**Abstract** To provide a reference for wetlands elsewhere we analysed soil nutrients and the vegetation of floodplains and fens in the relatively undisturbed Biebrza-valley, Poland. Additionally, by studying sites along a water-table gradient, and by comparing pairs of mown and unmown sites, we aimed with exploring long-term effects of drainage and annual hay-removal on nutrient availabilities and vegetation response. In undrained fens and floodplains, N mineralization went slowly ( $0\text{--}30\text{ kg N ha}^{-1}\text{ year}^{-1}$ ) but it increased strongly with decreasing water table (up to  $120\text{ kg N ha}^{-1}\text{ year}^{-1}$ ). Soil N, P and K pools were small in the

undisturbed mires. Drainage had caused a shift from fen to meadow species and the disappearance of bryophytes. Biomass of vascular plants increased with increasing N mineralization and soil P. Annual hay-removal tended to have reduced N mineralization and soil K pools, but it had increased soil P. Moreover, N concentrations in vascular plants were not affected, but P and K concentrations and therefore N:P and N:K ratios tended to be changed. Annual hay-removal had induced a shift from P to K limitation in the severely drained fen, and from P to N limitation in the floodplain. The low nutrient availabilities and productivity of the undisturbed Biebrza mires illustrate the vulnerability of such mires to eutrophication in Poland and elsewhere. In nutrient-enriched areas, hay removal may prevent productivity increase of the vegetation, but also may severely alter N:P:K stoichiometry, induce K-limitation at drained sites, and alter vegetation structure and composition.

## Introduction

The surface area of valley mires—notably fens and floodplains in river valleys and river plains—is relatively small, but their contribution to regional

biodiversity is large (Naiman and Decamps 1997). Floodplain mires have become scarce in Europe because rivers are regulated and dikes prevent flooding (Nienhuis 2006). Moreover, many floodplain mires have been converted into agricultural grasslands by draining and fertilizing them. Also the area of fens has been largely reduced because they were drained and developed for agriculture in the past (Stanners and Bourdeau 1995). The remaining fens are often surrounded by agricultural land which affects their hydrology (Wassen et al. 1996). Also drinking water extractions have altered the hydrology in mires. Nowadays, many remaining valley mires in Europe are protected reserves, but they are often subjected to various degrees of drainage (Grootjans et al. 1985, 1986; Wassen et al. 1996). Drainage and alteration of the natural flooding regime influence mire plant communities directly through changed hydrological conditions causing a shift from mire to grassland species, or indirectly through altered nutrient availabilities and subsequent eutrophication (Grootjans et al. 1985, 1986; Laine et al. 1995a). The latter may ultimately result in vegetation dominated by a few tall species.

Drainage can increase soil nutrient availabilities considerably (Laiho and Laine 1994; Laine et al. 1995a; Bridgham et al. 1998; Olde Venterink et al. 2002a), but to what extent is rather unclear, partly because a good reference for nutrient availabilities at relatively undisturbed conditions is lacking. From a study in which annual N mineralization rates were measured in two wet meadows before and after a deep ditch was created, we know that drainage may largely increase mineralization and N availability for plants (Grootjans et al. 1985, 1986). However, field studies of annual mineralization rates in undrained mires are rare, and studying the effect of drainage experimentally is generally not allowed in these protected areas. Effects of drainage on other nutrients such as P and particularly K are even less understood, but may be different to those on N, since availabilities of N, P and K are largely regulated by different mechanisms (Sundström et al. 2000; Olde Venterink et al. 2002a).

Natural resource managers try to mitigate nutrient enrichment in mires by specific measures, such as annual mowing and hay-removal, grazing, or burning. Worldwide, mires have been mown by local farmers, but in North America and Europe it ceased

during the second half of the 20th century. In Western Europe it is currently applied mainly by nature conservation organizations; in protected wetlands it is common practice. According to nutrient budget calculations in Western European mires, annual hay-removal seems to cause a relatively larger net export of P and K from the ecosystem than of N, which would lead to P and/or K limitation in the long term (Koerselman et al. 1990; Olde Venterink et al. 2002b). Reduced K concentrations in plants after 9 years of hay-removal (Oomes et al. 1996) and reduced N-mineralization rates only after 26–45 years of hay-removal (Olff et al. 1994) in various Dutch fen meadows are consistent with this view. In regions with a lower atmospheric N deposition, such as the Biebrza valley in North-Eastern Poland, hay-making does not have to induce a shift from N towards P and/or K limitation according to budget calculations (Wassen and Olde Venterink 2006). The effects of mowing and hay-removal on soil nutrient availabilities, however, have not been investigated in the Biebrza mires.

The aim of this study was to analyze soil nutrient dynamics in an array of mires, and evaluate the long-term effects of drainage and hay-removal on nutrient availabilities and limitation. We selected the mires in an area where other human disturbances are relatively small for European standards: the Biebrza valley. For practical reasons we studied annual N mineralization and soil extractable pools of N, P and K. We hypothesized that:

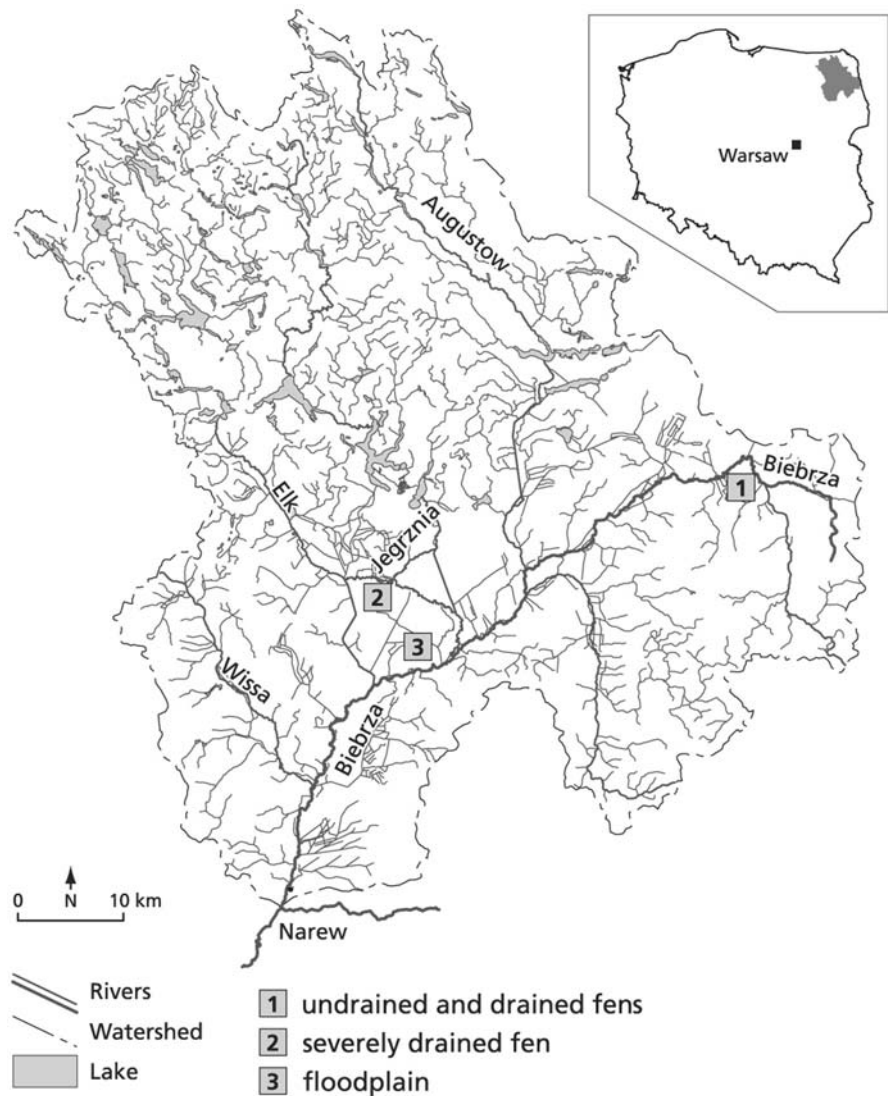

1. Mineralization rates are very slow and nutrient pools are small in undisturbed mires.
2. Drainage increases N mineralization rates and productivity of the vegetation.
3. Mowing and hay-removal reduces soil nutrient pools and productivity of the vegetation.

## Methods

### Study sites

This year-round study was carried out at eight field sites in the Biebrza National Park, NE Poland (Fig. 1). The Biebrza valley was very suitable for our study since it contains a wide variety of fens and floodplains in a relatively small area. The area is

**Fig. 1** Location of the research sites in the valley of the river Biebrza, Poland

relatively undisturbed; large parts of the catchment are undrained and atmospheric N deposition is low compared to Western Europe (5–10 compared to 20–60 kg N ha<sup>-1</sup> year<sup>-1</sup>; Wassen et al. 2005). Until World War II, mowing and hay-removal was common practice in the Biebrza valley and carried out almost annually in large parts of the valley. After that, the practice of hay-making was abandoned in most parts of the valley. We have been studying vegetation-soil-hydrology relationships in Biebrza fens and floodplains for the last 20 years.

For this study, we selected some sites in two undrained fens and one severely drained fen where we

carried out studies in the past (e.g., Wassen et al. 1990, 1995; Wassen and Joosten 1996; De Mars et al. 1996, 1997; Wassen and Olde Venterink 2006; Fig 1). We supplemented our intended drainage gradient with a drained fen located nearby the undrained fens. This fen had a summer water table in between the undrained and severely drained fen (Table 1). In the drained and the severely drained fens, we selected mown and unmown sites nearby each other. We also choose an undisturbed floodplain where we could select a mown and unmown site close to each other (Fig. 1). For the undrained fens we could only include unmown sites, since these types of fens are no longer

Information about mowing was derived from local farmers. The water table was measured from peat profile observations or water levels in nearby piezometers, well or ditches. Soil variables are means of the samples from all periods ( $n = 25$ – $30$ ), except N mineralization ( $n = 5$ ). Vegetation variables  $n = 3$ . Moisture dynamics is mean soil moisture of the wettest month minus that of the driest. Different letters indicate significant differences among the eight sites (ANOVA, Tukey,  $P < 0.05$ )

mown in the Biebrza, probably because hay-making in these low-productive fens is not profitable for the local farmers. All sites were on peat with a depth of minimally 1.5 m (Oswit 1973; Zurek 1984; Palczynski 1984; Okruszko 1990, 1993). Number of years that our sites have been mown, or not been mown, as well as other habitat descriptors are presented in Table 1. As far as we could trace back, none of the sites had ever been fertilized. Further details about our floodplain and fens are:

1. The mown and unmown floodplain sites were located about 450 m from each other in the middle course of the river, near the village of Goniadz (Fig. 1). Floodplains in the middle course of the Biebrza, including our sites, are flooded every spring, but in summer water levels drop below the surface (Wassen et al. 2003). Mowing and hay-removal was carried out with tractors and other heavy machines in the floodplain.
2. The undrained fens are located in 'Transect A' of our previous studies (e.g., Wassen et al. 1990, 1995; Wassen and Joosten 1996; De Mars et al. 1997), along the upper course of the river Biebrza (Fig. 1). Both fens are located in an undrained area north of the settlement Szusalewo, where the groundwater level is near soil surface during large parts of the year (De Mars et al. 1997), as it was also at the start of our experiment in June 2002 (Table 1), and were flooding with river water never occurs (Okruszko 1990; Wassen et al. 1990). Both fens can be classified as moderately rich-fens (sensu Vitt and Chee 1990), but differ in presence and abundance of fen species as well as in site factors such as pH and calcium saturation due to differences in fluxes of groundwater (Wassen and Joosten 1996).
3. The fen south of Szusalewo is principally the same fen type as the undrained one (Okruszko 1990; Palczynski 1984), but it has been marginally drained by the local farmers by means of shallow ditches, for at least 25 years. Here we selected the two (mown and unmown) drained rich sites about 300 m from each other (Fig. 1). Mowing and hay-removal was done with a tractor. The unmown site has not been mown for at least 25 years. Water table and soil moisture conditions indicate dryer conditions than the undrained fens (Table 1).

4. The two sites in the severely drained fen were located about 100 m from each other in the middle course of the Biebrza valley, along the Dead Elk River (Fig. 1). This area has been severely drained for about 150 years because of the digging of a deep canal, and since then the area has been mown and hay is removed, the last decades using machines. Besides a mown site, we selected a site that has not been mown for at least 5–10 years. The summer groundwater level is at about 2 m below soil surface. The peat in the top soil is strongly aerated and decomposed. For further information about this area we refer to Kajak and Okruszko (1990) and De Mars et al. (1996).

Although we carefully selected our sites to avoid bias from inherent different soil conditions—e.g., mown and unmown sites in nearby located pairs—we note that we explicitly assumed that the initial soil conditions of the undrained, drained, and severely drained fens were comparable, as well as those of the unmown and mown pairs of sites. In every site, one measuring plot was selected at random (the central subplot C), and four other subplots were selected 10-m. in N, E, S, and W direction.

### Vegetation

In the third week of June 2002, we cut the above-ground standing biomass of vascular plants just above the soil in 50 cm × 50 cm frames, and bryophytes if present, in three subplots ( $n = 3$  per site). Biomass of vascular plants was divided into living and dead. The plant material was dried for 48 h at 70°C, weighed, and Kjeldahl digested. N concentrations in the digests were analyzed colorimetrically, P and K concentrations by means of an ICP (cf. Olde Venterink et al. 2002b). N:P, N:K and K:P ratios in the living above-ground biomass of vascular plants were used as indicators for the type of nutrient limitation, following class borders of Olde Venterink et al. (2003); i.e., N limitation at  $N:P < 14.5$  and  $N:K < 2.1$ , P- (co)-limitation at  $N:P > 14.5$  and  $K:P > 3.4$ , K- (co)-limitation at  $N:K > 2.1$  and  $K:P < 3.4$ . In early July 2003, we recorded the species composition at one square 10 m<sup>2</sup> plot at every site, using the Braun-Blanquet method in which individual species cover is estimated according to a six point scale: + = 1–5%;

1 = 5–15%; 2 = 15–25%; 3 = 25–50%; 4 = 50–75%; 5 ≥ 75% and in which mean height and total cover of different vegetation layers is estimated as well.

### Soil nutrients and related properties

We measured annual net N mineralization at every site by in situ soil incubation, following the technique described by Olff et al. (1994) and Olde Venterink et al. (2002b). We measured net N mineralization between June 2002 and July 2003, during four periods of 6–8 weeks and one winter period of 6 months. The winter period had to be this long because the floodplains were inaccessible because of flooding. At the start of every period, we took one pair of soil cores (10 cm depth, 4.8 cm diameter) at every subplot ( $n = 5$  per site). We took the soil cores in pairs (1–5 cm from each other) with sharpened PVC tubes. One of the paired tubes was incubated, the other transported to the laboratory in Warsaw and extracted after a night at 2°C. Soil extractable N (NO<sub>3</sub> and NH<sub>4</sub>) was determined by extraction with 1 M KCl. We calculated net mineralization rates by subtracting values in initial soil cores from that in the incubated cores for each of the five periods.

Soil extractable P and ammonium-exchangeable K in the top 10 cm soil was assessed at every subplot by soil extraction with ALA (0.1 M NH<sub>3</sub> + 0.4 M acetic acid + 0.1 M lactic acid solution; Koerselman et al. (1993) and Olde Venterink et al. (2002b). Additionally, HCl extractable K was determined for every subplot (cf. Olde Venterink et al. 2002b). The HCl extractable K pool includes both ammonium-exchangeable K as well as an additional K fraction in the soil which is available for plants by soil acidification (Jungk and Claassen 1986). The ALA and HCl extractions were carried out with every initial soil core of the mineralization experiment (25 samples per site).

Bulk density, soil moisture content and pH<sub>KCl</sub> were measured in the initial soil cores. All nutrient values were calculated per unit area using values per unit dry soil and the average bulk density of the top 10-cm soil per site. In addition to the average moisture content, we calculated the difference in soil moisture between the wettest and the driest measurement as an assessment of the annual soil moisture dynamics.

## Data analysis

We tested whether the soil nutrient rates and pools, vegetation characteristics, and site conditions were significantly different among the eight sites by means of Tukey tests after one-way ANOVA. The data were log or square-root transformed to meet the assumptions of ANOVA. To evaluate general effects of drainage, we calculated regressions between soil and vegetation variables versus the water table in June 2002, as well as versus the annual soil moisture dynamics. To visualize these general effects of mowing we calculated the average soil and vegetation variables in the mown sites as percentage of those variables in the paired unmown sites (e.g., mown and unmown floodplain). To test for general effects of hay-making we calculated ANOVAs with mown as a fixed factor and site as a random factor, using the mean values of soil and vegetation variables

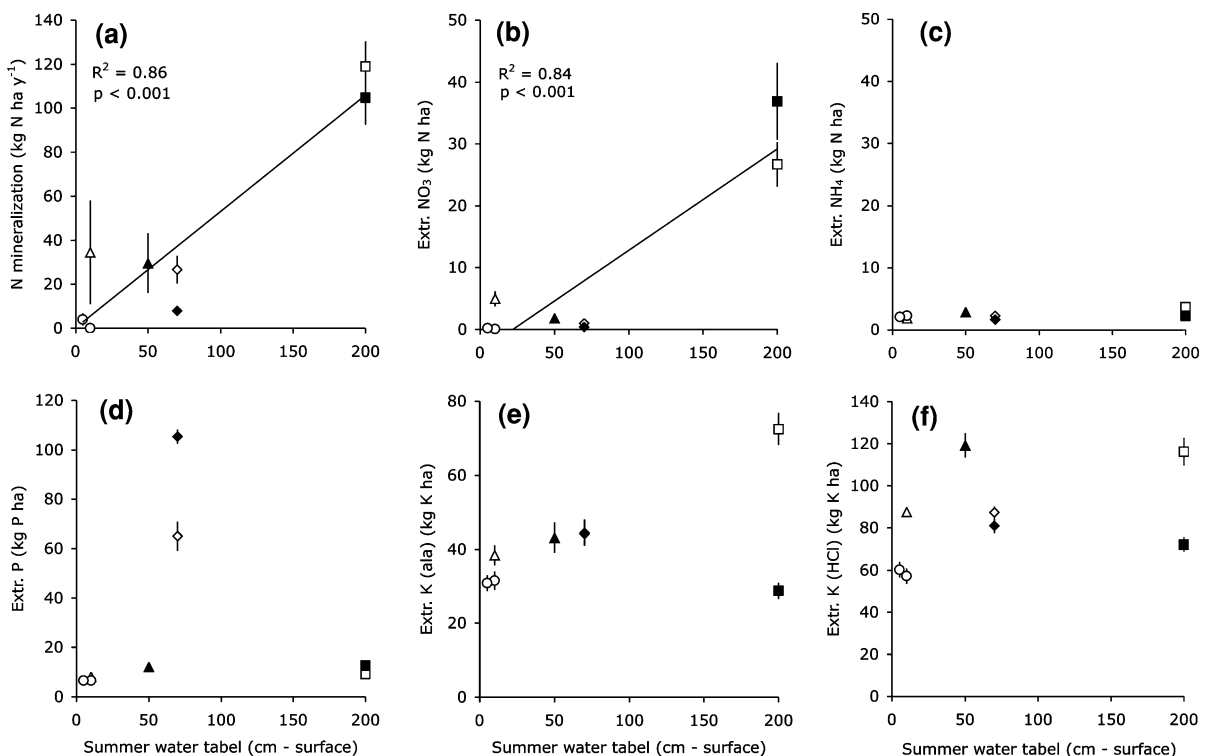

per site to avoid pseudoreplication. Statistics were carried with SPSS 16.0.

## Results

### Floodplains and undrained fens

N mineralization rates were close to zero in the undrained fens, and soil N, P and K pools were very low (Fig. 2). In the floodplain, N mineralization rates and soil N and P pools were still rather low, but soil K pools, in particular HCl-extractable-K, were higher than in the undrained fens (Fig. 2, Table 1).

The floodplain vegetation was characterized by tall sedges (Appendix 1) and had a high biomass of vascular plants (Fig. 3). The undrained fens had a low biomass of vascular plants, but a high biomass of bryophytes (Fig. 3; Table 1). Besides low-productive

fen species, one of the undrained fens (fen 1) contained 'poor fen' species as *Vaccinium oxycoccus* and *Andromeda polifolia*, whereas, the other undrained fen contained more calciphilous species such as *Carex flava*.

N, P and K concentrations in living biomass were rather similar in the floodplain and undrained fens (Fig. 4). The nutrient ratios indicated P (co)-limitation in the floodplain and in undrained fen 2, and N limitation in undrained fen 1 (Fig. 4; Table 1). The stock of N, P and K in aboveground vascular plants was higher in the floodplain than in the undrained fens, but for N and P this difference was not found if nutrient in bryophytes were taken into account; i.e., stock in total living biomass (Table 1).

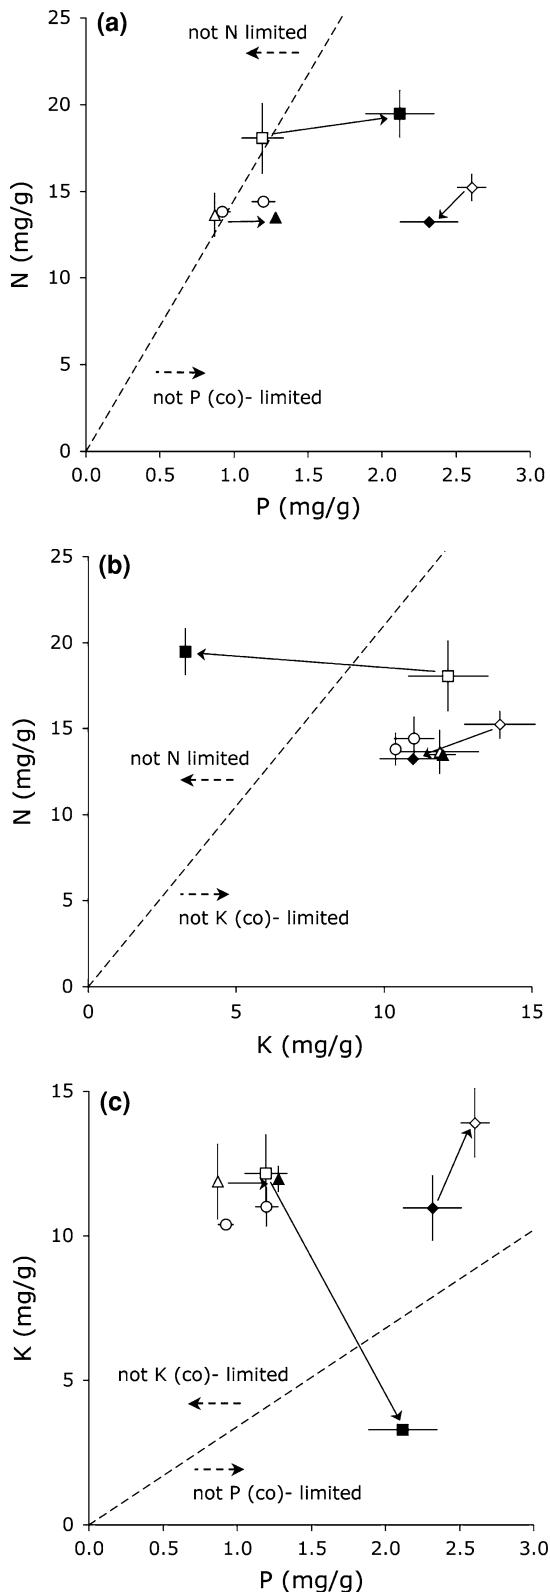

#### Effects of drainage

N-mineralization rates and soil nitrate pools increased significantly with decreasing summer water table (Fig. 2a, b), and N mineralization also with annual soil moisture dynamics ( $P < 0.05$ ; data not shown). ALA extractable K-pools increased with decreasing water table in seven of the eight sites; the mown severely drained fen strongly deviated from this pattern (Fig. 2e). A similar pattern, but with a larger variation, was observed for the HCL-extractable K-pools (Fig. 2f). Soil P-pools were much higher in the drained fen compared to the undrained fens, but not in the severely-drained fen (Fig. 2d; Table 1).

The vegetation composition changed strongly along the drainage gradient: from a fen vegetation with species such as *Menyanthes trifoliata* and *Carex diandra* to a meadow vegetation with species as *Holcus lanatus* and *Luzula campestris*. The drained fen contained both fen and meadow species (Appendix 1). In summer 2002, bryophyte biomass completely disappeared along the drainage gradient in fens (Fig. 3b), and biomass of living vascular plants increased ( $P < 0.05$ ; Fig. 3a; not taking the high biomass in floodplains into account). Vegetation recordings in summer 2003 showed a strong decrease in cover by bryophytes along the drainage gradient, but also showed that bryophytes did not completely disappear in the drier sites (Appendix 1).

N concentrations in vascular plants were rather high in the severely drained fen although not significantly higher than in the other unmown fens,

**Fig. 4** Concentrations of N and P (a), N and K (b), or K and P (c) in the living above-ground biomass of vascular plants in various fens and floodplains in the Biebrza valley.  $\Delta$  unown floodplain,  $\blacktriangle$  mown floodplain,  $\circ$  unown undrained fens,  $\diamond$  unown drained fen,  $\blacklozenge$  mown drained fen,  $\square$  unown severely drained fen,  $\blacksquare$  mown severely drained fen. Symbols are means of three replicates both directions; error bars are SE. The dashed line in (a) represents N:P = 14.5, in (b) N:K = 2.1, and in (c) K:P = 3.4. N limitation is indicated at N:P < 14.5 and N:K > 2.1; P-limitation or NP co-limitation at N:P > 14.5 and K:P > 3.4; K-limitation or NK co-limitation at N:K > 2.1 and K:P < 3.4 (Olde Venterink et al. 2003). Solid arrows connect mown-unmown pairs of sites, and indicate the shift mowing had on nutrient ratios. Results of ANOVA-Tukey test comparisons among the sites are shown in Table 1

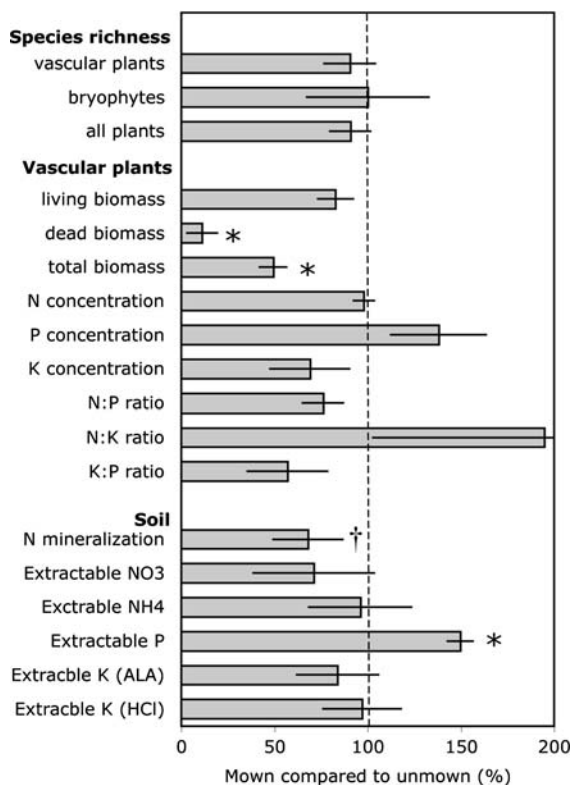

and P concentrations were high in the drained fen (Fig. 4). The nutrient ratios indicated N-limitation in the unown drained fen, and P (co)-limitation in the unown severely drained fen. The stock of N in vascular biomass increased along the drainage gradient in fens ( $P < 0.05$ ), but N in total biomass did not because of large N stocks in bryophytes in the undrained fens (living biomass in Table 1).

#### Effects of mowing and hay-removal

Average N-mineralization rates tended to be lower in mown compared to unown sites, but the general effect of mowing was only significant at the  $P < 0.1$  level (Fig. 5; Table 1). In general, soil P pools were higher in mown than in unown sites (Fig. 5), this difference was very obvious in the drained fen (Table 1). In the severely drained fen mowing had lead to smaller soil K pools, whereas, in the floodplain higher K pools were found in the mown site (Table 1), hence the general trend was not significant (Fig. 5).

Generally, there was a large reduction in standing dead biomass of vascular plants in mown sites, which also lead to a significantly lower total aboveground biomass (Fig. 5). We did not observe a marked effect of mowing on species composition, but there was a strong effect on vegetation structure in the floodplains, where mowing caused sedges to no longer grow in tussocks.

Mowing and hay-removal did not alter N concentrations, but tended to increase P and decrease K concentrations in vascular plants, and hence affect N:P and N:K ratios (but all not significant due to only  $n = 3$ ; Fig. 5). In the severely drained fen, mowing

**Fig. 5** General effects of long-term mowing on vegetation and soil nutrient characteristics. Bars show values of variables measured at mown sites divided by values of those variables measured at a paired unmown site, expressed in % of the unmown value. Error bars show SE of three replicated mown/unmown pairs (floodplain, drained fen severely drained fen). Significant differences: \* $P < 0.05$ , † $P < 0.1$  ANOVA with mowing as fixed factor and site as random factor

and hay-removal induced a shift from P (co)-limitation to K (co)-limitation, and in the floodplain from P (co)-limitation to N limitation (Fig. 4; Table 1). The hay-removal had significantly reduced K-stocks in vascular plants in the severely drained fen (Table 1).

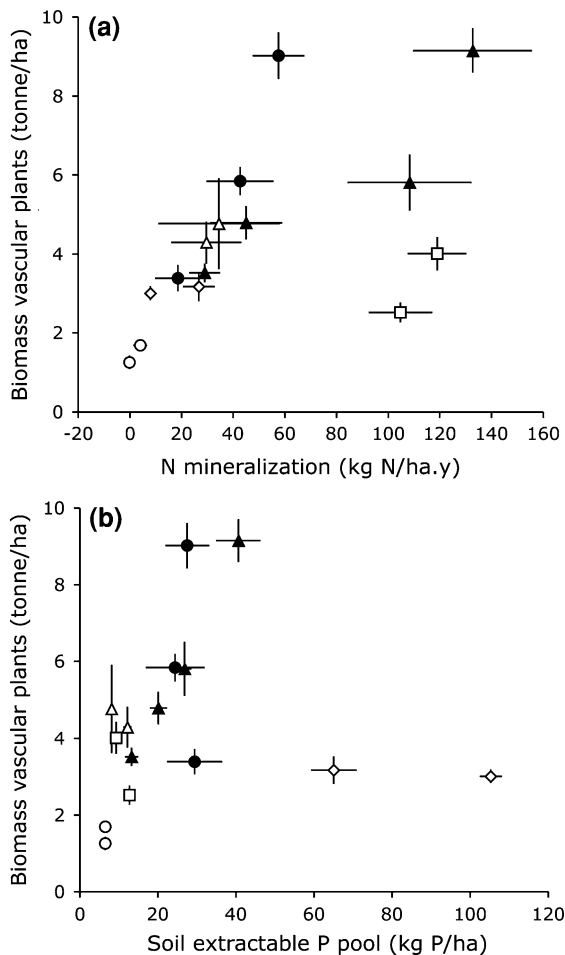

## Discussion

This study aimed at studying long-term effects of drainage on nutrient availability and vegetation productivity in mires, and analyzing if hay-removal would compensate for these effects. We compared sites that differed with respect to drainage or mowing, and assumed that the initial conditions had been the same; i.e., a similar approach used by others (e.g., Laiho and Laine 1994). The undisturbed fens and

floodplains were relatively poor in nutrients if compared to other river valley mires and floodplains (see below). Along the drainage gradient in fens we observed increases in N-mineralization, soil extractable NO<sub>3</sub>, as well as ALA-extractable P and K in some sites (Fig. 2). In the unmown fens this corresponded to an increase in above-ground living biomass of vascular plants, but in the severely drained fen biomass of these plants was not significantly increased if the fen was mown and hay was removed (Fig. 3). Hay-removal had resulted in a strong K-depletion and a shift from P (co)-limitation to K (co)-limitation in this mown and severely drained fen (Fig. 4). Overall, mowing increased soil extractable P and showed a tendency towards a reduction in N mineralization (Fig. 5). A combination of the two factors may have lead to a shift from P (co)-limitation to N limitation in the floodplain (Fig. 4). Mowing also altered vegetation structure and species composition. Although our study was without true replication (we only could ‘pseudo-replicate’ within the sites), our observations demonstrated that soil nutrient dynamics and vegetation response in relation to drainage and haymaking were more complex than a priori expected, although all our hypotheses were supported. For understanding the vegetation response we needed to take the dynamics of N, P and K into account.

## Variation among undrained mire types

Undrained fens and floodplains in the Biebrza valley were relatively poor in all nutrients (N, P and K). N mineralization in the undrained fens was very low compared to fens in Western Europe where annual rates are often higher than c. 50 kg N ha<sup>-1</sup> year<sup>-1</sup> and rates higher than 100 kg ha<sup>-1</sup> year<sup>-1</sup> are not an exception (Verhoeven and Arts 1987; Olde Venterink et al. 2002b; Fig. 6a). The extractable P and K pools in the Biebrza valley are smaller than those in Dutch and Belgian fens of Olde Venterink et al. (2002b; for P see Fig. 6b), but larger than those reported by Koerselman et al. (1993) for two other Dutch fens (for a review see Olde Venterink et al. 2002b). The indication of N limitation in our undrained fen 1 and P (co)-limitation in undrained fen 2 is consistent with vegetation samples taken 13 years earlier at the same sites (Wassen et al. 1995), although the differences in the N:P ratios between the two sites got smaller,

**Fig. 6** Above-ground biomass of living vascular plants in relation to the net N mineralization rate (**a**) or the ALA-extractable soil P pool (**b**) of various fen and floodplain types.  $\triangle$  floodplains Biebrza,  $\circ$  undrained fens Biebrza;  $\diamond$  drained fens Biebrza;  $\square$  severely drained fens Biebrza;  $\bullet$  fens Dommel/Zwarte Beek;  $\blacktriangle$  meadows Dommel/Zwarte Beek. Data from the Biebrza are from this study, data from the Dommel (The Netherlands) or Zwarte Beek (Belgium) are from Olde Venterink et al. (2002b). Mean values ( $\pm 1$  SE) per fen or floodplain type are shown. Graph (**a**) without the two severely drained fens:  $R^2 = 0.67$ ,  $P < 0.001$ . Graph (**b**) without the two drained fens:  $R^2 = 0.62$ ,  $P = 0.002$ , and not significant for the Biebrza types only

which also was observed by El-Kahloun et al. (2005). Fertilisation experiments performed in 1992 demonstrated N-limitation in both fens 1 and 2 (Wassen et al. 1998); in fen 2 the N:P ratio (13.5) of the control plot was close to the 15.0 in the present study. An N:P ratio of 15 is almost equal to the critical N:P value of 14.5 (for herbaceous wetland vegetation in

the temperate zones, Olde Venterink et al. 2003), and hence does not indicate a strong solo-limitation by N or P. Both N limitation and P limitation occur in undrained fens in Europe and North America (Bridgman et al. 1996; Verhoeven et al. 1996; Bedford et al. 1999; Olde Venterink et al. 2003; Walbridge and Navaratnam 2006).

Although annual N mineralization rates were somewhat higher in the floodplains than in the undrained fens in the Biebrza Valley, they were still very low compared to floodplains of other European rivers. Annual N mineralization rates of about 100–260 kg N ha<sup>-1</sup> year<sup>-1</sup> were reported for floodplains along the rivers Torridge (UK; Van Oorschot et al. 1997) and Garonne (F; Pinay et al. 1995). Spink et al. (1998) reported a large variation in N mineralization rates (–1 to 40 kg N ha<sup>-1</sup>) during 4-week summer periods in some European and N-American floodplains, as well as highly variable soil extractable P pools (0–1500 kg P ha<sup>-1</sup>). In our floodplains N mineralization was on average 20–25 kg N ha<sup>-1</sup> for the summer period (data not shown), which was consistent with rates of 9–42 kg N ha<sup>-1</sup> for a similar period in the Biebrza floodplain 30 km downstream in 1990 (Wassen et al. 2003). Soil extractable K pools in the Biebrza floodplains were comparable to those in flooded meadows along the river Dommel (NL), whereas, extractable P pools were clearly smaller in the Biebrza floodplains (cf. Olde Venterink et al. 2002b). Unlike most other European rivers which generally have catchments in which the main land use is agriculture and urban area, the Biebrza catchment is covered with forests, lakes and non-intensively used agricultural land. The smaller soil extractable nutrient pools in the Biebrza floodplains is not because of low overbank flooding frequency, but because the river water of the Biebrza has low P-concentrations (Wassen et al. 2003). Nutrient inputs from flooding were assessed at 31 kg N, 7 kg P and 2 kg K ha<sup>-1</sup> year<sup>-1</sup> in the Biebrza floodplain (Wassen and Olde Venterink 2006, and unpublished data), compared to 42–240 kg N and 15–102 kg P ha<sup>-1</sup> year<sup>-1</sup> for floodplains along the Rhine (Olde Venterink et al. 2006), and >500 kg N in riparian forests along the Garonne (Pinay et al. 1995). Nutrient ratios in the studied floodplain vegetation indicated slight P (co)-limitation. A previous fertilization in a floodplain site 30 km downstream, which had a higher productivity, showed no biomass

response to N, P or K addition (Wassen et al. 1998, 2003). Floodplain vegetation in Western Europe, but also of other Polish rivers, is generally N-limited or limited by other factors such as light (Van Oorschot et al. 1997; Spink et al. 1998; Anthéunisse et al. 2006). The local difference between Biebrza floodplain sites might be related to local variation in soil texture (loam, sand, organic matter), or it may reflect differences among years and climatic conditions (cf. Olde Venterink et al. 2001).

### Effects of drainage

Nitrogen mineralization and extractable  $\text{NO}_3$  clearly increased along the drainage gradient in our fens (Fig. 2). This is consistent with laboratory studies where soil cores were subjected to drainage and aeration (Heathwaite 1990; Updegraff et al. 1995; Bridgham et al. 1998; Olde Venterink et al. 2002a). The N mineralization rate was not dramatically increased in the drained fens, and still rather slow compared to for instance rates in Western European meadows (cf. Fig. 6a, and review in Olde Venterink et al. (2002b)). In the severely drained sites, N mineralization rates were strongly increased ( $>100 \text{ kg N ha}^{-1} \text{ year}^{-1}$ ), just as in other fen meadows where the water levels have been severely lowered in summer (Grootjans et al. 1985, 1986).

The relevance of increased N mineralization rates for above-ground biomass production becomes evident by plotting the biomass of vascular plants against N mineralization rates (Fig. 6a, open symbols). If we do not take the severely drained fens (open squares) into account, there is a strong significant correlation between the two variables. This pattern also fits remarkably well with similar data from a previous study in rich fens and meadows in The Netherlands and Belgium (Fig. 6a, closed symbols). Including these previous data in the comparison, it becomes even clearer that the severely drained sites are outliers; i.e., in these sites biomass production seems not to be controlled by N availability but by another limiting resource, e.g., water or potassium (see below). Plants may also have invested more biomass in roots under these dry conditions. Nevertheless, the clear relationship in Fig. 6a points to a rather general pattern between N mineralization and above-ground biomass production of vascular plants. This indicates that N has an important role as

limiting factor. The patterns from the sites in the Biebrza valley and those in The Netherlands and Belgium fit remarkably well, particularly if undrained fens (open en closed circles) and drained sites (diamonds, closed triangles) are analyzed separately, and if one realizes that another important N source as atmospheric N deposition differs considerably between the two regions ( $10 \text{ vs. } 40 \text{ kg N ha}^{-1} \text{ year}^{-1}$ ; cf. Wassen and Olde Venterink 2006). The steeper pattern for undrained sites than for the drained sites may be explained by an underestimation of net N mineralization in the constantly wet sites through higher denitrification rates in the incubated soil (cf. Olde Venterink et al. 2002a; Wassen and Olde Venterink 2006), rather than higher N use efficiency in the fen species compared to the meadow species.

We have assessed also relationships between biomass versus extractable soil P and K pools for the sites in Fig 6. For the K pools this did yield significant patterns (data not shown). The pattern for the P pool was significant if the sites in the drained Biebrza fen were not included (Fig. 6b). This analysis illustrates the remarkably high extractable P pools in the drained fen. One reason for this might be that these sites are subjected to repeated drying-wetting cycles, which might be more important for P-release in wetlands than drainage as such (Olila et al. 1997; Olde Venterink et al. 2002a). However, considering that these P pools are very much higher than those in all other sites in Fig 6b, including the severely drained fens, we can not rule out that the difference was due to inherent differences in soil-P rather than an effect of drainage.

Many endangered wetland plants are short growing species and poor light competitors. Considering that endangered plant species only occur at sites with an above-ground biomass of vascular plants below  $6 \text{ ton ha}^{-1}$  (Moore et al. 1989; Wheeler and Shaw 1991; Wassen et al. 2005), it can be read from Fig 6a that the net N mineralization rates should not exceed 40 and  $60\text{--}80 \text{ kg ha}^{-1} \text{ year}^{-1}$  for undrained fens and drained fens/meadows, respectively. Hence, N mineralization rates in many Western European fens and meadows seem to be high for the endangered species (cf. Olde Venterink et al. 2002b). Furthermore, the ALA extractable P pool should not exceed  $25 \text{ kg P ha}^{-1}$  (Fig. 6b). The loss of endangered species in Western Europe is often ascribed to high atmospheric N deposition rates (Bobbink et al. 1998; Stevens et al.

2004); high N mineralization rates and increased soil P pools provide alternative explanations. The latter would fit with our observation that many endangered wetland species in Western Europe persist at P-limited conditions (cf. Olde Venterink et al. 2003; Wassen et al. 2005).

The drained and severely drained fens in this study did not contain fewer plant species than the undrained fens (Appendix 1). However, fen species were replaced by meadow species. Drainage also resulted in a dramatic loss of bryophyte biomass and cover, similar to the pattern described in drained Finnish peatlands (Laiho et al. 2003). In summer 2002, bryophytes were almost completely absent in the drained fens or floodplains, but in 2003 they covered up to 40–50% of the soil in some sites (Appendix 1). The difference among years may be due to differences in (micro) climate and feedbacks with vascular plants (e.g., Limpens et al. 2004). The disappearance of bryophytes could be due to reduced soil wetness, or a result of eutrophication and competition for light (Berendse et al. 2001; Kotowski and Van Diggelen 2004; Van der Wal et al. 2005).

#### Effects of mowing and hay-removal

The annual mowing and hay-making resulted in a significantly lower aboveground biomass due to a lower amount of dead biomass (Fig. 5). In the severely drained fen, mowing could also prevent a large biomass increase of living vascular plants. In fen meadows and fens in the UK and The Netherlands, a clear reduction in biomass is found through long term hay-removal (Marrs 1985; Koerselman et al. 1990; Berendse et al. 1992; Bakker and Olff 1995).

Olff et al. (1994) also found a reduced N mineralization rate in meadows after long-term hay-removal. Our overall comparison of the three pairs of mown-unmown sites showed a tendency ( $P < 0.1$ ) that supports these results (Fig. 5). We note, however, that the relatively small reduction in N mineralization through hay-making can by far not compensate for the largely increased N mineralization through severe drainage (Fig. 2).

Soil extractable P was higher in the mown sites. We can not explain this result from the use of heavy mowing machines and soil compaction, since bulk density was only higher in the floodplain and not in

the fens, and extractable N and K pools were not consistently increased (Table 1; Fig 2). In contrast, Olff et al. (1994) observed a four fold decrease in total P concentrations with increasing time of haymaking. The effect of haymaking on soil P availability requires further study.

Mowing and annual hay removal had a strong effect on potassium availability in the severely drained fen. A stronger effect of annual hay removal on K than on P or N also was found for some fens and wet meadows in The Netherlands, Belgium and Norway (Koerselman et al. 1990; Øien and Moen 2001; Olde Venterink et al. 2002b). In many wetland sites, the soil K pool is relatively small (Laine et al. 1995b; Olde Venterink et al. 2002b), and output by hay compared to the soil nutrient pool, is often much higher for K than for N or P (Koerselman et al. 1990; Olde Venterink et al. 2002b). In the present study, we did not analyse total nutrient pools in the soil. Extractable K pools were reduced in the mown plots, but only if they were also severely drained (Fig. 2e, f). In drained peat, K can easily leach to deeper soil layers since it is not biologically immobilized in contrast to N and P (cf. Braekke 1987; Sundström et al. 2000). Without K input from dead aboveground plant material, and with a large annual K output in hay, the vegetation can quickly mine the K pool in the top soil (Olde Venterink et al. 2002b). This interactive effect of drainage and mowing on K availability and K limitation agrees with previous studies (Kajak and Okruszko 1990; De Mars et al. 1996; Van Duren and Pegtel 2000). The large K-output by haymaking may cause a shift from N or P limitation towards K limitation particularly in drained mires (Olde Venterink et al. 2002b). Such a shift was indeed indicated for our severely drained and mown site by the nutrient ratios in the aboveground vegetation (Fig. 4). An acute shift to K limitation could lead to severe growth problems for plants and disappearance of most of the herbaceous species (Okruszko 1990). In the dataset of Wassen et al. (2005), we observed only nine K limited sites out of 276 sites; the K limited sites were all drained. These sites, however, were not particularly species poor, and some K-limited sites contained endangered species. Hence, it can not be concluded that K limitation will generally lead to poor species composition.

### Some implications for conservation management

The Biebrza mires contain target plant communities and serve as reference ecosystems for nature conservation and restoration elsewhere in Europe. Results of our study show that low availabilities of particularly N and P seem crucial prerequisites for preserving fen plant communities. Nitrogen mineralization should be close to zero, and at least below 40 kg N ha<sup>-1</sup> year<sup>-1</sup>, otherwise productivity of vascular plants may exceed the level above which endangered species no longer occur, unless another resource is growth-limiting (e.g., P or K). To avoid increased N mineralization rates, peatland drainage should be avoided and drained peatland should be rewetted. We note that rewetting may be successful (Van Bodegom et al. 2006), but also has the risk of initiating a strong P release which may stimulate eutrophication rather than prevent it (Lamers et al. 1998; Olde Venterink et al. 2002a).

Annual hay-making may strongly alter N:P:K stoichiometry, and particularly at drained conditions

it may induce K limitation. Kajak and Okruszko (1990) reported that previously species-rich meadow vegetation in severely drained and K-limited sites at Biebrza, could be restored only after K-fertilization. We do not recommend K fertilization as a general management measure at K limited sites because of the productivity increase that can be expected and the negative effects this might have on particularly endangered species. Some drained mires may only be restored by top soil removal and subsequent rewetting (Lamers et al. 2006).
