 conjugate, since DM1, having a more reactive thiol, would likely be inactivated more quickly in the extracellular space by disulfide interchange with, for example, cystine. Additionally, it has been shown that the DM4 metabolite is efficiently *S*-methylated by the target cell *in vivo* (DM3 has also been shown to be efficiently S-methylated by COLO205 cells in vitro; unpublished data), while the DM1 metabolite is not.[3] This *S*-methylation prevents any possibility of thiol−disulfide exchange reactions of the DM4 metabolite, which may contribute to greater bystander activity. Finally, the increased hydrophobicity of the more substituted DM3 and DM4 thiols relative to DM1 may also promote more efficient passage across cell membranes and tighter binding to microtubules leading to better bystander killing. The data presented in this report showing that the 0:2 and 0:1 huC242 conjugates have superior *in vitro* bystander activity as well as superior *in vivo* efficacy supports a role for bystander killing in the *in vivo* activities of these conjugates.

The superior *in vivo* antitumor activity and improved therapeutic window of the 0′:2 disulfide-linked conjugate reported here for the huC242 maytansinoid conjugates has also been observed for other AMCs in development including antibody maytansinoid conjugates targeting αv integrin, CD19, CD33, and CD138.[8,9,32,33] However, the relationships reported here may not be true for all AMC targets. For example, one notable exception is trastuzumab-SMCC-DM1 targeting HER2, where the noncleavable thioether-linked conjugate has comparable activity to the disulfide-linked conjugates in xenograft models.[4] The accumulated preclinical data therefore suggests that the optimal linker for each AMC may depend on multiple factors and needs to be explored for each target and antibody.

For the CanAg-targeting huC242 antibody discussed in this report, the disulfide-linked huC242-SPDB-DM4 (0′:2) maytansinoid conjugate showed the best antitumor activity in the preclinical models. On the basis of the combined efficacy and tolerability results reported here, we conclude that this conjugate has an improved therapeutic window relative to the 1:0 conjugate, cantuzumab mertansine, which had previously been studied in clinical trials[25−27] and provides a rationale for its clinical development.

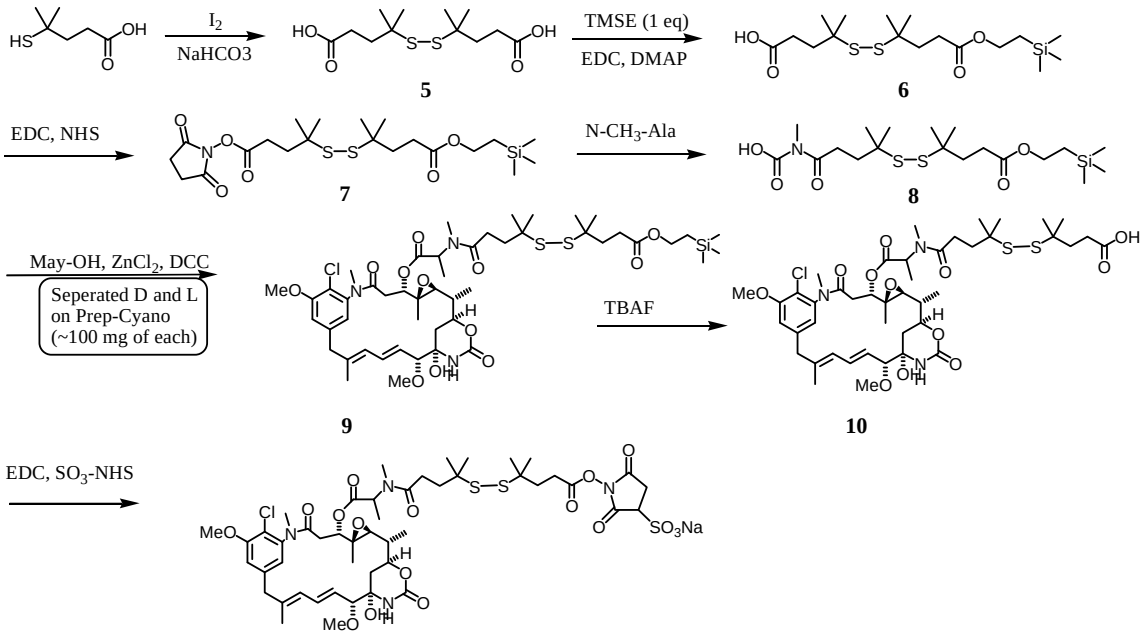
SYNTHESIS OF SULFO-NHS-SMPP-DM1.

Scheme 1. Preparation of *N*-sulfosuccinimidyl ester of $N^{2'}$-Deacetyl-$N^{2'}$-[3-(3-carboxy-1,1-dimethyl-propyl-dithio)-1-oxopropyl]-maytansine (sulfo-NHS-SMPP-DM1).

***$N^{2'}$*-deacetyl-*$N^{2'}$*-[3-(5-nitropyridine-2-dithio)-1-oxopropyl]-maytansine (2).** To a 25 mL flask containing a solution of 2,2'-Dithiobis(5-nitropyridine) (100 mg, 0.323 mmol) in tetrahydrofuran (10 mL) and 4-methylmorpholine was added dropwise to a solution of DM1 **(1)** (106 mg, 0.145 mmol) in *N,N*-dimethylformamide (5 mL). After 90 min most of the solvent was removed by rotary evaporation and the residue was taken up in a minimum volume of *N,N*-dimethylformamide. The mixture was purified by preparative reverse phase HPLC on a Waters C8 symmetry shield 5 μm column (100 x 19 mm) at ambient temperature using a 19 mL/min flow rate, eluting with a linear gradient of acetonitrile (5% to 95% over 25 min) in deionized water containing 0.2% formic acid. Desired product **(2)** eluted at 23 min. Product containing fractions were combined and solvent was removed under vacuum to give 93 mg (72% yield) of product. ^{1}H NMR(400 MHz, $CDCl_3$) δ 9.13 (1H, s). 8.24 (1H, d, *J* = Hz), 7.75 (1H, d, *J* = Hz), 6.86 (1H, d, *J* = 1.5 Hz), 6.75 (1H, d, *J* = 11 Hz), 6.70 (1H, d, *J* = 1.5 Hz), 6.47 (1H, dd, *J* = 11,15 Hz), 6.25 (1H, s), 5.67 (1H, dd, *J* = 9, 15 Hz), 5.45 (1H, q, *J* = 7 Hz), 4.81 (1H, dd, *J* = 3, 12 Hz), 4.32 (1H, t, *J* = 10 Hz), 4.02 (3H, s), 3.71 (1H, d, *J* = 12 Hz), 3.55 (1H, d, *J* = 9 Hz), 3.39 (3H, s), 3.25 (3H, s), 3.08-3.20 (2H, m), 2.88 (3H, s), 2.60-2.82 (2H, m), 2.22 (1H,

dd, *J* = 3, 14 Hz), 1.68 (3H, s), 1.60 (3H, s), 1.35 (3H, d, *J* = 5 Hz), 1.33 (3H, d, *J* = 5 Hz), 0.84 (3H, s).



$N^{2'}$-Deacetyl-$N^{2'}$-[3-(3-carboxy-1,1-dimethyl-propyl-dithio)-1-oxopropyl]-maytansine (3). $N^{2'}$-deacetyl-$N^{2'}$-[3-(5-nitropyridine-2-dithio)-1-oxopropyl]-maytansine (60 mg, 0.067 mmol) was dissolved in *N,N*-dimethylformamide (1.0 mL) and 50 mM potassium phosphate buffer pH 7.5 (0.80 mL) to which a solution of 4-mercapto-4-methyl pentanoic acid (*1*) (22 mg, 0.149 mmol) in tetrahydrofuran (0.22 mL) was added dropwise. After 1 h the solution was purified by preparative reverse phase HPLC on a waters C8 symmetry shield 5 μm column (19 x 100 mm) at ambient temperature using a 19 mL/min flow rate, eluting with a linear gradient of acetonitrile (5% to 95% over 30 min) in deionized water containing 0.2% formic acid; the desired product eluted at 22 min. Product containing fractions were combined and solvent was removed under vacuum to give 50 mg (84% yield) of product. ^{1}H NMR(400 MHz, $CDCl_3$) δ 6.81-6.83 (1H, m), 6.64-6.68 (1H, m), 6.55-6.62 (2H, m), 6.47 (1H, dd, *J* = 11,15 Hz), 5.60-5.69 (1H, m), 5.17-5.25 (1H, m), 4.81 (1H, dd, *J* = 3, 12 Hz), 4.32 (1H, t, *J* = 10 Hz), 3.98 (3H, s), 3.63 (1H, d, *J* = 12 Hz), 3.48 (1H, d, *J* = 9 Hz), 3.36 (3H, s), 3.23 (3H, s), 3.08-3.14 (1H, m), 2.91-3.0 (2H, m), 2.90 (3H, s), 2.71-2.88 (1H, m), 2.57-2.70 (2H, m), 2.30-2.40 (2H, m), 2.22 (1H, m), 1.80-1.92 (1H, m), 1.64 (3H, s), 1.49-1.61 (1H, m), 1.20-1.40 (18H, m), 0.80 (3H, s).

***N*-sulfosuccinimidyl ester of $N^{2'}$-Deacetyl-$N^{2'}$-[3-(3-carboxy-1,1-dimethyl-propyl-dithio)-1-oxopropyl]-maytansine (4).** To a 2.0 mL vial was added $N^{2'}$-Deacetyl-$N^{2'}$-[3-(3-carboxy-1,1-dimethyl-propyl-dithio)-1-oxopropyl]-maytansine (10 mg, 0.011 mmol) and *N*-hydroxysulfosuccinimide sodium salt (4 mg, 0.018 mmol) suspended in anhydrous dimethyl formamide (140 μL) to which was added a solution of dicyclohexylcarbodiimide (5 mg, 0.027 mmol) in anhydrous *N,N*-dimethylformamide (60 μL). After 16 h the mixture was passed through a glass wool plug into a 500 μL capacity test tube and 2-propanol (250 μL) was added with mixing. The resulting precipitate was centrifuged to give a pellet and supernatant was removed by aspiration. The pellet was re-suspended in 2-propanol (200 μL) then centrifuged and supernatant was removed by

aspiration. The pellet was dried by vacuum centrifugation to give 10.8 mg (91% yield) which was used without further treatment. MS $(M - Na)^-$ for $C_{45}H_{60}ClN_4NaO_{17}S_3$ calculated 1059.3, found 1059.3.

SYNTHESIS OF SULFO-NHS-SMPP-DM4.

Scheme 2. Preparation of sulfo-NHS ester of $N^{2'}$-Deacetyl-$N^{2'}$-(4-methyl-4-(2-methyl-5-carboxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine (sulfo-NHS-SMPP-DM4).

4,4'-disulfanediylbis(4-methylpentanoic acid) (5). In a 250 ml round bottom flask was added 4-Mercapto-4-methylpentanoic acid[1] (2 g, 13.5 mmol) dissolved in ethyl acetate (25 mL) and to this stirring solution was added a 10% aqueous solution of sodium bicarbonate (25 mL). A solution of concentrated iodine in ethyl acetate was added dropwise until the color persisted (change from yellow to a burnt amber, ~35 mL). The solution was allowed to stir an additional 30 minutes to ensure that the color persists. The aqueous layer was then removed and a fresh aqueous solution containing 10 ml of 10% sodium bicarbonate and 15 ml of water was added to the ethyl acetate layer and stirred an additional 30 minutes. The aqueous layer was removed and the combined

aqueous layers were extracted with ethyl acetate (2 x 50 mL) and separated. The aqueous layer was then acidified with concentrated hydrochloric acid (~10 mL) and extracted with ethyl acetate (2 x 50 mL). The combined organic layers were then washed with brine (2 x 50 mL), dried over anhydrous sodium sulfate, filtered, and concentrated to give 4,4'-disulfanediylbis(4-methylpentanoic acid) (1.8 g, 90%) as a yellow solid. ^{1}H NMR (400 MHz, $CDCl_3$): δ 11.30 (br. S, 2H), 2.46 (t, 4H, *J* = 8.0 Hz), 1.88 (t, 4H, *J* = 8.0 Hz), 1.26 (s, 12H).

4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2yl disulfanyl) pentanoic acid (6). 4,4'-disulfanediylbis(4-methylpentanoic acid) (1.0 g, 3.4 mmol) was dissolved in methylene chloride (18 mL) and pyridine (2 mL) with stirring. To this solution was added 2-(trimethylsilyl)ethanol (0.14 mL, 1.0 mmol), dimethyl-aminopyridine (0.065 g, 0.5 mmol), and *N*-(3-Dimethylaminopropyl)-*N′*-ethylcarbodiimide (0.340 g, 2 mmol) and the resulting mixture was allowed to stir at room temperature for 2.5 hours. The reaction was then quenched with hydrochloric acid (1.0 N, 15 mL) to a pH of 3-4 and then extracted with methylene chloride (2 x 30 mL). The combined organic layers were washed with brine (2 x 50 mL), dried over anhydrous sodium sulfate, filtered, and concentrated. The residue was purified on silica gel eluting with 35% ethyl acetate in hexane which contained 1% acetic acid to give 4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoic acid (0.25 g, 42% based on recovered starting material (0.550 g)). ^{1}H NMR (400 MHz, $CDCl_3$): δ 9.5 (br s, 1H), 4.11 (t, 2H, *J* = 6.8 Hz), 2.45 (t, 2H, *J* = 8.0 Hz), 2.35 (t, 2H, *J* = 8.0 Hz), 1.88 (m, 4H), 1.23 (s, 12H), 0.94 (t, 2H, *J* = 6.8 Hz), 0.00 (s, 9H).

NHS ester of 4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoate (7). 4-methyl-4-((2-methyl-5-oxo-5-(2 (trimethylsilyl)ethoxy)-pentan-2-yl)disulfanyl)pentanoic acid (0.260 g, 0.66 mmol) was dissolved in methylene chloride (4 mL) and to this solution was added *N*-Hydroxysuccinimide (0.095 g, 0.825 mmol), and *N*-(3-Dimethylaminopropyl)-*N′*-ethylcarbodiimide (0.157 g, 0.825 mmol) and the reaction was allowed to stir at room temperature with monitoring. After 2 hours an additional portion of *N*-Hydroxysuccinimide and *N*-(3-Dimethylaminopropyl)-*N′*-

ethylcarbodiimide (0.15 eq of each) was added and the reaction stirred an additional hour. The reaction was then concentrated, dissolved in ethyl acetate (25 mL) and extracted with 50 mM potassium phosphate buffer (pH 6.0, 25 mL) and brine (25 mL), dried over anhydrous sodium sulfate, filtered, and concentrated. The residue was loaded onto a silica gel column eluting with 50% ethyl acetate in hexane and fractions containing the desired product were pooled and concentrated to give the NHS ester of 4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoate (0.285 g, 88%). ^{1}H NMR ($CDCl_3$): δ 4.11 (t, 2H, *J* = 8.4 Hz), 2.79 (s, 4H), 2.69 (t, 2H, *J* = 8.4 Hz), 2.35 (t, 2H, *J* = 8.0 Hz), 1.94 (t, 2H, *J* = 8.0 Hz), 1.84 (t, 2H, *J* = 8.4 Hz), 1.26 (s, 6H), 1.23 (s, 6H), 0.94 (t, 2H, *J* = 8.4 Hz), 0.00 (s, 9H).

methyl(4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoyl)carbamic acid (8). *N*-methyl-alanine (0.087 g, 0.84 mmol) was dissolved in a 1:1 mixture of *N*,*N*-Dimethylformamide and water (7 mL) and next triethylamine was added (0.156 mL, 1.12 mmol). To this mixture was added dropwise a solution of the NHS ester of 4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl) ethoxy)pentan-2-yl)disulfanyl)pentanoate (0.275 g, 0.56 mmol) in *N*,*N*-Dimethyl-formamide (4 mL) and the reaction mixture was allowed to stir for 3 hours at room temperature. The reaction was quenched by adding 3M hydrochloric acid until the pH reached ~2 and the reaction was then diluted with ethyl acetate (25 mL) and washed with hydrochloric acid (1M, 25 mL), then brine (25 mL). The combined organic layers were washed with ethyl acetate (2 x 25 mL) and the combined organic layers were dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo. The residue was purified on silica gel using 75% ethyl acetate in hexane containing 1% acetic acid and fractions containing the desired product were pooled and concentrated to give methyl(4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoyl)carbamic acid (0.240 g, 90%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 10.57 (br s, 1H), 4.12 (t, 2H, *J* = 8.4 Hz), 2.96 (s, 4H), 2.45 (m, 2H), 2.36 (t, 2H, *J* = 8.4 Hz), 1.84 (m, 4H), 1.26 (s, 6H), 1.22 (s, 6H), 0.94 (t, 2H, *J* = 8.4 Hz), 0.00 (s, 9H).

$N^{2'}$-Deacetyl-$N^{2'}$-(4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine (9). Maytansinol (0.150g, 0.27 mmol) was dissolved in methylene chloride (4 mL) and cooled to 0^{o} in an ice bath. A solution of methyl(4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoyl)carbamic acid (0.325 g, 0.69 mmol) dissolved in methylene chloride (3 mL) was added dropwise to the cold maytansinol solution followed by a solution of *N,N'*-Dicyclohexylcarbodiimide (0.341 g, 6.6 mmol) dissolved in methylene chloride (4 mL). After one minute a 1.0 M solution of zinc chloride in diethyl ether (0.195 mL) was added and the ice bath was removed and the reaction allowed to stir for an additional two hours. The reaction was then diluted with ethyl acetate (25 mL) and passed through a glass wool plug to remove any residual solids. Concentrated aqueous sodium bicarbonate (25 mL) was added and the mixture was extracted with ethyl acetate (3 x 25 mL) and the combined organic layers were washed with brine, dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo. The residue was purified by reverse phase HPLC using a preparative Cyano column (250 x 50 mm) at 118 mL/min with an isocratic elution of 68% hexane, 24% ethyl acetate, and 8% isopropanol to give both the purified L- (0.110 g) and D- (0.115 g) isomers of *$N^{2'}$*-Deacetyl-*$N^{2'}$*-(4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine. ^{1}H NMR (400 MHz, $CDCl_3$): δ 6.81 (s, 1H), 6.76 (d, 1H, *J* = 11.2 Hz), 6.62 (s, 1H), 6.42 (dd, 1H, *J* = 11.2, 15.2 Hz), 6.22 (s, 1H), 5.68 (dd, 1H, *J* = 9.2, 15.2 Hz), 5.42 (q, 1H, *J* = 6.9 Hz), 4.77 (dd, 1H, *J* = 2.8, 12.0 Hz), 4.26 (t, 1H, *J* = 10.4 Hz), 4.14 (t, 2H, *J* = 8.4 Hz), 3.97 (s, 3H), 3.66 (d, 1H, *J* = 12.4 Hz), 3.49 (d, 1H, *J* = 9.2 Hz), 3.45 (s, 3H), 3.25 (s, 3H), 3.10 (d, 1H, *J* = 12.8 Hz), 3.04 (d, 1H, *J* = 9.2 Hz), 2.84 (s, 3H), 2.27-2.64 (m, 3H), 2.16 (dd, 1H, *J* = 2.8, 14.4 Hz), 1.75-1.88 (m, 4H), 1.63 (s, 3H), 1.56 (d, 1H, *J* = 13.2 Hz), 1.42-1.47 (m, 1H), 1.15-1.29 (m, 21H), 0.96 (t, 2H, *J* = 8.8 Hz), 0.79 (s, 3H), 0.04 (s, 9H). MS $(M + Na)^{+}$ for $C_{49}H_{76}ClN_3O_{12}S_2Si$: calculated 1025.4, found 1048.5.

L-$N^{2'}$-Deacetyl-$N^{2'}$-(4-methyl-4-(2-methyl-5-carboxy)pentan-2-yl)disulfanyl) pentanoyl)-maytansine (10). In a small vial dissolved *L-$N^{2'}$*-Deacetyl-*$N^{2'}$*-(4-methyl-4-((2-methyl-5-oxo-5-(2-(trimethylsilyl)ethoxy)pentan-2-yl)disulfanyl)pentanoyl)

maytansine (0.028 g, 0.0276 mmol) in anhydrous tetrahydrofuran (1.0 mL) and to this solution was added a 1.0M solution of Tetrabutylammonium fluoride in tetrahydrofuran (0.055 mL, 0.055 mmol) and the raction monitored by TLC. After 30 minutes the reaction was quenched with concentrated aqueous ammonium chloride (5 mL) and extracted into ethyl acetate (10 mL). The organic layer was separated and washed with brine, dried over anhydrous sodium sulfate, filtered and concentrated in vacuo. The residue was purified on silica preparative TLC by developing using 5% methanol, 2% acetic acid, and 93% methylene chloride. The band containing the desired product was scraped and filtered using the same ratio of solvents used to develop the plate to give *N*$^{2'}$-Deacetyl-*N*$^{2'}$-(4-methyl-4-(2-methyl-5-carboxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine (0.013 g, 82% based on recovered starting material (0.010 g)). MS (M + Na)$^+$ for $C_{44}H_{64}ClN_3O_{12}S_2$: calculated 925.4, found 948.3.

***N*-sulfosuccinimidyl ester of N$^{2'}$-Deacetyl-N$^{2'}$-(4-methyl-4-(2-methyl-5-carboxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine (11).** In a small vial *N*$^{2'}$-Deacetyl-*N*$^{2'}$-(4-methyl-4-(2-methyl-5-carboxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine (0.016 g, 0.0173 mmol) and a stir bar were added followed by the addition of *N*-Hydroxysulfosuccinimide sodium salt (0.094 g, 0.043 mmol) dissolved in *N*,*N*-Dimethylformamide (1 mL). After allowing this solution to stir for 5 minutes a solution of *N*,*N'*-Dicyclohexylcarbodiimide (0.009 g, 0.043 mmol) in *N*,*N*-Dimethylformamide (0.5 mL) was added and the reaction was wrapped in aluminum foil and allowed to stir at room temperature overnight. The mixture was concentrated in vacuo to a volume of ~0.3 mL and the mixture passed through a short plug of wool to remove the precipitate that had formed. The mixture was next diluted with isopropanol (1.5 mL) giving a cloudy mixture which was shaken, cooled in a dry ice acetone bath for 30 seconds, and centrifuged. The isopropanol was pipetted off and diethyl ether (1.0 mL) was next added to the residue and the mixture shaken, cooled, and centrifuged again. The diethyl ether was then pipetted off and the remaining residue placed under vacuum. The Sulfo-NHS ester of *N*$^{2'}$-Deacetyl-*N*$^{2'}$-(4-methyl-4-(2-methyl-5-carboxy)pentan-2-yl)disulfanyl)pentanoyl)-maytansine (9.2 mg) thus obtained was monitored by HPLC and

found to be 95% pure and was used as such without any further purification. MS (M – Na)$^-$ for $C_{48}H_{66}ClN_4NaO_{17}S_3$: calculated 1124.3, found 1101.4.

Supporting Information

ABSTRACT: Antibody−maytansinoid conjugates (AMCs) are targeted chemotherapeutic agents consisting of a potent microtubule-depolymerizing maytansinoid (DM1 or DM4) attached to lysine residues of a monoclonal antibody (mAb) using an uncleavable thioether linker or a stable disulfide linker. Most of the administered dose of an antibody-based therapeutic is slowly catabolized by the liver and other tissues of the reticuloendothelial system. Maytansinoids released from an AMC during this catabolic process could potentially be a source of toxicity. To investigate this, we isolated and identified liver metabolites in mice for three different [^{3}H]AMCs with structures similar to those currently undergoing evaluation in the clinic. We then synthesized each metabolite to confirm the identification and assessed their cytotoxic potencies when added extracellularly. We found that the uncleavable mAb-SMCC-[^{3}H]DM1 conjugate was degraded to a single major maytansinoid metabolite, lysine-SMCC-[^{3}H]DM1, that was nearly 50-fold less cytotoxic than maytansine. The two disulfide-linked conjugates, mAb-SPP-[^{3}H]DM1 and mAb-SPDB-[^{3}H]DM4, were also found to be catabolized to the analogous lysine-linked maytansinoid metabolites. However, subsequent reduction, *S*-methylation, and NADPH-dependent oxidation steps in the liver yielded the corresponding *S*-methyl sulfoxide and *S*-methyl sulfone derivatives. The cytotoxic potencies of the oxidized maytansinoids toward several human carcinoma cell lines were found to be 5- to 50-fold less potent than maytansine. Our results suggest that liver plays an important role in the detoxification of both cleavable and uncleavable AMCs.

INTRODUCTION

Antibody−drug conjugates (ADCs) are targeted chemotherapeutic agents that utilize the specificity of monoclonal antibodies (mAb) to deliver potent cell killing agents to cancer cells that express the target antigen.[1−3] Several antibody maytansinoid conjugates (AMCs) that utilize the tubulin-targeting maytansinoid thiols, $N^{2'}$-Deacetyl-$N^{2'}$-(3-mercapto-1-oxopropyl)-maytansine (DM1) and $N^{2'}$-Deacetyl-$N^{2'}$-(4-mercapto-4-methyl-1-oxopentyl)-maytansine (DM4), are currently being evaluated in clinical trials. The most advanced of these conjugates, trastuzumab-SMCC-DM1 (T-DM1), is in multiple advanced clinical trials for the treatment of HER-2 positive metastatic breast cancer.[4] Two other AMCs, SAR3419 (huB4-SPDB-DM4) and lorvotuzumab mertansine (huN901-SPP-DM1), have both shown promising results in early clinical trials for the treatment of B-cell malignancies and for treating solid and liquid tumors that express CD19 and CD56, respectively.[5,6] Three additional AMCs are in phase I testing.[7−9]

The AMCs currently in the clinic utilize three different linkers to attach the maytansinoid (DM1 or DM4) to a tumor-specific humanized antibody (Figure 1). T-DM1 utilizes an uncleavable thioether linker while the other candidates utilize disulfide linkers (Figure 1). During the preclinical evaluation of each AMC, conjugates with the different linkers were prepared and evaluated. The AMC that was found to yield the widest therapeutic window—as defined by the difference between the minimally effective dose (MED) in mouse xenografts models and the maximum tolerated dose (MTD)—was selected. In the majority of cases, preclinical evaluation of the disulfide-linked AMCs were found to yield the widest therapeutic window,[6−8,10] despite their having an MTD that was about 2-fold lower than that of the uncleavable versions.[11] An exception to these findings was the uncleavable T-DM1 conjugate that was found to be slightly more active in mouse xenograft models than several disulfide-linked versions.[11]

Several studies point to enhanced bystander killing of the disulfide-linked conjugates as a possible explanation for their typically greater activity when compared with uncleavable conjugates in mouse xenograft models.[10,12,13] Internalization and lysosomal processing of the uncleavable conjugate in targeted cancer cells yields the lysine-SMCC-DM1 metabolite. While this metabolite is highly cytotoxic to the targeted cell in which it is formed, it is unable to penetrate and kill neighboring "bystander" tumor cells. Internalization and lysosomal processing of the disulfide-linked conjugates yields the analogous lysine-linker-maytansinoid derivatives. However, additional intracellular

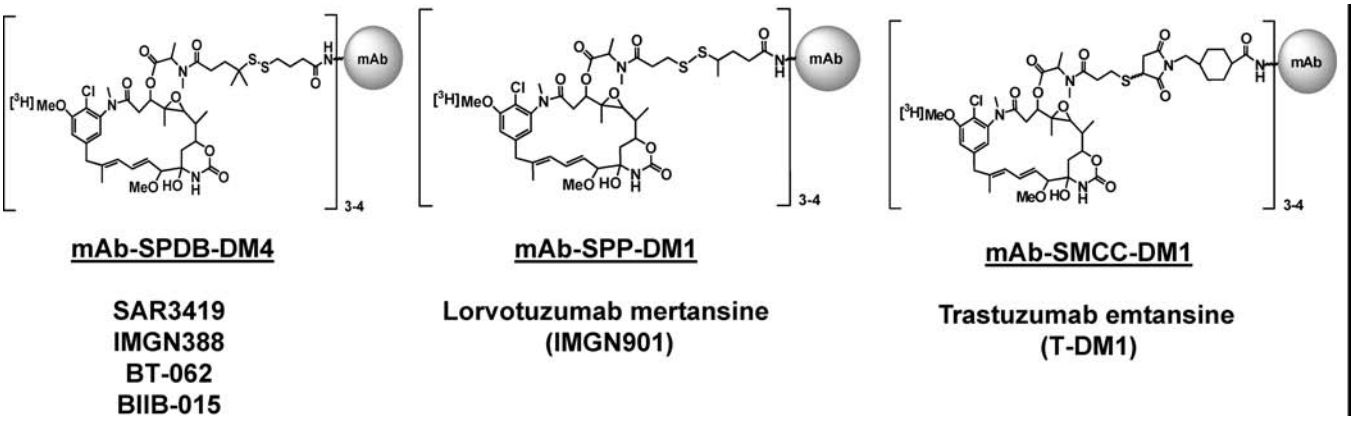

Figure 1. Structures of antibody−maytansinoid conjugates prepared for the current study. Tritium was incorporated into the C-20 methoxy group to allow for the detection of maytansinoid metabolites. Antibody-maytansinoid conjugates currently under clinical evaluation with similar structures that lack this tritium label are listed.

reduction and *S*-methylation steps yield hydrophobic maytansinoid derivatives that are potentially able to diffuse throughout the tumor, reaching tumor cells that would otherwise not accumulate sufficient maytansinoid to kill them due to low expression of the target antigen or inaccessibility to the conjugate. These diffusible metabolites may also increase the toxicity of the disulfide-linked conjugates by exposing healthy tissues to free maytansinoids. Significant levels of the catabolites would be expected to form in the liver which is known to be the primary site of antibody catabolism.[14,15] Other tissues of the reticuloendothelial system (RES) constitute additional potential catabolic sites for AMCs. Maytansinoid catabolites formed in these other tissues would ultimately be cleared through the liver since excretion studies have found liver to be the major route of AMC clearance (unpublished data). Given this central role of liver in antibody catabolism and clearance of AMCs, we set out to characterize the major maytansinoid catabolites and metabolites of the uncleavable mAb-SMCC-DM1 conjugate and the cleavable mAb-SPP-DM1 and mAb-SPDB-DM4 conjugates. Our findings suggest that catabolism and liver metabolism plays an essential role in limiting the potential toxicity of AMCs.

EXPERIMENTAL PROCEDURES

Reagents. RPMI 1640 and glutamine were from Cambrex Bioscience. Ultima Flo M scintillation fluid and Solvable were from PerkinElmer Life and Analytical Sciences. All cells were obtained from the American Type Culture Collection. All chemicals were obtained from Sigma Aldrich. The Gemini 5 μm C-18 column (0.46 × 25 cm) was obtained from Phenomenex and the 5 μm C8 column (150 × 2.1 mm) from Kromasil. The ULTRA-TURRAX T8 dispersing instrument with a S8N dispersing tool was obtained from IKA Works Inc. All antibody−maytansinoid conjugates were prepared at ImmunoGen from humanized anti-CD56 mAb, huN901[16] using methods described elsewhere by Widdison et al.[17] The linkers *N*-succinimidyl 4-(*N*-maleimidomethyl) cyclohexane-1 carboxylate (SMCC), *N*-succinimidyl 4-(2-pyridyldithio)butyrate (SPDB), and *N*-succinimidyl 4-(2-pyridyldithio) pentanoate (SPP), are all *N*-hydroxysuccinimide esters that react with amino groups of the protein. The ratio of linked maytansinoid molecules per antibody molecule (D/A) and the specific radioactivities for each conjugate was as follows: huN901-SPP-[^{3}H]DM1 (3.5 D/A, 852 mCi/mmol DM1), huN901-SMCC-[^{3}H]DM1 (3.6 D/A, 284 mCi/mmol DM1), and huN901-SPDB-[^{3}H]DM4 (2.9 D/A, 300 mCi/mmol DM4). The maytansinoid metabolites—lysine-N^{ϵ}-SPP-DM1, lysine-N^{ϵ}-SMCC-DM1, DM1-SMCC, lysine-N^{ϵ}-SPDB-DM4, *S*-methyl-DM1, *S*-methyl-DM4-sulfoxide, *S*-methyl-DM1 sulfoxide, and *S*-methyl-DM4 sulfone were synthesized at ImmunoGen (manuscript in preparation). The DM1, DM4, and *S*-methyl-DM4 were prepared as previously described.[17]

In Vitro Cell Proliferation Assays. The cytotoxic potencies of the maytansinoids toward human carcinoma cell lines were assessed using a WST-based cell viability assay. Cells were seeded in 96-well flat-bottom plates at a density of 1000 cells/well for A375, BJAB, COLO 205, and KB, and 5000 cells/well for MOLT-4. Dilutions of the AMC or free maytansinoid solutions were added to cells and incubated for 5 days at 37 °C with 6% CO_2. The WST-8 agent was added and developed for 1 h for A375, COLO 205, and KB, and 2 h for BJAB and MOLT-4. Surviving fractions of cells were plotted versus conjugate or maytansinoid concentrations for determining IC_{50} values.

Mouse Studies. Female CD-1 mice were obtained from Charles River Laboratory (Raleigh, North Carolina). Mice were intravenously injected with a bolus of 300 μg/kg (based on DM1 or DM4) of the conjugates or 1 mg/kg of free [^{3}H]DM4 or [^{3}H]DM1. Two mice were sacrificed at each of the designated time points following treatment. The gall bladder containing the bile was collected from the mice treated with [^{3}H]DM4 and [^{3}H]DM1 and frozen at −80 °C. After bile collection, the systemic circulation was flushed by injecting 5 mL PBS into the left ventricle and draining through an incision in the inferior vena cava. The whole liver tissues were collected in 50 mL preweighed polypropylene tubes and frozen at −80 °C.

Extraction of [^{3}H]Maytansinoid Metabolites from Liver Tissue. The liver tissues were thawed on ice, cut into small pieces, and homogenized with five volumes (v/w) 10 mM Tris-HCl buffer, pH 7.5 containing 5 mM *N*-ethylmaleimide (NEM). The NEM was added to prevent thiol/disulfide exchange reactions during the workup by capping the thiol groups. The homogenates were placed on ice for 2 h to ensure complete alkylation, and then a portion of each homogenate (0.4 mL) was added to a 20 mL glass scintillation vial. The radioactivity associated with each homogenate was determined after solubilization with Solvable as described for tumor homogenates

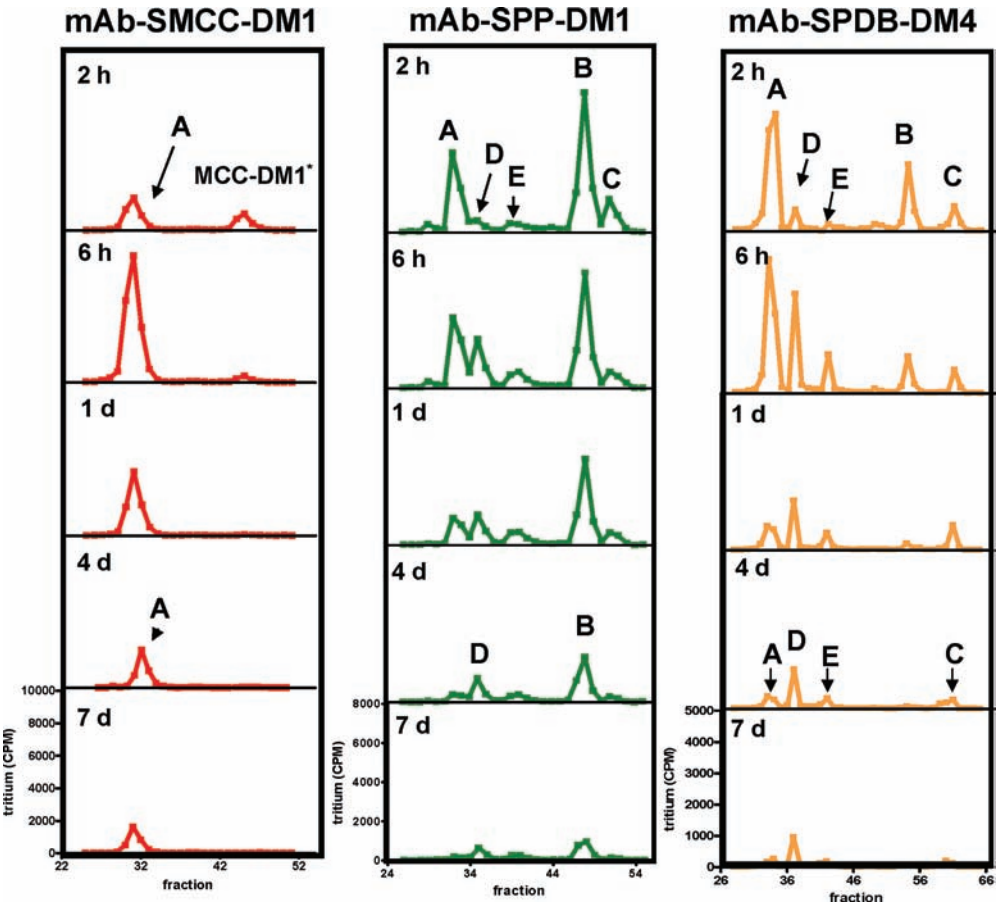

Figure 2. Maytansinoid metabolites of cleavable and uncleavable [^{3}H]AMCs formed in liver over time. Mice (n = 10) were treated with a single 300 μg/kg dose (based on DM1 or DM4) of mAb-SMCC-[^{3}H]DM1, mAb-SPP-[^{3}H]DM1, or mAb-SPDB-[^{3}H]DM4, and two mice from each group were sacrificed after 2 h, 6 h, 1 d, 4 d, and 7 d and liver tissues samples were collected. Liver tissues were homogenized and portions of the homogenates were extracted and analyzed for ^{3}H-maytansinoid metabolites by HPLC. The effluent from the samples was collected in 0.5 mL fractions, and the radioactivity corresponding to each fraction was determined by LSC. Alternatively, fractions in duplicate runs corresponding to the tritium peaks were analyzed by LC/MS for metabolite identification. The chromatograms show the fraction number on the abscissa and the counts per minute of tritium (CPM) on the ordinate. The sole metabolite (A) of the uncleavable conjugate is lysine-SMCC-DM1. The five metabolites for mAb-SPP-DM1 are lysine-SPP-DM1(A), DM1 (B), *S*-methyl-DM1 (C), *S*-methyl-DM1 sulfoxide (D), and *S*-methyl-DM1 sulfone (E). The corresponding five metabolites of mAb-SPDB-DM4 (lysine-SPDB-DM4, DM4, *S*-methyl-DM4, *S*-methyl-DM4 sulfoxide, and *S*-methyl-DM4 sulfone) are also denoted A−E.

previously.[18] [^{3}H]Maytansinoid metabolites were extracted by the procedure described previously with slight modifications.[18] Aliquots of the homogenates (0.4 mL) were extracted three times with 3.4 volumes of ethyl acetate/methanol (7.5:1, v/v), and the pooled extracts were evaporated to dryness in an evacuated centrifuge. The dried extracts were dissolved in 0.12 mL of 20% aqueous acetonitrile containing 0.025% trifluoroacetic acid (TFA) and 25 mM catechol (to prevent oxidation), and the metabolites were separated by reversed-phase HPLC. In separate experiments, we found that 83% of the synthetic standard, *S*-methyl-[^{3}H]DM1, could be recovered from the liver homogenate using this method. In addition, extracts from fresh liver homogenates mixed with mAb-SPDB-[^{3}H]DM4 were found to contain none of the metabolites, indicating that the ex vivo workup released no artifacts (data not shown). The radioactivity associated with the metabolites in Figure 2 was converted to pmol/g of metabolite using the specific radioactivity of the DM1 and DM4 and the measured liver weights. The values were multiplied by 1.2 to account for the extraction efficiency (83%) of the synthetic *S*-methyl-[^{3}H]DM1.

Extraction of [^{3}H]Maytansinoid Metabolites from Bile. The gall bladder containing the bile was mixed with 20% aqueous acetonitrile containing 5 mM NEM (0.12 mL), vortexed, and allowed to sit for 30 min to ensure complete alkylation of thiol groups. The debris was removed from the samples by sedimentation (13 000*g*, 5 min) and the supernatants were analyzed for metabolites by HPLC and liquid scintillation counting.

Analytical Methods. All maytansinoids were separated on a Gemini 5 μm C-18 column (0.46 × 25 cm) equilibrated with 20% aqueous CH_3CN containing 0.025% TFA. The chromatogram was developed with a 1 min hold at 20% aqueous CH_3CN containing 0.025% TFA, followed by a linear gradient of 2% CH_3CN/min for 15 min, and then 1% CH_3CN/min for 20 min with a flow rate of 1 mL/min. The effluent was collected in 0.5 mL fractions. Tritium (cpm) associated with each fraction was determined by mixing each vial (0.5 mL) with 4 mL Ultima Gold liquid scintillation cocktail and counting for 5 min in a Tri-Carb 2900T liquid scintillation counter. Alternatively, fractions in duplicate runs corresponding to the peaks of tritium were evaporated to dryness, dissolved in 0.02 mL 50% aqueous CH_3CN, and

dx.doi.org/10.1021/bc100498q |*Bioconjugate Chem.* 2011, 22, 728–735

analyzed for maytansinoids by liquid chromatography mass spectrometry (LC/MS). The [^{3}H]-maytansinoid metabolites were separated on a 5 μm C-8 column (150 × 2.1 mm) equilibrated with 15% aqueous CH_3CN containing 0.1% TFA. The chromatogram was developed with four linear gradients: 1.1% CH_3CN/min for the first 15 min, 1.6% CH_3CN/min for 10 min, 1% CH_3CN/min for 10 min, and 1.6% CH_3CN/min for 20 min with a flow rate of 0.22 mL/min.

RESULTS

Administration of Antibody−[^{3}H]Maytansinoid Conjugates to Mice. Three different antibody maytansinoid conjugates (AMCs) with structures similar to those currently undergoing clinical evaluation were prepared for in vivo evaluation (Figure 1). The three conjugates were prepared from a humanized anti-CD56 antibody that does not cross-react with any antigen in mice, using either tritium-labeled DM1 or DM4 to enable the detection of maytansinoid metabolites.[18] Mice were administered a single intravenous dose of 300 μg/kg (based on DM1 or DM4) of each ^{3}H-conjugate, and after 2 h, 6 h, 1 d, 4 d, or 7 d, mice were sacrificed and liver tissues were collected. The liver tissues were homogenized and alkylated with NEM to prevent thiol−disufide exchange reactions, and then analyzed for metabolites following extraction as described in Experimental Procedures.

[^{3}H]Maytansinoid Metabolites. Figure 2 shows the metabolites isolated from the livers of mice treated with the three ^{3}H-conjugates. The metabolites were identified by comparing their HPLC retention times and mass spectral fragmentation patterns to synthetic standards as described previously[18] (data not shown). The major metabolite of the uncleavable mAb-SMCC-[^{3}H]DM1 in all of the samples was lysine-N^{ϵ}-SMCC-DM1, suggesting complete proteolysis of the polypeptide backbone of the antibody component to its constituent amino acids. We also recently found this lysine-linker-maytansinoid to be the major metabolite in tumor tissue following administration of the anti-CanAg targeting huC242-SMCC-[^{3}H]DM1 to SCID mice bearing CanAg positive COLO 205 tumors.[18] We did not detect any additional liver metabolites, suggesting little if any metabolism of the maytansinoid macrocycle or the thioether linker. The additional minor peak in the 2 h sample was identified as *N*2′-[3-[[1-[[4-(carboxy)cyclohexyl]methyl]-2,5-dioxo-3-pyrrolidinyl]thio]-1-oxopropyl]-*N*2′-deacetyl-maytansine (MCC-DM1, 22.5 min, M + Na = 997.4)—an unconjugated maytansinoid species present at low levels in the preadministration conjugate preparation (less than 5% of the total maytansinoid in the conjugate sample).

As was observed for the uncleavable conjugate, significant levels of the lysine-linker-maytansinoid metabolites were detected in the liver extracts from the mice treated with the disulfide-linked conjugates (peak A, Figure 2) suggesting that the initial steps for AMC metabolism are linker independent. In addition to the lysine-linker-maytansinoids, DM1, DM4 (isolated as the stable NEM-trapped adducts DM1-NEM and DM4-NEM, formed during homogenization, Figure 2, peak B), and *S*-methyl DM4 (peak C) were also found to be significant metabolites of mAb-SPP-DM1 and mAb-SPDB-DM4, respectively. All of these metabolites had been identified in extracts from cancer cells exposed to the conjugates in previous studies.[10,18] Presumably, these liver metabolites are formed by lysosomal degradation, disulfide reduction, and *S*-methylation of DM4 thiol—steps similar to those described previously for targeted cancer cells.[10]

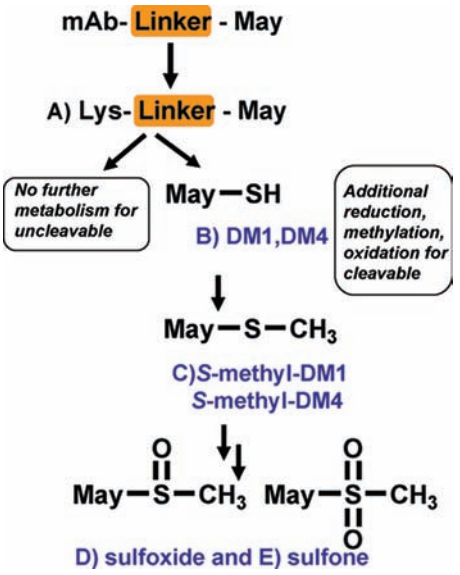

Figure 3. Scheme for the in vivo metabolism of cleavable and uncleavable AMCs. Initial catabolism of both cleavable and uncleavable conjugates yields the corresponding lysine-linker-maytansinoid (May) metabolites. For the uncleavable mAb-SMCC-DM1, the lysine-SMCC-DM1 is the only observed metabolite. For the cleavable disulfide-linked conjugates mAb-SPDB-DM4 and mAb-SPP-DM1, additional reduction yields DM4 and DM1, respectively. These free maytansinoid thiols are then methylated by an endogenous *S*-methyl transferase to form *S*-methyl-DM1 and *S*-methyl-DM4. Subsequent oxidation steps yield the corresponding sulfoxide and sulfone derivatives.

Importantly, several additional liver metabolites of the disulfide-linked conjugates were identified that were not observed in cancer cells from our prior studies. We observed *S*-methyl-DM1 from the livers of the mice treated with mAb-SPP-DM1 (peak C), which was unexpected because it was not identified as a tumor metabolite of mAb-SPP-DM1 in our previous study.[18] These observations suggest that, while the efficiency of DM1 *S*-methylation by several carcinoma cells was found to be very poor, and much lower than for DM4,[18] the liver has the capacity to more readily *S*-methylate both maytansinoid thiol compounds relative to tumor cells. The oxidized sulfoxide and sulfone derivatives of the *S*-methyl-DM1 or *S*-methyl-DM4 metabolites were also observed in the liver extracts of mice treated with the two disulfide-linked AMCs (peaks D and E in Figure 2). Ex vivo oxidation of both *S*-methyl-DM1 and *S*-methyl-DM4 to the corresponding sulfoxide and sulfone derivatives by human liver microsomes required NADPH, indicating that the oxidation was enzyme mediated (data not shown).

The metabolites of the three conjugates isolated from the liver tissues suggest the scheme for the metabolism of AMCs displayed in Figure 3 where the initial step for the catabolism of both cleavable and uncleavable AMCs is degradation of the intact conjugate to the corresponding lysine-linker-maytansinoid. For the uncleavable mAb-SMCC-DM1, no further metabolism is observed. For the cleavable conjugates, additional reduction yields the maytansinoid thiols allowing for the additional *S*-methylation and oxidation steps that ultimately yield the *S*-methyl sulfoxide and *S*-methyl-sulfone metabolites.

Exposure of Liver Tissue to Maytansinoid Metabolites. The concentration of the total metabolites of the conjugates in the liver tissue at each time (pmol/g) was determined from the

radioactivity associated with the metabolites (Figure 2) and plotted in Figure 4A. The AUCs for the metabolites of the three conjugates over 7 d were very similar, suggesting that the exposure of the liver tissue to the maytansinoid metabolites was linker independent. The fraction of the metabolite levels in Figure 4 as a percentage of total maytansinoids in the liver (intact conjugate + metabolites) was over 50% indicating that the observed metabolites represent the majority of the maytansinoids in the liver (Supporting Information Figure S1). While the exposure levels were similar for the three conjugates, the chemical structures of the metabolites of the three conjugates were notably different with the charged lysine-SMCC-DM1 as the predominant metabolite of the uncleavable conjugate and mixture of the lysine-linker-metabolite and the additional four metabolites described in Figure 3 comprising the metabolites of the disulfide linked conjugates. Differences in the distribution of the metabolites of the two disulfide-linked conjugates are evident in the radiograms shown in Figure 2. To more easily compare the metabolite distributions of the two disulfide-linked conjugates, the percentages of the total recovered metabolites of each of the five observed metabolites (calculated from Figure 2) were plotted at each time point in Figure 4B. Clear differences in the percentages for the five metabolites of the two conjugates were evident at each time point. The metabolite representing the largest fraction of the mAb-SPP-DM1 conjugate at 2 h was DM1 (34%) followed by lysine-SPP-DM1 (33%), *S*-methyl-DM1 (12%), *S*-methyl-DM1 sulfoxide (12%), and *S*-methyl-DM1 sulfone (9%). In contrast, lysine-SPDB-DM4 constituted the largest fraction of the metabolites of the mAb-SPDB-DM4 conjugate at 2 h (56%) followed by DM4 (24%), *S*-methyl-DM4 (10%), *S*-methyl-DM4 sulfoxide (7%), and *S*-methyl-DM4 sulfone (3%). The percentages for these five metabolites all change markedly over the first 24 h with decreases of the lysine-SPDB-DM4, DM4, and lysine-SPP-DM1 metabolites and increases for the sulfoxide and sulfone derivatives. From 24 h to 7 d, the metabolite percentages for all metabolites remain relatively constant even though the total metabolite levels are decreasing. The relative levels of lysine-SPP-DM1 and lysine-SPDB-DM4 versus DM1 and DM4, respectively, at the early time points (2−24 h) likely reflect the relative reactivity of the respective disulfide links to intracellular thiol−disulfide exchange reactions. Furthermore, DM1 levels may remain higher relative to DM4 levels throughout the time course (Figure 4B) if the rate of *S*-methylation of DM1 by liver cells is slower than for DM4, as described previously in human carcinoma cells.[18]

In Vitro Cytotoxic Potencies Associated with the Liver Metabolites. The metabolites reported here were all synthesized and the purified compounds were assayed for their cytotoxic potencies on a panel of tumor cell lines (Table 1). The *S*-methyl-DM1 and *S*-methyl-DM4 maytansinoids had similar potency to maytansine, and were about 1000-fold more cytotoxic than the lysine-linker-maytansinoids. Values for DM1 and DM4 are not presented because their IC_{50} values were highly variable when measured in vitro, likely due to the rapid formation of mixed disulfides via thiol/disulfide exchange reactions with cystine present at 0.2 mM in the culture medium (disulfides in serum proteins may also contribute to such reactions). The IC_{50} values for the *S*-methyl-DM1 sulfoxide were found to range from 7.1 nM to 23 nM—200- to 500-fold less potent than the *S*-methyl DM1 metabolite, whereas the *S*-methyl-DM4 sulfoxide was found to be 12- to 20-fold less cytotoxic than the *S*-methyl-DM4. The IC_{50} values for the *S*-methyl-DM1 sulfone and *S*-methyl-DM4 sulfone metabolites were 2- to 7-fold more potent than their sulfoxide precursors. That the *S*-methyl-DM4 sulfoxide is more cytotoxic than the *S*-methyl-DM1 sulfoxide toward the carcinoma cell lines is perhaps a consequence of the three extra carbons of DM4 (compared to DM1) that increase its hydrophobicity and may thus increase cell permeability. Nonetheless, the oxidation of the maytansinoid metabolites in the liver clearly serves to reduce the cytotoxic potencies of the metabolites of both disulfide-linked conjugates.

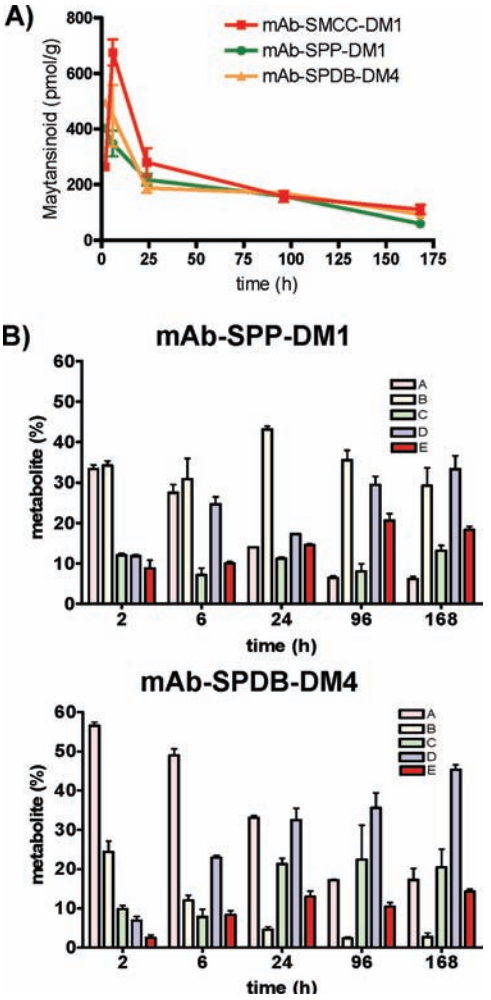

Figure 4. Exposure of liver tissue to maytansinoid metabolites in mice. (A) The levels for the total maytansinoid metabolites in liver tissue at 2 h, 6 h, 1 d, 4 d, and 7 d following a single intravenous administration of 300 μg/kg (DM1 or DM4 dose) of mAb-SMCC-[^{3}H]DM1 (■), mAb-SPP-[^{3}H]DM1 (●), and mAb-SPDB-[^{3}H]DM4 (▲). The radioactivities associated with the metabolites in Figure 2 were converted to pmol/g of metabolite using the specific radioactivities of the DM1 and DM4 and the measured liver weights as described in Experimental Procedures. (B) Amounts of the five observed metabolites of the disulfide-linked conjugates at each time as percentages of total metabolite levels. The percentages for each of the five metabolites of the two disulfide-linked conjugates were calculated by dividing the amount of each metabolite (pmol/g) by the sum of the five metabolites (shown in A). The five metabolites for mAb-SPP-DM1 are lysine-SPP-DM1(A), DM1 (B), *S*-methyl-DM1 (C), *S*-methyl-DM1 sulfoxide (D), and *S*-methyl-DM1 sulfone (E). The corresponding five metabolites of mAb-SPDB-DM4 (lysine-SPDB-DM4, DM4, *S*-methyl-DM4, *S*-methyl-DM4 sulfoxide, and *S*-methyl-DM4 sulfone) are also denoted A−E.

Table 1. Cytotoxic Potencies of Maytansinoids Towards Human Carcinoma Cell Lines in Vitro[a]

	in vitro IC_{50} (nM)				
metabolites	A375 (melanoma)	BJAB (B-cell)	COLO205 (colon)	KB (cervix)	MOLT-4 (T-cell)
Maytansine[b]	0.045	0.033	0.081	0.047	0.09
lysine-N^{ϵ}-SPP-DM1[b]	9.7	50	61	10	>100
lysine-N^{ϵ}-SPDB-DM4[b]	1.8	6.6	17	3.3	16
lysine-N^{ϵ}-SMCC-DM1[b]	8.1	7.5	17	9.7	16
S-methyl-DM1[b]	0.020	0.012	0.033	0.022	0.030
S-methyl-DM4[b]	0.017	0.014	0.031	0.026	0.027
S-methyl-DM1 Sulfoxide	9.7	7.1	17	23	19
S-methyl-DM1 Sulfone	-	1.7	5.9	3.5	-
S-methyl-DM4 Sulfoxide	0.55	0.55	1.3	0.12	1.9
S-methyl-DM4 Sulfone	0.075	0.17	0.63	0.80	1.1
DM1-MCC	22	21	50	29	50

[a] All metabolites were chemically synthesized. Cell-killing activities of the metabolites were measured after 5 days using a WST-based cell viability assay. [b] IC_{50} values were established previously[18] and shown here for comparison to liver-generated maytansinoid metabolites.

Metabolism of Intravenously Administered [^{3}H]DM4 and [^{3}H]DM1. Significant amounts of DM1, *S*-methyl-DM1, DM4, and *S*-methyl-DM4 metabolites were observed in the liver tissues up to 7 d after administration of the conjugates. If cleared from the liver without first being oxidized, these highly potent metabolites would likely be toxic to healthy tissue exposed to the metabolites during elimination. To test the efficiency of the liver oxidation, CD-1 mice were given a single dose of 1 mg/kg of unconjugated [^{3}H]DM1 or [^{3}H]DM4 (near the maximum tolerated dose), and after 1 h, mice were sacrificed and analyzed for maytansinoid metabolites in the liver tissue, bile, and plasma (Figure 5). Analysis of plasma indicated that the administered DM4 was rapidly *S*-methylated, possibly by the same *S*-methyltransferases in red blood cells shown to methylate the thiols of exogenous molecules such as penicillamine.[19] Conversely, little *S*-methyl DM1 was observed in the plasma of the mice treated with DM1—consistent with its slow rate of *S*-methylation in cancer cells. For the mice treated with DM4, nearly equivalent amounts of *S*-methyl DM4, *S*-methyl-DM4 sulfoxide, and *S*-methyl-DM4 sulfone were observed in the liver tissue after 1 h. The corresponding *S*-methyl DM1, *S*-methyl-DM1 sulfoxide, and *S*-methyl-DM1 sulfone metabolites were observed in the liver tissues of mice treated with DM1. In addition, significant levels of DM1 were observed in the liver tissues and bile—again suggesting a lower rate for the *S*-methylation of DM1 as compared to DM4. Although significant levels of the highly cytotoxic *S*-methyl DM1 and *S*-methyl-DM4 metaboiltes were observed in the liver tissues of the mice, little of the *S*-methyl maytansinoids were observed in the bile samples with nearly all of the metabolites being the *S*-methyl sulfoxide and *S*-methyl-sulfone metabolites, suggesting efficient oxidation steps prior to billiary elimination.

DISCUSSION

Our results suggest that liver plays an important role in the detoxification of both cleavable and uncleavable antibody−maytansinoid conjugates (AMCs). The lysine-SMCC-DM1 was the only metabolite observed for the noncleavable mAb-SMCC-DM1 conjugate. Significant levels were observed in the liver just 2 h following administration of the conjugates, consistent with other in vivo mouse studies that have reported efficient liver catabolism of radiolabeled antibodies[20,21] and antibody-auristatin conjugates.[22−24] The lysine-SMCC-DM1 metabolite of the uncleavable mAb-SMCC-DM1 was previously shown to have low cytotoxic potency toward human carcinoma cells in cell-based viability assays;[18] the low potency is most likely due to its inability to penetrate the cell due to the charged groups of the lysine residue. The lysine-SMCC-DM1 was found to be highly cytotoxic to the cancer cells in which it was formed following internalization and lysosomal degradation of the mAb-SMCC-DM1.[10] The lysine-SMCC-DM1 metabolite released by intracellular processing in the liver tissue could also be potentially cytotoxic. However, preclinical studies have shown the uncleavable T-DM1 conjugate to be well-tolerated at high doses (50 mg/kg) in rats,[11] and the uncleavable anti-CD79b conjugate, 10D10-SMCC-DM1, was found to be well-tolerated when administered to cynomologus monkeys at ∼30 mg/kg for two doses three weeks apart, although mild and reversible elevation of liver enzymes and minimal degeneration of hepatocytes in the monkeys was noted.[25] Furthermore, the dose-limiting toxicity observed in patients treated with T-DM1 was thrombocytopenia—no adverse liver toxicity was observed.[4] These observations suggest that the exposure of liver tissue to the lysine-SMCC-DM1 metabolite of the mAb-SMCC-DM1 conjugate reported here does not induce clinically significant liver toxicity at doses expected to be efficacious.[4,11] One factor that may contribute to the ability of liver tissue to generate and eliminate lysine-SMCC-DM1 from mAb-SMCC-DM1 conjugates without undue toxicity is that maytansinoids, as tubulin-binding agents,[26] are antimitotic and mature, fully differentiated, nondividing cells of organs such as liver may be able to tolerate significant exposure.

Analysis of the metabolites in liver tissues from mice treated with the cleavable disulfide-linked conjugates suggested the pathway for their degradation and metabolism shown in Figure 3. As was observed for the uncleavable conjugate, the two disulfide-linked conjugates were first degraded to yield the lysine-linker-maytansinoid metabolites. The amounts of these lysine-linker-maytansinoid metabolites were highest at the earliest 2 h time points. Unlike the lysine-SMCC-DM1 metabolite of the uncleavable conjugate, the lysine-SPDB-DM4 and lysine-SPP-DM1 metabolites of the disulfide-linked conjugates were found to undergo further intracellular transformations. The initial steps are similar to those described for the activation of the two conjugates in cancer cells.[18] First, the lysine-SPDB-DM4 and lysine-SPP-DM1 metabolites are reduced to DM4 and DM1, respectively, likely due to thiol−disulfide exchange reactions. Next, *S*-methylation of the released maytansinoid thiols yields *S*-methyl-DM1 and *S*-methyl-

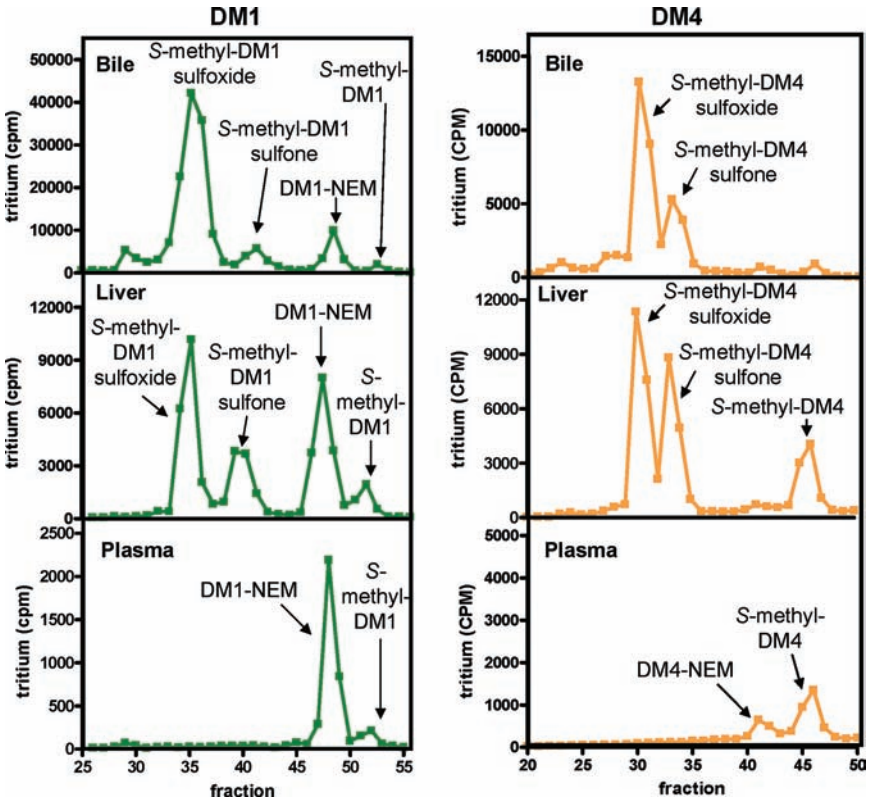

Figure 5. Maytansinoid metabolites in plasma, liver, and bile 1 h following a single bolus intravenous administration of [^{3}H]DM4 and [^{3}H]DM1. Mice ($n = 2$) were given a single bolus intravenous administration of 1 mg/kg [^{3}H]DM4 or [^{3}H]DM4, and after 1 h, mice were sacrificed and the plasma, bile, and liver tissues were extracted for metabolites. Extracts were analyzed by HPLC as described in Figure 2 for the disulfide-linked conjugates. The chromatograms show the fraction number on the abscissa and the counts per minute of tritium (CPM) on the ordinate.

DM4. These diffusible and highly cytotoxic maytansinoids are then efficiently oxidized in the liver to polar *S*-methyl-maytansinoid sulfoxide and sulfone derivatives that have reduced cytotoxic potencies most likely due to low cell permeability.

Interestingly, we observed no metabolism of the macrocyclic core of the maytansinoid molecule in any of the liver extracts. In a separate in vitro study, incubation of maytansine with purified human liver microsomes was reported to yield minor amounts of *O*-demethylation on the macrocyclic portion of maytansine.[27] However, the authors noted that the observed *O*-demethylation may have arisen from the low purity of the maytansine used in the experiment. We repeated the in vitro experiments using purified maytansine and human liver microsomes and could detect no metabolism on the macrocycle of maytansine (unpublished data), suggesting that the observed demethylation in the prior study[27] was presumably due to impurities in the maytansine. The resistance of maytansine to metabolism would explain why the most common and dose-limiting toxicity in patients treated with maytansine was gastrointestinal toxicity.[28] In contrast, gastrointestinal toxicity has not been found to be dose-limiting in patients treated with AMCs. While the reason for this difference may stem from the slower clearance rate for the antibody-drug conjugates as compared to the small molecule maytansine, the detoxification of the conjugates via the metabolism described here may also reduce their gastrointestinal toxicities.

Supplemental figure S1

Supplemental Figure 1. Exposure of liver tissue to total maytansinoids and protein-free maytansinoids. Liver tissues were analyzed at 2 h, 6 h, 1 d, 4 d, and 7 d following a single intravenous administration of 300 μg/kg (DM1 or DM4 dose) of mAb-SMCC-[^{3}H]DM1 (■), mAb-SPDB-[^{3}H]DM4 (▲) mAb-SPP-[^{3}H]DM1 (●) as described in Fig. 2. A) The total radioactivity associated with the liver homogenates determined by liquid scintillation counting of solubilized tissues were converted to the percentage of the total injected dose (based on DM1 or DM4) accumulated per gram of liver tissue (%ID/g). B) The radioactivity of extractable metabolites as a percentage of the total injected dose (based on DM1 or DM4) accumulated per gram of liver tissue (%ID/g). To determine the %ID/g, the radioactivity associated with HPLC-purified metabolites was divided by the total amount of radioactivity injected to the mice and by the weights associated with the liver samples. The data was then multiplied by 1.2 to account for the recovery (82%) of the synthetic *S*-methyl-[^{3}H]DM1 that had been added to liver homogenates during extraction in separate experiments. C) The amount of protein-free maytansinoid metabolites as a percentage of the total maytansinoids in the liver tissues. The percentages were calculated from the values in A and B.

Renal Excretion of Recombinant Immunotoxins Containing *Pseudomonas* Exotoxin

Roberta Traini and Robert J Kreitman*

Laboratory of Molecular Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20892, United States

ABSTRACT: Recombinant immunotoxins BL22 (CAT-3888) and LMB-2, composed of Fv fragments of anti-CD22 and CD25 MAbs, respectively, have produced major responses in patients with hematologic malignancies, and are also associated with renal toxicity, particularly with BL22. Characterization of the renal excretion of recombinant immunotoxins, which have 2−4 h half-lives in plasma, has not been reported in humans. To study the renal excretion of recombinant immunotoxins, urine from patients treated with BL22 was collected and the recombinant protein visualized after trichloroacetic acid (TCA) precipitation or anion exchange chromatography. BL22 viewed by immunoblot was found in the urine of patients within 8 h after dosing as an intact protein, and progressively degraded to fragments of <20 kDa within 1 day. We studied the stability of BL22 and LMB-2 added to urine at different time points and pH. When exposed to urine *ex vivo*, BL22 time-dependent proteolysis was similar to that observed in treated patients. By N-terminal sequencing, proteolysis was documented at positions 348−349 and 350−351 of BL22, and 339−340 and 341−342 of LMB-2, and other proteolytic sites were observed as well. Our data suggest that BL22 is excreted into the urine in a potentially cytotoxic form, even after its plasma level declines, and may remain intact long enough to cause renal toxicity.

BL22 (CAT-3888) and LMB-2 are recombinant immunotoxins that have been tested in patients with leukemia and lymphoma.[1−4] BL22 contains an anti-CD22 Fv fragment fused to truncated *Pseudomonas* exotoxin A (PE).[5] LMB-2 is composed of the Fv fragment of the anti-Tac mAb, recognizing the α-subunit of the IL-2 receptor (CD25), fused to the same truncated toxin as BL22.[6] The truncated toxin in both BL22 and LMB-2 is called PE38 and contains PE amino acids 253−364 and 381−613. Domain III, containing amino acids 395−613, contains the ADP ribosylation activity which catalytically inactivates elongation factor-2 (EF-2). Residues in domain II, amino acids 253−364 and 381−394, contain a proteolytic cleavage site and residues which translocate domain III to the cytosol.[7] PE38 is missing domain Ia, the binding domain of PE, which binds to normal cells.

LMB-2 induced major responses in a variety of B-and T-cell CD25+ hematologic malignancies, including hairy cell leukemia (HCL), chronic lymphocytic leukemia (CLL), cutaneous T-cell lymphoma (CTCL), Hodgkin's disease (HD), and adult T-cell leukemia (ATL).[1,2] BL22 had a complete remission rate of 47−61% in purine analogue-resistant HCL and has also shown some activity in CLL.[3,4,8] The dose-limiting toxicity of BL22 was due to a reversible hemolytic uremic syndrome (HUS) with kidney damage observed in 11% of the phase I patients. LMB-2 did not cause HUS, but did result in mild renal toxicity in some patients.

There is little known about the renal excretion of recombinant immunotoxins. In mice, at 45 and 90 min after an injected dose of LMB-2, 42.1% and 22.3%, respectively, of the injected dose per gram, was found in the kidney, a higher concentration than any other tissue.[9] However, anti-Tac(Fv)-PE38KDEL, a more toxic version of LMB-2, showed no histologic evidence of renal toxicity even at a dose which caused hepatic toxicity.[10] In humans, the half-lives of LMB-2 and BL22 are 2−4 h in the blood.[2,4,8] Characterization of urinary excretion of recombinant immunotoxin in humans has not yet been reported. As a first step to better understanding the mechanism of HUS with BL22, we decided to first characterize BL22 and LMB-2 after renal excretion. To determine stability of recombinant immunotoxins in urine, we examined urine from patients treated with BL22 and LMB-2, and also exposed the immunotoxins *ex vivo* to normal urine.

MATERIAL AND METHODS

TCA Precipitation. Aliquots of 1520 μL urine were treated with 380 μL of 60% TCA (final 12% TCA). After a brief vortex, the samples were centrifuged at 17 000 *g* for 5 min at 4 °C. The supernatant was aspirated and the pellet washed with 1 mL of 6% TCA. The samples were centrifuged, as above, for 2 min and the pellets washed with 1 mL of 93% acetone. The samples were centrifuged again for 2 min and the pellets resuspended in 10 μL of reducing SDS loading buffer and heated to 100 °C. Before loading the samples on SDS-PAGE, they were centrifuged at 17 000 *g* for 4 min at room temperature (RT).

Q-Sepharose Purification. Urine (100 mL) with or without exogenous BL22 1 μg/mL was diluted 5× with Buffer A (20 mM Tris pH 7.4 + 1 mM EDTA) at 4 °C, centrifuged in a 1 L bottle at 6000 *g* for 10 min at 4 °C, and then filtered over a cellulose acetate 0.2 μm filter.

The filtrate was then applied to 5 mL of Q-Sepharose Fast-Flow anion exchange resin (GE Healthcare, Piscataway, NJ), washed in buffer A, and the protein eluted with buffer A containing 30% (v/v) buffer B (buffer A with NaCl 1 M) in 4 mL fractions. The fractions with peak protein concentration, as assessed by Pierce BCA assay (Thermo Scientific, Rockford, IL), were then assessed by immunoblot.

Immunotoxin Stability in Urine. To observe the stability of the immunotoxins in the urine, BL22 or LMB-2 was added to patient or healthy donor urine at a final concentration of 1 μg/mL, and incubated at 37 °C for 1, 8, and 24 h. The stability was tested at pH 5, 7, and 8. Urine samples were taken before adding immunotoxin, immediately after adding BL22 or LMB-2, and after 1, 8, and 24 h of incubation at 37 °C. The samples were TCA precipitated following the above protocol, loaded on SDS-PAGE 8−16% gradient gels (InVitrogen, Carlsbad, CA), and then detected by Western blot. For the Western blot, the primary antibody was affinity-purified rabbit anti-PE, the secondary antibody was horseradish peroxidase (HRP)-conjugated affinity-purified goat antirabbit immunoglobulin (JacksonImmuno Research, West Grove, PA), and the kit for detection of HRP was the SuperSignal West Pico Chemiluminescent assay (Thermo Scientific).

ADP-Ribosylation Assay. Wheat germ extract (10 μL) was incubated in 250 μL aliquots containing 50 mM Tris pH 8.0 and EDTA 1 mM, and {^{14}C}-nicotinamide adenine dinucleotide (NAD), with sample added last, as described.[10] BL22 or LMB-2 was incubated in urine (pH 7.0) at 100 μg/mL for 24 h at 37 °C, and complete cleavage verified by SDS-PAGE. 10 μL (1 μg) samples were added to the 240 μL wheat germ and {^{14}C}-NAD mixtures, and incubated for 15 min at 25 °C. The 250 μL aliquots were treated with 1 mL of 12% cold TCA, centrifuged, and the pellets washed twice with 1 mL 6% TCA. The pellets were each dissolved in 0.1 mL of 0.1 N NaOH, transferred to vials, neutralized with 0.5 mL of 0.4 M acetic acid, and finally mixed with scintillation fluid and counted.

RESULTS

The relatively small size (63 kDa) and short half-life (2−4 h) of recombinant immunotoxins suggest their rapid excretion into the urine. If so, their renal toxicity could in part be due to intoxication of the cells lining the collecting system, which could increase the concentration and exposure time of immunotoxin to glomerular endothelium. To characterize the urinary excretion of recombinant immunotoxins, urine from patients receiving immunotoxin was analyzed for the presence of toxin as well as their breakdown products, and stability of BL22 and LMB-2 was tested after exposure to urine.

Immunoblot Analysis of Urine from Patients Treated with BL22. To determine whether BL22 is excreted into the urine of patients, urine was analyzed before and at different time points after i.v. injection of 30−40 ug/kg of BL22. Figure 1A shows an immunoblot where TCA-precipitated protein, reduced in 2-mercaptoethanol, was analyzed by SDS-PAGE and exposed to polyclonal rabbit anti-PE. The major band 1−4 h after the end of the 30 min infusion corresponded to VH-PE38 (51 kDa), the reduced form of BL22 missing VL. As expected, the 13 kDa VL fragment was not visualized with the anti-PE polyclonal antibody. A contaminant present in pretreatment urine was visualized at >100 kDa. At 4−7 h after BL22 infusion, a ~17 kDa fragment first appeared and became the dominant band by 7−12 h after infusion. At 20−28 h after infusion, the VH-PE38 band decreased and bands at 17 and 6−8 kDa increased. However, even after 20 h after infusion, a significant percentage of full-length VH-PE38 remained. At 12−20 h, an unidentified band was also observed slightly higher than 51 kDa. Another representative

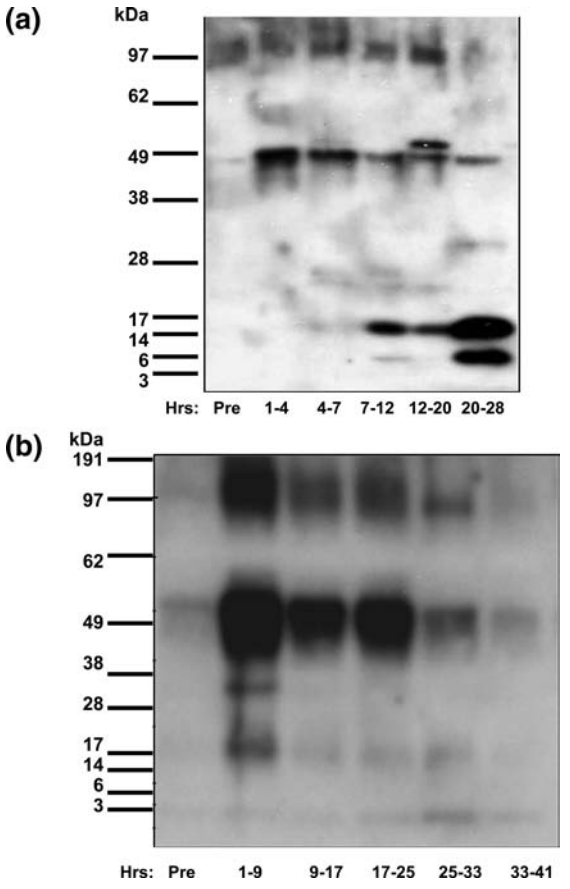

Figure 1. BL22 in urine of patients BH31 (A) and BH36 (B). 1.6 mL aliquots of urine from the indicated hours after end of 30 min infusion of BL22 (30 μg/kg) were subjected to TCA precipitation, and 15 μg of total protein/lane was added (except 3.75 μg at 1−4 h in A).

patient is included in Figure 1B, showing the major band at 51 kDa initially at 1−9 h, and then by 9−33 h a decrease in the 51 kDa band combined with an increase in the 17 kDa and smaller fragments. Interestingly, after 33 h, the 17 kDa and smaller kDa fragments were less visible for this patient, indicating further degradation and/or excretion.

Effect of Urine on the Integrity of Recombinant Immunotoxin. Since degradation of BL22 could occur prior to entering the collecting system, or upon exposure to urine, or both, the composition of BL22 was analyzed after *ex vivo* exposure of BL22 to urine. The calculated isoelectric point (pI) of BL22 is 5.08, based on the full sequence missing the carboxyl terminal lysine residue, which is rapidly removed upon exposure to plasma.[11] To determine whether the degradation of BL22 in the presence of urine is related to pH, possibly by inducing conformational changes close to the isoelectric point, the urine tested was adjusted to pH 5, 7, and 8. BL22 was incubated with urine at a final concentration of 1 μg/mL for 1 h at 37 °C, and the TCA-precipitated protein analyzed by Western blot. As shown in Figure 2A, normal urine at all 3 different pH conditions did not degrade the BL22 to lower molecular weight bands. Urine from the CLL patients produced slight degradation of BL22, producing 2 lower bands of molecular weights which were similar between patients BC01 and CL10. However, as shown by Coomassie-stained gels (Figure 2D−F), even normal urine is able to degrade BL22 after 24 h incubation, particularly at pH 7 and 8. On the Coomassie gel, the reduced VL

dx.doi.org/10.1021/bc1005152 |*Bioconjugate Chem.* 2011, 22, 736–740

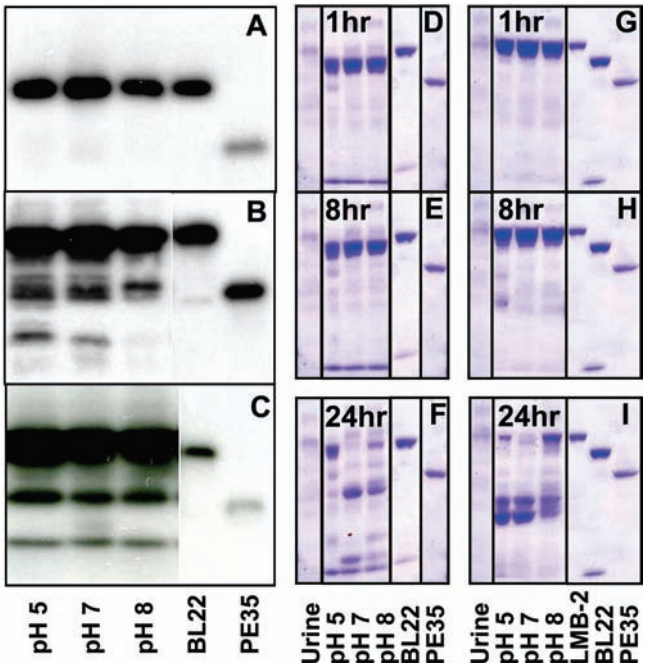

Figure 2. Degradation of BL22 and LMB-2 by normal urine. Immunoblots show BL22 incubated at a final concentration of 1 μg/mL for 1 h with urine at the indicated pH from a normal donor (A), and CLL patients BC01 (B) and CL10 (C). Controls include 2 ng of BL22 and PE35. Coomassie-stained gels in D-F include urine alone at pH 7 (first lane) followed by 2 μg BL22 added to normal urine incubated at 37 °C for the indicated time periods at the indicated pH. LMB-2 was incubated similarly in G−I and the indicated control lanes included LMB-2, BL22, and PE35.

fragment at 13 kDa is visible as shown in the BL22 control band. Figure 2G−I shows significant degradation of LMB-2 by urine at 24 h, which appeared less at pH 8. Since LMB-2 contains a linker rather than a disulfide bond connecting the VH to VL, no lower band representing a variable domain was expected.

Characterization of Degradation Products of Recombinant Immunotoxins. To determine which regions of the PE sequence are susceptible to urinary proteases, LMB-2 and BL22 were incubated with urine for 16 h at 37 °C and the products analyzed. As shown in Figure 3, BL22 was cleaved into 3 visible bands on reducing SDS-PAGE. The lowest band (C) co-migrated with the 12 kDa VL band. The upper band (A) was lower in molecular weight than the 35 kDa PE35 protein, indicating that, if the Arg279-Gly280 Furin protease site in BL22 was cleaved outside the cell, producing PE35, at least one additional site within this sequence was also cleaved. Cleavage of the Arg279-Gly280 Furin protease in PE is known to occur with proteases other than furin.[12] As shown in Figure 3, the size of the upper band (A) in cleaved BL22 was similar to upper band (E) in cleaved LMB-2. The size of the lower band (F) in LMB-2 is similar to the size of the 12 kDa VL band C in BL22 plus the slightly larger band B in BL22. Thus, the degradation products in Figure 3 are compatible with BL22 and LMB-2 each being cleaved once on the C-terminal side of the Arg279-Gly280 Furin cleavage site, with the difference between BL22 and LMB-2 being reduction in BL22 of the engineered disulfide bond linking Cys44 of VH with Cys100 of VL.

Identification of Urinary Protease Sites in Recombinant Immunotoxins. To determine the exact locations of cleavage in

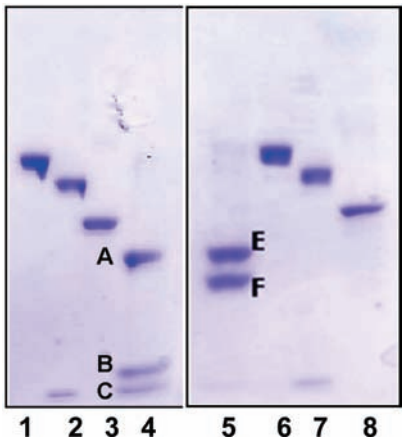

Figure 3. Characterization of proteolytic products of BL22 and LMB-2 in urine. BL22 or LMB-2 at 200 μg/mL was incubated with normal urine for 16 h at 37 °C at pH 7, and 2 μg was added to lane 4 or 5, respectively. Control molecules included 1 μg of LMB- 2 (63 kDa, lanes 1 and 6), BL22 (51 kDa + 12 kDa, lanes 2 and 7), and PE35 (35 kDa, lanes 3 and 8).

LMB-2 and BL22 by urinary proteases, the bands in BL22 and LMB-2 from Figure 3 were subjected to amino terminal sequencing. The N-terminal sequences are listed in Table 1. Bands B and F contained sequences corresponding to the N-terminus of the VH fragment of reduced BL22 and the N-terminus of LMB-2, respectively. The amino terminal end of the upper band (A) in BL22 indicates that the toxin is cleaved at 2 locations only 2 amino acids apart, Glu348-Arg349 and Phe350-Val351. Surprisingly, in LMB-2 the toxin was also cleaved in 2 locations 2 amino acids apart, but the cleavage sites, Ala339-Leu340 and Thr341-Leu342, were slightly different than those of BL22. Thus, even though the urine sample and toxin sequences were identical, BL22 and LMB-2 were cleaved within the toxin slightly differently.

ADP-Ribosylation Activity of Cleaved Recombinant Immunotoxins. To determine if the cleaved LMB-2 and BL22 fragments would retain ADP-ribosylation activity, they were incubated as in Figure 2F and I, in urine at pH 7.0 at 100 μg/mL for 24 h at 37 °C, when SDS-PAGE as in Figure 2F,I verified essentially complete cleavage. No cleavage was observed in urine at time 0. As shown in Figure 4, incubation of LMB-2 or BL22 with urine for either 0 or 24 h did not significantly decrease enzymatic activity. Figure 4 shows that 100 ng of LMB-2 alone had 21% less activity than 1 ug of LMB-2 alone and 19% less than completely cleaved LMB-2 after 1 h incubation with urine. Thus, in this semiquantitative assay, cleaved fragments of LMB-2 and BL22 retain 20−100% of their original ADP-ribosylation activity.

DISCUSSION

To study the renal toxicity of recombinant immunotoxins containing truncated PE, anti-CD25 and anti-CD22 recombinant immunotoxins LMB-2 and BL22 were detected and characterized in urine, either after i.v. injection of BL22 in patients or after incubation of LMB-2 or BL22 with urine. We found evidence of proteolysis of both LMB-2 and BL22, which varied with both time and pH. N-terminal analysis showed that incubation with urine resulted in cleavage of LMB-2 at Ala339-Leu340 and Thr341-Leu342, and cleavage of BL22 at Glu348-Arg349 and Phe350-Val351. Incubation with urine did not destroy enzymatic activity of the immunotoxins.

Table 1. Amino Terminal Sequencing of Degradation Products of BL22 and LMB-2 in Urine

protein	fragment	sequence	location of N-terminus of fragment
BL22	Band A	R F V R Q G T G N D or V R Q G T G N D E A	Amino acid 349 of PE Amino acid 351 of PE
BL22	Band B	M E V Q L V E S G G G	Amino terminus of BL22 VH
LMB-2	Band E	L T L A A A E S E R or L A A A E S E R F V	Amino acid 340 of PE Amino acid 342 of PE
LMB-2	Band F	M Q V H L Q QS G A E	Amino terminus of LMB-2 VH

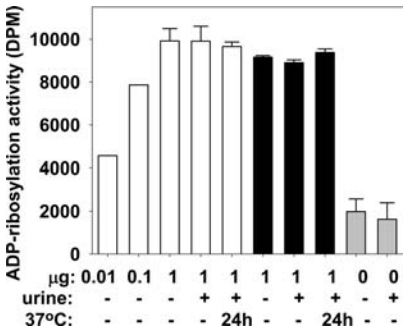

Figure 4. ADP-Ribosylation activity of urine-cleaved BL22 and LMB-2. LMB-2 (white) or BL22 (black) was tested for ADP-ribosylation activity using the indicated amounts in μg. As indicated, LMB-2 and BL22 were each mixed with urine for either 0 or 24 h at 37 °C, and the final 2 lanes (gray) show PBS and urine alone, respectively.

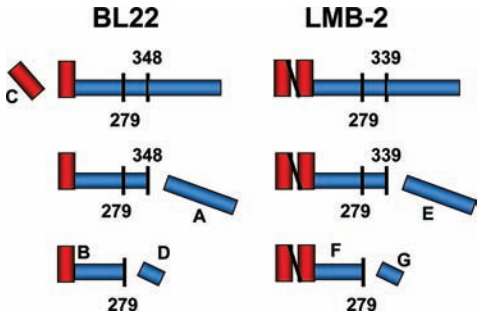

Figure 5. Model for urine protease fragments of BL22 and LMB-2. Fv and toxin fragments are shown in red and blue, respectively. Fragments labeled A−G represent bands on SDS-PAGE (Figure 3) except for bands D and G, which are too small.

Cleavage Locations within BL22 and LMB-2 for Urine Proteases. Based on SDS-PAGE (Figure 3) and N-terminal sequencing (Table 1), a model of proteolysis of recombinant immunotoxins by urine is shown in Figure 5, where BL22 and LMB-2 are cleaved prior to Arg349 and Leu340, respectively. Reduction of BL22 is expected to produce a free VL (Figure 5, fragment C), consistent with the ~13 kDa band C in Figure 3. Fragment A if containing amino acids 349−364 and 381−613 would be consistent with band A at 29 kDa. The remainder of VH-PE38 would include VH followed by the C3 connector (ASGGPE)[6] followed by amino acids 253−348 of PE, with estimated molecular weight of ~24 kDa. Since band B in Figure 3 is much smaller than 24 kDa, it is possible that BL22 is also cleaved between 253 and 348 such that the carboxyl terminal fragment (Figure 5, fragment D) would be too small to be visible. If the second proteolysis site were the Furin cleavage site between Arg279 and Gly280, fragment B would be ~16 kDa, most consistent with band B in Figure 3. Because of the covalent $(G_4S)_3$ linker between VH and VL of LMB-2, reduction alone would not result in fragmentation of LMB-2. Proteolytic cleavage of LMB-2 by urine before Leu340 would result in a carboxyl terminal fragment of ~30 kDa, represented by fragment E in Figure 5 and possibly corresponding to the upper band E in Figure 3 lane 5. If LMB-2 were also cleaved at the Arg279-Gly280 Furin site, the amino-terminal fragment F in Figure 5 would contain VH and VL connected by the linker, followed by the C3 connector, and finally followed by PE amino acids 253−279 (~28.5 kDa). In that case, the ~7 kDa fragment G in Figure 5 would be too small to see on the gel. Based on their size, fragments A and E, each with known amino-terminal sequence, should contain the ADP-ribosylating activity present in amino acids 395−602.[13] However, gel analysis could not exclude additional proteolysis just before amino acid 602, which could destroy ADP ribosylation activity. Therefore, urine-cleaved LMB-2 and BL22 were tested directly for ADP ribosylation activity, which was found to be retained (Figure 4). Thus, for either BL22 or LMB-2, the cleavage products in urine leave open the possibility that a fragment with cytotoxic activity may be nonspecifically internalized into renal endothelial cells or cells lining the collecting system, resulting in renal toxicity.

Renal Toxicity with Recombinant Toxins. Determining the mechanism of renal toxicity from recombinant immunotoxins can be difficult, since vascular leak syndrome can result in hypotension which can cause renal toxicity secondarily by pre-renal azotemia. However, denileukin diftitox was reported to result in proteinuria and microscopic hematuria in 6% of patients and this appeared dose-related,[14] suggesting that for at least some of the 10% of patients reported with an increase in creatinine, renal toxicity was related to direct intoxication of glomerular endothelium or renal tubules by the toxin. In the phase I trial of LMB-2, increased creatinine and proteinuria were observed in 9% of patients, and no cases of HUS were observed.[2] In the phase II trial of BL22, one cycle resulted in proteinuria in 33% of patients, microscopic hematuria in 19%, and creatinine elevation in 6%.[8] Including retreatment cycles, 3 (9%) of 36 phase II and 5 (11%) of 46 phase I patients receiving BL22 had HUS.[4,8] While the mechanism is unknown, functional plasma ADAMTS-13 was detected in all cases, and HUS during phase II resolved completely without plasmapheresis, suggesting that the syndrome may be due to endothelial damage localized to the kidney without a circulating inhibitor requiring removal. Thus, renal toxicity due to nonspecific internalization of ADP-ribosylation activity into the glomerular endothelium or tubular epithelium could possibly predispose or precipitate HUS. It should be noted that internalization of Shiga-like toxin into renal endothelium can cause HUS, and the toxin itself kills cells by ricin-like inhibition of protein synthesis, much like PE.[15] Based on our data, it may be advisible to maintain adequate hydration of patients for at least 24−48 h after a dose of BL22, and alkalinization of urine would not be recommend. We believe that additional knowledge of the behavior of recombinant immunotoxins during renal excretion

dx.doi.org/10.1021/bc1005152 |*Bioconjugate Chem.* 2011, 22, 736–740

may be important to ensure optimal safety of these potentially useful agents.

Supporting Information

ABSTRACT: Engineering proteins for selective tissue targeting can improve therapeutic efficacy and reduce undesired side effects. The relatively high dose of recombinant human acid α-glucosidase (rhGAA) required for enzyme replacement therapy of Pompe disease may be attributed to less than optimal muscle uptake via the cation-independent mannose 6-phosphate receptor (CI-MPR). To improve muscle targeting, Zhu et al.[1] conjugated periodate oxidized rhGAA with bis mannose 6-phosphate bearing synthetic glycans and achieved 5-fold greater potency in a murine Pompe efficacy model. In the current study, we systematically evaluated multiple strategies for conjugation based on a structural homology model of GAA. Glycan derivatives containing succinimide, hydrazide, and aminooxy linkers targeting free cysteine, lysines, and *N*-linked glycosylation sites on rhGAA were prepared and evaluated *in vitro* and *in vivo*. A novel conjugation method using enzymatic oxidation was developed to eliminate side oxidation of methionine. Conjugates derived from periodate oxidized rhGAA still displayed the greatest potency in the murine Pompe model. The efficiency of conjugation and its effect on catalytic activity were consistent with predictions based on the structural model and supported its use in guiding selection of appropriate chemistries.

INTRODUCTION

Pompe disease, or glycogen storage disease type II, is an autosomal recessive disorder whose underlying pathology is an accumulation of glycogen in lysosomes in many tissues, principally cardiac and skeletal muscle.[2] The accumulation of glycogen results from a deficiency in the glycogen-degrading lysosomal enzyme, acid α-glucosidase or GAA, leading to cardiac, skeletal, and respiratory muscle tissue damage and organ failure. The disease has a heterogeneous clinical presentation, from infants who have a rapidly progressive form of the disease resulting in early death, to older children and adults whose disease progresses at a slower rate but usually results in wheelchair use and the need for a ventilator as a consequence of the severe muscle weakness. Like most lysosomal enzymes, GAA contains mannose 6-phosphate (Man-6-P) in its oligomannose-type *N*-glycans, which directs its transport inside the cell from the Golgi to the lysosome via Man-6-P receptors.[3] GAA is initially synthesized as a 110 kDa protein in ER and Golgi of the cells, followed by proteolytically processing in the lysosome to mature forms.[4,5]

The enzyme replacement therapy with alglucosidase alfa (recombinant human α-glucosidase, rhGAA, Myozyme, Genzyme Corp) is used successfully for treating Pompe patients resulting in reduced cardiac hypertrophy, reduced the need for ventilation support, improved motor function, and increased life expectancy in infants.[6−11] However, even at doses which were high relative to other enzyme replacement therapeutics, the extent of glycogen clearance in skeletal muscle cells was found to vary among the infants treated with the enzyme.[12] The need for high dose has also been observed in clearing skeletal muscle glycogen of GAA knockout mouse, a murine Pompe model.[12,13] These findings could be caused by inefficient targeting of the recombinant enzyme to lysosomes through cation-independent Man-6-P receptor (CI-MPR) expressed on the surface of muscle cells, as rhGAA contains on average only a single Man-6-P and even lower amounts of bis Man-6-P, the preferred ligand for the receptor.[14] This hypothesis is supported by the finding that conjugation of bis Man-6-P bearing glycans to the terminal sialic acids of rhGAA (neoGAA) resulted in a ∼5-fold greater potency for clearing lysosomal glycogen in muscle of GAA knockout mice than the unmodified enzyme.[1,15,16]

Although the sialic acid-mediated conjugation strategy targeting the 6−7 copies of sialic acids in rhGAA[13] yielded a conjugate with greatly improved functional outcome in the murine Pompe model,[1] there are multiple approaches to produce such neoglycoproteins.[17] At one extreme, a single glycan can be conjugated to the single free cysteine on rhGAA via thiol-based chemistry to generate a defined product profile. At the other extreme, 10−20 copies of neoglycans can be conjugated to the 15 lysines, N-terminal amine, and possibly histidines on rhGAA through amine-based chemistry. Finally, the carbohydrate on rhGAA can be oxidized with an enzyme specific to galactose instead of periodate, resulting in galactose-mediated conjugation.

In the current study, we explored these three alternative conjugation strategies and compared the resulting conjugates with sialic acid-mediated conjugates both *in vitro* and *in vivo*.

EXPERIMENTAL PROCEDURES

Materials. rhGAA and neuraminidase from *Clostridium perfringens* were produced by Genzyme Corp. Bis Man-6-P neoglycans were synthesized as described previously.[1,16] SFB (or S-4FB, succinimidyl 4-formylbenzoate) and pentafluorobenzamide poly(ethylene glycol) 4 (PEG4/PFB) were purchased from Solulink Corp (San Diego, CA). Galactose oxidase (GAO) was obtained from Worthington Biochemicals (NJ). 1,4-Di-(3′-[2-pyridyldithiol]-propionamido) butane (DPDPB) was obtained from Pierce (Rockford, IL). Other reagents, including catalase and sodium periodate, were obtained from Sigma (St. Louis, MO).

Sialic Acid-Mediated (SAM) Conjugation. Glycan conjugation to sialic acids was performed according to a method described by Zhu et al.[1] except that buffer exchanges were performed by diafiltration on Pellicon XL 50 or Amicon ultra-4 (Millipore, MA).

Thiol-Based Conjugation. A thiol-reactive form of bis Man-6-P neoglycan was prepared by a condensation of the acid form with a previously described thiol-reactive linker (3-nitro-2-pyridinesulfenylethylamine, nipsylethylamine, NEA).[18] A crude fraction of the free-acid form of bis Man-6-P neoglycan was converted to the triethylammonium (TEA) salt by neutralization with TEA followed by chromatography on a Superdex Peptide column (GE Healthcare, NJ) using 30% acetonitrile and 0.1% TEA bicarbonate as a mobile phase. Pooled fractions were lyophilized and conjugated with NEA in a reaction containing glycan:NEA:EDAC:NHS:HOBt:TEA (1:1:1.5:1:1:1 mol:mol) incubated overnight at 25 °C with gentle shaking. The product was purified on a Superdex Peptide column as described above and lyophilized. The NEA-glycan was reconstituted in water and incubated with rhGAA at 15-fold molar excess over protein in 50 mM sodium phosphate and 50 mM hydroxylamine (pH 7.2) for 2 h at 25 °C. The pH was adjusted to 6.2 with 50 mM sodium phosphate (pH 4.1) and the incubation continued overnight. The product was buffer-exchanged into 25 mM sodium phosphate (pH 6.2) using Amicon (Millipore, MA). rhGAA (~3.5 mg/mL) was also modified with a thiol-reactive cross-linker by reaction with 60- to 108-fold molar excess of DPDPB in 25 mM sodium phosphate (pH 6.2) with 10−20% organic solvent overnight at 25 °C. The extent of the reaction was determined by monitoring the absorbance at 343 nm of released 2-thiopyridone observed in an ultrafiltrate (Microcon YM-30, Millipore, MA) on a Beckman DU640 spectrophotometer or the spectrum of unfiltered material corrected for light scattering using the spectral data above 400 nm and instrument software.[19]

Lysine-Mediated Conjugation. Lysine residues in rhGAA were modified with SFB to introduce aldehydes, followed by reaction with modified neoglycans to form either hydrazone or oxime linked conjugates. rhGAA was reacted with a 20-fold molar excess of SFB in 150 mM sodium chloride and 50 mM sodium phosphate (pH 7.2) for 30 min, followed by buffer exchange into 100 mM sodium acetate (pH 5.5). The SFB modified protein was then coupled with bis Man-6-P neoglycan (hydrazide) for 2 h at room temperature. Alternatively, it was reacted with bis Man-6-P neoglycan (aminooxy) in 100 mM sodium acetate (pH 5.6) for 6 h at 37 °C. The final products were buffer-exchanged into 25 mM sodium phosphate, 2% mannitol, and 0.005% Tween-80 (pH 6.25).

Galactose Aldehyde-Mediated (GAM) Conjugation. rhGAA was desialylated with 20 mU/mg *Clostridium perfringens* neuraminidase for 6 h at 37 °C in 25 mM sodium phosphate, 2% mannitol, and 0.005% Tween-80 (pH 6.25) and then treated with GAO (2−10 μg/mg) in the presence of catalase (2 U/mg) overnight at 37 °C. rhGAA was purified away from neuraminidase and GAO by anion-exchange chromatography. The reaction mixture was diluted with an equal volume of water and applied to a Poros 50D column equilibrated with 10 mM sodium phosphate (pH 6.9). Following a wash with 10 mM sodium acetate (pH 5.0), the protein was step eluted with 150 mM sodium acetate (pH 5.0). A 16.6-fold molar excess of bis Man-6-P neoglycan (aminooxy) was added directly to the eluate and the mixture incubated for 6 h at 37 °C. The product was then buffer-exchanged into 25 mM sodium phosphate, 2% mannitol, and 0.005% Tween-80 (pH 6.25) either by diafiltration with Pellicon XL 50 or by centrifugal ultrafiltration over Amicon filters (Millipore, MA) to yield GAM6.

Quantitation of Monosaccharides Including Man-6-P and Galacturonic Acid (GalA). The Man-6-P content was determined as described previously.[20] Hydrolysates were filtered through S Mini H cartridges (Sartorius, NY) and ribose-5-phosphate used as an internal standard. The number of glycans conjugated and conjugation efficiencies were calculated assuming 2 mol Man-6-P per mole neoglycan and correcting for the Man-6-P content of the starting rhGAA. Galactose and GalA were also quantified using HPAEC-PAD on a Dionex HPLC.[21,22] The GalA was identified using LC/MS/MS of glycans released with PNGase F and resolved by normal-phase HPLC (TSK gel amide-80 column) in an acetonitrile−water gradient with 10 mM ammonium formate (pH 4.0). Mass spectrometry detection of glycans was performed in-line, in negative ion mode, using QStar or LCT time-of-flight mass spectrometers.

HPLC-Based Cation-Independent Man-6-P Receptor (CI-MPR) Binding. Binding of rhGAA or neoGAA conjugates to CI-MPR was determined by HPLC affinity chromatography with soluble bovine CI-MPR (purified from fetal bovine serum) immobilized on Poros EP resin using step elution with Man-6-P. Protein was detected by intrinsic protein fluorescence (290 nm excitation/340 nm emission), and the relative amount of protein eluting at each step was determined by integration of the peak areas.

GAA Activity Assay. Enzymatic activity was determined using *p*-nitrophenyl-α-D-glucopyranoside as substrate as described.[13] One unit of activity is defined as the hydrolysis of 1 μmol of substrate per min at 37 °C.

Protein Structure Modeling. Two secondary structure prediction algorithms PSIPRED[23] and SSPRO[24] were used to align the GAA sequence with the structure of human intestinal maltase-glycoamylase (MGAM, PDB code 2QMJ),[25] followed by manual adjustment and model building in *Prime 2.1* (Schrödinger, OR). Loops of the resulting GAA model were refined using the default sampling for loops of 5 residues or shorter and the extended protocol for loops longer than 5 residues. Side chains were unfrozen within 7.5 Å of the corresponding loop and the energy cutoff was set to 10 kcal.

Animal Studies. For the determination of serum clearance, 3 groups of 5 male and 5 female GAA knockout mice at 3−6 months of age (Charles River Laboratories, Wilmington, MA) received a single intravenous administration of rhGAA, GAM, and SAM conjugates (GAM6 and SAM6) at 20 mg/kg. Blood samples for analysis were collected via the retro-

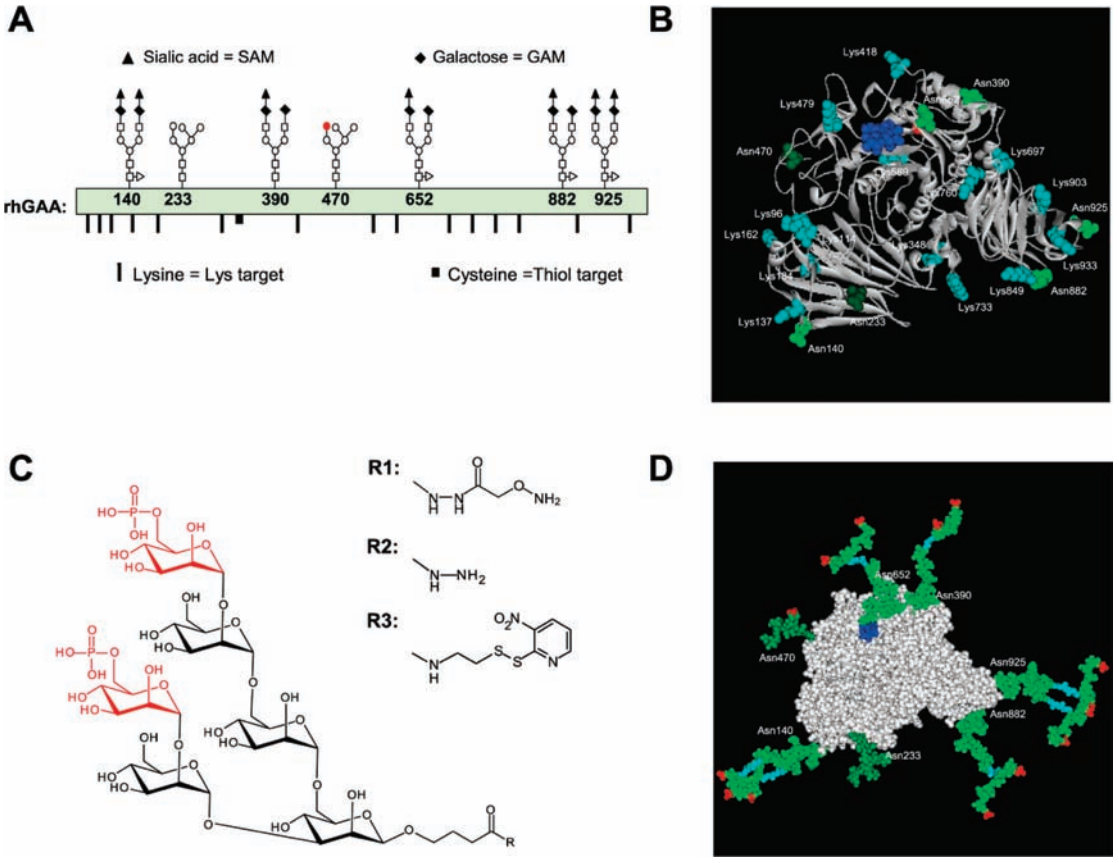

Figure 1. Structures for rhGAA, its conjugate, and bis Man-6-P neoglycan. (A) Linear structure of rhGAA. The positions of the lysine, cysteine, sialic acid, and galactose sites for neoglycan conjugation are shown. (B) A GAA structural model based on a crystal structure of human intestinal MGAM (see text). The *N*-linked glycosylation sites are shown in green (sites occupied by complex-type glycans as light green and those occupied by oligomannose-type glycans as dark green). Lysines are shown in light blue. Red ball: sulfur atom in the single free cysteine. Dark blue: acarbose substrate present in the MGAM structure. (C) Structure of the bis Man-6-P hexasaccharide glycan with different linkers (R groups): R1, aminooxy; R2, hydrazide; R3, thiol-reactive NEA group. (D) Potential structure for neoGAA SAM conjugate. Models for the predominant *N*-glycans identified at each glycosylation site in rhGAA were added to the protein structure shown in B, followed by linkage of a hypothetical model for the synthetic neoglycan with aminooxy linker (R1) as shown in C. Light green: complex-type *N*-glycans and bis Man-6-P neoglycans. Light blue: aminooxy linker. Red: terminal glycan phosphate. Other labels are similar to those in B.

orbital plexus in conscious mice. The concentrations of rhGAA, GAM6, and SAM6 in serum were determined by GAA activity assay.[13]

For the determination of efficacy in glycogen clearance from mouse, GAA knockout mice (3−6 months) were divided into 10 dose groups of 3 males and 3 females. Each group received vehicle; 20, 60, or 100 mg/kg rhGAA; and 4, 12, or 20 mg/kg of the GAM6 or SAM6 once a week for a total of 4 weeks. In order to prevent hypersensitivity induced by test articles, all groups received 5 mg/kg diphenhydramine (Baxter Deerfield, IL) intraperitoneally prior to each dose after the first administration. In the event that animals displayed clinical signs of hypersensitivity, an additional dose of 5 mg/kg diphenhydramine was administered intraperitoneally. Animals were euthanized 7 days after the last dose by CO_2 asphyxiation. Heart, quadriceps, triceps, diaphragm, and psoas were harvested and analyzed for glycogen content as described previously.[1,13,15,16] Statistical analysis was performed using one-way analysis of variance (ANOVA) followed by a Newman-Keuls test. A probability value of $p < 0.05$ was considered statistically significant. Animal experiments were conducted in accordance with the National Institutes of Health *Guide for the Care and Use of Laboratory Animals* (U.S. Department of Health and Human Services, NIH Publication No. 86−23) and were approved by Genzyme's Animal Care and Use Committee.

Other Methods. MALDI-TOF MS analysis was performed using a Voyager DE-PRO mass spectrometer as described in the previous report.[5] Protein aggregation was determined by HPLC size exclusion chromatography.[26] Identification of oxidized methionine residues was performed as described previously.[27] Uptake of proteins into rat L6 myoblasts was performed as described.[1,15,16]

RESULTS

neoGAA Conjugation Strategies. The rhGAA sequence contains a single free cysteine residue, 15 lysines, and 7 *N*-linked glycosylation sites (Figure 1A). In order to better design alternative conjugation strategies, the GAA structure was investigated. A homology model of GAA based on the structure of an α-glucosidase (maltase, MalA) from *S. solfataricus* has been published previously.[28] However, only half of the GAA could be modeled based on the 30% sequence identity with MalA over the 452 amino acid residues. To obtain structural information for

dx.doi.org/10.1021/bc1005416 |*Bioconjugate Chem.* 2011, 22, 741–751

the remainder to identify other potential sites of conjugation, we developed a model (Figure 1B) based on human intestinal maltase-glycoamylase (MGAM). Both GAA and MGAM belong to the glycosyl hydrolases family 31,[25] and the same enzyme class 3.2.1.20. GAA and the N-terminal catalytic subunit of MGAM (PDB codes 2QLY and 2QMJ) also share 44% sequence identities over 860 residues. The result shows the same overall fold of the glycosyl hydrolase family 31 enzymes with 5 structural domains: a trefoil type-P domain, a β-sandwich domain, N-terminal to the catalytic $(\beta/\alpha)_8$ TIM barrel domain, followed by two additional C-terminal β-sandwich domains. As expected from the strong homology to MGAM, the position of residues within the active site, including Trp-516 and Asp-518 within the WIDMNE element, which were previously identified in GAA by cross-linking of a substrate analogue and site-directed mutagenesis,[29] were preserved in the model and near the acarbose binding site. On the basis of this structural model, the lysines and *N*-linked glycosylation sites are found in solvent-exposed positions distributed relatively evenly over the entire structure without any notable clustering, suggesting those sites as potential alternative conjugation sites.

Conjugation of a synthetic bis Man-6-P neoglycan (Figure 1C) to sialic acids on rhGAA *N*-glycans provides a substantial increase in the efficacy in GAA knockout mice.[1,16] A structural model of such a conjugate was generated by linking in silico models of the dominant glycan forms at each site[13] extended in solution consistent with their hydrophilicity and addition of a model of the synthetic glycan assuming charge repulsion of the bis-phosphates (Figure 1D). This model suggested potentially rather large extensions of the existing GAA structure were possible. This observation suggested that conjugation of bis Man-6-P neoglycans to alternative sites might provide advantages in preserving the activity of the protein against its natural substrate glycogen, a complex polysaccharide which may be sterically hindered from interacting at the active site by large glycans nearby. A number of different conjugation chemistries targeting different functional groups were then explored. Bis Man-6-P hexasaccharide neoglycans were synthesized with different appended functionalities (Figure 1C), including terminal aminooxy (R1), hydrazide (R2), and thiol-reactive NEA groups (R3), for conjugating to either aldehydes or thiols.

A particularly interesting target was the single free thiol group (Cys-374) in rhGAA, since exclusive coupling to this site would provide a homogeneous conjugate. The structural model however suggested relatively limited access to this residue, which was confirmed by negligible conjugation of thiol-reactive NEA-neoglycan (data not shown). Quantitative modification of the thiol group was successful using a hydrophobic homobifunctional cross-linking reagent with spacer arm of 19.9 Å, 1,4-di-(3′-[2-pyridyldithiol]propionamido) butane (DPDPB, Pierce) but only in the presence of organic cosolvents, which resulted in very strong light scattering and formation of a precipitate (data not shown). These results suggest that modification of Cys-374 may be achieved, but only under harsh conditions unlikely to preserve the structural integrity of the protein and creating undesirable aggregation.

Conjugation to lysines was attractive because of the higher lysine content of rhGAA than sialic acids employed in previous conjugates[1,15,16] could allow a higher degree of modification. Conjugates containing neoglycans hydrazone-linked to lysines modified with an aromatic aldehyde (SFB) were obtained with Man-6-P contents consistent with up to ~4 mol neoglycan per mole rhGAA, in agreement with the conjugate molecular weights obtained by MALDI-TOF MS (Figure 2A and B). However, an accelerated stability study performed in pH 6.2 buffer at 40 °C resulted in more than 50% loss of neoglycan over 14 days (Figure 2A and B). These results indicate that the hydrazone bond between neoglycan hydrazide and the benzaldehyde linker was not stable for extended periods.

To increase the stability, the hydrazone linkage was replaced with a more stable oxime by use of an aminooxy form of the bis Man-6-P neoglycan (Figure 1C). Oxime linkages are known for their high stability over a broad range of pH including the mildly acidic conditions for storage buffer used here.[30] As shown in Figure 2C, a 16.6-fold molar excess of glycan was saturating for the Man-6-P content with the introduction of 5 mol neoglycan per mole rhGAA (10 mol Man-6-P per mole protein). Higher molar ratios of neoglycan failed to further increase the Man-6-P content. The number of neoglycans coupled was also significantly lower than the incorporated SFB benzaldehyde content determined by absorbance (~8−9 mol/mol). A high level of aggregation was also frequently observed (Figure 2D). In an attempt to overcome this problem, conjugation was also performed using a PEGylated version of SFB (PEG4/PFB, Solulink), in which the lysine-reactive pentafluoroester group is separated from the aromatic formylbenzoate by a hydrophilic PEG4 spacer. This failed to produce significant decrease in aggregation (data not shown), suggesting a very limited tolerance of the protein for hydrophobic substitutions.

The susceptibility of the protein to aggregation in response to hydrophobic modifications suggests the importance of maintaining a hydrophilic surface environment. Carbohydrate-mediated conjugation chemistries were therefore evaluated since the aldehydes required for conjugation could be generated directly by an oxidation step without the need for linkers containing hydrophobic functional groups. Aldehydes on terminal carbohydrate residues would be expected to be well-separated from the protein surface. Seven *N*-linked glycosylation sites are present on rhGAA including oligomannose, phosphorylated oligomannose, and complex-type glycans (Figure 1A and B).[13] Among these sites, Asn-390, Asn-652, Asn-882, and Asn-925 are occupied mainly by sialylated complex-type glycans, while a significant amount of oligomannose-type glycans are present on Asn-140, Asn-233, and Asn-470, with a higher abundance on Asn-233 and Asn-470. A fraction of the oligomannose-type glycans bear either a single (mono Man-6-P) or two phosphates (bis Man-6-P), resulting in an average Man-6-P content of 1 mol per mole in rhGAA. The complex-type glycans contain approximately 6−7 sialic acid and 10 galactose residues as potential sites of conjugation. Two methods for coupling these glycans were compared: a chemical oxidation process directed at sialic acids and an enzymatic approach targeting galactose.

Conjugation using sialic acid-mediated (SAM) chemistry was performed using a method described previously.[1] As expected, after periodate treatment, sialic acid was undetectable by HPAEC-PAD analysis, consistent with the complete oxidation to the aldehyde form (data not shown). Conjugation of the neoglycan with this intermediate was found to be highly reproducible, with yields of 13−17 mol Man-6-P per mole GAA consistent with an overall process efficiency approaching 100%. Strikingly different than the amino acid directed chemistries, the level of protein aggregation was consistently less than 3%. However, treatment by periodate also resulted in the nearly

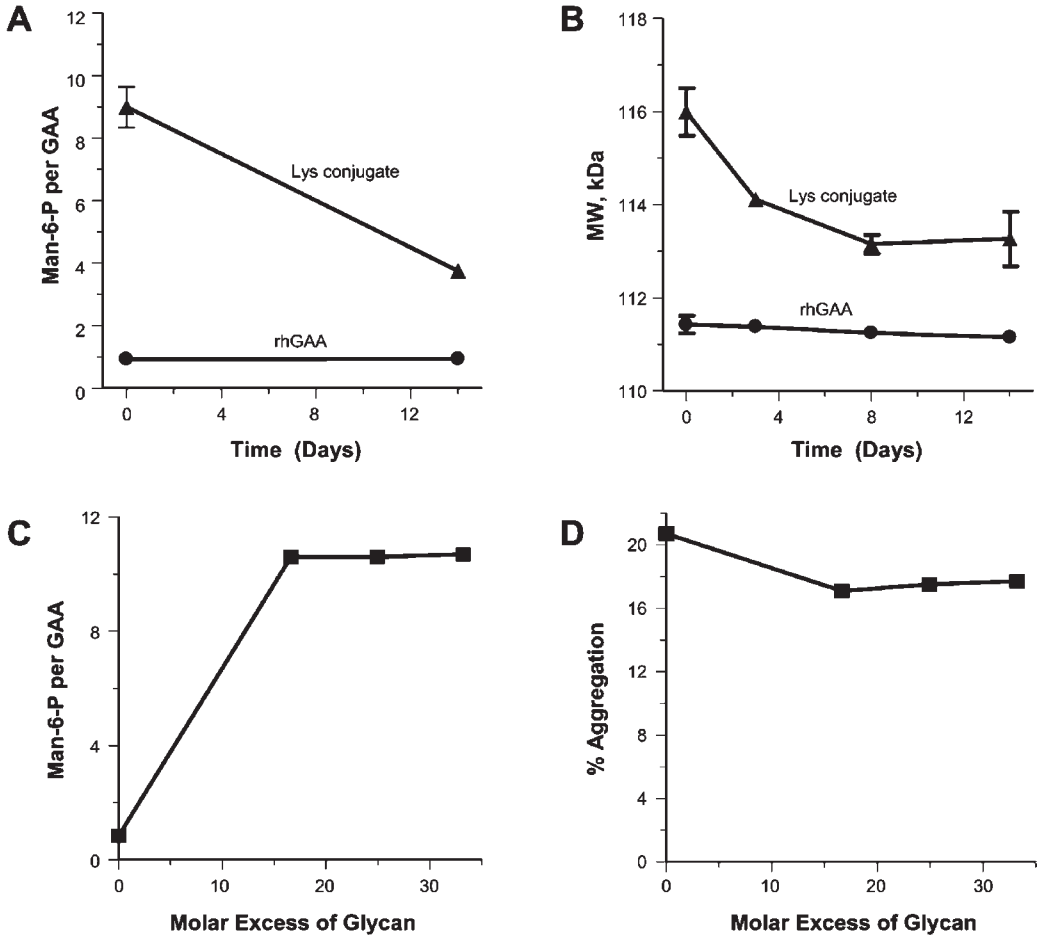

Figure 2. Properties of neoGAA conjugates prepared by introducing aldehyde groups at lysines. (C) Conjugation of SFB modified rhGAA with increasing amounts of aminooxy neoglycan. (D) Aggregation of the same conjugates in C as determined using size exclusion chromatography.

complete oxidation (>95%) of two methionine residues, Met-172 and Met-173, in the final conjugate (Figure 3A).

The generation of aldehyde groups on the glycans by enzymatic oxidation of galactose residues (GAM) with galactose oxidase (GAO) was explored as a means to avoid undesirable side products of chemical oxidation. However, since rhGAA is highly sialylated and GAO reacts only with galactose at the terminal position on glycans,[13,31] the protein was first treated with neuraminidase to remove the terminal sialic acids and expose the galactose residues. Following oxidation with GAO, the aldehydes were then coupled with the bis Man-6-P neoglycan (aminooxy) to yield a conjugate (GAM6) with an oxime-linked glycan. Initial evaluation showed that desialylation of rhGAA was complete after treatment with neuraminidase for 6 h at 20 mU/mg rhGAA. Following GAO treatment (10 μg/mg), conjugation was saturated with a 16.6-fold molar excess of the neoglycan over rhGAA, yielding active conjugates with high neoglycan contents (11−12 mol Man-6-P per mole protein) and low aggregation (<3%). The Man-6-P content of these conjugates suggested that 50−60% of the galactose residues had been coupled to neoglycan. Unexpectedly, ~26% of Met-172 and Met-173 were again found in oxidized form, as in the SAM process (Figure 3A). This oxidation may have occurred as a result of the presence of hydrogen peroxide, a byproduct of the GAO reaction. Consistent with this, inclusion of small amount of catalase (2 U/mg rhGAA) was found to be effective in eliminating this oxidation side product (Figure 3A).

SDS-PAGE of the SAM and GAM products showed a shift in the mobility of the predominant 110 kDa form of the protein, as expected from an increase in overall molecular weight as a result of neoglycan conjugation (Figure 3B). A smaller shift in mobility was obtained by GAM modification than SAM, most likely due to the removal of sialic acids during the GAM process, and relatively larger effect of the sialic acids on mobility than polypeptide mass. However, the GAM method also appeared to be more selective, in that the shifts in mobility were only apparent with the 110 kDa form, whereas the processed forms of rhGAA (76 kDa and 70 kDa)[4,5] were also modified by the SAM process. Trace amounts of high molecular weight products showing parallel molecular weight shifts were also visible in the SAM and GAM conjugation products after silver staining of overloaded SDS-PAGE gels (Figure 3B), likely reflecting a small amount of aggregated proteins possibly also conjugated with neoglycan.

The lower yield of noeglycan in the conjugates obtained with the GAM process was somewhat surprising, given the higher galactose than sialic acid content in rhGAA. The efficiency of each step in the process was thus followed by carbohydrate composition analysis of the intermediates and final product. As expected, neuraminidase treatment resulted in complete removal of sialic acids, and galactose was nearly undetectable following

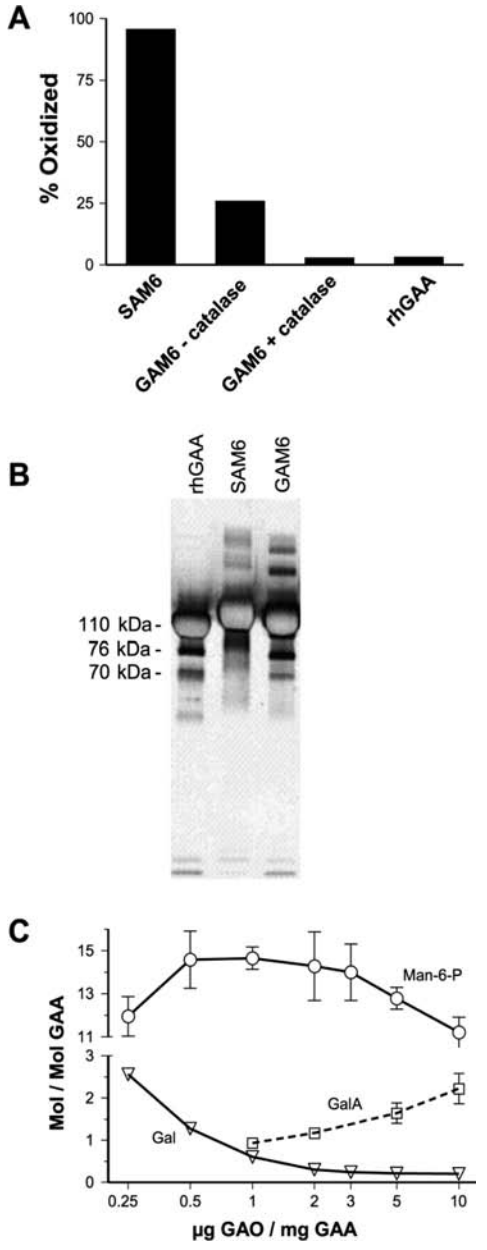

Figure 3. Characterization of SAM and GAM conjugates. (A) Oxidation of Met-172 and Met-173 determined by LC/MS. GAM6 was prepared with or without catalase. (B) SDS-PAGE of the SAM and GAM conjugates, followed by silver stain. The 110 kDa is precursor form, while 76 kDa and 70 kDa are processed forms of rhGAA. (C) Effect of GAO:rhGAA ratio on Man-6-P, GalA, and residual galactose levels in GAM conjugate.

GAO treatment at 10 μg/mg (data not shown). However, following GAO treatment, galacturonic acid (GalA), in which the C6 position of galactose is fully oxidized to the carboxylic acid form, was also identified by LC/MS/MS of protein glycans released by PNGase F. This product likely arose by further oxidation of the desired galactose aldehyde to the carboxylic acid form by the action of GAO during the reaction,[32,33] suggesting that the lower efficiency observed with GAM conjugation under these conditions may have resulted from the conversion of the aldehyde to the unconjugatable acid form. To improve on the Man-6-P content, the GAO:rhGAA ratio was varied to limit the extent of the reaction. The Man-6-P, GalA, and remaining galactose contents of the final conjugates were then determined by quantitative HPAEC-PAD. As shown in Figure 3C, the final Man-6-P content of the conjugates varied significantly with the amount of GAO used during the oxidation step. The highest level of Man-6-P was observed at ~1 μg GAO per mg GAA, with ~7 neoglycans coupled per rhGAA (15 mol/mol Man-6-P per rhGAA). Below this optimum GAO:GAA ratio, significant amounts of unmodified galactoses were observed (>1 mol/mol), which increased with further decreases in GAO. Above the optimum, a reduction in the amount of residual galactose was accompanied by a higher GalA content and a decrease in the final Man-6-P content, consistent with the loss of aldehyde groups available for conjugation. Even at the optimum ratio, a significant amount of both GalA and residual galactose were present.

***In Vitro* Comparison of SAM and GAM Conjugates.** The enzyme activity of a panel of SAM and GAM conjugates containing a wide distribution of neoglycan content was determined. All of the conjugates showed some reduction in specific activity relative to the rhGAA control (Figure 4A), and the loss in activity inversely correlated with the Man-6-P content of the conjugate (r^2 = 0.87, p < 0.0001). There was no significant difference between the activity of conjugates with comparable Man-6-P contents prepared by either the SAM or GAM process.

Binding of rhGAA and neoGAA to the cation-independent Man-6-P receptor (CI-MPR) was followed by HPLC-based affinity chromatography using immobilized bovine CI-MPR (Figure 4B). To assess receptor affinity, protein was applied to the column and the bound fraction eluted with steps of increasing Man-6-P concentration. Representative profiles from rhGAA, SAM, and GAM conjugates are shown in Figure 4B. The majority of unmodified rhGAA either failed to bind or eluted with a low concentration of Man-6-P (0.25 mM) in the mobile phase. In contrast, more than 95% of both GAM and SAM conjugates were bound and could be eluted only with 5 mM Man-6-P or above. SAM and GAM conjugates showed a similar profile by this method.

The uptake of rhGAA and neoGAA by rat L6 myoblast cells *in vitro* was followed to determine if differences in the conjugation method had an effect on the efficiency of internalization through CI-MPR. As shown in Figure 4C, more than 10-fold higher GAA activity was observed in cells incubated with neoGAA conjugates than with rhGAA lacking neoglycan over a wide range of protein concentrations. GAM and SAM conjugates showed a comparable saturable uptake with EC_{50} of ~5 nM (0.5 μg/mL) protein. The EC_{50} for rhGAA could not be determined in this experiment due to its low level of uptake.

Serum Half-Life and Glycogen Clearance in the GAA Knockout Mouse. The serum clearance of rhGAA and neoGAA was determined following tail vein injection at single dose (20 mg protein/kg) to GAA knockout mice. All proteins including rhGAA and neoGAA conjugates were rapidly cleared from circulation with serum half-lives ($T_{1/2}$) between 0.5 and 2.3 h (Figure 5). Both GAM and SAM conjugates demonstrated faster clearance than rhGAA ($T_{1/2}$ of 24% and 37% of rhGAA, respectively). The GAM conjugate was cleared most rapidly with a serum half-life of 33 min, and its serum concentration was below the limit of quantitation at both 240 and 480 min. The SAM conjugate was cleared at a relatively slower rate than GAM conjugate and it was below the limit of quantitation at 480 min with a serum half-life of 51 min.

The impact of bis Man-6-P neoglycan conjugation on glycogen clearance by rhGAA and both neoGAA conjugates (GAM6

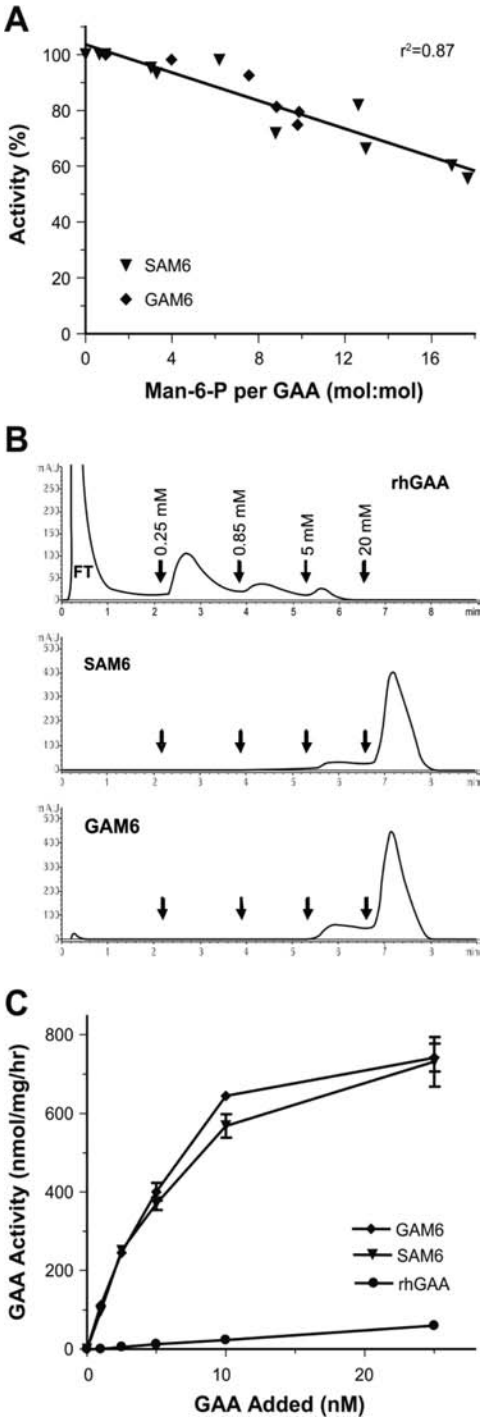

Figure 4. *In vitro* activity of neoGAA SAM and GAM conjugates. (A) Effect of Man-6-P content on GAA enzyme activity, which is presented as % activity from rhGAA. SAM6 (triangles) and GAM6 (diamonds) were prepared with different molar excess of bis Man-6-P neoglycan over GAA. (B) Binding of rhGAA, SAM6, and GAM6 to Man-6-P receptor (CI-MPR) affinity columns, which were eluted with increasing concentrations of Man-6-P as indicated by arrows. (C) Uptake of rhGAA or neoGAA by L6 myoblast cells *in vitro*.

and SAM6) was followed in GAA knockout mice. In this study, rhGAA and neoGAA conjugates were administered in four weekly doses via tail vein injection. The amount of glycogen in heart and skeletal muscles was measured one week after the final

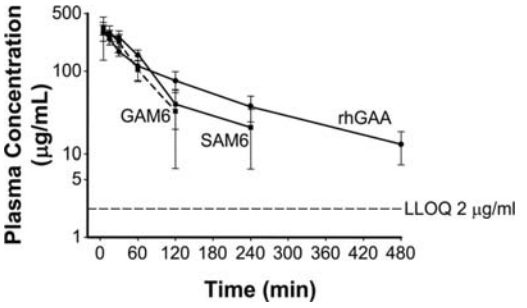

Figure 5. Serum clearance of neoGAA SAM and GAM conjugates in the GAA knockout mice. Animals were administered with rhGAA or neoGAA conjugates via the tail vein as a single bolus injection. The amount of proteins was determined using the GAA activity assay of blood collected at 5, 15, 30, 60, 120, 240, and 480 min post injection. The Man-6-P contents were 0.9, 13.3, and 11.3 mol per mole for rhGAA, SAM6, and GAM6, respectively.

administration. The dose ranges tested were 5-fold higher for rhGAA than for the neoGAA conjugates in order to obtain comparable glycogen clearance. At the lowest dose level, rhGAA (20 mg/kg) reduced glycogen in the heart by only 17% (Figure 6A). By comparison, the SAM conjugate produced a greater reduction (61%) in glycogen at a 5-fold lower dose (4 mg/kg), while the GAM conjugate at 4 mg/kg was less effective, showing a modest clearance comparable to rhGAA administered at 20 mg/kg (Figure 6A). At the intermediate dose level (60 mg/kg rhGAA and 12 mg/kg for neoGAAs), rhGAA or the SAM conjugate achieved 90% and 94% glycogen clearance, respectively, while the GAM conjugate reduced glycogen by 51%. Finally, at the highest dose level (100 mg/kg rhGAA and 20 mg/kg for neoGAAs), essentially complete clearance of glycogen was obtained with rhGAA or a 5-fold lower dose of the SAM conjugate but not the GAM conjugate, which showed a somewhat lower efficacy (79%). The dose required to achieve 50% reduction in glycogen in the heart was estimated as ~40, 12, and <4 mg/kg for rhGAA, GAM, and SAM conjugates, respectively.

In skeletal muscle, both rhGAA and SAM conjugate at the highest dose (100 mg/kg and 20 mg/kg, respectively) showed significant efficacy, reducing glycogen by 77% and 80% in the quadriceps, respectively (Figure 6B). In contrast, the GAM conjugate at 20 mg/kg achieved a lesser (59%) reduction. Triceps and diaphragm showed similar responses to treatment (data not shown). At an intermediate dose, the SAM conjugate (12 mg/kg) also cleared more glycogen (81%) than the GAM conjugate at the same dose or rhGAA at a 5-fold higher dose (45% or 56% reduction, respectively) in the quadriceps. Neither rhGAA nor the neoGAA conjugates were able to significantly clear glycogen from any skeletal muscle at the lowest dose. We conclude that the conjugates prepared using SAM chemistry are somewhat more potent than neoGAA generated using the GAM method.

We considered the possibility that the terminal GalA found in the GAM conjugate might contribute to its faster clearance and lower efficacy in glycogen clearance in muscle by the undesirable delivery to nontarget tissue by mechanisms such as uptake by the asialoglycoprotein receptor. To test this, GAM6 was prepared with either 2 μg/mg or 10 μg/mg GAO, yielding conjugates with a 2-fold difference in GalA content, which were administered at 20 mg/kg for 4 weekly doses to GAA knockout mice. However, no significant difference was observed in the clearance of glycogen in either heart or skeletal muscle between these two

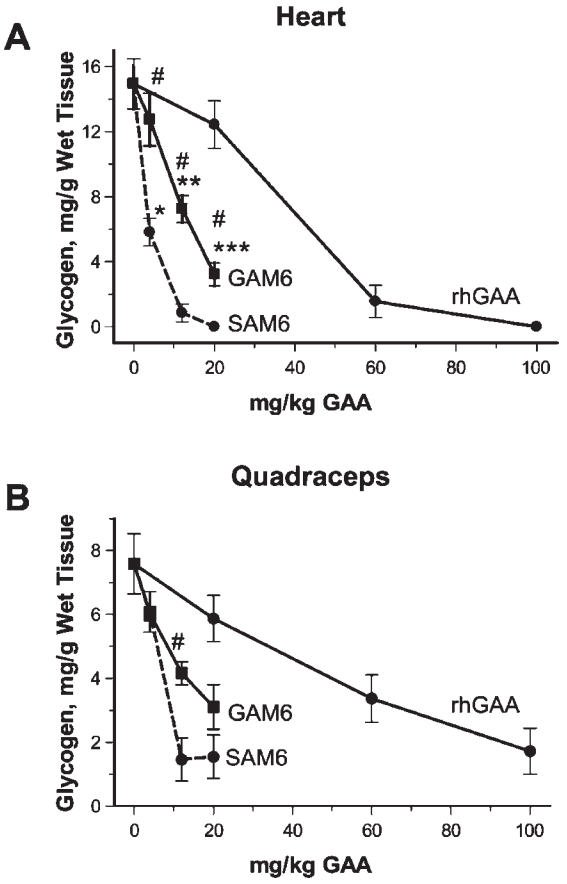

Figure 6. Glycogen clearance in the GAA knockout mice after treated with neoGAA SAM and GAM conjugates. Glycogen levels in heart (A) and quadriceps (B) determined following 4 weekly doses of rhGAA and neoGAA conjugates. rhGAA and neoGAA conjugates were the same as described in Figure 5. $^{*}p < 0.05$ as compared to rhGAA at 20 mg/kg dose; $^{**}p < 0.05$ as compared to rhGAA at 60 mg/kg dose; $^{***}p < 0.05$ as compared to rhGAA at 100 mg/kg dose; $\#p < 0.05$ as compared to equivalent doses of SAM6.

preparations (data not shown). Both conjugates showed similar serum clearance after a single dose injection at 20 mg/kg.

■ DISCUSSION

We have compared a number of strategies to conjugate synthetic bis Man-6-P neoglycans to rhGAA targeting either amino acids or protein carbohydrates. The simplest approach of conjugation to the unique free thiol group from Cys-374, although highly attractive from a development standpoint, was achieved only under partially denaturing conditions, and was consistent with the structural model in which the sulfur is only partially visible from protein surface, suggesting that its availability for modification may be quite limited. In contrast, lysine residues which are largely solvent-exposed in the structural model were modified at a higher efficiency by an amine-reactive aromatic bifunctional linker, SFB, which supported glycan conjugation through oxime chemistry. However, the extent of modification was ultimately limited by protein aggregation, suggesting that the higher efficiency obtained with SFB is a consequence of its aromaticity, with the expected reactivity toward lysines in partially buried positions. A number of lysines in the structural model are available to participate in interdomain salt bridges or hydrogen bonds. In addition, others occur between structural domains with relatively lower solvent accessibility and whose modification could destabilize the structure.

In contrast, both the GAM and SAM carbohydrate-directed chemistries for neoglycan conjugation were each more successful in achieving high Man-6-P levels and yielded stable conjugates with little aggregation in a consistent fashion. Both chemistries produced conjugates with very high affinities for the Man-6-P receptor (Figure 4B) which were internalized with high efficiency by rat myoblasts. On the basis of our GAA structural model with added model structures for the neoglycans coupled to complex-type glycans at the 5 known complex-type *N*-glycosylation sites,[13] a wide spatial distribution of bis Man-6-P appears to be achievable by both methods (Figure 1D). Such a distribution could provide for simultaneous interaction of Man-6-P residues with CI-MPR, which has been reported to have at least 3 Man-6-P binding domains.[34] Coupling of the bis Man-6-P neoglycans to the terminal sugars of *N*-glycans as suggested by the model may also produce an array of charged glycan structures, creating a charge shell and increasing the overall protein hydrophilicity and solubility and thereby suppressing any tendency toward aggregation.

Our parallel evaluation of these chemistries demonstrated a higher overall efficiency of conjugation with SAM than GAM in spite of the higher number of galactose than sialic acid conjugation sites. Even by use of the optimal amount of GAO in the GAM process, the observed yield of Man-6-P (15 mol per mol) in GAM6 was significantly less than the expected 20 mol per mol based on the protein galactose content, part of which is accounted for by overoxidation to the nonconjugatable form GalA. However, even accounting for the loss through GalA formation, the efficiency of the neoglycan coupling step appears to be lower than SAM (~75−85% vs ~100% for SAM). It is possible that the first neoglycan coupled to one of the two terminal sugars on biantennary *N*-glycans sterically interferes with coupling of a second glycan to the other terminus. Such an effect might be expected to be more pronounced for the galactose residues closer to the structurally crowded environment of the branch point than for the more distal sialic acid coupling sites in SAM.

Oxidation of galactose aldehyde to the acid GalA form by GAO has been described previously.[32] This reaction is relatively inefficient compared with the generation of the aldehyde, although catalase has also been shown to drive the reaction, likely due to oxygen regeneration.[32] However, a structural model of galactose docked with GAO[35−37] suggests that the additional hydroxyl group in the aldol form of the aldehyde can be easily accommodated in the active site, making discrimination of the two substrates difficult. The relative efficiency of the two oxidation events on rhGAA *N*-glycans appears to be sufficiently similar to render the exclusive preparation of an aldehyde form difficult and a challenge to defining a rational strategy to engineer GAO to limit its choice of substrates. Other strategies, such as controlling the available oxygen, may be possible but have not been explored because of the technical difficulty in both properly modeling and translating the process to production scale.

Although both GAM and SAM conjugates show a comparable high-affinity binding to CI-MPR and similar uptake into myoblast cells, SAM6 consistently showed higher efficacy *in vivo*. The high doses of either rhGAA or neoGAA which are required to achieve efficacy in these animal models compared to other enzyme replacement therapeutics suggest that muscle uptake is

inefficient and that delivery is critically dependent upon the circulating half-life to achieve a high systemic exposure. Thus, the lower efficiency of glycogen clearance obtained with GAM conjugate may result from its lower bioavailability due to faster clearance from circulation. It should be noted that the circulating level remaining even after clearance of 90% of both conjugates is still well above the EC_{50} for cell uptake via CI-MPR (5 nM or ~0.5 μg/mL, Figure 4C). Nonetheless, the window during which the protein concentration exceeds this level is longer for the SAM conjugate (Figure 5). It is also possible that a higher enzyme concentration in circulation is required to drive an inefficient transport process across the continuous endothelial layer into the interstitial space prior to the CI-MPR dependent uptake by myocytes. In this view, at a low enzyme concentration in the interstitial space well below the EC_{50} for uptake, a much greater effect of the degree of phosphorylation on the net uptake would be expected. In this situation, the higher Man-6-P content of the SAM conjugate would confer a modest advantage in addition to its longer circulating half-life.

The current study unexpectedly also identified a significant inverse correlation between the neoglycan content and GAA enzyme activity against a low molecular weight synthetic substrate (Figure 4A). On the basis of the GAA structural model, the *N*-linked glycosylation site at Asn-652, which is occupied mainly by sialylated complex-type glycans,[13] is in close proximity to the active site of rhGAA previously identified by site-directed mutagenesis [29] and the substrate site identified by acarbose binding in the MGAM structure which is preserved in the GAA model (Figure 1B). It is possible that an extended structure with bis Man-6-P neoglycan conjugated at this site interferes with substrate binding at the active site. With glycogen as the substrate, conjugation produced a significant increase in K_m and without a significant effect on V_{max}, consistent with steric hindrance of substrate binding (data not shown). However, any reduction in specific activity could be easily offset by a larger increase in uptake of conjugates achieved by neoglycan conjugation (Figure 4C). It is also possible that the neoglycans are either released by a low pH or removed by the action of glycosidases once in the lysosome, leading to a processed form of the enzyme similar to that obtained with rhGAA and with comparable activity.[30,38] Even without processing, however, the concentration of the glycogen substrate accumulated in Pompe myocytes is likely to minimize any effect on K_m. The intracellular fate of the neoGAA is currently under investigation.

CONCLUSION

A number of alternative strategies to conjugate synthetic bis Man-6-P neoglycans to rhGAA were investigated. Of these, oxime chemistry directed at the aldehydes generated chemically or enzymatically on carbohydrates was found to be most practical, consistently demonstrating high conjugation efficiency, low aggregation, and a high linkage stability. To eliminate the side oxidation of methionines by periodate during the SAM process, a novel three enzyme remodeling system (GAM) was devised to selectively generate a large number of aldehydes for conjugation. Although both SAM and GAM conjugates bound the Man-6-P receptor with comparable affinity which exceeded that for rhGAA, conjugate prepared by SAM chemistry displayed higher *in vivo* potency than GAM conjugate, likely as a result primarily of slower serum clearance. These results provide the support for the SAM conjugation process for further development as a next generation therapeutic for Pompe disease. Nonetheless, the GAM method produced a highly defined product profile typical of a more selective enzyme-mediated process, including fewer oxidative side products. This approach still achieved a significant increase of *in vivo* potency over unmodified rhGAA, suggesting that it represents an approach for improving targeting of proteins which show a higher sensitivity to periodate oxidation.

Chemical and Enzyme-Assisted Syntheses of Norbuprenorphine-3-β-D-glucuronide

Jinda Fan,[†,∥] Sarah M. Brown,[‡,∥] Zhude Tu,[†] and Evan D. Kharasch*[,‡,§]

[†]Department of Radiology, [‡]Department of Anesthesiology, and [§]Department of Biochemistry and Molecular Biophysics, Washington University in St. Louis, 660 S. Euclid Avenue, St. Louis, Missouri 63110, United States

ABSTRACT: Norbuprenorphine-3-β-D-glucuronide (nBPN-3-β-D-G, **1**) is a major phase II metabolite of buprenorphine, a pharmaceutical used for the treatment of opioid addiction. The pharmacological activity of compound **1** is not clear because investigations have been limited by the lack of chemically pure, well characterized **1** in sufficient quantities for *in vitro* and *in vivo* experiments. This work describes two concise, new methods of synthesis of **1**, a chemical and an enzyme-assisted synthesis. The chemical synthesis used a strategy based on a combination of Koenig-Knorr coupling and amino-silyl protection. The enzyme-assisted synthesis used dog liver to convert the substrate norbuprenorphine (nBPN, **2**) to **1**. Both methods provided **1**, characterized by ^{1}H NMR and tandem mass spectrometry, with purity >96%. The fractional yield of the enzyme-assisted synthesis was greater than that of the chemical synthesis (67% vs 5.3%), but due to larger reaction volumes, the chemical synthesis afforded greater amounts of total **1**.

INTRODUCTION

Drugs are metabolized in a two-phase biotransformation process that renders the drug more readily excreted in urine or bile. The first phase often produces a dealkylated or a hydroxylated metabolite that may then also undergo conjugation to a polar group such as glucuronic or sulfonic acid in the second phase. Phase I and phase II metabolites can circulate in concentrations equal to or greater than the parent drug, and in many instances have pharmacological activity that contributes significantly to the overall effects of the parent drug.[1,2] Thus, drug metabolites have the potential to be clinically important, and indeed, this is true in numerous instances. Many active phase I metabolites have been developed as new drugs. Some well-known examples are acetaminophen, a metabolite of phenacetin, fexofenadine, a metabolite of terfinadine, and nortryptyline, a metabolite of amitriptyline.[1] The opioid drug class has over 10 clinically important metabolites, including the phase 1 metabolites hydrocodone and hydromorphone.[2,3] This drug class also has important active phase II metabolites, the best described being morphine-6-glucuronide (M6G), which has greater pharmacological activity than the parent drug.[3,4] M6G has undergone phase III clinical trials as a drug for the treatment of postoperative pain,[5,6] showing benefit over the parent drug for producing analgesia with significantly fewer negative side effects (nausea, etc.), and less risk of respiratory depression.[7] The high potential for the contribution of drug metabolites to the overall effect of the parent drug has led to a recent guidance from the FDA wherein any major metabolite, defined as one comprising >10% of parent drug systemic exposure at steady-state, be considered for safety assessment (Guidance for Industry: Safety Testing of Drug Metabolites, Food and Drug Administration, Center for Drug Evaluation and Research, http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm079266.pdf).

Buprenorphine (BPN) is a phenanthrene opioid used in the treatment of opioid addiction, and to a lesser extent, pain.[8] It is extensively metabolized to 3 main metabolites: an N-dealkylated product, norbuprenorphine (nBPN), and two *O*-glucuronides, buprenorphine-3-β-D-glucuronide (BPN-3-β-D-G) and norbuprenorphine-3-β-D-glucuronide (nBPN-3-β-D-G).[9] These metabolites are present in the circulation at concentrations greater than or equal to that of BPN. Plasma concentrations of nBPN and nBPN-3-β-D-G, specifically, are typically greater than that of BPN following an oral dose, and the area under the plasma concentration versus time curve for nBPN and nBPN-3-β-D-G is approximately 2 and 10 times greater, respectively, than that of the parent drug.[10−13] While there are some data regarding the pharmacological activity of nBPN,[12,14] the biological properties of the glucuronides and their contribution to the pharmacology of the parent drug remain unknown. The high concentration of nBPN-3-β-D-G and the precedent for active glucuronides warrant the investigation of the biological activity of this metabolite. However, such an investigation has been inhibited by the limited availability of the metabolites in quantities necessary for *in vitro* and *in vivo* studies. Thus, the development of an efficient means of nBPN-3-β-D-G synthesis is of considerable importance.

Glucuronides can be synthesized chemically, usually by the Koenigs−Knorr method.[15] However, glucuronides are notoriously more difficult to prepare than the corresponding glucopyranoside.

Schmidt and co-workers have shown a difficulty scale: 3-deoxy-2-glyculosonates < ketoses < deoxy sugars < aldoses < glycuronates.[16] Of all common sugars, glucuronides require the highest activation for a given aglycone. Alternatively, glucuronide conjugates can be prepared through enzyme-assisted synthesis using liver microsomal enzymes.[17−20] The purpose of this investigation was to evaluate the synthesis of nBPN-3-D-G by two routes: enzyme-assisted synthesis using dog liver and chemical synthesis involving the development of silyl as a protective group.

EXPERIMENTAL SECTION

Chemicals and General Methods. All reagents were from Sigma-Aldrich (St. Louis, MO), unless otherwise noted. Norbuprenorphine glucuronide was purchased from Cerillant (Round Rock, TX) for use as an analytical standard. Norbuprenorphine was a generous gift from the National Institute on Drug Abuse. All organic solvents were distilled before use. After drying over Na_2SO_4, organic solvents were concentrated under diminished pressure at <40 °C (bath temperature), and NMR spectra were recorded at 300 MHz (^{1}H), in $CDCl_3$ or DMSO. Tetramethylsilane (TMS) was used as the internal standard (δ 0) for ^{1}H spectra. Chemical shifts are expressed in ppm. Preparative chromatography was performed using Merck 60 PF_{254} silica gel. Analytical thin layer chromatography (TLC) was performed on glass TLC plates coated with silica gel (Analtech) and visualized with UV light.

Formation of 1-[2-(Trimethylsilyl)ethoxycarbonyloxy]benzotriazole (TeocOBt) (3). Synthesis of Teoc-OBt was modified from published methods.[21] Briefly, to a solution of 2-trimethylsilyletanol (1.0 g, 8.5 mmol) in toluene (5 mL) at −10 to −5 °C was added powdered anhydrous potassium carbonate (1 g). To this vigorously stirred suspension, a 20% solution of phosgene in toluene (6.25 mL) was added dropwise over 14−30 min. On completion of the addition, the mixture was stirred over an ice bath for 30 min, followed by 1 h at room temperature. After stirring, nitrogen was bubbled through the mixture with the hood closed to remove the majority of the excess phosgene. The last traces of phosgene were removed from the mixture by rotary evaporation at a temperature <40 °C. The solids were then filtered off through a pad of anhydrous magnesium sulfate and washed with dry ether. The combined filtrate and washings were evaporated at a temperature not higher than 50 °C. The resultant oily carbonochloridate was used without further purification.

2-Trimethylsilylethyl carbonochloridate (1.54 g, 8.5 mmol) was taken up in acetonitrile (25 mL). The solution was cooled to 0 °C and solid 1-hydroxy-benzotriazole monohydrate (1.5 g, 11 mmol) was added with vigorous stirring followed by a solution of triethylamine (1.0 g, 10 mmol) in acetonitrile (2.5 mL). The mixture was stirred at low temperature for 15 min, then at room temperature overnight. The mixture was poured into water (100 mL) and extracted with ether (3 × 40 mL). The organic extracts were combined, washed with water (2 × 40 mL), 1 N hydrochloric acid (40 mL), and again water (2 × 40 mL), dried with sodium sulfate, and evaporated to dryness. The residue was taken up in boiling hexane (150−200 mL) and the solution allowed to cool. Crystallization, completed by storage at −15 °C, yielded a white solid (1.31 g, 58.7% for the two-step synthesis). ^{1}H NMR ($CDCl_3$): δ 0.12 (s, 9H, Si(CH_3)$_3$), 1.29 (t, 2H, *J* 9.0 Hz, SiCH_2), 4.65 (t, 2H, *J* 9.0 Hz, OCH_2), 7.54 (t, 1H, *J* 7.5 Hz, Ph*H*), 7.77 (t, 1H, *J* 7.5 Hz, Ph*H*), 8.02 (d, 1H, *J* 7.5 Hz, Ph*H*), 8.22 (d, 1H, *J* 7.5 Hz, Ph*H*). MS (ESI)$^+$ [M+H]$^+$ calcd 264.1; found 264.2.

Formation of *N*-(Trimethylsilyl)ethoxycarbonyl-norbuprenorphine (Teoc-nBPN) (4). To a 1,4-dioxane (2 mL) solution of nBPN (109 mg, 0.26 mMol) (**2**) and TeocOBt (69.6 mg, 0.26 mmol) (**3**), diisopropylethylamine (55 μL, 0.32 mMol) was added. The mixture was stirred at ambient temperature overnight. Solvent was removed under vacuum, and the residues were dissolved in ethyl acetate (10 mL), then washed with water (2 × 10 mL) and saline (10 mL), and finally dried over Na_2CO_3. The crude product was purified by flash-chromatography (25:75 ethyl acetate/hexanes) to produce Teoc-nBPN (**4**) as a white solid (118.3 mg, 80.4%). ^{1}H NMR ($CDCl_3$): δ 0.05 (s, 9H, Si(CH_3)$_3$), 0.99 (s, 9H, C(CH_3)$_3$), 1.26 (m, 2H, SiCH_2), 1.28 (m, 2H, CHCH_2C), 1.34 (s, 3H, CCH_3), 1.57 (m, 2H, CH_2CH_2C), 1.84, (m, 2H, CH_2CH_2C), 1.90 (m, 1H, C*H*), 2.05 (m, 2H, CCH_2CH_2), 2.84 (m, 2H, PhCH_2CH), 2.97 (m, 1H, NC*H*C), 3.53 (s, 3H, OCH_3), 4.14 (m, 2H, NCH_2C), 4.21 (m, 2H, OCH_2CH_2), 4.46 (s, 1H, OC*H*C2), 5.76 (s, 1H, O*H*), 6.54 (D, 1H, *J* 5.1 Hz, Ph*H*), 6.73 (D, 1H, *J* 5.1 Hz, Ph*H*). Formation of *N*-(Trimethylsilyl)ethoxycarbonyl-norbuprenorphine-3-β-D-acetoglucuronide (Teoc-nBPN-3-β-D-AcG) (6). Teoc-nBPN (**4**) (116.3 mg, 0.21 mmol), Ag_2CO_3 (58 mg, 0.21 mmol), and 4 Å molecular sieves (200 mg) were dispersed in freshly distilled quinoline (2 mL, 17 mmol). Acetobromo-α-D-glucuronic acid methyl ester (167 mg, 0.42 mmol) was added to this mixture with stirring at 0 °C under argon. The mixture was allowed to warm to ambient temperature over an hour and was kept at ambient temperature overnight. Molecular sieves were removed by filtration. The precipitate was thoroughly washed with ethyl acetate (3 × 5 mL). The organic phase was combined, washed with brine (10 mL), dried over Na2SO4, and concentrated. The crude product was purified by flash chromatography with gradient eluents (from 25:75 to 50:50 ethyl acetate/hexanes) to produce Teoc-nBPN-3-β-D-G (**5**) as a white solid (33.1 mg, 18.0%). ^{1}H NMR ($CDCl_3$): δ 0.05 (s, 9H, Si(CH_3)$_3$), 0.99 (s, 9H, C(CH_3)$_3$), 1.26 (m, 2H, SiCH_2), 1.28 (m, 2H, CHCH_2C), 1.34 (s, 3H, CCH_3), 1.56 (m, 2H, CH_2CH_2C), 1.72, (m, 2H, CH_2CH_2C), 1.84 (m, 1H, C*H*), 2.04 (s, 9H, CH_3COO), 2.10 (m, 2H, CCH_2CH_2), 2.85 (m, 2H, PhCH_2CH), 2.97 (m, 1H, NC*H*C), 3.50 (s, 3H, OCH_3), 3.71 (s, 3H, COOCH_3), 4.14 (m, 2H, NCH_2C), 4.21 (m, 2H, OCH_2CH_2), 4.42 (s, 1H, OC*H*C2), 5.29 (m, 4H, C*H* on glucuronide), 5.71 (s, 1H, OC*H*), 6.54 (D, 1H, *J* 7.8 Hz, Ph*H*), 6.73 (D, 1H, *J* 7.8 Hz, Ph*H*). MS (ESI)$^+$ [M+Na]$^+$ calcd 896.4; found 896.5.

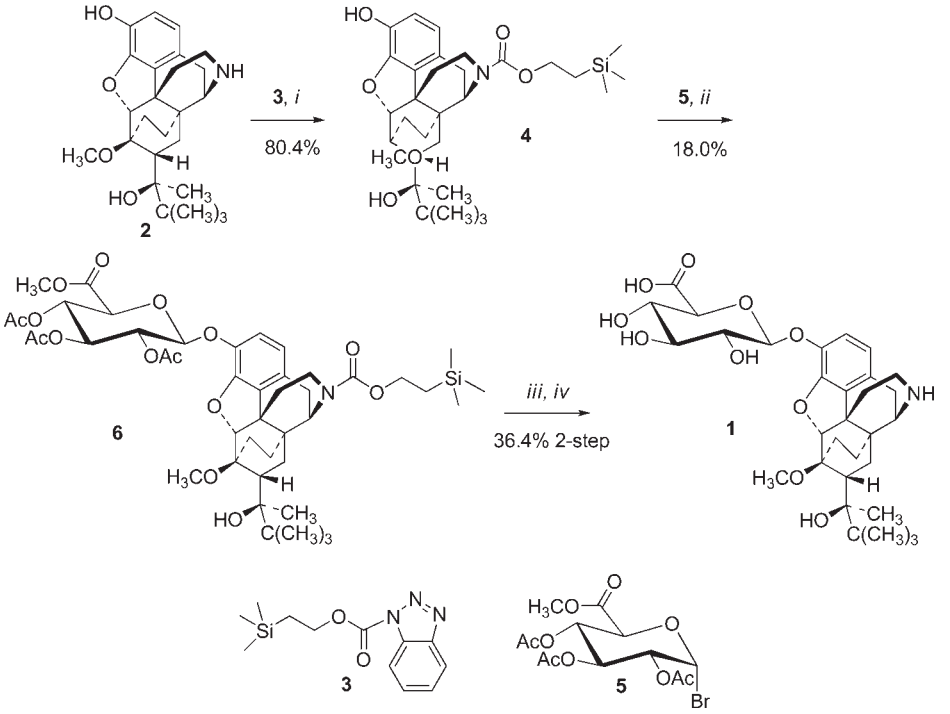
Chemical Synthesis of nBPN-3-β-D-G (1). *N*-(Trimethylsilyl) ethoxycarbonyl-norbuprenorphine-3-β-D-acetoglucuronide (**5**) (65.6 mg, 0.075 mmol) was dissolved in THF/H_2O (v/v 4:1 6.5 mL). Two molar KOH solution (225 μL, 0.45 mmol) was added with stirring at 0 °C. The mixture was then allowed to warm to ambient temperature and then kept at ambient temperature for two hours. After 2 h, acetic acid (8.6 μL, 0.17 mL) was added, and the mixture was extracted with dichloromethane (3× 15 mL). The combined organic phase was washed with saline (5 mL), dried over Na_2SO_4, and concentrated. This produced Teoc-nBPN-3-β-D-G (**7**) as a light yellow solid (54.7 mg 98%) which was used for the next step reaction without purification. To a solution of *N*-(Trimethylsilyl)ethoxycarbonyl-norbuprenorphine-3-β-D-glucuronide (Teoc-nBPN-3-β-D-G) (**7**) (55 mg, 0.075 mmol) in THF (4 mL), TBAF (71 mg, 0.225 mmol) was added and stirred at ambient temperature overnight. The crude product was partially purified by flash-chromatography (20:80 methanol: dichloromethane), followed by purification with a preparative

dx.doi.org/10.1021/bc100550u |*Bioconjugate Chem.* 2011, 22, 752–758

HPLC system to nBPN-3-β-D-G (**1**) as a white solid (16.1 mg, 36.4% for two steps).



Preparation of S9. Fresh liver was obtained from a beagle dog that had been euthanized under a Washington University Animal Studies Committee approved protocol. The tissue was cut in to approximately 30 g pieces, with the removal of as much connective tissue as possible. The tissue was washed with ice-cold phosphate buffered saline (PBS) with stirring, with 6 changes of PBS. The washed tissue pieces were reduced in 3 volumes (by weight) of buffer (10 mM potassium phosphate, pH 7.4, with 0.25 M sucrose) in a chilled Waring blender and then homogenized on ice using a motorized glass-Teflon homogenizer. The homogenate was transferred to polystyrene tubes, centrifuged at 9,000*g* for 20 min, and the supernatant collected as the "S9 fraction", containing both cytosolic proteins and microsomes. Protein content of S9 was quantified by the Bradford assay.

Enzyme-Assisted Synthesis. In a typical 1 mL incubation, 640 μL of reaction buffer (100 mM potassium phosphate, pH 7.1, 1 mM MgCl, and 5 mM saccharic acid lactone) was added to 200 μL of S9 (10 μg/μL protein) in a glass test tube and the mixture sonicated for 1 min. After sonication, 10 mM nBPN (4 mg/mL), 10, 20, 30, or 50 mM UDPGA, and 150 mL of an NADPH-generating system (1.7 mg/mL β-$NADP^+$, 7.8 mg/mL glucose-6-phosphate, and 6 units/mL glucose-6-phosphate dehydrogenase, prewarmed to 37 °C) were added. The mixture was vortexed and then incubated overnight in a 37 °C water bath with gentle shaking. Larger reaction volumes (up to 5 mL without a decrease in yield) were also occasionally used. Ten millimolar aminobenzotriazole was added prior to the addition of nBPN to three of the 1 mL reaction tubes.

Partial Purification of nBPN-3-β-D-G from the Biocatalyzed Reaction. The reaction was terminated by protein precipitation with three volumes of ice-cold acetonitrile. The supernatant was evaporated under nitrogen to approximately 1 mL and then loaded onto a C18 solid phase extraction column (Sep-Pak C18 Plus 10 g, Waters Co. Massachusetts USA), preconditioned by washing with 3 column volumes of methanol followed by 3 column volumes of water. After loading the sample, the column was washed with 10 mL of water. The sample was eluted with 3 column volumes of methanol and then concentrated by centrifugation under vacuum.

HPLC Purification of nBPN-3-β-D-G. nBPN-3-β-D-G synthesized using either method was purified by preparative HPLC. The compound of interest was separated from impurities over a Sunfire Prep C18 OBD 19 mm × 150 mm x 5 μm column (Waters) using an 85% A (H_2O with 0.1% formic acid)/15% B (acetonitrile with 0.1% formic acid) isocratic method, with a 10 min run time on an Agilent 1100 series LC system. Fractions were collected every minute and analyzed by selected ion monitoring on an Agilent 1100 MSD instrument for the presence of nBPN-3-β-D-G (m/z 590). Fractions containing nBPN-3-β-D-G were pooled and dried by lyophilization. Purity of the synthesized compound was determined by a calibration curve. A 1 mg/mL solution of the synthesized compound was prepared in 0.1% formic acid. A 6-point calibration curve of the purchased standard, ranging from 0.1 mg/mL to 2 mg/mL was prepared. The synthesized compound, at 1 mg/mL, 0.5 mg/mL, and 0.25 mg/mL was analyzed with the calibration curve by selected ion monitoring on the Agilent 1100 LC-MS. The purity was determined as >95% based on comparison to the equation of the calibration curve.

Scheme 1. Synthesis of Norbuprenorphine-3-β-D-glucuronide (nBPN-3-β-D-G)[a]

[a] Reagents and conditions: (i) Et_3N, 1,4-dioxane; (ii) Ag_2CO_3, quinoline; (iii) KOH, H_2O/THF; (iv) TBAF, THF protection of the amine on nBPN with Teoc was followed by coupling Teoc-nBPN to a glucuronic acid by the donor acetobromo-α-D-glucuronic acid methyl ester (**5**) to give Teoc-nBPN-3-D-G (**6**). This step was followed by the hydrolysis of acetyl groups with a base and then the removal of the Teoc protecting group with fluoride, to yield nBPN-3-β-D-G (**1**).

dx.doi.org/10.1021/bc100550u |*Bioconjugate Chem.* 2011, 22, 752–758

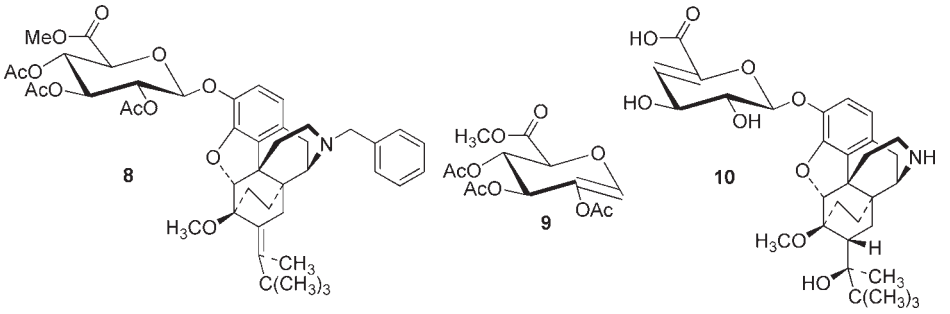


Figure 1. Structure of some of the byproducts of chemical synthesis. Dehydration product **8** formed during the coupling step when silver triflate was used; HBr elimination of **5** formed **9**; $\Delta_{4,5}$-glucuronides formed during the coupling and hydrolysis steps.

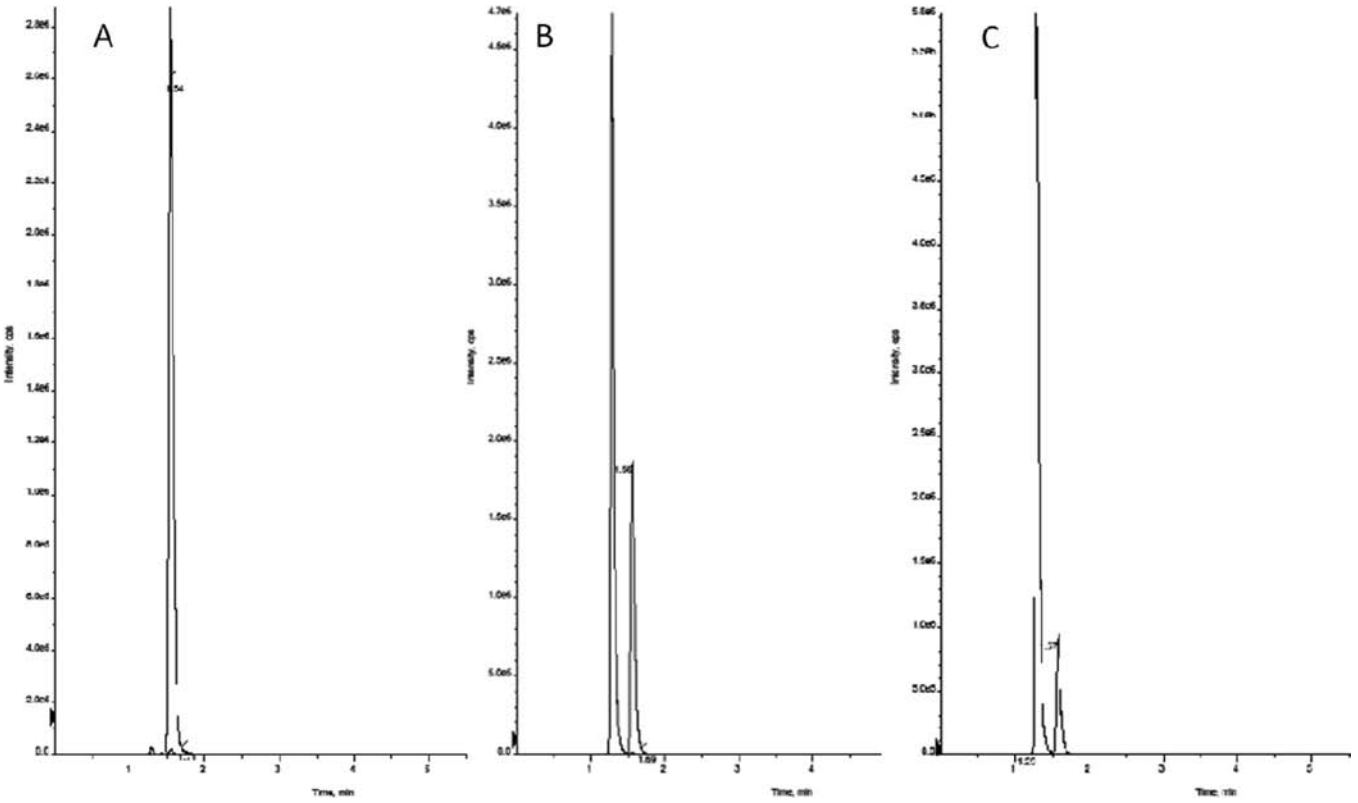

Figure 2. Addition of ABT to the enzyme-assisted reaction increased the conversion of nBPN to nBPN-3-β-D-G. HPLC analysis of the reaction mixture immediately preceeding incubation showed one peak (RT = 1.56 min) corresponding to nBPN (panel A). After overnight incubation, a second peak (RT = 1.28 min) corresponding to nBPN-3-β-D-G was observed (panel B). Addition of 10 mM ABT to the reaction resulted in a greater conversion of nBPN to nBPN-3-β-D-G (panel C).

Mass Spectral Characterization. Fragmentation was characterized by a product ion scan in positive electrospray mode on an 4000 QTRAP MS/MS (Applied Biosystems). The compound in solution (H_2O with 0.1% formic acid) was introduced to the source by direct infusion at a rate of 20 μL/min. MSD parameters: collision energy, 52 eV; declustering potential, 92 eV; exit cell potential, 10 eV; curtain gas, 15 eV; ion spray voltage, 5200 eV; collision gas, medium; ion source gas 1, 40; and ion source gas 2, 50.0. Fragmentation of the reference material was compared to that of the chemically and biologically synthesized compound.

NMR of nBPN-3-β-D-G. ^{1}H NMR ($CDCl_3$): δ 0.97 (s, 9H, $C(CH_3)_3$), 1.28 (m, 2H, $CHCH_2C$), 1.34 (s, 3H, CCH_3), 1.56 (m, 2H, CH_2CH_2C), 1.72, (m, 2H, CH_2CH_2C), 1.84 (m, 1H, CH), 2.05 (m, 2H, CCH_2CH_2), 2.78 (m, 2H, $PhCH_2CH$), 2.84 (m, 1H, $NCHC$), 3.42 (s, 3H, OCH_3), 3.48 (m, 1H, $CHOH$), 4.43 (s, 1H, OCH), 4.94 (m, 4H, $CHOH$), 5.06 (m, 1H, $CHOH$), 5.18 (m, 1H, $CHOH$), 5.46 (s, 1H, OCH), 6.55 (D, 1H, J 8.4 Hz, PhH), 6.87 (D, 1H, J 8.4 Hz, PhH). MS $(ESI)^+$ $[M+H]^+$ calcd 590.3; found 590.2.

RESULTS AND DISCUSSION

Chemical glucuronidation of nBPN with **5** under nonaqueous conditions was performed using the synthetic scheme shown (Scheme 1). While glycosylation of nBPN with protected, simple aldopyranosyl bromide to give its glucuronide directly has been reported, the reactions were performed in aqueous conditions

dx.doi.org/10.1021/bc100550u |*Bioconjugate Chem.* 2011, 22, 752–758

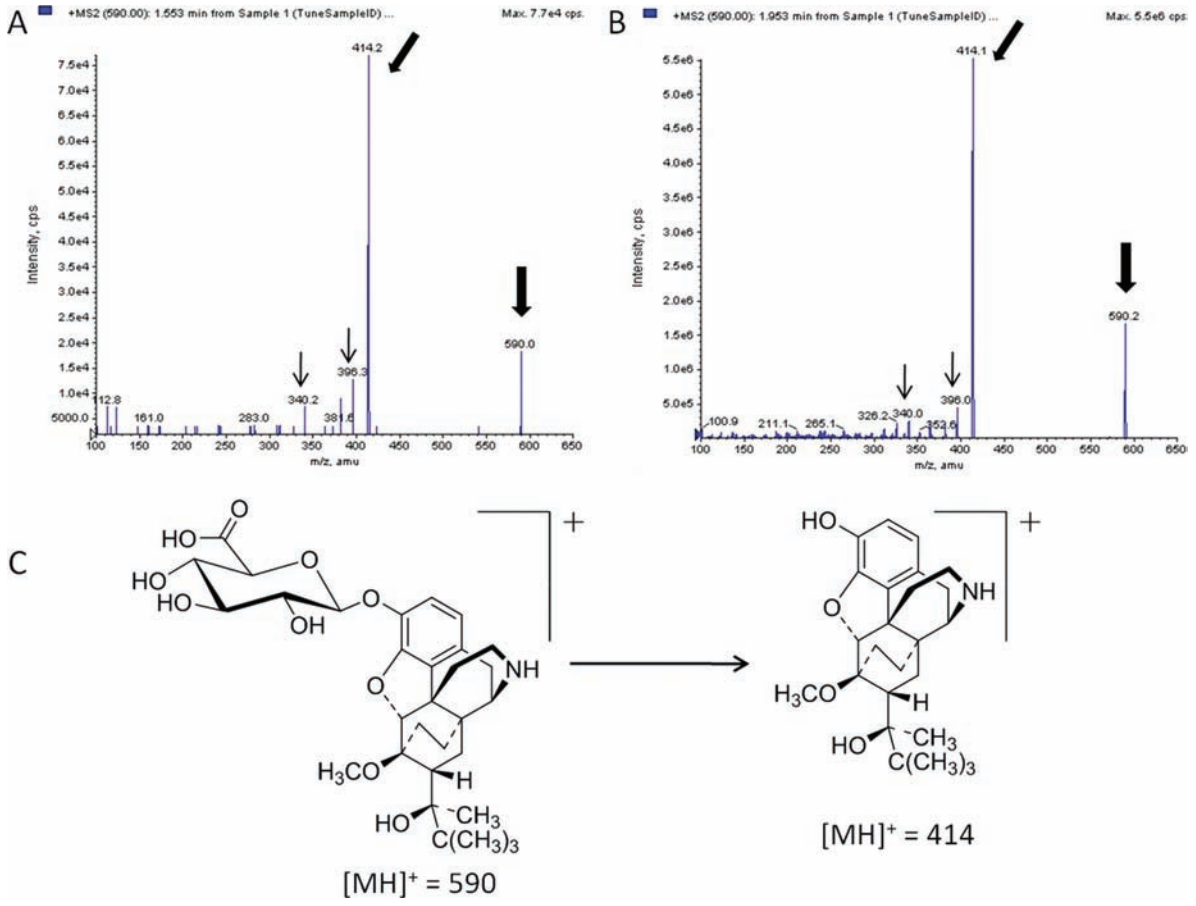

Figure 3. Purchased nBPN-3-β-D-G standard and the synthesized nBPN-3-β-D-G have the same fragmentation pattern. nBPN-3-β-D-G precursor (m/z 590) fragments at the 3-ether linkage to give the product ion m/z 414 (bold arrows). Two less abundant product ions are m/z 396 and m/z 340 (small arrows). The purchased standard (A) and the synthesized product (B) had the same fragmentation pattern.

with hydroxide catalysis,[22] and work from other groups suggests that C-ring cleavage is in fact the predominant reaction under these conditions.[23] The presence of two competitive glucuronic acid acceptors on nBPN, the phenol and secondary amine functional groups, necessitated protection of the amine group before the addition of glucuronic acid to prevent the formation of *N*-glucuronide. The amine group was protected with trimethylsilylethoxycarbonyll (Teoc), as it is stable to mild acid and base, and can be removed with the fluoride ion.[24,25] The use of a benzyl group as the amine protecting group was also tested, and although the benzyl groups were cleanly removed from *N*-benzyl protected nBPN (**2**) under relatively mild conditions such as palladium−carbon catalyzed hydrogenolysis, under the same conditions the deprotection of *N*-Bn-nBPN-3-β-D-G (**8**) was not successful because the glucuronic bond could not withstand even these mild hydrogenolysis conditions. A variety of other hydrogenolysis conditions were tried without success, including Pd/C catalyzed hydrogenolysis with H_2 in tetrahydrofuran (THF) or methanol/ethyl acetate at room temperature and Pd/C catalyzed hydrogenolysis with ammonium formate in THF, refluxed at 70 °C. TeocOBt, synthesized by modifying a reported procedure,[21] was used to protect nBPN, giving Teoc-nBPN in good yield. The coupling of Teoc-nBPN (**4**) with **5** to generate Teoc-nBPN-3-β-D-AcG (**6**) under the Koenigs−Knorr reaction conditions was the most challenging step of the synthesis. The commercially available glucuronidation intermediate,[26,27] 1α-bromo sugar **5**, was selected as the sugar source for this synthesis. The most common solvents used for the coupling reaction have been benzene, toluene, and quinoline; quinoline was used as both a base and solvent. Removal of any water produced is critical for the coupling reaction; 4 Å molecular sieves were used for the removal of water. A persistent byproduct from such coupling reactions is the glycosene or 2-acetoxyglycal **9**, formed by HBr elimination (Figure 1). A variety of salts can provide silver ions for the coupling reaction, and although silver trifluoromethanesulfonate (triflate) was used for the synthesis of retinyl glucuronide[28] to give a markedly better yield than Ag_2CO_3, we found that using silver triflate produced the dehydrated product **8** as the major product. Hence, Ag_2CO_3 was used. Following the success of the coupling reaction, the acetyl protecting groups and the Teoc protecting group were removed sequentially with KOH in H_2O/THF and TBAF in THF, respectively. During our synthesis, the formation of $\Delta_{4,5}$-glucuronides (dehydroglucuronides, **10**) was observed (Figure 1). Dehydroglucuronides are a particularly relevant byproduct of this step, as they may be formed in trace or even significant amounts during any basic hydrolysis. Similar results were obtained by Tajima,[29] who showed that the elimination was also facilitated by a 1β-substituent.

Enzyme-assisted synthesis was accomplished via incubation of nBPN, UDP-glucuronic acid, and an NADPH generating system with a fraction of liver homogenate. *In vivo*, norbuprenorphine is glucuronidated by hepatic uridine-5′-diphosphoglucuronosyltransferases (UGT).[30] These enzymes are located

dx.doi.org/10.1021/bc100550u |*Bioconjugate Chem.* 2011, 22, 752–758

in the endoplasmic reticulum, which are obtained as microsomes by differential ultracentrifugation of liver homogenate. An alternative is to use S9, a fraction of liver homogenate containing both microsomes and cytosol. The benefit to using S9 is the ease of preparation; instead of multiple ultracentrifugation steps, it is obtained by collecting the supernatant following one 9,000*g* spin of total homogenate. Dog liver was used as it is more readily available than human liver, and despite reports of low circulating concentrations of all BPN metabolites in dogs administered intravenous BPN,[31] dog liver was as efficient as the human liver for the conversion of BPN to BPN-3-β-D-G.[17] An NADPH-generating system rather than NADPH was used to supply a reductive cofactor, and while NADPH is not necessary for UGT enzymatic activity, it has been shown to enhance the activity of these enzymes.[32−35] UDP-glucuronic acid was added in equimolar (or greater) amount to nBPN. The S9 fraction was sonicated immediately prior to the addition of the reaction components in order to create pores in the microsomal membranes.[18] The progress of the reaction was monitored by LC/MS. An aliquot was removed from the total incubation, and the reaction stopped by adding three volumes of ice-cold acetonitrile. The supernatant was analyzed by selected ion monitoring on an 1100 MSD (Agilent) following the m/z 590 for the glucuronide and m/z 414 for the parent compound after LC separation. The conversion of nBPN to nBPN-3-β-D-G was not complete, even after an overnight incubation. In an effort to increase the yield of the glucuronide, we repeated the reaction with UDP-glucuronic acid in 2-, 3-, and 5-fold molar excess and found that the latter resulted in the greatest conversion (36%). In every reaction, we observed a peak with a mass to charge ratio (m/z) of 576 at a signal intensity equal to that of the nBPN-3-β-D-G (m/z 590) and nBPN (m/z 414). Since this is a 14 amu difference from the glucuronide (m/z 590), we hypothesized that this might correspond to a demethylated form of the glucuronide. Dealkylation by cytochrome P450 enzymes is a common step in drug metabolism. To test the hypothesis that this compound was a demethylated metabolite of nBPN-3-β-D-G, aminobenzotriazole (ABT), a nonspecific cytochrome P450 inhibitor,[36] was added to the reaction. While the addition of ABT to the reaction did not affect the presence or relative amount of m/z 576, it did increase the conversion of nBPN to nBPN-3-β-D-G, from 36 to 68% (Figure 2). Having thus optimized the reaction conditions, a set of 30 1-mL reactions was initiated. Following incubation, extraction, and purification, approximately 10 mg of nBPN-3-β-D-G was obtained.

Both the biologically and chemically synthesized compounds were characterized by HPLC and tandem mass spectrometry. Comparison to that of a purchased certified reference material showed that both the synthesized and reference compounds had the same retention time (1.28 min), and a mix of the two clearly showed only one peak. Additionally, the fragmentation pattern of the synthesized compound was compared to the fragmentation pattern of the certified reference standard; both fragmented to give one major product ion with m/z of 414, corresponding to the mass of nBPN after the loss of glucuronic acid (Figure 3).

In conclusion, nBPN-3-β-D-G was successfully prepared by two routes: a 4-step chemical synthesis using a silyl protecting group and an enzyme-assisted synthesis using a metabolically active fraction of dog liver. While the enzyme-assisted synthesis had a greater yield per batch, the batch volume was limited, and multiple reactions were required for significant yield. The chemical synthesis resulted in more product per batch, albeit with a lesser overall yield. Preparative HPLC was required for the final purification of nBPN-3-β-D-G prepared by either the chemical or biological synthetic route. Structure of the final product was confirmed by ^{1}H NMR, and purity was determined to be >95%.

Supporting Information

ABSTRACT: Three oligodeoxyribonucleotides (ODN) covalently labeled with near-infrared (NIR) fluorochromes were synthesized and characterized with a goal of comparing *in vitro* a hairpin-based and a duplex-based FRET probe designed for the detection of human recombinant NF-κB p50/p65 heterodimer binding to DNA. Using deoxyguanosine phosphoramidite with a phosphorus-linked aminoethylene (diethylene glycol) hydrophilic linker, we synthesized ODNs with internucleoside reactive sites. The hairpin loop amino linker was modified with IRDye 800CW (FRET acceptor), and the 3′-end was modified with Cy5.5 (FRET donor) using a dithio-linker. To obtain a duplex probe, we conjugated Cy5.5 and 800CW to complementary strands at the distance of ten base pairs in the resultant duplex. No quenching of dyes was observed in either probe. The FRET efficiency was higher in the duplex (71%) than in the hairpin (56%) due to a more favorable distance between the donor and the acceptor. However, the hairpin design allowed more precise ratiometric measurement of fluorescence intensity changes as a result of NF-κB p50/p65 binding to the probe. We determined that as a result of binding there was a statistically significant increase of fluorescence intensity of Cy5.5 (donor) due to a decrease of FRET if normalized by 800CW intensity measured independently of FRET. We conclude that the hairpin based probe design allows for the synthesis of a dual fluorescence imaging probe that renders signal changes that are simple to interpret and stoichiometrically correct for detecting transcription factor−DNA interactions.

INTRODUCTION

NF-κB is a fast-acting transcription factor with an established role in carcinogenesis and cancer progression due to NF-κB-mediated control of expression of the genes involved in the antiapoptotic response to tumor surveillance, regulation of tumor angiogenesis, and cell motility.[1] Several studies utilizing fluorescence energy transfer demonstrated that the interaction of NF-kB proteins with fluorescent labeled ODNs can be measured directly.[2,3] We previously reported ODN duplex probes carrying two covalently linked fluorescent dyes for detecting interactions with transcription factors that specifically recognize the DNA sequence encoded by the duplex.[4,5] These probes encoding NF-κB binding sequence were used for determining p50/p65 protein-mediated interference with the fluorescence resonance energy transfer from the donor near-infrared dye (Cy5.5) to a near-infrared acceptor.[5] Near-infrared fluorochromes potentially allow FRET measurements in live tissues due to a lower absorption and scattering of light in the near-infrared range of light.[6,7] The detection of such protein-mediated interference with FRET was accomplished by using either a migration shift assay or plate-capture based assay.[5,8] However, a disadvantage of the probes based on ODN duplexes as opposed to a hairpin, i.e., single self-complementary ODN, is in the effort required for purification of components that constitute the probe. Moreover, since such a hairpin is capable of carrying an equal number of donor and acceptor dyes, variations occurring in the formulations of duplexes during their preparation would also be eliminated.

However, linking of two different fluorescent dyes to a single hairpin would require introducing 3′- and 5′-terminal linkers with differential reactivity toward dye derivatives, i.e., for example, 3′-thio and 5′- amino linkers.[9] After the modified ODN folds with the formation of a hairpin, the dyes linked to the ends of the ODN are in a close proximity resulting in partial or complete quenching.[9] Alternatively, the aminohexyl linkers bridging the dye to dC, dA, or dG bases can also be used for the same purpose. In the latter case, the linked dyes can potentially interact with nucleoside bases and/or get partially buried in the DNA duplex. As an alternative, we used previously developed novel phosphoramidite synthons that by design allow the amino-linkers to be positioned between any adjacent nucleosides, i.e., between any bases in the sequence.[10] This synthon was

incorporated into a loop region of a hairpin probe. The 3′-end of the hairpin carried a reducible dithio bond enabling modifications with maleimides of cyanine dyes. We chose Cy5.5 maleimide to be used as the donor and IRDye 800CW as the acceptor components of FRET pair for the following reasons: (1) the excitation maximum of the donor lies in the near-infrared range of light that corresponds to the maximum depth of penetration in tissue; (2) there is a large spectral emission/excitation spectral overlap suggesting high theoretical energy transfer efficiency; (3) both dyes are hydrophilic and 800CW dye is very stable. Here, we report fluorescent and transcription factor binding properties of this newly designed hairpin probe.

MATERIALS AND METHODS

Materials. The reagents for ODN synthesis and purification were obtained from Glen Research (Sterling VA). A nucleoside phosphoramidite synthon ATG-dG-P developed for introducing internucleoside linkers was synthesized using an approach described in ref 10. The chemical structure of ATG-dG-P is shown in the Supporting Information. Cyanine fluorochrome Cy5.5 maleimide and Cy5.5 NHS ester were purchased from GE Healthcare (Piscataway NJ); IRDye 800CW NHS ester was obtained from Li-COR (Lincoln NE). All other chemicals were obtained from Sigma-Aldrich (St. Louis MO).

Oligodeoxyribonucleotide Synthesis and Chemical Modification. The semiautomated ODN synthesis of three oligonucleotides (ODN1, ODN2, and H-ODN, the sequences are shown below and in Figure 2), ODN purification, and characterization were performed as in ref 10. The capped 3′-dithiolinker was introduced by using a commercially available CPG derivative (Glen Research). The conjugation of Cy5.5 (donor) or IRDye 800CW (acceptor) fluorochromes to the internucleoside amino linkers was initially performed using ODN1, ODN2, and H-ODN (Figure 1). The conjugation of the donor fluorochrome (Cy5.5 mono maleimide) to H-ODN was performed after reducing hydroxypropyl dithiopropyl linker at the 3′-end of the hairpin with 1 M DTT and precipitation of the obtained reduced intermediate from ethanol/sodium acetate. The obtained ODNs were isolated on a C18-HPLC column using a gradient of acetonitrile in 0.1 M TEAA, pH 7.0, precipitated from ethanol/sodium acetate and characterized by using electrospray mass spectrometry: ODN1-Cy5.5 5′-**AGCC**TG*(Cy5.5) GAAAGTCCCAC**ATCG**-3′ *m/z* calc 7525.3, found 7527; ODN2-CW800 5′-**CGAT**G*(800CW)TGGGACTTTCCA**GGCT**-3′ *m/z* calc 7633.2, found 7634; H-ODN: 5′-**CTG**GAAAGTCCCACTG*-AAGTGGGACTTTCCAGpO$(CH_2)_3SS(CH_2)_3$OH-3′ *m/z* calc.

Spectral Measurements. All UV spectral measurements were performed at room temperature with a Cary 50 spectrophotometer (Varian). All fluorescence spectral measurements were carried out at room temperature in quartz microcuvettes using a Cary Eclipse fluorescence spectrophotometer (Varian).

Preparation of Hairpin and ODN Duplexes. Hairpin and ODN duplexes were prepared by adding a prespecified amount of hairpin or mixing equimolar amounts of the corresponding ODNs dissolved in 25 mM Hepes, 1 mM $MgCl_2$, 50 mM NaCl, pH 7.4. The solutions were heated to 95 °C for 5 min to dissociate any intrastrand secondary structures, and allowed to cool at room temperature to attain equilibrium. Hairpin and duplex formation were confirmed by measuring UV and fluorescence spectra.

Electrophoretic Mobility Shift Assays (EMSAs). EMSAs were performed using a mixture containing hairpin or ODN duplexes 20 nM incubated 30 min at RT in a volume of 0.01 mL NF-κB p50/p65 solution in PPB. Samples were loaded and run on 15% TBE Ready Gels (Bio-Rad Laboratories, Hercules CA) using 0.5× TBE buffer. The gels were imaged and digitized using an Odyssey Infrared Imaging system (LI-COR Biosciences, Lincoln NE).

Fluorescence Measurements Using Odyssey Infrared Imaging System. (Li-COR Biosciences, Lincoln NE.) The instrument utilizes simultaneous solid diode excitation of fluorescence at 685 and 785 nm and measures emitted light by using a dichroic mirror which transmits light above 810 nm ("800 channel" fluorescence band) and reflects light below 750 nm ("700 channel" fluorescence band). Fluorescence signals were processed to filter out scattered and stray light. The obtained images (16 bit TIFF) were analyzed, colorized, and fused using *ImageJ* 1.38 (NIH).

Calculation of Experimental Distance Values (*r*). The efficacy of energy transfer depends on the distance between the donor and acceptor dyes.[11] The Förster distance R_0,[12] where 50% of the donor excitation energy is transferred to the acceptor, is defined as $R_0 = 9.78 \times 10^3 (\kappa^2 \eta^{-4} \phi_D J(\lambda))^{1/6}$ where ϕ_D is the fluorescent quantum yield of the donor, i.e., 0.28; κ^2 is a factor accounting for the relative orientation of transition dipole moments of donor and acceptor. Isotropic orientation of donor and acceptor in space was assumed so that $\kappa^2 = 2/3$;[13] η is the refraction index of the solvent (for water, $\eta = 1.33$); $J(\lambda)$ is an overlap integral of the donor absorption spectrum and the acceptor emission spectrum and is given by

$$J(\lambda) = \frac{\int_0^\infty F_D(\lambda)\varepsilon_A(\lambda)\lambda^4 \, d\lambda}{\int_0^\infty F_D(\lambda) \, d\lambda}$$

where $F_D(\lambda)$ is the fluorescence spectrum of the donor at wavelength λ, and $\varepsilon_A(\lambda)$ is the absorption spectrum of the acceptor at wavelength λ. The total electronic coupling was assumed as Coulombic coupling,

The donor and acceptor distance r was calculated as

$$E = \frac{R_0^6}{R_0^6 + r^6}$$

$$E = 1 - \frac{F_{DA}}{F_D}$$

where E is the efficiency of energy transfer, R_0 the Förster distance, and F_D and F_{DA} the relative fluorescence intensity of the donor in the absence and in the presence of the acceptor, respectively.

The efficiency of energy transfer (E) was calculated from donor quenching using the equation $E = 1 - F/F_0$, where the steady-state relative fluorescence intensity is measured in the presence (F) and absence (F_0) of the acceptor.[14,15]

Molecular Modeling. Modeling was performed with *Molecular Operating Environment v 2.0* software (MOE, Chemical Computing Group Inc., Montreal, CA) using *AMBER-94* force field parameter sets. The transition dipole moment directions of cyanine dyes were used as given in ref 16.

Statistical Analysis. All experiments were performed in triplicate. Values were expressed as the mean ± the standard deviation (SD) and compared using double-tailed unpaired *t* test with Welch's correction (*Prism 4.0*, GraphPad).

RESULTS

Using a two-stage synthesis that took advantage of differential conjugation chemistries, we synthesized a 32 bp ODN bearing thio- and amino- group terminated linkers that self-assembles into a hairpin structure (Figure 1, Figure 2A). Consequently, an NF-κB duplex binding site, (i.e., GGAAAGTCCC Ig-box derived p50/p65-binding sequence) is formed in the resultant

Spectral analysis of ODN probes: (A) absorbance spectra of Cy5.5- and dual Cy5.5/800CW labeled H-ODN probe; (B) absorbance spectra of Cy5.5-ODN1, 800CW-ODN2, and the resultant dual fluorescent duplex probe; (C) fluorescence spectra of Cy5.5-labeled hairpin and duplex probe showing Cy5.5 fluorescence spectra in the absence of FRET and the spectra of dual labeled probes with resultant FRET (shown by an arrowhead). Cy5.5 fluorescence was excited at 675 nm.

oligonucleotide duplex as a result of self-complementarity of the ODNs (Figure 2B).

Furthermore, the synthesized oligonucleotide was covalently modified with a pair of near-infrared fluorochromes capable of forming a FRET pair, i.e., one of the fluorochromes was conjugated to the internucleoside phosphate linker in the hairpin's loop (800CW, acceptor) and the other fluorochrome (Cy5.5, donor) was linked to the terminus. During the synthesis, 5′-terminal phosphorothioates were introduced to achieve higher stability against endonucleases.[4] The hairpin structure and the sites of fluorochrome dye conjugation are shown in Figure 2A. The linkers in the hairpin can theoretically exist in multiple conformations including limiting stretched or coiled states with the distance between nitrogen atoms of the linkers ranging from 23 to 70 Å. According to our calculations, the Förster distance between the NIR donor and acceptor pair (Cy5.5/800CW) corresponded to 68.8 Å. Actual FRET efficiency measurements obtained using the hairpin and duplex probes showed that FRET in the duplex probe was more efficient, i.e., 71% vs 56% FRET in the hairpin. On the basis of these results, we estimated that the distance between Cy5.5 and 800CW in the hairpin was close to the Förster distance, i.e., 66.3 Å, whereas in the duplex, the distance was 59.3 Å. The latter difference in distances between the donor and acceptor fluorochromes was confirmed by applying AMBER-94 force field parameter sets in Molecular Operating Environment (MOE, Figure 2A,B). The close quenching of the dyes was not anticipated due to the relative rigidity of the DNA duplex combined with the distance separating the donor and the acceptor that allows simplified assumption of Coulombic interaction as a dominant dipole coupling mechanism.[16] Spectral measurements demonstrated that the Cy5.5 absorbance spectrum in a hairpin linked to the 3′-Cy5.5 fluorochrome (Figure 3A, broken line) was similar to that of the hairpin with two linked dyes, i.e., Cy.5 and 800CW (Figure 3A, solid line). This result suggests that both fluorochromes do not engage in close interactions, i.e., there is no intramolecular π-bond overlap resulting in static quenching of fluorescence.

The same was true for a duplex probe consisting of two separate complementary ODNs that were used as a control in our studies. The spectrum of the duplex also resembled the superimposed spectra of individual dyes linked to individual ODNs (Figure 3B). The FRET effect in both hairpin and duplex was confirmed by measuring fluorescence spectra (Figure 3C). After exciting fluorescence at 675 nm (i.e., at the Cy5.5 excitation maximum in water), we observed a decrease of Cy5.5 fluorescence in a two-fluorochrome conjugate (hairpin-Cy5.5 −800CW) when compared to a single dye hairpin-Cy5.5 (Figure 3C). We also measured a concomitant 120% increase of fluorescence intensity in the range corresponding to the 800CW fluorescence peak (i.e., 790−810 nm). Therefore, our observations confirmed the role of Cy5.5 as a donor in FRET. Even higher loss of Cy5.5 fluorescence due to FRET was observed in the case of a duplex probe after hybridizing with 800CW-linked oligonucleotide. These spectra were used to calculate the Förster distances (see above).

Since the dual-fluorochrome labeled hairpin duplex has a fixed donor and acceptor stoichiometry (1:1 mol/mol), we decided to investigate whether the fluorescence intensity ratio of the donor/acceptor changes after the binding of a heterodimer of p50 and p65 NF-κB proteins, i.e., whether the hairpin probe responds to the binding. We used an electrophoretic separation technique to

The p50/p65 NF-κB complex migration is marked by an asterisk. The free duplex probe shown with an arrow (left); migration of the free hairpin probe is shown with an arrowhead (right). (B) Ratio of fluorescence intensities of 800CW to Cy5.5 (Fl800/Fl700) measured using the EMSA gels (shown in A) showing a lack of difference between free (bar 1) and NF-κB p50/p65 bound (bar 2) Cy5.5-ODN1/800CW-ODN2 duplex probe (p = 0.8) and significant differences between free Cy5.5/800-H-ODN hairpin probe (bar 3) and NF-κB p50/p65 bound hairpin probe (p = 0.01), n = 4.

separate hairpin ODN complexed with transcription factor from free hairpin (Figure 4A lanes 5−8). We also compared the obtained results with the data acquired using the control NF-κB binding duplex composed of two complementary ODNs (Figure 4A, lanes 1−4). To determine the efficacy of probe binding, we initially used a 6-fold molar excess of NF-κB proteins over ODN probes during the incubation and tested ODNs labeled with a single Cy5.5 dye only (Figure 4A lanes 1,2; 5,6). By measuring reference fluorescence intensity at 800 nm (excitation at 780 nm), which is not appreciably affected by p50/p65 binding in dual-labeled probes (Figure 4A, lanes 3,4 and 7,8), or by using a single dye labeled probe, we determined that overall the hairpin was binding NF-κB proteins more efficiently, whether single dye labeled (69 ± 20% vs 38 ± 11%) or dual labeled (76 ± 2% vs 69 ± 16%), where the first number corresponds to the bound fraction of the hairpin, and the second corresponds to the bound duplex fraction. Moreover, the binding of dual-labeled probes on average appeared to be more efficient than binding of single-labeled ones although the differences were statistically insignificant. In the absence of p50/p65, only about 0.5% of total fluorescence was detectable in the upper part of the plate in both cases.

Furthermore, we determined the ratio of normalized fluorescence intensities of Cy5.5 donor at 700 nm and 800CW acceptor dye at 800 nm in ODN bands after separating the complex from the free ODN probes using electrophoresis. We compared the relative changes of Cy5.5 dye fluorescence intensity after the probes were incubated in the presence of p50/p65 NF-κB proteins. A lack of change in Cy5.5 intensity would indicate that after the protein heterodimer binds to either probe (i.e., duplex or hairpin) there is no change in FRET efficacy. An increase of Cy5.5 fluorescence intensity would indicate that the FRET efficacy decreased, i.e., that the protein binding interferes with FRET. First, we determined the ratios of fluorescence intensities (FI_{800}/FI_{700}) in free ODN probes.

The FI_{800}/FI_{700} ratio was higher in the case of the duplex than the hairpin (Figure 4B). The reason for this is that, during duplex preparation for EMSA analysis, the addition of a small excess of ODN carrying 800CW acceptor fluorochrome is required to ensure that the thermodynamic equilibrium is shifted toward the formation of a duplex from the individual single ODNs. In contrast, thermodynamic stability of hairpins is high at intermediate temperatures, relatively low ionic strength (<0.2 M), and the low ODN concentrations used in our study. Therefore, only a minor fraction of hairpins went through a hairpin-to-duplex transition as observed during the electrophoresis (Figure 4A lanes 5, 7). In both single Cy5.5-dye labeled free duplex and free hairpin, the intensity of fluorescence in the 700 nm channel was 2 times higher than in the case of double-labeled ODNs, indicating the presence of FRET effect in double-labeled probes. The majority of the double-labeled hairpin ODN appeared as a yellow color band as an overlay of green (800 nm) and red (700 nm) pseudocolor fluorescence signals. The above was reflected in the ratios of measured band intensities (Figure 4B) where in the case of a double-labeled duplex probe the ratio of fluorescence intensities (FI_{800}/FI_{700}) is closer to 1:1 than in the case of duplex probe. The intensity ratio itself reflects the relative concentrations of the two fluorochromes and is affected by quantum yields of fluorescence for each fluorochrome and the sensitivity of the light detector. The binding of NF-κB proteins caused not only a shift in migration of the fluorescence band, but also a change in the measured FI_{800}/FI_{700} ratio. There was a statistically significant decrease of this ratio measured in the band corresponding to the complex of a double-labeled hairpin probe with p50/p65 (P < 0.05; Figure 4A, asterisk). There was a much smaller decrease of the FI_{800}/FI_{700} ratio in the case of the duplex probe (Figure 4B)

and the measured differences were insignificant. This result can be interpreted as a consequence of a high signal in 800 nm fluorescence channel created by trailing of the excess of 800CW labeled ODN.

DISCUSSION

The detection of functional protein and nucleic acid complexes capable of regulating gene expression in live cells and whole organisms is one of the major goals of molecular imaging. The imaging of transcriptional activation in cells has been previously accomplished by using genetic constructs, e.g., knocked-in reporter expression cassettes.[17,18] However, the genetic approach is limited in that the imaging signal by design is produced by the protein product of gene expression, which introduces a number of uncertainty factors, which include mRNA and protein stability. These issues potentially complicate the interpretation of results.

We have investigated an alternative method that may allow the direct comparative analysis of transcription factor activity or transcription factor concentration in cells or animals. Several rapid-acting primary transcription factors, including the important ubiquitous NF-κB, undergo maturation in the cytoplasm as a result of the processing of precursor proteins in response to extracellular signaling. We previously investigated the potential of NF-κB detecting probes, which were designed to take advantage of the NF-κB protein-mediated interference with FRET within double-labeled ODN duplexes which encode the transcription binding sequences.[4,5,8] In the current report, we compared a single hairpin-forming ODN and a duplex-forming ODN probe, both of which carried two NIR dyes separated by a similar number of nucleotide base pairs. By using an electrophoretic assay for separating transcription-factor bound and free probes, we could monitor changes in FRET efficacy by directly measuring a change in fluorescence intensity of the donor fluorochrome (Cy5.5) normalized by fluorescence of the acceptor (800CW) dye. The latter measurement did not depend on FRET efficacy, since the fluorescence of the acceptor fluorochrome 800CW was excited at its characteristic maximum. The obtained results showed that the hairpin design had both advantages and disadvantages. The main advantage is in that the dye ratio per probe was much easier to control in the case of the hairpin, which resulted in more reliable measurements of the effects of NF-κB proteins on donor fluorescence. The disadvantage was in the need to implement two different chemistries of dye conjugation in order to link one of the dyes to the ODN terminus in order to achieve a donor/acceptor 1:1 molar ratio.

In conclusion, we showed that dual-labeled fluorescent hairpin probes can be designed with two NIR dyes that form a FRET pair. With this design, an equimolar ratio of donor and acceptor dyes enables the detection of transcription factor protein binding to the probe. The relatively modest effect observed during the in vitro tests suggests that the probe design would benefit from further optimization in order to be useful for reliable intracellular imaging.

Supporting Information

ABSTRACT: Nanoscale materials have been envisioned as carriers for various therapeutic drugs, including radioisotopes. Inorganic nanoparticles (NPs) are particularly appealing vehicles for targeted radiotherapy because they can package several radioactive atoms into a single carrier and can potentially retain daughter radioisotopes produced by *in vivo* generators such as actinium-225 (^{225}Ac, $t_{1/2}$ = 10 d). Decay of this radioisotope to stable bismuth-209 proceeds through a chain of short-lived daughters accompanied by the emission of four α-particles that release >27 MeV of energy. The challenge in realizing the enhanced cytotoxic potential of *in vivo* generators lies in retaining the daughter nuclei at the therapy site. When ^{225}Ac is attached to targeting agents via standard chelate conjugation methods, all of the daughter radionuclides are released after the initial α-decay occurs. In this work, ^{225}Ac was incorporated into lanthanum phosphate NPs to determine whether the radioisotope and its daughters would be retained within the dense mineral lattice. Further, the ^{225}Ac-doped NPs were conjugated to the monoclonal antibody mAb 201B, which targets mouse lung endothelium through the vasculature, to ascertain the targeting efficacy and *in vivo* retention of radioisotopes. Standard biodistribution techniques and microSPECT/CT imaging of ^{225}Ac as well as the daughter radioisotopes showed that the NPs accumulated rapidly in mouse lung after intravenous injection. By showing that excess, competing, uncoupled antibodies or NPs coupled to control mAbs are deposited primarily in the liver and spleen, specific targeting of NP-mAb 201B conjugates was demonstrated. Biodistribution analysis showed that ~30% of the total injected dose of La(^{225}Ac)PO_4 NPs accumulated in mouse lungs 1 h postinjection, yielding a value of % ID/g >200. Furthermore, after 24 h, 80% of the ^{213}Bi daughter produced from ^{225}Ac decay was retained within the target organ and ^{213}Bi retention increased to ~87% at 120 h. *In vitro* analyses, conducted over a 1 month interval, demonstrated that ~50% of the daughters were retained within the La(^{225}Ac)PO_4 NPs at any point over that time frame. Although most of the γ-rays from radionuclides in the ^{225}Ac decay chain are too energetic to be captured efficiently by SPECT detectors, appropriate energy windows were found that provided dramatic microSPECT images of the NP distribution *in vivo*. We conclude that La(^{225}Ac)PO_4–mAb 201B conjugates can be targeted efficiently to mouse lung while partially retaining daughter products and that targeting can be monitored by biodistribution techniques and microSPECT imaging.

INTRODUCTION

Recently, there has been widespread interest in biomedical applications of nanomaterials for diagnostic and therapeutic purposes. Various inorganic nanoparticles (NPs) have been coupled to antibodies, and the resulting conjugates have been shown to act as targeted drug delivery systems or imaging agents.[1−8] Although monitoring the biodistribution of these NPs has been dominated by fluorescence imaging,[9−17] a few quantitative studies using radioactive NPs have been published.[9,18−21] Radionuclides with specific emission properties can be incorporated into NPs and used for radioimmunotherapy and radioimaging. Nanoparticles are particularly well-suited for the delivery of α- or β^--emitters for radioimmunotherapy. One advantage is the potential for containment of several radioactive atoms within a single carrier. This feature is useful when a target tissue has only a few receptors per cell, limiting the dose that can be delivered.[22] A second potential advantage is the sequestration of daughter radioisotopes from *in vivo* generators such as ^{225}Ac.[22−28] *In vivo* generators utilize parent radioisotopes that decay to radioactive daughters which themselves decay quickly, potentially amplifying the dose at a target site. One such generator is ^{225}Ac, which has four short-lived α-emitting daughters (^{221}Fr, $t_{1/2}$ = 4.9 min; ^{217}At, $t_{1/2}$ = 32.3 ms; ^{213}Bi, $t_{1/2}$ = 46.8 min; ^{209}Pb, $t_{1/2}$ =3.25 h) in two decay chains leading to stable ^{209}Bi (Figure 1).[23,24] Decay through these chains releases >27 MeV of energy, ~90% of which is associated with four sequentially emitted α-particles with individual energies ranging from 5.7 to 8.4 MeV.[23,29,30] Retaining the decay daughters of *in vivo* radioisotope generator systems at the site of targeting would

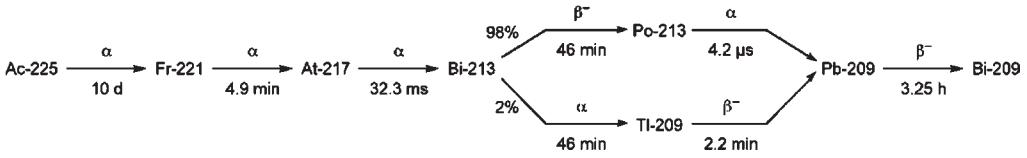

Figure 1. ^{225}Ac decay scheme. Decay of ^{225}Ac to stable ^{209}Bi releases >27 MeV of energy, ~90% of which is associated with four sequentially emitted α-particles with individual energies ranging from 5.7 to 8.4 MeV. Adapted from refs 23 and 24.

improve the specificity of the delivered absorbed dose by limiting nontarget toxicity.[29−34]

In this paper, we detail the synthesis and biofunctionalization of $LaPO_4$ (monazite) NP doped with ^{225}Ac [La(^{225}Ac)PO_4] to study the ability of metal phosphate nanomaterials to target biological epitopes and sequester radionuclides and daughter products, minimizing their release in biological systems. A model system of vascular targeting was used to evaluate NPs performance *in vivo*. This system has numerous advantages for testing the stability of radioconjugates and the retention of daughter radioisotopes from *in vivo* generators.[35,36] First, the radiolabeled monoclonal antibody 201B to murine thrombomodulin (TM) efficiently targets and delivers >30% of the total dose to lung endothelium, the major site of TM expression.[37,38] Targets on the surface of vasculature or circulating cells are necessary for efficient delivery of large constructs such as NPs [18,19] or liposomes,[39] since they do not effectively exit the vascular space.[21,40−42] Second, targeting with this antibody occurs within minutes of injection and depends on antibody specificity, not trapping of aggregated particles.[18,19] Third, radio-iodinated (^{125}I) mAb 201B is retained in lung with a half-life of 2−4 days,[38,39,43] allowing long-term studies. These properties permitted the first demonstration of specific targeting of the ^{225}Ac-doped NPs and determination of the fate of daughter radioisotopes (primarily ^{213}Bi) at various times after delivery. Through both standard biodistribution studies and microSPECT/CT (single photon emission computed tomography/X-ray computed tomography) imaging, we found that La(^{225}Ac)PO_4 NPs attached to a specific antibody can be targeted rapidly and efficiently to lung endothelium and that a significant fraction (~80%) of the daughter radionuclides are retained at the targeting site within 24 h. We conclude that $LaPO_4$ NPs have the potential to improve radioimmunotherapeutic efficacy of ^{225}Ac by effectively targeting the appropriate site while partially retaining daughter nuclides and that the distribution of ^{225}Ac and daughter radionuclides can be monitored by biodistribution techniques and microSPECT imaging.

EXPERIMENTAL SECTION

Reagents and Materials. The following chemicals were used as received: $LaCl_3 \cdot 7H_2O$ (99.9%, Aldrich), H_3PO_4 crystals (≥98%, Aldrich), tri-*n*-butyl phosphate (99%, EM Science), phenyl ether (99%, Acros), tri-*n*-octylamine (>90%, TCI), *n*-hexyl ether (>98%, TCI), hexadecane (≥99%, Aldrich), hexane (HPLC grade, 99.9%, Fisher), anhydrous tetrahydrofuran (≥99.9%, Aldrich), 6-aminohexanoic acid (≥99%, Aldrich), NaOH (99.99%, Aldrich), $Na_2HPO_4 \cdot 2H_2O$ (≥99%, Fluka), $NaH_2PO_4 \cdot H_2O$ (≥99.5%, Fluka), and tris(hydroxymethyl)aminomethane hydrochloride (tris-HCl, ≥99%, Fluka). All other chemical reagents used (HNO_3, HCl, and H_2O_2) were of analytical grade or better.

Nanoparticle purification was performed by dialysis using Spectra/Por regenerated cellulose membranes with a molecular weight cutoff of 10 (or 25) kDa. The dialysis tubing was washed thoroughly of all preservatives before use. Centrifugation was performed using an Eppendorf MiniSpin Plus (radius = 6 cm) in 1.5 mL polypropylene microcentrifuge tubes. Sonication was performed with a Branson microprobe sonicator at power setting 1. BALB/c female mice were obtained from Taconic, Germantown, NY. The monoclonal antibodies mAb 201B and mAb 33 were prepared and purified as previously described.[38,39] Clodronate-containing liposomes were obtained from the Department of Molecular Cell Biology VUmc, FdG, PO Box 7057, 1007 MB Amsterdam, The Netherlands.

Radioactivity Measurements. Gamma-spectrometry for *in vitro* measurements was performed using a calibrated intrinsic Ge detector (crystal active volume ~100 cm^3) and PC-based Multichannel Analyzer (MCA, Canberra). The detector has a resolution of 0.8 at 5.9 keV, 1.0 at 123 keV, and 1.9 at 1332 keV. Energy and efficiency calibrations were determined with γ-ray sources traceable to the National Institute of Standards and Technology. The γ-ray energies and their absolute intensities in parentheses used for determination of ^{225}Ac were 218.0 keV (11.58%) and 440.4 keV (26.1%) from the decay of ^{221}Fr ($t_{1/2}$ = 4.9 min) and ^{213}Bi ($t_{1/2}$ = 46.8 min), respectively.

An automated γ-ray scintillation counter consisting of a well-type NaI (Tl) detector (Perkin-Elmer Wizard model 1480) was used for the biodistribution studies detailed below. The two-channel discriminator windows were set to bracket the 218 keV (from ^{221}Fr) in the lower and 440 keV (from ^{213}Bi) in the upper energy windows. Organs (lungs, liver, spleen, and kidneys) harvested for the *in vivo* release of ^{213}Bi experiment were counted ~20 min after collection to ensure 99% equilibrium between ^{221}Fr and ^{225}Ac. The count rates in the lower window (^{221}Fr) and upper window (^{213}Bi) were indicative of ^{225}Ac and ^{213}Bi activities in the samples, respectively. Accordingly, the ^{213}Bi activities were corrected for decay during the 20 min waiting period. Alternatively, to ensure equilibrium between ^{213}Bi and ^{225}Ac, the same samples were recounted after 3 h and the count rates in the upper window were used for the equilibrium value of ^{213}Bi activity. The two approaches yielded similar results.

Preparation of $^{225}AcCl_3$. Actinium-225 was separated from a mixture of ^{225}Ra and ^{229}Th as described earlier.[44,45] The purified ^{225}Ac was evaporated to near-dryness on a hot-plate under an IR heat lamp, followed by addition of 0.5 mL of conc. HNO_3 and 3 drops of 30% H_2O_2 to the residue, and gentle evaporation of the solution to dryness. The unobservable residue was dissolved in 0.2 mL of 0.1 M HCl to afford $^{225}AcCl_3$ (with a negligible content of nitrate). Assay of a 5 μL aliquot of the purified ^{225}Ac sample (5 mCi) indicated the presence of <1% of ^{225}Ra and $<(1 \times 10^{-4})$% ^{229}Th.

Synthesis of La(^{225}Ac)PO_4 NPs. All reactions were performed in a radiochemical laboratory using a microscale apparatus consisting of a reflux condenser and inert gas adapter connected to a 5 mL Pyrex V-vial set within an aluminum heating block. For a typical preparation, 5.0 mg (14 μmol) of $LaCl_3 \cdot 7H_2O$ was

dx.doi.org/10.1021/bc100574f |*Bioconjugate Chem.* 2011, 22, 766–776

dissolved in 200 μL of 0.1 M HCl containing 5.4 mCi (0.41 nmol) of $^{225}AcCl_3$, and the solution was evaporated to dryness. An additional 200 μL aliquot of 0.1 M HCl was added to redissolve the $La^{3+}/^{225}Ac^{3+}$ mixture, and again the solution was evaporated to dryness. The solid was subsequently dissolved in a mixture of 75 μL of tri-*n*-butyl phosphate and 75 μL of phenyl ether and heated to 100 °C under vacuum with stirring. Residual water was removed by three cycles of evacuating for 30 min followed by backfilling with argon gas at this temperature. Concurrently, a solution was prepared containing 17.0 mg (0.17 mmol) of crystalline H_3PO_4 and 75 μL (0.17 mmol) of tri-*n*-octylamine dissolved in a mixture of 230 μL of tri-*n*-butylphosphate and 460 μL of *n*-hexyl ether by stirring at room temperature. Again, residual water was removed by three cycles of evacuation for 30 min followed by backfilling with argon gas at room temperature. A 60 μL aliquot of the H_3PO_4 solution (containing 14 μmol of H_3PO_4) was then added to the $La^{3+}/^{225}Ac^{3+}$ solution at 100 °C and the resulting reaction mixture was heated to 200 °C under an argon atmosphere and held at this temperature with stirring for 2 h. The initially colorless reaction mixture turned slightly brown during this time. After cooling to room temperature, the product was precipitated from the colloid by adding a mixture of 0.5 mL of hexane and 1.0 mL of hexadecane and then separated by centrifuging at 14 000 × *g* for 20 min. The product was washed with two cycles of redispersion in a mixture of 0.5 mL of hexane and 1.0 mL of hexadecane followed by centrifugation at 14 000 × *g* for 2 min. The activity of the product was 3.3 mCi, and the radiochemical yield for this step was 61%. The supernatant from each step was saved for radioactivity assay.

Surface Modification and Purification of La(^{225}Ac)PO_4 NPs. Freshly synthesized La(^{225}Ac)PO_4 NPs (containing 3.3 mCi of ^{225}Ac) were dispersed in 0.5 mL of tetrahydrofuran, added to a solution containing 200 mg of 6-aminohexanoic acid (AHA, 1.5 mmol) dissolved in 400 μL of 0.1 M NaOH, and stirred for 10 min at 90 °C. A 0.6 mL aliquot of 0.1 M tris-HCl buffer (pH = 9) was added to the mixture and stirred for an additional 5 min, whereby the solution clarified slightly. The surface-modified NPs were dialyzed (total sample volume ~1.5 mL) three times for 2 h each against 500 mL of 0.02 M phosphate buffer (pH = 6.5). Eventually, the NPs settled to the bottom of the membrane and a slightly discolored residue partitioned to the top of the dialysis solution. A 5 mL portion of each dialysate solution was saved for radioactivity assay. The activity of the final purified product was 2.4 mCi with an overall radiochemical yield of 44%. A portion of the surface-modified NPs (containing ~600 μCi of ^{225}Ac) was tested for *in vitro* leaching of radionuclides (detailed below), while the remainder (~1.7 mCi) was used for *in vivo* biodistribution and SPECT/CT experiments.

***In Vitro* Release of ^{225}Ac, ^{221}Fr, and ^{213}Bi from La(^{225}Ac)PO_4 NPs.** A sample of La(^{225}Ac)PO_4 NPs (~600 μCi) in 450 μL of phosphate buffer solution was dialyzed (total sample volume ~0.5 mL) against 500 mL of 0.02 M phosphate buffer for a period of 1 month. Periodically, a 5 mL aliquot of the dialysate was withdrawn and assayed for radioactivity. Samples were counted at 1 cm distance from the surface of a calibrated high-purity Ge detector (see Radioactivity Measurements section above). To determine ^{221}Fr activity, the time duration between withdrawal of the sample from the dialysis bag and start of the measurement was about 1 min, and the sample was counted for 2 min. This same measurement also provided quantitative measurements of ^{213}Bi activity. The quantity of ^{225}Ac was determined by recounting the same sample for 1 h using the same geometry on the following day.

Antibody Conjugation. The AHA surface-modified La(^{225}Ac)PO_4 NPs, containing ~1.6 mCi of activity and dispersed in ~1.5 mL of 0.02 M phosphate buffer (pH = 6.5), were sonicated at lowest power for 30 s. The NPs were then coupled to 300 μg of either mAb 201B or control antibody mAb 33 per 1 mg of NPs using conventional carbodiimide chemistry.[18] For this reaction, 2 μL each of 0.1 M 3-sulfo-*N*-hydroxysuccinimide (as sodium salt, sulfo-NHS) and 0.4 M 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC) aqueous solutions were added to the NP suspension and incubated for 10 min before addition of the mAbs. After overnight reaction at room temperature on a rotating disk to promote mixing, the solution was quenched by addition of glycine to a final concentration of 0.1 M. The suspension was sonicated as described above, and the mixture was separated on a 5 mL Aca34 Ultragel filtration column (Sigma) equilibrated in 0.01 M phosphate buffer, pH = 7.6, and 0.15 M NaCl (PBS) containing 5 mg/mL bovine serum albumin (BSA). The majority of the radioactivity (>90%) eluted in the void volume. The mAb-conjugated NPs were injected into mice tail veins within 1 h of preparation (see below).

***In Vivo* Mouse Biodistribution Experiments.** All experiments involving mice were performed according to the Institutional Animal Care and Use Committee of the University of Tennessee approved protocol 1502. Five-week-old female BALB/c mice (body mass ~15 g, 2 weeks postdelivery) were used for all biodistribution and imaging experiments. Three groups, consisting of five mice per group, were each injected intravenously (tail vein) with 0.2 mL of NP-mAb conjugates containing 5 μCi of ^{225}Ac. Groups 1 and 2 were injected with La(^{225}Ac)PO_4-mAb 201B conjugates, while group 3 was treated with La(^{225}Ac)PO_4-mAb 33, the control antibodies. Additionally, group 2 mice were injected with 0.1 mL of clodronate-containing liposome suspension 24 h prior to injection with radioactive NP-mAb conjugates. This procedure has been shown to enhance targeting of ZnS/Cd^{125m}Te NPs to endothelial tissue in the vascular model system by temporary depletion of phagocytic cells in the liver and spleen.[19,46,47] An additional separate group of three mice were also injected with 0.2 mL of La(^{225}Ac)PO_4-mAb 201B conjugates containing 5 μCi of ^{225}Ac for *in vivo* retention studies. Mice were housed with food and water *ad libitum* in a light/dark cycle environment before sacrificing at 1, 4, and 24 h postinjection for imaging and biodistribution experiments and 1, 4, 24, 48, and 120 h postinjection for *in vivo* retention studies.[18,48] Biodistribution studies were performed on lungs, liver, spleen, and kidneys to evaluate the amount of both ^{225}Ac and ^{213}Bi in target organs by measuring weighed tissue samples in a γ-ray scintillation counter at a specific time postsacrifice and again after the radioisotopes had achieved isotopic equilibrium (>3 h). Quantities of ^{225}Ac and ^{213}Bi present at the time of animal sacrifice were determined by appropriate crossover and decay corrections described above.

microSPECT/CT Imaging. Small animal imaging[48] was performed using a microCAT II+ SPECT dual modality platform (Siemens Preclinical Imaging, Knoxville, TN). Mice, treated 24 h prior with 100 μL of clodronate-containing liposomes, were injected intravenously with 0.2 mL containing 45 μCi of La(^{225}Ac)PO_4-mAb 201B conjugates (group 1, 2 mice per group); 45 μCi of La(^{225}Ac)PO_4-mAb 201B conjugates mixed with 300 μg of cold, uncoupled mAb 201B (competitor group 2, 1 mouse

per group); or 45 μCi of La(^{225}Ac)PO_4 mAb 33 conjugates (control group 3, 2 mice per group). Animals were sacrificed by overdose of isoflurane at 1 h postinjection and imaged via microSPECT/CT 3 h later when the ^{225}Ac and its daughters had reached equilibrium. SPECT data for the final images were acquired within energy windows of 12−268 keV at a detector operating bias of 760 V. Energy windows of 230−344 keV on detector 1 and 206−308 keV on detector 2, both operating at 700 V, were also examined. Data were collected using 2 mm pinhole collimators positioned ~60 mm from the center of rotation. Forty-five projections were acquired at 8° azimuths, each for a period of 60 s. Each projection was normalized using a corrected flood image to improve overall image quality and accuracy. The flood image was obtained by removing the collimator and detector housings. An ^{225}Ac source at equilibrium with daughter radioisotopes (^{221}Fr and ^{213}Bi) was used to uniformly flood both detectors over a 12 h time frame. The resulting data were normalized to unity and used to correct the individual SPECT projection data for nonlinear detector response. The data were reconstructed postacquisition using an 84 × 84 × 114 matrix, with isotropic voxels, and an ordered subset expectation maximization algorithm with eight subsets. Computed tomography (CT) data were collected following SPECT data acquisition[49] with 360° of rotation and one projection per degree. Data were acquired using an exposure time of 210 ms per projection and X-ray settings of 80 kVp and 500 μA. CT images were reconstructed in real time from a 512 × 512 × 768 matrix with 77 μm isotropic voxels using an implementation of the Feldkamp filtered back-projection algorithm (Cobra; Exxim Computing, Pleasanton, CA). CT and SPECT images were manually coregistered and visualized using the *Amira* image analysis software package (v 4.0; TGS, San Diego, CA). The CT data were rendered as a volume to aid in showing the location of the ^{225}Ac uptake. The SPECT data were also volume rendered in this fashion and registered to the CT data to better demonstrate the uptake of the different NP-mAb conjugates (or uncoupled mAbs). These volume renderings may not result in a linear scale that could reliably show relative uptake of the radioisotope.

RESULTS

Nanoparticle Synthesis and Surface Modification. The La(^{225}Ac)PO_4 NPs were synthesized by the reaction of $LaCl_3$ (14 μmol) with H_3PO_4 (14 μmol) in high-boiling organic solvents.[50] Solubility of the reagents in the solvents (*n*-hexyl and phenyl ether) is achieved by coordination of La^{3+}/$^{225}Ac^{3+}$ and H_3PO_4 by tri-*n*-butylphosphate and tri-*n*-octylamine surfactants, respectively. Addition of 5.4 mCi (0.41 nmol) of ^{225}Ac as the chloride salt to the reaction mixture ensured sufficient radioactivity for biodistribution and SPECT/CT imaging experiments while leaving the bulk chemical composition of the NPs unchanged. The synthesis is reproducible, and repeat experiments provided an average decay-corrected radiochemical yield of 66 ± 4% (n = 3). The NP surfaces were subsequently derivatized with 6-aminohexanoic acid (aminocaproic acid) using an adaptation of a reported procedure[51] and dialyzed against pH = 6.5 phosphate buffer solution for purification. Surface modification improved the aqueous dispersibility, although the product settles out of solution within 24 h, and the discolored residue at the top of the dialysis solution was likely displaced hydrophobic surfactants and solvents. The entire process, including synthesis, surface modification, and purification, took 24 h, with an overall average

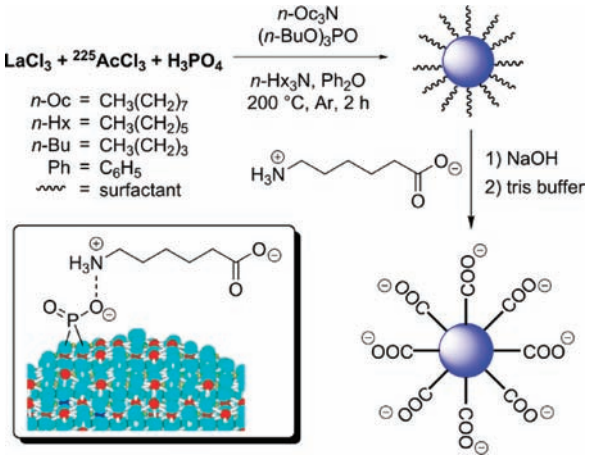

Figure 2. Schematic depiction of synthesis and surface modification of La(^{225}Ac)PO_4 NPs. Equimolar quantities of $LaCl_3$ (14 μmol) and H_3PO_4 (14 μmol), along with 5.4 mCi of $^{225}AcCl_3$ and tri-*n*-butylphosphate and tri-*n*-octylamine surfactants, react at 200 °C for 2 h within a phenyl ether/*n*-hexyl ether solvent mixture to form La(^{225}Ac)PO_4 NPs. The surfaces of the NPs were subsequently modified with 6-aminohexanoic acid. The amine moieties electrostatically bond to the phosphate groups on NP, leaving carboxylate functionalities at the surface.

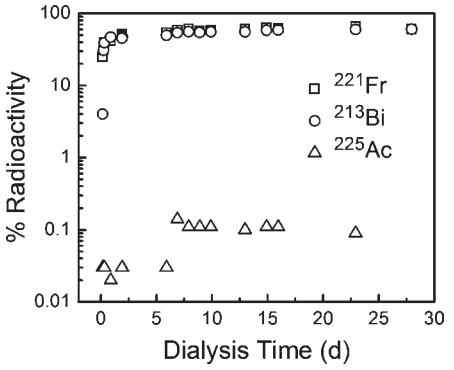

Figure 3. *In vitro* release of ^{225}Ac, ^{221}Fr, and ^{213}Bi from La(^{225}Ac)PO_4 NPs. While ^{225}Ac is nearly quantitatively retained, ~50% of ^{221}Fr and ^{213}Bi are released from the $LaPO_4$ NPs over a period of 30 days. Activity of ^{225}Ac = 600 μCi, pH = 6.5 phosphate buffer. For further details and determination of ^{221}Fr and ^{213}Bi activity, see Experimental Section.

decay-corrected yield of 47 ± 5% (n = 3). During this time, 7% of the initial radioactivity was lost to decay ($t_{1/2}$ = 10 d), and the remaining radioactivity was distributed among the residual organic supernatants and solvents in addition to the reaction vessel, stir bar, pipet tips, aqueous washes, and dialysis membranes. The NP synthesis and surface modification steps are depicted in Figure 2. Transmission electron microscopy of cold $LaPO_4$ NPs synthesized in an analogous protocol (no $^{225}AcCl_3$ added to the $LaCl_3$-tri-*n*-butylphosphate solution) confirmed the presence of unaggregated, 3−5-nm-diameter NPs.[52]

***In-Vitro* Release of ^{225}Ac, ^{221}Fr, and ^{213}Bi from $LaPO_4$ NPs.** To probe the release of ^{225}Ac as well as ^{221}Fr and ^{213}Bi daughters from the monazite host *in vitro*, a small portion of the surface-modified and purified La(^{225}Ac)PO_4 NPs was further dialyzed against pH = 6.5 phosphate buffer solution over a period of 1 month. Aliquots of the dialysate were assayed periodically to determine the amount of each radioisotope present in solution

dx.doi.org/10.1021/bc100574f |*Bioconjugate Chem.* 2011, 22, 766–776

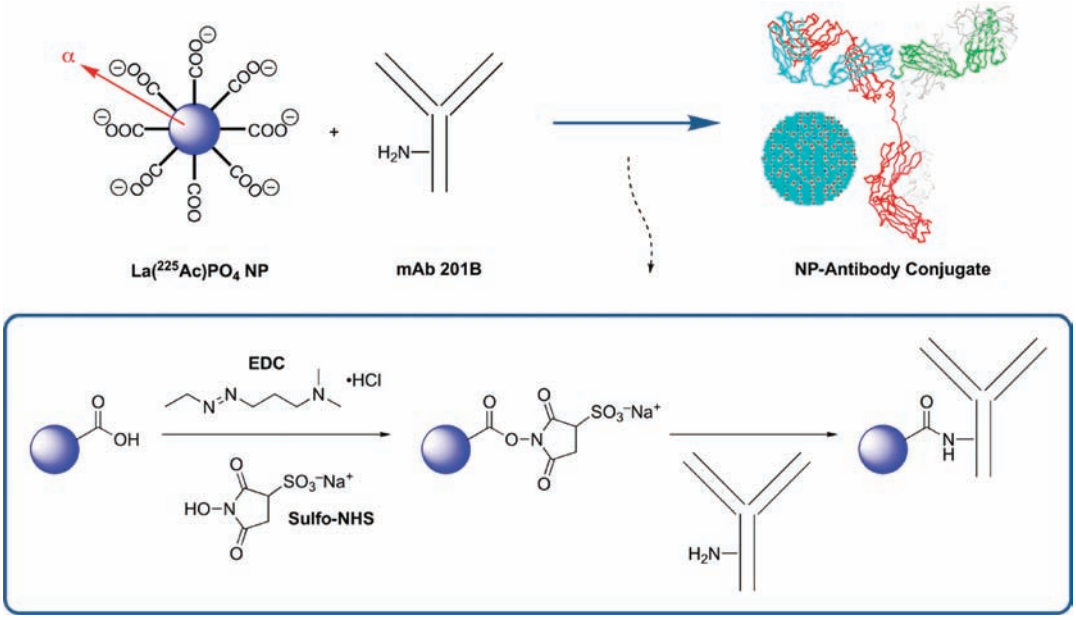

Figure 4. Schematic depiction of La(^{225}Ac)PO_4 NPs−mAb conjugation process. The 6-aminohexanoic acid modified La(^{225}Ac)PO_4 NPs with carboxylate moieties on the surfaces connect to free amine groups on the antibody via carbodiimide coupling to form the NP−mAb conjugate.

(Figure 3 and Supporting Information Table S1). The fraction of ^{225}Ac which was found in the dialysate increased from 0.03% of the initial quantity to 0.1% over the first 5−7 d and then remained constant over the next 25 d. Within the first 4 h, 24% of the initial quantity of ^{221}Fr was detected in the dialysate, which increased rapidly to ∼50% within 6 d and then remained relatively constant at ∼60% over the following 25 d. The fraction of ^{213}Bi in the dialysate was similar to that of ^{221}Fr, except for the first time point (3.8 h), at which time only 4% of ^{213}Bi was found in the dialysate. Note that, in Figure 3, the *y*-axis data are plotted on a logarithmic scale since the measured activity of ^{225}Ac in solution was vastly smaller compared to the activity of ^{221}Fr and ^{213}Bi. The higher initial fraction of ^{221}Fr measured in the dialysate is an indication that transport of ^{213}Bi through the NP lattice, the phosphate buffer, and/or the dialysis membrane is much slower than that of ^{221}Fr. Note that the majority of the ^{213}Bi detected in the dialysate originates from the decay of ^{221}Fr and is not directly released from the NPs. Eventually, an equilibrium was reached between ^{221}Fr and ^{213}Bi in the dialysate, since ^{221}Fr decays with a half-life ∼1/10 that of ^{213}Bi (see Discussion). These results indicate that, while the ^{221}Fr and ^{213}Bi daughters were only partially sequestered, the ^{225}Ac parent was nearly quantitatively retained in the $LaPO_4$ NPs.

Nanoparticle−Antibody Conjugation. The La(^{225}Ac)PO_4 NPs were coupled to mAb 201B and the control antibody, mAb 33, by linking the carboxylate moieties on the NP surfaces to amine groups on the antibodies through carbodiimide chemistry (Figure 4) as previously reported.[18,19] The molecular weight of a 5 nm diameter $LaPO_4$ NP with an estimated density of 5.12 g/mL[53] is 200 kDa. Using this estimate, the molecular ratio of mAb to NP in the reaction mix was ∼1:2.5. After coupling, the NP−mAb conjugates were briefly probe-sonicated at low power to break up any large aggregates and size-selected by gel filtration. The fraction of NP-mAb 201B or NP-mAb 33 that fractionated in the column void volume, corresponding to 1−5 MDa in size, comprised 95% of the initial radioactivity loaded on the column. Yields in excess of 50% were obtained, with 59 ± 9% (n = 2) and 92 ± 10% (n = 3) of the NP−mAb 201B conjugates eluting from the column in two separate experiments. Since the $LaPO_4$ NPs have molecular weights of ∼200 kDa, the 1−5 MDa gel fraction likely contains multiple NPs conjugated to multiple antibodies, and not aggregates of NPs.[18,19] A small portion of the remaining radioactivity consisting of large aggregated material filtered out on top of the resin. The specific activities of the NP preparations were ∼1.7 mCi of ^{225}Ac/mg of unconjugated $LaPO_4$ NPs, ∼1.2 mCi/mg of La(^{225}Ac)PO_4-mAb 201B conjugates, and ∼1.1 mCi/mg of La(^{225}Ac)PO_4-mAb 33-conjugates. (Values were corrected for 42 h of decay.) Once the NP−antibody conjugates were size-selected, they were diluted in BSA-containing buffer, where no significant aggregation over time was observed. Test samples were analyzed on SDS polyacrylamide gel electrophoresis. Greater than 95% of the radioactivity moved through the stacker gel (4% acrylamide) but did not enter the separation gel (10% acrylamide) confirming the gel filtration results that the NP-mAb conjugates were about 1−5 MDa in size.

Biodistribution of Targeted and Control NP−mAb conjugates in Normal and Clodronate-Treated Mice. La(^{225}Ac)PO_4 NP−antibody conjugates were injected intravenously into normal and clodronate-treated BALB/c mice within 1 h after column elution to avoid any aggregation or radiolysis that might occur, as well as minimize the loss of specific activity. Clodronate liposomes were injected 24 h prior to injection of NP−mAb conjugates. Groups of five mice were sacrificed at various periods (1, 24, and 48 h) postinjection and the organs collected for biodistribution analysis of radioisotopes in tissue by examining the γ-ray emissions of ^{213}Bi once in equilibrium with ^{225}Ac.

Within 1 h postinjection, the NPs coupled to mAb 201B (group 1 mice) primarily targeted the lungs (235% ID/g and ∼30% ID/lung), and while uptake measured in the liver (23.8% ID/g) and spleen (29.1% ID/g) was significant, the concentrations were approximately 10- and 8-fold less, respectively, compared to the concentration in the lungs (Table 1 and Supporting Information Figure S1). In contrast, the NPs coupled to the control mAb 33 (group 3 mice) did not accumulate

Table 1. Biodistribution of Targeted La(^{225}Ac)PO_4-mAb Conjugates in BALB/c Mice[a]

	injected dose per gram of tissue (ID/g) (%) ($\chi \pm \sigma$, n = 5)		
	time postinjection (h)		
tissue	1	24	48
	Targeted with mAb 201B (Group 1)		
Liver	24 ± 6	42 ± 12	48 ± 9
Spleen	29 ± 8	162 ± 33	297 ± 71
Kidney	2.9 ± 0.9	2.7 ± 0.3	2.7 ± 0.6
Lung	235 ± 29	184 ± 25	212 ± 28
	Clodronate-treated mice targeted with mAb 201B (Group 2)		
Liver	16 ± 7	20 ± 2	23 ± 3
Spleen	7.2 ± 2.1	18 ± 3	40 ± 3
Kidney	2.8 ± 1.6	1.6 ± 0.4	2.1 ± 0.4
Lung	279 ± 40	261 ± 20	276 ± 16
	Targeted with mAb 33 (Group 3)		
Liver	66 ± 3	74 ± 7	78 ± 4
Spleen	38 ± 8	66 ± 14	95 ± 19
Kidney	0.44 ± 0.03	0.38 ± 0.05	0.49 ± 0.04
Lung	2.0 ± 1.0	0.68 ±0.34	1.1 ± 0.2

[a] Number of mice per group = 5; Activity injected (i.v.) in each mouse = 5 μCi. Groups 1 and 2: La(^{225}Ac)PO_4 NPs-mAb 201B. Group 3 (control): La(^{225}Ac)PO_4 NPs-mAb 33. Group 2 mice were injected 24 h prior with 100 μL of clodronate-containing liposomes. Organs were analyzed in a γ-ray scintillation counter after ^{225}Ac and its daughters had reached equilibrium (~3 h).

significantly in the lungs (1.99% ID/g) but were predominately deposited in the liver (65.9% ID/g) and spleen (38.0% ID/g) (Table 1 and Supporting Information Figure S1). These results clearly indicate that the NPs bound to mAb 201B exclusively target the lungs and NP-mAb 33 conjugates do not. Over the course of 24 h, approximately 30% of the radioactivity in the NP-mAb 201B conjugates was lost from the lungs. By 5 d, the activity in the liver almost doubled from 23.8% to 42.1% ID/g. The concentration in the spleen increased dramatically from 29.1% to 161.8% ID/g, which is likely due to the atrophy of the spleen due to radiotoxicity, resulting in a much smaller organ weight (data not shown). After 24 h, activity in the liver for NP-mAb 33 conjugates increased by only 10% while the radioactivity in the spleen almost doubled. These trends continued in a similar fashion over the subsequent 24 h period for both NP-mAb 201B and NP-mAb 33 conjugates. Note that a small but measurable quantity of radioactivity was present in the kidneys and remained relatively constant over time due to the excretion of the ^{213}Bi daughter.

For clodronate-treated mice (group 2 mice), the NP-mAb 201B activity in the lung (279% ID/g) was higher compared to that in untreated mice (235% ID/g) at 1 h postinjection, while accumulation in the liver (15.9% versus 23.8% ID/g, respectively) and spleen (7.15% versus 29.1% ID/g, respectively) was lower (Table 1 and Supporting Information Figure S1). After 24 h, the activity of NP-mAb 201B conjugates in the lungs was reduced by only 10% in clodronate-treated mice and remained relatively constant thereafter compared to a 30% loss of radioactivity from the lungs of untreated mice. Accumulation of NP-mAb 201B

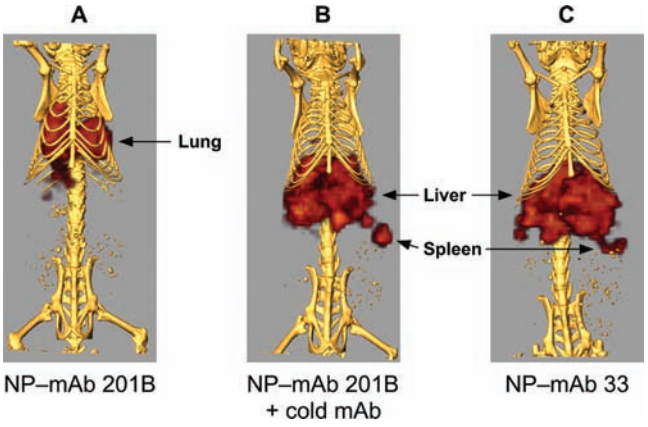

Figure 5. Whole body microSPECT/CT images of La(^{225}Ac)PO_4 targeted NPs of mice. NPs conjugated with mAb 201B target the lungs (A) but redistribute to the liver and spleen while in the presence of additional competing, unconjugated mAb 201B (B) as do NPs coupled to the control, mAb 33 (C). BALB/c mice treated 24 h prior with 100 μL of clodronate-containing liposomes were injected i.v. with 45 μCi of La(^{225}Ac)PO_4-mAb 201B (groups 1), 45 μCi of La(^{225}Ac)PO_4-mAb 201B mixed with 300 μg cold mAb 201B (competitor-group 2) or with 45 μCi of La(^{225}Ac)PO_4 mAb 33 (control-group 3). Animals were sacrificed by overdose of isoflurane at 1 h postinjection and imaged via microSPECT/CT 3 h later when the ^{225}Ac and daughters had reached equilibrium. Only the higher quality images per group of mice are shown. For further details, see Experimental Section.

conjugates in the liver and spleen of clodronate-treated mice increased slowly, but steadily, with time. Thus, temporary depletion of phagocytic cells enhanced both the accumulation and retention times in the lungs similarly to a previously reported study.[19]

microSPECT/CT Imaging. To confirm and illustrate the biodistribution data presented earlier, three-dimensional, whole-body microSPECT/CT images of mice treated with the following conjugates were collected: (A) La(^{225}Ac)PO_4-mAb 201B conjugates (NP-mAb 201B), (B) ~100-fold molar excess of uncoupled, cold, competing mAb 201B added prior to injection of NP-mAb 201B, and (C) control NP-mAb 33 conjugates. Mice were sacrificed 1 h postinjection and imaged 3 h postsacrifice when ^{225}Ac was in equilibrium with ^{213}Bi. The SPECT data, obtained by measuring the primary γ-ray emission of ^{221}Fr at 218 keV (the primary γ-ray of ^{213}Bi at 440 keV is too energetic to be collected efficiently by the thin microSPECT detectors), were superimposed onto the images of mouse skeletons from subsequent CT scans. The images clearly indicate that the radioactivity from NP-mAb 201B conjugates was present in the lungs while only slight levels of radioactivity were detected in the spleen and liver (Figure 5A). In contrast, when the NP-mAb 201B conjugates were mixed with an excess of competing mAb 201B, the majority of the radioactivity was found in the spleen and liver (Figure 5B). NPs conjugated with control mAb 33 likewise localized in the spleen and liver (Figure 5C). These results together show that the observed localization of NP-mAb 201B conjugates to the lung represents specific, antibody-mediated interaction with a saturable receptor.[38] Note that only the highest quality SPECT/CT images per group of mice are depicted in Figure 5.

***In Vivo* Release of ^{213}Bi following La(^{225}Ac)PO_4 NP Targeting to Mouse Lungs.** Data in Table 2 show the activity of ^{213}Bi daughter in the lungs and kidneys as a function of time

Table 2. *In Vivo* Release of ^{213}Bi following Targeting of La(^{225}Ac)PO_4-mAb 201B Conjugates to Lung of Mice[a]

time postinjection (h)	release of ^{213}Bi from lung (average % ± σ)	ratio of ^{213}Bi to ^{225}Ac activity in kidney (average ± σ)
1	39.8 ± 2.5 (n = 3)	12.1 ± 3.6 (n = 3)
4	34.9 ± 2.7 (n = 3)	10.4 ± 2.2 (n = 3)
24	20.1 ± 0.9 (n = 3)	8.5 ± 0.2 (n = 3)
48	24.5 ± 1.2 (n = 3)	8.3 ± 2.1 (n = 3)
120	13.1 (n = 1)	4.4 (n = 1)

[a] Activity injected (i.v.) in each mouse = 5 μCi of La(^{225}Ac)PO_4 NPs-mAb 201B. For determination of ^{213}Bi and ^{225}Ac activities, organs were assayed immediately after harvesting and then reassayed in 3−4 h, respectively. See Experimental Section for details regarding data treatment.

postinjection. Mice were injected with La(^{225}Ac)PO_4-mAb 201B conjugates and sacrificed at various time periods (1, 4, 24, 48, and 120 h) postinjection. The lungs, liver, spleen, and kidneys were collected for biodistribution analysis by examining the γ-ray emissions immediately after sacrifice and 3 h thereafter once ^{213}Bi and ^{225}Ac equilibrium was reestablished. The analysis showed a deficiency of ^{213}Bi activity (relative to the equilibrium ^{213}Bi/^{225}Ac ratio) in the lungs, liver, and spleen, and an elevated level of ^{213}Bi activity in the kidneys. Excess ^{213}Bi present in the kidneys is due to relocation of ^{213}Bi from elsewhere in the mouse. The data in Table 2 indicate that, at 1 h postinjection, ∼40% of ^{213}Bi produced from ^{225}Ac decay was released from the lungs. This result is consistent with the loss of ^{213}Bi from NPs *in vitro* (∼50%) detailed above. However, the release of ^{213}Bi from the lungs was reduced with time: after 24 h, only ∼20% of the ^{213}Bi was released from the lungs and just over ∼10% was released 5 d post-targeting. Although the data in Table 2 suggest an apparent increase for 48 h, considering the 5−10% errors associated with calculated values, it is believed that the general trend of decreasing release of ^{213}Bi holds. The data in Table 2 also indicate that, for the 1 h time point, the activity ratio of ^{213}Bi to ^{225}Ac in the kidneys was 12:1, which decreased over time, reaching a value of ∼4 after 120 h. This trend is also consistent with the decrease in ^{213}Bi release from the lungs over time.

DISCUSSION

Recent interest has focused on incorporating radionuclides with specific emission properties within nanoscale materials for site-specific radioimmunotherapy and diagnostic imaging. It is well-known that α-emitters can be very effective therapeutics against small, localized tumors.[34,35,37] In particular, 8 MeV α-particles (such those produced in the decay chain of ^{225}Ac) deliver their absorbed dose within a distance of ∼100 μm or approximately 10 cell diameters, thus limiting damage to non-target cells.[31] This potential has been realized in recent clinical trials of ^{213}Bi coupled to anti-CD33 mAb for treatment of acute myeloid leukemia.[34] Actinium-225 has been proposed as an attractive alternative to the ^{213}Bi treatment[25,54] since the former nuclide has a much longer half-life ($t_{1/2}$ = 10 d) and a single atom can produce 4 α-particle emissions with a total energy release of > 27 MeV per decay,[23,29,44] making it a potent radioisotope if all the energy is deposited at the tumor site. Two major issues limit this approach. The first problem is the overall low labeling yield of coupling antibodies to ^{225}Ac. In the best conventional method, ^{225}Ac is coordinated to DOTA (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), purified, and coupled to antibodies. The efficiency of the first (coordination) step is fairly high and the reaction can be forced to completion by increasing temperature and pH. However, the efficiency of the second (coupling) step at best is ∼10%.[25] The second problem is the potential loss of daughter radioisotopes (^{221}Fr and ^{213}Bi) from the chelator after decay of ^{225}Ac, which adds significantly to the *in vivo* global toxicity of ^{225}Ac.[55] The major advantage of incorporating ^{225}Ac within the NPs is to sequester the daughter radionuclides ^{221}Fr, ^{217}At, and ^{213}Bi at the site of targeting to mitigate the unintentional, nonspecific radiotoxicity.[54]

Monodisperse $LaPO_4$ NPs have been synthesized in both organic and aqueous media and investigated for their fluorescent and scintillation properties.[50,56−59] Rare earth phosphates with the monazite structure, such as bulk $LaPO_4$, have been studied extensively in the context of nuclear waste treatment for long-term sequestration of radioactive lanthanides and actinides. In the monazite crystal lattice, the lanthanide ion is bound to nine surrounding oxygen atoms[53] with sufficient energy to reduce leaching from energetic nuclear decay processes. Numerous studies have demonstrated that monazite is resistant to radiation damage, even under heavy metal ion bombardment.[60−62] The radiation-tolerant crystal structure of monazite, combined with its low aqueous solubility, makes it an ideal NP system for sequestering radionuclides and daughter products. Additionally, the small size of the NPs (∼5 nm) is much less than the average range (60−100 μm) of the 5−8 MeV α-particles in water, allowing facile escape of α-particles from the NP lattice.[23,44]

We have successfully and reproducibly synthesized 3−5-nm-diameter $LaPO_4$ NPs doped with ^{225}Ac with an overall radiochemical yield of 47 ± 5% (n = 3) following surface modification and purification. For *in vitro* and *in vivo* studies, the specific activity was ∼1.7 mCi of ^{225}Ac per mg of $LaPO_4$ (La/Ac ≈ 30 000). A 5-nm-diameter $LaPO_4$ NP contains on the order of 1000 La^{3+} ions, and thus, at La/Ac ≈ 30 000, there is approximately 1 Ac^{3+} ion per 30 NPs, leaving ample capacity for increased specific activity for therapy applications. Due to similar chemical properties and comparable ionic radii, the La^{3+} and $^{225}Ac^{3+}$ were expected to form isomorphous mixed crystals; i.e., $^{225}Ac^{3+}$ ions may replace La^{3+} ions in the crystal lattice and thus be "carried". Moreover, competition of common impurities in lanthanum (Fe^{3+}, Ca^{2+}, and Zn^{2+}) with $^{225}Ac^{3+}$ for cation sites within the monazite lattice is expected to be minimal. These hypotheses were confirmed in two ways. First, ∼66% of the initial $^{225}Ac^{3+}$ was captured in La(^{225}Ac)PO_4 NPs before surface modification and dialysis. Second, the observed loss of <0.1% of ^{225}Ac *in vitro* from La(^{225}Ac)PO_4 NPs indicates that Ac^{3+} is tightly bound within the NPs as expected. Data in Figure 3 (and Supporting Information Table S1) also show that ∼50% of the ^{221}Fr and ^{213}Bi (from the decay of ^{221}Fr) daughters were released from the NP lattice. The rate of release of these daughter radioisotopes remained constant *in vitro* over the 30 d observation period. While specific activities on the order of 1.7 mCi/mg of NP are sufficient for *in vivo* biodistribution and imaging studies, more ^{225}Ac can be incorporated within the NPs as required for therapeutic purposes.

Release of a daughter may result either from direct ejection during nuclear recoil or from leaching as a consequence of lattice damage. The recoiling ^{221}Fr nucleus has a kinetic energy of 107 keV and an expected range of about 20 nm in bulk monazite.[63,64] On this basis, one would expect essentially all of the ^{221}Fr would be ejected from a ∼5-nm-diameter particle. The observed 50%

retention of the daughters in the NP suggests that a fraction of the recoil energy may partition into translation of the whole NP rather than being dissipated entirely through atomic displacements, as occurs in the bulk, resulting in a shorter recoil range. Because momentum (p) is conserved in nuclear recoil ($p_\alpha = p_{recoil}$), the corresponding recoil energy depends on the mass of the recoiling particles. The minimum energy (E_r^{min}) available for bond breaking within the NP can be calculated as $E_r^{min} = E_r^{max} \cdot M_1/(M_1 + M_2)$, where E_r^{max} is the maximum recoil energy, M_1 is the atomic weight of the recoiling ^{221}Fr nucleus (221 amu), and M_2 is the molecular weight of the NP ($\sim 2 \times 10^5$ amu). At this limit, the result is $\sim 10^3$-fold reduction in the recoil energy and hence much shorter recoil range in the NPs versus bulk.[30] The actual recoil energy imparted to the ^{221}Fr nuclei most likely has a value between the two extremes. We are currently preparing ^{225}Ac-doped $LaPO_4$ NPs capped with a shell of cold $LaPO_4$ in an effort to reduce daughter escape through both direct ejection and leaching.

The dialysis experiments show a higher fraction of ^{221}Fr than ^{213}Bi in the dialysate after 4 h but essentially equal fractions at later time points over the span of 1 month. This observation suggests that transport of ^{213}Bi through the NP lattice, phosphate buffer, and/or dialysis membrane may be slower than that of ^{221}Fr. Because it is a singly charged alkali metal ion, and its phosphates exhibit considerable aqueous solubility, Fr^+ should not be strongly bound in the monazite lattice, nor should it be strongly adsorbed to monazite surfaces. Therefore, it is reasonable to assume that the ^{221}Fr concentration in the dialysate is representative of that inside the membrane. In contrast, Bi^{3+} is multiply charged, its phosphates exhibit poor aqueous solubility, and it may either be retained within or adsorbed to monazite surfaces. In solution, Bi^{3+} may further form colloidal hydroxides or phosphates that impede transport of Bi^{3+} ions through solution and the dialysis membrane. Very little activity (<1% of initial activity) remains associated with the dialysis membrane itself.

After synthesis, the NP surfaces were reacted with AHA, which improves dispersibility in water and phosphate buffer solution and provides functionality to connect the NPs to targeting antibodies. Although the product settles out of aqueous solution within 24 h, the NPs could be easily redispersed by sonication at low power. Meiser et al. first described surface modification of $LaPO_4$ NPs with AHA whereby the amine ends bind electrostatically to phosphate moieties on the NP surfaces, displacing existing surfactants, and forming $PO^-—^+H_3N$ ionic bonds that appear to be stable *in vitro*.[51] Consequently, free carboxylate functional groups are present on the NP surfaces. In this work, the *in vivo* results provided indirect evidence for the aqueous stability of the ionic linkages since retention of ^{213}Bi (and hence NP-mAb 201B conjugates) at the target site for 5 d suggests that the AHA remains bound to the NP surfaces over this time span as well. This stability is consistent with the findings of Xiong et al. in which AHA was used as a linker for up-converting nanophosphors.[65]

Once the NPs were synthesized, surface functionalized, and purified, they were coupled to either targeting or control antibodies. The carboxylate groups present on the NP surfaces react with exposed amine functionalities on mAb side chains, via conventional carbodiimide chemistry, to form amide bonds. Monoclonal antibody 201B has been shown to accumulate rapidly and efficiently in mouse lung and has been used in targeted imaging and therapy experiments.[18,19,37−39] The NP−mAb binding is to a lumenal epitope on the protein thrombomodulin (TM), which mediates targeting inside the vascular space. Since NPs, antibodies, and other large molecules do not exit the blood vessels readily, a vascular epitope is necessary for efficient targeting of NPs.[21,40−42] The targeting efficacy and biodistribution of the NP−antibody conjugates in female BALB/c mice was determined after sacrifice by measuring the radioactivity in major organs and confirmed through micro-SPECT/CT imaging of the entire animal. The biodistribution data as well as the SPECT/CT images clearly show that La-(^{225}Ac)PO_4 NPs conjugated to mAb 201B accumulated rapidly in the lungs. When excess uncoupled mAb 201B was added to the NP antibody preparation, the NPs accumulated in the liver and spleen, a result also observed in the NPs targeted with the control antibody (mAb 33). The biodistribution and imaging results are consistent with previous experiments involving ZnS/Cd^{125m}Te NPs where the NP-mAb 201B conjugates primarily targeted mouse lungs.[18,19]

The fact that the targeting process is dependent on the binding specificity of the mAb clearly differentiates it from the trapping of microaggregates such as microaggregated albumin (MAA) in small lung capillaries. In addition, targeted NPs are retained in the lungs for several days, whereas MAA is cleared from the lungs within hours. Furthermore, the NP−mAb conjugates are <100 μm in effective diameter, which leads to accumulation in the reticuloendothelial (RE) cells of the liver and spleen as opposed to trapping in lung capillaries.[19] All studies to date have shown that, once injected into the mice, NPs are recognized by the RE system chiefly of the liver and spleen.[41,66−68] Indeed, the biodistribution experiments detailed above show that the La-(^{225}Ac)PO_4-mAb conjugates are eventually redistributed to the liver and spleen. The efficient homing of mAb 201B targeted NPs to lung blood vessels partially circumvents the liver and spleen uptake by phagocytes, but does not eliminate it. [The NP-mAb 33 conjugates are quickly cleared from circulation postinjection (Table 1 and Supporting Information Figure S1)]. Thus, targeting can be further improved by injecting mice with clodronate liposomes, which temporarily inhibits the RE system by poisoning phagocytes.[19,46,47] Nanoparticle accumulation and retention in the lungs increased in clodronate-treated mice versus normal mice (Table 1 and Supporting Information Figure S1), which is consistent with, although not as dramatic as, the results in previous experiments involving ZnS/Cd^{125m}Te NPs.[19]

The goal of demonstrating at least partial retention of ^{225}Ac daughter radioisotopes within the NPs was achieved. As discussed earlier, at any time during the 1 month observation period, ~50% of the daughter radioisotopes remained within the NPs during *in vitro* leaching experiments. When the same tests were performed on NPs targeted to the lungs, at 1 h postinjection, ~50% of the daughter radioisotopes were retained at the target site. In contrast, while the ^{213}Bi loss from the NPs *in vitro* remained constant (~50%) for many days, the ^{213}Bi loss from the mouse lung decreased markedly (to ~10%) within 5 d after the initial targeting. We speculate that the NP-mAb 201B conjugates may have been taken into the endothelial cells lining the lung capillaries (endocytosed), such that ^{213}Bi released from the NPs was trapped within the cells, retarding its diffusion through the tissue and accounting for the decreased release over time. This hypothesis is supported by work of McDevitt et al., who showed that when ^{225}Ac was taken into prostate cancer cells, the daughter radioisotopes were trapped therein.[25]

This work with La(^{225}Ac)PO_4-mAb 201B conjugates demonstrates the potential for radioimmunotherapy and diagnostic imaging in the same NP−antibody constructs. Additionally,

the retention of ^{225}Ac as well as the partial *in vitro* and *in vivo* retention of the daughters, ^{221}Fr and ^{213}Bi, demonstrates the potential of NPs for trapping radionuclides after high-energy emissions. When ^{225}Ac is attached to antibodies with conventional molecular chelators such as DOTA, all the daughter radionuclides are released after the initial α-decay occurs.[25,30,33,55] Similarly, when ^{225}Ac is encapsulated in fullerenes, the daughter radioisotopes are released, likely due to breaking of the fullerene cage by the energy of nuclear decay recoil.[69,70] However, by employing $LaPO_4$ NPs to contain the radioisotopes rather than chelators, we show that nearly all of the ^{225}Ac and ∼50% of the ^{221}Fr and ^{213}Bi daughters are retained within the NPs *in vitro*, a dramatic improvement over conventional approaches. Although these NPs represent an improvement over other approaches, the extreme toxicity of α-particles from the escaped daughters ^{221}Fr and ^{213}Bi still presents a risk.[29,32,33] The toxicity could be reduced via the core−shell approach described above,[56] where a few nanometers thick shell of cold $LaPO_4$ can be epitaxially deposited onto the La(^{225}Ac)PO_4 core. The additional material at the surfaces should help with sequestering the decay daughters of ^{225}Ac doped within the NP cores.

CONCLUSIONS

In this paper, we incorporate ^{225}Ac within $LaPO_4$ NPs as a means of trapping radioisotopes and associated daughter products within an inorganic matrix to mitigate their unintentional release *in vivo*. We show via microSPECT/CT imaging and standard biodistribution techniques that La(^{225}Ac)PO_4 NPs coupled to the monoclonal antibody mAb 201B to murine thrombomodulin accumulates rapidly in mouse lung after intravenous injection. Furthermore, >80% of the ^{213}Bi daughter radioisotope is retained within the NP at the target site after 120 h *in vivo*. These results demonstrate the potential applicability of nanoscale materials for sequestering toxic daughter radionuclides. Improvements in the current NP technology will be necessary to achieve sufficiently complete daughter retention for clinical applications.

Near-Infrared pH-Activatable Fluorescent Probes for Imaging Primary and Metastatic Breast Tumors

Hyeran Lee, Walter Akers, Kumar Bhushan, Sharon Bloch, Gail Sudlow, Rui Tang, and Samuel Achilefu*

Department of Radiology, Washington University, St. Louis, Missouri 63110, United States

ABSTRACT: Highly tumor selective near-infrared (NIR) pH-activatable probe was developed by conjugating pH-sensitive cyanine dye to a cyclic arginine-glycine-aspartic acid (cRGD) peptide targeting $\alpha_v\beta_3$ integrin (ABIR), a protein that is highly overexpressed in endothelial cells during tumor angiogenesis. The NIR pH-sensitive dye used to construct the probe exhibits high spectral sensitivity with pH changes. It has negligible fluorescence above pH 6 but becomes highly fluorescent below pH 5, with a pK_a of 4.7. This probe is ideal for imaging acidic cell organelles such as tumor lysosomes or late endosomes. Cell microscopy data demonstrate that binding of the cRGD probe to ABIR facilitated the endocytosis-mediated lysosomal accumulation and subsequent fluorescence enhancement of the NIR pH-activatable dye in tumor cells (MDA-MB-435 and 4T1/*luc*). A similar fluorescence enhancement mechanism was observed in vivo, where the tumors were evident within 4 h post injection. Moreover, lung metastases were also visualized in an orthotopic tumor mouse model using this probe, which was further confirmed by histologic analysis. These results demonstrate the potential of using the new integrin-targeted pH-sensitive probe for the detection of primary and metastatic cancer.

INTRODUCTION

Optical molecular imaging often utilizes activatable probes where the fluorescence signal can be amplified by selective molecular events. These include the use of enzyme activity,[1−8] pH,[9−12] or the presence of reactive oxygen/nitrogen species [13] to visualize specific biological processes associated with the disease state. In particular, tumor-related enzyme activatable probes are widely used to visualize tumor biomarkers in vivo.[14−21] However, most tumor biomarkers are also a part of normal physiological processes, and thus, imaging sensitivity and specificity are hampered by high background signal from the nontarget tissues. Other tumor hallmarks such as acidosis and hypoxia have been explored as alternative approaches to enzyme-mediated imaging strategy to improve signal-to-background ratio. Acidosis has been an attractive target for tumor imaging,[22] and this strategy is based on the underlying principle that the tumor's extracellular metabolic microenvironment is relatively acidic because of the activated Na^+/H^+ exchanger (NHE1) and the H^+/lactate co-transporter systems in cancer cells.[23] However, there remains a challenge to design a probe targeting acidic tumor features. First, tumor cells have acidic interstitial extracellular pH (pHe, 6.2−6.9) rather than acidic intracellular pH (pHi) with a small pH difference from normal cells (7.3−6.4).[23] Second, the pK_a of the fluorescent probe has to match the acidic extracellular tumor pH. To overcome these challenges, Urano et al. recently developed pH-activatable BODIPY dyes that target the human epidermal growth factor receptor type 2 (HER2) for tumor imaging ex vivo.[11] The report demonstrated the potential of using pH-activatable dyes for tumor imaging with improved specificity by targeting acidic tumor organelles while minimizing signals from nontarget tissue. However, BODIPY dyes exhibit absorption maxima in the visible region where tissue penetration of light is shallow and thus less optimal for noninvasive in vivo imaging. Therefore, near-infrared (NIR) imaging probes are essential for deep tissue light penetration and low autofluorescence. In particular, NIR fluorescent probes that respond to pH changes within a physiologically relevant range would enhance tumor imaging while minimizing the background fluorescence.

With this goal in mind, we employed two complementary strategies to improve tumor targeting sensitivity and specificity of a NIR pH activatable probe: (1) conjugation of a pH-sensitive NIR dye to $\alpha_v\beta_3$ integrin receptor (ABIR)-avid peptide, cRGD, to promote selective accumulation of the probe in tumor cells and tissue; and (2) fluorescence amplification in the highly acidic lysosomes of tumor cells while minimizing fluorescence from nontarget tissues. RGD peptides have been shown to exhibit high binding affinity for ABIR that are up-regulated in tumor cells.[24−27] In addition, the new fluorescent probe is silent in the NIR window at pH > 5 but highly fluorescent in the acidic environment (pH < 5), with a pK_a value of 4.7 that closely matches lysosomal pH (Figure 1). We explored the probe's versatility as an imaging probe to detect primary and metastatic breast tumors in both subcutaneous and orthotopic mouse models.

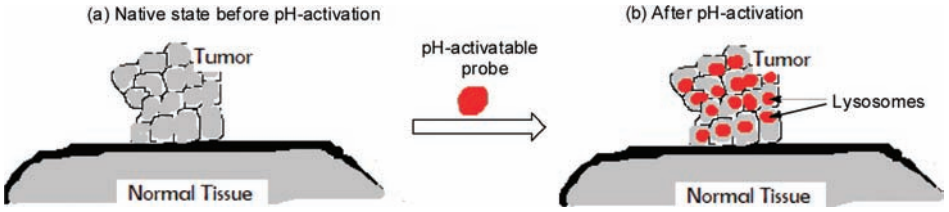

Figure 1. Selective pH activation of tumor in acidic lysosomal compartments. (a) Tumor in native state before pH activation and (b) selective activation of pH probe in lysosomal compartment of tumor cells with minimal fluorescence in nonlysosomal compartments of tumor cells and normal (non-target) tissue.

indole, sodium (2,3,3-trimethyl-3*H*-indole-5-yl)sulfonate (**2**) and Vilsmeier−Haack reagents **3** and **5** were prepared according to published procedures.[28,29] ^{1}H NMR data were recorded on a 300 MHz spectrometer at ambient temperature in DMSO-d_6 and referenced to tetramethylsilane (TMS) as an internal standard. High resolution mass spectra (HR-MS) were recorded on a hybrid linear ion trap-Fourier transform mass spectrometer.

Synthesis of pH-Activatable Dye 1. A mixture of the indole intermediate **2** (100 mg, mmol) and Vilsmeier−Haack reagent **3** (90 mg, mmol) were heated under reflux in the presence of sodium acetate (55 mg, 0.67 mmol) in 10 mL mixed solutions of CH_3CN/H_2O (95%/5%, v/v) for 20 h. After cooling, 5% of HCl in H_2O was added to the resultant mixture. MeOH was then added after the removal of H_2O, and the crude material was subjected to reverse-phase C-18 column chromatography eluting CH_3CN/H_2O to afford 46 mg of the desired dye. Yield 76%. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.47 (s, 12 H), 1.80 (m, 2H), 2.62 (m, 4H), 6.14 (br d, J = 14 Hz, 2H), 7.17 (d, J = 8 Hz, 2H), 7.61 (d, J = 8 Hz, 2H), 7.72 (s, 2H), 8.25 (br d, J = 14 Hz, 2H). NIR/vis: λ_{abs} = 778 nm, λ_{em} = 791 nm, $\varepsilon = 1.4 \times 10^5$ M^{-1} cm^{-1} (pH < 5), λ_{abs} = 516 nm (pH > 5), pK_a = 4.7. Φ_F (MeOH): 0.036. ESI-MS, m/z: 615 ($M^+ - Na + H$, 100%).

Meso-Carboxy Functionalized Dye 4. To a solution of sodium [1-(4′-sulfonatobutyl)-2,3,3-trimethyl-3*H*-indolium]-5-sulfonate (**2**, 45 mg, 0.17 mmol) was added Vilsmeier−Haack reagent **5** (35 mg, 0.086 mmol) in 10 mL mixed solutions of EtOH/acetic anhydride (1:1, v/v) in the presence of sodium acetate (14 mg, 0.17 mmol). This solution was then heated under reflux for 24 h. The reaction progress was monitored by UV/vis and LC-MS until starting materials **2** and **3** were almost consumed and the dye **4** was formed as the major product. After cooling, the crude material was subjected to reverse-phase C-18 column chromatography eluting with CH_3CN/H_2O to afford 11 mg of green dye powder. Yield 18%. ^{1}H NMR (300 MHz, DMSO-d_6) δ 1.26 (s, 12 H), 1.90 (m, 2H), 2.60 (m, 4H), 6.09 (br d, J = 14 Hz, 2H), 6.96 (br d, J = 14 Hz, 2H), 7.04 (d, J = 8 Hz, 2H), 7.34 (d, J = 8 Hz, 2H), 7.52 (d, J = 8 Hz, 2H), 7.61 (s, 2H), 8.15 (d, J = 8 Hz, 2H). NIR/vis: λ_{abs} = 755 nm, λ_{em} = 773 nm, $\varepsilon = 1.2 \times 10^5$ M^{-1} cm^{-1} (pH < 5), λ_{abs}= 513 nm (pH > 5). Φ_F (MeOH): 0.084. ESI-MS, m/z: 701 ($M^+ - Na + H$, 100%).

Peptide Synthesis and Conjugation with pH-Activatable Dye 4 (6, 7). Cyclic RGD **6** was prepared as previously described.[24] Conjugation of the peptide with dye was performed on solid supports. cRGD (**6**, 3.64 mg, 4 μmol), 2-(6-chloro-1*H*-benzotriazole-1-yl)-1,1,3,3-tetramethylaminium hexafluorophosphate (HCTU, 1.7 mg, 4.1 μmol), and *N*-methylmorpholine (0.45 μL, 4.1 μmol) were added at room temperature to **4** (2.8 mg, 4 μmol) in 0.2 mL anhydrous DMSO. The vortexing continued for 1 h at RT in the dark, and the reaction mixture was poured over 2 mL ice-cold water and purified by HPLC equipped with a C18 (22 × 250 mm, 10 μm) HPLC column. HPLC mobile phase was a mixture of solvent A = H_2O + 0.1% formic acid, and solvent B = CH_3CN + 0.1% formic acid at a flow rate of 12 mL/min. After lyophilization, compound **7** was obtained as a green powder (2.88 mg, 45%).

Deprotection of 7. Compound **7** was dissolved in a 1 mL mixture of 95% trifluoroacetic acid (TFA), 2.5% triisopropylsilane, and 2.5% water. The solution was vortexed at RT for 2.5 h, the residues were dissolved in 2 mL ice-cold water, and the product was purified by reverse phase HPLC as described above (retention time 23 min). After lyophilization, the dye−cRGD conjugate **8** (cyclo(Arg-Gly-Asp-D-Phe-Lys)-NH_2; 1.84 mg, 85%) was obtained as green powder. Yield 85%. MALDI-TOF MS m/z 1285 ($[M - Na + H]^+$, calcd 1285).

Spectral Properties and pK_a Measurements. The absorption and emission spectra were determined using a spectrophotometer and fluorometer, respectively. The molar extinction coefficient was determined by Beer's law at low concentrations of 0.1−0.6 μM. The relative fluorescence quantum yield was determined by using the equation[30]

$$\Phi_{F(x)} = (A_s/A_x)(F_x/F_s)(n_x/n_s)^2\Phi_{F(s)}$$

where $\Phi_{F(X)}$ is the fluorescence quantum yield, A is the absorbance, F is the area under the emission curve, n is the refractive index of the solvents used in the measurement, and the subscripts s and x represent the standard and unknown, respectively. Indocyanine green (ICG) was used as a reference standard, which has the value of 0.078 in MeOH.[31]

The spectral properties of NIR pH dye were determined in water, using a spectrophotometer for absorption and a fluorometer for fluorescence measurement. For pH titrations, dye **1** in water was acidified with dilute aq. HCl until the desired pH was obtained by titrating the solution with dilute aqueous NaOH with constant ionic strengths of 0.1 M. The pH of the solution was continuously measured with a pH meter. At each pH point, the absorption and fluorescence measurements were determined. The pK_a value was calculated from the sigmoidal dose−response curve fit using GraphPad *Prism 5.0* software.

Cell Culture. 4T1/*luc* breast cancer cells were purchased from Sibtech, and MDA-MB-435 breast cancer cells were purchased from ATCC. Cells were maintained in humidified atmosphere containing 5% CO_2 at 37 °C in DMEM culture medium supplemented with 10% fetal calf serum, 100 units/mL penicillin, and 100 units/mL streptomycin.

Tissue Homogenate Assays. Liver was dissected from rats after euthanasia and snap-frozen. Frozen tissue was homogenized

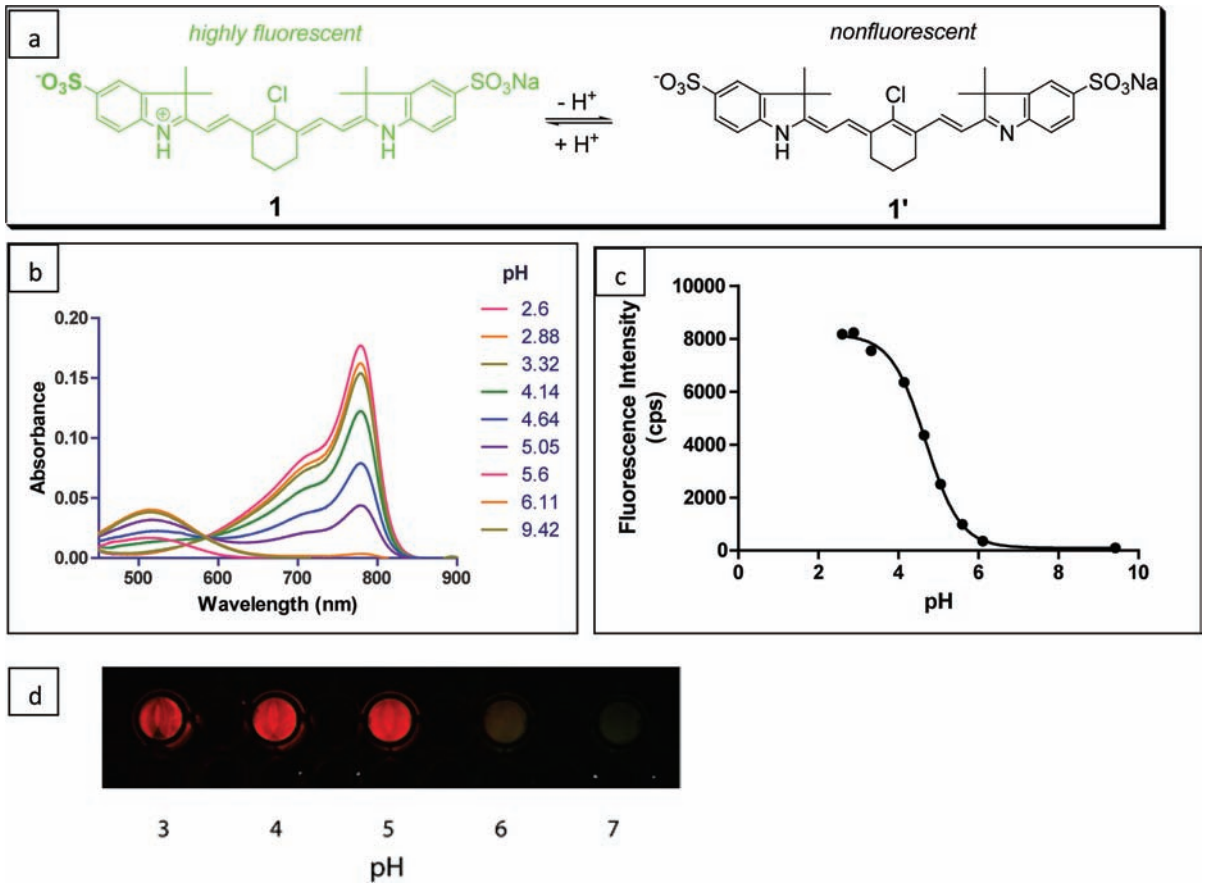

Figure 2. (a) Structure of pH-sensitive dye **1** in acidic and basic media. The reversible pH-sensitivity of dye **1** arises from the protonation−deprotonation of indolium nitrogen atom. (b) pH-dependent absorption spectral changes in the pH range 2.6−9.4. (c) pH response of dye **1** using fluorescence intensity at 795 nm to give pK_a of 4.7. (d) Fluorescence intensity change of dye **1** in liver tissue homogenate in the pH range 3−7.

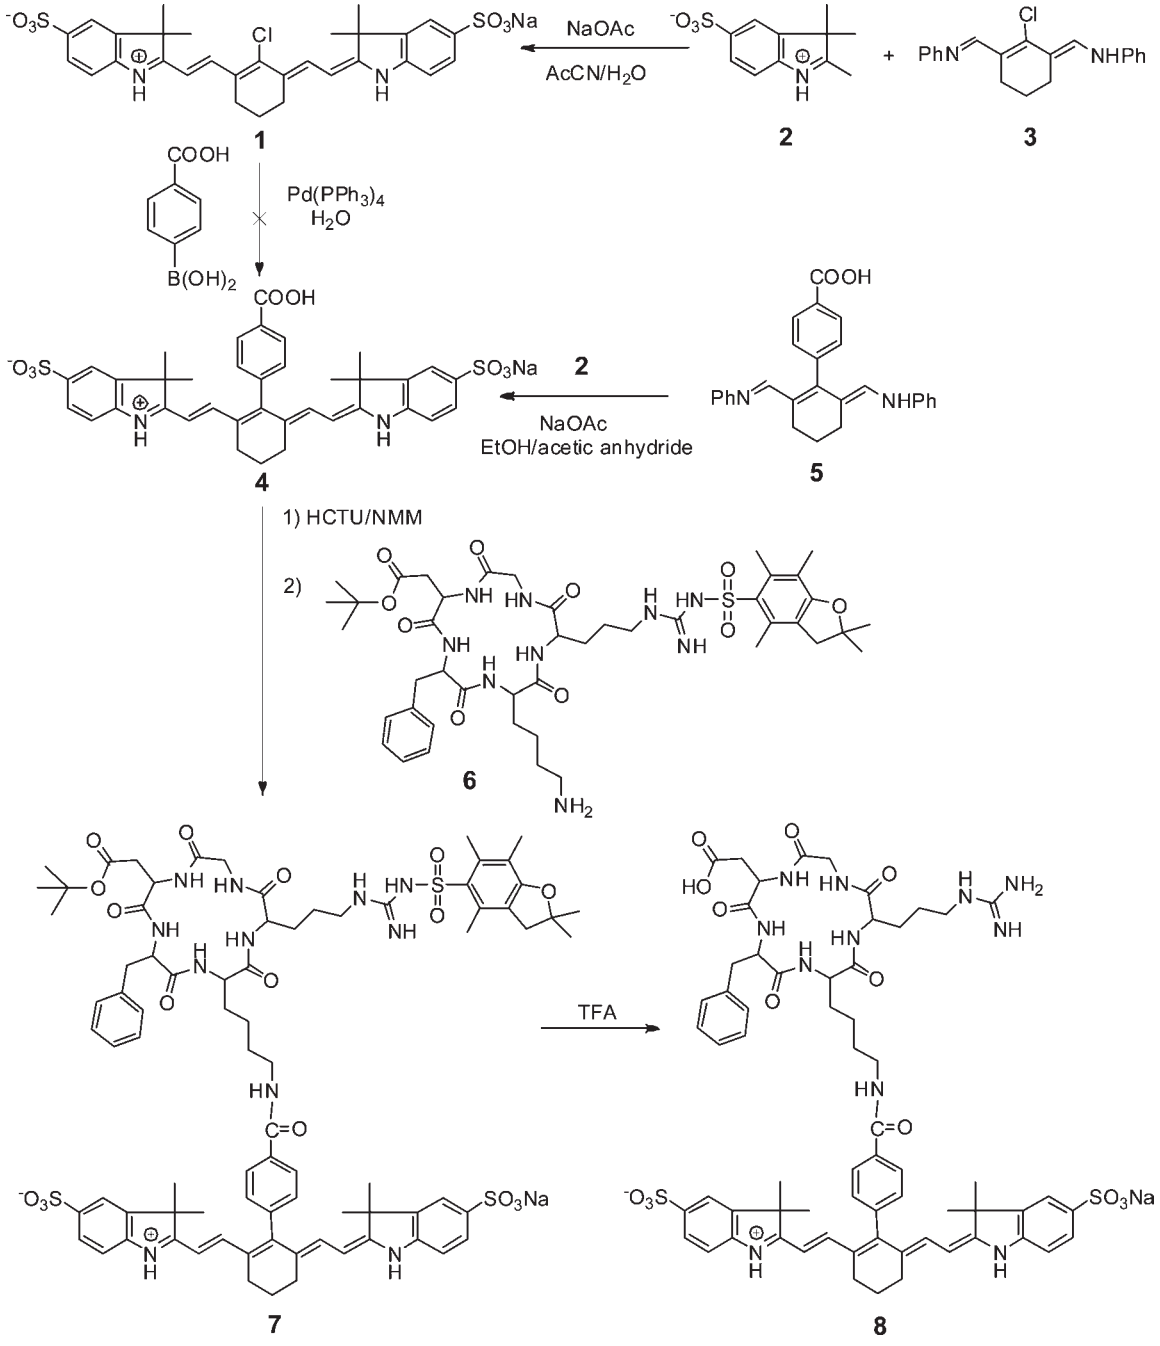
using a Bessman tissue pulverizer followed by addition of sterile saline. The pH values of tissue homogenates were adjusted by addition of HCl to give pH in the range 3−7. Tissue homogenate solutions were pipetted into 96-well microtiter plates. NIR pH-activatable dye **1** was dissolved in DMSO and added to homogenate wells and mixed for a total volume of 0.25 mL per well and dye concentration of 10 μM. Fluorescence imaging was performed using the Pearl NIR fluorescence imaging system (LICOR Biosciences, Lincoln, NE) and eXplore Optix time-domain diffuse optical imaging system (Advanced Research Technologies, Montreal, Canada). The Pearl imaging system acquires images in brightfield as well as excitation and emission at 685/710 nm and 785/810 nm, respectively. The eXplore Optix utilizes a 780 nm pulsed laser for excitation with emission detected at 830 nm using time-correlated single photon counting (TCSPC) for fluorescence intensity measurements.

Confocal Microscopy of Internalization of Dye 8 into MDA-MB-435 and 4T1/*luc* Cells. Cells were grown on LabTek microscope slides. Cells were treated for 1, 4, or 6 h with dye **8**. For lysosomal staining, 100 nM Lysotracker Green was added for the last 2 h of incubation. After treatment, cells were rinsed with PBS containing 1 mM $CaCl_2$, mounted with ProLongGold mounting medium (Invitrogen), and covered with a coverslip. The slides were imaged the next day using a 60×/1.20 M, 0.13−0.21 NA water immersion objective, as well as 488 and 633 nm lasers for excitation.



In Vivo and ex Vivo Tumor Imaging of Breast Cancer. All animal studies were performed in accordance with protocols approved by the Washington University School of Medicine Animal Studies Committee. Breast tumors were initiated in mice by injecting luciferase transfected mouse mammary carcinoma (4T1*luc*) cells either subcutaneously in 6-week-old female NCR nude mice or orthotopically into the mammary fat pad in 6-week-old female balb/c mice. After tumors had grown to 5−7 mm diameter, imaging studies were performed. The probe **8** was dissolved in DMSO then diluted with water for final concentration of 20 μM in 20% DMSO and 80% water. Probe **8** solution was injected intravenously via lateral tail vein (2 nmol/mouse, n =3). Fluorescence imaging was performed using the eXplore Optix TD-DOI system and the Pearl NIR imaging system at 1, 4, 6, and 24 h post injection. After the 24 h in vivo imaging time point, the mice were euthanized and organ tissues removed, placed on disposable Petri dish, and imaged as described above. Region of interest (ROI) analysis was performed using *ImageJ* image analysis software or Pearl imaging software. Mean fluorescence intensities were measured for each tissue to assess biodistribution of probe **8**.

RESULTS AND DISCUSSION

Synthesis and Spectral Properties of pH-Activatable NIR Fluorophore. For efficient tumor imaging, the pH-sensitive dye

Scheme 1. Synthetic Route to $\alpha_v\beta_3$-Targeting pH-Sensitive Dye 8

should possess the following features: (1) minimal or no fluorescence in neutral to basic media but highly fluorescent in acidic media (pH < 7); (2) maximum excitation wavelength in the NIR region (λ_{max} > 700 nm); (3) good water solubility; and (4) functionalizable group for conjugation to biomolecules. Among many pH-sensitive fluorophores, NIR-absorbing norcyanines satisfy most of these criteria. The typical molecular framework of norcyanines has a pH-sensitive site on the heterocyclic ring due to the presence of one or more nonsubstituted nitrogen atoms. Previously, our group and others reported the syntheses and spectral properties of NIR pH-sensitive dyes.[10,32] The limited water-solubility and lack of functionalizable groups for subsequent conjugation with biomolecules make these dyes less optimal for in vivo imaging. To overcome these drawbacks, we first developed a symmetrically substituted water-soluble norcyanine dye **1**. Dye **1** (Figure 2a) exhibited characteristic pH-dependent spectral changes, with absorption maxima in the NIR window in acidic media. A hypsochromic shift to the visible region was observed in basic media to give **1′** with calculated pK_a of 4.7 (Figure 2b,c).

This reversible, pH-dependent spectral shift arises from the protonation and deprotonation of the indolium ring nitrogen. The distinct characteristic alternation of π electronic charges that define a "polymethine state"[33] is lost during the deprotonation process, which results in the hypsochromic shift of the absorption maxima of these dyes from NIR to visible wavelength. To further

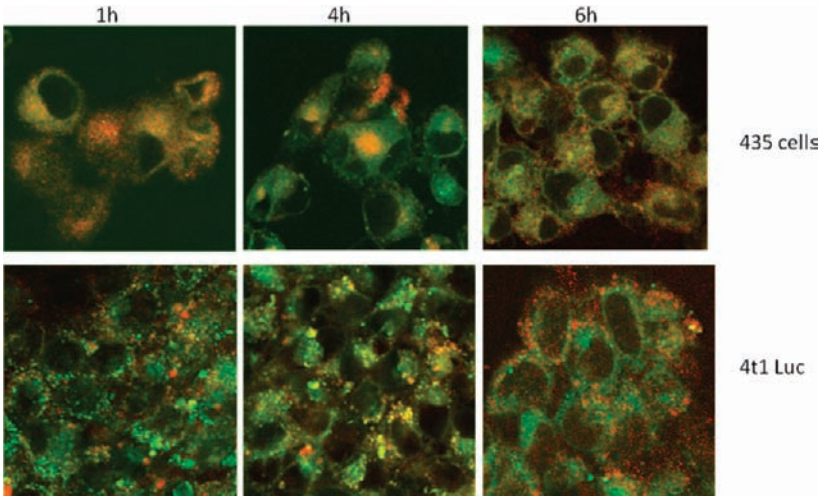

Figure 3. Lysosomal accumulation with MDA-MB-435 cells or 4T1 *luc* cells after incubation with **8** at 1, 4, and 6 h. When Dye8 (red) overlaps with the lysosomal stain (green) the resulting image is orange. The punctuate distribution of fluorescence is consistent with fluorescence activation occurring in the lysosomes.

explore the behavior of probe in tissue homogenates, fluorescence imaging was performed using homogenized liver tissues. The pH of tissue homogenates was adjusted by adjusting tissue pH with HCl to give the range 3−7. Expectedly, the fluorescence intensity of pH-activatable dye **1** at 800 nm was not detected at pH > 6, suggesting that the dye will have low background fluorescence in extracellular tissue (Figure 2d). In contrast, at pH < 6, bright fluorescence was observed. These data are in good agreement with the pK_a value determined in aqueous solution. The results indicate that fluorescence will be detected in acidic tissue compartments such as lysosomes.

Conjugation of pH-Sensitive Dye with a Tumor-Targeting cRGD for Selective Tumor Imaging. For efficient tumor targeting and selective activation of pH probes in the lysosomes, dye **1** was conjugated to ABIR targeting RGD peptides. The RGD sequence has high affinity for ABIR, which is overexpressed by many tumor cells. In addition, binding of this peptide to ABIR results in receptor-medicated endocytosis and lysosomal accumulation of the molecular probe in cancer cells. Synthesis of the molecular probe was achieved by introducing carboxylic acid functionality to the NIR pH-sensitive dye **1**. Previously, we reported the synthesis of *meso*-phenylcarboxylic acid functionalized dye using a modified Suzuki-Miyaura method.[34] However, attempts to incorporate free carboxy functionality using dye **1** failed to produce the desired dye **4**. The presence of unsubstituted heterocyclic nitrogen may promote a complex formation with palladium catalyst to give a dimeric isomer with absorption maxima in the visible range. Such compounds do not have apparent pH-dependent spectral properties. To overcome these drawbacks, Vilsmeier reagent **3** was first reacted with 4-carboxyphenyboronic acid under Suzuki-coupling conditions to give the intermediate **5**. Further heating of **5** with indolium moiety **2** in basic medium finally gave the desired dye **4** as a green solid.

Among many RGD peptides available to label the carboxy-functionalized fluorophore **4**, we chose cyclo(Arg-Gly-Asp-D-Phe-Lys)-NH_2 peptide. This peptide sequence includes an ABIR-targeting peptide motif as well as a free $-NH_2$ functionalizable group for conjugation to pH-sensitive dye **4**. Briefly, activation of carboxy-functionality of dye **4** with HCTU in *N*-methylmorpholine (NMM) followed by the reaction with the lysine residue of the cyclic peptide **6** provides the dye−peptide conjugate **7**. Removal of protecting groups with TFA affords the desired targeting probe **8**.

Internalization Studies. On the basis of the pK_a of the dye, selective accumulation of the probe in the late endosome or lysosome of tumor cells is necessary for fluorescence activation of the probe. Lysosomal uptake of pH probe **8** in 4T1/*luc* and MDA-MB-435 cells was evaluated by co-staining with Lysotracker green, a lysosome selective stain at 1, 4, and 6 h. Co-localization of pH-activatable probe **8** with Lysotracker and subsequent fluorescence amplification is evident in both cell lines, although higher accumulation of the probe was observed in MDA-MB-435. The cellular distribution of fluorescence was punctuate, as opposed to diffuse, which is consistent with fluorescence activation occurring in intracellular compartments such as the lysosomes and not in the cytosol. These data demonstrate the feasibility of using pH probe **8** for selective fluorescence activation in the target tumor lysosomes.

In Vivo Tumor Imaging of Breast Cancer 4T1/*luc*. To evaluate the feasibility of imaging tumor with pH-activatable probe, we developed subcutaneous 4T1/*luc* tumor in mice. The tumors were developed on the flanks of rodents, a model frequently used in our lab with minimal metastasis. The localized tumor allows direct assessment of the new probe in this confined in vivo environment. Selective uptake of the ABIR-targeted pH-activatable probe **8** for in vivo tumor imaging is shown in Figure 4A. The accumulation in tumor and subsequent fluorescence activation of pH probe **8** is evident as early as 1 h postinjection (Figure 4B) and reached maximum contrast by 4 h postinjection (Figure 4C).

In Vivo and ex Vivo Tumor Imaging of Orthotopic Breast Cancer 4T1/*luc*. Orthotopic tumor models closely resemble the biological environment of human tumors compared to subcutaneous xenografts models. To demonstrate the versatility of the pH probe **8** in imaging orthotopic tumor models and validate the selective amplification fluorescence in acidic compartment of tumor cells, we administered **8** to mice with orthotopic syngeneic breast tumors. In vivo fluorescence imaging results are shown in Figure 5. Immediately after injection, the fluorescence signal was equivalent to preinjection signal but increased with time. Fluorescence intensity increased in the tumor and liver regions,

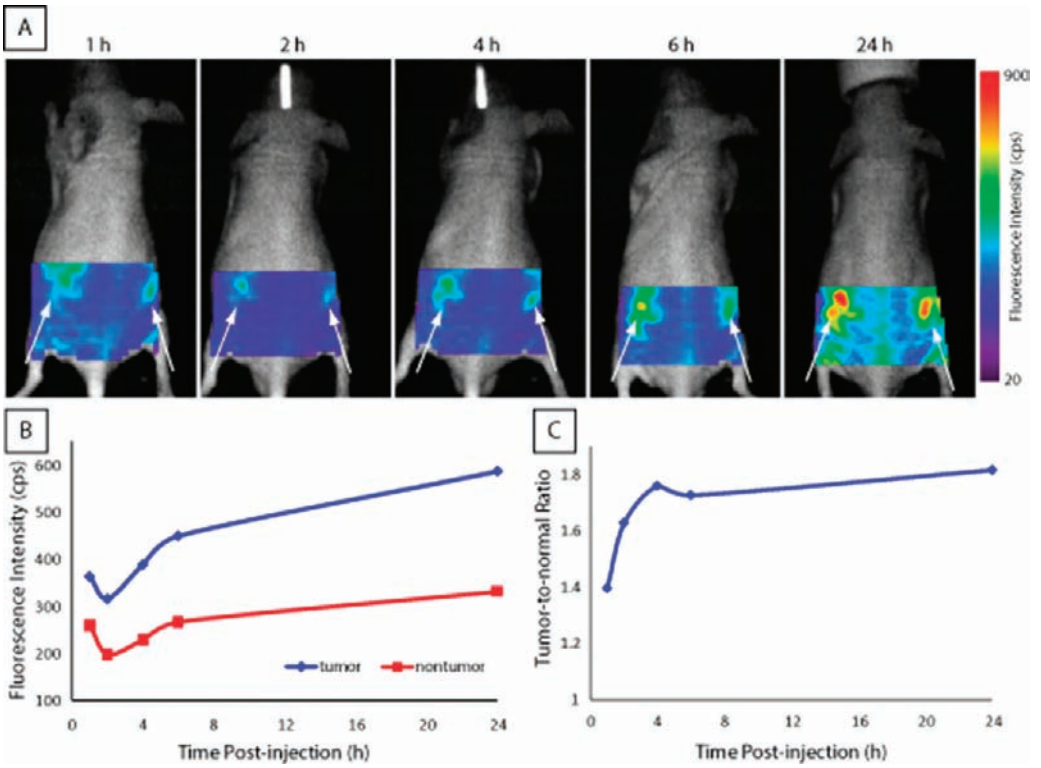

Figure 4. (A) Fluorescence image of NIR pH-activatable probe **8** in 4T1/*luc* tumor-bearing mouse at indicated times after intravenous administration. Arrows indicate bilateral subcutaneous tumor locations. (B) Plot of average fluorescence intensity values for tumor regions compared with nontumor control region selected in vivo imaging data. (C) Plot of in vivo tumor contrast at each time point showing that high contrast was achieved by 4 h and was maintained for at least 24 h postinjection.

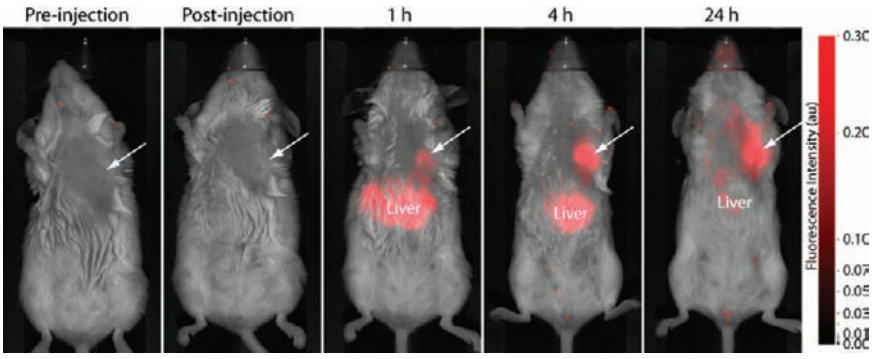

Figure 5. Fluorescence images of NIR pH-activatable probe **8** in orthotopic 4T1/*luc* tumor-bearing mice at various time points. Fluorescence intensity in the tumor region (arrow) increased with time relative to nontumor areas, reaching a plateau by 24 h.

indicating uptake of **8** in tumor cells and hepatocytes, respectively. The fluorescence intensity in the tumor region was high at 4 h after injection and remained high for up to 24 h postinjection. On the basis of previous studies with NIR dye-labeled cRGD peptides, uptake of the probe in the tumor cells is mediated by ABIR-endocytosis. As shown by the cell microscopy study, the observed fluorescence amplification is attributed to delivery of the probe to the lysosomes, which are more acidic than other cellular organelles. The increase in fluorescence is time-dependent and correlates with the trafficking of the probe from the early endosomes, through late endosomes, to the lysosomes. This pathway corresponds to an increase in intracellular acidity of the organelles. The liver is the primary excretion organ for this molecular probe, which is probably acidified in the process of the hepatobiliary excretion pathway. Fluorescence intensity increased to a lesser extent in other organs, reflecting the expression of ABIR in other tissues than the tumor.

The high tumor-specific contrast was confirmed by ex vivo tissue imaging (Figure 6A). Region of interest (ROI) analysis of ex vivo tissue fluorescence confirmed the tumor fluorescence signal enhancement observed in vivo (Figure 6B). Ex vivo fluorescence images of organ tissues show an excellent tumor-to-muscle ratio with an average value of 11:1 (tumor/muscle). High fluorescence was also detected in the kidneys and liver, indicating a mixed route of elimination from the body. Interestingly, tumor metastases (~1 mm) were detected in the lungs of

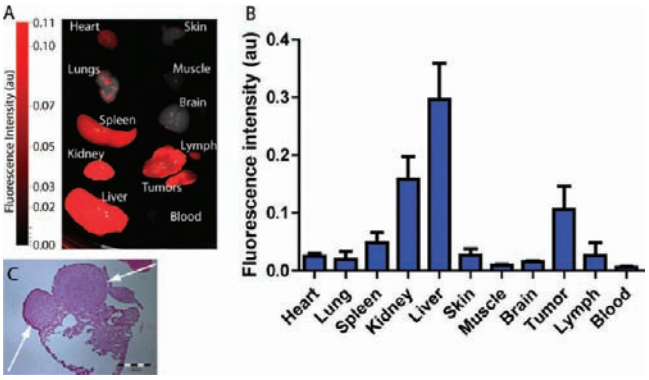

Figure 6. (A) Ex vivo fluorescence biodistribution image of **8** in organ tissues from 4T1/*luc* orthotopic tumor bearing mice at 24 h postinjection. (B) Fluorescence intensity data from ROI analysis of organ tissues. (C) Histologic confirmation of ~1 mm tumor metastases (arrow) in the lungs. Metastases to the lymph nodes were not confirmed.

one mouse by fluorescence imaging (Figure 6A), which was further confirmed by histological analysis (Figure 6C). It is well established that 4T1/*luc* tumors exhibit high metastastatic spread to the lungs.[35] The high fluorescence detected in these small tumor nodules further demonstrates the capability of detecting tumors in their natural environments due to the pH enhanced contrast mechanism.

CONCLUSION

We have developed ABIR-targeting NIR pH-activatable probe for in vivo imaging applications with high tumor selectivity. This pH-activatable probe offer several advantages over other NIR probes. First, NIR pH-sensitive probes are ideal for in vivo applications due to low background signal. Second, selective accumulation and subsequent fluorescence activation of pH-activatable probe in tumor lysosomes offer improved specificity with the high fluorescence signal from tumor compared to nontarget tissues. The results of in vitro and in vivo studies demonstrate the potential imaging applications of NIR pH-activatable probes for primary and metastatic tumor detection with high sensitivity and specificity.

Structural Perturbation of Human Hemoglobin on Glutathionylation Probed by Hydrogen−Deuterium Exchange and MALDI Mass Spectrometry

Gopa Mitra,[†] Monita Muralidharan,[†] Jennifer Pinto, Krishnamachari Srinivasan, and Amit Kumar Mandal*

Molecular Medicine & Clinical Proteomics, St. John's Research Institute, St. John's National Academy of Health Sciences, Bangalore, India

ABSTRACT: Glutathionyl hemoglobin, an example of post-translationally modified hemoglobin, has been studied as a marker of oxidative stress in various diseased conditions. Compared to normal hemoglobin, glutathionyl hemoglobin has been found to have increased oxygen affinity and reduced cooperativity. However, detailed information concerning the structural perturbation of hemoglobin associated with glutathionylation is lacking. In the present study, we report structural changes associated with glutathionylation of deoxyhemoglobin by hydrogen/deuterium (H/D) exchange coupled to matrix assisted laser desorption ionization (MALDI) mass spectrometry. We analyzed isotope exchange kinetics of backbone amide hydrogen of eleven peptic peptides in the deoxy state of both hemoglobin and glutathionyl hemoglobin molecules. Analysis of the deuterium incorporation kinetics for both molecules showed structural changes associated with the following peptides: α34−46, α1−29, β32−41, β86−102, β115−129, and β130−146. H/D exchange experiments suggest that glutathionylation of hemoglobin results in a change in conformation located at the above-mentioned regions of the hemoglobin molecule. MALDI mass spectrometry based H/D exchange experiment might be a simple way of monitoring structural changes associated with post-translational modification of protein.

INTRODUCTION

Glutathione (γ-L-glutamyl−L-cysteinyl−glycine), a tripeptide, is the most abundant antioxidant in erythrocytes. It plays a crucial role in detoxifying ROS (reactive oxygen species) like hydroxyl, peroxo, and superoxo radicals by shifting the redox equilibrium from reduced glutathione (GSH) to oxidized glutathione (GSSG). In normal adult erythrocytes, the concentration of reduced and oxidized glutathione is 2.3 mM and 0.004 mM, respectively.[1] The enzyme glutathione reductase reduces GSSG to GSH, thus maintaining the redox balance in the cell. Under conditions of oxidative stress, GSSG accumulates inside the cell and subsequently undergoes thiol exchange with accessible free cysteine residues in protein resulting in protein glutathionylation. Recent studies have demonstrated protein glutathionylation in various medical conditions.[2−6]

Hemoglobin, the key molecule in oxygen transport, is a tetrameric protein consisting of α and β globin chains in duplicate. The interactions between amino acid residues within inter and intra subunits of Hb govern the dynamic equilibrium between its oxy and deoxy states, which eventually drives its function. Glutathionylation of protein is an example of nonenzymatic post-translational modification. In glutathionyl hemoglobin (GSHb), glutathione binds to Cys93 of the β globin chain through disulfide bond. Glutathionyl hemoglobin has also been reported to have 6-fold higher oxygen affinity compared to normal hemoglobin (HbA). The Hill coefficient at half saturation (n_{50}) is 1.5 for GSHb compared to 2.9 in HbA. The above-mentioned functional abnormality is presumed to be due to structural modification in hemoglobin associated with glutathionylation. Several studies have reported glutathionyl hemoglobin as a possible biomarker of oxidative stress in various medical conditions such as hyperlipidemia,[7] diabetes mellitus,[7] Friedreich's ataxia,[8] atherosclerosis,[2] and chronic renal failure.[9] In addition, Garel et al. reported that glutathionylation of sickle hemoglobin (HbS) results in inhibition of HbS polymerization that manifests in reduction of sickling of erythrocytes.[10]

Using nuclear magnetic resonance spectroscopy, Craescu et al. reported structural perturbations in GSHb compared to HbA. These include perturbation of β-heme pocket particularly in F helix, destabilization in the salt bridge between βAsp94 and βHis146, and the hydrogen bond between βAsp99 and αTyr42 at the $\alpha_1\beta_2$ interface.[11] However, details concerning perturbation in the hemoglobin structure on glutathionylation have not yet been reported.

Hydrogen/deuterium (H/D) exchange coupled to mass spectrometry has evolved into a useful tool for understanding solution-phase dynamics of protein molecules. In this method, protein is exposed to a solvent having a different isotope of hydrogen, viz, deuterium. The exchange of hydrogen atoms takes place depending on the local environment, as well as the inductive and charge effect of neighboring atoms. Thus, hydrogens attached to oxygen, nitrogen, and sulfur atoms exchange rapidly, whereas those attached to carbon atoms exchange very slowly. The exchange of peptide backbone amide hydrogens is

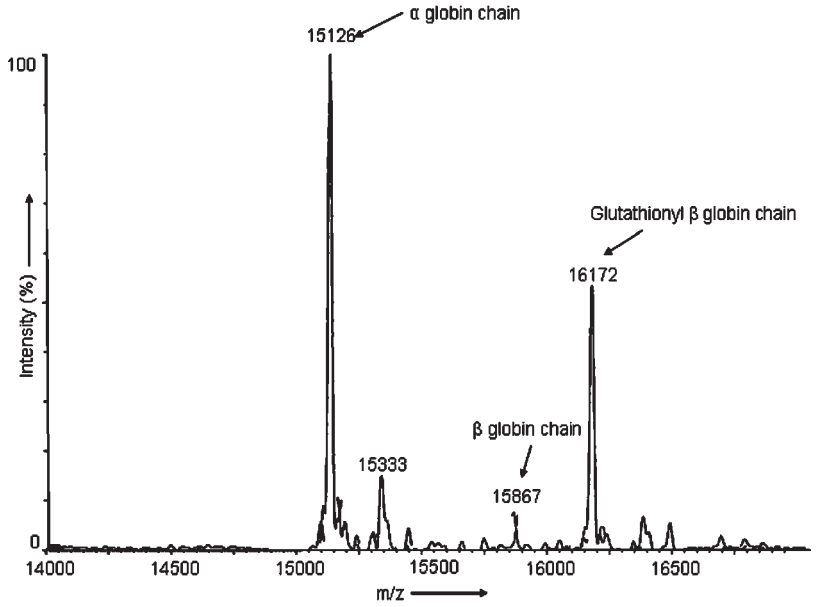

Figure 1. MALDI mass spectra of glutathionyl hemoglobin synthesized in vitro. Masses of different polypeptide chains are marked. The peak with m/z 16 172 represents the glutathionyl β globin chain, while peaks with m/z 15 867 and 15 126 represent the normal β and α globin chain, respectively.

mostly studied in the H/D exchange reaction with deuterium present in the surroundings, as they exchange on a convenient and measurable time scale. Depending on solvent accessibility and hydrogen bonding strength, the different peptide amide hydrogens undergo isotopic exchange at different rates. The side chain hydrogens exchange very rapidly, which are beyond the experimental measurement limit. Subsequent proteolytic cleavage of deuterated polypeptide followed by mass spectrometric measurement of proteolytic peptides provides the kinetics of deuterium incorporation. This in turn helps in understanding the conformational dynamics of the protein in those selective regions.

In the present study, we have investigated the structural and dynamic features of the deoxy state of normal hemoglobin and glutathionyl hemoglobin, through H/D exchange of peptide amide hydrogens probed by MALDI mass spectrometry.

EXPERIMENTAL PROCEDURE

Materials. Pepsin crystalline, deuterium oxide (99.9%), 2,2′-dithiodipyridine (2-PDS), Sephadex G-50, sodium hydrosulfite, reduced glutathione (GSH), and sinapinic acid were purchased from Sigma (St. Louis, MO). Synthesis-grade trifluoroacetic acid (TFA) was from Merck, Germany, whereas poly(ethylene glycol) (PEG) mix, the external calibrant for mass spectrometer, was purchased from Waters, Milford, MA. α-Cyano-4-hydroxy cinnamic acid (CHCA) was obtained from Fluka, Germany. The nitrogen controller unit for the mass spectrometer was supplied by Peak Scientific. All other chemicals used were of analytical grade.

Extraction of Hemoglobin. Whole blood was collected from healthy volunteers. Venous blood anticoagulated with EDTA was used for the study. Plasma was aspirated off after centrifugation of whole blood at 3000 rpm for 10 min at 25 °C. The erythrocytes, obtained as precipitate, were washed with 0.9% NaCl (aqueous) thrice and then lysed with eight volumes of ice cold distilled water. The hemolysate was centrifuged at 12 000 rpm for 10 min at 4 °C to remove the erythrocyte membranes. The clear supernatant was used to measure hemoglobin concentration using UV−vis (Shimadzu spectrophotometer) at 548 nm and concentration was calculated using ε = 12.51 mM^{-1} cm^{-1}.

Chemical Modification of Hemoglobin. Chemical modification of HbA with 2-PDS was performed using modified protocol as reported by Garel et al.[10] In short, 7.0 mM 2-PDS was incubated with 0.7 mM hemoglobin in 50 mM aqueous ammonium bicarbonate solution (pH 7.4) for 1 h at 0 °C. The excess PDS was removed by allowing the reaction mixture to pass through a Sephadex G-50 spin column. The thiopyridinyl hemoglobin was then allowed to react with reduced glutathione (GSH) in a molar ratio of HbA/GSH = 1/40 at 0 °C for 1 h. This reaction mixture was passed through a Sephadex G-50 spin column to remove excess GSH. To monitor the extent of glutathionylation of hemoglobin, 1 μL of the reaction mixture was mixed with 1 μL of sinnapinic acid (10 mg/mL in ACN/H_2O: 40/60, containing 0.1% TFA) and spotted on a MALDI plate. The ratio of ion counts obtained in the mass spectrum indicated more than 85% conversion of hemoglobin into glutathionyl hemoglobin (Figure 1).

Preparation of Deoxyhemoglobin. Hemoglobin (20 μM) was added to 50 mM ammonium bicarbonate/D_2O buffer (pD 7.4) containing 66 mM sodium hydrosulfite. The dissolved oxygen in solution was removed by sodium hydrosulfite to ensure that hemoglobin was in the deoxy state. Pure nitrogen gas was continuously bubbled through the solution at a rate of 40 mL/min to maintain the deoxy state of hemoglobin throughout the exchange experiment. The resulting solution was used for isotope exchange kinetics experiments. A similar procedure was followed for glutathionyl hemoglobin.

Hydrogen−Deuterium (H/D) Exchange Experiment. H/D exchange was initiated in hemoglobin by the addition of 15-fold excess of 50 mM ammonium bicarbonate/D_2O buffer (pD 7.4) at 25 °C with the concentration of hemoglobin at 20 μM. Isotope exchange kinetics was followed for 2 h. At different time intervals, 10 μL of reaction mixture was taken out and diluted with 90 μL of

dx.doi.org/10.1021/bc100602f |*Bioconjugate Chem.* 2011, 22, 785–793

ice cold aqueous 0.1% TFA (pH 2.5) to facilitate the quenching of the H/D exchange. Immediately, 2 μL of aqueous pepsin solution was added to the acidic protein solution (enzyme/substrate ratio 1:10, mol/mol). Digestion was carried out for 5 min at 0 °C. 1 μL of digested sample and 1 μL matrix (5 mg/mL of α-cyano-4-hydroxy cinnamic acid in 2:8:1 acetonitrile/ethanol/0.1% aqueous TFA, pH 2.5) were mixed together, and 0.5 μL of this mixture was spotted on the MALDI plate. The spot was dried rapidly using moderate vacuum in a desiccator, and following drying, the MALDI plate was then immediately loaded into a mass spectrometer for mass analysis. The above experimental procedure was followed to ensure that there was minimal loss of incorporated deuterium (back exchange of D to H) in the exchange experiment.[12]

Completely deuterated hemoglobin (100% control) was used to calculate the number of deuterium lost during the analysis, whereas unlabeled hemoglobin (0% control) was used to calculate the number of deuterium gained during analysis. For 0% control experiment, hemoglobin was dissolved directly into a solution equivalent to postquench conditions containing pepsin. For 100% control experiment, the isotope exchange reaction was continued for 6 h followed by digestion and analysis. The 100% control data and 0% control data were used to calculate the molecular mass of peptides in conditions where hemoglobin was fully deuterated and not deuterated, respectively.

In H/D exchange experiments, the exchangeable hydrogen present in the side chain group of amino acid residues and that in terminal groups undergo exchange and back exchange at a rapid rate. Therefore, in the present study the exchange kinetics of backbone amide hydrogens were monitored. The occurrence of back exchange of amide hydrogens during analysis was addressed using the procedure described by Nazabal et al.[12] In brief, the exchange reaction was quenched by rapid cooling and acidification, which increased the half-life of back exchange by several orders of magnitude.[13,14] For example, one unit decrease in pH leads to a 10-fold decrease in exchange rate of peptide amide hydrogen, which attains minima at pH 3. Similarly the above exchange rate decreases by 3-fold per 10 °C decrease in temperature.[15] MALDI MS spectra were collected on all samples.

Mass Spectrometry. All MS analyses were performed on a Waters Synapt HDMS mass spectrometer equipped with a MALDI source. Analyses were conducted in the positive ion mode. MALDI MS spectra for proteolytic peptides were recorded in the 900 to 3500 m/z range in positive ion V mode using 200 Hz solid-state laser (λ = 355 nm). The mass spectrometer was calibrated using an external calibrant, PEG mix. Mass spectra were acquired by integrating an average of 50 shots/spot and analyzed using *MassLynx* software version 4.1.

Sequencing of Peptic Peptides. Tandem mass spectrometry was used to obtain sequence information of peptide molecular ions. Peptide digest solution (1 μL) was mixed with 1 μL of α-cyano-4-hydroxy cinnamic acid matrix solution and 1 μL of the mixture was spotted on the MALDI plate. Mass spectra were recorded for the digest, and subsequently, tandem mass spectra of selected precursor ions were acquired using 200 Hz laser (λ = 355 nm) and by increasing trap collision energy. The generated tandem mass spectra were analyzed by manual assignment of product ions to obtain sequence information of precursor ion.

Data Analysis. The spectra were baseline corrected and the isotope averaged centroid mass of each molecular ion (M_t) was measured using the software *HX Express* Version Beta (http://www.hxms.com/HXExpress). The number of deuterium incorporated in a peptide at a given time t was calculated as per the following eq 1:[16]

$$D(t) = \frac{(M_t - M_0)}{(M_\infty - M_0)} \times N \quad (1)$$

where M_t is the observed centroid mass of the peptide at time t, M_0 is the observed mass at zero time control experiment, M_∞ is the observed mass for a fully deuterated experiment (100% control experiment), and N is the total number of backbone amide hydrogens in the peptide. Four data sets obtained for each peptide ion were averaged. At a fixed pH and temperature and in the presence of large excess of D_2O, the isotope exchange of each peptide amide hydrogen follows pseudo first order kinetics. In principle, for a peptide fragment consisting of N amide hydrogens, the deuterium content can be described by summation of N exponential terms[17]

$$D = N - \sum_{i=1}^{N} \exp^{-k_i t} \quad (2)$$

where D is the deuterium content of the peptide at time t, k_i is the rate constants for ith amide hydrogen, and N is the total number of peptide amide hydrogens present in the fragment.

In practice, peptide backbone amide hydrogens can be categorized on the basis of their corresponding H/D exchange rate constants into fast, intermediate, and slow exchanging group according to the following equation:

$$D = N - Ae^{-k_1 t} - Be^{-k_2 t} - Ce^{-k_3 t} \quad (3)$$

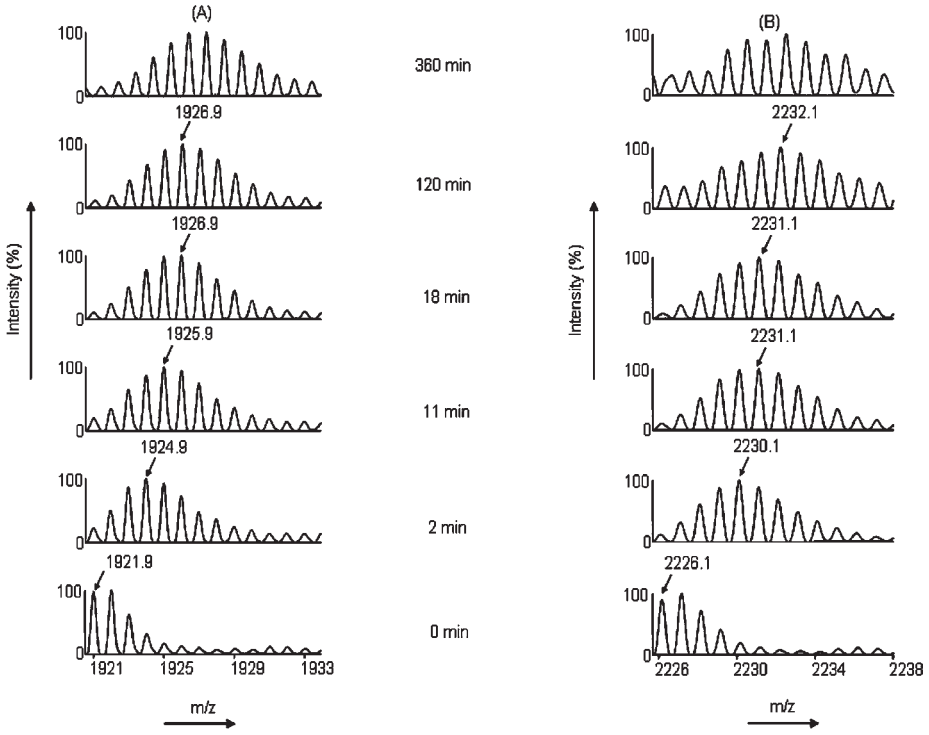
where A, B, and C are the number of fast, intermediate, and slow exchanging amide hydrogens with rate constants k_1, k_2, and k_3, respectively. The isotope exchange rates were quantitatively assessed by fitting the data obtained from eq 1 into eq 3.[16] The exchange rate constants and the population of amide hydrogens in different groups were varied to minimize the sum of squared residuals (SSR). MS *Excel* solver was used to obtain the best fitted curve. The SSR for each data set was calculated using the following equation:

$$\mathrm{SSR} = \sum_i ((y_{i\mathrm{obs}} - y_{i\mathrm{calc}})/y_{i\mathrm{obs}})^2$$

$y_{i\ \mathrm{obs}}$, $y_{i\ \mathrm{calc}}$ were calculated from eq 1 and eq 3, respectively.[18]

RESULTS AND DISCUSSION

Human hemoglobin has one cysteine residue in each α globin subunit (αCys104) and two cysteine residues in each β globin subunit (βCys93, βCys112). Among the three cysteine residues, βCys93 is the preferred site for glutathione binding, which is 5-fold more accessible than βCys112, whereas αCys104 is completely buried and thus inaccessible to glutathione.[9] In spite of the large excess of GSH compared to GSSG in a normal erythrocyte, glutathionylation of hemoglobin occurs to a small extent (~3% of total Hb).[9] In this study, we have synthesized glutathionyl hemoglobin in vitro. Figure 1 shows the MALDI mass spectra of glutathionyl hemoglobin synthesized in vitro, where glutathionyl β globin chain appeared with m/z 16 172 along with a normal β-globin chain (m/z 15 867) and normal α-globin chain (m/z 15 126). The synthesized GSHb molecule with at least 85% abundance was chosen for further experiments.



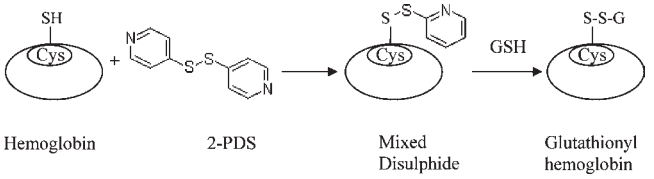


Figure 2. MALDI mass spectra for the peptide 1921.9 m/z obtained on hydrogen/deuterium exchange kinetics. Panels A and B represent the isotope exchange kinetics for the peptide fragment in HbA and GSHb, respectively. Glutathionylation leads to an increase in the mass of the peptide from 1921.9 to 2226.1. The spectra labeled as 0 and 360 min represent the data for 0% control and 100% control experiments, respectively.

A schematic representation of hemoglobin glutathionylation has been provided below.

An illustration of the actual mass spectra obtained for H/D exchange kinetics of peptic peptides is shown in Figure 2, Figure 3, and Figure 4. In the H/D exchange process, on replacement of one hydrogen atom by one deuterium, the envelope corresponding to a peptide molecular ion shows an increase in mass by one unit. As more hydrogens are replaced by deuterium with time, the envelope shows a progressive mass shift, which eventually represents kinetic behavior of H/D exchange process for that peptide. Figure 2 represents mass spectra of a β globin fragment with m/z 1921.9, consisting of residues 86 to 102. Panel A shows the mass spectra obtained from 1921.9 m/z for normal hemoglobin, while panel B represents the data for glutathionyl peptide. Upon glutathionylation, the mass of the peptide fragment shifted to 2226.1 m/z. On H/D exchange, the mass of the peptide fragment increased with time. The spectra labeled as 0 and 360 min represent the 0% control data and the 100% control data, respectively. Figure 3 represents mass spectra obtained for the α globin fragment (α34−46) with m/z 1585.8. Panels A and B represent the isotope exchange kinetics for the peptide in HbA and GSHb molecules, respectively. Similarly, Figure 4 represents mass spectra of a β globin fragment with m/z 1494.8 consisting of residues 1 to 14, and panels A and B show kinetic behavior of the peptide fragment with time for HbA and GSHb, respectively.

After quenching the H/D exchange kinetics followed by pepsin digestion, we analyzed a total of eleven peptides by MALDI-MS. The sequence coverage obtained from the identified peptides was 29.7% for α globin and 67.8% for β globin chains, respectively. A few peptides in the close m/z range had overlapping envelopes after mass shift due to H/D exchange, which made the analysis improbable for those peptides and was hence excluded in sequence coverage for globin chain analysis.

Figure 5, Figure 6, and Figure 7 represent plots of kinetic data for deuterium incorporation in eleven different peptic peptides obtained from both HbA and GSHb molecules. The peptide amide hydrogens have been grouped into fast (A), intermediate (B), and slow (C) exchanging for each peptide fragment, and the corresponding rate constants have been assigned as k_1, k_2, and k_3, respectively. The number of differently grouped peptide amide hydrogens and corresponding rate constants for all eleven peptic peptides are listed in Table-1.

The analysis of tandem mass spectra followed by sequence assignments confirmed that the peptic fragment of HbA with m/z 1921.9 originated from the β globin chain spanning residues 86−102, consisting of βCys93 residue. The same fragment in the GSHb digest appeared at m/z 2226.1, showing a shift in mass by 305 Da consistent with a glutathione moiety attached to βCys93 by disulfide linkage. Figure 5A represents the best fit curve according to eq 3, obtained from deuterium incorporation kinetics data for HbA (trace 1) and GSHb (trace 2). Sequence analysis of peptide fragments showed that the numbers of exchangeable amide hydrogens are 15 and 17 for HbA and

dx.doi.org/10.1021/bc100602f |*Bioconjugate Chem.* 2011, 22, 785–793

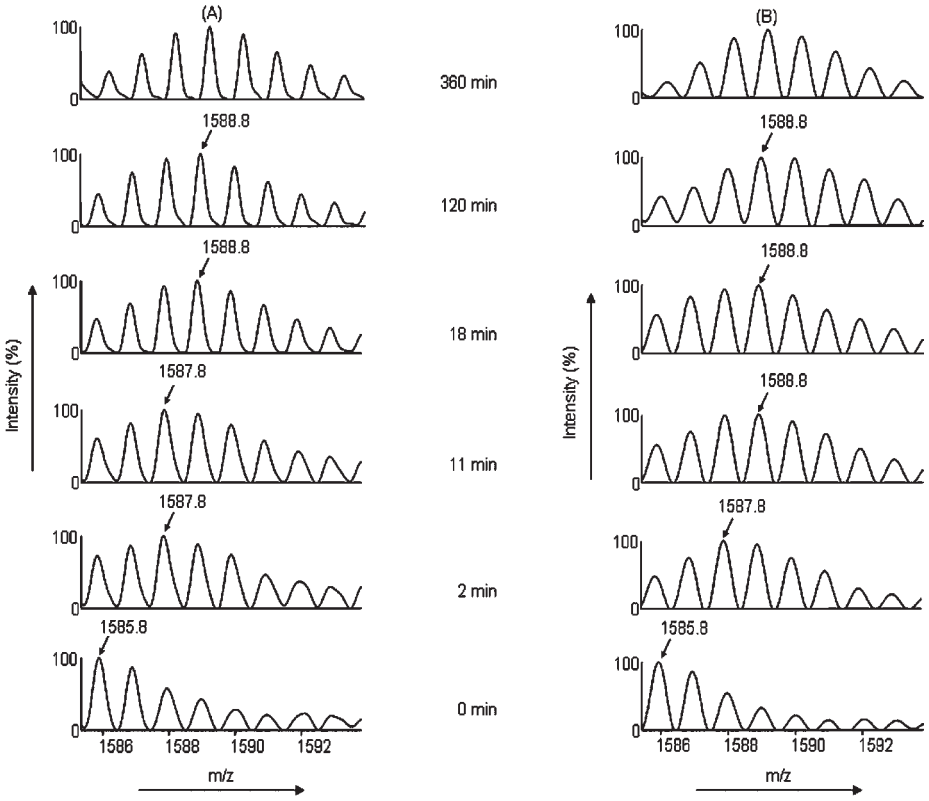

Figure 3. MALDI mass spectra for the peptide 1585.8 *m/z* obtained on hydrogen/deuterium exchange kinetics. Panels A and B represent the isotope exchange kinetics for the peptide fragment in HbA and GSHb, respectively. The spectra labeled as 0 and 360 min represent the data for 0% control and 100% control experiments, respectively.

GSHb, respectively. The numbers of fast exchanging amide hydrogens are 1.23 and 8.0 for peptides 1921.9 *m/z* and 2226.1 *m/z*, respectively (Table 1). Being a tripeptide, the glutathione moiety has two exchangeable peptide amide hydrogens. We assumed that these two amide hydrogens in GSHb were exposed to solvent molecules. Therefore, among the eight fast exchanging hydrogens in peptide 2226.1 *m/z*, two are contributed by the glutathione moiety. Hence, the number of fast exchanging peptide amide hydrogens for the peptide 1921.9 *m/z* changed from 1.2 to 6.0 upon glutathionylation. The increase in the number of fast exchanging hydrogens was compensated by a simultaneous decrease in the number of slow and intermediate exchanging hydrogens in peptide 2226.1 *m/z*. The average rate constants for all H/D exchange steps increased. The covalent binding of glutathione to HbA is expected to perturb the conformation of amino acid residues in the vicinity of βCys93. The large change in the fast exchanging peptide amide hydrogen number indicated that glutathionylation resulted in a significant change in solvent accessibility of those hydrogens in the β86−102 segment of hemoglobin. Craescu et al. reported that in GSHb the hydrogen bond between βAsp99 and αTyr42, which is a characteristic feature of deoxyhemoglobin in its $\alpha_1\beta_2$ interface, is destabilized and the salt bridge between βHis146 and βAsp94 is also perturbed.[11] Due to limitations in assigning HDX to a single amide linkage, it may be concluded that glutathionylation drives an increase in the solvent accessibility in the β86−102 region, which in turn suggests that the region became highly dynamic due to loss of localized tertiary and quaternary interactions.[19,20]

The peptic peptide fragment with *m/z* 1635.8 was found to be a β globin chain segment containing residues 115 to 129 with 12 exchangeable backbone amide hydrogens. Figure 5B shows the fitted curve of H/D exchange kinetics data for the peptic fragment 1635.8 *m/z*. The values of kinetic parameters as well as the number of differentially populated exchangeable amide hydrogens showed that glutathionylation caused an increase in rate constants for all exchange processes with a simultaneous increase in the number of exchangeable hydrogens for fast and intermediate exchanging groups (Table 1). The observed data clearly show that as a result of glutathionylation there is a substantial change in the solvent accessibility in this region of hemoglobin. Adachi et al. reported that βHis116 plays a crucial role in stabilizing $\alpha_1\beta_1$ interactions and inhibits hemoglobin oxidation.[21] Though structural change in this region of glutathionyl hemoglobin has not yet been reported, our H/D exchange data suggest that glutathionylation led to a significant structural change in this segment of the hemoglobin molecule resulting in the region being highly dynamic.

The sequence assignment of a peptide fragment with *m/z* 1585.8 indicated that it is an α globin chain fragment containing amino acid residues 34 to 46. This fragment has 10 exchangeable peptide amide hydrogens. Figure 5C shows fitted curves of isotope exchange kinetics data of 1585.8 for both HbA and GSHb. The fitted parameters indicated that the rate constant for slow exchanging amide hydrogens increased while that of intermediate exchange pattern decreased. The rate of fast exchange kinetics remained almost unaltered on glutathionylation. The number of fast exchanging hydrogens increased considerably,

dx.doi.org/10.1021/bc100602f |*Bioconjugate Chem.* 2011, 22, 785–793

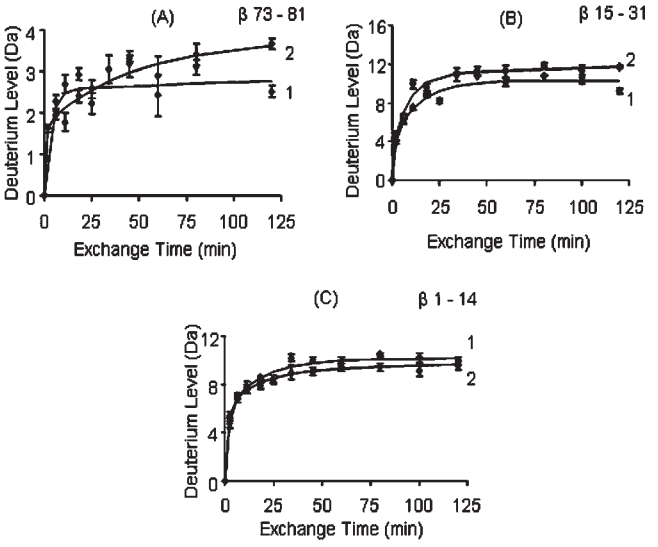

Figure 7. Representation of hydrogen/deuterium exchange kinetics of peptic peptides. The *Y*-axis is labeled with the number of deuterium incorporated and the *X*-axis with the corresponding exchange time. Trace 1 in each panel (filled diamond) represents the best fit curve of the exchange kinetics for the corresponding peptide obtained from native hemoglobin digestion, and trace 2 in each panel (hollow diamond) represents the same for the peptide obtained from glutathionyl hemoglobin digestion. Panel A represents peptide fragment 967.5 m/z (β73−81). Panel B represents peptide fragment 1798.9 m/z (β15−31). Panel 7C represents peptide fragment 1494.8 m/z (β1−14).

whereas the numbers for intermediate and slow exchanging hydrogens decreased. Though the change in the incorporation pattern of deuterium is not unidirectional, it suggests some conformational rearrangement in the vicinity of this peptide. The crystallographic data of deoxyhemoglobin showed that βHis97 was linked to αPro44 and αThr41.[22,23] Using nuclear magnetic resonance spectroscopy, it was reported that the three T-like inter subunit contacts are perturbed upon glutathionylation of hemoglobin. These are the carboxyl group of βHis146 and ε amino groups of αLys40, βHis97 and αPro44, βAsp99 and αTyr42.[11] Garel et al. concluded that glutathionylation leads to perturbation in conformation of four α globin residues αLys40, αThr41, αTyr42, and αPro44.[10] Thus, inter subunit contacts of many amino acid residues belonging to this peptide fragment undergo changes on glutathionylation of hemoglobin.

Sequence assignment of the peptide fragment with m/z 1868.9 confirmed that it was a β chain fragment spanning residues 130 to 146 with 16 exchangeable amide hydrogens. Figure 5D illustrates the best fit curve of H/D exchange kinetics of 1868.9 for both HbA and GSHb molecules. From the values of fitted parameters (Table 1), it is clear that glutathionylation caused an increase in the rate constant of amide hydrogens for fast and intermediate exchange kinetics, while that of slow exchanging hydrogens decreased. The number of fast and slow exchanging hydrogens increased, whereas that of intermediate exchange kinetics decreased on glutathionylation for this peptide fragment. One of the key features in localized structural perturbation of GSHb is the destabilization of the salt bridge between βHis146 and βAsp94.[11] βHis146 which contributes 40% to the alkaline Bohr effect in hemoglobin is the C-terminal most amino

[a] The corresponding rate constants are given by k_1, k_2, and k_3, respectively. [b] For the peptide 1921.9, after glutathionylation, the mass is 2226.1 and the number of exchangeable hydrogen is 17, taking into account two hydrogens from the glutathione moiety.

dx.doi.org/10.1021/bc100602f |*Bioconjugate Chem.* 2011, 22, 785–793

acid residue in the 1868.9 fragment.[24] Therefore, glutathione-mediated destabilization of deoxyhemoglobin might have made this region more dynamic such that the fast exchanging amide hydrogen displayed several-fold increase in its isotope exchange rate with a concomitant increase in its number.

One of the most intense peaks in the MS profile of pepsin digest was obtained at 1308.6 m/z. Sequence analysis identified it as a β chain fragment consisting of residues β32 to β41. The number of exchangeable backbone amide hydrogens is eight in this fragment. Figure 6A shows the best fitted curve of isotope exchange data for the fragment 1308.6 in both HbA and GSHb molecules. The analysis of H/D exchange data of this peptide indicates that on glutathionylation the fast and slow exchanging rate constants increased while that of the intermediate exchange process decreased. The number of differentially populated amide hydrogens got rearranged among the groups. In an earlier study, crystal structure data of deoxyhemoglobin showed that the αY42A mutation in hemoglobin caused destabilization of hydrogen bonds between αAsp94 and βTrp37.[25] NMR data also reported that glutathionylation leads to perturbation in interchain contact between αTyr42 and βAsp99.[11] Therefore, it is possible that glutathionylation causes weakening of the βTrp37-αAsp94 hydrogen bond that might have resulted in a small change in the solvent exposure of this segment of peptide. The peptide of m/z 1161.6 has the overlapping sequence with 1308.6, spanning residues β32 to β40. Figure 6B shows the best fitted curve of isotope exchange data for the fragment 1161.6 in both HbA and GSHb molecules. Analysis of H/D exchange data for the rate constants as well as the number of exchangeable hydrogens showed that the peptide followed the same trend as 1308.6, with the exception of fast exchange rates, which showed a slight decrease in the case of the 1161.6 peptic fragment.

Pepsin digestion of both hemoglobin and glutathionyl hemoglobin generated two overlapping peptide fragments from α subunit of the molecule, one with m/z 1153.6 which corresponds to residue spanning α12 to α23 and the other with m/z 2910.4 spanning residues α1 to α29. The numbers of exchangeable backbone peptide amide hydrogens are 11 and 27 for fragments 1153.6 and 2910.4, respectively. The deuterium exchange kinetics of peptide fragments 2910.4 and 1153.6 in both HbA and GSHb is shown in Figure 6C and D, respectively. From the values of best fitted parameters, it is clear that on glutathionylation the peptides 2910.4 exhibited a considerable increase in the number of fast exchanging amide hydrogens with a concomitant decrease in the intermediate and slow exchanging amide hydrogens. For the peptide fragment 1153.6 m/z, the same trend was observed. Information related to glutathionylation mediated structural change in this segment of hemoglobin is not yet reported. Our observed results for 2910.4 m/z indicate that this segment of hemoglobin has become more dynamic upon glutathionylation. The fragment 2910.4 m/z belongs to the N terminus of α globin chain, a region important for hemoglobin allostery.[26] The change in rate constants for both the peptides, 2910.4 and 1153.6, did not behave exactly in the same manner on modification. This is quite possible, as the peptide 2910.4 is extended in both N and C terminal ends compared to the peptide 1153.6. The difference in peptide length may also lead to significantly different subtotal solvent interaction.

Sequence assignment of the peptide fragment with m/z 967.5 confirmed that it was a β chain fragment spanning residues 73 to 81 with 8 exchangeable amide hydrogens in it. Figure 7A illustrates the best fit curve of H/D exchange kinetics data of the peptide 967.5 m/z for both HbA and GSHb molecules. The fitted parameters (Table-1) show that the rate constants increased for all kinetics step, while the number of intermediate and slow amide hydrogens increased and that of fast exchanging hydrogens decreased. There is no substantial structural perturbation in this peptide segment of the molecule. It is possible that while primary structural information shows this peptide is located in close proximity to the glutathione-binding site but the actual spatial orientation of this peptide segment may not be close enough to the modified site to get perturbed significantly. Unavailability of crystal structure of GSHb molecule makes the interpretation difficult. Moreover, backbone amides without any solvent accessibility in X-ray structures sometime show isotope exchange in solution. This might be due to the presence of small openings or mobile defects in the protein structure allowing diffusion of D_2O into the protein,[27,28] or local unfolding of protein structure or global unfolding mechanisms.[29−33]

The two other peptide fragments with m/z 1798.9 (β15−31) and 1494.8 (β1−14) showed small changes in both isotopic exchange rates and in the number of exchangeable amide hydrogens accompanying glutathionylation of hemoglobin (Figure 7B and C, respectively). Therefore, these regions of hemoglobin may be highly solvent shielded and/or have strong secondary and tertiary structures.

CONCLUSION

The primary goal of the study was to analyze the structural changes of hemoglobin on glutathionylation. The isotope exchange kinetics of peptide backbone amide hydrogen with deuterium, recorded in MALDI-MS, has been used to provide insights into the conformational rearrangements occurring in tetrameric hemoglobin. The novelty of the hydrogen−deuterium exchange method coupled with MALDI mass spectrometry lies in its simplicity and requirement of very small amount of protein, compared to other conventional techniques like NMR spectroscopy and X-ray crystallography. The technique could be immensely useful in extracting information in structural change on protein−ligand interaction, post-translational modification of protein, and protein folding−unfolding pathway. Our results clearly indicate structural rearrangement of hemoglobin molecule upon nonenzymatic post-translational modification of βCys93. The perturbation has been found to be delocalized on residues in the following segments of both the globin chains: α34−46, α1−29, β32−41, β86−102, β115−129, and β130−146. GSHb, a biomarker of oxidative stress under various diseased conditions, is a good model system to study structural perturbation associated with glutathionylation. Further study is required to correlate the structural changes and increased oxygen affinity of GSHb following H/D exchange in dynamic equilibrium between its oxy and deoxy forms and comparing it with that of normal hemoglobin.

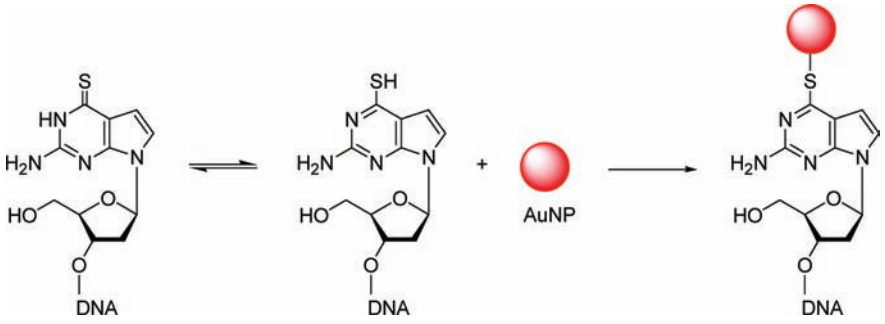
Supporting Information

ABSTRACT: A new protocol for the covalent attachment of oligonucleotides to gold nanoparticles was developed. Base-modified nucleosides with thiooxo groups were acting as molecular surface anchor. Compared to already existing conjugation protocols, the new linker strategy simplifies the synthesis of DNA gold nanoparticle conjugates. The phosphoramidite of 7-deaza-6-thio-2′-deoxyguanosine (**6**) was used in solid-phase synthesis. Incorporation of the sulfur-containing nucleosides can be performed at any position of an oligonucleotide; even multiple incorporations are feasible, which will increase the binding stability of the corresponding oligonucleotides to the gold nanoparticles. Oligonucleotide strands immobilized at the end of a chain were easily accessible during hybridization leading to DNA gold nanoparticle network formation. On the contrary, oligonucleotides immobilized *via* a central position could not form a DNA-AuNP network. Melting studies of the DNA gold nanoparticle assemblies revealed sharp melting profiles with a very narrow melting transition.

INTRODUCTION

DNA guided assemblies of metal nanoparticles have great potential for advanced material applications, in biomedical sciences, and as diagnostics tools.[1,2] DNA nanoparticle conjugates have been employed in nucleic acid detection and labeling and were utilized as barcodes, biosensors, or carriers for the delivery of DNA.[1−6] Additionally, they can be used for the bottom-up assembly of nanoarchitectures.[7,8] Among the accessible metal nanoparticles, gold nanoparticles (AuNPs) gained particular attention due to their chemical inertness and the ease of surface modification.[1,9,10] DNA gold nanoparticle (DNA-AuNP) conjugates combine the favorable properties of gold colloids with those of DNA. A number of key advantages for using the DNA molecule as a "construction material" are (i) its unique molecular recognition properties, (ii) its easy access by automated DNA synthesis or enzymatic polymerization, and (iii) its self-assembly capacities to form multistranded aggregates allowing the construction of DNA-based nanoscaled devices.[7,11]



To meet the above-mentioned applications, the conjugates must be stable in aqueous buffer systems, even at elevated temperature. For this, several strategies were developed for preparing DNA-AuNP conjugates.[12−15] The common protocol employs oligonucleotides with 3′ or 5′-terminal thiol groups introduced by linker units. The covalent attachment to AuNPs proceeds *via* the thiol functionality thereby making use of its strong affinity to the noble metal gold. There is still a controversial discussion on the mechanism of immobilization. However, an X-ray structure of a thiol monolayer protected gold nanoparticle has been reported recently.[16] Further developments in the field of DNA-AuNPs include the incorporation of sulfur functionalities into the oligonucleotide chain as an alternative to the conventional alkylthiol linker.[17,18] Phosphorothioate-modified DNA was utilized for gold nanoparticle conjugation either by directly coupling the DNA backbone to AuNPs[19] or by using a short linker molecule connecting the DNA backbone and the AuNPs.[20]

It is worth mentioning that tRNAs contain a large diversity of modified nucleosides;[21] a few of them bear thio functions at the nucleobase. Examples are 2-thiouridine, 4-thiouridine, or 2-thiocytidine including derivatives with various substituents in the 5-position. Nucleosides with thiooxo groups have already been incorporated into artificial DNA, either chemically or by polymerases.[22−25] Consequently, we initiated a study to use these naturally occurring modification sites for oligonucleotide immobilization on gold nanoparticles.

Scheme 1. Reaction Route for the Formation of Oligonucleotide AuNP Conjugates with Thionucleoside 1 as Anchor Molecule and Proposed Conjugate Structure

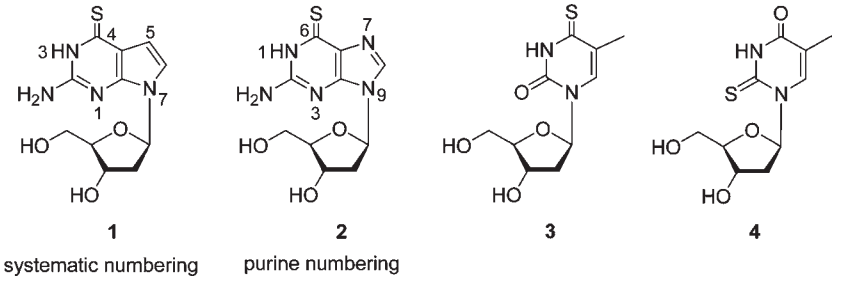

Figure 1. Thionucleosides **1**−**4** employed in this study.

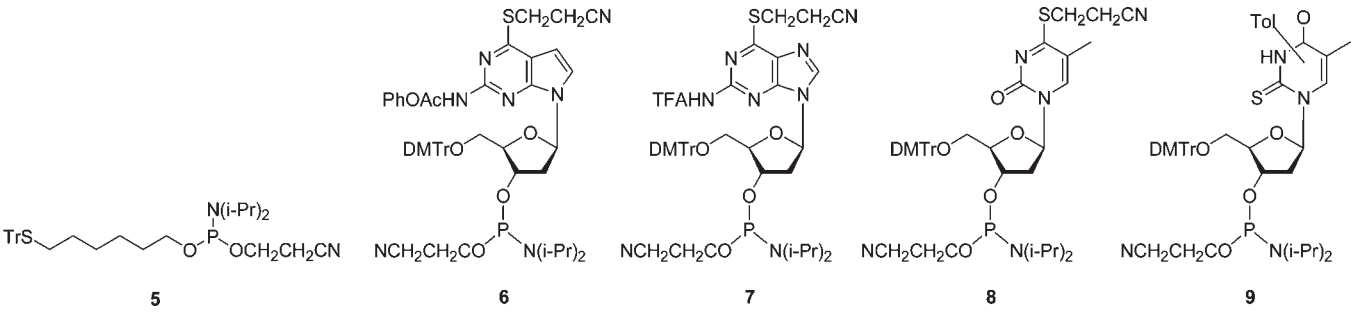

Figure 2. Phosphoramidite building blocks of the hexylthiol linker and the thionucleosides employed for oligonucleotide synthesis.

Herein, we report on a new strategy for conjugation of DNA with gold nanoparticles. In a first step, oligonucleotides are synthesized bearing a thiooxo function ("thio" anchor) at the nucleobase; in a second step, these oligonucleotides are directly attached to the gold surface without prior sulfur protection (Scheme 1). From that background, we selected the four nucleosides 7-deaza-6-thio-2′-deoxyguanosine (**1**), 6-thio-2′-deoxyguanosine (**2**), 4-thio-2′-deoxythymidine (**3**), and 2-thio-2′-deoxythymidine (**4**) for our study as shown in Figure 1. They were introduced into oligonucleotides *via* phosphoramidite chemistry to become an integer part of single-stranded oligonucleotides.

The thiooxo group was utilized as a molecular anchor to gold nanoparticles. First, the stability of the different thiooxonucleosides toward the conditions of solid-phase oligonucleotide synthesis was investigated, and conjugation to the gold surface was tested. Hybridization experiments employing DNA gold nanoparticle conjugates proved the formation of stable DNA-AuNP hybrids with thionucleosides, similar to those linked by conventional protocols.

EXPERIMENTAL PROCEDURES

General Methods and Materials. All chemicals were purchased from Acros, Aldrich, Sigma, or Fluka. The 5′-alkylthiol modifier 6-(triphenylmethyl)-S-$(CH_2)_6$-*O*-2-cyanoethyl diisopropylphosphoramidite (**5**) and phosphoramidites **7**−**9** were obtained from Glen Research (Virginia, USA) (Figure 2). 4-*tert*-Butylphenoxyacetyl protected canonical phosphoramidites were purchased from Millipore (Massachusetts, USA). Solvents were of laboratory grade. Thin-layer chromatography (TLC) was performed on TLC aluminum sheets covered with silica gel 60 F254 (0.2 mm, VWR International, Germany). Flash column chromatography (FC): silica gel 60 (VWR International, Darmstadt, Germany) at 0.4 bar; UV-spectra were recorded on a U-3000 spectrophotometer (Hitachi, Japan); λ_{max} (ε) in nm,

dx.doi.org/10.1021/bc200069j |*Bioconjugate Chem.* 2011, 22, 794–807

ε in $dm^3\ mol^{-1}\ cm^{-1}$. NMR spectra: DPX 300 spectrometer (Bruker, Germany) at 300 MHz for ^1H, 75 MHz for ^{13}C and 121.5 MHz for ^{31}P. The J values are given in Hz; δ values in ppm relative to Me_4Si as internal standard, or 85% H_3PO_4 for ^{31}P. For NMR spectra recorded in DMSO, the chemical shift of the solvent peak was set to 2.50 ppm for ^1H NMR and 39.50 ppm for ^{13}C NMR. Elemental analyses were performed by the Mikroanalytisches Laboratorium Beller, Göttingen, Germany. MALDI-TOF mass spectra were recorded in the linear negative mode with an Applied Biosystems Voyager DE PRO spectrometer with 3-hydroxypicolinic acid (3-HPA) as a matrix. Reversed-phase HPLC was carried out on a 4 × 250 mm RP-18 (10 mm) LiChrospher 100 column (VWR International) with a Merck-Hitachi HPLC pump (model L-6250) connected with a variable wavelength monitor (model 655-A), a controller (model L-500), and an integrator (model D-2500). Melting curves were measured with a Cary-100 Bio UV−vis spectrophotometer (Varian, Australia) equipped with a Cary thermoelectrical controller with a heating rate of 1 °C/min. The T_m values were calculated by *Meltwin 3.0* program. Nanopure water (resistance <0.055 μS/cm) from MembraPure water system (Astacus) was used for all experiments.

*7-(2-Deoxy-β-D-erythro-pentofuranosyl)-2-phenoxyacetamino-7H-pyrrolo[2,3-d]pyrimidin-4(3H)-thione (**10**).* Compound **1**[26] (1.6 g, 5.50 mmol) was dried by repeated coevaporation with anhydrous pyridine (3 × 5 mL), then suspended in pyridine (5 mL). To this solution, trimethylsilyl chloride (3.6 mL, 28.17 mmol) was added at room temperature. After 1 h, phenoxyacetyl chloride (1.1 mL, 7.96 mmol) was introduced, and the solution was stirred at room temperature for another 4 h. The mixture was cooled to 0 °C, diluted with H_2O (5 mL), and stirred for 10 min. Then, aq. ammonia (5 mL) was added, and the solution was stirred for an additional 15 min. The solvent was evaporated to dryness. Purification by FC (silica gel, column 8 × 15 cm, CH_2Cl_2/MeOH, 50:1→25:1) gave **10** as a colorless foam (1.9 g, 81%); mp 205 °C. TLC (CH_2Cl_2/MeOH, 9:1): R_f 0.53. UV λ_{max} (MeOH)/nm 333 (ε/$dm^3\ mol^{-1}\ cm^{-1}$ 47 600). Anal. ($C_{19}H_{20}N_4O_5S$) C, H, N. ^1H NMR (300 MHz, DMSO-d_6): δ = 2.15−2.23 (m, 1H, H_α-2′), 2.38−2.47 (m, 1H, H_β-2′), 3.51−3.54 (m, 2H, H-5′), 3.81−3.84 (m, 1H, H-4′), 4.33−4.36 (m, 1H, H-3′), 4.88 (s, 2H, Pac-CH_2), 4.95 (t, J = 5.3 Hz, 1H, HO-5′), 5.30 (d, J = 3.6 Hz, 1H, HO-3′), 6.41 (m, 1H, H-1′), 6.64 (d, J = 3.7 Hz, 1H, H-5), 6.96−7.01 (m, 3H, phenoxy), 7.29−7.34 (m, 2H, phenoxy), 7.49 (d, J = 3.7 Hz, 1H, H-6), 11.99 (br s, 1H, N−H), 12.89 (br s, 1H, CO-NH).

*4-[(2-Cyanoethyl)thio]-7-(2-deoxy-β-D-erythro-pentofuranosyl)-2-phenoxyacetamino-7H-pyrrolo[2,3-d]pyrimidine (**11**).* 3-Bromopropionitrile (4.0 mL, 48.07 mmol) and anhydrous K_2CO_3 (3.0 g, 21.71 mmol) were added to 25 mL dry DMF and the mixture was stirred vigorously. Compound **10** (1.9 g, 4.45 mmol) was dissolved in 5 mL dry DMF and added dropwise to the stirred solution within 30 min. The reaction mixture was stirred overnight until completion of the reaction (monitored by TLC). The solvent was removed by coevaporation with xylene and the residue was applied to FC (silica gel, column 8 × 15 cm, CH_2Cl_2/MeOH, 500:1→100:1). The main zone yielded **11** as a colorless solid (1.2 g, 55%). TLC (CH_2Cl_2/MeOH, 95:5): R_f 0.22. UV λ_{max} (MeOH)/nm 301 (ε/$dm^3\ mol^{-1}\ cm^{-1}$ 26 700), 244 (73 300). Anal. ($C_{22}H_{23}N_5O_5S$) C, H, N. ^1H NMR (300 MHz, DMSO-d_6): δ = 2.18−2.25 (m, 1H, H_α-2′), 2.50 (m, 1H, H_β-2′), 3.16 (t, 2H, CH_2−CN), 3.51−3.56 (m, 4H, H-5′, H-5″, CH_2−S), 3.84−3.85 (m, 1H, H-4′), 4.36−4.37 (m, 1H, H-3′), 4.94 (t, J = 5.4 Hz, 1H, HO-5′), 5.00 (s, 2H, Pac-CH_2), 5.32 (d, J = 5.3 Hz, 1H, HO-3′), 6.54−6.59 (m, 2H, H-5, H-1′), 6.93−6.98 (m, 3H, phenoxy), 7.28−7.33 (m, 2H, phenoxy), 7.65 (d, J = 3.9 Hz, 1H, H-6), 10.69 (s, 1H, CO-NH).

*4-[(2-Cyanoethyl)thio]-7-[2-deoxy-5-O-(4,4′-dimethoxytrityl)-β-D-erythro-pentofuranosyl]-2-phenoxyacetamino-7H-pyrrolo[2,3-d]pyrimidine (**12**).* Compound **11** (469.5 mg, 1.00 mmol) was coevaporated with anhydrous pyridine (3 × 5.0 mL) and then dissolved in pyridine (5.0 mL). To this solution, 4,4′-dimethoxytriphenylmethyl chloride (440.5 mg, 1.30 mmol) was added and the mixture was stirred at r.t. for 3 h. The reaction was quenched by the addition of MeOH and the mixture was evaporated to dryness. The mixture was subjected to FC (column 4 × 10 cm, elution with CH_2Cl_2/acetone, 20:1) to give **12** as a colorless foam (555.8 mg, 72%). TLC (CH_2Cl_2/MeOH, 95:5): R_f 0.61. UV λ_{max} (MeOH)/nm 302 (ε/$dm^3\ mol^{-1}\ cm^{-1}$ 14 400), 240 (53 500). Anal. ($C_{43}H_{41}N_5O_7S$) C, H, N. ^1H NMR (300 MHz, DMSO-d_6): δ = 2.27−2.31 (m, 1H, H_α-2′), 2.55−2.64 (m, 1H, H_β-2′), 3.13−3.17 (m, 4H, CH_2−CN, H-5′, H-5″), 3.52−3.56 (m, 2H, CH_2−S), 3.71 (s, 6H, OCH_3), 3.95 (m, 1H, H-4′), 4.37 (m, 1H, H-3′), 5.00 (s, 2H, Pac-CH_2), 5.37 (d, J = 4.2 Hz, 1H, HO-3′), 6.52−6.56 (m, 2H, H-5, H-1′), 6.78−7.35 (m, 18H, phenoxy), 7.46 (d, J = 3.6 Hz, 1H, H-6), 10.69 (s, 1H, CO-NH).

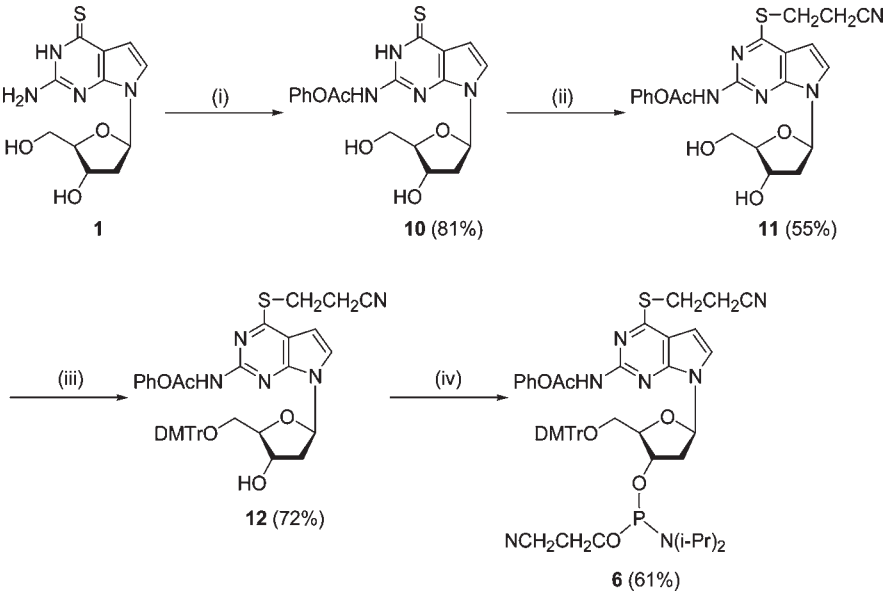
*4-[(2-Cyanoethyl)thio]-7-[2-deoxy-5-O-(4,4′-dimethoxytrityl)-β-D-erythro-pentofuranosyl]-2-phenoxyacetamino-7H-pyrrolo-[2,3-d]pyrimidine 3′-[(2-cyanoethyl)-N,N-diisopropylphosphoramidite] (**6**).* Compound **12** (555.8 mg, 0.72 mmol) was dissolved in anhydrous CH_2Cl_2 (3.0 mL) under argon and was reacted with (2-cyanoethyl)diisopropylphosphoramido chloridite (225 μL, 0.95 mmol) in the presence of $^iPr_2EtN$ (220 μL, 1.27 mmol) at room temperature. After 20 min, the reaction mixture was diluted with CH_2Cl_2 and the solution was washed with a 5% aqueous $NaHCO_3$ solution, followed by brine. The organic solution was dried over anhydrous Na_2SO_4, filtered, and concentrated. The residue was subjected to FC (column 4 × 10 cm, CH_2Cl_2/acetone, 25:1) yielding **6** as a colorless foam (429.1 mg, 61%). TLC (CH_2Cl_2/acetone, 95:5): R_f 0.64. ^{31}P NMR (121.5 MHz, $CDCl_3$): δ = 148.56; 148.69.

Hydrolytic Stability of Thiooxonucleosides. The hydrolytic stability of thiooxonucleosides **1**−**4** and **11** under standard deprotection conditions (25% aqueous NH_3, 14−16 h, 60 °C) was monitored by reversed-phase HPLC (RP-18, 250 × 4 mm). Nucleosides **1**−**4** and **11** (about 1 mg) were dissolved in 1 mL of 25% aq. ammonia in a sealed vessel and incubated at 60 °C. After 16 h incubation, aq. ammonia was removed by evaporation and the residue was redissolved in 1 mL HPLC buffer A. 50 μL aliquots of each sample were injected into the HPLC, and the spectra were recorded at 260 nm (for spectra see Supporting Information).

Synthesis, Purification, and Characterization of Oligonucleotides. The syntheses of oligonucleotides were performed on a DNA synthesizer, model 392−08 (Applied Biosystems, Weiterstadt, Germany) at 1 μmol scale. For oligonucleotides containing 7-deaza-6-thio-2′-deoxyguanosine (**1**), 2-thio-2′-deoxythymidine (**4**), or the hexylthiol linker, the corresponding phosphoramidites **5**, **6**, and **9** were used, and the standard synthesis protocol for 3′-(2-cyanoethyl phosphoramidites) was followed.[27] The average coupling yield was always higher than 95%. Oligonucleotides containing the hexylthiol linker, **1** or **4**, were cleaved from solid support with 25% aq. NH_3 and

deprotected for 14−16 h at 60 °C (standard deprotection conditions). Oligonucleotides containing 6-thio-2′-deoxyguanosine (**2**) and 4-thio-2′-deoxythmidine (**3**) were prepared using the corresponding phosphoramidites **7** and **8**, and reagents required for the fast deprotection procedure.[28] For that, 4-*tert*-butylphenoxyacetyl protected canonical phosphoramidites and the capping reagent 4-*tert*-butylphenoxyacetic anhydride instead of acetic anhydride were used. The coupling efficiency was always higher than 95%. Oligonucleotides incorporating **2** or **3** were cleaved from solid support and deprotected in 25% aq. NH_3 solution containing 50 mM NaSH at room temperature overnight (recommended conditions of the supplier). The DMT-containing oligonucleotides were purified on reversed-phase HPLC in the DMT-on modus (Merck-Hitachi-HPLC; RP-18 column) with the following gradient system [A: 0.1 M $(Et_3NH)OAc$ (pH 7.0)/MeCN 95:5; B: MeCN]: 3 min, 20% B in A, 12 min, 20−50% B in A and 25 min, 20% B in A, flow rate 1.0 mL/min. The solvent was evaporated, and the residue was treated with 2.5% $CHCl_2COOH/CH_2Cl_2$ (400 μL) for 5 min at 0 °C to remove the 4,4′-dimethoxytrityl residue. The detritylated oligomers were purified again by reversed-phase HPLC [gradient: 0−20 min 0−20% B in A; flow rate 1 mL/min]. The oligomers were desalted on a short column (RP-18, silica gel) using H_2O for elution of the salt, while the oligomers were eluted with MeOH/H_2O (3:2). The oligonucleotides were lyophilized on a Speed-Vac evaporator to yield colorless solids which were frozen at −24 °C. The 5′-alkylthiol-modified oligonucleotides 5′-d(trityl-S-$(CH_2)_6$-T_{10}-TAG GTC AAT ACT) (**40**) and 5′-d(trityl-S-$(CH_2)_6$-T_{10}-AGT ATT GAC CTA) (**41**) were only purified in the DMT-on modus by reversed-phase HPLC (RP-18) as described above.

The enzymatic hydrolysis of the oligonucleotides was performed as described[29] with snake venom phosphodiesterase (EC 3.1.15.1, *Crotallus adamanteus*) and alkaline phosphatase (EC 3.1.3.1, *Escherichia coli* from Roche Diagnostics GmbH, Germany) in 0.1 M Tris-HCl buffer (pH 8.3) at 37 °C. The hydrolysis product was analyzed by reversed-phase HPLC (RP-18). Quantification of the constituents was made on the basis of the peak areas, which were divided by the extinction coefficients ε_{260} of the nucleosides: dA 15400, dC 7300, dG 11700, dT 8800, 7-deaza-6-thio-2′-deoxyguanosine (**1**) 10100, 6-thio-2′-deoxyguanosine (**2**) 7300, 4-thio-2′-deoxythymidine (**3**) 1500. MALDI-TOF mass spectra were recorded in the linear negative mode with an Applied Biosystems Voyager DE PRO spectrometer with 3-hydroxypicolinic acid (3-HPA) as a matrix. The detected masses were identical with the calculated values (see Supporting Information).



General Procedure for the Preparation of Oligonucleotide Gold Nanoparticle Conjugates Employing Thiooxonucleosides as Molecular Anchor. The gold nanoparticle solution (15 nm particle diameter) was prepared from a $HAuCl_4$ solution by citrate reduction according to the protocol originally reported by Turkevitch[30] and later described by Letsinger and Mirkin.[13] The nanoparticle concentration was determined by UV/vis using $\varepsilon_{520} = 4.2 \times 10^8\ M^{-1}\ cm^{-1}$ (UV/vis_{max}: 520 nm).[31] The gold nanoparticles (~3 nM) were functionalized with oligonucleotides **18**−**29** and **36**−**39** containing thiooxonucleosides **1**−**4** at different positions within their sequences. The DNA-AuNP conjugates **Au18**-**Au29** and **Au36**-**Au39** were prepared by mixing 1 mL of the respective AuNP solution with the aq. solution of the purified oligonucleotide (1−5 μL) to yield a final oligonucleotide concentration of 3 μM. The coupling reaction was performed at slightly elevated temperature (40 °C). After standing for 20 h, 5 μL of a 2 M NaCl, 0.2 mM phosphate buffer solution (pH 7.0) was added under constant stirring to bring the colloidal solutions to a 0.01 M NaCl concentration. The solution was allowed to stand for 6−8 h. The NaCl concentration was increased stepwise using 2 M NaCl and 0.2 mM phosphate buffer solution (pH 7.0). First, the colloids were salted to 0.02 M NaCl and allowed to age for another 6−8 h, then salted to 0.05 M NaCl with 6−8 h of incubation, and were finally salted to 0.1 M NaCl. Subsequently, the DNA gold nanoparticle solutions were centrifuged (8000 rpm, 45 min) and the clear supernatant was taken off to remove unbound oligonucleotides. The precipitate was redispersed in 1 mL of a 0.1 M NaCl, 10 mM phosphate buffer solution (pH 7.0). After incubation (24 h, 40 °C), the conjugate solutions were centrifuged and washed again with the same buffer, finally yielding 1 mL of the DNA-AuNP conjugates **Au18**-**Au29** and **Au36**-**Au39** (Table 1). The DNA-AuNP conjugates were characterized by UV/vis spectroscopy and stored at 4 °C.

Scheme 2. Synthesis of Phosphoramidite Building Block 6[a]

[a] Reagents and conditions: (i) Me_3SiCl, phenoxyacetyl chloride, pyridine, aq. NH_3, 4 h, r.t.; (ii) 3-bromopropionitrile, anh. K_2CO_3, DMF, overnight, r.t.; (iii) DMTr-Cl, pyridine, 3 h, r.t.; (iv) (2-cyanoethyl)diisopropylphosphoramido chloridite, *N,N*-diisopropylethylamine, anh. CH_2Cl_2, 20 min, r.t.

All conjugates show plasmon resonance at around 524 nm indicating a nonaggregated state (Table 1 and Supporting Information).

Preparation of DNA-AuNP Conjugates Employing the Hexylthiol Linker As Anchoring Site. DNA-AuNPs employing oligonucleotides with terminal alkylthiol linkers were prepared by a protocol reported previously.[13,32] The DNA-AuNP conjugates **Au40** and **Au41** were characterized by UV/vis spectroscopy showing plasmon resonance at 523 nm which is correlated to a nonaggregated state (for spectra, see Figure S2, Supporting Information).

Scanning Electron Microscopy (SEM). A typical sample was prepared by dropping a DNA-AuNP conjugate into a silicon wafer which was then subsequently dried and imaged.

RESULTS AND DISCUSSION

The conventional protocol for the attachment of oligonucleotides onto gold nanoparticle surfaces makes use of oligonucleotides modified at their 5′- or 3′-termini by an alkylthiol linker.[5,12−14,32−34] However, this protocol is laborious and accompanied by drawbacks to form SH-modified oligonucleotides ready for immobilization. This includes (i) the detritylation of the protected thiol-group with silver nitrate, (ii) removal of excess silver nitrate and (iii) desalting of the free thiol-modified oligonucleotides. Furthermore, the immobilization of the reactive oligonucleotides to the gold nanoparticles has to be performed shortly after preparation to reduce unwanted side reactions (e.g., disulfide formation). Moreover, silver ions or metallic silver which can bind to both oligonucleotides and gold nanoparticles are difficult to remove quantitatively.

In this study, we made use of the sulfur atom of thiooxonucleosides to conjugate oligonucleotides to gold nanoparticles. The sulfur atom of these nucleosides is expected to bind to the gold surface *via* the thiooxo group or the corresponding mercapto group. Recently, the triphosphate of 4-thio-2′-deoxythymidine was incorporated enzymatically into DNA, and the sulfur functionality was used to attach the DNA oligonucleotides to gold electrodes.[35,36] For our study, we selected the thiooxonucleosides **1**−**4** for incorporation into oligonucleotides *via* phosphoramidite chemistry. In this respect, the stability of **1**−**4** against nucleophilic sulfur displacement under alkaline deprotection conditions was investigated. Thiooxonucleosides **1**−**4** were used as a molecular anchor to the gold nanoparticle surface and their capability to form DNA-AuNPs was evaluated.

Building Block Synthesis. The phosphoramidites **5**−**9** were selected for oligonucleotide syntheses (Figure 2). Compounds **5** and **7**−**9** are commercially available, while phosphoramidite **6** has to be synthesized using nucleoside **1** as starting material.[26]

For the protection of the amino group, the phenoxyacetyl residue[37] was chosen, and the protocol of transient protection (→ **10**, 81% yield) was used (Scheme 2). The thiooxo function was protected with the cyanoethyl group (→ **11**, 55% yield) as described for the parent purine compound **2**.[38] The protected intermediate **11** was converted into the 5′-*O*-DMT derivative **12** under standard conditions. Phosphitylation with 2-cyanoethyl-*N,N* diisopropyl-phosphoramidochloridite furnished the phosphoramidite **6** (61% yield, Scheme 2).

All compounds were characterized by UV-spectra and ^{1}H- and ^{13}C NMR spectra as well as by elemental analysis (Table 2 and Experimental Procedures section). The assignments of ^{13}C NMR chemical shifts of the sugar moiety and the protecting groups were made on the basis of ^{1}H−^{13}C gated-decoupled spectra (for more data, see Supporting Information) in combination with already published data.[38] For 7-deaza-6-thio-2′-deoxyguanosine (**1**), the chemical shifts for C2 and C6 were only assigned tentatively.[38] Therefore, now we used the deuterium isotope upfield shift approach to assign the carbon-2 signal,[39,40] which is directly connected with the amino group. In a DMSO solution, containing a H_2O/D_2O mixture, the carbon-2 signal is split into two singlets (Figure S6, Supporting Information): the original one and one which is shifted 0.04 ppm upfield. Consequently, C2 was assigned to the 152.2 ppm signal and C6 to the 175.7 ppm signal (Table 2).

[a] Measured in DMSO-d_6 at 298 K. [b] Systematic numbering. [c] Purine numbering. [d] Superimposed by the DMSO signal. [e] c^7G_d: 7-deaza-2′-deoxyguanosine; ^{13}C NMR chemical shifts taken from ref 41.

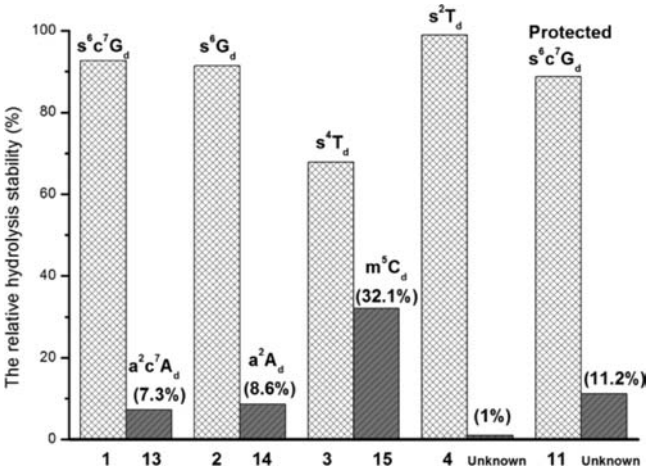

Figure 3. Graph showing the alkaline hydrolysis stability of thiooxonucleosides **1**−**4** and protected **11**. After incubation in a solution of 25% aq. NH_3 at 60 °C for 16 h, compounds **1**−**4** and **11** were analyzed by reversed-phase HPLC at 260 nm. Relative quantification was calculated on the basis of peak areas which were divided by the extinction coefficient (ε_{260}) of the respective nucleoside (for details see Supporting Information). $s^6c^7G_d$: 7-deaza-6-thio-2′-deoxyguanosine (**1**), $a^2c^7A_d$: 2-amino-7-deaza-2′-deoxyadenosine (**13**), s^6G_d: 6-thio-2′-deoxyguanosine (**2**), a^2A_d: 2-amino-2′-deoxyadenosine (**14**), s^4T_d: 4-thio-2′-deoxythymidine (**3**), m^5C_d: 5-methyl-2′-deoxycytidine (**15**), s^2T_d: 2-thio-2′-deoxythymidine (**4**), **11**: 6-[(2-cyanoethyl)thio]-2-phenoxyacetamino-7-deaza-2′-deoxyguanosine.

Moreover, compared to the parent nucleoside 7-deaza-2′-deoxyguanosine (c^7G_d; Table 2), the sulfur atom of thionucleoside **1** attached to carbon-6—instead of the oxygen atom of c^7G_d—induces a significant downfield shift of 17.2 ppm on C6.

Stability of Thiooxonucleosides 1−4 toward Alkaline Hydrolysis. Prior to oligonucleotide synthesis, the stability of the thiooxo group of nucleosides **1**−**4** toward the standard oligonucleotide deprotection conditions (25% aq. NH_3, 16 h, 60 °C) was investigated. This study was motivated by earlier reports on sulfur-amino group exchanges of 6-thio-2′-deoxyguanosine (**2**) (→ 2-amino-2′-deoxyadenosine, **14**)[24] and 4-thio-2′-deoxythymidine (**3**) (→ 5-methyl-2′-deoxycytidine, **15**)[42] under alkaline conditions. Moreover, the unknown compound **11** employing a cyanoethyl protecting group at the sulfur function and a 2-phenoxyacetamino group was also subject of this study. With this experiment, we intended to confirm the applicability of the cyanoethyl protecting group at sulfur-6 under standard oligonucleotide deprotection conditions and conversion to the desired 7-deaza-6-thio-2′-deoxyguanosine (**1**).

Thus, nucleosides **1**−**4** and **11** were incubated in 25% aq. NH_3, 16 h, 60 °C (standard oligonucleotide deprotection conditions) and analyzed by reversed-phase HPLC at 260 nm. Byproducts were identified by coelution with authentic nucleosides (for experimental procedure and HPLC profiles, see the Supporting Information).

The thiooxo group at position-6 of purine nucleosides or position-2 of pyrimidine nucleosides is considerably more stable compared to position-4 of pyrimidine nucleosides. Accordingly, among nucleosides **1**−**4**, the thiooxo group of 4-thio-2′-deoxythymidine (**3**) is the most labile one toward the standard oligonucleotide deprotection conditions (32% conversion to 5-methyl-2′-deoxycytidine, **15**). On the contrary, the thiooxo group of 2-thio-2′-deoxythymidine (**4**) was the most stable one, and less than 1% conversion into an unidentified product was detected (Figure 3 and Supporting Information). The thiooxo groups of the purine and 7-deazapurine nucleosides **1** and **2** showed similar stabilities (**1**: 7% conversion, **2**: 9% conversion, Figure 3). For the protected compound **11**, conversion into an unidentified side product amounts to 11% which is within the same range as for nucleosides **1** and **2**. However, it should be noted that, for **11**, the stability of the sulfur function is related to deprotection and conversion from 6-cyanoethyl(thio) into the desired 6-sulfur group (Figure 3 and Supporting Information). From the above-described experiments, the following order of stability of the thiooxo groups of nucleosides **1**−**4** and **11** toward alkaline hydrolysis (25% aq. NH_3, 16 h, 60 °C) was deduced: **4** > **1** > **2** > **11** > **3** (Figure 3).

Oligonucleotide Synthesis and Characterization. With the informations of the alkaline hydrolysis experiments in hand, a series of unmodified and modified oligonucleotides (**16**−**39**) containing thiooxonucleosides **1**−**4** at different positions were synthesized on solid phase at 1 μmol scale (Table 4), and the accessibility of pure oligomers was studied. Two different protocols of oligonucleotide syntheses were employed: (i) oligonucleotide synthesis using fast deprotectable building blocks and (ii) standard oligonucleotide synthesis employing standard building blocks. Oligonucleotides incorporating 4-thio-2′-deoxythymidine (**3**) or 6-thio-2′-deoxyguanosine (**2**) were synthesized under conditions already reported in the literature utilizing phosphoramidites **7** and **8** which are suitable for fast deprotection conditions.[38,43] Oligonucleotides were cleaved from solid support and deprotected in a 25% aq. NH_3 solution containing 50 mM NaSH at room temperature overnight. Sulfur exchange was avoided by employing the protocol of fast deprotection[28] and the presence of sodium hydrogensulfide. In contrast, oligonucleotides containing 2-thio-2′-deoxythmidine (**4**) or 7-deaza-6-thio-2′-deoxyguanosine (**1**) were synthesized and deprotected

dx.doi.org/10.1021/bc200069j |*Bioconjugate Chem.* 2011, 22, 794–807

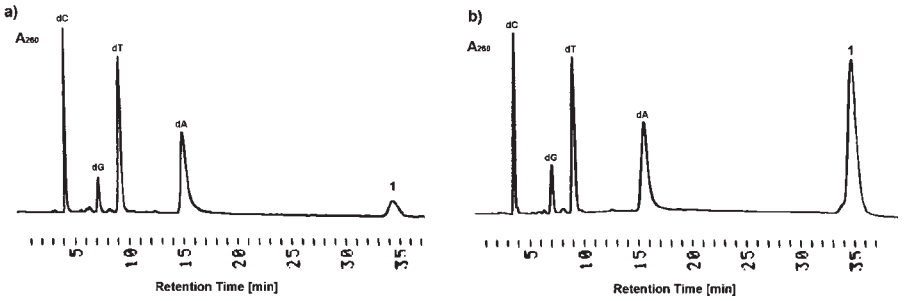

Figure 4. HPLC elution profiles of (a) the enzymatic hydrolysis products of oligonucleotide **30** obtained after hydrolysis with snake venom phosphodiesterase and alkaline phosphatase in 0.1 M Tris−HCl buffer (pH 8.5) at 37 °C and (b) the artifical mixture of the hydrolysis products of oligonucleotide **30** and thiooxonucleoside **1**. Column: RP-18 (200 × 10 mm); gradient [A: 0.1 M (Et_3NH)OAc (pH 7.0)/MeCN 95:5]: 100% A; flow rate: 0.7 mL/min.

under standard conditions (25% aq. NH_3, 14−16 h, 60 °C) in the absence of sodium hydrogensulfide. The oligonucleotides were isolated and purified by reversed-phase HPLC (for details see Experimental Procedures).

The nucleobase composition of the modified oligonucleotides was also confirmed by tandem enzymatic hydrolysis with snake-venom phosphodiesterase (EC 3.1.15.1, *Crotallus adamanteus*) followed by alkaline phosphatase (EC 3.1.3.1, *Escherichia coli*) in 0.1 M Tris-HCl buffer (pH 8.5) at 37 °C as described previously.[29] As an example, the HPLC profiles of the nucleoside composition of oligonucleotide **30** after enzymatic hydrolysis (Figure 4a) and the artificial mixture of the hydrolysis products of **30** and nucleoside **1** (Figure 4b) are shown depicting the correct nucleobase composition of the oligonucleotide.

Both MALDI-TOF mass spectrometry (Supporting Information, Table S1) and enzymatic hydrolysis confirm that deprotection of oligonucleotides containing **1** under standard conditions (25% aq. NH_3, 14−16 h, 60 °C) yields the desired 7-deaza-6-thio-2′-deoxyguanosine (**1**) as constituent of the respective oligonucleotides, as no significant side products pointing toward sulfur exchange were detected. These findings make **1** highly advantageous over its purine congener **2** from which severe side product formation was reported when treated under these conditions.[38]

A problem associated with oligonucleotides containing thionucleosides is disulfide formation leading to cross-linked oligonucleotides. Manuscripts reporting on interstrand cross-linking through thionucleosides describe template directed protocols and the application of mild oxidants to achieve disulfide formation.[44,45] In addition, according to Waters and Connolly,[24] disulfide formation is only observed when oligonucleotides are kept in aqueous solution at neutral pH values at room temperature. Therefore, to avoid disulfide formation, we always stored our oligonucleotides as dry material at −20 °C. Throughout synthesis, purification, and characterization of oligonucleotides incorporating thionucleosides **1**−**4**, we did not make any observations indicating cross-linking of oligonucleotides due to disulfide formation. As mentioned above, in all cases, the detected masses of oligonucleotides were identical with the calculated values (Supporting Information, Table S1). Moreover, it should be noted that covalent binding to AuNPs can be achieved *via* thiol groups as well as disulfides.[17,46]

Preparation of Oligonucleotide Gold Nanoparticle Conjugates. Next, the applicability of thionucleosides **1**−**4** as components of single-stranded oligonucleotides was evaluated for nanoparticle conjugation. Selected key properties of the corresponding DNA-AuNP conjugates, such as stability in the presence of NaCl, UV/vis absorption maximum, and the ability to hybridize with complementary conjugates, were compared to DNA-AuNP conjugates utilizing the 5′-hexylthiol linker as molecular anchor.

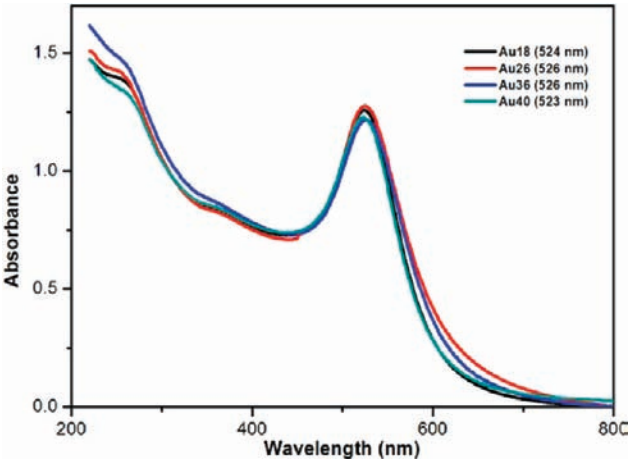

Figure 5. UV/vis profiles of selected DNA-AuNP conjugates in 0.1 M NaCl, 10 mM phosphate buffer, pH 7.0.

The unmodified AuNPs were functionalized with oligonucleotides **18**−**39** containing one or multiple thiooxonucleosides (**1**−**4**) at different positions. For that, 1 mL of the unmodified AuNP solution was mixed with the aqueous solution of the respective purified oligonucleotide (1−5 μL) to yield a final oligonucleotide concentration of 3 μM. The conjugation was performed at slightly elevated temperature (40 °C). The NaCl concentration of the DNA-AuNP solution was increased stepwise with phosphate buffer (2 M NaCl, 0.2 mM phosphate buffer, pH 7.0) to a final NaCl concentration of 0.1 M. Unbound oligonucleotides were removed from the DNA-AuNP solutions by a repeated washing and centrifugation protocol with 0.1 M NaCl, 10 mM phosphate buffer (pH 7.0) (for details see Experimental Procedures). During the whole procedure, the DNA gold nanoparticle solutions stayed deep red in color. However, we found that the preparation of DNA-AuNP conjugates with oligonucleotides **20**−**21** or **24**−**25** incorporating **2** and **4** were encountered with difficulties. Contrary to all other samples, conjugation of **20**−**21** and **24**−**25** to AuNPs failed several times (50% failure). Moreover, the centrifugation speed had to be reduced significantly from 8000 rpm (standard speed) to 5800 rpm; otherwise, it was not possible to redisperse the precipitate. Finally, all DNA-AuNP

Table 3. Applicability of Thiooxonucleosides 1−4 and 5′-Hexylthiol Linker for Gold Nanoparticle Conjugate Formation[e]

[a] Measured at 260 nm in 0.1 M NaCl, 10 mM phosphate buffer (pH 7.0), with 5 μM single-strand concentration. [b] Spacer T_{10} = 5′-d(TTT TTT TTT T). [c] ΔT_m was calculated as $T_m^{\text{base mismatch}} - T_m^{\text{base match}}$.

conjugates **Au18**-**Au29** and **Au36**-**Au39** showed the expected plasmon resonance at around 524 nm indicating a nonaggregated state (Table 1, Figure 5, and Figure S2, Supporting Information). It is worthwhile to mention that the same absorption maximum (524 nm) is also observed for DNA-AuNP conjugates **Au36**-**Au39**, in which the attachment succeeds through thionucleoside **1** situated within an internal position of the respective oligonucleotide (Figure 5). Thus, it can be concluded that thionucleoside **1** can also function as a molecular anchor for AuNPs through an internal position of an oligonucleotide.

For comparison, oligonucleotides **40** and **41** incorporating a 5′-hexylthiol linker were conjugated to AuNPs (→ **Au40**, **Au41**; Table 1) employing the conventional protocol reported earlier by others.[47] The UV/vis spectra of DNA-AuNP conjugates **Au40** and **Au41** show a plasmon resonance at 523 nm (Table 1, Figure 5).

Next, the stability of DNA-AuNP conjugates **Au18**-**Au29** containing the different thiooxonucleosides **1**−**4** and **Au40**, **Au41** employing the hexylthiol linker was evaluated at higher salt concentration (0.2 M NaCl, 10 mM phosphate, pH 7.0 buffer solution). For that, UV/vis spectra of the DNA-AuNP conjugate solutions were recorded at different time intervals and compared (for UV/vis profiles at the different time intervals see the Supporting Information, Figure S3). This experiment was performed to provide more information on the applicability of **1**−**4** for AuNP conjugation and hence on the stability of the different conjugates (Table 3). The DNA-AuNP conjugates **Au22**-**Au25** using 4-thio-2′-deoxythymidine (**3**) or 2-thio-2′-deoxythymidine (**4**) as anchor molecules were unstable in the presence of higher NaCl concentration. This became immediately evident for DNA-AuNPs **Au24** and **Au25** containing 2-thio-2′-deoxythymidine (**4**), due to aggregation of the DNA-AuNPs (solutions turned black) followed by precipitation (Table 3, entry 4), whereas DNA-AuNPs **Au22** and **Au23** showed partial precipitation which was deduced from a significant decrease in the maximum of the UV/vis absorption profile (36%) after overnight incubation compared to the original profile (0 h incubation) (Figure S3, Supporting Information). However, the plasmon resonance of conjugates **Au22** and **Au23** was almost unchanged (524.5 nm), but the red color of the solutions was much fainter compared to the original solutions. According to these observations, we classified DNA-AuNP conjugates using 4-thio-2′-deoxythymidine (**3**) as anchor molecule (**Au22** and **Au23**) as not stable in the presence of higher NaCl concentration (see Table 3, entry 3).

dx.doi.org/10.1021/bc200069j |Bioconjugate Chem. 2011, 22, 794–807

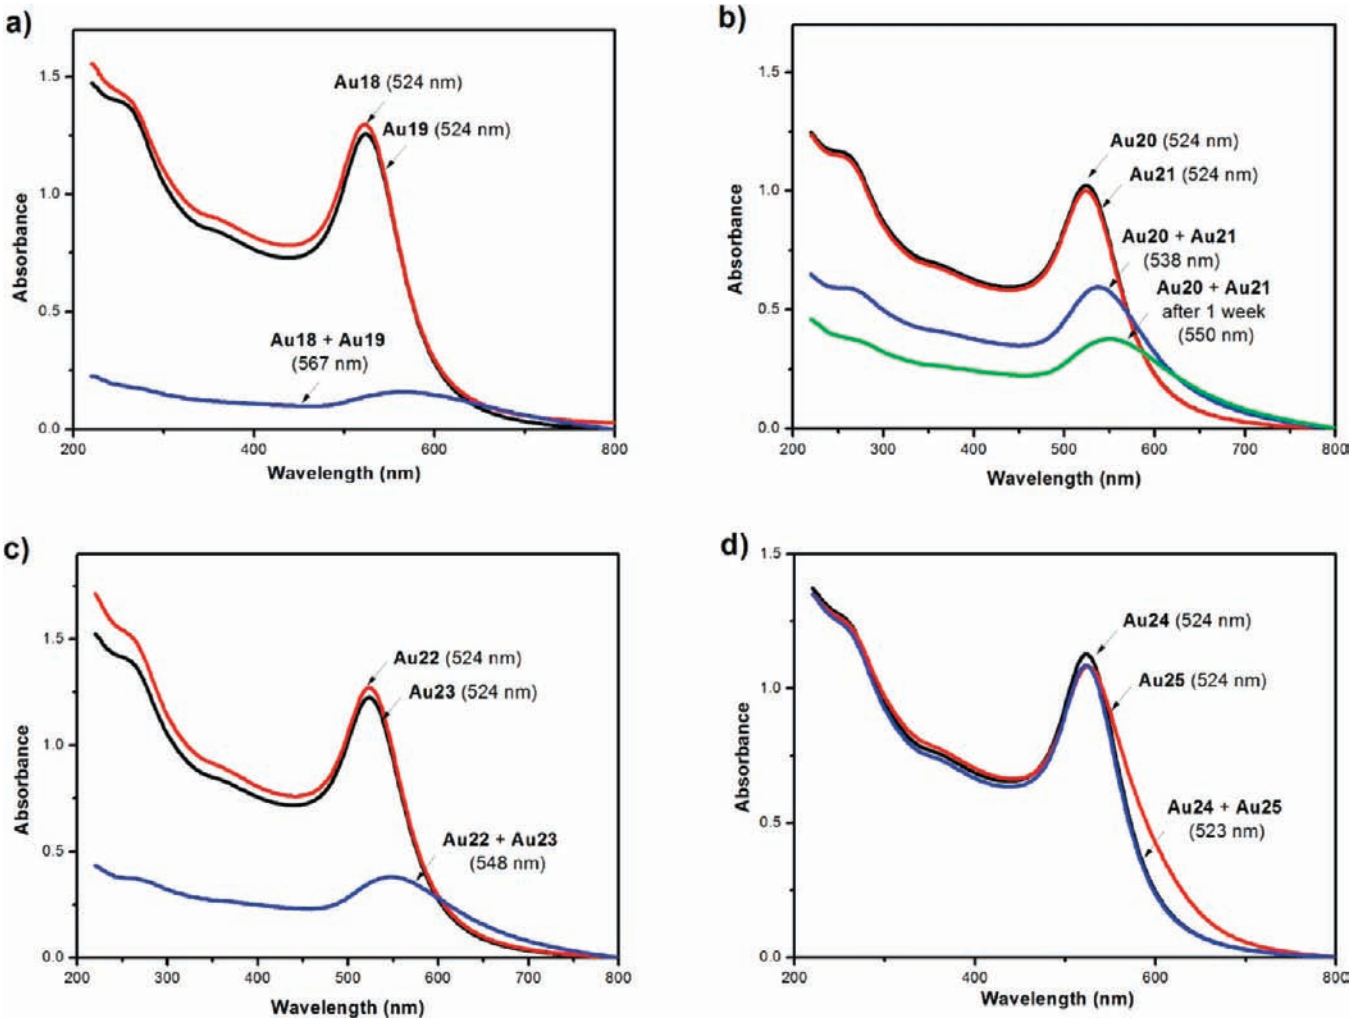

Figure 6. UV/vis spectra of (a) DNA-AuNP conjugates **Au18**, **Au19** using 7-deaza-6-thio-2′-deoxyguanosine (**1**) as anchor, and the DNA-AuNP network **Au18•Au19** formed after overnight incubation (blue curve). (b) DNA-AuNP conjugates **Au20** and **Au21** using 6-thio-2′-deoxyguanosine (**2**) as anchor (red and black curves), the DNA-AuNP network **Au20•Au21** formed after overnight incubation (blue curve) and after several days of incubation (green curve). (c) DNA-AuNP conjugates **Au22** and **Au23** using 4-thio-2′-deoxythymidine (**3**) as anchor and the DNA-AuNP network formed by **Au22•Au23** after overnight incubation (blue curve). (d) DNA-AuNP conjugates **Au24** and **Au25** using 2-thio-2′-deoxythymidine (**4**) as anchor (red and black curves) and after overnight incubation (blue curve).

On the contrary, the DNA-AuNPs **Au18**-**Au21** using 7-deaza-6-thio-2′-deoxyguanosine (**1**) or 6-thio-2′-deoxyguanosine (**2**) as conjugation site (Table 3, entry 1−2) and **Au40**, **Au41** making use of a hexylthiol linker (Table 3, entry 5) were of comparable stability, and all conjugates were significantly more stable than **Au22**-**Au25** under the higher salt concentration (see also Supporting Information, Figure S3).

Similar results were found for DNA-AuNP conjugates **Au26**-**Au29** having consecutive 7-deaza-6-thio-2′-deoxyguanosine (**1**) modifications at the 5′-end of oligonucleotides **26**−**29**, after overnight incubation in 0.2 M NaCl, 10 mM phosphate, pH 7.0 buffer solution (data not shown).

Duplex Stability of Oligonucleotides Containing Thiooxonucleosides 1−4 and Oligonucleotide Gold Nanoparticle Conjugates. It is well-known that in thiooxonucleosides the replacement of the oxygen atom by sulfur leads to a destabilization of duplex DNA since the thio group is a poorer hydrogen bond acceptor than the normal carbonyl, and bulkiness of the sulfur atom can interfere with hybridization.[48]

For clarification, hydridization studies were performed with non-immobilized oligonucleotide duplexes incorporating compounds **1**−**4** (Table 4). Single or multiple thiooxonucleosides (**1**−**4**) were incorporated as overhanging ends together with a 5′-d$(T)_{10}$ spacer. Table 4 shows that all duplexes have similar T_m values (47 °C) as the parent unmodified duplex 5′-d(TAG GTC AAT ACT) (**16**) • 3′-d(ATC CAG TTA TGA) (**17**).

As 7-deaza-6-thio-2′-deoxyguanosine (**1**) has not been incorporated into oligonucleotides before, its properties as a constituent of duplex DNA were investigated in more detail. Thus, consecutive and random positions have been selected for modification with **1**, and T_m values were determined.

A single replacement of nucleoside **1** in the center or at the periphery of the 12-mer duplex reduced the stability of the duplex. The effect was more pronounced when **1** was incorporated in the center of the oligonucleotide duplex (**16•31**: ΔT_m = −7 °C) than at the periphery (**16•30**: ΔT_m = −4 °C). Multiple modifications led to a significant further destabilization (ΔT_m = −30 °C for **32•33**) (Table 4). Consistently, two

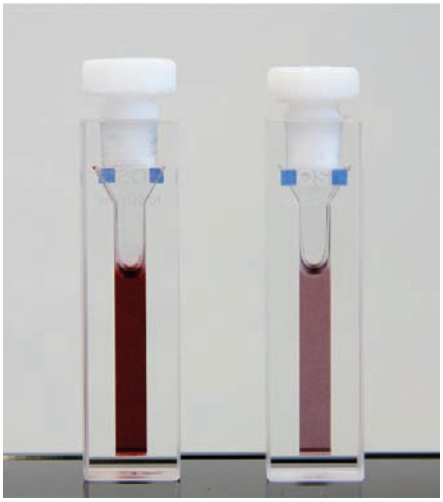

Figure 7. Left cuvette: unmodified deep red gold nanoparticle solution. Right cuvette: purple DNA-AuNP conjugate solution after assembly of **Au18•Au19** (12 h incubation, the sample is shown after intensive shaking).

incorporations of nucleoside **1** within the center or at the periphery of 24-mer duplexes (**36•37**, **38•39**) lead to a strong decrease of the duplex stability when compared to the parent unmodified duplex **34•35** ($\Delta T_m = -10$ °C for **36•37** and $\Delta T_m = -12$ °C for **38•39**). As can be seen from Table 4, 7-deaza-6-thio-2′-deoxyguanosine (**1**) has a strong destabilizing effect on duplex stability similar to that reported for the parent 6-thio-2′-deoxyguanosine (**2**).[48]

Next, hybridization experiments were performed with oligonucleotide gold nanoparticle conjugates. In a typical experiment, two DNA-AuNP conjugates carrying oligonucleotides with complementary sequences were mixed together (equal concentrations), e.g., DNA-AuNP conjugates **Au18** and **Au19** using 7-deaza-6-thio-2′-deoxyguanosine (**1**) as molecular anchor. After incubation overnight at 5 °C, the propensity of hybridization was evaluated by UV/vis measurements. Almost all complementary DNA-AuNP conjugates show hybridization evidenced by slow red shifting and broadening of the plasmon resonance band (Table 3 and Figures 6, 7) with the exception of the complementary conjugates **Au24** and **Au25** which utilize 2-thio-2′-deoxythymidine (**4**) as molecular anchor.

In the case of the complementary conjugates **Au18•Au19**, **Au22•Au23**, and **Au40•Au41**, hybridization led to the formation of a DNA gold nanoparticle network which precipitated from solution (→ dark red precipitate with a clear supernatant) within one night. After intensive shaking of the DNA-AuNP solution, the precipitate can be redispersed leading to a purple solution with UV/vis maxima of 567 nm for **Au18•Au19** (Figure 6a), 548 nm for **Au22•Au23** (Figure 6c), and 554 nm for **Au40•Au41** (spectra not shown).

On the contrary, the UV/vis spectrum of the DNA-AuNP solution containing the complementary conjugates **Au20** and **Au21**, which use 6-thio-2′-deoxyguanosine (**2**) as molecular anchor, shows only a moderate red shift (524 nm→538 nm) of the plasmon resonance band accompanied by a smaller decrease of the absorption and only a slight broadening of the plasmon resonance band (Figure 6b, blue curve). However, no precipitation of the DNA-AuNPs was observed after incubation overnight. Prolonged incubation of about 1 week finally led to the precipitation of the DNA gold nanoparticle network. After intensive shaking of the DNA-AuNP solution **Au20•Au21**, the

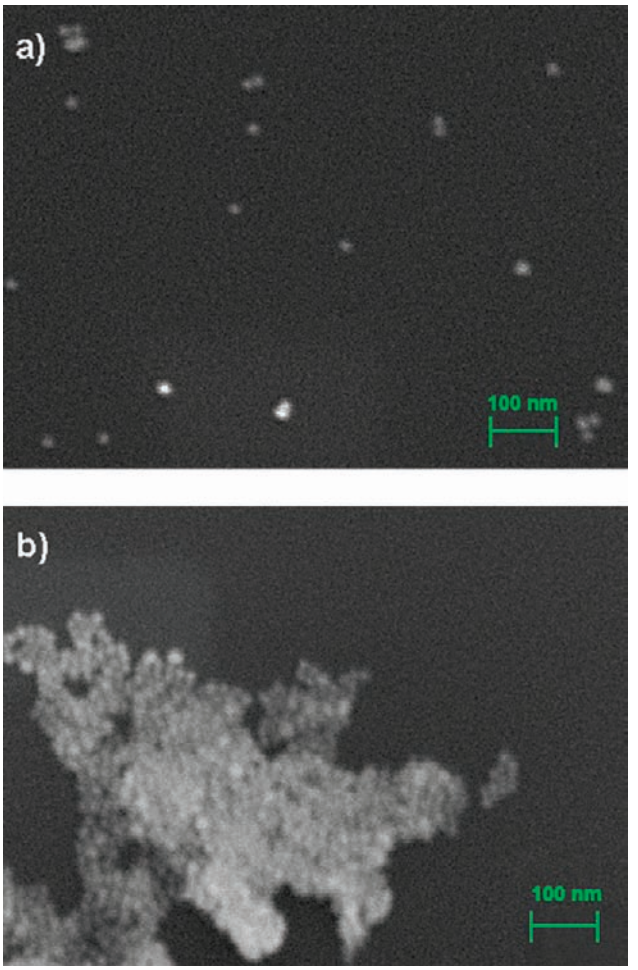

Figure 8. (a) SEM image of DNA-AuNP conjugate **Au18** employing 7-deaza-6-thio-2′-deoxyguanosine (**1**) as molecular anchor in 0.1 M NaCl, 10 mM phosphate buffer (pH 7.0); (b) SEM image of the DNA-AuNP network formed by complementary conjugates **Au18** and **Au19** in 0.1 M NaCl, 10 mM phosphate buffer (pH 7.0).

precipitate was redispersed leading to a purple solution with a UV/vis maximum of 550 nm (Figure 6b, green curve). Although the experiments was repeated several times, no network formation was observed for the complementary conjugates **Au24** and **Au25** containing 2-thio-2′-deoxythymidine (**4**), even after prolonged incubation of 1−2 weeks. The absorption maximum of the DNA-AuNP solution of **Au24** and **Au25** remained unchanged at around 524 nm (Figure 6d).

Taking together with the results summarized in Table 3, it can be concluded that, from all tested thionucleosides (**1**−**4**), the capability of 7-deaza-6-thio-2′-deoxyguanosine (**1**) as component of DNA oligonucleotides to form stable DNA gold nanoparticle conjugates is superior to that of thionucleosides **2**−**4**. DNA-AuNPs containing **1** are of comparable stability to those obtained from oligonucleotides containing the hexylthiol linker. On the contrary, thionucleosides **2**−**4** showed different drawbacks. For thionucleoside **2**, the time required for hybridization was much longer than for **1**. Up to now, we do not have an explanation regarding the prolonged incubation time required for the DNA-AuNP network formation of DNA-AuNPs with 6-thio-2′-deoxyguanosine (**2**) as molecular anchor. DNA-AuNPs with **3** and **4** were unstable in the presence of higher NaCl

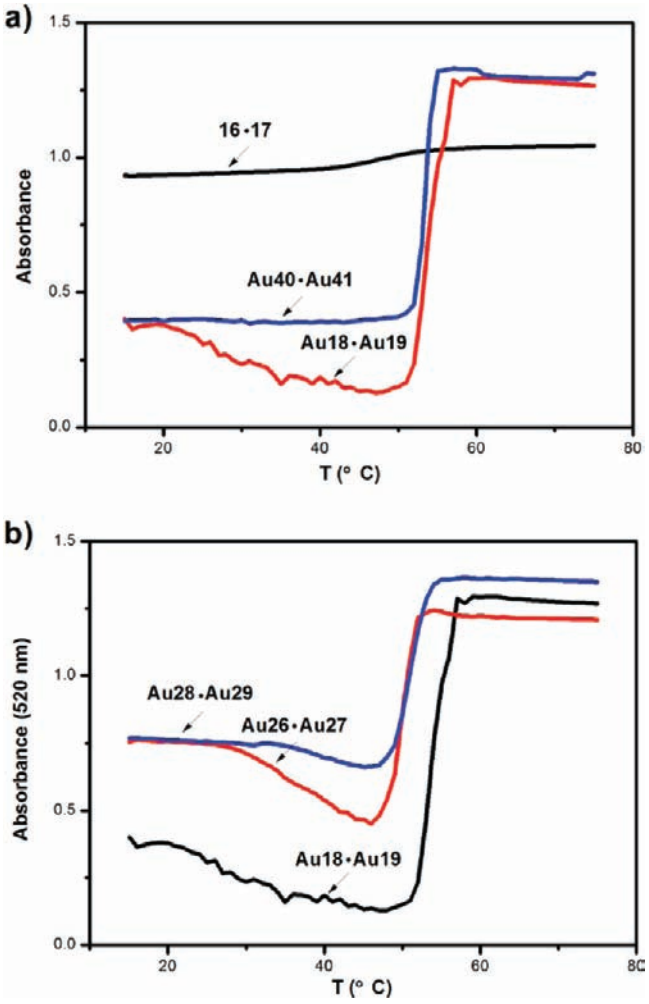

Figure 9. (a) Melting profile of the free duplex **16•17** determined at 260 nm (blue curve), and melting profiles of the DNA-AuNP assemblies of **Au18•Au19** (red curve) and **Au40•Au41** (blue curve) determined at 520 nm. (b) Melting profiles of the DNA-AuNP assemblies of **Au18•Au19** (black curve), **Au26•Au27** (red curve), and **Au28•Au29** (blue curve) determined at 520 nm.

concentration, and in addition, DNA-AuNPs with **4** are incapable of hybridization.

Thus, exemplarily, we selected DNA-AuNP solutions containing **1** to perform scanning electron microscopy (SEM) to visualize network formation. A representative section of an image showing the DNA-AuNP network formed by complementary conjugates **Au18** and **Au19** containing thionucleoside **1** is presented in Figure 8b. The SEM image shows the formation of large assembled networks of DNA-AuNP conjugates. Besides the assembled network, the neighboring area is remarkably "empty". For comparison, SEM images of nonassembled DNA-AuNP conjugates, such as **Au18** (Figure 8a), show small clusters of DNA-AuNPs which are fairly regularly distributed. The formation of large assembled networks as in Figure 8b was not observed in the case of **Au18**.

On the basis of the above-described results, melting studies were focused on DNA-AuNP conjugates employing thionucleoside **1** at different positions within the oligonucleotide chain. For comparison, T_m values were also determined for DNA-AuNP conjugates utilizing the hexylthiol linker. For this, the solutions

Table 5. T_m Values of DNA-AuNP Assemblies Incorporating Thionucleoside 1 and the Hexylthiol Linker.[a,b,c]

DNA-AuNP Assemblies	T_m [°C]

[a] Measured at 520 nm in 0.1 M NaCl, 10 mM phosphate buffer (pH 7.0), with A_{520} = 2.1 for each DNA-AuNP conjugate solution. [b] Red ball = 15-nm-diameter gold nanoparticle. [c] Spacer T_{10} = 5′-d(TTT TTT TTT T). *n.m.* no melting observed.

containing the DNA-AuNP networks were heated (15 °C → 75 °C), and the vis absorption change at 520 nm was observed while stirring the DNA-AuNP solution. The T_m values were determined by taking the maximum of the first derivative of a melting transition and are enlisted in Table 5.

A typical sharp melting profile of **Au18•Au19** is shown in Figure 9a indicating a T_m value of 54 °C for the network of DNA-AuNPs assembled by duplex **18•19**. For comparison, the dissociation of the network formed by the conjugates **Au40** and **Au41** containing complementary oligonucleotides with hexylthiol linker was investigated under exactly the same conditions as described for the **Au18•Au19** assembly. For **Au40•Au41**, an almost identical T_m value of 53 °C was determined (Figure 9a and Table 5). It should be noted that both assemblies employ the same sequence consisting of a 12-mer oligonucleotide for base pairing and a 10-mer poly dT spacer, while the only difference is the molecular anchor being 7-deaza-6-thio-2′-deoxyguanosine (**1**) for **Au18•Au19** and the hexylthiol linker for **Au40•Au41**. Moreover, both assemblies exhibit melting profiles with a very narrow melting transition (about 4 °C) as demonstrated in Figure 9a, whereas for the parent free oligonucleotide duplex **16•17**, melting occurs over a much broader temperature range (about 20 °C) (Figure 9a). This finding is consistent with observations made earlier by others reporting that oligonucleotide duplexes covalently bound to gold nanoparticles show highly cooperative melting properties of the network forming duplexes, which is reflected by a sharp melting transition.[12,18,49]

Next, complementary DNA-AuNPs functionalized with multiple 5′-terminal thionucleosides **1** were allowed to hybridize (→ **Au26•Au27**, **Au28•Au29**). In both cases, the recognition sequence of **18•19** was used together with the 5′-d$(T)_{10}$ linker as described above. As shown in Table 5, these conjugate

assemblies exhibit very similar T_m values (**Au26•Au27**: T_m = 50 °C; **Au28•Au29**: T_m = 51 °C). The melting profiles of **Au26•Au27** and **Au28•Au29** also display a narrow melting transition range (around 4 °C) and are depicted in Figure 9b. However, compared to the T_m value found for the assembly **Au18•Au19** employing only one thionucleoside **1** per oligonucleotide strand, these values are 3−4 °C lower but still within the same range.

The melting behavior of complementary DNA-AuNP conjugates carrying 24-mer oligonucleotides which use thionucleoside **1** as anchor molecule at internal positions within their sequence was also investigated (**Au36-Au39**, Table 5). The oligonucleotides of **Au36-Au39** are composed of a twofold repeated recognition sequence allowing formation of 24 base pairs or partial hybridization (12 base pairs).

The DNA-AuNP conjugates **Au38** and **Au39** employing 24-mer complementary oligonucleotides with compound **1** located in the center of each oligonucleotide cannot form a DNA-AuNP interlinked network. Even prolonged incubation did not lead to a color change of the combined conjugate solution, and no shift of the vis maximum was observed. Thus, it can be concluded that no hybridization occurred, which is due to the negative effect of an internal thiooxo group on hybridization. Moreover, hybridization is probably additionally hindered by the short distance to the immobilization site of the gold nanoparticles.

On the contrary, a T_m value of 53 °C was detected for the closely related assembly **Au36•Au37** with thionucleoside **1** being located at the periphery of the 24-mer oligonucleotide sequences. This T_m value is consistent with that of **Au18•Au19** employing a complementary 12-mer duplex for assembly. In this regard, the observed T_m value points to a partial hybridization of the complementary oligonucleotides within the DNA-AuNP assembly. Two principle situations appear to be most conclusive, (i) a matched duplex with fraying ends and base pairing only in the center of the duplex and (ii) a shift of the complementary sequences with respect to each other leading to partial hybridization of the duplex and leaving the unpaired nucleosides as spacers between the recognition site and the gold nanoparticles. We think that a partial overlap of the recognition sites are responsible for the almost identical T_m values of **Au36•Au37** and **Au18•Au19**. Thus, the second recognition element is acting simply as spacer extending the distance to the gold nanoparticles not taking part in the hybridization process.

CONCLUSIONS

We have shown that thiooxo groups of base-modified nucleosides can be used as molecular anchors to conjugate oligonucleotides to gold nanoparticles. Compared to already existing gold nanoparticle conjugation protocols, the new linker strategy simplifies immobilization of oligonucleotides to gold nanoparticles. The method reduces additional steps such as (i) detritylation of the linker with silver nitrate which has to be performed immediately before the conjugation reaction and (ii) removal of excess silver nitrate, followed by (iii) desalting of the oligonucleotide.

Thionucleosides can be used in place of canonical DNA constituents. Incorporation of the sulfur containing nucleosides can be performed at any position of an oligonucleotide; even multiple incorporations are feasible, which will increase the binding stability of the corresponding oligonucleotides to the gold nanoparticles. 7-Deaza-6-thio-2′-deoxyguanosine (**1**) shows advantages over other thionucleosides, such as **2**−**4**, regarding stability during oligonucleotide synthesis, deprotection, and purification. Thus, solid-phase synthesis with phosphoramidites, e.g., with **6**, as well as enzymatic polymerization with corresponding triphosphates employing polymerases or terminal transferases can be performed. 7-Deaza-6-thio-2′-deoxyguanosine (**1**) can replace dG. The lower stability of nucleoside **1**•dC base pairs compared to those with dG or 7-deaza-2′-deoxyguanosine resulting from the bulkiness of the thiooxo group will not affect hybridization when the incorporation of **1** occurs outside of the recognition sequence. UV/vis spectra and hybridization properties of DNA-AuNP conjugates using thionucleoside **1** as molecular anchor reveal properties which are comparable to those containing the commercial hexanethiol linker.

Hydrolytic stability of thiooxonucleosides in aq. ammonia

The hydrolysis stability of thiooxonucleosides **1**-**4** (Scheme S1) under standard deprotection conditions (25% aqueous NH_3, 14-16 h, 60°C) was monitored by reversed-phase HPLC (RP-18, 250 x 4 mm). Nucleosides **1**-**4** (about 1 mg) were dissolved in 1 mL 25% aq. ammonia in a sealed vessel and incubated at 60°C. After 16 h incubation, aq. NH_3 was removed by evaporation and the residue was redissolved in 1 mL HPLC buffer A. 50 µL of each sample were injected into the HPLC apparatus, and the HPLC profile was recorded at 260 nm (Figure S1). The following solvent gradient system was used: [A: 0.1 M (Et_3NH)OAc (pH 7.0)/MeCN 95:5; B: MeCN; gradient: 0–15 min 0–30% B in A, 30–40 min 30–40% B in A, 40–45 min 40–0% B in A, flow rate 0.7 mL/min]. The products were identified by coelution with standard nucleosides. Quantification of the constituents was made on the basis of the peak areas, which were divided by the extinction coefficients of nucleosides (ε_{260}). Extinction coefficients were determined in HPLC buffer A. 7-Deaza-6-thio-2'-deoxyguanosine (**1**) 10100, 2-amino-2'-deoxytubercidin (**13**) 9000, 6-thio-2'-deoxyguanosine (**2**) 7300, 2-amino-2'-deoxyadenosine (**14**) 8600, 4-thio-2'-deoxythymidine (**3**) 1500, 5-methyl-2'-deoxycytidine (**15**) 5900.

Novel Method to Label Solid Lipid Nanoparticles with ^{64}Cu for Positron Emission Tomography Imaging

Erica Andreozzi, Jai Woong Seo, Katherine Ferrara, and Angelique Louie*

Department of Biomedical Engineering, University of California, Davis, California, United States

ABSTRACT: Solid lipid nanoparticles (SLNs) are submicrometer (1−1000 nm) colloidal carriers developed in the past decade as an alternative system to traditional carriers (emulsions, liposomes, and polymeric nanoparticles) for intravenous applications. Because of their potential as drug carriers, there is much interest in understanding the *in vivo* biodistribution of SLNs following intravenous (i.v.) injection. Positron emission tomography (PET) is an attractive method for investigating biodistribution but requires a radiolabeled compound. In this work, we describe a method to radiolabel SLN for *in vivo* PET studies. A copper specific chelator, 6-[*p*-(bromoacetamido)-benzyl]-1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAT), conjugated with a synthetic lipid, was incorporated into the SLN. Following incubation with $^{64}CuCl_2$ for 1 h at 25 °C in 0.1 M NH_4OAc buffer (pH 5.5), the SLNs (∼150 nm) were successfully radiolabeled with ^{64}Cu (66.5% radiolabeling yield), exhibiting >95% radiolabeled particles following purification. The ^{64}Cu-SLNs were delivered intravenously to mice and imaged with PET at 0.5, 3, 20, and 48 h post injection. Gamma counting was utilized post imaging to confirm organ distributions. Tissue radioactivity (% injected dose/gram, %ID/g), obtained by quantitative analysis of the images, suggests that the ^{64}Cu-SLNs are circulating in the bloodstream after 3 h (blood half-life ∼1.4 h), but are almost entirely cleared by 48 h. PET and gamma counting demonstrate that approximately 5−7%ID/g ^{64}Cu-SLNs remain in the liver at 48 h post injection. Stability assays confirm that copper remains associated with the SLN over the 48 h time period and that the biodistribution patterns observed are not from free, dissociated copper. Our results indicate that SLNs can be radiolabeled with ^{64}Cu, and their biodistribution can be quantitatively evaluated by *in vivo* PET imaging and *ex vivo* gamma counting.

INTRODUCTION

Solid lipid nanoparticles (SLNs) have emerged as an efficient, nontoxic, and versatile colloidal drug carrier system that avoids some of the disadvantages of liposomes and polymeric nanoparticles.[1] Because SLNs are composed of physiological lipids (i.e., fatty acids; mono, di, and triglycerides; phospholipids; etc.), they tend to show high compatibility and biodegradability and have a lower risk of the acute and chronic toxicity that is often associated with polymeric nanoparticles.[3,4] Furthermore, because SLNs comprise a solid lipid core instead of an aqueous core, they offer better protection against chemical degradation to their drug cargo than liposomes, and also facilitate sustained drug release due to the zero-order kinetic breakdown of the solid lipid matrix.[1,3,4] The solid lipid matrix of the SLN core can be modified to incorporate either hydrophobic or hydrophilic cargo.[4−6] The capability of SLNs to stably carry various types of cargo proteins[7,8] (cyclosporine,[9] insulin,[10] thymopentin,[11] etc.), antibiotics (tobramycin[12]), therapeutic agents[13] (camptothecin,[14] doxorubicin,[15] DNA,[16,17] siRNA,[18]), and diagnostic agents (gadolinium,[19,20] iron oxide nanoparticles,[21]) under various routes of administration (i.e., oral,[10] parenteral,[22] dermal,[23,24] ocular,[25,26] pulmonary,[27] and intravenous[28]) has generated increasing interest in their use as drug carriers.

To date, most of the studies evaluating SLNs as a drug carrier have focused on the delivery of the SLN cargo (i.e., encapsulated drug)[14,29] to the target site without investigating the fate of the SLN carrier itself. However, with the potential for release of cargo, it is crucial to understand the biodistribution of the carrier. This is especially important in guiding the appropriate SLN modifications necessary to control drug targeting behavior in a variety of applications. The aim of this work was to radiolabel SLNs with a positron emitting radionuclide (i.e., ^{64}Cu) in order to track their biodistribution *in vivo* using positron emission tomography (PET). PET is a noninvasive, nuclear imaging technique that is capable of visualizing deep tissues with a high sensitivity of 0.02−0.10 cps/Bq (2−10%)[30] and generating a three-dimensional image of living subjects. Using mathematical reconstruction methods and correction factors, quantitative information can be extracted from the images, and radioisotope concentration can be measured in a specific region of interest (ROI).[30,31] Herein, we describe a method to radiolabel SLNs with positron emitter ^{64}Cu (half-life = 12.7 h)[32] through the incorporation of a lipid-PEG-chelate (6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAT) conjugated to a synthetic lipid)[2] into the phospholipid monolayer comprising the SLN surface (Figure 1). PET imaging was used to track the biodistribution of

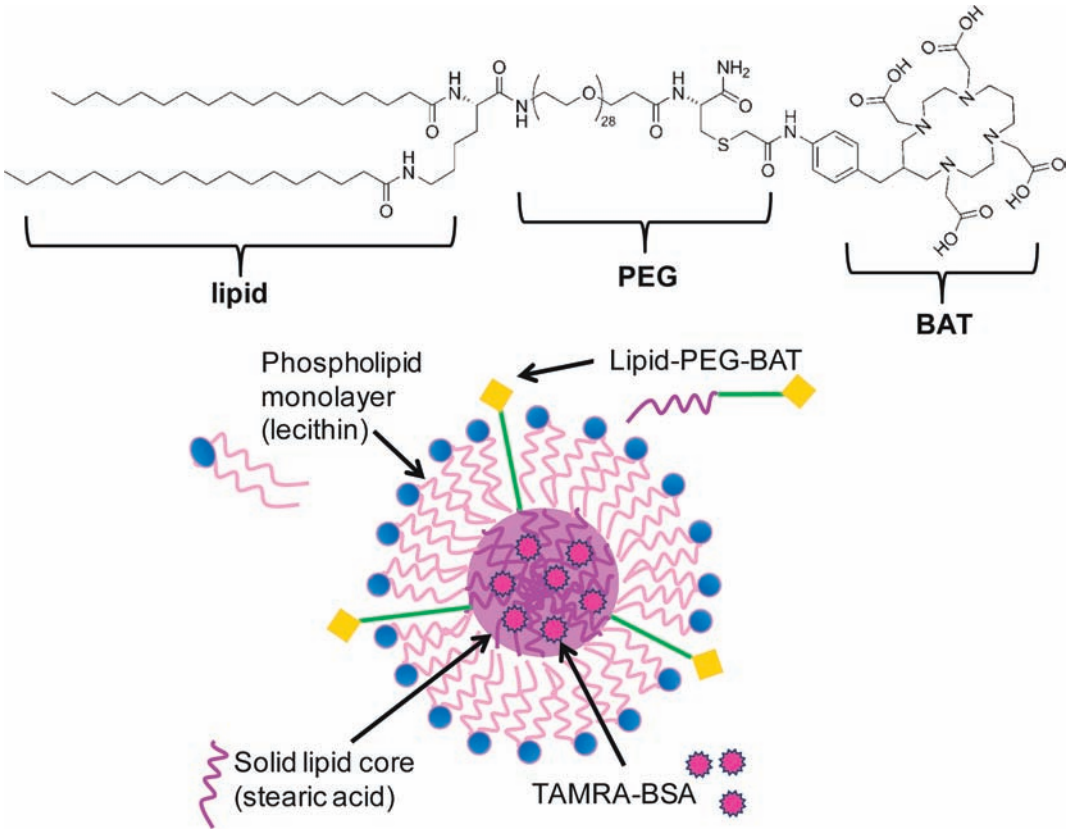

Figure 1. Schematic of SLN-BAT. The lipid-PEG-BAT (left) molecule is incorporated into the SLN such that the stearic acid lipid tail is embedded in the stearic acid lipid core, while the PEG is associated with the lecithin monolayer, and the BAT chelator remains accessible from outside the SLN (right). We anticipate that van der Waals forces would cause the lipid portion of the lipid-PEG-BAT molecule to associate with the lipid core of the SLN and therefore be incorporated inside. We also anticipate that van der Waals forces would cause the hydrophilic PEG portion of the lipid-PEG-BAT to be associated with the hydrophilic headgroups of the lecithin molecule, leaving the BAT accessible on the surface of the SLN. By testing the ability for the SLNs to radiolabel ^{64}Cu, we validate the incorporation of lipid-PEG-BAT into the SLN and the accessibility of the BAT groups on the surface.

the SLN and followed up to 48 h following intravenous (i.v.) administration.

EXPERIMENTAL PROCEDURES

Materials. Laboratory-grade vegetable lecithin, stearic acid, and 1-butanol were purchased from Fisher Chemical (Pittsburgh, PA). Sodium taurodeoxycholate hydrate, high-purity ammonium acetate (≥99.995%), and Sephadex (G-25, G-50) were purchased from Sigma-Aldrich (St. Louis, MO). Bovine serum albumin was from Acros Organics, Belgium, distributed by Fisher Scientific. 5-(and-6)-Carboxytetramethylrhodamine, succinimidyl ester (5(6)-TAMRA, SE) *mixed isomers* (TAMRA) (*Ex* = 555 nm, *Em* = 580 nm) was purchased from Invitrogen Corporation (Carlsbad, CA). Formvar coated copper grids (300 Mesh) were purchased from SPI Supplies (West Chester, PA). $^{64}CuCl_2$ was purchased from Washington University (St. Louis, MO). Nanopure water (18.0 MΩ·cm) was prepared from deionized water using a Barnstead nanopure filtration unit.

Encapsulation of Fluorescently Labeled Protein into SLN. *Fluorescent Labeling of BSA.* Bovine serum albumin (BSA) was labeled with the fluorophore, 5(6)-carboxytetramethyl-rhodamine *N*-hydroxy-succimide ester (TAMRA), following the standard Invitrogen protocol for labeling proteins with amine-reactive fluorophores. First, BSA was dissolved in 0.1 M sodium bicarbonate buffer (10 mg/mL). TAMRA (10 mg/mL in dimethyl sulfoxide) was slowly added to the BSA solution in a 2:1 molar ratio of TAMRA to BSA under continuous stirring for 1 h at room temperature. The unlabeled TAMRA was separated from the BSA-TAMRA conjugate through a Sephadex (G-25) packed bed column equilibrated with 0.1 M sodium bicarbonate buffer. After separation, the BSA-TAMRA conjugate was dialyzed (50,000 MWCO) for 3 days with 0.1 M sodium citrate (pH 7.2) to remove buffer salts.[33] BSA-TAMRA was encapsulated into solid lipid nanoparticles (SLNs) using a modification of a water/oil/water method.[11,34]

Incorporation of Labeled BSA into SLN: Water/Oil/Water Method. A warm W/O phase was first prepared by adding a warm aqueous solution of BSA-TAMRA (300 mg/mL) to a mixture of molten stearic acid, lecithin, and 1-butanol at 78 °C (Table 1). The W/O phase was then cooled to room temperature, and a portion of this warm solid phase was added to a warm mixture of nanopure water, lecithin, sodium taurodeoxycholate, and 1-butanol at 76 °C forming a W/O/W emulsion (amounts given in Table 1). The W/O/W (∼0.3 mL) was then dispersed in 10 mL of cold nanopure water (1/33, v/v) at 4 °C under rapid stirring, forming SLNs. The resulting SLN suspension was filtered through Millipore polyethersulfone syringe-filter units (0.22 μm pore size, Millipore) to select for particles of <220 nm. Then, the SLN-BSA-TAMRA suspension (10 mL) was washed

Table 1. Preparation of SLN with Optical Cargo: W/O and W/O/W Phase Composition

W/O phase		W/O/W phase	
material	amount	material	amount
Stearic acid	67.2 mg, 0.24 mol	Nanopure water	158.3 mg
Lecithin	40.2 mg, 0.05 mol	Lecithin	8.5 mg, 0.01 mol
1-Butanol	32.6 mg, 0.44 mol	Sodium taurodeoxycholate	10.4 mg, 0.02 mol
BSA-TAMRA (aq)	10.2 mg, 0.0002 mol	1-Butanol	2.8 mg, 0.04 mol
	N/A	W/O phase	18.00 mg

(3×) with nanopure water and concentrated (2 mL) using an Amicon ultrafiltration cell with 100 000 MWCO membrane filters (Millipore).

Characterization (Size, Morphology, Encapsulation Efficiency, Toxicity) of SLN. The average size and polydispersity index (PDI) of the protein-loaded SLNs were determined with dynamic light scattering (DLS) immediately following synthesis (Nanotrac 150 particle size analyzer, Microtrac). Particle size was also measured using transmission electron microscopy (TEM) (Phillips CM-120) operating at 80 keV. The SLN suspensions were diluted 10- and 20-fold and plated onto Formvar coated copper grids (300 Mesh) to dry overnight. Images were analyzed using *ImageJ* software (National Institutes of Health) and $n = 500$ particles were measured to yield average particle diameter. In addition to size analysis, the zeta potential of the SLNs was measured with a NICOMP 380 ZLS (Particle Sizing System, CA).

The amount (mg) of BSA-TAMRA found in the retentate (SLN-BSA-TAMRA) and the elutant (free BSA-TAMRA) after ultrafiltration was determined by measuring the fluorescence intensity (Fluoromax) at 580 nm and used to characterize the amount of fluorescently labeled protein encapsulated by the SLN. The % encapsulation efficiency (%EE) of the protein within the SLNs was calculated according to the following equation:

$$\%\mathrm{EE} = [\mathrm{BSA-TAMRA(mg)in\ retentate}]/[\mathrm{BSA-TAMRA\ (mg)in\ retentate + elutant}] \times 100\%$$

Cytotoxicity Measurements. Madin-Darby canine kidney cells (MDCK), a kind gift from the Reen Wu lab (University of California, Davis), were plated onto 96 well plates at a seeding density of $\sim 1 \times 10^3$ cells per well. The cells were maintained in phenol-red free Dulbecco's Eagle minimum essential medium (DMEM), supplemented with 2 mM L-glutamine, 10% fetal bovine serum (FBS), and streptomycin/penicillin (100 U/mL) at 5% CO_2 and 37 °C. The medium was changed every other day until the cells reached confluency, then the cells were washed three times with phosphate buffered saline (PBS)[35] and 100 μL of a 25 mM (lipid concentration) solid lipid nanoparticle (SLN) suspension was added above the cell monolayer in each well for the experimental group, while phenol-red free DMEM was added for the control. The SLNs in this suspension were reconstituted in DMEM free of phenol-red indicator in order to prevent any interference with the cell viability fluorescence assay measurements. The cells were incubated with the SLN for 24 h (5% CO_2, 37 °C) and then the medium was removed. Next, 100 μL of a LIVE/DEAD working solution (Invitrogen) containing 1 μM calcein AM and 2 μM EthD-1 was added to each well and allowed to incubate at room temperature for 30 min. Calcein (Ex/Em ~495 nm/~515 nm) is only retained in live cells, and cell viability was quantified by measuring the fluorescence (Ex/Em ~495 nm/~525 nm) of the cells using a microplate spectrophotometer (Safire II, Tecan Group Ltd.) The average fluorescence (Ex/Em ~495 nm/~515 nm) intensities of the cells incubated with and without SLNs (lipid concentration = 25 mM) were measured. A two-tailed *t*-test was performed to determine if there was a significant difference in viability between the cells that had been incubated with the SLNs and controls.

Radiolabeling, Purification, and Stability of Protein-Loaded SLNs. *Incorporation of BAT Chelator into the SLN (SLN-BAT).* Solid lipid nanoparticles (SLNs) were synthesized using the same W/O and W/O/W phase compositions as above, shown in Table 1, with the exception of adding 164.7 μg (0.062 μmol, 0.5% mol/mol ratio BAT to lipid) lipid-PEG-BAT (164.7 μL of 1 μg/μL solution) to the warm mixture of nanopure water, lecithin, sodium taurodeoxycholate, and 1-butanol before the addition of the W/O phase in the W/O/W formation. We used lipid-PEG-BAT conjugate previously synthesized by Fmoc solid-phase synthesis and purified by reverse-phase high-performance liquid chromatography (HPLC), with the mass confirmed by matrix-assisted laser desorption/ionization (MALDI) (measured, 2662).[2] The W/O/W (~0.3 mL) was then dispersed in 10 mL of cold nanopure water (1/33, v/v) at 4 °C under rapid stirring, forming SLNs. The SLNs were then filtered through Millipore polyethersulfone syringe-filter units (0.22 μm pore size, Millipore) to select for particles of <220 nm and particle size was determined using DLS. Immediately after sizing, the SLN suspension (10 mL) was washed (3×) and concentrated to 200 μL using an Amicon ultrafiltration cell with 300,000 MWCO membrane filters (Millipore).

^{64}Cu Radiolabeling of SLN-BAT (^{64}Cu-SLN). An aliquot of 0.1 M ammonium acetate (NH_4OAc solution, pH 5.6) was added to the concentrated SLN-BAT solution to adjust the pH to 5.5. Copper-64 chloride ($^{64}CuCl_2$) solution (4.1−5.1 mCi, 151.7−188.7 MBq in 10 mM HCl) was combined with the SLN-BAT solution, resulting in final concentration of ~10 mCi/mL and ~1.3 mCi/mg lipid. After vortexing, this solution was incubated for 1 h at room temperature. Then, EDTA solution (0.1 M, 30 μL, 1/10 v/v ratio) was added (final EDTA concentration 10 mM) to the mixture and incubated for 30 min at room temperature in order to chelate the unbound ^{64}Cu. Free ^{64}Cu-EDTA was removed from the ^{64}Cu-SLN suspension (0.3 mL) by chromatography through a G-50 Sephadex column (GE Healthcare, NJ) eluted with 0.9% saline, and the eluted fractions (~1.0 mL) were collected in 1.5 mL centrifuge tubes. Radioactivity of the ^{64}Cu-SLN suspension before and after column purification was measured with a Fluke Biomedical Dose calibrator (34−162 CAL/RAD MARK IV, Cleveland, OH). The radiolabeling yield (%) for the SLNs was determined by dividing the radioactivity of the largest fraction by the sum of all the fractions (total activity) and multiplying by 100. Thin-layer

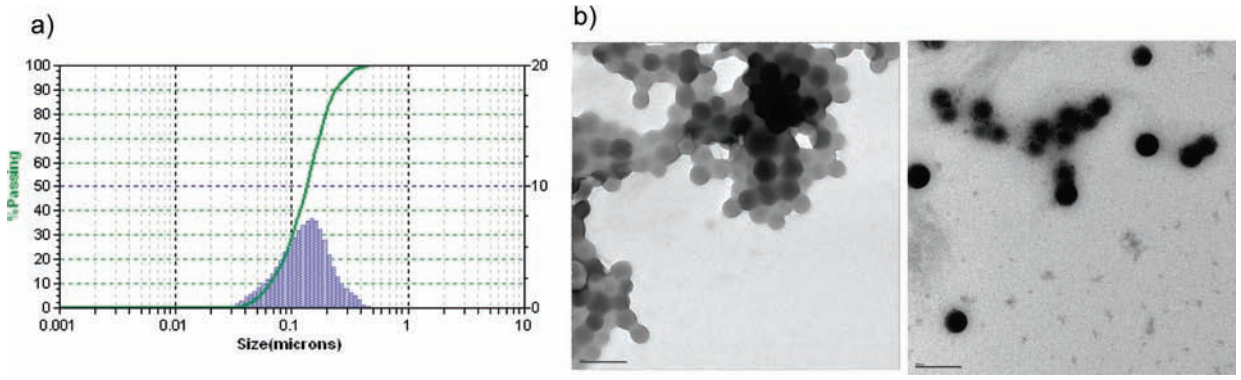

Figure 2. Size characterization of SLNs. (a) Average hydrodynamic diameter (145.2 ± 7.0 nm) of the optical SLNs, measured using dynamic light scattering (DLS). (b) Transmission electron microscopy (TEM) images of the 10-fold (left) and 20-fold (right) diluted SLN suspensions showing the mean dehydrated SLN diameter = 89 nm; scale bar = 100 nm.

chromatography (TLC) of the purified ^{64}Cu-SLNs was run on aluminum-backed silica gel sheets (silica gel 60 F_{254}, EMD, NJ), developed with methanol/ammonium acetate (10%) (50/50, v/v), and the radio TLC was recorded by a radio-TLC Imaging Scanner (Bioscan, NW).

Stability of ^{64}Cu-SLNs. ^{64}Cu-labeled SLNs were incubated in calf bovine serum (100%, pH 7.4) and saline solutions with varying pH (5.5, 4.0, and 2.0) for up to 48 h in order to assess the stability of the complexed copper before and after administration in mice. An aliquot (100 μL) was removed at each time point (0.5, 3, 20, and 48 h) and measured for initial activity (before purification) using a dose calibrator. The aliquots were incubated for 10 min with 10 μL (1/10, v/v) EDTA (0.1 M in water) and centrifuged through filter tubes (Millipore, molecular weight cutoff [MWCO] = 10,000, Billerica, MA) at 14,500 rpm for 30 min to separate dissociated ^{64}Cu-EDTA in solution from the labeled SLNs on the filter. The activity remaining on the filter post purification was measured and divided by the initial activity to calculate the percentage (%) of label remaining on the SLNs. Comparisons between values were determined using the least-squares means *t*-test, and differences observed were considered significant when $p < 0.01$. For further confirmation of stability, radio TLC was performed on aliquots of ^{64}Cu-SLNs incubated with serum for 24 and 48 h. EDTA was used to chelate unbound ^{64}Cu in both the centrifugation purification and radio TLC measurements.

***In Vivo* Studies: Biodistribution and Pharmacokinetics of ^{64}Cu-SLN Using PET Imaging and Gamma Counting.** All animal studies were conducted under a protocol approved by the University of California, Davis, Animal Use and Care Committee. A total of 3 mice (female, 39.71 ± 3.11 g, Charles River, MA) were examined over the course of this study. Mice were initially anesthetized with 3.0% isofluorane, then maintained at 2.0−2.5% isoflurane, and catheterized to ensure proper tail vein injection. Injections (280−320 μL) of ^{64}Cu-SLN (409.01 ± 43.11 μCi, 15.1 ± 1.6 MBq, 9.9 ± 1.6 mg) in 0.9% saline were administered via tail vein injection, yielding a lipid dose of 0.27 ± 0.04 mg/g animal and 38.36 ± 7.16 μCi/mg lipid (1.4 ± 0.3 MBq/mg lipid). Static PET scans (0.25, 1.0, 0.75, and 1.0 h duration scans) were acquired for each animal (anesthetized with 1.5% isoflurane maintenance dose) at 0.5, 3.0, 20, and 48 h post injection using the MicroPETII scanner.[36] The MicroPETII consists of 17,640 LSO crystals each measuring 0.975 × 0.975 × 12.5 mm^3, which are arranged in 42 contiguous rings, with 420 crystals per ring. The scanner has an axial field of view (FOV) of 4.9 cm and a transaxial FOV of 8.5 cm.[37] The limited transaxial FOV of ∼8.5 cm only enabled signal acquisition from the top of the head to the liver region. Therefore, signal from organs below the liver (i.e., kidney, bladder, etc.) was not included in the images. The reconstructed spatial resolution is ∼1 mm with an absolute system sensitivity of 2.26%.[36] Static scans yield a single image that represents the average intensities for a given acquisition time.

The static PET scans were reconstructed with a maximum a posteriori (MAP) algorithm and used to obtain quantitative activity levels in each organ of interest as a function of time. Tissue radioactivity was determined using the mean activity value given by the *ASIPro Virtual Machine* software (CTI Molecular Imaging) from defined regions of interest (ROI) within these MAP files. All values for ROI were decay corrected to the zero hour time point for comparison, and the percent injected dose (%ID) was determined by dividing the corrected ROI value for a given organ by the injected dose and multiplying by 100. A time activity curve (TAC) for blood was generated by drawing 0.03 cm^2 ROIs within the heart (∼5 slices) for all time points (0.5, 3, 20, 48 h) and expressing the mean measured activity as the percentage of injected dose per cubic centimeter (%ID/cc). A monoexponential curve was fit to the data series and used to estimate the blood half-life for the ^{64}Cu-SLNs.

After the 48 h PET scans, the mice were euthanized by administration of sodium pentobarbital (150 mg/kg) and perfused with 60 mL of 0.9% saline. Organs of interest were harvested and weighed and radioactivity was measured using a Wallac Wizard Automatic Gamma Counter model 1470 (Perkin-Elmer, Waltham, MA) at 52−55 h post i.v. injection. One-way analysis of variance (ANOVA) was conducted in *Prism* (GraphPad software Inc. San Diego, CA) and used to assess the significance of organ biodistribution.

RESULTS AND DISCUSSION

Preparation and Characterization (Size, Morphology, Charge, Toxicity) of Protein-Loaded SLNs. Because the size and the charge of nanoparticles are known to significantly influence their fate *in vivo*, it was important to measure these particle properties for SLNs. Using dynamic light scattering (DLS), the mean hydrodynamic diameter of the SLNs was

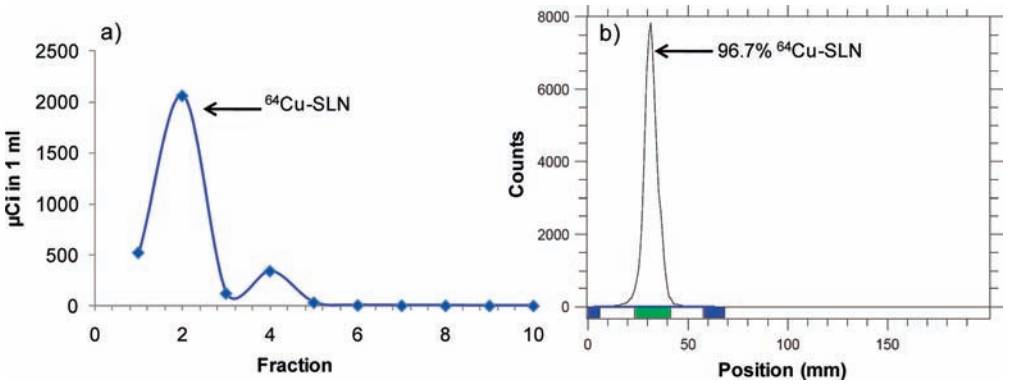

Figure 3. Radiolabeling yield (%) and purification of SLNs. (a) Elution profiles of ^{64}Cu-SLN after incubation with $^{64}CuCl_2$ (1 h) and EDTA (25 min) at 25 °C and separation through a size-exclusion column. (b) Following purification, radio TLC of ^{64}Cu-SLN on a silica plate was developed with methanol/ammonium acetate (10%) (50:50, v/v) and recorded by a radio-TLC imaging scanner. Results show >95% radiolabeled nanoparticles.

determined to be 145 ± 7.0 nm (Figure 2a). From the TEM images in Figure 2b, we observe that the SLNs exist as a uniform, monodisperse population of spherical particles with a diameter of 86 ± 0.6 nm (n = 500 particles, *ImageJ*). We believe that the difference in SLN diameter measured from DLS (∼150 nm) compared to TEM (∼90 nm) is due to the inability of TEM detect the hydration shell that surrounds the phospholipid monolayer of the SLN. By either measurement, the SLNs fall into the 20−200 nm size range reported for particles capable of avoiding rapid clearance through the kidneys,[6] thus making them attractive carriers for *in vivo* drug delivery.

To assess the stability of the SLN in suspension, we measured their zeta potential. A high zeta potential will confer stability (i.e., the solution or dispersion will resist aggregation) with the dividing line between stable and unstable suspensions generally considered to be at ±30 mV, and with maximum electrostatic stabilization reached at around ±60 mV.[38] The SLNs were measured to have a zeta potential of −36 mV, indicating an electrically stable, anionic particle solution. Previous studies show that negatively charged particles of ≥ −30 mV have good stability and could be optimal for drug delivery.[39,40] Aside from governing particle stability, zeta potential also influences particle recognition by the reticuloendothelial system (RES). In a previous study by Manjunath et al., highly negatively charged (−35.1 ± 0.5 mV) SLNs exhibited higher effective bioavailability (60.4%) of the encapsulated drug than less negatively charged particles (−18.2 ± 0.3 mV) SLNs (44.4%).[29] This is consistent with other studies showing that liposomes formed with negatively charged phospholipids maintained prolonged circulation time in mice.[41]

In order to provide an optical handle to track SLN during purification and characterization, we synthesized SLNs containing bovine serum albumin (BSA) labeled with the fluorophore, TAMRA. The encapsulation efficiency (EE, %) of BSA-TAMRA within SLNs was approximately 86.9 ± 5.3%, which is relatively high in comparison to other reported hydrophilic cargoes.[3−5,8,42] For example, the maximum EE for the hydrophilic drug Zidovudine (an antihuman immunodeficiency viral agent) in SLNs composed of stearic acid was 27%.[43] Because lipophilic agents have high solubility in the lipid microemulsion preceding SLN formation, SLNs are more efficiently loaded with lipophilic drugs. Entrapment of hydrophilic drugs inside the hydrophobic matrix of SLNs is a bit more challenging because the drug has a tendency to partition into the water phase during the fabrication process.[43] SLNs thus incorporate hydrophilic drugs at lower encapsulation efficiencies.[7,42,44−46] Zidovudine,[43] Atazanavir,[46] thymocratin,[47] insulin,[10] diminazene,[48] and thymopentin[11] are examples of hydrophilic drugs that have been successfully incorporated into SLNs. Interestingly, Singh et al. found that fatty acids (i.e., stearic acid) were superior to triglycerides to enhance entrapment efficiency.[49] This is consistent with our observations of high EE for BSA-TAMRA (hydrophilic protein) encapsulated in our SLNs, whose primary lipid was stearic acid. Furthermore, encapsulation of the hydrophilic HIV protease inhibitor, Atazanavir, into SLNs of similar size (∼167 nm) and composition (stearic acid) to our SLNs resulted in a similar EE (∼90%).[46] These results suggest that using stearic acid as the primary lipid component of our SLNs is favorable for achieving high EE of hydrophilic cargo.

Toxicity of the SLNs was assessed *in vitro*. Incubation (24 h) of SLNs at a lipid concentration of 25 mM with MDCK cells (data not shown) showed no statistical difference (p-value = 0.51) in viability compared to controls. The 25 mM lipid concentration that was tested *in vitro* was ∼2.5 times larger than the concentration of the injected dose to be used for *in vivo* studies. The lipid (molecular weight ∼500 g/mol) dose to each mouse was approximately 10 mg, yielding a circulating lipid dose of ∼10 mM, assuming total mouse blood volume of ∼2 mL. These results are consistent with previous investigations of stearic acid based SLNs that found them to be nontoxic to human promyelocytic leukemia (HL60) and human breast adenocarcinoma (MCF-7) cell lines.[42,50] In comparison to SLNs, FDA-approved polyester nanoparticles, i.e., poly(lactic-*co*-glycolic acid) (PLGA), polylactic acid (PLA), etc., were 10- to 20-fold more toxic to human granulocytes.[9,42] The low cytotoxicty of SLNs makes them very attractive for drug delivery, especially to highly sensitive organs like the brain.[42] Also, the ability to load drugs into SLNs with a high encapsulation efficiency (EE), such as 86.9 ± 5.3% observed with our system, further reduces the potential for cytotoxicity by reducing the dose of particles required to achieve a pharmacological effect. Overall, these *in vitro* cytotoxicity studies suggest that SLNs are nontoxic and that they can be used for *in vivo* animal imaging studies.

Preparation and Characterization (Radiolabeling, Purification, Stability) of ^{64}Cu-SLNs. Because the goal of this study was to track the biodistribution of the SLN carrier and not the cargo, we used a surface chelation method to radiolabel the SLNs

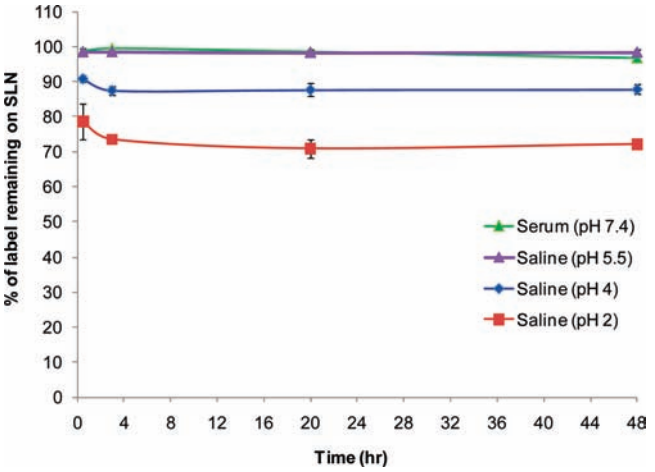

Figure 4. Stability of SLNs. Stability of radiolabeled solid lipid nanoparticles (SLNs) over 48 h in serum (pH 7.4), saline (pH 5.5), saline (pH 4), and saline (pH 2). Bars represent mean ± standard deviation (n = 3/group).

with ^{64}Cu. This chelation method required the incorporation of a lipid-PEG-chelate conjugate into the SLN so that the chelator remains accessible at the surface for ^{64}Cu chelation. We previously showed that liposomes could be radiolabeled after incorporation of this lipid-PEG-chelate conjugate into the liposome bilayer.[2]

High SLN Radiolabeling Yield (%). A ^{64}Cu-specific chelator, 6-[*p*-(bromoacetamido)benzyl]-1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (BAT), conjugated to stearic acid (lipid-PEG-BAT) has been previously synthesized and used to radiolabel liposomes with ^{64}Cu,[2] and we hypothesized that this lipid-PEG-BAT molecule could function similarly to radiolabel our SLNs. We anticipated that the lipid portion of the lipid-PEG-BAT molecule would be incorporated into the solid lipid core, the PEG would be associated at the level of the lecithin headgroups, and the BAT would remain accessible on the surface. The elution profiles of radiolabeled SLNs following column purification are shown in Figure 3a, with fraction 2 representing the purified ^{64}Cu-SLN population. Fraction 2 was analyzed by radio-TLC as shown in Figure 3b. The TLC peak (green bar, 96.7%) represents ^{64}Cu-SLNs, which remain at the baseline. The negligible amount (2.94%) of free ^{64}Cu in the purified ^{64}Cu-SLN suspension confirms >95% radiolabeled particles. The radiolabeling yield (%) of SLNs was approximately 66.8%.

High Stability of Radiolabeled SLNs. A stability assay was performed in order to confirm that Cu-64 remains associated with the SLN over the 48 h time period and that the biodistribution patterns observed are not from free, dissociated Cu-64. Figure 4 shows that, over time (0.5, 3, 20, and 48 h), the SLNs in saline and serum do not lose radiolabel. The saline solution is a control to test the stability of the particles in solution before intravenous (i.v.) administration, while the serum solution mimics blood circulation. Because the molecular weight of the lipid-PEG-BAT is less than the 10,000 MWCO of the centrifugal filters used for purification, both dissociated free copper and dissociated lipid-PEG-BAT molecules are removed during centrifugation purification, while nanoparticles are retained in the filtrate. Radio TLC experiments (Figure 5) confirm that no peak corresponding to free ^{64}Cu (~85 mm, retention factor (R_f) = 0.66) was observed for filtrates after 24 and 48 h incubation in serum,

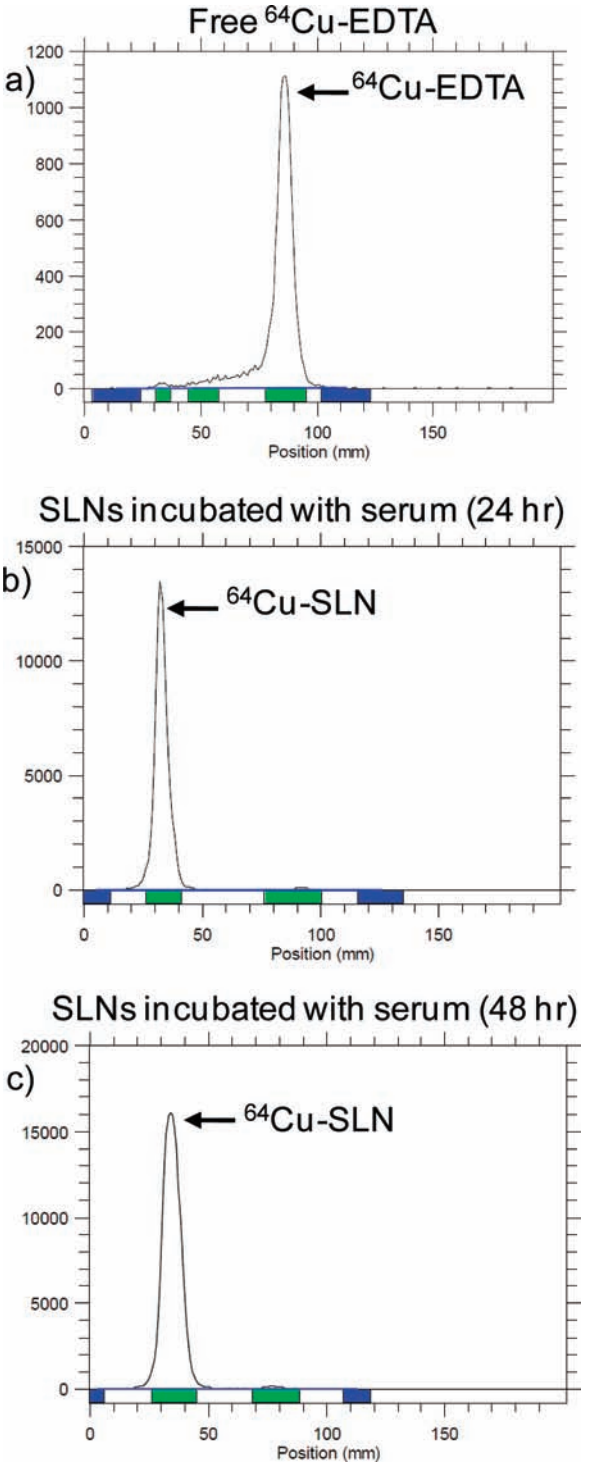

Figure 5. Radio TLC of SLNs incubated with serum. Cu-EDTA (a) and SLNs incubated with serum at 24 (b) and 48 h (c) were developed on a silica plate with methanol/ammonium acetate (10%) (50:50, v/v) and recorded by a radio-TLC imaging scanner. The absence of free ^{64}Cu-EDTA in (b) and (c) confirm that the ^{64}Cu-SLNs were stable in plasma after 24 and 48 h.

verifying the stability of these radiolabeled particles in the bloodstream up to 48 h. Overall, the results of this stability assay confirm that there is no significant loss ($p < 0.01$) of free copper or free lipid-PEG-BAT (chelated with Cu-64) from the SLNs in

dx.doi.org/10.1021/bc100478k |*Bioconjugate Chem.* 2011, 22, 808–818

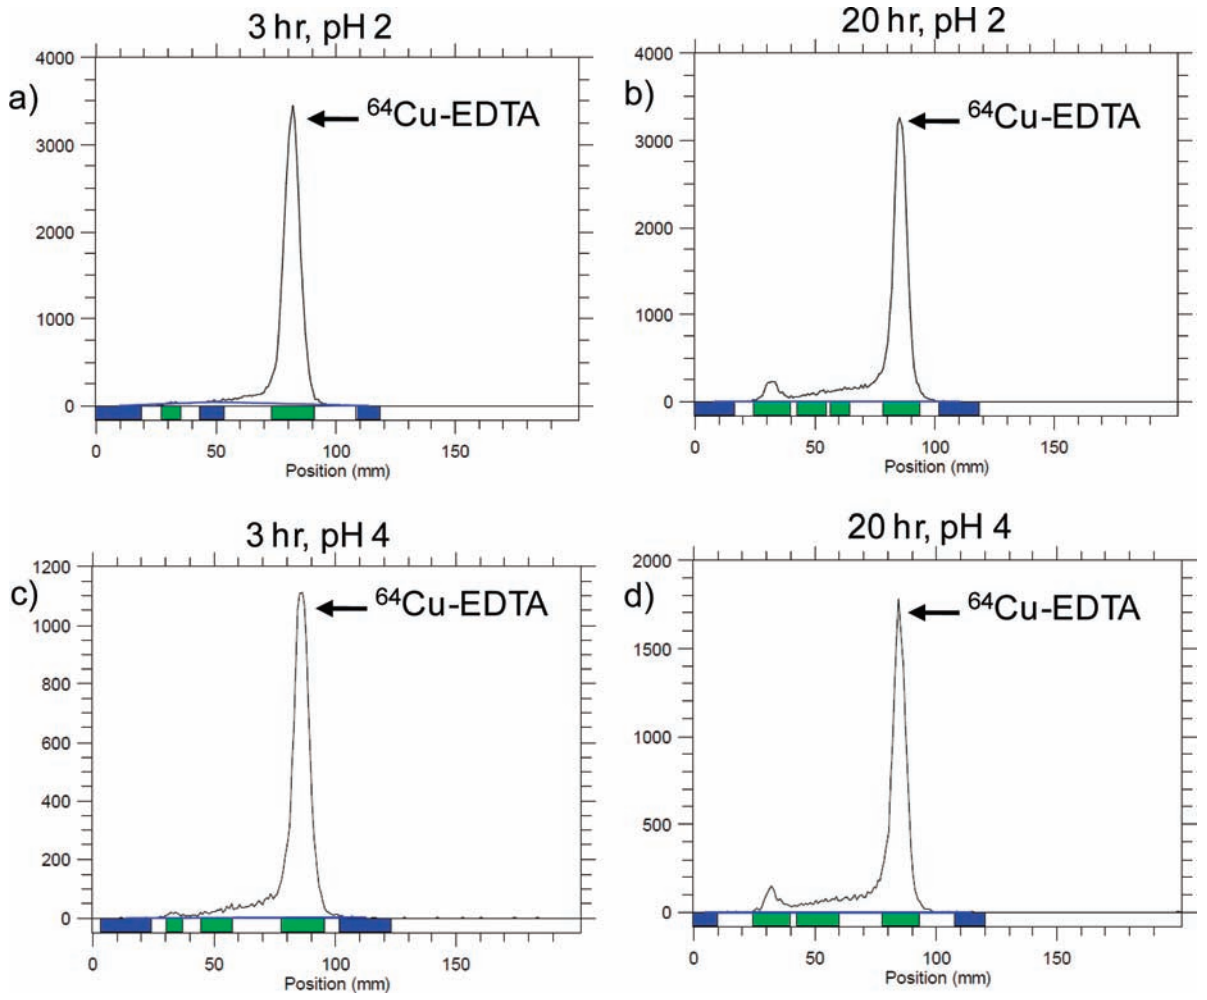

Figure 6. Radio TLC of supernatant resulting from centrifugation filtration of SLNs incubated with saline (pH 2) and saline (pH 4) at 3 and 20 h. Samples were developed on a silica plate was developed with methanol/ammonium acetate (10%) (50:50, v/v) and recorded by a radio-TLC imaging scanner. The TLC plots confirm that the loss of radiolabel observed (Figure 4) for ^{64}Cu-SLNs incubated with saline (pH 2) and saline (pH 4) were a result of ^{64}Cu-EDTA dissociating from the particle in these extreme conditions.

saline or plasma. Although the SLNs were quite stable in serum and in saline at pH 5.5, they showed a significant loss (p value > 0.01) of label over time when incubated in pH 2 and pH 4. Radio TLC was performed on the supernatants collected after centrifugation filtration of the SLNs incubated with saline (pH 2) and saline (pH 4) at 3 and 20 h. It is clear from these TLC plots (Figure 6) that saline (pH 2) and saline (pH 4) supernatant yield single peaks corresponding to ^{64}Cu (~85 mm, R_f = 0.66). This confirms that the loss of radiolabel for saline (pH 2) and saline (pH 4) observed in Figure 4 was due to free ^{64}Cu dissociating from the particle in these extreme conditions. Therefore, the observed ^{64}Cu dissociation at these conditions is not of significant concern.

Preliminary Biodistribution and Pharmacokinetics of ^{64}Cu-SLN *in Vivo* Using PET Imaging and Gamma Counting. Radiolabeling SLNs with ^{64}Cu facilitates the use of positron emission tomography (PET) for the investigation of SLN biodistribution *in vivo*. Imaging seldom has been used to describe the biodistribution of SLNs following i.v. administration. Instead, most researchers label SLNs with a gamma-emitting radioisotope and report biodistribution by gamma counting organs. For example, gamma counting methods have been used to describe full-body biodistribution of Technetium-99 m (^{99m}Tc)-labeled SLNs following endotracheal administration to mice[51] and Iodine-125 (^{125}I)-labeled SLNs following intravenous injection to rats.[28] Our results confirm a method to radiolabel solid lipid nanoparticles with ^{64}Cu through the incorporation of a lipid-PEG-BAT chelating molecule into SLNs carrying a cargo of fluorescently labeled hydrophilic protein (bovine serum albumin).

Preliminary biodistribution and blood clearance of the radiolabeled SLNs (^{64}Cu-SLNs) was assessed in the mouse model. From the biodistribution plot (Figure 7) obtained by gamma counting organs at 52−55 h post i.v. injection, we observe that the liver radioactivity (6.6 ± 0.7%ID/g) was significantly higher (p < 0.01) than all other organs, including heart (1.1 ± 0.4%ID/g), lung (1.2 ± 0.5%ID/g), gastrointestinal (GI) tract (1.7 ± 0.9%ID/g), right (2.2 ± 0.2%ID/g) and left (1.7 ± 1.1%ID/g) kidneys, spleen (2.9 ± 1.1%ID/g), and brain (0.03 ± 0.01%ID/g). This organ biodistribution obtained from gamma counting organs was compared with the *in vivo* biodistribution obtained from PET imaging. Figure 8a−d displays the biodistribution of ^{64}Cu-SLNs in mice from representative coronal PET images at 0.5, 3, 20, and 48 h post i.v. injection. There was obvious

dx.doi.org/10.1021/bc100478k |*Bioconjugate Chem.* 2011, 22, 808–818

radioactivity in the carotids (C) and the heart (H), at 0.5 and 3 h post injection (Figure 8a and b) indicating continuing circulation of the ^{64}Cu-SLNs; this signal disappeared by 20 h post injection (Figure 8c), indicating that the ^{64}Cu-SLNs had primarily cleared the bloodstream. Figure 8a,b also shows high liver (L) and spleen (S) activity, indicating that the ^{64}Cu-SLNs were cleared through the reticuloendothelial system (RES) by 0.5 and 3 h post injection. By 20 h post injection (Figure 5c), there was faint activity in the spleen, but more prominent was the activity in the intestines (I) and the liver (L). Verkade et al. showed that liposome-associated phosphatidylcholine is predominantly degraded by the liver, and that these degradation products are partially secreted into bile. Thus, the radioactivity we observe in the intestines is hypothesized to result from the liver slowly breaking down the SLNs and releasing radioactivity through the bile duct.[52] This is consistent with previous studies from Seo et al. showing radioactivity accumulation in the intestines following i.v. administration of radiolabeled liposomes in mice.[2] Only liver activity remains visible at 48 h post injection (Figure 8d), suggesting that ^{64}Cu-SLNs were primarily cleared through the RES by this time. Radioactivity in the liver (L) decreased over time as shown in Figure 6e (25.4 ± 0.9, 22.1 ± 4.0, 11.9 ± 0.9, and 5.6 ± 1.3%ID/g at 0.5, 3, 20, and 48 h, respectively), validating that SLNs do not remain in liver long-term.

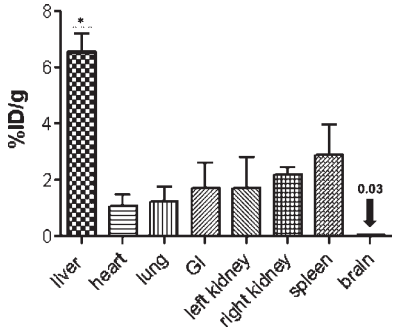

Figure 7. Biodistribution with gamma counting. Biodistribution of ^{64}Cu-SLNs in mice at 52−55 h post injection. Error bars represent mean ± standard deviation (n = 3). Liver activity (%ID/g) is significantly higher (p value <0.01) than that all other organs.

The liver activity at 52−55 h measured by gamma counting (6.6 ± 0.7%ID/g) was consistent with the liver activity measured by PET quantification (Figure 8e), which showed an average of 5.7 ± 1.1%ID/g at 48 h. The heart activity was also consistent between the two methodologies of quantization yielding values of 0.9 ± 0.1%ID/g with PET and 1.1 ± 0.4%ID/g with gamma counting. Nevertheless, the low activity of the other organs (lungs, GI, right kidney, left kidney, spleen, and brain) at 48 h results in the inability for the microPETII to appropriately detect their organ boundaries; at earlier time points, the activity is high enough to avoid this issue. Therefore, the use of a more sensitive (3×) PET scanner (absolute system sensitivity ~7%), such as the F120 produced by Siemens Medical Solutions, Inc. will enable one to appropriately define organ boundaries at the later time points (i.e., 48 h) in future studies.

Blood clearance was assessed by monitoring signal from the heart over time. The time activity curve (TAC) of blood in Figure 9 showed that ^{64}Cu-SLNs were still circulating in the bloodstream after 3 h, but were almost entirely cleared from

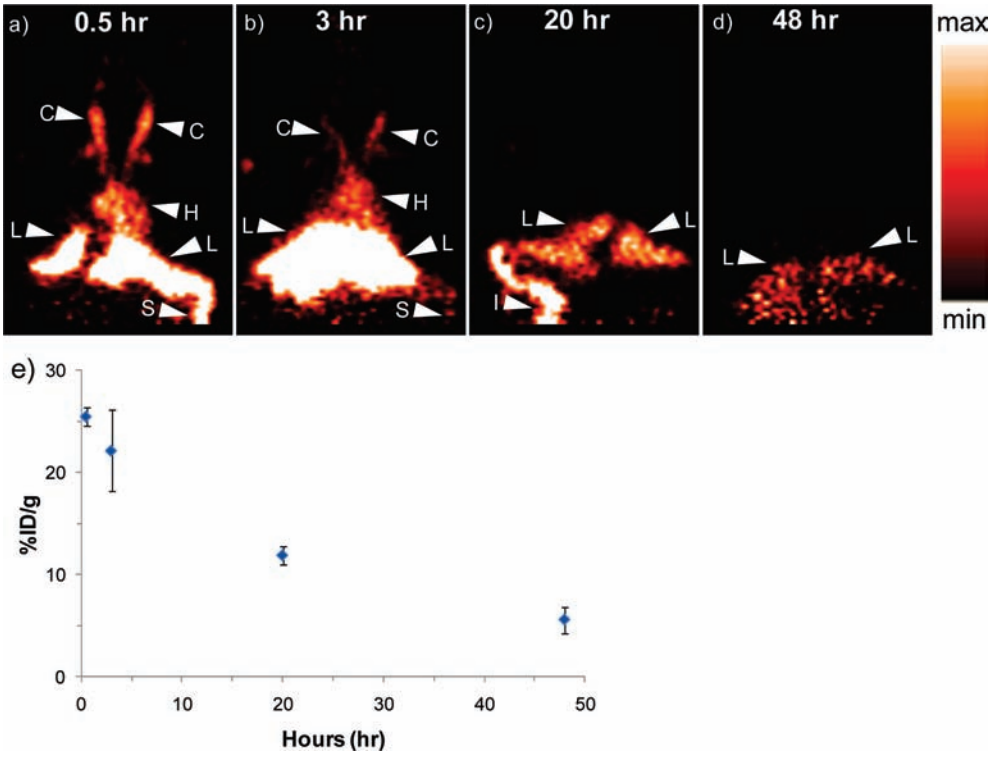

Figure 8. Preliminary biodistribution with PET. Coronal view of a microPET image acquired at (a) 0.5 h, (b) 3 h, (c) 20 h, and (d) 48 h post i.v. injection of ^{64}Cu-SLNs. Radioactive signal is present in C = carotid, H = heart, L = liver, S = spleen, and I = intestines. A relative scale (the brightest spot is maximum) was applied for the images. (e) Liver biodistribution obtained using ROI analysis on the microPET images. Error bars represent mean ± standard deviation (n = 3).

dx.doi.org/10.1021/bc100478k |*Bioconjugate Chem.* 2011, 22, 808–818

the bloodstream by 48 h. The monoexponential curve was fit to the data, yielding a correlation coefficient of 0.99. The blood half-life for the ^{64}Cu-SLNs was estimated to be approximately 1.4 h. This is very different behavior from free ^{64}Cu or free ^{64}Cu radiolabeled lipid-PEG-BAT that result in blood half-lives ~5−10 min and are known to clear almost entirely from the bloodstream at 15 min post i.v. injection.[2] The 1.38 ± 0.12 h blood half-life of our ^{64}Cu-SLNs was also much longer than that of most polymeric nanoparticles, which are reported to have blood lives of only a few minutes. For example, polysorbate 80 (P80) coated poly(α-butyl cyanoacrylate) (PBCA) nanoparticles loaded with ^{125}I radiolabeled quinoline derivatives and delivered to mice by intravenous (i.v.) injection were almost entirely cleared after 1 h, with a blood half-life of ~5 min.[53] Similarly, P80-coated poly(lactic-*co*-glycolic acid) (PLGA) nanoparticles labeled with ^{99m}Tc were cleared very rapidly from the blood after i.v. injection in mice, with 1.28 ± 0.07%ID/g remaining at 1 h post injection and a blood-half-life of only a few minutes.[54] Overall, the RES-mediated clearance of the SLNs from the bloodstream can be reduced further by coating the SLNs with a hydrophilic or flexible polymer and/or surfactant such as poly(ethylene glycol) (PEG) or polysorbate.[55] Coating with PEG has been shown to improve the pharmacokinetic profile of particles by reducing opsonization, phagocytosis, and clearance by the liver and RES.[55] We will investigate the influence of various hydrophilic coatings in order to reduce SLN clearance by the RES and prolong their circulation time in the bloodstream. This will facilitate the possibility of longer imaging studies to assess SLNs biodistribution *in vivo*.

Because of their lipophilic nature, most interest in SLNs involves their use as carriers for drug delivery to the brain.[3,6,42,55,56] The adsorption of a plasma protein, ApoE, onto the nanoparticles surface is thought to facilitate SLN uptake into the brain through the low density lipoprotein (LDL) receptors on the brain endothelial cells lining the blood brain barrier (BBB). From a close examination of the brain distribution (Figure 5), we observe approximately 0.03 ± 0.03%ID/g of activity at 52−55 h post injection. This small amount of SLNs delivered to the brain could be enhanced through surface modifications, such as coating with P80.[53] P80 remains to be the most successful "stealth" coating for delivering therapeutic agents into the brain,[39,42,57−60] reporting values as high 0.52%ID/g in the brain.[61] In a recent study, P80 coating of SLNs containing riluzole facilitated a significantly higher dose of riluzole to the brain in comparison to free riluzole alone.[62] Since P80 coating has also demonstrated the ability to enhance BBB transport,[63] we will coat radiolabeled SLNs with P80 and use PET to investigate the ability for SLNs to target the brain *in vivo*.

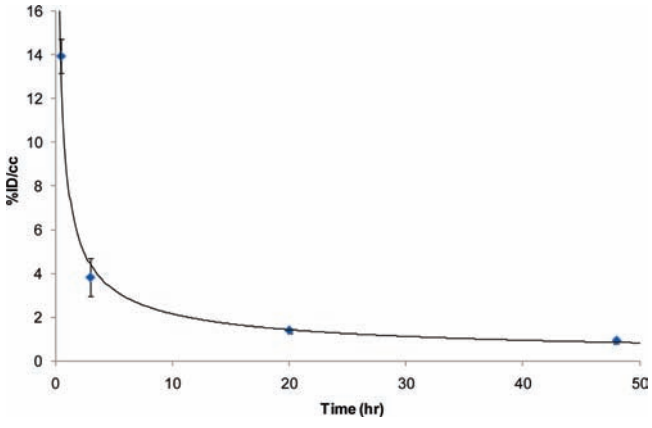

Figure 9. Time activity curve (TAC) of blood after bolus i.v. injection of ^{64}Cu-SLNs in mice. TACs were obtained with region-of-interest (ROI) analysis using *ASIPro* software and expressed as the percentage of injected dose per cubic centimeter (%ID/cc). Error bars represent mean ± standard deviation (n = 3). The monoexponential curve fit to the data was as follows: $y = 8.4363x^{-0.593}$.

CONCLUSION

Solid lipid nanoparticles (SLNs) are a versatile colloidal drug carrier system that combines the advantages of both liposomes and polymeric nanoparticles. Because of the potential for SLN to facilitate controlled drug delivery to a target tissue, there is much interest in understanding their *in vivo* biodistribution following intravenous (i.v.) injection. By incorporating a lipid-PEG-BAT chelator into the SLN monolayer, we have developed a method to radiolabel SLNs with ^{64}Cu for noninvasive mapping of biodistribution *in vivo* using PET. Preliminary *in vivo* biodistribution of these SLNs (^{64}Cu-SLNs) was evaluated in mice up to 48 h post i.v. injection using PET, and these values were then compared to *ex vivo* biodistribution from gamma counting of organs. The blood half-life for the ^{64}Cu-SLNs was ~1.4 h, which is longer than typical polymeric nanoparticles of similar size. Gamma counting confirmed significant activity in the liver at 48 h post i.v. injection. Coating SLNs with hydrophilic polymers such as PEG will be investigated in the future to reduce SLN clearance by the RES (kidneys, liver, and spleen) and increase the blood half-life. Longer blood circulation times will further enhance the appeal of SLNs as drug carriers, and the ability to radiolabel these SLNs for noninvasive assessment of biodistribution *in vivo* using PET will accelerate their development in the field of drug delivery, especially those drugs targeted to the brain.

Supporting Information

ABSTRACT: We demonstrate here a rapid and cost-effective technique for nanoscale patterning of functional molecules on the surface of a DNA origami. The pattern is created enzymatically by transferring a functionalized dideoxynucleotide to the 3′-end of an arbitrary selected set of synthetic DNA oligonucleotides positioned approximately 6 nm apart in a 70 × 100 nm^2 rectangular DNA origami. The modifications, which are performed in a single-tube reaction, provide an origami surface modified with a variety of functional groups including chemical handles, fluorescent dyes, or ligands for subsequent binding of proteins. Efficient labeling and patterning was demonstrated by gel electrophoresis shift assays, reverse-phase HPLC, mass spectrometry, atomic force microscopy (AFM) analysis, and fluorescence measurements. The results show a very high yield of oligonucleotide labeling and incorporation in the DNA origami. This method expands the toolbox for constructing several different modified DNA origami from the same set of staple strands.

INTRODUCTION

The field of designed artificial molecular self-assembly was revolutionized in 2006 by the invention of DNA origami,[1] a technique where a long, single-stranded DNA scaffold is folded into well-defined structures by a large number of smaller synthetic DNA oligonucleotides—so-called staple strands. Since then, the development and application of the DNA origami has evolved rapidly, resulting in a number of different two- and three-dimensional DNA structures with enormous potential.[2−7] In this process, it has also been demonstrated that DNA origami can function as a molecular pegboard, where the large number of uniquely positioned staple strands not only hold the origami together, but also function as handles for modifying the origami at specific positions. By chemically modifying specific staple strands, it is possible to functionalize the origami in well-defined positions with nanometer precision.[8−11] However, this process has so far required individual synthesis of the chemically modified staple strands for each of the selected positions on the origami.

We describe here an inexpensive enzymatic technique to label ensembles of unmodified stable strands that can direct the insertion of functional groups at selected locations of the DNA origami (Figure 1A). The technique relies on DNA nucleotidylexotransferase (terminal transferase) to attach modified dideoxynucleotide triphosphates to the 3′-end of an arbitrary subset of oligonucleotides to be incorporated at specific positions in the DNA origami. The use of dideoxynucleotides ensures that only a single modified nucleotide is attached. The method was applied to a rectangular origami comprising a 7-kilobase-long M13mp18 phage single-stranded DNA and 222 synthetic DNA oligonucleotides. The potential of the approach is demonstrated by attaching biotin-, amine-, digoxigenin-, and fluorescent groups to selected sites of the origami (Figure 1B). Hence, the technique provides a practical route for generating a large number of different modification patterns from just one set of staple-strands. Compared to the traditional method, where origami modifications are introduced by phosphoamidite chemistry in the individual staple strands, this method provides a rapid, efficient, and cost-effective protocol for functionalizing DNA origami.

EXPERIMENTAL PROCEDURES

Materials. Terminal transferase, antidigoxigenin monoclonal antibodies, biotin ddUTP, and DIG (digoxigenin)ddUTP were purchased from Roche Applied Science. The propargylamino ddUTP was purchased from Jena Bioscience. The Texas Red ddATP was purchased from Perkin-Elmer. THTA (tris-(1-[3-hydroxypropyl]triazolyl-4-methyl)amine) was synthesized according to the literature procedure.[8] All DNA oligonucleotides are purchased from DNA Technology A/S, Aarhus, Denmark. M13mp18 was purchased from New England Biolabs. Streptavidin was purchased from Sigma Aldrich. Water was purified using a Millipore Milli-Q purification system. SYBR Gold and SYBR Safe were both purchased from Invitrogen.

Terminal Transferase Reaction. Under standard conditions, 100 pmol oligonucleotide in total and 1 nmol of modified

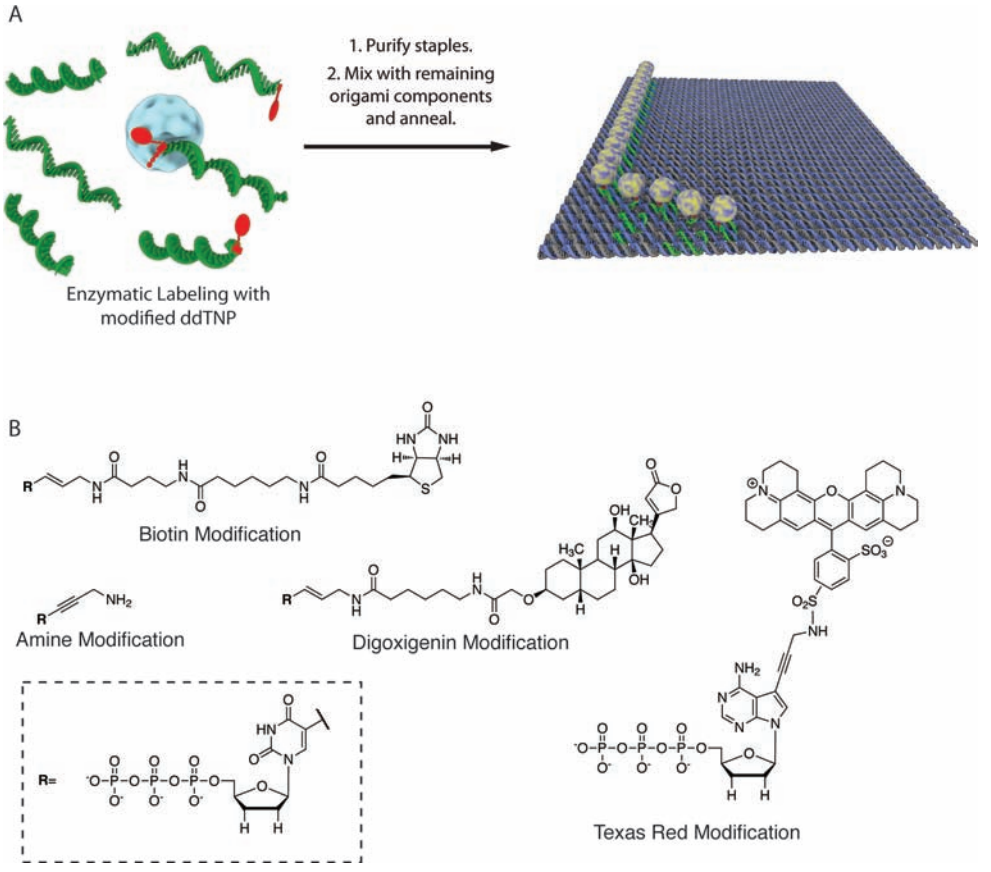

Figure 1. (A) Schematic representation of the DNA origami labeling process. The strands intended for modification are mixed and labeled by terminal transferase in a single reaction. After purification, the modified strands are annealed with the remaining origami components to create the patterned DNA origami. (B) Overview of the chemical structures of the modified dideoxynucleotide triphosphates applied in this study.

ddNTP were mixed in 20 μL with reaction buffer (1×), $CoCl_2$ (5 mM), and incubated with terminal transferase (20 U/μL) for 15 min at 37 °C. The reaction is stopped by adding EDTA (20 mM final concentration). Strands used for subsequent origami formation were precipitated with NaOAc (0.3 M, pH = 5.2) and 2.5 volumes of EtOH (−20 °C, 96%) for 15 min on dry ice, followed by centrifugation for 30 min at 20 000 *g*. The pellet was washed once with EtOH (−20 °C, 70%). Depending on the length of the oligonucleotides, up to 90% yield was obtained (see Supporting Information for details). Further purification considerations can also be seen in the Supporting Information.

RP-HPLC Analysis. The analysis was performed using a Hewlett-Packard Agilent 1100 Series and Phenomenex Clarity 3 μm Oligo-RP 4.6 × 50 mm columns. The standard gradient used was acetonitrile (MeCN)/TEAA (triethylammonium acetate, 0.1 M, pH = 7) with a 10−20% gradient over 15 min. Yields were determined by comparing integrals with a reference.

MALDI-TOF MS Analysis. Mass spectra were recorded using a Bruker Daltonics Autoflex MALDI−TOF MS spectrometer using AnchorChip as target plates using a mixture consisting of 90% 3-hydroxypicolinic acid (50 mg/mL) in H_2O/MeCN (1:1) and 10% diammonium citrate (50 mg/mL) in water as matrix.

Gel Shift Assay. A mixture of the selected staple strands for the DNA origami were labeled, precipitated, and purified as mentioned above. The 17 selected strands are given in Supporting Information, and the pattern is schematically indicated in Figure 1. The binding assay was performed with 5 pmol oligonucleotide and a 3× excess of ligand in buffer A (150 mM NaCl, 3 mM $MgCl_2$, 100 mM Tris-HCl, pH = 7.4). Glycerol loading buffer was added to 7% glycerol and the samples were analyzed in a 6% native PAGE gel, run at 4 °C. The DNA was stained with SYBR gold and scanned with a Typhoon Trio scanner from GE Healthcare at the following settings: laser, 488 nm; emission filter, 555 BP 20; photomultiplier, 450 V; sensitivity, normal.

To assay the modification efficiency, the reaction mixture was denatured by adding formamide/EDTA buffer (final concentration of 80% formamide, 8 mM EDTA) to the terminal transferase reaction and then heated to 95 °C. The samples were analyzed on a 16% denaturing polyacrylamide gel, with 5 pmol substrate in each lane. Following gel electrophoresis, the gel was stained with SYBR Gold for 15 min and scanned with a Typhoon scanner at the following settings: laser, 488 nm; emission filter, 555 BP 20; photomultiplier, 450 V; sensitivity, normal.

DNA Origami Assembly. For modified DNA origami, 17 of the staple strands were mixed, labeled, and purified prior to DNA assembly (Supporting Information). DNA origami assembly was performed by mixing 5 nM M13 ssDNA with 10× excess of staple strands in 50 μL TAE/Mg^{2+} buffer B (40 mM Tris−acetate, 1 mM EDTA, 12.5 mM Mg^{2+}, pH = 8.3). The assembly reaction was performed by incubating the samples at 95 °C for 5 min, followed by a temperature decrease of −0.1 °C/second until 60 °C, and afterward a decrease of −0.1 °C/minute until 20 °C. If "click" reactions were to be performed on the origami, the buffer was substituted with 50 μL HEPES/Mg^{2+}

dx.doi.org/10.1021/bc2000098 |*Bioconjugate Chem.* 2011, 22, 819–823

buffer C (20 mM HEPES, 12.5 mM Mg^{2+}, pH = 7.4) to avoid problems associated with TAE.[12] Furthermore, the annealing ramp was altered to 65 °C→4 °C overnight.

Fluorescence Measurements. The selected staple strands were labeled according to the general procedure (2, 4, or 8 staples per batch) with a 5-fold excess of ddUTP-Texas Red and a 2-fold reduction in terminal transferase concentration. The product was purified by RP-HPLC with a MeCN/TEAA gradient of 10% → 40%. The labeled and purified staple strands were combined with the rest of the origami components and annealed. The samples were analyzed in a 1% agarose gel run at 60 V at 5 °C for three hours in Buffer D (50 mM Tris, 45 mM boric acid, 0.5 mM EDTA, 5 mM $Mg(OAc)_2$, pH = 8.3). Texas Red fluorescence in the origami was quantified using a Typhoon Trio scanner with the following settings: laser, 532 nm; emission filter, 610 BP 30; photomultiplier, 600 V; sensitivity, normal. The gel was subsequently stained with SYBR Safe, and imaged again at following settings: laser, 488 nm; emission filter, 520 BP 20; photomultiplier, 600 V; sensitivity, normal. Controls were performed to ensure there was no "bleedthrough" of the fluorophores.

Alkyne Formation. The mixture of 17 staple strands (100 pmol of each) was labeled using a 20-fold reduced amount (2 U/μL final) of terminal transferase as compared to the recommendation by the company. The reaction mixture was lyophilized, redissolved, reacted with the NHS-ester of 4-pentynoic acid, precipitated, redissolved, and purified by preparative HPLC. The exact conditions and durations for each step are given in the Supporting Information.

"Click" Reaction. Origami containing alkyne-modified staple strands were purified using a Microcon centrifugal filter (100 000 Da, MWCO, 300 *g* speed, 15 min) followed by washing twice with HEPES/Mg^{2+} buffer C. Twenty microliters of the purified origami solution was mixed with a prepared coupling solution (20 μL) containing $CuSO_4$ (0.1 mM), THTA (0.5 mM), sodium ascorbate (2.5 mM), and azide functionalized biotin (2 mM).[8] After incubation for 30 min, the solution was filtered using a Microcon centrifugal filter (100 000 Da, MWCO, 300 *g* speed, 15 min) followed by washing twice with HEPES/Mg^{2+} buffer C.

AFM Imaging. The sample (3−5 μL) was deposited on freshly cleaved mica and left to adsorb for a few minutes. The liquid cell was washed twice with a TAE/Mg^{2+} buffer B to remove excess staple strands. When imaging the alkyne-modified origami, the buffer was exchanged to HEPES/Mg^{2+} buffer C. To image the streptavidin or antibody pattern, a 100-fold excess of the protein was added and left to absorb for 10 min. The sample was subsequently washed to remove excess protein. The AFM used was an Agilent AFM series 5500 (Agilent Technologies, USA) with 0.08 N/m force constant silicon nitride cantilevers with sharpened pyramidal tip (OMCL-TR400PSA, Olympus, Atomic Force F&E GmbH, Mannheim, Germany). After engagement, the tapping amplitude setpoint was typically 2.0 V and the scan rates ranged from 1 to 2 Hz. During the liquid AFM imaging, the highest resolution was usually obtained with minimal loading forces applied and optimized feedback parameters. Several 512 × 512 pixel AFM images were recorded from separate locations across the mica surfaces to ensure reproducibility of the results. All the images were analyzed using *Gwyddion 2.21* software.

■ RESULTS AND DISCUSSION

DNA origami is typically self-assembled by mixing the DNA staple strands and phage ssDNA before annealing. To create a specific functionalized pattern on the origami, the terminal transferase enzyme was used to add a single modified nucleotide to a subset of the staple strands prior to the self-assembly reaction. To analyze the efficiency of the reaction, we selected 17 staple strands that are arranged in a pattern resembling the letter "L" on a rectangular origami (Figure 1A) and labeled them with either biotin-modified ddUTP or digoxigenin (DIG)-modified ddUTP. Effective modification was demonstrated by electrophoretic mobility shift assay before and after adding the corresponding ligand (streptavidin for biotin and anti-DIG antibody for DIG; Figure 2). Multiple bands were observed for both for the untreated and dideoxynucleotide-modified strands, probably due to the sequence and length variation of the oligonucleotides. The dideoxynucleotide-modified strands migrate slightly more slowly owing to the extra nucleotide. Upon addition of the corresponding protein ligand, a large shift was seen for both the DIG-modified and the biotin-modified staple strands, indicating that the correct modification had been attached. No gel shift was observed if streptavidin is added to the DIG-modified DNA and *vice versa*, confirming the specificity of ligand binding.

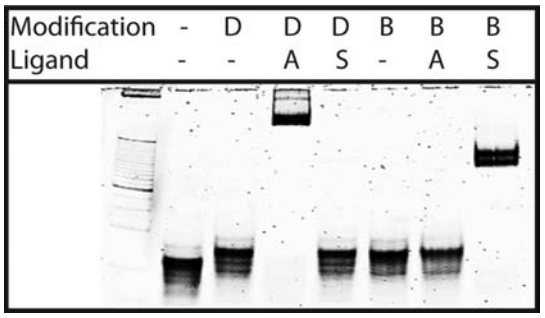

Figure 2. Gel mobility shift assay of the 17 non- (-), biotin- (B), or DIG-modified (D) staple strands bound to streptavidin (S) or DIG−antibody (A).

The integrity of the modifications after self-assembly of the origami was analyzed by AFM. However, in previous AFM studies it has been noted that rectangular DNA origami have a tendency to adsorb on the mica with the 3′ ends pointing toward the mica surface.[9] To ensure better accessibility, we altered the origami design to expose the 3′ ends at the opposite side of the origami (Supporting Information Figure S1). AFM analysis of the origami decorated with either streptavidin or antibody clearly resembled the designed pattern. Furthermore, nearly all origami displayed a right-turned L suggesting that the 3′ends are preferably facing upward as intended (Figure 3A,B; Supporting Information Figures S2 and S3). The short distance between the modifications and the multivalent binding nature of the protein used enables the proteins to bind more than one ligand; therefore, a 1:1 binding is not expected.

Although biotin and DIG labeling provides a variety of interesting possibilities, even more applications become achievable if a reactive chemical moiety, such as primary amines, are incorporated, demonstrated here by incorporating propargylamino-ddUTP. After the enzymatic incorporation by terminal transferase, the primary amine was reacted with activated esters of small organic molecules containing either alkynes or azides (see Supporting Information for more details) routinely used in the Huisgen-Meldal-Sharpless cycloaddition reaction (click reaction).[13,14] This reaction is widely used in bioconjugation because of is chemoselectivity and high yields. To test the efficiency of the combined enzymatic and chemical reactions,

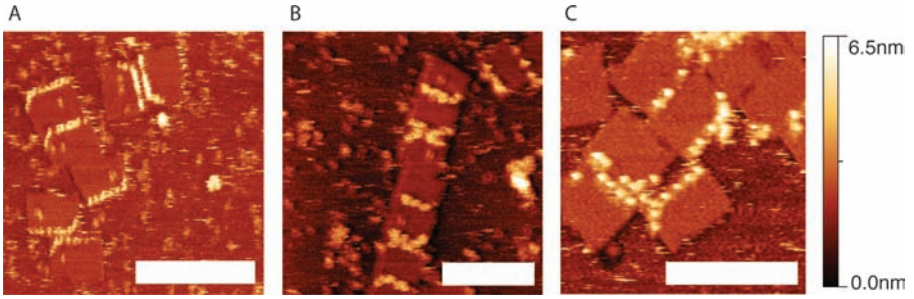

Figure 3. AFM image of a rectangular DNA origami modified with different modifications. (A) DNA origami with streptavidin attached to the patterned biotin modification. (B) DIG modification pattern imaged after DIG antibody addition. (C) Alkyne-modified DNA origami, which is subsequently reacted with azide-biotin compound and imaged after streptavidin addition. The expected letter "L" pattern is seen at all origami. The white scale bar is 200 nm.

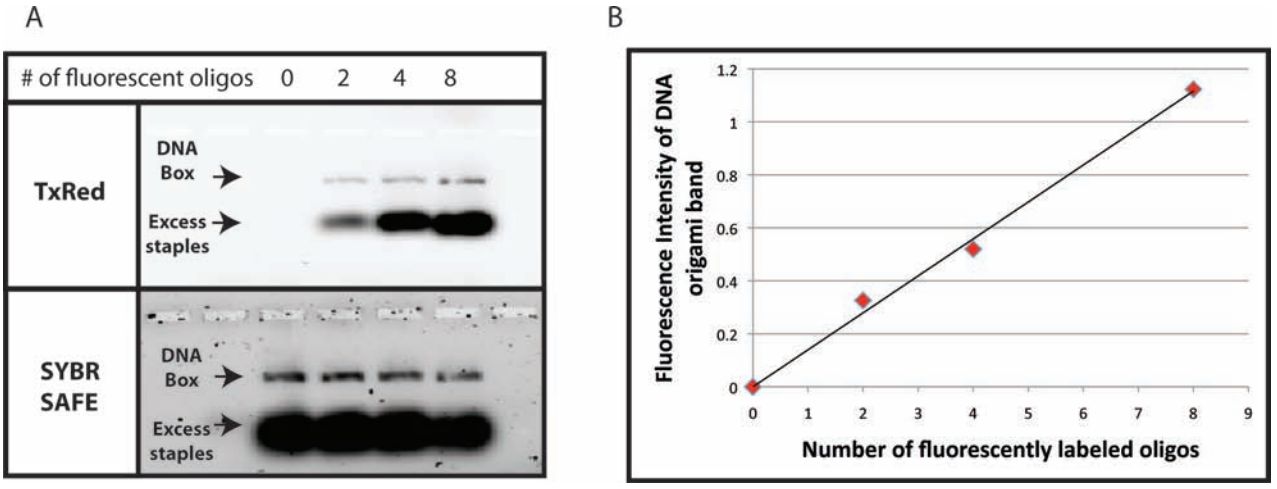

Figure 4. Fluorometric quantification of relative functionalization efficiency. (A) Fluorescent scan of an agarose gel containing DNA box origamis with a variable amount of fluorophore labeled staple strands. Scans shown in the upper and lower panels are performed with settings to detect exclusively TxRed fluorophore and SYBR safe stain, respectively. The positions of the DNA box origami and excess staple strands are marked. (B) A graph showing the TxRed fluorescence intensity of the origami bands, normalized to the intensity of the SYBR safe signal as a function of the number of labeled staple strands.

the origami was assembled from staple strands containing the same set of L-pattern-forming modified strands as above, but now labeled with propargylamino ddUTP followed by a treatment with the alkyne-tethered NHS-activated ester. After assembly of the DNA origami, the alkyne-modified staple strands were reacted with an azide-biotin followed by streptavidin addition (Supporting Information Figure S4). AFM images revealed L-patterns on the assembled origami structures. (Figure 3C; Supporting Information Figure S5).

Fluorescence Measurements. To quantify the relative degree of incorporation of modified oligoes into the DNA origami more accurately, we used the terminal transferase technique to attach a fluorescent (Texas Red) ddATP to different staple strands within a previously published three-dimensional DNA Box origami[3] (staple strands are listed in Supporting Information). A selected set of staple strands were fluorescently labeled, combined with the remaining origami components, and annealed. DNA boxes containing 0, 2, 4, or 8 fluorescently labeled staple strands were prepared and analyzed by agarose gel electrophoresis. The fluorescence in the band corresponding to the box was quantified by fluorescence scanning. The gel was subsequently stained with SYBR Safe and rescanned with different optical settings to quantify the amount of origami present (Figure 4A). The yield of Texas Red incorporation, normalized to the SYBR Safe signal, indicated a linear relationship between the fluorescence and number of labeled staple strands confirming that the efficiency of modified strand incorporation occurred independently of the other modifications in the DNA origami (Figure 4B).

Optimization. The cost of the modified nucleotide and the transferase enzyme are the limiting factors for scaleup of our method. To optimize the reaction conditions for larger quantities of modified DNA origami, we investigated the effect of lowering the concentration of the ddNTPs and the enzyme from the conditions suggested by the supplier. Denaturing PAGE was employed to assay the labeling efficiency at various conditions. In an experimental setup, where biotin-ddUTP was added in 0.5, 1, 2, 5, and 10 equiv to 5 μM DNA substrate, 5 equiv appears to be sufficient to obtain near complete incorporation (Figure 5A). Lowering the concentration to 2 equiv showed a decline in efficiency.

Next, we examined the possibility of lowering the enzyme concentration from the standard 20 U/μL in the presence of a 5× excess of the modified ddNTP (Figure 5B). The result indicated that the enzyme concentration can be reduced 27-fold

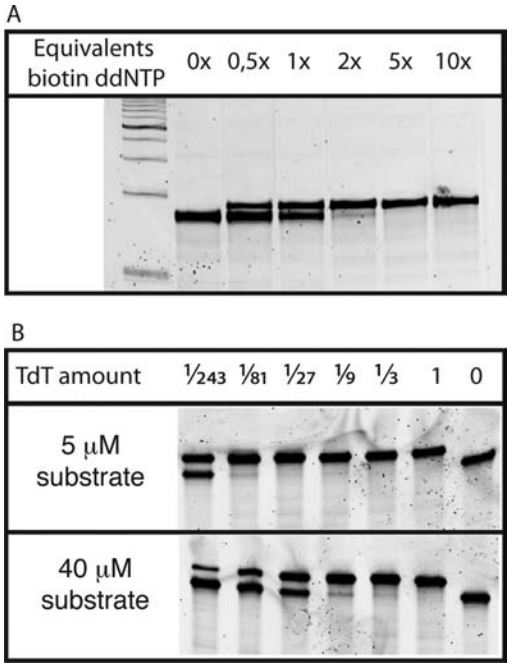

Figure 5. (A) Optimization of the terminal transferase reaction by biotin-ddNTP titration. Products were analyzed on 16% denaturing PAGE gel, with the upper band corresponding to the attachment of an extra nucleotide. (B) Titration of the enzyme (TdT) concentration. Top panel: standard reaction conditions using 5 μM substrate oligo (relative TdT concentrations are indicated above; 1 = 20 U/μL). Lower panel: high substrate concentration using 40 μM substrate oligo.

without compromising the efficiency to a detectable level. However, at higher substrate concentration (40 μM) the reaction is only completed with the standard amount of enzyme (20 U/μL). These results show that the standard protocol can be varied to limit the use of modified nucleotide and enzyme. However, it is possible that the labeling efficiency depends on the type of modified nucleotide used. We therefore recommend that similar labeling tests be performed when developing the method for a new ddNTP or enzyme batch, before scaling up the synthesis of modified DNA origami.

In summary, we have demonstrated a fast and robust method for modifying DNA origami in a desired pattern. It is a highly attractive alternative to the application of individually chemically labeled staple strands in terms of labor, cost, and processing time. The initial labeling reaction is quantitative as shown by gel mobility shift assays, and the AFM analysis revealed that the modifications are incorporated at the intended positions, creating the desired pattern on a DNA origami. In particular, the amine-modified staple strands hold great promise for a large variety of possible subsequent modifications. With all the applications of DNA origami yet to be unveiled, this method will clearly facilitate this process and make the field of modified DNA origami more accessible to the general user.

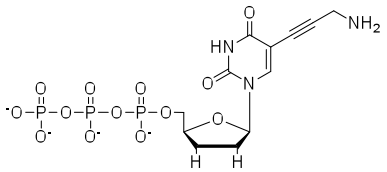
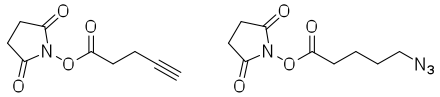
Characterization and yields

To test the purity and recovery yield for oligos labelled by terminal transferase a 42-nucleotide oligo was labelled with the following three ddNTPs;



Biotin-16-2',3'-dideoxy-uridine-5'-triphosphate



Digoxigenin-11-2',3'-dideoxy-uridine-5'-triphosphate

5-Propargylamino-2',3'-Dideoxy-uridine-5'-triphosphate

The amine modified ddNTP was further modified with an NHS-azide and an NHS-alkyne (below)

The oligonucleotide (200 pmol) was mixed with 10 equivalents of modified ddNTP (2 µL, 1 mM), Roche reaction buffer (4 µL, 5x) , $CoCl_2$(4 µL, 25 mM) and Roche recombinant terminal transferase (2 µL, 40 U/µL). This is 1/10 of the amount recommended by the supplier. The solution was incubated on a thermoshaker at 37°C for 30 min. EDTA (4 µL, 100 mM) was added and the solution was heated to 70°C to stop the reaction. Then the sample was diluted and NaOAc(pH=5.2) added (final volume 100 µL, $C_{(NaOAc)}$= 300 mM), this was followed by addition of cold ethanol (99%, 250 µL). The sample was incubated on dry ice for 15 min before centrifugating at 4°C for 30 min (20000 RCF). The supernatant was discarded and

the pellet redissolved in TEAA buffer (100 µL, 0.1 M, pH=7) and analyzed using RP-HPLC. The retention time and integral were compared to the starting oligo. As shown in the table below, the recovery yields after the reaction and precipitation were between 80-90% (calculated from HPLC integrals) and a single peak in all chromatograms indicated that HPLC purification was not necessary for most uses. The yields can vary depending on the purity of starting oligos, and as the procedure involves precipitation, shorter oligos might also provide lower yields. Mass spectrometric analysis of the HPLC purified samples clearly showed that the reaction was successful.

For the oligos modified with azides and alkynes, the starting oligo was enzymatically modified with the propargylamine as described above and precipitated. The pellet was redissolved in water (50 µL) and mixed with either an azide-NHS ester or an alkyne-NHS ester dissolved in DMF (50 mM, 50 µL). To this mixture MeCN (50 µL) and Et_3N (1 µL) was added. The mixture was left to react at rt for ½ h before precipitation and HPLC purification as described above.

Oligonucleotide	*Retention time (min)*	*Yield (%)*	*Calc. Mass*	*Found Mass*
Unmodified	7.2	-	12148	12149
Biotinylated	10.0	90	12902	12903
Digoxigenin modified	14.9	81	13021	13020
Amino modified	7.4	89	12475	12476
Alkyne modified	9.0	30	12555	12555
Azide modified	9.9	48	12600	12595

Purification considerations

The buffer used for the terminal transferase reaction is comprised of $CoCl_2$ and $K(CH_3)_2AsO_2$, which may influence origami assembly if transferred to the assembly reaction. Therefore, it is very important to purify the strands from the enzymatic reaction. Typically, precipitating in NaOAc and washing the pellet as described in Methods and Materials is sufficient.

We have however observed that if we for one origami label many strands individually instead of in a one-pot reaction the quality is worse. We hypothesize that this is due to a larger quantity of excess buffer derived from the individual labelling reactions. Therefore, we recommend HPLC/spin column purification, or several washing steps after pelleting the labelled oligos.

Batchwise alkyne modification

The mixture of 17 staple strands (100 pmol of each) were mixed with amino-modified ddNTP (17 µL, 1 mM, 10 equivalents), Roche reaction buffer (68 µL, 5x), $CoCl_2$ (68 µL, 25 mM), water (121.5 µL) and Roche recombinant terminal transferase (8.5 µL, 400U/µL). The solution was incubated on a thermoshaker at 37°C for 30 min. EDTA (34 µL, 0.2 M) was added and the mixture was freeze dried. The reaction mixture was redissolved in water (85 µL).
An aqueous solution of amino-modified staple strands (~ 0.85 nmol, 50 pmol of each, 42.5 µL) was mixed with the NHS ester of 4-pentynoic acid (4.25 µmol, 100 mM, 42.5 µL) in DMF, acetonitrile (42.5 µL), triethylamine (1.7 µL) and Milli-Q water (40.8 µL). The solution was incubated on a thermoshaker at 25°C overnight. The DNA was precipitated with glycogen (2 µL, 20mg/ml), NaOAc (3 M, 17 µL, pH 5) and cold ethanol (99%, 680 µL). The sample was incubated on dry ice for 15 min before centrifugating at 4°C for 30 min (20000 RCF). The supernatant was discarded and the pellet redissolved in TEAA buffer (150 µL, 0.1 M, pH=7) and purified by RP-HPLC. The yield (0.38 nmol, 45%) was determined by concentration measurement using a NanoDrop®.

Fluorophore labelling procedure

The selected staple strands (400 pmol mix pr. labelling reaction) were mixed with ddUTP-Texas Red® (2 μL, 1 mM, 5 equivalents), Roche reaction buffer (16 μL, 5x), $CoCl_2$ (16 μL, 25 mM) and Roche recombinant terminal transferase (2 μL, 400 U/μL). The solution was incubated on a thermoshaker at 37°C for 40 min. EDTA (16 μL, 100 mM) was added and the solution was heated to 70°C for 10 min to stop the reaction. Subsequently, the oligos were precipitated by adding NaOAc (15 μL, 5 M, pH = 5.2), cold EtOH (99%, 300 μL), incubating on dry ice for 30 min and centrifuging (40 min, 4°C, 20000g). The supernatant was decanted off, the pellet sonicated with washing solution (75% EtOH in water, 400 μL), centrifuged (40 min, 4°C, 20000g), the supernatant was removed and the last residue of solvent was removed by evaporation in a speed vac before the product was redissolved in water (100 μL). Three quarters (75 μL) of this was buffered (to 0.1M TEAA, pH = 7) and run through preparative RP-HPLC (10 → 40% MeCN over 15 min), product containing fractions (retention time: 9-12 min) were collected and freeze dried, redissolved and yields determined to 20-29% from UV-absorption measurements.

ABSTRACT: Interest in developing diverse nanoparticle (NP)-biological composite materials continues to grow almost unabated. This is motivated primarily by the desire to simultaneously exploit the properties of both NP and biological components in new hybrid devices or materials that can be applied in areas ranging from energy harvesting and nanoscale electronics to biomedical diagnostics. The utility and effectiveness of these composites will be predicated on the ability to assemble these structures with control over NP/biomolecule ratio, biomolecular orientation, biomolecular activity, and the separation distance within the NP-bioconjugate architecture. This degree of control will be especially critical in creating theranostic NP-bioconjugates that, as a single vector, are capable of multiple functions in vivo, including targeting, image contrast, biosensing, and drug delivery. In this review, a perspective is given on current and developing chemistries that can provide improved control in the preparation of NP-bioconjugates. The nanoscale properties intrinsic to several prominent NP materials are briefly described to highlight the motivation behind their use. NP materials of interest include quantum dots, carbon nanotubes, viral capsids, liposomes, and NPs composed of gold, lanthanides, silica, polymers, or magnetic materials. This review includes a critical discussion on the design considerations for NP-bioconjugates and the unique challenges associated with chemistry at the biological−nanoscale interface—the liabilities of traditional bioconjugation chemistries being particularly prominent therein. Select bioorthogonal chemistries that can address these challenges are reviewed in detail, and include chemoselective ligations (e.g., hydrazone and Staudinger ligation), cycloaddition reactions in click chemistry (e.g., azide−alkyne cyclyoaddition, tetrazine ligation), metal-affinity coordination (e.g., polyhistidine), enzyme driven modifications (e.g., HaloTag, biotin ligase), and other site-specific chemistries. The benefits and liabilities of particular chemistries are discussed by highlighting relevant NP-bioconjugation examples from the literature. Potential chemistries that have not yet been applied to NPs are also discussed, and an outlook on future developments in this field is given.

INTRODUCTION

Nanoparticles (NPs) are materials with dimensions that are typically less than 100 nm. In many cases, NPs are synthetic colloids prepared from metals, alloys, semiconductors, carbon allotropes, or polymers. Other NP materials are biologically derived and include bacteriophages and other viral particles, liposomes, or biopolymers such as polysaccharides. The interest in NP materials is as diverse as the range of materials, with target applications in biology and medicine, catalysis, energy, electronics, and computing, to name only a few. In particular, the application of NPs in biological diagnostics, imaging, and therapeutics is an active area of research necessitating highly interdisciplinary efforts that combine materials science with expertise in biology and medicine. The ability to prepare NP-bioconjugates in a controlled manner is fundamental to these research efforts and is the focus of this review.

While NPs have their own intrinsic properties, it is generally necessary in biological applications to impart additional properties or functions through physical or chemical coupling between a NP and one or more molecules. For biologically derived NPs, a common example is labeling with a fluorescent dye or another type of reporter molecule to enable tracking and detection. The converse is often true in the case of many synthetic materials, where the NP enables detection but requires conjugation to a

biological moiety for targeting or bioactivity. The association of one or more biologically relevant molecules at the interface of a NP defines a NP-bioconjugate, and combines the unique optoelectronic or physicochemical properties of NP materials with biological activity such as selective binding. Biomolecules of interest may include one or more of the following:

- Peptides, proteins, and antibodies
- Enzymes and ribozymes
- Oligonucleotides and aptamers
- Carbohydrates
- Lipids
- Drugs or other biologically active small molecules
- Reporter molecules or contrast agents (e.g., radiolabels, fluorescent dyes)

Analogous to traditional protein labeling chemistry, NP-bioconjugates can be prepared via the formation of new chemical bonds between functional groups associated with a NP and the biomolecule or small molecule of interest. NPs may also offer the potential for association through dative or coordinate bonding, electrostatic interactions, and van der Waals interactions. Moreover, it can often be necessary to account for a second conjugate preparation, where the biomolecule of interest is also conjugated with a reporter molecule. This is frequently the case in biosensing applications that use NPs. In general, the structure of a NP-bioconjugate affects its function, and the controlled display of biomolecules on NPs is paramount in obtaining conjugates with well-defined and reproducible properties.

To date, researchers have largely relied upon the traditional chemistries associated with protein labeling for the preparation of NP-bioconjugates. However, the range of bioconjugate chemistries used with NPs has lagged behind the multitude of biological applications proposed. Although traditional bioconjugate chemistries have been adequate for proof-of-concept studies, the optimization of NP-bioconjugates for real applications (e.g., clinical) will require much greater control than these chemistries can offer. "Shotgun" or heterogeneous approaches for the preparation of NP-bioconjugates are rarely suitable for maximizing the potential of NPs in biological applications. Rather, clean, efficient, and bioorthogonal conjugation reactions are required to eliminate undesirable side reactions, minimize nonspecific NP-bioconjugate activity, improve reproducibility in production, and maximize efficacy. This review highlights the emergence of novel approaches for the preparation of NP-bioconjugates that target these goals. The following sections highlight the properties of different NP materials and provide examples of their application as NP-bioconjugates. The ideals and challenges associated with NP-bioconjugates are discussed along with bioconjugation chemistry derived from chemoselective ligations, cycloaddition reactions, metal-affinity coordination, and enzymatic labeling in the context of their application to NPs. The reader should note that references to "standard bioconjugate chemistry" or "standard techniques" imply the family of currently used chemistries that were developed for modifying biomolecules with fluorophores and other labels. These are the techniques that are described extensively in Hermanson's *Bioconjugate Techniques* and Haugland's *The Handbook: A Guide to Fluorescent Probes and Labeling Technologies*.[1,2] Carbodiimide chemistry for coupling amines and carboxyls, succinimidyl (NHS) ester, or isothiocyanate targeting of primary amines, and maleimide reactions with thiols are typical examples.

NANOPARTICLE MATERIALS, PROPERTIES, AND APPLICATIONS

This section provides a brief overview of the NPs commonly used in biological applications: the different materials, their unique properties at the nanoscale, and the general features of their surface chemistry. The interested reader can find further details in the cited references, and should note that the list of materials and coatings described here is far from comprehensive. Figure 1 presents a summary of select NP materials and properties.

Gold and Silver. Gold NPs (Au NPs) typically range in size from 1 to 100 nm and are characterized by strong optical absorption and light scattering. These optical properties arise from the phenomenon of localized surface plasmon resonance (LSPR), wherein the conduction band electrons of an Au NP oscillate collectively and in resonance with certain wavelengths of incident light.[3−5] Solid spherical Au NPs exhibit a weakly size-dependent LSPR band in their extinction spectra that is located in the visible region of the spectrum. Rod-shaped Au NPs exhibit two LSPR bands that correspond to transverse and longitudinal oscillations of electrons. The longitudinal resonance mode is located in the near-infrared region of the spectrum, and is highly tunable by changing the aspect ratio of the nanorod. Hollow or dielectric-filled Au NPs are referred to as gold nanoshells and also exhibit a strong tunable LSPR mode that depends on the thickness of the shell. The wavelength-dependent intensity of the LSPR is very sensitive to changes in the dielectric environment surrounding the Au NP, as well as plasmonic coupling between NPs, and this has provided a mechanism for biological sensing based on colorimetric changes that result from selective binding interactions at the surface of Au NPs.[6] The ability of Au NPs to efficiently quench fluorescence has also been used to develop sensing methods.[7] Recent reviews have highlighted these applications.[3,4,8,9] The LSPR effect in Au NPs can also amplify Raman scattering due to local electric field enhancement at the NP during optical interrogation and provides another modality for sensing.[10,11] In imaging applications, Au NPs are potentially a very sensitive probe that can provide elastically scattered light intensities that are orders of magnitude larger than the fluorescence emission of dyes.[3,4,12] Furthermore, the absorption of light by Au NPs and the rapid thermalization of that energy are ideal for use in photothermal therapy.[3,4,13,14] Silver NPs (Ag NPs), Au−Ag alloyed NPs, and Au/Ag core/shell NPs are emerging as an alternative to Au NPs.[5] The LSPR effect with Ag NPs offers a narrower resonance, stronger elastic light scattering, and greater enhancement of Raman scattering potentially providing better sensitivity than Au NPs for some biological applications. Fluorescent Au and Ag NPs have been synthesized,[15] although their applications have not been widely characterized. Ag NPs also have strong antimicrobial properties that are being considered for use in medical applications.[16]

A wide array of synthetic methods for preparing Au and Ag NPs have been reported and are reviewed elsewhere.[17−22] The predominant chemistry for modifying Au NPs is the self-assembly of thiols via chemisorption.[3−5,12,23] Small molecules, polymers, and a variety of biomolecules can be anchored to Au NPs through thiol-terminated linkers. Bifunctional thiol ligands that display, for example, carboxyl or amine groups also enable further modifications using standard techniques to prepare Au NP-bioconjugates. The chemisorption of thiols on silver[24] can also be applied to the preparation of Ag NP-bioconjugates.[25]

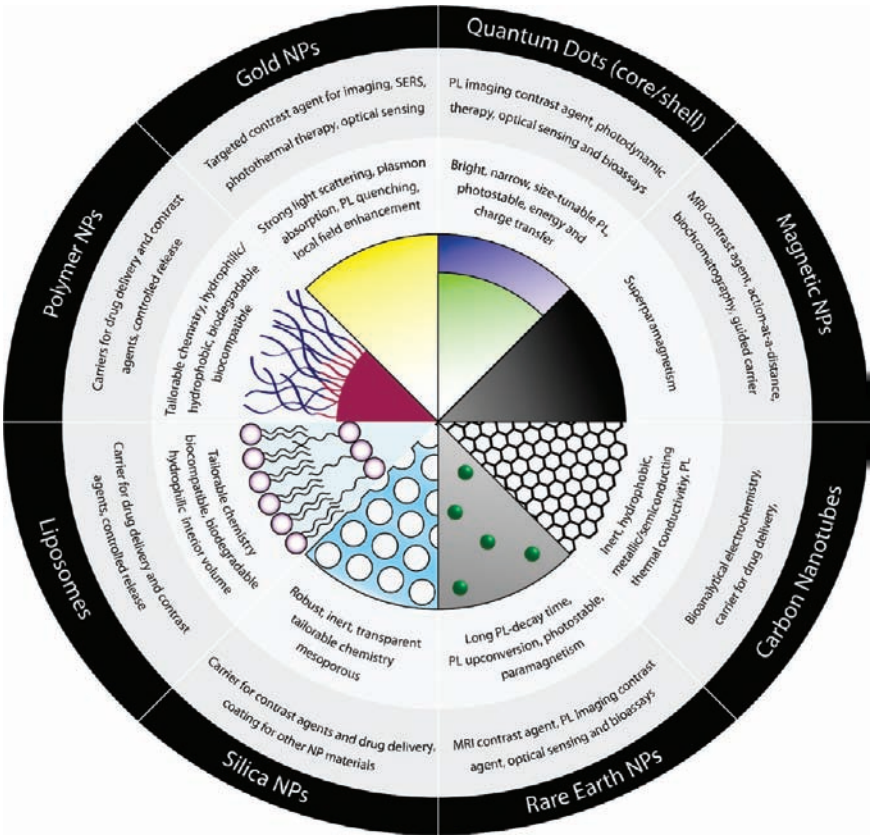

Figure 1. Select nanoparticle (NP) materials, their properties of interest, and prominent biological applications.

Semiconductors. Colloidal quantum dots (QDs) are luminescent crystalline NPs composed of semiconductor materials with radii that are typically between 2 and 10 nm.[26−28] Many different II−VI or III−V semiconductors,[29,30] alloys thereof,[31] and group IV semiconductors[32,33] have been used to synthesize colloidal QDs. In bioapplications, the interest has been in materials that offer visible or near-infrared photoluminescence (PL). The most widely used materials are CdX/ZnS QDs (X = Se, Te), where a CdX core is overcoated with a few atomic layers of wider bandgap ZnS or other binary semiconductor materials to improve its luminescence properties.[34,35] The optical properties of QDs are much different than their bulk analogues and arise from the quantum confinement of charge carriers within the dimensionality of the nanocrystal.[36−39] High-quality QDs exhibit a narrow PL band that can be tuned across a region of the visible or near-infrared spectrum by synthetically growing different nanocrystal sizes; the limits of the tunable emission range are determined by the choice of material.[26−28] Furthermore, the PL emission of QDs is more photostable than that of organic dye molecules, QDs offer stronger one- and two-photon absorption across a broader spectral range, and—similar to dye molecules—QDs can participate in energy transfer mechanisms that can modulate PL. The interest in QDs for biological applications is rooted in these more favorable optical properties. Several reviews have highlighted the use of QDs as probes for cellular, tissue, or in vivo imaging,[40] and in biological sensing.[41,42] Despite the success of CdX/ZnS QDs, there is a current trend toward developing QD materials that do not incorporate heavy metals and offer deep red or near-infrared PL at small nanocrystal dimensions. Examples include InP and CuInSe as core materials.[43,44] Quantum rods have also been developed and are essentially elongated QDs with a nonunity aspect ratio.[45,46] The optical properties of quantum rods are not dissimilar to those of QDs, but do exhibit some unique features such as polarized emission.

As synthesized with native alkyl coordinating ligands, II−VI QDs such as CdSe/ZnS are hydrophobic and insoluble in aqueous media. The two most common strategies for imparting aqueous solubility are the use of bifunctional ligand coatings and bifunctional polymer coatings.[26,28,47] The former coordinate to the QD surface through a chemical function (e.g., thiol, imidazole) and replace the native hydrophobic ligands; the latter have pendant alkyl chains that interdigitate with the native ligands via hydrophobic interactions. In both cases, a second and polar chemical function—such as a carboxylate, amine, or poly(ethylene glycol) (PEG) chain—mediates aqueous solubility. Mixtures of different ligands and the use of copolymers enable the modification of QDs with multiple functional groups. Ligand coatings are advantageous in that more compact QDs are obtained;[48] however, polymer coated QDs tend to have superior brightness and photostability. Standard bioconjugate techniques, such as carbodiimide coupling, are widely used with both ligand and polymer stabilized QDs. Ligand coatings have also frequently enabled the preparation of bioconjugates through self-assembly driven by coordination to the QD surface. Typical coating and bioconjugate methods for quantum rods are analogous to those for QDs.

Magnetic Materials. Magnetic NPs are typically less than 20 nm in diameter and have been prepared from different materials, including Co, Fe, Mn, Ni, γ-Fe_2O_3, Fe_3O_4, FePt, and other oxides or alloys.[49−56] Magnetic NPs are interesting due to

dx.doi.org/10.1021/bc200065z |*Bioconjugate Chem.* 2011, 22, 825–858

the combination of physical size and colloidal dispersion, the capacity for "action at distance" using magnetic fields, and their effectiveness as negative contrast agents in T2 weighted magnetic resonance imaging (MRI).[57,58] In addition to MRI imaging, magnetic NPs have potential as concurrent drug delivery vehicles or therapeutic agents in hyperthermia treatments with the added possibility of magnetic targeting. Magnetic NPs are also useful in bioaffinity chromatography methods (i.e., magnetic capture) for sample purification, analyte preconcentration, or toxin decorporation. These diverse applications are discussed in several reviews.[54,59−62] There has also been a recent trend toward the synthesis of "dumbbell" magnetic NPs that are inorganically linked dimers of a magnetic NP and a second class of NP. Most commonly, the latter is an optically active NP material such as gold or CdS[63,64] that allows the combination of optical tracking with the functionality of magnetic NPs. In addition to dumbbell NPs, analogous core/shell structures are also possible.[64]

Most synthetic methods yield hydrophobic magnetic NPs that are unsuitable for direct biological application. Similar to QD synthesis, the native ligands can be exchanged with bifunctional ligands or the NPs coated with polymer molecules. Functional groups that can bind to the surface of many magnetic NP materials include carboxylic acids, catechols, phosphates, sulfates, and amines. The groups that mediate aqueous solubility can often be used for subsequent bioconjugation using standard techniques. A second strategy commonly used with magnetic NPs is to coat them with an inorganic material such as silica, which can provide a hydrophilic protective layer against oxidation. The wide range of chemistry available to tailor the surface functionality of silica (*vide infra*) provides flexibility and the opportunity for bioconjugation in this approach.

Carbon Allotropes. Several different types of NP are derived from carbon allotropes. Carbon nanotubes (CNTs) are the most well-known of these materials, and are sheets of graphene rolled up into a seamless tube. If the nanotube is composed of a single graphene sheet, it is referred to as a single-walled carbon nanotube (SWCNT). In contrast, if it is composed of multiple sheets of graphene rolled concentrically, it is called a multiwalled carbon nanotube (MWCNT)—essentially a Russian doll of SWCNTs. Typical diameters of SWCNTs are 0.3−3.0 nm, whereas the diameter of MWCNTs can reach more than 100 nm. CNT lengths can vary from nanometers to micrometers. In bioapplications, it is the electronic and optical properties of CNTs combined with their large surface-to-volume ratios which are of interest.[65,66] A SWCNT can be metallic or semiconducting depending on its roll-up vector. The size of the band gap in chiral SWCNTs is dependent on the nanotube diameter, and photostable near-infrared PL can be associated with the band gap. Recent reviews have detailed the special properties and biological applications of CNTs,[67,68] including applications in electrochemical and electro-optical biosensing,[69−71] and as cellular delivery vectors and imaging probes.[72−74]

Similar to CNTs, fullerenes are composed of a graphene sheet, but are wrapped up into a closed, approximately spherical polyhedron rather than a tube. This geometry arises through the incorporation of five-membered rings into the otherwise six-membered ring structure of graphene. Buckminsterfullerene, C_{60}, is the most well-known example; however, C_{70} and other variants are also common. Fullerenes are interesting due to their photochemical activity (e.g., singlet oxygen production and DNA cleavage), their redox properties (e.g., radical scavenging), hydrophobicity, and electrophilicity (e.g., enzyme inhibition). The interested reader is referred to several reviews on the biological application of fullerenes.[75−77]

Both CNTs and fullerenes are extremely hydrophobic and poorly soluble in aqueous media; therefore, additional functionalization is required for most bioapplications. Two general strategies are utilized in this respect: the adsorption or complexation of macromolecules and surfactants, or alternatively, covalent modification of the carbon NP. For example, cyclodextrins or polyvinylpyrrolidone can be used to coat and solubilize C_{60}, while cycloaddition reactions are widely used to introduce new functional groups.[77] In the case of CNTs, a bifunctional pyrene molecule (e.g., 1-pyrenebutanoic acid succinimidyl ester) can irreversibly adsorb through π-stacking interactions and be used as a reactive linker for bioconjugation.[78,79] The method most commonly used for the covalent modification of CNTs is oxidation under acidic conditions, where carboxyl groups are introduced selectively at the highly curved tips of the CNT.[65,80] Modification of the sidewall is usually less efficient, and largely limited to defect sites. The introduction of carboxyl groups can enable many standard bioconjugate techniques including carbodiimide coupling. However, the drawback to this approach is a degradation of the electronic properties of the CNT due to the loss of π-conjugation at reaction sites. Further details on the chemistry of CNTs—including covalent modification schemes such as cycloaddition and reactivity with diazonium salts—can be found in reviews written by Tasis and co-workers.[81,82]

Other carbon allotropes have recently emerged as biologically useful nanomaterials, including two-dimensional graphene and graphene oxide sheets,[83,84] carbon quantum dots, as well as nanodiamonds.[85] In contrast to CNTs and fullerenes, nanodiamonds are not based on the sp^2-hybridized carbon centers of graphene. Rather, nanodiamonds are a lattice of tetrahedral sp^3-hybridized carbon centers, and exhibit visible and photostable PL due to the presence of defect sites.[86] The surface of nanodiamonds has intrinsic reactivity, and many synthetic preparations yield an interfacial layer of oxidized carbon groups. Carboxylated nanodiamonds are compatible with many standard bioconjugate techniques, are economical to synthesize, and are being explored as fluorescent cellular probes.[86]

Rare Earth Metals. The use of trivalent lanthanide ions in biology is well established. For example, Gd^{3+} is used as a contrast agent in MRI,[87] while Eu^{3+} and Tb^{3+} are used in time-resolved fluorescence immunoassays.[88] Historically, the properties of these ions have been harnessed in the form of chelates; however, incorporation of lanthanides into NPs provides many new opportunities and advantages.[89,90] Lanthanide ions have visible or near-infrared PL with narrow spectral bandwidth, excellent photostability, and decay times that are 10^3−10^6-fold longer than other luminophores.[89,90] The excitation of visible PL is possible using both ultraviolet and near-infrared light, where the latter is possible through the efficient luminescence upconversion exhibited by Er^{3+}, Tm^{3+}, and Ho^{3+} ions.[91−93] Although individual lanthanide ions tend to be weak absorbers, localizing multiple ions in a NP host can increase the effective absorption cross section. In the case of upconversion, more strongly absorbing lanthanide ions such as Yb^{3+} can be co-doped into the NP host as sensitizers that absorb NIR light and transfer the excitation energy to the emitter or activator ions (e.g., Er^{3+}).[91−93] In MRI, Gd^{3+} creates positive contrast in T1-weighted imaging through paramagnetic interactions with water. NPs provide the opportunity to concentrate multiple Gd^{3+} ions in small volume but retain a large surface area-to-volume ratio to promote

interactions between Gd^{3+} and water. Further optimization of MRI contrast is possible through the slower rotational diffusion of NPs compared to chelates and the ability to use NP surface chemistry to maximize the water exchange rate.[94]

Lanthanide NPs are typically composed of a lanthanide oxide (e.g., Y_2O_3), phosphate (e.g., $LaPO_4$), or (sodium) fluoride (e.g., LaF_3, $LaNaF_4$).[91,92,95] Most lanthanide ions easily substitute for another in a host lattice. In optical applications, luminescent dopant ions are typically incorporated at not more than a few percent. Sensitizer doping can be more substantial, on the order of 20%.[91,92] In the case of magnetic resonance applications, a Gd^{3+}-based NP material (e.g., GdF_3, Gd_2O_3) is generally used, and other lanthanide ion dopants can add luminescence functionality. Lanthanide NPs can be prepared by either aqueous or organic solvent routes,[92,96,97] where the latter require further surface modification for use in biological applications. In either case, aqueous lanthanide NPs are usually stabilized by surfactant ligands or polymers with carboxylate or phosphate groups that coordinate to the NP surface and also potentiate bioconjugation. A coating of hydrophilic silica can also be prepared around a lanthanide NP.[98] This provides a robust and hydrophilic coating, along with the opportunity for diverse surface modification and bioconjugation (*vide infra*).

Silica. Silica is a robust, hydrophilic, and biocompatible material that can be readily modified with diverse chemical functionality. As a consequence, silica is widely used as an inorganic coating for NPs of different composition (e.g., QDs,[99,100] magnetic NPs,[101−103] lanthanide NPs,[98] and Au NPs[104]), or as a NP-based carrier of functional molecules.[105] Using the diversity of silane chemistry,[106] a silica shell or coating can be tailored to have functional groups that can include, but are not limited to, amine, aldehyde, carboxyl, epoxy, and thiol groups. In addition to the use of silica as a structural shell on other NP materials, NPs composed of silica can be prepared with sizes that typically range between tens and hundreds of nanometers. The Stöber or reverse microemulsion methods are most commonly used for the synthesis of silica NPs.[107] In bioapplications, the ability to dope silica NPs with another material is of great utility. For example, up to 10^4 dye molecules can be incorporated into silica NPs (ca. 50−75 nm diameter) during synthesis.[108] The photostability of the dyes is greatly enhanced within the silica NP matrix, and the concentration of thousands of dye molecules into a single entity provides ultrabright labels for fluorescence imaging and assay applications. In addition, silica NPs can be used as carriers in drug delivery.[109,110] In this case, drug molecules must not be permanently incorporated within the NPs. The addition of surfactants and other manipulations of reaction conditions during silica NP synthesis can yield mesoporous silica NPs with pore sizes as small as 1 nm or as large as many tens of nanometers. These nanoscale mesopores allow both cargo transport and release and are therefore attractive for drug delivery applications. Typical values for pore surface area and volumes are close to 10^3 m^2 g^{-1} and 2 cm^3 g^{-1}, respectively, thereby offering small molecule (e.g., drug) cargo capacities on the order of $10^1−10^2$ mg g^{-1}.[110]

Polymer and Amphiphile Nanoparticles. Polymer and other amphiphile-based NPs are currently the most prominent materials being utilized as nanoscale drug carriers. These include: polymeric NPs, dendrimers, liposomes, polymersomes, and micelles.[111−114] The interest in these materials arises from the combination of nanoscale size with the nearly infinite diversity of physical properties and chemical functionality that can be obtained through organic chemistry. Polymer and amphiphile NPs can be designed to do the following:

- Carry molecular cargo externally or internally
- Carry hydrophilic or hydrophobic cargo
- Release cargo gradually
- Exhibit "smart" physicochemical responses to environmental stimuli (e.g., pH, thermal response) to selectively release cargo
- Evade the reticuloendothelial system and other immune responses
- Biodegrade
- Target different tissues or cell types

These different properties are tailored through the selection of the chemical composition of the polymer NPs. Bioconjugates of polymer and amphiphile NPs are typically prepared to assist targeting—antibody conjugates being particularly common. While there is no characteristic surface chemistry due to the diversity of materials, the introduction of carboxyl or amine groups into the polymer/amphiphile composition for purposes of bioconjugation is routine. Overall, the bioconjugation chemistry of these NPs is generally dictated by the functional groups associated with the material(s).

Polymer NPs are typically agglomerates of polymer chains with dimensionality that can range across the nanoscale. For example, poly(lactic acid) (PLA) and poly(lactic-*co*-glycolic acid) (PLGA) derivatives are commonly used to prepare NPs and are advantageous due to their biodegradability.[115] Dendrimers are fractal-like, hyperbranched polymers that can be size-controlled through their stepwise growth. A common example is polyamidoamine dendrimers, which form spherical NPs and display a high density of surface amine groups.[116,117] Liposomes and polymersomes are spherical NPs with unilamellar or multilamellar structures that separate and encapsulate an aqueous interior from bulk aqueous solvent. The lamellae of liposomes and polymersomes are composed of a bilayer of either lipids or synthetic block copolymer amphiphiles, respectively, with a hydrophobic midplane to separate the two aqueous volumes. Distearoylphosphatidylcholine is an example of a lipid material commonly used for assembling liposomes. In contrast to liposomes, micelles consist of amphiphiles or surfactants that assemble into spherical assemblies with a hydrophobic interior that excludes aqueous solvent and is thus able to carry hydrophobic molecular cargo. Micelles are typically prepared using the same types of amphiphiles as polymersomes—PEG-PLA is a common example.[113]

Viral Particles. Plant virus and bacteriophage capsids are natural examples of protein NPs. In nature, viruses are designed to carry genetic cargo, penetrate cells, and release their cargo—a natural parallel with the target application of many polymer and amphiphile-based NPs. Viral capsids are thus emerging as potential vehicles for drug delivery and contrast agents.[118−121] The unique advantage of such materials is that, in contrast to many synthetic NP materials, there is almost no polydispersity in their size and morphology. Being composed of many identical protein subunits, viral capsids offer a well-defined and regular array of amino acid residues for chemical modification or bioconjugation at both their interior and exterior surfaces. They are also amenable to recombinant modification allowing site-specific placement of unique groups such as cysteine-thiols where needed. The MS2 bacteriophage and cowpea mosaic virus (CPMV) capsids have dimensions of approximately 27 and 28 nm,[122,123] respectively, and are two prominent viral NP candidates being prototyped for drug delivery and other bioconjugate applications.[124]

■ REPRESENTATIVE APPLICATIONS OF NANOPARTICLE BIOCONJUGATES

A comprehensive summary of NP-bioconjugate applications is beyond the scope of this review. Only a few select examples of their application are given herein to illustrate the utility of NP-bioconjugates.

Diagnostic Assay. The properties of optically active NPs can enable new possibilities in biological detection with high sensitivity. For example, Cao et al. developed a solid-phase hybridization assay[10] and protein microarray[125] (Figure 2) using Au/Ag NPs conjugated with dye-labeled oligonucleotides as reporters. The surface enhanced Raman scattering spectra of the dye on the NP provided both an analytical signal and analyte-specific fingerprint. In the case of the hybridization assay, detection was possible down to 20 fM. As described by Faulds et al., the narrow features of Raman spectra can enable multiplexed detection without the spatial registration of capture probes.[126,127] This is an example of a new method that exploits the special properties of a NP and relies on the preparation of a NP-bioconjugate to harness those properties.

Targeted Contrast Agent. Optically active NPs provide advantages in diagnostic imaging, particularly in terms of sensitivity and facilitating improved multicolor analyses. Liu et al. used QD-antibody conjugates that targeted four different protein biomarkers in histological tissue specimens from prostatectomy procedures (Figure 3).[128] Multispectral imaging of the heterogeneous fluorescence staining pattern enabled the observation of single malignant cells and progressive cancer development within the complex microenvironment of the histological specimens. These results are an example of how the uniquely advantageous properties of a NP can facilitate advances in an established technique such as immunohistochemical staining. Although not explored in this example, the large two-photon cross section of QDs could potentially be exploited—in addition to advantages in brightness and multiplexing—to suppress tissue autofluorescence for far more sensitive immunohistochemical detection.

Multimodal Contrast Agent. Different medical imaging techniques have different capabilities for spatial and temporal resolution, tissue penetration, and contrast generation. A single probe that could provide contrast in different imaging modalities would be highly advantageous in diagnostics. NPs provide the opportunity to incorporate multiple materials into a single probe to enable multiple imaging modalities and thus allow for better overall contrast or resolution. Cheung et al. explored the use of different formulations of soluble Gd^{3+}-rich and Tb^{3+} (or Eu^{3+}) doped lanthanide fluoride NP aggregates for multimodal imaging (Figure 4).[94] The NPs provided contrast enhancement in MRI imaging that was sufficient to enable animal perfusion imaging at NP doses that were 10-fold smaller than those associated with standard Gd^{3+} chelates. In addition, at the X-ray energies

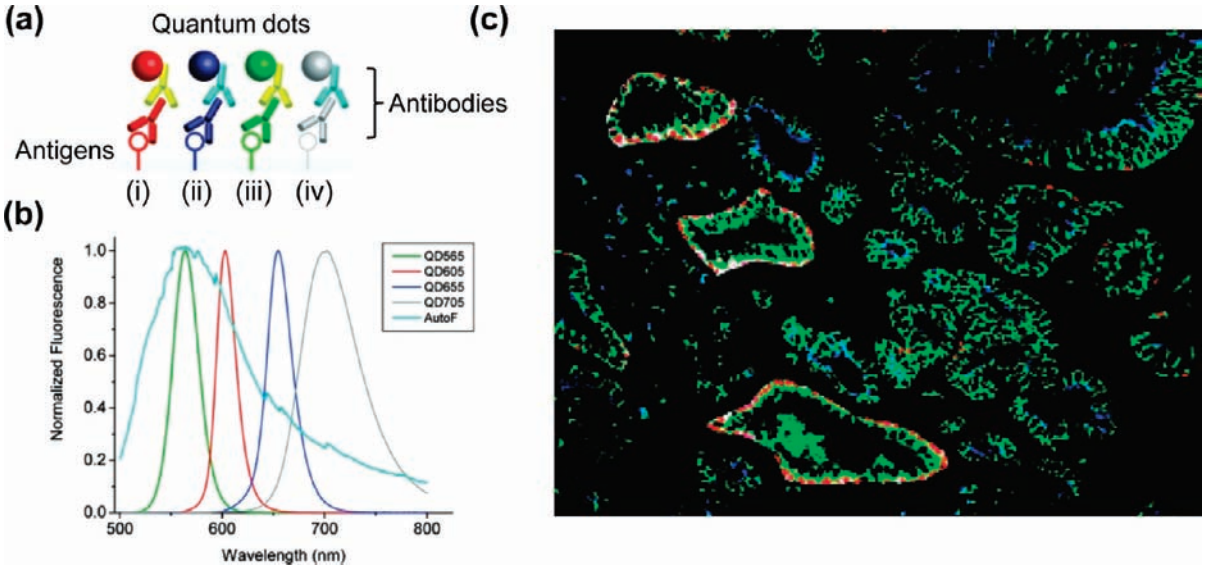

Figure 3. Multiplexed fluorescence immunostaining of prostate tissue specimens using QD-antibody conjugates. (a) Primary antibodies targeted tissue antigens and were labeled with secondary antibody-QD conjugates (i—iv). As shown in (b), the QD emission peaks were at (i) 605, (ii) 655, (iii) 565, and (iv) 705 nm. The tissue autofluorescence (AutoF) background is shown for reference. (c) Processed fluorescence images highlighting four different protein biomarkers using the four colors of QD, shown in blue, green, red, and white pseudocolors. The staining pattern can differentiate between healthy and cancerous tissue. Figure adapted with permission from ref 128. Copyright 2010 American Chemical Society.

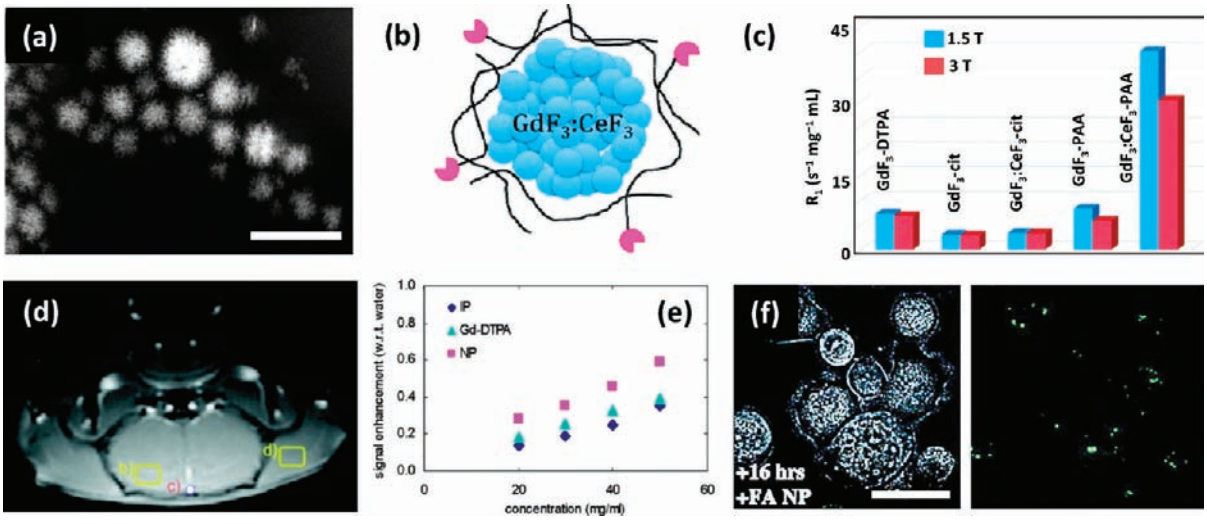

Figure 4. Potential for multimodal NPs. (a) STEM image of GdF_3:CeF_3 NP aggregates stabilized with poly(acrylic acid) (PAA). The scale bar is 150 nm. (b) Pictorial representation of $GdFe_3$:$CeFe_3$ NP aggregates stabilized with PAA. The mean aggregate size is ca. 70 nm, while the fundamental unit size is estimated to be 10—12 nm. (c) Mass relaxivities (R_1) for aqueous dispersions of different NP formulations. The GdF_3:CeF_3 NP aggregates have a much larger relaxivity than the commonly used Gd^{3+}-diethylenetriaminepentaacetic acid (DTPA) chelate. (d) Dynamic contrast enhancement MRI image of a rat brain using GdF_3:CeF_3 NP aggregates as a perfusion contrast agent. (e) Comparison of X-ray (25 kV) image signals as a function of mass concentration for aqueous PAA-stabilized $NaGdF_4$:Eu^{3+} NP aggregates and the commonly used contrast agents Gd^{3+}-DTPA and iopromide (IP). The NPA aggregates provide superior contrast. (f) Transmitted light (left) and confocal fluorescence (right) images of SK-BR-3 cells showing uptake of folate (FA)-modified $NaGdF_4$:Tb^{3+} NP aggregates. The scale bar is 20 μm. The punctate pattern of green emission in the fluorescence image is characteristic of endosomal uptake, and comparison with the transmitted light image indicates that the NPs are located within the cells. Figure adapted with permission from ref 94. Copyright 2010 American Chemical Society.

associated with mammography, the NPs were shown to have greater X-ray attenuation than the standard iopromide contrast agent used in computed tomography (CT). Luminescence from Tb^{3+} also provided the opportunity for fluorescence imaging of SK-BR-3 breast cancer cells using folate-conjugated NPs that promoted cellular uptake.[94] Although a single NP vector has not yet been fully developed to provide these three contrast mechanisms concurrently, this example makes clear the long-term potential for NP materials as multimodal contrast agents using a combination of fluorescence, MRI, and CT.

Drug Delivery Vehicle. NPs offer the potential to maximize the local efficacy of drugs while concurrently minimizing systemic

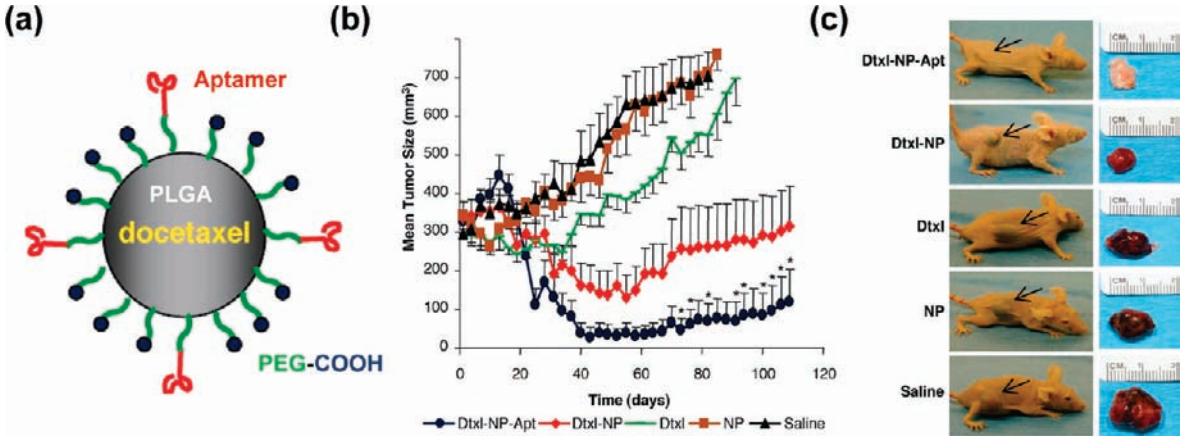

Figure 5. An example of drug delivery using polymeric NPs. (a) Poly(D,L-lactic-*co*-glycolic acid) or PLGA NPs were modified with prostate specific membrane antigen binding aptamer (Apt) and encapsulated the drug Docetaxel (Dtxl). (b) Quantitative and (c) qualitative changes in tumor size following administration of different formulations. The Dtxl-NP-Apt conjugate was the most efficacious, followed by the untargeted Dtxl-NP. The Dtxl alone was the least efficacious. Figure adapted with permission from ref 129. Copyright 2006 National Academy of Sciences, USA.

toxicity, thereby improving the quality of life and prognosis for patients undergoing chemotherapy. For example, Farokhzad et al. demonstrated that polymer NP-bioconjugates could increase the efficacy of chemotherapeutic treatment in mouse tumor models.[129] The drug Docetaxel was encapsulated within NPs composed of PEG-PLGA and conjugated with nucleic acid aptamers that targeted prostate specific membrane antigen. As shown in Figure 5, when compared to treatment with only Docetaxel, the NP(Docetaxel)-aptamer conjugates were found to cause concomitant and substantial reductions in both tumor size and treatment toxicity. Although treatment with NP(Docetaxel) was more efficacious than only Docetaxel, it was less than that with NP(Docetaxel)-aptamer conjugates, highlighting the importance of adding targeting to the NP-drug vector via the aptamer.

Theranostic Agent. "Theranostics" describes the combination of diagnostic and therapeutic utility in a single entity and has the potential to significantly enhance the treatment of disease. NPs have two important features that are highly favorable to theranostic application: (1) dimensionality that can allow cellular delivery and biodistribution and (2) nontrivial surface area or volume that can be derivatized with potentially many different molecules to impart a variety of functions (e.g., targeting, delivery). As shown in Figure 6, Cheng et al. recently reported the synthesis of trifunctional mesoporous silica NPs for theranostics.[130] The NP surface was decorated with cyclic Arg-Gly-Asp (cRGDyK) peptides to target the NPs to overexpressed integrins on cancer cells, and near-infrared fluorescent dye molecules were incorporated within the silica framework for visualization. In addition, a photosensitizer used in photodynamic therapy was loaded into the nanopores of the silica NP. Cellular studies indicated a high degree of targeting specificity and cytotoxicity. In some cases, NPs can also offer intrinsic features for theranostic purposes. For example, QDs allow the direct sensitization of conjugated photodynamic therapy drugs attached to them, while Au NPs can provide concomitant photothermal effects.[131,132]

The examples above highlight representative uses of several NP materials in different applications. For each material, many more applications have been reported, and similarly, for each application, many other NP materials have been used. Nonetheless, in nearly all cases, the controlled preparation of NP-conjugates is necessary to effectively combine and use the unique properties of both the NP material and the biomolecule for the intended application.

NANOPARTICLES AND BIOCONJUGATE CHEMISTRY

Challenge of Nanoparticles. It is difficult to generalize the many challenges associated with preparing NP bioconjugates. The diversity of NPs is such that dimensionality can vary by 2 orders of magnitude (1−100 nm) between materials, with each exhibiting different degrees of polydispersity. Nonetheless, several common features are important to recognize:

- NPs are large compared to most molecules.
- NPs are sufficiently small to be functionalized for colloidal solubility and are able to diffuse.
- NPs have nontrivial surface area and can occupy or contain nontrivial volumes that vary over a wide range of magnitudes based on NP size.
- NPs tend to exhibit heterogeneity across a population.

NPs thus have a character that is intermediate between molecules and bulk interfaces. Arguably, the closest molecular analogue for a NP is a protein. Proteins are large compared to most other molecules and are soluble, adopting a three-dimensional structure where the character of the amino acid residues exposed to solution largely determines protein solubility and the potential labeling methods. It is thus not surprising that much of the initial work in the preparation of NP-bioconjugates drew inspiration from standard protein labeling chemistries, such as those shown Figure 7. Despite the conceptual similarity between NPs and proteins, there are important differences between protein labeling and NP bioconjugation. Consider the labeling of proteins with fluorescent dyes: excesses of reactive dyes are frequently used to shotgun label proteins, and these approaches are often effective given the monoreactivity of the dyes and the availability of many reactive amino acid residues (e.g., lysine) at the surface of a folded protein. The degree of labeling is measured experimentally and the reaction optimized empirically. Since the size of the dye label is comparable to the size of the amino acid residues, the perturbation of the protein tends to be minimal. However, as outlined above, NPs are quite dissimilar to dye molecules by virtue of the nontrivial size and functionalization with polyreactive coatings.

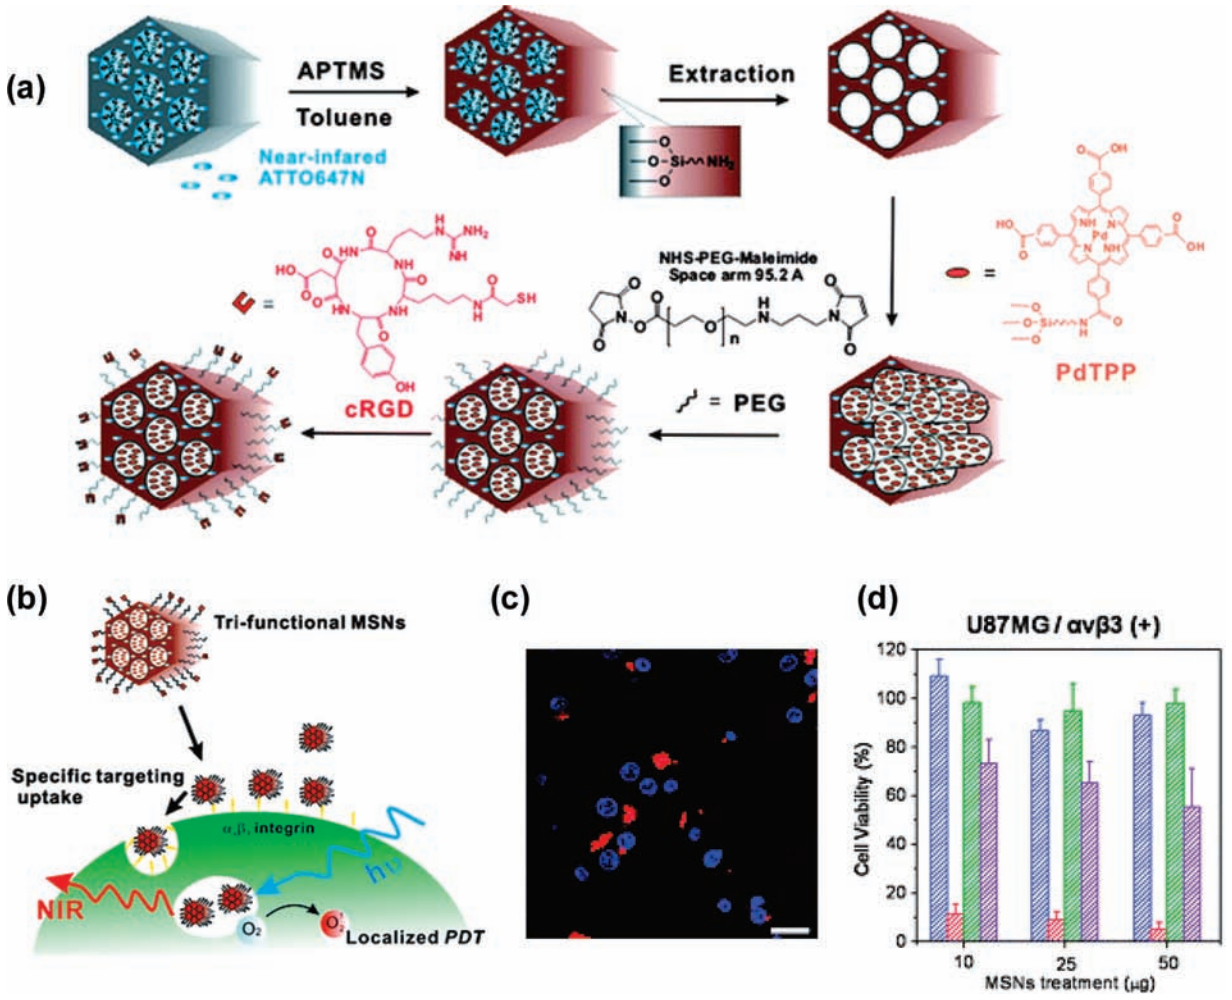

Figure 6. Trifunctional mesoporous silica NPs (MSNs) for theranostics. (a) Synthesis scheme showing incorporation of the Atto647N near-infrared fluorescent dye for tracking, surface modification with (3-aminopropyl)trimethoxysilane (APTMS), encapsulation of a Pd-porphyrin (PdTPP) photosensitizer for photodynamic therapy (PDT), and further surface modification with PEG and cyclic Arg-Gly-Asp (cRGD) for targeting $\alpha_v\beta_3$ integrin. (b) Theranostic scheme illustrating targeting, uptake, tracking, and localized PDT. A good example of the potential liabilities of shotgun labeling methods is the popular cross-linking reaction between amines and carboxylic acids using carbodiimide activation (e.g., 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide, or EDC), shown in Figure 7c. It is often the case that a NP displays a high density of carboxylic acid groups and a target biomolecule of interest has one or more primary amines. One of the disadvantages of carbodiimide chemistry is that the reactive *o*-acylisourea intermediate formed through the activation of carboxylic acids is prone to rapid hydrolysis.[1] As a consequence, a large excess of carbodiimide must be used to drive the desired cross-linking reaction to completion. Unfortunately, overactivation of the NP carboxyl groups—which often mediate aqueous solubility—can cause the loss of colloidal stability and aggregation due to the poor solubility of the *o*-acylisourea intermediate. This can be only partially ameliorated by converting the *o*-acylisourea to a more stable reactive intermediate using *N*-hydroxysuccinimide (NHS) or a sulfonated derivative thereof.[1] A sulfonated succinimidyl ester intermediate has greater solubility and helps maintain colloidal stability during the reaction. Although the succinimidyl ester intermediate is not resistant toward hydrolysis, it hydrolyzes more slowly than the *o*-acylisourea intermediate, and this tends to increase reaction efficiency. The conversion of the *o*-acylisourea intermediate to a (sulfo)fluorophenyl ester provides yet greater resistance toward hydrolysis[133] but, like NHS, is still limited by the dependence on EDC for *in situ* activation. Although EDC-driven coupling is a very powerful and popular chemistry that is often made to work with NPs, it is critical to realize that successful use of this shotgun cross-linking between a carboxylated NP and an aminated biomolecule (or *vice versa*) is not equivalent to controlling the display of that biomolecule on the NP.[134]

There are several criteria that define ideal chemistries for the controlled display of biomolecules on NPs, and these can often be difficult to realize in practice:

- The average number or ratio of biomolecules per NP (i.e., the conjugate valence) is both predictable and reproducible on the basis of reaction stoichiometry.

dx.doi.org/10.1021/bc200065z |*Bioconjugate Chem.* 2011, 22, 825–858

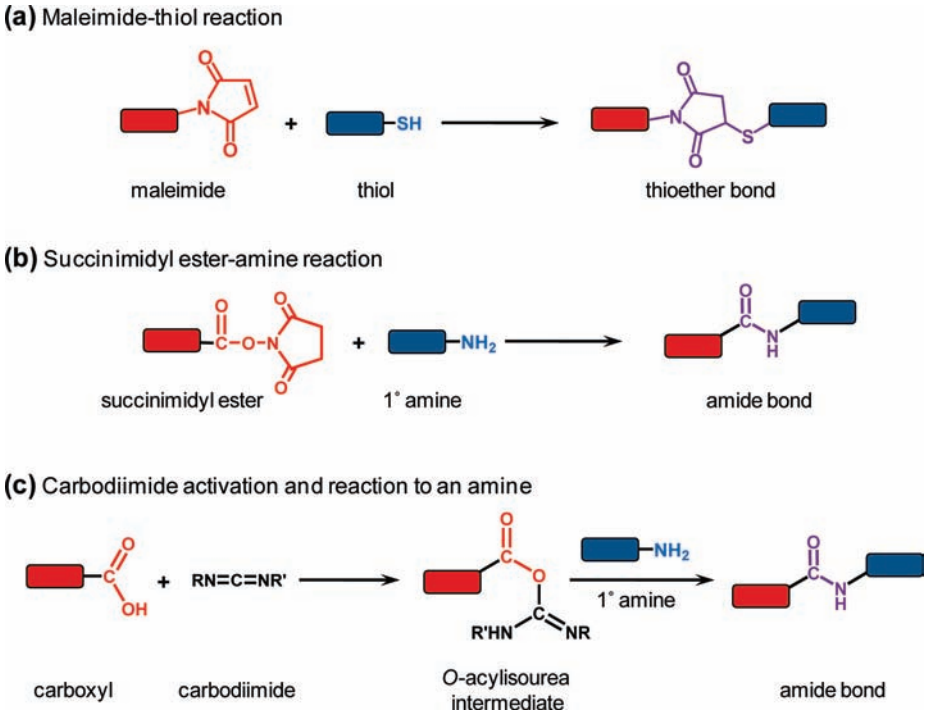

Figure 7. Standard bioconjugation reactions, including (a) maleimide−thiol, (b) succinimidyl ester-amine, and (c) carbodiimide-mediated coupling between carboxyls and amines.

- The NP-conjugates have minimal polydispersity in their valence across the ensemble.
- The attachment point of a biomolecule to the surface of the NP is both predictable and reproducible.
- The distance between the NP to a given moiety of a biomolecule is both predictable and reproducible.
- A corollary of the previous two points is that biomolecular orientation is controlled.
- The activity of a biomolecule or the efficacy of a small molecule is minimally compromised by its attachment to a NP. Similarly, NP functionality is not compromised.
- The linkage between the NP and the biomolecule is stable under most conditions, but is potentially labile under selected conditions (i.e., drug delivery). Stability or lability as a function of time, temperature, and pH may be important.
- The bioconjugate reaction proceeds to completion rapidly (<1 h) under mild aqueous conditions (i.e., does not require extremes of temperature or pH).
- The bioconjugate reaction is not prone to competing reactions (e.g., hydrolysis).
- The bioconjugate reaction is orthogonal to other bioconjugate chemistries (i.e., highly chemoselective).
- A corollary of the previous point is that the display of one type of biomolecule is compatible with the concurrent display of other biomolecules, as desired, using previous, parallel, or subsequent coupling reactions.

Given these considerations, it is clear that there are several challenges associated with the controlled display of biomolecules on NPs. Continuing with the example of carbodiimide coupling, polydispersity in NP size and surface area results in variability in the number of carboxylic acid groups available for activation per NP. This is exacerbated by the competition between overactivation and hydrolysis, which are very sensitive to reaction conditions such as pH and temperature. Therefore, reaction stoichiometry does not directly translate into conjugate valence. In the case of certain synthetic NPs, it is possible to address this challenge through the chemistry used to coat the NP. The display of multiple functional groups or a "mixed" surface, where one group mediates solubility and other groups mediate reactivity, offers a distinct advantage. Mei et al. prepared CdSe/ZnS quantum dots and Au NPs coated largely with unreactive methoxy-terminated PEG ligands, while also incorporating a small percentage of reactive carboxyl terminated PEG ligands.[135] The PEG provides aqueous solubility while allowing the carboxyl groups to be fully converted into reactive intermediates via EDC. Thus, some control can be exercised over the final conjugates by driving the cross-linking reaction to saturation. However, control over the conjugate valence and its polydispersity must be achieved in the preparation of the coated NPs—the conjugate reaction itself is still not well controlled. Moreover, the strategy is best suited for the preparation of small molecule-NP conjugates: it is generally impractical to use large excesses of biomolecules in conjugate reactions with NPs. In addition to biomolecules being a more limited resource, biomolecule solubility can be limited (often to micromolar concentrations) and it may not always be possible to efficiently purify NP-bioconjugates from excess biomolecules (e.g., low conjugate valence and similar size between NP and biomolecule).

Another challenge that can be associated with using carbodiimide coupling and NPs is control over biomolecular orientation in the conjugate. Proteins often have many lysine residues that can participate in carbodiimide coupling. The size of the NP is also nontrivial, and the point of attachment is important for bioconjugate function. If the binding site of an antibody or enzyme is oriented toward and in close proximity to the surface of the NP, then some loss of activity can be expected. Indeed, this effect of orientation has been observed with QD-antibody

conjugates.[136] A distribution of attachment points results in a distribution of orientation in NP-protein conjugates, and thus a distribution of protein activity or mixed avidity. Furthermore, the reactivity of many different amino acid residues can potentially result in undesirable side-reactions. It is generally the case that proteins have a comparable number of carboxyl (e.g., glutamic acid, aspartic acid) and lysine residues. Thus, protein−protein cross-linking efficiently competes with NP-protein coupling when using EDC chemistry. Multiple lysine residues can also drive protein-mediated NP-NP cross-linking. Such side reactions only increase the challenge of controlling bioconjugate valence and orientation, while introducing additional heterogeneity across an ensemble.

In contrast to proteins, it is often possible to design synthetic oligonucleotides and oligopeptides that are monoreactive. While this allows for control over the attachment, it does not necessarily guarantee orientation. Flexible linkages allow the biomolecules in NP-conjugates to adopt conformations that interact with the surface of the NP. For example, it has been shown that oligonucleotides can strongly adsorb to NPs such as CdSe/ZnS QDs,[137] gold NPs,[138] and carbon nanotubes.[139] It is critical to note that the interactions between a NP and a biomolecule in a conjugate are a function of the combination of the NP, its interfacial chemistry, and the biomolecule. Therefore, efforts to control the display of biomolecules on NPs must consider these factors in addition to the details of the coupling chemistry.

There are many applications in biosensing that require good control over conjugate valence and biomolecule orientation. As noted earlier, additional complexity is associated with these applications due to the frequent tendency toward "nested" conjugate preparation. That is, an optically active NP is conjugated with a biomolecule, and that biomolecule is also conjugated with a small molecule that acts as a reporter. Good examples are QD probes for protease activity. A peptide sequence cleaved by a target protease is connected to a QD at one terminus and a fluorescent dye at its other terminus. The peptide creates the proximity required for Förster resonance energy transfer (FRET), and this proximity is lost as a consequence of target protease activity, thereby generating an optical signal for transduction.[41,42,140] The important point is that FRET is sensitive to both the acceptor ratio and separation distance between the QD and dye in this configuration. Therefore, two-fold control over the preparation of the NP-bioconjugate is required for optimal function in this type of sensing.

There are also challenges associated with the preparation of NP-small molecule conjugates. Depending on the application, control over conjugate valence may not be critical. In the case of drug delivery, the intent is often to "load up" the NP to concentrate delivery. Providing that NP solubility is not compromised, shotgun-labeling strategies can thus be effective for preparing NP-drug conjugates. Many drugs and other small molecules can also be synthesized with a uniquely reactive group, used in excess in conjugate reactions, and are amenable to the efficient purification of NP-conjugates. These factors offer a degree of control that is often more difficult to achieve with large biomolecules. However, the relatively small size of drugs and other small molecules compared to NPs can also be a potential challenge. The mode of action of many drugs requires interaction with, for example, the binding site of a protein. NP-conjugated drug molecules can have availability for this interaction, but it must be mediated through long and flexible linkers, or triggered release of the drug from the NP under suitable conditions.

Overall, the controlled display of biomolecules on NPs is not a trivial feat. Although the optimization of most experiments will not necessarily require satisfying *all* of the ideal criteria discussed above, most would benefit tremendously by the development and use of bioconjugate chemistries that come close to satisfying a majority of these criteria.

Bioorthogonality. The example of EDC bioconjugate chemistry is a notorious one: it is both widely used and has several liabilities. However, there are many other standard bioconjugation chemistries that have, at least to some degree, similar liabilities. For example, isothiocyanate derivatives of biomolecules are amine reactive and stable in aqueous solution, potentially providing a greater degree of control. However, the resulting thiourea linkage can degrade,[141] and a major limitation is still the ubiquitous nature of lysine residues in proteins. In contrast, cysteine residues are scarce in proteins, and bioconjugate chemistries that target the reactive thiol of cysteine residues can potentially ameliorate many of the liabilities associated with EDC. For example, maleimides hydrolyze more slowly than *o*-acylisourea intermediates, and while the latter are reactive toward all good nucleophiles (e.g., amine, thiol, hydrazide), the reaction of maleimides with thiols is highly selective at near-neutral pH. This selectivity, combined with the ability to recombinantly engineer unique cysteine residues into proteins and synthetically insert them into peptides, can provide a well-defined point of attachment between a biomolecule and a maleimide-activated NP. This enables a degree of control over biomolecular orientation and largely avoids issues associated with undesirable cross-linking or other side reactions.

The idea of highly selective or specific bioconjugate chemistry reactions is captured in the concept of "bioorthogonality."[142−144] Bioconjugate chemistries that are bioorthogonal are those that do not have significant reactivity toward the functional groups that are intrinsic to biomolecules. This generally encompasses amine, carboxyl, hydroxyl, and thiol groups. However, to be strictly bioorthogonal, the chemistry must also be unreactive toward alkenes, amides, disulfides, esters, phosphodiesters, and a plethora of other functional groups that can be found within the biological milieu. The best candidates for strictly bioorthogonal reactions appear to be cycloaddition reactions from click chemistry. These reactions can enable clean and efficient labeling in biological matrices as complex as serum.[145] Other reactions, such as that between a hydrazide and an aldehyde/ketone (hydrazone ligation), are not strictly bioorthogonal, but can be *effectively* bioorthogonal if biological aldehydes/ketones are not native to a particular experimental matrix of interest. Several reactions with bioorthogonal character are discussed in detail later. An important caveat to bioorthogonal chemistries is that the functional groups providing the high reaction specificity are generally not naturally occurring. In the case of synthetic oligonucleotides and oligopeptides, incorporating a moiety with the necessary functional group(s) is readily accomplished during synthesis. However, in the case of proteins, the use of bioorthogonal chemistry may require a nested bioconjugate reaction using more traditional labeling chemistry. A common strategy is the use of heterobifunctional cross-linkers with a non-bioorthogonal reactive moiety (e.g., succinimidyl ester, maleimide) that introduces the desired bioorthogonal functional group(s) of interest through shotgun or site-directed labeling methods. An alternative to heterobifunctional cross-linkers is the incorporation of unnatural amino acids into proteins. These unnatural amino acids can have, for example, an azide or alkyne functionality on the side chain.[146]

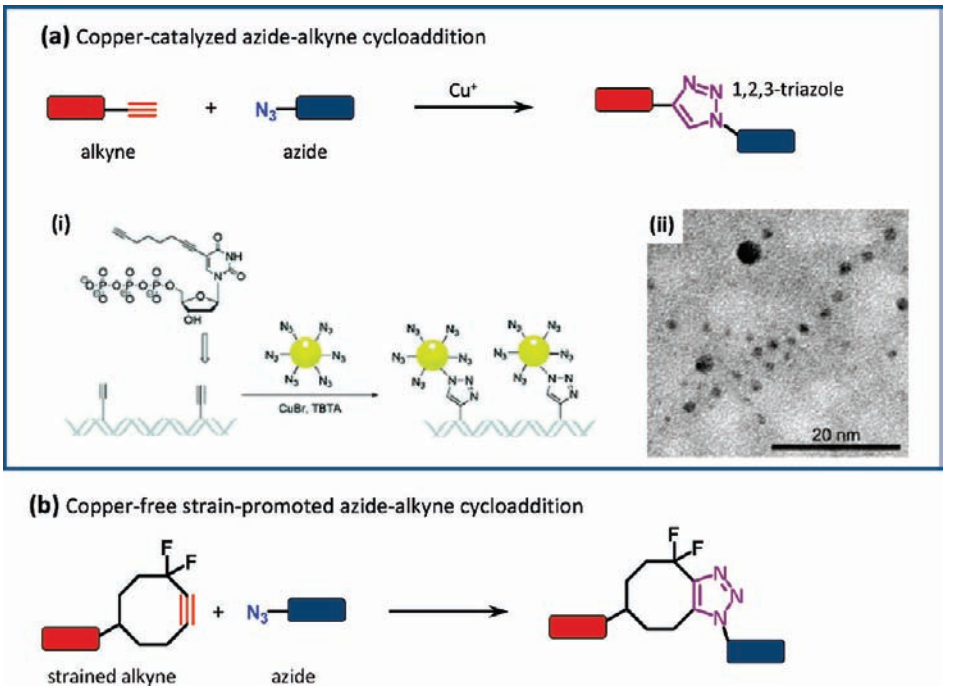

Figure 8. Azide−alkyne cycloaddition (AAC) reactions: (a) copper-catalyzed (CuAAC); (b) copper-free/strain-promoted. The example of the CuAAC shows (i) the use of alkyne-modified thymidine bases along double-stranded DNA to align azide-modified Au NPs. Most NP-bioconjugates are prepared in clean matrices (e.g., buffers) and subsequently applied in a biological matrix. Bioorthogonal chemistry is therefore important because it potentially offers some control over NP bioconjugation by providing a well-defined point of attachment between the NP and the biomolecule, and does so without undesirable side reactions. Furthermore, bioorthogonal chemistries can facilitate nested conjugate reactions with control at each step. For example, a peptide can be coupled to a NP through a bioorthogonal reaction and concurrently labeled with a dye or other reporter through more traditional methods at lysine or cysteine residues. Similarly, the use of bioorthogonal chemistries also potentiates the controlled attachment of multiple biomolecules to a NP—for example, two different peptide sequences, a mixture of a peptide and an oligonucleotide, an antibody and a drug molecule, or other combinations of biomolecules that impart multifunctionality to a NP. This could take the form of two distinct bioorthogonal chemistries that are applied concurrently or in succession to conjugate a NP with two different biomolecules, and where the biomolecule orientations and conjugate valences are controlled and biological activities are not compromised. Such a level of control is extremely challenging to achieve using bioconjugate chemistries wherein two biomolecules compete for common reaction sites at a NP or have potential side-reactions with one another. The development of multifunctional NP-bioconjugates thus stands to benefit immensely from bioorthogonal reactions—particularly combinations that are also mutually orthogonal.

Bioorthogonality is just one important part of the toolkit that researchers are developing for the preparation of NP-bioconjugates. Another important part of the toolkit is reaction efficiency. Ideal conjugate chemistries use reactants that are stable in aqueous solution, proceed efficiently at 1:1 stoichiometries and at low concentrations, and have short reaction times at ambient or physiological temperature in aqueous media. Many of the chemistries that satisfy these criteria do not use an active cross-linker (e.g., EDC), but rather make use of a catalyst or strained bonds to drive the coupling reaction. Overall, the controlled display of biomolecules on NPs requires three ingredients: bioorthogonal reactivity, high reaction efficiency, and controlled NP properties.

■ ADVANCES IN NANOPARTICLE BIOCONJUGATION CHEMISTRY

Covalent Chemistries. *Cycloaddition Reactions.* A cycloaddition is a reaction where two unsaturated molecules combine to form a cyclic adduct in which the number of σ bonds increases.[147] Since biological macromolecues rarely contain moieties with nonaromatic double bonds, cycloaddition strategies have significant potential for bioorthogonality and have found increasing utility for the selective modification of NPs. The Huisgen 1,3-dipolar cycloaddition, illustrated in Figure 8a, is a reaction between an alkyne and an azide that produces a triazole linkage. In the presence of a copper(I) salt, the reaction is greatly accelerated, regioselective, and highly efficient. Referred to as the "copper-catalyzed azide−alkyne cycloaddition" (CuAAC), and well-known as the flagship reaction of the "click" chemistry family, this reaction has become a valuable ligation method for the preparation of bioconjugates. The CuAAC reaction is advantageous in that it is bioorthogonal and proceeds under relatively mild conditions in aqueous solution. In addition to being used in drug synthesis, controlled surface modification, protein labeling, and activity-based protein profiling,[148,149] the CuAAC has also been used to control the display of biomolecules on NPs.

Viral capsid bioconjugates were one of the first NP systems to which CuAAC chemistry was extensively applied. Bioconjugates

of this naturally occurring biological NP family have been prepared using CuAAC with fluorescent dyes,[150−155] MRI contrast agents,[154,156,157] biotin,[152,154] linear and branched polysaccharides,[150,155,158−160] peptides,[155,161] and proteins.[141,155] In most cases, the initial alkyne or azide functional group is introduced onto the virus capsid using a succinimidyl ester derivative that couples to available lysine residues. For example, CPMV was modified with an NHS-alkyne derivative and subsequently "clicked" with an azide-terminated PEG-folate conjugate for tumor cell targeting experiments.[162] Both CPMV and bacteriophage Qβ have been modified with lanthanide complexes to explore the biodistribution, toxicology, and pathology of viral particles in mice.[157,163] Here, the CPMV was modified with an NHS-azide derivative and clicked with an alkyne derivative of a Gd^{3+}-tetraazacyclododecanetetraacetic acid chelate. NP hybrids composed of C_{60} labeled Qβ bacteriophage particles have also been prepared using CuAAC chemistry.[164] It was estimated that 30−40 C_{60} molecules were attached per Qβ particle, with the final NP hybrids showing uptake in HeLa cells.

The CuAAC reaction has also been used to prepare controlled bioconjugates with a variety of inorganic NP materials. Examples include the enzymes trypsin, luciferase, and lipase being conjugated to Au NPs.[165−167] In the former, Au NPs were coated with a carboxyl-functionalized polymer, reacted with an amine-PEG-azide linker using EDC activation, and clicked with alkyne labeled trypsin. The trypsin was labeled via the reaction of its lysine residues with EDC activated 4-pentynoic acid. The activity of trypsin-Au NP conjugates prepared in this manner was 3-fold higher than analogous conjugates prepared using electrostatic adsorption or direct EDC coupling between the lysine residues and Au NPs.[165] As shown in Figure 8a (i) and (ii), alkyne modified nucleobases have also been used for the controlled alignment of azide functionalized Au NPs along a DNA strand at regular intervals.[168] Magnetic Fe_3O_4 NPs coated with silica/aminosilane have been functionalized with alkyne or azide groups and then clicked to display monosaccharides and disaccharides, the Tn antigen, the flag peptide, biotin, human serum albumin, and maltose binding protein (MBP).[169−171] Silica NPs have also been clicked to form conjugates with fluorescent dyes and bovine serum albumin.[172] In addition to the use of cross-linker chemistry to introduce azide or alkyne groups to the NPs with conventional functional groups (e.g., carboxyl, amine), azide and alkyne derivatives of silanes have been synthesized and used to coat NPs.[171,173] The CuAAC has been further applied to the preparation of fullerene[174] and carbon nanotube[175−177] bioconjugates with carbohydrates, porphyrins, and phthalocyanine derivatives. The alkyne functionality was introduced to CNTs through a diazonium salt, and introduced to C_{60} through a cyclopropanation reaction. Numerous reports detail the use of the CuAAC reaction for the synthesis of dendrimers, polymers, polymeric micelles, and polymersomes. These studies and the preparation of bioconjugates can be found in other reviews.[178−180]

The major limitation of the CuAAC reaction is the requirement of a Cu^+ catalyst. In cellular and protein-based applications, the cytotoxicity of Cu^+ and its ability to mediate protein modifications are potentially limiting. Although much of the undesired reactivity can be mitigated through the use of copper ligands and organic scavengers,[181] the use of a Cu^+ catalyst is nonetheless poorly suited to some experimental systems. To address this challenge, the Bertozzi group pioneered the use of strain-promoted AAC as an alternative ligation route that does not require a catalyst—"copper-free click chemistry". As illustrated in Figure 8b, the copper catalyst is avoided by using an alkyne in a strained geometry, such as by inclusion in a cyclooctyne-based ring system.[182,183] The copper-free AAC approach has already been utilized in several biological studies and applications.[184−187] However, it should be noted that the strained alkyne moiety is intrinsically more reactive toward other nucleophiles, and thus, chemoselectivity is potentially reduced in some systems. The application of the copper-free AAC reaction in the preparation of NP-bioconjugates has been limited, likely due to challenges associated with solubility and the multistep synthesis of the strained cyclooctyne structures. One of the few examples is the conjugation of QDs with mannosamine.[188] The use of the strain-promoted AAC was motivated by the irreversible PL quenching effect copper ions have on CdSe/ZnS QDs, and utilized an azido-derivative of mannosamine in combination with amine-modified QDs that were reacted with a carboxyl-derivative of cyclooctyne via EDC. In another example, chitosan-*g*-PEG NPs with available azide groups were conjugated to antibodies that had been labeled with a NHS-PEG-cyclooctyne derivative.[189] In this case, depolymerization initiated by the presence of Cu^+ motivated the use of the strain-promoted AAC.

In addition to reactions between an azide and an alkyne, cycloaddition reactions can occur between tetrazine and strained double bonds, such as those in *trans*-cyclooctene or norbornene, via a [4 + 2] cycloaddition. Tetrazine ligations are inverse-electron-demand Diels−Alder reactions that proceed rapidly (up to 2000 M^{-1} s^{-1}) without a catalyst, and with nearly 100% conversion at micromolar reactant concentrations and room temperature.[190] The reaction, illustrated in Figure 9a, is bioorthogonal and produces only nitrogen as a byproduct. Due to its relative novelty, application of tetrazine ligation to NPs has been more limited than CuAAC. Han et al. prepared QD-epidermal growth factor (EGF) conjugates using the tetrazine ligation,[191] where EGF was labeled with a succinimidyl ester derivative of 3-phenyl-1,2,4,5-tetrazine, and a QD coated with an amine-functionalized polymer was modified with a succinimidyl ester derivative of norbornene. The QD-EGF conjugates were prepared *in vitro* and subsequently used to label cells that expressed EGF receptor in vivo. The bioorthogonality of the chemistry enabled in situ conjugation, where cells were first incubated with tetrazine labeled EGF and subsequently exposed to norbornene-modified QDs for labeling. The tetrazine ligation has been used similarly by Haun et al. to prepare dye-labeled magnetic NP-antibody conjugates.[192] In this case, the strained alkene was a succinimidyl ester derivative of trans-cyclooctene that was used to label an anti-EGF receptor antibody rather than the NP. Amino-functionalized and dye-labeled magnetic NPs were modified with a succinimidyl ester derivative of 3-phenyl-1,2,4,5-tetrazine. The ligation reaction was then applied to cellular labeling, and could be done *in vitro* prior to cellular labeling, or *in situ* after labeling cells with antibody-cyclooctene conjugates.

Similar to the tetrazine ligation, Shi et al. have used a [4 + 2] cycloaddition reaction between a maleimide-labeled antibody and furan groups associated with the corona of poly(2-methyl-2-carboxytrimethylene-carbonate-*co*-D,L-lactide)-*graft*-poly(ethylene glycol)-furan biodegradable micellular NPs.[193] The chemistry is illustrated in Figure 9b. The maleimide was introduced site-specifically at the carbohydrate chains within the Fc region of the anti-HER2 antibodies (targeting breast cancer cells). This cycloaddition reaction was utilzed due to its selectivity and efficiency under mild conditions to help preserve antibody activity and avoid cross-linking reactions. The bioorthogonality

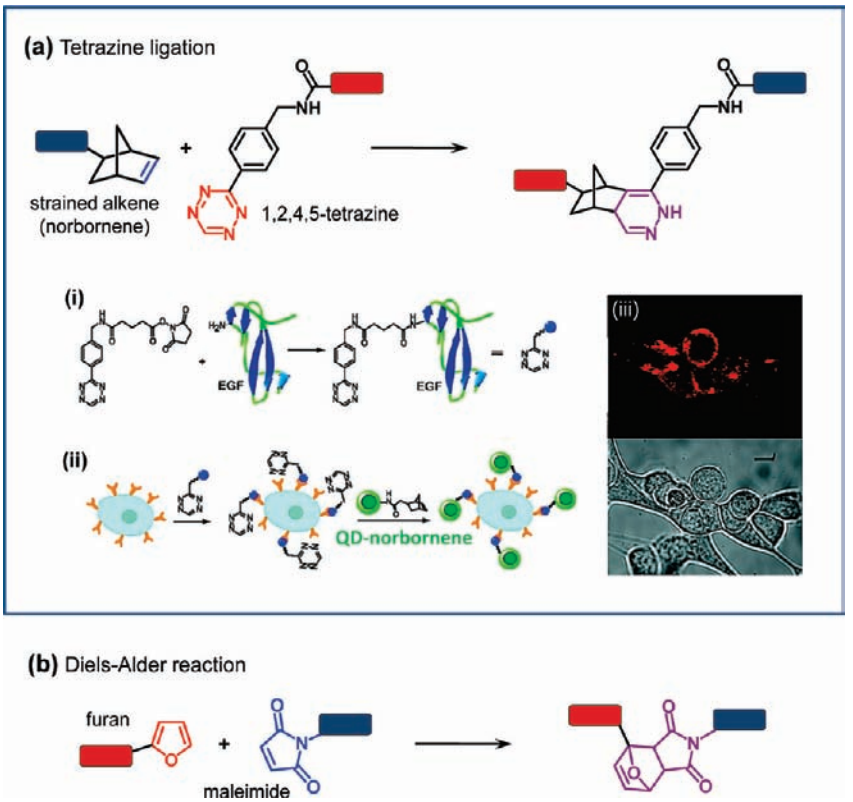

Figure 9. Cycloaddition reactions: (a) tetrazine ligation; (b) Diels–Alder reaction. The example of the tetrazine ligation shows (i) the labeling of epidermal growth factor (EGF) with a succinimidyl ester derivative of 1,2,4,5-tetrazine, and (ii) two-step labeling of cells with norbornene-modified QDs. of this chemistry requires the absence of other nontargeted thiol groups and control of pH to prevent the undesired reaction of amines with the maleimide.

Staudinger Ligation. Originally described in 1919, the Staudinger reduction is the reaction of a terminal azide with a phosphine to produce an aza-ylide intermediate that hydrolyzes under aqueous conditions to produce a primary amine.[194] In 2000, Saxon and Bertozzi developed a modified "Staudinger ligation," shown in Figure 10a, where the aza-ylide is trapped by an adjacent electrophilic carbonyl group to yield an amide bond after hydrolysis.[195] As a consequence of its bioorthogonality and chemoselectivity, the Staudinger ligation has been extensively used for joining or labeling biomolecules with applications that include the fluorescent labeling of proteins and DNA, protein immobilization to surfaces, and specific labeling of unnatural glycoproteins on cell-surfaces.[196] The shortcoming of this chemistry is the potential oxidation of phosphines under ambient conditions or by metabolic enzymes, which is commonly overcome through the use of excess reagents. It should also be noted that "traceless" Staudinger ligations have been developed, where the phosphine oxide is cleaved from the ligated intermediate during hydrolysis to form an amide.[197,198] Although the Staudinger ligation has been used with biomolecules in several studies, there have been only a few reports of the preparation of NP-bioconjugates. Zhang et al. used the Staudinger ligation to prepare liposome–lactose conjugates,[199] where the liposomes incorporated a phospholipid with a triphenylphosphine modification of its headgroup. The Staudinger ligation has also been used to attach RGD peptides to polyamidoamine-DNA NPs for improved cellular uptake of the NPs.[200]

Hydrazone and Oxime Ligations. The reaction between hydrazino groups (or hydrazido groups) and carbonyls (e.g., aldehydes or ketones) yields hydrazones as illustrated in Figure 10b. Although the reaction is reversible, the equilibrium favors the hydrazone under aqueous conditions ($K_{eq} = 10^4$–10^6 M^{-1}).[201] Forward and reverse reaction rates are slow at neutral pH but can be accelerated at acidic pH or with the use aniline as a catalyst.[201,202] The latter enables fast and efficient ligation (minutes to hours) at neutral pH and, since it is typically straightforward to remove aniline from the bioconjugates following the reaction, can yield relatively stable linkages due to the slow uncatalyzed rate of hydrolysis at neutral pH (10^{-6} s^{-1}).[201] In addition, hydrazone ligation is chemoselective and potentially bioorthogonal to the functional groups in proteins, oligonucleotides, and carbohydrates—the exception being reducing ends of the latter. As such, it is another attractive method for the preparing NP-bioconjugates.

Brunel et al. modified the lysine residues of CPMV NPs using sulfo-succinimidyl 4-formylbenzoate, and subsequently decorated the NP with two different hydrazido-terminated synthetic peptide sequences using hydrazone ligation.[203] The modified CPMV NP was then used as an imaging probe for cells and tumor xenografts, where one peptide was used for targeting and the other was modified with PEG for biocompatibility and fluorescently labeled for tracking. In a similar strategy, the use of arylhydrazino-terminated peptides has also been applied to the preparation of QD-bioconjugates.[204,205] As shown in Figure 10b, a "starter" peptide displaying a C-terminal hexahistidine sequence that enabled self-assembly onto CdSe/ZnS QDs (*vide infra*) and

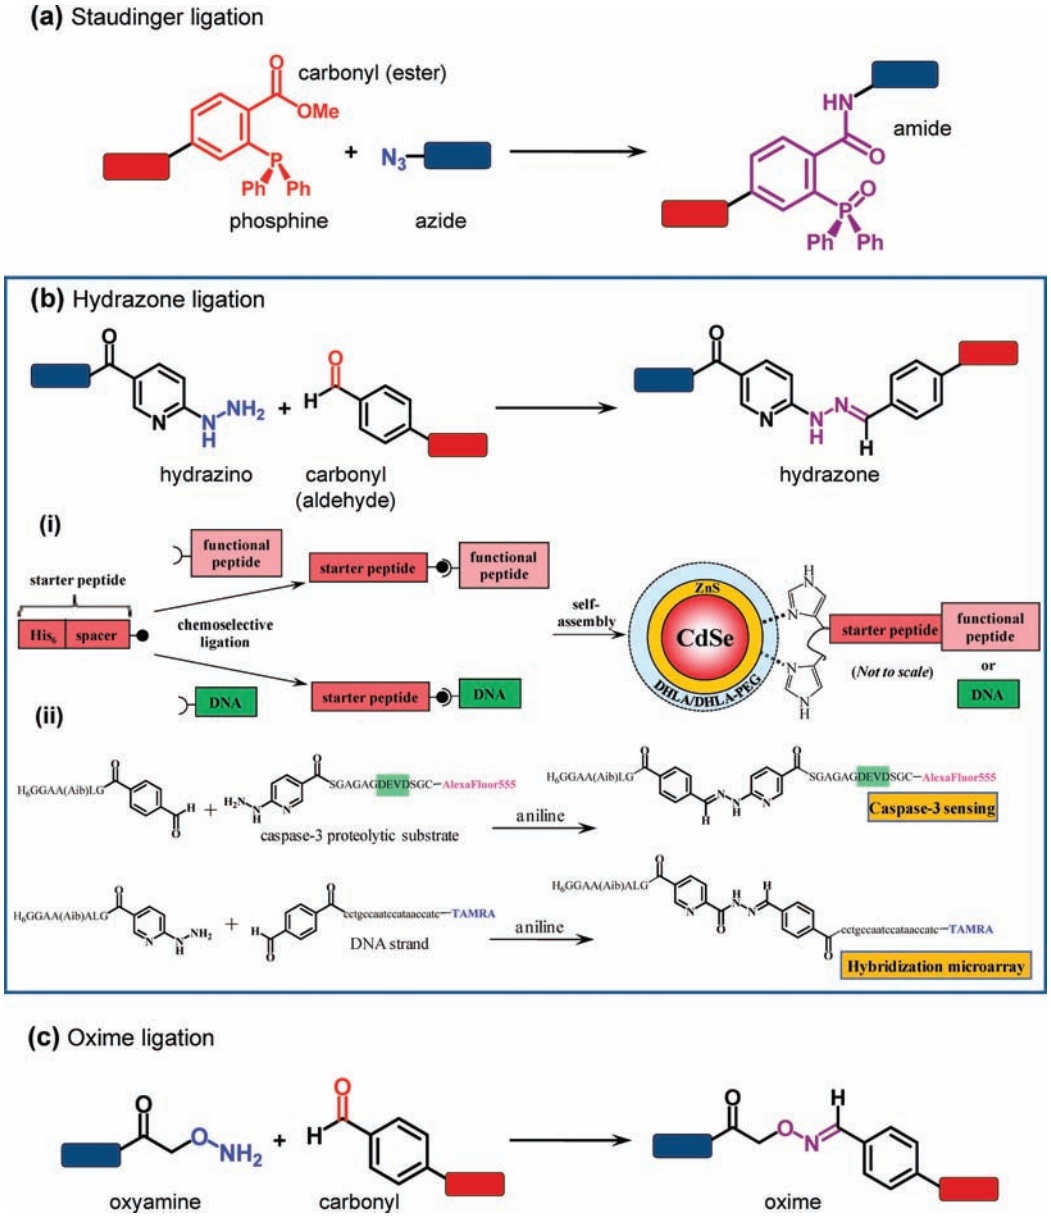

Figure 10. Chemoselective ligations: (a) the Staudinger ligation; (b) hydrazone ligation; (c) oxime ligation. The example for the hydrazone ligation (b) shows (i) a strategy for the modular assembly of functional peptides or DNA on QDs using a terminal polyhistidine "starter peptide" modified with a HYNIC or benzaldehyde group at the opposite terminus. The functional peptide or DNA is modified with the complementary functionality for hydrazone ligation (benzaldehyde or HYNIC, respectively). Two examples of modular assembly are shown in (ii), and include a peptide substrate for proteolytic monitoring and a DNA probe. Part of (b) is adapted with permission from ref 204. an N-terminal 4-formylbenzoyl group was the basis for this strategy. Aniline-catalyzed hydrazone ligation between the starter peptide and another peptide or oligonucleotide modified with a terminal 2-hydrazinonicotinoyl group (HYNIC) yielded cell-penetrating peptides, protease substrates, or hybridization probes that were subsequently self-assembled to the QD to yield the final active bioconjugate. The nucleophilic aniline catalyst increased the conjugation rate and enabled the coupling reaction to proceed without an excess of hydrazine peptide (cf. Brunel et al.[203]). The hydrazone ligation could be done prior to or after *in situ* assembly of the starter peptide on the QD.[204,205]

Rather than being considered a potential liability, the pH-sensitivity of the hydrazone bond may actually be attractive for use in drug delivery. In the physiological pH range between 7.3 and 7.5, the hydrazone bond hydrolyzes very slowly and is thus stable over the time course of many experiments. However, the hydrolysis of the hydrazone bond becomes appreciable at the slightly acidic pH range (pH 5−6) associated with endosomes and lysosomes. As a consequence, doxorubicin has been conjugated to magnetic NPs[206,207] and Au NPs[208,209] through hydrazone linkages for targeted NP-drug conjugate delivery at physiological pH and subsequent drug release following endocytic cellular uptake. An analogous conjugation strategy has also been used with a *cis*-platin prodrug and polymer NPs.[210] In these studies, the hydrazido group was introduced to the NP through chemical modification of its stabilizing ligands or polymer coating. This included the hydrazinolysis of ester groups,[207−209] and the reaction of carboxyl groups with adipic acid dihydrazide via

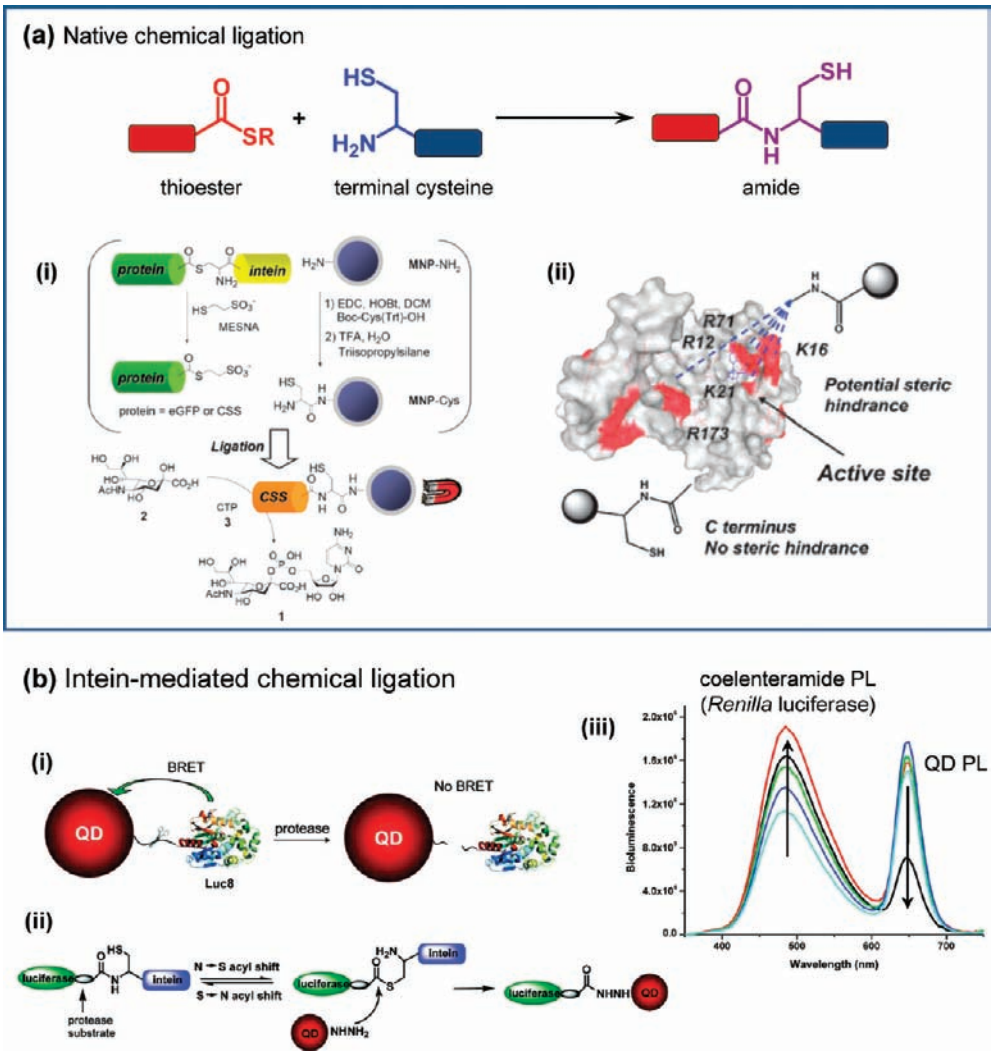

Figure 11. (a) Native chemical ligation between a thioester and a terminal cysteine. The example shows (i) enzyme (CSS) bioconjugate preparation using an intein to generate a thioester for native chemical ligation to a cysteine modified magnetic NP; and (ii) a comparison of the steric hindrance at the active site of CSS between labeling at the C-terminus via native chemical ligation and labeling at lysine (K) or arginine (R) residues. (b) Intein-mediated chemical ligation. The example shows (i) a proteolytic sensing strategy using QD-luciferase conjugates and BRET, (ii) the corresponding intein-mediated ligation chemistry, and (iii) loss of BRET between the excited state *Renilla* luciferase product (coelenteramide) and QDs. Increasing protease activity is in the direction of the arrows. Part of (a) is reproduced from ref 223. Copyright 2008 Royal Society of Chemistry. Figure in (b) are adapted with permission from ref 231. Copyright 2008 American Chemical Society.

carbodiimide coupling.[206] In particular, doxorubicin facilitates use of the hydrazone bond strategy since it has an intrinsic ketone group for site-specific ligation with hydrazido-modified NPs.

An oxime is the product of the ligation reaction between an oxyamine and an aldehyde or a ketone (Figure 10c). Although an oxime is more stable toward hydrolysis than a hydrazone ($K_{eq} \geq 10^8$ M^{-1}), it is similarly characterized by slow reaction rates at neutral pH and efficient ligation requires catalysis by aniline.[201,211] Oxime ligation has been used to prepare fluorescent dye and cell-penetrating peptide conjugates of polysaccharide NPs displaying a reducing chain end.[212] Both the dye and the peptide were aminooxy-modified for these purposes. Similarly, glycan conjugates of Au NPs coated with bifunctional aminooxy-alkyl-thiol ligands have been prepared via oxime ligation with the reducing ends of glycans.[213,214] This strategy was motivated by the observation of poor glycan-protein binding specificity when conjugates were prepared through reductive amination of the glycan.[215] In another example, the exterior lysine residues of capsids of bacteriophage MS2 were modified with succinimidyl 4-formylbenzoate and bound to a fluorescent dye synthetically modified with a PEG linker that terminated in an oxyamine group.[216]

Native Chemical Ligation. The reaction between a peptide with an N-terminal cysteine and a second peptide with a C-terminal thioester to yield an amide bond is illustrated in Figure 11a, and is referred to as native chemical ligation (NCL).[217−219] The reaction proceeds via transthioesterification, which links the peptides through an intermediate thioester that undergoes a spontaneous intramolecular S→N acyl shift rearrangement to form the amide and regenerate the cysteine side chain thiol. The reaction is highly chemoselective and does not require protection of any other amino acid side chains (including nonterminal cysteine residues, which do not form a stable amide). Furthermore, the C-terminal thioester may be associated

with any amino acid. These properties combine to make NCL an attractive chemistry for linking peptides to other peptides, proteins, or other substrates.

NCL has been used to chemoselectively modify lipid micelles and liposomes with single domain antibodies and a recombinant collagen binding protein, CNA35.[220−222] The phospholipids were modified at the headgroup with a cysteine terminated PEG chain, and a C-terminal thioester was introduced to the proteins using self-cleavable intein domains that were associated with the protein expression system. Similar expression techniques have been used with enhanced green fluorescent protein (eGFP) and CMP-sialic acid synthetase (CSS) to generate a C-terminal thioester that could be ligated with cysteine modified magnetic NPs (Figure 11a).[223] The magnetic NPs were synthesized with an amine coating, coupled with protected cysteine using carbodiimide/hydroxybenzotriazole activation, and deprotected for the NCL reaction. The conjugation of CSS to the magnetic NPs using NCL yielded a much smaller decrease in activity (33%) compared to nonchemoselective coupling via suberic acid bis-*N*-hydroxysuccinimide ester cross-linker (77%). This was attributed to the random enzyme orientation associated with reaction of the cross-linker with arbitrary CSS amine groups. Becker et al. have also used NCL to control the orientation of enzymes in NP-bioconjugates.[224] In this case, a guanosine triphosphate hydrolase (small GTPase) was expressed with an N-terminal peptide sequence that was cleaved at a cysteine residue by a protease. A bifunctional linker was synthesized with a terminal thioester and protected terminal thiol, where the former facilitated ligation to the GTPase and the latter was deprotected for subsequent assembly on Au NPs.

Expressed Protein Ligation. Biological expression of C-terminal thioester or N-terminal cysteine peptides enable the NCL strategy to be applied to large proteins and protein fragments with inteins.[225−227] Inteins are 100−800 residue polypeptide sequences found within proteins that are able to chemically excise themselves and rejoin the parent protein with a peptide bond in a reaction catalyzed by an active thioester intermediate.[225,228,229] This autocatalytic process is also referred to as intein-mediated protein splicing, and to date, more than 200 intein sequences have been identified in a wide range of protein families. Inteins are useful in applications such as protein synthesis, surface immobilization, and conjugation with fluorescent probes or affinity handles.[226,228,230] The chemistry of intein-mediated processes is complex and quite diverse, and the interested reader is referred to other reviews for further details.[225,226,228,229]

As shown in Figure 11b, Rao's group used intein chemistry to prepare QD-protein conjugates that functioned as bioluminescent protease sensors.[231] A *Renilla* luciferase fusion protein with two in-line C-terminal peptide sequences was genetically engineered. The peptide sequences were a VPLSLTMG sequence recognized and cleaved by matrix metalloproteinase-7 (MMP-7), and a 198-residue *GyrA* intein sequence. Carboxyl-coated QDs were modified with adipic acid dihydrazide using carbodiimide coupling, and the thioester group of the intein underwent nucleophilic attack by the distal hydrazide of the QDs. This ultimately cleaved out the intein sequence and resulted in a QD-luciferase conjugate linked through a protease substrate. In application, the addition of the luciferase substrate coelenterazine resulted in efficient bioluminescence resonance energy transfer (BRET) between the luciferase and the proximal QD. The addition of MMP-7 cleaved the bioconjugate linkage, disrupted BRET, and thus allowed monitoring of proteolytic activity.[231] Protein bioconjugates of liposomes and lipid bilayer-coated silica NPs have also been prepared using split intein ligation or trans-splicing.[232] In an elegant demonstration, two synthetic peptides—one modified with the C-terminal segment of a split DnaE intein, and the other modified with palmitoyl side chains for anchoring in a lipid bilayer—were joined by NCL and incorporated onto the lipid coated NPs. An eGFP fusion with the N-terminal segment of the split DnaE intein was then introduced and associated with the C-terminal segment resulting in excision of the intein to yield eGFP-NP conjugates.

Diazonium-Coupling to Tyrosine Side Chains. The reaction between a phenol and a diazonium salt to produce an azo compound is well-known in organic synthesis. In the case of proteins, diazonium salts can selectively react with the phenol and imidazole groups of tyrosine and histidine, respectively. The reaction to label the *ortho* position of tyrosine is illustrated in Figure 12a. Both tyrosine and histidine residues are typically low-abundance amino acids, found only sparingly in most proteins, and this may provide opportunities for site-specific labeling.

The Francis group has specifically modified tyrosine residues native to the interior surfaces of empty MS2 bacteriophage particles with nitro-phenyl diazonium salts.[233−236] The nitro-phenyl diazonium salts were linked to other functional groups that enabled the attachment of reporters such as organic dyes, MRI contrast agents, and radiolabels for positron emission tomography. As illustrated in Figure 12a, the diazonium reaction also allowed selective bioconjugation to the interior of the MS2 particles, while allowing lysine residues native to the exterior surface to be modified in orthogonal reactions. The latter included functionalization of the MS2 particles with succinimidyl esters of PEG and targeting ligands.[235] Although a nitro-phenyl diazonium salt derivative of a reporter may be prepared directly (e.g., fluorescein[2,81,82]), greater versatility has been achieved through the use of nitro-phenyl diazonium salts that can introduce a bioorthogonal functional group at tyrosine residues. For example, the Francis group labeled MS2 tyrosine residues with aldehyde functionalized nitro-phenyl diazonium salts for subsequent oxime ligations,[235] and developed a four-step hetero-Diels−Alder reaction that allowed further chemical modification.[122] Diazonium coupling to tyrosine was used to introduce ketones on the surface of tobacco mosaic virus (TMV) particles for coupling to PEG through secondary oxime ligation.[237] Similarly, Bruckman et al. have labeled TMV particles with alkyne-functionalized phenyl diazonium salts for subsequent CuAAC ligation with PEG, peptides, and dyes.[238]

Oxidative Coupling to Aniline-Containing Side Chains. The one-to-one oxidative coupling of aniline with *N*,*N*-diethyl-*N*′-acylphenylene diamine using sodium periodate was recently reported for the attachment of peptides to the surface of bacteriophage MS2.[239] The reaction is shown in Figure 12b, and is both chemoselective and efficient at low reactant concentrations. A single residue of the unnatural amino acid *p*-amino-L-phenylalanine was incorporated into MS2 through amber suppression methods to facilitate this coupling. A peptide with a phenylene diamine modified *N*-terminus was then oxidatively coupled to the virus particles. The peptides selected for coupling allowed the conjugate to achieve specific delivery to neuroblastoma, breast cancer cell lines, and kidneys, and target the matrix metalloproteinase 2 and 9 enzymes. Oxidative coupling to aniline was also used to decorate the exterior surface of MS2 particles with zinc porphyrins for photocatalysis[240] and a DNA aptamer for cellular delivery.[241]

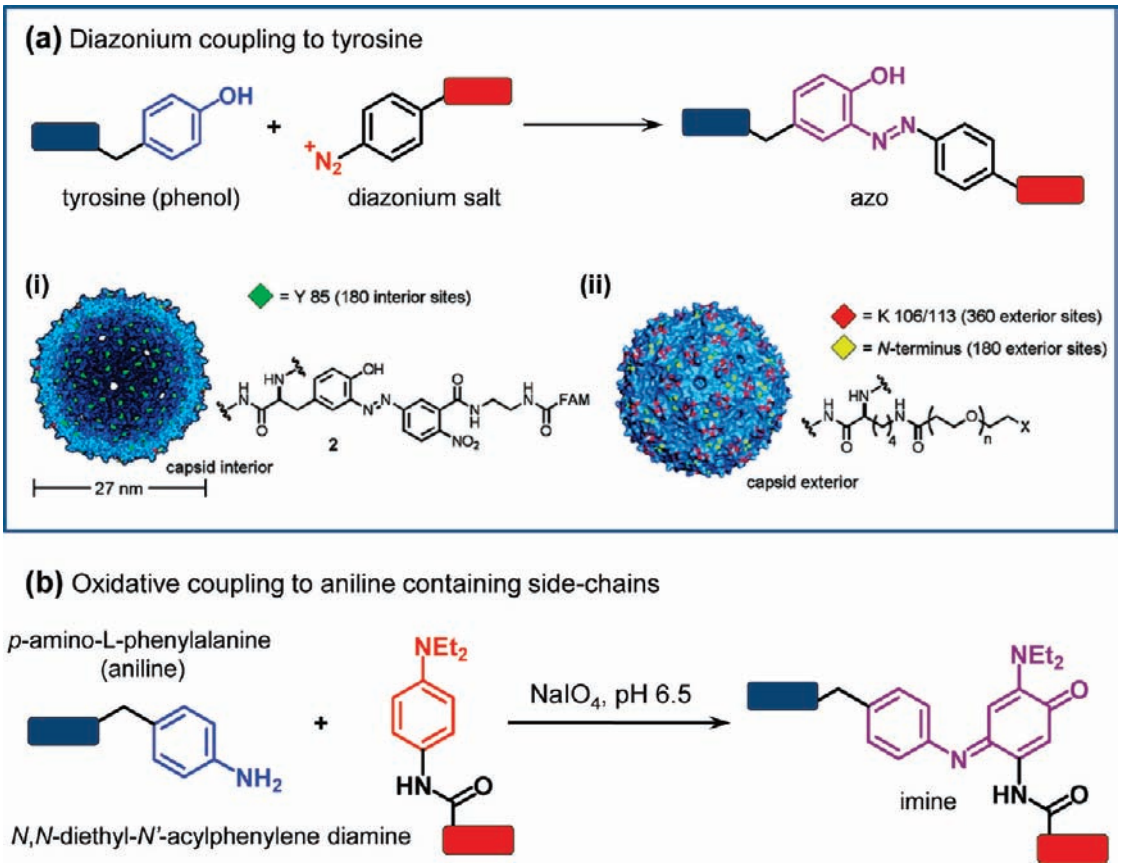

Figure 12. Coupling to protein/peptidyl side chains: (a) diazonium coupling to tyrosine residues; and (b) oxidative coupling to aniline containing side chains (e.g., *p*-amino-L-phenylalanine). The example for diazonium coupling to tyrosine shows (i) modification of tyrosine residues on the interior surface of an MS2 capsid with a fluorescent dye using a diazonium salt, and (ii) orthogonal coupling of PEG to exterior surface lysine residues using succinimidyl ester chemistry. Self-Assembly. In contrast to the examples of the previous section, NP bioconjugate reactions based on self-assembly are not characterized by the formation of new covalent bonds. Rather, these reactions tend to be driven by comparatively weak coordination (or dative) bonding, wherein stability is dictated by equilibrium dissociation constants. Self-assembled NP bioconjugates are therefore sensitive to the concentrations of NP and biomolecule both during the preparation, and in subsequent application. However, through the use of moieties that self-assemble through multidentate coordination (e.g., polyhistidine vs monomeric histidine), the stability of self-assembled NP-bioconjugates can be greatly improved and allow use at the low concentrations ($\leq 10^{-6}$ M) typical of biological applications. Compared to covalent methods, self-assembly methods are advantageous in that they generally offer rapid and facile bioconjugation without the need for additional reagents, and can often provide better control as a result.

Polyhistidine Coordination. The polyhistidine motif is well-known for its role in the purification of proteins using immobilized metal ion affinity chromatography (IMAC) where it binds to Co^{2+}, Cu^{2+}, Ni^{2+}, Zn^{2+} and other divalent metal cations immobilized on solid supports through carboxylated chelates. These ions are also components of many different NP materials, including QDs and magnetic NPs. The imidazole ring of histidine, which coordinates divalent metal ions, can also interact with noble metals such as gold and silver. These properties suggest that polyhistidine can potentially be used to prepare bioconjugates from a variety of inorganic NPs. Indeed, this has been confirmed experimentally with several different materials, although there is certainly further untapped potential.

Our research group pioneered the use of polyhistidine tags for self-assembly with QDs. As shown in Figure 13a, we found that histidine could coordinate to the Zn^{2+} ions at the inorganic surface of CdSe/ZnS QDs and drive the self-assembly of QD-bioconjugates. The rapid and stable association of polyhistidine with the ZnS shell has proved highly advantageous for the preparation of QD-bioconjugates with polyhistidine-tagged recombinant proteins[242] and synthetic peptides.[140,204,243] Dissociation constants are typically in the range 10^{-1}–10^{2} nM and tend toward 1 nM in bulk solution, with equilibrium binding being reached within a few minutes at room temperature.[244] As a consequence, polyhistidine self-assembly enables control over QD-bioconjugate valence through an approximately one-to-one correlation with stoichiometry. This correlation applies to the average valency, where the actual distribution of QD-bioconjugate valences is known to follow a Poisson distribution—especially at lower ratios.[245] In addition, the polyhistidine motif offers several intrinsic advantages for assembly to CdSe/ZnS QDs:

- The polyhistidine motif is bioorthogonal, since it is not normally found in natural proteins.
- The polyhistidine motif is routinely introduced to recombinant proteins to facilitate purification.
- The small size of polyhistidine motif does not disrupt native protein function.

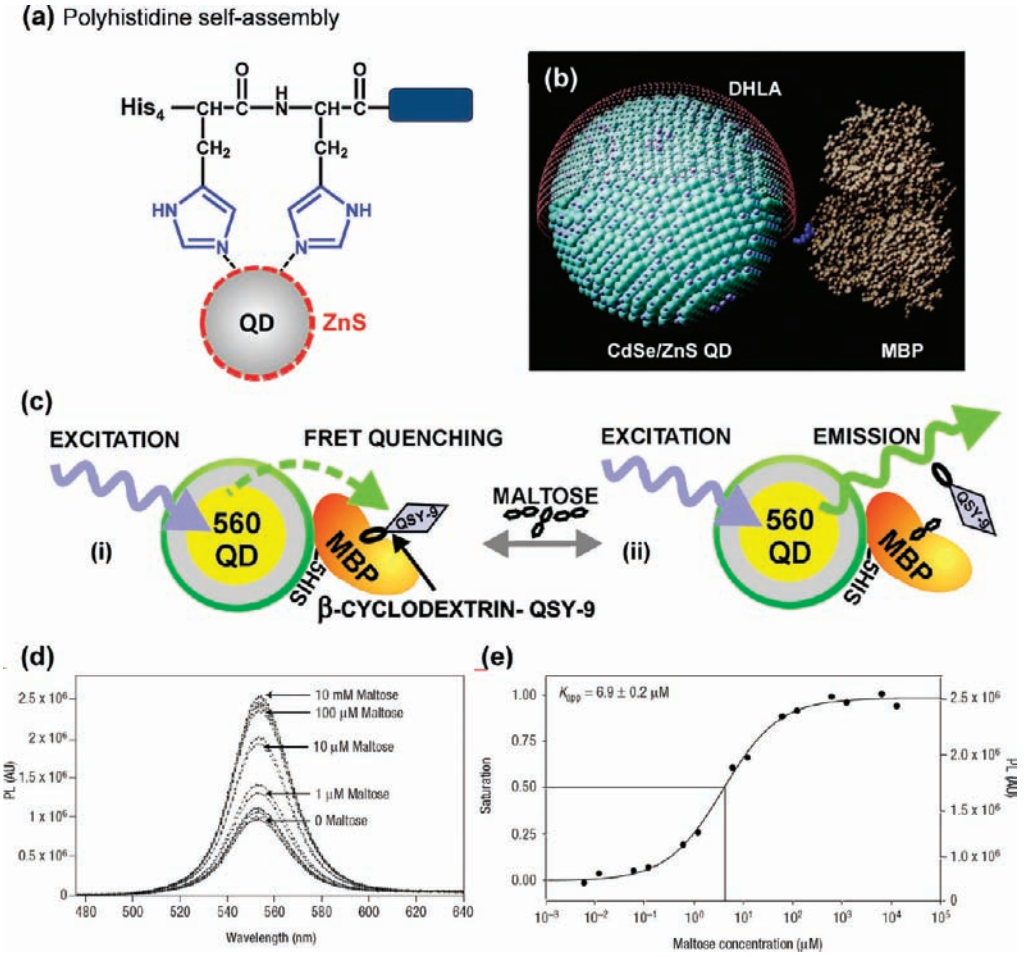

Figure 13. (a) Self-assembly of polyhistidine to the inorganic ZnS surface of a NP *via* direct coordination of the imidazole moieties. An example of the use of this bioconjugate chemistry is a FRET-based sensor for maltose using QD-His_5-maltose binding protein (MBP) conjugates. An experimentally validated model of MBP assembled to a CdSe/ZnS QD is shown in (b). The polyhistidine tag is highlighted in blue. The sensing scheme (c) is based on (i) binding of dark quencher (QSY-9)-labeled β-cyclodextrin by MBP, creating the proximity for quenching of the 560 nm emitting QD PL via FRET. The introduction of maltose (ii) displaces the quencher-labeled cyclodextrin and restores the QD PL in proportion to the maltose concentration. The QD PL recovery and a maltose binding isotherm are shown in (d) and (e), respectively. The image in (b) is reproduced from ref 246. The images in (c−e) are reproduced from ref 256.

- The single point of attachment offered by the polyhistidine motif eliminates undesirable cross-linking reactions and even enables control over biomolecular orientation.

Considering the latter point, a series of FRET experiments were used to determine the orientation of recombinant MBP assembled to a QD (Figure 13b). It was found that the polyhistidine tag interacted with the surface of the QD so as to orient the protein toward bulk solution.[246] To further enhance control over orientation and spacing, we have exploited structural peptide motifs in combination with polyhistidines. These peptide motifs have included a rigid variable-length peptide based on a repeating tyrosine-glutamic acid-histidine-lysine (YEHK) β-sheet,[247,248] and the inclusion of a rigid helical linker-spacer between an N-terminal polyhistidine tract and a C-terminal peptide suitable for use as proteolytic substrate.[140] The rigid helical linker was based on α-amino isobutyric acid and alanine, with glycine hinges to separate its structure from the polyhistidine and proteolytic substrate.

Polyhistidine self-assembly with QDs has been extended to the preparation of QD-oligonucleotide conjugates through use of modular "starter" peptide sequences with a hexahistidine tract at one terminus and a reactive group at the other. The latter have included pyridyl disulfide[249] and iodacetyl groups[250] that react with thiol-terminated oligonucleotides to form disulfide and thioether bonds, respectively. Thioether bonds are stable under most conditions; disulfides are labile under reducing conditions. Additional versatility is possible through polyhistidine starter peptides (Figure 10b) with a terminal benzaldehyde group that enables hydrazone ligation to a peptide or oligonucleotide modified with a terminal HYNIC group.[204,205] This bioorthogonal chemistry is compatible with two different strategies: ligation with the polyhistidine starter peptide prior to assembly with QDs,[204] or ligation after prior assembly of the polyhistidine starter peptide with QDs.[205]

The control provided by polyhistidine self-assembly has greatly facilitated the development of QD-based cellular probes,[243,251] and biosensors that use FRET (Figure 13c−e) or charge transfer for signal transduction.[252−258] The interactions associated with the latter arise from conjugation with reporter-labeled biomolecules and are very sensitive to both

dx.doi.org/10.1021/bc200065z |*Bioconjugate Chem.* 2011, 22, 825–858

the number of reporters per QD and the separation distance between reporter and QD, thus necessitating a high degree of control over the final bioconjugate architecture. In addition to CdSe/ZnS QDs, polyhistidine tagged recombinant enzymes have been assembled with CdS QDs.[259] Magnetic Ni/NiO NPs and Au NPs have also been found to assemble with polyhistidine tagged proteins or peptides.[260−262] A study of the assembly of polyhistidine tagged human acidic fibroblast growth factor with Au NPs found that the multichelate effect of the histidine imidazole groups was able to displace the strong thiol−Au NP interaction associated with a zwitterionic cysteine-containing peptide coating.[262] Dynamic measurements suggested that the fibroblast growth factor protein sampled a range of orientations at the Au NP surface before adopting a lowest energy state with attachment via the polyhistidine tag. While virus capsids have often been engineered with polyhistidine tags to facilitate purification, there is also the potential bioconjugation through polyhistidine. For example, heme groups have been conjugated to recombinant hepatitis B virus particles with N-terminal polyhistidine tags,[263] and also to Qβ particles with C-terminal polyhistidine tags.[264] Here, the assembly was driven by coordination to the iron center of heme.

Nickel(II) and Nitrilotriacetic Acid. Although direct polyhistidine coordination to the surface of NPs is a highly effective method for preparing controlled NP-bioconjugates, its application is limited to certain NP materials and thin coatings of solubilizing ligands that allow access to the inorganic surface of NPs. A more universal approach for the self-assembly of polyhistidine appended biomolecules to NPs is the use of nickel(II)-nitrilotriacetic acid (Ni^{2+}-NTA) modified NP coatings as shown in Figure 14a. This approach is borrowed from IMAC, where polyhistidine tags are known to bind to Ni^{2+}-NTA with dissociation constants on the order of $K_d = 10^{-13}$ M.[265] This affords many of the advantages and control associated with direct polyhistidine coordination while also being compatible with any NP material that displays a surface coating that can be chemically modified. The NTA-functionalization of a NP coating is facilitated by the availability of several NTA precursors and analogues. Many different NP materials have been modified with NTA for binding polyhistidine tagged proteins, including QDs,[265−268] Au NPs,[269] CNTs,[270] silica NPs,[271,272] and magnetic NPs.[273] The development of NTA-coated CNTs (Figure 14a) for controlled protein conjugation was motivated by the prior observation of protein denaturation on the hydrophobic surface of CNTs.[270] This was minimized by the use of NTA for conjugation. Importantly, Susumu et al. demonstrated that the polyhistidine-Ni^{2+}-NTA interaction in QD conjugates remained stable when delivered to the cellular cytosol.[268]

The most common approach for introducing NTA has been to activate NP coatings toward a nucleophilic derivative of NTA. For example, QDs and magnetic NPs displaying carboxyl groups have been activated with EDC/NHS toward N_α,N_α-bis(carboxymethyl)-L-lysine—an amine-terminated derivative of NTA.[266,267,273] Alternatively, succinic anhydride has been used to activate polyglycerol coated magnetic NPs toward the same lysine-NTA derivative,[274] and glutaraldehyde has been used for the same purpose with amine terminated silica NPs.[271] Silica NPs have also been directly modified with a silane derivative of NTA.[272] Thiolated derivatives of NTA have been shown to self-assemble on Au NPs[269] and QDs,[275] or react with amine functionalized polymer-coated QDs that had been activated with sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC).[265]

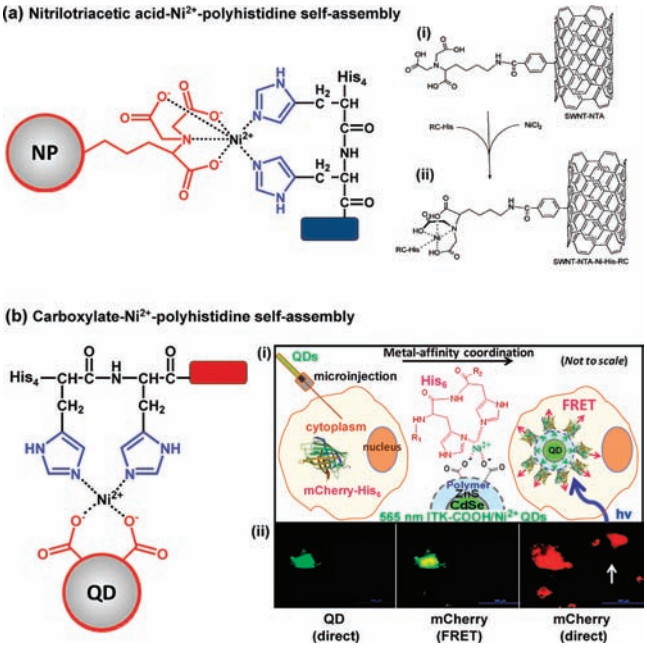

Figure 14. Self-assembly of polyhistidine through coordination to Ni^{2+} supplemented (a) nitrilotriacetic acid (NTA) coated NPs or (b) carboxylate coated NPs. The example for (a) shows (i) an NTA modified CNT and (ii) Ni^{2+} supplementation with the introduction of a polyhistidine tagged protein (RC-His). The example for (b) shows (i) the microinjection of carboxylate coated QDs into cells expressing polyhistidine tagged fluorescent protein (mCherry-His_6) and (ii) fluorescence images showing the intracellular QD-protein assembly through FRET between the QD and mCherry. The white arrow indicates a control cell expressing mCherry but not injected with QDs. Part of (a) is adapted with permission from ref 270. Part of (b) is adapted with permission from ref 278. Using carbodiimide coupling, Au NPs coated with dihydrolipoic acid have been modified with Co^{2+}-NTA for self-assembly with polyhistidine tagged enzymes that largely retained their native activity.[276] Similarly, magnetic NPs with Cu^{2+}-NTA have also been prepared.[274]

Chelating agents such as NTA rely, at least in part, on the ability of carboxyl groups in close proximity to simultaneously coordinate a metal ion. It appears that the density of carboxyl groups associated with NP coatings may also be sufficient in this respect. Yao et al. demonstrated that carboxyl functionalized polymer-coated QDs were able to chelate Ni^{2+} directly, and thereby enable the controlled assembly of polyhistidine tagged *Renilla* luciferase enzyme for use in BRET-based sensing.[277] Boeneman et al. found that this interaction is surprisingly robust and efficient and could be extended to an intracellular environment.[278] Cells that expressed a polyhistidine tagged fluorescent protein (mCherry) were microinjected with Ni^{2+}-supplemented carboxyl polymer-coated QDs allowing the self-assembly process to occur *in vivo* (Figure 14b). This suggests suitability for similar *in vivo* bioconjugation of QDs with other target proteins.

Metallothionein Coordination. Metallothioneins (MTs) are low-molecular-weight proteins in which approximately one-third of the amino acid residues are cysteine. As a consequence, MTs have a high affinity for binding heavy metal ions. Similar to polyhistidine tags, MT tags that are appended to proteins can tightly bind the inorganic surface of QDs and Au NPs. The

Benson group demonstrated that a MT fusion of MBP was able to self-assemble on ligand coated CdSe QDs, CdSe/ZnS QDs, and Au NPs with dissociation constants on the order of 10^1-10^2 nM.[279] The interaction was strongest for Au NPs and weakest for CdSe/ZnS QDs. Furthermore, a direct comparison between MT-MBP and pentahistidine-MBP found that the former was bound more tightly to CdSe QDs.[279] In application, a C-terminal MT tag was used to assemble a lead-binding variant of phosphate binding protein onto to CdSe/ZnS QDs.[280] The protein was labeled with ruthenium phenanthroline to drive charge transfer quenching of QD PL in a manner dependent on the lead concentration present. MTs have also been used to assemble peptides and zinc finger proteins with Au_{11} nanoclusters,[281,282] and to drive the bacterial synthesis of a variety of different NP materials.[283] An interesting feature of the Benson group's MT strategy is that it was possible to site-specifically label a cysteine residue associated with a fusion protein of interest.[279] In the case of MT-MBP, the introduction of Cd^{2+} ion acted as a protecting group due to strong binding and folding by the MT domain. An activated maleimide label was thus able to attach specifically at the cysteine residue associated with the MBP. Removal of the Cd^{2+} using a chelating agent restored the availability of the MT domain for assembly with NPs. Thus, the use of MT tags enables the control over protein orientation in a NP-conjugate while retaining the ability to use mutant cysteine residues as unique labeling sites.

FlAsH/CrAsH System. In 1998, Roger Tsien's group reported a novel fluorescein-based dye that contained two As^{3+} atoms coordinated by 1,2-ethanedithiol at the 4′ and 5′ dye positions.[284] This compound—described as a fluorescein arsenical helix binder, FlAsH—could selectively interact with proteins that contained vicinal thiols in the amino acid sequence Cys-Cys-X_n-Cys-Cys. This motif displaced the ethanedithiol ligands and bound FlAsH, resulting in a 50 000-fold increase in dye fluorescence and provided sufficient affinity and selectivity to label proteins in vivo. A follow-up study demonstrated that the enhancement of dye fluorescence was maintained after protein denaturation.[285] More recently, the FlAsH dye was modified to contain an additional carboxyl group.[285,286] This so-called CrAsH dye exhibits a greater fluorescence enhancement than FlAsH upon binding to the tetracysteine motif under physiological conditions and offers improved signal-to-noise for in vivo experiments.[286] Typical dissociation constants for biarsenical ligands with tetracysteine motifs are approximately $10^{-11}-10^{-12}$ M.[285]

The combination of the affinity of the CrAsH dye for the tetracysteine motif and its available carboxyl group render it potentially useful as a cross-linker for NP bioconjugation. For example, Genin et al. used the CrAsH dye to prepare QD-integrase protein conjugates.[287] CdSe/ZnS QDs were coated with a mixture of PEG-modified phospholipids that displayed both terminal (unreactive) methoxy and (reactive) amine groups. The CrAsH molecule was ligated to the QD using EDC, and the integrase protein was recombinantly modified with a tetracysteine motif for subsequent assembly of the QD-bioconjugate. FlAsH and CrAsH are both organic dyes, and thus highly susceptible to photobleaching. The QD-CrAsH conjugate addresses this limitation via the superior photostability of QDs: the CrAsH PL photobleached within tens of seconds affording pure QD PL that was stable over an extended period of time. Ultimately, the utility of this approach may not be in the use of the CrAsH dye itself, but in exploiting similar, nonfluorescent arsenyl ligands for NPs that coordinate with tetracysteine motifs to accomplish controlled bioconjugation.

Enzyme Catalyzed Bioconjugation. *Biotin Ligase.* Biotin binding by avidin proteins is the strongest noncovalent interaction currently known with a dissociation constant of 10^{-15} M.[288] The specificity and stability of the interaction, combined with the ability to biotinylate a wide variety of biomolecules—as well as the ability to label avidin proteins with reporters—has resulted in the diverse use of biotin−avidin chemistry in bioconjugate preparation, immobilization, and labeling. The desire for site-specific biotinylation has driven the development of biotin ligase enzyme systems. For example, *E. coli* biotin ligase (BirA) transfers endogenous biotin to a specific lysine side chain found in a fifteen-residue acceptor peptide (AP) in an ATP-dependent manner.[289] Figure 15a illustrates the generic use of BirA in bioconjugation. Modifying different proteins with this AP sequence enables the enzymatic site-specific biotinylation of recombinant proteins that can, for example, be used in biological sensing[290] or cellular labeling.[291,292]

The Ting group adopted the use of BirA ligation to label cellular receptors with QDs.[293,294] The extracellular receptors in HeLa cells and neurons were modified with AP sequences and biotinylated by exogenous BirA present in the growth media. This allowed the rapid (2 min) and specific labeling of the live HeLa cells using streptavidin-conjugated QDs.[293] Similar labeling was also demonstrated using CHO cells.[295] Subsequent work used BirA in combination with yeast biotin ligase for multiplexed labeling (Figure 15a).[294] In this case, a yeast acceptor peptide was evolved to provide a second and orthogonal tag for two-color labeling of cell surface proteins, where the two different AP sequences defined the labeling specificity. In an alternative strategy, orthogonal two-color QD tracking of single interferon receptor units on live cells was achieved through the combination of BirA and polyhistidine-nickel(II)-NTA interactions.[296] The latter required the use of NTA-modified QDs as a chemistry that was orthogonal to streptavidin-coated QDs, and clearly demonstrated the great potential of orthogonal labeling chemistry—even at the single-molecule level. In addition to QDs, the Ting and Bartlett groups also used BirA to selectively label adeno-associated virus particles.[297] The virus capsid was engineered to display an available AP sequence that was then labeled by BirA with a chemically synthesized ketone isostere of biotin. The ketone group was chemoselectively labeled with a hydrazido-modified fluorescent dye for optical tracking and a hydrazido-terminated cyclic arginine-gylcine-aspartate (RGD) as a tumor-homing and cell-penetrating peptide. Magnetic NPs biosynthesized by *Magnetospirillum magneticum* have also been modified to display AP on their surface.[298]

Carrier Proteins. Peptidyl and acyl carrier proteins (PCP, ACP) can be specifically modified with a variety of fluorophores or affinity handles by phosphopantetheinyl (PPT) transferase. This enzyme catalyzes the transfer of the PPT unit from coenzyme A (CoA) to a conserved serine in the carrier protein.[292,299,300] Since both the carrier protein and PPT transferase tolerate a wide range of substitutions at the terminal end of the CoA, this system has been used to label ACP-fusion proteins with fluorophores, biotin, and digoxigenin.[299] George et al. utilized PPT to specifically biotinylate ACP fusion proteins displayed on yeast cells for labeling with streptavidin-coated QDs.[299] In addition, CoA-modified QDs have been used to label a PCP-tagged MBP that retained its binding function in subsequent assays, and also a PCP-tagged transferrin receptor at the membrane of CHO-TRVb cells.[295]

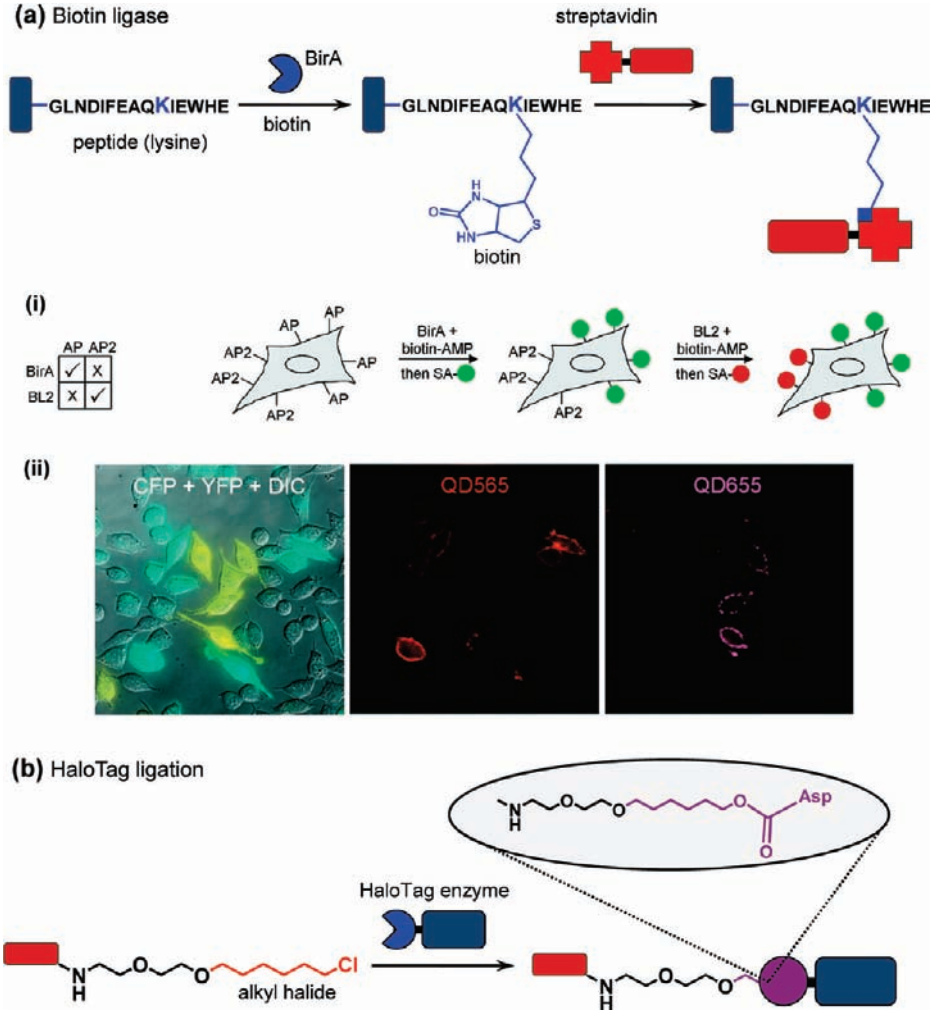

Figure 15. Enzymatic labeling systems: (a) biotin ligase and (b) HaloTag ligation. The example for biotin ligase shows (i) a two-step two-color cellular labeling scheme using two orthogonal biotin ligase enzymes (BirA and BL2) with two acceptor peptides (AP and AP2). Cellular labeling with streptavidin (SA)-coated green-emitting QDs (QD565) followed the ligation of biotin to AP. In turn, subsequent cellular labeling with SA-coated red-emitting QDs (QD655) followed the ligation of biotin to AP2. Differential interference contrast and fluorescence images of cells labeled with the two different colors of QD are shown in (ii). The two types of cells expressing AP and AP2 individually are distinguished by the expression of either cyan fluorescent protein (CFP) or yellow fluorescent protein (YFP), respectively. Enzyme—substrate/Inhibitor Binding. The ability of enzymes to selectively bind their target substrates and/or certain inhibitors is another potential route to the preparation of NP-bioconjugates. For example, the cutinase enzyme was inserted into the membrane protein integrin LFA-1 and used to bind QDs that were modified with its inhibitor *para*-nitrophenyl phosphonate (pNPP) in a cellular labeling reaction.[301] The pNPP-QDs were prepared from the activation of amine coated QDs with SMCC and a subsequent reaction with an alkyl thiol derivative of pNPP. Similarly, it has been shown that glutathione-*S*-transferase can bind to Au NPs coated with a mixed surface of thiol-terminated tri(ethylene glycol) and glutathione with high specificity.[302] Since glutathione-*S*-transferase-fusion proteins are routinely prepared,[303] this technique may also have potential for controlling the orientation of proteins attached to glutathione-modified NPs.

HaloTag. The HaloTag protein is a recombinantly modified haloalkane dehalogenase (www.Promega.com) that can be fused with other proteins of interest and used to covalently bind synthetic HaloTag ligands. The ligands are typically fluorescent dyes, affinity handles (e.g., biotin), or solid surfaces modified with a chloroalkane linker.[304] In the wild-type dehalogenase enzyme, the His272 residue acts as a base and catalyzes the hydrolysis and release of the substrate intermediate, thereby allowing enzyme regeneration. In contrast, the modified HaloTag enzyme expresses a mutated Phe272 that cannot act as a base and traps the reaction intermediate as a stable covalent adduct (Figure 15b). Both *in vitro* and *in vivo* labeling with fluorophores via the HaloTag system have been demonstrated.[304] The use of NPs modified with a HaloTag ligand offers the potential for control over the orientation of the HaloTag fusion protein partner in bioconjugation preparation. The Rao group demonstrated that carboxyl-coated QDs could be modified with a bifunctional amino-chloroalkane ligand that enabled subsequent ligation with a HaloTag-*Renilla* luciferase fusion protein.[305] BRET was used to track loading of the HaloTag-luciferase fusion protein, which depended on the number of chloroalkane ligands associated with the QD. The HaloTag system was also used for

in vivo labeling of cells with Streptavidin-coated QDs.[306] In this case, the HaloTag protein was expressed at a cell membrane anchoring domain and ligated with a biotin HaloTag ligand that was able to bind the Streptavidin-coated QDs.

■ PROMISING CHEMISTRIES FOR FUTURE DEVELOPMENT

This review has described several bioconjugate chemistries that are novel in their application to NPs, and offer greater control over NP-conjugate properties than traditional labeling chemistries. In many cases, the studies described represent more proof-of-concept than widespread applicability. Nonetheless, the advantages of the chemistries are evident—particularly the retention of native biomolecule structure and function through bioorthogonality. Despite this success, the toolkit for preparing NP-bioconjugates is far from complete. Fortunately, the continued development of new bioconjugation chemistries for biolabeling and modification will continue to drive new and improved NP-biological applications.

Several promising covalent chemistries are similar to some of the reactions previously described in this review, utilizing similar reactive moieties or analogous concepts in bioorthogonality. One such example relies on the aforementioned scarcity of free thiols in biological macromolecules, which makes the selective introduction of thiols (e.g., cysteine mutation) and their subsequent chemical modification an attractive approach for selective bioconjugation. To this end, several groups have developed alternative electrophiles to the ubiquitous *N*-alkylmaleimide moiety. For example, Bernardes et al. have used the site-selective introduction of dehydroalanine side chains into proteins and a subsequent Michael addition with thiol-modified labels.[307] While the dehydroalanine residues are not as reactive as N-alkyl maleimide groups, they have the advantage of site specific introduction through the elimination of cysteine residues using *O*-mesitylenesulfonylhydroxylamine,[307] or through genetic incorporation of either phenylselenocysteine[308,309] or selenalysine[310] followed by oxidative elimination with hydrogen peroxide. Another example is conceptually similar to the use of strained alkynes for CuAAC and utilizes the reaction between 1,3-nitrones (in place of the azide group) and alkynes. This strain-promoted alkyne-nitrone cycloaddition strategy has been used to N-terminally modify peptides[311] and proteins[312] with a biotin derivative of bicyclo[6.1.0]nonyne and a PEG-modified dibenzocyclooctyne, respectively, through the conversion of an N-terminal serine residue to a 1,3-nitrone. Nitrones will also undergo cycloadditions with maleimides.[313] Another novel cycloaddition strategy has addressed the challenge of chemical instability often associated with highly reactive moieties. Song et al. have taken advantage of photoactivation of 2,5-diaryl tetrazoles at 302 nm to generate a highly reactive nitrile imine that chemoselectively reacts with alkenes via a 1,3-dipolar cycloaddition to yield a stable pyrazoline cylcoadduct (Figure 16a).[314,315] One attractive aspect of this "photoclick chemistry" is that the resulting pyrazoline ligation product is fluorescent, facilitating direct observation of the reaction in complex systems. The compatibility of the reaction with physiological buffers and the wide utility of photoactivation in biological systems suggest the potential for broad application of this approach for *in vivo* labeling.

There are many other reactions that are well-known in organic synthesis and which hold great potential for the controlled display of biomolecules on NPs. Figure 16 highlights a few of these chemistries that, to our knowledge, have not yet been applied in the preparation of NP-bioconjugates. Several groups have focused on the unique reactivity of the tyrosine phenol ring, which is found on the surface of many proteins. For example, two-component[316] and three-component[317,318] Mannich condensations (Figure 16b) and ene-forming reactions with cyclic diazocarboxamides[319] have found utility. Some other reactions with significant promise for NP bioconjugation include *N*-terminal transamination with secondary oxime ligation,[320−322] olefin cross-metathesis (Figure 16c),[323−325] and palladium cross-coupling reactions (*vide infra*). Olefin cross-metathesis—awarded the 2005 Nobel Prize in Chemistry—is a highly efficient and reliable reaction in which carbon−carbon double bonds are broken and reformed catalytically.[326−328] In traditional formats, the limitation of olefin cross-metathesis has been poor compatibility with aqueous solvents and thus poor suitability for use in bioconjugate preparation. However, renewed interest in this type of transformation is leading to advances in catalyst design[329] and has allowed the expansion of this chemistry into low percentage mixtures of organic and aqueous solvent, thereby enabling limited utility with biomolecules.[324] In an early example of the application of olefin cross-metathesis to bioconjugation, Mortell et al. synthesized carbohydrate inhibitors of cell agglutination.[330] More recently, Lin et al. demonstrated olefin cross-metathesis in 30% *tert*-butanol/phosphate buffer between allyl alcohols and allyl sulfides that were chemoselectively conjugated to *subtilisin Bacillus lentus* protein.[323] With further developments, it is anticipated that olefin cross-metathesis will be a valuable addition to the toolkit for preparing NP-bioconjugates. Carbon−carbon bond formation via palladium catalysis (Figure 16d) has also been shown to have significant potential in the area of bioconjugation, and was recognized by the 2010 Nobel Prize in Chemistry for its larger contributions to the field. The Suzuki-Miyaura reaction consists of a cross-coupling reaction between an aryl halide (ArX, where X = I, Br) and a boronic acid (aryl or alkenyl) that is catalyzed by a palladium complex.[331] This chemistry has been used for the site-selective modification of peptides and proteins with small molecule boronic acids in aqueous solution, using *p*-boronophenylalanine,[332] *p*-iodophenylalanine,[333] or *p*-iodobenzyl modified cysteine side chains.[334] Similarly, the palladium catalyzed Mizoroki-Heck reaction[335] (unsaturated halides with alkenes) and Sonogashira coupling[336] (unsaturated halides with alkynes) have been applied to the covalent modification of peptides and proteins that incorporated *p*-iodophenylalanine[337−339] or were acylated with iodobenzoic acid.[340] The role of the palladium catalysts begs the question of whether composite NP materials—for example, dumbbells with a palladium NP component—might be able to catalyze their own bioconjugation.

Considering potential advances in self-assembly, the research of the Belcher group should be noted.[341−343] They have focused on the development of peptide sequences that coordinate specific metals through genetic engineering of bacteriophage M13. This work has led to many novel peptide sequences for assembly of metal-based materials. While the interest of the Belcher group has been in biomineralization and patterning applications, there may be potential for the development of metal NP-biological hybrid materials and bioconjugates. There may also be new opportunities in the synthesis of artificial amino acids designed to strongly bind NP materials and the subsequent incorporation of oligomeric tracts of these residues into synthetic

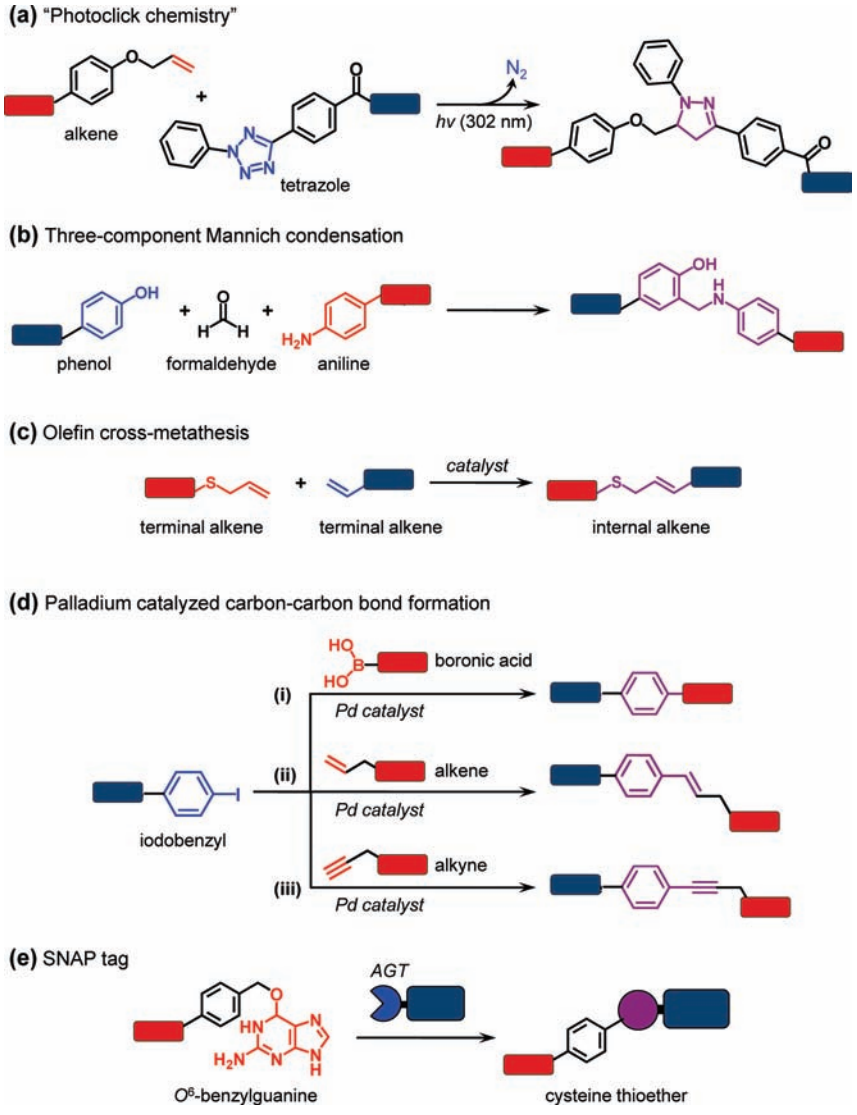

Figure 16. Promising chemistries for the future development of bioorthogonal NP bioconjugation chemistry: (a) "photoclick chemistry"; (b) three-component Manich condensations; (c) olefin cross-metathesis; (d) palladium catalyzed carbon−carbon bond formation; and (e) SNAP tag enzyme labeling. These and other promising chemistries are described in the text.

peptides or expressed proteins—analogous to the use of oligohistidine with semiconductor QDs.

The use of enzymatic labeling methods with NPs is still emerging, and many methods remain untapped. The most prominent of these is arguably the SNAP tag. The engineered human DNA repair enzyme alkylguanine-DNA alkyltransferase (AGT or SNAP-tag, www.neb.com) can be used as a tag for self-labeling, where a variety of modified O^6-benzylguanine derivatives can function as substrates for the AGT enzyme and are attached via the irreversible transfer of an alkyl group to a cysteine residue (Figure 16e).[344] Since its inception, the SNAP tag system has been significantly improved through the development of faster and more efficient enzymes. In addition, a wide range of benzylguanine substrates modified with fluorescent dyes or affinity handles are available, and have been demonstrated to be suitable for a multitude of *in vivo* cellular labeling applications.[292] Recent modifications of the SNAP-tag enzyme can also specifically target O^2-benzylcytosine derivatives, thereby enabling an orthogonal labeling approach using two enzymes.[345] Given the relative ease of modifying a variety of substrates with benzylguanine derivatives, it is only a matter of time until this system is used to label NPs in a manner akin to the HaloTag. Additional enzymatic labeling systems with good potential include dihydrofolate reductase, which can covalently bind trimethoprim;[346] transglutaminase, which can attach cadaverine-modified probes to small glutamine (Q) expressing peptide substrates, termed Q-tags;[347] and lipoic acid ligase, which can functionalize APs with various substituted substrates.[348]

SUMMARY AND CONCLUSIONS

This review has highlighted the recent application of non-traditional chemistries to the preparation of NP-bioconjugates, including chemical reactions to form new covalent bonds, self-assembly strategies, and enzymatic methods. These methods are novel in their application to NP materials and advance the degree of control over properties such as NP-bioconjugate valence, biomolecule orientation, reproducibility, and potential for

further bioconjugation. In turn, control over these properties is paramount in optimizing the function of NP-bioconjugates in applications such as diagnostic imaging, sensing, and drug delivery.

Efficient and bioorthogonal cycloaddition and ligation reactions enable greater levels of control in the display of one or more bio/molecules on NPs—particularly in terms of biomolecule orientation and conjugate valence. To date, many of these new developments in NP bioconjugation have followed the "rediscovery" of many classical synthetic organic chemistry reactions for protein labeling, and this trend is likely to continue. The potential limitation is the continued reliance on traditional labeling chemistries to introduce bioorthogonal groups to biomolecules. However, labeling NPs and biomolecules individually with bifunctional molecules (e.g., NHS-alkyne) using traditional methods, followed by an efficient bioorthogonal reaction (e.g., CuAAC), is more reliable and controllable than using traditional methods to couple the NP and biomolecule directly. This highlights the important point that bioorthogonal chemistries are not meant to completely replace standard bioconjugation approaches, but rather to supplement and augment them. Unnatural amino acid incorporation and other sophisticated methods of introducing bioorthogonal functional groups can provide an even greater degree of control than standard labeling techniques, but are much more time and resource intensive, while also more limited in their applicability.

The self-assembly of biomolecules to QDs using polyhistidine and metallothionein tags has been shown to provide excellent control over bioconjugate valence and orientation. Beyond synthetic peptides and recombinant proteins, the development of modular activated polyhistidine peptides extends the preparation of bioconjugates to include native proteins and synthetic oligonucleotides. Although limited in scope to date, it is anticipated that many of the chemical reactions described herein will be adaptable to modular polyhistidine tags and enable a highly versatile, chemoselective, and bioorthogonal toolkit for the controlled display of biomolecules on QDs and other metal-based NPs. Self-assembly methods are highly advantageous due to the overall simplicity and the determination of conjugate valence on the basis of stoichiometry and equilibrium constants. Self-assembly is also free of the irreproducibility that is often associated with chemical activation and cross-linkers. The disadvantage of self-assembly methods tends to be the scope of their applicability, which can be limited by NP composition and the properties of its coating. In some cases, self-assembly methods may also not be as robust as the formation of new covalent bonds.

Enzymatic labeling methods can be particularly advantageous in that they are highly specific, have little or no opportunity for cross-reactivity, do not require activated intermediates, and can provide a unique point of attachment. However, while enzyme reactions are efficient, they are not necessarily rapid, nor are they as readily scalable as chemical reactions. The scope of the applicability of different enzyme labeling methods is also limited, and variable between different methods. Enzymatic self-labeling (e.g., HaloTag) generally requires the preparation of a fusion protein. This significantly increases NP-bioconjugate size, can potentially affect the activity of the protein of interest, and is limited to NP-protein conjugates. Furthermore, both self-labeling enzymes and enzymes that modify a substrate generally require that molecular or peptidyl tags be introduced to the biomolecules of interest, thus creating the same potential challenges as the introduction of bioorthogonal groups for chemical labeling. In the case of slow reactions, the activity and long-term stability of the enzyme under different conditions of temperature or pH, and in various biological milieus, can be important to labeling efficiency. Moreover, the steric effect of a NP on enzyme labeling efficiency remains an open question.

The critical message is that traditional labeling chemistries (e.g., carbodiimide) are poorly suited to the controlled display of biomolecules on NPs. The novel application of reactions drawn from organic chemistry and biochemistry to NPs, as well as self-assembly, has provided new levels of control over the properties of NP-bioconjugates. This added control comes at a cost of increased complexity or a limited scope of applicability. Therefore, it is crucial that the toolkit of bioconjugate chemistries for different NP materials continue to be developed so that there are methods for the controlled preparation of NP-bioconjugates in every application. In turn, the function and efficacy of these NP materials in biological applications will be greatly advanced.
